We have studied the reaction of both D- and L-penicillamine with pyridoxal hydrochloride and examined the products by single crystal X-ray diffraction. The structure of the title compound, **A**, formed by the reaction of D-penicillamine and pyridoxal was determined. Crystals are orthorhombic, $P2_12_12_1$, with cell dimensions $a = 9.507(5)$, $b = 19.185(5)$, $c = 7.766(2)$ Å and $Z = 4$. The structure was solved by standard methods and refined to $R = 0.088$, $R_w = 0.079$ for 2433 independent reflections. **A** exists as a zwitterion, and bond lengths and angles are normal. In the solid state, **A** and the corresponding product obtained from L-penicillamine, **B**, have identical geometrical structure but are of opposite chirality; that is, D-penicillamine produces the 2*R*,4*S* diastereomer and L-penicillamine produces the 2*S*,4*R* diastereomer (with no *S*,*S* and *R*,*R* components). In solution, however, NMR spectra show the presence of both pairs of diastereomers (2*R*,4*S* and 2*S*,4*S*; 2*S*,4*R* and 2*R*,4*R*). In neutral or alkaline solution there appears to be a rapid epimerization at the thiazolidine carbon atom attached to the pyridoxal moiety. Features of the mass, ^{1}H NMR, vibrational, and electronic spectra are also discussed.

Key words: D-penicillamine, vitamin B6, pyridoxal hydrochloride, therapeutic uses, bischemical reactions, structures.

R. FAGGIANI, H. E. HOWARD-LOCK, C. J. L. LOCK et R. ORGIAS. Can. J. Chem. **69**, 1 (1991).

On a étudié la réaction des D- et L-pénicillamines avec le chlorhydrate du pyridoxal et on a examiné la nature des produits obtenus par diffraction des rayons-X par un cristal unique. On a déterminé la structure du composé **A** mentionné dans le titre et formé par la réaction de la D-pénicillamine avec le pyridoxal. Les cristaux sont orthorhombiques, $P2_12_12_1$, avec $a = 9{,}507(5)$, $b = 19{,}185(5)$ et $c = 7{,}766(2)$ Å et $Z = 4$. On a résolu la structure par les méthodes standards et on l'a affinée jusqu'à des valeurs de $R = 0{,}088$ et $R_w = 0{,}079$ pour 2433 réflexions indépendantes. Le composé **A** existe sous le forme d'un zwitterion; ses angles et les longueurs de ses liaisons sont normaux. À l'état solide, les composés **A** et **B** possèdent des structures géométriques identiques, mais de chiralités opposées; c'est-à-dire que la D-pénicillamine conduit au diastéréoisomère 2*R*,4*S* alors que la L-pénicillamine conduit au diastéréoisomère 2*S*,4*R* (sans contamination par les composantes *S*,*S* ou *R*,*R*). Toutefois, en solution, les spectres RMN montrent qu'il existe deux paires de diastéréoisomères (2*R*,4*S* et 2*S*,4*S*; 2*S*,4*R* et 2*R*,4*R*). Il semble que, en solutions neutres ou alcalines, il se produit une épimérisation rapide de l'atome de carbone de la thiazolidine qui est attaché à la portion pyridoxal. On discute aussi des caractéristiques spectrales (masse, RMN du ^{1}H, vibrationnels et électroniques) de ces produits.

Mots clés : D-pénicillamine, vitamine B6, chlorhydrate du pyridoxal, usage thérapeutique, réactions bischimiques, structures.

[Traduit par la revue]

Introduction

D-(−)-Penicillamine is a synthetic amino acid, which has been used in the treatment of rheumatoid arthritis since 1973 when its efficacy as an anti-arthritic drug was firmly established. In addition, D-(−)-penicillamine has an older, well-established use in the treatment of patients suffering from Wilson's disease, as well as uses in the treatment of heavy metal poisoning, cystinuria, multiple sclerosis, and chronic aggressive hepatitis (1).

Only the stereochemically pure D-isomer of penicillamine is employed as a therapeutic agent because it has been shown that the administration of the racemate or the L-isomer causes greater toxicity. Penicillamine causes inhibition of the kynurenine pathway and pyridoxine metabolism (2), the reduction of the activities of liver transaminases and liver cysteine desulfhydrase (3, 4), the inhibition of collagen fibre crosslinking (5), and the inhibition in bone marrow of DNA, RNA, and protein synthesis (6). In all but the last of the toxic effects cited above, penicillamine is acting on an ubiquitous coenzyme called pyridoxal-5-phosphate. This fact is borne out by studies that have shown that the administration of penicillamine creates a need for supplements of vitamin B_6, a pyridoxal-5-phosphate precursor (2, 7).

The principal derivatives of vitamin B_6 are pyridoxal, pyridoxal-5-phosphate, pyridoxamine, and pyridoxine, all of which are interconvertible in vivo (2). The postulated targets of penicillamine are the aldehydes, pyridoxal and pyridoxal-5-phosphate. The aldehydic function present in these structures has been shown to be the site through which the coenzyme binds to different apoenzymes to form active holoenzymes. This binding takes the form of a Schiff's base linkage (8).

Penicillamine, being an aminothiol, reacts with aldehydes to form five-membered ring thiazolidine-4-carboxylic acids, which are stable under physiological conditions (9). More significantly, competition experiments have shown that aminothiols can react with Schiff's bases to form thiazolidines (10). This result implies that penicillamine can interact directly with enzyme bound pyridoxal, and such a reaction is believed to occur when penicillamine is administered as a drug.

Previous work has provided substantial evidence that the thiazolidine products of the reactions are formed in solution (9), but the preparation of the reaction products in the solid state has been dealt with only fleetingly. Heyl *et al.* (11) reported the preparation of a thiazolidine product from pyridoxal and penicillamine but their characterization of the product was minimal, and was confined to an elemental analysis and a melting point.

We became interested in the factors that control the absolute

stereochemistry at the C2 position of the thiazolidine ring. In this study, we have attempted to add to the present understanding of the chiral nature of the penicillamine – vitamine B_6 interaction by preparing and characterizing the thiazolidine products (**A** and **B**) arising from the separate reactions of D-(−)- and L-(+)-penicillamine, respectively, with pyridoxal.

A

B

The reaction products 2-(2′-methyl-3′-hydroxy-5′-hydroxymethylenepyridine-C4′)-5,5-dimethyl-4-thiazolidine carboxylic acid (**A** = 2*R*,4*S*; **B** = 2*S*,4*R*) were prepared in a crystalline form to allow study of their configurations by single crystal X-ray diffraction. Although the crystal structures of both **A** and **B** were determined, they are enantiomers with no significant differences in their structures; hence only data for **A** are reported here. Spectroscopic characterization (NMR, vibrational, electronic, mass) of the reaction products was also undertaken.

Experiments

Pyridoxal hydrochloride, L-(+)-penicillamine (free base), and D-(−)-penicillamine (free base) were of reagent grade as supplied by Sigma Chemical Co., St. Louis, MO. All other reagents were of standard laboratory grade.

*2-(2′-Methyl-3′-hydroxy-5′-hydroxymethylenepyridine-C4′)-5,5-dimethyl-4-carboxylic acid (**A** and **B**)*

Pyridoxal hydrochloride (0.5000 g, 2.5 mmol) was dissolved in 50 mL of water and the pH adjusted to 8.0 by the dropwise addition of dilute NH_4OH. The pH was monitored with a pH meter (Corning model 120). To this solution was added 0.3665 g (2.5 mmol) of D- or L-penicillamine (to give the products **A** and **B**, respectively). The mixture was stirred at room temperature with a magnetic stirrer until the gradual disappearance of the characteristic yellow colour of pyridoxal signalled that the reaction was complete (about1 h). The solution was filtered by suction to remove any unreacted solids, and was stored undisturbed at room temperature in the dark. Some crystallization was evident after 24 h but the solution was allowed to sit for 4 days before being filtered. The pale yellow crystals were collected by suction on a fritted glass filter and washed successively with water, ethanol, and ether. Yield: 0.5661 g (77.4%) (**A**), 0.5968 g (81.5%) (**B**).

Analysis (by Guelph Chemical Laboratories Ltd., Guelph, Ontario) for **B**: calcd. for $C_{13}H_{18}N_2O_4S$: C 52.5, H 6.0, N 9.4, S 10.7; found: C 52.5, H 6.2, N 9.4, S 9.9. For **A**, $[\alpha]_D^{27}$ +19.4° (*c* 1, 0.1 N HCl); for **B**, $[\alpha]_D^{27}$ −19.7° (*c* 1, 0.1 N HCl). **A** and **B** were insoluble in saturated hydrocarbon solvents, chlorinated methanes, and ether. They were slightly soluble in methanol and ethanol and were soluble in dimethyl sulfoxide on warming. Solubility in water depended on pH; they were insoluble in neutral water but soluble in acidic or basic solutions.

*2-Phenyl-5,5-dimethylthiazolidine-4-carboxylic acid (**C** and **D**)*

Benzaldehyde (0.05 mL, 0.5 mmol) was mixed with 0.0733 g (0.5 mmol) of either D- or L-penicillamine (to give the products **C** and **D**, respectively) in 10 mL of water at pH 8.0 (pH adjusted with dilute NH_4OH). The solution yielded a white precipitate after 2 h of stirring. The precipitate was collected by suction and washed with ethanol and ether. Yield: 0.0490 g (41%) (**C**), 0.0341 g (29%) (**D**).

Spectral measurements

Infrared specrtra were recorded over the range 4000–200 cm^{-1} on a Perkin Elmer model 283 spectrophotometer with samples in the form of KBr pellets (at a concentration of ~1–10% by weight). The spectra were calibrated with polystyrene. Infrared spectra were also recorded in the range 500–100 cm^{-1} on a Nicolet 7199 FT-IR spectrometer with samples prepared as Nujol mulls between polyethylene plates. These spectra were automatically corrected for background noise. Raman spectra were obtained by excitation of solid samples with λ 5145 Å radiation from an Innova 90 series argon ion laser operating at an output power of 0–2 W. The spectra were recorded on a Spex 14018 double monochromator. The spectrometer was calibrated against neon and indene, and the wavenumber readout was accurate to ±2 cm^{-1}. Ultraviolet–visible spectra were recorded on a Hewlett Packard 8451 Å diode array spectrophotometer. The samples were contained in quartz cuvettes with path lengths of 1 cm; sample concentrations were 10^{-5}–10^{-4} molar. All spectra were of water solutions and run against an overlaid water reference. Sample solutions of varied pH were prepared by the addition of 0.1 N HCl or 0.1 N KOH to standard solutions. The optical activities of aqueous solutions were measured with use of the sodium D line (589 nm) and a Perkin Elmer 241 MC polarimeter, the sample chamber temperature being kept at 27°C. Samples were prepared in 0.1 N HCl solution at concentrations of 10 g L^{-1} and were measured against an overlaid reference solution. Mass spectral data were obtained with a VG micromass 7070F spectrometer equipped with a Digital PDP-8 computer. The electron impact method of ionization was used, with an electron potential of 70 eV, direct probe introduction, an ion source temperature of 220°C, and an emission current of 100 μA. The ^1H NMR spectra were recorded at 90 MHz on a Varian EM 390 spectrometer. Samples were prepared in DMSO-d_6 and D_2O solutions at concentrations of approximately 20 g L^{-1} of solvent. Tetramethylsilane and trimethylsilylpropionic acid were used as internal standards.

Collection of the X-ray diffraction data

The X-ray studies were carried out on single crystals sealed in Lindeman capillary tubes, in order to protect against decomposition. Precession photographs of the crystals indicated that they were orthorhombic. The unit cell parameters were obtained from least-squares fit of χ, φ, and 2θ for 15 reflections in the range $19.1° < 2\theta < 31.8°$, measured on a Syntex $P2_1$ diffractometer having graphite monochromated MoKα radiation (λ = 0.71069 Å). Crystal data and other parameters related to data collection are summarized in Table 1. The density of the crystals was measured by suspension in a dichloromethane–bromoform mixture. Intensities were also measured with use of the Syntex $P2_1$ diffractometer and a coupled θ(crystal)–2θ(counter) scan. The methods of selection of scan rates and initial data treatment have been described (12, 13). Corrections have been made for Lorentz and polarization effects but not for absorption. This will make a maximum error in F_o of 1.0%.

Solution of the structure

Phases were determined by direct methods with use of 230 reflections with $|E| > 1.789$ and 12 sets of starting phases. All non-hydrogen atoms were found in the resulting *E* map. Subsequent refinement and electron density difference syntheses revealed all the hydrogen atoms except one. Attempts to refine hydrogen atoms led to divergent functions, so the hydrogen atoms were placed at the positions given in the difference synthesis with temperature factors of about twice those of the atoms to which they were attached, and were not refined in further cycles. Temperature factors for sulfur and oxygen atoms and adjacent carbon atoms were made anisotropic. The significance of the additional parameters was tested at each stage (14). Full-matrix least-squares refinement, which minimized $\Sigma w(|F_o|-|F_c|)^2$, was continued until the maximum shift/error was <0.1. No corrections were needed for secondary extinction.

Scattering curves were taken from Cromer and Waber (15) and anomalous dispersion corrections were taken from Cromer (16) and applied to the curves for S, N, O, and C. The atom parameters are listed in Table 2.[3,4]

Discussion

The structure of **A** is shown in Fig. 1 and bond distances and angles are given in Table 3. As can be seen, the configuration at the chiral C2 carbon atom is *R* while that at C4 is *S*. The conformation is such that the hydrogen atoms at C2 and C4 are *trans*. The thiazolidine ring resembles an open envelope with C5 lying 0.682(5) Å out of the rough plane of the other four atoms. This is different from both (*S*)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid (21) and (*R*)-thiazolidine-4-carboxylic acid (22). The small N3,C4,C1,O1 torsion angle (11.9(4)°) is in agreement with those in related structures we and others have examined (21–25) and again appears to be caused by non-bonding steric interactions rather than intramolecular hydrogen bonding. Although the N3...O1 distance is short, the N3—H3...O2 angle (118°) lies well outside the N...O/N—H...O relationship established by Brown (26). The pyridine ring (max. dev. C2′, 0.007(6) Å) and the exocyclic atoms (largest dev. C51′, 0.035(9); O5′, 0.066(9); C2, 0.053(8) Å) are very close to planar. The dihedral angle of 60.7(2)° between the pyridine ring and the thiazolidine ring is determined by the strong internal hydrogen bond between O3′—H3′ and N3. Since N3 is roughly coplanar with the pyridine ring, the thiazolidine ring may be regarded as bent out of the pyridine ring plane about a C2—N3 hinge.

[a,b]Atoms are related to those in Table 2 by the relationships *a*; -*x*, *y*-1/2, 3/2-*z*; *b*; -*x*, y-1/2, 1/2-*z*.
[c]No errors are given since the hydrogen atom parameters were not refined.

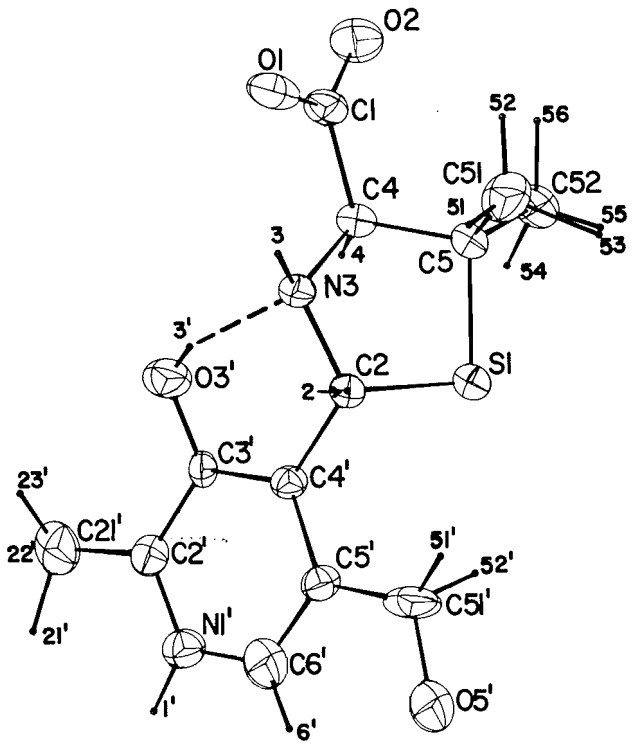

FIG. 1. The molecule of **A** showing the atom numbering. The view is down the H2—C2 bond. Hydrogen atoms are indicated by affixes only in smaller print.

The bond lengths and angles within the thiazolidine ring are consistent with values found for (*S*)-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid, except for the C2—N3—C4 angle, which is significantly larger (113.2(4)° vs. 108.6(4)°, 107.9(4)°) (21) and closer to the value found for protonated amines as in bis((*S*)-5,5-dimethylthiazolidine-4-carboxylic acid)hydrogen chloride hydrate (112.2°, 109.7°) (27). The structural results show no protonation of the nitrogen atom, although there is a very strong internal hydrogen bond to it (N3...O3′, 2.535(5) Å). In the difference map, however, a small peak appeared on the same N3...O3′ axis, about 1 Å from the nitrogen atom, but this disappeared when attempts were made to refine it with partial occupancy. It may be that, in the crystal, there is a small amount of the $O^-...NH_2^+$ tautomer, as well as the major OH...NH tautomer, which could not be detected by the X-ray refinement procedure. The distances and angles within the carboxylate ion differ from those found in both the above structures and are close to those found in (*R*)-thiazolidine-4-carboxylic acid, which exists as the zwitterion tautomer (22). The bond lengths and angles in the pyridoxal ring agree well with average values for a number of N-protonated pyridoxyl rings (28–34). In particular the C6′—N1′—C2′ angle is significantly larger (122.9(4)° vs. 111.3°) than a comparable angle in a non-protonated pyridoxyl ring (35), an effect first noted by Singh (36).

The packing is shown in Fig. 2 and is dominated by the strong hydrogen bonds between adjacent molecules related by the 2_1 axes along the *b* direction. N1′...O1 (2.620(5) Å) is between molecules related by the axis at $x = 0$, $z = 3/4$, whereas O5′...O2 (2.70(5) Å) is between molecules related by the $x = 0$, $z = 1/4$ axis. The resultant bonding of one molecule to four others provides a hydrogen bonding net in the *c* direction as well. Interactions in the *a* direction are van der Waals.

The ^{1}H NMR chemical shifts and assignments for **A** and **B** are presented in Table 4 together with those of **C** and **D** so that analogies can be drawn between the spectra. Both sets of spectra can be readily interpreted if it is assumed that pairs of diastereomers are present in solution for each compound (**A** has *S*,*S* and 2*R*,4*S* and **B** has *R*,*R* and 2*S*,4*R*). This is shown by the splitting of all peaks except that for H6′. We assume that the lack of visible splitting of the H6′ proton peak is caused by limita-

m = multiplet

[a]**A** and **B** are solutions of 2*R*,4*S* and 2*S*,4*R* 2-(2′methyl-3′-hydroxy-5′-hydroxymethylenepyridine-C4′)-5,5-dimethylthiazolidine-4-carboxylic acid. **C** and **D** are solutions of the 2-phenyl-5,5-dimethylthiazolidine-4-carboxylic acids derived from *S*-penicillamine and *R*-penicillamine respectively.

tions in resolution of the NMR instrument or chance coincidence. Comparison of the spectra of **C** and **D** with those of **A** and **B**, together with consideration of the intensities, shows that the peak at $\delta \approx 2.3$ is caused by the methyl group of the substituted pyridine ring. The resonance at $\delta \approx 7.82$ is assigned to the hydrogen atom at the C6′ position of the substituted pyridine ring and the resonance at $\delta \approx 4.45$ to the CH_2 protons at the 5′ position. The proton of the C4 position of the thiazolidine ring can be assigned the resonances at ≈5.92 and ≈6.3. The assignment is consistent with assignments of similar compounds examined by other workers (37). The C51 and C52 methyl group protons are assigned by analogy to penicillin (38).

The assignment of the resonances to *S,R* and *S,S* (or *R,S* and *R,R*) is based on the work of McMillan and Stoodley (37). Talking about the protons at C2 and C4 in similar compounds, they state: "In particular, if both stereoisomers at C2 are available, the isomer in which the C4 proton appears at lower field possesses the *trans* configuration." Thus the "*trans*" diastereomer, which is the one of which the structure was determined, is the major component in solution and this is more stable. The apparent contradiction, that only one diastereomer was found in the solid state, whereas the ^{1}H NMR spectra showed that in solution both diastereomers were present (that is, a solution of **A** contained both 2*R*,4*S* and *S,S* diastereomers with the corresponding pair for **B**), can be explained in two ways:

(a) The products **A** and **B** were obtained from a mixture of diastereomeric crystals but the crystals chosen for study just happened to be 2*R*,4*S* and 2*S*,4*R*.

(b) The products **A** and **B** in the solid state are single diastereomers that undergo epimerization in solution to give a mixture of diastereomers.

Possibility (a) was tested by performing a powder diffraction study on the product **B**. The measured diffraction pattern agreed with that calculated from the single crystal parameters. It was concluded therefore that possibility (b) holds: rapid epimerization of the thiazolidine products **A** and **B** occurs in solution probably by means of a Schiff's base intermediate (39). The

diastereomer found in the solid state is that which is least soluble and will be determined not only by molecular stability but also by intermolecular interactions.

The infrared and Raman spectra of **A** and **B** were identical (as were those of **C** and **D**). The frequencies and assignments of the major vibrational bands of the starting materials D-penicillamine and pyridoxal hydrochloride, and of **A**, are listed comparatively in Table 5.[3] The two strong bands between 2500 and 1900 cm^{-1} are typical of medium strong O—H...N bonding in the solid state. That the compounds **A** and **B** exist as zwitterions in the solid state is shown by the presence of strong bands at ca. 1620 and 1400 cm^{-1}, typical of ν_a and ν_s of the CO_2^- group, and the absence of a strong νC=O absorption at 1720 cm^{-1}. Assignments are based on previous work by ourselves (23) and others (40, 41).

The electronic spectra were of interest because the reaction between penicillamine and pyridoxal was monitored by the appearance of a peak at 326 nm, which is characteristic of thiazolidines of pyridoxal (42). The ultraviolet–visible spectra of **A** were examined at three pH values: 3.2, 7, and 10.2. The spectral results are given in Table 6. The spectra of the starting material, pyridoxal hydrochloride, were also obtained at several pH values. For pyridoxal at pH 1.5, where the pyridine nitrogen

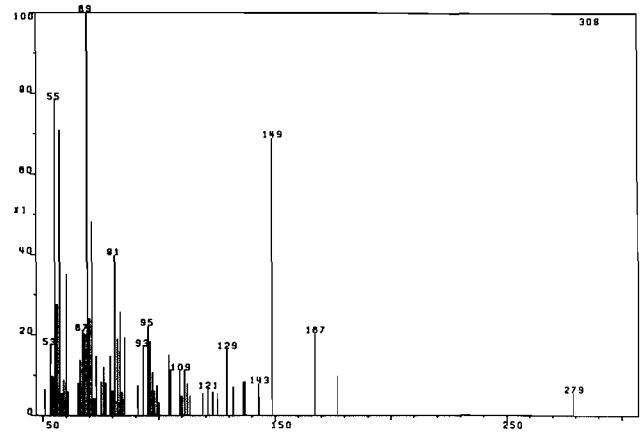

FIG. 3. The mass spectrum of **A**.

atom is protonated, only one absorption maximum at 286 nm is evident, while at pH 12.5, where the phenolic group is deprotonated, three maxima are present. Pyridoxal forms bright yellow solutions at pH values greater than 7.5 because of the presence of the phenoxide-like chromophore.

Compound **A** also has a pH dependent UV spectrum. Formation of the thiazolidine reduces the extent of the delocalization of the phenoxide-like chromophore, and hence the absorption maxima occur at lower wavelengths and the characteristic yellow colour observed for pyridoxal solutions is not present.

A titration of **B** against 0.01 N HCl shows the presence of three titratable protons at pK values of 4.5, 7.5, and 10.1. By comparison with ^{13}C NMR studies done by other workers (43), we have made the following assignments: pK_a 4.5, proton of pyridinium nitrogen; pK_a 7.5, proton of N3 of thiazolidine ring; pK_a 10.1, phenolic hydrogen. These assignments can also be seen to support the pH dependent ultraviolet data.

The mass spectrum is shown in Fig. 3. No parent peak, P^+, is seen; the highest peak at m/e = 279 corresponds to $(P-OH_3)^+$, but the fragment cannot be identified. The principal features below m/e = 200 are very similar to the corresponding spectra for pyridoxal phosphate and pyridoxal, for which the fragmentation patterns have been fully discussed (44, 45). There is little evidence of fragments from the thiazolidine ring through the normal 1,4 cleavage. Peaks at m/e = 69 and 55 have been observed previously for decompositions of thiazolidines derived from D-penicillamine (21). In that case the m/e = 69 peak was derived from a 1,4 fragmentation, whereas in this case it can only be derived from a 2,5 fragmentation. The m/e = 55 peak can also arise from the 2,5 fragmentation, even though the first fragment (m/e = 114) is not observed.

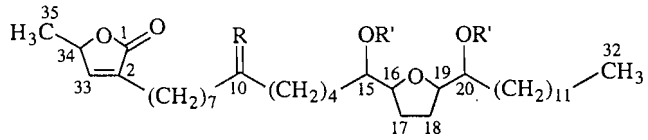
Reçu le 16 mai 1990

DIEGO CORTES, SAW HLA MYINT, ALAIN LAURENS, REYNALD HOCQUEMILLER, MICHEL LEBOEUF et ANDRÉ CAVÉ. Can. J. Chem. **69**, 8 (1991).

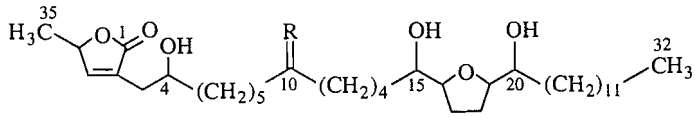
Le fractionnement par solvants du contenu des graines d'*Annona muricata* (Annonaceae), guidé par l'activité toxique envers les larves de crevettes et les cellules cancéreuses KB, a permis d'isoler deux nouvelles γ-lactones mono-tétrahydrofuraniques cytotoxiques : la corossolone **1** et la corossoline **2**. La structure de ces deux acétogénines cytotoxiques a été déterminée par analyse des données spectrales, en particulier RMN et SM. La corrélation chimique entre **1** et **2** a été établie par réduction de la corossolone par $NaBH_4$. **1** et **2** constituent les premiers exemples d'acétogénines mono-tétrahydrofuraniques non fonctionnalisées en 4.

Mots clés : Annonaceae, acétogénines, cytotoxicité, corossol, *Annona muricata*.



DIEGO CORTES, SAW HLA MYINT, ALAIN LAURENS, REYNALD HOCQUEMILLER, MICHEL LEBOEUF, and ANDRÉ CAVÉ. Can. J. Chem. **69**, 8 (1991).

The fractionation by solvents of the contents of the seeds of *Annona muricata* (Annonaceae), guided by the toxic activity towards the brine shrimp larva and the KB cancer cells, has enabled us to isolate two new cytotoxic mono-tetrahydrofuran γ-lactones: corossolone **1** and corossolin **2**. The structure of these two cytotoxic acetogenins was determined by analysis of the spectral data, NMR and MS in particular. The chemical correlation between **1** and **2** was established by the $NaBH_4$ reduction of corossolone. **1** and **2** constitute the first examples of mono-tetrahydrofuran acetogenins with an unfunctionalized C-4.



Key words: Annonaceae, acetogenins, cytotoxicity, soursop, *Annona muricata*.

Introduction

Depuis l'isolement de l'uvaricine en 1982 (1), près d'une trentaine de γ-lactones tétrahydrofuraniques ont été isolées, toutes à partir d'espèces de la famille des Annonacées (2, 3). La plupart d'entre elles comportent un enchaînement bis-tétrahydrofuranique (2); seules quelques unes ne possèdent qu'un seul noyau tétrahydrofurane (4–6). Dans ce dernier groupe tous les produits isolés jusqu'ici ont une fonction oxygénée sur le C-4. L'étude des graines d'*Annona muricata* nous a conduits à l'isolement de cinq acétogénines, dont deux produits originaux : la corossolone **1** et la corossoline **2**, premiers représentants d'un nouveau groupe d'acétogénines mono-tétrahydrofuraniques caractérisées par l'absence de fonctionnalisation en position 4, et trois déjà décrites : l'annonacine **3** (4), l'annonacinone **4** (6) et la murisoline **5** (7). Les cinq acétogénines isolées présentent, à des degrés divers, une cytotoxicité sur lignées cellulaires KB et VERO.

1: R = O; R' = H : corossolone
2: R = H,OH; R' = H : corossoline
6: R = O; R' = Ac
7: R = H,OAc; R' = Ac

3: R = H,OH : annonacine
4: R = O : annonacinone
5: R = H,H : murisoline

Résultats et discussion

Le spectre IR de la corossolone **1** contient une bande de carbonyle de γ-lactone insaturée (1745 cm^{-1}), ainsi qu'une bande à 1700 cm^{-1} attribuable à un carbonyle cétonique non conjugué. La formule moléculaire de **1**, $C_{35}H_{62}O_6$, est déduite du spectre de masse à haute résolution de son dérivé diacétylé **6** : MH^+ *m/z* 663,4844 (trouvé); 663,4835 (calculé pour $C_{39}H_{67}O_8$).

Sur le spectre de RMN du ^1H dont l'attribution est réalisée par analyse du spectre 2D ^1H–^1H COSY, on remarque tout d'abord l'aspect typique des signaux dus à une γ-lactone α,β-insaturée substituée en α par une chaîne aliphatique (1) : δ 6,99 (d), 4,99 (dq) et 1,40 (d). La corrélation hétéronucléaire ^1H–^{13}C permet d'attribuer les résonances des carbones C-33, C-34 et C-35 à respectivement δ 148,9, 77,4 et 19,2 (tableau 1). L'existence d'un seul cycle tétrahydrofuranique, comme dans le cas de l'annonacine (4), de la goniothalamicine (5) et de la murisoline (7), est mise en évidence par corrélation entre la RMN du ^1H (δ 3,78, m, H-16 et H-19) et du ^{13}C (δ 82,6 et 82,5). La présence habituelle des deux hydroxyles en α et α′ du cycle tétrahydrofuranique est constatée par corrélation ^1H (δ 3,40, m, H-15 et H-20) et ^{13}C (δ 74,0 et 73,7) : voir tableau 1. En RMN du ^1H, l'absence du système ABX caractéristique des acétogénines hydroxylées en position 4 (8), ainsi que la présence de deux triplets (δ 2,38, 4H, H-9 et H-11 et

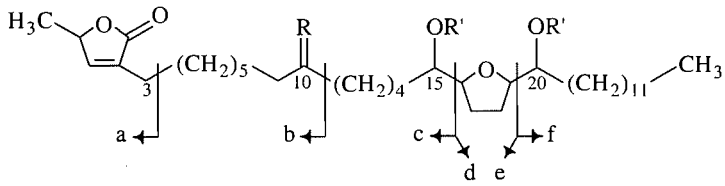
*Attributions réalisées grâce aux spectres de corrélation homonucléaire (^1H–^1H COSY), de corrélation hétéronucléaire (^1H–^{13}C) et de RMN du ^{13}C SPIN ECHO (10). RMN du ^1H, constantes de couplage (J, Hz) : J_{3-4} = 7,2; J_{8-9} = J_{11-12} = 7,5; J_{31-32} = 5,8; J_{33-34} = 1,5; J_{34-35} = 6,7.

δ 2,25, 2H, H-3), indiquent que la corossolone **1** est l'une des rares acétogénines non substituées en 4 (1, 9), mais substituée par une fonction cétonique sur l'une des chaînes aliphatiques (δ 211,4 en RMN du ^{13}C et ν 1700 cm^{-1} en IR). La position en 10 du carbonyle de **1** est déduite de l'étude des fragments observés sur les SM de la corossolone **1** et de la diacétylcorossolone **6** (tableau 2).

Le pic moléculaire en SM de la corossoline **2** (MH^+ 581), ainsi que les pics provenant de la fragmentation entre les carbones C-10 et C-11 (fragment b: voir tableau 2), comportent deux unités de masse de plus que dans le cas de la corossolone **1**, ce qui indique la présence d'un hydroxyle sur le C-10. Les déplacements chimiques observés en RMN du ^1H et du ^{13}C (tableau 1) ont été attribués par le même raisonnement que pour **1**. Enfin, la corrélation chimique entre **1** et **2** a été établie par réduction du carbonyle de la corossolone **1** : l'action de $NaBH_4$ conduit à la formation d'une dihydrocorossolone, identique (co-CCM, IR, RMN et SM) à la corossoline naturelle **2**.

En ce qui concerne la stéréochimie des acétogénines **1** et **2**, nous avons tenté de déduire la configuration relative des centres chiraux du système tétrahydrofuranique α,α′-dihydroxylé (C-15/C-16 et C-19/C-20) de l'étude détaillée des déplacements chimiques en RMN du ^1H de leurs dérivés acétylés **6** et **7**, par rapport aux données des différents stéréoisomères bis-tétrahydrofuraniques diacétylés préparés récemment par synthèse (11, 12). Comme dans le cas de la murisoline **5** (7), les dérivés acétylés de la corossolone **1** et de la corossoline **2**, mais aussi ceux de l'annonacine **3** et de l'annonacinone **4**, présentent des déplacements chimiques très proches pour les paires de carbones C-15/C-20 et C-16/C-19, ce qui permet d'envisager pour ces acétogénines la même configuration relative que celle de la murisoline : *threo, trans, threo* (7).

Les cinq acétogénines isolées des graines d'*A. muricata* présentent donc une certaine homogénéité structurale, puisqu'elles appartiennent toutes au groupe des acétogénines monotétrahydrofuraniques. Disposant de ces cinq acétogénines, il a paru utile de dégager les données spectrales pouvant permettre de différencier les acétogénines de ce type, selon qu'elles sont substituées ou non en 4 et (ou) en 10 par une fonction oxygénée.



(a) En RMN du ^1H, on constate un blindage des protons en 33 et 34 de la lactone (−0,20 et −0,04 ppm respectivement) des produits non hydroxylés en 4 (corossolone **1**, corossoline **2** et dérivés), par rapport aux produits hydroxylés en 4 (annonacine **3**, annonacinone **4** et murisoline **5**). Cet effet est également observé en RMN du ^{13}C (−3,1 et −0,7 ppm respectivement) (voir figure 1).

(b) Le système ABX, mis en évidence sur le spectre de RMN du ^1H des acétogénines hydroxylées en 4, est absent dans le cas des acétogénines non hydroxylées en 4; ces dernières présentent en revanche un triplet vers δ 2,25 correspondant au CH_2-3 (voir figure 1).

(c) Le spectre de masse, en ionisation chimique, des acétogénines hydroxylées en position 10 (corossoline **2** et annonacine **3**), ne présente pas les coupures caractéristiques en α du cycle tétrahydrofuranique (pics c et e, tableau 2); cependant, les fragments correspondant à la perte d'une

*(1) : perte de H_2O; (2) : perte de CO; (3) : perte de AcOH; (4) : perte de Ac; [ ] : pic très peu abondant.

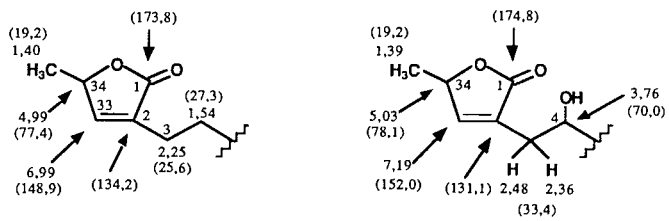

FIG. 1. Différences en RMN du ^1H et du ^{13}C (entre parenthèses), entre la corossolone **1** (acétogénine non hydroxylée en position 4) et la murisoline **5** (7) (acétogénine hydroxylée en 4).

molécule de H_2O à partir de la coupure en α ou α′ du tétrahydrofurane constituent fréquemment les pics de base de ces molécules. Dans le cas des acétogénines portant une cétone en 10 (corossolone **1**, annonacinone **4**), les pics c et e sont présents, mais avec une intensité d'environ 60% par rapport aux fragments c − H_2O ou e − H_2O. En revanche, chez les acétogénines non hydroxylées en 10, telles que la murisoline **5**, on constate la présence de pics de forte intensité correspondant à la coupure entre les carbones C-15 et C-16 (pic c) et entre les carbones C-19 et C-20 (pic e). Ces observations peuvent être aussi appliquées à d'autres acétogenines mono- et bis-tétrahydrofuraniques (1–3).

Enfin, l'étude de l'activité cytotoxique de la corossoline et de la corossolone a été réalisée. La cytotoxicité de la corossoline **2** sur cellules KB ($0,3 \times 10^{-2}$ μg/mL) et sur cellules VERO (10^{-1} μg/mL) est légèrement supérieure à celle de la corossolone **1** (KB : $0,3 \times 10^{-1}$ μg/mL; VERO : 3×10^{-1} μg/mL). D'autre part, ces acétogénines sont plus actives sur la lignée cancéreuse KB que sur les cellules fibroblastiques de rein de singe (VERO).

Partie expérimentale

Pouvoirs rotatoires mesurés sur polarimètre Schmidt–Haensch, type Polartronic I. Spectres enregistrés sur les appareils suivants : UV, Unicam SP 1800; IR, Perkin–Elmer 257; RMN du ^1H et du ^{13}C, Bruker AC-200, respectivement à 200 et à 50 MHz; SM, Nermag–Sidar; SM haute résolution, Kratos MS-80.

Matériel végétal

Les graines d'*A. muricata* ont été récoltées en Guyane française, à Cayenne. Un échantillon d'herbier est conservé au Centre ORSTOM, à Cayenne, sous la référence HJ 2395.

Cytotoxicité

La cytotoxicité a été évaluée par le Laboratoire de virologie–immunologie de la Faculté de pharmacie de Châtenay-Malabry, selon le protocole standard sur cellules épithéliales humaines provenant d'un carcinome de l'épiderme buccal (KB) et sur cellules fibroblastiques de rein de singe (VERO).

Extraction et isolement

Les graines broyées (860 g) sont traitées successivement par l'éther de pétrole, le dichlorométhane et le méthanol. À partir de l'extrait à l'éther de pétrole partiellement évaporé et filtré, on obtient 2,1 g d'un précipité blanc (A). La concentration du filtrat fournit 175 g d'une huile qui est extraite plusieurs fois par le méthanol. Les extraits méthanoliques, après évaporation du solvant sous pression réduite, livrent 8,3 g d'un extrait solide (B). (A) et (B) donnent les réactions des γ-lactones α,β-insaturées (Kedde). Par chromatographie sur colonne de gel de silice 60 H de 1,5 g de (A) et élution par le mélange CH_2Cl_2/AcOEt (4 : 6), les acétogénines suivantes sont successivement obtenues : corossolone **1** (20 mg), corossoline **2** (25 mg), annonacine **3** (230 mg), annonacinone **4** (60 mg) et murisoline **5** (80 mg). Les mêmes acétogénines sont ensuite obtenues par chromatographie de (B).

Corossolone 1

$C_{35}H_{62}O_6$; F 55–57°C (acétate d'éthyle); $[\alpha]_D$ +15° (*c* 0,13;

MeOH); UV, λ_{max}, EtOH, nm (log ε) : 219 (3,58); IR, ν_{max} (film) : 3415, 2910, 2840, 1745, 1700, 1465, 1410, 1375, 1310, 1065, 1030, 955, 715 cm^{-1}; SM, IC (NH_3) : m/z 596 $(M + NH_4)^+$, voir tableau 2; RMN du ^1H et du ^{13}C : voir tableau 1.

Diacétylcorossolone ***6***

À 5 mg de corossolone **1**, dissous dans 0,1 mL de pyridine, on ajoute 0,2 mL de Ac_2O et on laisse agir 1 nuit à température ambiante. La diacétylcorossolone **6** est obtenue quantitativement. SM haute résolution, IC : m/z 663,4844 (MH^+) trouvé; 663,4835 calculé pour $C_{39}H_{67}O_8$; m/z 603,4633 $(MH - AcOH)^+$ trouvé; 603,4624 calculé pour $C_{37}H_{63}O_6$; m/z 543,4372 $(MH - 2AcOH)^+$ trouvé; 543,4413 calculé pour $C_{35}H_{59}O_4$; m/z 421,2603 (coupure C-19/C-20 : tableau 2) trouvé; 421,2589 calculé pour $C_{24}H_{37}O_6$, tableau 2; RMN du ^1H et du ^{13}C : tableau 1.

Dihydrocorossolone (= corossoline 2)

Le composé **1** (5 mg) en solution dans 1 mL de MeOH est traité par 3 mg de $NaBH_4$ à température ambiante pendant 4 h. Après traitement habituel, la dihydrocorossolone obtenue s'avère identique au produit **2** : corossoline (co-CCM, IR, RMN et SM). SM, IC (CH_4) : m/z 581 (MH^+).

Corossoline 2

$C_{35}H_{64}O_6$; F 45–50°C (acétate d'éthyle); $[\alpha]_D$ +19° (c 0,2; MeOH); UV, λ_{max}, EtOH, nm (log ε) : 212 (4,08); IR, ν_{max} (film) : 3420, 2910, 2840, 1740 cm^{-1}; SM, IC (CH_4): m/z 581 (MH^+), tableau 2; RMN du ^1H et du ^{13}C : tableau 1.

Triacétylcorossoline 7

Obtenue à partir de **2** (Ac_2O/Pyr); SM, IC (CH_4): m/z 707 (MH^+), tableau 2; RMN du ^1H et du ^{13}C : tableau 1.

Remerciements

Le présent travail a été partiellement financé par une subvention DR 8911 du Département de recherche de la Faculté de pharmacie de Châtenay-Malabry, Université de Paris-Sud.

Les auteurs expriment leur gratitude au Dr. J. Cotte-Laffite, du Laboratoire de virologie–immunologie de la Faculté de pharmacie de Châtenay-Malabry, pour l'étude de cytotoxicité réalisée sur les acétogénines d'*A. muricata*.

L'un des auteurs (S.H.M.) remercie le gouvernement français pour l'attribution d'une bourse de coopération France-Birmanie.

Received, April 17, 1990

FRANK R. FRONCZEK, RICHARD D. GANDOUR, THOMAS M. FYLES, PHILIPPA J. HOCKING, SUSAN J. MCDERMID, and P. DANIEL WOTTON. Can. J. Chem. **69**, 12 (1991).

The synthesis of crown ethers derived from *meso*-tartaric acid was investigated. The sodium salt of the bis(dimethylamide) of *meso*-tartaric acid reacted with diethylene glycol ditosylate to give a mixture of 18-crown-6 tetraamide and 27-crown-9 hexaamide crown ethers. The 2*R*,3*S*,11*S*,12*R* 18-crown-6 isomer crystallized in triclinic space group $P\bar{1}$ (a = 7.557(2), b = 8.866(2), c = 10.4133(13) Å, α = 94.13(2). β = 95.86(2), γ = 99.26(2)°, R = 0.040 for 2090 observed of 3129 unique reflections). The structures of the remaining products were then assigned from the NMR spectra. The solution conformations of the amide crown ethers were examined by NMR, and provide a rationale for the product distribution obtained. One of the 18-crown-6 isomers and a mixture of the two 27-crown-9 isomers were hydrolyzed to the respective crown ether carboxylic acids, and the stability constants for complexation of cations were determined by potentiometric titration. The *meso* tetra- and hexacarboxylates are remarkably nonselective and inefficient cation complexing agents, compared to related crown ethers from *R*,*R*-(+)-tartaric acid, due to the unfavorable conformational control exerted by the tartaro units.

Key words: crown ether synthesis, complexation, crown ether conformation, *meso*-tartaric acid, crystal structure.

FRANK R. FRONCZEK, RICHARD D. GANDOUR, THOMAS M. FYLES, PHILIPPA J. HOCKING, SUSAN J. MCDERMID et P. DANIEL WOTTON. Can. J. Chem. **69**, 12 (1991).

On a réalisé des synthèses d'éthers couronnes dérivés de l'acide *méso*-tartrique. On a fait réagir le sel de sodium du bis-diméthylamide de l'acide *méso*-tartrique avec le ditosylate du diéthylèneglycol et on a obtenu un mélange des éthers 18-couronne-6 tétramide et 27-courone-9 hexamide. L'isomère 2*R*,3*S*,11*S*,12*R* de l'éther 18-couronne-6 cristallise dans le groupe d'espace $P\bar{1}$ (a = 7,557(2), b = 8,866(2) et c = 10,4133(13) Å, α = 94,13(2), β = 95,86(2) et γ = 99,26(2)°; R = 0,040 pour 2090 observées à partir de 3129 réflexions uniques). On a attribué les autres structures sur la base de leurs spectres RMN. En se basant sur la RMN, on a examiné les conformations en solution de l'amide des éthers couronnes et on a ainsi obtenu une explication pour la distribution des produits. On a hydrolysé un des isomères de l'éther 18-couronne-6 ainsi qu'un mélange de deux isomères de l'éther 27-couronne-9 et on a ainsi obtenu les acides correspondants; faisant appel à un titrage potentiométrique, on a déterminé leurs constantes de stabilité pour la complexation de cations. Comparés aux composés correspondants issus de l'acide *R*,*R*-(+)-tartrique, les tétra- et hexa-carboxylates *méso* sont des agents complexants de cations remarquablement inefficaces et non-sélectifs; cet propriété est le résultat d'un contrôle conformationnel non favorable exercé par les unités tartriques.

Mot clés: synthèse d'éthers couronnes, complexation, conformation d'éthers couronnes, acide *méso*-tartrique, structure cristalline.

[Traduit par la Rédaction]

Conformational control of ligand structure is a well-established strategy of ligand design (1, 2), and typically involves the incorporation of a conformationally well-behaved sub-unit into the ligand structure. Nowhere is this more evident than in the numerous macrocycles derived from *R*,*R*-(+)-tartaric acid (3–16). The tartaric acid units exhibit a strong preference for an *anti* disposition, resulting in well-defined conformations in solution (4, 6–8, 13) and in the solid state (17–19). This offers control over lateral interactions from the side arms derived from the carboxylic acid groups (4, 6, 20), results in partial rigidification of flexible ligands (7, 8, 15, 20), and places charged carboxylates in close proximity to bound cations thereby enhancing complex stability (6, 15).

The solution conformation of the parent *R*,*R*-(+)-tartaric acid (21) has *anti* carboxylates. In contrast, the conformation of the *meso* isomer is *gauche* between the carboxylates, observed as an equilibrium mixture of two equivalent *gauche* isomers (21). We expected that a crown ether derived from *meso*-tartaric acid would be capable of a similar conformational equilibrium, and would offer an alternative architecture for manipulation of substituents. We had previously prepared a crown ether diacid derived from *meso*-tartaric acid as a reference compound for comparison with the *R*,*R*-(+)-18-crown-6 diacid (15). The *meso*-diacid crown ether was an ineffective cation-complexing agent; we naively ascribed this to an unfavorable entropy component of the complexation (15).

To more fully explore the complexation chemistry of the *meso* series, we set out to prepare the *meso* 18-crown-6 tetracarboxylic acid incorporating two equivalents of tartaric acid. Unlike the *R*,*R* case, where a single isomer is formed, the *meso* series produces two isomers; a C_{2v} isomer (**3**, Fig. 1), and a C_{2h} isomer (**4**). This report examines the synthesis of the *meso* 18-crown-6 tetraacids, obtained as a mixture with 27-crown-9 hexaacids, and the conformational and complexation properties of all these materials. The study provides further insight into the role of conformational control as a factor in both macrocycle synthesis and complex formation.

Results and discussion

Synthesis

Following the synthetic approach used in the *R*,*R* series (3, 11), the sodium salt of the bis(dimethylamide) of *meso*-tartaric

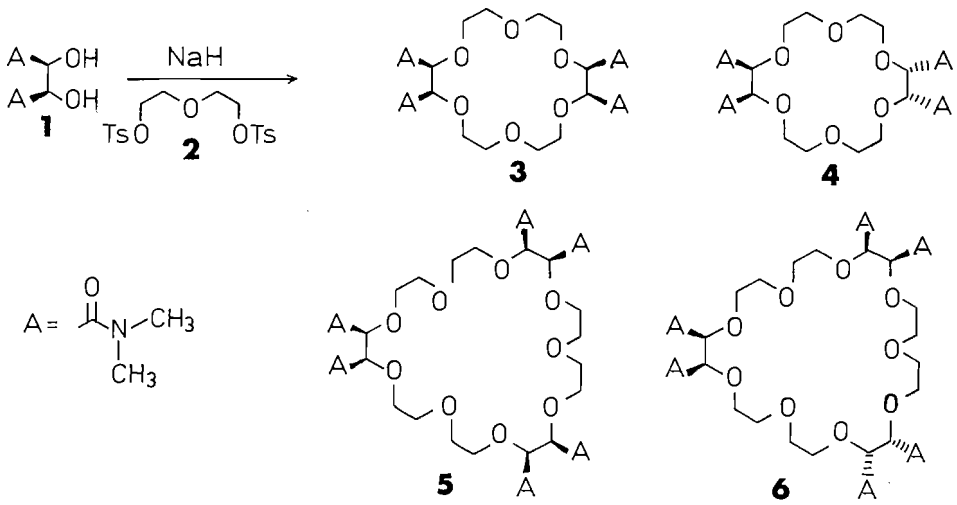

FIG. 1. Synthesis of crown ether amides from *meso* tartaramide.

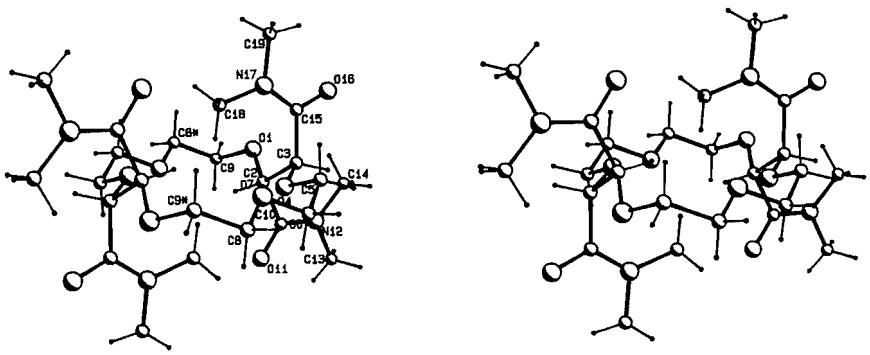

FIG. 2. Stereoscopic view of the solid state structure of **4** showing atom numbering.

acid (**1**) in DMF was treated with an equivalent amount of the ditosylate of diethylene glycol (**2**, Fig. 1). The resulting mixture of oily products was subjected to column chromatography and the fractions were examined by ^{1}H and ^{13}C NMR. Ultimately we were able to recognize four crown ether components. The first could be isolated by acetone trituration of partly purified fractions. Crystals suitable for X-ray structure determination were obtained; Fig. 2 illustrates the structure and identifies the C_{2h} isomer **4**. A second compound mixed with **4** in some fractions was shown to be an isomer by MS and elemental analysis, thus must be the C_{2v} isomer **3**. Other fractions contained a mixture of a compound characterized by a single methine peak in the ^{13}C NMR (78.4 ppm.) and a compound with three methine peaks in the ^{13}C NMR (77.1, 77.5, and 77.8 ppm). Careful gel permeation chromatography of fractions enriched in the "1 methine" product allowed a purified sample to be characterized. It too was an isomer by elemental analysis, but showed a molecular ion in the mass spectrum corresponding to the next higher oligomer, 27-crown-9. From the symmetry implied by the ^{13}C NMR spectrum, this material must be the threefold symmetric isomer **5**. An approximately 1:1 mixture of the "3 methine" material and **5** gave the elemental analysis expected of an isomer and the same mixture gave a mass spectrum identical to **5** alone. On this basis we identified the 3 methine isomer with **6**.

The yields of **3**–**6** are modest. From an initial charge of 40 mmol of **1**, the yields of **3**–**6** are 0.13, 0.45, 0.43, and 0.46 mmol respectively. These correspond to yields of 0.7, 2.2, 3.2, and 3.4% based on the theoretical formation of either 20 mmol of 18-crown-6 or 13.3 mmol of 27-crown-9 derivatives. The total yield of crown ether products is thus 9.5%, compared with yields of 16 (11) and 19% (3) of the single isomer in the *R*,*R* series. Minor amounts of the *R*,*R* series 27-crown-9 derivative can be isolated from the reaction mixture, but these amount to "less than 1% yield" (6). There are thus some key differences between the *R*,*R* and *meso* series: the latter give lower overall yield of crown ethers of any type, but a substantially higher yield of the higher oligomer.

To complete the synthesis, purified **4** and a 1:1 mixture of **5** and **6** were separately hydrolyzed in aqueous acid to give the 2*R*,3*S*,11*S*,12*R*-tetraacid (RSSR18C6A$_4$) and mixed hexaacids m27C9A$_6$ (Fig. 3). Both products gave the expected elemental analysis and equivalent weight by potentiometric titration. Surprisingly, RSSR18C6A$_4$ is relatively insoluble in water: a saturated solution is only 5×10^{-3} M. This is in contrast to the *R*,*R* isomer, which is at least 100-fold more soluble.

Complexation of cations

Complex formation in solution can be described in terms of a cumulative formation constant β_{lmh} defined by the equilibrium between l ligands of charge $-z$, m cations of charge $+y$, and h protons (eq. [1]:

$$[1]\quad lL^{-z} + mM^{+y} + hH^{+} \rightleftharpoons L^{-z}{}_l M^{+y}{}_m H^{+}{}_h$$

$$[2]\quad \beta_{lmh} = \frac{[L^{-z}{}_l M^{+y}{}_m H^{+}{}_h]}{[L^{-z}]^l [M^{+y}]^m [H^{+}]^h}$$

The cumulative formation constants are defined in terms of concentrations. We use corrections for calibration of the pH meter in terms of hydrogen ion concentration (22–26) to give

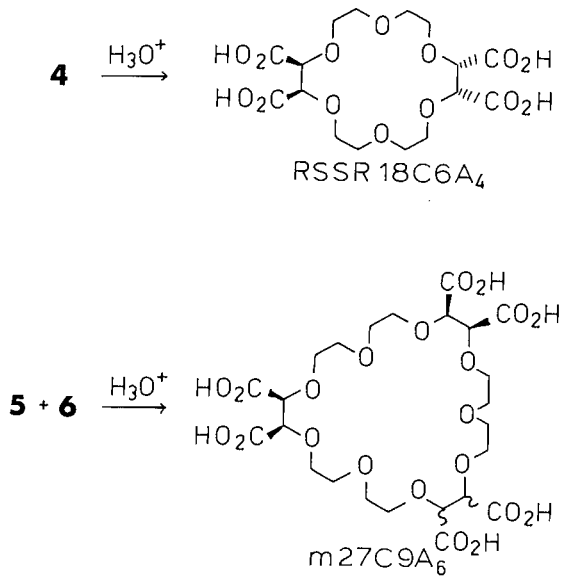

FIG. 3. Synthesis of crown ether polycarboxylic acids.

β_{lmh} values (27) that can be converted to thermodynamic constants through activity coefficient corrections (28, 29).

The acidity and formation constants for complexation of cations by the ligands derived from *meso*-tartaric acid were determined by potentiometric titration (15, 27, 30) (Table 1). These values may be compared with previously determined values for RRRR18C6A$_4$ (15), supplemented by a few new results, also given in Table 1. A cursory inspection of the data shows that the *meso* tetraacid is an inferior cation complexing agent compared to the *R,R* derivative. The differences range from a factor of about 20 for the Na^+ and K^+ to factors of 20–100 000 for the Ca^{2+} and Cd^{2+} complexes. In contrast, the Li^+ and Cs^+ complexes of the *meso* tetraacid are both *more* stable than the corresponding complexes of the *R,R* isomer. The Li^+ complex is 50-fold more stable for the *meso* ligand. The extent of the enhancement is not clear for the Cs^+ complex, because the formation constant could not be determined for the *R,R* derivative.

There are also clear selectivity differences between the two series. Among the univalent cations, the *R,R* derivative favors the larger cations Tl^+ and K^+ and exhibits an 18-crown-6 selectivity modified by a strong electrostatic component (15). The "crown ether" selectivity is absent in the *meso* case. Indeed, K^+ is the most weakly bound of the monovalent ions. As well, the alkaline earth selectivity is reversed between the two series. Even more dramatic is the reversal of the Zn^{2+}/Cd^{2+} selectivity, which involves relatively little difference in the values for zinc, coupled to drastic destabilization of the cadmium complex in the *meso* case.

In contrast, the *meso* 27-crown-9 mixture of isomers offers relatively few surprises. The mixture is relatively unselective apart from a divalent/monovalent selectivity expected from electrostatic considerations. The 27-crown-9 isomer from the *R,R* series binds K^+ with a formation constant of $\log \beta_{110} = 4.0$ (6); thus it appears that the *meso* isomers are less effective cation complexing agents at this ring size as well. A trend favoring larger cations can be discerned, but the selectivities are modest. We rationalize the complexation results in terms of the different macrocycle conformations in the two series; a detailed discussion follows.

Conformational analysis: solid state

An analysis of the conformational differences between the *meso* and *R,R* series explains the complexation and synthetic results. Numerous studies confirm that crown ethers from *R,R*-(+)-tartaric acid adopt a conformation with the carboxylate-derived groups in axial positions on the macrocycle, both in the solid state (17–19) and in solution (4, 6–8, 13). This conformational preference results from preference for an *anti* torsion angle between the carboxylates of the parent tartaric acid (21).

The solid state structure of **4** (Fig. 2) illustrates this conformational bias in the *meso* series. The carboxamide groups are *anticlinal* (C10—C2—C3—C15 torsion angle = 145.8(2)°), as are the tartaro oxygens (O1—C2—C3—O4 torsion angle = 147.1(2)°). The methine hydrogen on C2 points into the cavity, and the oxygen O1 lone pairs out from the macrocycle (Fig. 2). A convergent six-oxygen binding site can only be formed by rotation about both O1—C2 units. The other structural features are typical of crown ethers; the crown C—O bond lengths vary little (1.426 ± 0.005 Å), the C—C bond lengths of the ethylene units are relatively short (1.494 (2) and 1.501 (2) Å), and the average C—O—C bond angle (112.4 ± 1.0°) is somewhat larger than the average C—C—O bond angle (109.5 ± 2.8°) (31).

The observed centrosymmetric conformation is not identical to the "C_i" conformation adopted by uncomplexed 18-crown-6 (32). Polar maps of the torsion angles (Fig. 4)[2] compare the solid-state structures of **4** and 18-crown-6. The major differences are the two torsion angles involving CH_i—O—C—C, where CH_i refers to the carbons with a hydrogen pointing into the cavity. These torsion angles in **4** (C2—O1—C9—C8', 88.8(2)°) and in 18-crown-6 (C9'—O1—C2—C3, −79.7°) differ only in the sign of the torsion angle. Otherwise the remaining 16 torsion angles differ by less than 27.5°. A recently reported structure of a complex of 18-crown-6 with succinic acid (35) has a polar map similar to **4** (Fig. 4). Again the principal differences are a single pair of torsion angles, which in this case involves the rotation about O—CH_i—C—O. The torsion angles are *anticlinal* in **4** (O1—C2—C3—O4, 147.1(2)°) and *gauche* in the succinic acid complex (O8—C9—C12—O11, 73.6(2)° (ref. 35)). From a frequency analysis, Parenteau and Brisse (35) show the torsion angle in the complex (C6—C7—O8—C9, 90.1(2)°) differs "significantly from that normally found" in 18-crown-6-complexes. In **4**, this angle corresponds to the C8'—C9—O1—C2 (88.8(2)°). In addition, the 16 similar torsion angles differ by less than 15.8°.

Conformational analysis: solution

The solid state conformation of **4** prompted us to investigate

[2]Polar maps offer a means to recognize similarity of torsion angles between dissimilar structures (33, 34).[3,4] For an 18-membered ring, the endocyclic torsion angle of each bond is plotted on polar coordinates as the vertices of an octadecagon. A positive torsion angle is plotted from the center of the circular map (0° plus the torsion angle) and a negative torsion angle is plotted from the outer edge (360° minus the torsion angle). In the first instance, the bonds are numbered starting from the O—C bond adjacent to a tartaro unit following the nomenclature convention, thus there are four possible starting points for **4**; the other possible maps of the conformations can be generated by rotation, reflection, and rotation/reflection.[4]

[d]Precipitation of the ligand precludes titration.

the solution conformations of these crown ethers, by measuring the $^1H-^1H$ coupling constants for the tartaro units. The two hydrogens are equivalent, but the ^{13}C satellites on either side of the resonance arise from an AA'X spin system, from which we can measure $^3J_{HH}$. A similar study of the *R,R* series has been reported (4). The amides **3**, **4**, and **5** give values of $^3J_{HH}$ of 5.0, 5.8, and 7.4 (±0.1) Hz respectively. Using either a single Karplus equation or one extended to correct for the electronegativity of the substituents (8, 36) gives an estimated value of $^3J_{HH}$ of 8.3 Hz for the *anticlinal* conformation in the solid state. The equations predict a value of 2 Hz for the *gauche* conformation. Neither of these limiting cases is the exclusive conformation, and the data compel a significant population of conformations having an *anti* or *anticlinal* relationship between the carboxamides in solution. This conclusion provides a rationalization of the synthetic results and an understanding of the complexation differences between the *meso* and *R,R* series of crown ethers.

Ring closure

From the synthetic perspective, the critical feature is the conformation of the acyclic precursor immediately preceding ring closure to the 18-crown-6 ring size. In the *R,R* isomers, an *anti* disposition of carboxamides places the adjacent oxygens *gauche*, as found in the final product and which facilitates ring

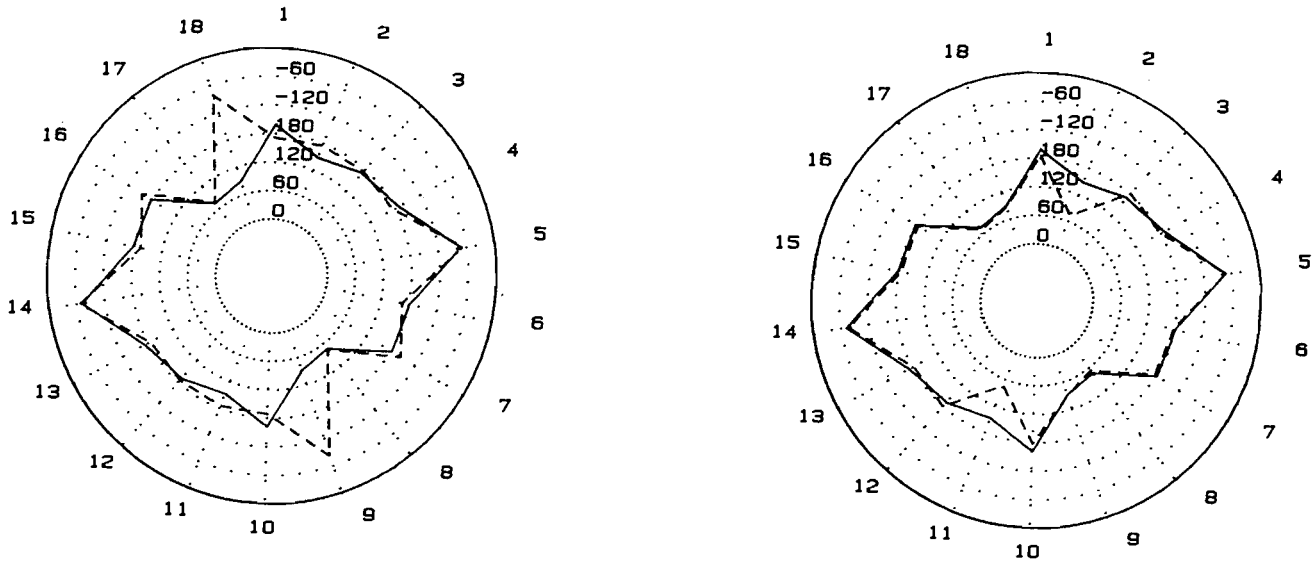

FIG. 4. Polar maps of endocyclic torsion angles. Left: overlap of **4** (—) and 18-crown-6 (32) (---); Right: overlap of **4** (—) and 18-crown-6·succinnic acid complex (35) (---).

closure. If the *meso* acyclic precursor adopts a similar *anticlinal* disposition of carboxamides, the oxygens are also *anti* to one another. This retards ring closure to the 18-crown-6 macrocycle, and prolongs the precursor lifetime in solution. This enhances intermolecular oligomerization and leads to larger ring sizes. It is sufficient to postulate a conformational bias toward an *anti* disposition of oxygens that would be less prone to closure of any ring size. Similar conformational effects on macrocyclization yield are known, notably in the opposite case of enhanced yields of benzo crown ethers relative to unsubstituted crown ethers (37). Precursor lifetime clearly plays a role in determining the ultimate ring size distribution in unsubstituted crown ethers (38); our case is a conformationally biased version of the same process.

Cation complexation

Given a conformational bias in the amides, the carboxylic acids should lie even further towards an *anti* disposition of carboxylates due to electrostatic and dipole effects. A conformation akin to the solid state structure of the precursor amide is thus likely for the tetraacid RSSR-18C6A$_4$ in aqueous solution. Such a conformation offers two scenarios for cation complexation. In cases of favorable cation size or charge, the ligand could act as a simple chelate without reorganization. This might be occurring in the Li^+, Mg^{2+} (high surface charge density), and Cs^+ (large ionic radius) complexes of RSSR-18C6A$_4$, all of which are more stable than their *R,R* counterparts. Conversely, reorganization could accompany cation binding to produce complexes similar to those of the *R,R* series. The energy costs of the reorganization would be exhibited as a smaller stability constant for cation complexation. This scenario is apparently more likely and predicts the general observation of lower stability constant in the *meso* series. The reorganization energy cost and the ultimate stability constant in the 27-crown-9 ring size are both smaller, hence the differences are less pronounced.

The picture that emerges of either *meso* or chiral tartaric acid crown ethers is one of controlled conformations dominated by the influence of the tartaro units. In the *R,R* series, the favored *gauche* conformation of the two oxygens enhances both the synthesis and the cation complexation. In the *meso* series, the favored *anticlinal* conformation diminishes both the synthetic efficiency and the cation complexation.

Experimental

General details

Melting points were taken on a Reichardt hot stage microscope (uncorrected). Proton NMR spectra were recorded with a Perkin–Elmer R32 (90 MHz, CW) or Bruker WM 250 (250 MHZ, FT) spectrometer in $CDCl_3$ or CD_3OD solvent with Me_4Si as internal standard or in D_2O with external Me_4Si in $CDCl_3$ as reference. Carbon NMR spectra were recorded at 62.8 MHz (WM 250) in $CDCl_3$ or CD_2Cl_2 with the central solvent line as standard, or in D_2O with a frequency reference for this solvent previously calibrated against external Me_4Si in $CDCl_3$. Simulation of the second order AA'X spectra for determination of $^3J_{HH}$ was done using a locally constructed package[5] based on UEAITR (39) and NMRPLOT (39). The mass spectra were recorded with a Finnegan 3300 GC–MS instrument with methane chemical ionization. Elemental analyses were performed by Canadian Microanalytical Services, New Westminster, B.C., and are quoted in percentages.

Dimethylformamide was dried over freshly activated 4 Å molecular sieves and dichloromethane was distilled prior to use; other chemicals were used as received. Diethylene glycol ditosylate (**2**) (40) and *meso-N,N,N'N'*-tetramethyltartaramide (**1**) (15) were prepared as previously reported.

2R,3S,11S,12R-N,N,N',N',N'',N'',N''',N'''-Octamethyl-1,4,7,10,13,16-hexaoxacyclooctadecane-2,3,11,12-tetracarboxamide (4)

A 1-L three-necked flask was purged with nitrogen and charged with 3.20 g of NaH (60% in oil, 80 mmol). The solid was washed with four 20-mL portions of pentane, suspended in 100 mL of dry DMF, and a slurry of 8.28 g of **1** (40 mmol) was added in 250 mL of dry DMF. The mixture was allowed to stir at ambient temperature overnight to produce a clear solution, to which 16.64 g of **2** (40 mmol) in 100 mL of dry DMF was added. The mixture was heated to 70°C for 7 h, the DMF was removed under reduced pressure at 40°C, and the resultant off-white solid was evacuated overnight. The solid was slurried in dichloromethane, filtered through Celite, and the filtrate was evaporated to an oil. The oil was dissolved in water (250 mL) and successively extracted with two 250-mL portions each of pentane, ether, dichloromethane, and chloroform. The aqueous layer was further extracted in a

continuous liquid/liquid extractor with dichloromethane for 24 h. The combined chlorocarbon extracts were dried over $MgSO_4$, evaporated to an oil, and evacuated for several hours to yield 5.8 g of crude product. Addition of acetone (75 mL) and filtration gave white crystals, which were recrystallized from acetone to give 0.13 g of **4**. The acetone filtrate and mother liquors were combined and evaporated to give 5.5 g of an oil used for the isolation of more **4**, plus **5** and **6** by chromatography as outlined below.

The configuration of **4** was established by X-ray crystallography (below). The total yield of **4** in this preparation, including the material isolated by chromatography (see below), was 0.25 g (2.4%): mp 198°C, ^{1}H NMR (δ, $CDCl_3$): 2.98 and 3.24 (2s, 24H, N $(CH_3)_2$), 3.56 (m, 24H, OCH_2), 4.80 (s, 4H, OCH); ^{13}C NMR (δ, CD_2Cl_2): 36.2 and 37.3 (N $(CH_3)_2$), 69.2 and 71.3 (OCH_2), 80.6 (OCH), 169.2 (CO); MS (*m/z*): 549 (M + 1), 503 (−Me_2NH), 472 (−DMF). Anal. calcd. for $(C_{12}H_{22}N_2O_5)_n$: C 52.56, H 8.08, N 10.21; found: C 52.51, H 8.17, N 10.19.

2R,3S,11R,12S,20R,21S-N,N,N′,N′,N″,N″,N‴,N‴,N⁗,N⁗,N⁗⁗,N⁗⁗-Dodecamethyl-1,4,7,10,13,16,19,22,25-nonaoxacycloheptacosane-2,3,11,12,20,21-hexacarboxamide (5) and 2R,3S,11R,12S,20S,21R-N,N,N′,N′,N″,N″,N‴,N‴,N⁗,N⁗,N⁗⁗,N⁗⁗-dodecamethyl-1,4,7,10,13,16,19,22,25-nonaoxacycloheptacosane-2,3,11,12,20,21-hexacarboxamide (6)

The acetone filtrate from the preparation of **4** (5.5 g) was adsorbed on 28 g of neutral alumina, which was added to a column of neutral alumina (3.5 × 35 cm, 245 g) and eluted with a CH_2Cl_2/MeOH solvent gradient (0, 0.25%, 0.5%, 1.0%, 5.0% MeOH, 1 L each, 500-mL fractions). The fractions eluting with 1% MeOH contained 1.17 g of mixed crown ethers **3**–**6**. Trituration of the oily mixture with acetone yielded solid **4** with **3** as a minor contaminant (see below for isolation of **3**).

The acetone soluble materials were dissolved in a minimum volume of 0.5% MeOH in CH_2Cl_2 and chromatographed on neutral alumina (2.5 × 30 cm, 150 g) using a CH_2Cl_2/MeOH solvent gradient (800 mL 0.5%, 800 mL 0.75%, 1.5 L 1.0% MeOH in CH_2Cl_2). The first 200 mL of the 0.75% MeOH fraction contained **3** mixed with small amounts of **5** and **6** (86 mg). The remaining 600 mL of the 0.75% MeOH fraction and the first 1 L of the 1% MeOH fraction contained **5** and **6** as a mixture (0.68 g). From NMR, the yields of **5** and **6** are 3.2 and 3.4% respectively. The final 500 mL of the 1% MeOH fraction contained **5** and **6** together with additional components not included in the yield calculation.

A small sample of purified **5** was obtained by gel filtration of the 86 mg fraction mixture of **3**, **5**, and **6** on Sephadex LH20 using 4:3 CH_2Cl_2/MeOH as eluent. The first fraction running at the void volume (8.8 mg) was "pure" **5** by NMR analysis; the remaining fractions were mixed, but could be used for the isolation of **3** (below). A further amount of **5** was obtained by gel filtration of the final 1% MeOH fraction. In total, 65 mg of **5** was isolated from various fractions by this tedious gel filtration process, which permitted characterization and $^3J_{HH}$ coupling constants to be determined.

5: clear oil; ^{1}H NMR (δ, $CDCl_3$): 2.95 and 3.11 (2s, 36H, $N(CH_3)_2$), 3.48 (m, 36H, OCH_2), 4.60 (s, 6H, OCH); ^{13}C NMR (δ, CD_2Cl_2): 36.3 and 37.5 ($N(CH_3)_2$), 69.9 and 71.1 (OCH_2), 78.4 (OCH), 169.8 (CO); MS (*m/z*): 823 (M + 1), 777 (−Me_2NH), 749 (−DMF). Anal. calcd. for $(C_{12}H_{22}N_2O_5)_n$: C 52.56, H 8.08, N 10.21; found: C 52.61, H 8.10, N 10.25.

6: obtained only as a mixture with **5**; clear oil; ^{1}H NMR (δ, $CDCl_3$): 2.95 and 3.11 (2s, 36H, $N(CH_3)_2$), 3.48 (m, 36H, OCH_2), 4.62 (br s, 6H, OCH); ^{13}C NMR (δ, CD_2Cl_2): 36–38 (6 lines, $N(CH_3)_2$), 69–71 (m, OCH_2), 77.1, 77.5, and 77.8 (OCH), 170.2 (br, CO); MS (*m/z*) mixture (1:1) with **5**: 823 (M + 1), 777 (−Me_2NH), 749 (−DMF). Mixture (1:1) with **5**, Anal. calcd. for $(C_{12}H_{22}N_2O_5)_n$: C 52.56, H 8.08, N 10.21; found: C 52.56, H 8.27, N 10.22.

2R,3S,11R,12S-N,N,N′,N′,N″,N″,N‴,N‴-Octamethyl-1,4,7,10,13,16-hexaoxacyclooctadecane-2,3,11,12-tetracarboxamide (3)

The mixed fractions from the gel filtration of **3**, **5**, and **6** could be used as a source of pure **3**. Thus an 80 mg fraction, free of **4**, was chromatographed on neutral alumina using 0.75% MeOH in CH_2Cl_2 as eluent (isocratic). A total of 72 mg of **3** was isolated from the early fractions. Yield 0.7%; ^{1}H NMR (δ, $CDCl_3$): 2.97 and 3.22 (2s, 24H, $N(CH_3)_2$), 3.64 (m, 24H, OCH_2), 4.64 (s, 4H, OCH); ^{13}C NMR (δ, CD_2Cl_2): 36.2 and 37.3 ($N(CH_3)_2$), 69.1 and 71.3 (CH_2), 81.0 (OCH), 168.9 (CO); MS (*m/z*): 549 (M + 1), 503 (−Me_2NH), 472 (−DMF). Mixture (1:1) with **4**, Anal. calcd. for $(C_{12}H_{22}N_2O_5)_n$: C 52.56, H 8.08, N 10.21; found: C 52.50, H 8.09, N 10.18.

2R,3S,11R,12S-1,4,7,10,13,16-Hexaoxacyclooctadecane-2,3,11,12-tetracarboxylic acid (RSSR18C6A4)

The tetraamide **4** (0.19 g, 0.35 mmol) was dissolved in 2.5 M HCl (30 mL) and heated at 80°C for 24 h to produce a suspension of a white solid. Removal of the solvent at reduced pressure and evacuation to remove the bulk of the HCl gave a white solid, which was suspended in 20 mL of water and recovered by filtration to yield 120 mg of RSSR18C6A$_4$ (0.25 mmol, 72% yield); ^{1}H NMR (δ, CD_3OD): 3.72 (m, 16H, OCH_2), 4.48 and 4.53 (2s, 4H, OCH); ^{13}C NMR ((δ, CD_3OD): 71.4 and 71.9 (OCH_2), 81.3 (br, OCH), 172.6 (CO). Anal. calcd. for $C_{16}H_{24}O_{14}\cdot 2H_2O$: C 40.34, H 5.93; found: C 40.52, H 5.83. Equivalent weight calcd. for RSSR18C6A$_4\cdot 2H_2O$: 119 g/equiv.; found: 117.9 g/equiv.

Mixture of 2R,3S,11R,12S,20R,21S- and 2R,3S,11R,12S,20S,21R- 1,4,7,10,13,16,19,22,25-nonaoxacyclohepacosane-2,3,11,12,20,21-hexacarboxylic acids (m27C9A6)

A mixture of **5** and **6** (1:1, 0.21 g, 0.25 mmol) was dissolved in 2.5 M HCl (30 mL) and heated at 80°C overnight. The solvent was removed by evaporation at reduced pressure and the bulk of the excess HCl was removed by evacuation to give an oily solid. The solid was dissolved in water (50 mL) and passed down an acidic ion exchange column (Dowex 50W, 250 g). The resin was washed with water and the eluent fractions with pH <3 were combined, evaporated, and evacuated overnight to yield 0.14 g of m27C9A$_6$ (0.20 mmol, 80% yield): ^{1}H NMR (δ, D_2O): 3.5 (m, 28H, CH_2O), 4.4 (m, 6H, OCH); ^{13}C NMR (δ, D_2O): 69.7–70.7 (OCH_2), 79.9 (br, OCH), 172.6 (CO). Anal calcd. for $C_{24}H_{36}O_{21}\cdot 3H_2O$: C 40.34, H 5.93; found: C 40.21, H 5.91. Equivalent weight calcd. for m27C9A$_6\cdot 3H_2O$: 119 g/equiv.; found: 118.1 g/equiv.

Stability constant determinations

Solutions of acid (0.05 M HNO_3) and base (0.05 M tetramethylammonium hydroxide (TMAOH)) were prepared and standardized against primary standards. A constant ionic strength was maintained (0.1 M) by the addition of tetramethylammonium nitrate (TMAN) to both the standard acid and base, as well as by using a 0.1 M TMAN medium for titrations. Standard metal ion solutions (0.05 M) were made from the corresponding nitrates. All reagents were analytical grade or better and were dried before use. The equivalent weight was determined from the average of several titrations and was used to establish ligand homogeneity and purity before the stability constant determinations.

The general procedures and apparatus have been described previously (5, 8, 27). The electrode system was calibrated using commercially available buffers at pH 2.00 and pH 9.18 and linearity was confirmed at pH 6.86 and 4.01. For pK_a determinations, a 4 mL solution of the ligand (approx. 4×10^{-4} M) in 0.1 M TMAN was titrated with standard Me_4NOH containing 0.1 M TMAN to beyond the strong acid – strong base end point (60 μL per ligand equivalent with 0.05 M base) in 2–4 μL aliquots (min. 18 points per ligand equivalent). The data file was processed using SCOGS (30) to yield β_{l0h} for the ligand.

For stability constant determinations, two procedures were used. One followed the procedure for pK_a determination directly, with the addition of an equivalent of metal nitrate solution to the free acid before titration with the base. The other used the solution resulting from the pK_a titration by addition of an equivalent of metal nitrate to the basic solution. This mixture was then back-titrated with standardized 0.05 M HNO_3 (containing 0.1 M TMAN) to the starting acidic pH. The second method, however, is inappropriate for metals that form insoluble

hydroxo complexes. Formation constants of the hydroxo complexes for the relevant metal ions were chosen from the literature (41): log β [species]: 0.7 [$CaOH^+$, $SrOH^+$, $BaOH^+$]; 4.3 [$NiOH^+$]; 5.7 [$CuOH^+$]; 13.1 [$Cu(OH)_2$]; 16.9 [$Cu_2(OH)_2^{2+}$]; 33.7 [$Cu_3(OH)_4^{2+}$]; 4.7 [$ZnOH^+$]; 9.86 [$Zn(OH)_2$]; 5.7 [$Zn(OH)_3^-$]; 3.8 [$CdOH^+$]; 6.9 [$PbOH^+$]; 10.8 [$Pb(OH)_2$]; 13.3 [$Pb(OH)_3^-$]. The reliability of the values, assessed from reproducibility between duplicate solution preparations from salts, is ±0.1 in pK_a and ±0.2 in log β.

Crystal structure determination

Intensity data were collected by ω–2θ scans of variable rate designed to yield measurements with $I = 50\sigma(I)$ for all significant reflections, using an Enraf–Nonius CAD4 diffractometer equipped with Mo Kα radiation (λ = 0.71073 Å) and a graphite monochromator. Unit-cell dimensions and crystal orientation were determined by a least-squares fit to the setting angles of 25 reflections having 20° < 2θ < 24°. A maximum of 120 s was placed on the scan time spent on any reflection; scan rates varied from 0.61 to 4.0 deg min^{-1}. One hemisphere of data ($h \pm k \pm l$) having 2° < 2θ < 55°, $0 \leq h \leq 9$, $-11 \leq k \leq 11$, $-13 \leq l \leq 13$, was collected. Crystal data are given in Table 2. Data reduction included corrections for background, Lorentz, polarization, and a 4.5% linear intensity decay correction. A total of 3129 unique data was collected, of which 2090 had $I > 3\sigma(I)$ and were used in the refinements. $Z = 1$ in space group $P\bar{1}$ requires that the molecule be centrosymmetric. The structure was solved by direct methods and refined by full-matrix least squares minimizing $\Sigma w (|F_o| - |F_c|)^2$ with weights $w = \sigma^{-2}(F_o)$ using the scattering factors of Cromer and Waber (42) and the Enraf–Nonius SPD programs. Non-hydrogen atoms were refined anisotropically, and hydrogen atoms were located on difference maps and refined isotropically. Thermal parameters for three hydrogen atoms tended to refine to slightly negative values and thus were fixed. The refinement converged with maximum of 0.21 σR = 0.40, R_w = 0.044, S = 2.063, and residual densities of 0.25 and −0.17 e Å^{-3}. Definitions are $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w(F_o)^2)^{1/2}$; $S = (\Sigma w(|F_o| - |F_c|)^2/(NO - NV))^{1/2}$, where NO = 2090 observations and NV = 257 variables. Table 3 gives the atomic positional parameters and Table 4 gives the torsion angles of non-hydrogen atoms.[6]

Received February 19, 1990[3]

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

DAVID L. BURGOYNE, SHICHANG MIAO, CHARLES PATHIRANA, RAYMOND J. ANDERSEN, WILLIAM A. AYER, PETER P. SINGER, WILLIAM C. M. C. KOKKE, and DONALD M. ROSS. Can. J. Chem. **69**, 20 (1991).

The structure of imbricatine (**1**), a cytotoxic metabolite of the starfish *Dermasterias imbricata*, has been determined by spectroscopic analysis and chemical degradation. Synthesis of model compounds **7** and **18** provided evidence for the absolute configuration and constitution of the benzyltetrahydroisoquinoline substructure of imbricatine.

Key words: imbricatine, asteroid, alkaloid.

DAVID L. BURGOYNE, SHICHANG MIAO, CHARLES PATHIRANA, RAYMOND J. ANDERSEN, WILLIAM A. AYER, PETER P. SINGER, WILLIAM C. M. C. KOKKE et DONALD M. ROSS. Can. J. Chem. **69**, 20 (1991).

Faisant appel à des analyses spectroscopiques et à une dégradation chimique, on a déterminé la structure de l'imbricatine (**1**), un métabolite cytotoxique de l'étoile de mer *Dermasterias imbricata*. La synthèse des composés modèles **7** et **18** fournit une preuve de la configuration absolue et de la constitution de la sous-structure benzyltétrahydroisoquinoléine de l'imbricatine.

Mots clés : imbricatine, astéroïde, alcaloïde.

[Traduit par la revue]

Many marine invertebrates exhibit escape responses to chemicals released by their predators. One of the best known examples is the detachment and swimming behavior of the sea anemones *Stomphia coccinea* and *S. didemon* in reaction to contact with certain species of marine asteroids (1, 2). Sea anemones are sessile animals that normally respond to tactile stimulation by contracting and covering their oral disc with a portion of their body column. However, *S. coccinea* and *S. didemon* respond to contact with the starfish *Dermasterias imbricata* in a "striking and extraordinary manner: the anemones release their basal discs from the substratum, and then propel themselves through the water by means of a series of whiplike motions" (2). A number of years ago it was shown that a single metabolite of *D. imbricata* was responsible for eliciting the "swimming response" in *S. coccinea* and *S. didemon* (1–4). Subsequently, we reported the constitution and partial stereochemistry of imbricatine (**1**), the *D. imbricata* metabolite responsible for eliciting the unusual anemone "swimming" behavior (5–7). We now wish to report additional details of the structure elucidation of imbricatine (**1**), including the determination of its absolute configuration and confirmation of the nature of the benzyltetrahydroisoquinoline substructure by synthesis.

Specimens of *Dermasterias imbricata* were collected by hand using SCUBA (−5 to −20 m) in Howe Sound and Barkley Sound, British Columbia. Freshly collected animals were immediately immersed in methanol and allowed to soak at room temperature for 3 days. The methanol was decanted and filtered through Celite to give a crude extract that was capable of eliciting the swimming response in specimens of *S. coccinea* maintained for bioassay purposes in a running seawater aquarium (4, 6, 7). Concentration of the crude methanol extracts *in vacuo* gave an aqueous slurry that was diluted with three equivalent volumes of water and then passed over XAD-4 resin. Elution of the retained substances from the XAD-4 resin with hot methanol gave an active eluate that was further fractionated on a Biogel-P2 column (eluent: H_2O/HOAc 99:1). All of the fractions from the Biogel-P2 chromatography that showed a uv λ_{max} at both 283 and 292 nm and elicited anemone swimming were pooled and further purified by Sephadex LH-20 chromatography (eluent: MeOH/H_2O 8:2) to give pure imbricatine (**1**) (6–7 mg/starfish) as a water soluble white solid. As little as 50 nanograms (50 μL of a 2×10^{-6} M solution) of pure imbricatine (**1**) was capable of eliciting the swimming response in 100% of the bioassay specimens of *S. coccinea* (6). No other swimming elicitors were found in the *D. imbricata* extracts. Imbricatine also displays significant activity in the L1210 (ED_{50} < 1 μg/mL) and P388 (T/C 139 at 0.5 mg/kg) cytotoxicity assays.

The molecular formula of imbricatine, $C_{24}H_{26}N_4O_7S$, was determined from the mass spectra of the parent compound (FABMS (M^+ + H), *m/z*: 515 Da) and the dimethylpentacetyl derivative **2** (FABMS, *m/z*: M^+ + H) 753; HREIMS (M^+ − OAcbenzyl), *m/z*: 603.1756, $C_{27}H_{31}N_4O_{10}S$ (ΔM −0.5 mmu)) prepared from **1** by esterification (MeOH/HCl) and acetylation (Ac_2O/pyridine).

A *N*-methyl-5-thiohistidine fragment could be identified in **1** by comparing ^1H and ^{13}C nmr resonances in the spectrum of

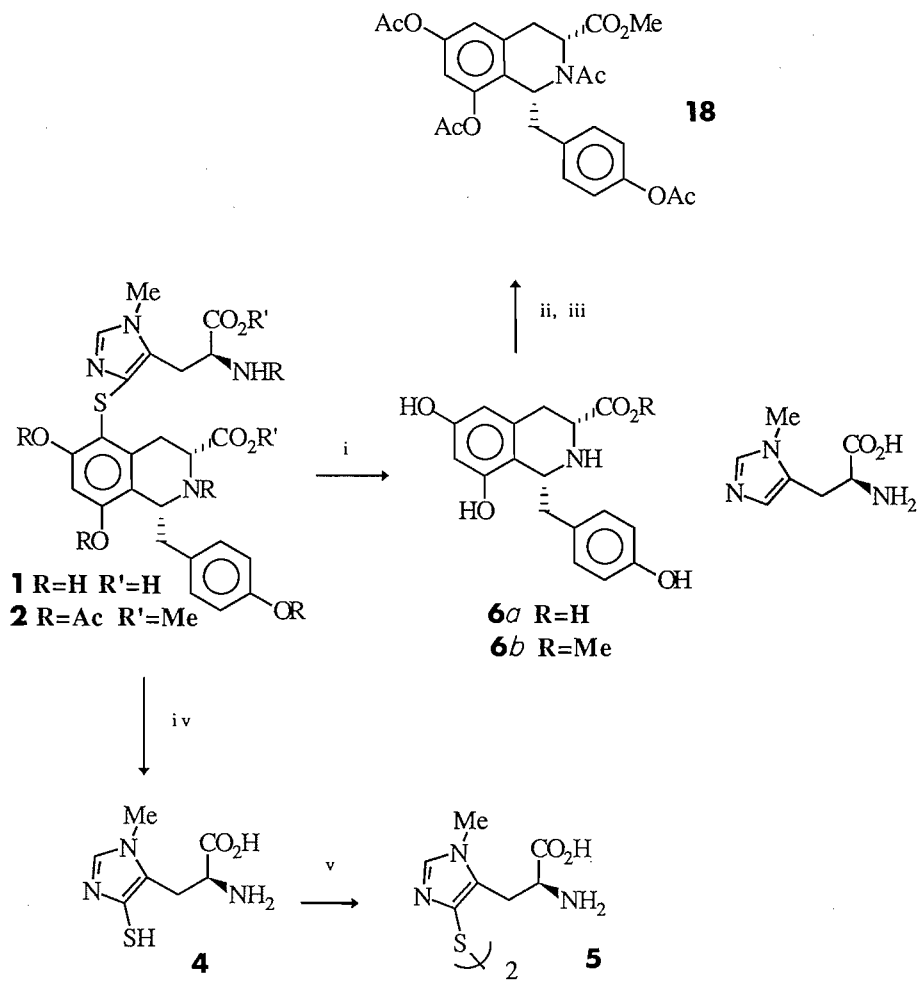
imbricatine to the values reported for the symmetrical disulfide **3** first isolated from echinoderm eggs (8, 9) (Tables 1 and 2). Reduction of imbricatine (**1**) with Raney nickel (Scheme 1) liberated *N*-methyl histidine, which was shown by tlc analysis to be identical to 3-methylhistidine and different from 1-methylhistidine. This result indicated that the position of *N*-methylation in the histidine residue of imbricatine (3-methyl) was different from that reported for the disulfide from echinoderm eggs (1-methyl). It was subsequently shown by an unambiguous synthesis of disulfide **5** that the structure originally assigned to the disulfide from echinoderm eggs (i.e., **3**) was incorrect and needed to be revised as **5** (9). Treatment of imbricatine with red phosphorus in refluxing HI (Scheme 1) liberated the histidine thiol **4**, which was oxidized by iodine in aqueous HCl to the disulfide **5** (10). The spectral data collected on the disulfide **5** obtained from imbricatine were in complete agreement with the literature values (8, 9) and its specific rotation ($[\alpha]_D$ +67° (lit. (9) $[\alpha]_D$ +77°) indicated that the histidine residues had the L configuration.



The second product obtained from the Raney nickel reduction of imbricatine was the benzyltetrahydroisoquinoline fragment **6a**. Compound **6a** gave a parent ion ($M^+ + H$) in the CIMS at *m/z* 316 Da and fragment ions at 270 ($M^+ - CO_2H$), 242 ($M^+ - NH{=}CHCO_2H$ via a retro Diels–Alder), 208 ($M^+ -$ HO-benzyl) and 164 ($M^+ -$ (HO-benzyl + CO_2)) Da typical of benzyltetrahydroisoquinolines with a carboxylic acid substituent at C3 (11). The EIHRMS spectrum of **6a** failed to show a parent ion; however, an intense fragment ion at *m/z* 208.1611 Da ($C_{10}H_{10}NO_4$, ΔM +0.1 mmu), which was assigned to a $M^+ -$ (HO-benzyl) fragment ion, was consistent with a molecular formula of $C_{17}H_{17}NO_5$ for the intact molecule. Only 15 resonances were observed in the ^{13}C nmr spectrum of **6a** (Table 2), demonstrating that the molecule contained some element of symmetry. The ^{1}H nmr resonances at δ 6.70 (d, J = 8 Hz, 2H) and 7.01 (d, J = 8 Hz, 2H) (Table 1) and ^{13}C nmr resonances at δ 126.9 (C), 130.2 (2 × CH), 115.0 (2 × CH), and 156.0 (C) (Table 2) were assigned to the phenyl ring in the benzyl residue of **6a**. The ^{1}H and ^{13}C chemical shifts of these resonances were in close agreement with those that we recorded for tyrosine, suggesting that the phenyl ring in **6a** contained only a *para*

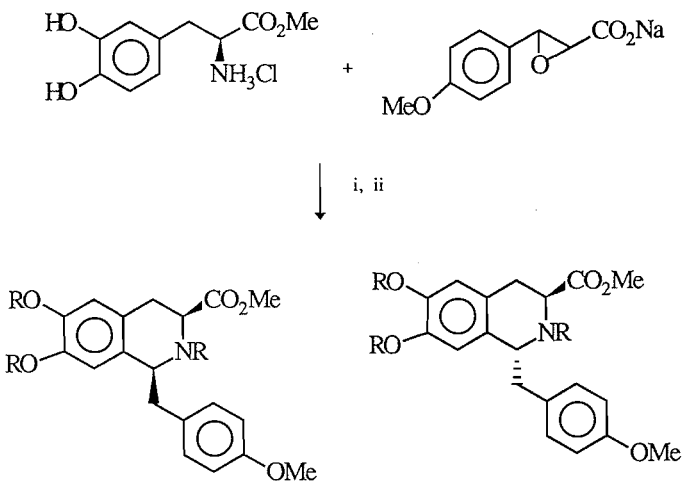
Reagents and reaction conditions: (i) Raney nickel, reflux, 1 h; (ii) HCl, MeOH, reflux, 2.5 h; (iii) Ac_2O, pyridine, r.t., 24 h; (iv) red phosphorus, aqueous HI (57%), N_2, reflux, 48 h; (v) 0.1 N HCl, I_2, r.t., 26 h.

SCHEME 1.



hydroxyl substituent, thereby accounting for the symmetry required by the ^{13}C nmr data. Additional deshielded ^1H resonances at δ 6.08 (d, J = 2 Hz) and 6.22 (d, J = 2 Hz) were assigned to protons on the aromatic ring of the tetrahydroisoquinoline moiety. The magnitude of the scalar coupling between these protons (2 Hz) showed that they were *meta* to each other and their chemical shifts suggested that the other substituents on the ring were a pair of *meta* hydroxyls. The remaining resonances in the ^1H nmr spectrum of **6***a* were assigned to the two CH-CH_2 fragments (δ (4.57, dd, J = 8, 4 Hz, H1), 3.12 (dd, J = 14, 4 Hz, H12), 2.80 (dd, J = 14, 8 Hz, H12′), 3.20 (dd, J = 12, 4 Hz, H3), 2.90 (dd, J = 16, 4 Hz, H4), 2.71 (dd, J = 12, 16 Hz, H4′)) in the reduced ring and the benzyl substituent of the isoquinoline nucleus.

The ^1H nmr spectrum of imbricatine (**1**), in contrast to that of the Raney nickel reduction product **6***a*, contained only a single resonance (δ 6.42, s) that could be assigned to a proton on the aromatic ring of the tetrahydroisoquinoline portion of the molecule (Table 1). Therefore, the other nonphenolic position of the ring had to be occupied by a thioether linkage to the methylhistidine residue. Both the $H4_e$ and $H3_a$ resonances were strongly deshielded in imbricatine (**1**: δ 4.03, $H4_e$: 3.76, $H3_a$) relative to the resonances assigned to the corresponding protons in the Raney nickel reduction product (**6***a*: δ 2.90, $H4_e$: 3.12, $H3_a$). The observed difference in chemical shifts for these two protons in compounds **1** and **6***a* could best be explained if the thioether linkage in imbricatine was attached to C5 of the isoquinoline nucleus, which in turn placed the two phenolic hydroxyls at C6 and C8. A pair of SINEPT experiments optimized for polarization transfer through a J $^{13}C/^1H$ of 7 Hz supported this assignment. Irradiation of H1 (δ 4.67) in imbricatine (**1**) gave polarization transfer into C8 (δ 155.8) and C10 (137.7), while irradiation of H7 (δ 6.42) gave polarization transfer into C5 (δ 110.0), C6 (159.7), C8 (155.8), and C9 (112.7).

Difference nOe experiments involving irradiation of H1 and H3 in imbricatine (**1**) failed to provide definitive proof for the relative stereochemistries at C1 and C3. Therefore, we synthesized the model compounds **9** and **10**, starting from optically pure L-dopa, in order to obtain reference data for the determination of both the relative and absolute configurations at C1 and C3 in the Raney nickel reduction product **6** and ultimately in imbricatine (**1**) itself.

Scheme 2 outlines the synthetic route used to prepare model compounds **9** and **10**. Earlier workers had found that the *cis* isomer was the major product (3.2:1 *cis*/*trans*) formed in the Pictet–Spengler coupling reaction when the phenylglycidate reactant contained methoxy substituents at both C3 and C4 on the phenyl ring (12). We found an identical 3.2:1 ratio of the *cis* to *trans* products with the 4-methoxyphenylglycidate shown. The *cis* configuration of the C1 and C3 substituents in **9** was

confirmed by a difference nOe experiment involving irradiation of H1 in compound **7** that induced nOe's in H3 and one of the H12 protons. Comparison of the ^1H nmr spectra of the model compounds **9** ($(CDCl_3)$ δ: 1.87 (s, CH_3CON), 2.88 (dd, J = 14, 8 Hz, H12), 3.21 (m, $H4_a$ and $H4_e$), 3.28 (dd, J = 14, 6 Hz, H12′), 4.49 (t, J = 10 Hz, $H3_a$), 4.73 (dd, J = 8, 6 Hz, $H1_a$)) and **10** (see Experimental) to that of derivative **18** ($(CDCl_3)$ δ: 1.80 (s, CH_3CON), 2.88 (dd, J = 14, 8 Hz, H12), 3.24 (m, $H4_a$ and $H4_e$), 3.30 (dd, J = 14, 6 Hz, H12′), 4.48 (t, J = 10 Hz, $H3_a$), 5.04 (dd, J = 8, 6 Hz, $H1_a$)) confirmed the benzyltetrahydroisoquinoline nature of the reduction product **6***a* and demonstrated that the C1 and C3 substituents in **6***a* were *cis* as shown.

A more direct proof of the C1, C3 relative stereochemistry in **6***a* was obtained from a difference nOe experiment carried out on its methyl ester **6***b*. Irradiation of the resonance assigned to H1 (δ 4.45: acetone-d_6 plus four drops of benzene-d_6) in **6***b* induced nOe's in the resonances assigned to H3 (δ 3.42) and H12 (δ 3.48) consistent with the *cis* relative stereochemistry shown. The *trans* reduction product **20***a* was produced as a minor side product in the Raney nickel reduction reaction (Scheme 1) if the catalyst was added in large excess and the reaction was allowed to reflux for at least 3 h. The circular dichroism (CD) spectrum of **20***b* (Fig. 1, see discussion below) indicated that it was epimeric with **6***b* at C1.

3

20*a* R=H
20*b* R=Me

The CD spectra of model compounds **7** and **8** prepared from L-dopa, as indicated in Scheme 2, and the CD spectra of the methyl esters **6***b* and **20***b* of the *cis* and *trans* Raney nickel reduction products **6***a* and **20***a* are shown in Fig. 1. The Cotton effects observed for the *cis* (1*S*,3*S*) model compound **7** and the *cis* Raney nickel reduction product methyl ester **6***b* in the long wavelength region (290–298 nm), the middle range wavelength region (234–238 nm), and in the short wavelength region (200–220 nm) are each of opposite signs for the two compounds. Since the model compound **7** has the 1*S*,3*S* absolute configuration, the CD results demonstrate that the *cis* Raney nickel reduction product **6***a* and its methyl ester **6***b* have the 1*R*,3*R* absolute configuration. Similarly, the CD curve of the *trans* Raney nickel reduction product methyl ester **20***b* corresponds to the mirror image of the spectrum for the *trans* model compound **8** (Fig. 1) and, therefore, **20***b* must have the 1*S*,3*R* absolute configuration. Imbricatine has the same absolute configurations at C1 and C3 as the *cis* Raney nickel reduction product **6***a* and its methyl ester **6***b*; therefore, the absolute configuration of imbricatine (**1**) is 1*R*,3*R*,7′*S* as shown.

Imbricatine (**1**) is apparently the first example of a benzylisoquinoline alkaloid to be isolated from a nonplant source and it appears to be the first member of this class of alkaloids to have the C6/C8 hydroxylation pattern and a thiohistidine substituent. The biogenetic origin of the hydroxyl substitutents at C6/C8 is of considerable interest since all the plant alkaloids in this family are derived from L-dopa, which gives rise to C6/C7 hydroxylation (13). Then D amino acid configuration at C3 and the C6/C8 hydroxylation pattern indicate that the isoquinoline fragment of imbricatine (**1**) is probably not derived from L-dopa but rather from some other precursor such as D-3-(3,5-dihydroxyphenyl)-alanine, an amino acid that has not been previously described. We have prepared 3-(3,5-dihydroxyphenyl)alanine methyl ester **13** as the racemate and used it as a starting point in a biogenetic-type synthesis of **18**, a derivative of the benzyltetrahydroisoquinoline alkaloid fragment of imbricatine (**1**). Compound **18** was independently prepared from the Raney nickel reduction product **6***a* (Scheme 1), providing synthetic verification of the constitution of the benzyltetrahydroisoquinoline fragment of imbricatine (**1**). Scheme 3 outlines the synthesis of both **13** and **18**.

The synthesis of **13** started with methyl 3,5-dihydroxybenzoate, a readily available precursor that contains the required arrangement of alkyl and hydroxyl substituents on the benzene ring. Protection of the phenols as the benzyl ether derivatives, followed by LAH reduction of the methyl ester and tosylation of the resulting benzyl alcohol, gave the alkylating agent **11**. Alkylation of diethyl acetamidomalonate with the tosylate **11** following literature procedures gave **12** in excellent yield (14). Hydrolysis and decarboxylation of **12** gave the protected amino acid, which was routinely converted into the amino acid methyl ester **13**. The Pictet–Spengler reaction of methyl

ester **13** with sodium 3-(4-benzyloxyphenyl)glycidate gave an inseparable mixture of the *cis* and *trans* benzyltetrahydroisoquinoline products **14** and **15** (12). Acetylation of the mixture of **14** and **15** gave the triacetoxy derivatives **16** and **17**, which could be separated by preparative thin-layer chromatography. The relative stereochemistries at C1 and C3 in **16** and **17** were established by comparison of their H1 and H3 coupling constants to those observed for the model compounds **9** and **10** where the relative stereochemistries had been rigorously established. The *trans* isomer was the major product (**17**:*trans*/**16**:*cis* 6.5:1) formed in the Pictet–Spengler reaction of methyl ester **13**, presumably due to an unfavorable steric interaction between the benzyl substituent at C1 and the C8 hydroxyl during the formation of the *cis* isomer. Removal of the benzyl protecting group in **16** by catalytic hydrogenation and acetylation of the resulting phenolic product gave the *cis* benzyltetrahydroisoquinoline derivative **18**, which was identical by tlc, ^{1}H nmr, and mass spectral comparison to compound **18** prepared by methylation (HCl/MeOH) and acetylation (Ac_2O/pyridine) of the Raney nickel reduction product **6***a*. The *trans* isomer **19** prepared from **17** by the same sequence of reactions had tlc and ^{1}H nmr characteristics different from compound **18** prepared from **6***a*.

It is well documented that many marine invertebrates utilize chemical cues to recognize their predators; however, relatively little information is available concerning the chemical structures of the messengers (16). Several studies examining the basis of escape and avoidance of marine invertebrates to seastars have found that saponins are the active substances (16*a*, 16*c*, 17). These results, in combination with the widespread occurrence of saponins in seastars (18), have fostered the common perception that most seastar initiated behavioral responses are elicited by saponins. Our results have shown that the metabolite of the seastar *D. imbricata* responsible for eliciting swimming in *Stomphia* sp. is not a saponin, but rather the very interesting new alkaloid imbricatine (**1**). This discovery suggests that a blanket assumption that other seastar initiated avoidance responses are caused by saponins is probably unjustified. Careful quantitative bioassay guided fractionation of seastar extracts is required to fully characterize the chemical mediator(s) of the responses.

Experimental

Imbricatine (1)

Imbricatine (**1**) was extracted and purified as described in the text. White amorphous solid; ir (KBr disc): 3700–2500 (b), 1630, 1595, 1515, 1447, 1397, 1244, 1175, 1080, 840 cm^{-1}; ^{1}H nmr see Table 1; ^{13}C nmr see Table 2; FABMS, *m/z* (M^+ + H): 515, $C_{24}H_{26}N_4O_7S$ + H.

Methylation and acetylation of imbricatine to give 2

Imbricatine (**1**) (9 mg) was dissolved in methanol saturated with gaseous HCl and the solution was refluxed for 2.5 h. The solvent was evaporated to dryness *in vacuo* and acetic anhydride (2 mL) and pyridine (2 mL) were added to the residue. After stirring 24 h at room temperature the acetylation reagents were removed *in vacuo* and the residue was purified by reverse phase hplc (CH_3CN/H_2O 3:7) to give derivative **2** (9 mg). **2**: ^{1}H nmr (400 MHz, $CDCl_3$) δ: 7.34,(s,1H), 7.29(d, *J* = 8 Hz,2H), 7.02(d, *J* = 8 Hz,2H), 6.89(bs,1H), 6.15(bd, *J* = 8 Hz,1H), 5.06(bt, *J* = 6 Hz,1H), 4.73(bdd, *J* = 6, 12 Hz,1H), 3.87(s), 3.75(s,1H), 3.61(s,3H), 3.36(dd, *J* = 6, 14 Hz,1H), 3.17(m,1H), 3.10(bd, *J* = 16 Hz,1H), 2.89 (dd, *J* = 6, 14 Hz,1H), 2.41(s,3H), 2.28(s,3H), 2.18(s,3H), 1.90(s,3H), 1.74(s,3H) ppm; FABMS, *m/z*: 753 ($C_{36}H_{40}N_4O_{12}S$ + H); EIHRMS, *m/z*: 603.1756 (M^+ − OAcbenzyl), $C_{27}H_{31}N_4O_{10}S$ (Δ*M* −0.5 mmu).

Raney nickel reduction of imbricatine (1)

Imbricatine (**1**) (16 mg) was refluxed with 0.5 mL of Ra-Ni suspension for 1 h under N_2. The reaction mixture was vacuum filtered and the Ra-Ni residue was washed with hot MeOH. The combined filtrate, after removal of MeOH under vacuum, was chromatographed on Sephadex LH20 using 9:1 MeOH/H_2O as the eluent to give crude compound **6***a*, which was further purified on reverse phase HPLC (20:80 MeOH/H_2O) to obtain pure **6***a* (8 mg). **6***a*: ^{1}H nmr, see Table 1; ^{13}C nmr, see Table 2; CIMS, *m/z*: 316 (M^+ + H), 272, 242, 270, 208, 198, 164, 162, 152, 137, 124, 121, 109, 108, 107; EIHRMS, *m/z*: 208.1611 (M^+ − HObenzyl), $C_{10}H_{10}NO_4$ (ΔM +0.1 mmu). When imbricatine was refluxed with a large excess of Ra-Ni suspension for longer than 3 h, the reaction mixture turned a dark red and a mixture of the *cis* reduction product **6***a* and its C1 epimer **20***a* was formed. Methylation of the mixture as described below for **6***a* gave a mixture of **6***b* and **20***b* that was separated by preparative reverse phase tlc (6:4 MeOH/H_2O).

*Methylation of compound 6*a

The Raney nickel reduction product **6***a* was refluxed with HCl/MeOH for 1 h under nitrogen. After removal of the solvent, the reaction mixture was chromatographed on normal phase tlc(4:1 EtOAc/$CHCl_3$) to afford pure **6***b* as a yellow solid; ^{1}H nmr (400 MHz, acetone-d_6) δ: 7.02 (d, *J* = 8.6 Hz, H15, H17), 6.71 (d, *J* = 8.6 Hz, H14, H18), 6.33 (d, *J* = 1.9 Hz, H5), 6.12 (d, *J* = 1.9 Hz, H7), 4.41 (dd, *J* = 7.8, 3.0 Hz, H1), 3.68 (s, 3H, $COOCH_3$), 3.43 (dd, *J* = 13.5, 3.0 Hz, H12a), 3.42 (dd, *J* = 11.0, 3.0 Hz, H3), 2.71 (dd, *J* = 13.4, 7.8 Hz, H12b), 2.69 (dd, *J* = 15.2, 3.0 Hz, $H4_{eq}$), 2.47 (dd, *J* = 15.2, 11.0 Hz, $H4_{ax}$) ppm: EIMS, *m/z* (rel. int.): 236 (50, M^+ − HOphenyl), 222 (49, M^+ − HObenzyl), 191 (8), 176 (30), 162 (53).

*Compound 20*b: obtained as a pale yellow solid; ^{1}H nmr (400 MHz, acetone-d_6) δ: 7.13 (d, *J* = 8.5 Hz), 6.80(d, *J* = 8.5 Hz), 6.31(d, *J* = 1.8 Hz), 6.17(d, *J* = 1.8 Hz), 4.22(dd, *J* = 10.0, 2.5 Hz), 4.01(dd, *J* = 10.5, 4.5 Hz), 3.70(s, 3H), 3.14(dd, *J* = 13.5, 2.5 Hz), 2.88(dd, *J* = 15.3, 4.5 Hz), 2.73(dd, *J* = 15.3, 10.5 Hz), 2.68(dd, *J* = 13.5, 10.0 Hz) ppm; EIMS, *m/z*(rel. int.): 270(5, M^+ − CO_2Me), 222(100, M^+ − HObenzyl); CIMS, *m/z*: 330(100).

Reductive hydrolysis of imbricatine (1)

Red phosphorus (150 mg) was added to a solution of imbricatine (**1**) (100 mg) in 57% aqueous HI and the reaction mixture was refluxed under N_2 for 48 h. At the end of this period, the reaction mixture was filtered to remove the solid phosphorus and the filtrate was evaporated under vacuum. The residue was taken up with 5 mL aqueous HCl (pH 2) and chromatographed on Sephadex LH20 using 1:1 MeOH/H_2O as an eluent to give the histidine thiol **4** (34 mg).

Oxidation of the thiol 4 to the disulfide 5

To a solution of histidine thiol **4** (17 mg) in 2 mL 0.1 N aqueous HCl was added a few crystals of I_2. The reaction mixture was stirred at room temperature for 26 h, diluted with 4 mL water, extracted with $CHCl_3$ to remove I_2, and then chromatographed on Sephadex LH20 using 1:1 MeOH/H_2O as an eluent. Disulfide **5** (15 mg) was obtained. **5**: ^{1}H nmr(300 MHz, D_2O) δ: 8.78(s, 1H), 4.20(t, *J* = 8 Hz, 1H), 3.85(s, 3H), 3.30(dd, *J* = 15, 8 Hz, 1H), 3.35(dd, *J* = 15, 8 Hz, 1H) ppm.

