In conclusion, preferred orientations are likely to occur in aqueous solutions of substances bearing groups through which favourable interactions can be established. The preferred orientation makes different the behaviour of substances which, on the basis of the sign of the enthalpic coefficients, at first glance could have been considered as simply hydrophobic. Then α-amino acids in the mixed solvent behave as typical hydrophobic solutes, having coefficients proportional to the square of the number of aliphatic carbon atoms. For alkane-1,2-diols (19, 20), because of the presence of a side-on orientation, the interaction coefficients have instead a linear dependence on the third power of the number of aliphatic carbon atoms. In contrast, α-amino acids in water, as shown by the above discussion, behave in a complex manner (linear dependence of the coefficients on the first power of the number of carbon atoms), thus indicating that the interactions between the charges compete with the hydrophobic interactions.

The rates of methyl transfer between benzohydroxamates and sulfonates show large β_{nuc} values (ca. 0.8) indicating much charge transfer to the C atom, similar to the results of *N,N*-dialkylaminofluorene anions. A small α effect shows that even in methyl substrates, with certain leaving groups, the effect is displayed. Investigation of the β_{lg} shows that from the leaving group side of the reaction it is a normal S_N2 reaction. Correlation of the reactivity with computed gas phase ionization potentials shows that desolvation of anions is probably not important. These results suggest an α-effect model that explains the larger size of the effect at carbonyl groups in terms of greater solvation of the charge transferred to the O atom.

Key words: α effect, Brønsted plot, ionization potentials, cyclic voltammetry, β_{lg}, β_{nuc}, AMI, $E_{\frac{1}{2}}$.

KENNETH R. FOUNTAIN, DANIEL P. FOUNTAIN, BERNICE MICHAELS, D. BRENTON MYERS, JON K. SALMON, DEAN A. VAN GALEN et PAT YU. Can. J. Chem. **69**, 798 (1991).

Les vitesses de transfert des groupements méthyles entre des benzohydroxamates et des sulfonates présentent des valeurs de β_{nuc} élevées (environ 0,8) qui indiquent un important transfert de charge vers l'atome de C, semblable à celui observé avec les anions *N,N*-dialkylaminofluorènes. Un faible effet α montre que, même avec des substrats méthyles de certains nucléofuges, on peut observer cet effet. Une étude du β_{lg} montre que, par rapport au groupement nucléofuge, il s'agit d'une réaction S_N2 normale. Une corrélation de la réactivité avec les potentiels d'ionisation en phase gazeuse calculés montre que la désolvatation des anions n'est probablement pas importante. Ces résultats suggèrent un modèle d'effet α qui explique l'importance plus grande de l'effet au niveau des groupements carbonyles en termes de plus grande solvatation de la charge qui est transférée à l'atome d'oxygène.

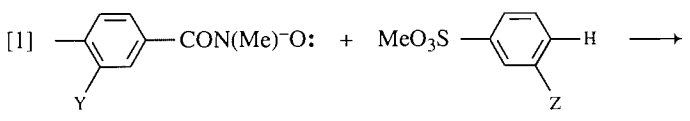
Mots clés : effet α, courbe de Brønsted, potentiels d'ionisation, voltamétrie cyclique, β_{lg}, β_{nuc}, AMI, $E_{\frac{1}{2}}$.

[Traduit par la rédaction]

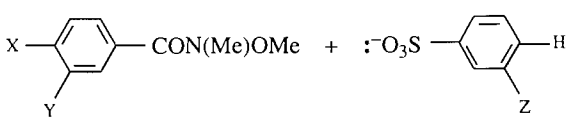
Introduction

The α effect is displayed by nucleophiles having a lone pair of electrons on an atom neighboring the atom undergoing nucleophilic attack, such as **1**. The α effect is defined as an enhanced reactivity compared to nucleophiles of similar pK_a. The effect has been a source of much debate for several decades (1). It is strongest at unsaturated sites, such as the carbonyl group (lg, 13), but small α effects are also found at the benzylic group (2), and in displacement of *p*-nitrophenylsulfate ions from methyl groups by hydrazine and HO_2^- anion (3, 23).

1



N-Methylbenzhydroxamate ions (G-NMBH), **2**, have long been known as α nucleophiles (1), but systematic studies to show the effect of structural variation on their reactivity are lacking. They are known to give α effects with *p*-nitrophenylacetate (PNPA) of ca. 45, or with 2,4-dinitrophenyltosylate of 145 (18, 22). The α effect in these cases was determined by comparison with phenols of pK_a similar to the G-NMBH acids. The α effect of G-NMBH anions toward benzyl bromide was smaller (= 13) (2). No study of the α effect of these nucleophiles in methyl transfers has yet appeared. Methyl transfer between substituted *N*-methylbenzhydroxamate ions (G-NMBH) and methyl arenesulfonates is the subject of this paper.



2

The reaction of G-NMBH ions with methylarenesulfonates is shown in reaction [1]. Our goals in studying this reaction are (a) to ascertain the differences in α-effect behavior between this reaction and the reactions with carbonyls and benzyl substrates; (b) to determine the existence of an α effect in this system; and (c) to interpret the findings in terms of current models of the S_N2 transition state (TS), which deal with the possibility of single electron transfer character (SET character) in transition state formation (4). Because so many factors have been advanced as reasons for the α effect (1), it is important to begin explanation from the simplest possible substrate system capable of structural variation in both the nucleophile and leaving group, and to sort out the factors involving these two groups. When the systems become increasingly more complex, as in the benzyl system, carbonyl systems, etc., additional factors can be analyzed as they enter the more complex substrate system. By means of this step-by-step approach, all of the factors usually cited for causes of the α effect can be explored experimentally.

In this study, reaction [1] is useful, even though the total range of reactivity of the G-NMBH anions is limited, because internal acid–base catalysis, such as found with benzhydroxamate ions, is eliminated (2). The data for the more complex

carbon systems, carbonyl and benzyl, are already known, so the very simplest carbon system of this study can provide useful insight.

Results

Preparation of N-methylbenzhydroxamic acids and their sodium salts

The *N*-methylbenzhydroxamic acids (G-NMBHH) were made by known methods (5, 6) or by a method worked out by our group (see Experimental). All new compounds gave satisfactory (±0.4) microanalytical data. Each G-NMBHH was converted into its sodium salt (G-NMBHNa), structure **2**, by treating a methanol solution of the G-NMBHH with a stoichiometric amount of sodium methoxide in methanol. Removal of solvent on a rotary evaporator gave salts that were dihydrates. On careful heating, several salts decomposed nearly quantitatively to their anhydrous forms.[2]

Characterization of these G-NMBHH acids by gas chromatography – mass spectrometry (GC–MS) was interesting because the parent ions were very weak. The base peaks were all at m/e values corresponding to the amides, showing extrusion of O atoms. *o*-Alkylated G-NMBH display similar behavior (8, 9).

Preparation of methylarenesulfonates

The literature provided methods for synthesis of most of these (10). All new compounds were made in analogous reactions. All compounds gave acceptable analytical results.

Kinetic studies

Two types of kinetic studies were employed: following the disappearance of the methyl signals of the methyl *p*-methoxybenzenesulfonate (MPMBS) in the ^{1}H NMR as it reacted with the G-NMBH anion (G = substituting group), and competition reactions in which two substituted NMBH anions competed for a limited amount of MPMBS. Preliminary Brønsted plots (not shown) gave broken lines, suggesting that the more basic G-NMBH anions accept protons (deuterons) from the methanol-d_4. The more basic anions, beginning with NMBH anion itself, were then used in competition experiments. Comparison of k_{rel} with the known rate of *p*-NO_2NMBH determined the rate constants for the more basic anions. Table 1 summarizes the results.

Competition reactions determined the relative rates for methyl transfer to 4X,3Y-NMBH anions in water – 20% dioxane by adding 1.0 molar equivalent of MPMBS in 1,4-dioxane to 10.0 molar equivalents (each) of two different 4X,3Y-NMBH anions. The reaction mixtures were analyzed after 20 min by GC-MS. Experiments with authentic materials established that our integrator was linear in grams of material to ±3%. The relative rate constants are summarized in Table 2.

Determination of pK_a values

The most complete pK_a study of 4X,3Y-NMBHH in water is by Crumbliss and co-workers, who report (5) on four substituents ($\rho = 0.60$; $R = 0.91$). We determined two additional values under conditions similar to those of the Crumbliss group (11). Our results are combined with the values of Crumbliss in Table 3. Figure 1 shows the Hammett plot, which contains two extrapolated points from the following equation: $pK_a = -0.67\Sigma\sigma + 8.39$ ($R = 0.99$, excluding extrapolated values). From this equation the remaining values in water could be found, as shown in Table 3.

[2]This experiment was performed by Desert Analytics, Box 41838, Tucson, AZ 85717, U.S.A.

pK_a values of 4X,3Y-NMBH-H in anhydrous methanol were determined spectroscopically, using *p*-nitrophenol as an indicator (pK_a = 11.15, ref. 12*a*) for the more acidic (<12.5) 4X,3Y-NMBH-H compounds. Preliminary determinations of the least acidic 4X,3Y-NMBH-H compounds showed them to have pK_a's of ca. 13.5, using *p*-nitrophenyl as an indicator. This value puts them beyond the useful range of *p*-nitrophenol for accurate determinations, so *p*-bromothymol blue (pK_a = 12.4,

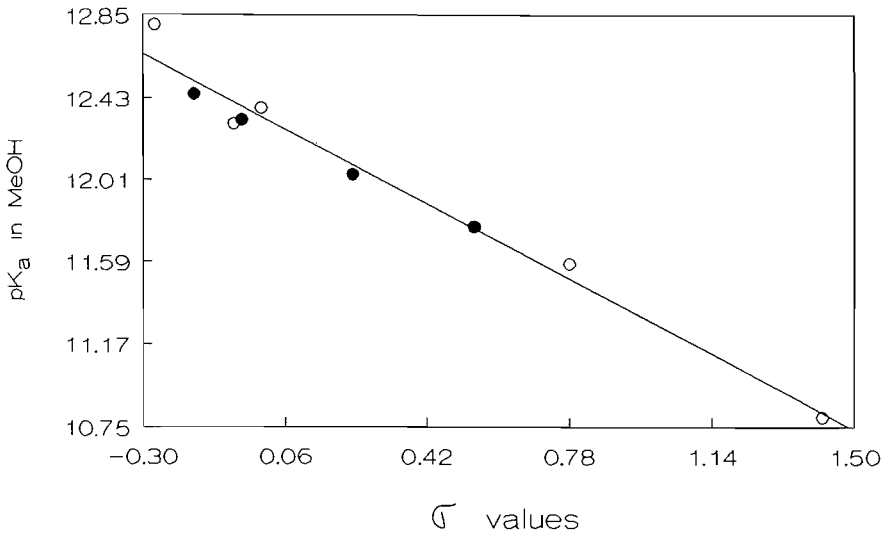

FIG. 2. Hammett plot of pK_a of G-NMBH-H in anhydrous methanol at 25°C (±0.1).

ref. 12*b*) was used. The pK_a values obtained, using eq. [2] (with the molarity quantities determined spectroscopically), are also shown in Table 3. Figure 2 gives the Hammett plot ($R = 0.98$) and shows the extrapolated values (used in making Brønsted plots) as filled circles. The correlation equation is $pK_a = -1.02\Sigma\sigma + 12.27$ ($\rho = -1.41$ in kcal/σ unit).

$$[2] \quad pK_{Ind} - pK_{Unkn} - \log\frac{[Unkn^-]}{[UnknH]} - \log\frac{[Ind]}{[IndH]}$$

Determination of the α effect

Competition reactions, as in the determination of relative rate constants, ensure consistency of methods. The G-NMBH-H acids were matched in pK_a by phenols.

Determining the expression of the α effect can be done in two ways: (1) finding an extra reactivity in the α nucleophile on a Brønsted plot (β_{nuc}), and (2) establishing the rate constant ratio of the α nucleophile and a normal nucleophile of matched pK_a (13, 14). We decided to obtain the expression for the α effect by direct competition of NMBH anions with pK_a matched phenols, *m*-nitrophenol (pK_a = 12.44) (15), and 3,4-dichlorophenol (pK_a = 12.93) (15) in MeOH. The result obtained is thus a minimum expression of the α effect for the NMBH anion because the pK_a's of the phenols are both slightly higher than those of the 4X,3Y-NMBH acids.

Competition reactions were run using a 10 molar equivalent excess of both the phenolate salt and the 4X,3Y-NMBH anion in 1.00 mL of methanol-d_4 containing excess MeO-d_3^-. One molar equivalent of methyl 4-methoxybenzenesulfonate was added, and the reaction mixture analyzed by GC–MS. Authentic materials supplied retention times and authentic MS results. The $k_{G\text{-}NMBH}/k_{m\text{-}NO_2phenolate}$ equals 3.50 ± 0.42. When a similar experiment using 3,4-dichlorophenolate was done with NMBH anions, $k_{NMBH}/k_{3,4\text{-}diCl\ phenolate} = 2.48 \pm 0.15$. These results are in line with Buncel's α-effect values for displacement of *p*-nitrophenylsulfate anions by HO_2^- ion.

Using phenolate anions as normal nucleophiles requires a set of phenolate ions with pK_a values matching those of the 4X,3Y-NMBH anions. Some of the substitutions cause resonance stabilization of the phenolates, thus perhaps lowering nucleophilic activity. Jencks deals with this issue (16) in a study of displacements by phenolates on 1-acetoxy-4-methoxy-

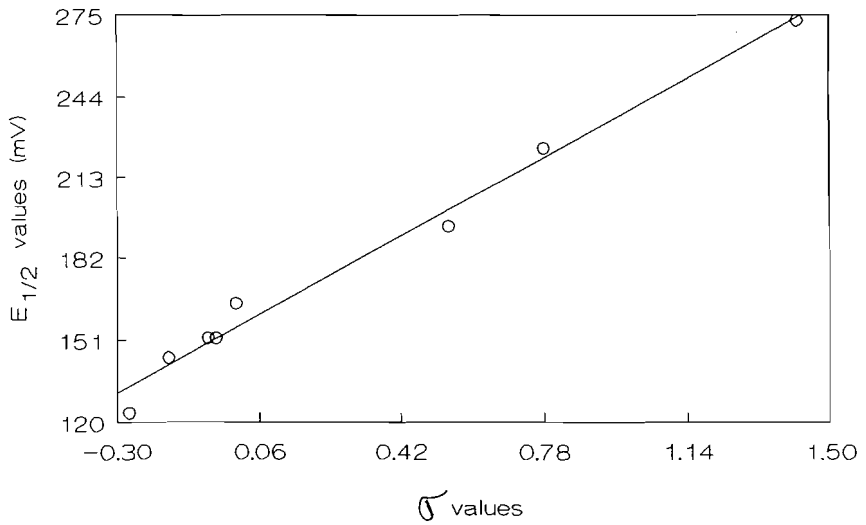

FIG. 3. Hammett plot of $E_{\frac{1}{2}}$ values of G-NMBH anions in anhydrous methanol at 25°C.

pyridinium perchlorate. By comparing reactivity of phenolate with that of the anions of fluorinated alcohols, he showed that there "was no evidence for a specific contribution of resonance delocalization in the phenolate ions to the β_{nuc} values or to the curvature of the Brønsted plot ..." Additionally, phenoxide ions have been the traditional nucleophiles for comparison with oxygen α nucleophiles (17, 18), which justifies our use of these anions.

Solvents play a great role in the expression of the α effect. Buncel and Um (14*a*) have shown that the α effect, comparing *p*-chlorophenylate with butane-2,3-dione monoximate ion (toward PNPA substrate) is 121 in 90 mol% DMSO and 96 in 100 mol% water. It was therefore interesting to see if an α effect existed in both solvent systems in the present study. The possibility of solvent isotope effects is implicit in this study, but these are expected to be small so will be neglected.

Determination of the α effect with NMBH anion (pK_a of NMBH-H = 8.28 in water) and *m*-nitrophenylate (pK_a of the phenol = 8.26 in water) in pure water was frustrated by the lack of solubility of the alkylation agent in water. Competition experiments in 20% dioxane – 80% water mixtures overcame this lack of solubility sufficiently to observe the α effect. The α effect found was 3.52 ± 0.42 for NMBHNa vs. *m*-nitrophenolate anion in water, and 4.81 ± 0.25 for NMBHNa vs. 3,5-dichlorophenolate in methanol. Interpretation of these numbers is not yet available, due to the effects of solvent composition on the α effect, as mentioned above. We are content to have shown the α effect in both solvents used in this study.

Determinations of $E_{\frac{1}{2}}$ *values of 4X,3Y-NMBHNa in methanol*

The oxidation potentials of a series of 4X,3Y-NMBHNa salts were determined in anhydrous methanol as outlined in the experimental section. The oxidations were reversible in methanol, but in water the $E_{\frac{1}{2}}$ values were not obtained, due to electrode fouling, or to slow, heterogeneous electron transfer.

The 4X,3Y-NMBH anions were oxidized at a freshly polished glassy carbon electrode. At slower scan rates, the radical resulting from NMBH anion oxidation undergoes significant chemical reaction on the time scale of the experiment, as evidenced by a relative decrease in the cathode peak for reduction of the radical. Thus, scan rates of at least 200 mV/s were employed for $E_{\frac{1}{2}}$ measurements. The values are listed in Table 4 and summarized as the Hammett plot in Fig. 3. The equation is $E_{\frac{1}{2}} = 83.18\Sigma\sigma + 155.96$ ($R = 0.99$; 8 points) ($\rho = 1.91$ kcal/σ unit).

Computations of AM1 IPs

Ionization potentials (IPs) were computed using QCMP no. 024 (Stewart's MOPAC, version 4.0) on a Zenith PC, using a CCG 032 coprocessor board (Denver, Colorado). Full minimization of geometry was obtained in each case, as shown by diagonalizing the Hessian matrix to find only positive and non-zero eigenvalues, showing that the geometries obtained were stationary states. The results are summarized in Table 5.

Leaving group study

The rates of reaction [1] as a function of various arenesulfonate leaving groups were determined by NMR kinetics in the same manner as for methyl *p*-methoxybenzenesulfonate. The rate constants are summarized in Table 6 for *p*-ClNMBHNa.

The last column of Table 6 shows the pK_{lg} parameter developed by Hoffman and co-workers (19) from data on methyl transfers between arenesulfonate ions in sulfolane, by Lewis *et al.* (20). These parameters have been proven useful in classification of the degree of leaving of arene sulfonates in various nucleophilic reactions. They are used in the discussion section to examine reaction [1] from the leaving group side.

Correlations of data

The Brønsted plot of pK_a vs. log k_{nuc} for reaction [1] in water is presented in Fig. 4 and the correlation for methanol-d_4 in Fig. 5. The β_{nuc} values (slopes) of these plots are 0.84 and 0.86 (r = 0.98 and 0.97 respectively). Figure 6 shows the Brønsted–Lewis study, using the pK_{lg} values of Hoffman (19), as summarized in Table 6. The equation is log $k_{nuc} = -0.44\ pK_{lg} - 1.06$ (r = 0.98).

Correlations of log k_{nuc} with $E_{\frac{1}{2}}$ (ox) appear in Fig. 7 for the 4X,3Y-NMBH anions in methanol-d_4. The $E_{\frac{1}{2}}$ values also correlate with Hammett σ values, thus acting as a check on the ability to correlate the rate constants. The numbering follows Table 4.

AM1 IP values correlated with σ (plot not shown; R = 0.98): equation, IP = 0.58Σσ + 2.65. From this equation other IP values used in the following correlation could be obtained.

AM1 gas phase ionization potentials are correlated with log k_{nuc} in Fig. 8. The omission of point 6 (4X = OMe, 3Y = H) gave improved correlation ($R = 0.95$). The large slopes show strong dependence on gas phase ionization potential. A similar correlation for the MNDO calculated IPs reported by Bugner (21) for the arenesulfonate leaving groups gave a good linear regression fit ($R = 0.96$, slope = −1.88; plot not shown). The point for the 4-MeO substituent was again considerably off the line.

A correlation of log k_{nuc} for reaction [1] (not shown) with the MNDO HOMO values calculated by Bugner (21) gave a good fit ($R = 0.96$). This plot is interesting because the MNDO calculations refer to gas phase only, and it shows that a gas phase parameter correlates with a solution phase measurement. This subject is discussed below.

Discussion

The correlations of kinetic data in this paper clearly show that methyl transfer to G-NMBH anions is unique in several aspects. First, the size of β_{nuc} both in water and in methanol-d_4 is large compared with the carbonyl and benzylic systems. Table 7 summarizes the available data.

Clearly the behavior of methyl transfer to the G-NMBH anions from arenesulfonates differs substantially from transfers of other groups to these hydroxamate anions. Also, the β_{nuc} values for water and methanol are very similar, showing a relative lack of solvent effects in this system. The α effect in the present work is consistent with the α effect for methyl transfers to HO_2^- from the *p*-nitrophenylsulfate ion (5.7–11.0) (23). The large β_{nuc} values are associated with very small α effects. We can estimate the β_{nuc} for the phenolate anions by using the known rate constants (Table 1) for 4X,3Y-NMBH anions and the values for the α effect with the substituted phenolate anions of similar basicity (this procedure followed the method of ref. 23). Equations [2] summarize the process. In water–dioxane the β_{nuc} was 0.30; in methanol-d_4 it was 0.31, showing essential agreement for the methylation of phenoxides by the methylating agents used in this study. These β_{nuc} values are the same order of magnitude as for other alkylating agents, where the β_{nuc} range is 0.16 for methylation by the methylsulfate anion ($MeOSO_3^-$) to 0.37 for butylation by butyl bromide (25).

$$[2a] \quad \alpha \text{ effect} = \frac{k_{4X,3Y\text{-NMBH}-}}{k_{G\text{-phenO}-}}$$

$$[2b] \quad \beta = \frac{\log k\text{G-PhenO}_1^- - \log k\text{G-PhenO}_2^-}{\Delta pK_a}$$

The result of larger values of β_{nuc} for transfers of methyl groups to 4X,3Y-NMBH anions is similar to that reported by Buncel *et al.* (23) for methyl transfer to HO_2^-. In that report the authors argued that an increased β_{nuc} showed that there was an anti-Hammond character in the behavior of the transition state (TS) (i.e., the TS was more covalently bound than for normal nucleophiles). The results of the present study could be interpreted in the same way.

TABLE 8. Summary of β_{lg}^{Me} of diverse mechanisms

System	β_{lg}	Type	References
MeO_3SAr	0.45	k_s	19, 27, 28
EtO_3SAR	0.45	k_s	27, 28
$AllylO_3SAr$	0.51	k_s	29
endo-2-Norbornyl-O_3SAr	0.56	k_s–k_c	28
exo-2-Norbornyl-O_3AR	0.57	k_Δ	28
CyclobutylO3SAr	0.55	k_Δ	31
2-AdamantylO_3Ar	0.57	k_Δ–k_c	30
2-(phenylthio)ethyl-O_3SAr	0.44	k_Δ	31

The concept of β_{lg}, based on the equilibrium constant values for transferring methyl groups between arenesulfonate anions (26), pioneered by Hoffman and Shankweiler (19*a*), was used to examine the extent of leaving group departure from the C atom. The essential idea of this method is that transfer of a proton between nucleophiles is not an adequate model for transfer of a methyl group. The ability to transfer a methyl group is ranked by the log of the equilibrium constant, pK_{lg}, between benzenesulfonate anion and a substituted benzenesulfonate anion. These pK_{lg} values have been used to map diverse systems of leaving group behavior. Table 8 shows a summary of the literature applications made (28). β_{lg}^{Me} is the slope of a plot of $-pK_{lg}$ vs. log k_{nuc} for methyl transfer. Its range is 0–1.0, showing no bond breaking to complete bond breaking.

The reason for presentation of these already published data is to attempt to locate the reaction type of our present system. The value of $\beta_{lg} = 0.44$ ($R = 0.98$) for our system means it resembles the leaving group portion of an ordinary S_N2 process. A k_Δ process, such as the 2-(phenylthio)-O_3SAr (neighboring group participation) could not be ruled out from these data alone. A referee pointed out a problem of interpreting the leaving group study using the β_{lg} values. This problem is discussed in the next few paragraphs.

Lewis[3] has reported a ρ value of 2.6 for the equilibrium constants for methyl transfer between arenesulfonate anions in sulfonate, on which the calculations of pK_{lg} depend. This ρ

[3]Lewis *et al.*, see ref. 17, Chap. 3.

value is nearly equal to that for ionization of benzoic acids in non-protic solvents (e.g., $\rho = 2.48$ in DMSO) (32). This ρ value will be solvent dependent, and should be ca. 1.3–1.6 in methanol (30). When corrected for the difference in ρ values in the two solvents the β_{lg} for G-NMBH anions would range from ca. 0.84 to 0.69. This range of β_{lg} values would show the NMBH anion methylation to be very tight from the nucleophile side and very loose from the leaving group side. This consideration also affects all the uses made of β_{lg} by McManus, Hoffman, *et al.* (19).

One might remark, since the studies of Hoffman, McMannus *et al.* have ranged over several previously well-established mechanistic types, without consideration of the differences in solvents, that the limitation due to solvent-dependent ρ values should be of no concern to us if all we are doing is comparing the present system with other well-known systems. It is possible, however, to finesse the consideration by calculating the ρ value for the *p*-Cl-NMBH anion reaction with the series of substituted methylarenesulfonates and comparing this value with known ρ values from the literature for other systems. From a Hammett correlation (not shown) this ρ value was determined as 1.29 ($\pm$0.07). The ρ values for comparison are as follows: for solvolysis of allylarenesulfonates in MeOH, 1.36 ($\pm$0.07), and in EtOH, 1.47 ($\pm$0.10); ethanolysis of methyl *p*- and *m*-nitrobenzenesulfonates at 70°C has $\rho = 1.32$ ($\pm$0.05) (30); for methanolysis of the same ester at 50°C, $\rho = 1.25$ ($\pm$0.04 (30). In contrast, methanolysis of 1-adamantyl esters had ρ values ranging from 1.82 to 1.65 (15–25°C) (30). (This treatment parallels Lewis' treatment in ref. 17, Chap. 3.)

We can conclude that the 4X,3Y-NMBH-methylarenesulfonate series resembles known systems that have a small amount of leaving group departure. Both β_{lg} and ρ considerations bear this out. An additional benefit is that the β_{lg} study parallels the ρ study (i.e., is valid for the present case). This statement is supported by observing that the ρ value correlates with the β_{lg} for the same reaction. Table 9 summarizes the data.

One can conclude that reaction [1], from the leaving group side, resembles an ordinary S_N2 reaction. From the nucleophile side the β_{nuc} of ca. 0.8 shows excessive bonding ($0.8 + 0.45 \approx 1.25$), which in turn suggests a very tight TS. What is the likely source of this excessive bond order?

The correlation of log rate constant with $E_{\frac{1}{2}}$ values assures us that the rate constants can be correlated, and that they probably have some claim of being accurate. The $E_{\frac{1}{2}}$ values also correlate with the pK_a values of the 4X,3Y-NMBH-H (not shown; $R = 0.98$). By itself this tells us little more than the Brønsted plots. The ionization potentials, discussed in the next paragraphs, help explain the results.

Correlation of the gas phase ionization potentials (IP), computed by the AM1 Hamiltonian in MOPAC (and diagonalization of the Hessian matrix to obtain only positive eigenvalues to ensure that each anion geometry was actually a stationary state), shows that single electron transfer character may be important in TS formation. There is no apparent reason why a gas phase computation should correlate with a solution phase measurement, particularly in protic media (38). This peculiarity of α nucleophiles was observed previously by us in cation–anion recombination chemistry (34), and by Bugner (21) for correlation of the IPs of the arenesulfonate ions (MNDO) with solution chemistry.[4]

[4]See ref. 36 for examples of the relationship between IP (gas) and IP (solution).

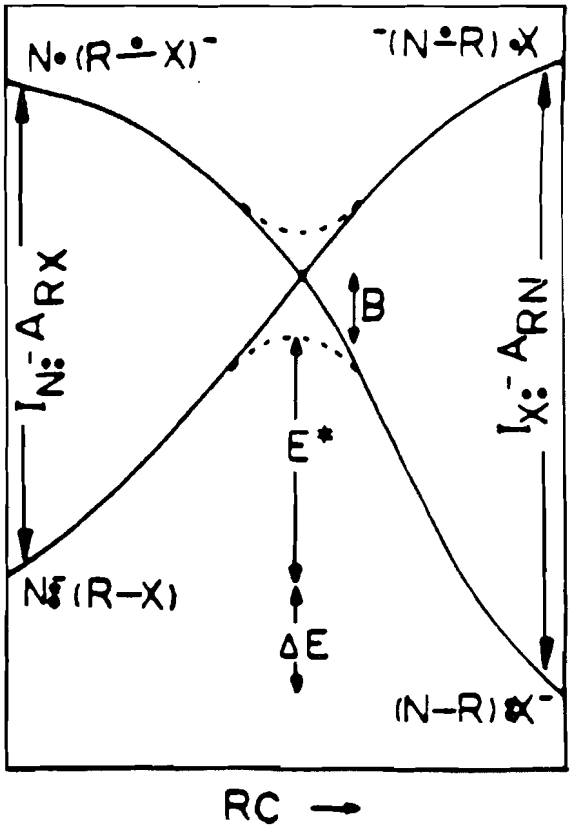

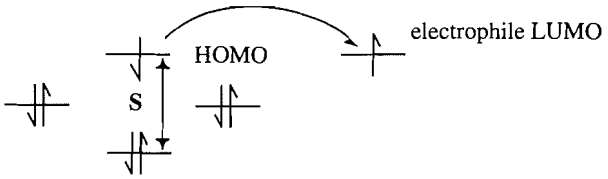

FIG. 9. Valence state configuration mixing model diagram.

Shaik's valence bond configurational mixing model (VBCM) of the S_N2 transition state (4) allows for direct inclusion of ionization potentials for both entering and leaving groups. Figure 9 summarizes the model. The transition state energy arises as a fraction of the energy gap between the ground state of the encounter complex of the nucleophile and the electrophile, and the excited state of the same complex. This excited complex has the same geometry as the ground state encounter complex. The gap is given by $I - A_{RX}$ where I is the ionization potential for the nucleophile, and A_{RX} is the electron affinity for the electrophile. As the energy of the upper state level falls and the energy of the lower state rises, the geometry of each state becomes distorted toward the geometry of its electronically corresponding partner on the diagram. At the TS the two states avoid crossing through quantum mixing of states, and the quantum hybrid representing the TS contains contributions describing transfer of a single electron, along with more conventional contributors. The degree of mixing of this single electron contribution into the TS is what is meant by "single electron transfer character," and the degree to which these

α-Nucleophiles configuration

SCHEME 1. Hoz model of the α effect.

single electron contributors mix into the TS hybrid governs how important single electron transfer characters is in TS formation.

The Hoz model (13*a*) for the α effect is summarized in Scheme 1 as a single electron transfer that contributes to an important degree to TS formation. This model shows that the α nucleophile easily transfers an electron to form a very stable radical, due to the orbital splitting retained after the single electron transfer has occurred. Thus, the mixing of a state resembling Scheme 1 into the TS involves a net stabilization of the TS because of mixing in this added stability. The α nucleophiles of this study are easily able to form radicals (35). It is therefore consistent that if one accepts the VBCM model for the S_N2 reaction and the Hoz model for the α effect, that the large β_{nuc} values should be interpreted as showing an increase of electronic transfer toward the C atom (large SET character).

The correlation of log k_{nuc} with a *gas phase* IP shows that desolvation of these α nucleophiles is perhaps not a strongly necessary process in TS formation. In Shaik's treatment of ionization potentials in nucleophilic activity (36) the ionization potentials all refer to the solvent phase. The facts that in simple cation–anion recombination (CAR) reactions the gas phase IPs of α nucleophiles correlated with N_+ values (35), and that in the present work a similar correlation also holds, show that desolvation of these nucleophiles is not important. If the SET character of the TS is important in TS formation for S_N2 reactions, and if the Hoz model is essentially correct in describing the α effect, then the data of this present study show that large β_{nuc} may be characteristic of reactions in which a large SET character in TS formation occurs.

In support of this view, Bordwell has reported (37) on the dual SET character – S_N2 behavior of 9-dialkylaminofluorenide ions. These ions, because they have the structure >C̈—N̈<, are also α nucleophiles. Their β_{nuc} values are all near 1.0 or larger. It would be a useful check if in this latter case a study of the S_N2 reactions from the leaving group side were also available.

Our basic contention is that these large β_{nuc} values, in the same systems where leaving group studies show essentially normal S_N2 behavior, are characteristic of reactions where a large SET character is present in TS formation. If this contention is tentatively accepted, several aspects of the α effect can be explained as outlined in the next few paragraphs.

The α effect is largest at carbonyls, followed by the benzylic position, then by methyl transfer. The α effect in mixtures of DMSO–water shows a dependence on solvent, with the greatest α effect coming at 50 mol% DMSO, comparing butane-2,3-dione monoximate anion with *p*-chlorophenoxide for attack at PNPA. When the structural environment around the C atom undergoing attack can carry away negative charge, e.g., for the carbonyl O atom, the α effect is largest and responds to solvent composition through easy solvation of the heteroatom (O) to give greater stability to the TS most able to transfer charge to the heteroatom. When the environment is less able to carry away negative charge, as in the benzylic case, solvation is harder for the TS because the delocalized charge is not so well solvated. In addition, the benzylic case probably involves a more open transition state in which greater carbocation character contributes, thus making both the attacking nucleophile and the leaving group more easily solvated than the C atom undergoing attack. Finally, in the methyl transfer case, apart from the leaving group, the only places into which charge can be dispersed are the H atoms on the C. These atoms are not particularly well solvated, nor are they very good at charge dispersal. The TSs here are tighter, so greater transfer of charge (greater β_{nuc}) will be observed. These ideas are corroborated in the literature in two ways. First, the bond lengths of the α nucleophiles, which have been studied by *ab initio* 4-31G computations (39*a*), are much shorter that those for normal nucleophiles. (The knowledge claimed in the thesis cited is that there is not much difference in geometries between α nucleophiles and normal nucleophiles, but in the geometries presented in the archives and in p. 114 of the thesis the Walden inversion has occurred at the TS for each α nucleophile, whereas the TSs for normal nucleophiles precede the inversion point). A case in point is that C—O bond length for OH displacing F^- is 1.973; the bond length for HOO^- displacing F^- is 1.815. Wiberg has calculated that alkoxide ions have shortened C—O bonds (implying greater bond order than in the corresponding alcohols) and greater charge on the H atoms (39*b*). The method he used was Bader's "atoms in molecules" theory in which bond critical points, where the electron density is a minimum, are related to bond lengths through the ratio of the distance between centers to the critical point. If electronegativities are equal, the critical point is midway between the atoms. If not, it is located closer to the more electronegative atom (7). There is a connection between this work and the present explanation as follows. The extra charge on the O atom of an alkoxide crudely models the additional charge on the O atom of the hydroxamate, which is due to greatly increased SET character in the TS, as in the Hoz model. (The -O—H group of the alcohol does not have this single extra negative charge.) The C—O bond increases bond order in response to this single (extra) charge in the alkoxide, and charge flows out to the H atoms. Because the O atom of the hydroxamate also contains extra negative charges (because of increased SET character in TS formation) it should also increase the bond order to the C atom undergoing nucleophilic attack. Secondly, Shi and Boyd (24), also using the Bader method, calculated at the post Hartree–Fock level (MP2, second-order Moller–Plesset perturbation level) that as charge flows toward C in an S_N2 reaction it is distributed to the H atoms. The α effect is thus much less in methyl transfer, though β_{nuc} increases, because solvation of the (now more negative) H atoms cannot include such features as H bonding. In fact, dipole–dipole bonding is not very good either.

The structural feature that distinguishes carbonyl compounds from the benzylic or methyl compounds is that excess charge easily delocalizes to the very electronegative O atom. This means that solvent stabilization of the TS (i.e., involving H bonding) is more important than with the other two cases.

The correlation of gas phase IPs of the arenesulfonates with reactivity shows that this closely related set of leaving groups in the same solvent is affected either to no extent at all, or, more likely, to the same extent by the solvent. Thus, only the gas phase IP component changes in the expression for solution phase IPs (29). One must then address the problem of solvating excess charge placed on the methyl group by the G-NMBH

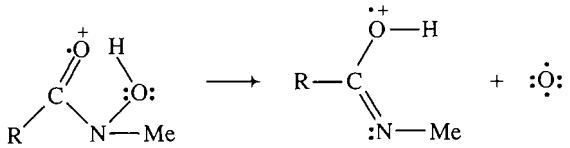
anion. Solvating the relatively nonpolar C—H bonds is not connected with a substantial diminution of TS energy because these atoms cannot hold much charge. In this scheme, examination of the leaving group behavior in the benzylic case, where solvation of the leaving group is presumably more advanced due to cation-like contributions to the TS formation, may shed light on the general validity of this explanation of the α effect. Experiments of this type, using benzylarenesulfonates, are in progress in this laboratory.

Experimental



Spectroscopy

The ^{1}H NMR spectroscopy was performed on a Varian EM 360 or on a Varian XL 200 nmr spectrometer. Infrared spectroscopy was done on either a Beckman IR or a Nicolet FT IR spectrometer as KBr pellets or Nujol mulls. GC–MS determinations were made on a Hewlett–Packard GC 5890 with a 5970 series mass selective detector and a model 7946 computer work station (5). The column was a 12-m cross-linked methyl silicon gum capillary column, 0.2 mm × 0.33 μm film thickness.

Preparation of material

N-Methylbenzohydroxamic acids rearrange on heating to the *O*-acylated, thermodynamically controlled product (5*b*). However, Crumbliss and co-workers have detailed a good method for ensuring synthesis in good yield and high purity (5*a*), and some NMBH acids (NMBH-H) were made by this method. A simpler method that gave modest yields of great purity of the NMBH-H was developed as follows.

In a typical procedure, a 10.0 g (120 mmol) sample of *N*-methylhydroxylamine hydrochloride (Aldrich, 98% purity) was dissolved in 50 mL of water in an Erlenmeyer flask and neutralized with a 2.1-fold molar excess of solid sodium carbonate at ice-water bath temperature. *p*-Chlorobenzoyl chloride (20.95 g, 120 mmol) (Aldrich, 99% purity) was dissolved in sufficient *p*-dioxane (**CAUTION**: cancer suspect agent!) to give a 25% solution. This solution was added dropwise over 45 min with cooling and magnetic stirring. After an additional 3 h the precipitate was filtered (62% yield) to give 14.88 g of very pure material. Recrystallization from turbid acetone–water solutions, chilled in the refrigerator overnight, gave material that was 100% by GC–MS. The physical properties of the new G-NMBH-H appear in Table 10 with the microanalytical results. All compounds had ^{1}H NMR spectroscopy consistent with their structures. The GC–MS work displayed an interesting feature. At injection port temperatures above 260°C two peaks appeared in the GC trace of several G-NMBH-H. The second peak, at shorter retention time, was due to the corresponding *N*-methylbenzamide as shown by the MS. Lowering the inlet temperature to ca. 220–240°C gave a single peak of usually 100% purity (see ref. 5*a*). The MS of these peaks was always that of the corresponding amides. These compounds apparently extrude O easily, either by thermal excitation or by electron ionization. A cyclic transition state, leading to a distonic ion species, could account for this finding as shown below (8, 9). It is interesting that some *N*-phenylhydroxamic acids undergo a similar extrusion of O at 25°C in $CDCl_3$; see ref. 33.

Known compounds had physical properties consistent with literature values, and were analyzed by GC–MS to at least 98% purity.

Preparation of methylarenesulfonates was by literature methods (20), with analytical data given in Table 11.

Sodium salts of G-NMBH-H

Sodium salts were generated from the corresponding 4X,3Y-NMBH-H by dissolving the 4X,3Y-NMBH-H in methanol and adding an equivalent amount of standardized NaOMe in MeOH. Solvent removal or precipitation with ether gave the pure salts in dihydrated forms. IR examination of the air-dried salts showed substantial water content. This was confirmed by microanalysis (Desert Analytics). Table 12 represents typical results. First the salts were analyzed as received. Then, drying carefully under N_2 gave monohydrates; finally, the anhydrous salts were obtained by heating under N_2 for a longer period.

Similar results were obtained for other salts. The anhydrous salts readily acquired water on standing at ambient conditions. The hydration of these salts was extensive in each case, all forming dihydrates and losing water only after lengthy heating, sometimes with decomposition.

Kinetics

Kinetics were performed on the XL 200 by following the ^{1}H NMR signal of the methyl group of the methyl arenesulfonate at ca. 3.7 ppm. A 10.0 μL sample of dichloromethane was inserted in each kinetic run as an inert internal standard for measuring signal intensities. Samples of substrates and 4X,3Y-NMBH salts were weighed into calibrated pycnometers of 1.00 mL nominal volume, quickly diluted, and placed into the NMR magnet. Data were collected as an arrayed experiment, using the preacquisition delay (PAD) feature of the instrument. Temperature control was by the VT probe and was 29.5 ± 0.5°C. Typical data from a run appear in Table 13, and are plotted in Fig. 10.

A scalar for the I' signals was used. Scalar = I^0_{std}/I'_{std}. Each I' was multiplied by the scalar for that time and the $I - x$ column results. A factor relating the slope of the plot of $1/(I - x)$, Fig. 10, was used by equating the $I^0 = 207.403$ to the molar concentration. Here $M = 0.150$, so the factor is $207.304/0.150M = 1379.4\ M^{-1}$. The slope of Fig. 10 is 1.60×10^{-5}. The rate constant is $k = 1.60 \times 10^{-5} \times 1379.4 = 0.220\ M^{-1}\ min^{-1}$.

Kinetic runs were at least duplicated. No regression coefficient less than 0.98 was accepted. The results for all the runs are in the tables, with the error limits noted there.

Competition reactions

(a) The determinations of the rate constant of 3,5-diNO_2NMBH anion

The GC–MS of straightforward ^{1}H NMR kinetic determinations showed essentially no 3,5-diNO_2NMBH-OMe present, but instead a large amount of methyl 3,5-diNO_2benzoate-d_3 was found. Also the

[a]Intensity of the CH_2Cl_2 signal, as printed out at time t, by the instrument.
[b]The raw intensity of the OMe group of the methylarenesulfonate.
[c]Adjusted intensity at time t. (A referee pointed out that plotting the peaks as a fraction of the standard peak is an alternate method.)

kinetic results had apparent rate constants that were the largest of the entire 4X,3Y-NMBH group. The regularity of the other points in Fig. 5 indicates that this result is due to something other than the reaction we expected. This fact was confirmed when we performed competition experiments. The method used is outlined in ref. 10, and care was taken to ensure a ratio of at least 10:1 of both NMBH and 3,5-diNO_2NMBH anions. Thus, 209 mg (1.0 mmol) of NMBH anion (Na salt) and 299.0 mg (1.0 mmol) of sodium 3,5-diNO_2NMBH were dissolved in 1.0 mL of methanol-d_4 and 20.2 mg (0.1 mmol) of p-$MeOC_6H_4SO_3Me$ was added via preweighed microlitre syringe. After 15 min the reaction mixture was quenched with glacial acetic acid, and the mixture analyzed by GC–MS. Relative response factors for the compounds were determined by running known mixtures of authentic material. The response was within 3% of linear in grams.

The area ratio was related to the rate constant as follows:

$$[\text{NMBH-OMe}]/[3,5\text{-No}_2\text{NMBH-OMe}] = 26.884/7.167 = 3.75$$

When corrected for the MW ratio this is

$$k_{rel} = 3.75 \times 255.18/165.19 = 5.79$$

The rate constant was found by multiplying $0.029 \times 1/5.79 = 0.0050$; $\log k = -2.301$. (**Note**: These figures represent averages of duplicate runs. The $k_{avg.} = 0.0050 \pm 0.00045$). Only two significant figures were kept for all rate constants.

(b) Competition reactions of the most basic G-NMBH anions in excess base

The competition reaction experiments were set up as for the 3,5-diNO_2NMBH, except that Na methanol-d_4–methoxide-d_3 mixtures were used. Sufficient base was used (0.165 M) to ensure the deprotonation of the nucleophiles. Typically, relative rates were determined vs. p-NO_2NMBHNa, by dissolving the salt to be compared in the excess base mixture. (The MeONa-d_3 was made from NaH and methanol-d_4 in a glove box under argon.) The solutions were divided into two parts by syringe, and to each part was added an amount of methyl p-methoxybenzenesulfonate equal to 0.1 molar equivalent, as described for the 3,5-NO_2NMBHNa experiments. A typical result is given for 4-MeO-NMBHNa vs. NMBHNa.

Samples of 20.6 mg NMBHNa and 23.9 mg of 4-MeONMBHNa (0.1 mmol each) were weighed into two preweighed, dried vials. To each vial 1.00 mL of 0.165 M NaOMe-d_3 was added. The contents of the two vials were mixed thoroughly and divided into two portions. To each portion was added 0.005 mmol of methyl p-methoxybenzenesulfonate via a microlitre syringe. GC–MS gave peaks that could be identified by their MS, and by comparison with authentic material as described above for 3,5-diNO_2NMBH. The rate constants were computed as follows:

$$\frac{\text{Area ca. 9.973 min}}{\text{Area ca. 10.54 min}} = \frac{18.86}{96.19} = 0.196$$

$$k_{\text{NMBHNa}}/k_{p\text{-MeONMBHNa}} = 0.196 \times 195/165 = 0.232$$

The NMBHNa, in competition with p-NO_2NMBHNa, gave a rate

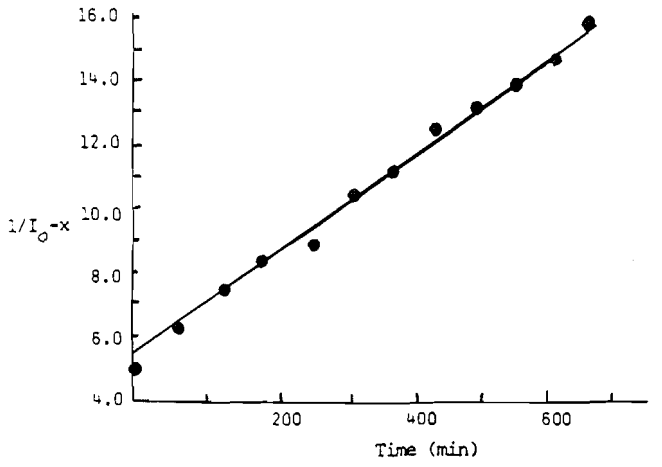

FIG. 10. Kinetic plot for *p*-ClNMBH anion reacting with methyl *p*-methoxybenzenesulfonate in methanol-d_4 at 29.5°C (±0.5).

constant of 0.0642 (±0.0002) and values determined by competition with NMBHNa were corrected to *p*-NO_2NMBHNa to give the results in Table 1.

Similarly the aqueous phase results were determined in 20% dioxane – 80% water. The salts were weighed into vials to 0.1 mg accuracy and each dissolved in 2.000 mL of the solution. The solutions were mixed and divided into two equal parts with a syringe. To each part was added 6.00 microlitres of alkylation agent (less than 0.1 mmolar equivalent in each case). After standing for an hour at 29.5°C (±0.1) in a circular bath (see below), the aqueous phase was extracted with 1.00 mL of methylene chloride and the aqueous layer removed with a pipette. Analysis by GC–MS was performed, and the GC peaks identified both by comparison of retention times with authentic samples and with their MS results. Table 2 summarizes the results.

Determination of pK_a values of 4X,3Y-NMBH

The p*K*a values of the 4X,3Y-NMBH-H indicated in Table 3 were determined by back titration of their sodium salts in solutions that were 2.0 M in KNO_3, using Nanopure water (Barnsted system). The titration was done in a jacketed cell at 25°C (±0.1) using a glass electrode and a standard Markson pH Meter (model 90). The temperature control was supplied by a Neslab–Endocal RTE-9 circulator. The sodium salts were titrated with standard HCl, and the pH–volume data plotted (ref. 10, p. 8).

The pK_a values in anhydrous methanol were determined by the overlapping indicator method,[5] using *p*-nitrophenol as the indicator (Aldrich Indicator Grade >99.99%). A sample determination is illustrated below.

The determination of the pK_a of 3,5-diNO_2NMBH-H is illustrated. A solution, 1.141×10^{-4} M in 3,5-diNO_2NMBH-H in anhydrous methanol, was treated with a 0.5000 equivalent amount of 0.0082 M NaOMe in anhydrous MeOH (distilled from Mg and I_2) to give a solution that was 5.705×10^{-5} M in salt and acid when diluted to 250.00 mL. The molar absorption values for 3,5-diNO_2NMBH and *p*-nitrophenolate were obtained from solutions of known concentration of the acids reacted with excess NaOMe/MeOH. They are $a_{3,5} = 1543.3$ (at 400 nm), and 4697.3 (at 300 nm); $a_{pNO_2} = 21\,502.2$ (400 nm) and 7025.2 (300 nm). The absorbance of this solution, when mixed with a similarly prepared solution, 5.655×10^{-5} M in *p*-nitrophenol and its anion in equal amounts, was 1.9062 (400 nm) and 0.4792 (300 nm). All determinations were made on a Beckman DU70, with all numerical values read digitally. Solution of the simultaneous equations relating the contributions of components at the indicated wavelengths gave concentrations of [*p*-NO_2-$C_6H_4O^-$] = 6.58×10^{-5} M and [3,5-diNO_2NMBH$^-$] = 8.65×10^{-5} M. From these values, and the known starting concentrations of the acids and salts, the concentrations of the conjugate acids could be calculated. Because each species present is a weak acid, the solution is highly buffered, and a_{H^+} is constant. Equation [2] therefore holds if the activity coefficients are 1.000, a reasonable assumption for these solutions. Computation of the pK_a follows from the known value of 11.15 for *p*-nitrophenol (see ref. 12*a*).

The pK_a of *p*-MeONMBH-H in anhydrous methanol was determined in the same way except that bromothymol blue (pK_a = 12.4) (see ref. 12*b*) was the indicator. The NMBH anions and conjugate acids are all known to follow Beer's law (40), see eq. [2].

Considerable overlapping of UV bands of the indicator and the 4X,3Y-NMBH anions occurred, but this handicap was overcome by using λ = 313 nm for the *p*-nitrophenyl, and λ = 390 nm for the conjugate base in excess 0.1 M NaOMe in MeOH. A region of absorbance was found for each 4X,3Y-NMBH anion used where the indicator did not absorb (except for 3,5-diNO_2NMBH-H, where a simultaneous equation had to be solved). Measurements were made in this region on the conjugate base of the 4X,3Y-NMBH-H in excess 0.1 M NaOMe in MeOH. The pK_a was computed from the known concentration of 4X,3Y-NMBH-H, the known concentration of the *p*-nitrophenyl and its measured anion concentration, and the measured 4X,3Y-NMBH anion concentration.

The results are displayed as a Hammett plot in Fig. 3. From this plot the pK_a values were obtained for those 4X,3Y-NMBH-Hs not having a region of absorbance free from overlap with the absorbance of the indicator. The Hammett plot for the pK_a values in anhydrous methanol is interesting because it shows that the solvent has a large effect on the sensitivity of the basicity of 4X,3Y-NMBH anions to the substituents on the ring. The ratio of values, MeOH/H_2O = 1.94, is close to the ratio of transfer of benzoic acid from water to methanol (=1.54) (41). The basicities of the 4X,3Y-NMBH anions become much more sensitive to substituents in the nonaqueous solvent, so their S_N2 reactivity is also expected to increase. There is a regular increase in basicity of 4X,3Y-NMBH anions as water content of the medium decreases. The ρ value in 80% methylcellusolve is 0.95 (40), which shows the same conclusion.

Determination of the α effect

This determination was performed in a manner similar to the competition reactions. A typical run is described.

A 20.9 mg (0.10 mmol) sample of NMBHNa was dissolved with 16.1 mg (0.10 mmol) of sodium *m*-nitrophenoxide (from NaOMe plus *m*-nitrophenol, Aldrich, 99% purity) in 1.0 mL of methanol-d_4. To this mixture was added 0.2 μL of *p*-MeO-$C_6H_4SO_3$Me. After 1 h the reaction was quenched with glacial acetic acid (subsequent work showed this step was unnecessary), and analyzed by GC–MS. The peak at 3.346 min has the MS of *m*-nitroanisole; that of 3.810 min was that of the NMBH-OMe. The product ratio was PR = 72.71/21.77 = 3.34; α effect = 3.34 × 153/165 = 3.10. Repetition gave a value of 3.94 for an average of 3.52 ± 0.42. Similar experiments with *p*-MeONMBHNa and 3,5-dichlorophenol gave an α effect of 4.81 ± 0.25 (two trials).

In an entirely analogous manner, the α effect for NMBHNa vs. sodium *m*-nitrophenoxide was determined in 80% H_2O – 20% dioxane. The value was 8.7 ± 1.2.

Determination of oxidation potentials, $E_{\frac{1}{2}}$

The oxidation potentials of 4X,3Y-NMBH anions were determined by cyclic voltammetry as follows: the sodium salts were dissolved in anhydrous methanol containing 0.1 M tetrabutylammonium perchlorate as the supporting electrolyte. Cyclic voltammetric experiments were performed using a model 273 PAR potentiostat/galvanostat with a PAR 175 universal programmer. Electronic IR compensation was used for all electrochemical experiments. A Nicolet model 310 digital storage oscilloscope was used to collect the potential–current data. A three-electrode cell configuration was used, with a glassy carbon working electrode, a silver/silver chloride reference electrode, and a Pt wire auxiliary electrode. At scan rates greater than 200 mV/s the reversibility is evidenced by the presence of a cathodic peak of approximately equal magnitude to the anodic peak. This cathodic peak corresponds to the reduction of the NMBH radical that is formed electrochemically on the anode scan. For many compounds, a relative

[5]A brief discussion of the principles of this method is given in ref. 38.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

decrease in the cathodic peak is observed for scan rates less than ca. 200 mV/s, suggesting that the radical is undergoing a chemical reaction on these time scales. The results are collated in Table 4.

Determination of reactivity as a function of leaving group

The reactivity of *p*-ClNMBHNa in anhydrous methanol-d_4 was determined with several substituted methyl arenesulfonates in the same manner as outlined in this section for the study of various 4X,3Y-NMBHNa salts with methyl *p*-methoxybenzenesulfonate. The results are summarized in Table 6 and Fig. 6 of the results section.

Phosphoric amides. Part 11.[1] Intramolecular reactivity of phosphorotriamidates

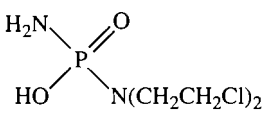
SIEGELINDE BAUERMEISTER, AGNES M. MODRO, TOM A. MODRO,[2] AND ANDRZEJ ZWIERZAK[3]
Department of Chemistry, University of Pretoria, Pretoria 0002, South Africa

Received September 24, 1990

SIEGELINDE BAUERMEISTER, AGNES M. MODRO, TOM A. MODRO, and ANDRZEJ ZWIERZAK. Can. J. Chem. **69**, 811 (1991).

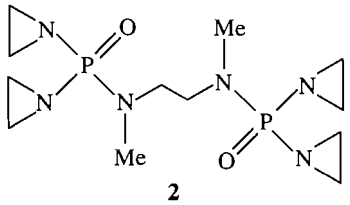
Five *N*-(2-chloroethyl)phosphorotriamidates, $(RNH)_2P(O)NHCH_2CH_2Cl$, have been synthesized, and their behavior under strongly basic conditions was studied. For *N*-alkyl derivatives (R = Me, $PhCH_2$), base-promoted intramolecular displacement of chloride yielded the *N*-phosphorylated aziridine, $(RNH)_2P(O)NC_2H_4$, as the exclusive cyclization product. For *N*-aryl derivatives (R = Ar), both the aziridine and the 1,3,2-diazaphospholidine, $RNHP(O)NHCH_2CH_2NR$, products could be obtained in comparable yields. The *N*-aromatic cyclic products are mutually interconvertible: 1,3,2-diazaphospholidines rearrange to the corresponding aziridines upon treatment with base, while bromide ions catalyze the reverse isomerization.

Key words: phosphoramidates acidity, *N*-phosphorylated aziridines – 1,3,2-diazaphospholidines isomerization, 1,3 vs. 1,5 cyclization.



SIEGELINDE BAUERMEISTER, AGNES M. MODRO, TOM A. MODRO et ANDRZEJ ZWIERZAK. Can. J. Chem. **69**, 811 (1991).

On a réalisé la synthèse de cinq *N*-(2-chloroéthyl)phosphorotriamidates, $(RNH)_2P(O)NHCH_2CH_2Cl$, et on a étudié leur comportement dans des conditions fortement basiques. Pour les dérivés *N*-alkylés (R = Me, $PhCH_2$), le déplacement intramoléculaire du chlorure, catalysé par les bases, fournit l'aziridine *N*-phosphorylée, $(RNH)_2P(O)NC_2H_4$, comme seul produit de cyclisation. Pour les dérivés *N*-arylés (R = Ar), on peut obtenir avec des rendements comparables l'aziridine ainsi que la 1,3,2-diazaphospholidine, $RNHP(O)NHCH_2CH_2NR$. Les produits cycliques *N*-aromatiques sont mutuellement interconvertibles; les 1,3,2-diazaphospholidines se transposent en aziridines correspondantes par traitement avec des bases alors que les ions bromures catalysent l'isomérisation inverse.



Mots clés : acidité de phosphoramidates, isomérisation aziridines *N*-phosphorylées – 1,3,2-diazaphospholidines, cyclisations 1,3 vs. 1,5.

[Traduit par la rédaction]

The phosphoramide mustard **1** is believed to be the active metabolite of the anti-tumor alkylating drug, cyclophosphamide, its cytotoxic action involving the cross-linking produced in cellular DNA (1). The alkylating reactivity of **1** is attributed to its intramolecular cyclization to the aziridinium ion, followed by the intermolecular reaction of that intermediate with a biological nucleophile (2). *N*-Phosphorylated aziridines (e.g., *aphamide* **2**) are known inhibitors of cell division, the property

1

2

responsible for their application as insect chemosterilants. Their sterilizing, as well as carcinogenic, action is again attributed to the alkylation of biological centers (3).

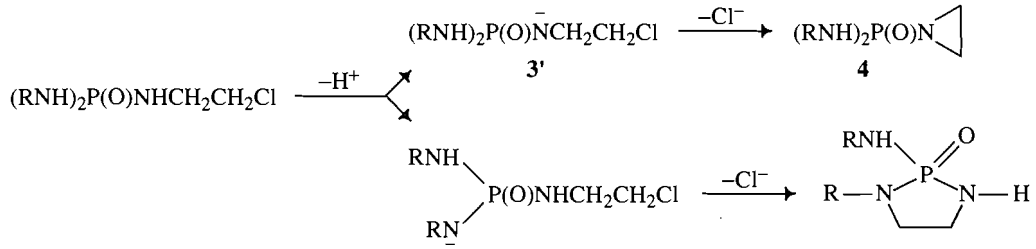
Intramolecular reactivity of a system of type **1** can, however, involve not only the 1,3 displacement of chloride ion (aziridinium ion formation), but also the 1,5 substitution in the NPNCCCl system, yielding the 1,3,2-diazaphospholidine product. Such cyclization was in fact postulated (4) and demonstrated (5) for the nonenzymatic hydrolysis of cyclophosphamide itself. Similarly, a compound like **2** may undergo a nucleophilic ring opening reaction not only with an external nucleophile, but via the attack of the endocyclic nitrogen, yielding the isomeric 1,3,2-diazaphospholidine skeleton. Such an intramolecular 1,5 opening of the aziridine ring was postulated (2) in the ^{31}P nmr spectroscopic study on the chemistry of phosphoramide mustard derivatives.

In this paper we report our results on the intramolecular reactivity of the *N*-(2-chloroethyl) substituted phosphorotriamidates **3**, in which the base-promoted cyclization via the nucleophilic displacement of chloride ion can lead directly to the aziridine **4** or 1,3,2-diazaphospholidine **5** derivatives (Scheme 1).

The proportion of the isomeric products **4** and **5** should be determined by the proportion of the respective conjugate bases **3'**, **3''**, and by the relative rates of the 1,3 and 1,5 cyclization steps. The first factor depends on the relative substituent effects of groups R and the 2-chloroethyl group on the acidity of the adjacent NH function. The second (kinetic) factor is more difficult to ascertain. Contrary to popular belief, the closure of three-membered rings is not necessarily favored over the formation of larger systems, and the k_3/k_5 ratio for different intramolecular reactions can vary from very high to very low values (6). The other problems addressed in this work relate to the structural effects and reaction conditions required for the base- or nucleophile-promoted mutual isomerization of products **4** and **5** via the respective anionic intermediates.

Results and discussion

Substrates **3** were prepared from phosphoryl chloride, according to eq. [1].



[1] $$P(O)Cl_3 \xrightarrow{ClCH_2CH_2NH_3^+Cl^-} ClCH_2CH_2NHP(O)Cl_2 \xrightarrow{4\ RNH_2} \mathbf{3}$$

The relative acidity of the NH functions in substrates **3** was assessed by examining the chemical shifts of the NH proton signals in the ^1H nmr spectra of those compounds. Although the relationship between the δ value of a proton and its acidity is only an approximate one (7), significant differences in the δ values found for the chemically non-equivalent NH groups in

SCHEME 1

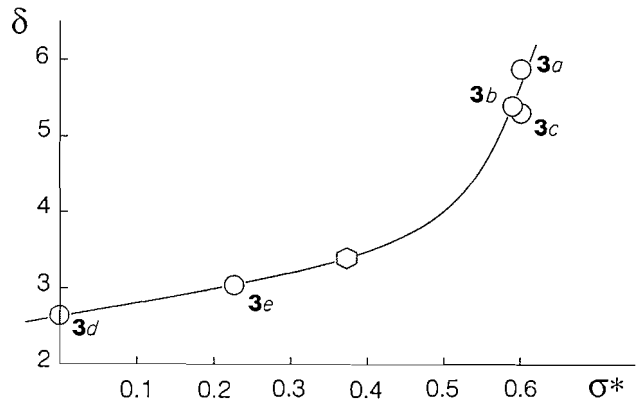

FIG. 1. δ_{NH} (ppm, $CDCl_3$, $c = 0.2$ M) vs. σ* for substrates **3**. ○: RHN: ⬡: average value for $HNCH_2CH_2Cl$ in **3***a–e*.

3 were used to determine the relative acidity order. Figure 1 shows the dependence of the shielding of the NH protons in **3** on Taft's polarity constants[4] of N substituents. The observed trend indicates that for the *N*-aromatic substrates, **3***a–c*, the conjugate base **3''**, and for **3***d,e*, the conjugate base **3'** should represent the major form of the deprotonated substrate. It was expected therefore that substrates **3***d,e* should yield aziridines **4**, *unless* the 1,3 ring closure in this system is much *slower* than the alternative 1,5 cyclization. For **3***a–c*, on the other hand, the diazaphospholidine **5** should be expected as the major product, *unless* the 1,3 cyclization is much *faster* than the direct cyclization of **3''** to **5**. We have found that when substrates **3***a–e* are treated with bases in the presence of phase-transfer catalyst (PTC, tetra-*n*-butylammonium bromide or bisulfate (9)),[5] they react smoothly according to Scheme 1 and the product composition depends on the substrate and the reaction conditions. For each **3** the reaction products were isolated in the pure state and characterized by nmr (^1H, ^{31}P) spectroscopy and elemental analyses. The results of cyclization of substrates **3** are given in Table 1.

For the *N*-alkyl substrates **3***d,e* the regioselectivity of the cyclization was complete; the corresponding *N*-phosphorylated aziridines **4** were the exclusive products, stable under reaction conditions. We confirmed this preference for the 1,3 cyclization of *N*-alkylphosphoroamidates on one additional example, i.e., diamidoester, *O*-methyl-*N*-methyl-*N'*-(2-chloroethyl)diamidophosphate **6**. Again, this substrate yielded, upon treatment with base, exclusively the aziridine **7** (eq. [2]), with no trace

[2] (MeO) (MeNH)P(O)$NHCH_2CH_2Cl$ —base→ **6**

(MeO) (MeNH)P(O)N **7**

of the corresponding 1,3,2-diazaphospholidine being formed (as demonstrated by comparison with an authentic sample). Although these results confirm the expected preferential (or exclusive) formation of **3'** (or the corresponding conjugate base of **6**) in the deprotonation step, they do not by themselves provide any conclusive information about the relative rates of the cyclization steps.

For the *N*-aromatic substrates **3***a–c* the results obtained are more complex. When the reactions were carried out in the presence of a small excess of the base (or for short periods), comparable quantities of both cyclization products, **4** and **5**, were formed. The formation of both products (which were isolated as pure compounds and were found to be stable under neutral conditions) demonstrates that for **3***a–c* the 1,5 cyclization can compete successfully with the 1,3 ring closure. When large excess of a base was used, and when reactions were carried out under more drastic conditions, the aziridine derivatives **4** were, however, formed as the exclusive products. It is clear therefore that those two types of compounds initially formed can undergo, under the reaction conditions, subsequent interconversion, finally yielding **4** as the sole reaction product. Those secondary reactions were then tested by investigating independently the effect of base (sodium hydride), and of tetrabutylammonium bromide on the individual cyclic products **4***a–e* and **5***a–e*, obtained either directly from the corresponding substrates **3** (**4***a–c*; **5***a–c*; **4***d,e*), or prepared by an independent route (**5***d,e*). This route involved formation of the 1,3,2-diazaphospholidine by the reaction of the corresponding *N*-substituted ethylenediamine with the *N*-substituted phosphoroamidodichloridate (eq. [3]).

With respect to the *N*-aromatic compounds, **4***a–c*, TBABr was found to catalyze their complete conversion to the 1,3,2-

[4]No proper parameters that describe ionization of the RNH function are available. The Taft's scale (in which σ* values could be found (8) for all N substituents) ignores the resonance effects, as can be seen from the upward curvature of the plot for the NAr substituents.

[5]Since sodium (or potassium) salts of **3** are insoluble in benzene (and other solvents tested), the addition of PTC was necessary for the reaction to proceed at reasonable rates.

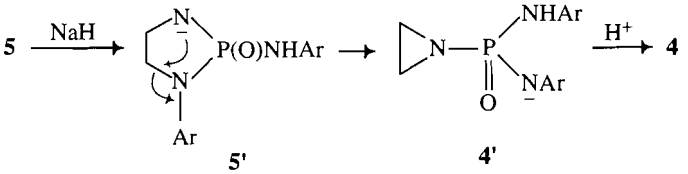
5*d*, *e*

diazaphospholidine derivatives **5***a–c*. The reaction most likely proceeds via the nucleophilic opening of the aziridine ring, internal proton transfer, and the 1,5 ring closure (Scheme 2). When the reaction mixture was quenched with water, the ^{31}P nmr spectrum of the product always revealed, in addition to **5** (and, in some cases, unreacted **4**), small quantities of the product with the δ ^{31}P almost identical to that of the corresponding **3**. We assigned this signal to the conjugate acid of **6***a* (or **6***b*); thus we took it as evidence for the first step of the interconversion. The driving force for the **6***a* → **6***b* proton transfer should stem, of course, from the difference in the pK_a values of the NH groups of the ArNH and the $BrCH_2CH_2NH$ functions (*vide supra*). With **4***d* and **4***e*, although the bromide-induced opening of the aziridine ring (Scheme 2) should also take place, the subsequent proton transfer, prerequisite for the isomerization, is not favored by the pK_a difference of the respective NH groups. As a consequence, when **4***d*, **4***e* were treated with TBABr in benzene, they gave, even after prolonged heating under reflux, only minor (less than 10%) quantities of the corresponding **5**, the bulk of the substrate remaining unchanged.



4, *a*: Ar = Ph
b: Ar = 4-MeC_6H_4
c: Ar = 4-$MeOC_6H_4$

SCHEME 2

With respect to the base, the situation is as follows. All *N*-phosphorylated aziridines **4***a–e* were stable upon prolonged treatment with sodium hydride. The absence of the isomerization results most likely from the reluctance of the conjugate base of **4** to undergo the intramolecular opening of the aziridine ring. Such a reaction, corresponding to the "5-*endo-tet*" cyclization process, should be disfavored on stereochemical grounds (10).

N,N'-Diaryl 1,3,2-diazaphospholidines **5***a–c* differ greatly in their reactivity under basic conditions from their *N*-alkyl (methyl, benzyl) analogues **5***d,e*. The former compounds, when heated in benzene solution in the presence of sodium hydride, undergo quantitative conversion to the corresponding isomeric products **4**. This interconversion, also responsible for the gradual disappearance of products **5**, initially formed by the base-promoted cyclization of **3***a–c*, can be explained by the following sequence (Scheme 3):

SCHEME 3

The **5'** → **4'** rearrangement illustrates the known (11) preference for the formation, if possible, of a three-membered ring. In this case, however, we observe a rather unusual example of a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

"3-*exo-tet*" ring closure proceeding via the *syn* (and not, as in most cases, *anti*) orientation of the nucleophilic center (N^-) and the departing group (ArN^-). Both *N*-alkyl substrates **5***d*,*e* were found to be unaffected by sodium hydride, even after long periods of treatment. We explain this difference in stability by the difference in the structural conditions for the rearrangement of the conjugate base of **5** to the conjugate base of **4** (see Scheme 3). For **5***a*–*c*, the 1,3 ring closure is facilitated by the departure of a relatively good leaving group, i.e., the ArN anionic group. In the case of **5***d*,*e*, the rearrangement would involve the departure of a much poorer (more basic) leaving group, such as the RN^- group. It is worth noting that, in all substrates **5**, the parallel deprotonation of the exocyclic NH function could, in principle, also lead to a rearrangement process, but that pathway would again lead to the formation of a 1,3,2-diazaphospholidine system.

Experimental section

Solvents and commercially available substrates were purified by conventional methods immediately before use. The nmr spectra were recorded on a Bruker AC 300 MHz spectrometer in $CDCl_3$, and the chemical shift values are given relative to TMS (^1H) and trimethyl phosphate (^{31}P). For column chromatography Merck Kieselgel 60 (0.063–0.200 mm) was used as a stationary phase. The products were collected as homogeneous (according to tlc) fractions.

Substrates

N-*Benzylethylenediamine* was prepared from ethylenediamine (4 mol-equiv.) and benzyl bromide (1 mol-equiv.) by heating the mixture at reflux for 3 h. After washing with water and drying, pure product was obtained by distillation, 47% yield, bp 100°C (0.1 Torr; 1 Torr = 133.3 Pa); n_D^{20} 1.5417; ^1H nmr δ: 1.35 (3H, s, disappears in D_2O, NH), 2.61 (2H, t, J_{HH} 5.7 Hz, CH_2N), 2.73 (2H, t, J_{HH} 5.7 Hz, CH_2N), 3.73 (2H, s, CH_2Ph), 7.25 (5H, br s, Ph). Anal. calcd. for $C_9H_{14}N_2$: C 72.0, H 9.4, N 18.6; found: C 72.4, H 9.1, N 18.8%.

N-*Methylphosphoroamidodichloridate* was prepared from phosphoryl chloride and methylammonium chloride (12); 98% yield, purified by bulb-to-bulb distillation (oven temp. 110°C/0.2 Torr); n_D^{22} 1.4732; ^1H nmr δ: 2.72 (3H, d, J_{HP} 19.5 Hz, NMe), 5.07 (1H, br s, NH); ^{31}P nmr δ: 16.8.

N-*Benzylphosphoroamidodichloridate* was prepared in the same manner from phosphoryl chloride and benzylammonium chloride in almost quantitative yield (crude product); ^1H nmr δ: 4.25 (2H, d, J_{HP} 14.7 Hz, CH_2), 5.20 (1H, br s, NH), 7.31 (5H, br s, Ph); ^{31}P nmr δ: 13.6. The product was thermally unstable and could not be distilled without decomposition. It was therefore used for preparation of **5***e* without purification.

N-*(2-Chloroethyl)phosphoroamidodichloridate*

Phosphoryl chloride (3.9 mol-equiv.) and well-dried and finely powdered 2-chloroethylammonium chloride (1 mol-equiv.) were mixed and heated at reflux with exclusion of moisture for 16 h. The excess $POCl_3$ was distilled off and the residue was purified by distillation; 94% yield, bp 98–99°C (0.05 Torr); n_D^{25} 1.5031; ^1H nmr δ: 3.43 (2H, m, NCH_2), 3.64 (2H, t, J_{HH} 5.9 Hz, CH_2Cl), 5.04 (1H, br s, NH); ^{31}P nmr δ: 13.1.

Phosphorotriamidates 3; general procedure

A ca. 5 M solution of *N*-(2-chloroethyl)phosphoroamidodichloridate (1 mol-equiv.) in the appropriate solvent was added dropwise with stirring and cooling (−5 to 0°C) to the ca. 4 M solution of the required amine (4 mol-equiv.) in the same solvent. The mixture was then stirred at room temperature overnight, the amine hydrochloride was filtered off, and the organic solution was washed with water and dried ($MgSO_4$). After removal of the solvent the crude **3** was purified as indicated below.

3*a*: Prepared in $CHCl_3$, 93% yield. Purified by two crystallizations (benzene/$CHCl_3$ 1:1, followed by ethanol), mp 117–118°C; ^1H nmr δ: 3.33 (2H, m, NCH_2), 3.50 (2H, t, J_{HH} 5.5 Hz, CH_2Cl), 3.59 (1H, br s, $NHCH_2$), 5.71 (2H, d, J_{HP} 7.8 Hz, 2 × NHPh), 6.94 (2H, t, J_{HH} 7.2 Hz, H_{ortho}), 7.09 (3H, m, H_{meta}, H_{para}); ^{31}P nmr δ: 0.55. Anal. calcd. for $C_{14}H_{17}ClN_3OP$: C 54.3, H 5.5, N 13.6; found: C 54.5, H 5.4, N 13.5%.

3*b*: Prepared in ether, 67% yield. Purified by crystallization from ethanol/water; mp 154–155°C; ^1H nmr δ: 2.24 (6H, s, 2 × $ArCH_3$), 3.33 (3H, m, $NHCH_2$), 3.52 (2H, t, J_{HH} 5.4 Hz, CH_2Cl), 5.26 (2H, d, J_{HP} 6.9 Hz, 2 × NHAr), 6.94 (4H, d, J_{HH} 8.4 Hz, H_{meta}), 7.00 (4H, d, J_{HH} 8.4 Hz, H_{ortho}); ^{31}P nmr δ: 1.09. Anal. calcd. for $C_{16}H_{21}ClN_3OP$: C 56.9, H 6.3, N 12.4; found: C 56.7, H 6.1, N 12.4%.

3*c*: Prepared in $CHCl_3$, 45% yield. Purified by crystallization from ethanol; mp 150–150.5°C;. ^1H nmr δ: 3.30 (3H, m, $NHCH_2$), 3.50 (2H, t, J_{HH} 5.6 Hz, CH_2Cl), 3.72 (6H, s, 2 × OCH_3), 5.24 (2H, d, J_{HP} 7.7 Hz, NHAr), 6.74 (4H, d, J_{HH} 8.9 Hz, H_{meta}), 6.99 (4H, d, J_{HH} 8.9 Hz, H_{ortho}); ^{31}P nmr δ: 1.80. Anal. calcd. for $C_{16}H_{21}ClN_3O_3P$: C 52.0, H 5.7, N 11.4; found: C 51.9, H 5.5, N 11.3%.

3*d*: Prepared in benzene, 63% yield. Purified by column chromatography (ethanol); ^1H nmr δ: 2.55 (6H, d, J_{HP} 12.2 Hz, 2 × NCH_3), 2.60 (2H, br s, 2 × NHMe), 3.06 (1H, m, $NHCH_2$), 3.24 (2H, m, CH_2N), 3.58 (2H, t, J_{HH} 5.8 Hz, CH_2Cl); ^{31}P nmr δ: 16.85. Anal. calcd. for $C_4H_{13}ClN_3OP \cdot 2H_2O$: C 21.7, H 7.7, N 19.0; found: C 21.3, H 7.3, N 18.6%.

3*e*: Prepared in ether, 97% yield. Purified by crystallization from ether/cyclohexane; mp 63–64°C; ^1H nmr δ: 2.95 (3H, br s, 3 × NH), 3.21 (2H, m, NCH_2), 3.50 (2H, t, J_{HH} 5.5 Hz, CH_2Cl), 4.07 (4H, d of d, J_{HP} 10.1 Hz, J_{HH} 7.1 Hz, 2 × CH_2Ph), 7.28 (10H, br s, 2 × Ph); ^{31}P nmr δ: 13.36. Anal. calcd. for $C_{16}H_{21}ClN_3OP$: C 56.9, H 6.3, N 12.4; found: C 56.5, H 6.7, N 12.0%.

O-*Methyl*-N-*methyl*-N′-*(2-chloroethyl)phosphorodiamidate 6*

Dry methylamine was passed through the solution of *N*-(2-chloroethyl)phosphoroamidodichloridate (2.05 g, 0.010 mol) in dioxane (14 mL) with stirring and cooling (below 25°C). After the exothermic reaction subsided, 10 mL of dioxane was added, the mixture was filtered, the precipitate was washed with dioxane followed by chloroform, and the combined filtrates were concentrated under reduced pressure. Crude *N*-methyl-*N*′-(2-chloroethyl)diamidophosphorochloridate was obtained as colorless oil (1.73 g, 91%) and was used without further purification; ^1H nmr δ: 2.68 (3H, d, J_{HP} 10.1 Hz, NMe), 3.31–3.44 (2H, m, NCH_2), 3.45 (1H, br s, NH), 3.64 (2H, t, J_{HH} 5.6 Hz, CH_2Cl), 4.25 (1H, br s, NH); ^{31}P nmr δ: 20.7.

A solution of this product (1.7 g, 0.091 mol) in dry methanol (4 mL) was added dropwise at room temperature to the solution of one mol-equiv. of CH_3ONa in methanol (8 mL). The mixture was stirred for 20 h, filtered, and evaporated under reduced pressure. A small volume of chloroform was added, the suspension was filtered through a layer of anhydrous $MgSO_4$ and evaporated, yielding the crude product (1.39 g, 82%). Pure **6** was obtained by column chromatography ($CHCl_3$/acetone, 3:1) as a colorless oil; ^1H nmr δ: 2.52 (3H, d of d, J_{HP}, J_{HH} 12.3, 5.7 Hz, NMe), 2.90 (1H, br s, NH), 3.17 (2H, m, NCH_2), 3.29 (1H, br s, NH), 3.53 (2H, t, J_{HH} 5.8 Hz, CH_2Cl), 3.59 (3H, d, J_{HP} 11.2 Hz, OMe); ^{31}P nmr δ: 15.5. Anal. calcd. for $C_4H_{12}ClN_2O_2P$: C 25.7, H 6.5, N 15.0; found: C 25.3, H 6.4, N 14.9%.

Reactions of substrates 3 with bases

Base, followed by PTC, was added to a ca. 0.1 M solution of **3** in benzene, and the mixture was stirred vigorously with exclusion of moisture. The proportion of the reagents, the reaction time, and temperature are given in Table 1. The reaction was stopped when the ^{31}P nmr spectrum of a sample showed complete disappearance of **3**. After filtration, the solution was washed with small portions of water until neutral, dried ($MgSO_4$), evaporated, and the residue was identified and purified as described below. *N*-Phosphorylated aziridines **4**

were obtained by carrying out the reaction under conditions allowing for the exclusive formation of **4** (see Table 1, last entries for all substrates).

4*a* (2 mol-equiv. of NaH, 5 mol% TBABr, reflux, 8 h): 88% yield; purified by column chromatography (acetone/CH_2Cl_2, 2:1); mp 183–184°C; ^{1}H nmr δ: 2.30 (4H, d, J_{HP} 16.2 Hz, C_2H_4N), 5.48 (2H, d, J_{HP} 8.4 Hz, 2 × NHAr), 6.69–7.23 (10H, m, 2 × Ph); ^{31}P nmr δ: 12.1. Anal. calcd. for $C_{14}H_{16}N_3OP$: C 61.5, H 5.9, N 15.4; found: C 61.2, H 5.9, N 15.4%.

4*b* (4 mol-equiv. of 1:1 NaOH/K_2CO_3, 10 mol% TBABr, reflux, 19 h): 92% yield; purified by column chromatography (pet. ether); oil; ^{1}H nmr δ: 2.22 (6H, s, 2 × CH_3), 2.25 (4H, d, J_{HP} 11.4 Hz, C_2H_4N), 5.78 (2H, d, J_{HP} 8.7 Hz, 2 × NHAr), 6.95 (4H, d, J_{HH} 8.4 Hz, 2 × 2,6-H), 6.99 (4H, d, J_{HH} 8.4 Hz, 2 × 3,5-H); ^{31}P nmr δ: 12.8. Anal. calcd. for $C_{16}H_{20}N_3OP$: C 63.8, H 6.7, N 13.9; found: C 63.4, H 6.3, N 13.5%.

4*c* (2.5 mol-equiv. of *t*BuOK, 10 mol% TBABr, reflux, 18 h): 55% yield; purified by crystallization from $CHCl_3$/pet. ether (1:1); mp 47–51°C; ^{1}H nmr δ: 2.22 (4H, d, J_{HP} 15.6 Hz, C_2H_4N), 3.68 (6H, s, 2 × OCH_3), 5.80 (2H, d, J_{HP} 8.7 Hz, 2 × NHAr), 6.69 (4H, d, J_{HH} 8.8 Hz, 2 × 2,6-H), 7.00 (4H, d, J_{HH} 8.8 Hz, 2 × 3,5-H); ^{31}P nmr δ: 13.4. Anal. calcd. for $C_{16}H_{20}N_3O_3P$: C 57.7, H 6.1, N 12.6; found: C 57.3, H 6.2, N 12.2%.

4*d* (4 mol-equiv. of 1:1 NaOH/K_2CO_3, 10 mol% TBABr, room temp., 108 h): 37% yield. The compound was purified by filtering the benzene solution through a Celite/$MgSO_4$ layer and evaporating, affording a very hygroscopic oil; ^{1}H nmr δ: 2.02 (4H, d, J_{HP} 15.0 Hz, C_2H_4N), 2.48 (2H, br s, 2 × NH), 2.67 (6H, d of d, J_{HP}, J_{HH} 11.5, 5.4 Hz, 2 × NMe); ^{31}P nmr δ: 26.0.

4*e* (1.2 mol-equiv. of NaH, 10 mol% TBABr, room temp., 30 h): 85% yield. Purified by crystallization from benzene/pet. ether (1:1); mp 58–60°C; ^{1}H nmr δ: 2.04 (4H, d, J_{HP} 15.2 Hz, C_2H_4N), 3.01 (2H, m, 2 × NH), 4.13 (4H, 2 × d of d, J_{HP}, J_{HH} 9.2, 7.2 Hz, 2 × CH_2Ph), 7.29 (10H, br s, 2 × Ph); ^{31}P nmr δ: 22.9. Anal. calcd. for $C_{16}H_{20}N_3OP$: C 63.8, H 6.7, N 14.0; found: C 63.4, H 6.5, N 13.9%.

7: Substrate **6** (0.16 g, 8.6×10^{-4} mol) and NaH (9.4×10^{-4} mol) in benzene (5 mL) were stirred at room temperature for 96 h. Aqueous ethanol (1.5 mL) was added, the mixture was filtered through a layer of Celite/$MgSO_4$, washed with chloroform, and evaporated. Aziridine derivative **7** was obtained as a pale yellow oil in 65% yield; ^{1}H nmr δ: 2.03 (4H, d, J_{HP} 15.5 Hz, C_2H_4N), 2.60 (3H, d of d, J_{HP}, J_{HH} 11.4, 5.7 Hz, NMe), 3.00 (1H, br s, NH), 3.62 (3H, d, J_{HP} 11.0, OMe); ^{31}P nmr δ: 23.7. Anal. calcd. for $C_4H_{11}N_2O_2P \cdot H_2O$: C 28.6, H 7.8, N 16.7; found; C 28.7, H 7.3, N 16.5%.

1,3,2-Diazaphospholidines **5**

N-Aryl derivatives **5***a–c* were isolated by column chromatography from the mixtures obtained upon treatment of the corresponding substrates **3** with base (see Table 1, first entries for **3***a–c*).

5*a* (acetone/CH_2Cl_2, 2:1): 36% yield. Crystallized from $CHCl_3$/pet. ether (1:1); mp 203.5°C; ^{1}H nmr δ: 2.87 (1H, d, J_{HP} 10.5 Hz, *endo*-NH), 3.40–3.54 (1H, m) and 3.58–3.64 (3H, m) (CH_2CH_2), 5.43 (1H, d, J_{HP} 6.6 Hz, *exo*-NH), 6.82–6.97 (5H, m, Ph), 7.08–7.25 (5H, m, Ph); ^{31}P nmr δ: 13.1. Anal. calcd. for $C_{14}H_{16}N_3OP$: C 61.5, H 5.9, N 15.4; found: C 61.1, H 6.0, N 15.2%.

5*b* (acetone/CH_2Cl_2, 2:1): 26% yield. Crystallized from $CHCl_3$/acetone (1:1); mp 180–182°C; ^{1}H nmr δ: 2.20 (3H, s, Me), 2.23 (3H, s, Me), 2.85 (1H, br s, *endo*-NH), 3.34 (1H, m) and 3.65 (3H, m) (CH_2CH_2), 5.37 (1H, d, J_{HP} 6.6 Hz, *exo*-NH), 6.74 (2H, d, J_{HH} 8.1 Hz, 3,5-H of the *endo*-NAr), 6.94 (2H, d, J_{HH} 8.1 Hz, 2,6-H of the *endo*-NAr), 7.02 (2H, d, J_{HH} 8.6 Hz, 3′,5′-H of the *exo*-NAr), 7.08 (2H, d, J_{HH} 8.6 Hz, 2′,6′-H of the *exo*-NAr); ^{31}P nmr δ: 13.6. Anal. calcd. for $C_{16}H_{20}N_3OP$: C 63.8, H 6.7, N 13.9; found: C 63.4, H 6.2, N 13.5%.

5*c* (acetone/CH_2Cl_2, 1:1): 37% yield; mp 200–202°C; ^{1}H nmr δ: 2.73 (1H, d, J_{HP} 10.1 Hz, *endo*-NH), 3.36 (1H, m) and 3.56 (3H, m) (CH_2CH_2), 3.71 (3H, s, OMe), 3.74 (3H, s, OMe), 4.95 (1H, d, J_{HP} 7.5 Hz, *exo*-NH), 6.69 (2H, d, J_{HH} 8.8 Hz, 2,6-H of *endo*-NAr), 6.78 (2H, d, J_{HH} 8.4 Hz, 2′,6′-H of *exo*-NAr), 6.81 (2H, d, J_{HH} 8.4 Hz, 3′,5′-H of *exo*-NAr), 7.11 (2H, d, J_{HH} 8.8 Hz, 3,5-H of *endo*-NAr); ^{31}P nmr δ: 14.6. Anal. calcd. for $C_{16}H_{20}N_3O_3P$: C 57.6, H 6.0, N 12.6; found: C 57.2, H 6.1, N 12.4%.

N-Alkyl derivatives **5***d,e* were prepared as follows. A 0.3–0.5 M solution of the corresponding *N*-substituted ethylenediamine (1 mol-equiv.) and triethylamine (2 mol-equiv.) in dioxane/ether (3:1) was added dropwise with stirring and cooling at 0–5°C to the ca. 1 M solution of the corresponding *N*-substituted phosphoroamidodichloridate in the same solvent. After addition the mixture was stirred at room temperature overnight and filtered. For **5***d* the filtrate was saturated with dry gaseous ammonia, filtered again, and evaporated. Pure **5***d* was obtained as highly hygroscopic, colorless crystals in 11% yield; mp (sealed capillary) 75–78°C; ^{1}H nmr δ: 2.44 (3H, d of d, J_{HP}, J_{HH} 12.7, 5.5 Hz, *exo*-NMe), 2.54 (3H, d, J_{HP} 9.3 Hz, *endo*-NMe), 2.63 (2H, br s, 2 × NH), 2.98–3.37 (4H, m, CH_2CH_2); ^{31}P nmr δ: 27.6. Anal. calcd. for $C_4H_{12}N_3OP$: C 32.2, H 8.1, N 28.2; found: C 32.3, H 8.5, N 27.8%.

For **5***e* the filtrate was evaporated under reduced pressure and the residue was dissolved in benzene and washed three times with water. After drying and evaporating of solvent the crystalline product was obtained in 80% yield. Purified by crystallization from benzene/pet. ether (1:1); mp 101–103°C; ^{1}H nmr δ: 2.38 (1H, d, J_{HP} 7.8 Hz, NH), 2.75 (1H, br s, NH), 2.88–3.37 (4H, m, CH_2CH_2), 3.90–4.19 (4H, m, 2 × CH_2Ph), 7.10–7.45 (10H, m, 2 × Ph); ^{31}P nmr δ: 24.8. Anal. calcd. for $C_{16}H_{20}N_3OP$: C 63.8, H 6.7, N 14.0; found: C 63.4, H 6.5, N 13.9%.

O-Methyl-1-methyl-1,3,2-diazaphospholidine

Methylphosphorodichloridate (2.0 g, 0.013 mol) in dichloromethane (10 mL) was added dropwise with stirring and cooling at −5 to −10°C to the solution of *N*-methylethylenediamine (0.99 g, 0.013 mol) and triethylamine (2.72 g, 0.027 mol) in dichloromethane (25 mL). The mixture was then stirred at room temperature for 22 h and filtered. The residual triethylammonium chloride was removed from the filtrate by stirring it with solid NaOH/K_2CO_3 mixture, filtering, and evaporating under reduced pressure. The product was obtained as a viscous oil (0.82 g, 42%); ^{1}H nmr δ: 2.57 (3H, d, J_{HP} 9.5 Hz, NMe), 2.98 (1H, br s, NH), 3.10–3.38 (4H, m, CH_2CH_2), 3.58 (3H, d, J_{HP} 11.9 Hz, OMe); ^{31}P nmr δ: 27.2. The ^{31}P nmr spectrum showed absence of any other phosphorus containing products, and the ^{1}H nmr spectrum revealed only the presence of some residual triethylammonium chloride.

Interconversions of **4** *and* **5**

Individual compounds **4** or **5** were dissolved in benzene, the required amount of sodium hydride or TBABr was added, and the mixture was stirred at the temperature and for the duration identical to those applied to the corresponding substrates **3**. After filtration and evaporation of the solvent, the products were examined by nmr (^{1}H and ^{31}P) spectroscopy and identified by comparison with the spectra of the authentic samples.

Carbohydrate protein interactions. Syntheses of agglutination inhibitors of wheat germ agglutinin by phase transfer catalysis

RENÉ ROY[1] AND FRANÇOIS D. TROPPER
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received November 1, 1990

RENÉ ROY and FRANÇOIS D. TROPPER. Can. J. Chem. **69**, 817 (1991).

Starting from chloride **1**, a series of *para*-substituted aryl 2-acetamido-2-deoxy-β-D-glucopyranosides were prepared using phase transfer catalysis conditions with tetrabutylammonium hydrogen sulfate in 1 M sodium hydroxide and methylene chloride at room temperature. Zemplén de-*O*-acetylation afforded the unprotected glycosides. Optimization of reaction conditions was evaluated. Several functional group manipulations were effected to widen the number and nature of the *para*-substituents.

Key words: phase transfer catalysis, aryl 2-acetamido-2-deoxy-β-D-glucopyranosides.

RENÉ ROY et FRANÇOIS D. TROPPER. Can. J. Chem. **69**, 817 (1991).

En utilisant le chlorure **1** comme produit de départ, une série 2-acetamido-2-deoxy-β-D-glucopyranosides d'aryles *para*-substitués ont été préparés en utilisant des conditions de catalyse par transfert de phase avec le bisulfate de tétrabutylammonium comme catalyseur dans l'hydroxyde de sodium 1 M et le chlorure de méthylène à la température de la pièce. Une de-*O*-acétylation de Zemplén a fourni les glycosides déprotégés. Les paramètres permettant d'optimiser les conditions de réactions ont été évalués. Quelques transformations de groupes fonctionnels ont été éffectuées afin d'élargir le nombre et la nature des substituants en position *para*.

Mots clés : catalyse par transfert de phase, aryle 2-acétamido-2-deoxy-β-D-glucopyranosides.

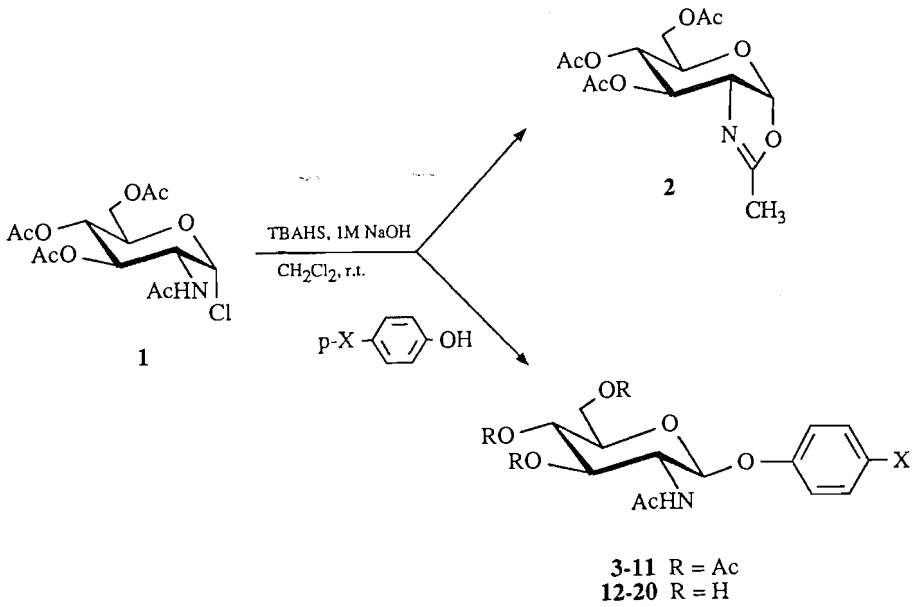
Introduction

Carbohydrate–protein interactions are of paramount importance in cellular recognition, in bacterial and viral colonization, and in tumor associated phenomena. We have been engaged in studies of the fundamental aspects of these interactions at the molecular level. The nature and the accessibilities of sugar moieties on native glycoproteins prompted us to synthesize a number of well-defined artificial glycoconjugates to be used as models in binding studies with lectins (1–4).

Of particular interest to the present study was the observation that *p*-nitrophenyl 2-acetamido-2-deoxy-β-D-glucopyranoside was a better inhibitor than the corresponding free monosaccharide in inhibition of agglutination of model glycoproteins with the lectin from wheat germ (wheat germ agglutinin, WGA) (5). The X-ray of WGA showed the presence of tyrosyl residues in the carbohydrate binding sites (5). To verify the possibility of charge transfer complex interactions between the electron-rich tyrosyl residues and the electron-poor aromatic glycosides, an efficient synthesis of aryl glycosides was required. Therefore, a series of aryl 2-acetamido-2-deoxy-β-D-glucopyranosides was synthesized to probe these potential electronic contributions and to evaluate their contributions to the relative binding energies with the lectin.

Phase transfer catalysis (PTC) has been recently applied to the syntheses of aryl glycosides (6–9). However, there was no application of this efficient procedure for the preparation of *O*-aryl 2-acetamido-2-deoxy-β-D-glucopyranosides until our own preliminary work (10). The most general method used so far was based on the reactions of the homologous sodium phenoxides in aqueous acetone (11, 12). In our hands this method was deemed unsatisfactory in terms of yields. The present work describes in full the efficient and stereospecific syntheses of this class of compounds using PTC conditions at room temperature with yield ranging from 66 to 93%.

Results and discussion



In continuation of our efforts (10, 13) to utilize phase transfer catalysis in glycoside syntheses of aryl 2-acetamido-2-deoxy-β-D-glucopyranosides, it was hypothesized that formation of the expected 2-methyl-(3,4,6-tri-*O*-acetyl-1,2-dideoxy-α-D-glucopyrano)-[2,1-*d*]-oxazoline **2** could be prevented if nucleophilic attack by the phenoxides at the anomeric center could occur at a faster rate than the attack by the catalyst counteranions. Nucleophilic attack by counteranions such as chlorides and bromides would lead to reactive β-glycosyl halides followed by anchimeric displacement by the neighboring acetamido group to give the oxazoline **2**. In this respect, it became obvious that non-nucleophilic and hydrophilic anions such as hydrogen sulfate would solve part of the problem. One should realize, however, that for each nucleophilic substitution by the phenoxide, there is one chloride anion released. Thus, nucleophilic competition at the anomeric center would still exist between the phenoxide and the chloride anions. To minimize this possibility, two equivalents of phenoxide were used throughout. Encouraged by the successful application of this technique to the synthesis of a glycosyl azide (14), we have investigated the effect of various catalysts and reaction conditions.

In the first set of experiments, the phenoxide was purposely omitted; the use of tetrabutylammonium bromide did provide a good yield of the expected oxazoline. This catalytic two-phase system is conceptually similar to the reaction conditions previously used by Lemieux and Driguez (15) for the synthesis of **2** in acetonitrile alone. The efficiency of a number of ammonium salts was then compared. Not surprisingly (16), the more hydrophobic tetrabutylammonium cation (TBA) was slightly more effective (~2 times faster) than the corresponding benzyltriethylammonium (BTEA) chloride or bromide in methylene chloride. With 0.2 molar equivalent (limiting conditions) of the catalyst over the phenoxide and TBA cations, the iodide anions gave more oxazoline than the bromides or the chlorides. These differences disappeared, however, under non-limiting conditions (1 equiv.) as shown in quantitative experiments using chloride, bromide, iodide, hydroxide, or hydrogen sulfate anions and TBA cations in methylene chloride (Scheme 1).

It was also observed that the reaction with phosphonium salts (17), such as ethyltriphenylphosphonium bromide, was faster

SCHEME 1

than with the ammonium salt. However, irreversible formation of by-products, such as ethyl diphenylphosphine oxide[2] or ylide, consumed the catalyst and complicated the purification steps, thus rendering these catalysts inappropriate for the actual goals. When benzene was used as solvent in place of methylene chloride with TBA bromide, the reaction rate was found to be much slower, even under refluxing conditions.

The basicity of the aqueous phase was then examined. Molar sodium hydroxide gave faster reactions and therefore fewer by-products (oxazoline and hydrolysis) then 0.5 M (or less concentrated) NaOH and sodium carbonate or hydrogen carbonate. At a concentration of 2 M NaOH the reaction was even faster for most phenoxides. The concentration of the catalyst was also tested. With TBA bromide the reactions were faster with increasing concentrations (0.1–1 equiv.). The reactions did not proceed in the absence of the catalyst. At high concentration, fewer by-products were observed. The consumption of the chloride **1** was also faster under refluxing conditions but at the expense of more side reactions. The other products isolated were those having a hydrolyzed anomeric center, and partially de-*O*-acetylated phenyl glycosides. Transesterification by the phenoxides is postulated as a reaction pathway since acetylated phenols were isolated in a few instances. In view of the possibility of forming the glycosides **3–11** directly from the oxazoline **2**, the former was used under the optimum set of conditions described above. Treatment of the oxazoline **2** with *p*-hydroxybenzaldehyde and TBAHS (1 equiv.) and 1 M NaOH in methylene chloride at room temperature gave no glycoside, thus illustrating that the oxazoline was not an intermediate in the glycoside syntheses.

As shown in Table 1, the use of tetrabutylammonium hydrogen sulfate (TBAHS) in 1 M NaOH and methylene chloride at room temperature afforded good yields (66–93%) of the aryl 2-acetamido-2-deoxy-β-D-glucopyranosides **3–11** with a wide variety of *para* substituents as originally observed (10). The desired products could be purified from silica gel chromatography or by direct crystallization from the evaporated organic extracts. All the anomeric protons of the per-acetylated derivatives appeared between 5.03 and 5.55 ppm with vicinal coupling constants in accord with β-D(1,2-trans)-linkages ($J_{1,2}$ 8 Hz). The anomeric carbon signals appeared between 97.1 and 100.2 ppm with $^1J_{^{13}C\text{-}1,H\text{-}1}$ of 160 Hz, also consistent with β-linkage (axial H-1) (Table1) (18,19).

To widen the range and nature of the substituents, chemical transformations of the nitro and formyl groups were effected (Scheme 2). Thus, reduction of the *p*-nitro derivatives **9** or **18** under catalytic transfer hydrogenation (20) with 10% Pd/C and ammonium formate in methanol afforded the corresponding *p*-amino derivatives **21** and **22** in essentially quantitative yields. Usual *N*-acetylation (pyridine, acetic anhydride) of **21** afforded **23**, also in quantitative yield. Oxidation of the per-acetylated *p*-formylphenyl glycoside **10** with bromine in basic solutions of methanol according to Lichtenthaler *et al.* (21) gave directly the *p*-carbomethoxphenyl glycoside **25** in 55% yield. Reduction of the aldehyde **10** using sodium borohydride afforded the *p*-(hyroxymethyl)phenylglycoside **27** in quantitative yield.

Finally, Zemplén de-*O*-acetylation of all the per-acetylated derivates with sodium methoxide in methanol afforded excellent yields of the aryl 2-acetamido-2-deoxy-β-D-glucopyranosides **12–20, 22, 24, 28** (Table 2). Selected NMR signals are also indicated in Table 2.[3]

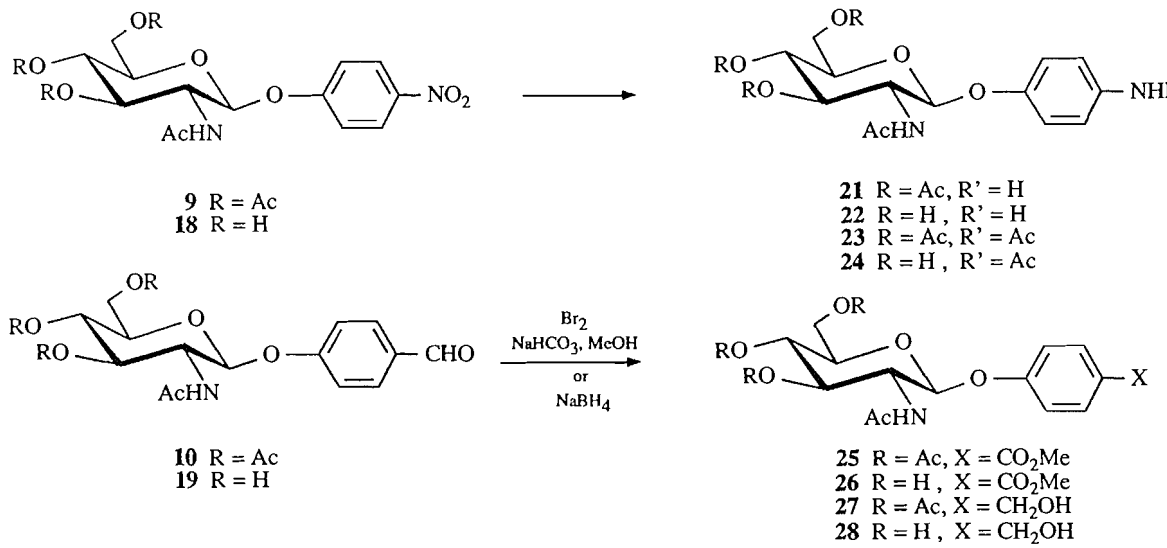
Experimental

General methods

Melting points were determined on a Gallenkamp apparatus and are uncorrected. The ^1H and ^{13}C NMR spectra were recorded on a Varian XL-300 or a Varian Gemini 200 at 300 and 200 MHz respectively for protons and at 75.4 and 50.3 MHz respectively for carbons. The proton chemical shifts (δ) are given relative to internal chloroform (7.24 ppm) for $CDCl_3$ solutions, to internal acetone (2.216 ppm) for D_2O solutions, and to DMSO (2.50 ppm) for DMSO-d_6 solutions. The carbon chemical shifts are given relative to deuterochloroform at 77.0 ppm, to internal acetone (31.1 ppm) for D_2O solutions, and to DMSO-d_6 (39.5 ppm).

The analyses were done as a first-order approximation. Optical rotations were measured on a Perkin Elmer 241 polarimeter and were run at 23–25°C for 0.5–1.0% solutions in chloroform unless otherwise

[2]Identified by MS and ^1H NMR spectroscopy, mp 122.6–123.8°C.



[3]Complete analyses of ^1H and ^{13}C NMR data can be found in refs. 18 and 19.

stated. Mass spectra were recorded on a VG 7070-E spectrometer. Elemental analyses were performed by Guelph Chemical Laboratories Ltd. (Guelph, Ont.) or M-H-W Laboratories (Phoenix, AZ). Thin-layer chromatography (TLC) was performed using silica gel 60-F254 plates and column chromatography on silica gel 60 (230–400 mesh, E. Merck No. 9385). The developed plates were sprayed or dipped with a solution of ceric sulfate (1%) and ammonium molybdate (2.5%) in 10% aqueous sulfuric acid and heated at ~150°C. All solvents and reagents used were reagent grade and, when required, further purifications were accomplished following published procedures (22). The chloride **1** was prepared according to Horton (23); the product was, however, usually contaminated. It was therefore purified by flash chromatography in ethyl acetate/hexane (1:1); on a large scale, up to 7 g could easily be purified, stored cold, and desiccated for 8 months without any decomposition.

Aryl2-acetamido-3,4,6-tri-O-acetyl-2-deoxy-β-D-glucopyranosides **3–11**

Typical procedure

Chloride **1** (0.28 mmol), tetrabutylammonium hydrogen sulfate or bromide (1 equiv.), and the phenols (2 equiv.) were vigorously stirred at room temperature in methylene chloride (1 mL) and 1 M sodium hydroxide (1 mL). The reactions were monitored by TLC ($CHCl_3$–EtOAc–*n*-ProH, 25:5:2, v/v/v). After complete consumption of the chloride **1** (30–45 min), the reaction mixtures were worked up by adding ethyl acetate (10 mL). The resulting organic phases were successively washed with 1 M NaOH (3 × 10 mL) followed by water (2 × 10 mL) and, finally, with saturated brine (10 mL). The dried organic phases (Na_2SO_4) were evaporated under reduced pressure. The resulting residues were purified by preparative TLC using the above eluent. The aryl glycosides were extracted from the silica gel using ethyl acetate and crystallized from ethanol to give **3–11** in 66–93% yields.

The above procedure could be efficiently accomplished on a large scale by direct crystallization of the residues obtained after the liquid–liquid extractions and evaporation of the organic phase. In the case of **9** (*p*-NO_2), the phenoxide was not entirely soluble in the two-phase mixture; gentle warming rendered it soluble. Previously known compounds (OAc and free OH) had physical constants (mp and $[\alpha]_D$) that generally agreed with those of the literature (11, 12, 24).

[d]Satisfactory microanalyses were also obtained for the halogens.

Zemplén de-O-acetylation to aryl 2-acetamido-2-deoxy-β-D-glucopyranosides

Two general methods were employed. These were based on the solubility properties of the acetylated glycosides. Method A was used for glycosides soluble or moderately soluble in methanol. These were de-*O*-acetylated in MeOH under standard conditions. The glycosides were dissolved in MeOH to which was added a catalytic amount of 1 M NaOMe in MeOH. The reaction mixtures were stirred for 1–2 h at room temperature with monitoring by TLC ($CHCl_3$–MeOH, 4:1). The sodium cations were removed with Amberlite IR-120 cationic resin (H^+). The solutions were filtered and evaporated to dryness. All the glycosides were obtained in almost quantitative yield by crystallization from ethanol or isopropanol. Method B: for glycosides that were not very soluble in MeOH, an equal volume of benzene was added as cosolvent. The solutions were then treated with 1 M NaOMe as above. The de-esterified glycosides progressively precipitated out of the solutions. Complete precipitation was ensured by adding an equal volume of hexane or ether. The solutions were cooled and the products filtered. They were always of analytical purity but were usually recrystallized from ethanol.

*Reduction of **9** to the acetylated* p-*aminophenylglucoside **21***

Compound **9** (176 mg, 0.376 mmol), 10% palladium on charcoal (15 mg), and ammonium formate (90 mg, 4 equiv.) were suspended in MeOH (20 mL). The solution was brought to a full boil for 2 min in a stopped round-bottom flask after which time TLC ($CHCl_3$–MeOH, 4:1) indicated complete reaction. The solution was filtered through Celite, which was rinsed with MeOH, and the solution evaporated to a white solid. Extraction of this residue with ethyl acetate washing with saturated sodium hydrogen carbonate (2 × 20 mL) and water (2 × 20 mL) gave pure **21** (160 mg, 97%) after the usual processing of the organic phase. An analytical sample of **21** was obtained by recrystallization from warm (not boiling) ethanol.

*Reduction of **18** to the free* p-*aminophenylglucoside **22***

Compound **18** (50 mg, 0.146 mmol) was refluxed for 10 min in MeOH (2.5 mL) containing ammonium formate (50 mg, 5.3 equiv.) and 10% palladium on charcoal (6 mg). Some ammonium formate sublimed in the condenser. The reaction was stopped when TLC (CH_3CN–acetone – 10% aq. HOAc, 5:3:1) indicated complete conversion of **18** (R_f 0.56) to **22** (R_f 0.35). Isolation by filtration and evaporation afforded pure **22** (44 mg, 98%).

p-N-*Acetamidophenyl 2-acetamido-3,4,6-tri*-O-*acetyl-2-deoxy-β-D-glucopyranoside **23***

The *p*-aminophenyl glycoside **21** (0.52 g, 1.164 mmol) was treated with pyridine (20 mL) and acetic anhydride (10 mL) for 1 h at room temperature. Methanol (10 mL) was then added to destroy the excess anhydride and after 45 min the solvents were evaporated to dryness with some coevaporation from toluene. Crystallization of the residue from ethanol gave **23** in 96% yield (2 crops, 531 mg).

p-*Carbomethoxphenyl 2-acetamido-3,4,6-tri*-O-*acetyl-2-deoxy-β-D-glucopyranoside **25***

To a solution of *p*-formylphenylglycoside **10** (350 mg, 0.776 mmol) and sodium hydrogen carbonate (800 mg) in MeOH (15 mL) was added bromine (300 μL). The reaction mixture was stirred at room temperature for 90 min, after which time TLC still indicated some starting aldehyde. Subjecting the reaction mixture to refluxing conditions or addition of excess bromine did not improve the situation. Ethyl acetate (40 mL) was added and the resulting organic phase was repeatedly washed with distilled water until the solution became clear. Usual processing of the organic phase (Na_2SO_4) and evaporation afforded a white solid. Purification by flash chromatography with ethyl acetate – hexane – 0.5% methanol (1:1) with change to 2:1 (v/v) gave pure **25** (206 mg, 55%). Crystallization from ethanol gave an analytical sample of **25**.

p-*(Hydroxymethyl)phenyl 2-acetamido-3,4,6-tri*-O-*acetyl-2-deoxy-β-D-glucopyranoside **27***

The *p*-formylphenylglycoside **10** (240 mg, 0.532 mmol) and sodium borohydride (15 mg, 0.395 mmol) were stirred at room temperature for 3 h in a mixture of ethanol (4 mL) and methylene chloride (2 mL). TLC in chloroform – ethyl acetate – *n*-propanol (25:5:2) showed complete reaction: R_f 0.39 (**10**), R_f 0.20 (**27**). Chloroform (20 mL) and 0.5 M HCl (20 mL) were added to the reaction mixture. The organic phase was washed with saturated sodium hydrogen carbonate (20 mL) followed by water (20 mL). The usual processing afforded **27** (240 mg, quant.) as a homogeneous white solid. An analytical sample was obtained from ethyl acetate–hexane.

Information concerning the solubilization of hydrocarbons in ionic surfactant micelles was obtained from ^2H NMR relaxation, ^1H NMR chemical shifts, and ^1H NMR paramagnetic relaxation measurements. The rotational motion of deuterated hydrocarbons, which is related to the micellar microviscosity at the location of the hydrocarbons, was probed by ^2H NMR relaxation. The relaxation data are interpreted using both the two-step and the single-step models, and the results are discussed in terms of the micellar microviscosity and the location of the hydrocarbons in micelles. The location of the hydrocarbons in micelles was further investigated by determining the aromatic ring current-induced ^1H chemical shifts along the surfactant alkyl chain and by comparing the ^1H spin-lattice relaxation enhancement of the hydrocarbons and the surfactant alkyl chain, induced by Mn^{2+} on the micellar surface. The hydrocarbons used include benzene, naphthalene, acenaphthalene, triphenylene, cyclohexane, cyclododecane, and *tert*-butylcyclohexane and the surfactants studied are hexadecyl-, tetradecyl-, and dodecyltrimethylammonium bromide; hexadecyl-, tetradecyl-, and dodecylpyridinium halide; and sodium dodecyl sulfate. The results indicate that the micellar microviscosity at the location of saturated hydrocarbons is approximately 5 cP for both the cationic and anionic micelles, whereas the micellar microviscosity at the location of unsaturated hydrocarbons is much higher. The unsaturated hydrocarbons are found to reside primarily near the surfactant headgroup in the cationic micelles, but are distributed evenly throughout the anionic SDS micelles. The saturated hydrocarbons appear to be located in the interior of the micelles.

Key words: NMR, relaxation, solubilization, surfactant, micelle.

Utilisant la relaxation RMN du ^2H, les déplacements chimiques en RMN du ^1H et des mesures de relaxation paramagnétique en RMN du ^1H, on a obtenu de l'information concernant la solubilisation d'hydrocarbures dans des micelles d'agents de surface ioniques. Pour étudier le mouvement de rotation des hydrocarbures deutérés qui est relié à la microviscosité micellaire au point de location des hydrocarbures, on a fait appel à la relaxation en RMN du ^2H. On a interprété les données de relaxation utilisant les modèles en une ainsi qu'en deux étapes et on discute des résultats en fonction de la microviscosité micellaire et de la position des hydrocarbures dans les micelles. On a réalisé une étude plus approfondie de l'influence de la position des hydrocarbures dans les micelles en déterminant les déplacements chimiques induits par le courant du noyau aromatique le long de la chaîne alkyle de l'agent de surface et en comparant les augmentations des relaxations spin-réseau du ^1H des hydrocarbures et de la chaîne alkyle de l'agent de surface qui sont induites par du Mn^{2+} sur la surface micellaire. Les hydrocarbures utilisés sont le benzène, le naphtalène, l'acénaphtalène, le triphénylène, le cyclohexane, le cyclododécane et le *tert*-butylcyclohexane alors que les agents de surface étudiés sont les bromures d'hexadécyl-, de tétradécyl- et dodécyl-triméthylammonium, les halogénures d'hexadécyl-, de tétradécyl- et de dodécylpyridinium et le dodécylsulfate de sodium. Les résultats indiquent que la microviscosité micellaire à la position des hydrocarbures saturés est égale à approximativement 5 cP pour les micelles tant cationiques qu'anioniques; par ailleurs, la microviscosité micellaire à la position des hydrocarbures insaturés est beaucoup plus élevée. On a trouvé que, dans les micelles cationiques, les hydrocarbures insaturés résident principalement près du groupe de tête de l'agent de surface; par ailleurs, dans les micelles de DSS, ils sont distribués d'une façon homogène. Il semble que les hydrocarbures saturés se situent à l'intérieur des micelles.

Mots clés : RMN, relaxation, solubilisation, agent de surface, micelle.

[Traduit par la rédaction]

Introduction

The presence of micelles in aqueous solution has a profound effect on the solubilization of some organic molecules that are normally insoluble or only sparingly soluble in water (1, 2). Micellar solubilization is of importance in many industrial processes such as detergency, emulsion polymerization, oil recovery, etc. (3, 4), and in a variety of fundamental research topics such as micellar modeling of biological membranes (5). The solubility of organic molecules in the micellar pseudophase is generally represented by the distribution coefficient between the micellar and aqueous phases. The distribution coefficients, which can be determined easily by use of the NMR paramagnetic relaxation method (6) or the NMR pulse gradient spin-echo self-diffusion method (7), are dependent on the structures of the solubilizate and the surfactant that constitute the micelles. In addition to the solubilization equilibrium, the microviscosity of the micellar interior and the location of the solubilizate within the micelles may also be important in many applications of micellar solubilization.

In recent years, the dynamic behavior of surfactant molecules in micelles has been investigated extensively by means of ^{13}C and ^2H NMR relaxation measurements on surfactant molecules (8–11); the NMR relaxation data are generally interpreted using the two-step model developed by Wennerström *et al.* (12). However, studies on the motion of solubilizates within the micelles are limited (13–16). In the absence of strong solute–solvent interactions the effective rotational correlation time, τ_c, of a solute molecule is related to the solvent viscosity, η, and the absolute temperature, T, by eq. [1] (17, 18):

$$[1] \quad \tau_c = C\eta/T + \tau_o$$

where C is a constant that can be measured experimentally or

estimated using the hydrodynamic slip model. In hydrodynamic models, C is directly proportional to the volume of the solute molecule and τ_0 is a "free rotor" correlation time that is generally negligible compared to τ_c. Using this approach (eq. [1]), Stark *et al.* (14) studied nitrobenzene solubilized in hexadecyltrimethylammonium bromide (HTAB) and sodium dodecyl sulfate (SDS) micelles and deduced micellar microviscosities in the range 8–17 cP. Rotational correlation times of nitrobenzene were monitored using ^{13}C NMR relaxation data. Because of the rather poor inherent sensitivity of ^{13}C NMR spectroscopy, Stark *et al.* (14) used 100 mM solutions of nitrobenzene in 330 mM surfactant solutions. Such high concentrations of solubilizate may cause significant distortions in micellar structure since micelle size and shape are modified substantially by additives (19). From ^2H NMR studies, Eriksson *et al.* (13) concluded that the rotational diffusion of benzene and cyclohexane solubilized in HTAB and SDS is only 2 to 3 times slower than it is in the corresponding hydrocarbons, dodecane and hexadecane. Stilbs *et al.* (15) reported the results of a detailed ^2H NMR study of *trans*-decalin solubilized in several alkyltrimethylammonium halides and sodium alkyl sulfates. Their results indicate micellar microviscosities in the range of 3–10 cP. In contrast, fluorescence depolarization studies (20, 21) of 2-methylanthracene indicate much larger micellar microviscosities (17–50 cP). One study (22) reported a microviscosity of 670 cP for pyrene solubilized in aqueous solutions of sodium taurocholate. The dynamics of deuteriochloroform solubilized in rod-shaped alkylammonium chloride micelles was investigated recently by Canet *et al.* (16), using ^2H NMR relaxation.

Hydrocarbons can be solubilized either in the micellar interior or near the micellar surface, according to Mukerjee's "two-state" model (1). One of the most widely used methods for determining the location of aromatic hydrocarbons solubilized in micelles is to monitor the ring current shifts on the ^1H resonances of the surfactant alkyl chain (23–27). It is assumed that the observation of an aromatic ring current shift on a surfactant segment is evidence that on average the aromatic solubilizate is located in the vicinity of the surfactant segment. On the other hand, the absence of a ring current shift is taken to indicate a low aromatic solubilizate concentration in that region or an independent isotropic motion of the aromatic molecule and the surfactant segment (28). The solubilization site of hydrocarbons micelles has also been studied by measuring the ^1H spin–spin relaxation enhancement of the hydrocarbon molecules induced by paramagnetic probes located on the micellar surface (29). This enhancement is proportional to the inverse sixth power of the average distance between the protons and the paramagnetic ions on the micellar surface, if the interaction is purely dipolar. However, several assumptions were involved in the calculation, including the thickness of the micellar headgroup region (29). The locations of small aliphatic alcohols in micellar solutions have also been characterized recently by comparing the Mn^{2+}-induced relaxations of the alcohols in cationic and anionic surfactant systems (30).

In this paper, a combination of ^2H NMR relaxation, ^1H NMR chemical shifts, and ^1H NMR paramagnetic relaxation measurements is used to investigate the solubilization of a number of hydrocarbons in a series of ionic surfactant systems. Rotational motion of hydrocarbons in micelles is probed by ^2H NMR relaxation. The micellar microviscosity can be deduced from the rotational correlation time of the hydrocarbon. The dynamic behavior of hydrocarbons in micelles is related to their location. The effect of surfactant head group charge and alkyl chain length is also examined. Information concerning the location of hydrocarbons in micelles is obtained from aromatic ring current-induced ^1H shifts or from the comparison of Mn^{2+}-induced ^1H spin-lattice relaxation enhancements between the surfactant alkyl chain and the hydrocarbons. The hydrocarbons studied include benzene, naphthalene, acenaphthalene, triphenylene, cyclohexane, cyclododecane, and *tert*-butylcyclohexane and the surfactants used are *n*-alkyltrimethylammonium bromide (dodecyl-, tetradecyl-, and hexadecyl-), *n*-alkylpyridinium halide (dodecyl-, tetradecyl-, and hexadecyl-), and sodium dodecyl sulfate.

Theory

Deuterium NMR relaxation

For a spin $I = 1$ nucleus, such as deuterium, nuclear relaxation rates are given by (31):

$$[2] \quad R_1 = 1/T_1 = (3/10)\pi^2\chi_Q^2(1 + \eta^2/3)[J(\omega_0) + 4J(2\omega_0)]$$

and

$$[3] \quad R_2 = 1/T_2 = (3/10)\pi^2\chi_Q^2(1 + \eta^2/3)[(3/2)J(0) + (5/2)J(\omega_0) + J(2\omega_0)]$$

where R_1 and R_2 are the rates of spin-lattice and spin–spin relaxation respectively, χ_Q is the deuterium quadrupolar coupling constant, e^2qQ/h, η is the nuclear electric field gradient asymmetry parameter (less than 0.1 for the molecules in this study), and $J(\omega)$ is the spectral density function:

$$[4] \quad J(\omega) = \frac{\tau_c}{1 + (\omega_0\tau_c)^2}$$

ω_0 is the Larmor frequency ($\omega_0 = 2\pi\nu_0$) and τ_c is the rotational correlation time. For rotational diffusion, $\tau_c = (6D_r)^{-1}$ where D_r is the rotational diffusion constant. Plots of $\log_{10} T_1$ and $\log_{10} T_2$ vs. $\log_{10}\tau_c$ for $\nu_0 = 55.43$ MHz, and $\chi_Q = 190$ kHz are shown in Fig. 1 (the order parameter, S, equals zero).

The rate of spin-lattice relaxation is a maximum when $\omega_0\tau_c = 0.6158$. This corresponds to $T_1 = 2.2$ ms, $T_2 = 1.4$ ms, and $\tau_c = 1.7$ ns in Fig. 1 ($S = 0.0$). Under the so-called extreme narrowing condition, $\omega_0\tau_c \ll 1$, $J(0) = J(\omega_0) = J(2\omega_0) = \tau_c$, and

$$[5] \quad R_1 = R_2 = (3/2)\pi^2\chi_Q^2(1 + \eta^2/3)\tau_c$$

In the previously mentioned ^2H NMR study by Eriksson *et al.* (13), it was observed that $T_1 = T_2$ for benzene-d_6 in both SDS and HTAB solutions where the mole fraction of benzene in a benzene–HTAB mixture is 0.1. However, at higher benzene to HTAB mole ratios, $T_1 > T_2$. This was attributed to the formation of long, rod-shaped micelles in the presence of high concentrations of benzene. Under these conditions, Eriksson *et al.* (13) used the two-step model (12), which assumes two correlation times, one to describe rapid local motion and another to describe a slower motion over distances of the order of the dimensions of the micellar aggregates. It was further assumed that the spectral density function $J(\omega)$ is a sum of two Lorentz functions (9–13),

$$[6] \quad J(\omega) = S^2\frac{\tau_c^s}{1 + (\omega_0\tau_c^s)^2} + (1 - S^2)\frac{\tau_c^f}{1 + (\omega_0\tau_c^f)^2}$$

where τ_c^s and τ_c^f are rotational correlation times for the slow and fast motions and S is a local order parameter taken over

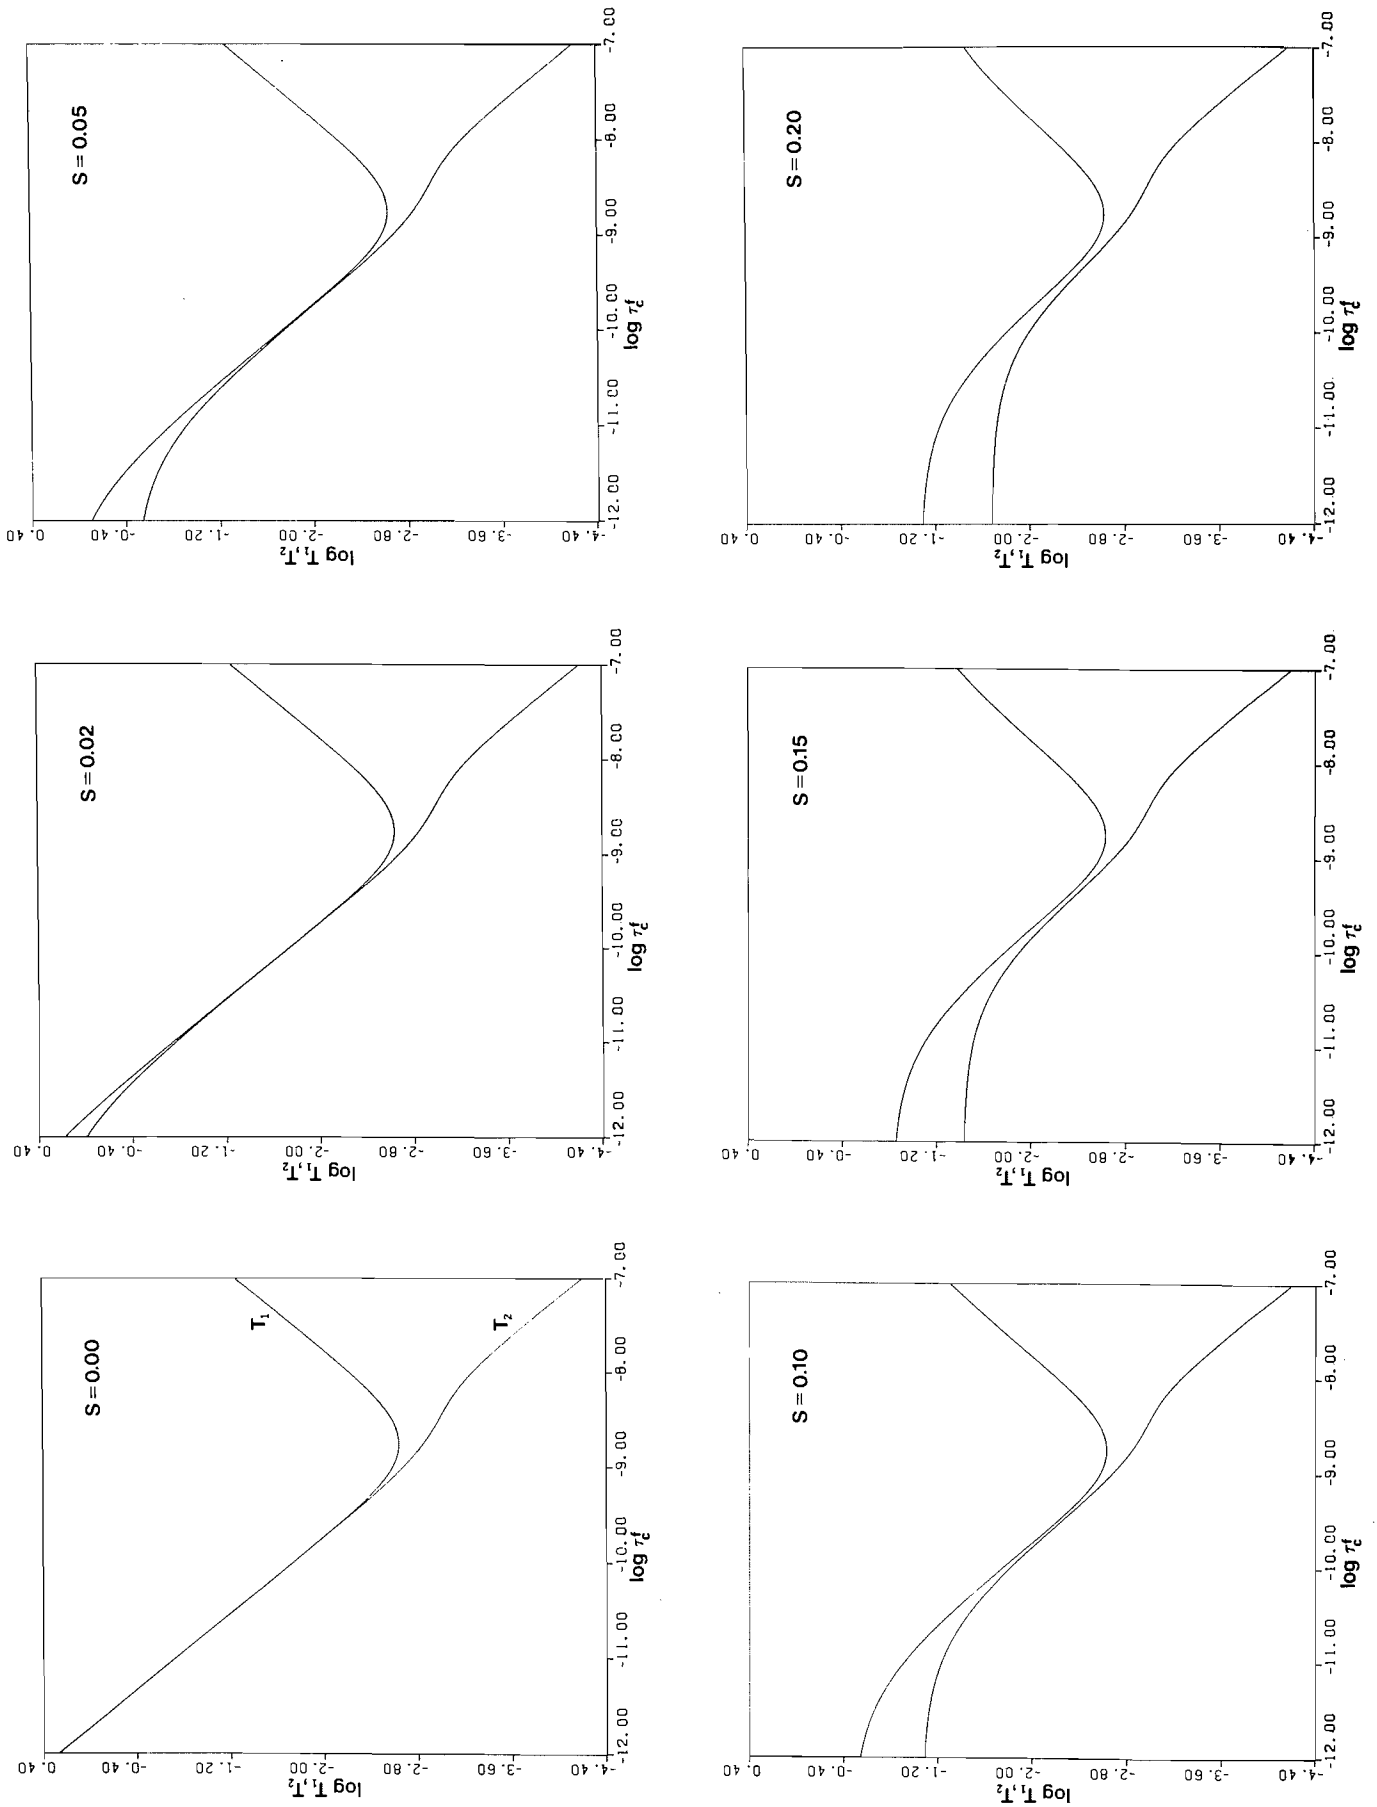

FIG. 1. $\log_{10} T_1$ and T_2 vs. $\log_{10} \tau_c^f$ at $\nu_0 = 55.43$ MHz, as a function of S. $\tau_c^s = 5$ ns.

For personal use only.

times longer than τ_c^f, but shorter than τ_c^s. If the fast motion is sufficiently rapid to satisfy the extreme narrowing condition, $\omega_0\tau_c^f \ll 0$, eq. [6] becomes

$$[7] \quad J(\omega) = (1 - S^2)\tau_c^f + S^2\frac{\tau_c^s}{1 + (\omega_0\tau_c^s)^2}$$

Typical values of τ_c^s for surfactant micelles appear to be 1–10 ns (8–12), while values of τ_c^f and S will be dependent on the solubilizate. For example, for benzene-d_6 and cyclohexane-d_{12}, S values of approximately 0.08 and 0.01, respectively, have been reported (13). In the study of benzene-d_6 in HTAB, Eriksson and co-workers (13, 32) obtained S from ^2H quadrupolar splittings measured in the hexagonal liquid crystalline phase.

The difference between the two-step model and the single-step model can be illustrated in Figs. 1 and 2. It is important to recognize that if S is very small, the two-step model is essentially the same as the single-step model, and if S is significant, the two-step model predicts that: (i) $T_2 < T_1$ and (ii) both T_1 and T_2 are field dependent, since $\omega_0\tau_c$ may be comparable to or greater than 1. Figure 1 presents a plot of $\log_{10} T_1$ and $\log_{10} T_2$ vs. $\log_{10}\tau_c^f$ at 55.43 MHz since we carried out deuterium T_1 and T_2 measurements on several solubilizates at this frequency. The value of S was varied at 0.0, 0.02, 0.05, 0.10, 0.15, and 0.20, and the quadrupolar coupling constant and the slow motion correlation time were taken to be 190 kHz and 5 ns, respectively. From calculations using eqs. [2]–[6] with $\nu_0 = 55.43$ MHz, $\tau_c^s = 5$ ns, and $S = 0.1$, it is apparent that T_1 values in the range 5–50 ms will result in values of τ_c^f and τ_c (eq. [5]) that agree within 15% of one another. ^2H T_1 measurements have been carried out at both 15.36 MHz and 55.43 MHz, hence the plots of $\log_{10} T_1$ at these two frequencies vs. $\log_{10}\tau_c^f$ with $\tau_c^s = 1$ ns are given in Fig. 2.

In their study of *trans*-decalin-d_{18}, Stilbs *et al.* (15) found that T_1 and T_2 were equal within experimental error and that there is no field dependence of the rates of relaxation. This implies that the local order parameter, S, is small for *trans*-decalin-d_{18}.

The rotational correlation times (τ_c^f and τ_c^s) and the order parameter, S, can be calculated directly from eqs. [2], [3], and [7] if three or more than three independent relaxation data are obtained, e.g., in this study T_1 at 55.4 and 15.36 MHz and T_2 at 55.43 MHz were determined. Subtracting eq. [2] from eq. [3], and combining with eq. [7], one obtains

$$[8] \quad S^2 = (10/3)\pi^{-2}\chi_Q^{-2}\left[(3/2)\tau_c^s + \frac{(3/2)\tau_c^s}{1 + (\omega_0\tau_c^s)^2} - \frac{3\tau_c^s}{1 + (2\omega_0\tau_c^s)^2}\right]^{-1}(1/T_2 - 1/T_1)$$

$$[9] \quad \tau_c^f = (1/5)(1 - S^2)^{-1}\left[(10/3)\pi^{-2}\chi_Q^{-2}T_1^{-1} - \frac{S^2\tau_c^s}{1 + (\omega_0\tau_c^s)^2} - \frac{4S^2\tau_c^s}{1 + (2\omega_0\tau_c^s)^2}\right]$$

If τ_c^s is estimated (2–10 ns), S and τ_c^f can be calculated from T_1 and T_2 at 55.43 MHz using eqs. [8] and [9]. Also, by varying τ_c^s, many sets of τ_c^s, S, and τ_c^f can be obtained; however, only one set will give the same T_1 as that determined experimentally at 15.36 MHz.

Paramagnetic relaxation

In a solution containing paramagnetic transition metal ion complexes, the enhancement of the spin-lattice relaxation rate of a ligand nucleus is given (33, 34) by

$$[10] \quad R_{1p} = 1/T_1^p - 1/T_1^0 = \frac{P_M}{\tau_M + T_{1M}}$$

where T_1^p and T_1^0 are the measured relaxation rates in the presence and absence of paramagnetic species, respectively. P_M is the mole fraction of ligand in the bound state, τ_M the lifetime of the ligand in the complex, and T_{1M} the spin-lattice relaxation time of the ligand nuclei in the bound state. Equation [10] is valid provided the transition metal ion concentration is much lower than that of the ligand concentration. The complete expression for T_{1M} is given by the Solomon–Bloembergen–Morgan equation (35–37), which contains both the dipolar and the scalar terms. However, since in this paper Mn^{2+} is used as paramagnetic probe, only the dipolar term needs to be considered (38, 39).

$$[11] \quad 1/T_{1M} = (2/5)S(S + 1)\gamma_I^2\gamma_S^2\hbar^2 r_{IS}^{-6}\frac{\tau_R}{1 + (\omega_I\tau_R)^2}$$

Here S is the total electron spin, γ_I and γ_S the nuclear and electron magnetogyric ratios, ω_I the Larmor frequency of the nucleus I, r_{IS} the distance between the nuclear spin and the electron spin, and τ_R the correlation time for isotropic rotational motion of the complex. In the Mn^{2+}–alkylphosphate system, it has been found that R_{1p} decreases with increasing temperature, indicating $T_{1M} \gg \tau_M$ (39). Thus, R_{1p} is directly proportional to the inverse sixth power of the average distance between the Mn^{2+} on the surface and the nucleus in the micelles. It is reasonable to assume that this condition also holds for the Mn^{2+}–SDS system since the interaction between Mn^{2+} and SDS is much weaker than that between Mn^{2+} and alkyl phosphate (39). If the contributions of internal motion to the paramagnetic relaxation are the same for surfactant segments and the solubilizate (37), a comparison of the paramagnetic relaxation enhancement between the surfactant segments and the solubilizate can provide information on the location of the solubilizate inside the micelles.

Experimental

Materials and sample preparation

Dodecyl-, tetradecyl-, and hexadecyltrimethylammonium bromide (DTAB, TTAB, and HTAB) were obtained from Sigma Chemical Co. These products were purified by repeated recrystallization from acetone. Dodecylpyridinium chloride (DPC) and hexadecylpyridinium bromide (HPB) were obtained from Tokyo Kasei Kogyo Co. Ltd. and Eastman Kodak Co., respectively, and purified by repeated recrystallization from acetone and treatment with active carbon. Tetradecylpyridinium bromide (TPB) was synthesized by reacting 1-bromotetradecane (Eastman Kodak, purified by fractional distillation) with a small excess of pyridine (40). The reaction product was purified by extraction with diethyl ether followed by repeated recrystallization from acetone and treatment with active carbon. None of these products showed a minimum in surface tension, and cmc values were in good agreement with literature values (41). For sodium dodecyl sulfate we used both a commercial product (Aldrich, "99% pure"), and a highly purified sample prepared by reacting fractionally distilled 1-dodecanol (Eastman Kodak) with chlorosulfonic acid, followed by ether extraction and recrystallization (42). The NMR relaxation measurements of solubilized hydrocarbons reported here did not prove sensitive to the different degree of purity of these two

samples. Surfactant solutions were prepared by weight using distilled and deionized water ($\kappa < 5 \times 10^{-7}$ ohm^{-1} cm^{-1}) for ^{2}H NMR experiments, and D_2O (99.8%) for ^{1}H NMR experiments, at a temperature well above the Kraft point. A weighed amount of hydrocarbon was added and the solution was shaken, normally for 24 h. In a number of cases the concentration of solubilized hydrocarbon was determined by UV spectroscopy. The result of the UV concentration determination was in good agreement with the calculated concentration.

NMR measurements

Deuterium NMR spectra were recorded at 55.427 MHz (B_0 = 8.48 T) using a Nicolet 360 NB spectrometer and at 15.36 MHz (B_0 = 2.35 T) using a Varian XL-100 spectrometer. Proton NMR chemical shift and relaxation measurements were carried out at 361.05 MHz on the Nicolet 360 NB spectrometer and the COSY spectrum was recorded at 500.13 MHz on a Bruker AMX 500 spectrometer. Spin-lattice relaxation times were measured using an inversion–recovery sequence in which alternate $\pi/2$ pulses are phase shifted by 180° (43) and a composite π pulse is used to compensate for imperfect B_1 homogeneity (44). All T_1 values were calculated from peak heights obtained at 12 or more different variable delays, using a nonlinear three-parameter least-squares fitting procedure (45) available on the Nicolet software (both instruments). Spin–spin relaxation times were measured by the Carr–Purcell–Meiboom–Gill method (46).

On any given sample, we believe that the deuterium relaxation times T_1 and T_2 are reproducible to ±5% and ±10%, respectively. Proton NMR chemical shifts were referred to the HOD residue (δ = 4.63 ppm) and typical errors in chemical shift measurements are 0.002 ppm. Error limits for proton T_1 values are less than 5%.

Results and discussion

Deuterium NMR relaxation

Deuterium spin-lattice relaxation times at 55.43 MHz for several hydrocarbons solubilized in alkyltrimethylammonium bromides, alkylpyridinium halides, and SDS micelles are given in Tables 1, 2, and 3, respectively. Deuterium T_1 and T_2 values determined at 55.43 MHz for benzene-d_6, naphthalene-d_8, cyclohexane-d_{12}, and cyclododecane-d_{24} solubilized in several different surfactant solutions are given in Table 4. Also, T_1 values for benzene-d_6, naphthalene-d_8, acenaphthalene-d_{10}, and cyclododecane-d_{24} solubilized in HTAB and SDS at two different resonant frequencies are compared in Table 5. First, we outline below how to obtain effective rotational correlation times for each of these solubilizates from the relaxation data in Tables 1–5.

As already mentioned in the theory section, the local order parameter, S, is small for saturated hydrocarbon solubilizates such as cyclohexane, *trans*-decalin, and cyclododecane, hence the single-step analysis and two-step model are essentially equivalent. This hypothesis is supported by the observation that for these solubilizates T_1 and T_2 are equal within experimental error (Table 4) and that the ^{2}H T_1 values for cyclododecane are independent of the frequencies used in this study (Table 5). Since χ_Q = 174 kHz in cyclohexane (47), τ_c for each of the saturated hydrocarbon solubilizates can be calculated by substitution into eq. [5] and the result is τ_c (ps) = $2.231/T_1$ (s).

[a]Data for H-2, H-3, H-6, and H-7.

In the case of the planar unsaturated hydrocarbons, the local order parameter is expected to be larger. For naphthalene in the cationic hexadecyltrimethylammonium surfactants we obtain $\tau_c^s = 9.0$ ns, $S = 0.10$, and $\tau_c^f = 62$ ps, using eqs. [2], [7], [8], and [9] ($\chi_Q = 193$ kHz (48, 49)), based on the two-step model. The correlation time for slow motion, τ_c^s, is in good agreement with that of hexadecyltrimethylammonium micelle in aqueous solution, $\tau_c^s = 7.6$ ns (50), obtained from ^{2}H relaxation data. We have also determined the order parameter of naphthalene in the hexadecyltrimethylammonium bromide hexagonal phase to be 0.12 from the ^{2}H powder pattern.[2] If the single-step model (eq. [5]) is used, we calculate $\tau_c = 60$ ps, very close to the τ_c^f (62 ps) from the two-step model. It is important to note that naphthalene has a T_1 value in the range 0.02–0.05 s in the cationic surfactant micelles, and that the single- and two-step models yield similar values for τ_c^f (see Figs. 1 and 2). A similar situation is expected for acenaphthalene in cationic alkyltrimethylammonium surfactant micelles.

For naphthalene in SDS, the T_1 and T_2 values at 55.43 MHz are the same within experimental error and no field dependence of T_1 is apparent (Tables 4 and 5). These comments also apply to acenaphthalene in SDS, and suggest that the effective order parameter, S, for naphthalene and acenaphthalene in SDS is much smaller than it is in the cationic surfactants.

Because of the low solubility of triphenylene in these surfactant systems, low signal-to-noise ratios at 15.36 MHz made it impossible to obtain reliable T_1 values at this frequency. However, the reliable high-field T_1 values in the range 0.0075–0.017 s suggest that τ_c values calculated using the single-step model will be in fair agreement with those obtained using the two-step model.

Benzene is rather a special case; it should be recognized that benzene has an appreciable solubility in the aqueous phase. In DTAB and SDS micellar solution, the fraction of benzene in the micellar phase has been determined to be 83% (6) and 85% (52), respectively, hence the corrected ^{2}H relaxation time of benzene in the micellar phase can be calculated. For benzene in HTAB micelles, we obtain $T_1 = 0.11$ s, $T_2 = 0.08$ s at 55.43 MHz, and $T_1 = 0.076$ s at 15.36 MHz. Based on the two-step model, τ_c^s, S, and τ_c^f are calculated to be 6.5 ns, 0.056, and 16 ps ($\chi_Q = 187$ kHz (32)), respectively. The order parameter for benzene in a HTAB hexagonal phase was determined by Eriksson and co-workers to be 0.084 (13, 32). The single-step model (eq. [5]) gives $\tau_c = 17$ ps for benzene in HTAB, in good agreement with the correlation time for fast motion in the two-step model. In the case of benzene in SDS, T_1 is independent of frequency and T_1 and T_2 at 55.43 MHz are equal within experimental error, indicating a small S value.

In Table 6 we have summarized the NMR rotational correlation times calculated using the single-step model (eq. [5]) for each of the solubilizates examined in this study. Values of τ_c for each solubilizate (concentration 5 mM) in *n*-hexane and *n*-hexadecane are also given. These values are probably accurate to better than ±10%.

Rotational correlation times for cyclohexane solubilized in the various micellar systems range from 3.0 to 5.1 ps. These values are not much longer than the rotational correlation time for cyclohexane in *n*-hexadecane, i.e., 2.7 ps. Similar comments apply to cyclododecane where τ_c values in the surfactant solutions are in the range 13–16 ps, while in *n*-hexadecane $\tau_c = 12$ ps. Since the viscosity of *n*-hexadecane is 3.34 cP (53), it can be concluded that the micellar viscosity at the location of cyclohexane and cyclododecane is approximately 5 cP for both cationic and anionic SDS micelles, in good agreement with the results of Stilbs *et al.* (15) for *trans*-decalin in micelles (3–10 cP).

Rotational correlation times of the planar unsaturated hydrocarbons are significantly longer in the alkyltrimethylammonium micelles than in SDS or in *n*-hexadecane. For example, for naphthalene solubilized in DTAB and SDS, $\tau_c = 50$ and 24 ps, respectively. The longer rotational correlation times in the cationic surfactant systems compared to SDS must be the result of different solubilization sites. The locations of hydrocarbons in micelles will be further characterized in the next two sections, using aromatic ring current-induced ^{1}H shift and paramagnetic relaxation enhancement methods.

Aromatic ring current-induced proton chemical shifts

^{1}H NMR spectra were recorded for 0.050 *m* HTAB, HPB, and SDS solutions containing 0–0.030 *m* benzene or 0–0.010 *m* naphthalene. The assignments of surfactant spectra were based on standard decoupling and two-dimensional (COSY) techniques. One typical example is shown in Fig. 3, which gives the ^{1}H spectra of 0.050 *m* HTAB in the absence and presence

of 0.010 *m* naphthalene. Upon the addition of naphthalene, the largest effect was observed for the chemical shift of the HTAB β-CH_2 proton resonance. The peaks corresponding to the γ-CH_2 group in HTAB (Fig. 3) were previously assigned to the methylene protons adjacent to the terminal methyl group of the alkyl chain in decyltrimethylammonium bromide by Jagannathan *et al.* (30). This latter assignment is inconsistent with the earlier work by Zachariasse *et al.* (54). Our decoupling spectra and COSY spectrum (Fig. 3c) of DTAB clearly show strong correlation between the β-CH_2 and the γ-CH_2 resonances and between the $(CH_2)_n$ and the ω-CH_3 resonances, providing full support to the assignment by Zachariasse *et al.* (54).

Figures 4, 5, and 6 illustrate the chemical shift changes along the surfactant methylene chains in 0.050 *m* HTAB, HPB, and SDS solutions when different amounts of benzene (0.005–0.030 *m*) are solubilized. For the cationic surfactants HTAB and HPB, the effects of benzene solubilization on the surfactant alkyl chain shifts are in the order β-CH_2 > γ-CH_2 > α-CH_2. Similar changes in chemical shift are not observed for $(CH_2)_n$ and ω-CH_3. In the case of the anionic surfactant SDS, the effects of benzene solubilization on the proton chemical shifts are in the order β-CH_2 ~ $(CH_2)_n$ > α-CH_2 ~ ω-CH_3. These results suggest that on average benzene molecules favour the headgroup region of the cationic surfactant micelles, but, in the anionic SDS surfactant micelles, benzene molecules are distributed more uniformly throughout the micelles.

When 0.010 *m* naphthalene is used as solubilizate, similar results are observed in the 0.050 *m* HTAB, HPB, and SDS systems, as shown in Fig. 7. Maximum chemical shift changes are observed for the β-CH_2 resonances in cationic surfactants HTAB and HPB. In the case of SDS micelles, the distribution of naphthalene is also more uniform.

These observations may clarify the result obtained in the previous section where the rotational correlation times of arenes are significantly longer in the alkyltrimethylammonium bromide micelles than in the anionic SDS micelles. The longer rotational correlation times for arenes in cationic micelles are reasonable if they are located near the headgroups, since it has been established that there is a gradient in the local motion along the surfactant hydrocarbon chain, with methylene groups near the headgroup moving more slowly than those in the micellar interior (8). The increase in rotational correlation time, with the cationic surfactant alkyl chain length, for any arene solubilizate (Table 6) is also evidence that solubilization occurs primarily near the surface of cationic surfactant micelles. Aromatic ring current-induced shifts of benzene in cationic HTAB and anionic SDS surfactant micelles were reported earlier by Fendler *et al.* (55). These authors also found that benzene is primarily located

near the surface of HTAB micelles, but solubilized in the interior of the SDS micelles. However, our NMR results contradict the conclusion that benzene is solubilized in the core of the cationic DTAB micelles, drawn recently from UV spectrometry measurements (56).

^1H paramagnetic relaxation

The locations of both saturated and unsaturated hydrocarbons in micelles can be determined by comparing the ^1H NMR paramagnetic relaxation enhancement of the hydrocarbons induced by Mn^{2+} ions on the micellar surface with those of surfactant alkyl chain segments. As stated in the theory section, the relaxation enhancement is proportional to the inverse sixth power of the distance between the paramagnetic centre and the nucleus. If the hydrocarbon is located near the micellar surface, the relaxation enhancement of the hydrocarbon should be similar to that of the α-CH_2 group, while if it is located in the micellar interior, its relaxation enhancement should be similar to that of the ω-CH_3 group.

The ^1H spin-lattice relaxation enhancements of different SDS segments and of naphthalene in a SDS (0.050 *m*)/naphthalene (0.010 *m*)/Mn^{2+} (0.0002 *m*) system are given in Fig. 8. These enhancements are expressed in the ratio of R_{1p} of the protons of interest to those on the micellar surface, i.e., the α-CH_2 protons. Figure 8 indicates that the value of spin-lattice relaxation enhancement of naphthalene is between those of surfactant segments β-CH_2 and $(CH_2)_n$. The spin-lattice relaxation enhancements of different SDS segments and the *tert*-butyl group of *tert*-butylcyclohexane in SDS (0.050 *m*)/*tert*-butylcyclohexane (0.005 *m*)/Mn^{2+} (0.0002 *m*) system are presented in Fig. 9. The relaxation enhancement of the *tert*-butylcyclohexane is smaller than that of ω-CH_3.

The relaxation enhancement on the naphthalene can be easily understood. If the naphthalene molecules are evenly distributed in the SDS micelle, statistically most of them would be solubilized near the surface of the spherical micelles (57). On the other hand, it is surprising to find that saturated hydrocarbon *tert*-butylcyclohexane is located in the centre of SDS micelles. This finding may explain the fact that rotational correlation times for saturated hydrocarbons in SDS are much shorter than those of unsaturated hydrocarbons (Table 6), since the local motion increases from α-CH_2 to ω-CH_3 in the SDS hydrocarbon chain (58). However, it should be noted that the internal

motions of the hydrocarbon and the surfactant alkyl chain segment can also contribute to the paramagnetic relaxation enhancement (59), which may complicate the interpretation.

Summary

The solubilization of a number of hydrocarbons, saturated and unsaturated, in cationic *n*-alkyltrimethylammonium bromide, *n*-alkylpyridinium halide, and anionic SDS micelles was investigated by means of ^2H NMR relaxation, aromatic ring current-induced ^1H NMR shifts, and ^1H paramagnetic relaxa-

tion enhancement. For saturated hydrocarbons in all these micelles and for unsaturated hydrocarbons in SDS micelles, ^2H T_1 and T_2 values are equal within experimental error and independent of field strength, indicating insignificant local order parameters in these systems. Relaxation data of naphthalene and benzene in HTAB micelles were interpreted using both two-step and single-step models. The correlation times for fast motion obtained with the two-step model agree very well with the correlation times obtained with the single-step model using the data obtained at 55.43 MHz.

Rotational correlation times for saturated hydrocarbons (cyclohexane or cyclododecane) in all these micelles are close to those in *n*-hexadecane. The micellar viscosity at the sites where saturated hydrocarbons are solubilized can be estimated to be approximately equal to or slightly higher than the viscosity of *n*-hexadecane (3.34 cP). The rotational correlation times for unsaturated hydrocarbons (benzene, naphthalene, acenaphthalene, or triphenylene) in cationic surfactant micelles are significantly longer than those in *n*-hexadecane, which can be attributed to the fact that the unsaturated hydrocarbons are solubilized near the headgroups of the cationic surfactants.

The solubilization sites of benzene and naphthalene in HTAB, HPB, and SDS were further characterized by monitoring the aromatic ring current-induced ^1H chemical shifts. The results demonstrate that the unsaturated hydrocarbons are solubilized near the surface of cationic HTAB and HPB micelles, but are distributed evenly in anionic SDS micelles. Information concerning the location of naphthalene and *tert*-butylcyclohexane in anionic SDS micelles is also obtained from the ^1H spin-lattice relaxation enhancement induced by Mn^{2+} on the micellar surface. These data also indicate that naphthalene is solubilized uniformly throughout the SDS micelles, while *tert*-butylcyclohexane is primarily located in the centre of the micelles.

From the results presented it is clear why different probes give different micellar microviscosities. Aromatic hydrocarbons, including many fluorescence probes, generally indicate higher micellar microviscosities (51, 60), since they are primarily solubilized near the micellar surface (cationic surfactants), or evenly distributed throughout the micelle (anionic surfactants). On the other hand, saturated hydrocarbons are located in the micellar interior, hence probing the low microviscosity region.

A nitrogen-15 nuclear magnetic resonance study of the tetracycline antibiotics

RONALD D. CURTIS AND RODERICK E. WASYLISHEN[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

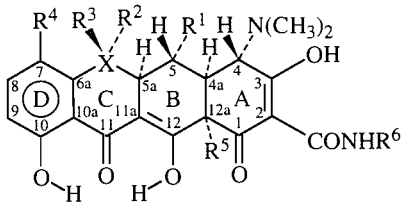
Received September 4, 1990

RONALD D. CURTIS and RODERICK E. WASYLISHEN. Can. J. Chem. **69**, 834 (1991).

Natural abundance ^{15}N NMR has been used to study several tetracycline antibiotics in the solid state and in solution. In the solid state, the ^{15}N chemical shifts of the tetracycline free bases are sensitive to the site of protonation in the "A" ring. A high frequency shift of 14 ppm is observed for the keto form of oxytetracycline (N protonated) relative to the enol form of oxytetracycline (O protonated). Comparison of ^{15}N chemical shifts in the solid and solution states indicates for the first time that the structural integrity (site of protonation and hence conformation) of the tetracyclines is maintained in $(CD_3)_2SO$ solutions. In addition, the solid state ^{15}N CP/MAS NMR spectra are sensitive to subtle conformational changes of the "A" ring amide substituent.

Key words: antibiotics, tetracyclines, ^{15}N NMR, molecular structure.

RONALD D. CURTIS et RODERICK E. WASYLISHEN. Can. J. Chem. **69**, 834 (1991).



On a utilisé a RMN du ^{15}N en abondance naturelle pour étudier plusieurs tétracycline antibiotiques, à l'état solidé et en solution. À l'état solide, les déplacements chimiques du ^{15}N des tétracyclines sous la forme de bases libres sont sensibles aux sites de protonation dans le cycle « A ». On observe un déplacement de 14 ppm vers les hautes fréquences pour le forme cétonique de l'oxytétracycline (N protonée) par rapport à la forme énolique de l'oxytétracycline (O protonée). Une comparaison des déplacements chimiques du ^{15}N à l'état solidé et en solution indique pour la première fois que l'intégrité structurale (site de protonation ainsi que conformation) des tétracyclines est maintenue en solutions dans le $(CD_3)_2SO$. De plus, les spectres RMN du ^{15}N CP/MAS sont sensibles à des changements subtils de conformation du substituent amide du cycle « A ».

Mots clés : antibiotiques, tétracyclines, RMN du ^{15}N, structure moléculaire.

[Traduit par la rédaction]

Introduction

The tetracyclines, **1**, are an important family of antibiotics that are widely used in human and veterinary medicine (1–4). X-ray crystallographic studies of several tetracyclines have revealed that subtle changes in molecular structure can lead to dramatic changes in the overall conformation of the tetracycline (5–16). For example, X-ray diffraction results have indicated that the "A" ring of anhydrous oxytetracycline exists in a neutral "enol" form, **2**, whereas the dihydrate of oxytetracycline exists exclusively in the "keto" form, **3** (6). The principal differences between these two tautomers are the sites of protonation of the A ring, the conformation about the C_{4a}—C_{12a} bond axis, and the relative extent of intermolecular and intramolecular hydrogen bonding. OTC° has been shown to exist with a hydrogen atom bonded to O-3 and the *N,N*-dimethylamino nitrogen not protonated as in **2**, whereas OTC± is present as a zwitterion in the solid state with a hydrogen atom bonded to the *N,N*-dimethylamino group as in **3** (6). Conformational differences between OTC° and OTC± are primarily associated with the orientation of the A ring relative to the approximately planar B, C, and D rings. For OTC°, the A ring is flipped up and oriented at approximately 110° with respect to the B, C, and D rings. In this form, the $N(CH_3)_2$ group is directed above the B, C, and D plane and the dihedral angle, H—C_4— C_{4a}—H, is approxi-

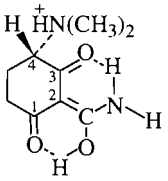
OTC±



3

mately 170° (6). On the other hand, OTC± adopts a conformation such that the A ring is oriented approximately coplanar with the B, C, and D rings and the $^{+}N(CH_3)_2H$ group is situated below this plane. The dihedral angle, H—C_4—C_{4a}—H, in this case is approximately 74° (6). It has been postulated that both structural forms are important for the in vitro mechanism of activity (6). More specifically, the anhydrous free base, **2**, is most likely the predominant form found in hydrophobic regions such as the alkyl chains of membranes, whereas the hydrated tautomeric form, **3**, is the principal species present in hydrophilic regions such as blood plasma (6, 17).

The hydrochloride salts of most tetracyclines have the same basic overall conformation; however, the orientation of the amide substituent on the A ring can be either as in **4** or in **5** (10–15). The hydrochloride salt of DOXYTC crystallizes from aqueous ethanol with two crystallographically unique molecules per unit cell (13). One of the two nonequivalent molecules in DOXYTC·HCl exists with the A ring in conformation **4** while the other is in conformation **5** (13). The only other known example of this phenomenon for the tetracycline family is the observation of two different amide conformations for single crystals of OTC·HBr (15).

4

5

A previous investigation of several solid tetracyclines in this laboratory demonstrated the utility of high-resolution solid state ^{13}C CP/MAS NMR for distinguishing the enol and keto forms (**2** vs. **3**) of the tetracycline free bases (18). This method relied on the nature of the line shapes observed in ^{13}C CP/MAS NMR spectra for the carbon atoms that are directly bonded to a quadrupolar nitrogen nucleus (19, 20). There have been several ^{1}H and ^{13}C NMR studies of the tetracyclines in solution and these have been reviewed by Casy and co-workers (21). However, to date, no ^{15}N NMR data have been reported for the tetracycline antibiotics in either the solid or solution states. Given the inherent sensitivity of ^{15}N chemical shifts to changes in the local electronic environment (22), it was anticipated that this method would provide a sensitive probe of the site of protonation of the A ring of the tetracyclines. To this end, the solid tetracycline antibiotics indicated in **1** were examined by natural abundance ^{15}N CP/MAS solid state NMR. To determine if the structural integrity of the tetracyclines is maintained in solution, ^{15}N NMR spectra of several derivatives were investigated in $(CD_3)_2SO$ and pyridine-d_5 solutions for comparison with the results from the solid state.

Experimental

The hydrochloride salts of OTC, CTC, DEMTC, DOXYTC, and MINTC and the free base hydrates of TC and OTC were purchased from the Sigma Chemical Company. The hydrochloride salt of TC was purchased from the Aldrich Chemical Company. ROLITC·HCl was supplied by C. Marcotte of the Pharmaceutical Division of Hoechst Company in Montreal. The anhydrous form OTC° was prepared by azeotropic distillation of a toluene solution of OTC± (6). DIAOTC was prepared by the addition of acetic anhydride to a solution of OTC° in anhydrous dioxane (23). The 1:1 tetracycline urea adduct was precipitated from a saturated aqueous solution of urea by the addition of tetracycline hexahydrate (24). A sample of 6-STC·HCl was supplied by R. Kirchlechner of Merck Company in Darmstadt, West Germany. For completeness, additional solid samples of the hydrates of TC and OTC and the hydrochloride salt of DEMTC were all crystallized according to the methods outlined in their respective X-ray studies (5, 6*a*, 14). Purity of the prepared samples (i.e., OTC° and DIAOTC) was checked by the appearance of their respective solid state ^{13}C CP/MAS NMR spectra (18).

Nitrogen-15 CP/MAS NMR spectra of solid samples were recorded on a Bruker MSL-200 spectrometer operating at 20.30 MHz (B_0 = 4.7 T). The tetracycline samples (~500 mg) were ground into fine powder and packed into cylindrical rotors (7 mm o.d.) made from aluminum or zirconium oxide. Proton cross polarization (CP) to the ^{15}N nuclei was performed under the conditions of the Hartmann–Hahn match with ^{15}N and ^{1}H $\pi/2$ pulse widths of 3.5–5 μs and contact times of 3–5 ms. All NMR spectra were acquired with high-power decoupling and magic angle spinning (MAS) rates of 3–5 kHz. For the ^{15}N CP/MAS NMR experiments, approximately 5000 transients were required to obtain a S:N ratio of about 10:1. This was readily obtainable overnight with recycle times of 4–6 s. Prior to Fourier transformation, sensitivity enhancements corresponding to 20 Hz of line broadening were applied to the ^{15}N FIDs. For the dipolar dephasing NMR experiments (25), the decoupler was turned off prior to acquisition for approximately 60–100 μs. Nitrogen-15 CP/MAS NMR spectra are referenced with respect to NH_3(liq.)(293 K) at 0 ppm by setting the ammonium ion signal of doubly isotropically enriched $^{15}NH_4{}^{15}NO_3$ at 23.80 ppm.

Samples for ^{15}N solution state NMR were prepared as saturated solutions in $(CD_3)_2SO$ (ca. 1 M) or pyridine-d_5 just prior to obtaining the NMR spectra. Solution NMR spectra were recorded on a Nicolet-360 NMR spectrometer with ^{1}H and ^{15}N operating frequencies of 361.05 and 36.61 MHz, respectively. With the exception of OTC°, all ^{15}N spectra were acquired using the INEPT pulse sequence (26) with a delay time between ^{1}H $\pi/2$ and π pulses of 2.78 ms and a delay time for refocussing the ^{15}N signals of 2.25 ms. The ^{15}N NMR spectrum of OTC° in $(CD_3)_2SO$ was acquired using bilevel broadband decoupling and a delay of 30 s between acquisition of transients. The ^{15}N NMR spectrum of OTC° in pyridine-d_5 was acquired using a single pulse experiment without proton decoupling and a recycle time of 30 s. The ^{15}N $\pi/2$ pulse length was typically 60–65 μs. Signal averaging on the order of 5000–10 000 transients was employed for all samples. Line broadening of 15 Hz was applied to all FIDs prior to Fourier transformation. Solution ^{15}N NMR spectra were referenced with respect to liquid NH_3 (293 K) at 0 ppm by setting the observed ^{15}N chemical shift of external formamide at 112.3 ppm (27).

Results and discussion

The ^{15}N chemical shifts of several solid tetracycline antibiotics are given in Table 1. Since only two ^{15}N resonance signals were present (in most samples) for these compounds, assignment of the resonances was straightforward. Without exception, the high frequency resonance was assigned to the amide nitrogen.

The ^{15}N CP/MAS NMR spectra provided two distinct methods for distinguishing between the "enol", **2**, and zwitterionic "keto", **3**, tautomeric forms of the tetracycline free bases in the solid state. First, the ^{15}N chemical shift of the *N,N*-di-

†Estimated error, ±1.0 ppm.

methylamino nitrogen is expected to be sensitive to its presence in an amine or in an aminium ion. For example, in a solution NMR study of a series of 15 tertiary amines, the average ^{15}N chemical shift of the protonated amine was 12.8 ppm to high frequency (i.e., higher δ) of the free base (28, 29). Comparison of the ^{15}N NMR results for OTC± and OTC° in Table 1 indicates that the chemical shift of OTC± is 13.9 ppm to high frequency of the corresponding value for OTC°. The corresponding ^{15}N CP/MAS NMR spectra are shown in Figs. 1a and 1b for OTC± and OTC°, respectively. It should also be pointed out that the ^{15}N chemical shift of OTC° is similar to that observed for the *N,N*-dimethylamino nitrogen of DIAOTC ($\delta_{iso} = 20.6$ ppm). This is an important observation since it has been concluded from X-ray diffraction experiments that DIAOTC exists exclusively in the "enol" form (9).

The results obtained from the dipolar dephasing NMR experiments (25) on several of the tetracyclines **1**, provided an alternative method for studying the tautomeric state of the "A" ring in the solid state. The CP/MAS ^{15}N NMR spectrum obtained for OTC° using the dipolar dephasing pulse sequence is shown in Fig. 1c. Comparison with Figs. 1a and 1b indicates that there is no ^{15}N NMR signal observed for the amide nitrogen in the NMR spectrum of OTC° acquired with the dipolar dephasing pulse sequences. This is not surprising since this nitrogen is strongly dipolar coupled to the two directly bonded hydrogens; therefore, the corresponding signal dephases rapidly during the time the decoupler is off (25). Of greater significance, the ^{15}N NMR signal corresponding to the *N,N*-dimethylamino nitrogen of OTC° was still present in this NMR spectrum (Fig. 1c). Analogous results were obtained when a dipolar dephasing ^{15}N NMR experiment was performed on a sample of

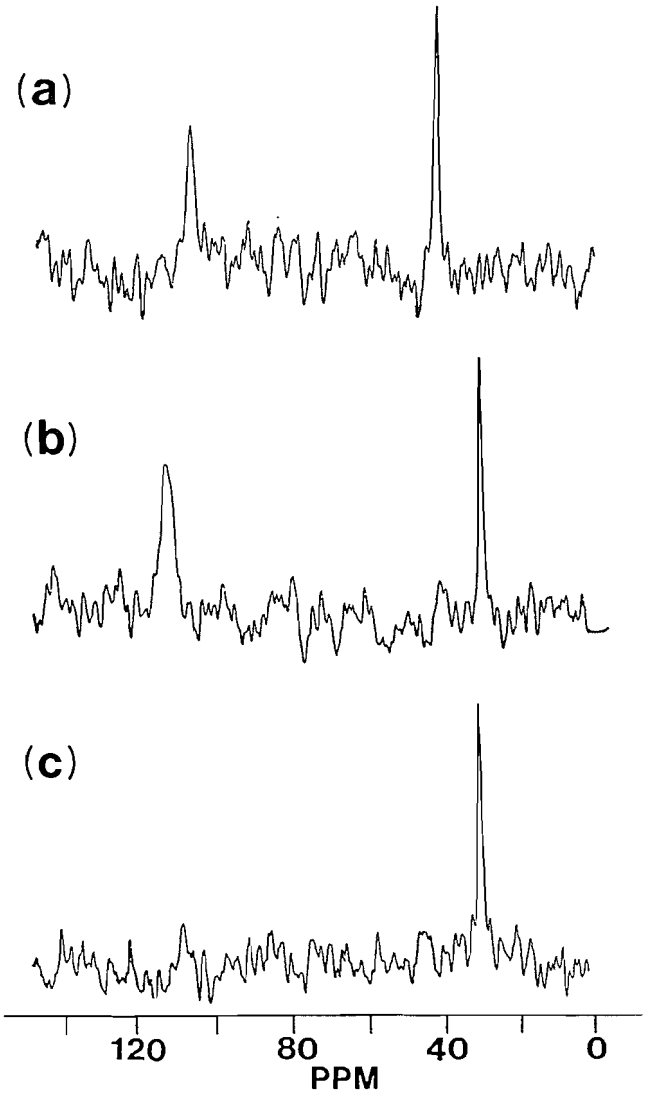

FIG. 1. Nitrogen-15 CP/MAS NMR spectra of solid samples of (a) oxytetracycline dihydrate, OTC±; (b) anhydrous oxytetracycline, OTC°; and (c) anhydrous oxytetracycline, OTC°, acquired with the dipolar dephasing pulse sequence using a delay time before acquisition of 65 μs.

DIAOTC indicating that both OTC° and DIAOTC exist exclusively in the neutral "enol" tautomeric form in the solid state.

The ^{15}N chemical shifts for TC·HCl, OTC·HCl, OTC±, and OTC° in $(CD_3)_2SO$ and pyridine-d_5 solutions are given in parentheses in Table 1. Preliminary ^{15}N solution NMR experiments were performed using the INEPT pulse sequence (26) without proton decoupling on samples of OTC·HCl dissolved in $(CD_3)_2SO$. This solvent was chosen since relatively concentrated solutions of OTC·HCl could be prepared (ca. 1 M) and because previous ^1H NMR experiments indicated that the conformational integrity of OTC·HCl is maintained when dissolved in this solvent (30). It is important to point out that the INEPT experiment is a polarization transfer technique that depends on the presence of a spin–spin coupling (J) between the nuclei involved (26). In this study, polarization transfer occurs from the directly bonded hydrogens to the nitrogen and therefore a $^1J(^{15}N, ^1H)$ coupling is essential for the INEPT NMR experiment to be applied successfully. Since no previous ^{15}N NMR investigations of the tetracyclines have been reported, a value for $^1J(^{15}N, ^1H)$ for the amide and protonated *N,N*-di-

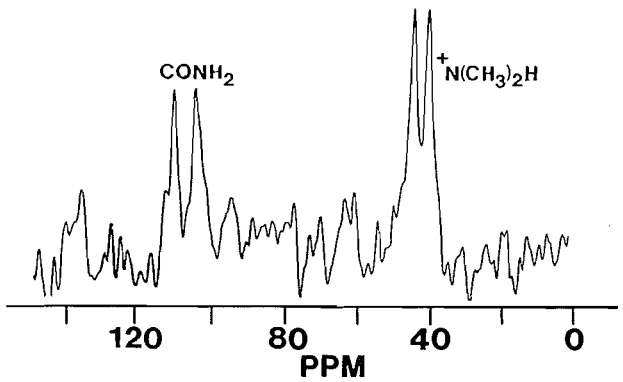

FIG. 2. A nitrogen-15 CP/MAS NMR spectrum of solid doxycycline hydrochloride, DOXYTC · HCl.

methylamino nitrogens was assumed to be similar to that reported for formamide (i.e., approximately 90 Hz) (21). This value for $^1J(^{15}N, ^1H)$ was then used to calculate the spin dephasing delay time ($J/4$) required for performing the INEPT NMR experiment (26). Subsequent acquisition of a ^{15}N NMR spectrum of OTC · HCl in $(CD_3)_2SO$ provided a proton coupled ^{15}N NMR spectrum. In this NMR spectrum, the amide resonance signal was a 1:0:−1 triplet with a $^1J(^{15}N, ^1H)$ of 95 ± 5 Hz whereas the low frequency signal for the *N,N*-dimethylamino resonance was observed as a 1:−1 doublet with a $^1J(^{15}N, ^1H)$ of 62 ± 5 Hz. The average of these two values was then used to calculate the spin dephasing delay for further ^{15}N NMR experiments performed with the INEPT sequence and proton decoupling.

Inspection of Table 1 indicates that the observed ^{15}N chemical shifts of the tetracyclines in solution are similar to the corresponding chemical shifts observed in the solid state. In addition, both TC · HCl and OTC · HCl exhibited a signal due to the *N,N*-dimethylamino nitrogen in their respective solution ^{15}N NMR spectrum. Since a resolvable spin–spin coupling between hydrogen and nitrogen is essential for the INEPT experiment to work (26), it can be concluded that TC · HCl and OTC · HCl exist exclusively with a protonated *N,N*-dimethylamino nitrogen in $(CD_3)_2SO$. More importantly, the low frequency resonance signal was not observed when a ^{15}N solution NMR spectrum of OTC± was acquired under experimental conditions identical to those for the hydrochloride salts. Based on this observation, it can be concluded that the *N,N*-dimethylamino nitrogen of OTC± in $(CD_3)_2SO$ does not have a resolvable $^1J(^{15}N, ^1H)$. This situation could result if the nitrogen were not protonated or if it were involved in rapid proton exchange. The ^{15}N NMR spectra of OTC° dissolved in $(CD_3)_2SO$ and pyridine-d_5 solutions were acquired with and without proton decoupling, respectively. For both samples, the ^{15}N NMR signal observed for the *N,N*-dimethylamino nitrogen was a single peak ($\nu_{1/2} \leq 6$ Hz).The observed ^{15}N chemical shifts for the *N,N*-dimethylamino nitrogen in $(CD_3)_2SO$ and pyridine-d_5, 25.3 ppm and 22.3 ppm, are in reasonable agreement with the corresponding value determined for OTC° in the solid state, 27.7 ppm. Thus, based on the similarity of ^{15}N chemical shifts in the solid and solution states and on the results from the INEPT experiments, it can be concluded that the structural integrity of the two tautomeric forms, **2** and **3**, is maintained in $(CD_3)_2SO$ and pyridine-d_5 solutions. In addition, the hydrochloride salts of TC and OTC also maintain their structural forms (i.e., with the *N,N*-dimethylamino nitrogen protonated) when dissolved in $(CD_3)_2SO$.

The ^{15}N CP/MAS NMR spectrum for a solid sample of DOXYTC · HCl is shown in Fig. 2. Two independent sets of isotropic resonances are apparent for the amide and protonated *N,N*-dimethylamino nitrogen of this sample. The observation of two sets of isotropic ^{15}N resonances is consistent with the reported X-ray diffraction results for this compound (13). The chemical shift difference observed for the dimethylamino nitrogen resonances was approximately 4 ppm, whereas for the amide nitrogen signals the chemical shift difference was approximately 6 ppm. For OTC · HBr, which also exists with two crystallographic nonequivalent forms (15), the ^{15}N chemical shifts of the *N,N*-dimethylamino nitrogens were also different by approximately 4 ppm. For this sample, the amide resonance signals were significantly broadened such that the ^{15}N chemical shifts could not be resolved. Several hydrochloride salts of the tetracycline family of antibiotics have been shown to exist in the solid state with only a single conformation of the amide substituent. For example, TC · HCl and OTC · HCl have been shown to exist in the solid state with the amide nitrogen oriented *cis* to the oxygen at C-1, **4**, (10, 11). On the other hand, DEMTC · HCl has been shown to exist in crystalline form with the opposite conformation of the amide substituent (i.e., amide nitrogen *trans* to O-1 as in **5**) (14). Although the ^{15}N chemical shifts of solid TC · HCl and OTC · HCl are approximately 1.4 ppm and 1.7 ppm to high frequency of the corresponding value for DEMTC · HCl (Table 1), the small range of ^{15}N chemical shifts for the amide nitrogen prevents any definitive assignment of the amide conformations in these systems.

Several other points regarding the solid state ^{15}N CP/MAS NMR spectra should be mentioned. The ^{15}N signal observed at 81.9 ppm for TC · UREA provides definitive evidence for the inclusion of the urea molecule in the crystalline solid. This value is similar to the ^{15}N chemical shift determined for a saturated solution of urea in H_2O/ethanol, 76 ppm (31). For MINTC · HCl, an additional resonance signal was observed at 48.9 ppm. This signal was assigned to the *N,N*-dimethylamino nitrogen attached at the C-7 position of the aromatic D ring. When a dipolar dephasing CP/MAS NMR spectrum of this compound was obtained, neither *N,N*-dimethylamino nitrogen exhibited a ^{15}N signal. This provided definitive evidence that both nitrogens are protonated in the solid state. Finally, the ^{15}N CP/MAS NMR spectrum of solid ROLITC · HCl consisted of single peaks for the *N,N*-dimethylamino and the amide nitrogens; however, a doublet (peak separation ~5 ppm) was observed for the nitrogen of the pyrrolidine ring. We have no explanation for this observation at this time.

Conclusions

Natural abundance ^{15}N CP/MAS NMR has proven to be a valuable method for studying the structural forms of the tetracycline free bases in the solid state. The inherent sensitivity of the ^{15}N chemical shifts to *N*-protonation and the conclusive evidence obtained with the dipolar dephasing experiments provide an even more sensitive probe of the structure of the "A" ring than previous ^{13}C CP/MAS NMR experiments (18). In addition, comparison of solid state ^{15}N chemical shifts with corresponding values in $(CD_3)_2SO$ and pyridine-d_5 solutions provides the first definitive evidence that the structural integrity of the tetracyclines is maintained in solution.

Received August 31, 1990

This paper is dedicated to Professor Paul de Mayo on the occasion of his 65th birthday

DONALD R. ARNOLD, XINYAO DU, and KERSTIN M. HENSELEIT. Can. J. Chem. **69**, 839 (1991).

The effect of *meta*- and *para*-methoxy substitution on the reactivity of some radical cations has been determined. The compounds chosen for study were 1-(3-methoxyphenyl)-1-phenylethylene (**7**), 1-(4-methoxyphenyl)-1-phenylethylene (**8**), 3-(3-methoxyphenyl)indene (**9**), 3-(4-methoxyphenyl)indene (**10**), methyl 2-(3-methoxyphenyl)-2-phenylethyl ether (**11**), methyl 2-(4-methoxyphenyl)-2-phenylethyl ether (**12**), *cis*- and *trans*-2-methoxy-1-(3-methoxyphenyl)indane (**13**), and *cis*- and *trans*-2-methoxy-1-(4-methoxyphenyl)indane (**14**). The radical cations of these compounds were generated by photosensitization (electron transfer) using 1,4-dicyanobenzene (**3**) as the electron acceptor. The three reactions studied were: (1) The addition of nucleophiles (methanol) to the radical cation of the arylalkenes, a reaction that yields the *anti*-Markovnikov addition product. (2) The carbon–carbon bond cleavage of radical cations, which yields products derived from the radical and carbocation fragments. (3) The deprotonation of the radical cation, a reaction that can be used to invert the configuration at a saturated carbon centre. The mechanisms of these reactions are discussed and the factors that need to be considered in order to predict reactivity are defined. Molecular orbital calculations (UHF/STO-3G) were carried out on the radical cations of the model compounds 3- and 4-vinylanisole and 3- and 4-methylanisole.

Key words: photochemistry, photosensitize (electron transfer), radical cation, radical.

DONALD R. ARNOLD, XINYAO DU et KERSTIN M. HENSELEIT. Can. J. Chem. **69**, 839 (1991).

On a déterminé l'effet de substituants en *méta* et en *para* sur la réactivité de quelques radicaux cations. Les composés choisis pour cette étude sont : les 1-(3-méthoxyphényl)-1-phényléthylène (**7**), 1-(4-méthoxyphényl)-1-phényléthylène (**8**), 3-(3-méthoxyphényl)indène (**9**), 3-(4-méthoxyphényl)indène (**10**), 1-méthoxy-2-(3-méthoxyphényl)-2-phényléthane (**11**), 1-méthoxy-2-(4-méthoxyphényl-2-phényléthane (**12**), les *cis*- et *trans*-2-méthoxy-1-(3-méthoxyphényl)indane (**13**) et les *cis*-et *trans*-2-méthoxy-1-(4-méthoxyphényl)indane (**14**). On a généré les cations radicaux de ces composés par photosensibilisation (transfert d'électron), en utilisant le 1,4-dicyanobenzène (**3**) comme accepteur d'électrons. Les trois réactions étudiées sont : (1) l'addition de nucléophiles (méthanol) aux cations radicaux des arylalcènes, une réaction qui conduit à un produit d'addition *anti*-Markovnikov; (2) le clivage de la liaison carbone–carbone des cations radicaux qui conduit à des produits qui dérivent des fragments radicalaires et carbocationiques et (3) la déprotonation des cations radicaux qui peut être utilisée pour inverser la configuration à un site carboné saturé. On discute des mécanismes de ces réactions et on définit les facteurs qu'il faut considérer afin de pouvoir prédire la réactivité. On a effectué des calculs d'orbitales moléculaires (UHF/ STO-3G) sur les cations radicaux des composés modèles, 3- et 4-vinylanisole et 3- et 4-méthylanisole.

Mots clés : photochimie, photosensibilisation (transfert d'électron), cation radical, radical.

[Traduit par la rédaction]

Introduction

Extensive studies over the past several years in the area of photosensitization (electron transfer) have greatly increased our understanding of the structure and fundamental behaviour of radical ions (2). One of the benefits to be derived from this knowledge is the discovery of new reactions that may become generally useful for organic synthesis. Three of these reactions are: (1) The addition of nucleophiles to the radical cations of arylalkenes, a reaction that yields the *anti*-Markovnikov addition product. (2) The carbon–carbon bond cleavage of radical cations, which yields products derived from the radical and carbocation fragments. (3) The deprotonation of the radical cation, a reaction that can be used to invert the configuration at a saturated carbon centre. Among the first examples of these reactions were: (reaction [1]) the photosensitized (electron transfer) addition of methanol to 1,1-diphenylethylene (**1**) (3); (reaction [2]) the subsequent cleavage of the radical cation of the product, methyl 2,2-diphenylethyl ether (**2**) (4); and (reaction [3]) the photosensitized (electron transfer) *trans* to *cis* isomerization of 2-methoxy-1-phenylindane (**6**) (5).[3] As useful as these reactions may become, the scope and limitations will have to be defined before they will even be considered during the initial planning of a synthesis strategy.

The mechanisms initially proposed for these reactions are shown in Schemes 1, 2, and 3. Subsequent study has generally supported these proposals (1, 6–8) and these mechanisms now provide a framework for the discussion of the scope of these reactions. While many questions remain to be answered, progress has been made to the point where several of the factors that can limit each reaction have been identified.

The purpose of this study was to determine the effect of *meta*- and *para*-methoxy substitution on these three reactions. The compounds chosen for study were 1-(3-methoxyphenyl)-1-phenylethylene (**7**), 1-(4-methoxyphenyl)-1-phenylethylene (**8**),

[3]Reactions [2] and [3] are both bond cleavage reactions; the first is a cleavage of a carbon–carbon bond and the second is cleavage of a carbon–hydrogen bond, that is, loss of a proton. While these reactions may compete with one another, it is unlikely that carbon–carbon bond cleavage will lead to isomerization under these conditions (7*c*,*d*); reaction of the carbocation with methanol (6 M) will be too rapid (9).

3-(3-methoxyphenyl)indene (**9**), and 3-(4-methoxyphenyl)indene (**10**) for reaction [1]; methyl 2-(3-methoxyphenyl)-2-phenylethyl ether (**11**) and methyl 2-(4-methoxyphenyl)-2-phenylethyl ether (**12**) for reaction [2]); and *cis*- and *trans*-2-methoxy-1-(3-methoxyphenyl)indane (**13**), and *cis*- and *trans*-2-methoxy-1-(4-methoxyphenyl)indane (**14**) for reaction [3].

Results

The required compounds were readily prepared by standard methods. The alkenes were obtained by dehydration of the alcohols, which were prepared by Grignard reactions. The ethers were prepared from the alkenes via the alcohols, by using the hydroboration, aqueous hydrogen peroxide oxidation, methylation sequence. The procedure shown in Scheme 4, for the preparation of 3-(4-methoxyphenyl)indene (**10**) and *trans*-2-methoxy-1-(4-methoxyphenyl)indane (**14**), is typical.

The irradiation conditions used for all of these reactions were similar to those used in the previous studies (3–5) so the results can be compared. Most of the irradiations were carried out in acetonitrile–methanol (3:1) solution, with 1,4-dicyanobenzene (**3**) added as a photosensitizer (electron acceptor), using the output of a 1-kW medium-pressure mercury vapour lamp filtered through Pyrex. The temperature of the photolysate generally was held at 10°C. Previous studies have shown that the carbon–carbon bond cleavage reaction (reaction [2]) can be thermally activated in some cases; therefore, when no cleavage was observed upon irradiation at 10°C, the irradiation was also attempted at 80°C. Progress of the reaction was followed by capillary column gas chromatography with mass selective detection (gc/ms).

The irradiation of 1-(3-methoxyphenyl)-1-phenylethylene (**7**) under the conditions used for reaction [1] gave an excellent yield (96%) of the *anti*-Markovnikov methanol addition product, methyl 2-(3-methoxyphenyl)-2-phenylethyl ether (**11**) (reaction [4]). In marked contrast, when 1-(4-methoxyphenyl)-1-phenylethylene (**8**) was irradiated under these conditions, the *anti*-Markovnikov addition product, methyl 2-(4-methoxyphenyl)-2-phenylethyl ether (**12**), was only a minor product (<5%). The major reaction (80%) led to a mixture of the stereoisomeric two-to-one (alkene/methanol) adducts **15**. This mixture was not fully characterized; **15** is relatively unstable. When the reaction mixture was allowed to stand for a period of days, under ambient conditions, *E*- and *Z*-1,4-di(4-methoxyphenyl)-1,4-diphenyl-1-butene (**16** *E* and *Z*) were isolated as

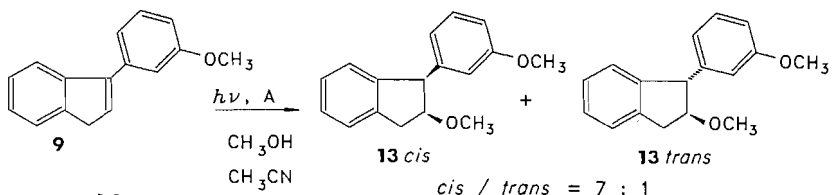
An = 4–methoxyphenyl
Ph = phenyl

the major products (reaction [5]). Examination of the ^{1}H nmr spectrum of the crude reaction mixture, immediately after the irradiation, indicates that **16** *E* and *Z* are initially only minor products.

The same pattern of reactivity was observed with the isomeric indenes. The 3-methoxyphenyl derivative **9** gave a mixture of the *cis*- and *trans-anti*-Markovnikov methanol adducts **13** (74%, *cis*/*trans* = 7:1), whereas little or no one-to-one adduct was obtained upon irradiation of the 4-methoxyphenyl derivative **10** (reactions [6] and [7]).

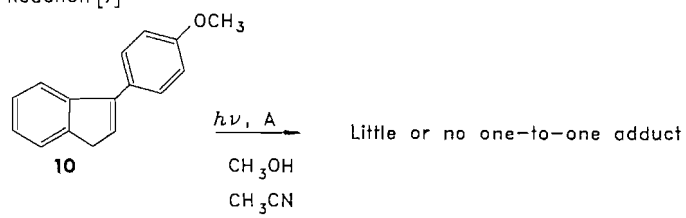
No reaction was observed when methyl 2-(3-methoxyphenyl)-2-phenylethyl ether (**11**) was subjected to the irradiation conditions (reaction [8]) that cause cleavage of the unsubstituted derivative (reaction [2]). There was also no reaction when this irradiation was carried out at the higher temperature (80°C). Furthermore, this ether was also stable to irradiation at 80°C when the solvent was acetonitrile–methanol-*O*-*d* (3:1); no deuterium was incorporated in **11** recovered after prolonged irradiation.

Again, with this reaction, the isomers behave differently. Irradiation of methyl 2-(4-methoxyphenyl)-2-phenylethyl ether (**12**) in the acetonitrile–methanol-*O*-*d* solution leads to relatively efficient deuterium incorporation at the bis-benzylic position (reaction [9]). No carbon–carbon bond cleavage was observed.



This pattern of reactivity is repeated in the indane series. No reaction (cleavage, isomerization, deuterium incorporation) was observed upon prolonged irradiation of *trans*-2-methoxy-1-(3-methoxyphenyl)indane (**13**) (reaction [10]). Analogous irradiation of *trans*-2-methoxy-1-(4-methoxyphenyl)indane (**14**) leads to relatively efficient isomerization to a mixture of the *cis* and *trans* isomers (reaction [11]). When the irradiation of **14** was carried out in the acetonitrile–methanol-*O*-*d* (3:1) solvent mixture, deuterium incorporation occurred at the bis-benzylic position.

The behaviour of the model compounds, 3- and 4-methylanisole (**17** and **18**), was also studied. The *meta* isomer **17** was relatively stable to irradiation in acetonitrile–methanol-d_4 (3:1) solution; a small amount of deuterium was incorporated in the recovered starting material after prolonged irradiation (reaction [12]). In marked contrast, deuterium was efficiently incorporated in the methyl group of the *para* isomer **18** under these conditions, and two other products were formed: 4-cyano-4′-methoxy-diphenylmethane (**19**) and 1,2-di(4-methoxyphenyl)-ethane (**20**) (reaction [13]). There was no evidence for exchange of the methoxy methyl group in either isomer.



The oxidation potentials of the compounds of interest were determined by cyclic voltammetry. There was no evidence for reduction of the radical cation during the reverse cathodic sweep at a sweep rate of 100 mV s^{-1}. Therefore, the oxidation potentials were estimated to be 0.028 V less than the anodic peak potentials (10). These data, along with the oxidation potentials of several related compounds, are summarized in Table 1 (11).

The spin and charge density distribution on the radical cations of the model compounds: 3-vinylanisole (**21**), 4-vinylanisole (**22**), 3-methylanisole (**17**), and 4-methylanisole (**18**), were calculated. The *ab initio* molecular orbital calculations were carried out with Pople's Gaussian 86 series of programmes (12). The six carbons of the aromatic ring and the atoms directly attached were constrained to a plane; the remaining structural features were fully optimized at the UHF/STO-3G level. The spin density was taken as the square of the coefficient at the

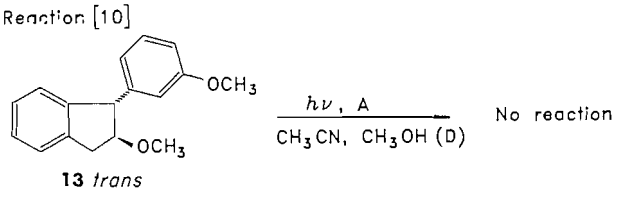
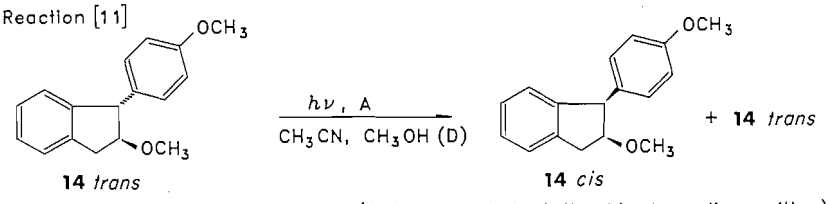
atomic p_z-orbital in the singly occupied molecular orbital (SOMO) and the charge distribution was calculated by Mulliken population analysis (13). The limitations of this method have been discussed (14). These data are summarized in Figs. 1 and 2.



Structural assignments

The structures assigned to the starting materials and products rest primarily upon a thorough analysis of the ^1H and ^{13}C nmr spectra. There is an interesting difference in the ^1H nmr spectra of the 1-(3-methoxyphenyl)- and 1-(4)methoxyphenyl)-1-phenylethylenes (**7** and **8**). The 4-methoxyphenyl derivative shows the two vinyl protons as a distinct pair of doublets (δ 5.39 and 5.36, J = 1.26 Hz) (15), whereas, in the spectrum of the 3-methoxyphenyl derivative, the signals due to the vinyl protons are coincidentally equivalent (δ 5.44).



The stereochemical assignment of the *trans*-2-methoxy-1-(3-methoxyphenyl)indane and *trans*-2-methoxy-1-(4-methoxy phenyl)indane ethers (**13** *trans* and **14** *trans*) is firmly established by the regioselective *cis* addition during the hydroboration step (16). Knowing the stereochemistry of the *cis* and *trans* isomers of **13** and **14**, it is interesting to compare the magnitude of the vicinal coupling constants between the bis-benzylic proton (X) and the proton adjacent to the methoxy group (Y), both of which are part of ABXY patterns in the aliphatic region of the ^1H nmr spectra. In conformationally mobile cyclopentane rings, it is well known that there is no correlation between the magnitude of the vicinal proton coupling constant and configuration. On the other hand, when the rings cannot deviate appreciably from planarity, J_{cis} is larger than J_{trans}, as expected from the Karplus rule (17). These splitting patterns were analyzed with the aid of computer simulation, and the observed coupling constants (J_{XY}) are greater for the *trans* than for the *cis* isomer in both cases. The same pattern was observed in the case of the unsubstituted derivative (5); however, the differences are small: 2-methoxy-1-phenylindane (**6**) (J_{XY}: *trans* 6.3, *cis* 6.2 Hz), the 3-methoxyphenyl derivative (**13**) (J_{XY}: *trans* 6.31, *cis* 6.17 Hz), and the 4-methoxyphenyl derivative (**14**) (J_{XY}: *trans* 6.27, *cis* 6.20 Hz).

The major initial product (80%) from the irradiation of **8** (reaction [5]) was separated from the crude photolysate by dry-column flash chromatography. A tentative structural assignment, methyl 1,4-di(4-methoxyphenyl)-1,4-diphenyl-1-butyl ether (**15**), presumably a mixture of the diastereomers, was made on the basis of the ^1H nmr spectrum. In particular, the spectrum indicates the presence of three methoxy groups (δ 3.70, 3.68, and 2.93) and a low-field triplet signal (δ 3.74, J = 7.0 Hz), integrating for one hydrogen, attributed to the proton at the bis-benzylic position. This two-to-one adduct is readily converted to a mixture of the isomers of 1,4-di(4-methoxyphenyl)-1,4-diphenyl-1-butene (**16** *E* and *Z*) upon loss of methanol. The distinction between **16** *E* and *Z* was made on the basis of the difference in chemical shift of the vinyl protons; this proton resonates at lower field in the *E* isomer (15). The difference is small, δ 5.91 for **16***E* and δ 5.88 for **16***Z*, similar to the difference observed for the two vinyl protons in **8** (Δδ = 0.05 ppm).

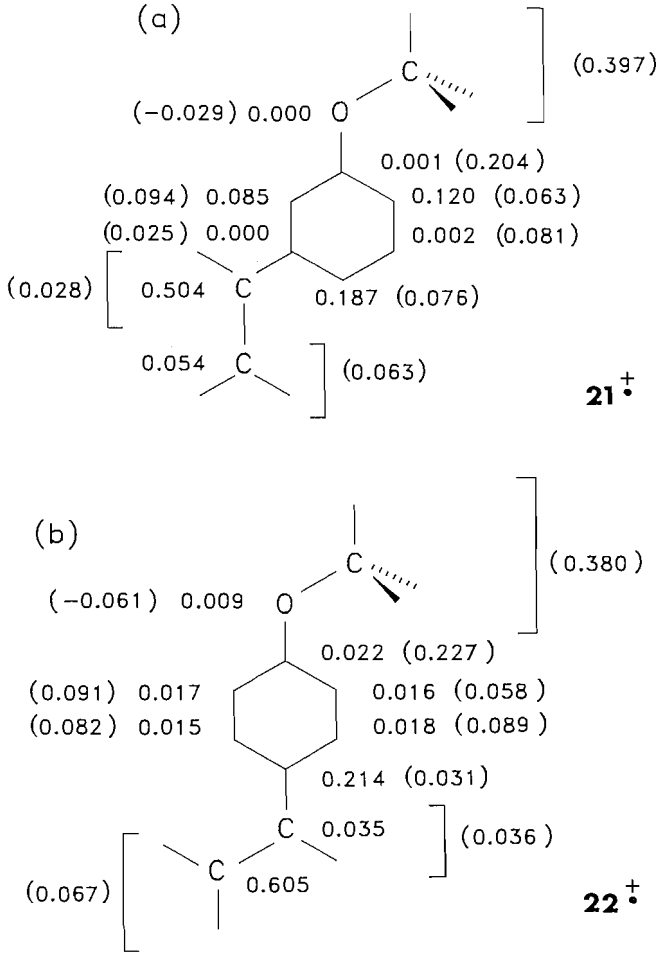

FIG. 1. Calculated spin and (charge) distribution on the radical cations: (a) 3-vinylanisole (**21**$^{+\cdot}$) and (b) 4-vinylanisole (**22**$^{+\cdot}$).

Discussion

The first three steps in the mechanisms (Schemes 1–3) proposed for all three of these reactions are the same. In each case the initial excitation is of the electron-accepting photosensitizer (A), 1,4-dicyanobenzene (**3**). The long-wavelength adsorption spectrum of **3** extends to wavelengths longer than 280 nm, the short wavelength cutoff of Pyrex glass. The arylalkenes and alkanes are essentially transparent in this region.

The energetics of the electron transfer process (step 2) can be calculated using the Weller equation (eq. [14]) where F is the Faraday constant, and the last term in the brackets takes into account the Columbic attraction between the radical cation and the radical anion at the encounter distance (18). The singlet excited state of 1,4-dicyanobenzene (**3**) will accept an electron at the diffusion-controlled rate from any prospective donor having an oxidation potential less than 2.4 V.[4] This includes all of the arylalkenes and alkanes studied here (Table 1). Previous work has shown that the fluorescence of **3** is quenched at essentially the diffusion-controlled rate by both 1,1-diphenylethylene (**1**) and by methyl 2,2-diphenylethyl ether (**2**) (4). The oxidation potentials of the methoxy derivatives, both *meta* and

[4]Electron transfer from the donor to the excited state of the acceptor will occur at the diffusion-controlled rate as long as it is exergonic by more than 12 kJ mol^{-1} (18). The singlet energy of 1,4-dicyanobenzene (**3**) ($E_{0,0}$ (A)) is 407.97 kJ mol^{-1} and the reduction potential ($E^{red}_{1/2}$ (A)) is −1.66 V (sce); the Coulombic attraction ($e/\epsilon\alpha$) is 0.06 eV in acetonitrile (4). All of the electrode potentials mentioned in this paper are referenced to the saturated calomel electrode (sce).

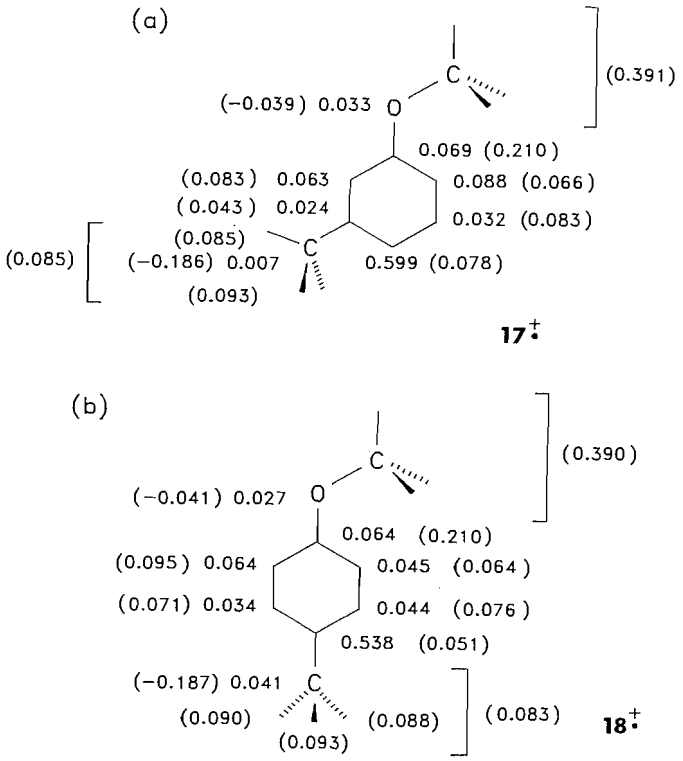

FIG. 2. Calculated spin and (charge) distribution on the radical cations: (a) 3-methylanisole ($17^{+\cdot}$) and (b) 4-methylanisole ($18^{+\cdot}$).

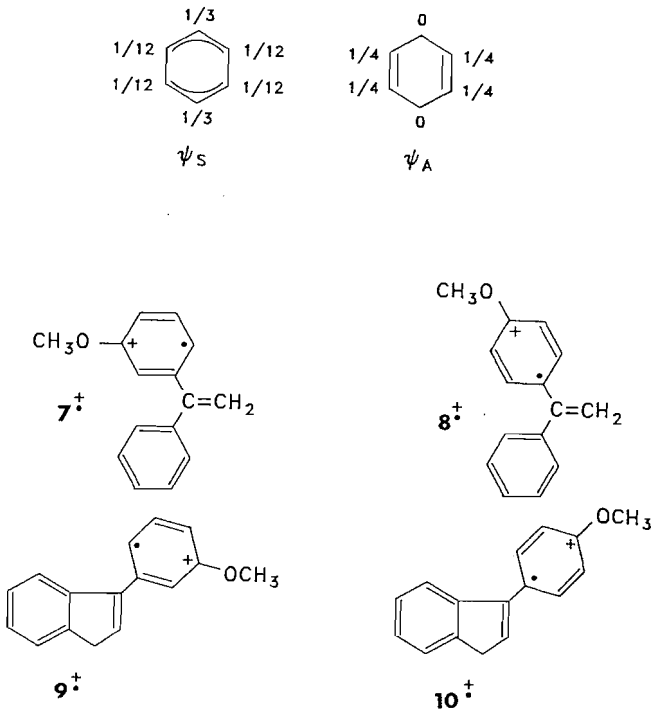

FIG. 3. The radical cation of benzene is a linear combination of the degenerate orbitals ψ_s and ψ_A. Spin and odd electron distribution.

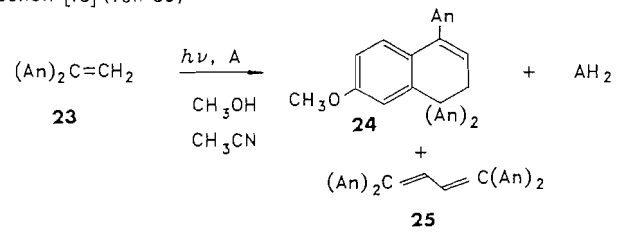
para, are significantly lower (ca. 0.5 V less) than those of the unsubstituted compounds in all three series (Table 1); therefore, electron transfer (step 2) is even more favourable with these derivatives than it is with the unsubstituted analogues.

$$[14]\quad \Delta G_{et} = F[E^{ox}_{1/2}(D) - E^{red}_{1/2}(A) - e/\epsilon\alpha] - E_{0,0}(A)$$

$$[15]\quad \Delta G_{-et} = F(E^{red}_{1/2}(A) - E^{ox}_{1/2}(D))$$

Back-electron transfer from the radical anion of the electron acceptor to the radical cation of the donor within the radical ion pair (step 3) is the main competing deactivation pathway for all three reactions. The free-energy change for this process (ΔG_{-et}, eq. [15] is exergonic by 280 kJ mol^{-1} even in the least favourable case, that is, electron transfer from $3^{-\cdot}$ to $10^{+\cdot}$. This process is so exergonic that the rate falls within the Marcus inverted region (19). Back-electron transfer may be slower with the unsubstituted derivatives; methoxy substitution lowers the oxidation potential relative to the unsubstituted derivative in each series, so the process is less exergonic with the methoxy-substituted derivatives. Nevertheless, the rate of back-electron transfer has been measured in similar systems, and when the process is exergonic by 280 kJ mol^{-1}, the rate is ca. 10^8 s^{-1} (20). Step 3 is slow enough that diffusive separation of the radical ions from within the solvent cage, or reaction of the radical cation while still within the solvent cage, may compete.

The addition of nucleophiles to the radical cation of arylalkenes



Step 4 in Scheme 1 involves the addition of the nucleophile methanol to the radical cation of the arylalkene. The singly occupied molecular orbital (SOMO) of the benzene radical cation is a linear combination of the degenerate symmetric and antisymmetric orbitals, ψ_s and ψ_A respectively (Fig. 3) (21). Substitution on benzene removes this degeneracy. Both the methoxy and the vinyl substituents stabilize adjacent positive charge and spin; the greatest influence is stabilization of the positive charge by interaction with the nonbonding pair of electrons on the methoxy group. This conclusion is supported by the relative oxidation potentials of benzene (2.30 V), styrene (1.84 V), and anisole (1.76 V) listed in Table 1. It seems likely that the SOMO of the *meta*- and *para*-methoxy substituted derivatives have the antisymmetric structures $7^{+\cdot}$ and $8^{+\cdot}$. The influence of the methoxy substituent in these structures provides the greatest delocalization (stabilization) of spin and charge. This simple empirical explanation of the effect of *meta*- and *para*-methoxy substitution is consistent with the quantum mechanical calculations of spin and charge density distribution.

The results of calculations carried out on the radical cations of the model compounds 3-vinylanisole (**21**) and 4-vinylanisole (**22**) are shown in Figs. 1a and 1b. In both cases, more than half of the positive charge density is associated with the methoxy group (the sum of the charge density on the *ipso* carbon, the oxygen, and the methyl group is 0.601 ($21^{+\cdot}$) and 0.607 ($22^{+\cdot}$)). There is little charge density on the terminal carbon of the alkene in either case (0.063 ($21^{+\cdot}$), 0.067 ($22^{+\cdot}$)). On the other hand, the spin density at the terminal carbon in the SOMO of the radical cation of 4-vinylanisole ($22^{+\cdot}$) (0.605) is significantly greater than that of 3-vinylanisole ($21^{+\cdot}$) (0.054).

The observed differences in the reactivity of **7** and **8** can now be explained: The rate of additon of a nucleophile (methanol) to the radical cation is dependent upon charge density. The addition to the terminal carbon of both $7^{+\cdot}$ and $8^{+\cdot}$ is slowed down by the methoxy substitution. The rate of addition of the radical cation to the neutral alkene depends upon the spin density on the terminal carbon in the SOMO. The spin density on the terminal carbon of the SOMO of $8^{+\cdot}$ is high relative to that of $7^{+\cdot}$. The addition of $8^{+\cdot}$ to the neutral molecule **8** is relatively fast. Therefore, with $7^{+\cdot}$, reaction with methanol is faster than reaction with the neutral molecule **7**; with $8^{+\cdot}$, relatively rapid reaction with the neutral molecule **8** effectively competes with reaction with methanol.

Reaction [16] (ref. 6e)

An = 4-methoxyphenyl
A = 9,10-dicyanoanthracene
AH_2 = 9,10-dihydro-9,10-dicyanoanthracene

The reactivity of the *para*-,*para'*-dimethoxy derivative analogous to **8**, 1,1-di(4-methoxyphenyl)ethylene (**23**), under conditions similar to those used for reaction [1], has been reported (6*e*). In this case the *anti*-Markovnikov methanol adduct was not observed; instead, the dimers **24** and **25** were obtained (reaction [16]. The rate of reaction of the radical cation $\mathbf{23}^{\ddagger}$ with methanol (Scheme 1, step 3) was estimated to be 10^7 $M^{-1}\,s^{-1}$, almost two orders of magnitude slower than reaction of $\mathbf{1}^{\ddagger}$ with methanol.

While the rate of reaction with methanol was significantly affected, the rate of addition of $\mathbf{23}^{\ddagger}$ to the neutral alkene **23** ($10^{10}\,M^{-1}\,s^{-1}$), on the way to dimer formation (**24** and **25**), was unaffected by the *para*-methoxy substitution (6*e*). The spin density on the terminal carbon of the SOMO of $\mathbf{23}^{\ddagger}$ is sufficient to maintain the rate of this reaction near the diffusion-controlled limit.

The rates of reaction of the analogous di(4-methoxyphenyl)-methyl, (4-methoxyphenyl)phenylmethyl, and diphenylmethyl cations with nucleophile (water) have been measured. While the effect of each additional substituent is not additive, each *para*-methoxy group significantly decreases the rate of reaction of the cation (9).

Methoxy substitution may also influence the electron transfer process involved in the reduction of the diarylalkyl radical by the radical anion of the electron acceptor (Scheme 1, step 5). The reduction potential of the radical must not be significantly greater (more negative) than that of the electron-accepting photosensitizer. These potentials are known or can be estimated (22). In the case of the parent system, the reduction potential of the 1,1-diphenylethyl radical is −1.34 V (22*a*) and the reduction potential of 1,4-dicyanobenzene (**3**) is −1.66 V (4); consequently, reduction of the diphenylethyl radical by the radical anion $\mathbf{3}^{\cdot-}$ is thermodynamically favourable. *para*-Methoxy substitution will make the radical harder to reduce; the reduction potential of the diphenylmethyl radical (−1.14 V) is 0.19 V less negative than that of the (4-methoxyphenyl)phenyl-methyl radical (−1.33 V) (22*b*). Assuming a similar incremental effect of a *para*-methoxy group in the diphenylethyl series, the reduction potential of the (4-methoxyphenyl)phenyl-ethyl radical will be ca. −1.5 V. *meta*-Methoxy substitution has less of an effect on the reduction potential of the radical; the reduction potential of the (3-methoxyphenyl)phenylmethyl radical (−1.16 V) is almost the same as that of the unsubstituted analogue (22*b*). Therefore reduction of the intermediate radical by the electron acceptor radical anion ($\mathbf{3}^{\cdot-}$) (step 5 in Scheme 1) will still be favourable when the radical is substituted by one *meta*- or *para*-methoxy group. Additional *para*-methoxy substitution, as in the di(4-methoxyphenyl)ethyl radical, may increase the reduction potential of the radical to the point that reduction to the anion by the 1,4-dicyanobenzene radical anion is endergonic.

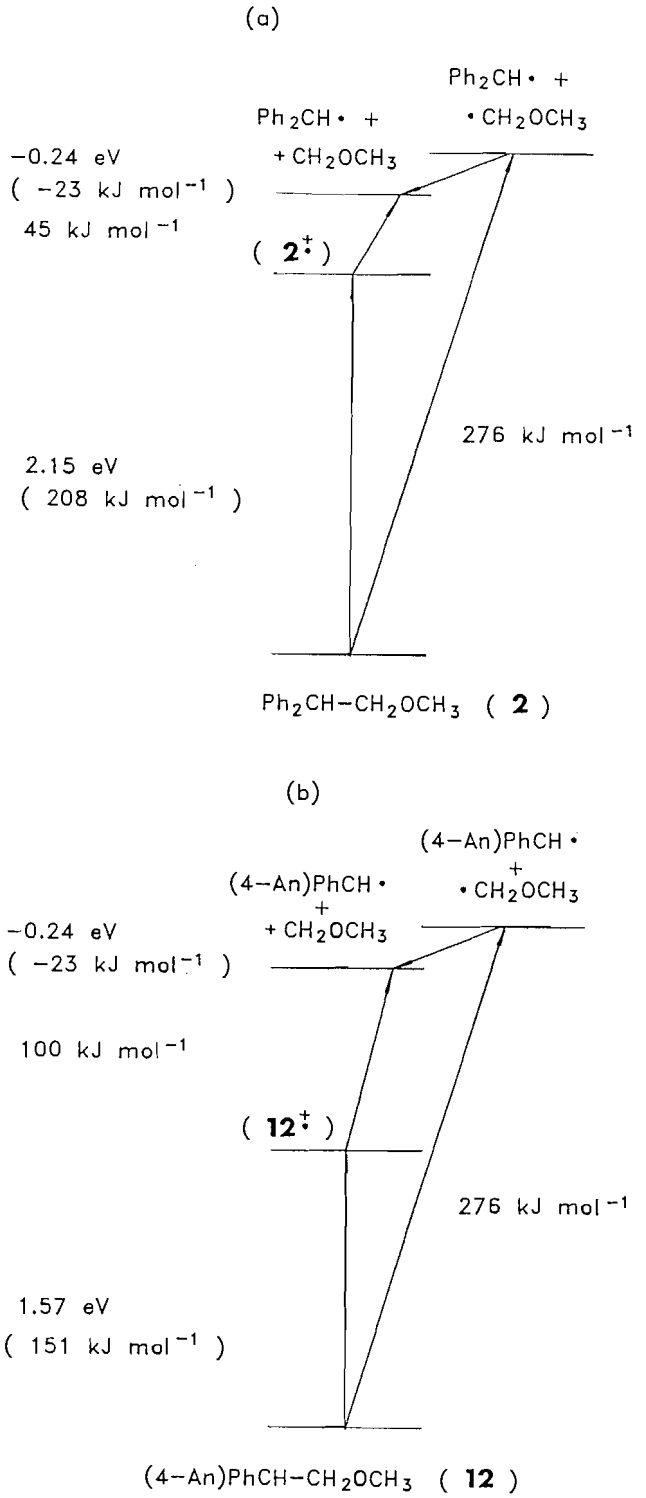

FIG. 4. Thermochemical cycles useful for estimating the bond dissociation energy of the radical cations of (a) methyl 2,2-diphenylethyl ether (**2**) and (b) methyl 2,2-(4-methoxyphenyl)ethyl ether (**12**).

The formation of **15** as the primary product in reaction [5] and the formation of the dimers **24** and **25** in reaction [16] can now be explained. The 1,4-radical cation that results from addition of $\mathbf{8}^{\ddagger}$ to **8** will react with methanol and the resulting radical will be reduced to the anion by $\mathbf{3}^{\cdot-}$; subsequent protonation of the anion yields **15**. Reaction of the 1,4-radical cation that results from addition of $\mathbf{23}^{\ddagger}$ to **23** with methanol will be slower and reduction of the radical by the anion radical of 9,10-dicyano-

For personal use only.

anthracene ($E^{red}_{1/2} = -0.88$ V) is unfavourable; consequently, in this case cyclization and deprotonation of the 1,4-radical cation occurs instead of reaction with methanol or reduction of the radical to the anion.

Protonation of the anion by methanol (step 6) will be rapid and irreversible in every case.

The carbon–carbon bond cleavage of radical cations

The *meta*- and *para*-methoxy substituents may influence the crucial step in the proposed mechanism for reaction [2] (step 4, Scheme 2) in three (at least) ways: substitution will influence the energetics of the cleavage process; there is a required conformation of the SOMO relative to the vulnerable carbon–carbon bond that will be affected by substitution, and the electronic configuration of the SOMO will be important for this reaction, as it is for the addition reaction described above.

Consider first the thermodynamic requirements for cleavage. Previous studies have shown that the bond dissociation enthalpy of the carbon–carbon bond of the radical cation must be less than ca. 60 kJ mol^{-1} for cleavage to occur at a rate that is rapid enough to compete with deactivation by back-electron transfer (1, 7*a*). This bond dissociation energy (ΔH_C) can be estimated by consideration of the thermochemical cycle shown in Fig. 4, and represented by eq. [17] and [18] (1*b*).

$$[17]\quad \Delta H_C = \Delta H_{BDE} + F(E^{ox}_{1/2}(R\cdot) - E^{ox}_{1/2}(R{-}R)) - T(\Delta S(R{-}R) - \Delta S(R{-}R^{+}))$$

When $\Delta S(R{-}R) \approx \Delta S(R{-}R^{+})$:

$$[18]\quad \Delta H_C = \Delta H_{BDE} + F(E^{ox}_{1/2}(R\cdot) - E^{ox}_{1/2}(R{-}R))$$

Carbon–carbon bond cleavage of the radical cation yields the radical and carbocation fragments; the carbocation is associated with that fragment having the lower oxidation potential (1*b*). The oxidation potential of the diphenylmethyl radical (0.35 V) is significantly greater than that of the methoxymethyl radical (−0.24 V), so that when $\mathbf{2}^{\ddagger}$ cleaves, the methoxymethyl carbocation is formed. The oxidation potentials of the (3-methoxyphenyl)phenylmethyl radical (0.38 V) and the (4-methoxyphenyl)phenylmethyl radical (0.16 V) are also greater than that of the methoxymethyl radical (22*b*). Thus, cleavage of the radical cations $\mathbf{11}^{\ddagger}$ and $\mathbf{12}^{\ddagger}$ should also occur to give the methoxymethyl carbocation.

The bond dissociation enthalpy (ΔH_{BDE}) for the vulnerable bis-benzylic carbon–carbon bond of **2** has not been measured, but an estimate (276 kJ mol^{-1}) can be made from the known bond dissociation enthalpy of the corresponding bond in 1,1-diphenylethane, and some additional heat of formation data to assess the effect of the adjacent methoxy group (23).[5] The oxidation potential of **2** (Table 1) and the methoxymethyl radical (−0.24 V) are known (22). These data were used to construct the thermochemical cycle required for the calculation of the ΔH_C for **2** shown in Fig. 4a. The calculated value, ΔH_C = 45 kJ mol^{-1}, is well below the established threshold energy above which cleavage will not occur, and the observed reactivity of **2** is consistent. Methoxy substitution, both *meta* and *para*, will have a relatively small effect on the bond dissociation energy of the neutral molecules. While *para*-methoxy substitution will weaken the benzylic bond (i.e., stabilize the benzylic radical), *meta*-methoxy substitution will strengthen this bond; however, the effect is small (<4 kJ mol^{-1}) in both cases (24). On the other hand, the effect on the oxidation potential of these molecules is relatively large (Table 1). The combined influence of these factors, shown in Fig. 4b for **12**, is an increase in the bond dissociation enthalpy of the radical cation $\mathbf{12}^{\ddagger}$ (ΔH_C = 100 kJ mol^{-1}) to well above the threshold. Consequently, the observed lack of carbon–carbon bond cleavage upon photosensitized (electron transfer) irradiation of **11** and **12** (reactions [8] and [9]) can be explained on thermodynamic grounds.

While the lack of reactivity of the *meta* derivative **11** can be explained on the basis of energetics, the importance of the electronic configuration of the SOMO will become evident. The SOMOs of both **11** and **12** will have the ψ_A configuration (Fig. 3), which has considerable spin density at the position *para* to the methoxy group, and carbon–carbon bond cleavage of the radical cation $\mathbf{12}^{\ddagger}$ might occur. However, there is little spin density at the position *meta* to the methoxy group, and $\mathbf{11}^{\ddagger}$ might be unreactive for this reason, even if the energy requirement was met.

The results of the *ab initio* molecular orbital calculations on the radical cations of the model compounds 3-methylanisole (**17**) and 4-methylanisole (**18**), shown in Figs. 2a and 2b, lend support to this line of reasoning. More than half of the spin density is at the carbon *para* to the methoxy group in both isomers. There is much less spin and charge density at the carbon *meta* to the methoxy group.

The reactivity of the indane derivatives, **13** and **14**, is of particular interest. In the parent system, both *cis*- and *trans*-2-methoxy-1-phenylindane (**6**) are reported to undergo configurational isomerization under these conditions (reaction [3]), but there was no evidence for carbon–carbon bond cleavage in either case. The configurational isomerization was attributed to deprotonation of the radical cation followed by reduction of the resulting radical and reprotonation (Scheme 3). The explanation offered for the lack of carbon–carbon bond cleavage was that the SOMO in these molecules is largely associated with the fused aryl ring and is therefore held in a conformation orthogonal to the vulnerable bis-benzylic carbon–carbon bond. The oxidation potential of **6** is less than that of the acyclic analog **2**, consistent with this explanation.

Substitution by the electron-donating methoxy group in the *para* position of **14** lowers the energy of the SOMO associated with this unfused ring to the extent that it is below that of the fused ring. This shift in the site of the SOMO is evident from the lower oxidation potential of **14** (Table 1). Now the radical cation can attain a conformation that will allow overlap of the SOMO associated with the unfused ring with the vulnerable bis-benzylic carbon–carbon bond. Furthermore, the electronic configuration of the *para*-methoxy substituted ring will be ψ_A, which has considerable spin density at the *para* position, and cleavage could occur. The lack of carbon–carbon bond cleavage of $\mathbf{14}^{\ddagger}$ must be attributed to lack of sufficient energy as described above for the acyclic analog $\mathbf{12}^{\ddagger}$.

In the case of the *meta*-methoxy isomer, while the SOMO

[5]The carbon–carbon bond dissociation energy of ethane, calculated from the heats of formation of the methyl radical (147 kJ mol^{-1}) and ethane (−83.7 kJ mol^{-1}) is 377 kJ mol^{-1}. The carbon–carbon bond dissociation energy of ethyl methyl ether, calculated from the heat of formation of the methyl radical, the heat of formation of the methoxymethyl radical (−11.7 kJ mol^{-1}), and the heat of formation of ethyl methyl ether (−216 kJ mol^{-1}) is 351 kJ mol^{-1}. The methoxy group lowers the adjacent carbon–carbon bond dissociation energy in this case by 25.9 kJ mol^{-1}. The bond dissociation energy for the bis-benzylic carbon–carbon bond in 1,1-diphenylethane is 301 kJ mol^{-1}. If a methoxy group has the same effect on the bis-benzylic carbon–carbon bond of methyl 2,2-diphenylethyl ether (**2**), this bond dissociation energy will be 276 kJ mol^{-1}.

should again be associated largely with the unfused ring, the configuration of the SOMO (ψ_A) bears little spin or charge density at the position *meta* to the methoxy group. The radical cation **13**$^{+\cdot}$ has neither the required electronic configuration nor sufficient energy to cleave.

Step 6 of Scheme 2 involves reduction of the radical by the radical anion of the photosensitizer analogous to step 5 in Scheme 1. As was described above, the reduction potentials of the diphenylmethyl radical (−1.14 V), the (3-methoxyphenyl)-phenylmethyl radical (−1.16 V), and the (4-methoxyphenyl)-phenylmethyl radical (−1.33 V) are all well below that of 1,4-dicyanobenzene (−1.66 V), so, if cleavage had occurred, reduction of the radical would have been favourable in every case.

Deprotonation of the radical cation

The crucial step in the reaction that leads ultimately to incorporation of deuterium and to isomerization is deprotonation of the radical cation from the benzylic position (Scheme 3, step 4). The dramatic increase in acidity of the radical cation relative to that of the neutral molecule is well known (8, 25). The acidity of the bis-benzylic hydrogen of the radical cation of 1,1-diphenylethane, estimated from a thermochemical cycle (eq. [19] (25*a*)), is $pK_a = -14$; this is acidic enough for deprotonation to take place in acetonitrile–methanol (3:1).[6] Since *meta*- and *para*-methoxy substitution have a relatively small effect on the benzylic carbon–hydrogen bond dissociation energy (24), the major influence of methoxy substitution will result from the significant decrease in the oxidation potential of the molecule.

$$[19]\quad pK_{a(RH^{+\cdot})sol} = \frac{1}{2.303\,RT}(-FE^0_{RH} + \Delta G^0_{tr(H^+)sol} + \Delta G^0_{BDE(RH)g} - \Delta G^0_{f(H)g})$$

For compounds with similar carbon–hydrogen bond dissociation free energies, a decrease in the oxidation potential of 0.1 V corresponds to a decrease of 2 pK_a units in the acidity of the radical cation. Methoxy substitution (both *meta* and *para*) lowers the oxidation potential by ca. 0.5 V (Table 1); therefore, these derivatives are ca. 10 pK_a units less acidic than the unsubstituted analogues. Nevertheless, deprotonation from these radical cations, presumably with methanol acting as the base, may still be exergonic.

The radical cations of the *para*-methoxy derivatives, **12**, **14**, and the model compound **17**, undergo deprotonation as evidenced by deuterium incorporation and, in the case of **14**, isomerization (reactions [9], [11], and [13]). Deprotonation from the radical cations of these *para* derivatives must be rapid enough to compete with deactivation by back-electron transfer (Scheme 3, step 3). In contrast, the radical cations of the *meta*-methoxy derivatives, **11**, **13**, and **16**, are either stable or much less reactive under these conditions (reactions [8], [10], and [12]). The thermodynamic acidity of the *meta* and *para* derivatives is similar, the rate of deactivation by back-electron transfer is similar; therefore the difference in reactivity can be attributed to differences in the rate of deprotonation that can be explained in terms of the electronic configuration of the SOMO.

Figures 2a and 2b show the spin and charge distribution in the radical cations of the model compounds, 3-methylanisole (**17**) and 4-methylanisole (**18**). The SOMOs of both isomers have the ψ_A configuration. The total spin and charge and the spin and charge distribution on the individual atoms of the *meta*- and *para*-methyl groups are similar. The spin and charge are higher on the position *para* to the methoxy group in both isomers and loss of a proton from the *para*-methyl group should be favoured. The experimental observations are consistent. With the radical cations of the *meta*-methoxy derivatives **11**$^{+\cdot}$ and **13**$^{+\cdot}$, little or no deprotonation occurs. The radical cation of 3-methylanisole (**17**$^{+\cdot}$) does deprotonate, but less efficiently than does the *para* isomer.

The relatively efficient incorporation of deuterium in the *para*-methyl group of 4-methylanisole (**18**) is accompanied by the formation of two minor side products: 4-cyano-4′-methoxydiphenylmethane (**19**) and 1,2-di(4-methoxyphenyl)ethane (**20**). These products are indicative of the formation of the intermediate 4-methoxybenzyl radical. Coupling of this radical gives **20** and attack of this radical at the *ipso* position of the 1,4-dicyanobenzene radical anion (**3**$^{-\cdot}$), followed by loss of cyanide ion, leads to **19**.

More than half of the charge density in the radical cations **18**$^{+\cdot}$ and **19**$^{+\cdot}$ is associated with the methoxy group. There is significant charge on the carbon bearing the methoxy group. It is plausible that nucleophilic (methanol) attack occurs at this *ipso* position. However, there was no evidence for exchange of the methoxy-methyl group when the irradiation of either **18** or **19** was carried out under the usual conditions, but with acetonitrile–methanol-d_4 (3:1) as the solvent.

The difference in reactivity of the radical cations of *meta*- and *para*-substituted anisoles has been observed before. The side-chain oxidation, promoted either electrochemically or chemically (by cerium(IV) ammonium nitrate), of 5-substituted-1,2,3-trimethylbenzenes has been investigated, and the relative reactivity of the 2- and 1-methyl groups has been determined (27). Both reactions show similar substituent effects. The 2-methyl group is selectively attacked when the substituent is methoxy ($k_2/k_1 > 200$; no product of reaction at the 1-methyl was observed). This selectivity was similarly attributed to the electronic distribution in the radical cation, the key step in the reaction being deprotonation.

The oxidation of **17** and **18** with Co(III) (LiCl) has been studied (28). Products resulting from both side-chain oxidation and substitution in the ring were obtained upon oxidation of the *meta* isomer (substitution/side chain = 38%/3%). On the other hand, there was no substitution in the ring in the case of the *para* isomer (side-chain oxidation product, 65%).

Perspective

The scope and limitations of reactions of the type illustrated in reactions [1]–[3] can be defined by consideration of each step in the mechanistic schemes (Schemes 1–3). These are complex reactions. Several highly reactive species are involved. Frequently, the ultimate result of a particular irradiation will depend upon the ratios of several competing rapid processes. One of these processes will always be deactivation by back-electron transfer, in which case, no reaction will occur.

The explanations offered to explain the results depend upon thermochemical considerations, knowledge of the conforma-

[6]The acidity of the bis-benzylic hydrogen of the radical cation of 1,1-diphenylethane can be estimated from the bond dissociation free energy ($\Delta G^0_{BDE(RH)}$) and the standard oxidation potential (E^0_{RH}) using Method 1 (eq. [19]) described in 25*a*. The required data are $\Delta H_{BDE(RH)} = 339 \pm 8$ kJ mol^{-1} (26*a*); $\Delta S_{BDE(RH)} = 110 \pm 4$ J mol^{-1} (26*b*); so that $\Delta G^0_{BDE(RH)} = 316 \pm 25$ kJ mol^{-1}. $E^{ox}_{1/2} = 2.13$ V (vs. sce) (Table 1); accepting this value as an estimate of the standard oxidation potential, $E^0_{RH} = 2.37$ V (vs. standard hydrogen electrode); $\Delta G^0_{tr(H^+)CH_3CN} = 46.0$ kJ mol^{-1} (26*d*); $\Delta G^0_{f(H)g} = 203.2$ kJ mol^{-1} (26*c*).

tion of the reactant, and information concerning the electronic configuration and spin and charge distribution of the radical ions. While much remains to be done before the scope and limitations of these reactions will be defined, progress has been made. Clearly the effort to develop these reactions will continue — they are potentially useful.

Experimental

General information

The ^{1}H nmr spectra were recorded on a Varian Associates EM360L or a Nicolet narrow bore 360 MHz spectrometer and are reported in parts per million (δ) downfield from tetramethylsilane (TMS). The ^{13}C nmr spectra were recorded on the Nicolet spectrometer operating at 90 MHz. Infrared spectra were recorded on a Perkin Elmer 283B spectrometer and are reported in wavenumbers (ν) relative to the 1601.8 cm^{-1} absorption of polystyrene.

Irradiations were generally carried out through Pyrex using acetonitrile–methanol (3:1) as the solvent and 1,4-dicyanobenzene (**3**) as the electron-accepting photosensitizer. Irradiations at 10°C utilized a 1-kW medium-pressure mercury vapour lamp (CGE HR 1000 DX 36-15) with a quartz cooling jacket immersed in a constant temperature bath. A Hanovia 450-W medium-pressure mercury vapour lamp with a quartz cooling jacket was used for irradiations carried out at 80°C. The irridiation tubes were placed in a Pyrex vessel with a built-in cooling jacket that also serves as a short-wavelength (<280 nm) filter, connected to a circulating water bath (Julabo model F10V).

Progress of the irradiations was followed by gas chromatography (gc) on a Hewlett Packard 5890A instrument with a Hewlett Packard 5970 mass selective detector (ms) interfaced with a Hewlett Packard 9816 microcomputer. The column was 25 m × 0.2 mm, 5% phenyl methyl silicone on fused silica, with a film thickness of 0.25 μm. Quantitative gas chromatography was carried out on a Hewlett Packard 5890A gc fitted with an OV-1701 column (30 m × 0.26 mm, 0.25 μm film thickness) and a flame ionization detector (fid). The digital signal from the detector was transmitted to a Hewlett Packard 3392A integrator and acquired on a Commodore PC-II. A Varian Aerograph 1200 gc (column: 5 m × 0.53 mm, methyl silicone on fused silica) was also used for analyses. An Aerograph Autoprep A-700 gc using a 1.8 m × 1 cm aluminum column packed with 10% SE-30 on Chromosorb 60/80 NAW was used for isolating samples for analytical purposes. Preparative medium-pressure liquid chromatography (MPLC) was carried out using a 1 m × 2.5 cm column packed with TLC grade silica gel (Merck, without binder) at 14 psi helium (1 psi = 6.89 kPa). The columns were eluted with a solvent gradient, usually hexanes – methylene chloride, and the eluent was monitored by a UV spectrophotometer – fraction collector. Flash chromatography was performed by the method developed by W. C. Still (29) using 200–425 mesh silica gel (Mallinckrodt, 60 A or Baker 40).

Cyclic voltammetry was used to measure the oxidation potentials reported in Table 1. The apparatus has been described previously (30). The working electrode was a platinum sphere (1 mm), the counter electrode was a platinum wire, and a saturated calomel electrode was used as the reference. The electrolyte was tetraethylammonium perchlorate (0.1 M), the solvent was freshly distilled acetonitrile, and the concentration of substrate was approximately 1 mM. Since the cyclic voltammograms indicated that the oxidation processes were not reversible, the half-wave potentials could not be determined directly. The half-wave potential can be estimated as 0.028 V before the anodic peak potential (10).

Materials

Solvents were distilled prior to use. Acetonitrile (Fisher ACS grade) was distilled successively from sodium hydride and phosphorus pentoxide, passed through a column of basic alumina, then refluxed over calcium hydride for 24 h under a nitrogen atmosphere, and finally fractionally distilled. 1,4-Dicyanobenzene (Aldrich) was purified by treatment with decolorizing carbon (Norite) in methylene chloride, sublimation, and then recrystallization from 95% ethanol. Tetraethylammonium perchlorate (Aldrich) was recrystallized from 95% ethanol and then dried in a vacuum oven for 12 h at 80°C. 3-Methoxyacetophenone, 4-methoxyacetophenone, α-methoxyacetophenone, bromobenzene, 3-bromoanisole, 4-bromoanisole, indanone, and the borane–tetrahydrofuran complex were obtained from Aldrich Chemical Co., and were used without further purification.

1-(3-Methoxyphenyl)-1-phenylethylene (7)

This alkene (**7**) was prepared by dehydration of the alcohol formed by the Grignard reaction involving 3-methoxyacetophenone (7 g, 0.047 mol) and phenylmagnesium bromide from bromobenzene (7 g, 0.045 mol). The Grignard reaction mixture was worked up by pouring over cold, concentrated hydrochloric acid (6M). The product was extracted into ether. The ether extract was washed with saturated aqueous sodium bicarbonate and sodium chloride. The extract was then dried over magnesium sulphate, and the solvent was evaporated to give the alkene (**7**), which was purified by flash chromatography to a colourless oil. 1-(3-Methoxyphenyl)-1-phenylethylene (**7**) (6.7 g, 77%): ir (neat) ν: 3079 (w), 2951 (w), 2837 (w), 2362 (w), 1599 (m), 1575 (s), 1487 (s), 1429 (s), 1239 (s), 1047 (s), 896 (s), 775 (s), 685 (s); ^{1}H nmr (360 MHz, $CDCl_3$) δ: 7.34 (m, 9H), 5.44 (s, 2H), 3.74 (s, 3H); ^{13}C nmr ($CDCl_3$) δ: 159.43, 149.92, 142.94, 141.3, 129.05, 128.18, 128.09, 127.66, 120.84, 113.96, 113.16, 55.16.

1-(4-Methoxyphenyl)-1-phenylethylene (8)

A small amount of bromobenzene was added to a flask containing magnesium metal turnings (1.3 g, 0.058 mol) and an iodine crystal in ether (100 mL), and the reaction started immediately. A solution of bromobenzene (7.0 g, 0.045 mol) in ether (40 mL) was added slowly. Once the addition was complete, the reaction mixture was stirred at room temperature for 1 h. The mixture was then cooled to 0°C with an ice bath, and 4-methoxyacetophenone (7.0 g, 0.045 mol) in ether (40 mL) was added dropwise. This mixture was stirred for 24 h at room temperature, poured into a beaker of ice and concentrated hydrochloric acid, and extracted with ether. The ether extract was washed successively with saturated aqueous sodium bicarbonate and saturated aqueous sodium chloride, and then dried over magnesium sulphate. Evaporation of the solvent gave a light yellow solid, which was purified by flash chromatography, eluting with hexanes–ether (7:3), to give the alkene (**8**) as a colourless solid that was recrystallized from hexane (mp 74.7–75.0°C, 7.5 g, 80%); ir (KBr disc) ν: 3007 (w), 2937 (w), 2952 (w), 2835 (w), 1598 (s), 1600 (s), 1489 (s), 1286 (s), 1242 (s), 1110 (m), 1023 (s), 897 (s), 835 (s), 779 (s), 702 (s); ^{1}H nmr (360 MHz, $CDCl_3$) δ: 7.10 (m, 9H), 5.39 (d, 1H, J = 1.26 Hz), 5.35 (d, 1H, J = 1.26 Hz), 3.83 (s, 3H); ^{13}C nmr ($CDCl_3$) δ: 129.33, 128.26, 128.06, 127.58, 127.45, 113.45, 112.88, 77.32, 76.97, 76.62, 55.27.

3-(3-Methoxyphenyl)indene (9)

Additon of the Grignard reagent prepared from 3-bromoanisole (10.75 g, 0.058 mol) to indanone (6.7 g, 0.051 mol), followed by the strong hydrochloric acid work-up, gave 2-(3-methoxyphenyl)indene (**9**) (7.2 g, 73%); ir (neat) ν: 3062 (w), 2937 (w), 2837 (w), 1597 (m), 1577 (s), 1485 (s), 1475 (s), 1282 (s), 1231 (s), 1048 (s), 768 (s), 717 (s), 694 (s); ^{1}H nmr (60 MHz, $CDCl_3$) δ: 7.2 (m, 8H), 6.3 (s, 1H), 3.7 (s, 3H), 3.4 (s, 2H); ^{13}C nmr ($CDCl_3$) δ: 159.65, 144.99, 144.63, 143.69, 137.39, 130.89, 129.46, 126.06, 124.78, 123.99, 120.23, 120.05, 113.16, 112.95, 55.00, 38.03.

3-(4-Methoxyphenyl)indene (10)

To a flask containing magnesium metal turnings (1.4 g, 0.057 mol) and an iodine crystal, in anhydrous ether (50 mL), a small portion of 4-bromoanisole was added and the mixture was heated until the reaction started. A soluton of 4-bromoanisole (10.8 g, 0.058 mol) in ether (60 mL) was added slowly to the reaction mixture. When the addition was complete, the mixture was refluxed for 1 h, then cooled to room temperature, and a solution of indanone (6.7 g, 0.051 mol) in ether (60 mL) was added dropwise. This reaction mixture was refluxed for 1 h and was then stirred overnight at room temperature. The reaction mixture was poured onto a slurry of ice and concentrated hydrochloric acid; this mixture was then extracted with diethyl ether. The extract was washed with saturated aqueous sodium bicarbonate and with saturated aqueous sodium chloride, and then dried over magnesium sulphate.

The solvent was evaporated to give a dark yellow oil. By working up the reaction mixture with strong hydrochloric acid, the initally formed indanol was dehydrated directly to the indene. The crude product was purified by flash chromatography, eluting with hexanes, to give 3-(4-methoxyphenyl)indene (**10**) as a colourless low melting (54.8–55.8°C) solid (9.1 g, 0.041 mol, 80%); ir (KBr disc) ν: 3020 (w), 2958 (w), 2940 (w), 1613 (m), 1508 (s), 1460 (s), 1255 (s), 1239 (s), 1176 (s), 1025 (s), 835 (s), 772 (s), 757 (s), 716 (s); ^{1}H nmr (360 MHz, $CDCl_3$) δ: 7.58 (dm, 1H, J = 7.6 Hz), 7.54 (d, 2H, J = 8.83 Hz), 7.51 (dm, 1H, J = 7.6 Hz), 7.31 (tm, 1H, J = 7.6 Hz), 7.24 (td, 1H, J = 7.6, 1.2 Hz), 6.97 (d, 2H, J = 8.83 Hz), 6.49 (t, 1H, J = 2.2 Hz), 3.83 (s, 3H), 3.47 (d, 2H, J = 2.2 Hz); ^{13}C nmr ($CDCl_3$) δ: 159.2, 144.7, 144.5, 144.1, 129.7 (two carbons), 129.0, 128.8, 126.0, 124.7, 124.0 (two carbons), 120.2, 114.0, 55.3, 38.0; ms, m/z (relative intensity): 222 (100), 207 (46), 179 (25), 178 (43).

*Methyl 2-(3-methoxyphenyl)-2-phenylethyl ether (**11**)*

1-(3-Methoxyphenyl)-1-phenylethylene (**7**) (1.0 g, 5 mmol) and 1,4-dicyanobenzene (**3**) (0.041 g, 0.32 mmol) were dissolved in acetonitrile–methanol (3:1) (30 mL) and irradiated through Pyrex. After 6 h irradiation, essentially all of the alkene had been converted to the *anti*-Markovnikov methanol addition product (**11**); 1,4-dicyanobenzene (**3**) was unchanged. The solvent was evaporated and the resulting yellow residue was purified by flash chromatography using hexanes–ether (7:3) as the eluent. The ether (**11**) was obtained, in good yield, as a colourless oil (1.1 g, 96%); ir (neat) ν: 3095 (w), 3054 (w), 3032 (w), 2932 (m), 2896 (m), 2876 (m), 2836 (m), 1600 (s), 1582 (s), 1491 (s), 1450 (s), 1258 (s), 1148 (m), 1115 (s), 1140 (m), 694 (s); ^{1}H nmr (360 MHz, $CDCl_3$) δ: 7.02 (m, 9H), 4.28 (t, 1H, J = 7.36 Hz), 3.91 (d, 2H, J = 7.36 Hz), 3.77 (s, 3H), 3.37 (s, 3H); ^{13}C nmr ($CDCl_3$) δ: 143.64, 141.87, 129.35, 120.37, 77.205, 75.89, 58.91, 55.09, 50.99. Exact Mass calcd. for $C_{16}H_{18}O_2$: 242.1307; found: 242.1304.

*Methyl 2-(4-methoxyphenyl)-2-phenylethyl ether (**12**)*

Attempts to make the ether **12**, by the photosenstized (electron transfer) addition of methanol to the alkene (**8**) were unsuccessful. Two alternative methods were used.

Method 1

To a flask containing 1-(4-methoxyphenyl)-1-phenylethylene (**8**) (2.62 g, 0.0125 mol), a tetrahydrofuran solution of the boron hydride–tetrahydrofuran complex (13.5 mL of 1.0 M, 0.013 mol) was added slowly and the reaction was stirred overnight. The reaction mixture was poured into water (50 mL) and an aqueous solution of sodium hydroxide and hydrogen peroxide (15 mL of 6 M NaOH in 20 mL of 30% H_2O_2) was added dropwise. This mixture was stirred for 2 h at room temperature. The product was extracted into ether and washed with saturated aqueous solutions of ammonium chloride and sodium chloride (Rochelle salt was added to help break up the emulsion that formed). The ether layer was dried over magnesium sulphate and the solvent was evaporated. 2-(4-Methoxyphenyl)2-phenyl-1-ethanol (2.6 g, 93%) was obtained as a colourless oil. This alcohol was used in the next step, without further purification; ^{1}H nmr (360 MHz, $CDCl_3$) δ: 7.20 (m, 9H), 4.07 (s, 1H), 4.04 (s, 2H), 3.70 (s, 3H).

The alcohol described above (2.6 g, 0.011 mol) was added to a suspension of sodium hydride (4.2 g, 0.199 mol) in ether (60 mL) and the mixture was stirred, under nitrogen, for 1 h. Dimethyl sulphate (4.3 mL, 0.046 mol) was added and the mixture was heated under reflux for 20 h. The work-up involved pouring the reaction mixture into saturated aqueous ammonium chloride, and separating the ether layer, which was then stirred over an aqueous ammonium hydroxide solution. The ether extract was washed with water and saturated aqueous sodium chloride and then dried over magnesium sulphate. Evaporation of the solvent gave the crude product, which was purified by flash chromatography, eluting with hexanes–ether (3:1), to give methyl 2-(4-methoxyphenyl)-2-phenylethyl ether (**12**) as a colourless oil (2.5 g, 93%); ir (neat) ν: 3050 (w), 3036 (w), 2934 (w), 2836 (w), 1610 (m), 1510 (s), 1490 (m), 1448 (m), 1246 (s), 1172 (m), 1116 (m), 1102 (m), 1030 (m), 692 (m); ^{1}H nmr (360 MHz, $CDCl_3$) δ: 7.02 (m, 9H), 4.21 (t, 1H, J = 7.25 Hz), 3.84 (d, 2H, J = 7.25 Hz), 3.67 (s, 3H), 3.31 (s, 3H)); ^{13}C nmr ($CDCl_3$) δ: 158.10, 142.39, 134.23, 129.03, 128.39, 113.83, 77.34, 58.87, 55.18, 50.11. Exact Mass calcd. for $C_{16}H_{18}O_2$: 242.1307; found: 242.1302.

Method 2

A small amount of 4-bromoanisole was added to a flask fitted with an overhead mechanical stirrer and containing magnesium metal turnings (1.4 g, 0.061 mol), an iodine crystal, and ether (60 mL). The mixture was heated until the reaction started. An ether solution of 4-bromoanisole (10 g, 0.054 mol in 40 mL) was added slowly, then the mixture was heated under reflux for 1 h, cooled, and a solution of α-methoxyacetophenone (7.6 g, 0.051 mol) in ether (60 mL) was added dropwise. The resulting mixture was refluxed 1 h and was then allowed to stir overnight at room temperature. The reaction mixture was poured into a beaker of ice and hydrochloric acid (6 M). The organic layer was separated, washed with saturated aqueous sodium bicarbonate and saturated aqueous sodium chloride, dried over magnesium sulphate, and the solvent was evaporated. The resulting yellow oil was chromatographed over silica gel, eluting with a hexanes–ether gradient. 2-Methoxy-1-(4-methoxyphenyl)-1-phenylethanol (8.2 g, 68%) was obtained as a colourless oil. This alcohol was used in the next step without further purification.

To a flask containing aluminium trichloride (9.0 g, 0.093 mol) in ether (100 mL), lithium aluminium hydride (1.7 g, 0.045 mol) was added slowly and the mixture was allowed to stir at room temperature for 1 h. To this complex, a solution of 2-methoxy-1-(4-methoxyphenyl)-1-phenylethanol (4.2 g, 0.027 mol) in ether (60 mL) was added dropwise. This reaction was refluxed for 24 h, cooled to room temperature, and was then poured into aqueous sodium hydroxide (6.0 M, 100 mL) and extracted with ether. The ether extract was washed successively with water and saturated aqueous sodium chloride, and was then dried over magnesium sulphate. The solvent was evaporated to give methyl 2-(4-methoxyphenyl)-2-phenylethyl ether (**12**), a yellow oil (3.2 g, 69%), which has been described above.

*The photosensitized (electron transfer) irradiation of 1-(4-methoxyphenyl)-1-phenylethylene (**8**) in acetonitrile–methanol*

A solution of 1-(4-methoxyphenyl)-1-phenylethylene (**8**) (1.28 g, 6.1 mmol) and 1,4-dicyanobenzene (**3**) (0.65 g, 5.1 mmol) in acetonitrile–methanol (3:1) (122 mL) was irradiated, through Pyrex, with the 1-kW mercury vapour lamp for 72 h. Analysis (gc/ms) indicated that reaction was complete, **8** was consumed, and that the *anti*- Markovnikov additon product (**12**) of methanol to the alkene was a minor (<5%) product. The structure of **12** was established by comparison (gc/ms, retention time, and mass spectral fragmentation pattern) with an authentic sample; ms, m/z (relative intensity): 242 (4.9), 197 (100; $C_{14}H_{13}O$), 182 (9.4), 165 (13.0), 153 (18.9), 91 (3.1), 77 (4.7).

The solvent was evaporated and the crude reaction mixture was separated from unreacted **3** by dry-column flash chromatography using ethyl acetate (6%) in hexane as the eluent. A colourless oil (80%), giving one peak in the gc/ms, was obtained in the early fractions. The assigned structure (**15**), a mixture of the diastereomers, was based upon the ^{1}H and ^{13}C nmr and mass spectra. The ^{1}H nmr spectrum of the two diastereomers were indistinguishable; ^{1}H nmr (360 MHz, $CDCl_3$) δ: 7.28–7.00 (m, 14H), 6.77–6.73 (two overlapping doublets, 4H, J = 8 Hz), 3.74 (t, 1H, J = 7.99 Hz, coupled to the proton at 1.95–1.76 ppm), 3.698 (s, 3H), 3.684 (s, 3H), 2.93 (s, 3H), 2.28–2.14 (m, 2H), 1.95–1.76 (m, 2H). The proton decoupled ^{13}C nmr spectrum showed pairs of peaks for some of the carbons indicative of two diastereomers; ^{13}C nmr ($CDCl_3$) δ: 158.05 (s), 157.73 (s), 145.65 (s), 145.40 (s), 137.39 (s), 137.13 (s),128.59 (d), 128.30 (d), 128.09 (d), 127.74 (d), 127.59 (d), 126.72 (d), 126.38 (d), 125.92 (d), 113.68 (d), 113.07 (d), 81.99 (s), 55.13 (q), 50.56 (d), 49.86 (q), 33.47 (t), 28.83 (t); ms, m/z (relative intensity): 422 (0.8), 421 (0.4), 420 (0.9), 419 (1.3), 418 (3.1), 227 (16.1; $C_{15}H_{15}O_2$), 223 (69.2), 210 (16.1), 197 (100; $C_{14}H_{13}O$), 165 (10.6), 153 (9.1), 115 (21.0), 91 (8.7), 77 (2.6).

This initial product (**15**) is unstable; loss of methanol occurs when the sample is stored over a period of days at room temperature. The final product is a mixture (ca. 1:1) of *Z*- and *E*-1,4-di(4-methoxy-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

phenyl)-1,4-diphenyl-1-butene (**16** *Z* and *E*). These isomers were separated by gc/ms and were partially separated upon medium-pressure column chromatography (MPLC) using a solvent gradient of toluene – ethyl acetate. **16***Z*, colourless crystals from hexane – methylene chloride, mp 115.4–115.6°C; ir (KBr disc) ν: 3046 (m), 3016 (m), 2986 (w), 2946–2886 (s), 2828 (s), 1603 (vs),1583 (m), 1503 (vs), 1460 (s), 1441 (s), 1303 (s), 1283 (s), 1244 (vs), 1173 (vs), 1156 (s), 1030 (vs), 815 (vs), 775 (s), 755 (s), 695 (vs); ^{1}H nmr (360 MHz, $CDCl_3$) δ: 7.34–6.97 (m, 14H), 6.77 (d, 2H, J = 8.43 Hz), 6.71 (d, 2H, J = 8.63 Hz), 5.88 (t, 1H, J = 7.15 Hz), 4.01 (t, 1H, J = 7.9 Hz), 3.70 (s, 3H), 3.69 (s, 3H), 2.80 (t, 2H, J = 7.59); ^{13}C nmr ($CDCl_3$) δ: 158.69 (s), 157.91 (s), 144.82 (s),142.03 (s), 140.34 (s), 136.58 (s), 135.42 (s), 129.80 (d), 128.94 (d), 128.28 (d), 128.10 (d), 127.93 (d), 126.86 (d), 126.23 (d), 126.02 (d), 113.73 (d), 113.58 (d), 113.39 (d), 55.30 (q), 50.92 (d), 36.01 (t). The mass spectra of the *E* and *Z* isomers were essentially the same: ms, m/z (relative intensity): 422 (0.1), 421 (0.4), 420 (0.9), 419 (0.8), 418 (1.8), 223 (62.1), 197 (100; $C_{14}H_{13}O$), 165 (12.5), 153 (9.8), 115 (23.4), 91 (6.5), 77 (1.6). Anal. calcd. for $C_{30}H_{28}O_2$: C 85.68, H 6.71; found: C 85.51, H 6.76. **16***E* was not completely separated from the *Z* isomer by MPLC; ^{1}H nmr (360 MHz, $CDCl_3$) δ: 5.91 (t, 1H, J = 7.07 Hz), 4.04 (t, 1H, J = 7.53 Hz), 3.76 (overlapping singlets, 6H), 2.85 (t, 2H, J = 7.52).

*The photosensitized (electron transfer) irradiation of 1-(4-methoxyphenyl)-1-phenylethylene (**8**) in acetonitrile – deuterated methanol*

The irradiation of **8** was carried out as described above except the solvent was acetonitrile–methanol-*O*-*d* (3:1). Under these conditions the base peak in the mass spectrum of **12**, **15**, and **16** *Z* and *E* was m/z = 198 ($C_{14}H_{12}DO$), instead of 197. This is consistent with the incorporation of one deuterium atom at the bis-benzylic position of these products. When methanol-d_4 was used in the solvent mixture instead of methanol, the large peak in the mass spectrum of **15** at m/z = 227 was replaced by one at 230 ($C_{15}H_{12}D_3O_2$) indicating the incorporation of the deuterated methoxy group.

cis-*(and* trans-*)2-Methoxy-1-(3-methoxyphenyl)indane (**13**)*

These *meta*-methoxy isomers were prepared by the methods described above for the analogous acyclic analogue (**11**).

Method 1

The *trans* isomer was obtained by the Grignard reaction, hydroboration, oxidation, methylation sequence.

Hydroboration of the indene (**9**) (9.1 g, 0.041 mol) with boron–tetrahydrofuran (40 mL) followed by oxidative work-up, as described above for the preparation of **11**, gave *trans*-1-(3-methoxyphenyl)-2-indanol (3.84 g, 50%), which was used in the next step without further purification.

Methylation of *trans*-1-(3-methoxyphenyl)2-indanol (3.8 g, 0.016 mol) by the NaH, dimethyl sulphate procedure gave *trans*-2-methoxy-1-(3-methoxyphenyl)indane (**13***trans*) (3.2 g, 79%); ir (neat) ν: 3080 (w), 3010 (w), 2920 (m), 2816 (m), 1600 (s), 1582 (s), 1484 (s), 1456 (s), 1434 (m), 1256 (s), 1246 (m), 1110 (s), 1096 (m), 1046 (m), 736 (s); ^{1}H nmr (360 MHz, C_6D_6) δ: 6.95 (m, 8H), 4.39 (d, 1H, J = 6.31 Hz), 4.09 (ddd, 1H, J = 6.31, 6.52, 6.84 Hz), 3.33 (s, 3H), 3.11 (dd, 1H, J = 6.84, 15.70 Hz), 3.10 (s, 3H), 2.89 (dd, 1H, J = 6.52, 15.70 Hz); ^{13}C nmr (C_6D_6) δ: 160.05, 145.36, 140.87, 129.78, 126.54, 125.57, 124.80, 121.14, 114.82, 112.26, 90.85, 58.40, 57.18, 54.71, 38.15.

Method 2

Irradiation of 3-(3-methoxyphenyl)indene (**9**) in acetonitrile–methanol gave a mixture of the *cis* and *trans anti*-Markovnikov methanol addition products (**13** *cis* and *trans*).

A solution of 3-(3-methoxyphenyl)indene (**9**) (0.70 g, 0.3 mmol), and 1,4-dicyanobenzene (**3**) (0.58 g, 0.5 mmol) in acetonitrile–methanol (3:1) (20 mL) was irradiated, through Pyrex, with the 1-kW mercury vapour lamp for 36 h. Analysis (gc/ms) indicated that reaction was complete, with formation of the *anti*-Markovnikov addition products of methanol to the alkene. Both the *cis* and *trans* isomers were formed (*cis*/*trans* = 7:3). The solvent was evaporated and the products were separated by MPLC (74% combined yield). *cis*-2-Methoxy-1-(3-methoxyphenyl)indane (**13***cis*): ^{1}H nmr (360 MHz, C_6D_6) δ: 7.02 (m, 8H), 4.27 (d, 1H, J = 6.17 Hz), 3.98 (ddd, 1H, J = 6.02, 6.17, 4.27 Hz), 3.38 (s, 3H), 3.12 (dd, 1H, J = 15.90, 4.27 Hz), 2.95 (s, 3H), 2.91 (dd, 1H, J = 15.90, 6.03 Hz); ^{13}C nmr (C_6D_6) δ: 160.05, 144.6, 141.2, 129.02, 126.54, 125.59, 124.79, 121.18, 114.80, 112.29, 90.88, 58.42, 57.19, 54.67, 38.15. Anal. calcd. for (**13***cis*) $C_{17}H_{18}O_2$: C 80.28, H 7.13; found: C 80.63, H 7.25.

trans-*2-Methoxy-1-(4-methoxyphenyl)indane (**14**trans)*

Key steps in this synthetic sequence involve the hydroboration of the indene (**10**) followed by oxidation to the *trans*-indanol and methylation. This reaction sequence yields exclusively the *trans* isomer (**14***trans*) (Scheme 4).

A solution of the borane–tetrahydrofuran complex in tetrahydrofuran (1.0 M, 40 mL, 0.040 mol) was added through a gas-tight syringe, to a flask containing 3-(4-methoxyphenyl)indene (**10**) (9.1 g, 0.041 mol) under nitrogen. This mixture was refluxed for 18 h and was then poured into water (50 mL). The reaction was cooled in ice and a solution of sodium hydroxide (6.0 M, 30 mL) and hydrogen peroxide (30%, 25 mL) was added dropwise. The reaction mixture was stirred at room temperature for 1 h and was then extracted with diethyl ether. The extract was washed successively with water, saturated aqueous ammonium chloride, and saturated aqueous sodium chloride, and was then dried over magnesium sulphate. Evaporation of the solvent gave *trans*-1-(4-methoxyphenyl)-2-indanol, which was purified by recrystallization from 95% ethanol to colourless needles, mp 109.2–109.8°C (9.0 g, 90%); ^{1}H nmr (360 MHz, $CDCl_3$) δ: 7.26–7.12 (m, 3H), 7.10 (d, 2H, J = 8.71 Hz), 6.92 (d, 1H, J = 7.30 Hz), 6.87 (d, 2H, J = 8.71 Hz), 4.43 (ddd, 1H, J = 6.86, 6.94, 7.46 Hz), 4.11 (d, 1H, J = 6.94 Hz), 3.79 (s, 3H), 3.28 (dd, 1H, J = 15.52, 6.86 Hz), 2.93 (dd, 1H, J = 15.52, 7.46 Hz. 2.14 (s, (OH), 1H); ^{13}C nmr ($CDCl_3$) δ: 158.7, 143.9, 140.3, 133.8, 129.4 (two carbons), 127.2, 127.0, 125.2, 124.6, 114.2 (two carbons), 82.3, 59.5, 55.3, 40.1.

A solution of *trans*-1-(4-methoxyphenyl)-2-indanol (7.18 g, 0.030 mol) in diethyl ether was added slowly to a suspension of NaH (7.2 g, 0.300 mol) in ether (60 mL), which was then stirred at room temperature for 1 h. Dimethyl sulphate (11.3 g, 0.090 mol) was added to the mixture, which was then heated under reflux for 24 h. The reaction mixture was then poured onto an ice–concentrated hydrochloric acid mixture. The product was extracted into ether, which was then stirred over aqueous ammonia for 2 h to remove excess dimethyl sulphate. The ether layer was successively washed with water and saturated aqueous sodium chloride, and was then dried over magnesium sulphate. The solvent was evaporated to give a yellow oil (7.5 g). This crude product was chromatographed over silica gel, eluting with a hexane–ether gradient, to give *trans*--2-methoxy-1-(4-methoxyphenyl)indane (**14***trans*) (5.3 g, 73%) as a colourless oil; ir (neat) ν: 3004 (w), 3000 (w), 2916 (m), 2901 (m), 2816 (m), 1610 (m), 1510 (s), 1456 (m), 1300 (w), 1246 (s), 1175 (m), 1110 (m), 1030 (m), 740 (m); ^{1}H nmr (300 MHz, $CDCl_3$) δ: 7.26–7.14 (m, 3H), 7.10 (d, 2H, J = 8.60 Hz), 6.91 (d, 1H, J = 7.17 Hz), 6.86 (d, 2H, J = 8.60 Hz), 4.27 (d, 1H, J = 6.27 Hz), 4.12 (ddd, 1H, J = 6.27, 6.42, 6.71 Hz), 3.80 (s, 3H), 3.35 (s, 3H), 3.33 (dd, 1H, J = 15.73, 6.71 Hz), 2.93 (dd, 1H, J = 15.73, 6.42 Hz); ^{13}C nmr (C_6D_6) δ: 158.98, 144.94, 140.80, 135.64, 129.80, 128.26, 128.00, 127.73, 127.25, 125.52, 124.80, 114.32, 91.14, 57.48, 57.25, 54.79, 38.09. Anal. calcd. for (**14***trans*) $C_{17}H_{18}O_2$: C 80.28, H 7.13; found: C 80.06, H 7.13.

*cis-2-Methoxy-1-(4-methoxyphenyl)indane (**14** cis)*

3-(4-Methoxyphenyl)indene (**10**) was stable to photosensitized (electron transfer) irradiation in acetonitrile–methanol. *cis*-2-Methoxy-1-(4-methoxyphenyl)indane (**14***cis*) was isolated from the irradiation mixture following the photosensitized (electron transfer) isomerization of *trans*-2-methoxy-(4-methoxyphenyl)indane (**14***trans*).

A solution of *trans*-2-methoxy-(4-methoxyphenyl)indane (**14***trans*) (0.4 g, 1.6 mmol) and 1,4-dicyanobenzene (**3**) (0.15 g, 1.2 mmol) in acetonitrile–methanol (3:1) (30 mL) was irradiated at 10°C through Pyrex with a 1-kW mercury vapour lamp. Progess of the reaction was followed by gc/ms. After 12 h of irradiation the gc/ms indicated that

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

14*cis* had formed; **14***cis* / **14***trans* (4:6). The solvent was evaporated and the products were separated by MPLC using a hexanes–ether gradient. cis-2-Methoxy-1-(4-methoxyphenyl)indane (**14***cis*): ^{1}H nmr (300 MHz, $CDCl_3$) δ: 7.29 (d, 1H, J = 6.91 Hz), 7.23–7.13 (m, 2H), 7.09 (d, 2H, J = 8.7 Hz), 7.04 (d, 1H, J = 7.20 Hz), 6.84 (d, 2H, J = 8.7 Hz), 4.42 (d, 1H, J = 6.2 Hz), 4.23 (ddd, 1H, J = 6.20, 5.84, 4.83 Hz), 3.79 (s, 3H), 3.16 (dd, 1H, J = 15.98, 5.84 Hz), 3.13 (s, 3H), 3.09 (dd, 1H, J = 15.98, 4.83 Hz); ^{13}C nmr ($CDCl_3$) δ: 158.3, 144.7, 140.9, 131.3, 130.7, 126.9, 126.8, 125.2, 124.7, 113.4, 85.0, 57.7, 55.1, 54.5, 37.8.

*The photosensitized (electron transfer) irradiation of 3-(4-methoxyphenyl)indene (**10**) in acetonitrile–methanol*

An acetonitrile–methanol (3:1) (30 mL) solution of **10** (200 mg, 0.90 mmol) and **3** (40 mg, 0.31 mmol) was irradiated, under the conditions described above, for 40 h. Analysis (gc/ms) of the photolysate indicated that neither **14***cis* nor **14***trans* was formed.

*The photosensitized (electron transfer) irradiation of methyl 2-(3-methoxyphenyl)-2-phenylethyl ether (**11**) in acetonitrile–methanol*-O-d

An acetonitrile–methanol-*O-d* (3:1) (30 mL) solution of **11** (200 mg, 0.83 mmol) and **3** (70 mg, 0.55 mmol) was irradiated, under the conditions described above, for 50 h. Analysis (gc/ms) of the photolysate indicated that no reaction had occurred.

*The photosensitized (electron transfer) irradiation of methyl 2-(4-methoxyphenyl)-2-phenylethyl ether (**12**) in acetonitrile–methanol*-O-d

An acetonitrile–methanol-*O-d* (3:1) (30 mL) soluton of **12** (700 mg, 2.9 mmol) and **3** (200 mg, 1.6 mmol) was irradiated, under the conditions described above, for 8 h. Analysis (gc/ms) of the photolysate indicated that ca. 70% of one deuterium was incorporated at the bis-benzylic position.

The photosensitized (electron transfer) irradiation of trans-*3-methoxy-2-(3-methoxyphenyl)indane (**13**) in acetonitrile–methanol*-O-d

An acetonitrile–methanol-*O-d* (3:1) (25 L) soluton of **13** (586 mg, 2.3 mmol) and **3** (160 mg, 125 mmol) was irradiated, under the conditions described above, for 100 h. Analysis (gc/ms) of the photolysate indicated that no reaction had occurred.

The photosensitized (electron transfer) irradiation of trans-*2-methoxy-1-(4-methoxyphenyl)indane (**14**trans) in acetonitrile–methanol*-O-d

A solution of *trans*-2-methoxy-1-(4-methoxyphenyl)indane (**14***trans*) (20 mg, 0.078 mmol) and 1,4-dicyanobenzene (**3**) (2.7 mg, 0.0215 mmol) in acetonitrile–methanol-*O-d* (3:1, 2 mL), in a Pyrex tube, was irradiated at 10°C with the 1-kW mercury vapour lamp. Progress of the reaction was followed by gc/ms. The increase in the abundance of the M + 1, M + 2, and M + 3 peaks in the mass spectrum was monitored using the selected ion monitor acquisition mode. The contribution due to naturally occurring ^{13}C was subtracted and the relative abundance of each peak was used to calculate the percent deuterium incorporation. After 100 h of irradiation, deuterium (48% of one deuterium) was incorporated in the *trans* isomer and in the *cis* isomer (100% of one deuterium). The *trans* isomer was isolated; the ^{1}H nmr spectrum showed that the original quartet-like coupling pattern at 4.12 ppm had partly become a triplet-like pattern. Integration indicates that 12.8% deuterium incorporation had occurred at 4.27 ppm (carbon 1, the bis-benzylic position), 31.0% at 3.33 ppm, and 8.5% at 2.93 ppm (carbon 3, the mono-benzylic positions). The ^{1}H nmr spectrum of the *cis* isomer showed that the doublet at 4.42 ppm and the quartet-like pattern at 4.23 ppm had disappeared; a triplet-like pattern appeared at 4.23 ppm (proton on carbon 2).

*The photosensitized (electron transfer) irradiation of 3-methylanisole (**17**) in acetonitrile–methanol*-O-d

A solution of 3-methylanisole (**17**) (50 mg, 0.41 mmol) and 1,4-dicyanobenzene (**3**) (30 mg, 0.23 mmol) in acetonitrile–methanol-*O-d* (3:1, 4 mL), in a Pyrex tube, was irradiated at 10°C with the 1-kW mercury vapour lamp. Progress of the reaction was followed by gc/ms as described above and, after 170 h, 3% of one deuterium atom was incorporated. No other products were detected (gc/ms).

*The photosensitized (electron transfer) irradiation of 4-methylanisole (**18**) in acetonitrile–methanol*-O-d

A solution of 4-methylanisole (**18**) (60 mg, 0.49 mmol) and 1,4-dicyanobenzene (**3**) (30 mg, 0.23 mmol) in acetonitrile–methanol-*O-d* (3:1, 5 mL), in a Pyrex tube, was irradiated at 10°C with the 1-kW mercury vapour lamp. Progress of the reaction was followed by gc/ms as described above and, after 170 h, 8% of one deuterium atom was incorporated. There were minor products detected (gc/ms). Two of these were identified as 4-cyano-4′-methoxydiphenylmethane (**19**) and 1,2-di(4-methoxyphenyl)ethane (**20**) by comparison (gc/ms, retention time, mass spectral fragmentation pattern, and ^{1}H nmr spectra) with anthentic samples. The ^{1}H nmr spectrum of the recovered starting material indicated that the deuterium (6%) was incorporated in the *para*-methyl group.

Acknowledgements

This work was supported by a grant from the Natural Sciences and Engineering Research Council of Canada. We thank Dr. D. L. Hooper at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University for the 360 MHz nmr spectra and for help in the preparation of the manuscript. Mr. B. Millier developed the software that interfaces the gas chromatograph (gc/fid) and the integrator to the PC. We also thank Dr. R. K. Boyd and Mr. D. J. Embree at the Atlantic Regional Laboratories of the National Research Council of Canada for the mass spectra run on the ZAB-E spectrometer.

Total synthesis of *d,l*-quassin

NADA STOJANAC AND ZDENEK VALENTA[1]

Department of Chemistry, University of New Brunswick, Bag Service no. 45222, Fredericton, N.B., Canada E3B 6E2

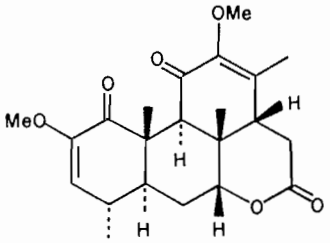
Received November 12, 1990

NADA STOJANAC and ZDENEK VALENTA. Can. J. Chem. **69**, 853 (1991).

The completion of the total synthesis of *d,l*-quassin **1** is described. Key steps are a facile intramolecular acylation of a protected cyanohydrin carbanion (**4** → **5**), a selective deprotonation with trioctyl methyl ammonium hydroxide leading to the removal of HCN from **8**, and the unusual sequence **5** → **12** in which the ring C enol ether of **5** is converted selectively into ring C diosphenol of **12**.

Key words: quassin, synthesis, selective base, diosphenols, acylation.

NADA STOJANAC et ZDENEK VALENTA. Can. J. Chem. **69**, 853 (1991).



On décrit le parachèvement de la synthèse totale de la *d,l*-quassine (**1**). Les étapes clés sont une acylation intramoléculaire facile d'un carbanion de cyanohydrine protégée (**4** → **5**), une déprotonation sélective avec l'hydroxyde de trioctylméthylammonium conduisant à l'enlèvement du HCN du produit **8** et la séquence inhabituelle de **5** → **12** au cours de laquelle le cycle C de l'éther énolique **5** est transformé sélectivement en cycle diosphénol C du produit **12**.

Mots clés : quassine, synthèse, base sélective, diosphénols, acylation.

[Traduit par la rédaction]

Introduction

We wish to report the completion of the total synthesis of *d,l*-quassin **1**, a mild insecticide of *Quassia amara* (1), by a 13-step sequence from the previously reported ester hemiacetal **2**[2] (2) by a strategy that includes the use of a highly selective base and an unusual regioselective introduction of the two diosphenol groupings.[3]

1

To facilitate the cyclization of ring A in **2**, we have chosen the attack of a nucleophilic C(1) upon the unencumbered primary ester group (see arrow in **2**), The required nitrile **4** was prepared from **2** in four steps (see Scheme 1). For a good yield, it proved essential to perform the hemiacetal acetylation and C(14)-OH dehydration in two steps. The hydrogenation of the 14,15-olefin proceeded exclusively from the convex side. Throughout the sequence **2** → **4**, including the -OAc → -CN exchange (4), a mixture of C(1) epimers was formed and was used without separation (^{1}H nmr ($CDCl_3$) singlets in **2** at δ 5.45 and 5.32, in **3** at δ 6.28 and 6.15, and in **4** at δ 4.86 and 4.74). Lithium pyrrolidide (rather than one of the standard hindered bases) was then used for cyclization of epimeric mixture **4**[4] to **5**, because it alone completely deprotonated both epimers at low temperature. No amide formation (by base attack of the ester group) occurred under the reaction conditions.

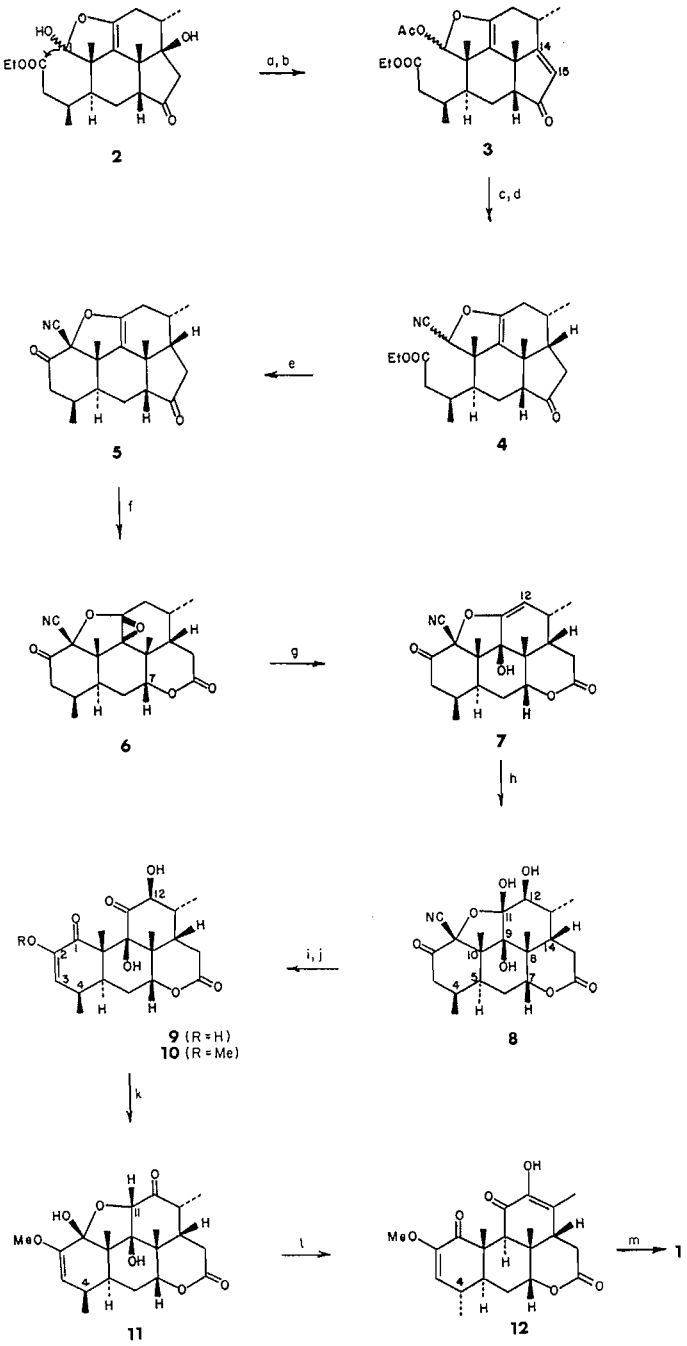
Compound **5**, mp 188–190°C, containing all four rings of quassin, was then oxidized to epoxy lactone **6**, mp 254–256°C (^{1}H nmr ($CDCl_3$) C7-H δ 4.31, t, $w/2$ = 6 Hz) via the isolable epoxy diketone.[5] Triol **8**, mp 208–210°C (^{1}H nmr (acetone-d_6) C(12)-H δ 3.78, d, J = 12.61 Hz) was then produced from **6** in two steps. Only pyridinium *p*-toluenesulfonate (5) gave a quantitative yield of allyl alcohol **7**, mp 257–260°C (^{1}H nmr (acetone-d_6) C(12)-H δ 4.81, d, J = 2.50 Hz) in the **6** → **7** conversion.

The four nonepimerizable chiral centers of quassin (C(5), C(7), C(8), and C(10)) and the epimerizable center C(14) all have the desired relative configuration in triol **8**. It could furthermore be anticipated, based on previous deuteration experiments (1*d*) that the axial β-methyl group at C(4) in **8** as well as the H-atom to be introduced at C(9) would adopt the thermodynamically favoured quassin configuration on equilibration at an appropriate later stage. Thus, since triol **8** is at the same oxidation level as quassin, it only remained to eliminate HCN in **8** and subsequently to dehydrate (C(9)-OH) via an 11, 12-enol or enolate. These proved to be exceptionally delicate operations.

Treatment of **8** with not more than 1 mol equivalent of trioctyl methyl ammonium (TOMA) hydroxide[6] gave diosphenol **9**, mp 248–252°C (^{1}H nmr ($CDCl_3$) C(3)-H δ 6.06, d, J = 5.71 Hz; C(12)-H δ 3.50, d, J = 12.70 Hz) in good yield. However, an excess of TOMA hydroxide irreversibly rearranged

[1]Author to whom correspondence may be addressed.

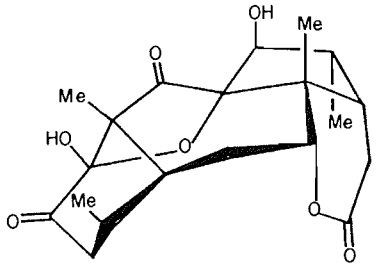
[2]**2** was obtained in 13 steps from 2,6-dimethyl-1,4-benzoquinone and 1,3-dimethyl-6-(1′-acetoxyethyl)-1,3-cyclohexadiene. The ^{1}H nmr spectrum of **2** indicated an equilibrium mixture of the two diastereomeric hemiacetals and a small amount of the keto aldehyde.



[3]Quassin has previously been synthesized by Grieco and co-workers (3*a*) and by Watt and co-workers (3*b*). The strategies used by these two laboratories are fundamentally different from the approach reported here.

[4]The two pure epimers of **4** could be prepared by $NaBH_4$ reduction of the 5-membered ketone in **4**, separation of the two alcohols on silica, and reoxidation.

[5]Only a small amount (5–8%) of the epoxy bislactone, formed by the oxidation of both keto groups in **5**, was isolated.



[6]This was prepared from TOMA chloride (Aliquat 336, Aldrich Chem. Co.) by repeated passage through basic ion-exchange resin Amberlite IRA-400 (OH) (Aldrich Chem. Co.), which was extensively washed with methanol before the exchange.

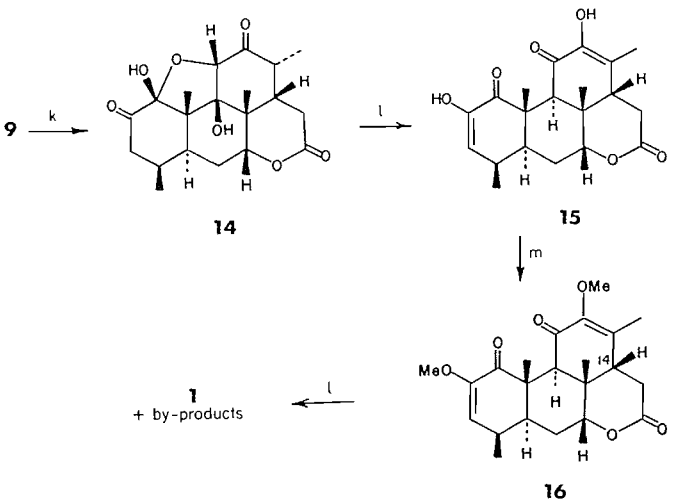
(a) Ac_2O, NaOAc, C_6H_6, reflux, 30–45 min (tlc monitored), yield >90%; (b) Ac_2O, Py, 100°C, 3 days (tlc monitored), yield >80%; (c) H_2/PtO_2, EtOH, room temp., yield quantitative; (d) $(CH_3)_3SiCN$, $BF_3.Et_2O$, CH_3NO_2, room temp., 6 h (tlc monitored), yield 66% chromatographed; (e) LiC_4H_8N, THF, −78°C, 30 min – 1 h (tlc monitored), yield 68–79% chromatographed; (f) MCPBA, $NaHCO_3$ + Na_2CO_3, CH_2Cl_2, room temp., 3–5 days (tlc monitored), yield 40–50% chromatographed; (g) PPTS, CH_2Cl_2 + $CHCl_3$ (1:1), reflux, 2–3 days (tlc monitored), yield >95%; (h) OsO_4, C_6H_6, Py cat, room temp., 5–7 days (tlc monitored), yield 50–60% chromatographed; (i) TOMA hydroxide, C_6H_6–H_2O (1:1), 80°C, 10 min or 50°C, 1 h (tlc monitored), yield 60–80% chromatographed; (j) CH_2N_2, Et_2O, MeOH, 5°C, 5–7 days (tlc monitored), yield 55–60% chromatographed; (k) Bi_2O_3, HOAc, 100°C, 10–12 h (tlc monitored), yield >95%; (l) DBN, C_6H_6, reflux, 7 h (tlc monitored), yield 79%; (m) $(CH_3)_2SO_4$, NaOH aq. (2 N), room temp., 25 h, yield 71% chromatographed.

SCHEME 1



13

the initially formed **9** to **13**.[7] The required dehydration eliminating the C(9)-OH group could therefore not be achieved under basic conditions at this stage.

Compound **9** was first methylated with diazomethane in ether, to give **10**, mp 201–203°C (^{1}H nmr ($CDCl_3$) C(3)-H δ 5.77, d, J = 5.71 Hz; C(2)-OCH_3 δ 3.65, s; C(12)-H δ 3.50, d, J = 12.77 Hz). Treatment of **10** with Bi_2O_3 in hot acetic acid (6) then effected the desirable ketol rearrangement **10** → **11**, mp 196–198°C (^{1}H nmr ($CDCl_3$) C(11)-H δ 5.07, s; C(3)-H δ 4.80, d, J = 5.08 Hz, C(2)-OCH_3 δ 3.57, s) rather than the expected C(12)-oxidation.[8]

Dehydration and C(4)-epimerization were now achieved in a one-pot reaction of **11** with DBN in boiling benzene,[9] to give norquassin **12** (^{1}H nmr ($CDCl_3$) C(3)-H δ 5.29, d, J = 2.22 Hz; C(2)-OCH_3 δ 3.57, s; C(9)-H δ 3.08, s; C(13)-CH_3 δ 1.87, s).[10] Methylation (7) of **12** provided synthetic *d,l*-quassin **1**, mp 187–188°C (^{1}H nmr ($CDCl_3$) C(3)-H δ 5.29, d, J = 2.57 Hz; C(7)-H δ 4.26, t, $w/2$ = 6 Hz; C(12)-OCH_3 δ 3.65, s; C(2)-OCH_3 δ 3.57, s; C(9)-H δ 2.97, s; C(13)-CH_3 δ 1.86, s; C(10)-CH_3/C(8)-CH_3 δ 1.54/1.18, s; C(4)-CH_3 δ 1.10, d, J = 6.91 Hz).

(l) DBN, C_6H_6, reflux, 3.30 h (tlc monitored), yield 80%; (m) $(CH_3)_2SO_4$, NaOH aq. (2 N), room temp., 47 h, yield 52% chromatographed.

SCHEME 2

[7]Small amounts of **13** were produced even when not more than 1 mol equivalent of TOMA hydroxide was used. Thus, this base does effect the **9** → **13** rearrangement, but fortunately the rearrangement rate is slower than that of HCN elimination.

[8]No reaction took place without Bi_2O_3 under these conditions!

[9]The intermediate 4-epinorquassin could be isolated by running the reaction at higher dilution.

[10]The ^{1}H nmr spectrum of norquassin **12** proved identical to that of the compound prepared by partial demethylation of quassin with BBr_3.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

It proved essential to have the ring A diosphenol methylated and the ring C diosphenol nonmethylated during the C(4)-epimerization. Thus, when 4-epiquassin **16** (Scheme 2), mp 217–219°C (^{1}H nmr ($CDCl_3$) C(3)-H δ 5.46, d, J = 4.84 Hz; C(12)-OCH_3 δ 3.64, s; C(2)-OCH_3 δ 3.59, s; C(9)-H δ 2.91, s; C(13)-CH_3 δ 1.85, s) prepared by double methylation of 4-epibisnorquassin **15** (**9** → **14** → **15** → **16**) was reacted with DBN in boiling benzene, only a low yield of quassin was obtained. 14-Epiquassin (isoquassin (1*c*, 1*e*)) and desmethoxylated ring C, D, dienones were formed as by-products. The ring C diosphenolate thus acted as a "protecting group" for C(14)-H during the above successful **11** → **12** transformation.

Of the five (formal) carbonyl groups of quassin, only that at C(1) was produced by the oxidation of a secondary OH group and, with the exception of the CN auxiliary in compounds **4**–**8**, no carbonyl group was protected in the course of this synthesis.

Received August 22, 1990

GEORGE R. PETTIT, DIPANJAN SENGUPTA, CHERRY L. HERALD, NANCY A. SHARKEY, and PETER M. BLUMBERG. Can. J. Chem. **69**, 856 (1991).

Bryostatin 2 (**1***a*) has been converted to bryostatin 1 (**1***e*) and bryostatin 12 (**1***i*) by a selective protection and deprotection involving the C-26 hydroxyl group. The new bryostatins **1***g*, **1***k*, and **1***m* were also prepared starting from bryostatin 2. The C-7 substituents of natural bryostatins 4 and 5 were revised from isovalerate → pivalate employing comparative ^{1}H and ^{13}C NMR studies of the semi-synthetic bryostatins **1***k* and **1***m* and the natural products.

Key words: bryostatin 2 → 1, selective conversion, bryostatins 4 and 5, pivalates.

GEORGE R. PETTIT, DIPANJAN SENGUPTA, CHERRY L. HERALD, NANCY A. SHARKEY et PETER M. BLUMBERG. Can. J. Chem. **69**, 856 (1991).

On a transformé la bryostatine 2 (**1***a*) en bryostatine 1 (**1***e*) et en bryostatine 12 (**1***i*) grâce à une protection et une déprotection sélective impliquant le groupement hydroxyle en C-26. On a aussi préparé les bryostatines **1***g*, **1***k* et **1***m* à partir de la bryostatine 2. En se basant sur des études comparatives de RMN du ^{1}H et du ^{13}C, effectuées sur les bryostatines semi-synthétiques **1***k* et **1***m* et sur les produits naturels, on propose une révision de la nature de substituants en position C-7 des bryostatines 4 et 5 d'isovalérate à pivalate.

Mots clés : bryostatine, conversion sélective, bryostatines 4 et 5, pivalates.

[Traduit par la rédaction]

The marine Bryozoan *Bugula neritina* has been found to contain a series of biologically and chemically exciting constituents now known as the bryostatins (2*a*–*g*). Other interesting biosynthetic products of the Phylum Bryozoa such as the β-lactam bearing chartellines have recently been isolated from *Chartella papyracea* (3). Bryostatin 1 (**1***e*) has been found to profoundly affect protein kinase C at picomolar concentrations (4*a*). Uniquely among protein kinase C modulators, whereas bryostatin 1 activates protein kinase C in vitro, it antagonizes phorbol ester responses in many biological systems (4*b*) and is deficient in tumor promoting activity (4*c*,*d*). Bryostatin 1 has powerful immunopotentiating activities (4*e*,*f*). The ability of bryostatin 1 to initiate cytotoxic T lymphocyte development (4*f*), and to induce production of interleukin-2 (4*f*,*g*) and growth of normal bone marrow cells (4*h*), combined with its strong *anti*tumor (4*i*) promoter and antineoplastic effects resulted in its selection for clinical development by the U.S. National Cancer Institute. To increase significantly the availability of bryostatin 1 (**1***e*) it became very important to convert bryostatin 2 (**1***a*), which was also obtained from *Bugula neritina* in nearly equal amounts, to bryostatin 1 in an efficient and selective way. Realization of this objective was accomplished as follows.

The bryostatin hydroxyl groups at C-3, C-9, and C-19 were earlier found (2*b*) to resist acetylation (under mild conditions), presumably due to intramolecular hydrogen bonding, while the C-7 and C-26 hydroxyl groups were readily acetylated (2*b*,*g*). Thus, synthetic conversion was undertaken by methods utilizing selective protection of the C-26 hydroxyl group. The steric environment of the two hydroxyl groups (viz. C-7 and C-26) suggested that a bulky silyl ether[3] would offer an attractive possibility.

Application of *tert*-butyldimethylsilyl chloride (6) was found very effective for selective protection of the bryostatin 2 C-26 hydroxyl group. Bryostatin 2 (**1***a*) was allowed to react (7) at room temperature with excess *tert*-butyldimethylsilyl (TBDMS) chloride in the presence of 4-(*N*,*N*-dimethyl)aminopyridine (and triethylamine in dimethylformamide) to produce 26-*tert*-butyldimethylsilyl ether **1***b* and bryostatin 2 7,26-di-*tert*-butyldimethylsilyl ether **1***c*. The disilyl ether was reconverted to bryostatin 2 employing 48% hydrofluoric acid – acetonitrile (1:20) (8). The yield of monosilyl ether **1***b* was 71% on the basis of total recovered bryostatin 2. Treatment of the C-26 silyl ether with acetic anhydride – pyridine (room temperature) gave acetate **1***d*. The C-26 hydroxyl was regenerated using 48% hydrofluoric acid – acetonitrile (1:20 at 0–5°C). The product was isolated in 80% overall yield (from **1***a*) by silica gel column chromatography and found to be identical with natural bryostatin 1 (**1***e*).

The high resolution SP-SIMS spectrum of bryostatin **1***e* displayed *m*/*z* 911 $(M + Li)^+$ and 927 $(M + Na)^+$ corresponding to the molecular formula $C_{47}H_{68}O_{17}$. The ^{1}H NMR spectrum revealed an acetate chemical shift at δ 2.04, the C-7 proton signal at δ 5.14 (dd, J = 12, 4.9 Hz), and the three-proton doublet of the C-27 methyl at δ 1.23 (J = 6.5 Hz). The significant downfield shift of the C-7 proton from δ 3.95 (**1***a*, **1***b*) to δ 5.14 (**1***e*) further confirmed acetylation at the C-7 hydroxyl group.

Selective protection of the C-26 hydroxyl group in bryostatin 2 allowed us to selectively introduce other groups at C-7.

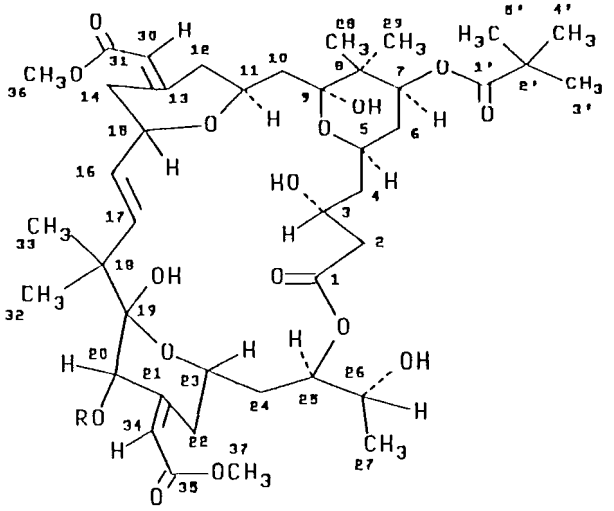
Treatment of 26-*tert*-butyldimethylsilyl ether **1***b* with butyric anhydride and pyridine, followed by deprotection, led to bryostatin 2 7-butyrate (**1***i*) identical to bryostatin 12 (**1***i*). Bryostatin 2 7-propionate (**1***g*) was obtained in an analogous manner.



Conversion of bryostatin 2 to bryostatin 2 7-isovalerate (**1***k*) and bryostatin 2 7-pivalate (**1***m*) provided convincing support for the revision[4] of C-7 substituents in bryostatins 4 (**2***a*) (2*d*) and **5** (**2***b*) (2*e*). Esterification of bryostatin 2 26-OTBDMS (**1***b*) with isovaleric acid in the presence of dicyclohexylcarbodiimide and 4-pyrrolidinopyridine (10) in methylene chloride provided ester **1***j*. The TBDMS protecting group was removed to afford the new bryostatin **1***k*. Treatment of bryostatin 2 26-OTBDMS (**1***b*) with pivalic anhydride and 4-(*N*,*N*-dimethyl)aminopyridine (50–55°C) (for a review, see ref. 11) in methylene chloride provided bryostatin 2 26-OTBDMS-7-pivalate (**1***l*). Removal of the protecting group afforded bryostatin 2 7-pivalate (**1***m*) in 42% overall yield from **1***b*. The ^{1}H NMR spectrum of bryostatin **1***m* showed a strong singlet for the pivalate unit at δ 1.17 (Table 1) and a multiplet for the C-7 proton at δ 5.08 (dd, J = 11.8, 4.8 Hz), whereas bryostatin **1***k* showed a doublet at δ 0.93 (J = 6.3 Hz, Table 1) for the isovalerate unit.

The isovalerate → pivalate revision was further supported by the ^{13}C NMR spectra of natural bryostatins 4 and 5 (Table 2).

[4]In 1988, during another reisolation of bryostatins 4 and 5, recharacterization employing high-field NMR techniques suggested possible presence of a pivalate ester at C-7. The realization of this minor modification at C-7 was made possible by newer NMR techniques and these structural changes have already been entered in a contribution by Pettit *et al.* (9).

Comparison of the ^{1}H and ^{13}C NMR spectra of natural bryostatins 4 and 5 with those of the semi-synthetic bryostatins **1***m* and **1***k* confirmed the C-7 pivalate substitution. The strong singlet at δ 1.17 in the ^{1}H NMR spectrum of semi-synthetic bryostatin **1***m* (Table 1) was nearly identical to the singlet at δ 1.16 and δ 1.19 of natural bryostatins 4 and 5, respectively. Moreover, the bryostatin **1***m* gave rise to ^{13}C chemical shifts at δ 177.99 (C-1′), 39.01 (C-2′), and 27.14 (C-3′, -4′, and -5′, Table 2), in close agreement with the ^{13}C NMR shifts displayed by the C-7 substituents of natural bryostatins 4 and 5. The proton spectrum of bryostatin **1***k* showed a doublet due to two methyl groups at δ 0.93 (J = 6.3 Hz) (Table 1) and the ^{13}C NMR spectrum gave evidence of C-1′ at δ 172.81, C-2′ at δ 43.75, C-3′ at δ 24.93, and C-4′ and -5′ at δ 22.35 (Table 2), thereby substantiating that bryostatins 4 (**2***a*) and 5 (**2***b*) contain the unusual pivalate ester group at C-7 (2*d*,*e*, 9).

In initial biochemical characterization, the binding affinities of bryostatins **1***g*, **1***k*, and **1***m* for protein kinase C were determined by competition of [^{3}H]bryostatin 4 binding as described previously for bryostatins 1–10 (4*i*). The assay conditions involve reconstitution of protein kinase C in Triton X-100/phosphatidylserine. Although these conditions give

2, *a* R = -$COCH_2CH_2CH_3$, bryostatin 4
1″ 2″ 3″ 4″

b R = -$COCH_3$, bryostatin 5
1″ 2″

significantly lower affinity than found for the enzyme reconstituted under the more physiological conditions of phospholipid alone, they permit quantification under equilibrium conditions. The K_i values for bryostatins **1***g*, **1***k*, and **1***m* were 1.7 ± 0.5, 0.74 ± 0.23, and 0.73 ± 0.17 nM (mean ± range, n = 2 experiments) respectively. Similar values were thus observed for the isovalerate and pivalate esters, with slightly less activity for the propionate ester **1***g* and the acetate ester (bryostatin 1, K_i = 1.4 ± 0.2 nM, 4*i*).

The strategy for selective reaction at the C-7 hydroxyl group of bryostatin 2 with protection and deprotection of the more reactive C-26 hydroxyl now opens a useful pathway to a variety of new bryostatins (12). In time, that will allow further study of the structure/activity relationships among this fascinating group of marine animal antineoplastic constituents.

Experimental section

General procedures

Solvent solutions from reaction mixtures washed with water were dried over anhydrous sodium sulfate. All chromatographic solvents were redistilled. Silica gel (E. Merck, Darmstadt, 70–230 mesh) was employed for column chromatography and silica gel GHLF uniplates (Analtech, Inc., Newark, DE) were used for thin-layer chromatography (TLC). The TLC plates were viewed with UV light and developed with anisaldehyde – sulfuric acid spray reagent followed by heating. The NMR spectra were measured using a Bruker AM-400 instrument with deuteriochloroform employed as solvent. All high and low resolution fast atom bombardment (FAB) mass spectra (13) were recorded using a Kratos MS-50 mass spectrometer (Mid West Center for Mass Spectrometry, University of Nebraska, Lincoln, NE).

*Bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1***b*). General procedure*

The following procedure for silyation, acylation, and desilyation was repeated in analogous fashion for each bryostatin interconversion. A solution of bryostatin 2 (**1***a*, 50 mg), 4-(*N*,*N*-dimethyl)aminopyridine (15 mg), *tert*-butyldimethylsilyl chloride (40 mg), and triethylamine (20 μL) in dimethylformamide (2 mL) was stirred at room temperature (under argon) for 22 h. The reaction mixture was diluted with ice water, stirred for 10 min, and extracted with methylene chloride. The organic phase was washed with saturated aqueous sodium bicarbonate, followed by water, dried, and solvent evaporated under reduced pressure. The residue was purified by column chromatography on silica gel (1:1 hexane – ethyl acetate) to afford silyl ether **1***b* (21.8 mg), bryostatin 2 7,26-di-*tert*-butyldimethylsilyl ether **1***c* (21.4 mg), and bryostatin 2 (5.5 mg). The silyl protecting groups in **1***c* were removed with 48% hydrofluoric acid – acetonitrile (1:20, 10 mL). The reaction mixture was stirred at 0–5°C (1.5 h), diluted with water, and extracted with methylene chloride. The chlorocarbon phase was washed with saturated aqueous sodium bicarbonate followed by water, and dried. The residue (from solvent removal at reduced pressure) was separated by silica gel column chromatography (1:1 hexane – ethyl acetate) to afford 17.2 mg of bryostatin 2. On the basis of total recovered bryostatin 2, the yield of monosilyl ether **1***b* was 71%. The 400 MHz ^{1}H NMR spectrum of silyl ether **1***b* displayed significant

chemical shifts at δ 0.07 (s, 3H), 0.11 (s, 3H), 0.90 (s, 9H), 1.08 (d, 3H, J = 5.6 Hz), 3.65 (s, 3H), 3.68 (s, 3H), 3.73 (m, 1H), and 3.95 (m, 1H).

*Conversion of bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1**b) to bryostatin 1 (**1**e)*

A solution of bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1***b*, 1.6 mg) in acetic anhydride (100 μL) and pyridine (150 μL) was stirred for 18 h (room temperature), diluted with methanol, and stirred for an additional 30 min. Solvent was removed (reduced pressure) and the residue was chromatographed on a column of silica gel (1:1 hexane – ethyl acetate) to afford 1.2 mg (72%) of acetate **1***d*. The product (**1***d*) was subjected to desilylation by treating with 48% hydrofluoric acid – acetonitrile (1:20, 100 μL). The reaction mixture was stirred at 0–5°C (1.5 h), diluted with water, and extracted with methylene chloride. The organic phase was washed with saturated aqueous sodium bicarbonate, water, and dried. After solvent removal (reduced pressure) the residue was purified by silica gel column chromatography (1:1 hexane – ethyl acetate) to afford bryostatin 1 (**1***e*, 0.8 g, 80%), identical with the natural product (by comparison with TLC, analytical HPLC, SP-SIMS (13), and ^1H NMR).

*Conversion of bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1**b) to bryostatin 2 7-propionate (**1**g)*

Bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1***b*, 2 mg) was treated with propionic anhydride (100 μL) – pyridine (130 μL) and stirred for 18 h at room temperature. The product was purified as described directly above to afford **1***f* (2.0 mg, 95%). Desilylation and purification as described above afforded bryostatin **1***g* (1.5 mg, 88%): for ^1H NMR data see Table 1.

*Conversion of bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1**b) to bryostatin 12 (**1**i)*

Bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1***b*, 2.7 mg) was esterified (20 h) with butyric anhydride (100 μL) in pyridine (120 μL) employing the same procedure as utilized above to provide ester **1***h* (1.9 mg, 73%). Desilylation (150 μL of the 1:20 48% hydrofluoric acid – acetonitrile) as described above gave bryostatin 12 (**1***i*, 0.8 mg, 47%), identical to the natural product (by comparison with TLC, SP-SIMS (13), and ^{1}H NMR spectra.

*Conversion of bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1**b) to bryostatin 2 7-isovalerate (**1**k)*

A solution of isovaleric acid (5 μL), *N,N*-dicyclohexylcarbodiimide (10 mg), bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1***b*, 4.6 mg), and 4-pyrrolidinopyridine (1.3 mg) in methylene chloride (150 μL) was stirred at room temperature for 5 h (under argon). The *N,N*-dicyclohexylurea was removed by filtration, and the filtrate was concentrated (reduced pressure). The residue was separated by column chromatography on silica gel (1:1 hexane – ethyl acetate) to afford isovalerate **1***j* (4.5 mg, 90%). Removal of the silyl group as summarized above (cf., **1***e*, 150 μL of the 1:20 reagent) afforded bryostatin 2 7-isovalerate (**1***k*, 2.2 mg, 55%); FAB-MS (DTT/DTE as matrix), *m/z*: 969 $[M + Na]^+$ for $C_{50}H_{72}O_{16}Na$ (20% of base peak), and 911 $[M + H - 2H_2O]^+$ as base peak; for the ^{1}H and ^{13}C NMR data refer to Tables 1 and 2.

*Conversion of bryostatin 2 26-*tert*-butyldimethylsilyl ether (**1**b) to bryostatin 2 7-pivalate (**1**m)*

To a solution of bryostatin 2 26-*tert*-butyldimethylsilyl ether (6.9 mg) in methylene chloride (150 μL) were added 4-(*N,N*-dimethyl)aminopyridine (45 mg) and pivalic anhydride (40 mg). The reaction mixture was stirred at 52–55°C for 4 h (under argon) followed by addition of methanol at room temperature. The residue obtained following solvent removal was separated by column chromatography on silica gel (1:1 hexane – ethyl acetate) to afford pivalate **1***l* (5.7 mg, 76%). Desilylation was performed as described earlier to afford bryostatin **1***m* (2.8 mg, 56%): FAB-MS (3-NBA LiI as matrix), *m/z*: 969 $[M + Na]^+$ for $C_{50}H_{72}O_{16}Na$ (10% of base peak), 953 $[M + Li]^+$ for $C_{50}H_{72}O_{16}Li$ as base peak; for the ^{1}H and ^{13}C NMR data consult Tables 1 and 2.

Acknowledgments

Very necessary financial assistance was provided by Eleanor W. Libby, the Waddell Foundation (Donald Ware), the Fannie E. Rippel Foundation, The Robert B. Dalton Endowment Fund, the Arizona Disease Control Research Commission, the National Cooperative Drug Discovery Group Grant AI 25696-02-03, NIAID, the Outstanding Investigator Grant CA 44344-01A1 awarded by the Division of Cancer Treatment, National Cancer Institute, DHHS, and by the U.S. Army Medical Research and Development Command under Grant No. DAMD-17-89-Z-9021. Comparison of chemical and electrochemical reduction of cyanamides: an example of cathodic decyanation

MICHEL CARIOU[1] AND JACQUES SIMONET

Laboratoire d'électrochimie, Équipe de recherche associée au Centre national de la recherche scientifique, N° 439, Université de Rennes 1, Campus de Beaulieu, 35042 Rennes CEDEX, France

Received October 17, 1990

MICHEL CARIOU and JACQUES SIMONET. Can. J. Chem. **69**, 861 (1991).

Most disubstituted cyanamides exhibit a very low cathodic activity and are therefore difficult to reduce. However, the cathodic cleavage of diarylcyanamides can be carried out directly and leads to the corresponding diarylamine; the action of sodium causes the same cleavage. Alkylarylcyanamides display no cathodic step, but can be reduced indirectly by redox catalysis; this allows the determination of the standard potential corresponding to the first electron transfer. The macroscale electrolysis, in the presence of the catalyst, leads to the alkylarylamine by cleavage, whereas the action of sodium gives mainly a cyanoguanidine. Dialkylcyanamides are electroreducible neither directly, nor indirectly, whereas by action of sodium they trimerize almost quantitatively into triazines.

Key words: cyanamide, decyanation, electroreduction, redox catalysis.

MICHEL CARIOU et JACQUES SIMONET. Can. J. Chem. **69**, 861 (1991).

La plupart des cyanamides disubstitués présentent une très faible activité cathodique et, par conséquent, se réduisent difficilement. Cependant, la coupure cathodique des diarylcyanamides peut être effectuée directement et conduit à la diarylamine correspondante; l'action du sodium provoque la même coupure. Les alkylarylcyanamides ne présentent pas de pic cathodique, mais peuvent être réduits indirectement par catalyse rédox; cela permet alors la détermination du potential standard correspondant au premier transfert d'électron. L'électrolyse préparative, en présence du catalyseur, conduit à l'alkylarylamine par coupure, alors que l'action du sodium donne principalement une cyanoguanidine. Les dialkylcyanamides ne sont électroréductibles ni directement, ni indirectement, alors que par action du sodium ils se trimérisent presque quantitativement en triazines.

Mots clés : cyanamide, décyanation, électroréduction, catalyse rédox.

Introduction

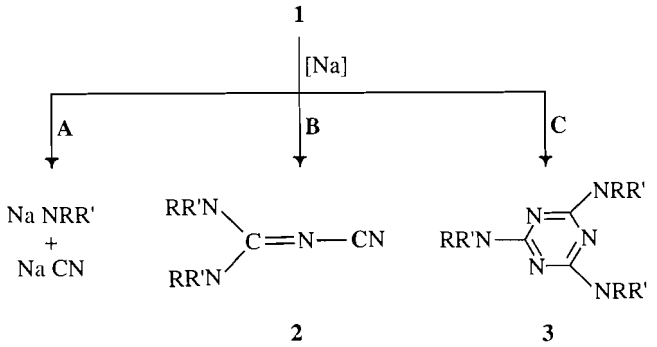
The cathodic cleavage of the C—N bond is not current at all in electrochemistry. The only reported reactions (1) concern the degradation of ammonium salts under electron transfer. The cleavage of those onium salts was also carried out indirectly (2). On the contrary, the reduction of amines (even activated ones such as benzylic and allylic amines) has never been observed, nor even suggested. This lack of reactivity is probably due to the donating effect of the electron-rich amino group. We want to report here the behaviour of cyanamides of general formula:

RR'N—CN

1 *a* R = R' = Me
b R = R' = Ph
c R = Me, R' = Ph

Results and discussion

1. *Action of alkali metals*



In search of new organic solvents usable in lithium batteries, we observed in our laboratory (3) for the first time the almost complete trimerization of *N*-cyanopyrrolidine, a disubstituted cyanamide, on mere storage over lithium shavings for about 12 h. This preliminary observation led us to study the action of alkali metals on several disubstituted cyanamides **1**; sodium (in dispersion) is the best metal for this study, because it is more reactive than lithium and less hazardous than potassium (4).

The action of sodium on cyanamides **1** gives rise to three types of reactions according to the nature of R and R':

A. Cleavage into cyanide and dialkylamide, when R and R' are aromatic (R = R' = Ph: **1***b*) or simply bulky (R = R' = *i*Pr).

B. Formation of cyanoguanidines **2**, when R = Me and R' = Ph: **1***c*.

C. Trimerization into 2,4,6-tris(*N*,*N*-dialkylamino)-1,3,5-triazines **3**, only when R = R' = alkyl, as in the case of **1***a*:

These chemical reactions with sodium may occur under electron transfer catalysis. Consequently, it was of interest to test the cathodic behaviour of molecules of type **1**, in order to compare chemical and electrochemical reactivities and also, possibly, to elucidate mechanisms.

2. *Cyclic voltammetry*

The three model cyanamides **1** were tested with a mercury microelectrode as a working electrode and the $Ag/AgI/I^-$ 0.1 M system as a reference electrode; the electrolyte was a solution of 0.1 M tetraethylammonium perchlorate in dimethylformamide dried over molecular sieves (4 Å).

Cyanamide ***1***b

Only **1***b* exhibits a voltammetric step, located at very negative potential values: $E_p = -2.13$ V (Fig. 1). The step is irreversible and corresponds to a one-electron reaction; the monoelectronic character was checked by comparison with the voltammogram of naphthalene. **1***b* does not exhibit any redox catalysis: no indirect reduction by the stilbene radical anion formed at E^0 =

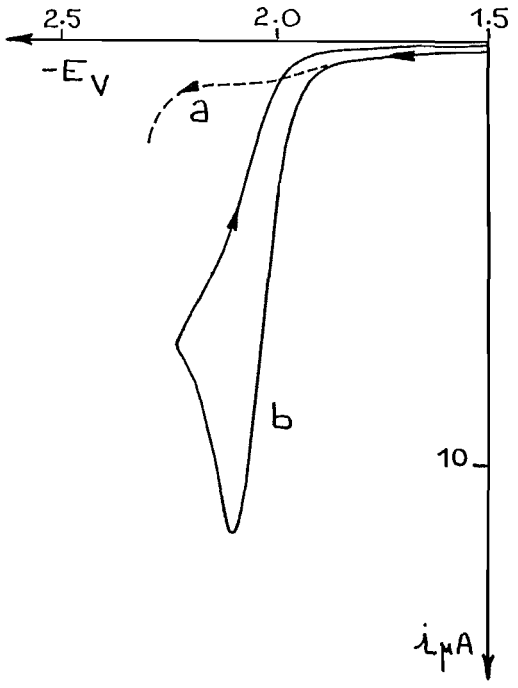

FIG. 1. Voltammetries of cyanamide **1***b*. Electrolyte: DMF–TEAP 0.1 M. Hg microelectrode. Reference: Ag/AgI/I^- 0.1 M system. Sweep rate: 0.1 V s^{-1}. Curve a: background response. Curve b: in the presence of 2.5×10^{-3} M of **1***b*.

−1.67 V, while a kind of catalysis is visible at the level of the second step ($E = -1.95$ V), which is, however, fully irreversible.

Actually, one can expect a redox catalysis phenomenon for cyanamides by analogy with the classical case of alkyl halides where the C—X bond, able to cleave after an electron transfer, is comparable to the N—CN bond of cyanamides (see below).

*Cyanamide 1*c

Cyanamide **1***c*, less activated than **1***b*, does not display any cathodic step. However, here the use of redox catalysis allows us to observe a catalytic current for **1***c*, with mediators (Ar) such as naphthalene (Fig. 2) and biphenyl. The theory defined for electrochemical–chemical (EC) systems can completely apply (5). Results fit in nicely with a monoelectronic reduction of **1***c*; this is analogous to what is observed with **1***b*.

The kinetically limiting process is the electron transfer rate from the catalyst radical anion $Ar^{\cdot-}$ to substrate **1***c*. Catalytic efficiency increases with catalyst concentration, which is what we observed by varying this concentration while maintaining constant the excess factor γ (ratio of cyanamide to catalyst concentration: $\gamma = C^0_{1c}/C^0_{Ar}$).

The values found for the electron exchange rate constant in solution are as follows: $k_1 = 265$ s^{-1} with the naphthalene anion, $k_1 = 1960$ s^{-1} with the biphenyl anion. Comparison of the high rate of the cleavage process for **1***c* with the absence of redox catalysis for **1***b* leads us to think that, with more conjugated structures, the rate of cleavage of the radical anion is much slower. By using the method developed by Savéant and co-workers (5), these values of k_1 permit access to the standard potential of cyanamide **1***c* despite the absence of a cathodic peak:

$$E^0_{Ar} - E^0_{1c} = 0.058 \log k_2/k_1$$

$$E^0_{1c} = E^0_{Ar} + 0.058 \log k_1 - 0.58$$

(since k_2 (diffusion) = 10^{10} M^{-1} s^{-1} for dimethylformamide,

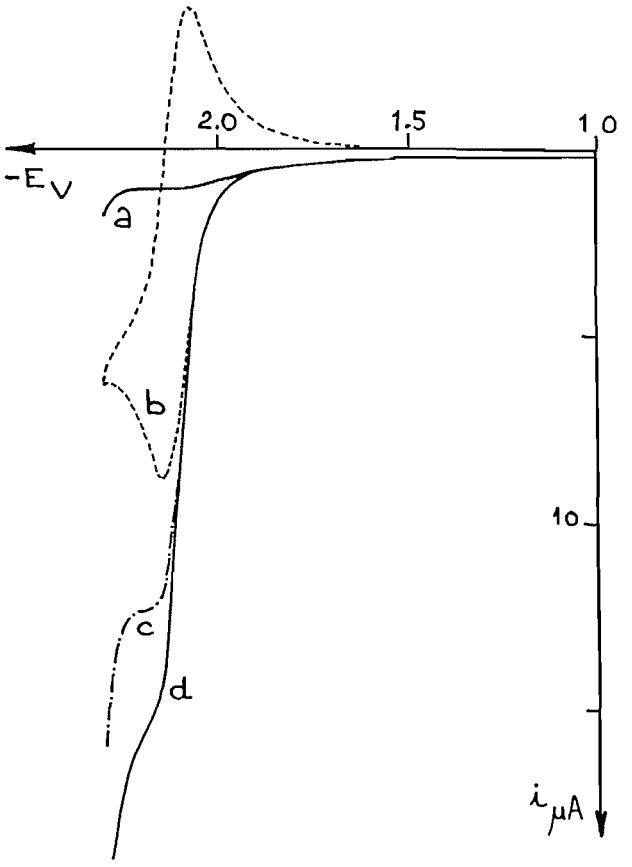

FIG. 2. Redox catalysis relative to cyanamide **1***c* in the presence of naphthalene as an electron carrier. Electrolyte: DMF–TEAP 0.1 M. Hg microelectrode. Reference Ag/AgI/I^- 0.1 M system. Sweep rate: 0.1 V s^{-1}. Curve a: background response. Curve b: naphthalene voltammetric response, $c = 2.5 \times 10^{-3}$ M. Curve c: preceding solution containing **1***c*, $c = 5 \times 10^{-3}$ M. Curve d: solution b containing **1***c*, $c = 7.5 \times 10^{-3}$ M.

the solvent used for the voltammetry studies). With naphthalene as a mediator: $E^0_{1c} = -1.94$ V + 0.058 log 265 − 0.58 = −2.38 V; and with biphenyl as a mediator: $E^0_{1c} = -2.00$ V + 0.058 log 1960 − 0.58 = −2.39 V. So the average standard potential of cyanamide **1***c*: $E^0 = -2.385$ V vs. Ag/AgI/I^- 0.1 M, lies at the level of the accessible limit of the electrolyte.

*Cyanamide 1*a

Despite numerous attempts utilizing mediators with very negative standard potentials (*trans*-stilbene, biphenyl, naphthalene, acenaphthene), in the case of dialkylcyanamide **1***a* no indirect reduction was observed.

3. *Macroscale electroreductions: comparison with the action of sodium*

*Cyanamide 1*b

We observed previously that **1***b* exhibits a one-electron step in cyclic voltammetry. However, in macroscale electroreduction, the electricity consumption is close to 1.8 F mol^{-1}, with almost quantitative formation of diphenylamine (92%):

$$Ph_2N{-}CN \xrightarrow[e^-]{\text{Hg, DMF–TEAP, –2.10 V}} (Ph_2N{-}CN)^{\cdot-} \xrightarrow{-NC^-} Ph_2N^{\cdot} \xrightarrow[\text{slow}]{e^-,\ H^+} Ph_2NH$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

This means that the monoelectronic first step is the kinetically limiting process, while the second electron transfer is slow. Note that, in the case of diphenylcyanamide **1***b*, the results of preparative electroreduction and action of sodium are exactly the same: cleavage of the C—N single bond.

Cyanamide ***1***c

The indirect preparative electroreduction of methylphenylcyanamide **1***c* exhibits the same cleavage reaction, also with an electricity consumption of 2 F mol^{-1} and quantitative formation of N-methylaniline. The mechanism and conclusions are the same as in the case of **1***b*:

$$\mathrm{PhMeN{-}CN} \xrightarrow[e^-]{\text{Hg, DMF–TEAP, –2.00 V}} (\mathrm{PhMeN{-}CN})^{\cdot-} \xrightarrow{-NC^-} \mathrm{PhMeN^{\cdot}} \xrightarrow[\text{slow}]{e^-,\,H^+} \mathrm{PhMeNH}$$

This electroreduction gives a result different from the action of sodium on cyanamide **1***c*: beside 19% of *N*-methylaniline, 61% of cyanoguanidine **2***c* was isolated. Anderson *et al.* (6) also obtained this cyanoguanidine, by reacting PhMeN—CN with Ph Li (yield: 58%) or with PhMeN Li (75%). From their results and observations, the following mechanism can be proposed:

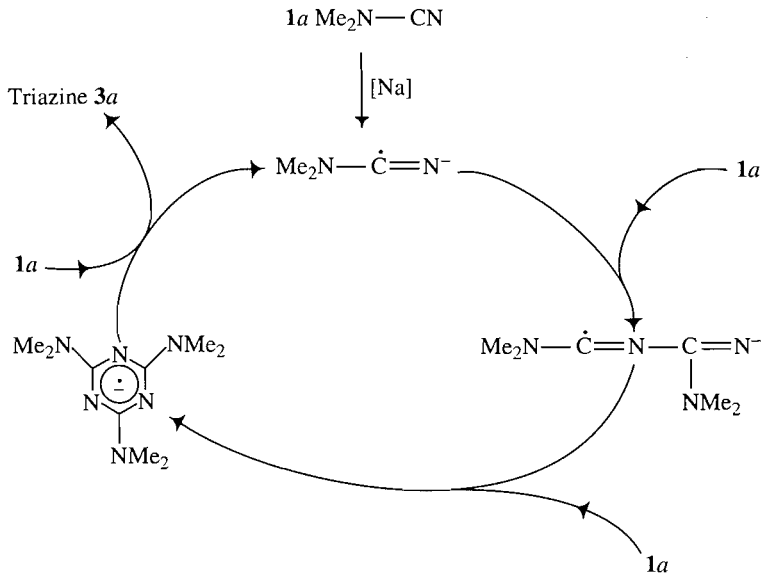
$$\mathbf{1}c \xrightarrow{Na} \mathbf{1}c^{\cdot-}\,Na^+ \longrightarrow NaCN + \mathrm{PhMeN^{\cdot}} \xrightarrow{Na} \mathrm{PhMeN^-}\,Na^+$$

$$\xrightarrow{\mathbf{1}c} \begin{matrix}\mathrm{PhMeN}\\ \mathrm{PhMeN}\end{matrix}\!\!>\!C{=}N^-\,Na^+$$

$$\xrightarrow{\mathbf{1}c} \begin{matrix}\mathrm{PhMeN}\\ \mathrm{PhMeN}\end{matrix}\!\!>\!C{=}N{-}CN + \mathrm{PhMeN^-}\,Na^+$$

2*c*

At the start, the formation of a catalytic quantity of $PhMeN^-$ is sufficient, since it is continually regenerated. But one can also suggest a mechanism in which radical anion $\mathbf{1}c^{\cdot-}$ adds directly, without prior cleavage, to cyanamide **1***c*; it is therefore a simple coupling reaction catalyzed by sodium:



$$\mathbf{1}c^{\cdot-} \xrightarrow{\mathbf{1}c} \mathbf{2}c^{\cdot-} \xrightarrow{\mathbf{1}c} \mathbf{2}c + \mathbf{1}c^{\cdot-}$$

However, in cyclic voltammetry, when cyanamide **1***c* is added to the radical anion of cyanoguanidine **2***c* (formed at −1.60 V versus Ag/AgI/I^- 0.1 M, on a mercury microelectrode in DMF–TEAP), there is no redox catalysis; this is not surprising, because the potential gap is high ($E^0_{1c} - E^\circ_{2c} = 0.8$ V).

Cyanamide ***1***a

Considering the propensity of dialkylcyanamides **1** to trimerize into triazines **3** under the action of sodium, we attempted the electrochemical trimerization (cathodic induction of electron transfer) of cyanamide **1***a*. Despite many and various attempts, at constant current intensity, the formation of triazine **3***a* was never observed by the following procedures: reduction by quaternary ammonium amalgam, according to experimental conditions defined previously (7), in DMF–TEAP; electroreduction at a glassy carbon cathode in $MeCN–Bu_4NBF_4$; redox catalysis on mercury pool, in DMF-TEAP, in the presence of acenaphthene; electroreduction in toluene–$(C_6H_{13})_4N\ ClO_4$ (it was impossible to exceed 2 mA in intensity). Therefore, it appears clear that electron transfer does not occur under extreme electrochemical conditions.

However, in the presence of a catalytic amount of sodium (less than 5%), dimethylcyanamide **1***a* was converted into triazine **3***a* in almost quantitative yield, very likely according to a catalytic cycle initiated by a monoelectronic transfer, where the anion radical of **3***a* is the reducing species of **1***a* ($E^0_{1a} > E^0_{3a}$):

This is quite different from the mechanism proposed previously (see ref. 6, p. 2316) for the same trimerization carried out in the presence of phenyllithium (yield of triazine **3***a*: 14%).

Thus, the behaviour of cyanamides towards reducing species on the one hand, and a metallic cathode on the other hand, can be dramatically changed as a function of experimental conditions. The reason why electrochemical dimerization (of cyanamide **1***c* into cyanoguanidine **2***c*) and electrochemical trimerization (of cyanamide **1***a* into triazine **3***a*) failed could be the radically different experimental conditions; the action of sod-

ium was carried out in toluene, a nonpolar solvent, whereas electroreductions were performed in polar solvents such as dimethylformamide and acetonitrile where radical anions, if formed, are strongly solvated and therefore far less reactive.

Experimental

N,N-dimethylcyanamide **1***a* was a commercial product.

Preparation of N-*methyl*-N-*phenyl-cyanamide* **1**c *(8, 9)*

To an ice-cold mixture of magnesium carbonate (6.95 g), ether (80 mL), water (9 mL), and cyanogen bromide (25 g) was added, dropwise, over 40 min with stirring, *N*-methylaniline (25.25 mL). At the end of the addition, the ice bath was removed and stirring was maintained for 1 h. Then the mixture was extracted with 150 mL of ether, washed several times with water, and dried over K_2CO_3. After the usual work-up, distillation gave 22.2 g (72%) of methylphenylcyanamide **1***c*: bp 140°C (16 Torr; 1 Torr = 133.3 Pa); mp 28°C; IR (KBr) ν (CN): 2225; NMR ($CDCl_3$), δ: 3.30 (s, 3H, Me), 6.96–7.00 (m, 5H, Ph).

Preparation of N,N-*diphenylcyanamide* **1**b *(10)*

A mixture of magnesium carbonate (6.95 g), acetonitrile (80 mL), water (9 mL), cyanogen bromide (25 g), and diphenylamine (39.44 g) was refluxed for 12 days; after cooling, it was extracted with 250 mL of ether, washed several times with water, and dried over K_2CO_3. The usual work-up, followed by careful distillation, allowed us to isolate 24.7 g (54%) of diphenylcyanamide **1***b*: bp 185–195°C (16 Torr); mp 74°C (cylcohexane) IR (KBr) ν (CN): 2250; NMR ($CDCl_3$), δ: 7.10–7.65 (m, Ph).

Chemical cleavage of diphenylcyanamide **1**b

A mixture of 0.25 g of sodium (dispersion) and 2.0 g of diphenylcyanamide **1***b* in 50 mL of toluene was warmed at 80°C for 10 h, with stirring; then 200 mL of dichloromethane was added, the organic layer was washed several times with water, and dried over K_2CO_3; after the usual work-up, 1.40 g of diphenylamine was obtained (identified by its melting point, IR spectrum and TLC). The presence of cyanide in the aqueous layer was proven by the Prussian blue precipitate test.

Electrochemical cleavage of diphenylcyanamide **1**b

In a three-compartment H-shaped cell, 5 mmol (0.97 g) of diphenylcyanamide **1***b* in 65 mL of DMF–TEAP 0.1 M were electrolyzed, on a mercury pool (A = 15 cm^2) at −2.10 V (vs. Ag/AgI/I^- 0.1 M) for 24 h. The electricity consumption was 1.8 F mol^{-1}. The catholyte was diluted with 300 mL of ether, washed several times with water, and dried over K_2CO_3. After the usual work-up, 0.78 g (92%) of diphenylamine was isolated and identified as above. The presence of cyanide in the aqueous layer was also proven as above.

Indirect cathodic cleavage of methylphenylcyanamide **1**c*, in the presence of naphthalene as a redox catalyst*

In a three-compartment H-shaped cell, 5 mmol (0.661 g) of methylphenylcyanamide **1***c* in 65 mL of DMF–TEAP 0.1 M, together with 1 mmol (0.128 g) of naphthalene, were electrolyzed, on a mercury pool (A = 15 cm^2) at −2.0 V (vs. Ag/AgI/I^- 0.1 M) for 48 h. The electricity consumption was about 2 F mol^{-1}. The catholyte was diluted with 300 mL of ether, washed several times with water, and dried over K_2CO_3. After the usual work-up, 0.56 g of oil was obtained, identified by TLC, IR, and NMR spectroscopy as *N*-methylaniline contaminated with a little naphthalene; NMR ($CDCl_3$), δ: 2.77 (s, 3H, Me), 3.50 (dome, 1H, NH). The presence of cyanide in the aqueous layer was proven by the Prussian blue precipitate test.

Reaction of sodium with methylphenylcyanamide **1**c*: preparation of 2-cyano-1,3-dimethyl-1,3-diphenyl-guanidine* **2**c

A mixture of 0.40 g of sodium (dispersion) and 3.60 g of methylphenylcyanamide **1***c* in 50 mL of toluene was stirred, at room temperature, for 24 h; then 200 mL of dichloromethane was added, the organic layer was washed several times with water, and dried over K_2CO_3; after the usual work-up, 3.4 g of a mixture of oil and crystals was obtained, which after crystallization in 11 mL of ethanol allowed us to isolate a first crop of 1.0 g of cyanoguanidine **2***c*. Purification of the filtrate by silica gel column chromatography with CH_2Cl_2–MeOH 98:2 as an eluent gave a further amount of 1.1 g of cyanoguanidine **2***c* (overall yield 61%) and 0.55 g of *N*-methylaniline (19%): mp 128°C (ethanol) (lit. (6) mp 126°C); IR (KBr) ν (CN): 2180; NMR ($CDCl_3$), δ: 3.38 (s, 6H, Me), 6.65–6.90 (m, 4H, Ph), and 6.97–7.35 (m, 6H, Ph).

Reaction of sodium with dimethylcyanamide **1**a*: preparation of 2,4,6-tris(*N,N-*dimethylamino)-1,3,5-triazine* **3**a

A mixture of 0.40 g of sodium (dispersion) and 8.1 mL (0.1 mol) of dimethylcyanamide **1***a* in 80 mL of toluene was stirred at room temperature for 3 h. Then the sodium was filtered off on glasswool; the solution was diluted with 70 mL of ether, washed several times with water, and dried over K_2CO_3. After the usual work-up, 6.6 g (94%) of crude crystals of triazine **3***a* were obtained; recrystallization from 55 mL of ethanol allowed us to isolate 5.3 g (74%) of colorless needles; mp 176°C (lit. (6) mp 173°C); IR (KBr) ν (triazine): 1500, 1390; NMR ($CDCl_3$), δ: 3.13 (s, NMe_2).

Received October 6, 1990

NORMA SBARBATI NUDELMAN and JORGE JAVIER P. FURLONG. Can. J. Chem. **69**, 865 (1991).

INDO calculations have been performed on substituted 2′-hydroxychalcones. The results show that the intramolecularly hydrogen-bonded *trans-s-cis* conformation is the most stable. The calculations assist in assignment of NMR signals and interpretation of kinetic determinations. The calculated energy of the intramolecular hydrogen bond is compared with IR data when available and with experimentally determined heats of formation of the chalconates. Regarding the isomerization to flavanones, calculations of the ring A rotation in the chalconates show that it is exergonic; on the contrary, complete rotation of the styryl system encounters a strong barrier. MNDO calculations on this process show similar trends. These results indicate that this last rotation is involved in the slow step, which is consistent with kinetic determinations.

Key words: chemical interactions, theoretical calculations, substituted hydroxychalcones, flavanones.

NORMA SBARBATI NUDELMAN et JORGE JAVIER P. FURLONG. Can. J. Chem. **69**, 865 (1991).

On a effectué des calculs INDO sur des 2′-hydroxychalcones substituées. Les résultats montrent que la conformation *trans-s-cis* avec liaison hydrogène intramoléculaire est la plus stable. Des calculs aident à l'attribution des signaux RMN et à l'interprétation des données cinétiques. Lorsqu'elles sont disponibles, on a comparé les énergies calculées pour la liaison hydrogène intramoléculaire avec les données IR et avec les chaleurs de formation des chalconates déterminée expérimentalement. En ce qui a trait à l'isomérisation en flavanones, les calculs relatifs à la rotation du cycle A des chalconates démontrent que cette réaction est exergonique; au contraire, la rotation complète du système styryle est soumise à une forte barrière. Des calculs MNDO sur ce processus suggèrent les mêmes tendances. Ces résultats indiquent que cette dernière rotation est impliquée dans l'étape lente, ce qui est en accord avec les déterminations cinétiques.

Mots clés : calculs théoriques des reactions chimiques, hydroxychalcones substituées, flavanones.

[Traduit par la rédaction]

Introduction

There are no experimental studies on the conformation of 2′-hydroxychalcones, **1**, and in previous kinetic studies on their conversion into flavanone (2, 3) the conformation is not defined. The importance of the stereochemistry in discussion of chemical reactivity is being widely recognized and nowadays considerable efforts are being devoted to the evaluation of the preferred molecular conformations (4–6). ^{1}H and ^{13}C NMR spectroscopy (4*a*, 7) and, more recently, MO calculations (4*b*, 5, 6, 8) have been successfully used in the elucidation of conformational preferences as well as in the evaluation of energy and entropy barriers.

In our kinetic studies (9, 10) on the mechanism of cyclization of substituted 2′-hydroxychalcones, assumptions were made about the preferred substrate conformations (mainly suggested by NMR determinations (9)), and some internal rotations were proposed to be involved in the rate-determining step (10). Since such conformational changes are not amenable to experimental determination and, curiously, some recent papers presume different substrate conformations (11, 12), the purpose of the present work was to study those points by SCF MO calculations.

Results and discussion

Method of calculation

The molecules under study are of a moderately large size, rendering an *ab initio* MO analysis too expensive. Turning our attention to semiempirical methods, several points are worthy of mention. Buemi *et al.* (13) reported that the MINDO/3 method is unable to differentiate between the *cis* and *trans* conformations of the methoxy moiety in 4-methoxy-2-nitroaniline. Using the PCILO method, problems have been met with optimization of the geometry (14). Although some shortcomings of CNDO/2 and INDO-like methods in describing conjugative effects are documented (15), they have been successful in showing relative stabilities and optimized geometries (6, 16). MNDO gives good heats of formation and relative reactivities but its weakness in accounting for hydrogen bonds is well known (ref. 1, and references therein). The INDO method was thus preferred for the purpose of this work: in some cases MNDO (1) calculations were also carried out and the results given for both methods were compared. Calculations were performed using the INDO method (17) with 3*d* orbitals included (18). The standard program was modified to an extended basis of maximum 99 atomic orbitals; consistency with experimental results, where data exist, gave us confidence in the method. The starting geometries were calculated using standard bond lengths and angles except for the following bonds: $C_{\alpha,\beta}$—H (19), C_{Ar}—O^-, C4—N, N—O, and ONO (20), for which optimized values of structurally related compounds were used.

Substrate conformation. Intramolecular hydrogen bonding

There has been considerable progress in theoretical and conceptual studies of hydrogen-bonded systems. In our previous kinetic studies (9) we proposed that compound **1** exists in

TABLE 1. Energy differences for several conformers of 2′-hydroxychalcone as a function of the O—H bond length and the COH bond angle[a]

Conformer	$d_{O—H}$, Å	COH angle, degrees								
		120	118	114	112	110	108	106	104	102
Structure[b]	0.97	12.8	11.9	105.1						
with	1.00							4.2	3.1	
intramolecular	1.05		4.3	2.2	1.3	0.7	0.3	0	0	0.3
H-bond	1.10			3.9	2.8			0.6	0.4	
	1.15			9.2						
Structure[c,d]	0.97	6.7								
without	1.00					1.5				
intramolecular	1.05			0.3	0.1	0	0.1	0.3		
H-bond	1.10					3.9		4.0		

[a]In kcal mol^{-1}, with respect to the most stable conformer.
[b]Minimum energy conformer: d = 1.07 Å, ∠COH = 105°.
[c]All the COH angles are negative (no intramolecular hydrogen bond).
[d]Minimum energy conformer: d = 1.03 Å, ∠COH = −110°.

the *trans-s-cis* conformation shown, suitable for the establishment of an intramolecular hydrogen bond. This was also suggested by analysis of IR data (21, 22) and by a Pariser–Parr–Pople (CNDO/S) calculation (23). In contrast, in recent papers (2, 3, 11, 12) the phenolic moiety is assumed to be in a conformation that does not allow the intramolecular H-bond. It was then of interest to investigate the degree of stabilization that could be achieved through the interaction involved in the hydrogen bond establishment.

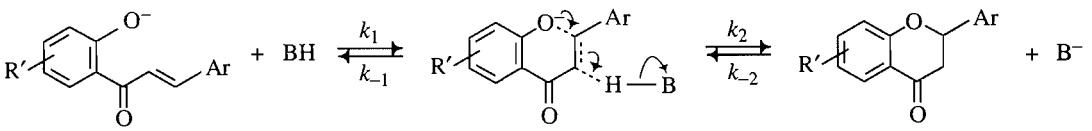
1

2 R = 4-NO_2 R′ = H
3 R = H R′ = H
4 R = 3-O^- R′ = H
5 R = 4-O^- R′ = H
6 R = H R′ = 4′-O^-

The search for the minimum energy structure in this case was performed by varying the C2′OH angle and the O—H length, d. Similarly, the most stable conformer with no hydrogen bond interaction was calculated by considering the 2′OH group rotated 180°. The results for 2′-hydroxychalcone are gathered in Table 1; they are given as the excess in total energy (in kcal mol^{-1}) with respect to the minimun energy conformer in each case, calculated from the plots of energy as functions of d and of the C2′OH (not shown). The difference in energy between the most stable conformers (d = 1.07 Å, C2′OH = 105°, and d = 1.03 Å, C2′OH = −110°, for the structures that are bonded and those that are not, respectively) is 13.7 kcal/mol, indicating the stabilizing effect of the intramolecular hydrogen bond. The calculated value compares satisfactorily with the experimental value (10.2 kcal/mol^{-1}) obtained by Shigorin (21) by IR determinations. The calculated dipolar moment, μ = 4.5 D, for the minimum energy conformer, is fairly close to the μ = 3.94 D found in dioxane solution (24). On the contrary, the MNDO results are not consistent with experimental data. In fact, when INDO geometries were allowed to optimize (OH length and C2′OH angle) by the MNDO procedure, not only the energies (the structure that is not H-bonded is 6 kcal/mol^{-1} more stable), but also the final values of the parameters (d = 0.94 Å, C2′OH = 121°, and d = 0.95 Å, C2′OH = −113°, for the structures with and without H-bonds, respectively) are not reasonable. As mentioned before, MNDO does not account for the H-bond stabilization.

Substituent effects on the H-bond strength were evaluated by similar calculations performed with substituted chalcones **2–6**, for which experimental data are not available. Geometry optimization was carried out by allowing variations in the O—H length and in C2′OH; the calculated values were plotted for each substituted chalcone as was done with **3**. The results are gathered in Table 2. Substituents on ring B have a strong influence on the strength of the H-bond since they only affect the electron density on the carbonyl group. It can be observed in Table 2 that electron-withdrawing groups reduce the strength whereas electron-attracting groups increase it. Comparison of the oxyanion group effect for the 4 and the 4′-positions reinforces this conclusion. The oxyanion in the 4′-position (chalcone **6**), negatively affects the charge distribution on the phenolic group, thus slightly weakens the H-bond. Considering the structure that is not H-bonded, there is an additional stabilization provided by the interaction between the O—H and 4′-O^-. Its magnitude was calculated from the difference between the total energy of the monoanion of resorcinol with the same values of O—H and COH and the energy of the minimum energy conformer of resorcinol (d = 1.07 Å, COH = 104°). This energy difference (0.65 kcal mol^{-1}) could be added to the calculated value in Table 2 for a best estimation.

From the above data it is clear that in all cases the H-bonded structure is preferred. The heat of formation of each 2′-oxyanion was determined experimentally (Table 2) and an acceptable qualitative correlation was found between these and the calculated H-bond energies (the stronger the H-bond, the higher the heat of formation of the corresponding chalconate). The only exception is compound **6**.



The atomic populations for both minimum energy conformers were calculated in each case, and also the atomic population involved in the intramolecular hydrogen bond, which is given in the last column of Table 2. It can be observed that there is good correlation of these data with the energy of the H-bond for the different compounds gathered in the table and also with the experimental ΔG; even compound **6** correlates well, which gives us confidence in the correction suggested.

SCHEME 1

In conclusion, taking into account all the above considerations, the H-bonded *trans-s-cis* conformation seems to be preferred in all the 2′-hydroxychalcones studied, and this conformation should be taken into account in mechanistic and spectroscopic studies on these compounds.

Internal rotations in the 2′-hydroxychalcone

In the mechanism we propose for cyclization in alkaline solution (9, 10) the H-bond is broken, the 2′–OH is converted into the oxyanion, and two internal rotations are needed: (a) rotation of ring A and (b) rotation about the single bond, which changes the *trans-s-cis* into the *trans-s-trans* conformer (Scheme 1).

INDO calculations of the rotation of ring A show that there is no rotational barrier. In fact, when ring A was allowed to rotate in steps of 30° from 0° to 180° in the 2′-chalconate the total energy steadily diminishes (Table 3). The total energy change involved in the rotation is −9.03 kcal mol^{-1}.

Figure 1 shows the charge distribution calculated for the 2′-chalconate in the new conformation (the values corresponding to the conformation shown by **1** are given in parentheses). It is clear from the values that the rupture of the H-bond and rotation of ring A produce a $+0.072e$ change in the H_α charge, which is responsible for the δ 0.35 downfield shift observed in the ^{1}H NMR spectrum for the H_α signal. Also, the change in the H_β charge distribution explains the observed NMR shift (0.25 upfield). These results confirm previous assignments of NMR signals (9).

Once ring A has rotated, a second rotation is needed in order to attain the required conformation for cyclization (see Scheme 1). Table 3 shows INDO calculations of the energy change for the *trans-s-cis* into the *trans-s-trans* 2′-chalconate. Sieiro *et al.* (25) found that the CNDO/2 method fails to predict the right values when the rotation axis is a delocalized bond. It is probable that something similar may occur with the INDO method due to the underestimation of the loss in π interaction. Nevertheless, although the absolute values of Table 3 likely do not represent the real data, it is clear that they show a minimum for a rotation angle close to 90° and then strong repulsive interaction in the last steps of the rotation (rotation angle >160°, where steric interactions between O$^-$ and H_β should be important). For the case of the vinyl-butadienyl-ketone rotation (26), a single energy minimum was found in the potential

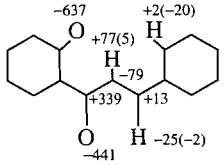

FIG. 1. Charge distribution ($10^{-3}e$) for the 2′-chalconate. Net atomic charges calculated for the minimum energy conformer of 2′-hydroxychalcone are shown in parentheses.

energy curve calculated by the CNDO/2 method. The same occurs in the present calculations; the minimum is reached when the styryl moiety is located perpendicular to the plane of the benzoyl system (Table 3).

The MNDO calculations shown in Table 4, although giving different ΔE values, show a similar trend, which leads to the same conclusions. An energy minimum is observed for a rotation angle of about 75° (estimated by the intercept of the curves in the energy vs. angle plot), and a strong barrier is encountered for a more advanced rotation (>150°). It can be observed in the table that for an intermediate rotation angle of around 120° there is no energy barrier, the distance 2′O...H_β is reasonable, and the distribution of net atomic charges favours the occurrence of the proposed mechanism (see Scheme 1).

In fact, both methods of calculation show that complete rotation of the styryl system encounters a strong barrier and it is unlikely to occur without some additional assistance.

In previous papers (9, 10) we proposed that complete rotation into the *trans-s-trans* conformation occurs in concert with proton addition to the C_α and phenoxide attack at the C_β. The proposal was based on the finding of general acid catalysis (9) and of huge isotope effects (10). The two concerted additions mentioned change the hybridization of the C_α and C_β in the transition state and contribute to diminishing the energy barrier as suggested by Tables 3 and 4. Data from both tables indicate that rotation to the *trans-s-trans* conformation takes place in the rate-determining step. This proposal finds strong support in the present results. In fact, the high electron density on C_α and the electron deficiency on C_β shown in Table 4, after enough rotation of the styryl system has occurred, tend to promote the reactions of the second step depicted in Scheme 1.

Conclusions

INDO calculations performed on several 2′-hydroxychalcones indicate the preferred conformation in each case and allow an estimate of the strength of the intramolecular hydrogen bond in the different minimum energy conformers. The calculated energies compare satisfactorily with experimental values when available, which gives us confidence in the method. Internal rotation of ring A and of the styryl system were also calculated: the first was found to occur spontaneously, while the second encounters a strong barrier in the last steps. MNDO calculations on this process show similar trends. These results are wholly consistent with previous proposals that the chalcones exist originally in the *trans-s-cis* conformation and cyclization to flavanones involves concerted rotation through the CO—C_α bond and annulation in the slow step. MNDO calculations afford strong support to the proposed mechanism for this step, but they do not account for the H-bond stabilization in the 2′OH-chalcone.

Thermodynamic treatment of multicomponent fused salt solutions: common anion reactive systems approximation

S. N. FLENGAS
Department of Metallurgy and Materials Science, University of Toronto, Toronto, Ont., Canada M5S 1A4
Received July 8, 1990

S. N. FLENGAS. Can. J. Chem. **69**, 870 (1991).

From a modified F.F.G. (1) thermodynamic cycle, equations have been developed from which the molar and partial molar excess thermodynamic properties of j-component molten salt solutions may be predicted from binary data.

The theory is applicable to reactive molten salt systems and particularly to charge asymmetric fused salt solutions with common anions.

It is shown that for a system having $j+1$ components, such as MX_q–AX–BX$\cdots$ $\cdots$JX, any molar or partial molar property of mixing for MX_q, may be calculated from available data on corresponding j-binary systems, such as MX_q–AX, MX_q–BX, and $\cdots MX_q$–JX.

The equations are of the general form,

$$\underset{(\text{in } j+1 \text{ component system})}{\Delta Z_{MX_q}} = \frac{X_2}{1-X_1}(\Delta Z_{MX_q})_{MX_q\text{–AX}} + \frac{X_3}{1-X_1}(\Delta Z_{MX_q})_{MX_q\text{–BX}} + \cdots + \frac{X_j}{1-X_1}(\Delta Z_{MX_q})_{MX_q\text{–JX}}$$

The latter is applicable only when the multicomponent and the binary solutions have the same MX_q content and same temperature.

The theoretical expressions have been found to predict quite well available data on ternary and quarternary systems.

New composition parameters for expressing the compositions in quarternary and quinary systems have been established.

Key words: molten salt solutions, multicomponent systems, ternary systems, quarternary systems, quinary systems.

S. N. FLENGAS. Can. J. Chem. **69**, 870 (1991).

Utilisant un cycle thermodynamique F.F.G. modifié, on a développé des équations à l'aide desquelles on peut prédire, à partir de données binaires, les propriétés thermodynamiques molaires et molaires partielles en excès de solutions de sels fondus à j-composantes.

On peut appliquer la théorie à des systèmes de sels réactifs et, en particulier, àdes solutions de sels fondus chargés d'anions communs.

On a démontré que — pour un système comportant $j+1$ composantes, comme MX_q–AX–BX$\cdots$ $\cdots$JX — on peut calculer toutes les propriétés molaires et molaires partielles de mélange de MX_q à partir des j systèmes binaires correspondants, comme MX_q–AX, MX_q–BX et $\cdots MX_q$–JX.

Les équations sont de la forme générale,

$$\underset{(\text{in } j+1 \text{ component system})}{\Delta Z_{MX_q}} = \frac{X_2}{1-X_1}(\Delta Z_{MX_q})_{MX_q\text{–AX}} + \frac{X_3}{1-X_1}(\Delta Z_{MX_q})_{MX_q\text{–BX}} + \cdots + \frac{X_j}{1-X_1}(\Delta Z_{MX_q})_{MX_q\text{–JX}}$$

La dernière n'est applicable que lorsque le multicomposant et les solutions binaires contiennent le même MX_q et qu'ils sont à la même température.

On a trouvé des expressions théoriques qui permettent de prédire assez bien les données disponibles des systèmes ternaires et quaternaires.

On a établi de nouveaux paramètres de composition pour exprimer les compositions dans des systèmes quaternaires et quinaires.

Mots clés: solutions de sels fondus, multicomposant systèmes, systèmes ternaires, systèmes quarternaires, systèmes quinaires.

[Traduit par la revue]

Introduction

The thermodynamic properties of binary fused salt solutions have been the object of several systematic investigations and extensive compilations of thermodynamic data are available.

However, similar information for ternary solutions is very limited and for quarternary systems there is hardly any information at all. Yet systems of industrial and of metallurgical importance are usually multicomponent, and the application of thermodynamics to the calculation of equilibria and to the efficiency of chemical reactions is usually restricted by the lack of the appropriate experimental data.

Regarding binary systems, an activity isotherm is usually obtained from about five experimental measurements. In a ternary system, the Gibbs isothermal surface may be covered with about 25 separate experiments on activities, and, for a quarternary system a minimum of about 200 experiments are needed in order to cover adequately the entire composition range. It is evident that the large number of experiments required have discouraged researchers from undertaking the systematic investigation of multicomponent systems.

Because of the shortage of experimental data, there is considerable theoretical and practical interest in the establishment of expressions from which the thermodynamic properties of ternary and quarternary molten salt systems may be predicted from available data on the corresponding binary solutions.

For ternary metallic solutions several such equations have been proposed. These include the analytical expressions by Kohler (2), Bonnier and Caboz (3), and Muggianu *et al.* (4), and those derived by Alcock and Richardson (5), and Toop (6).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

The relative merits of each of these expressions have been compared by Spencer *et al.* (7), Ansara (8), and Hillert (9).

In general, these expressions include terms representing the thermodynamic properties of the three binary component systems and differ mainly in the kind of composition parameters used and in the composition path to be followed within the ternary isothermal composition surface.

Saboungi and Blander (10) have extended the Conformal Ionic Solution theory to additive ternary molten salt solutions. However, the derived expressions were rather complex, and, even for mixtures of monovalent salts, they required fourth order terms. Their applicability to a large number of ternary charge asymmetric systems has not been demonstrated.

The thermodynamic properties of charge asymmetric molten salt solutions are of considerable theoretical and practical interest, as they are characterized by very low activity values and by highly exothermic enthalpies of mixing. This behaviour is usually interpreted as indicating strong interactions between the ionic specie in solution, and to the formation of complex species. To interpret such systems Pelton and Thompson (11) have proposed a Discrete Complex Anion Model which has been applied to systems such as binary $MgCl_2$-containing systems and to the system $MgCl_2$–NaCl–$CaCl_2$ (12).

In previous publications from this laboratory (13–17) a "hybrid" regular solution model representing the combination of a reaction mechanism followed by the regular mixing of the products of reaction, has been applied to the derivation of equations which allow the calculation of the thermodynamic properties of ternary and quarternary charge asymmetric fused salt solutions from the properties of the component binary systems. However, this model was based on the assumption that all complex-forming reactions proceeded to completion and the thermodynamic requirement of equilibrium between specie in solution was not considered.

In the present publication, equations relating thermodynamic properties of multicomponent, common anion charge asymmetric fused salt solutions to the properties of the component binary system, are derived using a modified form of the F.F.G. thermodynamic cycle (1) which is ideally suited to mixed equilibria. The theoretical treatment makes use of well established thermodynamic relationships and is applicable to systems in which all chemical reactions reach equilibrium.

For the treatment it is necessary to consider solutions that contain at least one charge asymmetric component, MX_q, as in the system, MX_q–AX–BX–$\cdots$ JX in which the components AX and BX etc. are acting as ligand donors for reactions like,

$$[1] \qquad MX_q + rAX \rightarrow A_rMX_{q+r}$$

An exact knowledge of the type or the stoichiometry of the complex specie formed is not required for the derivation of the thermodynamic relationships.

Thermodynamic treatment of multicomponent molten salt solutions

For the thermodynamic treatment a $j + 1$ component, common anion and charge asymmetric molten salt system, like the solution of MX_q–AX–BX$\cdots$JX, will be considered.

The derivation is based on a modified form of a thermodynamic cycle for successive reactions first proposed by Flood, Förland, and Grojtheim (1). The steps considered are given in Table 1.

The cycle consists of chemical reactions [*a*], [*b*] $\cdots$ [*j*] and of two mixing reactions [1] and [2]. Standard states are chosen as the pure molten salts at all temperatures. Mole numbers are taken as,

$$n_2 + n_3 + \cdots + n_j = 1$$

and the summation,

$$n_2MX_q + n_3MX_q + \cdots + n_jMX_q$$

represent 1 g. mol of pure molten MX_q. Through addition of reactions in the sequence [*a*] + [*b*] + $\cdots$ + [*j*] − [1] + [2], the overall reaction of MX_q with a mixed melt is obtained as reaction [3]. Reaction [3] may be taken as "standard" if the two solutions $[(AX)_{n_2}\cdot(BX)_{n_3}\cdots(JX)_{n_j}]$, and $[(A_rMX_{q+r})_{n_2}\cdot(B_rMX_{q+r})_{n_3}\cdots(J_rMX_{q+r})_{n_j}]$, are chosen as the "standard states" for the mixed system containing all species at their equilibrium compositions.

In Table 1 the "standard free energy" for reaction [3] is given by eq. [4] and it defines the mixed equilibrium constant K_M, as in eq. [5]. The "standard state" for MX_q is still the state of pure molten MX_q at all temperatures. For the other compounds JX and J_rMX_{q+r} etc., their standard states, respectively, are the above mentioned "mixed" solutions (Appendix 1).

From the well known relationships, [4] and [5*a*] in Table 1, eq. [5] may be written in terms of the partial molar free energies of mixing, $\overline{\Delta G_i}$, and is given as eq. [6]. The latter may be simplified through conversion of the standard states using eqs. [7] and [8], which are derived in Appendix 1.

From eqs. [3], [4], [6], [7], [8] and Appendix 1, eq. [9] is readily derived. In the latter the quantities $\overline{\Delta G}''_{JX}$ and $\overline{\Delta G}''_{J_rMX_{q+r}}$ represent partial molar Gibbs free energies of mixing; expressed with respect to pure molten JX and pure molten J_rMX_{q+r} as standard states, respectively, where J stands for A, B, $\cdots$ J.

Considering reactions [*a*], [*b*], [*c*] $\cdots$ [*j*] in Table 1, the equilibrium constant for a *j*-type reaction may be written in terms of activities as,

$$[j\text{-}1] \qquad k_j = \frac{a_{J_rMX_{q+r}}}{a_{MX_q}\cdot a_{JX}^{n_j}}$$

Following the same general method, as for the derivation of eq. 9 in Table 1, it is readily shown that for a binary system,

$$[j\text{-}2] \qquad \underset{(MX_q\text{–}JX)}{\overline{\Delta G}_{MX_q}} = \Delta G_j^0 - r\overline{\Delta G}''_{JX} + \overline{\Delta G}''_{J_rMX_{q+r}}$$

In this equation $\overline{\Delta G}''_{JX}$ and $\overline{\Delta G}''_{J_rMX_{q+r}}$ refer to the binary solution JX–MX_q at equilibrium. Standard states of reference are the pure molten salts.

From Table 1 equations similar to [*j*-2] may be derived for all the other complex forming reactions in binary solutions and are designated, respectively, as [*a*-2], [*b*-2], etc.

Considering solutions representing the same mole fraction for MX_q, it will be assumed that the partial molar Gibbs free energies of mixing for pairs like AX–A_rMX_{q+r}, BX–B_rMX_{q+r}, $\cdots$ JX–J_rMX_{q+r}, in the multicomponent system, have approximatley the same values as in the corresponding binary solutions.

The combination of eq. [9] with equations like [*a*-2], [*b*-2] $\cdots$ [*J*-2], yields eq. [10]. Also, by introducing eq. [11], the final expression [12] relating Gibbs free energies of mixing of multicomponent to binary systems is obtained.

TABLE 1. Equilibria in mixed systems

Equation	*Chemical reactions*	*Gibbs free energy*
[*a*]	$n_2\mathrm{MX}_{q(l)} + n_2 r\mathrm{AX}_{(l)} = n_2 A_r\mathrm{MX}_{q+r(l)}$	$n_2\Delta G^0_a$
[*b*]	$n_3\mathrm{MX}_{q(l)} + n_3 r\mathrm{BX}_{(l)} = n_3 B_r\mathrm{MX}_{q+r(l)}$	$n_3\Delta G^0_b$
[*j*]	$n_j\mathrm{MX}_{q(l)} + n_j r\mathrm{JX}_{(l)} = n_j \mathrm{J}_r\mathrm{MX}_{q+r(l)}$	$n_j\Delta G^0_j$
	Mixing reactions	
[1]	$n_2 r\mathrm{AX}_{(l)} + n_3 r\mathrm{BX}_{(l)} + \cdots n_j r\mathrm{JX}_{(l)} = r[(\mathrm{AX})_{n_2}\cdot(\mathrm{BX})_{n_3}\cdots(\mathrm{JX})_{n_j}]_{\text{solution}}$	$r\Delta G_{\mathrm{M}}$
[2]	$n_2\mathrm{A}_r\mathrm{MX}_{q+r(l)} + n_3\mathrm{B}_r\mathrm{MX}_{q+r(l)} + \cdots n_j\mathrm{J}_r\mathrm{MX}_{q+r(l)}$ $= [(\mathrm{A}_r\mathrm{MX}_{q+r})_{n_2}\cdot(\mathrm{B}_r\mathrm{MX}_{q+r})_{n_3}\cdots(\mathrm{J}_r\mathrm{MX}_{q+r})_{n_j}]_{\text{solution}}$	ΔG_{M}

where $n_2 + n_3 + \cdots n_j = 1$

From eqs [*a*] + [*b*] + $\cdots$ [*j*] − [1] + [2]

[3] $$\mathrm{MX}_{q(l)} + r[(\mathrm{AX})_{n_2}\cdot(\mathrm{BX})_{n_3}\cdots(\mathrm{JX})_{n_j}]_{\text{solution}} = [(\mathrm{A}_r\mathrm{MX}_{q+r})_{n_2}\cdot(\mathrm{B}_r\mathrm{MX}_{q+r})_{n_3}\cdots(\mathrm{J}_r\mathrm{MX}_{q+r})_{n_j}]_{\text{solution}}$$ (standard state reaction)

[4] $$\Delta G^0_{\mathrm{R,M}} = n_2\Delta G^0_a + n_3\Delta G^0_b + \cdots n_j\Delta G^0_j - r\Delta G_{\mathrm{M}(1)} + \Delta G_{\mathrm{M}(2)} = -RT\ln K_{\mathrm{M}}$$

[5] $$\mathrm{K_M} = \frac{a^{n_2}_{\mathrm{A}_r\mathrm{MX}_{q+r}}\cdot a^{n_3}_{\mathrm{B}_r\mathrm{MX}_{q+r}}\cdots a^{n_j}_{\mathrm{J}_r\mathrm{MX}_{q+r}}}{a^{n_2 r}_{\mathrm{AX}}\cdot a^{n_3 r}_{\mathrm{BX}}\cdots a^{n_j r}_{\mathrm{JX}}\cdot a_{\mathrm{MX}_q}}.$$

Standard states: for MX_q, the standard state is the pure molten MX_q; for $\mathrm{A}_r\mathrm{MX}_{q+r}$, $\mathrm{B}_r\mathrm{MX}_{q+r}$, $\cdots\mathrm{J}_r\mathrm{MX}_{q+r}$, the standard state is the solution $[(\mathrm{A}_r\mathrm{MX}_{q+r})_{n_2}\cdot(\mathrm{B}_r\mathrm{MX}_{q+r})_{n_3}\cdots(\mathrm{J}_r\mathrm{MX}_{q+r})_{n_j}]$; for AX, BX, $\cdots$ JX, the standard state is the solution $[(\mathrm{AX})_{n_2}, (\mathrm{BX})_{n_3}, \cdots(\mathrm{JX})_{n_j}]$.

[5*a*] From $\overline{\Delta G}_i = RT\ln a_i$

[6] $$\overline{\Delta G}_{\mathrm{MX}_q} = \Delta G^0_{R(\mathrm{M})} + \sum_{n_2}^{n_j} n_j\,\Delta G_{\mathrm{J}_r\mathrm{MX}_{q+r}} - \sum_{n_2}^{n_j} n_j\,\Delta G_{\mathrm{JX}}$$ $$(\mathrm{J} = \mathrm{A}, \mathrm{B}\cdots, \mathrm{J}\ \text{and}\ j = a, b, \cdots j)$$

	For the mixed system at a given composition (solutions as standard states)		In mixed system with respect to pure molten JX or $\mathrm{J}_r\mathrm{MX}_{q+r}$ as standard states		In solutions having compositions,* (*a*) $(\mathrm{AX})_{n_2}\cdot(\mathrm{BX})_{n_3}\cdots(\mathrm{JX})_{n_j}$ and (*b*) $(\mathrm{A}_r\mathrm{MX}_{q+r})_{n_2}\cdot(\mathrm{B}_r\mathrm{MX}_{q+r})_{n_3}\cdots(\mathrm{J}_r\mathrm{MX}_{q+r})_{n_j}$
[7]	$\overline{\Delta G}_{\mathrm{JX}}$	=	$\overline{\Delta G}''_{\mathrm{JX}}$	−	$\overline{\Delta G}'_{\mathrm{AX}}$
[8]	$\overline{\Delta G}_{\mathrm{J}_r\mathrm{MX}_{q+r}}$	=	$\overline{\Delta G}''_{\mathrm{J}_r\mathrm{MX}_{q+r}}$	−	$\overline{\Delta G}'_{\mathrm{J}_r\mathrm{MX}_{q+r}}$

* pure molten JX and $\mathrm{J}_r\mathrm{MX}_{q+r}$ as standard states

From [3], [4], [6], [7], [8], in a $n_j + 1$ component system,

[9] $$\begin{aligned}\overline{\Delta G}_{\mathrm{MX}_q} = {} & n_2\left[\Delta G^0_{\mathrm{R}(a)} - r\overline{\Delta G}''_{\mathrm{AX}} + \overline{\Delta G}''_{\mathrm{A}_r\mathrm{MX}_{q+r}}\right] + \\ & + n_3\left[\Delta G^0_{\mathrm{R}(b)} - r\overline{\Delta G}''_{\mathrm{BX}} + \overline{\Delta G}''_{\mathrm{B}_r\mathrm{MX}_{q+r}}\right] + \cdots \\ & + n_j\left[\Delta G^0_{\mathrm{R}(j)} - r\overline{\Delta G}''_{\mathrm{JX}} + \overline{\Delta G}''_{\mathrm{J}_r\mathrm{MX}_{q+r}}\right]\end{aligned}$$

For binary solutions having the same X_{MX_q}, in $n_j + 1$ component system, from eq. [9].

[10] $$\overline{\Delta G}_{\mathrm{MX}_{q(y)}} = n_2\left(\overline{\Delta G}''_{\mathrm{MX}_q}\right)_{\mathrm{MX}_q-\mathrm{AX}_{(y)}} + n_3\left(\overline{\Delta G}''_{\mathrm{MX}_q}\right)_{\mathrm{MX}_q-\mathrm{BX}_{(y)}} + \cdots n_j\left(\overline{\Delta G}''_{\mathrm{MX}_q}\right)_{\mathrm{MX}_q-\mathrm{JX}_{(y)}}$$

TABLE 1. (*concluded*)

Equation	*Chemical reactions*	*Gibbs free energy*

Also

[11] $$n_j = \frac{n_j/\sum n}{n_2 + n_3 + \cdots n_j/\sum n} = \frac{X_j}{X_2 + X_3 + \cdots X_j}$$

where X's are mole fractions.

In $n_j + 1$ component system

[12] $$\overline{\Delta G}_{MX_{q(y)}} = \frac{X_2}{X_2 + X_3 + \cdots X_j} (\overline{\Delta G}''_{MX_q})_{MX_q\text{–}AX(y)} + \frac{X_3}{X_2 + X_3 + \cdots X_j} (\overline{\Delta G}''_{MX_q})_{MX_q\text{–}BX(y)} + \cdots \frac{X_j}{X_2 + X_3 + \cdots X_j} (\overline{\Delta G}''_{MX_q})_{MX_q\text{–}JX(y)}$$

where MX_q–JX are binary systems

This expression allows the calculation of the activities of MX_q in a multicomponent system, from their values in the component binary systems, when the mole fraction of MX_q is the same throughout.

From the well known van't Hoff expression

[13] $$\left[\frac{d(\overline{\Delta G}_i)}{d\left(\frac{1}{T}\right)}\right]_{P,X_i} = \left[\frac{\overline{\Delta H}_i}{R}\right]_{\text{at same } X_i}$$

it is readily seen that partial molar enthalpies of mixing are also expressed by equations similar to eq. [12] in Table 1.

In general it may be shown that any molar or partial molar solution property for MX_q in a multicomponent system may be written as:

[14] $$\underset{(1,2\cdots J+1)}{\Delta Z_{MX_q}} = \frac{X_2}{1 - X_1} (\Delta Z_{MX_q})_{1,2} + \frac{X_3}{1 - X_1} (\Delta Z_{MX_q})_{1,3} + \cdots \frac{X_j}{1 - X_1} (\Delta Z_{MX_q})_{1,j}$$

where X_{MX_q} and temperature are the same for the multicomponent as for the binary mixtures.

The assumptions that the Gibbs partial molar free energies of mixing for components like JX and J_rMX_{q+r}, are "frozen" at their levels in the binary solutions for compositions representing the same MX_q content, have important structural and theoretical implications. They can only be valid if the cations A^+, B^+, and J^+ are randomly distributed and when short range interactions of the next neighbour type, like in a sequence A^+ X^- M^{q+}, are significant.

Ternary charge asymmetric fused salt solutions

The composition of a ternary system is usually represented by points within a Gibbs equilateral triangle. Pure components are situated at the corners, as shown in Fig. 1.

Any composition point P is found by drawing through P lines parallel to each of the three sides. The complement of the distance from each corner to the respective line through P gives the amount of the particular component. If the composition variable is the mole fraction, then the values thus calculated must satisfy the relationship

[15] $$X_1 + X_2 + X_3 = 1$$

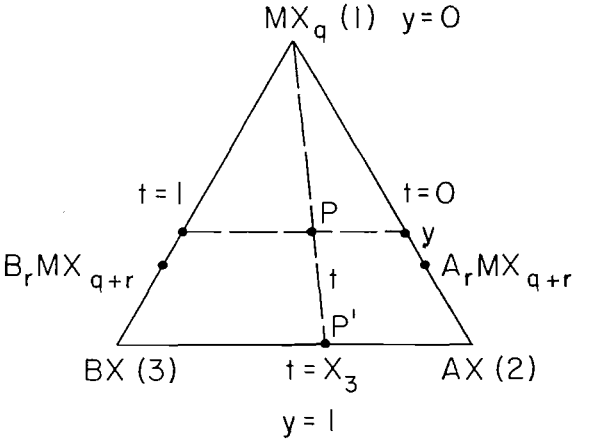

FIG. 1. Composition paths in a ternary system $t = X_3/(X_2 + X_3)$ and $y = 1 - X$.

where 1, 2, and 3 are components MX_q, AX, and BX, respectively.

A tie-line from 1 to the 2,3 binary represents compositions for which,

[16] $$t' = \frac{X_2}{X_3} = \text{constant}$$

but since t' goes to inifinity as X_2 goes to zero, it is more convenient to define

[17] $$t = \frac{X_3}{X_2 + X_3}$$

which varies from 0 and 1.

At constant X_i, the parameter y is defined as $y = 1 - X_1$. In the binary 1–2, $t = 0$, and in the binary 1–3, $t = 1$. For pure component 1, $y = 0$, and for all values of t in the 2–3 binary $y = 1$.

It is also readily calculated that

[19] $$X_1 = 1 - y$$

[20] $$X_2 = y(1 - t)$$

[21] $$X_3 = ty$$

from eqs. [12] and [5a] in Table 1, and eqs. [19], [20], [21],

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

the corresponding expressions for the activities and for the other molar and partial molar properties in ternary solutions are derived, respectively, as,

$$[22] \quad a_{MX_{q(1,2,3)_y}} = a^{(1-t)}_{MX_{q(1,2)_y}} \cdot a^{t}_{MX_{q(1,3)_y}}$$

and as,

$$[23] \quad \Delta Z_{MX_{q(1,2,3)_y}} = (1-t)\Delta Z_{MX_{q(1,2)_y}} + t\Delta Z_{MX_{q(1,3)_y}}$$

where 1,2 and 1,3 refer to the binary systems, AX–MX_q and BX–MX_q, respectively. ΔZ could represent molar volumes, enthalpies, or Gibbs free energies of mixing.

Quarternary charge asymmetric fused salt solutions

Compositions in a quarternary system are represented (18) by points within the volume of an equilateral tetrahedron, as shown in Fig. 2. The four vertices correspond to the pure components MX_q, AX, BX, and DX, and the edges represent the six binary systems MX_q–AX, MX_q–BX, MX_q–DX, AX–BX, BX–DX, and DX–AX.

The triangular faces represent the four ternary systems MX_q–AX–BX, MX_q–AX–DX, MX_q–BX–DX, and AX–BX–DX.

It is a property of all equilateral tetrahedra that lines originating from any internal point P, drawn parallel to the four different faces, have a total length equal to one edge, and each of these segments may be taken to define the mole fraction of a particular component occupying an apex.

In view of the complexity of such three-dimensional plots, useful composition paths have been defined mathematically, and the composition parameters, y, t, and S have been defined in terms of mole fractions by the following expressions (17):

$$[24] \quad y = 1 - X_1$$

where $1.0 > y > 0$

$$[25] \quad t = \frac{X_4}{X_3 + X_4}$$

where $1.0 > t > 0, t = 1$ along the MX_q–DX binary, and $t = 0$ along the MX_q–BX binary.

$$[26] \quad S = \frac{X_2}{X_2 + X_3 + X_4}$$

where $0 > S > 1, S = 1$ along the MX_q–AX binary and $S = 0$ for all compositions in the ternary MX_q–BX–DX.

Considering Fig. 2, in which MX_q is placed at the apex of the tetrahedron, constant "t" represents the pseudo-quarternary composition surface LMN. All compositions along that surface have in common the constant ratio of $X_4/(X_3 + X_4)$.

Also, constant "y" represents compositions along a pseudo-ternary surface parallel to the base of the equilateral tetrahedron having a constant X_{MX_q} content.

The intersection of the planes, t and y, defines the line "S".

The relationship between primary mole fractions and the composition parameters y, t, and S, is readily found as,

$$[27] \quad X_1 = X_{MX_q} = 1 - y$$

$$[28] \quad X_3 = y(1-t)(1-S)$$

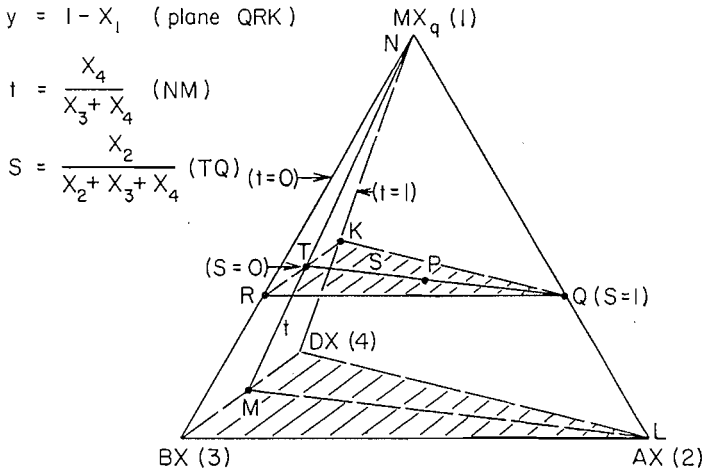

FIG. 2. Isothermal composition diagram in a quarternary system represented by an equilateral tetrahedron; t, y, S are composition parameters. Equilateral triangle QRK represents a section of the quarternary having the same MCl_q content.

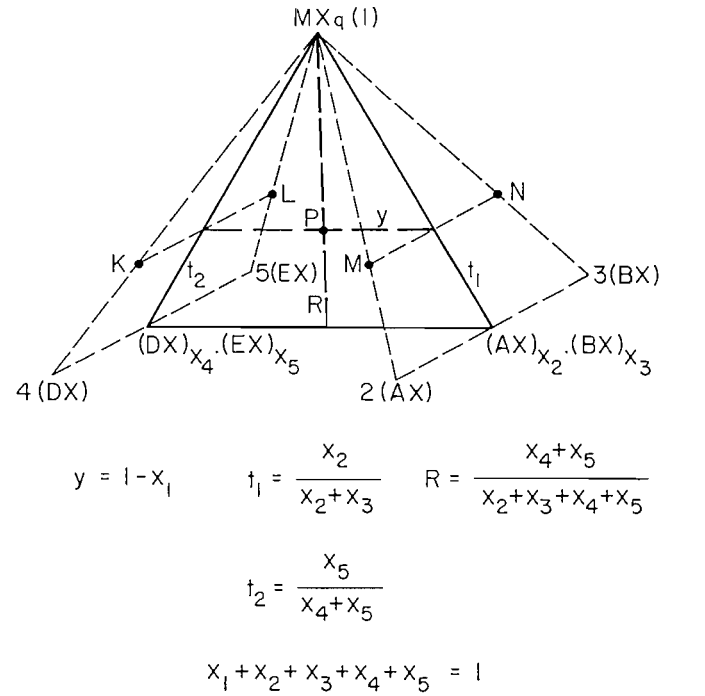

FIG. 3. Representation of compositions in a quinary system; y, t_1, t_2, R are composition parameters.

$$[29] \quad X_2 = ys$$

$$[30] \quad X_4 = ty(1-S)$$

Considering the S path QT, within the quarternary tetrahedron shown in Fig. 2, all compositions along QT have the same X_{MX_q} content and the same ratio of DX to BX. However, as S changes from 0 (point T) to 1 (point Q), the amount of AX in the quarternary changes in proportion to S (eg. [26]) and the value of any thermodynamic property measured along the S-composition path should reflect the reactivity of AX towards MX_q. In this melt, the ratio of DX/BX remains con-

For personal use only.

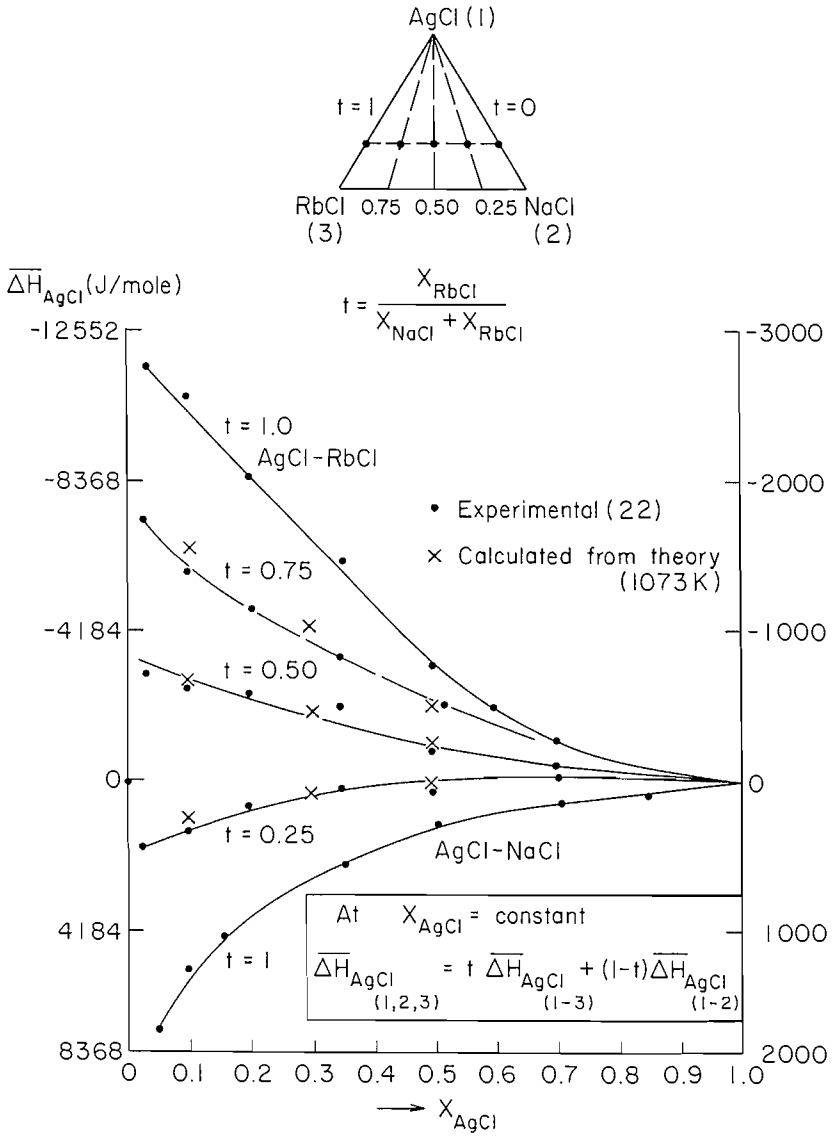

FIG. 4. Comparison between calorimetric and electrochemical data in the system NaCl–RbCl–AgCl.

stant, but the absolute amounts of these two components decrease as they are replaced by AX.

It follows that the y, S, and t parameters proposed in this paper define quarternary composition paths along which it is possible to follow the relative contributions of the various salt components to the magnitude of the thermodynamic properties of the solutions.

When expressions [27]–[30] are applied to the general expressions [12] and [5a], the corresponding equations for a quarternary system are derived as,

$$[31] \qquad a_{MX_{q(1,2,3,4)_y}} = a^{S}_{MX_{q(1,2)_y}} \cdot a^{(1-S)(1-t)}_{MX_{q(1,3)_y}} \cdot a^{t(1-S)}_{MX_{q(1,4)_y}}$$

and

$$[32] \qquad \Delta Z_{MX_{q(1,2,3,4)_y}} = S\Delta Z_{MX_{q(1,2)_y}} + (1-S)\left[t\Delta Z_{MX_{q(1,4)_y}} + (1-t)\Delta Z_{MX_{q(1,3)_y}}\right]$$

Extension of the theory to quinary molten salt solutions

For a five component system there is no simple geometric method for the graphic representation of the composition. In general, a $j+1$ component system requires plots in J dimensions (18, 19).

For the purpose of this treatment the composition of a five component system is represented on the surface of a Gibbs equilateral triangle in which the apex is occupied by the reactive molten MCl_q component and the other two vertices are occupied by solutions having fixed ratios of ligand donors (5), as in Fig. 3.

For the system MX_q–AX–BX–DX–EX having the mole fraction composition defined by x_1, x_2, x_3, x_4, and x_5, respectively, the composition parameters are defined as,

$$[33] \qquad y = 1 - x_1$$

$$[34] \qquad t_1 = \frac{x_3}{x_2 + x_3}$$

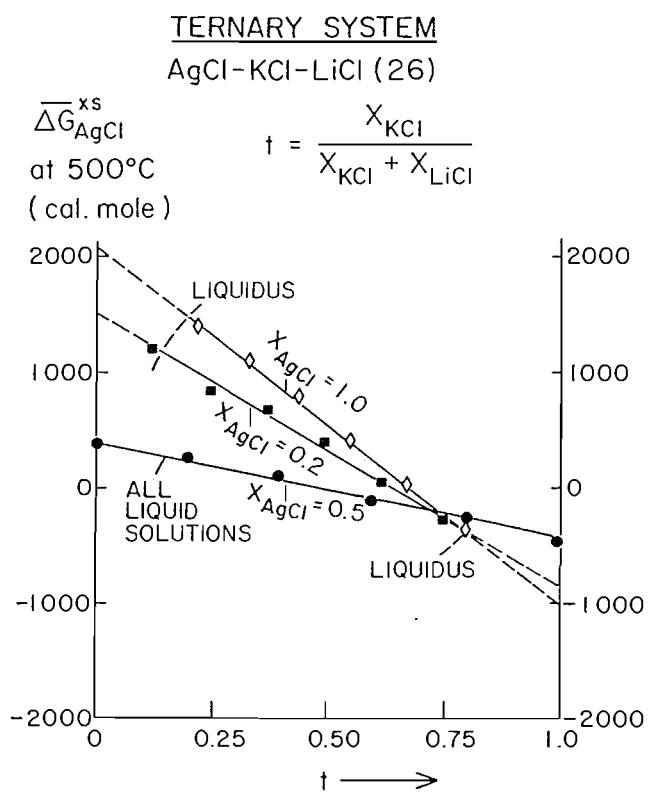

FIG. 5. Plots of $\overline{\Delta G}^{XS}_{AgCl}$ versus t for the ternary system AgCl–KCl–LiCl (26). Points are experimental. Straight lines have been calculated from eq. [23].

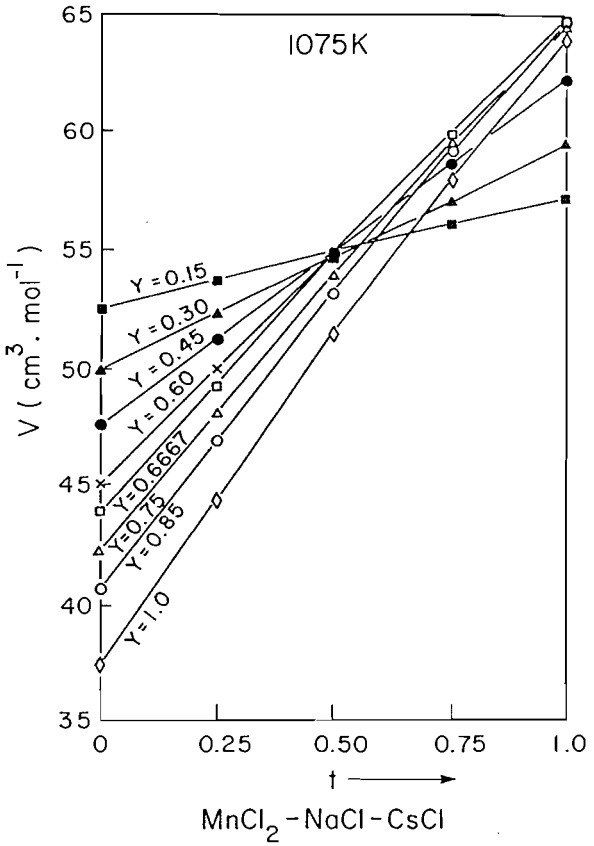

FIG. 6. Plots of the molar volumes V versus t for various y values in the ternary system $MnCl_2$–NaCl–CsCl (23) calculated from eq. [23].

[35] $$t_2 = \frac{x_5}{x_4 + x_5}$$

[36] $$R = \frac{x_2 + x_3}{x_2 + x_3 + x_4 + x_5}$$

The relationship between conventional mole fractions and the above composition parameters are readily derived as

[37] $$x_1 = 1 - y$$

[38] $$x_2 = yR(1 - t_1)$$

[39] $$x_3 = yRt_1$$

[40] $$x_4 = (1 - t_2)(1 - R)y$$

[41] $$x_5 = t_2(1 - R)y$$

Through introduction of eqs. [37]–[41], into eqs. [12] and [5a], the quinary system expressions are derived as,

[42] $$a_{\underset{(\text{In quinary})_y}{MX_q}} = a^{R(1-t_1)}_{MX_{q(1,2)_y}} \cdot a^{Rt_1}_{MX_{q(1,3)_y}} \cdot a^{(1-R)(1-t_2)}_{MX_{q(1,4)_y}} \cdot a^{(1-R)t_2}_{MX_{q(1,5)_y}}$$

Similarly,

[43] $$\Delta Z_{MX_{q(\text{quinary})_y}}$$

$$= (1 - R)\left[t_2 \Delta Z_{MX_{q(1,5)_y}} + (1 - t_2)\Delta Z_{MX_{q(1,4)_y}}\right]$$

$$+ R\left[t_1 \Delta Z_{MX_{q(1,3)_y}} + (1 - t_1)\Delta Z_{MX_{q(1,2)_y}}\right]$$

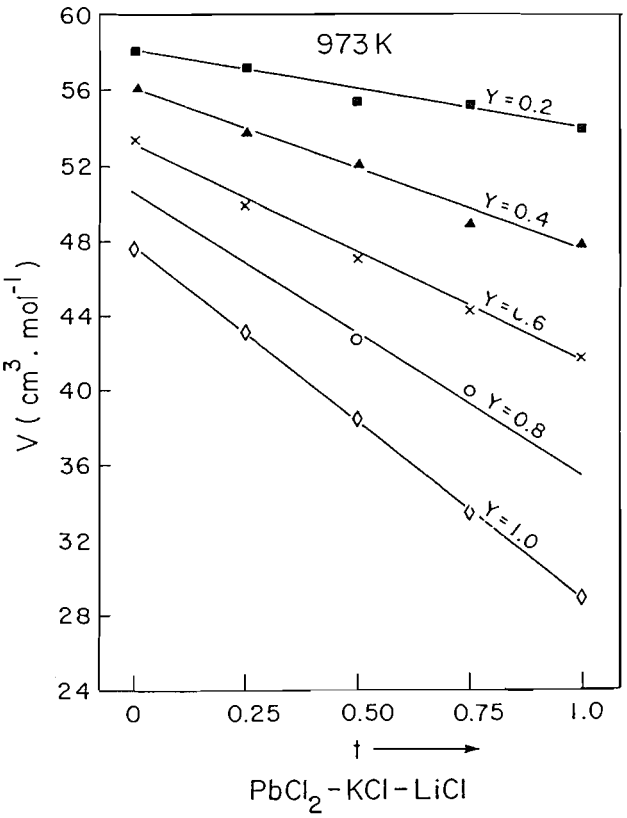

FIG. 7. Plots of the molar volumes versus t for various y values in the ternary system $PbCl_2$–LiCl–KCl (27). Points are experimental. Straight lines have been calculated from eq. [23].

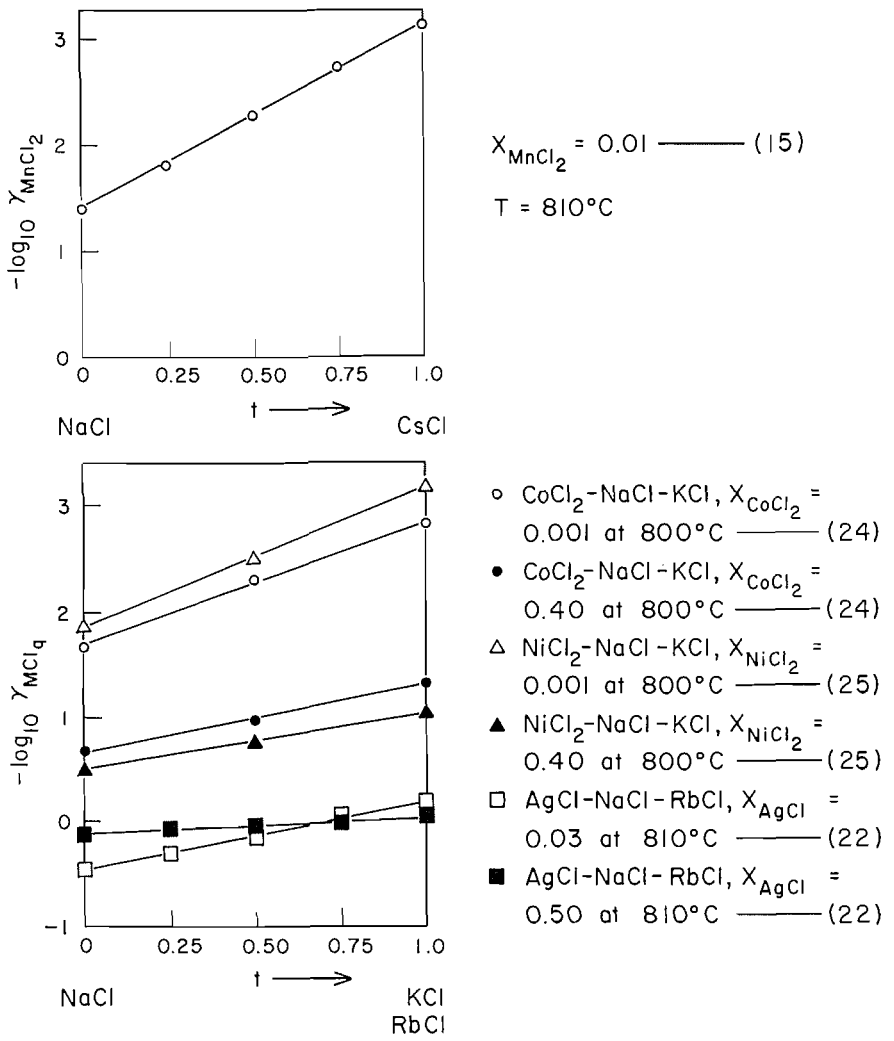

FIG. 8. log γ_{MCl_q} plotted as function of t for various systems. Points are experimental while straight lines have been calculated from eq. [22] expressed in terms of activity coefficients.

Limiting values for the y, t_1, t_2 and R terms are $y = 1$ for pure MX_q, $y = 0$ in the quarternary AX–BX–DX–EX, $t_1 = 1$ in pure AX, $t_1 = 0$ in pure BX, $t_2 = 1$ in pure EX, $t_2 = 0$ in pure DX, $R = 0$ in AX–BX binary, and $R = 1$ in DX–EX binary.

Equation [43] implies that the partial molar free energies of mixing for the reactive M_q component are linear functions of R, when y has a common value for the binary and the quinary solutions and t_1 and t_2 are fixed to represent given ratios.

Agreement with experimental evidence

There is overwhelming evidence for the validity of the expressions [22], [23], for "reactive" or charge asymmetric ternary systems, for which there is reliable information on the corresponding binaries.

Table 2 lists some of the ternary systems for which agreement between theory and experimental values is excellent.

For example, the binary systems AgCl–NaCl and AgCl–CsCl have been investigated by the emf method (31) and by calorimetry (32, 33). Enthalpy of mixing information on the binary NaCl–CsCl is also available (34) and the electrochemical and the calorimetric data are in very good agreement. The ternary system AgCl–NaCl–CsCl has been investigated by the emf method (21) and the comparison between experimental and calculated excess free energies of mixing is excellent.

The binary systems AgCl–NaCl and AgCl–RbCl have been investigated in this laboratory (31) and by Kleppa and associates (32, 33) calorimetrically.

These data indicate that the NaCl–AgCl system exhibits exothermic enthalpies of mixing, while the RbCl–AgCl system mixes endothermically and should be described as a "reactive system". The ternary system AgCl–NaCl–RbCl has also been investigated by the emf method in this laboratory (22) and, as shown in Fig. 4, there is excellent agreement between experimental and calculated molar enthalpies of mixing over the entire composition range.

Plots of $\overline{\Delta G}^{XS}_{AgCl}$ versus t for the system AgCl–KCl–LiCl investigated by Gruner and Thompson (26), shown in Fig. 5, are also linear, indicating the compliance of this system with eq. [22].

The $MnCl_2$ – alkali chloride systems are of interest as they demonstrate negative deviations from ideality, which increase dramatically from the $MnCl_2$–NaCl to the $MnCl_2$–CsCl binary.

For these systems the agreement between the calorimetric (34) and the electrochemical (35) enthalpies of mixing is very good. For the ternary $MnCl_2$–NaCl–CsCl (23) molar volumes calculated from the corresponding expression

$$[44] \qquad V^{\text{ternary}}_{1,2,3} = (1-t)V_{(1,2)_y} + tV_{(1,3)_y}$$

Quarternary system	Method/property	T (°C)	Authors
$MnCl_2$–NaCl–KCl–CsCl	EMF/$(E - E^0)$	650–850	Pickles and Flengas (17)

are shown in Fig. 6, and indicate excellent agreement with the experimental data.

Molar volumes for the system $PbCl_2$–LiCl–KCl, measured by Gutierrez and Toguri (27) and shown in Fig. 7, are in excellent agreement with calculated values from binary data using eq. [23].

Figure 8 demonstrates the validity of eq. [22] in a number of ternary systems.

Agreement between experimental and calculated partial molar free energies of mixing is also found for the systems $MgCl_2$–NaCl–KCl and $PbCl_2$–LiCl–KCl, as shown in Fig. 9.

The recently reported NaCl–$CaCl_2$–$MnCl_2$ system is of interest as it represents a ternary containing two ligand acceptors, e.g. $CaCl_2$ and $MgCl_2$, and NaCl as the single ligand donor.

If $t = X_{MgCl_2}/(X_{CaCl_2} + X_{MgCl_2})$ and NaCl is placed at the apex of the Gibbs triangle, the calculated and experimental enthalpies of mixing shown in Table 3 are in good agreement with theory, considering that the ternary Gibbs–Duhem had been used for the calculation of the activities for the three components (12)

Similar agreement between experimental data and theory is demonstrated by all the systems given in Table 2.

Regarding quarternary systems, the only system which has been systematically investigated by the emf method is the system $MnCl_2$–NaCl–KCl–CsCl (17).

From available data on binary systems (35), the theoretical plot of $\overline{\Delta G}_{MnCl_2}$ as a function of S for a number of t values

TABLE 3. Integral enthalpies of mixing in the system NaCl–$MgCl_2$–$CaCl_2$ (26) for $t = X_{CaCl_2}/(X_{CaCl_2} + X_{MgCl_2})$ and $y = 1 - X_{NaCl}$

		ΔH_M (J/mol)

0.85	0.18	−2 509	−2 748

*From ternary Gibbs–Duhem integration (12). Only the a_{MgCl_2} in the ternary was measured electrochemically.

†From calorimetric data on the binary systems NaCl–$MgCl_2$ and NaCl–$CaCl_2$.

[32] $\Delta H_{M(1,2,3)} = (1 - t)\ \underset{(NaCl-CaCl_2)}{\Delta H_M} + t\ \underset{(NaCl-CaCl_2)}{\Delta H_M}$

which cover entire y-planes within the quarternary, has been calculated from eq. [31].

Figures 10*a*, 10*b*, 10*c*, and 10*d* show the actual comparison between experimental (17) and calculated values of $\overline{\Delta G}_{MnCl_2}$ for four different y compositions.

It is seen that all compositions along a constant y-plane,

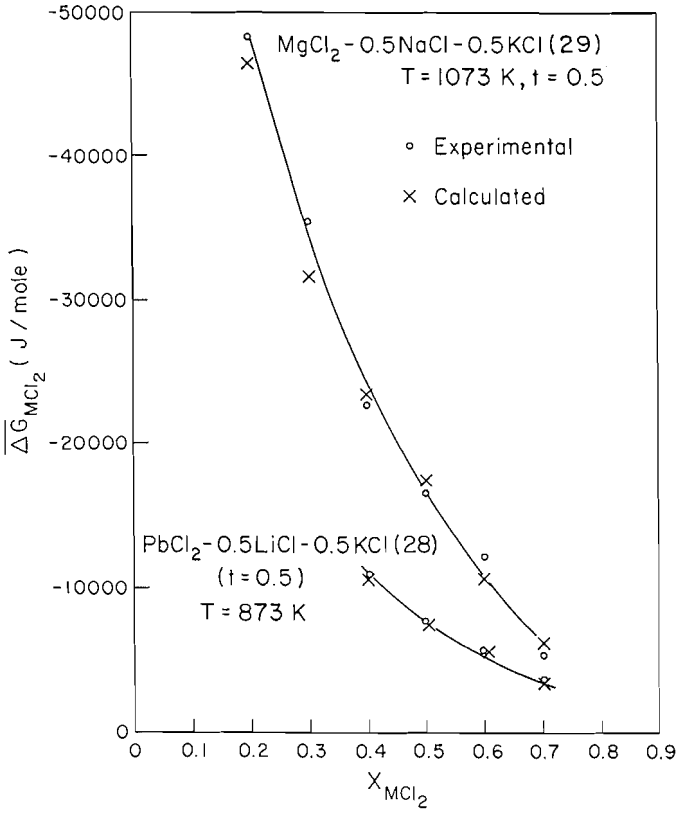

FIG. 9. Plots of $\overline{\Delta G}_{MCl_2}$ versus X_{MCl_2} for $t = 0.5$ for the systems $PbCl_2$–LiCl–KCl (28) and $MgCl_2$–NaCl–KCl (29).

which are obtained when t is changed from 0 to 1, are represented by a family of curves which are terminated in the three component binary systems, as shown on the graph.

Equations [31] and [32] are applicable only if the ligand acceptor component $MnCl_2$ is placed at the apex of the tetrahedron, while the three ligand donors, namely NaCl, KCl, and CsCl, are located at the three remaining vertices.

In a recent publication (38) from this laboratory "formal" formation potentials in the dilute solutions of the binary systems $CoCl_2$–ACl, $NiCl_2$–ACl, $FeCl_2$–ACl, $FeCl_3$–ACl, $CrCl_2$–ACl, $CrCl_3$–ACl, CuCl–ACl, $CuCl_2$–ACl, and $ThCl_4$–ACl where A was respectively NaCl, KCl, or CsCl, were investigated by emf measurements. Also, "formal" potentials were measured in the corresponding ternary systems in which the solvents were respectively the equimolar mixtures NaCl–KCl, NaCl–CsCl and KCl–CsCl.

In all cases it was shown that the "formal" formation potentials of the ternary systems were in good agreement to within 2 to 5% with values calculated from the theoretical expression,

$$[45] \qquad E^0_{f(1,2,3)} = (1-t)E^0_{f(1,2)_y} - tE^0_{f(1,3)_y}$$

which is equivalent to eq. [32] written for an excess partial molar free energy.

Standard "formal" potentials, E^0_f, are related to the usual "standard" potentials, E^0_s, by the well-known relationship

$$[46] \qquad E^0_f = E^0_s - \frac{RT}{ZF} \ln \gamma_n$$

where γ_n is the Henrian activity coefficient for a salt in solution. In such dilute solutions the formation of a complex species and its coordination is expected to have reached a limiting value and a complex should remain unchanged over the entire "Henrian" concentration range.

Therefore, dilute solutions ought to be ideally suited for investigating relationships between multicomponent and their component binary systems.

Conclusions

It has been shown that the thermodynamic properties of non-ideal and non-regular charge asymmetric fused salt systems may be predicted from data on the component binary systems, along isothermal composition paths representing a constant content of the charge asymmetric or reactive component MX_q.

Although the derivation of eqs. [22] and [23] for ternary systems, [31] and [32] for quarternary systems, and [42] and [43] for quinary systems, have been based on assumptions that complexes are formed, such assumptions are not really necessary. Any kind of internal reactivity should satisfy the theoretical treatment and the derived expressions should be applicable.

Regarding quarternary systems, the introduction of the composition parameters y, t, and S serves in the planning of experiments and in reducing the large numbers of compositions to be studied in order to adequately characterize a quarternary system. The use of these composition parameters makes it possible to plot thermodynamic data along well-defined composition paths and to identify the effects of competing interactions on a charge asymmetric cation. For example, the different complexing effects of CsCl or KCl on $MnCl_2$ become evident as the quarternary solutions become richer in CsCl or KCl, respectively.

The successful application of eqs. [22], [23], [31], and [32] to non-ideal charge asymmetric fused-salt solutions indicates that in ternary, quarternary, and possibly even in higher order systems, reactions within the binary solutions account for most of the internal reactivity which is responsible for deviations from ideality.

In quarternary systems which may deviate from eq. [31] or [32], plots such as Figs. 10*a*, 10*b*, 10*c*, and 10*d* are useful in that they display the thermodynamic data in a systematic way. For example, isoactivity paths are readily obtained, and activity plots covering an entire S-composition surface are readily constructed.

Regarding five component systems, an experimental verification of the derived expressions could not be made at this time, because of the lack of the appropriate experimental data. However, in systems for which the ternary and the quarternary approximations have been found to be applicable, it is reasonable to expect that the corresponding five component systems should also approximately obey eqs. [42] and [43].

The present treatment takes into account that reacting systems reach equilibrium and it should not be described as a "model". The formulation of specific complex species is not required except in a most general way. Equation [9] is derived on the basis of a rigorous thermodynamic cycle and the generic eq. [10] is justified on the assumptions that the partial molar properties for the alkali chlorides and for the complex compounds are "frozen" at their levels in the corresponding binary solutions at same MCl_q content. Such assumptions are expected to be valid only if short range coulombic interactions are truly significant and if the cations A, B, ⋯, J are randomly distributed in the multicomponent mixed melt.

Although an exact knowledge of the structure of complexes is not necessary for the thermodynamic treatment, there are certain indirect indications regarding their probable configu-

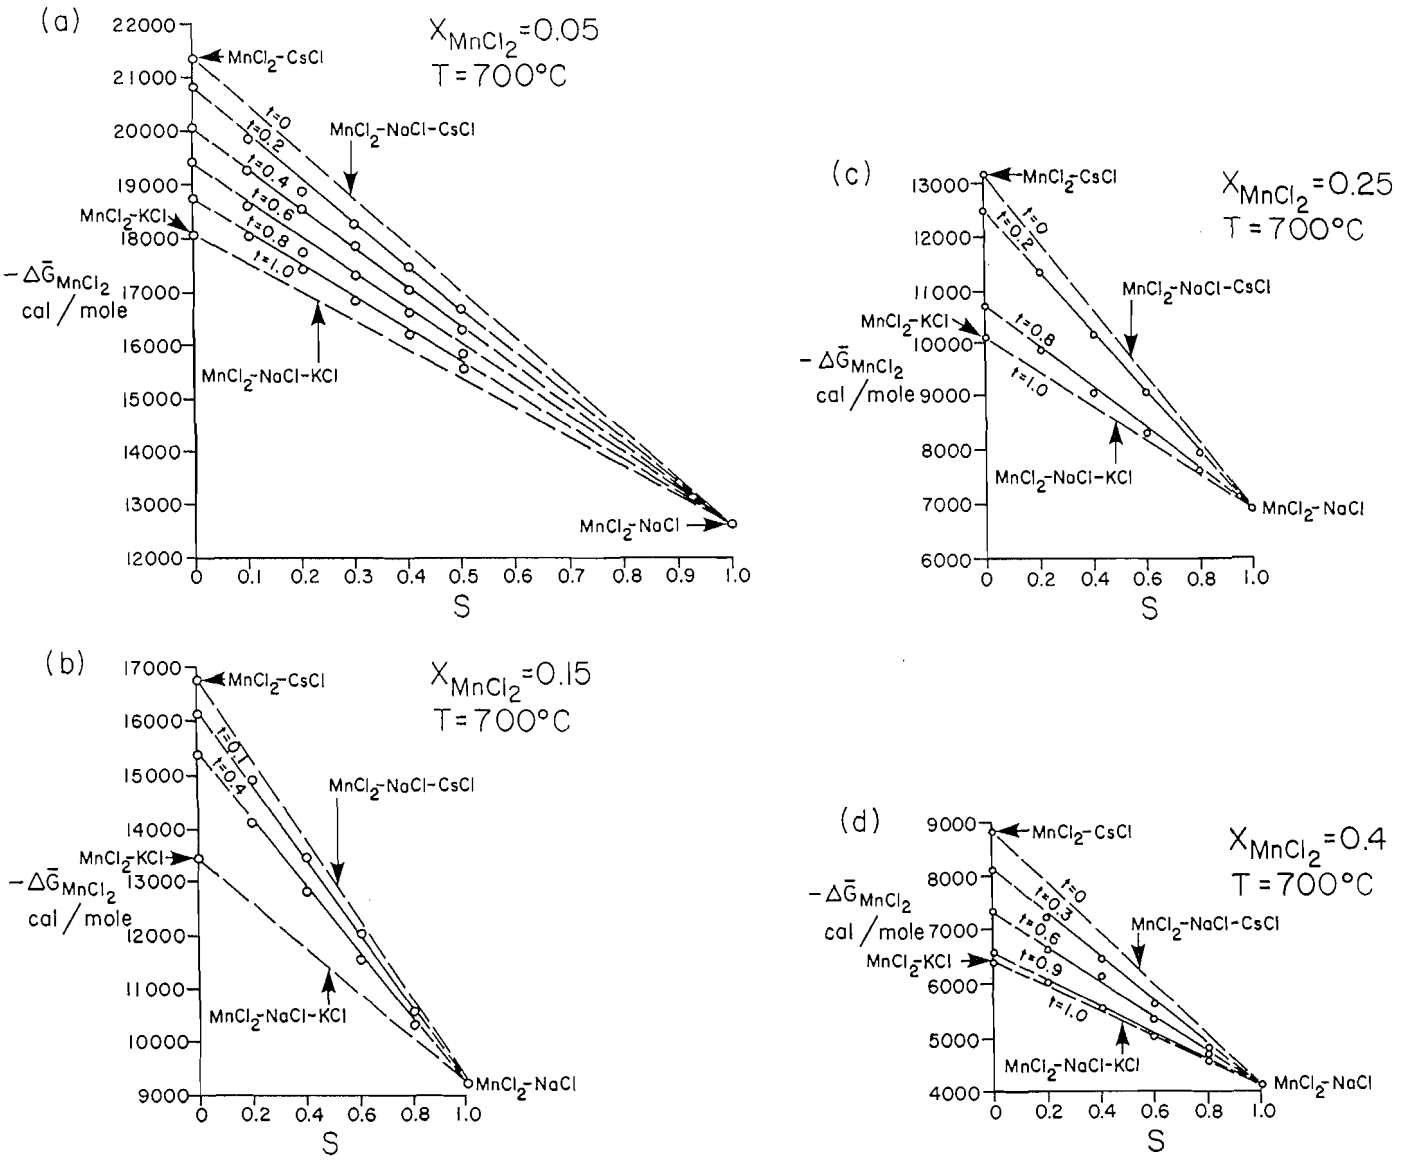

FIG. 10 (a–d). Excess partial molar free energies of mixing for the quarternary system $MnCl_2$–NaCl–KCl–CsCl (17) as functions of s and for various t values. Points are experimental. Straight lines are theoretical.

ration. For example, structural evidence (39) as well as measurements of electrical conductivities and molar volumes (23) suggest that solutions of $MnCl_2$ in alkali chloride melts appear to contain tetrahedrally coordinated complexes of the type $MnCl_4^{2-}$. Similarly, thermodynamic evidence indicates that the solutions of $ZrCl_4$, $HfCl_4$, $NbCl_5$, and $TaCl_5$ (36, 37) in alkali chlorides contain octahedrally coordinated complexes of the type MCl_6^{2-} or MCl_6^-. In all these systems, the negative deviations from ideality increase as the size of the alkali metal cation increases as in the sequence LiCl–NaCl–KCl–RbCl–CsCl (36, 37).

These trends reflect the effects of competing interactions between the M^{q+} and alkali metal cations for the same Cl^- anions, in which the alkali chloride acts as a ligand donor and the reactive metal chloride MCl_q is the ligand acceptor. Alkali metal cations like Li^+, because of their small ionic radius are strongly attracted to their chloride anions and effectively the LiCl salt is less "dissociated" than other alkali metal chlorides containing larger cations like K^+, Rb^+, or Cs^+. The difference in the strength of the complexes which are formed when a reactive metal chloride MCl_q is mixed with either of the alkali chlorides ACl or BCl should be reflected by the difference in the bond distances in configurations of the type M—Cl—A or M—Cl—B.

Summary

(A) For a multicomponent system MX_q–M_2AX–$n_3BX\cdots n_jJX$ where $n_2 + n_3 + \cdots + n_j = 1$, $X_2 + X_3 + \cdots + X_j = 1 - X_1$,

[S-1] $$\Delta Z_{MX_q} = \frac{X_2}{1-X_1}\left(\Delta Z_{MX_q}\right)_{AX\text{-}MX_q} + \frac{X_3}{1-X_1}\left(\Delta Z_{MX_q}\right)_{BX\text{-}MX_q} + \cdots + \frac{X_j}{1-X_1}\left(\Delta Z_{MX_q}\right)_{JX\text{-}MX_q}$$

for X_{MX_q} values which are the same in the binary and in the multicomponent systems.
ΔZ is any partial or molar solution property.

(*B*) For a ternary system MX_q–n_2AX–n_3BX

$$y = 1 - X_{MX_q} = 1 - X_1 \qquad \overline{\Delta H}_{MX_{q(y)}} = (1-t)\overline{\Delta H}_{MX_{q(1,2)(y)}} + \overline{\Delta H}_{MX_{q(1,3)(y)}} \qquad \text{[S-2]}$$

$$t = \frac{X_3}{X_2 + X_3} \qquad (1,2,3)$$

or

$$X_1 = 1 - y \qquad a_{MX_{q(1,2,3)(y)}} = \left(a^{1-t}_{MX_q}\right)_{1,2(y)} \left(a_{MX_q}\right)^{t}_{1,3(y)} \qquad \text{[S-3]}$$

$$X_2 = y(1-t)$$

$$X_3 = ty$$

For a quarternary system MX_q–n_2AX–n_3BX–n_4CX

$$y = 1 - X_1 \qquad \overline{\Delta H}_{MX_{q(y)}} = S\left(\overline{\Delta H}_{MX_q}\right)_{1,2(y)} + (1-S)\left[t\left(\overline{\Delta H}_{MX_q}\right)_{1,4(y)} + (1-t)\left(\overline{\Delta H}_{MX_q}\right)_{1,3(y)}\right] \qquad \text{[S-4]}$$

$$t = \frac{X_4}{X_3 + X_4} \qquad (1,2,3,4)$$

$$S = \frac{X_2}{X_2 + X_3 + X_4}$$

or

$$X_1 = 1 - y \qquad a_{MX_{q(y)}} = a^{S}_{MX_{q(1,2)(y)}} \cdot a^{(1-S)(1-t)}_{MX_{q(1,3)(y)}} \cdot a^{t(1-S)}_{MX_{q(1,4)(y)}} \qquad \text{[S-5]}$$

$$X_2 = yS$$

$$X_3 = y(1-t)(1-S) \qquad (1,2,3,4)$$

$$X_4 = yt(1-S)$$

For a quinary system MX_q–n_2AX–n_3BX–n_4CX–n_5DX

$$y = 1 - X_1 \qquad \overline{\Delta H}_{MX_{q(y)}} = (1-R)\left[t_2\left(\overline{\Delta H}_{MX_q}\right)_{1,5(y)} + (1-t_2)\left(\overline{\Delta H}_{MX_q}\right)_{1,4(y)}\right] + \qquad \text{[S-6]}$$

$$t_1 = \frac{X_3}{X_2 + X_3} \qquad (1,2,3,4,5)$$

$$t_2 = \frac{X_5}{X_4 + X_5} \qquad R\left[t_1\left(\overline{\Delta H}_{MX_q}\right)_{1,3(y)} + (1-t_1)\left(\overline{\Delta H}_{MX_q}\right)_{1,2(y)}\right]$$

$$R = \frac{X_2 + X_3}{X_2 + X_3 + X_4 + X_5}$$

or

$$X_1 = 1 - y \qquad a_{MX_q(y)} = a^{R(1-t_1)}_{MX_{q(1,2)(y)}} \cdot a^{Rt_1}_{MX_{q(1,3)(y)}} \cdot a^{(1-R)(1-t_2)}_{MX_{q(1,4)(y)}} \cdot a^{(1-R)t_2}_{MX_{q(1,5)(y)}} \qquad \text{[S-7]}$$

$$X_2 = y(1-t_1)R$$

$$X_3 = yRt_1$$

$$X_4 = y(1-t_2)(1-R) \qquad X_{MX_q} = \text{Common}$$

$$X_5 = yt_2(1-R)$$

Appendix 1. Standard state conversion

Considering reaction [3] at equilibrium, the "overall" mixed system contains species such as MX_q, AX,$\cdots$JX and $A_rMX_{q+r}, \cdots J_rMX_{q+r}$, at their equilibrium concentrations which are determined by the condition that $\Delta G_R = 0$.

Reaction [3] could also be taken as "standard", if the solutions

$$[(AX)_{n_2} \cdot (BX)_{n_2} \cdots (JX)_{n_j}]$$

and

$$[(A_rMX_{q+r})_{n_2} \cdot (B_rMX_{q+r})_{n_3} \cdots (J_rMX_{q+r})_{n_j}]$$

where

$$n_2 + n_3 + \cdots + n_j = 1$$

are taken as the "standard states" in the "overall mixed" system which contains all of the above species.

For components AX, BX, $\cdots$ JX in this "overall mixed" melt, the standard state is the solution of fixed composition given as $[(AX)_{n_2} \cdot (BX)_{n_3} \cdots (JX)_{n_j}]$, at all temperatures.

Similarly, the standard state for either A_rMX_{q+r}, $B_rMX_{q+r}, \cdots$ and J_rMX_{q+r}, is the solution containing n_2 moles, A_rMX_{q+r}, n_3 moles B_rMX_{q+r}, and $\cdots n_j$ moles J_rMX_{q+r}. The terms $r\Delta G_{m(1)}$ and $\Delta G_{M(2)}$ in eq. [4] of Table 2 are readily eliminated during the conversion of the standard states to those representing the pure liquids at same temperatures. $\overline{\Delta G}_{MX_q}$ represents the partial molar Gibbs free energy of mixing for pure molten MX_q, as before.

Activities are defined by relationships like

$$[A\text{-}1] \qquad a_{JX\ (\text{in "mixed" melt})} = \frac{(P_A) \text{ over "mixed" melt}}{(P_A^1) \text{ over "standard" solution } [(AX)_{n_2} \cdot (BX)_{n_3} \cdots (JX)_{n_j}]}$$

and

$$[A\text{-}2] \qquad a_{J_rMX_{q+r}\ (\text{in "mixed" melt})} = \frac{(P_{J_rMX_{q+r}}) \text{ over "mixed" melt}}{(P^1_{J_rMX_{q+r}}) \text{ over "standard" solution } [(A_rMX_{q+r}) \cdots (J_rMX_{q+r})]}$$

For conversion purposes Gibbs free energies will be defined as follows: $\bar{G}_{JX}$ = for JX in the "overall" mixed system at the equilibrium composition (reaction [3] at equilibrium); G^0_{JX} = for pure molten JX; and $\bar{G}'_{JX}$ for JX in the "standard" solution $[(AX)_{n_2} \cdot (BX)_{n_3} \cdots (JX)_{n_j}]$.

Gibbs free energies of mixing may be expressed in terms of the two different standard states given. These are

$$[A\text{-}3] \qquad \overline{\Delta G}''_{JX\ (\text{in "mixed" system})} = \bar{G}_{JX} - G^0_{JX}$$

$$[A\text{-}4] \qquad \overline{\Delta G}'_{JX\ (\text{in "standard" solution})} = \bar{G}'_{JX} - G^0_{JX}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

and,

[A-5] $$\underset{\text{(in "mixed" system)}}{\overline{\Delta G}_{JX}} = \bar{G}_{JX} - \bar{G}'_{JX}$$

From eqs. [A-3], [A-4], and [A-5],

[A-6] $$\overline{\Delta G}_{JX} = \overline{\Delta G}''_{JX} - \overline{\Delta G}'_{JX}$$

Similarly, considering the standard states for pure molten J_rMX_{q+r} as $G^0_{J_rMX_{q+r}}$ and of J_rMX_{q+r} in the standard solution $(A_rMX_{q+r})_{n_2} \cdot (B_rMX_{q+r})_{n_3} \cdots (J_rMX_{q+r})_{n_j}$ as $\overline{G}'_{J_rMX_{q+r}}$, it is possible to relate the partial molar Gibbs free energy of mixing for J_rMX_{q+r}, by the expression

[A-7] $$\overline{\Delta G}_{J_rMX_{q+r}} = \underset{\text{[A-5]}}{\overline{\Delta G}''_{J_rMX_{q+r}}} - \overline{\Delta G}'_{J_rMX_{q+r}}$$

where $\overline{\Delta G}''_{J_rMX_{q+r}}$ is the Gibbs free energy of mixing for J_rMX_{q+r} with respect to the state of J_rMX_{q+r} in the "standard" solution.

Equations [A-6] and [A-7] in this appendix are also listed as eqs. [7] and [8] in Table 1.

Solvent structure effects on solvated electron reactions with ions in 2-butanol/water mixed solvents

SEDIGALLAGE A. PEIRIS AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 27, 1990

SEDIGALLAGE A. PEIRIS and GORDON R. FREEMAN. Can. J. Chem. **69**, 884 (1991).

The Smoluchowski–Debye–Stokes–Einstein equation for the rate constant k_2 of a bimolecular reaction between charged or polar species

$$k_2 = \kappa RTfr_r/1.5\eta r_d$$

was used to evaluate effects of bulk solvent properties on reaction rates of solvated electrons with $NO_{3,s}^-$, H_s^+, Tl_s^+, Cu_s^{2+}, and Al_s^{3+} in 2-butanol/water mixed solvents. To explain detailed effects it was necessary to consider more specific behavior of the solvent. Rate constants k_2, activation energies E_2, and pre-exponential factors A_2 of these reactions vary with the composition of 2-butanol/water mixtures. The values of E_2 were in general similar to activation energies of ionic conductance $E_{\Lambda 0}$ of the solutions, except for much higher values of E_2 of (e_s^- + $NO_{3,s}^-$) in alcohol-rich solvents and of (e_s^- + Al_s^{3+}) in pure water solvent. The solvent apparently participates chemically in the $NO_{3,s}^-$ reaction, and the Al_s^{3+} reaction is multistep. Rate constant and conductance measurements of thallium acetate solutions in 2-butanol containing zero and 10 mol% water were complicated by the formation of ion clusters larger than pairs.

Key words: alcohol/water mixed solvents, ions, reaction kinetics, solvated kinetics, solvated electron, solvent effects.

SEDIGALLAGE A. PEIRIS et GORDON R. FREEMAN. Can. J. Chem. **69**, 884 (1991).

On a utilisé l'équation de Smoluchowski–Debye–Stokes–Einstein

$$k_2 = \kappa RTfr_r/1.5\eta r_d$$

pour la constante de vitesse k_2 d'une réaction entre des espèces chargées ou polaires pour évaluer les effets des propriétés globales du solvant sur les vitesses de réaction des électrons solvatés avec des $NO_{3,s}^-$, H_s^+, Tl_s^+, Cu_s^{2+} et Al_s^{3+} dans des solvants mixtes de 2-butanol/eau. Pour offrir une explication détaillée des effets, il est nécessaire de considérer un comportement plus spécifique du solvant. Les constantes de vitesses, k_2, les énergies d'activation, E_2, et les facteurs pré-exponentiels, A_2, de ces réactions varient avec la composition des mélanges de 2-butanol/eau. Les valeurs de E_2 sont généralement similaires aux énergies d'activation de la conductance ionique $E_{\Lambda 0}$ des solutions; les seules exceptions sont les valeurs beaucoup plus élevées observées pour les valeurs de E_2 de (e_s^- + $NO_{3,s}^-$) dans les solvants riches en alcool et de (e_s^- + Al_s^{3+}) dans l'eau pure. Apparemment, le solvant participe chimiquement à la réaction du $NO_{3,s}^-$ alors que la réaction du Al_s^{3+} se ferait en plusieurs étapes. Les mesures de constante de vitesse et de conductance de solutions d'acétate de thallium dans du butanol contenant de zéro à 10 mol% d'eau sont compliquées par la formation d'agrégats ioniques plus gros que des paires.

Mots clés : solvants mixtes alcool/eau, ions, cinétiques de réactions, électron solvaté, effets de solvants.

[Traduit par la rédaction]

Introduction

This article is a continuation of the study of solvent structure effects on solvated electron reactions in alcohol/water mixed solvents (1–4). Alcohol/water mixtures are good systems to study the effects of solvent structure on solvated electron reactivity because varying the composition of the mixture results in strong variations in the solvent structure, as reflected in physical properties such as viscosity (5) and dielectric relaxation time (6).

In this article we report solvent composition effects on the rates of (e_s^- + $NO_{3,s}^-$), (e_s^- + Tl_s^+), (e_s^-, Cu_s^{2+}), and (e_s^- + Al_s^{3+}) in 2-butanol/water mixed solvents. The subscript "s" is used on the ions to emphasize the fact that the solvating molecules influence the reaction.

Experimental

2-Butanol was obtained from Aldrich Chemical Co. (99+%, spectroscopic grade, gold label). It was dried for two weeks on Davison Molecular Sieves 3 Å and then treated for one day under UHP argon (Liquid Carbonic Canada Ltd.) with sodium borohydride (~2 g/L) at ~330 K. The alcohol was then fractionally distilled under argon through an 80 × 2.3 cm column packed with glass helices, discarding the first 20% and last 40%. The water content of the collected 40%, measured by Karl-Fisher titration, was 0.1 mol%. The solvated electron half-life after a 100 ns pulse of 1.9 MeV electrons (~3 J/kg, 2×10^{16} eV/g) at 298 K was about 4 μs.

Water was purified in a Barstead Nanopure II ion exchange system. The solvated electron half-life after a 100 ns pulse of radiation was 20 μs.

Lithium nitrate (99.999%, Aldrich, gold label), thallium acetate (96%, BDH Chemicals Ltd.), Copper(II) perchlorate (Aldrich reagent grade), aluminium(III) perchlorate (98%, Aldrich Chemical Co.), and perchloric acid (70%, Fisher Scientific Co.) were used as received. The salts were stored in a vacuum desiccator that contained fresh P_2O_5 powder.

Techniques

Methods of sample preparation from solid solutes were as described in ref. 7. Perchloric acid samples were made by measuring 70% perchloric acid solution with a glass pipet to prepare 50 mol/m^3 stock solutions, and then diluting as previously described.

Methods of irradiation, dosimetry, and optical measurement were similar to those described in ref. 8.

The first-order decay rate constants k_{obs} of e_s^- were calculated from the half-lives $t_{1/2}$. The computer calculated $t_{1/2}$ values as a function of time along each absorbance decay trace (~50 points/cm) and plotted the half-life curve together with the optical absorbance decay trace. A horizontal $t_{1/2}$ line ($t_{1/2}$ independent of time) showed that the decay was first-order.

Electrical conductance measurements were as described in ref. 9.

Dissolved CO_2 was removed from the conductance cell by bubbling UHP argon through the solution, then the cell was sealed with Parafilm. A small amount of chemical reaction sometimes occurred at the higher temperatures, detected by drift of the conductance. In these cases a fresh sample was used for each measurement.

Values of viscosities were obtained from ref. 10. Values of relative permittivities were obtained from refs. 11 and 12.

Results and discussion

The second-order rate constant k_2 were obtained as described in ref. 4*a*.

Water and 2-butanol were only miscible in the composition regions 0–66 mol% water and 97–100 mol% water.

Diffusion and reaction

The rate constants data were analyzed according to the modified Arrhenius equation (4),

$$[1] \quad k_2/f = A_2 \exp(-E_2/RT)$$

where E_2 is the overall energy of activation of the reaction and A_2 is the pre-exponential factor. The factor f reflects the effect of the electrostatic interaction between the reactants on their probability of attaining the closeness of approach r_r at which reaction occurs (13):

$$[2] \quad f = \frac{U(r_r)}{k_B T}[\exp(U(r_r)/k_B T) - 1]^{-1}$$

where $U(r_r)$ is the interaction energy of the reactants at distance r_r, k_B is Boltzmann's constant, and T is the temperature. When the reactants repel each other $U(r_r)$ is positive and the value of f is <1. For attraction $U(r_r)$ is negative and f is >1.

For the interaction of e_s^- with a solute of charge $z\xi$, $U(r_r)$ is given by

$$[3] \quad U(r_r) = -z\xi^2/4\pi\epsilon_0\epsilon r_r$$

where $-\xi$ is the charge on the electron, ϵ_0 is the permittivity of vacuum, and ϵ is the relative permittivity of the solvent between the electron and the ion. The value of r_r is larger than the van der Waals diameter of a water molecule (0.28 nm), so short range interactions are ignored and the static value of ϵ is used. The value of ϵr_r is chosen somewhat arbitrarily, so if a value of ϵ less than the static value were preferred, it would be used with a larger r_r.

For the interaction of e_s^- with a neutral, polar solute molecule S,

$$[4] \quad U(r_r) = -M\xi \cos\theta/4\pi\epsilon_0\epsilon r_r^2$$

where M is the dipole moment of S and θ is the angle of approach of e^- to the dipole axis of S.

In Figs. 1 and 2 values of f are plotted for nitrobenzene and for ions of different z and appropriate values of r_r (2), for a range of values of ϵ and T. The value of ϵ of each solvent at each T used in the experiments was obtained by interpolation of data in refs. 11 and 12.

Each value of k_2 was divided by the value of f at the corresponding values of (ϵ, T, r_r) to remove the simple coulombic effect from k_2.

The rate constants for the reactions of e_s^- with the counter ions perchlorate, acetate, and lithium are less than 10^3 m^3/mol s in water (14). Therefore, the observed rate constants are due to $NO_{3,s}^-$, H_s^+, Tl_s^+, Cu_s^{2+}, and Al_s^{3+}. Arrhenius plots of log (k_2/f) against T^{-1} are shown for $NO_{3,s}^-$ in Fig. 3*A*, for H_s^+ in Fig. 4*A*,

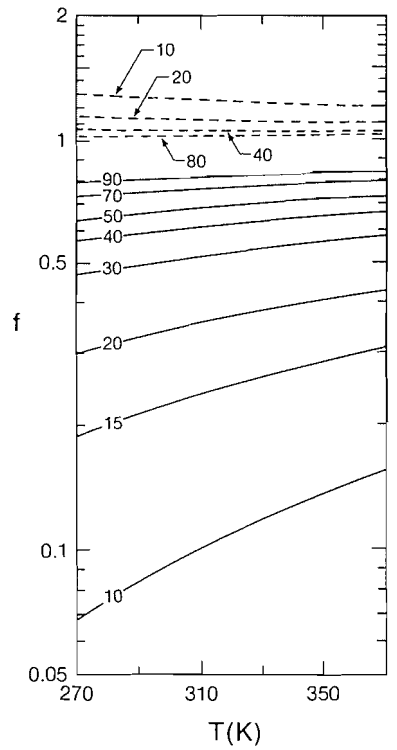

FIG. 1. Temperature dependence of the Debye factor f at different values of dielectric permittivity ϵ. ---, nitrobenzene, using r_r = 1.0 nm, θ = 0 rad, and $M = 1.4 \times 10^{-29}$ C m in eq. [4]. —, NO_3^-, using r_r = 1.5 nm in eq. [3]. Values of ϵ are indicated.

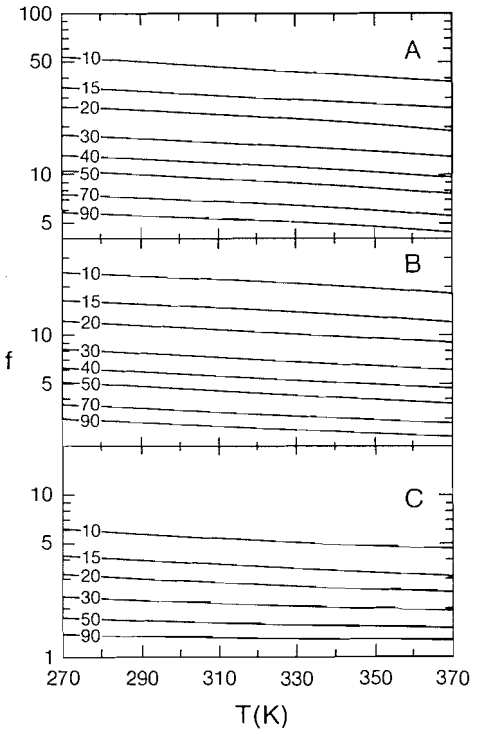

FIG. 2. Temperature dependence of the Debye factor f at different values of dielectric permittivity ϵ in eq. [3]. *A*: z = +3, using r_r = 0.35 nm. *B*: z = +2, using r_r = 0.5 nm. *C*: z = +1, using r_r = 1.0 nm.

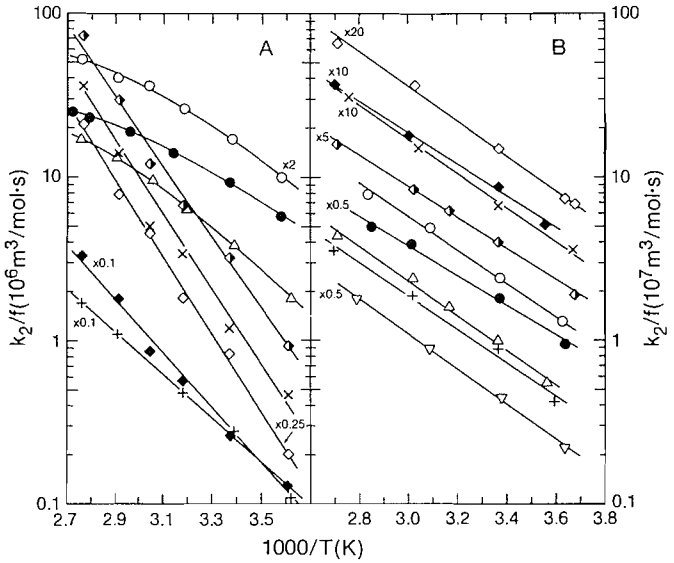

FIG. 3. Arrhenius plots of $k_2(e_s^- + NO_{3,s}^-)/f$ (*A*) and $k_2(e_s^-$ + nitrobenzene)/f (*B*) in 2-butanol/water mixed solvents. Symbols representing mol% water are given in Table 1, except: △, (*A*, 66; *B*, 68); +, (*A*, 51; *B*, 50); ◆, (*A*, 34; *B*, 35).

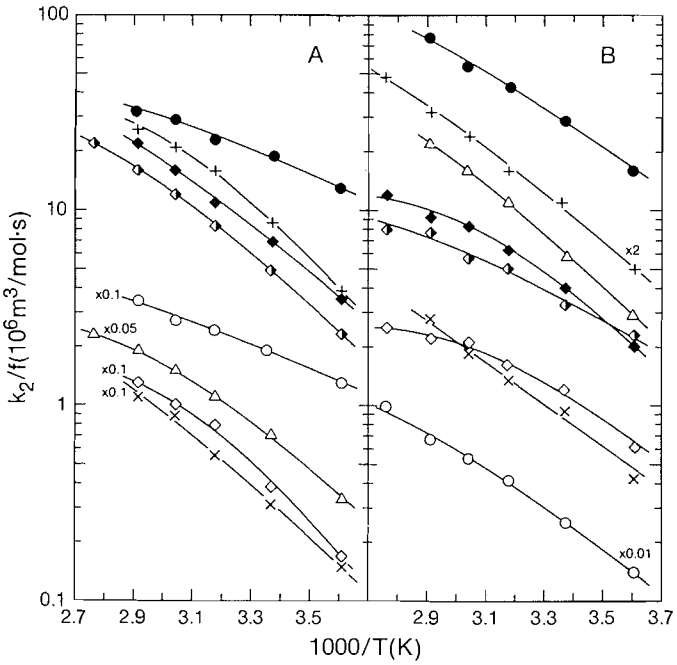

FIG. 4. Arrhenius plots of $k_2(e_s^- + H_s^+)/f(A)$ and $k_2(e_s^- + Tl_s^+)/f$ (*B*) in 2-butanol/water mixed solvents. Symbols representing mol% water are given in Table 1, except △, 66; +, 51; ◆, 34.

for Tl_s^+ in Fig. 4*B*, for Cu_s^{2+} in Fig. 5*A*, and for Al_s^{3+} in Fig. 5*B*. The mol% of water represented by the symbols in these figures are shown in Table 1.

The reaction of e_s^- with nitrobenzene is nearly diffusion controlled (7, 15) and we use it as a reference (4*a*). Arrhenius plots of k_2/f for nitrobenzene are given in Fig. 3*B*, using k_2 values from ref. 16.

For a diffusion controlled reaction E_2 is essentially that for the mutual diffusion of e_s^- and S, which encounter each other

and react,

[5″] $(e_s^-, S) \rightarrow$ products

In slow reactions most encounter pairs diffuse apart again,

[−5′] $(e_s^-, S) \rightarrow e_s^- + S$

in which case the measured E_2 is mainly the activation energy of reaction [5″]. The values of E_2 for nitrobenzene do not vary greatly with solvent composition (Fig. 6*A*), and are similar to E_η for viscosity (Fig. 7).

For the reaction of $(e_s^- + NO_{3,s}^-)$ the values of E_2 in the water-rich solvents are similar to those for nitrobenzene. However, in the alcohol-rich solvents E_2 increases with alcohol content (Fig. 6*A*). The value of E_2 in pure 2-butanol is about three times that in pure water. The value of A_2 increases along with E_2 (Fig. 6*B*) in such a way that the value of k_2/f for $e_s^- + NO_{3,s}^-$ at 298 K is independent of water content at <60 mol% water (Fig. 8). The strong variations of E_2 and A_2 indicate that the alcohol participates chemically in the $e_s^- + NO_{3,s}^-$ reaction; details of the participation are not yet known (4*a*).

On the water-rich side of the solvent immiscibility gap the values of k_2/f for $(e_s^- + NO_{3,s}^-)$ are larger (Fig. 8), due to the

lower viscosity of the liquid (Table 2) and the consequently higher diffusion coefficients.

The values of k_2/f for the cation reactions differ by factors up to ten (Fig. 8), but the solvent dependences of k_2/f do not reflect those of the corresponding values of E_2 and log A_2 (Fig. 6). The most remarkable observation is that, while in pure alcohol solvent the values of E_2 and log A_2 for the reactions of the anions and cations differ greatly, the values in the mixed solvent near 60 mol% water are similar, then separate differently in pure water solvent (Fig. 6 and ref. 4). At the present early stage of investigation of solvent effects we can only say that this peculiarity points to an unexpected influence of solvent on reaction rates.

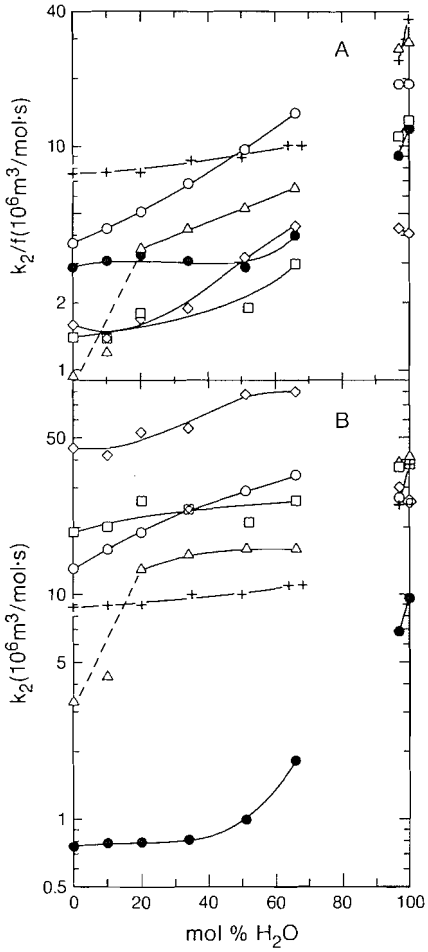

FIG. 8. Solvent composition dependence of $k_2/f(A)$ and $k_2(B)$ at 298 K. Symbols as in Fig. 6.

Values of the activation energy of diffusion of e_s^- in the mixed solvents are not known, but the activation energy of conductance $E_{\Lambda 0}$ of the reactant salt gives a rough idea of E_2 that might be expected for a diffusion controlled reaction (4*b*). Plots of $E_{\Lambda 0}$ against solvent composition are shown in Fig. 7. There are many significant differences between the values of $E_{\Lambda 0}$ and E_2 (Fig. 6), which cannot yet be interpreted.

Values of the reaction rate parameters are summarized in Tables 2 and 3.

Effect of solvent viscosity

The Smoluchowski–Debye–Stokes–Einstein equation for the rate constant k_2 of a bimolecular reaction between charged or polar species is given by (16)

$$[6] \qquad k_2 = \kappa RTfr_r/1.5\eta r_d$$

where κ = probability that a reactant encounter-pair will react, η = solvent viscosity (kg/m s), and r_d and r_r are the effective radii for mutual diffusion and reaction, respectively. Rearrangement of [6] gives the dimensionless ratio of reaction parameters $\kappa r_r/r_d$, which is a sort of reaction efficiency parameter:

$$[7] \qquad \kappa r_r/r_d = k_2\eta/5.5fT$$

where the constant 5.5 (J/mol K) represents $R/1.5$. The values of this ratio at 298 K for nitrobenzene are about three times those for $NO_{3,s}^-$ in all these solvents (Fig. 9*A*). In the pure alcohol

solvents the values of $\kappa r_r/r_d$ for $e_s^- + NO_{3,s}^-$ at 298 K are 5.3 in 2-butanol, 2.7 in 2-propanol, ~1.7 in *tert*-butanol, and 0.25 in 1-propanol. The values in the propanols were calculated from data in ref. 4*a*, and that in *tert*-butanol was estimated from data in ref. 2 ($k_2 \approx 1 \times 10^5$ m^3/mol s, $r_r \approx 1.5$ nm, $f \approx 0.16$, $\epsilon = 12.5$, $\eta = 4.45 \times 10^{-3}$ Pa s). The variation of $k_2(e_s^- + NO_{3,s}^-)$ with water content in *tert*-butanol (Fig. 4 of ref. 2, note that ◇ represents NO_3^- and ■ represents CrO_4^{2-}) is similar to that in 1-propanol (Fig. 7*A* of ref. 4*a*), and these are quite different from the behavior in the two secondary alcohols (Fig. 7*A* of ref. 4*a* and the present Fig. 8*B*). The secondary alcohols participate more readily in the $e_s^- + NO_{3,s}^-$ reaction than do the primary and tertiary alcohols. The secondary alcohols possess a relatively reactive C—H group that the primary and tertiary alcohols lack, so perhaps this enters the overall reaction.

In the 2-butanol/water solvents the relative values of $\kappa r_r/r_d$ for the different cations change with solvent composition (Fig. 9*A*). The lower values of the ratio for Cu_s^{2+} and Al_s^{3+} are attributed to difficulty in forming the relatively unstable Cu_s^+ and Al_s^{2+} ions from e_s^- and Cu_s^{2+} and Al_s^{3+}, respectively (4*b*). In aqueous solution the Cu_s^+ ion is unstable with respect to Cu_s^{2+} and Cu. The equilibrium

[8] $$2Cu_s^+ \rightleftharpoons Cu_s^{2+} + Cu_s$$

lies far to the right, and compounds of Cu(I) are covalent (17). Compounds of Al(II) are not known. The overall reaction with Al_s^{3+} might be either

[9] $$Al_s^{3+} + e_s^- \rightarrow (AlOH)_s^{2+} + H_s$$

or

[10] $$3Al_s^{3+} + 3e_s^- \rightarrow 3Al_s^{2+} \rightarrow\rightarrow Al_s^0 + 2Al_s^{3+}$$

In support of reaction [9], the equilibrium constant for the hydrolysis of Fe_s^{3+}

[11] $$Fe_s^{3+} \rightleftharpoons (FeOH)_s^{2+} + H_s^+$$

increases eight times when 40 mol% methanol is added to pure water solvent (18). It does not change much when more alcohol is added. We measured pH values of solutions of $Al(ClO_4)_3$ in pure water and in 32 mol% 1-propanol in water.

[12] $$Al_s^{3+} \rightleftharpoons (AlOH)_s^{2+} + H_s^+$$

The equilibrium constant calculated from these pH values increased twenty times ($K = 9.2 \times 10^{-3}$ mol/m^3 to 0.19 mol/m^3) when 32 mol% 1-propanol was added to the water. Apparently dissociation reactions of type [12] increase when alcohol is added to aqueous solution. This could explain why the overall rate constant for e_s^- reaction in the Al_s^{3+} solutions increases abnormally, relative to those of other positive ions, when alcohol is added to pure water solvent (4*b*). The effective concentration of the reactant is larger because of the presence of both $(AlOH)_s^{2+}$ and H_s^+.

Comparison with ionic conductivities

The diffusion coefficients D_i of the reacting species are related to their molar conductivities λ_i (C m^2/V s mol), so the solvent dependence of $k_2/fT[(\lambda_i/z_i^2) + \lambda_e]$ indicates the solvent dependence of the effective reaction radius κr_r (4*a*):

[13] $\kappa r_r = 1.48 \times 10^{-16} k_2/fT[(\lambda_i/z_i^2) + \lambda_e]$

where λ_e is the molar conductivity of e_s^- and the units of 1.48×10^{-16} are C K/sr V ion. Note that r_r has units m/entity sr. The entity is the pair of reactants, where one is considered to be at the center of a sphere and the other is approaching it at a particular solid angle. The reaction probability κ is averaged over all angles (4πsr) of approach.

In alcohol-rich solvents the plots of specific conductance against concentration for $LiNO_3$ were sublinear, which indicates ion pair formation:

[14] $Li_s^+ + NO_{3,s}^- \rightleftharpoons (Li_s^+, NO_{3,s}^-)$

Association constants of [14] were estimated from the curved plots at different temperatures; by comparison of various individual cation and anion mobilities in water (19) the ionic conductivities in these solvents were assumed to be $\lambda(NO_{3,s}^-) \approx 2\lambda(Li_s^+)$. The equation for the association constant K is

[15] $K = x/(a - x)^2$

where x is the amount of association of Li_s^+ and $NO_{3,s}^-$, and the total concentrations are a. Then the conductance C of the solution is given by

[16] $C = 3\lambda_{Li^+}(a - x)$

where λ_{Li^+} is the molar conductance of Li_s^+; $C_0(Li_s^+ + NO_{3,s}^-) \approx (3\lambda_{Li^+}a)$ is the value of C at $x = 0$. Arrhenius plots of

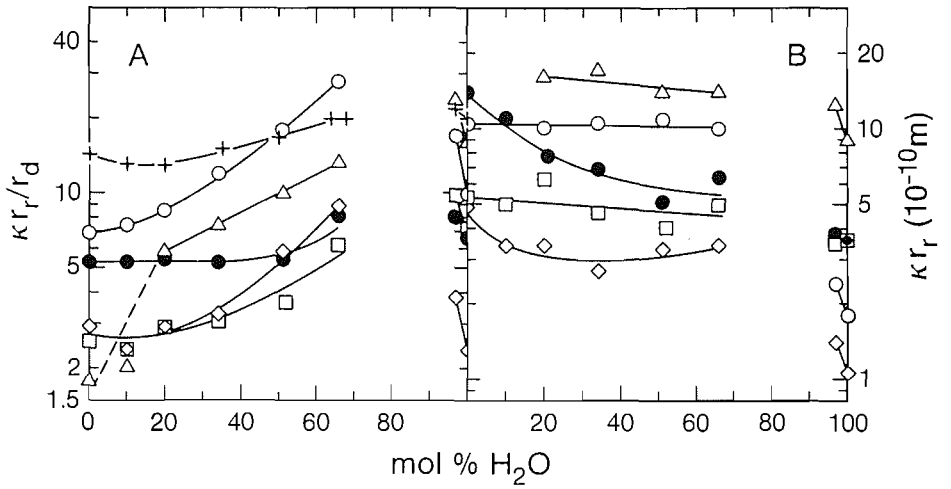

FIG. 9. Solvent composition dependence of $\kappa r_r/r_d$ (*A*) and κr_r (*B*) at 298 K. Symbols as in Fig. 6.

the estimated association constants are given in Fig. 10. The association constants increase with increasing temperature, due to the concomitant decrease of permittivity. The amount of association in the solutions used for rate constant measurements at these water concentrations varied from 53% (at 343 K in pure 2-butanol) to 3% (at 277 K in 20 mol% water).

Ion association also occurred in the thallium acetate solutions at zero and 10 mol% water. The value of the association constant K at 298 K was roughly 3000 m^3/mol in pure 2-butanol and 200 m^3/mol at 10 mol% water. However, the conductances of solutions in the thallium acetate concentration range 0.02–0.4 mol/m^3 were not sufficiently sublinear to be explained by simple ion pairing:

[17] $\quad Tl_s^+ + Ac_s^- \rightleftharpoons [Tl_s^+, Ac_s^-]$

It appears that larger, charged clusters formed at higher salt concentrations:

[18] $\quad [Tl_s^+, Ac_s^-] + Tl_s^+ \rightleftharpoons [2Tl_s^+, Ac_s^-]$

[19] $\quad [Tl_s^+, Ac_s^-] + Ac_s^- \rightleftharpoons [Tl_s^+, 2Ac_s^-]$

and so on.

The formation of larger clusters is probably the cause of the low apparent values of k_2 in the pure 2-butanol and 10 mol% water solvents (Fig. 8*B*).

The solvent dependence of the molar conductivities Λ_0 of the salts and the acid at 298 K are shown in Fig. 11.

In pure water at 298 K the ratios of the λ's of e_s^- (18): $NO_{3,s}^-$:H_s^+:Tl_s^+:Cu_s^{2+}:Al_s^{3+} (20) are 4.7:1.9:9.1:2.0:3.0:4.9, so the diffusion coefficients ($\propto \lambda_i/z_i^2$) are in the ratios 4.7:1.9:9.1:2.0:0.8:0.5. Thus diffusion of e_s^- dominates the relative motion of each reactant pair except for that with H_s^+. The values of the individual ionic conductivities in the mixed solvents are not known, so we have to use approximations. In water the ratio $[\lambda(e_s^-) + \lambda(NO_{3,s}^-)]/\Lambda_0(Li_s^+ + NO_{3,s}^-) = 2.3$, $[\lambda(e_s^-) + \lambda(H_s^+)]/\Lambda_0(H_s^+ + ClO_{4,s}^-) = 1.3$, $[\lambda(e_s^-) + \lambda(Tl_s^+)]/\Lambda_0(Tl_s^+ + Ac_s^-) = 2.2$, $[\lambda(e_s^-) + 0.25\lambda(Cu_s^{2+})]/(1/2)\Lambda_0(Cu_s^{2+} + 2ClO_{4,s}^-) = 1.6$, and $[\lambda(e_s^-) + 0.11\lambda(Al_s^{3+})]/(1/3)\Lambda_0(Al_s^{3+} + 3ClO_{4,s}^-) = 1.5$. This ratio for Li_2CrO_4 (4) is $[\lambda(e_s^-) + 0.25\lambda(CrO_{4,s}^{2-})]/(1/2)\Lambda_0(2Li_s^+ + CrO_{4,s}^{2-}) = 1.8$. Thus eq. [13] can be approximated as

[20] $\quad \kappa r_r \approx 1 \times 10^{-16} z_i k_2/fT\Lambda_0$

where z_i is the number of charges on the reactant ion.

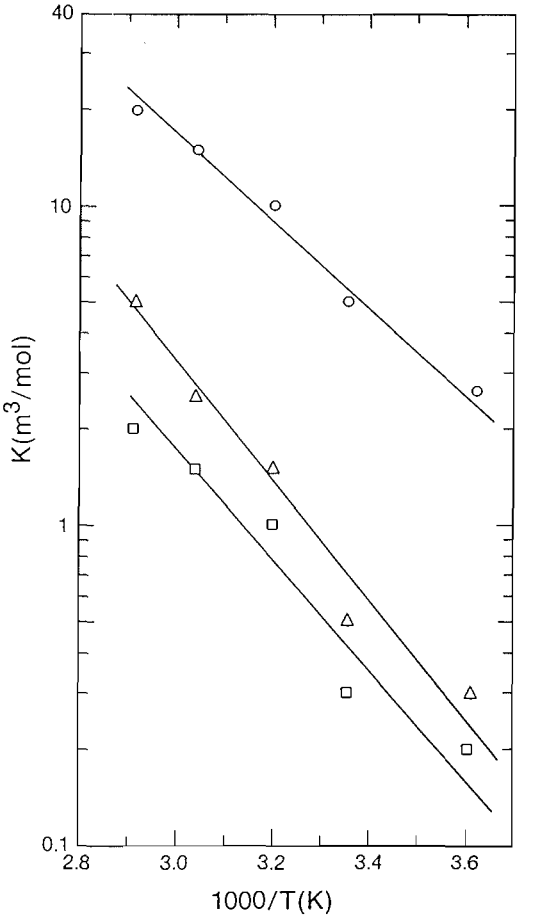

FIG. 10. Arrhenius plots of the association constant of Li_s^+ and $NO_{3,s}^-$ ions in 2-butanol/water mixtures. Mol% water: ○, 0; △, 10; □, 20. $\Delta H = 30 \pm 5$ kJ/mol.

The approximate values of κr_r obtained from eq. [20] are plotted against solvent composition in Fig. 9*B*. The shapes of the curves are somewhat different from those in Fig. 9*A* partly because the effective radii for diffusion r_d are solvent dependent, and partly because $\lambda(e_s^-)$ probably has a somewhat different solvent composition dependence than does $\lambda(Li_s^+)$ or $\lambda(ClO_{4,s}^-)$.

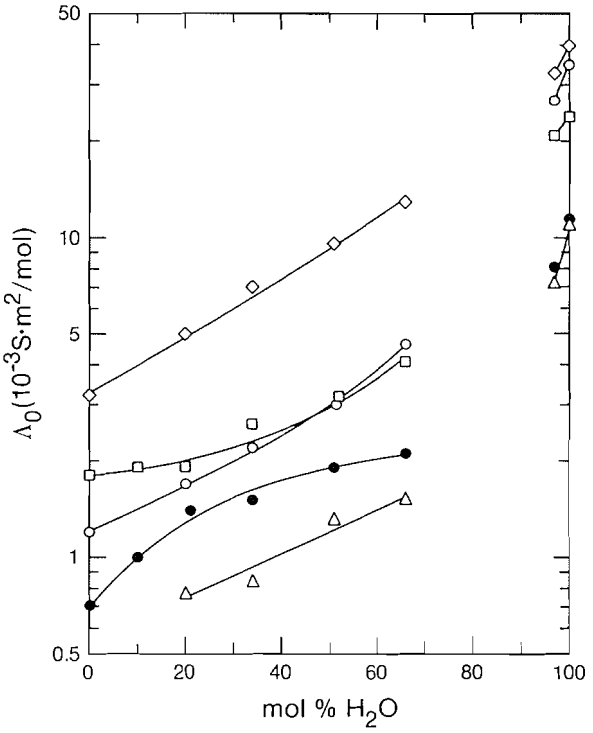

FIG. 11. Solvent composition dependence of molar conductivities of ions in 2-butanol/water at 298 K. ◇, $Al(ClO_4)_3$; □, $Cu(ClO_4)_2$; △, TlAc; ○, $HClO_4$; ●, $LiNO_3$.

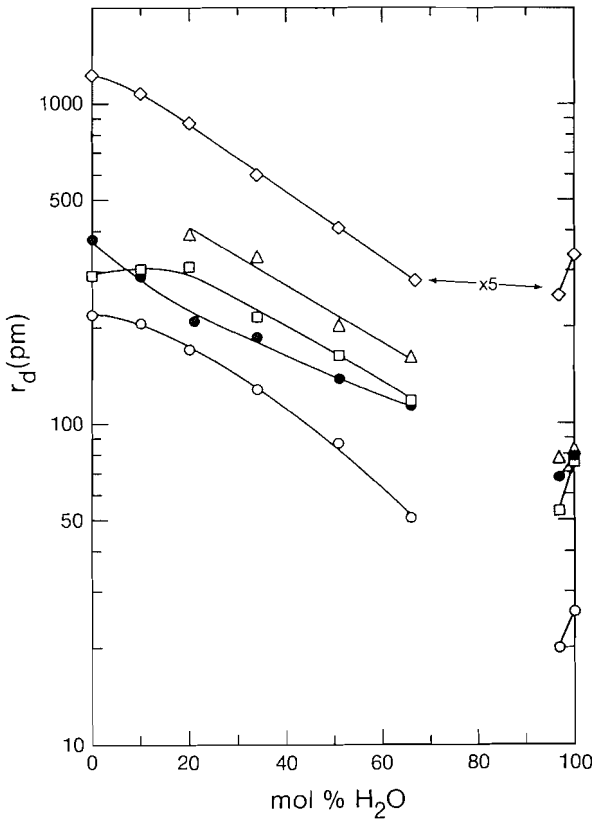

FIG. 12. 2-Butanol/water composition dependence of the effective radius for mutual diffusion of: ◇, $Al^{3+} + ClO_4^-$; □, $Cu^{2+} + ClO_4^-$; △, $Tl^+ + Ac^-$; ○, $H^+ + ClO_4^-$; ●, $Li^+ + NO_3^-$.

The Stokes radius r_d for mutual diffusion of the ions is given by (4*a*):

$$[21] \quad r_d = 8.2 \times 10^{-16} \Big/ \eta \left(\frac{\lambda_+}{z_+^2} + \frac{\lambda_-}{z_-^2} \right)$$

where 8.2×10^{-16} has units C^2/mol ion sr. Note that r_d also has units of (m/entity sr), and that the viscous force is assumed to be exerted over the surfaces of spherical ions, $4\pi r_{d+}^2$ and $4\pi r_{d-}^2$. Furthermore, $r_d^{-1} = r_{d+}^{-1} + r_{d-}^{-1}$, so r_d emphasizes the more mobile ion. Separate values of λ_+ and λ_- in the mixed solvents are not available, so values of r_d cannot be calculated from molar conductivities when $z_+ \neq z_-$. In pure water the values of $[(\lambda_+/z_+^2) + \lambda_-] = 9.6$ and 8.8 (10^{-3} S m^2/mol) for Cu_s^{2+} and Al_s^{3+} perchlorates at 298 K, respectively (4*b*). These values are a bit closer to the values of $\Lambda_0(\text{salt})/z_+$, 12.4 and 13.0 ($10^{-3}$ S m^2/mol), than to those of $\Lambda_0(\text{salt})/z_+^2$, 6.2 and 4.3 ($10^{-3}$ S m^2/mol), respectively. We therefore estimated r_d for the Cu_s^{2+} and Al_s^{3+} salt solutions from

$$[22] \quad r_d \approx 8 \times 10^{-16} z_+ / \eta \Lambda_0$$

Values of r_d estimated from eq. [22] are plotted in Fig. 12. With the exception of 100% to 97 mol% water the values of r_d increase with alcohol content of the solvent. The increase of r_d is attributed to solvation of the ions by alcohol molecules, which are larger than water molecules. The values of r_d in 2-butanol solutions are also larger than those in 1-propanol and 2-propanol solutions (4). The ratio of molar volumes alcohol/water at 298 K are 4.2 for 1-propanol, 4.3 for 2-propanol, and 5.2 for 2-butanol (21).

The apparent decrease in r_d when a few mol% of alcohol are added to water might indicate that the microscopic viscosity of the solvent in the vicinity of the ions is smaller than the bulk viscosity; the ions remain in the disordered water. This would explain the maxima in $\kappa r_r/r_d$ at ~90 mol% water in the propanol solvents (4*b*).

It should be mentioned that for the Li_s^+, $CrO_{4,s}^{2-}$ solutions (4*a*), the required value of $[\lambda_+ + (\lambda_-/z_-^2)] = 8.2 \times 10^{-3}$ S m^2/mol in water is closer to $\Lambda_0(\text{salt})/z_-^2 = 6.2 \times 10^{-3}$ S m^2/mol than to $\Lambda_0(\text{salt})/z_- = 12.4 \times 10^{-3}$ S m^2/mol, so in that case we estimated r_d from

$$[23] \quad r_d \approx 8 \times 10^{-16} z_-^2 / \eta \Lambda_0$$

This work points to the need of renewed interest in electrolyte solutions.

Conclusions

The reactivity of solvated electrons with solutes is determined not only by the electron affinity of the solute, but also by electron–solvent, solute–solvent, and solvent–solvent (solvent structure) interactions. The solvent structure affects the diffusion rates of the reactants as well as the solvation energies of the reactants, transition state, and products.

For (e_s^- + $NO_{3,s}^-$) the solvent apparently participates chemically in the reaction. The activation energy E_2 and the pre-exponential factor A_2 of (e_s^- + $NO_{3,s}^-$) decrease greatly as water is added to 2-butanol solvent.

The effective reaction radii κr_r for (e_s^- + Cu_s^{2+}) and (e_s^- + Al_s^{3+}) are relatively low because of the difficulty of forming the relatively unstable Cu_s^+ and Al_s^{2+} from reactions of e_s^- with Cu_s^{2+} and Al_s^{3+}, respectively. In pure water the value of κr_r for (e_s^- + H_s^+) is low because of relative difficulty of the reaction sequence $e_s^- + H_s^+ \rightarrow [H_3O]_s \rightarrow H_s + H_2O_s$.

1-*n*-Propyl- and 1-*n*-butyl-3-hydroxy-2-methyl-4-pyridinone complexes of group 13 (IIIA) metal ions

LINDA SIMPSON, STEVEN J. RETTIG, JAMES TROTTER,[1] AND CHRIS ORVIG[1]

Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Z1

Received October 22, 1990

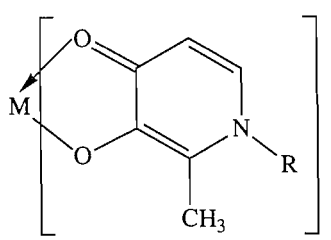
LINDA SIMPSON, STEVEN J. RETTIG, JAMES TROTTER, and CHRIS ORVIG. Can. J. Chem. **69**, 893 (1991).

The aluminum, gallium, and indium tris(ligand) complexes of 3-hydroxy-2-methyl-1-*n*-propyl-4-pyridinone and 1-*n*-butyl-3-hydroxy-2-methyl-4-pyridinone have been prepared and characterized. All six compounds were prepared in a one-pot synthesis from maltol, *n*-propyl-, or *n*-butylamine and an appropriate metal(III) salt, and were completely characterized (IR, FAB-MS, ^{1}H NMR, ^{27}Al NMR, elemental analysis). Three of the six complexes were studied by single-crystal X-ray diffraction and were found to form trihydrates, unlike their 1-methyl and 1-ethyl analogues, which formed dodecahydrates. The *n*-butylpyridinone complex $Al(C_{10}H_{14}NO_2)_3\cdot 3H_2O$ ($Al(nbp)_3\cdot 3H_2O$) and *n*-propylpyridinone complexes $Al(C_9H_{12}NO_2)_3\cdot 3H_2O$ ($Al(npp)_3\cdot 3H_2O$), and $Ga(C_9H_{12}NO_2)_3\cdot 3H_2O$ ($Ga(npp)_3\cdot 3H_2O$) were essentially isostructural, crystallizing in the space group $P\bar{3}$ with the following crystal parameters for $Al(nbp)_3\cdot 3H_2O$ ($Al(npp)_3\cdot 3H_2O$, $Ga(npp)_3\cdot 3H_2O$): a = 15.885(1) (15.328(1), 15.367(2)) Å, c = 7.280(8) (7.231(2), 7.256(2)) Å, Z = 2. The data were refined by using 1280 (1377, 1802) reflections with $I > 3\sigma(I)$ to R and R_w values of 0.047 (0.057, 0.055) and 0.061 (0.077, 0.081), respectively. They form *fac* geometries with infinite chains of hydrogen bonds parallel to the c axis similar to those found in the 1-methyl and 1-ethyl complexes. They lack the hexagonal channels of water molecules which characterized the dodecahydrates and are therefore not exoclathrates.

Key words: metal complexes, hydroxypyridinone ligands, exoclathrate, hydrogen bonding, crystal structures.

LINDA SIMPSON, STEVEN J. RETTIG, JAMES TROTTER et CHRIS ORVIG. Can. J. Chem. **69**, 893 (1991).

On a préparé et caractérisé les complexes tricoordinés de l'aluminium, du gallium et de l'indium avec la 3-hydroxy-2-méthyl-1-*n*-propyl-pyridin-4-one et la 1-*n*-butyl-3-hydroxy-2-méthyl-pyridin-4-one. On a préparé les six composés par des synthèses "bouillabaisses" impliquant le maltol, les *n*-propyl- ou *n*-butyl-amines et le sel métallique(III) approprié et on les a caractérisés complètement par ir, sm-bar, rmn du ^{1}H, rmn du ^{27}Al et analyse élémentaire. On a examiné trois des six complexes par diffraction des rayons-X par des cristaux uniques et on a trouvé qu'ils forment des trihydrates alors que leurs analogues 1-méthyle et 1-éthyle forment des dodécahydrates. Le complexe de la *n*-butylpyridinone, $Al(C_{10}H_{14}NO_2)_3\cdot 3H_2O$ ($Al(nbp)_3\cdot 3H_2O$) et les complexes de la *n*-propylpyridinone, $Al(C_9H_{12}NO_2)_3\cdot 3H_2O$ ($Al(npp)_3\cdot 3H_2O$) et $Ga(C_9H_{12}NO_2)_3\cdot 3H_2O$ ($Ga(npp)_3\cdot 3H_2O$) sont essentiellement isostructuraux et ils cristallisent dans le groupe d'espace $P\bar{3}$ avec a = 15,885(1) (15,328(1) et 15,367(2)) Å et c = 7,280(8), 7,231(2) et 7,256(2) Å respectivement pour $Al(nbp)_3\cdot 3H_2O$ ($Al(npp)_3\cdot 3H_2O$ et $Ga(npp)_3\cdot 3H_2O$) : dans tous les cas Z = 2. On a affiné les données à l'aide de 1280, 1377 et 1802 réflexions avec $I > 3\sigma(I)$, jusqu'à des valeurs de R et R_w de 0,047, 0,057 et 0,055 et 0,061, 0,077 et 0,081 respectivement. Comme leurs analogues 1-méthyle et 1-éthyle, ils existent dans des géométries *fac* avec des chaînes infinies de liaisons hydrogènes parallèles à l'axe c. Ils ne comportent pas de canaux hexagonaux de molécules d'eau qui caractérisent les dodécahydrates ; ils ne sont donc pas des exoclathrates.



Mots clés : complexes métalliques, ligands hydroxypyridinone, exoclathrate, liaisons hydrogènes, structures cristallines.

[Traduit par la rédaction]

Introduction

The coordination chemistry of group 13 (IIIA) metals is of great interest because of their varied biological effects. Aluminum (1) has been implicated in the etiology of certain diseases and isotopes of gallium (2,3) and indium (3) are used in the diagnosis of disease. Research in these laboratories has focussed on the development of ligands which will bind effectively to these metals, both *in vitro* and *in vivo*. In the course of this work, a series of pyridinonato metal complexes with unexpected and novel crystallographic properties was discovered (4–8).

N-Substituted-3-hydroxy-2-methyl-4-pyridinones, initially chosen for their efficiency in binding group 13 metal ions (9, 10), formed tris(ligand)metal(III) dodecahydrate complexes when the *N*-substituent was methyl or ethyl (the complexes $M(dpp)_3$ and $M(mepp)_3$) (4–8). These crystallized in a manner unknown amongst inorganic hydrates; unusual hydrogen bonding was observed in the solid state. Single crystal X-ray diffraction revealed that water molecules formed hydrogen bonded hexagonal channels, which were in turn linked by other water molecules to the oxygen atoms which chelate the metal atom. This extensive network bears a closer resemblance to one of the crystalline forms of ice (I_h) (11) than to the typical structure of inorganic hydrates.

3

M = Al, Ga, In

R = H,	$M(mpp)_3$
R = CH_3	$M(dpp)_3$
R = C_2H_5	$M(mepp)_3$
R = *n*-C_3H_7	$M(npp)_3$
R = *n*-C_4H_9	$M(nbp)_3$
R = *n*-C_6H_{13}	$M(mhpp)_3$

Increasing the size of the metal atom (12) in these $ML_3\cdot 12H_2O$ complexes from aluminum (effective six-coordinate ionic radius, r = 0.535 Å) to gallium (r = 0.620 Å) to indium (r = 0.800 Å) seemed to have little effect upon the intricate hydrogen bonding network (5, 6). Also, increasing the size of the nitrogen substituent R from methyl to ethyl left intact the extensive hexagonal water channel network exoclathrate (8). The work described in this contribution was undertaken in order to probe the steric limitations of these unusual structures. It was hypothesized that an *n*-propyl group as the nitrogen substituent might form an exoclathrate, but that perhaps the lattice would not accommodate a more sterically demanding *n*-butyl group, and hence a different structure would be found. The synthesis, characterization, and X-ray crystallographic

studies of the tris(3-hydroxy-2-methyl-4-pyridinonato)-metal(III) complexes with an *n*-propyl or *n*-butyl group as the nitrogen substituent are described.

Experimental

All chemicals were reagent grade, were used without further purification, and were received from the following chemical companies: amines and maltol (Sigma); $AlCl_3 \cdot 6H_2O$ (Anachemia); $Ga(NO_3)_3 \cdot 9H_2O$ (Johnson Matthey); $In(NO_3)_3 \cdot 5H_2O$ (Alfa). Melting points were measured with a Mel-Temp apparatus and are uncorrected. The reaction conditions, based on a one-pot synthesis (13), were the same for aluminum, gallium, and indium with any given ligand. Preparative details are given for the aluminum complexes; only reactant concentrations and yields are given for the corresponding gallium and indium complexes. All yields are based on metal complex trihydrates. Elemental analyses were performed by Mr. Peter Borda of this department on samples of anhydrates prepared from the hydrates by drying in vacuo at 80°C for 24 to 48 h (5). The pyrone conversion reaction was monitored by thin layer chromatography (TLC) on silica gel plates eluted with 5% methanol in methylene chloride. Optimum yields were obtained after 3 days. Infrared spectra were recorded on a PE 783 spectrophotometer and were referenced to polystyrene. For the Ga complexes, FAB-MS peaks were in the natural isotopic ratio of 3:2 ^{69}Ga to ^{71}Ga. ^1H NMR spectra were referenced to TMS. ^{27}Al NMR spectra were referenced to $Al(H_2O)^{3+}$.

*Tris(3-hydroxy-2-methyl-1-*n*-propyl-4-pyridinonato)aluminum(III)*, $Al(npp)_3$. $AlCl_3 \cdot 6H_2O$ (1.68 g, 6.95 mmol) and maltol (2.62 g, 20.7 mmol) were dissolved in distilled deionized water (50 mL). *n*-Propylamine (10.0 mL, 121 mmol) was added and the reaction mixture was stirred under nitrogen for 3 days, during which time a precipitate formed. The suspension was filtered, and recrystallization of the solid from hot water yielded a pale yellow–orange solid. This solid was then dissolved in a small volume of hot water and the volume reduced to 10 mL by heating at 70°C. This suspension was filtered while still hot, to give a pale yellow–orange coloured product. The yield was 2.59 g (64%), mp 300°C (dec). Infrared (cm^{-1}, KBr disk): 1610, 1560, 1520, 1495 ($\nu_{C=O}$ and ν_{ring}); 720, 580 (b), 470 (ν_{Al-O}). FAB-MS (*m/z*): 884 ± 1 ($M_2L_5^+$) (14), 526 (HML_3^+), 359 (ML_2^+). ^1H NMR (δ at 400 MHz in $CDCl_3$, atom numbering as in Fig. 1): 0.94 (t, 3H, C(9)H_3), 1.74 (sextet, 2H, C(8)H_2), 2.44 (s, 3H, C(1)H_3), 3.83 (t, 2H, C(7)H_2), 6.54 (d, 1H, C(5)H), 7.06 (d, 1H, C(6)H). ^{27}Al NMR ($CDCl_3$): 37 ppm ($W_{1/2}$ = 730 Hz). *Anal.* calcd for $C_{27}H_{36}AlN_3O_6$: C 61.70, H 6.90, N 8.00; found: C 62.00, H 7.01, N 7.97.

*Tris(3-hydroxy-2-methyl-1-*n*-propyl-4-pyridinonato)gallium(III)*, $Ga(npp)_3$. $Ga(NO_3)_3 \cdot 9H_2O$ (1.00 g, 2.39 mmol), maltol (0.91 g, 7.22 mmol), and *n*-propylamine (5.0 mL, 60.8 mmol) were used in water (50 mL). The yield was 1.17 g (78%), mp 290°C (dec). Infrared (cm^{-1}, KBr disk): 1600, 1550, 1510, 1485 ($\nu_{C=O}$ and ν_{ring}); 710, 570 (b), 410 (b), (ν_{Ga-O}). FAB-MS (*m/z*): 971 ± 2 ($M_2L_5^+$), 568, 570 (HML_3^+), 401, 403 (ML_2^+), 236 (ML^+). ^1H NMR (δ at 400 MHz in $CDCl_3$): 0.95 (t, 3H, C(9)H_3), 1.73 (sextet, 2H, C(8)H_2), 2.41 (s, 3H, C(1)H_3), 3.83 (t, 2H, C(7)H_2), 6.47 (d, 1H, C(5)H), 7.07 (d, 1H, C(6)H). *Anal.* calcd. for $C_{27}H_{36}GaN_3O_6$: C 57.06 H 6.38, N 7.39; found: C 57.17, H 6.44, N 7.52.

*Tris(3-hydroxy-2-methyl-1-*n*-propyl-4-pyridinonato)indium(III)*, $In(npp)_3$. $In(NO_3)_3 \cdot 5H_2O$ (1.00 g, 2.55 mmol), maltol (1.00 g, 7.93 mmol), and *n*-propylamine (5.0 mL, 60.8 mmol) were used in water (50 mL). The yield was 1.30 g (76%), mp 280°C (dec.). Infrared (cm^{-1}, KBr disk): 1600, 1540, 1500, 1485 ($\nu_{C=O}$ and ν_{ring}); 705, 555, <300 (ν_{In-O}). FAB-MS (*m/z*): 1062 ± 2 ($M_2L_5^+$), 614 (HML_3^+), 447 (ML_2^+), 281 (ML^+). ^1H NMR (δ at 400 MHz in $CDCl_3$): 0.91 (t, 3H, C(9)H_3), 1.71 (sextet, 2H, C(8)H_2), 2.46 (s, 3H, C(1)H_3), 3.84 (t, 2H, C(7)H_2), 6.53 (d, 1H, C(5)H), 7.06 (d, 1H, C(6)H). *Anal.* calcd. for $C_{27}H_{36}InN_3O_6$: C 52.87, H 5.92, N 6.85; found: C 52.45, H 5.85, N 6.70.

*Tris(1-*n*-butyl-3-hydroxy-2-methyl-4-pyridinonato)aluminum(III)*, $Al(nbp)_3$. $AlCl_3 \cdot 6H_2O$ (1.68 g, 6.96 mmol) and maltol (2.66 g, 21.1 mmol) were dissolved in distilled deionized water (50 mL). *n*-Butylamine (13.0 mL, 130 mmol) was added and the reaction mixture was stirred under nitrogen for 3 days, during which time a precipitate formed. The suspension was filtered, and recrystallization of the solid from hot water yielded a beige solid. This solid was then dissolved in a small volume of hot water and the volume reduced to 10 mL by heating at 70°C. This suspension was filtered while still hot, to give a beige coloured product. The yield was 2.37 g (55%), mp 180°C (dec.). Infrared (cm^{-1}, KBr disk): 1610, 1560, 1520, 1490 ($\nu_{C=O}$ and ν_{ring}); 720, 590 (b), 470 (b), (ν_{Al-O}). FAB-MS (*m/z*): 954 ± 1 ($M_2L_5^+$), 568 (HML_3^+), 387 (ML_2^+). ^1H NMR (δ at 400 MHz in $CDCl_3$): 0.96 (t, 3H, C(10)H_3), 1.37 (sextet, 2H, C(9)H_2), 1.69 (q, 2H, C(8)H_2), 2.44 (s, 3H, C(1)H_3), 3.86 (t, 2H, C(7)H_2), 6.48 (d, 1H, C(5)H), 7.07 (d, 1H, C(6)H). ^{27}Al NMR ($CDCl_3$): 37 ppm ($W_{1/2}$ = 920 Hz). *Anal.* calcd. for $C_{30}H_{42}AlN_3O_6$: C 63.48, H 7.46, N 7.40; found: C 63.41, H 7.55, N 7.51.

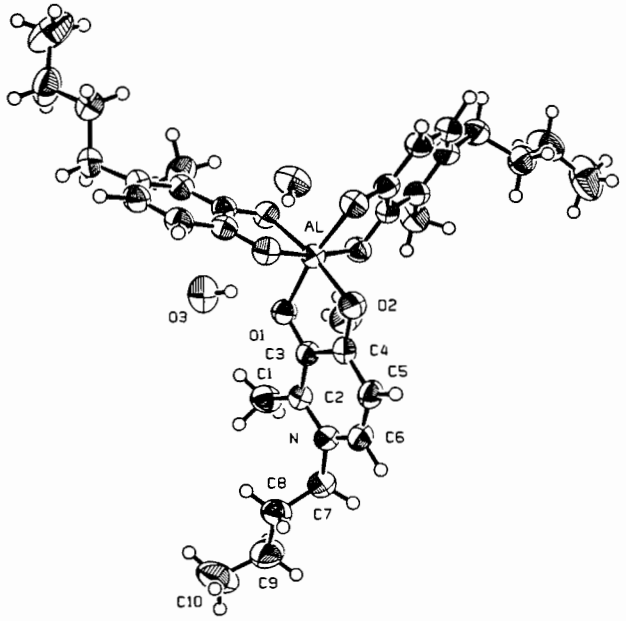

FIG. 1. ORTEP view of the $Al(nbp)_3 \cdot 3H_2O$ unit down the *c* axis.

*Tris(1-*n*-butyl-3-hydroxy-2-methyl-4-pyridinonato)gallium(III)*, $Ga(nbp)_3$. $Ga(NO_3)_3 \cdot 9H_2O$ (1.03 g, 2.47 mmol), maltol (0.93 g, 7.38 mmol), and *n*-butylamine (5.0 mL, 50 mmol) were used in water (50 mL). The yield was 1.19 g (73%), mp 170°C (dec). Infrared (cm^{-1}, KBr disk): 1605, 1550, 1510, 1485 ($\nu_{C=O}$ and ν_{ring}); 7.15, 570 (b), 410 (b), (ν_{Ga-O}). FAB-MS (*m/z*): 1040 ± 2 ($M_2L_5^+$), 610, 612 (HML_3^+), 429, 431 (ML_2^+), 250 (ML^+). ^1H NMR (δ at 400 MHz in $CDCl_3$): 0.96 (t, 3H, C(10)H_3), 1.36 (sextet, 2H, C(9)H_2), 1.69 (q, 2H, C(8)H_2), 2.44 (s, 3H, C(1)H_3), 3.86 (t, 2H, C(7)H_2), 6.53 (d, 1H, C(5)H), 7.06 (d, 1H, C(6)H). *Anal.* calcd. for $C_{30}H_{42}GaN_3O_6 \cdot 0.5H_2O$: C 58.17, H 7.00, N 6.78; found: C 57.93, H 6.84, N 6.45.