Measurement of the optical rotation of disulfide 5

Disulfide **5** (10 mg) was dissolved in 1.0 mL 0.1 N aqueous HCl and the optical rotation was measured using a 1-dm cell. The specific rotation $[\alpha]_D^{20}$ was found to be +67°.

Synthesis of the model compounds 7 and 8

Methyl-L-dopa (580 mg) in 10 mL MeOH was added to a solution of sodium 3-(4-methoxyphenyl)glycidate in 15 mL of water. The mixture was brought to pH 4 with AcOH and stirred at 35°C for 36 h. At the end of the reaction period, the mixture was concentrated under vacuum to yield an aqueous suspension which was partitioned between EtOAc (15 mL) and 10% HCl (15 mL). The aqueous layer was neutralized with K_2CO_3 and extracted with EtOAc (15 mL × 3). The EtOAc solution was washed with water, dried over Na_2SO_4, and concentrated under

For personal use only.

vacuum to afford a brown residue that was chromatographed on normal phase hplc (3:2 EtOAc/$CHCl_3$) to give **7** (145 mg) and **8** (45 mg).

Compound 7: obtained as a white solid; ^{1}H nmr (270 MHz, DMSO-d_6) δ: 7.17(d, J = 8 Hz, 2H), 6.84(d, J = 8 Hz, 2H), 6.70(s, 1H), 6.43(s, 1H), 4.00(J = 8, 4 Hz, 1H), 3.70(s, 3H), 3.58(s, 3H), 3.48(dd, J = 11, 5 Hz, 1H), 3.21(dd, J = 14, 4Hz, 1H), 2.71(dd, J = 16, 5 Hz, 1H), 2.56(dd, J = 14, 8 Hz, 1H) ppm; CIMS, m/z(rel. int): 344 (M^+ + H, 16), 284(1), 222(100), 162(11), 134(1), 121(13); EIHRMS, m/z: 343.1403 (M^+), $C_{17}H_{21}NO_5$ (ΔM −1.7 mmu).

Compound 8: obtained as a pale yellow oil; ^{1}H nmr (400 MHz, DMSO-d_6) δ: 7.18 (d, J = 8 Hz, 2H), 6.88 (d, J = 8 Hz, 2H), 6.60 (s, 1H), 6.47 (s, 1H), 4.00(dd, J = 10, 4 Hz, 1H), 3.87(dd, J = 9, 5 Hz, 1H), 3.74(s, 3H), 3.63(s, 3H), 2.86(dd, J = 14, 4 Hz, 1H), 2.79(dd, J = 16, 5 Hz, 1H), 2.74(dd, J = 14, 4 Hz, 1H), 2.64(dd, J = 16, 8 Hz, 1H) ppm; EIHRMS, m/z: 343.1412 (M^+), $C_{17}H_{21}NO_5$ (ΔM −0.8 mmu).

Acetylation of model compounds 7 and 8

Compounds **7** (25 mg) and **8** (25 mg) were reacted independently with acetic anhydride (2 mL) and pyridine (2 mL) at room temperature for 24 h to give the triacetyl derivatives **9** and **10** respectively.

Compound 9: white solid; ^{1}H nmr see Table 1; ^{13}C nmr (75 MHz, $CDCl_3$) δ: 172.7(s), 170.6(s), 168.1(s), 168.0(s), 158.5(s), 141.2(s), 140.4(s), 135.5(s), 130.6(d), 129.3(s), 122.7(d), 121.7(d), 114.0(d), 61.2(d), 55.4(d), 55.1(q), 52.3(q), 42.5(t), 29.7(t), 21.2(q), 20.4(q), 20.5(q) ppm; CIMS, m/z: 470(M^+ + H), 428, 348, 306, 264, 222, 162, 121; EIHRMS, m/z: 348.1093 (M^+ − MeObenzyl), $C_{17}H_{18}NO_7$ (ΔM +1.0 mmu).

Compound 10: clear oil; ^{1}H nmr (400 MHz, $CDCl_3$: exists as a 1: 1.4 mixture of conformers) δ: 6.98 (s), 6.89(s), 6.87(d, J = 8 Hz), 6.79(d, J = 8 Hz), 6.70(s), 6.69(s), 6.53(s), 5.36(t, J = 5 Hz), 4.92(t, J = 7 Hz), 4.86(dd, J = 8, 4 Hz), 4.63(dd, J = 6, 3 Hz), 3.78(s), 3.75(s), 3.58(s), 3.51(s), 3.3(m), 3.1–2.85(m), 2.43(dd, J = 16, 6 Hz), 2.26(s), 2.25(s), 2.24(s), 2.23(s), 2.13(s), 2.06(s) ppm; CIMS, m/z: 470 (M^+ + H); EIHRMS, m/z: 348.1090 (M^+ − MeObenzyl), $C_{17}H_{18}NO_7$ (ΔM +0.7 mmu).

Preparation of methyl 3,5-dibenzyloxybenzoate

Methyl 3,5-dihydroxybenzoate (5.0 g, 29 mmol) and K_2CO_3 (20.0 g) were stirred in 100 mL of anhydrous acetone for 30 min. Benzyl bromide (7.5 mL) was added slowly over a period of 5 min and the mixture was refluxed for 1 h. Filtration and evaporation to dryness *in vacuo* yielded a crude product that was purified by flash chromatography (400 mL 9:1 Hex/EtOAc, 400 mL, 8:2 Hex/EtOAc, 400 mL 7:3 Hex/EtOAc) to yield methyl 3,5-dibenzyloxybenzoate (9.4 g, 27 mmol: 92%), mp 66.0–67.5°C; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 7.32(m, 10H), 7.28(d, J = 2.3 Hz, 2H), 6.76(t, J = 2.3 Hz, 1H), 4.97(s, 4H), 3.82(s, 3H) ppm; EIHRMS, m/z: 348.1364 (M^+), $C_{22}H_{20}O_4$ (ΔM +0.2 mmu).

Preparation of 3,5-dibenzyloxybenzyl alcohol

$LiAlH_4$ (0.012 g) was added slowly to methyl 3,5-dibenzyloxybenzoate (0.1 g, 0.29 mmol) in 10 mL of diethyl ether. The mixture was refluxed for 2.5 h and quenched with 10 mL of water. 20% NaOH (10 mL) was added and the mixture was extracted three times with diethyl ether (3 × 15 mL) and the ether layers were dried over magnesium sulfate. Evaporation *in vacuo* gave 3,5-dibenzyloxybenzyl alcohol (0.087 g, 0.27 mmol, 95% yield), mp 78.5–79.0°C; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 7.31(m, 10H), 6.56(bs, 2H), 6.50(bs, 1H), 4.94(s, 4H), 4.50(s, 2H), 2.29(bs, 1H) ppm.

Preparation of 3,5-dibenzyloxybenzyl tosylate (11)

Sodium hydride (0.019 g 80% dispersion in oil) was added to a stirred solution of 3,5-dibenzyloxybenzyl alcohol (0.20 g, 0.63 mmol) in 10 mL of benzene. Tosyl chloride (0.12 g) was added slowly over a period of 10 min and the mixture was stirred for 9 h at room temperature. The resulting solution was centrifuged and the supernatant withdrawn. Evaporation of the benzene *in vacuo* yielded a mixture of the product 3,5-dibenzyloxybenzyl tosylate and starting material. Purification using flash chromatography (7:3 Hex/EtOAc) yielded the desired tosylate **11** (0.11 g, 0.23 mmol); ^{1}H nmr (400 MHz, $CDCl_3$) δ: 7.76(d, J = 8.2 Hz, 2H), 7.34(m, 10H), 7.28(d, J = 8.2 Hz, 2H), 6.54(t, J = 2.2 Hz, 1H), 6.46(d, J = 2.2 Hz, 2H), 4.96(s, 2H), 4.94(s, 4H), 2.39(s, 3H) ppm.

Preparation of benzylacetamidomalonate 12

Diethyl acetamidomalonate (0.13 g, 0.61 mmol) and sodium hydride (0.018 g 80% dispersion in oil) were stirred in benzene (5 mL) and DMF (5 mL) for 15 min. 3,5-Dibenzyloxybenzyl tosylate **11** (0.068 g, 0.14 mmol) was added slowly and the mixture was stirred at room temperature for 6 h. Evaporation *in vacuo* followed by flash chromatography (3:2 EtOAc/Hex) gave compound **12** (0.069 g, 0.13 mmol, 92% yield), mp 138.5–140.0°C; ^{1}H nmr (400 MHz, $CDCl_3$) δ: 7.34(m, 10H), 6.56(s, 1H), 6.51(t, J = 2.2 Hz, 1H), 6.26(d, J = 2.2 Hz, 2H), 4.98(s, 4H), 4.23(m, 4H), 3.58(s, 2H), 1.95(s, 3H), 1.27(t, J = 7.1 Hz, 6H) ppm; EIHRMS, m/z: 519.2254 (M^+), $C_{30}H_{33}NO_7$ (ΔM −0.3 mmu).

Hydrolysis and decarboxylation of 12

Compound **12** (0.055 g, 0.11 mmol) was dissolved in 10 mL of dioxane and 20% NaOH (2 mL) was added. The mixture was stirred under reflux for 3 h. After cooling, glacial acetic acid (2 mL) was added and the reaction was refluxed for an additional hour. After cooling, the mixture was extracted three times with 10-mL portions of EtOAc. Evaporation of the EtOAc *in vacuo* gave the crude 3,5-dibenzyloxy-*N*-acetamidophenylalanine (0.041 g, 0.099 mmol, 93% yield), which was used directly in the next step; ^{1}H nmr (400 MHz, CD_3OD) δ: 7.35(m, 10H), 6.53(bs, 2H), 6.45(bs, 1H), 4.80(s, 4H), 4.51(bs, 1H), 3.15(dd, J = 4.1, 13.6 Hz, 1H), 2.90(dd, J = 7.5, 13.6 Hz, 1H), 1.88 (s, 3H) ppm.

Preparation of methyl-3-(3,5-dihydroxyphenyl)alanine (13)

N-Acetamido-3-(3,5-dibenzyloxyphenyl)alanine was stirred in hydrazine (2 mL) at 100°C for 24 h. The mixture was evaporated to dryness *in vacuo*, taken up in methanol saturated with HCl, and refluxed for 1 h. The mixture was then evaporated to dryness *in vacuo* and taken up in methanol. Stirring under H_2 in the presence of Pt/C at room temperature for 10 h gave, after reverse phase flash chromatography (100% H_2O, 80% H_2O/acetone, 60% H_2O/acetone), the amino acid methyl ester **13**: ^{1}H nmr (400 MHz, CD_3OD) δ: 6.25(t, J = 1.8 Hz, 1H), 6.22(d, J = 1.8 Hz, 2H), 4.26(t, J = 6.6 Hz, 1H), 3.83(s, 3H, 3.36(s, 1H), 3.10(dd, J = 6.6, 13.8 Hz, 1H), 3.05(dd, J = 6.6, 13.8 Hz, 1H), 2.62 (s, 1H) ppm; EIHRMS, m/z: 211.0851 (M^+), $C_{10}H_{13}NO_4$ (ΔM +0.7 mmu).

Preparation of the benzyltetrahydroisoquinolines 14 and 15

Sodium 3-(4-benzyloxyphenyl)glycidate (15) (0.15 g, 0.53 mmol) in 10 mL of water was added to a solution of compound **13** (0.11 g, 0.53 mmol) in 15 mL of methanol. Acetic acid (2 mL) was added and the mixture was stirred at 35°C for 17 h under N_2. The solvent was evaporated *in vacuo* and the crude material was taken up in EtOAc. The organic layer was washed twice with 1 N HCl and once with H_2O and dried over sodium sulfate. Evaporation of the EtOAc to dryness gave 0.20 g of the crude mixture. Purification was accomplished using silica gel (1:1 Hex/EtOAc) to yield an inseparable mixture (0.079 g, 0.19 mmol, 36% yield) of the tetrahydroisoquinolines **14** and **15**. Data for the mixture of **14** and **15**: EIHRMS, m/z: 419.1728 (M^+), $C_{25}H_{25}NO_5$ (ΔM −0.4 mmu); Compound **15**: ^{1}H nmr (400 MHz, CD_3OD) δ: 7.37(m, 5H), 7.17(d, J = 8.1 Hz, 2H), 6.97(d, J = 8.1 Hz, 2H), 6.22(s, 1H), 6.13(s, 1H), 5.06(s, 2H), 4.31(d, J = 10.0 Hz, 1H), 4.01(d, J = 11.3 Hz, 1H), 3.74(s, 3H), 3.29(m, 2H), 2.85(m, 2H) ppm; Compound **14**: ^{1}H nmr (400 MHz, CD_3OD) δ: 7.37(m, 5H), 7.06(d, J = 8.1 Hz, 2H), 6.88(d, J = 8.1 Hz, 2H), 6.26(s, 1H), 6.06(s, 1H), 5.03(s, 2H), 4.46(bs, 1H), 3.44(m, 1H), 2.78(m, 3H) ppm.

Acetylation of the mixture of 14 and 15:

The tetrahydroisoquinoline mixture (**14** and **15**) (0.030 g, 0.072 mmol) was stirred in pyridine (2 mL) and acetic anhydride (2 mL) for 19 h. Evaporation of the reagents *in vacuo* yielded 0.048 g of the crude mixture. Purification was accomplished on preparative tlc (1:1

Hex/EtOAc) to yield **16** (0.0035 g, 0.0064 mmol) and **17** (0.023 g, 0.042 mmol). Compound **16**: ir (NaCl window): 3031, 2925, 2853, 1769, 1652, 1615, 1510 cm^{-1}; ^1H nmr(400 MHz, $CDCl_3$) δ: 7.40(m, 5H), 7.22(d, J = 8.7 Hz, 2H), 6.92(d, J = 8.7 Hz, 2H), 6.93(d, J = 2.1 Hz, 1H), 6.88(d, J = 2.1 Hz, 1H), 5.06(s, 2H), 5.03(dd, J = 5.3, 8.0 Hz, 1H), 4.46(t, J = 9.6 Hz, 1H), 3.85(s, 3H), 3.25(m, 3H), 2.81(dd, J = 5.3, 13.7 Hz, 1H), 2.29(s, 3H), 2.20(s, 3H), 1.71(s, 3H) ppm; EIHRMS, m/z: 545.2043 (M^+), $C_{31}H_{31}NO_8$ (ΔM −0.7 mmu). Compound **17** existed as a mixture of conformers. *Major conformer*: ^1H nmr (400 MHz, $CDCl_3$) δ: 7.33(m, 5H), 6.89(d, J = 2.2 Hz, 1H), 6.75(d, J = 8.6 Hz, 2H), 6.67(d, J = 2.2 Hz, 1H), 6.66(d, J = 8.6 Hz, 2H), 5.64(dd, J = 2.8, 6.7 Hz, 1H), 5.01(s, 2H), 4.54(dd, J = 2.4, 5.4 Hz, 1H), 3.49(s, 3H), 3.24(dd, J = 6.7, 13.2 Hz, 1H), 2.86(m, 2H), 2.25(s, 3H), 2.16(s, 3H), 2.12(s, 3H), 2.10(m, 1H) ppm. *Minor conformer*: ^1H nmr (400 MHz, $CDCl_3$) δ: 7.33(m, 5H), 6.93(d, J = 2.2 Hz, 1H), 6.86(s, 4H), 6.79(d, J = 2.2 Hz, 1H), 5.18(t, J = 6.3 Hz, 1H), 5.04(s, 2H), 4.83(dd, J = 3.5, 6.4 Hz, 1H), 3.57(s, 3H), 3.02(dd, J = 3.5, 16.3 Hz, 1H), 2.95 (second order d, J = 6.3 Hz, 1H), 2.93(second order d, J = 6.3 Hz, 1H), 2.86(m, 3H), 2.26(s, 3H), 2.22(s, 3H), 1.99(s, 3H) ppm; EIHRMS, m/z: 545.2043 (M^+), $C_{31}H_{31}NO_8$ (ΔM −0.7 mmu).

Preparation of compound 18

The *cis* benzyltetrahydroisoquinoline **16** (0.0039 g, 0.0071 mmol) was stirred in methanol (2 mL) under H_2 in the presence of Pt/C catalyst for 3 h. The mixture was filtered and evaporated to dryness *in vacuo*. Purification was accomplished using preparative tlc (9:1 EtOAc/Hex) to yield the phenol, which was stirred in pyridine (1 mL) and acetic anhydride (1 mL) at room temperature for 15 h. Evaporation of the reagents *in vacuo* followed by purification using preparative tlc (9:1 EtOAc/Hex) yielded compound **18**: ^1H nmr (400 MHz, $CDCl_3$) see Table 1; EIHRMS, m/z: 497.1691 (M^+), $C_{26}H_{27}NO_9$ (ΔM +0.5 mmu).

Preparation of compound 19

An identical procedure was employed to prepare the *trans* isomer **19** starting from **17**. The *trans* isomer **19** existed as a mixture of conformers. EIHRMS, m/z: 438.1556 ($M^+ - C_2O_2H_3$), $C_{24}H_{24}NO_7$ (ΔM +0.3 mmu). *Major conformer*: ^1H nmr(400 MHz, $CDCl_3$) δ: 6.88(d, J = 2.1 Hz, 1H), 6.86(d, J = 8.6 Hz, 2H), 6.79(d, J = 8.6 Hz, 2H), 6.71(d, J = 2.1 Hz,1H), 5.65(dd, J = 2.8, 7.2 Hz, 1H), 4.59(dd, J = 2.5, 5.3 Hz, 1H), 3.49(s, 3H), 3.21(dd, J = 7.2, 13.0 Hz, 1H), 2.97(m, 3H), 2.26(s, 3H), 2.25(s, 3H), 2.15(s, 3H), 2.13(s, 3H) ppm. *Minor conformer*: ^1H nmr (400 MHz, $CDCl_3$) δ: 6.99(m, 4H), 6.94(d, J = 2.6 Hz, 1H), 6.82(d, J = 2.6 Hz, 1H), 5.21(t, J = 6.2 Hz, 1H), 4.86(dd, J = 3.5, 6.3 Hz, 1H), 3.57(s, 3H), 3.08(dd, J = 3.5, 16.3 Hz, 1H), 2.95(m, 3H), 2.28(s, 3H), 2.27(s, 3H), 2.22(s, 3H), 2.06(s, 3H) ppm.

NIKOLA B. MILIĆ, ŽIVADIN D. BUGARČIĆ, and PREDRAG T. DJURDJEVIĆ. Can. J. Chem. **69**, 28 (1991).

Hydrolysis of aluminum(III) ion in 3.0 *M* $(Na)NO_3$ medium was studied by emf method at 25°C. Data cover the range 1–78 *mM* Al(III) within the pH range of 2.0–4.5. At a definite pH, the extent of hydrolysis increases with increasing aluminium concentration, thereby indicating the presence of polynuclear hydrolysis products. The least squares treatment of the data indicates the formation of polynuclear hydrolytic complexes $Al_2(OH)_2^{4+}$, $Al_2(OH)_4^{2+}$, and $Al_3(OH)_4^{5+}$. With the reactions written in the form

$$p\ Al^{3+} + qH_2O \rightleftarrows Al_p(OH)_q^{(3p-q)} + qH^+$$

the stability constants obtained were $\log \beta_{2,2} = -7.55 \pm 0.21$, $\log \beta_{2,4} = -16.41 \pm 0.13$, and $\log \beta_{3,4} = -13.24 \pm 0.08$. Distribution curves indicate that the complex $Al_3(OH)_4^{5+}$ is predominant.

Key words: hydrolysis, aluminum(III) ion, hydrolytic complexes, aluminum(III) ion hydrolysis.

NIKOLA B. MILIĆ, ŽIVADIN D. BUGARČIĆ et PREDRAG T. DJURDJEVIĆ. Can. J. Chem. **69**, 28 (1991).

Opérant à 25°C, dans un milieu contenant 3,0 M de $NaNO_3$ et faisant appel à la méthode de la f.e.m., on a étudié l'hydrolyse de l'ion aluminium(III). Les données couvrent les concentrations allant de 1 à 78 mM de Al(III) et les pH allant de 2,0 à 4,5. A un pH donné, le taux d'hydrolyse augmente avec une augmentation de la concentration en aluminium; ce résultat indique qu'il y a des produits d'hydrolyse de nature polynucléaire. L'examen des données par la méthode des moindres carrés indique qu'il y a formation des complexes d'hydrolyse polynucléaires $Al_2(OH)_2^{4+}$, $Al_2(OH)_4^{2+}$ et $Al_3(OH)_4^{5+}$. Avec les réactions écrites sous la forme

$$p\ Al^{3} + qH_2O \rightleftarrows Al_p(OH)_q^{(3p-q)} + qH^+$$

on à obtenu les constantes de stabilité suivantes: $\log \beta_{2,2} = -7{,}55 \pm 0{,}21$, $\log \beta_{2,4} = -16{,}41 \pm 0{,}13$, et $\log \beta_{3,4} = -13{,}24 \pm 0{,}08$. Les courbes de distribution indiquent que le complexe $Al_3(OH)_4^{5+}$ est prédominant.

[Traduit par la revue]

Introduction

Although aqueous hydrolysis of aluminum(III) ion has been studied extensively (1–20) the composition and stability of its predominating hydrolytic complexes remains unclear. Kubota's data (5) indicate that monomer $Al(OH)^{2+}$ is formed in a wide range of concentration of sodium perchlorate media (0.01–1.0 *M*).[3] Brosset's data (6, 7) in 2 *M* $NaClO_4$ medium at 40°C indicate the formation of only polynuclear species. Aveston (8) found dimer $Al_2(OH)_2^{4+}$ and tridecamer $Al_{13}(OH)_{32}^{7+}$ in 1 *M* $NaClO_4$ medium. Mesmer and Baes (9) found $Al_2(OH)_2^{4+}$, $Al_3(OH)_4^{5+}$, and $Al_{13}(OH)_{32}^{7+}$ at elevated temperatures (62.5–149.8°C). Brown *et al.* (10), in 0.1 *M* KNO_3 medium, found $Al(OH)^{2+}$, $Al(OH)_2^{+}$, $Al(OH)_4^{5+}$ and a species of high nuclearity for which they presented a stoichiometry-dependent equilibrium constant. Formation of tridecamer was observed by Bottero *et al.* (11–13). Akitt's previous ^{27}Al-NMR measurements (14, 15) indicate the formation of dimer $[(H_2O)_4Al(\mu\text{-}OH)_2Al(H_2O)_4]^{4+}$ and tridecamer $[AlO_4Al_{12}(OH)_{24}(OH_2)_{12}]^{7+}$, while recent data (16–18) obtained at very high magnetic fields indicate the presence of tridecamer and trimer $Al_3O_2(OH)_4^{+}$, as well as oligomeric mixture with stoichiometry close to $[Al_n(OH)_{2.5n}(H_2O)_{5n}]^{0.5n+}$. In the presence of acetate (19, 20) only dimer was found.

In our studies (21–23) of the metal ion hydrolysis, an effect of ionic medium on the extent of hydrolysis and on the composition of hydrolytic complexes and their stability, was observed. Thus discordance in explanation of the hydrolytic behaviour of aluminum might be a result of varying experimental conditions under which the hydrolysis was studied. Thus more reliable information on hydrolytic complexes of aluminum can be obtained by investigating its hydrolysis in various types of ionic media under the same experimental conditions. As part of a wider work this study is on the hydrolysis of aluminum(III) ion in 3.0 *M* $(Na)NO_3$. We used an emf method at 25°C over a wide range of aluminum concentration and pH value.

Experimental

Chemical and analysis

Aluminum nitrate stock solution was prepared from recrystallized $Al(NO_3)_3 \cdot 9H_2O$, Merck, p.a. To prevent hydrolysis of aluminum(III) ion in the stock solution, an appropriate amount of nitric acid was added. Its free concentration was determined potentiometrically using a Gran plot method (24). The aluminum content was determined by precipitation with ammonium hydroxide. The precipitates were ignited at 1100°C, and weighed as Al_2O_3. Reproducibility was within ±0.2%.

Sodium nitrate stock solution was prepared from recrystallized $NaNO_3$, Merck, p.a. The content was determined by evaporating a known volume of solution to dryness at 150°C.

Sodium hydroxide stock solution was prepared in polyethylene bottle as a 50% solution from solid NaOH, Merck, p.a. After a few days, Na_2CO_3 was removed by filtering through a G-4 Jena glass filter. The solution was diluted with 3.0 *M* $NaNO_3$ and standardized against potassium hydrogenphthalate, Merck, p.a.

Nitric acid was made by dilution of HNO_3, Merck, Suprapure, and standardized against NaOH. All solutions were prepared using boiled distilled water.

Nitrogen gas, used for stirring and providing an inert atmosphere for titration, was purified by passing through 10% NaOH and 10% H_2SO_4. Before reaching the titrant, the gas was saturated with H_2O vapor by bubbling it through water and 3.0 *M* sodium nitrate.

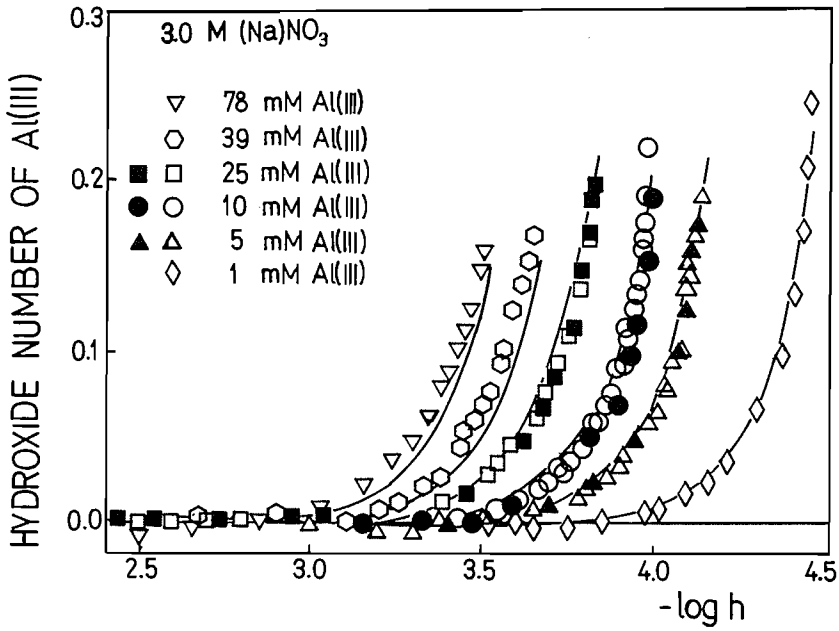

FIG. 1. Hydrolysis of the aluminum(III) ion in sodium nitrate medium (full symbols denote back titrations).

Apparatus and procedure

All emf measurements were carried out as potentiometric titration by using a Wilhelm bridge and constant ionic medium, 3.0 *M* (Na)NO_3[4]. Thus the composition of aluminum(III) solutions was *B* mol dm^{-3} Al^{3+}, *H* mol dm^{-3} H^+, (3.0 − 3*B* − *H*) mol dm^{-3} Na^+, 3.0 mol dm^{-3} NO_3^-, where *B* and *H* denote the total concentration of aluminum(III) and hydrogen ions, respectively.

During measurements the titration vessel and the Wilhelm bridge were inserted in a paraffin oil thermostat at 25.0 ± 0.1°C, which was placed in a room thermostated at 25.0 ± 0.5°C. The cell was

(−) glass electrode | aluminum(III) solution, HNO_3, 3.0 *M* (Na)NO_3 | RE (+)

As reference electrode (RE) the following half cell was used

Ag,AgCl | 3.0 *M* $NaNO_3$, 0.01 *M* $AgNO_3$

The glass electrode was commercial (Beckman, pH 0–11), while the Ag,AgCl electrode was prepared according to Brown (25). Titrations of aluminum(III) solutions were carried out by adding sodium hydroxide from one burette and aluminum(III) solution in the same portion from a second burette. The aluminum solution in second burette was twice the concentration of the aluminum solution in the titration vessel. In this way the total concentration of the aluminum(III) ion was kept constant throughout each titration. Since all solutions were prepared in the corresponding concentration of sodium nitrate, the total concentration of nitrate ions was kept constant, at 3.0 *M* . The concentration of free H^+ (denoted as *h*) at each point was calculated by the Nernst formula

$$E = E_o + E_j + 59.16 \log h$$

where *E* is the measured potential, E_o a constant which includes the standard potential of the glass electrode, and E_j the liguid junction potential. E_o and E_j were both determined in each titration in the area in which the extent of hydrolysis was negligible. The potential was repeatedly measured after each addition of the solutions from the burettes, until a remaining drift of ≤ 0.2 mV/h was reached. In the beginning of the titration a constant value of emf was obtained within 10 min. In the pH range where hydrolysis of the aluminum(III) ion becomes significant, attainment of the equilibrium was rather slow, particularly at higher values of hydroxide number, $Z_{Al} > 0.3$. The emf was measured with a Beckman digital pH meter, Model 4500, with a resolution of ± 0.2 mV.

Results and discussions

The emf data of the hydrolysis of 1.0, 5.0, 10.0, 25, 39, and 78.0 *mM* Al^{3+} ion in 3.0 *M* (Na)NO_3 medium are presented in Fig. 1. This figure gives the average number of hydroxide ions reacted per aluminum(III) ion, Z_{Al}, as function of the free hydrogen ion concentration, −log *h*. Z_{Al} was calculated from the analytical excess of hydrogen ions, *H*, the measured concentration of the free hydrogen ion, *h*, and the total concentration of the aluminum(III) ion, *B*, according to the expression

$$[1] \quad Z_{Al} = (h - H)/B$$

The data obtained show that the aluminum(III) ion in 3.0 M (Na)NO_3 medium starts to hydrolyse between pH 2.0 and 4.5, depending upon its concentration. Thus as the aluminum concentration increases hydrolysis starts at lower pH values (Fig. 2). "Start of hydrolysis" corresponds to the formation of the first hydrolytic complex. From an experimental point of view, the start of hydrolysis corresponds to the first positive hydroxide number, Z_{Al}, beyond the average random error. Thus in Fig. 2, this point occurs when Z_{Al} is 0.01.

The separate curve (Fig. 1) for each concentration of aluminum(III) indicates the formation of polynuclear hydrolytic complexes. The composition of complexes and their stability constants were determined assuming aluminum(III) ion interacts with the water molecules to form one or more hydrolytic complex of the general formula $Al_p(OH)_q^{(3p-q)}$, according to reaction

$$[2] \quad pAl^{3+} + qH_2O \rightleftarrows Al_p(OH)_q^{(3p-q)} + qH^+$$

where the amount of H^+ ions set free is equivalent to the amount of OH^- ions bound to aluminum(III) ion. The general formula $Al_p(OH)_q^{(3p-q)}$ is understood to also include an unknown amount of H_2O as a solvent and possibly also include medium ions. In reaction [2] the hydration of individual ions and complex formation of aluminum(III) ion with nitrate ions are

[4]The notation of the ionic medium is in accordance with refs. 1–3.

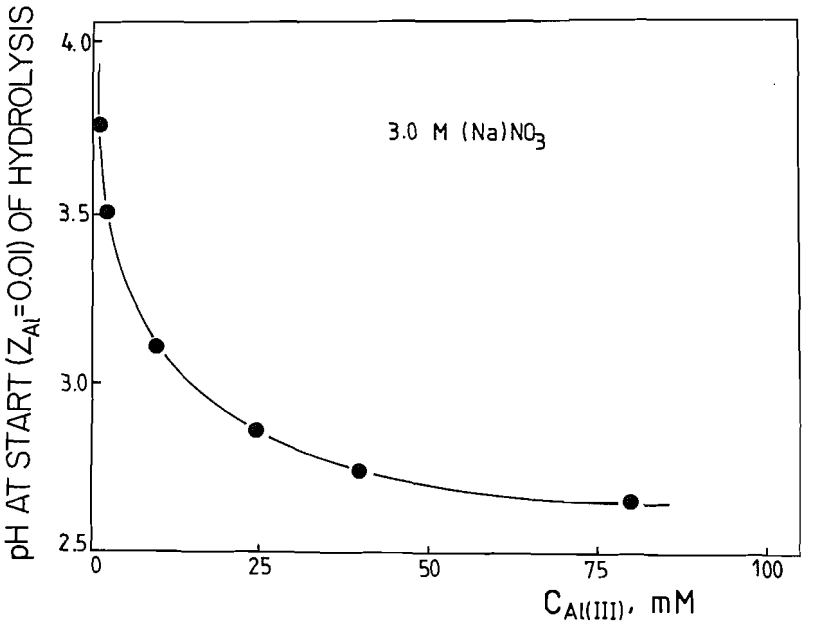

FIG. 2. The correlation between the start of hydrolysis (pH at $Z_{Al} = 0.01$) and the total aluminum(III) ion concentration.

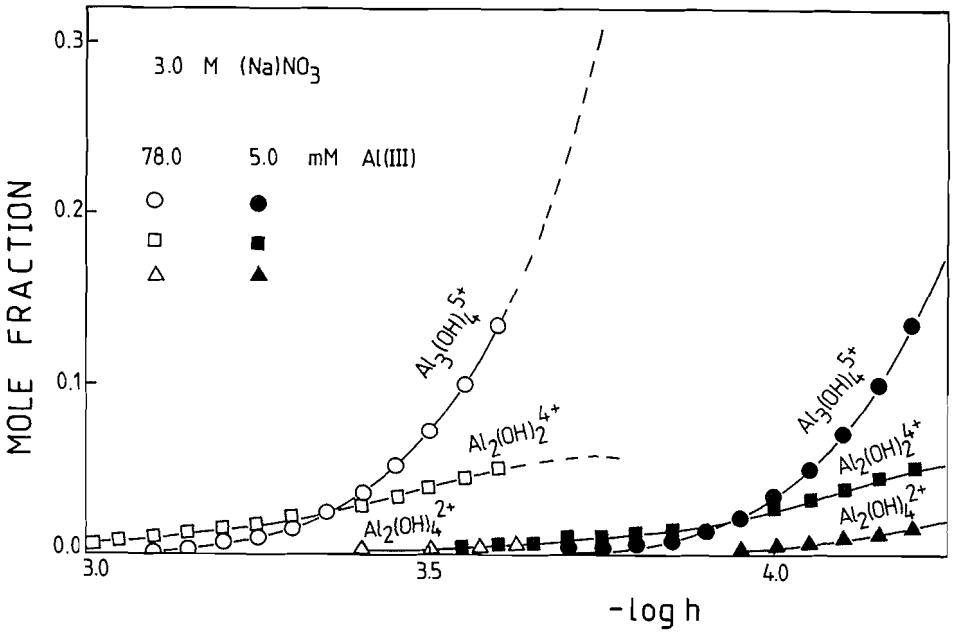

FIG. 3. Distribution of the hydrolytic complexes at 5.0 and 78.0 *mM* Al^{3+}. The distribution curves of the free Al^{3+} ion are omitted due to extension mole fraction scale.

omitted. The concentration of both nitrate ions and water molecules is much higher than the concentration of aluminum(III) ion, therefore it is not possible to determine the changes in concentration of nitrate ions and water molecules. To avoid variable effects of complex formation of aluminum(III) ion with nitrate ion, its concentration was kept high and constant, 3.0 *M* NO_3^-. Under such conditions, an eventual complex formation should appear as a constant effect and should not affect the number of OH^- ions in the hydrolytic complexes.

The composition of the hydrolytic complexes and their stability constants were determined by minimizing the error square sum

$$[3] \quad U = \Sigma(Z_{calc} - Z_{exp})^2$$

where Z_{exp} denotes the experimental value of Z_{Al} (eq. [1]) and Z_{calc} the calculated value using the tested (p,q) values and stability constants

$$[4] \quad Z_{calc} = (\Sigma q\beta_{pq}\, h^{-q}b^p)/(b + \Sigma p\beta_{pq}h^{-q}b^p)$$

In eq. [4] β_{pq} denotes the stability constant of the hydrolytic complex according to eq. [5]

$$[5] \quad \beta_{pq} = c_{pq}h^q b^{-p}$$

c_{pq} denotes the concentration of the hydrolytic complex, and b and h the free concentrations of the metal ion and hydrogen

ion, respectively. The minimization given by eqs. [3] and [4] has been performed using the generalized least-squares program LETRAGROP (26). The data obtained indicate the formation of two dimeric complexes, $Al_2(OH)_2^{4+}$ and $Al_2(OH)_4^{2+}$, and the trimer, $Al_3(OH)_4^{5+}$, with the following stability constants: log

TABLE 2. Hydrolytic complexes of the aluminum(III) ion in 3.0 *M* $(Na)NO_3$ medium at various levels of the hydroxide number

	Stability constants, $\log(\beta_{pq} \mp 3\delta)$

<0.05	−7.43 ∓ 0.22	—	−13.38 max −13.14
<0.15	−7.41 ∓ 0.17	—	−13.28 ∓ 0.11
<0.30	−7.55 ∓ 0.21	−16.41 ∓ 0.13	−13.24 ∓ 0.08

$\beta_{2,2} = -7.55 \pm 0.21$, $\log \beta_{2,4} = -16.41 \pm 0.13$ and $\log \beta_{3,4} = -13.24 \pm 0.08$, respectively. Many other models were also tested (Table 1) but in all these cases calculation gave either negative values of β_{pq} or larger values of U_{min}.

Since some recent works (10, 16) denied or questioned the presence of $Al_2(OH)_2^{4+}$ we tested for this complex in a number of models (Table 1). The dimer was accepted in all models tested, but with rather high error. A similar controversial situation is true of the tridecamer. Therefore we tested its presence in combinations with other species using all six data for total aluminum concentrations but tridecamer was rejected in every case. We also tested for tridecamer by calculating the concentration of aluminum(III) ion separately. Tridecamer was accepted only at 5 *mM* Al(III) and rejected at all other aluminum concentrations. The presence or absence of dimer and tridecamer complexes may be a result of different experimental conditions, therefore it will be of interest to investigate the aluminum(III) ion hydrolysis by both NMR and emf measurements under the same experimental conditions. In a study of the hydrolysis of thorium(IV) ions (22), we obtained an excellent agreement betweem emf and calorimetric data under the same experimental conditions.

Since some data (5, 10) in very dilute solutions (0.1–1 *mM* Al^{3+}) and at low hydroxide numbers indicated the formation of mononuclear species we have also treated the data of 1 and 5 *mM* Al^{3+} with $Z_{Al} < 0.05$, separately. However, the two monomers $AlOH^{2+}$ and $Al(OH)_2^+$ were rejected in combination with the dimers and trimer. Since polymerization process of monomers to polynuclear species is extensive, the existence of monomers depends very much on the ageing time of hydrolyzed solutions. If potential is measured immediately after the addition of base, the data might indicate the presence of monomers. More reliable information on the composition of the hydrolytic species can be obtained from data at equilibrium state. However, equilibrium, may take a long time to get established, depending on the nature of the metal ion, the degree of hydrolysis, and medium effect. In our work, the time necessary for achieving constant potential readings was between 15 min and 3 h, depending on Z_{Al} values. To check for equilibrium, we measured the potential for more than 10 h (overnight) without adding the base. The results indicate that a "constant potential" reflects the equilibrium state, or, at least a state which is very close to equilibrium. This might be why our data did not indicate the presence of monomeric hydrolytic complexes. A high concentration of ionic medium may be another explanation for our results. In our work the medium was 3.0 *M*. Consequently, the concentration of free water molecules was lowered because of the stoichiometry and hydration of medium ions. Under such conditions one may expect that the formation of polynuclear hydrolytic complexes will be more pronounced.

Using the Haltafall program (27) the distribution of $Al_2(OH)_2^{4+}$, $Al_2(OH)_4^{2+}$, and $Al_3(OH)_4^{5+}$ as a function of pH was calculated (Fig. 3). These plots show that $Al_3(OH)_4^{5+}$ is the predominant complex. Its concentration increases with increasing total aluminum(III) ion concentration.

Assuming that formation of polynuclear hydrolytic complexes is a result of polymerization, it is obvious that polynuclearity should increase with increasing Z_{Al}. To check that, all data were divided into three groups ($Z_{Al} < 0.05$, $Z_{Al} < 0.15$, $Z_{Al} < 0.30$) and each of them was treated separately. The results obtained (Table 2) indicate that at low Z_{Al} values only the formation of dimer $Al_2(OH)_2^{4+}$ is significant. At higher Z_{Al} values, the trimer also appeared. However, two dimers, $Al_2(OH)_2^{4+}$, $Al_2(OH)_4^{2+}$, and one trimer $Al_3(OH)_4^{2+}$ are found over the entire Z_{Al} range, with stability constants differ only slightly from one range of Z_{Al} values to another.

Spinel ferrites as catalysts: A study on catalytic effect of coprecipitated ferrites on hydrogen peroxide decomposition

PREETI LAHIRI AND SUSANTA K. SENGUPTA

Department of Chemistry, Faculty of Science, Banaras Hindu University, Varanasi-221005, India

Received December 5, 1989[1]

PREETI LAHIRI and SUSANTA K. SENGUPTA. Can. J. Chem. **69**, 33 (1991).

Some ferrospinels act as catalysts for the decomposition of H_2O_2, their effectiveness is dependent on the composition of the catalyst. This study is to find the most effective catalyst of stoichiometry $M^{II}Fe_2^{III}O_4$. A set of ferrites of different composition $M^{II}Fe_2^{III}O_4$ (M^{II} = Mn, Co, Ni, Cu, Zn, Cd) was synthesized by co-precipitation and characterized by chemical analysis, X-ray diffractometry, and B.E.T. technique. A comparative assessment of the catalytic power of these ferrites from investigations of their influence on the kinetics of H_2O_2 decomposition in a neutral medium was made. An analysis of the data on specific rate, and the Eyrings activation parameters for the reaction sharply reveal the following: (*a*) The catalytic power follows the order $MnFe_2O_4 > CoFe_2O_4 > CuFe_2O_4 > NiFe_2O_4 > CdFe_2O_4 > ZnFe_2O_4$, $MnFe_2O_4$ is much more highly effective than the others (50–100 fold). (*b*) A compensation effect has been noted from the observed linearity with slightly less than unity slope between $T\Delta^*S^0$ and Δ^*H^0 over the entire series.

Key words: Ferrospinels, catalysis, hydrogen peroxide decomposition kinetics.

PREETI LAHIRI et SUSANTA K. SENGUPTA. Can. J. Chem. **69**, 33 (1991).

Quelques ferrospinelles catalysent la décomposition du H_2O_2; le degré de la catalyse dépend de la composition du catalyseur. On a entrepris la présente étude dans le but de trouver le catalyseur de stoechiométrie $M^{II}Fe_2^{III}O_4$ le plus efficace. Faisant appel à une méthode de coprécipitation, on a synthétisé un ensemble de ferrites de composition $M^{II}Fe_2^{III}O_4$ (M^{II} = Mn, Co, Ni, Cu, Zn, Cd) que l'on a caractérisées par des analyses chimiques, par la diffraction des rayons-x et par la technique BET. On a évalué les pouvoirs catalytiques relatifs de ces ferrites en examinant leur influence sur la cinétique de la décomposition du H_2O_2 en milieu neutre. Une analyse de données spécifiques et des paramètres d'acivation de Eyring conduit aux conclusions suivantes: (*a*) Le pouvoir catalytique décroit dans l'ordre suivant: $MnFe_2O_4 > CoFe_2O_4 > CuFe_2O_4 > NiFe_2O_4 > CdFe_2O_4 > ZnFe_2O_4$; le $MnFe_2O_4$ est toutefois beaucoup plus actif que les autres (de 50 à 100 fois plus). (*b*) On a noté un effet de compensation de la linéarité; sur toute la série, la pente entre le $T\Delta^*S^0$ et la Δ^*H^0 es légèrement inférieure à l'unité.

Mots clés : ferrospinelles, catalyse, peroxyde d'hydrogène, cinétique de décomposition.

[Traduit par la revue]

Introduction

Ferrospinels which form a series of isostructural compounds ($M^{II}Fe_2O_4$, M^{II} a bivalent metal ion) structurally belong to two major types: normal $(M^{II})_{tet}[Fe^{III}Fe^{III}]_{oct}O_4$ and inverse $(Fe^{III})_{tet}[M^{II}Fe^{III}]_{oct}O_4$. These mixed oxides, well known for their use as high frequency transformer cores, magnetic memories and switches, also have attractive catalytic properties. Among the applications mention must be made of highly selective oxidation of butene to butadiene (1), synthesis of ammonia (2), and decomposition of hydrogen peroxide (3). H_2O_2 decomposoiton is catalyzed by a number of ferrites and the effectiveness of the catalysts is dependent on the ferrite composition. Cobalt ferrite, CoF_2O_4, an inverse spinel catalyzes the decomposition of H_2O_2 to such an extent that it is matched only by the highly powerful, expensive catalysts like platinum, palladium, or silver oxide (4). This has, in fact, led to a number of important investigations on the use of cobalt ferrites $Co_xFe_{3-x}O_4$ ($0 \leq x \leq 3$) as electrocatalysts for oxygen reduction electrode process (5). Several catalysts were tried to search for a ferrospinel with optimum catalytic activity for the decomposition of H_2O_2. Examples include $Co_xFe_{3-x}O_4$, $Cu_xFe_{3-x}O_4$, and $Ni_xFe_{3-x}O_4$ ($0 \leq x \leq 3$) (6–8). The intrinsic catalytic power was found to be Co > Cu > Ni. Among the cobalt ferrites, $Co_{1.5}Fe_{1.5}O_4$ is the most active (6). Chemical composition, crystal structure, electronic, electrochemical, topochemical, and microstructural factors have been found to contribute to the overall activity of the catalysts (3). Peroxide decompositions are generally studied in the alkaline media, the media in which H_2O_2 is intrinsically unstable because of base catalysis by OH^- (9). In view of this complication, the present comparative assessment of the intrinsic activity of transition metal ferrites ($M^{II}Fe_2O_4$ where M = Mn, Co, Ni, Cu, Zn, Cd) towards peroxide decomposition was done in a neutral medium (pH 6.6).

Experimental

Preparation and characterisation of ferrospinels

Among the various synthetic routes considered by Goldstein and Tseung, hydroxide coprecipitation is the best for achieving high surface area for the spinel catalyst (3). A series of ferrospinels, MFe_2O_4 (M = Mn, Co, Cu, Ni, Cd, Zn) was synthesized by mixing appropriate amount of metal sulfate solution (Analar Grade) and ferrous ammonium sulfate (Analar Grade) with the appropriate volume of freshly prepared 5 M NaOH at 73 ± 1°C. More base was added until the precipitate formed attained a pH value of 10–10.5. The resultant precipitate was heated for 4 h. The brown deposit was filtered, the residue was washed until alkali-free, dried in an oven at 110°C, and sieved to 200 B.S.S. mesh size.

Chemical analysis was done complexometrically to determine the stoichiometry of the metal ions present in the sample. The powder samples were subjected to X-ray diffraction analysis, carried out on a Philips automatic X-ray diffractometer with a PW 1729 X-ray generator using Cu-K_α (1.5418 Å) radiation. The values obtained for the *d*-plane spacings and their relative intensities of reflection of MFe_2O_4 (M = Zn, Cd, Co, Ni, Cu, Mn) were compared with those in International tables for X-ray crystallography to determine the phases present. The Brunauer, Emmett, and Teller (B.E.T.) specific surface areas of the samples were measured by nitrogen adsorption at 77 K after degassing the catalyst at 301 K for 6 h.

Measurement of catalytic activity of the peroxide decomposition reaction kinetics

The catalytic activity of the ferrospinels for hydrogen peroxide decomposition was evaluated by rate of evolution of oxygen from the

liquid phase. A measured amount of catalyst (5–200 mg), depending upon the nature of catalysts, was injected into a thermosttated reaction vessel containing 2 cm^3 of 0.8 M H_2O_2 in 8 cm^3 of distilled water (pH 6.64 ± 0.01) for each specimen, H_2O_2 was standardized immediately before use by standard $KMnO_4$ solution. The peroxide decomposition is represented by

[1] $2H_2O_2 = 2H_2O + O_2$

The rate of evolution of gaseous O_2 was monitored with a gasometric assembly. The time-dependent volume, V_t of the evolved oxygen was monitored at 2 min intervals in all cases. The infinity reading, V_∞ was recorded by completing the reaction at 100°C. pH variation during the reaction was only ±0.04. Eyrings activation parameters were investigated over the temperature range 303–318 K.

Results and discussion

Results of chemical (complexometric) and XRD analyses revealed the presence of only spinel phases of stoichiometry $M^{II}Fe_2O_4$ (Table 2). However, we found contamination of the copper ferrite sample with CuO (Table 2). Moreover, no broad halos characteristic of amorphous phases could be detected on the diffraction pattern. The cation valency distribution between tetrahedral and octahedral sublattices characteristic of the spinel phases detected are included in Table 1. Thus whereas zinc and cadmium ferrites are normal spinels, copper, nickel, and cobalt ferrites are inverse ones, all having the stoichiometry $M^{II}Fe_2O_4$. In manganese ferrite, manganese distribution between tetrahedral and octahedral sublattices is 1:1. It is worth noting that the distribution depends upon the technique of preparation. It is 4:1 in the samples prepared by ceramic method as against 1:1 in the coprecipitated method, a result substantiated by ^{55}Mn NMR spectra (10). The catalytic activity of Fe_3O_4, known to be too low, was excluded in this study (3). It is noteworthy that catalytic activity of simple oxides of M^{II}, Fe^{III}, and their simple mixtures for decomposition of H_2O_2 in neutral media was found to be negligible. Thus for copper ferrite, which is contaminated with CuO, the observed catalysis is completely due to the spinel phase, as is the case of other ferrites. Results of specific surface area (Table 1) as determined by the B.E.T. technique show that this microstructural feature varies to some extent over a range (30–73 m^2/g) among the samples prepared.

TABLE 3. Specific rate constants at different temperatures for ferrite catalysts

Catalyst	Specific rate constants (k) $g^{-1}\ min^{-1}\ 10^2$ (±5%) 303 K	308 K	313 K	318 K
$ZnFe_2O_4$	2.46	4.16	5.60	8.20

proportional to the mass of the catalyst at least in our experiment (2–200 mg). The data on the rate constant per unit mass (k) of catalyst presented in Table 3 revealed that the catalytic activity of the prepared samples follow the order Mn > Co > Cu > Ni > Cd > Zn in MFe_2O_4. This order holds consistently at four different temperatures (Table 3).

The key objective of our investigation was to establish an order of intrinsic catalytic activities for MFe_2O_4 in the decomposition of H_2O_2 a property far more dependent on composition of the catalyst than on their microstructural differences. One possible way to ascertain an intrinsic catalytic activity is to utilize a kinetic parameter which is normalized for catalyst microstructure. Since B.E.T. specific surface area is a key microstructural factor, we chose the specific decomposition rate per unit B.E.T. surface area (k_n) as the microstructure-normalized parameter. The intrinsic activity in terms of k_n (Table 4) was found to follow the order Mn > Co > Cu > Cd > Ni > Zn ferrite, virtually the same order as k. It is further revealing that whereas Mn, Co or Zn ferrite has significantly different catalytic effectiveness than any other member, Cu, Cd, and Ni ferrites do not exhibit that much difference amongst themselves. Moreover, the order in k_n was found to be the same at the four different temperatures. It may be noted that k_n of copper ferrite, when corrected for activity due to the CuO (an inactive phase) present, would not change the activity order among the ferrites.

The results were analyzed using Eyring's equation

$$\log\left(\frac{k}{T}\right) = \log\left(\frac{K}{h}\right) + \frac{\Delta^*S^0}{2.303R} - \frac{\Delta^*H^0}{2.303R}\left(\frac{1}{T}\right)$$

K = Boltzmann constant. Activation entholpies (Δ^*H^0) and entropies (Δ^*S^0) were calculated using the log (k/T) vs. $1/T$ plot. It is seen that the activation enthalpies show a significant variation (38–83 kJ mol^{-1}) for the series (Table 4). This is not unexpected in view of the differences in composition and structure amongst the catalysts. This wide variation in Δ^*H^0 with composition also minimizes the possibility of diffusion of H_2O_2 to the surface of the catalyst as a major factor controlling the decomposition kinetics (3). It is interesting to note that the order observed in k_n, Δ^*H^0, and Δ^*S^0 among the ferrites differ significantly from one another. The order found is Cu > Ni ≈ Cd > Zn > Mn > Co ferrite in Δ^*H^0 and Cu > Mn > Ni ≈ Cd > Zn > Co ferrite in Δ^*S^0 as against Mn > Co > Cu ≈ Cd ≈ Ni > Zn ferrite in k_n (Table 4). However, $T\Delta^*S^0$ vs. Δ^*H^0 plot yields a straight line of slope slightly less than unity (0.88) (Fig. 1) showing the constancy of peroxide decomposition mechanism over the entire ferrite series and a high degree of compensation between Δ^*H^0 and Δ^*S^0 (11). Evidently, activation entropies which can be related to the entropy of adsorption of the reactant (7) play a key role in determining the order of intrinsic activity among the ferrites. Mn and Zn ferrites have similar Δ^*H^0 values but very different Δ^*S^0 values. Their k_n values are also very different.

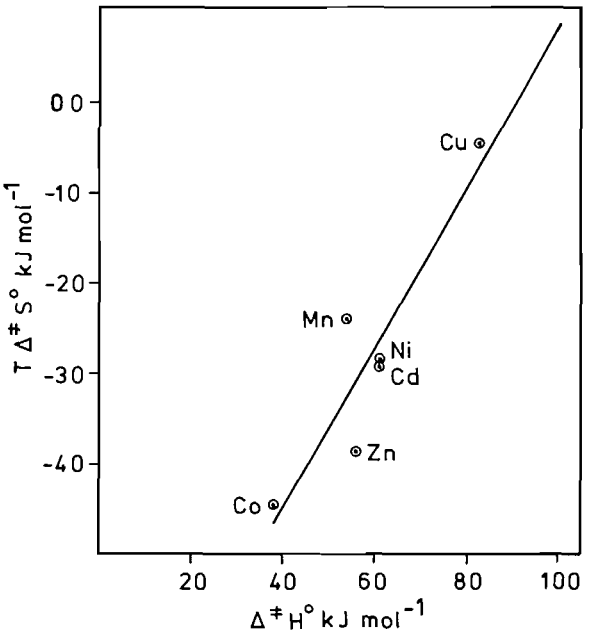

FIG. 1. Compensation effect. Plot of $T\Delta^*S^0$ vs Δ^*H^0 for the decomposition of H_2O_2 on ferrospinels MFe_2O_4 surfaces.

It has been seen from a number of kinetic studies on ferrite-catalyzed decomposition of H_2O_2 (3) that several factors, such as chemical composition, electronic structure, redox characteristics, topochemical effects, and pH, govern the intrinsic activity of ferrospinel catalysts. For the series chosen topochemical factors are insignificant to explain the observed order. pH effects were kept at a minimum level because of the choice of a neutral medium (pH 6.64 ± 0.04).

It is generally agreed that the electronic structure and the ease of M^{II} (or Fe^{II})/Fe^{III} (or M^{III}) redox conversions initiated by M^{II} (or Fe^{II}) centres on the spinel lattice are among the principal factors governing the intrinsic catalytic activity for the decomposition of H_2O_2. Taking these factors into account, the observed order for intrinsic catalytic activity among MFe_2O_4 for H_2O_2 decomposition may be re-expressed as

$$[Mn_{0.5}^{II}—Fe_{0.5}^{III}]_{tet} + [Fe_{0.5}^{II}—Mn_{0.5}^{III}]_{oct} > [Co^{II}—Fe^{III}]_{oct} > [Cu^{I}—Fe^{III}]_{oct} \approx [Cd^{II}]_{tet} \approx [Ni^{II}—Fe^{III}]_{oct} > [Zn^{II}]_{tet}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

$[Fe^{II}—Fe^{III}]_{oct}$ is not mentioned because of the known low activity of Fe_3O_4 (3).

The conclusion that emerges is that the operation of the redox couples $(Mn^{II}/Fe^{III})_{tet}$, $(Fe^{II}/Mn^{III})_{oct}$, along with $(Mn_{tet}^{II}/Mn_{oct}^{III})$, must be sufficiently unhindered to make manganese ferrite the most active, and significantly more effective than the well-known cobalt ferrite. The low activity of zinc ferrite is not unexpected in the light of the foregoing discussion. However, $(Cu^{I}/Fe^{III})_{oct}$ as well as $(Ni^{II}/Fe^{III})_{oct}$ redox couples must be sufficiently restricted, more so the latter to make their intrinsic activity comparable to that of cadmium ferrite. The activity of cadmium ferrite compared to that of zinc ferrite appears unexpected in view of the above factors. It needs more examination to find some explanation for its activity. However, the present investigation has led to the finding that manganese ferrite is potentially a very powerful catalyst significantly more so than cobalt ferrite for the decomposition of hydrogen peroxide.

The homogeneous conversion of methane to higher hydrocarbons in the presence of ethylene in the temperature range 925–1023 K

ALAIN R. BOSSARD AND MARGARET H. BACK
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received June 26, 1990

ALAIN R. BOSSARD and MARGARET H. BACK. Can. J. Chem. **69**, 37 (1991).

Mixtures of ethylene and methane have been pyrolyzed in the temperature range 925–1023 K for the purpose of converting methane to higher hydrocarbons. Addition of methane to thermally-reacting ethylene increases the rate of formation of propylene but decreases the rates of formation of the other major products, ethane, acetylene, and butadiene. Hydrogen abstraction from methane is a major propagation reaction and causes a shift in the radical distribution from ethyl and vinyl radicals, the main radicals in the pyrolysis reactions of ethylene alone, to methyl radicals, which lead to the formation of propylene. At 1023 K with a pressure of ethylene of 6.5 Torr and of methane of 356 Torr, 1.5 mol of methane is converted to higher molecular weight products for every mole of ethylene reacted. The rate of conversion of methane in the homogeneous system is lower than in catalytic reactions but the product is entirely hydrocarbon and no methane is lost to carbon monoxide or carbon dioxide.

Key words: methane, ethylene, kinetics, pyrolysis, fuels.

ALAIN R. BOSSARD et MARGARET H. BACK. Can. J. Chem. **69**, 37 (1991).

Dans le but de transformer du méthane en hydrocarbures de poids moléculaires plus élevés, on a pyrolysé des mélanges d'éthylène et de méthane à des températures allant de 925 à 1023 K. L'addition de méthane à de l'éthylène qui réagit d'une façon thermique provoque une augmentation de la vitesse de formation du propylène; elle provoque aussi une diminution des vitesses de formation des autres produits majeurs : éthane, acétylène et butadiène. L'abstraction d'un atome d'hydrogène du méthane est une des principales réactions de propagation et elle provoque un déplacement important dans la distribution radicalaire qui passe d'une prépondérance des radicaux éthyles et vinyles, les radicaux principaux dans les réactions de pyrolyse de l'éthylène seul, vers les radicaux méthyles qui conduisent à la formation du propylène. A 1023 K, à des pressions d'éthylène de 6,5 Torr et de méthane de 356 Torr, 1,5 mole de méthane se transforme en hydrocarbures de poids moléculaires plus élevés pour chaque molécule d'éthylène qui réagit. La vitesse de conversion du méthane dans le système homogène est plus faible que dans les réactions catalytiques; toutefois, les produits ne sont que des hydrocarbures et il n'y a pas de perte de méthane en monoxyde et en dioxyde de carbone.

Mots clés : méthane, éthylène, cinétique, pyrolyse, combustibles.

Introduction

Most of the efforts directed to the conversion of natural gas into higher molecular weight fuels have focussed on the use of catalysts as a means of overcoming the thermodynamic disadvantage of the overall process. For example, several metal oxides have been found effective in the oxidative coupling reaction of methane and their development and improvement has received considerable attention in recent years (1–4). Catalysts, however, while effective in many regards, have a number of limitations. In the methane conversion the presence of the oxide leads to the formation of carbon monoxide and carbon dioxide and represents a loss of carbon as fuel. Homogeneous conversion of methane would not involve this loss process and such systems therefore warrant investigation along with catalytic processes. Direct thermal decomposition of methane is not practical because of its high stability; at the high temperatures necessary for reaction rapid conversion to carbon occurs (5, 6). To overcome this problem a sensitizer may be used to induce decomposition at lower temperatures, favouring the production of the less stable hydrocarbon products. One such system involves the pyrolysis of mixtures of methane and ethylene. A description of this system and some results from the pyrolysis of these mixtures have been reported (7) and only a brief summary of the reactions will be given here.

The thermal reactions of ethylene at temperatures in the neighbourhood of 800 K involves both decomposition and polymerisation and occurs by a chain reaction mechanism (8). Initiation by the bimolecular reaction of ethylene,

[1] $2C_2H_4 \rightarrow C_2H_3 + C_2H_5$

is followed by addition, abstraction, decomposition, and isomerisation of the ethyl, vinyl, and other radicals. In pure ethylene methane and ethane are the only saturated products and are formed by hydrogen-abstraction by the corresponding radical.

[2] $CH_3 + C_2H_4 \rightarrow CH_4 + C_2H_3$

[3] $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$

Addition of methane will not add new initiation processes, since methane is stable at these temperatures, but will add a new propagation reaction.

[4] $C_2H_5 + CH_4 \rightarrow C_2H_6 + CH_3$

Thus in the ethylene system, where the ethyl radical is one of the major chain-carrying radicals, methane is converted to ethane.

When the relative amount of methane is small, the actual and relative concentrations of the various radicals in the system will not be altered; only the rate of formation of ethane will be increased. With larger amounts of methane, however, reaction [4] will shift the balance of radicals in favour of the methyl radical and the products of the chain reaction will be altered. As expected under these conditions, propylene becomes the product most affected by the presence of methane. The ratio CH_4/C_2H_4 is therefore an important parameter in the selectivity of the products. Equally important is the concentration of ethylene which controls the overall rate of the reaction. Thus optimum performance of the system with respect to conversion of methane requires a balance between these two factors.

In the earlier study covering the temperature range 774–853 K (7) the conversion of methane and the selectivity of the products was measured as a function of the relative and absolute concentrations of methane and ethylene. Although the selectivity for formation of ethane and propylene was high, the rate of the reaction was too slow to be practical; the limitation was the rate of the initiation of the chain reaction by ethylene. These studies have now been extended to higher temperatures, 925–1123 K, for the purpose of increasing the overall rate of the conversion of methane. Significant changes in the mechanism of the reaction which caused considerable shift in the product distribution were observed in the higher temperature region and this paper describes the results of these studies.

Experimental

The experiments were performed in a static pyrolysis system. A quartz reaction vessel of 0.21 L was placed in the center of a three-zone Lindberg Furnace, Model 54457. Mixtures of reactants were admitted to the reactor by expansion from calibrated volumes. Samples were removed for analysis after the required time of reaction. Details of the procedures for preparation of the mixtures were given previously (7, 9).

Products were analyzed using a Hewlett-Packard Gas Chromatograph Model 5710A with flame detector. Two columns were used to obtain analysis for a wide range of products. A silica gel column (40/60 mesh, 1.5 m × 6.5 mm o.d. copper tubing) at 30°C separated small quantities of the product ethane from the large quantities of the reactants. After elution of the ethylene the column was programmed at 16°C min^{-1} to 250°C and analysis was obtained for benzene and toluene. Other C_6 or C_7 compounds of similar structure, such as cyclohexene or cyclohexadiene, may have been included in these peaks but no attempt at further separation was made. A Durapak column (phenylisocyanate/Porasil C, 80/100 mesh, 6 m × 6.5 mm o.d. copper tubing) maintained at 25°C gave good separation of acetylene, allene, propylene, and butenes. A single peak corresponding to a C_5 compound was also detected and analyzed in certain experiments.

Research Grade methane (99.99%) and Research Grade ethylene (99.99%) were obtained from Matheson Gas Products, Whitby, Ont., and, except for rigorous degassing, were used without further purification. Impurities in the reactants, mainly ethane and acetylene, were too small to affect the kinetics of the reaction but correction to the yields of these products were made where necessary.

Results and discussion

Twenty series of experiments, in which yields of products were measured as a function of the reaction time, were done at the following temperatures: 925, 974, and 1023 K. The conditions of initial pressures of ethylene and methane are summarized in Table 1. The pyrolysis of ethylene alone was also studied at each temperature.

A. Initial stages of the reaction

The main products from the pyrolysis of ethylene alone at 925 K are, in order of importance, butadiene, propylene, ethane, methane, acetylene, and butene-1. This distribution remained much the same at the two higher temperatures except that by 1023 K acetylene replaced propylene as the second most abundant product, next to butadiene. At this temperature butadiene accounted for 80% of the products and acetylene 10%. Examples of the yields of the major products as a function of time at 1023 K in the presence and absence of methane are shown in Figs. 1–4. The reaction was too fast in this temperature range to allow accurate measurement of initial rates under all conditions. Relative initial rates were, however, reliably measured by extrapolation of the ratios of the yields of products to zero time. These ratios are summarized in Table 2.

TABLE 1. Initial pressure of ethylene and ratios of methane/ethylene for each temperature

Temperature (K)	Pressure of ethylene (Torr)	$\frac{CH_4}{C_2H_4}$
925	25	4, 16
	12.5	4, 16
974 and 1023	12.5	4, 16
	6.25	4, 16
	6.5	55

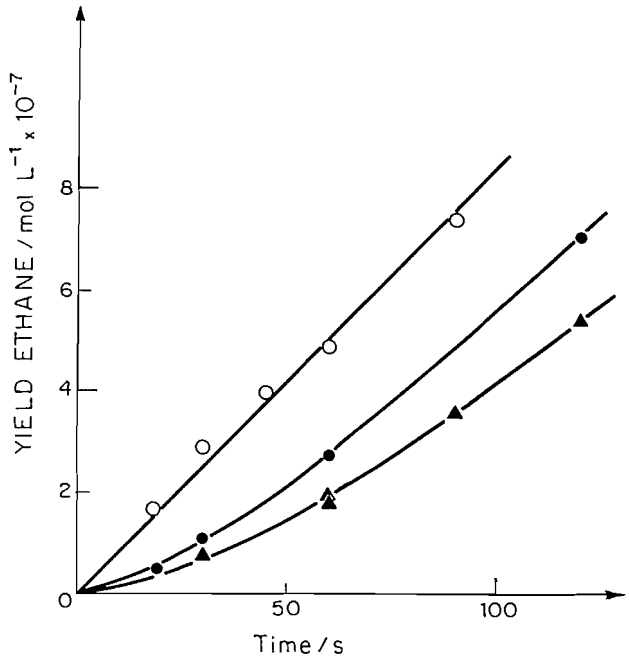

FIG. 1. Yield of ethane as a function of time. Initial pressure of ethylene 12.5 Torr. T = 974 K. Pressure of methane, ○: 0 Torr; ●: 50 Torr; △: 200 Torr.

The mechanism of the thermal reactions of ethylene in the temperature region of 800 K was discussed in an earlier report (7). Following initiation by reaction [1], addition and abstraction reactions of the ethyl and vinyl radicals and addition, isomerization, and decomposition reactions of higher radicals led to the formation of the major products, methane, ethane, propylene, and butene-1. Carbon–carbon bond rupture was the only decomposition process of the radicals which was sufficiently fast to compete with addition to ethylene. In the present experiments the appearance of butadiene and acetylene as major products indicates that at higher temperatures dissociation of radicals by carbon–hydrogen bond splitting is an important loss process. As these dissociation reactions begin to compete effectively with additions to ethylene the product distribution shifts from monoolefins to more unsaturated products, of which butadiene, acetylene, and benzene were the main examples identified in the present experiments. The trend to unsaturation leads also to the formation of polyaromatic

hydrocarbons and eventually to carbon. Thus the yields of the light products approached constant or maximum values with time even at conversions less than 1%. This contrasts with the auto-acceleration of the rates of formation of these products observed in the lower temperature region.

The following simplified mechanism shows these modifications to the mechanism outlined for the low temperature region and accounts for the main features of the reaction in the initial stages.

No decomposition of methane itself was observed under the conditions of the present experiments; its effect is solely as a source of methyl radicals in the propagation reactions, as indicated by reactions [14]–[16]. The occurrence of these reactions completely changed the product distribution. At the highest temperature in the absence of methane, butadiene accounted for ~80% of the products, whereas with the highest pressure of methane the products contained ~85% propylene. Addition of methane increased the rate of formation of propylene, but decreased the rate of formation of all other products. This trend towards increasing importance of propylene in the presence of methane was observed in the previous experiments and was more noticeable at the higher temperatures. At the

lowest temperature, 774 K, methane did not significantly affect the rate of formation of propylene but at 853 K the rate of formation of propylene was increased more than that of ethane.

The rise in importance of propylene is a direct consequence of the participation of methane in the chain propagation reactions. Radical abstraction from methane shifts the radical distribution in favour of methyl radicals at the expense of the ethyl and vinyl radicals and methyl radicals lead directly to propylene. Propylene will therefore become a major product as, with increasing temperature, abstraction is increasingly favoured over addition.

The more surprising observation was that the rates of formation of the other main products, ethane, acetylene, and butadiene, all decreased in the presence of methane. This suggests that abstraction from methane by the radicals depicted in reactions [14] and [15] is not fast enough to compete with their decomposition. Methane therefore reacts mainly with the hydrogen atoms produced in the decomposition rather than with the parent radical. In the absence of methane the hydrogen atoms are converted back to ethyl and vinyl radicals by addition and abstraction from ethylene; in the presence of methane they are converted to methyl radicals. Thus propylene will be formed through reactions [7]–[9] at the expense of the products formed by reactions of the ethyl and vinyl radicals.

On the basis of the simplified mechanism the rates of formation of the main products in the presence of methane are given as follows:

$$[17]\quad R_{C_2H_6} = k_2[C_2H_5][C_2H_4] + k_{14}[C_2H_5][CH_4]$$

$$[18]\quad R_{C_3H_6} = bk_3[C_2H_5][C_2H_4] + ak_8[CH_3][C_2H_4]$$

$$= bk_3[C_2H_5][C_2H_4] + a(1-c)[C_2H_5]\left[bk_3[C_2H_4] + k_{14}[CH_4] + k_{16}K_4\frac{[CH_4]}{[C_2H_4]}\right] + k_{15}[C_2H_3][CH_3]$$

where

$$a = \frac{k_9}{k_{-8}+k_9},\quad b = \frac{k_5}{k_{-3}+k_5},\quad c = \frac{k_7}{k_7+k_8}$$

$$[19]\quad R_{C_2H_2} = k_{13}[C_2H_3]$$

$$[20]\quad R_{C_4H_6} = dk_{10}[C_2H_3][C_2H_4]$$

where

$$d = \frac{k_{11}}{k_{-10}+k_{11}}$$

and

$$[21]\quad [C_2H_3] = [C_2H_5]\left\{\frac{k_2[C_2H_4] + k_{12}K_4 + cbk_3[C_2H_4] + ck_{14}[CH_4] + ck_{16}K_4\frac{[CH_4]}{[C_2H_4]}}{k_{10}[C_2H_4] + (1-c)k_{15}[CH_4] + k_{13}}\right\}$$

and the concentration of hydrogen atoms is controlled through equilibrium of reaction [4].

Table 2 shows that the ratios of the rates of formation of all products to the rate of formation of propylene decrease sharply as methane is added to the system until the ratio of methane/ethylene reaches about four. Further additions of methane have much less effect on the ratios and in some cases a limiting value is obtained. This initial decrease shows that the second term in the expression for the rate of formation of propylene becomes the major contribution to its rate at relatively low ratios of methane/ethylene, before the rates of formation of the other products are affected. With sufficiently large amounts of methane, however, the rates of formation of the other products become dominated by the terms involving methane and the ratios therefore eventually become independent of methane.

This behaviour is illustrated by the ratio $R_{C_2H_6}/R_{C_3H_6}$ shown in Fig. 5 for the three lower temperatures of the previous study and for 925 K. The initial sharp decrease in the ratio observed at 925, 974, and 1023 K was progressively less pronounced with decreasing temperature and in fact at the lowest temperature the ratio increased with additions of methane, but still approached a constant value. These ratios would not be expected to change much with further reaction and the system thus has the advantage of allowing a fixed product distribution by adjustment of the reactant ratio and the temperature.

The limitations of the simplified mechanism are shown by the

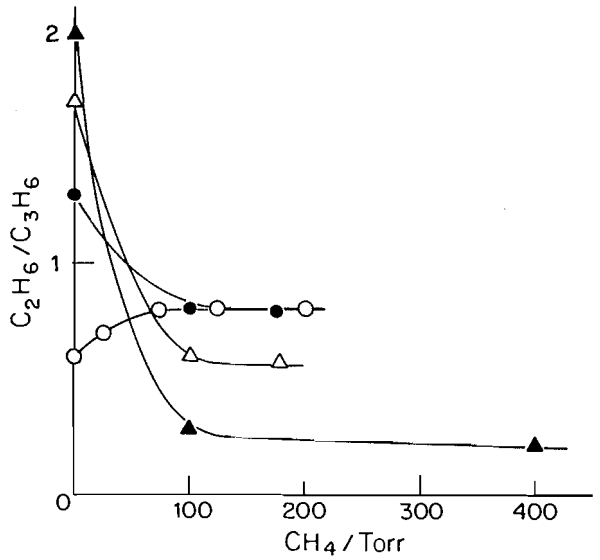

FIG. 5. Ratio of the initial rate of formation of ethane to the initial rate of formation of propylene. Initial pressure of ethylene 25 Torr. Temperature ○: 774 K; ●: 824 K; △: 853 K; ▲: 925 K.

ratios of acetylene/butadiene. These are practically independent of methane concentration, as predicted, except for some increase at the highest ratio of methane to ethylene. They should, however, be inversely proportional to the concentration of ethylene whereas little change in the ratio was observed with a change in the initial concentration of ethylene. A possible loss process for butadiene is the Diels–Alder addition to ethylene. This reaction has been shown to be a major source of cyclic olefins in thermal reactions of ethylene and other light olefins (10) and its occurrence in the present system would act to increase the ratio C_2H_2/C_4H_6 at high pressures of ethylene. An additional source of acetylene could be the alternative decomposition of butenyl radicals,

[22] $C_4H_7 \rightarrow C_2H_2 + C_2H_5$

and the order of the rate of this reaction with respect to ethylene is the same as that for butadiene. Such additional reactions nevertheless represent relatively minor adjustments to the mechanism and it may be concluded that the simple scheme provides a reasonable description of the system.

B. Later stages of the reaction

An important question for this system is the efficiency of the conversion of methane into higher molecular weight products. What fraction of the products arise through reaction with methane and what fraction through reaction with ethylene? A series of experiments was performed at each of the temperatures 974 and 1023 K, using a low pressure of ethylene, 6.5 Torr, and a high pressure of methane, 356 Torr, and allowing the reaction to proceed until the conversion was sufficient to allow quantitative measurement of the amount of ethylene reacted (up to about 15% conversion). At the same time the yields of all products up to C_7 were measured. The relation between the yields of products and the conversion of the reactants is given as follows:

[23] $\Sigma C_{\text{Products}} = \Delta CH_4 + 2\Delta C_2H_4$

At both temperatures propylene was the major product in the initial stages but with increasing conversion passed through a maximum yield and at 1023 K was surpassed by the secondary product, benzene. The results are shown in Figs. 6 and 7.

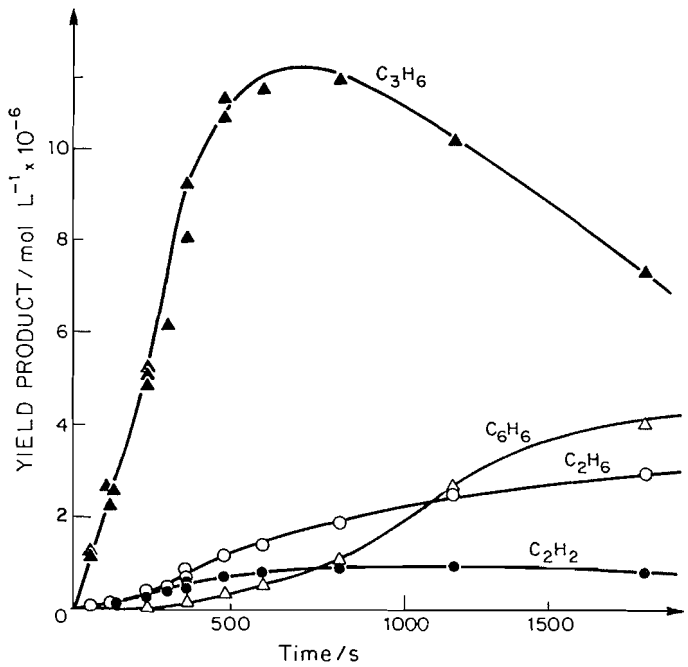

FIG. 6. Yield of products as a function of time at 974 K. Initial pressure of ethylene, 6.5 Torr; initial pressure of methane 356 Torr. ○: C_2H_6; ●: C_2H_2; △: C_6H_6; ▲: C_3H_6.

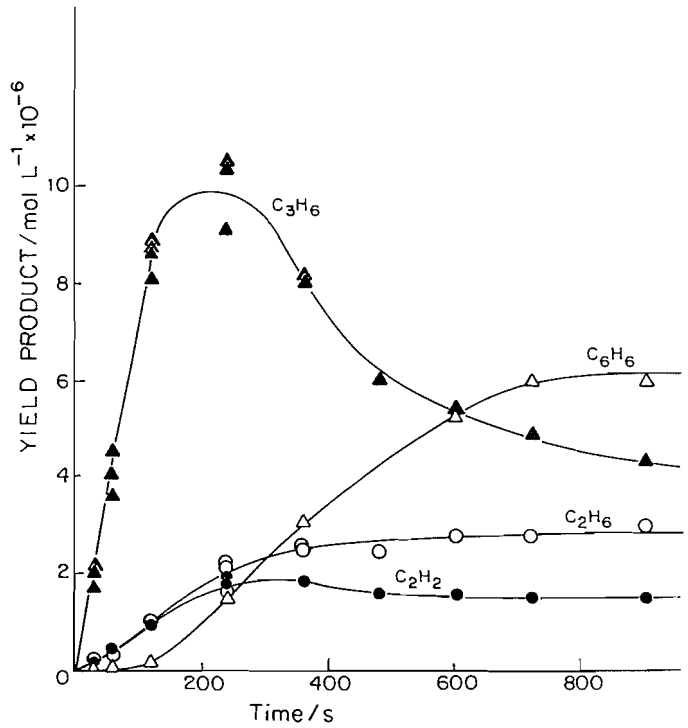

FIG. 7. Yield of products as a function of time at 1023 K. Initial pressure of ethylene 6.5 Torr; initial pressure of methane 356 Torr. ○: C_2H_6; ●: C_2H_2; △: C_6H_6; ▲: C_3H_6.

Butadiene is not shown on these figures because at 1023 K its yield closely matches that of acetylene; at 974 K its yield is slightly less than twice the yield of acetylene. At 1023 K the total quantity of product, expressed as $\Sigma C/2$, is compared to the loss of ethylene over the course of the reaction in Fig. 8. At low conversions the yield of products exceeds the ethylene reacted and the difference represents the product derived from methane

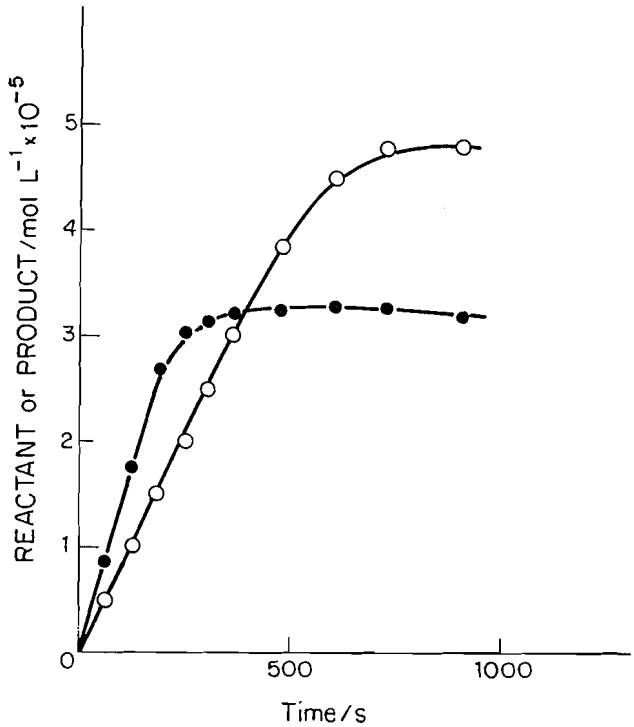

FIG. 8. Relation between ethylene consumed ΔC_2H_4, and total product, $\Sigma C/2$, at 1023 K. Initial pressure of ethylene 6.5 Torr; initial pressure of methane 356 Torr. ○: ΔC_2H_4; ●: $\Sigma C/2$.

according to eq. [23]. At higher conversions the yield of products analyzed (up to C_7) falls below the ethylene consumed and higher molecular weight products, not analyzed, including carbon, are important in this region.

From Fig. 8 the maximum conversion of methane into products occurs at 180 s. At 974 K the maximum occurred at 480 s. Table 3 summarizes the relation between the ethylene reacted and the methane converted for both temperatures. At the maximum, at 974 K, 0.8 mol of methane react for every mole of ethylene, while at 1023 K the ratio is 1.5. This appears to indicate an efficient use of methane, but in the experiments the ratio of methane/ethylene is high, making the percentage conversion of methane low.

An important characteristic of the reaction is the rate of conversion of methane. Because of the small percentage conversion of methane in all the experiments a direct measurement of the rate of conversion was not possible. In the experiments in the lower temperature region the rate of conversion was estimated from the increase in the rate of formation of ethane in the presence of methane. In the higher temperature region the main product increased by the presence of methane is propylene. The rate of loss of methane in these experiments may therefore be estimated from the rate of formation of propylene in the presence, R_a^0, and in the absence, R^0, of methane, as follows:

$$-R_{CH_4} = R_a^0 - R^0$$

The maximum rate of conversion of methane at each temperature, usually obtained at the highest pressure of ethylene, is summarized in Table 4.

Although these rates are below those achieved in catalytic reactions (typically in the neighbourhood of 5% s^{-1}), an important feature of the reaction is that the products are entirely hydrocarbon and no methane is lost to the formation of carbon monoxide or carbon dioxide. The percentage conversion of

TABLE 3. Relation between methane converted and ethylene reacted, $P^0_{C_2H_4} = 6.5$ Torr; $P^0_{CH_4} = 356$ Torr

T (K)	Time of reaction (s)	ΔC_2H_4 (mol L^{-1})	ΣC (mol L^{-1})	ΔCH_4 (mol L^{-1})	$\frac{\Delta CH_4}{\Delta C_2H_4}$
974	480	1.66×10^{-5}	4.61×10^{-5}	1.29×10^{-5}	0.8
1023	180	1.50×10^{-5}	5.33×10^{-5}	2.33×10^{-5}	1.5

TABLE 4. Maximum rate of conversion of methane at each temperature

T (K)	Pressure of ethylene (Torr)	Pressure of methane (Torr)	Rate of conversion (% s^{-1})
774	200	200	1.2×10^{-5}
824	50	350	1.5×10^{-5}
853	50	200	2.0×10^{-5}
925	25	100	1.0×10^{-5}
974	12.5	50	5.0×10^{-3}
1023	12.5	50	1.4×10^{-2}

methane in this system is of necessity low because high concentrations of methane are required to prevent formation of polyaromatic hydrocarbons and carbon. For recovery of the light hydrocarbon products a recycling system would be essential.

Conclusions

As a sensitizer for the conversion of methane, ethylene has certain advantages. The selectivity of the products for ethane or propylene may be controlled through the temperature and the ratio of methane to ethylene. If the conversion is kept low the formation of polyaromatic compounds and carbon can be avoided even at temperatures of 1000 K. The rate of conversion may be increased and controlled through use of additional sensitizers.

Étude chimique et cinétique de l'oxydation homogène en phase gazeuse d'alcanes légers. II. Propane et mécanisme généralisé

B. VOGIN,[1] F. BARONNET[2] ET G. SCACCHI

Département de chimie physique des réactions, Unité de recherche associée n° 328 du Centre national de la recherche scientifique, Institute-national polytechnique de Lorraine – École nationale supérieure des industries chimiques, 1, rue Grandville, BP 451, 54001 Nancy CEDEX, France

Reçu le 31 mai 1990

B. VOGIN, F. BARONNET et G. SCACCHI. Can. J. Chem. **69**, 43 (1991).

Une étude expérimentale détaillée de l'oxydation du propane en phase gazeuse homogène à 350°C et à pression subatmosphérique a été entreprise dans le but d'identifier et de doser les produits primaires principaux de la réaction. Les résultats expérimentaux ont été interprétés par un mécanisme radicalaire en chaînes s'appuyant sur ces résultats et sur l'évaluation des constantes de vitesse des processus élémentaires proposés par les méthodes de la Cinétique Thermochimique. Les processus élémentaires proposés sont discutés et comparés aux observations expérimentales. Les résultats obtenus et leur interprétation font l'objet d'une comparaison avec une étude détaillée de même nature faite sur l'exemple de l'isobutane. Comme dans ce dernier cas, il apparaît deux chemins réactionnels parallèles, l'un prédominant conduisant à l'oléfine conjuguée (ici propylène) et l'autre à la formation de l'époxyde de cette oléfine (ici oxyde de propylène). De substantielles similitudes entre l'oxydation de l'isobutane et celle du propane ont pu être mises en évidence, ce qui renforce la cohérence des résultats obtenus.

Mots clés : oxydation, cinétique, mécanisme réactionnel, propane, cinétique thermochimique.

B. VOGIN, F. BARONNET, and G. SCACCHI. Can. J. Chem. **69**, 43 (1991).

An experimental study of the homogeneous gas phase oxidation of propane at 350°C and subatmospheric pressure has been performed in order to identify and to measure the major primary products of the reaction. The experimental results have been interpreted by a chain radical mechanism, deduced from these results and from estimates of the rate constants for the elementary steps obtained by the methods of Thermochemical Kinetics. The proposed elementary steps are discussed and compared with the experimental observations. The results that we have obtained and their interpretation are compared with a similar detailed investigation performed on the oxidation of isobutane. As in the case of isobutane, two parallel reaction pathways appear, a dominant one leading to the conjugated alkene (propylene) and another one leading to the epoxide of this olefin (here propylene oxide). The oxidation of isobutane and that of propane appear to be quite similar, which corroborates the results that we have obtained.

Key words: oxidation, kinetics, reaction mechanism, propane, thermochemical kinetics.

I. Introduction

I.1. Généralités et rappels

Ce second mémoire fait suite à un premier travail publié sur l'oxydation de l'isobutane (1). Dans ce premier article, nous avions fait une mise au point bibliographique assez complète sur les publications traitant de l'oxydation des alcanes légers. Rappelons seulement que notre objectif est essentiellement de proposer un mécanisme réactionnel suffisamment complet permettant de rendre compte des observations expérimentales effectuées lors de l'oxydation d'alcanes légers vers 300–350°C à relativement faible avancement.

L'étude bibliographique précitée (1) nous avait conduits à conclure que les données publiées dans la littérature ne permettaient pas de construire un mécanisme suffisamment sûr et détaillé. Cette situation nous avait incités à reprendre une étude expérimentale spécifiquement orientée vers les réactions d'oxydation d'alcanes légers à faible avancement.

Nous nous étions d'abord intéressés au cas de l'isobutane (1). Dans le présent travail, nous allons examiner l'exemple du propane et généraliser les conclusions auxquelles nous avons abouti.

I.2. Données bibliographiques de l'oxydation du propane

Il existe un certain nombre d'articles généraux sur les réactions d'oxydation d'alcanes mentionnés dans le mémoire précédent, tels ceux de Pollard (2) et de Benson (3, 4). D'autres travaux de Benson (5, 6) abordent ces questions mais sont plus orientés vers les problèmes liés aux flammes froides ou aux inflammations; une recherche bibliographique a souligné le faible nombre de publications susceptibles d'apporter des réponses aux questions que nous nous posons sur les réactions du propane; c'est ainsi que, dans la mise au point de Pollard (2), aucun article sur la chimie de l'oxydation de cet alcane n'est répertorié.

La majeure partie des articles publiés sur l'oxydation du propane concerne les réactions catalytiques qui ont des applications industrielles plus directes que la réaction non catalytique. Comme dans le cas de l'isobutane, nous avons éliminé les articles correspondant à des études effectuées à trop grand avancement, l'analyse du mécanisme devenant alors quasi impossible, ainsi que les articles décrivant la réaction non-isotherme (flammes froides et inflammations de 2ème stade).

Dans le cas de l'oxydation homogène du propane, il apparaît que les quelques auteurs qui ont étudié la réaction se sont penchés surtout sur les effets de parois. En effet, la grande quantité de CO_2 formée dans les premiers instants de la réaction observée par Shtern et co-auteurs (7–9), ainsi que la formation de propène, ont conduit ces auteurs à associer ces observations à une hétérogénéité de la réaction. Cependant l'addition de gaz inerte ou l'augmentation du rapport surface sur volume du réacteur ne modifiant pas la répartition des produits, ces mêmes auteurs ont conclu, dans une étude postérieure, à l'homogénéité de la réaction, ce qui paraît d'ailleurs plus en accord avec les observations faites sur d'autres alcanes légers, *n*-butane par exemple (10, 11).

Étant donné que notre étude précédente sur l'isobutane suggérait qu'il était illusoire d'appliquer directement les théories de

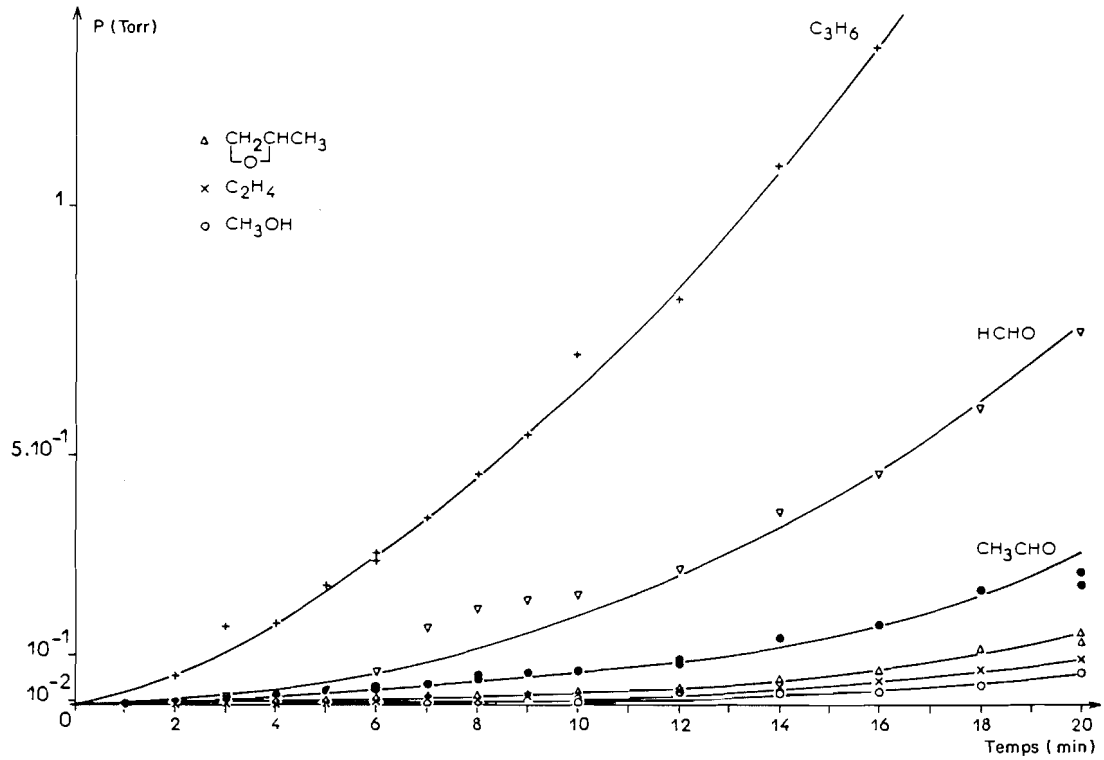

FIG. 1. Oxydation du propane à avancement modéré : courbes de formation des produits principaux en fonction du temps. Pression initiale du mélange équimoléculaire propane–oxygène : 125 Torr. Température de réaction 350°C (623 K).

Fish (12) ou de Knox (13) pour tenter de décrire en détail la chimie du système, une approche rationnelle de l'étude de la réaction d'oxydation du propane à faible avancement nécessitait une investigation expérimentale suffisamment détaillée.

Le choix du propane paraissait justifié également d'un point de vue pratique car il présente l'avantage de posséder un atome de carbone en moins que les butanes, ce qui devrait restreindre la gamme des produits formés et faciliter l'étude expérimentale, en particulier au niveau des analyses.

II. Étude expérimentale de l'oxydation du propane

II.1. Appareillage et analyses

L'appareillage utilisé (réacteur statique à volume constant), le mode opératoire et les méthodes analytiques (chromatographie en phase gazeuse essentiellement) ont été décrits dans notre mémoire précédent (1). Rappelons que le formaldéhyde est dosé par colorimétrie, méthode nettement moins sensible que la chromatographie en phase gazeuse utilisée pour les hydrocarbures, d'où une certaine dispersion des points, car à la moindre sensibilité de la méthode s'ajoutent les erreurs liées au piégeage et à la mise en solution du formaldéhyde formé.

II.2. Conditions expérimentales

La plupart des expériences ont été effectuées à 350°C, à une pression de mélange équimoléculaire C_3H_8/O_2 de 125 Torr (1 Torr = 133,3 Pa), dans un réacteur de Pyrex de 250 cm^3, pour des temps de réaction généralement compris entre 1 et 20 min; l'avancement de la réaction est voisin de 1% pour un temps de réaction de 5 min.

Contrairement au cas de l'isobutane, nous n'avons pas jugé nécessaire de redéterminer un diagramme pression–température, de tels diagrammes ayant été établis à plusieurs reprises par différents auteurs (14–16). Celui de Newitt et Thornes (14) est d'ailleurs un «classique» figurant dans de nombreux ouvrages. À partir de ces diagrammes, corroborés par des modélisations (17), nous avons pu vérifier que les conditions choisies correspondent à une zone de réaction lente.

Les problèmes liés à la reproductibilité des expériences avaient fait l'objet d'investigations détaillées dans le cas de l'isobutane; l'oxydation du propane n'appelle pas de commentaires particuliers de ce point de vue, compte-tenu de l'expérience acquise avec l'isobutane. Comme le montrent les points représentatifs de la formation des produits en fonction du temps, la reproductibilité des expériences apparaît suffisante pour l'étude entreprise.

Par ailleurs nous avons décidé d'étudier directement la réaction à faible avancement, compte-tenu des études faites avec l'isobutane; en effet, nos méthodes d'analyse permettent de mettre en évidence avec une sûreté suffisante les produits primaires principaux de la réaction. Il ne paraissait donc pas nécessaire de faire des bilans à plus fort avancement (de façon à ce qu'ils soient significatifs) entre propane consommé et produits formés. Ceci justifie les conditions expérimentales indiquées précédemment.

II.3. Résultats expérimentaux pour les mélanges propane–oxygène

Les produits dosés se composent d'hydrocarbures : propène, éthylène et méthane, et de produits oxygénés : formaldéhyde, acétaldéhyde, propionaldéhyde, acétone, méthyloxiranne, oxétanne, monoxyde et dioxyde de carbone et eau oxygénée. Le dosage de l'eau présentant des difficultés, les quantités d'eau formée n'ont pas été déterminées, mais sa production est relativement importante.

Les courbes de formation au cours du temps des produits sont rassemblées sur les figures 1–3 comportant des échelles différentes.

Afin de déterminer la nature primaire ou secondaire des produits dosés, nous avons établi figure 4 un «diagramme horizontal» où nous avons représenté en fonction du temps le pourcentage molaire de chaque produit dosé (pression du produit considéré divisée par la somme des pressions des produits dosés) à l'exclusion des réactifs et de l'eau; ceci ne donne que des valeurs relatives puisque l'eau n'est pas comptabilisée et, en particulier, il n'est pas possible de remonter à partir de ce diagramme à des équations stoechiométriques.

Les produits qui s'extrapolent à une valeur non nulle pour $t = 0$ peuvent être considérés comme les produits primaires de la réaction.

La gamme de produits primaires comprend donc le propène, le formaldéhyde, l'acétaldéhyde, l'eau oxygénée, le méthyloxiranne et peut-être l'éthylène.

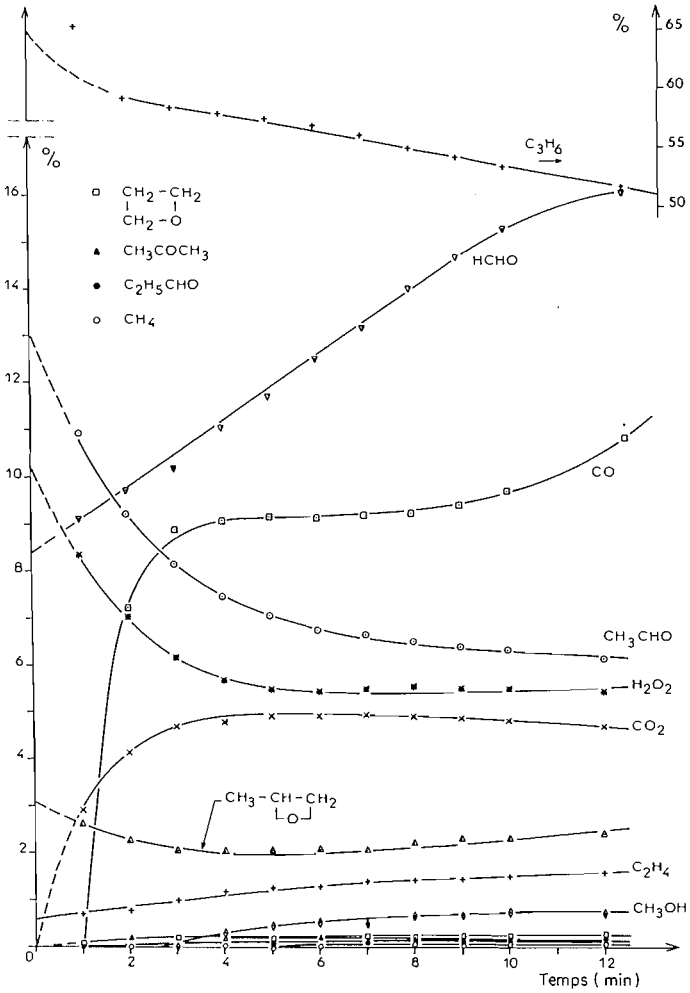

FIG. 4. Représentation du pourcentage molaire des différents produits : pression du produit i/Σ(pressions des produits mesurés) en fonction du temps. Mêmes conditions expérimentales que fig. 1 (l'eau est exclue de cette représentation).

Par ailleurs, les produits secondaires sont composés de monoxyde et dioxyde de carbone, méthanol, oxétanne, acétone, propionaldéhyde et méthane. Le tableau 1 regroupe les estimations du pourcentage initial de ces produits, ainsi qu'à 5 min de réaction (colonnes propane seul).

II.4. Résultats expérimentaux pour les mélanges propane–propène–oxygène

Compte-tenu de la réactivité des alcènes, il paraît logique de supposer que l'alcène conjugué formé lors de l'oxydation d'un alcane s'oxyde à son tour, et vient superposer son mécanisme à celui de l'alcane. Il peut ainsi devenir difficile de déterminer l'origine exacte des produits lorsqu'il y a ambiguïté possible, comme c'est souvent le cas. Nous avons tenté de lever en partie la difficulté en étudiant l'oxydation de l'alcane à très faible avancement pour éviter certaines réactions secondaires parasites. Pour essayer de cerner de plus près la nature des produits formés, nous avons décidé d'effectuer l'étude de l'oxydation du mélange alcane – alcène conjugué en ajoutant du propène au propane dans la proportion de 5% de la pression totale des hydrocarbures, le rapport hydrocarbures–oxygène restant fixé à 1 pour modifier le moins possible le comportement du système par rapport à l'oxydation de l'alcane seul. De même, la température de réaction est maintenue à 350°C et la pression initiale à 125 Torr.

Les courbes de formation au cours du temps des produits de l'oxydation commune propane–propène sont rassemblées sur les figures 5–7 comportant des échelles différentes.

TABLEAU 1. Pourcentages molaires des produits formés dans l'oxydation du propane et de mélanges propane–propène (5% de propène) à 5 min de réaction et extrapolés à avancement nul ($t = 0$), d'après les figures 4 et 8

	Pourcentages molaires			
	Mélange propane–propène		Propane seul	
Produit	$t = 0$	$t = 5$ min	$t = 0$	$t = 5$ min
CH_4	0	0,1	0	0
C_2H_4	2,5	3,4	0,6	1,2
C_3H_6	[9,6]	17,0	64,8	57,4
HCHO	[37,5]	23,9	8,4	11,7
CH_3CHO	9,4	9,1	13,0	7,0
C_2H_5CHO	0	0,2	0	0,1
CH_3COCH_3	Traces	0,1	Traces	0,2
CH_3OH	0	0,9	0	0,5
CO	0	15,0	0	9,2
CO_2	0	6,0	0	4,9
H_2O_2	[30,0]	13,7	10,2	5,5
$CH_3-CH-CH_2$ (O)	10,3	9,9	3,0	2,1
CH_2-CH_2 / CH_2-O	0,7	0,7	Traces	0,2
Total	[100,0]	100,0	100,0	100,0

La distinction des produits primaires est à nouveau réalisée par la construction d'un diagramme horizontal représentant le pourcentage du produit considéré (rapporté à la somme des produits dosés) en fonction du temps (fig. 8). Les valeurs utilisées pour ce diagramme sont obtenues après lissage des valeurs expérimentales par le tracé de courbes optimales : celles des figures 5–7.

Nous pouvons à nouveau tenter une détermination des produits primaires : formaldéhyde, eau oxygénée, méthyloxiranne, acétaldéhyde, propène, éthylène et oxétanne, et secondaires : méthane, propionaldéhyde, acétone, méthanol, monoxyde et dioxyde de carbone.

Les pourcentages initiaux et à 5 min de réaction, sont rapportés dans le tableau 1, où figurent aussi les valeurs des mêmes grandeurs dans le cas de l'oxydation du propane seul.

Il faut noter que la valeur du pourcentage donnée pour le propène dans le cas de l'oxydation du mélange propane–propène n'a guère de signification. D'une part, elle résulte de la différence de deux valeurs du même ordre de grandeur (valeur du dosage – valeur de la quantité initiale) ce qui donne un résultat très faible et par conséquent une incertitude d'un niveau très élevé. D'autre part, ce résultat lui-même représente en réalité la différence entre la quantité de propène produite par la réaction d'oxydation du propane et la quantité consommée par oxydation du propène. Il est donc préférable de comparer les pourcentages relatifs des produits en excluant le propène. Les valeurs correspondantes figurent dans le tableau 2. Ce même tableau mentionne les rapports des pourcentages initiaux des produits primaires : pourcentage pour l'oxydation du mélange propane–propène divisé par le pourcentage pour l'oxydation du propane seul, le propène étant toujours exclu des calculs. On observe alors que l'ajout de propène favorise la formation d'éthylène, de formaldéhyde, d'eau oxygénée, de méthyloxiranne et d'oxétanne, tandis que celle de l'acétaldéhyde est fortement diminuée, ce qui est contraire à des hypothèses utilisées dans des modélisations antérieures (17).

Comme pour l'oxydation de l'isobutane, nous allons proposer un mécanisme qui sera confronté aux résultats expérimentaux.

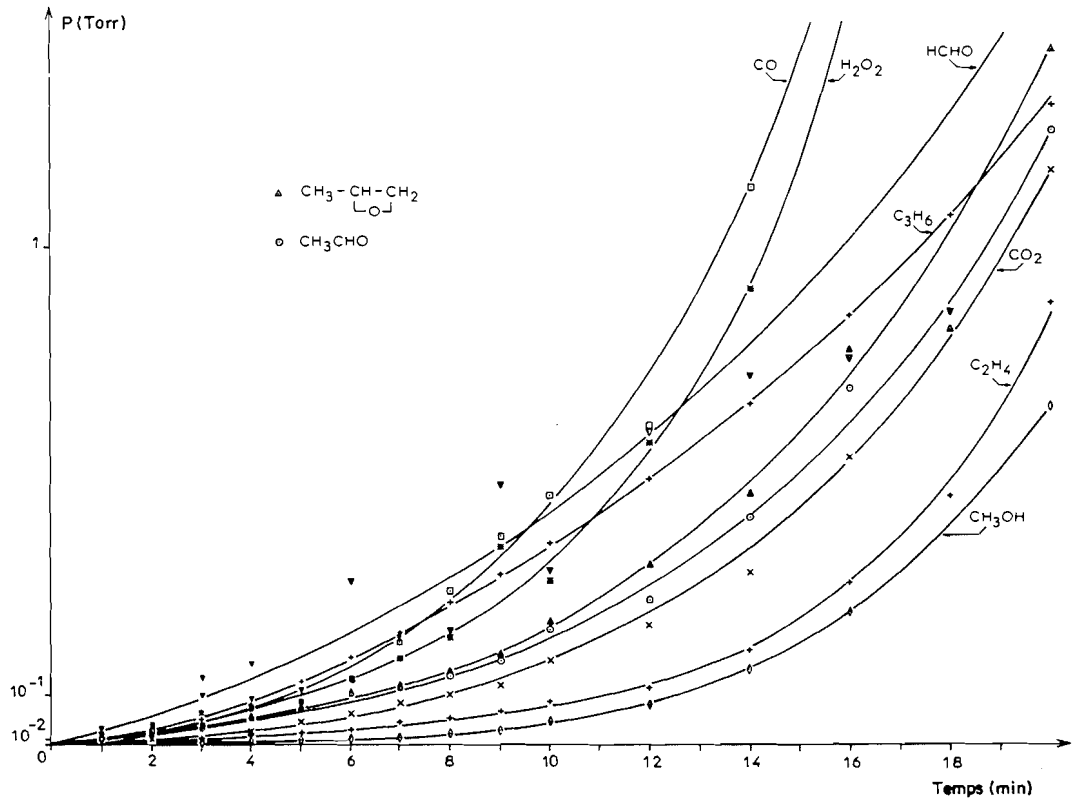

FIG. 5. Oxydation du mélange propane–propène à 5% de propène

$$\frac{\text{propène}}{\text{propène + propane}} = 0{,}05 \qquad \frac{\text{propène + propane}}{\text{propène + propane + oxygène}} = 1$$

Courbes de formation des *produits principaux* en fonction du temps. Pression initiale 125 Torr. Température : 350°C (623 K).

III. Détermination du mécanisme de la réaction et commentaires

III.1. Détermination du mécanisme[3]

Nous avons suivi la même méthodologie que dans l'étude conduite dans le cas de l'isobutane (1) en nous appuyant d'une part sur les résultats expérimentaux et d'autre part sur les connaissances fondamentales acquises en chimie radicalaire, en utilisant également les techniques d'estimation des constantes de vitesse des processus élémentaires. Ici encore, ce que nous cherchons à écrire, ce ne sont pas des réactions globales mais des processus élémentaires vrais compatibles avec les principes de la cinétique (réversibilité microscopique, moindre changement de structure, etc...) et les données récentes acquises en thermochimie. Comme dans le cas de l'isobutane, les processus retenus tiennent compte aussi des schémas généraux écrits par d'autres auteurs (Fish (12) et Knox (13) en particulier) pour rendre compte des oxydations d'alcanes.

Nous avons cherché à écrire le mécanisme réactionnel de manière rationnelle et systématique, en analysant les diverses catégories de processus élémentaires pouvant intervenir, compte-tenu de la structure des radicaux dérivés de la molécule de propane par arrachement d'hydrogène.

Amorçage

Deux formes isomères du radical propyle $C_3H_7\cdot$ (*iso*- et *n*-) sont susceptibles d'être formées par la réaction :

$$C_3H_8 + O_2 \longrightarrow C_3H_7^{\bullet} + HO_2^{\bullet}$$

généralement retenue comme amorçage primaire dans les réactions d'oxydation en phase gazeuse homogène, bien que sujette à controverse et discutée par certains auteurs (4, 5) en ce qui concerne en particulier les valeurs préconisées pour sa constante de vitesse. En réalité ce point n'est pas fondamental car très rapidement le relais de l'amorçage est pris par les branchements dégénérés.

Les radicaux susceptibles d'être formés sont donc :

(i) par arrachement d'un des deux atomes d'hydrogène secondaires :

$CH_3—{}^{\bullet}CH—CH_3$ radical isopropyle : $(R^{1\bullet})$ ou $i\text{-}C_3H_7^{\bullet}$

$DH^0\ (iC_3H_7 - H) = 95{,}0$ kcal mol^{-1} (18,21)

(ii) par arrachement d'un des six atomes d'hydrogène primaires :

$CH_3—CH_2—{}^{\bullet}CH_3$ radical *n*-propyle : $(R^{2\bullet})$ ou $n\text{-}C_3H_7^{\bullet}$

$DH^0\ (nC_3H_7 - H) = 98{,}0$ kcal mol^{-1} (18,21)

À 350°C, la formation du radical isopropyle est environ 5,5 fois plus rapide que celle du radical *n*-propyle, compte-tenu de la différence des énergies d'activation des deux processus et du nombre d'atomes d'hydrogène arrachables dans les deux cas.

Addition d'une molécule d'oxygène sur les radicaux alcoyle. On considère ensuite l'addition réversible de l'oxygène sur les radicaux isopropyle et *n*-propyle :

$$R^{\bullet} + O_2 \underset{}{\overset{(2)}{\rightleftharpoons}} RO_2^{\bullet}$$

Les deux radicaux peroxyalcoyle obtenus sont :

$CH_3—\underset{\displaystyle OO^{\bullet}}{\underset{|}{CH}}—CH_3$ et $CH_3—CH_2—CH_2OO^{\bullet}$

$(R^1O_2^{\bullet})$ $(R^2O_2^{\bullet})$

3. Dans l'ensemble de ce travail nous utiliserons les unités : L, mol, s, kcal.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

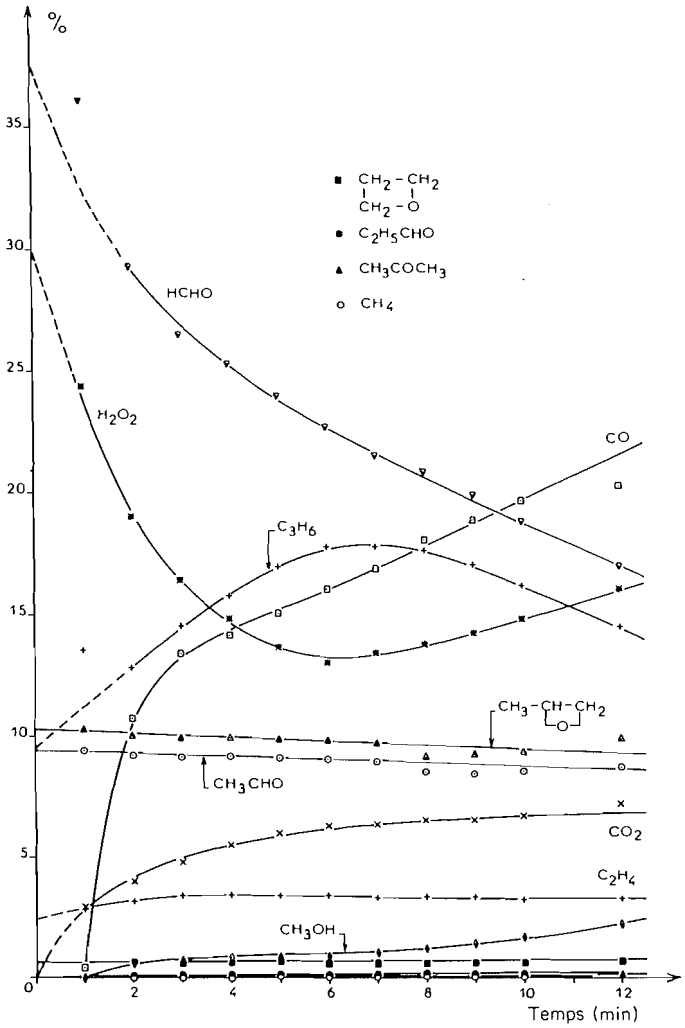

FIG. 8. Représentation du pourcentage molaire en fonction du temps des différents produits formés dans l'oxydation du mélange propane–propène. Mêmes conditions expérimentales que fig. 5.

et ils sont supposés se former avec la même vitesse, comme toute oxydation de radical alcoyle.

Isomérisation des radicaux peroxyalcoyle. En accord avec les schémas retenus par Fish (12), les radicaux peroxyalcoyle sous les deux formes isomères $R^1O_2\cdot$ et $R^2O_2\cdot$, comme dans le cas de l'isobutane, peuvent s'isomériser par transfert interne d'hydrogène en radicaux hydroperoxyalcoyle ·QOOH

$$RO_2\cdot \underset{}{\overset{(3)}{\rightleftharpoons}} \cdot QOOH$$

Ces processus d'isomérisation des deux formes isomères des radicaux peroxyalcoyle conduisent à 5 formes de radicaux hydroperoxyalcoyle $\cdot Q^1OOH$–$\cdot Q^5OOH$ par formation de complexes activés à 6 centres (réaction (3.4)),[4] à 5 centres (réactions (3.1) et (3.3)) et à 4 centres (réactions (3.2) et (3.5)). Ces deux derniers processus sont négligeables devant les autres en raison de l'énergie d'activation élevée nécessaire à la formation du complexe activé à 4 centres.

Les formules semi développées de ces cinq formes seront données ultérieurement dans le tableau 6 qui récapitule les valeurs des grandeurs thermodynamiques nécessaires à l'estimation des constantes de vitesse. Les processus (3.3) et (3.4) issus tous deux du radical $nC_3H_7COO\cdot(R^2O_2\cdot)$ apparaissent plus rapides que le processus (3.1) selon les calculs des constantes de vitesse qui seront donnés plus loin dans le tableau 7. Cette tendance n'est pas compensée par les valeurs des constantes d'équilibre présentées dans le tableau 3, si l'on tient compte du rôle des processus inverses.

Les concentrations des radicaux $\cdot Q^3OOH$ et $\cdot Q^4OOH$ seraient donc a priori plus élevées que celle de $\cdot Q^1OOH$, renversant ainsi l'ordre d'importance estimé à première vue à partir de la facilité de formation des radicaux alcoyle.

Formation des produits de réaction

À partir des différentes formes isomères des radicaux ·QOOH, nous proposons dans le tableau 4 les différents processus élémentaires possibles, y compris dans le souci d'être complet, ceux qui pourraient a priori être considérés comme négligeables; ils portent des numéros supérieurs à 4.7 (cf. tableaux 8 et 9).

Pour interpréter la formation d'aldéhydes, il paraît logique de tenir compte de la décomposition des deux radicaux alcoxy $RO\cdot$ ($R^1O\cdot$ et $R^2O\cdot$) obtenus par dismutation des radicaux peroxyalcoyle $R^1O_2\cdot$ et $R^2O_2\cdot$.

Ces réactions de dismutation sont souvent envisagées et leur constante de vitesse peut être estimée proche de $10^{9,5}$ L mol^{-1} s^{-1}.

Les données relatives aux radicaux alcoxy figurent dans le tableau 5.

Les remarques que nous avons faites dans le cas de l'isobutane (1) demeurent valables dans le cas du propane. Ici encore, l'écriture de *tous* les processus élémentaires possibles conduirait à un mécanisme global particulièrement complexe qui ne serait que d'une efficacité très limitée, voire inexistante, pour interpréter nos résultats expérimentaux. Ce que nous cherchons, c'est à simplifier ce schéma réactionnel pour déterminer les réactions élémentaires *essentielles* permettant de rendre compte des caractéristiques cinétiques et chimiques observées expérimentalement. Il va de soi que les concentrations relatives des diverses espèces radicalaires permettent une première simplification.

Mais, pour mener à bien cette simplification, il faudrait disposer aussi des constantes de vitesse de tous les processus élémentaires pouvant être écrits. Les données disponibles dans la littérature sont généralement incomplètes et peu précises et il peut se poser des problèmes de cohérence entre ces données.

Nous avons donc utilisé à nouveau, comme dans le cas de l'isobutane (1), la méthode semi-empirique d'estimation des constantes de vitesse développée par Benson sous le nom de Cinétique Thermochimique (18). Rappelons que ces méthodes nécessitent d'abord l'estimation des grandeurs thermodynamiques (ΔH^0_f, S^0, C_p^0) par des méthodes d'additivité de groupes pour les molécules ou en tenant compte des paramètres structuraux pour les espèces radicalaires (méthode dite du composé modèle).

Dans cet exemple, nous avons effectué les calculs de ΔH^0_f et S^0 à 300 K; ils sont utilisés à 623 K sans corrections en raison du nombre important de valeurs de C_p^0 non tabulées. Remarquons que les variations en fonction de la température sont généralement relativement faibles et que les erreurs sur ΔH^0 et ΔS^0 se compensent, au moins en partie, lors du calcul de ΔG^0.

Les résultats des calculs des grandeurs thermodynamiques sont donnés dans le tableau 6.

À partir de la relation entre ces grandeurs thermodynamiques

4. La numérotation des réactions correspond à celle des tableaux 8 et 9 présentés plus loin.

Total	100,0	100,0	100,0	100,0	

TABLEAU 3. Constantes d'équilibre à 623 K et tailles des cycles dans l'état de transition lors de l'isomérisation des radicaux peroxyalcoyle ($R^1O_2\cdot$ et $R^2O_2\cdot$) dérivés du propane en radicaux hydroperoxyalcoyle ·QOOH

Réaction	Constante d'équilibre	Taille du cycle dans l'état de transition	Radical formé
3.1	$1{,}25\cdot10^{-2}$	5	$\cdot Q^1OOH$
3.2	13	4	$\cdot Q^2OOH$
3.3	0,11	5	$\cdot Q^3OOH$
3.4	$6{,}0\cdot10^{-3}$	6	$\cdot Q^4OOH$
3.5	1,24	4	$\cdot Q^5OOH$

ΔH^0 et ΔS^0 et la constante d'équilibre K

$$-RT \ln K = \Delta H^0 - T\Delta S^0$$

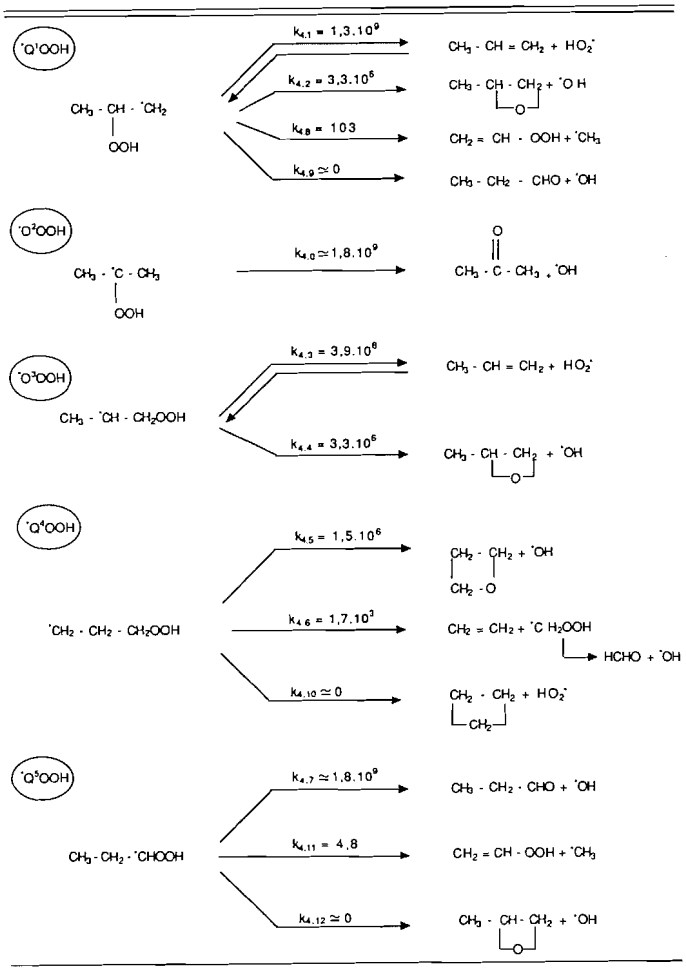
la connaissance de ΔH^0, ΔS^0 et de la constante de vitesse de la réaction directe k_d ou inverse k_i conduit à l'estimation de la valeur de l'autre, ce qui suppose souvent des approximations raisonnables obtenues par des analogies avec des réactions voisines.

Les résultats de l'évaluation des grandeurs cinétiques sont donnés dans le tableau 7.

Dans ce tableau, nous donnons les valeurs estimées à l'aide des calculs décrits précédemment du facteur préexponentiel A, de l'énergie d'activation E et de la constante k calculée à 623 K (unités : L, mol, s).

Les processus élémentaires, écrits en tenant compte de l'expérience antérieure dans des systèmes voisins (1) et des connaissances acquises en chimie radicalaire, que nous avons retenus, compte-tenu de la discussion précédente et de l'estimation des constantes de vitesse calculées à 623 K, sont donnés dans les tableaux 8 et 9, le premier présentant les processus

TABLEAU 4. Processus élémentaires de décomposition des radicaux hydroperoxyalcoyle ·QOOH intervenant dans l'oxydation du propane



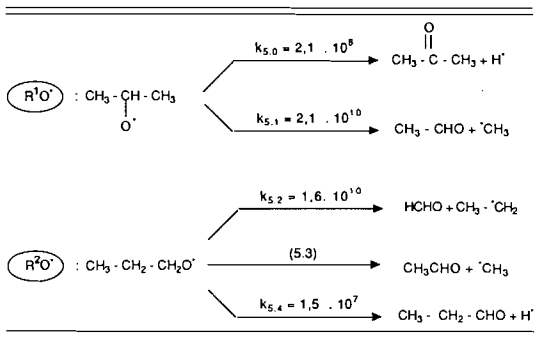


TABLEAU 5. Processus élémentaires de décomposition des radicaux alcoxy à 3 atomes de carbone susceptibles de figurer dans le schéma d'oxydation du propane

élémentaires générés à partir du radical isopropyle, le second à partir du radical *n*-propyle.

III.2. Commentaires sur le mécanisme et discussion

Généralités

Il serait fastidieux de discuter ici chaque chemin réactionnel retenu, d'une part par rapport aux autres chemins réactionnels possibles et d'autre part en le comparant avec les formations de produits observées expérimentalement, d'autant plus que des formations de nature secondaire, au sens cinétique du terme, peuvent compliquer cette analyse. Une telle comparaison détaillée a été faite dans un mémoire de thèse (25); nous n'en donnerons ici que les points les plus importants.

Une première étape dans une telle comparaison est d'estimer les rapports des concentrations des radicaux ·QOOH, en utilisant des calculs effectués à partir de l'approximation de l'état quasi-stationnaire, compte-tenu de l'estimation des constantes de vitesse mentionnée précédemment. Ces calculs font apparaître en particulier des écarts substantiels par rapport aux concentrations évaluées à partir des équilibres isolés. C'est le cas par exemple pour les radicaux $\cdot Q^1OOH$ à la suite du processus (4.1)

(4.1) $CH_3—\underset{\underset{OOH}{|}}{CH}—\cdot CH_2 \longrightarrow CH_3—CH{=}CH_2 + HO_2\cdot$

qui, par sa constante de vitesse élevée ($1{,}3 \times 10^9$), agit comme une sorte de «pompe à radicaux». L'équilibre isolé $(\cdot Q^1OOH)/(R^1OO\cdot)$ peut être estimé à $1{,}25 \times 10^{-2}$ alors que dans notre schéma réactionnel la valeur du rapport des concentrations stationnaires serait de l'ordre de $1{,}9 \times 10^{-5}$ dans nos conditions expérimentales.

Un phénomène analogue est observé avec $\cdot Q^3OOH$ puisque l'on obtient un rapport $(\cdot Q^3OOH)/(R^2OO\cdot)$ voisin de 0,11 à l'équilibre isolé alors que dans notre schéma réactionnel nous obtenons une valeur du rapport des concentrations stationnaires de $(\cdot Q^3OOH)$ et $(R^2OO\cdot)$ voisine de $2{,}4 \times 10^{-4}$, suite à un déplacement analogue dû au processus (4.3):

(4.3) $CH_3—\cdot CH—CH_2—OOH \longrightarrow CH_3—CH{=}CH_2 + HO_2\cdot$

avec $k_{4.3} \cong 3{,}9 \times 10^8$.

On peut obtenir les rapports des concentrations des radicaux hydroperoxyalcoyle en éliminant dans les calculs les concentrations des radicaux peroxyalcoyle. Il apparaît ainsi que pour un radical $\cdot Q^1OOH$, il y a $1{,}2 \times 10^{-5}$ radical $\cdot Q^2OOH$ et que pour un radical $\cdot Q^3OOH$, il y a 20 radicaux $\cdot Q^4OOH$ et $1{,}7 \times 10^{-7}$ radical $\cdot Q^5OOH$, toujours dans les conditions de l'état quasi-stationnaire. Les concentrations des radicaux $\cdot Q^2OOH$ et $\cdot Q^5OOH$ sont donc négligeables. Il est également possible de comparer la concentration des radicaux $\cdot Q^1OOH$ à celles des radicaux $\cdot Q^3OOH$ et $\cdot Q^4OOH$.

Pour un radical $\cdot Q^1OOH$, il y a :

$1{,}2 \times 10^{-5}$ radical $\cdot Q^2OOH$

1,3 radical $\cdot Q^3OOH$

26 radicaux $\cdot Q^4OOH$

$2{,}1 \times 10^{-7}$ radical $\cdot Q^5OOH$

Le radical hydroperoxyalcoyle prépondérant est donc $\cdot Q^4OOH$, $\cdot CH_2$-CH_2-CH_2-OOH, ce qui paraît logique puisqu'il n'est pas consommé par un processus rapide.

TABLEAU 6. Grandeurs thermodynamiques (ΔH^0_f et S^0) pour les espèces intervenant dans le mécanisme proposé d'oxydation du propane (calcul à 300 K)

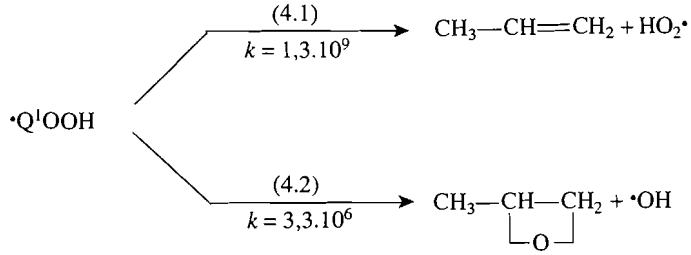
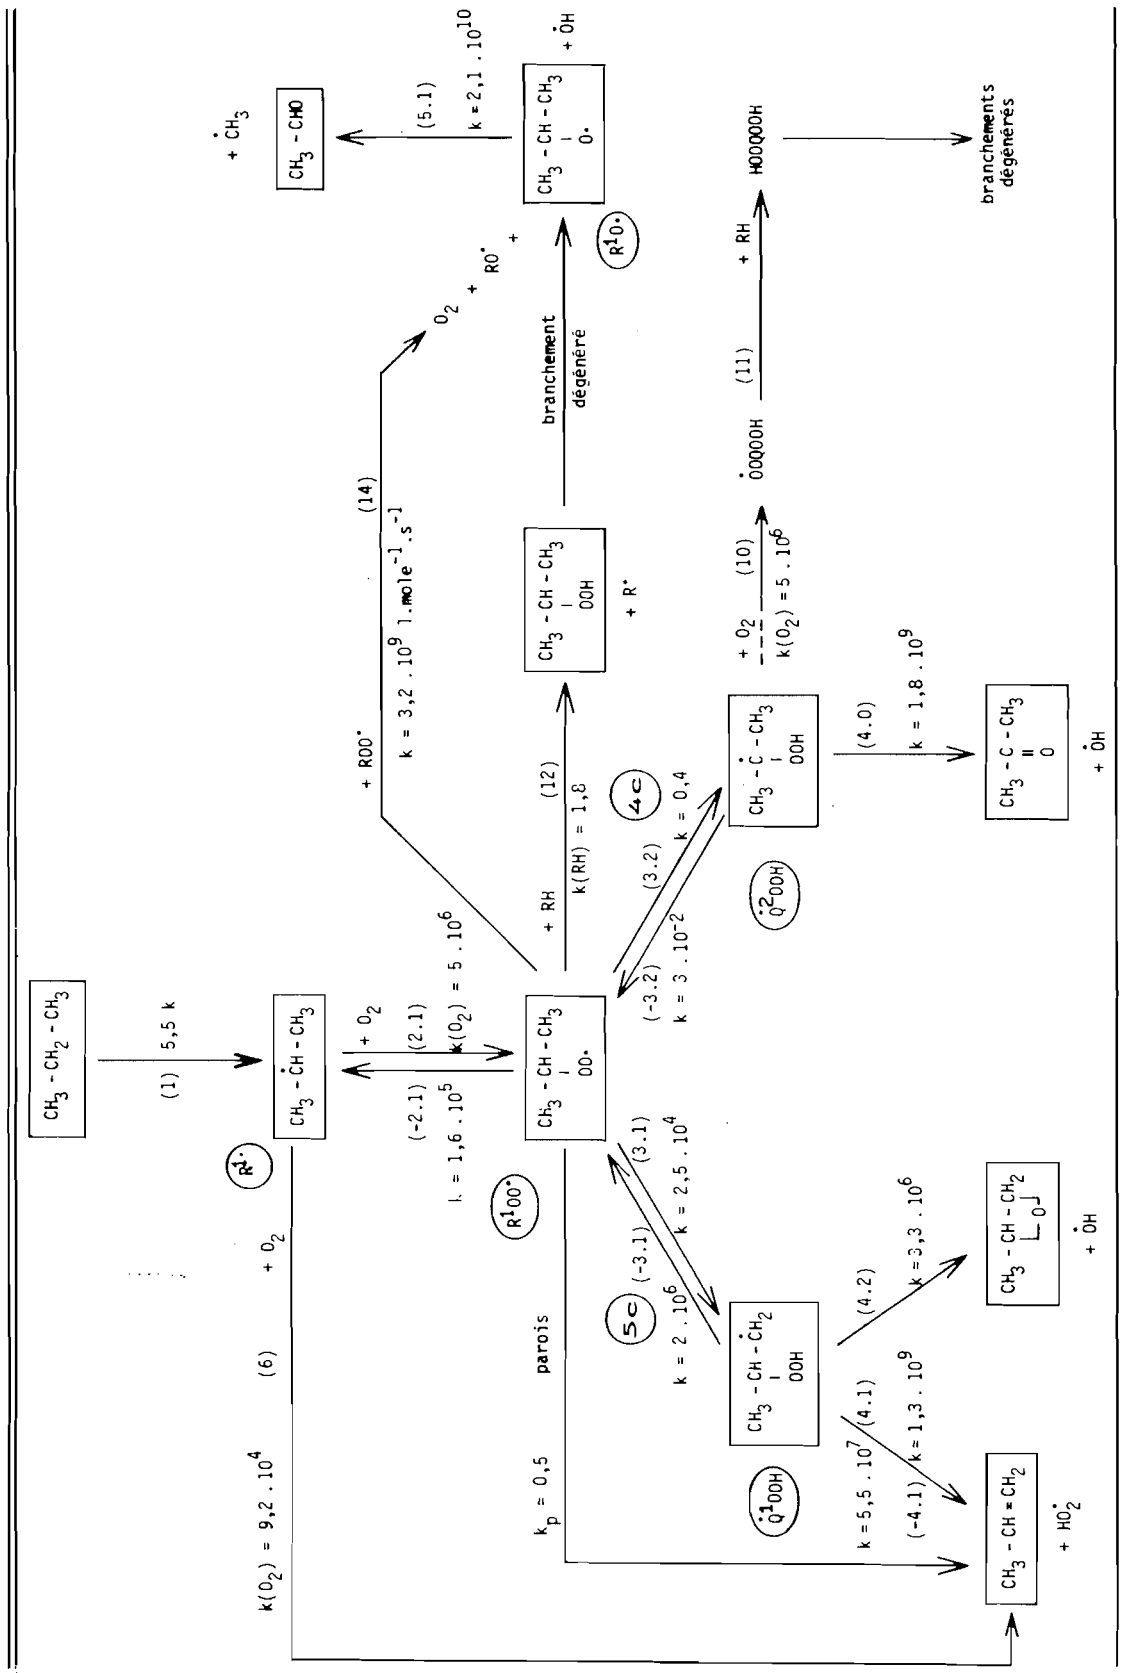
[a]Pour l'arrachement d'un atome H primaire.
[b]Pour l'arrachement d'un atome H secondaire.
[c]Pour l'arrachement d'un atome H tertiaire.



Il est certain que pour vérifier l'adéquation du mécanisme proposé et de l'expérience, l'idéal serait de simuler la formation de l'ensemble des produits formés, pour obtenir en particulier les courbes de pressions partielles des produits en fonction du temps, en effectuant les ajustements requis des valeurs numériques des constantes de vitesse. Une première tentative faite dans ce sens (26) a montré la complexité du problème, tant au niveau des méthodes numériques requises qu'à celui de l'ajustement des constantes puisque les méthodes de Benson ne conduisent qu'à une valeur approximative.

Il nous a donc paru plus réaliste de nous borner dans le cadre de ce mémoire à étudier de manière plus qualitative un certain nombre d'exemples caractéristiques.

Comparaison des formations de propène et de méthyloxiranne



Les chaînes issues des deux radicaux alcoyle produisent conjointement le propène et le méthyloxiranne :

À partir du radical ·Q^{1}OOH :

For personal use only.

TABLEAU 9. Mécanisme d'oxydation du propane (processus élémentaires issus du radical *n*-propyle, CH_3-CH_2-·CH_2)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

À partir du radical $\cdot Q^3OOH$:

$$\cdot Q^3OOH \xrightarrow[k = 3{,}9.10^8]{(4.3)} CH_3{-}CH{=}CH_2 + HO_2\cdot$$

$$\cdot Q^3OOH \xrightarrow[k = 3{,}3.10^6]{(4.4)} CH_3{-}\underset{\displaystyle O}{\underset{|}{CH}}{-}CH_2 + \cdot OH$$

En négligeant les réactions inverses on obtient le rapport des vitesses de formation :

$$\frac{v_{C_3H_6}}{v_{MeOx}} = \frac{k_{4.1}(\cdot Q^1OOH) + k_{4.3}(\cdot Q^3OOH)}{k_{4.2}(\cdot Q^1OOH) + k_{4.4}(\cdot Q^3OOH)} = \frac{k_{4.1} \times 0{,}78 + k_{4.3}}{k_{4.2} \times 0{,}78 + k_{4.4}}$$

$$\frac{v_{C_3H_6}}{v_{MeOx}} = \frac{1{,}3.10^9 \times 0{,}78 + 3{,}9.10^8}{3{,}3.10^6 \times 0{,}78 + 3{,}3.10^6} \cong \boxed{240}$$

Remarque : le propène est produit en quantités pratiquement équivalentes par les deux processus (4.1) et (4.3).

La valeur expérimentale du rapport des vitesses de formation correspond au rapport des pourcentages initiaux des deux produits :

$$\frac{\%C_3H_6}{\%MeOx} = \frac{64{,}8}{3} \cong \boxed{22}$$

On retrouve les ordres de grandeur obtenus lors de l'étude de l'isobutane et on peut donc admettre également une concordance relativement bonne entre les résultats expérimentaux et les valeurs estimées par la cinétique thermochimique.

Nous n'avons pas tenu compte des parts de propène susceptible d'être formé par la voie oléfinique (6) et aux parois, car elles sont négligeables :

Processus oléfinique :

$$R^{1}\cdot + O_2 \xrightarrow{(6)} C_3H_6 + HO_2\cdot \qquad k_6 \cong 5.10^6\ L\ mol^{-1}\ s^{-1} \quad (23)$$

$$R^{2}\cdot + O_2 \xrightarrow{(6)} C_3H_6 + HO_2\cdot \qquad \Rightarrow k_6(O_2) \cong 8.10^3\ s^{-1}$$

Réactions aux parois :

$$R^1OO\cdot \xrightarrow{\text{parois}} C_3H_6 + HO_2\cdot \qquad k_p \cong 0{,}5\ s^{-1} \quad (24)$$

$$R^2OO\cdot \xrightarrow{\text{parois}} C_3H_6 + HO_2\cdot$$

Importance de la voie oléfinique :

$$\frac{v_{4.1} \times v_{4.3}}{\Sigma v_6} = \frac{k_{4.1}(\cdot Q^1OOH) + k_{4.3}(\cdot Q^3OOH)}{k_6(O_2)(R^1\cdot) + k_6(O_2)(R^2\cdot)} = \frac{(\cdot Q^1OOH)[k_{4.1} + k_{4.3} \times 1{,}3]}{(R^1\cdot) \times k_6(O_2) \times [1 + 0{,}18]} = \boxed{100}$$

La part oléfinique semble très faible : voisine de 1%, ce qui n'est pas en accord avec les théories de Knox. Cependant la valeur du rapport obtenue ne permet pas d'être catégorique, compte-tenu des imprécisions des méthodes d'estimation.

Importance des réactions aux parois :

$$\frac{v_{4.1} \times v_{4.3}}{\Sigma v_p} = \frac{k_{4.1}(\cdot Q^1OOH) + k_{4.3}(\cdot Q^3OOH)}{k_p(R^1OO\cdot) + k_p(R^2OO\cdot)} = \frac{(\cdot Q^1OOH)[k_{4.1} + k_{4.3} \times 1{,}3]}{(R^1OO\cdot) \times k_p \times [1 + 0{,}15]} = \boxed{6.10^4}$$

La formation de propène aux parois serait négligeable d'après nos estimations ce qui n'est pas l'avis d'Atherton *et al.* qui considèrent que l'alcène conjugué est formé de manière prédominante à la surface dans le cas de l'oxydation du propane aux environs de 600 K (24).

Étude de l'éthylène et de l'oxétanne

Le radical $\cdot Q^4OOH$ peut se décomposer principalement selon deux processus :

$$\cdot CH_2{-}CH_2{-}CH_2{-}OOH \xrightarrow[k_{4,5} = 1{,}5.10^6]{(4.5)} \underset{\displaystyle CH_2{-}O}{\underset{|}{CH_2}}{-}CH_2 + \cdot OH$$

$$\cdot CH_2{-}CH_2{-}CH_2{-}OOH \xrightarrow[k_{4,6} = 1{,}7.10^3]{(4.6)} CH_2{=}CH_2 + \cdot CH_2OOH \longrightarrow HCHO + \cdot OH$$

Le rapport théorique des vitesses de formation est alors :

$$\frac{v_{C_2H_4}}{v_{\square_O}} = \frac{k_{4.6}}{k_{4.5}} = \frac{1{,}7.10^3}{1{,}5.10^6} = \boxed{1{,}1.10^{-3}}$$

Comme dans le cas de l'oxydation de l'isobutane, ce résultat fait apparaître une anomalie, car l'expérience montre que l'on obtient au moins 10 fois plus d'éthylène que d'oxétanne. Cependant, lors de l'oxydation du propane, nous avons pu doser cet hétérocycle alors que son homologue (le méthyl-3-oxétanne) n'a pas été mis en évidence dans les produits de l'oxydation de l'isobutane. Nous pouvons examiner le rapport théorique des vitesses de formation du propène et de l'oxétanne pour vérifier la cohérence entre les processus issus de radicaux $\cdot QOOH$ différents.

$$\frac{v_{C_3H_6}}{v_{\square_O}} = \frac{k_{4.1}(\cdot Q^1OOH) + k_{4.3}(\cdot Q^3OOH)}{k_{4.5}(\cdot Q^4OOH)} = \frac{k_{4.1} + k_{4.3} \times 1{,}3}{k_{4.5} \times 26} = \frac{1{,}3.10^9 + 3{,}9.10^8 \times 1{,}3}{1{,}5.10^6 \times 26} \cong \boxed{46}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

En utilisant ce rapport et d'après le pourcentage initial expérimental du propène qui est 64,8, celui de l'oxétanne devrait donc être 1,4. Ce résultat est trop élevé car la valeur expérimentale observée est de l'ordre de 0,1; cependant l'écart n'est pas extravagant, compte-tenu des méthodes d'estimation des constantes de vitesse.

Pour en revenir à l'éthylène, il faudrait proposer un autre processus permettant d'expliquer sa formation de façon plus importante. Nous proposons la décomposition du radical alcoxy $R^2O\cdot$:

$$CH_3—CH_2—CH_2—O\cdot \xrightarrow[k = 1{,}6.10^{10}]{(5.2)} HCHO + CH_3—\cdot CH_2$$

$$\downarrow$$

$$CH_2{=}CH_2 + H\cdot$$

Cependant, comme dans le processus (4.6), la formation de propène est accompagnée de celle de formaldéhyde dont le pourcentage initial est 8,4, soit 10 fois plus que l'éthylène. Comme le formaldéhyde n'est pas formé par d'autres processus indépendants, on peut considérer que le radical éthyle s'oxyde plus rapidement qu'il ne donne d'éthylène, ceci pour expliquer le déficit par rapport au formaldéhyde. Les valeurs des constantes confirment cette proposition.

$$C_2H_5\cdot + O_2 \longrightarrow C_2H_5OO\cdot \qquad k = 10^{9,5} \Rightarrow k(O_2) \cong 5.10^6 \quad (18)$$

$$C_2H_5\cdot \longrightarrow C_2H_4 + H\cdot \qquad k \cong 5.10^{-2} \quad (27)$$

Quoi qu'il en soit, une partie non négligeable de radicaux éthyle doivent conduire, directement ou indirectement par «déshydrogénation», à la formation d'éthylène en quantités suffisantes pour expliquer les résultats expérimentaux.

Autres produits dont produits carbonylés

Il paraît intéressant d'examiner également la formation d'autres produits dont les produits carbonylés et les peroxydes.

Acétaldéhyde. Cet aldéhyde est un produit primaire important de l'oxydation du propane. Cependant, sa formation nécessite la perte d'un atome de carbone à partir du squelette du propane et la fermeture d'une double liaison carboxylique. Seul un processus de décomposition du radical alcoxy $R^1O\cdot$ permet d'écrire directement la formation d'acétaldéhyde par coupure relativement facile d'une liaison C—C :

$$CH_3—\underset{\displaystyle O\cdot}{\underset{|}{CH}}—CH_3 \xrightarrow[k = 2{,}1.10^{10}]{(5.1)} CH_3—CHO + \cdot CH_3$$

Pour conserver le caractère primaire du produit, il est indispensable de considérer les radicaux $R^1O\cdot$ provenant de la dismutation des radicaux $R^1OO\cdot$ et non pas ceux provenant de la décomposition d'hydroperoxydes intermédiaires.

Le radical $R^2O\cdot$ peut également donner de l'acétaldéhyde :

$$CH_3—CH_2—CH_2—O\cdot \xrightarrow{(5.3)} CH_3—CHO + \cdot CH_3$$

Cependant ce processus est certainement moins important que le précédent car il nécessite, après la rupture de la liaison C—C, le transfert d'un atome d'hydrogène pour rapprocher le centre radicalaire de l'atome d'oxygène, lui aussi porteur d'un électron célibataire.

La réaction concurrentielle est la fermeture du biradical, supposé formé, en oxiranne. Nous avons déjà mentionné dans l'étude de l'isobutane que Flowers et Parker considèrent que la réaction de transfert est prépondérante devant la formation d'époxyde (28, 29).

Les radicaux méthyle accompagnant la formation d'acétaldéhyde ne donnent pas de méthane puisque les résultats expérimentaux le font apparaître comme nettement secondaire. En effet, l'addition d'une molécule d'oxygène sur un radical méthyle est un processus plus facile que la métathèse.

Formaldéhyde. Nous avons déjà mentionné la formation du formaldéhyde lorsque nous avons exploité les résultats concernant l'éthylène; elle peut avoir lieu par deux processus :

$$\cdot Q^4OOH : \cdot CH_2—CH_2—CH_2—OOH$$

$$\xrightarrow[k = 1{,}7.10^3]{(4.6)} CH_2{=}CH_2 + \cdot CH_2OOH \longrightarrow HCHO + \cdot OH$$

$$R^2O\cdot : CH_3—CH_2—CH_2—O\cdot$$

$$\xrightarrow[k = 1{,}6.10^{10}]{(5.2)} HCHO + CH_3—\cdot CH_2$$

dont le deuxième est très probablement prépondérant. Il faut noter que cet aldéhyde provient exclusivement de la chaîne issue du radical *n*-propyle.

Certains auteurs, comme Quinn (communication privée), envisagent la formation de formaldéhyde à partir de radicaux méthyle, ce qui serait une façon de consommer ces derniers, produits par des processus déjà mentionnés, par exemple :

$$CH_3\cdot + O_2 \longrightarrow CH_3OO\cdot$$

$$CH_3OO\cdot + O_2 \longrightarrow \left[\begin{array}{l} CH_2 \\ H \quad O \\ \cdot \\ O \quad\ O \\ \quad O \end{array}\right] \longrightarrow HCHO + O_2 + \cdot OH$$

On peut se demander si ce processus est réellement élémentaire en raison des multiples ruptures de liaison nécessaires à l'obtention des produits.

On peut comparer les rapports théoriques et expérimentaux des deux aldéhydes en ne considérant que le processus supposé prépondérant : (5.2) pour le formaldéhyde et (5.1) pour l'acétaldéhyde :

$$R^2O\cdot : CH_3—CH_2—CH_2—O\cdot$$

$$\xrightarrow[k = 1{,}6.10^{10}]{(5.2)} HCHO + CH_3—\cdot CH_2$$

$$R^1O\cdot : CH_3—\underset{\displaystyle O\cdot}{\underset{|}{CH}}—CH_3 \xrightarrow[k = 2{,}1.10^{10}]{(5.1)} CH_3CHO + \cdot CH_3$$

$$\frac{v_{CH_3CHO}}{v_{HCHO}} = \frac{k_{5.1}(R^1O\cdot)}{k_{5.2}(R^2O\cdot)}$$

on peut estimer que le rapport des concentrations des radicaux RO· est le même que celui des radicaux ROO· :

$$\frac{(R^1O\cdot)}{(R^2O\cdot)} = \frac{(R^1OO\cdot)}{(R^2OO\cdot)} = \frac{(R^1OO\cdot)}{(R^1\cdot)} \times \frac{(R^1\cdot)}{(R^2\cdot)} \times \frac{(R^2\cdot)}{(R^2OO\cdot)} \cong 10$$

ainsi

$$\frac{v_{CH_3CHO}}{v_{HCHO}} = \frac{2{,}1.10^{10}}{1{,}6.10^{10}} \times 10 = \boxed{13}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

Le rapport expérimental étant $\%CH_3CHO/\%HCHO = 13/8,4 \cong \boxed{1,6}$, la cohérence des résultats est correcte.

Propionaldéhyde. Les analyses des produits mettent en évidence la nature secondaire du propionaldéhyde, ce qui est envisageable suite à l'étude des processus de formation :

$$R^2O\cdot : CH_3—CH_2—CH_2—O\cdot \xrightarrow[k = 1,5.10^7]{(5.4)} CH_3—CH_2—CHO + H\cdot$$

$$\cdot Q^5OOH : CH_3—CH_2—\cdot CH—OOH \xrightarrow[k \cong 1,8.10^9]{(4.7)} CH_3—CH_2—CHO + \cdot OH$$

La rupture d'une liaison C—H lors du processus (5.4) rend celui-ci négligeable devant son homologue (5.2) où intervient la rupture d'une liaison C—C :

$$R^2O\cdot : CH_3—CH_2—CH_2—O\cdot \xrightarrow[k = 1,6.10^{10}]{(5.2)} HCHO + CH_3—\cdot CH_2$$

Par contre, le processus (4.7) est rapide, mais le radical $\cdot Q^5OOH$ qui se décompose résulte d'une isomérisation du radical $R^2OO\cdot$ avec passage par un complexe activé à 4 centres, donc difficile et négligeable devant les isomérisations conduisant aux radicaux $\cdot Q^3OOH$ et $\cdot Q^4OOH$. Il est donc logique de n'avoir pas mis en évidence la formation de propionaldéhyde dans les instants initiaux de la réaction d'oxydation du propane.

Acétone. Le cas de l'acétone est exactement identique à celui du propionaldéhyde. Ce dernier était issu exclusivement du radical *n*-propyle de façon à ce que l'atome d'oxygène restant dans la molécule soit situé en bout de chaîne. Dans le cas de l'acétone, l'atome d'oxygène doit être porté par le carbone central impliquant l'oxydation du radical isopropyle. Ainsi le premier processus (5.0) fait intervenir la rupture d'une liaison C—H et le deuxième, (4.0), correspond à la décomposition du radical $\cdot Q^2OOH$ issu d'une isomérisation à 4 centres.

$$R^1O\cdot : CH_3—\underset{\displaystyle O\cdot}{\underset{|}{CH}}—CH_3 \xrightarrow[k = 2,1.10^8]{(5.0)} CH_3—\underset{\displaystyle O\cdot}{\underset{\|}{C}}—CH_3 + H\cdot$$

$$\cdot Q^2OOH : CH_3—\underset{\displaystyle OOH}{\underset{|}{\cdot C}}—CH_3 \xrightarrow[k \cong 1,8.10^9]{(4.0)} CH_3—\underset{\displaystyle O}{\underset{\|}{C}}—CH_3 + \cdot OH$$

L'observation de traces d'acétone à l'instant initial est compatible avec ce qui précède.

Peroxydes. Le dosage des peroxydes a été réalisé en utilisant la méthode que nous avons mise au point au laboratoire et améliorée entre l'étude de l'isobutane (1) et celle du propane (31, 32). Nous avons constaté que l'oxydation du propane donne des quantités notables de peroxydes,[5] ce qui n'était pas le cas de l'oxydation de l'isobutane. En effet, le pourcentage initial obtenu est 10,2, ce qui les place parmi les produits importants, après le propène et l'acétaldéhyde et juste avant le formaldéhyde. Il peut s'agir d'hydroperoxydes provenant de la réaction (12) :

$$ROO\cdot + RH \xrightarrow{(12)} ROOH + R\cdot$$

ou d'eau oxygénée produite selon le même type de processus et selon la réaction entre deux radicaux hydroperoxyle :

$$HO_2\cdot + RH \xrightarrow{(7)} H_2O_2 + R\cdot \qquad k = 1,1.10^3 \text{ L mol}^{-1} \text{ s}^{-1}\ ^6$$

$$HO_2\cdot + HO_2\cdot \xrightarrow{(14a)} H_2O_2 + O_2 \qquad k = 10^{9,3} \text{ L mol}^{-1} \text{ s}^{-1} \quad (34)$$

Nous pouvons estimer un rapport des vitesses de formation des porteurs de chaîne $\cdot OH$ et $HO_2\cdot$ afin de vérifier la cohérence de résultats :

$$\frac{v_{HO_2\cdot}}{v_{\cdot OH}} = \frac{k_{4.1}(\cdot Q^1OOH) + k_{4.3}(\cdot Q^3OOH)}{k_{4.2}(\cdot Q^1OOH) + k_{4.0}(\cdot Q^2OOH) + k_{4.4}(\cdot Q^3OOH) + [k_{4.5} + (\cong k_{4.6})](\cdot Q^4OOH) + k_{4.7}(\cdot Q^5OOH)}$$

$$\frac{v_{HO_2\cdot}}{v_{\cdot OH}} = \frac{k_{4.1} \times 1,3.k_{4.3}}{k_{4.2} + 1,3.k_{4,4} + 26(k_{4.5} + k_{4.6})} \cong \boxed{40}$$

Il y a effectivement prédominance des radicaux $HO_2\cdot$ mais elle n'est pas marquée de façon très nette.

Autres produits. Deux autres produits de réaction ont également retenu notre attention : l'eau et le dioxyde de carbone.

Contrairement au cas de l'isobutane, nous observons une formation secondaire de dioxyde de carbone, ce qui paraît plus logique compte-tenu du schéma mécanistique homogène retenu ainsi que de la nature secondaire de l'oxyde de carbone.

Il est certain que l'eau est formée en quantités importantes mais son analyse présente un certain nombre de difficultés qui nous ont fait renoncer à son dosage : condensation et adsorption dans les tubulures de l'appareillage statique, adsorption dans l'ampoule de chromatographie et difficulté de l'analyse chromatographique elle-même d'où une importante dispersion des résultats. Une estimation à partir d'une comparaison des bilans en carbone et hydrogène laisse prévoir que la formation d'eau est environ 50% plus importante que celle du propène à 5 min de réaction.

III.3. Influence du propène

Il est certain qu'une étude logique de l'influence de cet alcène sur l'oxydation du propane aurait nécessité, à titre de référence, l'étude de l'oxydation homogène du propène, réaction pour laquelle la littérature semble peu abondante. Cependant l'importance de cette tâche et la connaissance limitée atteinte jusqu'à présent des schémas généraux d'oxydation des alcènes nous ont conduits à différer cette étude et à nous contenter d'une étude plus superficielle.

Il avait été montré dans un article publié en 1971 par Sochet *et al.* (35) que les principaux produits d'oxydation du propane et

5. La méthode de dosage ne permettant pas de distinguer les hydroperoxydes de l'eau oxygénée, nous pouvons être amenés à utiliser indifféremment l'un ou l'autre terme pour dénommer l'ensemble des peroxydes dosés. Nous avons déjà mentionné les difficultés d'établir une distinction entre les différents peroxydes (33).

6. Pour l'arrachement d'un atome d'hydrogène secondaire (23).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

du propène sont sensiblement les mêmes ce qui paraît impliquer une certaine similitude dans les mécanismes réactionnels. De même, il apparaît (cf. Lucquin et coll. (36); Shtern (37)) une appréciable similitude dans l'allure des limites de zones réactionnelles (réaction lente, flammes froides, inflammation de 2ème stade) dans le plan pression–température, le propène tendant cependant à s'auto-enflammer pour des pressions moins élevées que le propane, ce qui paraît suggérer une réactivité plus élevée.

L'ajout de propène (5% du total propane + propène) provoque une augmentation de la quantité des produits formés. Une estimation de l'avancement à 5 min de réaction donne 0,47% pour le propane seul et 0,60% pour le mélange propane + propène. Ces résultats sont en accord avec ceux de la littérature (37, 38) qui ont constaté le rôle promoteur du propène lors de l'oxydation du propane. Nous avons mentionné précédemment dans le tableau 2 les rapports des pourcentages de formation des produits primaires, lors de l'oxydation du propane seul et du mélange propane–propène, le propène n'étant pas comptabilisé dans les produits.

Il est connu que la présence de la double liaison dans la molécule de propène modifie les énergies de liaison C—H (18).

propane : $DH^0(nC_3H_7 - H) = 98{,}0$ kcal mol^{-1}
$DH^0(iC_3H_7 - H) = 94{,}5$ kcal mol^{-1}

propène : $DH^0(\text{allyl} - H) = 87$ kcal mol^{-1}
$DH^0((CH_3—CH{=}CH) - H) = 108$ kcal mol^{-1}

$DH^0\left(\left(\begin{matrix}CH_3\\ \diagdown\\ C\\ \diagup\\ CH_2\end{matrix}\right) - H\right) \cong 104$ kcal mol^{-1}

La molécule de propène est ainsi plus réactive que celle du propane en raison de l'affaiblissement des liaisons C—H allyliques.

Ces résultats nous paraissent présenter de plus l'intérêt de conduire à des données sur l'oxydation du radical allyle. En effet, il ne fait aucun doute que le radical, stabilisé par résonance, joue un rôle important dans la réaction. Le radical allyle peut s'oxyder et donner le radical allylperoxy $CH_2{=}CH\text{-}CH_2OO\cdot$. Cependant, cette réaction paraît essentiellement différente de celle de l'oxydation du radical isopropyle; développons un peu cette comparaison en estimant les constantes d'équilibre des réactions (2.1) et (2.1′).

$$CH_3—\cdot CH—CH_3 + O_2 \underset{}{\overset{(2.1)}{\rightleftharpoons}} CH_3—\underset{\displaystyle OO\cdot}{\underset{|}{CH}}—CH_3$$

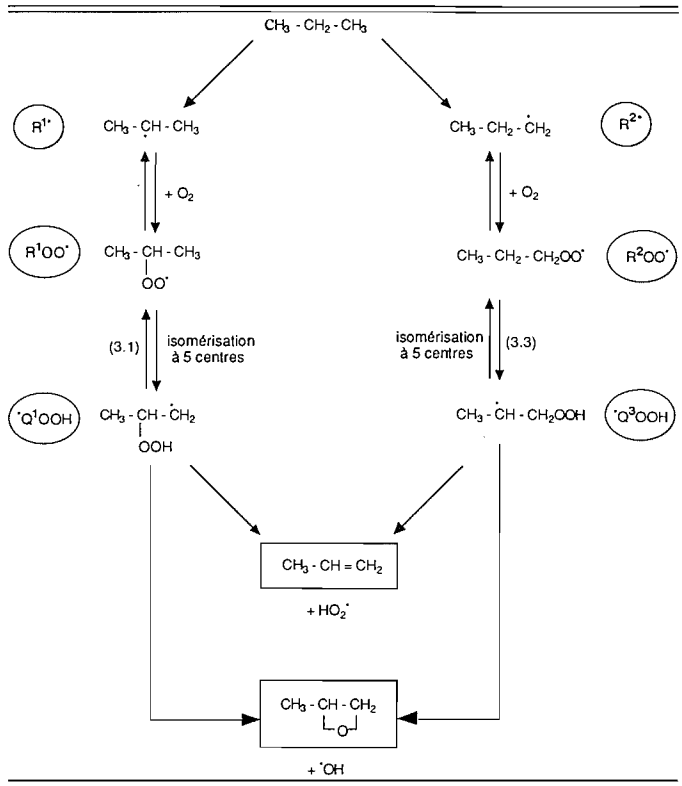
$$CH_2{=}CH—\cdot CH_2 + O_2 \overset{(2.1')}{\rightleftharpoons} CH_2{=}CH—CH_2—OO\cdot$$

$\Delta_R H^0_{2.1} = -12{,}9 - 0 - 17{,}1 = -30{,}0$ kcal mol^{-1}

$\Delta_R S^0_{2.1} = 79{,}7 - 49{,}2 - 66{,}8 = -36{,}1$ cal mol^{-1} K^{-1}

$\Delta_R H^0_{2,1'} = 22{,}4 - 0 - 39{,}1 = -16{,}7$ kcal mol^{-1}

$\Delta_R S^0_{2.1'} = 78{,}6 - 49{,}0 - 61{,}6 = -32$ cal mol^{-1} K^{-1}



à 623 K :

$$K_{2.1} = \frac{(iC_3H_7OO\cdot)}{(i\cdot C_3H_7)(O_2)} = \frac{k_{2.1}}{k_{-2.1}} = 2{,}2.10^4$$

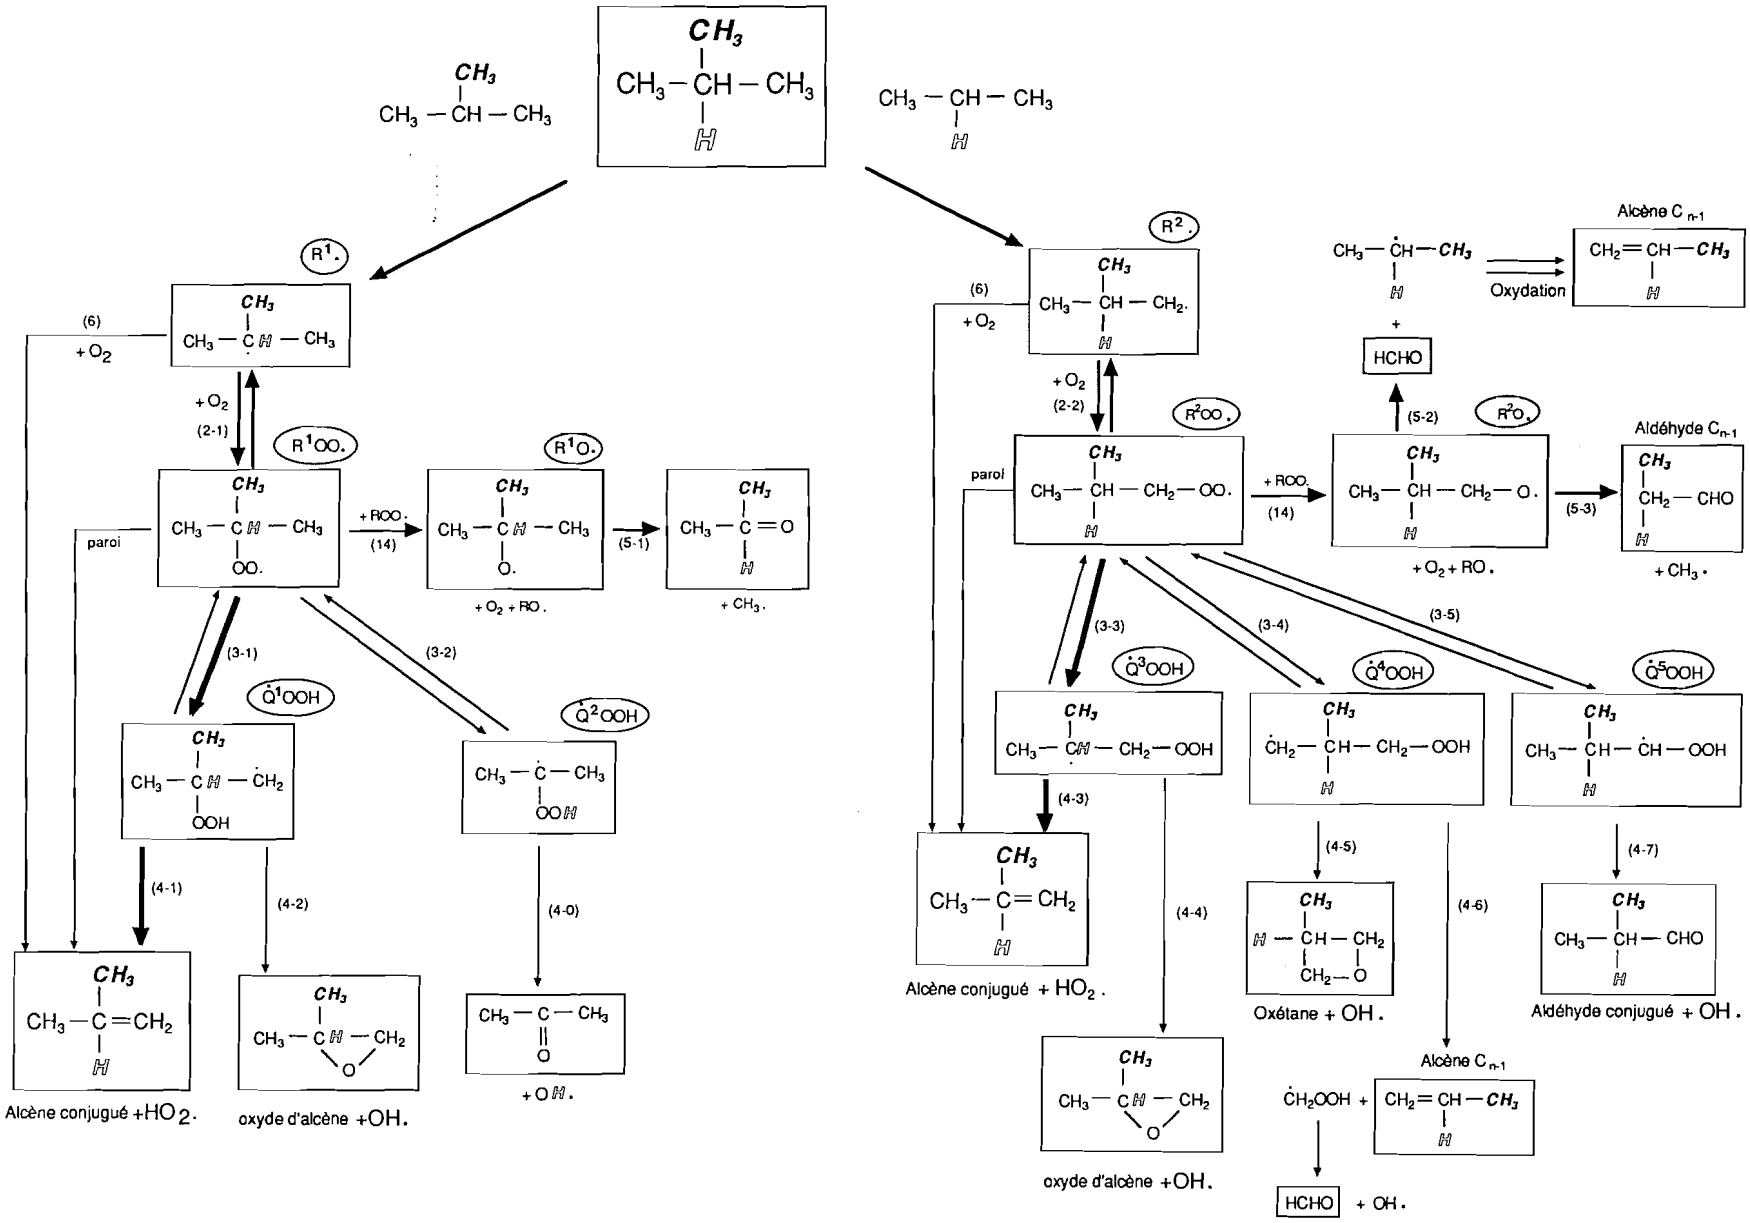
$$K_{2.1'} = \frac{(ROO\cdot)}{(R\cdot)(O_2)} = \frac{k_{2.1}}{k_{-2.1'}} = 3{,}7$$

Les valeurs des constantes montrent que l'équilibre de la réaction d'oxydation du radical allyle est déplacé, relativement à l'oxydation des autres radicaux alkyle, plutôt dans le sens de la désoxydation. Ceci rejoint donc les conclusions de Benson à propos de l'oxydation des radicaux méthylallyle (3). Ceci confirme aussi des observations récentes de Slagle et Gutman (39).

TABLEAU 10. Mécanisme simplifié d'oxydation du propane

Ces observations nous paraissent également susceptibles de donner une interprétation, au moins qualitative, des caractéristiques spécifiques de l'oxydation du cyclopentane (indice d'octane de recherche de mélange 141) par rapport à d'autres cyclanes, cyclohexane par exemple (indice d'octane recherche 84) (40).

Une étude plus poussée des réactions du radical allylperoxy suggère d'ailleurs que le sort prédominant de ce radical dans la réaction serait le retour au radical allyle par perte d'une molécule d'oxygène et non une isomérisation comme dans le cas de radicaux peroxyalcoyle (25) en accord avec des travaux récents de Slagle et Gutman (39).



Il paraît ainsi raisonnable de penser que l'oxydation du propène (seul ou en mélange avec C_3H_8) a lieu à la suite de réactions sur la double liaison de la molécule, en particulier de l'addition de radicaux $HO_2\cdot$ et les produits obtenus suggèrent une addition de type anti-Markownikoff (radical $CH_3\text{-}\cdot CH\text{-}CH_2OOH$).

IV. Synthèse des résultats obtenus et comparaison avec l'isobutane

Les résultats expérimentaux que nous avons obtenus et les calculs de Cinétique Thermochimique ont donc conduit à interpréter l'oxydation du propane par le mécanisme présenté dans les tableaux 8 et 9. Comme dans le cas de l'isobutane (1), il apparaît que le propène est formé selon deux processus d'importance voisine après isomérisation des deux radicaux peroxyalcoyle.

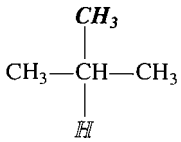
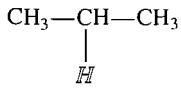
TABLEAU 11. Mécanisme généralisé permettant de rendre compte de l'oxydation de l'isobutane et du propane

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.



La formation de méthyloxiranne (oxyde de propène) a lieu parallèlement à celle du propène. L'eau oxygénée est produite en quantités notables à partir des radicaux hydroperoxyle $HO_2\cdot$ dont la formation est relativement importante dans les premiers instants de la réaction.

Le schéma réactionnel très simplifié des processus prépondérants est représenté dans le tableau 10. Cette représentation schématique du mécanisme de l'oxydation du propane apparaît très similaire à celle du mécanisme d'oxydation de l'isobutane qui a été présentée dans le mémoire correspondant (1).



En réalité, si l'on compare de manière plus précise le mécanisme détaillé de l'oxydation de l'isobutane présenté dans notre premier mémoire (1) et le mécanisme détaillé qui figure dans les tableaux 8 et 9 du présent mémoire une nette similitude apparaît. Une comparaison détaillée, par exemple en prenant les processus élémentaires un par un ou même en les regroupant par classes (décomposition, isomérisation, etc...) serait particulièrement fastidieuse.

Nous préférons faire cette comparaison sur une base plus originale en regroupant les mécanismes rendant compte de l'oxydation du propane et de l'isobutane sur un seul tableau, en adoptant une présentation adaptée à cette comparaison.

La molécule de propane et celle d'isobutane sont représentées par la même formule :

Lorsqu'on s'intéresse au propane, la formule correspondante s'écrit

pour passer du propane à l'isobutane, il suffit de remplacer dans la formule générale l'atome d'hydrogène représenté par $\mathcal{H}$ par un groupe méthyle $\boldsymbol{CH_3}$.

En effectuant cette substitution, on s'aperçoit dans le tableau 11 que les deux mécanismes sont remarquablement semblables. Il existe donc une bonne cohérence entre les deux mécanismes d'oxydation présentés : isobutane (1) et propane (présent travail) ce qui conduit ainsi à un schéma général d'oxydation des alcanes légers.

V. Conclusion

En dehors de la généralisation mentionnée ci-dessus, le présent travail, ainsi d'ailleurs que celui effectué sur l'exemple de l'isobutane, souligne l'importance d'allers et retours constants entre l'expérience et le calcul. L'évaluation des constantes de vitesse des processus élémentaires par les méthodes de la Cinétique Thermochimique constitue un guide précieux pour la simplification des schémas réactionnels.

Il aurait pu être intéressant de développer également dans le cadre de ce travail une comparaison plus poussée avec les résultats d'autres auteurs. Cependant cette comparaison est déjà partiellement implicite, en particulier au niveau des estimations des constantes de vitesse et lors de l'utilisation des données de la littérature, le présent mécanisme reprenant fréquemment des réactions élémentaires déjà proposées par d'autres auteurs comme Benson (4, 5), Fish (12) ou Knox (13).

L'aspect original de cette contribution, en dehors de l'utilisation systématique de la Cinétique Thermochimique et de la comparaison interactive avec l'expérience, nous paraît aussi d'avoir toujours insisté sur la nature *primaire* des processus présentés, afin de proposer un mécanisme d'oxydation de l'alcane étudié, et non pas des produits de cette réaction, comme l'alcène conjugué. Un rapide examen d'articles traitant de l'oxydation d'alcanes légers montre que ces préoccupations sont souvent absentes de l'esprit de la plupart des auteurs ayant travaillé dans ce domaine. Les processus écrits ne sont pas toujours des processus élémentaires et la nature, primaire ou secondaire, des produits en résultant est le plus souvent ignorée. Les tentatives de corrélation semi-quantitatives (comparaison entre vitesses de formation des produits et ordre de grandeur des constantes de vitesse) sont généralement inexistantes. C'est également pour cette raison que nous ne nous sommes pas intéressés aux réactions faisant intervenir des flammes froides, où les résultats expérimentaux sont plus spectaculaires, mais où, également, les mécanismes d'oxydation présentent une bien plus grande complexité, ne serait-ce qu'en raison de la non isothermicité de la réaction. Or, pour faire de la cinétique, il est essentiel de maîtriser le paramètre température.

Il nous semble également intéressant de mentionner que, compte-tenu de la complexité des réactions abordées, un certain nombre de points seraient susceptibles de justifier des développements supplémentaires. Il serait certainement intéressant de tenter une simulation de la réaction à partir du schéma que nous proposons. Cependant, les premiers essais que nous avons faits ont montré la complexité d'une telle tâche, complexité pouvant provenir d'une part de l'imprécision des constantes de vitesse et d'autre part de l'insuffisance des méthodes numériques mises en oeuvre dans ces essais.

Des progrès très importants ont certainement été réalisés grâce à des mécanismes complexes comportant un nombre très élevé de processus comme ceux proposés par Dryer et co-auteurs (41) sur l'exemple du *n*-butane. À l'opposé tout en reconnaissant les mérites de tels travaux, P. Gray (30) insiste également sur l'apport très positif de schémas très simples. La présente approche nous paraît un compromis entre ces deux points de vue qui a surtout l'intérêt de mettre en évidence les étapes essentielles permettant de rendre compte de la chimie de la réaction.

Remerciements

Les auteurs remercient la Société ATOCHEM (initialement PCUK) pour l'aide matérielle apportée sous la forme d'une bourse de thèse (B.V.) lors de la réalisation de ce travail.

Controlled diastereoselection in 2-lithio-1,3-dithiane additions onto α-substituted γ-lactols. Model studies toward bryostatins from (*R*)-pantolactone

RENÉ ROY[1] AND ALLAN W. REY
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received July 30, 1990

RENÉ ROY and ALLAN W. REY. Can. J. Chem. **69**, 62 (1991).

Homochiral α-substituted γ-lactols **3** and **4** derived from (*R*)-pantolactone **1** were used in 2-lithio-1,3-dithiane additions to afford very high controls in diastereoselectivities arising from 1,2-asymmetric inductions. Thus non-chelation controlled nucleophilic addition on **3** gave the *anti* diastereomer **5** as the major product (92% de), while the chelation controlled addition on **4** furnished the *syn* diastereomer **7** (96% de) as the almost exclusive product. The stereochemical outcomes of these reactions were proven unambiguously by locking the conformation of the *syn*- and *anti*-triol adducts **7** and **8** through their respective acetonides and by nuclear Overhauser enhancement measurements. The lack of 1,3-dioxolane formation in the case of the *anti*-triol **8** was taken as a further confirmation of the absolute configuration at the newly created stereocenter.

Key words: byrostatin, pantolactone, α-hydroxylactol, dithiane.

RENÉ ROY et ALLAN W. REY. Can. J. Chem. **69**, 62 (1991).

Les γ-lactols homochirals **3** et **4** α-substitués dérivés de la (*R*)-pantolactone **1** ont été utilisés dans des réactions d'additions avec le carbanion lithié du 1,3-dithiane pour fournir un très haut contrôle diastéréosélectif provenant d'une induction asymétrique-1,2. Le stéréocontrôle de l'addition nucléophilique sur **3** en l'absence de phénomène de chélatation a donné le diastéréomère *anti* **5** comme produit majeur tandis que la chélatation comme moyen de stéréocontrôle de l'addition nucléophilique sur **4** a conduit presque exclusivement au diastéréomère *syn* **7** comme produit final. Les résultats stéréochimiques de ces réactions ont été prouvés de façon non-ambigüe en fixant la conformation des adduits *syn*- et *anti*-triol **7** et **8** par la formation de leurs dérivés acétals respectifs et par des mesures d'effets nOe. L'absence de formation de 1,3-dioxolane dans le cas du triol-*anti* **8** a été considérée comme preuve supplémentaire de la configuration absolue au nouveau centre stéréogénique formé.

Mots clés : byrostatine, pantolactone, α-hydroxylactol, dithiane.

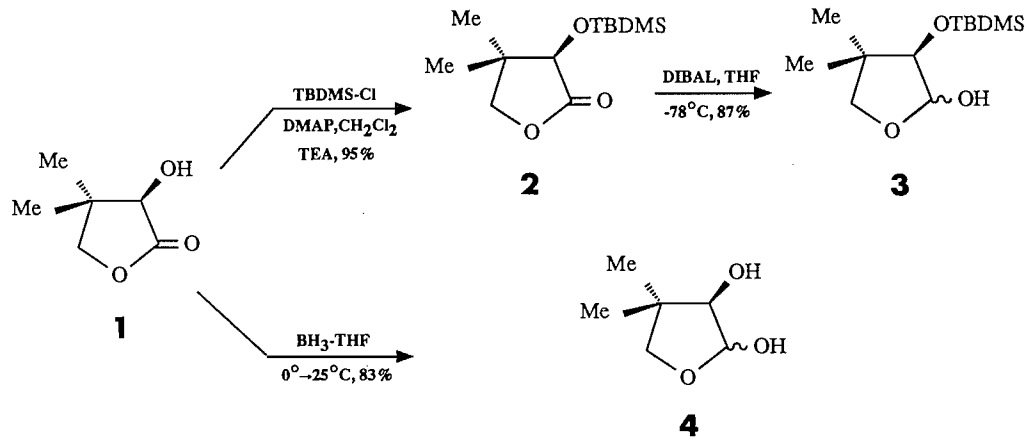
Introduction

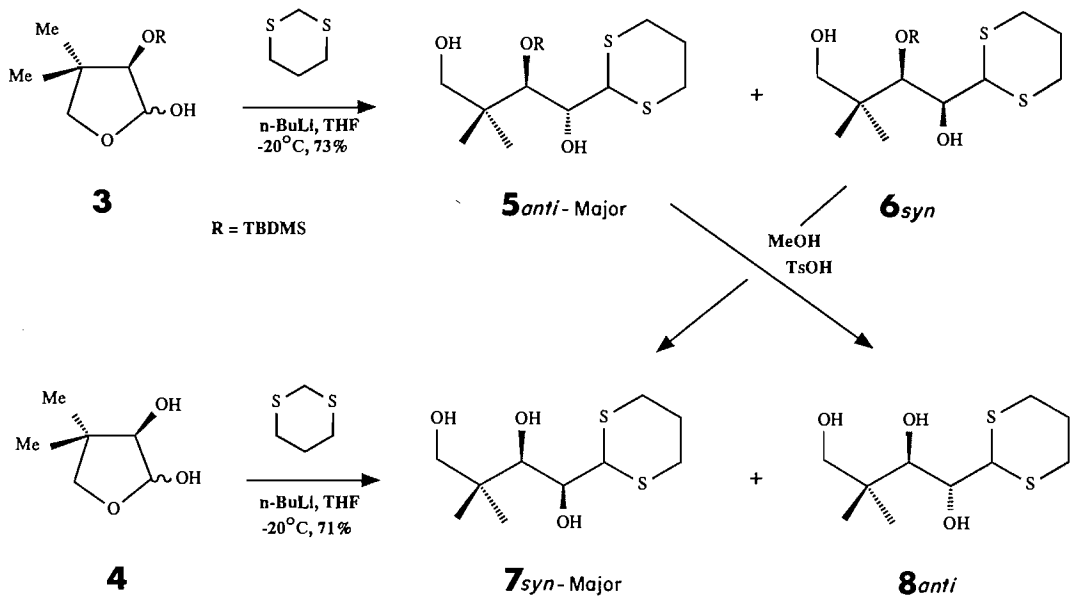
During synthetic endeavors (1–3) toward the construction of the antineoplastic macrolides bryostatins (4), chiral fragments containing quaternary *gem*-dimethyl carbon centers were required. Within the chiral pool, (*R*)-pantolactone **1** was sought as a useful chiral template. As such, **1** has scarcely been utilized for the enantiomeric synthesis of complex natural products (5, 6). On the other hand, **1** and its (*S*)-enantiomer (7) have received increased interest as chiral auxiliaries in asymmetric Diels–Alder cycloadditions (7, 8) and in diastereoselective ketene protonations (9).

Although there have been numerous examples of 1,2-induction in acyclic stereoselections (10), examples of similar or remote inductions in γ- or δ-lactols have received limited attention (11). We wish to describe herein the results obtained with 2-lithio-1,3-dithiane additions onto α-substituted γ-lactols. The effects of 1,2-chelation and non-chelation on the diastereoselectivities will be evaluated. The above findings should provide important clues for the choice of (*R*)-pantolactone derived chiral templates.



Results and discussion

2-Lithio-1,3-dithiane additions onto 3 and 4



To evaluate the extent of the asymmetric induction onto homochiral α-substituted γ-lactols, we required derivatives **3** and **4**. The silyl ether protecting group was chosen because it has been clearly established as a non-chelating group in nucleophilic addition assisted by Lewis acid (12). Thus, we anticipated good *syn*/*anti* complementary diastereoselection upon addition of 2-lithio-1,3-dithiane on **3** and **4** since the α-hydroxylactol derivative **4**, as opposed to **3**, should allow strong 1,2-chelation. First, protection of the hydroxyl group of (*R*)-pantolactone **1** as its *tert*-butyldimethylsilyl ether in the usual manner (TBDMSiCl, CH_2Cl_2, DMAP) furnished the crystalline lactone **2** in 95% yield. Reduction of the lactone with diisobutylaluminum hydride (DIBAH, THF, −78°C) afforded the lactol **3** (87%) as an anomeric mixture (2.3:1). When the above reduction was attempted in toluene, over-reduction occurred to a large extent. Attempts to reduce the α-hydroxylactone **1** to the γ-lactol **4** under a similar set of conditions (DIBAH/THF or toluene) inevitably gave the triol as the major product. Reduction with slightly acidic (H_2SO_4) sodium borohydride (13) also gave the triol as the major product. Finally, controlled reduction to the lactol **4** was achieved using borane–THF complex (83%) (14) (Scheme 1).

Metalation of 1,3-dithiane according to Seebach and Corey (15) (*n*-BuLi, THF, −20°C, 2 h) and subsequent addition of the resulting 2-lithio-1,3-dithiane onto **3** afforded a mixture of *anti* and *syn* adducts **5** and **6** with very high diastereoselectivity in favour of the predicted *anti* diastereomer **5** (73% yield) (Scheme 2). Due to the complexity of the ^{1}H NMR spectrum of the crude reaction mixture, the ratio of **5** to **6** was assessed from the ^{1}H NMR spectra of the unprotected triols **7** and **8** obtained by acidic methanolysis of the crude mixture (MeOH, TsOH, ~quant.). The relative integration for the dithianyl protons (identified as H1′) at 4.04 ppm ($J_{1',1}$ = 8.8 Hz) for the *syn* diastereomer **7** and at 4.55 ppm ($J_{1',1}$ = 2.7 Hz) for the *anti* and major diastereomer **8** indicated an *anti* to *syn* (**5**,**8**:**6**,**7**) ratio (*vide infra*) of 96:4 (92% de). The same ratio was obtained from the integrations of the chemical shifts of the H2 protons at 3.79 ppm ($J_{1,2}$ ~ 0 Hz) for **7** and at 3.58 ppm ($J_{1,2}$ = 8.4 Hz) for **8**. The small coupling constant (~0 Hz) between H1 and H2 in **7** (*syn*) and the larger one (8.4 Hz) for the same protons in **8** (*anti*) was diagnostic of the absolute stereochemistries of the diastereomers based upon previous empirical rules with aldol adducts (16). For instance, when seen as a Newman projection,

[1]Author to whom correspondence may be addressed.

SCHEME 1

SCHEME 2

the conformer **7**-*A* should be preferred over conformer **7**-*B* because of a dominant unfavourable interaction between the dithiane residues (Di) and the neopentyl group (R), thus bringing the H1 and H2 protons into a *gauche* relationship (<~60°, $J_{1,2} \sim 0$ Hz). Likewise the conformer **8**-*A* should be favoured over **8**-*B* for similar reasons, thus bringing the H1 and H2 protons into an *anti* relationship (<~180°, $J_{1,2} = 8.4$ Hz). A third rotamer for each of the above Newman projections was not accounted for, since they would be equivalent to the unfavourable rotamers **7**-*B* and **8**-*B* with the dithianyl and neopentyl groups in *gauche* relationships (Fig. 1).

When the above 2-lithio-1,3-dithiane addition was effected onto the unprotected α-hydroxylactol **4**, a high stereocontrol for the reversed diastereofacial selectivity was achieved based on α-chelation (1,2-induction) (Scheme 2). Indeed, the *syn* diastereomer **7** was obtained as the major product (71%) after silica gel chromatography, together with a small amount of the *anti* diastereomer **8**. The ratio of *syn*-**7** to *anti*-**8** was also determined from the ^{1}H NMR spectrum of the crude reaction mixture, which indicated a ratio of *syn*/*anti* of 98:2 (96% de) (Table 1).

Determination of the absolute stereochemistries of 7 and 8

The coupling constants between the protons at the two

stereocenters did not allow unambiguous determination of the absolute chirality at the newly created stereogenic center. Therefore, to obtain confirmation of the diastereofacial selectivities, a series of transformations was initiated in order to lock the conformation of the acyclic adducts. To achieve this goal, we elected to tether the C-1 and C-2 hydroxyl groups through formation of their respective 1,3-dioxolanes, following Gerlach's strategy (17). It was expected that proton nuclear Overhauser enhancement (nOe) studies would provide definitive establishment of the C-1 chirality.

Thus, the anticipated *syn* adduct **7** was first subjected to standard acetonation conditions (2,2-dimethoxypropane, TsOH, benzene, 25°C, 18 h). An unexpected mixture of acetonides was obtained. Further studies revealed that three regioisomeric acetonides **9**, **11**, and **14**, which could be separated by silica gel chromatography, were produced in 13%, 42%, and 30% yields respectively (Scheme 3). Equilibration to the expected thermodynamic 1,3-dioxolane **9** was apparently slow under the above experimental conditions. However, later experimentation demonstrated that this equilibration was significantly faster when acetone and TsOH alone were used. In this case, exclusive

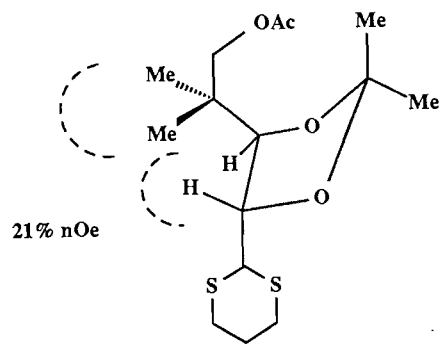

FIG. 2

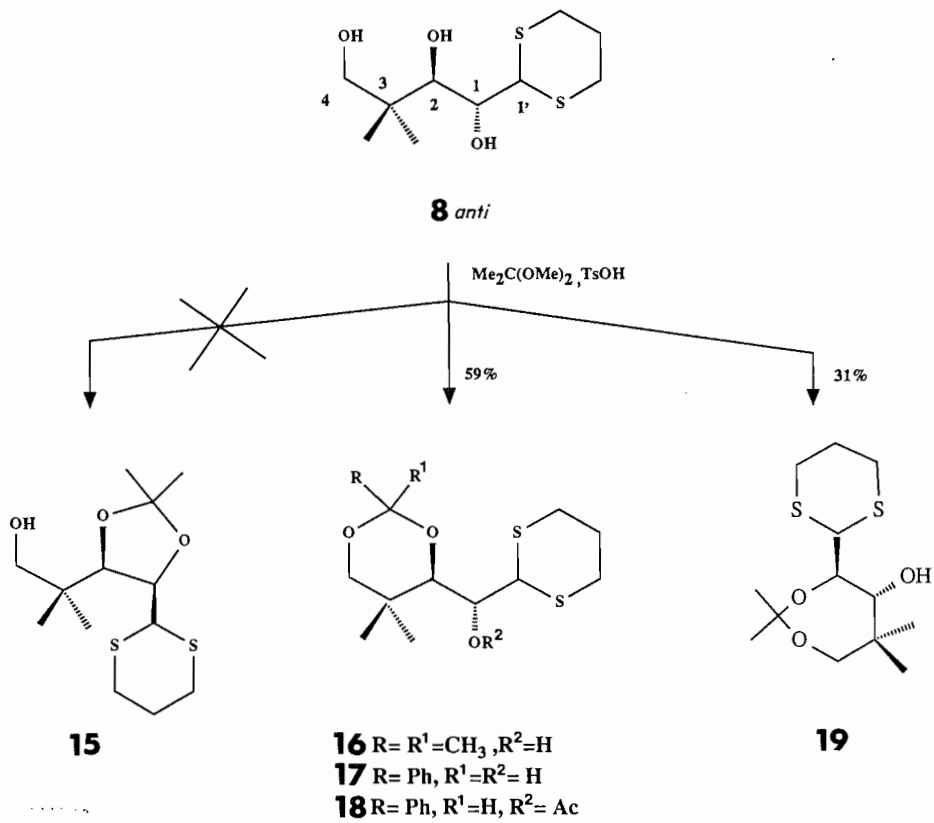
formation of **9** occurred in only 3 h at room temperature (Scheme 3). The regioselectivity of the 1,3-dioxolane **9** was confirmed by acetylation of the remaining primary hydroxyl group (Ac_2O, pyridine, 92%). This resulted in an expected downfield shift (~0.5 ppm) of the diastereotopic C-4 methylene protons of **10** (3.97 and 3.86 ppm) relative to those of **9** (3.47 and 3.42 ppm). ^1H NMR nOe experiments demonstrated that, for the acetylated 1,3-dioxolane **10**, there was a 21% intensity enhancement between the H-1 proton (dd at 4.14 ppm) and the *gem*-dimethyl protons (2 s at 0.96 and 0.99 ppm). This observed nOe is only consistent with the proposed (1*S*,2*R*)-1,2-*syn* stereochemistry. No nOe should result in the *anti* configuration (Fig. 2).



The identity of the 1,3-dioxane acetonide **11** was determined by comparing its ^1H NMR spectral data to those of its related benzylidene acetal **12**. The pertinent ^1H NMR data are given in

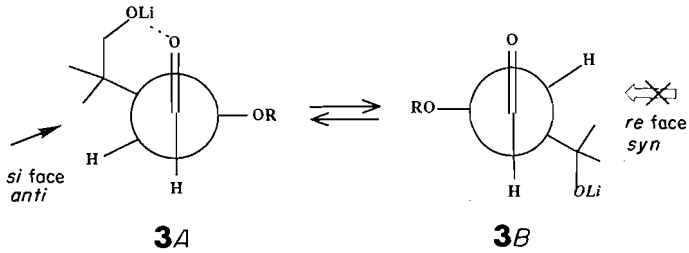
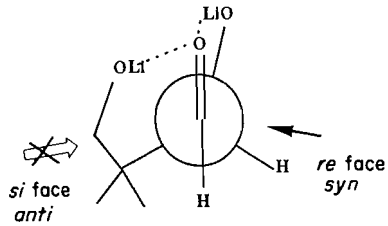


SCHEME 4

Table 2. The six-membered benzylidene acetal **12** formed between the C-2 and C-4 hydroxyl groups of the *syn*-triol **7** was the sole product obtained upon *trans*-acetalization of **7** with benzaldehydedimethylacetal (TsOH, benzene, 1 h, 25°C, 87%). The structure of **12** was further confirmed by acetylation of the remaining secondary C-2 hydroxyl group (Ac_2O, DMAP, pyridine, 86%).

When the expected *anti*-triol **8** was exposed to the same acetonide-forming conditions described above for the *syn*-triol **7** (2,2-dimethoxypropane, TsOH, 18 h, 90%), only two products were obtained in a ratio of 2:1 (Scheme 4). They were assigned structures **16** (59%) and **19** (31%) following similar arguments and derivatization (Ac_2O, pyridine) to those described above. No 1,3-dioxolane product corresponding to **15** was obtained. The only valid explanation for the lack of formation of the five-membered acetonide **15** is that it would require an unfavourable *cis* orientation of both the *gem*-dimethyl and the 1,3-dithiane substituents. Inspection of Dreiding models illustrates that this situation would be extremely sterically demanding, hence this product was not formed. This offers further evidence for the absolute stereochemistry at C-1.



Again, the structure of the 1,3-dioxane acetonide **16** was confirmed by comparison of its coupling patterns and chemical shifts to the analogous six-membered benzylidene acetal **17** ($PhCH(OMe)_2$, TsOH, benzene, 84%). Table 2 gives the relevant ^1H NMR data. Acetylation of the benzylidene acetal **17**

FIG. 4

(Ac_2O, DMAP, pyridine, 74%), as described above for **12**, demonstrated that the secondary C-1 hydroxyl group was, as expected, free.

Rationale for the observed diastereoselection

Felkin–Anh modification (18) of the Cram model (19) can provide a satisfactory explanation for the observed diastereoselection in the non-chelated situation with **3**. Indeed, as shown by the Newman projections (Fig. 3), conformer **3**-*A* of the protected γ-lactol **3** should be favoured over conformer **3**-*B* for the nucleophilic attack on the *si* face of the carbonyl following the Bürgi–Dunitz (20) trajectory. The *re*-face attack on conformer **3**-*B* is hindered by the neo-pentyl function. If one would consider the bulky neopentyl group as the one perpendicular to the carbonyl group, the reversed diastereoselection would have been obtained. It is also conceivable that the high diastereoselection obtained through conformer **3**-*A* might have been assisted by an added interplay of 1,4-chelation with the neopentylic alkoxide. The above results indicate that the more polar silyloxy protecting group might override the bulkier neopentyl group in its perpendicular arrangement to the carbonyl group in order to maximize electronic effect (σ*-orbital energies).

This situation may be contrasted to the one obtained from the unprotected γ-lactol **4** in which strong 1,2-chelation (and possibly added 1,4-chelation) surely favours *re*-face attack to provide the *syn*-triol adduct **7** as the almost exclusive diastereomer formed (Fig. 4).

In conclusion, good yields and a high degree of diastereoselection have been obtained in 2-lithio-1,3-dithiane additions onto both α-protected and α-unprotected γ-lactols. The absolute stereochemistry of the diastereomers has been unequivocally established using nOe measurements on locked conformers using acetal formations. These model studies are being used for the construction of bryostatin fragments (2). Moreover, it is also of interest to mention that there are only limited examples of diastereoselections in α-substituted γ-lactols. An interplay of 1,2- and possibly 1,4-chelation has been invoked to explain the stereochemical outcome of the nucleophilic additions observed during this study. Further work is in progress to delineate the above factors.

Experimental

Melting points were determined on a Gallenkamp apparatus and are uncorrected. The ^1H and ^{13}C NMR spectra were recorded on a Varian XL-300 or a Varian Gemini 200 spectrometer at 300 and 200 MHz respectively for protons and at 75.4 and 50.3 MHz respectively for carbons. The proton chemical shifts (δ) are given relative to internal Me_4Si (δ = 0) for $CDCl_3$ solutions. The carbon chemical shifts are given relative to deuterochloroform at 77.0 ppm. The analyses were done as a first-order approximation. Optical rotations were measured on a Perkin Elmer 241 polarimeter and were run at room temperature (~25°C). IR spectra were taken in chloroform using a Perkin Elmer 783 spectrophotometer. Mass spectra were recorded on a VG 7070-E spectrometer for CI and EI. Elemental analyses were performed by Guelph Chemical Laboratories Ltd. (Ont.) or M-H-W Laboratories (Phoenix, AZ). Thin-layer chromatography (TLC) was performed using silica gel 60-F254 plates and column chromatography on silica gel 60 (230–400 mesh, E. Merck No. 9385). The developed plates were sprayed or dipped with a solution of ceric sulfate (1%) and ammonium molybdate (2.5%) in 10% aqueous sulfuric acid and heated at ~150°C. Purifications by Chromatotron were performed on a Harrison Research Chromatotron model 7924 using silica gel 60-F254 rotors (1, 2, or 4 mm thickness). (*R*)-(−)-Pantolactone (Aldrich) was dried in a Dean–Stark apparatus using benzene as solvent. All solvents and reagents used were reagent grade and, when required, further purifications were accomplished following published procedures (21). Titrations of the organolithium reagents were done using diphenylacetic acid (22).

(R)-[(tert-Butyldimethylsilyl)oxy]pantolactone 2

To a solution of dry (*R*)-pantolactone (**1**) (2.00 g, 15.4 mmol) in dichloromethane (40 mL) was added triethylamine (2.69 mL, 19.3 mmol), *tert*-butyldimethylsilyl chloride (2.79 g, 18.5 mmol), and DMAP (0.39 g, 3.2 mmol). After stirring for 1 day at room temperature, the mixture was diluted with ether (100 mL) and washed with 0.2 N HCl, saturated aqueous $NaHCO_3$, and brine (50 mL of each). The organic layer was dried over Na_2SO_4 and concentrated *in vacuo*. The white amorphous residue was recrystallized in hexanes, yielding 3.76 g (95%) of the silyl ether **2** as white needles melting at 95.6–96.3°C; $[\alpha]_D$ +33.8° (*c* 1.0 in $CHCl_3$); IR (CH_2Cl_2) ν_{max}: 3050, 2959, 2858, 2302, 1791, 1252, 1132 cm^{-1}; ^1H NMR (300 MHz) δ: 3.97 (d, A of AB, J = 8.9 Hz, 1H, H4), 3.97 (s, 1H, H2), 3.86 (d, B of AB, J = 8.9 Hz, 1H, H4'), 1.12 (s, 3H, *gem* CH_3), 1.03 (s, 3H, *gem* CH_3), 0.91 (s, 9H, $C(CH_3)_3$), 0.18 (s, 3H, $SiCH_3$), 0.11 (s, 3H, $SiCH_3$); ^{13}C NMR (50.4 MHz) δ: 176.9 (C1), 76.5 (C2), 75.5 (C4), 40.7 (C3), 25.4 ($C(CH_3)_3$), 22.7, 18.8 (*gem* CH_3's), 18.0 ($SiC(CH_3)_3$), −4.8, −5.7 ($Si(CH_3)_2$); MS (EI) *m/z*: 187 (M^+−57, 20%), 143 (M^+−101, 35%). HRMS calcd. for $C_8H_{15}O_3Si$ (M^+−$C(CH_3)_3$): 187.0791; found: 187.0796.

(R)-[(tert-Butyldimethylsilyl)oxy]pantolactol 3

The silylated γ-lactone **2** (1.91 g, 7.81 mmol) was dissolved in THF (30 mL) and cooled to −78°C. Diisobutylaluminum hydride (1.0 M in THF, 10.9 mL, 10.9 mmol) was added over a 15 min period via a pressure-equalizing addition funnel. This mixture was stirred for 3 h and then quenched by addition of Glauber's salt ($Na_2SO_4 \cdot 10H_2O$, ~6 g). After warming to ambient temperature, the Glauber's salt was removed by filtration under suction. The filter cake was returned to the flask and refluxed with 50 mL of ethyl acetate (5 min), and filtered. This procedure was repeated with another 50 mL of ethyl acetate. The filtrates were combined and washed with 0.2 N HCl (2 × 50 mL), saturated aqueous $NaHCO_3$ (50 mL), and brine (50 mL), dried over Na_2SO_4, and concentrated *in vacuo* to yield a white amorphous solid. Purification by silica gel flash chromatography (2:8 ether/hexanes) and recrystallization from hexanes afforded 1.67 g (87%) of the silylated γ-lactol **3** as white needles melting at 48.5–51.5°C. When different,

(R)-(−)-Pantolactol ***4***

Over a period of 1 h, borane–tetrahydrofuran complex (1.0 M in THF) was added to (*R*)-(−)-pantolactone (**1**) (6.00 g, 46.1 mmol) in THF (100 mL) at 0°C. After stirring for 12 h at room temperature, the reaction was quenched by careful addition of water until the evolution of hydrogen had ceased. The solvent was then removed *in vacuo* to leave a colourless syrup. Several coevaporations with 60 mL of a 2% acetic acid in methanol solution were accomplished, followed by silica gel flash chromatography (7:3 ether/hexanes). This yielded the hydroxy γ-lactol **4** (5.00 g, 82%) as a colourless oil. When different, the data for the minor anomer (1.4:1 anomeric ratio) are given in brackets; $[\alpha]_D$ −2.7° (*c* 2.2 in $CHCl_3$); IR (thin film) ν_{max}: 3395, 2971, 2881, 1471, 1382, 1031 cm^{-1}; ^1H NMR (200 MHz) δ: 5.41–5.47 (5.21–5.26) (m, 1H, H1), (3.82) (d, A of AB, *J* = 8.4 Hz, 1H, H4), 3.73) (d, B of AB, *J* = 8.4 Hz, 1H, H4′), 3.66 (d, A of AB, *J* = 8.1 Hz, 1H, H4), 3.62–3.69 (m, 1H, H2), 3.45 (d, B of AB, *J* = 8.1 Hz, 1H, H4′), 2.85–2.91 (2.51–2.61) (br s, 1H, OH exchangeable), 1.06, 1.04 (1.10, 1.06) (s, 6H, *gem* CH_3's); ^{13}C NMR (50.4 MHz) δ: 97.5 (103.4) (C1), 78.2 (84.1) (C2), 77.2 (78.5) (C4), 41.5 (41.6) (C3), 25.4, 19.5 (23.7, 19.3) (*gem* CH_3's); MS (CI ether) *m/z*: 133 (M^++1, 15%), 131 (M^+−1, 8%), 115 ((M^++1)-18, 96%). Anal. calcd. for $C_6H_{12}O_3$: C 54.53, H 9.15; found: C 54.34, H 8.97.

*(1R,2R)-1,2-*anti*-3,3-Dimethyl-1-(1,3-dithian-2-yl)-2-[(*tert*-butyldimethylsilyl)oxy]-1,4-butanediol* ***5***

To 1,3-dithiane (1.26 g, 10.5 mmol, purified by vacuum sublimation) in THF (30 mL) at 20°C was added *n*BuLi (1.5 M in hexane, 7.00 mL, 10.5 mmol) and the solution was stirred for 2 h, whereupon a solution of the silylated γ-lactol **3** (1.03 g, 4.18 mmol) in THF (5 mL) was added via canula. The mixture was stirred a further 2 h and then placed in the refrigerator (−10°C) for 18 h, whereupon it was quenched by addition of 2 mL of saturated aqueous NH_4Cl and allowed to warm to room temperature. The solution was then diluted with ethyl acetate (80 mL) and extracted with 0.2 N HCl (30 mL), saturated aqueous $NaHCO_3$ (30 mL), and brine (30 mL), dried over Na_2SO_4, and concentrated *in vacuo* to provide a syrup. Further purification by flash chromatography (4:6 ether/hexanes) yielded 1.12 g (73%) of the diol adduct **5** as a colourless syrup; $[\alpha]_D$ −6.2° (*c* 1.8 in $CHCl_3$); ^1H NMR (300 MHz) δ: 4.30 (d, *J* = 5.9 Hz, 1H, H1′), 3.90 (dd, *J* = 5.1, 5.9 Hz, 1H, H1), 3.84 (d, *J* = 5.1 Hz, H2), 3.61 (d, A of AB, *J* = 11.3 Hz, 1H, H4), 3.35 (d, B of AB, *J* = 11.3 Hz, 1H, H4′), 2.66–2.96 (m, 4H, $CH_2(CH_2S)_2$), 2.41–3.00 (br s, 2H, OH exchangeable), 1.88–2.16 (m, 2H, $CH_2(CH_2S)_2$), 1.04, 0.93 (s, 6H, *gem* CH_3's), 0.92 (s, 9H, $C(CH_3)_3$), 0.18, 0.11 (s, 6H, $Si(CH_3)_2$); MS (CI ether) *m/z*: 367 (M^++1, 1%), 329 (M^+−37, 83%).

*(1S,2R)-1,2-*syn*-3,3-Dimethyl-1-(1,3-dithian-2-yl)-1,2,4-butanetriol* ***7***

This material was prepared using a procedure similar to the one described above for the conversion of **3** to **5**. Thus, the 2-hydroxy γ-lactol (**4**) (0.44 g, 3.33 mmol) when treated with 2-lithio-1,3-dithiane (11.7 mmol) yielded, after purification by flash chromatography (6:4 ether/hexanes), 0.60 g (71%) of the *syn*-triol adduct **7** as a white solid melting at 63.0–64.5°C; $[\alpha]_D$ −36.4° (*c* 2.5 in $CHCl_3$); ^1H NMR (300 MHz) δ: 4.04 (d, *J* = 8.8 Hz, 1H, H1′), 3.93 (d, *J* = 8.8 Hz, 1H, H1), 3.79 (s, 1H, H2), 3.63 (d, A of AB, *J* = 11.4 Hz, 1H, H4), 3.34 (d, B of AB, *J* = 11.4 Hz, 1H, H4′), 2.71–3.00 (br s, 3H, OH exchangeable), 2.62–2.93 (m, 4H, $CH_2(CH_2S)_2$), 1.99–2.07 (m, 2H, $CH_2(CH_2S)_2$), 1.00, 0.95 (s, 6H, *gem* CH_3's); MS (CI ether) *m/z*: 253 (M^++1, 92%), 235 ((M^++1)-18, 73%), 149 (M^+−103, 68%), 133 (M^+−119, 64%).

*(1R,2R)-1,2-*anti*-3,3-Dimethyl-1-(1,3-dithian-2-yl)-1,2,4-butanetriol* ***8***

The silyl ether **5** (0.96 g, 2.62 mmol) was dissolved in methanol (30 mL), catalytic TsOH (~10 mg) was added, and the solution was stirred at ambient temperature for 5 h. At this point, TLC (ether) indicated the reaction to be complete and it was subsequently processed by addition of an excess of Dowex 1-X8 resin in the ^-OH form, filtration, and removal of solvent *in vacuo* to yield a resinous material. This was further purified by flash chromatography (7:3 ether/hexanes) to provide a quantitative yield (0.66 g) of the triol adduct **8** as a solid melting at 108.0–109.1°C; $[\alpha]_D$ −33.3° (*c* 2.5 in $CHCl_3$); ^1H NMR (300 MHz) δ: 4.55 (d, *J* = 2.7 Hz, 1H, H1′), 3.93 (dd, *J* = 2.7, 8.4 Hz, 1H, H1), 3.58 (d, *J* = 8.4 Hz, 1H, H2), 3.54 (d, A of AB, *J* = 11.3 Hz, 1H, H4), 3.45 (d, B of AB, *J* = 11.3 Hz, 1H, H4′), 2.86–3.01 (m, 4H, $CH_2(CH_2S)_2$), 2.52–2.79 (br, s, 3H, OH exchangeable), 1.85–2.14 (m, $CH_2(CH_2S)_2$), 1.04, 0.93 (s, 6H, *gem* CH_3's); MS (EI) *m/z*: 149 (M^+−103, 6%); MS (CI ether) *m/z*: 253 (M^++1, 24%), 235 ((M^++1)-18, 11%), 149 (M^+−103, 20%), 133 (M^+−119, 27%).

Acetonide formation on the syn*-triol* ***7***

Triol **7** (0.89 g, 3.53 mmol) was dissolved in 10 mL of a 40% 2,2-dimethoxypropane in benzene solution containing a catalytic amount of TsOH (~15 mg) and the solution was stirred at ambient temperature. After overnight contact, the reaction mixture was neutralized by the addition of triethylamine and the solvent was evaporated under vacuum. The residue was diluted in ethyl acetate (40 mL) and washed with 0.2 N HCl, saturated aqueous $NaHCO_3$, and brine (30 mL portions). Drying over Na_2SO_4 and concentration *in vacuo* afforded a colourless oil. Purification by preparative TLC (1:1 ether/hexanes) yielded three products: 0.13 g (13%) of **9**, 0.43 g (42%) of **11**, and 0.31 g (30%) of **14** (five, six-, and seven-membered ring acetonides, respectively) as colourless oils. The order of polarity in the above solvent was (R_F): **14**(0.33), **9**(0.38), **11**(0.50). Submitting triol **7** (55.6 mg, 0.221 mmol) to the acetonide-forming conditions acetone/catalytic TsOH (25°C) afforded the thermodynamic 1,3-dioxolane acetonide **9** as the exclusive product after 3 h (85%).

*(1S,2R)-1,2-*syn*-1,4-O-Benzylidiene,3,3-dimethyl-1-(1,3-dithian-2-yl)-1-butanol* ***12***

To the triol **7** (98.5 mg, 0.39 mmol) in benzene (10 mL) was added benzaldehyde dimethylacetal (234 μL, 1.56 mmol) and a catalytic amount of TsOH (~10 mg). After stirring for 1 h at ambient temperature, the reaction mixture was neutralized with triethylamine and the solvent removed under vacuum. The residue was diluted in ethyl acetate (40 mL) and washed successively with 0.2 N HCl, saturated aqueous $NaHCO_3$, and brine (30 mL of each), dried over Na_2SO_4, and concentrated under reduced pressure. The oil was further purified by Chromatotron chromatography (2:8 ether/hexanes), providing the benzylidene acetal **12** as a colourless oil (115 mg, 87%); ^{1}H NMR (300 MHz) δ: 7.33–7.53 (m, 5H, aromatic), 5.63 (s, 1H, CHPh), 4.23 (d, *J* = 6.6 Hz, 1H, H1′), 3.95 (s, 1H, H2), 3.90 (d, *J* = 6.6 Hz, 1H, H1), 3.73 (d, A of AB, *J* = 11.1 Hz, 1H, H4), 3.66 (d, B of AB, *J* = 11.1 Hz, 1H, H4′), 2.80–3.02 (br s, 1H, OH exchangeable), 2.74–2.91 (m, 4H, $CH_2(CH_2S)_2$), 1.84–2.15 (m, 2H, $CH_2(CH_2S)_2$), 1.25, 0.85 (s, 6H, *gem* CH_3's); MS (CI ether) *m/z*: 341 ($M^+ + 1$, 79%), 323 (($M^+ + 1$)-18, 4%), 235 (($M^+ + 1$)-106, 59%).

*(1S,2R)-1,2-*syn*-1-Acetoxy-2,4-O-Benzylidene-3,3-dimethyl-1-(1,3-dithian-2-yl)-butane* ***13***

The alcohol **12** (61.2 mg, 0.180 mmol) was stirred at room temperature in pyridine (5.0 mL) containing acetic anhydride (1.0 mL) and DMAP (8.2 mg, 0.067 mmol). After 5 h, the excess acetic anhydride was quenched by addition of methanol (1 mL) for 1 h and the solution was concentrated under reduced pressure. The remaining syrup was taken up in ethyl acetate (30 mL) and washed with 0.2 N HCl, saturated aqueous $NaHCO_3$, and brine (20 mL of each). The organic layer was dried over Na_2SO_4 and concentrated *in vacuo*. Further purification was accomplished by Chromatotron chromatography (1:9 ether/hexanes) to yield 59.3 mg (86%) of the acetate **13** as a colourless oil; ^{1}H NMR (300 MHz) δ: 7.32–7.52 (m, 5H aromatic), 5.60 (dd, *J* = 1.3, 10.1 Hz, 1H, H1), 5.48 (s, 1H, CHPh), 4.35 (d, *J* = 1.3 Hz, 1H, H1′), 3.91 (d, *J* = 10.1 Hz, 1H, H2), 3.70 (d, A of AB, *J* = 10.7 Hz, 1H, H4), 3.63 (d, B of AB, *J* = 10.7 Hz, 1H, H4′), 2.88–3.00 (m, 2H, $CH_2(CH_2S)_2$), 2.48–2.63 (m, 2H, $CH_2(CH_2S)_2$), 2.11 (s, 3H, OAc), 1.96–2.10 (m, 2H, $CH_2(CH_2S)_2$), 1.15, 0.91 (s, 6H, *gem* CH_3's).

Acetonide formation on the anti*-triol* ***8***

The acetonides on triol **8** were prepared in a manner similar to the one described above for the conversion of **7** to **9**, **11**, and **14** (40% 2,2-dimethoxypropane in benzene, 25°C, 18 h). Thus, 155 mg (0.613 mmol) of triol **8** yielded two products. They were identified as the six-membered (**16**) and seven-membered (**19**) ring acetonides (**16** less polar than **19**). The yields for **16** and **19** were 59% and 31%, respectively, and both products were obtained as colourless oils.

*(1R,2R)-1,2-*anti*-2,4-O-Isopropylidene,3,3-dimethyl-1-(1,3-dithian-2-yl)-1-butanol* ***16****:* ^{1}H NMR (300 MHz) δ: 4.52 (d, *J* = 1.9 Hz, 1H, H1′), 3.82 (dd, *J* = 1.9, 8.9 Hz, 1H, H1), 3.70 (d, *J* = 8.9 Hz, 1H, H2), 3.56 (d, A of AB, *J* = 11.6 Hz, 1H, H4), 3.20 (d, B of AB, *J* = 11.6 Hz, 1H, H4′), 2.79–3.02 (m, 4H, $CH_2(CH_2S)_2$), 1.96–2.41 (br s, 1H, OH exchangeable), 1.81–2.16 (m, 2H, $CH_2(CH_2S)_2$), 1.39, 1.36 (s, 6H, $(RO)_2C(CH_3)_2$), 1.07, 0.92 (s, 6H, *gem* CH_3's); MS (CI ether) *m/z*: 293 ($M^+ + 1$, 15%), 275 (($M^+ + 1$)-18, 1%), 235 (($M^+ + 1$)-58, 52%).

The photochemistry of 1-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene

CHRISTOPHER OWEN BENDER,[1] DEAN SUTHERLAND CLYNE, AND DOUGLAS DOLMAN
Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received June 13, 1990

CHRISTOPHER OWEN BENDER, DEAN SUTHERLAND CLYNE, and DOUGLAS DOLMAN. Can. J. Chem. **69**, 70 (1991).

The title compound (**10**) was prepared, along with the 4-cyano isomer (**11**), by the direct irradiation of 5-cyanobenzocyclooctatetraene (**9**); the yields were 82% (Φ_{10} = 0.0030) and 12% (Φ_{11} = 0.0004) respectively. Triene **10** was thermally and photochemically reactive. Heating solutions of **10** at 150°C for 1 h gave COT **9** quantitatively. On direct irradiation **10** forms 5-cyanobenzosemibullvalene (**12**; 5%, Φ = 0.019), COT **9** (70%, Φ = 0.56), and 1-cyanonaphthalene (14%, Φ = 0.078). Sensitized irradiation of **10** gave **9** exclusively (92%, Φ = 0.88). COT **9** was also produced by the direct irradiation of semibullvalene **12** (75%, Φ = 0.13). Studies with deuterium labelled **10** suggest that the photoformation of COT **9** involves a simple electrocyclic opening of the cyclobutene ring of the triene. Additionally, the labelling results indicate that the formation of semibullvalene **12** from **10** derives from the operation of two reaction pathways, the major one of which appears to be a Zimmerman di-π-methane rearrangement. The mechanism proposed for the minor pathway to **12** has not been observed in other bicyclo[4.2.0]octatrienes.

Key words: mechanisms, rearrangements, photochemistry, di-π-methane.

CHRISTOPHER OWEN BENDER, DEAN SUTHERLAND CLYNE et DOUGLAS DOLMAN. Can. J. Chem. **69**, 70 (1991).

La photolyse directe du cyano-5 benzocyclooctatetraène (**9**) conduit aux cyano-1 et -4 benzo-2,3 bicyclo[4.2.0]octatriènes-2,4,7 (**10** et **11**) avec des rendements de 82% (Φ_{10} = 0.0030) et 12% (Φ_{11} = 0.0004) respectivement. Le triène **10** est réactif thermiquement et photochimiquement. À 150°C, des solutions de **10** se transforment en **9** en rendements quantitatifs. Par irradiation directe, **10** conduit au cyano-5 benzo semi-bullvalène (**12**; 5%, Φ = 0.019), à **9** (70%, Φ = 0.56) et au cyano-1 naphtalène (14%, Φ = 0.078). Par irradiation sensibilisée, **10** conduit à **9** uniquement (92%, Φ = 0.88). Le composé **9** se forme aussi de la photolyse directe du semi-bullvalène **12** (75%, Φ = 0.13). Des études de marquages au deuterium suggèrent que **9** se produit photochimiquement du triène par un mécanisme qui comporte l'ouverture électrocyclique de l'anneau du cyclobutène de **10**. De plus, des études de marquages démontrent qu'il y a deux mécanismes qui entrent en jeux dans la transformation **10** → **12**. Le mécanisme majeur dérive d'une transposition di-π-méthane de Zimmerman. Un nouveau mécanisme est proposé pour la voie mineure qui fournit **12**.

Mots clés : mécanismes, transpositions, photochimie, di-π-méthane.

Introduction

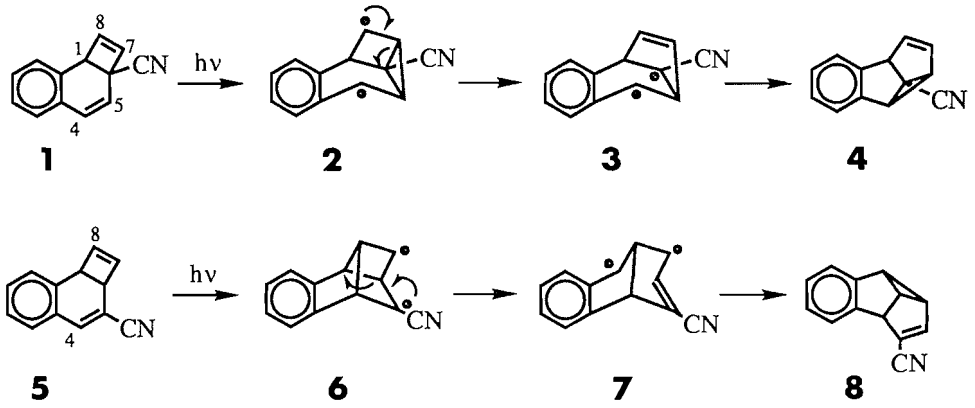
It has been shown recently that semibullvalenes (i.e., SBs) can be produced from the light-induced isomerization of benzobicyclo[4.2.0]octa-2,4,7-trienes (1–5). Mostly their formation can be rationalized by a Zimmerman di-π-methane rearrangement (6) involving initial bridging between C-5 and C-7 of the two vinyl portions of the trienes (e.g., **1** → **4**; Scheme 1).[2] In one case, however, that of 5-CN derivative **5** (4), the results of deuterium labelling experiments suggested that an alternative mechanism gives SB product through initial bridging of C-4 to C-8 (note **5** → **8**; Scheme 1). We have now examined the photochemistry of 1-cyano-2,3-benzobicyclo[4.2.0]octa-2,4,7-triene (**10**) and herein report on yet a third pathway to SB formation in this intriguing triene system.

Results

Compound **10** was obtained as the major product from the direct irradiation of 5-cyanobenzocyclooctatetraene (i.e., 5-CN-BCOT, **9**), a known compound (10), with light of wavelength ≥318 nm; small amounts (ca. 11–12%) of the alternate 2π + 2π ring closure isomer **11** were also produced (see Scheme 2). Like the cyanolated trienes **1** and **5** (2, 4), **10** was found to be thermally labile, and readily reverted to COT **9** upon modest warming (e.g., $t_{1/2}$ = 4.0 h at 70°C) and at all useful working temperatures on the gc. The isomerization is essentially quantitative on heating at ca. 150°C for 1.0 h.

The structure of **10** was assigned on the basis of spectral evidence. Importantly, the proton nmr spectrum revealed the coupling constant between H-7 and H-8 to be 2.8 Hz, which falls within the characteristic range (2.5–3.7 Hz) of vinylic coupling in cyclobutenes (11). Additionally, all other features of the spectrum are closely analogous to those reported for the related positional isomers **1** (2) and **5** (4), and a comparison of their spectral details is given in Table 1.

Photochemically, triene **10** reacts efficiently under both direct (Pyrex-filtered light transmitting at ≥295 nm) and sensitized (uranium-glass-filtered light transmitting at ≥315 nm; dimethylaminobenzophenone) irradiation conditions to give COT **9** as the major product.[3] Chemical yields (gc analysis) and quantum yields (Φ's) for the reactions are given in Scheme 2. Photoproduct **12**, a new compound, was found to be a stable crystalline solid, unlike 6-, 7-, and 8-cyanobenzosemibullvalene, all of which undergo facile polymerization upon solvent removal (refs. 3, 2, 4, respectively). The structure of 5-cyanobenzotricyclo[3.3.0.$0^{2,8}$]octa-3,6-diene (i.e., SB **12**) was deduced from spectroscopic data alone. Most informative was the proton nmr spectrum, which shows the coupling constants and chemical shifts that are diagnostic for the rigid benzosemibullvalene skeleton. The nmr data of **12** are compared with those of the related benzosemibullvalenes **13** (12) and **4** (10) in Table 2 (note structures in Scheme 3).



Next, the photochemistry of SB **12** was examined to ascertain

[2]The original version of the Zimmerman di-π-methane rearrangement mechanism (6) is used throughout this article. For leading publications on the issue of "1,3-vinyl, vinyl-bridging" and "1,2-vinyl-migration" versions of the rearrangement see refs. 7–9.

[3]Under the conditions used in this study, detectable amounts of triene **11** and of its major photoproduct 2-cyanobenzotricyclo-[3.3.0.$0^{2,8}$]octa-3,6-diene were not observed during irradiations of **10**; SB **12** is not a photoproduct of **11**. The photochemistry of **11** will be reported in a subsequent paper.

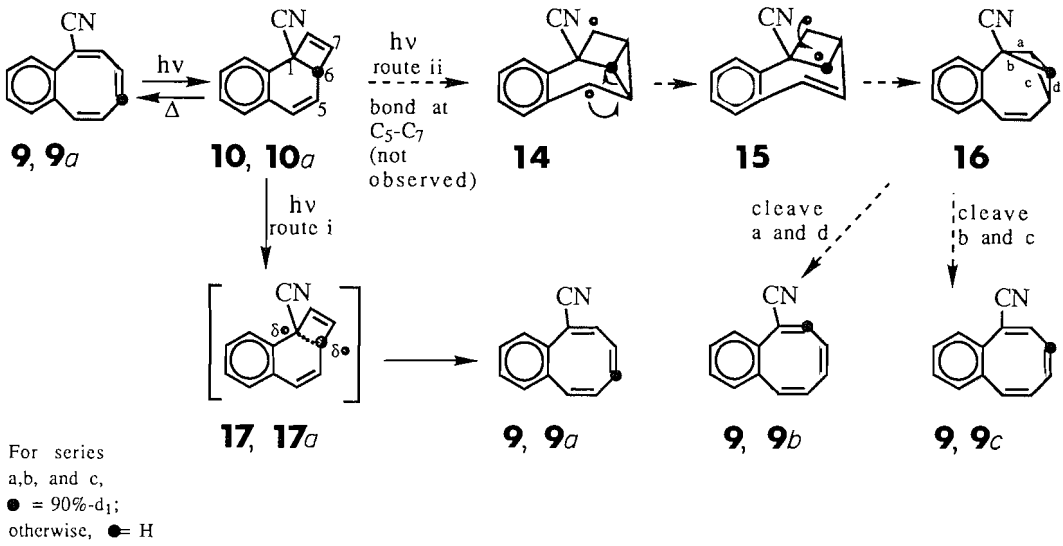
its possible involvement in the production of COT **9**. Under the conditions used in the direct (Pyrex-filtered light) and sensitized (*p*-dimethylaminobenzophenone) irradiations of triene **10**, SB **12** was found to be stable. However, upon direct irradiation with light filtered through Corex glass, SB **12** efficiently ($\Phi = 0.13$) and cleanly rearranged to give COT **9** as the exclusive product (Scheme 3). The triplet excited state of SB **12** appears to be unreactive since attempts at sensitization with acetone led only



SCHEME 3

to the slow disappearance of starting material without the formation of isomeric products (gc evidence).