*Tris(1-*n*-butyl-3-hydroxy-2-methyl-4-pyridinonato)indium(III)*, $In(nbp)_3$. $In(NO_3)_3 \cdot 5H_2O$ (1.01 g, 2.59 mmol), maltol (1.09 g, 8.67 mmol), and *n*-butylamine (5.0 mL, 50 mmol) were used in water (50 mL). The yield was 1.60 g (87%), mp 255°C (dec). Infrared (cm^{-1}, KBr disk): 1600, 1540, 1500, 1490 ($\nu_{C=O}$ and ν_{ring}); 705, 555 (b), <300 (ν_{In-O}). FAB-MS (*m/z*): 1129 ± 2 ($M_2L_5^+$), 656 (HML_3^+), 475 (ML_2^+), 295 (ML^+). ^1H NMR spectrum (δ at 400 MHz in $CDCl_3$): 0.94 (t, 3H, C(10)H_3), 1.33 (sextet, 2H, C(9)H_2), 1.67 (q, 2H, C(8)H_2), 2.47 (s, 3H, C(1)H_3), 3.87 (t, 2H, C(7)H_2), 6.54 (d, 1H, C(5)H), 7.06 (d, 1H, C(6)H). *Anal.* calcd. for $C_{30}H_{42}InN_3O_6 \cdot 1.5H_2O$: C 52.79, H 6.64, N 6.16; found: C 52.91, H 6.37, N 6.11.

X-ray crystallographic analyses

Crystallographic data for $Al(nbp)_3 \cdot 3H_2O$, $Al(npp)_3 \cdot 3H_2O$, and $Ga(npp)_3 \cdot 3H_2O$ appear in Table 1. Data were collected in the unique volume of reciprocal space. Three standard reflections were selected on the basis of good intensity and spatial distribution from the reflections used to determine the orientation matrix. Their intensity and orientation

[a]Temperature 21°C, Cu-K_α radiation (λ_{K_α} = 1.54178 Å), graphite-monochromated, ω–2θ scan, Rigaku AFC6S diffractometer, caclulations performed on a VAX-based TEXRAY system (Molecular Structure Corp.), $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2)^{1/2}$, $w = 4F_o^2/\sigma^2(F_o^2)$, $\sigma^2(F_o^2) = [S^2(C + R^2B) + (pF_o^2)^2]/L_p^2$ where S = scan rate, C, = peak count, R = scan time/background time, B = background count, L_p = Lorentz-polarization factor, p = p-factor, function minimized: $\Sigma w(|F_o| - |F_c|)^2$.

indicated that there was not any significant crystal decay or crystal movement.[2] The intensities of three standard reflections were essentially constant throughout data collections. The data were corrected for Lorentz and polarization effects, the space group ($P\bar{3}$, #147) was indicated by the E-statistics, the transmission factors for absorption correction were calculated, and the absorption correction was applied after data processing.

A three dimensional Patterson map was used to locate the metal atom (Al or Ga). The positions of all other non-hydrogen atoms were obtained from subsequent electron density difference Fourier maps. In all three structures, all hydrogen atoms were located and their positions and isotropic thermal parameters were refined. In the solution of the $Al(npp)_3 \cdot 3H_2O$ structure, the three hydrogen atoms on the methyl carbon of the n-propyl substituent were placed in calculated positions and their isotropic thermal parameters were fixed.

Further refinement of all parameters, including anisotropic temperature factors for all non-hydrogen atoms, was done by full-matrix least-squares methods and minimized with the function $\Sigma w(|F_o| - |F_c|)^2$. Neutral atom scattering factors were taken from ref. 15*a*. Anomalous disperson effects were included in F_{calcd} (16); the values for $\Delta f'$ and $\Delta f''$ were those of Cromer (ref. 15*b*). A correction for secondary extinction (17) was applied to $Al(nbp)_3 \cdot 3H_2O$ (coefficient = 0.29804 × 10^{-5}) as well as to $Ga(npp)_3 \cdot 3H_2O$ (coefficient = 0.47472 × 10^{-5}). Refinement was terminated when the maximum shift/error was less than 0.015 and there was only a small peak of residual electron density (Table 1).

[2]TEXSAN/TEXRAY structure analysis package was used. This includes versions of the following: DIRDIF, direct methods for difference structures, by P. T. Beurskens; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; ORTEP II, illustrations, by C. K. Johnson.

Atomic positional parameters and equivalent isotropic thermal parameters are given in Table 2. Selected bond distances, angles, and hydrogen-bonding data are given in Tables 3, 4, and 5, respectively. Anisotropic thermal parameters, intramolecular bond lengths and angles involving hydrogen, least squares planes, and torsion angles for the three compounds are included as supplementary material as are tables of observed and calculated structure factor amplitudes for each of the three compounds.[3]

Results and discussion

The one-pot reaction which was originally successful with methylamine (13) and ethylamine (13) also works with n-propylamine, and n-butylamine. Attempts to synthesize the i-propylamine and t-butylamine analogues of the tris(3-hydroxy-2-methyl-4-pyridinone)metal(III) complexes were unsuccessful, however. Several solvent systems were tried, but tris(maltolato)metal(III) products (14) were isolated. The basicities of all six of these amines are comparable (pK_a about 10.6 (18)) so steric bulk at nitrogen likely determines the yield; each of the successful syntheses involves a linear primary amine. Steric factors must retard the conversion reaction with branched amines. An extensive study on the conversion reaction for the uncomplexed ligands concluded that more basic and less hindered amines gave the greatest yields of 4-pyridinones (19).

The first crystal suitable for crystallographic analysis formed from a dilute aqueous solution of the $Al(nbp)_3$ complex. The

unit cell parameters indicated that the exoclathrate water network had been perturbed by the larger butyl group. The complex crystallized in the same space group as the exoclathrates, $P\bar{3}$; however, the length of the *a* axis (15.885 (1) Å) was almost 1 Å shorter than the corresponding axis for the N—CH_3 $Al(dpp)_3$ complex (16.600(2) Å (4, 5)). The empirical formula proved to be $Al(nbp)_3 \cdot 3H_2O$, a trihydrate. X-ray quality crystals of both $Al(npp)_3$ and $Ga(npp)_3$ were subsequently produced from dilute

TABLE 4. Selected bond angles (deg) for $Al(nbp)_3 \cdot 3H_2O$, $Al(npp)_3 \cdot 3H_2O$, and $Ga(npp)_3 \cdot 3H_2O$ with estimated standard deviations in parentheses

aqueous solutions and these too were trihydrates $M(npp)_3 \cdot 3H_2O$. This suggested that the steric requirements of the exoclathrate structure were greater than originally expected; addition of a single methylene unit to the alkyl nitrogen substituent was sufficient to completely disrupt the water network. The three compounds were isostructural (the $Al(nbp)_3 \cdot 3H_2O$ complex with one more methylene group in the nitrogen substituent than the other two complexes). The structures can therefore be discussed concurrently.

The crystallographically imposed symmetry ($Z = 2$ in $P\bar{3}$) of the *fac* isomer results in an asymmetric unit consisting of 1/3 of a metal ion, one ligand, and one water molecule (Fig. 1). Although the water molecule does not coordinate the metal atom, hydrogen bonding interactions with the chelating oxygen atoms do make an important contribution to the lattice. The threefold symmetry about the central metal atom is common to all of the tris(*N*-substituted-3-hydroxy-2-methyl-4-pyridinonato)metal(III) complexes, including the exoclathrates (4–8).

Comparisons of these three new structures with the exoclathrates can be made since the atomic labelling system for the trihydrates is consistent with the labelling for the exoclathrates.

Distortions from true octahedral geometry around the metal atom are evinced by the metal–oxygen bond lengths and oxygen–metal–oxygen bond angles (Tables 3 and 4). The M—O(1) bond lengths are consistently shorter than the M—O(2) bond lengths. Not surprisingly, despite partial delocalization of the carbonyl formal double bond at O(2), the deprotonated 3-hydroxy oxygen atom O(1) tends to form a stronger bond with the central metal atom.

Examination of the packing arrangement (which will be discussed in detail later) reveals that the distance between these *fac* tris-ligand metal units is largely determined by the single water molecule O(3) of the asymmetric unit. Hydrogen bonds to this water molecule join the chelating oxygen atom O(1) in one unit cell to a second chelating oxygen atom O(2) in a neighbouring unit cell. This hydrogen bonding network parallels the *c* axis (the C_3 or 3 axis). The lengths of these hydrogen bonds do not vary significantly among the three structures (Table 5), indicating that the tris-ligand metal complex must distort in order to be accommodated by the pocket in the hydrogen bonding network. Similar but stronger distortions are observed in the exoclathrate complexes, in which the hydrogen bonds are shorter and more numerous: compare *c* for $Al(npp)_3 \cdot 3H_2O$ (7.231(2) Å) with that for $Al(mepp)_3 \cdot 12H_2O$ (6.827(1) Å) (5). There is a compression along the 3 axis, a twisting of the chelate plane, and further distortion from true octahedral geometry.

The compression along the 3 axis is seen in the compressed O(1)—M—O(2) bond angles; they are significantly less than 90° (Table 4). Among these three complexes, this compression is greatest for $Ga(npp)_3 \cdot 3H_2O$, where the O(1)—M—O(2) bond angle reaches a minimum value of 82.72 (9)°. Comparison with the exoclathrate structures shows that this O(1)—M—O(2) bond angle is smaller only in $In(dpp)_3 \cdot 12H_2O$ (77.87(6)°) (6). The decrease in the O(1)—M—O(2) bond angle is accompanied by a related increase in the exocyclic O(1)—M—O(2)′ bond angle. This increase is accordingly greater for the Ga complex than for the two Al complexes (Table 4). The exocyclic O(1)—M—O(1)′ and O(2)—M—O(2)′ bond angles are close to the ideal values (90 ± 1°).

Chelation causes a compression in the interior angles of the chelate ring. Although the free ligands with *n*-propyl or *n*-butyl substituents were not synthesized, the structures of Hmpp (N—H) and Hdpp (N—CH_3) (20), as well as Hmepp (8) are known. The O(1)—C(3)—C(4) and O(2)—C(4)—C(3) angles in these uncomplexed ligands are within 1.3° of 120° (Table 4) but have decreased in both the Al and Ga complexes to ~115.7° (Table 4). These O—C—C bond angles are similar to the analogous angles in the exoclathrate structures.

The increased size of the metal ion is accompanied by a reduction in chelate ring strain, as evidenced by the degree of compression of the O—C—C bond angles. By this criterion, Ga best fits the npp^- anion, as it causes the least deviation from the free ligand values. The planarity of the chelate rings C(3)—O(1)—M—O(2)—C(4) varies in the opposite direction. Deviation from planarity of this chelate ring is greatest for the $Ga(npp)_3$ complex, in which the mean deviation from the plane is 0.051 Å, compared with 0.044 Å for $Al(npp)_3$ and 0.047 Å for $Al(nbp)_3$.

This buckling of the chelate ring, as well as the compression along the C_3 axis, actually increases directly with the ionic radius of the metal center. The effective six-coordinate ionic radius of gallium is 0.620 Å, while that of aluminum is 0.535 Å (12). The increased buckling of the chelate ring (mean deviation from the chelate plane), as well as the compression along the 3 axis (compression of the O(1)—M—O(2) bond angle), in the Ga complex is due to its larger ionic radius. Indium has an effective six-coordinate ionic radius of 0.800 Å, thus $In(dpp)_3 \cdot 12H_2O$ complex has a smaller O(1)—M—O(2) bond angle than its Ga analogue.

The delocalization in the C—O bonds is directly related to the difference between the O(1)—C(3) and O(2)—C(4) bond lengths. This difference is 0.025 Å for $Al(npp)_3 \cdot 3H_2O$, 0.028 Å for $Al(nbp)_3 \cdot 3H_2O$, and 0.035 Å for $Ga(npp)_3 \cdot 3H_2O$, indicating that the delocalization in the C—O bonds is slightly greater in the Al complexes than in the Ga complex (Table 3). The extent of delocalization is clearly seen by comparing bond lengths with the related dihydroxy ligands, the catechols. The average C—O distance (calculated from a number of different metal complexes) is 1.36 Å for the catecholate anion and 1.29 Å for the delocalized semiquinone radical anion (21). The O(1)—C(3) bonds are significantly shorter (mean bond length = 1.328(7) Å) than the catecholate bond, and the O(2)—C(4) bonds are the same length (mean bond length = 1.299(6) Å) as the semiquinone bond (within the estimated standard deviation). The same trend was observed for the exoclathrate complexes.

In each complex the pyridinone ring is slightly nonplanar, the distortion being toward an N—C(4) boat for all three structures. The maximum deviation from the mean plane is 0.019(3) Å for each of the trihydrate structures. There are no significant differences in the ring bond lengths between $Al(nbp)_3 \cdot 3H_2O$, $Al(npp)_3 \cdot 3H_2O$, and $Ga(npp)_3 \cdot 3H_2O$ (Table 3). There are also no significant differences in the ring bond angles between the three complexes (Table 4). These ring bond lengths and bond angles are comparable to those found in the exoclathrate structures, indicating that there is no significant difference in double bond delocalization within the ring between these structures.

Crystal packing forces, which favour the minimum energy lattice, are similar for all three trihydrates. $Al(nbp)_3 \cdot 3H_2O$, $Al(npp)_3 \cdot 3H_2O$, and $Ga(npp)_3 \cdot 3H_2O$ all crystallize in the trigonal space group $P\bar{3}$. This is the same space group found for the exoclathrates, which means that the trihydrates are isomorphous with the dodecahydrates.

There are two tris-ligand metal units in the unit cell, and three lattice water molecules per metal complex molecule. Figure 2 shows a view of the packing of the unit cell of $Al(nbp)_3 \cdot 3H_2O$. $Al(npp)_3 \cdot 3H_2O$ and $Ga(npp)_3 \cdot 3H_2O$ pack similarly, the only difference being one less methylene group in the nitrogen substituent. The ligand contains non-polar hydrophobic *N*-substituents (*n*-propyl or *n*-butyl). The complexes crystallized such that hydrophobic layers of *N*-substituted pyridinone rings alternated with hydrophilic layers of water molecules.

The packing of these tris-ligand metal units is different from that of the previous exoclathrate structures. An important feature of the exoclathrate unit cell is the neat tucking of the hydrophobic ring substituents (the methyl and ethyl groups) into the center core of the unit cell, with the hexagonal water channels at each corner. The C(2) methyl substituents in the exoclathrates are not nearly as crowded toward the center of the unit cell as they may at first appear, one of these methyl groups points up the *c* axis, while the other points down (as they do in Fig. 2 as well). The hydrophobic ligands are completely enclosed by the ubiquitous water molecules in the exoclathrate. In the trihydrates, Fig. 2 reveals that there are no hexagonal water channels at the corners of the unit cell.

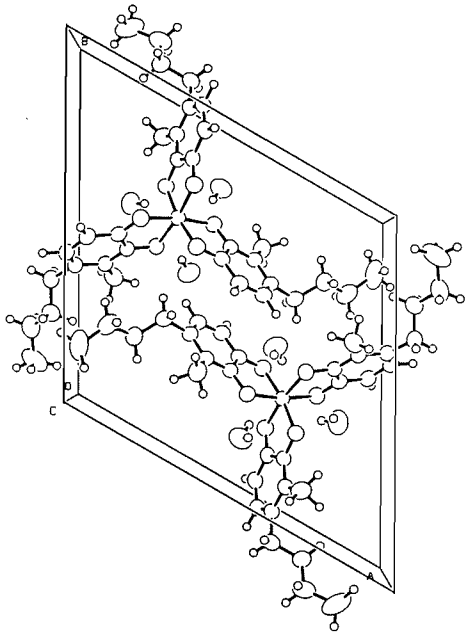

FIG. 2. ORTEP view of the unit cell packing in $Al(nbp)_3 \cdot 3H_2O$ down the *c* axis.

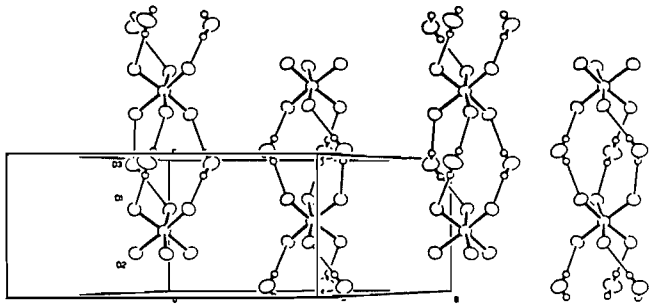

FIG. 3. ORTEP view of the hydrogen bonding network in $M(npp)_3 \cdot 3H_2O$ down the *a* axis; only the MO_6 octahedral coordination sphere and water O and H atoms are included (thick lines denote covalent bonds, thin lines denote hydrogen bonds).

The space between the hydrophobic ligand and the hydrophilic water fence in the exoclathrate appeared sufficient to accommodate one more methylene group. This is not the case, and the single extra methylene group of the *n*-propyl substituent precludes the formation of the extensive hexagonal water channels of the exoclathrates, resulting in a more conventional hydrogen bonding network. Despite the reduced number of water molecules in the unit cell, hydrogen bonding does increase the crystal lattice stability. The water molecules form an important hydrogen bonding network with the oxygen atoms which chelate the metal atom of the trihydrate crystal. Table 5 summarizes the bond distances and angles involved in this network. The oxygen atoms which chelate the metal atom in the trihydrate have no hydrogen atoms directly attached to them so they are hydrogen atom acceptors. The oxygen atoms of the water molecules are hydrogen atom donors.

The hydrogen bonding in the trihydrates is weaker than in the exoclathrates. In the trihydrates, the H···O and O···O distances are longer than in the exoclathrates. Comparison of the hydrogen bond distances and angles in Table 5 shows that there are

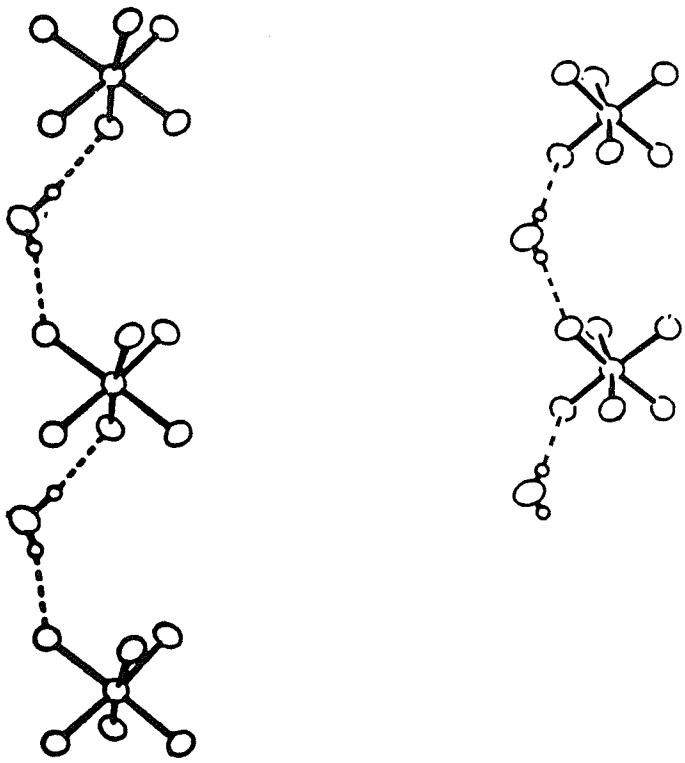

FIG. 4. ORTEP view of a part of the hydrogen bonding network of waters in $M(mepp)_3 \cdot 12H_2O$ (on the left, from ref. 8) and $M(npp)_3 \cdot 3H_2O$ (right). This view down the *a* axis shows the infinite chains of hydrogen bonds which occur down the *c* axis in both the exoclathrates and the trihydrates. Solid lines denote covalent bonds, while dashed lines denote hydrogen bonds.

no significant differences in the water network among the three trihydrate structures. The weaker hydrogen bonding is not surprising; in the trihydrates two or the three oxygen atoms involved in the water network are chelating a metal atom. A weak hydrogen bond, however, has an enthalpy of ca. 20 kJ mol^{-1}, so that even the less intricate hydrogen bonding network observed in the trihydrate structures will result in substantial stabilization of the lattice.

This (less unconventional) network is built up of water molecules which hydrogen bond chelating oxygen atoms in neighbouring unit cells. An ORTEP view of this network is given in Fig. 3. These water molecules form an infinite chain down the *c* axis. They join the hydroxy O(1) in one ligand to the carbonyl oxygen O(2) of a ligand rotated by 120° and translated by one unit cell. The O···H and O···O distances vary from 1.9 to 2.25 Å and from 2.84 to 3.04 Å respectively (Table 5). The chelating carbonyl O(2) consistently forms shorter and hence stronger O···H bonds than the chelating hydroxy O(1). This may reflect the delocalization of the formal double bond of the carbonyl C(4)—O(2). It is also consistent with the fact that O(1) forms stronger bonds with the metal atom than O(2) (M—O(1) is shorter than M—O(2)).

The structural differences between the trihydrates and the dodecahydrates are exaggerated by the increased complexity of the water network in the latter. The extended hydrogen bonding network of the exoclathrate can be reduced to that shown in Fig. 4 by removal of the hexagonal water rings (O(4), O(5)), as well as the bridging water molecules to which they are directly attached (O(6)). The hydrogen bonding network is thus simplified to an infinite chain down the *c* axis. The similarity to

the infinite chain of hydrogen bonded water molecules of the trihydrate structures is striking; in Fig. 4, comparison of the simplified exoclathrate and the trihydrate structures shows that in the former the essential features of the trihydrate are reproduced intact. In fact, all of these structures are isostructural, except that the exoclathrates have more hydrogen bonds to (and including) the hexagonal water channels to accommodate. Very recently, van der Helm and collaborators reported (22) at a conference the structures of the trihydrate complexes $M(mepp)_3 \cdot 3H_2O$ where M = Al, Ga, Fe; as reported, they are isostructural with the trihydrates reported here. These are a direct link to the exoclathrates since they involve one of the ligands characteristic of the exoclathrates *without* the dodecahydrate structure. We have been unable to prepare any hydrates of $M(dpp)_3$ or $M(mepp)_3$ except the dodecahydrates.

The tris(3-hydroxy-2-methyl-4-pyridinonato)metal complex could not distort sufficiently to allow the *N*–*n*-propyl substituent to be accommodated within the rigid hydrogen bonded exoclathrate lattice. The perturbation of the complicated, energetically favoured water network of the exoclathrates resulted in the retention of the infinite chain of hydrogen bonds down the *c* axis. The interactions between the larger tris-ligand metal molecules appear to take precedence over those between the smaller water molecules, and this helps to explain why the hydrogen bonding seen in the trihydrate structures is more conventional for inorganic hydrates.

Two new complexes of stoichiometry 2:1 are reported for the donors tetrathiafulvalene (TTF) and tetramethyltetraselenafulvalene (TMTSF) with the acceptor paranitrophenylmalononitrile (PNPMA). Both compounds are semiconductors with a resistivity of about $4 \times 10^{-4}\ \Omega$ m for $(TMTSF)_2PNPMA$ and $0.58\ \Omega$ m for $(TTF)_2PNPMA$. The larger conductivity of the first complex can be attributed to the disorder of the PNPMA anions. Vibrational spectra were obtained by FTIR and Raman spectroscopy, in order to determine the degree of charge transfer in these systems. Both complexes have the electron distribution $(D^{+0.4})_2A^{-0.8}$. As a result the donors D stack in tetramerized units and exhibit vibronic activation of certain symmetric monomer modes, thus indicating the presence of strong electron–vibrational interactions in the donor stacks.

Key words: TTF and TMTSF salts, charge transfer complexes, IR and Raman spectra, degree of charge transfer, paranitrophenylmalononitrile (PNPMA).

On a observé deux nouveaux complexes de stoechiométrie 2:1 pour les donneurs tétrathiafulvalène (TTF) et tétraméthyltétrasélénafulvalène (TMTSF) avec l'accepteur *p*-nitrophénylmalononitrile (PNPMA). Les deux composés sont des semiconducteurs dont la résistance est d'environ $4 \times 10^{-4}\ \Omega$ m pour le $(TMTSF)_2PNPMA$ et $0{,}58\ \Omega$ m pour le $(TTF)_2PNPMA$. On peut attribuer la conductivité plus grande du premier complexe au désordre des anions PNPMA. Les spectres de vibration ont été déterminés par IR-TF et par spectroscopie Raman pour évaluer le degré de transfert de charge dans ces systèmes. Les deux complexes ont une distribution électronique $(D^{+0,4})_2A^{-0,8}$. Il en résulte que les donneurs D s'entassent dans des unités tétramères et présentent de l'activation vibronique de certains modes monomères symétriques qui indiquent la présence de fortes interactions électron-vibrationnelle dans les entassements de donneurs.

Mots clés : sels de TTF et de TMTSF, complexes de transfert de charge; spectres IR et Raman, degré de transfert de charge, *p*-nitrophénylmalononitrile (PNPMA).

[Traduit par la rédaction]

Introduction

The organic conducting salts of tetramethyltetraselenafulvalene (TMTSF) of the type $(TMTSF)_2X$, called Bechgaard salts, have attracted great attention due to the discovery of superconductivity in these systems below 10 K, the rich variety of electronic and magnetic ground states depending on the anion present, the temperature, and the pressure (1–5). In such compounds one finds in the presence of nonsymmetric *inorganic* anions a high temperature metallic state which extends down in temperature to 100 K below which an anion ordering transition is observed.

In the previous work we investigated the influence of nonsymmetric organic anions on the conductivity of TMTSF and TTF salts (TTF = tetrathiafulvalene) (6). For that purpose we synthesized paranitrophenylmalononitrile (PNMA), an organic planar acceptor similar to the well known donor tetracyanoquinodimethane (TCNQ), except that one malononitrile group is replaced with a nitro group (see Fig. 1). Complexation with TTF and TMTSF results in complexes of stoichiometry D_2A, where D is the donor and A the acceptor. The donors form linear chains of tetramers (Fig. 1). In the TTF compound, the anions are ordered and form sheets perpendicular to the stacks, with an inversion center between pairs of anions. In the TMTSF compound, the donor stacking is similar but the anions are highly disordered (7). Both compounds are semiconductors with a room temperature resistivity of about $4 \times 10^{-4}\ \Omega$ m for $(TMTSF)_2PNPMA$ and $0.58\ \Omega$ m for the TTF salt. The much higher conductivity of the TMSTF was thus attributed to the random distribution of the anions (6).

In the TTF salt, the ordered distribution of the PNPMA ions creates an effective periodic perturbation on the electronic band of the conducting electrons in the donor chain. Assuming an oxidation state $D^{+1/2}$, the electronic band is 3/4 full. Thus any perturbation with a period 4a, i.e., four times the lattice spacing between the donors, will introduce a Peierls gap in the electronic spectrum, and the system will become semiconducting (8). As seen from Fig. 1, both the tetramerization of the TTF donor stack and the periodicity of the PNPMA anions produce such perturbations of periodicity 4a. In the TMSF compound, only the donor stacking is present; no ordering of the anions is found. In the present work, we report IR and Raman spectra of both the ordered and disordered compounds in order to establish the corresponding charge transfer states. We also present a simple model of electron–vibration couplings in the cation tetramers

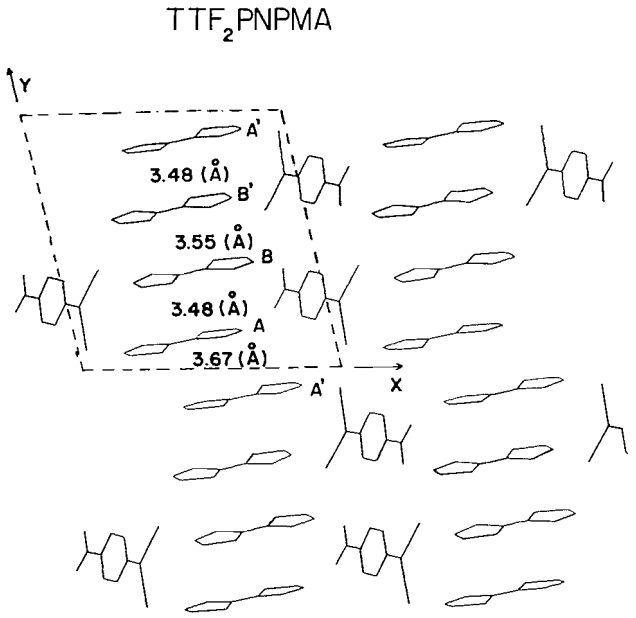

FIG. 1. Projection along (stacking) y axis of the sample $(TTF)_2$-PNPMA.

in terms of a tetramer molecular orbital description, i.e., a delocalized model, in order to explain the splittings observed in the spectra.

Experimental details

Single crystals of these complexes were prepared and described elsewhere (7). Chemical analysis showed 2:1 stoichiometry. Raman spectra were taken using a Jobin Yvon spectrometer equipped with holographic gratings and photon counting electronics. The excitation source was argon and krypton ion lasers operating with a power lower than 5 mW to avoid sample damage. Infrared absorption spectra were obtained using a FTIR spectrometer BOMEM model DA3; a cooled detector of Ge doped with Cu was used in the frequency range 400 to 4000 cm^{-1}. All infrared measurements were made on powder and low temperature spectra were obtained by thermally anchoring the sample to a controlled cold finger. The temperature was measured with Au–Chromel thermocouples with an accuracy of ± 3 K.

Electron-A_g mode coupling in a tetramer

The crystal structure of TTF_2PNPMA is triclinic (6). The separation along the TTF chains is not regular, but can be described as tetrameric, with quasiisolated tetramers ABBA. The AB, BB, and AA distances are respectively 3.48, 3.55, and 3.67 Å (Fig. 1). We will assume as a first approximation that we have a perfect tetramer AAAA and examine the possible electronic couplings to symmetric modes. In a dimer, it is well known that A_g modes of ions appear unchanged in frequency in the Raman spectrum, whereas these same modes can appear in the IR spectrum but are considerably shifted in frequency due to the interaction of the electron transfer with the A_g modes of the two molecules of the dimer (9–13).

We take a Hückel-type Hamiltonian for the electrons in the tetramer, including a first order coupling of electrons to a single symmetric vibration mode on each site. Such a model has been considered previously in the strong electron correlation limit, i.e., a valence bond model (Heitler London or Hubbard) (14). In the present case we shall examine the weak correlation limit for which a delocalized molecular orbital model is appropriate as in the dimer case (9–13). Our starting Hamiltonian neglecting electron correlation is therefore:

$$[1] \quad H_e = -t \sum_{i=1}^{3} [C_i^+ C_{i+1} + C_{i+1}^+ C_i]$$

$$[2] \quad H_{ev} = \sum_{i=1}^{4} Q_i C_i^+ C_i$$

$$[3] \quad H_V = \frac{1}{2\gamma^2} \sum_{i=1}^{4} (Q_i^2 + \omega_0^2 Q_i^2)$$

$C_i^+(C_i)$ is the creation (annihilation) operator for electron occupation of a molecular orbital on site i; t is the transfer (hopping integral) between two neighbouring site orbitals; $Q_i = \gamma q_i$, where q_i is a vibrational normal mode of a molecule at site i of frequency ω_0; $\gamma = \partial\epsilon/\partial q_i$ is the change in energy of a site molecular orbital due to change in the bond length of the mode q_i by the electron population $C_i^+ C_i$. γ is *nonzero* only for symmetric (A_g) modes. This interaction produces a change in the equilibrium bond length only, i.e., there is no frequency change from this linear perturbation (9–13). The last equation [3] represents the vibrational energy of the four independent site modes of frequency ω_0.

Diagonalization of the electronic energy, i.e. eq. [2] is achieved in terms of the *delocalized orbitals* for the tetramer which are linear combinations of the site molecular orbitals. Such a delocalized representation is obtained from the unitary transformation

$$[4] \quad C_i' = UC_i; \quad U = \begin{bmatrix} a & b & b & a \\ b & a & -a & -b \\ b & -a & -a & b \\ a & -b & b & -a \end{bmatrix}$$

where $a = 0.3718$, $b = 0.6015$ for a tetramer (15). Defining the new Hamiltonian $H' = U^+ H U$ in this delocalized basis, we obtain the following Hamiltonian matrix after transforming $H_e + H_{ev}$ (eqs. [2] and [3]), and defining dimer modes,

$$[5] \quad \begin{aligned} Q_{1g} &= Q_1 + Q_4, & Q_{2g} &= Q_2 + Q_3 \\ Q_{1u} &= Q_1 - Q_4, & Q_{2u} &= Q_2 - Q_3 \end{aligned}$$

$$[6] \quad H' = \begin{pmatrix} a^2Q_{1g} + b^2Q_{2g} + \epsilon_1 & ab(Q_{1u} + Q_{2u}) & ab(Q_{1g} - Q_{2g}) & a^2Q_{1u} - b^2Q_{2u} \\ ab(Q_{1u} + Q_{2u}) & a^2Q_{1g} + b^2Q_{2g} + \epsilon_2 & b^2Q_{1u} - a^2Q_{2u} & ab(Q_{1g} - Q_{2g}) \\ ab(Q_{1g} - Q_{2g}) & b^2Q_{1u} - a^2Q_{2u} & a^2Q_{1g} + b^2Q_{2g} + \epsilon_3 & ab(Q_{1u} + Q_{2u}) \\ a^2Q_{1u} - b^2Q_{2u} & ab(Q_{1g} - Q_{2g}) & ab(Q_{1u} + Q_{2u}) & a^2Q_{1g} + b^2Q_{2g} + \epsilon_4 \end{pmatrix}$$

TABLE 1. Infrared vibrational frequencies of $PNPMA^0$, $TMTSF^+$, $(TMTSF)_2PNPMA$, K^+PNPMA^-, TTF^+, and $(TTF)_2PNPMA$

where $\epsilon_1 = -1.618t$, $\epsilon_2 = -0.618t$, $\epsilon_3 = +0.618t$, $\epsilon_4 = +1.618t$.

We now examine two limit cases. The first case, $t \ll \langle Q_i \rangle$ would correspond to strong electron–vibrational coupling. In such a limit, taking $a = b = 1/2$ gives four *independent* vibrational normal modes for the tetramer:

[7] $$Q_{1g} + Q_{2g}, \quad Q_{1u} + Q_{2u}, \quad Q_{1g} - Q_{2g}, \quad Q_{1u} - Q_{2u}$$

Clearly, from the new Hamiltonian [6] one sees that the totally symmetric tetramer mode ($Q_{1g} + Q_{2g}$) would uncouple completely from the electron motion. Thus in the limit of large electron–vibrational coupling, this Raman-active, totally symmetric mode would undergo *no* frequency change as in the case of dimers. By symmetry, the second and fourth modes in eq. [7] are IR-active whereas the third would be Raman-active. All three would undergo frequency changes since they couple different electronic states.

The case $t \gg \langle Q_i \rangle$ is the limit which applies to our system, since new electronic bands appear below 600 nm in the visible spectrum of the complexes which cannot be ascribed to isolated molecular transitions (Fig. 2). Equation [6] shows that the four dimer modes described in eq. [5] have their frequency shifted from ω_0 as they are all involved in nondiagonal electronic couplings. Especially noteworthy is the fact that Q_{1g}, the in-phase vibration of the two outer molecules, and Q_{2g}, the in-phase vibration of the two inner molecules, produce the same bond length changes in all four energy levels of the tetramer. These bond length changes produce no frequency shifts.

We now apply second order perturbation theory to obtain the frequency shifts of each dimer mode in the tetramers. Thus for Q_{1g} and Q_{2g}, we obtain the effective potentials,

[8] $$V_g = \frac{(ab)^2}{\epsilon_1 - \epsilon_3}(Q_{1g}^2 + Q_{2g}^2) = \left(\frac{-0.02}{t}\right)(Q_{1g}^2 + Q_{2g}^2)$$

The frequency change $\Delta\omega_g = -0.02\gamma^2/t$, obtained by expanding to first order with respect to γ^2/t, is therefore *identical* for these two dimer modes, i.e. Q_{1g} and Q_{2g}, whose in-phase collective vibration is Raman active. Similar calculations for the other tetramer modes give

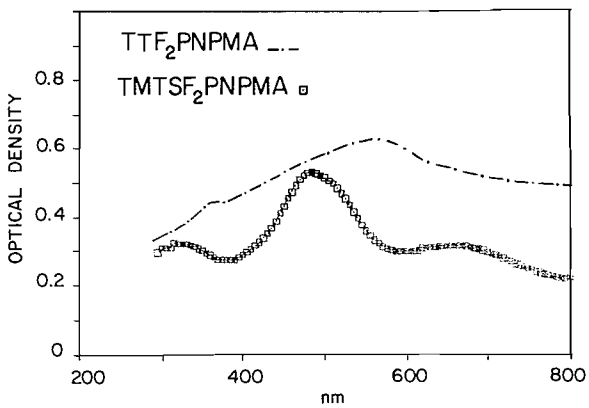

FIG. 2. Ultraviolet and visible absorption spectra of $(TMTSF)_2$-PNPMA and $(TTF)_2PNPMA$.

[9] $$\Delta\omega(Q_{1u}) = \frac{-0.05\gamma^2}{t}; \qquad \Delta\omega(Q_{2u}) = \frac{-0.1\gamma^2}{t}$$

for the two collective combinations, of out-of-phase IR-active dimer modes.

In conclusion, we have shown that one should expect in the spectra of tetramer stacks of ions, the following correlation: appearance of A_g modes in the Raman spectra at lower frequencies than the monomer ion; A_g modes in the IR spectrum are also displaced to lower frequencies but now split in two due to the two different collective dimer vibrations, Q_{1u} and Q_{2u} (eq. [5]). The ratios of the frequency shifts should occur in the order

[10] $$\Delta\omega_g{:}\Delta\omega_{1u}{:}\Delta\omega_{2u} = 1{:}2.5{:}5$$

Hence one expects A_g modes to appear as doublets in the IR but as single lines in the Raman. The IR lines should undergo larger frequency shifts than the Raman lines.

The present model assumes weak electron correlation, i.e., an independent particle model, so that optical properties depend on the delocalized tetramer molecular orbitals C' (eq. [4]). Another limiting model is the strong electronic correlation

valence bond model (Heitler–London or Hubbard), where the description is in terms of monomer, i.e., localized configurations (14). Such a localized model also predicts fine structure in the IR-active A_g modes but no analysis of the Raman-active modes has yet been performed in this strong correlation limit.

Results and discussions

Infrared absorption spectra of $(TMTSF)_2PNPMA$, $(TTF)_2$-PNPMA are presented in Figs. 3 and 4, respectively. Some large bands are observed between 1000 and 1600 cm^{-1} in both complexes. The infrared spectra of the neutral compounds $TMTSF^0$, TTF^0, and $PNPMA^5$ (Fig. 5) exhibit only sharp bands in that region. Broad bands are indicative of strong interaction between conduction electrons and molecular vibrations (9–13). In Table 1 we report the IR vibrational frequencies of $(TMTSF)_2PNPMA$, $(TTF)_2PNPMA$, and the individual ions. A detailed comparison of these frequencies permits us to determine the degree of charge transfer by establishing a pairwise correspondence between vibrational modes of the neutral, e.g., $PNPMA^0$ and the corresponding anion as in

K^+PNPMA^-. The concept of ionization frequency shifts (Δν) linear with charge transfer is well established and has been applied to many electron donor as well as acceptor molecules. It can be used when the effective molecular configuration symmetry is retained upon ionization as in our complexes (16–18).

An estimate of the degree of charge ρ is best obtained from molecular vibrational frequencies which display the highest ionization shift. Comparing the neutral compound $PNPMA^0$ to the anion $PNPMA^-$, the frequency of the vibrational mode C—NO_2 is increased from 1528 to 1597 cm^{-1} (Table 2). We utilised the frequency shift of this vibrational mode to evaluate the partial charge on PNPMA in our complexes and the results are reported in Table 2. The degree of charge transfer is partial for the anion, i.e. (−0.8) for $(TMTSF)_2PNPMA$ and also for $(TTF)_2PNPMA$. It remains almost unchanged at 14 K. The most important new feature in going to lower temperatures is the growth of peaks in the region from 1350 to 1430 cm^{-1}. These can be attributed to A_g modes of the cations activated by the coupling of the conduction electrons to intramolecular vibrational modes (9–13). The mode at 1357 cm^{-1} of $(TTF)_2PNPMA$ is characterized as the vibronic intensity enhancement of the A_g ν_3 modes of the $(TTF^+)_2$ dimer observed previously in solution (19). The splitting of these bands at 1348, 1357 cm^{-1} can be explained by the presence of TTF tetramer inferred from X-ray data (Fig. 1) and the corresponding model described in the previous section.

To determine the degree of charge on the donors, Raman spectra are preferable since the excitation by Ar^+ and Kr^+ lasers produces Raman intensities which display a resonance character (Figs. 6, 7), thus allowing us to identify the C=C ν_3 vibrations. Furthermore, as shown in the previous section, Raman-active modes should show no splittings from the electron–vibration couplings inherent in these systems. From the neutral compound $TMTSF^0$ to the cation, the frequency of the C=C mode is shifted from 1539 to 1399 cm^{-1} (Table 3). We utilise the maximum frequency shift of this vibrational mode to estimate the charge on TMTSF in $(TMTSF)_2PNPMA$. The same approach was used to evaluate ρ of $(TTF)_2PNPMA$, and the results are reported in Table 3. Again the degree of charge transfer is partial (+0.4) for both $(TMTSF)_2PNPMA$ and $(TTF)_2PNPMA$.

In conclusion, we note that the fundamental difference between A_g modes in stacked dimers as opposed to tetramers in organic conductors is that in the former the frequency of A_g monomer modes remains unperturbed in the Raman spectra due to electron–vibration couplings. This enables one to use these

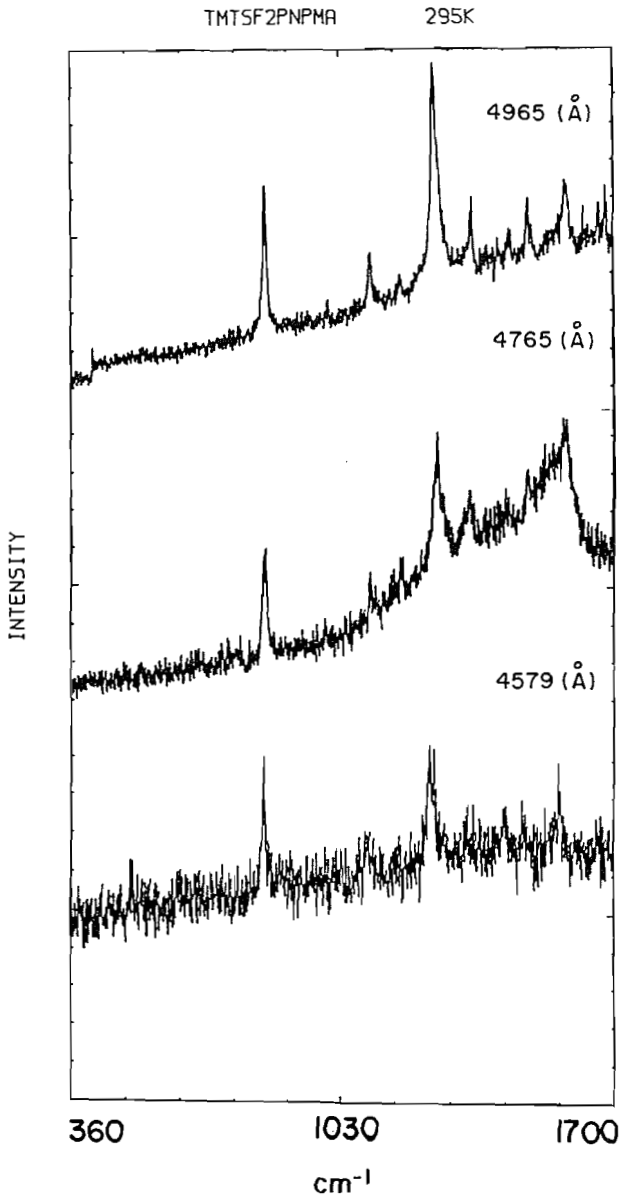

FIG. 6. Raman spectra of $(TMTSF)_2PNPMA$.

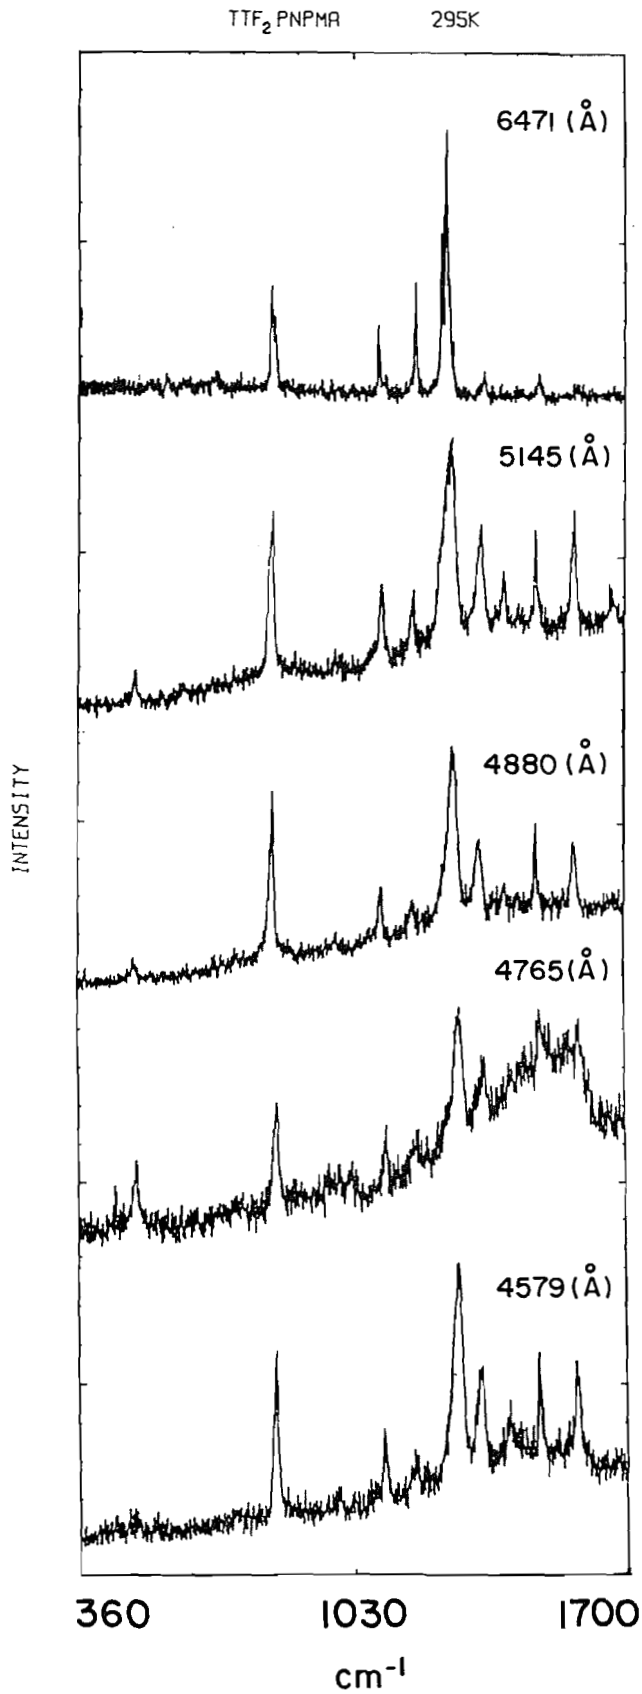

FIG. 7. Raman spectra of $(TTF)_2PNPMA$.

spectra as useful tools to measure the degree of charge transfer in the stacks. In the case of tetramers, our single model, eqs. [1]–[3] showed that now the A_g modes appear in the Raman spectrum slightly downshifted in frequency with respect to the isolated monomer as a result of the electron–vibrational coupling in the stack. However, the A_g mode lines remain single lines as opposed to the IR active combinations of these same A_g modes which undergo larger frequency shifts and further generally appear as doublets (see Table 1).

We have used therefore the frequency shifts of IR modes of the acceptor PNPMA, to established its degree of charge transfer as it appears as isolated monomers in the crystal (Fig. 1) and hence is not expected to undergo electron–vibrational coupling. For the donors TTF and TMTSF, the most reliable estimates of degree of charge transfer from frequency shifts of A_g modes was obtained from the Raman spectrum, since we have shown by our model, it is the Raman lines which undergo the smallest electron–vibrational coupling effects as well as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

no splittings of the individual lines. Thus both charge transfer estimates, i.e. from the IR frequencies of the acceptor and the Raman spectra of the donors, were found to agree remarkably well. We conclude therefore that both semiconductors can be described by the stoichiometric and electronic formula $(D^{+0.4})_2A^{-0.8}$. This is consistent with a tetrameric stacking of the donors, since $D^{+1/2}$ linear chains are known to undergo Peierls tetramerization as a result of the electron–vibrational couplings which are also responsible for the frequency shifts and IR activation of A_g modes. As a consequence, Peierls systems are usually known to undergo metal–semiconductor transitions (8). Both compounds reported here exhibited normal semiconducting behaviour between 77 and 400 K and no phase transition was found from conductivity measurements in this temperature range (6). The metal–semiconducting transition probably occurs at higher temperatures than 400 K.

Experimental and theoretical conformer distributions of 3-methylbenzaldehyde

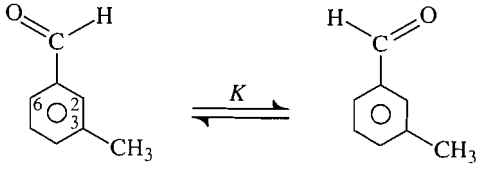
TED SCHAEFER,[1] KERRY J. COX, AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2
Received, November 5, 1990

TED SCHAEFER, KERRY J. COX, and RUDY SEBASTIAN. Can. J. Chem. **69**, 908 (1991).

The long-range coupling constants between the aldehydic and ring protons of 3-methylbenzaldehyde, in CS_2/C_6D_{12} and acetone-d_6 solutions, imply an equilibrium constant, $K(O\text{-}cis/O\text{-}trans)$ of 1.07(4) in both solvents at 300 K. The small preference for the *O-cis* conformer in both solutions suggests that the *O-cis* conformer is also the more abundant in the vapor, indicating a reassignment of recently reported electronic bands in this state. Geometry-optimized molecular orbital computations, using the AM1, STO-3G, and 6-31G bases, confirm the slightly lower energy of the free *O-cis* conformer. The ^6J(H,CHO) of +0.015(1) Hz for the acetone solution has the correct sign and magnitude implied by a recent simple model for this coupling constant. Other long-range coupling constants are also discussed in terms of their mechanisms.

Key words: conformations, 3MB; NMR, 3MB; spin–spin coupling constants, 3MB; MO computations, 3MB.

TED SCHAEFER, KERRY J. COX et RUDY SEBASTIAN. Can. J. Chem. **69**, 908 (1991).



Les constantes de couplage à longue distance entre le proton aldéhydique et les protons du cycle du 3-méthylbenzaldéhyde, dans des solutions de CS_2/C_6D_{12} et d'acétone-d_6, impliquent que la constante d'équilibre, $K(O\text{-}cis/O\text{-}trans)$, est égale à 1,07(4) dans chacune des solutions suggère que le conformère *O-cis* est aussi le plus abondant en phase gazeuse et qu'il est nécessaire de réattribuer des bandes observées récemment dans cet état. Des calculs d'orbitales moléculaires avec géométrie optimisée, réalisés à l'aide de bases AM1, STO-3G et 6-31G, confirment que l'énergie du conformère *O-cis* libre est légèrement plus faible. Sur la base d'un modèle récent pour cette constante de couplage, le signe et l'amplitude de la ^6J(H,CHO), +0,0015(1) Hz, pour la solution dans l'acétone, sont corrects. On discute aussi d'autres constantes de couplage à longue distance en fonction de leurs mécanismes.

Mot clés : conformations, 3MB; RMN, 3MB; constantes de couplage spin–spin, 3MB; calculs d'OM, 3MB.

[Traduit par la rédaction]

Introduction

A recent discussion (1) of the phosphorescence excitation spectrum of jet-cooled 3-methylbenzaldehyde (3MB) tentatively assumes that the *O-trans* conformer in the ground electronic state is somewhat more abundant than the *O-cis* conformer ($K < 1$). The reported values of K range from 11 for the vapor at 368 K (2), based on torsional frequencies, to 1.22 for a 0.5 M solution in $CHCl_2F/CCl_2F_2$ at 123 K (3), as assessed from the ^{13}C nmr spectrum of the distinct conformers. An early ^1H nmr spectrum of 3MB in acetone solution at ambient temperature (4) gave K as ≥ 2.3, as indicated by the long-range coupling constant, ^5J(H,CHO), between the aldehydic and *meta* ring proton.

O-trans *O-cis*

Now, a methyl group is certainly a weak perturber (1) of the benzaldehyde moiety and intuition suggests that K must be little different from unity and relatively insensitive to environment. Precise measurements of ^5J(H,CHO) are possible with modern instruments and this coupling constant is a good indicator of K (5). Such measurements are reported here for 3MB in the nonpolar CS_2/C_6D_{12} solvent mixture as well as in the polar solvent acetone-d_6. In addition, molecular orbital computations of the conformational energies of the free molecule allow a comparison with those derived from ^5J(H,CHO). It appears that the *O-cis* is only slightly more abundant than the *O-trans* conformer, roughly independent of solvent.

[1]Author to whom correspondence may be addressed.

Experimental

Dilute solutions of 3MB in CS_2/C_6D_{12} and acetone-d_6 (see Table 1 for details) were filtered into 5-mm o.d. nmr sample tubes. These were degassed by five freeze–pump–thaw cycles and were then flame-sealed under vacuum. The ^1H nmr spectra were acquired on an AM 300 Bruker spectrometer in a manner described in detail (6) previously; see also the caption to Fig. 1. The spectra were acquired with and without decoupling of the methyl protons and were analyzed with the computer program NUMARIT (7), as extensively altered by R. Sebastian. The ensuing chemical shifts and coupling constants can be found in Table 1. Figure 1 displays the aldehydic proton spectrum, illustrating the spectral quality attainable with due care.

AM1 (8) and *ab initio* molecular orbital calculations, employing STO-3G (9) and 6-31 G (10) basis sets, of the conformational energies of 3 MB were performed on an Amdahl 5870 system with the program GAUSSIAN 86 (11). Optimization procedures allowed all bond angles and lengths to vary for a given conformation with the constraint, however, that the aromatic moiety remain planar.

Results and discussion

Table 1 contains the spectral parameters for 3MB in a polar and a nonpolar medium. It can be seen that, even at 300 MHz, the ring protons are strongly coupled in the sense that the chemical shift differences for certain pairs are quite small; for example, H-4 and H-5 have less than a 3 Hz difference in their shifts in the CS_2/C_6D_{12} solution. In consequence, certain spectral parameters correlate relatively strongly (footnotes to Table 1) and the precision of analysis for the nonpolar solution is lower than desirable. Nevertheless, some reliable conformational information can be extracted.

The cis–trans *equilibrium*

Because the barrier to rotation about the Csp^2—Csp^2 bond in 3MB is at least 30 kJ/mol (3) in solution and is most likely (12) very near 20 kJ/mol in the vapor, a discussion in terms of planar conformers (the methyl groups, of course, rotate almost freely)

is a good approximation at ambient temperatures; even at 368 K, RT is only about 3 kJ/mol.

In benzaldehye, ^5J(H,CHO) ≡ ^5J is 0.431(2) and 0.430(1) Hz in CS_2/C_6D_{12} and acetone-d_6 solutions, respectively (13). As discussed previously (5), ^5J, as a σ-electron coupling constant in the effectively planar conformers (the essentially zero coupling constant between the aldehydic and methyl protons in 3MB confirms this conclusion), vanishes in the *O-cis* conformer above. Hence, because the methyl group lies far from the coupling pathway in 3MB and is also a weakly perturbing substituent, one has ^5J(H,CHO) in the *O-trans* conformer as 0.861(4) Hz in either solution (even in 2-fluorobenzaldehyde, the sum of the two ^5J values is 0.869(2) and 0.850(2) Hz in the nonpolar and polar solvent systems, respectively (5), indicating a small perturbation by the much stronger perturber placed closer to the coupling fragment). For 3MB, ^5J is 0.413(3) and 0.418(1) Hz in CS_2/C_6D_{12} and acetone-d_6, respectively, implying a K of 1.07(4) in both solutions. The error estimate follows from an average ^5J of 0.415(5) Hz in the two solutions and the estimate of 0.861(4) Hz for ^5J in the *O-trans* conformer.

The inference is drawn of a conformational equilibrium insensitive to solvent polarity. It is possible that the K of 1.22 obtained from peak intensities in the ^{13}C nmr spectrum of 3MB at 123 K is in good agreement with the present result. If the entropy difference between the conformers vanishes in all solvents, then the free energy difference of 170 ± 100 J/mol at 300 K implies a K of 1.18 (12) at 123 K. If, indeed, K is independent of solvent, then the *O-cis* conformer is also very likely slightly the more abundant in the vapor, suggesting the opposite of the assignment in ref. 1. It is therefore of interest to have a molecular orbital result for the relative stability of the conformers of 3MB.

Molecular orbital computations

Table 2 presents AM1, STO-3G, and 6-31G MO energies for the *O-cis* and *O-trans* conformers of 3MB, together with the energies of each conformer as influenced by two orientations of the methyl group, one with a C—H bond in the aromatic plane and pointing towards the other substituent, the other with this C—H bond pointing away from the aldehydic group. The upshot is that the total energy of the *O-cis* conformer is 120, 160, and 490 J/mol lower than that of the *O-trans* conformer at the AM1, STO-3G, and 6-31G levels of molecular orbital theory, respectively. Naively, ignoring zero point energy differences, for example, these energy differences imply a K of 1.03, 1.07, and 1.22 at 300 K. At these levels of molecular orbital theory, therefore, it appears that the *O-cis* will be more abundant than the *O-trans* conformer at the temperature of the jet-cooled vapor.

Figure 2 displays the 6-31G structures of the most stable *O-cis* and *O-trans* conformers. These may well be useful to molecular spectroscopists. The figure caption also provides some useful statements.

The dipole moment of 3MB in benzene solution (19) at 298 K is 2.93 D (from which it was concluded that only the *O-cis* conformer is present). This number lies between the *ab initio* estimates in Table 2. The mean of these estimates, weighted by the abundances measured in CS_2/C_6D_{12} and acetone-d_6 solutions above, yields a dipole moment of 3.07 D. Alternatively, addition of 0.9 D to each of the STO-3G values similarly yields a dipole moment of 2.94 D, reflecting the underestimate and

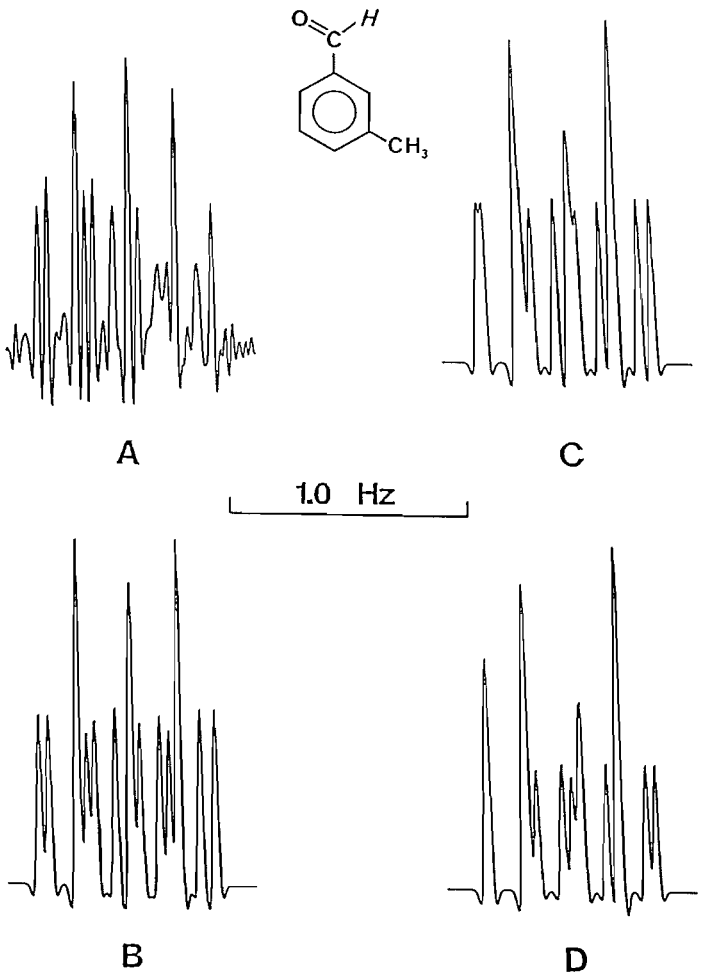

FIG. 1. In A the ^{1}H nmr spectrum at 300 MHz of the aldehydic proton of 3-methylbenzaldehyde, as a 4.0 mol% solution in acetone-d_6, is displayed under conditions in which the methyl protons are decoupled (the methyl protons are coupled by less than 0.01 Hz to the aldehydic proton in the single resonance spectrum). The spectrum in A extends over 0.8 Hz, the acquisition time for each of 32 free induction decays was 54.6 s, the digital resolution was better than 0.005 Hz/point, the probe temperature was 300 K, and considerable resolution enhancement was applied before Fourier transformation, causing some intensity distortion. In B the simulated spectrum uses the spectral parameters from Table 1 and has ^6J(H-4,CHO) as +0.015 Hz. In C the simulated spectrum has ^6J(H-4,CHO) as −0.015 Hz and in D it is taken as zero. The spectrum is sensitive to the sign and magnitude of this coupling constant because of the strongly second-order nature of the ring proton spectrum. A model mentioned in the text demands that ^6J(H-4,CHO) be positive.

[d]Total energy is −382.319 590 au.

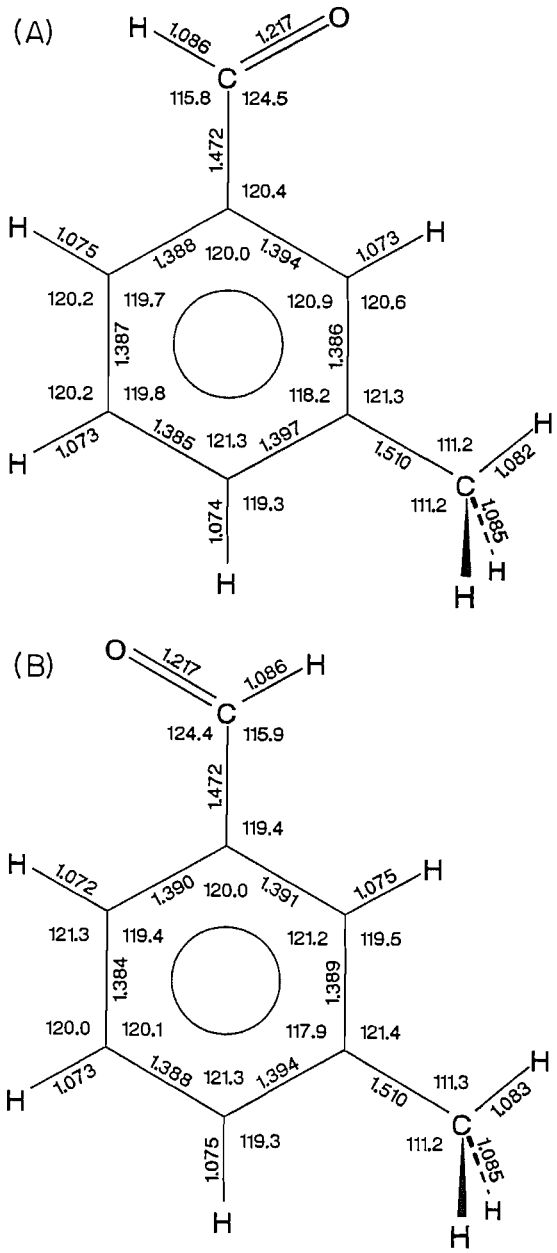

FIG. 2. The most stable 6-31G structures of the *O-cis* and *O-trans* (B) conformers of 3-methylbenzaldehyde are presented. The computed internal angles, averaged over the two conformations of the methyl group, are reproduced very closely by addition of the empirical angular substituent parameters (20) for the CH_3 and COOH groups (CHO not being listed). There is no obvious structural detail suggestive of why the *O-cis* is of slightly lower energy than the *O-trans* conformer, except perhaps that, in the former, the C=O bond lies *trans* to the shorter *ortho* C—C bond; it has been argued (21) that an energetic advantage arises from such an orientation.

overestimate, respectively, of the dipole moment of benzaldehyde by the STO-3G and 6-31G bases.

The coupling constants, $^4J(H, CHO) = {}^4J$ *and* $^6J(H, CHO) = {}^6J$

In benzaldehyde, ^4J is −0.16 Hz (13) and, as discussed previously (13, 14), is a composite of contributions of positive σ- and negative π-electrons. Furthermore (13), an electronegative substituent in the *meta* position polarizes the σ electrons at the neighbouring *ortho* position, causing an increase in the σ-electron component of ^4J. For the most electronegative substituent, fluorine, ^4J(H-2,CHO) vanishes, the two compo-

For personal use only.

nents having cancelled each other (5). The polarization is of interest also because the greater stability of the *O-cis* conformer in 3-fluorobenzaldehyde has been attributed (3) to an attractive interaction between the C═O and the (polarized) *ortho* C—H bond. For 3MB in acetone-d_6 solution, the two ^4J values are indistinguishable from the ^4J of benzaldehyde in the same solvent (Table 1), as expected for a negligible polarization by the methyl substituent. In CS_2 solution, ^4J is -0.15 Hz in benzaldehyde, not very different from the values quoted for 3MB; the general precision of the analysis for this solution is inferior to that for the polar solution.

^6J is $+0.01_5$ Hz for 3MB in acetone-d_6 solution (see Fig. 1). A simple model (13), involving an ionic valence bond structure, predicts ^6J as $+0.012$ Hz in 3MB. The apparent ^6J of $+0.024(3)$ Hz in CS_2/C_6D_{12}, however, cannot be discounted entirely even though, in our opinion, the spectral quality and complexity suggests its relative unreliability. Again, ^6J in 3,5-dimethylbenzaldehyde (13) was not observed; the model implies it as $+0.017$ Hz. It must be noted that, in this molecule, the symmetry of the spin system is high, unlike that in 3MB in which the sign and magnitude of ^6J for the acetone-d_6 solution is manifested, not as a direct splitting, but via the asymmetry of a tightly coupled spectrum (see Fig. 1).

It is concluded that the most reliable of the ^6J results, under discussion here, is in agreement with the model in question.

The long-range methyl proton coupling constants

$^4J(H,CH_3)$ is a predominantly $\sigma-\pi$ coupling constant, containing also a σ-electron component (15). Its magnitude is also sensitive to the bond order of the intervening aromatic C—C bond (16, 17), rising in magnitude as the bond order increases. In toluene, $^4J(H,CH_3)$ is $-0.702(1)$ Hz in a CS_2/C_6D_{12} solvent mixture (18). For the same solvent, ^4J(H-4,CH_3) is $-0.697(2)$ Hz for 3MB and ^4J(H-2,CH_3) is $-0.741(1)$ Hz. These numbers imply a larger bond order of the C(2)—C(3) than of the C(3)—C(4) bond, consistent with an obvious resonance structure. The 6-31G geometries in Fig. 2 do not support this interpretation, judging by the relevant computed C—C bond lengths. Hence the larger magnitude of ^4J(H-2,CH_3) may arise, not from the π-electron contribution, but from an increased σ-electron component induced by the carbonyl group attached *ortho* to H-2.

In toluene, the $^5J(H,CH_3)$ of $0.329(1)$ Hz does not differ significantly from the $0.324(2)$ Hz of 3MB in CS_2/C_6D_{12} but is somewhat smaller than the $0.343(1)$ Hz in the acetone-d_6 solution; presumably because the substituent lies far from the coupling pathway, it does not perturb to any extent either the $\sigma-\pi$ or σ-electron contributions (18) to $^5J(H,CH_3)$.

$^6J(H,CH_3)$ in toluene is $-0.602(2)$ Hz (18) and is relatively insensitive to intrinsic substituent perturbations. For 3MB, ^6J is $-0.601(1)$ Hz in the acetone-d_6, but $-0.588(1)$ Hz in the nonpolar solution.

Conformation and dynamics in solution of an *N*-quaternarized benzophenone derivative: a molecule active as UV filter

CECILIA ANSELMI, MARISANNA CENTINI, MIRELLA SCOTTON, AND ALESSANDRO SEGA[1]

Istituto di Chimica Organica, Piano dei Mantellini, 44, 53100 Siena, Italy

Received August 16, 1990

CECILIA ANSELMI, MARISANNA CENTINI, MIRELLA SCOTTON, and ALESSANDRO SEGA. Can. J. Chem. **69**, 913 (1991).

The dynamics and conformation of *N,N*-dimethyl-*N*-[3-(benzoyl-4-phenoxy)]-*N*-*n*-dodecylammonium bromide, **1**, have been established in two solvents ($CDCl_3$ and DMSO-d_6) by the use of ^{13}C spin-lattice relaxation rates, non-selective and selective proton spin-lattice relaxation rates, and ^1H–{^1H} nuclear Overhauser enhancement (nOe) experiments. The data obtained are consistent with two main mean conformations for compound **1**: a "linear" conformation in $CDCl_3$ and a folded conformation in DMSO-d_6 where the alkyl chain forms a loop toward the aromatic moiety.

Key words: UV filter, carbon and proton relaxation rates, nuclear Overhauser enhancement experiments, solvent dependent conformations.

CECILIA ANSELMI, MARISANNA CENTINI, MIRELLA SCOTTON et ALESSANDRO SEGA. Can. J. Chem. **69**, 913 (1991).

Faisant appel aux vitesses de relaxation spin-réseau du ^{13}C, à des vitesses de relaxation spin-réseau du ^1H sélectives ainsi que non-sélectives et à des expériences d'eOn ^1H–{^1H}, on a déterminé les dynamiques et la conformation du bromure de *N,N*-diméthyl-*N*-[3-(benzoyl-4-phénoxy)]-*N*-*n*-dodécylammonium, **1**, dans deux solvants ($CDCl_3$ et DMSO-d_6). Les données obtenues suggèrent l'existence de deux conformations principales pour le composé **1** : une conformation «linéaire» dans le $CDCl_3$ et une conformation repliée dans le DMSO-d_6 dans laquelle la chaîne alkyle forme une boucle avec la portion aromatique.

Mots clés : filtre UV, vitesses de relaxation du ^{13}C et du ^1H, expériences d'effet Overhauser nucléaire, conformations qui dépendent du solvant.

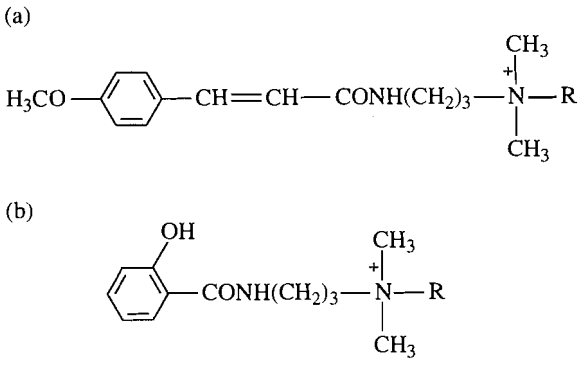
Introduction

Research into the synthesis of molecules active as sunscreens has become of great importance (1, 2). These molecules, besides having a high protective efficacy, must also have (i) the capacity of adhering to and of being retained by the keratin of the skin, thus resisting removal by bathing and perspiration (a property known as substantivity (3)) and (ii) a very low toxicity.



In our study aimed at identifying new sunscreens (4–8), we synthesized a series of *N*-quaternarized benzophenone derivatives (see Fig. 1). In this series, however, maximum substantivity was reached by the *n*-C12 derivative; this was accompanied by the highest level of antibacterial activity (9). These results are compatible with those obtained for the *N*-quaternarized derivatives of cinnamic and salicylic acids (10) (see Fig. 2): the *n*-C12 derivative shows the highest degree of antibacterial activity and substantivity. On the other hand, it is well known that several anionic or cationic detergents containing the *n*-C12 alkyl chain are the most efficient agents for detergency–adsorption–denaturation–permeability–irritation interactions (11). Garcia Dominguez *et al.* put forward an interesting rationalization of this "odd" behaviour of *n*-C12 detergents in their interaction with keratinic proteins (11). They maintained that the success of this mechanism is due to the fact that the *n*-C12 alkyl chain is able to adopt a coiled structure: in this way the surface/volume ratio of the molecule is reduced to a minimum. It is likely that this is of great importance when the adsorbed molecule migrates inside the protein structure.

Significant analogies appear to exist between this mechanism and that of the antibacterial activity of quaternary cationic detergents proposed by other authors (12). From these studies, it would appear that the substantivity of an *N*-quaternarized sunscreen for a keratinic substrate might not be unconnected with an antibacterial action, concomitant damage to the cell membrane and contents, and skin irritation phenomena.

R = *n*-C_{12}, *n*-C_{14}, *n*-C_{16}, *n*-C_{18}
m = 2,3

FIG. 1. *N*-Quaternarized benzophenone derivatives.

R = C_2, *n*-C_8, *n*-C_{12}, *n*-C_{16}

FIG. 2. *N*-Quaternarized derivatives of (a) cinnamic and (b) salicylic acids.

However, compound **1** shows a lower antibacterial activity than the corresponding *n*-C12 derivatives of cinnamic and salicylic acids. Therefore it is very likely that, with appropriate modification of the molecular structure, antibacterial activity can be minimized or eliminated without reducing the high degree of substantivity. Our study was designed to investigate the dynamics and conformation of compound **1** in solution (see

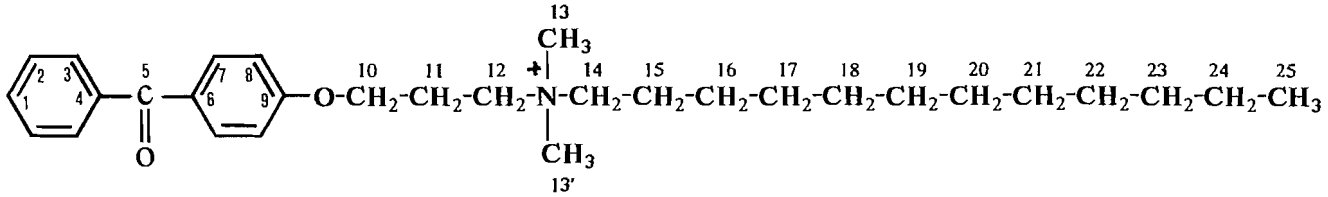

FIG. 3. *N,N*-Dimethyl-*N*-[3-(benzoyl-4-phenoxy)propyl]-*N*-*n*-dodecylammonium bromide. The numbering system is that used throughout the text.

Fig. 3), as we consider this to be the initial step in analysing the behaviour of these molecules.

It is recognised that the environment in which the molecule – keratinic protein interaction takes place plays a fundamental role in the conformation of the molecule; taking this into consideration, this study was carried out using two solvents that differ widely in their properties: $CDCl_3$ and DMSO-d_6.

Results and discussion

^1H and ^{13}C assignments were made on the basis of semi-empirical methods (13*a*,*b*), reference to data in the literature (13*a*), and ^{13}C–{^1H} nuclear Overhauser enhancements (nOe's).

Dynamics and conformation of compound ***1***

(a) In $CDCl_3$

^{13}C chemical shifts and relaxation rates (R_1) of compound **1** in $CDCl_3$ are shown in Table 1.

It is known that ^{13}C R_1 ($R_1 = 1/T_1$), relaxation rates, are almost exclusively determined by dipolar interactions with directly bonded or nearby protons, thus allowing suitable delineations of the molecular dynamics (13*c*, 14). The motional features of aromatic carbons were considered first since they have fewer degrees of freedom than side-chain carbons.

For ring A, the relaxation rate of C1 was faster than those of the other carbon atoms, suggesting that C1–C4 is the main rotation axis for this aromatic ring. The relaxation rates of C2 and C3 were very similar, such that an anisotropic model consisting of rotational reorientation around the main rotation axis with some degree of internal motion could be applied (15) (eq. [1] with $A = 0.25(3\cos^2\alpha - 1)^2$, $B = 3(\sin^2\alpha\cos^2\alpha)$, and $C = 0.75(\sin^4\alpha)$).

$$[1]\quad \frac{1}{nT_1} = \frac{\hbar^2\gamma_H^2\gamma_C^2}{r_{CH}^6}\tau_c A\left\{A + B\frac{3\tau_g A}{3\tau_g A + \tau_c A} + C\frac{6\tau_g A}{6\tau_g A + \tau_c A}\right\}$$

In eq. [1], $\tau_c A$ is the main rotation correlation time, $\tau_g A$ is the correlation time for librational motions of aromatic ring A, r_{CH} is the length of the C—H bond, n is the number of protons attached to the carbon under consideration, and α is the angle between the main rotation axis and the C–H vector. The main correlation time, $\tau_c A$, can be calculated by considering the relaxation rate R_1 ($= 1/T_1$) of C1: since the C1–H1 vector lies on the main axis, eq. [2] can be applied.

$$[2]\quad \frac{1}{nT_1} = \frac{\hbar^2\gamma_H^2\gamma_C^2}{r_{CH}^6}\tau_c$$

This holds for a pure dipole–dipole relaxation mechanism within the extreme narrowing region (16). As all protonated carbons exhibit maximum ^{13}C–{^1H} nuclear Overhauser effects,

eq. [2] was used to extract $\tau_c A$, and $\tau_g A$ was then obtained by applying eq. [1] (see Table 2).

The same analysis holds for ring B: the relaxation rates of C7 and C8 are very close to each other and the main rotation axis is C6–C9, as would be expected for a *para*-disubstituted benzene. Thus the same anisotropic model can be applied.

However, it is impossible to calculate $\tau_c B$, the main correlation time of ring B, from the relaxation rates of carbon atoms. Here it is necessary to use proton relaxation rates; indeed the H7–H8 vector is parallel to the main axis C6–C9, and by taking advantage of double selective and selective relaxation rates we can write eq. [3] (see later for a discussion on proton relaxation rates):

$$[3]\quad R_{7,8}^7 - R_s^7 = \sigma_{7,8} = \frac{1}{2}\frac{\hbar^2\gamma_H^4}{r_{7,8}^6}\tau_c B$$

where $r_{7,8}$ is the H7–H8 interproton distance (it has been determined from neutron scattering data: $r_{7,8}$ = 2.45 Å (17)).

Then, from eq. [3] we obtained $\tau_c B = 1.52 \times 10^{-10}$ s and, again applying eq. [1], the corresponding correlation time for

[a]See the text for discussion.

librational motions was calculated, $\tau_g B = 0.84 \times 10^{-10}$ s. The correlation times of side-chain carbons were evaluated from eq. [2] (see Table 2).

The analysis of correlation times reveals three main considerations: (i) the motion of the aromatic rings is dephased as a consequence of great internal freedom; (ii) the correlation times from C10 to C14 have values very close to each other and to τ_cB; (iii) from τ_c15 onwards the correlation times steadily decrease: segmental motion takes place.

These facts strongly suggest the presence of a main rotation axis parallel or nearly parallel to the C6–C9 axis and passing through the quaternary nitrogen atom; the carbon skeleton from C10 to C14 should develop on and along this axis as depicted in Fig. 4. This conclusion, and the presence of segmental motion from C15 onwards, brings about the broad picture of a "linear" main mean conformation for **1** in $CDCl_3$.

To examine the conformation(s) of compound **1** more closely, we then made use of proton relaxation rates and the homonuclear $^1H-\{^1H\}$ nuclear Overhauser effect.

TABLE 4. Non-selective (R_{ns}) (s^{-1}), mono-selective (R_s) (s^{-1}), and double-selective (R_{ds}) (s^{-1}) spin-lattice relaxation rates for selected protons of compound **1** (0.1 M $CDCl_3$ and DMSO-d_6 solutions)

	$CDCl_3$	DMSO-d_6
R_{ns}^7	1.09	1.12
R_s^7	0.76	0.79
$R_{7,8}^7$	0.96	0.94
R_{ns}^8	1.67	1.85
R_s^8	1.18	1.28
R_{ns}^7/R_s^7	1.44	1.42
R_{ns}^8/R_s^8	1.42	1.44

^1H chemical shifts in 0.1 M $CDCl_3$ and DMSO-d_6 solutions are summarized in Table 3.

Non-selective (R_{ns}^i), mono-selective (R_s^i), and double-selective (R_{ds}^{in}) proton spin-lattice relaxation rates of selected protons of compound **1** are shown in Table 4.

The measurement of ^1H non-selective, mono-selective, and double-selective spin-lattice relaxation rates has been suggested as a suitable aid to conformational studies in solution (18–20).

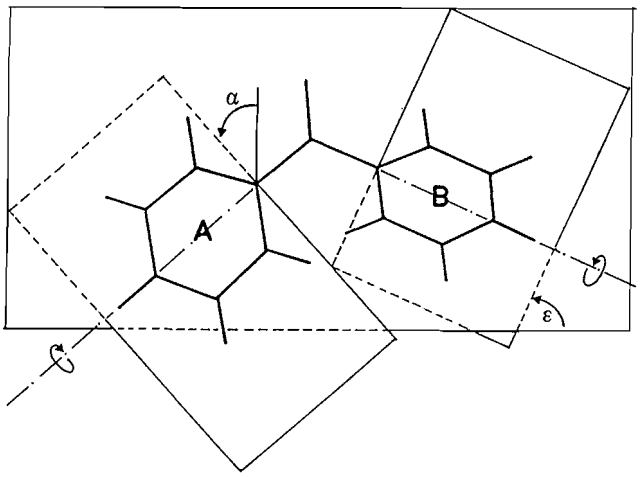

FIG. 5. Conformation of the benzophenone moiety.

In fact, the ratio (R^i_{ns}/R^i_s) for any proton i allows evaluation of the extent to which pairwise dipole–dipole interactions provide the relaxation mechanism (the ratio is 1.5 for a purely dipolar mechanism).

In the limit of 100% contribution from the ^1H–^1H dipole–dipole relaxation mechanism, eqs. [4]–[6] can be given:

$$[4] \quad R^i_{ns} = \sum_{i \neq j} \rho_{ij} + \sum_{i \neq j} \sigma_{ij}$$

$$[5] \quad R^i_s = \sum_{i \neq j} \rho_{ij}$$

$$[6] \quad R^{in}_{ds} = \sum_{i \neq j} \rho_{ij} + \sigma_{in}$$

where ρ_{ij} and σ_{ij} are the direct- and cross-relaxation rates respectively for any proton pair (eqs. [7] and [8]) (21) where r_{ij} is the interproton distance, ω is the proton Larmor frequency, and τ_c is the motional correlation time.

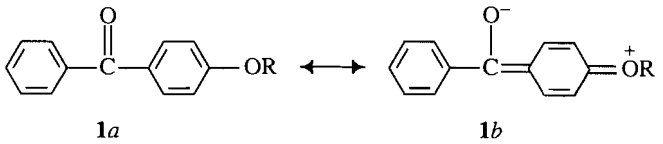
$$[7] \quad \rho_{ij} = \frac{1}{10}\frac{\hbar^2\gamma_H^4}{r_{ij}^6}\left\{\frac{3\tau_c}{1+(\omega\tau_c)^2} + \frac{6\tau_c}{1+(2\omega\tau_c)^2} + \tau_c\right\}$$

$$[8] \quad \sigma_{ij} = \frac{1}{10}\frac{\hbar^2\gamma_H^4}{r_{ij}^6}\left\{\frac{6\tau_c}{1+(2\omega\tau_c)^2} - \tau_c\right\}$$

It is evident from eqs. [5] and [6] that eq. [9] holds,

$$[9] \quad R^{in}_{ds} - R^i_s = \sigma_{in} = \frac{1}{10}\frac{\hbar^2\gamma_H^4}{r_{in}^6}\left\{\frac{6\tau_c}{1+(2\omega\tau_c)^2} - \tau_c\right\}$$

which, in the limit of the extreme narrowing region, reduces to eq. [10]:



$$[10] \quad \sigma_{in} = \frac{1}{2}\frac{\hbar^2\gamma_H^4}{r_{in}^6}\tau_c$$

Then the measurement of double-selective and mono-selective proton spin-lattice relaxation rates allows determination of proton–proton distances if τ_c is known from other sources (or vice versa as was applied formerly in eq. [3]). It is also possible to calculate the distance between the H3 and H7 protons; indeed:

$$[11] \quad R^7_{ns} - R^7_s = \sigma_{7,3} + \sigma_{7,8}$$

$$[12] \quad R^7_{7,8} - R^7_s = \sigma_{7,8}$$

$$[13] \quad \sigma_{7,3} = (R^7_{ns} - R^7_s) - (R^7_{7,8} - R^7_s)$$

1*a* 1*b*

FIG. 6. Mesomeric forms of substituted benzophenones.

and, then, from eq. [10], using $\tau_c B = 1.52 \times 10^{-10}$ s we obtained $r_{7,3} = 2.6$ Å. This distance alone is insufficient to define the conformation of the benzophenone moiety (see Fig. 5). One of the angles (α or ε) must also be specified. It is well known that benzophenone cannot be coplanar ($\alpha = \varepsilon = 0°$) due to the steric repulsion between *ortho* protons (22, 23). The values of these two angles were calculated using various techniques (24*a*–*d*) and the most reliable values are $\alpha = \pm 30°$ and $\varepsilon = \pm 30°$ (for this geometry $r_{3,7} = 2.4$ Å).

The presence of a *para* substituent does not at first seem to influence the conformation of benzophenone as do *ortho* and *meta* substituents (25); however, in *para*-substituted benzophenones, it has been demonstrated that the chemical shift of the C4 carbon atom correlates with the F and R substituent constants in a reversed manner (26) (F is the field/inductive constant and R is the resonance constant) (27). The observations on *para*-substituted benzophenones show that C4 is not in direct conjugation with the *para* substituent and the situation can be described by the mesomeric forms **1***a* and **1***b* (see Fig. 6). Then, in the real structure, the carbonyl group should be nearly coplanar with ring B, at which point the $r_{3,7}$ distance allows the calculation of $\alpha = \pm 74°$.

From proton relaxation data of the H8 proton it is also possible to calculate the mean distance between the H8 and H10 protons ($\bar{r}_{8,10}$):

$$[14] \quad R^8_{ns} - R^8_s = \sigma_{8,7} + \sigma_{8,10}$$

$$[15] \quad \sigma_{8,10} = (R^8_{ns} - R^8_s) - (R^8_{7,8} - R^8_s)$$

from which, using $\tau_c B = 1.52 \times 10^{-10}$ s, $r_{8,10} = 2.3$ Å.

To investigate the possible main conformation(s) of the alkyl chain we made use of the homonuclear Overhauser effect.

The origins of the ^1H–$\{^1H\}$ nOe have been extensively investigated and a comprehensive review published (21). We did not find any non-trivial nOe effect; the measurements were also repeated in a 0.01 M solution without any significant results: only trivial nOe's were observed.

These data confirm the presence of a "linear" main mean conformation for **1** in $CDCl_3$ solution: the main rotation axis is as previously defined and, in addition, the segmental motion of the alkyl chain takes place along this axis; this does not exclude the possibility of folding, but stable main conformation(s) with extensive folding of the alkyl chain must definitely be ruled out.

(b) In 0.1 M DMSO-d_6

^{13}C chemical shifts and relaxation rates (R_1) of compound **1** in DMSO-d_6 are shown in Table 5.

It is important to note that in this solvent C1 and C7 carbon atoms have the same chemical shift (134.05 ppm); the corresponding relaxation rate ($R_1 = 2.04$) is very close to the relaxation rate of C8 ($R_1 = 2.08$), as is to be expected. On the other hand, analysis of the spectra of the inversion–recovery sequence for the determination of T_1 shows that the resonance at 134.05 ppm behaves as a single line. In a recent paper (28) on the dynamics of *para*-substituted benzophenones, where the *para* substituents are *n*-alkyloxy groups (n = 8, 11, 13) or *n*-alkyl and ω-alkenyl esters of *para*-benzophenone carboxylic

TABLE 6. Nuclear Overhauser enhancements[a] for selected proton resonances of compound **1** (0.1 and 0.01 mol dm^{-3} in DMSO-d_6, T = 298 K)

		Enhancement	
Proton irradiated	Proton observed	0.1 M	0.01 M
H15	H12	0.050	0.046
H25	H7	0.064	0.057

[a]Errors in the nOe's were evaluated at ±10%.

acid, it appears that the relaxation rate of C1 is always very close to or equal to those of C7 and C8 (this is also true for the 0.1 M solution of **1** in $CDCl_3$). For this reason, we consider R = 2.04 to be the relaxation rate of C1 as well.

The same arguments as those developed for the delineation of the dynamics of **1** in $CDCl_3$ were used, and the application of eqs. [1] and [2] yielded all the τ_c and τ_g values (see Table 2).

Analysis of the correlation times revealed the following: (i) τ_gB is practically equal to τ_cB (1.12×10^{-10} s and 1.14×10^{-10} s respectively): internal librational motions for ring B are absent; also τ_cA (1.03×10^{-10} s) is close to τ_cB, so internal motions of the benzophenone moiety as a whole are severely restricted; (ii) τ_c10 and τ_c11 have values close to τ_cA and τ_cB, suggesting that this part of the chain reorients jointly with the benzophenone moiety; the methylene carbon atoms directly bonded to the quaternary nitrogen atoms, C12 and C14, show the longest τ_c in the molecule, corresponding to the slowest motions; (iii) from C15 onwards, segmental motion takes place.

Points (i) and (ii) are in striking contrast with the situation

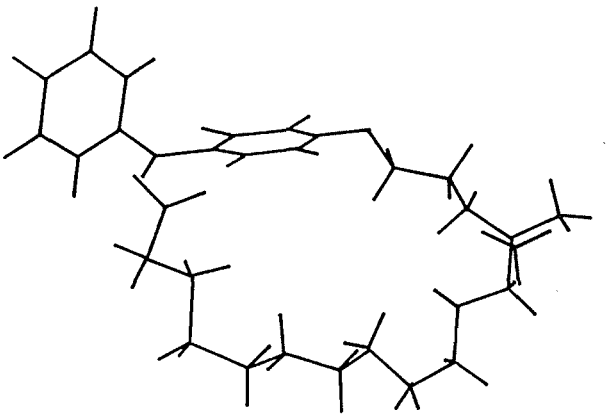

FIG. 7. Projection of the Dreiding model of the "most probable" conformation of compound **1** in 0.1 M DMSO-d_6 solution as inferred from NMR experiments.

outlined in $CDCl_3$: these differences are probably a consequence of the different main mean conformation(s) presented by **1** in the two solvents.

Once again possible further information on the conformation can be obtained using proton relaxation rates and the ^1H–{^1H} nuclear Overhauser effect. (For ^1H chemical shifts and coupling constants see Table 3.)

From proton relaxation rates, the interproton distances $r_{3,7}$ = 2.4 Å and $r_{8,10}$ = 2.1 Å were extracted; the same rationale as applied before permitted the evaluation of $\alpha = \pm 60°$. The geometry of the benzophenone moiety changes slightly on passing from $CDCl_3$ to DMSO.

Surprising results were obtained from the nOe's: neat nuclear Overhauser effects are present between H12 and H15 and between H7 and H25 (see Table 6). These same effects are present with practically the same values in a 0.01 M solution: thus they are intramolecular effects.

These nOe's are consistent with a folded conformation where the alkyl chain forms a loop toward the aromatic ring B (see Fig. 7). This main conformation as deduced from nOe's is consistent with the corresponding dynamic situation: (i) in the folded conformation the molecule adopts an ellipsoidal shape; the main axis of the ellipsoid (which passes near or through the nitrogen atom) is very probably the main rotation axis; (ii) the presence of the alkyl chain in the proximity of the aromatic moiety has little influence on its main conformation, but it greatly affects its local motions: indeed, it competes with the aromatic moiety for the same spatial region; as a consequence, internal motions in the benzophenone moiety are severely restricted (above all, those of ring B).

We maintain that this drastic change in the main mean conformation in the two solvents could be brought about by three main factors: (i) the ion–dipole interactions between the quaternary nitrogen atom and DMSO that slow down the corresponding motions (29); (ii) the more-or-less central location of the nitrogen atom in the molecule; and (iii) the lyophobic environment created by DMSO, which leads the alkyl chain and the benzophenone moiety to expose the least possible surface area to the solvent. (The latter is accomplished by adopting a folded conformation in which the two frameworks converge upon each other.)

This change in the main mean conformation in the two solvents either masked or eliminated any evidence of a coiled structure, i.e., the type of conformation associated with antimicrobial activity, toxicity, and irritation of the skin.

However, it is possible that the molecule adopts its main mean conformations in response to environmental changes: a property which could be correlated with its antimicrobial activity.

Experimental

The compound under investigation was synthesized as already described (9). Solutions were made in 99.8% DMSO-d_6 and 99.8% $CDCl_3$ and were carefully deoxygenated. NMR measurements were carried out with a Varian XL-200 Fourier transform spectrometer. Chemical shifts were referred to internal TMS. Spin-lattice relaxation rates were measured using the inversion–recovery pulse sequence; 4 and 100 FIDs were collected for ^1H and ^{13}C T_1 measurements respectively. The relaxation rate was calculated with a three-parameter exponential regression analysis of the recovery curves of longitudinal magnetization components.

Selective and double-selective relaxation rates were measured using inversion–recovery pulse sequences where the π pulse was given by the proton decoupler at selected frequencies at low power for relatively long times (30). A typical setting for a selective π pulse was 20 db power attenuation and 20 ms pulse width. The selective rate was measured (31) in the initial slope approximation by considering only the first part of the recovery curve; ^{13}C–$\{^1H\}$ and ^1H–$\{^1H\}$ nOe's were measured with gated decoupling techniques using nOe difference pulse sequences.

C—H...O=C and C—H...H—C interactions in the side chains of 2-isopropylbenzaldehyde. A negative $^5J(CHO,CH(CH_3)_2)$

TED SCHAEFER[1] AND KERRY J. COX
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received October 1, 1990

TED SCHAEFER and KERRY J. COX. Can. J. Chem. **69**, 919 (1991).

The ^1H nuclear magnetic resonance spectra of 2-isopropylbenzaldehyde in CS_2/C_6D_{12} and acetone-d_6 solutions provide the chemical shifts and coupling constants of all the protons. The long-range coupling constants involving the side-chain protons yield certain sums of the populations of the four putatively planar conformations. The *o-anti* conformers have a fractional population of 0.55(3) in the polar and of 0.49(3) in the nonpolar solvent. The conformers in which the methine C—H bond lies *cis* to the aldehyde group have a fractional population of 0.83(3) in both solutions. The close approach of the methine and aldehydic hydrogen atoms in one conformer is indicated by a negative proximate coupling constant between their protons of −0.39(1) Hz. The chemical shifts of the ring and of the side-chain protons are consistent with the conformer populations deduced from the long-range coupling constants and also with the indications that the side chains do not, on average, deviate from "coplanarity" with the ring by much more or less than in the parent compounds. The C—H...H—C and C—H...O=C interactions in the *o-syn* and *o-anti* conformers are most likely repulsive and of very similar magnitude and lead to a significant deshielding of the protons in these moieties. Molecular orbital computations are also reported and are an aid in estimating the populations of the individual conformers. The STO-3G MO structures have H...H and H...O distances well below the sums of the van der Waals radii of hydrogen and oxygen atoms in the conformers with the methine C—H bond placed *cis* to the aldehyde group, yet these are computed to be by far the most abundant by the STO-3G as well as by AM1 algorithms.

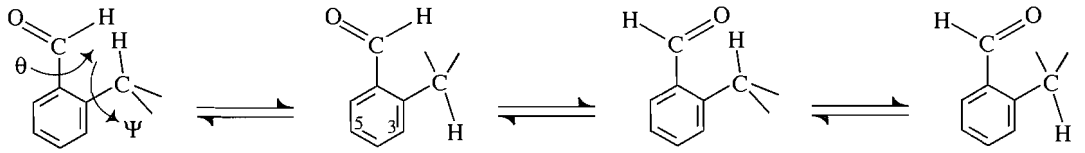
Key words: 2-isopropylbenzaldehyde, conformations of; 2-isopropylbenzaldehyde, proximate spin–spin coupling constants in; MO calculations, STO-3G, and AM1 on 2-isopropylbenzaldehyde, ^1H NMR and long-range spin–spin coupling constants in 2-isopropylbenzaldehyde.

TED SCHAEFER et KERRY J. COX. Can. J. Chem. **69**, 919 (1991).

Les spectres en résonance magnétique nucléaire du ^1H du 2-isopropylbenzaldéhyde dans des solutions de CS_2/C_6H_{12} et d'acétone-d_6 permettent de déterminer les déplacements chimiques et les constantes de couplage de tous les protons. Les constantes de couplage à longue distance impliquant les protons de la chaîne latérale fournissent certaines sommes de populations des quatre conformations putativement planaires. Les populations fractionnaires des conformères *o-anti* sont respectivement de 0,55(3) et de 0,49(3) dans les solvants polaire et non-polaire. Les populations fractionnaires des conformères dans lesquels la liaison C—H méthine est *cis* par rapport au groupement aldéhydique sont égales à 0,83(3) dans les deux solvants. Le grand rapprochement des atomes d'hydrogène méthinique et aldéhydique dans un conformère se reflète par une constante de couplage de proximité négative (−0,39(1) Hz) entre leurs protons. Les déplacements chimiques des protons du cycle et de la chaîne latérale sont en accord avec les populations de conformères déduites à partir des constantes de couplage à longue distance ainsi qu'avec les indications à l'effet que, en moyenne, les chaînes latérales ne dévient pas plus de la «coplanéité» avec le cycle que les composés parents. Les interactions C—H...H—C et C—H...O=C dans les conformères *o-syn* et *o-anti* sont probablement répulsives et d'amplitudes très semblables et elles conduisent à un déblindage important des protons de ces portions. On a aussi effectué des calculs d'orbitales moléculaires qui sont utiles pour évaluer les populations des conformères individuels. Dans les structures des OM STO-3G, les distances H...H et H...O sont beaucoup plus faibles que les sommes des rayons de van der Waals des atomes d'hydrogène et d'oxygène dans les conformères où la liaison méthine C—H est *cis* par rapport au groupement aldéhydique; il n'en reste pas moins que, d'après des calculs avec une base STO-3G ainsi qu'avec des algorithmes AM1, ces structures sont les plus abondantes.

Mots clés : 2-isopropylbenzaldéhyde, conformations; 2-isopropylbenzaldéhyde, constantes de couplage de proximité; calculs OM, STO-3G, AM1, 2-isopropylbenzaldéhyde; RMN ^1H et constantes de couplage à longue distance, 2-isopropylbenzaldéhyde.

[Traduit par la rédaction]



Introduction

There is considerable evidence, extracted mainly from crystallographic data bases in recent years (1), for the existence of intermolecular hydrogen bonding by C—H bonds. Such hydrogen bonds, defined in terms of close contacts, involve slightly acidic C—H bonds found in acetylenic, ethylenic, and sometimes in alkanic groupings. The latter normally contain one or more electronegative substituents attached to the carbon atom of the C—H bond. However, there exist recent reports of inter- and intramolecular hydrogen bonds formed by C—H bonds of methyl groups and the oxygen atoms in water or ether linkages (2, 3). Infrared spectra of intermolecular C—H hydrogen bonds formed in host matrices are also abundant (4).

It is perhaps not always clear that a short contact arises from the formation of a C—H..X hydrogen bond, caused predominantly by electrostatic attraction (1), it being conceivable that the intermolecular contact is determined by other crystal packing forces or possibly by repulsive intramolecular interactions in a molecule. For example, for the crystal of 2,4,6-trinitrotoluene (5) an intramolecular C—H...O bond is deduced from an H...O distance of 2.39 Å, a distance of less than 2.70 Å being sometimes taken as indicative of a hydrogen bond (6, 7), and is apparently confirmed (8) by infrared and nmr spectra in solution. However, the nitro groups placed *ortho* to the methyl substituent are twisted substantially out of the aromatic plane. One might surmise that repulsion between the substituents causes this twist and that the short H...O contacts are therefore a consequence of an energetic compromise between repulsion,

1 θ = 0 Ψ = 0 2 3 4

which causes the twist, and the conjugationally driven tendency to coplanarity of the nitro groups; the internal barrier to rotation in nitrobenzene is 13.6 kJ/mol or perhaps somewhat lower (9).

The capacity of the methine C—H bond of the isopropyl group as a proton donor in a hydrogen bond is probably very little different from that of a C—H bond in a methyl group. The carbonyl group, however, is an excellent acceptor in a hydrogen bond. Suppose that the carbonyl group is constrained to one or two orientations in a molecule, as in benzaldehyde, for example, in which the internal rotational barrier in solution is greater than 30 kJ/mol (10). The barrier is large compared to thermal energies at 300 K, so that a planar conformation is a good approximation in the description of the molecule. By way of contrast, the barrier to rotation about the C_{sp^2}—C_{sp^3} bond in isopropylbenzene in solution is very likely less than 10 kJ/mol (11). Hence, in 2-isopropylbenzaldehyde, where a six-membered-ring intramolecular C—H...O=C hydrogen bond, analogous to the strong one (12, 13) in the 2-hydroxy derivative, is conceivable (such bonds forming in preference to intermolecular ones (14)), a high stability of such a bond should be evinced by a preponderant population of **3**.

Alternatively, repulsive interactions in **3** and **1** might be relieved by twists about the C_{sp^2}—C_{sp^3} bond rather than about the exocyclic C_{sp^2}—C_{sp^2} bond (the idealized planar conformers, **1**–**4**, are understood to be those in which the C_{sp^3}—C_{sp^3} bonds are staggered about the aromatic C—H(3) bond in **1** and **3** and C—H or C=O bonds of the aldehyde group in **2** and **4**). The anticipated, repulsive C—H...H—C forces in **1**, models indicating an H,H distance of less than 2 Å, would favor **3**, given that congestion in **2** and **4** renders small their populations.

Now, long-range coupling constants between aldehydic and ring protons in benzaldehyde and its derivatives (15, 16) and between benzylic and ring protons in isopropylbenzene (11) are stereospecific. Those over five formal bonds are closely related to the populations of **1**–**4**, while those over six bonds are a measure of the out-of-plane motion of the side chains (deviations of θ and ψ from zero in **1**, for example). Accordingly, analyses of the ^{1}H nmr spectra in a nonpolar as well as in a polar solvent should provide information about the populations of **1**–**4** and about their solvent dependence. Such analyses are reported here. A by-product of the latter is the detection of a negative coupling constant between the aldehydic and methine protons, very likely a proximate interaction, providing evidence for a close approach of these protons in **1**. In addition, some molecular computations of the relative energies and of the geometries of the four conformers represent an attempt at gauging attraction or repulsive forces between the side-chain moieties.

Experimental

The 2-isopropylbenzaldehyde was prepared (17) as follows. To 6.1 mmol of 2-bromoisopropylbenzene (Lancaster) in 25 mL of diethyl ether under nitrogen was added 14.3 mmol of lithium. The formation of aryl-lithium intermediate was aided by immersing the vessel in an ultrasound bath for 2 h at room temperature. Still under nitrogen, 6.1 mmol of *N,N*-dimethylformamide was added and the reaction proceeded, with stirring, for 30 min. The reaction was quenched with an excess of aqueous NH_4Cl (saturated). The mixture was shaken with 25 mL of diethyl ether. The ether layer was dried over $MgSO_4$ and evaporated. The product was purified on a silica gel column with hexane as a solvent. The yield was ca. 40%.

Solutions of 2-isopropylbenzaldehyde in CS_2/C_6D_{12}/TMS and acetone-d_6/TMS solvent mixtures (see Table 1 for details) were filtered into 5-mm o.d. nmr sample tubes. These were degassed by four cycles of the freeze–pump–thaw procedures and then flame-sealed to yield symmetrical closures.

The ^{1}H nmr spectra were accumulated on a Bruker AM300 spectrometer at a probe temperature of 300 K. Figure 1 displays the spectrum of the aldehydic proton in acetone-d_6 solution; the caption gives the acquisition conditions. The figure also illustrates an experiment (18) designed to determine the sign of $^5J(CHO,CH(CH_3)_2)$.

The ^{1}H nmr spectra were analyzed with the computer program NUMARIT (19), extensively reworked by R. Sebastian in this laboratory. The spectral parameters appear in Table 1, together with analytical conditions.

STO-3G MO (20) and AM1 (21) computations employed the program GAUSSIAN 86 (22) on an Amdahl 5870 computer. All bond angles and lengths were optimized with the constraint that the carbon and hydrogen atoms of the benzene moiety remain in a plane. CNDO/2 and INDO MO FPT (23, 24) computations of spin–spin coupling constants utilized the STO-3G geometries.

Results and discussion

The populations, $p_1 + p_2$ *(o-anti) and* $p_3 + p_4$ *(o-syn)*

The available evidence (12, 25) strongly suggests that ^5J(H,CHO) in benzaldehyde and its derivatives is highly stereospecific; ^5J(H-3,CHO) ≡ $^5J_3$ in **1**, for example, is implied as vanishing whereas ^5J(H-5,CHO) ≡ $^5J_5$ is large. If this is so, then $p_1 + p_2$ follows from the coupling constants in Table 1 as $^5J_5/(^5J_3 + {}^5J_5)$ or 0.58 in acetone-d_6 and as 0.52 in CS_2/C_6D_{12}; hence $p_3 + p_4$, the sum of the fractional populations of **3** and **4**, the *o-cis* conformers, is 0.42 and 0.48, respectively. The higher population of the *o-anti* conformers in the more polar solvent is consistent (26) with their higher computed dipole moments at the STO-3G level of *ab initio* molecular orbital theory (see below).

This treatment assumes that the all-*trans* ^5J_t, that is, ^5J(H,CHO) in **1** and **3**, is not perturbed by the isopropyl substituent. In that event, $^5J_5 + {}^5J_3$ should be the same as in benzaldehyde, where this sum is 0.860(2) Hz in acetone-d_6 and 0.862(4) in CS_2/C_6D_{12} (25); in 2-fluorobenzaldehyde, for example, $^5J_3 + {}^5J_5$ does not deviate from these sums by more than 0.01 Hz (16). However, in 2-isopropylbenzaldehyde the sums are about 0.05 Hz smaller than in benzaldehyde, implying that the limiting values of ^5J_t need not be the same in the *o-syn* and *o-anti* conformers. Defining $^5J_{3,t}$ and $^5J_{5,t}$ as these values and the populations of the *o-syn* conformers, say, in the two solutions as the other two unknowns, one obtains four equations. These yield $^5J_{5,t}$ as 0.895 Hz and $^5J_{3,t}$ as 0.723 Hz, and $p_1 + p_2$ as 0.53 and 0.47 in acetone-d_6 and CS_2/C_6D_{12}, respectively. $^5J_{3,t}$ is much less than its value in benzaldehyde

TABLE 1. The ^{1}H nmr spectral parameters for 2-isopropylbenzaldehyde at 300 K in CS_2/C_6D_{12} and acetone-d_6 solutions

Parameter	CS_2/C_6D_{12}[a]	Acetone-d_6[b]	Parameter	CS_2/C_6D_{12}[a]	Acetone-d_6
ν(CHO)	3059.957(1)[c]	3112.755(1)	^4J(H,CHO)	−0.273(1)	−0.264(1)
ν(CH)	1185.5	1214.0	^5J(H-3,CHO)	0.383(1)	0.341(1)
ν(CH_3)	378.2[e]	385.1[e]			
ν_3	2208.959(1)	2262.350(1)	^5J(H-5,CHO)	0.421(1)	0.473(1)
ν_4	2230.121(1)	2281.980(1)	^6J(H-4,CHO)	−0.014(1)	−0.017(1)
ν_5	2175.037(1)	2218.858(1)	^5J(H-4,CH)	0.500(1)	0.503(1)
ν_6	2300.599(1)	2349.096(1)	^5J(H-6,CH)	0.167(1)	0.168(1)
$^3J_{34}$	7.877(1)	7.905(1)[f]	^6J(H-5,CH)	−0.265(1)	−0.252(1)
$^3J_{45}$	7.326(1)	7.340(1)	^5J(CHO,CH)	−0.376(1)	−0.388(1)[d]
$^3J_{56}$	7.687(1)	7.721(1)	Transitions calcd.	192	192
$^4J_{35}$	1.191(1)	1.179(1)	Observed peaks	127	122
$^4J_{46}$	1.546(1)	1.545(1)	Transitions assigned	137	138
$^5J_{36}$	0.503(1)	0.515(1)	Largest difference	0.007	0.006
^4J(H,CH)	−0.559(1)	−0.555(1)	Root-mean-square error	0.002_5	0.002

[a] 4.0 mol% in CS_2, containing also 10 mol% of C_6D_{12} and 0.5 mol% TMS.
[b] 4.0 mol% in acetone-d_6 with 0.5 mol% TMS.
[c] In Hz at 300.135_2 MHz to high frequency of internal TMS. Numbers in parentheses are the standard deviations in the last significant figure.
[d] From the double resonance sign determination (Fig. 1).
[e] ^3J(CH,CH_3) is 6.86 Hz in both solutions and ^5J(H-3,CH_3) is ±0.10(2) Hz.
[f] The commonly larger coupling constants between ring protons in the more polar solvent for benzene derivatives is fairly general (11, 25) and is not an artefact of the analyses.

and reminiscent of the 0.623(4) Hz in salicylaldehyde in which ^5J(H-5,CHO) vanishes, the molecule existing as one conformer (12). The unprecedented perturbation of ^5J(H-3,CHO) in salicylaldehyde may well be a consequence of the perturbation of the carbonyl group orbitals during formation of the relatively strong hydrogen bond (it is known (27) that the $2p_z$ orbital on oxygen plays a significant role in the transmission of nuclear spin state information). The apparently somewhat smaller reduction of $^5J_{3,t}$ in the *o-syn* conformers of 2-isopropylbenzaldehyde suggests that the C—H...O=C interaction also causes a decrease in ^5J(H,CHO). This result does not establish this interaction as attractive; repulsion might also decrease the coupling magnitude. CNDO/2 and INDO MO FPT computations on the STO-3G structures yield $^5J_{3,t}$ in **3** as 0.1 Hz smaller in magnitude than $^5J_{5,t}$ in **1**, in qualitative agreement with the deduction above.

However this may be, it is probably safe to conclude that $p_1 + p_2$ is $0.55_5 \pm 0.02_5$ in acetone-d_6 and $0.49_5 \pm 0.025$ in CS_2/C_6D_{12} solutions at 300 K. These numbers are the averages of the two sets of estimates above and the errors easily encompass the small uncertainties in the measured coupling constants.

The o-syn and o-anti *populations in the vapor by extrapolation*

The populations of the *o-syn* and *o-anti* conformers above correspond to free energy differences at 300 K of −0.55 ± 0.25 kJ/mol in acetone-d_6, favoring *o-anti*, and 0.05 ± 0.25 kJ/mol in CS_2/C_6D_{12}. Because the *o-anti* conformers are more polar than the *o-syn* (see below), the reaction field model (26) predicts a stabilization of the former in acetone-d_6. Furthermore, empirically (see p. 562 of ref. 26) it is found that the stabilization of the more polar form by CS_2 relative to the vapor is approximately that by acetone-d_6 relative to CS_2. Hence an estimate of the stability of the conformers in the vapor follows as 0.65 ± 0.35 kJ/mol in the free energy difference, *o-syn* favored, corresponding to an equilibrium constant of 1.28 ± 0.15.

If the free energy difference in the acetone-d_6 solution is equated to the enthalpy difference, then the *o-syn* population at 113 K is 0.36 ± 0.06. At about this temperature in a CHF_2Cl solution, concentration not given (17), this population, based on the ^{1}H nmr spectrum at 100 MHz of the aldehyde proton, is reported as 0.15. Given the different solvent, the possibility of small entropy differences between the conformers, and the possibility of some error in the measurements at low temperatures (compare, for example, the substantial differences in the estimates of the populations of the conformational isomers of 2-methylbenzaldehyde obtained by ^{13}C and ^{1}H nmr measurements at low temperatures (17, 28)), the disagreement is very likely only apparent.

The populations, $p_1 + p_3$, *and* $p_2 + p_4$

These populations are retrievable from ^5J(H-4,CH) ≡ $^5J_4$ and ^5J(H-6,CH) ≡ $^5J_6$, treated as follows. These coupling constants contain a σ−π component, proportional to $\langle \sin^2 \psi \rangle$, see **1**; this expectation value is given by ^6J(H-5,CH)/$^6J_{90}$ where $^6J_{90}$ is ^6J when the methine C—H is twisted out of the aromatic plane by 90° and is −1.12 Hz (11). Hence $\langle \sin^2 \psi \rangle$ is −0.259(7)/−1.12 or 0.231(6). Proceeding as before (11), the σ−π components of $^5J_4$ and $^5J_6$ are 0.073(2) Hz. The σ components are obtained by subtraction of this number from the $^5J_4$ and $^5J_6$ values in Table 2, to yield 0.428(4) and 0.095(3) Hz, respectively. Hence $p_1 + p_3$ follows as 0.428(4)/0.523(7) or 0.82(2), implying that $p_2 + p_4$, the population of the conformers in which the methyl groups lie near the aldehyde moiety, is 0.18(2).

Again, however, $^5J_4 + {}^5J_6$, at 0.669(2) Hz, is larger than in isopropylbenzene (11), where this sum is 0.591(5) Hz in the same solvents. Because $^6J_5$ is effectively the same in the two compounds, the difference must be attributed to an increase in either $^5J_4^{\sigma}$ or $^5J_6^{\sigma}$ in the derivative. The CNDO/2 and INDO MO FPT computations, using the optimized STO-3G MO geometries, imply that $^5J_4^{\sigma}$ is larger than $^5J_6^{\sigma}$ by 0.1 Hz. Therefore, attribution of 0.428(4) + 0.078(7) = 0.506(11) Hz

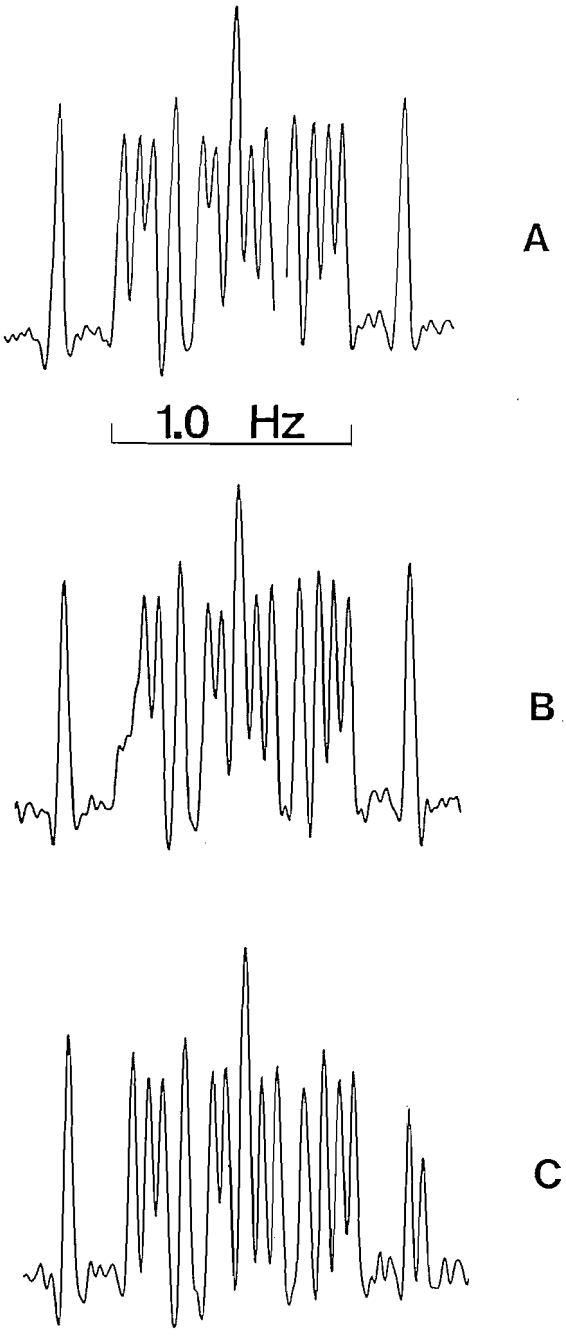

FIG. 1. In A the ^{1}H nmr spectrum of the aldehydic proton of 2-isopropylbenzaldehyde is shown for a 4.0 mol% solution in acetone-d_6 at 300 K, as controlled by the Bruker variable temperature device. The spectrum, obtained from 16 decays, occupies just over 1.4 Hz. The acquisition time per free induction decay is 41 s, the digital resolution is 0.006 Hz/point, and resolution enhancement (lb = −0.13 and gb = 0.60) has been applied before Fourier transformation. In B the same spectrum is shown under conditions in which a weak second radiofrequency field is applied to the peak at highest frequency in the multiplet due to H-5. For that peak the spin states of the ring protons coupled to H-5 are all positive, using the convention that positive spin states of coupled protons give rise to peaks at high frequency in the spectrum under observation; the spin state of the methine proton is negative, however, given that ^6J(H-5,CH) is negative because it is a $\sigma-\pi$ coupling constant (11). Together with the known (12) signs of ^4J(H,CHO), negative, and of ^5J(H,CHO), positive, it follows that the second peak from the left in A should be perturbed if ^5J(CH,CHO) is negative. This is observed to be the case (the J values in Table 1 can be used to construct the aldehyde spectrum and each peak can be labelled with the proton spin states of the other nuclei). In C the aldehydic proton spectrum is that for which a peak in the H-5 region is again being weakly irradiated by a second radiofrequency field; this time the spin states of H-4, H-6, and the methine proton are positive, but that of H-3 is negative. Accordingly, the peak at lowest frequency in A represents a transition with an energy level in common with the irradiated transition in the H-5 region if ^5J(CH,CHO) < 0. The result in C confirms the result in B.

[g]The fractional populations at 300 K based on a Boltzmann weighting.

to $^5J_4^\sigma$ and 0.095(3) Hz to $^5J_6^\sigma$, results in a $p_2 + p_4$ of 0.16(1); 0.078 Hz is the difference between 0.669(2) and 0.591(5) Hz above.

It appears that $p_1 + p_3 = 0.83(3)$ and $p_2 + p_4 = 0.17(3)$, independent of solvent. In view of the change in $p_1 + p_2$ induced by the more polar solvent, attributed to the higher dipole moment of the *o-anti* conformer in the previous section, this independence suggests that C=O...H—C and C—H...H—C repulsions in the side chains, or attractions, are nearly the same in magnitude. Furthermore, these interactions are relatively strongly favored over those of CHO with the methyl groups, the latter presumably being staggered about the C—H or C=O bonds of the aldehydic group.

That **2** and **4** have low populations is also suggested by the (probably proximate) coupling constants between the *ortho* ring protons and the methyl protons. In isopropylbenzene (11) the magnitude is ±0.04(1) Hz, whereas in the present compound ^5J(H-3,CH_3) is ±0.10(2) Hz. If this coupling constant is mediated by direct interactions, then it is expected to have a sizeable magnitude in only **1** and **3**. Comparison of the two magnitudes implies their consistency with a low population of **2** and of **4**.

Confirmation of the populational differences was also sought in STO-3G MO and AM1 computations, amenable to reasonable computing times.

*The theoretical relative energies of **1–4***

Presented in Table 2, the relative energies and dipole moments of the four planar conformers of 2-isopropylbenzaldehyde display large differences between the *ab initio* and semiempirical results. Populations in this table, derived from a simple exponential weighting, emphasize the disparity between the predictions for p_1 and p_3. However, there is agreement insofar as p_2 and p_4 are calculated as small at 300 K in the vapor and p_4 is computed as 0.02 and 0.00 by the two methods. In solution, the (more realistic) STO-3G dipole moments suggest

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

that p_2 is additionally favored over p_4, the latter having the smaller dipole. The relative instability of **4**, in which the C=O bond bisects the CH_3—C—CH_3 bond angle, is understandable in terms of repulsion between the proximate bonds. With the C—H bonds of the methyl groups staggered about the neighbouring linkages, implying the usual parallel C—H arrangements of the methyl moieties, the C—H...O distances can be as small as 1.6 Å, clearly a strongly destabilizing situation.

Some insight into the relative computed stabilities of **1**–**4** can be had from computations of the relative energies of the analogous conformers of 2-methylbenzaldehyde. Geometry optimization with the STO-3G basis set, but keeping the nuclei of the aromatic moiety in a plane, yields the relative energies of **1**–**4** as 7.41, 1.22, 3.70, and 0.00 kJ/mol, respectively. In other words, conformers analogous to **2** and **4** are now the stable ones, implying also that C—H...H—C and C—H...O=C interactions in **1** and **3** of 2-isopropylbenzaldehyde are repulsive but less so than are the C—H,$(CH_3)_2$ and C=O,$(CH_3)_2$ interactions in **1** and **3** of this compound.

The STO-3G basis indicates an attractive C—H...O=C arrangement *relative* to C—H...H—C in both molecules. AM1 computations indicate the opposite, the latter being 1.48 kJ/mol more favorable in the methyl and 1.95 kJ/mol in the isopropyl derivative. Similar remarks apply to the energies of **2** and **4** for both molecules: AM1 favors H,H over H,O interactions whereas the STO-3G basis does the opposite. The experimental data above, extrapolated to the vapor phase for 2-isopropylbenzaldehyde, are consistent with a small bias towards C—H...O=C arrangement for the isolated molecules, qualitatively favoring the STO-3G MO computations.

The STO-3G computations on **1** and **3** allowed θ and ψ to vary (see **1**); however, the twists about the exocyclic bonds did not exceed 0.2° during the minimization procedures, implying the local stability of the planar conformers. That the aldehyde group does not deviate substantially from the aromatic plane, at least in solution, is indicated by the apparent ^6J(H,CHO) of −0.015(3) Hz (Table 1). This coupling constant was not manifested by a detectable splitting in the ^{1}H nmr spectra, but is a result of the least-squares fits of the Hamiltonian to the spectra. ^6J(H,CHO) has a value near −0.33 Hz when θ is 90° (27) and varies as $\sin^2\theta$. Hence the expectation value of the latter and, by implication, that of θ, is small in **1** and **3**, the predominant conformers at 300 K. According to these computations, the repulsion between the side chains in **1** and **3** is insufficient to yield a local barrier to their planarity. However, STO-3G MO methods rather overestimate the barrier to rotation about the exocyclic bond in isopropylbenzene (11) but not in benzaldehyde. Accordingly, it is an approximation to speak of planar **1** and **3**, although the long-range coupling constants suggest no greater an average twist about the C_{sp^2}—C_{sp^3} bond in the present molecule than in isopropylbenzene.[2]

The repulsive nature of the C—H...H—C and C—H...O=C interactions in **1** and **3** is implied by their STO-3G structures in Fig. 2. The figure caption elaborates on this matter.

Finally, were the theoretical populations of *one* of the less abundant **2** and **4** in Table 2 roughly correct, then the experimental data would yield reliable values of the populations of the other three conformers. This conundrum is discussed next.

[2]A referee states that molecular mechanics calculations on **1** and **3** suggest "substantial out-of-plane twisting of the methine C—H bond". Accordingly, the STO-3G results should be taken as tentative.

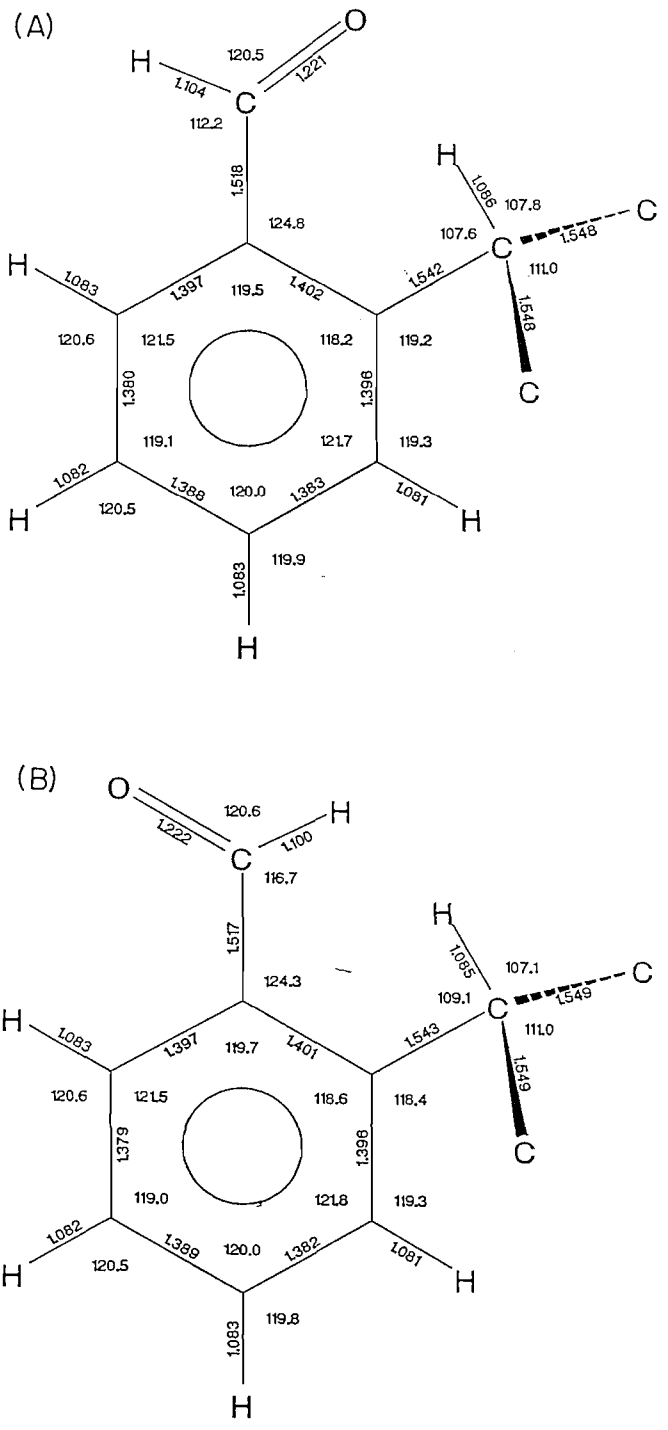

FIG. 2. The STO-3G structures of the planar conformers, (A) **1** and (B) **3**, are shown. The total energy of the *o-syn* conformer is −454.859 792 au, the relative energies of other conformers being given in Table 2. Compared with the structures of benzaldehyde (37) and isopropylbenzene (11), the C(O)C(1)C(2) and C(1)C(2)C(CH_3) bond angles suggest repulsion between the side chains; they bend away from each other in both conformers. Nevertheless, the computations imply that these structures represent local energy minima in that there is not a barrier to planarity. The energy of the process, 2-isopropylbenzaldehyde + benzene → isopropylbenzene + benzaldehyde (the isodesmic reaction (38)) is −14.6 kJ/mol for **1**, indicating an unfavorable substituent interaction, and is −10.5 kJ/mol for **3**. For salicylaldehyde, a similar procedure, using a 6-31G basis (13) gives +23.8 kJ/mol. The present STO-3G structures of **1** and **3** can serve as a starting point for computations with larger basis sets.

TABLE 3. Experimental populations of the planar conformers of 2-isopropylbenzaldehyde at 300 K

Conformer(s)	Acetone-d_6	CS_2/C_6D_{12}	Vapor
$(p_1 + p_2)^a$	$0.55_5 \pm 0.025$	$0.49_5 \pm 0.025$	0.43 ± 0.08

[f]The uncertainties in p_1 and p_3 are all as given in one instance.

Limits of the individual populations of ***1–4***

Table 3 contains a variety of populational estimates, including the sums of *o-anti* and *o-syn* populations as well as the population sums of conformers in which the methine C—H bond lies *cis* or *trans* to the aldehyde group. These sums, as derived from the long-range coupling constants, could imply a somewhat larger *o-syn* than *o-anti* population in the vapor phase. The reverse occurs in the polar solvent, attributable to the higher dipole moments (Table 2) of the *o-anti* conformers. By way of contrast, the population of the conformers with a *cis* orientation of the methine C—H bond is apparently independent of solvent polarity, presumably because these conformers are very much more stable than those with a *trans* orientation of this bond.

Unfortunately, the present experimental and theoretical approaches do not allow a reliable decision as to the relative individual populations of these two conformers. Accordingly, it can only be stated that p_2 and p_4 are each $0.08^{+0.11_5}_{-0.08_5}$ in both solvents and probably also in the vapor phase at 300 K. In consequence, any estimates of p_1 and p_3, the conformers in which the methine C—H bond closely approaches the C—H or C=O bond of the aldehyde group, carry a large uncertainty. It does appear reasonable, however (last two rows of Table 3), that the C=O...H...C interaction is less repulsive in the free molecule than is the C—H...H...C interaction in the side chains. In the polar solvent, the larger dipole moment of p_1 causes the stabilization of p_1, carrying the C—H...H—C arrangement.

The chemical shifts of the side-chain protons

Table 4 presents the chemical shifts of the side-chain protons in benzaldehyde, isopropylbenzene, and their 1,2 and 1,4 derivatives. Comparison of the shifts in the parent compounds with those in the 1,4 derivative gives an indication of the shift changes caused by long-range interactions. These changes are relatively small compared to those which occur in the 1,2 derivative for the aldehydic and methine protons.

Taking the 1,4 derivative as a reference, the shielding of the aldehydic proton in the 1,2 derivative decreases by 0.35 ppm in CS_2/C_6D_{12} and by 0.38 ppm in acetone-d_6. Attribution of the deshielding to the presence of the *o-anti* conformer, in which intense mean-square electric fields due to the close approach of the various vibrating C—H bonds (29, 30) are the cause of the lower screening of the aldehydic proton, allows a rough estimate of its chemical shift in this conformer. Use of the populations of the *o-syn* and *o-anti* conformers deduced in previous sections and assignment of δ(CHO) of the *o-syn* conformer as that in the 1,4 derivative, entails a δ(CHO) in the *o-anti* conformer of 10.67(4) in acetone-d_6 and of 10.54(4) in CS_2/C_6D_{12}. Then it follows that the difference in chemical shifts between the *o-anti* and *o-syn* conformers is 0.68(4) and 0.69(4) ppm in the two solutions. If δ(CHO) values for benzaldehyde are instead used as those of the *o-anti* conformers in the two solutions, the difference becomes 0.56(4) in both solvents. At 113 K, the chemical shift difference is observed (17) as 0.55 ppm for a solution of unknown concentration in CHF_2Cl. The present discussion can be taken as confirmation of the, at that time, equivocal assignment (17) of the deshielded peak to the *o-anti* conformer.

Turning to the methine proton, the same approach yields δ(CH) in **1** + **3** as 4.26(5) in acetone-d_6 and 4.16(5) in CS_2/C_6D_{12} solutions. Hence the methine proton is deshielded by about 1.2_5 ppm in either solution when the methine bond is oriented *cis* to the aldehydic functionality. The lower screening is no doubt a composite of electric field, magnetic anisotropy, and intramolecular van der Waals perturbations (30–32). These are impossible to assess quantitatively. The deshielding is consistent with a close approach of the methine C—H bond to the C—H and C=O bonds in **1** and **3**, which together have a fractional population of 0.83(3) in both solutions. Given the deshielding of the aldehyde proton in **1**, which is not greatly different in population from **3**, it is possible that the C—H...H—C interaction in **1** also acts to lower the screening of the methine proton by, say, about 0.6(1) ppm. In that event, the C=O...H—C interaction in **3** deshields the methine proton by about 0.6(1) ppm. It is possible, but improbable, that this represents a shift due to formation of a weak hydrogen bond, such bonds evincing a decrease in screening of the proton in the bond. In our opinion, a large part of the descreening in **3** arises from other sources.

That the shielding of the methine proton in **1** and **3** is much the same is consistent with the experiments at 113 K (17), in which distinct methine peaks are not observed for the conformers displaying different aldehydic proton signals.

Finally, the effective constancy of δ(CH_3) in the 1,2 and 1,4 derivatives in Table 4 is most easily interpreted as due to the low populations of **2** and **4**, particularly of the latter, and in line with the discussion in previous sections.

The chemical shifts of the ring protons

Based on the chemical shifts of isopropylbenzene (11), benzaldehyde (25), and benzene (33) in CS_2 solution at 300 K, an additivity scheme implies that, in 2-isopropylbenzaldehyde, 7.300, 7.441, 7.243, and 7.675 are δ_3–δ_6, in that order. The measured values are 7.360, 7.430, 7.247, and 7.665. Allowing for small differences in concentration of the various compounds, it is noteworthy that only δ_3 demonstrates a significant deviation. The H-3 protons are deshielded by 0.06 ppm, relative to the shielding expected from additivity, interpretable as caused by intramolecular van der Waals forces of the methyl groups in the large populations of **1** and **3**. If $p_1 + p_3$ were 0.5 instead of 0.83(3), then the deviation of δ_3 would presumably be less than 0.01 ppm. The very similar populations of the *o-syn* and *o-anti* conformers in CS_2/C_6D_{12}, equal to within experimental error, probably account for the insignificant deviations of δ_4–δ_6, particularly the latter. These shifts also imply that the side chains do not deviate from planarity by much more or

For personal use only.

less than in the parent compounds; a considerably increased nonplanarity of the carbonyl group of the derivative, for example, should surely manifest itself by nonadditivity of δ_4 and δ_6. Accordingly, the suggestion (17) that the lower barrier to rotation of the aldehydic group in 2-isopropylbenzaldehyde arises from its nonplanarity in the rotational ground state, needs reexamination. Those long-range coupling constants sensitive to θ and ψ (see **1**) also indicate the validity of the above interpretation of δ_4–δ_6.

The proximate coupling constant, $^5J(CHO,CH(CH_3)_2)$

The use of the STO-3G MO geometries of the planar conformers in CNDO/2 and INDO MO FPT computations of $^5J(CHO,CH(CH_3)_2) \equiv {}^5J_p$, gave rise to −0.30 Hz for **1**, in which the C—H bonds are proximate. Of course, ^5J_p is very sensitive to the interatomic distance (34, 35), the contact contribution to the coupling constant depending on the overlap of orbitals on the atoms or bonds carrying the coupled nuclei (36), so that the present result is taken as confirmation of the proximate mechanism of ^5J_p, determined as −0.376(1) Hz in CS_2/C_6D_{12} and as −0.388(1) Hz in acetone-d_6 solution. The slightly larger magnitude in the latter is consistent with the larger *o-trans* population in this solvent. Similar computations for the other conformers yielded small, positive, ^5J_p values; these may or may not be artefacts of the parameterization but agree with the idea that a close C—H...H—C approach of bonds in the side chains is accompanied by a negative coupling constant.

Because ^5J_p is very likely sizeable only in **1** and because $p_1 < 0.5$ in both solutions, it follows that its magnitude in this conformer is likely near 1 Hz. For obvious reasons, ^5J_p cannot at present be used to deduce p_1.

It is interesting that no evidence exists in the ^{1}H nmr spectra for spin–spin coupling between the aldehydic and methyl protons. Were there such evidence, (no doubt) it would have been taken as an indication of the existence of **2**, in which the methyl groups lie rather near the C—H bond of the aldehyde group.

Conclusion

The experimental data suggest that C—H...H—C and C=O...H—C interactions in the side chains of 2-isopropylbenzaldehyde are roughly isoenergetic. Consideration of the STO-3G MO structures in Fig. 2, in which the H...H and H...O distances are 1.92 and 2.05 Å and hence markedly below the sum of the van der Waals radii of the hydrogen and oxygen atoms of 1.2 and 1.4 Å, respectively, implies repulsive interactions for these bond arrangements. Hence there is no evidence for an intramolecular C=O...H—C hydrogen bond, although the H...O distance, if met in a crystal, likely would be taken as evidence for a hydrogen bond. It would be of interest to have an assignment of the stretching frequencies of the aldehydic and methine C—H bonds in this molecule, together with a comparison of these frequencies in the parent molecules.

Molecular orbital and ^1H nuclear magnetic resonance studies of the inversion potentials of thianthrene and thioxanthene

TED SCHAEFER,[1] RUDY SEBASTIAN, AND CHRISTIAN BEAULIEU[2]
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received October 10, 1990

TED SCHAEFER, RUDY SEBASTIAN, and CHRISTIAN BEAULIEU. Can. J. Chem. **69**, 927 (1991).

The inversion potentials, obtained from STO-3G, STO-3G(*), 3-21G, 3-21G(*), and 4-31G basis sets, are reported for thianthrene and thioxanthene, molecules in which both or only one of the methylene groups have been replaced by sulfur in 9,10-dihydroanthracene. Comparison with the available experimental data suggests that the split-valence bases lead to an overestimate, possibly by about 10 kJ/mol, of the inversion barrier in the crystal, whereas the STO-3G and STO-3G* basis sets underestimate this barrier. It appears that the inversion barrier for thianthrene is much lower in solution than in the crystal. The long-range coupling constants between the methylene and ring protons for thioxanthene in solution are consistent with an inversion barrier somewhat smaller than those obtained with the split-valence bases but rather larger than those predicted with the STO-3G basis set. The bond lengths and angles in the equilibrium structures of the two molecules, as computed with the 3-21G(*) basis, agree reasonably well with those in their crystals, except that the theoretical folding angles are smaller than measured. These discrepancies become less marked when expectation values are calculated from the theoretical inversion potentials at finite temperatures.

Key words: MO calculations, inversion potentials of thianthrene and thioxanthene; ^1H NMR, thioxanthene; spin–spin coupling constants, long range, in thioxanthene.

TED SCHAEFER, RUDY SEBASTIAN et CHRISTIAN BEAULIEU. Can. J. Chem. **69**, 927 (1991).

Utilisant des ensembles STO-3G, STO-3G(*), 3-21G, 3-21G(*) et 4-31G, on a calculé les potentiels d'inversion du thianthrène et du thioxanthène, des molécules dans lesquelles l'un ou les deux groupements méthylènes du 9,10-dihydroanthracène ont été remplacés par des soufres. Une comparaison des résultats des calculs avec les données expérimentales disponibles suggère que les ensembles à valence partagée conduisent à des surévaluations, pouvant aller jusqu'à 10 kJ/mol, de la barrière à l'inversion dans le cristal; par ailleurs, les ensembles STO-3G et STO-3G(*) sous-évaluent cette barrière. Il semble que la barrière à l'inversion du thianthrène est beaucoup plus faible en solution que dans le cristal. Les constantes de couplage à longue distance entre le méthylène et les protons du cycle du thioxanthène en solution sont en accord avec une barrière d'inversion inférieure à celles obtenues avec les ensembles à valence partagée, mais plus élevée que celles prédites par l'ensemble STO-3G. Les longueurs des liaisons et les angles dans les structures en équilibre des deux molécules, telles que calculées avec un ensemble 3-21G(*), sont en bon accord avec celles observées dans les cristaux; toutefois, les angles théorique de repliement sont plus faibles que ceux mesurés. Ces différences deviennent moins marquées lorsque les valeurs attendues sont calculées à partir des potentiels théoriques d'inversion à des températures finies.

Mots clés : calculs d'OM, potentiels d'inversion du thianthrène et du thioxanthène; RMN ^1H, thioxanthène; constantes du couplage à longue distance du thioxanthène.

[Traduit par la rédaction]

Introduction

Geometry-optimized STO-3G and 4-31G molecular orbital computations give 8.6 and 7.8 kJ/mol, respectively, for the inversion barrier in 9,10-dihydroanthracene, compatible with the available experimental data (1). The folding angle is computed as very near 141° in the boat form, as compared to 144.7° in the crystal (2). Replacement of both methylene groups by sulfur atoms, to give thianthrene, entails a folding angle of 128° (3, 4), or 127.14(3)° at 163 K and 128.09(5)° (5) in the crystal; both angles are reasonably compatible with electron diffraction data for the vapor (6). In benzene solution, the dipole moment and Kerr constant of thianthrene suggest a folding angle of approximately 142° (7). The inversion barrier, opposing the formation of a planar molecule with a folding angle of 180°, ranges from 15 ± 3 kJ/mol (enthalpy of activation) in a polymer matrix, as derived from dielectric loss measurements (8), to 26 kJ/mol (9), estimated from approximate molecular mechanics calculations in connection with dielectric loss studies in a benzene solution at 293 K. For the free molecule, presumably at 400 K (6), inversion barriers as low as 16.7 or as high as 29.2 kJ/mol could be fit to the radial distribution curve in the electron diffraction experiments; the folding angle is 128–130°. In contrast to the results for the solid and vapor, the analyses of the nmr spectra of thianthrene in nematic solvents imply a folding angle of 141.6(2)° in one anisotropic solvent (10) at 307 K and 140.6(4)° in another (11) at 308 K; the folding angle was 139.8(7)° for the 2,7-dichloro derivative (11). No large-amplitude motion was assumed in the derivation of these angles, implying the assumption of an inversion barrier large compared to thermal energies. A recent molecular mechanics calculation (12) has the folding angle as 130° for a boat form of C_{2v} symmetry and the inversion barrier as 19.2 kJ/mol, rather lower than the 25–29 kJ/mol in an early calculation combining Hückel molecular orbitals with estimates of strain and σ-bond deformation energies (13). One has the peculiar conclusion that, in solution, the molecule is less puckered by about 10° than in either the vapor or solid state. In contrast, dibenzo-*p*-dioxin is planar in the solid state and puckered in solution (14).

Turning to thioxanthene, in which one of the methylene groups of 9,10-dihydroanthracene is replaced by a sulfur atom, the folding angle in the crystal is 135.3(1)° and the intermolecular separations are larger than the van der Waals contact distances (15). This indication, that crystal packing forces do not appreciably deform the molecule, is supported by the folding angle of 135 ± 8° estimated from molar Kerr contants at 298 K in CCl_4 and C_6H_6 solutions (16). Such a degree of pucker is consistent with the magneto-optical rotation of thioxanthene

in $CHCl_3$ solution at 293 K (17). The dipole moment at 303 K in C_6H_6 and the ^1H nmr chemical shift of the methylene protons in $CDCl_3$ at 309 K are apparently interpretable in terms of a planar or a rapidly inverting, nonplanar, molecule (18). No evidence for slow inversion on the nmr time scale (presumably indicated by a difference in the chemical shifts of the methylene protons in the puckered conformation of thioxanthene) was found at 193 K, the lowest temperature for which suitable solvents could be found (18).

In the present report, long-range coupling constants between the methylene and ring protons are discussed in terms of the degree of pucker of thioxanthene and in terms of *ab initio* molecular orbital computations meant to provide not only the folding angle for the free molecule but also the barrier to inversion. Similar computations are given for thianthrene and these may be compared to inversion barriers provided by the other theoretical methods discussed above. A comparison between theoretical and experimental structures is also presented.

Experimental

Thioxanthene (K & K Laboratories) was prepared for ^1H nmr studies as 4 mol% solutions in CS_2/C_6D_{12}/TMS and C_6D_6/TMS solvent mixtures (Table 1). These solutions were filtered into 5-mm o.d. nmr sample tubes, were degassed by five cycles of the freeze–pump–thaw technique, and were then flame-sealed. The ^1H nmr spectra were obtained on a Bruker AM300 nmr spectrometer in a manner previously described in detail (19).

Ab initio molecular orbital computations utilized an Amdahl 5870 system and employed the program GAUSSIAN 86 (20) with various basis sets (21). For thianthrene, the geometry-optimization procedure allowed all bond angles and lengths to vary, with the constraint, however, that the molecule retain C_{2v} symmetry in the folded form. For thioxanthene, the constraints included a mirror plane containing the sulfur atom and the carbon atom of the methylene group, as well as planarity of the two aromatic fragments. Computations were performed for as many as nine values of the folding angle (see below).

Results and discussion

Molecular orbital computations

(i) Thianthrene

Table 1 presents the relative computed energies of thianthrene as a function of the folding angle, θ. The structures of planar and folded thianthrene are given in Fig. 1, as calculated with the basis set, 3-21G(*). The bond lengths and angles involving heavy atoms agree very closely with the most recent X-ray determination (5), if averages of the various experimental values are compared with the parameters in Fig. 1(a). Comparison of the planar structure, Fig. 1(b), with the equilibrium geometry implies that bond angle distortion, mainly at sites in the heterocyclic ring, accounts for much of the instability of the planar form. The expectation value, $\langle\theta\rangle$, of the folding angle at 300 K is computed as 126.3°, not far from the 127.1° found in the crystal at 163 K (5).

This comparison raises the question of the inversion potential appropriate to various states of the molecule. The theoretical potentials for the free molecule from the various basis sets are written in the form of eq. [1]

$$[1]\quad V(\phi)/\text{kJ mol}^{-1} = A\phi^2 + B\phi^4 + C\exp(D\phi^2)$$

where $\phi = \theta - 180°$, and are as shown.

Basis	$A/10^{-2}$	$B/10^{-6}$	C	$D/10^{-4}$
STO-3G	−1.20(3)	0.80(10)	9.97(23)	3.71(6)
STO-3G(*)	−0.84(3)	0.66(8)	6.17(19)	4.18(12)
3-21G	−2.64(3)	1.54(23)	31.62(32)	2.44(9)
3-21G(*)	−2.81(4)	1.83(23)	31.97(40)	2.53(10)
4-31G	−2.73(3)	1.69(22)	31.81(32)	2.49(9)

The errors are given for a 95% confidence interval, Fig. 2, illustrating the fit to the computed energies for the 4-31G basis. The split-valence basis sets yield an inversion barrier near 31 kJ/mol, while the STO-3G and STO-3G(*) bases predict a barrier rather less than 10 kJ/mol in magnitude (see also Table 1).

The temperature-dependent folding angle in the crystal indicates "butterfly" motion even at 163 K; the four outermost carbon atoms still have the largest thermal parameters (5) at this temperature. The values of $\langle\theta\rangle$ were computed at three temperatures with the potentials in eq. [1] and are shown

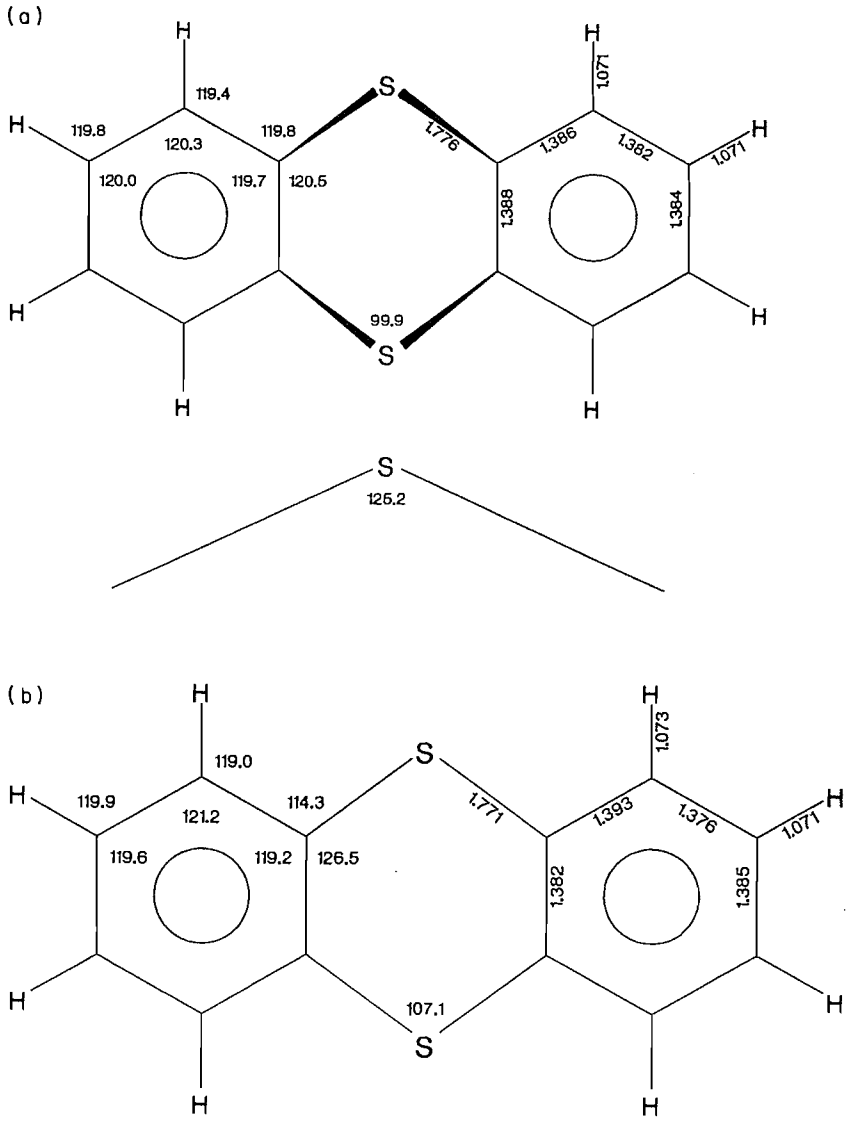

FIG. 1. The equilibrium 3-21G(*) structure of thianthrene is shown in (a), the computation having assumed C_{2v} symmetry. There is rather good agreement with the latest X-ray structure (5). In (b) the computed planar geometry suggests, by comparison with that in (a), that bond angle distortions in the central ring are the primary cause of its instability.

together with literature values for the folding angle. Differences

Basis/method	$\langle\theta\rangle_{163}$/degree	$\langle\theta\rangle_{300}$	$\langle\theta\rangle_{400}$
STO-3G	134.5	136.4	137.9
STO-3G*	138.5	141.2	142.6
3-21G	124.3	124.8	125.2
3-21G(*)	126.0	126.4	126.8
4-31G	125.2	125.7	126.1
Crystal (5)	127.14(3)	128.09(5)	—

Benzene (7)	—	142.0	—
Vapor (6)	—	—	129(1)

in the theoretical barriers have also been noted for 1,4-dithiin (the aromatic moieties in thianthrene are replaced by C=C bonds). For this molecule, the minimal basis set (12, 22) is assessed as underestimating the inversion barrier, whereas the split-valence bases, including 3-21G(*) and 6-31G* (using 3-21G(*) optimized geometries), are felt (22) to overestimate the barrier.

These comparisons suggest that the inversion barrier in thianthrene lies somewhere between those from the STO-3G and split-valence bases given in Table 1, possibly a value not far from the 15 ± 3 kJ/mol estimated from the dielectric loss measurements on a polymer matrix (8) or the 19.2 kJ/mol obtained by molecular mechanics (12). The much larger folding angle obtained in anisotropic (10, 11) or isotropic (7) solutions of thianthrene is most simply interpreted as a consequence of a lower inversion barrier in these intermolecular environments. It may be noted that $\langle\theta\rangle$ at 300 K is given as 141.2° by the low STO-3G(*) inversion potential, very near the average, 141.1°, of the angles obtained in two anisotropic solutions near 307 K. It would be of interest to apply the various theoretical potentials above to the dipolar nmr parameters (10, 11) and to the electron diffraction patterns.

It may also be noted that STO-3G MO calculations on thioanisole (23) give the barrier to rotation about the C_{sp^2}—S bond as 6.2 kJ/mol, not far from the 5.5(4) kJ/mol found for a benzene solution.

Finally, it is to be noted that the accuracy of a computed equilibrium geometry does not necessarily imply a corresponding accuracy in the internal barrier computed with the same

For personal use only.

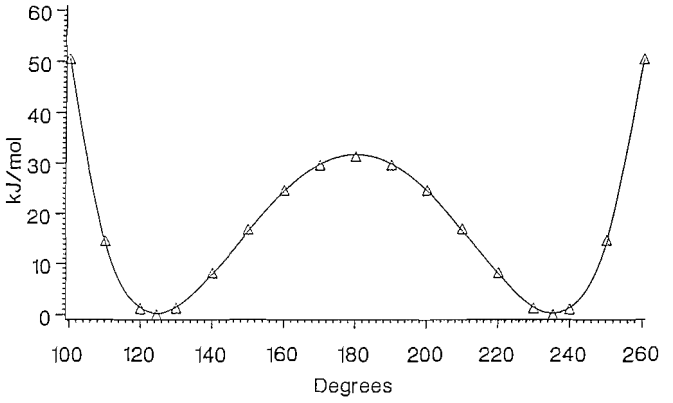

FIG. 2. The inversion potential of thianthrene is shown, as computed with the basis set, 4-31G. The triangles give the computed relative energies, whereas the solid curve represents eq. [1] of the text, an analytical form for the inversion potential.

basis set. For example, the internal barrier in benzaldehyde is best given by the minimal basis set, when compared to split-valence bases as large as 6-31G* (24), whereas the equilibrium geometry is better reproduced by the larger bases. Thus, while the 3-21G equilibrium structure for thianthrene (Fig. 1(a)) is rather close to the experimental structure in the crystal (5), it does not follow that the inversion potential is correct.

The dipole moment of thianthrene is 1.42 D in benzene at both 298 and 323 K (7, 25). Clearly, the minimal basis set underestimates, while the split-valence bases overestimate, its magnitude. The mean of the STO-3G and 3-21G(*) or 4-31G values, at their respective equilibrium geometries (Table 1), is within 0.1 D of experiment. The overestimates are typical for compounds containing sulfur (26).

(ii) Thioxanthene

The computed energies of thioxanthene appear in Table 2 as a function of the folding angle for the bases, STO-3G, STO-3G(*), and 4-31G. The folding angles at equilibrium (see footnote in Table 2) for those computed with the basis sets 3-21G and 3-21G(*) are, on average, computed as 4.6° larger than in thianthrene; the 4-31G basis has this number as 6.3°. In the crystal, this difference in angle is near 7° (5, 15). Figure 3 displays the equilibrium structure computed with the 3-21G(*) basis set. The bond lengths and angles in the central ring appear to agree with those deduced (15) from X-ray diffraction patterns to within experimental error. The folding angle is, however, some 5° less than that in the crystal. Probably by coincidence, the STO-3G basis has a folding angle, 136.6° at equilibrium, rather closer to the 135.3(1)° derived for the crystal. Of course, the expectation value of the angle will depend on temperature and on the inversion potential.

The terms of eq. [1] are shown for the various basis sets, appropriate to thioxanthene,[3] as are the (classical) average

Basis	$A/10^{-2}$	$B/10^{-6}$	C	$D/10^{-4}$	$\langle\theta\rangle_{300}$/deg
STO-3G	−1.36(2)	0.46(17)	9.60(8)	4.89(10)	140.2
STO-3G(*)	−1.20(4)	1.30(18)	7.60(22)	4.64(11)	143.4
4-31G	−2.51(6)	1.25(43)	22.79(4)	3.54(15)	132.2

folding angles at 300 K derived from these potentials. These averages all lie within the 135 ± 8° estimated from Kerr constants in CCl_4 and C_6H_6 solutions at 298 K (16). In the next section, the long-range proton–proton coupling constants are discussed with a view to a narrowing of the range of the folding angle appropriate to solutions.

Rather as for thianthrene, the mean of the computed dipole moments of the equilibrium structures at the STO-3G and 4-31G level of *ab initio* molecular orbital theory, being 1.25 D (Table 2), effectively coincides with the 1.25 D reported for CCl_4 and C_6H_6 solutions (16).

The ^1H nmr parameters for thioxanthene

(i) Spectral analysis

The ^1H nmr spectra were analyzed with the computer program NUMARIT (27), as extensively modified by R. Sebastian. The plethora of closely spaced peaks in the methylene proton region, caused by long-range coupling constants to eight ring protons, precluded assignments of computed to measured transitions in this region. The small range of chemical shifts in the ring proton region had the consequence that large correlations existed between many spectral parameters obtained from the analyses.

This fact very likely accounts for differences between coupling constants within the ring as deduced for the two solutions. For example, $^3J_{34}$ is correlated by 0.72 with ν_3 in the C_6D_6 solution; hence its value of 7.447(7) Hz is much less reliable than the 7.410(3) Hz obtained for the CS_2 solution in Table 3. Similar statements could be made about other coupling constants among ring protons. Fortunately, the coupling constants between the methylene and ring protons did not suffer significantly from such correlations. It is these which are of use in the conformational analysis of thioxanthene.

(ii) The long-range methylene proton coupling constants

In toluene (19), $^6J(H,CH_3)$ is −0.602(2) Hz and is proportional to $\langle\sin^2\psi\rangle$, where ψ is the angle by which the α C—H bond twists out of the benzene plane. Hence $^6J_{90}$, the value of $^6J(H,CH_3)$ when ψ is 90°, is −1.204(4) Hz because the internal barrier is very low and therefore $\langle\sin^2\psi\rangle$ is 0.5. The latter value holds as long as the methyl group reorients about the C_{sp^2}—C_{sp^3} bond in a time short compared to J^{-1}, where J is long-range coupling constant over six bonds for *any* value of ψ: the methyl group has threefold symmetry.

The magnitude of $^6J_{90}$ depends on the electronegativity of the α substituent, E_x. In benzyl fluoride, $^6J_{90}$ is −0.94 Hz (28), and is assessed as −1.16 Hz in ethyl benzene (29). The available E_x scales all have the phenyl as more electronegative than the methyl group (30). The assumption of a linear relationship between $^6J_{90}$ and E_x, together with the comparisons of

[3]A referee comments that the planar conformation of thioxanthene is not necessarily the transition state for inversion; a force constant analysis, using computing times unavailable to us, is necessary for such a characterization.

130	1.50	0.72	2.18	0.28	0.06	1.77	109.32	−7.87
120	12.78	0.69	14.29	0.27	7.90	1.77	118.31	−1.61
110	43.99	0.63	46.29	0.26	36.36	1.77	125.65	2.14

[a]In kJ/mol, E(minimum) being −885.272 474 (STO-3G), −885.313 804 (STO-3G*), and −894.463 688 (4-31G) au.

[b]The angles by which the methylene C—H bonds are twisted out of the aromatic planes.

[c]For the 3-21G basis, the planar molecule (θ = 180°) is 23.70 kJ/mol less stable than that with a θ of 128.8_4°, which has a total energy of −890.912 424 au. For the 3-21G(*) basis set, these numbers are 21.64 kJ/mol, 130.0_4°, and −891.020 026 au.

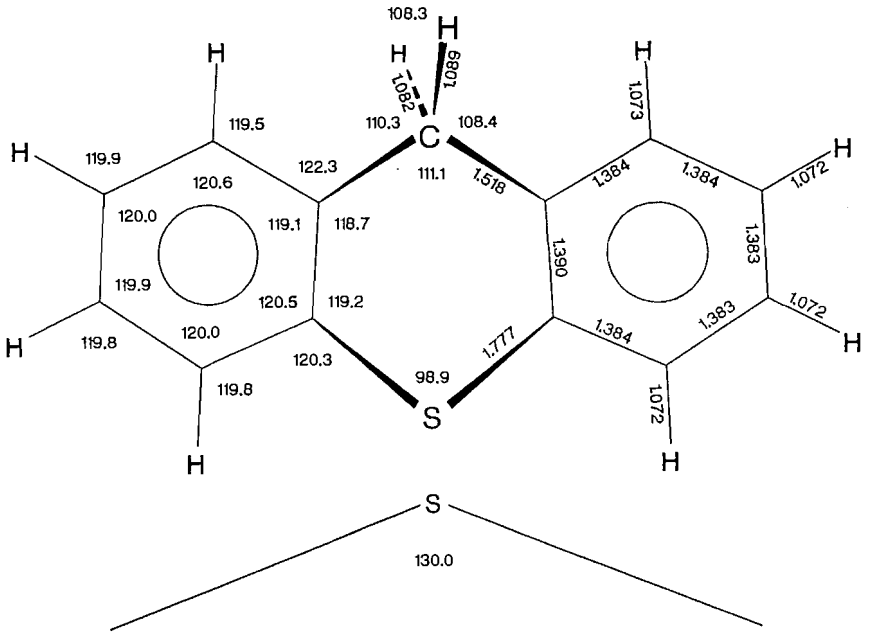

FIG. 3. The 3-21G(*) structure of thioxanthene is displayed, the agreement with the geometry in the crystal being rather good in that the CSC and CC(H_2)C angles agree to within experimental error. However, the folding angle is some 5° less than in the crystal, reminiscent of a similar discrepancy between split-valence bases and experiment for 9,10-dihydroanthracene (1) where, again, other bond lengths and angles show good agreement between experiment and theory. Of course, the expectation value of the folding angle depends on the temperature and on the inversion potential and will be higher than the equilibrium value (see text).

E_x (30), yields $^6J_{90}$ as −1.13(2) Hz for thioxanthene. The immediate and trivial consequence is that the molecule cannot be planar in solution. Planarity implies a ψ near 60°, a $\sin^2\psi$ near 0.75, and hence a $^6J(H,CH_2)$ near −0.85 Hz; the measured value is −0.551(3) Hz in both solvents (Table 3). In fact, at 300 K the value of $\langle\sin^2\psi\rangle$ is −0.551(3)/−1.13(2) or 0.49(1).

The theoretical inversion potentials for thioxanthene, applied to the ψ values for the methylene C—H bonds in Table 2 (shown only for the 4-31G geometries because they are very similar for the geometries obtained from all the basis sets), yield $\langle\sin^2\psi\rangle$ as shown.

Method	$\langle\sin^2\psi\rangle_{300}$	$\langle\sin^2(\psi/2)\rangle_{300}$
STO-3G	0.529	0.302
STO-3G(*)	0.547	0.295
4-31G	0.470	0.328
$^6J(H,CH_2)$	0.49(1)	0.32(4)

It appears that the inversion potential is computed as somewhat high with the basis, 4-31G, and, by implication, with the 3-21G and 3-21G(*) bases (footnote in Table 2). The STO-3G and STO-3G(*) bases seem to yield too small an inversion barrier.

The long-range coupling constant, $^5J(H,CH_3)$, in toluene has been written (19) as $^5J/Hz = {}^5J^{\pi}\sin^2\psi + {}^5J^{\sigma}\sin^2(\psi/2)$, where $^5J^{\pi}$ is 0.336 Hz and $^5J^{\sigma}$ is 0.322 Hz. $^5J^{\pi}$ in thioxanthene should scale in the same way as $^6J_{90}$ but $^5J^{\sigma}$ is not known for this compound. However, if $\sin^2(\psi/2)$ applies to $^5J(H\text{-}2,CH_2)$, then $1 - \sin^2(\psi/2)$ is appropriate to $^5J(H\text{-}5,CH_2)$. The two coupling constants are 0.276(8) and 0.414(6) Hz, respectively, where the averages for the two solutions are quoted. The quantities $^5J^{\sigma}$ and $\langle\sin^2(\psi/2)\rangle$ then follow as 0.384(26) Hz and 0.32(4) at 300 K. Because of the large uncertainties in $^5J(H,CH_2)$ it can be said only that this value of $\langle\sin^2(\psi/2)\rangle$ is consistent with the conformational deductions from $^6J(H,CH_2)$.

In toluene (19), $^4J(H,CH_3)$ obeys the equation (31): $^4J/Hz = -1.08\langle\sin^2\psi\rangle - 0.32\langle\cos^2\psi\rangle$. Applied to thioxanthene, this relationship has $^4J(H,CH_2)$ as −0.69(1) Hz because $\langle\sin^2\psi\rangle = 0.49(1)$. The measured number is −0.824(3) Hz. However, for $\psi < 90°$, this relationship appears (31) to underestimate the magnitude of ^4J for some molecules. In one of these, **1**, a ψ of

1

45° corresponds to a ^4J of −0.84 Hz, for example, and $\sin^2 45°$ is, of course, 0.5. Hence, apart from other considerations, such as the appropriate bond order of the intervening aromatic C—C bond (32), ^4J in thioxanthene cannot be taken as evidence against the conformational indications based on $^6J(H,CH_2)$.

Thiol esters in organic synthesis. XVI.[1] Formation of α,β-unsaturated thiol esters via a Wadsworth–Emmons process

HSING-JANG LIU, PATRICIA A. ROSE, AND DOUG J. SASAKI
Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 9, 1990

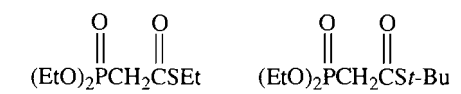
HSING-JANG LIU, PATRICIA A. ROSE, and DOUG J. SASAKI. Can. J. Chem. **69**, 934 (1991).

α,β-Unsaturated thiol esters could be readily prepared via a Wadsworth–Emmons reaction using diethyl alkylthiocarbonylmethylphosphonate, which proved to be superior in reactivity to the corresponding Wittig reagent.

Key words: α, β-unsaturated thiol esters, Wadsworth–Emmons reaction.

HSING-JANG LIU, PATRICIA A. ROSE et DOUG J. SASAKI. Can. J. Chem. **69**, 934 (1991).

On peut facilement préparer les esters de thiols α,β-insaturés en faisant appel à une réaction de Wadsworth–Emmons utilisant l'alkylthiocarbonylméthylphosphonate de diéthyle dont la réactivité est supérieure à celle du réactif de Wittig correspondant.



Mots clés : esters de thiols α, β-insaturés, réaction du Wadsworth–Emmons.

Thiol esters are stable acid derivatives and yet highly versatile synthetic intermediates. Their increased utility in synthesis has attracted extensive efforts in developing new methods of preparation.[2] Several years ago, Keck *et al.* reported the preparation of α,β-unsaturated thiol esters using ethylthiocarbonylmethylenetriphenylphosphorane (2). This Wittig reagent was shown to react with aldehydes with high stereoselectivity (2), and has been applied to the synthesis of (+)-colletodiol (3). However, no report has appeared regarding its reaction with ketones. In our hands, attempted reaction of this reagent with 4-*tert*-butylcyclohexanone and 6-undecanone failed completely even after extended reaction time at temperatures greater than 60°C. Herein we wish to report the use of diethyl alkylthiocarbonylmethylphosphonate to facilitate the preparation of α,β-unsaturated thiol esters. This Wadsworth–Emmons reagent shows a greater propensity to react with carbonyl compounds.

Both ethyl (**1**, bp 114–116°C/0.6 Torr; 1 Torr = 133.3 Pa) and *tert*-butyl phosphonates (**2**, bp 147–149°C/3.6 Torr) were examined. These compounds were readily prepared in ca. 90% yield by treatment of the corresponding α-bromo thiolacetate with triethyl phosphite (4, 5) in refluxing benzene overnight, followed by distillation. These reagents were found to readily undergo reactions with aldehydes and ketones. A typical reaction sequence involved generating the anion by dropwise addition of a solution of the phosphonate ester (1.1 equiv.) in tetrahydrofuran to a stirred suspension of sodium hydride (1.1 equiv.) under argon at 0°C. The reaction mixture was stirred until bubbling ceased (~10 min) and then the carbonyl compound (1 equiv.) was added. The resulting solution was warmed to room temperature and allowed to react until completion as indicated by thin-layer chromatography (silica gel).

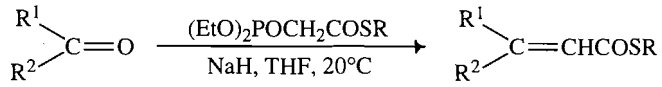
1 **2**

The procedure is apparently general. A number of carbonyl compounds were examined and the results are compiled in Table 1. Both reagents, **1** and **2**, showed comparable reactivity. As expected, aldehydes were found to react with the reagents more rapidly then ketones (1–2 h vs. ~16 h). A single stereoisomer (*trans*) was obtained from all the aldehydes examined (Entries 7–10). This stereoselectivity compares favorably with that observed previously using the Wittig reagent (2). The principle difference between the two types of reagents, however, lies in their reactivity towards carbonyl compounds. With the Wittig reagent, the reaction towards aldehydes requires more than 12 h at ~60°C (2). With the phosphonates, the reaction readily occurred at room temperature in less than 2 h (Entries 7–10). A more profound difference was observed for ketones. While the Wittig reagent failed to react (*vide supra*), phosphonates **1** and **2** reacted with ketones smoothly to give the expected condensation products in greater than 80% yield (Entries 1–3, 5, and 6). As the only exception, the reaction of **2** and 4-*tert*-butylcyclohexanone (Entry 4) gave a substantial amount of the β,γ-unsaturated thiol ester, apparently as a result of the concomitant migration of the double bond.

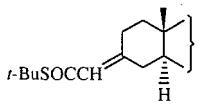
In conclusion, phosphonates **1** and **2** proved to be considerably more reactive towards carbonyl compounds than the corresponding Wittig reagent. Their reaction with aldehydes and ketones provides a general procedure for the preparation of synthetically useful α,β-unsaturated thiol esters.

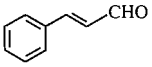
Experimental

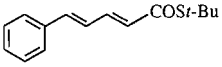
General

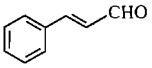


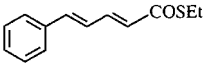
The ir spectra were determined using a Nicolet 7199 FTIR or Nicolet MX-1 FTIR spectrometer and, except where otherwise stated, were obtained as a $CHCl_3$ cast. High resolution mass spectra (hrms) were obtained using a Kratos AE1 MS50 high resolution mass spectrometer. Elemental analyses were determined by the microanalytical laboratory of this department. The ^{1}Hmr spectra were obtained as $CDCl_3$ solutions using the following spectrometers: Bruker WH-200 (200 MHz) and Bruker AM-400 (400 MHz). Flash chromatography was performed according to the procedure of Still *et al.* (6) using silica gel (Merck) of 230–400 mesh. All solvents were distilled prior to chromatography. Thin-layer chromatography was performed on Merck aluminum-backed plates precoated with silica gel 60 GF_{254}. All reactions were run under an argon atmosphere. Tetrahydrofuran (THF) was distilled from a blue solution of sodium benzophenone ketyl under an argon atmosphere. Methylene chloride and benzene were distilled over calcium hydride. Bromoacetyl bromide was purchased from Aldrich Chemical Company, Inc. *S-tert*-Butyl bromoacetate was prepared directly from acetic acid according to the procedure[3] of Luo of this laboratory.

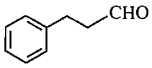


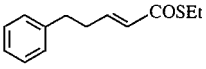












[1]For part XV of this series, see ref. 1.

[2]A review article on the preparation and synthetic applications of thiol esters is being prepared by us.

[3]This procedure will soon be published.

TABLE 1. Preparation of α,β-unsaturated thiol esters

Entry	Carbonyl compound	Phosphonate	Time (h)	Product(s)	Isolated % yield
1		**2**	23	 **3**	85
2		**1**	19	 **4**	87
3		**1**	17	 **5**	80
4		**2**	20	 **6**  **7** **6/7** = 5:2	82
5		**1**	16	 **8**	92

7		**2**	1	 **10**	76
8		**1**	1	 **11**	72
9		**1**	1	 **12**	83
10	$CH_3(CH_2)_{20}CHO$	**2**	1.5	 **13**	92

Diethyl ethylthiocarbonylmethylphosphonate (1)

Bromoacetyl bromide (0.87 mL, 10 mmol) was dissolved in 20 mL of CH_2Cl_2 and cooled to 0°C. Ethyl mercaptan (0.74 mL, 10 mmol) dissolved in 5 mL of CH_2Cl_2 was added dropwise. After addition, the solution was warmed to room temperature and left to stir overnight. The resulting solution was washed with a 5% sodium carbonate solution (2 × 25 mL), water (2 × 25 mL), and brine (25 mL). The combined organic layers were dried over magnesium sulfate, filtered, and concentrated. This afforded ~2 g of *S*-ethyl bromoacetate, which was used without purification. The Wadsworth–Emmons reagent was then formed by mixing triethyl phosphite (1.72 mL, 10 mmol) with the bromoacetate thus obtained in 10 mL of benzene at room temperature, followed by heating to reflux with stirring for 24 h. Distillation under reduced pressure (114–116°C/0.6 Torr) afforded the desired product **1** in 91% yield (2.19 g); ir: 1684 (C=O) cm^{-1}; ^{1}Hmr (200 MHz) δ: 4.16 (dq, $J = J' = 7.5$ Hz, 4H, -OCH_2), 3.20 (d, $J = 21$ Hz, 2H, -PCH_2),

2.92 (q, J = 7 Hz, 2H, -SCH_2CH$_3$), 1.34 (t, J = 7.5 Hz, 6H, -OCH$_2$CH_3), 1.26 (t, J = 7 Hz, 3H, -SCH$_2$CH_3); hrms M$^+$: 240.0582 (calcd. for $C_8H_{17}PO_4S$: 240.0585).

Diethyl tert-*butylthiocarbonylmethylphosphonate (2)*

A solution of *S-tert*-butyl bromoacetate (28.4 g, 0.135 mol) and triethyl phosphite (23.3 mL, 0.135 mol) was heated to reflux with stirring for 24 h. Distillation under reduced pressure (147–149°C/3.6 Torr) afforded the desired product **2** in 89% yield (31.1 g); ir: 1679 (C=O) cm^{-1}; ^{1}Hmr (400 MHz) δ: 4.15 (dq, J = J' = 7.5 Hz, 4H, -OCH_2), 3.13 (d, J = 21 Hz, 2H, -PCH_2), 1.47 (S, 9H, -C(CH_3)$_3$), 1.30 (t, J = 7.5 Hz, 6H, -OCH$_2$CH_3); hrms M$^+$: 268.0898 (calcd. for $C_{10}H_{21}PO_4S$: 268.0898).

General procedure for forming the α,β-*unsaturated thiol esters*

All reactions were carried out using the general procedure illustrated below with cyclohexanone and reagent **2**. The time required for each reaction is to be found in Table 1.

To a dried 50-mL three-necked flask containing 1 mL of THF was added sodium hydride (42 mg, 60% dispersion in oil, 1.1 mmol). This was cooled to 0°C, with stirring, and the Wadsworth–Emmons reagent **2** (287 mg, 1.1 mmol) in 0.5 mL of THF was slowly added. The mixture was stirred until bubbling ceased (~10 min), indicating complete formation of the anion. Freshly distilled cyclohexanone (1.0 mmol, 111 mg) in 0.5 mL of THF was added and the reaction mixture was slowly warmed to room temperature and stirred overnight. The solution was quenched with 10 mL of 1M HCl, extracted into CH_2Cl_2 (3 × 20 mL), and the combined organic extracts washed with 20 mL of brine, dried over magnesium sulfate, filtered, and concentrated. Flash chromatography (20% ether/petroleum ether) produced 186 mg (86%) of compound **3** as an amorphous solid; ir: 1664 (C=O), 1623 (C=C) cm^{-1}; ^{1}Hmr (200 MHz) δ: 5.84 (t, J = 1Hz, 1H, =CH), 2.78 (m, 2H, =CCH_2), 2.14 (m, 2H, =CCH_2), 1.62 (m, 6H, -CH_2CH_2CH_2), 1.47 (s, 9H, -C(CH_3)$_3$); hrms M$^+$: 212.1221 (calcd. for $C_{12}H_{20}OS$: 212.1235).

The thiol esters **4**–**13** showed the following spectral data. Compound **4**; ir: 1668 (C=O), 1624 (C=C) cm^{-1}; ^{1}Hmr (200 MHz) δ: 5.86 (s, 1H, =CH), 2.89 (q, J = 7 Hz, 2H, -CH_2CH$_3$), 2.78 (m, 2H, =CCH_2), 2.14 (m, 2H, =CCH_2), 1.62 (m, 6H, -CH_2CH_2CH_2), 1.28 (t, J = 7 Hz, 3H, -CH$_2$CH_3); hrms M$^+$: 184.0921 (calcd. for $C_{10}H_{16}OS$: 184.0922). Anal. calcd. for $C_{10}H_{16}OS$: C 65.17, H 8.75, S 17.40; found: C 65.04, H 8.96, S 17.28.

Compound **5**; ir: 1667 (C=O), 1626 (C=C) cm^{-1}; ^{1}Hmr (200 MHz) δ: 6.10 (t, J = 2 Hz, 1H, =CH), 2.90 (q, J = 7 Hz, 2H, -CH_2CH$_3$), 2.74 (m, 2H, =CCH_2), 2.38 (m, 2H, =CCH_2), 1.70 (m, 4H, -CH_2CH_2), 1.25 (t, J = 7 Hz, 3H, -CH$_2$CH_3); hrms M$^+$: 170.0765 (calcd. for $C_9H_{14}OS$: 170.0765).

Compounds **6** and **7** were isolated as an inseparable mixture of α,β and β,γ isomers (2:1 ratio). The mixture showed the following spectral data; ir: 1680 (sh, C=O), 1667 (unsaturated thiol ester C=O), 1625 (C=C) cm^{-1}; hrms M$^+$: 268.1858 (calcd. for $C_{16}H_{28}OS$: 268.1861). The ^{1}Hmr (400 MHz) spectrum showed the following signals for the major isomer **6**: δ: 5.51 (m, 1H, -C=CHCOSR), 3.65 (m, 2H, =CCH_2), 2.20 (t, J = 6 Hz, 2H, =CCH_2), 0.87 (s, 18H, -C(CH_3)$_3$). The minor isomer **7** showed the following peaks in the ^{1}Hmr (400 MHz) spectrum: δ: 5.35 (tt, J = 2, J' = 7 Hz, 1H, -CH=CCH$_2$CO), 4.15 (br d, J = 7 Hz, 2H, -CH_2CO), 0.85 (s, 9H, -C(CH_3)$_3$), 0.83 (s, 9H, -C(CH_3)$_3$).

Compound **8**; ir: 1671 (C=O), 1627 (C=C) cm^{-1}; ^{1}Hmr (200 MHz) δ: 5.86 (s, 1H, =CH), 3.80 (m, 1H, =CCHH), 2.88 (q, J = 7 Hz, 2H, -SCH_2CH$_3$), 2.20 (m, 2H, =CCH_2), 1.90 (m, 3H), 1.25 (t, J = 7 Hz, 3H, -SCH$_2$CH_3 overlapping with m, 3H), 0.84 (s, 9H, -C(CH_3)$_3$); hrms M$^+$: 240.1539 (calcd. for $C_{14}H_{24}OS$: 240.1548). Anal. calcd. for $C_{14}H_{24}OS$: C 69.95, H 10.06, S 13.34; found: C 70.10, H 10.16, S 13.23.

Compound **9** was an inseparable mixture of *E* and *Z* isomers present in a 1:1 ratio; ir: 1667 (C=O), 1622 (C=C) cm^{-1}; ^{1}Hmr (400 MHz) δ: 5.80 (s, 0.5H, =CH), 5.82 (s, 0.5H, =CH), 1.50 (s, 9H, -C(CH_3)$_3$), 0.95 (s, 3H, -CH_3), 0.90 (d, J = 6 Hz, 3H, -CHCH_3), 0.86 (d, J = 6 Hz, 3H, -CH(CH_3)$_2$), 0.84 (d, J = 6 Hz, 3H, -CH(CH_3)$_2$), 0.65 (s, 3H, -CH_3); hrms M$^+$: 500.4050 (calcd. for $C_{33}H_{56}OS$: 500.4052.

Compound **10**; ir (CH_2Cl_2 cast): 1662 (C=O), 1621 (C=C) cm^{-1}; ^{1}Hmr (200 MHz) δ: 7.2–7.5 (m, 6H, C_6H_5 and -CH=), 6.85 (d, J = 15 Hz, 1H, Ar-CH=), 6.80 (dd, J = 15, J' = 10 Hz, 1H, Ar-CH=CH-), 6.20 (d, J = 15 Hz, 1H, =CH-CO), 1.52 (s, 9H, -C(CH_3)$_3$); hrms M$^+$: 246.1078 (calcd. for $C_{15}H_{18}OS$: 246.1078).

Compound **11**; ir: 1668 (C=O), 1659 (C=C) cm^{-1}; ^{1}Hmr (200 MHz) δ: 7.4 (m, 6H, C_6H_5 and -CH=), 6.96 (d, J = 15 Hz, 1H, Ar-CH=), 6.80 (dd, J = 15, J' = 10 Hz, 1H, Ar-CH=CH-), 6.28 (d, J = 15 Hz, 1H, =CH-CO), 2.98 (q, J = 7 Hz, 2H, -SCH_2CH$_3$), 1.28 (t, J = 7 Hz, 3H, -SCH$_2$CH_3); hrms M$^+$: 218.0766 (calcd. for $C_{13}H_{14}OS$: 218.0765).

Compound **12**; ir: 1672 (C=O), 1632 (C=C) cm^{-1}; ^{1}Hmr (200 MHz) δ: 7.3 (m, 5H, C_6H_5), 6.94 (dt, J = 15.5, J' = 6.5 Hz, 1H, -CH=CHCO), 6.15 (dt, J = 15.5, 1.5 Hz, 1H, =CHCO), 2.95 (q, J = 7 Hz, 2H, -SCH_2CH$_3$), 2.78 (m, 2H, Ar-CH_2), 2.48 (m, 2H, -CH_2CH=), 1.26 (t, J = 7 Hz, 3H, -SCH$_2$CH_3); hrms M$^+$: 220.0923 (calcd. for $C_{13}H_{16}OS$: 220.0922).

ALBERTO HERNANDEZ GAINZA and ROY IKEMEFULA KONYEASO. Can. J. Chem. **69**, 937 (1991).

An excess concentration of base quinine (Q) reacts with a sulphonphthalein diacidic dye XH_2, (bromocresol green, $BCGH_2$, or bromophenol blue, $BPBH_2$) in dichloromethane solution to form an ion associate ($X^{2-}(QH^+)_2$) of stoichiometry 1:2 (dye:amine). Benzethonium chloride (ClB) reacts with the 1:2 ion associate to form an ion associate (QH^+, X^{2-}, B^+) and quinine hydrochloride $ClQH^+$. This substitution reaction is a chemical equilibrium with formation constants of 1.50 ± 0.67, 1.61 ± 0.54, 1.07 ± 0.29, 1.04 ± 0.20, and 0.84 ± 0.26 for BCG and 1.86 ± 0.59, 1.47 ± 0.23, 1.40 ± 0.65, 1.13 ± 0.37, and 1.11 ± 0.27 for BPB at 283.16, 288.16, 293.16, 298.16, and 303.16 K respectively. The thermodynamic parameters determined by van't Hoff's equation are $\Delta H^0 = -21.766 \pm 7.482$ kJ mol^{-1}, $\Delta S^0 = -73 \pm 51$ J mol^{-1} K^{-1}, and $\Delta G^0 = -1.134 \pm 0.972$ kJ mol^{-1} for BCG and $\Delta H^0 = -18.678 \pm 7.482$ kJ mol^{-1}, $\Delta S^0 = -61 \pm 26$ J mol^{-1} K^{-1}, $\Delta G^0 = -0.916 \pm 0.401$ kJ mol^{-1} for BPB (ΔG^0 at 293.16 K; and ΔH^0 and ΔS^0 determined in the range 283–303 K).

Key words: bromocresol green – quinine–benzethonium, ion associate mixture, bromophenol blue – quinine–benzethonium, equilibrium constants, thermodynamic parameters.

ALBERTO HERNANDEZ GAINZA et ROY IKEMEFULA KONYEASO. Can. J. Chem. **69**, 937 (1991).

Les colorants diacides sulphonphtaléiniques, XH_2 (le vert de bromocrésol, BCG, et le bleu de bromophénol, BPB) réagissent avec des concentrations élevées de la quinine base, Q, dans le chlorure de méthylène en formant des paires d'ions de stoechiométrie 1 : 2 (colorant : quinine). Le chlorure de benzéthonium, ClB, réagit avec le paire d'ions 1 : 2 en formant des ions associés (QH^+, X^{2+}, B^+) et du chlorohydrate de quinine. On a démontré l'existence d'un équilibre chimique entre la paire ionique 1 : 2 et les ions associés et on a calculé les constantes d'équilibre correspondant à la formation des ions associés (QH^+, BCG^{2-}, B^+) et (QH^+, BPB^{2-}, B^+) qui sont respectivement égales à 1,50 ± 0,67, 1,61 ± 0,54, 1,07 ± 0,29, 1,04 ± 0,20 et 0,84 ± 0,26; et 1,86 ± 0,59, 1,47 ± 0,23, 1,40 ± 0,65, 1,13 ± 0,37 et 1,11 ± 0,27 à 283,16, 288,16, 293,16, 298,16 et 303,16 K. Les paramètres thermodynamiques correspondant à la formation des (QH^+, BCG^{2-}, B^+) et (QH^+, BPB^{2-}, B^+) sont respectivement : $\Delta H^0 = -21,766 \pm 7,482$ kJ mol^{-1}, $\Delta S^0 = -73 \pm 51$ J mol^{-1} K^{-1} et $\Delta G^0 = -1,134 \pm 0,972$ kJ mol^{-1} (à 293,16 K); et $\Delta H^0 = -18,678 \pm 7,482$ kJ mol^{-1}, $\Delta S^0 = -61 \pm 26$ J mol^{-1} K^{-1}, $\Delta G^0 = -0,916 \pm 0,401$ kJ mol^{-1} à 293,16 K (ΔH^0 et ΔS^0 déterminés en faisant la moyenne de la relation de van't Hoff dans un intervale de 283–303 K).

Mots clés : vert de bromocrésol – quinine–benzéthonium, mélange d'ions associés, bleu de bromophénol – quinine–benzéthonium, constantes d'équilibre, paramètres thermodynamiques.

Introduction

Sakai proposed a new method for the analysis of various quaternary ammonium ions (B) by extraction of ion associates mixed with bromocresol green (BCG) and quinine (Q) (1) or bromophenol blue (BPB) and quinine (2). Sakai's method was empirical and the nature of the ion associate mixture dye–quinine – ammonium ion was suggested but was not proved (1, 2). This new method of analysis is of great interest since it is specific and the methods of analysis based on the extraction of ion pairs are not specific (3–8). These unspecific methods have been widely proposed for the analysis of amines of pharmacological interest. The extraction of ion-associate mixtures could make possible the specificity of these methods of analysis, which are very important in pharmaceutical analytical chemistry. However, there is no information about the formation and stability of ion-associate mixtures.

In this paper, we obtained the ion-associate mixtures of BCG–Q–benzethonium and BPB–Q–benzethonium only in a dichloromethane medium. These reactions were performed only in organic medium, making possible the determination of the stoichiometry and stability of the ion-associate mixtures obtained. The stoichiometry of these ion associates could not be determined in a two-phase system, this being the reason why its existence could not be proved (1, 2).

Firstly, to obtain the dye–Q–benzethonium ion-associate mixture it is necessary to generate the dye–Q_2 ion associate in dichloromethane solution by neutralization of the dye with an excess of quinine base. In previous work, the neutralization reactions of the two protons of BCG and BPB dyes with quinine base and its hydrochloride salt (9), ajmaline and homatropine base (10), and atropine and tropine (11), in dichloromethane, have been studied. These studies showed that in an excess of amine base, given the low dielectric constant of the organic solvent, the stabilization of the dye with the amines is produced by formation of a dye–(amine)$_2$ ion associate, that is to say $X^{2-}(amineH^+)_2$. Therefore, the dye is present in negative, divalent form, as indicated by the scheme of reactions 1 and 2 in ref. 10 (or also reactions [3] and [4] in this paper).

In dichloromethane, the formation of the ion-associate mixture, dye–quinine–benzethonium, $X^{2-}QH^+B^+$, in strong excess of quinine base is established to be

$$[1] \quad X^{2-}(QH^+)_2 + ClB \rightleftharpoons X^{2-}QH^+B^+ + ClQH$$

where $X^{2-}(QH^+)_2$ is the ion associate obtained by the reaction of Q with the sulphonphthalein dye (the formation of $X^{2-}(QH^+)_2$ is complete in a strong excess of Q); ClB, benzethonium chloride; and ClQH, quinine hydrochloride. The existence of this reaction in dichloromethane is demonstrated in this paper. Furthermore the equilibrium constants, K, and the molar extinction coefficients of the ion-associate mixture, ε', of the reaction have been calculated. These have been determined through a procedure of iterative calculation proposed in this paper, which makes possible the determination of K, ε', and their corresponding errors. This procedure is similar to that

proposed by Rosseinsky and Kellawi (12) for addition reactions, whereas this method solves substitution reactions. The proposed method reduces to a minimum the square of the residuals using the Gauss procedure (13) with analytical derivation and the best values for K and ε' are obtained. The equilibrium constants have been calculated at various temperatures and the thermodynamic parameters have been determined by the van't Hoff equation.

The absorption spectra of BCG–Q–B and BPB–Q–B are identical to the spectra in the organic phase of the products obtained by Sakai (1, 2), which indicates that these are ion-associate mixtures.

Experimental part

Instruments and reagents

The spectrophotometric measurements were carried out with a Perkin–Elmer Lambda 5 spectrophotometer, using a Selecta Tectron thermostat with ±0.5°C accuracy, 1 cm quartz cells with Teflon stoppers, and an Amstrad PC1512SD microcomputer. Dichloromethane: Probus HPLC, with water content less than 0.02%. Anhydrous quinine base (Q): Sigma. Bromocresol green (BCG) and bromophenol blue (BPB): Merck. All solid reagents were of analytical grade and were stored in a desiccator with phosphorus pentoxide and used without previous purification. All dichloromethane solutions were used immediately after preparation.

Absorption spectra and stoichiometric balance

When a solution containing dye (BCG or BPB) and excess quinine base (Q) in dichloromethane (the $X^{2-}(QH^+)_2$ species is generated immediately, X can be BCG or BPB) is mixed with another which contains benzethonium chloride (ClB), a new absorption spectrum is observed with maximum wavelengths of absorption at 630 nm for BCG and 605 nm for BPB. This new spectrum suggests the existence of a new compound in the solution ($X^{2-}QH^+B^+$ in eq. [1], X can be BCG or BPB). The spectra of $X^{2-}(QH^+)_2$, $X^{2-}QH^+B^+$, and ClB in dichloromethane are shown in Figs. 1a and 1b. Figure 2 shows the effect of the concentrations of Q and ClB, in a mixture dye–Q–benzethonium with a constant concentration of dye, on the absorption spectrum.

The stoichiometry of these reactions has been determined using Job's method (14). The experimental data are shown in Tables 1 and 2. Since the reagent $X^{2-}(QH^+)_2$ shows some absorption at the same wavelength as that of the maximum absorption of the $X^{2-}QH^+B^+$ product (Figs. 1a and 1b), the law of Lambert–Beer can be expressed here as $A' = A_m - A_0 = x\{\varepsilon_{x^{2-}QH^+B^+} - \varepsilon_{x^{2-}(QH^+)_2} = x\varepsilon'$ (for derivation of this see Appendix). A_m is the experimental absorbance of the system given by eq. [1]; A_0 is the absorbance due to the $(X^{2-}(QH^+)_2)$ ion associate, this being equal to the total (or initial) dye concentration, a, in the experiment multiplied by the molar absorptivity of the $X^{2-}(QH^+)_2$ species ($A_0 = \varepsilon_{x^{2-}(QH^+)_2} \cdot a$). A is equally the absorbance found in a previous identical experiment where the species ClB was excluded; x is the concentration of the product of the reaction, $\varepsilon_{x^{2-}QH^+B^+}$ its molar extinction coefficient, and $\varepsilon_{x^{2-}(QH^+)_2}$ the molar extinction coefficient of the 1:2 ion associate ($X^{2-}(QH^+)_2$). The difference between $\varepsilon_{x^{2-}QH^+B^+}$ and $\varepsilon_{x^{2-}(QH^+)_2}$ is the ε' value. The value of the extinction coefficient of $X^{2-}(QH^+)_2$ has been determined using a solution of dye–quinine with an excess of quinine. The values of A' are shown in the last column of Tables 1 and 2. The stoichiometry of the reaction is always 1:1, according to Job's method, after subtracting the absorbance, A_0, due to the ion associate 1:2 (Tables 1 and 2). Supplementary information about the subject discussed in this section can be consulted in ref. 15.

Determination of the equilibrium constants

Figure 3 shows superposed absorption spectra of a solution containing BCG with excess Q to which increasing amounts of benzethonium chloride (ClB) are added. These spectra show various isosbestic points, which suggest the existence of a chemical equilibrium between the 1:2 ion associate and the new product ($X^{2-}QH^+B^+$). Similar spectra to those of Fig. 3 have been obtained for BPB. To determine the equilibrium constants and the molar extinction coefficients of the product, a series of solutions in dichloromethane containing mixtures of dye–Q (in excess quinine) and benzethonium chloride with the sum of the concentrations constant were prepared. The experimental data for BCG are shown in Table 3. These data correspond to the values of

A' and they have been obtained for various temperatures in order to determine the thermodynamic parameters of the reaction.

The equilibrium constant for reaction [1] is given by the following expression:

$$[2] \quad K = \frac{[X^{2-}QH^+B^+][ClQH^+]}{[X^{2-}(QH^+)_2][ClB]} = \frac{x^2}{(a-x)(b-x)}$$

where a and b are the initial (or total) concentrations of the dye (BCG or BPB) and benzethonium bromide (ClB) and x represents the concentrations of the products in the equilibrium (corresponding to eq. [1]). The procedure for calculation of the equilibrium constant, K, will be discussed subsequently.

Discussion

Tables 1 and 2 suggest a clear 1:1 stoichiometry for the product formed with each of the dyes. Accordingly, the reaction that takes place in the solution has to be reaction [1].

This is true only when Q is present in the solution in strong excess. With a slight excess of Q the stoichiometry is not clear. This is due to the fact that Q neutralizes the two protons of the dye generating the 1:1 and 1:2 ion associates by the following reactions (9–11):

$$[3] \quad XH_2 + Q \rightleftharpoons XH^-QH^+$$

$$[4] \quad XH^-QH^+ + Q \rightleftharpoons X^{2-}(QH^+)_2$$

where XH_2 is the free dye and XH^-QH^+ the 1:1 ion associate.

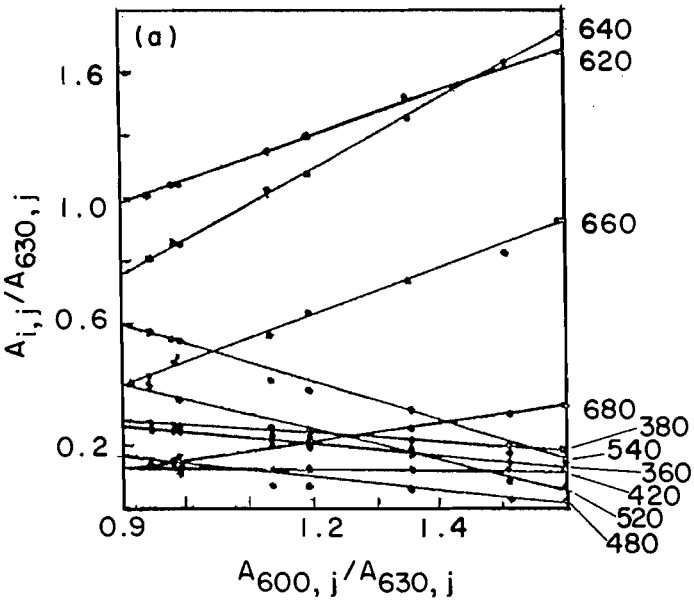
The XH^-QH^+ ion associate shows a maximum at approximately 415 nm and the $X^{2-}(QH^+)_2$ at 550 and 590 nm for BCG and BPB, respectively (ref. 9, and Fig. 2 for BCG). The formation of XH^-QH^+ is quantitative from the spectrophotometric point of view (therefore reaction [3] is not taking place in the solution) while that of the 1:2 ion associate is clearly a chemical equilibrium that is displaced towards the formation of this last compound with an increase in the concentration of the alkaloid base or a decrease in temperature (9–11). Therefore, in a slight excess of Q reactions [1] and [4] are present in the solution, which explains an uncertain stoichiometry under these conditions.

The simultaneous existence of reactions [1] and [4] in solution can be seen in Fig. 2 where a dye–Q–benzethonium mixture with constant concentration of dye increases its absorption intensity (at 630 nm for BCG and 605 nm for BPB) when the concentration of Q, dye, or both at the same time increases. This suggests that reactions [1] and [4] are chemical equilibria. The fact that reaction [1] is in equilibrium will be demonstrated subsequently.

Consequently, a dye–Q–benzethonium mixture in a slight excess of Q generates in solution three absorbing species XH^-QH^+, $X^{2-}(QH^+)_2$, and $X^{2-}QH^+B^+$ (lines II, III, and IV in Fig. 2); Fig. 2 demonstrates a case where absorption spectra with an isosbestic point are due to three absorbing species. On the other hand, in an excess of Q only the last two species are present (Fig. 3). This has been confirmed by Coleman's method (16), as can be seen in Figs. 4a and 4b.



The equilibrium constants at 293 K for reaction [4] are, respectively, 25 751 ± 2822 L mol^{-1} for BCG and 183 486 ± 61 775 L mol^{-1} for BPB in dichloromethane (9–11). Therefore, with a concentration of Q at least 100 times higher than that of BCG and 20 times higher than that of BPB, reaction [4] is totally displaced to the right. In this way it is guaranteed that reaction [4] is not taking place in the solution and therefore reaction [1] can be easily studied. A higher excess of Q does not affect the absorption measurements. This indicates that the excess concentration of Q is not important in the substitution reaction, a logical result since Q does not take part in reaction [1].

The previous discussion justifies that all experiments were carried out in a sufficient excess of Q to complete reaction [4].

The isosbestic points in Fig. 3 indicate the chemical equilibrium suggested in reaction [1]. Furthermore, Coleman's method (16) confirms the existence of two absorbing species (Fig. 4a) under the experimental conditions in Fig. 3 and also agrees with the condition that the sum of the concentrations of the two species is constant (Fig. 4b). Most spectrophotometric methods so far published are valid for addition reactions but this reaction is a substitution process. For this reason, we are proposing a procedure that permits the simultaneous calculation of the equilibrium constant, K, and the molar absorptivity, ε' ($\varepsilon' = \varepsilon_{x^{2-}QH^+B^+} - \varepsilon_{x^{2-}(QH^+)_2}$, obtained from data in Table 3. The relationship between the absorbance, A', of each solution, K, and ε' is given by the following equation:

$$[5] \quad \frac{ab}{A'^2} = \frac{a+b}{\varepsilon' A'} - \frac{1}{\varepsilon'^2(1-K^{-1})}$$

which is obtained by substituting A'/ε' for x in eq. [2]. The graphic plot of ab/A'^2 against $(a+b)/A'$ permits the

determination of K and ε' from the values of the ordinate and the slope obtained by the least-squares method. An example of this plot for BCG is shown in Fig. 5. In order to refine K and ε' and determine their corresponding errors, an iterative method similar to that of Rosseinsky and Kellawi (12), adapted to processes of type A + B $\rightleftharpoons$ C + D, has been proposed. This method begins with the values of K and ε' obtained from the graphic method already described. A computer program in

GWBASIC has been written to perform all these calculations. The program has been checked with synthetic absorbance data, obtaining an exact reproduction of the expected values of K and ε'. In the same way it was checked with synthetic data affected with random errors. The program reproduced the values of K and ε' expected, which were better than those obtained from the graphic method from Fig. 5.

The program gives the values of K and ε' with their respective confidence intervals with a 95% confidence level, root-mean-square deviation (r.m.s.d.) of the experimental absorbance values, and the values of the linear determination coefficient (r^2) obtained by the least-squares method. One additional advantage of the refinement procedure is that it eliminates experimental data with dispersion greater than 2 × (r.m.s.d.). In Table 4 the values obtained for BCG and BPB reagents are given. The values of r^2 obtained, which are close to 1, and the r.m.s.d. about the instrumental error suggest that reaction [1] is taking place in the solution. Another important result is that ε' is almost constant at different temperatures. The values from Table 4 indicate that the equilibrium constant K diminishes with an increase in temperature, making possible the determination of the thermodynamic parameters using van't Hoff's equation (17). The thermodynamic parameters have been obtained by plotting log $K \times \varepsilon'$ against $1/T$. Since the product of $K \times \varepsilon'$ is more exact than K, a more exact result for ΔH^0 and ΔS^0 is obtained (18, 19). The values of ΔS^0 and ΔH^0 obtained using least-squares methods are shown in Table 5 with their respective confidence intervals, for a confidence level of 95% from the Student "t"-test (20). An example of the alternative method to van't Hoff's plot is shown in Fig. 6.

As shown in Table 5, since the ΔH^0 values are negative, the reaction is exothermic; these ΔH^0 values are of the same sign but smaller than those of the neutralization reactions to form 1:2 ion associates (reaction [4]) in dichloromethane (9–11). The ΔS^0 values of the reactions are negative, which is considered to reflect the evidence that the degree of freedom of the system decreases, perhaps due to a stronger solvation sphere about the products of the reaction. These ΔS^0 values are also of the same sign but smaller than those of the neutralization reactions to form 1:2 ion associates (reaction [4]) in dichloromethane. The ΔG^0 values are close to zero and their confidence intervals suggest that they can either be negative or positive. Thus, a

mixture of the reagents in their normal states might not give a spontaneous reaction. Since at high temperature the K values decrease, this would be more probable.

Conclusions

Causing the ion associate 1:2 (dye–Q) to react with benzethonium chloride in dichloromethane permits determination of the stoichiometry, equilibrium constants, and thermodynamic magnitudes of a reaction of great analytical importance. The reaction is established as an exchange of ions where QH^+ is replaced with B^+ in a clear chemical equilibrium with equilibrium constants that agree with the van't Hoff equation. The values of the equilibrium constants indicate a reaction that is displaced towards the formation of the products and that this reaction can be favoured by reducing the temperature. The molar absorptivity of the ion associate dye–Q – ammonium ion is, by far, much greater than that corresponding to the ion associate dye–Q_2, which is also important from the analytical point of view.

Appendix

For the system A + B $\rightleftharpoons$ C + D, in equilibrium (corresponding to eq. [1]), the concentrations of the four species are $a - x$, $b - x$, x, and x respectively. In the system mentioned species A and C are exclusively absorbent. Reagent A shows some degree of absorption at the same wavelength for which reagent C exhibits the maximal absorbance. Therefore, the absorbance, A_m, of the system at peak wavelength of C for unit path length would be:

$$[6] \quad A_m = \varepsilon_A(a - x) + \varepsilon_C x = \varepsilon_A a + (\varepsilon_C - \varepsilon_A)x = A_0 + \varepsilon' x$$

where a and b are the initial concentrations of A and B; ε_A, ε_C, and ε' are the molar absorptivities of A, C, and the difference between the two, $\varepsilon_C - \varepsilon_A$, respectively; A_0 is the absorbance found in a previous identical experiment where species B was excluded, and x represents the concentration of C and D in equilibrium. If the difference, $A_m - A_0$, is represented by A', Beer's Law can be expressed as

$$[7] \quad A' = \varepsilon' x = \varepsilon' f(K,a,b)$$

The A' value depends on the ε' and x and therefore on K, a, and b. The quadratic solution for $x = f(K,a,b)$ from eq. [2] would be:

$$[8] \quad x = \frac{1}{2}\left\{\frac{a+b}{1-K^{-1}} \pm \sqrt{\left(\frac{a+b}{1-K^{-1}}\right)^2 - \frac{4ab}{1-K^{-1}}}\right\}$$

Differentiation of eq. [7] with respect to the parameters required, K and ε', yields:

$$[9] \quad \left(\frac{dA'}{dK^{-1}}\right)_{\varepsilon'} = \frac{\varepsilon'}{2}\left\{\frac{a+b}{(1-K^{-1})^2} \pm \frac{\dfrac{(a+b)^2}{(1-K^{-1})^3} - \dfrac{2ab}{(1-K^{-1})^2}}{\sqrt{\left(\dfrac{a+b}{1-K^{-1}}\right)^2 - \dfrac{4ab}{1-K^{-1}}}}\right\}$$

$$[10] \quad \left(\frac{dA'}{d\varepsilon'}\right)_K = x$$

If K is greater than 1 the positive sign is used in the equations while if $K < 1$ then it takes the negative sign. If $K = 1$ then $(dA/dK^{-1})_{\varepsilon'} = 0$ and $x = ab/(a + b)$. The partial derivatives of K^{-1} are calculated instead of those of K, just for algebraic convenience (12).

We require that K^{-1} and ε' fulfill these conditions:

$$[11] \quad \frac{d}{dK^{-1}}\Sigma(Ac - A')^2 = 0 \quad \text{and} \quad \frac{d}{d\varepsilon'}\Sigma(Ac - A')^2 = 0$$

Starting with initial values of K^{-1} and ε' obtained using the graphic method (eq. [5]), we can write the value of A_c, to be substituted in the eq. [11] in terms of a truncated Taylor series that involves corrections ΔK^{-1} and $\Delta\varepsilon'$ to K^{-1} and ε':

$$[12] \quad A_c = A_{c_i} + \Delta K^{-1}(dA/dK^{-1})_{\varepsilon'} + \Delta\varepsilon'(dA/d\varepsilon')_K$$

We now calculate ΔK^{-1} and $\Delta\varepsilon'$ from the normal equations derived from the conditions in eq. [11] described above. The A_{c_i} is calculated from the initial K^{-1} and ε' values. Solutions of the simultaneous equations for ΔK^{-1} and $\Delta\varepsilon'$ are the first-order corrections to the initial values of K^{-1} and ε'. The new improved values are then taken as trial values, and the procedure is repeated until convergence is obtained. The parameters in the final cycle ($\Delta K^{-1}/K^{-1} < 0.000002$ and $\Delta\varepsilon'/\varepsilon' < 0.000002$) are then the best-fitting values. The values obtained using the graphic method (eq. [5]) are suitable as initial values of K^{-1} and ε' since they are very close to the real values, and therefore within the convergence domain of this iterative method. The root-mean-square deviation (r.m.s.d.) is given by

$$[13] \quad \text{r.m.s.d.} = \{(\Delta A)^2/n\}^{0.5}$$

To carry out all these calculations, a computer program in GWBASIC was designed. This program uses the values of a, b, and A' to calculate all the results. The program also calculates the linear determination coefficient, r^2, obtained by the graphic method, and the root-mean-square deviation, r.m.s.d., the last being calculated by eq. [13] in the final cycle. Moreover, the

program eliminates those experimental data with values of $A_c - A' > 2 \times$ r.m.s.d. (A_c is the absorbance calculated with the values of K and ε' selected after a series of iterations). The inadequate points are eliminated one by one, and each time one value is eliminated, the calculation procedure is repeated so that the error does not affect the selected values of K and ε'. Finally, the standard deviations, $\gamma_K - 1$ and $\gamma_{\varepsilon'}$, are obtained from Rosseinsky's equations (12). The confidence intervals at the 0.95 level are calculated by Tchevicheff inequalities.[2]

Thermodynamic and kinetic acidities of *N*-(substituted benzyl) 4-phenylacetylpyridinium cations in aqueous solution

JOHN W. BUNTING AND P. PHILIPPE AUBIN[1]

Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

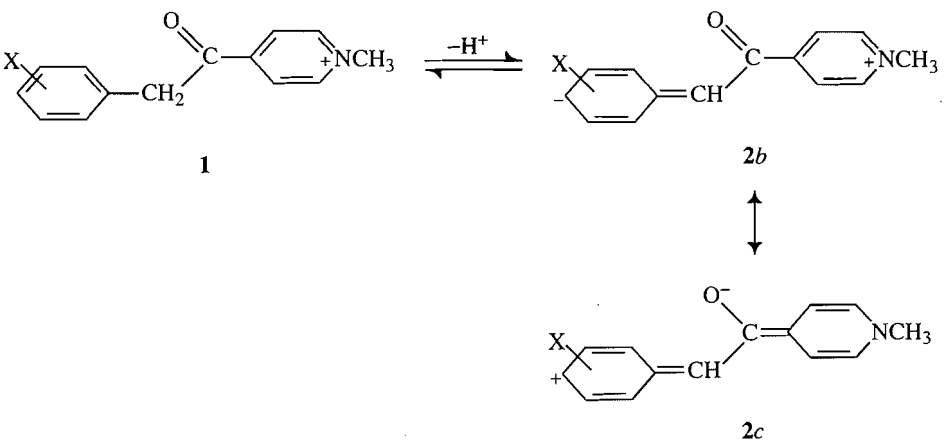
Received December 20, 1990

JOHN W. BUNTING and P. PHILIPPE AUBIN. Can. J. Chem. **69**, 945 (1991).

The pK_a values for the deprotonation of a series of eight 1-(X-benzyl)-4-phenylacetylpyridinium cations (**6**) have been measured in aqueous solutions of ionic strength 0.1 at 25°C: pK_a = $-0.18\sigma + 8.91$. The pseudo-first-order rate constants for deprotonation of these carbon acids have been measured over the range pH = 11–13, and have been found to display kinetic saturation effects that are consistent with the addition of hydroxide ion to the carbonyl group (pK_z) as the product of kinetic control upon basification of neutral aqueous solutions of these pyridinium cations, with the subsequent transformation of this anionic hydrate to the thermodynamically more stable enolate conjugate base. Analysis of the pH–rate profiles gives substituent effects upon pK_z ($\rho = -0.19$) and upon the second-order rate constant (k_{OH} ($\rho = 0.09$)) for deprotonation of **6** by hydroxide ion.

Key words: carbon acids, deprotonation, pK_a, kinetics, substituent effects.

JOHN W. BUNTING et P. PHILIPPE AUBIN. Can. J. Chem. **69**, 945 (1991).



Opérant en solutions aqueuses de force ionique 0,1, à 25°C, on a mesuré les valeurs de pK_a pour la déprotonation d'une série de huit cations 1-(X-benzyl)-4-phénylacétylpyridinium (**6**): pK_a = $-0{,}18\sigma + 8{,}91$. On a aussi mesuré les constantes de vitesse de pseudo-premier ordre pour la déprotonation de ces acides carbonés à des pH allant de 11 à 13 et on a observé qu'elles présentent des effets de saturation cinétique qui sont en accord avec l'addition d'un ion hydroxyde sur le groupe carbonyle (pK_z) conduisant au produit de contrôle cinétique lors de la basification de solutions aqueuses neutres de ces cations pyridinium avec une transformation subséquents de cet hydrate anionique vers l'énolate conjugué, thermodynamiquement plus stable. Une analyse des profiles du pH vs. vitesse permet de déterminer les effets de substituant sur pK_z ($\rho = -0{,}19$) et sur la constante de vitesse de réaction du deuxième ordre (k_{OH} ($\rho = 0{,}09$)) pour la déprotonation des acides **6** par l'ion hydroxyde.

Mots clés : acides carbonés, déprotonation, pK_a, cinétique, effets de substituant.

[Traduit par la rédaction]

The isomeric ketones **1** (pK_a = 9.02 for X = H (1)) and **3** (pK_a = 7.66 for X = H (2)) readily undergo deprotonation in aqueous solution to form their enolate conjugate bases (**2** and **4**, respectively). In previous studies, we explored the influence of substituents in the phenyl ring of each of **1** and **3** upon both the thermodynamic and kinetic acidities of these ketones, and derived Brønsted slopes for these reactions (1–4). These investigations have been instrumental in the development of a useful empirical modification to the Marcus relationship as it is applied to the study of rate–equilibrium relationships for the deprotonation of carbon acids (1, 2, 4, 5).

The relatively high acidities of the ketones **1** and **3** can be traced to the resonance stabilization provided by the contributors **2***a*–**2***c* and **4***a*–**4***c*, respectively, to the electronic structures

of the enolate conjugate bases. Each of **2** (λ_{max} = 446 nm for X = H (1)) and **4** (λ_{max} = 405 nm for X = H (2)) displays a long wavelength electronic absorption maximum that is consistent with a highly delocalized electronic structure. The importance of such resonance contributors is also apparent from the influence of substituents upon the acidities of these ketones. We have reported substituent effects for ring substituents (X) upon the pK_a values of both **1** (ρ = 1.29 (1)) and **3** (ρ = 1.38 (2)), and have also probed the importance of **4***b* and **4***c* through substituent effects upon the pK_a values of the *N*-(substituted benzyl) pyridinium cations, **5**, for which ρ = 0.47 was obtained (2).

5

We did not previously explore substituent effects upon the *N*-(substituted benzyl) 4-phenylacetylpyridinium cations (**6**), and the thermodynamic and kinetic acidities of this latter series of ketones are the subjects of the current work.

6

Experimental

Materials

4-Phenylacetylpyridine was available from an earlier study (1). The bromide salt of each *N*-(X-benzyl) 4-phenylacetylpyridinium cation (**6**·Br^-) was prepared by refluxing 4-phenylacetylpyridine with a slight excess of the appropriate X-substituted benzyl bromide in ethanolic solution overnight. Removal of the solvent on the rotary evaporator gave an oil that solidified upon stirring with anhydrous diethyl ether. The crude product was recrystallized from hexanol and characterized by ^{1}H NMR spectroscopy in trifluoroacetic acid solution.

pK_a *values*

All pK_a values were measured spectrophotometrically at 445 nm as described previously (1), in buffered aqueous solutions at ionic strength 0.1 and 25°C.

Kinetic studies

All rate data were obtained by mixing an aqueous solution of each **6**·Br^- with aqueous potassium hydroxide solutions of ionic strength 0.2 (KOH + KCl) in the Durrum–Gibson stopped-flow spectrophotometer at 25°C to give a final ionic strength of 0.1. The formation of the enolate conjugage base was monitored via the time dependence of the absorbance at 445 nm. All data collection and numerical analyses were performed as described in earlier work from this laboratory (1).

Results

In aqueous solutions, the cationic ketones, **6**, display pH-dependent electronic absorption spectra, which are very similar to those previously described (1) for the corresponding *N*-methyl cations (**1**). For all **6**, enolate formation in aqueous base is accompanied by the development of an absorbance maximum near 445 nm; this maximum is essentially independent of the X-substituent in the *N*-benzyl unit. The pH dependence of the absorbance at constant wavelength in the vicinity of this maximum accurately describes an acid titration. The pK_a values listed in Table 1 were obtained for a series of eight X-substituted **6** at 25°C.

The rates of formation of the conjugate base species from **6** are readily measured when neutral aqueous solutions of **6** are mixed with aqueous KOH/KCl solutions in the stopped-flow spectrophotometer. These reactions proved to be cleanly first order in [**6**], and the pseudo-first-order rate constants (k_{obs}) were evaluated over the range pH = 11–13 at ionic strength 0.1 and 25°C. Typical pH dependences for k_{obs} for the deprotonation of **6** are shown in Fig. 1. These pH–rate profiles display a similar kinetic saturation effect to that previously found (1) for the *N*-methyl cations, **1**. Scheme 1, in which **1** (or **6**) is represented as the carbon acid (CH), was shown to be consistent with this kinetic saturation phenomenon.

This scheme requires that a species Z, identified as the hydroxide adduct of the carbonyl group (*gem* diol anion), **7**, be the

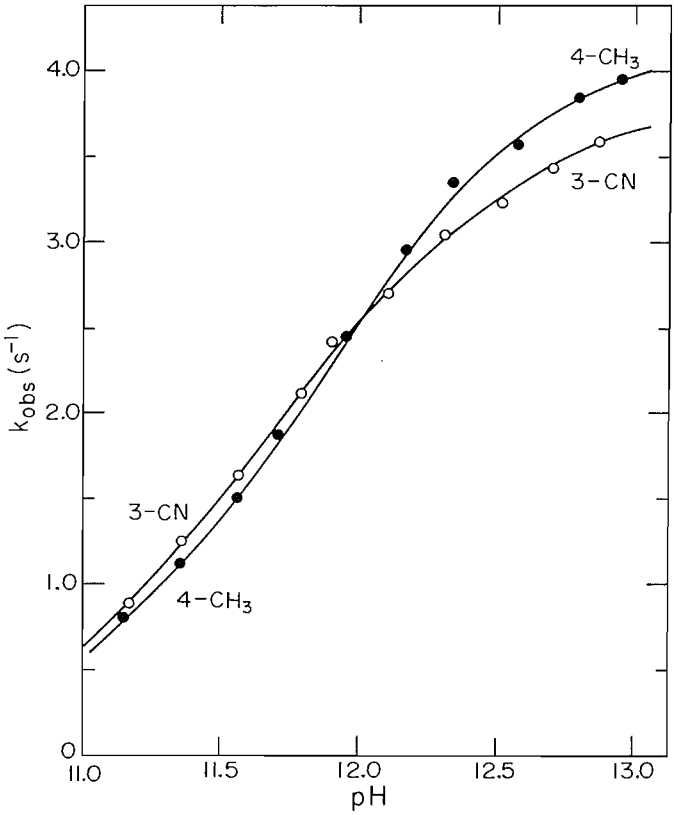

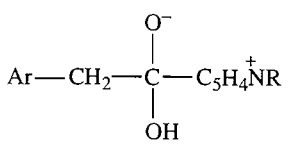

FIG. 1. The pH dependence of the pseudo-first-order rate constant (k_{obs}) for deprotonation of **6**:X = 4-CH_3 and **6**:X = 3-CN in aqueous solutions of ionic strength 0.1 at 25°C. Curves are calculated using eq. [1] and the appropriate parameters from Table 1.

kinetically controlled product upon mixing a neutral aqueous solution of **1** (or **6**) with aqueous base. Formation of **7** is complete within the mixing time of the stopped-flow instrument, and this species then subsequently isomerizes into the enolate conjugate base of **1**, which is the product of thermodynamic control in these reactions.

7

$$H^+ + Z^- \underset{}{\overset{K_Z}{\rightleftharpoons}} CH \overset{k_{OH}[^-OH]}{\rightleftharpoons} C^- + H_2O$$

SCHEME 1

Kinetic analysis of Scheme 1 leads to eq. [1], and the parameters, k_{OH} and pK_z, can be obtained upon fitting eq. [1] to the pH profiles of Fig. 1. Values for these two parameters, which were obtained via such an analysis for each of the cations **6**, are included in Table 1.

[1] $k_{obs} = k_{OH}[^-OH]/(1 + K_z[^-OH]/K_w)$

Discussion

The thermodynamic acidities of the *N*-benzyl ketones (**6**) indicate that they are slightly more acidic than the corresponding *N*-methyl ketone (**1**:X = H) (Table 1). A slightly greater, but still modest, increase in acidity from the *N*-methyl to the *N*-benzyl derivative was observed for **3** (X = H) and its *N*-benzyl analog (Table 2). There is a somewhat larger increase in acidity associated with *N*-benzyl substitution in comparisons of methylammonium and benzylammonium cations (Table 2).

Substituent effects upon the thermodynamic acidities of **6** in Table 1 are defined by the Hammett correlation:

[2] $pK_a = -0.18(\pm0.02)\,\sigma + 8.81(\pm0.01)$

The Hammett $\rho = 0.18$ in eq. [2] is considerably smaller than that found for any of the other cationic acids in Table 2. If one uses $\rho = 1.14$ for the tertiary benzyldimethylammonium cations as a reference, then $\rho = 0.18$ from eq. [2] indicates only a small fractional decrease in the effective charge upon the cationic nitrogen atom in **6** upon enolate formation. This result suggests a limited contribution from resonance contributors such as the *N*-benzyl analog of **2***c* to the electronic structure of the conjugate base, although the electronic absorption spectrum (λ_{max} = 445 nm) of this species is only readily rationalized in valence bond terms via a contribution from **2***c* to the electronic structure of the resonance stablized enolate species. The ρ values of Table 2 certainly indicate that **2***c* is far less important as a contributor to the electronic structure of the enolate conjugate base of 4-phenylacetylpyridinium cations than are **4***b* and **4***c* to the enolate conjugate base of the 4-phenacylpyridinium cations.

The pH–rate profiles of Fig. 1 for the deprotonation of **6** are identical to those analyzed previously (1) in terms of Scheme 1 for the corresponding *N*-methyl cation (**1**:X = H). Although the *N*-benzyl cations (**6**) are slightly stronger acids than their *N*-methyl analog (**1**:X = H), the kinetic acidity of **6**:X = H (as k_{OH}) is slightly lower than that of the *N*-methyl derivative (Table 1). Although the weak substituent dependence of k_{OH} leads to some experimental scatter in the data in Table 1, the general overall trend of parallel increases in the kinetic and thermodynamic acidities for substituted **6** in Table 1 seems to be well established. The substituent dependences on the kinetic parameters in Table 1 are described by the Hammett correlations of eqs. [3] and [4] and the Brønsted relationship of eq. [5].

[3] $\log k_{OH} = 0.09(\pm0.03)\,\sigma + 2.84(\pm0.01)$

[4] $pK_z = -0.19(\pm0.02)\,\sigma + 11.77(\pm0.01)$

[5] $\log k_{OH} = -0.48(\pm0.13)\,pK_a + 7.14(\pm1.16)$

The experimental uncertainty in the small ρ value in eq. [3] translates into an appreciable uncertainty in the Brønsted α value of eq. [5]. Within the limits imposed by this uncertainty, it

[c]Data from ref. 1.

seems that the Brønsted $\alpha = 0.48$ for **6** is quite similar to the previously reported (2) $\alpha = 0.45$ for substituent effects upon the deprotonation of **3**. The X-substituents in **3** and **6** both probe the electron density delocalization through the carbonyl group into an aromatic ring in the rate-determining transition state species for hydroxide ion catalyzed deprotonation. The similarity in the α values for **3** and **6** indicates that rate–equilibrium comparisons of substituent effects are independent of whether this carbonyl substituent is a phenyl ring or a pyridinium ring.

This result constrasts with the previously reported α values for **1** and **5** (Table 3) in which the substituent effects in the pendant ring on the enolate α-carbon atom indicate a dramatic discrepancy in Brønsted α values for substitution in a phenyl and in a pyridinium ring, and represent a dramatic difference in substituent effects upon the stabilization of the transition state and product species in these two closely related systems. The imbalanced transition state electronic effects that we noted previously (2) from the different α values for **3** and **5** have a direct analogy in the different α values that are now also apparent for **1** and **6** (Table 3).

Probably the most unexpected feature of the current experimental data lies in the similarity of the Hammett ρ values in eqs. [2] and [4]. We had originally assumed that pK_z would be similar for the *N*-methyl and *N*-benzyl derivatives, and essentially independent of the X-substituents in **6**. Since there is no apparent resonance interaction between the carbonyl group and the cationic nitrogen atom of the pyridinium ring of **6**, substituent effects in the *N*-benzyl unit of **6** appear to be quite remote from the carbonyl group that undergoes nucleophilic addition to give the hydrated anionic species in **7**. The only simple explanation for $\rho = 0.19$ for pK_z appears to be in terms of a variation of the effective charge on the cationic nitrogen atom with the X-substituent in the benzylic group, and the transmission of this charge variation to the carbonyl group via bond polarization effects.

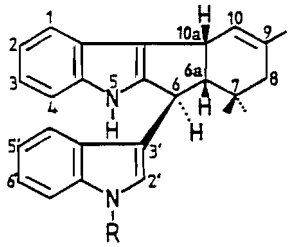
A detailed study directed toward the development of a versatile synthetic route to the interesting dimeric natural product yuehchukene (**1**) and its epimer, 6a-*epi*-yuehchukene (**2**), has been completed. Due to the anti-implantation activity associated with **1**, it was important to provide a synthetic strategy not only to **1**, but to a family of yuehchukene analogues that, hopefully, would reveal superior chemical stability and (or) elevated biological activity. The experiments described herein and which utilize the readily available and inexpensive isophorone (**6**) satisfy these requirements.

Key words: yuehchukene synthesis, yuehchukene analogues, anti-implantation activity.

JAMES P. KUTNEY, FRANCISCO J. LOPEZ, SHYH-PYNG HUANG, HIROSHI KUROBE, ROBERT FLOGAUS, KRYSTYNA PIOTROWSKA et STEVEN J. RETTIG. Can. J. Chem. **69**, 949 (1991).

On a réalisé une étude détaillée entreprise dans le but de développer une voie de synthèse versatile du yuehchukène (**1**) et de son épimère, le 6a-*épi*-yuehchukène (**2**), des produits naturels dimères intéressants. Compte tenu de l'activité anti-implantation associée au composé **1**, il était important de proposer une stratégie de synthèse qui ne conduirait pas seulement à **1**, mais à une famille d'analogues du yuehchukène qui pourraient éventuellement posséder une stabilité chimique supérieure et (ou) une activité biologique plus grande. Les expériences décrites dans ce travail, qui utilisent l'isophorone (**6**) (un produit facilement disponible et peu coûteux) comme produit de départ, satisfont à ces critères.



Mots clés : synthèse du yuehchukène, analogue du yuehchukène, activité anti-implantation.

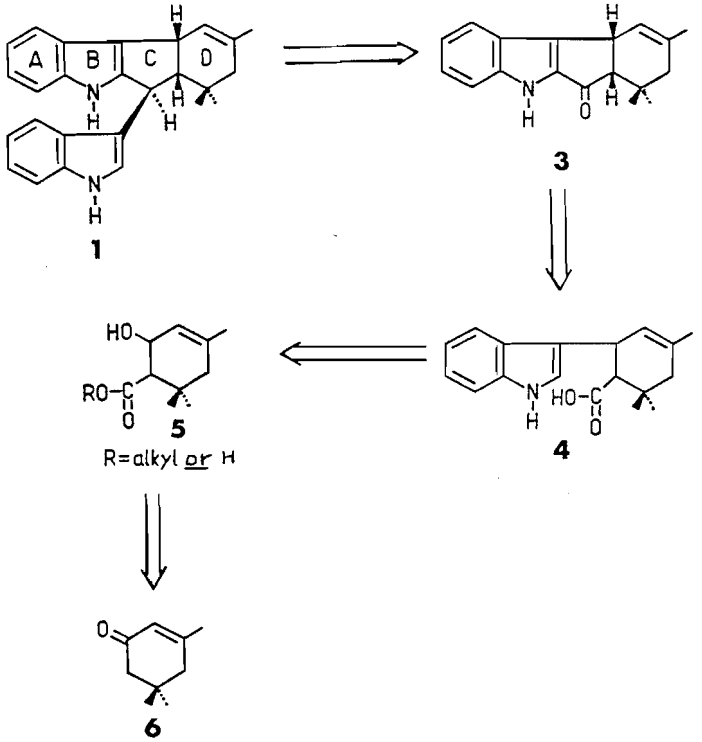
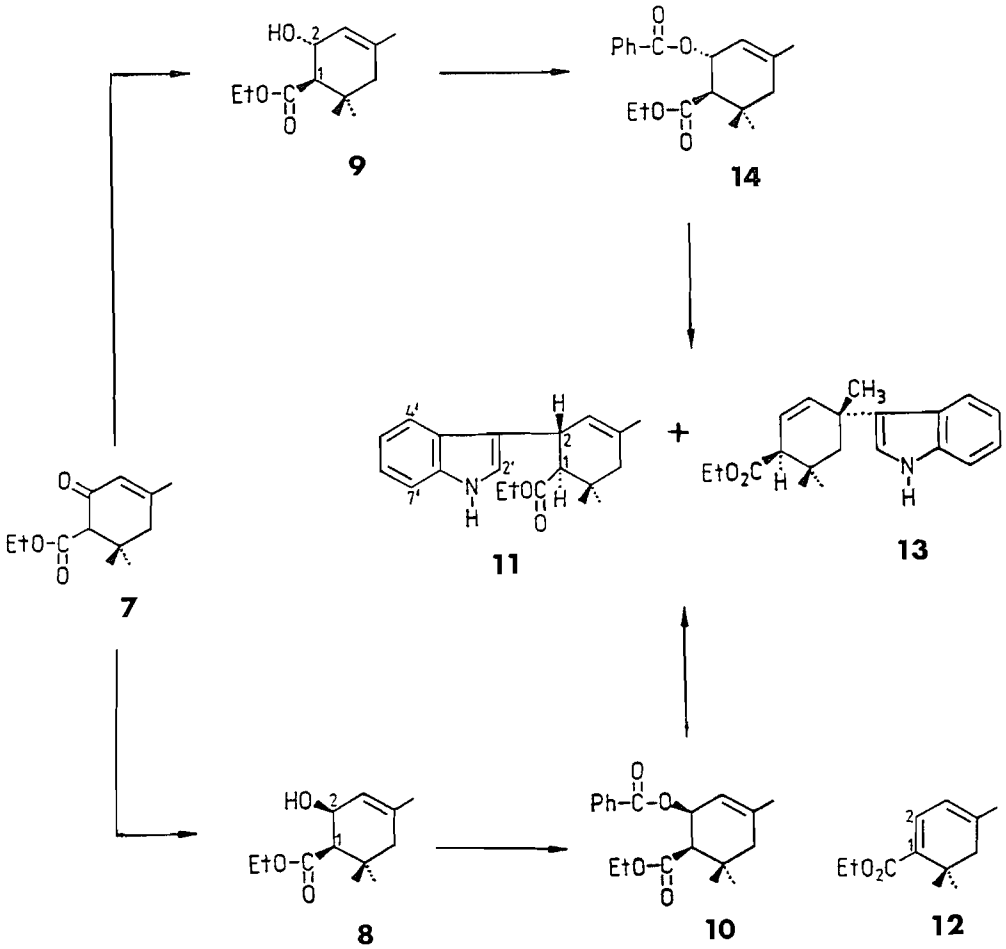
The genus *Murraya*, of the plant family *Rutacaea*, occurs throughout tropical and sub-tropical east Asia, from China and India in the north through to New Caledonia and northeastern Australia in the south. Chemically, *Murraya* species are characterized by the occurrence of carbazole, furoquinoline, and acridone alkaloids (1–4), coumarins (5, 6), and flavanoids (7). Yuehchukene (**1**), a novel type of dimeric indole natural product, was recently isolated in racemic form, in trace quantities (<18 ppm), from the roots of *M. paniculata* (8). Its name derives from the word yueh-chu, which is the name of the plant in Chinese.

Owing to the low yield of **1**, a survey of other *Murraya* species was carried out (2, 9) but the problem of low yield persisted.



1

2



The most interesting feature about yuehchukene is its biological activity. Crude extracts of *M. paniculata* have been used in China as an astringent and antidysenteric (10–12). They also showed strong cardiac depressant and antispasmodic activity (13) but the most interesting results came from the studies of Kong *et al.* (8, 11, 14, 15), which revealed that **1** possessed strong anti-implantation activity in rats. To fully exploit the pharmacological potential of this molecular system, it was considered appropriate to develop a versatile stereoselective synthetic route that, in addition to **1**, would also allow preparation of closely related analogues. The present study describes results that satisfy these objectives. A preliminary account of a portion of this study has appeared (16).

SCHEME 1. Retrosynthetic analysis for the synthesis of yuehchukene (**1**) and its analogues.

A retrosynthetic analysis was planned according to Scheme 1. The assembly of the target molecule was strategically envisaged so as to facilitate the required variations for the preparation of

[1]Author to whom correspondence may be addressed.

SCHEME 2. Conversion of keto-ester **7** to indole intermediates **11** and **13**.

desired analogues. Thus, for instance, the indole groups could be differently substituted or, even more interestingly, the protons at C-6a and C-10a in ketone **3** could have an *anti* relationship to produce a *trans* junction of rings C and D, thus providing the isomer, 6a-*epi*-yuehchukene (**2**). This strategy also has the advantage of starting from commercially inexpensive isophorone (**6**).

The initial studies were performed with the known keto-ester (**7**), available via condensation of mesityl oxide and ethyl acetoacetate (17), since it was envisaged (see later) that **7** could be subsequently available from **6** (Scheme 2). The keto-ester **7** was reduced with sodium borohydride in methanol to give *cis*-hydroxyester **8** in 71% yield and the epimeric alcohol **9** in 23% yield. The stereochemistry at C-1 and C-2 in these isomers was readily available from the ^{1}H NMR spectra (see Experimental).

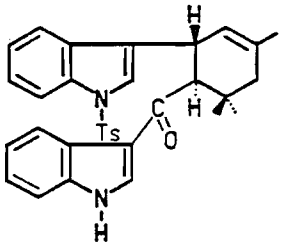
The next transformation required an activation of the hydroxyl group of **8** to facilitate its displacement by the indole moiety (see Scheme 1). Treatment of hydroxyester **8** with *p*-toluenesulfonyl chloride in the presence of various bases (DMAP, pyridine, Et_3N) gave the undesired product **12** as a result of overall elimination of water. Fortunately, the desired activation of the hydroxyl group could be achieved by treatment of **8** with benzoyl chloride and DMAP (18) in dichloromethane at 5°C to obtain the allylic benzoate **10** as an oil (85% yield).

Having in hand **10**, the nucleophilic substitution of the benzoate group was attempted by utilizing indolylmagnesium iodide in ether at 5°C. The desired indole-ester **11** was obtained in 42% yield along with the isomer **13** (31%).

The indole-ester **11** revealed particularly informative spectra and its structure was readily available from spectral analysis. The IR spectrum shows the characteristic sharp absorption band of N-H at 3480 cm^{-1} and the intense band of the carbonyl group at 1730 cm^{-1}. The mass spectrum reveals the molecular ion and the base peak at m/z 311. Finally, the ^{1}H NMR spectrum shows the proton at C-1 at 2.67 ppm as a doublet with a J value of 12 Hz due to the coupling with the proton at C-2, which in turn appears at 3.90 ppm as a multiplet. Irradiation of the latter signal simplified the doublet at 2.67 ppm to a singlet. Owing to the large coupling constant between these two protons (12 Hz), the *trans* stereochemistry was assigned. The proton at C-2′ appears at 6.99 ppm as a doublet with a J value of 3.2 Hz due to the coupling with the N-H proton, which appears at 7.92 ppm as a broad signal. The coupling was again corroborated by double resonance experiments. The signals of the other aromatic protons are sufficiently resolved so that assignments could also be made (see Experimental).

The product **13** was characterized mainly by ^{1}H NMR spectroscopy. Its IR spectrum shows the bands corresponding to N-H and C=O at 3480 and 1730 cm^{-1}. The ^{1}H NMR spectrum displays the vinylic protons as two pairs of doublet of doublets at 5.79 (J = 10 and 4 Hz) and 6.05 ppm (J = 10 and 2 Hz) being both coupled with the proton at C-1, which appears at 2.95 ppm as a doublet of doublets (J = 4 and 2 Hz). These assignments were corroborated by double resonance experiments. The stereochemistry shown in **13** was assigned later by correlation with another intermediate, the indole-acid **32** (Scheme 4) discussed later.