Mechanistic considerations

The formation of COT **9** from triene **10** can be rationalized by two literature precedented mechanisms. One is formally equivalent to a simple $2\sigma_s + 2\pi_s$ electrocyclic opening of the cyclobutene ring of triene **10** (route i, Scheme 4), a mechanism that has extensive documentation (13). A second possible pathway to COT **9** is a DPM rearrangement involving initial C-5 to C-7 bridging with subsequent formation of octavalene **16** and thermal reorganization to COT **9** (route ii, Scheme 4); independently generated 1,3-cyclobutanediyls similar to the proposed intermediate **15** have been reported to undergo coupling of the radical centres to give bicyclobutanes (14). A related mechanis-

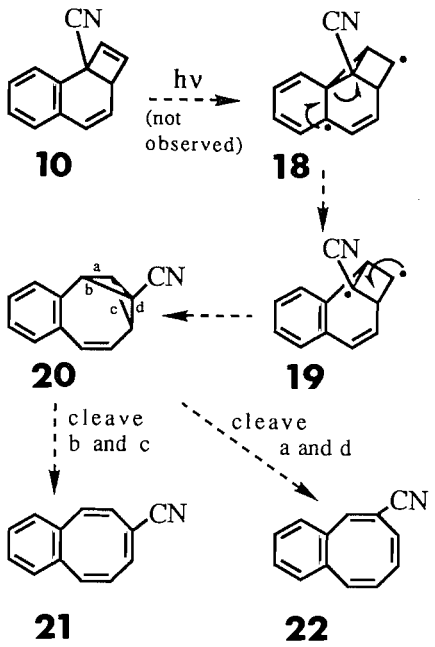
H-7	5.31 dd	5.20 dd	5.08 dd
H-8	2.91 dt	3.33 dd	2.60 dt

[a]Run in $CDCl_3$ (**4** and **12**) or CCl_4 (**13**) solvent.

[b]Coupling constants for **12** are $J_{1,2} = J_{1,8} = 6.0$, $J_{2,8} = 6.5$, $J_{6,7} = 5.0$, and $J_{7,8} = 2.5$ Hz; corresponding coupling constants for **4** and **13** are within 0.5 Hz.

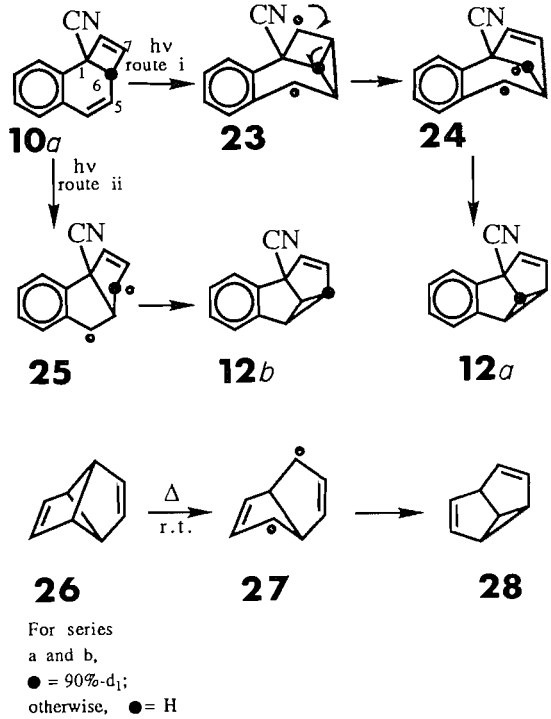
SCHEME 5

tic proposal was invoked by us to account for the formation of 6- and 7-cyano BCOT from 8-cyano-2,3-benzobicyclo[4.2.0]-octa-2,4,7-triene (3). Routes i and ii are skeletally nonequivalent and experiments with the deuterated compound **10***a* were undertaken to distinguish between them. Labelled **10***a* was obtained photochemically from the known (10) deuterated COT **9***a* (ca. 90%-d_1 at C-8). The direct and sensitized irradiation of **10***a* gave COT product with the deuterium attached exclusively to C-8, as determined by proton nmr analysis. Thus the DPM mechanism depicted by route ii (Scheme 4) does not participate in the formation of **9** from triene **10** (the integration results for COT **9***a* and all other labelled compounds are given in the Experimental).



The most surprising result from the labelling experiments was the observation that the semibullvalene material formed in the direct irradiation of **10***a* gave low proton integrations at two positions, 0.30H at C-1 and 0.80H at C-8, and corresponding to the presence of a mixture of two label isomers of structures **12***a* (66%) and **12***b* (24%), and nondeuterated SB **12** (10%). This finding was corroborated by the deuterium nmr spectrum of the sample, which comprised two peaks in the ratio of 3 (C1-D):1 (C8-D). The formation of **12***a* and **12***b* cannot be accounted for in terms of a single DPM rearrangement (*vide infra*).

Lastly, in connection with the labelling studies, the nmr proton integrations of the COT product obtained from the direct irradiation of the mixture of label isomers **12***a* and **12***b* were found to be unexceptional, and corresponded to the formation of COTs **9***a* and **9***b* in the ratio of 3:1, respectively. Mechanistically, this isomerization (**12** → **9**) is interpreted as being analogous to that invoked by Zimmerman, Pagni, and Givens to account for the conversion of parent benzosemibullvalene to benzocyclooctatetraene (12), and involves cleavage of the C1—C5 and C2—C8 bonds of the semibullvalene (Scheme 5).



Discussion

Despite the structural similarities of trienes **1** and **10**, which differ only in respect to which one of the two bridgehead carbons the cyano group is attached (C-6 or C-1, respectively), there are major differences in their photochemistry. The most dramatic is that found for the triplet reactivities: **1** (2) gives a semibullvalene (**4**) as the major product (90%), whereas **10** gives exclusively a COT (**9**) in 92% yield. The formation of COT **9** from T_1 of **10** is a striking result, since all previous studies with benzobicyclo[4.2.0]octatrienes have found SBs and (or) naphthalenes to be the triplet products (1–5). The SB **4** formed in the case of **1** was rationalized by the Zimmerman DPM rearrangement depicted in Scheme 1 (2), and the high efficiency of the process

SCHEME 6

SCHEME 7

($\Phi_{1\rightarrow3}$ = 0.68) was attributed to the presence of the radical delocalizing cyano group on the methane carbon (C-6) of the vinyl–vinyl DPM system.[4]

For triene **10**, the deuterium labelling experiments clearly rule out the involvement of a vinyl–vinyl DPM rearrangement in the formation of COT **9**, since no deuterium was found at C-6 or at C-7 of the product (i.e., route ii, Scheme 4, does not operate). Also, the possible operation of a benzo–vinyl DPM rearrangement, which *a priori* might be promoted by the cyano group on the methane carbon (C-1), seems unlikely since this would give the octavalene **20** and subsequently[5] the COTs **21** and **22** (see Scheme 6), neither of which was observed in photolysates of **10**; both **21** and **22** are known compounds (10) and were used for gc comparisons.

Formation of COT **9** via route i (Scheme 4), the mechanism in accord with the labelling results from both direct and sensitized irradiations, involves cleavage of the C1—C6 bond of triene **10**. The facile nature of this possibly concerted reaction is attributed to the weakened character of the bridging σ-bond, due to a "diradical-like" transition state (note structure **17**) in which the developing electron densities at C-1 and C-6 are afforded extensive delocalization. No similar degree of stabilization appears to be available to radical intermediates from potential vinyl–vinyl or benzo–vinyl DPM rearrangements of **10** (note structures **14** and **15** in Scheme 4, structures **18** and **19** in Scheme 6, and structures **23** and **24** in Scheme 7), or to their transition states, which they presumably resemble, and hence these isomerizations are less favorable.

Turning now to the direct irradiation of triene **10**, the product types formed are the same as those found in the case of triene **1** (2), though the SB formation from **10** is much less predominant than from **1**. Furthermore, the results from the deuterium runs indicate that the limited SB that is formed from **10** is furnished by two routes. The major route is consistent with a DPM rearrangement involving initial C5–C7 bridging (route i, Scheme 7), and is the same mechanism as suggested for the formation of SB **4** from triene **1** (2) (note Scheme 1). For this major pathway, perhaps SB **12** is formed to a lesser extent from triene **10** than is SB **4** from triene **1**, since delocalization of the radical centres of intermediate **24** is not as extensive as that available to radical centres in the corresponding intermediate (**3**) from triene **1**.

The minor pathway of SB **12** can be accounted for by a 1,2-shift mechanism that involves cleavage of the cyclobutene C1—C6 bond and rebonding between C-1 and C-5 to give intermediate **25** (route ii, Scheme 7). A species like **25**, viz. **27**, was invoked by Meinwald *et al.* (17) and by Zimmerman *et al.* (18) to account for the transformation of diene **26** to semibullvalene **28** at room temperature. Route ii is a novel pathway in bicyclo[4.2.0]octatriene photochemistry, and its operation here is seen as a further indication of the weakened character of the ring-junction σ-bond.

Finally, it is noteworthy that the formation of SB **12** from triene **10** is probably exclusively singlet derived, since it is not a product of sensitized irradiations. This is an unusual finding and contrary to the general observation that DPM rearrangements in rigid systems show a preference for triplet initiation (19).

Experimental

The nmr spectra were recorded on Bruker 300- or 400-MHz instruments, with TMS as internal standard. The chemical shifts are in δ units and the coupling constants (*J*) in Hz. The abbreviations br, s, d, t, q, and m refer to broad, singlet, doublet, triplet, quartet, and multiplet, respectively. The ir spectra were recorded on a Bomem MB 102 FT spectrometer. The uv spectra were measured on a Varian DMS 100S spectrometer; maxima are given in nm, with λ_{max} values in parentheses; sh = shoulder. Melting points are uncorrected. Elemental analyses were performed by Galbraith Labs, Inc., Knoxville, TN. Unless stated otherwise, column chromatography was carried out on Silica Gel 60

[4]For a discussion of the influence of substitution at the methane carbon in di-π-methane photochemistry, note the publications of Zimmerman *et al.* (15) and Paquette *et al.* (16).

[5]The possible intermediacy of octavalene **20** and its thermal reorganization to a ca. 1:1 mixture of **21** and **22** was discussed by us in a previous publication (3).

(Merck; 230–400 mesh) mixed with Sylvania 2282 phosphor and slurry packed into quartz columns permitting monitoring by a hand uv lamp, or on Lobar columns (Merck; size B, LiChroprep Si 60). The gc analyses were made on a Varian 3700 instrument (FID), coupled to a Varian CDS 111 computing integrator, and fitted with, unless otherwise stated, an SE-30 fused silica capillary column 30 m × 0.32 mm. For preparative gc separations, a Varian AP-90 instrument was used (0.25 in. × 8 ft of 7.5% SE-30 on DMCS 45/50; helium gas; 190°C). Cyclohexane solvent for photolyses was prepared by scrubbing with 20% fuming sulfuric acid, followed by washing with 10% aqueous sodium hydroxide, drying ($MgSO_4$), and finally distilling from calcium hydride. Sensitizers were distilled or recrystallized (after sublimation) prior to use.

General procedures for preparative photolyses

The apparatus consisted of a 450-W Hanovia medium pressure mercury arc surrounded by a water-cooled quartz immersion well. Unless otherwise stated, the light was filtered through either a cylindrical sleeve of Pyrex, or Corex, or uranium glass (Ace) or an aqueous lead nitrate solution (1 g $Pb(NO_3)_2$ and 100 g NaBr in 1 L water; transmittance was 0% below 318 nm) contained in a concentric filter jacket (10 mm path length). Four types of sample cell were used. Cell A (250 mL sample volume) consisted of a cylindrical vessel (Pyrex), which surrounded the immersion well. Cell B (200 mL sample volume) consisted of a cylindrical collar (Pyrex), which surrounded the aqueous filter jacket. Both Cells A and B were fitted with gas inlet and exit ports, and sample solutions were purged with argon prior to, and during, irradiations. Cell C (35 mL sample volume) was a quartz test-tube-like vessel, and Cell D (3.5 mL) was a quartz cuvette; sample solutions contained therein were deoxygenated by flushing with argon and sealed under a positive pressure; the solutions were magnetically stirred throughout the course of the irradiations.

Unless stated otherwise, compositions of photolysates containing the thermally unstable triene **10** were obtained by a combination of nmr spectroscopy and gc analyses. The gc runs were carried out at ≥185°C, at which temperatures the triene rearranged on the column to give COT **9** quantitatively, as determined by calibration against an internal standard (tetradecane).

Direct irradiation of cyclooctatetraene ***9***

A solution of 145.3 mg (0.81 mmol) of COT **9** (10) in 200 mL of cyclohexane was photolyzed at >318 nm for 12.75 h in Cell B. The photolysate analysed (nmr) for a triene photoproduct ratio (**10**:**11**) of ca. 7:1. The photolysate was concentrated and chromatographed on a Lobar column (2.5% ether–cyclohexane) into two bands. The second band contained 60.9 mg (42%) of triene **10**, mp 65–67°C (from hexane); ir (CCl_4): 2234 (C≡N) cm^{-1}; uv (hexane): 257 sh (5210), 265 (6460), 270 sh (5900), 283 sh (3120), 291 sh (1410), 294 sh (910), and 300 (660); ^1H nmr (400 MHz; $CDCl_3$), see Table 1; spin decoupling experiments: irradiation of H-4 collapsed H-5 to a d ($J_{5,6}$ = 4.5); irradiation of H-5 collapsed H-4 and H-6 to singlets; irradiation of H-6 collapsed H-5 to a d ($J_{5,4}$ = 10), and H-7 to a d ($J_{7,8}$ = 2.8); irradiation of H-7 collapsed H-8 to an s; irradiation of H-8 collapsed H-7 to an s; ^{13}C nmr (75.5 MHz; $CDCl_3$): 146.13, 140.29, 137.31, 130.27, 128.70, 128.33, 127.52, 126.49, 124.86, 121.32, 48.90, and 41.75 (one C not observed). Mass spectrum showed molecular ion at m/e = 179.0727 (94%), 178 (base peak); $C_{13}H_9N$ requires 179.0734. Anal. calcd. for $C_{13}H_9N$: C 87.12, H 5.06, N 7.82; found: C 87.09, H 5.15, N 7.81.

The first band was concentrated and the residue crystallized from 3 mL of hexane to give 62.8 mg (43%) of recovered COT **9**. The mother liquors were rechromatographed on a Lobar column (1% ethyl acetate – 20% toluene – 79% hexane) into two bands, the second of which contained 8.0 mg (6%) of COT **9**. The first band gave 8.6 mg (6%) of triene **11**, mp 74–76°C (from hexane); ir (CCl_4): 2224(C≡N) cm^{-1}; uv (hexane): 227 (17 800), 234 (15 800), 281 (5820), and 309 (1510); ^1H nmr (400 MHz; $CDCl_3$): 7.52 (m, 1H, 1 aromatic), 7.27 (m, 2H, 2 aromatics), 7.13 (m, 1H, 1 aromatic), 6.76 (d, 1H, H-5, $J_{5,6}$ = 4.5), 6.11 (br d, 1H, H-8, $J_{8,7}$ = 2.5), 6.07 (br d, 1H, H-7, $J_{7,8}$ = 2.5), 4.17 (d, 1H, H-1, $J_{1,6}$ = 4.5), and 3.79 (t, 1H, H-6, $J_{6,5} = J_{6,1}$ = 4.5); spin decoupling experiments: irradiation of H-6 collapsed H-1 and H-5 to singlets and modified H-7; irradiation of H-1 collapsed H-6 to a d ($J_{6,5}$ = 4.5) and modified H-8; irradiation of H-5 collapsed H-6 to a d ($J_{6,1}$ = 4.5); ^{13}C nmr (75.5 MHz; $CDCl_3$): 142.64, 141.40, 138.04, 134.53, 129.76, 128.11, 127.34, 126.46, 126.09, 117.44, 112.31, 43.69, and 42.87. Mass spectrum showed molecular ion at m/e = 179.0727 (93%), 178 (base peak); $C_{13}H_9N$ requires 179.0734.

Thermolysis of triene ***10***

A solution of 10.7 mg (0.060 mmol) of **10** in 2 mL of *n*-nonane was refluxed (ca. 150°C) for 1 h. The thermolysis product was chromatographed on Silica Gel 60 (0.9 cm × 10 cm; 5% ether–cyclohexane). Crystallization of the main band from hexane gave 10.3 mg (96%) of COT **9**, mp 65–67°C (lit. (10) mp 66–68°C).

Direct irradiation of triene **10**

A solution of 91.8 mg (0.51 mmol) of **10** and 8.6 mg of tetradecane (gc standard) in 250 mL of cyclohexane was irradiated (Pyrex filter) for 3.0 h in Cell A. The photolysate composition analysed (gc and nmr) for 7.7 mg (11%) of 1-cyanonaphthalene, 52.1 mg (57%) of COT **9**, 3.7 mg (4%) of SB **12**, and 17.4 mg (19%) of triene **10**. The photolysate was concentrated and chromatographed on a Lobar column (2.5% ether–cyclohexane). The first band eluted was 5.9 mg (9%) of 1-cyanonaphthalene (identified by gc, tlc, and nmr comparison with an authentic sample). The second band was a mixture of COT **9** and SB **12**. The third band contained 15.3 mg (17%) of recovered triene **10**. Preparative gc of the bulk of the second band on an SE-30 column eluted firstly 2.2 mg (2%) of SB **12**, followed by 39.6 mg (43%) of COT **9**, mp 65–67°C. For SB **12** (gc purity > 99%), mp 81–83°C (from hexane); ir (CCl_4): 2245 (C≡N) cm^{-1}; uv (hexane): 266 (290), 272 (370), and 280 (340); ^1H nmr (400 MHz, $CDCl_3$), see Table 2; spin decoupling experiments: irradiation of H-6 collapsed H-7 to a d ($J_{7,8}$ = 2.5); irradiation of H-7 collapsed H-6 to an s, and H-8 to a t ($J_{8,1} \approx J_{8,2}$ = 6.5); irradiation of H-1 collapsed H-2 to a d ($J_{2,8}$ = 6.5), and H-8 to a dd ($J_{8,7}$ = 2.5, $J_{8,2}$ = 6.5); irradiation of H-2 collapsed H-1 to a d ($J_{1,8}$ = 6.0) and H-8 to a dd ($J_{8,1}$ = 6.0, $J_{8,7}$ = 2.5); irradiation of H-8 collapsed H-1 to a d ($J_{1,2}$ = 6.0), H-2 to a d ($J_{2,1}$ = 6.0), and H-7 to a d ($J_{7,6}$ = 5.0). Mass spectrum showed molecular ion at m/e = 179.0724 (84%), 178 (base peak); $C_{13}H_9N$ requires 179.0734.

Sensitized irradiation of triene ***10***

A solution of 10.3 mg (0.058 mmol) of **10**, 10.5 mg of tetradecane (gc standard), and 6.3 mg (0.028 mmol) of *p*-dimethylaminobenzophenone in 15 mL of cyclohexane was irradiated for 25 min in Cell C with light filtered through a uranium glass sleeve. The photolysate composition analysed (gc and nmr) for 9.5 mg (92%) of COT **9** and 0% of **10** (i.e., complete conversion). The photolysate was concentrated and chromatographed on Silica Gel 60 (0.9 cm × 15 cm; 5% ether–cyclohexane). The first band gave 9.1 mg (88%) of COT **9**, mp 65–67°C (from hexane). The second band gave 5.6 mg (89%) of recovered sensitizer. No 1-cyanonaphthalene was observed in the photolysate (gc monitoring).

Direct irradiation of SB ***12***

A solution of 3.6 (0.020 mmol) of **12** and 2.8 mg of tetradecane (gc standard) in 3.5 mL of cyclohexane contained in Cell D was irradiated for 30 min with Corex-filtered light. The photolysate composition analysed (gc) for 1.2 mg (33%) of COT **9** and 2.0 mg (56%) of SB **12**. The photolysate was concentrated and chromatographed on a short column of Silica Gel 60 (0.9 cm × 5 cm; 3% ether–cyclohexane) to remove the tetradecane. The band containing the COT **9** and SB **12** was separated by preparative gc on an SE 30 column. The first component eluted was 1.2 mg (33%) of SB **12**. The second was 0.7 mg (19%) of COT **9** (identified by nmr).

Attempted sensitized irradiation of SB ***12***

(a) With p*-dimethylaminobenzophenone*

A solution of 2.7 mg (0.015 mmol) of **12**, 3.3 mg (0.015 mmol) of *p*-dimethylaminobenzophenone, and 3.6 mg of tetradecane (gc standard) in 3.5 mL of cyclohexane contained in Cell D was irradiated for 20 min with light filtered through a WG-360 glass (Schott) filter. The

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

photolysate composition analysed (gc) for 2.6 mg (96%) of SB **12** and 0.8 mg (24%) of the sensitizer; no other products were detected. The photolysate was concentrated and chromatographed on Silica Gel 60 (0.9 cm × 10 cm; 5% ether–cyclohexane) to give 2.2 mg (81%) of **12** (identified by nmr).

(b) With acetone

A solution of 2.7 mg (0.015 mmol) of SB **12**, and 1.9 mg of tetradecane (gc standard) in 3.5 mL of acetone was irradiated for 3.5 h in Cell D with Pyrex-filtered light. The photolysate analysed for 1.8 mg (67%) of SB **12**; no other products were detected. The SB **12** (1.4 mg; 52%) was recovered from the photolysate and identified as in part (a) above.

Labelled COT **9**a

Deuterated COT **9***a* (ca. 90% d_1 at C-8) was obtained as previously described (10); ^{1}H nmr (400 MHz; $CDCl_3$): 7.23–7.36 (m, 3.79H, 3 aromatics + residual $CHCl_3$), 7.00–7.05 (m, 1.00H, 1 aromatic), 6.90 (dd, 0.95H, H-6, $J_{6,7}$ = 4.5, $J_{6,9}$ = 1.5), 6.65 (d, 1.00H, H-10, $J_{10,9}$ = 11.5), 6.06 (d, 1.05H, H-9 + residual H-8, $J_{9,10}$ = 11.5), and 5.91 (br d, 0.97H, H-7, $J_{7,6}$ = 4.5). Integrations for **9***a* and for all subsequent deuterium labelled compounds were normalized by assigning integer values to one or more aromatic proton signals, unless otherwise stated; integration uncertainties are estimated to be within ca. ±0.05H.

Labelled triene **10**a *from COT* **9**a

A solution of 198.0 (1.10 mmol) of COT **9***a* in 200 mL of cyclohexane was photolyzed at >318 nm for 11.30 h in Cell B. The photolysate was worked up as in the case of the direct irradiation of unlabelled COT **9** to give 128.8 mg (65%) of triene **10***a*; ^{1}H nmr (400 MHz; $CDCl_3$): 7.45–7.48 (m, 1.00H, 1 aromatic), 7.24–7.31 (m, 3.35H, 2 aromatics + residual $CHCl_3$), 7.10–7.14 (m, 1.01H, 1 aromatic), 6.39 (d, 1.01H, H-4, $J_{4,5}$ = 10), 6.18 (d, 0.99H, H-7, $J_{7,8}$ = 2.8), 6.10 (d, 1.01H, H-8, $J_{8,7}$ = 2.8), 5.90 (d, 1.04H, H-5, $J_{5,4}$ = 10), and 4.00 (d, 0.08H, H-6, $J_{6,5}$ = 4.5).

Direct irradiation of triene **10**a

A solution of 128.8 mg (0.72 mmol) of **10***a* in 250 mL of cyclohexane was irradiated (Pyrex filter) for 4.0 h in Cell A. The photolysate was worked up as in the case of the direct irradiation of unlabelled triene **10** to give 46.1 mg (36%) of COT **9***a*, ^{1}H nmr (400 MHz; $CDCl_3$): 7.23–7.36 (m, 4.27H, 3 aromatics + residual $CHCl_3$), 7.00–7.05 (m, 1.00H, 1 aromatic), 6.90 (dd, 0.94H, H-6, $J_{6,7}$ = 4.5, $J_{6,9}$ = 1.5), 6.65 (d, 1.01H, H-10, $J_{10,9}$ = 11.5), 6.06 (d, 1.12H, H-9 + residual H-8, $J_{9,10}$ = 11.5), and 5.91 (br d, 0.98H, H-7, $J_{7,6}$ = 4.5); 1.6 mg (2%) of 1-cyanonaphthalene; 1.4 mg (1%) of SB mixture **12***a* and **12***b*, ^{1}H nmr (400 MHz; $CDCl_3$): 7.20–7.40 (m, 7.35H, 3 aromatics + residual $CHCl_3$), 5.62 (d, 0.98H, H-6, $J_{6,7}$ = 5.0), 5.31 (dd, 1.01H, H-7, $J_{7,6}$ = 5.0, $J_{7,8}$ = 2.5), 3.69 (m, 0.30H, H-1), 3.25 (d, 1.00H, $J_{2,8}$ = 7.0), and 2.91 (dd, 0.80H, H-8, $J_{8,2}$ = 7.0, $J_{8,7}$ = 2.5), normalized on the basis that sum of non-aromatic protons is 4.10H; ^{2}H nmr (400 MHz; $CHCl_3$): 3.70 (br s, D-1) and 2.91 (br s, D-8), integration ratio of (D-1):(D-8) was 3 (**12***a*):1 (**12***b*); and 38.9 mg (30%) of recovered triene **10***a*, ^{1}H nmr (400 MHz; $CDCl_3$): 7.45–7.48 (m, 1.00H, 1 aromatic), 7.24–7.31 (m, 2.95H, 2 aromatics + residual $CHCl_3$), 7.10–7.14 (m, 1.01H, 1 aromatic), 6.39 (d, 1.02H, H-4, $J_{4,5}$ = 10), 6.18 (d, 0.95H, H-7, $J_{7,8}$ = 2.8), 6.10 (d, 0.97H, H-8, $J_{8,7}$ = 2.8), 5.90 (d, 1.00H, H-5, $J_{5,4}$ = 10), and 4.00 (d, 0.08H, H-6, $J_{6,5}$ = 4.5).

Thermolysis of triene **10**a

A solution of 6.3 mg (0.035 mmol) of **10***a* in 2 mL of *n*-nonane was refluxed (ca. 150°C) for 40 min. The thermolysis product was worked up as in the case of the unlabelled triene **10** to give 6.2 mg (98%) of COT **9***a*; ^{1}H nmr (400 MHz; $CDCl_3$): 7.23–7.36 (m, 3.80H, 3 aromatics + residual $CHCl_3$), 7.00–7.05 (m, 1.00H, 1 aromatic), 6.90 (dd, 0.99H, H-6, $J_{6,7}$ = 4.5, $J_{6,9}$ = 1.5), 6.65 (d, 0.99H, H-10, $J_{10,9}$ = 11.5), 6.06 (d, 1.13H, H-9 + residual H-8, $J_{9,10}$ = 11.5), and 5.91 (br d, 1.03H, H-7, $J_{7,6}$ = 4.5).

Sensitized irradiation of triene **10**a

A solution of 6.8 mg (0.038 mmol) of **10***a* and 4.6 mg (0.020 mmol) of *p*-dimethylaminobenzophenone in 10 mL of cyclohexane was irradiated for 23 min in Cell C with light filtered through a uranium glass sleeve. The photolysate was worked up as in the case of the sensitized irradiation of unlabelled triene **10** to give 4.9 mg (72%) of COT **9***a*, ^{1}H nmr (400 MHz; $CDCl_3$): 7.23–7.36 (m, 4.15H, 3 aromatics + residual $CHCl_3$), 7.00–7.05 (m, 1.00H, 1 aromatic), 6.90 (dd, 1.00H, H-6, $J_{6,7}$ = 4.5, $J_{6,9}$ = 1.5), 6.65 (d, 0.99H, H-10, $J_{10,9}$ = 11.5), 6.06 (d, 1.11H, H-9 + residual H-8, $J_{9,10}$ = 11.5), and 5.91 (br d, 1.00H, H-7, $J_{7,6}$ = 4.5); and ca. 0.5 mg (ca. 8%) of recovered triene **10***a*, ^{1}H nmr (400 MHz; $CDCl_3$): 7.45–7.48 (m, 1.00H, 1 aromatic), 7.24–7.10 (m, H integration n/a, 3 aromatics + large residual $CHCl_3$), 6.39 (d, 0.95H, H-4, $J_{4,5}$ = 10), 6.18 (d, 0.99H, H-7, $J_{7,8}$ = 2.8), 6.10 (d, 0.96H, H-8, $J_{8,7}$ = 2.8), 5.90 (d, 0.98H, H-5, $J_{5,4}$ = 10), and 4.00 (d, 0.09H, H-6, $J_{6,5}$ = 4.5).

Direct irradiation of labelled SB mixture **12**a *and* **12**b

A solution of 1.6 mg (0.009 mmol) of SB mixture **12***a* and **12***b* in 3.5 mL of cyclohexane contained in Cell D was irradiated for 30 min with Corex-filtered light. The photolysate was worked up as in the case of the direct irradiation of unlabelled SB **12** to give 0.7 mg (44%) of recovered starting material, ^{1}H nmr (400 MHz; $CDCl_3$): 7.20–7.40 (m, 11.5H, 3 aromatics + residual $CHCl_3$), 5.62 (d, 0.99H, H-6, $J_{6,7}$ = 5.0), 5.31 (dd, 1.01H, H-7, $J_{7,6}$ = 5.0, $J_{7,8}$ = 2.5), 3.69 (m, 0.33H, H-1), 3.25 (d, 1.00H, $J_{2,8}$ = 7.0), and 2.91 (dd, 0.78H, H-8, $J_{8,2}$ = 7.0, $J_{8,7}$ = 2.5); and 0.3 mg (19%) of labelled COT mixture **9***a* and **9***d*, ^{1}H nmr (400 MHz; $CDCl_3$): 7.23–7.36 (m, 9.3H, 3 aromatics + residual $CHCl_3$), 7.00–7.05 (m, 1.00H, 1 aromatic), 6.90 (br d, 0.96H, H-6, $J_{6,7}$ = 4.5), 6.64 and 6.65 (s and d, 1.00H, H-10, $J_{10,9}$ = 11.5; ratio of s (**9***d*):d (**9***a*) ≈ 3:1), 6.03–6.08 (m, 1.04H, H-9 + H-8), and 5.89–5.95 (m, 0.96H, H-7).

Quantum yield determinations

Quantum yields were performed on an apparatus previously described (20), which includes an optical bench arranged for beam splitting into a ferrioxalate actinometer (21). Cyclohexane solutions (3.5 mL) of reactants (ca. (4.5–6.5) × 10^{-3} M) and sensitizer, if any (*p*-dimethylaminobenzophenone, ca. 1.0 × 10^{-3} M), were deoxygenated prior to irradiation by flushing with argon. A positive pressure of argon was maintained over the stirred solutions throughout the course of the irradiations. The quantum yields (Φ's) were obtained from several runs extrapolated to zero conversion. Product analyses were determined by a combination of gc (internal tetradecane standard) and high performance liquid chromatography (hplc; for the determination of relative amounts of COT **9** and triene **10**). The hplc analyses were performed on a normal phase 16 μm silica column (Waters, μ Porasil, 3.9 mm × 300 mm) with a Waters 501 hplc pump with detection by a Waters model 481 LC spectrophotometer. The eluting solvent system was 1% ethyl acetate in hexane. Photometric detection was carried out at 300 nm; chromatograms were integrated using a Waters 740 data module, and relative detector responses were calibrated against known mixtures of COT **9** and triene **10**. For the direct irradiation of triene **10**, light of wavelength 280 nm was used. For sensitized runs with *p*-dimethylaminobenzophenone, the sensitizer absorbed >95% of the incident light (366 nm) employed. For the direct irradiation of SB **12**, light of wavelength 275 nm was used.

A stereocontrolled intramolecular cycloaddition – sigmatropic rearrangement approach to a tricyclo[7.4.0^{1,6}.0^{1,10}]tridecane precursor for (±) gascardic acid

GERVAIS BÉRUBÉ AND ALEX G. FALLIS[1]

The Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received June 7, 1990

GERVAIS BÉRUBÉ and ALEX G. FALLIS. Can. J. Chem. **69**, 77 (1991).

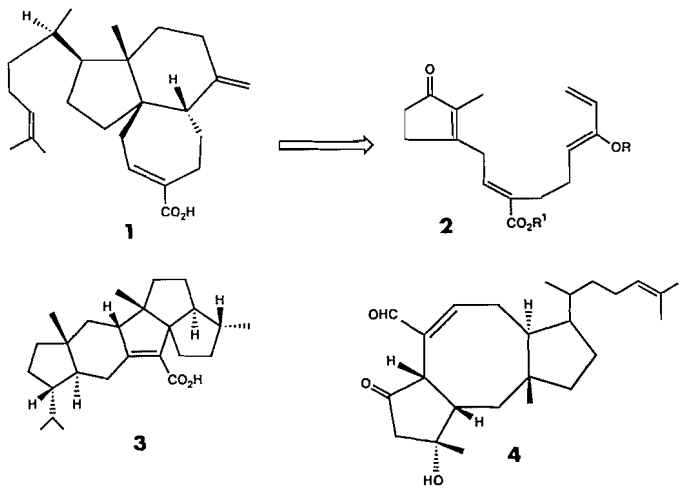
A general intramolecular Diels–Alder anionic oxy-Cope strategy for the synthesis of tricyclic skeletons and its application to the preparation of the gascardic acid precursor **21** is described. *In situ* generation of the appropriate cyclopentadiene **9** by isomerization (Et_3N) afforded the [4+2] adduct directly or with $EtAlCl_2$ as catalyst. The requisite potassium salt of the 1,5 diene **16** rearranged with concomitant epimerization at 67°C to the fused ring ketone **18**. Selective allylic oxidation and reduction provided **21**.

Key words: Diels–Alder, oxy-Cope, sesterterpene, synthesis, cycloaddition.

GERVAIS BÉRUBÉ et ALEX G. FALLIS. Can. J. Chem. **69**, 77 (1991).

On décrit une stratégie générale, basée sur des réactions de Diels–Alder intramoléculaire et d'oxy-Cope anionique, pour effectuer la synthèse des squelettes tricycliques ainsi que son application à la préparation du précurseur **21** de l'acide gascardique. Utilisant une isomérisation (Et_3N), on a réalisé une génération *in situ* du cyclopentadiène approprié **9** qui a fourni l'adduit [4+2] soit directement ou sous l'influence du $EtAlCl_2$ comme catalyseur. À 67°C, le sel de sodium approprié **16** du 1,5-diène se transpose avec une épimérisation concomitante qui conduit à la cétone cyclique condensée **18**. Son oxydation allylique sélective et une réduction subséquente conduisent au produit **21**.

Mots clés : Diels–Alder, oxy-Cope, sesterterpène, synthèse, cycloaddition.



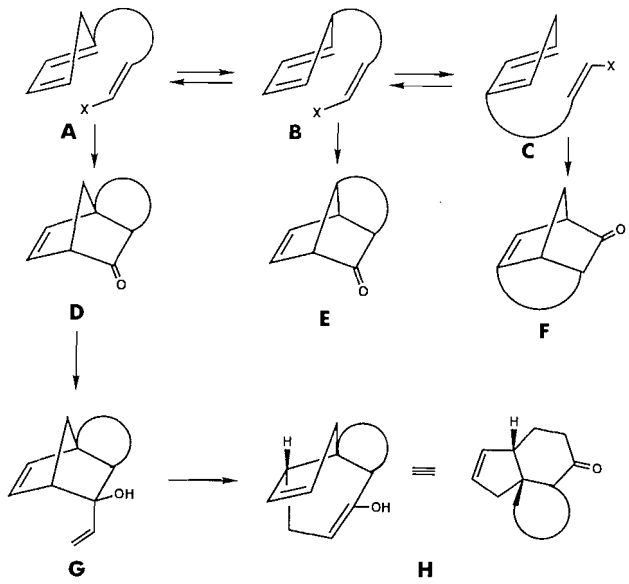
[Traduit par la revue]

Introduction

The sesterterpenes represent a structurally diverse family of C_{25} terpenes. The major polycyclic members include gascardic acid (**1**) (1), retigeranic acid (**3**) (2), and ophiobolin C (**4**) (3). These novel ring systems have attracted considerable synthetic interest and consequently all of them have succumbed to total synthesis (4). Gascardic acid possesses a unique tricyclo-[7.5.0^{1,7}.0^{1,11}]tetradecane skeleton whose structure was established via total synthesis (5) and X-ray diffraction (6). At present, this fused arrangement of five, six, and seven membered rings has not been encountered elsewhere in nature, although this structure shares with other angular triquinane natural products, such as retigeranic acid, a related spiro-fused tricyclic nucleus.

The presence of a spiro center in both gascardic and retigeranic acid that is common to the three fused rings suggested that a common synthetic approach to these skeletons was possible. In a retrosynthetic sense the double disconnection of the cyclohexene ring in gascardic acid would, in principle, allow the construction of the tricyclic framework by an intramolecular Diels–Alder cycloaddition **2** to **1**. However, cyclizations in which the diene and dienophile are linked by five atoms are difficult, particularly in carbocyclic systems (7–9). In addition, for retigeranic acid (**3**), a ring contraction of the cyclohexanone and the expulsion, from an unactivated center, of the extra carbon atom would be required. Closer scrutiny indicated that a more powerful combination would be to employ a different intramolecular cycloaddition followed by a [3,3] sigmatropic rearrangement. Thus in general, a stereocontrolled route to many multicyclic skeletons is available from a combination of these pericyclic transformations via an intramolecular Diels–Alder anionic oxy-Cope rearrangement strategy. As illustrated in Scheme 1, the length of the side chain may be varied and the resulting cyclohexanone contracted or expanded as required.

[1]Author to whom correspondence may be addressed.



Over several decades the Diels–Alder reaction has remained one of the most useful organic transformations. There is also considerable current interest in the intramolecular Diels–Alder reaction, which has been applied to a number of natural product syntheses with notable success due to the complex systems that can be assembled in a relatively rapid manner (9). Similarly, [3,3] sigmatropic (Cope) rearrangements are a powerful construction tool within the arsenal of the organic chemist. Thus the oxy-Cope variant has recently received increased attention as a versatile method for the synthesis of diverse natural product skeletons (10). We wish to report the details for the successful application of this combined strategy (**A–D–G–H**) to the synthesis of the gascardic acid intermediate **21**, in which the key ring junctions and substituents have the correct relative stereochemistry (11).

Results and discussion

Previous studies established that, in spite of the rapid [1,5] sigmatropic rearrangement that occurs at room temperature in

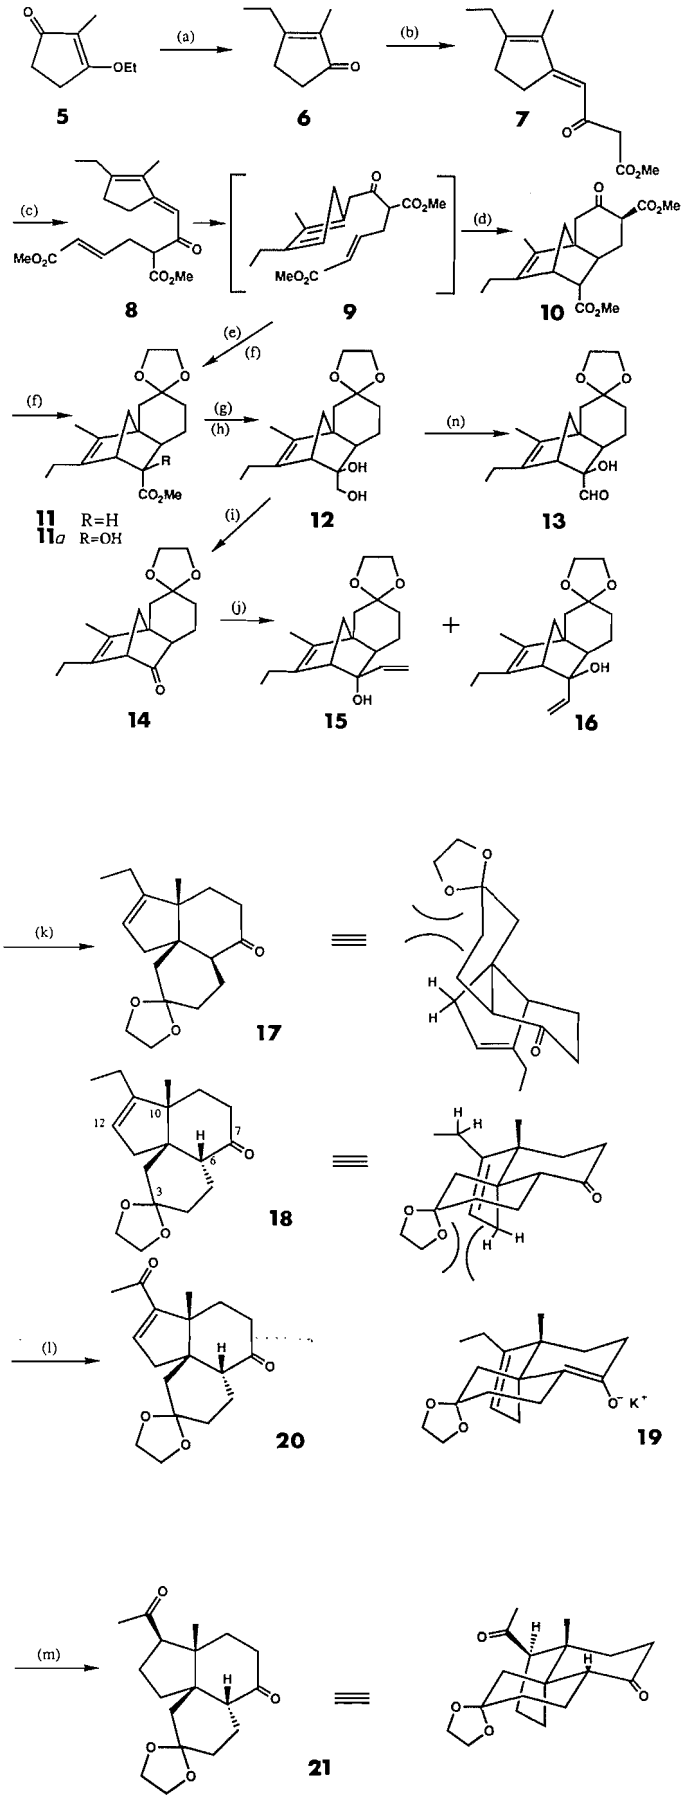
SCHEME 1

cyclopentadienes **A**–**C**, the cycloadditions will proceed to give the fused ring product **D** rather than the isomeric bridged ring or Bredt olefin adducts **E** and **F** (7, 8, 12). Our earlier investigations revealed that the cycloheptane ring could not be generated directly and that ultimately a ring expansion would be required (7). In addition, it was established that carrying the dimethylhexenyl substituent caused difficulties, due to competing ene reactions during the cycloaddition step. Furthermore, it is well known that nucleophilic addition to 2-norbornanone type ketones occurs preferentially from the *exo* face. Thus, we developed an epimerization procedure for cyclic vinyl tertiary alcohols via a [2,3] sulfoxide sigmatropic rearrangement, which may be utilized to circumvent this potential difficulty (13, 10*d*).

The detailed synthetic route is outlined in Scheme 2 and commences with the keto-enol ether **5** derived from 2-methyl-1,3-cyclopentanedione upon treatment with *p*-toluenesulfonic acid, molecular sieves, and ethanol in refluxing benzene (90%) (7). Ethyllithium, generated *in situ* in an ultrasonic bath (14) from bromoethane and Li/Na alloy, was condensed with **5** to give the cyclopentenone (98%). The dianion derived from methyl acetoacetate (15), by sequential treatment with sodium hydride and *n*-butyllithium, was added to this cyclopentenone and dehydration of the resulting alcohol was effected with 3 M HCl to afford the dienone-ester **7**. This material was a single regioisomer, formed as a consequence of the nonbonded interactions between the ring vinyl methyl function and carbonyl substitutent that are avoided in the *E* olefin. Alkylation of this keto-ester with methyl 4-bromocrotonate provided the triene-diester **8** (64%) accompanied by a small amount (8.5%) of the dialkylated product.

The requisite Diels–Alder precursor **9** was generated *in situ* from **8**. Treatment of **8** with $EtAlCl_2$ in dichloromethane at room temperature (21°C) catalyzed the cycloaddition with a high level of stereocontrol to give the single isomer **10** in modest yield (30%). This adds to the growing list of examples where alkylaluminum halides are the most satisfactory catalysts for effective control of intramolecular [4+2] cycloadditions (16). As discussed above, several different cyclopentadiene adducts might be envisaged but, as expected, only the tricyclo[6.2.1.$0^{1,6}$]undecene nucleus was formed. On a preparative scale it was more efficient to conduct the cyclization directly in refluxing toluene containing triethylamine (99%). Unfortunately the base created a mixture of stereoisomers that consisted of keto-ester epimers (~1:1) and *endo*/*exo* ester isomers (5:1.5). As a result, this material was used directly in subsequent transformations and the offending epimers transformed as follows. Selective hydrolysis and decarboxylation of the α-ester was effected with lithium chloride in aqueous dimethyl sulfoxide and the resulting cyclohexanone protected as its ethylene ketal to afford the ester **11** in which the adjacent cyclohexane bond was *exo* (43% overall yield from **8**). The identical sequence was employed, commencing with **10** to generate **11**.



Two different approaches to the tricyclic 1,5-diene **16** were examined. The ester enolate of **11** was generated at −78°C with lithium diisopropylamide (LDA) and quenched with oxygen to afford the hydroxy ester as a single isomer. Reduction of the methyl ester with $LiAlH_4$ gave the diol **12**. It had been anticipated that the alcohol **16** could be prepared directly by oxidation of the primary alcohol followed by Wittig reaction on the resulting aldehyde **13**. The desired oxidation was accomplished under Swern conditions (17), but unfortunately this hydroxy-aldehyde was very unstable and rendered this route impractical since the best yield was 23%. Consequently, the diol **12** was converted to the ketone **14** by periodate oxidation. In spite of the *exo* orientation of the adjacent cyclohexane ring, the carbonyl was attacked preferentially from the top face with vinyl magnesium bromide to give a 3:1 ratio of *endo* and *exo* alcohols **15** and **16**. Conditions to improve this ratio, using a variety of Lewis acids ($CdCl_2$, $ZnCl_2$, $TiCl_4$, $EtAlCl_2$, Et_2AlCl, etc.), were investigated with a view to preferentially complexing the *exo* surface, but the ratio did not change significantly.

Previous studies (18) established that significant acceleration is induced by potassium salts in anionic oxy-Cope rearrangements. Thus, as anticipated, the potassium salt of **16** underwent smooth sigmatropic rearrangement in refluxing THF to the tricyclic ketones **17** and **18** in 67% isolated yield. The initial product was a 1:1 mixture of these *trans* and *cis* cyclohexanones. The *trans* ring junction was strongly favored in the cycloheptane series required for gascardic acid (5) but this is not the case for these cyclohexanes. To generate the natural product stereochemistry, the *exo* cyclohexane bond in **16** must be isomerized via the intermediacy of enolate **19**. However, protonation was not selective as a consequence of the very similar nonbonded interactions that are present in each isomer, particularly between the cyclopentenyl methylene hydrogens and the ketal. This was confirmed by epimerizing **17** with sodium methoxide to give a 1:1 mixture of **17** and **18**. Nevertheless the ketal is important for the subsequent steps.

As illustrated, the cyclopentene ring C13 methylene group in **18** is relatively hindered, compared to the side-chain ethyl group attached to C11, due to the juxtaposition of the oxygen ketal at C3. Thus allylic oxidation with selenium dioxide followed by oxidation of the secondary alcohol with pyridinium chlorochromate (PCC) afforded the conjugated methyl ketone **20** rather than the corresponding cyclopent-11-en-13-one. Treatment of this unsaturated ketone **20** with lithium/ethylene diamine, followed by PCC to correct some reduction of the carbonyl function, provided the tricyclic triketone **21**. In view of the concave nature of the skeleton **20**, dissolving metal reduction should generate the methyl ketone with a *cis* orientation relative to the bridgehead C10 methyl group. This was

confirmed by ^{1}H nmr nOe difference spectra, which displayed strong (20–27%) signal enhancements for the methyl ketone (δ 2.19) and tertiary methyl (δ 0.74) signals consistent with the stereochemistry illustrated.

In conclusion, as illustrated by the synthesis of **21**, this intramolecular cycloaddition – [3,3] sigmatropic rearrangement strategy provides a general entry to diverse multicyclic skeletons contained in natural products such as gascardic acid. Several steps are required to complete the total synthesis, including exocyclic methylene introduction via a Wittig reaction, side-chain attachment, diazoester-based ring expansion, reductive elimination, and hydrolysis, but they have ample literature precedent in simpler systems. A related approach, based on these cycloaddition and rearrangement concepts, and which combines different pericyclic reactions, is being developed for the total synthesis of retigeranic acid.

Experimental

Melting points were determined in capillary tubes with a Thomas–Hoover Uni-Melt apparatus or a Fisher–Johns melting point apparatus, and are uncorrected. Infrared (ir) spectra were recorded on a Perkin–Elmer 783 or 983G infrared spectrophotometer. Proton magnetic resonance spectra (^{1}H nmr) were measured at 60 MHz with a Varian model EM 360 spectrometer, at 200 MHz with a Varian Gemini spectrometer, or at 300 MHz with a General Electric GN 300 spectrometer or a Varian XL-300 spectrometer in deuterochloroform. Carbon magnetic resonance spectra (^{13}C nmr) were measured at 75 MHz with a General Electric GN 300 spectrometer or a Varian XL-300 spectrometer. Chemical shifts are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard; the numbers of protons, multiplicity, and coupling constants are indicated in parentheses. Mass spectra were determined on a V. G. Micromass 7070 HS instrument using an ionization energy of 70 eV, or on a Hewlett Packard 5890A gas chromatograph 5970B mass selective detector equipped with a 12.5-m capillary column (0.2 mm i.d.) coated with cross-linked dimethyl silicone (0.33 μm). Flash column chromatography using E. Merck silica gel 60 (230–400 mesh) was employed for all column chromatography. Analytical thin-layer chromatography (tlc) was carried out on aluminum sheets precoated (0.2 mm layer thickness) with silica gel 60 F_{254} (E. Merck). The purity of all title compounds was judged to be ≥95% as determined by a combination of gc–ms, ^{1}H nmr, and ^{13}C nmr analysis.

Petroleum ether refers to a fraction with boiling range 30–60°C. Anhydrous diethyl ether (ether), tetrahydrofuran (THF), dimethoxyethane (DME), and dioxane were obtained by distillation from $LiAlH_4$ or potassium/benzophenone. Methanol and absolute ethanol were dried by distillation from magnesium. Dry hexamethylphosphoramide (HMPA), dimethylformamide (DMR), dimethyl sulfoxide (DMSO),

For personal use only.

and diisopropylamine were prepared by distillation from calcium hydride. Solutions in organic solvents were dried over anhydrous magnesium sulfate and stripped of solvent with a Büchi rotary evaporator connected to a water aspirator. Unless otherwise indicated, all reactions were conducted under an atmosphere of dry nitrogen.

*2-Methyl-3-ethylcyclopentenone (**6**)*

The Li/Na "alloy" was prepared as follows. Lithium (510 mg) and sodium (25 mg) were washed with petroleum ether and placed in a round bottom flask previously flushed with nitrogen. The metals were heated, with a heat gun, under vacuum until the sodium had melted. This initiated contact between the molten sodium and the solid lithium and the flask was allowed to cool to room temperature. The "activated lithium" prepared in this manner was highly effective for the preparation of alkyl lithiums using ultrasound.

The enone **5** (5.0 g, 35.7 mmol) was added to a suspension of activated lithium (570 mg Li/25 mg Na, 82 mmol) in ether. The mixture was irradiated with ultrasound (cleaning bath) while ethyl bromide was added dropwise. The irradiation was continued for 1 h (i.e., until the activated lithium disappeared); then the reaction mixture was quenched with water. The ethereal phase was washed thoroughly with water, dried, filtered, and concentrated to give **6**, 4.35 g (98%); ir (neat): 1695 (C=O), 1645 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.4 (6H, m, -CH_2CH_2-, CH_2CH_3), 1.69 (3H, br s, =C-CH_3), 1.1 (3H, t, J = 7.5 Hz, -CH_2CH_3).

*Methyl 3-oxo-4-*E*-(2-methyl-3-ethyl-2-cyclopentyl)butenoate (**7**)*

Methyl acetoacetate (4.1 mL, 4.4 g, 38 mmol) was added dropwise to a suspension of sodium hydride (1.52 g (60% in mineral oil), 38 mmol) in dry tetrahydrofuran (100 mL) maintained at 0°C. The reaction mixture was warmed to 60°C and stirring was continued for a further 20 min. The reaction was recooled to 0°C, butyllithium (14.7 mL of a 2.6 M solution in hexanes, 38 mmol) added, and the mixture stirred for a further 10 min. The enone **6** (4.15 g, 33.4 mmol) was added dropwise and the resulting solution was stirred for a further 20 min. The reaction mixture was diluted with ether (400 mL) and was stirred vigorously with 10% aqueous hydrochloric acid (100 mL) for 2 h. The organic portion was washed with water (5 × 50 mL), dried, filtered, and concentrated. This material was purified by flash chromatography (9:1, petroleum ether/acetone) to give 4.74 g (64%) of β-ketoester **7**; ir (neat): 1735 (C=O, ester), 1675 (C=O, enone), 1580 (C=C), 1145 (C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.05 (1H, s, -C=CH-), 3.72 (3H, s, -CO_2CH_3), 3.53 (2H, s, -$CH_2CO_2CH_3$), 3.01 (2H, m, -CH_3CH_2C=CH-), 2.51 (2H, br s, -CH_2CH_2C=CCH), 2.37 (2H, q, J = 7.7 Hz, -CH_2CH_3), 1.73 (3H, s, -C=CCH_3), 1.07 (3H, t, J = 7.7 Hz, -CH_2CH_3); ^{13}C nmr ($CDCl_3$) δ: 190.9, 172.2, 168.3, 164.0, 133.7, 110.9, 51.7, 49.9, 34.1, 31.0, 12.1, 9.6. Exact Mass calcd. for $C_{13}H_{18}O_3$: 222.1256; found: 222.1254.

*Methyl 5-carbomethoxy-6-oxo-7-(*E*)-(2-methyl-3-ethyl-2-cyclopentenyl)-2-(*E*)-heptenoate (**8**)*

A solution of β-ketoester **7** (725 mg, 3.26 mmol) in dry THF (5 mL) was added dropwise (cannula) to a suspension of potassium hydride (145 mg, 3.6 mmol) in dry THF (5 mL) maintained at 0°C. The reaction mixture was allowed to warm to room temperature and stirred for 20 min. Methyl 4-bromocrotonate (0.5 mL (85%), ≅637 mg, ≅3.5 mmol, Aldrich) was added and the resulting solution stirred at room temperature for 2 h. The reaction was diluted with ether (100 mL), washed with water (5 × 25 mL), dried, filtered, and concentrated. The residue was purified by flash chromatography (9:1, petroleum ether/acetone) to give 665 mg (64%) of triene **8** and 116 mg (8.5%) of dialkylated product; ^1H nmr ($CDCl_3$) δ: 6.91 (1H, d of t, J = 15.7 Hz, J = 7.2 Hz, -CH=$CHCO_2CH_3$), 6.07 (1H, s, -C=CH-), 5.89 (1H, d, J = 15.7 Hz, =$CHCO_2CH_3$), 3.73 and 3.71 (6H, 2 s, 2 × OCH_3), 3.69 (1H, t, J = 7.4 Hz, $CHCH_2$), 3.03 (2H, m, -CH_2-CH_2C=CH), 2.79 (2H, t (dd), J = 7.0 Hz, -$CHCH_2CH$=CH-), 2.54 (2H, br s, -CH_2CH_2C=CH-), 2.38 (2H, q, J = 7.6 Hz, -CH_2CH_3), 1.74 (3H, s, -C=CCH_3), 1.08 (3H, t, J = 7.6 Hz, -CH_2CH_3); ^{13}C nmr ($CDCl_3$) δ: 191.9, 174.0, 170.1, 166.6, 165.3, 145.5, 134.1, 122.9, 110.2, 58.0, 52.5, 51.5, 34.4, 31.6, 31.0, 23.3, 12.4, 9.9. Exact Mass calcd. for $C_{18}H_{24}O_5$: 320.1624; found: 320.1623.

Dialkylated product: ^1H nmr ($CDCl_3$) δ: 6.72 (2H, d of t, J = 15.5 Hz, J = 7.7 Hz, 2 × -CH=$CHCO_2CH_3$), 5.95 (1H, s, -C=CH-), 5.87 (2H, d, J = 15.5 Hz, 2× =$CHCO_2CH_3$), 3.74 (3H, s, -CO_2CH_3), 3.71 (6H, s, 2× =$CHCO_2CH_3$), 3.05 (2H, m, -CH_2CH_2C=CH-), 2.81 (4H, d, J = 7.7 Hz, 2× -CH_2CH=CH-), 2.52 (2H, br s, -CH_2CH_2C=CH-), 2.38 (2H, q, J = 7.5 Hz, -CH_2CH_3), 1.70 (3H, s, -C=CCH_3), 1.09 (3H, t, J = 7.5 Hz, -CH_2CH_3).

Diels–Alder cyclization

(a) With $EtAlCl_2$

Ethyl aluminum dichloride (1.8 mL of 1.8 M toluene solution, 0.96 equiv., Aldrich) was added to a solution of triene **8** (108 mg, 0.34 mmol) in dry dichloromethane (3 mL). After stirring for 16 h at 21°C, ether (30 mL) was added and the resulting solution was washed sequentially with 10% aqueous HCl (2 × 5 mL), with 5% aqueous sodium carbonate (2 × 5 mL), and with water (3 × 5 mL). The organic phase was dried, filtered, and concentrated. The residue was purified by flash chromatography (96:4, toluene/acetone) to give 32 mg (30%) of β-ketoester **10**; ir (neat):1720 (br C=O, β-ketoester and ester), 1645 (C=C), 1170 (C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.69 and 3.67 (6H, 2 s, 2× -CO_2CH_3), 3.37 and 3.10 (2H, 2 d, part A and B of an AB system, J_{AB} = 16.10 Hz, -CH_2C=O), 3.26 (1H, t, J ≅ 7.5 Hz, O=$CCHCO_2CH_3$), 2.82 (1H, m, -C=CCH-), 2.51 (1H, br s, -$CHCO_2CH_3$), 2.06 (2H, m, -$CHCH_2CH$-), 1.77 (3H, s, -C=CCH_3), 1.68–1.82 (3H, m, =$CCHHCH_3$, CHH bridge, -$CHCHCH_2$-), 1.40–1.50 (2H, m, =$CCHHCH_3$, CHH bridge), 0.90 (3H, t, J = 7.3 Hz, -CH_2CH_3); ^{13}C nmr ($CDCl_3$) δ: 200.0, 175.4, 170.5, 143.5, 132.9, 63.1, 52.1, 51.9, 51.7, 51.5, 48.2, 44.9, 44.4, 43.9, 32.2, 21.3, 10.8, 8.9.

(b) Thermal

The triene **8** (3.0 g, 9.37 mmol) and triethylamine (1.89 g, 2.6 mL, 18.6 mmol) were dissolved in dry toluene (140 mL) and refluxed for 72 h. The solvent was evaporated to give the Diels–Alder adducts **10** (≅3.0 g, 100%). The crude material was used directly in the next step. A sample was purified by flash chromatography (9:1, petroleum ether/acetone); ^1H nmr ($CDCl_3$) (60 MHz) *endo/exo* mixture, characteristic peaks, δ: 3.60–3.76 (6H, s, 2× CO_2CH_3), 1.60 (3H, s, -C=CCH_3), 0.8–1.2 (3H, t, J = 7.5 Hz, -CH_2CH_3). The Diels–Alder adducts **10** (~3.0 g, 9.37 mmol), lithium chloride (0.9 g, 21 mmol), and water (230 mg, 12.7 mmol) were dissolved in dimethyl sulfoxide (23 mL) and heated at 160°C for 1 h. Water (50 mL) was added and the resulting solution extracted with a mixture of ether/petroleum ether (1:4, 4 × 100 mL). The organic phase was washed with water (4 × 50 mL), dried, filtered, and concentrated. The oily residue (1.85 g, 75.5% of crude ketone, unprotected **11**) was used directly in the next step. A sample of this keto-ester was purified by flash chromatography (96:4, toluene/acetone); ^1H nmr ($CDCl_3$) (60 MHz) *endo/exo* mixture, characteristic peaks, δ: 3.65 and 3.58 (3H, s, -CO_2CH_3), 1.58 (3H, s, -C=CCH_3), 0.8–1.2 (3H, t, J = 7.5 Hz, -CH_2CH_3). The crude tricyclic ketone (unprotected **11**) (1.85 g, 7 mmol), ethylene glycol (556 mg, 500 mL, 9 mmol), and pyridinium *p*-toluenesulfonate (170 mg, 0.66 mmol) were dissolved in dry benzene (50 mL) and refluxed (Dean–Stark) for 6 h. The solvent was evaporated and the residue dissolved in ether (100 mL). The ether solution was washed with water (4 × 25 mL), dried, filtered, and concentrated. The residue was purified by flash chromatography to give 1.24 g (43%, for three steps) of dioxolane **11**; ir (neat):1725 (C=O, ester), 1650 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.93 (4H, s, -OCH_2CH_2O-), 3.67 and 3.60 (3H, 2 s, 2× -OCH_3, *exo/endo* 1.5:5), 3.00 (1H, m, -C=CCH-), 2.53 (1H, t (dd), J = 3.7 Hz, -$CHCO_2CH_3$), 1.63 and 1.53 (3H, 2 s, 2× C=CCH_3), 1.10–2.80 (11H, m, -$CHCH_2CH_2$-C-CH_2-, -CH_2CH_3, -CH_2- bridge), 0.96 and 0.85 (3H, 2 t, J = 7.5 Hz and 7.4 Hz, 2× -CH_2CH_3); ^{13}C nmr ($CDCl_3$) δ: (*endo*) 174.9, 141.1, 138.9, 109.3, 64.5, 63.9, 55.1, 54.5, 51.1, 49.8, 48.3, 39.8, 36.3, 34.0, 29.5, 20.6, 13.0, 9.3; (*exo*) 176.5, 140.0, 137.5, 111.1, 64.3, 63.6, 62.5, 53.4, 51.4, 44.6, 47.8, 46.1, 38.6, 31.6, 26.5, 21.5, 11.0, 8.5.

7-endo-*Carbomethoxy-9-ethyl-10-methyl-3,3-ethylenedioxytricyclo-[6.2.1.0^{1,6}]-9-undecene (**11**)*

The decarboalkoxylation and the acetalyzation of isomerically pure β-ketoester **10** was conducted as described above, using the following quantities: A. decarboalkoxylation: β-ketoester **10** (28 mg, 8.75 × 10^{-2} mmol), lithium chloride (10 mg, 0.23 mmol), and water (10 mg, 0.55 mmol) in dimethyl sulfoxide (3 mL). B. acetalyzation: ketone intermediate (15 mg, 5.7 × 10^{-2} mmol), ethylene glycol (27.8 mg, 25 mL, 0.45 mmol), and pyridinium *p*-toluenesulfonate (10 mg, 3.88 × 10^{-2} mmol) in benzene (20 mL). The crude material was purified by flash chromatography (96:4, petroleum ether/acetone) to give 4.5 mg (17%, 2 steps) of dioxolane **11**; ^{1}H nmr ($CDCl_3$) δ: 3.94 (4H, s, -OCH_2CH_2O-), 3.60 (3H, s, -CO_2CH_3), 3.00 (1H, m, -C═CCH), 2.53 (1H, t (dd), J = 7.7 Hz, -$CHCO_2CH_3$), 1.53 (3H, s, -C═CCH_3), 1.10–2.40 (11H, m, -$CHCH_2CH_2$-C-CH_2-, -CH_2CH_3, -CH_2- bridge), 0.96 (3H, t, J = 7.53 Hz, -CH_2CH_3).

7-endo-*Carbomethoxy-9-ethyl-10-methyl-3,3-ethylenedioxytricyclo-[6.2.1.0^{1,6}]-9-undecen-7-ol (**11**a)*

A solution of *n*-butyllithium (5.2 mL, 2.5 M in hexane, 13 mmol, Aldrich) was added dropwise to a stirred solution of dry diisopropylamine (1.44 g, 2 mL, 14.2 mmol) in dry tetrahydrofuran (10 mL) maintained at 0°C. After 10 min, the mixture was cooled to −78°C and a solution of ester **11** (800 mg, 2.6 mmol) in tetrahydrofuran (5 mL) was added dropwise. The resulting solution was stirred 1 h and dry oxygen was slowly bubbled through the solution for a period of 2 h (1 h at −78°C and 1 h from −78 to −10°C) after which time dimethyl sulfide (3 mL) was added. The solvent was evaporated and the residue dissolved in ether (200 mL). The ether solution was washed with water (5 × 50 mL), dried, filtered, and the solvent evaporated. The crude product was purified by flash chromatography (9:1, petroleum ether/acetone) to give starting material **11** (82 mg, 10%) and α-hydroxy ester intermediate **11***a* (360 mg, 43%); ir (KBr): 3395 (OH), 1734 (C═O), 1000–1170 (C—O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 3.94 (4H, m, -CH_2CH_2O-), 3.68 (3h, s, -CO_2CH_3), 2.80 (1H, s, -OH), 2.56 (1H, s, -C═CCH-), 2.30 and 1.26 (2H, d apparent, J = 8.8 Hz and d of t apparent, J = 8.8 Hz, J = 1.5 Hz, -CH_2- bridge), 2.14 (1H, sextet (d of q), J = 7.3 Hz, -$CHHCH_3$), 1.51 (3H, s, C═CCH_3), 1.45–2.05 (8H, m, -$CHHCH_3$, -$CHCH_2CH_2$-C-CH_2-), 0.94 (3H, t, J = 7.5, -CH_2CH_3); ^{13}C nmr ($CDCl_3$) δ: 175.8, 140.8, 139.3, 109.0, 83.4, 64.5, 63.8, 57.2, 54.9, 52.3, 48.8, 43.4, 36.4, 33.0, 22.4, 20.4, 13.0, 9.8. Anal. calcd. for $C_{18}H_{26}O_5$: C 67.06, H 8.13; found: C 66.78, H 8.11.

*9-Ethyl-10-methyl-3,3-ethylenedioxytricyclo[6.2.1.0^{1,6}]-9-undecen-7-one (**14**)*

Lithium aluminum hydride (1.48 g, 39 mmol) was added to a stirred solution of the α-hydroxy ester intermediate **11***a* (3.15 g, 9.78 mmol) in a mixture of dry ether and dichloromethane (1:1, 250 mL) maintained at 0°C. After the addition was complete, the ice bath was removed and the reaction mixture was stirred for 30 min after reaching room temperature. The reaction was recooled to 0°C, excess Glauber's salt (10 g) was slowly added, and the mixture was allowed to warm to room temperature and stirred for 1 h. Finally, anhydrous magnesium sulfate (10 g) was added and the slurry filtered and concentrated. The crude diol **12** (2.94 g) was used without further purification in the next step. An analytical sample was obtained by flash chromatography (7:3, petroleum ether/acetone); ir(neat): 3400 (OH), 1090 (C—O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 3.94 (4H, s, -OCH_2CH_2O-), 3.33 and 3.27 (2H, 2 d, part A and B of an AB system, J_{AB} = 10.74 Hz, -CH_2O), 2.68 (2H, br, 2× -OH)), 2.49 (1H, s, -C═CCH-), 1.48 (3H, s, -C═CCH_3), 1.20–2.30 (11H, m, -$CHCH_2CH_2$-C-CH_2-, -CH_2CH_3, -CH_2- bridge), 1.00 (3H, t, J = 7.5 Hz, -CH_2CH_3); ^{13}C nmr ($CDCl_3$) δ: 141.6, 139.3, 109.1, 84.1, 68.9, 64.5, 63.8, 54.4, 52.4, 48.1, 43.7, 36.5, 33.2, 23.2, 20.9, 13.2, 9.8. Exact Mass calcd. for $C_{17}H_{26}O_4$: 294.1831; found: 294.1828.

The diol **12** (2.87 g, 9.76 mmol), dissolved in a mixture of ether and dichloromethane (4:1, 250 mL) maintained at 0°C, was treated with periodic acid (4.4 g, 19 mmol) and sodium acetate (12 g, 146 mmol). The cooling bath was removed and the reaction was stirred for 1 h after reaching room temperature. The solution was filtered through Celite using ether as eluant. The filtrate was washed with water (6 × 50 mL), dried, filtered, and concentrated. The crude product was purified by flash chromatography to give 1.79 g (70% 2 steps) (30%, overall, from ester **11**) of ketone **14** along with 300 mg (14%) of the diketone from acetal cleavage; **14**: ir (neat): 1728 (C═O), 1650 (C═C), 1030–1150 (C—O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 3.94 (4H, s, -OCH_2CH_2O-), 2.85 (1H, s, -C═CCH-), 2.40 (1H, d, J = 14.7 Hz, -$CHCH_2CH_2$-), 1.50 (3H, s, -C═CCH_3), 1.40–2.20 (10H, m, -CH_2CH_2-C-CH_2, -CH_2CH_3, -CH_2- bridge), 0.94 (3H, t, J = 7.5 Hz, -CH_2CH_3); ^{13}C nmr ($CDCl_3$) δ: 216.3, 144.9, 138.5, 108.8, 63.6, 63.9, 59.1, 52.2, 48.7, 44.3, 36.6, 33.4, 23.6, 20.7, 12.8, 10.4. Exact Mass calcd. for $C_{16}H_{22}O_3$: 218.1307; found: 218.1282.

7-endo-*Carboxaldehyde-9-ethyl-10-methyl-3,3-ethylenedioxytricyclo[6.2.1.0^{1,6}]-9-undecen-7-ol (**13**)*

Excess triethylamine (10 drops), dimethyl sulfoxide (5 drops), and oxalyl chloride (3 drops) were added to a dry dichloromethane (2 mL) solution of diol **12** (11 mg, 0.037 mmol) maintained at 0°C. The reaction mixture was stirred for 20 min, then ether (10 mL) was added and the resulting solution washed with water (3 × 3 mL). The ethereal phase was dried, filtered, and concentrated to give an oil, which was purified by flash chromatography (4:1, petroleum ether/acetone) to give **13**, 2.5 mg (23%); ^{1}H nmr ($CDCl_3$) δ: 9.07 (1H, s, HC═O), 3.96 (4H, s, OCH_2CH_2O), 3.51 (1H, s, -OH), 2.53 (1H, s, HC-C═C), 1.58 (3H, s, CH_3-C═C), 1.20–2.40 (11H, m's, CH, CH_2's), 0.98 (3H, t, J = 7.5 Hz, CH_3-CH_2).

7-exo-*Ethenyl-9-ethyl-10-methyl-3,3-ethylenedioxytricyclo-[6.2.1.0^{1,6}]-9-undecen-7-ol (**15**) and 7*-endo-*ethenyl-9-ethyl-10-methyl-3,3-ethylenedioxytricyclo[6.2.1.0^{1,6}]-9-undecen-7-ol (**16**)*

Vinyl magnesium bromide (7 mL of a 1 M solution in tetrahydrofuran, Aldrich) was added dropwise to a stirred solution of ketone **14** (1.64 g, 6.26 mmol) in dry ether (100 mL) at room temperature (21°C). After 30 min, the reaction mixture was quenched with saturated aqueous ammonium chloride. The ethereal phase was washed with water (4 × 50 mL), dried, filtered, and concentrated. The crude products were purified by flash chromatography (95:5, petroleum ether/acetone) to give 370 mg (20.4%) of *exo*-alcohol **16** along with 1.15 g (63.5%) of *endo*-alcohol **15**. **16**: ir (KBr): 3445 (OH), 1622 (C═C), 1050–1130 (C—O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 5.67, 5.18, 4.95 (3H, 3 d of d, parts X, A, and B of an ABX system, J_{AX} = 17.3 Hz, J_{BX} = 10.7 Hz, J_{AB} = 1.5 Hz, -CH_X═CH_AH_B-), 3.95 (4H, m, -OCH_2CH_2O-), 2.36 (1H, s, -C═CCH-), 1.51 (3H, d, J = 0.93 Hz, -C═CCH_3), 1.20–2.35 (12H, m, -O*H*,-$CHCH_2CH_2$-C-CH_2-, -CH_2- bridge, -CH_2CH_3), 0.96 (3H, t, J = 7.5 Hz, -CH_2CH_3); ^{13}C nmr ($CDCl_3$) δ: 145.6, 141.3, 139.4, 110.7, 109.1, 82.8, 64.5, 63.7, 57.2, 51.6, 48.6, 46.7, 36.5, 33.2, 22.2, 21.3, 13.0, 9.7. Equilibration of 17 and 18

An epimeric sample of ketones **17** and **18** (~3:2) (52 mg, 0.178 mmol) dissolved in anhydrous methanol (3 mL) was added to a sodium methoxide solution (1 mL MeOH; Na, 2 mg). The resulting solution was warmed to 60°C over 1.5 h, then cooled to room temperature, concentrated, and ether (20 mL) and water (5 mL) added. The reaction mixture was extracted with ether, washed with brine, dried, filtered, and concentrated. The ^1H nmr analysis of the oil obtained indicated that it was a 1:1 mixture of epimers.

(1R, 6R*, 10R*)-10-Methyl-11-acyl-3,3-ethylenedioxytricyclo-[7.4.0^{1,6},0^{1,10}]-11-tridecen-7-one (20)*

Ketone **18** (33 mg, 0.114 mmol) was dissolved in dioxane (3 mL) containing freshly sublimed selenium dioxide (13.8 mg, 0.125 mmol) and heated at 80°C for 4 h. Water (5 mL) and ether (15 mL) were added to the cooled reaction mixture and the ether extracts were dried, filtered, and concentrated. The resulting oil (34.8 mg, 0.114 mmol) was dissolved in dichloromethane (3 mL) at 0°C and pyridinium chlorochromate (PCC) (40 mg), sodium acetate (20 mg), and 4Å molecular sieves (10 mg) were added. The reaction was stirred for 1 h during which time the temperature was allowed to rise to 21°C. Ether (20 mL) was added, the mixture was filtered through silica gel, concentrated, and chromatographed (hexane/acetone, 9:1) to provide the diketone **20**, 17 mg (49%); ir (neat): 3040 (=C-H), 1705 (C=O), 1658 (C=C-C=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 6.84 (1H, br t, J = 1 Hz, HC=C), 3.92 (4H, m, OCH_2CH_2O), 2.93, 2.88 (1H, dt, J = 1, 14 Hz, HC-C=O), 2.69, 2.48 (2H, dd, J = 2, 2.5 Hz, $CH_2C=O$), 2.35 (3H, s, $CH_3-C=O$), 2.2–1.4 (10H, m, CH_2's), 0.96 (3H, s, CH_3-C); ^{13}C nmr ($CDCl_3$) δ: 211.5, 196.5, 149.5, 145.8, 109.4, 64.6, 64.0, 55.6, 52.1, 48.4, 43.2, 39.4, 37.7, 31.7, 31.1, 27.8, 21.4, 19.6. Exact Mass calcd. for $C_{18}H_{24}O_4$: 304.1673; found: 304.1660. Anal. calcd. for $C_{18}H_{24}O_4$: C 71.03, H 7.95; found: C 71.14, H 8.01.

(1R, 6R*, 10S*, 11R*)-10-Methyl-11-acyl-3,3-ethylenedioxytricyclo[7.4.0^{1,6},0^{1,10}]-7-tridecanone- (21)*

Ethylene diamine (~5 mL) was condensed in a round-bottom flask equipped with a Dry Ice condenser, and lithium (2.3 mg, 1.3 mmol) was added, followed by the diketone **20** (14 mg, 0.046 mmol) dissolved in THF (1 mL). The reaction was stirred for 0.5 h, solid NH_4Cl added, the condenser removed, and the reaction warmed to 21°C. Ether (30 mL) was added and the ether solution washed with water (4 × 5 mL), dried, filtered, and concentrated. This material (13.2 mg) was a mixture of keto-alcohols (ir: 3550–3150 (br OH) cm^{-1}) and thus was treated directly with excess pyridinium chlorochromate (PCC) in dichloromethane (2 mL) as above. This afforded, after plc (hexane/acetone 7:3), the saturated diketone **21** in 24% yield; ir (neat):1702 (C=O), 1726 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 3.89 (4H, m, OCH_2CH_2O), 3.41 (1H, t, J = 9.1 Hz, HC-$COCH_3$), 2.57 (1H, dd, J = 6.15 Hz, HC-C=O), 2.29, 2.26 (2H, m, CH_2-C=O), 2.19 (3H, s, CH_3-C=O), 1–2 (12H, m, CH_2's), 0.74 (3H, s, CH_3-C); ^{13}C nmr ($CDCl_3$) δ: 210.5, 209.6, 109.4, 64.6, 63.9, 55.1, 54.2, 48.2, 48.1, 38.7, 34.3, 31.9, 30.9, 27.4, 22.8, 21.9, 19.1, 19.1. Exact Mass calcd. for $C_{18}H_{26}O_4$: 306.1829; found: 306.1805.

Vinyl ether hydrolysis. XXIV. 1-Methoxycyclooctene and the question of reversibility of the carbon protonation step[1]

A. J. KRESGE[2] AND Y. YIN

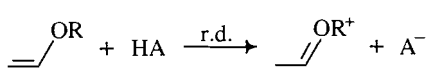
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received July 16, 1990

A. J. KRESGE and Y. YIN. Can. J. Chem. **69**, 84 (1991).

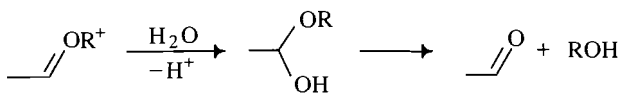
An argument is presented which suggests that hydrolysis of the vinyl ether group of 1-methoxycyclooctene may occur by reversible proton transfer from a catalyzing acid to the β-carbon atom of the substrate, instead of by the conventional reaction mechanism in which this proton transfer is rate determining and not reversible. Hydrolysis of this substrate is then examined by measuring rates of reaction in dilute aqueous solutions of strong mineral acids (perchloric and hydrochloric) as well as in buffer solutions of seven carboxylic acids, biphosphate ion, and 1,1,1,3,3,3-hexafluoro-2-propanol. General acid catalysis is observed and a Brønsted relation with the exponent $\alpha = 0.73$ is constructed. That, plus the isotope effects $k_H/k_D = 2.9$ and 6.0 for catalysis by hydronium ion and acetic acid respectively, as well as the lack of deuterium incorporation into the substrate when the reaction is carried out in D_2O with $D_2PO_4^-/DPO_4^{2-}$ buffer at pD = 8, show that carbon protonation of the substrate is not reversible and that the conventional reaction mechanism is operative.

Key words: 1-methoxycyclooctene, vinyl ether hydrolysis, rate-determining proton transfer, Brønsted relation, solvent isotope effect.



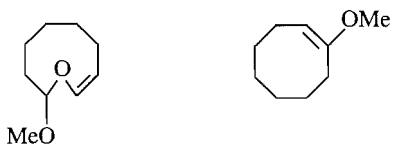
A. J. KRESGE et Y. YIN. Can. J. Chem. **69**, 84 (1991).

On présente un argument qui pourrait suggérer que l'hydrolyse du groupement éther vinylique du 1-méthoxycyclooctène peut se produire par le biais d'un transfert réversible d'un proton d'un catalyseur acide vers l'atome de carbone-β du substrat au lieu du mécanisme conventionnel dans lequel le transfert du proton n'est pas réversible et correspond à l'étape qui détermine la vitesse de la réaction. On a alors étudié l'hydrolyse de ce substrat en mesurant les vitesses de réactions dans des solutions aqueuses diluées d'acides minéraux forts (perchlorique et chlorhydrique) ainsi que dans des solutions tamponnées de sept acides carboxyliques, d'ion biphosphate et de 1,1,1,3,3,3-hexafluoropropan-2-ol. On a observé une catalyse acide générale et on a établi une relation de Brønsted avec un exposant $\alpha = 0{,}73$. Ces données, considérées avec les effets isotopiques $k_H/k_D = 2{,}9$ et 6,0 respectivement pour l'ion hydronium et l'acide acétique ainsi que le fait qu'il n'y a pas d'incorporation de deutérium dans le substrat lorsqu'on réalise la réaction dans le D_2O, avec un tampon de $D_2PO_4^-/DPO_4^{2-}$ et à un pD = 8, montrent que la protonation du carbone du substrat n'est pas réversible et que le mécanisme conventionnel s'applique à cette réaction.



Mots clés : 1-méthoxycyclooctène, hydrolyse d'éther vinylique, transfert du proton qui détermine la vitesse de la réaction, relation de Brønsted, effet isotopique du solvant.

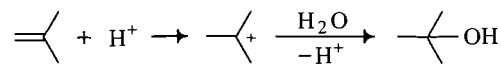
[Traduit par la revue]



The conventional reaction mechanism for acid-catalyzed hydrolysis of vinyl ethers consists of rate-determining protonation of the substrate on the β-carbon, eq. [1], followed by rapid

[1] 

hydration of the ensuing alkoxycarbocation and decomposition of the hemiacetal intermediate, eq. [2].[3] It was believed at one



[2] 

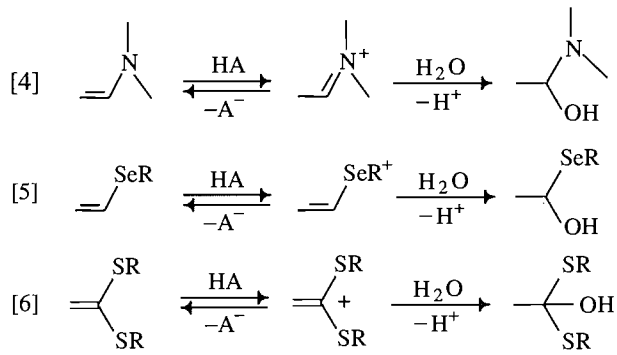
time that the hydrolysis of 9-methoxyoxacyclonon-2-ene, **1**, provided the sole exception to this mechanism in that carbon protonation became reversible in its reaction and some subsequent step was consequently rendered rate determining (2). It has been shown recently, however, that this substance does not react through its vinyl ether group but rather by hydrolysis of its acetal function (3), and that the process upon which this mechanistic assignment was based is not a vinyl ether hydrolysis at all. It thus appears that all of the considerable number of vinyl ethers examined so far undergo hydrolysis by non-reversible, rate-determining proton transfer to carbon.

1 **2**

It is likely, however, that the carbon protonation step in at least some of these hydrolyses is not rate determining by a very great margin, i.e., that cation hydration (eq. [2]) is not very much faster than cation deprotonation (reversal of eq. [1]). This is suggested by the fact that in the acid-catalyzed addition of water to simple olefins, eq. [3], cation hydration is only 1–2

[3] 

orders of magnitude faster than deprotonation (4); carbon protonation, moreover, is reversible and not rate determining in the hydrolysis of enamines (5), eq. [4]; vinyl selenides (6), eq. [5]; and ketene thioacetals (7), eq. [6]. It would seem, therefore, that examples of reversible carbon protonation might be found in the hydrolysis of vinyl ethers as well, and that this might be achieved through appropriate structural modification of the vinyl ether functional group.



One such structural modification could be incorporation of the vinyl ether group in an eight-membered ring, as in 1-methoxycyclooctene, **2**. This is suggested by the fact that, whereas carbon protonation is fully rate determining in the hydration of isobutene, eq. [3], deprotonation and cation hydration occur at comparable rates in the corresponding

[1]Part XXIII. See ref. 32.

reaction of 1-methylcyclooctene (8), eq. [7]. There would thus appear to be some feature of an eight-membered ring, perhaps a conformational effect, that promotes reversibility.

These comparisons of isobutene and 1-methylcyclooctene are for protonation by the hydronium ion in strongly acidic solutions where the only base available to deprotonate the cation is water. The stronger bases present in carboxylic acid and other buffer solutions will be more effective deprotonating agents and should therefore promote reversibility. Unfortunately, olefins such as isobutene and 1-methylcyclooctene are too unreactive to be studied conveniently in buffer solutions, but vinyl ethers are much more labile. We have consequently examined the hydration of 1-methoxycyclooctene in order to determine whether or not its carbon protonation step can be made reversible.

Experimental

Materials

1-Methoxycyclooctene was prepared from the corresponding ketal by *p*-toluenesulfonic acid catalyzed elimination of one equivalent of alcohol, following the procedure we have used before for synthesizing other cyclic vinyl ethers (9); ^{1}H NMR ($CDCl_3$) δ: 4.50 (1H, t, J = 8 Hz), 3.50 (3H, s), 2.5–1.5 (12 H br m); MS calcd. for $C_9H_{16}O$: 140.1201; found: 140.1204. All other materials were best available commercial grades and were used as received.

Kinetics

Rates of hydrolysis of 1-methoxycyclooctene were measured spectroscopically by monitoring the decrease in vinyl ether absorbance at λ = 220 nm. Reactions with half-lives greater than ca. 20 s were examined with a Cary 118 C spectrometer whose cell compartment was thermostatted at 25.0 ± 0.1°C. Runs were initiated by adding 5–10 μL of acetonitrile stock solution of substrate to 3.0 mL of aqueous acid or buffer solution that had come to thermal equilibrium with the spectrometer cell compartment; substrate concentrations in the final reaction solutions were ca. 1×10^{-4} M. Measurements of absorbance were continued for 3–4 half-lives; the data obeyed the first-order rate law accurately and the observed first-order rate constants were obtained by least-squares fitting to an exponential function (10).

Rates of fast reactions with half-lives less than ca. 20 s were determined using a Durrum–Gibson stopped-flow spectrometer operating at 25.0 ± 0.1°C. Measurements were continued for 10–12 half-lives; the data obeyed the first-order rate law accurately and the observed first-order rate constants were evaluated graphically as slopes of plots of $\ln(A - A_\infty)$ vs. time.

Results

Rates of hydrolysis of 1-methoxycyclooctene were measured in aqueous (H_2O) perchloric acid solutions over the concentration range 0.02–0.10 M and in aqueous (H_2O) hydrochloric acid solutions over the concentration range 0.009–0.05 M; ionic strength was maintained at 0.10 M through the addition of NaCl as required.[4] Observed first-order rate constants determined in both media were accurately proportional to acid concentration, and least-squares analysis gave the hydronium ion catalytic coefficients $k_{H^+} = 299 \pm 3\ M^{-1}\ s^{-1}$ for perchloric acid and $k_{H^+} = 291 \pm 7\ M^{-1}\ s^{-1}$ for hydrochloric acid. The mean of these two values, $k_{H^+} = 295\ M^{-1}\ s^{-1}$, is consistent with $k_{H^+} = 299\ M^{-1}\ s^{-1}$ estimated for 1-methoxycyclooctene from $k_{H^+} = 623\ M^{-1}\ s^{-1}$ for 1-ethoxycyclooctene (9*b*) and the rate reduction of 0.48 expected for changing an ethyl vinyl ether to the corresponding methyl vinyl ether (12).

Rates of hydrolysis of 1-methoxycyclooctene were also measured in aqueous D_2O solutions of DCl over the concentration range 0.01–0.05 M at constant ionic strength (μ = 0.10 M, NaCl).[4] Observed first-order rate constants were once again accurately proportional to acid concentration, and least-squares analysis gave the catalytic coefficient $k_{D^+} = 102 \pm 3\ M^{-1}\ s^{-1}$. Combination of this with the corresponding value for H_2O solutions provides the isotope effect $k_{H^+}/k_{D^+} = 2.89 \pm 0.09$.

Rate measurements were also made in buffer solutions of seven carboxylic acids, biphosphate ion, and 1,1,1,3,3,3-hexafluoro-2-propanol. To keep hydronium ion concentrations constant while buffer concentrations were varied, series of solutions of constant buffer ratio and constant ionic strength (μ = 0.10 M in all cases but hexafluoropropanol where μ = 0.40 M) were used.[4] Buffer failure (13) nevertheless occurred with some of the stronger carboxylic acids, causing hydronium ion concentrations to change significantly as the buffer concentration was varied. In such cases observed rate constants were adjusted to a common hydronium ion concentration; hydronium ion concentrations required for this purpose were obtained by calculation using literature pK_a's and activity coefficients recommended by Bates (14).

First-order rate constants were in all cases linear functions of buffer concentration, and catalytic coefficients were evaluated as slopes of buffer dilution plots. For three of the systems examined ($CH_3CO_2H/CH_3CO_2^-$, $C_2H_5CO_2H/C_2H_5CO_2^-$, and $H_2PO_4^-/HPO_4^{2-}$) measurements were made at three different buffer ratios; these results showed that the buffers were acting as general acid catalysts, as expected. The catalytic coefficients so obtained are listed in Table 1.

Measurements were also made in acetic acid buffers in D_2O solution; these data gave the catalytic coefficient $k_{DA} = (6.15 \pm 0.32) \times 10^{-2}\ M^{-1}\ s^{-1}$, which, when combined with the acetic acid catalytic coefficient for H_2O solution, provides the isotope effect $k_{HA}/k_{DA} = 5.95 \pm 0.37$.

Discussion

Acid-catalyzed reactions in which proton transfer from the catalyst to the substrate is reversible and some subsequent step is rate determining generally give inverse hydronium-ion isotope effects, $k_{H^+}/k_{D^+} < 1$; rate-determining proton transfer reactions, on the other hand, usually have hydronium-ion isotope effects in the normal direction, $k_{H^+}/k_{D^+} > 1$ (13). The isotope effect observed here for hydrolysis of 1-methoxycyclooctene, $k_{H^+}/k_{D^+} = 2.9$, thus suggests that proton transfer is in this case not reversible. The present isotope effect is also consistent with $k_{H^+}/k_{D^+} = 3.7$, predicted for a vinyl ether of this reactivity from a correlation of hydronium-ion isotope effects for hydrolysis of a group of vinyl ethers known to react by non-

[4]The data are summarized in ref. 11.

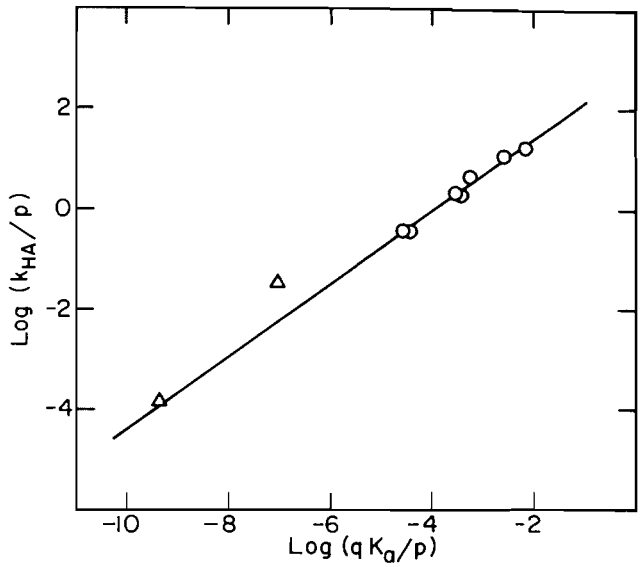

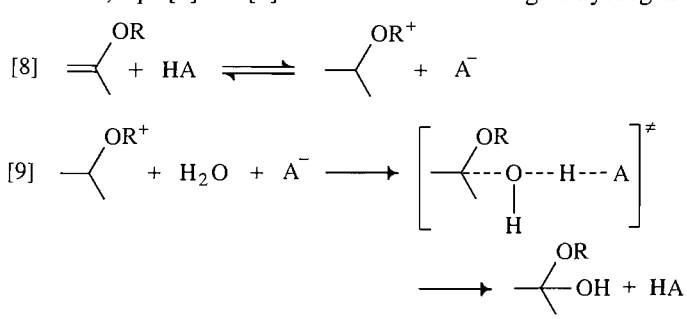

FIG. 1. Brønsted relation for the hydrolysis of 1-methoxycyclooctene in aqueous solution at 25°C catalyzed by carboxylic acids (○); the other points (△) are for, reading from left to right, $(CF_3)_2CHOH$ and $H_2PO_4^-$.

reversible rate-determining proton transfer. This evidence thus indicates that the hydrolysis of 1-methoxycyclooctene catalyzed by the hydronium ion occurs by the conventional mechanism of eqs. [1] and [2].

This conclusion is reinforced by the behavior of the present system in buffer solutions. The reaction shows general acid catalysis, as required for rate-determining proton transfer; reversible proton transfer, on the other hand, would produce specific hydronium ion catalysis.

The presently determined carboxylic acid catalytic coefficients give a Brønsted relation, illustrated in Fig. 1, whose exponent, $\alpha = 0.73 \pm 0.04$, is typical of vinyl ether hydrolysis reactions (9*a*). This Brønsted relation also shows individual deviations similar to those found for other vinyl ether (9*a*) and ketene acetal (15) hydrolyses: the points for chloro- and methoxyacetic acids lie above the correlation line whereas those for cyanoacetic and formic acids lie below. The point for the negatively charged catalyst $H_2PO_4^-$ also lies above the correlation line, as expected on the basis of electrostatic stabilization of the reaction's transition state, and as observed in other vinyl ether hydrolyses (16).

Although general acid catalysis is typical of vinyl ether hydrolysis by the conventional mechanism, it is also consistent with reversible carbon protonation provided that the subsequent rate-determining hydration of the alkoxycarbocation is assisted by base-catalyzed proton removal from the attacking water molecule, eqs. [8] and [9]. Such a scheme would give hydrogen

ion plus general base catalysis, which is operationally equivalent to general acid catalysis. General base catalysis of the reaction of carbocations with water and alcohols has in fact been observed (for some recent examples, see ref. 17). Such catalysis, however, seems to occur only with fairly stable cations in whose hydration the protonated alcohol or ether product that would be formed in the absence of catalysis, eq. [10], is a high-energy intermediate, i.e., lies above the

[10] $R^+ + H_2O \rightarrow ROH_2^+ \rightarrow ROH + H^+$

cation reactant on the free energy scale. With highly reactive cations, such as the methoxycarbenium ion formed in the present study,[5] the protonated alcohol or ether is of lower free energy than the reactant, and this intermediate is consequently no longer a high-energy species. There is therefore no need to avoid this intermediate, and general base catalysis disappears (17, 19).

The mechanism of eqs. [8] and [9] may also be ruled out on the basis of the isotope effect determined here for the hydrolysis of 1-methoxycyclooctene catalyzed by acetic acid. An estimate of the isotope effect expected for the mechanism of eqs. [8] and [9] may be made in the following way. The D:H isotopic fractionation factor for the hydroxyl group of acetic acid, $\phi = 0.96$ (20), is not very different from fractionation factors for carbon–hydrogen bonds of methylene groups, $\phi = 0.93$–1.05 (21), and the isotope effect on the equilibrium of eq. [8] will therefore be close to unity. The isotope effect on the reaction of eq. [9] is also likely to be close to unity. Two isotope effects on such reactions of stable carbocations with water have been reported, and both are small: $k_H/k_D = 1.2$ for the hydration of trianisylmethyl cation (22) and $k_H/k_D = 1.15$ for the hydration of 4,4′-di(*N*,*N*-dimethylamino)triphenylmethyl cation (17*b*). Large isotope effects, moreover, are never found for a reaction such as that of eq. [9], which involves proton transfer between electronegative atoms coupled with heavy atom reorganization (23). An overall isotope effect close to unity is therefore

[5]The rate constant for hydration of a simple analog of the present alkoxycarbocation, $CH_3C(OCH_3)CH_3^+$, has been estimated to be nearly diffusion controlled: $k = 1 \times 10^9\,M^{-1}\,s^{-1}$ (18).

predicted for the mechanism of eqs. [8] and [9]. This is very different from the observed value $k_H/k_D = 6.0$, and that argues strongly against the operation of this mechanism.

A final argument against reversible carbon protonation in the hydrolysis of 1-methoxycyclooctene may be made on the basis of the fact that we could detect no deuterium (by mass spectral analysis) in a sample of substrate recovered from a reaction mixture that had been allowed to go to half-completion in a D_2O–$D_2PO_4^-/DPO_4^{2-}$ buffer solution of pD = 8. Reversible carbon protonation would of course have led to hydrogen exchange and the incorporation of deuterium in the substrate. Evidently the HPO_4^{2-} ion is not sufficiently basic to promote reversibility.

The $(CF_3)_2CHO^-$ ion is also not basic enough to promote reversibility: the fact that the catalytic coefficient for $(CF_3)_2CHOH$ lies on the Brønsted correlation line (see Fig. 1) indicates that reaction in this buffer system occurs by the same mechanism (rate-determining proton transfer) as that established for the carboxylic acid buffers upon which this correlation is based. The property of eight-membered rings that promotes reversibility in olefin hydration thus appears to be insufficiently strong to do the same in vinyl ether hydrolysis.

Adsorption of tetrahexylammonium – bromothymol blue ion-pairs at the chloroform–water interface

LAWRENCE AMANKWA AND FREDERICK F. CANTWELL[1]
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 15, 1990

LAWRENCE AMANKWA and FREDERICK F. CANTWELL. Can. J. Chem. **69**, 88 (1991).

Porous membrane phase separators are used to study the adsorption of the cation tetrahexylammonium (Q^+), of the anion bromothymol blue (HB^-) and of the ion-pair formed between them (QHB) at the liquid–liquid interface in a rapidly stirred mixture of chloroform and aqueous buffer. Adsorption isotherms in all three cases follow the Langmuir equation. The anion HB^- is much more strongly adsorbed than the ion-pair QHB. The porous membrane technique readily permits measurement of simultaneous adsorption of the two species HB^- and QHB, and thereby allows a study of their competitive adsorption. When QHB is adsorbed in the presence of an excess of HB^- both the saturated (monolayer) interfacial concentration of QHB and the logarithm of the adsorption equilibrium constant for QHB decrease linearly with an increase in interfacial concentration of HB^-. This shows quantitatively that coadsorption of QHB and HB^- involves a direct competition for space at the interface and also that the presence of adsorbed HB^- changes the adsorbent properties of the interface. Analytical implications for solvent extraction are discussed.

Key words: interfacial adsorption, ion-pairs, liquid–liquid interface.

LAWRENCE AMANKWA et FREDERICK F. CANTWELL. Can. J. Chem. **69**, 88 (1991).

On a utilisé des membranes poreuses comme séparateurs de phases pour étudier l'adsorption du cation tétrahexylammonium (Q^+), de l'anion du bleu de bromothymol (HB^-) et de la paire d'ions (QHB) qu'ils forment entre eux, à l'interface liquide–liquide d'un mélange de chloroforme et de tampon aqueux soumis à une agitation rapide. Les isothermes d'adsorption des trois espèces suivent l'équation de Langmuir. L'anion HB^- est plus adsorbé que la paire d'ions QHB. La technique de la membrane poreuse permet de mesurer rapidement l'adsorption simultanée des deux espèces HB^- et QHB, ce qui permet d'étudier leur adsorption compétitive. Lorsque QHB est adsorbé en présence d'un excès de HB^-, la concentration interfaciale saturée (monocouche) de QHB ainsi que le logarithme de la constante d'équilibre d'adsorption de QHB diminuent tous les deux d'une façon linéaire avec une augmentation de la concentration interfaciale de HB^-. Cette observation démontre quantitativement que la coadsorption de QHB et de HB^- implique une compétition directe pour l'espace disponible à l'interface et aussi que la présence de HB^- adsorbé provoque des changements dans les propriétés adsorbantes de l'interface. On discute des implications analytiques pour l'extraction par des solvants.

Mots clés : adsorption interfaciale, paires d'ions, interface liquide–liquide.

Solvent extraction of ion-pairs has been (1) and remains (2, 3) an important technique for the analytical determination of ionic species. The equilibrium aspects of the distribution of ion-pairs between two *bulk* liquid phases have been extensively studied (1, 4) and, more recently, the kinetic aspects of ion-pair extraction between bulk liquid phases have been investigated (5).

Depending on the surface-activity of the sample ion, of the reagent ion and of the ion-pair formed between them, interfacial adsorption may play a major role in determining both the equilibrium and kinetic extraction behavior of ion-pairs. The use of porous membrane phase separators makes possible measurement of the amount of solute adsorbed at the liquid–liquid interface in a vigorously stirred solvent extraction system and therefore permits the measurement of adsorption isotherms of solutes between the interface and the bulk liquid phases (6–9). Adsorption isotherms previously have been measured by this technique for interfacial adsorption of ion-pairs formed between cationic metal–ligand complexes and simple anions (10) and for the ion-pair tetrahexylammonium picrate (QP) (11). Because the technique allows measurement of concentrations in both liquid phases it makes possible the discrimination of two species simultaneously adsorbed at the interface. This is an advantage over conventional techniques for measuring interfacial adsorption such as those based on interfacial tension or pressure. This advantage is utilized in studying the tetrahexylammonium-bromothymol blue system.

[1]To whom correspondence should be addressed.

Bromothymol blue is one of the most often used anionic reagents for ion-pair extraction (1). In the present study bromothymol blue anion, HB^-, which is surface-active, is used to form a surface-active ion pair, QHB, with tetrahexylammonium cation, Q^+, which also is surface-active. Equilibrium adsorption isotherms of the surface-active species at the chloroform–water interface are measured with the aid of a porous membrane phase separator and the competitive adsorption between the strongly adsorbed HB^- and the weakly adsorbed QHB is quantified.

Experimental section

Bromothymol blue is a diprotic acid H_2B with $pK_{a1} \approx 1.5$ (12) and $pK_{a2} \approx 7.1$ (13). The abbreviation BTB will be used when referring to the component, without specifying which conjugate species, H_2B, HB^-, or B^{2-}, are intended.

Reagents

Water was demineralized, distilled, and finally distilled over alkaline permanganate. Aqueous phosphate buffers at pH 5.0 and 6.5 were prepared from sodium hydrogen phosphate and sodium dihydrogen phosphate at an ionic strength of 0.050. Reagent grade chloroform was washed with water shortly before use. A 1×10^{-3} M solution of reagent grade tetrahexylammonium bromide (Eastman Kodak Co., Rochester, NY) was prepared in chloroform. Bromothymol blue (BDH Canada Ltd.) was purified by recrystallization from ethanol and used to prepare a 5×10^{-4} M solution in aqueous phosphate buffer at pH 5.00.

Apparatus

The extraction apparatus includes a thermostatted (20 ± 0.1°C)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

rapid-stir extraction cell with a porous membrane phase separator, a system to pump the separated liquid phase through an 8 μL flow cell in a spectrophotometer, a strip chart recorder and an IBM-XT microcomputer interfaced to the spectrophotometer. The apparatus previously has been described in detail (14). When the *chloroform phase* was being monitored the membrane phase separator consisted of two layers of 7.5 mil thick porous Teflon with 2–5 μm pore size (Zitex, No. E6060223, Chemplast, Wayne, NJ). When the *aqueous phase* was being monitored the membrane phase separator consisted of one layer of Whatman No. 2 filter paper. In all experiments 100.0 mL each of the chloroform and aqueous phases were combined in the rapid-stir cell. Stirring was at a constant speed of 2300 r.p.m. and the pumping rate was 1.0 mL/min. In some experiments the on-line spectrophotometer with flow cell was used to measure the absorbance of the separated phase while in other experiments a portion of the separated phase was collected and analyzed as described below. The latter approach was used for systems which gave a noisy baseline when the separated phase was pumped directly through the on-line spectrophotometer.

A Model 8451A diode array UV-Vis spectrophotometer (Hewlett-Packard) was used to make all absorbance measurements that were not made with the on-line flow-through spectrophotometer. An Accument Model 525 pH meter (Fisher Scientific) with combination electrode (Cat. No. 13-639-90) was used to measure pH.

Interfacial tensions were measured by the drop-volume technique (15) at 22 ± 1°C. Drops of chloroform were formed at a 0.318 cm O.D. Teflon tip using a 2-mL micrometer buret (Roger Gilmont, Great Neck, NY). The chloroform, which had previously been equilibrated with aqueous buffer, was slowly formed as drops in the same kind of chloroform-saturated aqueous buffer solutions as that used in the distribution experiments.

Liquid–liquid distribution

The distributions of tetrahexylammonium and of BTB between chloroform and aqueous bulk-liquid phases were measured by batch equilibration experiments (16). The measurements were repeated at several concentrations in order to generate the liquid-liquid distribution isotherms.

For BTB, chloroform and an aqueous pH 5.0 solution of NaHB were equilibrated. After turning off the stirrer and allowing coalescence of the phases, the concentration of BTB remaining in the aqueous phase was measured from its absorbance at 434 nm. The concentration of BTB in the chloroform phase was calculated from the difference between the initial and equilibrated aqueous phase concentrations.

For tetrahexylammonium at concentrations $\geq 1 \times 10^{-5}$ M, a chloroform solution of tetrahexylammonium bromide (QBr) and an aqueous pH 6.5 buffer were equilibrated. After phase coalescence the concentration of tetrahexylammonium remaining in the chloroform phase was determined by the "picrate method" in which an aliquot of the chloroform was shaken with aqueous sodium picrate and the concentration of tetrahexylammonium picrate in chloroform was measured spectrophotometrically (1, 16). The concentration of tetrahexylammonium in the aqueous phase was calculated by difference. When using initial concentrations of QBr $< 1 \times 10^{-5}$ M calculation by difference became too imprecise. In this case the concentrations of tetrahexylammonium at equilibrium were measured directly in both phases using suitable modifications of the "picrate method" cited above.

Interfacial adsorption

Using the rapid-stir cell, the equilibrium distributions between the chloroform–water interface and the bulk-liquid phases were measured for tetrahexylammonium, for BTB and for the ion-pair formed between them. Repeating the measurements at several concentrations produced the interfacial adsorption isotherms.

In general, the procedure involved combining chloroform and aqueous buffers containing one of the salts QBr, NaHB, or QHB. The two-phase mixture was stirred to achieve distribution equilibrium and, with the aid of the membrane phase separator, the concentration of solute was measured in one of the phases while the stirrer was still on. The stirrer was then shut off and, after the phases completely coalesced, the concentration of solute in the same phase was again measured. The amount of solute adsorbed at the liquid–liquid interface was calculated from the difference in concentrations with the stirrer off and on.

For tetrahexylammonium, the salt QBr was added initially to the chloroform phase, the aqueous buffer was pH 6.5 and the equilibrium concentration of tetrahexylammonium in chloroform was measured by the "picrate method" discussed above. For BTB, the salt NaHB was added initially to the aqueous pH 5.0 phase and the equilibrium concentration of BTB was measured via the absorbance of the aqueous phase at 434 nm. In a related study to demonstrate the effect of the ion-pair QHB on the interfacial adsorption of BTB, the experiment just described for BTB was repeated but with 4.0×10^{-5} M QHB also present, having been added initially to the chloroform phase.

For measuring the interfacial adsorption of the ion-pair QHB, this salt was added initially to the chloroform phase, the aqueous buffer was pH 5.0 and equilibrium concentrations in the chloroform phase were measured via absorbance at 440 nm. In a related study to see the effect of BTB on the adsorption of the ion-pair QHB, the experiment just described was repeated but with NaHB also present, having been added initially to the aqueous phase.

Results and discussion

The goal of the present investigation is a quantitative characterization of the interfacial adsorption of the ion-pair QHB and of the species Q^+ and HB^-. However, to achieve this goal it is necessary also to characterize their liquid–liquid distribution equilibria.

Experiments involving BTB or QHB were performed at pH 5.0, at which the predominant conjugate species of BTB in the aqueous phase is HB^-. Experiments involving QBr were performed at pH 6.5 to allow comparison with another system not reported in this paper. However, the behavior of QBr is expected to be independent of solution pH at all but very high or very low pH values so that its behavior at pH 5.0 can be assumed to be the same as that observed at pH 6.5.

Distribution of QBr

Shown as curve *A* in Fig. 1 is the liquid–liquid distribution isotherm of QBr between chloroform and aqueous buffer. The symbol C represents concentration and the subscripts "a", "o", "s", and "ns" mean "aqueous phase", "organic phase", "with stirring", and "with no stirring", respectively. In the aqueous phase QBr is dissociated into Q^+ and Br^- ions (1). The absence of micelle formation is demonstrated by the lack of a "break" in the Gibbs adsorption isotherm, discussed below.

In the chloroform phase the 1:1 ion-pair QBr is present (1). The anions from the buffer (*e.g.*, $H_2PO_4^-$) cannot be extracted into chloroform as ion-pairs with Q^+ (17, 18). The ion-pair QBr is present at too low concentrations to dimerize in chloroform (1). Dissociation of QBr in chloroform has not been studied but, based on the behavior of similar compounds in solvents of various dielectric constants, its dissociation constant is expected to be about 10^{-7} (19, 20). Thus, in the concentration range studied the undissociated ion-pair will predominate, but at the lower end of the range there could possibly be significant dissociation. If the undissociated ion-pair QBr were the only species present in chloroform curve *A* in Fig. 1 would be expected to show a marked upward concavity, which it does; and a plot of $C_{QBr,o}$ vs. $C^2_{Q^+,a}$ should be linear with slope equal to the ion-pair extraction constant, K_{IP} (1). Such a plot (not shown) is linear with zero intercept and a correlation coefficient $r = 0.985$. Its slope is $(2.1 \pm 0.2) \times 10^6$, which agrees with the literature value of $K_{IP} \approx 1 \times 10^6$ predicted for QBr (21). This suggests that, if present, dissociation is not extensive. However, whether or not ion-pair dissociation occurs in chloroform, the results

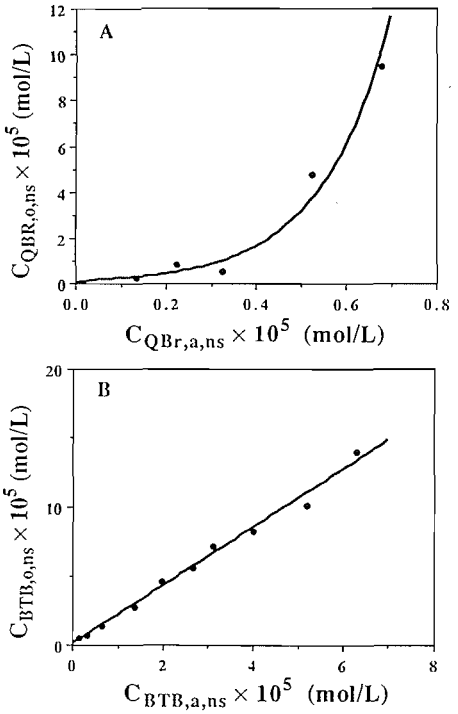

FIG. 1. Liquid–liquid distribution isotherms between chloroform and aqueous buffer of ionic strength 0.050: (*A*) for QBr at pH 6.5, solid line is an arbitrary fit to the data; (*B*) for BTB at pH 5.0, solid line is from linear regression.

obtained in this work can be used in the study of interfacial adsorption, as described below, because the method of measuring the concentration of quaternary ammonium in the chloroform phase is species-independent.