Following similar transformations to those described above,



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

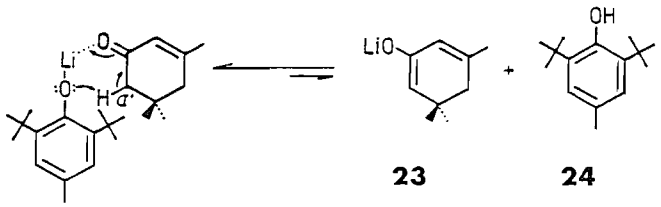
the minor *trans*-hydroxyester **9** (Scheme 2) was transformed to *trans*-benzoate **14** and, in turn, to the compounds **11** and **13** with practically the same yields and same ratio of **11**/**13** as obtained with **8** as starting material. Therefore, it seems that a carbocation intermediate or a similar species is involved in the overall conversion of **10** and **14** to the final products. An alternative rationale could involve **12** as an intermediate followed by 1,4- and 1,6-conjugate addition of the Grignard reagent.

The next step required the hydrolysis of **11** to the corresponding acid in accord with the retrosynthetic analysis (see **4**, Scheme 1). Unfortunately, treatment of **11** with either aqueous sodium hydroxide in refluxing ethanol or trimethylsilyl iodide in refluxing acetonitrile (19) did not afford the desired product; the starting material was recovered unchanged and direct cyclization of **11** to **3** also failed.

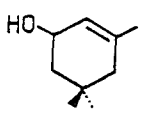
An alternative route to the yuehchukene system from ester **11** could involve initial attachment of the other indole unit and then subsequent cyclization. For this purpose, **11** was converted to its *N*-tosyl derivative and the latter was reacted with indolylmagnesium iodide in an effort to obtain the ketone **15** but only unreacted **11** was recovered even though similar reaction of **11** with *n*-butyllithium did afford the expected product **16**.

15



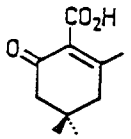
16

In view of the above, reconsideration of the synthetic strategy in terms of the corresponding acid **5** (Scheme 1) was made. The hydroxyester **8** could be hydrolyzed to the corresponding acid **18** (NaOH, room temperature, 5 days, 75% yield) but the low yield (16%) in the original preparation of **7** according to the literature procedure (17) demanded a superior synthetic route to **17**. A solution to this objective is now provided (Scheme 3).



The readily available and inexpensive isophorone (**6**), when treated with lithium 2,6-di-*tert*-butyl-4-methylphenoxide and carbon dioxide gas in diethyl ether at room temperature (20), gave keto-acid **17**. This product turned out to be too unstable for isolation after the acidic work-up of the reaction mixture, so reduction with sodium borohydride was performed *in situ* on the salt **19** to give, upon acidification, *cis*-hydroxy acid **18** in 46% overall yield. Small quantities (about 5%) of the corresponding *trans*-hydroxy acid **21** were also obtained. Since the remainder was recovered isophorone **6**, the effective yield in the overall conversion from **6** to **18** was 90%.

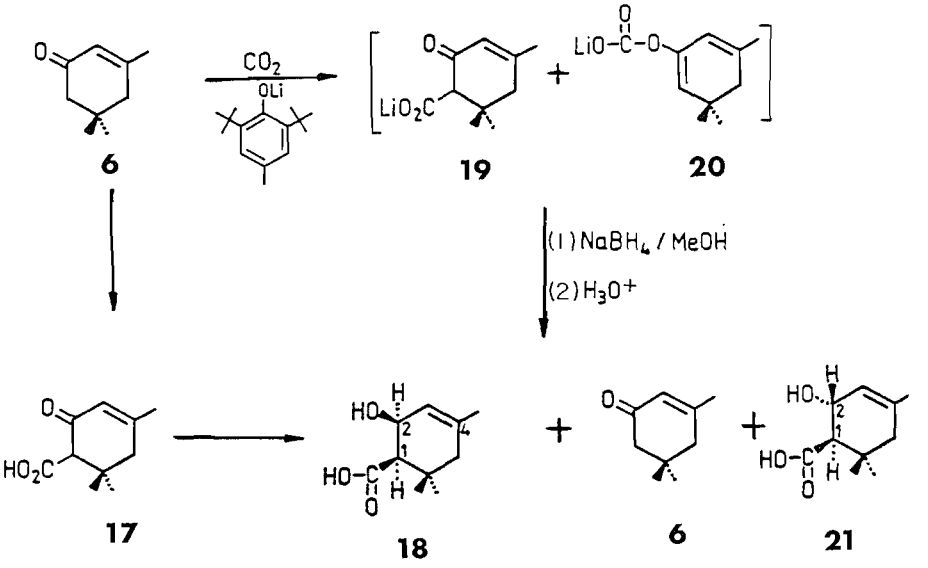
Several aspects of this transformation are worthy of comment. First of all, this appears to be the first case of a kinetic carboxylation of an α,β-unsaturated ketone under these mild conditions, although carboxylation of simple ketones with these reagents has been reported (20). Perhaps the reason that such a mild base (pK_a of conjugated acid = 12.3) (21) was capable of abstracting the α′ proton ($pK_a \simeq 20$) (**22** → **23** + **24**) is, in part, due to the complex-induced proximity effect (CIPE) (22), which refers to the chelation of the metal (lithium, in this case) to the carbonyl oxygen making the α′ proton more acidic and, at the same time, placing the base closer to the same proton. The reason for using such a bulky base was to prevent its carboxylation under the conditions of the reaction (20).



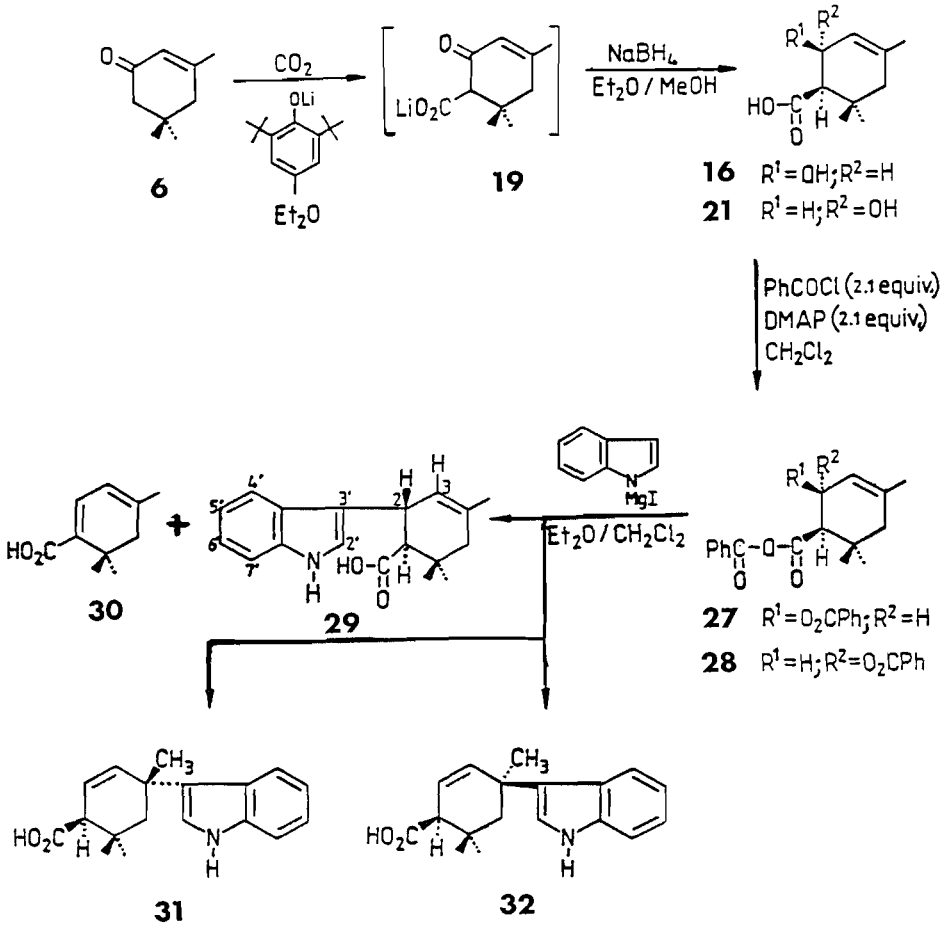
22 **23** **24**

The fact that isophorone (**6**), and *not* alcohol **25**, was recovered from the "one-pot" double transformation suggests that the carboxylation step was complete, thereby giving the products **19** and **20**. Sodium borohydride reacted only with **19** to give **18** while **20** decomposed back to **6** during the acidic work-up of the reaction mixture.

25



26



It should be noted that direct carboxylation with methylmagnesium carbonate[2] or bromomagnesium ureide – carbon dioxide adducts (24) affords mainly the undesired acid **26**.

The next step was the activation of the hydroxyl functionality in **18** in order to provide a good leaving group for subsequent nucleophilic displacement (Scheme 4). Thus, treatment of **18** with 2.1 equivalents of benzoyl chloride and DMAP in dichloromethane at 5°C furnished the unstable ester-anhydride **27**, which was obtained as a crude liquid and was not further purified. Treatment of **27** with indolylmagnesium iodide from 5 to 25°C gave rise to the long-desired indole-acid **29** (40% yield) as colorless crystals (mp 173–174°C). Careful purification of the crude mixture also gave by-products **30** (15%), **31** (26%), and **32** (3%). The structure and stereochemistry of **29** could be readily assigned from a detailed analysis of its spectroscopic properties. Apart from the mass spectrum, which provided the correct molecular ion (*m*/*z* 283), the ^{1}H NMR spectrum was particularly informative. The *gem*-dimethyl group protons appear as singlets at 1.08 and 1.14 ppm and the protons of the vinylic methyl group at 1.71 as a broad singlet. The AB system corresponding to the protons at C-5 appears at 1.76 and 2.15 ppm with a *J* value of 16 Hz. The hydrogen at C-2 appears at 3.93 ppm as a doublet with a *J* value of 10 Hz caused by the *trans* coupling with the proton at C-1, which appears at 2.71 ppm as a doublet. These assignments were corroborated by double resonance experiments. Thus, irradiation of the proton at C-2 causes the proton at C-1 to become a singlet, and irradiation of the proton at C-1 changes the signal of the proton at C-2 from doublet to singlet. The vinylic proton appears at 5.47 ppm as a broad singlet. The protons at C-2 and C-3 show only a small coupling to each other since a molecular model of **29** reveals that the dihedral angle between them is nearly 90°C. The proton at position 2′ of the indole moiety appears at 6.94 ppm as a doublet with a small *J* value of 2 Hz because of its coupling to the proton on the nitrogen atom (7.77 ppm), the latter also corroborated by decoupling experiments. The signals of the other aromatic protons were also identified. These assignments were based on nOe-difference and double resonance experiments. Irradiation at the N-H proton resonance enhances both the signal at 6.94

[2]J. P. Kutney and H. Kurobe. Unpublished results.

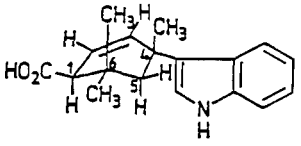
SCHEME 4. Overall sequence from isophorone (**6**) to indole intermediates **29**, **31**, and **32**.

ppm and the doublet at 7.33 ppm. Since the signal at 6.94 ppm had already been assigned to the aromatic proton at C-2′, the signal at 7.33 ppm must correspond to the proton at C-7′, and this was confirmed by a second nOe experiment. Irradiation at 5.47 ppm, which is the signal corresponding to the vinylic proton, increases the signals of only two aromatic protons: the signal at 6.94 ppm (proton at C-2′) and the doublet at 7.62 ppm. As can be seen from models, the only aromatic protons that are in proximity with the vinylic proton when the C-2—C-3′ bond is rotated are those at C-2′ and C-4′. Therefore, the doublet at 7.62 ppm was assigned to the proton at C-4′. The knowledge of the chemical shifts of the protons at C-4′ and C-7′ permitted the assignment of the signals of the protons at C-5′ and C-6′ by double resonance experiments. Thus, decoupling of the proton at C-4′ simplified only the signal at 7.08 ppm to a doublet. Therefore, the signal at 7.08 ppm (doublet of doublets, $J = 8,8$



Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12

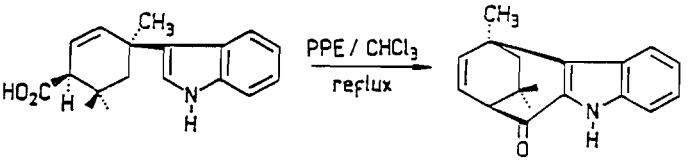
Hz, in the normal spectrum) corresponds to the proton at C-5′ and the signal at 7.17 ppm (doublet of doublets, J = 8,8 Hz) is assigned to the proton at C-6′.

The by-product diene **30**, obviously the result of base-catalyzed elimination, is readily characterized from its IR (3200–2800 and 1679 cm^{-1}) and typical homoannular diene UV absorption (λ_{max} 290 nm) spectra.

The isomeric nature of the interesting by-product indole-acids **31** and **32** was shown by the identical molecular ion peaks (m/z 283) in their mass spectra and their similarity in the ^1H NMR spectra. The stereochemistry of both compounds was determined on the basis of nOe-difference experiments. As a result of these experiments, the 3-dimensional structures of the main conformers of **31** and **32** are shown in **31A** and **32A**.

31A



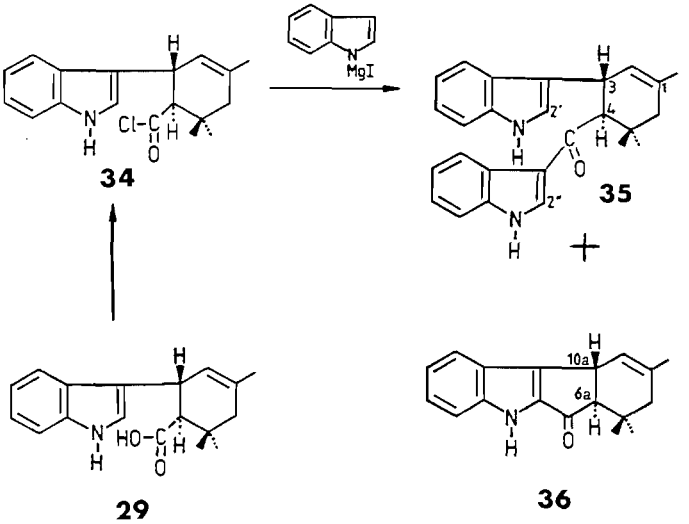
32A

The stereochemistry of **31** was determined as follows. Irradiation of the singlet due to the protons of the methyl group at C-4 (1.58 ppm) enhances the singlet due to the β-methyl group at C-6 (1.10 ppm) and the signals due to the vinylic proton at C-3 (6.06 ppm) and the β-proton at C-5 (1.99 ppm). Irradiation of the signal due to the other methyl group at C-6, namely, the α-methyl (0.95 ppm), enhances the signal of the axial proton at C-1 and both doublets due to the protons at C-5 (1.99 and 2.25 ppm). Finally, irradiation of the signal due to the proton at C-1 enhances the signal corresponding to the protons of the α-methyl at C-6 (but not the signal due to the β-methyl), the doublet of the α-proton at C-5 (2.25 ppm), and the signal of the vinylic proton at C-2. Therefore, these results indicate that the methyl group at C-4 has an *anti* relationship to the proton at C-1 in **31**. The stereochemistry of **32**, which could also be determined from the same results, was confirmed by the following experiments. Irradiation at 0.60 ppm, which is the signal due to one of the methyl groups at C-6, enhances both the doublet of the proton at C-2′ (6.92 ppm) and the doublet of the β-proton at C-5 (2.52 ppm). Therefore, the singlet at 0.60 ppm was assigned to the β-methyl group. Irradiation of the signal due to the other methyl group (1.13 ppm) namely, the α-methyl at C-6, enhances the signal of the axial proton at C-1 (3.02 ppm) and both doublets due to the protons at C-5 (1.73 and 2.52 ppm). Finally, irradiation of the signal of the proton at C-1 enhances both the singlet due to the α-methyl group at C-6 and the doublet due to the α-proton at C-5 (1.73 ppm). Therefore, the structure of **32** was confirmed to be as shown in **32A**.

The indole-acid **31** was transformed into the ester **13** discussed earlier (Scheme 2) under the neutral conditions of ethanol, triphenylphosphine, and diethylazodicarboxylate (25). The above NMR data were therefore also utilized to assign the structure and stereochemistry to ester **13**.

Additional quantities of the crucial intermediate **29** could be obtained when the *trans* benzoate **28**, obtained from esterification of the hydroxy acid **21** (Scheme 4), was treated with indolylmagnesium iodide. The reaction mixture with the same product ratio as obtained with the *cis* isomer **27** was obtained. This result again suggests a carbocationic intermediate is involved in the conversion to **29**, **31**, and **32**. Thus for preparative purposes, the mixture of alcohols **18** and **21** is directly converted to **27** and **28** and the latter, without isolation, is treated with the Grignard reagent to afford **29**, **31**, and **32**.

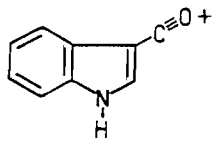
With indole-acid **29** on hand, the strategy outlined in Scheme 1 (**4** → **3**) was again considered. Intramolecular cyclization of **29** with either polyphosphoric acid (26) or polyphosphoric ester (PPE) (27) met with failure even though the indole-acid **32** underwent facile cyclization with PPE in chloroform to afford ketone **33** in 55% yield. The structure proof of **33** is presented later in this discussion.



32 **33**

Conversion of **29** into the corresponding acid chloride **34** and attempts to achieve an intramolecular Friedel–Crafts acylation under conditions ($ZnCl_2$, nitrobenzene) reported for acylation at position 2 of 3-substituted indoles (28) also failed.

On the other hand, reaction of **34** with indolylmagnesium iodide under careful conditions (initially at −50°C and then at −5°C) afforded the expected product **35** (18% yield) and, somewhat surprisingly, the previously desired ketone **36** (25% yield) (Scheme 5).



The most pertinent features in the mass spectrum of **35** are the molecular ion (m/z 382) and the base peak at m/z 144 corresponding to the fragment ion **a**. The ^1H NMR spectrum displays at 3.54 ppm the proton at C-4 as a doublet with a J value of 10 Hz, revealing a *trans* stereochemical relationship with the proton at C-3, which appears as a multiplet at 4.14 ppm. Also, integration of the aromatic proton region shows the presence of two indole systems with the proton at C-2′ appearing at 6.85 ppm as a doublet (J = 2 Hz) and the N-H protons at 7.59 and 7.98 ppm as broad signals. The proton at C-2″ appears downfield of 7.0 ppm due to the presence of the carbonyl group at the position 3″.

The IR spectrum of the crystalline ketone **36** (mp 129–131°C) shows the N-H absorption at 3464 cm^{-1} and the conjugated carbonyl group at 1683 cm^{-1}. The mass spectrum displays the molecular ion at m/z 265 and the base peak at m/z 250 due to the easy loss of a methyl radical. The ^1H NMR spectrum shows the N-H proton at 8.73 ppm and, most importantly, no aromatic

34 **35** **29** **36**

SCHEME 5. Conversion of indole-acid **29** to the ketones **35** and **36**

a

signals upfield of 7.0 ppm, thereby confirming the absence of the aromatic proton at C-2′ in the heterocyclic ring. Finally, the *trans* relationship between the protons at carbons 6a and 10a was assigned by X-ray diffraction analysis of the molecule. The results are presented in Fig. 1.

Efforts to increase the yield of **36** are summarized in Table 1. Careful monitoring revealed that the reaction only occurs at a temperature of −15°C or higher, giving both products in about the same ratio (expts. 1 and 2). When acid chloride **34** was added into indolylmagnesium iodide (expts. 1–4) there was a tendency to give a higher ratio of products **35**/**36** as the equivalents of the Grignard reagent were increased. On the other hand, when the addition was reversed (expts. 5–7), the yield of ketone **36** could be improved as the length of time for the addition of indolylmagnesium iodide was increased from 3 to 8 h. Therefore, it appears from these results that the abstraction of a proton from the nitrogen atom is faster than the addition of indolylmagnesium iodide to the carbonyl group, but the intramolecular cyclization is slow. When there is an excess of the Grignard reagent, compound **35** is predominantly formed (expt. 3). On the other hand, the ratio **36**/**35** is maximum when acid chloride **34** is maintained in excess (expts. 6 and 7).

Since ketone **36** was apparently formed by the behaviour of indolylmagnesium iodide acting as a base, attempts were made to increase even further the yield of **36** by utilizing a hindered base (LDA). Table 2 shows the results. Addition of 1.2 equivalents of LDA at −15°C gave only 15% of ketone **36** along with recovered indole-acid **29** (expt. 1). Increasing both the amount of LDA (to 2.5 equivalents) and the length of time for its addition (to 7 h, expt. 3) raised the yield by a factor of 2, although this was still low. On the other hand, increasing the temperature to 20°C did not give any **36** but rather the next expected intermediate, *cis*-ketone **37** (Scheme 6). Since the yield of both **37** and **29** was almost the same as the yield of **36** and **29** when the conditions of the reaction were the same (except for the temperature) (expts. 3 and 4), it seems that no further cyclization took place on warming but only the epimerization of **36** occurred. Furthermore, in a separate experiment, *trans*-ketone **36** was epimerized to *cis*-ketone **37** (85% yield) in the presence of LDA (−15 to 20°C) (Scheme 6).

The spectroscopic characteristics of crystalline *cis*-ketone **37** are, as expected, quite similar (but not identical) to those of *trans*-ketone **36**. Perhaps most noteworthy is that the coupling constant between the protons at carbons 6a and 10a in the ^{1}H NMR spectra of both compounds is the same (6 Hz). The most pronounced difference is their melting points: 129–131°C for **36** and 220–223°C for **37**.

In attempting to optimize the yield of the epimerization reaction, it was found that sodium methoxide in refluxing THF–MeOH gives the thermodynamically more stable *cis*-ketone **37** in quantitative yield.

In summary, the indole-acid **29**, via the routes outlined in Schemes 5 and 6, affords a potentially attractive entry into *both* the natural yuehchukene (**1**) and unnatural 6a-*epi*-yuehchukene (**2**) series.

The overall strategy (**3** → **1**, Scheme 1) in attaching the second indole unit onto the carbonyl function of the *trans*-

ketone **36** and, thereby, an entry into the natural series was now considered. The successful route to **1** is outlined in Scheme 7.

Mild hydride reduction ($NaBH_4$/MeOH) was unsuccessful in the conversion **37** → **38** but, fortunately, the more reactive reagent $LiAlH_4$ did reduce the ketone functionality to give alcohol **38** as the main product (65% yield), along with the epimeric alcohol **39** as a minor component (35%). Lithium tri-*sec*-butylborohydride (L-Selectride) (29) gave, as expected, only alcohol **38** but, unfortunately, in lower yield (50%).

The ^{1}H NMR spectrum of **38** displays, at 5.06 ppm, the signal of the hydrogen at C-6 as a broad signal, which becomes a distinct doublet (J = 6 Hz) only after exchange of the O-H proton with D_2O. This latter result shows that the proton at C-6 is coupled with both the O-H proton and the proton at C-6a. The O-H proton appears at 2.6–2.7 ppm and overlaps with the signals of the vinylic methyl group and one of the protons at C-8. On the other hand, the ^{1}H NMR spectrum of **39** shows the signal

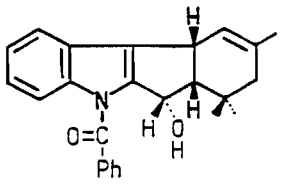
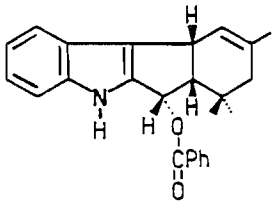
SCHEME 7. The synthesis of yuehchukene (**1**) and related analogues from ketone **37**.

of the proton at C-6, at 5.12 ppm as a doublet (J = 6 Hz) due to coupling with only the proton at C-6a, thus revealing no coupling with the O-H proton.

The distinction between the two alcohols was established by nOe-difference experiments performed with alcohol **39**. Thus, irradiation at the signal of the proton at C-6 did not affect the signal of the proton at C-6a but did show an effect on the signals of the protons of the methyl groups at C-7 and one of the protons at C-8. The conformational structure of **39**, shown as **39A**, shows the proximity between protons at C-6 and C-8. Therefore

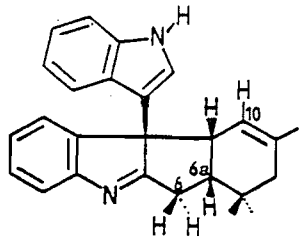


39A



the hydroxyl group in **39** bears a *cis* relationship to the proton at C-6a.

The next transformation involved a dibenzoylation of **38** using 4 equivalents of benzoyl chloride, 1.2 equivalents of DMAP, and 4 equivalents of triethylamine (18) in dichloromethane, to give rise to compound **40** as white crystals (76% yield). Its structure and stereochemistry were readily ascertained from the informative spectroscopic data (see Experimental). Addition of only one equivalent of benzoyl chloride to alcohol **38** gave rise to the chemoselective formation of compound **41** (and not **42**).



To complete the synthetic route, nucleophilic displacement of the benzoate group in **40** was appropriate. Reaction of **40** with indolylmagnesium iodide in ether–dichloromethane solution at 5°C afforded the expected benzoylyuehchukene (**43**) as a white foam (40% yield) but, in addition, two other isomeric compounds subsequently assigned the structures **44** (18% yield) and **45** (30% yield) (Scheme 7).

41

42

46

Benzoylyuehchukene (**43**) was characterized by IR, MS, and ^{1}H NMR spectroscopy. The IR spectrum reveals the N-H and carbonyl absorptions at 3480 and 1681 cm^{-1}, respectively. The mass spectrum shows the molecular ion at m/z 470 and the base peak at m/z 105 corresponding to the relatively stable cation PhC≡O$^+$. The ^{1}H NMR spectrum shows the proton at C-6 at 4.12 ppm as a doublet with a J value of 4 Hz. As expected, this chemical shift is at consideraly higher field than that of the starting benzoate **40** (6.39 ppm). The N-H proton appears at 7.73 ppm as a broad signal and the signal of the hydrogen at C-2′ of the heterocyclic ring of the newly incorporated indole appears at 6.15 ppm as a doublet with a J value of 2 Hz. This latter assignment was corroborated by decoupling the signal corresponding to the proton on the nitrogen atom, with the resulting collapse of the doublet at 6.15 ppm into a singlet. Finally, the structural assignment was firmly established when **43** was treated with sodium methoxide in methanol at 5°C to afford (±)-yuechchukene (**1**) in 90% yield. The synthetic material was identical with the racemic natural product isolated from the plant.

Compound **44**, formed by N-alkylation rather than C-alkylation, reveals in its IR spectrum the typical amide absorption at 1685 cm^{-1} and the mass spectrum displays the molecular ion at m/z 470, the base peak at 105, and an intense peak (relative intensity = 50%) at 354, not observed in **43** and due to the facile loss of indole from the molecular ion. The ^{1}H NMR spectrum shows the proton at C-6 at 5.53 ppm as a broad signal. The proton at C-2′ appears at 6.29 ppm as a doublet with a J value of 3.5 Hz. The result shows the coupling of the latter with the proton at C-3′, appearing at 6.48 ppm as a doublet with the same J value. Double resonance experiments confirm this assignment.

The stereochemistry at C-6 in **44** was assigned on the basis of nOe experiments. Thus, irradiation of the signal due to the proton at C-6a (2.85 ppm) shows enhancement of both the signal of the proton at C-10a (4.08 ppm) and the signal of the proton at C-2′ (6.29 ppm) but it does not affect the signal due to the proton at C-6 (5.53 ppm). Also, irradiation of the signal due to the proton at C-6 does not affect the proton at C-10a, but only the aromatic protons at C-2′ and possibly at C-7′. Therefore, the newly incorporated indole moiety was assigned to be in a *cis* relationship with the proton at C-6a.

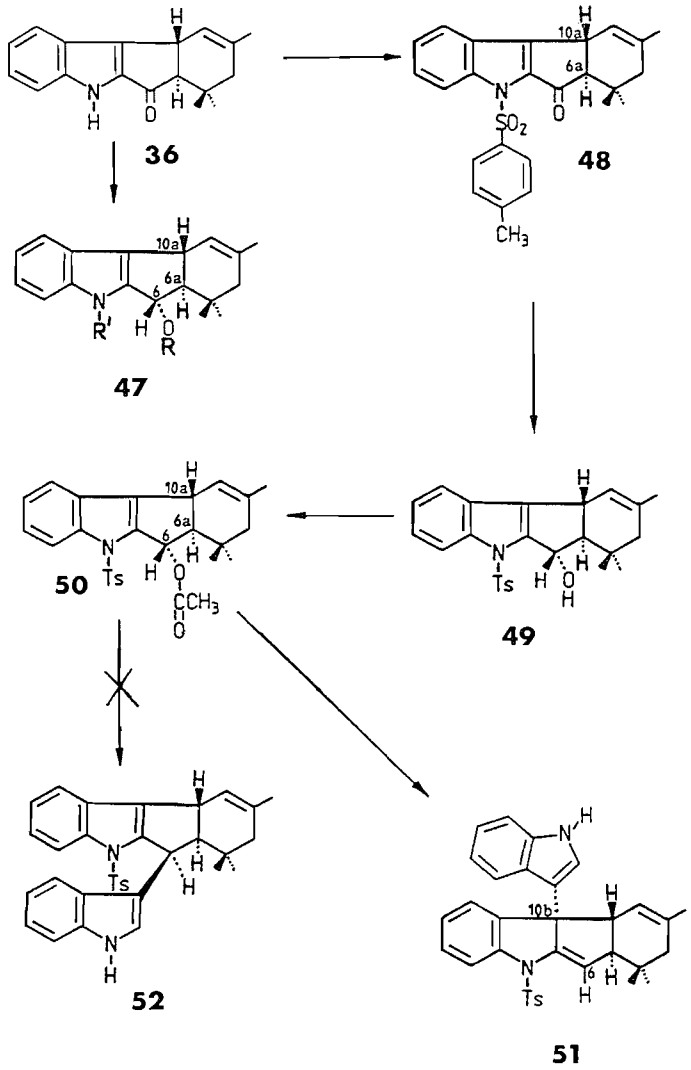
The unexpected compound **45** was characterized by IR, MS, ^{1}H NMR, and X-ray analysis (Fig. 1).

Since deprotection of **44** affords a new analogue of yuehchukene, which is one of the objectives of this project, that transformation was also carried out. Thus, treatment of **44** with sodium methoxide in methanol gave compound **46** in 97% yield. During this conversion, there was concomitant migration of the double bond to the more stable imine form. The IR spectrum of this unstable yellowish oil shows the N-H absorption at 3477 cm^{-1} and the mass spectrum displays the molecular ion as the base peak at m/z 366. The ^{1}H NMR spectrum shows the protons at C-6 and at C-6a as an ABC system. The C-6 protons appear at 2.29 ppm (doublet of doublets, J = 8, 18 Hz) and 2.83 ppm (doublet of doublets, J = 10, 18 Hz) while C-6a appears at 2.64 (multiplet). These assignments were corroborated by double resonance experiments. When the signal at 2.64 ppm was decoupled, both C-6 signals became doublets, showing that only *geminal* coupling exists with these protons. Also, the spectrum shows only one vinylic proton signal (4.72 ppm) (and not two as in **45**) corresponding to C-10, thereby establishing the proposed migration of the double bond to form the imine structure.

As noted earlier, the main objective of this study was to develop a versatile synthetic route that would afford not only an approach to the natural product but *also* to new analogues, which may portray similar efficacy as contraceptive agents but with lower toxicity, when evaluated in the pharmacological screening program.

With the above results in hand (Scheme 7), it was natural to consider the corresponding *trans*-ketone **36** so as to complete the synthesis of 6a-*epi*-yuehchukene (**2**). Unfortunately the corresponding intermediates in this series revealed a high degree of instability and low yields in the conversions so new chemistry had to be developed.

Although reduction of **36** ($LiAlH_4$, ether, 5°C) (Scheme 8) did afford the desired alcohol **47** (R = R′ = H′) in 90% yield, the subsequent conversion to the dibenzoyl derivative **47** (R = R′ = COPh) for further elaboration to the *epi*-yuehchukene system (compare **40** → **43**, Scheme 7), met with little success. Treatment of **47** (R = R′ = H) with various concentrations of benzoyl chloride afforded a low yield (15%) of the *O*-benzoyl derivative **47** (R = COPh; R′ = H) and extensive decomposition. The desired dibenzoyl derivative was never obtained.



To increase the stability of the intermediates, it was decided to protect the indole ring at an earlier stage of the synthetic route. The first choice was the *p*-toluenesulfonyl functionality since this group was expected to decrease the reactivity of the indole unit because of its electron-withdrawing properties.

Ketone **36** was converted to its tosyl derivative **48** in 90% yield by using *p*-toluenesulfonyl chloride in the presence of sodium hydride (Scheme 8). Reduction of **48** proceeded smoothly to the alcohol **49** (90% yield).

The stereochemistry at C-6 in **49** was assigned on the basis of nOe-difference experiments. Irradiation of the signal due to the proton at C-10a (3.38 ppm) enhances the signal of the proton at C-6 (5.27 ppm). This experiment also served to assign the β-methyl group at C-7 (1.05 ppm). Irradiation of the protons of this β-methyl group enhances both the signal of the proton at C-6 and that of the proton at C-10a, but shows no effect on the signal due to the proton at C-6a (2.42 ppm). Therefore, the stereochemistry at C-6 was assigned to have the O-H group and the proton at C-6a in a *cis*-relationship.

Treatment of alcohol **49** with acetic anhydride and DMAP in CH_2Cl_2 at room temperature gave acetate **50** in 75% yield. The use of acetic anhydride, instead of benzoyl chloride as used in the previous study, was an attempt to increase further the stability of the ester.

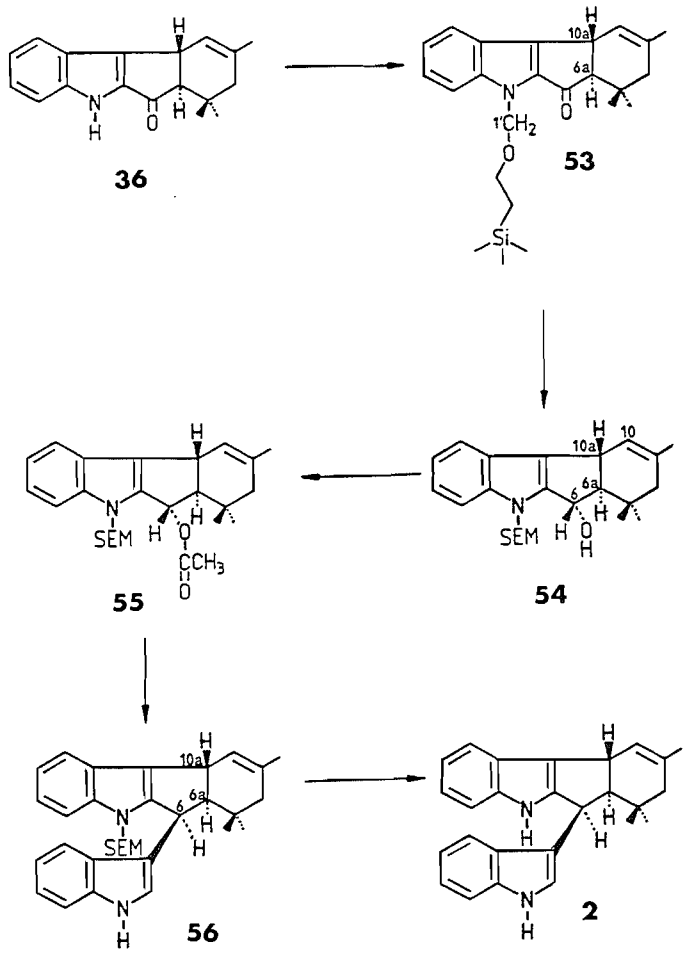
SCHEME 8. Conversion of ketone **36** to indoline **51**.

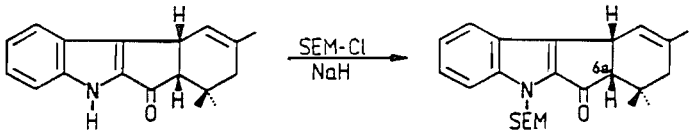
The next transformation in the sequence involved nucleophilic displacement of the acetate group by indolylmagnesium iodide. Unfortunately, the expected derivative of 6a-*epi*-yuehchukene (**52**, Scheme 8) could not be observed. Instead, the isomer **51** was obtained in 40% yield and characterized by the usual spectroscopic data (see Experimental).



It thus appears that, in this reaction, the approach of indolylmagnesium iodide to the C-6 carbon atom is considerably hindered by the axial methyl at C-7 and also, perhaps, by the bulky tosyl group. On the basis of this result, it was thought that perhaps the approach of the nucleophile might be easier with a less bulky protecting group on the indole system. Trimethylsilylethoxymethyl chloride (SEM-Cl) was chosen as another alternative to protect the indole moiety. SEM-Cl has not been previously utilized for the protection of the indole system, although it is usually employed to protect alcohols (30). However, it has been used for the protection of the pyrrole group (31) and it was felt that its applicaction in this study might prove fruitful. It was also anticipated that the introduction of this protecting group should increase the reactivity of the indole functionality when compared with the tosyl group. Scheme 9 summarizes the successful route.

Treatment of *trans*-ketone **36** with 1.5 equivalents of SEM-Cl in the presence of sodium hydride funished compound **53**. This unstable product was usually used *in situ* for the next reaction, but in one study it was isolated in a pure form (93% yield) to be characterized by IR, MS, and ^{1}H NMR spectroscopy. The infrared spectrum displays the absorption of the carbonyl group at 1695 cm^{-1} while the mass spectrum reveals the molecular ion at m/z 395 and the base peak at m/z 73 corresponding to the ratio $(CH_3)_3Si^+$. The ^{1}H NMR spectrum displays, at −0.1 ppm, a singlet that integrates for 9 protons and is due to the trimethylsilyl group; at 0.86 ppm, a multiplet corresponding to the protons of the methylene carbon bonded to the silicon; at 3.52 ppm, another multiplet due to the adjacent methylene carbon; and at 5.61 and 5.69 ppm, an AB system, with a coupling constant of 11.5 Hz, corresponding to the diastereotopic protons of the methylene carbon attached to the nitrogen atom.

That neither **36** nor **53** epimerized at C-6a, during the reaction conditions employed, was proved by obtaining a different product from the corresponding *cis*-ketone **37**, namely, compound **57**. In fact, the amount of sodium hydride was critical for the exclusive formation of **53**, especially with THF as the solvent. Any excess of sodium hydride in the conversion of **36** to **53** led to variable quantities of **57** as a by-product.



Treatment of ketone **53** in a pure form, or *in situ*, with $LiAlH_4$ at 5°C, or with DIBAL at −78°C (32), gave **54** as a single alcohol in 80–85% yield (67% overall for the one-pot reaction from **36** to **54**). The product, isolated as an oil, was then subjected to the usual spectroscopic measurements.

The stereochemistry at C-6 was again established on the basis of nOe-difference experiments. Irradiation of the signal due to

SCHEME 9. The synthesis of 6a-*epi*-yuehchukene (**2**) from ketone **36**.

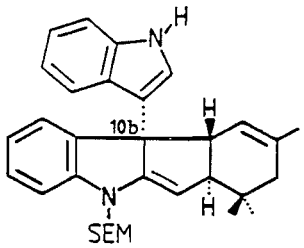
For personal use only.



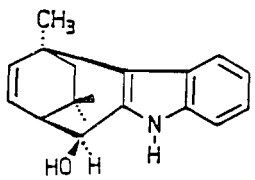
37 57

the proton at C-6 (5.12 ppm) enhances the signal of the proton at C-10a (3.41 ppm). Also, irradiation of the β-methyl at C-7 (1.03 ppm), which was assigned by irradiation of the signal due to the proton at C-10a, enhances both the signal of the proton at C-6 and that of the proton at C-10a, but not the one at C-6a. Therefore, the O-H group and the proton at C-6a were assigned to be in a *cis* relationship.

Treatment of alcohol **54** with an excess of acetic anhydride, DMAP, and triethylamine in dichloromethane at 20°C gave the corresponding acetate **55** (86% yield) as a colorless oil.

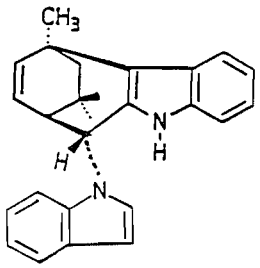
In the next step, the crucial displacement of the acetate group by indolylmagnesium iodide was attempted. Fortunately, treatment of acetate **55** with this reagent in ether–dichloromethane at 5°C furnished SEM-6a-*epi*-yuehchukene (**56**) as a white foam after isolation, and in 36% yield. Although this yield is apparently low, it might be considered quite satisfactory, firstly, because the other routes could not give the desired product and, secondly, because the newly incorporated indole still bears the strong 1,3 diaxial-like interaction with the β-methyl at C-7. The isomeric product **58**, in which the indole group is attached to the C-10b, was not observed in this case.

58



The structure of SEM-6a-*epi*-yuehchukene (**56**), including its stereochemistry, was characterized by IR, MS, and mainly ^{1}H NMR spectroscopy. The IR spectrum shows the N-H band at 3414 cm^{-1} and the mass spectrum gives the correct molecular ion at *m/z* 496. The ^{1}H NMR spectrum shows the proton at C-6 at 4.78 ppm, as a doublet, with a *J* value of 6 Hz because of its coupling with the proton at C-6a (2.70 ppm, dd, J = 11, 6 Hz). This analysis was corroborated by double resonance experiments. The β-methyl group at C-7 (assigned by nOe experiments, *vide supra*) appears as a broad singlet with the usual chemical shift of 0.34 ppm. The magnetic anisotropic effects of the newly incorporated indole group are probably the cause of this shielding.

The nOe-difference experiments provided the important data to establish the stereochemistry at C-6. Thus, irradiation of the signal due to the proton at C-6 enhances the signal of the proton at C-6a (2.70 ppm) but not the signal of the proton at C-10a (4.06 ppm). Also, irradiation of the signal due to the α-methyl group (1.13 ppm) (assigned by the enhancement of the β-methyl group when irradiating the signal due to the proton at C-10a) enhances both the signal of the proton at C-6a and the signal due to the proton at C-6. Therefore, the protons at C-6a and C-6 were assigned to bear a *cis* relationship.



Finally, the total synthesis of 6a-*epi*-yuehchukene (**2**) was accomplished by treatment of **56** with tetra-*n*-butylammonium fluoride in THF–HMPA at 40°C for 1 day to give **2** as a white foam (89% yield). Both the solvent and the reaction temperature were critical for the success of this reaction. Without HMPA, the reaction is much slower and apparently decomposition starts to take place. At 25–30°C there is no reaction and above 45°C decomposition of the reactant and (or) the product is a serious problem. On the other hand, deprotection of the indole system using lithium tetrafluoroborate in acetonitrile (33) led only to decomposition of **56**.

The IR spectrum of **2** displays the N-H absorption at 3400 cm^{-1}, the mass spectrum the molecular ion at *m/z* 366, and in the ^{1}H NMR spectrum the protons at each nitrogen atom appear at different chemical shifts. One of these broad signals appears at 8.89 ppm while the other is present at 9.10 ppm.

More recently, experiments designed to complete the structure elucidation of ketone **33**, mentioned earlier, were completed. Ketone **33**, upon reduction with lithium aluminum hydride, afforded alcohol **59** isolated as an oil. The latter was then converted to the corresponding benzoate, which, without purification, was treated directly with an ethereal solution of indolylmagnesium iodide. The resulting crystalline product, obtained by the expected nucleophilic displacement of the benzoate group, was subjected to X-ray analysis, which provided the structural assignment **60** to this compound (Fig. 1). On the basis of this assignment, it is clear that the structures of **59** and **33** are firmly established.

59

60

In spite of numerous frustrations and unanticipated difficulties in what appeared initially to be a rather straightforward series of objectives, the routes described are sufficiently versatile to provide a series of novel analogues of yuehchukene for appropriate biological screening within the anti-implantation area. It should be emphasized that many of the difficulties encountered are clearly due to the high chemical reactivity and (or) instability of the indolic intermediates. Unfortunately, the compounds are often unstable to air, acidic reagents, and (or) in various solvents normally employed in obtaining the spectral data. The natural product yuehchukene, for example, as well as its isomer **2**, are highly unstable unless kept in the cold under an inert atmosphere, and a similar situation prevails with a number of the intermediates obtained. In fact, it should be noted that yuehchukene instability is presenting a considerable problem in formulation studies involving extensive tests in animals. It is hoped that some of the intermediates, for example, the *N*-benzoyl derivative of natural yuehchukene (**43**) or the SEM derivative of 6a-*epi*-yuehchukene (**56**), which are more stable, will prove to be active in the anti-implantation screening tests.

Yuehchukene (**1**) has previously been synthesized in low yield by acid-induced dimerization of 3-isoprenylindole (35, 36) and via a different route (37). Neither study offers the versatility to prepare a "family" of yuehchukene analogues provided in the present study.

Experimental

Melting points were determined on a Nalge melting point apparatus and were uncorrected. The infrared spectra were recorded on Perkin–Elmer 710B and 1710 (Fourier transform IR) spectrometers either in chloroform solution (using sodium chloride cells of 0.1 mm path length) or as a neat liquid film. The ultraviolet spectra were recorded on a Cary 15 spectrometer, the extinction coefficients (log ε_{max}) are given in parentheses, and the wavelength(s) of the maxima in nanometers. The mass spectra were recorded on AEI-MS-9 (low resolution) or Kratos-MS-50 (high resolution) spectrometers. The ^{1}H NMR spectra were recorded on either Bruker WH-400 or Varian XL-300 spectrometers unless otherwise stated, in $CDCl_3$ solution, and the chemical shifts are reported in ppm relative to tetramethylsilane (internal standard). The optical rotations were recorded on a Perkin–Elmer 141 automatic polarimeter in a 10-cm cell at ambient temperature using the solvent and concentrations (g/100 mL) indicated in parentheses following the recorded rotation values. The elemental analyses were determined by Mr. P. Borda, Microanalytical Laboratory, The University of British Columbia. The X-ray diffraction analysis were performed by Dr. S. Rettig on a Rigaku AFC6 diffractometer. Column chromatography (34) was performed using 230–400 mesh silica gel supplied by E. Merck Co. Gas–liquid chromatography was performed on a Hewlett Packard model 5890 gas chromatograph, using a flame ionization detector and a 25 m × 0.21 mm fused silica capillary column: DB1701.

Ethyl 2β-hydroxy-4,6,6-trimethylcyclohex-3-ene-1β-carboxylate **8** *and ethyl 2α-hydroxy-4,6,6-trimethylcyclohex- 3-ene-1β-carboxylate* **9**

To a solution of keto-ester **7** (500 mg, 2.38 mmol) in methanol (10 mL) at room temperature under nitrogen, sodium borohydride (74 mg, 2.40 mmol) was added. The reaction mixture was stirred at room temperature for 2 h. Water (3 mL) and ammonium chloride (3 mL, sat. aq.) were added, and methanol was evaporated *in vacuo*. The residue was extracted with ether (3×, 10 mL) and the organic solution was washed with water (15 mL), brine (15 mL), dried over sodium sulfate, filtered, and concentrated *in vacuo* to yield a yellow oil. Purification by flash chromatography using hexanes/ether (7:3, v/v) gave *cis*-hydroxyester **8** (358 mg, 71%) and *trans*-hydroxyester **9** (116 mg, 23%) as colorless liquids. *cis*-Hydroxyester **8**: IR ν_{max} ($CHCl_3$): 3450, 2920, 1740 cm^{-1}. ^{1}H NMR (80 MHz) δ: 1.15 (3H, s, C6-CH_3), 1.22 (3H, s, C6-CH_3), 1.42 (3H, t, J = 7, C2′-H), 1.66 (1H, d, J = 17, C5-H), 1.72 (3H, brs, C4-CH_3), 2.07 (1H, d, J = 17, C5-H), 2.34 (1H, brs, O-H), 2.65 (1H, d, J = 6, Cl-H), 4.12 (2H, q, J = 7, Cl′-H), 4.40 (1H, m, C2-H), 5.42 (1H, brs, C3-H). MS *m/z*: 212 (M$^+$), 197, 194, 83. High resolution mass measurement, calcd. for $C_{12}H_{20}O_3$: 212.1412; found: 212.1408. Anal. calcd. for $C_{12}H_{20}O_3$: C 67.88, H 9.50; found: 67.73, H 9.48.

trans-Hydroxyester **9**: IR ν_{max} ($CHCl_3$): 3400, 2960, 1725 cm^{-1}. ^{1}H NMR (80 MHz) δ: 1.00 (3H, s, C6-CH_3), 1.05 (3H, s, C6-H), 1.30 (3H, t, J = 6, C2′-H), 1.59 (1H, d, J = 17, C5-H), 1.60 (1H, brs, O-H), 1.70 (3H, brs, C4-CH_3), 2.02 (1H, d, J = 17, C5-H), 2.25 (1H, d, J = 10, Cl-H), 4.20 (2H, d, J = 6, Cl′-H), 4.54 (1H, m, C2-H), 5.42 (1H, brs, C3-H). MS *m/z*: 212 (M$^+$), 197, 194, 121. High resolution mass measurement, calcd. for $C_{12}H_{20}O_3$: 212.1412; found: 212.1410. Anal. calcd. for $C_{12}H_{20}O_3$: C 67.88, H 9.50; found: C 67.66, H 9.62.

Ethyl 2β-benzoxy-4,6,6-trimethylcyclohex-3-ene-1β-carboxylate **10**

To a solution of hydroxyester **8** (300 mg, 1.43 mmol) and dimethylaminopyridine (DMAP, 189 mg, 1.54 mmol) in methylene dichloride (10 mL) at 5°C under nitrogen was added benzoyl chloride (0.18 mL, 1.54 mmol). The reaction mixture was stirred at 5°C for 3 h and then poured into water (10 mL) and the layers were separated. The aqueous phase was extracted with methylene dichloride (10 mL twice) and the combined organic phases were dried over sodium sulfate, filtered, and evaporated *in vacuo* to give a pale yellow oil. This crude product was purified by flash chromatography using hexanes/ether (9:1, v/v) to afford benzoate **10** (380 mg, 85%) as a colorless oil: IR ν_{max} ($CHCl_3$): 2975, 1725, 1610 cm^{-1}. ^{1}H NMR δ: 1.05 (3H, t, J = 6, C2′-H), 1.11 (3H, s, C6-CH_3), 1.15 (3H, s, C6-CH_3), 1.73 (1H, d, J = 18, C5-H), 1.76 (3H, brs, C4-CH_3), 2.26 (1H, d, J = 18, C5-H), 2.87 (1H, d, J = 6.7, Cl-H), 4.01 (2H, q, J = 6, Cl′-H), 5.51 (1H, brs, C3-H), 5.80 (1H, m, C2-H), 7.40 (2H, dd, J = 7.6, 7.6, C3″ and C5″-H), 7.53 (1H, tt, J = 7.6, 1.3, C4″-H), 8.10 (2H, dd, J = 7.6, 1.3, C2″ and C6″-H). MS *m/z*: 316 (M$^+$), 211, 194, 105. High resolution mass measurement, calcd. for $C_{19}H_{24}O_4$: 316.1675; found: 316.1667. Anal. calcd. for $C_{19}H_{24}O_4$: C 72.11, H 7.65; found: C 71.81, H 7.82.

Ethyl 2α-benzoxy-4,6,6-trimethylcyclohex-3-ene-1β-carboxylate **14**

Following the same conditions as above, *trans*-hydroxyester **9** (105 mg, 0.50 mmol) gave *trans*-benoate **14** (128 mg, 82%): IR ν_{max} ($CHCl_3$): 2980, 1730, 1710, 1605 cm^{-1}. ^{1}H NMR δ: 1.08 (3H, s, C6-CH_3), 1.09 (3H, s, C6-CH_3) 1.18 (3H, t, J = 7, C2′-H), 1.71 (3H, brs, C4-CH_3), 1.77 (1H, d, J = 18, C5-H), 2.09 (1H, d, J = 18, C5-H), 2.70 (1H, d, J = 10, C1-H), 4.13 (2H, q, J = 7, C1′-H), 5.52 (1H, brs, C3-H), 5.83 (1H, brd, J = 10, C2-H), 7.39 (2H, dd, J = 8, 8, C3″ and C5″-H), 7.52 (1H, t, J = 8, C4″-H), 8.00 (2H, d, J = 8, C2″-H and C6″-H). MS *m/z*: 316 (M$^+$), 271, 211, 165, 105. High resolution mass measurement, calcd. for $C_{19}H_{24}O_4$: 316.1675; found: 316.1662. Anal. calcd. for $C_{19}H_{24}O_4$: C 72.11, H 7.65; found: C 71.88, H 7.80.

Ethyl 2α-(3-indoyl)-4,6,6-trimethylcyclohex-3-ene-1β-carboxylates **11** *and* **13**

To a suspension of magnesium (116 mg, 4.80 mmol) in dry ether (5 mL) at room temperature under nitrogen, was added methyl iodide (0.3 mL, 4.80 mmol) dropwise. After stirring for 30 min, a solution of indole (590 mg, 5.10 mmol) in dry ether (5 mL) was added at 5°C. The mixture was stirred for 1 h at room temperature, then dichloromethane (3.5 mL) was added to bring the complex into solution. This freshly prepared solution of indolylmagnesium iodide (about 4.80 mmol) was added dropwise to a solution of benzoate **10** (500 mg, 1.61 mmol) in dry ether (10 mL) at 5°C. The reaction mixture was stirred for 2 h at 5°C and for 1 h at room temperature, and then decomposed with ammonium chloride (5 mL, sat. aq.). The layers were separated and the aqueous phase was extracted with dichloromethane (3×, 10 mL). The combined organic phases were washed with water (30 mL), brine (30 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a brown residue. Purification by flash chromatography using hexanes/ether (8:2, v/v) gave indole-ester **11** (206 mg, 42%) and with further elution the isomer **13** (158 mg, 31%) as pale yellow liquids. Indole-ester **11**: UV λ_{max} (log ε) (MeOH): 224 (4.50), 280 (3.78) nm. IR ν_{max} ($CHCl_3$): 3480, 2960, 1730 cm^{-1}. ^{1}H NMR δ: 0.99 (3H, t, J = 8, C2′-H), 1.03 (3H, s, C6-CH_3), 1.14 (3H, s, C6-CH_3), 1.73 (3H, brs, CR-CH_3), 1.74 (1H, d, J = 16, C5-H), 2.15 (1H, d, J = 16, C5-H), 2.67 (1H, d, J = 12, C1-H), 3.90 (1H, m, C2-H), 3.90 (2H, q, J = 8, C1′-H), 5.48 (1H, brs, C3-H), 6.99 (1H, d, J = 3.2, C2″-H), 7.06 (1H, dd, J = 8, 8, C5″-H), 7.15 (1H, dd, J = 8, 8, C6″-H), 7.31 (1H, d, J = 8, C7″-H), 7.61 (1H, d, J = 8, C4″-H), 7.92 (1H, brs, N-H). MS *m/z*: 311 (M$^+$), 296, 238, 222. High resolution mass measurement, calcd. for $C_{20}H_{25}NO_2$: 311.1885; found: 311.1879. Anal. calcd. for $C_{20}H_{25}NO_2$: C 77.14, H 8.09, N. 4.50; found: C 76.99, H 8.26, N 4.60.

Indole-ester **13**: UV λ_{max} (log ε) (MeOH): 225 (4.53), 283 (3.71) nm. IR ν_{max} ($CHCl_3$): 3480, 2980, 1730, 1635 cm^{-1}. ^{1}H NMR (80 MHz) δ: 0.75 (3H, s, C6-CH_3), 1.00 (3H, s, C6-CH_3), 1.27 (3H, t, J = 6, C2′-H), 1.58 (3H, s, C4-CH_3), 1.95 (1H, d, J = 14, C5-H), 2.25 (1H, d, J = 14, C5-H), 2.95 (1H, dd, J = 4, 2, C1-H), 4.20 (2H, q, J = 6, C1′-H), 5.79 (1H, dd, J = 10, 4, C2 or C3-H), 6.05 (1H, dd, J = 10, 2, C2 or C3-H), 6.95 (1H, d, J = 2.5, C2″-H), 7.06 (1H, dd, J = 8, 8, Ar-H), 7.15 (1H, dd, J = 8, 8, Ar-H), 7.23 (1H, d, J = 8, C7″-H), 7.74 (1H, d, J = 8, C4″-H), 7.93 (1H, brs, N-H). MS *m/z*: 311 (M$^+$), 296, 238, 117. High resolution mass measurement, calcd. for $C_{20}H_{25}NO_2$: 311.1885; found: 311.1880. Anal. calcd. for $C_{20}H_{25}NO_2$: C 77.14, H 8.09, N 4.50; found: C 76.96, H 8.22, N 4.39.

2β-Hydroxy-4,6,6-trimethylcyclohex-3-ene-1β-carboxylic acid **18** *and 2α-hydroxy-4,6,6-trimethylcyclohex-3-ene-1β-carboxylic acid* **21**

To a solution of 2,6-di-*tert*-butyl-4-methylphenol (231.8 g, 1.05 mmol) in dry ether (2.75 L) at −78°C under nitrogen was added dropwise a solution of *n*-butyllithium (0.625 L, 1.0 mol, 1.6 M in hexane). The suspension of white solid was warmed to room temperature and carbon dioxide gas was passed through the mixture for 10–12 min. A solution of isophorone **6** (50.05 mL, 0.33 mol) in dry ether (0.23 L) was then added with the precipitate dissolving completely. CO_2 was bubbled through the solution until no more absorption occurred. A positive pressure of CO_2 was then installed by connecting CO_2-filled balloons to the reaction flask. The stirring was continued for 4 days at room temperature. The reaction mixture was then cooled to 0°C, the balloons were removed, and a nitrogen flow was connected. To the lithium salt of the β-keto-acid **19** was added sodium borohydride (11.4 g, 0.37 mol) in methanol (0.5L) in three portions. After 2.5 h of stirring at 0°C, additional sodium borohydride (11.4 g, 0.37 mol) in methanol (0.5L) was added. The ice bath was removed and the stirring was continued for 3 h. The solvent was evaporated *in vacuo* and the residue was dissolved in ether (1.2 L) and water (1 L). After separating the layers, the aqueous phase was washed with ether (2×, 0.5 L) and acidified very carefully with HCl (10% aq.) to pH 5.5 at 5°C. Extraction with ethyl acetate (3×, 300 mL) followed by drying over sodium sulfate, filtration, and evaporation *in vacuo* gave a crude pale yellow solid. Crystallization from ether/hexane furnished *cis*-hydroxy acid **18** (28 g, 46%) as colorless crystals. Crystallization of the evaporated mother liquor with chloroform yielded *trans*-hydroxy acid **21** (2.5 g, 4%). *cis*-Hydroxy acid **18**: mp 115–118°C (ether/hexane). IR ν_{max} ($CHCl_3$): 3350–2500, 3010, 2970, 1718 cm^{-1}. ^1H NMR δ: 1.05 (3H, s, C6-CH_3), 1.15 (3H, s, C6-CH_3), 1.70 (1H, d, J = 17.5, C5-H), 1.73 (3H, brs, C4-CH_3), 2.07 (1H, d, J = 17.5, C5-H), 2.69 (1H, d, J = 6, C1-H), 4.45 (1H, brs, C2-H), 5.45 (1H, brs, C3-H). MS *m/z*: 184 (M^+), 166, 151, 121, 83. High resolution mass measurement, calcd. for $C_{10}H_{16}O_3$: 184.1100; found: 184.1099. Anal. calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 65.45, H 8.65.

trans-Hydroxy acid ***21***: mp 186–188°C ($CHCl_3$). IR ν_{max} (KBr): 3375, 3200–2300, 2950, 1710, 1635 cm^{-1}. ^1H NMR δ: 0.98 (3H, s, C6-CH_3), 1.08 (3H, s, C6-CH_3), 1.64 (1H, d, J = 17, C5-H), 1.69 (3H, brs, C4-CH_3), 2.01 (1H, d, J = 17, C5-H), 2.24 (1H, d, J = 10, C1-H), 4.48 (1H, m, C2-H), 5.41 (1H, brs, C3-H), MS *m/z*: 184 (M^+), 166, 151, 83. 2β-Benzoxy-4,6,6-trimethylcyclohex-3-ene-1β-carboxylic benzoic anhydride **27**

To a suspension of hydroxy acid **18** (20 g, 0.109 mol) in methylene dichloride (450 mL) was added dimethylaminopyridine (28 g, 0.228 mol) at room temperature. The mixture was stirred 10 min, then was cooled to 0–5°C under nitrogen. Benzoyl chloride (26.5 mol, 0.228 mol) was added and the stirring was continued for 4.5 h at 0–5°C. An aliquot (0.5 mL) was taken from the reaction mixture and was determined by GC to contain 72% product with no hydroxy acid. The reaction mixture was poured into water (200 mL), and the layers were separated. The aqueous phase was extracted with methylene dichloride (2×, 100 mL) and the combined organic phases were dried over sodium sulfate, filtered, and evaporated *in vacuo* to give **27** as a yellow oil that was used without further purification for the next reaction.

Compound **27**: IR ν_{max} ($CHCl_3$): 2960, 1795, and 1725 cm^{-1}. ^1H NMR δ: 1.22 (3H, s, C6-CH_3), 1.31 (3H, s, C6-CH_3), 1.78 (3H, brs, C4-CH_3), 1.80 (1H, d, J = 17, C5-H), 2.30 (1H, d, J = 17, C5-H), 3.10 (1H, d, J = 6, C1-H), 5.58 (1H, m, C3-H), 5.82–6.05 (1H, m, C2-H), 7.17–8.30 (10H, m, Ar-H).

2α-(3-Indolyl)-4,6,6-trimethylcyclohex-3-ene-1β-carboxylic acid **29**

To a suspension of magnesium (10.6 g, 0.44 mol) in dry ether (212 mL) at room temperature under nitrogen was added dropwise a solution of methyl iodide (27.2 mL, 0.44 mol) in dry ether (81.5 mL). After stirring for 30 min a solution of indole (54.4 g, 0.47 mol) in dry ether (330 mL) was added at 5°C. The mixture was stirred for 1 h at room temperature, then dichloromethane (213 mL) was added to bring the complex into solution. This freshly prepared solution of indolylmagnesium iodide (about 0.44 mol) was added dropwise to a solution of the crude benzoate **27** (38 g) in dry ether (203 mL) at 5°C. The reaction mixture was stirred for 2 h at 5°C, for 1 h at room temperature, and then decomposed with ammonium chloride (700 mL, sat. aq.). The layers were separated and the aqueous phase was extracted with ethyl acetate (3×, 200 mL). The combined organic layers were washed with water (800 mL), brine (800 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo*. The residue was dissolved in ether (500 mL) and 3-benzoylindole was separated by filtration. The resulting solution was extracted with sodium hydroxide solution (3×, 150 mL, 5% aq.) and the combined aqueous layers were cooled to below 10°C and acidified with hydrochloric acid (10% aq.) to pH 5. Extraction with ethyl acetate (3×, 300 mL) followed by washings with water (400 mL), and brine (400 mL), drying over sodium sulfate, and evaporation *in vacuo* yielded a crude foam (20 g). Purification by flash chromatography using hexanes/ethyl acetate (7:3, v/v) gave a mixture (14.36 g) of indole-acid **29** and compound **31** in a ratio 6:4 in favor of indole-acid **29** (i.e., 40% yield) as determined by ^1H NMR. Compounds **32** (0.64 g, 3%) and **30** (1.9 g, 15%) were also obtained from the column. Further purification of the mixture of **29** and **31** by flash chromatography using chloroform/hexanes (6.5:3.5, v/v) afforded indole-acid **29** (6.5 g, 30%), although always accompanied by some decomposition. Since there is no detriment to the yield of the next step in using the mixture of products, this last purification was usually avoided.

Indole-acid **29**: mp 173–174°C (ether–hexane). UV λ_{max} (log ε) (MeOH): 222 (4.51), 282 (3.76) nm. IR ν_{max} : 3480, 3400–2450, 3020, 2980, 1710, 1630 cm^{-1}. ^1H NMR δ: 1.08 (3H, s, C6-CH_3), 1.14 (3H, s, C6-CH_3), 1.71 (3H, brs, C4-CH_3), 1.76 (1H, d, J = 16, C5-H), 2.15 (1H, d, J = 16, C5-H), 2.71 (1H, d, J = 10, C1-H), 3.93 (1H, brd, J = 10, C2-H), 5.47 (1H, brs, C3-H), 6.94 (1H, d, J = 2, C2′-H), 7.08 (1H, dd, J = 8, 8, C5′-H), 7.17 (1H, dd, J = 8, 8, C6′-H), 7.33 (1H, d, J = 8, C7′H), 7.62 (1H, d, J = 8, C4′-H), 7.77 (1H, bs, N-H). Compound **30**: mp 115–117°C (ether/hexane). UV λ_{max} (log ε) (MeOH): 290 (4.1) nm. IR ν_{max} ($CHCl_3$): 3200–2800, 3048, 2959, 1680, 1642 cm^{-1}. ^1H NMR δ: 1.20 (6H, s, C6-CH_3), 1.85 (3H, brs, C4-CH_3), 2.13 (2H, s, C5-H), 5.81 (1H, dq, J = 6.5, 1.2, C3-H), 7.00 (1H, d, J = 6.5, C2-H). MS *m/z*: 166 (M^+), 151, 107. High resolution mass measurement, calcd. for $C_{10}H_{14}O_2$: 166.0994; found: 166.0995. Anal. calcd. for $C_{10}H_{14}O_2$: C 72.26, H 8.49; found: C 72.33, H 8.40.

6-Oxo-7,7-9-trimethyl-5,6,6aα,7,8,10aβ-hexahydroindeno-[2,1-b]indole **36**

Method A

To a solution of indole-acid **29** (450 mg, 1.6 mmol) in benzene (10

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

mL) at 0°C under nitrogen was added oxalyl chloride (0.21 mL, 2.4 mmol). After stirring for 24 h at room temperature, the solvent was removed *in vacuo* to give a dark residue, which was diluted with dry benzene (5 mL) and, again, the solvent was removed *in vacuo*. The acid chloride **34** was then dissolved in ether (10 mL) and a solution of indolylmagnesium iodide (3.5 equiv., prepared as described above, see experiment on compound **29**) in ether (8 mL), and dichloromethane (3.1 mL) was added dropwise for 8 h at −15°C under nitrogen. The reaction mixture was stirred for 14 h at room temperature, followed by quenching with ammonium chloride (10 mL, sat. aq.) and extraction with dichloromethane (3×, 10 mL). The organic phase was washed with sodium bicarbonate (10 mL, sat. aq.) and brine (10 mL), dried over sodium sulfate, filtered, and concentrated *in vacuo* to yield a dark oil. This crude product was purified by flash chromatography using hexanes/ether (8.5:1.5, v/v) to give *trans*-ketone **60** (194 mg, 46% overall) as a pale yellow powder. Further elution using hexanes/ether (6.5:3.5, v/v) furnished **35** (85 mg, 14%) as a yellowish foam.

Method B

To a solution of the acid chloride **34** (prepared from indole-acid **29** (198 mg, 0.7 mmol) as in Method A), in dry tetrahydrofuran (4 mL) at −15°C under nitrogen, was added dropwise a solution of lithium diisopropylamide in tetrahydrofuran prepared from diisopropylamine (0.25 mL, 1.75 mmol) for 7 h. After this time, the reaction mixture was further stirred for 1.5 h at −15°C and then quenched by the addition of ice (about 1 g) and ammonium chloride (2 mL, sat. aq.). After extraction with ethyl acetate (3×, 10 mL), the organic phase was washed with water/brine (10 mL, 1:1, v/v), brine (10 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a brown oil. Purification by flash chromatography using hexanes/ether (8.5:1.5, v/v) afforded pure *trans*-ketone **36** (55.6 mg, 30%). Further elution using hexanes/ether (6:4, v/v) recovered indole-acid **29** (53 mg, 27%).

trans-Ketone **36**: mp 129–131°C (acetone/hexane). UV λ_{max} (log ε) (MeOH): 232 (4.26), 307 (4.23) nm. IR ν_{max} ($CHCl_3$): 3464, 3040, 2960, 1683, 1625 cm^{-1}. ^1H NMR δ: 1.14 (3H, s, C7-CH_3), 1.47 (3H, s, C7-CH_3), 1.75 (3H, brs, C9-CH_3), 1.97 (1H, d, J = 18, C8-H), 2.07 (1H, d, J = 18, C8-H), 2.84 (1H, d, J = 6, C6a-H), 3.99 (1H, m, C10a-H), 6.24 (1H, brs, C10-H), 7.18 (1H, ddd, J = 8, 8, 1, Ar-H), 7.35 (1H, ddd, J = 8, 8, 1, Ar-H), 7.44 (1H, d, J = 8, Ar-H), 7.80 (1H, d, J = 8, Ar-H), 8.73 (1H, brs, N-H). MS m/z: 265 (M^+), 250, 222. High resolution mass measurement, calcd. for $C_{18}H_{19}NO$: 265.1466: found: 265.1466. Anal. calcd. for $C_{18}H_{19}NO$: C 81.48, H 7.22, N 5.28; found: C 81.16, H 7.09, N 5.23.

Compound **35**: UV λ_{max} (log ε) (MeOH): 219 (4.56) nm. IR ν_{max} ($CHCl_3$): 3465, 3025, 2960, 1637 cm^{-1}. ^1H NMR δ: 0.93 (3H, s, C5-CH_3), 1.27 (3H, s, C5-CH_3), 1.79 (1H, d, J = 18, C6-H), 1.80 (3H, brs, C1-CH_3), 2.30 (1H, d, J = 18, C6-H), 3.54 (1H, d, J = 10, C4-H), 4.14 (1H, m, C3-H), 5.59 (1H, brs, C2-H), 6.85 (1H, d, J = 2, C2′-H), 7.05–7.14 (3H, m, Ar-H), 7.15–7.24 (4H, m, Ar-H), 7.59 (1H, brs, N-H), 7.74 (1H, d, J = 8, Ar-H), 7.98 (1H, brs, N-H), 8.40 (1H, d, J = 8, Ar-H). MS m/z: 382 (M^+), 238, 144. High resolution mass measurement, calcd. for $C_{26}H_{26}N_2O$: 382.2044; found: 382.2042.

6-Oxo-7,7,9-trimethyl-5,6,6aβ,7, 8,10Aβ-hexahydroindeno-[2,1-b]indole **37**

Method A

To a solution of *trans*-ketone **36** (430 mg, 1.6 mmol) in dry tetrahydrofuran (6 mL) and dry methanol (15 mL) at room temperature under nitrogen was added sodium methoxide (10 mL, 0.03 M in methanol). The reaction mixture was refluxed for 1 h, cooled to room temperature, and then water (2 mL) and ammonium chloride (5 mL, sat. aq.) were added. The organic solvent was evaporated *in vacuo* and the resulting residue was extracted with methylene chloride. The organic phase was washed with water (10 mL), brine (10 mL), dried over Na_2SO_4, filtered, and evaporated *in vacuo* to yield a yellow solid. Recrystallization of this powder from acetone/hexane gave pure *cis*-ketone **37** (426 mg, 99%) as pale yellow crystals.

Method B

To a solution of *trans*-ketone **36** (24.6 mg, 0.093 mmol) in dry tetrahydrofuran (3 mL) at −15°C under nitrogen was added dropwise a solution of lithium diisopropylamide in tetrahydrofuran (prepared from diisopropylamine (0.03 mL, 0.21 mmol)). The reaction was warmed to room temperature and stirred for 2.5 h. Ice (about 0.5 g) and ammonium chloride (4 mL, sat. aq.) were added, followed by extraction with ethyl acetate (3×, 5 mL). The organic phase was washed with water/brine (7 mL, 1:1, v/v), brine (7 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a yellow solid. Crystallization from hexane/acetone furnished *cis*-ketone **24** (21 mg, 85%) as pale yellow crystals.

Method C

To a solution of acid chloride **34** (prepared from indole-acid **29** (281.5 mg, 0.99 mmol)) in dry tetrahydrofuran (5.6 mL) at −15°C under nitrogen was added dropwise a solution of lithium diisopropylamide in tetrahydrofuran (prepared from diisopropylamine (0.35 mL, 2.48 mmol)) for 7 h. After completion of the addition, the reaction mixture was allowed to reach room temperature. After stirring for 14 h, ice (about 1 g) and ammonium chloride (10 mL, sat. aq.) were added, followed by extraction with ethyl acetate (3×, 10 mL). The organic phase was washed with water/brine (10 mL, 1:1 v/v), brine (10 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a brown oil. Purification by flash chromatography using hexanes/ether (8.5:1.5, v/v) furnished *cis*-ketone **37** (71.2 mg, 27%) and further elution using hexanes/ether (6:4, v/v) returned indole-acid **29** (73.2 mg, 26%).

cis-Ketone **37**: mp 220–223°C (acetone/hexane). UV λ_{max} (log ε) (MeOH): 227 (4.29), 302 (4.25) nm. IR ν_{max} ($CHCl_3$): 3464, 3021, 2831, 1676, 1620 cm^{-1}. ^1H NMR δ: 0.92 (3H, s, C7-CH_3), 1.27 (3H, s, C7-CH_3), 1.69 (3H, brs, C9-CH_3), 1.76 (1H, d, J = 16.5, C8-H), 1.96 (1H, d, J = 16.5, C8-H), 2.89 (1H, d, J = 6, C6a-H), 4.05 (1H, m, C10a-H), 5.90 (1H, brs, C10-H), 7.18 (1H, ddd, J = 9, 8, 1.5, Ar-H), 7.36 (1H, ddd, J = 10, 9, 1.5, Ar-H), 7.48 (1H, dd, J = 10, 1.5, Ar-H), 7.79 (1H, dd, J = 8, 1.5, Ar-H), 9.75 (1H, brs, N-H). MS m/z: 265 (M^+), 250, 222. High resolution mass measurement, calcd. for $C_{18}H_{19}NO$: 265.1466; found: 265.1473. Anal. calcd. for $C_{18}H_{19}NO$: C81.48, H 7.22, N 5.28; found: C 81.19, H 7.10, N 5.10.

6α-Hydroxy-7,7,9-trimethyl-5,6α,6aβ-7,8,10aβ-hexahydroindeno-[2,1-b]indole **38** *and 6β-hydroxy-7,7,9-trimethyl-5,6α,6aβ-7,8,10aβ-hexahydroindeno[2,1-b]indole* **39**

Method A

To a solution of *cis*-ketone **37** (1.02 g, 3.85 mmol) in dry THF (40 mL) at 0°C under nitrogen was added lithium aluminum hydride (about 0.14 g, 4.0 mmol). After stirring for 1 h at 0.5°C and 1 h at room temperature, wet ether (15 mL, sat. aq.), sodium hydroxide (30 mL, 15% aq.), and water (10 mL) were slowly added. The mixture was extracted with ether (5×, 15 mL) and the organic phase was washed with water/brine (100 mL, 1:1, v/v), brine (50 mL), dried over magnesium sulfate, filtered, and evaporated *in vacuo* to yield a yellow solid. Purification by flash chromatography using hexanes/ether (8.5:1.5, v/v) afforded pure crystals of alcohol **38** (1.27 g, 65%) and further elution with hexanes/ether (7.5:2.5, v/v) afforded alcohol **39** (0.68 g, 35%) as a crystalline solid.

Method B

To a solution of L-selectride (0.24 mL, 0.24 mmol, 1 M in tetrahydrofuran) at −78°C under nitrogen was added a solution of *cis*-ketone **37** (21.7 mg, 0.08 mmol) in dry tetrahydrofuran (1.5 mL). The reaction mixture was stirred for 1 h at −78°C, 2 h at 0°C, and 1 h at room temperature. The reaction was then cooled to 0°C and a further portion of L-selectride (0.24 mL, 0.24 mmol, 1 M in tetrahydrofuran) was added. After stirring at room temperature overnight, water (0.1 mL), sodium hydroxide (0.3 mL, 3 M), and H_2O_2 (0.22 mL, 30% aq.) were added at 0°C. The mixture was stirred for 2 h at room temperature and then diluted with dichloromethane (5 mL). The aqueous layer was treated with excess of solid sodium chloride and extracted with dichloromethane (3×, 5 mL). The combined organic phases were washed with water (10 mL), brine (10 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a yellow oil. Purification by flash chromatography using hexanes/ether (8.5:1.5, v/v) gave unreacted *cis*-ketone **37** (8 mg, 36%), and alcohol **38** (11 mg, 50.3%).

5-Benzoyl-6α-benzoxy-7,7,9-trimethyl-5, 6α-6aβ,7,8,10aβ-hexahydroindeno[2,1-b]indole ***40***

To a solution of alcohol **38** (697 mg, 2.61 mmol), dimethyl aminopyridine (382 mg, 3.13 mmol), and triethylamine (7 mL) in dichloromethane (57 mL) at room temperature under nitrogen was added benzoyl chloride (1.21 mL, 10.44 mmol). After 1 day at reflux, the reaction mixture was cooled to room temperature and water (30 mL) was added. The organic phase was washed with sodium bicarbonate (30 mL, 10% aq.), water (30 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a pale yellow foam. Purification by flash chromatography using hexanes/ethyl acetate (9.3:0.7, v/v) gave **40** (942 mg, 76%) as white crystals.

Compound **40**: mp 171–174°C (ether/hexane). UV λ_{max} (log ε) (MeOH): 225 (4.27), 260 (4.02) nm. IR ν_{max} ($CHCl_3$): 3010, 2959, 1718, 1684, 1603 cm^{-1}. ^1H NMR δ: 1.03 (3H, s, C7-CH_3), 1.12 (3H, s, C7-CH_3), 1.54 (1H, d, J = 17, C8-H), 1.67 (3H, brs, C9-CH_3), 2.09 (1H, d, J = 17, C8-H), 2.74 (1H, dd, J = 5.5, 5.5, C6a-H), 3.84 (1H, m, C10a-H), 5.73 (1H, brs, C10-H), 6.40 (1H, d, J = 5.5, C6-H), 7.20–7.80 (14H, m, Ar-H). Yuehchukene ***1***

To a solution of benzoylyuehchukene **43** (200 mg, 0.43 mmol) in dry methanol (5 mL) at 5°C under nitrogen, was added sodium methoxide (freshly prepared from sodium (about 23 mg, 1 mmol) and methanol (4 mL)). After stirring at 5°C for 4 h, water (1 mL) and ammonium chloride (3 mL, sat. aq.) were added. The organic solvent was evaporated *in vacuo* and the residue was extracted with ethyl acetate (4×, 5 mL). The organic phase was washed with water (5 mL), brine (5 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a brown oil. This crude product was purified by flash chromatography using hexanes/ether (8.5:1.5, v/v) to give the synthetic yuehchukene **1** (140.3 mg, 90%) as a white foam.

Yuehchukene **1**: UV λ_{max} (MeOH): 225, 283. IR ν_{max} ($CHCl_3$): 3400, 2955, 1618 cm^{-1}: ^1H NMR δ: 0.86 (3H, s, C7-CH_3), 1.10 (3H, s, C7-CH_3), 1.63 (1H, d, J = 17, C8-H), 1.66 (3H, brs, C9-CH_3), 2.28 (1H, d, J = 17, C8-H), 3.15 (1H, dd, J = 8.5, 8.5, C6A-H), 4.02 (1H, m, C10a), 4.56 (1H, d, J = 8.5), 5.70 (1H, brs, C10-H), 6.98–7.12 (5H, m, Ar-H), 7.38 (1H, d, J = 8, Ar-H), 7.44 (1H, d, J = 8, Ar-H), 7.48 (1H, brs, N-H), 7.57 (1H, d, J = 8, Ar-H), 8.00 (1H, brs, N-H). MS m/z: 366 (M^+), 351, 254. High resolution mass measurement, calcd. for $C_{26}H_{26}N_2$: 366.2095; found: 366.2096.

Samples of synthetic **1** and natural **1** were compared by TLC, NMR, and IR spectra, and shown to be identical.

6α-Hydroxy-7,7,9-trimethyl-5,6α,6aα7,8, 10aβ-hexahydroindeno-[2,1-b]indole ***47***

To a suspension of lithium aluminum hydride (about 29 mg, 2 mmol) in tetrahydrofuran (1 mL) at 0°C under nitrogen was added a solution of *trans*-ketone **36** (212 mg, 0.80 mmol) in tetrahydrofuran (2 mL). After stirring for 2 h at 0°C, the reaction was quenched with wet ether (0.5 mL, sat. aq.), sodium hydroxide (0.5 mL, 15% aq.), and water (1 mL). After filtration through Celite, the filtrate was evaporated *in vacuo* to give a residue that was diluted with ether (5 mL). This ethereal solution was washed with brine (5 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo*. The crude product was purified by flash chromatography using hexanes/ether (8:2, v/v) to give alcohol **47** (192 mg, 90%).

Alcohol **47**: UV λ_{max} (log ε) (MeOH): 223 (4.49), 282 (4.07) nm. IR ν_{max} ($CHCl_3$): 3685, 3466, 3020, 1621 cm^{-1}. ^1H NMR δ: 1.06 (3H, s, C7-CH_3), 1.24 (3H, s, C7-CH_3), 1.60 (1H, brs, O-H), 1.71 (3H, brs, C9-CH_3), 1.84 (1H, d, J = 18, C8-H), 2.04 (1H, d, J = 18, C8-H), 2.18 (1H, dd, J = 8.5, 8.5, C6a-H), 3.45–3.56 (1H, m, C10a), 5.08

(1H, d, J = 8.5, C6-H), 6.15 (1H, brs, C10-H), 7.09 (1H, ddd, J = 8, 8, 1.5, Ar-H), 7.13 (1H, ddd, J = 8, 8, 1.5, Ar-H), 7.33 (1H, dd, J = 8, 1.5, Ar-H), 7.62 (1H, dd, J = 8, 1.5, Ar-H), 8.10 (1H, brs, N-H). MS m/z: 267 (M^+), 249, 234, 117. High resolution mass measurement, calcd. for $C_{18}H_{21}NO$: 267.1623; found: 267.1623.

*6-Oxo-5-(*p*-toluenesulfonyl)-7,7,9-trimethyl-5,6,6aα,7,8,10aβ-hexahydroindeno[2,1-b]indole* **48**

To a solution of *trans*-ketone **36** (600 mg, 2.26 mmol) in dichloromethane (5 mL) at 0°C under nitrogen was added sodium hydride (90 mg, 2.3 mmol, 60% dispersion in oil). After stirring for 10 min at room temperature, *p*-toluenesulfonyl chloride (450 mg, 2.4 mmol) was added to the reaction mixture at 0°C. The reaction was stirred for 2 h at room temperature, then quenched with ammonium chloride (5 mL, sat. aq.), and diluted with dichloromethane (5 mL). The organic phase was washed with brine (5 mL), dried over sodium hydroxide, filtered, and evaporated *in vacuo* to yield a yellow solid. Purification by flash chromatography using hexanes/ether (9:1, v/v) furnished tosyl-ketone **48** (853 mg, 90%) as pale yellow crystals.

Tosyl-ketone **48**: mp 123–124°C (acetone/hexane). UV λ_{max} (log ε) (MeOH): 297 (4.21), 243 (4.23), 222 (4.28) nm. IR ν_{max} ($CHCl_3$): 3032, 2959, 1713, 1605, 1381, 1123 cm^{-1}. ^1H NMR δ: 1.08 (3H, s, C7-CH_3), 1.44 (3H, s, C7-CH_3), 1.71 (3H, brs, C9-CH_3), 1.92 (1H, d, J = 18, C8-H), 2.04 (1H, d, J = 18, C8-H), 2.36 (3H, s, Ar-CH_3), 2.81 (1H, d, J = 8, C6a-H), 3.77–3.84 (1H, m, C10a), 6.12 (1H, brs, C10-H), 7.25 (2H, d, J = 8, C3′-H and C5′-H), 7.33 (1H, dd, J = 8, 8, Ar-H), 7.50 (1H, dd, J = 8, 8, Ar-H), 7.74 (1H, d, J = 8, Ar-H), 8.04 (2H, d, J = 8, C2′-H and C6′-H), 8.28 (1H, d, J = 8, Ar-H). MS m/z: 419 (M^+), 404, 263, 248. High resolution mass measurement, calcd. for $C_{25}H_{25}NO_3S$: 419.1555; found: 419.1556. Anal. calcd. for $C_{25}H_{25}NO_3S$: C 71.57, H 6.01, N 3.34; found: C 71.23, H 6.09, N 3.44.

*6α-Hydroxy-5-(*p*-toluenesulfonyl)-7,7,9-trimethyl-5,6α,6aα,7,8,-10aβ-hexahydroindeno[2,1-b]indole* **49**

To a suspension of lithium aluminum hydride (about 72 mg, 2 mmol) in tetrahydrofuran (2 mL) at 0°C under nitrogen was added a solution of tosyl ketone **48** (800 mg, 1.91 mmol) in tetrahydrofuran (4 mL). After stirring for 2 h at 0°C, the reaction was quenched with wet ether (1 mL, sat. aq.), sodium hydroxide (1 mL, 15% aq.), and water (2 mL). After filtration through Celite, the filtrate was evaporated *in vacuo* to give a residue that was diluted with ether (10 mL). This ethereal solution was washed with brine (10 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo*. The crude product was purified by flash chromatography using hexanes/ether (8.5:1.5, v/v) to give alcohol **49** (691 mg, 86%) as colorless needles.

Alcohol **49**: mp 118–119°C (ether/hexane). UV λ_{max} (log ε) (MeOH): 222 (4.43), 258 (4.40) nm. IR ν_{max} 3563, 3010, 2962, 1599, 1381, 1123 cm^{-1}. ^1H NMR δ: 1.05 (3H, s, C7-βCH$_3$), 1.28 (3H, s, C7-αCH$_3$), 1.70 (3H, brs, C9-H), 1.88 (1H, d, J = 17.5, C8-H), 2.09 (1H, d, J = 17.5, C8-H), 2.33 (3H, s, Ar-CH_3), 2.42 (1H, dd, J = 10, 8.5, C6a-H), 3.38 (1H, m, C10a), 4.10 (1H, d, J = 2, O-H), 5.27 (1H, ddd, J = 8.5, 2, 2, C6-H), 6.04 (1H, brs, C10-H), 7.19–7.34 (4H, m, Ar-H), 7.54 (1H, d, J = 7, C1-H), 7.84 (2H, d, J = 9, C2′-H and C6′-H), 7.91 (1H, dd, J = 8, 1.5, C4-H). MS m/z: 421 (M^+), 406, 251, 91. High resolution mass measurement, calcd. for $C_{25}H_{27}NO_3S$: 421.1711; found: 421.1715. Anal. calcd. for $C_{25}H_{27}NO_3S$: C 71.23, H 6.46, N 3.32; found: C 71.20, H 6.47, N 3.46.

*6α-Acetoxy-5-(*p*-toluenesulfonyl)-7,7,9-trimethyl-5,6α,6aα,7,8,10aβ-hexahydroindeno[2,1-b]indole* **50**

To a solution of alcohol **49** (100 mg, 0.24 mmol) and *N,N*-dimethylaminopyridine (37 mg, 0.31 mmol) in dichloromethane (5 mL) at room temperature was added acetic anhydride (0.027 mL, 0.29 mmol). The reaction mixture was stirred for 3 days at room temperature, then diluted with dichloromethane (5 mL) and washed with water (10 mL). The organic phase was washed with brine (10 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a yellow foam. This crude product was purified by flash chromatography using hexanes/ether (8:2, v/v) to obtain acetate **50** (82.5 mg, 75%) as a white foam.

Acetate **50**: UV λ_{max} (log ε) (MeOH): 221 (4.41), 257 (4.21) nm. IR ν_{max} ($CHCl_3$): 3019, 2960, 1739, 1599, 1373, 1170 cm^{-1}. ^1H NMR δ: 1.07 (3H, s, C7-CH_3), 1.09 (3H, s, C7-CH_3), 1.71 (3H, brs, C9-CH_3), 1.86 (1H, d, J = 17, C8-H), 2.04 (1H, d, J = 17, C8-H), 2.15 (3H, s, O=C-CH_3), 2.33 (3H, s, Ar-CH_3), 2.53 (1H, dd, J = 10, 9, C6a-H), 3.37–3.45 (1H, m, C10a-H), 6.05 (1H, brs, C10-H), 6.67 (1H, dd, J = 9, 2.5, C6-H), 7.20–7.32 (4H, m, Ar-H), 7.54 (1H, d, J = 8, C1-H), 7.81 (2H, d, J = 8, C2′-H and C6′-H), 8.04 (1H, d, J = 8, C4′-H). MS m/z: 463 (M^+), 403, 388, 308, 248. High resolution mass measurement, calcd. for $C_{27}H_{29}NO_4S$: 463.1817; found: 463.1818. Anal. calcd. for $C_{27}H_{29}NO_4S$: C 69.96, H 6.30, N 3.02; found: C 69.56, H 6.32, N 2.88.

*10bα-(3-Indolyl)-5-(*p*-toluenesulfonyl)-7,7,9-trimethyl-5,6aα,-7,8,10aβ,10bα-hexahydroindeno[2,1-b]indole* **51**

To a solution of indolymagnesium iodide in dry ether (12 mL) and dichloromethane (4 mL) at 0–5°C under nitrogen was added a solution of acetate **50** (540 mg, 1.17 mmol) in ether (7 mL). After stirring for 17 h at 5°C, the reaction mixture was quenched with ammonium chloride (8 mL, sat. aq.) and extracted with dichoromethane (3×, 8 mL). The organic phase was washed with water (8 mL), brine (8 mL), dried over sodium sulfate, and evaporated *in vacuo* to yield a brown oil. Purification by flash chromatography using hexanes/ether (7:3, v/v) gave compound **51** (250 mg, 41%) as a white powder.

Compound **51**: mp 207–208°C (acetone/hexanes). UV λ_{max} (log ε) (MeOH): 226 (4.73), 270 (4.08) nm. IR ν_{max} ($CHCl_3$): 3470, 2960, 1650, 1370, 1170 cm^{-1}. ^1H NMR δ: 0.71 (3H, s, C7-CH_3), 1.06 (3H, s, C7-CH_3), 1.54 (3H, brs, C9-CH_3), 1.63 (1H, d, J = 17, C8-H), 1.79 (1H, d, J = 17, C8-H), 2.33 (3H, s, Ar-CH_3), 2.76 (2H, m, C6a-H and C10a-H), 5.87 (1H, brs, C6-H or C10-H), 5.94 (1H, brs, C6-H or C10-H), 6.97–7.30 (8H, m, Ar-H), 7.25 (1H, d, J = 8, Ar-H), 7.59 (1H, d, J = 8, Ar-H), 7.65 (1H, d, J = 8, Ar-H), 7.76 (2H, d, J = C2′-H and C6′-H), 7.90 (1H, brs, N-H). MS m/z: 520 (M^+), 403, 388, 365. High resolution mass measurement, calcd. for $C_{33}H_{32}N_2O_2S$: 520.2184; found: 520.2179

6-Oxo-7,7,9-trimethyl-5-trimethylsilylethoxymethyl-5,6,6aα,7,8,-10aβ-hexahydroindeno-[2,1-b]indole **53**

To a solution of *trans*-ketone **36** (31 mg, 0.12 mmol) in dichloromethane (4 mL) at 0°C under nitrogen was added sodium hydride (4.5 mg, 0.15 mmol, 80% dispersion in oil). After stirring at 0°C for 1 h, 2-(trimethylsilyl)ethoxymethyl chloride (SEM-Cl), (0.03 mL, 0.175 mmol) was added and the stirring was continued for 40 min. Water (2 mL) and ammonium chloride (4 mL, sat. aq.) were added and the mixture was extracted with dichloromethane (3×, 4 mL). The organic phase was washed with water (6 mL), brine (6 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a yellow liquid. The product was immediately purified by flash chromatography using hexanes/ether (9.7:0.3, v/v) to obtain *trans*-SEM-ketone **53** (43 mg, 93%) as a yellow oil. This product turned out to be very unstable so it was usually utilized without purification for the next reaction. IR ν_{max} (film): 2954, 1695, 1615 cm^{-1}. ^1H NMR δ: −0.1 (9H, s, Si-$(CH_3)_3$), 0.86 (2H, m, C4′-H), 1.10 (3H, s, C7-CH_3), 1.42 (3H, s, C7-CH_3), 1.72 (3H, brs, C9-CH_3), 1.93 (1H, d, J = 17, C8-H), 2.03 (1H, d, J = 17, C8-H), 2.79 (1H, d, J = 7, C6a-H), 3.52 (2H, m, C3′-H), 3.94 (1H, m, C10a), 5.61 (1H, d, J = 11.5, C1′-H), 5.69 (1H, d, J = 11.5, C1′-H), 6.23 (1H, brs, C10-H), 7.19 (1H, dd, J = 8, 8, Ar-H), 7.36 (1H, dd, J = 8, 8, Ar-H), 7.53 (1H, d, J = 8, Ar-H), 7.77 (1H, d, J = 8, Ar-H). MS m/z: 395 (M^+), 73.

6α-Hydroxy-7,7,9-trimethyl-5-trimethylsilylethoxymethyl-5,6α,-6aβ,7,8,10aβ-hexadroindeno[2,1-b]indole **54**

Method A

To a solution of SEM-*trans*-ketone **53** (29.4 mg, 0.074 mmol) in dry toluene (2.5 mL) at −78°C under nitrogen was added diisobutylaluminium hydride (DIBAL) (0.11 mL, 0.11 mmol, 1 M in hexane). After stirring for 1 h at −78°C, solid ammonium chloride (about 20 mg) was added. The temperature was raised to 0°C, then water (2 mL) and ammonium chloride (5 mL, sat. aq.) were added. Careful extraction with ether (4×, 5 mL) followed by washing with brine (15 mL), drying

over sodium sulfate, filtration, and evaporation *in vacuo* yielded a yellow oil, which was purified by flash chromatography using hexanes/ether (8:2, v/v) to give alcohol **54** (19.4 mg, 80% based on recovered ketone) and unreacted **53** (5.2 mg).

Method B

To a suspension of sodium hydride (13.6 mg, 0.45 mmol, 80% dispersion in oil) (prewashed twice with dry ether (1 mL) in dry tetrahydrofuran (1 mL) at 0°C under nitrogen), was added *trans*-ketone **36** (100 mg, 0.38 mmol) in dry tetrahydrofuran (1.5 mL). After stirring for 40 min, SEM-Cl (0.073 mL, 0.415 mmol) was added and the reaction stirred for 2.5 h at 0°C. Lithium aluminium hydride (about 36 mg, 1 mmol) was then added and, after 30 min at the same temperature, the reaction was quenched with ice (about 0.5 g), and sodium hydroxide (4 mL, 15% aq.). Exhaustive extraction with ether (5×, 5 mL) followed by washing with water/brine (10 mL, 1:1, v/v), brine (10 mL), drying over sodium sulfate, filtration, and evaporation *in vacuo* yielded a yellow oil. Purification by flash chromatography using hexanes/ether (8:2, v/v) furnished pure alcohol **54** (100.2 mg, 67% overall). UV λ_{max} (log ε) (MeOH): 230 (4.44), 280 (3.89) nm. IR ν_{max} (film): 3440, 2960, 1660 cm^{-1}. ^1H NMR δ: −0.07 (9H, s, $Si(CH_3)_3$), 0.81–0.90 (2H, m, C4′-H), 1.03 (3H, s, C7-βCH_3), 1.21 (3H, s, C7-αCH_3), 1.70 (3H, brs, C9-CH_3), 1.84 (1H, d, J = 17, C8-H), 2.03 (1H, d, J = 17, C8-H), 2.10 (1H, dd, J = 9, 9, C6a-H), 3.30 (1H, d, J = 9, Hz, O-H), 3.41 (1H, m, C10a-H), 3.46–3.58 (2H, m, C3′-H), 5.12 (1H, ddd, J = 9, 9, 2, C6-H), 5.41 (1H, d, J = 11, C1′-H), 5.58 (1H, d, J = 11, C1′-H), 6.15 (1H, brs, C10-H), 7.06 (1H, ddd, J = 8, 8, 1.5, Ar-H), 7.13 (1H, ddd, J = 8, 8, 1.5, Ar-H), 7.44 (1H, d, 8, C4-H), 7.57 (1H, d, J = 8, C1-H). MS m/z: 397 (M^+), 379, 73. High resolution mass measurement, calcd. for $C_{24}H_{35}NO_2Si$: 397.2437; found: 397.2443. Anal. calcd. for $C_{24}H_{35}NO_2Si$: C 72.50, H 8.87, N 3.52; found: C 73.00, H 9.00, N 3.24.

6α-Acetoxy-7,7,9-trimethyl-5-trimethylsilylethoxymethyl-5,6α,5aα,7,8,10aβ-hexahydroindeno[2-1-b]indole ***55***

Method A

To a solution of alcohol **54** (46.5 mg, 0.12 mmol) and *N*,*N*-dimethylaminopyridine (DMAP) (21.4 mg, 0.18 mmol) in dichloromethane (1.5 mL) at 0–5°C under nitrogen were added acetic anhydride (0.094 mL, 1 mmol) and triethylamine (0.147 mL, 1.05 mmol). The reaction mixture was stirred for 2 h at room temperature, then water (5 mL) and dichloromethane (5 mL) were added and the layers separated. The organic phase was washed with brine (5 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a yellow oil. This crude product was purified by flash chromatography using hexanes/ether (9.5:0.5, v/v) to obtain acetate **55** (44 mg, 86%) as a colorless oil.

Method B

To a suspension of sodium hydride (37.3 mg, 1.24 mmol, 80% dispersion in oil) (prewashed twice with dry ether (1 mL) in dry tetrahydrofuran (2 mL)) at 0°C under nitrogen was added *trans*-ketone **36** (300 mg, 1.13 mmol) in dry tetrahydrofuran (3 mL). The mixture was stirred for 40 min at 0°C, then 2-(trimethylsilyl)ethoxymethyl chloride (SEM-Cl) (0.22 mL, 1.24 mmol) was added. Stirring was continued at 0°C for 2.5 h and then the reaction mixture was cooled to −15°C. Diisobutylaluminum hydride (DIBAL) (2.26 mL, 2.26 mmol, 1 M in hexane) was added and after 1 h at −15°C acetic anhydride (0.32 mL, 3.4 mmol) was added dropwise. After stirring for 16 h at 0°C the reaction mixture was poured into sodium bicarbonate (10 mL, sat. aq.), followed by extraction with ether (3×, 10 mL). The organic phase was washed with brine (20 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a dark oil. This crude product was purified by flash chromatography using hexanes/ether (9.5:0.5 v/v) to obtain acetate **55** (250.1 mg, 50.3% overall).

Acetate **55**: UV λ_{max} (log ε) (MeOH): 227 (4.49), 280 (3.94) nm. IR ν_{max} (film): 2955, 1737, 1659 cm^{-1}. ^1H NMR (CD_3CN) δ: −0.09 (9H, s, Si-$(CH_3)_3$), 0.77–0.90 (2H, m, C4′-H), 1.04 (6H, s, C7-CH_3), 1.71 (3H, brs, C9-CH_3), 1.87 (1H, d, J = 17, C8-H), 2.04 (1H, d, J = 17, C8-H), 2.11 (3H, s, O=C-CH_3), 2.50 (1H, dd, J = 10, 10, C6a-H), 3.43 (2H, dd, J = 9, 9, C3′-H), 3.50 (1H, m, C10a), 5.29 (1H, d, J = 11, C1′-H), 5.33 (1H, d, J = 11, C1′-H), 6.18 (1H, brs, C10-H), 6.43 (1H, d, J = 10, C6-H), 7.10 (1H, brdd, J = 8, 8, Ar-H), 7.18 (1H, brdd, J = 8, 8, Ar-H), 7.46 (1H, d, J = 8, C4-H), 7.62 (1H, d, J = 8, C1-H). MS m/z: 439 (M^+), 379, 75, 73. High resolution mass measurement, calcd. for $C_{26}H_{37}NO_3Si$: 439.2542; found: 439.2549.

6β-(3-Indolyl)-7,7,9-trimethyl-5-trimethysilylethoxymethyl-5,6β,6aα,7,8,10aβ-hexahydroindeno[2,1-b]indole ***56***

To a solution of indolylmagnesium iodide (prepared as above) in dry ether (5.5 mL) and dichloromethane (1.6 mL) at 0–5°C under nitrogen was added a solution of acetate **55** (492 mg, 1.12 mmol) in dry ether (3.7 mL). The reaction mixture was stirred for 2.5 h at 0–5°C, then water (3 mL) and ammonium chloride (5 mL, sat. aq.) were added. After extraction with ether (2×, 10 mL), the organic phase was washed with sodium bicarbonate (10 mL, sat. aq.), brine (10 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a brown viscous oil. This crude product was purified by flash chromatography using hexanes/ethyl acetate (96.5:3.5, v/v) to furnish SEM-*trans*-yuehchukene **56** (201 mg, 36%) as a pale yellow foam. UV λ_{max} (log ε) (MeOH): 223 (4.7), 280 (4.14) nm. IR ν_{max} (film): 3414, 3055, 2952, 1657 cm^{-1}. ^1H NMR (CD_3CN) δ: −0.16 (9H, s, $Si(CH_3)_3$), 0.34 (3H, brs, C7-βCH_3), 0.44–0.73 (2H, m, C4′-H), 1.13 (3H, m, C7-α-CH_3), 1.67 (1H, d, J = 17, C8-H), 1.70 (3H, s, CH_3), 2.05 (1H, d, J = 17, C8-H), 2.70 (1H, dd, J = 11, 6, C6a-H), 3.05–3.32 (2H, m, C3′-H), 4.06 (1H, m, C10a-H), 4.78 (1H, d, J = 6, C6-H), 4.98 (1H, brd, J = 11, C1′-H), 5.19 (1H, d, J = 11, C1′-H), 6.25 (1H, brs, C10-H), 6.30–7.85 (9H, m, Ar-H), 9.15 (1H, brs, N-H). MS m/z: 496 (M^+), 481, 75. High resolution mass measurement, calcd. for $C_{32}H_{40}N_2OSi$: 496.2909; found: 496.2908. Anal. calcd. for $C_{32}H_{40}N_2OSi$: C 77.37, H 8.12, N 5.64; found: C 77.10, H 8.21, N 5.40.

6a-epi-*Yuehchukene* ***2***

To a solution of SEM-*trans*-yuehchukene **56** (46 mg, 0.093 mmol) in dry tetrahydrofuran (1 mL) at room temperature under nitrogen were added tetra-*n*-butylammonium fluoride (1.85 mL, 1.85 mmol, 1 M in tetrahydrofuran) and hexamethylphosphoramide (HMPA) (0.7 mL). The temperature was increased to 40–45°C and the reaction mixture was maintained at this condition for 1 day. Then a further portion of tetra-*n*-butylammonium fluoride (1 mL, 1 mmol, 1 M in the tetrahydrofuran) and hexamethylphosphoramide (0.6 mL) was added and the stirring at 40–45°C was continued for another day. Water (2 mL) and ammonium chloride (5 mL, sat. aq.) were added and the mixture was extracted with ether (3×, 6 mL). The organic phase was washed with brine, dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a yellow oil. This crude product was purified by flash chromatography using hexanes/ether (9:1, v/v) to obtain *trans*-yuehchukene **2** (30.2 mg, 89%) as a white foam. UV λ_{max} (log ε) (MeOH): 324 (4.63), 280 (4.03) nm. IR ν_{max} (film): 3400, 2920, 1655 cm^{-1}. ^1H NMR (CD_3CN) δ: 0.32 (3H, s, C7-βCH_3), 1.15 (3H, s, C7-αCH_3), 1.67 (1H, d, J = 17, C8-H), 1.69 (3H, s, C9-CH_3), 2.05 (1H, d, J = 17, C8-H), 2.69 (1H, dd, J = 10, 7, C6a-H), 4.01 (1H, brd, J = 10, C10a-H), 4.70 (1H, d, J = 7, C6-H), 6.26 (1H, brs, C10-H), 6.70–7.17 (6H, m, Ar-H), 7.29 (1H, dd, J = 7, 3, Ar-H), 7.34 (1H, d, J = 8, Ar-H), 7.66 (1H, brd, J = 8, Ar-H), 8.89 (1H, brs, N-H), 9.10 (1H, brs, N-H). MS m/z: 366 (M^+), 351, 142. High resolution mass measurement, calcd. for $C_{26}H_{26}N_2$: 366.2095; found: 366.2090.

10α-Methyl-6-oxo-5,6,7β,10β-tetrahydro-7β, 10β-(1-1-dimethylethano)-cyclohept[b]indole ***33***

To a solution of indole-acid **28** (400 mg, 1.41 mmol) in dry chloroform (70 mL) at room temperature under nitrogen was added polyphosphate ester (PPE) (1.5 mL). The reaction mixture was refluxed for 1 h, followed by cooling and addition of water (20 mL). The organic phase was then washed with sodium bicarbonate (25 mL, sat. aq.), water (25 mL), brine (25 mL), dried over sodium sulfate, filtered, and evaporated *in vacuo* to yield a viscous oil. The crude product was purified on a short silica gel column using hexanes/ether (8.5:1.5, v/v) to give pure ketone **33** (190 mg, 55%) as colorless prisms. UV λ_{max} (log ε) (MeOH): 237 (4.33), 314 (4.32) nm. IR λ_{max} (KBr): 3300, 3060, 2960, 1620, 1601 cm^{-1}. ^1H NMR δ: 1.00 (3H, s,

C1′-CH_3), 1.18 (3H, s, C1′-CH_3), 1.63 (1H, d, J = 15, C2′-H), 1.97 (3H, s, C10-CH_3), 2.01 (1H, d, J = 15, C2′-H), 3.29 (1H, d, J = 7, C7-H), 6.18 (1H, dd, J = 8, 7, C8-H), 6.45 (1H, d, J = 8, C9-H), 7.10 (1H, dd, J = 8, 6, Ar-H), 7.29 (1H, dd, J = 8, 6, Ar-H), 7.38 (1H, d, J = 8, Ar-H), 8.04 (1H, d, J = 8, Ar-H), 8.86 (1H, brs, N-H). MS m/z: 265 (M^+), 250, 237, 209, 181. High resolution mass measurement, calcd. for $C_{18}H_{19}NO$: 265.1466; found: 265.1465. Anal. calcd. for $C_{18}H_{19}NO$: C 81.48, H 7.22, N 5.28; found: C 81.39, H 7.40, N 5.24.

6α-Hydroxy-10-α methyl 5,6,7β,10β-tetrahydro-7β,10β-(1,1-dimethylethano)-cyclohept[b]indole ***59***

To a suspension of lithium aluminium hydride (29 mg, 0.76 mmol) in 5 mL of tetrahydrofuran at −40°C, the cooled solution of ketone **33** (200 mg, 0.75 mmol) in 5 mL tetrahydrofuran was added. The reaction was stirred for 1 h at −40°C. Then the reaction mixture was quenched with 1 mL of H_2O, warmed up to room temperature, diluted with water, and extracted with dichloromethane. The organic layer was dried with sodium sulfate, evaporated to dryness, and purified on a silica gel column using hexane/ether (8.5:1.5, v/v) to give unreacted ketone **33** (23 mg, 12%) and one alcohol **59** (142 mg, 71%). ^{1}H NMR δ: 1.06 (3H, s), 1.17 (3H, s), 1.55 (1H, d, J = 15), 1.08 (3H, s), 2.23 (1H, bs), 2.42 (1H, dd, J = 3, 6), 4.96 (1H, s), 6.18 (1H, dd, J = 6, 8), 6.26 (1H, d, J = 8), 7.02 (1H, dd, J = 6, 8), 7.09 (1H, dd, J = 6, 8), 7.31 (1H, d, J = 8), 7.87 (1H, *d*, J = 8), 8.42 (1H, b). MS m/z: 267 (M^+) (100%), 252, 234. High resolution mass measurement, calcd. for $C_{18}H_{21}NO$: 267.1623; found: 267.1620.

6β-(N-Indolyl)-10α-methyl-5,6,7β,10β-tetrahydro-7β,10β-(1,1-dimethylethano)-cyclohept[b]indole ***60***

To a solution of alcohol **59** (140 mg, 0.522 mmol), dimethylaminopyridine (77 mg, 0.626 mmol), and triethylamine (1.4 mL) in dichloromethane (12 mL) at room temperature under nitrogen was added benzoyl chloride (0.25 mL, 2.1 mmol). After 18 h of reflux, the reaction mixture was cooled to room temperature and water (30 mL) was added. The organic phase was washed with sodium bicarbonate (10% aq.) and water, dried over sodium sulfate, filtered, and evaporated to dryness to yield crude benzoate of the alcohol **59**. Then, without futher purification, the crude benzoate was dissolved in a mixture of dry ethyl ether (2 mL) and dichloromethane (1 mL), and added dropwise to a solution of indolylmagnesium iodide (for preparation, see Experimental for compound **29**) in a mixture of ethyl ether (3 mL) and dichloromethane (1 mL). After stirring for 2 h at 0–5°C and 2 h at room temperature, water (2 mL) and ammonium chloride (6 mL, sat. aq.) were added, followed by extraction with dichloromethane (3 × 10 mL). The organic phase was washed with water (15 mL), brine (15 mL), dried over sodium sulfate, filtered, and evaporated to yield a brown oil. Flash chromatography on silica gel employing hexanes/ether (8:2) as eluent gave 124 mg (64.5%, calcd. based on alcohol **59**) of the compound **60**, as white crystals; mp 124–124.5°C. ^{1}H NMR δ: 1.11 (3H, s), 1.30 (3H, s), 1.54 (1H, d, J = 12), 1.92 (3H, s), 2.05 (1H, d, J = 12), 2.73 (1H, dd, J = 8, 4), 5.57 (1H, dd, J = 8, 8), 5.99 (1H, d, J = 4), 6.31 (1H, d, J = 8), 6.34 (1H, d, J = 4), 6.64 (1H, d, J = 4), 7.0–7.3 (5H, m), 7.42 (1H, d, J = 8), 7.59 (1H, d, J = 6), 7.7 (1H, s, b), 7.93 (1H, d, J = 8). MS m/z: 366 (M^+), 250, 194. High resolution mass measurement, calcd. for $C_{26}H_{26}N_2$: 366.2096; found: 366.2107.

Appendix

X-ray crystallographic analyses of **36**, **60**·½ CH_2Cl_2, *and* **45**·C_3H_6O

Crystallographic data for the three compounds appear in Table 3. The final unit-cell parameters were obtained by least squares on the setting angles for 25 reflections with 2θ = 32.3–50.4° for **36**, 40.1–88.0° for **60**, and 80.2–94.0° for **45**. The intensities of three standard reflections, measured every hour of X-ray exposure time throughout the data collections, remained essentially constant for all three compounds. The data were processed[3] and corrected for Lorentz and polarization effects, and absorption for **60**·½CH_2Cl_2 and **45**·C_3H_6O (analytical method).

The structure analysis of **36** was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of E-statistics, the choice being confirmed by subsequent calculations. The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from E-maps and subsequent difference Fourier syntheses. The asymmetric unit of **60** contains one half of a dichloromethane solvate molecule (situated on a crystallographic twofold rotation axis), and the asymmetric unit of **45** contains an acetone solvate molecule. All non-hydrogen atoms (except for the carbon atom of the dichloromethane molecule in **60**·½CH_2Cl_2) were refined with anisotropic thermal parameters. Hydrogen atoms were fixed in idealized positions (C(sp^2)—H = 0.97, C(sp^3)—H = 0.98, N—H = 0.92 Å, $U_H \propto U_{bonded\ atom}$) except for **45**·$C_3H_6O$ where all hydrogen atoms except those associated with the acetone molecule were refined with isotropic thermal parameters. Neutral atom scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International Tables for X-ray Crystallography (23). A parallel refinement of the structure of **60**·½CH_2Cl_2 having the opposite polarity gave slightly higher residuals, the R_w factor ratio being 1.005. Final atomic coordinates and equivalent isotropic thermal parameters

[3]Computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

(U_{eq} = 1/3 trace of diagonalized *U*), bond lengths, and bond angles appear in Tables 2–4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, and measured and calculated structure factor amplitudes for the three structures are provided as supplementary material.[4]

Discussion of crystal structures

The crystal structure of compound **36** consists of centrosymmetric hydrogen-bonded dimers (N(1)—H(N)···O(2-*x*,-*y*,2-*z*), H···O = 2.00, N···O = 2.864(5) Å, N—H···O = 157°). The junction between the cyclohexene and cyclopentanone rings (at C(4)—C(8)) is *trans* (see Fig. 1).[5] The indole moiety is planar to within 0.030(7) Å. The five-membered C(2–4),C(9–10) ring has a slightly distorted C(4)-envelope conformation, and the C(4–9) cyclohexene ring has a semiplanar conformation with C(4) displaced from the approximate plane of the other five

[4]Supplementary material mentioned in the text may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6.

Tables of hydrogen atom coordinates, and of bond lengths and angles involving hydrogen atoms, have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

[5]The crystallographic atom numbering shown in Fig. 1, which differs from that shown in schemes above, is employed in this section. Atom labels in Tables 4–7 correspond to those in Fig. 1.

atoms of the ring (see Table 7). There is evidence of considerable steric strain at the junction of the two five-membered rings. The (N(1),C(3)]C(2)—C(10)[C(4),C(11)) grouping is significantly non-planar (maximum deviation from the mean plane is 0.091(6) Å) and there is substantial angular distortion about both C(2) and C(10) (see Table 6). The short C(2)—C(3) distance of 1.448 Å is indicative of conjugation between the indole and carbonyl groups, while the C(3)—C(4) bond of 1.528 Å is long for a $C(sp^2)$—$C(sp^3)$ single bond. The detailed molecular geometry reflects both steric and electronic effects but is generally as expected.

Compound **60** crystallizes as a hemi-dichloromethane solvate with the CH_2Cl_2 molecule situated on a crystallographic C_2 axis. The crystal structure consists of well-separated molecules of **60** and CH_2Cl_2, the shortest intermolecular distances between non-hydrogen atoms being N(1)···C(11)($1 - x$, $1/2 - y$, $1/2 + z$) = 3.44(1) Å. The molecule **60** consists of a substituted indolo[2,3-*b*]bicyclo[3.2.2]non-6-ene ring system (Fig. 1). The indole moiety fused to the bicyclic system is planar within 0.03(1) Å, and both the 1-indolyl substituent at C(3) and the C(4)–C(5)═C(6)–C(7) group are planar within experimental error. As expected, there is less strain at the junction between the fused indole moiety and the seven-membered ring(s) of the bicyclo[3.2.2.] nonene system in **60** than at the corresponding junction between two five-membered rings in **36**. Bond lengths and angles (Tables 3 and 4) are generally as expected, with steric lengthening of some bonds between substituted atoms (e.g., C(3)—C(4) = 1.557, C(7)—C(8) = 1.520, C(15)—C(16) = 1.574, and C(15)—C(18) = 1.568 Å).

The solid state structure of **45**·Me_2CO consists of molecules of **45** linked into infinite chains by N—H···O hydrogen bonds (N(2)—H(N2)···O(1)($x - 1/2$, $1/2 - y$,$z - 1/2$), H···O = 2.25(3), N···O = 2.974(2) Å, N—H···O = 144(2)°) and well-separated acetone solvate molecules. The junction between the cyclopentene and cyclohexene rings (at C(8)—C(13)) is *cis* (see Fig. 1). Within the central system of four fused rings, the five-membered heterocyclic ring has a distorted C(15)-envelope conformation, the cyclopentene ring has a C(8)-envelope conformation, the cyclohexene ring has a semiplanar conformation with C(12) displaced from the approximate plane of the other five ring atoms, and the C(1–6) aromatic ring is planar within experimental error. The 3-indolyl substituent at C(7) and the phenyl group at C(19) are planar to within 0.014(2) Å and experimental error, respectively. The geometry about N(1) is nearly planar, the bond lengths involving this atom being consistent with interactions of N(1) with the three adjacent π-systems (the C(1–6) aromatic ring, the carbonyl group, and the C(14)═C(15) double bond). The angle between normals to the N(1) coordination group and the C(19)-carbonyl group mean planes (usually near zero for amides) is 29°. A weak intramolecular C—H···O interaction may be at least partially responsible for this (C(14)—H(14)···O, H···O = 2.51(2), C···O = 2.913(3) Å, C—H···O = 107(2)°). The C(20–25) phenyl ring is twisted 43° out of the plane of the carbonyl group. Strain in the fused ring system is indicated by a 0.140(2) Å deviation of N(1) from the C(1–6) mean plane, a significant non-planarity about the C(14)═C(15) double bond, and the lengthening of several intra-annular bonds (C(6)—C(7) = 1.527, C(7)—C(8) = 1.566, C(8)—C(13) = 1.557, and C(12)-C(13) = 1.544 Å). Remaining aspects of the molecular geometry (Tables 5–7) are as expected.

^{13}C nuclear magnetic resonance spectra of 3,6-disubstituted pyridazines[1,2]

GOTTFRIED HEINISCH AND WOLFGANG HOLZER[3]

Institute of Pharmaceutical Chemistry, University of Vienna, Währinger Strasse 10, A-1090 Vienna, Austria

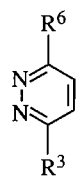
Received October 24, 1990

GOTTFRIED HEINISCH and WOLFGANG HOLZER. Can. J. Chem. **69**, 972 (1991).

The ^{13}C nuclear magnetic resonance spectra of 17 3,6-disubstituted pyridazine derivatives have been systematically analyzed. Chemical shifts and various $^{13}C,^{1}H$ coupling constants are reported. Attempts were made to correlate these data with results obtained from semiempirical molecular orbital calculations as well as with substituent electronegativities and Taft's substituent constants σ_I and σ_R^0.

Key words: 3,6-disubstituted pyridazines, ^{13}C NMR spectroscopy, $^{13}C,^{1}H$ spin coupling constants.

GOTTFRIED HEINISCH et WOLFGANG HOLZER. Can. J. Chem. **69**, 972 (1991).



On a fait des analyses systématiques des spectres de résonance magnétique nucléaire du ^{13}C de 17 pyridazines disubstituées en 3 et 6. On décrit les déplacements chimiques des carbones et quelques constantes de couplage entre ^{13}C et ^{1}H. On a essayé de trouver des corrélations entre ces résultats et les calculs semi-empiriques des orbitales moléculaire, les électronegativités des groupes substitués et les constants Taft σ_I et σ_R^0.

Mots clés : pyridazines 3,6-disubstituées, spectroscopie RMN du ^{13}C, constantes de couplage de spin $^{13}C,^{1}H$.

Introduction

Pyridazine derivatives continue to attract considerable attention due to a wide variety of interesting pharmacological activities observed (3). Most of the bioactive compounds so far investigated are characterized by a 3,6-substitution pattern and thus for their synthesis simple 3,6-disubstituted pyridazines of type **2**–**18** usually serve as appropriate starting materials. Many of these compounds were prepared several decades ago and only in some cases are there reports on selected ^{13}C nmr data (4–7), which, however, were obtained using different solvents and acquisition parameters. So far, a systematic investigation of ^{13}C chemical shifts and $^{13}C,^{1}H$ coupling constants of 3,6-disubstituted pyridazines has not been performed.

Here we report on the analysis of the ^{13}C nmr spectra of 17 simple 3,6-disubstitution products (**2**–**18**). Moreover, we attempt to correlate the data obtained with results derived from MO calculations (AM1) as well as with substituent electronegativities and Taft's substituent constants σ_I and σ_R^0.

Experimental

General

All nmr spectra were recorded in 5 mm sample tubes from DMSO-d_6 solutions (approximately 1 M) at 30°C on a Bruker AM 400 WB (operating frequency for ^{1}H: 400.14 MHz, for ^{13}C: 100.63 MHz) and (or) a Bruker AC 80 spectrometer (operating frequency for ^{1}H: 80.13 MHz, for ^{13}C: 20.15 MHz), both equipped with Aspect 3000 computers and standard software. The centre of the solvent peak was used as an internal standard, which was related to tetramethylsilane with 2.49 ppm for ^{1}H and 39.50 ppm for ^{13}C, respectively. ^{13}C chemical shifts were determined using the *J*-modulated spin-echo technique (8) with a decoupler switch-off delay of 6.9 ms for an average $^{1}J(^{13}C,^{1}H)$ coupling constant of 145 Hz and a relaxation delay of 6 s. According to the acquisition parameters used, the digital resolution here was 0.9 Hz/data point. ^{1}H-coupled ^{13}C nmr spectra with digital resolutions from 0.1 to 0.2 Hz/data point (acquisition times 5–10 s, spectral window and number of data points adjusted to obtain the desired digital resolution, pulse angle 51°, relaxation delay 6 s) were obtained using the gated decoupling mode. Heteronuclear decoupling experiments were carried out with single frequency CW irradiation of the appropriate proton resonance lines. ^{1}H chemical shifts and H,H coupling constants (needed for spin simulation) were derived from high-precision proton nmr spectra (digital resolution 0.1 Hz/data point) using exactly the same (concentrated) samples as for the acquisition of the coupled carbon spectra. Iterative analysis of all ^{1}H and ^{13}C nmr spectra was carried out with Bruker's PANIC spin-simulation program (a version of the well-known LAOCOON program); rms errors smaller than 0.05 Hz were obtained.

The ir spectra were recorded on a Jasco IRA-1 spectrophotometer. Mass spectra were obtained on a Varian MAT 311A instrument (70 eV), glc/ms analyses were performed on a Hewlett Packard 5890A/5970B-MSD (70 eV).

Melting points were determined with a Reichert–Kofler hot-stage microscope and are uncorrected.

MO calculations were carried out using the semiempirical AM1 method (9) as implemented in the AMPAC program package (10). All geometries were completely optimized without making any assumptions.

Materials

Pyridazine (**1**), 3,6-dichloropyridazine (**2**), 3-chloro-6-methoxypyridazine (**9**), 3,6-dihydroxypyridazine (**16**), 3-chloro-6-hydroxypyridazine = 6-chloro-3(2*H*)-pyridazinone (**17**), and 3-hydroxy-6-methylpyridazine = 6-methyl-3(2*H*)-pyridazinone (**18**) are commercially available (Aldrich). The following compounds were prepared according to reported procedures: **3** (11), **4** (12), **7**,[4] **10** (13), **11** (14), **12** (15), **13** (16), **14** (17), **15** (18).

The ^{1}H and ^{13}C nmr data for 3-chloro-6-iodopyridazine (**8**) (ms (*m/z*, %): 240, 242 (M^+, 100, 33), 152 (10), 127 (16), 85 (33); high-resolution ms: calcd. for M^+ (C_4H_2ClI): 239.895; found: 239.8947 ± 0.0024) were acquired from a sample contaminated with minor amounts of **2** (according to glc/ms analysis). This mixture was obtained following the procedure for the synthesis of 3,6-diiodopyridazine as given in ref. 12 (treatment of 3,6-dichloropyridazine (**2**) with NaI/HI in dry acetone) and subsequent column chromatography (silica gel, eluent: dichloromethane).

3,6-Di(phenylethinyl)pyridazine (6)

To a mixture of 500 mg (1.51 mmol) of 3,6-diiodopyridazine (**4**) (12) and 329 mg (3.22 mmol) of phenylacetylene in 10 mL of dry triethylamine, dimethyl sulfoxide was added dropwise until a clear solution was obtained. Then 22 mg (31 μmol) of bis(triphenylphosphine)palladium(II)chloride and 4 mg of copper(I) iodide were added and the mixture was stirred under Ar for 2 days. After removal of the solvents under reduced pressure, the residue was extracted several times with dichloromethane. The combined organic layers were washed with water, dried over anhydrous sodium sulfate, and evaporated. The remaining brown solid was subjected to column chromatography (silica gel, eluent: dichloromethane). Recrystallization from ethanol afforded 258 mg (61%) of straw-yellow crystals, mp 180–186°C (dec.); ir(KBr): 2220 (C≡C) cm^{-1}; ms (*m/z*, %): 280 (M^+, 37), 252 (26), 127 (11), 126 (100); high-resolution ms: calcd. for M^+ ($C_{20}H_{12}N_2$): 280.100; found: 280.1008 ± 0.003. For ^{1}H and ^{13}C nmr data see Tables 1, 2, and 4. Anal. calcd. for $C_{20}H_{12}N_2 \cdot 0.2H_2O$: C 84.60, H 4.40, N 9.87; found: C 84.70, H 4.56, N 10.14.

Results and discussion

^{13}C chemical shifts

In Table 1, chemical shift data of the parent pyridazine (**1**) and of the 3,6-disubstituted pyridazines **2**–**18** are given. The spectra were recorded from DMSO-d_6 solutions in order to achieve sufficient solubility for all compounds. Assignments of the chemical shifts of the ring carbon atoms were made using the *J*-modulated spin-echo sequence (8) to separate quaternary carbon atoms from those with attached protons.

Based on the chemical shifts for C-3 (C-6) in symmetrically disubstituted pyridazines **2**, **3**, **4**, **5**, and **16**, discrimination between C-3 and C-6 resonances of unsymmetrical pyridazine derivatives **8**–**13** and **17** could be achieved unambiguously. With compounds **14** and **18** the resonances of those carbon atoms bearing the methyl substituent could be assigned simply by taking into account the ^2J coupling between the side-chain protons and the ring carbon atom (see Table 4). A comparison of the chemical shifts (in DMSO-d_6) of the C-3 atoms in 3-methylpyridazine (159.69 ppm) and methyl 3-pyridazinyl ketone (155.55 ppm)[4] enabled us to also assign the resonances of C-3 and C-6 in compound **15**.

For most of the compounds under investigation in the present study, the ^{1}H chemical shifts were reported previously (compare refs. in Table 2; for reviews see refs. 22–24). The proton nmr data obtained using the same solutions as employed for recording the ^{13}C nmr spectra are summarized in Table 2. Selective heteronuclear decoupling experiments irradiating unambiguously assigned ^{1}H nmr lines finally enabled us to distinguish between the C-4 and C-5 resonances in all unsymmetrically 3,6-disubstituted compounds under investigation. In addition, with compounds **10**, **13**–**15**, and **18** bearing a methyl substituent, the assignments made could be confirmed on the basis of the $^3J(C,CH_3)$ coupling constant (see Table 4).

The observed substituent effects (Table 1) were found to follow general trends as known from the benzene or especially from the 2-pyridine series (32–34). Only with compounds **16**–**18** is the situation complicated due to hydroxypyridazine–pyridazinone tautomerism (6, 29, 31, 35). As found with compounds **10**–**12**, **14**, and **15**, the chemical shifts calculated by assuming the additivity of substituent effects (32) are in very good agreement with those observed. Ethyl 6-chloro-3-pyridazinecarboxylate (**12**) may serve as an illustrative example (see Fig. 1).

Since Spiesecke and Schneider (36), in 1961, reported a linear correlation between ^{13}C chemical shifts and local π-electronic densities for monocyclic $(4n + 2)$ π electron systems, the applicability of this relationship has been intensively investigated. Correlations of total charge densities (obtained from semiempirical MO calculations) and ^{13}C chemical shift values have also been attempted in the azine series (20, 37–42). Although in some cases close correlations were obtained, more recent reports (43) indicate that the results depend highly on the

9	4.1216	4.0964	4.1521	3.9372
10	4.0920	4.1237	4.1339	4.0763
13	4.1948	4.1024	4.1432	4.0639

MO method used. With compounds **1–5**, **8–10**, and **13**, an attempt to correlate the chemical shifts of the pyridazine carbon atoms with total charge densities (Table 3) obtained from AM1 calculations (9) met with a poor result (correlation coefficient when all carbon atoms are taken into consideration: −0.6120, slope of the correlation line: −118.67 ppm/electron).

Coupling constants

The coupling constants of the parent pyridazine and of 3,6-disubstituted derivatives **2–18** are summarized in Table 4.

All $^{13}C,^{1}H$ coupling constants follow from spin simulations (as mentioned in the experimental part) using X-approximation. Couplings over one and three bonds were assumed to be positive. In a few selected cases relative signs of coupling constants were determined via SPT or INDOR experiments. With the symmetrically substituted pyridazines **2–7** the vicinal H-4,H-5 coupling constants were derived from the ^{13}C satellite spectra. In these compounds the resonances of C-3 (C-6) were treated as parts of AA'X spin systems (X = ^{13}C), whereas the C-4 (C-5) lines were considered as parts of ABX systems due to a ^{13}C isotope effect (ca. 0.9 Hz upfield shift at 400 MHz spectrometer frequency) on the proton directly attached to the carbon-13.

In all unsymmetrically substituted compounds the carbon resonance lines were analyzed as parts of separate ABX three-spin systems or, in cases where additional couplings to methyl protons were observed, as ABY_3X systems (X = ^{13}C).

$^{1}J(^{13}C,^{1}H)$

The values of the one-bond carbon-proton coupling constants for C-4 and C-5 range from 165 to 180 Hz. A two-parameter correlation btween $^{1}J(^{13}C,^{1}H)$ and Taft's substituent constants

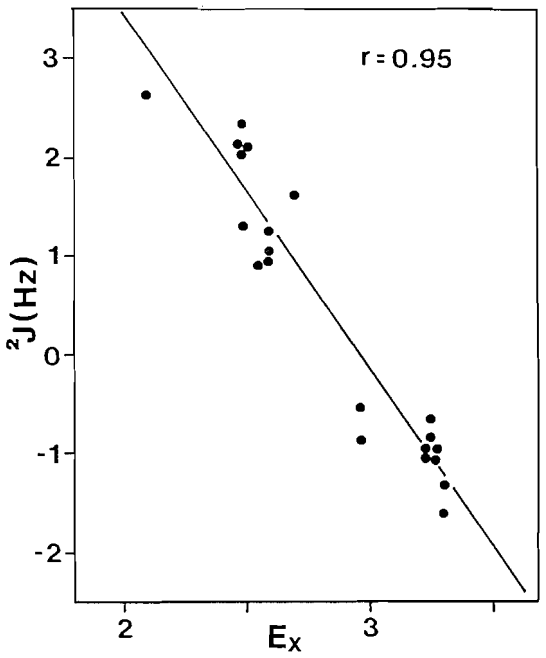

FIG. 2. Dependence of the geminal coupling constants C-3,H-4 and C-6,H-5 on the electronegativity E_x[5] of the substituents attached to the coupled carbon atom in pyridazines **1–5**, **8–15**.

σ_I and σ_R^0, as successfully applied in the benzene series (44), was attempted with symmetrical pyridazines **1–5**, **7**, and **16**, leading to the equation $^{1}J(^{13}C,^{1}H) = 168.40 + 28.44\sigma_I + 13.58\sigma_R^0$ and a satisfactory correlation ($r = 0.96$); values for σ_I and σ_R^0 were taken from refs. 45 and 46.

$^{2}J(^{13}C,^{1}H)$

The two-bond coupling constants C-3,H-4 or C-6,H-5, respectively, in the pyridazine derivatives studied have values ranging from −1.9 Hz to 2.7 Hz. It is well documented in the literature (refs. 32, pp. 470–472, and 44) that in benzoid compounds or heterocyclic aromatic systems $^{2}J(C,H)$ of the substituted carbon atom becomes more positive when the electronegativity of the substituent decreases. This trend is also observed with pyridazines **1–5** and **8–15** as shown in Fig. 2. As anticipated, the geminal coupling constants C-4,H-5 and C-5,H-4

[a]Assignments of ^2J(C-3,H-4) and ^3J(C-3,H-5) as given in ref. 21 have to be revised (see footnote 4).
[b]Obtained from the ^{13}C satellite spectrum.
[c]Because of collapsing lines the accuracy of the spin simulation is somewhat reduced.
[d]Not determined unequivocally.
[e]Signs not determined.
[f]^4J(H4,CH_3): 0.50[e] Hz.
[g]^4J(H4,CH_3): 0.44[e] Hz; ^5J(H5, $COCH_3$): 0.35[e] Hz.
[h]Compare footnote *b* in Table 1.
[i]^4J(H4,OH): 0.33[e] Hz.

(ranging from −1.0 Hz to 0.7 Hz) are only slightly affected by the electronegativity of a substituent attached to C-3 or C-6.

$^3J(^{13}C,^1H)$

The three-bond coupling constants C-3,H-5 and C-6,H-4 have values of 5.4–12.0 Hz and again there is a marked dependence on the electronegativity of the substituent attached to the coupled carbon atom. As expected, a parallel trend is observed with the vicinal coupling constants H-4,H-5 in 3,6-disubstituted pyridazines **2**–**18** (compare Table 4).

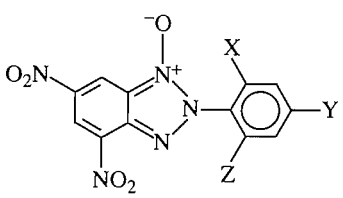
The course of the reactions of methoxide and *tert*-butoxide with 2-(2′,4′-dinitrophenyl)-4,6-dinitrobenzotriazole 1-oxide (**4**) clearly shows that the C-7 electrophilic site is significantly more reactive than the C-1′ site of the substrate. The reaction pathways of these alkoxides, which differ in basicity (as a measure of nucleophilicity) and steric bulk, were followed by 400 MHz ^{1}H nuclear magnetic resonance spectroscopy. While both alkoxides lead to immediate formation of the respective C-7 anionic σ-adducts, a greater percentage of C-7 adduct formation occurs with methoxide as attacking nucleophile. Reaction with excess alkoxide results in attack at C-1′ being observed, as well. This leads to formation of metastable C-1′ σ-adducts, whose rapid decomposition results in formation of 2,4-dinitrophenyl ethers and the dinitrobenzotriazole 1-oxyanion in an overall nucleophilic displacement reaction. Under these excess conditions, methoxide also causes a faster rate of displacement than does *tert*-butoxide as nucleophile. These results are discussed on the basis of the basicity of the nucleophiles, the relative electrophilicity of the positions in the substrate (C-7 versus C-1′), the steric hindrance involved in attack and in the resultant C-7 and C-1′ complexes, and in terms of an activation energy/reaction coordinate profile comparing the pathways for attack at the two electrophilic sites.

Key words: anionic σ-complexes, super-electrophiles, aromatic nucleophilic substitution (S_N Ar).



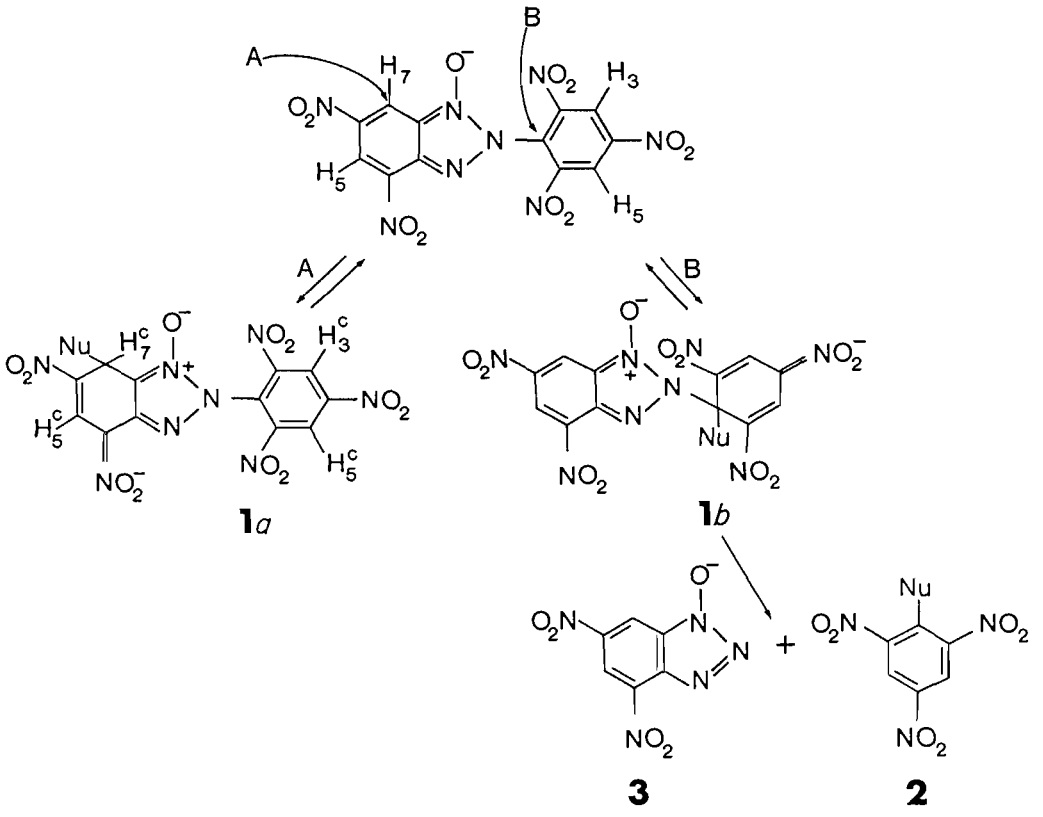
JULIAN M. DUST et ERWIN BUNCEL. Can. J. Chem. **69**, 978 (1991).

La nature des produits des réactions des ions méthylate et *tert*-butylate avec le 1-oxyde du 2-(2′,4′-dinitrophényl)-4,6-dinitrobenzotriazole (**4**) montre clairement que le site électrophile C-7 de ce substrate est beaucoup plus réactif que le site C-1′. Les voies réactionnelles de ces alcoolates, qui diffèrent tant par leur basicité (qui est une mesure de leur caractère nucléophile) que par leur encombrement stérique, ont été examinées par le biais de la résonance magnétique nucléaire du ^{1}H à 400 MHz. Alors que les deux alcoolates conduisent à la formation d'intermédiaires des adduits-σ anioniques en C-7, le pourcentage de formation d'adduit en C-7 est plus grand lorsque le méthylate agit comme nucléophile. Les réactions avec un excès d'alcoolate conduisent aussi à une attaque en position C-1′. Ceci donne lieu à la formation d'adduits-σ C-1′ métastables dont la décomposition rapide conduit à la formation d'éthers du 2,4-dinitrophénol et du 1-oxyanion du dinitrobenzotriazole provenant d'une réaction globale de substitution nucléophile. Lorsque les bases sont en excès, la vitesse de réaction du méthylate est aussi plus rapide que celle observés avec le *tert*-butylate. On discute de ces résultats en fonction de la basicité des nucléophiles, du caractère électrophile relatif des diverses positions du substrat (C-7 vs. C-1′), de l'empêchement stérique impliqué dans l'attaque et dans les complexes C-7 et C-1′ qui en résultent ainsi qu'en fonction d'un profil de l'énergie d'activation/coordonnées de la réaction permettant de comparer les diverses voies réactionnelles sur les deux sites électrophiles.

Mots clés : complexes-σ anioniques, super-électrophiles, substitution aromatique nucléophile (S_N Ar).

[Traduit par la rédaction]

We have been engaged in the study of the novel anionic σ-complexes (1) formed through the reactions of nucleophiles with the super-electrophile 2-nitroaryl-4,6-dinitrobenzotriazole 1-oxide series, **1**, **4**, and **5**, containing one or more electron-withdrawing NO_2 groups in the *N*-aryl moiety (2–5).



1 X = Y = Z = NO_2
4 Z = H, Y = Z = NO_2
5 X = Z = H, Y = NO_2

It has become clear that this family of electron-deficient heteroaromatic compounds have two sites available for reaction with nucleophiles, as illustrated on Scheme 1 for 2-(picryl)-4,6-dinitrobenzotriazole 1-oxide (Pi-DNBT, **1**): at C-7 of the benzotriazole 1-oxide moiety to yield a C-7 adduct, **1***a* (Path A), which is usually spectrally observable, and at C-1′ of the 2-nitroaryl ring to yield the displacement product, **2**, and the dinitrobenzotriazole 1-oxyanion, $DNBT^-$, as the anionic nucleofuge (**3**), via the metastable C-1′ adduct, **1***b* (Path B). For example, MeO^- reacts with **1** in accord with Scheme 1, but in the reaction of PhO^- as an ambident nucleophile, the C-7 adduct (formed via either oxygen or carbon centres) is not observed; only O-attack at the C-1′ position, accompanied by N-2:C-1′ bond scission, is found (2–4). With the other two members of the series, 2-(2′,4′-dinitrophenyl)-4,6-dinitrobenzotriazole 1-oxide (DNP-DNBT, **4**) and 2-(4′-nitrophenyl)-4,6-dinitrobenzotriazole 1-oxide (NP-DNBT, **5**), reaction with PhO^- showed marked differences from the behaviour found in the reaction with **1**. In these systems, C-7 adducts formed by the reaction of the *para* and *ortho* PhO^- carbon centres were observable, as well as the displacement products of O-centred attack at C-1′ of

SCHEME 1

the substrates, namely, the respective nitroaryl ether and **3** (5). The phenoxide carbon adducts of **4** and **5** were both formed in a 2:1 (*ortho*:*para*) ratio.

We had previously considered **1** to be a super-electrophile (6) of reactivity intermediate between that of the normal electrophile, 1,3,5-trinitrobenzene (TNB) (7, 8), and the super-electrophile, 4,6-dinitrobenzofuroxan (DNBF) (6, 9, 10), on the basis of its relative electrophilicity towards ethanethiol (2). The observation of the C-7 phenoxide C-adducts of **4** and **5** (in a statistical 2:1 *ortho*:*para* ratio) is a function not only of the high electrophilicity of the C-7 site but also of the decreased ratio of N-2:C-1′ bond cleavage exhibited by **4** and **5** as compared to **1**. This, in turn, is the result of the progressive decrease in electron-withdrawing power of the 2-nitroaryl ring that accompanies the decrease in the number of NO_2 groups attached to this ring. Thus, the C-7 site of all of the 2-nitroaryl-4,6-dinitrobenzotriazole 1-oxides is super-electrophilic, while the C-1′ site of these compounds displays conventional electrophilicity.

Interestingly, nmr spectral evidence was also found in the reaction of **4** with PhO^- for formation of a C-7 DNP-DNBT·OH^- adduct, **4***a*, generated from traces of water in the solvent (5).

Prompted by the interesting and variable behaviour found with PhO^- as compared to MeO^- (with **1** as substrate), and by **4** as compared to **1** (with PhO^- as ambident nucleophile), we have now extended our study to the reactions of **4** with two model alkoxides, ROK (R = CH_3 and $(CH_3)_3C$). These alkoxides represent a significant modulation in nucleophilicity as well as in steric bulk. Assuming, as an initial approximation, the common correlation of basicity and nucleophilicity (11), *tert*-butoxide (*t*-BuO^-) would be expected to exhibit enhanced nucleophilicity compared to methoxide (MeO^-) (12) in tandem with increased steric hindrance about the nucleophilic centre, based upon E_s, Taft's steric substituent constant (13).

The results we report herein will be discussed in terms of selectivity considerations and an activation energy/reaction coordinate profile. These approaches to the description of the various processes have proved useful in related systems (3–5).

Results

The reactions of **4** with the alkoxides (MeOK, *t*-BuOK) were monitored by 400 MHz ^1H nmr spectroscopy. Coupling constants (Hz) and chemical shifts (ppm) for all observed adducts are listed in Table 1. Integrals support the assignments made. Concentrations of these adducts could be determined at any given time by comparison of the integrals of these species to that for the singlet of 1,4-dibromobenzene (DBB) present in the reaction mixture in a known quantity (5). Spectral parameters are reported in Table 1.

Generally, reaction of **4** involves formation of: (a) the C-7 DNP-DNBT·OR^- adducts, **4***b* and **4***d*, (b) the products of N-2:C-1′ bond rupture formed through the unobserved C-1′ adducts, **4***c* and **4***e*, and (c) the C-7 DNP-DNBT·OH^- adduct, **4***a*. Furthermore, displacement of nitrite yields aromatic compounds that contain only a single NO_2 group. However, the presence of any or all of these products is dependent upon the concentration regime followed. Hence, the reactions of **4** were undertaken under several concentration regimes: equimolar and excess (2 and (or) 3 equivalents of ROK).

The alkoxides were prepared as high concentration solutions (1.4–4 M), by dissolution of metallic potassium in the parent alcohol. In this way the % ROH present in the $(CD_3)_2SO$ solvent never exceeded 10 mol% (in the 3 equivalent case) and was commonly less than 4 mol%. Reaction was initiated by injection of the appropriate amount of ROK (in ROH) into the nmr tube.

Reaction of 4 with MeOK

The initial spectrum (4 min) in the reaction of 1 equivalent of MeO^- with **4** (initial concentrations: ca. 0.023 M) contains

[e]Not fully resolved.

signals for the substrate, although these are diminished in intensity and broadened. We have previously attributed such broadness to the intervention of parallel free-radical (electron-transfer) reactions that are not involved in the main reaction pathway (5). Peaks for the C-7 DNP-DNBT·OMe$^-$ adduct, **4***b*, are noted at 3.293 (s, OCH_3), 5.959 (s, H_7^c), 8.186 (d, $H_{6'}^c$, J = 8.82), 8.762 (s, H_5^c), 8.782 (d, $H_{5'}^c$, J = 2.20), and 8.905 (d, $H_{3'}^c$, J = 2.20). In some well-tuned spectra the signals of the benzotriazole 1-oxide moiety, H_5^c and H_7^c, appear as doublets (J = 0.60). Note that the resonances attributable to H_5^c, should appear as a doublet of doublets (*ortho* and *meta* coupling) but only a doublet (*meta* coupling) can be observed; the remainder of the set of signals is partly obscured by the H_5^c singlet of **4***b* at 8.762.

No signals are seen under these conditions that can be assigned to the products of N-2:C-1′ bond scission via the C-1′ adducts, **4***c*; i.e., **3** and **6***a* are not visible.

At longer times or when the initial spectrum was acquired later (ca. 7 min) the foregoing peaks are joined by another partial set: ca. 5.9 (mostly obscured), 6.080 (d, 1H, J ca. 9), 8.135 (d, 1H, J ca. 9), and 8.672 (s, br, 1H). These signals are ascribable, in turn, to H_7^c, OH, $H_{6'}^c$, and H_5^c of the C-7 DNP-DNBT·OH$^-$ adduct, **4***a*. The remaining resonances are presumably hidden by the more intense signals for **4***b* or the broad signals due to **4**. The assignment of **4***a* can be made with certainty due to separate experiments with **4** and OH^-.[5] The longer time required for appearance of these signals is no doubt a result of the relatively low concentration of OH^- in the system.

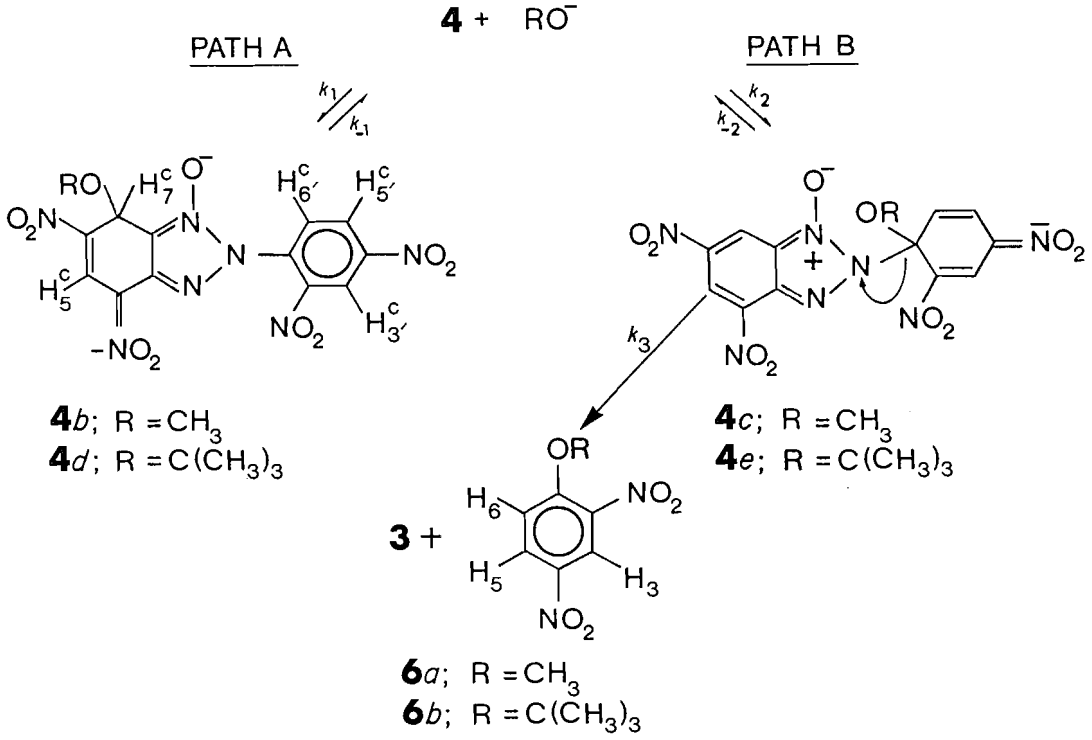
Necessary to the assignment of both **4***a* and **4***b* is the observation that the peaks due to these adducts disappear upon injection of trifluoroacetic acid (TFA). Simultaneously, the resonances due to **4** revert to almost their original intensity. This behaviour is in accord with the assignment of both **4***a* and **4***b* to oxygen-centred adducts since O-adducts are generally acid labile (ref. 1, pp. 454–457, and ref. 15), including those formed by substrates such as **1**, **4**, and **5** (2–5).

Addition of an excess of MeOK (3 equiv.) to an nmr tube (concentration of **4**: 0.022 M) results in the disappearance of the peaks due to **4** and concomitant appearance of the signals assignable to **4***b*. The resonances due to **4***a* are not observed although small peaks due to the cleavage products can be seen, notably the doublets at the anionic nucleofuge, **3**, at 8.725 and 8.720 (H_7 and H_5, J = 2.00).

[5]E. Buncel and R. A. Manderville. Unpublished data.

All peaks derived from the C-1′ adducts, **4***c*, intensify with time. At 3.5 h the peaks of 2,4-dinitroanisole (DNA, **6***a*) are clearly visible at 4.073 (s, OCH_3), 7.593 (d, H_6, J = 9.33), 8.533 and 8.509 (d, d, H_5, J = 9.33, 2.70); this assignment is verified by comparison with the spectrum of authentic DNA. The H_3 signal of DNA is buried beneath peaks due to **3**. Also at this time the spectrum has sharpened enough to permit a determination of the concentration of **4***b*: 0.020 M, i.e., **4***b* is formed in ca. 90% yield under these conditions.

Even so, other minor peaks can be discerned at 3.970 (s, 3H), 3.258 (s, 3H), 7.563 and 7.541 (d, d, J = 8.91, 2.71, partially obscured), 7.796 (d, 1H, J = 2.71), and 7.843 (d, 1H, J = 8.91). These peaks are consistent with the 1,2,4-trisubstituted benzene structure of 1,4-dimethoxy-2-nitrobenzene (DMN), where the signals at 3.258 and 3.970 are ascribable to the C-4 and C-1 methoxyls, respectively, and the peaks located at 7.563 and 7.541, 7.796, and 7.843 are due to H_5, H_3, and H_6, in turn.



The C-7 DNP-DNBT·OMe$^-$ adduct, **4***b*, is persistent under these conditions and declines in intensity slowly over the course of 57 h. During this time the peaks due to both **6***a* and DMN correspondingly increase in intensity, as do those due to the leaving group, **3**. Neither 2,4-dinitrophenol (or the derived aryloxide) nor the 1,1 DNA·OMe$^-$ adduct (17) appear at any time in the spectrum. The final spectrum does not contain any signals due to **4***a*.

Reaction of **4** *with* t-*BuOK*

As in the previous experiment, the spectrum obtained immediately after mixing the reagents (5 min) is broad and contains diminished peaks for **4**, under these equimolar conditions. The peaks can only be assigned with surety when the signals sharpen and resolve with time (ca. 1 h). The resonances attributable to the C-7 DNP-DNBT·OBut^- adduct, **4***d*, are as follows: 5.995 (s, H_7^c), 8.133 (d, $H_{6'}^c$, J = 8.79), 8.675 (s, H_5^c), 8.760 (d, d, $H_{5'}^c$, J = 8.79, 2.35), and 8.885 (d, $H_{3'}^c$, J = 2.35).

While **4***a* may be found in this reaction system, the evidence consists solely of one doublet at 6.072 (J = 7.55), which can be assigned tentatively to the OH of **4***a*.[5] The other resonances of **4***a* occur in the vicinity of the intense band attributed to **4***d* (Scheme 2). Significantly, not only the peaks of **4***d* disappear upon acidification but the doublet of the putative C-7 hydroxide adduct, **4***a*, as well, accompanied by intensification of the residual resonances of **4**. These observations are consistent with the assignment of **4***d* to an O-adduct since such adducts are acid-reversible (refs. 1, pp. 454–457, and 15).

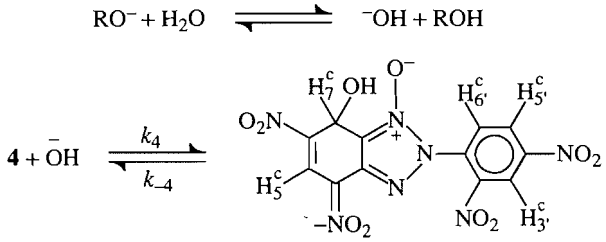
SCHEME 2

As in the reaction of MeO^-, no scission products derived from the C-1′ adduct, **4***e*, are noted during the period of monitoring (ca. 2 h). In contrast, a black viscous solution, devoid of interpretable peaks, results upon addition of 3 equivalents of *t*-BuOK to an nmr tube that contains **4**.

With 2 equivalents of the nucleophile the resonances due to **4** disappear completely and the peaks for **4***d* appear. Signals for **3** and the *tert*-butyl 2,4-dinitrophenyl ether **6***b* (8.159 (d, H_6, J = 8.89), 8.794 and 8.817 (d, d, H_5, J = 8.89, 2.51), and 8.920 (d, H_3, J = 2.51; *tert*-butyl singlet obscured)) are observed in the initial spectrum, but those due to **4***a* are not seen.



Even though the products of N-2:C-1′ bond rupture are recorded in the initial spectrum, the process of conversion of all of **4***d* into **3** and **6***b* is slow. In this regard, only **3** and a set of peaks indicative of a 1,2,4-trisubstituted benzene remain in the spectrum *acquired after 9 days*. These peaks correspond to the 2,4-dinitrophenoxide ion (generated in a control experiment by addition of a little KOH in H_2O to a $(CD_3)_2SO$ solution of the phenol): at 6.306 (d, H_6, J = 9.80), 7.779 and 7.758 (d, d, H_5, J = 9.80, 2.48), and at 8.591 (d, H_3, J = 2.48).

Unlike the other system studied, the DNP-DNBT/*t*-BuO^- reaction mixture does not appear to contain products ascribable to nitrite loss.

Discussion

Reaction pathways

There are interesting gradations in behaviour in the reactions of nucleophiles with the series of substrates **1**, **4**, and **5**. Whereas reaction of the alkoxides (MeO^-, *t*-BuO^-) at the C-7 position of **4** leads to formation of observable C-7 adducts, **4***b* and **4***d*, respectively, in a manner strictly comparable to the reaction of MeO^- with **1** via Path A (Scheme 1), these adducts are significantly more persistent than the analogous C-7 species formed by **1**, i.e., **1***a* (3, 4). This would appear to be a reflection of the overall decreased favourability of Path B for **4** relative to **1**, which coincides with removal of an electron-withdrawing nitro group from the 2-nitroaryl ring (5). This overwhelms the

4*a*

decreased favourability of Path A that might be expected as a result of decreasing the inductive electron-withdrawing power of the 2-nitroaryl moiety as it impinges on the remote C-7 position.

Interestingly, there is evidence for formation of **4***a*, the C-7 hydroxide adduct, in these systems. We have not noted comparable adduct formation in the related Pi-DNBT (2–4) or NP-DNBT (5) reaction systems. While this might be construed as indicative of an especial enhanced electrophilicity of the C-7 position of **4** as compared to **1** or **5**, it is more likely due to the relative concentration of nucleophile as compared to adventitious water present in the systems, as well as the relative basicities of the nucleophiles studied thus far.

With **1** as the substrate there is also the potential for reaction of the initially formed picryl ether with the nucleophile, particularly in those reactions where the nucleophile is present in excess. Picryl ethers react with alkoxides to form 1,1 and 1,3 isomeric adducts or either isomer alone (18, 19). In contrast the 2,4-dinitrophenyl ethers, generated through rupture of the N-2:C-1′ bond in the transient C-1′ adducts (**4***c* and **4***e*), do not appreciably react further with alkoxide under the reaction conditions to give observable adducts of **6***a* (or **6***b*) even when the alkoxide is initially present in excess.

The resultant 2,4-dinitrophenyl ethers, **6***a* (or **6***b*) (Scheme 2), do undergo further reaction, however. In the case of the *tert*-butyl 2,4-dinitrophenyl ether, **6***b*, reaction occurs at longer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

times to give rise to the 2,4-dinitrophenoxide ion, presumably via an elimination process involving *t*-BuO^-, OH^-, etc. Attack of OH^- directly on **4** to yield the hydroxide analog of **4***c* is less likely since it specifically requires OH^-, which is present in the DNP-DNBT/*t*-BuO^- system only in low concentration. (The C-7 hydroxide adduct, **4***a*, if present, is present below the limit of detection.) Further, nitrite displacement products may form in both DNP-DNBT/RO^- systems studied, although there is only compelling spectral evidence in the DNP-DNBT/MeO^- reaction. In this regard, it is likely that nitrite loss is only significant with MeOK as nucleophile.

Overall, then, the reaction pathways available to **4** in reaction with ROK are (a) attack at C-7 to give rise to persistent C-7 alkoxide adducts, **4***b* (or **4***d*) (and a minority of the C-7 hydroxide adduct, **4***a*) and (b) slow attack at C-1′ to give rise to unobserved C-1′ adducts, **4***c* (or **4***e*), which rapidly decay via N-2:C-1′ bond scission to form the appropriate 2,4-dinitrophenyl alkyl ether (**6***a* or **6***b*) and **3**, the anionic nucleofuge. These pathways are illustrated in Scheme 2.

Mechanism of nitrite loss

Loss of nitro groups from 1-X-2,4-dinitrobenzenes is well known (20) and also occurs in other related nitroarene systems (21, 22); nitro group displacement from an aromatic ring may even compete with S_NAr substitution in appropriate cases (23). Single electron transfer to an initially formed anionic σ-adduct to yield a radical (from which the nitro group is lost) has also been invoked as the central step in nitrite loss in a comparable system (24).

In the present study several observations are germane to determination of a possible mechanism. In considering the DNP-DNBT/MeO^- system, it is noteworthy that DMN, the nitrite displacement product, is seen only in conjunction with DNA, **6***a*, the immediate N-2:C-1′ scission product, and that DMN is not observed at all in the 1-equivalent experiment where **6***a* is also absent. Moreover, nitrite displacement from **4** prior to N-2:C-1′ bond rupture would yield a new substrate for which there is no nmr spectroscopic evidence. DMN may, therefore, derive from **6***a*. It is also significant that the nmr spectrum is sharp and well resolved even during the progressive increase in DMN concentration; nmr spectra are usually broadened even by low concentrations of paramagnetic species such as radicals (25, 26). Consequently, we favour a non-radical mechanism (in view of the sharpness of the nmr spectra), a mechanism that involves **6***a* as a possible precursor (27).

Kinetic description of pathways

With the exception of the mechanism for nitrite loss, Paths A and B (Scheme 2) essentially govern the reactivity of **4**. In consideration of Path A processes, the present evidence is in agreement with and emphasizes our previous assessment (5) that **4** is a super-electrophile that contains a C-7 centre of reactivity intermediate between comparable positions in TNB and DNBF (2–5). Consequently, immediately upon mixing, **4** is converted into the C-7 Meisenheimer adducts (**4***a*, **4***b*, and **4***d*), which decompose slowly. If OH^- and the alkoxides, MeO^- and *t*-BuO^-, were present in comparable and constant concentrations in the respective systems, the rate of disappearance of **4** would be described by:

$$[1] \quad -d[\mathbf{4}]/dt = k_1[\mathbf{4}][RO^-] + k_4[\mathbf{4}][OH^-] - k_{-1}[\text{C-7}] - k_{-4}[\mathbf{4}\text{a}]$$

where [C-7] refers to the concentration of the C-7 adducts, **4***b* or **4***d*. The derivation of eq. [1] further assumes that Path B does not intervene appreciably (*vide infra*). This would be a valid assumption only for the earliest portion of the equimolar experiments. Carried to its logical limit, observation of the system close to the time of mixing would yield simplified kinetic behaviour, where the reverse rate constants (k_{-1} and k_{-4}) could be ignored.

$$[2] \quad -d[\mathbf{4}]/dt = k_1[\mathbf{4}][RO^-] + k_4[\mathbf{4}][OH^-]$$

Equation [2] has the form of competitive second-order kinetic expressions (28) and, under the conditions outlined, could be used to evaluate the reactivity of each alkoxide towards the C-7 electrophilic centre, relative to hydroxide attack, i.e., give an estimate of the magnitude of k_1 as compared to k_4. It should be pointed out that the nmr experiment in DMSO-rich solvent may be a sufficiently fast observational technique to permit the application of eq. [2] to analysis of the RO^- systems. The related super-electrophile, DNBF, forms adducts with MeO^- and OH^- with equilibrium constants (K_{eq}) of the order of 10^{10} in the respective parent solvents (i.e., MeOH and H_2O) (29). While K_{eq} may be expected to be smaller for **4** than for DNBF (2–6), at the same time it is well recognised that for a given adduct the equilibrium constant for formation increases significantly with addition of DMSO to hydroxylic solvent; the increase in K_{eq} is the result primarily of an increase in the magnitude of the forward rate coefficient ($K_{eq} = k_f/k_r$) combined with a smaller decrease in the magnitude of the reverse rate coefficient (29). Thus, in the DMSO-rich solvent used in the present study, both k_1 and k_4 might be expected to be much greater than the corresponding constants for decomposition of the complexes back to **4** (i.e., k_{-1} and k_{-4}) and eq. [2] would be a reasonable kinetic description of the Path A part of the reaction in the period shortly after mixing.

Ideally, comparison of the initial concentrations of **4***a* relative to **4***d* or **4***b* would provide an assessment of the nucleophilicity of OH^- and RO^- towards the C-7 position of **4**. However, this analysis is hampered by the non-comparable initial concentrations of hydroxide ion and by the general broadness of the initial nmr spectra, which limits the accuracy of the determination of initial concentrations of the C-7 adducts.

If we consider Path B, the reaction of **4** with alkoxide to give the C-1′ adducts, **4***c* (or **4***e*) (Scheme 2), the inability to observe the C-1′ adducts in this or related reactions (2–5) suggests that the process of N-2:C-1′ bond scission is facile. This is also in agreement with the anticipated leaving group ability of **3**, a

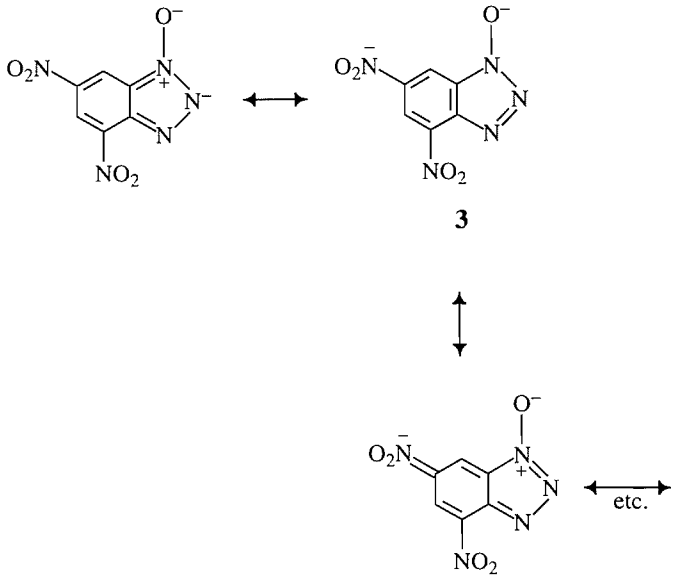

TABLE 2. The extent of formation of the C-7 DNP-DNBT·OR$^-$ adducts

Alkoxide; adduct	Time, min	% C-7 OR$^-$	% C-7 OH$^-$	% C-7[a]	pK_a^b	E_s^c
MeO$^-$; **4***b*	62	83.5	5.7	89.2	29.0	0.0

[c]Reference 13.

delocalized anion, as well as the steric congestion that is presumed to exist about the N-2:C-1′ bond in the C-1′ adduct. In consequence, we can expect that the rate constant associated with decomposition of the C-1′ adduct, k_3, is likely much larger than k_2, the rate constant assigned to formation of the C-1′ adduct; k_2 would likely be the rate-determining coefficient, since the C-1′ adduct once formed would presumably decompose to the displacement product, **6***a* (or **6***b*) and **3**, more readily than to starting material, **4**. In fact, the very slow rate of decomposition of C-7 adducts, **4***b* and **4***d*, indicates that in the early part of the reaction, shortly after mixing, Path B does not affect Path A.

Two general cases then arise from the later part of the reaction. First, the concentration of OH$^-$ may be significantly lower than that of either alkoxide. This appears to be reasonable in that **4***a* is seen only at longer times in both systems (>7 min after mixing) under equimolar conditions. The kinetic expression for the disappearance of the C-7 adducts is

$$[3] \quad -\mathrm{d[C\text{-}7]}/\mathrm{d}t = k_{-1}[\mathrm{C\text{-}7}] - k_1[\mathbf{4}][\mathrm{RO}^-]$$

where RO$^-$ represents either alkoxide.

If we further assume a steady-state concentration of the substrate, **4**, and rearrange to isolate the [**4**][RO$^-$] term, substitution into eq. [3] leads to

$$[4] \quad -\mathrm{d[C\text{-}7]}/\mathrm{d}t = (k_{-1}k_2)/(k_1 + k_2)[\mathrm{C\text{-}7}] + (k_1k_{-4})/(k_1 + k_2)[\mathbf{4}\mathrm{a}]$$

In the second case, the equilibrium between **4** and OH$^-$ might be ignored entirely. This appears to be a valid assumption in the reactions of **4** with an excess of alkoxide where **4***a* is not observed in the nmr experiments. In this case, the term involving **4***a* in eq. [4] can be removed and the equation simplifies to

$$[5] \quad -\mathrm{d[C\text{-}7]}/\mathrm{d}t = (k_{-1}k_2)/(k_1 + k_2)[\mathrm{C\text{-}7}] = k_{\mathrm{obs}}[\mathrm{C\text{-}7}]$$

Equations [1]–[5] also lack a term to account for OH$^-$ attack at C-1′ since the final product of such a reaction, 2,4-dinitrophenol (or the aryloxide), is only found in the DNP-DNBT/*t*-BuO$^-$ system where it likely arises from an elimination reaction involving the initially formed 2,4-dinitrophenyl *tert*-butyl ether, **6***b*.

In evaluating eq. [5] it is clear that both k_1 and k_{-1}, the rate constants that combine to give the equilibrium constant, K_1 (which governs the intrinsic stability of the C-7 alkoxide adducts), are important. Nor is it possible *a priori* to determine the trend in K_1 that would arise as the nucleophile is varied, since pK_a (as a measure of nucleophilicity) (12) and steric hindrance (13) run counter to each other in the series studied.

If attack at C-7 and C-1′ can be viewed as independent events then an estimate for k_{obs} should, theoretically, be obtained from the values for the individual rate constants for reaction of model systems. The rate constant for C-1′ attack could be estimated from the S_NAr reaction of 2,4-dinitrophenylimidazole or 2,4-dinitrophenylbenzpyrazole as suitable models. However, these data are not available from the literature. Moreover, simpler compounds such as 2,4-dinitrophenylpiperidine apparently undergo hydrolysis (as a model for alkoxide attack) via a displacement process involving a C-3 (or C-5) hydroxide adduct rather than the initial substrate (30). The central intermediate in this reaction is not the C-1 adduct, corresponding to **4***c* or **4***e* in Scheme 2, but a C-1,3,3 dianionic adduct. There is no nmr spectral evidence for a C-1,1,3 dianionic adduct or the precursor C-3′ (or C-5′) adduct(s) in the present study.

Similarly, an appropriate model for reaction at C-7 is lacking. DNBF is clearly more electrophilic than **4**, while TNB is less electrophilic than **4**, but we do not, as yet, have a quantitative measure for the reactivity of **4** relative to other electrophiles.

Further implications of eq. [5] will be examined below.

Selectivity considerations

The reactions of the 2-nitroaryl-4,6-dinitrobenzotriazole 1-oxides have proven to be amenable to analysis on the basis of qualitative selectivity arguments (3, 5). Selectivity (*S*) has been defined as the ratio of the forward rate constants for formation of the C-7 as compared to the C-1′ adduct, under selective equimolar conditions, i.e., $S = k_1/k_2$.

While the percentage of **4***b* (or **4***d*) formed reflects the stability (K_1) of the particular C-7 DNP-DNBT·OR$^-$ adduct and not just the relative tendency for RO$^-$ to react at the C-7 position, the ratio of the percentages of the two adducts formed (%C-7/%C-1′ = %C-7/%**3**) might serve as a guide to selectivity. This approach is modified by two general considerations. To the extent that reaction of OH$^-$ at C-7 of **4** prevents the reaction of RO$^-$ at that position, the percentage of **4***b* (or **4***d*) formed will be unduly low. More significantly, at the earliest moment at which the percentage of **4***b* (or **4***d*) can be accurately ascertained, **3** or **6***a* (or **6***b*), i.e., **4***c* (or **4***e*), are not observed. The cleavage reaction is very slow under 1 equivalent conditions. We have previously found the rate of cleavage to be slow in the DNP-DNBT/PhO$^-$ system as compared to the rate of cleavage in the reaction of **1** with PhO$^-$(5).

As Table 2 shows, the percentage of **4***b* formed at 62 min is 83.5% but the percentage of **4***d* formed at 67 min declines to 27.6%. This notable 3-fold decline in the percentage of the C-7 adduct produced would not be modified even if the percentages of **4***a* formed were *included* as a correction to the percentages of C-7 adducts found (Table 2). Clearly, attack at C-7 by *t*-BuO$^-$ is less favourable than attack by MeO$^-$. Other evidence from the related Pi-DNBT/MeO$^-$ and *t*-BuO$^-$ systems agrees with this assessment (31).

On the other hand, the excess nucleophile experiments offer some evidence about attack at C-1′ of **4**. Thus, with 3 equivalents of MeO$^-$, the scission reaction is observed to be complete within 56 h whereas with 2 equivalents of *t*-BuO$^-$ the comparable reaction *requires over 9 days*. These results suggest that the percentages of C-1′ adduct formed and, consequently, the mag-

For personal use only.

nitudes of k_2, decrease as the nucleophile is changed from MeO^- to t-BuO^-. In fact, there has been a 4-fold increase in the time taken for completion of the cleavage reaction and, hence, a 4-fold decrease in the reactivity of t-BuO^- towards C-1′ as compared to that of MeO^-.

Assuming the trend in reactivity of the nucleophiles towards C-1′ is preserved under the equimolar conditions, the combined results indicate that although k_1 declines for t-BuO^- as compared to MeO^-, k_2 declines to an even greater extent for t-BuO^-. Therefore, $S_{t\text{-BuO}^-}$ ($= k_1/k_2$) is greater than S_{MeO^-}. The less reactive nucleophile, t-BuO^-, has been the more selective; it reacts more readily at the C-7 position than at the C-1′ position, even relative to MeO^-.

In summary, in the equimolar nucleophile systems, t-BuO^- is more selective than MeO^-, although a higher percentage of the C-7 adduct is formed with MeO^- in comparison to t-BuO^-. It is apparent that attack at both C-7 and C-1′ positions is dominated by steric effects rather than by nucleophilicity, assuming pK_a (in DMSO) is a suitable measure of nucleophilicity. It is noteworthy that in a kinetic and equilibrium study of the reaction of a series of alkoxides (in the parent alcohols) with 1,3,5-trinitrobenzene Norris and Gan found that both the forward rate constants (k_f) and the equilibrium constant (K) for formation of the TNB·OBu-t^- adduct were smaller than the related constants for the addition of MeO^- to TNB to form the analogous complex (32). Ignoring any ion-pairing effects (33, 34), this constitutes further support for the view that selectivity in these electron-deficient systems is governed by steric factors.

Significantly, attack at C-1′ has not advanced appreciably at the moment of first observation of the systems, whereas the C-7 site is readily attacked by both RO^- and OH^-. Without doubt the C-7 position of **4** is super electrophilic compared to the C-1′ site.

Comparative energy profile

Kinetic eq. [5] adequately describes these reaction systems under the conditions of excess alkoxide or where formation and decomposition of **4***a* may be ignored. Since **4***a* may only serve as a reservoir for **4**, its formation and decomposition are peripheral to the overall course of the reactions. Therefore, eq. [5] will be taken as the appropriate description of the reaction systems.

Equation [5] can be rendered in the form of a comparative energy–reaction coordinate diagram. It is a prerequisite of the application of reactivity–selectivity arguments that the reactions should be described by the same energy profile (35, 36).

Figure 1 compares attack at the C-7 position (left-hand branch; Path A, Scheme 2) with attack at the C-1′ position (right-hand branch; Path B) as a function of the variation of the alkoxide. The Path A profile consists of the activation barriers associated with formation of **4***b* and **4***d*; the barrier for **4***b* is shown as lower than that for **4***d*, as a reflection of the expected steric hindrance to attack at C-7 for t-BuO^- as compared to MeO^-. This forward barrier corresponds to the rate constant k_1, for both alkoxides. By similar reasoning, **4***d* is presumed to be less stable than **4***b*; the tendency for t-BuO^- to leave from the C-7 adduct should be greater than for MeO^-, again on steric grounds. These qualitative considerations are derived from the observed selectivities for the alkoxides (*vide supra*), as well as our conclusion that the observed selectivity is a function primarily of steric factors.

The activation barriers associated with Path A are shown as lower than those of Path B, consistent with the super-electrophilicity of the C-7 position (2–5). In accord with the

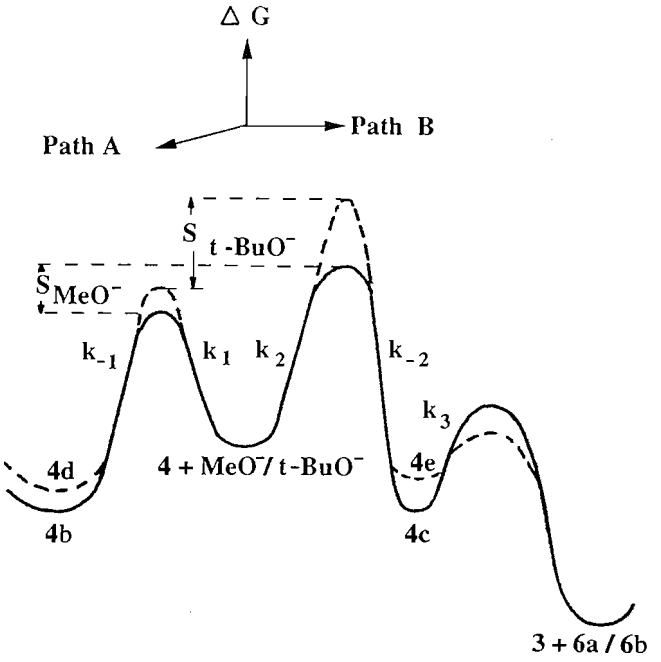

FIG. 1. Attack at C-7 of **4** is shown on the left-hand branch of the energy profile (Path A, Scheme 2) by MeO^- (solid line) and by t-BuO^- (dashed line). The right-hand branch represents attack at C-1′ of **4** (Path B) leading to formation of C-1′ adducts (**4***c* or **4***e*) as metastable intermediates. The selectivity, S, for the two nucleophiles is shown as the energy gap between the respective k_1 and k_2 activation barrier heights.

observed rates of disappearance of **4***b* (or **4***d*) when excess (2 or 3 equiv.) alkoxide was used, the initial barrier (k_2) for C-1′ attack (right-hand branch, Fig. 1) is shown as being significantly higher for t-BuO^- than for MeO^-. Conversely, congestion in the C-1′ adduct (**4***e* versus **4***c*) would presumably provide a driving force for decomposition of the C-1′ DNP-DNBT·OBu-t^- adduct to products (**3** and **6***b* versus **3** and **6***a*) relative to the C-1′ DNP-DNBT·OMe^- adduct. This is shown in the diagram (Fig. 1) as a reduced kinetic barrier for decomposition, i.e., k_3 is larger for **4***e* than for **4***c*.

The final products, the 2,4-dinitrophenyl ethers (**6***a* and **6***b*) and **3** are irreversibly formed and are stable. Since **3** is common to each of the alkoxide systems and since there is no spectral evidence to suggest a significant difference in stabilities of the ethers, the final state for each system is shown as having virtually the same energy. Similarly, Fig. 1 assumes that the initial states (**4** and MeO^- versus **4** and t-BuO^-) are of approximately the same energy. These simplifications permit a clear comparison of the energetics involved in these reactions and, on these grounds, might be justified. More importantly, the comparative energy profile also clearly shows that selectivity in these systems arises from the energy difference between the respective activation barriers for k_1 and k_2. This is illustrated in Fig. 1 by labelling the k_1 versus k_2 energy gap as $S_{t\text{-BuO}^-}$ or S_{MeO^-}. It is apparent from the diagram, then, that $S_{t\text{-BuO}^-}$ is greater than S_{MeO^-} even though the absolute energy barriers for MeO^- attack at either C-7 or C-1′ are individually lower than those for t-BuO^- attack at either of these sites. The energy gap that favours C-7 over C-1′ attack, however, is greater for t-BuO^- than for MeO^-. This is the source of the observed selectivity.

Finally, the comparative energy profile emphasizes that the C-7 position is the super-electrophilic site and is generally

favoured over the C-1′ site for nucleophilic attack in this system.

Conclusions

The present study clearly demonstrates the preference for attack by alkoxide nucleophiles at C-7 of 2-(2′,4′-dinitrophenyl)-4,6-dinitrobenzotriazole 1-oxide, **4**. In the reaction of **4** with MeO^- and *t*-BuO^-, the C-7 adducts, **4***b* and **4***d*, are more stable than the C-1′ adducts, **4***c* and **4***e*, respectively, since the latter possess a good leaving group, namely, the delocalized dinitrobenzotriazole 1-oxyanion, **3**. Reaction of **4** at the normal electrophilic position, C-1′, has been found to be quite slow, especially in comparison with attack at C-1′ of **1**.

The alkoxides exhibit significant selectivity, under equimolar conditions, in attack at the C-7 position over attack at the C-1′ site; a greater percentage of C-7 adduct formed with MeO^- than with *t*-BuO^-. Under excess alkoxide conditions, MeO^- also proved to be more reactive towards the C-1′ site than was *t*-BuO^-. The combined results show that *t*-BuO^-, the less reactive alkoxide, is the more selective in its preference for attack at the C-7 site. Reaction at both C-7 and C-1′ positions is controlled to a greater extent by steric hindrance (E_s) than by basicity (as a measure of nucleophilicity) of the attacking alkoxide.

The reactivity of **4** both as a normal and as a supernucleophile has been summarized with the aid of a comparative energy profile.

Experimental

Materials and equipment

$(CD_3)_2SO$ (Merck) was dried thrice sequentially with 4A molecular sieves prior to use. 1,4-Dibromobenzene (DBB, Eastman) was recrystallized twice from ethanol and dried *in vacuo* (<133.3 Pa). The purification of materials used and the method of preparation of **4** have been described in detail previously (5). Methanol (HPLC grade, Caledon) was purified by refluxing with and distillation from Mg turnings (37) and *tert*-butyl alcohol (HPLC grade, Caledon) was purified by similar treatment with CaH_2 (38). The respective alkoxides (MeOK, ca. 4 M; *t*-BuOK, ca. 1.4 M) were prepared from freshly cut potassium metal and the dry alcohol in a nitrogen-filled dry box. TRIS (tris(hydroxymethyl)aminomethane, Aldrich) was dried but otherwise used without purification. The ROK solutions were standardized against standard HCl, which had been previously standardized against weighed quantities of TRIS (39). 2,4-Dinitroanisole (DNA, **6***a*) was prepared by reaction of 2,4-dinitrochlorobenzene (Eastman) and MeOK in MeOH. Yield: 57%, mp 94–95°C (lit. (14) 94.5–95.5°C). The melting points were determined with a Thomas–Hoover melting point apparatus and are uncorrected.

The ^1H nmr experiments were carried out on a Bruker AM-400 spectrometer, operating at 400 MHz. Wilmad PP-507 nmr tubes were used in all experiments. Care was taken in assuring the cleanliness of the tubes; these were typically washed with acetone (2×), followed by MeOH (3×), followed by drying in an oven at ca. 90°C (12 h minimum), followed by thorough rinsing with CCl_4 (3–5×) and a final drying cycle at ca. 90°C. The routine adjustment of the spectrometer has been given before (5). All stock solutions and the nmr tubes were capped with rubber septa and all tubes were swept out with N_2 prior to the injection of reactants. All tubes were injected with a known volume of a stock DBB solution in $(CD_3)_2SO$ (0.1047 g, 0.443 M in 1.0 mL), which acted as an internal integration standard. CD_3COCD_2H served as the chemical shift standard (2.500 ppm relative to TMS).

*The ^1H nmr spectral characteristics of the substrates **1**, **4**, and **5***

Exact assignment of the peak positions for H_5 and H_7 in the substrates has only become possible recently. It previously appeared, on consideration of the proximity of the protons to the various nitro groups, that the doublet of **1** found at 9.454 should be assigned to H_7 and the doublet at 9.089 to H_5 of the substrate. However, the similarities in chemical shift for the full dinitrobenzotriazole 1-oxide series (**1**, **4**, and **5**) suggested that the reverse assignment held, i.e., that all of the substrate doublets that appear at ca. 9.1 be ascribed to H_5 of the substrates. The rationale here is that H_5 is more remote from the 2-nitroaryl ring and would be expected, on this basis, to be similar in chemical shift throughout the series. Moreover, the chemical shifts of the peaks of DNBF have recently been unambiguously assigned through isotopic labelled experiments (16). In $(CD_3)_2SO$ the H_5 doublet is found upfield of that for H_7; the H_5 doublet is located close to 9.0 ppm (16). The new assignments for H_5 and H_7 of the substrates, **1**, **4**, and **5**, are in agreement with the revised assignments for DNBF, a structurally related compound. Table 3 (below) lists the full spectral characteristics of the substrates; it supersedes any previous assignments of ^1H nmr parameters for this family (2–5).

*A representative nmr experiment: **4** and equimolar MeOK*

The DNP-DNBT stock solution (0.1329 M) was prepared by dissolution of a weighed quantity of **4** (0.2601 g; 6.649×10^{-5} mol) in $(CD_3)_2SO$ (0.50 mL). The initial spectrum was obtained from a sample consisting of $(CD_3)_2SO$ (400 μL), **4** (85 μL), and DBB (5 μL for a concentration of 4.52×10^{-3} M). The purity of the starting material having been confirmed by the first spectrum, 1 equivalent of MeOK (4 μL of 2.991 M MeOK in MeOH for a final concentration of MeOK of 0.0242 M and of **4** of 0.0229 M, a ratio of 1.06:1) was injected into the nmr tube. The FID (32 transients) was collected within 4 min of mixing the reagents. In later spectra 64–128 transients per FID sufficed to obtain the spectra reported herein. Spectra were recorded at various intervals, typically in rapid succession initially and then with greater periods between acquisitions.

Spectra were plotted from 4200 to 0 Hz and replotted from 3850 to 2050 Hz at a higher peak amplitude. Computer printouts of the chemi-

Hexachlorotellurate(IV) hydrolysis equilibria in hydrochloric acid. Measurement by Raman and ^{125}Te NMR spectroscopy and a reconsideration of earlier spectrophotometric results

J. B. MILNE
Department of Chemistry, University of Ottawa, Ottawa, Canada K1N 6N5
Received November 9, 1990

J. B. MILNE. Can. J. Chem. **69**, 987 (1991).

Solutions of TeO_2 (0.001 M) in HCl over a range of concentrations are shown to contain $TeCl_2(OH)_2$ in addition to $TeCl_6^{2-}$ and $TeCl_4(OH)^-$. The hydrolysis constants for $TeCl_6^{2-}$ and $TeCl_4(OH)^-$ have been determined from a reconsideration of earlier UV-visible spectrophotometric results (1)

$$TeCl_6^{2-} + H_2O = TeCl_4(OH)^- + HCl + Cl^-$$
$$K_1 = 3.78\ (\pm\ 0.01) \times 10^4\ M^3$$
$$TeCl_4(OH)^- + H_2O = TeCl_2(OH)_2 + HCl + Cl^-$$
$$K_2 = 456\ (\pm\ 24)\ M^3$$

The hydrolysis constants have also been determined by quantitative Raman spectroscopy ($K_1 = 2.21\ (\pm\ 0.16) \times 10^4\ M^3$; $K_2 = 442 \pm 57\ M^3$). The agreement between K_2 determined by the two methods is good but K_1 from spectrophotometry is much larger than that from Raman studies. This disagreement is attributed to ion-pairing which will be significant at the concentration at which the Raman measurements were made ($c(TeO_2) = 0.50$ M). The hydrolysis constant for $TeCl_6^{2-}$ was also determined from the ^{125}Te NMR spectra of TeO_2/HCl solutions, which consisted of one signal, indicating rapid Te exchange between all species. The hydrolysis constant, determined in this way ($K_1 = 1.92\ (\pm\ 0.07) \times 10^4\ M^3$) was also low compared to that determined from spectrophotometry.

Key words: solution, equilibria, tellurium, hydrochloric acid, Raman spectroscopy, ^{125}Te NMR spectroscopy, UV–visible spectrophotometry.

J. B. MILNE. Can. J. Chem. **69**, 987 (1991).

Il est montré que les solutions de TeO_2 (0,001 M) dans l'HCl contiennent $TeCl_2(OH)_2$ en plus de $TeCl_6^{2-}$ et $TeCl_4(OH)^-$. On a réexamine les résultats spectrophotométriques rapportés plus tôt (1) et à partir de ces données on a déterminé des ceux les constantes d'hydrolyse de $TeCl_6^{2-}$ et $TeCl_4(OH)^-$.

$$TeCl_6^{2-} + H_2O = TeCl_4(OH)^- + HCl + Cl^-$$
$$K_1 = 3{,}78\ (\pm\ 0{,}01) \times 10^4\ M^3$$
$$TeCl_4(OH)^- + H_2O = TeCl_2(OH)_2 + HCl + Cl^-$$
$$K_2 = 456\ (\pm\ 24)\ M^3$$

Les constantes d'hydrolyse ont été aussi determinées en faisant appel à la spectroscopie Raman quantitative ($K_1 = 2{,}21\ (\pm\ 0{,}16) \times 10^4\ M^3$; $K_2 = 442 \pm 57\ M^3$). L'accord entre le K_2 evalué par les deux méthodes est bon, mais le K_1 évalué par le spectrophotométrie est plus grand que celvi évalué par la spectroscopie Raman. Ce désaccord est attribué à la formation de paires d'ions qui sont importantes aux concentrations utilisées pour mésurer les spectres Raman ($c(TeO_2) = 0{,}5$ M). La constante d'hydrolyse de $TeCl_6^{2-}$ a aussi été évaluée en faisant appel à la spectroscopie RMN du ^{125}Te sur des solutions de TeO_2 dans le HCl. Les spectres montrent une seule bande qui indique l'échange rapide de Te. La constante d'hydrolyse, évaluée par la spectroscopie RMN ($K_1 = 1{,}92\ (\pm\ 0{,}07) \times 10^4\ M^3$) est aussi basse comparée à celle évaluée par la spectrophotométrie.

Mots clés: solution, équilibres, tellure, acide chlorohydrique, spectroscopie Raman, spectroscopie de RMN de ^{125}Te, spectroscopie électronique.

Introduction

A previous study of the equilibria, involving chlorotellurate(IV) species formed in hydrochloric acid, showed that besides hexachlorotellurate(IV), $TeCl_6^{2-}$, two other chlorotellurates were formed depending on HCl concentration, tetrachlorotellurate(IV), $TeCl_4(OH)^-$, and another species thought to be a monochlorotellurate(IV) (1). The $TeCl_6^{2-}$ hydrolysis constant for the formation of the $TeCl_4(OH)^-$ ion could not be evaluated and this was attributed to a significant variation in the activity coefficient factor over the range of HCl concentration studied. A reconsideration of this problem is occasioned by the successful treatment of equilibria involving Se(IV) species in hydrohalic acids (2, 3). This represents an extension of previous work concerning the complexes of tellurium (4).

Experimental section

Solutions were prepared from TeO_2 (Aldrich) and hydrochloric acid (J. T. Baker). Spectrophotometric measurements were made on a Varian DMS 90 UV–visible spectrophotometer, using 1 mm path length quartz cells. Quantitative Raman measurements were made as described earlier (5). Standard perchloric acid solution spectra were run before and after each TeO_2/HCl solution spectrum. The normalization assumption was that the 925 cm^{-1} band in 1 M perchloric acid has an area intensity of 6.45 cm^2. Spectra were run at 25 ± 0.1°C. The ^{125}Te NMR spectra were measured with a Varian XL-300 spectrometer operating at 94.745 MHz. All shifts were measured by sample replacement, using 1 M $Te(OH)_6$ in D_2O as standard. The signal of this standard is 712 ppm less shielded than dimethyl tellurium (6). Signal drift was negligible in the time required for the measurements. The HCl and water activites were taken from refs. 8 and 9.

Results and discussion

Spectrophotometry

Previous work (1) showed that the first hydrolysis step for the $TeCl_6^{2-}$ ion in 7–9 M hydrochloric acid solution is to the $TeCl_4(OH)^-$ ion. This is governed by the equilibrium constant,

$$[1] \quad K_1 = \frac{[TeCl_4(OH)^-][Cl^-]a(HCl)^2}{[TeCl_6^{2-}]a(H_2O)} \frac{y(TeCl_4(OH)^-)y(Cl^-)}{y(TeCl_6^{2-})}$$

The $y(X)$ represents the molar activity coefficient of X. It should be noted that $a(HCl)$ represents the mean molar ionic activity and not the overall activity for hydrochloric acid and, therefore, must be squared in eq. [1]. This was not done in the previous TeO_2/HCl work (1) and explains why K_1 could not be calculated. The identification of the second hydrolysis species will also be affected by this correction. New spectrophotometric measurements have been made and the absorbances at 375 and 295 nm for 0.001 M TeO_2 solutions in 2.5–10.0 M HCl solutions are listed in Table 1.

Moderate HCl concentrations (6.5–10.0 M)

From the extinction coefficient for $TeCl_6^{2-}$, $\epsilon_{375}(TeCl_6^{2-})$ (= 2820 mol^{-1} L cm^{-1}),[1] the concentration of $TeCl_6^{2-}$ may be calculated and that of $TeCl_4(OH)^-$, determined by difference (1). The concentrations of these ions are given in Table 2. The activity coefficient factor is essentially unity as calculated from the Debye–Hückel equation (8). From eq. [1], a plot of log $\{[TeCl_6^{2-}]/\{[TeCl_4(OH)^-][Cl^-]\}\}$ against log $\{a(HCl)/\sqrt{a(H_2O)}\}$ should give a straight line of slope 2 and intercept log K_1. Such a plot is shown in Fig. 1. The limiting slope is 2.0 and from the intercept, the first estimate of K_1 is 3.47 (± 0.01) × 10^4 M^3.

Low HCl concentrations (2.5–4.5 M)

From K_1, it may be shown that 3% or less of the total Te(IV) concentration (0.001 M) is present as $TeCl_6^{2-}$ at HCl concentrations of 4.5 M or less. A comparison of the change in absorbance at 295 and 375 nm with changing c(HCl) (6.5–10.0 M) shows that both the $TeCl_6^{2-}$ and $TeCl_4(OH)^-$ ions absorb at 295 nm. In the range of c(HCl) from 2.5 to 4.5 M, the shoulder at 295 nm is a prominent feature of the spectra due to the

[1]The absorbances and extinction coefficients reported previously (1) were for a 1 mm path length and are therefore one tenth of the values given here.

[d]Reference 8.

presence of $TeCl_4(OH)^-$. The absorbances at 295 nm for c(HCl) in the range 2.5 to 5.0 M are given in Table 3. As c(HCl) decreases, the absorbance at 295 nm, A_{295}, decreases, reflecting the decreasing concentration of $TeCl_4(OH)^-$, which is in equilibrium with a third Te(IV) species. A preliminary calculation of formation constants for various possible Te(IV) species, which could arise from hydrolysis of $TeCl_4(OH)^-$ (ignoring $[TeCl_6^{2-}]$) revealed that the constant varied least over the 2.5–4.5 M HCl range for the formation of a dichlorotellurate(IV). Species considered for this preliminary treatment were $TeCl_3O^-$, $TeCl_3(OH)$, $TeCl_2O$, $TeCl_2O(OH)^-$, $TeCl_2(OH)_2$, $TeCl_2(OH)_3^-$, $TeCl_2O_2^{2-}$, $TeClO_2^-$, $TeClO(OH)$, and $TeClO(OH)_2^-$. Equilibria involving more highly aquated species with the same Te/Cl ratio would differ little in the dependence on c(HCl) from those considered. The best preliminary fit to the data was found for $TeCl_2(OH)_2$ (K_2 = 328 (± 34) M^3).

The Raman spectra of solutions of TeO_2 in hydrochloric acid (1) indicate the presence of two Te(IV) species, $TeCl_6^{2-}$ and $TeCl_4(OH)^-$, at moderate HCl concentrations and a third species formed at low c(HCl) ($c(TeO_2)$ = 0.5 M; c(HCl) = 3–5 M). This third species exhibits a TeCl stretching band at 280 cm^{-1} and a broad TeO stretching band at 685 cm^{-1}, which is characteristic of TeO single bonding (7) and is consistent with the formation of $TeCl_2(OH)_2$. Other Te(IV) species such as $TeCl_2O$ and $TeCl_2O(OH)^-$ are not consistent with the Raman spectra. Neither of these latter two species, nor the $TeCl_2(OH)_3^-$ anion, fits the spectrophotometric data as well as $TeCl_2(OH)_2$.

A more accurate calculation of K_2 from the spectrophotometric results is obtained if the contribution of $TeCl_6^{2-}$, which is present in low concentration but has a high extinction coefficient at 295 nm, is allowed for. The calculation is made from the expression for K_1 (eq. [1]), that for K_2,

$$[2]\quad K_2 = \frac{[TeCl_2(OH)_2][Cl^-]a(HCl)^2}{[TeCl_4(OH)^-]a(H_2O)} \frac{y(TeCl_2(OH)_2)y(Cl^-)}{y(TeCl_4(OH)^-)}$$

the mass balance, and the expression for total absorbance

$$[3]\quad A_{295} = \epsilon_{295}(TeCl_6^{2-})[TeCl_6^{2-}] + \epsilon_{295}(TeCl_4(OH)^-)[TeCl_4(OH)^-] + \epsilon_{295}(TeCl_2(OH)_2)[TeCl_2(OH)_2]$$

The value of $\epsilon_{295}(TeCl_6^{2-})$, determined from the absorbance of the 10 M HCl solution in Table 1, is 11290 mol^{-1} L cm^{-1} and that of $\epsilon_{295}(TeCl_4(OH)^-)$, as calculated from the absorbance of the 8.0 and 8.5 M HCl solutions in Table 1, where interference from $TeCl_2(OH)_2$ would be least, is 3065 (± 5) mol^{-1} L cm^{-1}. The equilibrium constant, K_2, was determined by choosing the value of $\epsilon_{295}(TeCl_2(OH)_2)$, which gave the minimum variation in K_2 for all c_{HCl} from 2.5 to 4.5 M. The activity coefficient factor was assumed to be unity. The choice of $\epsilon_{295}(TeCl_2(OH)_2)$ = 190 mol^{-1} L cm^{-1} gave the values listed in Table 3 for which K_2 = 461 ± 23 M^3.

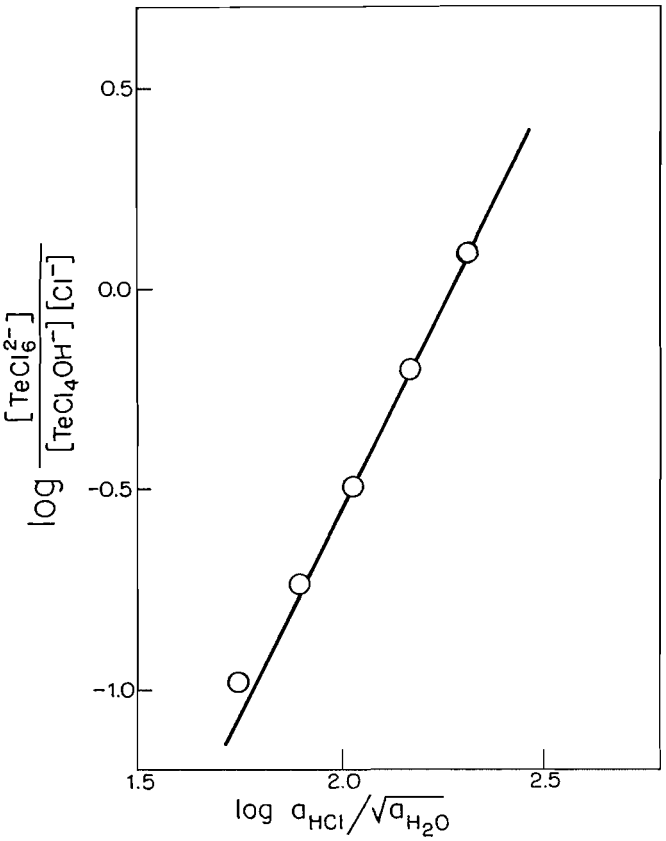

FIG. 1. Plot for the evaluation of K_1 from spectrophotometric results (see text).

To achieve an optimum fit to the observed absorbances over the entire HCl concentration range, it was necessary to allow for a small absorbance at 375 nm due to the $TeCl_4(OH)^-$ ion. From A_{375} at c_{HCl} = 5.0 and 6.0 M, $\epsilon_{375}(TeCl_4(OH)^-)$ was estimated

[a] $c(TeO_2) = 0.50$ M.
[b] Estimated precision = ±3%.
[c] $K_1 = 2.21 (\pm 0.16) \times 10^4$ M^3.
[d] $K_2 = 442 (\pm 57)$ M^3.

to be 140 ± 57 mol^{-1} L cm^{-1}. A new plot of the moderate HCl concentration data with this correction gave a slope of 2.0 and $K_1 = 3.78 (\pm 0.01) \times 10^4$ mol L^{-1}. Recalculation with the low c_{HCl} data, using this value of K_1, gives the best value for $K_2 = 456 \pm 24$ M^3 at $\epsilon_{295}(TeCl_2(OH)_2) = 190$ mol^{-1} L cm^{-1}.

From K_1, K_2, and the extinction coefficients, the concentrations of all Te(IV) species at various c_{HCl} and A_{295} and A_{375} can be calculated. These are listed in Table 1. Agreement between calculated and observed absorbances is good and equilibria in solutions of TeO_2 in HCl are best described in terms of the species $TeCl_6^{2-}$. $TeCl_4(OH)^-$, and $TeCl_2(OH)_2$.

Raman spectroscopic determination of K_1 *and* K_2

The Raman spectra of solutions of 0.5 M TeO_2 in hydrochloric acid of various concentrations have been reported earlier (1). Normalized scattering intensities for the TeO stretching modes of $TeCl_2(OH)_2$ and $TeCl_4(OH)^-$ ion at 650–90 cm^{-1} over a range of c_{HCl} (3.0–10.0 M) are listed in Table 4. The hydrolysis constant, K_1, may be evaluated from the data for 7.0–10.0 M HCl solutions, using the mass balance equations for Te(IV) and HCl, the expression for K_1 (eq. [1]), the charge balance, and the scattering intensity relation,

$$[4] \quad [TeCl_4(OH)^-] = i_{650}/I_{650}(TeCl_4(OH)^-)$$

where i_{650} represents the measured normalized scattering intensity at 650 cm^{-1} and $I_{650}(TeCl_4(OH)^-)$, the molar scattering intensity. The constant, K_1, can be evaluated by choosing $I_{650}(TeCl_4(OH)^-)$, which gives the smallest variation in K_1 for the solutions measured. However, the values of the activities of HCl and H_2O to be used in eq. [1] must be considered first. The use of a(HCl) and a_w which correspond to actual HCl concentration, would ignore the effect of the acids $(H^+)_2TeCl_6^{2-}$ and $H^+TeCl_4(OH)^-$, which is substantial due to the relatively large concentrations of these species, unlike in the case of the spectrophotometric measurements. Since it is the H^+ ion, which has the largest effect on these activities, a(HCl) and a_w, corresponding to $[H^+]$, and not to $[Cl^-]$, were used in the calculations. This assumes, effectively, that $y(HCl) = y(HTeCl_4(OH)) = 2y(H_2TeCl_6)$. A choice of 10.4 cm^2 M^{-1} for $I_{650}(TeCl_4(OH)^-)$ gave the best K_1 (= 2.21 (± 0.169) × 10^4 M^3). The uncertainty represents the range of variation of K_1 for the four HCl concentrations considered. The precision on the area intensity measurements (±3%) produces a precision on K_1 of ±10%.

From this Raman value for K_1, the expressions for the equilibrium constants (eqs. [1] and [2]), the mass balance for Te(IV) and chloride, the charge balance and the expression for the area intensity,

$$[5] \quad i_{650-90} = 10.4[TeCl_4(OH)^-] + I_{650-90}(TeCl_2(OH)_2)[TeCl_2(OH)_2]$$

K_2 may also be calculated. Various values of $I_{650-90}(TeCl_2(OH)_2)$ were chosen in increments of 0.1 cm^2 M^{-1} over the range 15–20 cm^2 M^{-1} and K_2 was calculated by an iterative process for each of the c_{HCl} from 3.0 to 6.0 M measured. The minimum variation was found with $I_{650-90}(TeCl_2(OH)_2) = 18.8$ cm^2 M^{-1} for which $K_2 = 442 (\pm 57)$ M^3. As before, the a(HCl) and $a(H_2O)$ correponding to $[H^+]$, and not to $[Cl^-]$ were used in the iterative process. The precision on the measurement of area intensities for the calculation of K_2 leads to greater uncertainty limits for this equilibrium constant (±40%) than in the case of K_1 (±10%).

Nevertheless, the agreement between K_2, calculated from UV–visible spectrophotometry, and K_2, from Raman spectroscopy is good. However, K_1 from Raman spectrometry (2.21 × 10^4 M^3) is substantially lower than that measured by spectrophotometry (3.78 × 10^4 M^3). This difference may be the result of ion pairing of H_3O^+ and $TeCl_6^{2-}$, which would be more important at the high Te(IV) concentrations used for the Raman spectra. The effect of ion pairing on the magnitude of ionic dissociation constants as determined by low and high concentration methods has been observed in other systems (10, 11). The effect of such ion-pairing on K_2 will be less significant, since uninegative anions appear as both reactant (Cl^-) and product ($TeCl_4(OH)^-$) in this case.

^{125}Te NMR measurement of K_1

The ^{125}Te NMR spectra of solutions of TeO_2 in HCl consist of a single resonance, indicating rapid exchange between all Te(IV) species present. Cooling of the solutions to −49°C (10.0 M solutions) and −69°C (7.0 M solutions) caused the signal to broaden and shift towards increased shielding but separation into individual signals for $TeCl_6^{2-}$, $TeCl_4(OH)^-$, or $TeCl_2(OH)_2$ did not occur. The rapid exchange of Te(IV) in these solutions is understandable where coordinately unsaturated species such as $TeCl_4(OH)^-$ and $TeCl_2(OH)_2$ may form ligand-bridged intermediates but the exchange involving $TeCl_6^{2-}$ is more problematic unless seven coordination occurs. A more attractive mechanism

TABLE 6. Hydrolysis constants, K_1, determined from ^{125}Te data[a] for 7 M HCl solutions[b]

$c(TeO_2)$	K_1 (M^3)
0.191	2.04(±0.02)
0.292	1.90(±0.02)
0.381	1.79(±0.01)
0.499	1.94(±0.01)

[a]Table 5.
[b]$\delta(TeCl_6^{2-}) = 1375 \pm 0.5$; $\delta(TeCl_4OH^-) = 1484$; $K_1 = 1.92 (\pm 0.07)$ M^3.

would involve the presence of a small concentration of $TeCl_5^-$ ion, which could form bridged structures with six coordination as intermediates like the known structures, $(TeCl_4(OH))_2^{2-}$ (4) and $Te_2Cl_{10}^{2-}$ (12). Such intermediates would probably go undetected by the methods used in this work. The chemical shifts of various solutions studied are given in Table 5. The solutions in 10.0 M HCl contain predominantly $TeCl_6^{2-}$ ion, while those in 7.0 M HCl have mainly $TeCl_4(OH)^-$ present. The chemical shifts for the 10.0 M HCl solutions lie close to that reported for $TeCl_6^{2-}$ in acetone (6) and, in acetonitrile (Table 5). The chemical shift for $TeCl_6^{2-}$ in HCl is estimated by extrapolation of the 10.0 M HCl data to zero $c(TeO_2)$ where the contribution of $TeCl_4(OH)^-$ is negligible. The shift for $TeCl_6^{2-}$ is found to be 1375.5 ± 0.5 ppm. The concentration of $TeCl_6^{2-}$ and $TeCl_4(OH)^-$ in the 7.0 M HCl solutions, where $[TeCl_6^{2-}]$ and $[TeCl_4(OH)^-]$ are present at comparable concentrations, may be calculated from the mass balance for Te(IV) and the observed chemical shifts, using the equation

$$[6] \quad \delta = \frac{\delta(TeCl_6^{2-})[TeCl_6^{2-}] + \delta(TeCl_4(OH)^-)[TeCl_4(OH)^-]}{c(TeO_2)}$$

The constant, K_1, may then be calculated with the same assumptions about a(HCl) and a_w and the activity coefficient factor used for the Raman work. The $TeCl_4(OH)^-$ ion in HCl solution is expected, on the grounds of nuclear screening, to be less shielded than the $TeCl_6^{2-}$ ion and the chemical shift is expected to be near that observed for the highly concentrated solutions of stoichiometry corresponding to that for $TeCl_4(OH)^-$ in water, i.e. near 1500 ppm. Using the extrapolated value for the shift for $TeCl_6^{2-}$, various $\delta(TeCl_4(OH)^-)$ were chosen to find the value for minimum variation in K_1 as calculated from [1], [6], and the mass and charge balance equations. The optimum value for $\delta(TeCl_4(OH)^-)$ was found to be 1484 ppm for a $\delta(TeCl_6^{2-})$ of either 1375 or 1376 ppm, which gave $K_1 = 1.92 (\pm 0.07) \times 10^4$ M^3. The individual calculated K_1 for each TeO_2 concentration are given in Table 6. This value is close to that calculated from Raman spectroscopy and is lower than K_1 determined by spectrophotometry. As in the case of the Raman measurements, the high TeO_2 concentrations used for the ^{125}Te NMR measurements favours ion pair formation, especially of the dianion, $TeCl_6^{2-}$, and this is the likely cause of the low value of K_1. It should be noted that the chemical shifts of the individual Te(IV) ions will change with their concentration but this effect will be small compared to that resulting from the shift in equilibrium.

Conclusion

Solutions of TeO_2 in hydrochloric acid contain three Te(IV) species, $TeCl_6^{2-}$, $TeCl_4(OH)^-$, and $TeCl_2(OH)_2$. For comparable haloacid concentrations, halo-coordination of Te(IV) is greater for chloride than for fluoride (*7d*). While the $TeX_4(OH)^-$ anion is formed in both cases, there is no evidence for formation of large concentrations of $TeCl_5^-$ in HCl solutions although TeF_5^- is the most highly halo-coordinated ion in the HF solutions.

These results show the expected trend in the acid dissociation of the various chlorotellurate(IV) acids,

$$H_2TeCl_6 > HTeCl_4(OH) > TeCl_2(OH)_2$$

showing that increasing chloro coordination gives stronger protonic acids.

Comparison with Se(IV) behaviour (2, 5) reveals the tendency towards higher coordination by water for the heavier chalcogen species of equal halide-to-chalcogen ratio. The three coordinate $SeOCl_2$ is formed in SeO_2/HCl solutions, while four coordinate $TeCl_2(OH)_2$ is formed in TeO_2/HCl solutions. Furthermore, for comparable hydrochloric acid concentrations, Te(IV) is more highly halocoordinated than Se(IV).

Hydrolysis constants determined for $TeCl_6^{2-}$ (K_1) by a low concentration method (spectrophotometry) and two high concentration methods (Raman and ^{125}Te nmr spectrometry) differ by a factor of about 2 in magnitude with K_1, determined by spectrophotometry, lying higher. The difference may be accounted for by the more favourable ion pair formation of the $TeCl_6^{2-}$ ion compared to the $TeCl_4(OH)^-$ ion. A similar argument has been applied to account for the dependence of acid dissociation constants on the concentration range of the method of measurement used (10, 11).

The structure of the CCl_n^- (n = 1–4) anions and electronic affinities of the corresponding neutrals

G. L. GUTSEV[1] AND TOM ZIEGLER[2]

Chemistry Department, The University of Calgary, 2500 University Drive N.W., Calgary, Alta., Canada T2N 1N4

Received October 10, 1990

G. L. GUTSEV and TOM ZIEGLER. Can. J. Chem. **69**, 993 (1991).

Electronic and geometrical structures for the ground states of the singly charged anions CCl_n^-, n = 1–4, and Cl_m^-, m = 2, 3, as well as the corresponding neutral species have been studied by Approximate Density Functional Theory (DFT). A full geometry optimization has been carried out on both anionic and neutral species. Vertical and adiabatic electron affinities were evaluated for the neutral species along with an estimate of the first ionization potential (FIP) for the anions. A discussion is given of the different dissociation channels for CCl_4^-. It follows from the present set of calculations that the anion CCl_4^- is non-rigid with a global minima corresponding to an elongated tetrahedron of C_{3v} symmetry.

Key words: Density Function Theory, electronic affinities.

G. L. GUTSEV et TOM ZIEGLER. Can. J. Chem. **69**, 993 (1991).

Faisant appel à la théorie des fonctions de densités approximatives, on a étudié les structures électroniques et géométriques des états fondamentaux des anions monochargés CCl_n^-, n = 1–4, et Cl_m^-, m = 2, 3, ainsi que des espèces neutres correspondantes. On a réalisé un optimisation sur la géométrie complète sur les espèces tant anioniques que neutres. On a évalué les affinités électroniques tant verticales qu'adiabatiques des espèces neutres et on a évalué le premier potentiel d'ionisation (PPI) dans anions. On présente une discussion de diverses voies de dissociation du CCl_4^-. Il ressort de cet ensemble de calculs que l'anion CCl_4^- n'est pas rigide et qu'il possède un minima global correspondant à la symétrie C_{3v} d'un tétraèdre allongé.

Mots clés : la théorie des fonctions de densités, affinités électroniques.

[Traduit par la rédaction]

1. Introduction

Many complex molecules possess a large cross section for electron attachment at quite low energies. This property has recently found applications in several areas of technology. The CCl_4 molecule is one of the most extensively studied species of this kind along with other halogen substituted methanes (1–8) and SF_6. Much of the experimental data on electron attachment is obtained from collision experiments with a beam of electrons (reaction [1]), alkali atoms (in the ground or excited states (reaction [2]), or some simple anions (9) (reaction [3]).

[1] $e^- + AB \dashrightarrow AB^{-*} \dashrightarrow A^- + B$

[2] $M + AB \dashrightarrow M^+ + (AB)^-$

[3] $M^- + AB \dashrightarrow M + AB^{-*} \dashrightarrow A^- + B$

The beam experiments afford in general cross sections and rate constants for the processes given above. The formation of the parent CCl_4^- anions seems to be sensitive to the nature of the beam experiment. Thus, the anion is formed with relatively low cross section in collision experiments involving potassium atoms (10) (reaction [2]). On the other hand, the anion is not detected (8) in collision experiments involving electron beams (reaction [1]).

The interpretation of the beam experiments has been hampered by a lack of information on the molecular parameters of CCl_4^- as well as the fragments formed on dissociation. The geometrical structure of CCl_4 has been studied extensively by experiments (11–19) as well as theory (20). The only geometrical information on CCl_4^- comes from an *ab initio* study (21) carried out with a minimal STO-3G basis, which is known to be insufficient (22) for negatively charged species. As for the possible fragments formed from CCl_4^- on dissociation, the neutral species such as Cl, Cl_2, CCl, Cl_3, CCl_3 have been the subject of a great number of investigations (see, e.g., refs. 23–25), and referenes therein). The data on the corresponding anions are, on the other hand, scarce.

The CCl_4^- anion was observed for the first time as early as 1953 (26–28) and the adiabatic electron affinity (EA_{ad}) of the parent CCl_4 molecule was first determined by magnetron techniques (29–31) to be equal to 2.06 eV. Dispert and Lacmann (10) confirmed this value by estimating EA_{ad} of CCl_4 as 2.0 ± 0.2 eV from potassium atom beam experiments according to reaction [2]. Dispert and Lacmann implied further from their experiment that the C—Cl distance in CCl_4^- should be as long as 2.18 Å, which is to be compared to the experimental C—Cl bond distance of 1.77 Å for CCl_4. The estimate of R(C—Cl) by Dispert and Lacmann was based on the assumption that CCl_4^- is tetrahedral. However, ESR experiments on CCl_4^- (21, 32), CBr_4^- (33), and SiH_4^- (34) seem to indicate a distorted tetrahedron of C_{3v} symmetry. It should be mentioned that the sulphur hexafluoride anion (35) appears to retain (36) the O_h symmetry of the SF_6 parent molecule.

The objectives of the present theoretical work have been to explore the potential energy surface of the CCl_4^- anion, to estimate the electron affinity of the parent CCl_4 molecule, and to probe the possible dissociation channels for the CCl_4^- anion. We have, in order to meet the latter objective, optimized the structures of CCl, CCl_2, CCl_3, Cl_2, Cl_3, as well as the corresponding anions. This family of compounds has not been previously the subject of a uniform theoretical study based on a single computational method.

Our theoretical approach will be based on the approximate Density Functional Theory. This theory has been applied extensively to transition metals. However, applications to main-group molecules are rather limited. We would like, in the present study, to demonstrate that the approximate Density Functional Theory provides rather accurate geometrical parameters as well as reasonable estimates of electron affinities for main-group molecules.

2. Computational details

All calculations were based on the simple Hartree–Fock–Slater (HFS) or Xα method (37) due to Slater. We have utilized the vectorized version of the HFS-LCAO program system developed by Baerends *et al.* (38, 39) and vectorized by Ravenek (39*b*). The numerical integration procedure applied in the calculations was developed by Becke (40). The geometry optimization procedure was based on the method developed by Versluis and Ziegler (41). All structures were determined at the HFS level of theory with a uniform exchange parameter, α_{ex}, of 0.7. The electronic configurations of the molecular systems were described by an uncontracted triple-ζ STO basis set (42) (ζ_{2s_C} = 1.28, 2.10, and 4.60; ζ_{2p_C} = 0.82, 1.48, and 2.94; $\zeta_{3s_{Cl}}$ = 1.6, 2.3, and 3.3; $\zeta_{3p_{Cl}}$ = 1.2, 2.05, and 2.85) augmented by two 3*d* functions on carbon (ζ_{3d_C} = 3.0 and 1.5) and chlorine ($\zeta_{3d_{Cl}}$ = 3.0 and 1.5). Our basis is of the composition recommended by Baker *et al.* (35) for negative ions. Their recommendation was based on an extensive series of *ab initio* calculations on electron affinities and emphasised the needed for diffuse basis functions. The 1*s*, 2*s*, and 2*p* electrons on Cl and the 1*s* electrons on C were assigned to the core and treated by the frozen-core approximation (38). A set of auxillary (43) *s*, *p*, *d*, *f*, and *g* STO functions, centred on all nuclei, was used to fit the molecular density and present Coulomb and exchange potentials accurately in each SCF cycle.

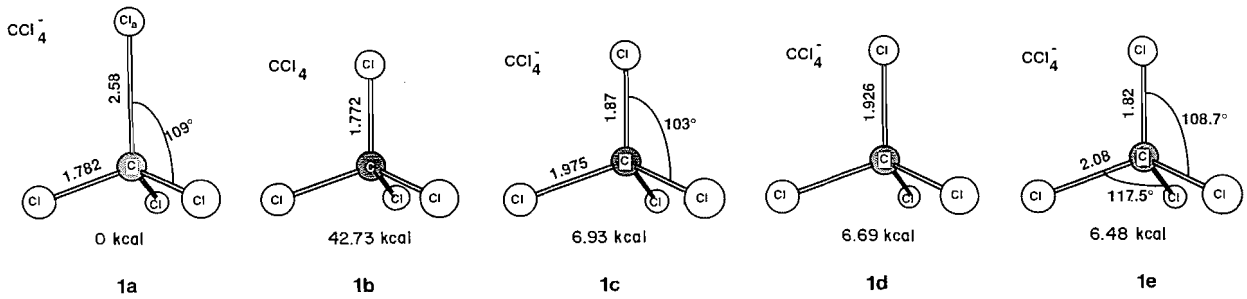
Electron affinities and bond energies were calculated by augmenting the HFS method (α_{ex} = 2/3) with the local correlation corrections due to Stoll *et al.* (44) in the parametrization by Vosko, Wilk, and Nusair (VWN) (45) as well as Becke's (46) non-local exchange corrections. The correlation correction (Stoll) was included self-consistently whereas Becke's correction was added as a perturbation based on the density from a HFS + Stoll SCF-calculation. The correlation correction by Stoll (44) as well as the exchange correction by Becke (46) eliminate the so-called self-interaction present in the original Local Density Approximation (LDA) due to Gunnarsson (37). It is also important to note that Becke's exchange correction ensures the correct asymptotic behaviour of the exchange potential $V_{ex}(r)$ when r is large (46). The extended version of the LDA method, which we shall refer to as LSD/NL, has been shown to afford metal–ligand and metal–metal bond energies of nearly chemical accuracy (± 5 kcal mol^{-1}) in calculations on metal carbonyls (47), binuclear metal complexes (48), alkyl and hydride complexes (49), as well as complexes containing M—L bonds for a number of different ligands (50). More than 50 molecular structures optimized by the HFS method have been compared with experiment (41). The agreement between experiment and theory is in most cases excellent. However, only four of the optimized structures were anions.

3. Computational results

CCl_4^-

We find for CCl_4^- that the optimized structure of lowest energy corresponds to an elongated tetrahedron, **1***a*, of C_{3v} symmetry. The axial C—Cl distance of 2.58 Å is seen to be elongated considerably compared to the calculated C—Cl distance of the neutral CCl_4 molecule, **1***b*, with R(C—Cl) = 1.77 Å. Three other local minima were located at slightly higher energies. The first, **1***c*, corresponds to a compressed tetrahedron with three long equatorial bonds of R(C—Cl) = 1.975 Å. It resembles closely the structure optimized by Bonazolla *et al.* (21) and is calculated to be 6.93 kcal higher in energy than **1***a*. A second structure, **1***d*, has a tetrahedral geometry with all four bonds stretched at R(C—Cl) = 1.926 Å and an energy of 6.69 kcal above **1***a*. We have finally located the structure **1***e* of C_{2v} symmetry with one pair of elongated bonds at R(C—Cl) = 2.08 Å and an open Cl—C—Cl angle of 117.5°. This structure is calculated to be 6.48 kcal mol^{-1} above **1***a* in energy.

The CCl_4^- anion in the tetrahedral conformation, **1***d*, can interconvert along the normal modes to the other structures (**1***a*, **1***c*, and **1***e*) with a negligible barrier of less than 2 kcal mol^{-1} on top of the thermodynamical energy difference between **1***d* and any of the structures **1***a*, **1***c*, and **1***e*. Thus the anion is essentially a non-rigid molecule according to our calculations. The fluxional behaviour of CCl_4^- is related to the fact that the unpaired electron occupies a strongly anti-bonding orbital which is distributed over different centers in the various conformations. The anti-bonding orbital for the most stable structure, **1***a*, is concentrated between the axial ligand Cl_a and carbon, **2**. Thus the odd electron resides in this case in the elongated axial bond. Each of the structures (**1***a*, **1***c–e*) can be seen as a channel for the decomposition of CCl_4^- with **1***a* representing a fragmentation of CCl_4^- into CCl_3 and Cl^-. We shall later return to this point. It is interesting that the optimized Cl_{ax}—C—Cl_{eq} angle in **1***a* still is close to tetrahedral. The angle will eventually increase as the C—Cl_{ax} bond is stretched to the CCl_3 + Cl^- dissociation. The structure of CCl_3 will be discussed later.



There are only indirect experimental data on the structure of CCl_4^-. Dispert *et al.* (10) inferred from their potassium atom beam experiment a C—Cl distance of 2.18 Å by assuming CCl_4^- to have a tetrahedral structure. This distance is somewhat longer than the 1.93 Å calculated in the present study for the tetrahedral conformation, **1***d*, of CCl_4^-. The ESR experiments by Bonazolla *et al.* (21) indicate clearly that CCl_4^- has a structure of C_{3v} symmetry with either an elongated, **1***a*, or compressed, **1***c*, tetrahedron. Our calculations point to the elongated structure, **1***a*, as the more stable; whereas Bonazolla *et al.* (21), based on an *ab initio* HF calculation with a minimal basis set, found CCl_4^- to have the structure of a compressed tetrahedron, **1***c*. It would be of interest to redo the *ab initio* study with the same extensive basis set as employed in our DFT calculations. Our calculated C—Cl bond distance of 1.772 Å for CCl_4 compares well with the experimental value of 1.769 Å (12*a*) and the calculated average bond energy $\bar{D}$(C—Cl) of 3.0 eV for CCl_4 is also in line with the experimental value of 3.3 eV.

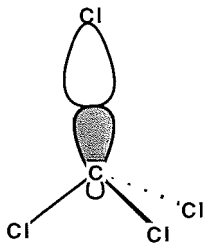


Table 1 presents calculations on the vertical (EA_{vert}) and adiabatic (EA_{ad}) electron affinities of CCl_4 as well as the first ionization potential (FIP) of CCl_4^-. FIP can also be viewed as EA_{vert} of CCl_4 at the equilibrium geometry of the anion CCl_4^-. Our calculated values are in reasonable agreement with experimental findings. The large observed (Table 1) difference between the vertical and adiabatic electron affinity of CCl_4 is in line with the substantial difference in geometry between CCl_4, **1***b*, and CCl_4^-, **1***a*.

CCl^-

Results from calculations on the neutral radical CCl and the anion CCl^- are presented in Table 2. For CCl, there are experimental data on the bond length (53) and the dissociation energy (51–53). Our theoretical bond length is very close to the experimental value whereas the theoretical bond energy differs by 0.5 eV from the observed value (Table 2). We expect part of the deviation to be due to experimental uncertainties.

Experimental data are not available for CCl^-. The additional electron enters into an anti-bonding 2π orbital. It is thus not surprising that CCl^- is calculated to have a long R(C—Cl) bond

2

distance of 1.91 Å and a modest bond dissociation energy of 1.56 eV (Table 2). It is interesting to note that the bond length and dissociation energy calculated for CCl^- in this work are in very close agreement with the highest levels of theory (MP4SDTQ) in a recent publication (54) where results from several *ab initio* methods were compared, Table 2.

CCl_2^-

Dihalocarbenes are important constituents in several organic and organometallic compounds. This class of extremely reactive intermediates has been studied extensively by theoretical (55–57) as well as experimental (58–60) techniques. Of particular interest has been the energy separation between the singlet $^1A_1$ ($a_1^2 b_1^0$) and the triplet $^3B_1$ ($a_1^1 b_1^1$) states (61–64) as well as their geometrical structures (65). It is well established that CCl_2 has a singlet ground state. However, only a rough experimental estimate of 31 ± 10 kcal mol^{-1} (63) is available for the singlet–triplet separation. Further, geometrical parameters are only known experimentally for the singlet (65). Our calculated singlet structure, **3***a*, is quite close to that obtained in the recent experimental (65) study by Fujitake and Hirota, Table 3. We calculate (Table 3) that the triplet, **3***b*, has a wider angle and a shorter C—Cl bond than the singlet, **3***a*. This trend, which can be explained readily from simple perturbational molecular orbital considerations (PMO), was also found in the theoretical study by Bauschlicher *et al.* (56), Table 3. Triplet–singlet separations obtained by *ab initio* methods for carbenes are quite sensitive to the extent of correlation included in the calculations. Hartree–Fock (56) affords only 0.1 kcal mol^{-1} for CCl_2 whereas GVB (56), Table 3, gives 13.5 kcal mol^{-1}. The most extensive *ab initio* calculation to date on CCl_2 applied the CCCl method by Goddard and Carter (63). The CCCl calculation afforded a separation of 25.9 kcal mol^{-1} (Table 3), which is close to our estimate of 23.7 kcal mol^{-1} and the rough experimental estimate of 31 ± 10 kcal mol^{-1}.

The CCl_2^- anion appears not to have been studied by *ab initio* methods. We calculate the anion to possess two states with an energy below that of a free electron and the neutral parent molecule in its $^1A_1$ ground state, **3***a*. The calculated ground state is of $^2B_1$ ($a_1^2 b_1^1$) symmetry. Its optimized geometry, **3***c*, is quite similar to the structure recently deduced by Murray *et al.* (66) from IR spectroscopy. Murray *et al.* (66) deduced a C—Cl bond distance of 1.91 Å and a bond angle of 103°. The second state, of $^2A_1$ ($a_1^1 b_1^2$) symmetry, **3***d*, has a wide Cl—C—Cl angle of 164° and a considerably stretched C—Cl bond of 2.18 Å. Murray *et al.* (66) have also determined EA_{ad} for CCl_2. Their experimental

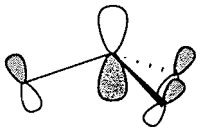
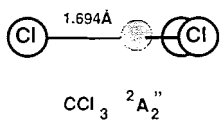
3d

value of 1.60 eV is in excellent agreement with our theoretical estimate of 1.61 Ev, Table 1.



CCl_3^-

We find the CCl_3 molecule to have a trigonal pyramidal equilibrium structure of C_{3v} symmetry, **4***a*, with a $^2A_1$ ground state where the unpaired electron is residing in a π^* orbital, **4***b*, with an a_1' designation. The geometry of CCl_3 has been investigated by *ab initio* methods (67–70) as well as ESR (71, 72) and vibrational spectroscopy (70). All studies point to a trigonal bipyramidal structure of C_{3v} symmetry. The most recent structural information comes from the work by Hudgens *et al.* (70) in which they deduce a Cl—C—Cl angle of 116.7° from IR spectroscopy and a C—Cl distance of 1.7142 Å from an *ab initio* calculation at the UHF/6-31G* level of theory. Both numbers are in close agreement with our findings, **4***a*.



The inversion of **4***a* through the trigonal planar transition state, **4***c*, was calculated to have a barrier of 2.541 kcal mol^{-1}. The best experimental estimate (70) gives 1.3 kcal mol^{-1}.

4a

4b

4c

Earlier experimental studies (10, 29–31) on the electron affinity of CCl_3 gave a low value for EA_{ad} of 1.3 eV. The more recent estimates (73–75) are somewhat higher at around 2 eV

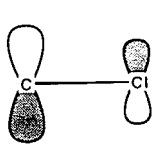


TABLE 4. Bond distances[c] (Å) and bond energies (eV) for Cl_2 and Cl_3 as well as their anions

Molecule	R(Cl—Cl)	D(Cl—Cl)
Cl_2	1.993 (1.988)[b]	2.02 (2.5)[c]
Cl_2^-	2.696 (2.65)[d]	1.78 (1.26)[b]
Cl_3 ($^2\Pi_u$)	2.179	0.45
Cl_3 ($^2A_1$)	2.159[e]	0.47
Cl_3^- ($^1\Sigma_g$)	2.317	1.73[f]
		1.97[g]

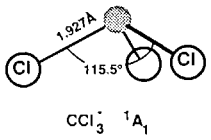
[f]For the process $Cl_3^- \rightarrow Cl_2 + Cl^-$.
[g]For the process $Cl_3^- Cl_2^- + Cl$.

(Table 1). Our calculated value at 2.36 eV is close to the most recent experimental estimate (74) of 1.9 ± 0.2 eV (Table 1).

We calculate an increase in the electron affinities through the series CCl_n $n = 1, 3$ as well as a decrease in FIP in CCl_n^-, $n = 1, 3$ (Table 1). The HOMO's of CCl_n^- (n = 1–3) are for all three anions essentially a π^* orbital represented by **5***a*, **5***b*, and **4***b* for CCl, CCl_2^-, and CCl_3, respectively. The calculated trends can be rationalized by observing that the excess electron density achieves a favorable increase in delocalization through the series **5***a* (CCl^-), **5***b* (CCl_2^-), and **4***b* (CCl_3^-). The CCl_4 molecule does not fit into the series since CCl_4^- has a σ^* type HOMO, **2**, rather than a HOMO with π^* character. The excess electron density in CCl_4^- achieves some delocalization on account of the substantially stretched C—Cl bond with R(C—Cl) = 2.58 Å. The calculated values for EA_{ad}, EA_{vert}, and FIP fall between those of CCl_3 and CCl_2, (Table 1).

5a



5b

The CCl_3^- anion appears not to have been studied previously by experimental or theoretical techniques. We find the CCl_3^- anion to have a $^1A_1$ (a'^2) ground state with a trigonal pyramidal structure, **6***a*, of C_{3v} symmetry where the C—Cl bond has been stretched to 1.93 Å. The inversion through the transition state, **6***b*, has a substantial barrier of 27 kcal mol^{-1}.

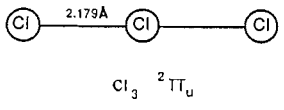
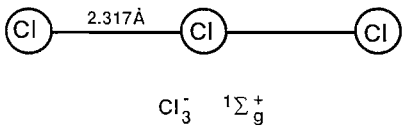
6b



Cl_2^- and Cl_3^-

Calculated bond distances and bond energies for Cl_2 and Cl_3 as well as their anions are compared in Table 4 with experimental data, where available. The theoretical values compare reasonably well with experiment for Cl_2 and Cl_2^- (Table 4). The experimental bond distance for Cl_2^- ($\sim$ 2.65 Å) is a rough estimate (76, 77) based on a Morse potential curve fitting technique. Bond distances calculated by the HFS method are usually on the short side and our value of 2.69 Å, Table 5, might well be a lower bound. It should be noted that a recent *ab initio* study (78) found R(C—Cl) = 2.65 Å. There have been several experimental (10, 79–82) and a few theoretical (78) studies on the electron affinity of Cl_2. Our calculated value of 3.0 eV for EA_{ad} is somewhat higher than the favoured value of 2.5 eV (Table 1).

The Cl_3 radical was calculated to have two nearly degenerate states. The first has a linear structure, **7***b*, with a $^2\Pi_u$ ($3\sigma_g^2 2\pi_u^3$) electronic state whereas the second, which is calculated to be 0.5 kcal mol^{-1} lower in energy has a bent structure, **7***a*, with a $^2A_1$ ($3\sigma_g^1 2\pi_u^4 = 5a_1^2 2b_1^2 4a_1^2$) electronic state. The near degeneracy between the two states parallels a similar degeneracy between $3\sigma_g$ and $2\pi_u$ as discussed by Sannigrahi and Peyerimhoff (83, 84). These authors obtained structures quite similar to ours. However, the bent structure, **7***a*, is, according to their MRD-Cl calculations 7 kcal mol^{-1} more stable than the linear structure, **7***b*. Experimental data are not available on the structure of Cl_3 radical.



7a

7b

We find the Cl_3^- anion to have a linear structure with a $^1\Sigma_g$ ($3\sigma_g^2 2\pi_u^3$) ground state and a Cl—Cl bond distance of 2.32 Å, **8**. Earlier calculations carried out within the HF method without (85) or with pseudopotentials (86) have predicted somewhat larger bond lengths (2.54–2.41 Å) for this anion. However, the bond distances calculated recently by the MRD-Cl (84) and

8

TABLE 6. Dissociation channels for CCl_4

Channel	Dissociation energy (eV) Calculated	Observed[a]
$CCl_4^- \rightarrow CCl_3 + Cl^-$	0.70	1.4
$CCl_2 + Cl_2^-$	1.13	3.8
$CCl_3^- + Cl$	1.58	3.6
$CCl + Cl_3^-$	2.25	—
$CCl_2^- + Cl_2$	2.57	4.4

[a]Semiquantitative estimates from the energy loss spectrum, see ref. 6.

DVM-X_α (87) methods of 2.34 and 2.35 Å, respectively, are quite close to our estimate. The calculated energies for the dissociation of Cl_3^- into $Cl_2 + Cl^-$ (1.73 eV) and $Cl_2^- + Cl$ (1.97 eV), Table 4, are quite close to the theoretical estimates of Tasker *et al.* (86) with 1.69 and 1.57 eV, respectively.

We find the adiabatic electron affinity of Cl_3 to be 4.5 eV, which is close to the range (4.6–5.1 eV) of experimental values (Table 1). We note that EA_{ad} and EA_{vert} for Cl_3 and FIP for Cl_3^- are calculated to be larger than the corresponding values in the dichloro systems (Table 1). This is not surprising since the excess electron density is better able to delocalize in Cl_3^- compared to Cl_2^-. We have for the sake of completeness included the calculated electron affinities of the carbon and chlorine atoms in Table 1.

Dissociation channels for CCl_4^- and bond dissociation energies for CCl_n (n = 1,4)

We find that the dissociation channel of lowest energy for CCl_n^- in all cases (n = 1, 4) corresponds to the process

[4] $CCl_n^- \rightarrow CCl_{n-1} + Cl^-$

The dissociation energy for reaction [4] is given in Table 5 for n = 1, 4. It follows that all the anions, CCl_n- (n = 1, 4), are stable with respect to the corresponding fragments CCl_{n-1} and Cl^-. The dissociation of CCl_n^- into CCl_{n-1}^- and Cl requires substantially more energy (Table 5), in accordance with the fact that Cl has a larger electron affinity than any of the CCl_n^- species (Table 5).

Lacmann *et al.* (6) have carried out collision experiments with CCl_4 and a beam of potassium atoms. The CCl_4^- anions formed according to reaction [2] will fragment due to the excess energy transferred from the potassium atoms during the collision. Lacmann *et al.* (6) were able to deduce a rough estimate of the energies for the different dissociation channels based on the energy loss spectrum. The estimates, which likely are rough upper bounds, are compared to calculated dissociation energies in Table 6. We have, in our calculations, considered all channels with a dissociation energy below 3 eV. There is a general agreement between theory and experiment as to the nature of the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

low-energy dissociation channels. However, the experimental estimates for the dissociation energies are most likely too high.

4. Concluding remarks

We have investigated the molecular and electronic structure of CCl_n^- ($n = 1, 4$) and Cl_m^- ($m = 2, 3$) as well as the parent neutral molecules using the approximate Density Functional Theory. We find a good agreement between observed and calculated structures for the neutrals, where experimental data are available. The structures of the anions have not been investigated by diffraction techniques and our calculations constitute the first extensive investigation on CCl_4^-, CCl_3^-, and CCl_2^-. The CCl_4^- anion was found to be non-rigid with several structures of similar energies (**1***a*, **1***c*–**1***e*) connected by low barrier paths. The global minima was calculated to have the structure of an elongated tetrahedron, **1***a*.

The calculated adiabatic affinities are, in general, in good agreement with experiment. We find for the series CCl_3, CCl_2, CCl as well as Cl_3, Cl_2, an increse in EA_{ad} with the number of Cl atoms. All members of the series accommodate the additional electron in a π-type orbital delocalized over all centers and the rise in EA_{ad} with the number of chlorine atoms stems from an increasing ability to delocalize the excess change.

The CCl_n anions were found to be stable with respect to dissociation into smaller fragments. The decomposition channel of lowest energy was in all cases calculated to be represented by

$$CCl_n^- \rightarrow CCl_{n-1} + Cl^-$$

A more detailed analysis was further provided for the decomposition of CCl_4^- in which all dissociation channels with an energy below 3 eV were identified as

[a] $CCl_4^- \rightarrow CCl_3 + Cl^- + 0.70$ eV

[b] $CCl_4^- \rightarrow CCl_2 + Cl_2^- + 1.13$ eV

[c] $CCl_4^- \rightarrow CCl_3^- + Cl + 1.58$ eV

[d] $CCl_4^- \rightarrow CCl + Cl_3^- + 2.25$ eV

[e] $CCl_4^- \rightarrow CCl_2^- + Cl_2 + 2.57$ eV

These are essentially the dissociation channels observed experimentally in beam experiments with potassium atoms. Our dissociation energies are considerably lower than the experimental estimates. However, these estimates are most likely upper bounds of the actual values.

We have in the present investigation made use of the LDA/NL method. It is shown elsewhere (92), for a larger sample of molecules, that this method affords better estimates of EA_{ad} than HFS and LDA. In fact, the calculated electron affinities are as accurate as the best available *ab initio* methods in which a substantial part of the electron correlation is taken into account. The success of the LDA/NL method compared to the HFS and LDA schemes stems in large measure from the elimination of the spurious self-interaction terms present in HFS and LDA. The non-local exchange correction due to Becke was introduced in the present work as a perturbation, without taking into account the SCF effects. We have found in a recent investigation (93) that the change in density induced by Becke's non-local correction is negligible and we expect this to be the case for the anions studied here.

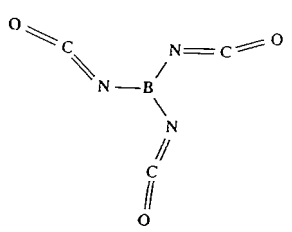
Ab initio calculating at the 3-21G, 6-31G*, 6-31G**, 6-311G*, and 6-311G** Hartree–Fock levels, have been performed on the unknown H_2BNCO and F_2BNCO molecules in order to establish the geometries of these isoelectronic propadienone analogues. For H_2BNCO the double split valence basis sets lead to linear BNCO chains, whereas *either* a triple split valence basis set, *or* the inclusion of correlation to second order (MP2/6-31G*) gives *trans*-bent structures. These have angles at nitrogen of 153.6° (6-311G*) or 149.9° (MP2/6-31G*), with the potential surface for angle bending extremely flat, and 0.5 kJ mol^{-1} (6-311G*) or 1.12 kJ mol^{-1} (MP2/6-31G*) separating the C_{2v} and C_s structures. For the bent structures there is a small *trans*-bend (4–6°) at the carbon atom. The F_2BNCO molecule is also linear at the 3-21G level, but is, however, already *trans*-bent (145.6° at nitrogen, 175.9° at carbon) at the 6-31G* Hartree–Fock level; 1.47 kJ mol^{-1} separates the bent and linear structures. The triple split valence basis set 6-311G* leads to a further decrease in the angle at nitrogen (141.0°), and a similar NCO angle (175.9°), with the bent structure favoured by 3.85 kJ mol^{-1}. MP2/6-31G* calculations give a minimum with an angle at nitrogen of 140.2°, and a bent-linear energy difference of 3.58 kJ mol^{-1}.

Key words: *ab initio* calculations, isocyanatoboranes, structures, quasilinearity, propadienone analogues.

SUSAN ELLIS, EDWARD G. LIVINGSTONE et NICHOLAS P. C. WESTWOOD. Can. J. Chem. **69**, 1000 (1991).

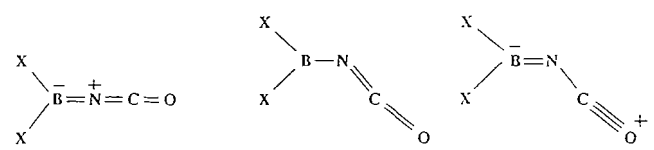


Dans le but d'établir les géométries des molécules inconnues H_2BNCO et F_2BNCO, analogues isoélectroniques de la propadiénone, on a effectué des calculs *ab initio* aux niveaux 3-21G, 6-31G*, 6-31G**, 6-311G* et 6-311G** de Hartree–Fock. Dans le cas de H_2BNCO, les ensembles de base à valence doublement partagée conduisent à des chaînes linéaires de BNCO alors que l'ensemble de base à valence triplement partagés *ou* l'inclusion d'une corrélation aux calculs du deuxième ordre (MP2/6-31G*) conduisent à des structures *trans*-déformées dans lesquelles les angles à l'azote sont de 153,6° (6-311G*) ou 149,9° (MP2/6-31G*), la surface de potentiel pour la déformation de l'angle est extrêmement plane alors que 0,5 (6-311G*) ou 1,12 kJ $mole^{-1}$ (MP2/6-31G*) séparent les structures C_{2v} et C_s. Pour les structures déformées, il y a une légère déformation-*trans* (4–6°) au niveau du carbone. La molécule de F_2BNCO est aussi linéaire au niveau 3-21G; elle possède toutefois déjà une déformation-*trans* (145,6° à l'azote et 175,9° au carbone) au niveau 6-31G* de Hartree–Fock alors que 1,47 kJ $mole^{-1}$ séparent les structures linéaires et déformées. L'ensemble de base 6-311G* à valence triplement partagée abaisse encore plus l'angle à l'azote (141,0°) alors que l'angle NCO est semblable (175,9°) et que la structure déformée est favorisée par 3,85 kJ mol^{-1}. Des calculs au niveau MP2/6-31G* fournissent un minimum pour un angle à l'azote de 140,2° et une différence d'énergie de 3,58 kJ mol^{-1} entre les formes linéaires et déformées.

Mots clés : calculs *ab initio*, isocyanatoboranes, structures, quasilinéarité, analogues de la propadiénone.

[Traduit par la rédaction]

Introduction



Recent experimental studies on the ultraviolet photoelectron spectra (UPS) of chloroisocyanatoboranes, $Cl_xB(NCO)_{3-x}$ (1), coupled with semiempirical MNDO calculations, have posed the question of non-linearity or linearity in the BNCO chain(s). It was shown that successive isocyanation of BCl_3 leads, ultimately, to a C_{3h} manx-like $B(NCO)_3$ structure (**1**) with individual BN bonds weaker than those in $BCl(NCO)_2$, or BCl_2NCO, and substantial bends at nitrogen (estimated from MNDO calculations to be 47.3° off-axis). Analysis of the gas phase infrared spectra of this molecule and the chloro- derivatives is underway to confirm the structures (2).

1

Of particular relevance to the geometries of monoisocyanato-substituted haloboranes is the competition between structures of the type, where a feature that determines the structure is the extent of $p\pi$ donation from X to the vacant $p\pi$ orbital on boron (possibly mediated by σ effects) making that centre less accessible for electron donation from nitrogen, and thereby reducing the likelihood of the linear structure (**2**).

UPS studies (1) cannot distinguish between linear (**2**) and bent (**3**, **4**) structures when X = Cl, due to the insensitivity of the

2 **3** **4**

calculated orbital energies to such energetically small structural changes; semiempirical MNDO results favor a bent (142.6° at nitrogen) Cl_2BNCO molecule by 6.7 kJ mol^{-1}. It has, however, been claimed (from infrared studies in solution) (3) that Cl_2BNCO has a co-linear BNCO group, and so this must remain an open question, particularly since the corresponding Me_2BNCO molecule, previously found by solution infrared to

have a linear BNCO group (4), has now been shown by electron diffraction to be bent at nitrogen (5). It is also clear that a substituent such as hydrogen, that does not compete for the vacant $p\pi$ orbital on boron, may tend to favor a more linear structure.

In this study we have performed *ab initio* calculations at the Hartree–Fock (HF) level, with basis sets up to the triple split valence 6-311G** [6-311G (*d*,*p*)] level, and with the inclusion of correlation to second order at the 6-31G* level (MP2/6-31G*), in order to investigate the question of linearity or non-linearity in the BNCO chain of the possible synthetic targets, H_2BNCO and F_2BNCO. These molecules are of especial interest in view of the UPS work (1), and are more computationally tractable than the already observed chloro-species. In addition, they are the isoelectronic analogues of the corresponding propadienone molecules, H_2CCCO and F_2CCCO, which have (especially in the former case) been subjected to a great deal of structural scrutiny, both by experiment (6–12) and theory (13–17). The parent propadienone molecule has been shown by microwave spectroscopy to be *trans*-bent (C_s) with a bond angle at C_2 of 144.5°. Interestingly, single configuration HF calculations with reasonably large basis sets up to 6-311G(*df*,*p*) fail to arrive at this structure (refs. 13, 15, and unpublished observations in ref. 7) preferring the linear C_{2v} form. Only with the introduction of correlation do experiment and theory closely agree, this being one of the first instances in which high level HF results predict the incorrect gross structure. The F_2CCCO molecule, recently generated (10, 11), has been shown to be *trans*-bent even at the HF 6-31G* level (angle $C_1C_2C_3$ = 132.8°), although a lower level of theory, 3-21G, leads to a linear structure. The microwave spectrum of this molecule was reported recently (12), confirming the *trans*-bent C_s structure of the higher level calculation. The experimental r_0 structures of both of these molecules are shown in Fig. 1.

The intention, therefore, is to investigate the H- and F-substituted isoelectronic boron–nitrogen analogues with a view to establishing the basis set and correlation dependencies of their molecular structures, and the influence of boron substituents on the BNC angle. In addition, since F_2BNCO has been suggested as an intermediate in the reaction of silyl isocyanate with boron trifluoride (18), it is a reasonable synthetic target, whereas the unsubstituted species, H_2BNCO, is likely to be more difficult to generate due to the propensity of monosubstituted boranes to disproportionate.

Computational methods

The geometric structures of H_2BNCO and F_2BNCO were fully optimized by means of analytic gradient procedures, using Gaussian 86 employing RHF wavefunctions with a variety of split valence plus polarization basis sets at the Hartree–Fock level, *viz.*, 3-21G, 6-31G*, 6-31G**, 6-311G*, and 6-311G**. Optimized structures for stationary points, both minima and transition states, were checked by frequency calculations, for respectively, zero and one negative hessian eigenvalue. Geometry optimization was also performed with the inclusion of some electron correlation (Møller–Plessett perturbation theory to second (MP2) order). The best energies are thus MP2/6-31G*. All calculations were performed using Gaussian 86 (19) on an IBM-3081K computer at the University of Guelph.

Results

The final structures for H_2BNCO and F_2BNCO at the different levels of theory are shown in Figs. 2 (*a*)–(*e*) and 3(*a*)–(*d*) in order of improving total energy. These energies (au) at the HF and post-HF levels are given in Tables 1 and 2.

Discussion

H_2BNCO

A perusal of the relevant literature reveals some previous calculations for H_2BNCO which, at the STO-3G and 4-31G levels, established the planarity of the molecules, the resulting optimization to linear BNCO chains, and the preference for isocyanate over cyanate structures (20).

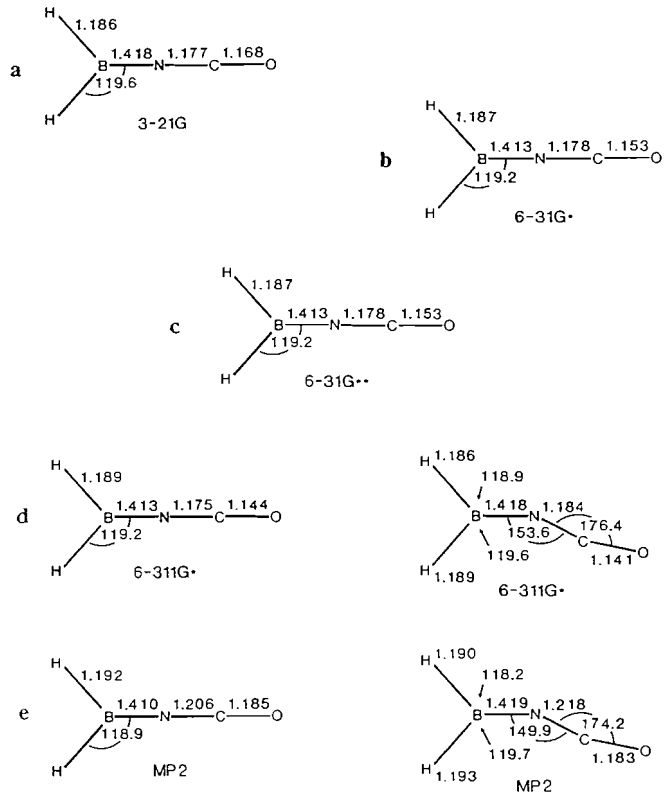

FIG. 2. Optimized structures for H_2BNCO at various levels of theory: (*a*) 3-21G; (*b*) 6-31G*; (*c*) 6-31G**; (*d*) 6-311G*; (*e*) MP2/6-31G*. In the latter two cases the linear (TS) and bent (minimum) structures are shown.

Starting at the 3-21G level, this molecule is predicted to have a linear BNCO chain (Fig. 2*a*) and, typical for this level of calculation on isocyanates, the NC and CO bond lengths are relatively close (21). With the 6-31G* basis, the largest routinely used at the HF level, a linear chain structure for H_2BNCO is also predicted (Fig. 2*b*) with a shortening of the CO bond. This result therefore parallels that for the isoelectronic H_2CCCO molecule, which also adopts a linear heavy atom structure at the 6-31G* HF-SCF level (13, 15). Such a result is not unexpected in the sense that the vacant $p\pi$ orbital on boron can accept π donation from nitrogen with no competition from the hydrogen substituents. This in turn provides an extended π electron system (**2**), leading to linearity in the BNCO chain, and a calculated (6-31G*) BN bond length of 1.413 Å, shorter than that predicted in H_3NBH_3 (1.689 Å) (22) and larger than that predicted in H_2NBH_2 (1.389 Å) (23) at the same level of theory. Polarization functions on the hydrogen atoms lead to no change in the calculated structure (Fig. 2*c*).

In a routine study the optimized geometry at the 6-31G* level would be used for a series of single point calculations involving electron correlation via perturbation theory, *e.g.* MP3/6-31G*//6-31G*. However, the history of propadienone is such that geometry optimization, with correlation included, was necessary to achieve a structure of the proper point group (C_s) (15). Keeping this in mind, structure optimization for H_2BNCO was carried out at the MP2 level with the 6-31G* basis set. The resulting optimized structure (Fig. 2*e*) has a *trans*-bent BNCO chain with a BNC angle of 149.9°, and an NCO angle of 174.2°. The linear structure is now a transition state to inversion at nitrogen. Thus it appears that H_2BNCO behaves with *ab initio* theory in a similar fashion to its isoelectronic carbon analogue, H_2CCCO.

The bent structure of H_2CCCO was interpreted from CAS SCF calculations (16) as being due to a mixing of the ground state with an excited state consisting of a double excitation into the $14a'$ virtual orbital, a low-lying σ level. The electron densities on the individual atoms indicated that the structure could be explained qualitatively through the importance of a resonance structure $H_2C{=}C^-{-}C{\equiv}O^+$, where the negative charge on the central carbon atom acts as a lone pair. In the H_2BNCO molecule, the in-plane lone pair on nitrogen can act in the same way to cause bending, leading to a lengthening of the B—N bond as predicted by the valence bond structure, (**3**). A comparison of the C_{2v} and C_s structures at the MP2/6-31G* level (Fig. 2*e*) shows this effect, and also indicates that upon bending, the NC bond lengthens and the CO bond shortens, a result similar to that seen for C_2C_3 and C_3O in H_2CCCO (15). These results indicate that an excited state of the form **4** may be contributing to the ground state (compare H_2CCCO) to give an unsymmetrical conformation. Since the two molecules are isoelectronic, it is possibly the same σ orbital (*viz.*, $14a'$ (C_s) or $4b_2$ (C_{2v})) that is involved in both cases. This could be confirmed by carrying out a limited configuration interaction (CI) calculation on H_2BNCO; such a calculation was not performed due to computational constraints. However, a representation of the low lying $4b_2/14a'$ orbital in the C_{2v}/C_s structures (where the HOMO is $3b_2/12a'$) is shown in Fig. 4; bending will stabilize this molecular orbital by decreasing the antibonding NC interaction, and introducing an electronic population transfer on the heavy atoms from 2*p* to 2*s*.

At this point it was decided to return to the HF level and carry out calculations using the less common triple split valence 6-311G* and 6-311G** basis sets. Interestingly, when either of these basis sets are used, the optimum structure is also *trans*-bent (Fig. 2*d*), and approaches the structure obtained when correlation is included. Thus the additional flexibility of the triple split valence basis set[2] is sufficient to cause the molecule to bend, a structural change that is not commonly observed for this kind of modification in the basis set. It should be noted that using 6-311G** with polarization functions on the hydrogen atoms has a negligible effect (not shown) on the 6-311G* structure.[3] The computed bent structure at the 6-311G* level does have some essential features that distinguish it from the MP2/6-31G* structure (Fig. 2*e*) in that all the bonds are shorter, particularly the NC and CO bonds (by *ca.* 0.02–0.04 Å), and there is a reduction in the off-axis angle. Such increases in bond lengths are typical for MP2 results, and more specifically, the NC and CO bond lengths in isocyanates calculated at this level have been observed to be overestimated by 0.01–0.02 Å when compared to experiment (21). Computational results at similar levels of theory for the F_2CCCO molecule (below), where there is an experimental structure for comparison, reach essentially the same conclusions.

Whether one considers the MP2/6-31G* or the HF 6-311G* structure, what is clear is that the energy difference between structures with bent (minima), or linear (transition states)

[2]Reference 24*a*. We note that recently this basis set has been described as being not a true valence triple-zeta basis set, but rather of double-zeta quality in *s* space (24*b*).

[3]However, this may not be true at the correlated level, but computational resources prohibited use of the preferable MP2/6-311G** calculations.

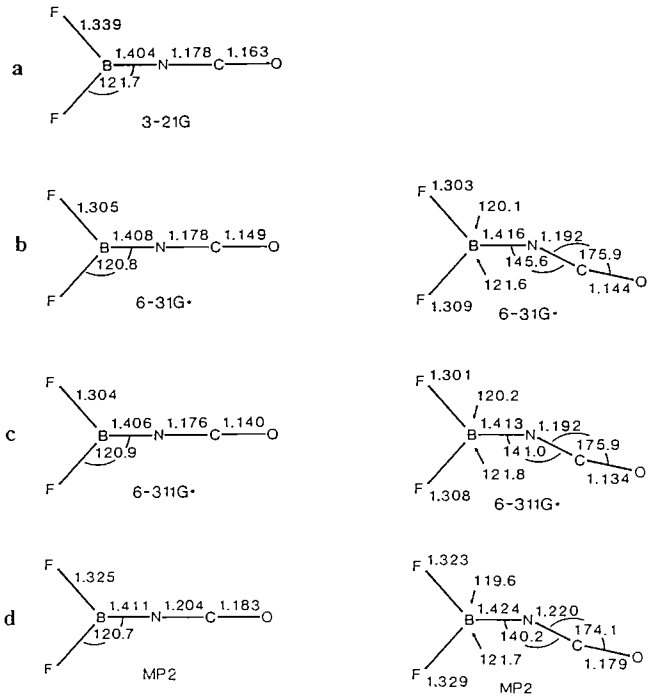

FIG. 3. Optimized structures for F_2BNCO at various levels of theory: (*a*) 3-21G; (*b*) 6-31G*; (*c*) 6-311G*; (*d*) MP2/6-31G*. In the latter three cases the linear (TS) and bent (minimum) structures are shown.

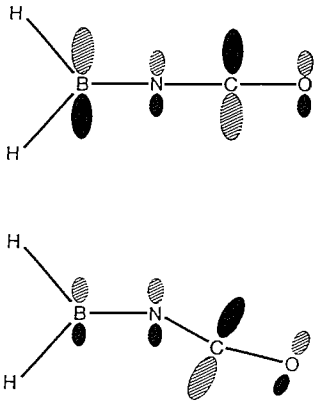

FIG. 4. Schematic of the $4b_2/14a'$ unoccupied molecular orbital of H_2BNCO in both linear and bent configurations; *s* character is not shown.

BNCO chains is very small. At the 6-311G* level the energy difference is 0.53 kJ mol^{-1}, and at the optimized MP2/6-31G* level, 1.12 kJ mol^{-1}. These values indicate a very flat potential surface with a low barrier to inversion at nitrogen, and from previous experience with H_2CCCO this barrier is likely to decrease (indeed it approximately halves) (15) at the higher MP3/6-31G* level, with a corresponding small decrease in the off-axis angle. The lowest calculated vibrational frequency (harmonic, unscaled) of the bent structure occurs at 82 cm^{-1}, 0.99 kJ mol^{-1} (6-311G*), or 106 cm^{-1}, 1.27 kJ mol^{-1} (MP2/6-31G*), and is associated with the in-plane BNC bending coordinate of b_2 symmetry, ν_{12}. Given that the harmonic approach fails for a double minimum potential (25), no significance should be attached to these numbers; they simply indicate the likelihood of a quasilinear molecule. Clearly, higher levels of theory beyond the single determinant framework are required to fully describe the bending potential in this molecule (26), and clarify the lack, or presence, of a double well.

We should reiterate that the lowest level of theory at which H_2BNCO bends, *viz.*, HF 6-311G*, the H_2CCCO molecule remains quite linear. Indeed, it is reported to remain linear up to the 6-311G (*df,p*) level (unpublished observations in ref. 7), although it is entirely feasible that additional polarization functions may cause it to bend at the HF level. When H_2CCCO does bend, at comparable levels of theory to those reported here for H_2BNCO, *viz.*, MP2/6-31G*, the linear-bent energy difference (estimated from Fig. 1 in ref. 15 to be 8.6 kJ mol^{-1}) is substantially greater than for the boron isocyanate analogue, and the angle at C_2 (136°) is calculated to be much smaller.

F_2BNCO

At the HF 3-21G level the optimized structure is linear (Fig. 3*a*), and can be compared with H_2BNCO at the same level (Fig. 2*a*). An interesting feature, which persists for the linear structure at higher levels of theory, is the reduction in the BN bond length upon replacing H by F, an effect analogous to that when F is placed adjacent to a multiple CC bond (27, 28). This is true also for F_2CCCO and H_2CCCO (Fig. 1), and can be ascribed to a stronger σ CC (or BN) bond, associated with an increased polarity of this bond. When the basis set is increased in size to 6-31G*, the optimized structure (Fig. 3*b*) is *trans*-bent with a BNC angle of 145.6°, an NCO angle of 175.9°, and a bent/linear energy difference of 1.47 kJ mol^{-1}. Thus the difluoro-derivative does not require a HF triple split valence basis set, or the inclusion of correlation, to make it bend, and this can be attributed to the competition for the boron $p\pi$ orbital imposed by the fluorine atoms, thereby limiting the ability of boron to accept electrons from nitrogen, leading to a dominance of resonance forms **3** and **4** over form **2**.

Even though correlation was not needed to achieve the bent structure for F_2BNCO, the difference between the C_{2v} and C_s structures is still very small. At the larger triple split valence 6-311G* level the bent structure (Fig. 3*c*, BNC angle now 141.0°) is only 3.85 kJ mol^{-1} lower in energy than the linear structure. A comparison of the optimized bent structures at the 6-31G* and 6-311G* levels indicates an increased bend at N, and concomitant decreases in the BN and CO bond lengths at the higher level of theory. To put this in perspective with regard to structural predictions, we have performed triple split valence 6-311G* calculations on F_2CCCO, and can confirm that this leads to an even better geometry; the $C_1C_2C_3$ angle is now 131.7° (experiment 130.6°) (12) compared to 132.8° calculated at the 6-31G* level (10).

Inclusion of correlation (Fig. 3*d*) follows the pattern observed for H_2BNCO, *viz.*, an increase in all bond lengths especially the NC and CO bonds (see ref. 21 for similar effects), and a decrease in the angle at nitrogen, although in this case the reduction from the 6-311G* value is only 0.8°, and the energy difference hardly changes (3.58 kJ mol^{-1}). Thus the effect of correlation on the angle is not as marked as in the H_2BNCO case, reflecting the fact that correlation in this case is not so critical in achieving the bent structure.

The first vibrational level of bent F_2BNCO, corresponding to the BNC in-plane bending frequency, is calculated (harmonic, unscaled) at 85 cm^{-1}, 1.02 kJ mol^{-1} (6-311G*) or 81 cm^{-1}, 0.97 kJ mol^{-1} (MP2/6-31G*), below the calculated barrier to inversion. Again these values must be taken *cum grano salis*, especially since this molecule may possess large amplitude vibra-

tional motion, with the feasibility of tunneling through the barrier, primarily from excited vibrational states. For what it's worth the out-of-plane frequency is calculated to be only 7–8 cm^{-1} higher, and so internal rotation may be a competitive process to in-plane inversion.

We note that fluorine substitution on H_2BNCO leads to a calculated increase in the off-axis angle of 12.6°, which follows closely the experimentally observed increase of 13.9° in this angle for the replacement of H by F in H_2CCCO (Fig. 1*a* and 1*b*) (8, 12). In addition, when compared to its isoelectronic carbon analogue, difluoropropadienone (Fig. 1*b*), F_2BNCO (Fig. 3*d*) is predicted to be significantly less bent (approximately 10° at the 6-311G* level), reflecting the fact that these substituted boron isocyanates have a greater tendency towards a linear BNCO structure, despite the fact that most isocyanates (except H_3SiNCO) have a distinctly off-axis substituent. A possible rationale for this observation, alluded to earlier, may be found in the effect of excited state contributions, which have not been evaluated in this study.

Conclusions

Ab initio calculations are reported for the propadienone analogue, H_2BNCO and the difluoro-derivative F_2BNCO. At reasonably high levels of theory (up to 6-31G**) the parent H_2BNCO molecule remains linear, until the introduction of a triple split valence basis set, *or* the inclusion of correlation (MP2/6-31G*), which both lead to a *trans*-bent structure. The linear-bent energy difference is extremely small, 0.53 kJ mol^{-1} (6-311G*), and 1.12 kJ mol^{-1} (MP2/6-31G*); in the 6-311G* case so small that ZPVE corrections can essentially cancel the difference, due to the non-inclusion of the negative frequency in the transition state. In addition to an analogy with the H_2CCCO case, we note that a similar conclusion regarding the influence of correlation on bending was reached recently for the isoelectronic molecule, H_2CCNN (29). In our work, the effect of the triple split valence basis set on the BNC angle is interesting; additional polarization functions on a double split valence basis set, *e.g.* 6-31G** clearly have no effect at all, as expected for simply a refinement of the hydrogen space. This implies that a somewhat more flexible and economical double valence basis set may be sufficient to cause bending in molecules of this type.

The difluoro-substituted F_2BNCO molecule is also predicted linear with a small basis set (3-21G), but is *trans*-bent at *both* the HF 6-31G*, and 6-311G* levels, with a correspondingly larger energy difference between the linear and bent forms, *e.g.*, 3.85 kJ mol^{-1}, at the 6-311G* level. The MP2/6-31G* calculation leads to a similar result, implying that in this case the HF level calculations with reasonable basis sets are sufficient to describe the structure.

The trends in the calculated structures between the H_2BNCO and F_2BNCO molecules track those features observed in the experimental structures for the analogous H_2CCCO and F_2CCCO molecules, although the propadienone analogues are significantly more bent, and have greater linear-bent energy differences. This study of the substituted boron isocyanates indicates that there are very subtle electronic effects pertaining to the question of linearity versus non-linearity in X_2BNCO molecules. Thus calculations at the HF 6-31G* level show BNC angles of 180° (X = H) 180° (X = CH_3) (5), 155.2° (X = Cl) (2), and 145.6° (X = F). Note that where X = CH_3, the recently reported experimental structure gives a BNC angle of 153.8°. The introduction of correlation can, as we have seen, affect these results, but the indicate is that π-donating substitutents tend to favor the bent structures **3** and **4**. Indeed, the earlier semiempirical work on the CL_2BNCO, $ClB(NCO)_2$, and $B(NCO)_3$ molecules (1) indicated a trend toward increasing bends at nitrogen due to the greater π-donating ability of the NCO donor. Subsequent to this theoretical study we can report that we have now generated the novel difluoro-molecule, F_2BNCO, and have investigated it by both UPS and FTIR (30). Computed Koopmans' orbital energies, and vibrational frequencies calculated during this study have proven useful for identification, and confirm the isocyanate formulation. Thus, the ν_{as} NCO and ν_s NCO modes are calculated (6-311G* and MP2/6-31G*) at 2514/2418 and 1694/1585 cm^{-1}, respectively, and are observed at 2330 and 1540 cm^{-1}. Partial corrections for anharmonic effects would substantially improve the correspondence between experiment and theory. Experiments involving microwave spectroscopy have also been initiated on this species, in order to investigate the question of linearity/non-linearity, although we would make the final remark that the computed dipole moment is extremely small (<0.1 D).

Received May 14, 1990

INÉS L. ACEVEDO, GRACIELA C. PEDROSA, and MIGUEL KATZ. Can. J. Chem. **69**, 1006 (1991).

Densities and viscosities were determined for the *n*-butylamine + 1,4-dioxane + carbon tetrachloride system at 298.15 K. Molar excess volumes and excess viscosities were calculated from the experimental results. Analytical expressions can be used to predict these excess properties from binary data, the empirical correlation of Cibulka being the best for this system.

Key words: density; mixture of *n*-butylamine + 1,4-dioxane + carbon tetrachloride; viscosity, mixture of *n*-butylamine + 1,4-dioxane + carbon tetrachloride; excess properties of ternary mixture.

INÉS L. ACEVEDO, GRACIELA C. PEDROSA et MIGUEL KATZ. Can. J. Chem. **69**, 1006 (1991).

Opérant à 298,15 K, on a déterminé les densités et les viscosités du système *n*-butylamine + 1,4-dioxane + tétrachlorure de carbone. Utilisant les données expérimentales, on a calculé les volumes molaires en excès ainsi que les viscosités en excès. On peut utiliser des expressions analytiques pour prédire ces propriétés en excès à partir de données binaires; la corrélation empirique de Cibulka est la meilleure pour ce système.

Mots clés : densité; viscosité; mélange *n*-butylamine + 1,4-dioxane + tétrachlorure de carbone; propriétés en excès du mélange ternaire.

[Traduit par la Rédaction]

Introduction

Data of excess volumes and excess viscosities are known for a number of binary liquid mixtures of non-electrolytes and they can be found in several articles. On the other hand, experimental data on excess volumes, densities, on viscosities of mixtures with more than two components are rather rare in the literature. It is therefore interesting to estimate excess volumes and excess viscosities of mixtures with more than two components from binary data.

Data for ternary systems can be found in the works of Redlich and Kister (1), Scatchard and co-workers (2), Tsao and Smith (3), Mathieson and Tynne (4), Kohler (5), Toop (6), Rastogi *et al.* (7), Radojković *et al.* (8), Jacob and Fitzner (9), Cibulka (10), Bertrand *et al.* (11), Nagata (12–14), and Singh *et al.* (15).

This work is to determine the molar excess volumes (V^E) and excess viscosities (η^E) for the *n*-butylamine (BA) + 1,4-dioxane (D) + carbon tetrachloride (CT) system at 298.15 K, and for the three corresponding binary systems, and to consider some empirical correlations assuming that interactions in a ternary mixture are closely dependent on the interactions of the constituents of the binary mixtures.

Experimental

The methods used in our laboratory have been described previously (16, 17). Densities were determined with a digital densimeter AP, model DMA 45. All weighings were made on a H315 Mettler balance.

A thermostatically controlled bath (constant to 0.01°C) was used. Temperatures were read from calibrated thermometers. Calibration was done with air and doubly distilled water, with an error of ± 0.1 kg m^{-3}.

Viscosities of the pure liquids and the mixtures were determined with a Cannon-Fenske viscosimeter calibrated with doubly distilled water and benzene. Kinetic energy corrections were applied to the viscosity data. The estimated error was ± 0.005 mPa s.

Materials and solutions

n-Butylamine (BA), Riedel de Häen (puriss.) was dried over potassium hydroxide pellets for 3 days, refluxed for 2 h, and fractionally distilled (18). 1,4-Dioxane (D), Fluka (puriss.) was distilled over sodium at reduced pressure and the middle fraction collected. Carbon tetrachloride (CT), Merck (puriss.) was used without purification.

Mixtures were prepared by mixing weighed amounts of the pure liquids. Caution was taken to prevent evaporation.

Results and discussion

The experimental results for the pure liquids are reported in Table 1 together with literature values for comparison.

Densities and viscosities of the binary mixtures can be calculated from the experimental data, with mole fraction from the following equation:

$$[1] \quad P = x_i P_i + x_j P_j + x_i x_j \sum_{\substack{k=0 \\ i<j}}^{n} a_k (x_i - x_j)^k$$

where P_i and P_j are properties of the pure components. Table 2 shows the values of the coefficients a_k as well as their standard deviations, calculated by the method of least squares with a VAX 11/780 computer.

η^E (mPa s)	0.146	−0.016	—	—	—	4×10^{-4}

The excess function of a binary system can be represented by a Redlich–Kister form of the type:

$$[2] \quad X^E = x_i x_j \sum_{k=0}^{n} a_k (x_i - x_j)^k$$

where X^E represents V^E or η^E, x_i and x_j are the mole fractions of components i and j, and a_k the polynomial coefficients. The methods of least squares were used to determine the values of the coefficients. In each case, the optimum number of coefficients was ascertained from an examination of the standard error of the estimate with n:

$$[3] \quad \sigma = [\sum (X^E_{obs} - X^E_{cal})^2/(n_{obs} - n)]^{1/2}$$

The values adopted for the coefficients and the standard error of estimates associated with the use of eq. [3] are summarized in Table 3.

Figure 1 shows the experimental values of V^E and η^E for the three systems. The continuous curves were calculated from eq. [2] using these values for the coefficients.

For the systems BA(1) + D(2) and BA(1) + CT(2) there are no values in the literature. For D(1) + CT(2) values of V^E are found in refs. 23 and 24. These authors work at temperatures different from ours and our results are closer to those of Adya *et al.* (24).

The experimental values of densities and viscosities of the ternary system are obtained by adding the third component to a constant relation of the other two. Molar excess volume is calculated with the following equation:

$$[4] \quad V^E = x_1 M_1(\rho^{-1} - \rho_1^{-1}) + x_2 M_2(\rho^{-1} - \rho_2^{-1}) + x_3 M_3(\rho^{-1} - \rho_3^{-1})$$

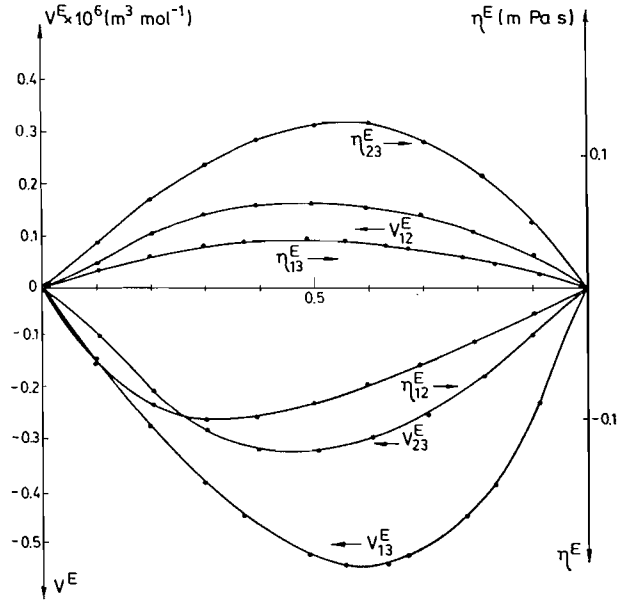

FIG. 1. Excess molar volumes and excess viscosities for binary systems at 298.15 K. Experimental results ····; continuous curves were calculated from eq. [2].

where M_1, M_2, and M_3 are the molecular weights of the components, ρ_1, ρ_2, and ρ_3 are the densities of the pure components, and ρ the density of the mixture.

The excess viscosity is defined by the following equation:

$$[5] \quad \eta^E = \eta - \exp(x_1 \ln \eta_1 + x_2 \ln \eta_2 + x_3 \ln \eta_3)$$

where η, η_1, η_2, and η_3 are the viscosities of the mixture and the

For personal use only.

pure components, where a logarithmic additivity law is assumed for ideal mixtures.

Table 4 shows the experimental values of densities and viscosities at different mole fractions.

Figures 2 and 3 show the experimental constant values of V^E_{123} and η^E_{123}.

If interaction in a ternary system $i + j + k$ is assumed to be closely dependent on the interactions of the constituents $i + j$, $j + k$, and $i + k$ mixtures, it should be possible to evaluate excess properties for ternary mixtures of non-electrolytes, when the corresponding properties for the binary $i + j$, $j + k$, and $i + k$ mixtures are known.

Redlich and Kister (1) proposed an equation in terms of mole fractions for the excess Gibbs free energy of a ternary mixture with the general form:

$$[6]\quad G^E_{123} = x_1x_2\sum_{\nu=0}^{r}(G_\nu)_{12}(x_1 - x_2)^\nu + x_1x_3\sum_{\nu=0}^{r}(G_\nu)_{13}(x_1 - x_3)^\nu + x_2x_3\sum_{\nu=0}^{r}(G_\nu)_{23}(x_2 - x_3)^\nu$$

and recommended the same general form for the excess enthalpy and volume.

Scatchard and co-workers (2) suggested an alternate form in the case of one polar component (component 1) mixed with two nonpolar components:

$$[7]\quad G^E_{123} = x_1x_2\sum_{\nu=0}^{r}(G_\nu)_{12}(2x_1 - 1)^\nu + x_1x_3\sum_{\nu=0}^{r}(G_\nu)_{13}(2x_1 - 1)^\nu + x_2x_3\sum_{\nu=0}^{r}(G_\nu)_{23}(x_2 - x_3)^\nu$$

Tsao and Smith (3) proposed an equation for predicting the excess enthalpy of a ternary system. For excess volume, this equation is:

$$[8]\quad V^E_{123} = \left(\frac{x_2}{1 - x_1}\right)V^E_{12} + \left(\frac{x_3}{1 - x_1}\right)V^E_{13} + (1 - x_1)V^E_{23}$$

in which V^E_{ij} refers to the excess volume for the binary mixtures at compositions x^0_i, x^0_j such that $x^0_i = x_i$ for the 1,2 and 1,3 binary systems, and $x^0_2 = x_2/(x_2 + x_3)$ for the 2,3 binary system.

This equation, like eq. [7], is asymmetrical and requires specification of some criteria for identifying component 1.

Mathieson and Tynne (4) proposed an equation which is intermediate between eqs. [6] and [7], using the following form for enthalpies:

$$[9]\quad H^E_{123} = x_1x_2\sum_{\nu=0}^{r}(H_\nu)_{12}\left(\frac{x_1 - x_2 - x_3}{2}\right)^\nu + x_1x_3\sum_{\nu=0}^{r}(H_\nu)_{12}\left(\frac{x_1 - x_3 - x_2}{2}\right)^\nu + x_2x_3\sum_{\nu=0}^{r}(H_\nu)_{23}(x_2 - x_3)$$

Kohler (5) proposed an equation for a ternary system of the following form:

$$[10]\quad V^E_{123} = (x_1 + x_2)^2V^E_{12} + (x_1 + x_3)^2V^E_{13} + (x_2 + x_3)^2V^E_{23}$$

Kohler's equation is symmetrical in that all three binary systems are treated identically. In this equation, V^E_{ij} refers to the excess volume of x^0_i, x^0_j in the binary mixtures, using

$$[11]\quad x^0_i = 1 - x^0_j = x_i/(x_i + x_j)$$

Toop (6) developed an equation for the excess Gibbs energy of mixing quite similar to that suggested previously by Tsao and Smith for excess enthalpies.

Rastogi *et al.* (7) suggested a form for predicting the excess

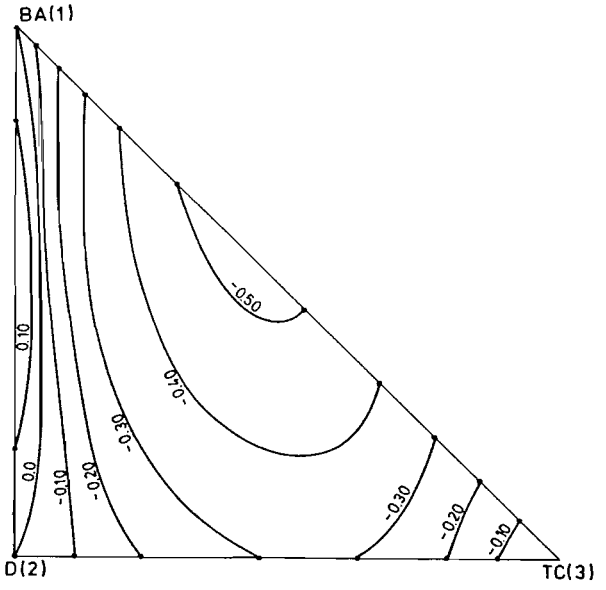

FIG. 2. Lines of constant excess molar volumes V^E ($\times 10^6$ m^3 mol^{-1}) for *n*-butylamine (1) + 1,4-dioxane (2) + carbon tetrachloride (3) system at 298.15 K.

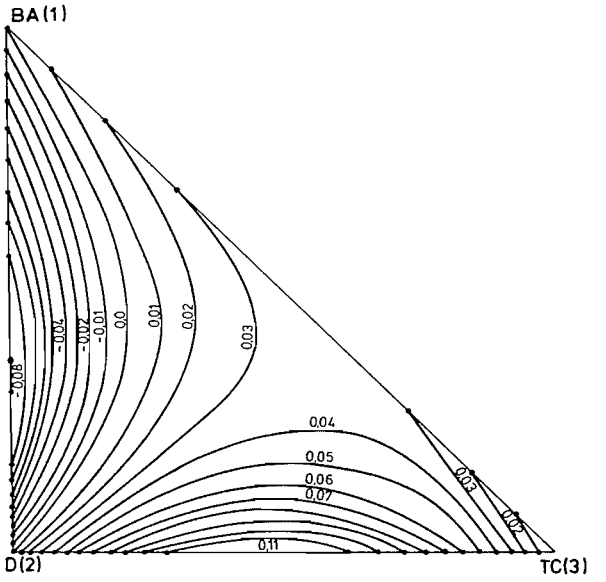

FIG. 3 Lines of constant excess viscosities η^E (mPa s) for *n*-butylamine (1) + 1,4-dioxane (2) + carbon tetrachloride (3) system at 298.15 K.

volume of a ternary system, similar to eq. [10].

$$[12]\quad V^E_{123} = \tfrac{1}{2}[(x_1 + x_2)V^E_{12} + (x_1 + x_3)V^E_{13} + (x_2 + x_3)V^E_{23}]$$

This expression is inappropriate for describing the system near infinite dilution.

Radojković *et al.* (8) considered an expression proposed by Redlich and Kister for excess Gibbs free energy. For excess molar volume:

$$[13]\quad V^E_{123} = V^E_{12*} + V^E_{23*} + V^E_{13*}$$

where V^E_{12*}, V^E_{23*}, and V^E_{13*} represent the excess molar volumes with x_1, x_2, and x_3 mole fractions in the ternary system calculated with eq. [2], using the coefficients in Table 3.

Jacob and Fitzner (9) suggested an equation for estimating the

TABLE 5. Standard deviations for *n*-butylamine (1) + 1,4-dioxane (2) × carbon tetrachloride (3) system at 298.15 K

Equation	$\sigma(V^E) \times 10^6$ (m^3 mol^{-1})	$\sigma(\eta^E)$ (mPa s)
[8]	0.07	0.03
[10]	0.11	0.02
[13]	0.10	0.02
[14]	0.10	0.02
[16][a]	0.03	0.01
[19][a]	0.06	0.02

[a]These equations contain three adjustable parameters.

properties of a ternary solution based on the binary data at composition nearest the ternary composition, using the following form for excess molar volume:

$$[14]\quad V^E_{123} = \frac{x_1x_2V^E_{12}}{\left(x_1 + \frac{x_3}{2}\right)\left(x_2 + \frac{x_3}{2}\right)} + \frac{x_1x_3V^E_{13}}{\left(x_1 + \frac{x_2}{2}\right)\left(x_3 + \frac{x_2}{2}\right)} + \frac{x_2x_3V^E_{23}}{\left(x_2 + \frac{x_1}{2}\right)\left(x_3 + \frac{x_1}{2}\right)}$$

so that for binary system at composition x_i^0, x_j^0:

$$[15]\quad x_i - x_j = x_i^0 - x_j^0$$

Cibulka (10) proposed the following equation:

$$[16]\quad V^E_{123} = V^E_{12*} + V^E_{13*} + V^E_{23*} + x_1x_2x_3(A + Bx_1 + Cx_2)$$

where A, B, and C are parameters calculated from experimental data.

Bertrand *et al.* (11) presents the following equation for an excess property in a multicomponen system:

$$[17]\quad Z^E_{123} = (x_1 + x_2)(f_1 + f_2)(Z^E_{12})^* + (x_1 + x_3)(f_1 + f_3)(Z^E_{13})^* + (x_2 + x_3)(f_2 + f_3)(Z^E_{23})^*$$

in which Z represents any extensive thermodynamic property described in terms of interaction parameters A_0 and the weighting factor f_i relates to the composition of the system. The superscript * represents a composition of a binary system which would be formed if all the third component is removed, so that for the $i - j$ system:

$$[18]\quad x_i^* = 1 - x_j^* = x_i/(x_i + x_j)$$

Nagata (12–14) has proposed more complex equations for the excess enthalpy of a ternary system of one alcohol + two hydrocarbons, taking association of the components into account.

Finally, Singh *et al.* (15) proposed an equation of the following form:

$$[19]\quad V^E_{123} = V^E_{12*} + V^E_{13*} + V^E_{23*} + x_1x_2x_3[A + Bx_1(x_2 - x_3) + Cx_1^2(x_2 - x_3)^2]$$

where A, B, and C are parameters characteristic of the mixtures evaluated by the method of least squares using a standard deviation defined in eq. [3].

We have used eqs. [8], [10], [13], [14], [16], and [19] to calculate excess molar volumes and excess viscosities in our system.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

The parameters obtained for V^E_{123} in Cibulka's equation are $A = 8.7571$; $B = -24.6172$; $C = -13.7019$. For η^E_{123} the parameters are $A = -2.4474$; $B = 5.3179$; and $C = 1.1798$.

The parameters obtained for V^E_{123} in the equation of Singh *et al.* are $A = -3.3083$; $B = -18.7442$; and $C = -81.6366$. For η^E_{123} the parameters are $A = -0.4753$; $B = 1.6449$; and $C = 19.6837$.

Table 5 shows the standard deviations for the excess volumes and viscosities calculated by using some of the equations previously mentioned for a ternary system.

Equation [16] shows the best agreement with the experimental data. Only eqs. [16] and [19] contain three adjustable parameters while the others include only experimental data for the corresponding binary mixtures. There is no preferred way of knowing which method will provide the best prediction for a given system. The last two methods use parameters which are obtained from experimental data. The fact that so many empirical equations have been developed suggests that no single equation can describe all types of available systems.

The synthesis of 3*H*-naphthol[1,8-*bc*]thiophene derivatives

PETER D. CLARK,[1] NICHOLAS M. IRVINE, AND PRATIBHA SARKAR
Department of Chemistry, The University of Calgary, 2500 University Drive N.W., Calgary, Alta., Canada T2N 1N4

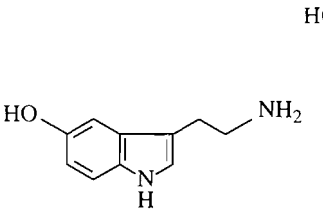
Received November 9, 1990

PETER D. CLARK, NICHOLAS M. IRVINE, and PRATIBHA SARKAR. Can. J. Chem. **69**, 1011 (1991).

Methods for the synthesis of keto derivatives of the little studied naphtho[1,8-*bc*]thiophene system have been developed. Using the readily available benzothiophene derivative 6,7-dihydrobenzo[*b*]thiophen-4(5*H*)-one **4**, a 3-keto-naphtho-[1,8-*bc*]thiophene **14** was synthesized by a tin(IV) chloride catalyzed cyclization of the acid chloride derivative of the saturated acid **13***b*. The bicyclic ketone **4** was also used to prepare the keto-sulfoxide **7**, which was cyclized to the 4-keto-naphtho-[1,8-*bc*]thiophene system **9** in a Pummerer-type rearrangement.

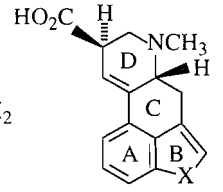
Key words: synthesis, organosulfur, naphtho[1,8-*bc*]thiophenones.

PETER D. CLARK, NICHOLAS M. IRVINE et PRATIBHA SARKAR. Can. J. Chem. **69**, 1011 (1991).



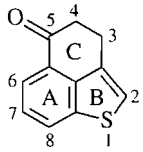
On a mis au point des méthodes de synthétiser les dérivés cétoniques du système naphto[1,8-*bc*]thiophène qui n'a pas été très étudié jusqu'à maintenant. Utilisant comme produit de départ la 6,7-dihydrobenzo[*b*]thiophén-4(5*H*)-one (**4**), un dérivé benzothiophène facilement disponible, on a réalisé la synthèse de la naphto[1,8-*bc*]thiophén-3-one (**14**) en faisant appel à une cyclisation, catalysée par la chlorure d'étain (IV), du chlorure d'acide de l'acide saturé **13***b*. On a utilisé la cétone bicyclique **4** pour préparer ie céto-sulfoxyde **7** qui, par une cyclisation impliquant une transposition du type de Pummerer, conduit au système naphto[1,8-*bc*]thiophón-4-one, **9**.

Mots clés : synthèse, organosulfure, naphto[1,8-*bc*]thiophénones.



[Traduit par la rédaction]

Introduction



Compounds and alkaloids containing the indole nucleus have a wide spectrum of pharmacological activity (1–4). Perhaps the best known examples of these compounds are the natural transmitter 5-hydroxytryptamine **1** (5) and derivatives of the ergoline ring system such as lysergic acid **2***a* (for a general review, see ref. 6). Replacement of the indole nitrogen by sulfur is known (7) to change the pharmacological action of **1** and related compounds and, in some cases, to produce isosteres with useful biological properties (8). Several workers have attempted to prepare the sulfur analogues of ergolines **2***b* but, to our knowledge, none have been successful (9–12). This paper describes the synthesis of naphtho[1,8-*bc*]thiophene derivatives, which should be useful intermediates in the preparation of thia-ergolines **2***b*.

1

2*a* = NH
2*b* = S

3

Very few derivatives of the naphtho[1,8-*bc*]thiophene system have been reported (9–11, 13–15). Most of the syntheses described have been in connection with development of routes of the preparation of thia-ergolines. Considerable effort (9, 10) was put into developing syntheses and the chemistry of the tricyclic ketone **3** as it was expected to be a useful intermediate in constructing ring D of thia-ergoline systems. Unfortunately, this (and related compounds) isomerizes readily to naphthalene derivatives in which the A and C rings become the aromatic nucleus (10). This problem may be overcome by working with derivatives in the early stages of the synthesis in which the A ring is saturated since these compounds would show little tendency to be involved in aromatization processes involving the C ring. Consequently, we have designed syntheses of the novel tricyclic ketones **9** and **14** and report on their preparation here.

Experimental

Melting points were determined using a Thiele tube apparatus containing silicon oil and were uncorrected. The IR spectra were recorded on a Nicolet 5DX spectrometer as neat liquids, thin films, or KBr discs. The ^1H and ^{13}C NMR spectra were recorded on a Bruker ACE 200 or a Bruker AM 400 spectrometer, at 200 and 400 MHz respectively, in $CDCl_3$ solution with either tetramethylsilane or chloroform as the internal standard. Assignments for ^{13}C spectra were made (where possible) on the basis of DEPT, 2D correlation experiments,[2] and chemical shift data. MS and GCMS were recorded on a Hewlett Packard 5970/5890 spectrometer. Elemental analyses were obtained from Canadian Microanalytical Service Ltd., B.C. Column chromatography was performed on Merck silica gel, grade 60, 230–400 mesh. Reagents were obtained from the Aldrich Chemical Company and, unless stated otherwise, were used without purification. Solvents were purified according to procedures described in ref. 16.

*6,7-Dihydro-5*H*-benzo[*b*]thiophen-4-one* **4**

This ketone was prepared either from thiophene or from 2-cyclohexen-1-one using methods described previously (17–20). Both methods are reliable although the preparation from 2-cyclohexen-1-one (20) is preferred for large-scale work.

Preparation of the ene-acetates **5**a *and* **5**b

These compounds were prepared by the following modifications of the literature method (21).

A solution of triethyl phosphonoacetate (22.4 g, 100 mmol) in dry tetrahydrofuran (100 mL) was added dropwise over 45 min to a suspension of sodium hydride (60% in oil, 3.7 g, 90 mmol) in dry tetrahydrofuran (100 mL) under an argon atmosphere. The resulting clear yellow solution was heated under reflux for 15 min and a solution of the ketone **4** (10.0 g, 66 mmol) in tetrahydrofuran (100 mL) was added in one portion. After 36 h at reflux, the resulting orange solution was cooled

and was added to water (300 mL). Organic material was recovered by extraction into dichloromethane (3 × 250 mL). The organic extracts were washed with water (3 × 100 mL), dried ($MgSO_4$), and evaporated. The residual tan colored oil was chromatographed on silica (5% ethyl acetate in hexanes) to remove residual phosphorus compounds and was distilled at reduced pressure to yield a colorless liquid (14.17 g, 97%; bp 105–125°C at 0.05 Torr (1 Torr = 133.3 Pa)). ^{1}H NMR[a] indicated that the product was a 63:37 mixture of *E* and *Z* isomers **5***a* and **5***b*; IR (ν_{max}, neat): 3107, 2933, 1706, 1612, 1174, 1150, and 1049 cm^{-1}; ^{1}H NMR, *E* isomer,[b] δ: 7.20 (d, *J* = 5.4 Hz, -C*H*=CH-), 7.06 (d, *J* = 5.4 Hz, -CH=C*H*), 6.11 (t, *J* = 1.7 Hz, -C=C*H*), 4.19 (q, -C*H*$_2$-CH$_3$), 3.20–3.05 (m, -C*H*$_2$-C=CH-), 2.89 (t, *J* = 6.1 Hz, -C*H*$_2$-S-), 1.95 (m, -CH$_2$-C*H*$_2$-CH$_2$-), 1.31 (t, -CH$_2$-C*H*$_3$); *Z* isomer,[c] δ: 7.81 (d, *J* = 5.5 Hz, -C*H*=CH-), 7.02 (d, *J* = 5.5 Hz, -CH=C*H*-), 5.65 (br, s -C=C*H*-), 4.18 (q, -C*H*$_2$-CH$_3$), 2.93 (t, -C*H*$_2$C=-CH-), 2.50–2.40 (m, -C*H*$_2$-S-), 1.96 (m, -CH$_2$-C*H*$_2$-CH$_2$-), 1.28 (t, -CH$_2$C*H*$_3$); ^{13}C NMR, *E* isomer, δ: 167.17 (*C*=O), 150.32, 144.73, and 134.71 (quaternary C), 123.24, 122.51, and 110.31 (-*C*H=CX), 59.42 (-OC*H*$_2$CH$_3$), 26.18, 25.29, and 23.53 (*C*H$_2$), 14.25 (OCH$_2$*C*H$_2$CH$_3$); Z isomer[c]: 166.45 (*C*=O), 146.81, 145.45, and 132.49 (quaternary C), 128.55, 120.88, and 112.03 (-*C*H=CX), 59.76 (-OC*H*$_2$CH$_3$), 35.51, 25.86, and 24.14 (*C*H$_2$), 14.15 (OCH$_2$*C*H$_3$). Anal. calcd. for $C_{12}H_{14}O_2S$: C 64.84, H 6.35, S 14.42%; found: C 65.22, H 6.55; S, 14.53%.

*4′-(4,5,6,7-Tetrahydrobenzo[*b*]thienyl) ethyl ethanoate* **6**

A solution of the ene-acetates **5***a* and **5***b* (20 g, 90 mmol) in toluene (700 mL) was stirred with 10% Pd on charcoal (4.5 g) for 24 h under a hydrogen atmosphere. The mixture was filtered through Celite and the crude product was recovered by evaporation of the solvent. Traces of unhydrogenated material were separated by flash chromatography on silica (5% ethyl acetate in hexanes) and the product was obtained as a colorless liquid (17.75 g, 88%) by distillation (bp 85–92°C at 0.05 Torr); IR (ν_{max}, neat): 2934, 1733, and 1175 cm^{-1}; ^{1}H NMR, δ: 7.01 (d, *J* = 5.2 Hz, -C*H*=CH-), 6.79 (d, *J* = 5.2 Hz, -CH=C*H*-), 4.16 (q, -OC*H*$_2$CH$_3$), 3.35–3.15 (m, -CH$_2$C*H*CH$_2$-), 2.74 (t, -C*H*$_2$-S-), 2.69 and 2.38 (each dd, -CH-C*H*$_2$CO-), 2.05–1.65 and 1.65–1.45 (m, -C*H*$_2$C*H*$_2$-), 1.26 (t, -OCH$_2$C*H*$_3$); ^{13}C NMR, δ: 172.35 (*C*=O), 137.37 and 136.21 (quaternary carbons), 126.13 and 121.73 (-*C*H=*C*H-), 60.11 (-OCH$_2$CH$_3$), 40.84, 28.61, 24.89, and 21.26 (four CH$_2$), 32.48 (-CH-). Anal. calcd. for $C_{12}H_{16}O_2S$: C 64.25, H 7.19, S 14.29%; found: C 64.00, H 7.04, S 14.31%.

Preparation of the keto-sulfoxide **7**

Dimethyl sulfoxide, freshly distilled from calcium hydride (30 mL, 420 mmol), was added dropwise to a stirred solution of *n*-butyllithium (36 mL of a 1.6 M solution in hexane, 58 mmol) in dry tetrahydrofuran (30 mL) at 0°C under an argon atmosphere. A solution of the ester **6** (5.0 g, 22.3 mmol) in dry tetrahydrofuran (10 mL) was added to the resulting cream colored slurry and the reaction mixture was allowed to warm to room temperature. The orange solution produced was added to water and the mixture was extracted with dichloromethane (3 × 150 mL). The organic extracts were washed with saturated sodium bicarbonate (2 × 100 mL) and with water (3 × 100 mL), dried ($MgSO_4$), and evaporated. The light brown residue was chromatographed on silica (ethyl acetate) to yield a light brown solid (4.8 g, 84%), which was a mixture of diastereomers of **7**. An analytically pure sample of the minor diastereomer was obtained as white crystals, mp 75–77°C, on crystallization from hexanes; IR (ν_{max}, neat): 2930, 1710, and 1035 cm^{-1}; ^{1}H NMR, δ: 7.03 (d, *J* = 5.3 Hz, -C*H*=CH-), 6.75 (d, *J* = 5.3 Hz, -CH=C*H*-), 3.90–3.60 (2 × q,[a] -COC*H*$_2$SO-), 3.45–3.25 (m, -CH$_2$C*H*CH$_2$-), 2.68, 2.66[a] (s, -SOC*H*$_3$), 3.02–2.65 and 2.05–1.40 (unres. m, methylene protons); ^{13}C NMR, δ: 201.39 (*C*=O), 136.95, 136.42 (quaternary carbons), 126.16, 121.94 (-*C*H=*C*H-), 64.55 [63.94][b] (*C*OCH$_2$SO), [51.7] 51.51 (*C*HCH$_2$CO), 39.03 [38.78] (SO*C*H$_3$), 30.81 (CH$_2$*C*HCH$_2$), 28.68, 24.76, and 21.18 (3CH$_2$ in six-membered ring). Anal. calcd. for $C_{12}H_{16}O_2S_2$: C 56.22, H 6.29, S 25.01%; found: C 55.86, H 6.21, S 24.87%.

[b]Values for the minor diastereomer given in square brackets.

*3-Methylthio-4,5,5a,6,7,8-hexahydro-3*H*-naphtho[1,8-*bc*]thiophen-4-one* **8**

A solution of *p*-toluenesulfonic acid monohydrate (3.71 g, 19.5 mmol) in 1.2 L of chloroform (distilled from P_2O_5 to remove ethanol) was heated under reflux for 3 h with removal of water via a Dean Stark trap. The sulfoxide **7** (2.5 g, 9.75 mmol) in chloroform (150 mL) was added and resulting orange-brown solution was heated under reflux for 15 min. The cooled reaction mixture was poured into saturated sodium bicarbonate (500 mL) and the organic layer was washed with bicarbonate (500 mL) and with water (2 × 500 mL), and then dried ($MgSO_4$). Evaporation of the chloroform gave a brown oil, which was purified by column chromatography on silica (10% ethyl acetate in hexanes). The pale yellow oil obtained (1.1 g, 47%) was used immediately as it darkened quickly on standing and decomposed on attempted distillation. Spectroscopic analysis indicated that **8** was formed as a mixture of diastereomers; IR (ν_{max}, neat): 3096, 2923, 1704, 1603, and 1435 cm^{-1}; ^{1}H NMR[a], δ: [7.11] 7.00 (s, -C*H*=C-), 4.20 [4.16] (s, -C*H*SCH$_3$-), 3.40–2.65 (unres. m, 5H), [2.15] 2.13 (s, -SCH$_3$), 2.20–1.10 (unres. m, 4H).

[a]Integration of signals at 7.0 and 2.1 ppm suggested that the product was a 2:1 mixture of diastereomers; values for the minor isomer are shown in square brackets.

*4,5,5a,6,7,8-Hexahydro-3*H*-naphtho[1,8-*bc*]thiophen-4-one* **9**

W-2 Raney nickel (ca. 6 g) was added to a solution of the methylthio ether **8** (1.3 g, 5.5 mmol) in acetone (100 mL) and the mixture was stirred at room temperature for 5 h. The catalyst was removed by filtration through Celite and the crude product was obtained by evaporation of the solvent. Column chromatography on silica (10% ethyl acetate in hexanes) yielded a pale orange solid that crystallized from hexane (charcoal) to yield off-white plates (0.44 g, 43%); mp 60–63°C; IR (ν_{max}, Nujol): 3095, 2930, 1712, 1446, 1393, 1325, 1228, and 1173 cm^{-1}; ^{1}H NMR (400 MHz),[a] δ: 6.79 (d, *J* = 0.9 Hz, -C*H*=C-), 3.59 (d, *J* = 21.0 Hz, 1H of =C-C*H*$_2$-CO), 3.47 (dd, *J* = 21 and 0.9 Hz, 1H of =C-C*H*$_2$CO), 3.05–2.85 (m, -CH$_2$C*H*CH$_2$-), 2.90–2.60 (m, C*H*$_2$S and 1 proton of CHC*H*$_2$CO), 2.20–2.10 (m, 1 proton of CHC*H*$_2$CO, 1 proton of CHC*H*$_2$CH$_2$, and 1 proton of CH$_2$C*H*$_2$CH$_2$S), 1.95–1.80 (m, 1 proton of CH$_2$C*H*$_2$CH$_2$S), and 1.4–1.25 (m, 1 proton of CHC*H*$_2$CH$_2$); ^{13}C NMR, δ: 209.0 (*C*=O), 135.63, 134.86, and 132.71 (quaternary carbons), 116.64 (*C*H=C-), 46.14 (-CHCH$_2$CO), 41.15 (=CCH$_2$CO), 32.22 (-C*H*-), 29.84 (CH$_2$*C*H$_2$CH), 24.64 (SC*C*H$_2$), and 23.45 (CH$_2$CH$_2$CH$_2$). Anal. calcd. for $C_{11}H_{12}OS$: C 68.72, H 6.29, S 16.67%; found: C 68.28, H 6.19, 17.04%.

[a]Assignments were made on the basis of proton–proton and proton–carbon correlation experiments.

*4-Methoxymethylene-6,7-dihydro-5*H*-benzo[*b*]thiophene* **10**a, **10**b

Phenyllithium (22 mL of a 2 M solution in cyclohexane–ether, 44 mmol) was added dropwise to a suspension of (methoxymethyl)-triphenylphosphonium chloride (**22**) (17.14 g, 50 mmol) in dry ether (100 mL) at 0°C under an argon atmosphere. After stirring the resulting red mixture for 15 min, the temperature was lowered to −65°C and a solution of the ketone **4** (3.04 g, 20 mmol) in anhydrous ether was added over 5 min. The reaction mixture was allowed to warm to room temperature, stirred vigorously for 5 h, and then poured into cold water (100 mL). The ether layer was collected and the aqueous layer was extracted with ether (3 × 25 mL). The combined organic extracts were washed with saturated sodium chloride solution, dried ($MgSO_4$), and evaporated. Column chromatography of the residue on silica (0–2% ethyl acetate in hexanes) gave a mixture (TLC, NMR) of the *E* and *Z* enol ethers **10***a* and **10***b*, which was distilled to yield a colorless liquid (2.7 g, 75%; bp 72–75°C at 0.03 Torr); IR (ν_{max}, neat): 2932, 2832, 1661, 1452, 1223, 1157, and 1124 cm^{-1}; ^{1}H NMR, δ: 7.58[a] (d, *J* = 5.3 Hz, -C*H*=CH-), 7.05–6.94 (unres. m, thiophenic H), 6.45[b] (t, *J* = 1.6 Hz, -C=C*H*OCH$_3$), 5.88[a] (t, *J* = 1.2 Hz, -C=C*H*OCH$_3$), 3.66 (s,

-OCH_3), 2.88–2.75 (m, -CH_2CH_2S-), 2.50–2.44[b] (m, -CH_2CH_2C=), 2.30–2.24[a] (m, -CH_2CH_2C=), 1.95–1.79 (m, -$CH_2CH_2CH_2$-); ms *m/e*: 180 (89).

NOTE: *a* and *b* refer to signals for the *Z* and *E* isomers respectively (see discussion).

*4'-(4,5,6,7-Tetrahydrobenzo[*b*]thienyl) methanal* ***11***

6 M Aqueous hydrochloric acid (6 mL) was added to a solution of the enol ethers **10***a* and **10***b* (8.06 g, 45 mmol) in tetrahydrofuran (100 mL) under argon and the mixture was heated under reflux for 15 h. A further 4 mL of the 6 M acid was added and the solution refluxed for an extra 2 h. The reaction mixture was cooled, evaporated to a small volume, and quenched with water (100 mL). The mixture was extracted with dichloromethane (4 × 20 mL) and the organic extracts were washed with saturated sodium bicarbonate (2 × 10 mL), brine (1 × 50 mL), dried ($MgSO_4$), and evaporated to yield **11** as a pale yellow oil[a] (7.80 g); IR (ν_{max}, neat): 2937, 2858, 2717, and 1725 cm^{-1}; ^{1}H NMR, δ: 9.66 (d, *J* = 2.2 Hz, -*CH*O), 7.15 and 6.88 (each d, *J* = 5.2 Hz, -*CH*=*CH*-), 3.54 (m, -CH_2*CH*CHO), 2.8 (t, -SCH_2CH_2-), 2.21–1.81 (m, -CH_2CH_2-); ^{13}C NMR, δ: 200.68 (-*C*HO), 138.23 and 129.06 (quaternary C), 126.4 and 122.5 (-*C*H=*C*H-), 48.75 (-*C*HCHO), 24.47, 22.57, and 21.19 (3 × CH_2); ms *m/e*: 166. The aldehyde was characterized as a 2,4-dinitrophenylhydrazone derivative, which crystallized from ethyl acetate as orange crystals, mp 210–213°C. Anal. calcd. for $C_{15}H_{14}N_4O_4S$: C 52.02, H 4.07, N 16.18, S 9.26%; found: C 51.51, H 4.16, N 15.94, S 9.24%.

[a]This product decomposed rapidly unless stored at low temperatures under an inert atmosphere, and was used directly in the next stage.

E-*3-(4'-(4,5,6,7-Tetrahydrobenzo[*b*]thienyl)) ethyl propenoate* ***12***

A solution of triethyl phosphonoacetate (16.08 g, 71.8 mmol) in dry tetrahydrofuran (100 mL) was added dropwise to a suspension of sodium hydride (60% in oil, 2.88 g, 72 mmol) in tetrahydrofuran (100 mL) under an argon atmosphere. The mixture was cooled to −60°C and a solution of the aldehyde **11** in tetrahydrofuran (100 mL) was added over a period of 10 min. The reaction mixture was allowed to warm to room temperature and was stirred for 1.5 h. Solvent was removed by rotary evaporation, the residue was quenched with water (100 mL), and the resulting mixture was extracted with dichloromethane (4 × 20 mL). Evaporation of the washed (brine, 1 × 50 mL) and dried ($MgSO_4$) extracts yielded an oil that was distilled (bp 116–119°C at 0.03 Torr) to give **12** as a clear liquid (9.50 g, 90% from **10***a* and **10***b*); IR (ν_{max}, neat): 2936, 1718, and 1652 cm^{-1}; ^{1}H NMR, δ: 7.05 (d, *J* = 5.2 Hz, S-*CH*=CH-), 7.0 (dd, -CHC*H*=CHCO$_2$-), 6.73 (d, *J* = 5.2 Hz, SCH=C*H*-), 5.79 (dd, *J* = 15.6 and 1.2 Hz, -CHCH=C*H*CO$_2$-), 4.18 (q, -OCH_2CH_3), 3.56 (m, -CH_2*CH*(C=)CH=), 2.78 (t, SCH_2CH_2-), 1.70–1.90 (m, -$CH_2CH_2CH_2$CH-), 1.29 (t, -OCH_2CH_3); ^{13}C NMR, δ: 166.64 (-*C*O$_2CH_2CH_3$), 151.49 (=*C*HCO$_2CH_2CH_3$), 136.87 and 134.59 (quaternary C), 127.28, 122.02, and 121.54 (thiophenic *C*H and remaining olefinic C), 60.23 (-OCH_2CH_3), 39.1 (-CH_2CH(C=)CH=), 28.64, 24.90, and 21.16 (3 × CH_2), 14.24 (-OCH_2CH_3); ms *m/e*: 236 (M^+). *3-(4'-(4,5,6,7-Tetrahydrobenzo[*b*]thienyl))propanoic acid* ***13***b

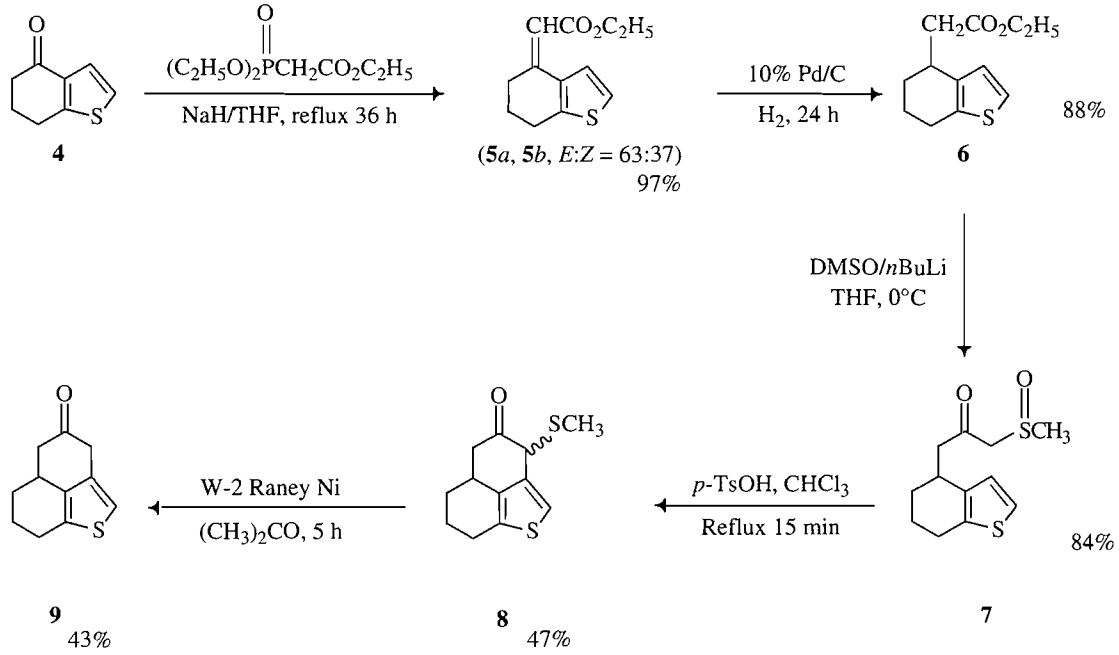
A mixture of the ester **13***a* (6.96 g, 29 mmol) and 1:1 absolute ethanol and 20% aqueous sodium hydroxide solution (140 mL) was heated under reflux for 2 h. The cooled reaction mixture was extracted with dichloromethane (2 × 20 mL), acidified with concentrated hydrochloric acid, and extracted with dichloromethane (3 × 20 mL). Evaporation of the washed (water) and dried ($MgSO_4$) extracts gave a solid residue that was recrystallized as pale yellow plates (5.26 g, 86%), mp 78–80°C from aqueous ethanol; IR (ν_{max}, KBr): 3000 (br) and 1704 cm^{-1}; ^{1}H NMR, δ: 10.10 (br s, -O*H*), 7.05 and 6.86 (two, d, *J* = 5.2 Hz, -SC*H*=C*H*-), 2.76 (t, -SCH_2CH_2-), 2.43 (dd, -$CH_2CH_2CO_2$H), 2.12 (m, -CH_2*CH*CH_2-), 2.0–1.41 (m, 3 × CH_2); ^{13}C NMR, δ: 180.13 (-*C*O$_2$H), 138.17 and 136.25 (quaternary C), 126.49 and 121.49 (-SC*H*=C*H*-), 34.97 (-CH_2*C*HCH_2-), 31.59, 30.47, 27.86, 25.10, and 21.65 (5 × CH_2); ms *m/e*: 210. Anal. calcd. for $C_{11}H_{14}O_2S$: C 62.83, H 6.71, S 15.22%; found: C 63.22, H 6.79, S 14.95%.



*4,5,5a,6,7,8-Hexahydro-3*H*-naphtho[1,8-*bc*]thiophen-3-one* ***14***

A solution of the acid **13***b* (1.05 g, 5 mmol) in dichloromethane (10 mL) was gently heated under reflux with thionyl chloride (1.19 g, 10 mmol) and pyridine (25 μL) under argon for 3 h. The mixture was concentrated by rotary evaporation and the crude acid chloride (IR 1798 cm^{-1}) was dissolved in carbon disulfide (5 mL). Under argon, the solution was cooled to 0°C, and tin tetrachloride (0.70 mL, 6 mmol) in carbon disulfide (15 mL) was added dropwise over 10 min. After carefully stirring the dark green mixture for 20 min at this temperature, it was heated under reflux for 2.5 h. The contents were cooled, evaporated to near dryness, and taken up into chloroform (50 mL). Ice (20 g) and hydrochloric acid (3 mL) were added, the organic layer was separated off, and the aqueous layer extracted with chloroform (3 × 10 mL). Organic extracts were combined, washed with brine (25 mL), dried ($MgSO_4$), evaporated down, and the residue was purified by flash column chromatography on silica (20% ethyl acetate in hexanes) to yield 0.74 g (77%) of **14** as a yellow solid. Recrystallization from hexanes produced pale yellow needles; mp 67–68°C; IR (ν_{max}, KBr): 3082, 2903, and 1681 cm^{-1}; ^{1}H NMR (400 MHz), δ: 7.92 (C*H*=C), 2.95–2.84 (dd, 1 proton of SCCH*H*$_2$), 2.80–2.62 (m, 1 proton of CH_2CO, 1 proton of SCCH_2 and CH_2*CH*CH_2), 2.55–2.44 (td, 1 proton of *CH*$_2$CO), 2.20–2.02 (m, 1 proton of $CH_2CH_2CH_2$, 1 proton of CHCH_2CH_2CO, and 1 proton of CHC$H_2CH_2CH_2$), 1.92–1.80 (m, 1 proton of $CH_2CH_2CH_2$), 1.66–1.52 (qd, 1 proton of CHCH_2CH_2CO), and 1.36–1.20 (m, 1 proton of CHC$H_2CH_2CH_2$); ^{13}C NMR, δ: 194.39 (-*C*=O-), 140.95, 136.01, and 135.92 (quaternary C), 128.02 (-SC*H*=), 40.12 (-CH_2CO-), 35.66 (-CH_2C*H*CH_2-), 31.08 (CH*C*H$_2CH_2$CO), 29.02 (CH*C*H$_2CH_2CH_2$), 24.15 (SC*C*H$_2$), and 23.36 (CH_2*C*H$_2CH_2$); ms *m/e*: 192 (M^+). Anal. calcd. for $C_{11}H_{12}OS$: C 68.71, H 6.29, S 16.68%; found: C 68.87, H 6.17, S 16.99%.

Results and discussion

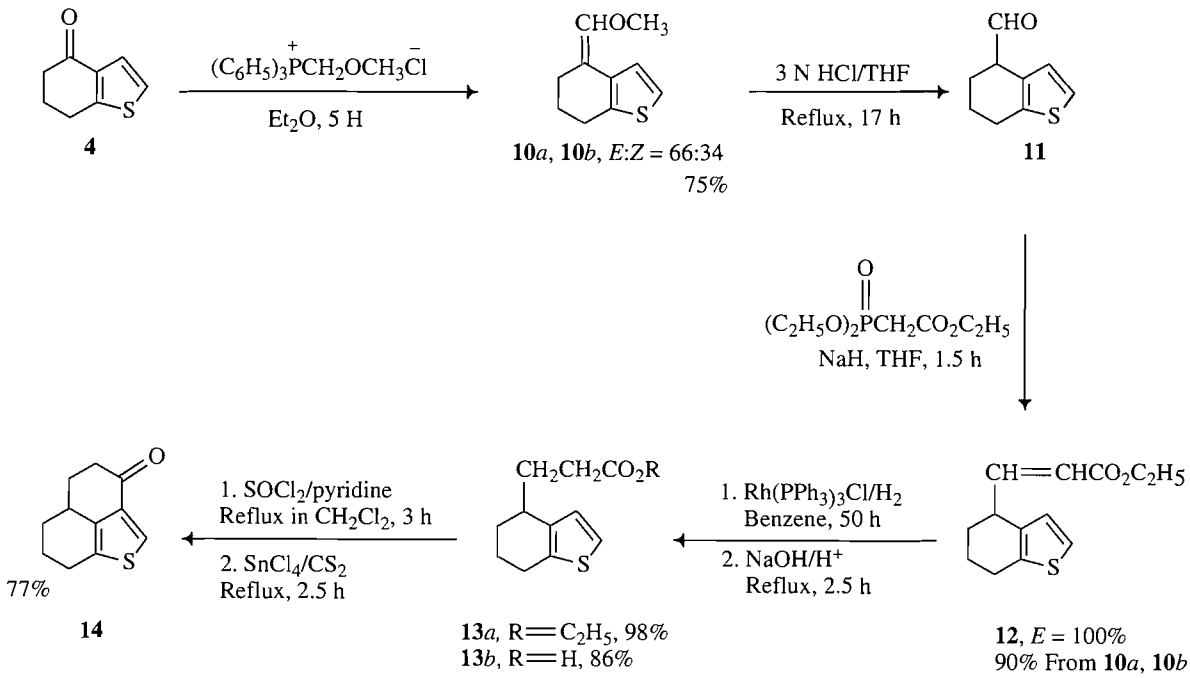
*4,5,5a,6,7,8-Hexahydro-3*H*-naphtho[1,8-*bc*]thiophen-4-one* ***9***

Synthesis of the naphthol[1,8-*bc*-]thiophenones requires benzo[*b*]thiophene compounds functionalized at the 3- and 4-positions. The bicyclic ketone **4** satisfies this requirement if both the carbonyl and the aromatic centres are viewed as substituents, and is readily available from either thiophene or from 2-cyclohexen-1-one (17–20). Our general strategy was to introduce a side chain at the 4-position, incorporating the carbonyl group of the target ketone and containing a functional group that could be cyclized onto the thiophene ring in an electrophilic process. This approach avoids using direct oxidation procedures to introduce the carbonyl group that could also oxidize the thiophenic sulfur.

SCHEME 1. Synthesis of 4,5,5a,6,7,8,-hexahydro-3*H*-naphtho[1,8-*bc*]thiophe-4-one.

Functionalization of the bicyclic ketone **4** at the 4-position using Wittig chemistry afforded the unsaturated ester **5** as a mixture of *E* and *Z* isomers (67:33) in almost quantitative yield. The reaction mixutre was readily analysed using ^{1}H NMR spectroscopy because the proximity of the ester function to the thiophenic proton H-3 in the *Z* isomer caused a considerable downfield shift of the resonance for H-3. The *E* to *Z* ratio was dependent on the base used to form the ylid; butyllithium produced the 67:33 *E*/*Z* mixture, and sodium hydride and potassium *tert*-butoxide produced 63:37 and 56:44 mixtures respectively. Various solvents and other reaction conditions were tried but it was not possible to produce either isomer as a major product.

A key step in the overall synthesis was the reduction of the double bond in **5** to produce the saturated ester **6**. Thiophenic compounds are difficult to reduce using conventional heterogeneous catalysts because of catalyst poisoning caused by adsorption of the sulfur to the active sites (23). In addition, high activity catalysts can desulfurize thiophenic systems. In general, homogeneous hydrogenation catalysts such as Wilkinson's catalyst are less susceptible to poisoning by aromatic sulfur compounds but often will not saturate hindered double bonds (24). In this case, hydrogenation using Wilkinson's catalyst resulted in rapid reduction of the *Z* isomer of **5** but left the *E* isomer, containing the more hindered double bond, unreduced. Since the *Z* isomer was the minor product of the Wittig reaction, this approach to the saturated ester **6** was not practical. After consideration of a number of other hydrogenation catalysts, it was found that both isomers of **5** were reduced quite conveniently (24 h, 88% yield) employing a standard Pd-on-carbon catalyst in a somewhat larger compound/catalyst ratio (5:1) than is usual.



Reaction of the saturated ester **6** with the lithium anion of dimethyl sulfoxide gave a good yield (85%) of the keto-sulfoxide **7** as a mixture of diastereoisomers. Treatment of **7** under acidic conditions resulted in a Pummerer-type rearrangement and cyclization to the keto-sulfide **8**. Raney nickel treatment of this product under mild conditions removed the thioether sulfur to give the desired tricyclic ketone **9** without desulfurization of the thiophenic ring. Despite the moderate yield for the cyclization, this synthesis has the advantage of introducing a carbonyl substituent directly into the 4-position of the naphtho[1,8-*bc*]thiophene ring system.

Clear evidence that the tricyclic product had been obtained was given by the observation of only one thiophenic proton in the ^{1}H NMR spectrum. Spectra recorded at 400 MHz showed that the signal for the thiophenic proton of **9** was a doublet (J = 0.9 Hz). Two of the lines of the quartet representing the signal for the methylene sandwiched between the carbonyl and the thiophene ring showed the same small coupling, and double irradiation experiments confirmed that the thiophenic proton was coupled to one of the protons of the methylene group at the 3-position. This coupling is similar to those observed in alkylaromatics (25). Using chemical shift arguments and shift correlation spectra[2] it was possible to assign all of the signals in the ^{1}H NMR spectrum of **9**. Perhaps the most interesting feature of this spectrum is the large difference in chemical shift for the methylene protons at C-6 (1.3 and 2.15 ppm). Examination of molecular models of **9** shows that one possible conformation of the B and C rings results in close contact between C-6 and the carbonyl group at C-4, thus explaining why one of the protons at C-6 is deshielded.

*4,5,5a,6,7,8-Hexahydro-3*H*-naphtho[1,8-*bc*]thiophen-3-one* ***14***

It should be possible to synthesize the 3-keto-substituted naphthothiophene **14** by cyclization of the acid chloride derivative of the carboxylic acid **13***b* under Friedel–Crafts-type conditions. Introduction of the appropriate substituent to the 4-position of the bicyclic ketone **4** was accomplished in three basic stages. Firstly, **4** was converted to the aldehyde derivative **11** by reaction with (methoxymethyl)triphenylphosphonium chloride and hydrolysis of the resultant mixture of enol ethers **10***a* and **10***b*. A satisfactory analysis for the enol ethers could not be

SCHEME 2. Synthesis of 4,5,5a,6,7,8,-hexahydro-3*H*-naphtho[1,8-*bc*]thiophen-3-one.

obtained. The enol ethers were formed as an *E*/*Z* mixture that hydrolyzed readily to the aldehyde **11**. Extension of the 4-substituent by two carbons and introduction of an ester functional group was accomplished by reaction of the aldehyde with triethyl phosphonoacetate under standard Wittig conditions in an overall yield of 90% from the enol ether mixture. This reaction yielded the unsaturated ester **12** as a single isomer, which was assigned as the *E* isomer on the basis of the value of the coupling constant for the olefinic protons (J = 15.6 Hz). Also, the observation that the resonance due to the thiophenic proton on C-3 had not been shifted appreciably (as might have been expected if the ester group was in close proximity, as it would be in the *Z* isomer and as was observed for the *Z* isomer of **5**) supports the conclusion that **12** was formed as the *E* isomer.

Saturation of the double bond in **12** using palladium-on-carbon was very slow and difficult to force to completion unless large quantities of catalyst were used. However, reduction using Wilkinson's catalyst, although slow, gave an almost quantitative yield of the saturated ester **13**. This reduction and the reduction of the *Z* isomer of **5** indicate the general utility of Wilkinson's catalyst for reducing double bonds in thiophene derivatives as long as the double bond is relatively unhindered. Standard chemistry involving saponification of **13***a*, conversion of the resulting carboxylic acid **13***b* to its acid chloride, and treatment of the acid chloride with $SnCl_4$ gave the 3-keto naphthothiophene **14** in an overall yield of 77%. It was difficult to maintain this yield for large-scale preparations (>2 g).

^{1}H NMR spectra of **14** confirmed that cyclization had taken place, as only one uncoupled singlet was observed in the aromatic region. The rest of the ^{1}H NMR spectrum of **14** was complex although a reasonable assignment was possible using shift correlation spectra[2] and from chemical shift arguments. Interestingly, as was observed in the ^{1}H NMR spectra of **9**, the signals for the two protons on C-6 occur at quite different chemical shifts, one being considerably more downfield than would be expected (2.08 and 1.28 ppm). Inspection of molecular models indicates that when overlap of the carbonyl substituent and the π-system of the thiophene ring is maximized, one of the protons on C-6 is in close contact with the carbonyl group and thus is shifted downfield.

Isotope effects in nucleophilic substitution reactions. VIII. The effect of the form of the reacting nucleophile on the transition state structure of an S_N2 reaction

YAO-REN FANG AND KENNETH CHARLES WESTAWAY[1]
Chemistry Department, Laurentian University, Sudbury, Ont., Canada P3E 2C6

Received August 27, 1990

YAO-REN FANG and KENNETH CHARLES WESTAWAY. Can. J. Chem. **69**, 1017 (1991).

A spectroscopic investigation indicated that lithium thiophenoxide exists as a contact ion pair complex in dry diglyme whereas the other alkali metal thiophenoxides exist as a solvent-separated ion pair complex in diglyme. The addition of small amounts of water converts the lithium thiophenoxide contact ion pair complex into a solvent-separated ion pair complex. A smaller secondary α-deuterium kinetic isotope effect and a larger Hammett ρ value are observed when the nucleophile is the contact ion pair complex in the S_N2 reaction between *n*-butyl chloride and thiophenoxide ion in diglyme. This indicates that the transition state for the contact ion pair complex reaction is tighter with a shorter nucleophile–α-carbon bond than the transition state for the solvent-separated ion pair complex reaction. The secondary α-deuterium kinetic isotope effects for the free ion and the solvent-separated ion pair complex reactions between sodium thiophenoxide and *n*-butyl chloride in DMF suggest that the loosest transition state is found when the nucleophile is the free ion.

Key words: transition state, S_N2, isotope, deuterium, Hammett ρ.

YAO-REN FANG et KENNETH CHARLES WESTAWAY. Can. J. Chem. **69**, 1017 (1991).

Une étude spectroscopique indique que, dans le diglyme sec, le thiophénolate de lithium existe sous la forme d'une paire d'ions de contact; dans le même solvant, les autres thiophénolates de métaux alcalins existent sous la forme d'une paire d'ions séparés par le solvant. L'addition de faibles quantités d'eau transforme la paire d'ions de contact du thiophénolate de sodium en une paire d'ions séparés par le solvant. Pour les réactions S_N2 entre le chlorure de butyle et l'ion thiophénolate effectuées dans le diglyme, l'effet isotopique secondaire α du deutérium est plus faible et la valeur ρ de Hammett est plus grande lorsque le nucléophile est une paire d'ions de contact. Ce résultat indique que l'état de transition de la réaction impliquant la paire d'ions de contact est plus compact, avec une liaison carbone α–nucléophile plus courte, que l'état de transition de la réaction avec la paire d'ions séparés par le solvant. Les effets isotopiques cinétiques secondaires des deutérium en α, observés pour les réactions des ions libres et des paires d'ions séparés par le solvant du thiophénolate de sodium avec le chlorure de butyle dans le DMF suggèrent que l'état de transition le plus lâche est celui impliquant l'ion libre.

Mots clés : état de transition, S_N2, isotope, deutérium, ρ de Hammett.

Introduction

Conductivity measurements, ultraviolet (uv) spectroscopy, and experiments with crown ethers have shown that alkali metal thiophenoxides can exist in different forms in organic solvents (1–3). At low concentrations, alkali metal thiophenoxides exist as free ions in methanol, DMF, and DMSO. At higher concentrations, that depend on the solvent, these salts exist as solvent-separated ion pair complexes, eq. [1].

[1] $$xM^+ + x^-SC_6H5 \rightleftarrows [M^+ (solvent)_y{}^-SC_6H_5]_x$$

Sodium thiophenoxide exists as a solvent-separated ion pair complex at all concentrations in the much less polar solvent, diglyme (1).

Buncel *et al.* (4, 5) used a spectroscopic test to determine whether an ion pair exists in solution as a contact ion pair or as a solvent-separated ion pair. The test involves determining how changing the metal ion in an ion pair affects the absorption maximum in the uv spectrum. When the alkali metal ion is changed in a contact ion pair, the electron density on the nucleophilic atom (the chromophore) is altered and the absorption maximum of the ion pair spectrum changes. If the ion pair is a solvent-separated ion pair, the metal ion is separated from the nucleophilic atom and changing the metal ion does not alter significantly the electron density on the nucleophilic atom. As a result, the absorption maximum for the ion pair does not change significantly when the metal ion of the ion pair is altered.

With one exception (lithium thiophenoxide in diglyme), the absorption maximum of the uv spectrum of alkali metal thiophenoxide ion pair complexes in methanol, in DMF, in DMSO, and in diglyme does not change significantly, Table 1, when the alkali metal ion is altered (1). Thus, the spectroscopic technique used by Buncel *et al.* to identify the structure of ion pairs indicates that all of the ion pair complexes, except for the lithium thiophenoxide in diglyme, are solvent separated (1–3). The large change that is found in the absorption maximum when lithium is substituted for sodium in the alkali metal thiophenoxide ion pair complex in diglyme indicates that the form of the lithium thiophenoxide ion pair complex is different from that of the other alkali metal ion pair complexes and suggests that the lithium thiophenoxide exists as a contact ion pair complex in diglyme.

We are unable to explain why the absorption maximum for the contact ion pair complex is greater than that found for the solvent-separated ion pair complex. It is worth noting, however, that the change observed in the absorption maximum when the solvent-separated ion pair complex is converted into the contact

ion pair complex (λ_{max} increases from 304 nm to 325 nm) is in the same direction as the change found when the free ion is converted into the solvent-separated ion pair complex, i.e., λ_{max} increases from 235 nm for the free ion to 267 nm for the solvent-separated ion pair complex in methanol and from approximately 280 nm for the free ion to 305 nm and 308 nm for the solvent-separated ion pair complex in DMSO and DMF, respectively (1). Thus, the absorption maximum always moves to longer wavelengths as the interaction with the cation increases.

Secondary α-deuterium kinetic isotope effects and Hammett ρ values have been measured for the solvent-separated (sodium and potassium) and the contact (lithium) ion pair complex reactions to determine how the form of the reacting nucleophile affects the transition state structure of the S_N2 reaction between *n*-butyl chloride and thiophenoxide ion in diglyme, eq. [2].

$$[2]\quad \left.\begin{array}{l}[M^+\ {}^-SC_6H_5]_x \\ \text{or} \\ [M^+(\text{solvent})_y\ {}^-SC_6H_5]_x\end{array}\right] + CH_3CH_2CH_2CL_2Cl \longrightarrow$$

$$CH_3CH_2CH_2CL_2SC_6H_5 + M^+ + Cl^-$$

$$L = H, D$$

Results and discussion

The secondary α-deuterium kinetic isotope effects found for the S_N2 reactions (2, 6) between *n*-butyl chloride and the solvent-separated (sodium thiophenoxide) ion pair complex and the contact (lithium thiophenoxide) ion pair complex are shown in Table 2. The secondary α-deuterium kinetic isotope effect of 1.07 found for the contact (lithium thiophenoxide) ion pair complex reaction in diglyme at 20°C is significantly lower than that found when the nucleophilic reagent is the solvent-separated (sodium thiophenoxide) ion pair complex (k_H/k_D = 1.14). Thus, it appears that the form of the reacting nucleophile has a marked effect on the magnitude of the secondary α-deuterium kinetic isotope effect and transition state structure.

Small amounts of a more solvating solvent, water, were added to the dry diglyme used in the lithium thiophenoxide contact ion pair complex experiments in an effort to convert the contact ion pair complex into the solvent-separated ion pair complex and confirm that the different secondary α-deuterium kinetic isotope effect was, indeed, due to a change in the form of the reacting nucleophile. The results in Table 3, and Fig. 1, show that this is possible. When small amounts of water are added to the dry diglyme, the secondary α-deuterium kinetic isotope effect initially remains constant. However, when the amount of water is increased from 2.0 to 3.0%, the isotope effect jumps from 1.07 to 1.12. Increasing the amount of water to 4.0% leads to a further increase in the isotope effect, i.e., to 1.13, a secondary α-deuterium kinetic isotope effect that is within experimental error of the isotope effect found when the solvent-separated sodium thiophenoxide ion pair complex is the reactant, Table 2. Increasing the amount of water in the solvent still further, i.e., to 7.5%, does not alter the secondary α-deuterium kinetic isotope effect of the lithium thiophenoxide reaction.

The ability to change the secondary α-deuterium kinetic isotope effect for the lithium thiophenoxide contact ion pair complex reaction from 1.07 to 1.14, the isotope effect for the reaction of the solvent-separated (sodium thiophenoxide) ion pair complex, by adding water is strong evidence that the change in secondary α-deuterium kinetic isotope effect is due to a change in the form of the reacting nucleophile rather than to a change in the cation. The contact ion pair complex is presumably converted into the solvent-separated ion pair complex because water is a more ionizing solvent than diglyme and solvates the ions in the ion pair complex more strongly.

The secondary α-deuterium kinetic isotope effect for the reaction of a different solvent-separated ion pair complex, potassium thiophenoxide, was measured in an effort to confirm that the change in the isotope effect was due to a change in the form of the reacting nucleophile and not to a change from the lithium to the sodium cation. The secondary α-deuterium kinetic isotope effect for the reaction with the solvent-separated potassium thiophenoxide ion pair complex is 1.13, Table 2. In fact, the isotope effects for all the reactions of the solvent-separated ion pair complexes are identical within experimental error. Thus, the different (smaller) secondary α-deuterium kinetic isotope effect is only found when lithium thiophenoxide is used in dry or almost dry diglyme and the uv spectrum indicates

that the form of the reacting nucleophile is different, i.e., the contact ion pair complex.

Form of reacting nucleophile and transition state structure

Once it had been established that different secondary α-deuterium kinetic isotope effects were found for the contact ion pair complex and the solvent-separated ion pair complex reactions, it was interesting to determine how the form of the reacting nucleophile affected the structure of the S_N2 transition state.

Secondary α-deuterium kinetic isotope effects and Hammett ρ values can be used to elucidate the structure of the transition states in the S_N2 reactions (7, 8). The initial state for the secondary α-deuterium kinetic isotope effect in both the contact ion pair complex and the solvent-separated ion pair complex reactions is the same, i.e., *n*-butyl chloride. Thus, the very different secondary α-deuterium kinetic isotope effects observed for the solvent-separated and contact ion pair complex reactions in diglyme require that the transition states for these two S_N2 reactions be significantly different. One might worry that changing the solvent from 1% aqueous diglyme to 4% aqueous diglyme would affect the magnitude of the secondary α-deuterium kinetic isotope effect because the partially formed chloride ion in the transition state could be more strongly solvated by hydrogen bonding to the extra H_2O molecules present when the reaction was done in 4% aqueous diglyme. This change in solvent would not affect the magnitude of the secondary α-deuterium kinetic isotope effect significantly, however. Theoretical calculations of the secondary α-deuterium kinetic isotope effect in the S_N2 reaction between benzyl chloride and an alkoxide ion (9) indicate that solvating the developing chloride ion with three hydrogen bonds to H_2O only changes the isotope effect by 0.0002. Since adding three hydrogen bonds (altering the reduced mass of the developing chloride ion) has a negligible effect on the secondary α-deuterium kinetic isotope effect, the different isotope effects observed in 1% and 4% aqueous diglyme must be due to a change in transition state structure. The magnitude of the secondary α-deuterium kinetic isotope effect is primarily dependant on the C_α–H(D) out-of-plane bending vibrations and, therefore, on the steric crowding around the C_α—H(D) bonds in the S_N2 transition state (7, 8, 10). In fact, the C_α–H(D) out-of-plane bending vibrations will be of higher energy (the secondary α-deuterium kinetic isotope effect will be smaller) when the α-carbon–nucleophile and α-carbon–leaving group bonds are short in the transition state (8). Applying this rationale to the experimental isotope effects in the two reactions indicates that the contact ion pair complex transition state must be tighter, with shorter nucleophile–α-carbon and (or) α-carbon–leaving group bonds than the solvent-separated ion pair complex transition state.

The tighter S_N2 transition state for the reaction with the contact ion pair complex seems probable because the small lithium cation has a large charge density and will tie up (reduce) the electron density on the sulfur atom of the nucleophile. This, in turn, would mean that the sulfur nucleophile would have to come closer to the α-carbon before it disturbed the α-carbon–chlorine bond sufficiently to cause reaction. If this occurred, the transition state would have a shorter S---C_α bond and, presumably, a tighter transition state. The smaller secondary α-deuterium kinetic isotope effect that is observed is consistent with this hypothesis.

Hammett ρ values were determined for the S_N2 reactions between *n*-butyl chloride and *para*-substituted lithium thiophenoxides in 1% and in 4% aqueous diglyme where the nucleophile is the contact ion pair complex and the solvent-separated ion pair complex, respectively. These ρ values were measured in an attempt (i) to determine the structure of the S_N2 transition states in more detail and (ii) to determine if the length of the sulfur–α-carbon bond is indeed shorter in the contact ion pair complex transition state. The Hammett ρ value of −1.39 found in the contact ion pair complex reaction is much larger than the ρ value of −0.56 found for the solvent-separated ion pair complex reaction, Table 4. Negative ρ values are found in both reactions because the sulfur of the nucleophile becomes less negative when the reactants are converted into the transition state. The addition of water to the solvent would be expected to alter the magnitude of the Hammett ρ value. If this effect were significant, it could alter the conclusions drawn about the relative lengths of the sulfur–α-carbon transition state bonds in 1 and 4% aqueous diglyme. However, the most aqueous solvent only contains 4% water rather than 1% water and the rate constants are only slightly (from 6% to 2.7 times) different in the two solvents. In contrast, the rate constant in a protic solvent (MeOH) is more than 100 times smaller than the rate constant in diglyme (1, 6). As a result, the effect of the change in solvent on the magnitude of the ρ value should be reasonably small. Since the change in the ρ value with the change from 1% water to 4% water is large, i.e., the ρ value is 2.5 times larger in the case where the nucleophile is the solvent-separated ion pair complex, it is probably safe to conclude that the change in ρ is related to a change in transition state structure.[2] If this is the case, the larger ρ value in the contact ion pair complex reaction indicates that more charge density has been lost from the sulfur atom in going

[2]A referee suggested that the Hammett ρ value could be affected by the change in solvent in another way. He proposed that the interaction between the nucleophile and the developing chloride ion in the transition state would be greater when the developing chloride ion is not solvated with hydrogen-bonded water molecules. If this interaction were different, the ρ value in 4 and 1% aqueous diglyme would be different because of a change in solvent rather than a change in transition state structure. However, it is not clear whether the interaction between the negative sulfur and the negative chloride ion would affect the magnitude of the ρ value. Presumably, the nucleophile would interact much more strongly with the partially positively charged α-carbon than with the leaving group. As a result, the proposed effect should be small. Since the ρ value in 1% aqueous diglyme is 2.5 times that in 4% aqueous diglyme, it seems probable that the sulfur–α-carbon bond is shorter in the transition state of the contact ion pair reaction.

Free ion	1.129 ± 0.010[a,c]	−2.05 ± 0.08[b,c]

[a]The error is $1/k_D[(\Delta k_H)^2 + (k_H/k_D)^2) \times (\Delta k_D)^2]^{1/2}$ where Δk_H and Δk_D are the standard deviations for the rate constants for the undeuterated and deuterated substrates, respectively (1).

[b]The correlation coefficients for the least-squares lines were 0.998.

[c]The original data is in ref. 1.

from the reactant to the contact ion pair complex transition state. Since the charge on the sulfur atom is reduced when the bond forms, the contact ion pair complex transition state must have the most S---C_α bond formation in the transition state, i.e., the shortest S---C_α transition state bond. The Hammett ρ values are consistent with the proposed hypothesis because they suggest that the contact ion pair complex reaction has the shortest sulfur–α-carbon transition state bond.

Thus, the secondary α-deuterium kinetic isotope effects and Hammett ρ values for the contact and the solvent-separated ion pair complex reactions in diglyme indicate that the S_N2 transition state is tighter, with at least a shorter S---C_α transition state bond when the nucleophile is the contact ion pair complex. To date, we have not been able to determine the chlorine kinetic isotope effect for these reactions. As a result, we do not know how the α-carbon–chlorine bond differs in the contact ion and solvent-separated ion pair complex transition states.

The same general trend is observed when the cation is removed and the nucleophile is changed from a solvent-separated ion pair complex to a free ion. A comparison of the secondary α-deuterium kinetic isotope effects for the solvent-separated ion pair complex and the free ion S_N2 reactions between sodium thiophenoxide and *n*-butyl chloride in DMF, Table 5, shows that the smaller isotope effect (k_H/k_D = 1.085 for the solvent-separated ion pair complex reaction versus k_H/k_D = 1.129 for the free ion reaction) is found in the reaction with the solvent-separated ion pair complex. Thus, it appears that the solvent-separated ion pair complex transition state is tighter and has shorter nucleophile–α-carbon and (or) α-carbon–leaving group bonds than the free ion transition state. Again, this seems reasonable because the cation in the solvent-separated ion pair complex should still reduce the electron density on the sulfur atom. If this occurs, the sulfur would have to come closer to the α-carbon to initiate the reaction and a tighter transition state should be found.

The secondary α-deuterium kinetic isotope effects for the solvent-separated ion pair complex and the free ion reactions in DMF lead one to conclude that the S_N2 transition state is tighter for the solvent-separated ion pair complex reaction than for the free ion reaction. However, the Hammett ρ values for the free ion and the solvent-separated ion pair complex reactions, Table 5, are, within experimental error, the same. This is opposite to the trend found in the contact and solvent-separated ion pair complex reactions.

An alternative explanation of the Hammett ρ values is that the S---C_α transition state bond is slightly shorter in the solvent-separated ion pair complex reaction but that the ρ value is misleading. The charge on the sulfur atom changes from −1.00 to 0 in the free ion reaction. The sodium ion in the solvent-separated ion pair complex would reduce the negative charge on the sulfur in the ion pair complex so the total change in charge on the sulfur atom in the reaction will be less than 1.00. As a result, the magnitude of the Hammett ρ value for the free ion reaction would be expected to be larger than that for the solvent-separated ion pair complex reaction given the same S---C_α transition state bond length. If this were the case, the identical ρ values in the solvent-separated ion pair complex and free ion reactions would really mean that the S---C_α bond is shorter in the reaction where the nucleophile is the solvent-separated ion pair complex.

However the Hammett ρ values should be interpreted, the secondary α-deuterium kinetic isotope effects indicate that the S_N2 transition states are tighter with shorter α-carbon–nucleophile and (or) α-carbon–leaving group bonds when the nucleophile is the solvent-separated ion pair complex. It does appear, however, that the difference between the S---C_α bond lengths in the free ion and the solvent-separated ion pair complex reaction are probably small. This is not surprising because one would expect that the difference in the length of the S---C_α transition state bond between the solvent-separated ion pair complex and the free ion reactions would be smaller than that between the contact ion pair complex and the solvent-separated ion pair complex reactions, i.e., when the cation is closer to the nucleophilic atom.

Conclusion

This study has shown that the secondary α-deuterium kinetic isotope effects and transition state structures are very different when the form of the reacting nucleophile is changed from a free ion to a solvent-separated ion pair complex to a contact ion pair complex. The contact ion pair complex transition state is tighter, with shorter nucleophile–α-carbon and (or) α-carbon–leaving group bonds, than the solvent-separated ion pair complex transition state. The same trend is found when the solvent-separated ion pair complex transition state is compared with the free ion transition state. The Hammett ρ values (i) indicate that the nucleophile–α-carbon bond is significantly shorter in the contact ion pair transition state than in the solvent-separated ion pair transition state and (ii) suggest that the nucleophile–α-carbon bonds in the solvent-separated ion pair and the free ion transition states are similar. The tighter transition states found when the cation is closer to the nucleophilic atom may arise because the nucleophile has to approach the α-carbon more closely before sufficient electron density is available to rupture the C—Cl bond and cause reaction.

Experimental

Preparation of reagents

Diglyme

Two litres of spectroscopic grade diglyme were purified by stirring with 50 g of ferrous sulfate dihydrate and 50 g of potassium hydroxide for 2 h at room temperature. After the solvent had been filtered, it was distilled at atmospheric pressure. The fraction boiling between 160 and 162°C was collected and dried over sodium metal for 8 h before use.

Butyl chloride

The preparation of the undeuterated and deuterated substrates is described elsewhere (1).

Kinetic measurements

The concentration of the unreacted thiophenoxide ion was determined by titrating 1 mL aliquots of the reaction mixture electrochemically with a standard silver nitrate solution (1, 11). The substrate concentration varied from 1.6 to 2.7 $\times$ 10^{-2} M and the alkali metal thiophenoxide (nucleophile) concentration ranged from 3.6 to 6.6 $\times$ 10^{-3} M in these experiments. The rate constants were obtained from the slope of the normal second-order plot (12). The reactions were followed to between 50 and 75% of completion. Good second-order plots, linear up to at least 75% of completion, were found for all the reactions. The correlation coefficients of the least-squares line for individual rate constants varied from 0.998 to 0.9999. Over 90% of the reactions had a correlation coefficient greater than 0.999.

The reaction of hexachlorocyclopentadiene with $(NSCl)_3$ at 65°C in the absence of a solvent produced hexachloro-3-cyclopentenylidenaminosulfenyl chloride, C_5Cl_6NSCl, in good yield. The derivatives C_5Cl_6NSX (X = Br, I, C_5Cl_6N, NPr_2^i, Ph) were prepared by treatment of C_5Cl_6NSCl with Me_3SiBr, Me_3SiI, Ph_3Sb, $^iPr_2NH$, and Ph_2Hg, respectively. The crystal structure of C_5Cl_6NSBr was determined by X-ray crystallography. Crystals of C_5Cl_6NSBr are triclinic, space group $P\bar{1}$ with $a = 9.626(2)$, $b = 9.810(2)$, $c = 13.736(2)$ Å, $\alpha = 79.68(1)$, $\beta = 88.62(1)$, $\gamma = 74.73(1)°$, $Z = 4$, final R and R_w values were 0.075 and 0.063, respectively, for 4850 unique observed reflections. The >C═NSBr moiety adopts a *syn* conformation and there are two different molecules of C_5Cl_6NSBr in the asymmetric units. The bond lengths are d(C═N) = 1.278(8) and 1.253(8), d(N—S) = 1.560(6) and 1.569(6), and d(S—Br) = 2.229(2) and 2.235(2) Å. The bond angles at nitrogen are 146.7(4) and 148.6(4) and those at sulfur are 116.8(2) and 116.5(2)°. The unusual geometry of the <C═NSBr moiety is explained in terms of negative hyperconjugation ($n_N \rightarrow \sigma_{SBr}^*$). A variable temperature ^{13}C NMR of C_5Cl_6NSCl provides evidence for a fluxional process ($\Delta G^*_{298} = 68.1 \pm 1.2$ kJ mol^{-1}) in solution. The dark purple compound $C_5Cl_6NS^+AsF_6^-$ was synthesized from the reaction of C_5Cl_6NSCl and $AgAsF_6$ in SO_2.

Key words: hexachloro-3-cyclopentenylidenamino sulfides, crystal structure, hexachloro-3-cyclopentenylidenaminosulfenyl bromide.

ALLEN APBLETT, TRISTRAM CHIVERS, JAMES F. FAIT et RAINER VOLLMERHAUS. Can. J. Chem. **69**, 1022 (1991).

La réaction de l'hexachlorocyclopentadiène avec le $(NSCl)_3$, à 65°C, en l'absence de solvant, conduit au chlorure d'hexachloro-3-cyclopenténylidènaminosulfényle, C_5Cl_6NSCl, avec un bon rendement. On a préparé les dérives C_5Cl_5NBX (X = Br, I, C_5Cl_6N, $NiPr_2^i$, Ph) par réaction du C_5Cl_6NSCl avec le Me_3SiBr, le Me_3SiI, le Ph_3Sb, la $^iPr_2NH$ et le Ph_2Hg, respectivement. On a déterminé la structure cristalline du C_5Cl_6NSBr par cristallographie des rayons-X. Les cristaux du C_5Cl_6NSBr sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 9{,}626(2)$, $b = 9{,}810(2)$ et $c = 13{,}736(2)$ Å, $\alpha = 79{,}68(1)$, $\beta = 88{,}62(1)$ et $\gamma = 74{,}73(1)°$, $Z = 4$, valeurs respectives de $R = 0{,}075$ et $R_N = 0{,}063$ pour 4850 réflexions observées. La portion >C═NSBr adopte une conformation *syn* et il existe deux molécules différentes de C_5Cl_6NSBr dans chaque unité asymétrique. Les longueurs des liaisons sont: d(C═N) = 1,278(8) et 1.253(8), d(N—S) = 1,560(6) et 1,569(6) et d(S—Br) = 2,229(2) et 2,235(2) Å. Les angles de liaison au niveau de l'azote sont 146,7(4) et 148,6(4)° alors que ceux au niveau du soufre sont de 116,8(2) et 116,5(2)°. On explique le géométrie inhabituelle de la portion >C═NSBr en fonction d'une hyperconjugaison négative ($n_N \rightarrow \sigma_{SBr}^*$). Les spectres rmn du ^{13}C du C_5Cl_6NSCl, mesurés à basse température, suggèrent qu'il existe une processus de fluxion ($\Delta G^{\ddagger}_{298} = 68{,}1 \pm 1.2$ kJ mol^{-1}) en solution. On a synthétisé le composé violet, $C_5Cl_6NS^+AsF_6^-$, par réaction du C_5Cl_6NSCl avec le $AgAsF_6$, dans le SO_2.

Mots clés : disulfures d'hexachloro-3-cyclopenténylidènamino; structure cristalline; bromure d'hexachloro-3-cyclopenténylidènaminosulfényle.

[Traduit par la rédaction]

Introduction

As part of our investigations of the utility of $(NSCl)_3$ as a reagent in sulfur–nitrogen (S–N) chemistry (1–3), we found that hexachlorocyclopentadiene reacts with $(NSCl)_3$ in the absence of a solvent to give high yields of C_5Cl_6NSCl (4). While our work was in progress Haas and Mischo reported the preparation of C_5Cl_6NSCl by a similar method (5). They also determined the X-ray crystal structures of C_5Cl_6NSX (X = Cl, CF_3) and observed some remarkable differences in the structural parameters of the >C═NSX moiety in these two derivatives that were ascribed to p_π–d_π interactions in the case of the chloride (5).

In this paper we report those aspects of our work that complement the findings of Haas and Mischo (5). These include (*a*) the X-ray crystal structure of C_5Cl_6NSBr, (*b*) the preparation and characterization of the novel purple cation $C_5Cl_6NS^+AsF_6^-$ and some new derivatives of the type C_5Cl_6NSX (X = I, NPr_2^i, Ph) and (*c*) the fluxional behaviour of C_5Cl_6NSCl as determined by variable temperature ^{13}C nmr studies. An explanation of the geometrical features of C_5Cl_6NSX compounds that is significantly different from that of Haas and Mischo (5) is also presented.

Experimental

Reagents and general procedures

All experimental procedures were performed under an atmosphere of dry nitrogen. Solvents were dried by heating at reflux with the appropriate drying agent and then distilled before use.

The following reagents were commercial products used as received: hexachlorocyclopentadiene (MCB), trimethylsilyl bromide and trimethylsilyl iodide (Petrarch), di(isopropyl)amine (Aldrich), diphenylmercury (Aldrich), triphenylantimony (Kodak). $(NSCl)_3$ was prepared from $S_3N_2Cl_2$ by the method described in ref. 2. $AgAsF_6$ was prepared from silver powder and arsenic pentafluoride (Ozark-Mahoning) in SO_2 (6).

Instrumentation

Infrared spectra were recorded as Nujol or Fluorolube mulls on CsI or polyethylene windows. The 4000–400 cm^{-1} range was recorded on a Nicolet DX-5 FTIR spectrometer while spectra in the 400–200 cm^{-1} region were obtained on a Perkin Elmer 457 grating infrared spectrometer. Mass spectra were obtained with a Kratos MS80 RFA instrument operating at 70 eV. ^{13}C nmr spctra were recorded on either a Bruker ACE 200 or, for variable temperature experiments, a Bruker AM 400 spectrometer. Chemical shifts are reported relative to Me_4Si in $CDCl_3$. ^{14}N nmr spectra were run on a Bruker AM 400 spectrometer and chemical shifts are reported relative to $MeNO_2$ (6). Ultraviolet–visible spectra were measured by use of a Cary 219 spectrophotometer.

Melting points were obtained in nitrogen-filled sealed capillaries.

Chemical analyses were performed by the Analytical Services Division of the Department of Chemistry, The University of Calgary, and by Canadian Microanalytical Service, New Westminster, B.C.

Preparation of C_5Cl_6NSCl

A mixture of $(NSCl)_3$ (1.95 g, 8.0 mmol) and hexachlorocyclopentadiene (6.50 g, 23.8 mmol) was heated at 65°C in a Schlenk tube for 48 h. The dark red reaction mixture was extracted with *n*-hexane (4 × 25 mL). Solvent was removed under vacuum and the residue was sublimed at 30°C/0.1 torr to give pale yellow crystals of C_5Cl_6NSCl (4.0 g, 10.3 mmol), which was recrystallized from CH_2Cl_2, mp 69°C (lit. (5): 68°C). *Anal.* calcd. for C_6Cl_7NS: C 16.95, N 3.95; found: C 16.63, N. 3.72. The infrared spectrum was in excellent agreement with that reported in the literature (5). ^{14}N nmr ($CDCl_3$) δ: −81.5 (cf. lit. δ(^{15}N) −81.0) (5).

Preparation of C_5Cl_6NSBr

A mixture of C_5Cl_6NSCl (0.35 g, 1.0 mmol) and Me_3SiBr (0.16 g, 1.1 mmol) in hexane (3 mL) was stirred at 23°C for 4 h. Removal of solvent under vacuum produced C_5Cl_6NSBr (0.38 g, 0.96 mmol) as a yellow solid. An analytically pure sample (mp 74°C) was obtained by recrystallization from *n*-hexane. *Anal.* calcd. for C_5BrCl_6NS: C 15.06, N 3.51; found: C 15.02, N 3.47. Infrared (cm^{-1}): 1646 (s), 1608 (s), 1206 (s), 1034 (s), 810 (vs), 692 (s), 637 (s), 583 (s), 419 (s), 355 (s). ^{14}N nmr ($CDCl_3$) δ: −75.0.

Preparation of $C_5Cl_6NS^+AsF_6^-$

A mixture of C_5Cl_6NSCl (0.50 g, 1.41 mmol) and $AgAsF_6$ (0.418 g, 1.41 mmol) was transferred to one arm of a two-bulb vessel under an atmosphere of dry N_2. Liquid SO_2 (25 mL) was condensed onto this mixture at −78°C to give an intensely purple solution. After 16 h the precipitate of AgCl (0.16 g, 1.12 mmol) was separated by filtration. Some of the AgCl adhered to the frit and could not be recovered. Removal of the SO_2 under vacuum produced dark purple crystals of $C_5Cl_6NS^+AsF_6^-$ (0.70 g, 1.38 mmol). An analytical sample was obtained by recrystallization from an SO_2–$CFCl_3$ mixture. *Anal.* calcd. for $C_5AsCl_6F_6NS$: C 11.83, Cl 41.89, N 2.76, S 6.31; found: C 10.98, Cl 41.65, N 2.53, S 5.35. Infrared (cm^{-1}): 1750 (m), 1581 (m), 1561 (m), 1259 (s), 1164 (s), 1063 (m), 1041 (sh), 860 (m), 836 (s), 811 (vs), 702 (vs, ν_3 AsF_6^-), 658 (m), 639 (m), 439 (m). Ultraviolet–visible (CH_2Cl_2): λ_{max} 562 nm.

Preparation of C_5Cl_6NSI

A cold solution of trimethylsilyl iodide (0.58 g, 2.9 mmol) in *n*-hexane (15 mL) was added to a solution of C_5Cl_6NSCl (1.0 g, 2.8 mmol) in *n*-hexane (15 mL) at −78°C. The solution became red immediately. After 1 h solvent was removed under vacuum and the brown solid was recrystallized from *n*-hexane at −20°C to give red crystals of C_5Cl_6NSI (0.50 g, 1.1 mmol). *Anal.* calcd. for C_5Cl_5INS: C 13.47, N 3.14; found: C 13.84, N 3.06. Infrared (cm^{-1}): 1617 (m), 1208 (vs), 1154 (m), 982 (m), 824 (s), 809 (vs), 653 (m), 636 (vs), 595 (s), 581 (m). ^{14}N nmr ($CDCl_3$) δ: −78.9.

Preparation of C_5Cl_6NSPh

1,2-Dichloroethane (30 mL) was added to a mixture of C_5Cl_6NSCl (1.0 g, 2.8 mmol) and Ph_2Hg (1.0 g, 2.8 mmol) and the solution was heated at reflux for 2 days. Solvent was removed under vacuum and the solid residue was extracted with CCl_4 (25 mL) to give an insoluble white solid identified as PhHgCl (0.44 g, 1.4 mmol) by infrared spectroscopy. Solvent was removed under vacuum and the residue was sublimed at 100°C/0.1 torr. The sublimate (0.67 g) was dissolved in CCl_4 (25 mL) and PhHgCl (0.08 g, 0.25 mmol) was separated by filtration. At 0°C the CCl_4 solution produced yellow crystals of C_5Cl_6NSPh (0.59 g, 1.5 mmol) mp 64°C. *Anal.* calcd. for $C_{11}H_5Cl_6NS$: C 33.37, H 1.27, N 3.54; found: C 33.17, H 1.45, N 4.14. Infrared (cm^{-1}): 1623 (s), 1577 (m), 1229 (s), 1209 (vs), 1158 (m), 811 (vs), 751 (s), 737 (vs), 725 (s), 702 (m), 687 (m), 662 (m), 595 (m).

Preparation of $C_5Cl_6NSNPr_2^i$

A mixture of C_5Cl_6NSCl (1.0 g, 2.8 mmol) and di(isopropyl)amine (0.57 g, 5.6 mmol) in CH_2Cl_2 (25 mL) was stirred at 23°C for 16 h. Solvent was removed under vacuum and the residue was treated with *n*-pentane (30 mL) to give a white precipitate (0.83 g) which was subsequently removed by filtration. At 0°C the filtrate yielded colourless crystals of $C_5Cl_6NSNPr_2^i$, (0.74 g, 1.7 mmol) mp 94°C. *Anal.* calcd. for $C_{11}H_{14}Cl_6N_2S$: C 31.53, H 3.37, N 6.69; found: C 31.44, H 3.47, N 6.91. Infrared (cm^{-1}): 1621 (m), 1206 (s), 1171 (m), 1158 (m), 1123 (m), 1094 (m), 971 (m), 812 (vs), 635 (s), 597 (s). ^1H nmr ($CDCl_3$) δ: 1.30 (d), 3.57 (septet).

Preparation of $C_5Cl_6NSNC_5Cl_6$

A solution of C_5Cl_6NSCl (0.89 g, 2.5 mmol) and Ph_3Sb (0.44 g, 1.25 mmol) in CH_2Cl_2 (3 mL) was stirred at 23°C for 4 days to give pale yellow crystals of $C_5Cl_6NSNC_5Cl_6$ (0.70 g, 1.2 mmol), mp 260°C (lit. (5): 263°C), which were isolated by filtration. *Anal.* calcd. for $C_{10}Cl_{12}N_2S$: C 19.81, N 4.62; found: C 19.92, N 4.54. The infrared spectrum was in good agreement with the values reported in the literature (5). δ(^{14}N) ($CDCl_3$)−83.8.

X-ray analysis of C_5Cl_6NSBr

A suitable transparent yellow plate was glued on a glass fibre, and mounted on an Enraf-Nonius CAD4 diffractometer. Unit cell parameters and their standard deviations were derived from the setting angles of 25 reflections in the range $7.40° < \theta < 14.31°$. Reduced cell calculations did not indicate any higher metric symmetry. Crystal and instrumental instability were monitored through the measurement of three standard reflections every 1 h of X-ray exposure time; there was no indication of crystal decomposition. The net intensities of the data were corrected for reflection width, scale variation, Lorentz, and polarization effects. Variance $\sigma^2(I)$ was calculated based on counting statistics. Crystal data are compiled in Table 1.

TABLE 1. Crystal data for C_5Cl_6NSBr

Formula	C_5Cl_6NSBr
M_w	398.744
System	Triclinic
Space group	$P\bar{1}$
a (Å)	9.626(2)
b (Å)	9.810(2)
c (Å)	13.736(2)
α (deg)	79.68(1)
β (deg)	88.62(1)
γ (deg)	74.73(1)
V (Å^3)	1230.69
Z	4
λ (MoK_α) (Å)	0.71069 (graphite monochromator)
Crystal size (mm)	0.32 × 0.56 × 0.15
Temperature (K)	298
D_c(g cm^{-3})	2.152
μ (cm^{-1})	46.06
Unique reflections	7164
Observed reflections	4850 ($I \geq 2.0\ \sigma$ (I))
F(000)	760
R	0.075
R_w	0.063

The bromine positions were located in an *E* map with phases derived from symbolic addition (7). The remaining atoms were located in difference maps after refining the scale and thermal parameters. The data were corrected for absorption using DIFABS (8) after isotropic refinement. All atoms were refined anisotropically using full-matrix least-squares calculations minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = {}^1/_{\sigma^2}(F_o)$. Final agreement factors, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2]^{1/2}$ were 0.075 and 0.063, respectively. A difference Fourier map calculated at the conclusion of refinements was essentially featureless. The final fractional coordinates of the two crystallographically independent molecules present in the asymmetric unit are presented in Table 2. Thermal parameters and F_o/F_c lists are available on request from the Depository of Unpublished

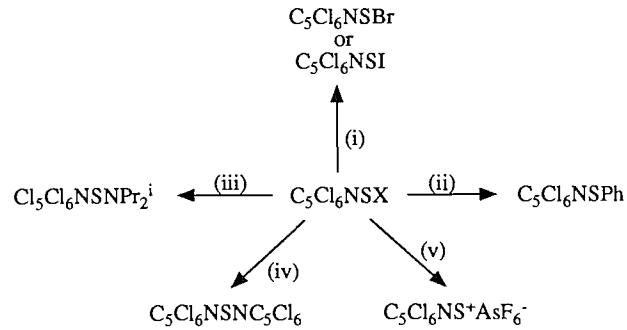
[a] $U_{eq} = \frac{1}{3}\Sigma U_{ij}a^*_i a^*_j \alpha_i \cdot \alpha_j$.

Data.[2] Neutral atom scattering factors were used with anomalous dispersion corrections applied (9). No corrections for extinction were made. All calculations were carried out on a Zenith 386 running UNIX V.3 at the University of Calgary with the program package XTAL (10).

Results and discussion



Preparation of C_5Cl_6NSX derivatives

The monomers NSF (11) and NSCl (12) undergo [2 + 4] cycloaddition reactions with hexafluorobutadiene to give six-membered rings. It was anticipated that NSCl would react with hexachlorocyclopentadiene in a similar manner to give **1**. Monomeric thiazyl chloride, generated from $(NSCl)_3$, does indeed react with C_5Cl_6 at 65°C in the absence of a solvent to give excellent yields of a 1:1 adduct. Haas and Mischo have demonstrated by X-ray crystallography that this adduct is **2***a* (X = Cl) and they have presented a plausible mechanism for the formation of **2***a* that involves a [2 + 1] addition of NSCl (acting as a nitrene) to one double bond of C_5Cl_6 as the initial step (5).

SCHEME 1. Preparation of C_5Cl_6NSX derivatives and $C_5Cl_6NS^+AsF_6^-$. (*i*) Me_3SiY (Y = Br or I), (*ii*) Ph_2Hg, (*iii*) 2^iPr_2NH, (*iv*) Ph_3Sb, (*v*) $AgAsF_6$.

This high yield synthesis of C_5Cl_6NSCl provides an opportunity to investigate simple substitution reactions involving the S—Cl bond. The results of such reactions are summarized in Scheme 1. Halogen exchange occurs readily at room temperature upon treatment of C_5Cl_6NSCl with the appropriate trimethylsilyl halide to give C_5Cl_6NSBr or C_5Cl_6NSI. The latter is a rare example of a thermally stable compound of the type RSI (13). The derivatives C_5Cl_6NSPh and $C_5Cl_6NSNPr_2^i$ are also obtained in good yields by the routes indicated in Scheme 1. The reduction of C_5Cl_6NSCl with Ph_3Sb produced $C_5Cl_6NSNC_5Cl_6$ rather than the corresponding disulfide.

The new hexachloro-3-cyclopentenylsulphenyl derivatives were characterized by elemental analyses, ^{13}C (see Table 6) and ^{14}N nmr, mass and infrared spectroscopy, and by X-ray crystallography in the case of C_5Cl_6NSBr. All derivatives showed a weak parent ion in the mass spectrum and the cleavage of the S—X bond as the major fragmentation process. The ^{14}N chemical shifts were observed in the range −75 to −85 ppm (relative to $MeNO_2(l)$). The infrared spectra of the series C_5Cl_6NSX (X = Cl, Br, I) show bands at *ca.* 1205, 810, 635, and 590 cm^{-1} characteristic of the C_5Cl_6NS moiety. An intense band at 452 cm^{-1} in the infrared spectrum of C_5Cl_6NSCl is replaced by a strong absorption at 355 cm^{-1} for C_5Cl_6NSBr. These bands are tentatively assigned to ν(S—Cl) and ν(S—Br), respectively.

Crystal structure of C_5Cl_6NSBr

The structure of C_5Cl_6NSBr is shown in Fig. 1, which depicts the two independent molecules in the asymmetric unit together with the atomic numbering scheme. The bond lengths and bond angles for the two C_5Cl_6NSBr molecules are given in Tables 3 and 4, respectively, and the structural parameters for the >C=NSX moiety in C_5Cl_6NSX (X = CF_3, Cl, Br) are compared in Table 5. The structures of C_5Cl_6NSBr and C_5Cl_6NSCl are very similar and they exhibit remarkable differences compared to that of $C_5Cl_6NSCF_3$. The most obvious difference is that the CF_3 derivative adopts a *anti* conformation **2***b* with respect to the S—N bond whereas the halides (X = Cl, Br) have the *syn* structure **2***a*. In addition, both C_5Cl_6NSBr and C_5Cl_6NSCl have short S—N bond distances of 1.56–1.57 Å and large angles of *ca.* 147° and *ca.* 116° at nitrogen and sulphur, respectively. The corresponding values of *d*(S—N) = 1.667 Å, < CNS = 124.3°, and <NSCF_3 = 94.9° for the CF_3 derivative are typical for a divalent sulfur compound (cf. *d*(S—N) = 1.675(2) Å, < CNS = 122.4(2) and 121.5(2)°, and <NSN = 94.7(1)° for $Ph_2CNSNCPh_2$ (14)). The S—Cl distance of 2.055 Å for C_5Cl_6NSCl and the average value of 2.233 Å for *d*(S—Br) in C_5Cl_6NSBr are slightly longer than the sum of covalent radii

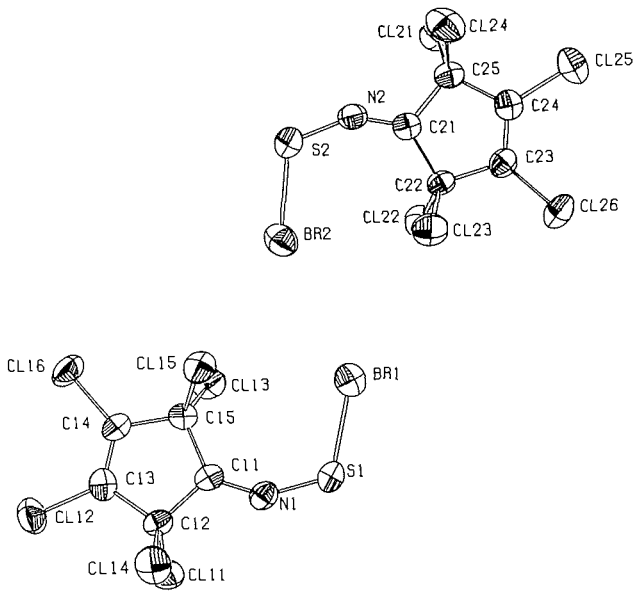

FIG. 1. ORTEP plots (50% probability ellipsoids) and atomic numbering scheme for the two different molecules of C_5Cl_6NSBr in the asymmetric unit.

(2.03 Å for S—Cl and 2.18 Å for S—Br (15)). The value of d(C=N) falls in the range 1.25–1.28 Å typical for a double bond (16) and does not show significant differences among the three derivatives.

Thus both C_5Cl_6NSCl and C_5Cl_6NSBr exhibit normal C=N bond lengths, short S—N bond lengths, anomalously large bond angles at N and S, and a *syn* geometry for the =CNSX unit. Any bonding model must explain all these structural features. In the case of C_5Cl_6NSCl, Haas and Mischo account for these observations in terms of "dative p_π–d_π interaction between the sp^2 hybridized nitrogen as donor and sulfur as acceptor" (5). We suggest that the unusual geometry of the =CNSX (X = Cl, Br) moiety is the result of *negative hyperconjugation* ($n_N \rightarrow \sigma_{SX}^*$) (17, 18). This interaction involves donation from the in-plane non-bonding orbital on N to the antibonding σ orbital of the sulfur–halogen bond. It is bonding with respect to the S—N bond and will be enhanced (better overlap) by wider angles at N and/or S. The C=N bond would not be significantly affected by this interaction, but the partial occupancy of the σ^*_{SX} orbital would be expected to result in a longer than single S—X bond as observed. Negative hyperconjugation cannot occur for *anti* structures of type **2***b* since the n_N and σ^*_{SX} orbitals are not favourably disposed for overlap in this geometry.

The structural features of C_5Cl_6NSX (X = Cl, Br) are reminiscent of those found for salts of the $ClSNSCl^+$ cation for which < SNS = *ca.* 150°, < NSCl = *ca.* 111°, and d(S—N) = *ca.* 1.53 Å (19). A natural bond order analysis of this cation at the 3-21G(*) level using the experimental geometry showed that the nitrogen in-plane lone pairs have 87% *p* character and donate 0.15e to σ_{SCl}^* orbital, of which only 0.018e$^-$ go into sulphur d orbitals (18). The positive charge presumably contributes to the shorter S—N and S—Cl (*ca.* 1.99 Å (19)) bond lengths in $ClSNSNCl^+$ compared to the corresponding values in C_5Cl_6NSCl.

^{13}C nmr spectra and fluxional behaviour of C_5Cl_6NSX derivatives

The ^{13}C nmr data for C_5Cl_6NSX derivatives are given in Table 6. Although two of the derivatives (X = CF_3, NC_5Cl_6) exhibit five reasonances consistent with the static structure **2***a* or **2***b*, the majority (X = Cl, Br, I, Ph, NPr^i_2, NSO and SCF_3) show three signals at room temperature indicating the equivalence of the pairs of carbon atoms C_b/C_c and C_d/C_e on the nmr time scale. The chemical shifts for C_b/C_c and C_d/C_e fall within the narrow ranges 78–85 and 135–143 ppm, respectively. The chemical shift of C_a is more sensitive to the nature of X with values from 140 to 174 ppm.

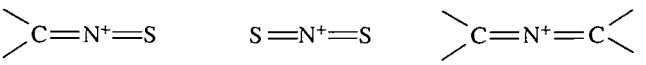

TABLE 3. Bond lengths (Å)

1		2	
Bond	Length	Bond	Length

S(1)—N(1)	1.560(6)	S(2)—N(2)	1.569(6)
N(1)—C(11)	1.278(8)	N(2)—C(21)	1.253(8)
C(11)—C(15)	1.499(7)	C(21)—C(22)	1.505(7)
C(11)—C(12)	1.514(8)	C(21)—C(25)	1.516(9)
C(12)—C(13)	1.492(8)	C(22)—C(23)	1.484(9)
C(12)—Cl(11)	1.779(5)	C(22)—Cl(23)	1.775(6)
C(12)—Cl(14)	1.785(6)	C(22)—Cl(22)	1.787(6)
C(13)—C(14)	1.321(8)	C(23)—C(24)	1.328(8)
C(13)—Cl(12)	1.702(7)	C(23)—Cl(26)	1.701(6)
C(14)—C(15)	1.501(9)	C(24)—C(25)	1.498(8)
C(14)—Cl(16)	1.685(6)	C(24)—Cl(25)	1.698(7)
C(15)—Cl(13)	1.780(5)	C(25)—Cl(24)	1.771(5)
C(15)—Cl(15)	1.780(6)	C(25)—Cl(21)	1.775(6)

A variable temperature ^{13}C nmr study revealed fluxional behaviour for C_5Cl_6NSCl. At −50°C, the ^{13}C nmr spectrum exhibits five resonances as expected for structure **2***a* (see Table 6). Upon warming the solution the resonances for C_d and C_e broaden and collapse symmetrically to give a singlet at 135.2 ppm while the chemical shift of C_a is independent of temperature. This change is reversible and can be explained in terms of a fluxional process. Since the addition of hexachlorocyclopentadiene to a solution of C_5Cl_6NSCl in $CDCl_3$ does not alter the position of the ^{13}C nmr signals of C_5Cl_6NSCl, a dissociative mechanism can be ruled out. The coalescence temperature is *ca.* 30°C, which corresponds to an interconversion barrier of 68.1 ± 1.2 kJ mol^{-1}. The observed fluxional behaviour can be explained either by rotation about the S—N bond or inversion at the nitrogen centre. For comparison, the rotational barrier for $ClSNH_2$ has been calculated to be 66.5 kJ mol^{-1} (18) while experimental values for *N,N*-dialkyl substituted compounds are in the range 60.7–64.9 kJ mol^{-1} (20). The inversion process would be facilitated by the negative hyperconjugative effect but it is not possible to distinguish between these two processes on the basis of the available data.

Preparation of $C_5Cl_6NS^+AsF_6^-$

Haas and Mischo reported the observation of a transient blue colour in the reaction of C_5Cl_6NSCl with $SbCl_5$ in SO_2 to give $C_5Cl_6NSNC_5Cl_6$ in 62% yield (5). We were intrigued by the possibility that the blue species is $C_5Cl_6NS^+$, which would represent the first example of a hybrid, **3**, of the well known NS_2^+ cation, **4**, (21) and the hypothetical cations, **5**, which are only known as transient species (22).

[a]Taken from ref. 5.
[b]This work.

The reaction of C_5Cl_6NSCl with $Ag^+AsF_6^-$ in SO_2 produced $C_5Cl_6NS^+AsF_6^-$ as very moisture-sensitive, dark purple crystals in almost quantitative yield. This salt was characterized by elemental analyses (C, Cl, N, and S), ^{13}C and ^{14}N nmr spectroscopy, infrared and uv–visible spectroscopy. The infrared spectrum shows the expected absence of the band at 452 cm^{-1}, attributed to ν(S—Cl) in C_5Cl_6NSCl, and a very strong absorption at 703 cm^{-1} due to $\nu_3(AsF_6^-)$. There are substantial differences in the frequencies and intensities of the ir bands of the cation compared to those of neutral C_5Cl_6NSX compounds, but the very strong band at 810 cm^{-1} is a prominent feature in the ir spectrum of $C_5Cl_6NS^+AsF_6^-$. The visible spectrum exhibits an absorption at 562 nm in CH_2Cl_2, but this salt decomposes rapidly in solvents other than SO_2 so that an accurate extinction coefficient could be obtained. Attempts to obtain crystals of $C_5Cl_6NS^+AsF_6^-$ suitable for an X-ray structural determination or to prepare $C_5Cl_6NS^+$ salts with other anions, e.g. $SbCl_6^-$, $AlCl_4^-$, have been unsuccessful.

Conclusions

The structural features of hexachloro-3-cyclopentenylaminosulphenyl halides, C_5Cl_6NSX (X = Cl, Br), can be explained in terms of the negative hyperconjugation effect. Variable temperature ^{13}C nmr studies of C_5Cl_6NSCl reveal a fluxional process that probably involves inversion at nitrogen. The dark purple salt, $C_5Cl_6NS^+AsF_6^-$, is readily obtained by the reaction of

C_5Cl_6NSCl with $AgAsF_6$ in SO_2. The preparation and structural determination of other examples of the hybrid cation R_2CNS^+ are being pursued.

TEJRAJ M. AMINABHAVI, SHRIKANT S. JOSHI, RAMACHANDRA H. BALUNDGI, and SHYAM S. SHUKLA. Can. J. Chem. **69**, 1028 (1991).

Densities and viscosities of ten binary and four ternary mixtures containing bromoform, bromobenzene, chlorobenzene, toluene, mesitylene, and dimethylformamide at 25°C have been measured over the whole range of mixture compositions. Excess molar volumes, apparent values of excess molar viscosities, and Gibbs energy of activation of flow have been calculated for these mixtures. The calculated results have been fitted to a linear regression equation to estimate the parameters and the standard deviation between the calculated and the experimental data.

Key words: ternary systems, excess quantities, bromoform, density, viscosity.

TEJRAJ M. AMINABHAVI, SHRIKANT S. JOSHI, RAMACHANDRA H. BALUNDGI et SHYAM S. SHUKLA. Can. J. Chem. **69**, 1028 (1991).

Opérant à 25°C et sur l'ensemble des mélanges de composition, on a mesuré les densités et les viscosités de dix mélanges binaires et de quatre mélanges ternaires contenant du bromoforme, du bromobenzène, du chlorobenzène, du toluène, du mésitylène et du diméthylformamide. Pour chacun de ces mélanges, on a calculé les volumes molaires en excès, les valeurs apparentes des viscosités molaires en excès et l'enthalpie libre d'activation d'écoulement. On a ajusté les résultats calculés à une équation de régression linéaire afin d'évaluer les paramètres et les écarts types entre les données expérimentales et calculées.

Mots clés : systèmes ternaires, quantités en excès, bromoforme, densité, viscosité.

[Traduit par la rédaction]

Introduction

Theoretical predictions of excess molar volumes of nonideal binary liquid mixtures have been satisfactory in explaining the sign and magnitude in terms of the extent of interactions between mixing components (1, 2). For ternary mixtures, the predictive approach is more complex and thus empirical methods based on experimental binary data have to be used (3, 4). However, if significant interactions among the liquids occur, considerable errors may be introduced if we attempt to express the excess molar volumes of ternary systems in terms of binary contributions. The study of transport properties of liquid mixtures, on the other hand, is also informative as it gives an insight into the intermolecular forces and the microscopic structure of liquids (5).

Previous work on binary systems has suggested that correlations of molecular order in addition to donor–acceptor type interactions play a significant role in studying the excess molar volumes of mixtures of bromoform with aromatic liquids (6–8). A search of the literature on ternary mixtures suggests the availability of several empirical relations used to calculate the excess volume (9–19). In this paper, we report the experimental densities and viscosities of ten binary and four ternary mixtures comprising bromoform, mesitylene, chlorobenzene, bromobenzene, dimethylformamide (DMF), and toluene. The density data were used to calculate the binary and ternary excess molar volumes and these results were analyzed in terms of the empirical ternary relations. The viscosity data were also used to predict the apparent values of excess molar viscosity and excess molar Gibbs energy of activation of flow.

Experimental

Materials

Bromoform (Thomas Baker, Bombay) was obtained in its highest purity grade (>99 mol% as claimed by the manufacturer) and was thus not purified further. The reagent grade solvents, namely, chlorobenzene, bromobenzene, DMF, toluene, and mesitylene were purified before use (20, 21). The physical properties of the pure liquids are in close agreement with the literature results. The purity of the solvents as tested by gas chromatography exceeded more than 99 mol%. Mixtures were prepared by weighing on a Mettler balance with a precision of 1×10^{-4} g.

Methods

Densities were determined with a single stem pycnometer having a bulb volume of about 10 cm^3 and a capillary of 1 mm internal diameter. Viscosities were determined with a Cannon–Fenske viscometer, size 100, calibrated with double distilled water and benzene. The details of the procedures have been described earlier (6–8). The pycnometer and viscometer were suspended vertically for sufficient time in a constant temperature bath maintained within ±0.01°C. The temperatures were read with certified thermometers. Densities and viscosities determined are accurate to ±0.0001 and ±0.003 units respectively. Densities (ρ) and viscosities (η) of the binary and ternary mixtures, over the entire scale of mole fractions at 25°C, have been measured.[4]

Results and discussion

Following our earlier suggestions (22), the excess molar volumes of binary mixtures, $V^E_{m,B}$, have been calculated from density data as

$$[1] \quad V^E_{m,B} = \left[\left(\sum_{i=1}^{2} M_i x_i\right) \Big/ \rho\right] - \sum_{i=1}^{2} (M_i x_i / \rho_i)$$

where M_i, x_i, and ρ_i represent the molar mass, mole fraction, and density of the ith component of the mixture, respectively; ρ refers to density of binary mixture. These results are further fitted to a Redlich–Kister–type formula (23).

$$[2] \quad V^E_{m,B} = x_1 x_2 \sum_{i=0}^{n} A_B^{(i)} (x_2 - x_1)^i$$

By using a nonlinear regression analysis (Marquardt algorithm) we have estimated the binary parameters $A_B^{(i)}$ of eq. [2]. In each case, the optimum number of coefficients was ascertained from an examination of the variation of the standard error (σ) of the estimate with:

$$[3] \quad \sigma = [\Sigma (X^E_{obs} - X^E_{cal})^2/(n - P)]^{1/2}$$

where n is the total number of data points and P is the number of coefficients considered ($P = 4$ in the present calculation). The estimated parameters and the standard deviations between the computed and observed values of $V^E_{m,B}$ are given in Table 1.

The plots of $V^E_{m,B}$ versus x_1 for all the systems at 25°C are shown in Fig. 1 together with the lines for the standard errors. The estimated error in $V^E_{m,B}$ varies in the range (2–5) × $10^{-8}\ m^3\ mol^{-1}$. The magnitude of the various binary mixtures follow the sequence: DMF + toluene < DMF + chlorobenzene < bromobenzene + DMF < chlorobenzene + toluene < bromobenzene + bromoform < bromobenzene + chlorobenzene ≃ bromobenzene + mesitylene < chlorobenzene + bromoform < mesitylene + chlorobenzene < mesitylene + bromoform.

To extend the discussion to ternary mixtures, it is legitimate to write the ternary excess molar volume, $V^E_{m,T}$ as

$$[4] \quad V^E_{m,T} = \left[\left(\sum_{i=1}^{3} M_i x_i \right) \Big/ \rho \right] - \sum_{i=1}^{3} (M_i x_i / \rho_i)$$

Here, ρ refers to density of the ternary mixture. Analogously, $V^E_{m,T}$ can also be measured directly from dilatometry (14). However, $V^E_{m,T}$ has been calculated from consideration of $V^E_{m,B}$ data of the binaries making up the ternary mixture. This approach has led to the development of several empirical relations to predict $V^E_{m,T}$ data. The popular ones among these are as follows:

Rastogi *et al.* model (4)

$$[5] \quad V^E_{m,T} = 0.5[(x_1 + x_2)V^E_{12} + (x_1 + x_3)V^E_{13} + (x_2 + x_3)V^E_{23}]$$

Radojkovic *et al.* model (9)

D. Chlorobenzene (1) + DMF (2) + bromobenzene (3)	0.16	1.83	−0.82	3.73	0.03

[8] $$V^E_{m,T} = 4\left[\frac{x_1x_2V^E_{12}}{(2x_1 + x_3)(2x_2 + x_3)} + \frac{x_1x_3V^E_{13}}{(2x_1 + x_2)(2x_3 + x_2)} + \frac{x_2x_3V^E_{23}}{(2x_2 + x_1)(2x_3 + x_1)}\right]$$

Tsao and Smith model (11)

[9] $$V^E_{m,T} = \left(\frac{x_2}{1 - x_1}\right)V^E_{12} + \left(\frac{x_3}{1 - x_1}\right)V^E_{13} + (1 - x_1)V^E_{23}$$

Sanchez and Lacombe (24, 25) also developed a theory to calculate excess quantities of ternary mixtures. Following this approach, we propose to compute $V^E_{m,T}$ from binary interactions obtained from $V^E_{m,B}$ data. The total volume $V^E_{m,T}$ of a ternary mixture can be expressed as

[10] $$V_{m,T} = \sum_{i=1}^{3} V_i x_i + \Delta V_{12} + \Delta V_{23} + \Delta V_{13} + \Delta V_{m,T}$$

where the various ΔV terms representing the changes in volume are given in terms of molar volumes of the respective binary mixtures. So eq. [10] becomes

[11] $$V_{m,T} = \sum_{i=1}^{3} V_i x_i + x_1x_2 \sum_{n=0}^{3} A_{12}^{(n)}(x_1 - x_2)^n + x_2x_3 \sum_{n=0}^{3} A_{23}^{(n)}(x_2 - x_3)^n + x_1x_3 \sum_{n=0}^{3} A_{13}^{(n)}(x_1 - x_3)^n + x_1x_2x_3 \sum_{n=0}^{3} A_T^{(n)}(x_2 - x_3)^n x_1^n$$

since the difference, $\left[V_{m,T} - \sum_{i=1}^{3} V_i x_i\right]$, represents $V^E_{m,T}$, which is obtained from the experimental density data and has been fitted to the following relationship:

[12] $$V^E_{m,T} - x_1x_2 \sum_{n=0}^{3} A_{12}^{(n)}(x_1 - x_2)^n - x_2x_3 \sum_{n=0}^{3} A_{23}^{(n)}(x_2 - x_3)^n - x_1x_3 \sum_{n=0}^{3} A_{13}^{(n)}(x_1 - x_3)^n = x_1x_2x_3 \sum_{n=0}^{3} A_T^{(n)}(x_2 - x_3)^n x_1^n$$

where $A_T^{(n)}$ represents the ternary interaction parameter. The various binary terms (as estimated from $V^E_{m,B}$ data) given in Table 1 are used along with $V^E_{m,T}$ estimated by eq. [4] to evaluate the ternary coefficients $A_T^{(n)}$ from eq. [12]. These data are included in Table 2. A detailed analysis of the various theoretical relations is summarized in Tables 2 and 3.

[a]A, B, C, and D refer to ternary mixtures given in Table 2.

ternary mixtures, were calculated (26–28) as:

$$[13] \quad \eta^E = \eta_m - \sum_{i=1}^{n} (\eta_i x_i)$$

$$[14] \quad \Delta G^{*E} = RT\left[\ln \eta_m V_m - \sum_{i=1}^{n} x_i \ln \eta_i V_i\right]$$

Quite often an exponential relation was also used to calculate η^E of the mixtures.

$$[15] \quad \eta^E = \eta_m - \exp\left(\sum_{i=1}^{n} x_i \ln \eta_i\right)$$

The computed values of η^E and ΔG^{*E} from eqs. [13] and [14] for binary mixtures have been fitted to eq. [2] to estimate the coefficients that are included in Table 4.

The results of η^E at 25°C calculated from eq. [13] along with the errors as indicated by the solid vertical lines are displayed in Fig. 2 for all the binary mixtures. The error analyses indicate that η^E results vary in the range of (2–4) × 10^7 Pa s. The results for ΔG^{*E} at 25°C are plotted in Fig. 3. The errors involved in the computation of ΔG^{*E} are estimated to be, at the most, around ± (2–3) J mol^{-1}. The magnitude of ΔG^{*E} for the various binary mixtures follows the sequence: bromobenzene + DMF > mesitylene + bromoform > DMF + chlorobenzene > bromo-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12

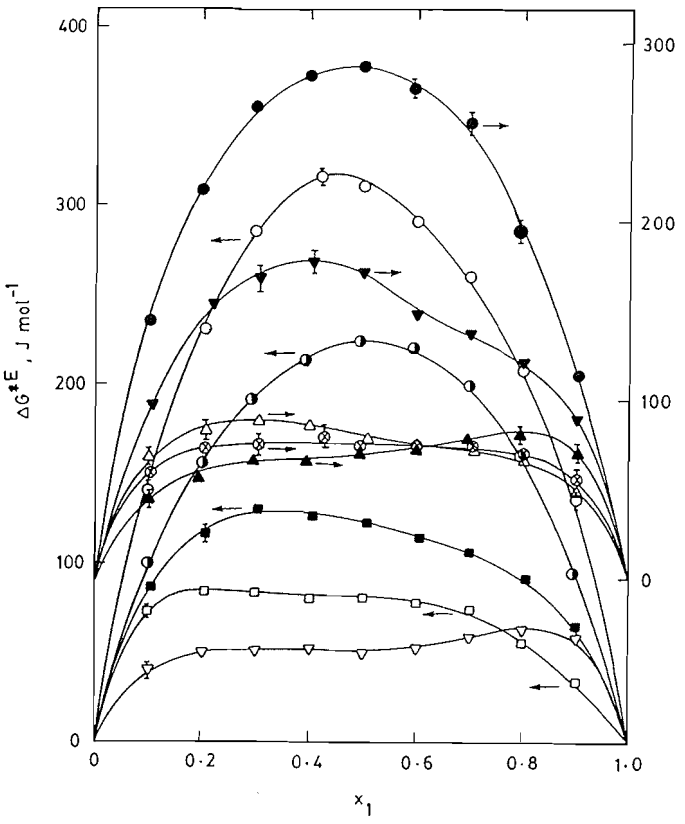

FIG. 3. Dependence of excess molar Gibbs energy of activation of flow (ΔG^{*E}) on mole fraction (x_1) at 25°C. Symbols have the same meanings as in Fig. 1.

benzene + bromoform > chlorobenzene + bromoform > DMF + toluene > chlorobenzene + toluene > bromobenzene + mesitylene > mesitylene + chlorobenzene > bromobenzene + chlorobenzene.

The ternary viscosity data have also been analysed in terms of eqs. [13]–[15] and these data are fitted to the following empirical relation:

$$[16] \quad X^E = x_1x_2x_3\left[\sum_{i=0}^{n} A_T^{(i)}(x_2 - x_3)^i x_1^i\right]$$

where X^E refers to η^E as calculated from eqs. [13] and [15] and ΔG^{*E} from eq. [14]. The estimated coefficients and the standard deviations are compiled in Table 5. The η^E as calculated from eq. [13] appears to be better than that given by eq. [15].

Synthetic transformations of cyclopropyl annulated dihydroisoquinolines[1]

IVAN LANTOS[2] AND HARALAMBOS E. KATERINOPOULOS[3]

Department of Synthetic Chemistry, Chemical R&D, SmithKline Beecham Pharmaceuticals, Philadelphia, PA 19101, U.S.A.

Received December 17, 1990

IVAN LANTOS and HARALAMBOS E. KATERINOPOULOS. Can. J. Chem. **69**, 1033 (1991).

Isomeric 3-cyano-3-methyl-2-acetyl-cycloprop[*c*]isoquinolines, **5** and **6**, were prepared by alkylation and cyclopropanation of Reissert compounds and their reactions under basic conditions were examined. Both compounds, under the influence of methoxide, yielded isoquinoline derived products resulting from cleavage of the peripheral C—C bond. The results are postulated to derive from attack of the methoxide on the acyl carbonyl, forming a tetrahedral adduct that undergoes ring opening.

Key words: cyclopropanation, ring opening, tetrahedral complex, pyramidalization.

IVAN LANTOS et HARALAMBOS E. KATERINOPOULOS. Can. J. Chem. **69**, 1033 (1991).

On a préparé les 3-cyano-3-méthyl-2-acétyl-cycloprop[*c*]isoquinoléines isomères, **5** et **6**, par alkylation et cyclopropanation de composés de Reissert et on a étudié leurs réactions dans des conditions basiques. Sous l'influence du méthylate, les deux composés fournissent des produits dérivés de l'isoquinoléine par clivage de la liaison C—C périphérique. On suppose que les produits obtenus sont le résultat d'une attaque du méthylate sur le groupe carbonyle de l'acétyle conduisant à un adduit tétraédrique qui subit ensuite une ouverture de cycle.

Mots clés : cyclopropanation, ouverture de cycle, complexe tétraédrique, pyramidalisation.

[Traduit par la rédaction]

Introduction

As the continuation of our previous work dealing with the ring expansion reactions of the dihydrocycloprop[*c*]isoquinoline heterocyclic system (1), we desired to prepare disubstituted analogs having *gem* substituents of different steric sizes in the 3-position. It appeared to us that the methyl and cyano groups were especially advantageous in this context not only on account of their ready accessibility by synthesis but also because of the potential to obtain both stereoisomers. In this report we detail the successful preparation of these desired isomeric 3-methyl-3-cyano compounds **5** and **6** together with the discovery that under basic conditions these compounds undergo a novel ring opening reaction previously not observed within this heterocyclic system. The reactivity of these compounds under thermal conditions will be described in a separate report.

Results

The successful strategy leading to the preparation of isomers **5** and **6** was based on the cyclopropanation of the Reissert adducts of isoquinoline (2). Treatment of the methylated Reissert adduct **4** with dibromocarbene (3) afforded **5** in moderate yield as shown in Scheme 1.

The relative stereochemical assignment was originally based on the known tendency of the carbenoid species to enter the molecule *anti* to the more bulky group, in this instance the methyl group. This stereochemical assignment was later confirmed by nOe experiments and by a single crystal X-ray structural determination. To prepare the isomer with the inverted substitution pattern in the 3-position, the alkylation–cyclopropanation sequence was reversed. Thus cyclopropanation of the base-sensitive Reissert adduct **2** was readily accomplished with the Seyferth reagent (4) and the resultant compound **3** was alkylated with NaH/MeI. The success of this latter reaction is noteworthy, since the cyclopropyl group is potentially sensitive to the incipient carbanion in the benzylic position. The stereochemical assignment of **3** is based on the assumption that the cyclopropyl moiety enters opposite to the 1-substituent, in this case the cyano group. Assignment of **6** rests on nOe spectral comparison with isomer **5**. Irradiation of the C-3 methyl of **5** gave significant enhancements of the aromatic proton at C-4, and the cyclopropyl proton at C-1a. In contrast, irradiation of the C-3 methyl protons of **6** gave no noticeable nOe of the C-1a cyclopropyl proton signal, although it did show an enhancement of the signal due to the proton at C-4.

If the stereochemical assignment of **3** is correct, then the introduction of the methyl group *syn* to the cyclopropyl unit in **6** is worthy of note since it occurs with retention of configuration. This is in contrast to our previous findings that the incoming molecule always enters *anti* to the existing more bulky substituent in the molecule. The results would indicate that deprotonation from the *syn* face results in a carbanion that, in accordance with the *gauche* (5) effect, being α to a nitrogen, retains some sp^3-like character and its stereochemical integrity upon treatment with electrophiles.

Having isomers **5** and **6** in hand allowed us to examine their reactivity under conditions that previously resulted in ring expansion. Disappointingly, we found the thermally induced reactions extremely sluggish and these results will be reported in a future communication. Much greater reactivity was observed, however, when compounds **5** and **6** were treated with NaOMe in refluxing methanol. The formation of three products, which were isolated after 6 h of reaction time, was observed almost immediately.

Based on spectroscopic and X-ray data, these proved to be the 1-methyl-4-dimethoxymethylisoquinoline (**8**) and the isomeric compounds **9** and **10** (R = CH_3). They were obtained, in product ratios of 1:3:1 and 7:1:1, from **5** and **6** respectively. Assignment of the structure of **9** (R = CH_3) is based on X-ray single crystal data, while that of **10** (R = CH_3) is supported by ^{1}H NMR. The stereochemical disposition of the methoxy group in **10** is supported by the nOe (approx. 10%) between the protons of the methyl group at C-3 and on the methoxy group. Such interactions were not observed between the respective groups in **9**. Clearly all three compounds result from a cyclo-

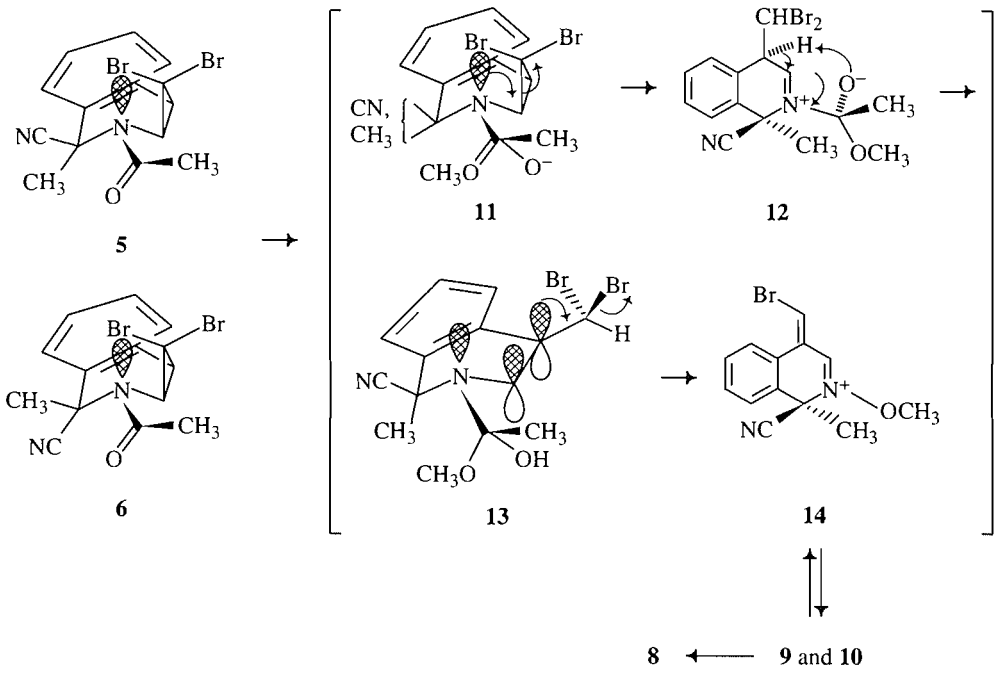
SCHEME 2

propyl fragmentation process wherein the peripheral C—C bond is cleaved in preference to the central bond. It could be demonstrated by further NaOMe treatment that **8** can be derived from **9** and **10** under the reaction conditions. Furthermore, interconversion of **9** and **10** under similar conditions could also be shown.

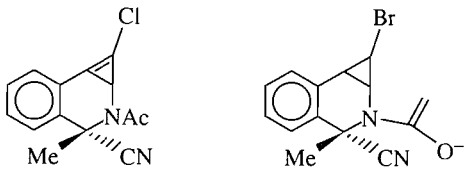
To examine the steric effect of the acyl substituent on the reaction, pivaloyl compound **7** was also prepared and treated with NaOMe in methanol. No change in the starting material was observed at room temperature, but a slow reaction resulting in the formation of **9** and **10** (R = *t*-butyl) was observed at reflux temperature.

Discussion



In attempting to arrive at a mechanistic interpretation for the foregoing reaction we considered the following observations: (1) the methoxide appears to be essential for the reaction yet the acetyl (acyl) group remains on the substrate after ring opening; (2) the same two products **9** and **10** are derived from both substrates **5** and **6** although in different amounts; furthermore **9**, the product where the methoxy group is *trans* to the methyl, is obtained in higher yield; and (3) the pivaloyl derivative yielded products of similar structure although displayed less reactivity, reacting only at elevated temperature.

We believe that most or all of these observations can be accommodated by a reaction mechanism involving the cascade of intermediates shown in Scheme 3. Observation 2 is consistent with the penultimate intermediacy of imminium species such as **14**, which can add methoxide from either side of the molecule. Based on steric arguments, this addition will preferentially take place from the side *anti* to the methyl, forming **9** (R = CH_3, *t*-Bu). It is attractive to postulate that **14** arises from intermediate **13**, which, having the least unfavourable 1,3 allylic interactions (6), will eliminate bromide to form the *trans* isomer only.



It is more difficult to interpret the role of the methoxide (observation 1) and the mechanism of formation of intermediate **12**. Base-induced cleavage of dihalocyclopropane carbocyclic systems has been previously noted by several authors (7) and the primary formation of cyclopropene-like intermediates (i.e., **15**) has been postulated.

It is unlikely that such intermediates would be involved in our case since their formation would not be greatly retarded by the presence of the bulky pivaloyl group in a position that is quite distant from the reaction center (observation 3) as it is in compound **7**. A second possibility requires formation of the enol **16** and cyclopropyl cleavage proceeding from this species. Again, the fact that the pivaloyl compound undergoes the same type of reaction excludes such an intermediate. The two mechanisms that would allow a satisfactory interpretation of the results appear not to be distinguishable by the data. They are (a) nucleophilic attack of the methoxide at C-1a, or (b) methoxide addition to the acyl carbonyl and formation of a tetrahedral adduct such as **11**, as the species actually suffering the ring cleavage. Based on the known propensity (8) of cyclopropyl compounds to undergo electrophilic ring cleavages, we current-

ly favour the latter mechanism for the reaction. The consequence of such adduct formation would be the pyramidalization of the nitrogen and this intermediate could undergo spontaneous opening of the cyclopropyl moiety to afford **12**. To gain additional support for this mechanistic proposal we have constructed the most likely conformers of such a tetrahedral adduct using MacroModel 2.5 (9) employing MM2.[4] The dihedral angle between the peripheral breaking bond and the lone pair of nitrogen was determined. It was found that pyramidalization of nitrogen results in significant changes in the molecular geometry with dihedral angles of 2.7° and 3.8° developing for the lone pair of electrons on the nitrogen and the peripheral bond of the cyclopropyl group in compounds **5** and **6** respectively. Such very small angles indicate an almost perfect alignment of the free electron pair with the peripheral bond of the cyclopropyl ring and it may be that such orbital interaction is the reason for the facile formation of 2-substituted isoquinolines rather than the desired 2-benzazepines. The severe steric crowding present in adducts **12** and **13** may lead to a geometry that, according to stereoelectronic considerations (10), would favour expulsion of the methoxide and thus retention of the acetyl (acyl) groups.

One additional comment must be made concerning the chemical behavior of this heterocyclic system. In spite of numerous attempts at conformational calculations, we have thus far been unable to explain the large differences in the reaction profiles between the unsubstituted compounds (which readily undergo ring expansion to benzazepines) and the compounds having 3-substituents (base-promoted reactions of which are detailed in this report). Studies to answer these mechanistic questions are ongoing.

[4]We used MM2 (ref. 11) as implemented by the MacroModel (9).

Experimental

General

Melting points were determined in open capillary tubes on a Thomas–Hoover melting point apparatus and are uncorrected. IR spectra were obtained as liquid films or in Nujol on a Perkin–Elmer 283 spectrophotometer and are expressed as reciprocal centimeters. ^{1}H NMR spectra were obtained in $CDCl_3$ solutions on a Bruker AM 250 MHz spectrometer and are expressed in parts per million downfield from TMS as internal reference. Mass spectra were recorded on a Hewlett Packard 5790 GC/MS or a Finnigan 3625 mass spectrometer.

2-Acetyl-1-methyl-1,2-dihydroisoquinaldonitrile (4)

To a solution of the Reissert compound **2** (2) (4.95 g, 0.025 mol) and methyl iodide (3.9 g, 0.028 mol) in DMF (100 mL) was added sodium hydride (0.66 g, 0.028 mol) over 1 h with cooling. The solution was stirred for 2 h at room temperature, diluted with ether, washed with water and brine, dried over magnesium sulfate, filtered, and the solvent was removed *in vacuo* to yield the crude product. This was treated with hexane to give 4.87 g (92%) of crystalline **4**; mp 73.5–74.5°C (lit. (2) mp 95–96.5°C). IR ν_{max}: 2230, 1685, 1640, 1315, 1265; ^{1}H NMR: 7.65–7.61 (m, 1H), 7.31–7.27 (m, 2H) 7.04–7.03 (m, 1H), 6.54 (d, J = 7.5 Hz, 1H), 5.77 (d, J = 7.5 Hz, 1H), 2.32 (s, 3H), 1.88 (s, 3H); mass spectrum, *m/e*: 212.

anti-*2-Acetyl-1,1-dibromo-3-methyl-1a,2,3,7b-tetrahydro-1H-cycloprop[c]isoquinaldonitrile (5)*

To a solution of **4** (1.5 g, 0.0071 mol) and benzyltriethyl ammonium chloride (1.0 g, 0.004 mol) in bromoform (20 mL) was added a 40% aqueous sodium hydroxide solution (20 mL) over 30 min with cooling. The solution was allowed to reach room temperature and was stirred overnight. It was diluted with ether, washed with water and brine, dried over magnesium sulfate, filtered, and the solvent was removed *in vacuo* to give a yellow residue that was purified by chromatography over silica gel using 1:1 ether–petroleum ether as eluent. Evaporation of the solvent afforded pure product **5** (860 mg, 31.5%), mp 191–193°C. IR ν_{max}: 2260, 1660, 1300, 1190; ^{1}H NMR: 7.74–7.40 (m, 1H) 7.46–7.39 (m, 3H), 4.02 (d, J = 10 Hz, 1H), 3.27 (d, J = 10 Hz, 1H), 1.82 (s, 3H), 1.51 (s, 3H); mass spectrum, *m/e*: 382. X-ray structural data available on request.

Reaction of anti-*2-acetyl-1,1-dibromo-3-methyl-1a,2,3,7b-tetrahydro-1*H*-cycloprop[c]iso quinaldonitrile (5) with sodium methoxide in methanol at room temperature*

A solution of **5** (670 mg, 0.0017 mol) and sodium methoxide (470 mg, 0.008 mol) in methanol (10 mL) was stirred at room temperature for 100 h. The solvent was removed *in vacuo* and the residue was rapidly passed through a silica gel column using 70% ether in petroleum ether as eluent to give 92 mg (14%) of starting material, 179 mg (32%) of compound **9**, 99 mg (17%) of compound **10**, and 30 mg (8%) of compound **8**, characterized by the following spectral analysis. **8**: IR ν_{max}: 2920, 1665, 1285, 1125; ^{1}H NMR: 8.53 (s, 1H), 8.32 (dd, J = 7.6 and 0.8 Hz, 1H), 8.17 (dd, J = 6.4 and 0.9 Hz, 1H), 7.74 (td, J = 5.6 and 1.4 Hz, 1H), 7.63 (td, J = 5.6 and 1.4 Hz, 1H), 5.8 (s, 1H), 3.40 (s, 3H), 3.00 (s, 3H); mass spectrum, *m/e* 217. Anal. calcd. for $C_{13}H_{15}NO_2$: C 71.87, H 6.96, N 6.45; found: C 71.65, H 7.18, N 6.47. **9**: IR ν_{max}: 2240, 1680, 1390, 1310, 1070; ^{1}H NMR: 8.02 (dd, J = 7.4 and 1.6 Hz, 1H), 7.82 (dd, J = 6.95 and 1.45 Hz, 1H), 7.52–7.43 (m, 2H), 6.74 (s, 1H), 5.29 (br s, 1H), 3.15 (s, 3H), 2.39 (s, 3H), 1.87 (s, 3H); mass spectrum, *m/e*: 334. Anal. calcd. for $C_{15}H_{14}N_2O_2Br$: C 53.91, H 4.22, 8.38; found: C 53.81, H 4.59, N 8.38. X-Ray structural data available on request. **10**: IR ν_{max}: 2240, 1680, 1395, 1310, 1065; ^{1}H NMR: 8.18 (dd, J = 6.2 and 1.4 Hz, 1H), 7.66 (dd, J = 6.0 and 1.8 Hz, 1H), 7.53–7.44 (m, 2H), 6.71 (s, 1H), 5.42 (br s, 1H), 3.21 (s, 3H), 2.38 (s, 3H), 2.13 (s, 3H); mass spectrum, *m/e*: 334. Anal. calcd. for $C_{15}H_{14}N_2O_2Br$: C 53.91, H 4.22, N 8.38; found: C 54.22, H 4.55, N 8.52.

Reaction of anti-*2-acetyl-1,1-dibromo-3-methyl-1a,2,3,7b-tetrahydro-1*H*-cycloprop[c]isoquinaldonitrile (5) with sodium methoxide in methanol at reflux temperature*

A solution of **5** (0.100 g, 0.25 mmol) and sodium methoxide (0.068 g, 1.2 mmol) in dry methanol (5 mL) was heated under reflux for 6 h). The solution was treated as described above to give **9**, 37 mg (39%), **10**, 11 mg (11.4%), and **8**, 8 mg (15%).

*Preparation of 2-acetyl-1,1-dibromo-1a,2,3,7b-tetrahydro-1*H*-cycloprop[c] -isoquinaldonitrile (3)*

A solution of **2** (0.99 g, 0.005 mol) and phenyltribromomethyl mercury (2.64 g, 0.005 mol) in toluene (50 mL) was heated at 80°C for 2.5 h. The precipitated phenylmercuric chloride was removed by filtration and the solvent was removed *in vacuo*. The residue was crystallized from ether–hexane to yield 745 mg (40%) of pure **3**, mp 174–175°C. IR ν_{max}(Nujol): 2260, 1695, 1340, 810, 580; ^{1}H NMR: 7.59–7.27 (m, 4H), 6.19 (s, 1H), 3.90 (d, J = 9.3 Hz, 1H), 3.37 (d, J = 9.3 Hz, 1H), 2.39 (s, 3H); mass spectrum, *m/e*: 368. Anal. calcd. for $C_{13}H_{10}N_2OBr_2$: C 42.19, H 2.72, N 7.57; found: C 43.08, H 2.83, N 7.91.

syn-*2-Acetyl-1,1-dibromo-3-methyl-1a,2,3,7b-tetrahydro-1*H*-cycloprop[c] isoquinaldonitrile (6)*

Compound **3** (1.38 g, 0.004 mol) was dissolved in DMF (40 mL) and the solution was cooled to −30°C. Sodium hydride (0.090 g, 0.004 mol) was added in one portion, and the suspension was stirred for 1 min. Methyl iodide (0.57 g, 0.004 mol) was added and the reaction was allowed to reach room temperature over 2 h. It was then diluted with ether, washed with water and brine, dried over anhydrous magnesium sulfate, filtered, and the solvent was removed *in vacuo* to yield the crude **6**, which was purified by chromatography over silica gel (50% ether in pet. ether). Evaporation of the solvent yielded 630 mg of the oily product **6** (45%), mp 150–151°C. IR ν_{max}: 2255, 1690, 1315, 780, 590; ^{1}H NMR: 7.51–7.39 (m, 4H), 3.77 (d, J = 10.2 Hz, 1H), 3.26 (d, J = 10.2 Hz, 1H), 2.41 (s, 3H), 2.20 (s, 3H); mass spectrum, *m/e*: 382.

Reaction of syn-*2-acetyl-1,1-dibromo-3-methyl-1a,2,3,7b-tetrahydro-1*H*-cycloprop[c] isoquinaldonitrile (6) with sodium methoxide in methanol at reflux temperature*

A solution of **6** (0.192 g, 0.5 mmol) and sodium methoxide (0.135 g, 2.5 mmol) in methanol (5 mL) was heated under reflux for 6 h. The GC/MS spectrum of the reaction indicated the formation of **8**:**9**:**10** in the 7:1:1 ratio.

Preparation of 2-[(1,1,1-trimethyl)acetyl]-1,2-dihydroisoquinaldonitrile

To a mixture of isoquinoline (64.5 g, 0.5 mol) and potassium cyanide (97.5 g, 1.5 mol) in methylene chloride (625 mL) and water (250 mL) was added 1,1,1-trimethyl acetyl chloride (120.6 g, 1.0 mol) at 0°C, over a 1 h period with vigorous stirring. The reaction was stirred at room temperature for 24 h, diluted with methylene chloride, and washed in a sequential order with water, dilute hydrochloric acid, water, dilute sodium hydroxide, water, and brine. The organic layer was separated, dried over anhydrous magnesium sulfate, and the solvent was removed to give a brown residue. This residue was purified by flash chromatography on silica gel using 50% ether in petroleum ether as eluent; 700 mg (1%) of the product was obtained, mp 110–111°C; 17.23 g (27%) of isoquinoline was also isolated. IR ν_{max}: 2215, 1655, 1620, 1170, 770; ^{1}H NMR: 7.37–7.27 (m, 3H), 7.20 (d, J = 6.2 Hz, 1H), 7.06 (d, J = 7.8 Hz, 1H), 6.59 (s, 1H), 6.09 (d, J = 7.8 Hz, 1H), 1.25 (s, 9H); mass spectrum, *m/e*: 240. Anal. calcd. for $C_{15}H_{16}N_2O$: C 74.97, H 6.71, N 11.66; found: C 75.45, H 6.75, N 11.81.

2-[(1,1,1-Trimethyl)acetyl]-1-methyl-1,2-dihydroisoquinaldonitrile

To a solution of 2-[(1,1,1-trimethyl)acetyl]-1,2-dihydroisoquinaldonitrile (0.7 g, 3.0 mmol) and methyl iodide (0.47 g, 3.3 mmol) in dimethylformamide (6 mL) was added sodium hydride (60% oil, 0.13 g, 3.3 mmol), and the product was isolated according to the procedure for the preparation of **4**. The product yield was 615 mg (81%), mp 109–109.5°C. IR ν_{max}: 1745, 1675, 1500, 780; ^{1}H NMR: 7.69–7.64 (m, 1H), 7.30–7.27 (m, 2H), 7.07–7.03 (m, 1H), 6.81 (d, J = 8.1 Hz, 1H), 5.77 (d, J = 8.1 Hz, 1H) 1.84 (s, 3H), 1.39 (s, 9H); mass spectrum, *m/e*: 254. Anal. calcd. for $C_{16}H_{18}N_2O$: C 75.56, H 7.13, N 11.01; found: C 75.55, H 7.11, N 10.63.

anti-*2-[(1,1,1-trimethyl)acetyl]-1,1-dibromo-3-methyl-1a,2,3,7b-tetrahydro-1*H*-cycloprop[c]isoquinaldonitrile (7)*

A mixture of the methyl-quinaldonitrile prepared in the previous experiment (0.51 g, 2.0 mmol) and benzyl triethylammonium chloride (0.25 g, 1.1 mmol) in bromoform (4.0 mL) was treated with 40% sodium hydroxide solution (4.0 mL) at room temperature for 24 h and the product was isolated as described for the preparation of **5**. The product was crystallized from ether, affording 105 mg (12.4%), mp 177–178°C. IR ν_{max}: 3100, 2243, 1662, 766; ^{1}H NMR: 7.7 (d, J = 6.7 Hz, 1H), 7.46–7.39 (m, 3H), 4.03 (d, J = 10.2 Hz, 1H), 3.27 (d, J = 10.2 Hz, 1H), 1.82 (s, 3H) 1.51 (s, 9H); mass spectrum, *m/e*: 424. Anal. calcd. for $C_{17}H_{18}N_2OBr_2$: C 47.91, H 4.26, N 6.57; found: C 48.50, H 4.39, N 6.67.

Reaction of anti-*2-[(1,1,1-trimethyl)acetyl]-1,1-dibromo-3-methyl-1a,2,3,7b-tetrahydro-1*H*-cycloprop[c]isoquinaldonitrile with sodium methoxide in methanol at reflux temperature*

To a solution of **7** (25 mg, 0.06 mmol) in methanol (3 mL) was added sodium methoxide (16 mg, 0.3 mmol) and the reaction was stirred at ambient temperature for 73 h. GC/MS and TLC monitoring indicated the presence of only starting material. The solution was then heated under reflux and after 4 h the GC/MS assay indicated the presence of **9** and **10** (R = *t*-butyl) and of the acetal **8** in a 7.5:5.8:1 ratio. The solvent was removed *in vacuo* and the products were separated on a 60F-254 silica gel analytical plate using 2% acetone in toluene as eluent to give **9**, 3.6 mg (16%), and **10**, 3.4 mg (15%). Spectral data: **9**: IR ν_{max}: 1663; ^{1}H NMR: 8.10 (d, J = 7.6 Hz, 1H), 7.81 (d, J = 7.6 Hz, 1H), 7.55 (d, J = 7.6 Hz, 1H), 7.49 (d, J = 7.6 Hz, 1H), 6.69 (s, 1H), 5.64 (s, 1H), 3.04 (s, 3H), 2.12 (s, 3H), 1.40 (9H, s, 9H); mass spectrum, *m/e*: 376; **10**: IR ν_{max}: 2237, 1663, 1066; ^{1}H NMR: 8.22 (d, J = 7.6 Hz, 1H), 7.67 (d, J = 7.6 Hz, 1H), 7.52 (d, J = 7.8 Hz, 1H), 7.46 (d, J = 7.8 Hz, 1H), 6.67 (s, 1H), 5.74 (s, 1H), 3.04 (s, 3H), 2.11 (s, 3H), 1.25 (s, 9H); mass spectrum, *m/e*: 376.

The ^{1}H nuclear magnetic resonance spectra of 2-cyanobenzaldehyde (2CNB) and 3-cyanobenzaldehyde (3CNB) in CS_2/C_6D_{12} and acetone-d_6 solutions at 300 K yield precise stereospecific long-range proton–proton coupling constants. These are used to establish the conformational population of the *o-cis* and *o-trans* conformers of these relatively polar molecules. For example, the fractional *o-cis* population of 2CNB changes from 0.12(4) in CS_2/C_6D_{12} to 0.46(6) in acetone-d_6, whereas that of 3CNB is 0.48(2) in both solvents. Extrapolation to the vapor phase, using a dielectric model, implies a negligible concentration of the *o-cis* conformer of 2CNB and a roughly 50% abundance of each conformer of 3CNB. Computations at various levels of molecular orbital theory provide estimates of the rotational barrier of the aldehyde moiety and confirm the planar structure of each conformer. The geometries of three conformers are given as obtained from the 6-31G MO basis and may be useful to molecular spectroscopists. Theoretical and experimental dipole moments are interpolated to yield estimates of their magnitudes for the four planar conformers. Somewhat less precise ^{1}H nmr spectral parameters (than for the above solutions) are also obtained for dilute solutions in benzene-d_6 at 300 K. The conformational distributions based on these parameters are compared with their only other measurement, based on dipolar moments in benzene at 298 K. Good agreement between the results of the two methods is found for 3CNB but not for 2CNB. It is suggested that specific interactions occur between benzene solvent and solute molecules, particularly for 3CNB, for which these interactions stabilize the conformer having a low dipole moment. Remarkable changes in the intraring proton–proton coupling constants occur in going from CS_2/C_6D_{12} to acetone-d_6 solution.

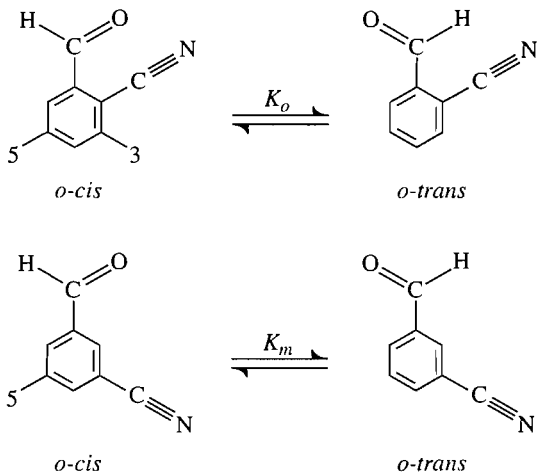
Les spectres de résonance magnétique nucléaire du ^{1}H du 2-cyanobenzaldéhyde (2CNB) et du 3-cyanobenzaldéhyde (3CNB), mesurées à 300 K, dans des solutions dans le CS_2/C_6D_{12} et dans l'acétone-d_6, fournissent des constantes de couplage proton–proton à longue distance très précise. On les a utilisées pour déterminer les populations conformationnelles des conformères *o-cis* et *o-trans* de ces molécules relativement polaires. Par exemple, la fraction de la population *o-cis* du 2CNB varie de 0,12(4) dans le CS_2/C_6D_{12} à 0,46(6) dans l'acétone-d_4; par ailleurs, celle du 3CNB est égale à 0,48(2) dans les deux solvants. Une extrapolation jusqu'à la phase vapeur, utilisant un modèle diélectrique, suggère que la concentration du conformère *o-cis* du 2CNB est alors négligeable, mais que celle du 3CNB est approximativement égale à 50%. Des calculs à divers niveaux de la théorie des orbitales moléculaires fournissent des évaluations de la barrière à la rotation de la portion aldéhydique et confirment la structure planaire de chaque conformère. Les géométries de trois conformères ont été évaluées sur la base d'OM 6-31G; elles pourraient être utiles aux spectroscopistes moléculaires. On a interpolé les moments dipolaires théoriques et expérimentaux pour obtenir des évaluations de leurs amplitudes pour les quatre conformères. On a aussi déterminé des paramètre spectraux (moins précis que ceux obtenus plus haut) de la rmn du ^{1}H, à 300 K, pour des solutions diluées dans le benzène-d_6. On compare les distributions conformationnelles déterminées à l'aide de ces paramètres avec celles obtenues à l'aide de leur seule autre mesure basée sur les moments dipolaires dans le benzène, à 298 K. Pour le 3CNB, on a observé un bon accord entre les résultats de ces deux méthodes; ce n'est toutefois pas le cas avec le 2CNB. On suggère que des interactions spécifiques se produisent entre les molécules du solvant (benzène) et du soluté, particulièrement avec le 3CNB, pour lequel ces interactions stabiliseraient le conformère de faible moment dipolaire. Il se produit des changements remarquables dans les constantes de couplage proton–proton intracycliques lorsqu'on passe des solutions dans le CS_2/C_6D_{12} à celles dans l'acétone-d_6.



Mots clés : 2- et 3-cyanobenzaldéhyde (2CNB et 3CNB) : RMN ^{1}H, conformations, constantes de couplage proton–proton à longue distance, calculs d'OM.

[Traduit par la rédaction]

Introduction

The spin–spin coupling constant between the aldehydic and *meta* protons in benzaldehyde and its derivatives is stereospecific (1), is apparently a pure σ electron mediated interaction for effectively planar molecules (2), and, when measured with precision, is perhaps the most sensitive indicator available for the *cis–trans* equilibria for *ortho* and *meta* substituted benzaldehydes in solution (3). The detailed discussion of ^5J(H-*m*, CHO) in 2- and 3-fluorobenzaldehyde (3) may be consulted for a comparison with other techniques for this purpose.

In the present report, this coupling constant is used to find the conformational equilibria for 2-cyanobenzaldehyde (2CNB) and 3-cyanobenzaldehyde (3CNB) as solutions in a nonpolar CS_2/C_6D_{12} solvent mixture as well as in the polar solvent,

acetone-d_6. Rough estimates are made for these equilibria in the vapor phase on the basis of a dielectric model and of some molecular orbital calculations. It turns out that the equilibrium for 2CNB is remarkably solvent dependent, compared to other *ortho* substituted benzaldehydes; that for 3CNB is much less dependent on solvent. The only previous work on these equilibria appears to be a study of the dipole moments in benzene solution (4); this solvent is chosen because of the low solubility of these compounds in CCl_4. It is concluded that 2CNB exists predominantly, perhaps exclusively, in the *o-trans* form whereas the *o-cis* conformer of 3CNB is present to the extent of 35 ± 2% at 298 K (4).

Experimental

2CNB from TCI and 3CNB from Aldrich were dissolved as dilute solutions (see Table 1 for details) in CS_2/C_6D_{12}/TMS and acetone-d_6/TMS solvent mixtures. These solutions were filtered into 5 mm o.d. nmr sample tubes, which were degassed by five freeze–pump–thaw cycles and were flame-sealed at the pump stage of the last cycle. The ^{1}H nmr spectra were acquired on a Bruker AM 300 spectrometer at a probe temperature of 300 K and in a manner previously described in detail (5). The digital resolution was at least 0.006 Hz/pt, acquisition times for the 32 or more free induction decays were 41–60 s. Line and Gaussian broadening parameters, typically −0.1 and 0.6, respectively, were applied to the decays before Fourier transformation. Care was taken to establish a persistently homogeneous external magnetic field; manual shimming on the TMS signal was necessary for this purpose. Some ^{1}H nmr spectra of 2CNB and 3CNB were also obtained for solutions in benzene-d_6.

Molecular orbital calculations were performed with the computer program Gaussian 86 (6), details of which can be found at appropriate places in the discussion to follow. The computations employed an Amdahl 5870 system.

Results and discussion

Spectral analyses

The ^{1}H nmr spectra of 2CNB and 3CNB were analyzed with the computer program NUMARIT (7), extensively modified by R. Sebastian in this laboratory. Table 1 contains the chemical shifts and proton–proton coupling constants obtained from the analyses. Figure 1 displays the aldehydic proton spectrum of 2CNB in acetone-d_6 solution, together with some theoretical simulations described in the figure caption.

The conformational equilibria of 2CNB and 3CNB in CS_2/C_6D_{12} and acetone-d_6 solutions

As stated above, ^5J(H, CHO) ≡ ^5J is stereospecific. In benzaldehyde, ^5J is 0.431(2) and 0.430(1) Hz in CS_2/C_6D_{12} and acetone-d_6, respectively (2). As discussed in detail previously (3), all the available evidence implies that ^5J vanishes for a conformation such as *o-cis* in 3CNB and that it has its maximum value for the *o-trans* orientation. The barrier to rotation about

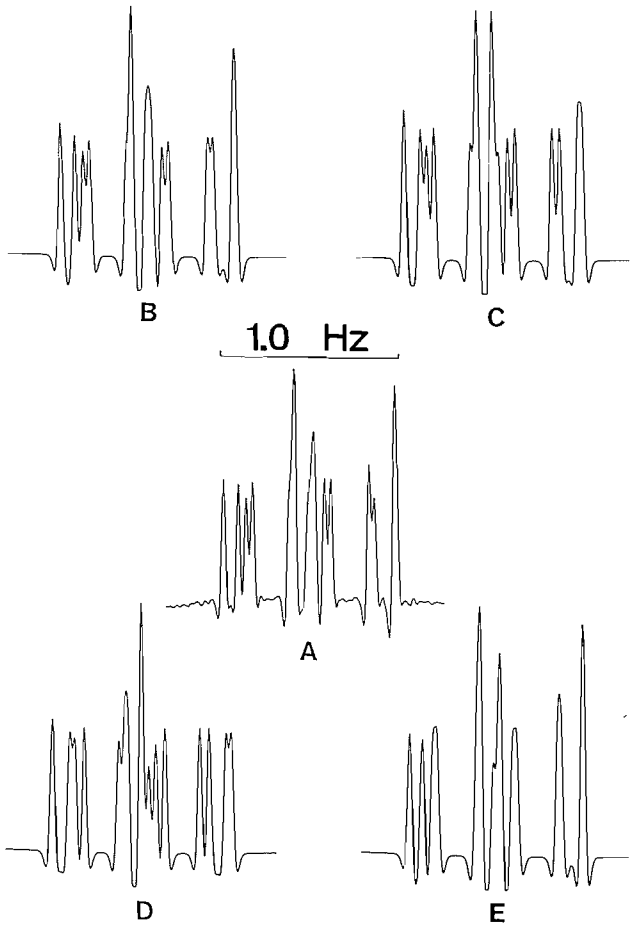

FIG. 1. In A the aldehydic ^{1}H nmr spectrum of a 4 mol% solution of 2CNB in acetone-d_6 is displayed. The width at half-height of single peaks, after some resolution enhancement, is near 0.03 Hz. In B the computed spectrum employs the chemical shifts and coupling constants in Table 1; in particular, ^6J(H-4,CHO) is −0.009 Hz. The agreement between the calculated and measured spectra is not exact, but is rather better than for the theoretical spectrum in C, which assumes ^6J(H-4,CHO) as 0.000 Hz, or for that in D, which is based on +0.010 Hz for this coupling constant. In E the simulated spectrum has ^6J(H-4,CHO) as −0.020 Hz.

the exocyclic Csp^2—Csp^2 bond for benzaldehyde is about 30 kJ/mol, so that a discussion in terms of planar conformations is a good approximation at ambient temperatures. Accordingly, for benzaldehyde one may write $^5J_3 \equiv {}^5J$(H-3, CHO) = 0.861(3) Hz for a conformer analogous to *o-cis* in 3CNB, and that $^5J_5 \equiv {}^5J$(H-5,CHO) vanishes.

In 3CNB, ^5J is essentially the same, or 0.452(3) Hz, in both solvents of Table 1. If the maximum in ^5J is independent of the cyano substituent then the fractional population of the *o-trans* form follows as 0.452(3)/0.861(3) or 0.52(1); K_m is therefore 1.08(4) at 300 K and the free energy difference favoring the *o-trans* form is 0.2(1) kJ/mol. That a ring substituent, not directly bonded to a carbon atom in the coupling pathway, does not significantly perturb ^5J is suggested, for example, by the effective identity of ^5J in benzaldehyde (2) and its 4-fluoro derivative (unpublished work in this laboratory). Even if the ring substituent is placed adjacent to the coupling path, it appears at first that large perturbations of ^5J do not occur.

Thus, for 2CNB in acetone-d_6 solution, the sum of the ^5J values is 0.858(2) Hz, compared to 0.860(2) for benzaldehyde (2). K_m follows as 1.27(3) and, at 300 K, the free energy of the *o-trans* is 0.60(5) kJ/mol lower than that of the *o-cis* conformer. In CS_2 solution, however, the two ^5J values sum to 0.894(2) Hz, substantially higher than the 0.862(2) Hz for benzaldehyde (2). If the extrema in $^5J_3$ and $^5J_5$ are both taken as 0.894(2) Hz, then K_o follows as 8.2(2), the fractional population of the *cis* conformer being 0.11 and the free energy difference between the conformers, 5.2(1) kJ/mol at 300 K. The, in our experience, rather large deviation of the sum of the ^5J values from its value in benzaldehyde is somewhat unsettling. An attempt at an assessment of the indicated intrinsic substituent effect on ^5J goes as follows. Define $^5J_{3,c}$ and $^5J_{5,t}$ as the ^5J numbers in the *o-cis* and *o-trans* forms of 2CNB; the other two, antizigzag, ^5J values vanish. Hence, for the two solutions, there exist four equations in four unknowns. These are the fractional populations of, say, the *trans* forms and $^5J_{3,c}$ and $^5J_{5,t}$, assumed to be independent of solvent. $^5J_{5,t}$ and $^5J_{3,c}$ follow as 0.907 Hz and 0.803 Hz, respectively, and the fractional population of the *trans* form as 0.88 in the CS_2/C_6D_{12} mixture and as 0.53 in the acetone-d_6 solution. Hence K_o is 7.2 in the former and 1.13 in the latter solution, corresponding to free energy advantages of 4.9 and 0.3 kJ/mol, respectively. Comparison of these magnitudes with those derived above suggests an uncertainty of 0.3 kJ/mol in the derived energy differences. In the light of a referee's remarks, the discussion in the following sections doubles this uncertainty and takes the free energy differences as $0.4_5 \pm 0.6$ and $5.0_5 \pm 0.6$ kJ/mol in the polar and nonpolar media, respectively.

It is interesting that $^5J_{5,t}$ is implied as larger than in benzaldehyde by about 0.05 Hz or 6%. True, in the *o-trans* conformer of 2CNB the very polar cyano group (the dipole moment of cyanobenzene is 4.0 D(8) compared, for example, to 1.4 D for fluorobenzene) lies parallel to the C—H bond of the aldehydic moiety and its dipolar field will act to polarize it in the sense C^-—H^+. This polarization is demonstrated by the chemical shift of the aldehydic proton (Table 1) in CS_2 solution and will be discussed below. An indication of the change in ^5J caused by such a perturbation of the charge distribution was sought from CNDO/2 and INDO MO FPT (9, 10) computations, done for the optimized STO 3G geometries. Indeed, $^5J_{5,t}$ was calculated as 0.926 Hz and $^5H_{3,c}$ as 0.842 Hz, with the CNDO/2 parametrization, in qualitative support of the treatment above. ^5J_t in benzaldehyde is calculated as 0.90 Hz and ^5J_c as 0.02 Hz. The two conformers are highly polar, the dipole moments being estimated in a later section as 6.2 and 4.5 D for the *o-cis* and *o-trans*, respectively. Hence a significant perturbation of the charge distribution in the aldehydic moiety by internal fields is perhaps feasible, leading to the implied perturbations in the extrema of ^5J. Of course, the apparent agreement between the above model and the computations may be coincidental. In any event, the uncertainty introduced into the populational distribution by such perturbations is reasonably small in solution. Extrapolation to the vapor will tend to amplify this uncertainty. Fortunately, as seen next, the bias in favor of the *o-trans* conformer of 2CNB in the vapor at ambient temperatures is very large indeed.

The conformer distribution in the vapor by extrapolation

(i) 2-Cyanobenzaldehyde

To a first approximation in the reaction field model of medium effects on conformational equilibria (11), the more polar conformer is stabilized relative to the less polar conformer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

in a medium of dielectric constant, ϵ, greater than unity; the stabilization energy is proportional to $(\epsilon - 1)/(2\epsilon + 1) \equiv x$. The dipole moment of the *o-cis* conformer of 2CNB is clearly higher than that of the other conformer, so that the increased population of the former in the more polar solvent, acetone-d_6, is expected. A quantitative calculation of the stabilization energies requires the dipole moments of the conformers, which must be estimated or computed. Furthermore, in second order the electric quadrupole moment of each conformer must be known in order to find the quadrupolar contributions to the energy of interaction with the dielectric medium; these contributions are also proportional to x. Additional interactions are also considered on occasion (11). The model has been rather successful in accounting for the relative conformer energies of polar cyclic and acyclic polar alkane derivatives in various solvents (11). With polar aromatic systems, our own experience (12) is that quantitative reproduction of relative conformer energies in solution is difficult, perhaps because of errors in the estimation of dipole and quadrupole moments; the squares of these quantities enter into the computations of stabilization energies.

However, empirically it is found (11) that the change in the energy difference between conformers on going from acetone to CS_2 as a solvent is close to that in going from CS_2 solution to the vapor (see eq. 13.18 and p. 562 of ref. 11 for a rationalization of this finding). Because the reaction field model yields free energy differences between conformers (13, 14) and because these are $0.4_5 \pm 0.6$ and $5.0_5 \pm 0.6$ kJ/mol for 2CNB in CS_2 and acetone-d_6 solutions, respectively, this procedure implies a free energy difference of $9.6_5 \pm 1.2$ kJ/mol in the vapor at 300 K, *o-trans* favored. Alternatively, if x is taken as 0.25 for the CS_2/C_6D_{12} solvent mixture and as 0.46 for the acetone solution, an extrapolation of an assumed linear relationship between the free energy difference and x (eq. 13.18 of ref. 11, examined in detail) yields the free energy difference as 10.9 ± 1.2 kJ/mol at 300 K. It appears that a reasonable, semiempirical, estimate is 10.3 ± 2.4 kJ/mol at 300 K. It follows that the fractional population of the *o-trans* conformer of 2CNB in the vapor at 300 K is 0.98(2). Accordingly, measurements on the vapor at ambient temperatures are predicted to involve the *o-trans* form almost exclusively.

(ii) 3-Cyanobenzaldehyde

This molecule presents an example of a molecule whose conformational distribution is independent of polarity of the two solvents, even though the dipole moments of the two conformers differ substantially (see below). If the constituent dipoles are sufficiently far apart (p. 507 of ref. 11), then the reaction field model becomes inappropriate and, at least for 3CNB, the orientation of the local aldehyde dipole, relative to that of a local dipole centered at the cyano group, is effectively unaltered by the surrounding medium (an accidental cancellation of dipolar and quadrupolar stabilization energies such as to leave the conformational distribution unaltered in the two solvents cannot be ruled out, however). The free energy difference between the two conformers is 0.2(2) kJ/mol at 300 K, where the apparent error has again been doubled. Accordingly, in the vapor the *o-trans* form will be probably slightly the more abundant and measurements at ambient temperatures will involve both conformers. It is of interest how molecular orbital computations for the free molecules compare with experiment and such computations are discussed below.

Conformational populations in benzene-d_6 solution

It is known (11) that, in the reaction field model of solvent perturbations of conformational energies, benzene often behaves *as if* it had a much higher dielectric constant than its static value of 2.3. Perusal of the available data (11) suggests that the effective dielectric constant varies from solute to solute and that it can be as low as 4.3 or even as high as 35, with 7.5 being a more common value. Specific interactions with the polar solute molecules are indicated by these observations. Because the dipole moments of 2CNB and 3CNB were measured in benzene solution (4), it is of interest to have an independent measure of their conformational behaviour in this solvent.

Although very nearly first order in appearance, the ^{1}H nmr spectra of 2CNB and 3CNB were not of the quality normally attainable (see, for example, Fig. 1) and their analysis gave data of rather lower precision than those reported for other solvents in Table 1. Hence the spectral parameters are not tabulated here.

However, for a <1.3 mol% solution of 2CNB in benzene-d_6, ^5J(H-3,CHO) is 0.210 ± 0.007 Hz and ^5J(H-5,CHO) is 0.654 ± 0.004 Hz. Their sum is 0.864 ± 0.011 Hz, the same as for 2CNB in acetone-d_6 solution, to within experimental error, or for benzaldehyde in acetone-d_6 solution (3). As before, the population of the *o-trans* conformer follows as 0.74(4) at 300 K, and the free energy difference between the conformers as 2.6 ± 0.6 kJ/mol. In terms of the reaction field model, the benzene-d_6 solvent behaves as if its dielectric constant were about 5 in this instance. The populational distribution is intermediate to those established for CS_2/C_6D_{12} and acetone-d_6 solutions and rather different from that estimated from the dipole moment (see below).

For a 4.0 mol% solution of 3CNB in benzene-d_6, ^5J(H-5, CHO) is 0.542 ± 0.002 Hz. It follows that the fractional population of the *o-trans* form has increased to 0.63(2) from the 0.52(2) measured for both of the other solvents. In any event, the free energy difference of 1.3 ± 0.2 kJ/mol between the conformers at 300 K agrees rather well with that of 1.5 ± 0.2 kJ/mol obtained from the dipole moment measurement (4), to be discussed further below.

Molecular orbital computations of conformational energies, dipole moments, and internal rotational barriers

It is known (15) that *ab initio* molecular orbital computations with a minimal basis set reproduce the internal rotational potential in benzaldehyde much more faithfully than those with split valence bases such as 6-31G and 6-31G*. Accordingly, the internal rotational potentials in 2CNB and 3CNB were computed with the basis STO-3G (16). Experience teaches that geometries of the planar conformers, however, are more reliably obtained from the 6-31G basis (17, 18). Such geometries are probably of interest in future investigations by molecular spectroscopy and hence were calculated here. Again, computed dipole moments vary from method to method and basis to basis (19). Some semiempirical orbital approaches yield dipole moments of benzene derivatives in rather good agreement with experiment (2, 20). Therefore, dipole moments were also computed by CNDO/2, INDO, and AM1 MO methods. As a matter of curiosity, the AM1 (21) method was also used to compute the internal rotational potential in 3CNB.

(i) Internal barrier and relative energies

Table 2 contains the results of the computations of the internal rotational potentials. The STO-3G energies of 2CNB are fit, to within a standard deviation of 0.03 kJ/mol, by eq. [1]:

$$[1]\quad V(\theta)/\text{kJ mol}^{-1} = 4.31 \sin^2(\theta/2) + 20.37 \sin^2\theta - 0.08 \sin^2(3\theta/2) - 0.80 \sin^2 2\theta - 0.15 \sin^2 3\theta - 0.02 \sin^2 4\theta$$

except that the energy at $\theta = 15°$ is overestimated by

TABLE 2. STO-3G and AM1 MO energies of 2-cyanobenzaldehyde and 3-cyanobenzaldehyde

[a]θ = 0 corresponds to the *o-trans* conformer.
[b]The total energy is −429.671 389 au.
[c]Geometry optimization allowed all bond angles and lengths to vary, with the constraint, however, that the carbon and hydrogen atoms of the benzene moiety remained in a plane.
[d]The total energy is −429.672 768 au.
[e]Equations [1] and [2] of the text reproduce these energies by Fourier series.

0.26 kJ/mol by this expression. The *o-trans* conformer corresponds to θ = 0°. The height of the barrier at θ = 90°, relative to θ = 0° (the *o-trans* barrier), is computed as 2.0 kJ/mol lower than in benzaldehyde (15). The only internal barriers known for 2-X-benzaldehydes are those measured for X = alkyl, by dynamic nmr (22, 23). For X = CH_3, the barrier is 3.6 kJ/mol (22) lower than for benzaldehyde in the same solvent system. The lower barrier is attributed to steric destabilization of the planar conformers. In 2CNB, the *o-cis* barrier is computed as 6.1 kJ/mol lower than in benzaldehyde, presumably due to destabilization of the *o-cis* conformer by dipole–dipole repulsion of the two dipoles and by a decrease of the Csp^2—Csp^2 mobile bond order caused by the cyano group that competes with the carbonyl group for π electrons. This competition could also account for the barrier decrease computed for the *o-trans* conformer. Measurement of the internal barrier in 2CNB by dynamic nmr would require the use of a rather polar solvent because otherwise very little of the *o-cis* conformer would exist at the requisite low temperatures (see the previous section). This measurement would be of interest because 2CNB is the only 2-X-benzaldehyde with a polar X for which a large population of the *o-cis* conformer exists, even in a polar solvent. Thus, a solution of 2-fluorobenzaldehyde in acetone-d_6 contains the *o-cis* conformer only to the extent of 15% (3).

The relative STO-3G MO energies of 3CNB in Table 2 are fit by eq. [2] with a standard deviation

$$[2]\quad V(\theta)/\text{kJ mol}^{-1} = 0.5\sin^2(\theta/2) + 23.8\sin^2\theta - 0.1\sin^2(3\theta/2) - 0.4\sin^2 2\theta$$

of 0.1 kJ/mol. The barrier at 90° for the more stable *o-trans* form, defined by θ = 0°, is essentially that computed for benzaldehyde (15), as is the fourfold component, in $\sin^2 2\theta$. In this instance, the *meta* substituent has a minor influence on the predominantly conjugative barrier to rotation of the carbonyl group, a result expected on the basis of simple resonance structures.

The internal barrier computed for 3CNB by AM1, at about 11.3 kJ/mol in Table 2, is much too low, as are the dipole moments of the planar conformers (see below).

However, the AM1 value of 0.76 kJ/mol favoring the *o-trans* over the *o-cis* conformer is in qualitative agreement with the other molecular orbital and experimental results in Table 3. The ^{5}J values in CS_2 and acetone solutions imply a slightly greater abundance of the *o-trans* conformer, in best agreement with the INDO MO calculations but also close to the predictions from the STO 3G MO computations (see the last column in Table 3). 3CNB therefore behaves qualitatively differently from 3-F-benzaldehyde, in which the *o-cis* conformer predominates both at 300 K (3) and 123 K (23); at the latter temperature it is also true for X = Cl, Br, CH_3 (23), but not at 300 K according to unpublished work in this laboratory. The explanation (23) advanced for this preference is that the inductive effect of the substituent causes polarization of the C^-—H^+ bond at position 2 in the indicated sense, thereby stabilizing the *o-cis* form by electrostatic interaction with the C^+=O^- bond.

The computed energy differences between the conformers of free 2CNB range from 0.3 kJ/mol to 14.7 kJ/mol in Table 3. The extrapolated value of 10.3 ± 2.4 kJ/mol, based on solution data, lies roughly midway between the STO-3G and 6-31G results. The latter basis suggests very small amounts of the *o-cis* conformer in the vapor phase at 300 K, in best agreement with the extrapolated population of 2 ± 2%.

For 3CNB all the theoretical computations have the *o-trans* form as most abundant, the range of p_t at 300 K being 0.53–0.61. The 6-31G basis now has the largest deviation from the extrapolated value of 0.52(2).

(ii) Dipole moments

Table 3 presents theoretical dipole moments of the planar conformers of 2CNB and 3CNB; estimates based on group moments (4) are also reproduced there. A lack of solubility in CCl_4 dictated the measurement of the dipole moments in benzene solution at 298 K(4). The authors (4) are aware of the peculiarity of benzene as a dielectric medium. In Table 3, the value of 0.92 for the fractional population, p_t, of the *o-trans* conformer of 2CNB in benzene is calculated from the measured dipole moment and the group moments. It should be noted that the authors (4) realize the uncertainty of their predicted dipole moments, arising from the proximity of the polar substituents, and conclude only that the *o-trans* form is strongly favoured.

Consider now the conformer populations of 2CNB in benzene-d_6 as deduced from ^5J(H,CHO). These populations, together with the dipole moments of the conformers estimated from group moments, imply a dipole moment of 5.3 D for 2CNB in benzene solution; the measured value is 4.9 D (4). Therefore at least one of the estimated dipole moments of the individual conformers is presumably too large.

Again, the dipole moments of the conformers, as given by the STO-3G basis, imply a dipole moment of 4.0 D in benzene solution. Therefore, at least one of the theoretical dipole moments must be underestimated. The minimal basis set underestimates (24) the dipole moments of benzaldehyde and cyanobenzene by 1.08 and about 0.5 D, respectively, so that this conclusion is expected. If, arbitrarily, the STO-3G values are increased by 1.0 D, then, together with the populations given by ^5J(H,CHO), the dipole moment of 2CNB in benzene at 300 K is calculated as 4.95(4) D, precisely as measured. According to a previous section, only the *o-trans* conformer is likely to occur in the vapor at ambient temperatures; it is tempting to predict that a dipole moment of 6.2 D will be observed.

6-31 G	6.36	1.93	(4.2)[f]	1.12	0.61
CNDO/2	4.42	1.08	(2.8)[f]	0.35	0.54
INDO	4.41	1.15	(2.8)[f]	0.29	0.53

[a]Dipole moment, μ, in Debye, measured in benzene at 298 K (4); the dipole moments of the two conformers are estimated from group dipoles (4).

[b]The free energy difference in kJ/mol at 298 K, calculated from the fractional population, p_t, of the *o-trans* conformer; p_t follows from the measured dipole moment of 4.94 D and the estimated conformer moments.

[c]The free energy difference between the *o-cis* and *o-trans* conformers at 300 K, as deduced from ^5J(H,CHO) by methods described in the text.

[d]The free energy difference in the vapor at 300 K, obtained by extrapolation of solution data on the basis of a dielectric model discussed in the text.

[e]The energy differences between conformers, obtained from the molecular orbital computations, are assumed to be free energy differences in the calculation of p_t at 300 K.

[f]The dipole moments in parentheses are those calculated for a benzene solution in which the computed dipole moments in the same row are used and the conformer populations are those implied by ^5J(H,CHO). Of course, the predicted dipole moment follows from $\mu^2 = p_t\mu_t^2 + (1 - p_t)\mu_c^2$.

[g]Calculated with the dipole moments of the conformers as estimated from the group moments in the row above and from the value of p_t obtained from ^5J(H,CHO).

Turning to 3CNB, the good agreement between the population distributions in benzene, based on ^5J(H,CHO) and group dipole moments, suggests the reliability of the latter. Again, the theoretical dipole moments of the conformers are in general too low, especially those from the AM1 computations.

The 6.31 G structures

Figures 2 and 3 reproduce the 6-31G geometries of the *o-trans* conformer of 2CNB and of the two conformers of 2CNB. These are the three conformers predicted to occur in the vapor near ambient temperatures. The structures may well be useful to molecular spectroscopists. See the figure captions for structural comments.

The other spectral parameters

(i) The ^1H nmr chemical shifts

Ordinarily, the protons of polar benzene derivatives are deshielded in passing from nonpolar to polar environments, a result mainly due to the reaction field induced in the solvent (27). In Table 1, the chemical shifts of all the protons in 3CNB, including that in the side chain, are an example of this phenomenon; the aldehydic proton is deshielded by 0.24 ppm in the acetone-d_6 relative to the CS_2/C_6D_{12} solution. In 2CNB, however, the shielding of the aldehydic proton is reversed and is 0.05 ppm higher in the acetone-d_6 solution. Almost certainly, it is the local electric field of the cyano group (28) which is responsible, the population of the *o-trans* conformer being so much larger in the nonpolar solvent; this deshielding must outweigh the anticipated shielding caused by the magnetic anisotropy of the C≡N grouping (29).

In benzene-d_6 solution, the protons are all screened relative to the CS_2 solution, as expected on the basis of the diamagnetic anisotropy of the benzene molecule (30, 31). The average of this screening is 0.86 ppm for the ring protons of 2CNB and is 0.62 ppm for those of 3CNB. The ratio of 1:4 for these numbers is the same as the ratio of the dipole moments of these compounds in benzene (Table 3). This result is qualitatively consistent with the dipole induced-dipole model for the aromatic solvent induced shift or ASIS (32, 33). However, the ASIS for the individual ring protons does not provide evidence for preferred association of the benzene molecule with the most polar site of the solute molecules (the largest ASIS occurs for H-4 in 2CNB and H-5 in 3CNB) and hence their values are not quoted here or discussed further. A dipole induced-dipole model would presumably predict stabilization of the more polar conformer by benzene; this occurs for 2CNB, but the opposite is true for 3CNB.

(ii) The intraring $^nJ(H,H)$

It is a general result in this laboratory that ^nJ(H,H) in benzene

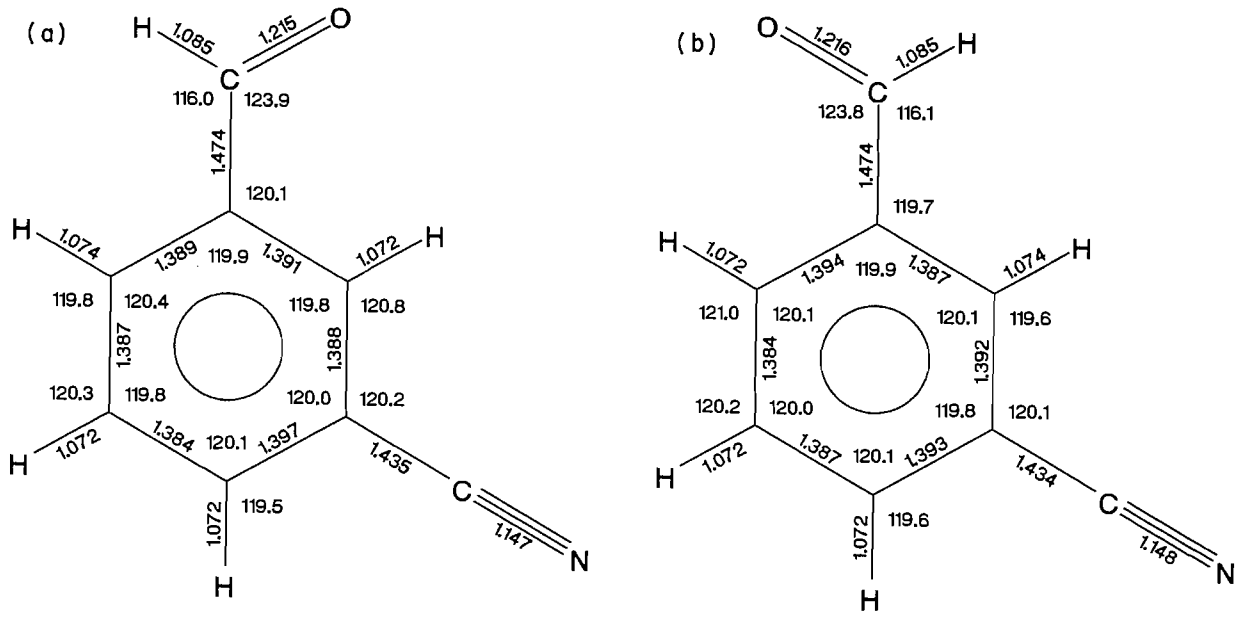

FIG. 2. The 6-31G structures of the (a) *o-cis* and (b) *o-trans* planar conformers of 3-cyanobenzaldehyde are displayed. Comparison with the 6-31G structures of the parent compounds (25) shows that the present internal ring angles are derivable additively from the parent compounds. The presence of the aldehyde group does not significantly alter the geometry at the cyano site (the converse is not true). At this level of theory, the experimental structure of cyanobenzene (26) is therefore to be used for the local site geometry. The total energies are −434.983 722 au for the *o-trans* and −434.983 295 au for the *o-cis* conformer.

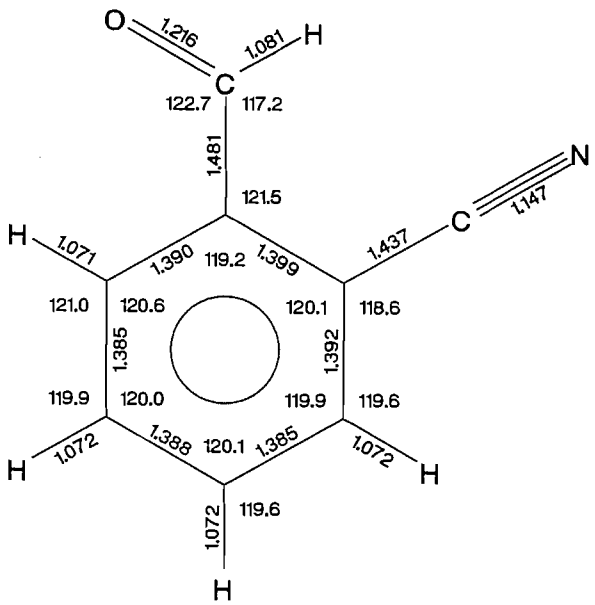

FIG. 3. The planar geometry of the *o-trans* conformer of 2-cyanobenzaldehyde, as given by the 6-31G basis, is shown and is predicted to be the conformer observable at ambient and lower temperatures. Its total energy is −434.980 755 au. The internal bond angles are no longer given by an additivity scheme (see Fig. 2). The local geometry at the substitution sites indicates repulsive forces between the substituents (compare the geometry with that in Fig. 2(b)).

derivatives are larger in acetone-d_6 than in CS_2/C_6D_{12} solutions. For nonpolar solutes such as isopropylbenzene, for example (34), the differences amount to 0.02 Hz or less, increasing to as much as 0.03 Hz for some ^nJ(H,H) in a polar solute such as benzaldehyde (2) or even 0.06 Hz for $^3J_{45}$ in 3-fluorobenzaldehyde (3). The striking result in Table 1 is that ^nJ(H,H) can differ by as much as 0.35 Hz in the two solvents. Furthermore, a given ^nJ(H,H) in 2CNB or 3CNB may be larger or smaller in acetone-d_6 than in CS_2/C_6D_{12}. The solvent dependence of ^nJ(H,H) in cyanobenzene is unknown. It is noted that $^4J_{24}$ in 3CNB, that is, the coupling constant across the site of substitution by the cyano group, as well as $^5J_{25}$, undergo the largest relative change; the former decreases by 0.35 Hz in the polar solvent and the latter increases by 0.20 Hz, or almost 50% of its value in CS_2/C_6D_{12}. This unprecedented and unexpected (35) behaviour is possibly related to a solvent dependent polarization of the aromatic π orbitals by the polar cyano group.[2] Thus, ^5J(H,H) is dominated by a $\sigma-\pi$ electron coupling mechanism (37) and displays the largest proportional change. The conformational behaviour of 3CNB is independent of the two solvents in Table 1, so that, unlike 2CNB, the variation in ^nJ(H,H) is not due to orientational changes in the carbonyl dipole.

(iii) ^{4}J*(H,CHO) and* ^{6}J*(H,CHO)*

^4J(H,CHO) in Table 1 can be understood in a manner previously discussed for other benzaldehyde derivatives (2). The values will not be discussed in detail, except to note that, for example, ^4J(H-2,CHO) has a smaller magnitude than ^4J(H-6,CHO) because the electrognegative cyano group polarizes the electron framework at C-2, with the consequence that the positive σ electron contribution to ^4J(H-2,CHO) is increased and partially cancels the negative π electron component.

^6J(H,CHO) in benzaldehyde has not been detected (2). Its value in some *meta* substituted benzaldehyde derivatives

[2]A recent computation (36) on vinyl cyanide shows that an electric field comparable in magnitude to the reaction field in acetone solution causes a redistribution of σ and π charges in the vinyl group; the π electrons follow the field while the σ electrons tend to counterbalance this movement. Measurements of ^nJ(H,H) in cyanobenzene and the appropriate cyanotoluenes as a function of solvent should prove informative. Certain long-range $^{n+1}J(H,CH_3)$ are good indicators of the π electron contributions to the corresponding ^nJ(H,H).

follows (2) the relationship: ${}^6J/\text{Hz} = 0.007 - 0.127\,\Sigma\sigma_{R,ST}$, where $\sigma_{R,ST}$ are the so-called standard resonance substituent constants for *meta* substituents (38). This constant for a cyano group is 0.01, so that ${}^6J$ in 3CNB is predicted as +0.006 Hz. This coupling is not detectable in the ^{1}H nmr spectrum, but is consistent with the spectral simulations described in the footnotes to Table 1.

The quantity, $\sigma_{R,ST}$, is a measure of the charge transfer between ring and substituent (16) and is not available for *ortho* substituents. However, if the value of the *para* substituent constant, +0.19 for the cyano group, is used in the relationship above, then ${}^6J$ in 2CNB is anticipated as −0.017 Hz. It appears (Table 1 and Fig. 1) that ${}^6J$ is very likely negative in this compound, but not larger than 0.02 Hz in magnitude. Large deviations from planarity of the aldehydic group are also contraindicated by this small magnitude (39), in agreement with the molecular orbital computations in a previous section.

Long-range $^1H,^{19}F$ and $^{13}C,^{19}F$ coupling constants and molecular orbital computations as indicators of internal motion in $C_6H_5OCF_3$ and its 4-fluoro derivative

TED SCHAEFER,[1] GLENN H. PENNER,[2] RUDY SEBASTIAN, JAMES PEELING, AND CHRISTIAN BEAULIEU
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received October 16, 1990

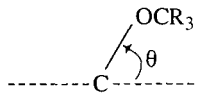
TED SCHAEFER, GLENN H. PENNER, RUDY SEBASTIAN, JAMES PEELING, and CHRISTIAN BEAULIEU. Can. J. Chem. **69**, 1047 (1991).

Internal rotational potentials for rotation about the Csp^2—O bond in $C_6H_5OCF_3$ and its 4-fluoro derivative are computed at the STO-3G and 3-12G levels of molecular orbital theory. As for anisole, the perpendicular conformer is calculated as least stable for $C_6H_5OCF_3$ but the height of the internal barrier is considerably lower than in anisole. The 4-fluoro substituent reduces the twofold component significantly, indicating reduced $p...\pi$ conjugation, but does not much change the values of the higher terms in the theoretical potentials. The internal potentials are rather flat with minima between about 30° and 45°, these angles measuring the twist away from planarity. The ^1H, ^{13}C, and ^{19}F nuclear magnetic resonance spectra in polar and nonpolar solution yield long-range coupling constants, $^nJ(^1H,^{19}F)$ and $^nJ(^{13}C,^{19}F)$. These parameters are qualitatively consistent with relatively low barriers to rotation about the Csp^2—O bonds in these molecules and with only a small dependence on solvent polarity.

Key words: $C_6H_5OCF_3$ and 4-F-$C_6H_4OCF_3$: ^1H NMR, ^{19}F NMR, conformations, MO computations.

TED SCHAEFER, GLENN H. PENNER, RUDY SEBASTIAN, JAMES PEELING et CHRISTIAN BEAULIEU. Can. J. Chem. **69**, 1047 (1991).

Opérant aux niveau STO-3G et 3-21G, on a calculé les potentiels rotationnels internes pour la rotation autour de la liaison Csp^2—O du $C_6H_5OCF_3$ et de son dérivé 4-fluoré. Comme dans le cas de l'anisole, on a calculé que le conformère perpendiculaire est le moins stable pour le $C_6H_5OCF_3$; toutefois, la hauteur à la barrière interne est beaucoup plus faible qu'avec l'ainsole. Le groupe 4-fluoro réduit considérablement la composante binaire, ce qui indique que la conjugaison $p...\pi$ est réduite; il ne provoque toutefois pas de changements dans les valeurs des termes supérieurs des potentiels théoriques. Les potentiels internes sont plutôt plats, avec des minima à des déviations d'environ 30° et 45° par rapport à la planéité. Les spectres de résonance magnétique nucléaire du ^1H, du ^{13}C et du ^{19}F, dans des solvants polaires en non polaires, fournissent les constantes de couplage à longue distance, $^nJ(^1H,^{19}F)$ et $^nJ(^{13}C,^{19}F)$. Ces paramètres sont qualitativement en accord avec les barrières à la rotation autour de ces liaisons Csp^2—O qui sont relativement basses dans ces molécules et qui ne présentent qu'une faible dépendance sur la polarité du solvant.



Mots clés : $C_6H_5OCF_3$ et 4-F-$C_6H_4OCF_3$: RMN ^1H, RMN ^{19}F, conformations, calculs d'OM.

[Traduit par la rédaction]

Introduction

Compared to the extensive experimental and theoretical work on the nature of the motion about the Csp—O bond in anisole (1, 2), that on trifluoromethoxybenzene is sparse. Allusive evidence comes from the Hammett σ constants (3–7), these being positive for the OCF_3 and negative for the OCH_3 group. The inductive σ constants of OCF_3 and OCH_3 are 0.55 and about 0.3, respectively, the larger value for OCF_3 being intuitively sensible, considering the electronegativity of fluorine (8); the mesomeric constants are about −0.2 and −0.44, respectively (8). Again, the delocalization constants (5) are reported as −0.16 and −0.55 for OCF_3 and OCH_3. Insofar as a major component of the barrier to rotation about the Csp^2—O bond in anisole originates (1) in $p-\pi$ conjugation, causing partial double-bond character, the numbers above imply a lower barrier in $C_6H_5OCF_3$ than in $C_6H_5OCH_3$. The proton chemical shifts of the *para* protons in these compounds, to be discussed below, also imply minimal $p-\pi$ conjugation in the fluorinated compound.

It appears that the only direct approach to the conformational properties of the OCF_3 group has been an investigation (9) of the dipolar couplings in ^1H and ^{19}F nmr spectra of the 4-fluoro and 4-iodo derivatives as solutions in a liquid crystalline solvent. For anisole, the planar conformer, with θ = 0 in **1**, is the most stable. For 4-F-$C_6H_4OCF_3$, the dipolar couplings between ^1H and ^{19}F can be fit (9) with a range of shapes of the internal rotational potential about the Csp^2—O bond, $V(\theta)$. Strongly favored planar or perpendicular (θ = 90°) conformers, those with internal barriers large compared to thermal energies at 300 K, can be rejected (9). However, the fits do not distinguish firmly between a pure twofold potential, with a minimum at θ = 90° and a maximum at θ = 0°, and one with an additional fourfold term, with a maximum at θ = 45°. Nevertheless, it is clear that the perpendicular is lower in energy than the planar conformer of 4-F-$C_6H_4OCF_3$. Because the fluorine substituent is a π electron donor and because the conjugation of the OCF_3 group with the aromatic π electron system is indicated as weak by the σ constants, it seems possible that the parent compound has a preferred planar conformation and that the 4-fluoro derivative does not. This possibility depends on the magnitude of the mobile bond order in the parent compound and on its perturbation by the 4-fluoro substituent. For example, the relatively weakly conjugative SH group in thiophenol has its barrier to internal rotation reduced almost to zero by such a perturbation (10).

R = H
R = F

Another potential source of information about the internal mobility in $C_6H_5OCF_3$ in solution are the long-range spin–spin coupling constants involving the ^{13}C and ^{19}F nuclei in the side

chain and the ^1H and ^{13}C nuclei in the aromatic moiety. Taking anisole as an analogy, the proximate coupling constant, $^5J(H,OCH_3)$, between the *ortho* and methyl protons is very sensitive to θ in **1**, as are $^6J(H,OCH_3)$ and $^6J(F,OCH_3)$, the σ–π coupling constants over six bonds (11–13). It is therefore of interest to obtain some analogous long-range coupling constants for $C_6H_5OCF_3$ and its 4-fluoro derivative in an attempt at their use in the conformational analysis of the OCF_3 group. These are reported here. Because CNDO/2 and INDO MO FPT computations (14) can provide useful qualitative information about the angle dependence of long-range coupling constants, such computations are also performed.

In addition, STO-3G (15) and 3-21G (16) MO computations of the internal barrier to rotation about the Csp^2—O bond are described.

Experimental

Dilute solutions of $C_6H_5OCF_3$ and 4-F-$C_6H_4OCF_3$ in acetone-d_6 and CS_2/C_6D_{12} (see Tables 3 and 4 for details) were filtered into 5 mm o.d. nmr sample tubes. These were degassed by four cycles of the freeze–pump–thaw procedure and were then flame-sealed under vacuum. The ^1H, ^{13}C, and ^{19}F nmr spectra were acquired on Bruker WH 90 and AM 300 spectrometers at probe temperatures of 300 K by standard procedures (17–19). The ^1H and ^{19}F nmr spectra were analyzed with the computer program NUMARIT (20), as reworked by R. Sebastian.

CNDO/2 and INDO MO FPT calculations (21) of coupling constants on the molecules above used the STO-3G MO geometries for the various conformations. The STO-3G and 3-21G MO computations employed GAUSSIAN 86 (22) on an Amdahl 5870. At each conformation all bond angles and lengths were optimized, with the proviso, however, that the nuclei of the aromatic moiety remain in a plane.

Results and discussion

The theoretical conformational energies

Table 1 contains the relative energies of the conformations defined by intervals of 15° in the angle of rotation, θ, about the Csp^2—O bonds in $C_6H_5OCF_3$ and its 4-fluoro derivative. These energies can be reproduced by the potentials described in Table 2.

(a) $C_6H_5OCF_3$

Noting that a vanishing θ refers to the planar conformer (see **1**), the data from the minimal basis set can be usefully compared with similar data for anisole (23). In this molecule, the twofold component, V_2, in $\sin^2\theta$, is 5.8 (2) kJ/mol while V_4 and V_6 are 2.4 (2) and −0.6 (2) kJ/mol, respectively. V_2 is directly related (1) to electronic interactions, most simply denoted as of π conjugative origin. At the STO-3G level of theory, in $C_6H_5OCF_3$ the twofold term has therefore decreased by 4.1 (2) kJ/mol, indicating much weaker conjugation across the Csp^2—O bond than in anisole. Although the gas phase barrier in anisole is not known, it must be emphasized that larger bases (1, 2, 24), including electron correlation (but without geometry optimization during the MP2 procedures (1, 2)), imply a V_2 of 9–10 kJ/mol. The substantial V_4 indicated by the minimal basis set for anisole is substantiated at higher levels of MO theory (1, 2, 10), its magnitude being much less sensitive to the basis than is V_2, and is likely (1) to be steric in origin. For $C_6H_5OCF_3$, on the other hand, V_4 is negative (of opposite sign to V_2) and an order of magnitude smaller than for anisole. It is not surprising that the CH_3 and CF_3 groups are thereby implied to be distinct in their interactions with the *ortho* C—H bond. What may be unexpected are the very similar V_6 terms in the STO-3G potentials for anisole and $C_6H_5OCF_3$; for the former molecule the 6-31G basis also has V_6 as −0.54 (5) kJ/mol. The implied consequence is that, unlike anisole, in which all the *ab initio* profiles (1) have an almost flat potential between 50° and 90° and a rapid rise between 0° and 50° for θ, the internal rotational potential for $C_6H_5OCF_3$ has a flat appearance between θ = 0° and about 40° and rises rapidly at larger θ values.

[a]The total energy is −632.716 247 au.
[b]The total energy is −637.684 897 au.
[c]The total energy is −730.174 946 au.
[d]The total energy is −736.006 727 au.

Because 3-21G computations on anisole (1) mimic 6-31G* energies reasonably well, the less computationally expensive basis was employed also for $C_6H_5OCF_3$ in an attempt at verification of the relatively low internal barrier. The twofold term of the 3-21G potential is very little different from that at the STO-3G level, but the positive V_6 means that the barrier height, at 2.3 kJ/mol, is 1 kJ/mol higher than that predicted by STO-3G. Also, V_4 is much larger in magnitude for the split valence basis. Nevertheless, the expectation value of θ is very similar for the two bases, being 39.2° and 39.8° at 300K with the minimal and the split-valence basis sets, respectively. Figure 1 illustrates the computed potentials and Fig. 2 the 3-21G geometry for the planar molecule; the caption of the latter discusses the changes in exocyclic bond angles during the internal rotaion.

(b) 4-F-$C_6H_4OCF_3$

As expected from a π electron donor, the STO-3G potential for 4-F-$C_6H_4OCF_3$ suggests a decrease of V_2 in the presence of the fluorine substituent. The decrease of 1.45 kJ/mol, to 0.24 kJ/mol, is roughly that (23) computed for the corresponding anisole species with this basis set. The higher terms are insensitive to the 4-fluoro substituent, implying their origin in interactions local to the substituent, as distinct from the delocalization implied by 2*p*...π conjugative phenomena responsible for the twofold term.

The 3-21G potential implies a decrease in V_2 of 1.2 kJ/mol relative to the parent molecule and, again, the higher terms are unchanged from those for the latter. However, whereas the STO-3G potential implies that the perpendicular conformer of 4-F-$C_6H_4OCF_3$ is 0.2 kJ/mol more stable than the planar, that from the split-valence basis gives the perpendicular conformer as less stable by 1.1 kJ/mol. The conformer of minimum energy has a θ near 47° (Table 1) while the minimal basis predicts 31.3°. Of course, both barriers are calculated as less than *RT* at 300 K, so that all angles, θ, are appreciably represented in the ensemble

[a]In kJ/mol, θ being zero for a conformation in which the carbon atom of the side chain lies in the aromatic plane. The multipliers of V_n are, respectively, $\sin^2(n/2)\theta$.

[b]Numbers in parentheses are the standard errors in the fit to the relative energies given in Table 1.

[c]This column refers to the STO-3G data for anisole (23).

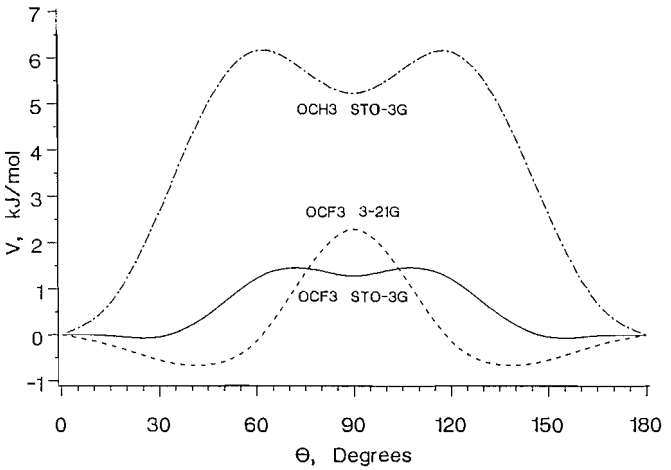

FIG. 1. The 3-21G and STO-3G MO potentials for rotation about the Csp^2—O bond in $C_6H_5OCF_3$ are compared with the STO-3G MO potential for $C_6H_5OCH_3$. Analytical expressions for these curves are given in the text, as are relative energies at intervals of 15° in the twist angle, θ. A θ of 0° defines a planar comformer, that in which the carbon atom of the side chain lies in the aromatic plane. The twofold term in the potential, indicative of $p...\pi$ conjugation, is smaller in $C_6H_5OCF_3$ and the fourfold term is negative, unlike its positive value in $C_6H_5OCH_3$.