The species of tetrahexylammonium bromide which is adsorbed at the liquid–liquid interface is expected to be the cation Q^+. Electroneutrality near the positively charged interface is provided by an equivalent surface excess of anions in the diffuse part of the electrical double layer in the aqueous phase (22, 23). In the experiment, when the stirrer is turned on Q^+ moves from *both* liquid phases to the newly-created interface (7). The moles of Q^+ adsorbed, $n_{ADS,Q}$ is calculated from the expression:

$$[1] \quad n_{ADS,Q} = C_{QBr,o,ns}\left(V_o + \frac{V_a}{D_{QBr,ns}}\right) - C_{QBr,o,s}\left(V_o + \frac{V_a}{D_{QBr,s}}\right)$$

in which D_{QBr} is the liquid–liquid distribution ratio:

$$[2] \quad D_{QBr} = \frac{C_{QBr,o}}{C_{QBr,a}}$$

When an adsorption isotherm is plotted as $n_{ADS,Q}$ versus $C_{QBr,o,s}$ (not shown) it is found that at $C_{QBr,o,s} \gtrsim 1 \times 10^{-5}$ M the curve flattens out and approaches a limiting value $n_{ADS,Q,SAT}$. In fact, this isotherm follows the Langmuir equation (24):

$$[3] \quad n_{ADS,Q} = \frac{n_{ADS,Q,SAT} K_Q C_{QBr,o,s}}{1 + K_Q \cdot C_{QBr,o,s}}$$

in which $n_{ADS,Q,SAT}$ is the moles of Q^+ adsorbed at monolayer saturation of the interface and K_Q is the equilibrium constant for

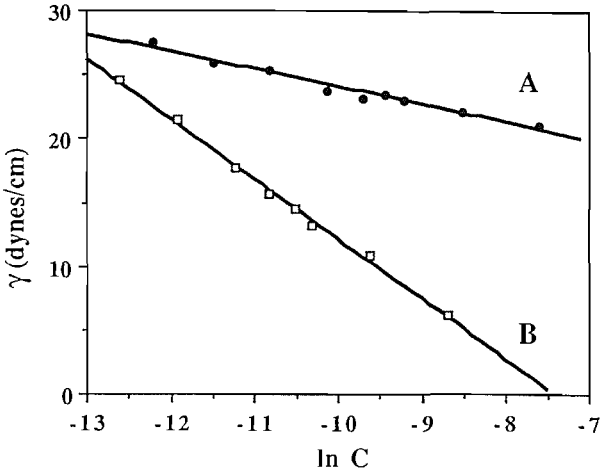

FIG. 2. Gibbs adsorption isotherm plots of interfacial tension versus natural logarithm of equilibrium concentration of: (*A*) QBr in chloroform phase; (*B*) BTB in aqueous phase. Solid lines are from linear regression.

adsorption of Q^+ from chloroform onto the interface. That the data fit the Langmuir equation can be demonstrated by plotting $C_{QBr,o,s}\ (n_{ADS,Q})^{-1}$ versus $C_{Br,o,s}$ (24). A straight line is obtained (not shown) with a slope of $(4.12 \pm 0.02) \times 10^5$ mol^{-1} and an intercept of (0.430 ± 0.035) L^{-1}. The value of K_Q is calculated from the ratio slope/intercept to be $(9.6 \pm 0.8) \times 10^5$ L/mol and the value of $n_{ADS,Q,SAT}$ is calculated from (slope)$^{-1}$ to be $n_{ADS,Q,SAT} = (2.43 \pm 0.01) \times 10^{-6}$ mol.

The quantity $n_{ADS,Q}$ can be converted to interfacial concentration (surface excess, Γ_Q (mol/cm^2), by the expression

$$[4] \quad \Gamma_Q = \frac{n_{ADS,Q}}{A}$$

where A is the total area (cm^2) of the liquid–liquid interface. Knowledge of A would, therefore, make it possible to plot the adsorption isotherm in the more conventional way of Γ_Q versus $C_{QBr,o,s}$. The interfacial area in the stirred liquid mixture can be calculated by comparing $n_{ADS,Q,SAT}$ with the Gibbs isotherm for tetrahexylammonium bromide measured independently in the same concentration range. The Gibbs isotherm is a plot of interfacial tension γ versus ln $C_{QBr,o}$ (6, 9, 24, 25). In the near-saturation region the Gibbs isotherm is expected to be linear with a slope of $-RTn_{ADS,Q,SAT}/A$. If γ is in dyn/cm then R is 8.314×10^7 ergs (mol K)$^{-1}$. As seen in curve *A* of Fig. 2, the experimental plot is linear. From its slope of -1.36 ± 0.09 dyn/cm the value of $n_{ADS,Q,SAT}/A$ is $(5.65 \pm 0.37) \times 10^{-11}$ mol cm^2. Dividing this into the value of 2.43×10^{-6} mol for $n_{ADS,Q,SAT}$ gives $A = 4.3 \times 10^4$ cm^2. This value of A corresponds to an average drop diameter for the dispersed aqueous phase of 0.014 cm which is close to the value predicted from hydrodynamic calculations for stirring at 2300 r.p.m. in this apparatus (14).

The interfacial adsorption isotherm for tetrahexylammonium bromide is shown in Fig. 3 as a plot of Γ_Q versus $C_{QBr,o,s}$. The value of $\Gamma_{Q,SAT}$ is, of course, equal ot $n_{ADS,Q,SAT}/A$, $(5.65 \pm 0.37) \times 10^{-11}$ mol/cm^2, obtained from the slope of the Gibbs isotherm.

Distribution of BTB

At the pH, ionic strength and BTB concentrations used the ion HB^- is the only species of BTB present in significant concentration in the aqueous phase (12, 13). The species of BTB which is

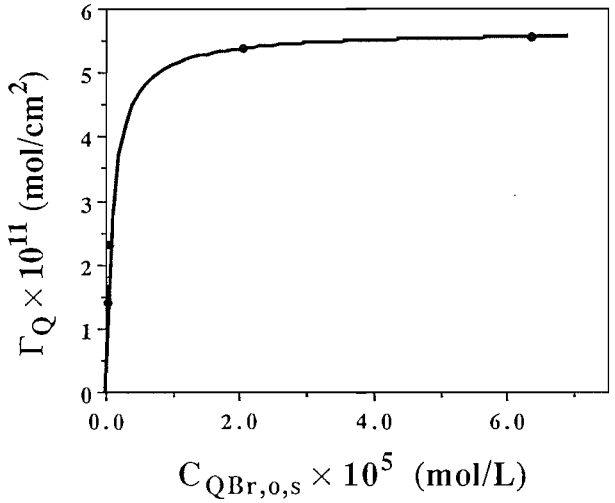

FIG. 3. Adsorption isotherm for QBr at the interface between 100 mL of chloroform and 100 mL of aqueous buffer at pH 6.5 and ionic strength 0.050, while stirring at 2300 r.p.m. Solid line is from linear regression of Langmuir plot (see text).

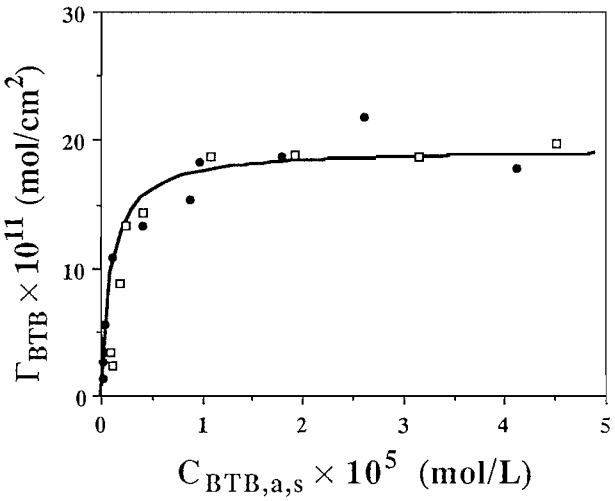

FIG. 4. Adsorption isotherms for NaBTB at the interface between 100 mL of chloroform and 100 mL of aqueous buffer of pH 5.0 and ionic strength 0.050, while stirring at 2300 r.p.m., in the absence (●) of excess QHB and in the presence (□) of 4.0×10^{-5} M added QHB. Solid line is from linear regression of Langmuir plot (see text).

present in the chloroform phase is the free-acid H_2B. The absence of NaHB in the chloroform phase is confirmed by the absence of absorbance at wavelengths greater than 290 nm (13). The liquid–liquid distribution isotherm is shown as a plot of $C_{BTB,o,ns}$ vs. $C_{BTB,a,ns}$ in curve *B* of Fig. 1. It is linear, since $[H_3O^+]_a$ is constant, with a slope of 2.09 ± 0.07 and zero intercept (0.10 ± 0.24).

The species of BTB which is adsorbed at the liquid–liquid interface is HB^-, with electroneutrality provided by an equivalent surface excess of Na^+ in the diffuse part of the electrical double layer. The moles of BTB adsorbed, $n_{ADS,BTB}$, is calculated from the expression:

$$[5] \quad n_{ADS,BTB} = C_{BTB,a,ns}(V_a + V_o D_{BTB,ns}) - C_{BTB,a,s}(V_a + V_o D_{BTB,s})$$

in which D_{BTB} is the liquid–liquid distribution ratio:

$$[6] \quad D_{BTB} = \frac{C_{BTB,o}}{C_{BTB,a}}$$

The analytical concentrations in the organic and aqueous phases, $C_{BTB,o}$ and $C_{BTB,a}$, are obtained from the isotherm in Fig. 1, curve *B*.

The properties of the adsorption isotherm of HB^- are obtained in a manner analogous to that discussed in the previous section: A plot of $C_{BTB,a,s}(n_{ADS,BTB})^{-1}$ versus $C_{BTB,a,s}$ is linear with a slope of $(1.48 \pm 0.06) \times 10^5$ mol^{-1} and an intercept of (0.15 ± 0.11) L^{-1}. The linearity of this plot shows that the isotherm is described by the Langmuir equation (24). The value of the equilibrium constant, K_{BTB}, is $(1.0 \pm 0.7) \times 10^6$ L/mol and that of $n_{ADS,BTB,SAT}$ is $(6.8 \pm 0.1) \times 10^{-6}$ mol. The value of the interfacial area *A* is obtained by dividing $n_{ADS,BTB,SAT}$ by $(1.93 \pm 0.04) \times 10^{-10}$ mol cm^{-2}, which is the value of $n_{ADS,BTB,SAT}(A)^{-1}$ calculated from the slope of the Gibbs isotherm for BTB (curve *B*, Fig. 2; slope is −4.7 ± 0.1). The value of *A* thus obtained is 3.5×10^4 cm^2, which is in reasonable agreement with the value of 4.3×10^4 cm^2 obtained in the previous section from the adsorption of Q^+.

The interfacial adsorption isotherm for BTB, shown as the closed-circle points in Fig. 4, is a plot of Γ_{BTB} versus $C_{BTB,a,s}$. The value of $\Gamma_{BTB,SAT}$ is $(1.93 \pm 0.04) \times 10^{-10}$ mol cm^{-2} from the slope of the Gibbs isotherm.

Distribution of QHB

For the experimental conditions used, the only compound formed between tetrahexylammonium and BTB which is present in significant concentration in chloroform is the 1:1 ion-pair QHB (1). Formation of the 2:1 ion-pair Q_2B (1, 26) and of the dimer $(QHB)_2$ (1, 27) is negligible. As is true for the ion-pair QBr, discussed above, the dissociation constant of the ion-pair QHB in chloroform has not been measured but can be estimated to be about 10^{-7} (1, 19, 20). Therefore, dissociation may or may not be significant at concentrations as high as 10^{-6} M. However, a calibration curve of absorbance at 440 nm versus $C_{QHB,o}$ in chloroform was found to be linear with zero intercept over the range of concentrations of interest. This indicates that either dissociation does not occur or, if dissociation does occur, the molar absorptivity of the species HB^- is the same as that of the species QHB. Either way, the concentration measured in chloroform is species-independent and the difference in absorbance at 440 nm with the stirrer off and on is an accurate measure of interfacial adsorption.

The species adsorbed at the interface is the neutral ion-pair QHB. It is not possible in this experiment to tell whether there is any dissociation of QHB into its constituent ions on the interface (11) because both of these ions are strongly adsorbed, as shown above. The moles of QHB adsorbed, $n_{ADS,QHB}$, is calculated from the expression:

$$[7] \quad n_{ADS,QHB} = (C_{QHB,o,ns} V_o) - (C_{QHB,o,s} V_o)$$

where $C_{QHB,o}$ is the analytical concentration of tetrahexylammonium bromothymol blue in the chloroform phase. Equation [7] is simpler than eqs. [1] and [5] because the ion-pair extraction constant for QHB between chloroform and water is $>10^{10}$ (26) so that D_{QHB} is very large and there is virtually none of this component present in the aqueous phase. The adsorption isotherm of QHB in the absence of an excess of either Q^+ or BTB is shown as a plot of Γ_{QHB} versus $C_{QHB,o,s}$ in curve *A* of Fig. 5. Values of Γ_{QHB} were calculated by dividing the values of $n_{ADS,QHB}$ by an interfacial area of 3.9×10^4 cm^2. This is an

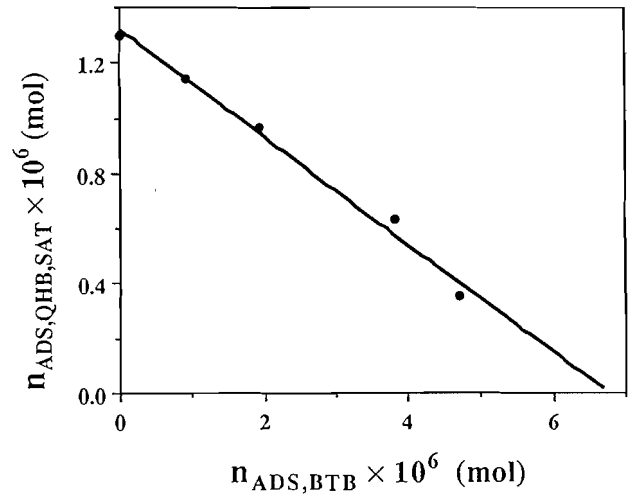

FIG. 6. Plot of moles of QHB adsorbed at interfacial saturation in the presence of excess NaBTB versus moles of BTB adsorbed. Solid line is from linear regression.

average of the values of A measured in the QBr system and in the NaBTB system, discussed above.

Comparing the initial slope of curve A in Fig. 5 with those of the curves in Figs. 3 and 4 shows that QHB is significantly less strongly adsorbed than either Q^+ or HB^-. The fact that the neutral ion-pair exhibits lower surface activity than either of its constituent ions is expected because it has less amphipathic character (24) due to the fact that the charge-centers on the ions tend to be buried in the interior of the ion-pair. The ion HB^- is so much more strongly adsorbed than QHB that the adsorption isotherm of HB^- (Fig. 4) is the same in the presence (closed circles) as in the absence (open squares) of 4.0×10^{-5} M QHB.

In contrast, the adsorption isotherms of QHB is markedly suppressed in the presence of excess NaBTB. This is seen in curves *A–E* in Fig. 5. Curve *A* was measured in the absence of excess NaBTB while curves *B* through *E* were measured in the presence of the indicated fixed concentrations of excess NaBTB. As the concentration of excess NaBTB is raised the adsorption isotherms of QHB show not only a decrease in their initial slope but also a decrease in their saturation plateau. These two effects are due to the coadsorption of HB^- and they can be quantified, in the following way.

When the experimental points for each of the five QHB isotherms in Fig. 5 are re-plotted as $C_{QHB,o,s}\ (n_{ADS,QHB})^{-1}$ versus $C_{QHB,o,s}$ five straight lines are obtained (not shown). Their slopes and intercepts are given in Table 1. The linearity of these plots demonstrates that QHB, both in the presence and absence of excess NaBTB, exhibits Langmuir adsorption behavior (24). The calculated values of K_{QHB} and $n_{ADS,QHB,SAT}$ for the Langmuir equation, as well as the values of Γ_{QHB} are also given in Table 1. In addition, equilibrium values of $C_{BTB,a,s}$ and $n_{ADS,BTB}$ for the experimental points in Fig. 4 are included in Table 1. The quantity $n_{ADS,BTB}$ is the moles of HB^- that are simultaneously adsorbed at the interface with QHB. For a given amount of added excess NaBTB the value of $n_{ADS,BTB}$ is constant, independent of the amount of QHB adsorbed, as discussed above.

When $n_{ADS,QHB,SAT}$ is plotted against $n_{ADS,BTB}$ a straight line results (Fig. 6), with slope of -0.195 ± 0.012 and intercept of $(1.32 \pm 0.03) \times 10^{-6}$ mol QHB. The intercept of this line on the *horizontal* axis is $(6.8 \pm 0.4) \times 10^{-6}$ mol BTB, which is identical to the saturation value of BTB from its isotherm in Fig. 4, $n_{ADS,BTB,SAT} = (6.8 \pm 0.1) \times 10^{-6}$ mol BTB. This indicates that the point at which the interface becomes covered with a monolayer of NaHB is identical to the point at which it will no longer adsorb any QHB. Furthermore, it can be shown that the negative reciprocal of the slope of the line in Fig. 6, *i.e.*, 5.1 ± 0.3, should be equal to the *ratio* of the area occupied per

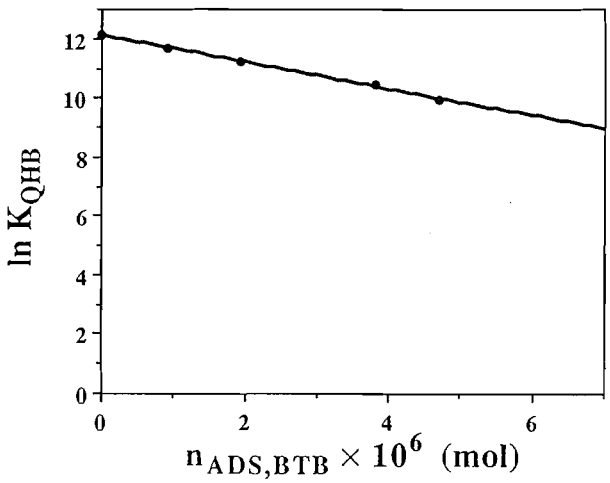

FIG. 7. Plot of natural logarithm of the equilibrium constant for the interfacial adsorption of QHB in the presence of excess NaBTB versus moles of BTB adsorbed. Solid line is from linear regression.

molecule of QHB to the area occupied per molecule of NaHB in their respective monolayers (24). This value of 5.1 ± 0.3 is in good agreement with the ratio $n_{ADS,BTB,SAT}$ $(n_{ADS,QHB,SAT})^{-1}$ = 5.2 ± 0.4 mol HB^- (mol QHB)$^{-1}$ obtained from Figs. 4 and 5*A* and it is also in good agreement with the value of $5._0$ which is estimated from measurements on space-filling molecular models (CPK Models) to be the ratio of the molecular area of QHB to that of HB^-. Thus, the effect of added NaBTB on the saturation plateau of the QHB isotherm is due to a simple competition for space at the interface.

A second effect of added NaBTB is that which leads to a decrease in the initial slope of the QHB isotherm (*i.e.* to a decrease in K_{QHB}). This effect also can be quantified. It is seen in Fig. 7 that a plot of ln K_{QHB} versus $n_{ADS,BTB}$ is also linear with a slope of $(-4.5 \pm 0.1) \times 10^5$ and intercept of 12.10 ± 0.03. The fact that K_{QHB} decreases with increasing coverage of the interface by HB^- implies that the chemical properties of the interface as an adsorbent are altered with the extent of coverage by HB^-. The linearity of the plot in Fig. 7 means that this change in chemical properties of the interface due to adsorbed HB^- occurs in such a way that the molar free energy of adsorption of QHB changes in a linear fashion with an increase in coverage of the interface by adsorbed HB^- (*i.e.*, $\Delta G = -RT \ln K_{QHB}$).

Thus the simultaneous adsorption of the strongly adsorbed ion HB^- with the weakly adsorbed ion-pair QHB involves both a competition of HB^- with QHB for space and a change in the chemical properties of the liquid–liquid interface brought about by adsorbed HB^-. Both effects lead to a decrease in adsorption of QHB with an increase in adsorption of HB^-.

Analytical implication

The interfacial adsorption behavior of the ion-pair QHB, summarized in Fig. 5 and Table 1, reveals that liquid–liquid distribution measurements made in systems where the ratio of interfacial area to bulk phase volume is large are potentially subject to special sources of error. If an analyte ion (*e.g.*, Q^+) is being determined by ion-pair extraction in the presence of a stoichiometric excess of added surface-active reagent ion (*e.g.*, HB^-), the fraction of the surface-active product ion-pair (*e.g.*, QHB) which gets adsorbed at the interface varies with the concentration of excess HB^-. This could lead to a non-linear dependence of optical absorbance in the organic phase on concentration of added analyte Q^+. Systems in which the area-to-volume ratio is large include not only those in which absorbance is measured during stirring (28) but also those, increasingly popular, systems in which automated solvent extraction is performed under segmented flow conditions (solvent extraction/flow injection analysis (2, 29–32)).

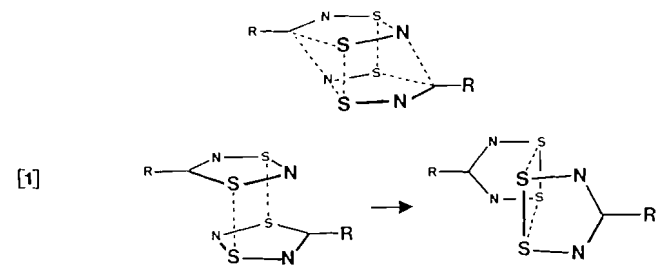
In the presence of a catalytic quantity of alkali metal mixtures of sulphur diimides RNSNR and R'NSNR' (R, R' = Ph, 4-C_6H_4Me, 4-C_6H_4OMe, $SiMe_3$, SPh) undergo a rapid scrambling of the R and R' groups. When R and R' are significantly different (*e.g.*, R = Ph, R' = $SiMe_3$ or SPh) the equilibrium is shifted to favour the unsymmetrical sulphur dimmide (R ≠ R'); the procedure thus represents an effective method for preparing such derivatives. A mechanism involving the centrosymmetric association and rearrangement of two sulphur diimide radical anions is suggested for the observed ligand scrambling. The synthesis and X-ray structure determination of the mixed diimide (4-$NO_2C_6H_4$)SNSN(4-C_6H_4OMe) is reported. The crystals are monoclinic, space group $P2_1/n$; the molecules stack as plates along the *a* axis in a head-to-head fashion, producing an interplanar spacing between consecutive S_2N_2 units of 3.421 Å.

Key words: sulphur diimide radical anions, skeletal rearrangements, (4-$C_6H_4NO_2$)SNSN(4-C_6H_4OMe), X-ray structure.

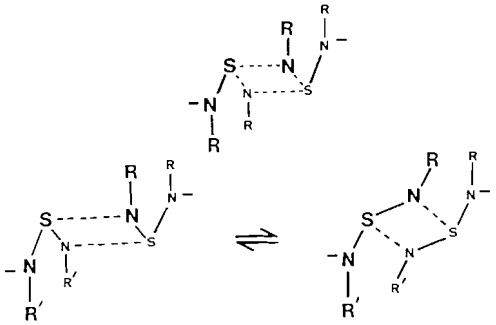
KETUT BESTARI, RICHARD T. OAKLEY et A. WALLACE CORDES. Can. J. Chem. **69**, 94 (1991).

En présence d'une quantité catalytique d'un métal alcalin, des mélanges des diimides du soufre RSNSNR at R'NSNR' (R, R' = Ph, 4-C_6H_4Me, 4-C_6H_4OMe, $SiMe_3$ et SPh) subissent un brouillage rapide des groupements R et R'. Lorsque R et R' sont des groupements assez différents (par exemple, R = Ph et R' = $SiMe_3$ ou SPh), l'équilibre est déplacé vers le diimide de soufre non-symétrique (R ≠ R'); cette procédure représente donc une méthode efficace pour préparer de tels dérivés. Pour expliquer le brouillage observé des ligands, on propose un mécanisme impliquant une association centrosymétrique et une transposition de deux anions radicaux des diimides du soufre. On rapporte la synthèse et la détermination de structure (par diffraction des rayons-X) du dimmide mixte (4-$NO_2C_6H_4$)SNSN(4-C_6H_4OMe). Les cristaux sont monocliniques, groupe d'espace $P2_1/n$; les molécules s'empilent le long de l'axe a sous la forme de plaquettes dans lesquelles elles sont arrangées d'une façon tête-à-tête provoquant un espacement de 3,421 Å entre les plans de deux unité successives de S_2N_2.



Mots clés : anions radicaux de diimides du soufre; transpositions du squelette; (4-$NO_2C_6H_4$)SNSN(4-C_6H_4OMe), structure par diffractions des rayons-X.

[Traduit par la revue]



Introduction

The chemistry of molecules built from congugated —S=N— linkages is characterized by a propensity for often baffling rearrangements. Although the mechanistic issues behind these structural changes are clearly complicated, two potentially general pathways for structural change have recently been identified (1). The first is the intramolecular migration of a nitrogen between adjacent sulphur atoms, the so-called "1,3-nitrogen shift" reaction. This process facilitates nitrogen scrambling in RCH_5S_3 molecules (2), and provides a low energy pathway for the *endo*/*exo* isomerization of trithiatetrazocines (3). The second type of skeletal rearrangement involves the association of radical species. In a seminal paper Passmore and co-workers demonstrated that 1,3,2,4-dithiadiazoyl radicals could be photochemically converted to their 1,2,3,5-isomers (reaction [1]) (4). They later proposed a mechanism involving the intermediacy of a radical dimer and, on the basis of CNDO calculations, explained the need for photochemical rather than thermal activation (5) in terms of the orbital symmetries of the reactant and product dimers.

As part of ongoing studies of thiazyl radicals (6) we also have been interested in radical rearrangements, in particular the possibility that simple sulphur diimide radical anions $[RNSNR]^{-\bullet}$ might undergo skeletal scrambling reactions similar to that described by Passmore. Sulphur diimide radical anions, which are isoelectronic with the $SO_2^{-\bullet}$ radical anion, can be generated by either chemical (7) or electrochemical (8) reduction of the corresponding sulphur diimides, but heretofore no study has been performed to test the susceptibility of these systems towards skeletal, and hence ligand, scrambling, as proposed in reaction [2]. In the present paper we provide an account of our work on this topic.

SCHEME 1

Results and discussion

Coupling of sulphinylamines

There are several reported routes for the preparation of symmetrically substituted suphur diimides, including (*i*) the condensation of an amide with thionyl chloride (9) and (*ii*) base (10) and (*iii*) alkali metal (11) promoted coupling of sulphinylamines. We have used all these methods (see Experimental section), particularly (*iii*), although this with one important modification; we adjusted the stoichiometry by changing the metal:RNSO ratio from 1:2 to 1:1, and in so doing significantly improved the yields of the products. We view the reaction as being analogous to that proposed (10) for the base-catalysed condensation of sulphinylamines. Accordingly we suggest that the reaction proceeds (Scheme 1) by the generation and association of the radical anions $[RNSO]^{-\bullet}$, followed by elimination of $SO_2^{-\bullet}$ to produce sulphur diimide. The driving force for the reaction can be attributed, in large part, to the lattice energy of the dithionite salt.

Cross coupling of sulphur diimides

The preparation of unsymmetrical sulphur diimides is not always straightforward. The most commonly sought materials are *N*-silylated derivatives (R = Me_3Si), for which the standard synthetic methods (12) are not particularly efficient. We have found that in the presence of catalytic amounts of alkali metals a mixture of two symmetrically substituted sulphur diimides undergo a rapid ligand exchange. We have tested the exchange reaction for a number of aryl- and silyl-substituted systems (R, R′ = Ph, 4-C_6H_4OMe, 4-C_6H_4Me, $SiMe_3$, SPh). In all cases the scrambling was initiated using only a catalytic quantity of reducing agent (typically 5–25 mol% potassium or sodium) to generate the radical anions. Equilibrium was established rapidly, certainly within minutes. The extent of the reaction, *i.e.*, the position of equilibrium of reaction [2], was monitored for most systems by gas chromatography (GC). The results indicate that for similar R and R′ groups the exchange produces a nearly statistical distribution of the three possible products. For less symmetrical combinations, e.g. R = aryl and R′ = Me_3Si or SPh, the equilibrium is displaced sufficiently to the right hand (cross reaction) side that the method can be used as a fast and efficient synthesis of the mixed sulphur diimide.

For the reaction involving —SPh groups GC analysis was not possible as the compounds were too involatile. For these systems, however, we found that ^{14}N NMR spectroscopy provided a useful analytical probe. As Fig. 1 illustrates, the clean formation of PhNSNSPh from the cross coupling of PhNSNPh and PhSNSNSPh was readily confirmed by the appearance of two

signals corresponding to the non-equivalent nitrogens of the product. Neither of the two starting materials was observed in the final reaction mixture.

Preparation and molecular structure of (4-$C_6H_4NO_2$)SNSN(4-C_6H_4OMe)

During the course of this work we became interested in the potential use of highly polar, conjugated sulphur nitrogen compounds as non-linear optical materials (13). To this end we synthesized (4-$C_6H_4NO_2$)SNSN(4-C_6H_4OMe) by condensing the mixed sulphur diimide (4-C_6H_4OMe)NSNSiMe_3 (prepared as described above) with 4-$NO_2C_6H_4SCl$. While the space group of this compound ($P2_1/n$) is not non-centrosymmetric, as would be required for second harmonic generation, it nonetheless reveals some interesting packing features. The molecular structure of this material is shown in Fig. 2*a*, while Fig. 2*b*

shows the stacking arrangement down the *a* axis. Table 2 provides a listing of non-hydrogen atom coordinates, while Table 3 summarizes pertinent bond lengths and angles. Within each molecule the S_2N_2 unit is planar to within ±0.009 Å. The nitrophenyl group makes a 2.5° dihedral angle with the S_2N_2 unit, while the methoxyphenyl ring is markedly twisted (41.2°) with respect to the S_2N_2 plane. Somewhat surprisingly, the molecules do not stack in a head-to-tail pattern (thereby aligning the donor and acceptor centres), but instead pack in a near vertical head-to-head fashion (Fig. 2*b*). The interplanar distance between the S_2N_2 units, 3.421 Å, is similar to the corresponding separations observed in stacked thiazyl heterocycles, *e.g.* benzo-1,3,2,4-dithiadiazine (3.29 Å) (14), naphtho[1,8-*cd*:4,5-*c'd'*]bis[1,2,6]thiadiazine (3.40 Å) (15), and near the graphite value (3.35–3.37 Å) (16). In $Me_3SiNSNSC_6H_4NO_2$, a much wider interplanar spacing (3.75 Å) is observed, and the molecules stack in a far more steeply inclined fashion, one that places the S—N(S) bond of one molecule over the aryl group of the next (17), thereby eliminating repulsive Me_3Si---Me_3Si interactions.

Association and rearrangement of radical anions

The reductive exchange reactions described above provide an important key to the understanding of skeletal rearrangements in sulphur–nitrogen chemistry. A discussion of the various issues requires, as a first step, recognizing the formal isoelectronic analogy between the cyclic internal radical anion **1** (6*a*) and simple acyclic sulphur diimides radical anions of the type $[RNSNR]^{-\bullet}$. The 5-electron 3-orbital π-manifold of these systems is illustrated in Fig. 3.

Association of sulphur diimide radicals can, in principle, occur in a variety of ways.[2] There is no solid state structural evidence on simple acyclic sulphur diimide radical anions, but in the related dithionite ion the dimeric unit is linked by a long S---S contact, with the two $SO_2^{-\bullet}$ anions eclipsed, *i.e.*, **3** (18).

[2]The equilibrium constants that have been measured for association of sulphur nitrogen radicals probably represent the net effect of different binding modes.

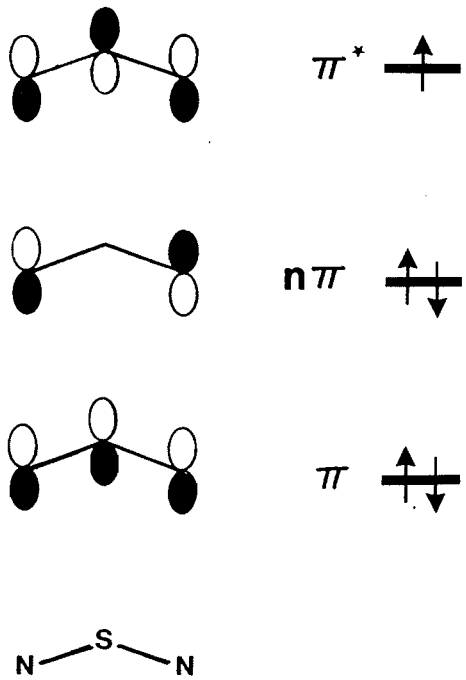

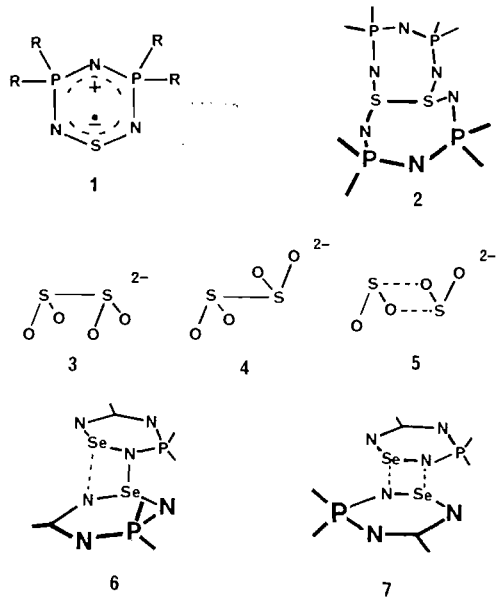

FIG. 3. Qualitative π-MO diagram for $[RNSNR]^{-\bullet}$ radical anions, illustrating nodal patterns.

A similar structure **2** is observed (19) for the dimer of the internal salt **1**, although in the latter case a crossover reaction (*i.e.* reaction [2]) has occurred, generating a twelve-membered ring from two six-membered rings. In orbital terms the weak radical–radical bond originates from the overlap of the two singly occupied molecular orbitals (SOMOs). Thus all the above evidence points to the S---S bridge as the preferred mode of association for $[RNSNR]^{-\bullet}$. Other, presumably higher energy structural possibilities can, however, certainly be imagined. In aqueous solution, for example, where less directional solvation forces replace the specific ion-pairing interactions of the ionic lattice, the dithionite anion is centrosymmetric (20). Structure **4** has been proposed, but we note that the head-to-tail modification **5** also possesses a centre of inversion.

Structure **5** is particularly appealing within the context of structural rearrangements described herein; an analogous head-to-tail fusion of two $[RNSNR]^{-\bullet}$ units provides the proposed pathway for the bond switching reaction of reaction [2]. While there is no direct precedent for this type of structure as a stable ground state, the mode of dimerization recently reported for the selenaphosphatriazinyl radical $[Ph_3PCN_3Se]^{\bullet}$, *i.e.* **6**, can be interpreted as a distortion of the ideal head-to-tail arrangement **7** (6*c*). In terms of chemical reactivity, however, there is no need for the centrosymmetric association to be a potential energy minimum; it needs only to correspond to a relatively accessible point on a reaction profile, one which affords a low energy pathway for rearrangement. Accurate calculations of the energies of such centrosymmetric structures would be useful to further work in this area.

Summary and conclusions

The ease of skeletal scrambling of simple sulfur diimides in the presence of catalytic amounts of reducing agents has many implications in sulphur nitrogen chemistry.[3] Conjugative effects notwithstanding, any open chain or cyclic compound containing the —N=S=N— unit will be susceptible to rearrangement upon reduction. The dimerization of S_2N_2 to S_4N_4 in the presence of reducing agents (21) perhaps represents an example of such a process (1); the necessary intermediate $S_2N_2^{-\bullet}$ anion has certainly been identified in the gas phase (22). Skeletal scrambling reactions can also be used to synthetic advantage, as demonstrated here by the preparation of several unsymmetrical derivatives. As a continuation of this work we are currently pursuing the development of polymeric sulphur diimides, i.e. $(—C_6H_4—NSN—)_x$, by chemical or electrochemical reduction of bifunctional sulphur diimides.

Experimental[4]

Reagents and general procedures

Aniline (Aldrich), 4-methylaniline (Aldrich), 4-methoxyaniline (Aldrich), thionyl chloride (Aldrich), benzene thiol (Aldrich), 4-nitrobenzene thiol chloride (Aldrich), chlorine gas (Matheson) were all commercial products and used as received, except thionyl chloride, which was freshly distilled before use. The sulphinylamines RNSO (R = C_6H_6, 4-MeC_6H_4, and 4-$MeOC_6H_4$) (12*a*), PhSCl (23), the sulphur diimides $Me_3SiNSNSiMe_3$ (9) and PhSNSNSPh (21, 24) were prepared according to standard literature methods. RNSNR (R = C_6H_5, 4-MeC_6H_4, and 4-$MeOC_6H_4$) were prepared by a modification (*vide infra*) of the method of Cramer (6). All solvents were dried (toluene/Na), hexane (CaH_2), diethyl ether (CaH_2), carbon tetrachloride (P_2O_5), methylene chloride (P_2O_5), tetrahydrofuran (K/benzophenone) were distilled immediately before use. All reactions were performed under an atmosphere of nitrogen (99.98% purity). Chemical analyses were performed by MHW Laboratories, Phoenix, AR. Infrared spectra (2000–250 cm^{-1}) were recorded as Nujol mulls (CsI windows) on a Nicolet 20SX/C FTIR spectrometer. Melting points were obtained on an electrothermal melting point apparatus and were uncorrected. Gas chromatograms were recorded on a Varian 3400 gas chromatograph equipped with flame ionization detector (FID). The stainless steel column (6′ × 1/8″ I.D.) was packed with 20% QF-1 (fluorinated hydrocarbon) on chromosorb W-80/100 mesh. The oper-

[3]Sulphur–oxygen chemistry may also be influenced by such reactions. For example, co-reduction of an aqueous mixture of $S^{16}O_2$ and $S^{18}O_2$ should afford $S^{16}O^{18}O$.

[4]Tables of crystallographic data (S1), H-atom coordinates (S2), bond lengths and angles (S3), anisotropic thermal parameters (S4) and observed and calculated structure factors for (4-$MeOC_6H_4$)NSNS(4-$C_6H_4NO_2$) (S5) (18 pages) may be purchased from the Depository of Unpublished Data, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

ating conditions were as follows: hydrogen flow rate 30 mL/min, air flow rate 30 mL/min, carrier gas (N_2) flow rate 30 mL/min, detector temperature 250°C, injector temperature 230°C, column temperature 210°C, chart speed 1 cm min^{-1}, sample volume 1.0 μL. GC–MS analyses were obtained on a VG Mass Lab 12000 equipped with an HP 5790 (GC), and a 30 m DB5 (capillary column). ^{14}N NMR spectra were recorded at 28.906 MHz (in THF ref. $NH_{3(l)}$) on a Bruker WH-400 spectrometer. Pulse widths of 60 μs and pulse delays of 1.0 s were used; good S/N ratios were achieved with 10 000 to 15 000 scans.

Preparation of RNSNR (R = C_6H_5, 4-MeC_6H_4, and 4-$MeOC_6H_4$) (general procedure)

Equimolar amounts of aryl sulfinylamine (RNSO) and freshly cut sodium (or potassium) metal were added to 250 mL of toluene in a round-bottomed flask equipped with a water condenser. The solution was then stirred and heated to reflux under nitrogen. At reflux temperature a vigorous reaction occurred to afford a deep red solution and a heavy precipitate of sodium dithionite. After 2 h, the reaction mixture was cooled to room temperature and finally quenched by bubbling air into the solution for 30 m. The solution was filtered and the resulting filtrate added to a separatory funnel and washed with water three times to remove any remaining water-soluble salts which might have been formed during the reduction. The solution was then dried over Na_2SO_4, and the solvent removed with a rotary evaporator to leave a red oily residue, which was recrystallized from hexane. The purity of the product was checked by GC.

Preparation of PhNSNPh

Starting materials were PhNSO (20.0 g, 0.144 mol) and sodium metal (3.30 g, 0.144 mol); yield (69%) of PhNSNPh (red oil at room temperature) with 96% purity (checked by GC).

Preparation of (4-MeC_6H_4)NSN(4-C_6H_4Me)

Starting materials were (4-MeC_6H_4)NSO (20.0 g, 0.13 mol) and sodium metal (3.0 g, 0.13 mol); yield (61%) of (4-MeC_6H_4)NSN(4-C_6H_4Me) (red crystals), mp 47–48°C. The purity of the product was 99% by GC.

Preparation of (4-$MeOC_6H_4$)NSN(4-C_6H_4OMe)

Starting materials were (4-$MeOC_6H_4$)NSO (15.0 g, 0.089 mol) and sodium metal (2.04 g, 0.089 mol). The residue was recrystallized from a mixture of 100 mL hexane and 5 mL toluene; yield (70%) of (4-$MeOC_6H_4$)NSN(4-C_6H_4OMe) (dark red crystals), mp 46–47°C. The purity of the product was 99% by GC.

General procedure for reductive scrambling of sulphur diimides

Prior to the reduction experiment, all glassware was washed and rinsed with Me_3SiCl and CH_2Cl_2, respectively, then oven dried overnight at 160°C. A solution containing equimolar amounts of the two symmetrical sulphur diimides (RNSNR and R′NSNR′) was prepared in 35 mL of THF. The resulting solution was then degassed by means of three freeze–pump–thaw cycles. A catalytic amount (5–25%) of freshly cut reducing agent (K or Na) was quickly added under nitrogen to the mixture. The deep red reaction mixture was stirred and held under nitrogen for about 2 h (preliminary studies showed that the reaction reached completion within 15 min) to ensure that equilibirum had been reached. The composition of the mixture was determined by removing aliquots via a syringe, quenching them immediately with oxygen, and analysing the resultant solutions by GC and GC–MS.

Scrambling of PhNSNPh and (4-MeC_6H_4)NSN(4-C_6H_4Me)

Materials used were PhNSNPh (0.35 g, 1.65 mmol), (4-MeC_6H_4)NSN(4-C_6H_4Me) (0.40 g, 1.65 mmol) and sodium metal (1.9 mg, 0.082 mmol). GC analysis of the mixture showed an integration of 1:2:1 ratio of PhNSNPh:(4-MeC_6H_4)NSNPh:(4-MeC_6H_4)NSN(4-C_6H_4Me). The unsymmetrical aryl sulphur diimide (4-MeC_6H_4)-NSNPh was identified by GC–MS analysis; mass spectrum (*m/e*) 228 (25), 213 (74), 137 (27), 123 (17), 91 (45), 77 (100).

Scrambling of (4-MeC_6H_4)NSN(4-C_6H_4Me) and (4-$MeOC_6H_4$)NSN(4-C_6H_4OMe)

Materials used were (4-MeC_6H_4)NSN(4-C_6H_4Me) (0.40 g, 1.65 mmol), (4-$MeOC_6H_4$)NSN(4-C_6H_4OMe) (0.45 g, 1.65 mmol) and sodium metal (1.9 mg, 0.082 mmol). GC analysis of the mixture showed an integration of 1:2:1 ratio of (4-MeC_6H_4)NSN(4-C_6H_4Me):(4-MeC_6H_4)NSN(4-C_6H_4OMe):(4-$MeOC_6H_4$)NSN(4-C_6H_4OMe). The unsymmetrical diimide (4-MeC_6H_4)NSN(4-C_6H_4OMe) was identified by GC–MS analysis; mass spectrum (*m/e*) 258 (19), 243 (65), 227 (20), 153 (23), 137 (25), 107 (77), 91 (54).

Scrambling of PhNSNPh and $Me_3SiNSNSiMe_3$

Materials used were PhNSNPh (5.0 g, 0.023 mol), $Me_3SiNSNSiMe_3$ (4.8 g, 0.023 mol), and sodium metal (0.03 g, 1.3 mmol). GC analysis of the equilibrium mixture showed an integration of 1:5:1 ratio of $Me_3SiNSNSiMe_3$:PhNSNSiMe$_3$:PhNSNPh. Evaporation of the solvent and fractional distillation gave PhNSNSiMe$_3$ (5.2 g, 53%) as an orange oil, bp 57–60°C/0.1 Torr (lit. bp 47°C/0.05 Torr (12*a*)). The purity of the distilled product was 96% by GC.

Scrambling of PhNSNPh and PhSNSNSPh

Materials used were PhNSNPh (0.5 g, 2.3 mmol, δN 297.7), PhSNSNSPh (0.65 g, 2.3 mmol, δN 273.4), and sodium metal (2.6 mg, 0.12 mmol). Analysis of the pre- and post-reduction mixture was performed by ^{14}N NMR. After reduction the NMR spectrum showed only two magnetically inequivalent nitrogens of PhNSNSPh at δN 261.7 and 300.6 ppm. Neither starting material was detected. Removal of the solvent (THF) *in vacuo* and subsequent recrystallization of the residual solid from cold hexane afforded PhSNSNPh (0.63 g, 2.7 mmol, 55%). An identical NMR spectrum was obtained from PhSNSNPh prepared by treating PhNSNSiMe$_3$ with PhSCl.

Preparation of (4-$MeOC_6H_4$)NSNS(4-$C_6H_4NO_2$)

A solution of 4-$NO_2C_6H_4SCl$ (0.79 g, 4.2 mmol) in 5 mL CH_2Cl_2 was added dropwise to a solution of (4-$MeOC_6H_4$)NSNSiMe$_3$ (1.0 g, 4.2 mmol) (obtained from a radical rearrangement reaction of (4-$MeOC_6H_4$)NSN(4-C_6H_4OMe) and $Me_3SiNSNSiMe_3$ described above) in CH_2Cl_2 (15 mL). The resulting red solution was allowed to react at room temperature for 1 h. The solvent was then removed *in vacuo*. The resulting solid was redissolved in 25 mL CH_2Cl_2 and placed in a sealed tank containing *n*-pentane. Slow diffusion of *n*-pentane into the CH_2Cl_2 solution led to formation of long red crystals of (4-$MeOC_6H_4$)NSNS(4-$C_6H_4NO_2$) (0.71 g, 53%) mp 167–169°C. *Anal.* calcd for $C_{13}H_{11}N_3O_3S_2$: C 48.59, H 3.45, N 13.08; found: C 48.62, H 3.43, N 13.23. Infrared (2000–250 cm^{-1}): 1575(m), 1496(s), 1458(s), 1377(s), 1317(m), 1289(s), 1247(s), 1211(m), 1184(m), 1085(s), 1026(s), 959(m), 928(w), 829(s), 798(w), 745(s), 722(m), 679(s), 569(w), 518(m), 298(s) cm^{-1}.

X-ray measurements

Red needles of (4-$MeOC_6H_4$)NSNS(4-$C_6H_4NO_2$) suitable for X-ray work were grown from pentane/CH_2Cl_2. The crystals were monoclinic, space group $P2_1/n$, $a = 3.950(1)$, $b = 12.437(2)$, $c = 28.354(5)$ Å, $\beta = 93.07(1)°$, $V = 1390.8(7)$ Å^3, $Z = 4$ at 293 K. The structure was solved by direct methods and refined by full-matrix least-squares analysis. The final R and R_w values of 0.043 and 0.048 were based on 744 unique data with $F > 3\sigma(F)$.

YUEZHU GU, JINGZHONG GUO, CHUANPU LIU, YONGJIA YIN, DEZHAO CAO, and JIYE CAI. Can. J. Chem. **69**, 100 (1991).

The reaction of metastable He(2^3S) and Ne($^3P_{0,2}$) atoms with methy halides has been investigated by flowing afterglow technique. Emission spectra have been observed and formation rate constants of some fragments have been measured. The rotational and vibrational temperatures of CH($A^2\Delta$) were also estimated.

Key words: flowing afterglow, methyl halides, metastable atoms.

YUEZHU GU, JINGZHONG GUO, CHUANPU LIU, YONGJIA YIN, DEZHAO CAO et JIYE CAI. Can. J. Chem. **69**, 100 (1991).

La réaction des atomes metastables de He(2^3S) et Ne($^3P_{0,2}$) avec halogenures de méthyle a été étudiée par la technique de courant de phosphorescence. Les spectres d'émission ont été observés et les constantes de vitesse de formation de quelques fragments ont été obtenues. Les temperatures rotationelle et vibrationelle de CH($A^2\Delta$) a été aussi determinée.

Mots clés : courant de phosphorescence, halogenures de methyle, atomes métastables.

Introduction

When rare gas atoms He and Ne are subjected to discharge, metastable atoms and ions are generated. The active species can react with the molecules and may produce fragments in electronically excited states. Tsuji *et al.* (1, 2) observed the dissociative charge transfer reaction of He^+ with CCl_4 and CBr_4. Setser and co-workers (3) investigated the reactions of He (2^3S) with diatomic moleclues N_2, CO, O_2, HCl, and HBr. Yencha and Wu (4) have discussed the energy transfer reactions of He(2^3S) and Ne($^3P_{0,2}$) with H_2O, H_2S, and CS_2. The reaction of He(2^3S) with NH_3 has been observed by Someda *et al.* (5). For reactions of He(2^3S) and Ne($^3P_{0,2}$) with five-atom molecules, Jones *et al.* (6) have reported the Penning ionization processes of CCl_4, CH_2Cl_2, $CHCl_3$, CBr_4, and other molecules.

In this work, we investigate the dissociative excitation of polyatomic molecules CCl_4, $CHCl_3$, CH_2Cl_2, CBr_4, CH_2Br_2, $CHBr_3$, CH_3Br, CH_2I_2, and CH_3I in flowing afterglows of helium and neon. The emission spectra of the fragments have been obtained and formation rate constants of CH(A, B, C) in different reactions have been evaluated. The rotational structure of the visible emission spectra from CH(A–X) has been analyzed to obtain information about rotational distribution of CH($A^2\Delta$, $v' = 0$) radical.

Experimental

The experimental assembly is essentially identical to that shown in Fig. 1 of ref. 7. Helium (or neon) gas was passed through a molecular sieve trap cooled by liquid nitrogen and excited to He(2^3S) (or Ne($^3P_{0,2}$)) in a hollow cathode discharge source. A right-angle light trap situated between the discharge source and reaction zone was used to avoid light leakage into the observation region. The system was pumped by a 150 L/s Roots pump. The reagent gases were degassed and purified by vacuum distillation before use and were admitted ca. 15 cm downstream from the discharge section. The total pressure was kept constant at 133 Pa.

Unfocussed emission from flames produced in the reactor was dispersed by a 0.75 m monochromator and detected by a cooled photomultiplier tube (RCA C31034A). Photon counting techniques were used for collecting emssion data. The wavelength response of the detection system had been previously calibrated with standard lamps.

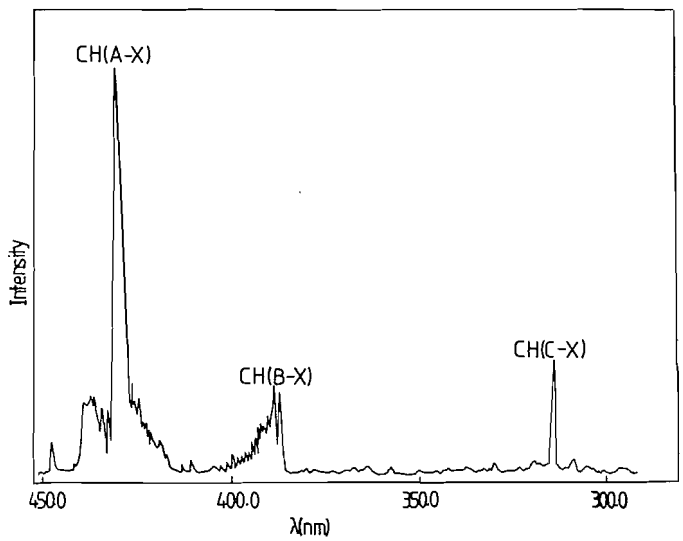

FIG. 1. Emission spectrum from the reaction He(2^3S) + CH_2Br_2.

Results and discussion

Emission spectra of the fragments

Strong conical blue flames were observed from the reactions of He(2^3S) and Ne($^3P_{0,2}$) with various methyl halides. Emission in the 200–500 nm region was recorded and analyzed. Typical emission spectra are shown in Figs. 1 and 2 and fragments with strong emission are listed in Table 1.

When He(2^3S) reacted with H-containing methyl halides strong emission from CH($A^2\Delta$–$X^2\Pi$), CH($B^2\Sigma$–$X^2\Pi$), and CH($C^2\Sigma$–$X^2\Pi$) was observed. Fewer emission bands were observed with Ne($^3P_{0,2}$). For the molecules CH_2Cl_2, $CHCl_3$, CCl_4, $CHBr_3$, CH_2Br_2, and CBr_4, Br_2*, and Cl_2* emission was obtained in the 250–350 nm and 240–260 nm regions, respectively. Tsuji *et al.* (1) reported the reaction between He^+ and CCl_4. Tokue and Ito (8) investigated the dissociation of CBr_4, $CFBr_3$, and $CHBr_3$ using electron-impact induced light emission. Compared with their emission spectra, we conclude that the broad emission in the 250–350 nm region is due to the

†This is the result of the reaction $Ne(^3P_{0,2}) + CCl_4$.

$D0_u^+-X^1\Sigma_g^+$, $D'2_g-A'^3\Pi(2_u)$, $E0_g^+-B^3\Pi(0_u^+)$ and $D'2_g-{}^3\Delta2_u$ transition of Br_2*; the Cl_2* emission is probably from $E^3\Pi_{Og}^+-B^3\Delta_{Ou}^+$ and $D^1\Sigma_u^+-X^1\Sigma_g^+$.

Relative electronically excited fragment populations

The relative populations of excited fragments have been evaluated from emission intensities of the various fragments. In the calculation we have accounted for the wavelength response of the detection system and the predissociation rate of $CH(C^2\Sigma)$ (9). The relation between the fragment yield and emission intensity is given by

$$R_p \propto f(\lambda)\, I_\lambda\, (1 + k\tau)$$

where R_p is the fragment yield, I_λ is the emission intensity, $1/f(\lambda)$ is the wavelength response of the detection system, τ is the level lifetime of the fragment, and k is the predissociation rate of the fragment. The results are listed in Table 2.

TABLE 2. Estimated relative populations of excited fragments produced in the helium flowing afterglow

	Estimated relative population when reagent is

†$k_Q(CH_2Cl_2) = 9.9 \times 10^{-10}$ cm^3 molecule s^{-1}; $k_Q(CHCl_3) = 10.7 \times 10^{-10}$ cm^3 molecule s^{-1} (6).

Formation rate constants of excited fragments

Providing there is no quenching, nonradiative decay, or pumping of the excited product state species P* from the observation zone, the steady-state photon emission rate from excited states equals the rate of excited state formation in some energy transfer reaction E^* + AB as expressed in eq. [1]:

$$[1] \quad I_p^* = k_p^*[E^*][AB]$$

If k_p^* is known for some reference molecule AB, the formation rate constant $k_p'^*$ for another reaction E* + BC can be obtained by comparing the relative integrated emission intensities (10):

$$[2] \quad \frac{I_p'^*}{I_p^*} = \frac{k_p'^*[E^*][BC]}{k_p^*[E^*][AB]}$$

$$k_p'^* = k_p^* I_p'^*[AB]/I_p^*[BC]$$

The key to the reference method is, of course, finding a reliable reference reaction. In our experiment, the reference reaction $He(2^3S) + CO(X) \rightarrow CO^+(B) + He$ was used, with a rate constant $k_{CO(B-X)} = 2.1 \times 10^{-11}$ cm^3 molecule s^{-1} (11). The formation rate constants of CH(*A*), CH(*B*), CH(*C*), and CCl(*A*) have been obtained in reactions of $He(2^3S)$ with $CHCl_3$, CH_2Cl_2, CH_2Br_2, and CH_3I. The results are summarized in Table 3.

*Rotational and vibrational distributions of CH(*A*)*

Relative emission intensities were analyzed to estimate the rotational and vibrational populations of $CH(A^2\Delta)$ formed in the reactions of $He(2^3S)$ with various H-containing methyl halides. All the CH(A—X) spectra obtained have complex structure due to overlapping of the different branches from the 0–0, 1–1, and 2–2 bands, but the R-branch lines of the 0–0 band are resolved

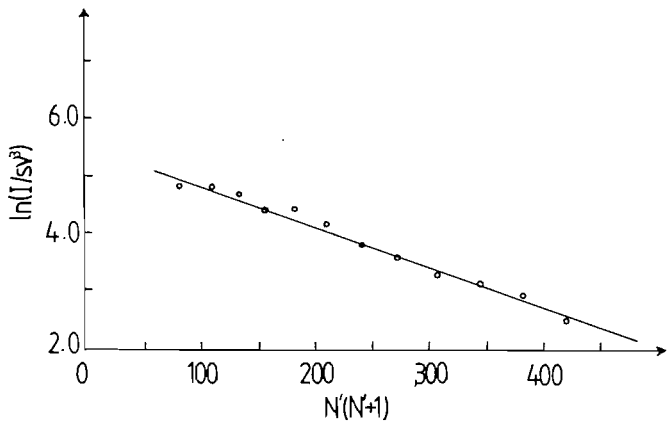

FIG. 3. ln $(I/S_{N'N''}\nu^3)$ plotted against $N'(N' + 1)$ for CH(A—X, 0—0) produced in reaction $He(2^3S) + CHCl_3$.

from those of the 1–1 and 2–2 bands for $N' > 6$. We used the intensities of the R-branch rotational lines from $v' = 0, N' > 6$ to estimated relative rotational populations of $CH(A^2\Delta, v' = 0)$. A semilog plot of $I_{N'N''}/\nu^3 S_{N'N''}$ against $N'(N' + 1)$ is shown in Fig. 3, where $I_{N'N''}$ is the relative emission intensity, ν is the transition and frequency, and $S_{N'N''}$ is the rotational line strength calculated with the Hönl–London formula (12). An approximately linear relationship for $CH(A^2\Delta, v^\circ = 0)$ indicates that the rotational populations can be represented in terms of a Boltzmann distribution. Analogous results were obtained for $CH(A^2\Delta, v' = 0)$ formed from various methyl halides. From the slope $-hcB_{v'}/kT_{rot}$, where $B_{v'}$ is the rotational constant, the effective rotational temperature, T_{rot}, can be evaluated. Table 4 gives the effective rotational temperatures of $CH(A^2\Delta, v' = 0)$ formed from various H-containing methyl halides.

By comparison of the (2, 2) and (0, 0) band Q-branch intensities, the vibrational population ratios (P_2/P_0) were estimated. If Boltzmann distributions are assumed for the vibrational populations, temperatures can be evaluated from these vibrational population ratios (P_2/P_0) with values listed in Table 4.

Taking experimental uncertainties (ca. ±500 K) into account, the rotational and vibrational temperatures of CH(*A*) obtained in this study are very similar to those obtained by electron impact on several methyl halides. In addition, the CH(A—X) emission specta obtained by electron impact on methane, acetylene, and ethylene are similar to those from the methyl halides (13). It is evident that the excess energies with which the excited CH radicals are formed differ in the various molecules excited by different processes, yet their *A* state internal energy distributions are similar. We intend to pursue further experimental and theoretical investigations on this subject.

Formation mechanism of excited fragments

Interactions between metastable atoms and gaseous molecules include several excitation channels, for example Penning ionization, dissociative excitation transfer, rearrangement ionization, ion-pair formation, and associative ionization. It has generally been accepted that for reagents with ionization potentials below the excitation energy of metastable He or Ne, chemiionization is the dominant quenching channel. Thus chemiionization reactions of metastable electronically excited He and Ne atoms have been actively studied in recent years. Jones *et al.* (6) studied the branching ratios for Penning ionization of several compounds, including the diatomic NO, N_2, Cl_2, O_2 and large molecules such as CCl_4, $CHCl_3$, CH_2Cl_2, CH_3Cl, etc., in flowing afterglows of He, Ne, and Ar. The experimental results show that the branching ratio was ~0.7, for the larger molecules in the low reagent concentration region. The data indicate that other channels are available. Much less is known about the dissociative excitation reactions of CH_nX_{4-n} in He and Ne flowing afterglow. Chang *et al.* (11) investigated the reaction of $He(2^3S)$ with CH_4, C_2H_4, and C_2H_2. Dissociative excitation was only 6% of the total quenching for C_2H_2 and even less for CH_4 and C_2H_4.

In the present work, emission spectra from excited neutral species were observed in the reaction of $He(2^3S)$ and $Ne(^3P_{0,2})$ with methyl halides. Branching ratios k/k_Q of $CH(A, B, C)$ and $CCl(A)$ were obtained for CH_2Cl_2 and $CHCl_3$ and listed in Table 3. Here k is the formation rate constant for production of excited fragments and k_Q is the rate constant for all quenching processes. Although the values are smaller than for the ionization channel, dissociative excitation can also be an important exit channel in the reaction of $He(2^3S)$ with CH_nX_{4-n}.

Concerning the formation mechanism of these neutral excited species, it may occur via an electron recombination reaction, analogous to the reaction of $He(2^3S)$ and CS_2 (14). Another possible process is dissociative excitation of the reagent molecule. In order to prove whether the formation of $CH(A, B, C)$ etc. is via ion–electron recombination, a trace amount of SF_6 as an electron scavenger was added to the reaction system. Our result showed the addition of SF_6 has no obvious effect in reducing the fragment emission intensities. This suggests that the fragment formation mechanism is not a process involving ion–electron recombination, but a dissociative excitation transfer process.

α-Guaiacoxyacetoveratrone, a lignin model compound, has been studied using a combination of laser flash photolysis and steady state quantum yields. Triplet lifetimes range from 175 to 600 ns while the quantum yields of photodegradation vary from 0.06 to 0.6, depending on the solvent. Singlet processes ($\Phi \sim 0.1$), previously unobserved for aromatic ketones, are implicated in the mechanism, and account for most or all of the degradation in aprotic solvents.

Key words: photodegradation, α-guaiacoxyacetoveratrone.

JOHN A. SCHMIDT, ALAIN B. BERINSTAIN, FRANCIS DE REGE, CYRIL HEITNER, LINDA J. JOHNSTON et J. C. SCAIANO. Can. J. Chem. **69**, 104 (1991).

Utilisant une combinaison de la photolyse éclair au laser et des rendements quantiques dans l'état stationnaire, on a étudié l'α-guaiacoxyacétovératrone, un composé modèle de la lignine. Les temps de vie des triplets vont de 175 à 600 ns alors que les rendements quantiques de la photodégradation varient de 0,06 à 0,6, suivant la nature du solvant. Des processus singulets ($\Phi \sim 0,1$), qui n'ont pas été observés antérieurement avec des cétones aromatiques, sont impliqués dans le mécanisme et ils permettent d'expliquer toutes, ou pratiquement toutes, les dégradations observées dans les solvants aprotiques.

Mots clés : photodégradation, α-guaiacoxyacétovératrone.

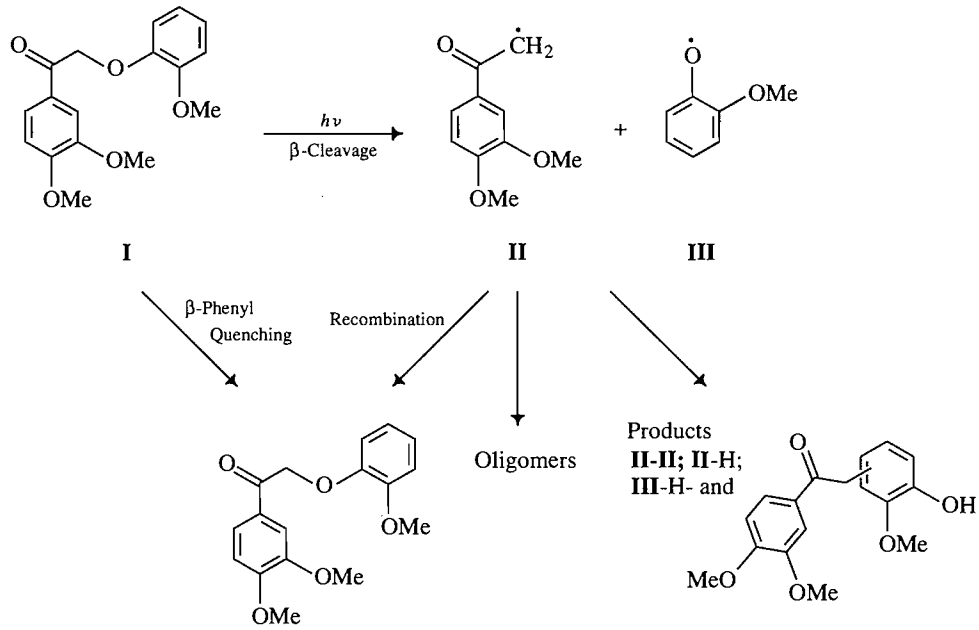
Mechanical and ultra-high yield pulps are used primarily for the manufacture of low-value grades of short-life papers such as newsprint, advertising, catalog, and directory papers. Their use in higher-value products is severely restricted by the rapid yellowing which occurs upon exposure to indoor illumination or daylight, a phenomenon attributed to photooxidation of lignin (1–6).

Hydrogen abstraction from phenolic groups and β-cleavage of aryloxy ketones are believed to lead to phenoxyl radicals and ultimately to yellowing, probably via quinone formation (6–8). Hydrogen abstraction from phenolic groups cannot be the only source of guaiacoxyl radicals since pulps with fully alkylated phenolic groups still yellow (although to a lower degree than do untreated pulps) (2, 3) and since Gierer and Lin have demonstrated that several nonphenolic phenacyl aryl ethers also undergo efficient degradation and induce yellowing (3). Castellan *et al.* have proposed the use of α-guaiacoxyacetovertatrone (**I**) as a model for the β-cleavage processes in lignin (9). This molecule contains some of the key features of lignin, such as the possibility of β-cleavage to yield phenoxyl radicals and a mechanism for β-phenyl quenching, a common pathway for triplet deactivation in ketones such as β-phenylpropiophenone and α-phenoxyacetophenone (10–12). Further, the lowest lying triplet of **I** is expected to have π,π^* character, a property that is presumably also common to the carbonyls in lignin.

The photochemistry of **I** (Scheme 1) is consistent with the following processes: (*i*) scavenging of phenacyl and phenoxyl radicals by hydrogen donors; (*ii*) *ortho-* and *para*-coupling giving phenacylguaiacols isomeric with **I**; (*iii*) dimerization of phenacyl radicals, and (*iv*) formation of yellow oligomeric material (3, 9). Finally, a non-product forming reaction, the recombination of phenoxyl and phenacyl radicals probably leads to regeneration of **I**. Similar processes are known for several α-aryloxyacetophenones (10–12). Their rate constants for α-C—O cleavage are in the $5 \times 10^6 - 2.7 \times 10^9\ s^{-1}$ range, where the higher values are for ketones with electron-donating substituents (e.g. 4-OCH_3) on the α-phenoxyl ring. Despite these high rate constants, the quantum yield of photocleavage can be low due to competition with efficient intramolecular deactivation via β-phenyl quenching.



We have carried out additional exploratory work on **I** in an attempt to understand better the mechanism of the light-induced yellowing of lignin. Our results prompt us to communicate them at this time: specifically, we have observed a remarkable solvent dependence of the quantum yields and evidence of important singlet processes in the photodegradation of **I**; in aprotic solvents such as acetonitrile and dioxane degradation may occur exclusively from the singlet manifold.

Laser excitation of the lowest energy absorption band of **I** in deaerated acetonitrile, dioxane, or alcohols generated a transient with $\lambda_{max} = 400$ nm and a weak absorption between 400–500 nm (Fig. 1). This transient is readily identified as triplet **I** on the basis of its similarity to the published spectra for substituted acetophenones (13), and to a previous report on the transient absorption spectrum of **I** in ethanol (9). The triplet decay (at 400 nm, insert in Fig. 1) was monitored in a variety of solvents and the data are listed in Table 1. The lifetimes are independent of the monitoring wavelength and varied from ~200 ns in either dioxane or 1,2-dimethoxyethane to 600 ns in 2-ethoxyethanol. The addition of 40% water to the alcohols leads to shorter lifetimes, while in aqueous aprotic solvents the triplet was substantially longer-lived than in the pure solvent.

To confirm the identity of the triplet state and to determine its reactivity towards the quenchers used in some of our steady-state experiments, we carried out quenching studies with several

substrates. Plots of the observed rate constant for triplet decay (k_{obs}) as a function of the concentration of quencher were linear and gave, from their slopes, the quenching rate constants (k_q) by various substrates (eq. [1], where k_0 is the rate constant for triplet decay in the absence of quencher). The rate constants obtained are $(3.0 \pm 0.8) \times 10^9\ M^{-1}\ s^{-1}$ for oxygen in ethanol, $(1.9 \pm 0.2) \times 10^9\ M^{-1}\ s^{-1}$ for 1,3-cyclohexadiene in 4:1 2-ethoxyethanol/water and $(2.1 \pm 0.3) \times 10^8\ M^{-1}\ s^{-1}$ for thiophenol in 1,2-dimethoxyethane. These values are typical for triplet quenching and leave no doubt as to the identity of the observed transient.

$$[1] \quad k_{obs} = k_q[\text{Quencher}]$$

Table 1 lists the quantum yields for consumption of **I** in several solvents. The quantum yields in pure alcohols (0.32–0.52) are higher than those observed in aprotic solvents. In the presence of 40% (v/v) water the quantum yields in aprotic solvents increased dramatically, while those in alcohols decreased slightly. The large changes induced by water in

solvents such as acetonitrile and dioxane may have four possible origins; (*a*) solvent effects on the amount of radical recombination leading to starting material, (*b*) solvent effects on the competition between β-phenyl quenching and β-C—O bond cleavage of the triplet excited state, (*c*) increased quantum yield of singlet photodegradation pathways in the presence of water, and (*d*) increased involvement of triplet processes in the cleavage of **I**.

For each of the aprotic solvents examined the quantum yields and triplet lifetimes increase upon addition of water, whereas addition of water to protic solvents decreases both quantum yield and triplet lifetime. This may suggest that one of the

factors controlling the yields may be the rate of triplet deactivation via β-phenyl quenching, which normally controls the triplet lifetimes in similar ketones, *i.e.* chemical decay is enhanced by a decrease in the rate of competitive processes. While the trends in Table 1 suggest that this is a contributing factor, it is also clear that the magnitudes of the effects on the quantum yields are too large to be solely explained by the changes in the triplet lifetime. In spite of the obvious relationship between lifetimes and quantum yields, further elaboration must await additional results at variable water concentrations, and in the presence of radical scavengers to prevent the back reaction.

It is frequently assumed that the photochemistry of aromatic ketones arises almost exclusively from the lowest triplet state. Quantum yields of intersystem crossing of ca. 1.0 are common in ketones such as benzophenone and acetophenone (15). However, there is clear evidence that this is not the case for **I**. Thus, addition of 0.1 M 1,3-cyclohexadiene has little or no effect on the quantum yield for consumption of **I** in acetonitrile or dioxane and reduces it to 0.1 in ethanol. A simple calculation shows that this diene concentration should quench *ca.* 99% of the triplets. Consumption of **I** under these conditions must reflect processes that occur within the singlet manifold of **I**. The evidence for singlet photoprocesses is not limited to the quantum yield data. Transient studies reveal long-lived transients (presumably singlet-derived) (particularly in polar hydroxylic solvents) that persist after triplet decay and are not quenched by dienes. Although we have not yet positively identified these signals (λ_{max} = 345 nm and 600–700 nm), we are currently examining the possible involvement of phenoxyl radicals and/or radical ions in these reactions, as well as the role of water.

Table 1 also shows the effects of oxygen (as air) and thiophenol on the consumption of **I** in acetonitrile. Oxygen appears to cause a minor increase in consumption yield which is probably due to radical scavenging that prevents the back reaction. That oxygen can scavenge phenacyl radicals is supported by Gierer and Lin's isolation of α-hydroxyacetoveratrone after photolysis of aerated solutions of **I** (3). Addition of thiophenol (0.01 M) increases the quantum yields substantially under conditions where only *ca.* half of the triplets will survive quenching. Radical scavenging may contribute here to the increase in yields (14). However, one must also consider that triplet quenching by thiophenol may involve hydrogen abstraction which would result in the consumption of **I**.[2] In the presence of thiophenol, oxygen decreases the quantum yield. Both observations suggest some triplet photoreduction by thiophenol which is partially prevented by a triplet quencher such as oxygen.

These results have shown that the solvent has a dramatic effect on both the triplet lifetime and the efficiency of photocleavage of **I**. The results point to the rate of triplet deactivation via β-phenyl quenching as one of the factors in controlling the quantum yields, particularly in hydroxylic solvents. Given our observation of previously unobserved singlet processes, it is obvious that other factors related to singlet reactivity must also be involved. Traditional attempts to prevent the photo-yellowing of lignin-rich papers have been largely based on addition of triplet quenchers and elimination of free phenolic groups. However, the results with **I** demonstrate the importance of both β-cleavage and singlet processes, neither of which will be affected by these two methods. It is obviously of interest to explore these processes in more detail, in both the model compound and in lignin, to better understand the processes involved in the yellowing of lignin-rich paper.[3]

Experimental

α-Guaiacoxyacetoveratrone (**I**) was synthesized by condensing α-bromoacetoveratrone and guaiacol in dry acetone in the presence of K_2CO_3 (18).

A description of the laser flash photolysis apparatus has been published (19). A Molectron UV-24 nitrogen laser (337 nm, ~8 nm pulses, <10 mJ/pulse) was used for excitation. Unless otherwise noted samples were deaerated by bubbling nitrogen through the sample and the solutions were flowed through a sample cell constructed from 3 × 7 mm^2 Suprasil tubing. Long-lived residual absorptions resulting from product accumulation were observed if flow samples were not used.

For the quantum yield experiments solutions of **I** (3.0 mL, 0.015 M) were irradiated with monochromatic light at 325 nm in 1 × 1 cm^2 quartz cells. For experiments under oxygen-free conditions the samples were sealed with rubber septa purged with oxygen-free nitrogen for 30 min. The dose absorbed was measured using a commercially available electronically integrating actinometer (QuantaCount, PTI, Deer Park, N.J.) calibrated using azoxybenzene (20). Disappearance of **I** was monitored using gas chromatography (Hewlett-Packard 5890A chromatograph, 25 m capillary column with HP-1 methyl silicone gum). Solutions were irradiated to ~10% conversion. For aqueous solvents the sample was extracted into diethyl ether. After drying and filtering the ether layer, the solvent was evaporated with a stream of nitrogen and the residue was taken up in 3.0 mL of the pure organic solvent employed for the irradiation.

New precursors for organometallic chemical vapor deposition of rhodium

R. KUMAR AND R. J. PUDDEPHATT
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 4, 1990

R. KUMAR and R. J. PUDDEPHATT. Can. J. Chem. **69**, 108 (1991).

The η-cyclopentadienyl (Cp) and η-allyl (C_3H_5) complexes [RhCp$(CO)_2$], [RhCp(cod)] where cod = 1,5-cyclooctadiene, [Rh(η-C_3H_5)$(CO)_2$], and [Rh(η-C_3H_5)$_3$] have been shown to be useful precursors for the chemical vapour deposition (CVD) of rhodium films. The rhodium films contain carbon impurities but these can be greatly reduced if CVD is carried out in the presence of hydrogen. The films adhere well to a silicon substrate. The pyrolysis of [RhCp$(CO)_2$] gives CO and [$Rh_2Cp_2(CO)_2$(μ-CO)] and [Rh_3Cp_3(μ-CO)$_3$] at intermediate stages. Pyrolysis of [Rh(η-C_3H_5)$_3$] or [Rh(η-C_3H_5)$(CO)_2$] gives 1,5-hexadiene as the only organic product, but similar pyrolysis in the presence of hydrogen gives much propene as well as 1,5-hexadiene.

Key words: rhodium, deposition, allyl, cyclopentadienyl.

R. KUMAR et R. J. PUDDEPHATT. Can. J. Chem. **69**, 108 (1991).

On a démontré que les complexes du η-cyclopentadiényle (Cp) et du η-allyle (C_3H_5) — [RhCp$(CO)_2$], [RhCp(cod)] dans lequel cod = cycloocta-1,5-diène, [Rh(η-C_3H_5)$(CO)_2$] et [Rh(η-C_3H_5)$_3$] — sont des précurseurs utiles pour la déposition chimique de vapeurs (DCV) de films de rhodium. Les films de rhodium contiennent des impuretés; toutefois, on peut les réduire beaucoup si l'on effectue les DCV en présence d'hydrogène. Les films adhèrent bien à un substrat de silicium. La pyrolyse du [RhCp$(CO)_2$] conduit à du CO et à du [$RhCp_2(CO)_2$(μ-CO)] et à du [$RhCp_3$(μ-CO)$_3$] aux étapes intermédiaires. La pyrolyse du [Rh(η-C_3H_5)$_3$] ou du [Rh(η-C_3H_5)$(CO)_2$] ne fournit que de l'hexa-1,5-diène comme produit organique; des pyrolyses semblables réalisées en présence d'hydrogène fournissent aussi du propène, en plus de l'hexa-1,5-diène.

Mots clés : rhodium, déposition, allyle, cyclopentadiényle.

[Traduit par la revue]

Introduction

There has been much recent interest in the formation of thin films of metals using chemical vapour deposition, CVD (1–3). These films have applications in microelectronics, optical devices, wear protection, and catalysis (4). Advantages of CVD include its ease of use, mild conditions of formation, and high performance of the films. Challenges for chemists include the design and synthesis of volatile precursors which decompose to the desired materials in pure form and under mild thermal or photochemical conditions as required for specific applications, and the determination of the mechanisms of CVD to enable the development of a rational approach to precursor design.

Most recent research has been focussed on CVD of gold, palladium, and platinum, noble metals most commonly used in microelectronics (5–9). Rhodium has been much less extensively studied (2, 10). Rhodium films are used in mirror optics, catalysis, and wear protection but, while rhodium has excellent electrical properties and corrosion resistance, its high cost has so far limited its application in microelectronics (11). This paper surveys some volatile organorhodium complexes, and reports on a study of thermal CVD of rhodium films from these compounds. Other researchers have reported CVD of rhodium using the precursors [$Rh_2(CO)_8$], [Rh_2(μ-Cl)$_2(CO)_4$], [Rh($CH_3COCHCOCF_3$)$_3$], [Rh($CH_3COCHCOCH_3$)(C_2H_4)$_2$], [Rh($CH_3COCHCOCF_3$)$(CO)_2$], and, very recently, [Rh(η-C_3H_5)$_3$] (1, 2, 8, 10), and the enhancement of CVD by lasers or by plasma has been demonstrated (1, 10).

Results and discussion

In this work, the new precursors used were the η-cyclopentadienyl derivatives [RhCp(cod)], Cp = μ-C_5H_5, cod = 1,5-cyclooctadiene, and [RhCp$(CO)_2$] and the η-allyl derivatives [Rh(η-C_3H_5)$(CO)_2$] and [Rh(η-C_3H_5)$_3$]. All were prepared by known procedures (12–15). For reference, some CVD experiments were also carried out with the known precursor [Rh_2(μ-Cl)$_2(CO)_4$] (2).

Formation and characterization of rhodium films

In a typical reaction, CVD was carried out in a vertical reactor operating at 10^{-2}–10^{-3} Torr. The substrate was a silicon wafer, which was heated to 130–270°C. Under these conditions, highly reflective rhodium films were formed and the film thickness typically grew at a rate of ~2 μm/h. The films were analyzed by XPS and some typical data are given in Table 1.

The rhodium films are rapidly contaminated by exposure to the atmosphere and, in all cases, the films were cleaned before analysis by argon sputtering for 30 s. Even so, the films consistently contained much carbon and oxygen impurities. These impurities were greatly reduced when the CVD was carried out using hydrogen carrier gas (Table 1). For example, using only 10^{-3} Torr H_2 as carrier gas and [Rh(μ-C_3H_5)$(CO)_2$] as precursor, the rhodium content increased from 48% to 94%, the carbon content decreased from 40% to 6%, and the oxygen content decreased from 12% to undetectably low levels. In other cases, the hydrogen effect was less dramatic (Table 1) but it was always observed.

A similar effect of hydrogen on film purity has been observed for CVD of platinum (8, 9). For CVD of platinum using dimethylplatinum(II) precursors, hydrogen also had a dramatic effect in lowering the temperature required for thermal CVD (9), but this type of effect was not observed for rhodium CVD (Table 1). For CVD using [RhCp(cod)] and [Rh(η-allyl)$_3$], there was a decrease in the temperature required for CVD but no such effect was observed with the precursors [Rh(η-C_3H_5)$(CO)_2$] or [RhCp$(CO)_2$]. Thus the hydrogen effects on film purity and CVD temperature appear to be independent of each other.

The rhodium films adhered strongly to the silicon surface as determined qualitatively by scratch and tape tests. The film resistivity of samples prepared under hydrogen averaged 28 ± 5 μΩ-cm while those prepared without hydrogen averaged 60 ± 20 μΩ-cm. Bulk rhodium has a resistivity at 20°C of 4.51 μΩ-cm. It is clear that residual carbon in the films is partially responsible for the lower conductivity of the rhodium

films prepared by CVD. Scanning electron microscopy (SEM) showed the presence of smooth rhodium films composed of crystallites with dimensions of *ca.* 200 Å across.

Studies of the thermolysis reactions

In a crude approximation of the CVD conditions, the precursors (~10 mg) were heated to 140°C in a large (500 mL) vessel sealed under vacuum. The gaseous products of thermolysis were then analyzed by GC, MS, or GC/MS while the residual rhodium complexes present after partial pyrolysis were extracted and examined by MS, IR, and NMR techniques. Pyrolysis of $[Rh_2(\mu\text{-}Cl)_2(CO)_4]$ gave CO as the major product with some $COCl_2$ in the later stages. $RhCl_3$ was also identified at intermediate stages. Thus the loss of CO appears to be the first step in the decomposition stage. Similarly, pyrolysis of $[RhCp(CO)_2]$ gave CO as the only volatile product and, as well as metallic rhodium, the complexes $[Rh_2Cp_2(CO)_2(\mu\text{-}CO)]$ and $[Rh_3Cp_3(\mu\text{-}CO)_3]$ were formed in the early stages of pyrolysis. These complexes were isolated in pure form and were identified by their characteristic NMR and IR spectra (16–20). It is already known that these compounds can be prepared by photolysis of solutions of $[RhCp(CO)_2]$ and that the reaction occurs by initial loss of CO followed by association (16–19). The thermolysis probably occurs in a similar way and it is intriguing to consider whether the cluster complexes may be formed during the CVD of rhodium from $[RhCp(CO)_2]$. The concentration of rhodium complexes in the gas phase during CVD may be too low to allow associative reactions but it is easy to envisage how such processes might occur in surface-bound organometallic complexes. Further studies of this possible mechanism of CVD are planned.

Pyrolysis of [RhCp(cod)] gave a very complex mixture of hydrocarbon products, which were not fully characterized, and the mass spectrum of the residue gave a peak at $m/e = 504$, corresponding to $[Rh_3Cp_3]^+$. However, in this case, attempts to isolate pure complexes from the partly pyrolyzed reaction mixture were unsuccessful. Nevertheless, it does appear that pyrolysis may give rhodium clusters at intermediate stages. The added complexity in this case is probably due to the competition between the loss of Cp or cod groups from rhodium in the initial stage of decomposition (21).

Pyrolysis of $[Rh(\eta\text{-}C_3H_5)_3]$ gave 1,5-hexadiene as the only volatile product, as determined by GC and GC/MS, but no rhodium clusters or dimers could be detected at intermediate stages. In this case, pyrolysis under a partial atmosphere of H_2 had a dramatic effect on the organic product. Thus, propene (32%) and 1,5-hexadiene (67%) were formed under these conditions, along with traces of other unidentified compounds. The product 1,5-hexadiene could be formed by concerted reductive elimination at rhodium or by loss of allyl radicals followed by radical recombination and is the only product in the absence of hydrogen. Hydrogen could react directly with allylrhodium species to give propene, though there are no precedents for reaction of H_2 with rhodium(III) organometallics. Therefore, partial reaction of the precursor to give lower oxidation state rhodium complexes might be necessary before hydrogen could oxidatively add. Formation of propene could then occur by reductive elimination. Alternatively, the reaction might be catalyzed by metallic rhodium, which is known to be a good hydrogenation catalyst. Although the present data do not define a mechanism, the hydrogen effect is shown to influence the temperature of CVD, the rhodium film purity, and the nature of the organic products using $[Rh(\eta\text{-}C_3H_5)_3]$ as precursor. Hence hydrogen is presumed to be involved directly in the mechanism of CVD.

Conclusions

These organometallic precursors for CVD of rhodium have high volatility; they decompose to rhodium at moderate temperatures and, in the presence of hydrogen, they give rhodium films which are of high purity and which adhere well to a silicon substrate. Thus they have considerable advantages over precursors used for CVD of rhodium in the past (1, 2, 10).

Experimental

Organorhodium complexes were prepared by literature methods (12–15) and were purified by sublimation. Their purity was confirmed by ^1H NMR.

The rhodium film thickness was determined by a stylus method using a Sloan Dektak II instrument. Conductivities were determined by a four point probe method (22). The compositions of the metal films were determined by XPS using a SSL SSX-100 instrument with a monochromatized Mg-Kα X-ray source (1253.6 eV). Spectra were computer fitted to 70% Gaussian lineshapes after background subtraction and using no constraint to the final fit. The surfaces were cleaned by sputtering for 30 s with argon ions before analysis. SEM micrographs of rhodium films were taken using a ISL DS-130 scanning electron microscope. Film adherence was tested qualitatively using the scratch and Scotch tape tests. Infrared spectra were obtained by using a Bruker IFS-32 instrument, NMR spectra by using a Varian XL200 spectrometer, and GC/MS by using a Varian 3400 GC coupled to a Finnigan MAT8230 mass spectrometer.

Chemical vapour deposition

The rhodium precursor (50 mg) was placed in a vertical CVD reactor. A silicon wafer substrate (*ca.* 0.5 cm diameter) was heated to the required temperature (130–270°C) and the apparatus was evacuated to 10^{-3} Torr. If necessary the precursor was warmed to give more rapid deposition but in no case was it necessary to heat to more than 50°C. Coatings up to 2 μm in thickness were deposited in 0.5–1 h. In some cases a slow stream of H_2 was passed over the rhodium precursor.

The minimum CVD temperature given in Table 1 is that when most rhodium precursor decomposed to give rhodium metal rather than simply subliming in the equipment. The temperatures 130, 180, 230, and 270°C were checked and the lowest temperature of CVD is given in Table 1. Analytical data were obtained on films prepared at a standard temperature of 270°C.

Thermal decomposition studies

In a typical experiment, $[RhCp(CO)_2]$ (10 mg) in an evacuated vessel (500 mL) was heated slowly to 180°C in an oil bath, until metallic rhodium was visible. The gases evolved were sampled by syringe and analyzed by GC/MS. The residue was extracted with CH_2Cl_2 (2 × 10 mL), then concentrated and separated by preparative thin layer chromatography. This gave red $[Rh_2Cp_2(CO)_3]$ (16) (IR: $\nu(CO)$ = 1986 cm^{-1}; lit. 1989 cm^{-1}, 1841 cm^{-1} in cyclohexane solution; ^1H NMR: δ = 5.50 ppm), and green $[Rh_3Cp_3(\mu\text{-}CO)_3]$ (17) (IR: $\nu(CO)$ = 1850 cm^{-1}, 1791 cm^{-1}; lit. 1849 cm^{-1}, 1793 cm^{-1} in CH_2Cl_2). Similar results were obtained for pyrolysis in the presence of H_2 (0.2 atm).

In similar pyrolyses of $[Rh(\eta\text{-}C_3H_5)(CO)_2]$, the products 1,5-hexadiene and propene were identified by GC/MS by comparison with authentic samples. No new rhodium complexes were identified.

Activity coefficients of NaCl in NaCl–NaOAc–H_2O at 25, 35, and 45°C

S. MANOHAR AND J. ANANTHASWAMY
Department of Chemistry, Osmania University, Hyderabad, India 500 007

Received April 20, 1990

S. MANOHAR and J. ANANTHASWAMY. Can. J. Chem. **69**, 111 (1991).

The activity coefficients of NaCl were estimated by measuring the EMFs of the cell

Na ion-selective electrode | NaCl(m_A), NaOAc(m_B) | Ag/AgCl

at four ionic strengths, *i.e.*, 0.5, 1.0, 2.0, and 3.0 mol/kg and at temperatures 25, 35, and 45°C. The results were analyzed in terms of Harned's rule, the Pitzer and Rush–Johnson–Scatchard treatments. Osmotic coefficients and excess free energies of mixing were calculated at all ionic strengths and temperatures studied.

Key words: activity coefficients, sodium chloride, sodium acetate, Pitzer formalism, Scatchard equation.

S. MANOHAR et J. ANANTHASWAMY. Can. J. Chem. **69**, 111 (1991).

On a évalué les coefficients d'activité du NaCl en mesurant les f.é.m. de la cellule :

électrode ion-sélective au Na | NaCl(m_A), NaOAc(m_B) | Ag/AgCl

à quatre forces ioniques, soit 0,5, 1,0, 2,0 et 3,0 mol/kg et à 25, 35 et 45°C. On a analysé les résultats en fonction de la règle de Harned et des traitements de Pitzer ainsi que de Rush-Johnson-Scatchard. On a calculé les coefficients osmotiques ainsi que les énergies libres en excès de mélange à toutes les forces ioniques et à toutes les températures étudiées.

Mots clés : coefficients d'activité, chlorure de sodium, acétate de sodium, formalisme de Pitzer, équation de Scatchard.
[Traduit par la revue]

Introduction

NaCl–NaOAc–H_2O is an interesting system because the osmotic coefficients of binary solutions of acetates is in reverse order to that of the chlorides (1, 2) *i.e.*, $\phi_{KCl} < \phi_{NaCl}$ but $\phi_{KOAc} > \phi_{NaOAc}$. The activity coefficients of NaCl in aqueous NaCl–NaOAc mixture have been measured by Lanier (3) at ionic strengths 1.0, 3.0, and 5.0 mol/kg with cation-selective glass electrode and a silver – silver chloride electrode at 25°C. Isopiestic vapour pressure measurements were carried out by Jones *et al.* (4) over the concentration range 1.8968–3.1210 mol/kg at 25°C. However, the effect of temperature on the activity coefficients of this sytem is not yet studied. This paper reports measurements of NaCl activity coefficients in aqueous solutions containing sodium acetate. The results were analysed in the light of Pitzer (5) and Scatchard (6, 7) treatments and the corresponding binary and ternary interaction parameters were calculated. The osmotic coefficients and excess free energies were also calculated using the Pitzer parameters ($^s\theta$ and Ψ).

Results

The activity coefficients of NaCl were calculated using the relation:

$$[1] \quad E_{NaCl-NaOAc} = E_0 + k \log (m_{Na} m_{Cl} \gamma^2_{NaCl} + K m_{Na} m_{OAc} \gamma^2_{NaOAc})$$

where $K m_{Na} m_{OAc} \gamma^2_{NaOAc}$ term will take into account the effect of sodium acetate on the cell EMF. $k = 2.303RT/nF$ is the Nernst slope and E_0 is the EMF of the pure NaCl solution at unit activity. The K values were in the range of 1×10^{-5} at all ionic strengths and temperatures studied and hence the $K m_{Na} m_{OAc} \gamma^2_{NaOAc}$ term in eq. [1] could be neglected. Thus eq. [1] could be rearranged as

$$[2] \quad \gamma^2_{\pm} = 1/(m_{Na} m_{Cl})\ 10^{(E_{NaCl-NaOAc} - E_0)/k}$$

Thus the mean activity coefficients ($\gamma_{\pm}$) of NaCl can be obtained by substituting the EMFs of the cell with NaCl–NaOAc aqueous mixtures ($E_{NaCl-NaOAc}$) in eq. [2]. All calculations are done on a computer (PC). The experimental mean activity coefficient data determined at I = 0.5, 1.0, 2.0, and 3.0 mol/kg and at 25, 35, and 45°C are listed in Table 1 as a function of y_B, the ionic strength fraction of NaOAc in the mixture. Thus $y_B = m_B/(m_A + m_B)$. The log γ_{NaCl} vs. y_B plots at 25°C are shown in Fig. 1.

Discussion

The Harned equations (8) given below were fitted to the experimentally determined activity coefficient data at each ionic strength using a least squares procedure.

$$[3] \quad \log \gamma_A = \log \gamma^0_A - \alpha_{AB} y_B$$

$$[4] \quad \log \gamma_A = \log \gamma^0_A - \alpha_{AB} y_B - \beta_{AB} y^2_B$$

The Harned slope (α_{AB}) and intercept (log γ^0_A) were obtained by linear regression. The Harned coefficient at I = 1.0 and at 25°C, viz., −0.0251 is in agreement with −0.0242 reported earlier by Lanier (3). Figure 1 shows that the log γ vs. y_B plots are linear at I = 0.5 and 1.0 mol/kg, whereas these plots are slightly curved at I = 2.0 and 3.0 mol/kg. Therefore, it is evident from the data listed in Table 2 that the linear Harned expression is not so adequate above I = 1.0 mol/kg. There was a good agreement between the experimentally obtained log γ^0_A (from intercept) calculated from the Harned equation involving the β_{AB} term and the literature log γ^0_A values. The same type of trend was also observed at 35 and 45°C. Addition of β_{AB} term indicates the possibility of ternary ionic interactions such as Na–Cl–OAc in these solutions at higher ionic strength.

The activity coefficients and osmotic coefficients of pure sodium chloride (9) and sodium acetate (10, 11) solutions could be calculated using the Pitzer equations given below with the following values of parameters at the experimental temperatures studied.

According to Guggenheim (12), an electrolyte mixture involves pair-wise interactions of only oppositely charged ions. Moreover, the change in activity coefficient with composition of the mixture can be predicted from the osmotic coefficients (ϕ^0) of the constituent electrolytes. For two univalent electrolytes with a common ion, such as NaCl (m_A) and NaOAc (m_B) the following expression can be written

[7] $$\ln(\gamma_A/\gamma_A^0) = (\phi_B^0 - \phi_A^0)y_B$$

where γ_A^0 is the activity coefficient in a pure solution of component A at the same ionic strength as in the mixture. But Pitzer (5) recognized the possibility of interactions between charges of the same sign as well. Hence, Pitzer included the binary interaction ($^s\theta$) and ternary interaction (Ψ) terms in the mixture equation. The Pitzer equation for the three-ion mixtures such as NaCl–NaOAc–H_2O can be written as

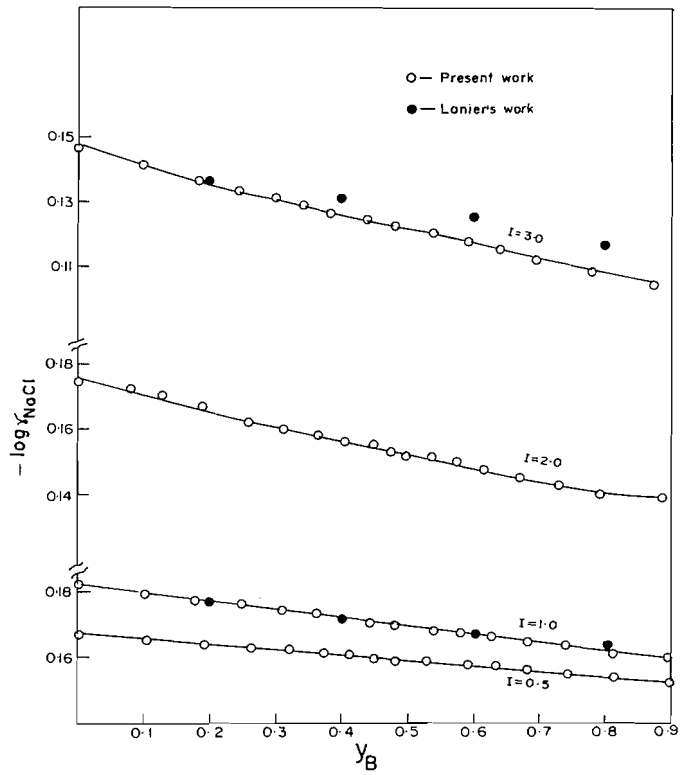

FIG. 1. Activity coefficients of NaCl in the NaCl–NaOAc–H_2O system at 25°C.

[8] $$\ln(\gamma_{NaCl}/\gamma^0_{NaCl}) = y_B(\phi_B^0 - \phi_A^0) + Iy_B{}^s\theta_{Cl-OAc} + 0.5I^2y_B(2 - y_B)\Psi_{Cl-OAc-Na}$$

where ϕ_A^0 and ϕ_B^0 are the osmotic coefficients of pure NaCl and NaOAc solutions at the same ionic strength as the mixture. Equation [8] was fitted to the activity coefficient data at all four ionic strengths at one temperature into a single least-squares program and the common $^s\theta$ and Ψ values were evaluated. The

TABLE 3. Pitzer and Scatchard parameters for the NaCl–NaOAc–H_2O system

	Pitzer parameters			Scatchard parameters		
T/°C	$^s\theta$	Ψ	RMSD × 10^5	b_{01}	b_{02}	RMSD × 10^5
25	−0.00545	−0.00205	2.90	−0.0109	−0.00405	3.29
35	−0.00451	−0.00202	2.98	−0.00879	−0.00416	3.19
45	−0.00357	−0.00122	2.76	−0.00723	−0.00235	4.67

evaluated $^s\theta$ values are −0.00545, −0.00451, and −0.00357 and Ψ values are −0.00205, −0.00202, and −0.00122 at 25, 35, and 45°C, respectively.

The neutral electrolyte treatment introduced by Scatchard (6) and later extended by Rush and Johnson (7) leads to the expression

$$[9]\quad \ln(\gamma_A/\gamma_A^0) = y_B(\phi_B^0 - \phi_A^0) + 0.5y_B(b_{01}I + b_{02}I^2 + b_{03}I^3 + b_{12}I^2 + b_{13}I^3) - 0.5y_B^2[(1/2)b_{01}I^2 + (2/3)b_{03}I^3 + (3/2)b_{12}I^2 + 2b_{13}I^3] + (1/3)y_B^3 b_{13}I^3$$

where ϕ_A^0 and ϕ_B^0 are the osmotic coefficients of the single components A and B at the same ionic strength as the mixture and can be calculated using the Pitzer equation [6]. The coefficients b_{mn} are mixing parameters accounting for the ion–ion interactions specific to the mixture. It appears that two parameters, namely b_{01}, b_{02}, are required to fit the experimental data accurately. Of these two, b_{01} represents the binary interaction between Cl–OAc and b_{02} represents the binary interaction between Cl–OAc and b_{02} the ternary interaction Na–Cl–OAc. Equation [9] was fitted to the activity coefficient data at all four ionic strengths into a single least-squares program to yield b_{01} and b_{02}. The evaluated values are $b_{01} = -0.0109$, −0.0088, and −0.0072 and $b_{02} = -0.00405$, −0.00416, and −0.00235 at 25, 35, and 45°C, respectively. Jones *et al.* (4) reported $b_{01} = -0.0156$ assuming b_{02} as zero at 25°C. Thus the different treatments of three uni-univalent ion mixtures are equivalent and the mixing parameters of Pitzer (5) and Scatchard (6, 7) models are interrelated because $b_{01} = 2^s\theta_{Cl-OAc}$ and $b_{02} = 2\Psi_{Cl-OAc-Na}$. When only two mixing interaction parameters are considered in each treatment, one gets the comparison as shown in Table 3. By combining eqs. [3], [8], and [9] it is evident that up to $I = 1.0$ mol/kg when the excess free energy of mixing can be accounted for satisfactorily in terms of only $^s\theta_{Cl-OAc}$ or b_{01}, these parameters are related to the Harned slope α_{AB} as

$$[10]\quad \alpha_{AB} = \frac{(\phi_A^0 - \phi_B^0 - I^s\theta_{Cl-OAc})}{2.3026} = \frac{(\phi_A^0 - \phi_B^0 - 0.5Ib_{01})}{2.3026}$$

By substituting $^s\theta_{Cl-OAc}$ or b_{01} values listed in Table 3 in the above equation the α_{AB} value could be calculated as −0.0150 and −0.0256 at $I = 0.5$ and 1.0, respectively. These values are in good agreement with the experimentally determined α_{AB} values of −0.0149 and −0.0257 (cf. Table 2).

Osmotic coefficients of this system were calculated using the Pitzer equation (5)

$$[11]\quad \phi = -A_\phi[\sqrt{I}/(1 + b\sqrt{I})] + \{(1 - y_B)B^\phi_{NaCl} + y_B B^\phi_{NaOAc} + y_B(1 - y_B)^s\theta_{Cl-OAc}\} + I^2\{(1 - y_B)C^\phi_{NaCl} + y_B C^\phi_{NaOAc} + y_B(1 - y_B)\Psi_{Cl-OAc-Na}\} + 1$$

TABLE 4. Osmotic coefficients for the NaCl–NaOAc–H_2O system

	Osmotic coefficient

and the resulting data are listed in Table 4 for all temperatures and ionic strengths. Our estimated osmotic coefficients at 25°C are in agreement with the experimental values of Jones *et al.* (4) with an RMSD = 1.690×10^{-3}.

Excess Gibbs free energies of mixing were calculated using the equation (13)

$$[12]\quad \Delta_m G^E = 2y_B(1 - y_B)I^2RT(^s\theta_{Cl-OAc} + I\Psi_{Cl-OAc-Na}/2)$$

and the values are listed in Table 5.

Experimental

Analytical grade sodium chloride (Glaxo India) was purified by precipitation from a saturated solution with hydrogen chloride gas. AR grade sodium acetate (Glaxo India) was used after careful drying at 120°C. The stock solutions of NaCl were standardized by volumetric titrations against standard silver nitrate solution. All solutions were prepared by weight and all titrations and dilutions were done using weight burettes.

The cell consisted of sodium ion-selective electrode and Ag/AgCl electrode:

Na ion-selective electrode	$NaCl(m_A)$ + $NaOAc(m_B)$	Ag/AgCl electrode

*Parenthesized entries are from the work of Jones *et al.* (4).

The sodium ion-selective glass electrode was obtained from Elico, India. The Ag/AgCl electrode used was the thermal type (14). These electrodes were immersed in aqueous NaCl(m_A)–NaOAc(m_B) solution placed in a double-walled glass vessel. The temperature was maintained constant within ±0.01 K by circulating thermostatted water. The electrodes were connected to a high impedance ($\approx 10^{12}\ \Omega$) unit gain amplifier. The output of this amplifier was measured by a Keithley 5½ digit electrometer/multimeter (model: DMM 191). The accuracy of EMF measurements was ±0.01 mV. The potentials of the sodium ion-selective electrode vs. Ag/AgCl electrodes were measured at all four ionic strengths studied and the potentials were plotted against log a_{NaCl}. The E_0 values were obtained from the intercept, where the activity of NaCl is unity. These values are given as a footnote to Table 1. Further experimental details are given earlier (15, 16).

Studies on the thermal coking of bitumen. I. The use of pyrene-d_{10} as a probe for evaluating the extent of hydrogen shuttling reaction

M. J. KIRK AND T. S. SORENSEN[1]

The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received July 16, 1990

M. J. KIRK and T. S. SORENSEN. Can. J. Chem. **69**, 116 (1991).

The organic reactions that take place during the thermal coking of bitumen are extremely complex and deep-seated, but obviously hydrogen atoms originally attached to carbons that form coke will have moved to a new carbon site (net addition of hydrogen, resulting in upgraded bitumen). Accompanying this process, one expects some general hydrogen shuttling between non-coking molecules. This paper describes an approach to determing the extent of this latter process by the addition of a small amount of perdeuterated pyrene to the bitumen prior to the coking operation. The *in situ* pyrene functions as in indicator, allowing one to establish the extent and other mechanistic details of the "hydrogen donor" reactions that take place during coking. There is no indication that the pyrene substantially modifies the normal course of the reaction, hence the analogy to an indicator.

Key words: bitumen coking, pyrene, hydrogen exchange, donor solvent, free radicals.

M. J. KIRK et T. S. SORENSEN. Can. J. Chem. **69**, 116 (1991).

Les réactions organiques qui se produisent au cours du cokage thermique du bitume sont extrêmement complexes et fondamentales; il est toutefois évident que les atomes d'hydrogène qui sont originalement attachés aux atomes de carbone qui donnent naissance au coke devront se déplacer vers de nouveaux sites carbonés (avec une addition nette d'hydrogène qui donne naissance à un bitume amélioré). On peut s'attendre à ce que ce processus soit accompagné d'un déplacement général des hydrogènes entre les molécules qui ne donnent pas de coke. Dans ce travail, on décrit une approche qui permet de déterminer l'importance de ce dernier processus; elle est basée sur l'addition d'une faible quantité de pyrène perdeutéré au bitume avant l'opération de cokage. Le pyrène fonctionne comme indicateur *in situ* qui permet d'évaluer l'importance ainsi que les autres détails mécanistiques des réactions des «donneurs d'hydrogène» qui se produisent durant le cokage. Il n'existe pas de données permettant de croire que le pyrène affecte d'une façon substantielle le cours de la réaction; d'où l'analogie à un indicateur.

Mots clés : cokage du bitume, pyrène, échange d'hydrogène, solvant donneur, radicaux libres.

[Traduit par la revue]

Introduction

Operational oil-sands (bitumen) plants in Alberta, Canada, use thermal coking as the primary upgrading method for converting bitumen into usable hydrocarbon fractions (coker gas oil). The coke produced (ca. 15% by weight of the raw bitumen) is high in sulphur and the utility of this material depends largely on extraneous factors such as the allowable levels of plant SO_2 emission, etc.

In looking chemically at coking there are two general aspects to consider:

1. what type of organic chemical reactions are responsible for coke formation?

2. what organic reactions or rearrangements have occurred in the production of the coker gas oil?

There have been many studies of the organic reaction mechanisms involved in the related coal upgrading area, particularly those involving donor solvents (for recent reviews, see ref. 1). Like the present study, several of these have involved deuterium labelling approaches (2). In the case of bitumen coking, there are fewer published studies, but the mechanisms involved in "cracking" have been studied extensively, often using model compounds (3).[2]

We have been interested in the possibility of adding substances (additives) to the bitumen prior to coking, in the hope that these additives could modify the subsequent coking process in desirable ways. There are two major improvements that one might ideally hope for: (1) a higher yield of coker gas oil and correspondingly less coke, and (2) in the coker gas oil produced, a reduction of aromatics in the diesel range distillates. When one heats a complex mixture such as bitumen to 475°C, homolytic cleavage of bonds will ensue. The resulting carbon or heteroatom centered radicals can be quenched by natural hydrogen atom donor sources in the bitumen but, when these are in short supply, radical recombination processes can also occur. The latter reactions in some instances probably lead to high molecular weight "mesophases" and eventually to coke. Hydrogen atom donor processes (and the extent of these) are thus expected to occupy a key role in the overall coking reaction. In the absence of added hydrogen gas (hydrocracking) or donor solvents (donor solvent upgrading), there is of course a fixed finite amount of donor hydrogen available in the bitumen itself, but one might speculate that certain additives would increase the hydrogen atom transfer rates during the coking process (hydrogen shuttling reactions) and that such rate increases might have desirable consequences on both coker gas oil yield and on its detailed composition.

In the present work, we describe a methodology for determining the extent of hydrogen atom transfer reactions accompanying the coking of bitumen, in the absence of additives. This study involves the addition of a relatively small amount of perdeuterated pyrene to the raw bitumen, which is subsequently coked in a laboratory-scale coker. The rationale behind this experiment is multifold:

1. Pyrene has a boiling point that is high enough so that it remains dissolved in the bitumen well into the coking temperature range. Pyrene itself is not prone to charring (coking) when distilled by itself, although the actual behaviour in a bitumen mixture could be different.

2. Pyrene has the potential to serve as a hydrogen donor but only if it is first reduced, i.e., it would obviously not initiate

hydrogen donor processes but is capable of serving as a convenient "detector" for such reactions (hydrogen shuttling, see also ref. 4).

3. If indeed deuterium donor reactions do occur, then the recovered pyrene can be analyzed for proton content. Since there are initially three different types of deuterons in pyrene, any preferential exchange involving these different sites should provide specific mechanistic information as to the type and specificity of reactions occurring during the coking.

4. If deuterium donor reactions do occur, the resulting deuterium content in the coker gas oil fractions can be investigated on a "global" basis by ^{2}H NMR spectroscopy or by MS for the individual components.

5. Some of these deuterium atoms transferred to the coker gas oil may be irreversibly incorporated, whilst others may be back exchangeable if one reexposes the gas oil to ordinary pyrene-h_{10} under conditions similar to those used in the original coking reaction. Such exchange reactions would provide information on the kinds of reactive radical intermediates that are produced either reversibly or irreversibly during the coking process.

Experimental

Chemicals

The coker feed bitumen used in these experiments was supplied by Alberta Research Council from Syncrude, Fort McMurray, Alberta, Canada. The pyrene-d_{10} (98+ at.% D) was supplied by MSD Isotopes, the tetralin-d_{12} (98+ % D) and pyrene-h (99+ 1%) were supplied by Aldrich Chemical company, and all were used without further purification.

Instruments

The deuterium NMR spectra were measured on a Varian XL 200 spectrometer operating at 30.7 MHz. The proton NMR spectra were carried out on a Bruker AC 200 instrument at 200 MHz. The direct probe MS analyses were carried out on a VG Micromass 7070F instrument.

Reaction vessels

The lab scale model coker, patterned from a design described by George (5), was built of 316 stainless steel. The coker consists of a pot (the height was 110 mm, the inner diameter was 100 mm) into which the bitumen was placed. The heating was provided by an arrangement of Nichrome wire embedded in a ceramic paste (1 cm thickness), which provided insulation and protected the element. The length of Nichrome was calculated on the basis of amperage required for the desired heating rate. A high output variac (20 amp) was required to provide power to the heating element. A positive pressure of nitrogen (100 mL/min) was continually flushed through the system so that the cracked products could be distilled over before further reaction occurred. The liquid products were collected successively in an ice (0°C) and then a Dry Ice/acetone (−78°C) cooled receptacle.

The tube bomb was constructed of 316 stainless steel. The length of the bomb was 160 mm, the internal diameter was 8 mm, and the approximate volume was 8 cm^3. The loaded tube bomb was placed in a preheated muffle furnance, which allows the tube bomb to reach operating temperatures within a few minutes. After reaction, the hot tube bomb was "quenched" with water, so the cool-down period is also very short.

Bitumen coking procedure

Bitumen (25 g) with pyrene-d_{10} (0.4 g) slurried into it was placed into the lab scale coker and the power was switched on. Heat-up, from room temperature to the final coking temperature of around 480°C, took 2 h to achieve.

Fractional distillation of the coker gas oil (20.3 g) was carried out using a spinning band column (10 × 670 mm), employing a ca. 10:1 reflux ratio. Fractions below 175°C were distilled under water aspirator vacuum and fractions from 175 to 425°C using a vacuum pump. The bp data reported were converted to 760 Torr (1 Torr = 133.3 Pa) pressure. Coking runs were made using both the pyrene additive and with no additives. The yield of coke was also quantified (4.8 g).

Fraction	Corrected boiling pt. (°C)	Weight (g)	Cumulative weight percentage
0	0–145	0.8	4.1
1	145–175	0.6	7.2
2	175–225	1.4	14.4
3	225–275	2.45	26.9
4	275–325	1.4	34.1
5	325–375	5.2	60.7
6	375–425	4.3	82.7
7	>425 (residue)	3.4	100

The coker gas oil fractions were then subjected to ^{2}H NMR analysis to examine deuterium incorporation into the different boiling ranges. The residual pyrene-d was then collected (mainly from fraction 5) and analyzed using direct probe MS, in order to quantify the amount of exchange occurring during the coking reaction. The recovered pyrene-d was finally analyzed using ^{1}H NMR, to study the selectivity of exchange from the pyrene-d_{10}. These experiments were performed in duplicate.

Exchange of pyrene-h_{10} *and tetralin-*d

A weight ratio of 2 parts of the tetralin and 1 part of the pyrene (2.8:1 molar ratio) was heated in the tube bomb for a period of 1 h at the preset temperatures 400, 425, and 450°C. The pyrene was isolated and analysed by mass spectrometry and by ^{1}H NMR spectroscopy. The former measurement gives the deuterium incorporation data shown in Fig. 1, while the NMR data give the positional substitution ratios shown in Fig. 2. The absolute values shown in Fig. 2 were based on the data in Fig. 1. The results shown in Fig. 2 for 450°C are close to the thermodynamic equilibrium result (there is a total of 63 mol% D in the total hydrogen (H + D) system).

Results and discussion

There is in fact extensive deuterium incorporation into the coker gas oil fractions. Table 1 summarizes the ^{2}H NMR data obtained for the different boiling fractions. The fraction containing the majority of the recovered pyrene-d (fraction 5, 325–375°C) is not shown because it was completely dominated by a ^{2}H peak for the recovered pyrene. ^{1}H NMR spectroscopy can be used to assign a number of proton environments but ^{2}H NMR involves a chemical shift dispersion of one seventh that of ^{1}H and also involves somewhat broader lines (quadripolar nucleus) and therefore only three regions are assignable.

We have assigned these three deuterium (proton) NMR regions as follows:

1. aromatic (6–10 ppm)
2. benzylic, allylic etc. (1.9–3.2 ppm)
3. aliphatic (0.5–1.9 ppm)

The latter division is somewhat arbitrarily set and represents only a qualitative measure of the corresponding deuterium/hydrogen types.

For comparison purposes, we have made the corresponding measurements for coker gas oil fractions, produced without pyrene addition, where ^{1}H NMR spectra have been obtained. A comparison of the two sets of data gives some idea of those degraded molecules that have interacted at some point with pyrene (or dihydropyrenes) in contrast to species that may have formed in other ways. By comparing the fractions of deuterium/hydrogen types in Table 1, it is evident that deuter-

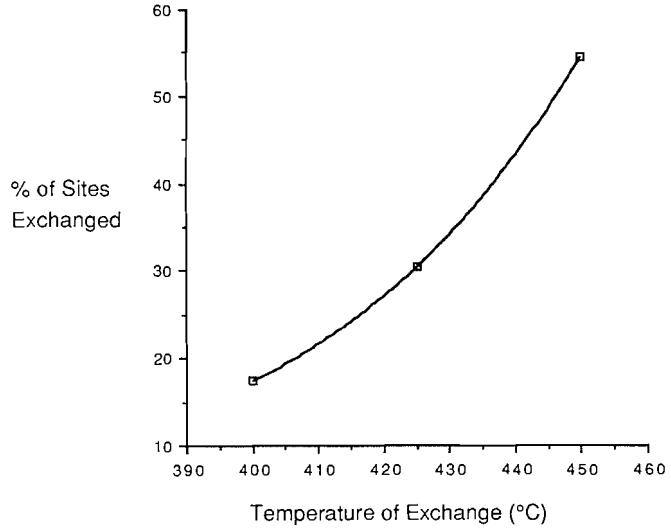

FIG. 1. Direct probe MS analysis of the recovered exchanged (originally h_{10}) pyrene.

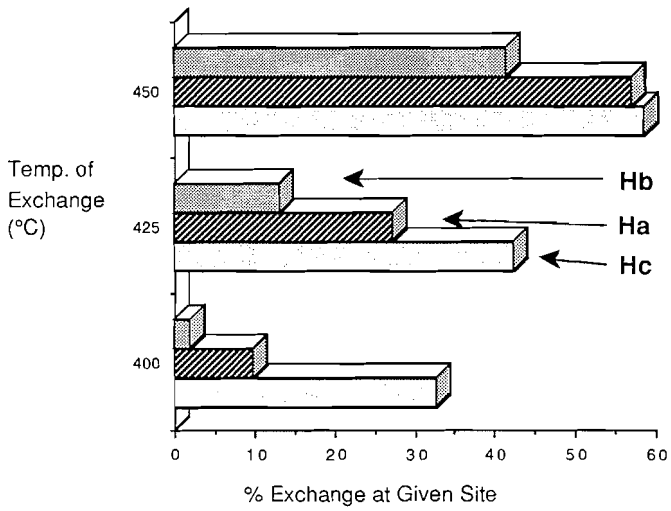

FIG. 2. ^{1}H NMR analysis of recovered (partially deuterated) exchanged pyrene-*h* in the model exchange reactions.

ium has found its way into more benzylic and aromatic sites than expected on a purely statistical basis.

The pyrene can be recovered in near quantitative yield (both by actual recovery and estimates based on quantitative GC measurements). The ^{1}H NMR spectrum of the recovered pyrene is compared in Fig. 3 to that of the ordinary pyrene-*h*. It is immediately obvious that selective H/D substitution has occurred in the pyrene-d_{10} and that the ring positions most exchanged are c and a followed by least substitution in position b. This selectivity can be explained if one considers the energies of the radicals produced on addition of a hydrogen atom to the pyrene-d_{10} molecule. Theoretical calculations carried out by Herndon *et al.* (6) and Stein and Golden (7) suggest that the most stable radical is formed by addition of a hydrogen atom to position c followed by a and lastly b.

The total amount of exchange can be roughly calculated from a direct probe MS of the recovered pyrene. The most intense peak in the molecular-ion envelope is still the d_{10} species and an approximate averaging of the various peaks gives an overall proton incorporation of 7.5 ± 1.5% (this small proton incorporation accounts for the singlets observed in the ^{1}H NMR

TABLE 1. NMR analysis of coker gas oil fractions in both spiked and non-spiked experiments

Boiling point range of fraction (°C)	Aliphatic (0–1.9 ppm)		Benzylic (1.9–3.2 ppm)		Aromatic (6.0–10.0 ppm)	
	^{2}H	^{1}H	^{2}H	^{1}H	^{2}H	^{1}H
145–175	0.57	0.84	0.34	0.14	0.09	0.02
175–225	0.53	0.80	0.38	0.14	0.09	0.06
225–275	0.50	0.78	0.35	0.16	0.15	0.06
>425	0.37	0.77	0.47	0.17	0.16	0.07

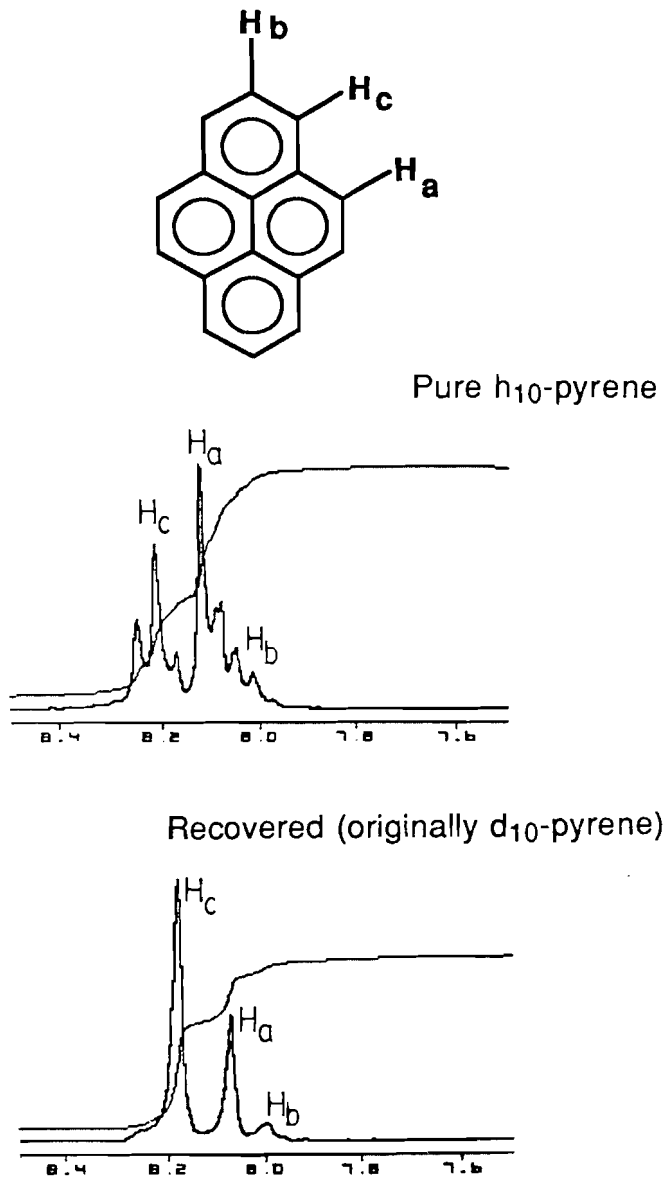

FIG. 3. ^{1}H NMR of recovered pyrene compared to pure pyrene-h_{10}.

spectrum shown in Fig. 3, i.e., the protons H_a, H_b, and H_c will overwhelmingly have deuterium neighbors and hence no ^{1}H–^{1}H couplings are evident). Assuming that this deuterium has all gone into the coker gas oil fractions, the total D/H content of the latter is calculated to be about 0.15%. The presence of the residual pyrene in the middle coker gas oil fractions makes a direct D/H analytical determination difficult.

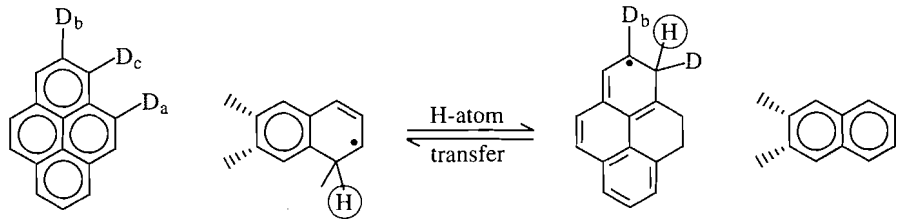

FIG. 4. Reversible H-donor reactions.

The 7.5% proton incorporation into the pyrene-d_{10} should be compared with the potential equilibrium value, and a rough estimate based on the relative weights of the pyrene and bitumen would suggest a number like 98–99% for the equilibrium proton incorporation. Clearly the experimental exchange value is very non-equilibrium and one would have considerable leeway in trying to find "additives" that might increase this proton incorporation. Another indication of the non-equilibrium nature of the exchange is found in the Table 1 data. Thus, the 7.5% deuterium exchanged out of the pyrene is found in many different environments, but benzylic and aromatic positions are favored, as we have noted previously, and as one might expect on established mechanistic grounds.

To assess whether coker gas oil deuterium incorporation is reversible, we carried out a further experiment in which a high boiling coker gas oil fraction (375–410°C) was heated to approximately 450°C for an hour in a tube bomb, in the presence of pyrene-h_{10}. The pyrene was then recovered and monitored for deuterium content using ^{2}H NMR, as was the recovered coker gas oil fraction. The result of this experiment indicated that there is indeed a reversible element of the whole deuterium incorporation. The deuterium type involved is the benzylic/allylic portion, i.e., the ^{2}H NMR spectrum of the recovered coker gas oil fraction is now depleted in benzylic deuterium, which is found to have exchanged into the recovered (initially h_{10}) pyrene, again with the selectivity already described (but in reverse).

To verify that the observed selectivity of exchange into the labelled pyrene is indeed a property of naturally present hydrogen-donor-type molecules in the bitumen, it was decided that a series of model exchange reactions should be carried out between a suitable D donor and pyrene-h_{10} at temperatures similar to those experienced in the coking experiment. We hoped to see the same selectivity in the exchange of deuterium into the pyrene as we saw in the bitumen experiment (in a reversed sense). These model exchange reactions were carried out in tube bombs at the temperatures shown in Fig. 1 for a period of 1 h. Once the pyrolyses were complete, the exchanged pyrene was recovered and analysed by direct probe MS, in order to discover the extent of substitution of deuterium into the pyrene-h. The results of this analysis are shown in Fig. 1.

From the MS data one can see that the extent of exchange varies with the temperature of the exchange reaction, as indeed one would expect. At 400°C the extent of exchange amounts to about 17% of the available sites in the pyrene. At 450°C the extent of exchange has increased substantially to about 55% of the available sites. If one remembers the statistical proportion of the three different available sites, 40% H_c, 40% H_b, and 20% H_a, we know, even before ^{1}H NMR analysis, that the site selectivity at 450°C will be lower because of the high degree of overall exchange.

The next step was the analysis of the recovered pyrene, using

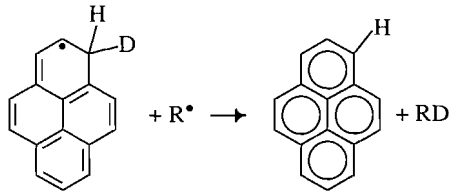

FIG. 5. Irreversible quenching of reactive radicals.

^{1}H NMR spectroscopy, in order to learn the site selectivity of the substituted deuterium atoms. Results of this analysis are illustrated in Fig. 2.

Looking at the results of the ^{1}H NMR spectra, it is evident that at 400°C the site selectivity is high and that the preferred exchange site is H_c followed by H_a and lastly H_b. This matches exactly the order seen in the bitumen/pyrene-d_{10} coking experiment.

Mechanistic considerations

In the coking of bitumen, one is dealing with a very complex mixture of compounds (for a recent discussion, see ref. 8) and mechanistic studies must deal with broad classes of reactions. Based on the results outlined in this work, and in fact on numerous previous studies in the coal area, the following two categories are both envisaged:

1. Reversible H-donor reactions (Fig. 4), where the dihydronaphthalene radical is used only for illustrative purposes to represent possible naturally occurring hydrogen donor molecules present in the bitumen. The formed dihydropyrenyl radical can in principle then reversibly react with a variety of naturally occurring aromatic compounds, transferring a deuterium atom or reversing the hydrogen atom transfer. This deuterium "shuttling" mechanism accounts for the deuterium incorporation into both aromatic and benzylic sites in the coker gas oil produced, and the extent of these reactions can be quantified.

2. Irreversible quenching of reactive radicals (Fig. 5). There are several ways in which the formation of reactive radicals can be envisioned. Side-chain cleavage from an aromatic radical is one well-known route (Fig. 6). Cleavage β to the aromatic ring also explains the high level of exchange into benzylic environments.

Reactive radicals, on quenching, can eventually produce alkane-type deuterium NMR signals. Such deuterium atoms are not expected to back exchange with pyrene-h_{10}, as indeed one observes. Again, this process can be quantified.

The amount of pyrene-d_{10} added to the bitumen is relatively small and we do not notice any particular changes in the overall coking reaction occurring in the presence of the pyrene, i.e., overall yield of the coker gas oil, the amounts of various boiling point cuts, aromaticity of these cuts, etc. (However, in coal upgrading, pyrene addition has been shown to affect the pro-

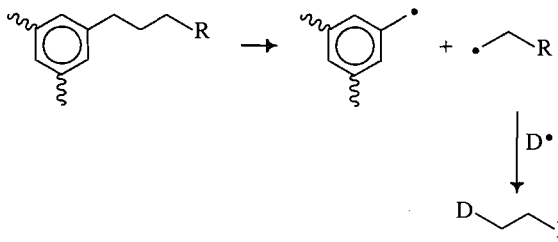

FIG. 6. Dealkylation resulting in formation of reactive radicals.

cesses (4) so some caution is perhaps warranted.) These pyrene-d_{10} exchange reactions therefore function very much like an indicator (i.e., an indicator of broad reaction types). In studying the effect of additives in the coking of bitumen, one now has some quantitative markers for comparison purposes.

Conclusions

The use of a deuterated polynuclear aromatic as a hydrogen shuttling probe is described. From the selectivity of H/D exchange in pyrene we know, not unexpectedly, that the pyrolysis reactions involve free radical processes. From analysis of the exchanged fraction, before and after the back exchange, we know something of the environments in which the mobile, exchanging species find themselves, and that some of these exchange reactions are reversible, i.e., the benzylic and aromatic protons/deuterons, and some (mainly aliphatic protons/deuterons) are not reversible.

The reaction mechanisms discussed in this work are not new, and in this regard we have added no new insights into this rather speculative area. We are primarily interested in developing *quantitative procedures for evaluating changes* in the extent and type of hydrogen shuttling reactions, and in this regard, the pyrene-d_{10} indicator fits most of our criteria.

The crystal and molecular structures of $Sn(O—t\text{-}Bu)_4$ and $[Sn(O—i\text{-}Pr)_4 \cdot HO—i\text{-}Pr]_2$ have been determined by single-crystal X-ray diffraction. $Sn(O—t\text{-}Bu)_4$ crystallizes in the monoclinic crystal system with space group $C2/c$, where $a = 17.382(6)$ Å, $b = 8.742(2)$ Å, $c = 15.518(5)$ Å, $\beta = 116.44(1)°$, $Z = 4$, and $R = 2.5\%$. $Sn(O—t\text{-}Bu)_4$ is monomeric in the solid state, with a distorted tetrahedral tin coordination environment. $[Sn(O—i\text{-}Pr)_4 \cdot HO—i\text{-}Pr]_2$ crystallizes in the monoclinic crystal system with space group $P2_1/n$, where $a = 11.808(3)$ Å, $b = 14.356(3)$ Å, $c = 12.380(2)$ Å, $\beta = 95.27(2)°$, $Z = 2$, and $R = 4.9\%$. $[Sn(O—i\text{-}Pr)_4 \cdot HO—i\text{-}Pr]_2$ exhibits an edge-shared, bi-octahedral structure in the solid state that is distorted due to the presence of asymmetric hydrogen bonding between axially coordinated alcohol ligands and an isopropoxide ligand. ^{13}C NMR and IR spectroscopic data have been recorded for $Sn(O—t\text{-}Bu)_4$ and $Sn(O—t\text{-}Bu\text{-}d_9)_4$ to establish criteria for unambiguous identification of solution structures of tin(IV) alkoxides. It is demonstrated that the two-bond $^2J_{^{13}C—O—^{119}Sn}$ coupling constant is larger for terminal alkoxide ligands than for μ^2-alkoxide bridges, and the $\nu(Sn—O)$ stretching frequency has been assigned. The dynamic solution behaviour of $[Sn(O—i\text{-}Pr)_4 \cdot HO—i\text{-}Pr]_2$ has been studied using variable temperature ^1H and ^{13}C NMR spectroscopy. The data obtained are consistent with a process that involves rapid reversible dissociation of isopropanol at room temperature. Upon cooling, the equilibrium concentration of the species with coordinated alcohol increases, and the molecule undergoes rapid intramolecular proton transfer ($\Delta G^{\ddagger} < 11.9$ kcal mol^{-1}). Upon further cooling, the ^{13}C NMR data are consistent with a solution structure analogous to that found in the solid state.

Key words: tin, alkoxide, NMR, dynamic, structure.

MARK J. HAMPDEN-SMITH, TERESA A. WARK, ARNOLD RHEINGOLD et JOHN C. HUFFMAN. Can. J. Chem. **69**, 121 (1991).

On a déterminé les structures cristallines et moléculaires du $Sn(O—t\text{-}Bu)_4$ et du $[Sn(O—i\text{-}Pr)_4 \cdot HO—i\text{-}Pr]$ par diffraction des rayons-X par des cristaux uniques. Le $[Sn(O—t\text{-}Bu)_4$ cristallise dans le système monoclinique, groupe d'espace $C2/c$, $a = 17,382(6)$, $b = 8,742(2)$ et $c = 15,518(5)$ Å, $\beta = 116,44(1)°$, $Z = 4$ et $R = 2,5\%$. À l'état solide, le $[Sn(O—i\text{-}Pr)_4 \cdot HO—i\text{-}Pr]$ est un monomère dans lequel la coordination de l'étain est un tétraèdre déformé et il cristallise dans le système monoclinique, groupe d'espace $P2_1/n$, $a = 11,808(3)$, $b = 14,356(3)$ et $c = 12,380(2)$ Å, $\beta = 95,27(2)°$, $Z = 2$ et $R = 4,9\%$. À l'état solide, le $[Sn(O—i\text{-}Pr)_4 \cdot HO—i\text{-}Pr]$ se présente sous une structure bi-octaédrique partageant une arète; elle est déformée à cause de la présence de liaisons hydrogènes asymétriques entre des ligands alcooliques coordonnés d'une façon axiale et un ligand isopropylate. On a déterminé les spectes IR et RMN du ^{13}C du $Sn(O—t\text{-}Bu)_4$ et du $Sn(O—t\text{-}Bu\text{-}d_9)_4$ afin d'avoir des critères non-ambigues pour caractériser les structures des alcoolates d'étain(IV) en solution. On a démontré que la constante de couplage à travers deux liaisons $^2J_{^{13}C—O—^{119}Sn}$, est plus grande pour les ligands alcoolates terminaux que pour les ponts alcoolates-μ^2; de plus, on a attribué la fréquence de, vibration $\nu(Sn—O)$. Faisant appel à la rmn du ^1H et du ^{13}C, à température variable, on a étudié le comportement dynamique du $[Sn(O—i\text{-}Pr)\cdot HO—i\text{-}Pr]$ en solution. Les données obtenues sont en accord avec un processus qui implique une dissociation réversible rapide de l'isopropanol, à la température ambiante. Par refroidissement, la concentration de l'espèce avec de l'alcool isopropylique augmente et la molécule subit un transfert intramoléculaire rapide de proton ($\Delta G^{\ddagger} < 11,9$ kcal mol^{-1}). Si on continue le refroidissement, les données de la rmn du ^{13}C obtenues sont en accord avec une structure en solution qui serait analogue à celle qui est trouvée à l'était solide.

Mots clés : étain, alcoolates, RMN, dynamque, structure.

[Traduit par la revue]

Introduction

The conversion of homoleptic metal alkoxides to metal oxides is currently under intense investigation as a route to new and existing ceramic materials (for recent reviews see ref. 1). The sol–gel process is suitable for the hydrolytic conversion of *soluble* metal alkoxides to metal oxides (2); whereas chemical vapour deposition (CVD) has been used for the preparation of thin films of metal oxides from *volatile* metal alkoxide precursors (3). A sound understanding of the mechanistic aspects of the conversion of metal alkoxides to metal oxides is an important aspect of this work since this knowledge may result in lower processing temperatures and better control over the particle size, morphology, and homogeneity of the final ceramic materials.

Studies of the *thermal* decomposition of titanium (4), zirconium (4), tin (5), and most recently, cerium alkoxides have been addressed (6). Many examples of hydrolytic decomposition of metal alkoxides have been published, but mechanistic data are relatively sparse even though the sol–gel hydrolysis of tetraethylorthosilicate has been extensively investigated (see *e.g.* ref. 7). For example, hydrolysis and subsequent thermal treat-

ment of tin alkoxide compounds yield high purity tin(IV) oxide powder (8), but there is little solid-state or solution structural data available on which to base mechanistic studies for homoleptic tin(IV) alkoxide compounds. Furthermore, there are no satisfactory spectroscopic criteria developed for the unambiguous assignment of solution structures of these species. On the other hand, homoleptic tin(II) alkoxide compounds have received much more attention, and a number of examples have been characterized in the solid state by single crystal X-ray diffraction (9). We have recently structurally characterized a homoleptic thallium(I)–tin(IV) alkoxide compound, which is polymeric in the solid state, but monomeric in benzene solution (10).

The work described here, concerning the characterization of simple homoleptic tin(IV) alkoxide compounds, is the first step in a systematic investigation of their solid-state and solution structures, the mechanistic aspects of condensation and characterization of the kinetic products of thermal and hydrolytic decomposition (11). Here we report the solid-state and solution structures of $Sn(O—t\text{-}Bu)_4$ and $[Sn(O—i\text{-}Pr)_4 \cdot HO—i\text{-}Pr]_2$.

Experimental section

All manipulations were carried out under an atmosphere of dinitrogen that had been dried and deoxygenated by passage through finely divided MnO and molecular sieves (12). All aromatic and hydrocarbon solvents used were distilled from sodium benzophenone ketyl and stored under nitrogen over 4 Å molecular sieves. Alcohols were purchased from Aldrich Chemical Co. and were dried by distillation from magnesium turnings under dinitrogen and stored over 4 Å molecular sieves (13). Infrared spectra were recorded on a Perkin-Elmer Model 1620 spectrometer, and NMR data were recorded on Bruker AC-250 spectrometer. NMR solvents were degassed with dry dinitrogen and stored over 4 Å molecular sieves. ^1H NMR spectra were referenced to the protio impurity in the deuterated solvents, and ^{13}C NMR spectra were referenced to the ^{13}C NMR resonance of the deuterated solvent. ^{119}Sn NMR spectra were referenced to the protio impurity in the deuterated solvents, and ^{13}C NMR spectra were referenced externally to $SnMe_4$ (= 0 ppm, $\Delta\nu_{1/2}$ = 1 Hz) and are quoted using the downfield positive sign convention. Molecular weights were determined cryoscopically by the freezing point depression of benzene.

I. Synthesis of Sn(O—t-Bu)$_4$

$Sn(O—t\text{-}Bu)_4$ was prepared by a modified method of Chandler *et al.* (14) as follows. To a three-necked, round-bottomed, one-litre flask fitted with a dinitrogen inlet, reflux condensor, pressure-equalized addition funnel, and magnetic stir bar was added 250 mL of *n*-pentane and 30.2 g (0.5 mol) of $SnCl_4$. The solution was cooled to 0°C, and 90 mL of Et_2NH dissolved in 40 mL of *n*-pentane was added dropwise over a period of 2 h. An exothermic reaction ensued with the formation of a white precipitate. A further 120 mL of Et_2NH in 100 mL of *n*-pentane was added, after which the solution was stirred at room temperature for 4 h. The mixture was then cooled to 0°C, the addition funnel charged with four 50 mL portions of *t*-BuOH (an excess), and each portion was added over 10 min. When the addition was complete, the ice bath was removed, the addition funnel replaced by a mechanical stirrer, and the mixture stirred for 14 h at room temperature. The stirrer was stopped and the mixture allowed to stand for 2 h and was then filtered. The remaining white solid was transferred to a Sohxlet extractor and extracted with 300 mL of *n*-pentane. All the *n*-pentane washings were combined to give a pale yellow solution from which the volatile components were removed *in vacuo* (10^{-2} Torr) to give a pale yellow solid. The solid was pumped *in vacuo* for two more hours to ensure removal of excess *t*-BuOH at the expense of losing some of the final product. The pale yellow solid was then sublimed at 10^{-2} Torr and 40°C onto a cold finger maintained at −78°C to give 168.9 g (0.41 mol) of large white crystals, a yield of 82.2% based on $SnCl_4$. Melting point 40.2–42.0°C (uncorrected). ^1H NMR data (C_6D_6, 20°C, 250 MHz): 1.57 ppm (s), $OC(CH_3)_3$; $^{13}C\{^1H\}$ NMR data (C_6D_6, 10°C, 62.9 MHz): 74.6 ppm (s), $^2J_{Sn—C}$ = 45 Hz, $OC(CH_3)_3$; 33.7 ppm (s) $^3J_{Sn—C}$ = 27 Hz, $OC(CH_3)_3$: ^{13}C NMR data (^1H coupled): 74.6 ppm (m), $^2J_{C—H}$ = 4 Hz, $OC(CH_3)_3$; 33.7 ppm, septet × quartet, $^1J_{C—H}$ = 125 Hz, $^3J_{C—H}$ = 4 Hz, $OC(CH_3)_3$: ^{119}Sn NMR data (C_6D_6, 20°C, 93.27 MHz): —371.4 ppm (s). Infrared data (KBr disc, cm^{-1}): 2976(m), 2914(m), 1468(m), 1393(s), 1362(s), 1246(s), 1183(s), 1031(m), 937(s, br), 775(s), 605(s), 462(s).

II. Synthesis of Sn(O—t-Bu-d$_9$)$_4$

$Sn(O—t\text{-}Bu\text{-}d_9)_4$ was prepared by a method analogous to that described for $Sn(O—t\text{-}Bu)_4$ above. The quantities of the reagents employed were as follows: $SnCl_4$, 1.75 mL (3.90 g, 0.015 mol); Et_2NH, 10 mL (an excess); DO—*t*-Bu-d_9, 6.44 g; *n*-pentane, 205 mL total. The final mixture obtained was filtered and extracted with three 50 mL portions of *n*-pentane. The *n*-pentane washings were combined and the volatile components removed *in vacuo*. The white solid obtained was sublimed to give 5.363 g of $Sn(O—t\text{-}Bu\text{-}d_9)_4$ (0.012 mol), a yield of 80%. ^{13}C NMR data (C_6D_6, 20°C, 62.9 MHz): 74.13 ppm (s), $^2J_{Sn—C}$ = 45 Hz, $OC(CD_3)_3$; 32.6 ppm, septet, approximately 1:3:6:7:6:3:1, $J_{C—D}$ = 19 Hz, $OC(CD_3)_3$. Infrared data (KBr disc, cm^{-1}): 2227(m), 2128(w), 2053(w), 1222(m), 1135(s), 1076(m), 1052(s), 873(s), 821(w), 737(w), 686(m), 568(s).

III. Single crystal X-ray diffraction study of Sn(O—t-Bu)$_4$

General operating procedures of the Indiana University Molecular Structure Center have previously been reported (15). A summary of the crystal data is given in Table 1.

A suitable crystal was selected and transferred to a goniostat by using standard inert atmosphere techniques and cooled to −155°C. A systematic search of a limited hemisphere of reciprocal space revealed a set of diffraction maxima that could be indexed to the space group $C2/c$. Subsequent solution and refinement confirmed this choice. Data were collected using a continuous θ–2θ scan with fixed backgrounds.

The structure was solved by a combination of direct methods (MULTAN) and Fourier techniques and refined by full-matrix least squares. All hydrogen atoms were clearly visible in a difference Fourier map phased on the non-hydrogen parameters. All hydrogen atoms were refined isotropically and all non-hydrogen atoms anisotropically. No absorption correction was performed. A final difference Fourier map contained four peaks of 0.5–07 e/Å^3 located within 1.1 Å of the Sn atom. All other peaks were less than 0.3 e/Å^3.

Fractional coordinates and isotropic thermal parameters are given in Table 2, atomic coordinates in Table 3, and atomic distances and angles are given in Tables 4 and 5, respectively. Figure 1 shows a view of the molecule that emphasizes the approximate tetrahedral coordination environment of the central tin atom.

IV. Synthesis of [Sn(O—i-Pr)$_4$·HO—i-Pr]

$Sn(O—t\text{-}Bu)_4$ (2.00 g; 4.9 mmol) was dissolved in 30 mL of THF and cooled to 0°. An excess of isopropanol (5.6 mL, 73 mmol) was added and the solution warmed to room temperature. After stirring for 1 h, the volatile components were removed *in vacuo*. The residue was taken up in the minimum amount of diethyl ether and cooled to −30°C for 12 h. During this time, clear colourless crystals formed and were filtered at 0°C. A total of 2.02 g of crude solid was recovered: a yield of 99.2%. In addition 1.25 g of crystalline material that analyzed as $[Sn(O—i\text{-}Pr)_4 \cdot HO—i\text{-}Pr]$ was recovered, a crystalline yield of 62.5%.

^1H NMR data (toluene-d_8; 250.13 MHz): 40°C, 7.25 ppm (br), 1H, O*H*; 4.66 ppm, septet, 5H $J_{n—n}$ = 6 Hz, OC*H*Me$_2$; 1.40 ppm (d), 30H, OCH*Me*$_2$: 25°C, 7.85 ppm (b), 1H, O*H*; 4.67 ppm (m, s), OCHMe$_2$; 1.45 ppm (d), 6 Hz, 30 H, OCH*Me*$_2$; 0°C, 8.54 ppm (b), 1H, O*H*; 4.60 ppm (b, m), 5H OC*H*Me$_2$; 4.68 ppm (b), ~1H, OC*H*Me$_2$; 4.47 ppm (b), ~3H, OC*H*Me$_2$; 1.74 ppm (b), ~6H, OCH*Me*$_2$; 1.43 ppm (b), ~24H, OCH*Me*$_2$: −50°C, 8.75 ppm (b), 1H, O*H*; 5.52 ppm (b), 1H, OC*H*Me$_2$; 4.72 ppm (b), 1H, OC*H*Me$_2$; 4.45 ppm (b), 3H, OC*H*Me$_2$; 1.76 ppm (d), 6 Hz, 6H, OCH*Me*$_2$; 1.49 ppm (d), 6 Hz, OCH*Me*$_2$; 1.42 ppm (b), OCH*Me*$_2$: −60°C, 8.88 ppm (t), 4.5 Hz, 1H, O*H*; 5.55 ppm (b), 1H, OC*H*Me$_2$; 4.72 ppm (b), 1H, OC*H*Me$_2$; 1.78

V. Single crystal X-ray diffraction study of [Sn(O—i-Pr)$_4$·HO—i-Pr]$_2$

Crystallographic data are given in Table 1. Crystals of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ were grown from diethyl ether solution −30°C, and a conically shaped specimen was mounted in a capillary tube. Photographic and diffraction data revealed $2/m$ Laue symmetry, and systematic absences indicated the space group $P2_1/n$. Unit-cell parameters were obtained from the angular settings of 25 reflections ($20° \leq 2\theta \leq 30°$). The data were empirically corrected for absorption.

A Patterson map was used to locate the unique Sn atom, and the structure was completed by difference Fourier synthesis. The crystallographic asymmetric group consists of one half of the dimer formula; the central Sn_2O_2 rhombus is located on a site of $\bar{1}$ symmetry. All non-hydrogen atoms were refined with anisotropic thermal parameters, and all hydrogen atoms were included as idealized, riding isotropic contributions (d(CH) = 0.96 Å).

All software and sources of scattering factors are contained in the SHELXTL (5.1) library (G. Sheldrick, Nicolet xRD, Madison, WI). Atomic coordinates are provided in Table 3 and selected bond distances and angles in Table 6.

Results and discussion

The title compounds were prepared by modifications of the literature methods (14, 16). Since $Sn(O—t\text{-}Bu)_4$ is a good source of other tin alkoxide compounds, its synthesis is described here in detail. As with alcoholysis of metal amides, precautions must be taken during *trans*-alcoholysis experiments to ensure that the starting-material substituents are completely removed. This generally involves thermal treatment, a dynamic inert atmosphere purge, or the addition of a large excess of alcohol.

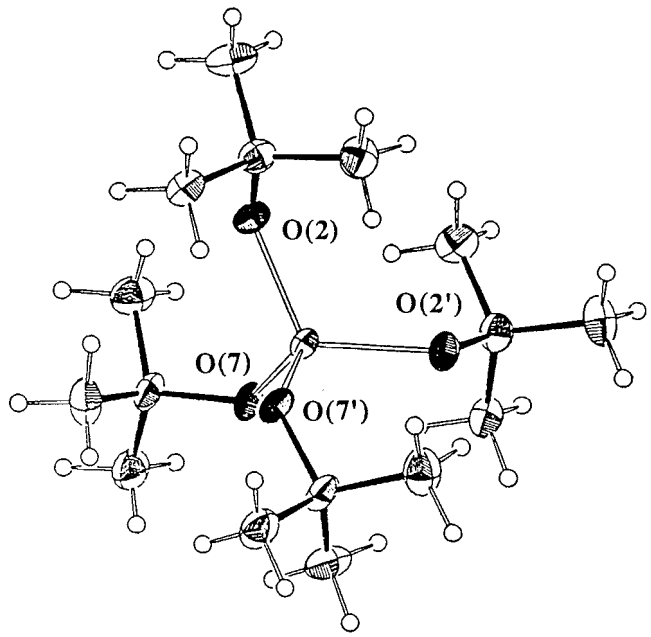

FIG. 1. Molecular structure $Sn(O—t\text{-}Bu)_4$.

(a) Solid-state structure Sn(O—t-Bu)$_4$

$Sn(O—t\text{-}Bu)_4$ is monomeric in the solid state and possesses a distorted tetrahedral coordination environment about the tin atom, as shown in Fig. 1. This probably results from the steric demands of the tertiary butoxide ligands. While the O(2)—Sn—O(2) and O(7)—Sn—O(7′) angles are enlarged, the other O—Sn—O angles are reduced compared to the tetrahedral angle. The Sn—O bond distances are shorter than the sum of their covalent radii and are comparable to the terminal Sn—O—*i*-Pr bond lengths in [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]. The only other structurally characterized homoleptic tin alkoxide compounds with terminal Sn—OR bonds are the tin(II) dimer $[Sn(O—t\text{-}Bu)_2]_2$

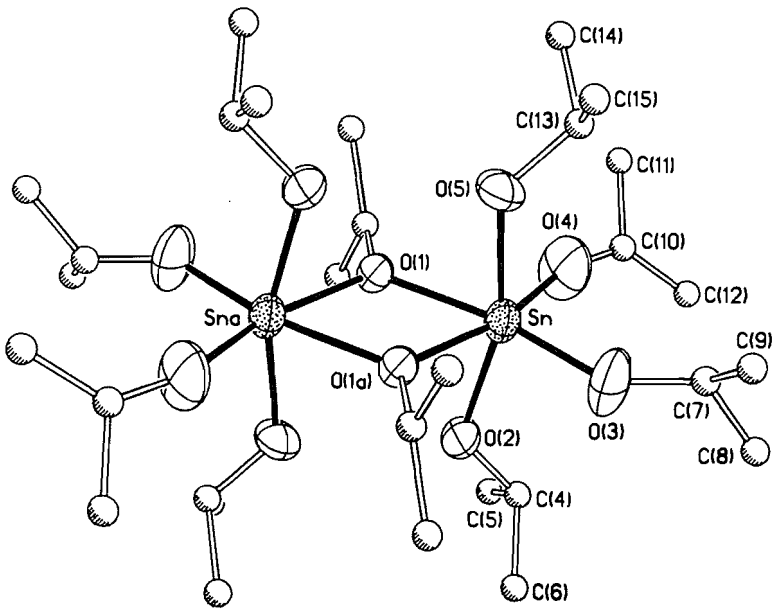

FIG. 2. Molecular structure of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$. High thermal activity in the —*i*-Pr carbon atoms required their depiction with arbitrary-radius spheres.

where Sn—O = 1.97(2) Å (17) and [Sn(O—*i*-Pr)$_3$(acac)]$_2$ where Sn—O = 1.974(3) and 1.957(7) Å (14). The angles at O(2) and O(7) are 125.0(2) and 124.1(2)°, respectively, in the region expected for an alkoxide ligand not involved in π-donation to the metal centre. Other bond lengths and angles within the tertiary butoxide ligands are normal.

*(b) Solution characterization of Sn(O—*t*-Bu)$_4$*

It has previously been demonstrated that Sn(O—*t*-Bu)$_4$ is monomeric in benzene solution (16*a*, 18). This is consistent with its high solubility in hydrocarbon solvents. Since this species contains terminal alkoxide ligands only, the solution spectroscopic data were examined carefully to explore whether or not a spectroscopic criterion could be set for unambiguously identifying terminal tin — tertiary butoxide bonds in solution. For example, using solution NMR spectroscopy, it should be possible to examine coupling constants to the NMR active isotopes of tin (^{119}Sn, 8.58% natural abundance, I = 1/2 and ^{117}Sn, 7.61% natural abundance, I = 1/2) (19) as a means of distinguishing terminal and bridging alkoxide ligands. While no $^4J_{^{119}Sn—O—C—C—^1H}$ is observed in the ^{1}H NMR spectrum of Sn(O—*t*-Bu)$_4$, we have measured $^2J_{^{119}Sn—O—^{13}C}$ = 45 Hz and $^3J_{^{119}Sn—O—C—^{13}C}$ = 27 Hz for the *terminal* tertiary butoxide ligands. This can be compared to the values of $^2J_{^{119}Sn—O—^{13}C}$ = 28 Hz and $^3J_{^{119}Sn—O—C—^{13}C}$ = 29 Hz obtained for $Tl_2Sn(OEt)_6$ where it was demonstrated that the ethoxide ligands were doubly bridging in solution (10). $^2J_{^{119}Sn—O—^{13}C}$ is expected to decrease in the following order: terminal alkoxide > μ^2-alkoxide > μ^3-alkoxide, as a result of the increasing Sn—O bond lengths and therefore decreasing *s*-character in the bonds).

We have also examined the solid state IR spectra of Sn(O—*t*-Bu)$_4$ and its deuterated analogue, Sn(O—*t*-Bu-d_9)$_4$, in some detail in order to unambiguously assign the position of the ν(Sn—O) terminal stretching frequency. In a number of studies, the position of ν(M—O) has been tentatively assigned (20), although there are little data concerning ν(Sn—O) stretches in homoleptic tin alkoxide compounds. Several workers (21) have tentatively assigned a band near 500 cm^{-1} to the ν(Sn—O) stretch in alkyl tin alkoxide compounds. The ν(Sn—C) symmetric and asymmetric stretches, however, occur in a region similar to ν(Sn—O), and there is some evidence for the coupling of these vibrations. Mazdiyasni and co-workers (22) examined the IR spectra of B, Al, Y, Ti, Zr, Hf, and Th isoproxide compounds and Ti, Zr, Hf, and Th tertiary-butoxide compounds, but did not venture to assign ν(M—O). The characteristic IR absorption frequencies of the tertiary butoxy group have been assigned by Ory (23). From a comparison of these data with those published for Ti(O—*t*-Bu)$_4$, it appears that the ν(Sn—O) terminal stretch in Sn(O—*t*-Bu)$_4$ occurs at 605 cm^{-1}. To confirm this value, the perdeuterated analogue, Sn(O—*t*-Bu-d_9)$_4$, was prepared. Using a simplified "diatomic molecule" approach, the ν(Sn—O) stretching frequency in Sn(O—*t*-Bu-d_9)$_4$ was calculated to be ~580 cm^{-1} by treating the labelled and unlabelled tertiary butoxide groups as point masses (82 and 73 mass units, respectively). This assumption has previously yielded satisfactory results in analogous ^{18}O labelling experiments (ref. 18, p. 119). The most notable differences in the IR spectra of the labelled and unlabelled compounds are the positions of ν(C—O) and ν(Sn—O) assigned to the two intense bands at 937 cm^{-1} and 605 cm^{-1} in Sn(O—*t*-Bu)$_4$, respectively. Two new intense bands for Sn(O—*t*-Bu-d_9)$_4$ appear at 873 cm^{-1} and 568 cm^{-1} that we assign to ν(C—O*) and ν(Sn—O*), respectively where O* = O—*t*-Bu-d_9). Both bands are observed at lower energy than predicted, but are in the range expected, based on this crude model. An empirical term can be defined as Δν(Sn—O—*t*-Bu): the difference observed between ν(Sn—O—*t*-Bu) and ν(Sn—O—*t*-Bu-d_9) stretching frequencies. From these data, Δν(Sn—O—*t*-Bu) = 37 cm^{-1}.

*(c) Solid-state structure of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$*

This compound is dimeric in the solid state (see Fig. 2) and possesses a structure similar to that proposed by Bradley *et al.* (25), that has recently been confirmed by Caulton and co-workers for zirconium and cerium analogues (26). The molecular architecture of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ can be described as distorted edge-shared, bi-octahedral containing two doubly bridging isopropoxide ligands, with four terminal alkoxide ligands (two bonded to each tin) in the same plane and four other

For personal use only.

ligands perpendicular to this plane (two on each metal) that are involved in hydrogen bonding. The molecule has a crystallographically imposed inversion centre. In the $(RO)_2Sn(\mu\text{-}OR)_2Sn(OR)_2$ plane, the terminal Sn—O distances (1.964(7) and 1.923(7) Å) are comparable to those observed in Sn(O—*t*-Bu)$_4$ (1.956(2) and 1.949(2) Å), while the Sn—(μ-OR) distances (2.080(4) and 2.091(4) Å) are significantly longer, but analogous to those of $[Tl_2Sn(OEt)_6]_\infty$ (2.02(3) and 2.05(4) Å) (10). Interestingly, the angles at the oxygen atoms of the terminal isopropoxide ligands in this plane are enlarged 139(8)° for O(3) and 160(9)° for O(4)), but not to the same extent as in the Zr analogue. In the zirconium analogue, this has been ascribed to O→Zr π-donation, and we note that in tin, the most obtuse Sn—O—C angle is associated with the shortest Sn—O bond. The bridging isopropoxide ligands are approximately planar, the sum of the angles about oxygen being 359.9°.

Perpendicular to the $(RO)_2Sn(\mu\text{—}OR)_2Sn(OR)_2$ plane, there are two isopropoxide ligands and two coordinated isopropanol ligands that are involved in hydrogen bonding. This results in a significant deviation from octahedral coordination about tin. The hydrogen bonding interaction in the solid state is evidenced by (*i*) the relatively long Sn—O(5) bond distances of 2.142(6) Å, (*ii*) the acute Sn—Sn—O(2) and Sn—Sn—O(5) angles of 81.1(2) and 80.9(2)°, respectively, (*iii*) the relative orientation of both organic fragments. These data are consistent with a markedly asymmetric hydrogen bond between O(2) and O(5), although the hydrogen atom was not located in the final difference map. The metrical parameters of the ligands containing O(5) and O(5a) are consistent with a coordinated alcohol; whereas the ligands containing O(2) and O(2a) (Sn—O(2) = 2.098(6) Å) are clearly deprotonated. Analogous features were recently observed in the solid state structures of [Zr(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ and [Ce(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ (26).

*(d) Solution characterization of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]*

At room temperature, benzene-d_6 and toluene-d_8 solutions of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr] exhibit only one time-averaged type of alkoxide ligand, as determined by ^{1}H and ^{13}C NMR spectroscopy. The presence of one equivalent of alcohol and four alkoxides is established by integration of the hydroxylic proton at 7.85 ppm versus the methine and methyl resonances. The resonances are slightly broadened at room temperature, but are sharp at +40°C. The other noteworthy feature of these spectra is the absence of *any* coupling to ^{119}Sn or ^{117}Sn in either the ^{13}C or the ^{1}H NMR spectra. This is consistent with an exchange process involving cleavage of the Sn—O bonds. Cryoscopic molecular weight determintion indicates the [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr] exhibits a molecular weight slightly less than that of a dimer in benzene solution at approximately 5°C.

Upon cooling toluene-d_8 solutions of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr], the ^{1}H NMR methine and methyl resonances broaden and coalesce until, at −50°C, three types of alkoxide ligands are observed in a 1:1:3 ratio, as shown in Fig. 3. The hydroxylic proton moves downfield to a chemical shift of 8.8 ppm and is observed as a triplet at −60°C. The coupling constant of 4.5 Hz is consistent with values of $^3J_{HOCH}$ observed in alcohols (27) and is consistent with facile, reversible proton exchange between coordinated alcohol and alkoxide ligands on the ^{1}H NMR timescale at this temperature. The ratio of these resonances seemed inconsistent with the solid-state structure adopted by [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$, so 2D ^{1}H NMR chemical shift-correlated experiments were performed at different temperatures.[2] While this *apparently* demonstrated that none of the chemically distinct methine protons were associated with diastereotopic isopropoxide ligands, it was not possible to distinguish accidental degeneracy of methyl groups by using this experiment.

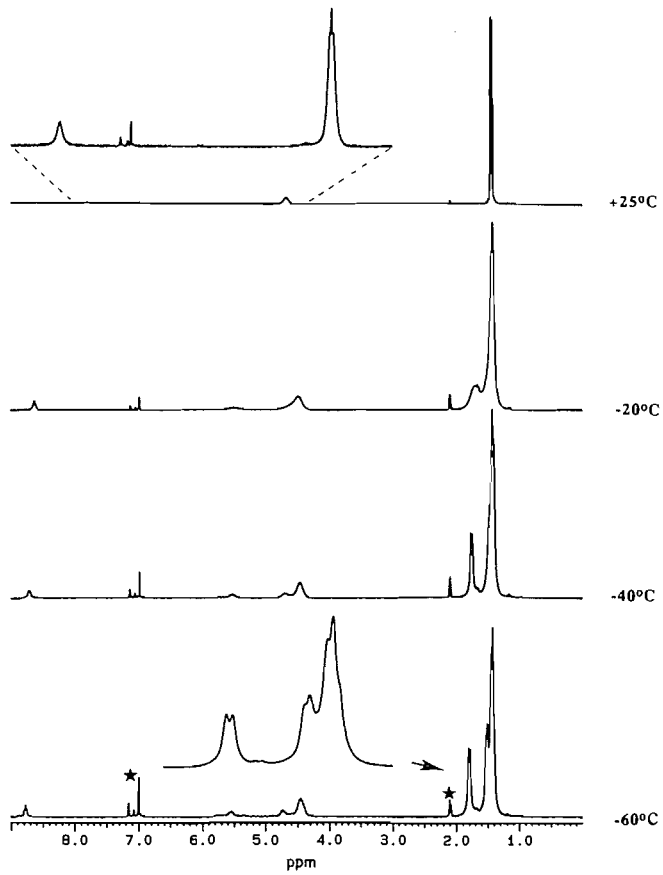

FIG. 3. Variable temperature ^{1}H NMR spectra of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ in toluene-d_8; * marks the protio impurity of the solvent.

To gain further insight, variable temperature ^{13}C NMR spectra were measured and are shown in Fig. 4. As the solution was cooled to −20°C, three types of O—*i*-Pr resonances were observed in a 1:2:2 ratio. Upon further cooling to −40°C, one of the resonances of relative intensity two broadened and began to coalesce into two different resonances of equal intensity. Unfortunately, the low solubility of this compound in toluene-d_8 below −40°C precluded further ^{13}C measurements. In the ^{119}Sn NMR sectrum at −40°C, a single type of tin environment was observed at −648.2 ppm (upfield of $SnMe_4$) with one set of ^{117}Sn satellites. The intensity and coupling constant (317.2 Hz) was consistent with the values expected for two-bond ^{119}Sn—^{117}Sn coupling constants (28) and established the dimeric nature of this compound at −40°C. Whether or not the ^{13}C NMR resonances of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ of relative intensity two are chemically equivalent or accidentally isochronous is not clear. The ^{13}C NMR data recorded at −20°C appear consistent with approximate D_{2h} symmetry shown below and can be assigned the following ratios: **A**:**B**:**C** = 1:2:2.

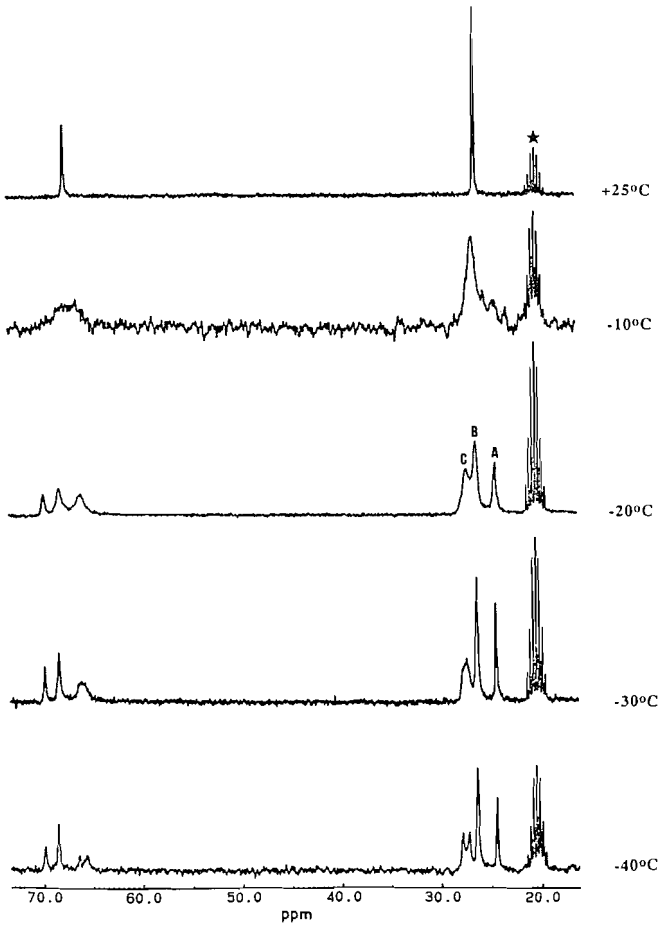

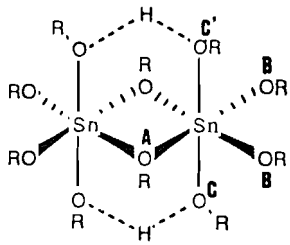

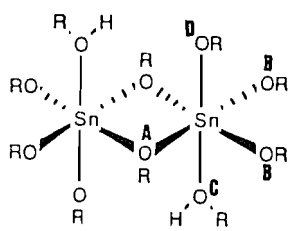

FIG. 4. Variable temperature. ^{13}C NMR spectra of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ in toluene-d_8; * marks the ^{13}C NMR resonance of the solvent.

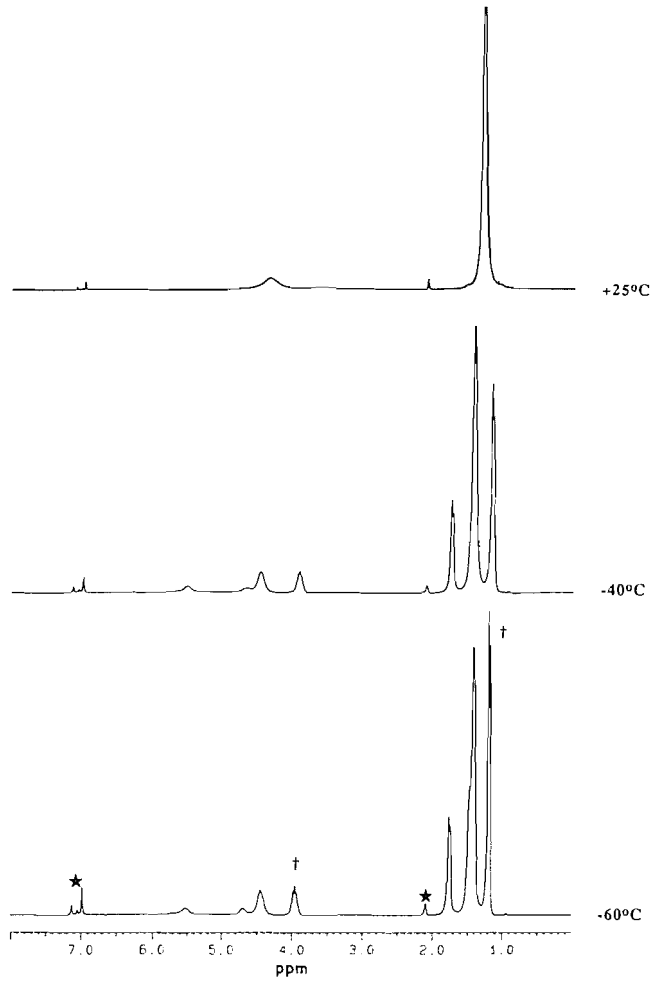
All of the isopropoxide ligands should be diastereotopic as a result of fast proton exchange between **C** and **C′**. As the solution is cooled further, the resonance of relative intensity two splits into two resonances. These data are consistent with a solution structure in which the molecule has average C_{2h} symmetry, as shown below.

The resonances previously attributed to rapidly exhanging **C** and **C′** should now be split into two of equal intensity. The methyl groups of isopropoxide ligands **B** should be diastereotopic, but may be isochronous. This interpretation assumes that proton exchange between **C** and **D′** (or **C′** and **D**) is slow compared to the ^{13}C NMR timescale. The activation barrier calculated for this process, based on the coalescence of **C** to **C′** and **D**, is 11.9 ±0.5 kcal mol^{-1}. Since the low-temperature limiting spectrum cannot be recorded, however, the frequency difference ($\delta\nu$) may be larger than that measured at −40°C, so $\Delta G^{\ddagger} < 11.9$ kcal mol^{-1}.[3]



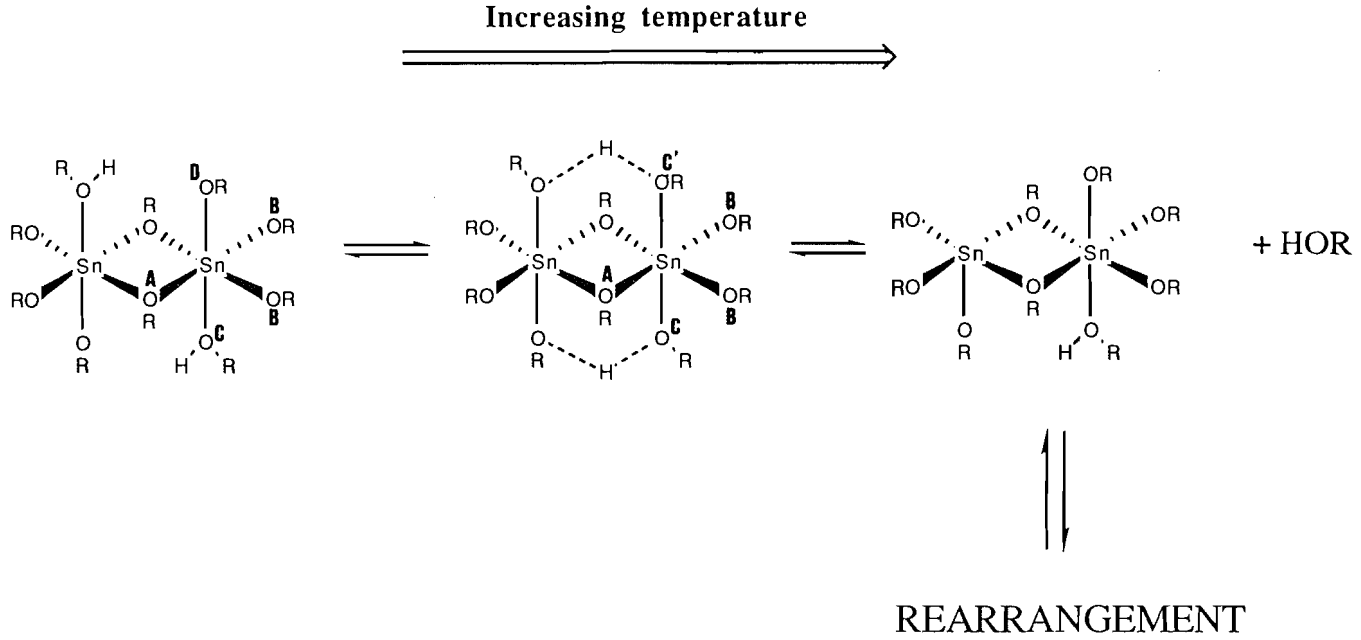


FIG. 5. Variable temperature ^1H NMR spectra of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ in toluene-d_8 to which three equivalents of HO—*i*-Pr have been added; * marks the protio impurity of the solvent; † marks the resonances due to HO—*i*-Pr.

As noted above, at −60°C, the hydroxylic proton was observed as a triplet in the ^1H NMR spectrum (Fig. 3), presumably due to rapid intramolecular exchange at this temperature on the ^1H NMR timescale. Since the intramolecular proton transfer is a degenerate process, only the $^3J_{H—O—C—H}$ coupling constant should be averaged when the coalescence temperature is reached for this process. The coalescence temperature calculated for the hydroxylic proton in the ^1H NMR spectrum based on $\Delta G^{\ddagger} < 11.9$ kcal mol^{-1} derived from the ^{13}C NMR data is ≤ ~−60°C. The interpretation of the ^{13}C NMR spectra is therefore consistent with the ^1H NMR data. The variable temperature ^1H NMR data can be explained if it is assumed that the methyl

[3]For example of $\delta\nu = 80$ Hz (same coalescence temperature) $\Delta G^{\ddagger} = 11.6$ kcal mol^{-1}.

SCHEME 1. Dynamic solution behaviour of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$

and methine resonances of relative intensity three are due to two superimposed types of isopropoxide ligands of relative intensities two and one. There is some evidence for this, as shown by expansion of the methyl region at −60°C (See Fig. 3).

We therefore propose the following mechanism to account for the observed exchange pheonomena in this system. (*i*) At room temperature, facile intermolecular isopropanol exchange occurs from dimeric [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ to give a coordinatively unsaturated tin centre capable of subsequent rapid intramolecular rearrangement. (*ii*) Upon cooling, the equilibirum of Scheme 1 is displaced to the left until the free alcohol is completely bound to form a dimeric species in which intramolecular proton transfer occurs rapidly between coordinated alcohol and axial alkoxide ligands bonded to adjacent tin centres. (*iii*) Upon further cooling, the proton transfer is slowed and [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ is structurally analogous to the geometry observed in the solid state. These processes are illustrated in Scheme 1.

To test this hypothesis, free isopropanol (3 equiv.) was added to a toluene-d_8 solution of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$, and variable temperature ^{1}H NMR spectra were recorded. At room temperature, only one type of O—*i*-Pr species was observed, but upon cooling to −60°C, resonances arising from [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ were observed together with resonances due to the free added HO—*i*-Pr. These data are shown in Fig. 5 and are consistent with the proposed exchange mechanism involving rapid exchange between free and coordinated alcohol at room temperature, but no exchange at −60°C on the ^{1}H NMR timescale. These data are also consistent with the low value (slightly less than dimeric) of molecular complexity determined by cryoscopic molecular weight determination in benzene at ~+5°C.

Finally, we note that, in the solid state, the isoproxide infrared stretching frequencies of [Sn(O—*i*-Pr)$_4$·HO—*i*-Pr]$_2$ are consistent with data previously reported for metal isopropoxide compounds, and we assign the ν(Sn—O) stretches to bands at 609 and 583 cm^{-1}.

Cyclodextrin-based enzyme models. Part 1. Synthesis of a tosylate and an epoxide derived from heptakis(6-*O*-*tert*-butyldimethylsilyl)-β-cyclodextrin and their characterization using 2D NMR techniques. An improved route to cyclodextrins functionalized on the secondary face

MARKO J. PREGEL AND ERWIN BUNCEL
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received April 2, 1990

MARKO J. PREGEL and ERWIN BUNCEL. Can. J. Chem. **69**, 130 (1991).

An improved route for the synthesis of cyclodextrin (CD)-based enzyme models having catalytic groups on the secondary face is presented. An epoxide derived from heptakis(6-*O*-*tert*-butyldimethylsilyl)-β-CD was prepared via intermediates that can be purified by conventional flash chromatography on a *preparative* scale. Reaction of β-cyclodextrin with *tert*-butyldimethylsilyl chloride in pyridine gave heptakis(6-*O*-*tert*-butyldimethylsilyl)-β-CD (**1**). Treatment of **1** with *N*-tosylimidazole and NaOMe in chloroform gave mono(2-*O*-tosyl) heptakis(6-*O*-*tert*-butyldimethylsilyl)-β-CD (**2**) in 22% yield. The latter was converted smoothly to mono(2^A, 3^A-anhydro) heptakis(6-*O*-*tert*-butyldimethylsilyl)-β-CD (**3**), in which one glucose subunit has been converted to a manno-epoxide, by treatment with KOEt in refluxing ethanol (87% yield). Compounds **1**, **2**, and **3** were characterized by a variety of one- and two-dimensional NMR techniques. These results open the door to attachment of catalytic groups to the cyclodextrin in a well-defined manner. Nucleophilic attack on the epoxide, followed by removal of the silyl groups, can be used to prepare a wide variety of enzyme model systems.

Key words: functionalized cyclodextrins, silylation, 2D NMR, enzyme models.

MARKO J. PREGEL et ERWIN BUNCEL. Can. J. Chem. **69**, 130 (1991).

On présente une méthode améliorée pour la synthèse de modèles basés sur la cyclodextrine (CD) possédant des groupements catalytiques sur la face secondaire. On a préparé un époxyde, à partir de l'heptakis(6-*O*-*tert*-butyldiméthylsilyl)-β-CD, par le biais d'intermédiaires qui peuvent être purifiés, sur une base *préparative*, par la chromatographie éclair conventionnelle. La réaction de la β-cyclodextrine avec le chlorure de *tert*-butyldiméthylsilyle dans la pyridine fournit l'heptakis(6-*O*-*tert*-butyldiméthylsilyl)-β-CD (**1**). Le traitement du produit **1** par du *N*-tosylimidazole et du NaOMe dans le chloroforme conduit au mono(2-*O*-tosyl)-heptakis(6-*O*-*tert*-butyldiméthylsilyl)-β-CD (**2**), avec un rendement de 22%. Ce produit a été facilement transformé en mono(2^A, 3^A-anhydro)heptakis((6-*O*-*tert*-butyldiméthylsilyl)-β-CD (**3**) duquel une unité de glucose a été transformée en manno-époxyde par un traitement avec du KOEt dans l'éthanol au reflux (rendement de 87%). Les composées **1**, **2** et **3** ont été caractérisés par une variété de techniques RMN en une et en deux dimensions. Ces résultats ouvrent la porte à l'attachement de groupements catalytiques dans des positions bien définies de la cyclodextrine. Une attaque nucléophile sur l'époxyde, suivie de l'enlèvement des groupements silyles, peut être utilisée pour préparer une grande variété de systèmes enzymatiques modèles.

Mots clés : cyclodextrines fonctionnalisées, silylation, RMN 2D, modèles d'enzymes.

[Traduit par la revue]

Introduction

Cyclodextrins (CDs) are of interest as enzyme models because they form inclusion complexes with hydrophobic guests in solutions of polar solvents (1–3). This is directly comparable to the formation of an enzyme–substrate complex and leads to saturation (Michaelis–Menten) kinetics, competitive inhibition, and selective rate accelerations in reactions involving cyclodextrins (2). Since cyclodextrins can be modified to attach catalytic groups, they have the two important attributes of enzymes: molecular recognition and multifunctional catalysis (3).

β-Cyclodextrin is a cyclic oligosaccharide made up of seven α-D-glucose subunits. As shown in Fig. 1, the secondary hydroxyl groups make up one face of the toroidal molecule. The secondary face of the cyclodextrin is of interest in making enzyme models because it is more open and is the preferential site for the binding of large molecules, including aromatic guests (4). However, in contrast to functionalization of the primary face of cyclodextrins, which has been extensively studied, the chemistry available for functionalization of the secondary face is less well developed. Preparative methods for secondary-functionalized cyclodextrins generally involve moderate yields and purification of synthetic intermediates by reverse-phase chromatography, which is scale-limited (5–8).

The synthesis of cyclodextrin-based enzyme model systems may be improved to allow for easier purification of intermediates, and consequently for synthesis on a larger scale, if a partially silylated cyclodextrin derivative is used as the framework for further modifications. Silylation of β-cyclodextrin primary hydroxyls should lead to a number of benefits. The resulting compound is expected to be much less polar than the parent cyclodextrin, making it soluble in organic solvents and allowing purification by chromatography on silica gel. The silyl groups are stable under ordinary conditions, but are easily removed when necessary (9–11). Thus, modification of silylated CDs would provide an improvement over previous approaches because the synthetic intermediates should be more easily purified, allowing work on a large scale.

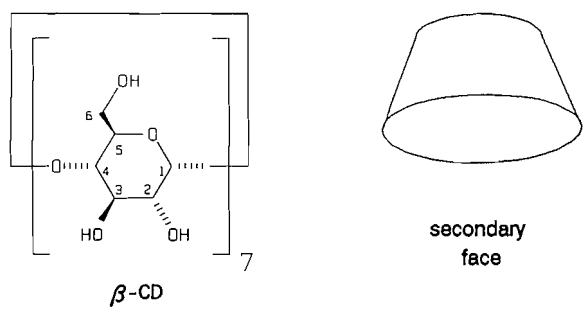

FIG. 1. β-Cyclodextrin and a representation of the shape of the molecule indicating the secondary face.

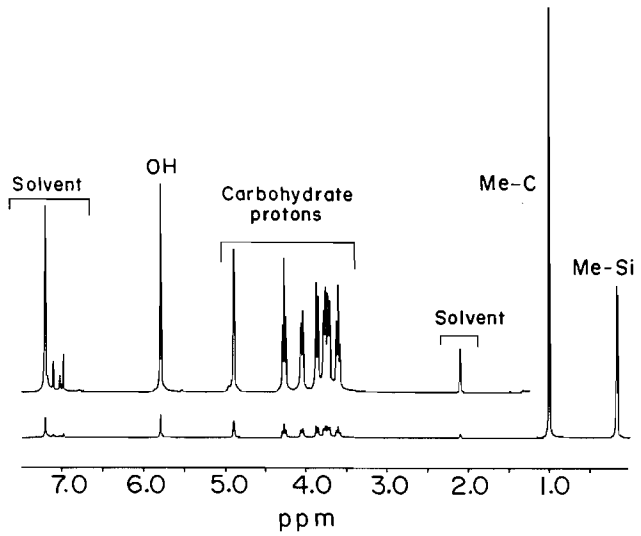

FIG. 2. ^{1}H NMR spectrum of **1** in deuterotoluene (3000–0 Hz). The carbohydrate region is expanded in Fig. 3.

The silylation of β-CD to produce heptakis(6-*O*-*tert*-butyldimethylsilyl)-β-CD (**1**) has been reported previously (12). Szejtli and co-workers originally reported the selective silylation of the primary hydroxyls of β-CD, using pyridine as a catalyst for the reaction of β-CD with *tert*-butyldimethylsilyl chloride; the silylated CD was isolated and characterized as the peracetate (12, 13). Treatment of the peracetate with Bu_4NF removed the silyl groups smoothly (12). Takeo *et al.* have recently prepared **1** in 70% yield by the reaction of β-CD with *t*-$BuMe_2SiCl$ in the presence of imidazole (14) and Fugedi has prepared **1** in 83% yield using pyridine as catalyst and solvent (15).

A number of compounds related to **1** have also been prepared, including heptakis(6-*O*-*tert*-butyldimethylsilyl)-α-CD (11, 16) and heptakis(6-*O*-*tert*-butyldimethylsilyl)-γ-CD (15), as well as 2,6-per(*tert*-butyldimethylsilyl)-α-CD (10, 16) and 2,6-per(*tert*-butyldimethylsilyl)-β-CD derivatives (17, 18).

The present work reports the synthesis and complete characterization of **1**, which is used as a precursor in the synthesis of two new compounds, a tosylate (**2**) and an epoxide (**3**). All three compounds are characterized with the aid of a variety of one- and two-dimensional (2D) NMR techniques. NMR studies of cyclodextrins, including the use of a variety of two-dimensional methods, have recently been reviewed (19). Two-dimensional methods are used because substituted cyclodextrins usually give complex, overlapped spectra. Spreading out overlapped signals into a second dimension often allows individual resonances to be resolved and assigned. This has been shown to be indispensable in the characterization of complex, unsymmetrically modified cyclodextrins (22). For example, Stoddart and co-workers have used COSY, *J*-resolved, and shift correlation experiments to assign the spectra of an unsymmetrical chemically modified CD, 2,6-per-*O*-methyl-3^A-*O*-methyl-β-CD (20).

Results and discussion

As part of our ongoing interest in the construction of cyclodextrin-based enzyme model systems, the use of a cyclodextrin that was soluble in nonpolar solvents as a framework for subsequent transformations appeared to offer a number of advantages. It was expected that such a CD and its derivatives could be easily purified by flash chromatography and this, in turn, would allow syntheses to be carried out on a larger scale than is presently possible. Large amounts of CD derivatives are desirable when multistep syntheses are undertaken and when the modified cyclodextrin is to undergo detailed kinetic studies.

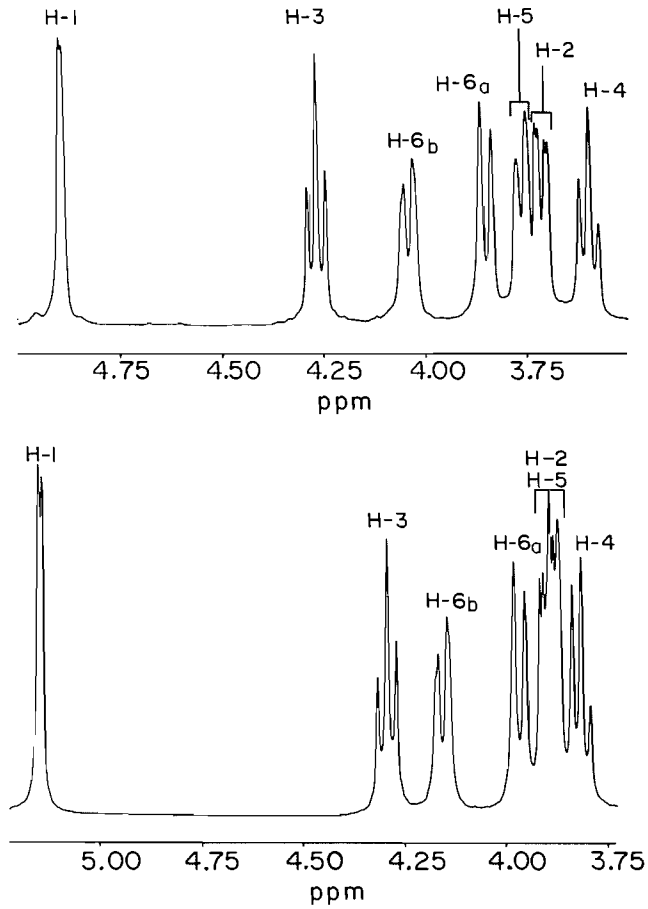

FIG. 3. ^{1}H NMR spectra of **1** in deuterotoluene (upper, 2000–1400 Hz) and deuterochloroform (lower, 2190–1590 Hz), showing resonances due to carbohydrate protons. The H-2 and H-5 resonances overlap in the spectrum recorded in $CDCl_3$.

Accordingly, a cyclodextrin silylated at its primary positions, **1**, was chosen as the starting point and was prepared as follows. Dry β-CD was allowed to react with 7.35 equivalents of *tert*-butyldimethylsilyl chloride in dry pyridine for 18 h at room temperature (eq. [1]). Heptakis(*tert*-butyldimethylsilyl)-β-CD (**1**) was isolated in 73% yield after flash chromatography. The preparative method was analogous to that reported by Fugedi (15). ^{13}C NMR data for **1** in $CDCl_3$ have been previously reported (14, 15), and the ^{13}C NMR data for the product of the present study compare well with the literature data. The ^{1}H, COSY, and ^{13}C–^{1}H shift correlation spectra for **1** have not been previously reported, and are presented below.

The complete ^{1}H NMR spectrum of **1** in deuterotoluene is shown in Fig. 2. The spectrum is remarkably simple because of the sevenfold symmetry of the compound. An expansion of the carbohydrate portion of the spectrum (Fig. 3) reveals distinct resonances for protons on carbons 1, 2, 3, 4, 5, and 6. The two protons on carbon 6, labelled H-6_a nd H-6_b, are nonequivalent (diastereotopic). In $CDCl_3$ solution, resonances assigned to protons on carbons 2 and 5 are overlapped (Fig. 3). Aromatic guests are known to deshield the H-3 and H-5 resonances of cyclodextrins (19), so the difference in spectra in the two

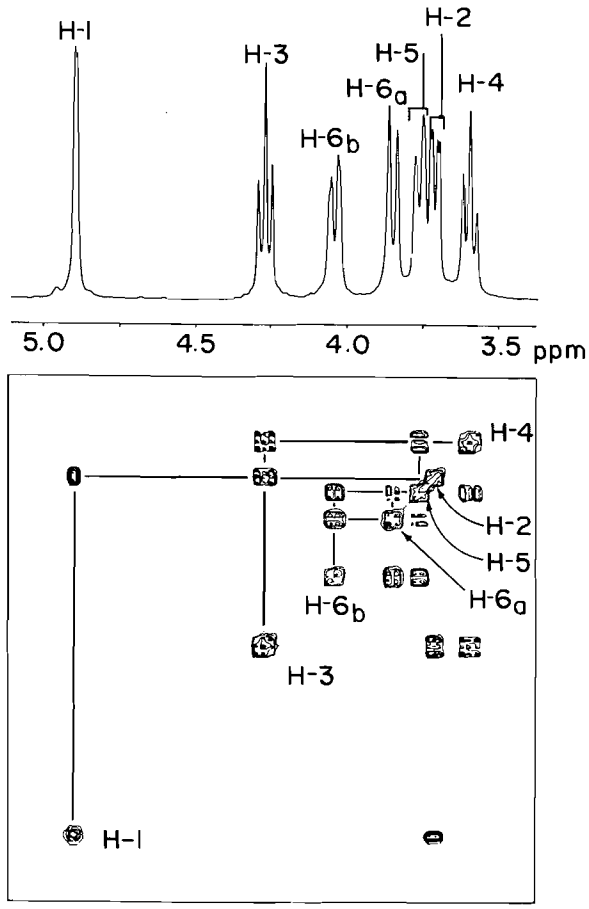

FIG. 4. Contour plot of the carbohydrate region of the COSY spectrum of **1** in deuterotoluene (2044–1349 Hz).

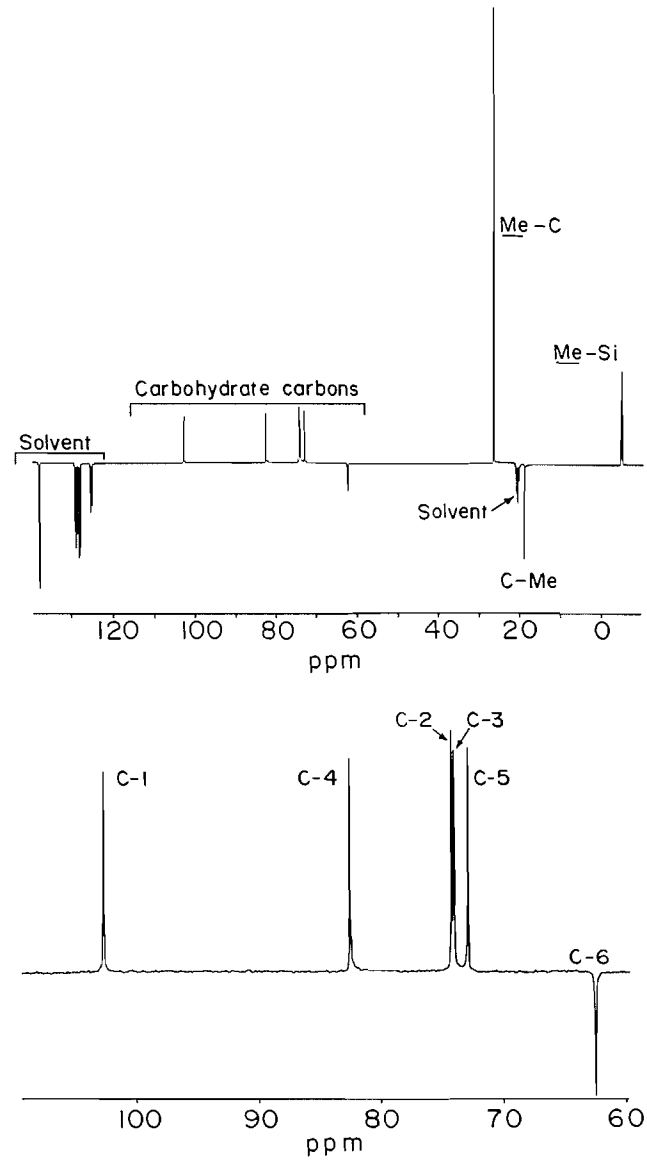
solvents can probably be ascribed to formation of an inclusion complex of deuterotoluene with the silylated CD.

The ^1H spectrum of **1** was assigned unambiguously by means of a COSY experiment, presented in Fig. 4. In this diagram, off-diagonal peaks connect coupled spins. Thus, as shown in Fig. 4, starting from the furthest downfield peak (H-1), all of the remaining resonances can be assigned.

The ^{13}C NMR spectrum of **1** was also recorded (Fig. 5). This is a *J*-modulated spectrum in which the carbon peaks are sorted according to the number of attached protons. Methyl and methine carbons point upwards; methylene and quaternary carbons point downwards. The peaks corresponding to the carbohydrate carbons were assigned by reference to the proton spectrum using a 2D ^{13}C–^1H shift correlation spectrum, presented in Fig. 6. This experiment yields responses that connect carbon peaks in one dimension to proton peaks in the other.



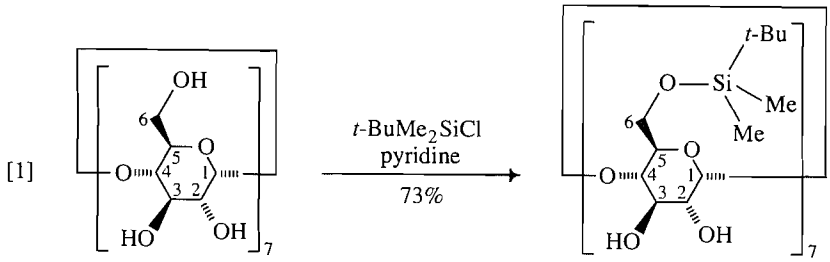


FIG. 5. *J*-Modulated ^{13}C NMR spectra of **1** in deuterotoluene (14 000 to −1000 Hz). The lower spectrum is an expansion showing resonances due to carbohydrate carbons (11 000–6000 Hz).

The title compound has two types of sites that can be modified further, the hydroxyl groups at C-2 and C-3 of each glucose unit. Ideally, tosylation of **1**, to produce **2**, would modify a single glucose subunit and would be specific for one type of hydroxyl on that subunit. In practice, one needs to check whether reaction has occurred at a C-2 hydroxyl, a C-3 hydroxyl, or both.

β-CD **1**

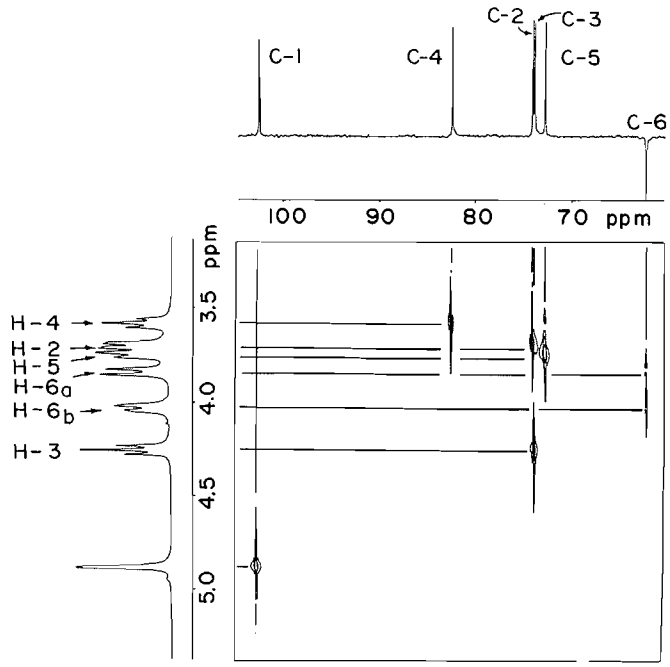

FIG. 6. Contour plot of the carbohydrate region of the $^{13}C-^{1}H$ shift correlation spectrum of **1** in deuterotoluene (^{1}H: 2151–1250 Hz, ^{13}C: 104.6–60.2 ppm).

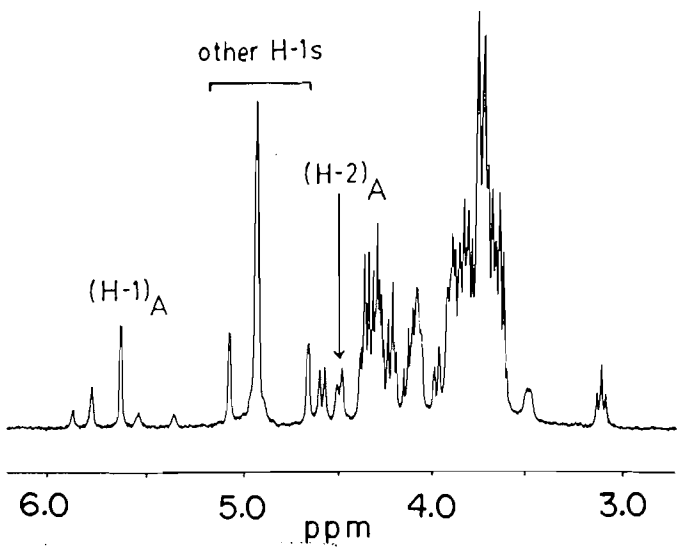

FIG. 7. The carbohydrate region of the ^{1}H NMR spectrum of **2** in deuterotoluene (2483–1092 Hz).

Reaction of **1** with *N*-tosylimidazole and sodium methoxide in chloroform gives **2** in 22% yield after flash chromatography (eq. [2]). This procedure has been shown to yield the C-2 tosylate in the reaction of 4,6-*O*-benzylidene-α-D-glucose (21).

The carbohydrate regions of the ^{1}H and ^{13}C NMR spectra are presented in Figs. 7 and 8, respectively. These spectra are complex and highly overlapped because modification of one of the seven subunits of the cyclodextrin destroys the symmetry of the molecule and all resonances are now nonequivalent.

In practice, resonances for the H-1's of the glucose units are easiest to analyze because they are well separated from other resonances. Three individual H-1 resonances are seen at 5.65, 5.07, and 4.63 ppm, as well as a larger (overlapped) group at

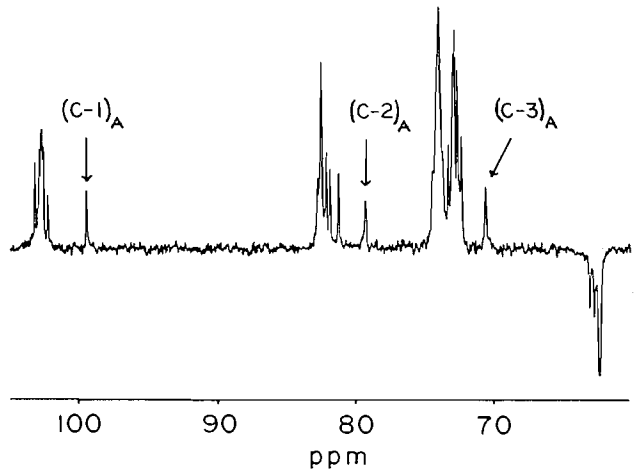

FIG. 8. The ^{13}C NMR spectrum of **2** in deuterotoluene (105.0–60.0 ppm).

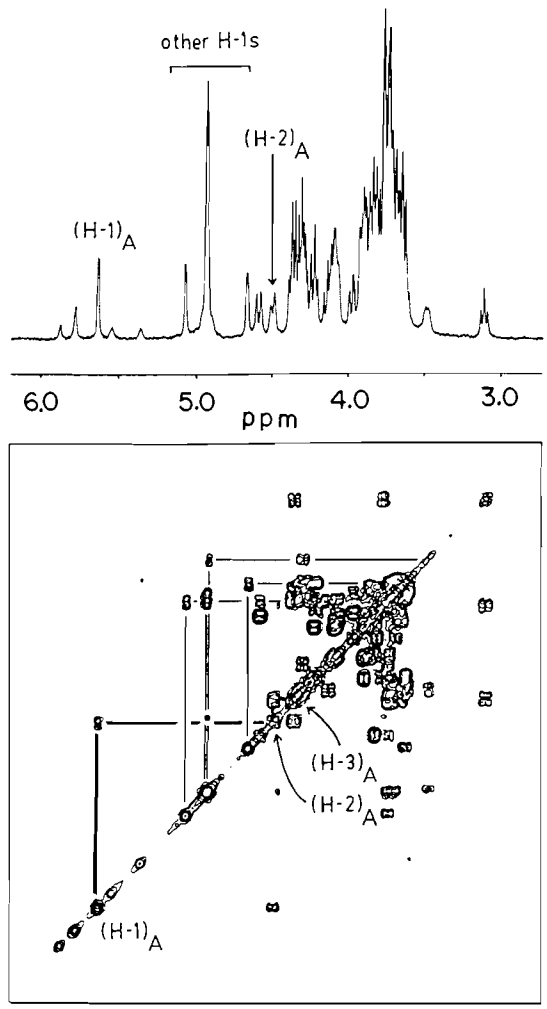

FIG. 9. Contour plot of the carbohydrate region of the COSY spectrum of **2** in deuterotoluene (2483–1092 Hz).

4.91 ppm. The lowest field H-1 signal is assigned to the subunit bearing the tosyl group (this subunit will be called subunit A and $(H\text{-}1)_A$ is labelled in Fig. 7). Examination of the COSY spectrum of **2**, presented in Fig. 9, shows that $(H\text{-}1)_A$ is coupled to an H-2 resonance at 4.50 ppm that is pulled downfield by ca. 0.8 ppm relative to H-2 resonances in parent silylated CD (**1**),

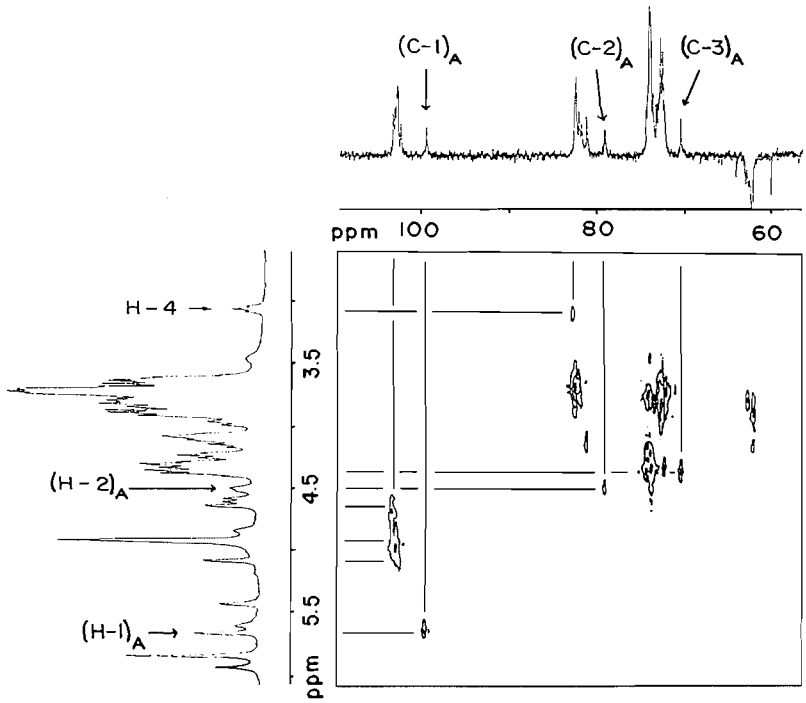

FIG. 10. Contour of the carbohydrate region of the $^{13}C-^{1}H$ shift correlation spectrum of **2** in deuterotoluene (^{1}H: 1047–2418 Hz, ^{13}C: 56.5–110.0 ppm).

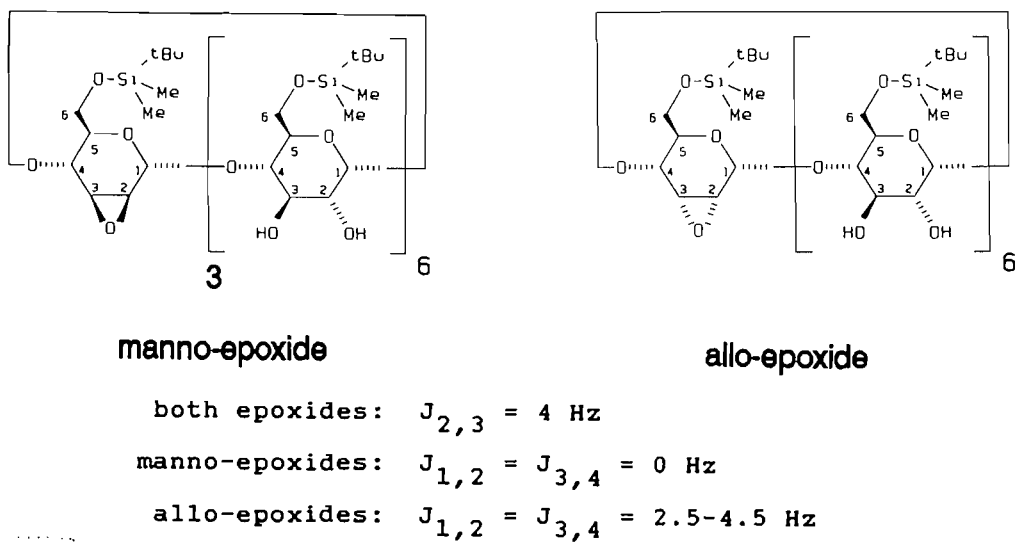

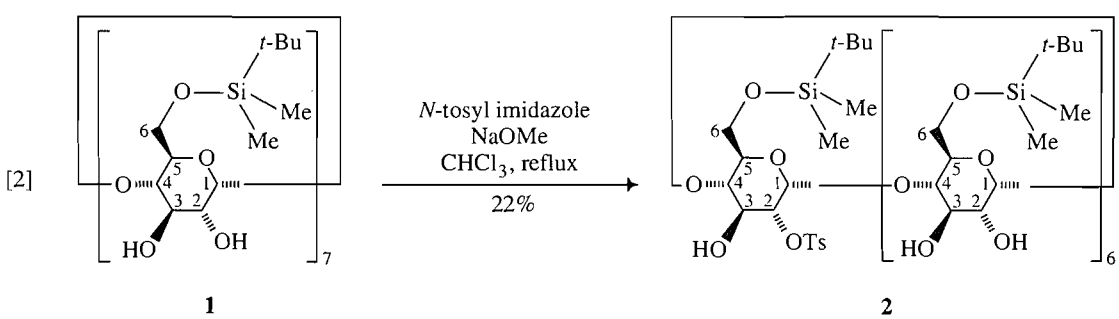

FIG. 11. Structural formulae and ^{1}H coupling constants for the allo- and manno-epoxides derived from **1**.

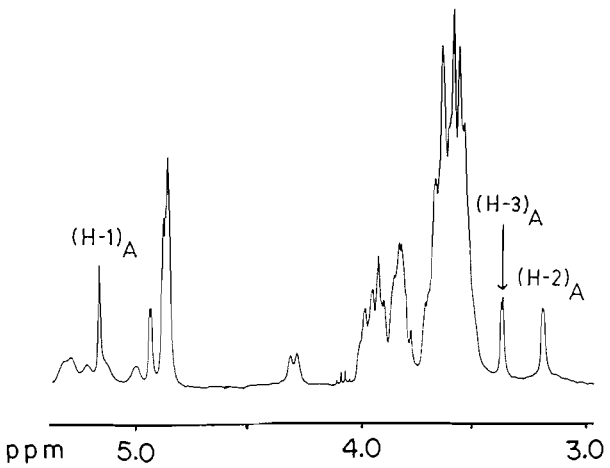

FIG. 12. The carbohydrate region of the ^{1}H NMR spectrum of **3** in deuterochloroform (2151–1185 Hz).

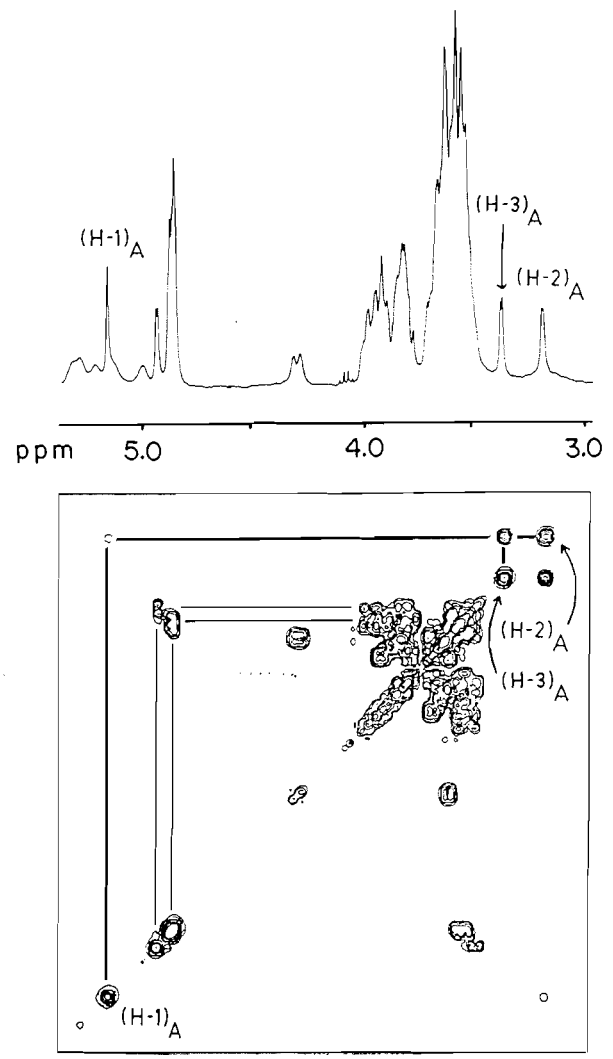

FIG. 13. Contour plot of the carbohydrate region of the COSY spectrum of **3** in deuterochloroform (2149–1192 Hz).

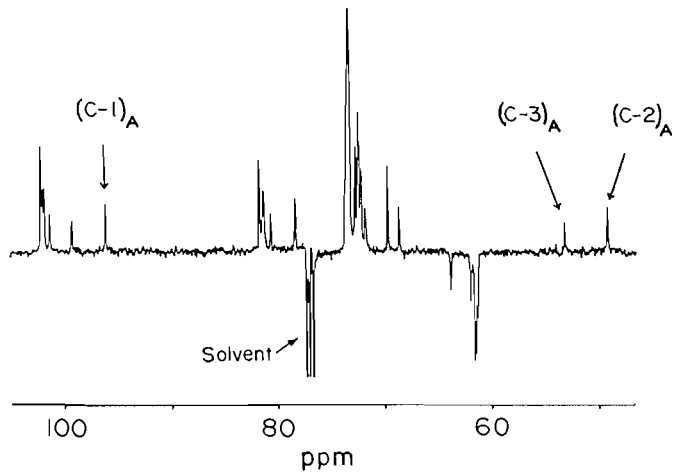

FIG. 14. The carbohydrate region of the *J*-modulated ^{13}C NMR spectrum of **3** in deuterochloroform (105.0–46.5 ppm).

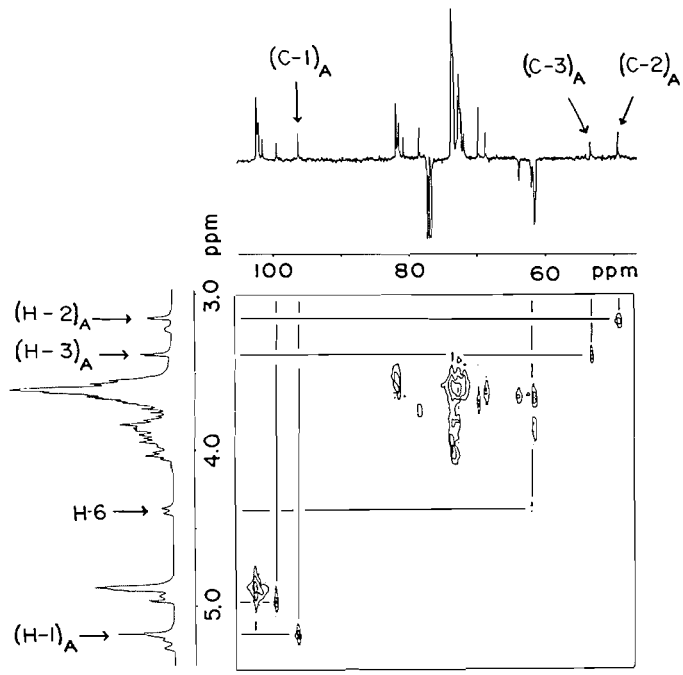

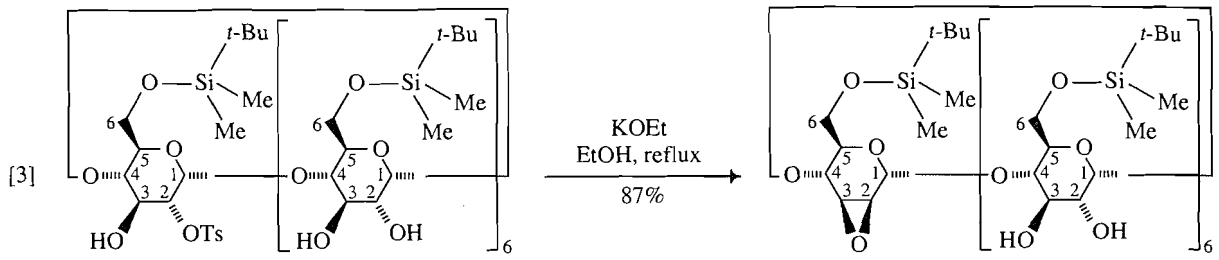

FIG. 15. Contour plot of the carbohydrate region of the ^{13}C–^{1}H shift correlation spectrum of **3** in deuterochloroform (^{1}H: 2151–1183 Hz, ^{13}C: 105.0–46.5 ppm).

which appear at 3.72 ppm. This is consistent with the electron-withdrawing effect of tosylation at C-2 of subunit A. All other H-1 resonances are coupled to H-2 resonances with chemical shifts similar to the H-2 resonances in **1**. The aromatic region shows only one set of ring protons and only one tosyl methyl group is observed. Examination of the ^{13}C spectrum of **2** also shows only one set of aromatic and methyl resonances for the tosyl group. Consequently, it appears that the reaction has produced the C-2 tosylate exclusively.

The ^{13}C–^{1}H shift correlation spectrum of **2** is presented in Fig. 10. It allows the assignment of $(C\text{-}1)_A$, $(C\text{-}2)_A$, and $(C\text{-}3)_A$ resonances from the known $(H\text{-}1)_A$, $(H\text{-}2)_A$, and $(H\text{-}3)_A$ resonances. $(C\text{-}1)_A$ and $(C\text{-}3)_A$ are shifted upfield from the C-1 and C-3 resonances of **1**, respectively, while $(C\text{-}2)_A$ is shifted

2 3

downfield from the C-2 resonances of **1**. This behavior is expected when a tosylate group is introduced at the C-2 position of **1**, and has been observed in comparisons of the spectra of β-CD and its C-2 tosylate (8).

The silylated CD epoxide **3** is prepared from the tosylate in good yield (87%) by treatment with 1 equivalent of KOEt in refluxing ethanol (eq. [3]).

Confirmation that a C-2 tosylate was produced above is possible from an examination of the spectra of the epoxide. A C-2 tosylate yields a manno-epoxide, while a C-3 tosylate yields an allo-epoxide, and ^{1}H coupling patterns are different in the two epoxides.

In both epoxides, one expects $J_{2,3}$ = 4 Hz. For manno-epoxides, weak coupling between hydrogens that are mutually *trans* results in $J_{1,2} = J_{3,4} = 0$ Hz. In contrast, $J_{1,2} = J_{3,4} =$ 2.5–4.5 Hz for allo-epoxides (22). Consequently, allo- and manno-epoxides are readily distinguished on the basis of the coupling patterns of their epoxide protons, as summarized in Fig. 11.

The H-2 and H-3 resonances of 2,3-anhydroaldopyranoses appear between 3.1 and 3.6 ppm in deuterochloroform solution (22). The carbohydrate region of the ^{1}H spectrum of epoxide **3** (Fig. 12) contains two *doublets* at 3.20 and 3.37 ppm, with coupling constants of 3.4 Hz. There is also one H-1 resonance at 5.19 ppm, which appears as a sharp *singlet*, i.e., coupling to H-2 has been lost. These observations and the absence of any other resonances in the epoxide region with more complex coupling patterns are consistent with a manno-epoxide structure and are parallel to observations for the manno-epoxide derived from unmodified β-CD (5).

The COSY spectrum of the epoxide (Fig. 13) confirms that the resonances assigned to $(H\text{-}2)_A$ and $(H\text{-}3)_A$ are mutually coupled and that $(H\text{-}2)_A$ is weakly coupled to $(H\text{-}1)_A$. Coupling of $(H\text{-}3)_A$ to $(H\text{-}4)_A$ was not detected.

The ^{13}C spectrum of the epoxide (Fig. 14) is also informative. The C-2 and C-3 resonances of 2,3-anhydro-4,6-*O*-benzylidene-α-D-allopyranose appear at 50.4 and 53.0 ppm, respectively, while those of the analogous manno-epoxide appear at 50.6 and 53.9 ppm, respectively (deuterobenzene solution) (23). The ^{13}C spectrum of **3** contains only two peaks in this region, at 49.1 and 53.1 ppm (deuterotoluene solution, spectrum not shown), confirming that the sample contains only one type of epoxide.

The ^{13}C–^{1}H shift correlation spectrum of **3** in $CDCl_3$ is shown in Fig. 15. The sharp downfield singlet at 5.19 ppm ($(H\text{-}1)_A$) correlates with a peak at 96.2 ppm in the ^{13}C spectrum, which is assigned to $(C\text{-}1)_A$. The upfield doublets assigned to $(H\text{-}2)_A$ and $(H\text{-}3)_A$ correlate with peaks at 49.1 and 53.1 ppm (the epoxide carbons, $(C\text{-}2)_A$ and $(C\text{-}3)_A$), as expected. The doublet at 4.30 ppm can now be assigned to an H-6 resonance because it correlates with a peak in the C-6 region of the ^{13}C spectrum.

Conclusions

The manno-epoxide derived from heptakis(6-*O*-*tert*-butyldimethylsilyl)-β-CD was prepared in three steps and 15% overall yield from β-cyclodextrin via intermediates that are easily purified. This allows reactions to be carried out on a larger scale than was previously possible. Synthetic intermediates were characterized by two-dimensional NMR methods and the stereochemistry of the final product was assigned. Attachment of catalytic groups to the cyclodextrin in a well-defined manner is now possible. Nucleophilic attack on the epoxide, followed by removal of the silyl groups, can be used in future work to prepare a wide variety of enzyme model systems.

Experimental

Methods and materials

NMR spectra were recorded on a Bruker AM 400 spectrometer (^{1}H: 400 MHz; ^{13}C: 100 MHz) in deuterotoluene or deuterochloroform solution. Chemical shifts are reported in parts per million downfield from TMS.

Representative parameters used to obtain the two-dimensional spectra were as follows: COSY: spectral width of 2500 Hz, centered at 6150 Hz, 256 experiments, each consiting of 8 scans stored in 1K of data, a recycle delay of 3 s. The transformed spectrum was symmetrized about the diagonal. Heteronuclear shift correlation: ^{1}H: spectral width of 2500 Hz, centered at 6150 Hz, ^{13}C: spectral width of 10 kHz, centered at 52 000 Hz, 256 experiments, each consisting of 48 scans stored in 1K of data, τ_1 = 3.5 ms, τ_2 = 2 ms.

Thin-layer chromatography (TLC) was performed using HP-TLC plates (Merck) coated with silica gel 60 in the following solvent system (A): ethyl acetate – ethanol–water 50:7:4 (v/v). Compounds were visualized by spraying the plates with a solution of 10% sulfuric acid containing 1% cerium sulfate and 1.5% molybdic acid, followed by heating.

Flash chromatography was performed using Kieselgel 60 (Merck, 230–400 mesh), following the procedure of Still *et al.* (24), using the following solvent systems: ethyl acetate – ethanol–water (B) 25:2:1, (C) 16:2:1, (D) 12:2:1, and (E) 50:2:1 (v/v).

Optical rotations were measured with a Perkin–Elmer 241 polarimeter using the sodium D line.

β-CD was dried overnight at 100°C under vacuum (<2 Torr; 1 Torr = 133.3 Pa). Pyridine was distilled from CaH_2 and stored over 3 Å molecular sieves.

Synthesis of 1

In a dry box, dried β-CD (3.72 g, 3.28 mmol) was weighed into a glass bulb fitted with a ground glass joint. The glass bulb was then attached to a three-neck round bottom flask equipped with a stirring bar and the flask was septum-sealed in the dry box. *tert*-Butyldimethylsilyl chloride (3.636 g, 24.1 mmol, 7.35 equiv.) was weighed into a septum-sealed vial.

Dry pyridine (35 mL) was added to the flask by syringe. The weighed CD was added to the stirred pyridine in small portions by inverting the glass bulb. Dry pyridine was also added to the vial containing the silyl chloride and the solution was then added to the CD solution dropwise by syringe. The reaction mixture was stirred overnight (18 h), then

For personal use only.

poured into ice-cold water (350 mL) and stirred vigorously for 10 min.[1] The resulting precipitate was filtered off, washed with ice-cold water, and dissolved in ethyl acetate (70 mL). The solution was washed with 5% aqueous HCl solution (3 × 50 mL), saturated aqueous $NaHCO_3$ solution (50 mL), and saturated brine (50 mL). Finally, the solution was dried (anhydrous Na_2SO_4), filtered, concentrated, and traces of solvent were removed at 100°C under vacuum (<2 Torr) to give 5.69 g (90%) of crude product.

A portion of the crude product (0.423 g) was purified by flash chromatography using a gradient elution with solvents B, C, and D. Pure **1** (0.342 g) was obtained, resulting in an overall yield of 73%, mp 299–300°C (dec., from ethanol) (lit. (14) mp 299–302°C (dec., from ethanol); $[\alpha]_D^{22}$ +111° (*c* 1.04, $CHCl_3$) (lit. (14) $[\alpha]_D^{22}$ +113° (*c* 1.4, $CHCl_3$)); ^1H NMR (toluene-d_8) δ: 0.18 (s, Me-Si), 1.02 (s, Me-C), 3.61 (t, J = 9 Hz, H-4), 3.72 (dd, J = 3.2, 9.5 Hz, H-2), 3.78 (d, J = 9.5 Hz, H-5), 3.86 (d, J = 11 Hz, H-6_a), 4.05 (dd, J = 2.5, 11 Hz, H-6_b), 4.28 (t, J = 9 Hz, H-3), 4.91 (d, J = 3 Hz, H-1); ^{13}C NMR (toluene-d_8) δ: −1.9 (*Me*-Si), 18.4 (Me-*C*), 26.1 (*Me*-C), 62.4 (C-6), 73.0 (C-5), 74.0 (C-3), 74.3 (C-2), 82.6 (C-4), 102.7 (C-1); ($CDCl_3$) δ: −5.2, −5.1 (*Me*-Si), 18.3 (Me-*C*), 25.9 (*Me*-C), 61.6 (C-6), 72.5 (C-5), 73.4 (C-3), 73.6 (C-2), 81.8 (C-4), 102.0 (C-1). Anal. calcd. for $(C_{12}H_{24}O_5Si)_7$: C 52.15, H 8.75; found: C 51.54, H 8.52.