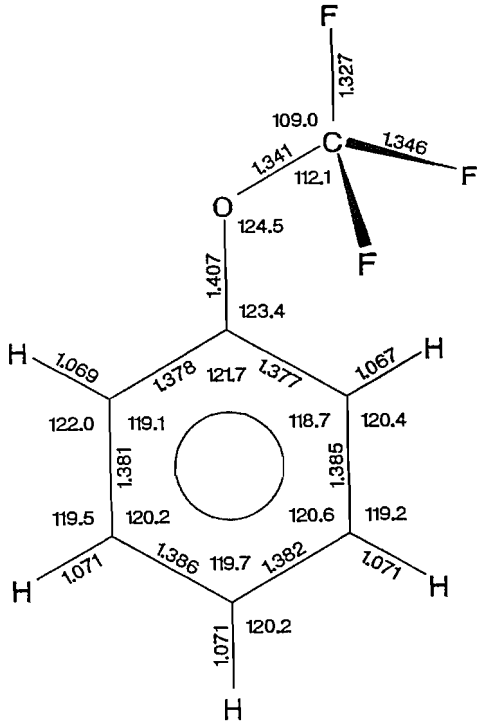

FIG. 2. The 3-21G geometry of the planar conformer of $C_6H_5OCF_3$ is displayed. It can serve as a starting point for higher level computations and may also be useful to molecular spectroscopists. Of some interest are the variations in the exocyclic bond angles during rotation about the Csp^2—O bond. These go as follows for the 3-21G (STO-3G) computations. At θ = 0°, for the planar conformer, ∠C(2)C(1)O is 123.4 (125.8) and becomes 119.0 (120.0) at θ = 90°. In a similar fashion, ∠C(1)OC varies from 124.5(116.5) to 120.2(112.1) as θ increases from 0 to 90°. In other words, rather like anisole (1), steric strain is indicated for the planar conformer. Furthermore, as θ increases from zero the CF_3 group twists by as much as 17° (STO-3G) or 6.5° (3-21G) in such a way as to minimize CF,CH contacts (the maximum twist occurs near θ = 45°); the twist vanishes again for the perpendicular conformer. At the 3-21G level for anisole (1), the maximum twist angle is about 14°. Of course, unlike $C_6H_5OCF_3$, V_2 and V_4 have the same sign in anisole.

at this temperature. This point is emphasized by $\langle\sin^2\theta\rangle$, computed as 0.488 and 0.480 at 300 K by the STO-3G and 3-21G bases, respectively. A $\langle\sin^2\theta\rangle$ of 0.5 corresponds to unhindered motion about the Csp^2—O bond.

By way of contrast, the potentials derived from intramolecular dipolar coupling constants for this compound in a nematic solvent can be written as $V(\theta)/\text{kJ mol}^{-1} = -13.5\sin^2\theta$ or $V(\theta)/\text{kJ mol}^{-1} = -1.8\sin^2\theta - 14.1\sin^2 2\theta$, the latter producing a slighter better fit (9). Both potentials have the perpendicular conformer as most stable, and yield $\langle\sin^2\theta\rangle$ as 0.885 and 0.656 at 300 K. Comparison with the MO potentials (Tables 1 and 2) would indicate a large solvent dependence of the internal rotational potential. The next section describes the information about the internal motion available from spin–spin coupling constants in CS_2/C_6D_{12} and acetone-d_6 solutions.

Long-range spin–spin coupling constants

(a) $^{5,6,7}J(H,CF_3)$ and $^7J(F,CF_3)$

The normal INDO MO FPT computations of long-range coupling constants between nuclei in the side chain and those in the aromatic moiety are known to reproduce their conformational dependence qualitatively. The magnitudes are not normally reproduced correctly, although certain computed H,H coupling constants happen nearly to coincide with experiment (25, 26). One exception to the general qualitative agreement between theoretical and experimental data is the proximate coupling constant, $^5J(F,CH_3)$, in a derivative of 2-fluoroanisole (27). It is

positive, but calculated as negative, for the most likely orientations of the methoxy group.

A similar discrepancy occurs for $^5J(H,CF_3)$ in $C_6H_5OCF_3$ and 4-F-$C_6H_4OCF_3$ (see Tables 3 and 4 and Fig. 3). In the former, $^5J(H,CF_3)$ is 1.04 Hz in acetone-d_6 solution. INDO MO FPT results for the STO-3G MO geometries are that $^5J(H,CF_3)$ is −0.75 Hz at $\theta = 0°$ in the *cis* orientation, increasing in magnitude to −1.22 Hz at $\theta = 45°$ and becoming 0.01 Hz at $\theta = 90°$. The theoretical numbers imply a proximate mechanism for the coupling constant in the sense that $^5J(H,CF_3)$ is computed as very small for the *ortho* proton *trans* to the CF_3 group in the conformations above and, at $\theta = 90°$, the computed coupling constant essentially vanishes because of the distance between the atoms carrying the coupled nuclei. The sign discrepancy means that the computed numbers cannot be used in a quantitative assessment of the conformational behaviour of the OCF_3 group, except insofar as the large magnitude of $^5J(H,CF_3)$ in either solution is not consistent with a stability of the perpendicular conformer large compared to *RT* at 300 K. For 4-F-$C_6H_4OCF_3$, $^5J(H,CF_3)$ is +0.95 Hz in acetone-d_6 and 0.94 Hz in CS_2/C_6D_{12} so that dramatic changes in the conformational distribution, caused by the 4-fluoro substituent, are contraindicated. Qualitatively, the smaller magnitude of $^5J(H,CF_3)$ is expected if θ values nearer 90° become more probable in the presence of the fluorine substituent, just as qualitatively predicted by the MO potentials in Table 2.

Turning to $^6J(H,CF_3)$, it is certainly finite and positive in 4-F-$C_6H_4OCF_3$ (see caption to Fig. 3), but only 0.01_5 Hz in magnitude. It is computed as 0.11 Hz between $\theta = 0°$ and 45° and then as 0.05 Hz between $\theta = 60°$ and 90°. It is impossible to derive the conformational behaviour from $^6J(H,CF_3)$.

Similar remarks apply to $^7J(F,CF_3)$ and $^7J(H,CF_3)$. The former is measured as +0.20 Hz and is computed as 0.19 ± 0.03 Hz for all angles. The latter is measured as ±0.13 Hz and is computed as 0.17 Hz at $\theta = 0°$, as 0.12 Hz at 45°, and as 0.00 Hz at $\theta = 90°$. While the measured value is consistent with higher probabilities for conformations with low θ values, the computed $^7J(H,CF_3)$ being 0.15 Hz at the conformation of lowest energy near 30°, it is clearly unwise to draw quantitative conformational conclusions except, again, to note that theory implies a vanishing $^7J(H,CF_3)$ if the perpendicular conformer is exclusively present.

(a) $^nJ(C,F)$

One computed *J* with a simple conformational dependence is ^6J(4-F,C) in 4-F-$C_6H_4OCF_3$. It varies, in Hz, as $0.90 \sin^2\theta$.

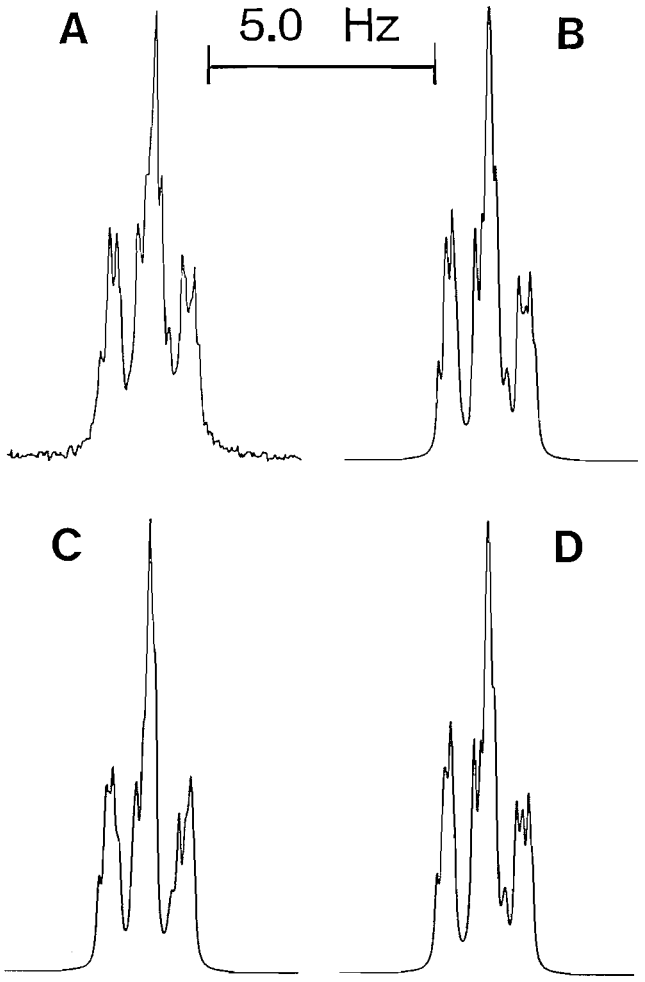

FIG. 3. In A is displayed the ^{19}F nmr spectrum at 84.7 MHz of the CF_3 group of 4-F-$C_6H_4OCF_3$ as a dilute solution in acetone-d_6; no resolution enhancement has been applied. The simulated spectra use the properly scaled spectral parameters obtained from the ^1H and ^{19}F nmr spectra at 300.1 and 282.4 MHz, respectively, acquired on an AM300 spectrometer (same sample). The tightly coupled proton spin system at the lower spectrometer frequency allows the direct determination of the signs of $^5J(H,CF_3)$, $^6J(H,CF_3)$, and $^7J(F,CF_3)$. This information is contained in the appearance of all the spectral regions but is here illustrated only for that of the CF_3 group. In B the simulated spectrum has a linewidth at half-height of 0.10 Hz and ^5J, ^6J, and ^7J are 0.950, 0.015, and 0.207 Hz, respectively, as given in Table 3. In C, ^5J is taken as negative because of the INDO MO FPT results (see text). The disagreement with experiment is apparent, as it is for all other sign combinations of the three coupling constants. In D, ^6J is taken as zero and the other two J's are positive. A ^6J of -0.015 Hz produces severe disagreement with experiment. The signs, of course, are relative to those of the coupling constants within the ring.

This is the angle dependence expected from a $\sigma-\pi$ mechanism (13, 25) and is also found for the analogous (13, 17, 28) coupling constants in 4-fluorophenyl-X-CH_3 (X = O,S,CH_2), for example. What is also common to the INDO MO FPT computations for such molecules is the underestimation of the coefficient of $\sin^2\theta$, that is, of $^6J_{90}$.

Thus, for 4-fluoroanisole, $^6J_{90}$ is computed as 0.7 Hz, the experimental value obtained from appropriate 2,6-disubstituted derivatives being 1.48 Hz (13). For X = CH_2, the underestimate is only 0.5 Hz, but substitution of hydrogen by an electronegative substituent on the methyl group causes a significant increase in the theoretical $^6J_{90}$ (17). Hence the increase in $^6J_{90}$ on passing from 4-F-$C_6H_4OCH_3$ to 4-F-$C_6H_4OCF_3$ is as anticipated. If the former molecule is taken as a reference, then the $^6J_{90}$ for the latter may be estimated[3] as 0.90 (1.48/0.7) or 1.90 Hz. In that event the measured value of ^6J(4-F,C), 1.00 Hz (Table 5), for 4-F-$C_6H_4OCH_3$ in acetone-d_6 solution yields $\langle\sin^2\theta\rangle$ as 0.526 at 300 K. The STO-3G potential gives $\langle\sin^2\theta\rangle$ as 0.488, while that from 3-21G yields 0.480. The potentials deduced for the molecule in the liquid crystal environment (9) entail $\langle\sin^2\theta\rangle$ values of 0.885 or 0.656. The larger of these numbers implies $^6J_{90}$ as 1.13 Hz, that is, 1.00/0.885 Hz. This magnitude is much too small, as judged by our experience with INDO MO FPT calculations for coupling constants of this kind. The $\langle\sin^2\theta\rangle$ of 0.885 comes from the purely twofold potential, unlikely in view of the *ab initio* computations. The value of 0.656 cannot be dismissed as easily. It implies a $^6J_{90}$ of 1.52 Hz, effectively the same as the 1.48 Hz found experimentally (13) for 4-fluoroanisole. However, the adjusted theory indicates a larger $^6J_{90}$ in the OCF_3 molecule, physically sensible because the fluorine atoms bonded to the carbon atom cause contraction of its *s* orbitals and thereby enhance the contact contribution to ^6J; alternatively, the electronegative fluorine substituents cause increased *s*-character at the coupled carbon atom (29). The molecular orbital calculations imply a $^6J_{90}$ of about 2.05 Hz. It is possible, of course, that the solvent alters the internal rotational potential although the coupling constants in Tables 3–5 imply only minor changes in the potential on passing from a nonpolar to a polar solvent environment.

Turning to $^nJ(C,CF_3)$, the INDO MO FPT values, using the STO-3G geometries, can be summarized and compared with experiments as follows. ^3J is calculated as 2.36 Hz at $\theta = 0°$ for $C_6H_5OCF_3$ and decreases to 1.70 Hz at 60°, after which it again increases to 2.02 Hz at $\theta = 90°$; the same trend occurs for the 4-fluoro derivative, but the computed values are 0.04–0.11 Hz larger. Comparison with the measured values of 1.8–1.9 Hz for the parent compound and 2.05 (3) Hz for the derivative (Table 5) suggests that the theoretical values are compatible with observation, but that they cannot at present be used to derive an internal rotational potential.

^4J, as averaged for C-2 and C-6, is calculated to drop slowly from 0.86 Hz at 0° to 0.69 Hz at 45° and then more rapidly to -0.13 Hz at $\theta = 90°$ for $C_6H_5OCF_3$; for the 4-fluoro derivative, the magnitudes are about 0.05 Hz larger between 0° and 60°. The values of 0.9–1.0 Hz in Table 5 are then consistent with a relatively low population of the perpendicular conformers or those closely approximating to them. This consistency is similar to that implied by the molecular orbital computations as well as by a number of the other coupling constants discussed above. It also suggests that the simple twofold potential, based on dipolar couplings, is quantitatively incorrect because it strongly favors large θ values. On the other hand, ^4J is roughly consistent with the alternative potential based on the dipolar couplings in a nematic solvent (9).

Again, ^5J, averaged for C-3 and C-5, is computed as 0.23 Hz at $\theta = 0°$, dropping off to 0.07 Hz at 45° and then, between 60° and 90°, remains at -0.05 Hz for $C_6H_5OCF_3$; for the 4-fluoro compound, the computed numbers between 0° and 45° are about 0.3 Hz larger. The measured ^5J for the latter, at 0.31 Hz, is perhaps somewhat larger than the 0.26 Hz for the parent com-

[3]It is apparently beyond our resources to synthesize, say, the 2,6-dibromo-4-fluoro derivative of $C_6H_5OCF_3$; this compound might give an experimental estimate of $^6J_{90}$.

TABLE 5. The ^{13}C nmr chemical shifts and $^nJ(C,F)^a$ for $C_6H_5OCF_3$ and 4-F-$C_6H_4OCF_3$

Parameter	$C_6H_5OCF_3$ CS_2/C_6D_{12}	$C_6H_5OCF_3$ Acetone-d_6	Parameter	4-F-$C_6H_4OCF_3$ Acetone-d_6[e]

[g]Numbers in parentheses are for 50% solutions in $CDCl_3$ at 295–297 K (31).

pound (Table 4). These numbers are qualitatively consistent with the molecular orbital potentials for $C_6H_5OCF_3$, which imply that the conformations with θ less than about 60° are more heavily populated than those with larger angles.

Finally, $^6J(C,CF_3)$ is calculated to vary little as θ changes, increasing slowly from 0.01 Hz at 0° to about 0.12 Hz for θ greater than 60°. The nonobservation of this coupling constant (Table 4) is therefore not a surprise.

The ring proton chemical shifts

For anisole, as a 2.5 mol% solution in CS_2/C_6D_{12} at 300 K (12), δ_o,δ_m, and δ_p are 6.729, 7.122, and 6.786, respectively. δ_H for benzene in such a solution is 7.218 (31), so that the larger screening by 0.432 ppm of the *para* protons is consistent with π electron donation (see references in ref. 31) by the methoxy group. δ_o, δ_m, and δ_p for $C_6H_5OCF_3$, for 5.0 mol% solution in the same solvent and at the same temperature, are 7.109, 7.299, and 7.202, respectively. Dilution shifts for anisole at least (32), in CCl_4, are negligible for purposes of the present comparison; it is most probable that the dilution shift for $C_6H_5OCF_3$ is less than 0.005 ppm between 5.0 and 2.5 mol%. Hence, the δ_H of benzene and δ_p of $C_6H_5OCF_3$ are essentially equal, implying that the OCF_3 group is a weak π electron donor. Qualitatively, a low barrier to rotation about the Csp^2—O bond in $C_6H_5OCF_3$ is therefore inferable, insofar as the barrier arises from p–π conjugation.

In $CDCl_3$, δ(C-4) of $C_6H_5OCF_3$ is smaller than that of benzene by 1.8 (30) whereas for anisole this number is 7.8, again consistent with a much lower delocalization of π electrons by the OCF_3 group. Some donative p–π conjugation is indicated, however, consistent with the planar conformer as the more stable relative to the perpendicular, and as computed by the molecular orbital methods above.

Conclusions

As expected intuitively, the molecular orbital computations predict a lower barrier to internal rotation about the Csp^2—O bond in $C_6H_5OCF_3$ than in anisole, $C_6H_5OCH_3$. The perpendicular conformer is still the least stable, theoretically, as is also indicated qualitatively by the long-range spin–spin coupling constants measured in CS_2 and acetone-d_6 solutions. The experimental data are consistent with at most a small dependence of the internal rotational potential on solvent polarity. Again as expected, the computations on 4-F-$C_6H_4OCF_3$ predict a further reduction of the internal barrier, probably caused by π electron donation from the substituent. Qualitatively, the long-range coupling constants are again consistent with a very low barrier in both solvents. These results suggest that of two possible internal rotational potentials, derived from intramolecular dipolar coupling constants for 4-F-$C_6H_4OCF_3$ in a liquid crystalline solvent, the purely twofold is probably incorrect. The other, having the perpendicular as 1.8 kJ/mol more stable than the planar conformer, cannot be rejected on the basis of the long-range indirect coupling constants.

NOTE ADDED IN PROOF: We have also studied $C_6H_5OCF_3$ and 4-F-$C_6H_4OCF_3$ with geometry-optimized 6-31G computations; the internal potentials (in kJ/mol) are $-2.652(3)\ \sin^2\theta + 0.928(3)\ \sin^2 2\theta - 0.180(3)\ \sin^2 3\theta$ and $-3.628(3)\ \sin^2\theta + 0.984(3)\ \sin^2 2\theta - 0.190(3)\ \sin^2 3\theta$, respectively. At 300 K, $\langle\sin^2\theta\rangle$ values are 0.641 and 0.687. The perpendicular conformers are now the most stable, with relatively small barriers to internal rotation; the mean out-of-plane angles are 56° and 59° at 300 K.

Selenium-77 and phosphorus-31 nuclear spin relaxation in tri-(*tert*-butyl) phosphine selenide

GLENN H. PENNER

Guelph–Waterloo Centre for Graduate Work in Chemistry, University of Guelph, Guelph, Ont., Canada N1G 2W1

Received October 24, 1990

GLENN H. PENNER. Can. J. Chem. **69**, 1054 (1991).

Selenium-77 and phosphorus-31 spin-lattice relaxation times are reported for tri-*tert*-butylphosphine selenide in chloroform-*d*, at 303 K and at several different magnetic field strengths. At moderate fields the ^{31}P–^{1}H dipole–dipole, spin-rotation, and chemical shift anisotropy mechanisms contribute significantly towards the ^{31}P T_1. At high fields chemical shift anisotropy dominates. The selenium-77 nuclear spin relaxes almost exclusively by spin rotation at low to moderate fields and the chemical shift anisotropy contribution only becomes significant at very high fields. This is due to an unusually small ^{77}Se CSA. The contribution due to ^{31}P–^{77}Se dipole–dipole interactions is small but significant.

Key words: ^{77}Se NMR, NMR relaxation, phosphine selenide.

GLENN H. PENNER. Can. J. Chem. **69**, 1054 (1991).

On a déterminé les temps de relaxation spin réseau du sélénium-77 et du phosphore-31 pour le sélénure de tri-*tert*-butylphosphine, dans le chloroforme-*d*, à 303 K et à diverses forces du champ magnétique. À des champs modérés, les mécanismes de dipôle–dipôle ^{31}P–^{1}H, de rotation de spin et d'anisotropie de déplacement chimique contribuent d'une façon importante à la valeur T_1 du ^{31}P. Aux champs plus élevés, l'anisotropie domine. Aux champs allant de faibles à modérés, la relaxation du spin nucléaire du sélénium-77 se fait presqu'exclusivement par une rotation de spin; la contribution de l'anisotropie du déplacement chimique ne devient importante qu'à des champs très élevés. Ce résultat est attribuable à une ADC du ^{77}Se inhabituellement faible. La contribution attribuable aux interactions dipôle–dipôle ^{31}P–^{77}Se est faible mais significative.

Mots clés : RMN ^{77}Se, relaxation de RMN, sélénures de phosphine.

[Traduit par la rédaction]

Introduction

Phosphorus-31 nuclear spin relaxation in organophosphorus compounds has been the subject of a number of studies (1). Two such studies on phosphine oxides have appeared recently (2, 3). Phosphorus-31 T_1 values have been reported for only one phosphine selenide (2). Investigations of ^{77}Se nuclear spin relaxation have been relatively rare (4–8). Selenium-77 T_1 values have been measured for the C=Se moiety (8) in a number of organoselenium compounds and a large contribution from chemical shift anisotropy was reported. Recently Pulkkinen, Jokisaari, and Kowalewski have reported the ^{77}Se spin-lattice relaxation in carbon diselenide at several fields (9). No investigation of the P=Se moiety has been reported. To study ^{31}P and ^{77}Se relaxation in the P=Se group, tri-*tert*-butylphosphine selenide, **1**, was chosen. Solid ^{77}Se and ^{31}P powder spectra of **1** have been measured[1] and provide values for the chemical shift anisotropies. Compound **1** is stable and relatively easy to synthesize (11).

$$((CH_3)_3C)_3P{=}Se$$

1

In general, when the extreme narrowing condition applies, the rate of spin-lattice relaxation for ^{31}P or ^{77}Se in **1** should consist of several contributions.

$$[1]\quad \frac{1}{T_1} = R_1 = R_1(\mathrm{DD},{}^{1}\mathrm{H}) + R_1(\mathrm{SR}) + R_1(\mathrm{CSA}) + R_1(\mathrm{DD,X})$$

The contribution from the dipole–dipole interaction between the ^{31}P or ^{77}Se nucleus (A) and the protons (H) is given by

$$[2]\quad R_1(\mathrm{DD},{}^{1}\mathrm{H}) = \frac{\gamma_H^2\gamma_A^2\hbar^2\tau_c}{r^6}$$

where γ is the magnetogyric ratio, r is the average A—H internuclear distance, and τ_c is the correlation time for molecular tumbling in solution. The $R_1(\mathrm{DD},{}^{1}\mathrm{H})$ term related to the nuclear Overhauser enhancement, η, by eq. [3].

$$[3]\quad \frac{R_1}{R_1,(\mathrm{DD},{}^{1}\mathrm{H})} = \frac{\eta_{max}}{\eta}$$

The spin-rotation contribution, $R_1(\mathrm{SR})$, is given as

$$[4]\quad R_1(\mathrm{SR}) = \frac{2IkTC^2}{3\hbar^2}\tau_J$$

where I is the moment of inertia, T is the temperature, C^2 is the square of the trace of the spin rotation tensor, and τ_J is the angular momentum correlation time. For a molecule undergoing small-step diffusion, τ_J and τ_c are related by the Hubbard equation,

$$[5]\quad \tau_c\tau_J = \frac{I}{6kT}$$

The chemical shift anisotropy contribution is given by

$$[6]\quad R_1(\mathrm{CSA}) = \frac{2}{15}\gamma_A^2B_0^2(\Delta\sigma)^2\tau_c$$

where B_0 is the magnetic field strength and $\Delta\sigma$ is the chemical shift anisotropy.

A dipolar coupling between the ^{31}P and ^{77}Se nuclei may also contribute towards the relaxation rate:

$$[7]\quad R_1(\mathrm{DD,X}) = \frac{\gamma_{Se}^2\gamma_P^2\hbar^2}{r^6}\tau_c$$

where r is the P—Se bond length.

Experimental

Commercial tri-*tert*-butylphosphine (Alfa Products) was stirred under nitrogen with excess selenium powder in dry toluene for 3 days. After filtering the excess selenium the toluene was evaporated, leaving tri-*tert*-butylphosphine selenide as light yellow crystals. The solid was recrystallized from pentane. The product was shown to be pure by ^{1}H, ^{13}C, ^{31}P, and ^{77}Se NMR spectroscopy (11).

Samples of 0.5 M **1** in $CDCl_3$ were prepared in 5 mm and 10 mm NMR tubes. After degassing by three freeze–pump–thaw cycles the tubes were vacuum sealed.

Spectra were acquired at 303 K on Bruker AC-200, Bruker AM-250, Bruker AM-300, Bruker AM-500, and Varian UNITY-600 NMR spectrometers. Relaxation time measurements employed the inversion–recovery pulse sequence with 7–10 delay values (depending on available spectrometer time) with a relaxation delay of 5 times the T_1. The resulting points were fit to the equation

$$[8] \quad M = A + B \exp(-\tau/T_1)$$

using the NLIN program of the SAS/STAT software package (12). Computations were performed on an IBM 3081-K mainframe computer.

Results and discussion

Contributions towards ^{31}P spin-lattice relaxation

Spin-lattice relaxation times for the center-band and ^{77}Se satellites are collected in Table 1. A linear regression yields eq. [9]. The ^{31}P solid powder spectrum has been measured,[1] yielding a $\Delta\delta$ value of 129 ppm. A rotational correlation time of 19.4 ps is obtained from the slope of eq. [9].

$$[9] \quad R_1 = (4.63 \pm 0.43) \times 10^{-2} + [(5.06 \pm 0.47) \times 10^{-4}]B_0^2$$

The maximum ^{1}H–^{31}P nuclear Overhauser enhancement, η_{max}, is 1.234. At 4.7 T (AC-200) and 303 K η is 0.486. Substitution of these values into eq. [3] yields a ^{1}H–^{31}P dipole–dipole contribution, $R_1(DD,^{1}H)$, of 0.023. This value and τ_c yields, via eq. [2], an average phosphorus–hydrogen internuclear distance of 2.1 Å.

The contribution of $R_1(DD,^{77}Se)$ can be calculated using eq. [7] and a P=Se bond length of 2.09 Å, the average of 12 values obtained from X-ray diffraction studies (13); the standard deviation is 0.02 Å. The calculated value of $R_1(DD,^{77}Se)$ is $(8 \pm 1) \times 10^{-4}$ s^{-1}. This relaxation mechanism should only affect the ^{77}Se satellites of the ^{31}P spectrum. The rather small calculated contribution of the ^{77}Se–^{31}P dipole–dipole mechanism is in accord with the nearly equal T_1 values for both the ^{31}P center band and ^{77}Se side bands. An exception to this is the observation at 11.74 T (AM-500), where the T_1 values for both ^{77}Se side bands are longer than for the center band. The T_1 values for the side bands may be different than those for the center band under various conditions. A ^{77}Se–^{31}P dipole–dipole contribution can be ruled out as this mechanism is independent of field under extreme narrowing conditions. Cross relaxation between the dipole–dipole and CSA mechanisms is field dependent (10, 14), but if this were the case the center-band T_1 value would be midway between the values for the side bands; this is not observed at 11.74 T. An instrumental reason for the observed difference in T_1 values may be non-uniform excitation of all resonances. Since the transmitter frequency is very near the center band (and the 90° pulse is calibrated using the center-band resonance), an insufficient excitation of the side-band resonances may be considered, although this seems rather unlikely since the 90° pulse in all experiments was less than 30 μs, which should be sufficiently short for uniform excitation of the 1000-Hz spectral region of interest.

TABLE 1. ^{77}Se and ^{31}P T_1 values for 0.5 M tri-*tert*-butyl phosphine selenide in $CDCl_3$

	Field (T)	T_1(s)
^{31}P[a]	4.70	17.1(17.7, 17.2)
	5.87	14.5(14.4, 14.3)
	7.05	14.6(15.2, 13.8)
	11.74	9.52(13.5, 11.8)
	14.09	6.51(6.68, 6.41)
^{77}Se[b]	4.70	74.6 73.8
	11.74	66 66

[a]Relaxation times for ^{77}Se side bands in parentheses.
[b]First T_1 entry is for highest frequency resonance.

TABLE 2. Contribution towards ^{31}P and ^{77}Se spin-lattice relaxation rates in tri-*tert*-butyl phosphine selenide[a]

	^{31}P	^{77}Se
$R_1(DD,^{1}H)$	0.0230	0.0000
$R_1(CSA)$	$(5.06 \times 10^{-4})B_0^2$	$(1.38 \times 10^{-5})B_0^2$
$R_1(SR)$	0.0225	0.0125
$R_1(DD, X)$	0.0008	0.0008

[a]Relaxation rates in s^{-1}; B_0 is the magnetic field strength in tesla.

The remaining contribution towards the ^{31}P relaxation rate is attributed to R_1 (SR), the spin-rotation mechanism. Subtracting $R_1(DD,^{1}H)$ and $R_1(DD,X)$ from the intercept in eq. [9] yields $R_1(SR) = 0.0225$ s^{-1}.

The various contributions towards the ^{31}P nuclear spin-lattice relaxation rate in the tri-*tert*-butylphosphine selenide are summarized in Table 2.

Contributions towards ^{77}Se spin-lattice relaxation

The selenium-77 T_1 values, measured at 4.7 and 11.74 T, are included in Table 1. Selenium-77 solid-state experiments on **1** yield a $\Delta\delta$ value of 34.7 ppm.[1] The field dependence of the ^{77}Se relaxation rate is given by eq. [10].

$$[10] \quad R_1 = 1.33 \times 10^{-2} + (1.38 \times 10^{-5})B_0^2$$

The slope yields a rotational correlation time of 32 ps. Considering the uncertainty in the two T_1 measurements (estimated to be about 10%) and the rather small slope in eq. [10], the τ_c value of 19.4 ps as derived from the ^{31}P data is the more reliable number.

No proton nOe was observed for ^{77}Se. Therefore the term $R_1(DD,^{1}H)$ can be neglected. The ^{31}P–^{77}Se dipole–dipole contribution $R_1(DD,^{31}P)$ is equal to the value previously calculated for $R_1(DD,^{77}Se)$. Although small, this contribution is not negligible. Assuming no cross-correlation effects, this term will equally affect the two resonances of the doublet (due to J coupling to ^{31}P).

If there are no other contributions to the ^{77}Se relaxation rate, the spin-rotation contribution, $R_1(SR)$, is obtained by subtracting $R_1(DD,^{31}P)$ from the intercept of eq. [10]. This leaves an $R_1(SR)$ value of 0.0125 s^{-1}. The contributions towards ^{77}Se spin-lattice relaxation in tri-*tert*-butylphosphine selenide are summarized in Table 2.

The ratios of the slopes, m(P) and m(Se), of eq. [9] and [10]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

should obey the relationships given in eq. [11].

$$[11]\quad \frac{\gamma(\mathrm{Se})\Delta\sigma(\mathrm{Se})}{\gamma(\mathrm{P})\Delta\sigma(\mathrm{P})} = \sqrt{\frac{m(\mathrm{Se})}{m(\mathrm{P})}}$$

Experimentally, we find that

$$[12]\quad \frac{\gamma(\mathrm{Se})\Delta\sigma(\mathrm{Se})}{\gamma(\mathrm{P})\Delta\sigma(\mathrm{P})} = 0.127$$

and

$$[13]\quad \sqrt{\frac{m(\mathrm{Se})}{m(\mathrm{P})}} = 0.165$$

Equations [12] and [13] are in fair agreement. If the ratio of slopes is adjusted to take into account that 19.4 ps is the much more reliable correlation time, eq. [13] yields a value of 0.129, which is in excellent agreement with eq. [12]. The ratio of the intercepts of eqs. [9] and [10], which are both reliable numbers, is equal to the ratio of the squares of the spin rotation constants:

$$[14]\quad \frac{C^2(\mathrm{Se})}{C^2(\mathrm{P})} = 0.555$$

Conclusion

In this study ^{77}Se and ^{31}P longitudinal relaxation times were measured for tri-*tert*-butylphosphine selenide in chloroform-*d* at 303 K and at several different magnetic field strengths. At moderate fields the ^{31}P–^{1}H dipole–dipole, spin-rotation, and chemical shift anisotropy mechanisms contribute significantly towards the ^{31}P T_1. At high fields (>400 MHz) chemical shift anisotropy dominates. The ^{77}Se nuclear spin relaxes almost exclusively by spin rotation. The chemical shift anisotropy contribution only becomes significant at very high fields (>500 MHz). This is due to an unusually small ^{77}Se CSA. The ^{31}P–^{77}Se dipole–dipole contribution accounts for 5–6% of the ^{77}Se relaxation rate at fields attainable with present NMR spectrometers.

Rate of the OH + C_6H_6 + He reaction in the fall-off range by discharge flow and OH resonance fluorescence

A. GOUMRI, J. F. PAUWELS, AND P. DEVOLDER

Laboratoire de Cinétique et Chimie de la Combustion URA CNRS 876, Université des Sciences et Techniques de Lille, Flandres-Artois, 59655 Villeneuve D'ASCQ Cedex, France

Received October 24, 1990

A. GOUMRI, J. F. PAUWELS, and P. DEVOLDER. Can. J. Chem. **69**, 1057 (1991).

The rate constant k_1 of the reaction

$$OH + C_6H_6(+ He) \longrightarrow \text{products } (+ He)$$

has been investigated by discharge flow resonance fluorescence of OH in the fall-off pressure range. From systematic measurements at five pressures between 0.5 and 9.5 torr, the Troe parameters k_0 and k_∞ (with $F_c = 0.6$) have been derived at two temperatures: room temperature and 353 K. For room temperature, (297 ± 3) K, these parameters are $k_0 = (1.7 \pm 0.5) \times 10^{-29}$ cm^6 molecule^{-2} s^{-1}, $k_\infty = (10 \pm 2) \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}. Our experimental results are consistent with addition as the dominant path, in agreement with flash photolysis investigations and with the existence of a fast reaction with NO_2 of the (OH—benzene) radical adduct. A numerical simulation shows that this latter reaction should have a rate constant of $(4 \pm 2) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} at 353 K.

Key words: gas phase kinetics, discharge flow, resonance fluorescence, reaction of OH with benzene, tropospheric chemistry.

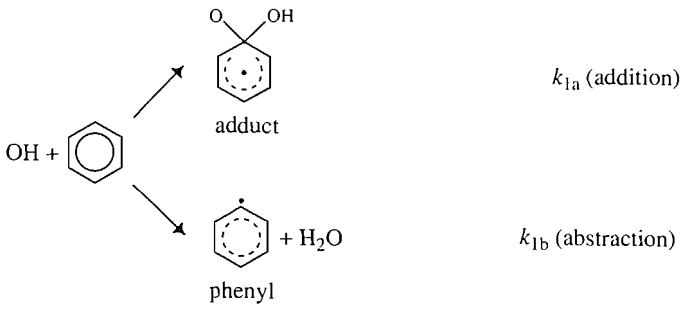
A. GOUMRI, J. F. PAUWELS et P. DEVOLDER. Can. J. Chem. **69**, 1057 (1991).

Opérant dans la région de la diminution de la pression et utilisant la fluorescence de resonance OH par la technique de l'écoulement continue, on a déterminé la constante de vitesse k_1 de la réaction

$$OH + C_6H_6(+ He) \longrightarrow \text{produits } (+ He)$$

A partir de mesures systématiques effectuées à cinq pressions différentes, entre 0,5 et 9,5 torr, on a déduit les paramètres de Troe, k_0 et k_∞ (avec $F_c = 0,6$), à deux températures : à la température ambiante et à 353 K. Pour la première, (297 ± 3) K, ces paramètres sont : $k_0 = (1,7 \pm 0,5) \times 10^{-29}$ cm^6 molecule^{-2} s^{-1} et $k_\infty = (10 \pm 2) \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}. Nos données expérimentales sont en accord avec un mécanisme impliquant une addition comme voie principale; cette conclusion est en accord avec les résultats de la photolyse éclair et avec le fait que le NO_2 réagit rapidement avec l'adduit radicalaire (OH—benzène). Une simulation numérique montre que cette dernière réaction devrait avoir une vitesse de réaction de $(4 \pm 2) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}, à 353 K.

Mots clés : cinétique en phase gazeuse, fluorescence de résonance, réaction de OH avec le benzène, chimie de la troposphère, technique de l'écoulement continue.



[Traduit par le rédaction]

Introduction

Aromatic hydrocarbons produced by car engines are important pollutants of the urban atmosphere (1); they are suspected to play an important role in the mechanism of photochemical smog, mainly via intermediates or end products of their trophospheric oxidation (nitroaromatics, cresols, ring opening products, ...) (1, 2). Benzene and its methylated derivatives (toluene, xylenes) are the most abundant trophospheric aromatic hydrocarbons (1, 2).

At room temperature, gas phase trophospheric oxidation of these aromatics is initiated by an attack by the OH radical (1–3) with a major contribution from the addition route.

For benzene, the abstraction route leads to a phenyl radical whereas the addition route gives a conjugated adduct radical, the hydroxycyclohexadienyl radical:

k_{1a} (addition)

k_{1b} (abstraction)

At higher temperatures ($T > 500$ K), direct (4) or end product (5) investigations are explained assuming the abstraction route is the dominant process.

This OH—benzene adduct radical has been directly observed by Zellner *et al.* (6) by long path absorption in the UV range. A geometry of this radical adduct has been proposed by Sloane and Brudzynski (7). The various subsequent steps of tropospheric oxidation have been discussed thoroughly by Atkinson *et al.* in a series of reviews (3) and by others (2). The measurements of the rate constant $k_1 = (k_{1a} + k_{1b})$ by absolute techniques have been the subject of various investigations. To clarify the following bibliographic discussion, let us classify these investigations into three categories: (i) measurements of k_1 at room temperature above 10 torr (i.e., in the high pressure limiting range), (*ii*) variable temperature measurements of k_1, (*iii*) variable pressure measurements of k_1 in the fall-off range (below 10 torr).

(i) Room temperature measurements in the high pressure range (4a, 8–12)

All measurements of k_1 at room temperature in the 25–760 torr pressure range have been performed with the same technique: flash (or laser) photolysis technique with the detection of OH by resonance fluorescence. There is satisfactory agreement between the various authors; from their data it is apparent that above ~25 torr (helium or argon), k_1 is already in the high

For personal use only.

pressure regime, with an average value of

$$k_1 = (11 \pm 2) \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

(ii) Variable temperature measurements (4, 8b, 9–11)

Variable temperature measurements have also been achieved by the flash photolysis technique. They fall in two temperature ranges, low temperature (i.e. below 400 ~ 450 K) and high temperature (up to 1000 K). From their observation of non-exponential OH decays (i.e. ln [OH] is non-linear versus reaction time in reactant pseudo-first order conditions) in the temperature range 320 ~ 400 K, a few authors (4*a*, 9–11) suggest a contribution from the unimolecular decay of the adduct radical:

$$C_6H_6OH \rightarrow C_6H_6 + OH \qquad k_{-1a}$$

This suggestion has been checked by Zetzsch *et al.* (8*b*, 13) on a quantitative basis: these authors were able to derive the variation of k_{-1a} versus temperature (up to 353 K):

[1] $$k_{-1a} = 3 \times 10^{12} \exp(-8200/T) \text{ s}^{-1}$$

However, in contrast to room temperature results, the measured values of k_1 are not in good agreement in this intermediate range (around 400 K), ranging from 1.93×10^{-13} cm^3 molecule^{-1} s^{-1} (11) to $4 \sim 5 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1} (9). This poor agreement is probably connected with the increasing onset of reaction [−1*a*]. At much higher temperatures (above 450 ~ 500 K), the reaction rate k_1 exhibits smaller values (i.e., below that at room temperature) and typical activation energy characteristic of abstraction reactions (4); the contribution of the addition route is considered to become negigible at these high temperatures due to the quickly established equilibrium:

$$OH + C_6H_6 \text{ (+M)} \rightleftarrows C_6H_6OH \text{ (+M)}$$

From their high temperature measurements, Tully *et al.* (4*a*) and Madronich and Felder (4*b*) can thus derive the following abstraction reaction rates (cm^3 molecule^{-1} s^{-1}):

[2] $$k_{1b} = 2.4 \times 10^{-11} \exp(-2260/T) \qquad (4a)$$

[3] $$k_{1b} = 3.5 \times 10^{-11} \exp(-2300/T) \qquad (4b)$$

(iii) Variable pressure measurements of k_1

In the fall-off range of k_1, below 20 ~ 25 torr, only three measurements have been reported: with the flash photolysis resonance fluorescence technique, Zellner *et al.* (9) and Zetzsch *et al.* (8*b*) both use argon as the diluent gas, with a large scatter of experimental data (Fig. 1) and the investigation of Baulch *et al.* (14) uses the same technique as ours (discharge flow resonance fluorescence).

The results of these three investigations are gathered in Fig. 1. It is obvious that the agreement is bad.

Our present measurements at room temperature have been performed to precise the pressure dependence of k_1 and to derive the Troe parameters k_0 and k_∞ (15). It is also interesting to compare the present results with those of Baulch *et al.* (14) who used the same technique and with the results of our previous investigation (16*a*) of the rate constant of the (OH + tolueme → products) reaction under the same conditions. Furthermore, we have chosen to investigate the temperature behavior of k_1 in the range 293–383 K for the following reasons: (*i*) OH additions on aromatic rings usually exhibit low (positive or negative) temperature coefficients (10) and (*ii*)

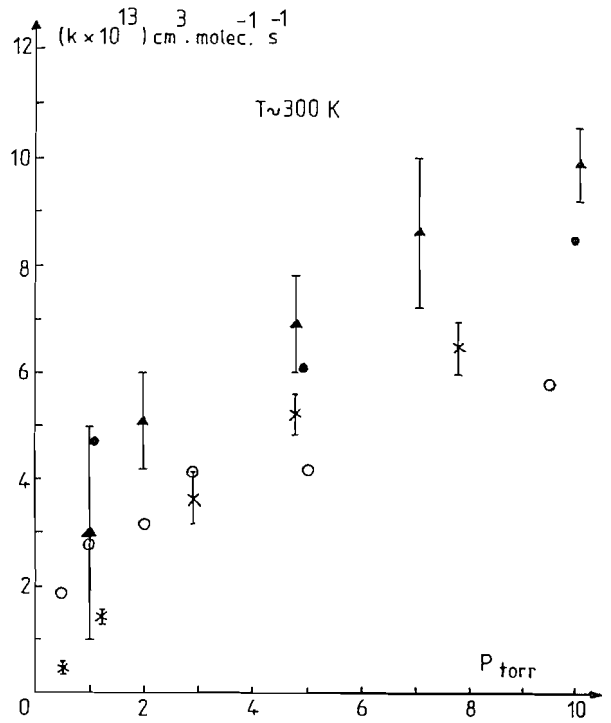

FIG. 1. Comparison of the measurements of k_1, versus pressure in the fall-off range: ▲, ref. 8; ●, ref. 9; ×, ref. 14; ○, this work.

as mentioned above, a few authors report the observation of non-exponential OH decay plots around 353 K. The latter observation needs further investigation.

Experimental

The experimental set up for OH resonance fluorescence and detection by photon counting has been descibed elsewhere (16*b*). Only some specific details of the present experiments are presented below.

The flow rate of benzene from degassed liquid is measured by diverting the pure benzene vapor flow (downstream the needle valve) from the flow tube to an evacuated calibrated reservoir and measuring the rate of pressure increase with an absolute capacitive gauge (0–10 torr). Other flow rates (He, H_2/He, NO_2/He) are regulated by flow controllers periodically checked by absolute techniques (wet testmeter or $\Delta P/\Delta t$ method). The flow tube pressure is measured at the fluorescence cell with an absolute 0–10 torr capacitive manometer. The pressure gradient (Poiseuille law) is taken into account to compute a mean corrected pressure P_c:

[4] $$P_c = P_{obs} + (\Delta P/\Delta z)\Delta z \text{ with } \Delta P/\Delta z = 5.9\ 10^{-3}\ \mu v/r^2$$

where μ = helium viscosity, v = flow velocity, r = tube radii. A systematic upstream correction of $\Delta z = 30$ cm, corresponding to the center of most OH decay curves, is applied.

For most experiments, OH radicals have been generated by the classical O atom transfer reaction:

$$H + NO_2 \rightarrow OH + NO$$

$$k = 1.3 \times 10^{-10} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

All these experiments have been performed with a large excess of initial NO_2 concentrations over initial H concentrations ([OH] ~ 5 to 10×10^{11} molecules cm^{-3}, [NO_2] ~ 5 to 50×10^{12} molecules cm^{-3}) because we noticed a decrease of the slope of the OH decay plot at lower NO_2 concentrations [NO_2] < 2×10^{12}); provided the use of these large NO_2 concentrations, the OH decay plots were insensitive to NO_2 concentrations.

It is well known that the main drawback of the flow tube technique

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

is the uncontrolled influence of wall reactions on the overall kinetics. Concerning the aromatics or related compounds, a few authors have already mentioned the presence of unstable signals; Bonanno *et al.* (ref. 17: O + benzene by ESR and mass spectrometry) report the existence of a steady slow decay of the oxygen atom concentration; also, Knutti and Buhler (ref. 18: H + benzene by mass spectrometry with a Teflon coating), mention the existence of very long stabilization times for benzene signals. On the contrary, these difficulties are not mentioned by a few other authors; for example, neither by Tappe *et al.* (ref. 19: O + various aromatics by mass spectrometry in a clean quartz reactor), Kim *et al.* (ref. 20: H + benzene by ESR and mass spectrometry in a boric acid coated tube), nor Hoyermann *et al.* (ref. 21: H + benzene by mass spectrometry with a quartz tube cleaned with HF). However, a very recent flow tube study of the kinetics of NH_2 with toluene has stressed the importance of the coating of the flow tube (22).

As a consequence, we have paid particular attention to the choice of the flow tube coating. Preliminary experiments with the thick Teflon flow tube used previously (16*b*) gave high and irreproducible values of k_1, larger than the value observed at 760 torr by flash photolysis techniques. We faced a similar situation during our previous experiments devoted to the measurements of the (OH + toluene → products) reaction rate (16*a*). These inconsistencies, already noticed by Le Bras *et al.* in their study of OH + thiophene (23) reaction, led us not to use Teflon. In contrast, coating with widespread halocarbon waxes (24) (either the 12-00 or 15-00 waxes), gave stable and reproducible signals, with low values of k_1 typical of the low pressure range of a fall-off behavior. Also the observed variation of k_1 with pressure (see below) can be fitted with a Troe-type fall-off curve consistent with high pressure measurements (100 to 760 torr) of k_1. This was also true for our previous measurements devoted to (OH + toluene → products) reaction rate measurements (16*a*) with which the present results appear to be self-consistent. We have thus performed all our measurements with the flow tube and the injector coated with halocarbon waxes.

A few experiments have also been performed to measure the rate constant of OH with C_6D_6:

$$OH + C_6D_6 + He \rightarrow \text{products} \qquad k_1'$$

in the following experimental conditions: 1 torr, 353 K. For that purpose, taking into account the very close vapor pressures of C_6H_6 and C_6D_6 (25), a specific experimental protocol is followed to measure the ratio k_1/k_1': a known flow rate of C_6H_6 is first established and the curve ln [OH] versus reaction distance is plotted; then, with all other experimental parameters remaining unchanged, the reservoir of C_6H_6 is changed for a reservoir of C_6D_6. The ratio of the pseudo-first order rate constants is thus a direct measure of k_1/k_1'. Within experimental uncertainty, we find

$$k_1/k_1' = (1 \pm 0.1) \text{ (at 353 K, 1 torr).}$$

Results and discussion

Systematic measurements of k_1 have been performed at two temperatures, room temperature (297 ± 3) K and 353 K; and five pressures (torr): 0.5, 1, 2, 3, 4, ~9.

A few experiments at intermediate temperatures and pressures have been performed to confirm the tendencies established by systematic measurements. The results of the systematic measurements are gathered in Table 1. A few OH decay plots corresponding to variable benzene concentrations are presented in Fig. 2. A few resulting pseudo-first order plots for varying temperature or helium pressure are presented in Fig. 3. Finally, the variation of k_1 as a function of pressure between 0.5 and 9 torr is presented in Figs. 4 (~300 K) and 5 (353 K).

Figures 4 and 5 show that, at both temperatures, the variation of k_1 with pressure exhibits a clear behavior of fall-off

TABLE 1. Averaged values of the rate constant k_1 (in 10^{-13} cm^3 molecule^{-1} s^{-1}) as a function of pressure for two temperatures; to characterize the scatter, the uncertainty is arbitrarily taken as the largest difference k_1 (average) − k_1 (experiment); the number of different experiments in parentheses

P	k_1

9	4.65 ± 1 (2)	5.7 ± 1 (3)

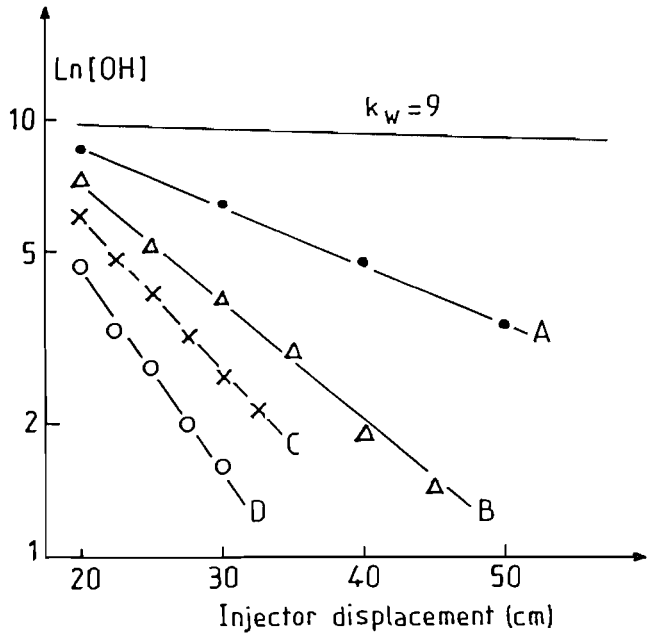

FIG. 2. Examples of a few OH decay plots (ln [OH] versus reaction distance) at 300 K and 1 torr; flow velocity = 1660 cm s^{-1}. Notations as follows: benzene concentration (in 10^{13} molecules cm^{-3}) first order decay rate constant (s^{-1}): *A*, 12.7–55; *B*, 26.9–106; *C*, 38.7–143; *D*, 52.2–182.

range. Moreover, over the whole pressure range covered by the experiments, k_1 exhibits a negative temperature dependency (Table 1), this corresponds to a "negative" activation energy ranging from −0.9 kcal mol^{-1} (at ~9 torr) to −2 kcal mol^{-1} (at 1 torr). These slight negative activation energies are in agreement with the results of Wallington *et al.* (11) and Zetzsch and co-workers (36) but in contrast to literature data by Perry *et al.* (10), Tully *et al.* (4*a*), and Lorenz and Zellner (9).

Derivation of Troe parameters

All our available experimental observations: (*i*) existence of a fall-off behavior, (*ii*) absence of isotope effect, and (*iii*) existence of a slightly negative temperature dependence, suggest that the addition channel (association reaction) should be the dominant one among the following possible channels:
Additional channel, i.e., formation of the stabilized adduct rad-

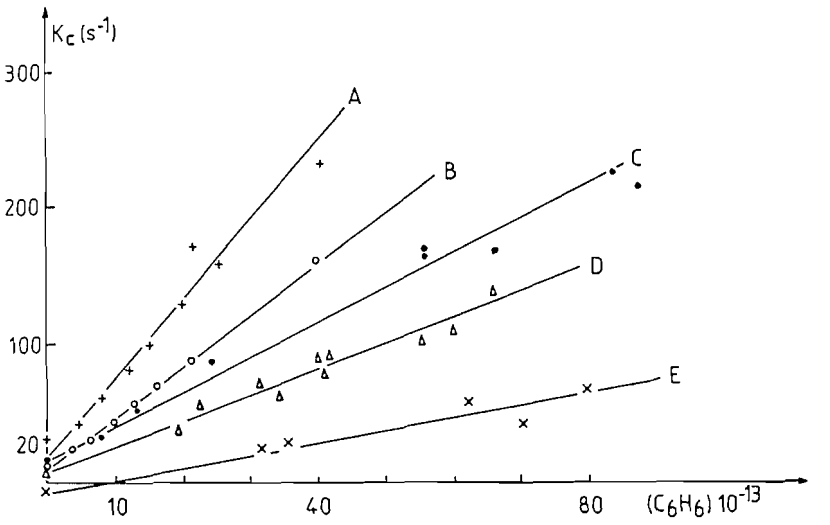

FIG. 3. First-order rate constants versus C_6H_6 concentrations for a few experiments: *A* (297 K, 9.6 torr), *B* (353 K, 4 torr), *C* (328 K, 2 torr), *D* (353 K, 1 torr), *E* (353 K, 0.5 torr).

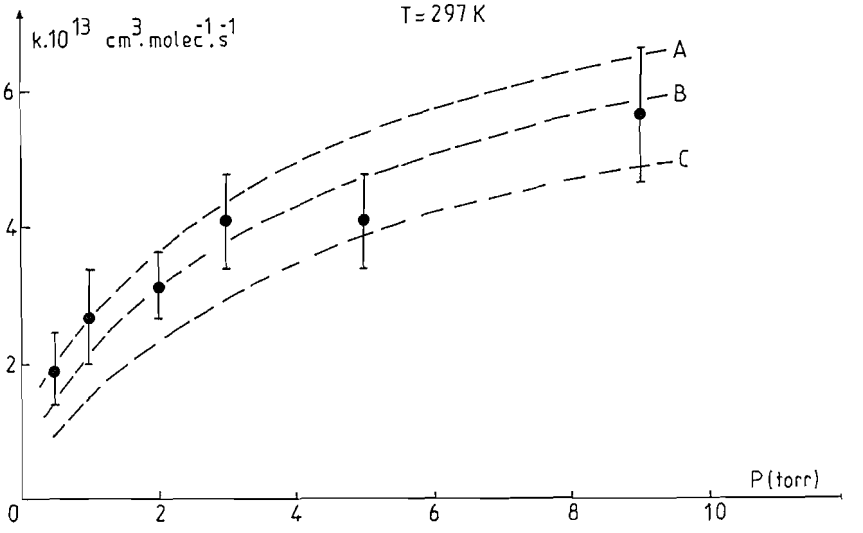

FIG. 4. Experimental results (×) at 297 K. The dotted lines correspond to three Troe theoretical curves with $k_\infty = 10^{-12}$ cm^3 molecule^{-1} s^{-1} and variable k_0 (in 10^{-29} cm^6 molecule^{-1} s^{-1}): *A* ($k_0 = 2.5$), *B* ($k_0 = 1.7$) best fit, *C* ($k_0 = 1$).

ical is

$$OH + C_6H_6\ (+M) \rightleftarrows C_6H_6OH^{\cdot} + (M) \qquad k_{1a},\ k_{-1a}$$

Abstraction channel, i.e. formation of phenyl radical is

$$OH + C_6H_6 \rightarrow C_6H_5^{\cdot} + H_2O \qquad k_{1b}$$

Formation of phenol is

$$OH + C_6H_6 \rightarrow C_6H_5OH + H \qquad k_{1c}$$

Formation of the phenoxy radical is

$$OH + C_6H_6 \rightarrow C_6H_5O^{\cdot} + H_2 \qquad k_{1d}$$

The suggestion ($k_{1a} \gg k_{1b}$, k_{1c}, k_{1d}) is also supported by (*i*) the available thermodynamic data and (*ii*) an extrapolation of the high temperature measurements of k_{1b} to the low temperature range.

(i) Thermochemical data

Figure 6 gathers the known thermochemical data for channels [1*a*] to [1*d*] extracted from reviews (26, 27) or articles by Zetzsch *et al.* (8*b*, *c*) and Manion and Louw (28). Inspection of Fig. 6 shows that the addition channel should be dominant at low temperature.

(ii) Extrapolated data

The extrapolated values of k_{1b} from both high temperature studies (4*a*, *b*)

$$297\ K \cdot k_{1b} = 0.13 \text{ or } 0.16 \times 10^{-13}\ cm^3\ molecule^{-1}\ s^{-1}$$

$$353\ K \cdot k_{1b} = 0.4 \text{ or } 0.52 \times 10^{-13}\ cm^3\ molecule^{-1}\ s^{-1}$$

also confirm the low contribution of the abstraction channel at low temperature (although such a large extrapolated temperature range may be questionable).

The above discussion allows us to compute the Troe parameters k_0 and k_∞ for an association reaction from a fit of our experimental data (k_1 versus pressure) to the following theoretical curve (15):

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

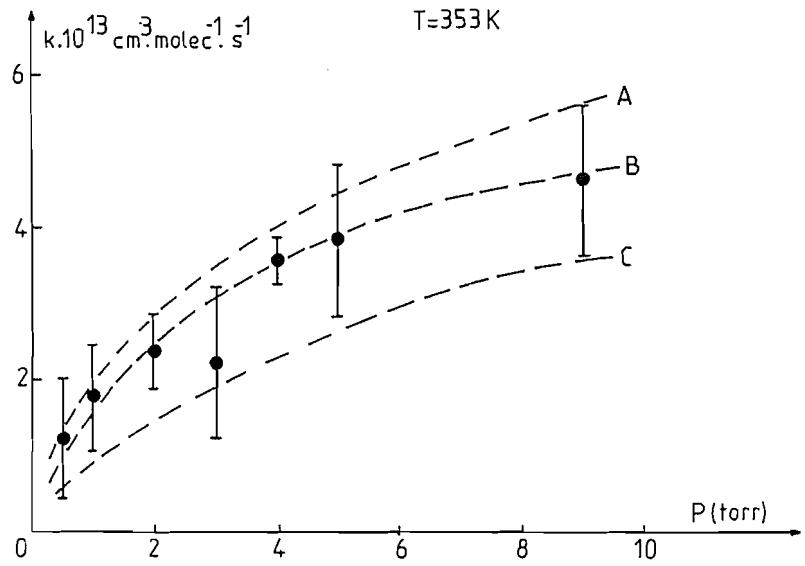

FIG. 5. Experimental results (×) at 353 K. The dotted lines correspond to three Troe theoretical curves with $k_\infty = 10^{-12}$ cm^3 molecule^{-1} s^{-1} and variable k_0 (in 10^{-29} cm^6 molecule^{-2} s^{-1}): *A* ($k_0 = 1.5$), *B* ($k_0 = 1$) best fit, *C* ($k_0 = 0.5$).

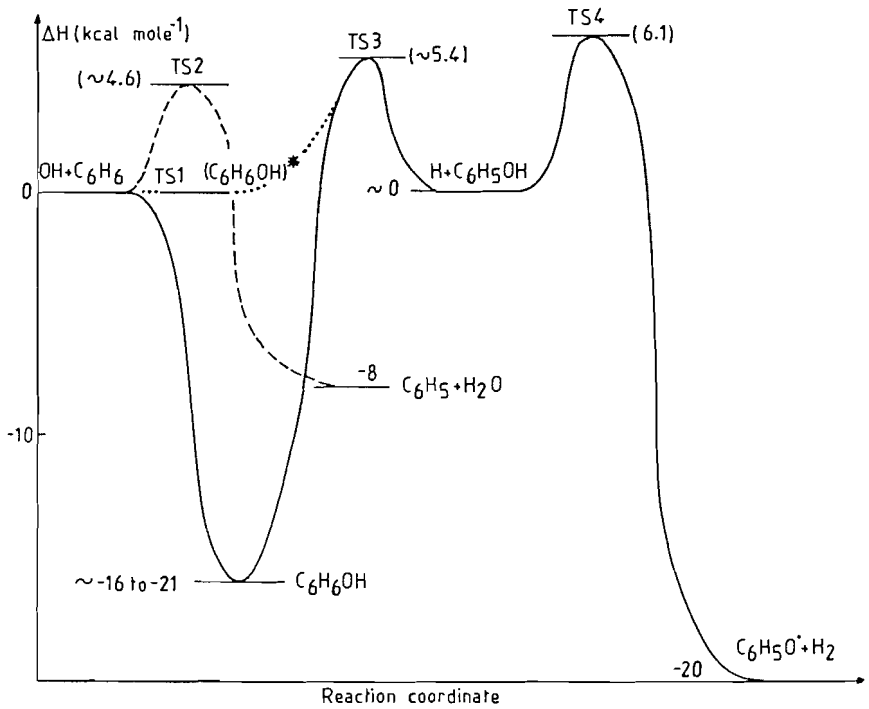

FIG. 6. Probable reaction enthalpies and activation energies of a few reaction paths in the (OH + benzene → products) reaction system.

[5] $$\log k = \log [k_0/(1 + k_0/k_\infty)] + \log \{0.6/\{1 + [\log(k_0/k_\infty)]^2\}\}$$

The following values are derived:
At (297 ± 3) K

$$k_0 = (1.7 \pm 0.5) \times 10^{-29} \text{ cm}^6 \text{ molecule}^{-2} \text{ s}^{-1}$$

$$k_\infty = (10 \pm 2) \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

At 353 K

$$k_0 = (1 \pm 0.2) \times 10^{-29} \text{ cm}^6 \text{ molecule}^{-2} \text{ s}^{-1}$$

$$k_\infty = (10 \pm 1) \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

The corresponding theoretical (predicted) Troe curves are plotted as lines *B* in Figs. 4 and 5 together with experimental data. As a whole, the agreement is good. From our values of k_0 and k_∞ at room temperature, it is possible to derive the value of the rate constant at atmospheric pressure: 9.3×10^{-13} cm^3 molecule^{-1} s^{-1}, which is in reasonable agreement with direct measurements or extrapolations of flash photolysis experiments.

It is interesting to compare our room temperature values of k_0 and k_∞ with those of other authors. With the standard broadening factor $F_c = 0.6$, Zetzsch *et al.* find (in argon) (8*b*):

$$k_0 = 3.02 \times 10^{-29} \text{ cm}^6 \text{ molecule}^{-2} \text{ s}^{-1}$$

$$k_\infty = 1.3 \times 10^{-12} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

With the same fixed value of k_∞ as Zetzsch, Baulch *et al.* (14) compute from a best fit:

$$F_c = 1.1 \qquad k_0 = 4.4 \times 10^{-30} \text{ cm}^6 \text{ molecule}^{-2} \text{ s}^{-1}$$

Since this value of F_c is considered too large, they also compute another k_0 adopting the standard $F_c = 0.6$: $k_0 = 1.36 \times 10^{-29}$ cm^6 molecule^{-2} s^{-1} (14). However, this latter set of parameters exhibits a bad agreement between prediction and experiment, especially at low pressures (below 2 torr). A comparison of the experimental results from both discharge flow experiments (ref. 14 and this work) is plotted in Fig. 7 together with the two best fitted curves according to expression [5].

Role of adduct secondary reactions

As mentioned in the Experimental section, the measurements of k_1 have been purposely performed using large NO_2 concentrations, in the 10^{13} molecules cm^{-3} range, to avoid OH regeneration via reaction [−1a]; this is connected to the expected role of NO_2 as an adduct scavenger:

$$C_6H_6OH + NO_2 \rightarrow \text{products} \qquad k_4$$

since large values of k_4 have been measured (6, 13); two measurements of k_4 are available, one by Zellner *et al.* (6): $k_4 = 0.85 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}, the other by Zetzsch *et al.* (13): $k_4 = 2.7 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}, both at room temperature.

However, to assess the correctness of our measurements and to evaluate k_4, we have performed a series of experiments and the corresponding simulations with a single variable parameter: the NO_2 concentration. An example of such measurements (at 1 torr and 353 K) is presented in Fig. 8. It appears that when $[NO_2]$ decreases from 10^{14} molecules cm^{-3} to ~0 (excess hydrogen atoms), the slope of the OH decay also decreases; a few experiments performed with the NO_2 free method (29) (i.e. when OH is formed by $F + H_2O \rightarrow HF + OH$) are also in agrement with the experiments at low NO_2 concentrations.

The corresponding simulations are based on the following mechanism: Approach to the equilibrium

$$OH + C_6H_6 + (M) \rightleftarrows \text{products} (+M) \qquad k_{1a,-1a}$$

Wall reactions

$$OH \rightarrow \text{products} \qquad k_w$$

$$\text{adduct} \rightarrow \text{products} \qquad k_w'$$

Adduct reactions

$$\text{Adduct} + NO_2 \rightarrow \text{products} \qquad k_4$$

$$\text{Adduct} + NO \rightarrow \text{products} \qquad k_4'$$

Reactant concentrations (C_6H_6, NO_2, NO, OH) and rate constants k_{1a} and k_w are from this work. Other rate constants are chosen as described below:

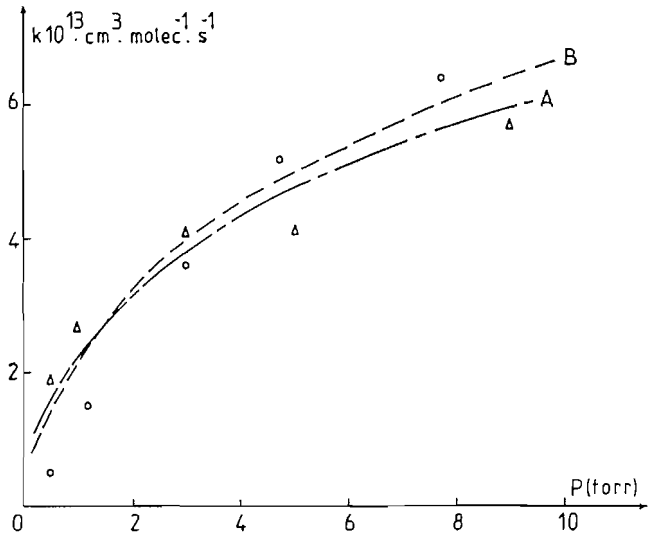

FIG. 7. Comparison of experimental and fitted curves from both discharge flow experiments (ref. 14, and this work). Experimental data: ○, ref. 14; △, this work. Troe fits: *A* (this work), *B* (ref. 14: $k_0 = 1.36 \times 10^{-29}$ cm^6 molecule^{-2} s^{-1}, $k_\infty = 1.4 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}).

(*i*) From the Arrhenius plot established by Zetzsch *et al.* (13) at 100 torr, k_{-1a} increases from ~5 s^{-1} at room temperature to ~300 s^{-1} at 353 K. However, these values of the reverse reaction constant rate are measured in the high pressure range of the fall-off curve (i.e. when k_{1a} and k_{-1a} approach their high pressure limiting values). To deduce the reduced value of k_{-1a} valid at our experimental pressure (1 torr), we have simply computed the following reducing factor from our data concerning the forward reaction: k_{1a} (1 torr)/$k_{1\infty}$; we can thus derive the values of k_{-1a} (at 1 torr) of ~1 s^{-1} at 297 K and ~40 s^{-1} at 353 K. Though the room temperature value of k_{-1a} is entirely negligible, this is no longer true at 353 K.

(*ii*) The value of $k_4' = 0$ remeasured recently after extensive purification of NO has been preferred (13).

(*iii*) The two last rate constants: $k_w' = (60 \pm 20)$ s^{-1} and $k_4 = (4 \pm 2) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} have been estimated from a fit of computed OH decay plots such as presented in Fig. 8; it is worth mentioning that this value of adduct wall recombination ($k_w' = 60$ s^{-1}) is a typical of one for benzyl-type radicals presently studied in the same flow tube (30) or for other adduct radicals (31). A few simulated OH decay curves (at 353 K, 1 torr) are presented in Fig. 8 for varying NO_2 concentrations: the first milliseconds, which reflect the approach to equilibrium, cannot be compared to the experiments since they correspond to the reaction distance between the oven and the center of the fluorescence cell; the end part of the curves is almost strictly exponential with a decay rate constant depending mainly of $[NO_2]$.

The agreement between simulations and experiments (at 353 K) is acceptable. The same kind of behavior has been observed during our previous work devoted to the (OH + toluene → adduct) investigations (16a); also, this is in agreement with the quantitative measurements of Zetzsch *et al.* (8).

It is also worth mentioning that our observations and simulations are quite similar to those presented by the system OH + $CS_2 \rightleftarrows$ adduct in the presence of an adduct reaction with O_2 (32, 33).

On the contrary, at room temperature, due to a much lower value of k_{-1a}, the contribution of reaction [−1a] is negligible

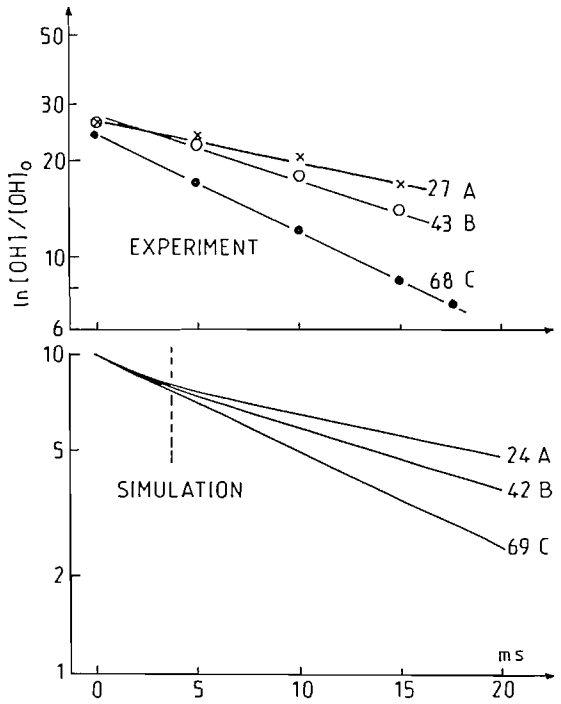

FIG. 8. Examples of experimental (up) and computed (down) OH decay plots. *Experimental data* (concentrations in molecules cm^{-3}): $P = 1$ torr, $T = 353$ K, $[OH] = 6 \times 10^{11}$. Curve *A*: $[C_6H_6] = 3.92 \times 10^{14}$, $[NO_2] = 4.5 \times 10^{13}$; curve *B*: $[C_6H_6] = 3.41 \times 10^{14}$, $[NO_2] = 1.7 \times 10^{12}$; curve *C*: $[C_6H_6] = 2.76 \times 10^{14}$, $[NO_2] = 0$. The numbers on the curves correspond to the measured decay rate (in s^{-1}) *Parameters of the simulation* (see text): concentrations as above, $k_{-1a} = 1.8 \times 10^{-13}$ cm^3 molecule^{-1} s^{-1}, $k_{-1a} = 40\ s^{-1}$, $k_w = 0$, $k_w' = 60\ s^{-1}$, $k_4 = 4 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}, $k_4' = 0$. The first 4 ms (left of dotted line), which correspond to the approach to equilibrium, are not observable (see text); the numbers of the curves correspond to the final exponential decay rate (s^{-1}).

within our reaction times (<40 ms). As shown by Baulch *et al.* (14), even in the absence of NO_2 (excess [H]), the contribution of reaction [−1a] is negligible. Our experiments confirm these expectations.

To conclude, the (fortunate) existence of a high reaction rate: adduct + NO_2 → products, together with our large NO_2 concentrations, explains our apparent discrepancy with flash photolysis non-exponential decays at 353 K.

At room temperature, our experimental results are in reasonable agreement with those of Baulch *et al.* (14), except in the low pressure range (below 2 torr) where we observe larger values. Though such a disagreement is not unusual, the use of excess [H] (over $[NO_2]$) by these authors (D. L. Baulch, private communication), in contrast to our experimental conditions, is one apparent difference. Thus, we tentatively assign the lower rate constants observed in ref. 14 to OH regeneration via the following reaction of the adduct with H atoms:

$$H + C_6H_6OH \rightarrow C_6H_7 + OH$$

Such a reaction is expected to be extremely fast by analogy with the two following closely related reactions of H atoms, which exhibit collision rates: (*i*) with the OH–ethene adduct (ref. 34: $k = 10^{-10}$ cm^3 molecule^{-1} s^{-1}, (*ii*) with the benzyl radical (ref. 35: $k = 5.5 \times 10^{-10}$ cm^3 molecule^{-1} s^{-1}), which is a conjugated radical with very similar spectroscopic properties to cyclohexadienyl type radicals.

Conclusion

The rate of the reaction OH + C_6H_6 + He → products has been investigated by discharge flow resonance fluorescence. From systematic measurements at two temperatures (297 ± 3 and 353 K) in the fall-off range velow 10 torr, the following Troe parameters have been derived (with $F_c = 0.6$):
At (297 ± 3) K

$$k_0 = (1.7 \pm 0.5) \times 10^{-29} \text{ cm}^6 \text{ molecule}^{-2} \text{ s}^{-1}$$

$$k_\infty = (10 \pm 2) \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

At 353 K

$$k_0 = (1 \pm 0.2) \times 10^{-29} \text{ cm}^6 \text{ molecule}^{-2} \text{ s}^{-1}$$

$$k_\infty = (10 \pm 1) \times 10^{-13} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}$$

In agreement with flash photolysis investigations and literature data our results are consistent with the formation of a radical adduct (OH–benzene adduct) as the primary reaction step. At 353 K, the influence of the NO_2 concentration can be rationalized on the basis of a fast reaction with NO_2 of this OH–benzene adduct ($(4 \pm 2) \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}), in good agreement with the recent results of Zetzsch *et al.* (36).

Acknowledgements

We thank D. L. Baulch (University of Leeds, U.K.) for a few discussions and C. Zetzsch and co-workers for both communication and discussion of their recent results (36).

Excess partial molar enthalpies in the water-rich region of the isobutyric acid – water system

WILLIAM W. Y. SIU, TERRANCE Y. H. WONG, LISA C. F. CHAO, AND YOSHIKATA KOGA[1]
Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received June 19, 1990[2]

The excess partial molar enthalpies of isobutyric acid (IBA), H_m^E(IBA), and those of H_2O, $H_m^E(H_2O)$, were measured in aqueous solutions of IBA. The temperature dependence of H_m^E(IBA) at the infinite dilution suggested that the structure enhancement of the solvent H_2O by IBA is weaker than those by *tert*-butanol (TBA) or 2-butoxyethanol (BE). The concentration dependence of H_m^E(IBA), and that of the enthalpic IBA–IBA interaction, $N\{\partial H_m^E(\text{IBA})/\partial n_B\}$, shows that there are two distinct mixing schemes bounded at about $x_B = 0.03$, before reaching the two phase separation. Namely, the IBA–IBA interaction is repulsive below this boundary, while above this boundary it becomes attractive leading eventually to phase separation at a higher concentration. The transition between the two schemes is associated with a peak(negative) anomally in the fourth derivative of the free energy, $N^2\{\partial^2 H_m^E(\text{IBA})/\partial n_B^2\}$.

Key words: excess partial molar enthalpies, isobutyric acid – water, transition in mixing scheme.

WILLIAM W. Y. SIU, TERRANCE Y. H. WONG, LISA C. F. CHAO et YOSHIKATA KOGA. Can. J. Chem. **69**, 1065 (1991).

On a mesuré les enthalpies molaires partielles en excès de l'acide isobutyrique (AIB), H_m^E(AIB), et de l'eau, $H_m^E(H_2O)$, dans des solutions aqueuses d'AIB. La relation entre la température et la valeur de H_m^E(AIB), à dilution infinie, suggère que l'augmentation de la structure du solvant (H_2O) par l'AIB est plus faible que celle provoquée par le *tert*-butanol (ATB) ou par le 2-butoxyéthanol (BE). La relation entre la concentration et la valeur de H_m^E(AIB) ainsi que l'interaction enthalpique AIB–AIB, $N\{\partial H_m^E)\text{AIB})/\partial n_B\}$, démontre que, près de $x_B = 0{,}03$, il existe deux schéma distincts de mélange avant d'atteindre la séparation en deux phases. Au-dessous de la frontière, l'interaction AIB–AIB est répulsive alors qu'au dessus de cette frontière elle devient attractive pour conduire éventuellement à une séparation de phase à une concentration plus élevée. La transition entre les deux schémas est associée à un pic (négatif) anormal dans la quatrième dérivée de l'énergie libre, $N^2\{\partial^2 H_m^E(\text{AIB})/\partial n_B^2\}$.

Mots clés : enthalpies molaires partielles en excès, acide isobutyrique – eau, transition dans le schéma de mélange.

Introduction

We have been directly measuring the excess partial molar enthalpies of aqueous solutions of non-electrolytes (1–6). Such data have provided more direct information on solute–solvent and solute–solute interactions in terms of enthalpy. As part of such continuing efforts, we report the results in the water-rich region of aqueous isobutyric acid (IBA) solutions. The IBA–H_2O system has been an object of various studies (7–12) on its static and dynamic properties near the upper critical solution temperature (UCST). As for thermal measurements, the excess (integral) molar enthalpies, H_m^E, were determined at 27.00°C (13). The data points, however, were spaced out in concentration. Graphical differentiation was therefore not applicable in calculating the partial molar enthalpies, H_m^E(i) (i = IBA or H_2O).

Experimental

The excess partial molar enthalpies, H_m^E(i) (i = IBA or H_2O) were measured by an LKB 8700 Bromma Precision Calorimeter. We used the titration method, the details of which were described elsewhere (3). The only modification is that a Brinkman Dispensette was used instead of a glass burette. Isobutyric acid of Aldrich, 99 + %, Gold Label, was used without further purification. Analytical gas chromatography showed that the actual purity was 99.74%. We also determined the phase separation point visually for six solutions. About 15 mL of a solution was stirred magnetically and was cooled in a water bath at a rate of 0.03 to 0.04°C per minute. The temperature of the water bath was measured by the same glass thermometer used in the thermal measurement. This thermometer had been previously calibrated to ±0.01°C at the ice point and the incongruent melting point of $Na_2SO_4 \cdot 10H_2O$ (38.38°C). The calibration was checked satisfactorily at 20.09°C with the vapour pressure of H_2O.

Results and discussion

The values of H_m^E(i) (i = IBA or H_2O) are listed in Table 1 and plotted in Fig. 1. The uncertainty for H_m^E(IBA) is estimated to be ±0.05 kJ mol^{-1} and that for $H_m^E(H_2O)$, ±0.03 kJ mol^{-1}. The values of the excess (integral) molar enthalpies, H_m^E, are evaluated and plotted in Fig. 2. Since the values of $H_m^E(H_2O)$ are not measured as closely spaced in concentration as those of H_m^E(IBA), a smooth curve is drawn between the points by taking into account of the Gibbs–Duhem relation,

$$(1 - x_B)\{\partial H_m^E(H_2O)/\partial x_B\} + x_B\{\partial H_m^E(\text{IBA})/\partial x_B\} = 0$$

The values of $H_m^E(H_2O)$ on the smooth curve were then used to calculate H_m^E as

$$H_m^E = (1 - x_B)H_m^E(H_2O) + x_B H_m^E(\text{IBA}).$$

The uncertainty in H_m^E is estimated to be ±0.03 kJ mol^{-1}. As shown in Fig. 2, comparison with existing data (13) appears reasonable.

It is surprising that although the sign of H_m^E(IBA) at the infinite dilution is negative, its absolute value is very small in comparison with those for *tert*-butanol (TBA) (1, 3), −17.4 kJ mol^{-1}, and 2-butoxyethanol (BE) (5, 6), −17.0 kJ mol^{-1}. As in the case of TBA and BE, it is likely that IBA molecules also enhance the structure of H_2O. That is to say, the value of H_m^E(IBA) at $X_B = 0$ should consist of an enthalpy gain due to the enhancement of the hydrogen bond network of H_2O and an enthalpy change of an IBA molecule due to breaking bonds from the surrounding IBA molecules in pure liquid followed by forming bonds with the nearest H_2O molecules. The former value for TBA was estimated to be about −10 kJ mol^{-1}. If this value applies to IBA, then the latter effect should be about +8 kJ mol^{-1}, resulting in a measured value of −2 kJ mol^{-1} for

H_m^E(IBA, $x_B = 0$). Since the heats of vapourization are 46.0 kJ mol^{-1} for IBA and 40.7 kJ mol^{-1} for H_2O, the value of +8 kJ mol^{-1} may not be unreasonable as an estimate for an IBA molecule to break out of the pure IBA environment and to form new bonds with the nearest H_2O molecules. However, for the structure enhancement of H_2O due to IBA to be of the same magnitude as for the case of TBA, the value of the excess partial molar heat capacity of IBA, $C_p^E(\text{IBA}) = \partial H_m^E(\text{IBA})/\partial T$, appears too small. Namely, at $x_B = 0$,

$$\Delta H_m^E(\text{IBA})/\Delta T = (-1.55 + 1.70) \times 10^3/(27.0 - 25.0) \approx 75 \text{ J K}^{-1} \text{ mol}^{-1}$$

in comparison with 280 J K^{-1} mol^{-1} for C_p^E(TBA). The latter value was attributed to breaking the enhanced hydrogen bond network on heating. Thus, we conclude that the degree of the structure enhancement of H_2O by IBA is not as large as that by TBA, or BE.

The derivative,

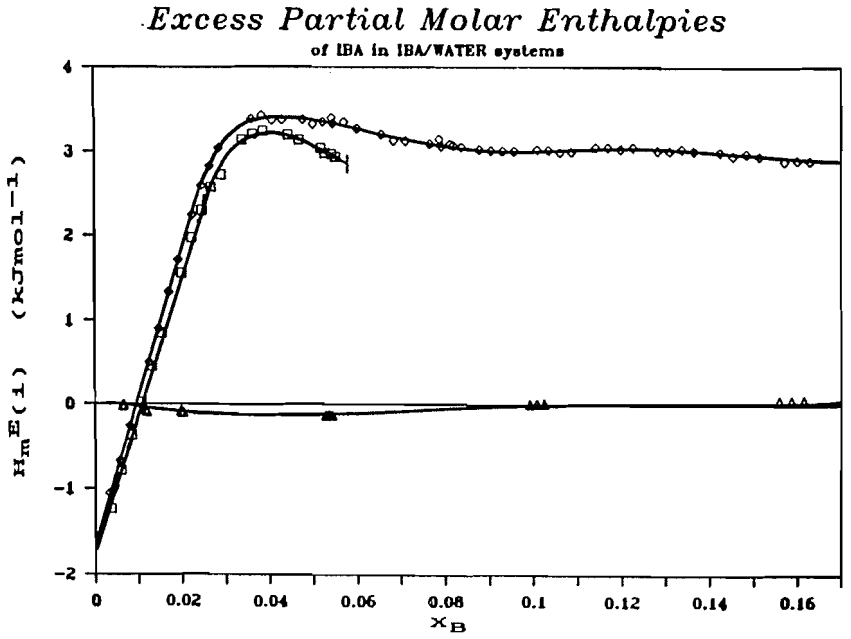

FIG. 1. Plot of excess partial molar enthalpy, $H_m^E(i)$ (i = BE or H_2O), versus x_B: □, i = IBA, 25.00°C; ◇, i = IBA, 27.00°C; △, i = H_2O, 27.00°C.

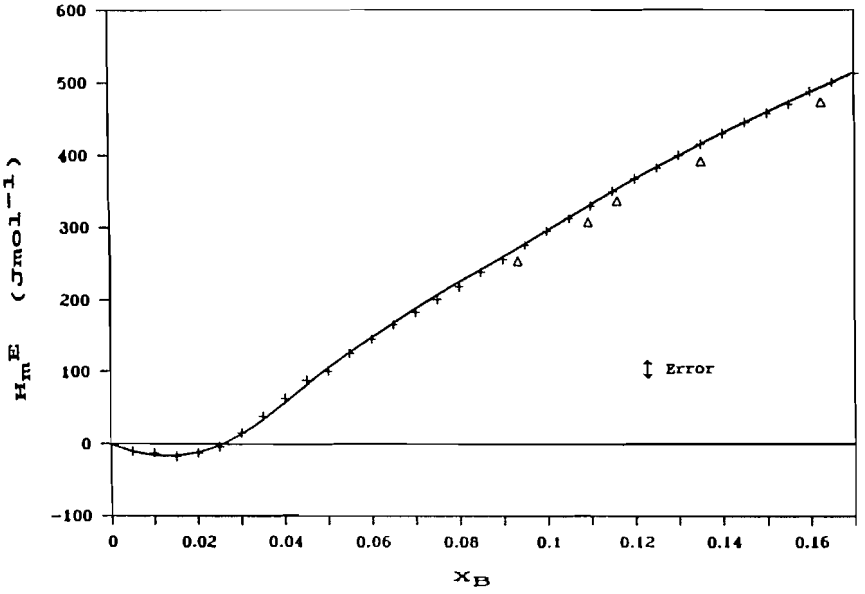

FIG. 2. The excess (integral) molar enthalpies, H_m^E, at 27.00°C: +, this work; △, ref. 13.

$$N\{\partial H_m^E(\text{IBA})/\partial n_B\} = (1 - X_B)\{\partial H_m^E(\text{IBA})/\partial X_B\}$$

are shown in Fig. 3*a*. As has been discussed elsewhere (3, 5, 6, 14–16), this derivative is a measure of IBA–IBA interaction in terms of enthalpy. Figure 3*a* indicates that the enthalpic IBA–IBA interaction is repulsive and stays constant up to $X_B \approx 0.02$. Even at the lowest concentration of measurement, $X_B \approx 0.003$ (one IBA in 300 H_2O molecules), an IBA molecule feels the presence of other IBA in a repulsive manner. This suggests that the IBA–IBA interaction is of a long range nature. Such a long range interaction may be operative via the hydrogen bond network of the solvent water. Indeed, it has been suggested that the portion of the hydrogen bond intact in liquid H_2O is above the percolation threshold (17–19). Thus, on average, a molecule of H_2O is connected to others in the entire bulk via hydrogen bonds.

For the range, $X_B > 0.03$, the enthalpic IBA–IBA interaction becomes attractive and stays constant until the system hits the two phase separation, at $x_B = 0.058$ and 25.00°C. The fact that the derivative of H_m^E(IBA) is negative near the UCST is a natural consequence of the stability criterion (22, 23). The stability criterion for a binary system, $(\partial^2 G_m/\partial x_B^2) \geq 0$, leads to $(\partial^2 H_m^E/\partial x_B^2) \leq 0$ near the UCST. Note that

$$(\partial H_m^E(\text{IBA})/\partial x_B) = (1 - x_B)(\partial^2 H_m^E/\partial x_B^2)$$

At 27.00°C, about 0.3°C above the highest UCST reported in literature (8), the values of H_m^E(IBA) appear to become constant in the range $0.09 < x_B < 0.12$, very close to the UCST. Indeed, a recent analysis, using a scaling law, of the cyclohexane–methanol system suggested $(\partial^2 H_m^E/\partial x_B^2) = 0$ at the critical point (24). While the uncertainty prevents the unequi-

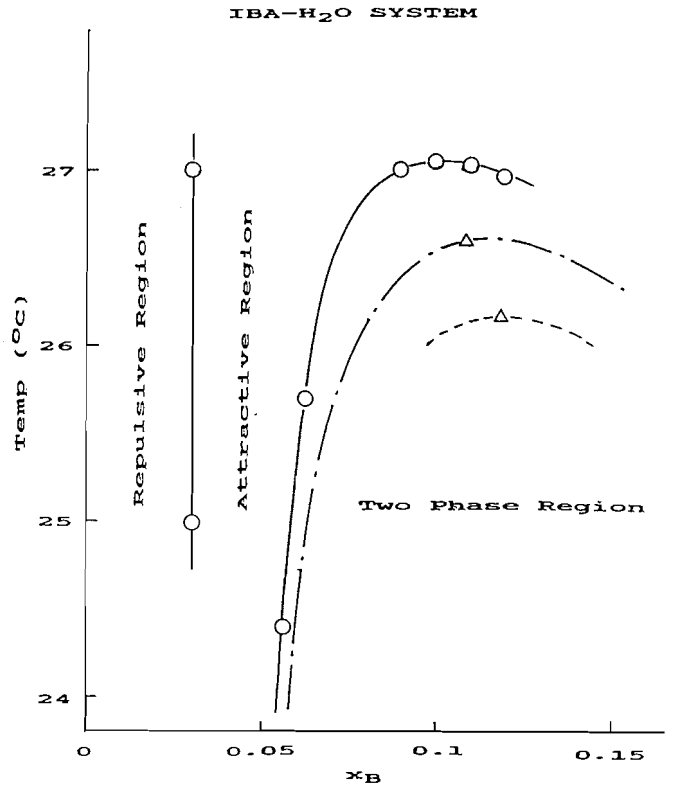

FIG. 4. Mixing scheme/phase diagram: ○, —, this work; ·····, ref. 8; -----, ref. 21; △, reported critical points.

vocal conclusion that the derivative of H_m^E(IBA) with respect to x_B is indeed zero, it was suggested by a referee to check the UCST for the present particular solutions. This suggestion was appropriate since impurities tend to alter the critical point as shown in a detailed study on the triethylamine–H_2O system (20).

The observed phase separation points, together with some literature values, are shown in Fig. 4 (8, 21). Since our method is based on visual observation in a cooling mode, the determined phase separation points may be lower bound values. In particular, for x_B = 0.0965, 0.1082, and 0.1183, i.e. near the presumed critical point, the effect of critical opalescence was so strong that the transition point was hard to pin-point. Furthermore, there should also be the effect of critical slowing-down present. Therefore, these three points must indeed be lower bound estimates. It is not our purpose to focus on the critical point and the possible effects of the various impurities. It suffices to note that for the present particular solutions the system is in two phase in the range $0.09 < x_B < 0.12$ at 27.00°C. Thus the values of H_m^E(IBA) appear to stay constant as shown in Fig. 1.

Our main focus is the transition in mixing scheme. The IBA–IBA interaction changes from a repulsive to an attractive mode at about x_B = 0.03. This crossover, however, does not seem as drastic as those for TBA (3, 14, 15) and BE (5, 6, 16). In other works, the enthalpic solute–solute interaction,

$$N\{\partial H_m^E(\text{IBA})/\partial n_B\}$$

the third derivative of the free energy, does not show any anomaly in contrast to the TBA and BE cases. Rather, the derivative once more with respect to n_B, $N^2\{\partial^2 H_m^E(\text{IBA})/\partial n_B^2\}$, the fourth derivative, shows a peak (negative) anomaly as shown in Fig. 3*b*. Thus the crossover from low concentration to high concentration mixing scheme in the IBA–H_2O system is qualitatively more subtle than those in the TBA–H_2O (3, 14, 15) and BE–H_2O (5, 6, 16) systems. This must be related to the apparent weakness of the effect of the solvent IBA on the structure of H_2O as discussed above. This boundary for the transition in mixing scheme is shown in Fig. 4.

While a more detailed and conclusive discussion must await the data of the excess partial molar entropies, S_m^E(i) (i = IBA or H_2O), it is safe to say that there are two mixing schemes present bounded at about x_B = 0.03 below the two phase separation.

Vibrational and electronic spectra of new liposoluble metalloporphyrins in a nonpolar noncoordinating solvent

MICHEL RINGUET,[1] DENIS GIRARD, AND CAMILLE CHAPADOS

Département de Chimie-biologie, Université du Québec à Trois-Rivières, Trois-Rivières, Qué., Canada G9A 5H7

Received September 5, 1990[2]

MICHEL RINGUET, DENIS GIRARD, and CAMILLE CHAPADOS. Can. J. Chem. **69**, 1070 (1991).

A new liposoluble porphyrin, 2,7,12,17-tetrahexyl-3,8,13,18-tetramethylporphin (THTMP), and its complexes with divalent (Mg, Co, Ni, Cu, Zn, Cd, Hg) and trivalent (Mn, Fe) metals have been synthesized. The electronic, infrared, and far-infrared spectra of these compounds were obtained in the same nonpolar, noncoordinating solvent, CCl_4. After comparison with the experimental data and the results of normal coordinate analyses from the literature, the assignment of the vibrational bands of THTMP and its complexes is made. Some correlations between the shifts of the metal sensitive bands in the diffferent regions and the structural characteristics of the porphyrin complexes are reported. Some emphasis is made on the magnesium complex in relation to chlorophyll.

Key words: Metalloporphyrin, porphyrin, infrared spectroscopy, far-infrared spectroscopy, electronic spectroscopy, nitrogen–metal bond, covalent radius, reduced mass.

MICHEL RINGUET, DENIS GIRARD et CAMILLE CHAPADOS. Can. J. Chem. **69**, 1070 (1991).

On présente la synthèse d'une nouvelle porphyrine liposoluble, la tétrahexyl-2,7,12,17 tétraméthyl-3,8,13,18 porphine (THTMP), et de ses complexes de métaux bivalents (Mg, Co, Ni, Cu, Zn, Cd, Hg) et trivalents (Mn, Fe). On a obtenu les spectres électroniques, dans l'infrarouge et dans l'infrarouge lointain, de ces substances en solution dans un même solvant non polaire et non coordonnant, le CCl_4. Les bandes vibrationnelles sont attribuées à la suite de comparaisons avec les spectres et les résultats d'analyses de coordonnées normales déjà publiés. On établit des corrélations entre les déplacements des bandes influencées par le métal dans les différentes régions spectrales et diverses caractéristiques physicochimiques des métalloporphyrines. On porte une attention particulière aux spectres de la porphyrine de magnésium en regard des spectres de la chlorophylle.

Mots clés : métalloporphyrine, porphyrine, spectroscopie infrarouge, spectroscopie dans l'infrarouge lointain, spectroscopie électronique, liaison azote–métal, rayon covalent, masse réduite.

Introduction

The studies of the absorption spectra shown by natural porphyrin–type pigments like the chlorophylls, heme, and their derivatives have led to a better understanding of the nature of the electronic transitions in these chromophores (1, 2). Studies on synthetic metalloporphyrins allowed a theoretical explanation of typical (3) and atypical (4) absorption spectra. Systematic experiments with a series of metalloporphyrins were done to determine the influence of the metal on the electronic structure of these pigments (5–7).

The Raman spectroscopy of the metalloporphyrins is an active field mostly because resonance Raman (RR) is facilitated by the availability of lasers whose emission wavelength coincide with the absorption bands of the metalloporphyrins (8, 9).

Infrared spectroscopy of the porphyrins is also studied intensively. Spectra of natural (10) and synthetic (11–17) metalloporphyrins were obtained which led to the assignment of almost all the 24 infrared active vibrational bands (18 E_u in-plane and 6 A_{2u} out-of-plane skeletal modes) of the porphin ring. Correlations between selected vibrational bands and various properties of the complexes were reported (18).

Normal coordinate analyses (9, 14, 19–22) on isotopic compounds have confirmed unequivocal assignment of most of the bands while the other bands have contradictory assignment. Willems and Bocian (23), in a RR study of nickel–formyldeuteroporphyrin, showed the difficulty of choosing the right assignment.

Unequivocal attribution of the ir bands of metalloporphyrins is complicated by the intense coupling between different vibrational modes and because the data reported so far were collected with porphyrins of different symmetry and in different media. Moreover, in the RR studies, excitation beams at different wavelengths give spectra with different intensity profile (22*b*). The crystal polymorphism, shown by metalloporphyrins of small-size metal ion such as Ni^{2+} and perhaps Co^{2+}, brings additional complication to the spectra which, according to Alden *et al.*, may have resulted in false interpretation of the normal coordinate analyses (24).

To solve the problem of comparing the data given by nonidentical substrates, numerous works were done on octaethylporphin (OEP) and its metal complexes. However, these compounds are not very soluble in nonpolar, noncoordinating solvent. KBr matrices, which were used in almost all previous ir studies, showed some interaction between the matrice and the porphyrin. The Nujol mull technique, used to obtain the far-infrared spectra, showed aggregation. The results obtained with these techniques could be misleading and, indeed, Katz *et al.* showed that the infrared spectra of chlorophyll, a Mg–porphyrin type compound, were strongly dependent on the aggregation states (25). These authors noticed that the spectra of porphyrins in solution, although difficult to obtain, gave sharper bands than with solids. These observations were verified in our laboratories (26).

The purpose of this work is to report (*1*) the synthesis of metalloporphyrin complexes soluble in nonpolar organic solvent and (2) their spectroscopic data obtained over a broad spectral range (visible, infrared, and far-infrared regions) in CCl_4 solutions. The use of the same noncoordinating solvent facilitates the comparison of the displacements of the bands in different spectral regions which the other studies could not do.

To achieve this goal, we synthesized a new liposoluble porphyrin, 2,7,12,17-tetrahexyl-3,8,13,18-tetramethylporphin (THTMP). This porphyrin has eight peripheral pyrrole carbons bonded to alkyl groups in a four-fold symmetry arrangement. These structural characteristics allow comparison with similar

natural porphyrins. THTMP was complexed with the bivalent cations of Co, Ni, Cu, Zn, Cd, and Hg to obtain two series in the periodic table, one within a period and the other within a group. The Mg complex was synthesized in order that we may compare its spectra with those of chlorophyll. The trivalent complexes of Mn and Fe, as chlorides, were made to complement the series with substrates giving atypical absorption spectra. Visible (300–700 nm), infrared (4000–500 cm^{-1}), and far-infrared (500–62 cm^{-1}) absorption spectra of solutions of these metalloporphyrins in CCl_4 were obtained and critically compared with the spectra of similar complexes found in the literature. The metal-sensitive bands are identified and the shifts of these bands are related to structural and chemical parameters of the complexes. This study complements our previous work on the aggregation and ionization states of surfactant porphyrins (27, 28).

Experimental

Synthesis

THTMP was made by a modified version of the method of Smith and Bisset for the synthesis of alkyl-substituted porphyrins (29).

2-Carboxybenzyl-3,5-dimethyl-4-hexylpyrrole

A mixture of 1-iodohexane (10 g), 2,4-pentanedione (7.1 g), and potassium carbonate (10 g) in dry acetone (10 mL) was refluxed under nitrogen for 24 h. Filtration of the reaction mixture and distillation under reduced pressure gave 3-hexyl-2,4-pentanedione (5.2 g, 60%).

A solution of sodium nitrite (8.5 g) in water (20 mL) was slowly added to a stirred solution of benzylacetoacetate (20 mL) in glacial acetic acid (40 mL), maintained below 10°C. The mixture was left in the dark and under nitrogen for 12 h, extracted with ether and evaporated to give benzylacetoacetate-oxime (22 g, 86%).

A mixture of 3-hexyl-2,4-pentanedione (3.0 mL) and benzylacetoacetate-oxime (12.0 mL) in glacial acetic acid (20 mL) was heated at 70°C and zinc powder (1.4 g) was slowly added. The solution was heated to boiling for 1 h, cooled, and poured over ice. The product was collected by filtration and recrystallized in methanol to give 2-carboxybenzyl-3,5-dimethyl-4-hexylpyrrole (1.35 g, 60%), mp 61–62°C; ν_{KBr}: 3320, 3045, 2960, 2920, 2850, 1670, 1585, 1500, 1265, 1085; ^1H $\partial(CDCl_3)$: 0.85 (t, 3H, CH_3CH_2—), 1.28 (m, 8H, 4 CH_2), 2.13 (s, 3H, CH_3-5), 2.27 (s, 3H, CH_3-3), 5.27 (s, 2H, CH_2—benzyl), 5.33 (s, 5H, arom.). *Anal.* calcd for $C_{20}H_{27}NO_2$: C 76.64, H 8.68, N 4.47; found: C 76.39, H 8.56, N 4.57.

2,7,12,17-Tetrahexyl-3,8,13,18-tetramethylporphin (THTMP)

2-Carboxybenzyl-3,5-dimethyl-4-hexylpyrrole (2.5 g) was dissolved in tetrahydrofuran (50 mL) and triethylamine (0.05 mL). Pd (10%) on charcoal (250 mg) was added to the solution which was hydrogenated at 162 kPa for 1 h. The mixture was filtrated over celite and evaporated under reduced pressure. The resulting oil was dissolved in glacial acetic acid (6.5 mL) and bromine (1.6 mL) was added dropwise. The mixture was stirred for 15 h. The sample was evaporated under reduced pressure, diluted with toluene, evaporated, diluted with cold ether, and filtrated. The orange solid obtained (dipyrromethenes) was dissolved in boiling formic acid (8.5 mL) and refluxed for 3 h. After cooling, the reaction mixture was diluted with water and extracted with chloroform. The extract was washed with water and with a saturated sodium bicarbonate solution, dried, and evaporated. The residue was column chromatographed on deactivated silica gel to afford THTMP which was recrystallized from $CHCl_3$:CH_3OH (355 mg, 25%), mp 132–133°C; ν_{KBr}: 3310, 2951, 2924, 2866, 2852, 1674, 1465, 1458, 678; ^1H $\partial(CDCl_3)$: −3.88 (s, 2H, NH), 1.1 (t, 12H, 4 CH_3-6′), 2.30 (t, 8H, 4 CH_2-2′), 3.52 (s, 12H, 4 CH_3-3,8,13,18), 3.79 (t, 8H, 4 CH_2-1′), 9.88 (s, 4H, meso). *Anal.* calcd. for $C_{48}H_{70}N_4$: C 81.99, H 10.04, N 7.97, found: C 81.71, H 10.22, N 7.54.

The metal complexes were prepared using four different methods. (*1*) The complexes of Mn, Fe, Co, Ni, Cu, and Zn were obtained by incorporating the metals from the corresponding salts ($MnCl_2$, $FeSO_4$, $Co(OAc)_2$, $Ni(OAc)_2$, $Cu(OAc)_2$, $Zn(OAc)_2$) by the acetate method (30). The Mn and Fe complexes were treated with air and HCl to allow oxidation and formation of chlorides. (*2*) The Mg complex was obtained by the reaction of propioxymagnesium bromide on THTMP at 70–75°C (31). (*3*) The Cd complex was obtained by refluxing a mixture of $Cd(OAc)_2$ and THTMP in benzene:DMF 3:4 for 5 h. (*4*) The Hg complex was obtained by refluxing $Hg(OAc)_2$ and THTMP in pyridine for 2 h. MgTHTMP was chromatographed on basic alumina. The other samples were recrystallized in the solvent systems indicated below. All the samples were dried in a vacuum dessicator over $CaCl_2$. From THTMP, the yields are MgTHTMP, 56%; MnTHTMPCl, 97%; FeTHTMPCl, 98%; CoTHTMP, 95%; NiTHTMP, 95%; CuTHTMP, 98%; ZnTHTMP, 85%; CdTHTMP, 70%; HgTHTMP, 35%.

Elemental analyses were made by Guelph Chemical Lab., Guelph, Ont., and showed that the substances were pure and anhydrous. MgTHTMP, mp 155–157°C. *Anal.* calcd. for $C_{48}H_{68}N_4Mg$: C 79.75, H 9.60, N 7.68; found: C 79.48, H 9.45, N 7.72. Spectrum recording

The absorption spectra were obtained from solutions of the porphyrins in spectrograde CCl_4 (Anachemia Chemicals; water <0.01%) at a concentration of 1×10^{-5} M. The spectra were recorded on a Perkin-Elmer IF553 spectrophotometer with a resolution of 1 nm. Two spectra were recorded for each sample; the spectral data were transferred to a computer (Cyber 174, from Control Data Co.) where the averages of the original spectra were made to give the figures in this paper. Spectra of 1×10^{-2} M solutions were also obtained; these were identical to the ones obtained with the 1×10^{-5} M solutions.

The vibrational spectra were obtained in the same solvent at a concentration of 1×10^{-2} M. KBr cells of 1 mm pathlength were used in the 4000–400 cm^{-1} region and high-density polyethylene cells of 5 mm pathlength were used in the 400–62 cm^{-1} region. The spectra were recorded on a Perkin-Elmer model 180 spectrophotometer with a resolution of 2 cm^{-1} in the 4000–400 cm^{-1} region and of 3 cm^{-1} in the 400–62 cm^{-1} region. The calibration was made with water vapor, ammonia, and carbon dioxide. The precision of the bands was better than 1 cm^{-1}. Compensation of the solvent bands was excellent except in two regions: 810–730 and 325–300 cm^{-1}. Three spectra were recorded for each sample, except for CoTHTMP whose spectrum varied with time. The averaging of the spectra, calibration and subtraction of the background were made with the Cyber 174 computer to give the figures presented in this paper.

The product–moment correlation coefficients (r) were obtained from standard statistical calculation of regression analysis (32). All data were plotted to ensure that a straight-line relationship had not been wrongly deduced.

Results and discussion

Synthesis

THTMP was obtained with an overall yield of 8% from the reagents 2,4-pentanedione and benzylacetoacetate. This result

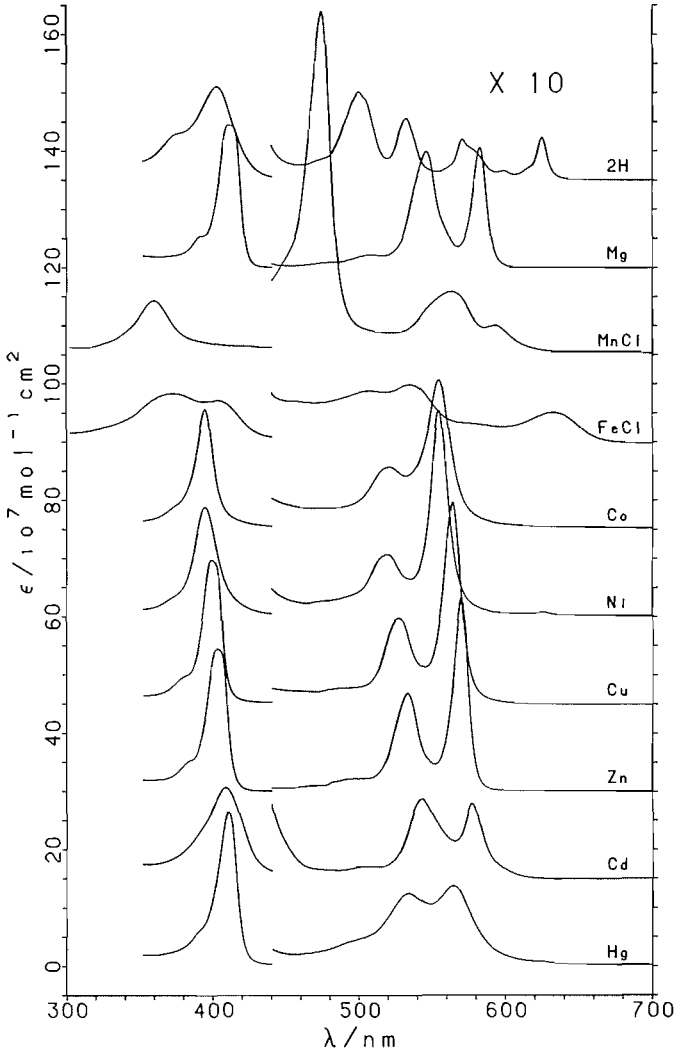

FIG. 1. Electronic spectra of THTMP and its metal complexes. Note the change of scale at 450 nm.

is comparable to the 4% overall yield obtained by Smith and Bisset (29) for some other hydrocarbon-soluble porphyrins. THTMP and its metal complexes were both crystalline and liposoluble (up to 1×10^{-2} M solution in CCl_4), which were the general characteristics required for the spectroscopic studies of pure compounds.

Spectroscopy

The UV–visible, infrared, and far-infrared spectra of free base THTMP and its metal complexes with Mg^{2+}, Mn^{3+}, Fe^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, and Hg^{2+} are shown in Figs. 1, 2, and 3, respectively. The structural formula of the metal complexes of THTMP and OEP (OEP = 2,3,7,8,12,13,17,18-octaethylporphin), including the symbols used to identify the carbon atoms of the porphin ring and the side-chains, are given in Fig. 4.

Within the series (Co, Ni, Cu, and Zn) of normal absorption spectra (1), the spectral shifts of the Soret, B(0,0), and the visible Q(0,0) and Q(1,0) bands of THTMP complexes are similar to those normally observed for porphyrins (33). For the ir work, the principal vibrational absorption bands with their assignments for THTMP and its metal complexes are given in Table 1. The assignments given in this table are based on experimental studies (10, 12) and normal coordinate analyses (9, 21, 22) made on similar porphyrins. For some unequivocally assigned bands, a difference of 5 to 10 cm^{-1} is often found between the positions observed for THTMP and its metal complexes and those reported for OEP and its complexes. These shifts are mostly due to a mass effect by the substituents since the shifts caused by solvents are less than 3 cm^{-1}. For some other bands, the differences between our data and those in the literature are greater than 10 cm^{-1}. In the following, we look closely at these bands. We will also identify the regions of the spectrum which are significantly modified by a change of the complexed metal.

Infrared region

The in-plane N—H deformation mode of the free base should be observed near 1220 cm^{-1} (20*a*). However, an intense C_m—H deformation band is found in this region which prevents the observation of the N—H band. In the spectrum of PP (PP = protoporphyrin IX dimethylester) (10), a band is observed at 1418 cm^{-1} and a similar one is observed at 1412 cm^{-1} for OEP (12). These bands as well as the band observed at 1407 cm^{-1} in the spectrum of THTMP (Fig. 2, Table 1) disappear in the corresponding metalloporphyrins. The transformation of the ir active modes of the free base into degenerate e_u modes in metalloporphyrins could be the cause of the disappearance of these bands.

A strong band observed at 1146 cm^{-1} was assigned by Ogoshi *et al.* (12) to the C_b—H and C_m—H out-of-plane deformations coupled with C_a—C_m stretching. Gladkov and Solovyov assigned this band to C_b—C_{let} coupled with C_b—C_a, C_a—N, and side-chain vibrations (20*b*, 21). This band, which is not metal dependant, is also observed in the spectrum of THTMP (Fig. 2, Table 1) which has no C_b—H group. These observations support the assignment of this band to the C_b—C_{1hex} stretching mode.

Only one C_m—H stretching band should be observed for the metalloporphyrins in the 3200 to 3000 cm^{-1} region (9, 22, 24). However, for the THTMP complexes, two or three bands are observed near 3210, 3170, and 3060 cm^{-1}. The position and intensity of these bands are sensitive to a change of metal. According to normal coordinate analyses (19*b*, 21, 22*b*), the lower frequency band should be assigned to the C_m—H stretching mode. The other bands are combination bands.

The band in the 1689–1674 cm^{-1} region is found too high to be assigned to the C=C, C=N stretching vibrations (9, 19*b*). Indeed, this band is assigned to a harmonic of the metal-sensitive C_m—H deformation band observed in the 844–836 cm^{-1} region. The bands assigned to the C=C, C=N, E_u skeletal modes of the porphyrins are situated between 1630 and 1400 cm^{-1} (19*b*, 22*b*). The bands observed at 1610 and 1505 cm^{-1} for THTMP are assigned to the vibrations of these groups. Some other components of these vibrations are possibly burried under the strong 1460 cm^{-1} C—H deformation bands. Because of symmetry modification, the 1610 and 1505 cm^{-1} bands almost disappear in the spectra of the metal complexes of THTMP.

Abe *et al.* assigned the band observed in the 1111–1104 cm^{-1} region to C_b—C_{let} and C_b—C_a stretching vibrations of OEP (19). On the contrary, Spiro *et al.* (9), Li *et al.* (22) and Gladkov and Solovyov (21) assigned this band to C_b—C_{let}—H and C_{let}—C_{2et}—H deformation modes coupled with C_a—N stretching of OEP. However, the spectra of the unsubstituted porphin and its metal complexes do not show a band in this region (14, 20, 22a).

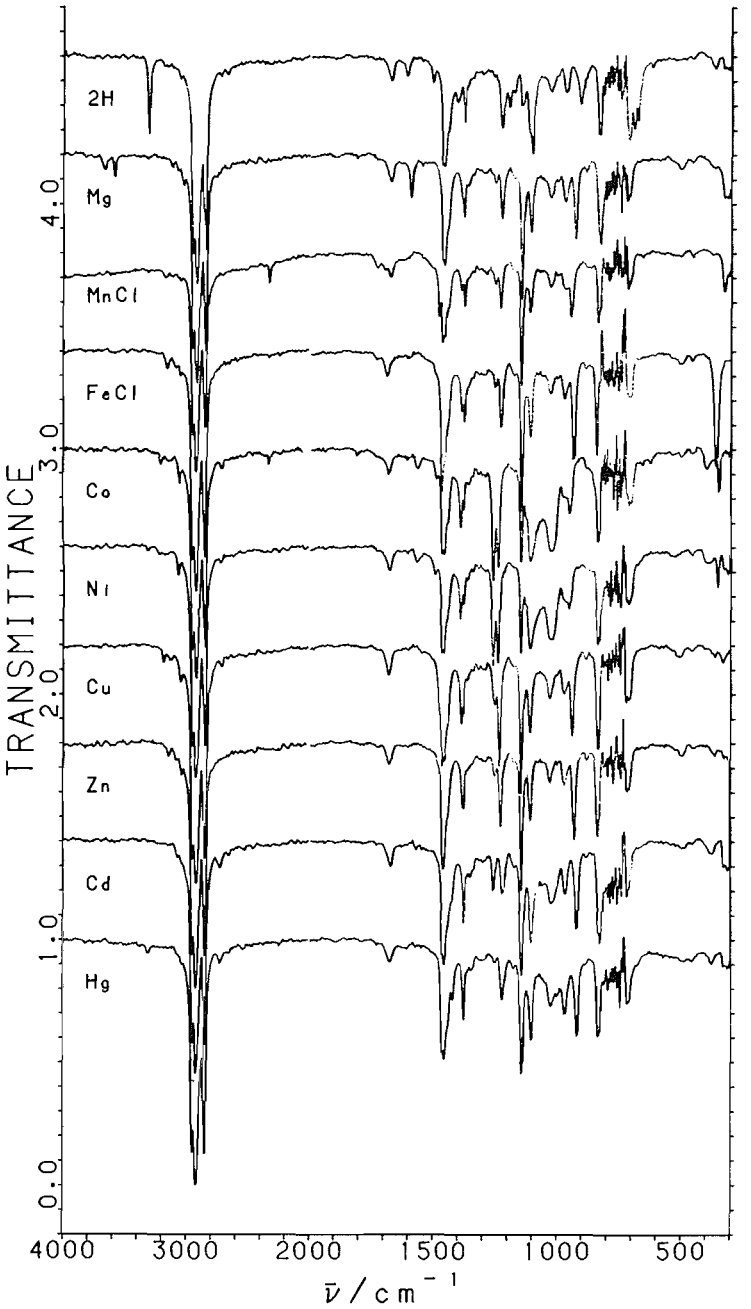

FIG. 2. Infrared spectra of THTMP and its metal complexes. The strong absorption by CCl_4 obscures the 810–730 cm^{-1} region.

Accordingly, the band near 1108 cm^{-1} cannot be assigned to pure C_b—C_a and C_a—N stretching vibrations. Since the position of the band is too high for C—C—H out-of-plane deformations, the bands found in the 1111–1104 cm^{-1} region are assigned to stretch vibrations of C_b—C_{1hex}, C_b—C_{1me}, and C—C of the side-chains.

Far-infrared region

Few data are available in the far-infrared region for the porphyrins. Moreover, the assignment of the N–metal vibrations in heme proteins and chlorophylls are not completely resolved (9, 34, 35). Therefore, there is a need for a study of simpler metalloporphyrins in the far-infrared (22*c*).

The metal-sensitive bands of THTMP complexes are observed in the 402–364, 354–192, and 226–101 cm^{-1} regions. Following the literature (9, 19*b*, 22*c*), the bands in the 354–192 cm^{-1} region are assigned to the N—metal out-of-plane stretch coupled with an out-of-plane deformation mode of the ring. Indeed, the band observed at 354 cm^{-1} for NiTHTMP corresponds to the position (351 cm^{-1}) calculated for the A_{2u} mode of NiOEP (9, 22*c*). The Mn—Cl and Fe—Cl stretching modes of the trivalent metal complexes are observed at 333 and 363 cm^{-1}, respectively. The assignments of the far-infrared bands will be discussed below where the spectra of the synthetic and the natural porphyrins are compared.

The bands observed in the 402–364 cm^{-1} region have not been definitely assigned in the literature. The intensities of these bands vary considerably with the metal. Since the intensity of

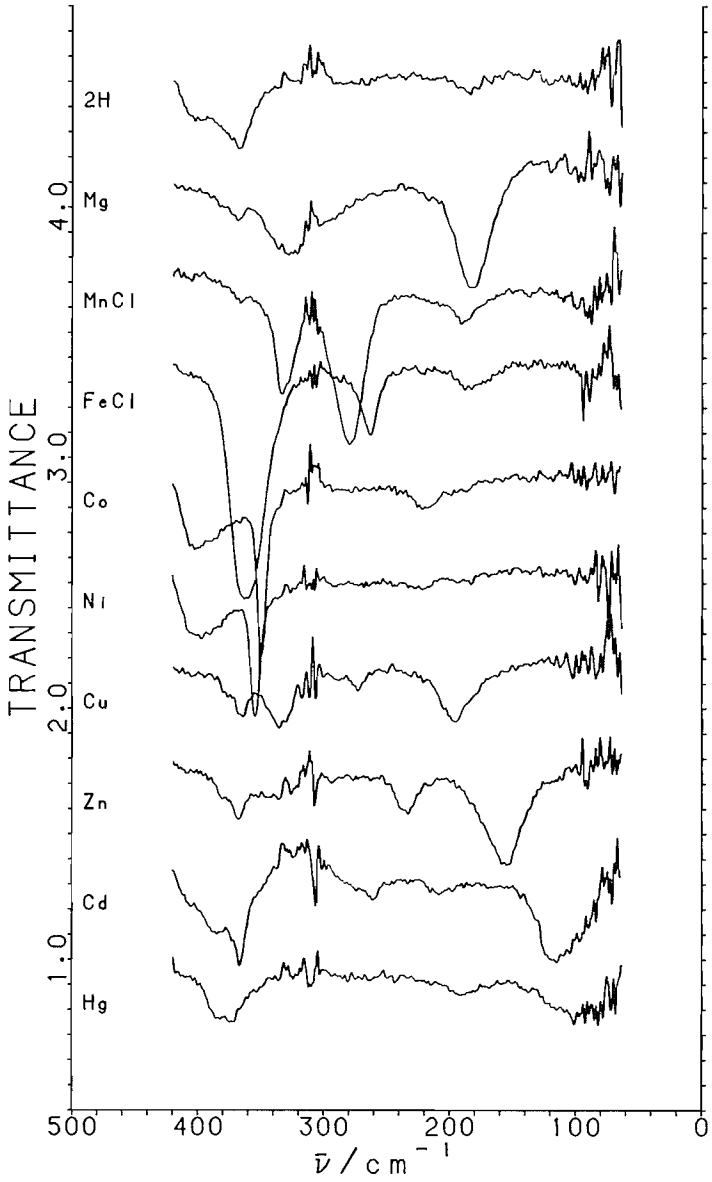

FIG. 3. Far-infrared spectra of THTMP and its metal complexes. The strong absorption by CCl_4 obscures the 325–300 cm^{-1} region.

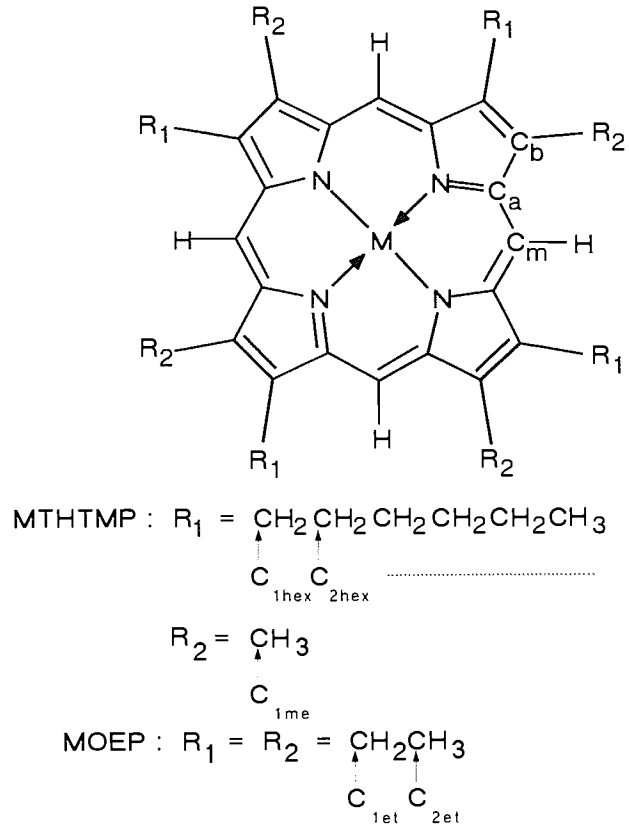

FIG. 4. Structural formulae of the metal complexes of THTMP and OEP with symbol identification of carbons.

the ir bands are related to a variation in the dipole moment derivatives and since only the central metal is varied in the porphyrins studied, the central metal affects the dipole moment derivative related to these far-infrared bands. Further studies are needed to understand this relationship.

Band shift/parameter correlations

Some correlations have been made between electronic and structural properties of metalloporphyrins and the positions of specific bands of their resonance Raman and their electronic spectra (6, 7, 12–14, 16, 31, 36–41). Similar relationships are observed between spectral shifts of ir bands and the following structural parameters: (*a*) the strength of the N—metal bond (13, 14); (*b*) the number of *d* electrons on the metal (16); (*c*) the center-to-nitrogen distance or core size (7, 35, 39–41); (*d*) the stability of the complexes (38); (*e*) the spectral shifts in the UV–vis region (7, 12, 42). The correlation factors between the ir displacement and the parameters mentioned are seldom greater than 0.9 even when the series of complexes are restricted to the ones formed with the elements of one single group or with the elements of a period in the periodic table. None of these correlations were made with far-infrared bands.

The correlations that we present here refer to the metal complexes of THTMP which show a typical electronic spectrum: Mg-, Co-, Ni-, Cu-, Zn-, Cd-, and HgTHTMP. Table 2 lists the structural characteristics and the positions of the absorption bands that are correlated. The most significant correlation factors are listed in Table 3.

Shelnutt and Ondrias (7) have shown that linear relationships are lost when porphyrins with different axial ligation state are studied. Accordingly, all the spectra presented here were obtained in CCl_4, a noncoordinating solvent, to prevent the axial ligation of the metal with the solvent. One exception is MgTHTMP which is highly hygroscopic and complexes with the few water molecules present in the CCl_4 solvent (43).

The correlation patterns obtained between the spectral shifts in the different spectral regions and the molar reduced mass of the N—metal bond are shown in Fig. 5. The correlation factors from the linear regression equation are very good ($r > 0.95$) for two series of complexes: the series of the metal complexes of the same group (Zn, Cd, Hg) (Table 3.A4) and the series of the metal complexes of the same period (Co, Ni, Cu, Zn) (Table 3.A3). However, the slopes of the regression lines for these two series are different so that the correlation factor becomes less significant when the set of six complexes is considered (Table 3.A2). When the Mg complex is added to the list, the correlation is completely lost (Table 3.A1). This is understandable because the Mg complex is more ionic than the other complexes and water is axially ligated to the Mg.

A correlation is found between the reduced mass of N—metal

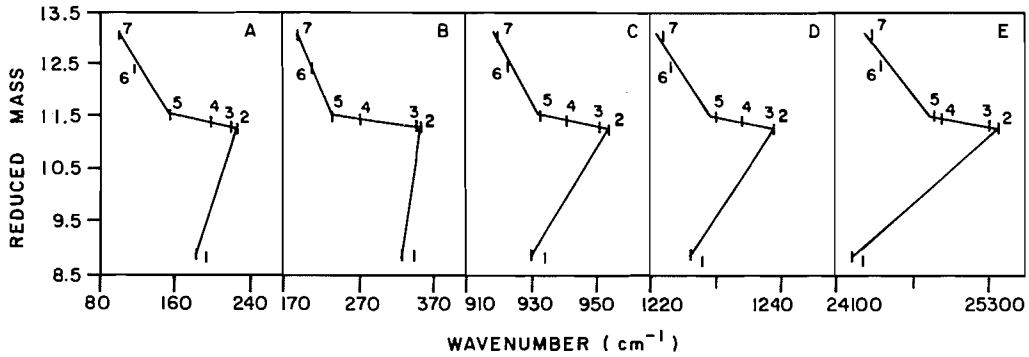

FIG. 5. Correlation curves between the reduced mass of the N–metal bond and the shift of absorption bands of THTMP metal complexes. *A*: band a, 101–226 cm^{-1}; *B*: band b, 349–192 cm^{-1}; *C*: band c, 954–920 cm^{-1}; *D*: band d, 1239–1222 cm^{-1}; *E*: B(0,0) band (Soret), 25381–24213 cm^{-1}. *1*: Mg; *2*: Ni; *3*: Co; *4*: Cu; *5*: Zn; *6*: Cd; *7*: Hg.

bond and the band situated in the 954–920 cm^{-1} region (Table 3.A). This observation supports the assignment of this band to a pyrrole ring mode involving the metal.

The relation between the B(0,0) (Soret) band and the reduced mass of the N—metal bond is given in Fig. 5*E*. The pattern in this figure is similar to the others (Fig. 5*A–D*) which show the correlation patterns of the metal-sensitive bands in the infrared and far-infrared regions. This is surprising since no direct relationship between the reduced mass of the N—metal bond and the electronic transition which give rise to the B(0,0) band has been established so far. However, within these series, an increase of the reduced mass corresponds to an increase of π-bonding between the metal and the porphyrinato ligand, this being due either to a greater number of *d* electrons on the metal, among a period, or to more polarizable *d* orbitals, among a group.

The spectral shifts of the Q(1,0) band are the only ones that correlate well with the electronegativity of the complexed metals, and only for the elements within a period (Table 3.B). This direct relationship has already been reported for other metalloporphyrins (7, 36, 38). Indeed, this correlation has led to the use of the position of the Q(1,0) band to evaluate the covalency of the N—metal bond (7). Our results confirm the general applicability of this relationship which states that a porphyrin complex of a metal of lower electronegativity shows its Q(1,0) band at higher wavelength.

The metals studied have high electronegativity. Therefore the covalent N—metal bonding prevails and the covalent radius of the metals gives an appropriate measure of their sizes. Indeed, a relation is observed between the spectral shifts and the covalent radii of the metals (Table 3.C). The four bands in the infrared and far-infrared regions give fair to good correlations, even when the Mg complex is included in the series. The covalent radius is indicative of the ability of a metal to fit into the porphin N_4-cavity and to form a linear metal—N—metal arrangement. This should reflect directly on the a, b, and c bands. The d band is assigned to an in-plane deformation of the C_m—H bond. Its sensitivity to the metal could be related to the modification of the force constants of the methine bridge when complexation is made with metals of different sizes (17, 24).

The position of the B(0,0) band of all the complexes (Table 3.C1) and the position of the visible Q(1,0) and Q(0,0) bands for the complexes containing an element in the same period (Table 3.C3) correlate with the covalent radii of the metals. This good correlation may be due to two factors (7, 12). The first one is the ruffling of the ring, which modifies the A_{2u}—π orbitals of the ring and therefore causes a change in the electronic ground state of the porphyrin. The second factor is an increased d_{metal}–$2p_{ring}$ orbital interaction which is due to more *d* electrons or to a greater polarizability of the *d* orbitals of the metal.

The similar dependence of the vibrational and electronic absorptions on various structural characteristics, added to the fact that the shifts of the most metal-sensitive bands of the vibrational spectra are not directly related to the reduced mass of the N—metal bond, demonstrates that the shifts of all these bands, even the vibrational ones, are related to an electronic rather than to a mass effect. A conclusion similar to this one has been reached by Owens and O'Connor in their study on hemes (2) and by Gladkov and Solovyov on OEP and other porphyrins (44).

The dependence of the various shifts of the selected bands on electronic effects is supported by the observation that the shift of the B(0,0) band correlates with the shifts of the four vibrational bands for the series of bivalent complexes (Table 3.D). However, the shifts of the bands in the visible region correlate with the shifts of the vibrational bands only for the complexes of the metals in the same period (Table 3.E–F). In this case, the change in the size of the valence orbitals might affect the vibrational and the electronic transitions in a different way. The shifts of the four bands in the infrared and far-infrared regions correlate one with the other (Table 3.G) and hence these shifts are due to similar effects which are mostly electronic.

Far-infrared spectroscopy of natural porphyrins

The far-infrared spectrum of MgTHTMP is of special interest because it can be compared with the spectra of chlorophyll in different aggregation states. Katz *et al.* have observed a band at 306–312 cm^{-1} for an aggregated species of chlorophyll in which the N—Mg bond is modified by an interaction of the magnesium atom with the carbonyl group of another chlorophyll molecule (25). The nonaggregated chlorophyll, produced by dissolving the pigments in a solvent system containing electron-donating molecules (MeOH and pyridine), gives two bands, one at 292 and the other at 195 cm^{-1} (25). However, in this nonaggregated species, the magnesium atom must interact with the solvent as an axial ligand. Thus, these bands are not related to an isolated N—Mg—N group.

The aggregation states and the external ligation of other natural porphyrins (heme proteins) are also of great interest (9). The magnesium derivative of protoporphyrin-IX in Nujol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

absorbs at 342, 319, and 189 cm^{-1}; Mg—hematoporphyrin-IX absorbs at 337, 261, 217, and 189 cm^{-1} (10). These compounds have carboxyl oxygens on their side-chains which can interact with the central magnesium. MgOEP in Nujol absorbs at 336, 214, and 129 cm^{-1} (12). For MgTHTMP in CCl_4, which, as we have shown before (43), axially ligates water molecules present in the solvent, we observe two bands situated at 328 and 182 cm^{-1} (Fig. 3). Assuming that the side-chains do not have a great influence on the symmetry of the Mg—porphyrin ring (7), the band found in the 195–180 cm^{-1} region could be assigned to the N—Mg vibration of the nonaggregated species associated with an axial ligand. Indeed MgOEP in Nujol, which is aggregated but not axially ligated, does not show this band (12). This complex shows a band situated at 214 cm^{-1} which is also found in the Mg–hematoporphyrin spectrum at 217 cm^{-1}. Accordingly, the hematoporphyrin samples would be made of both the axially ligated (band at 189 cm^{-1}) and nonligated (band at 217 cm^{-1}) species. A band corresponding to the nonligated species in the nonaggregated chlorophyll spectrum has yet to be observed. Such a band would be useful to establish the nature of the displacement observed in the spectrum of the ligated species.

Conclusion

The spectra of a new series of liposoluble metalloporphyrin complexes are presented over a very broad spectral range in a nonpolar, noncoordinating solvent. These data are helpful to make the assignment of the vibrational bands of metalloporphyrins, with special interest in the spectra of the natural porphyrins. Significant correlations are found between the shifts of metal sensitive bands and structural parameters.

Some bands in the far-infrared region are observed at positions close to the ones that had been calculated with normal coordinate analyses (9, 19*b*, 22). However, the shift of these bands do not correlate with the reduced mass of the N—metal bond and therefore these bands cannot be assigned to pure vibrational modes of the N—metal bond. This confirms the conclusion of Abe that there is a need for more studies in the far-infrared region for such compounds (19*b*). The intensities of the bands in this region vary greatly with the metal. In the other regions, no variation of this magnitude is observed. Further studies are needed to determine the nature of the variation observed in the far-infrared.

Some anomalies were observed during the course of this work. The high hygroscopicity of MgTHTMP in CCl_4, as shown by the associated water bands at 3665, 3587, and 1594 cm^{-1}, disappears in the solid sample. This peculiar behavior, which has some implications in the comprehension of the aggregation of chlorophyll, is discussed elsewhere in this journal (43). CoTHTMP in CCl_4 is decomposed. The transformation of this complex, as followed by visible and infrared spectroscopies, induces the formation of CO_2 molecules (45). Work is in progress to identify the cause of the instability of CoTHTMP in CCl_4.

ZDIRAD ŽÁK, ANTONÍN RŮŽIČKA, and TADEUSZ GŁOWIAK. Can. J. Chem. **69**, 1080 (1991).

Trisilver(I) amidoselenate-3-ammonia-2-water, $Ag_3SeO_3N \cdot 3NH_3 \cdot 2H_2O$, M_r = 551.70, is orthorhombic, space group $P2_12_12_1$ with a = 11.864(3), b = 14.550(3), c = 6.433(2) Å, Z = 4, D_m = 3.25, D_x = 3.30 Mg m^{-3}, radiation MoK$\bar{\alpha}$, λ = 0.71069 Å, μ = 8.62 mm^{-1}, $F(000)$ = 1024, T = 295 K. The structure was solved by direct methods and refined to R = 0.036 for 1759 observed reflections. In the structure, only two independent Ag atoms are directly bonded to the N(Se) atom of the amidoselenic group ($NSeO_3$) and these groups are joined by Ag into an infinite polymeric chain via [—N(Se)—Ag] bridges. The third Ag atom is present as a complex cation $[Ag(NH_3)_2]^+$. Each silver atom is coordinated by two N atoms: Ag(1) by N(Se) and a NH_3 molecule, Ag(2) by two N(Se) atoms, and Ag(3) by two NH_3 molecules. Important blood lengths are Ag(1)—N(Se), NH_3 2.111 and 2.110(8); Ag(2)—N(Se), N(Se^i) 2.106 and 2.096(7); and Ag(3)—NH_3, NH_3 2.115 and 2.150(10); N(Se)—Se 1.727(8); and Se—O 1.641, 1.647, and 1.639(7) Å.

Key words: Silver amidoselenate, silver–nitrogen bond, nitrogen–selenium bond.

ZDIRAD ŽÁK, ANTONÍN RŮŽIČKA, and TADEUSZ GŁOWIAK. Can. J. Chem. **69**, 1080 (1991).

L'amidosélenate d'argent $Ag_3SeO_3N \cdot 3NH_3 \cdot 2H_2O$ est orthorhombique groupe spatial $P2_12_12_1$ avec a = 11,864(3) b = 14,550(3) et c = 6,433(2) Å, Z = 4, D_m = 3,25, D_x = 3,30 Mg m^{-3}, radiation MoK$\bar{\alpha}$, λ = 0,71069 Å, μ = 8,62 mm^{-1}, $F(000)$, = 1024, T = 295 K. La structure a été résolue par les méthodes directes et affinée à un résidu de R = 0,036 utilisant 1759 réflections uniques observées. Dans la structure, seulement deux atomes d'argent indépendantes sont liés directement à l'atome d'azote N(Se) de la groupe amidosélénique ($NSeO_3$) et cettes groupes sont liées par Ag dans une chaîne polymérique infinie via les ponts [—N(Se)—Ag]. Le troisième atome d'argent est dans la forme du cation complex $[Ag(NH_3)_2]^+$. Chaque atome d'argent est coordiné par deux atomes d'azote: Ag(1) par N(Se) et par la molécule d'ammoniaque, Ag(2) par deux N(Se) atomes et Ag(3) par deux molécules d'ammoniaque. Les longueurs de liaison importantes sont: Ag(1)—N(Se), NH_3 2,111 et 2,110(8); Ag(2)—N(Se), N(Se^i) 2,106 et 2,096(7); Ag(3)—NH_3, NH_3 2,115 et 2,150(10); N(Se)—Se 1,727(8) et Se—O 1,641, 1,647 et 1,639 Å.

Mots clés : amidosélénate d'argent, liaison argent–azote, liaison azote–sélénium.

Introduction

By the reaction of $SeO_3NH_2^-$ ions with an excess of $AgNO_3$ in dilute water solutions of NH_3 and/or NaOH an amorphous orange–red precipitate of Ag_3SeO_3N is produced (1, 2):

$$SeO_3NH_2^- + 3Ag^+ + 2OH^- = Ag_3SeO_3N + 2H_2O$$

Two crystalline modifications of trisilver amidoselenate are known and can be distinguished by their X-ray powder diffraction patterns and IR spectra. The deep-red α-modification (the "red salt") is formed when the amorphous precipitate is boiled in the mother liquor for a few minutes, the light-red β-modification results if the precipitate is allowed to stay in the mother liquor at room temperature for some time (2, 3). The crystal structure of the "red salt" has already been determined (4, 5). Both α and β modifications dissolve easily in dilute water solution (1%) of ammonia and after a few hours of standing at room temperature, colourless needles of the "white salt" $Ag_3SeO_3N \cdot 3NH_3 \cdot 2H_2O$ crystallize from the solution. This salt is non-explosive and by the action of water it decomposes slowly to the β-modification of Ag_3SeO_3N (2).

A sulfur analogue of the "white salt", $Ag_3SO_3N \cdot 3NH_3 \cdot 2H_2O$, has been known for a long time (6) and its structure has recently been determined (7).

To understand the bonding in selenium(VI)–nitrogen compounds and to compare the structures of $Ag_3SeO_3N \cdot 3NH_3 \cdot 2H_2O$ and $Ag_3SO_3N \cdot 3NH_3 \cdot 2H_2O$, we have undertaken the X-ray structure determintion of the "white salt", the results of which comprise this article.

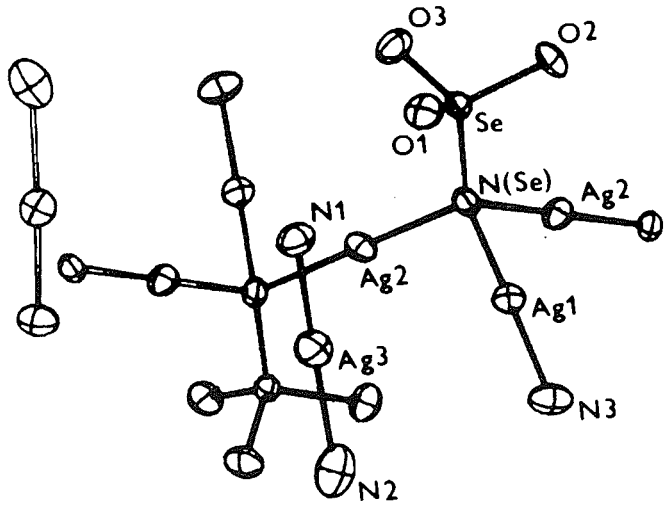

FIG. 1. A part of the structure showing the [—Ag—N(Se)—] chains. Water molecules and hydrogen atoms of ammonia molecules are omitted for clarity.

dronaphtalene. Preliminary lattice parameters and the space group were determined from Weissenberg and precession photographs. Final parameters were refined from 15 reflections $21° < 2\theta < 33°$, collected on a Syntex $P2_1$ diffractometer. Basic crystallographic data are summarized in the abstract.

The intensities of 2404 independent reflections were collected by the θ–2θ scan technique up to $2\theta = 66°$, $0 < h < 16$, $0 < k < 22$, $0 < l < 9$. The intensities were corrected for Lorentz-polarization and absorption effects. The absorption correction was calculated using program DIFABS from Syntex XTL program system. The minimum and maximum values of the absorption were 0.854 and 1.451, respectively. The stability of the crystal was checked by measuring two standard refections after every 50 measured but no significant decrease in their intensities was detected. From the total of 2404 reflections measured, 1759 with $I > 4\sigma(I)$ were taken for the structure solution and refinement.

The structure was solved by direct methods, the heavy atoms, silver and selenium, were located from the E-map. The electron density map based on the positions of the heavy atoms revealed the rest of the structure, except hydrogen atoms. These were placed according to possible H bonds 1.0 Å from the atoms to which they are bonded and assigned an arbitrary isotropic temperature factor of 6.0 Å^2. The refinement was performed by a full-matrix least-squares method on $|F_o|$ with weights $w = 1/(\sigma^2 + k|F_o|^2)$ with k empirically set to 0.002. Non-hydrogen atoms were refined anisotropically, hydrogen atoms were not refined. A secondary extinction correction according to Darwin (8), with an extinction parameter g set to 2.307×10^{-6}, was applied to the strongest reflections. The absolute configuration of the structure was determined from two simultaneous runs of least-squares refinement with the structure and its enantiomorph. The model which yielded a significantly lower value of R was accepted as the correct configuration. The refinement was stopped when the average shift of the parameters was less than 0.05. The final R and R_w values are 0.036 and 0.014 respectively. $R_w = [\Sigma w_i(|F_o| - |F_c|)^2/\Sigma w_i|F_o|^2]^{1/2}$, $S = 0.972$. For the atoms Ag and Se anomalous dispersion was taken into account. The programs used were SHELX 86 for the structure solution (9), Syntex XTL program system for absorption correction and the electron density map calculations (10), a part of UNIBOX program system for bond and angles calculations and for a secondary extinction correction (11), ORFLS least-squares program (12), and the figures were drawn by ORTEP (13). The atomic scattering factors of neutral atoms were those of Cromer and Mann (14), anomalous dispersion correction was from the International tables (15). The atomic parameters of non-hydrogen atoms including B_{eq} are given in Table 1. The lists of the atomic parameters of hydrogen atoms, anisotropic temperature factors of non-hydrogen atoms, and observed and calculated structure factors have been deposited, and are available from the Depository of Unpublished Data.[2]

Results and Discussion

The "white salt" $Ag_3SeO_3N \cdot 3NH_3 \cdot 2H_2O$ is formed by polymeric chains via [—Ag—N—] bridges and is isostructural with its sulfur analogue, $Ag_3SO_3N \cdot 3NH_3 \cdot 2H_2O$ (7). A part of the structure is shown in Fig. 1. Unlike the "red salt" Ag_3SeO_3N (4, 5) where all three Ag atoms are bonded to the N atom and its polymeric network created by [—Ag—N—Se—O—] chains, in the "white salt" only two independent Ag atoms, namely Ag(1) and Ag(2), are directly bonded to the N(Se) atom of the amidoselenic group ($NSeO_3$) and these groups are joined by Ag(2) into an infinite simple polymeric chain $[—Ag(2)—N(Se)—]_n$. The third Ag(3) atom is in the form of a complex cation $[Ag(NH_3)_2]^+$. No matter how closely are the "red" and "white" salts related from a chemical point of view, there seems to be a significant difference in the Ag—N and Se—N bond character in these compounds. The bonding in the "red salt" is thoroughly

TABLE 3. Comparison of the structures of the "red" and "white" salts; distances and angles are partly averaged

Bond	Distance (Å)	
	Ag_3SeO_3N	$Ag_3SeO_3N \cdot 3NH_3 \cdot 2H_2O$
Ag—NH_3		2.13(2)
Ag—N(Se)	2.164(8)	2.104(8)
Ag—O	2.23(1)	
Se—N(Se)	1.70(2)	1.727(8)
Se—O	1.651(8)	1.642(7)

Bonds	Angle (deg)	
	Ag_3SeO_3N	$Ag_3SeO_3N \cdot 3NH_3 \cdot 2H_2O$
Ag—N(Se)—Ag	107.3(6)	101(4)
N(Se)—Se—O	112.9(4)	110.8(4)
O—Se—O	105.8(5)	108.2(4)

Bonds	Torsion angle (deg)	
	Ag_3SeO_3N	$Ag_3SeO_3N \cdot 3NH_3 \cdot 2H_2O$
Ag(1)—N(Se)—Se—O(1)		−38.2(3)
Ag(2)—N(Se)—Se—O(2)	11.1	−33.3(3)
Ag(2^i)—N(Se)—Se—O(3)		−31.4(3)

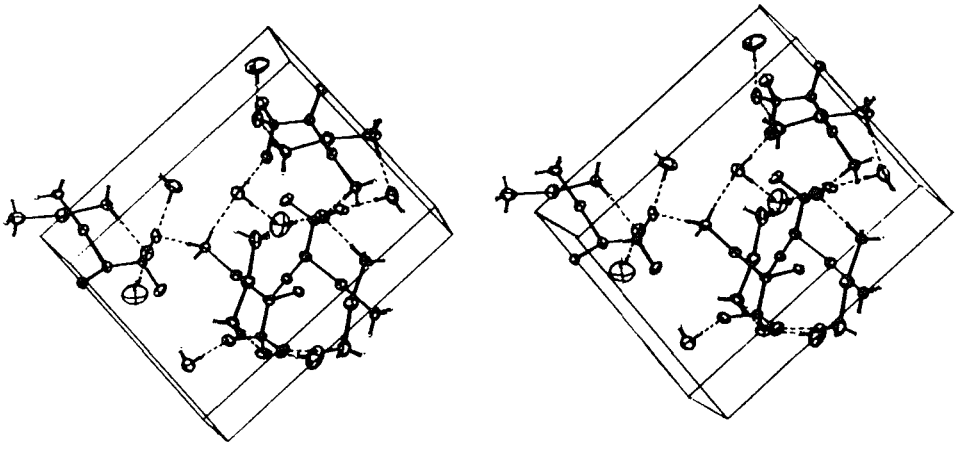

FIG. 2. A stereoview of the packing of the unit cell with possible hydrogen bonds.

studied by Kocman and Szymański (5). While in the "red salt" a partially ionic character of the Ag—N bond and a substantial π-bond contribution to Se—N bond is supposed, a rather high covalency of the Ag—N bond in the "white salt" is compensated by a decrease in π-bond contribution to the Se—N bond as follows from the mutual comparison of their bond lengths and valency angles (Tables 2 and 3). However, there is no significant change in the character of Se—O bonds, their lengths conform to values commonly encountered in selenates (16).

The Ag—N distances range from 2.096(7) to 2.150(10) Å, the longest belonging to the $[Ag(NH_3)_2]^+$ cation, and are comparable with those found in other related structures: 2.16–2.22(2) Å in $Ag_3SO_3N \cdot H_2O$ (17) and 2.08–2.17(2) Å in $Ag_3SO_3N \cdot 3NH_3 \cdot 2H_2O$ (7). Each Ag atom is coordinated approximately linearly by two N atoms: Ag(1) by N(Se) and $N(3)H_3$; Ag(2) by N(Se) and $N(Se^i)$; and Ag(3) by $N(1)H_3$ and $N(2)H_3 \cdot N(Se)$ and Se atoms are coordinated tetrahedrally as expected: N(Se) by 3Ag + Se, Se by N(se) + 3O and the entity $[Ag_3NSeO_3]$ has approximately a C_{3v} point symmetry. The Se—O and Ag—N bonds are staggered by approximately 34° (Table 3). The molecules of ammonia, besides the coordination of Ag atoms and water form hydrogen bonds towards the O atoms of the ($NSeO_3$) group and water molecules. Because the H atoms were placed linearly toward the possible acceptors, a proper discussion of the H bonds cannot be made. Their average length is 2.03 Å with minimum and maximum values of 1.80 and 2.47 Å, respectively. A stereoscopic drawing of the packing of the unit cell including possible H bonds is in Fig. 2.

La comparaison des résultats des approches empiriques et chimiométriques dans la modélisation de l'effet de solvant sur un ensemble de propriétés spectrales en RMN, IR et UV–visible, est abordée dans cet article. Les solvants sont caractérisés dans un premier temps par les échelles π^*, α et β qui décrivent respectivement la polarité–polarisabilité, l'acidité et la basicité par liaison hydrogène, et les 17 les plus informatifs possibles ont été choisis, tout en ayant des ensembles de paramètres orthogonaux. Nous avons essayé de rationaliser les effets observés sur les propriétés étudiées en utilisant des modèles empiriques linéaires simples faisant intervenir π^*, α et β de Kamlet, Taft, Abboud; E_T^N de Reichardt et A et B de Swain. Par ailleurs, une analyse en composantes principales est appliquée à ces effets et sur l'ensemble des propriétés que nous avons étudiées; il apparaît que la qualité des corrélations obtenues est en général satisfaisante et comparable à celle permise par l'approche empirique.

Mots clés : effet de solvant, approche empirique, approche chimiométrique.

ABDELOUAHED AUHMANI, HASSANE BITAR, ROGER PHAN TAN LUU, and LAURA BARRIOS. Can. J. Chem. **69**, 1084 (1991).

In this paper, we review a comparison of the empirical and chemiometrical approaches to the modelization of the effects of solvent on a number of NMR, IR and UV–visible spectral properties. The solvents have first been characterized by the π^*, α and β scales, which describe respectively the polarity–polarisability, the acidity, and the basicity by hydrogen bond; the 17 most representative, with orthogonal parameters, have been chosen. An attempt has been made to rationalize the observed effects on the observed properties by using simple linear empirical models like the π^*, α, and β parameters of Kamlet, Taft, and Abboud; E_T^N of Reichardt; and A and B of Swain. Furthermore, an analysis of the main components has been applied to these effects and to the properties examined; it appears that the quality of the correlations obtained is generally satisfactory and can be compared to the quality that can be observed with the empirical approach.

Key words: solvent effect, empirical approach, chemiometrical approach.

[Journal translation]

Introduction

La sensibilité des propriétés spectrales des solutés en RMN, IR, RPE et UV–visible à leur environnement moléculaire, a été souvent utilisée dans les études quantitatives des effets de solvant (1–10).

Afin de quantifier et de rationaliser ces effets, deux approches ont été adoptées : (i) l'approche empirique qui a donnée lieu à des échelles de solvant et dont on peut citer : π^*, α et β de Taft, Abboud et Kamlet (1, 11, 12); E_T de Reichardt (8); A et B de Swain *et al.* (13) et les paramètres de Koppel et Pal'm (14); (ii) l'approche chimiométrique appliquée par Sjöström et Wold (15), qui permet de définir une ou plusieurs composantes utilisées pour quantifier l'effet du milieu.

Le problème fondamental se pose lors de la comparaison des méthodes empirique et chimiométrique, car les ensembles de paramètres de la première ne sont pas en général parfaitement orthogonaux. Ceci a donné lieu à une importante controverse entre les partisans de chacune des deux approches qui s'est traduite par un échange d'articles très vifs entre Kamlet et coll. (16) d'un côté et Wold et coll. (15, 17) de l'autre.

Nous nous sommes proposés de comparer les résultats des échelles empiriques où, pris globalement, les paramètres ne sont pas parfaitement orthogonaux, avec ceux de l'analyse en composantes principales (18, 19) où, par construction, les différentes composantes le sont.

Pour ce faire, nous avons choisi et étudié un ensemble de propriétés sensibles à l'effet de solvant. En prenant comme référence les paramètres empiriques π^*, α et β, nous avons choisi à l'aide des méthodes de construction des matrices d'expériences optimales,[2,3] un ensemble de 17 solvants les plus informatifs possibles et ayant des ensembles de paramètres π^*, α et β orthogonaux.[4]

Les effets observés sur les propriétés étudiées ont été analysés d'une part au moyen des paramètres empiriques et d'autre part au moyen de l'analyse en composantes principales faite à l'aide du programme BMDP (20).

Partie expérimentale

Les solvants ainsi que les solutés, produits commerciaux, ont été purifiés par des méthodes standards (21).

1. Auteur à qui adresser toute correspondance.

2. Le choix a été fait à l'aide du programme NEMROD mis au point par R. Phan Tan Luu et D. Mathieu, L.P.R.A.I., Centre Universitaire de St Jérôme, U. d'Aix Marseille III, France.

3. D. Mathieu, Thèse, Marseille, 1981.

4. Les corrélations sont : entre π^* et β : $r^2 = 0{,}001$; entre π^* et α : $r^2 = 0{,}052$; entre α et β : $r^2 = 0{,}028$.

17	Hexafluoroisopropanol (HFIP)	0,65	0,00	1,96	1,068	—[b]	—[b]

[a]Les paramètres π^*, β et α utilisés dans les corrélations, ont été codés selon :

$\pi^*_{codé} = (\pi^* - 0{,}505)/0{,}505$ $\beta_{codé} = (\beta - 0{,}505)/0{,}505$ $\alpha_{codé} = (\alpha - 0{,}980)/0{,}980$

[b]Valeurs non mesurées.

Les spectres de RMN ont été obtenus à 36°C sur un appareil Varian FT 80A dans des tubes de 10 mm de diamètre. Les concentrations de solutés sont les plus faibles possibles et varient entre 0,05 et 0,1 M. Le composé deutéré (D_2O) nécessaire au verrouillage du champs magnétique est contenu dans un tube coaxiale de 5 mm. Tous les spectres ont été obtenus en découplage complet des protons et en abondances naturelles. En RMN du ^{13}C (20 MHz) le nombre d'accumulations varie de 2×10^3 à 3×10^4 avec un temps d'acquisition de 2 s. La largeur spectrale est de 4000 Hz, la résolution est de 0,05 ppm et la reproductibilité des déplacements chimiques (D.C.) est de 0,01 à 0,02 ppm. Les spectres du ^{31}P (32,023 MHz) sont enregistrés dans les mêmes conditions avec une largeur spectrale de 5000 Hz et un nombre d'accumulations variant de 5×10^2 à 5×10^3.

Les spectres UV–visible ont été enregistrés sur un appareil Cary 219; la température (25°C) a été maintenue constante à l'aide d'un thermostat Lauda K2R, les concentrations variant entre 3×10^{-5} et 5×10^{-5} M.

Les spectres IR ont été enregistrés sur un appareil Nicolet 20SX à 25°C, la concentration variant entre 10^{-3} et 10^{-5} M. Les cuves utilisées ont une épaisseur de 14 à 15 μm.

Résultats et discussion

Les solvants sélectionnés ainsi que les valeurs des paramètres empiriques (π^*, α et β), (E_T^N) et (A et B) sont regroupés dans le tableau 1.

Les propriétés que nous avons choisies sont :

1. Les signaux de RMN du ^{13}C des carbone des solutés suivants : méthylphénylsulfoxyde (A), tropone (B), pyridine (C), 4-picoline (D), *N,N*-diméthylamino-4 pyridine (E), acétyl-4 pyridine (F), cyano-4 pyridine (G), chlorobenzène (H), α,α,α-trifluorotoluène (I), tropolone (J), diméthylsulfoxyde (K) (Fig. 1).

Les D.C. sont mesurés par rapport au signal du carbone en position *méta* de l'α,α,α-trifluorotoluène utilisé comme référence interne, en suivant la méthode de Taft et coll. (1, 2).

2. Le signal de RMN du ^{31}P du phosphate de triméthyle (L) est mesuré par rapport à celui du phosphite de triisopropyle; le signal de l'oxyde de triphénylphosphine (M) est donné relativement à celui de la triphénylphosphine. Ces références sont également internes.

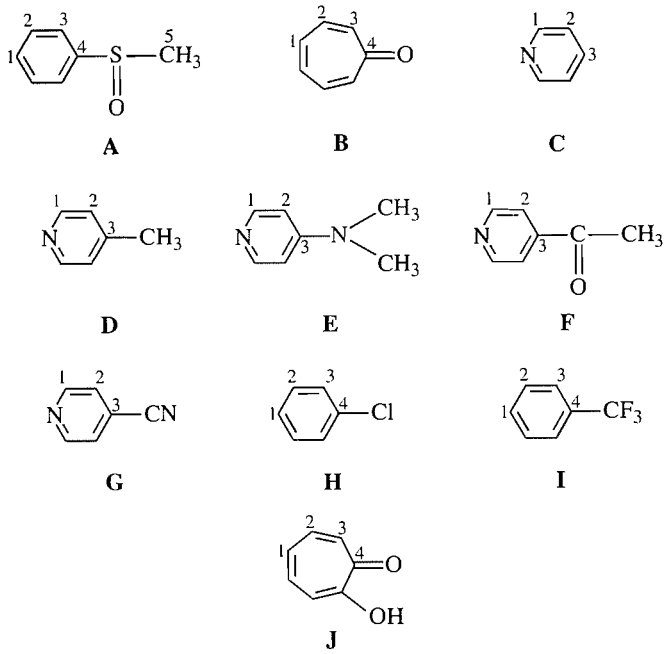

FIG. 1. Solutés étudiés en spectroscopie de RMN du ^{13}C.

3. Les fréquences des vibrations d'élongation : ν_{CO} de CF_3COOMe (N), CCl_3COOMe (O), CH_3COCH_3 (P), $HCONMe_2$ (R); ν_{CN} de $CH_3CH_2CH_2CN$ (Q) et ν_{SO} de CH_3SOCH_3 (K).

4. Les nombres d'onde au maximum d'absorption UV–visible ν_{max} de : nitro-4 aniline (S), *N*-méthylnitro-4 aniline (T), *N,N*-diméthylnitro-4 aniline (U), *N,N*-diéthylnitro-4 aniline (V), nitro-4 phénol (W), nitro-4 anisole (X), dinitro-3,4 phénol (Y) et β-carotène (Z).

Les résultats expérimentaux sont donnés dans les tableaux 1–6 du document complémentaire.[5]

5. Ce document peut être acheté de : Dépôt des données non publiées, service de fourniture de documents, ICIST, Conseil national de recherches Canada, Ottawa, Canada K1A 0S2.

NOTE : Les valeurs entre parenthèses sont obtenues pour les mêmes solvants que ceux pour lesquels les paramètres *A* et *B* sont connus.

Pour interpréter les effets observés sur chacune de ces propriétés, nous leurs avons appliquées des analyses empiriques et chimiométriques.

1. Approche empirique

Les effets observés ont été reliés aux paramètres empiriques à l'aide des modèles linéaires simples suivants :

$$[1] \quad P = P_0 + a_1\pi^* + a_2\beta + a_3\alpha$$

$$[2] \quad P = P_0 + bE_T^N$$

$$[3] \quad P = P_0 + c_1A + c_2B$$

Ces modèles ont été appliqués à chacune des propriétés étudiées et les résultats obtenus (coefficient de corrélation (r^2) et écart type de l'estimation (ETE)) sont regroupés dans les tableaux 2 et 3.

Les paramètres π^* tabulés ont été utilisés «naïvement», c'est à dire sans introduire le terme correctif dδ, dit de «polarisabilité» que l'on doit utiliser pour décrire le comportement des solvants aromatiques et polychlorés (11, 12). Son emploi aurait, bien entendu, amélioré la qualité des correlations.

L'analyse de ces résultats montre que les paramètres π^*, α et β donne des corrélations qui sont en général plus satisfaisantes. En effet, les coefficients de corrélation obtenus à l'aide de l'équation [2] sont nettement inférieurs à ceux de l'équation [1]; ceci est confirmé par les valeurs de l'écart type de l'estimation. On peut attribuer ceci au fait que le paramètre E_T est un mélange de polarité et d'acidité par liaison hydrogène (L.H.) (1); par la suite la contribution de la basicité n'est pas représentée.

En utilisant les paramètres *A* et *B*, nous remarquons que pour certains solutés, la corrélation est comparable à celle de l'équation [1], alors que pour d'autre et en particulier pour les donneurs de L.H., il apparait clairement que π^*, α et β donnent des résultats nettement meilleurs. Ceci est en accord avec les travaux de Abboud et coll. (22) qui ont analysé *A* et *B* et montré qu'ils sont liés entre eux lorsque les solvants donneurs de L.H. sont exclus de la corrélation.

Nous devons signaler que l'application des modèles plus

NOTE : Pour les valeurs entre parenthèses, cf. note du tableau 2.

complexes, faisant intervenir des termes carrés et d'interaction en π^* et β, n'a pas apportée d'améliorations significatives au niveau des corrélations. Nous limitons donc notre discussion aux résultats obtenus à partir de l'équation [1].[6]

L'analyse de ces résultats montre qu'ils sont en accord avec l'intuition chimique. En effet, l'application de l'équation [1] aux D.C. mesurés pour les solutés A–G a montré que la principale contribution aux effets observés est due à l'acidité par L.H. et, dans une proportion moindre, à la polarité–polarisabilité alors que la basicité ne participe pas à ces effets. Ceci est en accord avec la nature de ces solutés qui sont de bons accepteurs de L.H. et qui ont des moments dipolaires assez significatifs.

Pour les solutés H et I, les interactions dipolaires sont prédominantes et donc un seul paramètre à savoir, π^*, a été suffisant pour décrire les effets observés; les autres paramètres ont souvent des coefficients non significatifs.

Dans le cas de la tropolone (J), les effets de solvant sur les D.C. mesurés sont globalement moins importants que ceux de la tropone, ceci à condition de ne pas tenir compte des effets dus à la triéthylamine et à la tri-*n*-butylamine qui sont fortement basiques et qui peuvent conduire à une déprotonation de la fonction «phénol».

Les variations importantes obtenues dans ces deux solvants confirment cette hypothèse. En excluant ces deux valeurs, l'équation [1] a montré que la contribution de la basicité par L.H. est négligeable, ceci est dû à une L.H. intramoléculaire plus forte que celle qu'aurait ce soluté avec le solvant.

En RMN du ^{31}P, l'équation [1] montre que les effets observés sur les solutés L et M sont dus principalement aux effets d'association par L.H. et, à un degré moindre, aux interactions dipolaires. Le rapport a_3/a_1 montre l'importante contribution de α : a_3/a_1 (L) = 2,83 et a_3/a_1 (M) = 4,47.

6. Les résultats complets des corrélations selon l'équation [1] sont donnés dans les tableaux 7–10 du document complémentaire.

Les effets observés sur les fréquences de vibration IR des solutés N–Q et K, sont assez bien décrits à l'aide de l'équation [1]. Les principales contributions sont dues à π^* et α et sont en accord avec les caractères fortement dipolaire et accepteur de L.H. de ces solutés.

La modélisation avec π^*, α et β de l'effet du milieu sur les nombres d'onde au maximum d'absorption ν_{max}, est assez satisfaisante et permet une interprétation physique raisonnable des valeurs des différents coefficients. En effet pour la nitro-4 aniline (S), le nitro-4 phénol (W) et le dinitro-3,4 phénol (Y), ce sont principalement les effets de dipolarité et de basicité du solvant qui prédominent. Ceci est illustré par les valeurs assez importantes des coefficients a_1 et a_2 de l'équation [1] :

$$a_1(S) = -1{,}582 \pm 0{,}054 \quad a_2(S) = -1{,}379 \pm 0{,}043$$
$$a_1(W) = -0{,}869 \pm 0{,}092 \quad a_2(W) = -1{,}034 \pm 0{,}073$$
$$a_1(Y) = -1{,}732 \pm 0{,}126 \quad a_2(Y) = -1{,}353 \pm 0{,}098$$

La contribution de la basicité par L.H. diminue en passant de la nitro-4 aniline à son dérivé *N*-méthylé et elle n'est plus significative pour X = NMe_2, NEt_2 et OMe. Pour ces trois derniers, nous avons noté leur sensibilité particulière à π^*, sans sous-estimer celle de α et qui peut être expliquée par le comportement accepteur de L.H. du groupement nitro ainsi que par la nature du substituant X.

Nous avons analysé par ailleurs les valeurs de E_T des 17 solvants sélectionnés, à l'aide de π^*, α et β, et le résultat obtenu à montré l'importante contribution de l'acidité par L.H. à cette échelle.

2. Approche chimiométrique

Nous avons appliqué l'analyse multivariée et en particulier l'analyse en composantes principales pour rationaliser les multiples effets observés sur chacune des propriétés étudiés.

Une analyse déscriptive préalable de toutes les données expérimentales confirme que cet ensemble des mesures suit une distribution normale. Certaines valeurs qu'on n'a pas pû mesurées, ont été calculées à l'aide de l'équation [1]. Par ailleurs, les propriétés peu sensibles à l'effet du milieu et celles qui mettent en jeu un mécanisme de solvatation particulier, ont

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

été exclues de cette analyse. Ces propriétés sont : les D.C. δC2 et δC3 du soluté A; δC3 de B; δC1 et δC2 de E; δC2 et δC3 de F, δC3 de G; δC2 de H; les D.C. de J; ν_{max} de Y et celle de Z.

Dans un premier temps, nous avons réparti les différentes propriétés en trois sous-ensembles : 25 propriétés de RMN dans le premier, 6 propriétés IR dans le deuxième et 7 propriétés UV–visible dans le troisième. Pour décrire un minimum de 95% de la variance, la méthode d'analyse en composantes principales a donné trois facteurs pour chacun de ces trois sous-ensembles.

L'application de l'analyse en composantes principales à toutes les propriétés regroupées dans le même ensemble, a donné également trois facteurs qui décrivent 95% de la variance. Les valeurs de ces facteurs pour chacun des solvants séléctionnés sont données dans le tableau 4.

Ces facteurs ont été utilisés pour modéliser, selon l'équation [4], l'effet de solvant sur les différentes propriétés étudiées.

$$[4] \quad P = P_0 + f_1F_1 + f_2F_2 + f_3F_3$$

Les résultats des corrélations (tableaux 2, 3) sont assez satisfaisants et de qualité comparable à celle permise par l'analyse empirique.

Nous avons établi aussi une bonne corrélation pour chacun des trois sous-ensembles, en utilisant les facteurs propres à chacun d'entre eux. Cependant, le fait d'étendre cette analyse en utilisant les facteurs d'une famille pour décrire les effets d'une autre, donne des résultats nettement moins satisfaisants que ceux de la même famille.

On a tenté de relier les facteurs obtenus à partir de toutes les propriétés regroupées, aux paramètres π*, α et β et nous avons obtenu les équations suivantes :

$$[5] \quad F_1 = (0{,}603 \pm 0{,}034) - (0{,}519 \pm 0{,}047)\pi^* + (0{,}421 \pm 0{,}041)\beta + (1{,}691 \pm 0{,}023)\alpha$$
$$r^2 = 0{,}991 \qquad \text{ETE} = 0{,}108$$

$$[6] \quad F_2 = (2{,}129 \pm 0{,}065) - (2{,}719 \pm 0{,}089)\pi^* - (1{,}462 \pm 0{,}078)\beta + (0{,}104 \pm 0{,}045)\alpha$$
$$r^2 = 0{,}965 \qquad \text{ETE} = 0{,}207$$

$$[7] \quad F_3 = (-1{,}089 \pm 0{,}112) - (1{,}769 \pm 0{,}155)\pi^* - (2{,}351 \pm 0{,}136)\beta + (0{,}043 \pm 0{,}078)\alpha$$
$$r^2 = 0{,}900 \qquad \text{ETE} = 0{,}358$$

Ces régressions montrent qu'aucun de ces facteurs ne décrit à lui seul une propriété physique du solvant. En effet, on note pour F_1 une nette contribution de α alors que celles de π* et β sont moins importantes tout en restant non négligeables. D'autre part, F_2 ainsi que F_3 sont particulièrement sensibles à π* et β. Il s'en suit qu'il est difficile d'attribuer un sens physique à ces facteurs et par la suite aux coefficients f_i de l'équation [4]. Ceci limite l'interprétation physique des effets observés sur les propriétés étudiées, ce qui n'est pas le cas pour l'approche empirique.

Nous devons signaler aussi que dans les corrélations avec F_1, F_2 et F_3, aucune des contributions de ces facteurs n'est négligeable. Un modèle à un ou à deux facteurs s'avère en général insuffisant.

La méthode d'analyse en composantes principales permet cependant une prévision pour une famille de propriétés, meilleure que celle donnée par l'analyse empirique; mais, les facteurs obtenus ne peuvent pas être étendus à d'autres familles. Ceci est par contre possible dans l'approche empirique qui permet une comparaison des effets sur des familles de propriétés différentes.

TABLEAU 4. Valeurs des facteurs F_1, F_2 et F_3 pour les solvants utilisés

N°	Solvant	F_1	F_2	F_3
1	Cyclohexane	−0,670	2,010	−0,071
2	Triéthylamine	−0,361	0,744	1,452
3	Tri-*n*-butylamine	−0,620	0,822	0,809
4	Tetrachlorure de carbone	−0,578	1,520	−0,325
5	Carbonate de diéthyle	−0,537	0,283	0,038
6	Toluène	−0,874	0,425	−0,606
7	Acétonitrile	−0,569	−0,666	−0,667
8	Diméthyl-2,6 pyridine	−0,808	−0,774	−0,003
9	Dichlorométhane	−0,527	−0,068	−0,938
10	Diméthylsulfoxyde	−0,761	−1,955	−0,410
11	Nitrobenzène	−0,930	−0,874	−0,858
12	Tertiobutanol	0,807	−0,280	1,697
13	*n*-Butanol	0,919	−0,452	1,664
14	Méthanol	0,998	−0,413	1,014
15	Ethylène glycol	0,614	−1,250	−0,074
16	Trifluoro-2,2,2 éthanol	1,451	0,256	−1,097
17	Hexafluoroisopropanol	2,445	0,669	−1,627

Par ailleurs, l'approche empirique comme l'approche chimiométrique présentent des limitations chaque fois que la propriété étudiée fait intervenir un mécanisme de solvatation particulier. Ceci permet de dire que les deux méthodes «n'ignorent pas» les mécanismes physiques. Nous pouvons citer comme exemple le cas de la β-carotène (Z) pour laquelle l'application de l'approche empirique comme celle de l'analyse chimiométrique, donne des corrélations non satisfaisantes. Ceci est dû au fait que l'effet observé sur le maximum d'absorption de ce soluté, est énergétiquement modeste et dépend surtout des phénomènes de dispersion. En effet, une meilleure corrélation (éq. [8]) est obtenue en utilisant l'échelle π_2^* d'Abe (23) dépendant de l'indice de refraction n_D :

$$[8] \quad \nu_{max}(Z) = (23{,}51 \pm 0{,}08) - (1{,}530 \pm 0{,}076)\pi_2^*$$
$$r^2 = 0{,}900 \qquad \text{ETE} = 0{,}116$$

où

$$\pi_2^* = -1{,}137 + 1{,}098(n_D)^2$$

Conclusion

Nous avons essayé de comparer les résultats des approches empiriques et chimiométriques dans l'étude de l'effet de solvant sur un ensemble de propriétés spectrales en RMN, IR et UV–visible.

Les solvants ont été paramétrisés par les échelles π*, α et β et les 17 solvants les plus informatifs possibles ont été selectionnés à l'aide des méthodes de construction des matrices d'expériences optimales.

L'application des modèles empiriques linéaires simples faisant intervenir (π*, α et β), (E_T^N) et (A et B), a montré que les paramètres π*, α et β donnent généralement les meilleurs résultats.

D'une façon plus générale, nos résultats montrent que :

1. Lorsque les effets du milieu sur des propriétés physiques des solutés peuvent être décrits sous forme de combinaisons linéaires de trois variables explicatives mutuellement orthogonales (mesurant respectivement la polarité–polarisabilité, l'acidité et la basicité par L.H. du solvant) la qualité de la

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

description est tout à fait comparable à celle obtenue au moyen d'une analyse en composantes principales à trois vecteurs (un maximum de trois vecteurs justifiant au moins 95% de la variance). On peut passer, évidement, d'une description à l'autre au moyen d'une transformation unitaire (rotation dans l'espace R^3).

2. Lorsque les propriétés considérées montrent une faible sensibilité aux facteurs physiques ci-dessus, la méthode empirique échoue, en même temps que l'approche chimiométrique basée sur des composantes principales construites à l'aide des propriétés sensibles à ces facteurs.

Dès lors, il semble que dans un grand nombre de cas, le conflit entre les partisans de ces deux approches n'a pas de raison d'être.

Remerciements

Nous remercions vivement les professeurs J.-L. M. Abboud (C.S.I.C., Madrid), M. H. Abraham (University of Surrey, Royaume Uni), J. Elguero (C.S.I.C., Madrid) et C. Laurence (Faculté des sciences de Nantes) pour leurs fructueuses discussions et pour avoir lu le mauscrit. Nous remercions également G. Mille (Centre de spectroscopie moléculaire Université d'Aix-Marseille III) pour la réalisation des spectres IR.

Analysis of reactive ion transport in weakly ionized gas mixtures

KOICHI IINUMA
Department of Nuclear Engineering, Tohoku University, Sendai 980, Japan

Received May 15, 1990[1]

KOICHI IINUMA. Can. J. Chem. **69**, 1090 (1991).

A new formulation for the analysis of low density multiple-ion swarms drifting, diffusing, and inter-reacting in a neutral gas is proposed on a transport theory basis. A set of coupled three-dimensional transport equations for an arbitrary number of ion species, which governs the number densities of the ion swarms as functions of time and position coordinates, is exactly solved using a Fourier transform in a matrix representation. A picture of dynamic equilibrium state for hypothetical four ion swarms in a neutral gas is numerically obtained. Also, experimental data of transport coefficients and reaction rates for (Li^+, $Li^+ \cdot N_2$, $Li^+ \cdot 2N_2$)flN_2 system are examined in a complete reversible cyclic reaction scheme and compared with a Green's function method. The initial and boundary conditions, the analysis in gas mixtures, and the inelastic process associated with the present formulation are briefly discussed.

Key words: ion swarm, cluster ion, transport equation, ion–molecule reaction.

KOICHI IINUMA. Can. J. Chem. **69**, 1090 (1991).

Sur la base d'une théorie des transports, on propose une nouvelle formulation pour l'analyse d'essaims d'ions multiples de faible densité qui dérivent, diffusent et inter-agissent dans un gaz neutre. Utilisant une transformation de Fourier dans une représentation matricielle, on a résolu d'une façon exacte un ensemble d'équations de transport tridimensionnel couplées, pour un nombre arbitraire d'espèces ioniques, qui gouvernent le nombre décrivant les densités d'ions par essaim en fonction du temps et des coordonnées de position. On obtient un représentation numérique de l'état d'équilibre dynamique pour des essaims hypothétiques de quatre ions dans un gaz neutre. On a aussi examiné les données expérimentales pour les coefficients de transport et les vitesses de réaction du système (Li^+, $Li^+ \cdot N_2$, $Li^+ \cdot 2N_2$)/N_2 dans un schéma réactionnel cyclique complètement réversible et on les compare avec une méthode de la fonction de Green. On discute brièvement des conditions initiales et limites, de l'analyse des mélanges gazeux et des processus inélastiques associés avec la présente formulation.

Mots clés : essaim ionique, agrégat ionique, équation de transport, réaction ion–molécule.

[Traduit par la rédaction]

Introduction

The space–time dependence of concentrations of multiple chemical species in an ambient medium is generally governed by the competition between their transport processes and a complex reaction scheme composed of a series of elementary reactions. A set of coupled transport equations (diffusion equations), which involve a number of appropriate kinetic coefficients (transport coefficients and reaction rates), control the dynamic process of those inter-converting species irrespective of the chemical system being in gas, liquid or solid phase. This paper deals with the derivation of a general solution of an arbitrary number of coupled transport equations with respect to the same number of chemical concentrations, which are functions of time and position coordinates, within a framework of linear process. The "linear process" means that each transport equation is formed by a linear function in the concentrations of species of present interest, in which we are considering the non-equilibrium behaviour of multiple species dilutely dispersed in a large excess of other constituents considered at equilibrium. The particles of the dilute species are often referred to as "test particles". With this assumption, only (test particle)–moderator collisions need be considered. With the neglect of (test particle)–(test particle) collisions, the kinetic equations are (by definition) linear (pseudo-first order process). Even in this model, however, we can exactly treat the (test particle)–moderator reactions as multi-body processes (higher-order reactions). For this kind of nonthermal linear process it is possible to treat all the kinetic coefficients as functions of more general energy parameters than the temperature of surroundings. In usual transport analysis, the mean relative translational energy between each test particle and a surrounding molecule is employed as a basic energy parameter.

The experimental and theoretical study on reactive ion transport phenomena, which has a history of almost one hundred years, has been developed mainly in two research fields, gaseous electronics (1) and radiation chemistry (2), although there were somewhat different concerns between them on their early research stages. Namely, "non-reactive" transport process of charged particles in gases seemed to be a primary research subject in gaseous electronics, while time-dependence of the concentrations of chemical products was believed to provide the most useful information on the complex scheme of radiolysis in radiation chemistry, except for a few outstanding works on nonhomogeneous phenomena in tracks and spurs (2). Basically, the general solution of a set of coupled transport equations enables us to analyze this kind of time-dependent nonhomogeneous phenomena in a unified manner. In this paper we will concentrate our attention on the derivation of a general analysis for the reactive ion transport process in a neutral gas.

In usual ion swarm experiments, an external electric field (drift field, E) exerts a constant continuous force on each ion and causes the ions to flow through the gas at a certain drift velocity and diffusion rate. Moreover, other types of ions may be created by collisions of the initial ions with surrounding molecules with the proper reaction rates. The drift velocity, diffusion coefficient, and reaction rate are characteristic of the particular ion–gas combination, field strength, gas number density, and gas temperature. A transport equation involves the three kinetic coefficients and is applicable to all swarm experiments amenable to a hydrodynamic description in both thermal ($E = 0$) and nonthermal systems.

The transport coefficients of non-reactive mixtures are simple to measure because the experimental analysis of this system has been well established, and theory provides additional support for the observed results (3). In fact, many transport coefficients for various ion–molecule combinations are now available

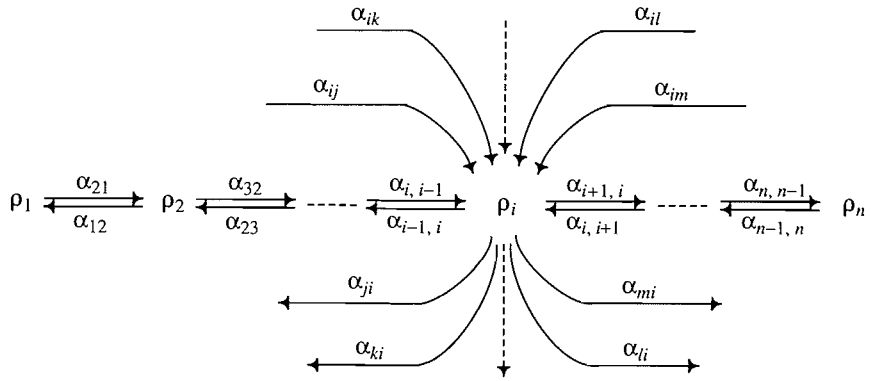
(4–6); they have been determined experimentally with a variety of sophisticated apparatus (3). However, when the simple transport phenomena are accompanied by a mutually inter-reacting scheme characteristic of multiple-ion swarms, the analytical treatment of the system will become more difficult mathematically, because the dynamical behaviour of all ion swarms requires the solution of a set of coupled transport equations. A great deal of effort has been devoted to solve the coupled equations since the mid-1950s (3). Gatland got a one noticeable full solution using Green's function method. There is an excellent review on this method and its theoretical and experimental backgrounds (7). Although its mathematical formulation, including the treatment of the boundary effects, is clear, the required "summing up" of the complicated histories of interconverting ions may limit its practical applicability for reaction schemes involving more than three ion swarms.

So far, appropriately simplified coupled equations have usually been set up and solved for the analysis of many inter-reacting systems. It is well known that a series of definitive experiments for higher-order clustering reactions were carried out by Kebarle and co-workers at the University of Alberta using several high-pressure mass spectrometers (8). By selecting experimental conditions where the diffusive effect was almost negligible, they determined scores of reaction rates for several consecutive reaction sequences from fairly simplified coupled rate equations in thermal systems (9). In addition to these thermal reaction data, a lot of data on reaction rates for bimolecular and termolecular ion–molecule reactions in nonthermal systems have been obtained by a number of groups (10, 11).



While reaction rates determined under conditions in which diffusion is neglected are useful, one would like a flexible method for probing reaction kinetics under conditions which include multiple species, diffusion, and field-driven drift. Recent growing interest in cluster ions and ion–molecule reactions in both fundamental and applied fields (12–15) has encouraged us to attempt a general formulation for the analysis of this kind of nonhomogeneous phenomena. The following section provides mathematical details on its derivation based on the drift tube experiment.

General formulation

Drift tube technique is a standard time-of-flight method for swarm experiments, where a pulse of charged particles travels through the gas under the influence of an external electric field supplied in a cylindrical tube. In a linear process (a process where all interactions between ions can be ignored), the drift velocity of each ion swarm is directly related to the mean translational energy between the ion and the neutral molecule by well known Wannier's formula (3). The mobility, diffusion coefficient, and reaction frequencies of the ion swarm are, in general, functions of the translational energy, kinetic theory of which from a "molecular" viewpoint has a long and brilliant history, and the reader can refer to several treatises for the subjects (3, 16–18).

The general inter-reacting scheme for n-ion swarms is depicted as follows:

[1]

where ρ_i is the number density of ith species ($i = 1, 2, \cdots\cdots, n$), and α_{ij} is the reaction frequency per ion, from species j to i. A commonly used chemical reaction rate, k_{ij}, is defined by the relation

$$[2] \qquad \alpha_{ij} = k_{ij}N^p$$

where N is the gas number density, and p is the order of reaction with respect to gas molecules.

The set of coupled transport equations for [1] becomes

$$[3] \qquad \frac{\partial \rho_i}{\partial t} = \nabla\cdot(\mathbf{D}_i\cdot\nabla\rho_i) - v_{di}\cdot\nabla\rho_i + R_i\rho_i + \sum_{k\neq i}^{n}\alpha_{ik}\rho_k$$

where

$$[4] \qquad R_i = -\sum_{j\neq i}^{n}\alpha_{ji}$$

The symbols $\mathbf{D}_i$ and v_{di} refer to the diffusion tensor and drift velocity of ith species, respectively. The derivation of eq. [3] and following mathematical formalization basically originated from Whealton–Woo's analysis for a ρ_1 ‰ ρ_2 system (19, 20) and Gatland's review (7). By introducing a cylindrical coordinate, we separate the solution into a radial part ($R_m(r)$) and an axialfltime part ($Z_{im}(z,t)$) as

$$[5] \qquad \rho_i(\boldsymbol{r},t) = \sum_{m=1}^{\infty} a_{im}R_m(r)Z_{im}(z,t)$$

where a_{im} are constants to be determined from the initial conditions. The separate transport equations, which are consistent with the boundary conditions and the assumption of diagonal diffusion tensors, are

$$[6] \qquad \frac{d^2R_m(r)}{dr^2} + \frac{1}{r}\frac{dR_m(r)}{dr} + \frac{\beta_m^2}{r_0^2}R_m(r) = 0$$

$$[7]\qquad \frac{\partial Z_{im}(z,t)}{\partial t} = D_{zi}\frac{\partial^2 Z_{im}(z,t)}{\partial z^2} - v_{di}\frac{\partial Z_{im}(z,t)}{\partial z} + \left(R_i - \frac{\beta_m^2}{r_0^2}D_{ri}\right)Z_{im}(z,t) + \sum_{k\neq i}^{n}\alpha_{ik}Z_{km}(z,t)$$

where β_m is the mth root of the zeroth-order Bessel function, and r_0 is the drift-tube radius. D_{zi} and D_{ri} are, respectively, longitudinal and transverse diffusion coefficients of the ith species. A solution to eq. [6] is

$$[8]\qquad R_m(r) = J_0(\beta_m r/r_0)$$

More precise treatment on the radial part, involving the initial radial distribution of the ion swarm, was given by Whealton and Woo (19, 20). Equation [7] is transformed from the axis coordinate (z) to the frequency (ω) by using a Fourier transform. A set of resulting ordinary differential equations is solved with respect to time, and formally unified into a simple matrix form as

$$[9]\qquad \mathfrak{Z}(\omega,t) = \exp(\mathbf{A}t)\,\mathfrak{Z}(\omega,0)$$

where $\mathfrak{Z}(\omega,t)$ and $\mathfrak{Z}(\omega,0)$ are n-component column vectors composed of the Fourier transformed solutions and initial conditions, respectively. An explicit form of the operator matrix $\mathbf{A}$ is

$$[10]\qquad \mathbf{A} = \begin{pmatrix} T_1, \alpha_{12}, \alpha_{13}, \cdots, \alpha_{1i}, \cdots, \alpha_{1n} \\ \alpha_{21}, T_2, \alpha_{23}, \\ \alpha_{31}, \alpha_{32}, T_3, \\ \vdots \quad \ddots \quad , \alpha_{i-1,i} \quad \vdots \\ \alpha_{i1}, \cdots, \alpha_{i,i-1}, T_i, \alpha_{i,i+1}, \cdots, \alpha_{in} \\ \quad , \alpha_{i+1,i} \quad \ddots \\ \vdots \quad \vdots \quad \vdots \quad T_{n-1}, \alpha_{n-1,n} \\ \alpha_{n1}, \cdots, \alpha_{ni}, \cdots, \alpha_{n,n-1}, T_n \end{pmatrix}$$

with

$$[11]\qquad T_i = -D_{zi}\omega^2 - iv_{di}\omega + R_i - (\beta_m/r_0)^2 D_{ri}$$

where i refers to the imaginary unit.

In chemical kinetics, the matrix algebra is a standard and conventional mathematical technique to solve the coupled rate equations (21), which may stem from the non-equilibrium theory of reaction developed by Zwolinski and Eyring (22). Unfortunately, the following theoretical progress for this useful method seems to be limited to the analysis of only time-dependent phenomena, and the method has never been combined with a Fourier transform technique on space coordinates until recently (see ref. 7, p. 426).

With the help of matrix algebra and the residue theorem in complex analysis, we obtain the explicit form of each element of the solution [9] as follows:

$$[12]\qquad \mathfrak{Z}_{im}(\omega,t) = -\sum_{j=1}^{n}\left\{\Delta_i(\lambda_j)\exp(\lambda_j t)\Big/\sum_{k=1}^{n}\Delta_{kk}(\lambda_j)\right\}$$

where λ_j is the jth root ($j = 1, 2, \cdots, n$) of the characteristic equation of matrix $\mathbf{A}$

$$[13]\qquad |\mathbf{A} - \lambda\mathbf{E}| = 0$$

where $\mathbf{E}$ is the unit matrix. $\Delta_i(\lambda)$ is denoted by the following nth order determinant

$$[14]\qquad \Delta_i(\lambda) = \begin{vmatrix} & & & (i\text{th column}) & \\ T_1 - \lambda, & \alpha_{12}, \cdots, -\partial_1(\omega,0), \cdots, & \alpha_{1n} \\ \alpha_{21}, & T_2 - \lambda, \cdots, -\partial_2(\omega,0), \cdots, & \alpha_{2n} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \alpha_{n1}, & \alpha_{n2}, \cdots, -\partial_n(\omega,0), \cdots, & T_n - \lambda \end{vmatrix}$$

$\Delta_{kk}(\lambda)$ is the cofactor of the (k,k) element in the determinant (13). The solution of eq. [7] as a function of z and t is represented in integral form as

$$[15]\qquad Z_{im}(z,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty}\mathfrak{Z}_{im}(\omega,t)\exp(i\omega z)\,d\omega$$

By substituting [8] and [15] back into [5], we obtain the final solution of the number density of the ith ion swarm for reaction sequence [1]. The solution [15] can basically be represented by an infinite sum of the Weber function (or the parabolic cylinder function). However, appropriate direct quadrature techniques to the real part of the integrand in [15] are recommended for practical analysis because of insufficient convergence of the expansion solution. While [5] is composed of an infinite sum in m, only the first few terms are necessary to adequately describe the most realistic initial conditions.

A rather important result in the limit of $z, r_0 \to \infty$ can be derived from [12]. As the drift length becomes much longer, the ratio of the integrals of the number densities with respect to time asymptotically converges to the following relation,

$$[16]\qquad \lim_{\substack{z\to\infty \\ r_0\to\infty}}\int_0^{\infty}\rho_1 dt : \lim_{\substack{z\to\infty \\ r_0\to\infty}}\int_0^{\infty}\rho_2 dt : \cdots : \lim_{\substack{z\to\infty \\ r_0\to\infty}}\int_0^{\infty}\rho_i dt : \cdots : \lim_{\substack{z\to\infty \\ r_0\to\infty}}\int_0^{\infty}\rho_n dt = |S_1| : |S_2| : \cdots : |S_i| : \cdots : |S_n|$$

with

$$[17]\qquad S_i = -\begin{vmatrix} & & & (i\text{th column}) & \\ R_1, & \alpha_{12}, \cdots, -C_1, \cdots, & \alpha_{1n} \\ \alpha_{21}, & R_2, \cdots, -C_2, \cdots, & \alpha_{2n} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \alpha_{k1}, & \alpha_{k2}, \cdots, -C_k, \cdots, & \alpha_{kn} \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ \alpha_{n1}, & \alpha_{n2}, \cdots, -C_n, \cdots, & R_n \end{vmatrix}$$

where C_k refers to an initial input of the kth species. This formula is substantial in the dynamic equilibrium state of reaction scheme [1], and holds exactly regardless of the initial conditions (even C_k's themselves). This is a natural consequence of the particle conservation law applied to a closed reactive system [1].

Numerical analysis of four-ion swarms

The analysis of four-ion swarms is a suitable subject to test the workability of present formulation. It may give us more general insight to the entire dynamic process, including the initial, transition, and dynamic equilibrium state, for the reactive ion transport involving more than five ion swarms. In fact, recent *in situ* ion composition measurements in atmospheric ion chemistry are going to reveal that scores of positive and negative ions take part in the complex reaction scheme of the earth's atmosphere (23, 24). Unfortunately, the number of measured transport coefficients and reaction rates for these compositions are still not quite satisfactory, and no complete

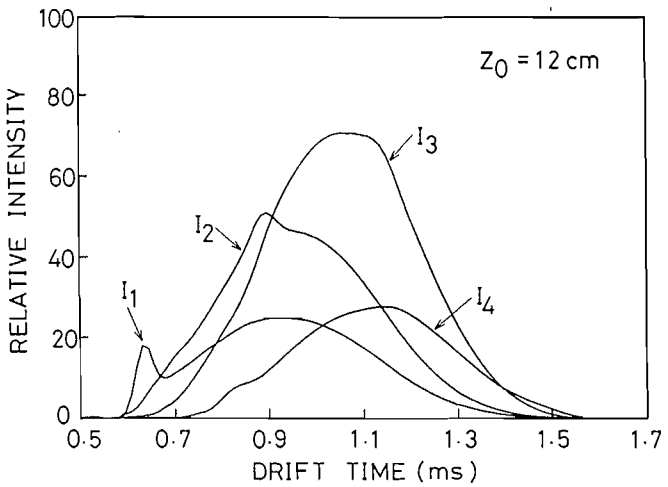

FIG. 3. Same as Fig. 1, with drift length of 12 cm.

set of kinetic coefficients for four ion swarms is available at the present time. We will therefore adopt a model composed of partly hypothetical four-ion swarms, roughly derived from the preliminary experiments carried out in our laboratory for the Na^+/HCl combination. While the system may have a complex scheme because of HCl's relatively large dipole moment, all reaction frequencies are still hypothetical.

The reaction scheme of four ion swarms comprises, in general, twelve elementary reactions. Now, we will represent [12] in a more tractable form as

$$[18] \qquad \Im_{im}(\omega,t) = \sum_{j=1}^{4} g_i(\lambda_j) \exp(\lambda_j t)/f(\lambda_j) \qquad (i = 1, 2, 3, 4)$$

The explicit forms of $g_i(\lambda)$ and $f(\lambda_j)$ are given in Appendix along with those of two and three ion swarms. In drift-tube experiments, one is usually interested in the ion–current profile with respect to drift time at the collector (arrival time spectrum), which is

$$[19] \qquad I_i(z_0,t) = 2\pi \int_0^{r_c} \left(-D_{zi} \frac{\partial \rho_i}{\partial z} + v_{di}\rho_i \right) r\,dr$$

where z_0 and r_c are the drift length and radius of the collector, respectively. Details of the present numerical calculation of [19] are as follows.

We employed four $\delta(z)$ functions as the initial conditions, the ratio of the number densities was set to be $\rho_1:\rho_2:\rho_3:\rho_4 = 10:5:3:6$. This ratio is absolutely not related to the real system at all. The differentiation of ρ_i with respect to z was carried out by using a numerical differential method. Because the integrand in [15] is an even function in ω, we changed the integral variable from ω to x as $\omega = -\log x$. The integral region ranging from $1 \mathrm{G} x \mathrm{G} 10^{-6}$ was employed, and a simple quadrature technique was applied to obtain four arrival time spectra at appropriate drift length and duration time. Four roots of the characteristic equation [13] were calculated from a standard formula for quartic equation of complex variables. Small oscillations of the solutions near the base line were occasionally observed. These were partly averaged. This kind of numerical instability, however, may easily be eliminated by employing more elaborate numerical techniques for an inverse Fourier transform than the present simple quadrature. Numerically obtained four arrival time spectra at five different drift lengths are shown in Figs. 1 to 5. Their transport coefficients and the twelve reaction frequencies are listed in Tables 1 and 2, respectively.

By carefully observing these five figures, we can find that the space–time evolution of the ion swarms is roughly classified into three phases, the initial phase, the non-equilibrium phase, and the dynamic equilibrium phase.

The initial phase (Fig. 1) corresponds to a primary step in the evolution, where we can separate the current profile of each arrival time spectrum into two component currents, the initial component and the product component. Relatively large and dominant component arises from the initially injected ions, an original Gaussian shape of which is well preserved during the transport process, and it may give us the most accurate information of its transport coefficients in the three phases. This component is accompanied by the small product component current(s) at its leading edge and/or trailing edge. This feature is helpful to us to estimate qualitatively (and sometimes quantitatively) which elementary reactions are taking place in the system. Each product component generally comprises several subcomponent ions, each arising from an elementary

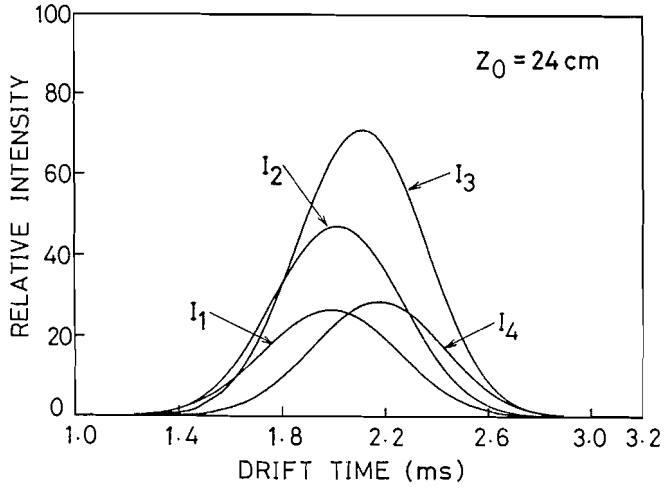

FIG. 4. Same as Fig. 1, with drift length of 24 cm. The ratio of the integrated number densities, which are directly obtained from these spectra by using a numerical quadrature, is $\rho_1:\rho_2:\rho_3:\rho_4$ = 1.000:2.404:4.551:2.448.

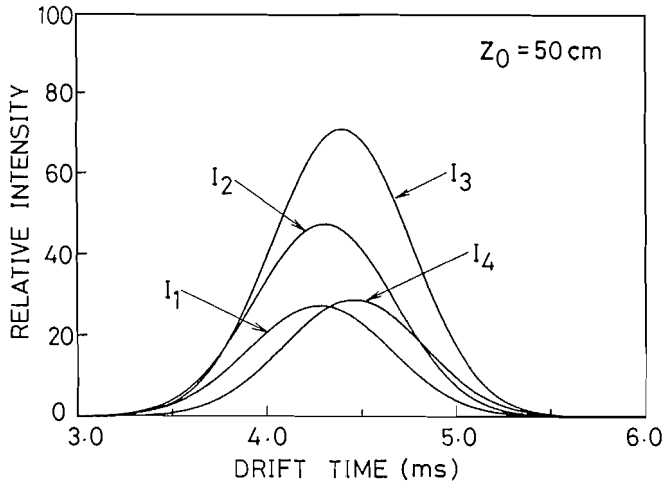

FIG. 5. Same as Fig. 4, with drift length of 50 cm. The ratio is $\rho_1:\rho_2:\rho_3:\rho_4$ = 1.000:2.405:4.555:2.454.

reaction of different original ions. Needless to say, all the product ions in the subcomponents are same species. These subcomponents can often be observed stepwise on the superimposed current profile of product ions (Fig. 1). By examining the relative positions between the steps and peaks of the initially injected components, we can roughly estimate the number of elementary reactions.

The non-equilibrium phase corresponds to an intermediate step in the evolution (Figs. 2 and 3), where the transport and reactive processes operate competitively and the current profiles of all arrival time spectra are subject to dramatic changes. While we can still find the traces of initially injected ions in each arrival time spectrum, these ions are destined to be buried in rapidly growing produced ions due to several reactions. It is almost impossible to determine the diffusion coefficients and drift velocities of all ion species from these spectra in a straightforward manner. However, one noteworthy point in Fig. 2 is that we cannot observe any remarkable reactive component ions at the leading edge of profile I_1, nor at the trailing edge of I_4. This means that the present reactive system is a closed

system in which only four ion species take part in the reaction scheme.

The dynamic equilibrium phase (Figs. 4 and 5) is the final step in the evolution. This apparently placid phase may be the most important phase from both theoretical and practical standpoints. A rather surprising fact is that all the ion swarms lose their initial individuality and seem to be drifting and diffusing with almost the same transport coefficients. These well-featured profiles may give us hope that we can easily determine the transport coefficients of each ion swarms from them. However, the most dominant process in this phase is the inter-reacting process between four ion species, where any direct information on the transport coefficients must be hidden almost completely into the spurious Gaussian profiles made up of several reactive component currents. Nevertheless, relation [16] holds exactly in this phase. The ratio calculated from [16] and [17] for the present system is $I_1:I_2:I_3:I_4$ = 1:2.40:4.53:2.45, which agrees well with both ratios obtained from the current profiles in Figs. 4 and 5 by using the direct numerical quadrature. The number density of each ion swarm was obtained from the current profile by dividing it with its drift velocity, by assuming that the diffusive component in [19] is almost negligible. That this assumption is reasonable is discussed later. Moreover, the practical importance of [16] is to be emphasized again, because the ratio is independent of initial conditions, diffusion coefficients, and drift velocities of all ion swarms, suggesting that we can derive several relations between the reaction frequencies from experimentally measured arrival time spectra. If certain reactions are significant in the system, the measured ratio may give us a group of considerably reliable reaction frequency data within the limit of experimental difficulties, even when the drift length of the apparatus is rather short. Unfortunately, [16] is not defined by each reaction frequency but by groups of mutually multiplied reaction frequencies. In real experimental analysis, however, elimination of the improbable reactions will make the relation mathematically far too simplistic.

While the above numerical calculations, based on a "hypothetical" transport/reactive system for four ion swarms, have

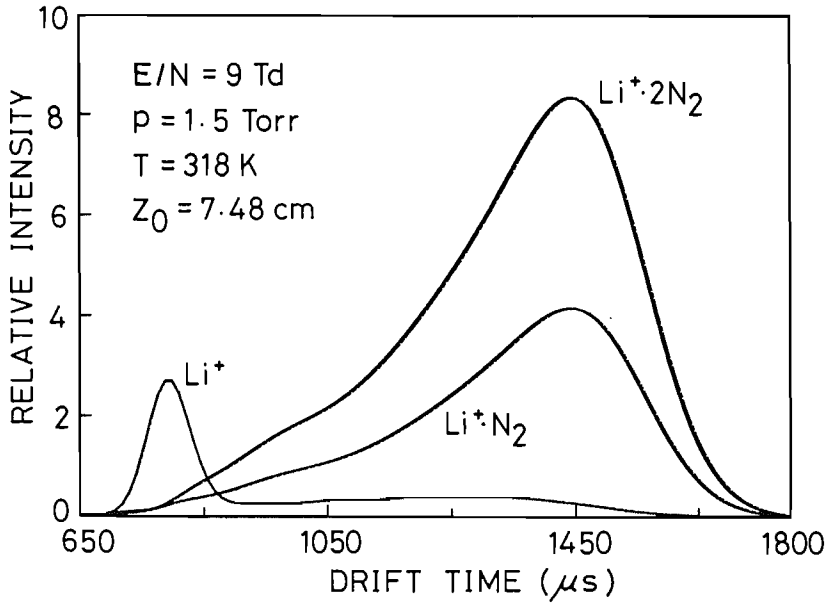

FIG. 6. Arrival time spectra of Li^+, $Li^+ \cdot N_2$, and $Li^+ \cdot 2N_2$ ions in nitrogen. $v_{d1} = 9.358 \times 10^3$, $v_{d2} = 4.933 \times 10^3$, $v_{d3} = 4.740 \times 10^3$ cm/s. $D_{z1} = D_{r1} = 62.55$, $D_{z2} = D_{r2} = 49.46$, $D_{z3} = D_{r3} = 47.52$ cm^2/s. Suffix 1, 2, and 3 correspond to Li^+, $Li^+ \cdot N_2$, and $Li^+ \cdot 2N_2$, respectively. $\alpha_{21} = 4150$, $\alpha_{12} = 320$, $\alpha_{32} = 45650$, $\alpha_{23} = 21860$, $\alpha_{13} = \alpha_{31} = 0$/s. Solid curves are obtained from the exact current eq. [19]. Dot–dashed curves are calculated by the drift component in [19].

been carried out to test the mathematical consistency and physical and chemical soundness of the present formulation, the results may hold in more general cases. Firstly, the three phases mentioned above exist in any transport/reactive process of multiple ion swarms in gases. Secondly, as time goes on, the space–time behaviour of the ion swarms apparently changes as a transport-dominant process to a reaction-dominant process. Thirdly, as the non-equilibrium phase nears its end, all ion swarms seem to be aggregating in appearance, drifting, and diffusing with almost the same transport coefficients, their current profiles becoming very Gaussian. Fourthly, the dynamic equilibrium phase gives us an indisputable information on the reaction frequencies. Finally, the accuracy and sensitivity of the measured kinetic coefficients strongly depend on the phase chosen for the ion swarms in the dynamic process.

Application to experimental analysis

Now, we will prove that the present formulation can justifiably be applied to real systems. Gatland *et al.* extensively analyzed a reactive ion transport process of Li^+, $Li^+ \cdot N_2$, and $Li^+ \cdot 2N_2$ (cluster) ions in N_2 by using a well-known Georgia Tech drift-tube mass spectrometer. They determined the mobilities, diffusion coefficients, and four reaction rates of the above ion species as functions of E/N (the ratio of the electric field strength to the neutral gas number density) (25). The Green's function method (7) was used to analyze the experimental arrival time spectra. We will treat the same system in a reversible cyclic reaction scheme by using the present formulation. The reaction scheme is depicted as

$$[20] \quad Li^+ \underset{\alpha_{12}}{\overset{\alpha_{21}}{\rightleftharpoons}} Li^+ \cdot N_2 \underset{\alpha_{23}}{\overset{\alpha_{32}}{\rightleftharpoons}} Li^+ \cdot 2N_2, \qquad \alpha_{13}, \ \alpha_{31}$$

At first, we reproduce three arrival time spectra obtained by Gatland *et al.* at 9 Td (units of E/N; 1 Td = 10^{-17} V cm^2). In our calculation, two reaction frequencies, α_{13} and α_{31}, were temporarily set to be zero, at this time the other kinetic coefficients were directly derived from their experimental data. We introduced a Gaussian-type initial condition only for Li^+ ions. This includes two adjustable parameters, steepness factor and shift factor. A method of their determination is discussed later. The effect of diffusive component in [19] to the ion–current profile was checked.

Three arrival time spectra calculated from [19] and those from only drift term in it are shown in Fig. 6. Two groups of results almost overlapped each other, indicating that the diffusive component is, in this case, negligibly small compared to the drift component. However, simple disposal of the diffusive component may occasionally give rise to a rather serious experimental error in the kinetic coefficients under certain experimental conditions, where the arrival time spectrum is often drastically deformed in the short distance of drift length. The truncation effect for the infinite sums in m of [5] also proved to be negligible after testing a few terms. This is generally true in the usual drift-tube analysis.

For the present formulation, a standard procedure of experimental analysis is as follows. Firstly, we determine the detection efficiency for each ion species from the preliminary experiments. Secondly, we measure two groups of arrival time spectra, those in initial phase and those in dynamic equilibrium phase. Thirdly, the ion–current profiles are to be divided by their own detection efficiencies, and a set of new spectra are reconstructed in both phases. Fourthly, by using the initial-phase spectra we determine the drift velocity and longitudinal diffusion coefficient of each ion swarm, and roughly estimate several reaction frequencies from the areas of current profiles. The drift-tube apparatus with movable ion source is strongly recommended; we obtain several arrival time spectra of different ion source positions with such apparatus. The set of spectra

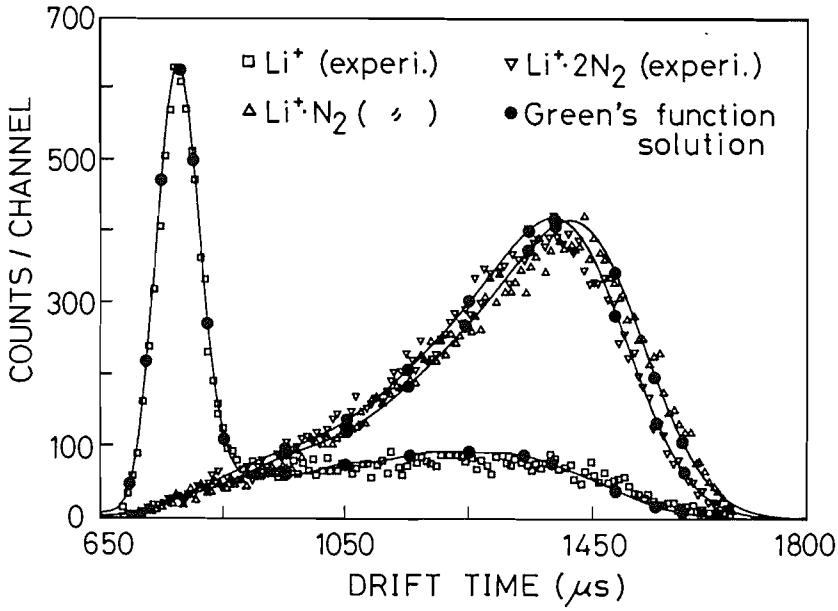

FIG. 7. A comparison of modified theoretical arrival time spectra with Green's function solutions and experimental data. The ratio of detection efficiencies is $I_1:I_2:I_3 = 1.00:0.44:0.22$. Experimental conditions and kinetic parameters for calculations are the same as in Fig. 6.

is useful in more accurate measurement of the above kinetic coefficients. Moreover, with the help of initial-phase spectra we can determine the two adjustable parameters involved in the initial condition from the set of initially injected spectra. The Gaussian-type initial condition is represented by a function, $F(r)\exp[-a(z-b)^2]$. $F(r)$ is a radial distribution of the initial condition, by which a_{im} in [5] can be evaluated using the orthogonality of Bessel functions. The steepness factor, a, is estimated from the full widths at half the maxima of the initially injected profiles at several distinct ion source positions. The shift factor, b, is closely connected to the end effects (3) arising at the ion source or the detector end of the apparatus, which is therefore estimated from the extrapolation length yielded by a standard experimental procedure for determining the drift velocity (3). Fifthly, we determine the ratio of reaction frequencies, [16], from the areas of the spectra measured in the dynamic equilibrium phase, by which we can re-examine the accuracy of the roughly estimated reaction frequencies and the pertinence of assumed number of elementary reactions. Finally, we substitute all these kinetic coefficients back into the appropriate number of solutions and reproduce the space–time behavior of the multiple-ion swarms. Any additional correction of these parameters must be iteratively carried out in the above procedure.

Three arrival time spectra of Li^+, $Li^+\cdot N_2$, and $Li^+\cdot 2N_2$ ions, involving a little surmise upon the magnitudes of detection efficiencies, are shown in Fig. 7 along with the experimental data and the Green's function solutions obtained by Gatland *et al.* (25). The experimental data were read off from their original figure by using our small digitizer, the reading error of which was estimated to be no worse than 0.5% for all data. The agreement between the present spectra and their solutions, which also were read off by the digitizer, seems to be excellent.

Now we examine the effect of non-neighbor reaction, α_{13} in [20], how much deformation arises in the original three spectra. Gatland *et al.* already pointed out the possibility of a α_{13} reaction. However, α_{31} reaction can be reasonably ruled out because the probability of four-body reaction is negligibly small at the pressure range (0.5–1.5 Torr) selected in their experiments. We therefore ignore this reaction. By examining the pressure dependence of a long tail in the Li^+ spectrum, they concluded that both reactions could be ignored. The present formulation is directly applicable to analyze this problem, and may give us more precise information to confirm their conclusion.

Three groups of arrival time spectra for three different reactive conditions are shown in Fig. 8. We are concerned with the source of the Li^+ ions produced in the long tail of the Li^+ spectrum; $Li^+\cdot N_2$ ions (α_{12} reaction), or $Li^+\cdot 2N_2$ ions (α_{13} reaction), or both ion species. Figure 8 shows that the deformation of the Li^+ spectrum arisen from the product ions is restricted only to its long tail area, and we cannot observe any remarkable difference in the deformation of initially injected component between three reaction schemes. The ions in the tail seem to be simply partitioned into α_{13}- and α_{12}-reaction products. The area of tail of No. 3 is almost twice as large as that of No. 1. These numerical results may support their claim that the Li^+ ions in the tail of the Li^+ spectrum are produced mainly by the α_{12} reaction. If we adopt other combinations of reaction frequencies, the ratio of initially injected area to tail area may disagree with that from experimentally obtained Li^+ spectrum. However, if the assumed detection efficiencies for the $Li^+\cdot N_2$ and $Li^+\cdot 2N_2$ ions are rather doubtful, the situation will become appreciably different.

We will now discuss briefly the analysis of the two ion swarms. Since this is the simplest reactive ion transport involving only two reaction rates and six transport coefficients, two ion swarms have been extensively analyzed by many researchers (3). Most of the methods, however, were limited to the analyses of rather specified ion/molecule (or electron/molecule) combinations in specified experimental conditions, except for the Green's function method. The present formulation may become another useful and more tractable method to treat the two ion swarm phenomena in a general manner. Furthermore, it is to be noted that the present method can easily be extended to treat more general transport coefficients like

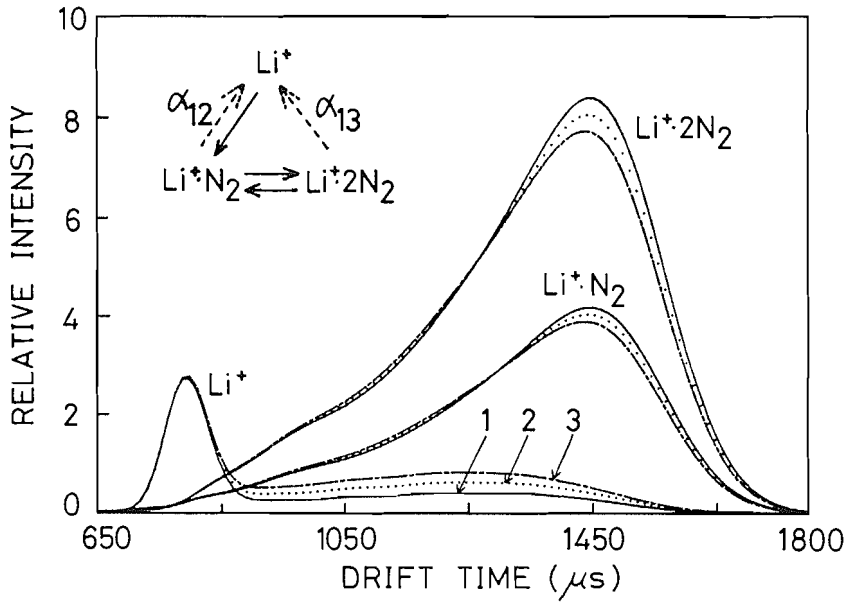

FIG. 8. Arrival time spectra for three different reaction schemes. The solid curves (No. 1) are calculated from the reaction scheme of $\alpha_{12} = 320$ and $\alpha_{13} = 0$/s (same as those of Fig. 6). Dotted curves (No. 2) are those of $\alpha_{12} = \alpha_{13} = 160$/s. Dot–dashed curves (No. 3) are those of $\alpha_{12} = 0$ and $\alpha_{13} = 320$/s. Other kinetic parameters are same as Fig. 6.

"skewness" of the ion swarms, introduced by Skullerud and co-workers in their recent analysis of the Li^+/He system without reactions (26).

Discussion

(a) Initial conditions

In this work, we have adopted two types of initial conditions, the δ function and Gaussian-type function, for the density distributions of initial ion swarms in the axial direction. The former may be useful to obtain the basic information of the dynamic process of multiple ion swarms, specifically to estimate the number of elementary reactions. The latter is recommended for the analysis of more realistic ion swarm phenomena. Basically, however, there is no specific restriction to the mathematical form of the initial condition for the present formulation. Any function can be employed as an initial condition by using a Fourier transform and the orthogonality of Bessel functions.

(b) Radial and axial boundary conditions

To solve the boundary value problem of transport equation, it is essential to choose an appropriate space coordinate suitable for the geometrical structure of experimental apparatus. The cylindrical coordinate is, in this sense, the best choice for the present drift-tube analysis, therefore we can easily introduce the radial boundary effects into [5]. A brief comment on the effects were given by Woo and Whealton (20). However, the treatment of the axial boundary conditions of [5] is not so simple, because [5] is a free boundary solution with respect to the axial coordinate. The method of "negative image swarm" developed by Lowke (27) and applied to analyzing the K^+/N_2 system by Milloy (28). This technique proves to be suitable in the present method. Both boundary conditions were extensively re-examined by Gatland in his review (7).

(c) Neutral gas mixtures

The analysis in gas mixtures is an interesting practical subject in many applied fields. Specifically, in ion chemistry of the earth's atmosphere we have to treat a complex reaction scheme of ion species with a mixture of nitrogen, oxygen, and other neutral species (13). In such a case, each reaction frequency involved in [3] is represented by a summation of several sub-reaction frequencies. If we assume that the mixture is composed of q-neutral gases, [2] is extended to a more general form as

$$[21] \qquad \alpha_{ij} = \sum_{p=1}^{\infty} k_{ij}(p) N_1^{p_1} N_2^{p_2} \cdots N_m^{p_m} \cdots N_q^{p_q}$$

with

$$[22] \qquad p = p_1 + p_2 + \cdots\cdots + p_m + \cdots\cdots + p_q$$

where N_m is the number density of mth neutral gas, p_m is the order of reaction with respect to mth neutral gas, and $k_{ij}(p)$ is the pth order reaction rate from species j to i. While several terms in [21] are absolutely meaningless in the analysis, this formula may be useful for us to classify the above sub-reaction processes into three groups, the direct associative reaction, the associative reaction accompanied by the stabilizing process, and the dissociative reaction. Two-body and three-body reactions are the simplest examples of first and second processes, respectively. The reader can refer to two reviews for details of these processes, the theory of which is mainly based on statistical mechanics (29, 30).

For the diffusion coefficients and drift velocities of ions in gas mixtures, we can resort to several approximate theories and elaborate calculations associated with Blanc's law (31).

(d) Inelastic process

The present formulation can basically cover the inelastic processes of excited ions and molecules in linear swarm phenomena, where the transport coefficients and reaction frequencies are determined phenomenologically as functions of mean translational energies and internal energy states of the species. More precise formulation may be derived from the Wang–Chang – Uhlenbeck – de Boer equation (32).

For personal use only.

(e) Non-linear process

The analysis of non-linear process may be one of the most formidable subjects not only in gas phase ion chemistry, but also in various research fields. In fact, not a few really measureable intermediates and products have been yielded by this process $(O^+(^2P)/O, O^+(^2D)/O, O^-/O_3, O_2^-/O_3, OH^-/O_3, O_3^-/O, CO_3^-/NO$, etc.) in the ionosphere. Moreover, the experimental study on plasma processes involving many charged particles and metastable molecules requires this kind of non-linear analysis. Unfortunately, the two mathematical techniques used to derive the present formulation are not easily extended to treat the non-linear process, because both Fourier transform and matrix algebra are, in essence, tools for analyzing linear phenomena in nature. Thus all contents in this paper may not be applicable to the analysis of non-linear process. However, the only conclusion, which may still hold even in a non-linear process, is that the dynamic equilibrium state is the ultimately attainable phase in the space–time evolution of inter-reacting multiple chemical species.

Summary

A new formulation for the analysis of reactive ion transport of multiple ion swarms in neutral gases has been proposed within the framework of linear process. The dynamic process has been classified into three phases, the initial phase, the non-equilibrium phase, and the dynamic equilibrium phase. A picture of the space–time evolution for four ion swarms has been numerically obtained. Experimental data of kinetic coefficients for $(Li^+, Li^+\cdot N_2, Li^+\cdot 2N_2)/N_2$ system determined by Gatland *et al.* have been examined in a reversible cyclic reaction scheme. Moreover, a procedure for the analysis of experimental arrival time spectra to determine the kinetic coefficients of multiple ion swarms has been obtained in the present formulation.

Appendix

The explicit forms of $g_i(\lambda)$ and $f(\lambda_j)$ in [18] for two, three, and four ion swarms are summarized here, where N_i is a Fourier transformed initial condition for ith ion species. Other notations were already defined in this paper. It is to be noted that the present formulae will become exactly the same as the well-known time-dependent solutions of a set of coupled rate equations for a first-order reaction sequence (9) when we ignore all the transport coefficients and several reaction frequencies of the ion species in them.

(1) Two-ion swarms

[A1] $$g_1(\lambda) = N_1\lambda - N_1T_2 + N_2\alpha_{12}$$

[A2] $$g_2(\lambda) = N_2\lambda - N_2T_1 + N_1\alpha_{21}$$

[A3] $$f(\lambda_1) = \lambda_1 - \lambda_2$$

[A4] $$f(\lambda_2) = \lambda_2 - \lambda_1$$

For personal use only.

(2) Three-ion swarms

[A5] $$g_1(\lambda) = N_1\lambda^2 + \lambda[N_2\alpha_{12} + N_3\alpha_{13} - N_1(T_2 + T_3)] + N_1(T_2T_3 - \alpha_{23}\alpha_{32}) + N_2(\alpha_{13}\alpha_{32} - \alpha_{12}T_3) + N_3(\alpha_{12}\alpha_{23} - \alpha_{13}T_2)$$

[A6] $$g_2(\lambda) = N_2\lambda^2 + \lambda[N_1\alpha_{21} + N_3\alpha_{23} - N_2(T_1 + T_3)] + N_1(\alpha_{23}\alpha_{31} - \alpha_{21}T_3) + N_2(T_1T_3 - \alpha_{13}\alpha_{31}) + N_3(\alpha_{13}\alpha_{21} - \alpha_{23}T_1)$$

[A7] $$g_3(\lambda) = N_3\lambda^2 + \lambda[N_1\alpha_{31} + N_2\alpha_{32} - N_3(T_1 + T_2)] + N_1(\alpha_{21}\alpha_{32} - \alpha_{31}T_2) + N_2(\alpha_{12}\alpha_{31} - \alpha_{32}T_1) + N_3(T_1T_2 - \alpha_{12}\alpha_{21})$$

[A8] $$f(\lambda_1) = (\lambda_1 - \lambda_2)(\lambda_1 - \lambda_3)$$

[A9] $$f(\lambda_2) = (\lambda_2 - \lambda_1)(\lambda_2 - \lambda_3)$$

[A10] $$f(\lambda_3) = (\lambda_3 - \lambda_1)(\lambda_3 - \lambda_2)$$

(3) Four-ion swarms

[A11] $$\begin{aligned} g_1(\lambda) = {} & N_1\lambda^3 + \lambda^2[N_2\alpha_{12} + N_3\alpha_{13} + N_4\alpha_{14} - N_1(T_2 + T_3 + T_4)] \\ & + \lambda\{N_1(T_2T_3 + T_2T_4 + T_3T_4 - \alpha_{23}\alpha_{32} - \alpha_{24}\alpha_{42} - \alpha_{34}\alpha_{43}) + N_2[\alpha_{14}\alpha_{42} + \alpha_{13}\alpha_{32} - \alpha_{12}(T_3 + T_4)] \\ & + N_3[\alpha_{14}\alpha_{43} + \alpha_{12}\alpha_{23} - \alpha_{13}(T_2 + T_4)] + N_4[\alpha_{12}\alpha_{24} + \alpha_{13}\alpha_{34} - \alpha_{14}(T_2 + T_3)]\} \\ & + N_1(\alpha_{34}\alpha_{43}T_2 + \alpha_{24}\alpha_{42}T_3 + \alpha_{23}\alpha_{32}T_4 - \alpha_{23}\alpha_{34}\alpha_{42} - \alpha_{24}\alpha_{32}\alpha_{43} - T_2T_3T_4) \\ & + N_2(\alpha_{12}T_3T_4 + \alpha_{13}\alpha_{34}\alpha_{42} + \alpha_{14}\alpha_{32}\alpha_{43} - \alpha_{14}\alpha_{42}T_3 - \alpha_{13}\alpha_{32}T_4 - \alpha_{12}\alpha_{34}\alpha_{43}) \\ & + N_3(\alpha_{13}T_2T_4 + \alpha_{12}\alpha_{24}\alpha_{43} + \alpha_{14}\alpha_{23}\alpha_{42} - \alpha_{12}\alpha_{23}T_4 - \alpha_{14}\alpha_{43}T_2 - \alpha_{13}\alpha_{24}\alpha_{42}) \\ & + N_4(\alpha_{14}T_2T_3 + \alpha_{12}\alpha_{23}\alpha_{34} + \alpha_{13}\alpha_{24}\alpha_{32} - \alpha_{12}\alpha_{24}T_3 - \alpha_{13}\alpha_{34}T_2 - \alpha_{14}\alpha_{23}\alpha_{32}) \end{aligned}$$

[A12] $$\begin{aligned} g_2(\lambda) = {} & N_2\lambda^3 + \lambda^2[N_1\alpha_{21} + N_3\alpha_{23} + N_4\alpha_{24} - N_2(T_1 + T_3 + T_4)] \\ & + \lambda\{N_1[\alpha_{24}\alpha_{41} + \alpha_{23}\alpha_{31} - \alpha_{21}(T_3 + T_4)] + N_2(T_1T_3 + T_1T_4 + T_3T_4 - \alpha_{34}\alpha_{43} - \alpha_{14}\alpha_{41} - \alpha_{13}\alpha_{31}) \\ & + N_3[\alpha_{24}\alpha_{43} + \alpha_{13}\alpha_{21} - \alpha_{23}(T_1 + T_4)] + N_4[\alpha_{23}\alpha_{34} + \alpha_{14}\alpha_{21} - \alpha_{24}(T_1 + T_3)]\} \\ & + N_1(\alpha_{21}T_3T_4 + \alpha_{23}\alpha_{34}\alpha_{41} + \alpha_{24}\alpha_{31}\alpha_{43} - \alpha_{24}\alpha_{41}T_3 - \alpha_{23}\alpha_{31}T_4 - \alpha_{21}\alpha_{34}\alpha_{43}) \\ & + N_2(\alpha_{34}\alpha_{43}T_1 + \alpha_{14}\alpha_{41}T_3 + \alpha_{13}\alpha_{31}T_4 - \alpha_{13}\alpha_{34}\alpha_{41} - \alpha_{14}\alpha_{31}\alpha_{43} - T_1T_3T_4) \\ & + N_3(\alpha_{23}T_1T_4 + \alpha_{13}\alpha_{24}\alpha_{41} + \alpha_{14}\alpha_{21}\alpha_{43} - \alpha_{24}\alpha_{43}T_1 - \alpha_{13}\alpha_{21}T_4 - \alpha_{14}\alpha_{23}\alpha_{41}) \\ & + N_4(\alpha_{24}T_1T_3 + \alpha_{14}\alpha_{23}\alpha_{31} + \alpha_{13}\alpha_{21}\alpha_{34} - \alpha_{23}\alpha_{34}T_1 - \alpha_{14}\alpha_{21}T_3 - \alpha_{13}\alpha_{24}\alpha_{31}) \end{aligned}$$

[A13] $$\begin{aligned} g_3(\lambda) = {} & N_3\lambda^3 + \lambda^2[N_1\alpha_{31} + N_2\alpha_{32} + N_4\alpha_{34} - N_3(T_1 + T_2 + T_4)] \\ & + \lambda\{N_1[\alpha_{21}\alpha_{32} + \alpha_{34}\alpha_{41} - \alpha_{31}(T_2 + T_4)] + N_2(\alpha_{34}\alpha_{42} + \alpha_{12}\alpha_{31} - \alpha_{32}(T_1 + T_4)] \\ & + N_3(T_1T_2 + T_1T_4 + T_2T_4 - \alpha_{24}\alpha_{42} - \alpha_{14}\alpha_{41} - \alpha_{12}\alpha_{21}) + N_4[\alpha_{24}\alpha_{32} + \alpha_{14}\alpha_{31} - \alpha_{34}(T_1 + T_2)]\} \\ & + N_1(\alpha_{31}T_2T_4 + \alpha_{21}\alpha_{34}\alpha_{42} + \alpha_{24}\alpha_{32}\alpha_{41} - \alpha_{21}\alpha_{32}T_4 - \alpha_{34}\alpha_{41}T_2 - \alpha_{24}\alpha_{31}\alpha_{42}) \\ & + N_2(\alpha_{32}T_1T_4 + \alpha_{12}\alpha_{34}\alpha_{41} + \alpha_{14}\alpha_{31}\alpha_{42} - \alpha_{34}\alpha_{42}T_1 - \alpha_{12}\alpha_{31}T_4 - \alpha_{14}\alpha_{32}\alpha_{41}) \\ & + N_3(\alpha_{24}\alpha_{42}T_1 + \alpha_{14}\alpha_{41}T_2 + \alpha_{12}\alpha_{21}T_4 - \alpha_{12}\alpha_{24}\alpha_{41} - \alpha_{14}\alpha_{21}\alpha_{42} - T_1T_2T_4) \\ & + N_4(\alpha_{34}T_1T_2 + \alpha_{12}\alpha_{24}\alpha_{31} + \alpha_{14}\alpha_{21}\alpha_{32} - \alpha_{24}\alpha_{32}T_1 - \alpha_{14}\alpha_{31}T_2 - \alpha_{12}\alpha_{21}\alpha_{34}) \end{aligned}$$

[A14] $$\begin{aligned} g_4(\lambda) = {} & N_4\lambda^3 + \lambda^2[N_1\alpha_{41} + N_2\alpha_{42} + N_3\alpha_{43} - N_4(T_1 + T_2 + T_3)] \\ & + \lambda\{N_1[\alpha_{21}\alpha_{42} + \alpha_{31}\alpha_{43} - \alpha_{41}(T_2 + T_3)] + N_2[\alpha_{32}\alpha_{43} + \alpha_{12}\alpha_{41} - \alpha_{42}(T_1 + T_3)] \\ & + N_3[\alpha_{23}\alpha_{42} + \alpha_{13}\alpha_{41} - \alpha_{43}(T_1 + T_2)] + N_4(T_1T_2 + T_1T_3 + T_2T_3 - \alpha_{23}\alpha_{32} - \alpha_{13}\alpha_{31} - \alpha_{12}\alpha_{21})\} \\ & + N_1(\alpha_{41}T_2T_3 + \alpha_{21}\alpha_{32}\alpha_{43} + \alpha_{23}\alpha_{31}\alpha_{42} - \alpha_{21}\alpha_{42}T_3 - \alpha_{31}\alpha_{43}T_2 - \alpha_{23}\alpha_{32}\alpha_{41}) \\ & + N_2(\alpha_{42}T_1T_3 + \alpha_{13}\alpha_{32}\alpha_{41} + \alpha_{12}\alpha_{31}\alpha_{43} - \alpha_{32}\alpha_{43}T_1 - \alpha_{12}\alpha_{41}T_3 - \alpha_{13}\alpha_{31}\alpha_{42}) \\ & + N_3(\alpha_{43}T_1T_2 + \alpha_{12}\alpha_{23}\alpha_{41} + \alpha_{13}\alpha_{21}\alpha_{42} - \alpha_{23}\alpha_{42}T_1 - \alpha_{13}\alpha_{41}T_2 - \alpha_{12}\alpha_{21}\alpha_{43}) \\ & + N_4(\alpha_{23}\alpha_{32}T_1 + \alpha_{13}\alpha_{31}T_2 + \alpha_{12}\alpha_{21}T_3 - \alpha_{12}\alpha_{23}\alpha_{31} - \alpha_{13}\alpha_{21}\alpha_{32} - T_1T_2T_3) \end{aligned}$$

[A15] $$f(\lambda_1) = (\lambda_1 - \lambda_2)(\lambda_1 - \lambda_3)(\lambda_1 - \lambda_4)$$

Stereoselective syntheses of isomers of 3,7-dimethylnonadecane, a sex pheromone of the alfalfa blotch leafminer (*Agromyza frontella* (Rondani))

DAVID MILLER, FRANÇOIS BILODEAU, AND ROBERT H. BURNELL[1]
Département de chimie, Université Laval, Québec (Québec), Canada G1K 7P4

Received July 24, 1990[2]

DAVID MILLER, FRANÇOIS BILODEAU, and ROBERT H. BURNELL. Can. J. Chem. **69**, 1100 (1991).

Two related stereoselective syntheses of 3,7-dimethylnonadecane, a sex pheromone of the alfalfa leafminer, are described to show that pulegone can serve as a useful starting material for the preparation of chiral aliphatic isoprenoid compounds. The schemes are designed to place the stereogenic center of pulegone at C.3 in one synthesis and at C.7 in the other so that the optical properties of the products can be compared with one another and with the values calculated using Brewster's rules.

Key words: chiral hydrocarbons, stereoselective synthesis, pheromone, *Agromyza frontella*.

DAVID MILLER, FRANÇOIS BILODEAU et ROBERT H. BURNELL. Can. J. Chem. **69**, 1100 (1991).

Deux synthèses apparentées de 3,7-diméthylnonadécane, la phéromone sexuelle de la mouche mineuse de la luzerne, sont présentées pour démontrer l'utilité de la pulégone naturelle comme substance initiale pour préparer certains produits aliphatiques isoprépiques. Les approches placent le carbone stéréogénique de la pulégone en C.3 dans un cas et en C.7 dans l'autre donc la comparaison des propriétés chiroptiques des deux échantillons peut fournir des indices de la stéréosélectivité des réactions critiques dans le schéma synthétique.

Mots clés: hydrocarbures chiraux, synthèses stéréosélectives, phéromone, *Agromyza frontella*.

Introduction

The alfalfa blotch leafminer (*Agromyza frontella* (Rondani)) is a dipteran insect, which spread rapidly in North America after its unintentional introduction from Europe in the late 1960's (1). Studies of mating behavior (2) and subsequent chemical analysis of hexane surface extracts of the male insects identified 3,7-dimethylnonadecane as a female sex pheromone component. Bioassay of the material from a synthetic mixture of racemic hydrocarbons confirmed the general identity of the natural product (3).

The methyl groups on the nonadecane chain are placed with isoprenoid spacing at positions that allow four possible stereoisomers, which probably do not have identical biological activity. It was of interest to design a synthesis that could give selective access to one or more of the stereoisomers. (*R*)-(+)-pulegone **1** was chosen as a chiral starting material due to its availability in a reasonably pure state and because of its fortuitous functionality. Both natural pulegone (4) and isopulegol (5) have been used as chiral starting materials in pheromone synthesis. Usually, however, they only serve as a source of (*R*)-(+)-citronellic acid (yield 50–60%) (6, 7) or its reduction product (*R*)-(+)-citronellol ($LiAlH_4$ reduction of the acid, 90%) (8). In the present syntheses the (*R*)-(+)-pulegone serves directly as the starting product and, should the enantiomeric synthesis be necessary, it can be transformed into (*S*)-(−)-pulegone (9). The commerical product (Aldrich) was fractionally distilled twice under high reflux ratio conditions and then further purified by argentation chromatography. GC analysis showed that the material used in the syntheses was >99% chemically pure and the specific rotation ($[\alpha]_D^{23}$ +21.3 (*c* 6.505, $CHCl_3$)) was unchanged by further purification. Unfortunately several different specific rotations are given in the literature for pulegone but all are similar to the value obtained above.

The first synthesis (Scheme 1) planned the involvement of the cyclic ketal **2** whose terminal double bond would permit, in a few steps, the addition of a methyl group. The ring of the homologous ketone **3***a* could be opened oxidatively (Baeyer–Villiger) and the resulting acyl group in the product **4***a* should allow the facile introduction of the C_{10} chain to complete the 3,7-dimethylnonadecane **5***a*. In this way the chirality at C.5 in pulegone would be located at C.7 in the synthesized pheromone. It was anticipated that there would be considerable induction of a particular stereochemistry at C.3. To a great extent the purpose of the synthesis was to ascertain how important this natural induction would be.

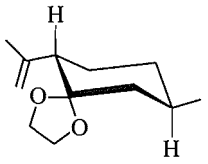
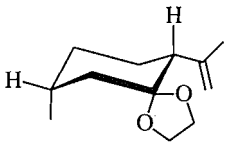
3*a* R = CH_3
3*b* R = $(CH_2)_{10}CH_3$

4*a* R = CH_3
4*b* R = $(CH_2)_{10}CH_3$



5*a* $R^1 = CH_3$; $R^2 = (CH_2)_9CH_3$
5*b* $R^1 = (CH_2)_{10}CH_3$; $R^2 = H$

SCHEME 1



The general method outlined above also afforded another route to the final product (Scheme 1). Using much the same methodology, a C_{11} chain could be added to the terminal double bond in ketal **2**, and the ester moiety in **4***b* arising from ring cleavage of the derived ketone **3***b* could be reduced to afford the hydrocarbon **5***b*. In this case, however, the C.5 chirality of pulegone would reside at the C.3 center of the pheromone. In theory, the two routes would allow us a comparison of the asymmetric induction achieved at the other chiral center.

Strong acid catalysed ketalization of pulegone is normally accompanied by double bond migration (10). In the case of

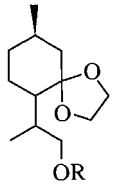
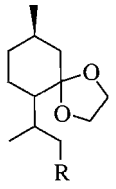
pulegone this introduces a second stereogenic carbon that will eventually lose its chirality, but its importance may be critical while establishing the stereochemistry at the adjacent methyl-bearing carbon, one of the two chiral centers in the final product. The conventional Dean–Stark procedure with benzene provided good yields of the spiroketal in 24–48 h and, with *p*-toluenesulfonic acid as the catalyst, diastereoisomers **2***a* and **2***b* were obtained in the ratio 5.7:1.[3] Since the ketal arises from a long equilibration it is assumed that the major component is **2***a*, in which the two substituents are equatorial to the six-membered ring.

Reexamination of the ketalization brought to light some interesting aspects of the process. Following the progress of the reaction by gas chromatography showed that the product formed more rapidly than all others is neither **2***a* nor **2***b* but rather **6**, in which the double bond has not migrated. After 4.25 h (benzene, *p*-TsOH, reflux Dean–Stark) the concentration of the kinetic product is as high as 16% but **6** disappeared with time to the profit of the normally isolated products. The kinetic product **6** was compared with a sample prepared under conditions where double bond migration is not usually observed (11).