Synthesis of **2**

Compound **1** (0.392 g, 0.203 mmol) and *N*-tosylimidazole (prepared according to ref. 21, 0.067 g, 0.303 mmol) were dissolved in chloroform (2.5 mL), then sodium methoxide (0.162 g, 0.300 mmol) was added and the mixture refluxed for 6 h. Chloroform (6 mL) was added and the reaction mixture was washed with water (10 mL), then dried (anhydrous Na_2SO_4). The crude product was purified by flash chromatography (solvent E), giving pure **2** (0.083 g, 22% yield), mp 199–200°C (dec., from ethanol); $[\alpha]_D^{19}$ +102° (*c* 0.83, $CHCl_3$); ^1H NMR (toluene-d_8) δ: 0.10–0.27 (Me-Si), 0.88–1.12 (Me-C), 2.15 (s, tosyl Me), 3.07 (t, H-4), 3.45 (H-2), 3.61–3.47 (heavily overlapped), 4.50 (d, (H-2)$_A$), 4.59 (d), 4.63 (s, H-1), 4.91 (H-1s), 5.07 (s, H-1), 5.65 (s, (H-1)$_A$), 8.18 (d, tosyl aromatic, other aromatic doublet obscured by solvent); ^{13}C NMR (toluene-d_8) δ: −4.9, −4.6 (Me-Si), 18.3 (*C*-Me), 21.3 (tosyl Me), 26.1 (*Me*-C), 62.3, 62.7, 63.0 (C-6s), 70.5 ((C-3)$_A$), 72.3, 72.6, 72.8, 73.3 (C-2s, C-3s), 74.0 ((C-2)$_A$), 79.2, 81.2, 81.8, 82.1, 82.5, 82.7 (C-4s), 99.5 ((C-1)$_A$), 102.3, 102.6, 102.7, 102.9, 103.2 (C-1s). Anal. calcd. for $C_{91}H_{174}O_{37}Si_7S$: C 52.32, H 8.40; found: C 51.79, H 8.18.

Synthesis of **3**

Following the procedure of Hough *et al.* (25), **2** (0.104 g, 4.96 × 10^{-5} mol) and potassium ethoxide (45 μL of a 1.132 M solution of KOEt in ethanol, 5.09 × 10^{-5} mol, 1.0 equiv.) were added to ethanol (1.2 mL). The solution was refluxed for 70 min, at which point TLC showed a single band. Ice water (10 mL) was added to the reaction mixture and the resultant precipitate was filtered off, washed with cold water, and dried under high vacuum to yield pure **3** (0.083 g, 87% yield), mp 259–260°C (from ethanol); $[\alpha]_D^{19}$ +99.3° (*c* 0.88, $CHCl_3$); ^1H NMR ($CDCl_3$) δ: 0.85 (Me-Si), 1.74 (Me-C), 3.20 (d, (H-2)$_A$), 3.37 (d, (H-3)$_A$), 3.53–4.02 (heavily overlapped), 4.30 (d, H-6), 4.89–4.91 (H-1s), 4.95 (s, H-1), 5.19 (s, (H-1)$_A$); ^{13}C NMR ($CDCl_3$) δ: −5.37 (Me-Si), 18.1 (*C*-Me), 25.8 (*Me*-C), 49.1 ((C-2$_A$), 53.1 ((C-3)$_A$), 61.3, 61.4, 61.6, 61.9, 63.8 (C-6s), 68.6, 69.7, 71.8, 72.2, 72.4, 72.7, 73.3, 78.3, 80.7, 81.3, 81.7 (C-2s, C-3s, C-4s), 96.2 ((C-1$_A$), 99.3, 101.3, 101.8, 102.0, 102.2 (C-1s). Anal. calcd. for $C_{84}H_{166}O_{34}Si_{79}$: C, 52.64; H, 8.73; found: C, 51.89; H, 8.66.

Cyclopropylketenes: preparation and nucleophilic additions[1]

ANNETTE D. ALLEN, LYNN M. BAIGRIE, LEYI GONG, AND THOMAS T. TIDWELL[2]
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

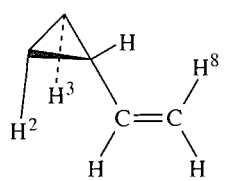
Received July 20, 1990

ANNETTE D. ALLEN, LYNN M. BAIGRIE, LEYI GONG, and THOMAS T. TIDWELL. Can. J. Chem. **69**, 138 (1991).

Phenylcyclopropylketene (**4**), *tert*-butylcyclopropylketene (**5**), and dicyclopropylketene (**6**) were formed by dehydrochlorination of the corresponding acyl chlorides by Et_3N in THF, and are the first cyclopropylketenes to be isolated and purified. Reaction of **4** with *n*-BuLi and capture of the intermediate enolates with Me_3SiCl gave the stereoisomeric silyl enol ethers *c*-PrCPh=C(OSiMe$_3$)-*n*-Bu with a 79:21 preference for formation of the *Z* isomer resulting from nucleophilic attack *syn* to cyclopropyl, whereas the corresponding reaction of *t*-BuLi gave a 9:91 preference for attack *anti* to cyclopropyl. Some isopropyl-, cyclopentyl-, and cyclohexylketenes gave comparable results. Analyses of the relative sizes of the ketene substituents in the ground state by steric parameters, and of the product stabilities by molecular mechanics, both fail to predict the observed similarities in the results with different *secondary* alkyl groups. The hydration reactivities of **4** and **6** show that, in neutral H_2O/CH_3CN, *c*-PrCPh=C=O is more reactive than *i*-PrCPh=C=O, a result ascribed as mainly due to the smaller size of cyclopropyl. *c*-Pr_2C=C=O has the same reactivity in neutral water as Et_2C=C=O, but is 22 times less reactive with acid, a result attributed to the inability of the β-cyclopropyl groups to directly stabilize the cationic transition state for protonation.

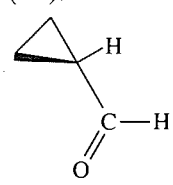
Key words: cyclopropylketenes, ketenes, nucleophilic addition, hydration kinetics.

ANNETTE D. ALLEN, LYNN M. BAIGRIE, LEYI GONG et THOMAS T. TIDWELL. Can. J. Chem. **69**, 138 (1991).



On a obtenu les phénylcyclopropyl- (**4**), *tert*-butylcyclopropyl- (**5**) et dicyclopropyl- (**6**) cétènes par déshydrochloration des chlorures d'acyles correspondants à l'aide du Et_3N dans le THF; il s'agit des premiers cyclopropylcétènes à être isolés et purifiés. La réaction du produit **4** avec le *n*-BuLi, suivie d'une capture des énolates intermédiaires par le Me_3SiCl, fournit les éthers énoliques silylés stéréoisomères *c*-PrCPh=C(OSiMe$_3$)-*n*-Bu qui sont présents dans un rapport de 79:21; l'isomère *Z* qui résulte d'une attaque nucléophile *syn* par rapport au cyclopropyle se forme d'une façon prépondérante. Par ailleurs, lors de la réaction avec le *tert*-BuLi, l'attaque se fait de préférence (9:91) en *anti* par rapport au cyclopropyle. Des analyses, d'une part, des grosseurs relatives des substituants cétènes dans l'état fondamental à l'aide de paramètres stériques et, d'autre part, des stabilités des produits à l'aide de la mécanique moléculaire ne permettent pas de prédire les similarités observées dans les résultats obtenus à l'aide de divers groupements alkyles *secondaires*. Les réactivités des produits **4** et **6** vis-à-vis de l'hydration montrent que, dans un mélange neutre de H_2O/CH_3CN, le *c*-PrCPh=C=O est plus réactif que le *i*-PrCPh=C=O; ce résultat est principalement attribué à une taille plus petite du cyclopropyle. En milieu neutre, le *c*-Pr_2C=C=O et le Et_2C=C=O ont la même réactivité; toutefois, en milieu acide, le dérivé cyclique est 22 fois moins réactif et ce résultat est attribué à l'inhabilité des groupements β-cyclopropyles à stabiliser directement l'état de transition cationique de la protonation.

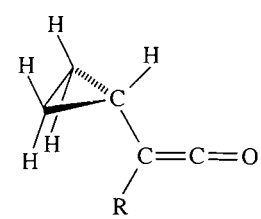
Mots clés : cyclopropylcétènes, cétènes, addition nucléophile, cinétique d'hydration.



[Traduit par la revue]

Introduction

The conjugative interaction of the cyclopropyl group with adjacent π-systems has long been a source of fascination to chemists (1*a*). Thus both vinylcyclopropane (**1**) (1*b*,*c*) and cyclopropanecarboxaldehyde (**2**) (1*d*) have favored conformations in which the cyclopropane ring is bisected by the plane of the adjacent sp^2 carbon, so that π-conjugation between the cyclopropane ring and the side chain is possible. In **1** the *s-trans* conformation shown is favored with a 2.9 kcal/mol barrier (1*b*) to rotation to a non-bisected *gauche* conformation 1.2 kcal/mol (1*b*) higher in energy. The *s-trans* conformation is favored by π-conjugation whereas the *gauche* conformation is favored by reduced non-bonding interactions involving H^2, H^3, and H^8, and by entropy (1*c*). The π-stabilization is estimated as 1.4 kcal/mol (1*c*). For **2** there is a slight preference for the *syn* conformer shown in the gas phase with a 4.3 kcal/mol barrier for conversion to the *anti* conformer (1*d*).



1

2

Cyclopropylketenes (**3**) combine some of the structural features of both **1** and **2**, and a conjugative interaction of the cyclopropyl group might be expected to stabilize ketenes, which are ordinarily prone to dimerization and reaction with various species (2). Surprisingly, however, there are only a few references to cyclopropylketenes in the literature, and these were generated as short-lived intermediates that usually reacted further under their conditions of formation (3) or were detected by their infrared spectra in cold matrices (3*c*) or in dilute solutions at room temperature (3*d*). Cyclopropylketene-derived products were also formed from a chromium carbene complex, but no evidence for the free ketene was obtained (3*f*). Because of our interest both in ketene chemistry (4) and in the conjugative properties of cyclopropane (1*a*) we have examined the preparation and properties of a few representative examples of these species with the goals of elucidating their electronic and chemical properties, providing a general route to their synthesis, and examining their synthetic utility.

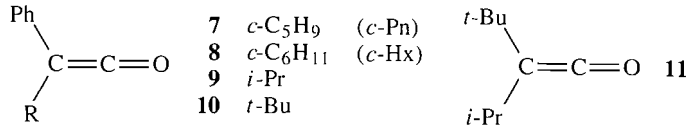
Results

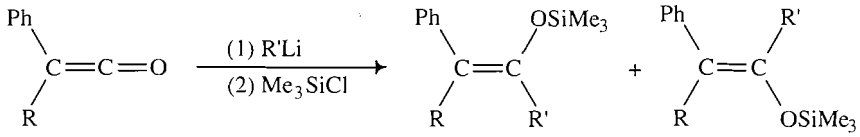
Phenylcyclopropylketene (**4**), *tert*-butylcyclopropylketene (**5**), and dicyclopropylketene (**6**) were readily prepared from the corresponding cyclopropyl ketones. Conversion of the ketones to the chain-extended carboxylic acids (5, 6) was equally satisfactory by use of the Wittig reagent $CH_3OCHPPh_3$ (*6a*) or a Peterson reaction with $CH_3OCH_2SiMe_3$ and *s*-BuLi (*6b*), following by hydrolysis of the intermediate methyl vinyl ether by HCO_2H/H_2O and oxidation with PDC (eq. [1]), in overall yields of about 40%. The acyl chlorides were obtained from the acids with $SOCl_2$ and converted to the ketenes by Et_3N in THF (eq. [2]). Ketene **5** was formed at reflux but **4** and **6** were

[1] *c*-PrCR=O $\xrightarrow[\text{or (1) } CH_3OCHLiSiMe_3\text{; (2) } H_3O^+]{\text{(1) } CH_3OCHPPh_3\text{; (2) } H_3O^+}$ *c*-PrCHRCH=O



[2] *c*-PrCHRCH=O $\xrightarrow[\text{(3) } Et_3N\text{, THF}]{\text{(1) PDC; (2) } SOCl_2}$ *c*-PrCR=C=O

R = Ph (**4**), *t*-Bu (**5**), *c*-Pr (**6**)



obtained by reaction at room temperature. After removal of the solvent *in vacuo* the ketenes were isolated, by vacuum distillation, as moderately stable yellow liquids in 32–55% yields based on the acyl chlorides.

Ketenes **4–6** were estimated to be greater than 95% pure by their ^1H nmr (200 MHz) spectra, and showed characteristic ir bands for the ketene carbonyl at 2097–2106 cm^{-1}, and uv maxima at 248, 240, and 280 nm ($\varepsilon \cong 10^4$) and 395, 373, and 376 nm ($\varepsilon < 100$) for **4**, **5**, and **6**, respectively. The ^1H and ^{13}C nmr spectra and mass spectra were consistent with the ketene structures, and correct high resolution exact mass parent ions were observed for **4** and **6**.

For comparison to **4–6**, phenylcyclopentylketene (**7**), phenylcyclohexylketene (**8**), phenylisopropylketene (**9**) (*4b*, *7a*), phenyl-*tert*-butylketene (**10**) (*4b*, *7b*), and *tert*-butylisopropylketene (**11**) (*7c*) were also prepared by dehydrochlorination of the acid chlorides by Et_3N (for **7–9** and **11**) or by dehydrohalogenation of the α-bromo acid chloride (for **10**).

Phenylcycloalkylketenes **4**, **7**, and **8** were added to solutions of *n*-BuLi (in hexane–THF) or of *t*-BuLi (in pentane) at −78°C and the resulting enolates were trapped with Me_3SiCl to give *Z*/*E* mixtures of silyl enol ethers **12–17** (eq. [3]). Stereochemical assignments for **12–17** were made based on the ^1H and ^{13}C nmr chemical shifts of the Me_3Si and *t*-Bu groups using the previously established (*4f*, *7d*) relation that the group *syn* to the phenyl group absorbed at higher field, and the *Z*/*E* ratios, estimated to be accurate to ±2%, were derived from the relative ^1H nmr peak areas, as summarized in eq. [3].

It was shown previously (*4f*) that the silylated enolates prepared similarly from phenylmethylketene and phenylethylketene were kinetic products and did not correspond to the product mixtures obtained under equilibrating conditions.

The reactions of **5** and **9–11** with *tert*-butyllithium followed by treatment with acetic anhydride or trimethylsilyl chloride gave the stereoisomeric enol acetates **18–22** or silyl enol ethers **23** and **24** in the *Z*/*E* ratios shown below in eq. [4].

[a] μ = 0.05 (NaCl).

The structures of **18**–**24** follow readily from their spectral properties. The only stereoisomers of **18** and **19** observed were assigned the *Z* configurations on the basis of the downfield ^{1}H nmr chemical shift observed for R^1 = *t*-Bu (δ 1.23 and 1.20, respectively), an effect attributed to the influence of the *syn* acetoxy group. For **20** the chemical shifts of these *t*-Bu groups were δ 1.19 and 1.07 for the structures assigned as *Z* and *E*, respectively, with the lower field signal assigned to the *t*-Bu *syn* to the acetoxy. For **21**–**24** the ^{1}H nmr chemical shifts of the *t*-Bu, CH_3CO, and $(CH_3)_3Si$ groups *syn* to the phenyl group have large upfield shifts relative to the stereoisomeric *anti* groups, as discussed previously (4*f*, 7*d*).

The hydration reactivities of **4** and **6** were measured in H_2O/CH_3CN mixtures, as these ketenes were too reactive for measurement by conventional means at 25°C in solely aqueous solutions. Rates in neutral H_2O/CH_3CN as a function of H_2O concentration, and in 20% H_2O/80% CH_3CN as a function of HCl concentration, were determined by uv as done previously (4*b*,*e*) and are reported in Table 2.

As found previously for other ketenes (4*b*,*e*), reasonable correlations of ketene reactivity with H_2O molarity were found: log k_{obsd} (**4**) = (0.0350 M^{-1} s^{-1}) [H_2O] − 0.901 s^{-1}, r = 0.992; log k_{obs} (**6**) = (0.0543 M^{-1} s^{-1}) [H_2O] − 1.89 s^{-1}, r = 0.998. The plots give extrapolated values of k_{obsd} for 100% (55.5 M) H_2O of 11.1 s^{-1} and 13.4 s^{-1}, respectively. The slope of the plot for **4** is less than that observed for other ketenes (4*b*,*e*) and by direct comparisons the ratio of k_{obs} for **4**/**6** has an average value of 5.8 (Table 2).

The reaction of **6** in 20% H_2O/CH_3CN was catalyzed by HCl with k_{obs} (**6**) = (1.46 M^{-1} s^{-1}) [HCl] + 0.0502 s^{-1}, with the intercept agreeing well with the measured value of k_{H_2O} = 0.0469 s^{-1}. Because of the high reactivity of **4** the value of k_{H^+} was approximated as 0.120 M^{-1} s^{-1} from the relation k_{obs} = k_{H^+}[HCl] + k_{H_2O} using the value of k_{obs} 0.400 s^{-1} at [HCl] = 1.21 M and a separately measured value of 0.255 s^{-1} for k_{H_2O}.

Discussion

The preparation of the cyclopropylketenes **4**–**6** (eqs. [1], [2]) provides a facile route to these interesting species, and other substituted cyclopropylketenes should be accessible by the same methodology. These ketenes show reasonable stability, in accord with the results of preliminary molecular orbital calculations (4*g*) at the 3-21G//3-21G level for the isodesmic reaction in eq. [5], which is calculated to be exothermic as shown by 1.9 kcal/mol. Thus cyclopropyl is predicted to be only modestly less stabilizing as a ketene substituent compared to methyl as opposed to a substituent on ethylene.

[5] *c*-PrCH=C=O + $CH_3CH=CH_2$ → *c*-PrCH=CH_2 + CH_3CH=C=O

The results of the alkyllithium additions to eqs. [3] and [4] show that cyclopropylketenes are also useful synthetic reagents for the preparation of enolate derivatives. These products should be useful for further synthetic transformations or for conversion to the corresponding ketones.

The *Z*/*E* selectivities for *n*-BuLi addition to the phenylcycloalkylketenes **4**, **7**, and **8** (eq. [3]) show that for the cyclopropyl and cyclopentyl substrates most of the product (79 and 88%, respectively) results from nucleophilic attack from the cycloalkyl substituted side, while for the cyclohexyl derivative this percentage drops to 44%. For *t*-BuLi there is a preference for addition to **4**, **7**, **8**, **9**, and **10** *syn* to the phenyl group. For the *secondary* alkyl groups this preference is 86 ± 5% independent of the alkyl group.

For consideration of the *Z*/*E* product ratios of these reactions, some measures of the steric size of some relevant substituents are given in Table 3 (8). These include the E_s parameter of Taft (8*a*), the Winstein–Holness *A* value (8*b*), the υ parameter of Charton (8*c*,*d*), Meyer's *G* and V^a parameters (8*e*), and the Ω parameter (8*f*).

The only steric parameter for cyclopropyl that has been reported is the Charton υ value of 1.06 (8*c*,*d*) but this value, derived from hydrolysis rates of a cyclopropane carboxylate ester, is recognized (8*d*) to contain a polar component and is not a reliable guide to the effective size of this group. By the use of the molecular mechanics program MacroModel (9*a*) we calculate an *A* value of 1.75 for this group, as $\Delta\Delta H_f^0$ between equatorial and axial cyclopropyl substituted cyclohexane or 4-*tert*-butylcyclohexane. Based on this value and those values

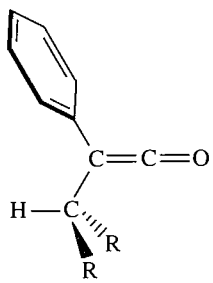
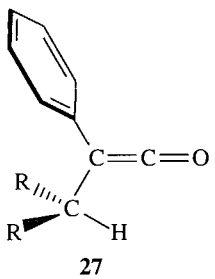
in Table 3, the order of effective sizes of secondary alkyl and cycloalkyl groups is *c*-Hx > *c*-Pn ≅ *i*-Pr > *c*-Pr. The effective size of phenyl is variable depending upon the direction of approach to the planar ring.



Notably none of the steric parameters in Table 3 predict the observed results for the stereochemistry of attack of the alkyllithiums on the ketenes. Not only are the predicted trends among the *secondary* alkyl groups not observed, but the preferred attack by *t*-BuLi *syn* to phenyl is not anticipated.

The preferred direction of attack of a nucleophilic reagent on a phenylcycloalkylketene is expected to result from the dynamic interplay of a variety of factors, including (a) conjugative stabilization of the ketene by the aryl group favoring coplanarity of the ring and the ketene; (b) steric interactions between the nucleophile and the phenyl group, which will be largest when the phenyl is planar, and smallest when it is perpendicular; (c) steric interactions between the cycloalkyl group and the phenyl group; (d) conjugation of the cyclopropyl group with the ketene; and (e) the effective size of the nucleophile.



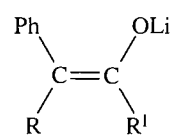
Some limiting conformations of phenylketenes with a *secondary* alkyl substituent are shown. For the ground state of the ketene, **25** is favored, as evidenced by molecular mechanics calculations. Conformations **26** and **27** represent those with

25

26

27

freest access to the carbonyl carbon by a nucleophilic reagent from the phenyl and alkyl sides, respectively, and likely resemble the conformation of the ketene in the actual transition state for nucleophilic addition.



Previous studies have shown a large variation in the stereoselectivity of attack on ketones as a function of the specific organolithium reagent used. Thus reaction of 7-oxabicyclo-[2.2.1]hept-5-en-2-one gave preferences for *exo* attack of 20:1, 11:1, 9:1, and 3.6:1 for CH_3, *n*-Bu, 1-hexynyl, and Ph lithium in Et_2O at 0°C, respectively (10*a*). There are a number of other examples where different organometallic reagents display different stereoselectivities (10*b*). The degree of aggregation of different organolithium reagents is known to vary widely and so it is not simple to evaluate the relative steric bulk of different organolithium reagents (10*b*, 11). There is also evidence that the stereochemistry of nucleophilic additions to ketones is affected by stereoelectronic factors, including the electronegativity of the alkyl portion of the organolithium reagent (10*c*).

TABLE 4. Calculated (MMX) heats of formation for lithium enolates PhCR=C(OLi)-*t*-Bu and *t*-BuC(*i*-Pr)=C(OLi)R

	ΔH_f^0 (kcal/mol)

t-Bu	46.19	35.45	10.74
t-BuC(*i*-Pr)=C(OLi)R			
H	37.76	37.55	0.21
t-Bu	−56.62	−45.86	−10.76

Another approach to the study of the stereochemistry of nucleophilic attack on ketones uses a combination of *ab initio* molecular orbital and molecular mechanics methods to predict the relative energies of the stereoisomeric transition states (10*d*,*e*). However, at its present state of development this method does not consider variations in the nucleophile.

The relative importance of steric approach control (or steric strain control) and product stability control have also been examined (10*f*). As a guide to the latter we have used the molecular mechanics program PCMODEL, which uses MMX, an enhanced version of the MMP2 force field (9*b*), to compare the product stability of stereoisomeric lithium enolates **28**, as shown in Table 4.

28*Z*

28*E*

The calculations predict that for PhCR=C(OLi)-*t*-Bu the *Z* isomer with *cis* *i*-Pr and *t*-Bu groups is more stable when R = *i*-Pr, but that for R = *t*-Bu the *E* isomer with the *t*-Bu groups *trans* is predicted to be more stable. In the addition

For personal use only.

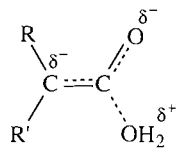
reactions (eq. [4]) the *E* isomer is favored in each case, although to a lesser extent for R = *i*-Pr.

For *t*-BuC(*i*-Pr)=C(OLi)R the calculations predict a slight preference for the *E* isomer with the *t*-Bu *cis* to the added H, whereas experimentally (eq. [4]) there is an 83:17 preference for formation of the *Z* isomer. For R = *t*-Bu the *Z* isomer is predicted to be favored, and this is the only product observed experimentally.

These calculations consider the products and not the transition states, and also ignore the solvent. Particularly in the case of the hydride addition, the reducing agent in the transition state is expected to be much more sterically demanding than the hydrogen in the product. Thus much more sophisticated calculations of the transition states will be needed to reliably predict the stereochemistry of these additions, but the present results do help delineate the complexity of the problem.

The generalization can be made that *t*-BuLi is less likely to add to phenylalkylketenes from the alkyl side compared to *n*-BuLi. However, the quantitative prediction of the stereochemistry of attack in these complex systems is beyond our present capability.

The reduction of *tert*-butylisopropylketene (**11**) by *tert*-butyllithium proceeds with an 83:17 selectivity for hydride delivery *syn* to the isopropyl group, whereas within the limits of detectability addition occurs exclusively from this direction. Hydride attack via a 6-membered transition state (**29**) is expected to have significantly lower steric demands than addition of a *tertiary* carbon nucleophile. There are previous examples of the reduction of ketenes by organometallic reagents and metal hydrides (2*d*, 4*d*).

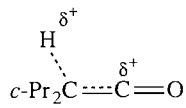


29

A referee has suggested that the stereoelectronic ("Cieplak") (10*c*) effects of the ketene substituents in $RR^1C{=}C{=}O$ may affect the stereochemistry of nucleophilic addition. Experiments to test this intriguing proposal have not been carried out.

Hydration reactivities

The hydration rate constants for *c*-PrCPh=C=O (**4**) (Table 2) with neutral H_2O in 20 and 30% H_2O are an average of 38 times greater than those of *i*-PrCPh=C=O (4*b*). The major cause of this greater reactivity of the cyclopropyl compound is presumably reduced steric crowding in the hydration transition state, which is proposed to resemble **30** (4*b*,*e*,*h*). The same interplay of steric factors involving the nucleophile and the ketene substituents, discussed above for organolithium additions, is expected to occur in the hydration. However, in the hydration the greater reactivity of the cyclopropyl derivative compared to the isopropyl analogue is in accord with the smaller size of the former group calculated by molecular mechanics. There is some evidence (1*a*) that cyclopropyl may stabilize developing negative charge, so an electronic factor may also contribute to the enhanced reactivity of the cyclopropyl derivative.



The extrapolated rate constant for *c*-PrCPh=C=O (**4**) in 100% neutral H_2O is 500 times less than that of 4700 s^{-1} for

30

PhCH=C=O (4*h*), indicating that there are significant steric repulsions for cyclopropyl compared to hydrogen. The rate constants of *c*-$Pr_2C{=}C{=}O$ (**6**) in 20, 30, and 50% H_2O/CH_3CN are almost identical to those of $Et_2C{=}C{=}O$ (4*e*), showing that the combined steric and electronic effects of these groups are the same in this process.

Comparison of k_{H^+} for *c*-$Pr_2C{=}C{=}O$ to that of 30.1 M^{-1} s^{-1} for $Et_2C{=}C{=}O$ in 20% H_2O/CH_3CN (4*e*) gives a rate ratio $k(Et_2C{=}C{=}O)/k(c\text{-}Pr_2C{=}C{=}O) = 21$. This result is consistent with results for cyclopropylalkenes (12), in which both *E* and *Z* *c*-PrCH=CH-*c*-Pr are less reactive than $CH_2{=}CH$-*c*-Pr, by an average factor of 30. These results are attributed (12) to ground state stabilization of the alkene by cyclopropyl and inductive destabilization of the cationic transition state resembling **31** by the cyclopropyl group, which cannot stabilize the developing positive charge by π-donation.

31

Summary

Cyclopropylketenes are readily accessible and rather persistent compounds. In reactions of organolithium reagents the stereochemical preferences for attack on ketenes bearing cyclopropyl substituents are comparable to those of other cyclic and acyclic secondary alkyl groups. This behaviour is not predicted by the steric parameters of the substituents or by molecular mechanics calculations of the product stabilities. In neutral hydration, cyclopropylketene **4** is more reactive than the isopropyl analogue, a result consistent with a smaller steric bulk for cyclopropyl. In acid hydration, the cyclopropyl group retards ketene hydration, as expected on the basis of inductive electron withdrawal by this group.

Experimental

Tetrahydrofuran (THF) and diethyl ether were distilled from sodium/benzophenone. Triethylamine and pentane were distilled from CaH_2 after refluxing overnight. Glassware was flame dried and cooled under N_2, and all reactions involving air-sensitive materials were conducted under a N_2 atmosphere. Spectra were measured using Varian T-60, Gemini 200, and (for **20***Z*) XL-400 nmr spectrometers, a Nicolet 5-DX ftir spectrophotometer, a Unicam AR25 Linear "Record" uv spectrophotometer, and VG-70-250S and AEI MS-30 mass spectrometers. Gas chromatographic analyses and separations were carried out using Varian 2700 flame ionization and Varian 90P instruments, respectively, with OV-17 columns unless noted.

2-Cyclopropyl-2-phenylacetic acid

At −78°C, *n*-BuLi (46.8 mL, 75 mmol, 1.6 M in hexane) was added dropwise to a suspension of (methoxymethyl)triphenylphosphonium chloride (25 g, 73 mmol) in 150 mL ether, which was then stirred 1 h at 0°C. Cyclopropyl phenyl ketone (7.16 g, 49 mmol) in 10 mL ether was added to this solution, which was then stirred 12 h at 25°C, poured into H_2O, and extracted with pentane. The organic layer was dried over Na_2SO_4, concentrated, and distilled (80–85°C, 2 Torr; 1 Torr = 133.3 Pa) to give an *E*/*Z* mixture of methyl 2-cyclopropyl-2-phenyl-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

vinyl ethers (6.40 g, 37 mmol, 75%), which was stirred overnight with 10 equivalents HCO_2H at 25°C, poured into H_2O, and extracted with ether. The ether extract was washed with H_2O and $NaHCO_3$, dried over $MgSO_4$, and concentrated to give crude 2-cyclopropyl-2-phenylacetaldehyde (5.92 g): ^{1}H nmr ($CDCl_3$) δ: 0.26 (m, 1), 0.39 (m, 1), 0.64 (m, 1), 0.75 (m, 1), 1.32 (m, 1), 2.80 (dd, J = 9.6 and 4.5 Hz, 1, PhCH), 7.3 (m, 5, Ph), and 9.68 (d, J = 4.5 Hz, 1, CHO).

To the above aldehyde in 50 mL ether was added dropwise a solution of $Na_2Cr_2O_7 \cdot 2H_2O$ (4.40 g), 2.72 mL of 98% H_2SO_4, and 18 mL of H_2O and the solution was stirred overnight, poured into water, and extracted with ether. The ether layer was extracted with NaOH and the aqueous layer was then acidified with HCl and extracted into ether. The ether solution was dried over $MgSO_4$ and evaporated to give the acid (2.00 g, 11.3 mmol, 30%), mp 89–91°C (lit. (*5a*) mp 92–93°C).

Other acids prepared similarly included dicyclopropylacetic acid (*5b*), 2-phenyl-3-methylbutanoic acid (*6a*), 2-phenyl-3,3-dimethylbutanoic acid (*6a*), and *2-cyclopropyl-3,3-dimethylbutanoic acid*, mp 48.5–50°C; ir (CCl_4): 1705 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.23 (m, 2), 0.50 (m, 1), 0.70 (m, 1), 1.05 (m, 1), 1.09 (s, 9, *t*-Bu), and 1.43 (d, J = 10.4 Hz, 1, CHCO); ms m/z: 156 (M^+, 0.3), 100 ($M^+ - C_4H_8$, 88), 57 (*t*-Bu$^+$, 100); hrms m/z calcd. for $C_9H_{16}O_2$ (M^+): 156.1150; found: 156.1159. This latter acid was obtained from the known ketone (*6f*). 2-Cyclopentyl- and 2-cyclohexylphenylacetic acids were obtained from Aldrich, and 2-isopropyl-3,3-dimethylbutanoic acid (*6c,d*) was obtained by the hydroboration/oxidation procedure of Newman *et al.* (*6e*). Some of the acids were also prepared by the use of $CH_3OCHLiSiMe_3$ (eq. [1]), as described previously (*4f*).

2-Cyclopropyl-3,3-dimethylbutanoyl chloride

To a solution of the acid (1.6 g, 10 mmol) in 20 mL CCl_4 was added $SOCl_2$ (50 mmol) dropwise at 25°C. The resulting mixture was stirred overnight, the solvent and excess reagent distilled at atmospheric pressure, and the product distilled (bp 45–46°C, 5 Torr): ir (CCl_4): 1795 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.34 (m, 2), 0.59 (m, 1), 1.08 (m, 1), 1.10 (s, 9, *t*-Bu), 1.96 (d, J = 10.4 Hz, 1, CHCO); ^{13}C nmr ($CDCl_3$) δ: 2.0, 7.1, 9.8, 28.0, 35.2, 73.1, 176.1; hrms m/z calcd. for $C_9H_{15}O$ ($M^+ - Cl$): 139.1119; found: 139.1074. The other acid chlorides were obtained similarly.

Phenylcyclopropylketene (4)

The acid chloride (2.00 g, 10.3 mmol) was dissolved in 30 mL of THF and Et_3N (7.2 mL, 51 mmol) was added at 0°C. The solution was allowed to warm to 25°C and stirred for 1.5 h more. The solvent was evaporated and the product distilled to give **4** (0.74 g, 46%) as a yellow oil: bp 50–52°C, 2 Torr; ir (CCl_4): 2102 (C=O) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 248, 395 nm; ^{1}H nmr ($CDCl_3$) δ: 0.46 (m, 2), 0.96 (m, 2), 1.54 (m, 1), 7.3 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: 4.4, 6.9, 44.7, 124.0, 124.3, 129.0, 133.5, 205.8; hrms m/z calcd. for $C_{11}H_{10}O$ (M^+): 158.0732; found: 158.0724.

tert-*Butylcyclopropylketene (5)* was prepared similarly, in 55% yield after 3.5 days reflux with Et_3N, as a yellow oil distilled at 25°C, 2 Torr; ir (CCl_4): 2097 (C=O) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 240, 373 nm; ^{1}H nmr ($CDCl_3$) δ: 0.28 (m, 2), 0.75 (m, 2), 1.14 (m, 1), 1.15 (s, 9, *t*-Bu); ^{13}C nmr ($CDCl_3$) δ: 3.8, 6.7, 30.1, 30.8, 46.9, 205.0.

Dicyclopropylketene (6) was prepared similarly, in 32% yield after 2 days stirring with Et_3N at 25°C, as a yellow oil distilled at 25°C, 2 Torr; ir (CCl_4): 2106 (C=O) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 280, 376 nm; ^{1}H nmr ($CDCl_3$) δ: 0.26 (m, 4), 0.66 (m, 4), 1.20 (m, 2); ^{13}C nmr ($CDCl_3$) δ: 5.5, 5.8, 46.1, 206.6; hrms m/z calcd. for $C_8H_{10}O$ (M^+): 122.0732; found: 122.0720.

Phenylcyclopentylketene (7) was obtained similarly in 54% yield: bp 82°C, 2 Torr; ir (CCl_4): 2095 (C=O) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 260, 385 nm; ^{1}H nmr ($CDCl_3$) δ: 1.40 (m, 2), 1.72 (m, 4), 2.13 (m, 2), 2.90 (m, 1), 7.3 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: 24.5, 32.3, 34.2, 45.8, 124.3, 124.8, 129.0, 133.4, 205.1; hrms m/z calcd. for $C_{13}H_{14}O$ (M^+): 186.1045; found: 186.1053.

Phenylcyclohexylketene (8) was obtained similarly in 50% yield: bp 110–112°C, 5 Torr; ir (CCl_4): 2091 (C=O) cm^{-1}; uv (CH_2Cl_2) λ_{max}: 264, 388 nm; ^{1}H nmr ($CDCl_3$) δ: 1.1–1.4 (m, 6), 1.8 (m, 2), 2.05 (m, 2), 2.45 (m, 1), 7.3 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: 25.9, 26.2, 32.5, 33.0, 41.0, 124.4, 124.9, 129.0, 132.4, 204.9; hrms m/z calcd. for $C_{14}H_{16}O$ (M^+): 200.1201; found: 200.1207.

Phenylisopropylketene (9) (*7a*) was obtained similarly in 38% yield after 12 h reflux with Et_3N: bp 90–94°C, 1.5 Torr: ir (CCl_4): 2096 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.20 (d, J = 6.5 Hz, 6, CH*Me*$_2$), 2.80 (septet, J = 6.5 Hz, 1, CH), 7.0 (m, 5, Ph).

*Phenyl-*tert*-butylketene (10)* (*7b*)

2-Phenyl-3,3-dimethylbutanoyl chloride (1.0 g, 4.7 mmol) was refluxed with Br_2 (1.5 g, 9.4 mmol) in 10 mL CCl_4. The CCl_4 was distilled and distillation gave the α-bromoacyl chloride (1.3 g, 4.6 mmol, 98%). A portion of this (1.0 g, 3.4 mmol) was added dropwise in 5 mL THF to a suspension of activated Zn dust (0.42 g, 6.4 mmol) in 15 mL of THF and refluxed 10 h. The solution was filtered through glass wool with N_2 pressure and the solvent evaporated. Distillation (73–76°C, 5 Torr) gave **10** (0.35 g, 2.0 mmol, 59%): ir (CCl_4): 2097 (C=O) cm^{-1}; ^{1}H nmr (CCl_4) δ: 1.22 (s, 9, *t*-Bu), 7.14 (s, 5, Ph).

tert-*Butylisopropylketene (11)* (*7c*) was obtained from the acyl chloride (0.15 g, 0.8 mmol) after overnight refluxing with Et_3N in THF. The solution was filtered and evaporated to give crude **11** (0.067 g, 0.48 mmol, 60%), which was purified by vpc (20% OV-17, 100°C): ir (CCl_4): 2090 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_4$) δ: 1.13 (d, J = 7 Hz, 6, CH*Me*$_2$), 1.15 (s, 9, *t*-Bu), 1.74 (septet, J = 7 Hz, 1, CH).

General procedure for reaction of ketenes with n-*BuLi*

To a solution of 30 mL of THF and *n*-BuLi (8.0 mmol, 1.6 M in hexane) at −78°C was added dropwise 2.0 mmol of ketene in 10 mL of THF. The mixture was stirred for 1 h at −78°C, and Me_3SiCl (10 mmol) was added in one portion. The solution was allowed to warm to room temperature, and stirred overnight. The solvent was evaporated, pentane was added, and the solution was removed from the residual white solid by filtration. Evaporation of the solvent left an oil, which was analyzed and purified by vpc. The Z/E isomers of **12–14** were not separated, but spectral assignments were made on the mixtures. For **12***E*, **13***E*, and **14***E* only the Me_3Si peaks in the ^{1}H nmr could be assigned with confidence, at δ 0.28, 0.25, and 0.26, respectively.

*(Z)-1-Cyclopropyl-1-phenyl-2-trimethylsilyloxy-1-hexene (12*Z*)*

Reaction of phenylcyclopropylketene (**4**) (0.25 g, 1.55 mmol) in 30 mL of THF with *n*-BuLi (6.33 mmol) gave 0.38 g of a crude oil by the procedure above. Preparative vpc gve **12***Z* (0.14 g, 0.49 mmol, 31%): ir (CCl_4): 1641 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: −0.14 (s, 9, Me_3Si), 0.16 (m, 2), 0.65 (m, 2), 0.97 (t, J = 7.0 Hz, 3, CH_3), 1.0–2.0 (m, 5), 2.40 (t, J = 7.8 Hz, 2, C=CCH_2), 7.3 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: −0.2, 3.5, 6.2, 12.3, 13.9, 22.5, 29.3, 32.5, 120.9, 125.6, 127.4, 130.4, 140.0, 149.8; hrms m/z calcd. for $C_{18}H_{28}OSi$ (M^+): 288.1909; found: 288.1935.

*(Z)-1-Cyclopentyl-1-phenyl-2-trimethylsilyloxy-1-hexene (13*Z*)* was isolated similarly in 30% yield: ir (CCl_4): 1646 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: −0.18 (s, 9, Me_3Si), 0.95 (t, J = 6.9 Hz, 3, CH_3), 1.2–1.8 (m, 12), 2.24 (t, J = 7.7 Hz, 2, C=CCH_2), 2.81 (m, 1), 7.2 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: −0.05, 13.9, 22.4, 24.5, 29.7, 31.5, 32.0, 41.8, 65.2, 112.4, 125.8, 127.6, 128.6, 128.8, 131.0, 147.0; hrms m/z calcd. for $C_{20}H_{32}OSi$ (M^+): 316.2222; found: 316.2217.

(Z)/(E)-1-Cyclohexyl-1-phenyl-2-trimethylsilyloxy-1-hexene (14) were obtained similarly and were separated by vpc (OV-17, 240°C). **14***Z*: ir (CCl_4): 1644 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: −0.19 (s, 9, Me_3Si), 0.96 (t, 3, J = 7.3 Hz, CH_3), 1.0–1.8 (m, 14), 2.23 (t, 2, J = 7.7 Hz, C=CCH_2), 2.81 (m, 1), 7.2 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: −0.2, 13.8, 22.2, 25.7, 26.6, 29.6, 31.5, 32.5, 40.3, 126.0, 127.5, 130.8, 139.9, 146.5. **14***E*: ir (CCl_4): 1644 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.26 (s, 9, Me_3Si), 0.75 (t, 3, J = 7.2 Hz, CH_3), 1.0–1.8 (m, 14), 2.23 (t, J = 7.7 Hz, 2, C=CCH_2), 2.40 (m, 1), 7.1 (m, 5, Ph); hrms m/z calcd. for $C_{21}H_{34}OSi$ (M^+): 330.2379; found: 330.2373.

For personal use only.

General procedure for reactions of ketenes **4–6** *with* t-*BuLi*

To *t*-BuLi (6.0 mmol) in 30 mL pentane at −78°C was added 1.50 mmol of neat ketene. The mixture was stirred for 2 h at −78°C, the pentane was evaporated, and 15 mL of THF was added. The resulting solution was then quenched with TMSCl or Ac_2O and stirred overnight, the THF was evaporated, and the residue was extracted with pentane and filtered. Evaporation of the pentane gave the crude product, which was then purified by vpc. The minor *Z* isomers of **15–17** were not isolated, but in the ^{1}H nmr the Me_3Si signals at δ −0.29, −0.30, and −0.30 and *t*-Bu signals at 1.34, 1.28, and 1.28 for **15***Z*, **16***Z*, and **17***Z*, respectively, could be assigned with confidence.

*(*E*)-1-Cyclopropyl-3,3-dimethyl-1-phenyl-2-trimethylsilyloxy-1-butene (***15***E)*

The reaction of phenylcyclopropylketene (**4**) (0.30 g, 1.90 mmol) by the procedure above and purification by vpc gave **15***E* (0.14 g, 0.48 mmol, 26%): ^{1}H nmr ($CDCl_3$) δ: 0.1 (m, 2), 0.33 (s, 9, Me_3Si), 0.5 (m, 2), 0.86 (s, 9, *t*-Bu), 1.96 (m, 1), 6.1 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: 0.9, 3.7, 13.8, 30.4, 37.9, 126.5, 127.1, 132.0, 137.6, 154.2; ms *m/z*: 273 ($M^+ - CH_3$).

*(*E*)-1-Cyclopentyl-3,3-dimethyl-1-phenyl-2-trimethylsilyloxy-1-butene (***16***E)*

The reaction of cyclopentylphenylketene (**7**) (0.34 g, 1.83 mmol) by the procedure above and purification by vpc gave **16***E* (0.16 g, 0.51 mmol, 28%): ir (CCl_4): 1616 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.31 (s, 9, Me_3Si), 0.84 (s, 9, *t*-Bu), 1.0–1.7 (m, 8), 3.10 (m, 1), 7.2 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: 1.1, 24.3, 30.3, 30.9, 31.2, 41.9, 126.3, 127.1, 132.4, 139.6, 153.3, hrms *m/z* calcd. for $C_{20}H_{32}OSi$ (M^+): 316.2222; found: 316.2218.

*(*E*)-1-Cyclohexyl-3,3-dimethyl-1-phenyl-2-trimethylsilyloxy-1-butene (***17***E)*

The reaction of cyclohexylphenylketene (**8**) (0.30 g, 1.5 mmol) by the procedure above and purification by vpc gave **17***E* (0.12 g, 0.39 mmol, 26%): ^{1}H nmr ($CDCl_3$) δ: 0.34 (s, 9, Me_3Si), 0.83 (s, 9, *t*-Bu), 0.9–1.2 (m, 10), 2.75 (m, 1), 7.2 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: 1.1, 25.8, 26.6, 30.6, 31.3, 39.4, 126.0, 126.8, 131.7, 136.0, 139.9, 152.0; hrms *m/z* calcd. for $C_{21}H_{34}OSi$ (M^+): 330.2379; found: 330.2392.

*(*Z*)-3-Acetoxy-4-cyclopropyl-2,2,5,5-tetramethyl-3-hexene (***18***Z)*

tert-Butylcyclopropylketene (**5**) (0.25 g, 1.81 mmol) was added dropwise to a solution of *t*-BuLi (9.1 mmol) in 20 mL of pentane at 0°C. The mixture was stirred at 25°C for 0.5 h and was refluxed for 24 h. The pentane was evaporated and 15 mL of THF was added followed by Ac_2O (1.03 mL, 10.9 mmol) in 10 mL of THF and the mixture was stirred overnight at 25°C. Then 10% HCl was added and the mixture was extracted with pentane; the organic layer was washed with $NaHCO_3$, H_2O, and brine, and was dried over $MgSO_4$. The solvent was evaporated and preparative vpc gave **18***Z* (0.08 g, 0.34 mmol, 19%): ir (CCl_4): 1748 (C=O), 1603 (C=C) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.73 (m, 2), 0.77 (m, 2), 1.22 (s, 9, *t*-Bu), 1.23 (s, 9, *t*-Bu), 1.35 (m, 1), 2.12 (s, 3, CH_3); ^{13}C nmr ($CDCl_3$) δ: 13.7, 21.4, 27.2, 30.0, 30.8, 37.3, 39.0, 136.7, 154.7, 170.1; cims *m/z*: 239 ($M^+ + 1$), 197 ($M^+ - C_3H_5$), 179 ($M^+ - OAc$).

Reaction of tert-*butylisopropylketene (***11***) with* tert-*butyllithium followed by acetic anhydride*

A solution of **11** was generated from the acyl chloride (0.5 g, 2.8 mmol) and Et_3N (0.85 g, 8.4 mmol) in THF as previously described. The filtered ketene solution was transferred to a solution of *t*-BuLi (1.7 M, 8.4 mmol) in 40 mL THF at −78°C. After stirring for 4 h at this temperature, the enolate solution was transferred with a double-tipped needle to a flask containing Ac_2O (0.86 g, 8.4 mmol) at 10 mL of THF at −78°C. The mixture was warmed to 25°C and worked up as before. The crude product (0.38 g, 1.9 mmol, 70%) was separated by vpc (140°C) and gave a 1:5 ratio of **19**/**20**.

The addition was also done in pentane by preparing the ketene in THF, removing the THF under vacuum, and redissolving the ketene in pentane. This solution of ketene in pentane was added at 0°C to a solution of *t*-BuLi (1.7 M, 8.4 mmol) in 20 mL of pentane. The mixture was stirred for 30 min at 0°C and transferred to a flask containing Ac_2O in THF at −78°C. The mixture was warmed to 25°C, poured into saturated aqueous Na_2CO_3, and worked up as before. The **19**/**20** product ratio as determined by vpc (140°C) was 2:1.

*(*Z*)-2,2,5,5-Tetramethyl-3-acetoxy-4-isopropyl-3-hexene (***19***)*: ir (CCl_4): 1746 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.16 (s, 9, *t*-Bu), 1.17 (d, *J* = 7.3 Hz, 3, CH_3), 1.20 (s, 9, *t*-Bu), 1.22 (d, *J* = 7.3 Hz, 3, CH_3), 2.10 (s, 3, OAc), 3.29 (septet, *J* = 7.3 Hz, 1, CH); ^{13}C nmr ($CDCl_3$) δ: 21.6, 21.9, 30.7, 31.9, 37.1, 37.5, 139.7, 151.4, 170.6; hrms *m/z* calcd. for $C_{15}H_{28}O_2$ (M^+): 240.2089; found: 240.2092.

*(*Z*)-1-Acetoxy-2-isopropyl-3,3-dimethyl-1-butene (***20***Z)*: ir (CCl_4): 1755 (C=O) cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.08 (d, *J* = 6.8 Hz, 6, *i*-Pr), 1.19 (s, 9, *t*-Bu), 2.14 (s, 3, OAc), 2.44 (septet, *J* = 6.8 Hz, 1, $CHMe_2$), 6.92 (s, 1, CHO); ^{13}C nmr ($CDCl_3$) δ: 21.1, 21.2, 24.8, 29.8, 35.2, 130.5, 137.7, 167.7; hrms *m/z* calcd. for $C_{11}H_{20}O_2$ (M^+): 184.1463; found: 184.1455. **20***E*: ^{1}H nmr ($CDCl_3$) δ: 1.07 (s, 9, *t*-Bu), 1.14 (d, *J* = 8 Hz, 6, $CHMe_2$), 2.15 (s, 3, OAc), 2.36 (septet of d, *J* = 8, 1 Hz, 1, $CHMe_2$), 6.95 (d, *J* = 1 Hz, 1, C=CH).

*(*E/Z*)-2,2,5-Trimethyl-3-acetoxy-4-phenyl-3-hexene (***21***)*

A solution of **9** (0.5 g, 3.1 mmol) in 5 mL of anhydrous THF was added to a solution of *t*-BuLi (1.7 M in hexane, 6.2 mmol) in 30 mL of THF at −78°C. The solution was stirred at this temperature for 5 h, and then added via a double-tipped needle to a solution of acetic anhydride (1.2 g, 12.0 mmol) in 10 mL of THF at −78°C. The solution was warmed to 25°C, poured into saturated Na_2CO_3, and stirred for 20 min. The product was extracted with ether, dried over $CaSO_4$, and concentrated under vacuum. The crude product was separated by vpc (20% TCEP, 150°C) to give **21** *Z*/*E* (0.62 g, 2.4 mmol, 77%) in a 1:4.3 ratio. **21***Z*: ir (CCl_4): 1749 (C=O) cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.94 (d, *J* = 7.5 Hz, 6, $CHMe_2$), 1.27 (s, 9, *t*-Bu), 1.38 (s, 3, OAc), 3.23 (septet, *J* = 7.5 Hz, 1, $CHMe_2$), 7.1 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: 19.9, 20.8, 21.0, 28.2, 29.9, 35.6, 126.1, 127.2, 129.6, 135.2, 137.4, 150.2, 169.8; hrms *m/z* calcd. for $C_{17}H_{24}O_2$ (M^+): 260.1776; found: 260.1761. **21***E*: ir (CCl_4): 1754 (C=O) cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.81 (d, *J* = 8 Hz, 6, $CHMe_2$), 0.88 (s, 9, *t*-Bu), 2.18 (s, 3, OAc), 2.76 (septet, *J* = 8 Hz, 1, $CHMe_2$, 7.19 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: 20.8, 21.0, 30.0, 30.3, 37.7, 127.2, 127.4, 131.7, 134.0, 136.7, 149.6, 169.9; hrms *m/z* calcd. for $C_{17}H_{24}O_2$ (M^+): 260.1776; found: 260.1773.

The silyl enol ethers **23** *Z*/*E* were prepared similarly by adding Me_3SiCl (12.3 g, 12.2 mmol) to the enolate solution generated from **9** and *t*-BuLi at 0°C. The mixture was warmed to 25°C, stirred for 2 h, filtered to remove LiCl, and the THF was removed under vacuum to give **23** *Z*/*E* in 78% crude yield, in a *Z*/*E* ratio of 1:6, as estimated by ^{1}H nmr. **23***Z*: ^{1}H nmr ($CDCl_3$) δ: −0.30 (s, 9, Me_3Si), 0.95 (d, *J* = 7 Hz, 6, *i*-Pr), 1.28 (s, 9, *t*-Bu), 6.8–7.1 (m, 5, Ph). **23***E*: ^{1}H nmr ($CDCl_3$) δ: 0.32 (s, 9, Me_3Si), 0.80 (d, *J* = 7 Hz, 6, *i*-Pr), 0.87 (s, 9, *t*-Bu), 3.12 (septet, *J* = 7 Hz, 1, CH), 7.08 (m, 5, Ph).

Phenyl-*tert*-butylketene (**10**) was reacted with *t*-BuLi in THF as described for phenyl-*i*-propylketene (**9**). Further reaction with Ac_2O in THF gave *(*E*)-2,2,5,5-tetramethyl-3-acetoxy-4-phenyl-3-hexene* (**22**) in 71% crude yield, which was purified by vpc (200°C): ir (CCl_4): 1754 (C=O) cm^{-1}; ^{1}H nmr (CCl_4) δ: 0.84 (s, 9, *t*-Bu), 0.98 (s, 9, *t*-Bu), 2.13 (s, 3, OAc), 7.2 (m, 5, Ph); ^{13}C nmr ($CDCl_3$) δ: 21.6, 30.7, 31.0, 36.1, 38.3, 126.5, 126.8, 131.5, 136.9, 139.5, 151.9, 170.5; hrms *m/z* calcd. for $C_{18}H_{26}O_2$ (M^+): 274.1933; found: 274.1939.

Crude **24***E* (65%) was prepared similarly by reaction with Me_3SiCl in THF and purified by vpc (150°C): ^{1}H nmr ($CDCl_3$) δ: 0.37 (s, 9, Me_3Si), 0.79 (s, 9, *t*-Bu), 1.02 (s, 9, *t*-Bu), 7.0 (m, 5, Ph).

For reactions of **9** and **10** carried out in pentane/hexane, *t*-BuLi in hexane was added to the ketenes in pentane as above. After warming to 25°C the solvent was evaporated and 10 mL anhydrous THF was added, and the solutions were quenched with Ac_2O or Me_3SiCl. Reaction of **9** gave **21** in a *Z*/*E* ratio of 1:5.4 as determined by vpc, and **23** in a *Z*/*E* ratio of 1:6, as determined by ^{1}H nmr.

The photochemistry of EDA complexes in micellar solutions. II. The stilbene–methylviologen system in the presence of oxygen

M. HAMITY AND R. H. LEMA

Universidad Nacional de Río Cuarto, Departamento de Química y Física, 5800 Río Cuarto, Córdoba, Argentina

Received February 23, 1990

M. HAMITY and R. H. LEMA. Can. J. Chem. **69**, 146 (1991).

The photolyses of electron donor–acceptor (EDA) complexes formed between both *cis*-stilbene (cS) and *trans*-stilbene (tS) as donors and methylviologen (MV^{+2}) as acceptor have been carried out in homogeneous ethanolic and in micellar sodium dodecyl sulfate (SDS) solutions, in the presence of oxygen. The stilbene loss quantum yields (Φ_{-S}) have been determined in both media. Quantum yields were observed to be dependent upon methylviologen concentration and the acidity of media. A reaction scheme is proposed, which accounts for experimental results and can be related to the photochemistry of MV^{+2} and its cation radical $MV^{\bullet+}$.

Key words: EDA complexes, micelles, methyl viologen, stilbene.

M. HAMITY et R. H. LEMA. Can. J. Chem. **69**, 146 (1991).

Opérant en solution éthanolique homogène et en solutions micellaires de dodécylsulfate de sodium (DSS), en présence d'oxygène, on a effectué la photolyse de complexes donneur–accepteur d'électrons (EDA) entre le *cis*-stilbène (cS) ou le *trans*-stilbène (tS) comme donneurs et le viologène de méthyle (MV^{2+}) comme accepteur. On a déterminé les rendements quantiques de perte de stilbène (Φ_{-S}) dans les deux milieux. On a observé que les rendements quantiques varient avec la concentration de viologène de méthyle et l'acidité du milieu. On propose un mécanisme réactionnel qui tient compte des données expérimentales et qui peut être relié à la photochimie du MV^{2+} et de son cation radicalaire $MV^{\bullet+}$.

Mots clés : complexes EDA, micelles, viologène de méthyle, stilbene.

Introduction

The photochemistry of stilbenes has been extensively studied (1). The major part of the experimental work in this field has been carried out in homogeneous solution by direct excitation (2, 3) and sensitization (4–6). Some attention has been given to reactions produced by photoexcitation of charge-transfer complexes formed by stilbenes with neutral organic molecules (7, 8).

The *cis*- and *trans*-stilbene cation radicals, ($cS^{\bullet+}$ and $tS^{\bullet+}$) have been proposed as intermediates in the photooxygenation of cS and tS (9) and in the *cis–trans* photoisomerization of cS (10). Both of them, generated via electron transfer reactions, have been detected and characterized (11–14).

Eriksen and Foote (9) obtained photoisomerization and photooxygenation of cS and tS, sensitized by 9,10-dicyanoanthracene in oxygenated acetonitrile, with benzaldehyde (Bzal) as the major oxygenation product. They proposed a mechanism in which the stilbene radical cation $S^{\bullet+}$, formed by electron transfer to excited dicyanoanthracene, reacted with superoxide ion $O_2^{\bullet-}$, produced by the reaction of oxygen with the dicyanoanthracene radical anion, to yield oxygenation products. Lewis *et al.* (10) confirmed for this system that the major photooxygenation product is Bzal and they found that oxygen enhances tS to cS photoisomerization in the polar solvent acetonitrile. They also report that, when the solvent is changed to benzene, oxygen increases 9,10-dicyanoanthracene photosensitized isomerization of both cS and tS, but no oxygenation products are observed. The latter effect is similar to that previously found on tS to cS isomerization via the exciplexes of tS with amines and fumaronitrile, attributed to oxygen-catalyzed intersystem crossing to excited triplet tS (15, 16).

In a previous work we carried out the photolysis, exciting the absorption charge transfer band, of the EDA complexes formed by cS and tS with MV^{+2} in micellar SDS solution and, for the sake of comparison, in homogeneous ethanolic solutions, in the absence of oxygen (17). We report here the results obtained by photolysis of the same systems in the presence of oxygen and the influence exerted on quantum yields by methylviologen concentration and the acidity of the media. We also consider here the possible relationship between the latter effects and the photoreactions of MV^{+2} in the presence of oxygen, studied earlier by several research groups (18, 19).

Experimental

Materials

Commercial methylviologen dichloride (Sigma), *trans*-stilbene (Schuchardt München), and *cis*-stilbene (Koch-Light) were used without further purification. The purity grade of both stilbenes was >99% by GLC.

Sodium dodecyl sulfate (B.D.H.) was washed with diethyl ether and recrystallized from ethanol.

Absolute stilbene loss quantum yields

All the samples, in a 1-cm square quartz cell, were irradiated under similar conditions, at λ >400 nm, with a Philips 1000-W quartz halogen lamp as the light source and a Melles Griot GG 400 filter. The solutions were magnetically stirred, solvent-saturated oxygen was continuously bubbled, and the temperature was maintained at (25 ± 0.1)°C. The concentrations used were as follows. Stilbenes: 1.3×10^{-2} M in 95% ethanol and 6×10^{-4} M in 0.1 M SDS; MV^{+2} was varied between 5×10^{-4} and 5×10^{-3} M in 0.1 M SDS and between 1×10^{-3} M and 2.4×10^{-2} M in ethanol. Ethanolic solutions with HCl concentrations between 0.5×10^{-5} and 1×10^{-5} M were obtained by dilution in 95% ethanol of concentrated commercial hydrochloric acid. In SDS micellar solution, the acidity was varied by adding dilute HCl to obtain a value of pH that was measured with a glass electrode and a Radiometer pHM 64 pH meter. Uranyl oxalate was used as actinometer (20). Oxalate loss was determined by titration with $KMnO_4$.

Stilbene concentrations were monitored by GLC with a Varian 2800 chromatograph using an OV-101 on Chromosorb G H/P 100–120 mesh column. The samples in SDS micellar solutions were treated, after irradiation, with $CaCl_2$ to precipitate SDS and then with *n*-pentane, containing *n*-dodecane as external standard, to extract organic components and separate them from water-soluble MV^{+2} (21). Prior to irradiation, *n*-dodecane was added as internal standard to ethanolic

5.00	—	27.3
1.00	—	53.1

solutions, which were then photolyzed and chromatographed. The estimated error in quantum yields is 10%.

Results and discussion

Photoreactions of cS complex in ethanol could not be detected under our experimental conditions. In 0.1 M SDS micellar solutions, in turn, the photoisomerization product was obtained, but the quantum yield was appreciably lower than that determined in the absence of oxygen (17) and it was observed to be influenced by acidity of the medium.

Quantum yields for tS loss (Φ_{-tS}) were evaluated in both media. Furthermore, the effect of MV^{+2} concentration and the acidity of the medium was studied.

Photolysis of the EDA complexes in ethanol

In the photolysis of the tS EDA complex, photoisomerization and oxygenation products were detected. During these experiments, an absorption band ($\lambda_{max} \sim 400$ nm) and a fluorescence band ($\lambda_{max} \sim 530$ nm) appeared, whose intensities increased with photolysis time and decreased with acidity of the medium. We believe that these bands are generated from certain products of secondary reactions of methylviologen that have already been observed by several authors (18, 19). Mau *et al.*, in particular, exciting the absorption band of MV^{+2} ($\lambda < 320$ nm) to produce methylviologen cation radical $MV^{\bullet+}$, observed the generation of a green fluorescence, the excitation and emission maxima wavelengths of which are similar to those observed by us and whose intensity decreased with increasing acidity of the solution (19).

In our experiments, tS concentration was kept constant and, to study the effect of secondary reactions, medium acidity (added HCl) or MV^{+2} concentration were varied. Table 1 shows the influence of both acid and methylviologen concentration on quantum yield.

Benzaldehyde (Bzal) was the main product in stilbene photooxygenation reactions (9, 10). In our experiments, the Bzal detected was not enough to get a mass balance. For this reason and to check for the occurrence of secondary reactions, we carried out the photolysis of the tS EDA complex under similar conditions, but with Bzal (0.1 M) added, and we observed an appreciable benzaldehyde consumption. Ethanolic solutions prepared with the same concentrations of Bzal alone and Bzal/tS did not evidence physical or chemical changes. However, a solution containing Bzal and MV^{+2} showed an absorption band ($\lambda_{max} \simeq 430$ nm) and a fluorescence band ($\lambda_{max\ excit} \simeq 440$ nm and $\lambda_{max\ em} \simeq 530$ nm), which disappeared by photolyzing at $\lambda > 400$ nm.[1]

According to the results outlined above, we believe that photolysis of the EDA complex of *trans*-stilbene with MV^{+2}, in the presence of oxygen, yields isomerization and oxygenation products, mainly benzaldehyde, which in turn undergoes secondary photoreactions with MV^{+2}. It is worth note that the fluorescence produced during the photolysis of the EDA complex is not due, at least in part, to the same species as that produced by mixing Bzal and MV^{+2}, because the latter disappears under photolysis, while the former increases with increasing irradiation time.

The following reaction scheme is presented to account for the above detailed experimental results:

$$tS + MV^{+2} \underset{}{\overset{K_{eq}}{\rightleftharpoons}} C \qquad (C = \text{EDA complex})$$

$$C + h\nu \xrightarrow{I_a} C^*$$

$$C^* \xrightarrow{k_0} (tS^{\bullet+} + MV^{\bullet+})$$

[1] $$(tS^{\bullet+} + MV^{\bullet+}) \xrightarrow{k_1} tS + MV^{+2}$$

[2] $$(tS^{\bullet+} + MV^{\bullet+}) \xrightarrow{k_2} tS^{\bullet+} + MV^{\bullet+}$$

[3] $$tS^{\bullet+} + MV^{\bullet+} \xrightarrow{k_3} tS + MV^{+2}$$

[4] $$MV^{\bullet+} + O_2 \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} MV^{+2} + O_2^{\bullet-}$$

[5] $$tS^{\bullet+} + O_2^{\bullet-} \xrightarrow{k_5} (tS\ldots O_2) \begin{cases} \rightarrow cS + O_2 \\ \rightarrow tS + O_2 \\ \rightarrow P_{ox.} \end{cases}$$

[6] $$MV^{+2} + O_2^{\bullet-} \xrightarrow{k_6} P_{GF}$$

[7] $$H^+ + O_2^{\bullet-} \xrightarrow{k_7} P$$

The EDA complex C is formed in the first step, for which the equilibrium constant value (K_{eq}) has been already measured (17). The complex is then excited through the absorption of a photon and produces the ionic radical pair in the solvent cage with a rate constant k_0. Solvent cage escape in step [2] competes with deactivation by step [1]. The free radical ions can either recombine (step [3]) or react, $MV^{\bullet+}$ with O_2 to give the superoxide ion $O_2^{\bullet-}$ (step [4]) and $tS^{\bullet+}$, by step [5], to give an intermediate ($tS\ldots O_2$), which in turn renders isomerization and oxygenation products.

The methylviologen ion (step [6]) and the added acid (step [7]) compete with $tS^{\bullet+}$ for the superoxide ion, thus leading to inhibition of reaction step [5] and therefore to a lowering of Φ_{-ts}, as is experimentally observed (Table 1). The quantum yield of stilbene loss is given as

[8] $$\Phi_{-tS} = \eta_c \cdot \eta_r$$

where

[9] $$\eta_c = \frac{k_2}{k_2 + k_1}$$

and

[10] $$\eta_r = \frac{k_5[O_2^{\bullet-}]}{k_5[O_2^{\bullet-}] + k_3[MV^{\bullet+}]}$$

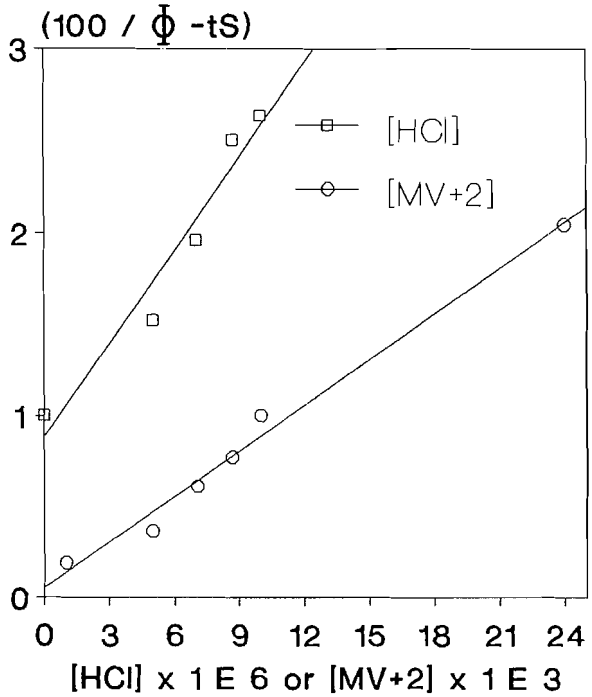

FIG. 1. Inverse of *trans*-stilbene loss quantum yield as a function of hydrochloric acid concentration (correlation coefficient $f_c = 0.974$) and methylviologen concentration ($f_c = 0.994$) in ethanol.

are the efficiencies of generation and of reaction, respectively, of $tS^{\bullet+}$. The rate constant for the reaction between $MV^{\bullet+}$ and O_2 was reported as $k_4 = 7.7 \times 10^8\ M^{-1}$ (23). According to this figure and notwithstanding the value of k_3, we can assume $k_4[O_2] \gg k_3[tS^{\bullet+}]$, because $[O_2] \gg [tS^{\bullet+}]$. Using steady state kinetics and taking $1 \gg \eta_r$, we obtain the following equation for stilbene loss quantum yield Φ_{-tS} and the concentration terms [HCl] and $[MV^{+2}]$:

$$[11] \quad (\Phi_{-tS})^{-1} = a[MV^{+2}] + b[HCl] + (\eta_c)^{-1}$$

where

$$[12] \quad a = \frac{k_3 k_6}{\eta_c k_4 k_5 [O_2]}$$

and

$$[13] \quad b = \frac{k_3 k_7}{\eta_c k_4 k_5 [O_2]}$$

By plotting the inverse of Φ_{-tS} vs. [HCl] at a constant methylviologen concentration and vs. $[MV^{+2}]$ without HCl added, a straight line is obtained in both cases, Fig. 1. The intercept of either line gives the η_c value, which is 0.19 ± 0.02. This is the maximum quantum yield for this system and, according to the proposed mechanism, represents the efficiency of solvent-cage escape for the photogenerated radical ion pair.

From the slopes of both lines, the ratio of rate constants for steps [7] and [6] of the reaction scheme can be obtained as

$$[14] \quad \frac{b}{a} = \frac{k_7}{k_6} = 2.04 \times 10^3$$

These steps correspond to the reactions of $O_2^{\bullet-}$ with H^+ and MV^{+2}, respectively, by which the two latter species are supposed to influence Φ_{-tS} as inhibitors. The value obtained in eq. [14] is in accord with the fact that higher concentrations of MV^{+2} than of HCl must be used to obtain a similar effect on quantum yield.

TABLE 2. *trans*-Stilbene loss quantum yields at several methylviologen concentrations and bulk water-phase proton concentrations in 0.1 M SDS solution at constant analytical concentration of $tS = 6 \times 10^{-4}$ M

$[MV^{+2}]_0\ 10^3$ M	$[MV^{+2}]_m\ 10^2$ M	$[H^+]_w\ 10^6$ M	$\Phi_{-tS}\ 10^3$
1.00	7.22	11.60	1.43
1.00	7.22	7.94	1.61
1.00	7.22	6.31	1.71
0.50	3.61	3.98	3.23
1.00	7.22	3.98	1.90
1.25	8.98	3.98	1.52
1.40	10.10	3.98	1.45

It is noteworthy that steps [4] and [6] in the proposed reaction scheme constitute a simplified mechanism for the photoreaction of MV^{+2} with O_2, yielding fluorescent products via methylviologen radical cation $MV^{\bullet+}$ (18, 19, 24, 25). Leest (24) has proposed that the reaction of $MV^{\bullet+}$ with O_2 regenerates MV^{+2} and takes place in two steps, the first equivalent to step [4] in our reaction scheme and a second slow step, $MV^{\bullet+}$ with $O_2^{\bullet-}$ to yield MV^{+2}. On the other hand, the dependence of Φ_{-tS} on methylviologen concentration suggests that MV^{+2} can react with $O_2^{\bullet-}$ as in step [6], yielding oxidation products from which can arise, at least in part, the green fluorescence observed. Finally, step [7] of the scheme, where HCl is competing with MV^{+2} for $O_2^{\bullet-}$, can account for the dependence of the green fluorescence upon solvent acidity, as observed by Mau *et al.* (19).

Photolysis of EDA complexes in SDS

The photolysis of the tS EDA complex was carried out using constant analytical concentrations of tS and SDS and changing pH (with HCl) or MV^{+2} concentration, as shown in Table 2. The influence of medium acidity and $[MV^{+2}]$ on quantum yield is similar to that observed in ethanol.

When a solution of tS EDA complex containing Bzal (10^{-3} M) is photolyzed, an increase of Bzal concentration is observed, in contrast to the consumption detected in ethanolic solution. A solution of Bzal (10^{-3} M) and MV^{+2} did not show chemical or physical changes similar to those observed in ethanol.

A fluorescence band with λ_{max} at 530 nm, which increased with irradiation periods and decreased with medium acidity, was detected in SDS, but its emission intensity was rather lower than that measured in ethanolic solutions.

The plots of inverse of tS loss quantum yields versus proton or methylviologen concentration are linear, as shown in Fig. 2. This is indicative that the reaction scheme presented to explain the experimental results in ethanol can also be used in SDS solutions. For micelle-bound reactants, as with MV^{+2} and the stilbenes (17), the concentration in the micellar pseudo-phase is given by

$$[MV^{+2}]_m = \frac{[MV^{+2}]_0 - [MV^{+2}]_w}{\bar{V} \cdot [SDS]_m} \simeq \frac{[MV^{+2}]_0}{\bar{V} \cdot [SDS]_m}$$

where the subscripts m, 0, and w indicate micellar, total, and water concentrations, respectively; $\bar{V}$ is the molar volume of micellized detergent; and $[SDS]_m$ is the micellized detergent concentration, i.e., ($[SDS]_0$ − cmc), where cmc is the critical micelle concentration. The values used were $\bar{V} = 0.14$ L/mol and cmc $= 1 \times 10^{-3}$ M (17).

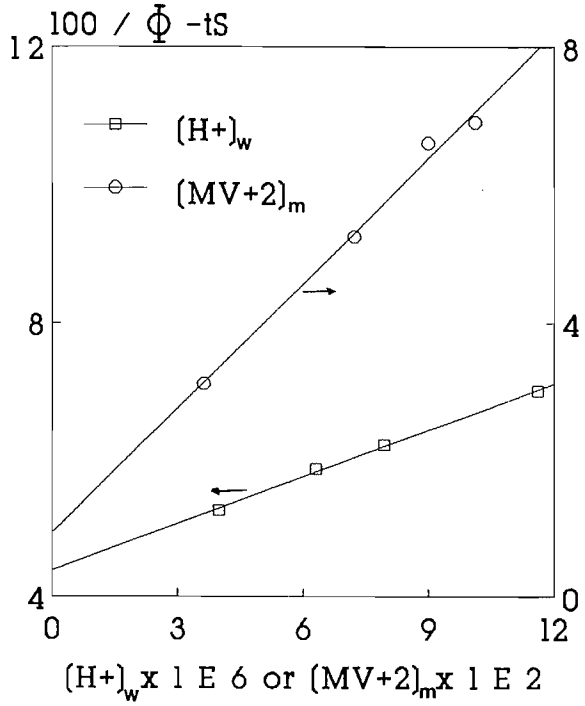

FIG. 2. Inverse of *trans*-stilbene loss quantum yield as a function of bulk water-phase proton concentration (correlation coefficient f_c = 0.999) and micellar-phase methylviologen concentration (f_c = 0.996) in 0.1 M SDS solution.

The medium acidity is given through the bulk water proton activity $a_H{}^w = 10^{-pH} \simeq [H^+]_w$, where pH is measured by a glass electrode. The local interfacial proton activity $a_H{}^m \simeq [H^+]_m$, at the surface of charged micelles, can be expressed by the following equation (26, 27):

$$[15] \quad [H^+]_m = [H^+]_w \cdot \exp -(F\Psi/RT) = [H^+]_w \cdot f$$

where F is Faraday's constant, R is the general gas constant, T is the temperature, and Ψ is the interfacial potential. The value of Ψ depends heavily on the completeness of the binding to the micelles of the probe molecule. When a lipoid dye, closely bound to SDS micelles, is employed, a value of −134 mV is obtained, but using a probe that takes part in an equilibrium at the micelle–water interface, the measured value for SDS micelles is −27 mV (27). Accordingly, eq. [11] can be rewritten as

$$(\Phi_{-tS})_m^{-1} = a_m[MV^{+2}]_m + b_m f[H^+]_w + (\eta_{cm})^{-1}$$

where a_m and b_m are micellar system parameters. From the plot in Fig. 2, the value of the slope a_m is 6.06×10^3 M^{-1}, which is similar to the corresponding ethanol parameter ($a = 7 \times 10^3$ M^{-1}).

According to eq. [12], a is a function of $\eta_c[O_2]$ and therefore, since $a \simeq a_m$, $\eta_c[O_2] \simeq \eta_{cm}[O_2]_m$. In ethanol, $[O_2] = 2.07 \times 10^{-3}$ M and, if $[O_2]_m$ is assumed to be nearly the same as the solubility of oxygen in water (2.65×10^{-4} M) (28), it can be concluded that the efficiency of solvent cage escape in SDS micellar solution (η_{cm}) is higher than that in ethanol (η_c). The mean value obtained from the intercepts of both lines in Fig. 2 is $\eta_{cm} = 0.44$, while from Fig. 1 a value of $\eta_c = 0.19$ was obtained.

If the mechanism in SDS micellar solutions is the same as in ethanol, the ratio of parameters b_m/a_m is approximately the same as that in eq. [14] for b/a in ethanol. From the value of the ratio of the slopes in Fig. 2 ($b_m f/a_m$) and making use of the previous assumption, we obtain $f = 1.8$. This nearly corresponds to the interfacial potential $\Psi = -27$ mV (27). Taking account of the pH value measured for SDS solutions without added acid (Table 2), the local interfacial pH calculated from eq. [15] is 5.1, which is similar to the generally accepted SDS micelle/water interface pH value (≃5).

[a]In the absence of oxygen.

Experiments with the cS EDA complex were carried out under experimental conditions similar to those for the tS complex. As shown in Table 3, oxygen inhibits the photoreaction of cS (17). An increase of medium acidity decreases this inhibition. A possible explanation is that the radical cation $cS^{\cdot+}$, from the equivalent of step [2] of the reaction scheme, converts irreversibly to $tS^{\cdot+}$:

$$(cS^{\cdot+} + MV^{\cdot+}) \xrightarrow{k_2'} cS^{\cdot+} + MV^{\cdot+}$$

$$cS^{\cdot+} \xrightarrow{k_{isom}} tS^{\cdot+} \longrightarrow tS$$

The radical ion $O_2^{\cdot-}$ can inhibit this reaction path by reacting with $cS^{\cdot+}$ through the equivalent to step [5]:

$$cS^{\cdot+} + O_2^{\cdot-} \xrightarrow{k_5'} (cS\ldots O_2) \longrightarrow cS + O_2$$

Both species, MV^{+2} and H^+, competing with $cS^{\cdot+}$ by $O_2^{\cdot-}$ (steps [6] and [7]), favor the isomerization sequence. This is shown in Table 3 for the case of protons: a decrease in pH supresses the inhibition by oxygen and the quantum yield is raised near to the value obtained in the absence of oxygen.

Conclusions

The results obtained in this work and those reported in a previous paper (17) indicate the occurrence of stilbene radical cation $S^{\cdot+}$ in the photoisomerization and photooxygenation of stilbene by excitation of the stilbene/methylviologen EDA complex.

The *trans*-stilbene radical cation $tS^{\cdot+}$, being much more stable than $cS^{\cdot+}$, is not expected to isomerize. This is confirmed by the lack of photoreaction of the tS complex in the absence of oxygen (17).

Since $cS^{\cdot+}$ is expected to undergo irreversible isomerization (1, 10), the lack of reaction of cS complex in ethanol, with and without oxygen in solution, suggests that the recombination of the radical ion pair in the solvent cage prevents cage escape and subsequent reactions of $cS^{\cdot+}$ · SDS micelles show a catalytic effect on this isomerization process, probably through the stabilization of the radical cation, as has already been observed in micellar systems for radical ions (22). The cS to tS isomerization process is observed in SDS both in the absence and in the presence of oxygen, with lower quantum yield in the latter case. This inhibition by oxygen is probably caused by the trapping of

For personal use only.

$cS^{\bullet+}$ by $O_2^{\bullet-}$ to regenerate starting material. The effect of HCl supports this assumption: the quantum yield is increased, predictably due to step [7], i.e., the reaction of acid with $O_2^{\bullet-}$.

On the other hand, the radical cation $tS^{\bullet+}$, which does not isomerize on its own, gives isomerization as well as oxidation products in the presence of oxygen. According to step [5] of our mechanism, the reaction products could be obtained through an intermediate ($tS...O_2$), which, in contrast to ($cS...O_2$), is reactive enough to give isomerization (probably through internal rearrangement) and oxidation products like Bzal (through a cleavage process). Acid added, in this case, produces a decrease in Φ_{-tS}, and MV^{+2} acts similarly, the probable reason in both cases being reaction with $O_2^{\bullet-}$ (steps [6] and [7]).

Our reaction scheme postulates the superoxide ion radical $O_2^{\bullet-}$ as an intermediate that is common to the reactions of both $S^{\bullet+}$ and MV^{+2}. The latter is proposed to undergo a reaction step (step [6]) as a probable route to fluorescent product generation.

Finally, secondary reactions of the benzaldehyde with MV^{+2} account for the lack of mass balance in stilbene photoreaction. We are currently studying the photochemistry of the benzaldehyde–methylviologen system.

We have investigated polarographically the dependence of the dioxygen yield on the concentration of 2,4-dinitrophenol in photooxidation of water in an octane/water system containing hydrated oligomer of chlorophyll, a water-soluble electron acceptor ferricyanide and a buffer. A linear correlation between the rate of dioxygen evolution and the photopotential at the interface between the two liquid phases is observed. Investigation of the dependences of photopotential and rate of dioxygen evolution on the dielectric permittivity of the nonaqueous phase has shown that with increasing dielectric permittivity, one can observe a decrease in both the reaction rate and the potential difference. The lifetime of chlorophyll in the course of water photooxidation reaction has been measured.

Key words: chlorophyll, oxygen, water photooxidation, oil/water interface, artificial photosynthesis.

Faisant appel à la polarographie, on a étudié la relation entre le rendement en dioxygène et la concentration de 2,4-dinitrophénol lors de la réaction de photo-oxydation de l'eau dans un système octane/eau contenant un oligomère hydraté de la chlorophylle, un ferricyanure soluble dans l'eau et accepteur d'électrons et un tampon. On a observé l'existence d'une corrélation linéaire entre la vitesse d'évolution du dioxygène et le photopotentiel à l'interface des deux phases liquides. Une étude sur les relations entre le photopotentiel ou la vitesse d'évolution du dioxygène et la permittivité diélectrique de la phase non-aqueuse montre qu'une augmentation de la permittivité diélectrique conduit à une diminution tant de la vitesse de la réaction que de la différence de potentiel. On a mesuré le temps de vie de la chlorophylle au cours de la réaction de photo-oxydation de l'eau.

Mots clés : chlorophylle, oxygène, photo-oxydation de l'eau, interface huile/eau, photosynthèse artificielle.

Introduction

Chemical models of photosynthesis are used for investigation of two types of reactions. In the photosynthesis processes the standard Gibbs free energy of a reaction is positive, and solar energy is used to perform work. In photocatalytic processes the free energy is negative and solar energy is used to overcome the activation barrier.

The interface between two immiscible liquids with immobilized photosynthetic pigments can serve as the simplest model of the biological membrane convenient for investigation of photoprocesses that are accompanied by spatial separation of charges.

It was shown previously by investigating the mass spectra, as well as polarographically on a dropping mercury electrode and on a Clark-type electrode, that illumination of the octane/water interface with visible light in the presence of chlorophyll and proton acceptor pentachlorophenol (PCPh) or 2,4-dinitrophenol (DNPh) in octane and an electron acceptor (NAD^+, $NADP^+$, or $K_3[Fe(CN)_6]$) in water there is evolution of dioxygen from water (1–12). In this case it appeared that with the evolution of one dioxygen molecule four ferricyanide molecules are reduced, and the reaction can be written as

$$[1] \quad 2H_2O + 4[Fe(CN)_6]^{3-} = O_2 + 4[Fe(CN)_6]^{4-} + 4H^+$$

This process is accompanied by the appearance of a photopotential at the octane/water interface and seems to occur on the interface since the photopotential and reaction rate are proportional to the surface concentration of chlorophyll and are independent of the thickness of both the aqueous and octane phases. Investigation of the action spectrum (the rate of dioxygen evolution) has shown that it reproduces the absorption spectrum of hydrated oligomer of chlorophyll (3, 5–8).

The rate of the reaction, accompanied by charge transfer through the interface of two immiscible liquids, as well as the corresponding variation in the interfacial potential difference depend on the dielectric permittivity of the nonaqueous phase (13–18). In this paper we have investigated experimentally the influence of the nature of a nonaqueous solvent on the photopotential and the rate of evolution of molecular dioxygen. It is known that at high concentrations, chlorophyll in nonaqueous solvents is aggregated: tetramers and dimers in dry octane, dimers in benzene and methylbutyl ketone, but appear as monomers or colloid particles in more polar solvents (19). A study of the influence of dielectric permittivity of the nonaqueous phase on the reaction course gives a clue for the interpretation of the mechanism.

Materials and methods

The Volta potential was measured by the vibrating electrode method

in the chain (1–10):

[2]	Au	Air	Oil proton acceptor chlorophyll	Water electron acceptor buffer	Water saturated with KCl	Hg_2Cl_2, Hg

and recorded automatically by a KSP-4 recorder.

The dioxygen, evolved from oil/water system after exposed to light, was determined in a polarographic cell by the usual plotting of polarization curves of oxygen reduction on a dropping mercury electrode dipped in aqueous solution. The duration of dioxygen evolution was also measured using a Clark-type electrode that was designed in the All-Union Institute of Medical Equipment. The diameter of the platinum cathode of the PL-2 grade was 20 μm and the gas-permeable polypropylene membrane (Radiometer, Denmark) was 25 μm thick. The indicator solution is a phosphate buffer. The electrode temperature coefficient is not in excess of 1.5% per °C, which practically rules out the influence of temperature effects on the action spectra. The electrode provided measurement of the oxygen concentration up to 10^{-8} M. The cell with the Clark-type electrode was illuminated by a KGM-300 W iodine incandescent lamp through a water filter and interference light filters ($\lambda_{0.5}$ = 10 nm). For determining the number of incident quanta we used a thermoelement and a ferrooxalate actinometer as described previously (4–8).

Solvents with different dielectric permittivity were chosen as the nonaqueous phase: octane, decane, benzene, methylbutyl ketone, nitrobenzene, and propylene carbonate. The proton acceptor PCPh or DNPh was distributed among the aqueous and organic phases since it was added 24 h before the experiment. Chlorophyll a and a water-soluble acceptor of electrons were introduced just before the start of the experiment. All solutions were prepared with twice-distilled water; and salts were twice-recrystallized. DNPh, PCPh, and potassium ferrocyanide were three times recrystallized by conventional techniques. Chlorophyll a was isolated by the familiar method (20) from nettle and was purified by a sucrose column.

The cell for polarographic measurements was thermostated and before the experiment was blown through to remove oxygen. Experiments were carried out at 20°C.

Results and discussion

During the illumination of the octane/water system containing chlorophyll, DNPh, and ferricyanide, photooxidation of water and evolution of molecular dioxygen occurs. Figure 1 presents the dependence of the concentrations of dioxygen evolved on the concentration of proton acceptor, DNPH, in octane, at different times of light exposure.

If chlorophyll and $K_3[Fe(CN)_6]$ are added to the equilibrated octane/water system containing 2,4-dinitrophenol, illumination at the interface results in a photopotential (Fig. 2) which depends on the wavelength and intensity of the incident light, as well as on the concentration of all reaction components. No photopotential appeared if both solvents, octane and water, were not previously equilibrated and mutually saturated.

Figure 2 presents the results of measurement of the photopotential in the chain (1) and the dependence of the rate of dioxygen evolution on the DNPh concentration. It is evident from Fig. 2 that there is a correlation between the rate of dioxygen evolution and the photopotential value. This signifies that the reaction (1) occurs directly at the interface between water and oil and is accompanied by the spatial separation of charges. Such a correlation between the rate of the charge transfer reaction and the variation in the interfacial potential difference is consistent with the phenomenological theory, developed earlier, of catalytic reactions at the interface between two immiscible liquids (13, 14).

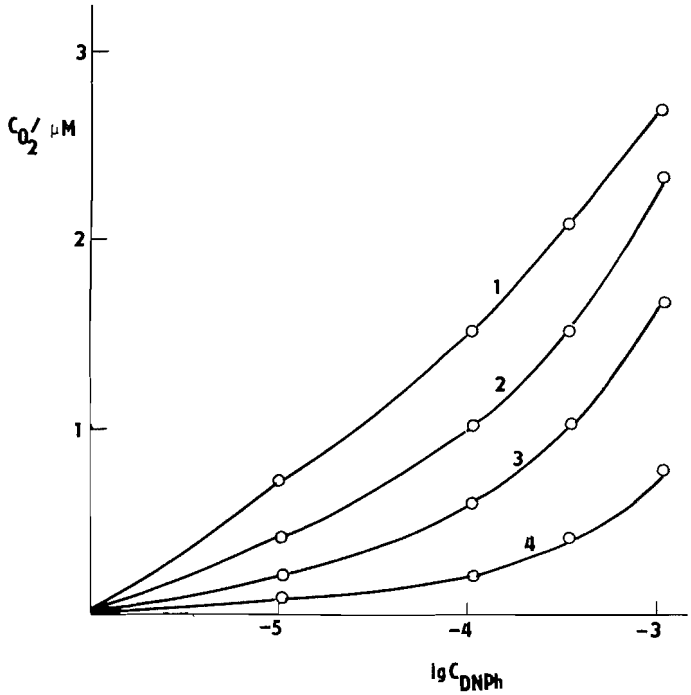

FIG. 1. Dependences of the concentration of dioxygen evolved under illumination on the DNPh concentration. Medium: octane/water, 2×10^{-6} M chlorophyll, 5×10^{-2} M $K_3[Fe(CN)_6]$, 2×10^{-2} M Tris-HCl, pH 7.4. Exposure time: *1*, 60 min; *2*, 45 min; *3*, 30 min; *4*, 15 min. Light intensity is 100 mW/cm^2.

According to the molecular mechanism of photooxydation of water in the octane–water system, as proposed in refs. 9 to 12, DNPh acts as a surface buffer capable of accepting protons, evolved in the course of the reaction (1), and thereby protecting chlorophyll against pheophytinization. DNPh, adsorbed at the interface octane/water, dissociates into $DNPh^-$ and H^+, charging octane negatively relative to water. The change in the Volta potential in the chain (1) as a result of the adsorption of DNPh at the interfaces octane–water or decane/water is −0.2 V. At the start of the photoreaction $DNPh^-$ accepts protons evolved and results in a positive photopotential corresponding to the transfer of protons from water to DNPh anions adsorbed at the interface.

Figures 3 and 4 present the dependences of the photopotential on the time of equilibration between octane and the aqueous phase. The time of contact is the time that has elapsed from the instant of addition of octane to the aqueous phase. Octane, preequilibrated for 24 h with the aqueous phase containing a Tris-HCl buffer at pH 7.4, will be called for brevity "wet". The "dry" octane was not previously in contact with the aqueous phase. It was demonstrated in ref. 3 that the reaction of water oxidation is catalyzed by a hydrated chlorophyll oligomer which is formed in the octane saturated with water. In the case of a brief contact with water for a few minutes, the adsorption spectra show no significant formation of aggregates and the adsorption layer at the interface is formed predominantly from "dry" monomeric chlorophyll. Under these conditions no evolution of dioxygen occurs and, as can be seen from Figs. 3 and 4 (curves 2), no photopotential appears either.

If chlorophyll is dissolved in water-saturated octane, immediately after the preparation of a two-phase system an additional maximum at 742 nm (3, 9, 10) appears; this peak belongs to the hydrated oligomer of chlorophyll. The molecular mechanism of water photooxidation by the hydrated oligomer of chlorophyll

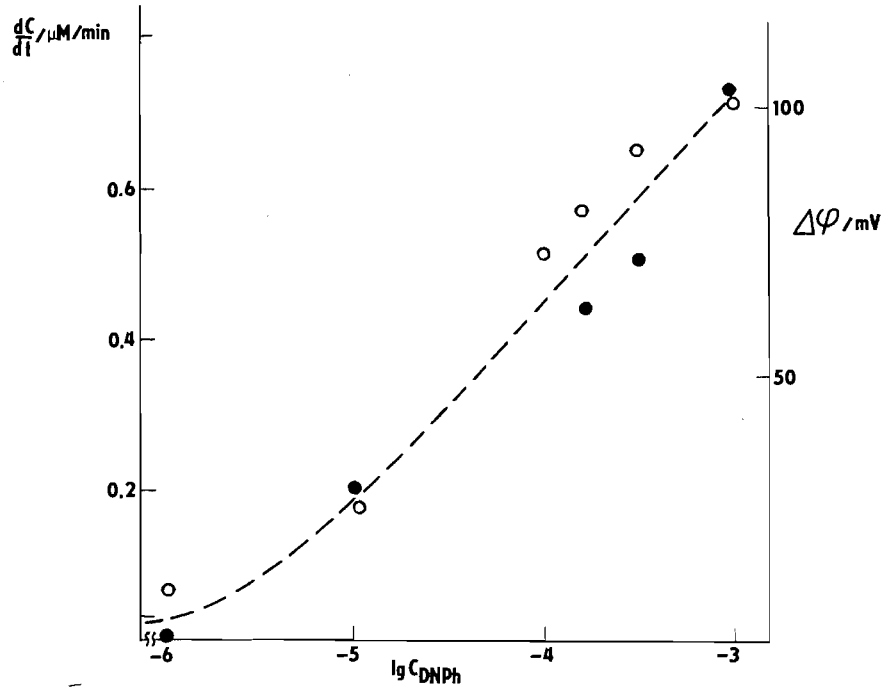

FIG. 2. Dependences of the rate of dioxygen evolution (●) and photopotential generation (○) on the DNPh concentration. The conditions are the same as in Fig. 1.

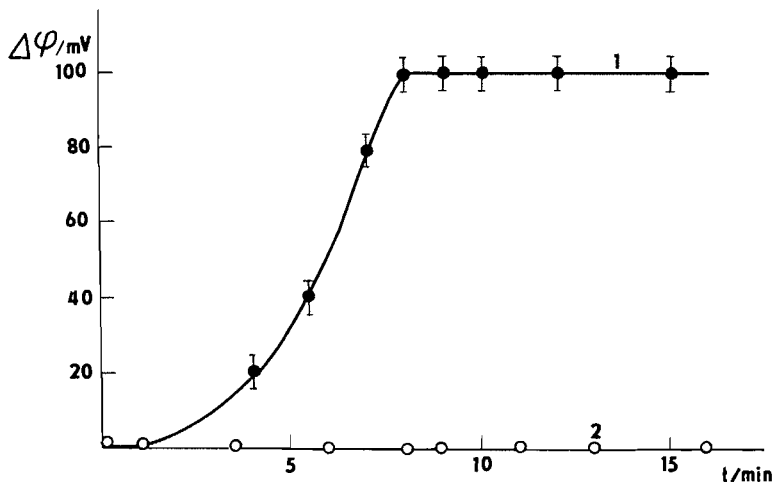

FIG. 3. Dependences of the photopotential, measured in the chain (*2*), on the time of contact of DNPh-free "wet" (*1*) and "dry" (*2*) octane with the aqueous phase. Octane contains 2×10^{-6} chlorophyll a. The aqueous phase contains 10^{-3} M DNPh, 2×10^{-2} M $K_3[Fe(CN)_6]$, 2×10^{-2} M Tris-HCl; pH 7.4.

was proposed in refs. 9 and 10. In all our experiments the photoevolution of molecular dioxygen and the generation of a photopotential were observed only when hydrated oligomers of chlorophyll is present in the system. The hydrated oligomers consist of 4–6 chlorophyll molecules and a few water molecules as shown by circular dichroism spectra (3).

To elucidate the role of DNPh, the results of the experiments are displayed in Figs. 3 and 4 (curve 1). In the first experiment (Fig. 3) DNPh was dissolved beforehand in the aqueous phase but was not added to the "wet" octane. In this case the photopotential appears immediately and increases monotonically for 5 to 10 min, then reaches its limiting value. The characteristic time of increase in the photopotential is limited by the diffusion of DNPh from water to octane. Since the volume of the aqueous phase is 10 times as large as that of octane the DNPh concentration in octane reaches a fairly high value in accordance with the distribution coefficient.

In the second experiment (Fig. 4) DNPh was dissolved beforehand in the "wet" octane but was not added to the aqueous phase. Under illumination a photopotential appeared but after approximately 5 min vanished because of the extraction of DNPh from a small amount of octane (1 mL) into the aqueous phase (10 mL).

Thus the presence of DNPh is indeed necessary in the octane phase for a photopotential to appear. We have detected no photooxidation of water to molecular dioxygen in the absence of a proton acceptor in the nonaqueous phase. As a proton acceptor one can use DNPh, pentachlorophenol, and uncouplers of oxidative phosphorylation.

Special experiments were carried out to determine how the

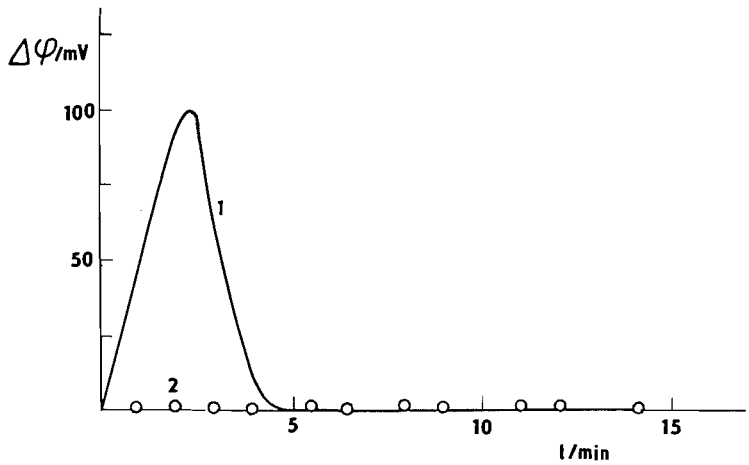

FIG. 4. Dependence of the photopotential, measured in the chain (2), on the time of contact of "wet" (1) and "dry" (2) octane with the aqueous phase. Octane contains 10^{-3} M DNPh and 2×10^{-6} M chlorophyll. The aqueous phase contains 2×10^{-2} M $K_3[Fe(CN)_6]$ and 2×10^{-2} M Tris-HCl and pH 7.4.

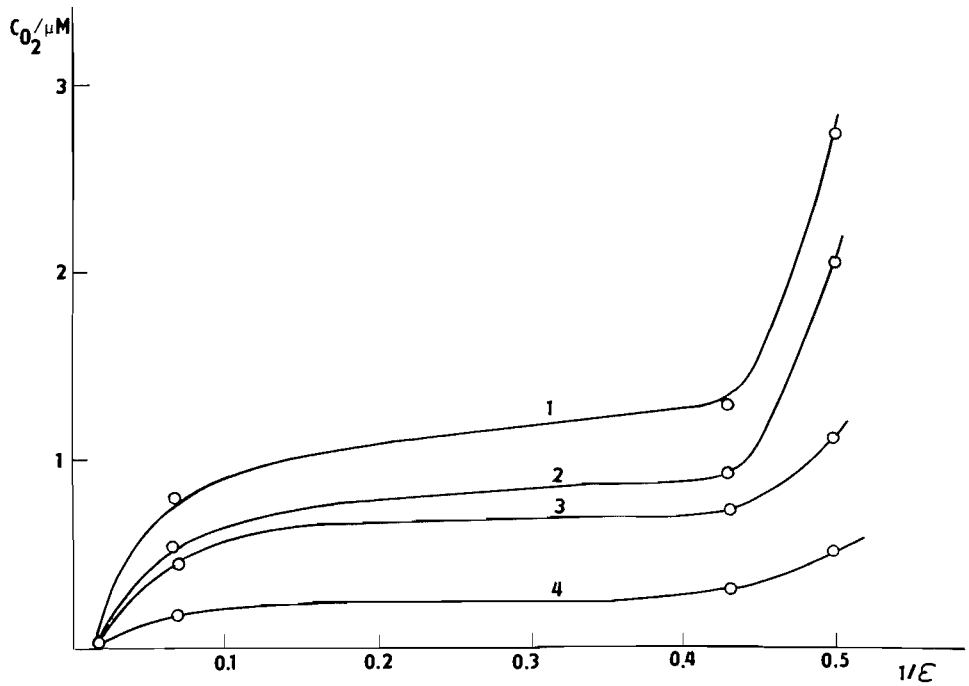

FIG. 5. Dependence of the dioxygen concentration on the dielectric permittivity of the nonaqueous phase ϵ. The medium: oil/water, 10^{-6} M chlorophyll, 10^{-3} M DNPh, 5×10^{-2} M $K_3[Fe(CN)_6]$, 2×10^{-2} M Tris-HCl, pH 7.4. Exposure time: *1*, 60 min, *2*, 45 min; *3*, 30 min; *4*, 15 min.

dielectric permittivity of a nonaqueous phase affects the rate of dioxygen evolution and photopotential. Figure 5 presents the dependence of the concentration of dioxygen evolved on the dielectric permittivity of the nonaqueous solvent, which were obtained at different exposure times. With increasing dielectric permittivity of the organic phase, the dioxygen yield abruptly decreases. Figure 6 is a comparison of the rate of dioxygen evolution and of the photopotential on the dielectric permittivity of a solvent immiscible with water. First of all it should be noted that in the same way as is evident from Fig. 2, there exists a correlation between the photopotential value and the reaction rate. The change in the Volta potential in the chain (2) under illumination, i.e. the photopotential at the octane/water interface, seems to reflect the change in the rate of the photoredox reaction which occurs at the interface.

In accordance with the theory of an elementary act of charge transfer through the interface of two immiscible liquids (13–18, 21, 22), the reaction rate constant in the approximation of Marcus (22, 23) is determined by the following expression

$$[3] \quad k = \frac{\omega}{2\pi} \mathcal{Y} \exp\left[-\frac{U_i}{kT} - \frac{(E_s + \Delta I + U_f - U_i)^2}{4E_s kT} \right]$$

where ω is the effective frequency, $\mathcal{Y}$ is the transmission coefficient, E_s is the energy of reorganization of the solvent, ΔI is the Gibbs energy of the reaction in separating the reagents and the reaction products to infinity, and U_i and U_f are the energies of bringing the reagents together and of separating the reaction products, respectively.

At high substrate concentrations, in accordance with the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

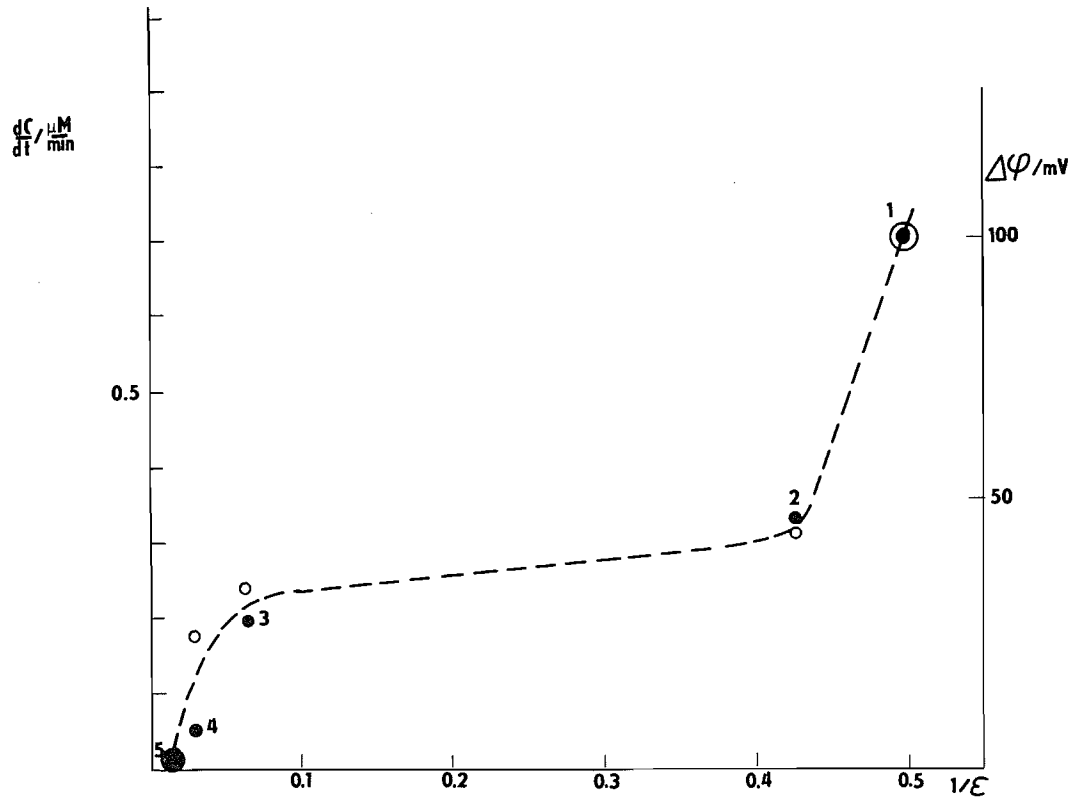

FIG. 6. Dependence of the rate of dioxygen evolution (●) and of the photopotential (○) on the dielectric permittivity of the "wet" nonaqueous phase: *1*, octene, decane; *2*, benzene; *3*, methylbutyl ketone; *4*, nitrobenzene; *5*, propylene carbonate. The conditions are the same as in Fig. 3.

theory developed in refs. 13 and 14, the photopotential is proportional to the reaction rate constant

$$[4] \quad \Delta\varphi = \frac{zFk}{Ck_{dif}}[chl]$$

where C is the capacitance of the electric double layer, [chl] is the concentration of chlorophyll, F is Faraday number, z is the charge of the particle, k_{dif} is rate constant of diffusion.

Substituting eq. [3] into eq. [4] yields

$$[5] \quad \lg \Delta\varphi \approx \frac{1}{\epsilon} \lg \frac{\Delta A}{kT} + \lg \frac{1}{\epsilon}$$

where A includes all the terms independent of the dielectric permittivity of the nonaqueous phase. The first term on the right side of eq. [5] is determined by the influence of the activation energy of the heterogeneous reaction while the second one, by the influence of the capacitance of the electric double layer, C, on the photopotential value. It is evident from Fig. 6 that the reaction rate and photopotential decrease similarly with increasing ϵ, which favours the theoretical calculations of the reaction rate as obtained from refs. 13–18.

The abrupt decrease in the reaction rate and in the photopotential in passing to polar solvents may also be caused by another factor: in nonpolar solvents chlorophyll is aggregated and in polar ones it is a monomer. This effect is distinctly visible on the absorption spectra. For the realization of a four-electron reaction of water photooxidation it seems to be necessary that the chlorophyll should occur as a hydrated oligomer (3). In this case the reaction could occur synchronously as a single act. If the chlorophyll is not aggregated and occurs as a monomer then the course of a synchronous water reaction becomes impossible due to a large value of the reorganization energy of the medium and, consequently, of the activation energy of the reaction. This problem was discussed in detail previously in refs. 9, 10, and 15 to 18. The four-stage one-electron oxidation of water by a chlorophyll monomer is impossible due to a low value of the redox potential ($E^0_{Chl/Chl^+} = 0.76$ V). As a result of these two factors no photooxidation of water by chlorophyll occurs at the water/polar nonaqueous solvent interface.

Thus the change in potential jump at the interface of two immiscible liquids reflects the photoredox reaction rate at the interface in the course of the water photooxidation reaction. The interface of two immiscible liquids can be used as a tool for studying the main processes of photosynthesis involving the spatial separation of charge. The use of solvents with different values of dielectric permittivity will make it possible to verify experimentally the conclusions of the theory of elementary charge transfer.

We have made special experiments on the duration of operation of the octane/water system in the course of the dioxygen photoevolution reaction. O_2 evolved in a stable manner during 3 h of illumination. Between the fourth and fifth hours of exposure the dioxygen evolution decreased and by the end of the fifth hour the evolution of O_2 stopped completely. In this case pH of the aqueous phase containing the Tris-HCl buffer remained neutral but practically all chlorophyll pheophytinized and the octane layer became brown. If any component necessary for the course of the water photooxidation reaction, e.g. DNPh or $K_3[Fe(CN)_6]$, was eliminated from the system then the spectrum of chlorophyll absorption in octane equilibrated with water practically remained unchanged during the 5 h. In the course of the reaction of dioxygen evolution at the interface the buffer capacitance of weak acid (DNPh or PChPh) is insufficient

For personal use only.

to protect the chlorophyll against pheophytinization at long exposure times.

It is very likely that at the earlier stages of the evolution of photosynthesis, chlorophyll was directly involved in photooxidation of water to molecular oxygen. Such a chemical reactor, however, was able to operate only for a few hours. Therefore, the structure and composition of the oxygen-evolving complex could undergo significant changes in the course of evolution of the photosynthesis apparatus to increase its stability and the functioning period.

In natural photosynthesis plastoquinone acts as a transmembrane carrier of electrons and protons between reaction centers of two photosystems in the case of noncyclic electron transfer. In a special experiment we replaced the electron acceptor in water and the proton acceptor in oil by 1,4-naphthoquinone which dissolves both in water and in oil and is able to take on protons as well as electrons. In this case, however, we did not succeed in detecting the dioxygen evolution in the octane/water system.

Elucidation of the mechanism of water photooxidation and of related processes is a major problem in photosynthesis and is of great significance in designing artificial systems for solar energy utilization. The quantum yield of the photocatalytic decomposition of water depends first of all on the efficiency of the photochemical charge separation. The most effective system should be a heterogeneous system in which the oxidant and the reductant are either in different phases or sterically separated. The difference in solubilities of the substrates and reaction products in both phases of such heterogeneous structure as octane/water interface can shift the reaction equilibrium to the other side; the redox potential scale is altered, which makes it possible to carry out the reaction that cannot be performed in homogeneous phase or that proceeds at a slow rate. Extraction of the reaction products and adsorption of the reaction components determine high catalytic properties of the interface between two immiscible liquids, recognized recently as interfacial catalysis (15–18).

Solvent structure effects on solvated electron reactions in mixed solvents: positive ions in 1-propanol/water and 2-propanol/water

SEDIGALLAGE A. PEIRIS[1] AND GORDON R. FREEMAN
Chemistry Department, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received July 10, 1990

SEDIGALLAGE A. PEIRIS and GORDON R. FREEMAN. Can. J. Chem. **69**, 157 (1991).

In models of the kinetics of chemical reactions in solution the solvent is commonly assumed to be a uniform continuum. An example is the Smoluchowski–Debye–Stokes–Einstein equation for the rate constant k_2 of a bimolecular reaction between charged or polar species:

$$k_2 = \kappa RTfr_r/1.5\ \eta r_d$$

where κ is the probability that a reactant encounter pair will react, R is the gas constant, T is the temperature, f is a factor that reflects the effect of electrostatic interaction between the reactants on their probability of attaining the closeness of approach r_r at which reaction occurs, η is the solvent viscosity, and r_d is the effective radius of the reactant entities for mutual diffusion. The equation is useful in evaluating effects of bulk fluid properties on reaction rates. Residual effects are attributed to more specific solvent behaviour.

Rate constants k_2, activation energies E_2, and pre-exponential factors A_2 of reactions of solvated electrons e_s^- with H_s^+, Ag_s^+, Cu_s^{2+}, and Al_s^{3+} ions vary with the composition of 1-propanol/water and 2-propanol/water mixed solvents. Plots of $k_2\eta/fT$ against solvent composition are nonlinear and change with the solvent pair and with reactant pair. Measured molar conductivities $\Lambda_0(H_s^+, ClO_{4,s}^-)$, $\Lambda_0(Ag_s^+, ClO_{4,s}^-)$, $\Lambda_0(Cu_s^{2+}, 2ClO_{4,s}^-)$, and $\Lambda_0(Al_s^{3+}, 3ClO_{4,s}^-)$ indicate that the values of r_d for the mutual diffusion of the cations and anions have a minimum near 90 mol% water, and that the values in pure propanol-1 or −2 (150–190 pm) are larger than those in pure water solvent (26 pm for H_s^+, 70 pm for the metal ions). The liquid structure influences both the rate of diffusion and the probability of reaction of a reactant encounter pair.