Hydroboration/oxidation of the ketal **2***a* allowed the anti-Markownikow addition to the terminal double bond, affording **7***a*. At this point, the stereochemistry of the final dimethylnonadecane was established and should be preserved to the end of the synthesis.

Primary alcohol **7***a* was converted to the unstable tosylate **7***b*, which was alkylated directly with dimethyllithium cuprate (80%). The resulting ketal **8***a* afforded the ketone **9***a* on hydrolysis (acetone–water, trace HCl: 89%).



The next three steps were optimized using 2*S*,5*R*-menthone **9***c* as a model. Standard Baeyer–Villiger oxidation of the latter

[3]More recently it was found that the final equilibrium could be tilted to 12:1 (**2***a* to **2***b*) by using benzene with camphorsulfonic acid. The yield was lower, however (63%).

with *m*-chloroperbenzoic acid led slowly but exclusively to the lactone **10***c* (83%) but, using the Whitesell conditions (12) in which solid sodium bicarbonate is introduced, the reaction had reached an optimal point after only 2.5 h and the isolated yield of lactone **10***c* (90%) was superior to that from the classical procedure. Methanolysis (MeOH, trace H_2SO_4) was virtually quantitative at room temperature and the hydroxy ester **11***c* was tosylated and reduced with lithium aluminium hydride to alcohol **12***c*. The latter gave spectra identical with those of the product obtained by the hydrogenation of geraniol. The model compounds **10***c*, **11***c*, and **12***c* were useful in the assignment of the ^{13}C nmr resonances.

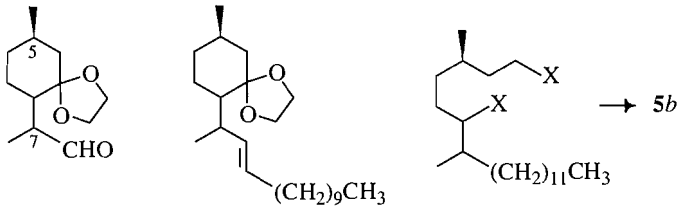
13

14



5*a*

In identical fashion homologous ketone **9***a* was oxidized to lactone **10***a* (quantitative), methanolysed to hydroxy ester **11***a* (84%), tosylated, and then reduced ($LiAlH_4$) to 3(*R*),7-dimethylnonanol **12***a* (40%). Oxidation of primary alcohol **12***a* using PCC in methylene chloride gave nonanal **13** (70%). The latter was treated with the ylide prepared from decyltriphenylphosphonium bromide giving 3,7-dimethylnonadec-9-ene **14**, which was hydrogenated over palladium on charcoal to afford the 3,7-dimethylnonadecane **5***a*, $[\alpha]_D$ +2.42.

It was hoped that essentially the same steps could be used in the alternate synthesis. However, the tosylate of **7***a* gave only traces of alkylated product when treated with diundecyllithium cuprate. Consequently, alcohol **7***a* was oxidized to aldehyde **15** (PCC, NaOAc, CH_2Cl_2, room temp.). Wittig reaction with triphenylundecylphosphonium bromide then afforded **16**, which was hydrogenated over Adams' catalyst to give ketal **8***b*. Hydrolysis gave the ketone **9***b*.

Ketone **9***b* was cleaved to lactone **10***b* by Baeyer–Villiger oxidation and methanolysis then afforded ester **11***b*. To remove both oxygen functions at the same time, the latter was reduced with hydride to the diol **17***a* but, despite numerous attempts, no conditions could be found to prepare the ditosyl derivative. Finally, the dibromide **17***b* was prepared using triphenylphosphine and bromine (13) and the halogen substituents removed by hydrogenolysis ($LiAlH_4$) to give the second pheromone **5***b*, $[\alpha]_D$ +3.76. In an alternate route hydroxy ester **11***b* was tosylated and reduced with hydride, affording the primary alcohol **12***b*. The tosylate of the latter was then reduced to **5***b* in the same manner.

Brewster has formulated a series of rules for predicting the

FIG. 1

sign and magnitude of the optical properties of hydrocarbons (14). The calculations and examples, such as those in Fig. 1, show that in long-chain hydrocarbons, only chiral centers near the ends of the chains contribute significantly to the molecular rotations. The rules suggest that our synthetic product **5***b*, in which (*R*)-(+)-pulegone's chirality is at C.3, should be dextrorotatory with an $[M]_D$ of 12°. The observed molecular rotation of +11.1° is in acceptable agreement with this calculated value. Comparing this result with that obtained for hydrocarbon **5***a* from the other synthesis allows an assessment of the stereochemistry induced at the other asymmetric carbon because in this case the chirality of pulegone is at C.7 where its effect should be negligible. From the molecular rotation of **5***a* ($[M]_D$ +7.2°) it appears that the first two reactions in the synthesis (ketalization and hydroboration) favor by a factor of 4:1 the configuration that leads to the (*S*)-3 geometry in the final product.

This implies a considerable rotational preference for the isopropenyl group in the ketal. Models suggest no clear preference but, if the major rotamer is that shown in **2***a*, the hydride in the diborane reaction arrives from the remote side of the molecule. Apparently the ketal oxygens do not actively deliver the borane reagent to the appropriate face of the double bond, as the sterically more demanding 9-BBN produced the same alcohol with essentially the same stereochemical preference.

Confirmation of the *S*-configuration at C.3 was obtained from another source. The aldehyde **15** was always treated promptly and with care to avoid epimerization, particularly during the Wittig reaction. It seemed wise to test just how effective the precautions were. At −78°C in the presence of basic catalysts, the aldehyde was virtually unchanged after 3 h but, after the same period at room temperature in methanol containing potassium carbonate, the ^{1}H nmr of the recovered product now showed two doublets for the aldehyde proton, the original at 9.62 and another at 9.26 δ. The latter was considerably more intense (1:3 from the nmr integration), which implies that this is the thermodynamically favoured aldehyde. When the two epimeric structures were examined by the Alchemy II program, the most favoured rotamer of the (*R*)-5,(*S*)-7 isomer of **15** was found to be more stable than the *R,R* compound by about 2 kcal/mol. The aldehyde used to continue the synthesis was the less stable and following this through the sequence (without loss of chirality) would lead to **5***b* with the (*S*)-3,(*S*)-7 configurations.

Experimental

Unless otherwise stated, the conditions and instruments used to characterize the products were as follows: melting points, Electrothermal, uncorrected; ultraviolet spectra, ethanol solutions (ε in parentheses), Hewlett–Packard 8450 A; infrared spectra, carbon tetrachloride solutions, Beckman 4250 and Perkin–Elmer 457; 200-MHz proton and 50-MHz carbon-13 magnetic resonance spectra, deuterochloroform solutions, standard TMS protons and carbon = 0 ppm (where relevant, multiplicity, integrated peak areas, coupling constants, and assignments in parentheses), "dis. D_2O" signifies that the peaks in question disappeared on shaking the solution with a small volume of D_2O, Varian XL-200; mass spectra, Hewlett–Packard 5992; GLC analyses, Varian 3700 and Hewlett–Packard 5792A, flame ionization, DB-1 and SE-30 columns. Elemental analyses were by Galbraith Laboratories, Knoxville, TN. High resolution mass spectra were recorded at the Centre régional de spectrométrie de masse, Université de Montréal. Unless otherwise recorded, dry column chromatography implies the use of Merck Kieselgel 60F (70–230 mesh) and elution with hexane–ether (proportions determined by prior thin-layer chromatography using Baker-flex Silica gel 1B-2F precoated plastic sheets).

First synthesis affording pheromone **5***a*

Ketalization of (R)-(+)*-pulegone*

(*a*) Before use, the *(R)*-(+)-pulegone was fractionally distilled twice and then further purified by argentation chromatography. GC analysis indicated >99% chemical purity and the $[\alpha]_D^{23}$ was +21.3 (*c* 6.505, $CHCl_3$). The pulegone (19.95 g; 131 mmol), ethylene glycol (9.7 g; 161 mmol), and *p*-TsOH (24 mg) were refluxed in benzene (300 mL) with a Dean–Stark separator for 115 h. After concentration, aqueous NaOH (100 mL, 10%) and ether (150 mL) were added. The separated organic phase was washed (water, brine), dried over $MgSO_4$, and concentrated to give a yellow oil. The fraction that distilled at 43°C/0.3 Torr (1 Torr = 133.3 Pa) (Vigreux, 22.7 g; 87%) proved to be a 5.7:1 mixture of the isomers **2***a* and **2***b*; colorless oil, $[\alpha]_D^{23}$ +3.81 (*c* 5.67, $CHCl_3$); ir (neat): 3080, 1645, 1205, and 1145 cm^{-1}; ^{1}H nmr δ: 0.87 (d, *J* = 6.2 Hz, Me-C.5), 1.76 (d, *J* = 1.8 Hz, Me-C.7), 2.16 (dd, *J* = 12.5 and 4.4 Hz, C.2-H), 3.85 (m, 4H, ketal CH_2), and 4.80 (m, 2H, $+CH_2$); ^{13}C nmr: Table 1; ms *m/z*: 196(2, M^+), 181(11), 139(15), 126(12), 114(15), 113(100), and 86(19). Exact Mass calcd. for $C_{12}H_{20}O_2$: 196.1463; found: 196.1435.

(*b*) Using exactly the same procedure, pulegone (8.49 g), ethylene glycol (3.92 g), and *p*-TsOH (11mg) were refluxed in benzene for 4.25 h (Dean–Stark). Gas chromatography showed the presence of unreacted pulegone, ketal **2***a*, and ketal **6** (16%). Distillation of the product gave a fraction that contained 56% of the ketal **6**. The nmr of the major component was δ: 0.84 (s, 3H, *Me*-CH), 1.62 (s, 3H, Me-C=C), and 1.86 (d, 3H, *J* = 1.5 Hz, Me-C=C).

(*c*) To excess trimethylsilyltrifluoromethane sulfonate (3 drops) in CH_2Cl_2 (1 mL) cooled to −78°C was added 1,2-bis(trimethylsiloxy)-ethane (2.08 g) and *(R)*-(+)-pulegone (0.85 g). After stirring at room temperature for 117 h, the reaction was stopped by adding pyridine (0.5 mL) and pouring into saturated aqueous $NaHCO_3$ (15 mL). The crude product obtained by ether extraction was quickly distilled under vacuum to afford a mixture of pulegone (23%) and ketal **6** (67%); ^{1}H nmr δ: 0.88 (d, 3H, *J* = 1.5 Hz, *Me*-CH), 1.66 (s, 3H, Me-C=C), 1.91 (d, 3H, *J* = 1.47 Hz, Me-C=C), 3.70–4.00 (m, 4H, $-OCH_2-CH_2O-$). The respective methyl peaks for pulegone are at 0.98, 1.75, and 1.95 δ. The ^{13}C nmr (Table 1) was obtained from the spectrum of this mixture.

Hydroboration of the ketal **2***a*

(*a*) To the ketal (17.7 g; 83 mmol) in dry THF (40 mL) was added dropwise a 1 M THF solution of B_2H_6 (100 mL). After stirring for 2 h at room temperature, water (15 mL) was slowly added, followed by H_2O_2 (20 mL, 30 vol.) and aqueous NaOH (20 mL, 30%). Ether was added after 30 min at room temperature and the separated organic layer was washed with brine and dried ($MgSO_4$). The oil obtained was fractionated, affording alcohol **7***a* (bp 74–78°C/0.5 Torr: 13.4 g; 82%); colorless oil, $[\alpha]_D^{20}$ −32.6 (*c* 4.05, MeOH); ir (neat): 3425 cm^{-1}; ^{1}H nmr δ: 0.78 (d, 6H, *J* = 7.0 Hz, Me at C.3 and C.7), 3.17 (dd, *J* = 11.0 and 5.1 Hz, CH_2OH), 3.36 (dd, *J* = 11.0 and 9.5 Hz, CH_2OH), 3.78 (m, 4H, ketal CH_2); ^{13}C nmr: Table 1; ms *m/z*: 214(4, M^+), 199(2), 183(28), 127(14), and 113(100).

(*b*) Under argon at 0°C, a solution of 9-BBN (120 mL of 0.5 M in THF) was added to the ketal **2***a* (11.0 g). After 2 h, the temperature was allowed to rise to ambiant and stirring was continued for 12 h. The mixture was cooled in ice, excess 9-BBN was destroyed with a small quantity of H_2O, and then aqueous NaOH (5 mL, 3 N) and H_2O_2 (10 mL, 30 vol.) were added. After stirring for 30 min the product was obtained by hexane extraction and then chromatographed (pet.

ether/ether 95:5) to afford some starting material **2***a* (1.12 g) and the alcohol **7***a* (10.36 g; 86%), $[\alpha]_D^{23}$ −35.85 (*c* 4.798, MeOH). Exact Mass calcd. for $C_{12}H_{22}O_3$: 214.1569; found: 214.1582. Other physical properties were identical with those for the product from method (*a*) (above).

Alkylation at C.8 via the tosylate

(*a*) *Preparation of the tosylate* **7**b. Freshly recrystallized *p*-tosyl chloride 10.0 g; 52.5 mmol) was added to the alcohol **7***a* (10.1 g; 47.2 mmol) in pyridine (30 mL) at 0°C. The mixture was stirred for 2.5 h at 0°C and then poured into 5% HCl (200 mL), washed with more HCl, then with saturated $NaHCO_3$, dried, and concentrated to give the crude tosylate **7***b* (17.1 g; 98%). The product was unstable at room temperature and was used without further purification; ir: 3100–3000, 1600, 1452, 1356, and 1175 cm^{-1}; ^1H nmr δ: 0.83 (d, *J* = 6.6 Hz), 0.95 (d, *J* = 7.0 Hz), 2.42 (s, Me-Ar), 3.75 (m, 4H), 4.43 (dd, *J* = 10.0 and 3.7 Hz, CH_2-OTs), 7.29 and 7.75 (2d, *J* = 8.4 Hz, Ar-H).

(*b*) *Reaction with dimethyl lithium cuprate*. A solution of methyl lithium (1.4 M in ether) was added drop by drop to a suspension of cuprous iodide (10.03 g; 54.2 mmol) in dry ether (25 mL) at 0°C until the bright yellow color initially formed had disappeared. Tosylate **7***b* (8.76 g; 23.77 mmol) in ether was added dropwise and the solution was stirred for 1 h at 0°C. Saturated aqueous NH_4Cl was added slowly with stirring and the resulting mixture then poured into water and extracted with ether. The organic phase was washed with brine, dried, concentrated, and purified by chromatography to afford **8***a* as a colorless oil (4.37 g; 82%), *1-ethylenedioxy-2-(1-methylpropyl)-5-methylcyclohexane*; $[\alpha]_D^{23}$ −17.1 (*c* 4.79, $CHCl_3$); ir (neat): 2980–2840 and 1100 cm^{-1}; ^1H nmr δ: 0.84 (m, 9H, Me-C), 1.3–1.8 (m, 10H, ring CH_2 and CH), 3.9 (m, 4H, ketal CH_2); ^{13}C nmr: Table 1; ms *m*/*z*: 212(7, M^+), 183(20), 155(11), 127(11), and 113(100). Exact Mass calcd. for $C_{13}H_{24}O_2$: 212.1776; found: 212.1836.

Hydrolysis of ketal **8**a *to ketone* **9**a

Ketal **8***a* (4014 g; 18.9 mmol) was taken up in acetone (50 mL) and water (7 mL). Three drops of concentrated HCl were added and the mixture refluxed for 15 min. After cooling, saturated aqueous $NaHCO_3$ was added, most of the acetone was evaporated, and the residue was diluted with water and extracted with ether. Concentration of the dried ethereal solution and chromatography of the oil gave the ketone **9***a* (3.01 g; 89%), *2-(1-methylpropyl)-5-methylcyclohexanone*; $[\alpha]_D^{23}$ −31.4 (*c* 0.92 $CHCl_3$); ir: 1707 cm^{-1}; ^{1} H nmr δ: (t, *J* = 6.6 Hz), 0.84 (d, *J* = 6.6 Hz), and 0.96 (d, *J* = 5.9 Hz, three C-Me), 2.29 (ddd, *J* = 11.8, 3.6, and 2.2 Hz, H-C.2); ^{13}C nmr: Table 1; ms *m*/*z*: 168(4, M^+), 139(8), 113(9), 112(100), 97(29), 84(20), 83(19).

Baeyer–Villiger oxidation of ketone **9**a

Ketone **9***a* (127 mg; 0.76 mmol) was added to a stirred solution of *m*-CPBA (180 mg of 80%; 0.76 mmol) in CH_2Cl_2 containing a suspension of $NaHCO_3$ (71 mg; 0.84 mmol) as suggested by Whitesell *et al.* (12). After stirring for 18 h at room temperature, aqueous KI and aqueous $NaHSO_3$ were added to reduce excess reagent. The organic phase was washed with brine, dried, and concentrated to afford the lactone **10***a* (140 mg; quant.), *3-methyl-6-(1-methylpropyl)-caprolactone*, colorless oil; ir: 1735 cm^{-1}; ^1H nmr δ: 0.86 (t, *J* = 5.9 Hz, Me-terminal), 0.88 (d, *J* = 6.6 Hz, Me-CH), 2.38 (dm, *J* = 13.2 Hz, H-C.2), 2.50 (dd, *J* = 13.2 and 12.1 Hz, H-C.2), 4.12 (dd, *J* = 9.2 and 3.3 Hz, H-C.6); ^{13}C nmr: Table 1; ms *m*/*z*: 184(0.9, M^+), 127(65), 126(7), 99(93), 98(41), and 81(100).

In the same manner 2(*S*),5(*R*)-menthone **9***c* was oxidized to the lactone **10***c* in 90% yield after 5.5 h. For comparison the ^{13}C nmr of the 3-methyl-6-isopropylcaprolactone **10***c*, mp 49°C, is given in the table. In the absence of the bicarbonate the yield was 80% after 27 h.

Methanolysis of lactone **10**a *to ester* **11**a

To the lactone **10***a* (2.81 g; 15.3 mmol) in MeOH (20 mL) was added concentrated H_2SO_4 (2 drops) and the mixture was refluxed for 5 min. After cooling, saturated aqueous $NaHCO_3$ was added, most of the MeOH was evaporated, and the residue was taken up in ether. Washing (brine), drying, and concentrating gave the hydroxy ester **11***a* (2.78 g; 84%), *methyl 6-hydroxy-3,7-dimethylnonanoate*, colorless oil; ir: 3450, 1722, 1200, and 1160 cm^{-1}; ^1H nmr δ: 0.81 (d, *J* = 6.0 Hz), 0.85 (t, *J* = 7.0 Hz), and 0.90 (d, *J* = 6.6 Hz, three C-Me), 2.09 (dd, *J* = 14.4 and 7.9 Hz, H-C.2), 2.29 (dd, *J* = 14.4 and 6.2 Hz, H-C.2), 3.43 (m, H-C.6), and 3.60 (s, Me-O); ^{13}C nmr: Table 1; ms *m*/*z*: no M^+, 185(0.6), 159(18), 127(100), 115(25), 87(18), and 81(44).

In the same manner, lactone **10***c* afforded *methyl 6-hydroxy-3,7-dimethyloctanoate* **11***c* in 97% yield, $[\alpha]_D^{20}$ −12.1 (*c* 7.68, $CHCl_3$); ir: 3440, 1737, 1200, and 1160 cm^{-1}; ^1H nmr δ: 0.87 (d, *J* = 6.6 Hz), 0.89 (d, *J* = 6.6 Hz), and 0.93 (d, *J* = 6.6 Hz, three C-Me), 2.10 (dd, *J* = 14.7 and 7.7 Hz, H-*C*2), 2.30 (dd, *J* = 14.7 and 5.9 Hz, H-C.2), 3.30 (m, *H*-C-OH), and 3.64 (s, *Me-O*); ^{13}C nmr: Table 1; ms *m*/*z*: no M^+, 185(0.5), 159(30), 153(11), 127(25), 109(20), 101(37), 87(47), and 81(57).

Conversion of hydroxy ester **11**a *to primary alcohol* **12**a

Tosyl chloride (414 mg; 2.17 mmol) was added to ester **11***a* (443 mg; 2.05 mmol) in dry pyridine (3 mL) and the solution was kept in the dark at 0°C for 6 h. Ether was added (50 mL) and the mixture was washed thoroughly with aqueous HCl, saturated aqueous $NaHCO_3$ and brine, and dried and concentrated to afford the tosylate (683 mg; 90%); ir: 2980, 1735, 1594, 1453, 1170 cm^{-1}; ^1H nmr δ: 0.81 (m, 9H, C-Me), 2.40 (s, Me-arom), 3.61 (s, COOMe), 4.47 (m, 1H, H-C.6), 7.28 (d, *J* = 8.4 Hz), and 7.74 (d, *J* = 8.4 Hz, arom-H).

The tosylate (3.75 g; 10.14 mmol, from above used without further purification) was dissolved in dry ether (100 mL) and reduced with $LiAlH_4$ (500 mg; 133.2 mmol) by stirring at room temperature for 4 h. Excess hydride was destroyed with 5% aqueous H_2SO_4 and, after adding more water, the product obtained by ether extraction was chromatographed (pet. ether/ether 3:2), affording *3,7-dimethylnonanol* **12***a* (690 mg; 40%) as a colorless oil; ir: 3325 cm^{-1}; ^1H nmr δ: 0.8 (d, *J* = 5.5 Hz), 0.84 (t, *J* = 5.9 Hz), and 0.88 (d, *J* = 6.6 Hz, three C-Me), 3.67 (t, *J* = 6.6 Hz), and 3.69 (t, *J* = 6.6 Hz, CH_2OH); ^{13}C nmr: Table 1; ms *m*/*z*: no M^+, 125(9), 97(14), 83(22), 71(23), 70(64), 69(54), and 55(100).

In the same manner ester **11***c* gave the corresponding tosylate (90%), which in turn afforded 3,7-dimethyloctanol **12***c* (70%). The latter was identical (ir, ^1H and ^{13}C nmr; for the latter see Table 1) with the product obtained by hydrogenating geraniol over 10% Pd on C in MeOH.

Oxidation of alcohol **12**a *to aldehyde* **13**

Alcohol **12***a* (170 mg; 1 mmol) in CH_2Cl_2 (1 mL) was added quickly to a suspension of PCC (370 mg; 1.7 mmol) in CH_2Cl_2. After 1 h a 1:1 mixture of ether and pentane was added and the mixture filtered through Celite and then rapidly chromatographed. The *3,7-dimethylnonanal* **13** (118 mg; 70%) was sensitive to air and was used immediately for the following step; ir: 2710, 1721 cm^{-1}; ^1H nmr δ: 0.78 (m, 6H) and 0.89 (d, *J* = 6.6 Hz, C-Me), 2.35 (ddd, *J* = 15.5, 5.9, and 2.2 Hz, H-C.2), 9.69 (t, *J* = 2.2 Hz, CHO); ^{13}C nmr: Table 1; ms *m*/*z*: no M^+, 157(4, M−CHO), 139(2), 112(2), 111(4), 107(6), 97(12), and 87(42).

Wittig reaction of aldehyde **13** *to give alkene* **14**

A 0.168 M solution of decyltriphenylphosphonium bromide in THF (5.4 mL; 0.9 mmol) prepared according to Sonnet (see ref. 14) was cooled to −10°C and *n*-butyllithium (0.79 mL of 1.14 M; 0.9 mmol) was added dropwise. The resulting orange solution of the ylide was cooled to −78°C and a solution of the aldehyde **13** (118 mg; 0.7 mmol) in THF was added dropwise. The mixture was allowed to warm to room temperature (ca. 2 h) and then poured into water and extracted with hexane. The product was chromatographed (silica gel:hexane) affording the *3,7-dimethyl-9-nonadecene* **14** (90 mg; 44%) as a colorless oil; $[\alpha]_D^{20}$ 0.3 (*c* 2.06, $CHCl_3$); ir: 2995 cm^{-1}; ^1H nmr δ: 0.85 (t, 6H, *J* = 5.5 Hz, two CH_3-CH_2), 0.86 (d, 6H, *J* = 6.6 Hz, two CH_3-CH), 5.37 (dm, 2H, *J* = 11.2 Hz, -CH=CH-); ^{13}C nmr: Table 1; ms *m*/*z*: 294(3.1, M^+), 195(3.5), 126(5.6), 125(10), 111(14), 97(28), 85(38), and 71(72). Exact Mass calcd. for $C_{21}H_{42}$: 294.3286; found: 294.3242.

Hydrogenation of alkene **14** *to alkane* **5**a

Alkene **14** (45.7 mg; 0.155 mmol) in hexane (25 mL) was shaken under hydrogen (35 psi; 1 psi = 6.9 kPa) in a Parr apparatus for 6 h. The mixture was filtered through Celite and chromatographed (silica

[a]In ppm from TMS = 0.

[b]For convenience, C.1 to C.10 are always the original carbons from pulegone. From C.11 upwards, the alkyl chains are numbered starting with the shorter (in **14** for example, the double bond carbons are C.1 and C.12). Incidental carbons (ketals, esters, etc.) are reported in parentheses.

gel:hexane) to give *3,7-(R)-dimethylnonadecane* **5***a* (quant: colorless liquid); $[\alpha]_D^{20}$ 2.42 (*c* 1.60, $CHCl_3$); the spectral data for this sample were identical with those described for alkane **5***b*.

Second synthesis affording pheromone **5**a

Oxidation of alcohol **7**a *to aldehyde* ***15***

Hydroxy ketal **7***a* (4.544 g; 21 mmol) was added to a stirred suspension of PCC (6.9 g; 32 mmol) and sodium acetate (0.7 g; 8.6 mmol) in CH_2Cl_2 (20 mL). After stirring for 80 min at room temperature, ether and pentane were added and the reaction mixture was filtered through Celite and then through a short silica gel column to give the *1-ethylenedioxy-2-(2-formylethyl)-5-methylcyclohexane* **15** (3.50 g; 79%); $[\alpha]_D^{23}$ −58 (*c* 3.2, $CHCl_3$); ir: 1720 cm^{-1}; ^1H nmr δ: 0.87 (d, *J* = 6.6 Hz), 1.02 (d, *J* = 6.3 Hz, two C-methyls), 2.65 (m, 1H, *H*-C-CHO), 4.0 (m, 4H, ketal CH_2), 9.64 (d, *J* = 3.3 Hz, CHO); ^{13}C nmr; Table 1; ms *m/z*: 212(1,M^+), 184(22), 183(20), 127(31), and 113(100).

Wittig reaction of aldehyde ***15*** *to give alkene* ***16***

n-Butyllithium (1.35 mL; 9.2 M) was added dropwise at −10°C under N_2 to a stirred THF solution of undecyltriphenylphosphonium bromide (6.173 g; 12.4 mmol, from refluxing undecyl bromide and triphenylphosphine in toluene for 36 h). The resulting dark red solution was cooled to −78°C, the aldehyde **15** (2.815 g; 13.39 mmol) was added dropwise, and the solution then allowed to warm to room temperature over 5 h. Water was added and the product was obtained by extraction with hexane, washing with aqueous sodium bisulfite, drying, and concentration. Rapid chromatographic purification afforded alkene **16** (2.27 g; 52%), *1-ethylenedioxy-2-(1-methyltridecenyl)-5-methylcyclohexane*, as a viscous oil; $[\alpha]_D^{20}$ −20.2 (*c* 3.825, $CHCl_3$); ir: 3010, 1640, 1103, and 1062 cm^{-1}; ^1H nmr δ: 0.85 (d, *J* = 6.2 Hz), 0.86 (t, *J* = 7.0 Hz), and 0.95 (d, *J* = 7.0 Hz, three C-methyls), 1.71 (m, 2H, H-C.6), 2.01 (m, 1H, H-C.7), 3.88 (m, ketal CH_2), and 5.25 (m, 2H, =CH-); ^{13}C nmr: Table 1; ms *m/z*: 350(2.6, M^+), 335(7), 240(13), 226(9), and 113(100). Exact Mass calcd. for $C_{23}H_{42}O_2$: 350.3284; found: 350.3167.

Hydrogenation of alkene ***16*** *to give ketal* ***8***b

Alkene **16** (2.27 g; 6.49 mmol), Adams' catalyst (175 mg), and hexane (50 mL) were shaken under H_2 in a Parr apparatus at 35 psi for 9.5 h. The mixture was filtered through Celite and concentrated to afford ketal **8***b* (2.122 g; 93%), *1-ethylenedioxy-2-(1-methyltridecyl)-5-methylcyclohexane* colorless liquid; $[\alpha]_D^{20}$ −25.4 (*c* 11.71, acetone); ir: 2980–2840, 1455, 1375, and 1100 cm^{-1}; ^1H nmr δ: 0.87 (m, 9H, methyls), 1.24 (br s, 18H, CH_2), 3.88 (m, 4H, ketal CH_2); ^{13}C nmr: Table 1; ms *m/z*: 352(11, M^+), 337(2), 183(24), 113(100). Exact Mass calcd. for $C_{23}H_{44}O_2$: 352.3190; found: 352.3341.

Hydrolysis of ketal **8**b *to give ketone* ***9***b

Ketal **8***b* (1.67g; 5.42 mmol) was dissolved in acetone (20 mL) and water (3 mL), concentrated HCl (2 drops) was added, and the mixture was refluxed for 2 h. Saturated aqueous $NaHCO_3$ was added, most of the acetone was evaporated, and the residue was taken up in ether, washed, and dried. Concentration gave a colorless liquid, which was chromatographed (silica gel: pet. ether/2% ether) to give ketone **9***b* (1.515 g: quant.), *2-(1-methyltridecyl)-5-methylcyclohexanone*; $[\alpha]_D^{20}$ 16.9 (*c* 1.88, $CHCl_3$); ir: 1707 cm^{-1}; ^1H nmr δ: 0.86 (t, *J* = 6.2 Hz), 0.87 (d, *J* = 6.6 Hz), and 0.98 (d, *J* = 6.2 Hz, three C-methyls), 1.8–2.6 (overlapping multiplets, 4H), 2.33 (m, 1H, H-C.2); ^{13}C nmr: Table 1; ms *m/z*: 308(0.8, M^+), 139(13), 113(10), and 112(100). Exact Mass calcd. for $C_{21}H_{40}O$: 308,3079; found: 308.3042.

Baeyer–Villiger oxidation of ketone **9**b

Following the procedure described for **9***a*, ketone **9***b* (1.364 g) afforded the lactone **10***b* (1.214 g: 85%) after chromatography (pet.

ether/2% ether) as a viscous oil that slowly crystallized, mp 49°C, *6-(1-methyltridecyl-3-methylcaprolactone*; $[\alpha]_D^{20}$ −10.5 (*c* 4.03, $CHCl_3$); ir: 1740 and 1262 cm^{-1}; ^1H nmr δ: 0.86 (t, *J* = 7.0 Hz), 0.93 (d, *J* 6.9 Hz), and 1.02 (d, *J* = 6.6 Hz, three C-methyls), 1.24 (m, 21H), 2.5 (m, 2H, CH_2CO), 4.14 (dd, *J* = 8.8 and 3.3 Hz, H-C.6); ^{13}C nmr: Table 1; ms *m/z*: 324(1, M^+), 240(3), 226(3), 156(22), 127(100), 99(58), and 98(24). Exact Mass calcd. for $C_{21}H_{40}O_2$: 324.3028; found: 324.3156.

Reduction of lactone ***10***b *to diol* ***17***a

To lactone ***10****b* (788 mg) in dry ether (40 mL) was added excess $LiAlH_4$ and the mixture was stirred overnight. After the cautious addition of a few drops of aqueous H_2SO_4, brine was added and the diol obtained by ether extraction. On standing, the *3,7-dimethyl-1,6-nonadecanediol* ***17****a* crystallized as a waxy solid (670 mg; 84%), mp 48°C; $[\alpha]_D^{20}$ −7.57 (*c* 9.345, $CHCl_3$); ir: 3340 cm^{-1}; ^1H nmr δ: 0.87 (m, 9H, C-methyls), 3.45 (m, H-C.6), and 3.67 (m, 2H, CH_2OH); ^{13}C nmr: Table 1; ms *m/z*: M^+, 240(0.6), 227(4), 226(3), 131(100), 113(87), and 95(80).

Dibromo alkane ***17***b *and reduction to alkane* ***5***b

Triphenylphosphine (362 mg; 1.38 mmol) was dissolved in CH_2Cl_2 (10 mL) and bromine was added dropwise until the yellowish color persisted. The diol ***17****a* (226 mg; 0.69 mmol) in CH_2Cl_2 (1 mL) was introduced and, after stirring at room temperature for 8 h, a few drops of MeOH were added and the solvent evaporated. Lixiviation with hexane (three times) afforded a solution that was chromatographed. Petroleum ether eluted the dibromide ***17****b* (231 mg; 74%), *1,6-dibromo-3,7-dimethylnonadecane*; $[\alpha]_D^{20}$ 3.30 (*c* 6.215, $CDCl_3$); ir: 2945, 1457, 1375, 1255, 1235, and 1205 (CH_2-Br) cm^{-1}; ^1H nmr δ: 0.8–1.03 (m, 9H, C-methyls), 3.43 (m, 2H, CH_2Br), and 4.00 (m, 1H, CH-Br); ^{13}C nmr: Table 1; ms *m/z*: no M^+, 375(9) and 373(9.9, M−Br), 163(4.5), 155(4.8), and 141(5.5).

The dibromide ***17****b* (151 mg) was refluxed with an excess of $LiAlH_4$ in dry THF (15 mL) for 2.5 h. After cooling, excess hydride was destroyed with aqueous 5% H_2SO_4. Ether was added and the organic phase washed with brine, dried, and concentrated and the crude product was chromatographed. Elution with hexane afforded the *3,7-dimethylnonadecane* ***5****b* (65.7 mg; 67%); $[\alpha]_D^{20}$ 3.76 (*c* 3.285, hexane); ir: 2880–2840, 1455, and 1372 cm^{-1}; ^1H nmr δ: 0.85 (t and d, 12H, *J* = 5.8 Hz, C-methyls), 1.25 (br s, 32H); ^{13}C nmr: Table 1; ms *m/z*: 296(4.8, M^+), 267(5), 239(4), 197(9), 196(13), and 141(5). Exact Mass calcd. for $C_{21}H_{44}$: 296.3443; found: 296.3337.

Alternate route from lactone ***10***b *to alkane* ***5***b

Methanolysis of lactone **10**b *to ester* **11**b. In the manner described previously, the lactone ***10****b* (623 mg) in MeOH (20 mL) containing H_2SO_4 (1 drop) was stirred at room temperature for 12 h. Neutralization and extraction afforded ester ***11****b* (670 mg; 98%) as a colorless oil; $[\alpha]_D^{23}$ −10.3 (*c* 4.75, $CHCl_3$); ir: 3400(br) and 1740 cm^{-1}; ^1H nmr δ: 0.83 (d, *J* = 6.3 Hz, Me-C.3), 0.85 (t, *J* = 7.7 Hz, Me-terminal), 0.93 (d, *J* = 6.6 Hz, Me-C.7), 2.11 (dd, *J* = 14.5 and 8.1 Hz, H-C.2), 2.31 (dd, *J* = 14.5 and 5.9 Hz, H-C.2), 3.64 (s, Me-O): ^{13}C nmr: Table 1; ms *m/z*: no M^+, 325(1), 159(57), and 127(100). Exact Mass calcd. for $C_{22}H_{44}O_3$: 356.3290; found: 356.3265.

Alcohol ***12***b *via the tosylate*. Hydroxy ester ***11****b* (668 mg) was stirred with tosyl chloride in pyridine (6 mL) at 0°C for 48 h. The crude tosylate (934 mg) obtained by extraction (see above) was taken up in ether (25 mL) and reduced at room temperature with $LiAlH_4$ (150 mg). Extraction and chromatography afforded the primary alcohol ***12****b* (503 mg; 88%); $[\alpha]_D^{20}$ 2.7 (*c* 3.07, $CHCl_3$); ir: 3400 cm^{-1}; ^1H nmr δ: 0.81 (d, 6H, *J* = 6.2 Hz) and 0.88 (d, 3H, *J* = 5.1 Hz, three C-methyls), 3.64 (dt, *J* = 4.2 and 1.8 Hz, CH_2OH); ^{13}C nmr: Table 1; ms *m/z*: no M^+, 294(M−18). Exact Mass calcd. for $C_{21}H_{44}O$: 312.3392; found: 312.3403.

Alkane ***5***b *via tosylate*. Alcohol ***12****b* (117 mg) and tosyl chloride (185 mg) were stirred in the dark in pyridine (7.0 mL) for 48 h. Extraction (as described above) afforded the crude tosylate (145 mg; 83%); ^1H nmr δ: 0.78 −0.89 (m, 9H, three Me-C), 2.44 (s, 3H, Me-Ar), 4.06 (t, *J* = 6.2 Hz, CH_2-OR), 7.33 and 7.79 (2d, *J* = 8.0 Hz, arom-H).

The tosylate (141 mg) was reduced with $LiAlH_4$ (23 mg) in ether (25 mL) at room temperature. To be sure of its purity, the crude product was chromatographed three times over silica gel (pet. ether), affording alkane ***5****b* (56 mg; 63%); colorless oil; $[\alpha]_D^{20}$ 3.76 (*c* 3.28, hexane). The other spectral properties were identical with the product from the route described above.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada and the Ministère de l'éducation du Québec (F.C.A.R.) for operating grants. We are indebted to Professor Jeremy N. Dans le but d'obtenir des complexes stables du fer(III) utilisables comme agents de contraste en imagerie de résonance magnétique, nous avons synthétisé une série de dihydroxamates analogues d'un sidérophore naturel : l'acide rhodotorulique. Ces nouveaux ligands sont obtenus par condensation du dichlorure de l'acide pyridine-2,6-dicarboxylique avec la *N*-aminopropyl-*N*-acétylhydroxylamine protégée et en introduisant en position 4 différents substituants : O-C_2H_5, O-nC_5H_{11}, O-nC_3H_6CN, O-$nC_4H_8NH_2 \cdot HCl$. Cinq ligands **18***a–e* ont ainsi été préparés.

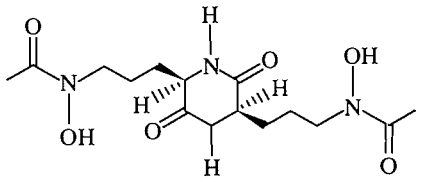
Mots clés : imagerie médicale, agents de contraste, acide rhodotorulique, synthèse d'analogues.



FRÉDÉRIC CHAUBET, NGUYEN VAN DUONG, JACQUES COURTIEU, ALAIN GAUDEMER, AURORE GREF, and A. L. CRUMBLISS. Can. J. Chem. **69**, 1107 (1991).

With a view to preparing stable iron(III) complexes that can be used as contrast agents in magnetic resonance imaging, we have prepared a series of dihydroxamates that are analogs of rhodotorulic acid, a natural siderophore. These new ligands have been synthesized by condensation of 2,6-pyridine dicarboxylic acid chloride with protected *N*-aminopropyl-*N*-acetylhydroxylamine. In addition to the ligand derived from 2,6-pyridine dicarboxylic acid, four other ligands have thus been prepared, having substituents O-C_2H_5, O-nC_5H_{11}, O-nC_3H_6CN, O-$nC_4H_8NH_2 \cdot HCl$. respectively, in the 4 position.

Key words: medical imaging, contrast agents, rhodotorulic acid, synthesis of analogs.

Introduction

Au-delà des progrès technologiques, l'utilisation de l'imagerie par résonance magnétique (IRM) pour le diagnostic médical a rapidement nécessité l'emploi de substances chimiques nouvelles permettant d'augmenter le contraste des images. Parmi celles-ci, les complexes d'ions métalliques paramagnétiques font l'objet à l'heure actuelle des études les plus nombreuses. Le problème principal consistant à protéger l'organisme de la toxicité de ces ions, nous avons porté notre choix sur les ligands spécifiques du fer(III) : les sidérophores. Les sidérophores sont des chélatants spécifiques du fer(III) de faible poids moléculaire et qui forment avec cet ion des complexes extrèmement stables (1). À l'état naturel, ces composés sont le plus souvent isolés de cultures de bactéries pour lesquelles ils assurent la séquestration et le transport du fer essentiel à leur croissance (2). lls appartiennent à deux grandes famille : les acides polyhydroxamiques et les polycatéchols. En plus d'une très grande spécificité, ces composés donnent avec l'ion ferrique des complexes ayant des constantes de stabilité thermodynamique souvent supérieures à 10^{25} M^{-1} (3, 4). La complexation est assurée essentiellement par des groupements hydroxamates ou catécholates. Depuis une quinzaine d'années, les sidérophores, du fait de leur assez faible toxicité, de la puissance et de la spécificité de complexation de l'ion ferrique, ont été employés en médecine pour traiter les empoisonnements par le fer (5, 6). Plus récemment, pour ces mêmes raisons, les complexes formés par ces composés avec le fer(III) ont été envisagés comme agents de contraste potentiels pour l'IRM (7). Dans cette optique, nous nous sommes intéressés aux acides polyhydroxamiques et plus particulièrement à l'acide rhodotorulique **I**, un dihydroxamate naturel produit par *Rhodotorula pilimanae* et formant avec l'ion ferrique un complexe binucléaire de formule générale Fe_2L_3 entre pH 2 et pH 12, domaine où il présente une constante de stabilité thermodynamique de $10^{62,2}$ (8, 9).

I

Notre objectif a été de synthètiser de nouveaux dihydroxamates susceptibles de se comporter vis-à-vis du fer comme l'acide rhodotorulique et pouvant se prêter à des variations structurales susceptibles d'en modifier les propriétés biologiques, en particulier leur biodistribution. Les voies de synthèses décrites pour l'acide rhodotorulique étant longues et ne permettant pas aisément l'introduction de modifications structurales (10–12), nous nous sommes engagés dans la synthèse d'analogues structuraux de ce composé d'accès un peu plus faciles par des voies de synthèse aptes à permettre

l'introduction de substituants variés indépendants des sites de complexation et ne perturbant pas cette dernière. À la lumière des travaux de Miller et coll. (13, 14), nous avons entrepris de synthétiser un modèle de sidérophore ayant pour unité centrale le noyau pyridinique et portant, en plus de deux fonctions hydroxamiques en positions α et α′, un substituant en position 4. Nous avons ainsi synthétisé les produits suivants II:

II

avec A = H, O-nC$_5$H$_{11}$, OC$_2$H$_5$, OC$_3$H$_6$CN, O-nC$_4$H$_8$NH$_2$·HCl. Ces composés forment une famille de ligands dihydroxamates tétradentés, aux propriétés chélatantes sans doute identiques mais dont on peut penser que les propriétés physiologiques dépendront de la nature du substituant A. La description de cette synthèse fait l'objet du présent article.

Partie expérimentale

1. Matériels et méthodes

Les spectres de RMN ^{1}H ont été enregistrés à 200 ou 250 MHz sur un appareil Bruker AM 200 ou AM 250. Les spectres de RMN ^{13}C ont été enregistrés à 50 MHz sur un appareil Bruker AM 200. Les déplacements chimiques δ sont exprimés en ppm par rapport au signal de résonance de tétraméthylsilane pris comme référence interne. Les abréviations utilisées sont les suivantes : s = singulet; d = doublet; d×d = doublet dédoublé; t = triplet; q^{dt} = quadruplet; q^{pt} = quintuplet; m = multiplet; J = constante de couplage en Hz. Les spectres infra-rouge ont été mesurés sur un appareil Beckman Acculab 10, en pastille de KBr ou entre deux lames de NaCl (film liquide). Les spectres de masse ont été enregistrés sur un appareils Ribermag R-10-10 par ionisation chimique (I.C.). Les valeurs données entre parenthèses représentent le pourcentage relatif des fragments. Les microanalyses ont été réalisées au Service Central de Microanalyse du CNRS (Gif-sur-Yvette et Vernaison). Les points de fusion ont été mesurés sur un banc Kofler étalonné ou au microscope à platine chauffante Reichert. Les chromatographies sur colonnes ont été effectuées avec de la silice Kieselgel 60 (70–230 mesh, Merck réf. : 7734, et 230–400 mesh, Merck réf. : 9385) et la chromatographie sur couche mince, sur gel de silice Kieselgel 60F254 (Merck réf. : 5735).

*3-(*tert*-Butoxycarbonylamino)-1-propanol* **2**

À une solution de 0,1 mol de 3-amino-1-propanol dans 150 mL d'un mélange dioxanne–eau (2 : 1) refroidie dans un bain de glace, on ajoute en une fois, sous agitation, 0,11 mol (24 g) de ditertiobutyldicarbonate. On complète le mélange réactionnel avec 50 mL de NaOH 1 N et on laisse la solution sous agitation à 5°C une nuit. Le dioxanne est évaporé et le produit de réaction est extrait par l'acétate d'éthyle. La phase organique est lavée successivement avec une solution de citrate 0,5 M, de l'eau, une solution de $NaHCO_3$ 5% et finalement avec une solution de NaCl concentré. Elle est ensuite séchée sur sulfate de sodium et le solvant est évaporé. Le produit **2** est obtenu avec un rendement de 92% et ne nécessite pas de purification ultérieure. IR (NaCl film), ν : 3300 (N-H,O-H); 1670 (C=O) cm^{-1}. RMN ^{1}H ($CDCl_3$) : 1,39 (s, 9H); 1,63 (q^{pt}, J = 6, 2H); 3,02 (d×d, J = 6, J = 7, 2H); 3,05 (s); 3,6 (t, J = 6, 2H); 4,95 (s, 1H). Spectrométrie de masse par I.C. (NH_3), m/z : 281 (M + H$^+$) (100). Anal. calc. pour $C_8H_{17}NO_3$: C 54,84; H 9,78; N 7,99; trouvé : C 54,94; H 9,72; N 8,18.

*3-(*tert*-Butoxycarbonylamino)-1-propanal* **3**

Une solution de 114,6 mmol de chlorure d'oxalyle dans 275 mL de CH_2Cl_2 anhydre est agitée dans un réacteur maintenu à −65°C. À l'aide d'une ampoule à brome on ajoute goutte à goutte une solution de 229 mmol de DMSO dans 55 mL de CH_2Cl_2 anhydre, en surveillant la température du milieu réactionnel afin qu'elle ne dépasse pas −40°C. Quand l'addition est terminée, on laisse agiter 3 min puis on ajoute en 5 min une solution de 104 mmol du produit **2** dans 104 mL de CH_2Cl_2 anhydre. Après 15 min d'agitation supplémentaires, on ajoute 520 mmol de triéthylamine, puis on retire le bain de refroidissement et on laisse revenir le mélange réactionnel à température ambiante. La solution est lavée avec 250 mL d'eau qui sont réextraits par 150 mL de CH_2Cl_2. Les phases organiques sont rassemblées et lavées avec HCl, 1%; Na_2CO_3, 5%; H_2O; puis NaCl. L'extrait est filtré sur papier Whatman, séché, et évaporé à sec. Le rendement brut est de l'ordre de 95% mais l'aldéhyde étant particulièrement instable nous n'avons pas cherché à le purifier et l'avons identifié par le signal RMN ^{1}H du groupement CHO à 9,87 ppm ($CDCl_3$). Il est immédiatement utilisé pour la réaction suivante.

*3-(*tert*-Butoxycarbonylamino)propanol-O-benzyloxime* **4**

Dans un mélange méthanol–eau (2 : 1) sont dissoutes 99,3 mmol de chlorhydrate de *O*-benzylhydroxylamine et cette solution est maintenue à 0°C. À l'aide d'une solution de KOH 6 N, le pH est ajusté à 5. On ajoute alors 90,3 mmol de l'aldéhyde **3** en maintenant le pH à 5. La solution est agitée toute 1 nuit à 5°C puis extraite avec 100 mL d'acétate d'ethyle. La phase organique est lavée successivement avec 50 mL de citrate 0,5 M (2 fois), 100 mL d'eau, et 100 mL de NaCl. L'extrait organique est séché sur sulfate de sodium et, aprés évaporation, on obtient une huile jaune. Le produit de réaction est purifié par chromatographie sur silice « flash » avec un mélange hexane – acétate d'éthyle (50 : 50) comme éluant. Le produit **4** est obtenu avec un rendement de 82% à partir de l'amino alcool protégé **2**. IR (NaCl film); ν : 3385 (N-H); 1690 (C=O); 1510 (C=C aromatiques) cm^{-1}. RMN ^{1}H ($CDCl_3$) : On identifie les deux isomères *syn* et *anti* de l'oxime dans des proportions respectives de 60% et 40%, confirmées par chromatographie en phase gazeuse (colonne Carbowax 120°C à 220°C, 40 min) : 1,42 (s, 9H); 2,33 (d×d, J = 6, 1,2H, isomère *syn*); 2,52 (d×d, J = 6, 0,8H, isomère *anti*); 3,26 (m, 2H); 4,82 (s, 1H); 5,03 (s, 1,2H, isomère *syn*); 5,08 (s, 0,8H, isomère *anti*); 6,72 (t, J = 5,5, 0,4H, isomère *anti*); 7,32 (m, 5H); 7,42 (t, J = 5,5, 0,6H, isomère *syn*). Anal. calc. pour $C_{15}H_{22}N_2O_3$: C 64,73; H 7,97; N 10,06; O 17,24; trouvé : C 64,41; H 8,06; N 10,32; O 17,33.

*1-(*tert*-Butoxycarbonylamino)-3-(benzyloxyamino)propane* **5**

Dans 50 mL d'acide acétique glacial sont dissoutes 29,1 mmol de l'oxime **4** et traitées avec 30,5 mmol de cyanoborohydrure de sodium ajoutées par petites portions, sous agitation à 10°C, et sous argon. Aprés 16 h d'agitation on ajoute 50 mL d'acétate d'éthyle. L'acide acétique est éliminé par évaporation et les traces d'acide sont neutralisées par une solution à 20% de KOH. La phase organique est lavée successivement par H_2O (2 fois), NaCl (1 fois) et séchée sur Na_2SO_4. Le solvant est évaporé et le produit brut est chromatographié sur silice flash avec le mélange hexane – acétate d'éthyle (2 : 1) comme éluant. On obtient une huile incolore avec un rendement de 70%. IR (NaCl film), ν : 3350 (N-H); 1690 (C=O); 1500 (C=C aromatiques) cm^{-1}. RMN ^{1}H ($CDCl_3$) : 1,4 (s, 9H, CH_3 du groupement *tert*-butyl); 1,68 (q^{pt}, J = 6,51, 2H); 2,96 (t, J = 6,5, 2H); 3,16 (d×d, J = 5,7, J = 6,5, 2H); 4,70 (s, 2H, H benzyliques); 4,82 (s, 1H, NH); 5,15 (massif); 7,33 (m, 5H, H aromatiques). Spectrométrie de masse par I.C. (NH_3), m/z : 281 (M+H$^+$)(100). Anal. calc. pour $C_{15}H_{24}N_2O_3$: C 64,26; H 8,63; N 9,99; O 17,12; trouvé : C 64,04; H 8,52; N 9,78; O 17,31.

*1-(*tert*-Butoxycarbonylamino)-3-(acétylbenzyloxyamino)-propane* **6**

Deux millimoles (2 mmol) de l'hydroxylamine *O*-benzylée **5** sont agitées dans un excès d'anhydride acétique à température ambiante pendant 3 h. On ajoute alors 20 mL d'acétate d'éthyle et on lave le mélange réactionnel avec KOH 5% plusieurs fois, puis avec NaCl jusqu'à ce que le pH soit neutre. L'extrait organique est séché sur Na_2SO_4 et évaporé. Le résidu huileux obtenu est chromatographié sur silice flash avec le mélange hexane – acétate d'éthyle (50 : 50) comme éluant. On obtient le produit **6** sous forme d'une huile incolore

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

avec un rendement de 73%. IR (NaCl film), ν : 3350 (N-H); 1700 (C=O de CONH); 1650 (C=O acétyl); 1500 (C=C aromatiques) cm^{-1}. RMN ^1H ($CDCl_3$) : 1,41 (s, 9H, CH_3 du groupement *tert*-butyl); 1,75 (q^{pt}, J = 6,5, 2H); 2,09 (s, 3H); 3,07 (d×d, J = 6,5, 2H); 3,68 (t, J = 6,5, 2H); 4,80 (s, 2H, H); 5,05 (massif); 7,36 (m, 5H). Spectrométrie de masse par I.C. (NH_3), m/z : 323 ($M+H^+$)(96), 267 [($M-Me_3C$)+H^+](100). Anal. calc. pour $C_{17}H_{26}N_2O_4$: C 63,33; H 8,19; N 8,69; O 19,85; trouvé : C 63,09; H 8,02; N 8,95; O 20,05.

Trifluoroacétate de 1-amino-3-(acétylbenzyloxyamino)propane **7**a

Dans un ballon, refroidi dans un bain de glace, on place 3 mmol du produit **6**, sous agitation et sous argon et, à l'aide d'une ampoule à brome, on ajoute 20 mmol d'acide trifluoroacétique, en 5 min. L'agitation est poursuivie à température ambiante pendant 1 demi-heure puis on ajoute à cette solution 50 mL d'éther anhydre. Le trifluoroacétate précipite. La suspension est maintenue à 5°C pendant 1 nuit, filtrée sur Büchner, et rincée à l'éther anhydre plusieurs fois pour éliminer le TFA excédentaire. Le produit est séché au dessiccateur chauffant à 60°C. On obtient le produit **7***a* sous forme d'une fine poudre blanche avec un rendement de 88%. *F* : 110–111°C. IR (KBr), ν : 3100 (N-H, O-H); 1710 (C=O de TFA); 1635 (C=O acétohydroxamique); 1450 (C=C aromatiques); 1200 (C-F) cm^{-1}. RMN ^1H (CD_3OD) : 1,88 (m, J = 6,5, 2H); 2(s, 1H); 2,84 (d×d, J = 7,6, 2H); 3,72 (t, J = 6,5, 2H); 4,85 (s, 2H); 7,34 (m, 10H). Spectrométrie de masse par I.C. (NH_3) : On analyse l'ion moléculaire M′ correspondant à M′−CF_3COOH, m/z : 223 (M′+H^+)(100), 117[(M−C_6H_5−OH)+H^+]. Anal. calc. pour $C_{13}H_{19}F_3N_2O_4$: C 50,00; H 5,69; N 8,33; F 16,95; trouvé : C 50,12; H 5,66; N 8,36; F 16,87.

Chlorhydrate de 1-amino-3-(acétylbenzyloxyamino)propane 7b

On dissout 3,24 mmol du produit **6** dans 70 mL d'éther à 0°C. Dans cette solution on fait barboter HCl gazeux (préalablement séché par H_2SO_4 pur) et aprés 1 demi-heure il se forme un précipité blanc floconneux. Le ballon est laissé au froid pendant 1 nuit, puis on filtre les cristaux blancs formés qui sont dissous dans le minimum de méthanol anhydre et précipités à nouveau par l'éther. Le produit est filtré sur Büchner et séché 24 h dans un dessiccateur à KOH pour conduire au chlorhydrate **7***b* pur avec un rendement de 22%. *F* : 69–74°C (litt. (14) *F* : 69–72°C. IR (KBr), ν : 3500 (N-H); 1630 (C=O acétohydroxamique); 1420–1470 (C=C aromatiques) cm^{-1}. RMN ^1H (D_2O) : 1,97 (q^{pt}, J = 6, 2H); 2,08 (s, 3H); 2,97 (t, J = 6, 2H); 3,81 (t, J = 6, 2H); 4,95 (s, 2H); 7,47 (m, 5H). Spectrométrie de masse par I.C. (NH_3) : On analyse l'ion moléculaire M′ =M−HCl, m/z : 223 (M′+H^+)(100). Anal. calc. pour $C_{12}H_{19}N_2O_2Cl{\cdot}1{,}9\ H_2O$: C 49,26; H 7,85; N 9,57; O 21,33; trouvé : C 49,26; H 7,64; N 9,61; O 21,01.

Dichlorhydrate de 1-amino-3-(benzyloxyamino)propane 7c

On évapore le premier filtrat de l'expérience précédente (**7***b*) et le solide jaunâtre obtenu est redissous dans le minimum de méthanol. Par addition d'éther on précipite un produit blanc floconneux. On laisse cette suspension à 5°C pendant 1 nuit. Le produit est filtré sur Büchner et sèché au dessiccateur à KOH. On obtient le dichlorhydrate **7***c* avec un rendement de 47%. *F* : 158°C. IR (KBr), ν : 3400 (N-H); 1410–1460 (C=C aromatiques) cm^{-1}. RMN ^1H (D_2O) : 2,11 (q^{pt}, J = 6, 2H); 3,08 (t, J = 6, 2H); 3,43 (t, J = 6, 2H); 5,11 (s, 2H); 7,48 (m, 5H). Spectrométrie de masse par I.C. (NH_3) : On analyse l'ion moléculaire M′ =M−2HCl, m/z : 181 (M′+H^+)(100), 107(C_6H_5C=OH^+). Anal. calc. pour $C_{10}H_{17}N_2OCl_2$: C 47,44; H 7,17; N 11,06; O 6,32; Cl 28,01; trouvé : C 47,68; H 7,24; N 10,86; O 6,29; Cl 27,82.

Dichlorure de l'acide-4-hydroxy-2,6-pyridinedicarboxylique **10**

Dans un ballon de 125 mL à deux tubulures on place 10,9 mmol d'acide 4-hydroxy-2,6-pyridine dicarboxylique (acide chélidamique). À l'aide d'une ampoule à brome munie d'une garde à potasse, on ajoute 43,6 mmol de dichlorophénylphosphine. Le mélange réactionnel est agité à 130°C pendant 3 h, sous argon. On observe un fort dégagement de HCl. On laisse alors revenir la température à 50°C (le mélange se solidifie) et on procède à une extraction du milieu par l'hexane bouillant (2×50 mL). Les extraits sont rassemblés, refroidis, et laissés 1 nuit à 5°C. Il se forme de minuscules cristaux. Après recristallisation dans l'hexane, ces cristaux sont filtrés, séchés, et sublimés sous vide pour conduire au produit **10** sous forme de paillettes cristallines blanches, avec un rendement de 57%. *F* : 96–98°C (litt. (26) *F* : 94–96°C). IR (KBr), ν : 1720–1750 (C=O); 1560 (C=C et C-N pyridinique) cm^{-1}. RMN ^1H (DMSO-d_6) : 8,3 (s). RMN ^{13}C (DMSO-d_6) (découplage large bande) : 168,5; 147,8; 128,9; 149,9. Spectre de masse par I.C. (NH_3), m/z : 255 ($M+NH_4^+$) (100), 238 ($M+H^+$)(45,8). Anal. calc. pour $C_7H_2Cl_3O_2$: C 35,26; H 0,85; N 5,87; O 13,42; trouvé : C 35,72; H 0,83; N 5,89; O 13,62.

4-Chloro-2,6-pyridinedicarboxylate d'éthyle **11**a

Dans 15 mL de dichlorométhane anhydre sont dissoutes 2 mmol du chlorure d'acide **10**. On ajoute 2 mL d'éthanol anhydre et la solution obtenue est chauffée à reflux sous agitation et sous atmosphère d'argon. Au bout de 2 h le solvant est évaporé et le résidu solide est recristallisé dans l'heptane pour conduire, après filtration sur Büchner, au produit **11***a* avec un rendement de 52%. *F* : 92–94°C. IR (KBr), ν : 2960–3060 (C-H alkyle); 1700 (C=O ester); 1555 (C=C et C-N pyridiniques) cm^{-1}. RMN ^1H ($CDCl_3$) : 1,4 (t, J = 6,9, 6H); 4,44 (q^{dt}, J = 6,9, 4H); 8,22 (s, 2H). Spectrométrie de masse par I.C. (NH_3), m/z : 258 ($M+H^+$)(100), 275 ($M+NH_4^+$)(24). Anal. calc. pour $C_{11}H_{12}ClNO_4$: C 51,27; H 4,69; N 5,44; Cl 13,76; trouvé : C 51,30; H 4,80; N 5,29; Cl 12,99.

4-Éthoxy-2,6-pyridinedicarboxylate d'éthyle **12**

Dans 5 mL de THF anhydre sont dispersées 11,7 mmol de NaH 60%. On y ajoute 1 mL d'éthanol anhydre, et la solution est agitée, sous argon, pendant 1 h à température ambiante. On ajoute alors 7,76 mmol du composé **11***a* dissous dans 10 mL de THF anhydre, et quelques milligrammes d'éther couronne (18-c-6). La solution est chauffée à reflux pendant 1 h, puis les solvants sont évaporés et le résidu final est repris dans 15 mL d'acétate d'éthyle. Après lavage avec NaCl 5% (2×10 mL), et séchage sur sulfate de sodium, l'extrait est évaporé. Une recristallisation du résidu dans l'heptane conduit au produit **12** sous forme de paillettes blanches avec un rendement de 70%. *F* : 87–88°C. IR (KBr), ν : 1700–1730 (C=O); 1580 (C=C et C-N pyridiniques) cm^{-1}. RMN ^1H ($CDCl_3$) : 1,43 (t, J = 6,9, 6H); 1,47 (t, J = 6,9, 3H); 4,19 (q^{dt}, J = 6,9, 2H); 4,45 (q^{dt}, J = 6,9, 4H); 7,73 (s, 2H). Spectrométrie de masse par I.C. (NH_3), m/z : 268 ($M+H^+$)(100), 195 [($M-COOCH_2CH_3$)+H^+](15).

Acide 4-pentoxy-2,6-pyridinedicarboxylique **13***a*

Préparation du pentanolate de sodium : 220 mg de NaH 60% sont dispersés dans 10 mL de pentane à 0°C. À l'aide d'une ampoule à brome on ajoute, goutte à goutte, 0,7 mL de 1-pentanol dans 5 mL de pentane. Après addition on laisse agiter pendant 1 demi-heure à température ambiante, puis le solvant est évaporé. Le résidu blanc obtenu est ensuite repris par 10 mL de benzène anhydre.

Préparation du produit **13***a*: 10 mmol de 1-pentanol sont ajoutées à une solution de 5 mmol du chlorure d'acide **10** dans 15 mL de dichlorométhane anhydre. Le mélange réactionnel est porté à reflux pendant 1 h. Il se produit un dégagement de HCl. Après évaporation du solvant, le résidu repris dans 15 mL de benzène anhydre est additionné à une solution de pentanolate de sodium (1,1 équivalent) dans 10 mL de benzène anhydre. On ajoute quelques milligrammes d'éther couronne (15-c-5) et on laisse la solution sous agitation et sous argon 1 nuit à température ambiante. Le benzène est alors évaporé et on ajoute au résidu huileux 25 mL d'une solution de KOH 0,4 M. La solution est portée à reflux pendant 2 h sous agitation vive. Après refroidissement et neutralisation, une extraction à l'éther (10 mL) permet d'éliminer le 1-pentanol excédentaire. Un solide blanc précipite par addition de HCl concentré à la solution. Le précipité est filtré sur Büchner, rincé avec H_2O glacée plusieurs fois et recristallisé dans l'éthanol. Le reflux au Dean–Stark dans le benzène permet d'éliminer toutes traces d'eau. Le produit **13***a*, lavé à l'éther anhydre et séché au dessiccateur sous vide, est obtenu pur avec un rendement de 75,7% sous forme d'une poudre pulvérulente de couleur crème. *F* : 154–155°C. RMN ^1H (CD_3OD) : 0,85 (t, J = 6,9, 3H); 1,36 (m, 4H); 1,78 (q^{pt}, J = 6,8, 2H); 4,2(t, J = 6,8, 2H); 7,69(s, 2H). Spectrométrie de masse par I.C. (NH_3), m/z : 254 ($M+H^+$)(11),

Dichlorure de l'acide 4-éthoxy-2,6-pyridinedicarboxylique ***14b***

Dans 10 mL de $SOCl_2$ sont dispersées 3,35 mmol du diacide **13*b*** avec quelques gouttes de DMF comme catalyseur. La solution est portée à reflux pendant 3 h, puis l'excès de $SOCl_2$ est éliminé à l'évaporateur rotatif. Les dernières traces de $SOCl_2$ sont entrainés par plusieurs évaporations successives de benzène anhydre ajouté au résidu. Le résidu est recristallisé dans l'hexane pour conduire au produit **14*b*** avec un rendement de 85%. *F* : 76–77°C (litt. (36) *F* : 76–78°C). IR (KBr), ν : 1750 (C=O); 1590 (C=C et C-N pyridiniques) cm^{-1}. RMN ^1H ($CDCl_3$) : 1,52 (t, *J* = 6,9, 3H); 4,26 (q^{dt}, *J* = 6,9, 2H); 7,79 (s, 2H). Spectrométrie de masse par I.C. (NH_3), *m*/*z* : 249 (M+H^+). Anal. calc. pour $C_9H_7Cl_2NO_3$: C 43,57; H 2,85; N 5,65; trouvé : C 43,78; H 2,96; N 5,52.

Dichlorure de l'acide 4-(3-nitrile-propyloxy)-2,6-pyridinedicarboxylique ***14c***

Dans 30 mL d'une solution 0,3 M de KOH sont dispersées 4,4 mmol de diester **16**. Cette solution est agitée à température ambiante pendant 18 h puis lavée avec 10 mL d'éther. La phase aqueuse est acidifiée avec HCl concentrée jusqu'à précipitation d'un produit blanc. Après 3 h à 5°C, le produit est filtré sur Büchner puis séché pendant 4 h avec un montage de Dean–Stark. Après filtration et plusieurs rinçages faits à l'éther anhydre, le produit est séché sous vide (pour retirer les traces d'éther) et dispersé dans 15 mL de $SOCl_2$ auxquels on ajoute une goutte de DMF. Après 6 h de reflux sous argon le $SOCl_2$ excédentaire est évaporé. Le résidu est repris par le benzène anhydre plusieurs fois et les solutions sont réévaporées afin d'entrainer les dernières traces de $SOCl_2$. La poudre jaune obtenue est recristallisée dans l'heptane pour conduire au chlorure d'acide **14*c***, sous forme de minuscules cristaux blancs, avec un rendement de 55%. *F* : 94°C. IR (KBr), ν : 2220 (C≡N); 1745–1765 (C=O); 1585 (C=C et C-N pyridiniques) cm^{-1}. RMN ^1H ($CDCl_3$) : 2,24 (q^{pt}, 2H, *J* = 6,7); 2,63 (t, 2H, *J* = 6,9); 4,30 (t, 2H, *J* = 5,5); 7,8 (s, 2H). Spectrométrie de masse par I.C. (NH_3), *m*/*z* : 287 (M+H^+)(100), 306 (M+NH_4^+)(16). Anal. calc. pour $C_{11}H_8N_2O_3Cl_2$: C 46,22; H 3,02; N 8,75; trouvé : C 46,02; H 2,81; N 8,76.

4-Hydroxy-2,6-pyridinedicarboxylate ***15***

Dans 180 mL d'éthanol anhydre contenant 2% d'acide sulfurique sont dispersés 100 mmol d'acide chélidamique **9**. La suspension est chauffée à reflux pendant 48 h, puis l'éthanol est évaporé. Le résidu de couleur crème est recristallisé dans 30 mL d'un mélange éthanol–eau (3 : 2). Après 1 nuit à 5°C, le solide blanc obtenu est filtré, dispersé dans le benzène et séché pendant 4 h avec un montage de Dean–Stark. La solution est filtrée à chaud. Le produit **15** cristallise dans la solution placée à 5°C. Après filtration sur Büchner et rinçage à l'hexane puis à l'éther anhydre, le diester **15** est obtenu pur sous forme d'une fine poudre blanche avec un rendement de 45%. *F* : 122–123°C (litt .(23) *F* : 120–121°C). IR (KBr), ν : 3450 (O-H), 1730–1740 (C=O); 1610 (C=C et C-N pyridiniques) cm^{-1}. RMN ^1H ($CDCl_3$) : 1,31 (t, 6H, *J* = 7), 4,33 (q^{dt}, 4H, *J* = 7), 7,56 (s, 2H), 11,5 (s large, 1H). Spectrométrie de masse par I.C. (NH_3), *m*/*z* : 240 (M+H^+)(100), 257 (M+NH_4^+)(3). Anal. calc. pour $C_{11}H_{13}NO_3$: C 55,23 H 5,48; N 5,86; O 33,44; trouvé : C 55,21; H 5,38; N 5,90; O 33,42.

4-(3-Nitrile-propyloxy)-2,6-pyridinedicarboxylate d'éthyle ***16***

Dans 50 mL de toluène anhydre sont ajoutées 26,2 mmol du diester **15** à 1,1 équivalent de NaOH (60%). La suspension est chauffée à 60°C sous argon pendant 3 h. On ajoute alors 28,8 mmol de 4-bromobutyronitrile, 2,5% d'éther couronne (15-C-5) et 130 mL de toluène anhydre. La solution est chauffée à reflux, sous argon, pendant 18 h, refroidie et la suspension obtenue filtrée sur filtre plissé. Le solide résiduel est dispersé dans 50 mL d'eau qui sont extraits par le dichlorométhane (2×50 mL). Les phases organiques sont rassemblées et les solvants évaporées. Le résidu est repris dans 50 mL de dichlorométhane et rincé successivement avec Na_2CO_3 saturée et H_2O. La phase organique est séchée sur papier Whatman. Après évaporation du dichlorométhane, l'huile résiduelle est chromatographiée sur silice flash avec le mélange : dichlorométhane – acétate d'éthyle – méthanol (70 : 30 : 2,5) pour conduire au produit **16** avec un rendement de 60%, sous forme d'une huile incolore qui cristallise lentement. IR (NaCl), ν : 2220 (C≡N; 1710–1740 (C=O); 1590 (C=C et C-N pyridiniques) cm^{-1}. RMN ^1H ($CDCl_3$) : 1,42 (t, *J* = 7,1, 6H); 2,2 (q^{pt}, *J* = 6,3, 2H); 2,6 (t, *J* = 7, 2H); 4,24 (t, *J* = 5,7, 2H); 4,44 (q^{dt}, *J* = 7,1, 4H); 7,75 (s, 2H). Spectrométrie de masse par I.C. (NH_3), *m*/*z* : 307 (M+H)$^+$(100). Anal. calc. pour $C_{15}H_{18}N_2O_5$: C 58,82; H 5,92; N 9,14; O 26,12; trouvé : C 58,71; H 6,14; N 9,27; O 26,13.

Méthode générale de synthèse des acides acétylhydroxamiques protégés ***17a–d*** *à partir des chlorures d'acide*

À une solution du chlorure d'acide dans le dichlorométhane anhydre (0,01–0,015 M) on ajoute 3 équivalents de trifluorocétate de 1-amino-3-(acétylbenzyloxyamino)propane **7*ab*** sous forme solide. La solution agitée est refroidie à 0°C et traitée par 5 équivalents de triéthylamine dans le dichlorométhane anhydre (0, 1–0, 15 M) ajoutés goutte à goutte sous atmosphère d'argon. Quand l'addition est terminée on prolonge l'agitation 1 nuit à 5°C puis 1 h à température ambiante. Le dichlorométhane est partiellement évaporé et la solution résiduelle est lavée successivement avec une solution de citrate 0,5 M, de l'eau, une solution de $NaHCO_3$ 0,5 M et finalement avec une solution concentrée de NaCl. La phase organique est séchée par filtration sur papier Whatman et évaporée. Le résidu est purifié par chromatographie sur silice flash avec un mélange dichlorométhane – acétate d'éthyle – méthanol (70 : 30 : 2,5).

N,N′-*Bis [3-(acétylbenzyloxyamino)propyl]-[4-pentoxy-2,6-pyridine]dicarbamide* ***17a***

Le produit **17*a*** est obtenu pur sous forme d'une huile incolore avec un rendement de 50%. RMN ^1H ($CDCl_3$) : 0,9 (t, *J* = 6,9, 3H); 1,39 (m, 4H); 1,77 (q^{pt}, 4H, *J* = 6,5), 1,92 (q^{pt}, *J* = 6,9, 2H); 2,1 (s, 6H); 3,46 (m, *J* = 6,4, 4H); 3,78 (t, *J* = 6,5); 4,1 (t, *J* = 6,8); 4,81 (s, 4H); 7,34 (m, 10H); 7,75 (s, 2H); 9,17 (t, *J* = 6,4, 2H). N,N′-*Bis[3-(acétylbenzyloxyamino)propyl]-2,6-pyridine-dicarbamide* **17**d

Le produit **17***d* est obtenu pur sous forme d'une huile incolore avec un rendement de 42% à partir du dichlorure de l'acide-2, 6-pyridine dicarboxylique commercial. IR (NaCl), ν : 3300–3400 (N-H); 1725 (C=O acétohydroxamique), 1690–1710 (C=O amide); 1515 (C-C aromatiques); 1040 (N-O) cm^{-1}. RMN ^1H ($CDCl_3$) : 1,92 (q^{pt}, J = 6,8, 4H); 2,1 (s, 6H); 3,46 (m, J = 6,4, 4H); 3,78 (t, J = 6,6, 4H); 4,81 (s, 4H); 7,36 (m, 10H); 7,96–8,26 (m, 3H); 9,2 (t, J = 6,5, 2H). Spectrométrie de masse par I.C. (NH_3), m/z : 576 ($M+H^+$). Anal. calc. pour $C_{31}H_{37}N_5O_6$: C 64,68; H 6,48; N 12,16; trouvé : C 64,39; H 6,39; N 11,93.

Méthode générale de synthèse des acides N-*acétylhydroxamiques* **18**a–d

À une solution 0,015 M de ligand protégé, dans le méthanol anhydre, on ajoute 10% en poids de Pd/C 10%. On agite la solution sous 1 atmosphère de H_2(1 atm=101,3 kPa) en suivant la réaction par chromatographie sur couche mince avec le mélange dichlorométhane – acétate d'éthyle – méthanol (70 : 30 : 2,5) comme éluant. Après 4–7 h, on filtre le catalyseur sur tissus de verre et on évapore le solvant. Le résidu est redissous dans le minimum de méthanol et on précipite le produit avec un mélange hexane – acétate d'éthyle (1 : 3). Après 1 nuit à 5°C, le produit est filtré, redissous dans le minimum de méthanol anhydre et précipité avec de l'acétate d'éthyle. Puis il est séché sous vide à température ambiante pendant plusieurs heures.

N,N′-*Bis[3-(acétylhydroxyamino)propyl]-[4-pentoxy-2,6-pyridine]dicarbamide* **18**a

Le produit **18***a* est obtenu pur sous forme d'une poudre jaune pâle avec un rendement de 85%. *F* : 133–135°C. IR (KBr), ν : 3200–3600 (O-H); 2980 (C-H alkyle); 1650–1670 (C-O amide); 1620–1640 (C=O acétohydroxamique); 850 (N-O) cm^{-1}. RMN ^1H (CD_3OD) : 0,84 (t, J = 6,9, 3H); 1,33 (m, 4H); 1,82 (m, 6H); 2,01 (s, 6H), 3,33 (m, J = 6,6, 4H); 3,63 (t, J = 6,6, 4H); 4,08 (t, J = 6,9, 2H); 7,62 (s, 2H). Spectrométrie de masse par I.C. (NH_3), m/z : 482 ($M+H^+$). Anal. calc. pour $C_{22}H_{35}N_5O_7$: C 54,87; H 7,33; N 14,54; trouvé : C 55,46; H 7,37; N 14,44.

N,N′-*Bis[3-(acétylhydroxyamino)propyl]-[4-éthoxy-2,6-pyridine]dicarbamide* **18**b

Le produit **18***b* est obtenu pur sous forme d'une poudre blanche avec un rendement de 75%. *F* : 138–140°C. IR (KBr), ν : 3150–3550 (O-H); 1670 (C=O amide); 1600–1620 (C=O acétohydroxamique); 845 (N-O) cm^{-1}. RMN ^1H (CD_3OD) : 1,35 (t, J = 6,9, 3H); 1,82 (m, 6H); 2,01 (s, 6H); 3,35 (t, J = 6,4, 4H); 3,63 (t J = 6,3, 4H); 4,15 (q^{dl}, J = 7, 2H). Spectrométrie de masse par I.C. (NH_3), m/z : 396 ($M+H^+$)(100). Anal. calc. pour $C_{19}H_{29}N_5O_7$: C 51,75; H 6,50; N 16,25; trouvé : C 51,93; H 6,65; N 15,94.

N,N′-*Bis[3-(acétylhydroxyamino)propyl]-[4-(3-nitrilepropyloxy)-2,6-pyridine]dicarbamide* **18**c

Le produit **18***c* est obtenu pur sous forme d'une poudre blanche avec un rendement de 85%. *F* : 137–139°C. IR (KBr), ν : 3320 (O-H libre); 3080–3160 (O-H lié); 2215 (C≡N); 1650 (C=O amide); 1600-1620 (C=O acétohydroxamique); 870 (N-O) cm^{-1}. RMN ^1H (CD_3OD) : 1,83 (q^{pt}, J = 6,6, 4H); 2,02 (s, 6H); 2,58 (t, J = 7, H_3); 3,36 (t, J = 6,6, 4H); 3,63 (t, J = 6,6, 4H); 4,20 (t, J = 5,8, 2H); 7,67 (s, 2H). Spectrométrie de masse par I.C. (NH_3), m/z : 479 ($M+H^+$). Anal. calc. pour $C_{21}H_{30}N_6O_7$: C 52,71; H 6,32; N 17,56; trouvé : C 53,11; H 6,33; N 17,54.

N,N′-*Bis[3-(acétylhydroxyamino)propyl]-2,6-pyridine-dicarbamide* **18**d

Le produit **18***d* est obtenu pur sous forme d'une poudre jaune pâle avec un rendement de 70%. *F* : 76–80°C. IR (KBr), ν : 3180–3500 (O-H); 2950 (C-H alkyle); 1610 (C=O amide); 1640–1660 (C=O acétohydroxamique); 840 (N-O) cm^{-1}. RMN ^1H (CD_3OD) : 1,82 (q^{pt}, J = 6,6, 4H); 2,00 (s, 6H); 3,36 (t, J = 6,7, 4H); 3,63 (t, J = 6,7, 4H); 7,99–8,15 (m, 3H). Spectrométrie de masse par I.C. (NH_3), m/z : 396 ($M+H^+$). Anal. calc. pour $C_{17}H_{25}N_5O_6$: C 51,64; H 6,37; N 17,71; trouvé : C 51,68; H 6,52; N 17,77.

Préparation du chlorohydrate de N,N′-*Bis[3-(acétylhydroxyamino) propyl]-[4-(4-amino-n-butyloxy)-2,6-pyridine]dicarbamide* **18**e

Dans 150 mL de méthanol anhydre sont dissous 300 mg du ligand protégé **17***c*. On y ajoute 490 mg de Pd/C 10% et 6 mL de HCl 0,1 N. La solution est agitée sous 1 atmosphère de H_2 pendant 16 h. Le catalyseur est filtré sur tissus de verre et le solvant est évaporé. Le résidu est traité de la même manière que pour la synthèse des ligands **18***a–d* pour conduire au ligand **18***e* avec un rendement total de 73% sous forme de cristaux hygroscopiques de couleur mauve. Ces cristaux sont lyophylisés et conservés dans un dessiccateur. *F* : 110–112°C. IR (KBr), ν : 3000–3600 (N-H, O-H); 1600 (C=O amide); 1620–1650 (C=O acétyle); 870 (N-O) cm^{-1}. RMN ^1H (CD_3OD) : 1,96 (m, 8H, H2, H3); 2,09 (s, 6H); 3,00 (t, J = 6,5, 2H); 3,43 (t, J = 6,5, 4H); 3,70 (t, J = 6,5, 4H); 4,22 (t, J = 5, 2H); 7,7 (s, 2H). Spectrométrie de masse par I.C. (NH_3) : on analyse l'ion moléculaire M′ =M−HCl, m/z : 483 ($M+H^+$)(74), 439 ($(M-COCH_3)+H^+$)(18,5), 425 ($(M-C_2H_6NH_2)+H^+$)(100). Anal. calc. pour $C_{21}H_{35}N_6O_7Cl$: C 48,60; H 6,80; N 16,19; Cl 6,83; trouvé : C 48,86; H 6,79; N 16,24; Cl 6,93.

Résultats

Le schéma de synthèse des ligands se divise en 3 séquences :

A. Synthèse des « bras hydroxamiques » à partir du 1-amino-3-propanol **1** (Schéma 1).

B. Synthèse à partir de l'acide chélidamique **9** du motif pyridinique substitué en position 4 par des groupes alcoxy et en α et α′ par 2 fonctions chlorure d'acide (Schémas 2 et 3).

C. Condensation des bras hydroxamiques avec le synthon pyridinique et libération des fonctions chélatantes (Schéma 4).

1. Synthèse des « bras hydroxamiques » (Schéma 1)

En nous inspirant des travaux de Miller et coll. (13, 14), nous avons pu optimiser la synthèse du trifluoroacétate de l'amino-1-(acétyl-aminobenzyloxy)-3-propane **7***a* qui a été obtenu à partir du 1-amino-3-propanol en six étapes avec un rendement de 37,5%. Parmi les méthodes décrites dans la littérature (15, 16) concernant la protection de l'amine primaire, seule la méthode de Moroder *et al.* (15) nous a permis d'obtenir quantitativement le produit **2** sous forme d'une huile ne nécessitant pas de purification. L'oxydation de l'alcool primaire **3** été menée par la méthode de Swern et coll. (17). L'aldéhyde **3**, très instable, n'a pu être purifié mais a été immédiatement traité par la *O*-benzylhydroxylamine (OBHA) dans un mélange méthanol–eau avec contrôle du pH (18). Après chromatographie sur silice flash, les deux isomères *syn* et *anti* de l'oxime **4** ont été obtenu avec un rendement de 82% à partir du produit **2**. Le spectre RMN ^1H du produit **4** réalisé à 250 MHz dans $CDCl_3$ permet d'identifier et de quantifier les isomères *syn* et *anti* dans des proportions respectives 60 : 40.

Le mélange de ces deux isomères, qui ne sont pas séparés,

SCHÉMA 1. Synthèse du « bras hydroxamique » **7***a*.

est traité par le cyanoborohydrure de sodium dans l'acide acétique (19) pour conduire à la *O*-benzyl-*N*-(3-(*tert*-butoxycarbonyl-amino)-hydroxylamine **5**. Après chromatographie, le produit pur est obtenu sous forme d'une huile laiteuse incolore avec un rendement de 70%. Son acétylation conduit avec un rendement de 73% au composé **6** caractérisé par l'apparition à 2 ppm du singulet du méthyle du groupement acétohydroxamique protégé. Le rendement de cette séquence réactionnelle a pu être amélioré en réalisant la réduction de la benzyloxime **4** et l'acétylation de l'hydroxylamine **5** sans isolement du produit **4** avec un rendement global de 65%. Par action de HCl gazeux sur le produit **6** dans l'éther éthylique anhydre, le composé **7***b* est obtenu avec un rendement de 22% bien inférieur à celui qui est rapporté dans la littérature (96%) (14). Nous avons pu déterminer que le produit majeur formé au cours de la réaction est en fait le dichlorhydrate **7***c* avec un rendement de 47%. (Nous avons pu séparer et identifier ces deux composés.) L'absence de signal à 2 ppm sur le spectre RMN ^{1}H du produit **7***c* ainsi que le spectre de masse ont permis de le différencier du produit **7***b* sans équivoque. Pour contourner cette difficulté, nous avons procédé à la déprotection du produit **6** par l'acide trifluoroacétique, ce qui conduit au produit **7***a* avec un rendement de 88% (20).

2. Préparation du synthon pyridinique substitué (Schéma 2)

Nous nous sommes basés essentiellement sur les travaux de Markees *et al.* (21–24) et de Bradshaw et coll. (25–27) pour établir notre stratégie de synthèse. Nous avons ainsi développé deux voies synthétiques parallèles à partir de l'acide chélidamique **9**.

La première voie conduit en une étape au dichlorure de l'acide 4-chloro-2,6-pyridine dicarboxylique **10** avec un ren-

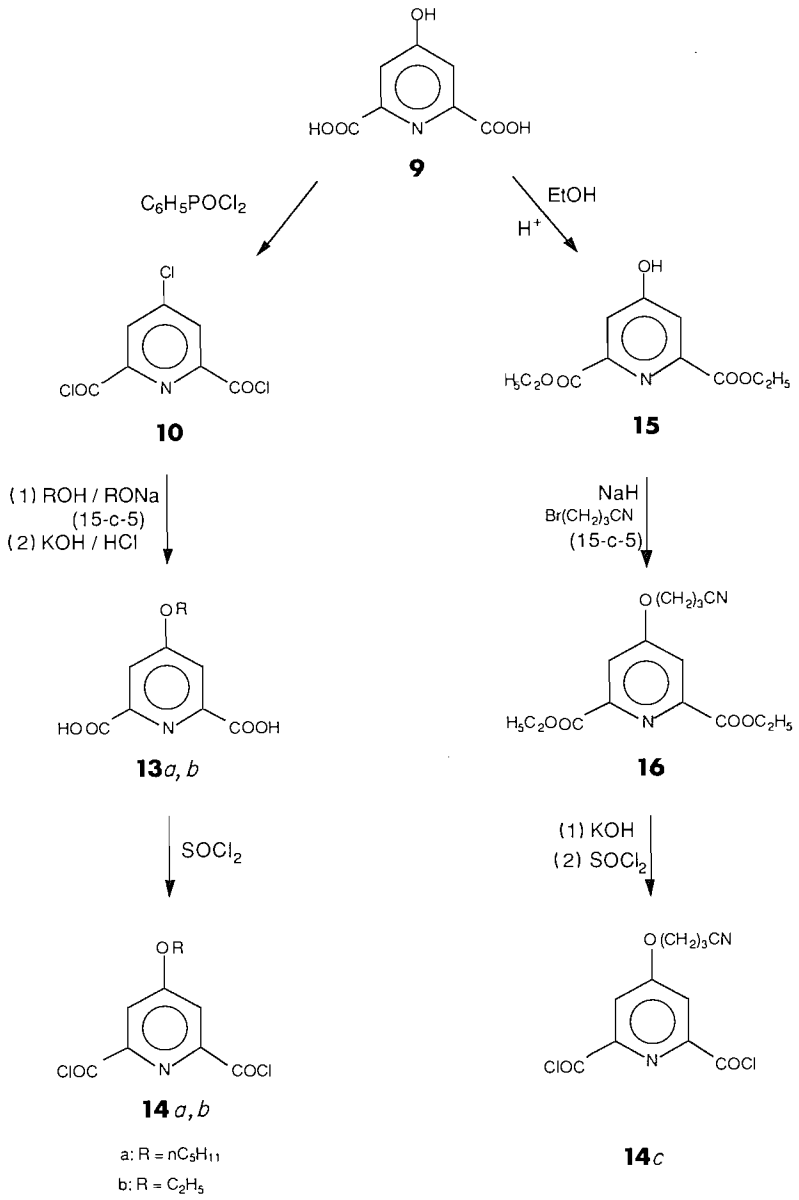

SCHÉMA 2. Synthèse des chlorures d'acide **14***a–c*.

dement de 57% et en 3 étapes aux dichlorures de l'acide 4-pentoxy-2,6-pyridine dicarboxylique **14***a* et de l'acide 4-éthoxy-2,6-pyridine dicarboxylique **14***b* avec des rendement globaux de 34% et de 35% respectivement.

La seconde voie conduit en 3 étapes au dichlorure de l'acide 4-(3-nitrile-*n*-butyloxy)-2,6-pyridine dicarboxylique **14***c* avec un rendement global de 17%.

(a) Synthèse des dichlorures de l'acide 4-pentoxy-2,6-pyridine dicarboxylique ***14***a *et de l'acide 4-éthoxy-2,6-pyridinedicarboxylique* ***14***b

L'acide chélidamique **9** traité par le dichlorure de l'acide phénylphosphonique ($C_6H_5POCl_2$) à 120°C (28) suivi d'une extraction *in situ* par l'hexane bouillant conduit, aprés sublimation, au dichlorure de l'acide 4-chloro-2,6-pyridinedicarboxylique **10**. Ce produit avait été précédemment obtenu par traitement avec le pentachlorure de phosphore (PCl_5) dans le tétrachlorure de carbone ou le chloroforme suivi d'une hydrolyse et d'un reflux dans le chlorure de thionyle ($SOCl_2$) (29) avec un rendement global équivalent ($C_6H_5POCl_2$: 57%; PCl_5 : 59%). Notre méthode présente cependant deux avantages : un gain de temps important et une meilleure reproductibilité des rendements. La substitution du groupement hydroxyle par un atome de chlore est démontrée en RMN ^{13}C par la variation du déplacement chimique de l'atome de carbone en γ (C-OH : δ = 166,7 ppm, C-Cl : δ = 150 ppm). À ce stade deux voies ont été envisagées pour préparer l'acide 4-pentoxy 2,6-pyridinedicarboxylique **13***b*.

Voie 1 (Schéma 3) : Le composé **10** est traité par l'éthanol dans le dichlorométhane afin d'obtenir le diester **11***a* avec un rendement de 52% après recristallisation dans l'heptane. Le produit **11***a* peut également être obtenu avec un rendement de 28% à partir de l'acide chélidamique **9** sans isolement, ni purification du chlorure d'acide intermédiaire **10**. La substitution aromatique de l'atome de chlore en position 4 par l'éthanolate de sodium conduit au produit **12** avec un rendement modeste de 35%. Cependant, l'utilisation d'éther couronne (15-c-5) permet d'augmenter ce rendement jusqu'à 70% (30, 31). En RMN ^1H, on note surtout la variation

SCHÉMA 3. Synthèse du chlorure d'acide **14***b*.

caractéristique de déplacement chimique des deux atomes d'hydrogène pyridiniques : 8,22 ppm (**11***a*) et 7,72 ppm (**12**). La saponification de l'ester **12** suivie d'une précipitation par HCl, conduit au diacide correspondant avec un rendement de 58%.

Voie 2 (Schéma 2) : Le produit **10** est traité par le *n*-pentanol ou l'éthanol puis saponifié pour conduire aux diacides *para* substitués **13***a* et *b* au cours d'une réaction « one pot » (26), avec un rendement global de 75% et 72% respectivement.

Aprés recristallisation dans l'éthanol, les diacides purs correspondants sont traités par $SOCl_2$ et conduisent aux chlorures d'acide avec des rendements de 80% pour **14***a* et de 85% pour **14***b*.

*(b) Synthèse du dichlorure de l'acide 4-(3-nitrile-*n*-butyloxy)-2,6-pyridinedicarboxylique **14**c*

Nous avons aussi envisagé la substitution du noyau pyridinique par un résidu alkyle portant une fonction nitrile. Cette fonction peut être conservée telle quelle ou être réduite par hydrogénation catalytique en amine primaire qui, sous forme de chlorhydrate, peut avoir une meilleure solubilité dans l'eau. Les travaux de Markees *et al.* (22, 23) nous ont suggéré une stratégie de synthèse du produit **14***c* différente de celle employée pour les chlorures d'acide **14***a* et **14***b*. La fonction hydroxyle de l'acide chélidamique peut être alkylée par un bromure de *n*-alkyle porteur d'une fonction nitrile . L'acide chélidamique **9** estérifié par l'éthanol en présence d'acide sulfuriqe comme catalyseur (32) conduit au produit **15** avec un rendement de 50%. Le traitement de **15** par NaH dans le benzène, suivi de l'addition de 4-bromobutyronitrile et d'une quantité catalytique d'éther couronne (15-c-5) (33), conduit au produit de substitution en position 4 avec un rendement de 60%. Finalement, après saponification, le traitement par $SOCl_2$ du diacide intermédiaire brut conduit au composé **14***c* avec un rendement de 55%.

3. Synthèse des ligands (Schéma 4).

La synthèse des ligands se réduit à deux étapes : (1) condensation des bras hydroxamiques protégés avec les différents chlorures d'acide substitués en position 4 sur le noyau pyridinique (**14***a–c*); (2) hydrogénolyse des groupements benzyliques protecteurs des fonctions acétohydroxamiques. Pour réaliser la condensation, nous avons appliqué la méthode proposée par Lee et Miller pour la synthèse des schizokinen (14) et qui consiste à effectuer la réaction dans le dichlorométhane à 0°C en présence de triéthylamine. Les rendements obtenus, aprés purification par chromotographie sur silice flash, varient de 30 à 50% suivant R. La déprotection des fonctions acétohydroxamiques des produits **14***a–c* s'effectue par hydrogénolyse de la liaison *O*-benzyle dans le méthanol, sous 1 atmosphère de H_2, en présence de Pd/C 10% comme catalyseur (13, 14, 34). Les rendements sont compris entre 70 et 85% suivant R. À ce stade une légère modification des conditions d'hydrogénolyse permet en une seule étape de libérer la fonction acétohydroxamique et de réduire le groupement nitrile du composé **17***c* en amine primaire avec un rendement de 72%. Aux quatre ligands potentiels **18***a–e* nous avons adjoint un cinquième composé dans lequel le noyau pyridinique n'est pas substitué en position 4. Le chlorure de l'acide pyridine-2,6-dicarboxylique, précurseur de ce produit, est disponible commercialement et a été condensé avec les bras hydroxam-

For personal use only.

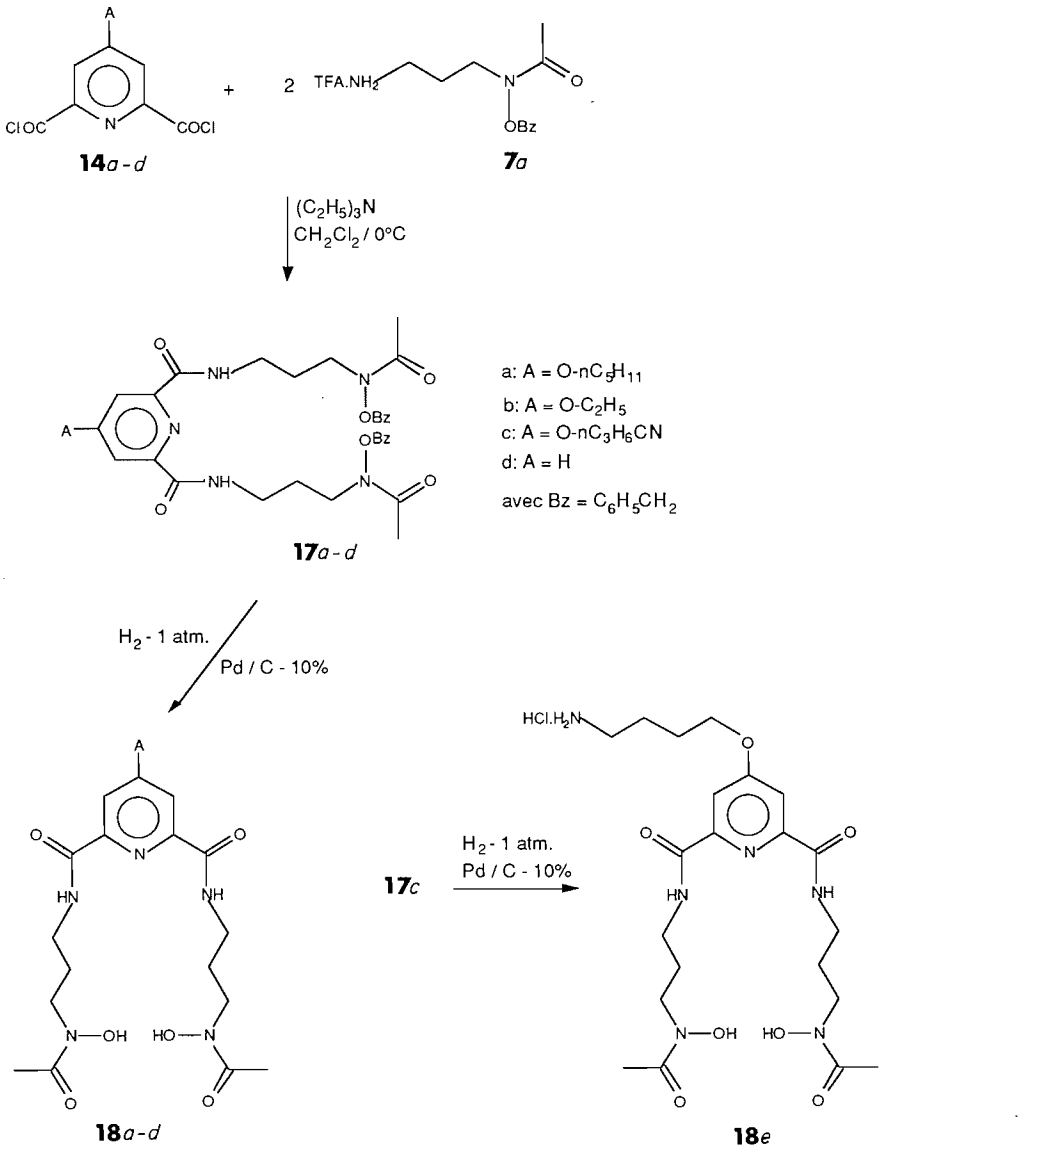

SCHÉMA 4. Synthèse des ligands **18***a–e*.

iques dans les mêmes conditions que pour les composés **17***a–c* pour obtenir le précurseur **17***d*. L'hydrogénolyse catalytique libère, de la même façon, les fonctions acétohydroxamiques pour conduire au produit **18***d* caractérisé en RMN ^1H par les signaux des 3 atomes d'hydrogène pyridiniques entre 7,7 et 8,1 ppm. Nous disposons alors de cinq ligands potentiels de l'ion ferrique, la présence des fonctions chélatantes libres étant confirmée qualitativement par un test avec $FeCl_3$ (35). Le produit **18***d* a été précédemment synthétisé par Miller et coll. (13) par une voie de synthèse faisant intervenir l'acétylation de l'hydroxylamine *O*-benzylée après condensation sur le noyau pyridinique.

Remerciements

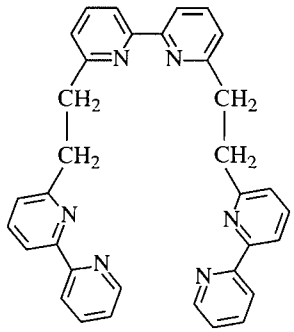
The synthesis of a series of 6,6′-diethynyl-2,2′-bipyridyls from the palladium-catalyzed coupling of 6,6′-dibromo-2,2′-bipyridine with a series of arylacetylenes is reported. The single crystal X-ray structure of 6,6′-phenylethynyl-2,2′-bipyridyl was determined. Crystal data: monoclinic, $A2/a$, with cell constants a = 10.0385(4), b = 9.2166(4), c = 21.4130(8) Å, and β = 102.981(3)°; $D_{calc.}$ = 1.226 g cm^{-3}, Z = 4, R_f = 0.045, S = 1.22, using 886 reflections of the 1443 unique reflections. The packing diagram indicates essentially that the molecules pack in a layered assembly with the nitrogen atoms of the dipyridyl groups on opposite sides and with a dihedral angle of 59.85(16)° between the pyridyl and phenyl groups. The acetylenic bond distances are normal.

Key words: acetylene, palladium, catalysis, coupling, monomers, crystal structure.

IAN R. BUTLER et CHANTAL SOUCY-BREAU. Can. J. Chem. **69**, 1117 (1991).

Faisant appel à un couplage catalysé par le palladium de la 6,6′-dibromo-2,2′-bipyridine avec une série d'arylacétylènes, on a réalisé la synthèse d'une série de 6,6′-diéthynyl-2,2′-bipyridyles. On a déterminé la structure cristalline du 6,6′-phénylélthylnyl-2,2′-bipyridyle par diffraction des rayons-X sur un cristal unique. Les cristaux sont monocliniques, groupe d'espace $A2/a$ avec a = 10,0385(4), b = 9,2166(4) et c = 21,4130(8) Å, β = 102,981(3)°, $D_{calc.}$ = 1,226 g cm^{-3}, Z = 4, R_f = 0,045, S = 1,22 utilisant 886 réflexions de 1443 réflexions uniques. Le diagramme d'entassement indique essentiellement que les molécules s'empilent en couches dans lesquelles les atomes d'azote des groupements dipyridyles se trouvent sur des côtés opposés avec un angle dièdre de 59,85(16)° entre les groupements pyridyle et phényle. La longueur de la liaison acétylénique est normale.



Mots clés : acétylène, palladium, catalyse, coupling, monomère, structure cristalline.

[Traduit par la rédaction]

Introduction

The catalytic coupling reaction of aryl halides with olefins and acetylenes (1–18), mediated by palladium(0), is a reaction that, in the past few years, has been widely used in organic synthesis. We have been interested in this reaction from the standpoint of elucidation of its mechanism; however, during related studies in the synthesis of novel substituted dipyridyl derivatives such as ferrocene-substituted dipyridyls, we developed an interest in the application of the methodology to the synthesis of some acetylene-substituted derivatives.

The palladium-catalyzed reaction of 2-bromopyridine with phenylacetylene was reported initially by Castro and Stephens (19) and later by Ames *et al.* (20) to give excellent yields of 2-pyridylphenylacetylene. In addition, the reaction of 2-bromopyridine with 2-methylbut-3-yne-2-ol (20) and with trimethylsilylacetylene (21, 22), respectively, has been reported, the products of each of these reactions being precursors to 2-ethynylpyridine. In one of our synthetic projects in ligand design and synthesis we were interested in the synthesis of the hexadentate ligand **1**. We envisaged a simple synthesis based on the palladium-catalyzed reaction of 6,6′-dibromo-2,2′-dipyridyl with 6-ethynyl-2,2′-dipyridyl followed by metal-catalyzed reduction. During the course of the synthesis of **1**, we recognized that this work overlapped significantly with another of our current research projects. We are actively engaged in the synthesis of a series of polyacetylene compounds to be used as monomers in the preparation of conducting organic polymers. Thus we decided that some of the acetylene intermediates prepared during the synthesis of **1** may be of a more general interest, and we decided to broaden the scope of the synthesis to include groups other than dipyridyl. The results of these efforts are discussed herein.

1

Experimental section

Solvents used were distilled prior to use, after drying by standard methods, unless otherwise stated. Ferrocenylacetylene (23), 2-pyridylacetylene (20), and 1-naphthylacetylene (24) were prepared following literature procedures. Chromatography was carried out using either neutral alumina (activity grade 1) on a conventional column or using silica gel (Merck 7749-60 PF_{254} plates) on a Harrison Research 7924 chromatatron. Bis(triphenylphosphine)palladium dichloride was prepared from palladium dichloride by adaptation of the literature procedure.[3] The ^{1}H NMR spectra were recorded on Varian XL-300 or Gemini-200 instruments using chloroform-*d*, unless otherwise mentioned (notation used: t = triplet, s = singlet, bd = broad doublet, m = multiplet, ad = asymmetric doublet). Mass spectra were obtained

[3]An excess of triphenylphosphine and palladium dichloride was stirred overnight in a biphasic mixture of dichloromethane, methanol, and water containing a small quantity of potassium chloride. This procedure is much simpler than the literature methods.

using a VG Analytical 7070E instrument equipped with digital processing, at the University of Ottawa Mass Spectroscopy Centre. All reactions were carried out under an inert (nitrogen or argon) atmosphere.

General product work-up procedure

On completion of the reaction the crude reaction solution was treated with water and dichloromethane (volumes equal to those used as solvent in the reaction). The organic layer was separated and the aqueous layer was further extracted with two portions of dichloromethane. The combined, dried ($MgSO_4$) organic phase was washed through a short neutral alumina column to remove black suspended solids. The volume was reduced under vacuum and the mixture chromatographed using the following procedures.

6,6′-Dibromo-2,2′-bipyridine

The title compound was synthesized using a modest adaptation of the literature procedure (25). The reaction was accomplished by lithiation of 2,6-dibromopyridine (59.5 g, 0.25 mol) with 1.6 M *n*-butyllithium (157 mL) solution in dry diethyl ether (500 mL) cooled to −90°C and stirred for 15 min under a N_2 atmosphere. Anhydrous cupric chloride (16.8 g, 0.13 mol) was then added in portions of 2 g at a time.[4] The reaction mixture was stirred at −70°C for 15 min. Once all the $CuCl_2$ had been added, the brown suspension was stirred for an additional 30 min and kept below −50°C.

Oxidation was carried out with compressed oxygen at −60 to −50°C by bubbling excess O_2 through the mixture for a period of 1 h. The suspension was hydrolyzed with dilute HCl (6 N, 250 mL), and filtered at room temperature. The ether fraction was evaporated to give an additional few grams of product. The solid was dried over Na_2SO_4 and separated on silica gel by column chromatography (eluent: hexane/ethyl acetate 1:1) to give 15 g of a beige solid (40–50% yield), mp 217–218°C (lit. (26) mp 218°C). Further purification by recrystallizing from benzene gave a white solid with mp 220–221°C (lit. (25) mp 221–223°C). ^{1}H NMR, 200 MHz ($CDCl_3$) δ: 8.35 (dd, 2H, $J_{5-3,5'-3'}$ = 0.66, $J_{5-4,5'-4'}$ = 7.66 Hz, *H*-5,5′), 7.75 (t, 2H, $J_{4-3,4'-3'}$ = 7.69, $J_{4-5,4'-5'}$ = 7.55 Hz, *H*-4,4′), 7.48 (dd, 2H, $J_{3-4,3'-4'}$ = 7.85, $J_{3-5,3'-5'}$ = 0.61 Hz, *H*-3,3′). EIMS, *m*/*z* (%): 314 (100), 312 (54), 235 (66), 233 (65), 189 (4.6), 153 (39), 126 (17.5), 116 (7.8), 77 (55), and 50 (31).

Preparation of **2**

Copper(I) iodide (0.16 g, 2 mmol) and bis(triphenylphosphine)palladium dichloride (0.35 g, 4 mmol) were stirred under nitrogen in triethylamine (100 mL) (20). 6,6′-Dibromo-2,2′-dipyridine (22.6 g, 72 mmol), followed by 2-methyl-3-butyn-2-ol (15.15 g, 180 mmol), was added to the mixture, and a precipitate was formed. After 18 h of stirring at room temperature, the solvent was evaporated under vacuum. Dichloromethane (100 mL) was added and the solution was washed with water (3 × 20 mL). The organic phase was dried over anhydrous magnesium sulfate and subsequently evaporated *in vacuo*. The crude product was separated on column chromatographic grade silica gel (eluent: hexane/ethyl acetate 1:1) to afford 21.2 g of nearly pure material. Purification was carried out with a second chromatography (column) to give 6,6′-(2-methylbut-3-yn-2-ol)-2,2′-bipyridine (18 g; 78% yield) with R_f (hexane/EtOAc 1:1) 0.19 and mp 160.5–161.5°C. IR (KBr), ν_{max}: 3380, 3280, 2980, 2940, 2240, 1570, 1450, 1370, 1290, 1200, 1170, 1110, 1080, 990, 970, 920, 810, 750, and 690 cm^{-1}. ^{1}H NMR, 200 MHz ($CDCl_3$) δ: 8.35 (dd, 2H, $J_{3-5,3'-5'}$ = 1.05, $J_{3-4,3'-4'}$ = 7.9 Hz, *H*-3,3′), 7.73 (t, 2H, $J_{4-3,4'-3'}$ = 7.8, $J_{4-5,4'-5'}$ = 7.7 Hz, *H*-4,4′), 7.39 (dd, 2H, $J_{5-3,5'-3'}$ = 1.08, $J_{5-4,5'-4'}$ = 7.7 Hz, *H*-5,5′), 2.29 (5, 2H, Ar-C≡C-C$(CH_3)_2$*O*H), 1.63 (s, 12H, Ar-C≡C-C$(CH_3)_2$OH). EIMS, *m*/*z* (%): 320 (13), 305 (15), 267 (35.8), 259 (12), 247 (25), 219 (70), 204 (15), 139 (28), 118 (99.7), 104 (100), 91 (85), 77 (56.6), and 42 (100). HRMS, calcd. for $C_{20}H_{20}N_2O_2$: 320.3940; found: 320.1513.

[4]We have observed in lithiation reactions of 2,6-dibromopyridine that 6,6′-dibromo-2,2′-bipyridine is produced without the necessity of using the copper salt.

Preparation of **3**a

6,6′-Diethynyl-2,2′-bipyridine was obtained by treatment of **2** (6.9 g, 0.022 mol) with sodium hydroxide (27) (0.8 g, 0.02 mol) in toluene (150 mL). The mixture was heated under reflux for 30 min. Decantation, evaporation under reduced pressure, and separation by silica gel chromatography (eluent: hexane/EtOAc) gave 3.0 g of nearly pure material. Rechromatography on silica gel afforded **3***a* (1.83 g; 42% yield); R_f (hexane/EtOAc 1:1) 0.54; mp 192–193°C; IR (KBr), ν_{max}: 3280, 2360, 1580, 1560, 1440, 1080, 980, 800, and 650 cm^{-1}. ^{1}H NMR, 200 MHz ($CDCl_3$) δ: 8.45 (dd, 2H, $J_{3-5,3'-5'}$ = 1.0, $J_{3-4,3'-4'}$ = 8.0 Hz, *H*-3,3′), 7.76 (t, 2H, $J_{4-5,4'-5'}$ = 7.7, $J_{4-3,4'-3'}$ = 7.9 Hz, *H*-4,4′), 7.48 (dd, 2H, $J_{5-3,5'-3'}$ = 1.06, $J_{5-4,5'-4'}$ = 7.7 Hz, *H*-5,5′), 3.16 (s, 2H, Ar-C≡C-C*H*). EIMS, *m*/*z* (%): 204 (100), 203 (25.7), 179 (97), 76 (3.7), 152 (15.5), 126 (2), 102 (11), 75 (20), and 50 (23.5). HRMS, calcd. for $C_{14}H_8N_2$: 204.2080; found: 204.0690.

Preparation of **3**b, **3**e

In the same manner as **3***a*, 6,6′-dibromo-2,2′-bipyridine (300 mg, 0.95 mmol) was coupled with phenylacetylene (197 mg, 1.9 mmol) in the presence of CuI (0.08 g) and $(PPh_3)_2PdCl_2$ (0.15 g) in triethylamine as solvent (30 mL). After 30 min at room temperature the usual work-up was performed and the crude dark solid was prepurified on a short silica gel column (chromatography) using hexane/CH_2Cl_2 in a 1:1 ratio as eluent. Further separation on silica gel (chromatatron TM, eluent: hexane/CH_2Cl_2 5:1) afforded 6,6′-bis-(phenylethynyl)-2,2′-bipyridine, 153 mg (45%) of a pure white solid of mp 195.8–196.2°C, R_f (hexane/CH_2Cl_2 1:2) 0.13. IR (KBr), ν_{max}: 3060, 2230, 1600, 1568, 1495, 1440, 805, 760, 690, and 640 cm^{-1}. ^{1}H NMR, 200 MHz ($CDCl_3$) δ: 8.46 (dd, 2H, $J_{3-5,3-5}$ = 1.1, $J_{3-4,3'-4'}$ = 7.9 Hz, *H*-3,3′), 7.81 (t, 2H, $J_{4-3,4'-3'}$ = 7.9, $J_{4-5,4'-5'}$ = 7.8 Hz, *H*-4,4′), 7.65–7.59 (m, 10H, Ph), 7.55 (dd, 2H, $J_{5-3,5'-3'}$ = 1.1, $J_{5-4,5'-4'}$ = 7.7 Hz, *H*-5,5′). EIMS, *m*/*z* (%): 356 (100), 355 (24), 279 (15.7), 193 (19), 167 (11), 149 (27), 72 (16), 57 (83), and 41 (41). HRMS, calcd. for $C_{26}H_{16}N_2$: 356.3854; found: 356.1325.

Using an identical procedure coupling 2-pyridylacetylene (1.03 g, 10 mmol) with 6,6′-dibromo-2,2′-dipyridine (1.57 g, 5 mmol) in the presence of CuI (0.08 g) and $(PPh_3)_2PdCl_2$ (0.15 g) gave bis-6,6′-(2-ethynylpyridinyl)-2,2′-dipyridine, **3***e* (89%). ^{1}H NMR, 300 MHz ($CDCl_3$) δ: 7.29 (ddd, 2H, $J_{5'''-4'''}$ = 7.8, $J_{5'''-6'''}$ = 4.8, $J_{5'''-3'''}$ = 1.4 Hz, *H*-5‴, *H*-5⁗), 7.63 (dd, 2H, J_{5-4} = 7.7, J_{5-3} = 1.1 Hz, *H*-5, *H*-5′), 7.67 (ddd, 2H, $J_{3'''-4'''}$ = 7.8, $J_{3'''-6'''}$ = 1.8 Hz, *H*-3‴, *H*-3⁗), 7.71 (td, 2H, $J_{4'''-6'''}$ = 2.7 Hz, *H*‴, *H*-4⁗), 7.84 (t, 2H, J_{4-3} = 8.0 Hz, *H*-4, *H*-4′), 8.50 (dd, 2H, *H*-3, *H*-3′), 8.65 (ddd, 2H, *H*-6‴, *H*-6⁗). Mass spectrum, parent ion *m*/*z* 358 (100%). Anal. calcd. for $C_{24}H_{14}N_4$: C 80.43, H 3.94, N 15.63; found: 80.41, H 3.86, N 15.57.

1-Naphthyl-2-trimethylsilylacetylene

Iodonaphthalene (10 mg, 39 mmol) was coupled with trimethylsilylacetylene (4.0 g, 40 mmol) in diethylamine (40 mL) in the presence of $(PPh_3)_2PdCl_2$ (0.18 g) and CuI (0.05 g) as catalyst. After stirring at room temperature for 18 h, the usual work-up was performed. Separation on a silica column (eluent: hexane) afforded the title compound, 7.0 g (80% yield) as a transparent oil; R_f (hexane) 0.27. IR (film) ν_{max}: 3060, 2960, 2900, 2160, 1590, 1510, 1400, 1250, 1160, 1080, 1050, 1020, 850, 800, 780, and 730 cm^{-1}. ^{1}H NMR, 200 MHz ($CDCl_3$) δ: 8.32 (dd, 1H, Ar), 7.33–7.84 (m, 6H, Ar), 0.32 (s, 9H, Ar-C≡C-Si$(CH_3)_3$). EIMS, *m*/*z* (%): 224 (42), 209 (100), 191 (2.6), 179 (10), 165 (16), 152 (4), 105 (13), 89 (3); HRMS, calcd. for $C_{15}H_{16}Si$: 224.3760; found: 224.1030. Anal. calcd. for $C_{15}H_{16}Si$: C 80.29, H 7.18; found: C 80.19, H 7.05.

1-Ethynylnaphthalene

In a round-bottom flask, under a N_2 atmosphere, were placed 1-naphthyl-2-trimethylsilylacetylene (1.0 g, 4.5 mmol) and a 1 M solution in THF of tetrabutylammonium fluoride (9 mL, 9 mmol) in dry THF (15 mL). The reaction was completed within 10 min at room temperature to give a reddish solution. Hydrolysis was carried out with a water (10 mL) and 2 M HCl (0.5 mL) solution. The solvent (THF) was removed *in vacuo* and the remaining material extracted with diethyl ether (4 × 25 mL) and CH_2Cl_2 (4 × 25 mL). The organic layer

For personal use only.

was washed with a saturated sodium chloride solution (20 mL), then dried over anhydrous $MgSO_4$ to give a crude brown oil (0.99 g). Separation on a short silica column (eluent: pentane) afforded 0.64 g (94% yield) of a pale yellow oil, R_f (pentane) 0.33. IR (film) ν_{max}: 3300, 3070, 2110, 1590, 1510, 1395, 1270, 1020, 800, and 780 cm^{-1}. ^1H NMR, 200 MHz ($CDCl_3$) δ: 8.39 (dd, 1H, Ar), 7.39–7.87 (m, 6H, Ar), 3.48 (s, 1h, Ar-C≡C*H*). EIMS, *m/z* (%): 152 (100), 126 (6.7), 98 (4), 86 (3), 74 (9), 62 (4), and 50 (5). Anal. calcd. for $C_{12}H_8$: C 94.70, H 5.29; found: C 94.46, H 5.51.

Reaction of 6,6′-dibromo-2,2′-bipyridine with 1-ethynylnaphthalene

6,6′-Dibromo-2,2′-bipyridine (200 mg, 0.64 mmol) and 1-ethynylnaphthalene (260 mg, 1.28 mmol), prepared by the palladium-catalyzed coupling of naphthyl iodide with 2-methyl-but-1-yne-2-ol followed by reaction with sodium hydroxide, were reacted in the presence of bis(triphenylphosphine)palladium dichloride (120 mg, 0.17 mmol) and copper(I) iodide (80 mg, 0.42 mmol) in 15 mL of diethylamine. Purification of the crude material on silica gel in the Chromatatron using hexane as eluent afforded 80 mg (30%) of an off-white solid, identified as bis-6,6′-(ethynyl-1-naphthalene)-2,2′-bipyridine, R_f (hexane/CH_2Cl_2 1:2) 0.09, mp 215–216°C. IR (KBr) ν_{max}: 3060, 2140, 1590, 1575, 1505, 1395, 1335, 1270, 1160, 1015, 950, 910, 870, 800, 770, 570, and 440 cm^{-1}. ^1H NMR, 200 MHz ($CDCl_3$) δ: 8.42 (dd, 2H, $J_{3-5,3'-5'}$ = 0.9, $J_{3-4,3'-4'}$ = 8.8 Hz, pyridyl *H*-3,3′), 7.85 (t, 2H, $J_{4-3,4'-3'}$ = 9.9, $J_{4-5,4'-5'}$ = 8.3 Hz, *H*-4,4′), 7.48 (dd, 2H, $J_{5-3,5'-3'}$ = 1.1, $J_{5-4,5'-4'}$ = 7.3 Hz, *H*-5,5′), 7.41–7.66 (m's, 14H, naphthyl). EIMS, *m/z* (%): 456 (12.7), 340 (14), 311 (7), 263 (20), 262 (100), 261 (16), 228 (9), 183 (70), 152 (14), 129 (34), 108 (41), 107 (7), 57 (36), 41 (25), and 28 (19).

NOTE: This reaction can also be achieved by coupling 1-iodonaphthalene (340 mg, 1.3 mmol) with 6,6′-diethynyl-2,2′-bipyridine, **3***a* (130 mg, 0.64 mmol), in DEA (20 mL) in the presence of CuI (0.04 g) and $(PPh_3)_2PdCl_2$ (0.08 g) as catalyst. The reaction gave yields of greater than 30%. A persistent by-product in the former reaction is 1,4-di(1-naphthyl)-1,3-buta-diyne, identified by spectral composition with an authentic sample.

Reaction of 2,6-dibromopyridine with ferrocenylacetylene

1. A mixture of 2,6-dibromopyridine (Aldrich) (300 mg, 1.26 mmol) and ferrocenylacetylene (600 mg, 2.36 mmol) was reacted using the general procedure with bis(triphenylphosphine)palladium dichloride (47 mg, 67 μmol) and copper(I) iodide (40 mg, 209 μmol) in diethylamine (15 mL). The reaction was monitored by TLC (eluent: hexane/diethyl ether 70:30). After 1.5 h a new orange band was observed with a lower R_f than the ferrocenylacetylene. The reaction mixture was worked up using the general method. Column chromatography gave the following bands in order of elution: (i) yellow band of ferrocenylacetylene (25 mg); (ii) an unidentified violet fraction (trace); (iii) a diffuse orange band that gave 6-bromo,2-ethynylferrocenylpyridine (total yield 360 mg, 0.98 mmol, 78%); (iv) red and violet bands (combined weight 100 mg), unidentified; mp 169–170°C. IR (KBr), ν_{max}: 2220, 1575, 1550, 1420, 1200, 1160, 1120, 1110, 1030, 1010, 980, 820, 800, and 680 cm^{-1}. ^1H NMR, δ: 4.24 (s, 5H, η^5-Cp), 4.28 (t, 2H, α-C_5H_4), 4.55 (t, 2H, β-C_5H_3), 7.38 (bad, 2H, *H*-3, *H*-5), 7.45 (at, 1H, *H*-4). Mass spectrum, *m/z* (rel. int. (%)): 368 (20.0), 367 (93.8), 366 (21.3), 365 (100.0), 362 (6.2), 286 (19.1), 285 (52.4), 230 (26.1), 229 (54.6), 228 (57.6), 227 (7.0), 203 (12.0), 202 (15.6), 165 (13.3), 164 (40.5). (High resolution mass spectrum was not possible since the standards used had a reference too close to *m/z* 365/7.)

2. A mixture of 2,6-dibromopyridine (200 mg, 0.84 mmol) and ferrocenylacetylene (400 mg, 1.94 mmol), bis(triphenylphosphine)palladium dichloride (30 mg, 43 μmol), and copper(I) iodide (30 mg, 157 μmol) in diethylamine (15 mL) was stirred for 24 h to give the following products after work-up and column chromatography: ferrocenylacetylene (20 mg); bis-1,4-ferrocenyl-buta-1,3-diyne (36 mg, 8.8%) (28); bis-2,6-(ethynylferrocenyl)pyridine (390 mg, 90.4%); mp: darkens between 240 and 305°C with polymerization. IR (KBr), ν_{max}: 2220, 1565, 1430, 1190, 1110, 800, and 500 cm^{-1}. ^1H NMR, δ: 4.24 (s, 10H, η^5-Cp), 4.26 (t, 4H, α-C_5H_4), 4.55 (t, 4H, β-C_5H_4), 7.36 (d, 2H, *H*-3, *H*-5′), 7.55 (t, 1H, *H*-4). Mass spectrum, *m/z* (rel. int. (%)): 496 (35.6), 495 (100.0, $M^{+\cdot}$), 493 (15.5), 429 (10.0), 374 (6.3), 316 (7.5), 315 (5.2), 309 (5.0), 253 (11.8), 247 (21.2).

Reaction of 6,6′-dibromo-2,2′-bipyridine with ferrocenylacetylene

1. A mixture of 6,6′-dibromo-2,2′-bipyridine (0.75 g, 23.8 mmol) and ferrocenylacetylene (23) (1.0 g, 4.76 mmol) was treated with bis(triphenylphosphine)palladium dichloride (50 mg, 71.3 μmol) and copper(I) iodide (50 mg, 262 μmol) for 24 h. Following work-up and column chromatography bis-1,4-ferrocenyl-buta-1,3-diyne (125 mg, 12.6%) (mp 197–198°C with polymerization. IR (KBr), ν_{max}: 3100, 2160, 1350, 1300, 1110, 1040, 1005, 910, 800 cm^{-1}. HRMS, calcd. for $C_{24}H_{18}Fe_2$: 418.1026; found: 417.9977) and bis-6,6′-(ethynylferrocene)-2,2′-bipyridine (300 mg, 0.524 mmol, 22%) were obtained. Examination of crude intermediate oily fractions of product obtained following column chromatography indicates the presence of 6-bromo-6′-(ethynylferrocene)-2′-bipyridine, parent ion at *m/z* 422/424. ^1H NMR, 300 MHz ($CDCl_3$) δ: 8.32 (d, 1H), 8.30 (d, 1H), 7.65, 7.66 (2t, 2H), 7.47, 7.48 (2d, 2H), 4.49 (t, 2H), 4.26 (s, 5H), 4.23 (t, 2H).

2. A similar reaction using ferrocenylacetylene (240 mg) and 6,6′-dibromo-2,2′-bipyridine (160 mg) with bis(triphenylphosphine)palladium dichloride (50 mg) and copper(I) iodide (30 mg) in diethylamine (20 mL) and THF (20 mL) for 48 h gave bis-6,6′-(ethynylferrocene)-2,2′-dipyridine (260 mg, 89%). Compound **3***d* is obtained as golden yellow microcrystals. It is only sparingly soluble in dichloromethane; mp darkens with polymerization between 240 and 305°C. ^1H NMR, δ: 8.40 (dd, 2H, $J_{5-4,5'-4'}$ = 1.0, $J_{5-3,5'-3'}$ = 7.9 Hz, *H*-5, *H*-5′), 7.78 (t, 2H, $J_{4-5,4-3}$, $J_{4'-5',4'-3'}$ = 7.9 Hz, *H*-4, *H*-4′), 7.49 (dd, 2H, $J_{4-5,4'-5'}$ = 1.0, $J_{3-4,3'-4'}$ = 7.8 Hz, *H*-3, *H*-3′), 4.59 (t, 4H, $J_{H\alpha\text{-}H\beta}$ = 1.8(5), *H*-α-C_5H_4), 4.28 (t, 4H, $J_{H\beta\text{-}H\alpha}$ = 1.8(5) Hz), *H*-β, C_5H_4), 4.27 (s, 10, η^5-C_5H_5). Mass spectrum, *m/e* (rel. int.): 573 (4.3), 572 (100.0, $M^{+\cdot}$), 529 (21.3), 509 (12.8), 508 (70.2), 507 (72.3), 505 (6.4), 454 (8.5), 451 (46.8), 446 (14.9), 444 (17.0), 442 (16.8), 386 (21).

The reaction of 6,6′-dibromo-2,2′-bipyridine with acetylene

The reaction of 6,6′-dibromo-2,2′-bipyridine (1.0 g, 3.2 mmol) with acetylene in the presence of a catalytic mixture of bis(triphenylphosphine)palladium dichloride (50 mg, 71.3 μmol) and copper(I) iodide (40 mg, 0.21 mmol) was carried out using the general procedure. Following the standard work-up, only small quantities of triphenylphosphine oxide and low molecular weight material, *m/z* 665, were observed. The bulk of the product was obtained as a dark brown-black polymeric material (0.64 g).

Structural determination of ***3***b

A suitable crystal of ***3****b* with approximate dimensions 0.15 × 0.15 × 0.10 mm, grown from dichloromethane and diethyl ether by the slow diffusion procedure, was mounted on a glass fibre. The data were collected using CuKα$_1$, λ = 1.54056 Å, radiation using a Picker diffractometer in a room thermostated at 24 ± 1°C. The unit cell parameters and the orientation matrix were obtained from the accurate setting of 32 reflections (100° < 2θ < 120° with CuKα$_1$ radiation). Three standard reflections were measured in every block of 100 measurements and no significant crystal decay was detected. Out of 1589 reflections measured, 1443 were considered unique, of which 886 had $I_{net} \geq 2.5\sigma(I)$. Crystal data: $C_{26}H_{16}N_2$, formula weight = 356.42; space group *A*2/*a* monoclinic[5] (centrosymmetric), *Z* = 4; $D_{calc.}$ = 1.226 g cm^{-3}; μ = 0.52 mm^{-1}; *a* = 10.0385(4), *b* = 9.2166(3), *c* = 21.4130(8) Å; β = 102.981(3)°; *V* = 1930.52(12) Å^3; *F*(000) electrons, 743.87. The polarization coefficient used was taken from ref. 29. The 2θ scan methods using the NRCVAX structure programme package (30, 31), and refined (non-hydrogen atoms anisotropic, hydrogen atom isotropic) using full matrix least squares with minimization of $\Sigma w(|F_o| - |F_c|)^2$ (unit weights). Hydrogen atoms were located in the difference map. The last cycle was calculated with 22 atoms, 160 parameters, and 886 out of the 1443 reflections.

[5]General positions in space group *A*2/*a*: *x*, *y*, *z*; ½ − *x*, *y*, −*z*; *x*, *y* + ½, *z* + ½; ½ − *x*, *y* + ½, ½ − *z*; −*x*, −*y*, −*z*; *x* − ½, −*y*, *z*; −*x*, −*y* − ½, −*z* − ½; *x* − ½, −*y* − ½, *z* − ½.

The esd's refer to the last digit printed.
B_{eq} is the average of the three principal values of the thermal ellipsoid.

The maximum shift/σ ratio was 0.002. Complex neutral scattering factors were taken from ref. 32. The largest peak in the final difference Fourier synthesis map was located 1.697 Å from H9. No absorption correction was made. The R value ($R = \Sigma||F_o| - |F_c||/\Sigma F_o$) for observed reflections was 0.045; Rw = 0.043 ($Rw = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w F_o^2]^{1/2}$), S = 1.22 ($S = [\Sigma(w(|F_o| - |F_c|)^2/$(no. of reflections − no. of parameters)]$^{1/2}$) and for all reflections R_f was 0.078 and Rw was 0.061. The deepest hole in the final difference Fourier synthesis was −0.102 e Å^{-3} and the highest peak was 0.110 e Å^{-3}. Data for bonds and angles are listed in Table 1 and positional parameters in Table 2. A PLUTO[6] plot of **3*b*** is shown in Fig. 1 and a packing diagram obtained from using NRCVAX PACKER programme is shown in Fig. 2. Anisotropic thermal parameters and final structure factor tables are available as supplementary material.[7]

Results and discussion

There has been much interest in 2,2′-bipyridine and 1,10-phenanthroline based ligands in view of the success in utilization of their complexes in a variety of processes ranging from the reported chemotherapeutic nature of, for example, derivatives of bis-(2,2′-bipyridyl)platinum and -palladium halides (33, 34), through the use of $[Ru(dipy)_3]^{2+}$ as a photosensitizer in the water splitting reaction (35), to the elegant work of Barton's group in the use of ruthenium complexes of modified phenanthrolyl ligands in site-specific DNA cleavage (36–38). Our own interest lies essentially in several areas, namely the preparation of conducting polymers with the ability to coordinate transition metals, and the possible modification of ligands to incorporate an electric field gradient within the molecules, thereby separating reduction and oxidation sites in photo-induced processes.

Our initial work in the dipyridyl system was to synthesize 6,6′-ethynyl-2,2′-bipyridine. This was achieved by the relatively simple modification of the chemistry described for the related pyridyl systems described by Ames *et al.* (20). The route

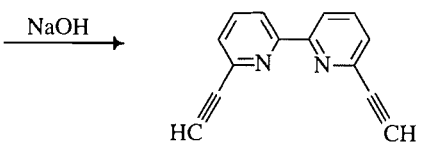
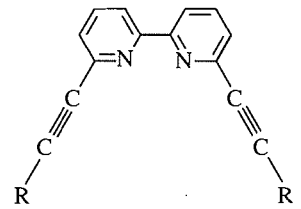
[a]The second half of the molecule is related by the twofold axis with equation ($\frac{3}{4}$, *y*, 1) through the middle of the C(1)—C(1a) bond. The coordinate transformation to obtain the second half is $\frac{1}{2} - x, y, 2 - z$.



chosen is to couple 2-methylbut-3-yne-2-ol with 6,6′-dibromo-2,2′-bipyridine (25, 39), which in turn is readily available from 2,6-dibromopyridine using a methodology devised by Holm *et al.* (25). The protecting group is removed by treatment of the intermediate diol **2** with sodium hydroxide. In contrast to

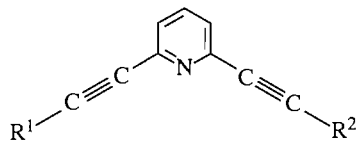
1



2

3*a*

the liquid 2-ethynylpyridine, which rapidly discolours in air and light in absence of added stabilizers, **3***a* is obtained as a colourless solid, which we have been able to store for periods longer than 2 years without apparent decomposition, although it does polymerize slowly in solution.



Using a similar strategy, we have been able to prepare a range of related compounds **3***b–e* from **1**. In the case of the ferrocenyl reactions, preliminary test reactions were carried out using 2,6-dibromopyridine. It was found that after 1 h at room

3

3*a*, R = H
3*b*, R = Ph
3*c*, R = 1-naphthyl
3*d*, R = ferrocenyl
3*e*, R = 2-pyridyl

temperature in the presence of approximately 5 mol% (with respect to 2,6-dibromopyridine) of catalyst the monobromo compound **4***d* could be isolated in high yield, while longer reaction times (24 h) gave the disubstituted compound **5***d*. The

4*d*, R^1 = Br, R^2 = -ferrocenyl
5*d*, $R^1 = R^2$ = -ferrocenyl

reactions were carried out at room temperature in diethylamine. In addition to the aforementioned reaction products, a considerable quantity of 1,4-ferrocenyl-but-1,4-diyne (28) is also obtained. Formation of the analogous intermediate monobromo compound is also observed in the reaction of 6,6′-dibromobipyridine, using short reaction times with ferrocenylacetylene, as well as considerable quantities of the diyne. The desired product **3***d* is obtained in high yield, on longer reaction times (24 h). Addition of THF to the amine solvent was found to be useful in increasing the solubility of the dibromo starting material and hence reaction rates. Compound **3***d* is formed as

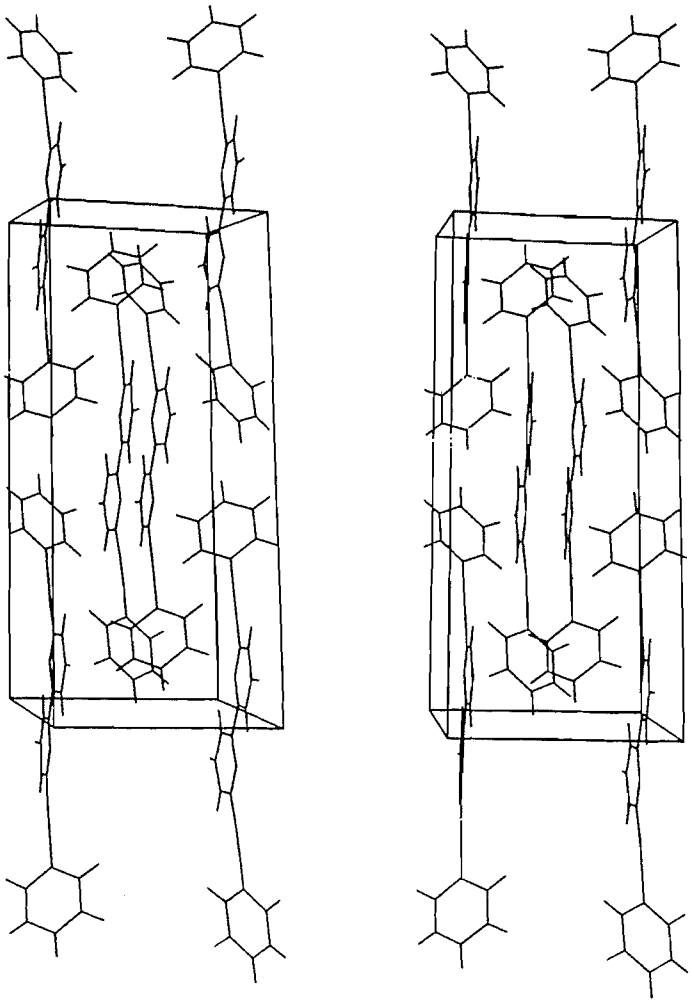


FIG. 2. A stereoscopic view packing diagram, produced using the PACKER programme in the NRCVAX package, showing the molecular packing of compound **3***b* in the unit cell. The *b* axis extends from the left to right and the *c* axis is vertical.

golden orange flakes and is, surprisingly, only sparingly soluble in dichloromethane. Initial attempts to react this compound with (1,5-cyclooctadienyl)palladium dichloride gave a powder from which we were unable to crystallize a single uncontaminated complex.

The ^{1}H NMR spectra for compounds **3***a–e* indicate little influence on the chemical shifts of the bipyridyl protons on changing substituents on the acetylene. The observed chemical shifts of the 3 and 3′ protons adjacent to the acetylene occur at approximately δ 7.5, while the 4 (4′) and 5 (5′) are observed at δ ~7.8 and 8.4 respectively.

The pyridyl rings in compound **3***b* are found with the nitrogen atoms on opposite sides, as expected, to minimize stereoelectronic interactions. The dihedral angle between the phenyl and pyridyl ring planes is 59.85(16)°. In Fig. 2, a packing diagram is shown, to illustrate the parallel packing of the molecules. The C—C triple bond length is 1.189(5) Å and is similar to that of other acetylenes. The closest contact carbon–carbon distance between the layers is approximately 3.6 Å. Compound **3***b*, if it were to serve as a useful ligand in transition metal chemistry, would be significantly hindered to chelated nitrogen coordination due to the pendant acetylenic group. Preliminary investigations indicate that the compound is capable of complex formation; however, there are indications that coordination of large transition metal ions is difficult. Our work in this area is continuing and we have been able to develop methods for the synthesis of novel polymeric compounds based on these monomers. The synthesis of bipyridylacetylene-coupled compounds of 2,2′-bipyridine is more complex and will be published separately.

Acknowledgements

This work was funded in part by a grant from the University of Ottawa faculty development fund, which is gratefully acknowledged. The palladium was supplied on loan from Johnston–Matthey Ltd. This work was made possible by the kind consideration of Professor Peter Morand of the University of Ottawa with whom C.S.-B. has completed her M.Sc. programme. We extend our thanks for the provision of his laboratory facilities to us to complete this work. I.R.B. thanks Dr. Eric Gabe and Yvon LePage of the National Research Council of Canada for their patience and guidance in the crystallographic structural determination and provision of facilities. Finally, we appreciate the extra funding from O.A.P., which was necessary to complete the project.

Catalysis by β-cyclodextrin in the reaction of *p*-nitrophenyl acetate with α-amino acids

MÓNICA BARRA AND RITA H. DE ROSSI[1]

Instituto de Investigaciones en Físico Química de Córdoba (INFIQC), Departamento de Químicas, Universidad Nacional de Córdoba, Suc. 16, C.C. 61, 5016 Córdoba, Argentina

Received May 4, 1990

MÓNICA BARRA and RITA H. DE ROSSI. Can. J. Chem. **69**, 1124 (1991).

The reactions of *p*-nitrophenyl acetate, **1**, with both enantiomers of the following α-amino acids: alanine (**2***a*), methionine (**2***b*), leucine (**2***c*), and tryptophan (**2***d*), were studied in the presence of β-cyclodextrin (β-CD). All the reactions were catalyzed by β-CD and no chiral discrimination was observed. The reactions of **1** with the D isomers of **2***a* and **2***d* were also studied in the presence of α- and γ-CD. In both cases the catalysis increased in the order α < γ < β-CD. Also, to analyze the influence of the polar nature of the nucleophile, the reactions of **1** with both enantiomers of the methyl esters of **2***a*, **2***c*, and **2***d* were studied in the presence of β-CD. The catalysis observed was significantly smaller than that for the reactions with the amino acids. It is suggested that the catalysis by CDs is due to the formation of a ternary hydrogen-bonding complex that results from the association of the amino acid with the complexed substrate. The effect of the size of the CD cavity on the observed catalysis is attributed to the geometrical requirements for the reaction. The decrease in catalysis in the reactions with the methyl esters is due to a weaker hydrogen-bonding association with these neutral nucleophiles.

Key words: cyclodextrins, catalysis, ester aminolysis.

MÓNICA BARRA et RITA H. DE ROSSI. Can. J. Chem. **69**, 1124 (1991).

On a étudié les réactions de l'acétate de *p*-nitrophényle, **1**, avec les deux énantiomères de acides α-aminés suivants : alanine, **2***a*, méthionine, **2***b*, leucine, **2***c*, et tryptophane, **2***d*, en présence de β-cyclodextrine (β-CD). Toutes les réactions sont catalysées par la β-CD et on n'a observé aucune discrimination chirale. On a aussi étudié les réactions du composé **1** avec les isomères D des produits **2***a* et **2***d*, en présence des α- et des γ-cyclodextrines. De plus, afin d'analyser l'influence de la nature polaire du nucléophile, on a étudié les réactions du composé **1** avec les deux énantiomères des esters méthyliques des composés **2***a*, **2***c* et **2***d*, en présence de β-CD. La catalyse observée est beaucoup plus faible que celle pour les réactions avec les acides aminés. On suggère que la catalyse par les CD est due à la formation d'une liaison hydrogène ternaire complexe résultant de l'association de l'acide aminé avec le substrat complexé. L'effet de la grosseur de la cavité de la CD sur la catalyse observée est attribué à des impératifs géométriques de la réaction. La diminution de la catalyse avec les esters méthyliques est due au fait que la liaison hydrogène avec les nucléophiles neutre est plus faible.

Mots clés : cyclodextrines, catalyse, aminolyse des esters.

[Traduit par la rédaction]

Introduction

Cyclodextrins (CDs) are cyclic oligomers of six to eight glucose units capable of forming inclusion complexes with a great variety of guest compounds (for recent reviews, see ref. 1). As a result, CDs exhibit catalytic properties in various reactions. However, it was recently shown that these catalytic properties may be due not only to the formation of an inclusion complex but also to the formation of a hydrogen-bonding complex (2). The effective formation of the latter results from the large proton-donating ability of the secondary hydroxyl groups located outside the cavity of CDs.

CDs are also capable of chiral recognition, a property that has been shown to have a marked interest in fundamental (3) as well as in applied studies (4). In this regard, we recently reported that the reactions of 1-fluoro-2,4-dinitrobenzene with both enantiomers of natural α-amino acids are selectively catalyzed by β-cyclodextrin (β-CD), the member containing seven glucose units (5). The catalysis and chiral discrimination are ascribed to the formation of a ternary inclusion complex where both reactants are included in the same cavity of β-CD. This study led us to continue analyzing the catalytic properties and potential chiral recognition by β-CD in nucleophilic substitution reactions with α-amino acids as nucleophiles. We wish to report here our results regarding the reaction of *p*-nitrophenyl acetate, **1**, with α-amino acids in the presence of β-CD.

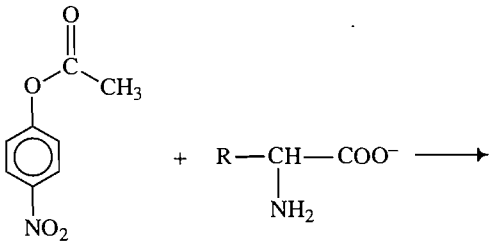
[1]Author to whom correspondence may be addressed.

Results

The reaction of **1** with α-amino acids **2** leads to the formation of *p*-nitrophenol and the corresponding *N*-acetyl-α-amino acids (eq. [1]). Depending on pH, the hydrolysis reaction of **1** competes with eq. [1].[2]

The aminolysis of esters proceeds through a bimolecular mechanism that involves the formation and decomposition of a tetrahedral addition intermediate, **3** (eq. [2]) (7). The decomposition of **3** is characterized by several proton transfers and therefore the aminolysis reaction may be suceptible to acid–base catalysis (8).

To determine the rate-limiting step corresponding to the reaction described in eq. [1], pseudo-first-order rate constants (k_{obs}) for the reaction of **1** with the L isomers of **2** were obtained as a function of amino acid concentration at constant pH (see Table I).[3] In all cases the plots of k_{obs} vs. the total concentration of **2** ($[\mathbf{2}]_T$) were linear, showing that the amino acids did not act as



[2]The amino acid is assumed to react only through the nitrogen and not through the carboxylate because it is known that amines are about 10^5 times more reactive than carboxylates, see ref. 6.

[3]Supplementary material: Table I containing the observed pseudo-first-order rate constants for the reaction of **1** with **2** (2 pages), Table II containing rate constants for the reaction of **1** with **4** at varying concentrations of β-CD (2 pages). catalysts. From the slopes of these plots and the fraction of the anionic form of the corresponding amino acid (nucleophilic species), the second-order rate constant of aminolysis k_A was calculated (Table 1). The values thus obtained decrease as the pK_a value decreases, consistent with the fact that the reactivity of **2** depends mainly on pK_a (9). Besides, the k_A values are independent of pH, indicating that HO^- is not a catalyst. The fact that the second-order rate constant of aminolysis does not depend on either the HO^- or the amino acid concentration indicates that the rate-limiting step for the reaction of **1** and **2** is the addition of the amino acid to generate the tetrahedral intermediate **3** (7).

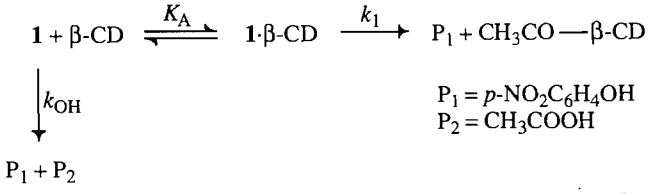
3

Effect of β-cyclodextrin



The reaction of **1** with **2** competes, under our experimental conditions (DMSO–water, 2% v/v; pH = 9.878; T = 25°C), with the hydrolysis reaction of **1**. Since it has been shown that the latter reaction is catalyzed by cyclodextrins through a covalent mechanism that involves the nucleophilic attack by one of the HO^- groups of the cyclodextrins on the substrate (10), it was necessary to determine first the kinetic parameters for the hydrolysis of **1** in the presence of β-CD. According to literature data the reaction pathways for this system can be represented as shown in Scheme 1, where **1**·β-CD represents the inclusion complex of **1** with β-CD, K_A represents the association equilibrium constant for this complex, and k_{OH} and k_1 represent the pseudo-first-order rate constants for the hydrolysis of the free substrate and for the release of *p*-nitrophenol by acetylation of β-CD, respectively.

The expression of the pseudo-first-order rate constant (k_{OH}^{CD})

SCHEME 1

for this scheme is given by eq. [3]:

$$[3]\quad k_{OH}^{CD} = \frac{(k_1 - k_{OH})K_A[\beta\text{-CD}]}{1 + K_A[\beta\text{-CD}]} + k_{OH}$$

Under our experimental conditions, k_{OH} was independently determined in the absence of β-CD whereas k_1 and K_A were calculated by nonlinear adjustment of eq. [3] for k_{OH}^{CD} values obtained at constant pH and varying β-CD concentrations (Table 2). The parameters thus obtained were $k_1 = (1.1 \pm 0.2) \times 10^{-2} s^{-1}$ and $K_A = (67 \pm 22)\ M^{-1}$.

This value of K_A is somewhat lower than that already reported, namely 164 ± 35 M^{-1} (10). To see whether this discrepancy is due to the different reaction conditions, we determined the kinetic parameters under the same conditions as those of the previous work, obtaining $K_A = 79 \pm 12\ M^{-1}$.

To investigate the effect of β-CD on the reaction described in eq. [1], pseudo-first-order rate constants (k_{obs}^{CD}) for the reaction of **1** with the D and L isomers of **2** were determined as a function of β-CD concentration ($[\beta\text{-CD}]_T$), at constant amino acid concentration and at constant pH (Table 3). In all cases, k_{obs}^{CD} increased as $[\beta\text{-CD}]_T$ increased, approaching a maximum saturation value similar to the behavior observed in enzyme kinetics (Fig. 1 is representative). These enzyme-like kinetics are also observed when the pseudo-first-order rate constants for the aminolysis reactions (obtained from the difference between k_{obs}^{CD} and the corresponding k_{OH}^{CD} are plotted vs. $[\beta\text{-CD}]_T$.

We also measured the reaction rate of **1** with the L-alanine **2***a* as a function of soluble starch (a linear analog of cyclodextrins) at constant pH and constant amino acid concentration (Table 3). The observed rate constant in the presence of 2×10^{-3} M starch is about 20% lower than in water at the same pH. These results indicate that the effect of β-CD on eq. [1] involves some specific type of interaction.

The reactions with the L isomers of alanine **2***a* and leucine **2***c* were also studied as a function of amino acid concentration, at

[c]Solvent acetonitrile–water (0.5% v/v), pH = 10.600, Na_2CO_3 buffer.

constant pH and constant β-CD concentration (Table 3). In both cases the plots of k_{obs}^{CD} vs. $[\mathbf{2}]_T$ are linear, indicating that the presence of β-CD does not induce a change in the rate-limiting step.

To analyze the effect of the size of the cyclodextrin, the reactions of **1** with the D isomers of alanine **2***a* and tryptophan **2***d* were studied as a function of α- (the member with six glucose units) and γ-cyclodextrin (the member with eight glucose units) concentrations (Table 4). In all cases k_{obs} increases linearly as CD concentration increases.

On the other hand, and in order to investigate the influence of the polar nature of the nucleophile on the aminolysis reaction of **1** in the presence of β-CD, we measured the rate of reaction of **1** with the D and L isomers of the methyl esters **4** of alanine, leucine, and tryptophan at pH ≈ 8.3. In the absence of β-CD, the pseudo-first-order rate constant for aminolysis k_A increases linearly with the concentration of ester (Table 5). The reactivity of these nucleophiles (Table 1) is lower than that corresponding to the α-amino acids (Table 2), in agreement with the fact that the proton ionization constants of the methyl esters are smaller than those of the α-amino acids (11). In the presence of β-CD the second-order rate constant of aminolysis shows enzyme-like kinetics as a function of $[\beta\text{-CD}]_T$ (Table II).[3] The catalysis observed is, however, significantly smaller than that for the reaction with **2**. For instance, the rate of aminolysis of **1** is increased by a factor of 7 in the presence of 15 mM β-CD when D-alanine is the nucleophile, and only by a factor of 1.5 when D-alanine methyl ester is the nucleophile.

Discussion

α-Amino acids are capable of forming 1:1 inclusion complexes with cyclodextrins (12) and, therefore, the catalysis observed in the reaction of **1** and **2** in the presence of β-cyclodextrin might involve the complexed amino acids. However, the association equilibrium constants for 1:1 inclusion complexes between β-CD and **2** are smaller than 10 M^{-1} in water (5), and therefore the amount of complexed amino acids will be less than 10% at the highest β-CD concentration used. Under these conditions, the catalytic pathway involving the reaction of **1** with **2**:CD complex would be observed only if it were very efficient.

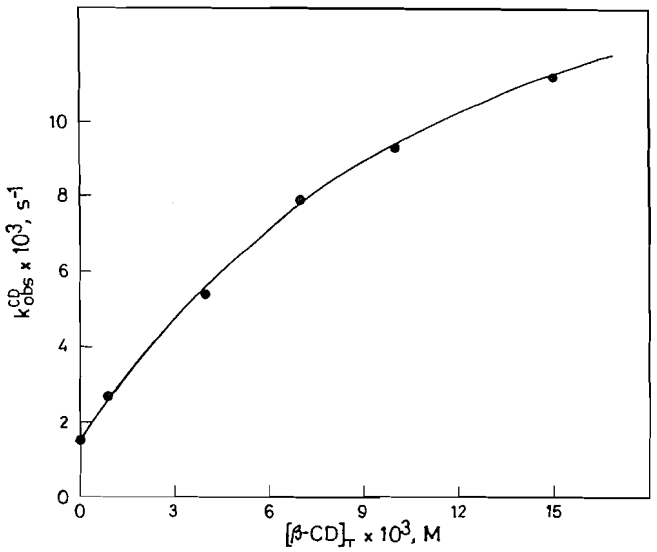

FIG. 1. k_{obs} vs. β-cyclodextrin concentration for the reaction of **1** with L-alanine (data from Table 3).

α-Amino acids are also capable of forming ternary inclusion complexes in which both reactants are included in the same cavity (5), and hence the catalysis might involve a complex of this type. However, since no significant dependence on the size of amino acid or on stereoisomerism has been observed, it is unlikely that the catalytic pathway involves a ternary complex where **1** and **2** are included in the CD cavity.

As we have mentioned previously, it has been shown that the cavity of cyclodextrins is not essential for complex formation and as a consequence, for catalysis (2). The P—O(2′) cleavage of 2′,3′-cyclic monophosphates of ribonucleosides is regioselectively catalyzed by α-cyclodextrin and the catalysis is ascribed to the formation of hydrogen-bonding complexes between α-CD and the ribonucleosides. The effective formation of this type of complex results from the large proton-donating ability of the secondary hydroxyl groups of cyclodextrins (2). Besides, it has also been observed that the hydrogen-bonding association of alcohol molecules with 1:1 inclusion complexes provides additional rigidity to the system, which has been shown to have a marked effect on the properties of the included molecule (13). Thus, the catalysis observed in the reaction of **1** with **2** in the presence of β-CD may be ascribed to the formation of a ternary hydrogen-bonding complex generated by the association between the α-amino acid and the inclusion complex **1**·β-CD as shown in Fig. 2. This association leads to an increase in the residence time of the nucleophile close to the reacting center of the electrophile, which results in a greater effect on rate (14).

We therefore suggest that the overall mechanism for the reaction of **1** with **2** in the presence of β-CD can be described as shown in Scheme 2, where T represents the ternary hydrogen-bonding complex, K_T represents the equilibrium association constant for this complex, and k_2 represents the first-order rate constant for the aminolysis reaction within the ternary complex.

The expression of k_{obs}^{CD} for this scheme is given by eq. [4]:

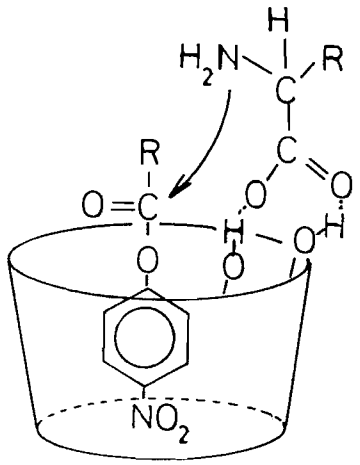
[b]Soluble starch instead of β-cyclodextrin is added; the concentration was calculated assuming FW = 1135.



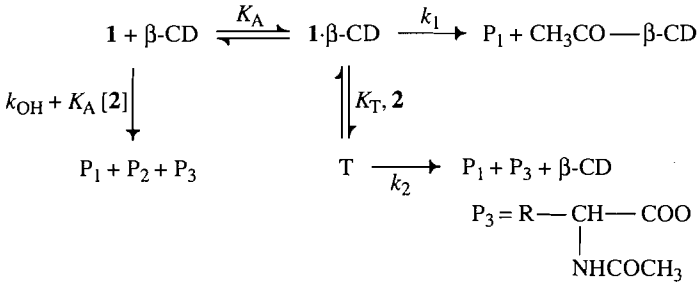


FIG. 2. Schematic representation of the ternary complex of cyclodextrin, *p*-nitrophenyl acetate, and an amino acid.

SCHEME 2

$$[4]\quad k_{obs}^{CD} = k_o + \frac{\{k_1 + k_2 K_T[\mathbf{2}] - k_o(1 + K_T[\mathbf{2}])\} K_A[\beta\text{-CD}]}{1 + K_A(1 + K_T[\mathbf{2}])[\beta\text{-CD}]}$$

$$k_o = k_{OH} + k_A[\mathbf{2}]$$

By nonlinear adjustment of eq. [4] for k_{obs}^{CD} values obtained at constant amino acid concentration and varying concentrations of β-CD, the parameters $P(1) = \{k_1 + k_2 K_T[\mathbf{2}] - k_o(1 + K_T[\mathbf{2}])\}K_A$ and $P(2) = K_A(1 + K_T[\mathbf{2}])$ were calculated (Table 6). The value of $P(2)$ is almost the same for all the amino acids and equal to K_A, indicating that $K_T[\mathbf{2}] << 1$ and therefore $K_T < 100\ M^{-1}$. Also, $P(1)$ does not depend on the stereoisomer.

The expression of k_{obs}^{CD} (eq. [4]) can be simplified to eq. [5]:

$$[5] \quad k_{obs}^{CD} = k_o + \frac{(k_1 + k_2 K_T [\mathbf{2}] - k_o) K_A [\beta\text{-CD}]}{1 + K_A [\beta\text{-CD}]}$$

Since k_1 and k_0 are known, it was possible to calculate the product k_2K_T from the $P(1)$ values (Table 6). The values of k_2K_T represent the rate constant for the reaction of the complex **1**·CD with **2**. Comparing these values with the second-order rate constants for **1** and **2** (Table 2), we conclude that the complex is 20–30 times more reactive than the free substrate.

For the reactions of **1** with **2***a* and **2***d* in the presence of α- and γ-cyclodextrins, the plots of k_{obs}^{CD} vs. $[CD]_T$ are linear, indicating that in both cases $K_A[CD] << 1$ and therefore $K_A < 7$ M^{-1}. These results are consistent with the fact that the structure, stability, and reactivity of cyclodextrin complexes depend on the size of the CD cavity (1). The catalytic factor, defined as $C = (k_1 + k_2 K_T [\mathbf{2}] - k_0) K_A$, is shown in Table 7 as a function of the type of cyclodextrin. With both amino acids, C increases in the order α < γ < β and, except with γ-CD, there is no dependence on the type of amino acid. The change in the catalytic factor cannot be attributed to changes either in K_A or in the catalysis for the hydrolysis reaction (k_1), since in such a case a difference of only a factor of three would be expected for α- and β-CD (10). The dependence of the catalytic factor on the size of the CD cavity would reveal a change in the geometry of the complex and hence must be determined by the geometrical requirements to reach the most appropriate distances for reaction. On the other hand, the higher catalysis observed in the reactions with **2***d* in the presence of γ-CD might be due to the contribution of other pathways such as the formation of a tight ternary inclusion complex, which would result in a greater effect on rate.

The effective formation of the hydrogen-bonding ternary complex, and therefore the catalysis, should be reduced if the hydrogen association is prevented. The catalysis observed in the reactions with the methyl esters of alanine, leucine, and tryptophan is significantly smaller than that for the reactions with **2**, and this result is interpreted as a consequence of a weaker association with these neutral nucleophiles. According to Scheme 2, the second-order rate constant for aminolysis (k_A) is given by eq. [6]:

[b]Hydrophobicity value (see ref. 15).

$$[6] \quad k_A^{CD} = \frac{(k_2 K_T - k_A) K_A [\beta\text{-CD}]}{1 + K_A [\beta\text{-CD}]} + k_A$$

Since k_A and K_A are known, we could calculate the product $k_2 K_T$ by nonlinear adjustment of eq. [4] for k_A^{CD} values obtained at varying concentrations of β-CD. The resulting data are shown in Table 8 together with the hydrophobicity values (f) for the corresponding α-amino acids (15). Comparing these values, we can see that the catalysis decreases as the pK_a decreases and f increases. The decrease in catalysis as measured by $k_2 K_T$ is higher than that expected from the decrease in the reactivity of the nucleophiles and it is also higher than the decrease observed in $k_2 K_T$ for reactions with **2** (compare the last columns of Tables 6 and 8). This result is ascribed to an increase in the influence of the hydrophobic substituent in the nucleophile on the properties of the ternary hydrogen-bonding complex.

Conclusions

We found that the reactions of *p*-nitrophenyl acetate **1** with α-amino acids **2** are catalyzed by β-CD. The catalysis is attributed to the formation of a hydrogen-bonding complex, which results from the association between the amino acid and the complexed substrate. The effective formation of this type of ternary complex is based on the ability of the nucleophile to form hydrogen bonds with the hydroxyl groups of CDs. This association results in an increase in the rate of reaction of **1** with **2** by about 20–30 times when the substrate is bound to β-CD. The decrease in catalysis observed in the reactions with methyl esters and hence the increase in the influence of the hydrophobic substituent in the nucleophile would be consistent with this mechanism. On the other hand, the dependence of the catalytic factor for the reaction of **1** and **2** upon the size of the CD cavity would be determined by the geometrical requirements for the reaction, this being a characteristic of noncovalent catalysis (1).

Experimental section

Aqueous solutions were made up from water purified in a Millipore apparatus. DMSO was distilled under vacuum and stored over molecular sieves (4 Å).

α-Cyclodextrin (Aldrich), β-cyclodextrin, γ-cyclodextrin, α-amino acids, D- and L-α-tryptophan methyl ester hydrochlorides, and soluble starch (Sigma) were used as received.

p-Nitrophenyl acetate was prepared by the reaction of *p*-nitrophenol (2 mmol) with acetic anhydride (2.5 mmol) in dry pyridine at room temperature. The mixture was stirred for 1 h in the dark, and the product was precipitated by the addition of cold water. The solid was filtered out, washed with aqueous bicarbonate, water, and ethanol, and then dried under vacuum, mp 77–78°C (lit. (16) mp 79–80°C).

Alanine and leucine methyl ester hydrochlorides were prepared by esterification of the corresponding α-amino acid with $SOCl_2$ in dry methanol. The mixture was stirred for 1 h at 0°C and then heated for 2 h at 40°C. After cooling, the solvent was removed under reduced pressure and the product was dried under vacuum. The melting points were in good agreement with the literature data: alanine, mp 110–111°C (lit. (17) mp 109–111°C); leucine, mp 151–152°C (lit. (18) mp 150–151°C).

Kinetic procedures

Reactions with α-amino acids were initiated by adding the substrate dissolved in DMSO to a solution containing all the other constituents, whereas the reactions with α-amino acid methyl esters were initiated by adding 1 N NaOH (in the amount necessary to reach the pH desired) to the solutions containing the substrate and all the other constituents in order to avoid the basic hydrolysis of the nucleophile. The total DMSO concentration was 2%.

All the reactions were run under pseudo-first-order conditions, at 25°C and at constant ionic strength using NaCl as compensating electrolyte. The observed rate constants were determined by following the appearance of *p*-nitrophenoxide ion at 400 nm. The change in absorbance during a kinetic run was recorded on a Beckman 24 spectrophotometer or on a Shimadzu 260 recording spectrophotometer, both with a thermostated cell compartment. The reactions with α-amino acids were followed up to 80–90% conversion, whereas the reactions with methyl esters were followed up to 50% conversion. We did not detect any deviation from the pseudo-first-order behavior in these conditions.

The pH of the solutions containing varying concentrations of cyclodextrin and constant concentrations of α-amino acid was adjusted to the pH of the solution without CD by adding a drop of dilute acid or base. The buffer was the same amino acid. The rate of hydrolysis of **1** at different β-CD concentrations was measured without buffer (Table 2, runs 1–6), with Na_2CO_3 buffer at pH 10.600, and with 0.5% acetonitrile (Table 2, runs 7–16), with latter being the conditions used in a reported work (10). To avoid the basic hydrolysis of α-amino acid methyl esters, the pH of these solutions was measured just at the beginning of each kinetic run and therefore was not adjusted. Thus it was necessary to determine the second-order rate constants for these reactions. Since the rate of acylation of CDs shows a first-order dependence on hydroxide ion below pH 11 (19), we used the observed rate constants for hydrolysis measured at pH 9.878 in the presence of β-CD (k_{OH}^{CD}) to calculate the second-order rate constant of aminolysis (k_A^{CD}) as follows:

$$[7] \quad k_A^{CD} = (k_{obs}^{CD} - k_{OH}^{CD}\, 10^{-9.878}/10^{-pH_{obs}})/[\mathbf{4}]$$

where k_{obs}^{CD} represents the observed pseudo-first-order rate constant, pH_{obs} represents the measured pH, and [**4**] represents the concentration of α-amino acid methyl ester in the neutral form, estimated by using the acid–base dissociation constant in water (11).

DETLEF REHOREK, EDWARD G. JANZEN, and YASHIGE KOTAKE. Can. J. Chem. **69**, 1131 (1991).

Chlorine atoms generated by photolysis of hexachloroethane add to *C*-phenyl-*N*-*tert*-butyl nitrone (PBN) to form persistent spin adducts that are readily detectable by EPR spectroscopy. The presence of chloride ions reduces spin adduct formation competitively. Chlorine atoms also react with tetraphenylarsenium ions to liberate phenyl radicals by radical replacement.

Key words: EPR, spin trapping, *C*-phenyl-*N*-*tert*-butyl nitrone, PBN, photolysis, chlorine atoms, tetraphenylarsenium ion, hexachloroethane.

DETLEF REHOREK, EDWARD G. JANZEN et YASHIGE KOTAKE. Can. J. Chem. **69**, 1131 (1991).

Les atomes de chlore générés par photoluse de l'hexachloroéthane s'additionnent à la *C*-phényl-*N*-*tetr*-butyl nitrone (PEN) pour former des adduits de spin persistants que l'on peut facilement détecter par RPE. Par compétition, la présence des ions chlorures réduit la formation d'adduits de spin. Les atomes de chlore réagissent aussi avec les ions tétraphénylarsénium avec libération de radicaux phényles par remplacement de radical.

Mots clés: RPE, piégeage de spin, *C*-phényl-*N*-*tert*-butyl nitrone, PBN, photolyse, atomes de chlore, ion tétraphénylarsénium, hexachloroéthane.

[Traduit par la rédaction]

Introduction

Due to non-zero orbital angular momentum, chlorine atoms are not detectable directly by EPR in liquid solutions. However, it has been shown (1) that chlorine atoms form persistent spin adducts with *C*-phenyl-*N*-*tert*-butyl nitrone (PBN) detectable by EPR spectroscopy even at ambient temperatures. Thus, formation of chlorine atoms by photoinduced cleavage of C—Cl bonds (2–4), photooxidation of a coordinated chloro ligand in metal complexes (5, 6), and electrochemical oxidation of chloride ions (2, 7) has been demonstrated by EPR spin trapping experiments in nonaqueous solutions. It is well known from flash-photolysis experiments in aqueous solutions that chlorine atoms react with chloride ions very rapidly to form $Cl_2^{\cdot-}$ radicals, eq. [1], with $k_1 = 2.1 \times 10^{10}$ L mol^{-1} s^{-1} and $k_{-1} = 1.1 \times 10^5$ s^{-1}, respectively.

$$[1] \qquad {}^{\cdot}Cl + Cl^- \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Cl_2^{\cdot-}$$

A similar behavior has been reported for other halogen atoms and pseudohalide radicals (8). However, so far this reaction has been documented by spin trapping experiments only for thiocyanatyl radicals, $\cdot SCN$ and $(SCN)_2^{\cdot-}$, which both form persistent spin adducts with nitrones (9). Here we wish to report on studies that elucidate the influence of chloride ions on spin trapping of chlorine atoms by PBN in acetonitrile solution.

Experimental

Chlorine atoms were generated by photolysis ($\lambda \geq 310$ nm) of hexachloroethane in acetonitrile. A 75-W Oriel high-pressure mercury lamp mounted on an optical bench and equipped with a Pyrex filter was used as the irradiation source. The samples were photolyzed directly in the cavity of the EPR spectrometer (Bruker model 200 D-SRC) using a quartz flat cell attached to an H-shaped mixing cell (10). A small sample of diphenylpicryl hydrazyl (DPPH) embedded in strips of scotch tape and attached to the back side of the flat cell was used as standard for quantitative measurement. All samples were purged with purified argon for 30 min prior to photolysis. While the concentrations of hexachloroethane (0.1 M) and spin trap (0.01 M) were kept constant, various amounts of either tetraphenylphosphonium chloride ($PPh_4^+Cl^-$) or tetraphenylarsenium chloride ($AsPh_4^+Cl^-$) were added. All chemicals were commercially available (Aldrich, Baker) at high purity. $PPh_4^+Cl^-$ and $AsPh_4^+Cl^-$ were dried by storing at 100°C for at least 2 h prior to use. Acetonitrile was freshly distilled and purified by passing through a column with activated alumina. 2,3,5,6-Tetramethylnitrosobenzene (nitrosodurene) was synthesized according to the literature (11). PBN is commercially available (Aldrich, Sigma). All experiments were carried out at 295 K.

Results and discussion

Homolytic cleavage of the carbon–chlorine bond is accomplished when hexachloroethane is photolyzed with UV light, eq. [2]. Moreover, it is known (12) that haloethyl radicals undergo further decomposition to give ethylene and a second halogen atom.

$$[2] \qquad C_2Cl_6 \xrightarrow{h\nu} \cdot C_2Cl_5 + \cdot Cl$$

$$[3] \qquad \cdot C_2Cl_5 \rightarrow C_2Cl_4 + \cdot Cl$$

Spin adducts of chlorine atoms were the only persistent radicals detected during photolysis of hexachloroethane. The hyperfine splitting constants of this spin adduct ($a_N = 1.233 \pm 0.005$ mT,

$$[4] \qquad C_6H_5CH{=}N(O)C_4H_9 + Cl\cdot \rightarrow C_6H_5CH(Cl)N(O\cdot)C_4H_9$$

$a_H = 0.083 \pm 0.005$ mT, $a_{35\text{-}Cl} = 0.620 \pm 0.005$ mT, $a_{37\text{-}Cl} = 0.512 \pm 0.005$ mT) are in agreement with the data reported in the literature (2–7). Since no spin adducts of $\cdot C_2Cl_5$ radicals were detectable, decomposition according to eq. [3] is assumed

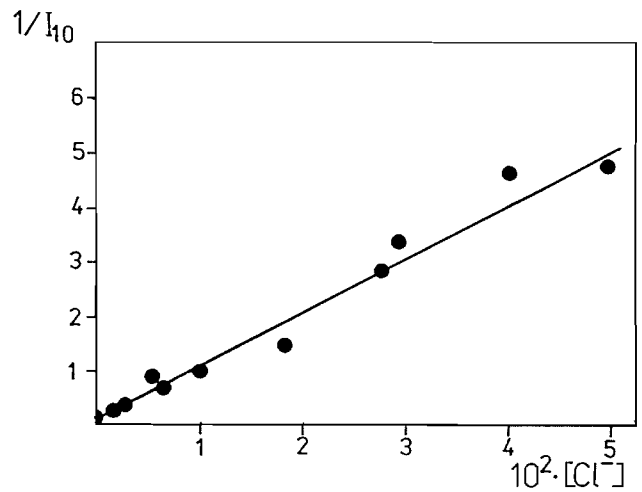

FIG. 1. Reciprocal of EPR intensity of Cl· adduct of PBN after 10 s ($1/I_{10}$) plotted against [$PPh_4^+Cl^-$].

to be fast as compared with additon to the spin trap. After prolonged photolysis, the EPR signal of the benzoyl *tert*-butyl aminoxyl radical (a_N = 0.808 ± 0.005 mT), whch is a known decomposition product of PBN, was also detected.

$C_6H_5C(O)N(O\cdot)C_4H_9$

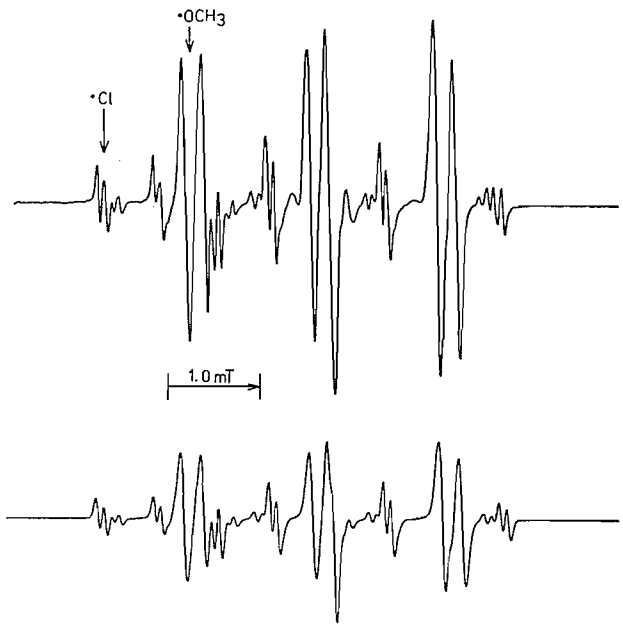
For a time interval of less than 60 s, the intensity of the EPR signal was linearly dependent on the irradiation time. For given concentrations of spin trap and hexachloroethane and constant irradiation time, the reproductibility of the EPR signal intensity was about ±20%. Deviations are probably due to fluctuations in the intensity of absorbed light mainly caused by slightly different positions of light. Upon addition of $PPh^{4+}Cl^-$, a decrease of chlorine atom spin adduct signal intensity was observed. The plot of $1/I_{10}$ vs. the concentration of chloride ions gave a straight line (Fig. 1). Here, I_{10} is the EPR signal intensity of the chlorine spin adduct after photolyzing the sample for 10 s. This linear relationship is in agreement with the simplified kinetic model given in Scheme 1 and from which the following relationship can be derived by assuming steady state condition for ·Cl and $Cl2_2^{\cdot-}$.

$$[5]\quad 1/I_{10} = \frac{1}{I_a \Phi I_0}\left(1 + \frac{k_1 k_2}{k_t(k_2 + k_{-1})}\frac{[Cl^-]}{[PBN]}\right)$$

Also in this equation I_{10} is assumed to express the average rate of formation of spin adducts. Here, I_a and Φ are the number of light quanta absorbed and the quantum yield of chlorine atom spin adduct, respectively; k_1, k_{-1}, k_2, and k_t are the rate constants defined in Scheme 1.

Using eq. [5], the rate constant $k_t = (1.2 \pm 0.4) \times 10^8$ L mol^{-1} s^{-1} for the trapping reaction can be obtained as a rough estimate from the plot shown in Fig. 1.

If $AsPh_4^+Cl^-$ is used as a source of chloride ions, an additional spin adduct of PBN with a_N = 1.469 ± 0.005 mT and a_H = 0.269 ± 0.005 mT (a_N = 1.465 ± 0.005 mT, a_H = 0.256 ± 0.005 mT in CH_2Cl_2) was detected. By using nitrosodurene as a spin trap, this spin adduct could be assigned to the phenyl radical adduct (a_N = 1.045 ± 0.005 mT, $a_{o,p\text{-}H}$ = 0.287 ± 0.005 mT (3H), $a_{m\text{-}H}$ = 0.100 ± 0.005 mT (2H)). Apparently, an attack of chlorine atoms occurs at the tetraphenylarsenium ion liberating a phenyl radical. Investigations were not undertaken in order to elucidate the fate of the tetraphenylarsenium ion. No chlorine spin adducts were detected for acetonitrile solutions containing water. Instead, the spectrum of



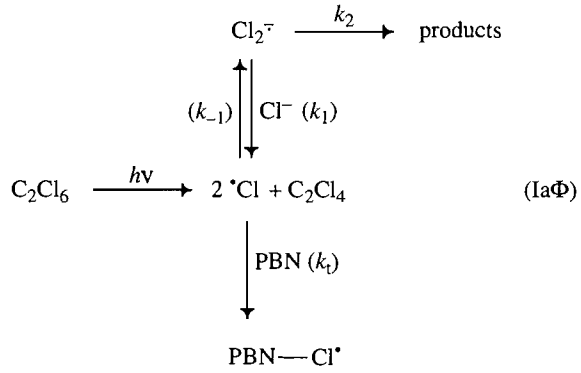


FIG. 2. EPR spectrum of spin adducts obtained during the photolysis of C_2Cl_6 (0.15 M) in benzene solution in the presence of PBN (0.04 M) and methanol (0.04 M). Bottom spectrum is reproduced by spectrum simulation using parameters in the text.

SCHEME 1

the hydroxyl adduct (a_N = 1.34 ± 0.005 mT, a_H = 0.200 ± 0.005 mT) was recorded. However, as previously shown (4), this signal is due to nucleophilic replacement of chloride by water rather than by trapping free ·OH radicals. Interestingly, the reaction between the chlorine spin adduct of PBN and methanol is fairly slow, and both chlorine and methoxy spin adducts could be detected when benzene solutions of C_2Cl_6 were photolyzed in the presence of traces of methanol (a_N = 1.387 ± 0.005 mT, a_H = 0.219 ± 0.005 mT) (Fig. 2).

Gilbert *et al.* (13) have reported formation of radical cations from the reaction of $Cl_2^{\cdot-}$ with alkoxy-substituted olefins. In the current studies, an alternative mechanism leading to hydroxy spin adducts, involving nitrone radical cations (14) rather than intermediate chlorine spin adducts of PBN, cannot be ruled out. However, in the case of methanol, the relatively slow transformation of chlorine spin adducts into methoxy spin adducts provides strong evidence for a nucleophilic replacement reaction route.

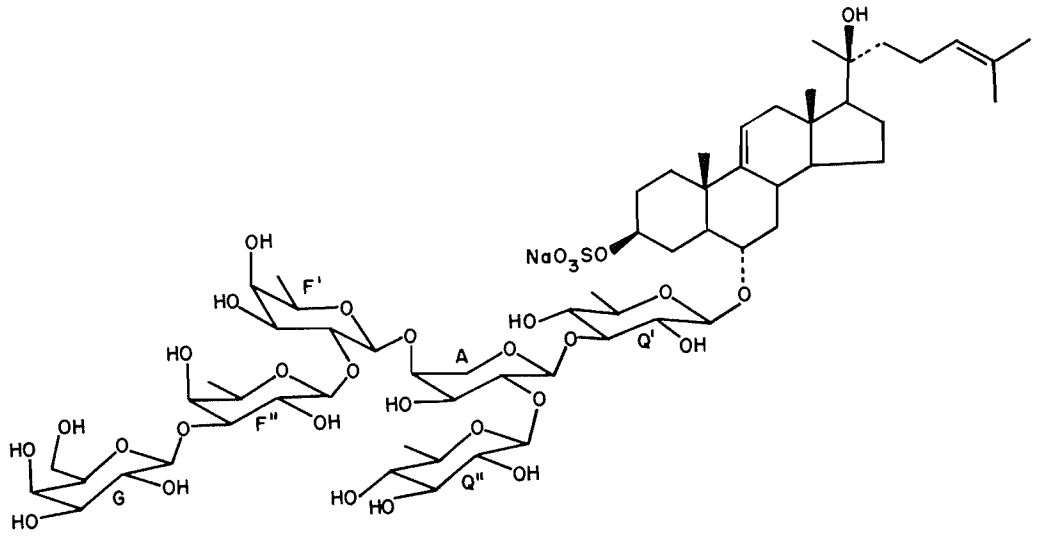
Received August 16, 1990[2]

JOHN A. FINDLAY, ZHENG-QUAN HE, and FRANÇOISE SAURIOL. Can. J. Chem. **69**, 1134 (1991).

The structure of forbeside D ($C_{62}H_{101}O_{31}SNa$), a saponin from the starfish *Asterias forbesi*, has been deduced entirely by nuclear magnetic resonance methods using a 300 MHz instrument. Based on 2D-COSY, HETCOR, single and multiple RCT, NOESY and HETCORSL experiments, the structure of forebeside D has been shown to be the monosodium salt of 6α-*O*-{β-D-galactopyranosyl-(1→3)-β-D-fucopyranosyl-(1→2)-β-D-fucopyranosyl-(1→4)-[β-D-quinovopyranosyl-(1→2)]-α-L-arabinopyranosyl-(1→3)-β-D-quinovopyranosyl}-20*S*-hydroxy-3β-sulfo-oxy-5α-cholesta-9(11),24-diene. This is the first example of a starfish saponin featuring an arabinopyranosyl unit.

Key words: marine saponin, *Asterias forbesi* saponin, forbeside D structure, structure elucidation by NMR.

JOHN A. FINDLAY, ZHENG-QUAN HE et FRANÇOISE SAURIOL. Can. J. Chem. **69**, 1134 (1991).



On a déterminé la structure du forbeside D ($C_{62}H_{101}O_{31}SNa$), une saponine isolée de l'étoile de mer *Asterias forbesi*, en faisant appel à des méthodes de résonance magnétique nucléaire à l'aide d'un appareil à 300 MHz. En se basant sur des expériences de 2D-COSY, HETCOR, RCT simple et multiple, NOESY et HETCORSL, on a démontré que le forbeside D est le sel de sodium du 6α-*O*-{β-D-galactopyranosyl-(1→3)-β-D-fucopyranosyl-(1→2)-β-D-fucopyranosyl-(1→4)-[β-D-quinovopyranosyl-(1→2)]-α-L-arabinopyranosyl-(1→3)-β-D-quinovopyranosyl]-20*S*-hydroxy-3β-sulfo-oxy-5α-cholesta-9(11),24-diène. Il s'agit de la première saponine d'étoile de mer à contenir un reste arabinopyranosyle.

Mots clés : saponine marine, saponine de l'*Asterias forbesi*, structure du forbeside D, détermination de structure par RMN.

[Traduit par la rédaction]

In 1987 we reported the structures of forbesides A, B (1), and C (2), the major saponins from the common Atlantic starfish *Asterias forbesi*. Recently we have turned our attention to the minor constituents of the "saponin" fraction and determined the structures of forebesides F, G, and H (3). Forbesides F and G proved to be related to forbeside C, which possesses a thornasterol aglycone connected at C6 to a pentasaccharide side chain. Forbesides F and G feature tetrasaccharide and trisaccharide side chains, respectively, and the nature of the sugars and their connectivity is as in forbeside C. They thus appear to be truncated versions of the prototype forbeside C. Forbeside H was shown to be related to forbeside A, differing only by the lack of the last three sugars of the hexasaccharide side chain. Thus all six saponins from *A. forbesi* so far reported by us feature the thornasterol algycone, and the structures of all were deduced virtually exclusively by NMR methods employing 500 MHz facilities complemented by FAB mass spectral data, and no chemical derivatization or degradation was employed.

We now wish to report the structure **1** for forbeside D, which features a different aglycone and hexasaccharide side chain.

[a]Assignments from HCORR and comparison with ref. 4.
[b]Assignments from 2D-COSY.

At the time we isolated and purified forbeside D we did not have access to a 500 MHz NMR facility and the structure was pursued with the aid of a Varian XL300 instrument.

The ^{1}H NMR spectrum of forbeside D at 300 MHz shows, in the downfield region, six anomeric sugar proton doublets at δ 5.23, 5.22, 5.15, 5.02, 4.95, and 4.94. The large coupling constant (J = 7.5 Hz) in each case indicates all anomeric protons have *trans* diaxial coupling partners at their respective C2 positions. The region δ 3.60–4.60 shows the overlapping resonances of the oligosaccharide ring protons. Four methyl doublets at δ 1.88, 1.69, and 1.57 (×2) indicate the presence of four 6-deoxy sugars. The rest of the signals in the upfield region δ 0.90–3.40 are assigned to the aglycone moiety. Five methyl singlets at δ 0.97, 1.06, 1.60, 1.71, and 1.78 are assigned to H19, H18, H21, H27, and H26, respectively. A multiplet at δ 4.85 for H3 and a broad signal at δ 5.27 for two olefinic protons (H11 and H24) are observed. These observations suggested the presence of an aglycone moiety that is identical with that of asterosaponin-4 isolated from *Asterias amurensis* by Okano *et al.* (4).

The ^{13}C NMR spectrum (Fig. 1) and DEPT analysis show six anomeric carbon signals at δ 106.55 (×2), 106.34, 104.91, 104.79, and 102.31. The four methyl signals at δ 19.40, 18.97, 17.81, and 17.66 are consistent with four 6-deoxy sugars in the oligosaccharide moiety. Twenty-one carbon signals assignable to C1–C21 of the aglycone of forbeside D are superimposable with those of forbeside A (1) so that they must share the same steroid ring system but with a different side chain. The ^{1}H and ^{13}C NMR spectra show the presence of a -CH=$C(CH_3)_2$ group and the ^{13}C NMR data of the aglycone of forbeside D (Table 1) are in excellent agreement with those of the free aglycone of asterosaponin-4 (4) except for the downfield shift of C6 (+11 ppm) indicative of a glycosidic linkage. Thus, the preliminary review of NMR data suggested that forbeside D contained a hexasaccharide chain attached to 6α,20*S*-dihydroxy-3β-sulfo-oxy-5α-cholesta-9(11),24-diene at position 6.

Using 2D-COSY-45 (5), single relay, multiple relay COSY (6), *J*-resolved (7), and 2D-NOESY (8) experiments, it is possible to establish the connectivity of all proton resonances in the oligosaccharide moiety as shown in Table 2.

Two quinovose units were identified by 2D-COSY (Fig. 2) and a series of RCT spectra (Fig. 3). Inspection of 2D-COSY-45, single relay, double relay, triple relay, and quadruple relay COSY spectra (Fig. 4) reveals that methyls at δ 1.69 for Q′1 and 1.88 for Q″6 show correlations via each ring proton through

[b]From 2D-COSY, 2D-RCT, 2D-NOESY.
[c]From 2D-J-resolved spectra and 1D ^1H NMR spectrum.
[d]Assignments confirmed by HETCORSL experiment.
[e]Estimate (signal overlap).

to Q′1 and Q″1, respectively. The connectivity and large coupling constants derived from 2D-J-resolved spectra (Fig. 5) are consistent only with β-linked quinovose units.

Methyls at δ 1.57 for F′6 and F″6 show correlation only from F′6 and F″ through F′5 and F″5 to F′4 (δ 4.10) and F″4 (δ 4.40), respectively. The lack of further relayed correlation is due to small coupling constants ($J_{3,4}$ and $J_{4,5}$), which implies the presence of two fucose units. Single relay COSY and multiple relay COSY spectra also show correlation from F′1 (δ 4.95) and F″1 (δ 5.02) to F′4 (δ 4.10) and F″4 (δ 4.40), respectively. Therefore sugars F′ and F″ are assigned to the fucose units. The assignment of chemical shifts of F′5 (δ 3.95) and F″5 (δ 3.80) are obtained from 2D-NOESY experiments, where F′1 (δ 4.95) shows strong *cis* diaxial NOEs with F′3 (δ 4.19) and F′5 (δ 3.95); F″1 (δ 5.02) shows strong *cis* diaxial NOEs with F″3 (δ 4.19) and F″5 (δ 3.80). The NOESY data thus affirm the β anomeric configuration for these sugar units.

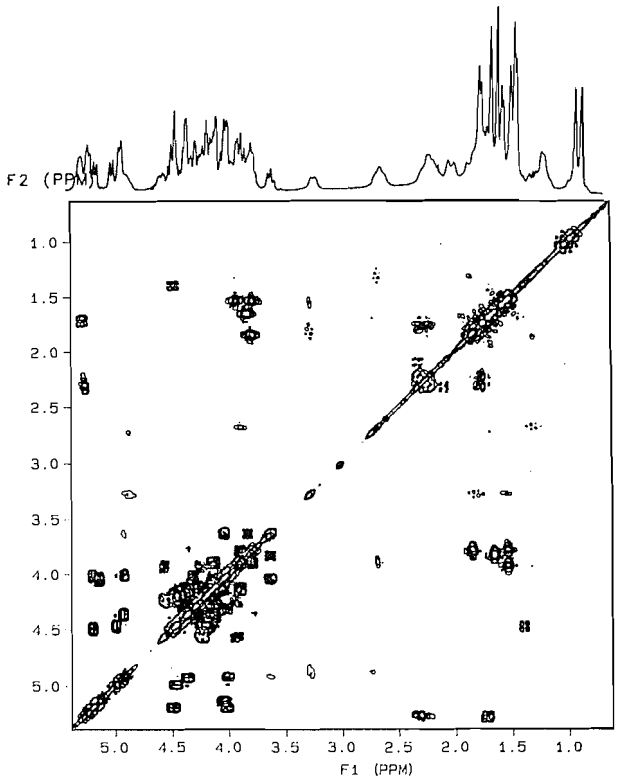

FIG. 2. COSY-45 spectrum of forbeside D.

From the anomeric doublet G1 at δ 5.22, one can locate G2 at δ 4.50 from 2D-COSY-45 spectra (Fig. 2). Single relay COSY spectra show correlation from G1 to G3 (δ 4.20). G3 is further coupled to G4 at δ 4.45, while multiple relay COSY spectra show no cross pattern from G3 to G4, which indicates the presence of a 4β-hydroxy sugar. In the 2D-NOESY spectra (Fig. 6), G1 shows strong *cis* diaxial NOEs with G5 at δ 4.15, which is coupled to G6A at δ 4.30 and G6B at δ 3.95. These findings are consistent only with a β-linked galactose unit. Inspection of the 2D-J-resolved spectrum (Fig. 5) further supported this conclusion due to the observation of double doublets at δ 4.20 for G3 ($J_{2,3}$ = 9.6 Hz, $J_{3,4}$ = 3.5 Hz) and double doublets at δ 4.45 for G4 ($J_{3,4}$ = 3.5 Hz, $J_{4,5}$ = 0.5 Hz).

From 2-D-COSY-45 spectra (Fig. 2) one can trace out the connectivity pathway from A1 at δ 5.23 to A2 at δ 4.02 and A3 at δ 4.31. Single relay COSY spectra also show correlation from A1 to A3 at δ 4.31, while multiple relay COSY spectra show no correlation from A3 to A4 due to a small coupling constant ($J_{3,4}$). In the 2D-COSY spectrum (Fig. 2), a double doublet (1H) is present at δ 4.60, constituting an ABX spin system. The geminal/vicinal coupling pattern is evident from the orientation of the cross peaks and the coupling constants of the proton signal at δ 4.60 ($J_{5,5}$ = 11.0 Hz, $J_{4,5\beta}$ = 3.0 Hz). The assignment of A5α at δ 3.95 was derived from 2D-NOESY spectra (Fig. 6) since A1 shows a strong *cis* diaxial NOE with the A5α proton; thus, A5 at δ 4.60 and A4 at δ 4.29 are assigned. The connectivity and coupling constants from 2D-J-resolved spectra (Fig. 5) are consistent only with an α-arabinose unit. The L configuration of arabinose is preferred because L-arabinose occurs in many starfish saponins while quinovose, fucose, and galactose have only been encountered in the D form in these sources to date.

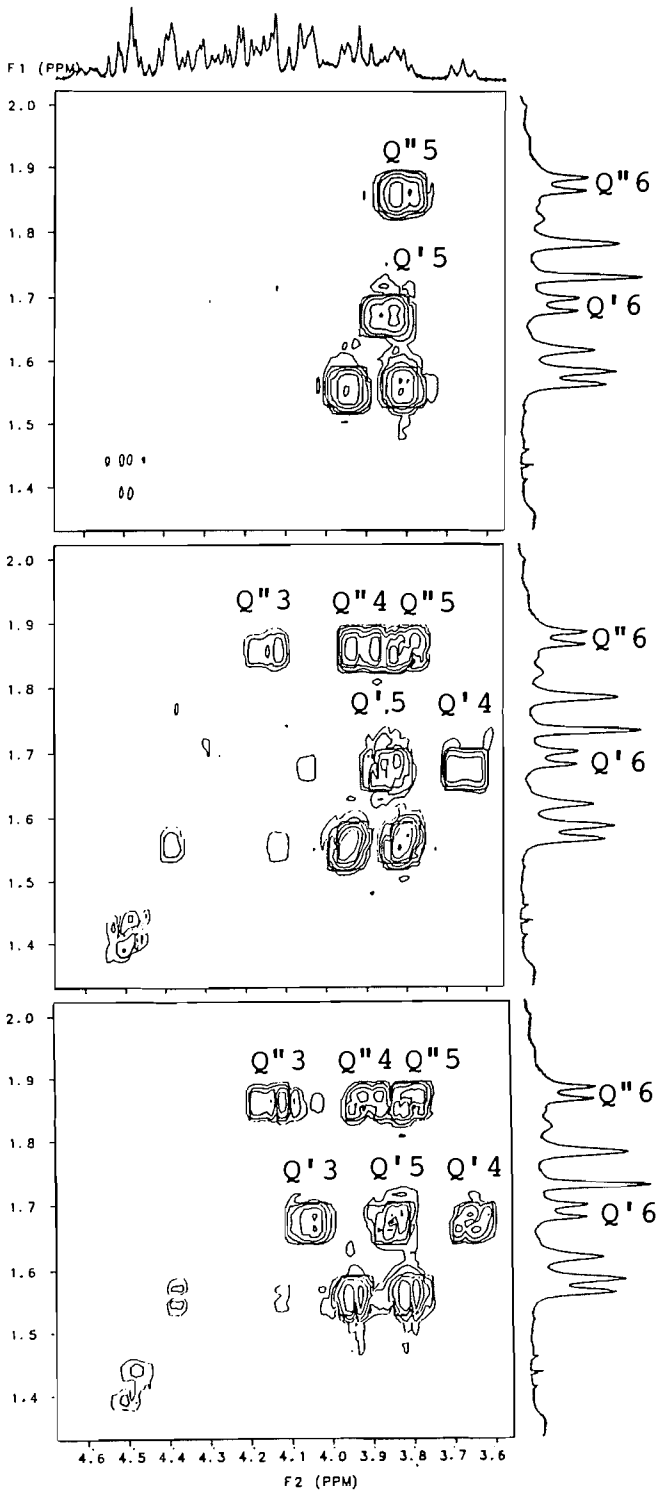

FIG. 3. Portions of COSY-45 spectra of forbeside D; upper, COSY; middle, single relay COSY; lower, double relay COSY.

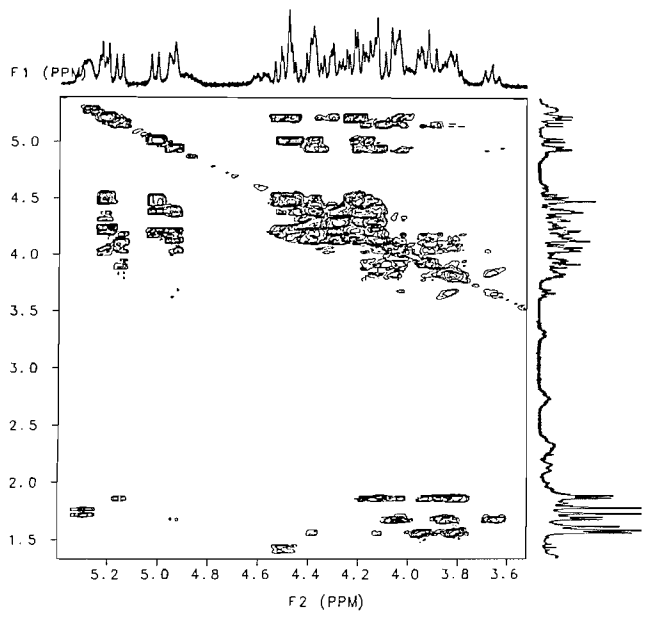

FIG. 4. Portions of quadruple relay COSY spectrum of forbeside D.

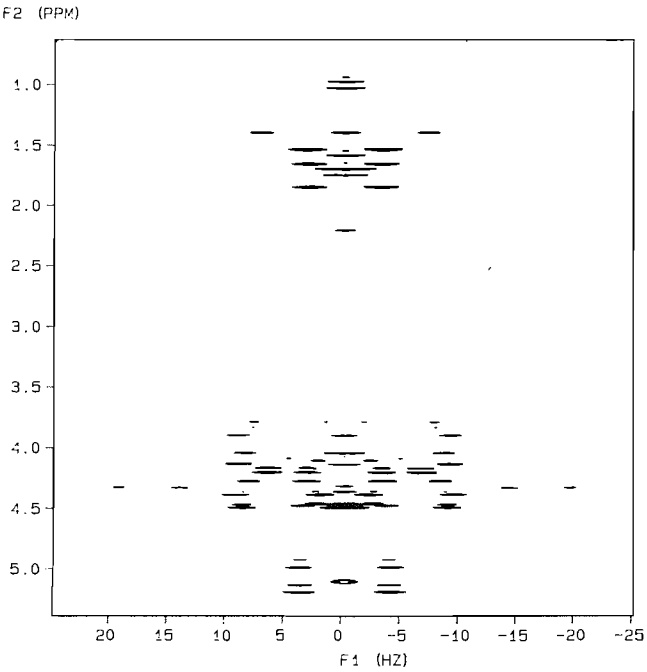

FIG. 5. *J*-Resolved spectrum of forbeside D.

So far, the six sugar units have been identified, solely by ^{1}H NMR experiments, as β-quinovopyranose (×2), β-fucopyranose (×2), β-galactopyranose, and α-arabinopyranose. The sequence of these sugar units in the oligosaccharide chain has been determined by 2D-NOESY and HETCOR (9) and HETCORSL (*vide infra*) experiments.

In the 2D-NOESY spectrum (Fig. 6), Q″1 at δ 5.15 shows strong diaxial NOE interaction with Q″3 at δ 4.15 and Q″5 at δ 3.80, as well as with A2 at δ 4.02 involved in the glycosidic linkage; F″1 at δ 5.02 shows strong diaxial NOE with F″3 at δ 4.19, F″5 at δ 3.80, and F′2 at δ 4.38; A1 at δ 5.23 interacts strongly through space with A3 at δ 4.31, A5α at δ 3.95, and Q′3 at δ 4.05; G1 interacts with G3 at δ 4.20, G5 at δ 4.15, and F″3 (or F′3, *vide infra*) at δ 4.19; Q′1 is correlated to Q′3 at δ 4.05, Q′5 at δ 3.85, and H6 at δ 3.92 of the aglycone; F′1 is correlated to F′3 at δ 4.19, F′5 at δ 3.95, and A4 at δ 4.29.

Inspection of the HETCOR spectrum (Fig. 7) led to the near complete assignment of ^{13}C chemical shifts for the oligosaccharide moiety. The carbon signals Q′3 at δ 89.80 (~ +12 ppm), A2 at δ 84.04 (~ +12 ppm), A4 at δ 78.81 (~ +9 ppm), F′2 at δ 82.71 (~ +10 ppm), F″3 at δ 84.49 (~ +10 ppm) are immediately assigned to glycosidic linkages due to glycosyla-

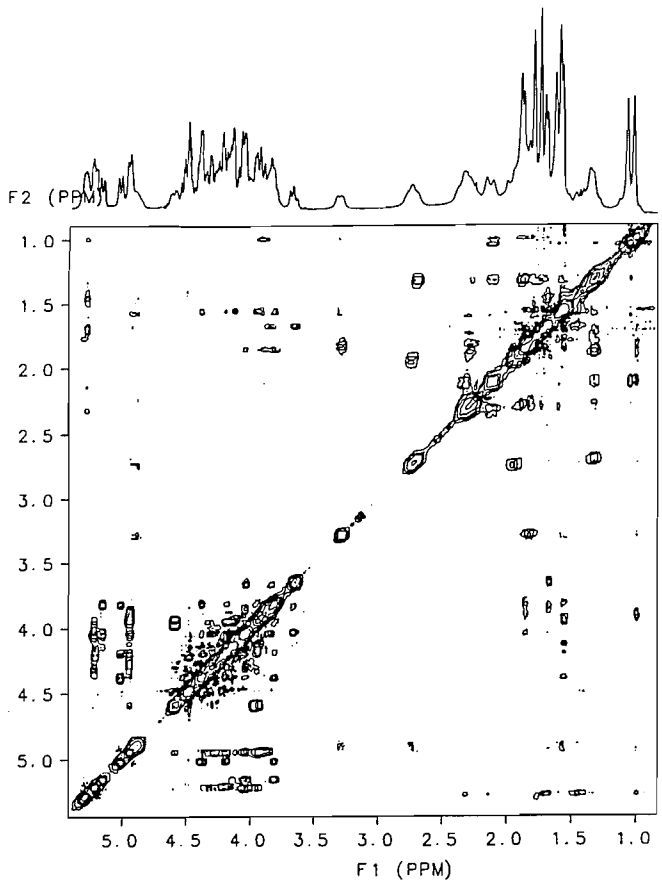

FIG. 6. 2D-NOESY spectrum of forbeside D.

tion shifts by comparison with unsubstituted β-D-quinovopyranosyl, β-D-fucopyranosyl (1, 10), and α-L-arabinopyranosyl units (11). NMR data for the terminal sugars Q″ and G in forbeside D are also in good agreement with those in versicoside A (10) and in forbeside C (2).

In view of the overlap of several proton signals, the analysis of the HETCOR spectrum was not without unambiguity. Thus it was not possible to assign with certainty the Q′2, Q′3, and A2 ^{13}C chemical shifts. Similarly, the F′3 and F″3 carbon assignments could not be decided on the basis of the HETCOR experiments due to coincidence of F′3H and F″3H. Incorrect assignment would of course lead to incorrect location of interglycosidic linkages since these are based, in part, on observation of glycosylation shifts. To overcome this difficulty a heterocorrelation spin lock (HETCORSL) (12) experiment was conducted. This provided unambiguous assignment of the several aforementioned ^{13}C signals. Conventional RELAY-HETCOR experiments (13) are much less sensitive than this more recent HETCOR-RELAY experiment using spin-locking mixing period (12) (HETCORSL). That is why this technique was selected to obtain data complementary to the NOESY experiment. In this HETCOR-RELAY technique, the magnetization transfer between coupled protons is achieved via the homonuclear Hartmann–Hahn cross polarization. The HETCORSL experiment required a more concentrated sample of forbeside D (30 mg) and this showed that some differences existed in ^{13}C and ^{1}H chemical shifts from those of the dilute sample (as per Table 2). Thus it was necessary to repeat COSY and single relay COSY experiments on the concentrated sample prior to interpreting the HETCORSL spectrum. Table 2 compares the ^{13}C chemical shifts for the anomeric and glycosidic carbons of the dilute and concentrated samples.

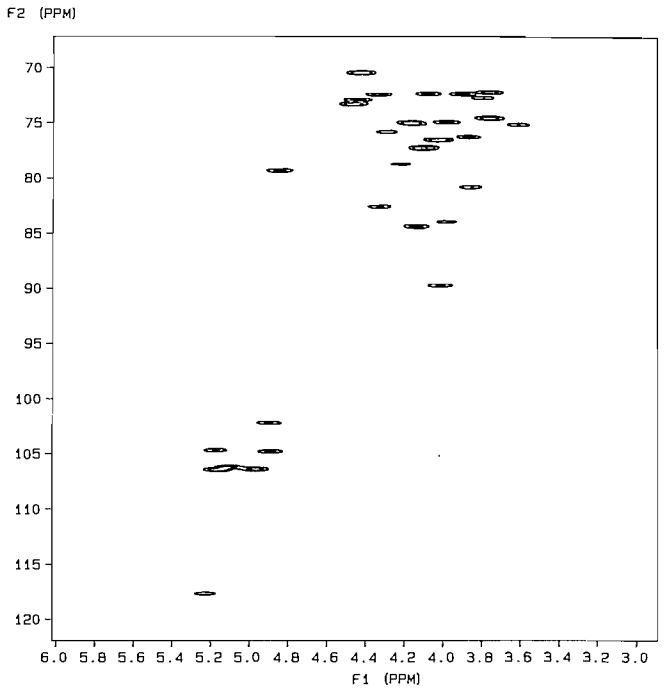

FIG. 7. Portion of HETCOR spectrum of forbeside D.

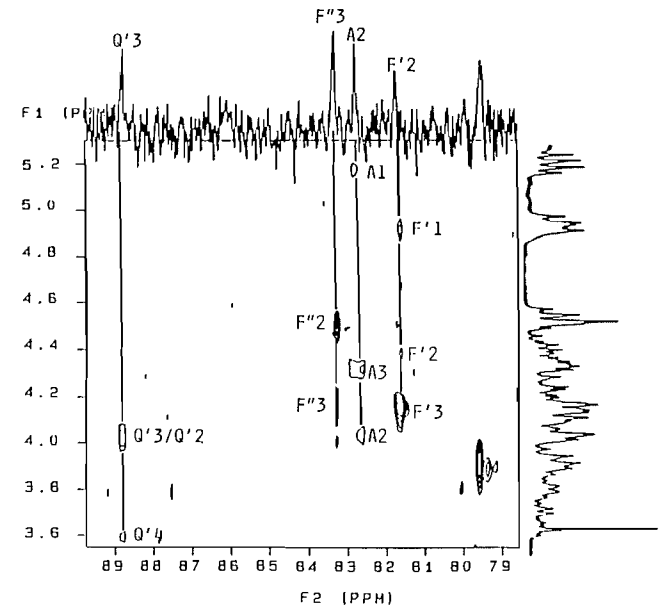

FIG. 8. Portion of HETCORSL spectrum of forbeside D.

The HETCORSL spectrum (see Fig. 8 for a portion) revealed that (a) the ^{13}C signal at δ 88.76 correlates with protons at Q′2, Q′3, and Q′4 and should thus be assigned to Q′3; (b) the signal at δ 83.35 correlates with protons F″2, F″3, and F″4 and must be assigned to F″3; (c) the signal at δ 82.82 correlates with A1, A2, and A3 and must be assigned to A2; (d) the carbon at δ 81.77 correlates with protons F′1 and F′3 and is therefore assigned to F′2. Thus it was possible to complete the ^{13}C chemical shift assignments in an unambiguous fashion and ascertain the sites of interglycosidic linkage via glycosylation shift. This corroborated and complemented the sequencing information derived from NOESY data.

Analysing the 2D-NOESY, HETCOR, and HETCORSL data, the sequence obtained can be summarized as follows:

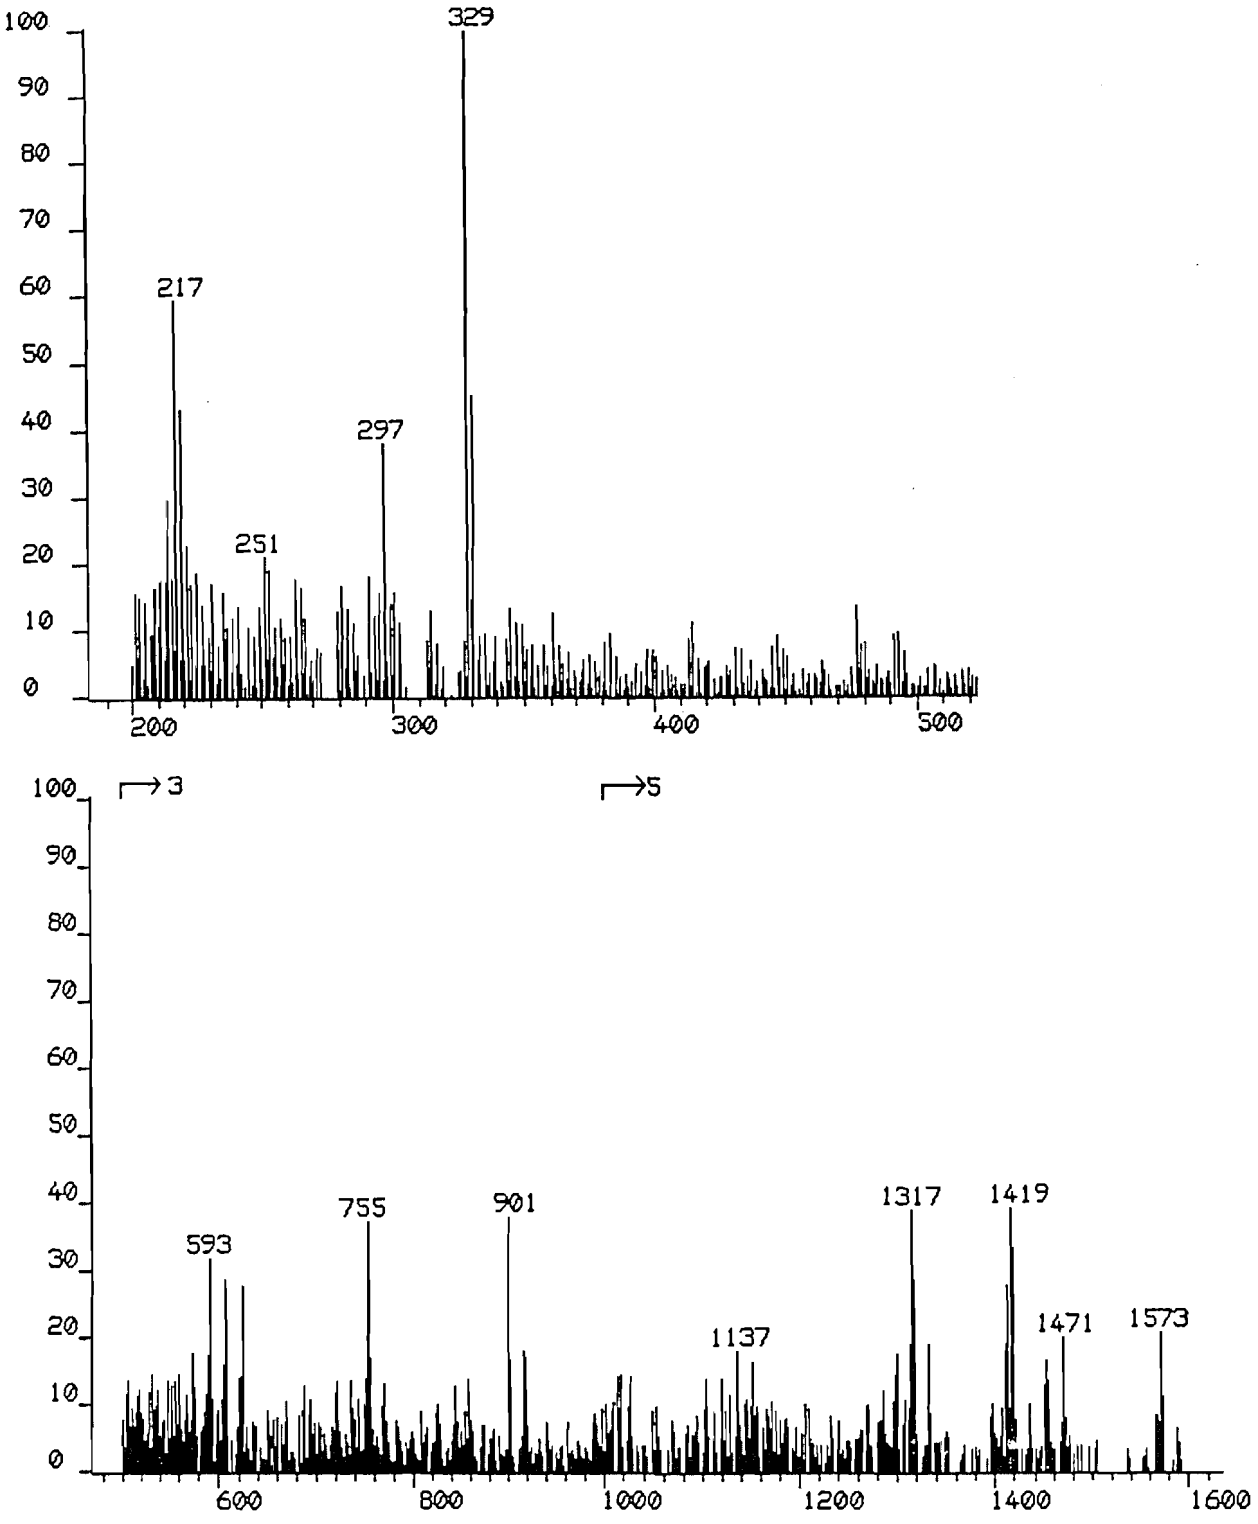

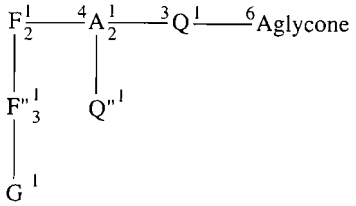

FIG. 91. +FAB mass spectrum of forbeside D.

All sugar units are linked to each other via an *O*-glycosidic bond.

The (+) FAB mass spectrum of fordeside D (Fig. 9) displays pseudomolecular ions at m/z 1419 $[M(C_{62}H_{101}O_{31}SNa) + Na]^+$ and 1397 $[M + H]^+$ indicative of a molecular mass of 1396, which supported the structure determined by NMR methods. It also shows a series of fragment ions readily interpreted on the basis of structure **1** (Table 3).

Hence, forbeside D is the monosodium salt of 6α-O-{β-D-galactopyranosyl-(1→3)-β-D-fucopyranosyl-(1→2)-β-D-fucopyranosyl-(1→4)-[β-D-quinovopyranoslyl-(1→2)]-α-L-arabinopyranosyl-(1→3)-β-D-quinovopyranosyl}-20*S*-hydroxy-3β-sulfo-oxy-5α-cholesta-9(11),24-diene **1**.

This new saponin is the first example of a starfish saponin with an arabinopyranosyl unit in the oligosaccharide moiety. It is also the first example of a marine saponin of this complexity whose structure has been deduced entirely on the basis of 300 MHz NMR spectra.

Experimental

Optical rotation was measured with a Perkin–Elmer 241 polarimeter. Mass spectra were recorded with a Kratos MS50 instrument using a magic bullet matrix. Forbeside D (30 mg) was isolated from the crude saponin mixture (4.5 g) obtained from *A. forbesi* as previously described (14). A 20-mg sample was used for all NMR experiments except the HETCORSL, which employed 30 mg of material.

Forbeside D, **1**: colorless powder, mp 213°C (dec.); $[\alpha]_D$ −4.7 (*c* 0.6, H_2O); NMR data, see Tables 1 and 2; (+)FAB-MS (magic bullet), see Fig. 9 and Table 3.

Instrumentation

The NMR spectra were obtained on a Varian XL-300 spectrometer equipped with a proton probe and a 5-mm broadband probe operating at 300 MHz for proton and 75.4 MHz for carbon. The samples were dissolved in a mixture of pyridine-d_5 and D_2O (5:1); the spectra were recorded at 30°C.

2-D-Proton NMR

The COSY-90 and COSY-45 spectra were acquired using 256 increments in the evolution time (t_1) each with four repetitions and a 1 s relaxation delay. The 2D matrix was 1024 × 1024 data points after processing. The data were pseudo echo shaped and symmetrized prior to plotting. The RELAY-COSY experiments were recorded using identical resolution and temperature conditions. The single RELAY experiment required 8 repetitions to complete the phase cycling whereas RELAY-2, RELAY-3, RELAY-4 experiments required 16, 32, and 64 repetitions, respectively.

The phase-sensitive NOESY experiment was recorded under identical conditions (resolution and temperature) as previous 2D experiments, except for the relaxation delay set to 2 s and the number of repetitions set to 16 transients. The mixing time used to perform this experiment was 0.3 s.

C-13 and 2D-heteronuclear experiments

For ^{13}C, a 60° pulse was used with an acquisition time of 0.97 s. Line broadening processing of 1 Hz was used. The DEPT and two-dimensional shift correlation (HETCOR) experiments were performed using 2 and 0.5 s repetition delays, respectively. The 90°C pulse provided by the decoupler was 47 μs. In the DEPT experiment, four spectra were acquired using 45°, 90°, 90°, and 135°; these spectra were edited to provide pure CH, CH_2 and CH_3 sub-spectra. In the 2D-heterocorrelation spectra, 128 free induction decays were acquired in the t_1 domain and 1024 data points were recorded in the t_2 domain. The 2D-heterocorrelation spectra were acquired for 10–15 h at 30°C. The data were pseudo echo shaped and zero filled in the t_1 domain to end up with a 512 × 1024 matrix.

The phase-sensitive relay (HETCORSL) experiment was acquired using 1 s relaxation delay for the 64 increments of the evolution domain. The spectra were recorded at 40°C for 14–15 h. Mild line broadening and zero filling were used to obtain a 512 × 1024 matrix. The spin lock mixing time was selected to be 24 ms, a time sufficient (from previous experiments) to relay magnetization to the next coupled neighboring proton.

Complexes of the crown thioether ligand 2,5,8-trithia[9]-*o*-benzenophane, (TT[9]OB). Synthesis and molecular structure of [Cu(NCS)(TT[9]OB)]

STEPHEN J. LOEB[1] AND GEORGE K. H. SHIMIZU

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

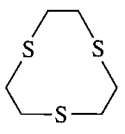
Received January 17, 1991

STEPHEN J. LOEB and GEORGE K. H. SHIMIZU. Can. J. Chem. **69**, 1141 (1991).

The macrocyclic thioether ligand 2,5,8-trithia[9]-*o*-benzenophane (TT[9]OB) reacts with $[Cu(CH_3CN)_4][ClO_4]$ to yield the Cu(I) complex $[Cu(CH_3CN)(TT[9]OB)][ClO_4]$. The coordinated acetonitrile molecule is displaced by the ambidentate, thiocyanate $(NCS)^-$ ion to form the neutral complex [Cu(NCS)(TT[9]OB)] which was characterized by infrared spectroscopy, ^1H NMR spectroscopy, and X-ray crystallography. The title complex crystallized in the orthorhombic space group *Pbca* with $a = 14.447(3)$ Å, $b = 15.034(4)$ Å, $c = 14.851(4)$ Å, $V = 3232.2(14)$ Å^3, and $Z = 8$. The structure refined to $R = 5.15\%$ and $R_w = 5.92\%$ for 1149 reflections with $F_o^2 > 3\sigma(F_o^2)$. The Cu(I) ion has a distorted tetrahedral coordination sphere with TT[9]OB occupying three sites while the fourth site is occupied by the thiocyanate ligand which is N-bound to the metal centre. A comparison is made of the molecular conformations of free TT[9]OB and that found for complexed TT[9]OB in [Cu(NCS)(TT[9]OB)] and $[Cu(Ph_2PMe)(TT[9]OB)][ClO_4]$.

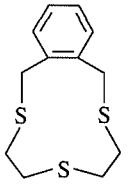
Key words: thioether, macrocyclic metal complex.

STEPHEN J. LOEB et GEORGE K. H. SHIMIZU. Can. J. Chem. **69**, 1141 (1991).



Le ligand thioéther macrocyclique 2,5,8-trithia[9]-*o*-benzénophane, (TT[9]OB) réagit avec le $[Cu(CH_3CN)_4][ClO_4]$ pour conduire au complexe de Cu(I), $[Cu(CH_3CN)(TT[9]OB)][ClO_4]$. La molécule d'acétonitrile coordinée est déplacée par l'ion thiocyanate $(NCS)^-$ ambident pour former le complexe neutre [Cu(NCS)(TT[9]OB)] que l'on a caractérisé par spectroscopies ir et rmn du ^1H et par diffraction des rayons-X. Les cristaux du complexe mentionné dans le titre sont orthorhombiques, ils appartiennent au groupe d'espace *Pbca*, avec $a = 14{,}447(3)$, $b = 15{,}034(4)$ et $c = 14{,}851(4)$ Å, $V = 3232.2(14)$ Å et $Z = 8$. On a affiné la structure jusqu'à des valeurs respectives de $R = 0{,}0515$ et $R_w = 0{,}0592$ pour 1149 réflexions avec $F_o^2 > 3\sigma(F_o^2)$. L'ion Cu(I) est entouré d'une sphère de coordination tétraédrique déformée qui est liée par l'azote au centre métallique. On a réalisé une comparaison des conformations moléculaires du TT[9]OB libre et du TT[9]OB complexé dans le [Cu(NCS)-(TT[9]OB)] et dans le $[Cu(Ph_2PMe)(TT[9]OB)[ClO_4]$.

Mots clés : thioéther; complexe métallique macrocyclique.



[Traduit par la rédaction]

Introduction

The coordination chemistry of macrocyclic thioether ligands is dominated by the conformational requirements of the free ligand. These cyclic molecules favour the adoption of "inside-out" or exodentate conformations with the S atoms oriented out of the macrocyclic cavity (1–4). It has been shown that this results from the tendency of $SCH_2CH_2SCH_2CH_2S$ chains to adopt a "bracket" structure with *anti* placements for C—C bonds and *gauche* placements for S—C bonds (4). An exception to this observation is the macrocyclic thioether 1,4,7-trithiacyclononane (9S3). For this unique thioether ligand, the exodentate conformation is unfavourable because the conformational constraints of the nine-membered ring force all C—C bonds to adopt *gauche* placements. As a result, the free ligand adopts an endodentate conformation which is essentially the same as the conformation required for *facial* coordination (5). Complexes of 9S3 exhibit remarkable stability and very often unusual coordination geometries and oxidation states that can be attributed to this preorganization of the ligand (1–11).

9S3

TT[9]OB

[1]Author to whom correspondence should be addressed.

The chemistry of 9S3 and recent results on the molecular structures of some acyclic polythioethers (4*c*) suggest that if SCH_2CH_2S linkages are to be used as the structural basis of metal-binding ligands, some perturbation should exist which forces S donor atoms to be preorganized in an endodentate conformation. We have proposed that the incorporation of rigid xylyl units into crown thioethers may limit the conformational flexibilty of the macrocyclic ring or introduce conformational strain into the macrocycle backbone resulting in an endodentate conformation or disposition towards such a conformation. We have recently shown that the reaction of $[Cu(CH_3CN)_4][X]$ with TT[9]OB yields the mononuclear cation $[Cu(CH_3CN)-(TT[9]OB)]^+$ for which the labile acetonitrile ligand can easily be replaced by neutral ancillary ligands such as phosphines and pyridines (12). To complete our studies on the Cu(I) coordination chemistry of TT[9]OB, we have investigated the interaction of the ambidentate anionic ligand $(NCS)^-$ with $[Cu(CH_3CN)(TT[9]OB)]^+$ and this paper describes these results.

Experimental section

General

$[Cu(CH_3CN)_4][ClO_4]$, TT[9]OB, and $[Cu(CH_3CN)(TT[9]OB)]-[ClO_4]$ were prepared using published methods (12, 13). KSCN, CH_3CN, CH_3NO_2, and all deuterated solvents were purchased from Aldrich and used as received. All reactions were conducted under an atmosphere of N_2 using standard Schlenk techniques and all solvents were degassed prior to use. ^1H NMR spectra were recorded at 300.1 MHz, on a Brüker AC300 spectrometer locked to the deuterated solvent. Infrared spectra were recorded on a Nicolet 5DX FTIR spectrometer. Elemental analysis were performed by Microanalytical Services New Westminister, British Columbia, Canada.

Preparation of [Cu(NCS)(TT[9]OB)]

To a solution of $[Cu(CH_3CN)(TT[9]OB)][ClO_4]$ (382 mg, 0.83 mmol) in CH_3CN (10 mL), KSCN (166 mg, 0.83 mmol) dissolved in CH_3CN (5 mL) was added dropwise. No visible change occurred as the two colourless solutions were mixed. The mixture was stirred for 3 h at room temperature during which time a white precipitate formed. The solvent was removed and the resulting off-white solid washed with water (3 × 20 mL) and then dried *in vacuo*. The product was then extracted into CH_3NO_2 and recrystallized by vapour diffusion of diethylether into this solution. Yield: 329 mg (64%). ^1H NMR (CD_3CN, 235 K): δ 7.46 (m, 4H, aromatic), 4.10 (d, 2H, benzylic, ^2J = 11.2 Hz), 3.88 (d, 2H, benzylic, ^2J = 11.2 Hz), 3.53 (m, 4H, SCH_2CH_2S), 2.92 (m, 4H, SCH_2CH_2S), IR (KBr): ν(NCS) 2095 cm^{-1}(s). *Anal* calcd, for $C_{13}H_{16}CuNS_4$: C 41.29, H 4.27, S 33.91; found C 41.38, H 4.14, S33.67.

X-ray crystallographic analysis of [Cu(NCS)(TT[9]OB)]

Colourless crystals of [Cu(NCS)(TT[9]OB)] were grown by vapour diffusion of diethylether into a CH_3NO_2 solution of the complex. The diffraction experiment was performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized MoKα radiation. The initial orientation matrix was obtained from 15 machine-centred reflections selected from a rotation photograph. Partial rotation photographs around each axis were consistent with an orthorhombic crystal system. Utimately, 25 high-angle reflections ($15.2° < 2\theta < 23.4°$) were used to obtain the final lattice parameters and orientation matrix. Machine parameters, crystal data, and data collection parameters are summarized in Table 1. Observed extinctions were consistent with the space group *Pbca* and this was confirmed by a successful solution refinement. Intensity data ($+h,+k,+l$) were collected in two shells ($4.5° < 2\theta < 40°$ and $40° < 2\theta < 45°$). The intensities of three standard reflections (0 0 2, 2 0 0, 3 2 2) were recorded every 197 reflections and showed no statistically significant changes over the duration of the data collection. The absorption coefficient was small and ψ-scans recorded (8 2 2, 4 1 1, 9 2 2, 12 2 3) showed no significant absorption effects. Thus, no absorption correction was applied to the data. The data were processed by using the TEXSAN software package (14) running on a VAX 3520 Workstation. A total of 2469 reflections were collected and 1149 unique reflections with $F_o^2 > 3\sigma(F_o^2)$ were used in the refinement.

The positions of the copper atom and the four sulfur atoms were determined by direct methods from the *E*-map with highest figure of merit. The remaining non-hydrogen atoms were located from a difference Fourier map calculation. In the final cycles of refinement, the copper, sulfur, and nitrogen atoms were assigned anisotropic thermal parameters and the carbon atoms were assigned isotropic thermal parameters. Refinement was carried out by using full-matrix least-squares techniques on *F* minimizing the function $\Sigma w(|F_o| - |F_c|)^2$, where $w = 1/\sigma^2(F_o)$ and F_o and F_c are the observed and calculated structure factors. Atomic scattering factors (15) and anomalous dispersion terms (16, 17) were taken from the usual sources. Fixed H-atom contributions were included with C—H distances of 0.95 Å and thermal parameters 1.2 times the isotropic thermal parameter of the bonded C atoms. No H atoms were refined, but all values were updated as refinement continued. This resulted in $R = \Sigma||F_o| - |F_c|/\Sigma|F_o|| = 0.0515$ and $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)^{1/2} = 0.0592$ at final convergence.

The Δ/σ value for any parameter in the final cycle was less than 0.001. A final difference Fourier map calculation showed no peaks of chemical significance; the largest was 0.53 electrons/Å^3 and was associated with the Cu atom. Atomic positional parameters are summarized in Table 2 and selected bond distances and angles are summarized in Table 3. Thermal parameters (Table S-1), hydrogen atom parameters (Table S-2), and values of $10|F_o|$ and $10|F_c|$ (Table S-3) are deposited as supplementary material.[2]

[2]Supplementary Tables S-1, S-2, and S-3 may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

Results

We have previously shown that the Cu(I) complex $[Cu(CH_3CN)(TT[9]OB)][ClO_4]$ can easily be prepared by displacement of three labile acetonitrile ligands from $[Cu(CH_3CN)_4][ClO_4]$ (12). This product is then ideal as a starting material for the incorporation of other ancillary ligands through displacement of the remaining acetonitrile ligand. The addition of one equivalent of potassium thiocyanate to $[Cu(CH_3CN)(TT[9]OB)][ClO_4]$ resulted in the quantitative formation of $KClO_4$ and a single copper containing product formulated as [Cu(NCS)(TT[9]OB)]. Elemental analysis was in agreement with this formulation in which the thiocyanate ion is bonded to the Cu(I) centre rather than $[Cu(CH_3CN)(TT[9]OB)][NCS]$ in

which a simple exchange of non-coordinated anions (NCS^- for ClO_4^-) had occurred.

The room temperature ^1H NMR spectrum (CD_3CN) of [Cu(NCS)(TT[9]OB)] shows three separate sets of broadened resonances assignable to aromatic, benzylic, and methylene SCH_2CH_2S protons. The broadening is likely due to some inversion at the S centres and contributions from ^{63}Cu quadrupole effects. At low temperature (CD_3CN, 235 K), these effects are diminished and the spectrum is well-resolved into discernible patterns. The aromatic region shows a multiplet pattern typical of *ortho* substitution (δ 7.47 (m)) and the benzylic region exhibits a pair of doublets (δ 4.10 (d), 3.88 (d), ^2J = 11.2 Hz) assigned to axial and equatorial protons on the seven-membered chelate ring. The methylene protons of the SCH_2CH_2S chain also resonate as two separate groups (δ 3.53 (m), 2.92 (m)) and are assigned as the protons of C9, C10 and C8, C11 consistent with that observed by ourselves for $[Cu(Ph_2PMe)(TT[9]OB)]^+$ and others for similar compounds containing five-membered chelate ring systems (12, 18). The infrared spectrum clearly shows the ν(NC) stretch of the thiocyanate ion at 2095 cm^{-1} which is indicative of coordinated thiocyanate.

Recrystallization of [Cu(NCS)(TT[9]OB)] by vapour diffusion of diethylether into a relatively dilute solution of the complex produced crystals suitable for X-ray diffraction. The unit cell contains eight molecules of [Cu(NCS)(TT[9]OB)]. A perspective view of [Cu(NCS)(TT[9]OB)], indicating the atom numbering scheme, is shown in Fig. 1. Selected listings of interatomic distances and angles are found in Table 3.

The Cu(I) ion is in a slightly distorted tetrahedral geometry with three coordination sites occupied by coordination to the S atoms of the TT[9]OB ligand and the fourth site occupied by the N atom of the thiocyanate ligand. The Cu—S distances are 2.328(3) Å and 2.359(3) Å for S1 and S3 associated with the *ortho*-xylyl fragment and 2.353 (3) Å for the central S2 atom. The Cu—N distance is 1.949(9) Å. The S—Cu—S angles for the five-membered chelate rings are 92.2(1)° and 91.5(1)° and the S1—Cu—S3 angle of the seven-membered chelate ring involving the *ortho*-xylyl fragment is 114.7(1)°. The parameters associated with the coordination of TT[9]OB to the Cu(I) centre compare well to those found for $[Cu(Ph_2PMe)$-(TT[9]OB)]. The S—Cu—N angles are 119.4(3), 127.9(3), and 108.2(3)° to S1, S2, and S3, respectively. The thiocyanate group is linear with the S4—N—C13 angle measuring 180(1)°. The sulfur–carbon distances in TT[9]OB range from 1.81(1) to 1.87(1) Å and carbon C(sp^2)—C(sp^2) bonds range from 1.37(1) to 1.43(1) Å. The two C(sp^3)—C(sp^3) bonds are 1.48(1) and 1.53 (1) Å and the two C(sp^2)—C(sp^3) bonds are

[c]Data taken from ref. 12. The two sets of values represent two crystallographically independent molecules.

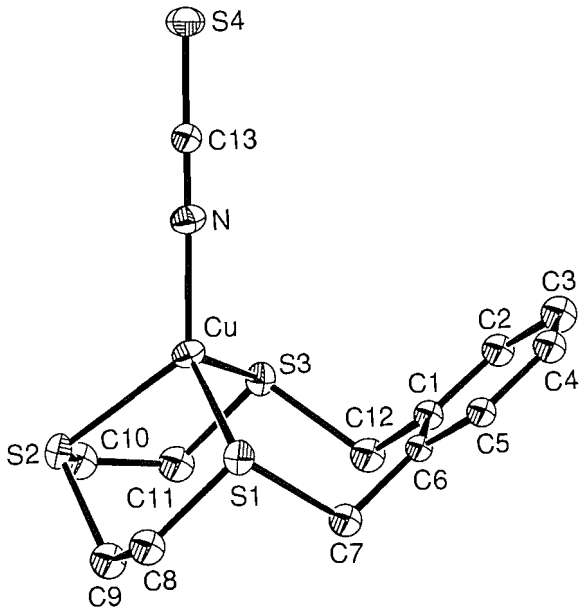

FIG. 1. Perspective ORTEP drawing of [Cu(NCS)(TT[9]OB)] showing the atom-numbering scheme. Thermal ellipsoids of 20% are shown.

1.50(1) and 1.51(1) Å. These parameters are typical for thioether ligands (4) and compare well to those obtained in TT[9]OB (19) and other complexes of TT[9]OB (12, 19, 20).

An interesting structural feature of [Cu(NCS)(TT[9]OB)] is the conformation of the TT[9]OB ligand as described by the torsional angles found in Table 4. The ligand adopts an asymmetric conformation which differs from that found for [Cu(Ph_2PMe)(TT[9]OB)][ClO_4]. The two five-membered chelate rings adopt opposite conformations (δ and λ) in [Cu(Ph_2PMe)-(TT[9]OB)][ClO_4] but adopt the same conformations (δ and δ or λ and λ) in [Cu(NCS)(TT[9]OB)]. Since the thiocyanate ligand offers no steric demands and there is no obvious electronic requirements for NCS^- as a ligand, it could be that the conformation observed for TT[9]OB in [Cu(NCS)(TT[9]OB)] is simply that favoured by the ligand in the absence of any perturbations from the ancillary ligand or anion. Although the energy difference between the two conformations is likely to be small, it should be noted that in our original conformational analysis of TT[9]OB we calculated (Table 4) the low energy endodentate conformation for the free ligand to be the asymmetric version found for TT[9]OB in [Cu(NCS)(TT[9]OB)].

Discussion

The coordination chemistry of 2,5,8-trithia[9]-*o*-benzenophane (TT[9]OB) is different from that found for most macrocyclic thioether ligands. Although the conformation of the free ligand is exodentate (12), there is considerable strain involved in the $SCH_2CH_2SCH_2CH_2S$ bracket and the ligand easily converts to an endodentate conformation (19, 20). This flexibility is in marked contrast to the rigid, preorganized conformation of 9S3.

Studies on the coordination chemistry of 9S3 with Cu(I) have shown that the structure of the complex formed can be very dependent on the ancillary ligands and the counterion used. For example, the product formed in the reaction of [Cu($CH_3CN)_4$][X] with 9S3 depends critically on the nature of X. If X is I^-, PF_6^-, BF_4^-, or ClO_4^-, the products formed are [Cu(I)(9S3)] (21), [Cu(9S3)$_2$][PF_6] (22), [Cu_2(9S3)$_3$][BF_4] (22), and [Cu_3(9S3)$_3$][ClO_4] (21), respectively. Only in the case of the soft anion I^- was a simple mononuclear species of the formula [Cu(9S3)(L)] found. It has recently been shown that if ancillary PPh_3 or $AsPh_3$ ligands are introduced during the reactions involving non-coordinating anions complexes of the type [Cu(PPh_3)(9S3)][X] can also be prepared (11, 23).

In contrast to 9S3, TT[9]OB forms only mononuclear complexes regardless of the nature X or the ancillary ligand. We have shown previously (12) that this is the case for cationic complexes of the formulation [Cu(L)(TT[9]OB)][X] and in this paper we have shown that the same is true for [Cu(NCS)(TT[9]OB)] in which the ancillary ligand is anionic and the complex is neutral. The structural analysis of [Cu(NCS)(TT[9]OB)] demonstrates the subtle conformational differences that can occur for complexes of TT[9]OB and emphasizes the flexible nature of TT[9]OB relative to the conformational rigidity of 9S3.

Structure and magnetic properties of $[Cp_2M(\mu\text{-}PEt_2)]_2$ (M = Ti, Zr)

DAVID G. DICK AND DOUGLAS W. STEPHAN[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received January 16, 1991

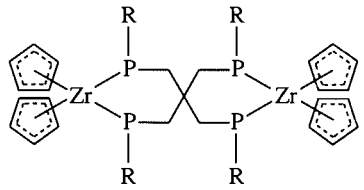
DAVID G. DICK and DOUGLAS W. STEPHAN. Can. J. Chem. **69**, 1146 (1991).

The complex $[Cp_2Ti(\mu\text{-}PEt_2)]_2$ (**1**) crystallizes in the monoclinic space group $P2_1/n$ with a = 16.591(3) Å, b = 8.662(2) Å, c = 37.407(2) Å, β = 102.40(1)°, Z = 8, and V = 5250(2) Å^3. The Ti_2P_2 core of the dimeric complex is planar and the angles at Ti and P are close to 90°. The Ti...Ti separations were found to be 3.732(1) and 3.706(1) Å in the two independent molecules in the unit cell. Bulk magnetic susceptibility measurements on solid **1** show that the species is diamagnetic over the range 5–340 K. The coupling constant for the antiferromagnetic interaction between the Ti centers of **1** is found to be at least -300 cm^{-1}. Extended Hückel Molecular Orbital calculations suggest that mixing of the frontier $1a_1$ orbitals of the Cp_2Ti fragments with the p orbitals of the phosphide fragments affords a mechanism for super-exchange through the ligands. In THF solution, variable temperature ^1H, and $^{31}P\{^1H\}$ NMR and EPR spectra for **1** are consistent with the generation of the paramagnetic monomeric species Cp_2TiPEt_2, **3**. As well, the data suggest thermal populations of the paramagnetic triplet state of the dimer may occur to a small extent at 340 K. In contrast, the analogous Zr dimer **2** shows no evidence of dissociation or of thermal population of the triplet state at temperatures to 340 K.

Key words: titanium phosphides, structures, magnetic properties.

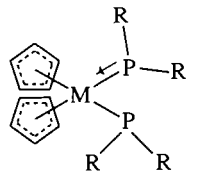
DAVID G. DICK et DOUGLAS W. STEPHAN. Can. J. Chem. **69**, 1146 (1991).

Le complexe $[Cp_2Ti(\mu\text{-}PEt_2)]_2$ (**1**) cristallise dans le groupe d'espace monoclinique $P2_1/n$, avec a = 16,591(3), b = 8,662(2) et c = 37,407(2) Å, β = 80,07(3)°, Z = 8 et V = 5250(2) Å^3. Le noyau Ti_2P_2 du complexe dimère est plan et les angles au niveau de Ti et de P se rapprochent de 90°. On a trouvé que les distances Ti...Ti sont égale à 3,732(1) et 3,706(1) Å respectivement dans les deux molécules indépendantes de la cellule de base. Des mesures de susceptibilité magnétique globale sur le composé **1** solide montrent que cette espèce est diamagnétique de 5 à 340 K. On a déterminé que la constante de couplage de l'interaction antiferromagnétique entre les centres Ti du composé **1** est égale à au moins -300 cm^{-1}. Des calculs d'OM étendus selon Hückel suggèrent que le mélange des orbitales frontières $1a$, de la portion Cp_2Ti avec les orbitales p des fragments phosphure conduisent à un mécanisme de super-échange à travers les ligands. En solution dans le THF, les spectres rpe et rmn du ^1H et du $^{31}P\{^1H\}$ à température variable du composé **1** sont en accord avec la génération d'espèces paramagnétiques monomères Cp_2TiPE_2, **3**. De plus, les données suggèrent que des populations thermiques de l'état paramagnétique triplet du dimère peuvent être présentes en petites quantités à 340 K. Par opposition, l'analogue dimère **2** du Zr ne présente pas de données suggérant l'existence d'une dissociation ou d'une population thermique de l'état triplet à des températures allant jusqu'à 340 K.



Mots clés : phosphures de titanium, structures, propriétés magnétiques.

[Traduit par la rédaction]



Introduction

As part of a continuing interest in early–late heterobimetallic (ELHB) complexes (1–11) we and others have recently described a route to monophosphido-bridged, ELHB species employing the Ti(III) or Zr(III) phosphido species $[Cp_2M(\mu\text{-}PR_2)]_2$ as precursors. While the chemistry of the derived ELHB complexes is a subject of ongoing investigations, further development in synthetic strategies to such complexes hinges on a thorough understanding of early metal phosphides.

The preparation of the first zironocene(IV) diphosphide species (**a**) was first reported by Ellerman and Poersch in 1967 (12). However, it was not until the report of Baker *et al.* in 1983 (13), that a complete spectroscopic and structural study of metallocene(IV) diphosphides of the form (**b**), was presented.

a (R =Ph)

b (M = Zr, Hf)
(R = Ph, Cy, Et)

The related Ti(III) and Zr(III) phosphide species were first synthesized in 1966 by Issleib and Hackert (14). Subsequent spectroscopic studies suggested several species were formed in the reactions of phosphides with metallocene dihalides (16, 17). The nature of these ill-characterized species was dependent on the mode of preparation, nature of the phosphide substituents, and temperature of reaction. Furthermore, variations in the magnetic properties of the resultant metallocene–phosphide species appear to depend on how the low-valent precursor was generated. This confusion spurred recent structural studies of the complexes $[Cp_2M(\mu\text{-}PMe_2)]_2$ (M = Ti (17), Zr (18)) in which the dimeric structure originally proposed by Issleib and Hackert was confirmed. In this report, we describe the structure and magnetic properties of the dimeric species $[Cp_2M(\mu\text{-}PEt_2)]_2$ (M = Ti, **1**; Zr, **2**). The magneto-structural relationship is discussed in light of Extended Hückel Molecular Orbital considerations.

Experimental section

General data

All preparations were done under an atmosphere of dry, O_2-free N_2 employing a Vacuum Atmospheres inert atmosphere glove box. Solvents were reagent grade, distilled from the appropriate drying agents under N_2, and degassed by the freeze–thaw method at least three times prior to use. ^1H NMR spectra were recorded on Bruker AC-300 spectrometer operating at 300 MHz. Trace amounts of protonated solvents were used as reference and chemical shifts are reported relative to $SiMe_4$. EPR spectra were recorded on a Varian E-12 EPR spectrometer employing DPPH as reference. Variable temperature magnetic susceptibilities were recorded using an S.H.E. Corporation Variable Temperature Superconducting Magnetometer/Susceptometer located at the Michigan State University, East Lansing, MI. Observed magnetic moments were corrected for TIP, the diamagnetism of the

bucket, and the diamagnetic contributions using Pascal's constants for C, H, and P. Combustion analyses were performed by Galbraith Laboratories Inc. Knoxville, TN, and Schwarzkopf Laboratories, Woodside, NY. Cp_2TiCl_2 and Cp_2ZrCl_2 were purchased from the Aldrich Chemical Co. $LiPEt_2$ was prepared by the literature method (11) from PEt_2H obtained from the Pressure Chemical Co.

Synthesis of $[Cp_2Ti(\mu\text{-}PEt_2)]_2$, ***1***

The compound $[Cp_2Ti(\mu\text{-}PEt_2)]_2$ **1** was prepared by literature method (14). A solution of $LiPEt_2$ (0.158 g, 1.65 mmol) in 10 mL of THF was added dropwise to a suspension of Cp_2TiCl_2 (0.200 g, 0.804 mmol) in 15 mL of THF. After 1 h of stirring the THF was removed under *vacuo* and 20 mL of benzene was added. The solution was filtered and the fitrate was reduced in volume to about 10 mL. Addition of pentane caused precipitation of the purple, cyrstalline product (0.133 g, 62%). *Anal.* calcd for $C_{28}H_{40}P_2Ti_2$: C 62.93, H 7.54; found: C 62.50, H 7.50. ^1H NMR (C_7D_8, δ, ppm, 295 K): 4.73 (s, Cp), 1.13 (br, s, Et). $^{31}P\{^1H\}$ (C_7H_8, δ, ppm, 185 K) 107.3 (s). EPR (C_7H_8, 323 K) $g = 1.979$.

Synthesis of $[Cp_2Zr(\mu\text{-}PEt_2)]_2$, ***2***

A solution of $LiPEt_2$ (0.145 g, 1.51 mmol) in 10 mL of THF was added dropwise to a solution of Cp_2ZrCl_2 (0.200 g, 0.684 mmol) in 15 mL of THF. After 1 h of stirring the THF was removed under *vacuo* and 20 mL of benzene was added. The solution was filtered and the filtrate was reduced in volume to about 10 mL. Addition of pentane caused precipitation of the red–brown, crystalline product (0.050 g, 24%). *Anal.* calcd for $C_{28}H_{40}P_2Zr_2$: C 54.15, H 6.49; found: C 54.00, H 6.50. ^1H NMR (C_7D_8, δ, ppm, 298 K): 4.65 (t, $|J_{P_H}| = 1.2$ Hz, Cp). 1.34 (s, CH_2), 1.33 (s, CH_3). $^{13}C\{^1H\}$ (C_7D_8, δ, ppm, 298 K): 94.3 (s, Cp), 19.8 (s, CH_2), 13.0 (s, CH_3). $^{31}P\{^1H\}$ (C_7H_8, δ, ppm, 298 K) 88.7 (s).

Extended Hückel molecular orbital calculations

Calculations and plotting were done employing the TRIBBL program package (19) operating on a VAX 11/785. Extended Hückel calculations were performed employing the EHT option of TRIBBL. Cartesian coordinates of the model compound $[Cp_2Ti(\mu\text{-}PH_2)]_2$ were derived from the structural data with the appropriate substitution of hydrogen atoms for the alkyl substituents employing PC-MODEL[1].

X-ray data collection and reduction

X-ray quality crystals of **1** were obtained directly from the preparations as described above. The crystals were manipulated and mounted in capillaries in a glove box, thus maintaining a dry, O_2-free environment for each crystal. Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation. The initial orientation matrix was obtained from 15 machine-centered reflections selected from rotation photographs. These data were used to determine the crystal system. Partial rotation photographs around each axis were consistent with monoclinic crystal system. Ultimately, 60 reflections ($20° < -\theta < 25°$) were used to obtain the final lattice parameters and the orientation matrices. Machine parameters, crystal data and data collection parameters are summarized in Table 1. The observed extinctions are consistent with the space group $P2_1/n$. The data set was collected in one shell ($4.5° < 2\theta < 45.0°$) and three standard reflections were recorded every 197 reflections. The intensities of the standards showed no statistically significant change over the duration of the data collection. The data were processed using the SHELX-76 program package on the computing facilities at the University of Windsor. The reflections with $F_o^2 > 3\sigma F_o^2$ were used in the refinement.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (21, 22). The Ti atom positions were determined using direct methods employing SHELX-86. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix, least squares techniques on F, minimizing the function $w(|F_o| - |F_c|)^2$ where the weight, w, is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of refinement all the Ti and P atoms were assigned anisotropic temperature factors. Carbon atoms were described isotropically. Hydrogen atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. In all cases the hydrogen atom contributions were calculated, but not refined. The final values of R and R_w are given in Table 1. The maximum Δ/σ on any of the parameters in the final cycles of the refinement and the location of the largest peaks in the final difference Fourier map calculations are also given in Table 1. The residual electron densities were of no chemical significance. The following data are tabulated: positional parameters (Table 2) and selected bond distances and angles (Table 3). Thermal parameters (Table S1), hydrogen atom parameters (Table S2), bond distances and angles associated with the cyclopentadienyl rings (Table S3) and values of 10 F_o and 10 F_c (Table S4) have been deposited as supplementary material.[2]

Maximum residual (e/Å^3)	0.60
Atom associated	C91

Results and discussion

The known reaction of Cp_2TiCl_2 with $LiPEt_2$ proceeds smoothly, accompanied by the colour changes from red to green to purple (14). The reaction by-product, P_2Et_4 is detected by $^{31}P\{^1H\}$ NMR, and can be removed under *vacuo*. Extraction of the remaining crude products into benzene affords an effective separation of the product **1** from LiCl affording **1** in reasonable yield (62%). The ^1H NMR spectrum of this product at ambient

temperature was consistent with the presence of cyclopentadienyl groups and resonances attributable to the ethyl moieties. Although the broadness of the observed resonances suggested the presence of paramagnetic centers, **1** was EPR silent at 298 K. In previous reports in which Cp_2TiCl_2 had been reduced in the presence of phosphide, the product was formulated as a diamagnetic dimer, $[Cp_2Ti(\mu\text{-}PR_2)]_2$ (14–16). Combustion analyses were consistent with the empirical formula Cp_2TiPEt_2 for **1**. The dimeric formulation, that is $[Cp_2Ti(\mu\text{-}PEt_2)]_2$ for **1** was confirmed by a X-ray structural study (*vide infra*).

In a similar fashion, the analogous zirconium reaction was performed. The colorless solution of Cp_2ZrCl_2 gradually became intense red in color with the addition of $LiPEt_2$. Following a work-up procedure similar to that used for **1**, the red–brown product **2** was isolated. The ^1H and $^{13}C\{^1H\}$ NMR spectra of **2** show resonances attributable to cyclopentadienyl groups and the ethyl moieties. The $^{31}P\{^1H\}$ NMR shows a single resonance at 88.7 ppm. Preliminary X-ray experiments[3] showed that crystals of **2** were isomorphous with those of **1**, suggesting that **2** is indeed isostructural to **1**. However, the poor quality of the crystals precluded a full structural study. These data and the results of combustion analyses are consistent with the formulation of **2** as $[Cp_2Zr(\mu\text{-}PEt_2)]_2$.

Structural study of **1**

The crystallographic study of **1** shows that the compound crystallizes in the monoclinic space group $P2_1/n$ with two discrete dimeric molecules per asymmetric unit. The closest approach between the dimers is 2.590 Å (H74...H1A). ORTEP drawings of the two molecules are shown in Fig. 1. Selected bond distances and angles are given in Table 3. The coordination sphere of the Ti atoms are best described as pseudo-tetrahedral, being comprised of two π-bonded cyclopentadienyl groups and two bridging, diethylphosphide moieties. The Ti—C, C—C and P—C bond distances are typical (11, 17, 24–34).

The Ti_2P_2 cores of the crystallographically independent molecules are essentially planar. The Ti—P distances, which range from 2,606(3)–2.631(3) Å, are similar to those reported for $[Cp_2Ti(\mu\text{-}PMe_2)]_2$ (17). The Ti—P distances are slightly shorter than the Zr—P distances found in $[Cp_2Zr(\mu\text{-}PMe_2)]_2$ (18), consistent with smaller covalent radius of Ti. The P—Ti—P angles in **1** were found to be 89.1(1) to 89.8(1)°. This is substantially smaller than the X—Ti—X angles found for related d^0 derivatives. For example, the S—Ti—S angle in $Cp_2Ti(SMe)_2$ is 93.7(1)° (25), while the P—Hf—P angle in $Cp_2Hf(PEt_2)_2$ is 98.64(3)° (13). The smaller angle observed for d^1 metallocene species has been explained in terms of the occupation of the $1a_1$ metal-based molecular orbital (27, 35).

[3]Repeated attempts to obtain crystals of $[Cp_2Zr(\mu\text{-}PEt_2)]_2$ **2** yielded only thin, plate-like crystals which were not of suitable quality for diffraction data collection. In the best case a twinned crystal was examined. The compound was found to crystallize in a monoclinic crystal system with a = 37.58(2) Å, b = 16.776(5) Å, c = 8.813(6) Å, β = 90.67(6)°, V = 5432(4) Å^3. Although this is isomorphorous to **1**, the poor crystal quality precluded further study.

The Ti—P—Ti′ angles in **1** were found to be between 90.2(1) and 90.8(1)°. In contrast to those found for **1**, the P—Ti—P and Ti—P—Ti′ angles in $[Cp_2Ti(\mu\text{-}PMe_2)]_2$ were found to average 83.3(1) and 96.5(1)°, respectively. In the analogous Zr complex (18) $[Cp_2Zr(\mu\text{-}PMe_2)]_2$, the P—Zr—P angle is 93.8(1)° while the Zr—P—Zr angle is 86.3(1)°. The differences in the angles about the respective M_2P_2 cores give rise to differing metal–metal distances. In **1**, the Ti...Ti average 3.719(1) Å while the corresponding distance in $[Cp_2M(\mu\text{-}PMe_2)]_2$ is 3.918(1) Å for M = Ti (17) and 3.653(1) Å for M = Zr (18). The substantial difference in Ti_2P_2 core geometry and metal–metal separations in **1** and $[Cp_2Ti(\mu\text{-}PMe_2)]_2$ may be attributed to steric interaction between the ethyl substituents on phosphorus and the cyclopentadienyl rings in **1**. This explanation is consistent with the observation of close approaches between the methylene protons of the ethyl moieties and the cyclopentadienyl groups ranging between 2.000 and 2.248 Å in **1**.

Solid state magnetic properties

X-ray quality crystals of **1** were used in all of the magnetic and spectroscopic studies described below. The magnetic susceptibility of a bulk sample of **1** was determined over the temperature range of 5–350 K (Fig. 2) employing a susceptometer. The magnetic data indicate that the sample is essentially diamagnetic with the amount of paramagnetic impurities confined to less than 0.4%. These data imply that antiferromagnetic coupling between the single electrons on the Ti centres in **1** is strong. This is consistent with the slight increase in magnetic moment at 340 K which may forecast the onset of a Curie transition at higher temperatures. However, no evidence for

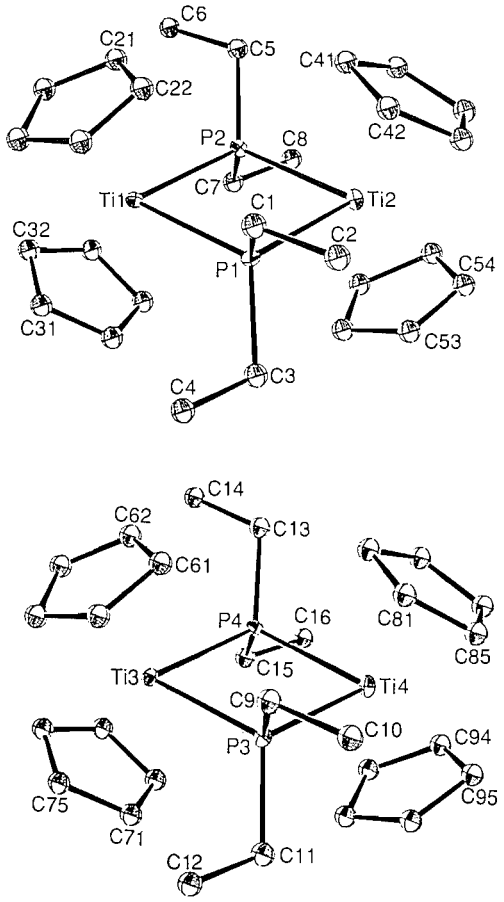

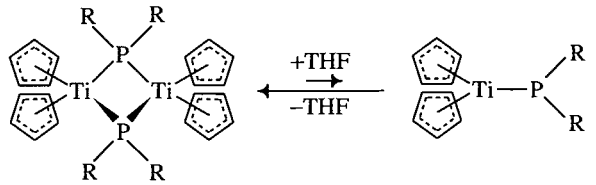

FIG. 1. ORTEP drawing of molecule **1**, 20% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity but are numbered such that the hydrogen atom numbers correspond to those of the carbon atoms to which they are bonded.

such a transition was obtained as the magnetic fields generated by this instrument are unstable at temperatures above 350° K, although the compound appears thermally stable in the absence of oxygen or moisture to at least 453 K. Based on the present data, an estimate of the coupling constant (J) is, at least, $-300\ cm^{-1}$. These observations are in contrast to those seen for $[Cp_2Ti(\mu\text{-}Cl)]_2$ and $[(MeCp)_2Ti(\mu\text{-}X)]_2$, X = Cl, Br, which exhibit typical antiferromagnetic coupling with Curie temperatures ranging from approximately 140 to 220 K and J values of -111, -160, and $-138\ cm^{-1}$ respectively (36).

A variable temperature, solid state EPR study of **1** showed a resonance at $g = 1.979$ at 350 K. In addition, a weak, half field transition is observed. The intensity of these peaks increases with increasing temperature and the generation of these signals is completely reversible with temperature. The temperature dependence and lack of an EPR signal at 298 K preclude assignment of the observed signals to paramagnetic impurities. Rather, these data suggest the thermal population of the triplet state ($S = 1$) of **1**. However, as mentioned above, the limitations of the apparatus preclude the confirmation of this postulate by high temperature magnetic measurements.

Solution magnetic properties

^1H NMR spectra of the product **1** in THF show resonances at 298 K that are attributable to cyclopentadienyl and ethyl protons, however the signals were observed to be comparatively broad. On cooling to 250 K the spectral lines sharpen and the cyclopentadienyl resonance shifts upfield (Fig. 3). In a similar vien, no $^{31}P\{^1H\}$ NMR signal was observed at 298 K; however, at 223 K a resonance with a linewidth at half height of 1000 Hz was observed at 107.3 ppm. On further cooling to 185 K the line sharpens dramatically to give a linewidth at half height of 110 Hz. These data are consistent with the generation of low concentrations of paramagnetic species with increasing temperature. Variable temperature, EPR studies were also undertaken (Fig. 3). At 298 K in THF, essentially no EPR signal is observed. Two EPR signals are seen on warming. The generation of these signals is reversible with temperature. A doublet at $g = 1.983$ with an $<a,^{31}P>$ value of 33.4 G is observed. This signal is assigned to the mononuclear species Cp_2TiPEt_2, **3**, which is easily generated by dimer dissociation. The formulation of the solvated mononuclear species is further supported by isolation and crystallographic study of the PMe_3 adduct, $Cp_2Ti(PPh_2)(PMe_3)$ (38). The concentration of **3** grows with increasing temperature and is the predominant paramagnetic species in solution at 373 K (eq. [3]). In addition, a singlet resonance at $g = 1.979$ is observed. The g value is identical to that observed in the high temperature solid state EPR spectrum of **1**. Although unconfirmed, this signal is tentatively assigned to the triplet state of **1**. Hyperfine coupling to the phosphorus nuclei is expected but not observed. This may arise as both broader line widths and substantially smaller hyperfine coupling constants are predicted for triplet state dimers (37).

1 **3**

The related Zr species **2** is diamagnetic at 298 K. The sharp lines in the ^1H and $^{31}P\{^1H\}$ NMR spectra show no change in the linewidth of the ^1H NMR resonance attributable to the cyclopentadienyl protons with increasing temperature to 373 K. Thus, unlike the Ti analog, no evidence of either the singlet–triplet or dimer–monomer equilibria is observed.

Bonding considerations

Extended Hückel Molecular Orbital calculations for the model system $[Cp_2Ti(\mu\text{-}PH_2)]_2$ shed some light on the mechanism of the antiferromagnetic coupling between the Ti centers in the dimer **1**. The results of these calculations can be interpreted by considering the frontier orbitals of the phosphide and titanocene fragments. Frontier orbitals for bent metallocenes have been discussed in detail by Hoffman and Lauher (35). Single crystal EPR studies (20), as well as theoretical considerations have shown that for mononuclear paramagnetic metallocene derivatives, the unpaired electron occupies the $1a_1$ metal fragment orbital. Mixing of these $1a_1$ metal fragment orbitals with the p_z orbitals in the bridging phosphorus atoms provides a route for through-ligand coupling of the unpaired electrons on the Ti centres (Fig. 4). This mechanism may explain the observed diamagnetism for **1** and $[Cp_2M(\mu\text{-}PMe_2)]_2$; however, it is surprising that strong antiferromagnetic coupling persists in spite of the substantial differences in the geometries of the M_2P_2 cores. An alternative explanation has been recently offered, in which the notion of a "super-long" bonds has been invoked to explain the diamagnetism of analogous Zr phosphido-bridged dimers (23). Further insight into the subtleties of the magneto-

structural relationships in these and related d^1 metal dimers awaits the acquisition of additional structural and high temperature, magnetic susceptibility data.

Summary

The dimers $[Cp_2M(\mu\text{-}PR_2)]_2$ (M = Ti, Zr) are diamagnetic at room temperature. The magnetic and structural data for the species $[Cp_2Ti(\mu\text{-}PEt_2)]_2$, **1**, have been examined in detail. Antiferromagnetic coupling is attributed to a through ligand mechanism involving a molecular orbital with both metal $1a_1$ and phosphorus *p* orbital character. The solid state susceptibility, EPR, and NMR data are consistent with dissociation of the dimer **1** to a mononuclear titanocene phosphide species. In addition, the possibility of thermal population of the triplet state of **1** is suggested. In contrast, the Zr dimer shows no evidence of thermal dissociation or population of a triplet state.

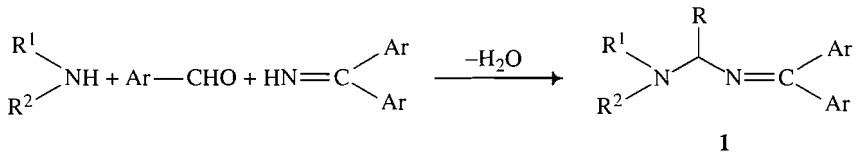
ALAN R. KATRITZKY, JINLONG JIANG, and PHILIP A. HARRIS. Can. J. Chem. **69**, 1153 (1991).

α-(Arylideneamino)alkylamines **4** are prepared in high yields by the reaction of 1-(benzotriazol-1-yl)-*N*-triphenylphosphorylidenemethylamine (betmip) **2** with lithium amides and treatment of the resulting intermediates **3** with aryl aldehydes.

Key words: benzotriazole, lithium amides, aryl aldehydes.

ALAN R. KATRITZKY, JINLONG JIANG et PHILIP A. HARRIS. Can. J. Chem. **69**, 1153 (1991).



On a préparé des α-(arylidèneamino)alkylamines **4** avec de bons rendements en faisant réagir la 1-(benzotriazol-1-yl)-*N*-triphénylphosphorylidèneméthylamine (betmip) **2** avec des amidures de lithium, puis en traitant les intermédiaires **3** avec des aldéhydes aromatiques.

Mots clés : benzotriazole, amidures de lithium, aldéhydes aromatiques.

[Traduit par la rédaction]

Introduction

Although alkyl diamines (aminals) are well-documented compounds, the corresponding unsaturated α-(diarylideneamino)alkylamines **1** have only been mentioned once in the literature in a report (1) outlining their preparation by a Mannich condensation between diarylketimines, secondary amines, and formaldehyde or aryl aldehydes (see Scheme 1). Diarylketimines require drastic conditions for their preparation, such as the use of sealed tubes at high temperature (2) or the use of molten ketones (3). Other imines with hydrogens on the nitrogen atoms spontaneously polymerize (4).

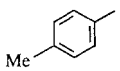

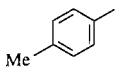

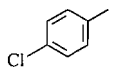

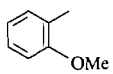

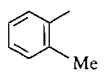

SCHEME 1

Results and discussion

1-(Benzotriazol-1-yl)-*N*-triphenylphosphorylidenemethylamine (betmip) **2** is a new reagent developed in our laboratory. Previously we demonstrated the usefulness of **2** in the novel synthesis of primary amines (5), 1,4,5-trisubstituted imidazoles (6), and in the preparation of carbodimides, imines, isothiocyanates, aziridines, and secondary amines (7). We now report a new route to α-(arylideneamino)alkylamines **4** via nucleophilic displacement of the benzotriazole moiety from **2** with lithium amides, and condensation of the resulting phosphazene intermediates **3** with aryl aldehydes (see Scheme 2).

The reaction can be carried out in one pot, without isolation of **3**, and the work-up and isolation procedures are straightforward. After removal of the benzotriazole lithium salt by filtration, the products were separated from the triphenylphosphine oxide side product by distillation. Mass spectrometric analysis (Table 1) of the products showed characteristic peaks resulting from the molecular ion and two fragmentation ions resulting from cleavage of both CH_2—N bonds. The ^{1}H (Table 2) and ^{13}C NMR (Table 3) spectra displayed distinctive signals due to the methylene CH_2 and imino CH=N groups.

In summary, our new method for the preparation of α-(arylideneamino)alkylamines **4** from 1-(benzotriazol-1-yl)-*N*-triphenylphosphorylidenemethylamine **2** offers a new convenient route to this novel class of compounds. Compounds of type

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

4 extend the range of aminal functionality, and offer interesting potential substrates for studies of physiological activity, of conformation, and of basicity. The reagent **2** can be readily prepared from benzotriazole in four steps on a large scale and high overall yield (7). It should be noted that attempts at extending this reaction to the use of enolizable aldehydes resulted only in aldol condensation products.

Experimental

^{1}H and ^{13}C NMR spectra were recorded on a Varian VXR 300 MHz spectrometer in $CDCl_3$ using TMS as an internal reference for ^{1}H spectra and $CDCl_3$ for ^{13}C NMR spectra (abbreviations used: s singlet; d doublet; m multiplet). Mass spectra were recorded at 70 eV on an AEI MS-30 mass spectrometer.

Tetrahydrofuran (THF) was dried by distillation from sodium benzophenone ketyl. 1-(Benzotriazol-1-yl)-*N*-triphenylphosphorylidenemethylamine (betmip) **2** (mp 99–101°C) was prepared by the procedure (7) developed in these laboratories.

General procedure for the preparation of α-(arylideneamino)alkylamines ***4***

Butyllithium (5.6 mL, 14 mmol, 2.5 M solution in hexanes) was added to a stirred solution of the secondary amine (14 mmol) in THF (50 mL) at −78°C under argon. A solution of betmip **2** (6.5 g, 16 mmol) in THF (30 mL) was added and stirring continued at room temperature for 20 h during which time a precipitate appeared. The aldehyde (14 mmol) in THF (15 mL) was added and the resulting solution stirred for a further 15 h. After removal of the THF under reduced pressure, the crude product was dissolved in anhydrous ethyl ether and the insoluble by-products filtered off. The solid by-products were washed several times with ether, the ether portions combined, and the ether removed to give the product as an oil. Distillation under vacuum gave the pure α-(arylideneamino)alkylamines **4**.

Cycloaddition d'ylures d'azométhine dérivés de la 3,4-dihydro-6,7-diméthoxy-3-méthoxycarbonyl-isoquinoléine

TAHAR LAKHLIFI, AHMED SEDQUI, BERNARD LAUDE,[1] NGUYEN DINH AN ET JOËL VEBREL

Laboratoire de chimie organique, Université de Franche-Comté, La Bouloie, 16 route de Gray, 25030 Besancon CEDEX, France

Reçu le 26 novembre 1990

TAHAR LAKHLIFI, AHMED SEDQUI, BERNARD LAUDE, NGUYEN DINH AN et JOËL VEBREL. Can. J. Chem. **69**, 1156 (1991).

La synthèse de trois précurseurs d'ylures d'azométhine comportant le squelette de la 3,4-dihydro-6,7-diméthoxy-3-isoquinoléine est décrite. Ces produits à caractère dipolaire réagissent avec des dipolarophiles éthyléniques activés pour donner diastéréospécifiquement des dérivés du 4′,5′-diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonylcyclohept-1-ène. Les paramètres de résonance magnétique protonique permettent de déterminer la stéréochimie des cycloadduits.

Mots clés : ylures d'azométhine cycliques, composés azabicycliques, stéréochimie.

TAHAR LAKHLIFI, AHMED SEDQUI, BERNARD LAUDE, NGUYEN DINH AN, and JOËL VEBREL. Can. J. Chem. **69**, 1156 (1991).

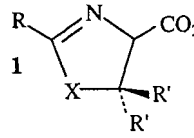
Three azomethine ylide precursors including the methyl 3,4-dihydro-6,7-dimethoxyisoquinoline-3carboxylate moiety were synthesized. The 1,3-dipolar species formed from these products react with activated dipolarophilic olefines leading diastereospecifically to derivatives of 4′,5′-dimethoxy-1,2-benzo-4,7-imino-4-methoxycarbonyl-1-cycloheptene. Proton magnetic resonance data allowed the determination of the stereochemistry of the cycloadducts.

Key words: cyclic azomethine ylide, azabicyclic compounds, stereochemistry.

Introduction

Les réactions de cycloaddition dipolaire-1,3 des ylures d'azométhine constituent une voie d'accès bien connue aux pyrrolines et pyrrolidines (1). L'espèce ylure d'azométhine peut aussi être insérée dans divers composés cycliques mésoioniques (2). En relation avec ces derniers, il faut signaler l'importante contribution de R. Huisgen et collaborateurs (3) à propos de l'utilisation des Δ-2-oxazolin-5-ones.

Plus récemment, la réactivité dipolaire-1,3 des imines d'α-aminoesters a été mise en évidence simultanément par Joucla et Hamelin (4) et l'équipe de Grigg (5). Cette réactivité a été par la suite largement étudiée par Grigg et collaborateurs (6). À notre connaissance, des imines cycliques dérivés d'α-aminoesters **1** (figure 1) ne sont signalées comme précurseurs d'ylures d'azométhine que dans deux publications des précédents auteurs (7, 8). Les espèces dipolaires dérivées d'imines cycliques alkyloxycarbonylées du type **1** permettent d'accéder à des composés azabicycliques pontés.



Par ailleurs, Kametani *et al.* (9) ont récemment décrit une synthèse totale de la (−)xylopinine à l'aide de dérivés de la (3*S*)3,4-dihydroisoquinoléine **2** (figure 2) optiquement active, préparés à partir de la L-DOPA selon la méthode de Schrecker et Hartwell (10).

Ces composés **2** sont à l'évidence des précurseurs d'ylures d'azométhine cycliques hexagonaux benzocondensés et nous avons décidé de tester leur réactivité en cycloaddition dipolaire-1,3 vis-à-vis de quelques dipolarophiles éthyléniques. Il n'était pas nécessaire d'utiliser un énantiomère du produit **2** puisque la forme dipolaire en fait disparaître la chiralité et nous avons donc travaillé en série racémique.

Synthèse des précurseurs d'ylures d'azométhine dérivés de la 3,4-dihydro-6,7-diméthoxy-3-méthoxycarbonyl-isoquinoléine *2*

Après avoir exploré diverses voies de synthèse, nous avons retenu et adapté celle décrite par Leonard (11) concernant la préparation de dérivés du 3,4-dihydro-2*H*-pyrrole (figure 2).

Le bromure de 3,4-diméthoxybenzyle est condensé avec un

1*a* R = H, X = S, R' = Me (7)
1*b* R = Ph, X = CH_2, R' = H (8)
1*c* R = Ph, X = $(CH_2)_2$, R' = H (8)

FIG. 1.

acylaminomalonate de diéthyle en présence d'hydrure de sodium dans le DMSO. Les 2-(3,4-diméthoxybenzyl)-2-acylaminomalonates de diéthyle **3** obtenus sont ensuite cyclisés en dérivés du 6,7-diméthoxy-3,4-dihydroisoquinoléine-3,3-dicarboxylate de diéthyle **4** par action de $POCl_3$. La dernière étape s'effectue par transformation du diester diéthylique en monoester méthylique. Dans le cas du produit **4***a* (R = H), on met en oeuvre une hydrolyse acide pour éviter la déshydrogénation du monoacide intermédiaire très rapide en milieu basique. Par contre, la saponification des produits **4***b* et **4***c* (R ≠ H) reste possible et elle est plus rapide que l'hydrolyse acide.

La purification des trois composés **2***a*–*c* doit être faite soigneusement pour éviter leur aromatisation très facile (cf. partie expérimentale). Les énantiomères de configuration absolue (*S*) des imines **2***a* et **2***b* préparés à partir de la L-DOPA par Kametani *et al.* (9) étaient mis en oeuvre à l'état brut (**2***b*(*S*)) ou sous forme de chlorhydrate (**2***a*(*S*), HCl). Seuls les paramètres de résonance magnétique protonique de ce dernier étaient décrits et sans que soient mentionnés ceux du proton H-3 (9).

Réactions de cycloaddition

Elles ont toutes été effectuées en solution dans le toluène et selon le cas soit en tube scellé, soit au reflux du solvant. Dans ces conditions, seuls trois dipolarophiles se sont révélés suffisamment réactifs : les *N*-méthyl et *N*-phénylmaléimide et le fumarate de diméthyle. Les rendements varient de 50 à 70%. D'autres substrats tels que les esters maléique, acrylique et benzylidènemalonique n'ont pas permis d'accéder au cycloadduit : on n'isole que le produit d'aromatisation du précurseur du produit dipolaire. Il se forme également à raison de 20% lors des réactions avec le fumarate de diméthyle et pour plus de 80% lors de l'action du composé **2***b* (R = CH_3) sur le *N*-méthylmaléimide et dans ce cas nous n'avons pas réussi à isoler le cycloadduit correspondant.

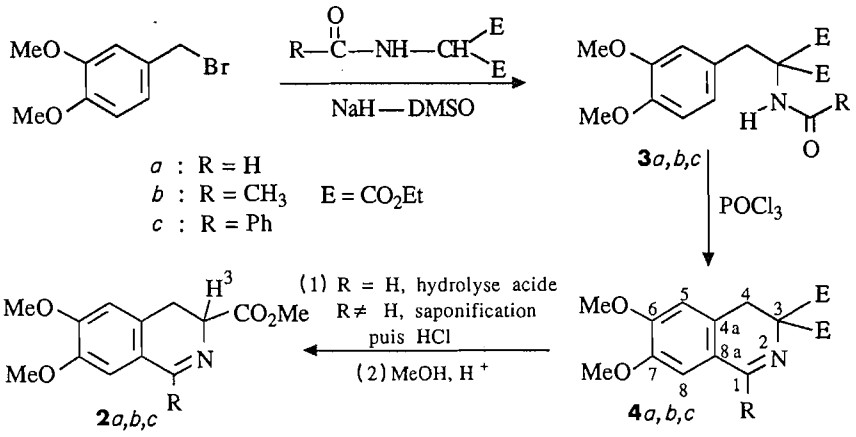

FIG. 2.

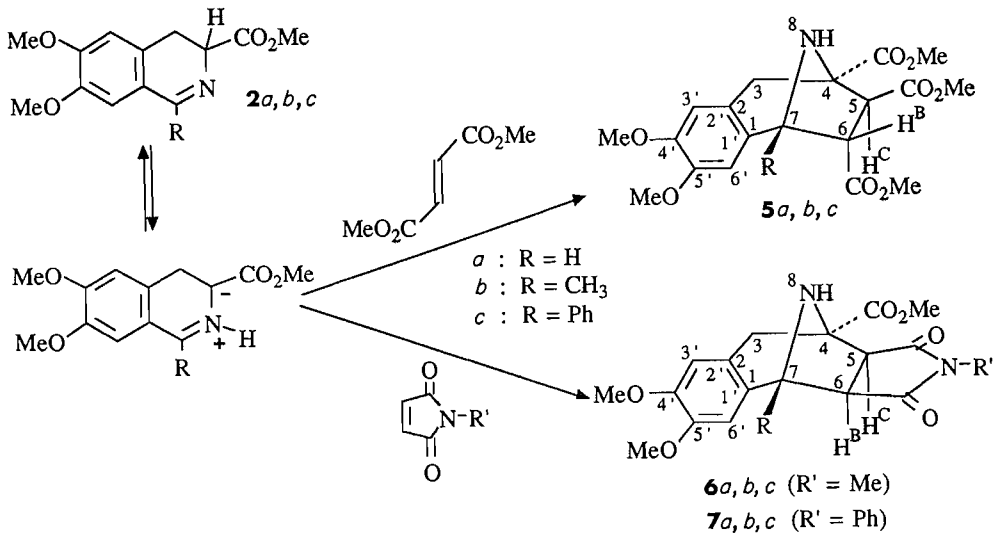

FIG. 3.

Toutes les réactions de cycloaddition sont diastéréospécifiques et les produits obtenus à partir de l'imine **2***a* (R = H) nous ont permis de statuer sans ambiguïté sur la stéréochimie de la réaction avec chaque dipolarophile (figure 3).

L'examen des spectres de résonance magnétique protonique des cycloadduits **5***a*, **6***a* et **7***a* (R = H^A) permet d'observer des signaux en accord avec les structures proposées (12). Ainsi dans le cas du produit **5***a* le proton H^A se manifeste sous forme d'un doublet (δ = 4,61 ppm, $J_{H^A-H^B}$ = 5,90 Hz) ce qui implique que le proton H^B (dd, δ = 3,70 ppm, $J_{H^A-H^B}$ = 5,90 Hz, $J_{H^B-H^C}$ = 7,30 Hz) est en position *exo*. D'autre part, l'inexistence d'un couplage entre H^A et H^B sur les spectres de résonance magnétique protonique des produits **6***a* et **7***a* prouve que l'approche entre les réactifs conduit exclusivement aux cycloadduits comportant le reste maléimido en *exo*. Il est raisonnable de penser que cette stéréochimie peut être valablement étendue aux cas des autres cycloadduits (R ≠ H) qui sont des dérivés du 4′,5′-diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonylcyclohept-1-ène.

Il nous a semblé intéressant de comparer le cours stéréochimique de nos réactions avec les maléimides avec celui décrit dans un travail antérieur par Lown et Matsumoto (13). Ces auteurs ont établi, à partir des paramètres de résonance magnétique protonique, la structure du cycloadduit **9** issu de la réaction de l'ylure d'azométhine cyclique benzocondensé **8** avec le *N*-phénylmaléimide (figure 4).

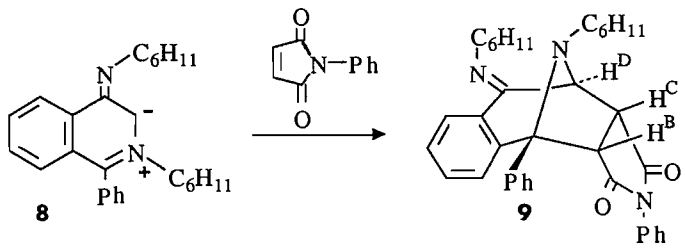

FIG. 4.

Cette stéréochimie *endo* ($J_{H^D-H^C}$ = 9 Hz) pour le reste *N*-phénylmaléimido est contraire à celle que nous avons établie pour les structures **6** et **7**. Mais cette contradiction apparente peut être levée en invoquant l'encombrement stérique dû au reste cyclohexyle fixé sur l'azote ponté de **9**. Ce groupement est suffisamment encombrant pour imposer à la réaction de cycloaddition une stéréochimie conduisant au cycloadduit le moins encombré.

Conclusion

Nous avons donc réussi à mener à bien une synthèse de trois précurseurs d'ylures d'azométhine comportant le squelette de la 3,4-dihydro-6,7-diméthoxyisoquinoléine présent dans de nombreux composés naturels. Ces produits à caractère dipolaire réagissent

avec des dipolarophiles éthyléniques très activés pour donner diastéréospécifiquement des dérivés du 4′,5′-diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonylcyclohept-1-ène.

Partie expérimentale

Les points de fusion déterminés sur banc Kofler ne sont pas corrigés. Les spectres d'absorption ir ont été obtenus avec un spectrophotomètre Beckman IR 33, les produits étant pastillés dans KBr. Les spectres de rmn protonique ont été obtenus avec un spectromètre Bruker-Spectrospin AC 200, les échantillons étant dissous dans $CDCl_3$ avec le tétraméthylsilane comme référence interne. Les microanalyses ont été assurées par le Service d'Analyses du CNRS à Vernaison.

Le benzamidomalonate de diéthyle est préparé selon la méthode de Leonard (11). Toutes les autres matières premières sont des produits commerciaux.

1. Bromure de 3,4-diméthoxybenzyle

À une solution refroidie à 0°C de 0,1 mol (16,82 g) d'alcool 3,4-diméthoxybenzylique dans 90 mL de benzène anhydre, on additionne goutte à goutte 15 mL de tribromure de phosphore. Après addition, le mélange réactionnel est agité pendant 2 h à température ambiante, versé sur de la glace et décanté. La solution aqueuse est extraite au benzène et les phases organiques sont rassemblées, lavées à l'eau et séchées sur sulfate de sodium. Après filtration et évaporation du benzène, le solide résiduel est recristallisé dans de l'éthanol absolu. On obtient 21,25 g (Rdt. 92%) de bromure de 3,4-diméthoxybenzyle, *F* 52–53°C; rmn ^{1}H, δ : 3,86 (s, 3H, OCH_3), 3,90 (s, 3H, OCH_3), 4,50 (s, 2H, CH_2), 6,24–7,06 (m, 3H).

*2. 2-(3,4-Diméthoxybenzyl)-2-acylaminomalonates de diéthyle (**3**)*

Mode opératoire général : Dans un Erlenmeyer bicol de 250 mL, on introduit sous courant d'azote sec, 1,20 g de NaH (à 80% dans l'huile minérale) et 20 mL de DMSO anhydre. À la suspension agitée magnétiquement, on ajoute goutte à goutte en 1 h une solution de 0,04 mol d'acylaminomalonate de diéthyle dans 60 mL de DMSO anhydre. On additionne ensuite lentement une solution de 0,04 mol (9,25 g) de bromure de 3,4-diméthoxybenzyle dans 40 mL de DMSO anhydre. La solution est maintenue sous agitation pendant 12 h à température ambiante puis versée sur de la glace. On extrait au chloroforme et lave plusieurs fois la phase organique à l'eau salée. Après séchage sur Na_2SO_4 et évaporation du solvant, l'huile résiduelle est reprise par un mélange hexane–propanol (3 : 1). Le solide cristallisé est ensuite filtré et essoré. Chacun des dérivés **3***a–c* est décrit ci-après :

*2-(3,4-Diméthoxybenzyl)-2-formamidomalonate de diéthyle (**3**a)*

On obtient 11,3 g de produit (Rdt. 80%), *F* 92–93°C; ir, ν_{max} : 3360 (NH), 1740 (ester), 1660 (amide); rmn ^{1}H, δ : 1,32 (t, 6H, *J* = 7,00 Hz), 3,65 (s, 2H)), 3,86 (s, 3H, OCH_3), 3,89 (s, 3H, OCH_3), 4,27 (q, 2H, *J* = 7,00 Hz), 4,30 (q, 2H, *J* = 7,00 Hz), 6,89 (sl, 1H, NH), 8,21 (d, 1H, *J* = 1,2 Hz, CHO), 6,50–6,80 (m, 3H). Anal. calc. pour $C_{17}H_{23}NO_7$: C 57,76, H 6,56, N 3,96; tr. : C 57,92, H 6,43, N 3,82.

*2-(3,4-Diméthoxybenzyl)-2-acétamidomalonate de diéthyle (**3**b)*

On obtient 12 g de produit (Rdt. 82%), *F* 81–82°C; ir, ν_{max} : 3280 (NH), 1745 (ester), 1640 (amide); rmn ^{1}H, δ : 1,31 (t, 6H, *J* = 7,00 Hz), 2,00 (s, 3H, R = CH_3), 3,64 (s,2H), 3,81 (s, 3H, OCH_3), 3,84 (s, 3H, OCH_3), 4,25 (q, 2H, *J* = 7,00 Hz), 4,28 (q, 2H, *J* = 7,00 Hz), 6,40 (sl, 1H, NH), 6,45–6,80 (m, 3H). Anal. calc. pour $C_{18}H_{25}NO_7$: C 58,82, H 6,86, N 3,81; tr. : C 58,94, H 6,67, N 3,76.

*2-(3,4-Diméthoxybenzyl)-2-benzamidomalonate de diéthyle (**3**c)*

On obtient 12,2 g de produit (Rdt. 71%), *F* 116–117°C; ir, ν_{max} : 3430 (NH), 1730 et 1750 (ester), 1660 (amide); rmn ^{1}H, δ : 1,32 (t, 6H, *J* = 7,00 Hz), 3,58 (s, 3H, OCH_3), 3,72 (s, 2H), 3,84 (s, 3H, OCH_3), 4,30 (q, 2H *J* = 7,00 Hz), 4,33 (q, 2H, *J* = 7,00 Hz), 7,30 (sl, 1H, NH), 6,50–6,75 (m, 3H), 7,40–7,80 (m, 5H). Anal. calc. pour $C_{23}H_{27}NO_7$: C 64,30, H 6,34, N 3,26; tr. : C 64,12, H 6,42, N 3,37.

*3. Dérivés du 6,7-diméthoxy-3,4-dihydroisoquinoléine-3,3-dicarboxylate de diéthyle (**4**)*

Mode opératoire général : Dans un Erlenmeyer de 100 mL, on place 0,01 mol de composé **3** dans 40 mL d'acétonitrile dans le cas de **3***a* ou **3***b* et dans 40 mL de xylène dans le cas de **3***c*. On ajoute à cette solution 5 mL de $POCl_3$ fraîchement distillé. On maintient ensuite à ébullition et sous agitation magnétique durant un temps variable (5 h pour **4***a* : R = H, 16 h pour **4***b* : R = CH_3 et 72 h pour **4***c* : R = C_6H_5). Après refroidissement, on dilue avec 100 mL de chloroforme (dans le cas de **4***a* et **4***b*) ou de benzène (dans le cas de **4***c*) et 50 mL d'eau puis alcalinise par du carbonate de sodium. Les deux phases sont séparées et la phase organique est lavée à l'eau salée et séchée sur sulfate de sodium anhydre. Après filtration et évaporation des solvants, le residu est repris par un mélange hexane–isopropanol (3 : 1). Le produit cristallisé est filtré et essoré. Chaque dérivé **4***a,b,c* est décrit ci-après :

*6,7-Diméthoxy-3,4-dihydroisoquinoléine-3,3-dicarboxylate de diéthyle (**4**a)*

On obtient 2,7 g de produit (Rdt. 81%), *F* 106–107°C; ir, ν_{max} : 1735 (ester); rmn ^{1}H, δ : 1,25 (t, 6H, *J* = 7,10 Hz), 3,34 (s, 2H, CH_2-4), 3,90 (s, 3H, OCH_3), 3,93 (s, 3H, OCH_3), 4,25 (4H, partie AB d'un système ABX_3, J_{AB} = 14,50 Hz), 6,73 (s, 1H, H–5), 6,90 (s, 1H, H–8), 8,42 (s, 1H, H–1). Anal. calc. pour $C_{17}H_{21}NO_6$: C 60,86, H 6,31, N 4,18; tr. : C 60,72, H 6,52, N 4,25.

*6,7-Diméthoxy-1-méthyl-3,4-dihydroisquinoléine-3,3-dicarboxylate de diéthyle (**4**b)*

On obtient 2,35 g de produit (Rdt. 67%), *F* 109–110°C; ir, ν_{max} : 1740 (ester); rmn ^{1}H, δ : 1,25 (t, 6H, *J* = 7,15 Hz), 2,54 (s, 3H, CH_3), 3,30 (s, 2H, CH_2-4), 3,90 (s, 3H, OCH_3), 3,93 (s, 3H, OCH_3), 4,22 (4H, partie AB d'un système ABX_3, J_{AB} = 13,50 Hz), 6,73 (s, 1H, H–5), 7,07 (s, 1H, H–8). Anal. calc. pour $C_{18}H_{23}NO_6$: C61,86, H 6,63, N 4,01; tr. : C 62,03, H 6,52, N 3,93.

*6,7-Diméthoxy-1-phényl-3,4-dihydroisoquinoléine-3,3-dicarboxylate de diéthyle (**4**c)*

On obtient 2 g de produit (Rdt. 48%), *F* 94–96°C; ir, ν_{max} : 1740 (ester); rmn ^{1}H, δ : 1,21 (t, 6H, *J* = 7,10 Hz), 3,38 (s,2H, CH_2-4), 3,70 (s, 3H, OCH_3), 3,93 (s, 3H, OCH_3), 4,20 (4H, partie AB d'un système ABX_3, J_{AB} = 14,40 Hz), 6,76 (s,1H, H-5), 6,79 (s, 1H, H-8), 7,42–7,51 (m, 5H). Anal. calc. pour $C_{23}H_{25}NO_6$: C 67,12, H 6,13, N 3,40; tr. : C 67,31, H 6,02, N 3,28.

*4. Dérivés du 6,7-diméthoxy-3,4-dihydroisoquinoléine-3-carboxylate de méthyle (**2**)*

(a) Hydrolyse acide par HCl 6 N (R = H) : 0,01 mol de diester **4***a* dans 40 mL de HCl 6 N sont portés à reflux pendant 6 h.

(b) Saponification par KOH 2 N (R = CH_3, Ph) : 0,01 mol de diester **4***b* ou **4***c* sont dissous dans 40 mL d'une solution méthanolique de potasse 2 N. La solution obtenue est portée à reflux pendant 2 h sous agitation magnétique. Le solvant est évaporé et le résidu repris par 50 mL de HCl 2 N.

(c) Traitement commun : La solution acide obtenue est lavée deux fois au chloroforme et décantée. La phase aqueuse est évaporée sous vide de la trompe à eau, le résidu est repris par du benzène et évaporé. On recommence trois fois cette opération puis reprend le résidu par 40 mL de méthanol absolu et 1 mL d'acide sulfurique concentré. Le mélange réactionnel est porté à reflux pendant 2 h puis le méthanol est éliminé par évaporation. L'huile résiduelle est reprise par de l'eau et le mélange

neutralisé par addition de petites quantités de carbonate de sodium en veillant à ne pas dépasser la valeur 7 du pH. On extrait alors au chloroforme, lave la phase organique par de l'eau salée et sèche sur Na_2SO_4 anhydre. Le solvant est évaporé sous courant d'azote et le résidu repris sans chauffer par un mélange d'hexane et de propanol (4 : 1). Les produits **2** cristallisés sont essorés et chacun d'entre eux est décrit ci-après :

6,7-Diméthoxy-3,4-dihydroisoquinoléine-3-carboxylate de méthyle (2a)

On obtient 1,67 g de produit (Rdt. 67%), *F* 138–140°C; ir, ν_{max} : 1725 (ester); rmn ^{1}H, δ : 2,96 (d, 2H, $J_{CH_2-H\text{-}3}$ = 10,20 Hz, CH_2-4), 3,85 (s, 3H, OCH_3), 3,91 (s, 3H, OCH_3), 3,95 (s, 3H, OCH_3), 4,32 (dt, 1H, ^3J = 10,20 Hz, $^4J_{H\text{-}3-H\text{-}1}$ = 2,90 Hz, H-3), 6,73 (s, 1H, H-5), 6,88 (s, 1H, H-8), 8,21 (d, 1H, $J_{H\text{-}1-H\text{-}3}$ = 2,90 Hz, H-1). Anal. calc. pour $C_{13}H_{15}NO_4$: C 62,62, H 6,07. N 5,62; tr. : C 62,81, H 5,96, N 5,72.

6,7-Diméthoxy-1-méthyl-3,4-dihydroisoquinoléine-3-carboxylate de méthyle (2b)

On obtient 1,98 g de produit (Rdt. 75%), *F* 110–111°C; ir, ν_{max} : 1730 (ester); rmn ^{1}H, δ : 2,45 (d, 3H, $J_{CH_3-H\text{-}3}$ = 1,90 Hz, CH_3-1), 2,92 (d, 2H, *J* = 9.80 Hz, CH_2-4), 3,83 (s, 3H, OCH_3), 3,91 (s, 3H, OCH_3), 3,93 (s, 3H, OCH_3), 4,20 (tq, $J_{H\text{-}3-CH_2}$ = 9,80 Hz, $J_{H\text{-}3-CH_3}$ = 1,90 Hz, H-3), 6,74 (s, 1H, H-5), 7,02 (s, 1H, H-8). Anal. calc. pour $C_{14}H_{17}NO_4$: C 63,84, H 6,51, N 5,32; tr. : C 63,67, H 6,43, N 5,47.

6,7-Diméthoxy-1-phényl-3,4-dihydroisoquinoléine-3-carboxylate de méthyle (2c)

On obtient 1,05 g de produit (Rdt. 32%), *F* 106–107°C; ir, ν_{max} : 1730 (ester); rmn ^{1}H, δ : 2,95–3,15 (partie AB d'un système ABX avec J_{AB} = 16,40 Hz, J_{AX} = 10,20 Hz, J_{BX} = 5,70 Hz, CH_2-4), 3,72 (s, 3H, OCH_3), 3,81 (s, 3H, OCH_3), 3,95 (s, 3H, OCH_3), 4,35 (partie X d'un système ABX avec J_{AX} = 10,20 Hz, J_{BX} = 5,70 Hz, H-3), 6,79 (s, 1H, H-5), 6,83 (s, 1H, H-8), 7,40–7,65 (m, 5H). Anal. calc. pour $C_{19}H_{19}NO_4$: C 70,12, H 5,89, N 4,31; tr. : C 70,27, H 5,75, N 4,42.

5. Cycloadditions dipolaires

(a) Au reflux du toluène : Un mélange de 1 mmol de dipôle **2** et 1,2 mmol de dipolarophile dissous dans 10 mL de toluène sec est chauffé à reflux sous atmosphère d'azote durant 48 h. Après refroidissement, le toluène est évaporé et le résidu recristallisé dans un solvant précisé dans chaque cas.

4',5'-Diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonylcyclohept-1-ène-exo-*5,6-(*N-*méthyldicarboximide) (6a)*

On obtient 0,185 g de produit (Rdt. 52%), *F* 210–211°C de l'éthanol; ir, ν_{max} : 3300 (NH), 1730 (ester), 1700 (imide); rmn ^{1}H, δ : 2,45 (sl, 1H, NH), 3,00 (s, 3H, N-CH_3), 3,16 (d, 1H, *J* = 17,00 Hz) et 3,22 (d, 1H, *J* = 17,00 Hz) : CH_2-3, 3,25 (d, 1H, *J* = 7,10 Hz, H-5 ou H-6), 3,35 (d, 1H, *J* = 7,10 Hz, H-6 ou H-5), 3,84 (s, 3H, OCH_3), 3,87 (s, 3H, OCH_3), 3,90 (s, 3H, OCH_3), 4,65 (s, 1H, H-7), 6,60 (s, 1H), 6.73 (s, 1H). Anal. Calc. pour $C_{18}H_{20}N_2O_6$: C 59,97, H 5,60, N, 7,78; tr. : C 59,95, H, 5,68, N 7,49.

4',5'-Diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonyl-7-phénylcyclohept-1-ène-exo-*5,6-(*N-*méthyldicarboximide) (6c)*

On obtient 0,265 g de produit (Rdt. 61%), *F* 250–251°C de l'isopropanol; ir, ν_{max} : 3300 (NH), 1730 (ester), 1700 (imide); rmn ^{1}H, δ : 2,86 (s, 3H, N-CH_3), 3,32 (sl, 1H, NH), 3,34 (d, 1H, *J* = 16,40 Hz) et 3,40 (d, 1H, *J* = 16,40 Hz) : CH_2-3, 3,47 (d, 1H, *J* = 7,10 Hz, H-5 or H-6), 3,94 (d, 1H, *J* = 7,10 Hz), H-6 ou H-5), 3,58 (s, 3H, OCH_3), 3,82 (s, 3H, OCH_3), 3,86 (s, 3H, OCH_3), 6,40 (s, 1H), 6,67 (s, 1H), 7,35–7,85 (m, 5H). Anal. calc. pour $C_{24}H_{24}N_2O_6$: C 66,00, H 5,55, N 6,43; tr. : C 65,87, H 5,58, N 6,37.

4',5'-Diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonylcyclohept-1-ène-exo-*5,6-(*N-*phényldicarboximide) (7a)*

On obtient 0,210 g de produit (Rdt. 50%), *F* 150–151°C du *n*-propanol; ir, ν_{max} : 3300 (NH), 1735 (ester), 1700 (imide); rmn ^{1}H, δ : 2,67 (sl, 1H, NH), 3,22 (d, 1H, *J* = 17,20 Hz) et 3,28 (d, 1H, *J* = 17,20 Hz) : CH_2-3, 3,38 (d, 1H, *J* = 7,10 Hz, H-5 ou H-6), 3,53 (d, 1H, *J* = 7,10 Hz, H-6 ou H-5), 3,85 (s, 3H, OCH_3), 3,87 (s, 3H, OCH_3), 3,89 (s, 3H, OCH_3), 4,77 (s, 1H, H-7), 6,63 (s, 1H), 6,75 (s, 1H), 7,20–7,55 (m, 5H). Anal. calc. pour $C_{23}H_{22}N_2O_6$: C 65,37, H 5,25, N 6,63; tr. : C 65,42, H 5,32, N 6,51.

4',5'-Diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonyl-7-méthylcyclohept-1-ène-exo-*5,6-(*N-*phényldicarboximide) (7b)*

On obtient 0,262 g de produit (Rdt. 60%), *F* 148–149°C de l'isopropanol; ir, ν_{max} : 3320 (NH), 1730 (ester), 1700 (imide); rmn ^{1}H, δ : 1,90 (s, 3H, CH_3-7), 2,69 (sl, 1H, NH), 3,23 (d, 1H, *J* = 16,80 Hz) et 3,31 (d, 1H, *J* = 16,80 Hz) : CH_2-3, 3,37 (d, 1H, *J* = 7,10 Hz, H-5 ou H-6), 3,47 (d, 1H, *J* = 7,10 Hz, H-6 ou H-5), 3,85 (s, 3H, OCH_3), 3,87 (s, 3H, OCH_3), 3,89 (s, 3H, OCH_3), 6,60 (s, 1H), 6,80 (s, 1H), 7,20–7,55 (m, 5H). Anal. calc. pour $C_{24}H_{24}N_2O_6$: C 66,00, H 5,55, N 6,43; tr. : C 65,78, H 5,62, N 6,35.

(b) En tube scellé : Dans un tube de 10 mL, on introduit 1 mmol de produit dipolaire, 1,2 mmol de dipolarophile et 5 mL de toluène anhydre. Le tube est scellé et placé à 150°C pendant 48 h. Après refroidissement, le mélange réactionnel est repris par du toluène, le solvant est évaporé et le résidu cristallisé dans un solvant (qui sera précisé dans chaque cas) est essoré.

4',5'-Diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonyl-7-phénylcyclohept-1-ène-exo-*5,6-(*N-*phényldicarboximide) (7c)*

On obtient 0,350 g de produit (Rdt. 70%), *F* 240–241°C du *n*-propanol; ir, ν_{max} : 3330 (NH), 1735 (ester), 1700 (imide); rmn ^{1}H, δ : 3,35 (sl, 1H, NH), 3,39 (d, 1H, *J* = 16,40 Hz) et 3,47 (d, 1H, *J* = 16,40 Hz) : CH_2-3, 3,56 (d, 1H, *J* = 6,80 Hz, H-5 ou H-6), 4,13 (d, 1H, *J* = 6,80 Hz, H-6 ou H-5), 3,69 (s, 3H, OCH_3), 3,83 (s, 3H, OCH_3), 3,89 (s, 3H, OCH_3), 6,50 (s, 1H), 6,65 (s, 1H), 7,10–7,90 (m, 10H). Anal. calc. pour $C_{29}H_{26}N_2O_6$: C 69.84, H 5,26, N 5,62; tr. : C 70,01, H 5,43, N 5,44.

4',5'-Diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonyl-exo-*5-méthoxycarbonyl*-endo-*6-méthoxycarbonylcyclohept-1-ène (5a)*

On obtient 0,192 g de produit (Rdt. 49%), *F* 163–164°C de l'éthanol; ir, ν_{max} : 3300 (NH), 1720 (ester); rmn ^{1}H, δ : 2,84 (sl, 1H, NH), 3,11 (d, 1H, *J* = 16,50 Hz) et 3,26 (d, 1H, *J* = 16,50 Hz) : CH_2-3, 3,62 (d, 1H, *J* = 7,30 Hz, H-5) 3,70 (dd, 1H, *J* = 7,30 Hz, *J* = 5,90 Hz, H-6) 4,61 (d, 1H, *J* = 5,90 Hz, H-7), 3,54 (s, 3H, OCH_3), 3,67 (s, 3H, OCH_3), 3,78 (s, 3H, OCH_3), 3,80 (s, 3H, OCH_3), 3,82 (s, 3H, OCH_3), 6,50 (s, 1H), 6,63 (s, 1H). Anal. calc. pour $C_{19}H_{23}NO_8$: C 57,98, H 5,90, N 3,56; tr. : C 58,12, H 5,95, N 3,46.

4',5'-Diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonyl-exo-*5-méthoxycarbonyl*-endo-*6-méthoxycarbonyl-7-méthylcyclohept-1-ène (5b)*

On obtient 0,245 g de produit (Rdt. 60%), *F* 131–132°C de l'isopropanol; ir, ν_{max} : 3320 (NH), 1720 (ester); rmn ^{1}H, δ : 1,90 (s, 3H, CH_3-7), 2,80 (sl, 1H, NH), 3,20 (d, 1H, *J* = 16,40 Hz) et 3,26 (d, 1H, *J* = 16,40 Hz) : CH_2-3, 3,28 (d, 1H, *J* = 7,40 Hz, H-5) 3,74 (d, 1H, *J* = 7,40 Hz, H-6), 3,50 (s, 3H, OCH_3), 3,61 (s, 3H, OCH_3), 3,76 (s, 3H, OCH_3), 3,81 (s, 3H, OCH_3), 3,83 (s, 3H, OCH_3), 6,57 (s, 1H), 6,61 (s, 1H). Anal. calc. pour $C_{20}H_{25}NO_8$: C 58,94, H 6,19, N 3,44; tr. : C 58,65, H 6,22, N 3,40.

4',5'-Diméthoxy-1,2-benzo-4,7-imino-4-méthoxycarbonyl-exo-*5-méthoxycarbonyl*-endo-*6-méthoxycarbonyl-7-phénylcyclohept-1-ène (5c)*

On obtient 0,330 g de produit (Rdt. 70%), *F* 159–160°C de l'isopropanol; ir, ν_{max} : 3300 (NH), 1730 (ester); rmn ^{1}H, δ : 2,30 (sl, 1H, NH), 3,31 (d, 1H, *J* = 16,20 Hz) et 3,39 (d, 1H, *J* = 16,20 Hz) : CH_2-3, 3,45 (s, 3H, OCH_3), 3,51 (s, 3H, OCH_3) 3,68 (s, 3H, OCH_3), 3,77 (s, 3H, OCH_3), 3,85 (s, 3H, OCH_3), 3,93 (d, 1H, *J* = 6,80 Hz, H-5), 4,25 (d, 1H, *J* = 6,80 Hz, H-6), 6,00 (s, 1H), 6,65 (s, 1H), 7,35–7,85 (m, 5H). Anal. calc. pour $C_{25}H_{27}NO_8$: C 63,94, H 5,80, N 2,99; tr. : C 64,08, H 5,92, N 2,77.

β-Substitution de la *méso*-tétraphénylporphyrine de zinc par voie électrochimique

ALAIN GIRAUDEAU[1] ET LANA EL KAHEF

Laboratoire d'électrochimie et de chimie-physique du corps solide, Unité de recherche associée au Centre national de la recherche scientifique, n° 405, Université Louis Pasteur, 4, rue Blaise Pascal, 67000 Strasbourg, France

Reçu le 9 février 1990[2]

ALAIN GIRAUDEAU et LANA EL KAHEF. Can. J. Chem. **69**, 1161 (1991).

L'oxydation par voie électrochimique de la *méso*-tétraphénylporphyrine de zinc dans des solutions mixtes acétonitrile–dichloroéthane et en présence de nucléophiles (Py, 3-Pic, $P\phi_3$, SCN^-) conduit à l'obtention de la métalloporphyrine correspondante monosubstituée. Pour chacun de ces nucléophiles, la substitution a lieu sur un carbone pyrrolique (β-substitution). Les conditions électrochimiques de ces substitutions sont discutées et nous proposons un bilan global pour cette réaction de substitution.

Mots clés : porphyrines, réactions électrochimiques, substitutions nucléophiles.

ALAIN GIRAUDEAU and LANA EL KAHEF. Can. J. Chem. **69**, 1161 (1991).

The electrochemical oxidation of the zinc tetraphenylporphyrin complex in a mixed acetonitrile–dichloroethane solution in the presence of nucleophiles (Py, 3-Pic, $P\phi_3$, SCN^-) leads to the formation of the corresponding monosubstituted metalloporphyrin. For each of these nucleophiles the substitution occurs at a pyrrole carbon atom (β-substitution). The electrochemical conditions of these substitutions are discussed and an overall reaction is proposed.

Key words: porphyrins, electrochemical reactions, nucleophilic substitution.

Introduction

L'oxydation par voie électrochimique d'hydrocarbures aromatiques mono- ou poly-nucléaires permet de réaliser des réactions très diverses telles des réactions d'addition, de dimérisation ou de substitution. Si dans de nombreux cas un même type de réaction peut être réalisé aussi bien par voie chimique qu'électrochimique, cette dernière n'en reste pas moins une méthode originale et très appropriée dès qu'un contrôle de l'étape d'oxydation s'avère être un paramètre important, malgré la multiplicité des paramètres rentrant en jeu dans ces processus d'électrosynthèse (potentiel de réaction, durée d'électrolyse, nature de l'électrode, du solvant ou du sel de fond) et dont le choix peut rendre prépondérantes certaines réactions secondaires.

Dans les métalloporphyrines, le macrocycle porphyrine est un système d'électrons conjugué qui peut être plus ou moins facilement oxydé pour donner les radicaux-cations correspondants (1–3). Cette facilité d'oxydation dépend du macrocycle lui-même, mais est essentiellement fonction de la nature et du degré d'oxydation du cation métallique central de la métalloporphyrine. Les complexes du zinc et du magnésium sont parmi les plus facilement oxydables et ont permis la mise en évidence de la réactivité des radicaux-cations correspondants en réalisant par oxydation chimique des substitutions nucléophiles sur les positions *méso* et (ou) β (4–7). De nombreuses études antérieures ont également traité en détail de la formation des isoporphyrines (8, 9) et se sont attachées à en décrire les mécanismes. Ces travaux ont mis aussi en évidence la possibilité de réaliser des substitutions nucléophiles sur les positions *méso* et (ou) β à partir des dications des porphyrines (9).

Les travaux sur l'oxydation électrochimique des métalloporphyrines en présence de nucléophiles ont été très largement développés, cependant ils se sont focalisés sur l'analyse de la complexation des cations métalliques centraux et très peu sur la réactivité du macrocycle porphyrine (10, 11). Seules à notre connaissance des travaux sur la cyanation de complexes aromatiques par voie électrochimique ont montré que par oxydation à potentiel contrôlé, l'octaéthylporphyrine de zinc formait successivement les complexes mono- à tétra-cyanés correspondants sur les positions *méso* (12, 13).

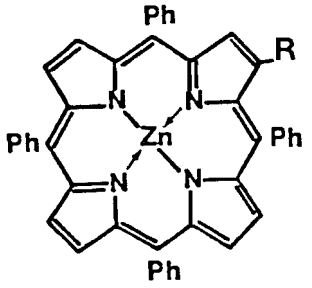

FIG. 1. Structure des porphyrines obtenues. R = Py^+, $3\text{-}Pic^+$, $P\phi_3^+$, SCN.

Récemment, nous avons mis en évidence la possibilité d'effectuer par voie électrochimique des substitutions en position β à partir de la *méso*-tétraphénylporphyrine de zinc, ZnTPP (14). Dans cet article nous décrivons cette réactivité à propos de plusieurs types de nucléophiles et nous donnons le bilan global de la réaction d'obtention de ces porphyrines substituées en position β (fig. 1).

Résultats et discussion

L'oxydation de la *méso*-tétraphénylporphyrine de zinc (ZnTPP) a lieu en deux étapes distinctes (10, 15), avec échanges réversibles successifs d'un électron selon le mécanisme suivant :

[1] $ZnTPP \rightleftarrows ZnTPP^+ + e^-$

[2] $ZnTPP^{+\cdot} \rightleftarrows ZnTPP^{2+} + e^-$

Notre travail et les résultats correspondants concernent uniquement l'étape [1]. Le produit d'oxydation qui est le cation radical $ZnTPP^{+\cdot}$ paramagnétique est aisément identifiable par son spectre d'absorption UV–VIS, sa grande stabilité permet même de l'isoler.

L'allure du signal anodique de la première étape d'oxydation n'est pas affectée par la présence d'un nucléophile; la vague d'oxydation obtenue par voltampérométrie stationnaire (V.S.) conserve la même amplitude et les tracés de voltampérométrie cyclique (V.C.) indiquent une réversibilité inchangée. Le seul

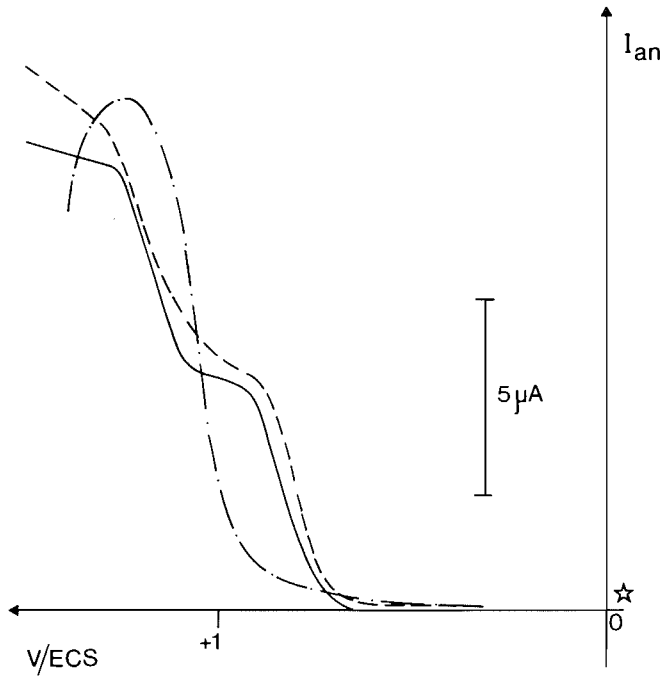

FIG. 2. Voltampérométrie stationnaire de la porphyrine **2**. Electrode, Pt; $\omega = 2000$ t min^{-1}; $v = 10$ mV s^{-1}. Milieu Et_2Cl_2, TBAP 0,1 M : (—). Milieu Et_2Cl_2–CH_3CN–Py, TEAP 0,1 M : avant électrolyse (---); après électrolyse (------).

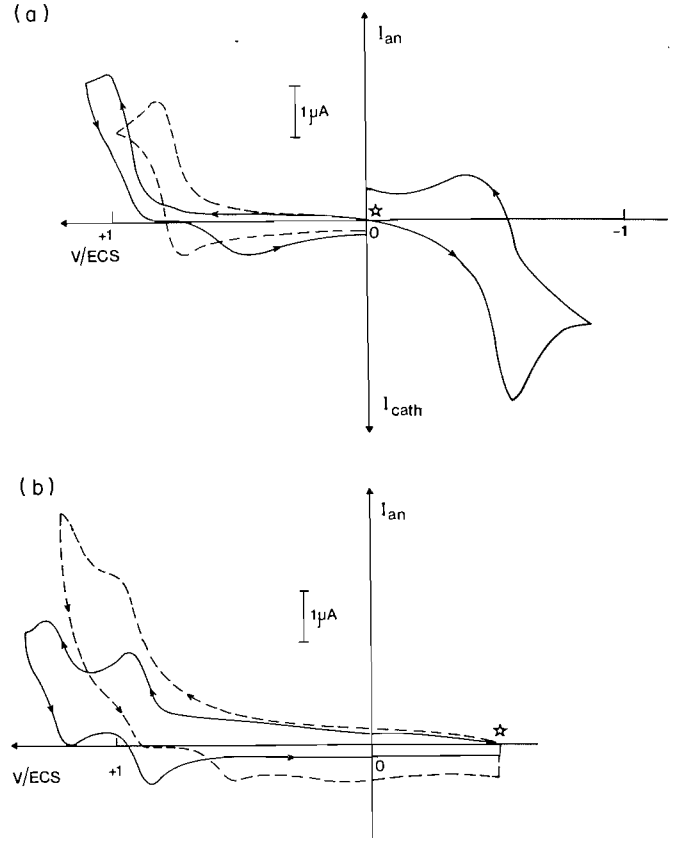

FIG. 3. (a) Voltamétrie cyclique de la porphyrine **2** en milieu Et_2Cl_2–CH_3CN–Py, TEAP 0,1 M. Electrode, Pt; $v = 0,1$ V s^{-1}. Avant électrolyse (---); après électrolyse (—). (b) Voltamétrie cyclique de la porphyrine **3** (5×10^{-4} M) en milieu Et_2Cl_2–CH_3CN, TEAP 0,1 M. Electrode, Pt; $v = 0,1$ V s^{-1}. Absence de pyridine (—); en présence de pyridine 10^{-2} M (---).

effet observé est un déplacement cathodique du potentiel de demi-vague (10) (fig. 2) traduisant la coordination du nucléophile (Nu) sur le métal central selon le mécanisme :

[3] $\quad ZNTPP + Nu \rightleftarrows ZnTPP\,(Nu)$

Lorsqu'on réalise une coulométrie exhaustive de ZnTPP au niveau de la première étape d'oxydation en présence d'un nucléophile, on observe une évolution du spectre optique qui conduit à la fin de l'oxydation à un spectre comprenant toujours une bande Soret intense et deux bandes d'absorption dans le visible (bandes α et β). Par rapport au spectre d'absorption de départ, l'ensemble du nouveau spectre obtenu est décalé vers les plus grandes longueurs d'ondes. En aucun cas on ne retrouve le spectre attendu du radical cation $ZnTPP^{+\cdot}$. Ce résultat suggère la formation d'une nouvelle porphyrine comportant une plus grande délocalisation de la densité électronique sur le cycle porphyrinique.

L'enregistrement des courbes $I = f(t)$ (courant–temps) pendant l'électrolyse montre d'une part que nous n'avons plus une décroissance exponentielle du courant comme observée dans le cas de l'électrolyse de ZnTPP en absence de nucléophile, d'autre part le courant résiduel de fin d'électrolyse n'est plus voisin de zéro. L'analyse de ces courbes $I = f(t)$ indique que nous sommes en présence au moins d'une réaction de type E.C. (Electrochimique–Chimique), ou E.C.E.C., et non plus du mécanisme purement électrochimique [1], de plus la valeur du nombre n d'électrons échangés par mole ZnTPP est comprise dans l'intervalle $2,2 \leq n \leq 2,6$, selon les expériences effectuées. Cette réaction chimique consécutive à l'oxydation de ZnTPP en présence de nucléophile n'est détectable ni par voltampérométrie cyclique (V.C.) ni par voltampérométrie stationnaire (V.S.). En effet le rapport I_{Pa}/P_{Pc} obtenu en V.C. (rapport du courant de pic anodique au courant du pic de réduction associé), pour la première étape d'oxydation, n'est pas modifié par l'addition de nucléophile sur la gamme des vitesses de balayage étudiées (50 mV s^{-1} à 1 V s^{-1}). Les tracés $I = f(c)$ et $1/I = f(\omega^{-1/2})$ (ω vitesse de rotation de l'électrode) obtenus à partir des courbes de V.S. sont linéaires passant par l'origine des coordonnées, analogues à ceux obtenus lors de l'étude de l'oxydation de ZnTPP en l'absence de nucléophile.

Ces résultats sont en accord avec une cinétique d'attaque nucléophile lente sur le produit d'oxydation (radical-cation) de ZnTPP.

En oxydation, l'étude d'une solution après électrolyse montre dans tous les cas l'apparition d'une nouvelle vague vers +1,0 V/ECS (fig. 2). La vague d'oxydation de ZnTPP a disparu. En V.C. ce signal apparaît comme correspondant à une réaction électrochimique irréversible (fig. 3a). Ce signal a été analysé et traduit l'oxydation irréversible du complexe β-substitué formé, en présence d'un excès du nucléophile correspondant. En effet, lorsqu'on réalise en milieu Et_2Cl_2–CH_3CN – TEAP 0,1 M l'oxydation des complexes β-substitués obtenus, on observe qu'ils s'oxydent en deux étapes monoélectroniques et réversibles et qu'en présence du nucléophile correspondant, on n'obtient plus qu'un seul signal dont l'amplitude a doublé (fig. 3b), le transfert électronique étant devenu irréversible.

En réduction, on observe sur la solution après électrolyse un premier signal cathodique vers –0,6 V/ECS auquel est associé un signal retour anodique vers –0,3 V/ECS (fig. 3a). Ces signaux ont été clairement identifiés et sont attribuables à la présence en solution après électrolyse des espèces NuH^+ et correspondent aux

TABLEAU 1. Potentiels d'oxydation (V/ECS) obtenus sur électrode (Pt) tournante ($\omega = 2000\,t\,min^{-1}$) en milieu Et_2Cl_2–CH_3CN (1 : 1) TEAP 0.1 M

réactions (16, 17) :

$$NuH^+ + e^- \longrightarrow Nu + 1/2H_2$$

$$1/2H_2 \longrightarrow e^- + H_2$$

Ces résultats permettent de proposer pour la formation de la métalloporphyrine β-substituée le bilan global suivant, en accord avec celui établi par Shine *et al.* (7) :

$$[4]\quad ZnTPP + 2Nu \xrightarrow{+0,82V} 2e^- + ZnTPP\ \beta\text{-}Nu^+ + NuH^+$$

Dans le cas où $Nu = SCN^-$ les observations décrites ci-dessus sont limitées, étant donné qu'à +0,5 V/ECS l'ion thyocianate SCN^- s'oxyde lui-même (18). La formation de ZnTPP (SCN) n'est plus la réaction majeure, de nombreuses réactions secondaires devenant prépondérantes, mais reste néanmoins décrite par le bilan [4] proposé.

La faible différence de potentiel (~120 mV) existant entre les vagues d'oxydation de ZnTPP et de la porphyrine β-substituée formée (tableau 1) montre qu'il est difficile de ne pas oxyder une fraction du produit d'arrivée désiré et permet de comprendre d'une part les valeurs n mesurées supérieures à 2 ainsi que, d'autre part, les valeurs plus élevées qu'attendues du courant résiduel de fin d'électrolyse. Cette faible séparation est également responsable de l'obligation d'électrolyser à des potentiels légèrement voisins du potentiel de demi-vague de l'espèce de départ lorsqu'on veut atteindre un rendement optimum du produit synthétisé.

Cette réactivité de la porphyrine de zinc ZnTPP vis-à-vis de nucléophiles avait déjà été mise en évidence (7) à partir de sels du radical-cation $ZnTPP^{\dot{+}}$ obtenus par voie chimique, cependant des travaux ultérieurs sur l'effet *in situ* de bases de Lewis au cours de l'oxydation électrochimique de ZnTPP n'avaient pas montré d'activité particulière (10) et conclu à la seule formation du radical-cation coordiné $ZnTPP(Nu)^{\dot{+}}$.

Ces observations apparemment contradictoires peuvent s'expliquer raisonnablement en considérant que les études sur la réactivité électrochimique de ZnTPP avaient surtout été conduites par des techniques de spectroélectrochimie en couches minces. Dans ces conditions, les temps d'électrolyse complète sont de l'ordre de la minute. Si on considère que la réaction chimique suivant le transfert électronique est lente, il est tout à fait normal de n'observer dans un premier temps que la formation du radical-cation coordiné. Cette interprétation est confortée par le fait qu'à l'échelle de temps de la voltampérométrie cyclique et même de la voltampérométrie stationnaire, aucun effet n'est observé lors de l'addition d'un nucléophile (si ce n'est sa coordination sur le cation métallique central). Une analyse des courbes de V.S. enregistrées dans nos conditions réactionnelles en appliquant les critères $I = f(c)$ et $1/I = f(\omega^{-1/2})$ ne laisse pas entrevoir de complications cinétiques, ce qui confirme bien que la réaction chimique consécutive au transfert électronique est lente.

Par rapport au spectre RMN de la métalloporphyrine de départ (ZnTPP), l'examen des spectres RMN des produits obtenus montre que la substitution a eu lieu sur une position β du macrocycle porphyrinique, l'aromaticité du cycle étant toujours conservée (7).

Le spectre RMN du complexe ZnTPP–β-SCN est le plus simple. Il montre clairement l'éclatement des signaux dûs aux sept protons β-H du macrocycle porphyrine. Le signal du proton β-H adjacent au substituant (SCN) apparaît, comme attendu, aux champs les plus forts (7) (9,05 ppm). Les six autres protons β-H n'apparaissent pas comme équivalents, l'un d'entre eux donnant un doublet à 8,69 ppm, alors que les cinq autres se confondent en un multiplet (8,87–8,82 ppm). Le doublet peut être raisonnablement attribué au proton β-H situé en *para* du groupe SCN.

Le spectre RMN du complexe ZnTPP–β-Py^+, ClO_4^- est analogue à celui de ZnTPP–β-SCN. Les signaux supplémentaires qui apparaissent, dûs aux protons du substituant (Py^+), se distinguent de ceux des protons β-H par leur intensité plus faible ainsi que leur plus grande largeur de raie. On retrouve les signaux des protons β-H du cycle porphyrinique à des champs voisins de ceux observés précédemment avec éclatement du multiplet 12H des protons *méta* et *para* des phényles en deux multiplets (9H et 3H) correspondants respectivement aux protons des trois phényles les plus lointains du substituant et aux protons du phényle voisin du substituant. Ces résultats sont en plein accord avec ceux décrits antérieurement par Schine *et al.* à propos du même complexe (7).

Lorsque la substitution a lieu avec la 3-picoline, on s'attend à ce que les quatre protons de la 3-picoline ne soient plus équivalents, ce qui est effectivement observé. Le signal du groupe méthyle apparaît aux champs faibles, comme attendu.

Enfin, la substitution avec la triphénylphosphine ($P\phi_3$) conduit à un spectre RMN plus complexe. On observe clairement le multiplet 15H dû aux protons du substituant ($P\phi_3^+$). Le déplacement de l'ensemble du spectre vers les champs plus faibles indique que le pouvoir électroattracteur du substituant est plus faible que celui des précédents; cette observation est également traduite par la valeur des potentiels d'oxydation mesurés pour ces métalloporphyrines (tableau 1).

Pour toutes ces porphyrines, le spectre d'absorption visible enregistré montre, par rapport à celui de la porphyrine de départ ZnTPP, un déplacement des bandes d'absorption vers les plus grandes longueurs d'ondes, caractéristique de la présence de substituants électroattracteurs (21).

Conclusion

L'ensemble de ces résultats montre clairement qu'il est possible de réaliser directement par voie électrochimique des mono-substitutions en positions β sur la porphyrine de zinc ZnTPP avec des nucléophiles bases de Lewis. Les rendements obtenus sont significativement plus élevés que ceux obtenus par la voie chimique. Ils varient de 50 à 63% alors que ceux correspondant à la voie chimique (7) sont plutôt de l'ordre de 35%. Ce résultat s'explique en tenant compte du fait que par voie chimique, une fraction du cation radical retourne à la forme neutre ZnTPP et donc non réactive, la voie électrochimique permettant elle de s'affranchir de cette terminaison puisque la réaction contrôlée est celle de l'oxydation de ZnTPP.

Enfin, la voie électrochimique présente l'avantage de per-

mettre la réalisation de substitutions difficiles (ou impossibles) par voie chimique; des travaux sont en cours à ce propos ainsi que pour détailler le bilan global proposé pour ces réactions d'électrosubstitution.

Récemment, nous avons montré également que la base libre H_2TPP pouvait réagir de manière similaire pour conduire à des complexes diversement substitués (22).

Partie expérimentale

La *meso*-tétraphénylporphyrine H_2TPP (**1**) et le complexe de zinc correspondant ZnTPP (**2**) ont été préparés suivant les méthodes habituelles décrites dans la littérature (19, 20). La pyridine (Py), la 3-picoline (3-Pic), le thiocyanate de sodium (NaSCN) et la triphénylphosphine ($P\phi_3$) qui ont conduit respectivement aux porphyrines de zinc β-substituées **3**, **4**, **5** et **6**, étaient des produits commerciaux (Merck) utilisés tels quels.

Appareillage

Les spectres de résonance magnétique nucléaire (RMN) du proton ont été enregistrés en solution dans l'acétone deutériée sur un appareil Brucker SY 200 à 200 MHz.

Les spectres d'absorption UV–VIS ont été effectués en solution CH_2Cl_2 sur un appareil Varian 2200.

Mesures électrochimiques

Voltampérométrie stationnaire et cyclique

L'appareillage était constitué d'un ensemble Bruker E1 30 M, d'un enregistreur Ifélec If 3802 et d'un voltmètre Minisis 2000. La cellule de mesure correspondait à un montage à trois électrodes. L'électrode de travail était un disque de platine (ϕ = 1 mm) et pouvait être utilisée sur une gamme de vitesses de rotation allant de 0 à 5000 t min^{-1}; la contre-électrode était un fil de platine. L'électrode de référence était constituée d'un électrode au calomel saturé (ECS) munie d'un pont de jonction contenant une solution Et_2Cl_2 – TBAP 0,2 M. Les solvants d'étude acétonitrile (CH_3CN) et dichloroéthane (Et_2Cl_2) produits Fluka (qualité puriss) ont été utilisés sans traitements particuliers. Le sel de conductibilité, perchlorate de tétraéthylammonium (TEAP), produit Fluka était purifié selon les méthodes décrites antérieurement (21). Pendant les mesures, la solution d'étude était maintenue sous atmosphère inerte (Argon U).

Electrolyses préparatives

Lors des électrolyses préparatives, les compartiments anodique et cathodique de la cellule de travail étaient séparés par un disque de verre fritté (porosité 4) et seul le compartiment anodique était maintenu sous atmosphère inerte. L'électrode de travail était un fil spirale de platine (ϕ = 0,8 mm) de longueur 30 cm. Le volume de solution dans le compartiment anodique était environ 50 mL.

Le potentiel de travail était contrôlé par un potentiostat Tacussel PRT 100 et sa valeur était fixée à +0,82 ± 0,02 V/ECS. L'évolution du courant d'électrolyse était suivie à l'aide d'un enregistreur Tacussel EPL_2; les durées d'électrolyse étaient en moyenne de 30 min.

Après électrolyse la solution était évaporée sous pression réduite pendant 20 min, puis la phase organique était extraite par lavage dans un mélange H_2O–Et_2Cl_2 (5 : 1).

La solution récupérée était concentrée (10 mL) puis chromatographiée. Après élutions la solution du complexe désiré était séchée (CaH_2), puis après filtration et évaporation du solvant, la porphyrine était recristallisée (Et_2Cl_2, *n*-pentane). Les cristaux obtenus étaient ensuite séchés sous vide à 100°C pendant 24 h.

Indanes monosubstituted and 1,2- and 1,3-disubstituted in the pentagonal ring were synthesized, and configurations were assigned to the 1,2-disubstituted compounds by means of nuclear magnetic resonance spectroscopy.

Key words: mono- and disubstituted indanes, conformation, configuration, ^1H and ^{13}C NMR, synthesis.

ELBA N. ALESSO, DORA G. TOMBARI, ADRIANA F. IBAÑEZ, GRACIELA Y. MOLTRASIO IGLESIAS et JOSÉ M. AGUIRRE. Can. J. Chem. **69**, 1166 (1991).

On a synthétisé des indanes mono- ainsi que 1,2- et 1,3-disubstitués sur le cycle pentagonal et on a attribué les configurations des composés 1,2-disubstitués à l'aide de la résonance magnétique nucléaire.

Mots clés : indanes mono- et disubstitués, conformation, configuration, RMN du ^1H et du ^{13}C, synthèse.

[Traduit par la rédaction]

To assign the stereochemistry of indanes obtained by treating 1,2-diarylethylamides and 1-arylethylamides with ethyl polyphosphate (EPP) (1, 2), as a preliminary step in the synthesis of naturally occurring indane structures, we started by preparing the simpler indane models and determining their stereochemistry by means of nmr spectroscopy.

The present work describes the synthesis of indanes monosubstituted and 1,2- and 1,3-disubstituted in the pentagonal ring. Table 1 shows the indanes that were synthesized as well as a summary of the main chemical shifts in ^{13}C and ^1H nmr spectra used to elucidate the stereochemistry of 1,2-disubstituted indanes. Further nmr data are listed in the experimental section.

Given their versatility and ready availability of the starting materials, the approaches presented in Scheme 1 were chosen to synthesize indanes **1**–**9** and **30**. Spectroscopic data for indanes **1**–**4** were assigned according to chemical shifts described for similar compounds in the literature (2, 3).

The *cis* configuration for the indane **5**, which was prepared from chalcone **10**, was assigned on the basis of (a) the stereochemistry of the hydrogenation reaction employed, bearing in mind the steric control exerted by the benzyl group located at C(1) in the indene **22**, and (b) ^1H nmr features of the compound, which agree with those described for *cis*-1-methyl-3-(3,4-dimethoxyphenyl)-5,6-dimethoxyindane in previous work (2).

Starting from indanone **16**, the two stereoisomeric indanes **6** and **7** were obtained. It is recognized that in the *cis* epimer of 1,2-disubstituted indanes the two extreme conformations **I***a* and **I***b* (Fig. 1) would contain an X—C(1)—C(2)—Y array having a smaller torsional angle than the *trans* epimer, which would be represented by the extreme conformations **II***a* and **II***b* (Fig. 1). Therefore it is reasonable to expect, in ^{13}C nmr, a shielding for terminal C atoms (e.g., for X = CH_2Ph) (5) in the *cis* epimer rather than the *trans*, and to a lesser degree this same shielding effect for central C atoms. This is commonly seen in *gauche* butane-type fragments as compared to *anti* fragments in the 1,2-disubstituted cyclopentanes (4).

It was observed that C(1) and C(2) in indane **6** were more shielded then those in **7** (C(1) = 49.60 ppm; C(2) = 50.80 ppm (**6**) and C(1) 55.00 ppm; C(2) = 55.00 ppm (**7**), respectively). As well, the benzyl methylene was more shielded in indane **6** than that in **7** (36.60 ppm and 40.69 ppm, respectively). More specifically, the chemical shift of benzyl methylene in epimer **7** was very similar to that in 1-benzyl-5,6-dimethoxyindane **4** (41.80 ppm). As a result of these observations the *cis* configuration was assigned to compound **6** and the *trans* to **7**. As indane **7** was obtained as a mixture with compound **6**, the comparison of the ^1H nmr spectral data was not suitable for assigning the stereochemistry of compounds **6** and **7**.

To synthesize stereoisomeric indanes **8** and **9**, 2-(3,4-dimethoxyphenyl)-3-phenylindenone **24** was prepared as starting material. A Clemmensen reaction (6) on **24** gave a mixture of stereoisomeric indanes **8** and **9**, in addition to indene **25** (Scheme 1). The *cis* configuration was assigned to the predominant indane **8** and the *trans* configuration to compound **9**. Assignment rationale included: (a) in the ^{13}C nmr spectra, signals for a diastereotopic pair of atoms showed a significant shielding difference (C(1) = 56.80 ppm; C(2) = 51.70 ppm for **8** and C(1) = 59.80 ppm; C(2) = 56.40 ppm for **9**); and (b) the ^1H nmr spectrum of isomer **8** showed lower shielding for H(1) and H(2) than that of isomer **9** (H(1) = 4.61 ppm; H(2) = 3.95 for **8** and H(1) = 4.34 ppm; H(2) = 3.75 ppm for **9**); that is, neither hydrogen atom in isomer **8** was shielded by the *cis* phenyl group bonded to the neighbouring carbon atom (7).

Galton *et al.* in 1970 (6) and Knorr *et al.* in 1980 (8) synthesized *cis*- and *trans*-1,2-diphenylindane by different routes, assigning the *trans* configuration to the isomer having the higher melting point and *cis* to the one with the lower (119–121°C and 83–85°C, respectively). The present authors disagree with such configurational assignment.

We decided to synthesize 1,2-diphenylindanes and compare the data of the ^1H nmr spectra with those obtained by the other

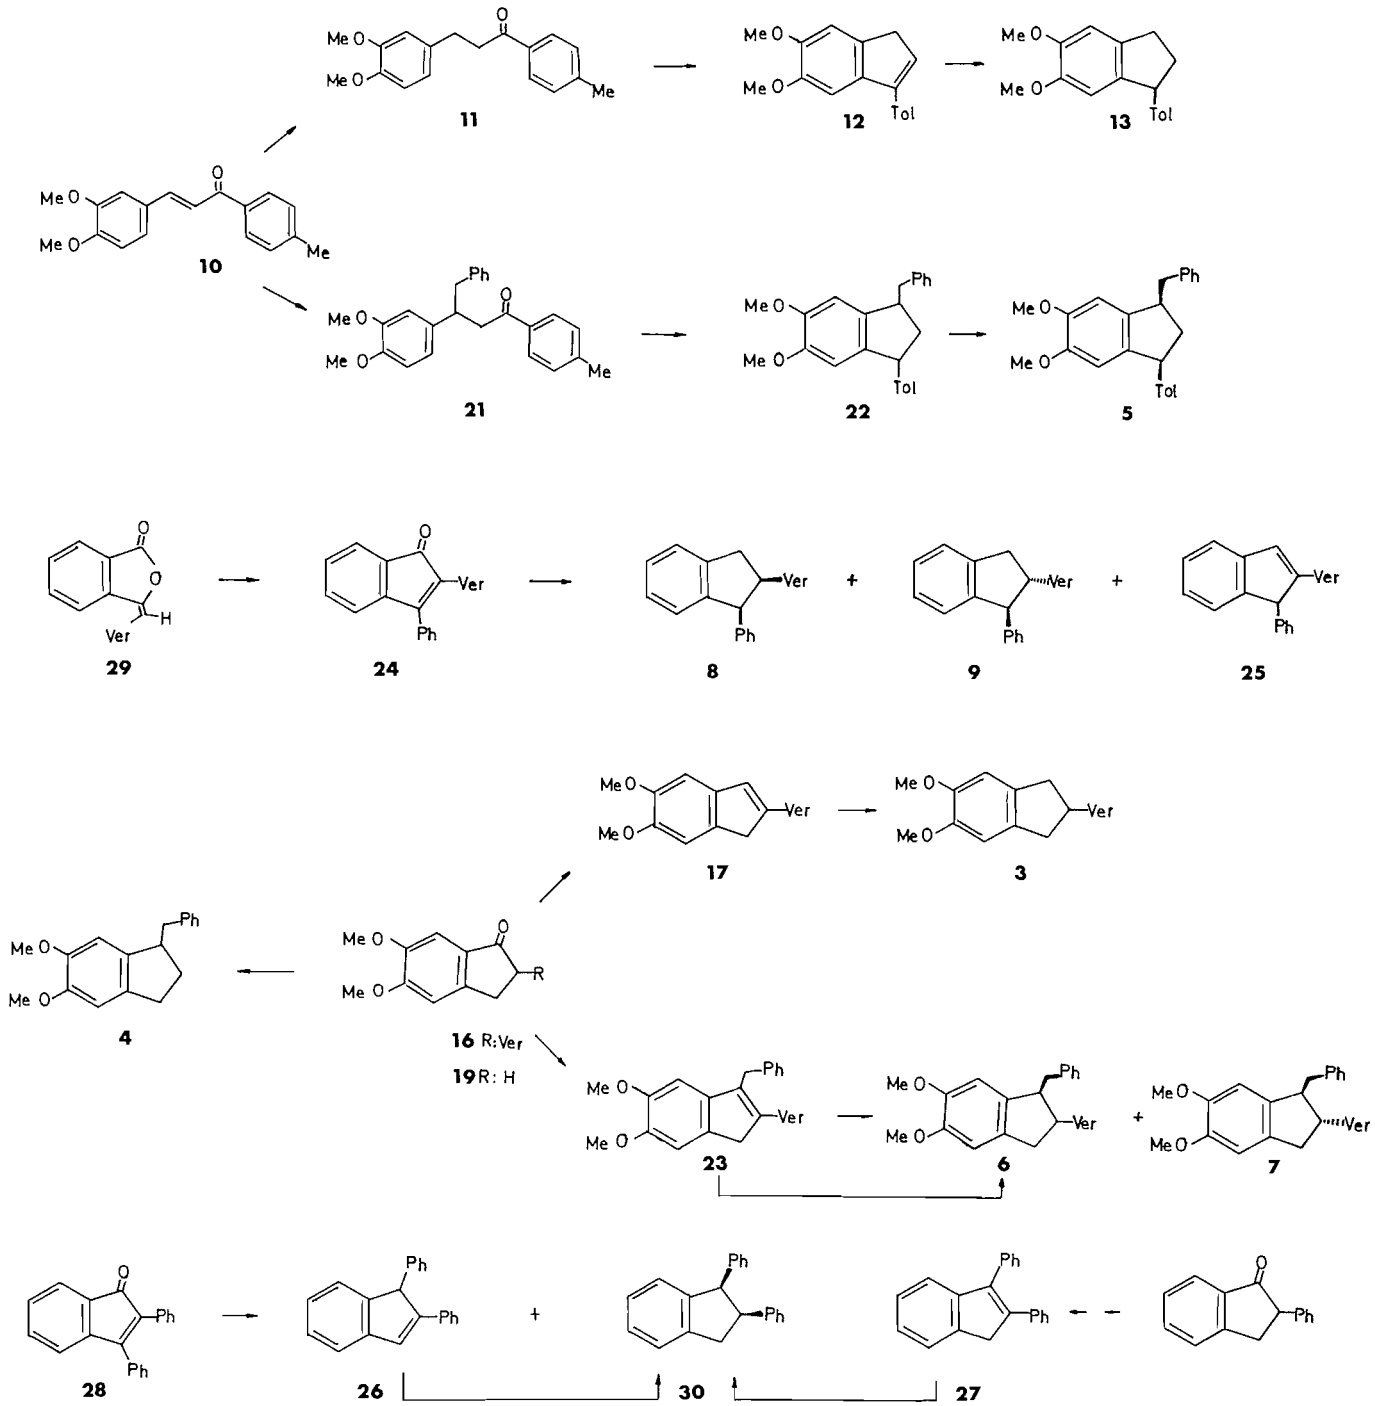
authors (6, 7) and, in addition, to analyze the ^{13}C nmr chemical shifts of these compounds.

The reduction of 1,2-diphenylindene **26** with Pd(C) 10% as well as the stereospecific hydrogenation of 2,3-diphenylindene **27** with platinum dioxide as catalyst afforded only indane **30** (mp 119–121°C). This indane was also obtained, together with indene **26**, by Clemmensen reduction (9) of 2,3-diphenylindenone **28**. The ^{1}H nmr spectrum for the indane **30** prepared by us agrees with that for the compound obtained by Galton and by Knorr with mp 119–121°C, and displays marked differences in the ^{1}H nmr spectrum from the compound having the lower melting point, as reported by Galton *et al.* (6) and by Knorr *et al.* (8). The comparison of H(1) and H(2) chemical shifts in these isomers shows shielding for hydrogen atoms corresponding to the isomer with the 119–121°C melting point. Furthermore, ^{13}C nmr chemical shifts in indane **30** corresponding to C(1), C(2), and C(3) agree with those for the equivalent carbon atoms in indane **8**, which was assigned the *cis* configuration.

Lastly, ^{1}H nmr spectra for indanes **6** and **8** disclose a highly shielded aromatic proton (a singlet integrating for one hydrogen atom at 6.06 and 6.09 ppm, respectively), and a similar pattern in one of the methoxyl groups (a singlet integrating for three protons at 3.57 and 3.47 ppm, respectively). Such greater shielding would agree with a preferential conformation for these compounds, whereby the 3,4-dimethoxyphenyl group linked to C(2) should be in the axial position, leaving the benzly or phenyl group bonded to C(1) in the *pseudo*-equatorial position (Fig. 1, **I***a*). That conformation would be valid in terms of energy, since it would preclude 1–3 diaxial interaction between the substituents linked to C(1) and H(3). In support, this shielding is not observed in indanes **3** and **9**, which indicates a preferentially equatorial location for the substituent bonded to C(2) in these compounds (Fig.1, **II***a*).

Experimental



Infrared spectra were obtained on a Shimadzu IR 440 spectrometer. The ^{1}H and ^{13}C nmr spectra were recorded on a Bruker WO 80 SYFT or Varian FT 80A spectrometer using solutions in deuteriochloroform; chemical shifts are reported as values relative to tetramethylsilane as internal standard. Cyclopentene ring carbon and aliphatic carbon shifts were determined by means of model values and APT (Attached Protons Test) experiments. Elemental analyses were carried out in our laboratories using a Coleman analyzer. Melting points (uncorrected) were obtained on a Thomas Hoover apparatus.

1-(4-Methylphenyl)-5,6-dimethoxyindane ***1***

The *1-(4-methylphenyl)-3-(3,4-dimethoxyphenyl)-2-propen-1-one* **10** (11) starting material for the synthesis of **1** was obtained by the general procedure used for the preparation of chalcones (10). Yield 82%; mp 95–96°C (EtOH); ir (mull): 1660 (C=O) cm^{-1}; ^{1}H nmr: 2.4 (s, 3H, CH_3-Ar), 3.9 (s, 6H, OCH_3), 6.70–7.60 (m, 7H, Ar and HC=CH), 7.80 (d, J = 9.0 Hz, 2H, Ar).

A solution of 1.39 g of the propen-1-one **10** in 15 mL of ethyl acetate was hydrogenated with 12 mg of platinum dioxide catalyst at room temperature and 40 psi (1 psi = 6.9 kPa) for 1 h. Removal of catalyst and solvent gave a solid, which crystallized from ethanol to afford colorless needles of *1-(4-methylphenyl)-3-(3,4-dimethoxyphenyl)propan-1-one* ***11***. Yield 73%; mp 46–48°C; ir (mull): 1680 (C=O) cm^{-1}; ^{1}H nmr: 2.4 (s, 3H, CH_3Ar), 2.8–3.5 (m, 4H, H-2 and H-3), 3.85 (s, 6H, OCH_3), 6.8 (s, 3H, Ar), 7.25 (d, J_{ortho} = 8.6 Hz, 2H, Ar), 7.9 (d, J_{ortho} = 8.6 Hz, 2H, Ar). Anal. calcd. for $C_{18}H_{20}O_3$: C 76.12, H 7.10; found: C 76.10, H 7.06.

A solution of 0.56 g of the propan-1-one **11** in 0.45 mL of phosphoric acid (85%) was added slowly with vigorous stirring to a mixture of 0.9 mL of concentrated sulfuric acid and 0.45 mL of phosphoric acid (85%) at 5°C. The reaction mixture was heated at 70–80°C for 30 min and then was poured into 50 mL of ice-water. The white precipitate was collected, washed with cold water, dissolved in chloroform, and the solution washed with sodium bicarbonate (10%) and dried. Evaporation of the solvent afforded a white solid, mp 103–107°C, which was

Ver: 3,4-dimethoxyphenyl; Tol: 4-methylphenyl

SCHEME 1

recrystallized from ethanol to give colourless crystals of *3-(4-methylphenyl)-5,6-dimethoxyindene* **12**. Yield 85%; mp 105–107°C; ^{1}H nmr: 2.4 (s, 3H, CH_3Ar), 3.4 (d, $J_{2,3}$ = 2.1 Hz, 2H, H-3), 3.90, 3.95 (s, 6H, OCH_3), 6.4 (t, $J_{2,3}$ = 2.1 Hz, 1H, H-2), 7.1 (s, 2H, H-4 and H-7), 7.2 (d, J_{ortho} = 8.0 Hz, 2H, Ar), 7.4 (d, J_{ortho} = 8.0 Hz, 2H, Ar). Anal. calcd. for $C_{18}H_{18}O_2$: C 81.27, H 6.82; found: C 81.25, H 6.75.

Hydrogenation of 0.3 g of indene **12** following the above procedure gave *1-(4-methylphenyl)-5,6-dimethoxyindane* **1** as a colorless oil. Yield 90%; ^{1}H nmr: 2.0 (m, 1H, H-2 *cis*), 2.33 (s, 3H, CH_3-Ar), 2.6 (m, 1H, H-2 *trans*), 2.9 (m, 2H, H-3), 3.73, 3.87 (s, 6H, OCH_3), 4.26 (brt, 1H, H-1), 6.49 (s, 1H, H-7), 6.81 (s, 1H, H-4), 7.08 (s, 4H, Ar); ^{13}C nmr: 20.70, 31.36, 36.9, 51.01, 55.6, 107.1, 107.7, 127.5, 128.8, 135.3, 135.6, 138.1, 142.4, 147.8. 147.9. Anal. calcd. for $C_{18}H_{20}O_2$: C 80.66, H 7.52; found: C 80.60, H 7.53.

2-Phenylindane **2**

A solution of 1.0 g of 3-benzylidenephthalide and 0.25 g of sodium in 20 mL of absolute ethanol was heated under reflux for 3 h. Acidification of the cooled reaction mixture gave a yellow solid, which was collected and recrystallized from ethanol to give *2-phenylindan-1,3-dione* **13**. Yield 82%; mp 148–149°C (lit. (6) mp 148–149°C). Clemmensen reduction of the 1,3-indandione following the general

For personal use only.

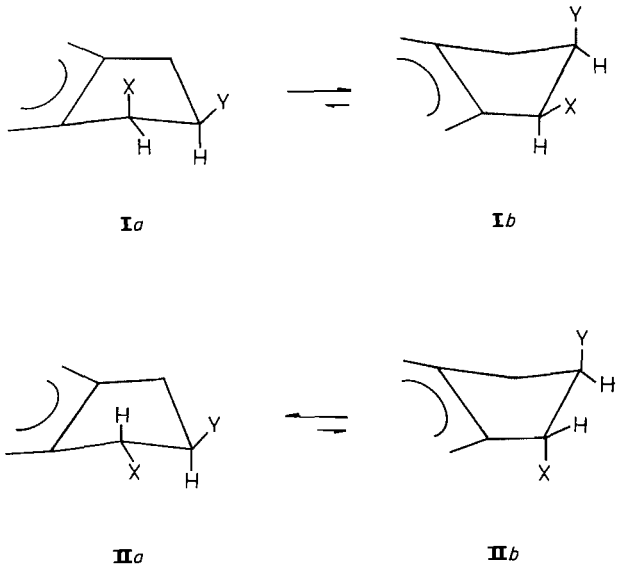

FIG. 1.

conditions of Galton *et al.* (6) afforded 2-phenylindene **14**, which was purified by p-tlc (2 mm thick) on Silica gel G F254. The plates were developed with cyclohexane–benzene 9:1. The *2-phenylindene* **14** was obtained as white crystals. Yield 75%; mp 166–168°C (hexane) (lit. (6) mp 167–168°C); ^{1}H nmr: 3.75 (s, 2H, CH_2), 7.0–7.75 (m, 10H, Ar and H-3).

A solution of 0.5 g of 2-phenylindene **14** in 5 mL of ethanol was hydrogenated with 0.1 g Pd(C) 5% catalyst at room temperature and 35 psi for 2 h. Removal of catalyst and solvent provided a colorless oil. The oil was distilled under reduced pressure to give *2-phenylindane* **2**. Yield 70%; bp 162–165°C/11 Torr) (lit. (6) bp 165°C/11 Torr) (1 Torr = 133.3 Pa); ^{13}C nmr: 40.76, 45.34, 124.16, 126.03, 126.29, 126.88, 128.28. 142.80, 145.29.

2-(3,4-Dimethoxyphenyl)-5,6-dimethoxyindane 3

A solution of 10 g of 3,4-dimethoxyphenylacetic acid, 13.68 g of 3,4-dimethoxybenzaldehyde, 6 mL of triethylamine, and 6 mL of acetic anhydride was refluxed for 35 min. After acidification (hydrochloric acid, 12 mL) the mixture was dissolved in ether, and the solution was washed with water and sodium hydroxide (10%). The combined extracts were acidified (concentrated hydrochloric acid) and filtered. The crude product was hydrogenated in 50 mL of ethanol with 0.9 g of Pd(C) 10% catalyst at room temperature and 35 psi for 2 h; after filtration, the solvent was removed to provide white crystals of *2,3-di-(3,4-dimethoxyphenyl)propanoic acid* **15**, mp 140–141°C. Five grams of the acid **15** were added to 50 g of polyphosphoric acid, and the viscous mass was mixed with an efficient mechanical stirrer and kept at 60–90°C for 2 h. The reaction mixture was then poured into 80 mL of ice-water. The aqueous solution was extracted with ether and the organic extract was washed with cold water, then with sodium bicarbonate solution (10%), and finally dried ($MgSO_4$). Evaporation of the solvent furnished the crude product. Yield 53%; mp 126–130°C. The material was recrystallized from ethanol to give small crystals of *2-(3,4-dimethoxyphenyl)-5,6-dimethoxyindan-1-one* **16**, mp 128–130°C (13); ^{1}H nmr; 3.30 (m, 1H), 3.35–3.90 (m, 2H), 3.80, 3.90, 3.95 (s, 12H, OCH_3), 6.60–6.80 (m, 3H Ar), 6.90 (s, 1H, H-4), 7.20 (s, 1H, H-7).

2-(3,4-Dimethoxyphenyl)-5,6-dimethoxyindene 17

This indene was prepared by the same procedure as described for **14**. Yield 78%; mp 208°C (lit. (12) mp 208°C (benzene)); ^{1}H nmr: 3.65 (s, 2H, CH_2), 3.70, 3.80 (s, 12H, OCH_3), 6.5–7.10 (m, 6H, Ar and H–3).

2-(3,4-Dimethoxphenyl)-5,6-dimethoxyindane 3

This indane was prepared by the same procedure as described for **2**. Yield 80%; mp 152°C (lit. (12) mp 152°C (ethanol); ^{1}H nmr: 2.82–3.67 (m, 5H, H–1 and H–2), 3.85, 3.86 (s, 12H, OCH_3), 6.78 (s, 2H, H–4 and H–7), 6.81 (s, 3H, Ar); ^{13}C nmr: 40.95, 45.34, 55.55, 55.66, 55.79, 107.53, 110.22, 110.96, 118.54, 134.16, 138.11, 147.14, 147.88, 148.61.

1-Benzyl-5,6-dimethoxyindane 4

5,6-Dimethoxyindan-1-one **19** (2) (1.92 g; 10 mmol) dissolved in anhydrous benzene was added to an excess of benzylmagnesium chloride (50 mmol) and the mixture was refluxed for 2 h. The reaction mixture was poured into ice mixed with acetic acid. The organic layer was separated and the aqueous solution was extracted with two portions of methylene chloride. The combined organic extracts were washed with a dilute solution of sodium bicarbonate followed by water, and finally were dried ($MgSO_4$) and the solvent was evaporated. Without further purification the indene **20** was hydrogenated in acetic acid with platinum dioxide at room temperature and 40 psi for 2 h. Removal of catalyst and solvent rendered a yellowish oil that was purified by p-tlc of Silica Gel G F254 and developed with benzene. The upper band afforded 1-benzyl-5,6-dimethoxyindane **4** as a pale yellow oil. Yield 49%; ^{1}H nmr: 2.0 (m, 2H, H–2), 2.75 (m, 4H, H–3 and CH_2-Ar), 3.3 (m, 1H, H–1), 3.75, 3.85 (s, 6H, OCH_3), 6.45 (s, 1H, H–7), 6.70 (s, 1H, H–4), 7.2 (s, 5H, Ar); ^{13}C nmr: 30.9, 32.2, 41.8, 46.3, 55.9, 107.5, 107.7, 125.8, 128.0, 129.0, 135.4, 138.3, 140.7, 147.5, 148.0. Anal. calcd. for $C_{18}H_{20}O_2$: C 80.66, H 7.52; found: C 80.77, H 7.60.

cis-*1-Benzyl-3-(4-methylphenyl)-5,6-dimethoxyindane 5*

The 1-(4-methylphenyl)-4-phenyl-3-(3,4-dimethoxyphenyl)butan-1-one **21**, starting material for the synthesis of indane **5**, was prepared by reaction of **10** with benzylmagnesium bromide and cuprous chloride (2). Yield 65%: mp 96–98°C (ethanol): ir (mull): 1680 (C=O) cm^{-1}; ^{1}H nmr: 2.4 (s, 3H, CH_3-Ar), 2.6–3.6 (m, 5H, H-2, H-3, and H-4), 3.9 (s, 6H, OCH_3), 6.85 (s, 3H, Ar), 7.2 (d, J_{ortho} = 8.0 Hz, 2H, Ar), 7.35 (s, 5H, Ar), 7.8 (d, J_{ortho} = 8.0 Hz, Ar). Anal. calcd. for $C_{25}H_{26}O_3$: C 80.28, H 7.01; found: C 80.34, H 7.07.

The indene **22** was obtained from **21** by the same procedure as described for **12** and without further purification was reduced by the same procedure as described for **1** to give **5** as an oil. Yield 89%; ^{1}H nmr: 1.70 (m, 1H, H-2), 2.3 (s, 3H, CH_3-Ar), 2.75 (m, 1H, H-2), 2.90 (m, 2H, CH_2-Ar), 3.30 (m, 1H, H-1), 3.7, 3.8 (s, 6H, OCH_3), 4.05 (dd, 1H, H-3), 6.4 (s, 1H, H-4), 6.65 (d, 1H, H-7), 7.05 (s, 4H, Ar), 7.20 (s, 5H, Ar); ^{13}C nmr: 20.80, 41.80, 44.86, 45.15, 49.69, 55.83, 55.88, 106.43, 107.84, 125.85, 127.97, 128.16, 128.89, 129.04, 135.68, 138.37, 138.71, 140.52, 142.23, 147.99, 148.23. Anal. calcd. for $C_{25}H_{26}O_2$: C 83.87, H 7.32; found: C 83.60, H 7.26.

cis- *and* trans-*1-Benzyl-2-(3,4-dimethoxyphenyl)-5,6-dimethoxyindane 6* and *7*

2-(3,4-Dimethoxyphenyl)-5,6-dimethoxyindanone (13) **16** (3.23 g; 10 mmol) and benzylmagnesium chloride (50 mmol) were treated in a manner similar to that described for **4**. The crude product was purified by p-tlc of Silica Gel G F254. The plates were developed with benzene. The p-tlc indicated the presence of one major component, which was identified as 3-benzyl-2-(3,4-dimethoxyphenyl)-5,6-dimethoxyindene **23**. It was obtained as an oil. Yield 70%; ^{1}H nmr: 3.60, 3.75, 3.85, 3.90 (s, 12H, OCH_3), 3.70 (s, 2H, H-3), 4.10 (s, 2H, CH_2-Ar), 6.65–7.00 (m, 5H, Ar), 7.20 (s, 5H, Ph). Anal. calcd. for $C_{26}H_{26}O_4$: C 77.68, H 6.52; found: C 77.73, H 6.60.

Hydrogenation of 210 mg of this indene **23** in 50 mL of ethanol with 300 mg of Pd(C) 5% at room temperature and 40 psi afforded 190 mg of the *cis* isomer **6** as an oil. Yield 90.4%; ^{1}H nmr: 2.40 (m, 3H, H-2 and H-3), 3.20 (m, 2H, CH_2-Ar), 3.57 (m, 1H, H-1), 3.75, 3.83, 3.87 (s, 12H, OCH_3), 6.06 (s, 1H, Ar), 6.70–7.20 (m, 9H, Ar); ^{13}C nmr: 36.1, 36.6, 49.6, 50.8, 55.5, 55.6, 55.7, 55.8, 107.6, 108.5, 111.01, 111.9, 119.9, 125.5, 127.7, 129.3, 134.0, 134.4, 137.6, 140.6, 147.0, 147.4, 147.9, 148.5. Anal. calcd. for $C_{26}H_{28}O_4$: C 77.29, H 6.99: found: C 77.36, H 7.07.

The indene **23** was reduced with sodium in boiling pentanol (8). The product, after acidic work-up, was filtered through a short column of basic alumina (Act. 1). Evaporation of the solvent gave an oil. Yield 35%; the ^{13}C nmr data for the oil showed a mixture of *cis* **6** and *trans* **7**.

trans Isomer **7**: ^{13}C nmr; 31.86, 40.69, 55.00, 55.52, 55.72, 55.95, 103.24, 107.53, 110.78, 110.94, 119.67, 125.68, 127.74, 128.17, 134.8, 134.72, 139.28, 139,37, 146,88, 147.62, 148.00, 148.30.

cis- *and* trans-*1-Phenyl-2-(3,4-dimethoxyphenyl)indane* ***8*** *and* ***9***

The 3-benzylidenephthalide **29** was treated with phenylmagnesium bromide, following the procedure described in the literature (9). The indenone **24** was obtained as a solid. Yield 44%. Recrystallization of **24** from ether – methylene chloride afforded orange needles, mp 134–135°C; ir (KBr): 1770 (C=O) cm^{-1}; ^1H nmr: 3.70, 3.75 (s, 6H, OCH_3), 6.70–7.70 (m, 12H, Ar). Anal. calcd. for $C_{23}H_{18}O_3$; C 80.77, H 5.31; found: C 80.88, H 5.28.

The indene **24** was reduced following Galton's procedure (6). The amalgamated zinc was prepared from 1 g of granulated zinc and 100 mg of mercuric chloride in 1.5 mL of water and 0.05 mL of concentrated hydrochloric acid. To the zinc amalgam was added 0.7 mL of water, a solution of 0.5 g of the indenone **24** in 6 mL of toluene, and 1.75 mL of concentrated hydrochloric acid. This mixture was heated under reflux for 24 h, during which time three 1.5-mL portions of concentrated hydrochloric acid were added. The toluene phase was separated, washed with water, and dried ($MgSO_4$). Evaporation of the solvent afforded a yellow oil (400 mg). A small portion of crystals was separated with the aid of several drops of ethanol. The white needles obtained were crystallized from ethanol. Yield 25%; mp 117–118°C. The structure of this compound was established and assigned to the *cis*-isomer **8**: ^1H nmr: 3.26 (d, J = 8 Hz, 2H, H-3), 3.47, 3.78 (s, 6H, OCH_3), 3.95 (J = 8 Hz, 1H, H-2), 4.61 (d, J = 8 Hz, 1H, H-1), 6.09 (s, 1H, Ar), 6.57 (m, 4H, Ar), 7.18 (m, 7H, Ar); ^{13}C nmr: 37.5, 51.7, 55.4, 55.7, 56.8, 110.4, 111.9, 120.5, 124.16, 125.4, 125.9, 126.8, 126.9, 127.6, 129.1, 133.7, 141.0, 143.8, 145.3, 147.3, 148.0. Anal calcd. for $C_{23}H_{22}O_2$: C 83.71, H 6.72: found: C 83.67, H 6.78.

The filtrate was evaporated and the residue (250 mg) was analyzed by p-tlc of Silica Gel G F254, and developed with benzene. The 1-phenyl-2-(3,4-dimethoxyphenyl) indene **25** was obtained as the upper band. Elution gave white crystals. Yield 23%: mp 127–128°C (ethanol); ^1H nmr: 3.77, 3.82 (s, 6H, OCH_3), 4.91 (brs, 1H, H-1), 6.73 (d, J_{ortho} = 8.8 Hz, 1H, Ar), 7.00–7.40 (m, 12H, Ar and H-3). Anal. calcd. for $C_{23}H_{20}O_2$: C 84.22, H 6.15; found: C 84.30, H 6.23.

The lower band yielded 95 mg of a mixture of *cis* and *trans* indanes **8** and **9**, which was established by ^1H nmr and ^{13}C nmr; ^1H nmr, mixture **8** and **9**: 3.26 (d, J = 8.0 Hz, H-3), 3.36–3.6 (m, H-3), 3.47, 3.73, 3.77, 3.84 (s, OCH_3), 3.75 (m, 1H, H-2), 3.95 (m, H-2), 4.34 (d, J = 8.8 Hz, H-1), 4.61 (d, J = 8.0 Hz, H-1), 6.09 (s, Ar), 6.52–6.76 (m, Ar), 7.0–7.4 (m, Ar); ^{13}C nmr: 37.5, 39.8, 51.7, 55.4, 55.7, 56.3, 56.8, 59.8, 110.4, 110.9, 111.1, 111.9, 119.1, 120.5, 124.1, 124.8, 125.4, 125.9, 126.4, 126.6, 126.8, 127.6, 128.3, 128.5, 129.1, 133.7, 135.6, 141.0, 142.8, 143.3, 143.8, 145.8, 147.2, 147.8, 148.6.

cis-*1,2-Diphenylindane* ***30***

(a) Clemmensen reduction

2,3-Diphenylindenone **28** (1 g) (6) was reduced by the Manning procedure (9). The liquid phase was decanted and extracted with portions of methylene chloride (2 × 10 mL): the organic extracts were washed and dried. Evaporation of the solvent gave 0.85 g of an orange oil, which was analyzed by p-tlc of Silica Gel G F254 and developed with petroleum ether 60–80°C. The upper band gave 0.48 g of 1,2-diphenylindene **26**. Yield 50%; mp 176–178°C (ethanol); ^1H nmr: 4.95 (s, 1H, H-1), 7.00–7.60 (m, 15H, Ar and H-3).

The lower band yielded 0.28 g of *cis*-1,2-diphenylindane **30**. Yield 29%; mp 119–121°C (lit. (6) mp 119–121°C); ^1H nmr: 3.30 (m, 2H, H-3), 4.05 (m, 1H, H-2), 4.70 (d, 1H, J = 8 Hz, H-1), 6.60–7.40 (m, 14H, Ar); ^{13}C nmr: 36.77, 51.70, 56.71, 125.32, 125.81, 126.70, 127.39, 127.94, 128.07, 128.25, 128.61, 128.92, 129.16, 140.87, 141.00, 142.16.

(b) Catalytic hydrogenation of 2,3-diphenylindene ***27***

A solution of 1.0 g of the indene **27** in 15 mL of ethanol was hydrogenated with 10 mg of platinum dioxide catalyst at room temperature and 40 psi for 1 h. Removal of catalyst and solvent gave the indane **10**. Yield 89%.

(c) Catalytic hydrogenation of 1,2-diphenylindene ***26***

The indene **26** was hydrogenated with Pd(C) 5% in ethanol at 50 psi. After 30 min the catalyst was removed and the filtrate was concentrated to give the *cis*-1,2-diphenylindane **30** as white needles, mp 121–122°C. The structure of this compound was established by ^1H nmr and ^{13}C nmr spectroscopy.

Stereochemical studies of the photochemical cycloaddition reaction of alkenes with *N*-benzoylindole and *N*-carboethoxyindole; evidence for biradical intermediacy[1]

DAVID J. HASTINGS AND ALAN C. WEEDON[2]

The Photochemistry Unit, Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 20, 1990[3]

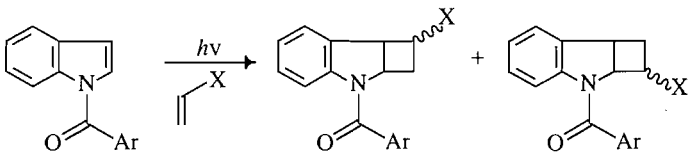
DAVID J. HASTINGS and ALAN C. WEEDON. Can. J. Chem. **69**, 1171 (1991).

The stereochemistries of the 2+2 cycloaddition products obtained from the photochemical addition reaction between *N*-benzoylindole or *N*-carboethoxyindole and the alkenes cyclopentene, cyclohexene, cycloheptene, *cis*- and *trans*-2-butene, and *cis*- and *trans*-4-octene are examined. The structures of the products are shown to be consistent with a photo-cycloaddition mechanism involving the intermediacy of triplet 1,4-biradical species. The quantum yields of adduct formation between *N*-benzoylindole and both *cis*- and *trans*-octene were measured as a function of alkene concentration. The results suggest that *cis*-octene reacts with the indole derivative's triplet excited state with a rate constant of $(1.7 \pm 0.3) \times 10^7\ M^{-1}\ s^{-1}$. The results are also consistent with the immediate products of this reaction being 1,4-biradicals, 98% of which revert to the ground state indole derivative and alkene, and only 2% of which proceed to cycloadduct. In marked contrast, the same treatment suggests that *trans*-octene reacts with the triplet excited state of *N*-benzoylindole with a rate constant estimated to be in the range of 1×10^6 and $6 \times 10^5\ M^{-1}\ s^{-1}$, and it appears that the 1,4-biradicals formed revert much less efficiently to the starting materials; it is estimated that between 67 and 100% of the 1,4-biradicals proceed to cycloadducts. In the reaction with *cis*-octene biradical reversion leads to the formation of *trans*-octene ("Schenk isomerization"); the quantum yield of this process is determined to be 0.074 ± 0.004, which may imply that approximately 75% of the biradicals collapse to *cis*-alkene and 25% collapse to the *trans* isomer.

Key words: indole, photocycloaddition, 1,4-biradicals.

DAVID J. HASTINGS and ALAN C. WEEDON. Can. J. Chem. **69**, 1171 (1991).

On a étudié les stéréochimies des produits de cycloaddition 2+2 obtenus par réaction d'addition photochimique entre le *N*-benzoylindole ou le *N*-carboéthoxyindole et les alcènes suivants : cyclopentène, cyclohexène, cycloheptène, *cis*- et *trans*-but-2-éne et *cis*- et *trans*-oct-4-ène. On démontre que les structures des produits correspondent à celles attendues sur la base d'un mécanisme de photo-cycloaddition impliquant des espèces 1,4-biradicalaires triplets comme intermédiaries. On a déterminé les rendements quantiques pour la formation des adduits entre le *N*-benzoylindole et les *cis*- et *trans*-octènes en fonction de la concentration d'alcène. Les résultats suggèrent que le *cis*-octène réagit avec l'état excité triplet du dérivé de l'indole avec une constante de vitesse de $(1{,}7 \pm 0{,}3) \times 10^7\ M^{-1}\ s^{-1}$. Les résultats sont aussi en accord avec l'existence de 1,4-biradicaux comme produits immédiats de cette réaction dont 98% retourneraient aux états fondamentaux de l'alcène et du dérivé de l'indole alors que seulement 2% conduiraient au produit de cycloadduction. Par ailleurs, un traitement similaire suggère que le *trans*-octène réagit avec l'état excité triplet du *N*-benzoylindole avec une vitesse de réaction qui se situerait entre 1×10^6 et $6 \times 10^5\ M^{-1}\ s^{-1}$ alors que les 1,4-biradicaux qui se forment sont beaucoup moins efficaces pour retourner aux produits de départ; on a évalué que 67–100% des 1,4-biradicaux conduisent aux cycloadduits. Dans la réaction avec le *cis*-octène, le retour des biradicaux vers les produits de départ conduit à la formation du *trans*-octène (« isomérisation de Schenk »); le rendement quantique de ce processus serait de l'ordre de $0{,}074 \pm 0{,}004$ ce qui implique qu'environ 75% des biradicaux conduisent à l'alcène *cis* alors que 25% fournissent l'isomere *trans*.



Mots clés : indole, photocycloaddition, biradicaux-1,4.

[Traduit par la rédaction]

Introduction

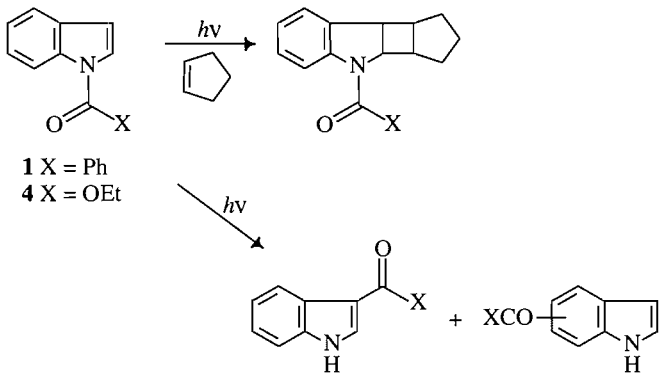
In 1973 Julian and Foster reported (1) that indoles possessing a benzoyl substituent on the indole nitrogen atom form cyclobutane adducts when irradiated with ultraviolet light in the presence of monosubstituted ethylenes (Scheme 1). The reaction was found to be regioselective, with the isomer **2** favoured over **3**. In a later investigation Ikeda *et al.* confirmed this result (2) and further demonstrated that the reaction is not stereoselective so that in **2** the carbon atom bearing the X-substituent can have both possible configurations.

In principle, this cycloaddition reaction could offer a powerful method for the synthesis of substituted indoles if methods for the selective cleavage or elaboration of the cyclobutane ring of the cycloadducts can be developed. The potential synthetic application of this reaction also requires a knowledge of the mechanism by which the photochemical cycloaddition step

1 Ar = Ph **2** **3**

SCHEME 1

proceeds, so that the effect of further variation of alkene and indole structure upon the reaction efficiency, regiochemistry, and stereochemistry can be predicted.



As part of a program of research that, it is hoped, will lead to useful synthetic applications, we have been examining the mechanism of the photochemical cycloaddition reaction between alkenes and *N*-acylindoles (3–5). We have found (3) that *N*-carboethoxyindole, **4** (Scheme 2), also undergoes the photochemical cycloaddition reaction with alkenes and that both *N*-carboethoxyindole and *N*-benzoylindole undergo a photo-Fries rearrangement reaction in competition with cycloaddition. The efficiency of each of these two competing reactions varies

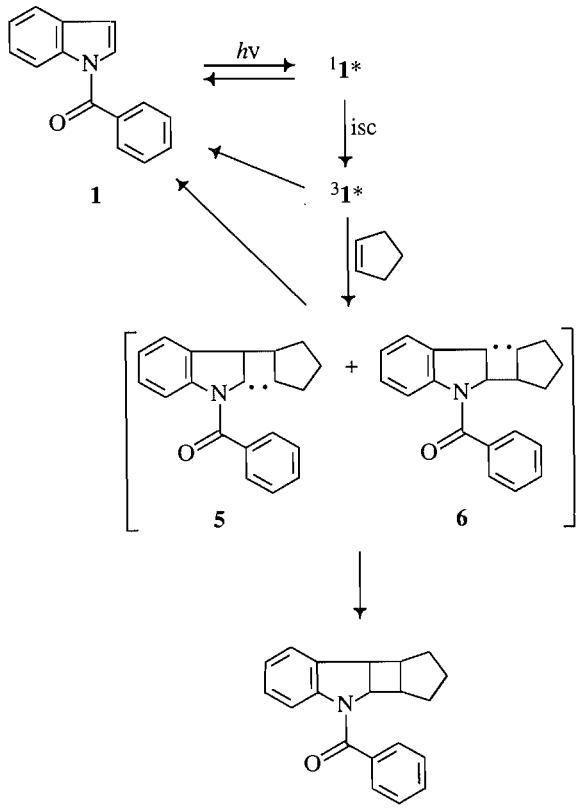
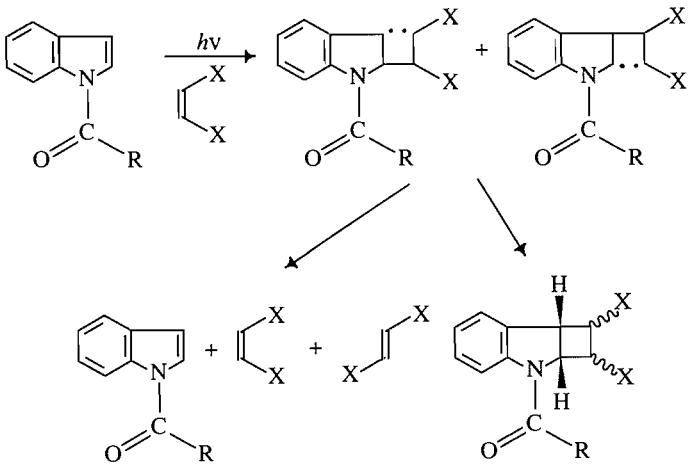
SCHEME 2

differently when either the solvent or the wavelength of the ultraviolet light used for excitation is changed, and this allows selection of one reaction path over the other (3).



We have also shown (4) for *N*-benzoylindole that the photochemical cycloaddition reaction proceeds by interception of the triplet excited state of the indole derivative by alkene. At high alkene concentrations all of the triplet excited states of *N*-benzoylindole are intercepted, so that the efficiency of the cycloaddition reaction (i.e., the quantum yield of cycloadduct formation, Φ) should approach the efficiency of triplet excited state formation (i.e., the quantum yield of intersystem crossing, Φ_{isc}); however, the value of Φ extrapolated to infinite alkene concentration for the addition of *N*-benzoylindole to cyclopentene was found to be 0.06, which is much smaller than the value of 0.30 determined for Φ_{isc}. To explain this discrepancy we have postulated (4) that an intermediate is formed from the reaction of the triplet excited state of the indole derivative with the alkene and that this intermediate can either proceed to cycloadduct or revert to the ground state starting materials. For the reaction of *N*-benzoylindole with cyclopentene, possible structures for this intermediate could be stereoisomers of the regioisomeric triplet 1,4-biradicals **5** and **6**, as shown in Scheme 3.

If triplet biradicals of the type **5** and **6** are indeed intermediates in this reaction, and if they do revert to the ground state precursors in competition with product formation, then this might be detectable if suitable 1,2-disubstituted alkenes are used as the alkene partner in the photochemical cycloaddition reaction. This possibility is illustrated in Scheme 4. If the putative intermediate biradicals shown in Scheme 4 are sufficiently long-lived, so that any memory of the stereochemistry of the starting alkene is lost, then the stereochemistry of the cyclobutene adducts will be mixed; in addition isomerized alkene will be observed in the reaction mixture. Alternatively, if no biradical intermediates are involved in the reaction, or if they are too short-lived for conformational relaxation, then different products might be expected depending upon which geometrical isomer of the alkene is used, and no isomerized alkene will be seen in the reaction mixture.



Reported here are the results of an investigation in which *N*-acylindoles have been irradiated in the presence of cyclic and noncyclic 1,2-dialkyl-substituted ethylenes and the stereochemistry of the products examined. These results are then discussed in terms of the possible intermediacy of biradical species.

Results of photochemical cycloaddition and elucidation of the structures of the photoproducts

The addition of a 1,2-disubstituted ethylene to an *N*-acylindole leads to the formation of four chiral centres. The maximum

SCHEME 3

SCHEME 4

number of stereoisomers that can be produced is, however, reduced by the presence of the cyclobutane–cyclopentane ring fusion, which is expected to be *cis* as shown in Scheme 4. Consequently if the two substituents on the ethylene are the same (so that no possibility of regioisomerism exists), then the photoaddition is expected to produce four pairs of enantiomers related as diastereomers. The major analytical problem in this work was to detect, separate, and assign the stereochemistries of these diastereomers.

Several groups have examined the use of nmr spectroscopy for stereochemical assignment of substituted cyclobutane rings (6–16). The use of ^{1}H–^{1}H coupling constants for the hydrogens

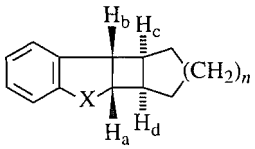
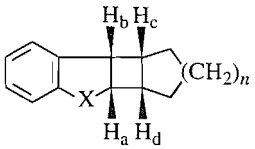
on the cyclobutane ring has met with some success but ambiguities can be caused by the conformational mobility of the puckered cyclobutane ring (14–16). Recently it was shown that nuclear Overhauser effects between cyclobutane ring hydrogens or substituents can lead to stereochemical assignments (6, 7); however, this has not been demonstrated to be a general method.



Because of these problems of stereochemical assignment the first alkene examined in this work was cyclopentene. It was anticipated that with this alkene only the two diastereoisomeric pairs of enantiomers represented by structures **7** and **8** would be formed since the sizes of the rings fused to the cyclobutane would preclude the formation of products in which the hydrogens at the cyclopentane–cyclobutane ring fusion positions could be *trans*. It was hoped that the spectroscopic characteristics of the cyclopentene adducts could then be used as models for deduction of the stereochemistry of adducts from other alkenes.



1. Irradiation of N*-benzoylindole and* N*-carboethoxyindole with cyclopentene*

Both gas chromatography (gc) and thin-layer chromatography (tlc) indicated the formation of a single product when a benzene solution of *N*-benzoylindole, **1**, and cyclopentene was irradiated with ultraviolet light under conditions such that only **1** was excited. However, following work-up and removal of unconsumed starting material, the ^{1}H nmr and ^{13}C nmr spectra of the product suggested the presence of two compounds in a 2:1 ratio. The major component was highly crystalline and this allowed its separation from the minor component, which was subsequently isolated from the mother liquors as an oil. The mass spectra of the isolated products indicated them to be adducts of **1** and cyclopentene, and the ^{1}H nmr spectra were consistent with the expected structures **7** and **8**. In particular, the cyclobutane methine protons were clearly visible; for the major isomer they appeared at 3.94, 3.32, 2.84, and 2.66 ppm and these are assigned to protons H_a, H_b, H_c, and H_d, respectively. These assignments are based partly upon the positions calculated using additive chemical shift correlations, and partly on the appearance of the signals and their coupling relationships as deduced from spin–spin decoupling experiments and two-dimensional homonuclear spectra. The signal assigned to H_a appeared as a broad singlet and its splitting by H_b and H_d was unresolved; this is ascribed to slow rotation of the adjacent *N*-benzoyl group. However, the signal assigned to H_b appeared as a double doublet with J = 7.5 and 2.9 Hz. Molecular models of **7** show that the structure is quite rigid and suggest that with the cyclobutane ring in either of its puckered conformations the dihedral angles between H_b and H_a are close to zero, and between H_b and H_c are close to 90°; in this situation the Karplus equations predict the small and large coupling constants observed.

In the minor photoadduct the signal assigned to H_a was also an unresolved broadened singlet and was seen at 4.70 ppm; the signal assigned to H_b was a double doublet at 4.05 ppm with coupling constants of 7.5 and 8.0 Hz. The observation of two large coupling constants between H_b and H_a, and H_b and H_c is consistent with the minor photoadduct having structure **8**, as judged by the inspection of the dihedral angles between the appropriate hydrogens in a molecular model of **8**. The relevant dihedral angles in this case are both close to zero.

To support the above assignments attempts were made to remove the benzoyl group from the photoadducts; it was hoped that in the absence of this group the signal assigned to H_a would be resolved so that the coupling constants to H_b and H_d could be measured independently. The benzoyl group was, however, totally resistant to hydrolysis under both basic and acidic conditions. Eventually it was found that treatment of the photoadducts with lithium aluminum hydride resulted in the formation of a mixture of the *N*-benzyl derivatives **9** and **10** as well as the products of cleavage, **11** and **12**. These compounds were separated by chromatography and their ^{1}H nmr spectra recorded. As anticipated, the signal assigned to H_a in these compounds was resolved as a double doublet and the coupling constants were consistent with the *cis-anti-cis* stereochemistry in **9** and **11**, and the *cis-syn-cis* stereochemistry seen in **10** and **12**. The coupling constant data for the cyclobutane methine hydrogens of these compounds are summarized in Table 1.

7 X = NCOPh, n = 1
9 X = NCH_2Ph, n = 1
11 X = NH, n = 1
13 X = CH_2, n = 1
15 X = NCO_2Et, n = 1
17 X = NCOPh, n = 2
21 X = CH_2, n = 2
25 X = NH, n = 2
29 X = NCOPh, n = 3

8 X = NCOPh, n = 1
10 X = NCH_2Ph, n = 1
12 X = NH, n = 1
14 X = CH_2, n = 1
16 X = NCO_2Et, n = 1
18 X = NCOPh, n = 2
22 X = CH_2, n = 2
26 X = NH, n = 2

The above assignments were further tested by a molecular modelling (MM2) calculation to derive the structures of the most stable conformations of **7**–**12**. The dihedral angles between the cyclobutane methine hydrogens in the most stable conformations were then substituted into the appropriate Karplus equation in order to predict the expected coupling constants. For ease of calculation and because the nitrogen parameters necessary for **7**–**12** were unavailable to us, the indane analogues **13** and **14** were used. The results for **13** and **14** are shown in Table 1 along with the actual coupling constants measured from the ^{1}H nmr spectra of **7**–**12**. The agreement between the calculated values for **13** and **14** and those measured for compounds **7**–**12** is qualitatively very good and quantitatively reasonable, and indicates that for these systems the calculation is reliable for deduction of stereochemistry from coupling constant data, even though indane is being used as a model for indoline, and even though no allowance is made for the effect of an electronegative substituent (the nitrogen atom) on the coupling constants.

The calculated structures of the most stable conformations of **13** and **14** were also used to predict the likely effect of a lanthanide shift reagent complexed to the nitrogen atom of **11** and **12** on the chemical shifts of the cyclobutane methine hydrogens. The calculated relative shifts of the cyclobutane methine hydrogens were then compared with the observed relative shifts when the shift reagent $Eu(fod)_3$ was added to deutero-chloroform solutions of **11** and **12**.

The change in chemical shift of a proton in a rigid molecule induced by a lanthanide shift reagent complexed to a remote Lewis base site in the same molecule is proportional to the magnitude of the pseudocontact interaction, ΔM, between the lanthanide and the proton. The magnitude of ΔM is proportional to $1/r^3$, where r is the distance between the lanthanide and the shifted proton. The magnitude of ΔM is also related to the angle, θ, between the line connecting the lanthanide with the shifted

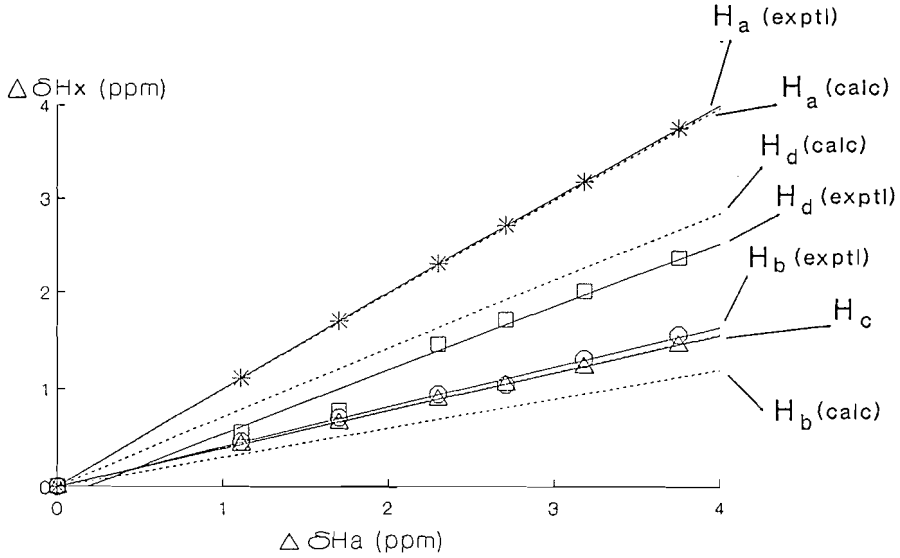


FIG. 1. Calculated (dotted lines) and observed (full lines) changes in chemical shift ($\Delta\delta H_x$) of cyclobutane methine protons in adduct **11** relative to the change in chemical shift of H_a ($\Delta\delta H_a$) consequent upon addition of Eu $(fod)_3$ to $CDCl_3$ solutions of **11**. The calculated and observed lines for H_c are coincident.

[a]The observed relative lanthanide-induced shift data are obtained from the gradients of the lines in the plot of the change in chemical shift of each proton relative to the change in chemical shift of H_a. Examples are shown in Figs. 1 and 2. The method for derivation of the calculated numbers is described in the text.

proton and the axis of the bond between the lanthanide and the basic site in the molecule, as defined by:

$$\Delta M \alpha \frac{1}{r^3}(3\cos^2\theta - 1)$$

Using this relationship for the most stable conformations of **11** and **12**, with the assumption that the lanthanide complex is attached from the less-hindered face of the molecule to a tetrahedral nitrogen atom, allows the expected relative changes in chemical shifts of the cyclobutane methine hydrogens to be calculated. These can then be compared with the experimental values. The results of such an experiment for compounds **11** and **12** are shown in Figs. 1 and 2 where the experimentally determined lanthanide-induced shifts are expressed relative to the shift observed for H_a, and the calculated values of $1/r^3 \times (3\cos^2\theta - 1)$ for each cyclobutane methine hydrogen are normalized relative to the value for H_a. The gradients of the lines in Figs. 1 and 2 are proportional to ΔM for each hydrogen and these are summarized in Table 2.

The experimental data in Figs. 1 and 2 and Table 2 indicate that for both **11** and **12** the cyclobutane methine closest to the site of lanthanide complexation (i.e., H_a) is the most greatly shifted. In addition, in **11** H_d is more greatly shifted than H_b and H_c, while in **12** H_b, H_c, and H_d are shifted to approximately similar extents. The predicted relative shifts for these hydrogens obtained using the calculated most stable conformations follow the same pattern, with H_a the most greatly shifted in both compounds and H_d more greatly perturbed in **11** only.

For the lanthanide-induced shift experiments it was found

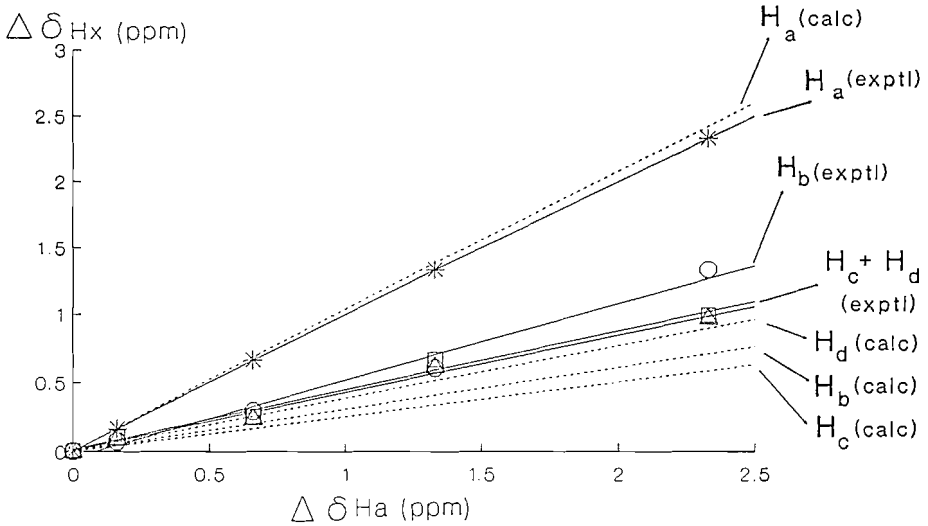

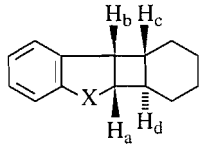

FIG. 2. Calculated (dotted lines) and observed (full lines) changes in chemical shift ($\Delta\delta H_x$) of cyclobutane methine protons in adduct **12** relative to the change in chemical shift of H_a ($\Delta\delta H_a$) consequent upon addition of Eu (fod)$_3$ to $CDCl_3$ solutions of **12**.

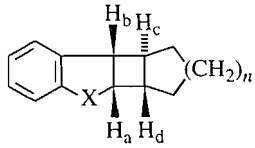

convenient to generate the amine adducts **11** and **12** by photochemical cycloaddition of cyclopentene to *N*-carboethoxyindole, **4**, rather than to *N*-benzoylindole, **1**. The initially formed adducts **15** and **16** were obtained in a 10:1 ratio and were immediately hydrolysed to **11** and **12** by strong base. This gave the amine adducts in good yield and uncontaminated by their benzylated analogues **9** and **10**, which were by-products formed in the removal of the photochemical activating group from the *N*-benzoylindole photoadducts. It was found necessary to use the free amine adducts **11** and **12** for the lanthanide-induced shift study, rather than the *N*-substituted analogues **7**–**10**, since with the latter the lanthanide shift reagent did not form sufficiently strong complexes to give accurately measurable changes in chemical shift.

2. *Irradiation of* N-*benzoylindole and* N-*carboethoxyindole with cyclohexene*

The photochemical cycloaddition of cyclohexene to *N*-benzoylindole could, in principle, yield the four diastereoisomeric pairs of enantiomers represented by **17**–**20**. In fact, when *N*-benzoylindole was irradiated in the presence of cyclohexene only two products were detected. These compounds were not separable by chromatography but one of them was highly crystalline and could be separated in pure form by recrystallization. The second product was isolated as an oil contaminated by small amounts of the crystalline isomer. The mass spectra of these compounds indicated them to be 1:1 adducts between the indole derivative and cyclohexene, and the ^{1}H nmr and ^{13}C nmr spectra were consistent with their being cyclobutane adducts analogous to those formed with cyclopentene. Most importantly, the four cyclobutane methine hydrogens were visible for each compound and their coupling constants could be measured. The coupling constants are shown in Table 1 for the crystalline product ("Isomer I") and its noncrystalline isomer ("Isomer II"). The expected coupling constants for the cyclobutane methine hydrogens in **17**–**20** were estimated from the dihedral angles in the most stable conformations of the indane analogues **21**–**24**. These conformations were derived from molecular modelling calculations in the same way as for the cyclopentane analogues **13** and **14**. The results are shown in Table 1; they suggest that Isomer II is the *cis-anti-cis* stereoisomer **17** because of the small values of J_{ad} and J_{bc} that are predicted for **21** and were seen in

19 X = NCOPh
23 X = CH_2
27 X = NH

20 X = NCOPh, $n = 2$
24 X = CH_2, $n = 2$
28 X = NH, $n = 2$
30 X = NCOPh, $n = 3$

the cyclopentene adduct analogues **7**, **9**, and **11**. However, for Isomer I the estimated and observed coupling constants do not allow determination of stereochemistry. This is because all the coupling constants in **22**, **23**, and **24** are predicted to be of similar magnitude to those in Isomer I.

As with the cyclopentene cycloadducts, the cyclobutane methine H_a was poorly resolved in the ^{1}H nmr spectra of the two cyclohexene adducts and the coupling constants to H_b and H_d could not be seen directly but had to be inferred from the splitting seen in the signals assigned to H_b and H_d. As before, the broadening of the signal for H_a was associated with slow rotation of the *N*-benzoyl group in these compounds. Treatment of the crystalline adduct (Isomer I) with lithium aluminum hydride yielded the *N*-benzyl derivative ("Isomer I,NBz") and the free amine ("Isomer I,NH") in which the signal ascribed to H_a was resolved. The coupling constants of the cyclobutane methine hydrogens seen in the ^{1}H nmr spectra of these two compounds are shown in Table 1 and are similar to those of the parent compound prior to reduction.

Irradiation of *N*-carboethoxyindole, **4**, with cyclohexene also gave two major products, but two minor products were also detected by gc. Examination of these four compounds by gc – mass spectroscopy indicated them to be 1:1 adducts of the indole derivative with the cyclohexene, and the ^{1}H nmr spectrum of the mixture indicated the presence of the characteristic pattern of methine signals associated with the cyclobutane adducts. Gas chromatography indicated that the products were formed in the ratio 1.1:2:142:100. The product mixture was not separated but instead was hydrolysed to the free amines and separated by chromatography. One of the two major isomers present was identical with the product of reduction of Isomer I formed from *N*-benzoylindole (i.e., Isomer I,NH). The ^{1}H nmr spectrum of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12

For personal use only.

the other major isomer suggested it to be structure **25**. This was inferred from the values of the coupling constants between the cyclobutane methine hydrogens and these are listed in Table 1.The *cis-anti-cis* relationship of the hydrogens is indicated by the smaller values of J_{ad} and J_{bc}. This assignment was confirmed by lithium aluminum hydride reduction of **17** (i.e., Isomer II), which gave the compound identified as **25** (designated Isomer II,NH).

Of the two minor cyclohexene–*N*-carboethoxyindole cycloadduct isomers present in the original mixture, only one was separated following hydrolysis, the other being inseparable from the major isomers present. This compound is designated "Isomer III,NH" and the coupling constants for the cyclobutane methine hydrogens are shown in Table 1. Comparison of these with the coupling constants predicted for **22**–**24** does not allow unambiguous assignment of any one of the possible structures **26**–**28** to this compound.

To allow a stereochemical assignment of Isomers I and III and to confirm the identification of Isomer II as **17**, the lanthanide-induced shift experiment already described for **11** and **12** was performed using Isomer I,NH and Isomer II,NH (i.e., **25**) and Isomer III,NH. The relative shifts observed for the cyclobutane methine hydrogens of these three isomers are shown in Table 2 and are compared with those estimated for **25**–**28** using conformations calculated (MM2) to be the most stable. For Isomer II,NH the shift reagent perturbs H_a and H_d most highly, and H_b and H_c are much less affected; this mirrors the behaviour of the *cis-anti-cis* cyclopentene cycloadduct **11** and confirms the assignment of structure **25** to Isomer II,NH based upon coupling constant data. Similarly, comparison of the calculated shifts for the methines of **26**–**28** with those found for Isomer I,NH and Isomer III,NH strongly suggests that the former is **2** (H_b, H_c, H_d all similarly shifted) and that the latter is **28** (H_c more shifted than H_b and H_d). It can also be inferred that neither Isomer I,NH nor Isomer III,NH can be **27** since neither shows the predicted selective shift of H_d.

3. *Irradiation of* N-*benzoylindole with cycloheptene*

As with cyclohexene, the photochemical cycloaddition of *N*-benzoylindole to cycloheptene could in principle lead to four pairs of enantiomers related as diastereoisomers. When the irradiation was performed under the same conditions as for cyclopentene and cyclohexene only two products were detected by gc. These were formed in a 20:1 ratio and were shown to be 1:1 adducts between **1** and cycloheptene by gc–ms. The two adducts were separated by chromatography; their ^{1}H nmr spectra exhibited the characteristic signals associated with the cyclobutane methine protons and confirmed them to be the expected cyclobutane adducts. The minor isomer is assigned as structure **29**, which possesses *cis-anti-cis* stereochemistry; this assignment is based upon the observation of coupling constants of 2.5 and 3.0 Hz for J_{ad} and J_{bc}, respectively, which by analogy with the other *cis-anti-cis* stereoisomers in this work is indicative of a *trans* relationship between protons H_a and H_d, and H_b and H_c. Unlike the other *cis-anti-cis* *N*-benzoyl-substituted adducts **7** and **17**, the H_a proton in **29** was not broadened and the coupling constants could be measured without removal of the *N*-benzoyl activating group. This was not the case with the major isomer from the cycloheptene reaction; however, the coupling constants for the H_b methine could be discerned and were 9 and 3 Hz. The former of these can be unambiguosly assigned to the expected larger *cis* coupling between H_a and H_b so that the latter must correspond to J_{bc}. The small value of 3 Hz is strongly suggestive of a *trans* relationship between H_b and H_c and, since the *cis-anti-cis* stereochemistry in **29** has already been assigned to the minor isomer, the major isomer must therefore have the structure **30**, which possesses a *trans* cycloheptane–cyclobutane ring fusion.

4. *Irradiation of* N-*benzoylindole with* cis *and* trans *2-butene and 4-octene*

Irradiation of *N*-benzoylindole with *trans*-2-butene gave all four possible diastereoisomeric 1:1 adducts **31** (Scheme 4) in a ratio 7:21:68:4 as determined by gc and gc–ms. The adducts were separated as a mixture from the other components of the reaction; in the ^{1}H nmr spectrum of the separated mixture the cyclobutane methines of the two major isomers could be discerned, as could high-field doublets corresponding to the methyl substituents on the newly formed cyclobutane rings. The adducts were not further separated. Irradiation of *N*-benzoylindole with the *cis* isomer of 2-butene gave the same four adducts in almost the same ratio (2:21:74:2); the identity of the products of the two reactions was confirmed by gc coinjection and by comparison of the ^{1}H nmr spectra, which were superimposable. Similar results were obtained with *cis* and *trans*-4-octene. In these cases only three of the four possible diastereoisomeric adducts **32** (Scheme 4) were present in detectable quantities; these were formed in the ratio 2:49:49 from the *trans* isomer and 10:47:43 from the *cis* isomer. As with the butene adducts, the cyclobutane methines of the two major octene adducts were clearly visible in the ^{1}H nmr spectrum of the product mixture.

In the reaction with the octenes the reaction mixture was also examined for the presence of isomerized alkene. No *cis*-4-octene was formed in the irradiation of **1** with *trans*-4-octene. However, in the irradiation of **1** with *cis*-4-octene it was found that the *trans* isomer was formed as the irradiation proceeded. In these experiments the concentration of *cis* alkene was kept very high relative to that of **1** so that the *trans* isomer formed would never build up to a high enough concentration to enable it to react with the excited state of **1**; thus the formation of a similar product distribution from both alkenes cannot be attributed to faster reaction of **1** with the *trans* isomer formed during the irradiation.

The formation of *trans*-4-octene during the irradiation of **1** with *cis*-4-octene was quantified at low conversions by measurement of the amount of *trans*-octene produced relative to the amount of light absorbed. The result is shown in Fig. 3 and the gradient of this plot yields a value for the quantum yield of formation of the *trans* isomer of 0.074 ± 0.004.

For reasons that will be discussed below, the quantum yields of formation of the adducts from both the *cis*- and *trans*-octenes were also measured as a function of alkene concentration; the results are given in Table 3.

Discussion

For the reasons outlined in the Introduction, if biradicals are intermediates in the photochemical cycloaddition reactions of *N*-carbonyl-substituted indoles with alkenes, and if their lifetimes are long compared with the time required for conformational relaxation, then it would be expected that *trans*-fused adducts would be obtained from *cis* alkenes and *cis*-fused adducts would be obtained from *trans* alkenes. The conclusion of this work is that this is indeed the case. Thus with cyclohexene three of the four possible diastereoisomeric adducts are formed; these are assigned the structures **17**, **18**, and **20** and of

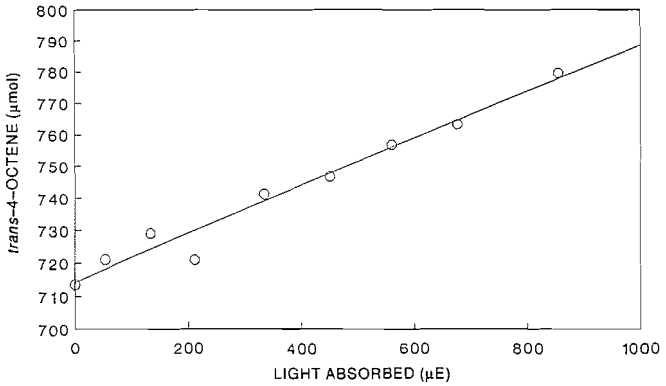

FIG. 3. Plot of amount of *trans*-octene formed during the irradiation (313 nm) of benzene solutions of *N*-benzoylindole, **1** (0.018 M), in the presence of *cis*-octene (5.31 M). The *cis*-octene used contained ca. 4% of the *trans* isomer at the start of the irradiation.

these **20** does not preserve the stereochemistry of the alkene. Similarly, with cycloheptene the major product is assigned the structure **30**, which has the same stereochemistry as **20**, the *trans*-fused product formed with cyclohexene, and does not preserve the stereochemistry of the alkene. With the noncyclic alkenes 2-butene and 4-octene, where both the *cis* and *trans* geometrical isomers of the alkene are available, almost the same distribution of products is obtained from each geometrical isomer. This is consistent with the intermediacy of the biradicals shown in Scheme 4 in which all memory of the alkene stereochemistry can be lost. It should be noted that each of the regioisomeric biradicals shown in Scheme 4 has two new chiral centres; it is not necessarily the case that each geometrical isomer of the alkene would produce the same proportions of the regioisomeric and diastereoisomeric biradicals and it is, in fact, quite surprising that the final distribution of the stereoisomeric cyclobutane adducts from each alkene geometrical isomer is so similar.

In our earlier work on the mechanism of photochemical cycloaddition between *N*-benzoylindole and cyclopentene (4), we examined the quantum yield of adduct formation as a function of alkene concentration and were able to show that the quantum yield varied with alkene concentration as predicted by the relationship shown in eq. [1]. This equation was derived assuming the validity of the mechanism shown in Scheme 3.

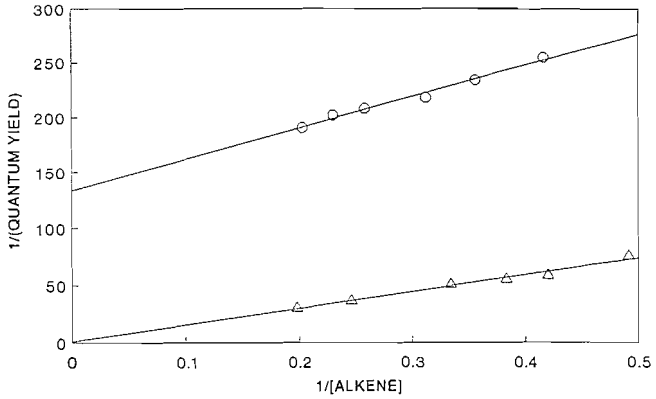

FIG. 4. Plot of reciprocal of quantum yield of formation of photocycloaddition product against reciprocal of alkene concentration for the irradiation (313 nm) of benzene solutions of *N*-benzoylindole, **1** (0.018 M), in the presence of either *cis*- or *trans*-4-octene (5.31 M). $$[1] \quad \frac{1}{\Phi} = \frac{1}{\Phi_{isc}}\left\{\frac{k_c}{k_r + k_c}\right\}^{-1}\left\{1 + \frac{k_d}{k_a[A]}\right\}$$

In eq. [1], Φ is the quantum yield of cycloadduct formation, Φ_{isc} is the quantum yield of intersystem crossing, k_d is the rate constant for decay of the triplet excited state of **1**, [A] is alkene concentration, and k_a is the rate constant for reaction of the triplet excited state of **1** with alkene. The rate constants k_c and k_r are those for cyclization of the intermediate biradical to product and reversion to starting materials, respectively. Thus the fraction $k_c/(k_c + k_r)$ is the fraction of the biradicals that proceed to the cycloadducts rather than reverting to the ground state starting materials. This treatment is an approximation since it assumes a single biradical intermediate is involved; because stereoisomeric and regioisomeric biradicals may well be intermediates, the fraction $k_c/(k_c + k_r)$ and k_a are composites for all the intermediate biradicals. The plot of $1/\Phi$ versus $1/[A]$ can be used to yield values of $k_c/(k_c + k_r)$ and k_a if Φ_{isc} and k_d are known. For *N*-benzoylindole, **1**, the values of Φ_{isc} and k_d have been independently determined as 0.39 ± 0.01 and $(3.6 \pm 0.4) \times 10^7\ s^{-1}$, respectively, using the triplet counting procedure; using these values, the quantities $k_c/(k_c + k_r)$ and k_a have been estimated as 0.16 and $(4.0 \pm 0.8) \times 10^6\ M^{-1}\ s^{-1}$, respectively, for the reaction of **1** with cyclopentene (4). This treatment was applied to the photoaddition of both *cis*- and *trans*-4-octene to **1**, and the data shown in Table 3 plotted according to eq. [1] are shown in Fig. 4.

For the addition of *cis*-octene to **1**, the intercept in Fig. 4 yields a value of $k_c/k_c + k_r$ of 0.019 ± 0.001, indicating that only 2% of the intermediate biradicals proceed to cyclobutane adducts and that the remainder revert to ground state **1** and alkene. In addition, the intercept indicates that at very high alkene concentration (i.e., when all of the triplet excited states of **1** are intercepted by alkene) the maximum value of Φ is 0.0075 ± 0.0002. Assuming a value of $3.6 \times 10^7\ s^{-1}$ for k_d, combination of the intercept of the plot for *cis*-octene with the gradient yields a value of k_a, the rate constant for reaction of the triplet excited state of **1** with *cis*-octene, of $(1.7 \pm 0.3) \times 10^7\ M^{-1}\ s^{-1}$, which is slightly faster than that observed for the reaction of **1** with cyclopentene.

The formation of *trans*-4-octene during the irradiation of **1** with *cis*-4-octene is an example of Schenk isomerization, i.e., a photochemical isomerization in which the isomerizing species

itself never attains the excited state. The isomerization of *cis*-octene to the *trans* isomer cannot be a result of energy transfer from the triplet excited state of **1** to the alkene since the triplet energy of the latter is higher than that of the indole derivative (4). The quantum yield of Schenk isomerization for *cis*-octene was determined to be 0.074 ± 0.004; the concentration of the alkene in this experiment was 5.31 M. At this concentration >70% of the triplet excited states of **1** are intercepted by the alkene (assuming $k_a = 1.7 \times 10^7$ and $k_d = 3.6 \times 10^7$); since $\Phi_{isc} = 0.39$, the maximum quantum yield of Schenk isomerization possible would be 0.27 if the 98% of the biradicals that do not cyclize to products revert to give only *cis*-octene. The value of 0.074 measured here would appear to indicate that the reverting biradicals prefer to give back *cis*-octene rather than the *trans* isomer. This assumes that no other energy-wasting step leading back to starting materials occurs between interception of the triplet excited state by alkene and the formation of the biradical intermediates; such an energy-wasting step could be exciplex formation and decay.

For the addition of *trans*-octene to **1**, the plot in Fig. 4 yields an intercept of 0.9 ± 3. This is indistinguishable from zero and its reciprocal cannot be used to obtain a reliable value of Φ extrapolated to infinite alkene concentration. However, it does allow limits for this value of Φ to be estimated; the *smallest* value possible, corresponding to the largest value of the intercept, is 0.26, while the largest is 0.39, the value determined for Φ_{isc}. This means that between 67 and 100% of the intermediate biradicals formed from the triplet excited state of **1** and *trans*-octene proceed to the product. Using these extreme values of the intercept, the gradient of the plot in Fig. 4 can be used to estimate limits on the values possible for k_a, the rate constant for reaction between triplet excited **1** and *trans*-octene. The values are 1×10^6 and $6 \times 10^5\ M^{-1}\ s^{-1}$, which are substantially slower than those determined for the photoaddition of **1** to cyclopentene and *cis*-octene.

Conclusions

The products formed from the photochemical addition of alkenes to *N*-benzoylindole and *N*-carboethoxyindole are consistent with the intermediacy of triplet 1,4-biradical intermediates. Quantum yield data suggest *cis*-octene reacts with the triplet excited state of *N*-benzoylindole faster than does the *trans* isomer, but that most of the biradicals revert to starting materials in the case of the former, and proceed to product for the latter.

Experimental

All nmr spectra were recorded in $CDCl_3$ solvent; ^1H nmr spectra were recorded at 200 MHz. The gc–ms analyses were performed using a Finnigan-MAT 8230 mass spectrometer coupled to a gas chromatograph equipped with an SE 54 capillary column.

General irradiation procedures

All preparative irradiations (gram scale) were carried out using a 450-W Hanovia medium pressure mercury lamp housed in a water-cooled Pyrex jacket, which was immersed in the solution to be irradiated. Benzene previously purged with nitrogen was used as the solvent and the solutions of **1** or **4** and the alkenes were briefly purged with nitrogen prior to irradiation. The solutions were stirred under an atmosphere of nitrogen during irradiations. Smaller scale preparative reactions (milligram scale) were performed in benzene solvent in Pyrex tubes sealed under nitrogen; the tubes were placed alongside a 400-W medium pressure mercury lamp housed in a water-cooled Pyrex jacket.

Preparation of N*-benzoylindole,* **1**

To a stirred suspension of indole (5 g, 0.043 mol), powdered NaOH (5 g, 0.125 mol), and $(Bu)_4NBr$ (0.2 g) in dry methylene chloride (150 mL) was added a solution of benzoyl chloride (9.25 g, 0.88 mol) in methylene chloride (25 mL) over 15 min. During addition, the reaction was cooled with ice. After 1.5 h stirring, H_2O (50 mL) was added and the reaction mixture was extracted with CH_2Cl_2. The extracts were dried (K_2CO_3) and solvent removed to give a red oil, which was crystallized from ether/hexanes to yield 8.6 g (91%) of white crystals, mp 63–64°C (lit. (17) mp 57–58°C).

Preparation of N*-carboethoxyindole,* **4**

Indole (12 g, 0.1025 mol), powdered NaOH (10 g), and $(Bu)_4NBr$ (0.5 g) in CH_2Cl_2 (150 mL) were stirred together and ethyl chloroformate (12.5 g, 0.115 mol) was added dropwise with ice cooling. After stirring for 1.5 h the reaction mixture was worked up as for **1** to give a red oil, which was distilled to yield 13.7 g (72%) of a clear pale yellow liquid, bp 133°C at 3 Torr (1 Torr = 133.3 Pa) (lit. (17) bp 142–144°C at 16 Torr); ^1H nmr δ: 8.20 (m, 1H), 7.6–7.0 (m, 4H), 6.55 (d, 1H), 4.43 (q, 2H), 1.38 (t, 3H).

Irradiation of N*-benzoylindole with cyclopentene*

As described in the general procedure, a solution of *N*-benzoylindole (1.626 g, 7.36 mmol) and cyclopentene (7.8 g, 111.5 mmol) in 300 mL of benzene was irradiated for 89 h. Removal of the benzene by distillation under reduced pressure afforded 2.13 g of a brown oil. The oil was purified by column chromatography (silica gel, 30% ether/70% hexanes) to yield unreacted *N*-benzoylindole (0.53 g) and a yellow oil (0.49 g) in which crystals formed. The white crystals were washed with hexanes to yield 0.3 g of *cis-anti-cis* photoadduct **7**, mp 123–126°C; ^1H nmr δ: 8.30 (br s, 1H), 7.44 (m, 5H), 7.4–7.0 (m, 3H), 3.94 (br s, 1H), 3.32 (dd, J = 7.5, 2.9 Hz, 1H), 2.84 (m, 1H), 2.66 (m, 1H), 1.80 (m, 2H), 1.62 (m, 2H), 1.31 (m, 2H); ^{13}C nmr δ: 25.4, 30.9, 32.4 (CH_2), 45.1, 46.2, 47.9, 63.7 (CH), 110.5, 118.3, 124.7, 126.4, 126.8, 127.6, 128.3, 128.4, 130.0, 137.5 (aromatic C), 193.8 (quaternary C=O); *m/e* (%) 289(4.1), 221(46), 105(100), 77(20); M^+ calcd.: 289.14666; found: 289.14654.

The remaining mother liquor was evaporated to yield 0.18 g of yellow oil, determined to be *cis-syn-cis* photoadduct **8**; ^1H nmr δ: 8.30 (br s, 1H), 7.44 (m, 5H), 7.4–7.0 (m, 3H), 4.70 (br s, 1H), 4.05 (br dd, J = 7.5, 8.0 Hz, 1H), 3.08 (br m, 2H), 1.80 (m, 2H), 1.62 (m, 2H), 1.31 (m, 2H); ^{13}C nmr δ: 27.1, 27.9, 28.9 (CH_2), 42.2, 43.4, 45.5, 61.7 (CH), 110.5, 118.3, 125.7, 126.4, 126.8, 127.3, 128.3, 128.4, 130.5, 137.5 (aromatic C), 195.0 (quaternary C=O); M^+ calcd.: 289.14666; found: 289.14656.

Reduction of N*-benzoylindole/cyclopentene adducts* **7** *and* **8**

A sample (570 mg, 1.97 mmol) of the crude products obtained from irradiation of *N*-benzoylindole with cyclopentene, which had been partially purified to remove unreacted *N*-benzoylindole, was dissolved in dry ether (25 mL) and reduced with excess lithium aluminium hydride (121 mg, 318 mmol). After 1 h the reaction was quenched by slow addition of water (50 mL) and the reaction mixture was extracted with ether. The ether extracts were washed with water, dried (K_2CO_3), and solvent removed to yield 534 mg of a green oil. Thin-layer chromatography (silica gel; 30% ether/70% hexanes) revealed the product to be a mixture of three compounds with R_f 0.49, 0.63, and 0.70. The green oil was chromatographed on a column of silica gel (15% ether/85% hexanes) to yield three fractions. The last fraction after removal of eluent yielded 99 mg of light pink crystals of secondary amine **11**, which was recrystallized from $MeOH/H_2O$, mp 95°C; ^1H nmr δ: 7.00 (m, 2H), 6.68 (m, 2H), 3.94 (s, 1H), 3.72 (dd, J = 7.5, 2.5 Hz, 1H), 3.33 (dd, J = 7.6, 2.5 Hz, 1H), 2.68 (m, 2H), 1.78 (m, 4H), 1.48 (m, 2H); ^{13}C nmr δ: 25.6, 31.8, 32.6 (CH_2), 47.2, 47.3, 49.1, 60.8 (CH), 109.9, 118.8, 124.4, 127.3 (aromatic CH), 134.1, 151.5 (quaternary C); *m/e* (%): 185(19), 117(100), 90(33); M^+ calcd.: 185.120449; found: 185.12049.

The second fraction yielded a red oil (50 mg), which crystallized from $MeOH/H_2O$ to afford white crystals of secondary amine **12**, mp 91°C; ^1H nmr δ: 6.93 (m, 2H), 6.62 (m, 2H), 4.81 (s, 1H), 4.42 (dd, J = 9.6, 9.0 Hz, 1H), 4.14 (dd, J = 9.6, 9.2 Hz, 1H), 3.08 (m, 2H), 1.9–1.1 (m, 6H); ^{13}C nmr δ: 26.6, 28.4, 28.8 (CH_2), 42.6, 45.0, 56.4 (CH), 109.1, 117.8, 126.0, 127.2 (aromatic CH), 130.0, 154.0 (quaternary C); *m/e* (%): 185(15), 117(100), 90(30); M^+ calcd.: 185.120449; found: 185.120992.

For personal use only.

The third fraction afforded 254 mg of a brown oil; a sample (60 mg) was chromatographed on preparative tlc plates (silica gel; 100% hexanes) to yield two bands. The first band gave 21 mg of a solid, which was recrystallized from ether/hexanes to afford white crystals of *cis-syn-cis* benzyl adducts **10**, mp 58.5°C; ^{1}H nmr δ: 7.22 (m, 5H), 6.91 (m, 2H), 6.55 (m, 1H), 6.32 (d, J = 4 Hz, 1H), 4.31 (AB, q, J = 16 Hz, 2H), 4.30 (dd, J = 9.4, 9.0 Hz, 1H), 4.11 (dd, J = 9.4, 9.0 Hz, 1H), 3.01 (m, 2H), 1.71 (m, 2H), 1.40 (m, 4H); ^{13}C nmr δ: 27.8, 28.4, 28.7 (CH_2), 42.2, 43.4, 45.5, 62.0 (CH), 51.3 (benzyl CH_2), 105.4, 115.7, 125.8, 116.7, 127.3, 127.4, 128.2 (aromatic CH), 129.5, 138.6, 154.7 (quaternary C); *m/e* (%): 275(3.4), 207(93), 91(100); M^+ calcd.: 275.167399; found: 275.167344.

The second band yielded 14.4 mg of crystals; these were recrystallized from ether/MeOH to afford *cis-anti-cis* benzyl adduct **9**, mp 55°C; ^{1}H nmr δ: 7.17 (m, 5H), 7.00 (m, 2H), 6.58 (m, 5H), 6.36 (d, J = 4 Hz, 1H), 4.33 (AB q, J = 15 Hz, 2H), 3.62 (dd, J = 7.6, 2.5 Hz, 1H), 3.29 (dd, J = 7.6, 2.7 Hz, 1H), 2.80 (d of t, J = 7.0, 2.7 Hz, 1H), 2.68 (d of t, J = 7.0, 2.5 Hz, 1H), 1.9–1.2 (m, 6H); ^{13}C nmr δ: 25.4, 31.5, 32.6 (CH_2), 45.2, 45.3, 46.3, 65.6 (CH), 49.8 (benzyl CH_2), 105.5, 116.5, 124.1, 126.8, 127.44, 127.46, 128.22 (aromatic CH), 133.8, 138.6, 152.3 (quaternary C); *m/e* (%): 275(9.2), 207(100), 91(96); M^+ calcd.: 275.167399; found: 275.167344.

Irradiation of N-*carboethoxyindole*, **4**, with cyclopentene

N-Carboethoxyindole (2.87 g, 15.2 mmol) in 300 mL of benzene containing cyclopentene (16.25 g, 239 mmol) was irradiated for 65 h. The benzene was removed to yield 3.58 g of brown oil. The gc analysis of the oil indicated ca. 30% conversion and the formation of three new products in a ratio of 1:1.24:6.34; gc–ms revealed parent ions for the three products to be *m/e* 189, 257, and 257 respectively. The first of these is isomeric with **4** and the latter two correspond to the adducts **15** and **16** produced from **4** with cyclopentene. A portion (300 mg) of the crude irradiation product was chromatographed on preparative tlc plates (silica gel; 50% ether/50% hexanes) and yielded three bands, which were analyzed by gc–ms. The first band (166 mg) contained a mixture of *N*-carboethoxyindole and the two adducts **15** and **16**, both of which had *m/e* 257(3.0%), 189(100%), 73(32%). The second band was identified as indole by gc–ms and confirmed by gc coinjection. The third band (7.5 mg) was identified as 3-carboethoxyindole, mp 122–124°C (lit. (18) mp 124°C); ^{1}H nmr δ: 8.68 (br s, N-H), 8.18 (m, 1H), 7.93 (d, J = 3 Hz, 1H), 7.30 (m, 3H), 4.40 (q, J = 7 Hz, 2H), 1.40 (t, J = 7 Hz, 3H).

Hydrolysis and decarboxylation of photochemical adducts **15** *and* **16**

A sample (1.66 g) of the crude product obtained from irradiation of *N*-carboethoxyindole with cyclopentene was hydrolyzed by refluxing for 3 h in 25 mL of MeOH/H_2O (2:1) saturated with KOH. The reaction mixture was cooled and acidified with concentrated HCl, and then refluxed for 20 min. The reaction mixture was cooled again and washed with ether. The ether washings were combined and extracted with 10% HCl. The aqueous acid extracts were combined and washed with ether and then CH_2Cl_2 to remove any remaining indole. They were then made basic with saturated NaOH and extracted with CH_2Cl_2. The organic extracts were washed with water, dried (Na_2SO_4), and evaporated to afford 212 mg of white solid. The gc–ms showed two peaks with *m/e* 185 in a ratio of 1:10. Isolation by column chromatography yielded 18 mg of indoline **12** and 190 mg of indoline **11**.

Irradiation of N-*benzoylindole with cyclohexene*

N-Benzoylindole (2.54 g, 0.0115 mol) was irradiated in 300 mL of benzene along with cyclohexene (8.5 g, 0.104 mol) for 48 h. The solution was filtered and solvent removed to yield 3.78 g of brown oil, which was purified on a silica gel column to give unreacted *N*-benzoylindole (1.28 g) and cycloadducts (0.95 g) that appeared as crystals in a yellow oil. Crystallization from CH_2Cl_2/ethyl acetate afforded 0.3 g of white crystals identified as *cis-syn-cis* adduct **18**, mp 170–171°C; ^{1}H nmr δ: 8.28 (br d, J = 4 Hz, 1H), 7.44 (m, 5H), 7.20 (m, 3H), 4.72 (br s, 1H), 4.00 (dd, J = 8.5, 9.0 Hz, 1H), 2.78 (br s, 2H), 1.9–0.9 (m, 8H); ^{13}C nmr δ: 20.9, 21.3, 22.2, 22.4, (CH_2), 32.7, 38.8, 45.3, 61.0 (CH), 118.4, 124.2, 126.1, 127.1, 127.9, 128.3, 130.2 (aromatic CH), 134.6, 137.2, 146.6, 169.0, 205.7 (quaternary C); *m/e* (%): 303(0.55), 221(26), 105(100); M^+ calcd.: 303.162314; found: 303.162570.

The mother liquid (0.7 g) remained as an oil and was identified as *cis-anti-cis* adduct **17**; ^{1}H nmr δ: 8.28 (br d, J = 4 Hz, 1H), 7.44 (m, 5H), 7.20 (m, 3H), 4.63 (br s, 1H), 3.56 (dd, J = 7.7, 2.5 Hz, 1H), 2.60 (m, 1H), 2.11 (m, 1H), 2.00 (m, 2H), 1.9–1.0 (m, 6H); ^{13}C nmr δ: 21.2, 21.6, 22.0, 22.3 (CH_2), 37.6, 39.8, 46.7, 63.7 (CH), 117.8, 126.0, 127.0, 129.3, 139.1, 134.0, 135.4, 136.3, 142.8, 144.7 (aromatic C), 197.2 (quaternary C=O).

Reduction of cis-syn-cis *adduct* **18**

Adduct **18** (106 mg, 0.37 mmol) was treated with lithium aluminium hydride (50 mg) in 15 mL of dry ether for 3 h. After quenching with water the reaction was extracted with ether; the ether extracts were washed with water, dried (K_2CO_3), and solvent removed to yield 81.5 mg of yellow oil, which tlc showed to contain two components that were separated as oils by preparative tlc.

The first of these (40.6 mg) was identified as Isomer I,NBz (see text); ^{1}H nmr δ: 7.61 (m, 1H), 7.15 (m, 5H), 7.00 (m, 1H), 6.59 (m, 1H), 6.38 (d, J = 4 Hz, 1H), 4.38 (AB q, J = 20 Hz, 2H), 4.36 (dd, J = 8.5, 9.2 Hz, 1H), 4.06 (dd, J = 8.5, 9.0 Hz, 1H), 2.78 (m, 1H), 2.66 (m, 1H), 1.50 (m, 4H), 1.24 (m, 4H); ^{13}C nmr δ: 21.1, 21.3, 21.9, 22.6 (CH_2), 34.6, 39.3, 45.4, 63.4 (CH), 51.2 (benzyl CH_2), 105.4, 116.3, 125.6, 126.9, 127.6, 127.2, 128.4, 128.8, 131.2, 138.8 (aromatic C); *m/e* (%): 289(3.5), 207(100), 91(75); M^+ calcd.: 289.183049; found: 289.183068.

The second component (9.2 mg) was identified as secondary amine **26**; ^{1}H nmr δ: 8.14 (br s, 1H), 7.20–7.00 (m, 3H), 4.21 (br s, 1H), 4.12 (s, N-H), 3.80 (ddd, J = 8.7, 9.0, 1.0 Hz, 1H), 2.78 (m, 2H), 2.2–1.6 (m, 8H); ^{13}C nmr δ: 25.2, 26.4, 32.0, 32.7 (CH_2), 34.3, 39.7, 44.6, 52.4 (CH), 111.3, 119.4, 119.7, 121.32, 121.6, 122.2 (aromatic CH); *m/e* (%): 199(2), 117(100), 90(30); M^+ calcd.: 199.136099; found: 199.136103.

Irradiation of N-*carboethoxyindole with cyclohexene*

N-Carboethoxyindole (2.2 g, 0.01 mol) was irradiated in 300 mL of benzene containing cyclohexene (15 g, 0.183 mol) for 48 h. Removal of the benzene afforded 3.55 g of brown oil. The gc analysis revealed five new products in a ratio of 1:1.1:2:142:100. The most minor peak showed *m/e* 189 by gc–ms, and gc coinjection with an authentic sample confirmed this product to be 3-carboethoxyindole. The other four peaks all possessed parent ions of *m/e* 271, indicative of 1:1 photoadducts between **4** and cyclohexene. Characterization of these compounds was not carried any further.

Hydrolysis and decarboxylation of photoadducts from irradiation of N-*carboethoxyindole with cyclohexene*

A sample (6 g) of the crude mixture of products from irradiation of *N*-carboethoxyindole with cyclohexene was hydrolysed by refluxing for 3 h in 75 mL of MeOH/H_2O (2:1) saturated with KOH. The reaction mixture was then acidified (conc. HCl) and refluxed further for 20 min. After cooling, the reaction mixture was washed sequentially with ether and CH_2Cl_2 and made basic by addition of aqueous NaOH. The basified solution was then extracted with CH_2Cl_2. The organic extracts were washed with H_2O, dried (Na_2SO_4), and the solvent removed to yield 4.14 g of brown oil. Gas chromatography revealed three peaks with ratios of 1:17:14. The major portion of the oil (4 g) was then chromatographed (silica gel column; 10% ether/90% hexanes) to yield three fractions. The first fraction (67 mg) afforded yellow crystals identified as secondary amine **28**, mp 69–72°C (ether/hexanes); ^{1}H nmr δ: 6.97 (m, 2H), 6.63 (m, 2H), 4.58 (dd, J = 6, 4 Hz, 1H), 3.98 (br s, N-H), 3.66 (dd, J = 8, 6 Hz, 1H), 2.20–1.90 (m, 2H), 1.90–0.80 (m, 8H); *m/e* (%): 199(7.5), 156(9), 117(100); M^+ calcd.: 199.13601; found: 199.13562.

The second fraction (0.93 g) was isolated as an oil and identified as secondary amine **26**; ^{1}H nmr δ: 7.0 (m, 2H), 6.63 (m, 2H), 4.42 (dd, J = 8, 8 Hz, 1H), 4.04 (dd, J = 8, 8 Hz, 1H), 3.88 (br s, N-H), 2.80 (m, 1H), 2.60 (m, 1H), 2.3–0.8 (m, 8H); *m/e* (%): 199(31), 156(51), 117(100); M^+ calcd.: 199.13601; found: 199.13582.

The third fraction (0.64 g) was isolated as a brown solid. Recrystallization from ether/hexanes afforded crystals of secondary amine **25**, mp 73–75°C; ^{1}H nmr δ: 7.1 (m, 2H), 6.74 (m, 2H), 4.18 (dd, J = 8, 4 Hz,

For personal use only.

1H), 3.65 (br s, N-H), 3.60 (dd, J = 8, 2 Hz, 1H), 2.8–2.25 (m, 2H), 2.25–1.00 (m, 8H); m/e (%): 199(25), 156(48), 117(100); M^+ calcd.: 199.13601; found: 199.13562.

Irradiation of N-*benzoylindole with cycloheptene*

N-Benzoylindole (1.94 g, 8.79 mmol) was irradiated in 300 mL of benzene with cycloheptene (8.7 g, 90.5 mmol) for 22 h. Removal of benzene afforded 2.5 g of a brown oil. The gc analysis showed approximately 40% conversion of the *N*-benzoylindole to three products in a ratio of 1:21:0.05. The oil was hydrolysed to remove unconverted **1** by stirring at room temperature for 3 h in 125 mL of MeOH/H_2O (2:2) saturated with NaOH. The mixture was extracted with ether; drying and removal of solvent yielded 1.1 g of a brown oil. The oil was steam distilled to remove indole and the aqueous stillpot extracted with ether to give 0.7 g of yellow oil. Thin-layer chromatography showed two components, R_f 0.15 and 0.10 (silica gel; 30% ether/70% hexanes). A sample of the oil (122 mg) was chromatographed by preparative tlc (silica gel; 40% ether/60% hexanes) and yielded two bands. The first band (5 mg) afforded an oily film and was assigned structure **29**; ^{1}H nmr δ: 8.25 (m, 1H), 7.80–7.45 (m, 5H), 7.31 (m, 2H), 7.15 (d, J = 4 Hz, 1H), 4.13 (dd, J = 8, 2.5 Hz, 1H), 3.59 (dd, J = 8, 3 Hz, 1H), 2.8–2.35 (m, 2H), 2.2–1.2 (m, 10H); m/e (%): 317(4), 221(100), 105(14); M^+ calcd.: 317.177984; found: 317.178169. The second band (95 mg) yielded an oil assigned structure **30**; ^{1}H nmr δ: 8.28 (br s, 1H), 7.44 (m, 5H), 7.30–6.90 (m, 4H), 4.43 (br s, 1H), 3.46 (dd, J = 9, 3 Hz, 1H), 2.54 (br m, 1H), 2.42 (m, 1H), 2.0–1.0 (m, 10H); m/e (%): 317(0.25), 221(34), 117(100); M^+ calcd.: 317.177984; found: 317.1778534.

Irradiation of N-*benzoylindole with* cis-*2-butene*

A solution of *cis*-2-butene in benzene was prepared by condensing *cis*-2-butene (5 mL) into benzene (5 mL) that had previously been purged with nitrogen. *N*-Benzoylindole (192 mg, 0.87 mmol) was added to the solution, which was then irradiated for 60 h. Gas chromatography revealed four products in the ratio 7:21:68:4. The gc–ms confirmed that the products were 1:1 cycloadducts of **1** with butene (first gc product, m/e (%): 277(1.7), 221(57), 105(100); second gc product, m/e: 277(2.0), 221(59), 105(100), 77(25); third gc product, m/e: 277(1.7), 221(60), 105(100), 77(25); fourth gc product, m/e: 277(2.0), 221(60), 105(100), 77(25)). A sample of the reaction mixture was partially purified by chromatography to give a mixture of the four adducts; in the ^{1}H nmr spectrum of the mixture of adducts a broad singlet at 4.3 ppm was assigned to superimposed signals corresponding to H_a in all the stereoisomers. Similarly, multiplets in the range 2.7–1.9 ppm were assigned to H_c and H_d of all the isomers present. The signal assigned to H_b of the most prevalent isomer was seen as a double doublet at 3.97 ppm, J = 3 and 8 Hz. That corresponding to H_b of the second most prevalent isomer was seen at 3.48 ppm as a triplet, J = 8 Hz. The methyl substituents of both major isomers were seen as overlapping doublets at 1.16 and 0.92 ppm, J = 6 Hz.

Irradiation of N-*benzoylindole with trans-2-butene*

A sample of *trans*-2-butene was prepared by dropwise addition of 2-butanol (100 mL) to 9 M H_2SO_4 (80 mL). The mixture was heated to 90°C (oil bath temperature) and a portion (5 mL) of the *trans*-2-butene, which distilled out, was condensed into benzene (5 mL) that had previously been purged with nitrogen. *N*-Benzoylindole (199 mg, 0.9 mol) was added and the mixture was irradiated for 44 h. Gas chromatography revealed formation of four products in the ratio 2.1:21:74:1.1. The four products were confirmed by gc coinjection to be the same as the products obtained by irradiation of *N*-benzoylindole with *cis*-2-butene (first gc product, m/e (%): 277(1.7), 221(57), 105(100), 77(23); second product, m/e: 277(3), 221(58), 105(100), 77(23); third product, m/e: 277(3), 221(58), 105(100), 77(24); fourth product m/e: 277(3), 221(60), 105(100), 77(24)). The ^{1}H nmr spectrum of the mixture of adducts following their separation by chromatography was identical with that of the mixture of adducts obtained from the irradiation of **1** with the *cis*-alkene.

Preparation of cis-*4-octene*

A sample of 4-octyne (12.2 g, 0.11 mol) was hydrogenated under 1 atm (101.3 kPa) of hydrogen using Lindlar's catalyst (0.8 g) and quinoline (10 mL) in pentane (300 mL) until gc analysis indicated 100% conversion of the octyne. The reaction mixture was filtered, washed with 10% HCl and H_2O, and dried over anhydrous Na_2SO_4. The solvent was removed and the product purified by fractional distillation, which yielded 8.1 g (67%) of *cis*-4-octene (94% pure by ^{1}H nmr analysis); bp 122°C; ^{1}H nmr δ: 5.36 (m, 2H), 2.02 (q, J = 4 Hz, 4H), 1.38 (m, 4H), 0.92 (t, J = 4 Hz, 6H); ^{13}C nmr δ: 129.9, 29.5, 23.1, 13.9.

Irradiation of N-*benzoylindole with* trans-*4-octene*

A solution of *N*-benzoylindole (1 g, 4.5 mmol) in benzene (20 mL) containing *trans*-4-octene (9 g, 80 mmol) was irradiated for 311 h. Removal of benzene yielded 1.18 g of brown oil; gc analysis indicated the presence of three products in the ratio 1:32:32 and 36% conversion of **1**. The oil was chromatographed (5% ether/95% hexanes) to remove *N*-benzoylindole and give 394 mg of yellow oil. The gc–ms of the oil showed three products all with parent ions of m/e 333 indicative of 1:1 photoadducts. First gc product, m/e (%): 333(0.81), 221(78), 105(100); second product, m/e: 333(1.7), 221(80), 105(100); third product, m/e: 333(1.1), 221(82), 105(100). In the ^{1}H nmr spectrum of the mixture a broad singlet at 4.42 ppm was assigned to H_a of both major isomers. Signals between 2.6 and 1.9 ppm were assigned to H_c and H_d of both major isomers also. A signal at 4.03 ppm (triplet, J = 8 Hz) was assigned to H_b of one of the major isomers, and a signal at 3.54 ppm (double doublet, J = 4 and 8 Hz) was assigned to H_b of the second major isomer.

Irradiation of N-*benzoylindole with* cis-*4-octene*

N-Benzoylindole (2.0 g, 0.01 mol) was irradiated in benzene (60 mL) with *cis*-4-octene (11.0 g, 0.09 mol) for 400 h. Removal of benzene afforded 2.14 g of brown oil, which gave three products (7% conversion) by gc analysis in a ratio of 1:5:5 with retention times equivalent to that of the *N*-benzoylindole/*trans*-4-octene irradiation products (confirmed by coinjection). The oil was chromatographed (5% ether/95% hexanes) to yield unreacted *N*-benzoylindole and 0.51 g of yellow oil. The gc–ms of the oil showed three products all with parent ions of m/e 333 indicative of 1:1 photoadducts. First gc product, m/e (%): 333(1.1), 221(78), 105(100); second product, m/e: 333(1.5), 221(75), 105(100); third product, m/e: 333(1.5), 221(79), 105(100). The ^{1}H nmr spectrum of the mixture was identical with that of the products of irradiation of **1** with *trans*-octene.

Schenk isomerization studies

Solutions (5.00 mL) of *N*-benzoylindole (19.6 mg, 0.0886 mmol) in benzene containing either *cis*-4-octene (2.8 g, 0.026 mol) or *trans*-4-octene (2.8 g, 0.026 mol) were prepared and samples (3.00 mL) were irradiated with 313 ± 2 nm light from a 100-W high-pressure mercury lamp. The light intensity was determined by actinometry with azoxybenzene. The amount of isomerized alkene formed was determined by gc with methylcyclohexane as a calibrated internal standard.

Quantum yield of cycloadduct formation in the photoaddition of cis- *and* trans-*4-octene with* ***1***

Solutions (5.00 mL) of *N*-benzoylindole (20.1 mg, 0.0911 mmol) in benzene containing either *cis*-4-octene (2.8 g, 0.026 mol) or *trans*-4-octene (2.8 g, 0.026 mol) were prepared and samples (3.00 mL) were irradiated with 313 ± 2 nm light from a 100-W high-pressure mercury lamp. The light intensity was determined by actinometry with azoxybenzene. The amount of adduct formed was determined by gc with tetracosane as a calibrated internal standard.

Azo pigments and their intermediates. A reinvestigation of the tetrazotization of 1,4-diaminoanthraquinone

KOCK-YEE LAW,[1] IHOR W. TARNAWSKYJ, AND SAMUEL KAPLAN
Xerox Webster Research Center, 800 Phillips Road, 0114-39D, Webster, NY 14580, U.S.A.

Received October 10, 1990

KOCK-YEE LAW, IHOR W. TARNAWSKYJ, and SAMUEL KAPLAN. Can. J. Chem. **69**, 1183 (1991).

The azotization of 1,4-diaminoanthraquinone (**1**) by *n*-amyl nitrite in glacial acetic was reinvestigated. The structure of a red-brown precipitate, which was previously identified as anthraquinone-1,4-tetrazonium dichloride (**3**) by Schaarschmidt, was found to be incorrect. In this work, we have identified the red-brown solid as 4-aminoanthraquinone-1-diazonium chloride (**2**), a diazotized product of **1**. The yield of **2** was 80%. The tetrazonium dichloride **3** was actually formed in minute quantity and is soluble in acetic acid. The tetrazonium product of **1** can be isolated as tetrafluoroborate salt **4** in 3.4% yield by adding fluoboric acid into the acetic acid solution. The structure **4** was confirmed by IR and cross-polarization magic angle spinning ^{13}C NMR spectroscopy. Further investigations showed that **1** can be quantitatively tetrazotized by nitrosylsulfuric acid in 78% sulfuric acid. The tetrazonium product was isolated as **4** in 74% yield.

Key words: 1,4-diaminoanthraquinone, diazotization, tetrazotization, azo pigments.

KOCK-YEE LAW, IHOR W. TARNAWSKYJ et SAMUEL KAPLAN. Can. J. Chem. **69**, 1183 (1991).

On a réexaminé la réaction de diazotation de la 1,4-diaminoanthraquinone (**1**) par le nitrite d'amyle dans l'acide acétique glacial. On a déterminé que la structure du précipité brun-rouge, qui avait été identifiée antérieurement par Schaarschmidt comme celle du dichlorure d'anthraquinone-1,4-tétrazonium (**3**), est incorrecte. Il s'agit plutôt du chlorure du 4-aminoanthraquinone-1-diazonium (**2**), un produit de diazotation du produit **1**. Le rendement en produit **2** est d'environ 80%. Le dichlorure de tétrazonium **3** se forme effectivement en très faibles quantités et il est soluble dans l'acide acétique. Le produit tétrazonium de **1** peut être isolé sous la forme d'un tétrafluoroborate (**4**), avec une rendement de 3,4%, par addition d'acide fluoborique à la solution d'acide acétique. On a confirmé la structure du produit **4** par spectroscopie IR et par polarisation croisée de l'angle magique en RMN du ^{13}C. D'autres essais ont permis d'établir que le composé **1** peut être tétrazoté d'un façon quantitative par l'acide nitrosylsulfurique, dans de l'acide sulfurique à 78%. Le produit tétrazonium peut alors être isolé sous forme de produit **4** avec un rendement de 74%.

Mots clés : 1,4-diaminoanthraquinone, diazotation, tétrazotation, colorants azoiques.

[Traduit par la rédaction]

Introduction

Azo dyes and pigments are the most important class of colorant produced in the dye industry, accounting for over 50% of total dyestuff production (1). Depending on the number of azo linkages (-N=N-), these compounds can be further classified into sub-groups, such as monoazo, bisazo, trisazo, and polyazo, etc. Azo compounds are generally prepared by first azotizing an aromatic amine to an azonium salt, followed by coupling the salt with an azoic coupler. The synthesis is simple and is economically attractive. As a result, numerous azo structures for a variety of applications have been synthesized in the industry. In 1975, Champ and Shattuck (2) showed that bisazo pigment Chlorodiane Blue (4,4′-bis(1″-azo-2″-hydroxy-3″-naphthanilide)-3,3′-dichlorobiphenyl) could photogenerate electron-hole pairs in bilayer xerographic devices. This disclosure seemed to inspire a very intensive subsequent effort where thousands of azo pigments with different variations in the amine and the coupler moiety were synthesized and evaluated for xerographic photoreceptor applications (3). Among the amine precursors, isomeric diaminoanthraquinones were studied because of their commerical availability, low cost, and nontoxicity. The uses of 1,5- (4), 2,6- (5), and 2,7-diaminoanthraquinone (6) as precursors have been reported. We were particularly attracted by the prospect of using 1,4-diaminoanthraquinone (**1**) as a presecursor for pigment synthesis, because (a) **1** is commercially available, (b) the azotization procedure for **1** is documented in the literature (7), and (c) **1** absorbs strongly in the red (λ_{max} ~590 nm in DMF). Any success in wavelength extension by 150–200 nm would elevate the utility of the resulting azo pigments, enabling them to be useful in diode laser printers, where photoresponse at 780 nm is needed.

Here we report our reinvestigation of the azotization of **1** by *n*-amyl nitrite. Our results show that the previous structure assignment of the red-brown solid, to anthraquinone-1,4-tetrazonium dichloride (**3**) by Schaarschmidt (7), was incorrect. From the elemental analysis results, and IR and CP MAS ^{13}C NMR spectral data, we reassign the red-brown solid to the diazotized product, 4-aminoanthraquinone-1-diazonium chloride (**2**). Compound **3** was in fact formed, but the yield was very low. A new procedure for the tetrazotization of **1** is reported.

Experimental

Materials

1,4-Diaminoanthraquinone was purchased from Lancaster Synthesis. Nitrosylsulfuric was bought from Aldrich. Fluoboric acid (purified, 48–50%), glacial acetic acid (reagent grade), concentrated hydrochloric acid, and concentrated sulfuric acid were obtained from Fisher. All of these materials were used as received. *n*-Amyl nitrite was prepared from *n*-amyl alcohol (Fisher) and sodium nitrite (Fisher) in the presence of sulfuric acid (8).

General techniques

Elemental analyses were performed by Galbraith Laboratories. IR spectra were taken in KBr pellets on a Perkin–Elmer model 1750 FTIR. Cross-Polarization Magic Angle Spinning (CP MAS) solid state ^{13}C NMR spectra were recorded on a Bruker CXP spectrometer operating at 50.3 MHz in a Cryomagnet Systems, Inc. superconducting magnet system. Proton-enhanced cross polarization used 3–4 ms contact times, high-power (H_1 = 12 G) proton decoupling, and recycle times of 3–6 s. Magic angle spinning (4–4.5 kHz) was performed in a Doty Scientific probe with approximately 100 mg of each sample packed into

6 mm o.d. sapphire rotors. The TOSS technique for sideband suppression was used for all measurements. Typically, 2000–4600 scans were averaged for each spectrum. Spectral assignment is facilitated by distinguishing the protiated and non-protiated carbons using a spin temperature reversal pulse sequence (9, 10). After the cross-polarization mixing periods and prior to carbon observation, proton rf phase is inverted for 100 μs. During this period the carbon spins cross-polarize in the reverse direction, protiated carbons the fastest and non-protiated carbons the slowest. Conveniently, after 100 μs, the protiated carbons are approximately nulled. We find this technique superior in its differentiation of protiated and non-protiated carbons to the commonly used delayed decoupling technique (11).

Azotization of 1,4-diaminoanthraquinone by n*-amyl nitrite*

1,4-Diaminoanthraquinone dihydrogen dichloride, 1.51 g (4 mmol),[2] which was prepared by refluxing 1,4-diaminoanthraquinone in concentrated hydrochloric acid, was suspended in 20 mL of glacial acetic acid. Freshly prepared *n*-amyl nitrite (2.4 mL) was added and the mixture was allowed to react at room temperature for about 2 h. A red-brown precipitate was formed and was isolated by filtration, yield 0.64 g. A second crop of the red-brown solid, 0.27 g, could be obtained by adding diethyl ether (~80 mL) to the filtrate solution. This red-brown solid, compound **2**, was identified as 4-aminoanthraquinone-1-diazonium chloride by elemental analysis data (recrystallized from warm water), and by IR and CP MAS ^{13}C NMR spectroscopy. The combined yield of **2** was ~80%.

To the filtrate solution, 15 mL fluoboric acid was added. After 15 min stirring at room temperature, a bright yellow precipitate, compound **4**, was isolated (0.06 g). Compound **4** was subsequently identified as anthraquinone-1,4-tetrazonium bis(tetrafluoroborate) by IR and CP MAS ^{13}C spectral data, yield 3.4%.

Tetrazotization of 1,4-diaminoanthraquinone

1,4-Diaminoanthraquinone (1.18 g, 5 mmol) was added to a stirred solution containing 2.5 g of nitrosylsulfuric acid in 15 mL 78% sulfuric acid. After stirring at room temperature for 2 h, a clear brown solution was obtained. The tetrazonium product was isolated as tetrafluoroborate salt **4** by adding 25 mL fluoboric acid to the product solution, yield 1.0 g (74%).

Results and discussion

Azotization of 1,4-diaminoanthraquinone by n*-amyl nitrite*

Synthesis and IR spectra

In 1916, Schaarschmidt (7) reported that 1,4-diaminoanthraquinone (**1**) could be tetrazotized in glacial acetic acid by an excess of *n*-amyl nitrite at room temperature, in the presence of hydrochloric acid. A red-brown solid was isolated and was recrystallized from warm (80°C) water. Schaarschmidt identified the red-brown solid as the tetrazotized product, anthraquinone-1,4-tetrazonium dichloride (**3**), on the basis of the nitrogen content of his sample (N calcd.: 16.86%; N found: 16.80%). The chemical yield of **3** was not reported.

We have reinvestigated Schaarschmidt's reaction and obtained identical results, i.e., a red-brown solid was isolated and recrystallized as reported. The C, H, N, Cl elemental analysis data of this solid are given in Table 1. By comparison with the calculated C, H, N, Cl values of the starting compounds and all possible products, we concluded that the red-brown solid is a diazonium product of **1**, 4-aminoanthraquinone-1-diazonium

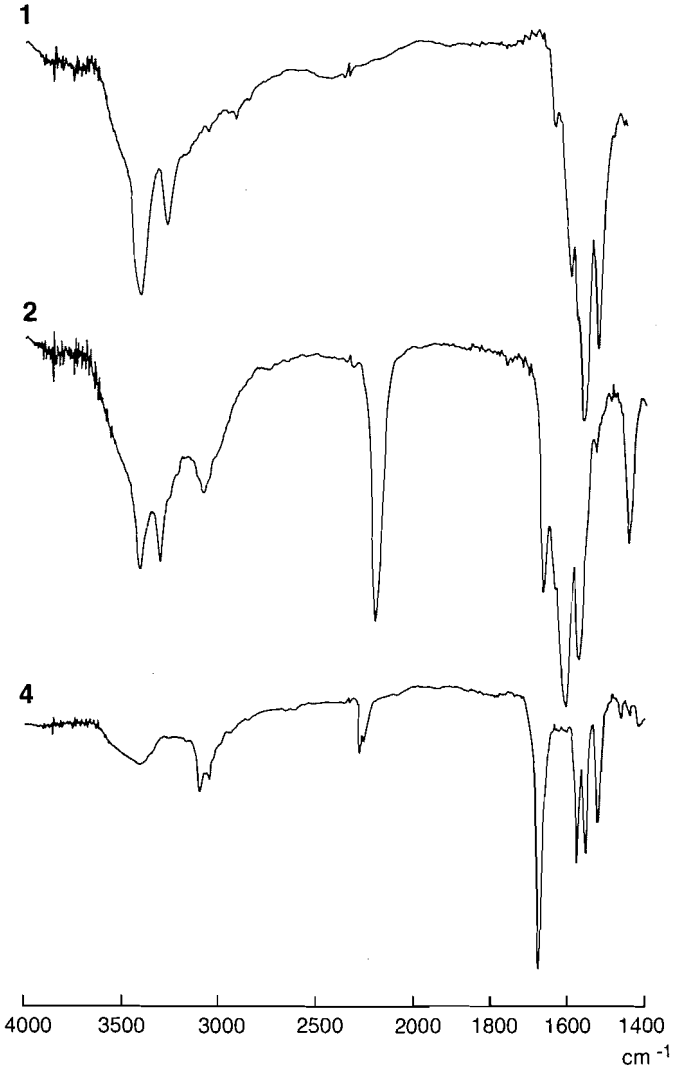

FIG. 1. IR spectra of compounds **1**, **2**, and **4**.

[2]Elemental analysis results show that the hydrogen chloride salt of **1** contains ~15% by weight of water.

chloride (**2**).[3] This structure assignment is substantiated by the IR and ^{13}C spectral data reported in this work.

Figure 1 shows the partial IR spectra of **1** and **2** in KBr pellets. The frequency data are listed in Table 2. In the spectrum of **2**, N–H stretchings at 3305 and 3440 cm^{-1} and a strong band at 2211 cm^{-1}, which can be assigned to the $-N^+\equiv N$ stretching (12, 13), are observed. The spectral data suggest that **1** was only partially azotized by *n*-amyl nitrite in acetic acid. The frequency of the $-N^+\equiv N$ stretching in **2** is lower than that of a typical diazonium salt (2283 cm^{-1}) and is comparable to those of 4-aminobenzene-1-diazonium tetrafluoroborate (2183 cm^{-1}) and 4-diethylaminobenzene-1-diazonium tetrafluoroborate (2150 cm^{-1}). The IR spectral data are thus consistent with the structure assignment of **2** because the decrease in $-N^+\equiv N$ stretching frequency can be ascribed to a resonance effect due to the *para* NH_2 group.

Accompanying the appearance of the $-N^+\equiv N$ stretching, a hypsochromic shift is observed in the C=O vibrational stretching, from 1650 cm^{-1} in **1** to 1680 cm^{-1} in **2**. The observed hypsochromic shift is also consistent with the structural assignment of **2**, simply implying that the intramolecular H-bonding between the C=O group and the NH_2 group has been altered due to azotization.

A bright yellow solid, compound **4**, could be isolated from the reaction by introducing fluoboric acid into the filtrate solution. The IR spectral data of this solid are included in Fig. 1 and Table 2. The absence of any N–H stretchings, along with the high-frequency weak bands at 2271 and 2292 cm^{-1} due to the $-N^+\equiv N$ groups (12, 13) and the strong high-frequency C=O stretching at 1690 cm^{-1}, leads us to propose that **4** is anthraquinone-1,4-tetrazonium bis(tetrafluoroborate), a tetrazotized product of **1**. The structure assignment of **4** is confirmed

[3]The carbon content of **2** is off by 0.52 ± 0.03% from the calculated value. We attributed the large difference to the existence of moisture in the sample because extensive high temperature drying of **2** was avoided due to concern of explosion in the drying oven. Moreover, hydrogen chloride salts of amines are known to be hygroscopic. It is likely that a small amount of water may be picked up by **2** during storage.

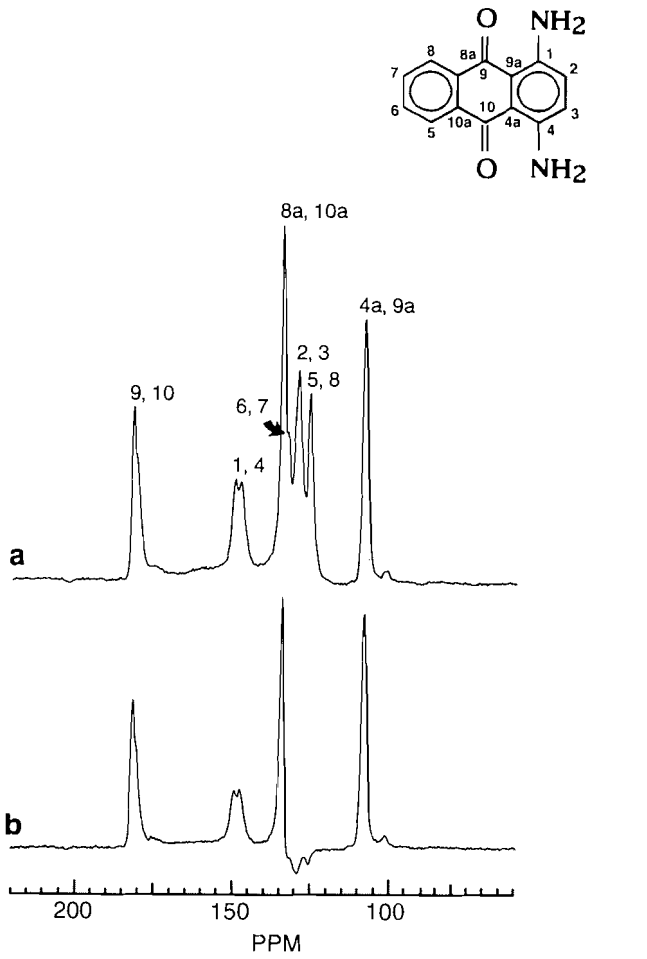

FIG. 2. CP MAS ^{13}C NMR spectra of **1**; (a) cross-polarization time = 3 ms, spinning rate = 4700 Hz, repetition time = 3 s, no. of scans = 3072; (b) same as (a) except with a 100-μs spin temperature reversal time inserted between the cross-polarization and observation periods.

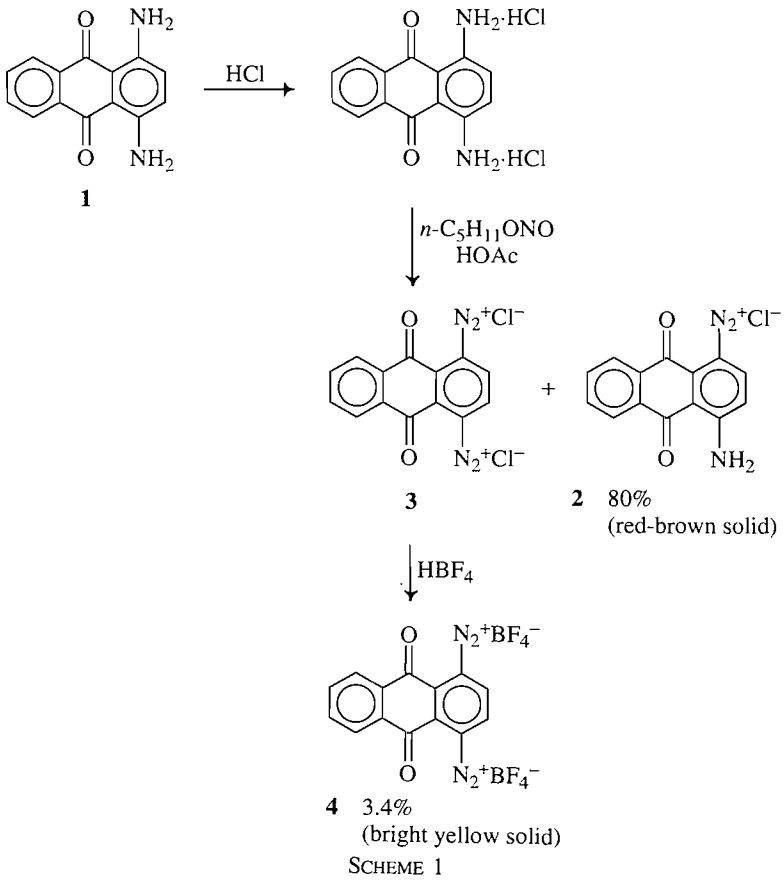
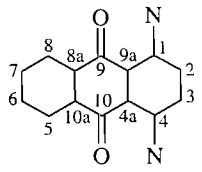


by its CP MAS ^{13}C NMR spectrum. Our results thus reveal that reaction of **1** with *n*-amyl nitrite also yields anthraquinone-1,4-tetrazonium dichloride (**3**) but in a very small quantity (3.4%). Compound **3** is soluble in the acetic acid product solution and the tetrazonium product can be isolated as tetrafluoroborate salt **4**. A schematic summarizing the reaction between 1,4-diaminoanthraquinone and *n*-amyl nitrite is depicted in Scheme 1.

CP MAS ^{13}C NMR studies

Figure 2a shows the CP MAS ^{13}C NMR spectrum of **1** and Fig. 2b shows the corresponding spin temperature reversal experiment with protiated carbons suppressed. Chemical-shift assignments are made by analogy to those observed in DMSO-d_6 (14) and the data are summarized in Table 3. Results show that the chemical shifts observed in the solid state are nearly identical to those observed in solution and that the signals of carbons 1 and 4 are characterized by the doublet splitting resulting from the quadrupolar interactions with neighboring ^{14}N nuclei (15).



The CP MAS ^{13}C NMR spectrum of **2** is presented in Fig. 3a. Non-protiated carbons of **2** are distinguished by a spin reversal experiment and the ^{13}C spectrum for these carbons is shown in Fig. 3b. The protiated carbons are plotted in Fig. 3c as the

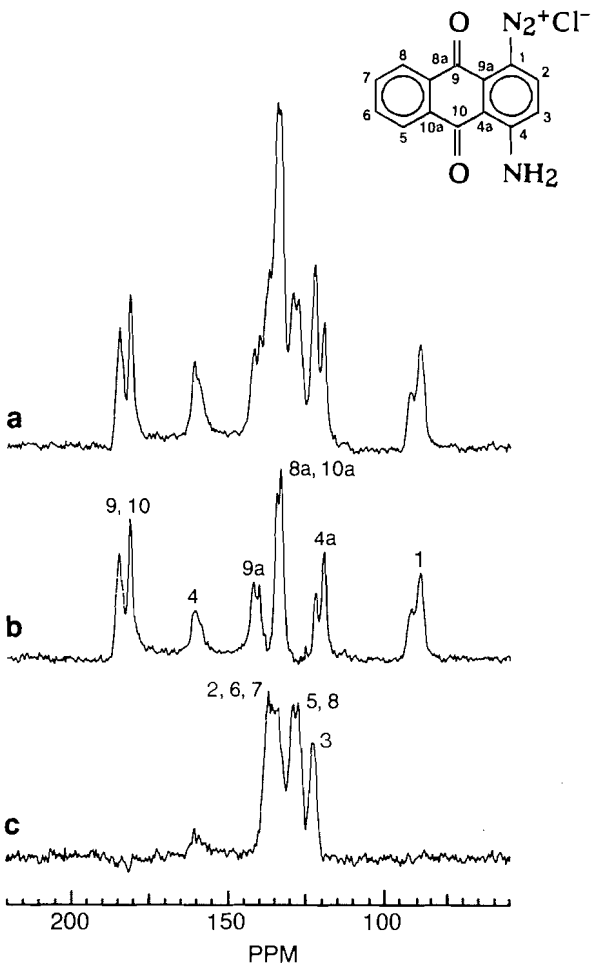

FIG. 3. CP MAS ^{13}C NMR spectra of **2**; (a) cross-polarization time = 4 ms, spinning rate = 4700 Hz, repetition time = 6 s, no. of scans = 4608; (b) same as (a) except with 100-μs spin temperature reversal; (c) spectrum (a) − spectrum (b).

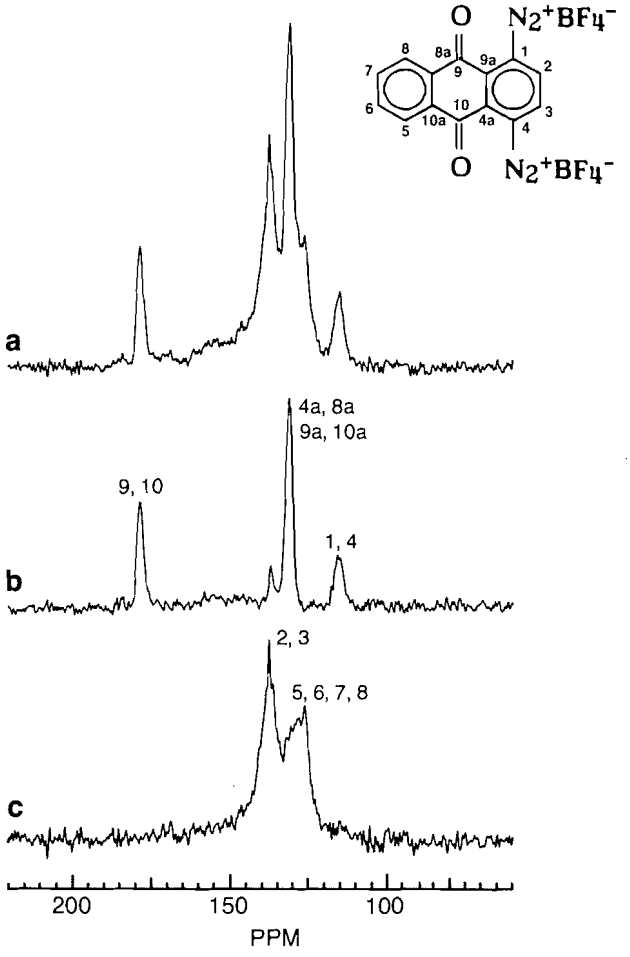

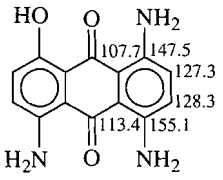

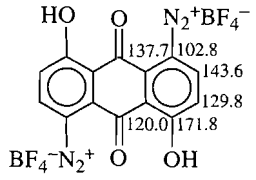

FIG. 4. CP MAS ^{13}C NMR spectra of **4**; (a) cross-polarization time = 4 ms, spinning rate = 4700 Hz, repetition time = 4 s, no. of scans = 2048; (b) same as (a) except with 100-μs spin temperature reversal; (c) spectrum (a) − spectrum (b).

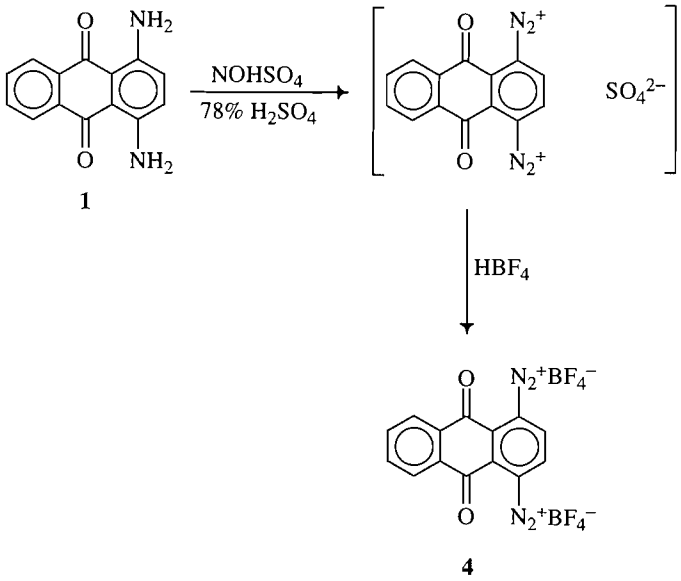
calculated difference of Figs. 3a and b. Chemical-shift assignments are made as follows. The two most downfield peaks at 180.9 and 184.5 ppm are assigned to the two nonequivalent carbonyl carbons. Because of the similarity of the chemical structure between **2** and a previously reported tetrazonium compound **5** (4,8-dihydroxyanthraquinone-1,5-tetrazonium bis(tetrafluoroborate)) (16), we can estimate the chemical-shift changes from **1** to **2** based on the changes from 1,5-diamino-4,8-dihydroxyanthraquinone (**6**) to **5**.

6

5

From the chemical-shift changes of **6** to **5**, the estimated chemical shifts for **2** are C1, 102 ppm; C2, 145 ppm; C3, 130 ppm; C4, 163 ppm; C4a, 114 ppm; and C9a, 138 ppm. By comparsion of these values with the spectral results in Figs. 3a and b, carbons 1, 2, 3, 4, 4a, and 9a are assigned (Table 3). The assignments are consistent with the observed asymmetric broadenings of carbons 1 and 4 due to the quadrupolar interactions with neighboring ^{14}N nuclei.[4] The splitting of peaks of C4a and C9a in **2** may be a consequence of crystal packing. The remaining carbons in **2** (carbons 5, 6, 7, 8, 8a, and 10a) are assigned by comparison with the ^{13}C shifts of **1**, because substituents at carbons 1 and 4 are known to exert very little effect on the chemical shifts of the carbons in the second benzene ring of the anthraquinone system.[5]



The CP MAS ^{13}C spectrum of **4** is given in Fig. 4a,[4] the non-protiated spectrum in Fig. 4b, and the protiated spectrum in Fig. 4c. The reduction of the number of non-protiated carbons from **2** to **4** suggests that **4** has a twofold symmetry and is the tetrazotized product of **1**.[6] The most downfield peak at 178.5 ppm is assigned to the two equivalent carbonyl carbons 9 and 10 and the most upfield peak at 115.5 ppm is assigned to carbons 1 and 4 because of the strong shielding effect produced

[4]The only useful NMR solvent for **2** and **4** is D_2SO_4. Attempts were made to record the solution ^{13}C NMR spectra of **2** and **4** in D_2SO_4 but failed due to the low thermal stability of these two compounds in sulfuric acid.

[5]Comparison of the ^{13}C data of a large number of monosubstituted anthraquinones (at C-1) and disubstituted anthraquinones (at C-1 and C-4) (14, 17) with those of anthraquinone (18) suggests that substituents at carbons 1 and 4 exert very little influence on the chemical shifts of the carbons in the second benzene ring.

[6]Elemental analysis was not performed for **4** because **4** was found to decompose slowly in the dark at room temperature.

SCHEME 2

by the diazonium group (19). The peak at 131.0 ppm, which is about twice the intensity of other non-protiated carbons, is attributable to carbons 4a, 8a, 9a, and 10a.

The protiated carbon spectrum of **4**, obtained by the subtraction of Fig. 4b from Fig. 4a, is depicted in Fig. 4c. Since substituents at carbons 1 and 4 are known to exert very small chemical-shift changes on carbons 5, 6, 7, and 8,[5] we assign the unresolved resonance at ~125–132 ppm to carbons 5, 6, 7, and 8 and the broad peak at 136–139 ppm to carbons 2 and 3. The broadening of the carbon peak of 2, 3 may in part be due to the undecoupled dipolar interaction between carbons 2 and 3 with the fluorine atoms of the adjacent tetrafluoroborate anion, analogous to the broadening effect previously observed in 4,8-dihydroxyanthraquinone-1-5-tetrazonium bis(tetrafluoroborate) (16). The ^{13}C NMR spectral data of **4** are consistent with its structure.

Tetrazotization of 1,4-diaminoanthraquinone by nitrosylsulfuric acid

While the yield of the tetrazonium salt of **1** synthesized by the *n*-amyl nitrite method was low, we found that **1** can be quantitatively tetrazotized by nitrosylsulfuric acid in 78% sulfuric acid. The tetrazonium product was isolated as tetrafluoroborate salt **4** in 74% yield (Scheme 2). The sample synthesized by the nitrosylsulfuric method was found to exhibit identical spectroscopic (IR) properties to that prepared by the *n*-amyl nitrite method.

Summary and remarks

The azotization reaction of 1,4-diaminoanthraquinone (**1**) by *n*-amyl nitrite in acetic acid was reinvestigated. The chemical structure of the red-brown solid isolated from the product mixture, which was assigned to anthraquinone-1,4-tetrazonium dichloride (**3**) by Schaarschmidt, was found to be incorrect. On the basis of elemental analysis results, and IR and CP MAS ^{13}C NMR data, we reassigned the red-brown solid to 4-amino-anthraquinone-1-diazonium chloride (**2**). Product analysis showed that **3** was formed in a very low yield in the mixture and that the tetrazonium product can be isolated as tetrafluoroborate salt **4** in 3.4% yield. The structure of **4** was confirmed by IR and CP MAS ^{13}C NMR spectroscopy. Further investigation showed that 1,4-diaminoanthraquinone can be tetrazotized quantitatively by nitrosylsulfuric acid in 78% sulfuric acid. The tetrazonium product, which was isolated as **4**, was obtained in 74% yield.

In many applications of NMR spectroscopy to chemistry, quantitation plays a key role. This paper argues that peak heights not only *can* be used for quantitative work in NMR but that for careful work they *should* be used. Integrals are accurate, but because they depend on many subjective factors, their precision is suspect. Peak heights are very reproducible on modern spectrometers and so, given this precision, the accuracy can be obtained as well by using calibration methods. An example of the application of these methods is given in the case of a ^{13}C labelling experiment that elucidates a photochemical transformation.

Key words: NMR, labelling, quantitation, peak heights, integrals.

ALEX D. BAIN, BRIAN J. FAHIE, TOMASZ KOZLUK et WILLIAM J. LEIGH. Can. J. Chem. **69**, 1189 (1991).

Dans plusieurs applications chimiques de la RMN, la quantification est importante. Dans ce travail, on fait valoir que non seulement les hauteurs de pics *peuvent* être utilisées dans des travaux quantitatifs de RMN mais que pour des travaux de qualité on *devrait* les utiliser. Les intégrales sont exactes mais, comme elles dépendent de plusieurs facteurs subjectifs, leur précision est suspecte. Les hauteurs des pics sont très reproductibles avec les spectromètres modernes et, tenant compte de cette précision, l'exactitude peut aussi bien être obtenue par des méthodes de calibration. On présente un exemple de l'application de ces méthodes dans le cas d'une expérience de marquage au ^{13}C qui permet d'élucider une transformation photochimique.

Mots clés : RMN, marquage, quantification, hauteurs des pics, intégrals.

[Traduit par la rédaction]

Introduction

NMR is certainly well known as one of the best methods for qualitative analysis: the identification of a molecule. Analysis of ^{13}C and ^{1}H spectra can often solve a structure completely, and the development of two-dimensional NMR methods has dramatically advanced this process (1, 2). These methods are based on spectral analysis, i.e., the positions of the lines in the spectrum, but quantitative analysis has also been an important part of NMR spectroscopy (3, 4). Counting protons using integrals is a very familiar part of proton NMR. Theory says that in the absence of saturation, the integral over a spectral line is directly proportional to the number of spins and the proportionality is the same for all lines in the spectrum. This simple quantitation can be extended and applied so that accurate and precise integration of NMR spectra is important in many fields (5–10). Measurements of enantiomeric and diastereomeric excess are crucial in the design of chiral synthesis. Particularly in isotopic labelling studies, such as the one described in this work, NMR is one of the few methods than can give a detailed picture of the mechanism of the reactions. The important data in this case are relative enrichments at different sites in the molecule (6, 7), so separations are impossible, and mass spectrometry is not selective enough to identify individual sites. However, the validity of these results depends crucially on the precision and accuracy of the quantitation of the NMR data.

Normal methods of quantitation using integration are not without problems (3, 4, 11, 12). In practice, the process involves several subjective decisions on the part of the operator. The choice of integration region, the phasing of the spectrum, and the correction of the baseline are all under the control of the operator, and each may profoundly affect the value of the integral. Careful work with good signal-to-noise ratios and standard conditions can minimize the variation of the results, but there will still be a random component due to the operator's particular choices as well as possible biases between operators (12). Typical estimates of the reliability of an integral are 3–5% (11). Even with relatively poor signal-to-noise, the random errors in an integral are quite small, because of the summation. However, the systematic errors due to the subjective decisions of the operator are much more dangerous and subtle.

This paper aims to avoid many of these problems through the use of peak heights, rather than integrals, in the quantitation of ^{13}C NMR spectra. This is by no means a novel idea (13), but with the improvements in computers and spectrometers, it deserves some further examination. Peak heights require much less operator intervention than integrals, and so are more adaptable to automatic spectral interpretation. Peak heights are precise, as will be shown, but accuracy may be lacking since lines may have different widths. Given the precision, however, the accuracy can be recovered through the use of statistical methods and calibration techniques (14). Generally speaking, an NMR spectrum consists of many repetitions of many data points, but all that is reported is the average. With more powerful computers in spectrometers, and off-line data processing, more care can be given to data analysis. Some very sophisticated methods have been applied to NMR data (15–17), but we suggest that some simple methods can also provide useful information. The application of these statistical methods to NMR spectra will not necessarily improve the data, but it will give a clear and honest estimate of its quality.

Principles

The experiment we propose is conducted as follows. Instead of accumulating many scans on a sample, the scans are broken up into blocks, as in the original block averaging methods, and then not only the average but also the standard deviation of each peak height can be calculated. The sample is also combined with a standard of known concentration, and the peak heights of the standard and the sample are compared. The experiment is then repeated for a series of concentrations of the reference compound. A plot of the peak height of the sample divided by the peak height of the reference against the reciprocal of the reference concentration should then be linear. The slope of this line will then reflect the relative enrichment of each site.

Much work has been published on the experimental para-

meters needed to obtain good quantitative data in NMR (3–12, 18). These include waiting for equilibrium to be re-established between pulses, suppression of the Overhauser effect, and good digital resolution in the spectrum to obtain a faithful representation of the lineshape. Often this research was aimed at finding out when these parameters became important, for instance, how rapidly pulses could be applied, relative to T_1, and still yield useful data. In this paper, we assume that all these precautions have been observed, and we concentrate on the analysis of the data itself.

The main motivation in pursuing peak heights rather than integrals, as a quantitative measure, is the observation that on a modern spectrometer the peak height is very stable. Experiments such as multiple quantum filters (INADEQUATE) and inverse detection methods routinely suppress lines belonging to ^{12}C species relative to their ^{13}C satellites (19–23). For this to happen, the ^{12}C peak must be stable to better than 0.55%. Also, in relaxation measurements it is the usual practice to use peak heights rather than integrals (13, 24). These are ideal conditions, of course, since the sample remains in the magnet all the time, and very little changes from one scan to the next. This performance gives us an estimate of the precision that is attainable.

The parameter, other than electronic stability, that will control the reliability of the peak heights is the stability of the peak widths in the spectrum. In ^{13}C spectroscopy, the linewidths in a proton-decoupled spectrum are mainly determined by two factors: the efficiency of proton decoupling and the apodization function that is applied to the data before Fourier transformation. Of course, the homogeneity of the magnetic field contributes, but it is much less important than in proton spectroscopy. In practice, the proton decoupling usually gives a relatively broad line compared to what can be achieved with careful work (25). Provided the lines are reasonably well separated, a heavy exponential function can be applied to the FID so that the linewidth in the spectrum is dominated by the filter function. Since the intensities in the spectrum are low-frequency information, an exponential filter will cause minimal distortions to the quantitative accuracy. Under these circumstances, the linewidths in the spectrum depend only minimally on the identity of the carbon nucleus or on the concentration of the species.

For accurate integration, the method of choice is to fit the data to a series of theoretical lines (Lorentzian, Gaussian, or some more general form) and then integrate the fitted line (11). The use of peak heights relaxes this assumption, since the only requirement is that the peak shape be stable. Asymmetries and baseline humps, which bedevil lineshape fitting, do not interfere with peak height quantitation.

Small overlaps of lines also affect peak heights less. The wings of a Lorentzian line are notoriously broad, and in the wings the integral only falls off as $1/(\omega - \omega_0)$, where ω_0 is the central frequency of the line. However, the height of the line falls off as $1/(\omega - \omega_0)^2$, so the effects on the peak height are much smaller.

Finally, phase corrections and baseline errors cause fewer problems with peak heights than with integrals. A simple calculation shows that an integral depends on the phase of a Lorentzian line as cos (α) where α is the phase angle relative to pure absorption. The dependence of peak height on α is

$$1/\left[1 + \left(\frac{1 - \cos(\alpha)}{\sin(\alpha)}\right)^2\right]$$