Key words: alcohol/water mixed solvents, positive ions, reaction kinetics, solvated electron, solvent effects.

SEDIGALLAGE A. PEIRIS et GORDON R. FREEMAN. Can. J. Chem. **69**, 157 (1991).

Dans les modèles de la cinétique des réactions chimiques en solution, on fait souvent l'hypothèse que le solvant est un milieu uniforme. Comme exemple, on peut citer l'équation de Smoluchowski–Debye–Stokes–Einstein relative à la constante de vitesse k_2 d'une réaction bimoléculaire entre des espèces polaires ou chargées :

$$k_2 = \kappa RTfr_r/1{,}5\ \eta r_d$$

dans laquelle κ est la probabilité qu'une paire de réactifs qui se rencontrent puissent réagir, R est la constante des gaz, T est la température, f est un facteur qui est le reflet de l'interaction électrostatique entre les réactifs sur la probabilité qu'ils ont de s'approcher jusqu'à une valeur de r_r à laquelle il se produit une réaction, η est la viscosité du solvant et r_d est le rayon effectif des entités qui réagissent pour la diffusion mutuelle. L'équation est utile pour évaluer les effets globaux des propriétés des fluides sur les vitesses de réactions. Les effets résiduels sont attribués à un comportement plus spécifique du solvant.

Les constantes de vitesse k_2, les énergies d'activation E_2 et les facteurs pré-exponentiels A_2 des réactions des ions solvatés e_s^- avec les ions H_s^+, Ag_s^+, Cu_s^{2+} et Al_s^{3+} varient avec la composition des solvants mixtes 1-propanol/eau et 2-propanol/eau. Les courbes de $k_2\eta/fT$ en fonction des compositions de solvants ne sont pas linéaires et elles varient avec la paire de solvant et la paire de réactif. Les conductivités molaires mesurées $\Lambda_0(H_s^+, ClO_{4,s}^-)$, $\Lambda_0(Ag_s^+, ClO_{4,s}^-)$, $\Lambda_0(Cu_s^{2+}, 2ClO_{4,s}^-)$ et $\Lambda_0(Al_s^{3+}, 3ClO_{4,s}^-)$ indiquent que les valeurs de r_d pour la diffusion mutuelle des cations et des anions passent par un minimum près de 90 mol% d'eau et que les valeurs dans le 1- (ou 2-) propanol purs (150 à 190 pm) sont plus grandes que celles dans l'eau pure (26 pm pour H_s^+ et 70 pm pour les ions métalliques). La structure du liquide influence la vitesse de diffusion ainsi que la probabilité qu'une paire des réactifs qui se rencontrent puissent réagir.

Mots clés : solvants mixtes alcool/eau, ions positifs, cinétique de réactions, électrons solvatés, effets de solvants.

[Traduit par la revue]

Introduction

This article continues the study of solvent structure effects on solvated electron reactions in mixed solvents (1–4). The last article (4) reported reactions with negative ions in 1-propanol/water and 2-propanol/water. We here describe solvent effects on rates of solvated electron reactions with several positive ions.

Experimental

Materials

The solvents and the method of their purification were described earlier (4).

Silver perchlorate (Strem, reagent grade), copper(II) perchlorate (Aldrich reagent grade), aluminum(III) perchlorate (98%, Aldrich Chemical Co.), and perchloric acid (70%, Fisher Scientific Co.) were used as received.

Techniques

Methods of sample preparation from solid solutes were as described in ref. 5. Perchloric acid samples were made by measuring 70% perchloric acid solution with a glass pipet to prepare 50 mol/m^3 stock solutions, and then diluting as previously described.

Methods of irradiation, dosimetry and optical measurements were similar to those described in ref. 6.

Electrical conductance measurements were as described in ref. 7. Dissolved CO_2 was removed from the conductance cell by bubbling UHP argon through the solution, then sealing the cell with Parafilm. A small amount of chemical reaction sometimes occurred at the higher temperatures, which was detected by drift of the conductance. In these cases a fresh sample was used for each measurement.

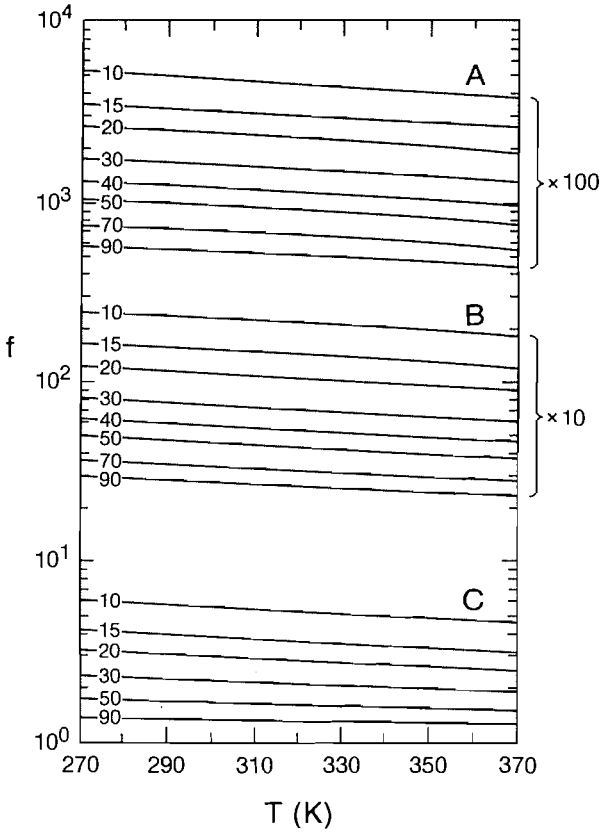

FIG. 1. Temperature dependence of the Debye factor f at different values of dielectric permittivity. A: for $z = +3$ using $r_r = 0.35$ nm. B: for $z = +2$ using $r_r = 0.5$ nm. C: for $z = +1$ using $r_r = 1.0$ nm. Values of ϵ are indicated.

Values of viscosities and relative permittivities of the mixed solvents were obtained from ref. 8.

Results and discussion

The second-order rate constants k_2 were obtained as described in ref. 4.

Diffusion and reaction

The rate constant data were analyzed according to the modified Arrhenius equation (4),

$$[1] \quad k_2/f = A_2 \exp(-E_2/RT)$$

where E_2 is the overall energy of activation of the reaction, and A_2 is the pre-exponential factor. The factor f reflects the effect of electrostatic interaction between the reactants on their probability of attaining the closeness of approach r_r at which reaction occurs:

$$[2] \quad f = \frac{U(r_r)}{k_B T}[\exp(U(r_r)/k_B T) - 1]^{-1}$$

where $U(r_r)$ is the interaction energy of the reactants at distance r_r, k_B is Boltzmann's constant, and T is the temperature.

For the interaction of e_s^- with a solute of charge $z\xi$, $U(r_r)$ is given by

$$[3] \quad U(r_r) = -z\xi^2/4\pi\epsilon_0\epsilon r_r$$

where $-\xi$ is the charge on the electron, ϵ_0 is the permittivity of vacuum, and ϵ is the relative permittivity of the solvent between the electron and the ion.

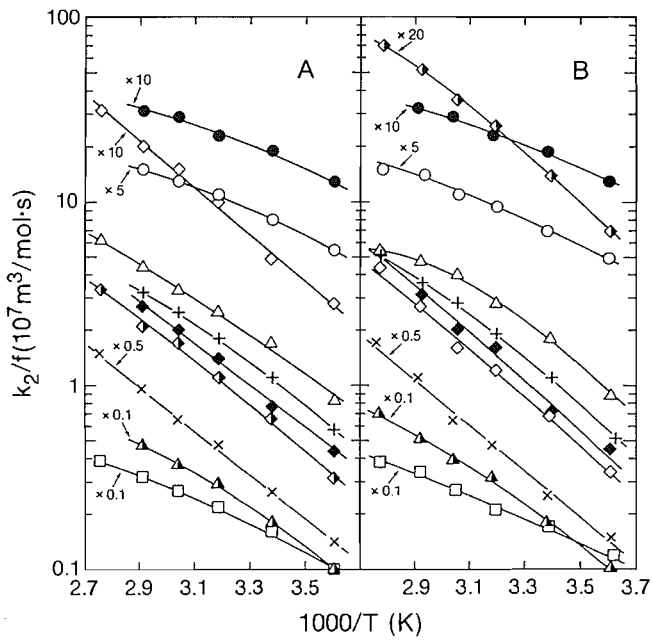

FIG. 2. Arrhenius plots of log $[k_2(e_s^- + H_s^+)/f]$ against T^{-1} in 1-propanol/water (A) and 2-propanol/water (B) mixed solvents. Symbols representing mol% water are given in Table 1, except ▲, (A, 81; B, 80), △, (A, 68; B, 70), +, (A, 51; B, 50), ◆, 35.

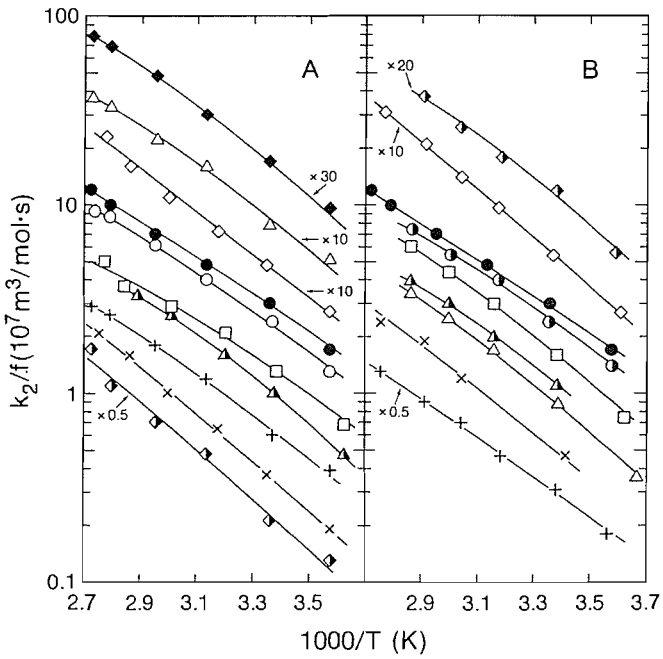

FIG. 3. Arrhenius plots of log $[k_2(e_s^- + Ag_s^+)/f]$ against T^{-1} in 1-propanol/water (A) and 2-propanol/water (B) mixed solvents. Symbols representing mol% water are given in Table 1, except ▲, (A, 80; B, 81); △, (A, 70; B, 71); +, (A, 50; B, 51); ◆, 36.

In Fig. 1 values of f are plotted for ions of different z, using appropriate values of r_r (2), for a range of values of ϵ and T. The value of ϵ of each solvent at each T used in the experiments was obtained by interpolation of data in ref. 8. The value of k_2 was divided by the value of f at the corresponding values of (ϵ, T, r_r).

The second-order rate constant for the counter ion, perchlor-

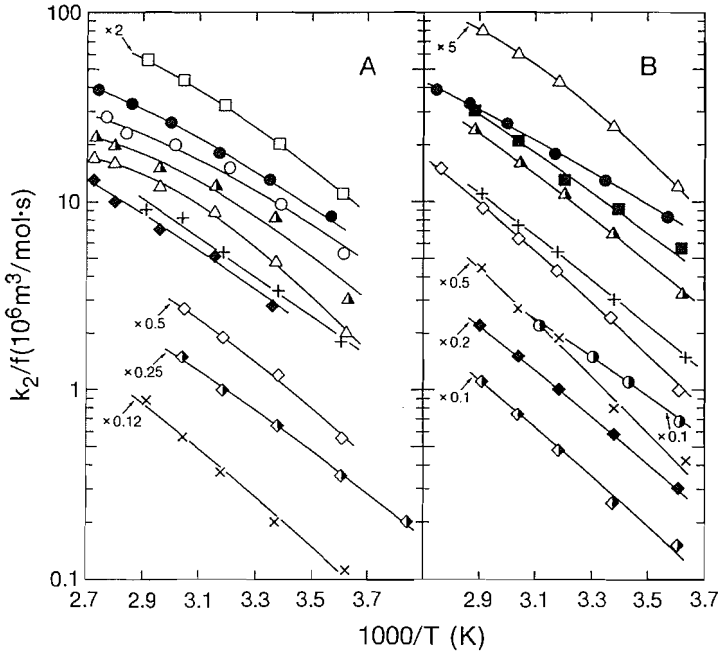

FIG. 4. Arrhenius plots of log $[k_2(e_s^- + Cu_s^{2+})/f]$ in propanol/water (*A*) and 2-propanol/water (*B*) mixed solvents. Symbols representing mol% water are given in Table 1, except: ▲, 81; △, 68; +, (*A*, 51; *B*, 52); ◆, (*A*, 33; *B*, 36).

ate, was less than 10^3 m^3/mol s in water (9). Therefore the observed rate constants are due to H_s^+, Ag_s^+, Cu_s^{2+}, and Al_s^{3+}.

Arrhenius plots of log (k_2/f) against T^{-1} are shown for H_s^+ in Fig. 2, for Ag_s^+ in Fig. 3, for Cu_s^{2+} in Fig. 4, and for Al_s^{3+} in Fig. 5. The mol% water represented by the symbols in these figures are shown in Table 1.

The solvent composition dependences of k_2/f at 298 K are shown in Fig. 6 *A* and *B* for 1-propanol/water and 2-propanol/water, respectively. The variation of k_2/f with the solvent composition is more drastic than that for k_2 itself (Fig. 6 *C* and *D*). In general k_2 increases with increasing charge on the positive ion. However, when the coulombic factor f is taken into account, k_2/f values for Ag_s^+ are greater than those for Cu_s^{2+} and Al_s^{3+}. For H_s^+, k_2/f has the highest values.

Addition of a small amount of water to pure 1-propanol caused k_2/f for Al_s^{3+} to drop, then increase again when more than 2 mol% of water was added (Fig. 6*A*). The initial drop did not occur in 2-propanol (Fig. 6*C*). The value of the optical absorption energy half way up the low energy (red) side of the band, E_r, is an approximate measure of the trap depth of the solvated electrons that react (5). Addition of a small amount of water causes the value of E_r to decrease in 1-propanol and to increase in 2-propanol (10). The decrease in 1-propanol has been explained in terms of the formation of a hydrogen bonded solvent structure which consists of two alcohol tetramers joined together by a water molecule between them, towards 10 mol% of water on the composition scale. This would tend to decrease the availability of OH functional groups to the electron solvation site (10). Thus addition of water to pure 1-propanol would decrease the solvation energy of the electron. The activation energy for $(e_s^- + Al_s^{3+})$ did not change appreciably in this region (Fig. 7*A*), but log A_2 decreased as a small amount of water was added to pure 1-propanol (Fig. 8*A*). Therefore the above-mentioned phenomenon could be linked to a decrease in entropy of activation caused by the structure of the solvent at this composition. This structure apparently does not form in secondary alcohols (10).

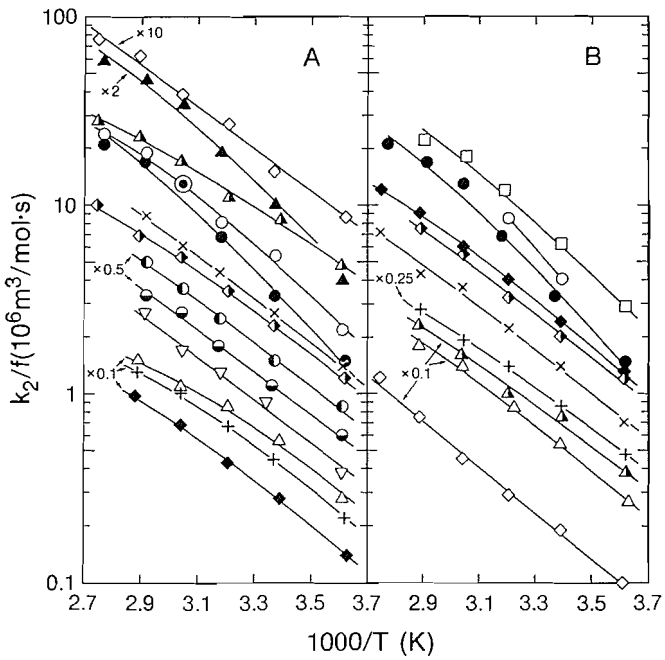

FIG. 5. Arrhenius plots of log $[k_2(e_s^- + Al_s^{3+})/f]$ in 1-propanol/water (*A*) and 2-propanol/water (*B*) mixed solvents. Symbols representing mol% water are given in Table 1, except: ▲, 81; +, (*A*, 51; *B*, 52); ◆, (*A*, 35; *B*, 36).

The plots of E_2 against mol% water in the solvent are *S* curves for Ag_s^+ and Cu_s^{2+} (Fig. 7). The curves for H_s^+ are concave toward the composition axis and those for Al_s^{3+} are convex toward that axis. The differences in curve shapes are due to differences in diffusion behavior of the cations and in the reaction probability of a reactant encounter pair, because the changes in e_s^- properties with solvent composition are the same for each cation.

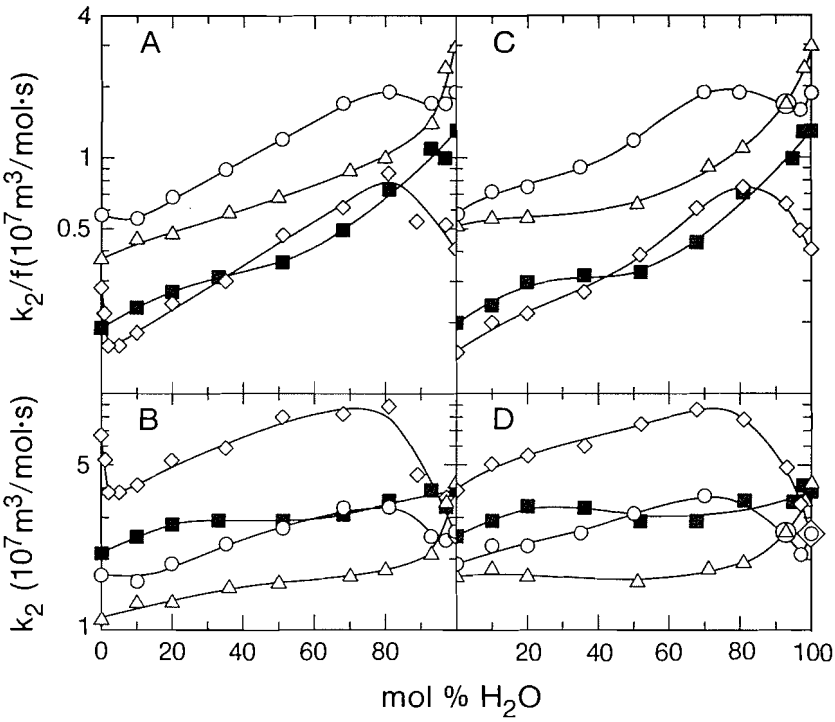

FIG. 6. Solvent composition dependences of k_2/f and k_2 at 298 K. ○, H_s^+; △, Ag_s^+; ■, Cu_s^{2+}; ◇, Al_s^{3+}; in 1-propanol/water mixtures (*A* and *B*), 2-propanol/water mixtures (*C* and *D*).

[5] $(e_s^- + C_s^{z+}) \rightleftharpoons (C^{(z-1)+})$

[6] $(C^{(z-1)+}) \rightarrow C_s^{(z-1)+}$

Reaction [4] represents the reversible formation of the reactant encounter pair, reaction [5] is the reversible electron transfer step, and reaction [6] is the relaxation of the new product and the solvent molecules around it. Reaction [6] in some cases involves further chemical reaction, for example

[6′] $H_3O(H_2O)_n \rightarrow H_s + H_2O_s$

The solvent dependences of log A_2 (Fig. 8) are qualitatively similar to those of E_2 (Fig. 7), with the exception of the $(e_s^- + Al_s^{3+})$ reaction in nearly pure 1-propanol. A correlation between E_2 and log A_2 in a series of reactions of a given type is common (11). It has to do with counterbalancing effects of entropies and enthalpies of activation. A higher $\Delta H^{\ddagger}$ (hence E_2) tends to make a broader reaction path (higher density of states) accessible, which means that $\Delta S^{\ddagger}$ (hence log A_2) is larger.

The activation energy of a reaction that is nearly diffusion-controlled should be similar to that of mutual diffusion of the reacting species. While we cannot measure the diffusion coefficient of e_s^-, the activation energy of conductance $E_{\Lambda 0}$ of the reactant salt gives a rough idea of E_2 values that might be expected for diffusion controlled reactions of the ions. Plots of $E_{\Lambda 0}$ against solvent composition are shown in Fig. 9. The values of $E_{\Lambda 0}$ and E_2 (Fig. 7) are mostly in the vicinity of 20 kJ/mol, but there are many differences in detail between E_2 and $E_{\Lambda 0}$ that cannot yet be interpreted.

Values of the reaction rate parameters are summarized in Tables 2–5.

Effect of solvent viscosity

The Smoluchowski–Debye–Stokes–Einstein equation for the rate constant k_2 of a bimolecular reaction between charged or polar species may be written (4)

[7] $k_2 = \kappa RTfr_r/1.5\,\eta r_d$

where κ = probability that a reactant encounter pair will react, η = solvent viscosity, and r_d = effective radius of the reactant entities for mutual diffusion. Equation [7] can be rearranged to obtain the dimensionless ratio of reaction parameters $\kappa r_r/r_d$:

[8] $\kappa r_r/r_d = k_2\eta/5.5Tf$

The values of this ratio for the present systems at 298 K are approximately in the order $H_s^+ > Ag_s^+ > Cu_s^{2+} > Al_s^{3+}$, and have maxima in the vicinity of 80 mol% water (Fig. 10). The values are similar in the two isomeric propanols at all water contents, with the exception of Al_s^{3+} in the pure propanol solvents. The extra reactivity of Al_s^{3+} in pure 1-propanol has been confirmed by repeated experiments and is not understood.

The effective radius of e_s^- for diffusion is small, presumably due to its deformability: 0.05 nm in water and 0.09 nm in 2-propanol (12). Thus for $\kappa \approx 1$ and $r_r \geq 0.5$ nm one expects $\kappa r_r/r_d > 10$ in water and >6 in 2-propanol. The reaction $(e_s^- + Ag_s^+)$ is approximately diffusion-controlled in the solvents of all compositions. The reaction $(e_s^- + H_s^+)$ is

TABLE 1. Symbols in Figs. 2–5, representing mol% of water in 1-propanol or 2-propanol

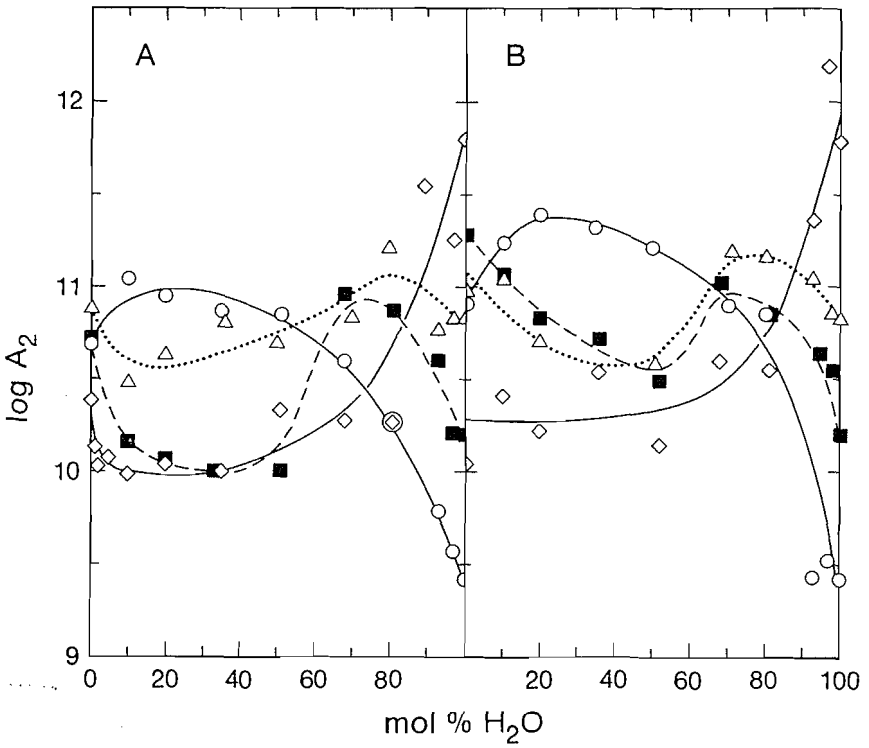

FIG. 8. Solvent composition dependence of log A_2 in 1-propanol/water (A) and 2-propanol/water (B) mixed solvents near 298 K. Symbols as in Fig. 6.

approximately diffusion-controlled in alcohols containing 0–80 mol% water, but in pure water solvent $\kappa \approx 0.5$. The lower efficiency of $(e_s^- + H_s^+)$ in water than in alcohol, with $\kappa = 0.3$ in water and 1.0 in methanol and ethanol, has been attributed to lower efficiencies of reactions [5] and [6] in water (13). The electron is a solvent-structure breaker in water and H^+ is a solvent-structure maker; this difference inhibits the intimate approach of the two species and slows reaction [5]. In alcohols the electron is a weak structure maker (13) and H^+ is a strong structure maker, so their intimate approach is not hindered by the solvent structure. It is also possible that the decomposition of the symmetrical $H_3O(H_2O)_n$, reaction [6′], is slower relative to the solvent viscosity than is that of the unsymmetrical $ROH_2(ROH)_m$:

[6″] $\quad ROH_2(ROH)_m \rightarrow H_s + ROH_s$

The lower values of $\kappa r_r/r_d$ for Cu_s^{2+} and Al_s^{3+} are attributed to difficulty in forming the relatively unstable Cu_s^+ and Al_s^{2+} from e_s^- and Cu_s^{2+} or Al_s^{3+}, respectively. In aqueous solution the Cu_s^+ ion is unstable with respect to Cu_s^{2+} and Cu. The equilibrium

[9] $\quad 2Cu_s^+ \rightleftharpoons Cu_s^{2+} + Cu_s$

lies far to the right, and compounds of Cu(I) are covalent (14). Compounds of Al_s^{2+} are not known. The overall reaction with Al_s^{3+} might be

[10] $Al_s^{3+} + e_s^- \rightarrow [AlOH]_s^{2+} + H_s$

or

[10′] $3Al_s^{3+} + 3e_s^- \rightarrow 3Al_s^{2+} \rightarrow\rightarrow Al_s^0 + 2Al_s^{3+}$

Comparison with ionic conductivities

The diffusion coefficients D_i of the ionic reactants are related to their molar electrical conductivities λ_i, so the solvent dependence of $k_2/f[(\lambda_i/z_i^2) + \lambda_e]T$ indicates the solvent dependence of κr_r (4),

[11] $\kappa r_r = 1.48 \times 10^{-16} k_2/f[(\lambda_i/z_i^2) + \lambda_e]T$

where λ_e is the molar conductivity of e^-.

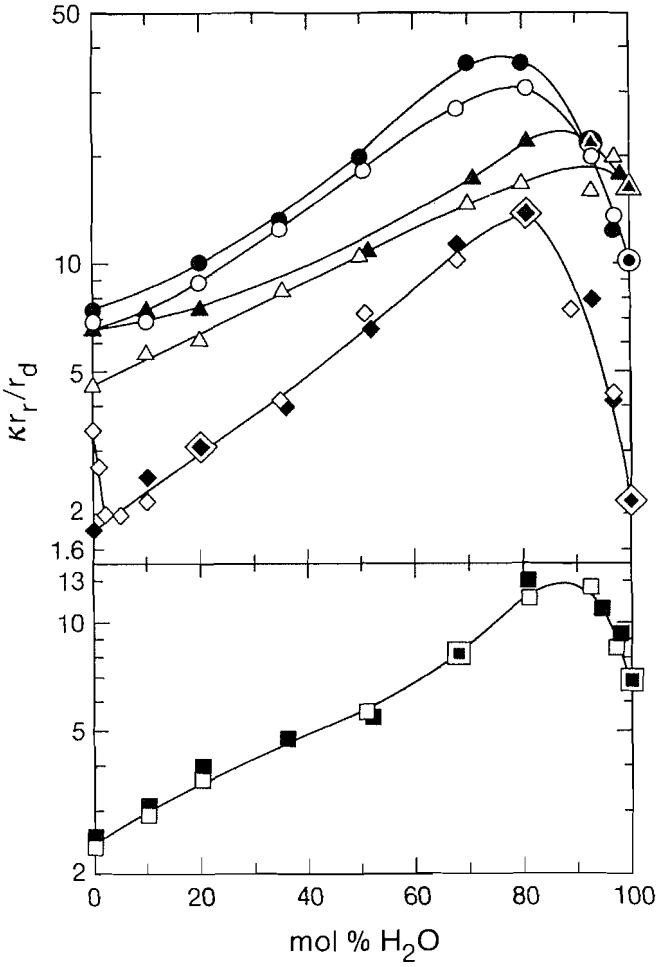

FIG. 10. Solvent composition dependence of reaction-parameter ratio $\kappa r_r/r_d$ at 298 K. Open symbols, 1-propanol/water; solid, 2-propanol/water; otherwise as in Fig. 6.

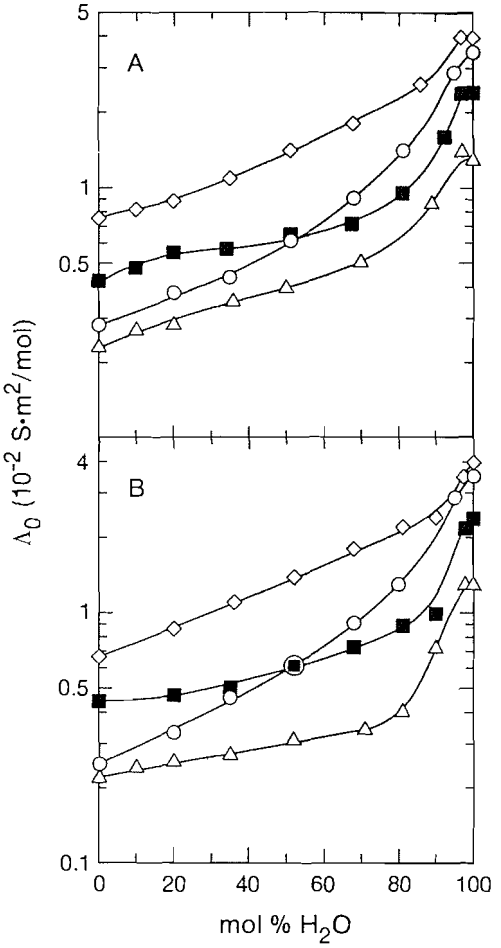

FIG. 11. Solvent composition dependence of molar conductivities at infinite dilution, Λ_0, of $HClO_4$, ○; $AgClO_4$, △; $Cu(ClO_4)_2$, ■; $Al(ClO_4)_3$, ◇; at 298 K in 1-propanol/water (*A*) and 2-propanol/water (*B*) mixed solvents. S = siemens = C/V.s.

The solvent dependences of the molar conductivities of the acid and salts at 298 K are shown in Fig. 11. At the low ion concentrations used to measure k_2 (Tables 2–5), $\Lambda = \Lambda_0$ in the alcohols as well as in water (15). The curves do not contain a minimum at about 70 mol% water where the viscosity is at a maximum (Table 2), as might be expected from Walden's rule (Stokes' law). This interesting behavior of ion diffusion through a composite solvent structure is worthy of separate study. The behavior accounts for the maxima in the curves in Fig. 10 (see eq. [8], which involves Stokes' law).

In pure water at 298 K the ratios of the λ's (16, 17) of e_s^-:H_s^+:Ag_s^+:Cu_s^{2+}:Al_s^{3+} are 4.7:9.1:1.6:3.0:4.9, so the diffusion coefficients ($\propto \lambda_i/z_i^2$) are in the ratios 4.7:9.1:1.6:0.8:0.5. Thus diffusion of e_s^- dominates the relative motion of each reactant pair except that with H_s^+.

The values of the individual ionic conductivities in the mixed solvents are not known, so we made approximations. In water the ratio $[\lambda(e_s^-) + \lambda(H_s^+)]/\Lambda_0(H_s^+, ClO_{4,s}^-) = 1.3$, $[\lambda(e_s^-) + \lambda(Ag_s^+)]/\Lambda_0(Ag_s^+, ClO_{4,s}^-) = 1.9$, $[\lambda(e_s^-) + 0.25\lambda(Cu_s^{2+})]/\frac{1}{2}\Lambda_0(Cu_s^{2+}, 2ClO_{4,s}^-) = 1.6$, and $[\lambda(e_s^-) + 0.11\lambda(Al_s^{3+})]/\frac{1}{3}\Lambda_0(Al_s^{3+}, 3ClO_{4,s}^-) = 1.5$. Thus eq. [11] can be approximated as

$$[12] \quad \kappa r_r \approx 1 \times 10^{-16} z_i k_2/f\Lambda_0 T$$

where z_i is the number of charges on the reactant cation.

The values of κr_r are much less dependent on solvent composition (Fig. 12) than are the apparent values of $\kappa r_r/r_d$ (Fig. 10). Thus the Stokes' value of r_d are solvent dependent.

The Stokes radius r_d for mutual diffusion of ions in an electrolyte solution is given by (4)

$$[13] \quad r_d = \left(\frac{1}{r_{d+}} + \frac{1}{r_{d-}}\right)^{-1} = 8.2 \times 10^{-16} \Big/ \eta\left(\frac{\lambda_+}{z_+^2} + \frac{\lambda_-}{z_-^2}\right)$$

Separate values of λ_+ and λ_- in the mixed solvents are not available, so there is a complication in the calculation of r_d when $z_+ \neq z_-$, as in the present Cu_s^{2+}, $ClO_{4,s}^-$, and Al_s^{3+}, $ClO_{4,s}^-$ solutions. In pure water solvent the values (17) of $[(\lambda_+/z_+^2) + \lambda_-] = 9.6$ and 8.8 (10^{-3} S m^2/mol) for the Cu_s^{2+} and Al_s^{3+} salts, respectively, are a bit nearer to the respective values of $\Lambda_0(\text{salt})/z_+$, 12.4 and 13.0 ($10^{-3}$ S m^2/mol), than to those of $\Lambda_0(\text{salt})/z_+^2$, 6.2 and 4.3 ($10^{-3}$ S m^2/mol), respectively. Furthermore, $\lambda_e = 18 \times 10^{-3}$ S m^2/mol (16) is greater than $\lambda_- = \lambda(ClO_{4,s}^-) = 6.7 \times 10^{-3}$ S m^2/mol in water at 298 K, so the value of $[\lambda_+/z_+^2) + \lambda_e]$ would be much closer to $\Lambda_0(\text{salt})/z_+$ than to $\Lambda_0(\text{salt})/z_+^2$. We therefore chose the approximation

$$[14] \quad r_d \approx 8 \times 10^{-16} z_+/\eta\Lambda_0$$

Values of r_d estimated from eq. [14] display a minimum in the vicinity of 90 mol% water (Fig. 13). The decrease of r_d as small amounts of alcohol are added to water indicates that the microscopic viscosity of the fluid in the vicinity of the ions

is lower than the shear viscosity of the bulk fluid. The ions evidently remain in the disordered water and do not associate with the more viscous structures that are nucleated by the alcohol molecules. The increase of r_d at higher alcohol concentrations is attributed to the larger size of the molecules that solvate the ions. The ratio of molar volumes alcohol/water at 298 K are 4.2 for 1-propanol and 4.3 for 2-propanol (18).

The low value of r_d for perchloric acid in water is due to the proton hopping mechanism (19), which is more efficient in water than in alcohol.

Conclusion

The reactivities of solvated electrons with solutes are dependent on the electron affinity of the solute, the electron–solvent and solute–solvent interactions, and the solvent structure. The solvent structure influences both the rate of reactant diffusion and the probability that a reactant encounter pair will react instead of diffusing apart again.

The activation energies E_2 of the reactions e_s^- with H_s^+, Ag_s^+, Cu_s^{2+}, and Al_s^{3+} are similar to the activation energies of conductance $E_{\Lambda 0}$ of the perchlorate electrolyte solutions in all the propanol/water solvents, except for Al_s^{3+} in pure water solvent. The value of E_2 for Al_s^{3+} in pure water solvent is unusually high, probably because the overall reaction is not a single step electron transfer. There are differences in the detailed shapes of the E_2 and $E_{\Lambda 0}$ curves that will provide important information when incorporated into a larger study.

The values of the reaction radius r_r multiplied by the probability of reaction κ of a reactant encounter pair in pure propanol-1 or -2 solvent are in the order $Ag_s^+ \approx H_s^+, > Cu_s^{2+} > Al_s^{3+}$, while in pure water solvent the order has changed to $Ag_s^+ > Cu_s^{2+} > H_s^+, > Al_s^{3+}$. Most of the change occurs in

Bimetallic titanium alkoxides: synthesis and structure of $Cp_2Ti(Ph)(\mu\text{-}OCH_2C(CH_3)_2CH_2O)(Ph)TiCp_2$; a precursor to macrocyclic metallocene derivatives

T. TIMOTHY NADASDI AND DOUGLAS W. STEPHAN[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 21, 1990

T. TIMOTHY NADASDI and DOUGLAS W. STEPHAN. Can. J. Chem. **69**, 167 (1991).

The reaction of Cp_2TiPh_2 with 2,2-dimethylpropane-1,3-diol proceeds with the evolution of benzene affording the bimetallic titanocene alkoxide species $Cp_2Ti(Ph)(\mu\text{-}OCH_2C(CH_3)_2CH_2O)(Ph)TiCp_2$, **1**. Complex **1** crystallizes in the monclinic space group *Cc* with $a = 25.448(7)$ Å, $b = 8.483(s)$ Å, $c = 14.512(3)$ Å, $\beta = 101.52(2)°$, $Z = 4$, and $V = 3070(1)$ Å^3. The structure was refined employing 1471 data with $F_o > 3\sigma F_o$ and 138 variables to R values of $R = 0.0588$ and $R_w = 0.0828$. the dimeric nature of **1** is confirmed. The coordination spheres of the two Ti centres are pseudo-tetrahedral. The Ti—C σ bonds were found to be 2.21(1) and 2.25(1) Å. Although the phenyl substituents are directed towards each other, steric effects appear to be overcome by the approximately perpendicular orientation of the phenyl rings (in fact the angle between the planes is 81.9°). The Ti...Ti separation in **1** is 6.725 Å. The implications of the preparation of **1** regarding the mechanism of formation of early metal macrocyclic compounds are discussed. In addition, the ramifications for the synthesis of dissymmetric early metal macrocycles are considered.

Key words: titanium alkoxides, alkoxide bridged, structure.

T. TIMOTHY NADASDI et DOUGLAS W. STEPHAN. Can. J. Chem. **69**, 167 (1991).

Le réaction du Cp_2TiPh_2 avec le 2,2-diméthylpropane-1,3-diol donnent lieu à une évolution de benzène et conduisent à la formation d'alcoolates de titanocène bimétalliques $Cp_2Ti(Ph)(\mu\text{-}OCH_2C(CH_3)_2CH_2O)(Ph)TiCp_2$ (**1**). Le complexe **1** cristallise dans le groupe d'espace *Cc*, avec $a = 25{,}448(7)$, $b = 8{,}483(2)$ et $c = 14{,}512(3)$ Å, $\beta = 101{,}53(2)°$, $Z = 4$ et $V = 3070(1)$ Å^3. On a affiné la structure à l'aide de 1471 données avec $F_o > 3\sigma F_o$ et 138 variables jusqu'à des valeurs de $R = 0{,}0588$ et $R_w = 0{,}0828$. On a confirmé la nature dimère du produit **1**. Les sphères de coordination des deux centres Ti sont pseudo-tétraédriques. On a trouvé que les longueurs de liaisons σ Ti—C sont égales à 2,21(1) et 2,25(1) Å. Même si les groupements phényles sont orientés l'un vers l'autre, il semble que les effets stériques sont éliminés par l'orientation approximativement perpendiculaire des noyaux phényles (l'angle entre les plans est en fait égal à 81.9°). Dans **1**, la séparation Ti...Ti est égale à 6,725 Å. On discute des implications de la préparation du composé **1** sur le mécanisme de formation des premiers termes de composés métalliques macrocycliques. De plus, on considère les ramifications sur la synthèse des premiers termes des macrocycles métalliques dissymétriques.

Mots clés : alcoolates de titane, structure alcoolate pontée.

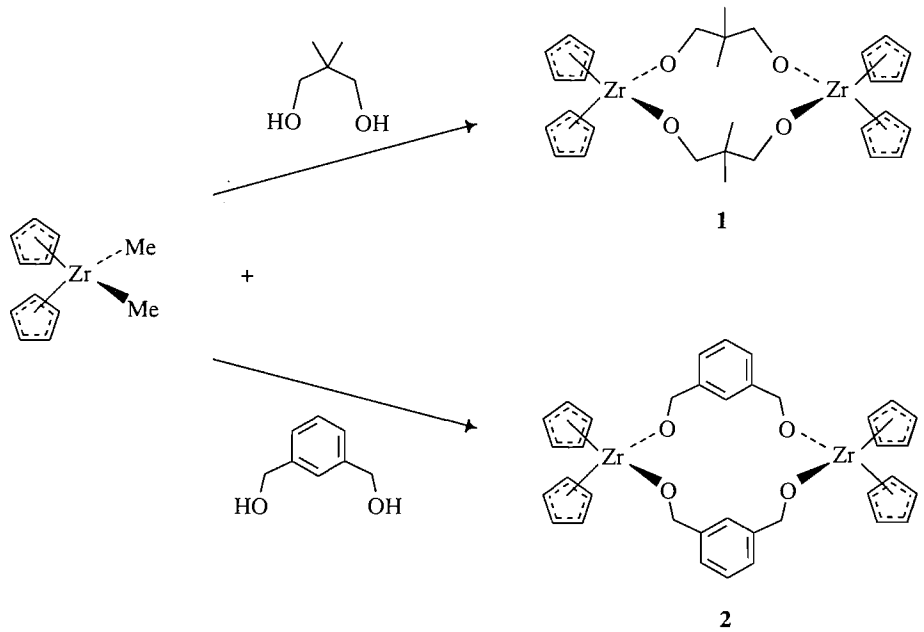
Introduction

Titania or zirconia are often employed as support materials for heterogeneous catalysts (1). These supports may act simply as a dispersent for the late metal centers or may play an active role in the catalytic cycle. In the latter case, such participation gives rise to the phenomenon known as strong metal-support interactions (SMSI) (1). Activation of substrate molecules by a Lewis acidic, early metal and a late metal center may account for the observed effects. We and others have investigated homogeneous systems in which early and late metals are linked in close proximity by bridging ligands (2). Such heterobimetallics are of interest both as models for the heterogeneous catalyst systems and because of their potential as catalysts in their own right. Fewer studies have focused on simple complexes of Ti or Zr that might model the Lewis acidic, early metal centers of titania or zirconia. Several groups (3–5), have reported the syntheses and reaction chemistry of a variety of early metal alkoxide complexes. The similarity of metal-alkoxide species to metal oxides and the propriety of such species as models for metal-oxide surfaces have been considered by others (3). Much of the work to date has focused on systems in which sterically demanding alkoxy or aryloxy ligands inhibit oligomerization and yield mononuclear early metal compounds (4, 5). In our initial investigations in this area, we described the specific formation of bimetallic macrocyclic Zr-alkoxide species via the reaction of dimethylzirconocene with diols (Scheme 1) (6).

In this report we describe the product of the related reaction of Cp_2TiPh_2 with 2,2-dimethylpropanediol, i.e., $Cp_2Ti(Ph)(\mu\text{-}OCH_2C(CH_3)_2CH_2O)(Ph)TiCp_2$ **1**. Compound **1**, which has been crystallographically characterized, may be an analog of the intermediates in the formation of the Zr macrocycles shown in Scheme 1. The ramifications for the mechanism of formation of the macrocyclic species and the implications for macrocycle design are considered and discussed.

Experimental section

General data



All preparations were done under an atmosphere of dry, O_2-free N_2 employing a Vacuum Atmospheres Inert atmosphere glove box. Solvents were reagent grade, distilled from the appropriate drying agents under N_2, and degassed by the freeze–thaw method at least three times prior to use. ^1H NMR spectra were recorded on a Bruker AC-300 spectrometer operating at 300 MHz. Trace amounts of protonated solvents were used as references and chemical shifts are reported relative to $SiMe_4$. Combustion analyses were performed by Galbraith Laboratories Inc. Knoxville, TN, and Schwarzkoff Laboratories, Woodside, NY. PhLi and Cp_2TiCl_2 were purchased from the Aldrich Chemical Co. Cp_2TiPh_2 was prepared by the literature method (7).

Synthesis of $Cp_2Ti(Ph)(\mu\text{-}OCH_2C(CH_3)_2CH_2O)(Ph)TiCp_2$, 1

To a THF solution (30 mL) of Cp_2TiPh_2 (1.00 g, 3.00 mmol) was added 2,2-dimethylpropane-1,3-diol (0.313 g, 3.00 mmol) and the

solution was stirred for 18 h at 60°C. Yellow blocks crystallized from solution on standing at 25°C in an atmosphere of N_2 for 20 days. (Yield (NMR) 80%.) *Anal.* calcd for $C_{37}H_{40}O_2Ti_2$: C 72.55, H 6.58; found: C 72.99, H 6.58. ^{1}H NMR (d_6-benzene, δ, ppm): 7.15 (m, 10H, Ph), 5.78 (s, 20H, Cp), 3.98 (s, 4H, CH_2), 0.80 (s, 6H, CH_3).

X-ray data collection and reduction

X-ray quality crystals were obained directly from the preparations as described above. The crystals were manipulated and mounted in capillaries in a glove box, thus maintaining a dry, O_2-free environment. Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation. The initial orientation matrix was obtained from 15 machine-centered reflections selected from a rotation photograph. These data were used to determine the crystal system. Partial rotation photographs around each axis were consistent with a monoclinic crystal system. Ultimately, 49 reflections ($20° < 2\theta < 25°$) were used to obtain the final lattice parameters and the orientation matrix. Machine parameters, crystal data, and data collection parameters are summarized in Table 1. The observed extinctions were consistent with the space groups $C2/c$ and Cc. Successful refinement confirmed the space group as Cc. The data, $h, k, \pm l$, were collected in one shell ($4.5° < 2\theta < 45.0°$) and three standard reflections were recorded every 197 reflections. The intensities of the standards showed no statistically significant change over the duration of the data collection. The data were processed using the TEXSAN program package employing a VAX 3520 workstation. The reflections with $F_o^2 > 3\sigma F_o^2$ were used in the refinement.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (8). The Ti atom positions were determined using direct methods employing MITHRIL. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out using full-matrix least-squares techniques on F, minimizing the function $w(|F_o| - |F_c|)^2$ where the weight, w, is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of refinement the titanium, oxygen, and the methylene and quaternary carbon atoms in the alkoxide bridge were assigned anisotropic temperature factors. The methyl, phenyl, and cyclopentadienyl groups were refined with individual isotropic thermal parameters; however, the geometry of the phenyl and cyclopentadienyl rings were constrained to be that of regular hexagons and pentagons, respectively. Hydrogen atom positions were calculated and recalculated before each successive least-square refinement. C—H bond lengths of 0.95 Å were assumed. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. In all cases the hydrogen atom contributions were calculated, but not refined. The final values of R and R_w are given in Table 1. The maximum Δ/σ on any of the parameters in the final cycles of the refinement and the location of the largest peaks in the final difference Fourier map calculation are also given in Table 1. The residual electron densities were of no chemical significance. The following data are tabulated: positional parameters (Table 2) and selected bond distances and angles (Table 3). Thermal parameters (Table S1), hydrogen atom parameters (Table S2), and values of 10 F_o and 10 F_c (Table S3) have been deposited as supplementary material.[1]

Results and discussion

The cleavage of metal–carbon bonds via protolysis with the subsequent formation of a metal–heteroatom bond is well known. Cleavage of an M—C (M = Ti, Zr) bond by reaction with alcohols is known to be a facile route to simple early metal alkoxide species (9, 10). In the same vein, we have shown that reactions of diols with Cp_2ZrMe_2 results in the rapid liberation of methane and the formation of macrocyclic zirconium alkoxides (Scheme 1) (6). While the chemistry of these and related macrocycles is a subject of ongoing study, it is also of interest to develop the means for controlled syntheses of such macrocycles. To that end, the reaction of Cp_2TiPh_2 with a diol was investigated. Reaction of Cp_2TiPh_2 with 2,2-dimethylpropanediol proceeds smoothly at 65°C over an 18 h period. Monitoring of the reaction by ^{1}H NMR showed the gradual growth in the resonance arising from benzene indicative of the protyolysis of the aryl group from Ti. In addition, new resonances attributable to phenyl, cyclopentadienyl, methylene, and methyl protons grew with time. Crystallization of the product was achieved by storage at 25°C for 20 days. The ^{1}H NMR of the isolated product indicated that the compound was the new species originally observed in the NMR scale trials. The ^{1}H NMR and combustion analysis data suggested the formulation $Cp_2Ti(Ph)$-(μ-$OCH_2C(CH_3)_2CH_2O$)(Ph)$TiCp_2$, **1**, and this was later

confirmed by X-ray crystallography (*vide infra*). Attempts to employ this reaction pathway failed to yield Ti macrocycles analogous to those reported for Zr. Neither addition of varying excesses of diol nor prolong refluxing in toluene led to further reaction of **1**. This is perhaps not surprising as it is known that in general, metal–aryl bonds tend to be more resistent to protyolysis than metal–alkyl bonds (11).

Structural study

A crystallographic study showed that **1** crystalizes in the space group *Cc* with four discrete dimeric molecules per unit cell. The closest non-bonded approach between these dimers is 2.400 Å (H42—H32). The Ti atom separation within the dimeric molecule is found to be 6.725 Å; this compares with a Zr...Zr distance of 5.898 Å in the macrocyclic dimer $Cp_2Zr(\mu\text{-}OCH_2C(CH_3)_2CH_2O)_2ZrCp_2$ (6). The coordination spheres of the Ti atoms in **1** are best described as pseudo tetrahedral. Two π-bonded cyclopentadienyl groups, a σ-bonded phenyl ring and an oxygen atom of the dialkoxide complete the coordination spheres of the Ti atoms. An ORTEP drawing of **1** appears in Fig. 1.

The Ti—C distances for the cyclopentadienyl groups averages 2.41(1) Å, typical of Cp_2Ti fragments. The rotational relationship of the cyclopentadienyl rings is between staggered and eclipsed being closer to the latter. The Ti—O bond distances in **1** are 1.80(1) and 1.82(1) Å. These compare with Ti—O distances of 1.855(2) and 1.750(2) Å found in $Cp_2Ti(OEt)Cl$ and $[CpTiCl_2OCMe_2]_2$, respectively (12). The two Ti—O—C angles in **1** were found to be 146.4(9) and 148.0(9)°. These angles are significantly larger than that of 133.2(2)° found in $Cp_2Ti(OEt)Cl$ (12) and significantly smaller than that of 166.2(2)° found in $[CpTiCl_2OCMe_2]_2$ (12). These variations in the Ti—O—C angles are consistent with the expected variations in Ti—O $d\pi$—$p\pi$ multiple bond character based on metal Lewis acidity considerations. Theoretical support for such early-metal–oxygen π-bonding has been previously described (6). The Ti—C distances for the σ-bonded phenyl rings were found to be 2.21(1) and 2.25 Å in **1**. These Ti—C distances are comparable to those found in Cp_2TiPh_2 (2.27(1) Å) (13) and in $(indenyl)_2TiMe_2$ (2.21(2) Å) (14) and yet are considerably longer than those found in $TiBz_4$ (2.14(1) Å) (15). The angle between the planes of the two phenyl rings is 81.9°. Presumably this orientation minimizes the possible intramolecular steric interactions between these groups. The C11 and C41 phenyl rings are oriented 15.2 and 12.4° out of the corresponding C—Ti—O planes, respectively. Again this orientation minimizes steric interactions with the cyclopentadienyl groups on the respective titanium atoms. The C—Ti—O angles in **1** were found to be 95.0(4) and 91.0(5)° at Ti1 and Ti2, respectively. The average of these angles compare with the C—Ti—O angle found in $Cp_2Ti(OEt)Cl$ (12) (93.1(1)°); however, the cause of the 4° variation in the O—Ti—C angles in **1** is not clear. The distances and angles within the bridging dialkoxide moiety are typical and require no further comment.

A

The formation of **1** has some implications for the synthesis of early-metal macrocyclic complexes. The driving force behind the quantitative formation of **1** rather than a chelated mononuclear species (**A**) is not understood but may arise as a result of the Ti—O multiple bond character. Such bonding requires a relatively large Ti—O—C angle. Chelation to Ti of a dialkoxide cannot accommodate this structural feature and thus one might conclude that $d\pi$—$p\pi$ bonding inhibits ring closure and favours bridging structures. Implicit in such an argument is, however, the correlation between the Ti—O—C angle and $d\pi$–$p\pi$ bonding. Although this relationship seems intuitively sensible, recent structural studies of Ta and Nb aryloxide complexes imply that the M—O—Ar angle is an extremely flexible parameter (4*x*). It may be that the effects of the extended π system present in such aryloxide species afford the dramatic variation observed. It is noteworthy that both structural and theoretical data support the presence of significant $d\pi$–$p\pi$ bonding between Zr and O in the previously described Zr macrocycles (Scheme 1) (6). A second point that may be relevant to macrocycle formation is the conformation of **1** observed in the solid state. The phenyl rings on the Ti atoms are oriented towards each other. This "inside" conformation (**B**) avoids steric interactions of the cyclopentadienyl rings with the substituents of the bridging dialkoxide moiety that would be present in an "outside" conformation (**C**). If indeed, analogs of **1** are intermediates in the formation of the related Zr macrocycles then the preference for the "inside" conformer may facilitate the formation of the macrocyclic products.

A further implication of the formation of **1** may arise from the kinetic inertness of the second aryl group on Ti. This too, appears to favour bridging dialkoxide groups and thus afford the formation of **1**. It may be possible to employ the differing reactivities of metal-alkyl and metal-aryl groups towards hy-

B

C

drolysis to construct dissymetric early metal macrocycles. This aspect is the subject of ongoing study.

Towards supported catalyst models: the synthesis, characterization, redox chemistry, and structures of the complexes $Ti(OAr')_4$ ($Ar' = C_6H_4(2\text{-}t\text{-}Bu)$, $C_6H(2,3,5,6\text{-}Me)_4$)

ROBERT T. TOTH AND DOUGLAS W. STEPHAN[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received, July 9, 1990

ROBERT T. TOTH and DOUGLAS W. STEPHAN. Can. J. Chem. **69**, 172 (1991).

Reaction of substituted phenoxides with $TiCl_4$ affords the species $Ti(OAr')_4$ ($Ar' = C_6H_4(2\text{-}t\text{-}Bu)$, **1**; $Ar' = C_6H(2,3,5,6\text{-}Me)_4$, **2**). The compound $Ti(OC_6H_4(2\text{-}t\text{-}Bu))_4$, **1**, crystallizes in the tetragonal space group $P\bar{4}2_1c$, with a = 15.203(4) Å, c = 8.026(3) Å, Z = 2, and V = 1855(2) Å^3. The compound $Ti(OC_6H(2,3,5,6\text{-}Me)_4)_4$, **2**, crystallizes in the orthorhombic space group *Pbcn*, with a = 16.539(7) Å, b = 16.136(6) Å, c = 27.716(12) Å, Z = 8, and V = 7397(9) Å^3. The geometry of the Ti coordination sphere in these complexes is best described as pseudo-tetrahedral. In the case of **1** strict crystallographic $\bar{4}$ symmetry is imposed. The complex **2** exhibits reversible cyclic voltammetric behaviour consistent with a one electron reduction to the Ti(III) analogue. Chemical reduction of **2** employing sodium amalgam affords the quantitative formation of $(C_6H(2,3,5,6\text{-}Me)_4O)_2Ti(\mu\text{-}OC_6H(2,3,5,6\text{-}Me)_4)_2Na(THF)_2$, **3**. The reaction of **3** with $[(COD)Rh(\mu\text{-}Cl)]_2$ does not afford the Ti(III)/Rh(I) early–late heterobimetallic (ELHB) complex $(C_6H(2,3,5,6\text{-}Me)_4O)_2Ti(\mu\text{-}OC_6H(2,3,5,6\text{-}Me)_4)_2Rh(COD)$. The nature of all products is not known; however, redox chemistry, in which electron transfer from Ti(III) to Rh(I) occurs is evidenced by the generation of **2** and Rh(0). In addition, ligand transfer reactions giving uncharacterized Rh-alkoxides are suggested by the spectral data. The implications and ramifications for the synthesis of alkoxide bridged ELHB models of bimetallic heterogeneous catalyst systems are discussed.

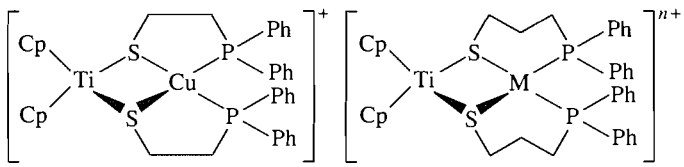
Key words: titanium phenoxides, redox chemistry, structures.

ROBERT T. TOTH et DOUGLAS W. STEPHAN. Can. J. Chem. **69**, 172 (1991).

Les réactions de phénolates substitués avec le $TiCl_4$ fournissent les espèces $Ti(OAr')_4$ [$Ar' = C_6H_4(2\text{-}t\text{-}Bu)$ (**1**) et $Ar' = C_6H(2,3,5,6\text{-}Me)_4$ (**2**)]. Le composé $Ti(OC_6H_4(2\text{-}t\text{-}Bu))_4$ (**1**) cristallise dans le groupe d'espace tétragonal $P\bar{4}2_1c$, avec a = 15,203(4) et c = 8.026(3) Å, Z = 2 et V = 1855(2) Å^3. Le composé $Ti(OC_6H(2,3,5,6\text{-}Me)_4)_4$ (**2**) cristallise dans le groupe d'espace orthorhombique *Pbcn*, avec a = 16.539(7), b = 16.136(6) et c = 27.716(12) Å, Z = 8 et V = 7397(9) Å^3. Dans ces complexes, la meilleure façon de décrire la sphère de coordination du Ti est de la considérer comme pseudo-tétraédrique. Dans le cas du composé **1**, une symétrie cristallographique $\bar{4}$ stricte est imposée. Le complexe **2** présente un comportement voltampérométrique cyclique réversible qui est en accord avec une réduction impliquant un électron et conduisant à l'analogue Ti(III). La réduction chimique du composé **2** à l'aide d'amalgame de sodium conduit à une formation quantitative du $(C_6H(2,3,5,6\text{-}Me)_4O)_2Ti(\mu\text{-}OC_6H(2,3,5,6\text{-}Me)_4)_2Na(THF)_2$ (**3**). La réaction du produit **3** avec du $[(COD)Rh(\mu\text{-}Cl)]_2$ ne fournit pas le complexe hétérobimétallique de la fin des premiers termes (ELHB) du Ti(III)/Rh(I), $(C_6H(2,3,5,6\text{-}Me)_4O)_2Ti(\mu\text{-}OC_6H(2,3,5,6\text{-}Me)_4)_2Rh(COD)$. La nature de tous les produits n'est pas connue; toutefois, la génération du composé **2** ainsi que du Rh(0) fournit des données expérimentales supportant une chimie d'oxydoréduction impliquant un transfert d'électron du Ti(III) au Rh(I). De plus, les données spectrales suggèrent l'existence de réactions de transferts de ligands conduisant à des alcoolates de Rh qui n'ont pas été caractérisés. On discute des implications de ces résultats et de leurs ramifications pour la synthèse d'ELBM pontés par le biais d'alcoolates qui seraient des modèles de systèmes catalytiques bimétalliques hétérogènes.

Mot clés: phénolates de titane, chimie d'oxydoréduction, structures.

[Traduit par la revue]



Introduction

In recent years our research has focused on the synthesis, characterization, and reactivity studies of complexes containing both early, oxophilic metals and late, electron-rich metal centres (1–19). Our interest in such species is prompted by the observation of strong metal-support interactions (SMSI) in heterogeneous catalyst systems (20). This phenomenon arises when late metals are dispersed on an early metal support such as titania. The result is a dramatic alteration of the reactivity patterns compared to dispersions of the same metal on other, non-Lewis acidic supports. The cause of the perturbations in reactivity is not clear, but one possibility that has some experimental support, is the direct role of the early metal in substrate activation (20). Alternatively, it has also been suggested that the support may act as an electron sink and thus the effects of the proximity of a Ti(III) centre on the reactivity of a late metal have come into question (20). In our efforts to study such questions, we have prepared several reducible early–late heterobimetallic (ELHB) species. Our initial efforts in this area involved the use of chelating phosphinethiolate ligands giving complexes of the form shown below (2–4). Structural data support the notion of dative interactions between the electron-rich, late metal and the d^0 Ti(IV) centres. Such metal–metal interactions may provide a vehicle for direct electron communication between the early and late metal centres, and thus may be related to the observations of SMSI. The implied role of reduced Ti centres in SMSI led us to study the redox chemistry of these heterobimetallics. These complexes undergo reversible chemical reduction affording the formally Ti(III)/M(I) (M = Cu, Rh) species. In the case of $CP_2Ti(\mu\text{-}SCH_2CH_2CH_2PPh_2)_2Rh$, the observation of coupling of the unpaired electron on Ti to Rh and P further suggests the possibility of a transannular, metal–metal communication (4).

Although these initial systems continue to be of interest, we are actively pursuing synthetic routes to other reducible ELHB compounds that may be more appropriate models for the metal centres in the heterogeneous systems where SMSI are observed. Thus, we have initiated efforts to prepare complexes in which a Ti centre is placed in an oxo environment (17, 18); the reason being that such a Ti environment will more effectively mimic the Ti centres of the support material, TiO_2. In this report, we describe some efforts to that end. The synthesis, characterization, electrochemical and structural studies of two complexes

M = Rh, $n = 1$; M = Ni, $n = 0$

of the general formula $Ti(OAr')_4$ are presented. Chemical reduction of these species with Na affords the Ti(III) species, $Ti(OAr')_4Na(THF)_2$. Attempts to derivatize this reduced material via metal ion exchange employing $[(COD)Rh(\mu\text{-}Cl)]_2$ failed to yield the desired Ti(III)/Rh(I) ELHB species. Rather, electron transfer occurred affording Ti(IV) and Rh(0). The results of these studies are presented and discussed and the utility of Ti(III) aryloxides for reduced ELHB complex synthesis is considered.

Experimental section

All preparations were done under an atmosphere of dry, O_2-free N_2 in a Vacuum Atmospheres' Inert Atmosphere glove box. The quality of the atmosphere was maintained employing a 5 cfm blower with a deoxygenation/drying catalyst column and a molecular sieve prepurifier canister. Solvents were reagent grade, distilled from the appropriate drying agents under N_2, and degassed by the freeze–thaw method at least three times prior to use. ^1H and $^{13}C\{^1H\}$ NMR experiments were performed using a Bruker AC-300 MHz spectrometer employing trace amounts of protonated solvent as the internal reference. Chemical shifts are reported relative to $Si(CH_3)_4$. Cyclic voltammetry was recored on a BAS CV-27 employing THF as the solvent, Bu_4NBF_4 as the supporting electrolyte, and Ag/AgCl as the reference electrode. Combustion analyses were performed by Galbraith Laboratories Inc., Knoxville, TN. Crystalline samples were shipped in ampoules sealed under an atmosphere of N_2.

Preparation of LiOAr'(Ar' = C_6H_4(2-t-Bu), C_6H(2,3,5,6-Me)$_4$)

These salts are prepared in a similar manner and thus a general route is described. HOAr' is stirred in hexane at 0°C while an equivalent of 2.5 M *n*-BuLi is slowly added. The reaction is allowed to stir while warming to 25°C over a 2 h period. The solvent is removed and the residue is washed with hexane. These solids were isolated and manipulated in a dry box and were used without further purification.

*Preparation of Ti(OAr')$_4$(Ar' = C_6H_4(2-t-Bu), **1**; C_6H(2,3,5,6-Me)$_4$, **2**)*

These compounds were prepared in a similar manner and thus only one description is given. To a slurry of $LiOC_6H_4$(2-*t*-Bu) (8.23 g, 52.7 mmol) in hexane (50 mL) was slowly added $TiCl_4$ (2.00 g, 1.16 mL, 10.5 mmol). The reaction was vigorously stirred for 12 h, during which time the mixture became yellow. Filtration of the solution followed by removal of the solvent yields a yellow powder. This material is extracted into benzene, filtered, and the solvent removed.

Recrystallization from pentane affords crystalline compound (yield: 5.85 g, 85%), **1**: ^1H NMR (d_6-benzene): δ (ppm), 7.37 (d of d, H_d), $|J^3_{H-H}| = 7.1$ Hz, $|J^5_{H-H}| = 1.3$ Hz, 7.19 (d of d, H_a), $|J^3_{H-H}| = 7.8$ Hz, $|J^5_{H-H}| = 1.6$ Hz, 6.91 (d of d of d, H_c), $|J^3_{H-H}| = 7.4$ Hz, 6.80 (d of d of d, H_b), 1.49 (s, 9H). $^{13}C\{^1H\}$ NMR (d_6-benzene): 127.09, 123.31, 123.21, 35.03, 30.33 ppm. *Anal.* calcd.: C 74.52; H 8.13; found: C 74.50; H 8.20, **2**: ^1H NMR (d_6-benzene): δ, 6.60 (s, 1H), 2.35 (s, 6H), 2.05 (s, 6H). $^{13}C\{^1H\}$ NMR (d_6-benzene): δ (ppm), 134.15, 128.52, 125.77, 122.82, 19.95, 13.31. *Anal.* calcd.: C 74.52; H 8.13; found: C 74.40; H 8.00.

*Generation of (C_6H(2,3,5,6-Me)$_4O)_2Ti(\mu$-OC_6H(2,3,5,6-Me)$_4)_2$ Na(THF)$_2$, **3***

To a yellow THF solution of **2** (0.070 g, 0.109 mmol) was added sodium amalgam (1.1 equiv. of Na). The mixture was stirred at 25°C for 2 h and the blue THF solution decanted from the amalgam. EPR (THF) g = 1.986.

*Reaction of **3** with $[(COD)Rh(\mu\text{-}Cl)]_2$*

To a THF solution of **3** (0.054 mmol generated as above) was added a THF solution of $[(COD)Rh(\mu\text{-}Cl)]_2$ (0.023 g, 0.054 mmol). With the addition of the Rh species the color of the solution changed from blue to greenish/brown. On standing for 24 h the solution became orange/brown and Rh metal plated on the surface of the flask. Monitoring of the reaction was accomplished by EPR and ^1H NMR. No EPR signal was observed. ^1H NMR data show resonances attributable to **1** and other uncharacterized diamagnetic products.

X-ray data collection and reduction

Diffraction experiments for compound **1** were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation (λ = 0.71069 Å) while the diffraction data for **2** was collected on a four-circle Rigaku AFC6 diffractometer also equipped with a graphite monochromator. The initial orientation matrices were obtained from 15 to 20 machine-centred reflections selected from a rotation photograph in the case of **1** and obtained by a zig–zag search routine in the case of **2**. These data were used to determine the crystal systems. Partial rotation photographs around each axis were consistent with a tetragonal crystal system for **1** while intensity measurements of equivalent reflections confirmed the Laue symmetry as *mmm* for the orthorhombic crystal system of **2**. The final lattice parameters and the orientation matrices were determined from 30 and 25 high-angle data ($20° < 2\theta < 25°$) for **1** and ($20° < 2\theta < 24°$) for **2**, respectively. The observed extinctions and ultimate structure refinements confirmed the space groups $P42_1c$ for **1** and *Pbcn* for **2**. *h, k, −l* were collected ($4.5° < 2\theta < 45.0°$) for **1**, while **2** and *h, k, −l* data were collected ($4.5° < 2\theta < 50.0°$). In each case, three standard reflections were recorded regularly during data collection. The intensities of the standards showed no statistically significant change over the duration of the data collection. The data were processed using the TEXSAN program package.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (21–23). The heavy atom positions were determined using direct methods. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinement was carried out by using full-matrix least-squares techniques on F, minimizing the function $w(|F_o| - |F_c|)^2$ where the weight, w, is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of the refinement of **1**, the titanium, oxygen, and methyl carbon atoms were assigned anisotropic temperature factors, while for **2** only the titanium atom was refined anisotropically. In both cases the phenyl ring carbon atoms were refined as rigid groups with individual isotropic thermal parameters. The hydrogen atom positions were calculated assuming a C—H bond length of 0.95 Å. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. The hydrogen atom contributions were calculated, but not refined. The residual electron densities, in each case, were of no chemical significance. Crystal data and data collection parameters are summarized in Table 1. Tables of positional parameters (Table 2) and selected bond distances and angles (Table 3) are reported. Thermal parameters (Table S1), hydrogen atom parameters (Table S2), and calculated and observed structure factors (Table S3) have been deposited.[2]

Results and discussion

The room temperature reaction of $TiCl_4$ with excess of the lithium salt of either 2-*t*-butylphenol or 2,3,5,6-tetramethylphenol led to the isolation, following the standard workup, of yellow microcrystalline solids. The isolated products are soluble in benzene, THF, diethyl ether, and hexane and are stable at room temperature for prolonged periods in the absence

of moisture and oxygen. The compounds also quickly degrade in protic or halogenated solvents. The ^{1}H NMR spectrum of the 2-*t*-butylphenol derivative showed resonances attributable to the expected aromatic and methyl protons indicative of the incorporation of the phenolate into the product **1**. The aromatic region of the ^{1}H NMR spectrum of **1** shows two doublets of doublets and two overlapping doublets of doublets of doublets (Fig. 1). Homonuclear decoupling experiments were used to confirm the coupling constant assignments. Selective irradiation of the methyl resonances permitted the observation of an NOE enhancement which confirmed the assignment of the resonances as shown in Fig. 1. The data are consistent with conformations of the ring substituents which are symmetric about the Ti atom. Similarly, the 2,3,5,6-tetramethylphenol derivative **2** exhibited the expected singlet resonance arising from the aromatic proton of the phenolate as well as the two singlets from the *ortho* and *meta* methyl groups. These data, in addition to the combustion analysis data, are consistent with the formulation of the products as Ti(OAr′)$_4$ (Ar′ = C$_6$H$_4$(2-*t*-Bu), **1**; Ar′ = C$_6$H(2,3,5,6-Me)$_4$, **2**). These formulations were subsequently confirmed by X-ray crystallographic studies (*vide infra*).

Similar reactions involving 2,6-di-*i*-propylphenolate and 2,6-di-*t*-butylphenolate have been described by Rothwell and co-workers (24, 25). In the former case, the isolated products were the homoleptic species M(OC$_6$H$_3$(2,6-*i*-Pr)$_2$)$_4$ (M = Ti, Zr). In the latter case, the yellow products were identified as M(OC$_6$H$_3$(2,6-*t*-Bu)$_2$)$_3$Cl (M = Ti, Zr). Attempts to effect further substitution were not successful. The authors surmized that the steric demands of the *ortho t*-butyl groups precluded the formation of Ti(OAr′)$_4$. Clearly, in the case of the present

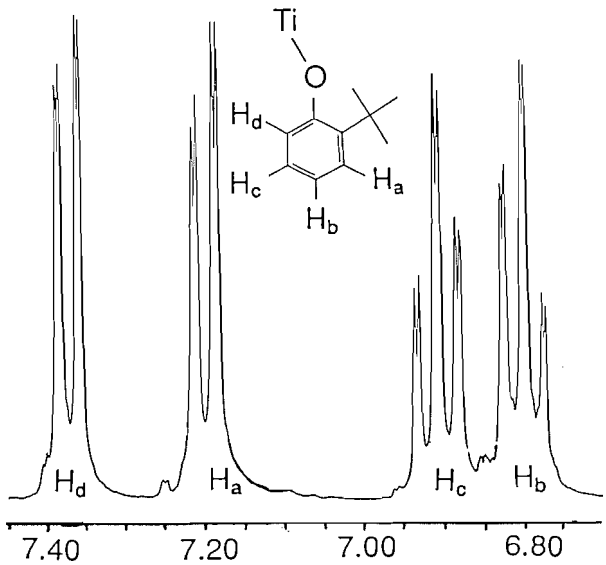

FIG. 1. Aromatic region of the ^{1}H NMR of **1**.

complexes, the lesser steric demands of 2-*t*-butylphenolate and 2,3,5,6-tetramethylphenolate permit ligand and substitutent conformations which allow the formation of tetraphenolate derivatives.

Structural studies

The X-ray crystallographic study of **1** showed that the molecule crystallizes in the space group $P42_1c$ with two independent molecules in the unit cell. The symmetry of the unit cell requires the Ti centre to occupy a site of 4 symmetry. The

*Bond distance in Å, bond angles in degrees. Estimated standard deviations in the least significant figure are given in parentheses.

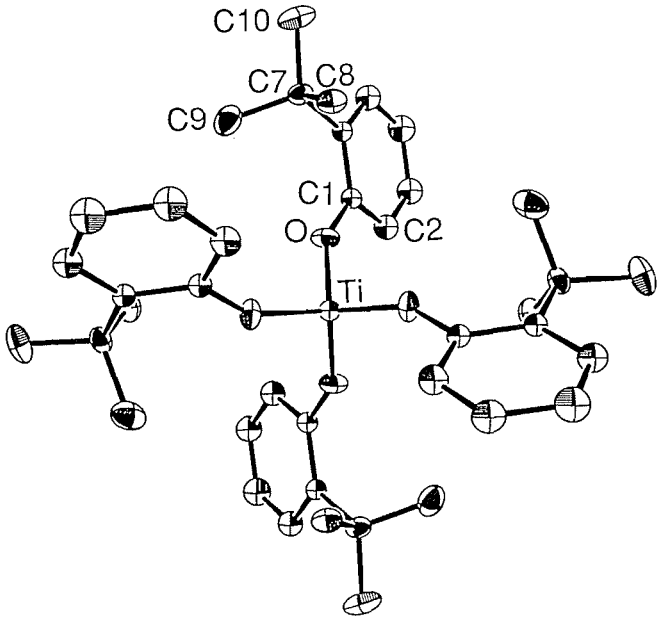

FIG. 2. ORTEP drawing of molecule **1**, 20% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity.

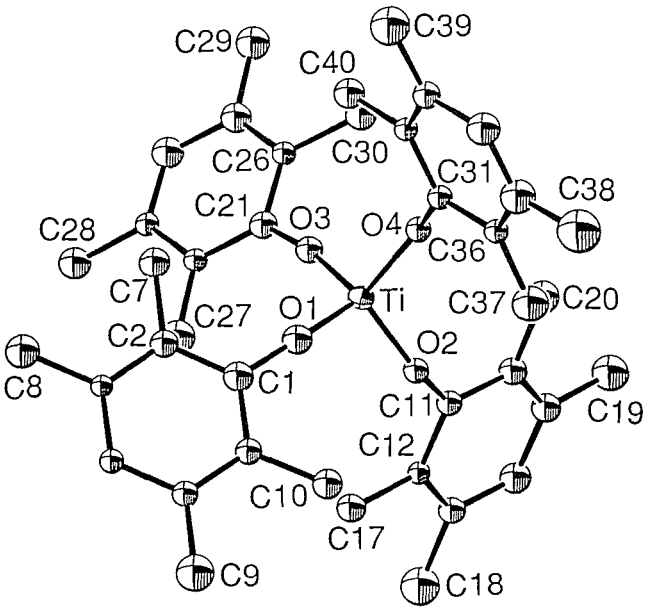

FIG. 3. ORTEP drawing of molecule **2**, 20% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity.

consequence of this crystallographically imposed symmetry is that the asymmetric unit contains only a single 2-*t*-butylphenolate ligand. Three other symmetry related ligands complete the coordination sphere of the Ti and maintain the strict 4 symmetry. An ORTEP drawing of molecule **1** is shown in Fig. 2. The closest approach between independent molecules is 2.539 Å (H8—H9).

A crystallographic study of **2** shows that the compound crystallizes in the space group *Pbcn* with eight molecules in the unit cell. The closest approach between molecules is found to be 2.205 Å (H47—H47). In this case, no crystallographic symmetry is imposed on the individual molecules and thus, the contents of the asymmetric unit is a single molecule of **2**. An ORTEP drawing of **2** is shown in Fig. 3.

Generally, Lewis acidic complexes readily form aggregates both in solution and in the solid state. For example, the complex $[Ti(OPh)_4 \cdot HOPh]$ has been shown to be a dimer (26). Smaller homoleptic alkoxide complexes of the early metals form higher aggregates, the nuclearity of which can be dependent on solvent, alkyl substituents and the metal (26). The mononuclearity of **1** and **2** is attributed to the bulk of the ligands. Similar complexes have been previously described where bulky substituents stabilize mononuclear complexes despite the Lewis acidity of the metal centre.

The coordination spheres of the Ti atoms of both **1** and **2** are pseudo-tetrahedral in geometry. In the case of **1**, the imposed symmetry results in O—Ti—O′ angles of 108.6(1) and 111.3(2)°. In a similar manner, the O—Ti—O′ angles about the Ti in **2** fall between 107.1(8)–111.8(7)°. The range of the angles about Ti can be attributed to the orientations of the aryl moieties. The conformation or packing arrangement of the aryl rings appears to be an accommodation of the steric demands of the *ortho* substituents. Closer proximity of these substituents to adjacent rings corresponds to the slightly larger O—Ti—O′ angles. The Ti—O distance observed in **1** is 1.779(3) Å while in **2** the Ti—O distances range between 1.76(2) and 1.79(2) Å. These distances are comparable to that of 1.78(1) Å for $Ti(OC_6H_3(2,6\text{-}i\text{-}Pr)_2)_4$ (24) and 1.80(1) Å found for $Ti(OC_6H_3(2,6\text{-}t\text{-}Bu)_2)_3I$ (24). The Ti—O distances found in **1** and **2** are shorter than both the terminal Ti—O bond distances of 1.86(2) Å found in the related Ti(III) species $(2,6\text{-}i\text{-}Pr)_2C_6H_3O)_2Ti(\mu\text{-}OC_6H_3(2,6\text{-}i\text{-}Pr)_2)_4Na(THF)_2$ (25) and the Ti—O distance of 1.807(8) Å found in $Ti(OC_6H_3(2,6\text{-}t\text{-}Bu)_2)(THF)_2Cl_2$ (27). This is consistent with the greater π-acceptor ability of Ti(IV) compared to that of Ti(III). The relatively short Ti—O distances are consistent with the proposition of Ti—O $d\pi$—$p\pi$ bonding. Such π interactions between a Lewis acidic titanium centre and oxygen, nitrogen, and phosphorus donors has been previously suggested (16–19). The Ti—O—C angle found in **1** is 151.9(3)°. For **2** the corresponding angles are 149(1), 149(1), 162(1), and 170(1)°. The corresponding angles in $Ti(OC_6H_3(2,6\text{-}i\text{-}Pr)_2)_4$ were found to be 166.1(3) and 164.5(3)° (24) while in $Ti(OC_6H_3(2,6\text{-}t\text{-}Bu)_2)(THF)_2Cl_2$ the Ti—O—C angle is 174.2(9)° (27). Presumably, the broad range observed for the Ti—O—C angles is a reflection of the structural compromise between the steric demands of the substituted phenoxides and the Lewis acidity of the metal centre. Bond distances and angles within the aryl substituents are as expected and require no further comment.

Redox chemistry

Cyclic voltammetric studies of **2** were performed in THF employing Bu_4NBF_4 as the supporting electrolyte and a Ag/AgCl electrode as the reference. The results are illustrated in Fig. 4. A quasi-reversible wave is observed at −1.19 V relative to Ag/AgCl. The peak separation of 220 mV is substantially greater than that expected for a completely reversible one-electron transfer, nonetheless repetitive scans at scan rates between 20 and 500 mV/s showed no decay in the current. The potential at which the redox chemistry occurs is consistent with a Ti(IV)/Ti(III) redox couple suggesting that the reduced species being generated is $[Ti(OC_6H(2,3,5,6\text{-}Me)_4)_4]^-$. Chemical reduction of **2** is achieved employing sodium. The EPR spectrum of the blue THF solution of **3** shows a single centre band resonance at $g = 1.986$, consistent with the

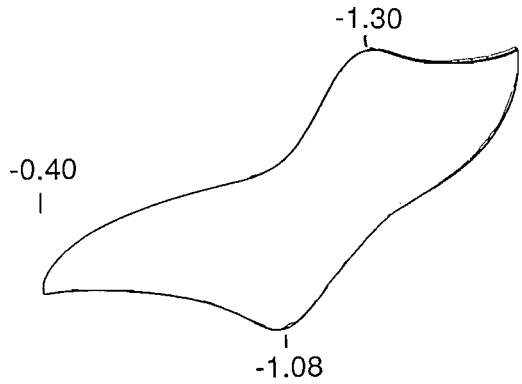

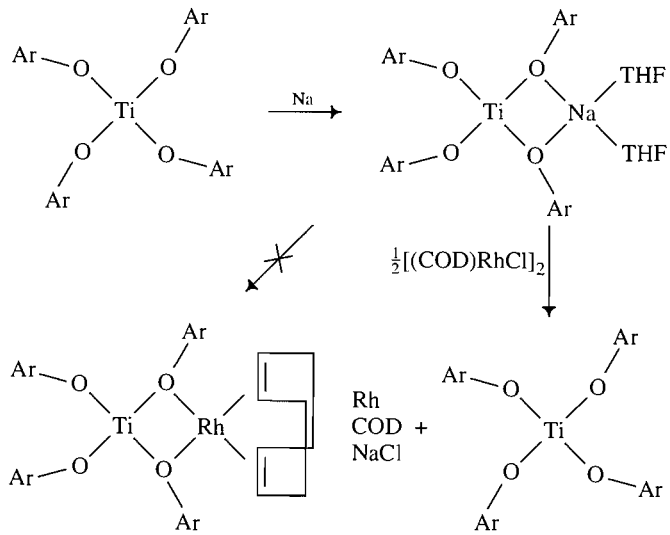

FIG. 4. Cyclic voltamogram of **2** in THF employing NBu_4BF_4 as the supporting electrolyte. The potential shown are referenced to Ag/AgCl electrode. The scan speed employed was 250 mV/s.

SCHEME 1

generation of a metal-based radical. The *extremely* air-sensitive Ti(III) species **3** is formulated as $(C_6H(2,3,5,6\text{-}Me)_4O)_2Ti(\mu\text{-}OC_6H(2,3,5,6\text{-}Me)_4)_2Na(THF)_2$ by analogy to the products of reduction of some related homoleptic early metal aryl-oxides described by Rothwell and co-workers (24).

Attempts to employ this anion as a metalloligand and effect complexation to Rh were undertaken. Reaction of **3** with $[(COD)Rh(\mu\text{-}Cl)]_2$ was performed in THF under strictly anaerobic conditions. Upon addition of the Rh species the solution becomes greenish/brown. Ultimately a grey precipitate appears and the solution becomes orange/brown. Monitoring of the reaction by EPR shows loss of the resonance attributable to **3**. The NMR of the final solution indicates the presence of **2** and other diamagnetic products. In addition Rh metal plates out on the surface of the flask. These data suggest a redox reaction in which the Ti(III) species **3** is oxidized to **2** with concurrent reduction of the Rh(I) to Rh(0). Alternatively, Rh-aryloxide species may be formed in ligand transfer reactions. Similar thiolate ligand transfers from Ti to Rh have been previously described (28). The formation of Rh-aryloxide species may account for the observation of other diamagnetic products; however, no single Rh-containing species could be isolated from the reaction mixtures. It may be that the reaction of **3** with Rh(I) chloride proceeds through the desired ELHB species $[(C_6H(2,3,5,6\text{-}Me)_4O)_2Ti(\mu\text{-}OC_6H(2,3,5,6\text{-}Me)_4)_2Rh(COD)]$; however, no evidence for the existence of this Ti(III)/Rh(I) intermediate has been observed (Scheme 1). This is in contrast to thiolato- and phosphido-bridged systems where Ti(III)/Rh(I) ELHB complexes can be isolated and unequivocally characterized (2–4, 16).

It appears that the oxidation potential of the Ti(III) species **3** is too negative to permit the use of this species as a metalloligand for Rh(I). It may be possible to shift the redox potential in a positive direction by tuning the nature of the substituents on the phenoxides. Presumably more electron-withdrawing substituents will help to stabilize Ti(III) and thus inhibit electron transfer. Alternatively strong electron-donor ligands on Rh would make the Rh centre less electron accepting and thus also serve to inhibit electron transfer from Ti(III). These approaches are being pursued in continuing efforts to mimic the heterogeneous catalyst systems.

π-Facial stereoselectivity in the Diels–Alder reactions of a rigid carbocyclic diene: spiro(bicyclo[2.2.1]heptane-2,1′-[2,4]cyclopentadiene)

D. Jean Burnell[1] and Zdenek Valenta[2]

Department of Chemistry, University of New Brunswick, Bag Service No. 45222, Fredericton, N.B., Canada E3B 6E2

Received August 1, 1990

D. Jean Burnell and Zdenek Valenta. Can. J. Chem. **69**, 179 (1991).

The plane-nonsymmetrical diene spiro(bicyclo[2.2.1]heptane-2,1′-[2,4]cyclopentadiene) (**2**) was synthesized, and the π-facial stereoselectivity of its Diels–Alder cycloadditions with three cyclic dienophiles was examined. Adduct ratios were very similar, and the selectivity is surmised to be mainly the result of steric interactions at the transition state.

Key words: facial stereoselectivity, Diels–Alder, cycloaddition.

D. Jean Burnell et Zdenek Valenta. Can. J. Chem. **69**, 179 (1991).

On a synthétisé le spiro(bicyclo[2.2.1]heptane-2,1′-[2,4]cyclopentadiène), un diène qui n'est pas symétrique par rapport au plan, et on a étudié la stéréosélectivité π-faciale de ses cycloadditions avec trois diénophiles cycliques. Les rapports d'adduits sont très similaires et on fait l'hypothèse que la sélectivité est principalement le résultat d'interactions stériques dans l'état de transition.

Mots clés : stéréosélectivité faciale, Diels–Alder, cycloaddition.

Introduction

The last decade has seen a great deal of interest in π-facial stereoselectivity in Diels–Alder reactions with plane-nonsymmetrical addends. Steric interactions between the diene and an incoming dienophile have been invoked to explain π-facial stereoselectivity in many instances (1–3). Enantioselective Diels–Alder reactions (4) work in this way, too, because the interaction of a plane-symmetrical diene with a chiral auxiliary on a dienophile, or with an achiral dienophile in the presence of a chiral Lewis acid catalyst, leads to steric interactions at the transition state that are different at the two diene faces.

The best known examples of kinetically controlled Diels–Alder reactions leading to sterically disfavored products are the reactions of 5-heteroatom-substituted cyclopentadienes (5, 6). More recently some other cyclic and acyclic heteroatom-substituted dienes have shown a similar proclivity (7).[3] However, some cyclic, purely hydrocarbon, diene molecules give cycloaddition products that arise predominantly by addition to the sterically more hindered face, and this has been rationalized as a result of mixing of framework σ orbitals into the diene π system (11). Previously we synthesized the plane-nonsymmetrical diene **1**, and we used the results of its reactions with various dienophiles to shed light on the transition state geometry of the Diels–Alder reaction (12). Our conclusions were based on an assumption that π-facial stereoselectivity in **1** should be governed by steric interactions between either face of the diene and the incoming dienophile. This assumption and some of our conclusions regarding the transition state geometry were consistent with MM2 models of the reactions of **1** (13). The synthesis of the bicyclo[2.2.1]heptane analog **2** is outlined in this paper. The results of thermally induced and Lewis acid catalysed reactions of **2** are described, and these results are used to help delineate the parameters that control π-facial stereoselectivity.

Results

Synthesis of diene 2

The synthesis of diene **2** was based on our route to diene **1** (12). The enamine **3** alkylated slowly with 2-chloro-3-iodo-1-propene in acetonitrile to give the chloro-aldehyde **4**, which was taken to the alcohols **7** and **8** without purification. Thus, hydrolysis of the vinyl chloride by mercuric acetate in formic acid provided the keto-aldehyde **5**, which cyclized readily in ethanolic KOH to the enone **6**, and reduction with sodium borohydride in the presence of cerium(III) chloride (14) yielded a 7:3 mixture of the epimeric alcohols.[4] Structure **7** was assigned to the major product based on a lanthanide-induced shift nmr study. The mixture of **7** and **8** was treated with *para*-toluenesulfonyl isocyanate, then heated in boiling benzene for 2 days to effect elimination. After chromatography through a short silica column, pure diene **2** was obtained as a colorless liquid. The diene showed absorptions at 205 and 258 nm in the ultraviolet, just like **1** (12). The four olefinic protons of **2** were completely resolved in its 360 MHz ^{1}H nmr spectrum,

[3]These results have been explained in terms of a number of through-space and through-bonds orbital interactions (6, 8), torsional considerations (9), and repulsive electrostatic effects (10).

[4]In contrast, reduction of the corresponding cyclopentenone attached to a bicyclo[2.2.2]octane system proceeded without any selectivity (12).

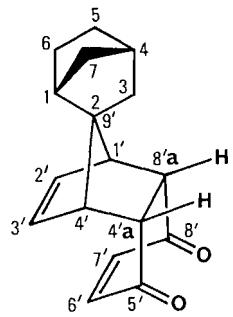
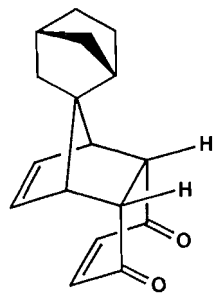
For personal use only.

and the ^{13}C nmr shifts were unremarkable except for the shifts of C-1 (δ 44.1) and C-3 (δ 33.9) that were significantly upfield of their expected positions. The overall, unoptimized, yield of diene **2** from the enamine **3** was 16.5%.



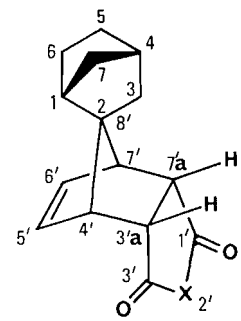
Diels–Alder reactions with 2

The diene **2** reacted readily with *para*-benzoquinone, maleic anhydride, and *N*-phenylmaleimide in boiling dichloromethane with yields of 96%, 98%, and 100%, respectively. Also, Lewis acid catalysed addition of *N*-phenylmaleimide to **2** in the presence of boron trifluoride etherate proceeded at −78°C in a yield of 95%. Each product showed two sets of signals in its 360 MHz ^1H nmr spectrum, attributable to a major and a minor adduct. Ratios of major to minor were obtained by careful integration of the nmr spectra. Thus, for the *para*-benzoquinone adducts the ratio was 69:31 (i.e. $\Delta\Delta G^{\neq} = 0.50$ kcal mol^{-1} at 40°C), for the maleic anhydride adducts it was 72:28 ($\Delta\Delta G^{\neq} = 0.58$ kcal mol^{-1}), and for the thermally produced *N*-phenylmaleimide adducts it was 69:31 ($\Delta\Delta G^{\neq} = 0.50$ kcal mol^{-1}). The rates of the three thermal reactions were similar, but the rate of the Lewis acid catalysed reaction was very much faster. Nevertheless, the ratio of adducts obtained from the catalysed *N*-phenylmaleimide reaction was 73:27 ($\Delta\Delta G^{\neq} = 0.39$ kcal mol^{-1} at −78°C), only slightly different from the corresponding thermal reaction.



Assignment of the structures of the major and the minor adducts

A detailed ^1H nmr assignment was made using one of the mixtures of *N*-phenylmaleimide adducts. Fortunately, the ^1H nmr spectra of the adduct mixtures derived from the other dienophiles were *very* similar, so this assignment could also be applied to the other mixtures.



The spectrum, excluding the aromatic signals, of the mixture of *N*-phenylmaleimide adducts is shown in Fig. 1(a). Signals due to the major and the minor adducts are evident. The eight-line pattern (the AB portion of an ABMX system) centred at δ 3.54 was readily assigned by its size, its chemical shift, and from a spin–spin decoupling study to the methines α to the carbonyls (C-3′a and C-7′a) of the major adduct. Irradiation at δ 3.54 with a fairly wide bandwidth resulted in nuclear Overhauser enhancement (nOe) of two geminally coupled (J = 12.5 Hz) signals: a doublet of doublets at δ 1.075 (7% enhancement) and a doublet of apparent triplets at δ 1.434 (8% enhancement). The latter had been buried in a complex part of the spectrum (see Fig. 1(b)). These two signals could only arise from the two protons on the C-3 methylene of the adduct. This result placed this methylene group in the proximity of the methine α to the carbonyls, i.e., the major adduct could only have been **11***a*. (A significant nOe had been observed between the corresponding protons in a major adduct derived from the symmetrical diene **1** (12), and that structure has since been corroborated unequivocally by X-ray crystallography (15).) Given the structure of the major adduct **11***a*, other signals in its nmr spectrum could be assigned with more precision. Since the doublet of doublets at δ 1.075 had less coupling than its geminal partner at δ 1.434, we assigned the former to the *endo* proton at C-3 and the latter was assigned to the *exo* C-3 proton (16). Irradiation of the C-3 *endo* proton's signal (δ 1.075) resulted in nOe of the upfield half of the eight-line pattern centered at δ 3.54, which was therefore attributed to the closer methine proton, i.e., the one on C-7′a. The decoupling experiments

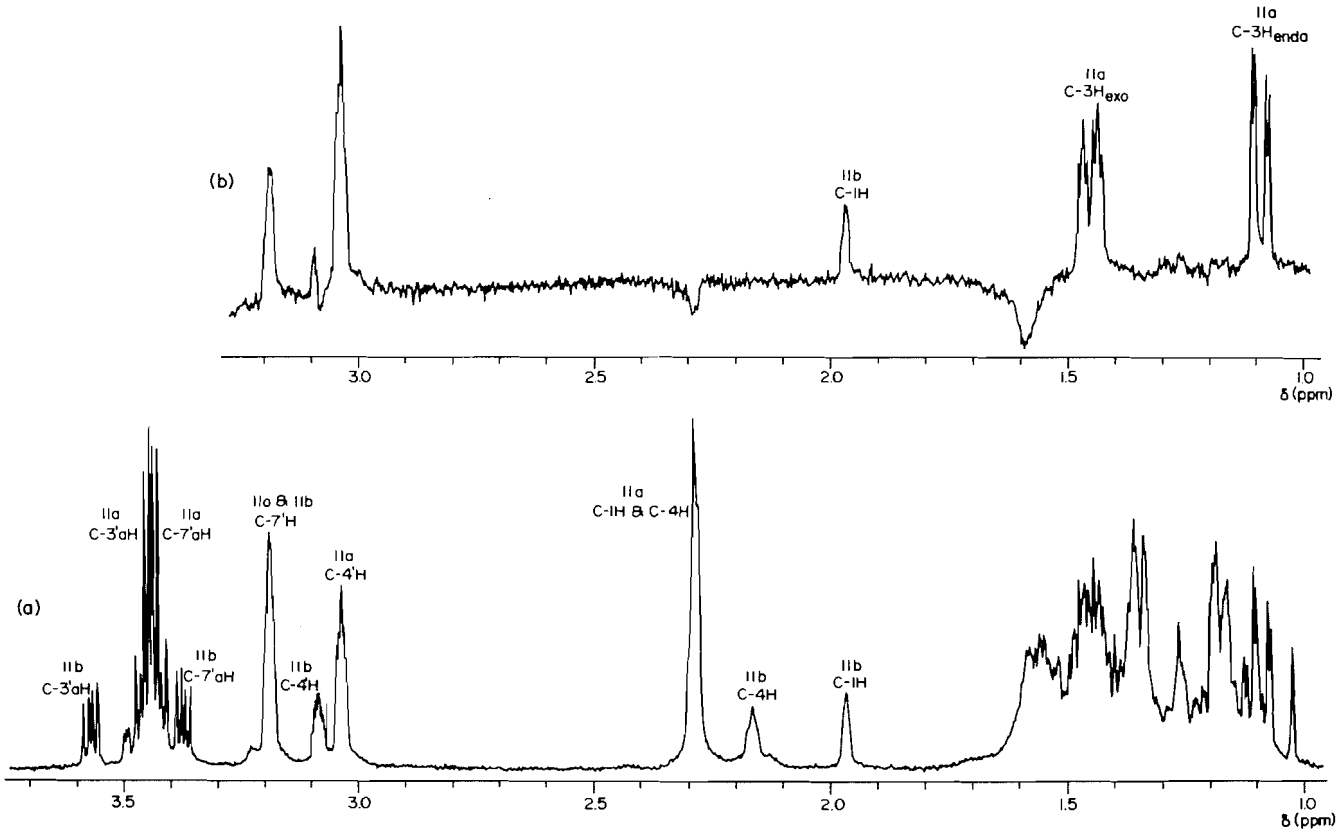

FIG. 1. (a) The upfield portion of the ^{1}H nmr spectrum (400 MHz) of the crude mixture of the adducts **11***a* (major) and **11***b* (minor) in $CDCl_3$. (b) Nuclear Overhauser difference spectrum (×16) of this mixture with irradiation centered at δ 3.54.

were then used to assign the remaining resonances, which are reported in detail in the Experimental.

Smaller doublet-of-doublet systems arising from the methines α to the carbonyls of the minor adduct flanked the corresponding signals from the major isomer (Fig. 1(a)). Irradiation at δ 3.54 affected the signals of the minor adduct, also. However, in this isomer it was a signal at δ 1.953, due to to one of the bridgehead methines of the saturated bicyclo[2.2.1]heptane moiety, that showed the greatest nOe (see Fig. 1(b)), so the minor adduct was assigned structure **11***b*. The relative positions of the signals for the major and the minor adduct were so similar for every adduct pair that it was clear that every major adduct has the same relative stereochemistry, i.e., the result of an *endo* addition *syn* to the C-3 methylene of **2** (**9***a*, **10***a*, and **11***a*), and every minor adduct had the same relative stereochemistry, i.e., the result of an *endo* addition *syn* to the C-1 methine of **2** (**9***b*, **10***b*, and **11***b*). Unfavorable steric interactions were expected to preclude the formation of *exo* addition products. In fact, no *exo* addition products were found.

Discussion

The π-facial stereoselectivity observed in the Diels–Alder reactions of isodicyclopentadiene and many related systems is controlled primarily by an electronic effect stemming from mixing of some σ orbitals from the plane-nonsymmetrical framework into the diene π system (11). Paquette *et al.* (17) have shown that some plane-symmetrical modifications to the isodicyclopentadiene system can reverse its π-facial stereoselectivity, and they correlated π-facial stereoselectivity with differences in nmr chemical shifts. Recently, Ipaktschi *et al.* (18) reported additions to a homo derivative of isodicyclopentadiene that also has π-facial stereoselectivity opposite to the parent compound. Thus, small differences in structure can produce large differences in π-facial stereoselectivity when there is appreciable mixing of framework σ orbitals and the diene π system. However, small differences are unlikely to produce large changes in selectivity when that selectivity is governed by steric interactions.

In our previous work with diene **1** we concluded tentatively that steric interactions were governing the π-facial stereoselectivity (12). However, we did note unusually high field ^{13}C nmr shifts for the C-1 and C-3 carbons of its bicyclo[2.2.2]octane moiety (δ 31.4 and 28.9, respectively). This suggested that some mixing of the framework σ orbitals into the π system might have been present, which in turn might have modulated the π-facial stereoselectivity. Diene **2** was intended to provide a diene similar to **1** from the point of view of the steric interactions that it would present to an incoming dienophile, but the dienes were different with respect to the composition of their plane-nonsymmetrical frameworks. However, just as in the case of diene **1** (12), the shifts of two of the carbons of the bicyclo-[2.2.1]heptane moiety of **2** were significantly upfield of their "expected" positions. (This is evident if one simply compares the shifts of the carbons of **2** with the shifts for the corresponding carbons in its synthetic precursors. Thus, the C-1 methine of **2** resonates at δ 44.1, but in **6**, **7**, and **8** these are at δ 49.4, 50.5, and 48.4, respectively. More dramatically, the C-3 methylene of **2** is at δ 33.9, whereas in **6**, **7**, and **8** these are at δ 45.4, 45.9, and 47.3, respectively. These differences are almost certainly too large to be dismissed as δ-substituent effects.)

We hoped that a comparison of the reactions of **2** with the reactions of **1** (12) might help to determine the relative

importance of the various effects that contribute to π-facial stereoselectivity in the Diels–Alder reaction. Diene **2** proved to be only slightly less selective than **1** with the same dienophiles. Furthermore, the ratios of adducts derived from **2** were very similar for the three dienophiles tested. The Lewis acid catalysed reaction with *N*-phenylmaleimide was, in terms of product ratio, only slightly more selective (but with a *smaller* $\Delta\Delta G^{\neq}$) than the thermally induced reaction, in spite of the large differences in rate and the fact that the Lewis acid complexed dienophile must be unsymmetrical. This parallels our earlier findings (2, 12) and recent results from Paquette's group (3). Furthermore, it serves to reinforce our assertion (2, 12) that the geometry of the transition state of the Diels–Alder reaction is much more sensitive to reaction rate in the *endo* region than in the *exo* region, where the plane-nonsymmetry resides in diene **2**.

The similarity of adduct ratios in reactions of **1** and **2** is expected when the π-facial stereoselectivity is controlled by steric interactions. What is more compelling is that a computational study (13) has confirmed that the π-facial stereoselectivity observed in the reactions of **2**, as well as in our previous study with **1**, can be attributed to steric interactions between the incoming dienophile and hydrogens on the bicyclo[2.2.1]heptane, or bicyclo[2.2.2]octane, moiety.

Experimental

Ultraviolet (uv) spectra were obtained with a Beckman model 25 spectrophotometer. Infrared (ir) spectra were recorded on a Perkin–Elmer 727B spectrophotometer in $CHCl_3$ solution. Routine ^1H nuclear magnetic resonance (nmr) spectra were obtained on a Varian T-60 instrument, and routine ^{13}C nmr spectra were run on a Varian CFT-20 instrument. The ^1H nmr spectra at 360 MHz of **2** and its adducts were via Mr. Alan Lee, Department of Medical Genetics, University of Toronto. The nOe and spin–spin decoupling work with a mixture of **11***a* and **11***b* was performed on a Bruker WH-400 instrument by Dr. Thomas T. Nakashima, Department of Chemistry, University of Alberta. Low resolution mass spectra (ms) were obtained on an Hitachi Perkin–Elmer RMU-6D instrument. High resolution mass spectra were determined by Dr. A. M. Hogg, Department of Chemistry, University of Alberta, on an AEI MS-50 spectrometer. Reactions were run under an atmosphere of dry nitrogen. Solvents were distilled, and aqueous solutions are implied by saturated NaCl, dilute $NaHCO_3$, etc.

2-(Pyrrolidinomethylene)-bicyclo[2.2.1]heptane (3)

Crude enamine **3** was obtained from a mixture of *endo* and *exo* bicyclo[2.2.1]heptane-2-carboxaldehyde by the method described in ref. 12. For **3**: ir ν_{max}: 3200 (very broad), 1720, and 1675 cm^{-1}; ^1H nmr δ: 5.89 (1H, apparent t), 3.07 (4H, br t), and 1.0–2.65 (m).

(1RS,2RS,4SR)-2-(2-Chloro-2-propenyl)-bicyclo[2.2.1]heptane-2-carboxaldehyde (4)

2-Chloro-3-iodo-1-propene (9.30 g, 46.0 mmol) and crude **3** (2.6 g, 14.7 mmol assuming pure **3**) in dry acetonitrile (approx. 200 mL) were heated under reflux for 4 days. The solution was evaporated to half its volume and 100 mL of a 1:1 mixture of H_2O and THF was added to the dark red solution. The mixture was stirred at room temperature overnight. Ether (100 mL) and H_2O (200 mL) were added. The organic extract was washed with 5% HCl (100 mL), 10% $Na_2S_2O_3$ (100 mL), saturated $NaHCO_3$ (100 mL), and saturated NaCl (2 × 200 mL). The solution was dried ($MgSO_4$) and concentrated. Column chromatography on silica gel (hexanes – ethyl acetate) provided 1.25 g (43%) of **4** as a pale yellow oil; ir ν_{max}: 2950, 2870, 2820, 2730 (m), 1720, 1635, and 885 cm^{-1}; ^1H nmr δ: 9.68 (1H, s), 5.22 (1H, d, J = 1.5 Hz), 5.07 (1H, br s, $W_{1/2}$ = 3 Hz), 3.03 (1H, br d, J = 16 Hz), 2.53 (1H, d, J = 16 Hz), and 1.1–2.4 (10, m); ^{13}C nmr δ: 205.5 (CHO), 138.5 (=CCl), 115.5 (=CH_2), 57.4 (C-2), 46.2 (CH_2), 45.0 (C-1), 38.1 (2C, C-4 and C-7), 34.7 (C-3), 27.6 (C-5), and 25.1 (C-6); ms m/z (%): 200 and 198 (0.6 and 1.9, M^+), 163 (19), 122 (76), 105 (20), 95 (36), 93 (64), 91 (37), 81 (41), 80 (40), 79 (52), 77 (33), 67 (100), 66 (46), 65 (28), 55 (23), and 53 (25).

(1RS,2RS,4SR)-2-(2-Oxopropyl)-bicyclo[2.2.1]heptane-2-carboxaldehyde (5)

Mercuric acetate (2.01 g, 6.29 mmol) was added to a solution of **4** (1.25 g, 6.29 mmol) in 98% formic acid (32 mL). This mixture was stirred at room temperature for 25 h. The mixture was poured into 300 mL of saturated NaCl and extracted with ether (3 × 100 mL). The combined organic layers were washed with saturated $NaHCO_3$ until gas evolution ceased, then with saturated NaCl (200 mL). The solution was dried ($MgSO_4$) and concentrated to provide crude **5** as a brown oil (0.62 g, 55%). A small portion was purified by preparative tlc to give a low-melting solid; ^1H nmr δ: 9.73 (1H, s), 3.33 (1H, d, J = 18 Hz), 2.53 (1H, d, J = 18 Hz), 2.10 (3H, s), and 1.9–2.5 (10H, m); ^{13}C nmr δ: 207.9 (CHO), 206.3 (C=O), 54.0 (C-2), 52.5 (CH_2), 45.7 (C-1), 40.2 (C-3), 38.8 (C-7), 37.9 (C-4), 29.9 (CH_3), 27.9 (C-5), and 25.0 (C-6).

(1RS,2RS,4SR)-Spiro(bicyclo[2.2.1]heptane-2,1'-[4]cyclopenten-3-one) (6)

A solution of crude **5** (533.6 mg, 2.96 mmol) in 50 mL of freshly prepared 5% (w/v) KOH in degassed absolute ethanol was heated under reflux for 2 h. The mixture was poured into cold H_2O (150 mL), which was extracted with ether (3 × 50 mL). The combined organic extracts were washed with H_2O (150 mL), 5% HCl (150 mL), dilute $NaHCO_3$ (100 mL), and saturated NaCl (100 mL). The solution was dried ($MgSO_4$) and the solvent was evaporated to provide the crude enone **6** as an oil (397.5 mg, 83%). A small portion was purified by preparative tlc: ^1H nmr δ: 7.62 (1H, d, J = 6 Hz), 6.05 (1H, d, J = 6 Hz), 2.4 (1H, br m), 2.39 (1H, d, J = 19 Hz), 2.19 (1H, d, J = 19 Hz), and 1.0–2.3 (9H, m); ^{13}C nmr δ: 209.8 (C=O), 171.0 (β =CH), 132.7 (α =CH), 53.3 (CH_2), 51.6 (C-2), 49.4 (C-1), 45.4 (C-3), 39.3 (C-7), 37.5 (C-4), 29.1 (C-5), and 24.4 (C-6); ms m/z (%): 162 (62, M^+), 134 (39), 95 (100), 94 (30), 91 (27), 79 (29), 77 (30), 68 (44), 67 (69), 66 (61), 65 (24), 55 (23), 53 (28), and 52 (21).

(1RS,2RS,4SR,4'SR)- and (1RS,2RS,4SR,4'RS)-Spiro(bicyclo-[2.2.1]heptane-2,1'-[4]cyclopenten-3-ol] (7 and 8, respectively)

A solution of **6** (138.7 mg, 0.855 mmol) in methanol (5 mL) was cooled in an ice-bath as $CeCl_3 \cdot 7H_2O$ (376.2 mg, 1.00 mmol) was added, followed by $NaBH_4$ (approx. 200 mg, 5.3 mmol) in small portions. The mixture was stirred at room temperature for 1 h. Addition of H_2O (15 mL) and ether (20 mL) produced some sticky material that necessitated filtration through Celite. The aqueous layer of the filtrate was reextracted with ether, and the combined organic extracts were washed with saturated NaCl, dried ($MgSO_4$), and concentrated to provide a mixture of the epimeric alcohols **7** and **8** (7:3, respectively, by ^{13}C nmr gated to suppress the nOe) as an oil (140.2 mg, 99%); ir ν_{max}: 3600, 3440 (br), 2945, and 2860 cm^{-1}; ^1H nmr δ: 5.6–6.0 (m) and 4.6–4.9 (m), 2.6 (br s, disappeared with D_2O), 2.43 (center of AB signal due to **8**), 2.22 (center of AB signal due to **7**), and 0.7–2.3 (m); ^{13}C nmr for **7** (from the mixture) δ: 142.0 (=CH), 133.1 (=CH), 77.2 (CHOH), 54.5 (C-2), 52.6 (CH_2), 48.4 (C-1), 47.3 (C-3), 39.0 (C-7), 37.3 (C-4), 29.0 (C-5), and 25.2 (C-6); ^{13}C nmr for **8** (from the mixture) δ: 143.3 (=CH), 132.0 (=CH), 76.8 (CHOH), 54.1 (C-2), 52.1 (CH_2), 50.5 (C-1), 45.9 (C-3), 39.0 (C-7), 37.2 (C-4), 29.0 (C-5), and 24.6 (C-6); ms m/z (%): 164 (23, M^+), 146 (5), 121 (28), 96 (75), 95 (100), 91 (23), 83 (23), 82 (27), 81 (35), 80 (39), 79 (38), 67 (54), 66 (25), 55 (23), 53 (21), and 41 (42).

Lanthanide-induced shift study of the mixture of 7 and 8

A solution of 140 mg of a mixture of **7** and **8** in $CDCl_3$ was doped with a small amount of tris(2,2,6,6-tetramethyl-3,5-heptanedionato)-europium(III) (Aldrich). After a few hours the solution was filtered through a glass-wool plug, and the proton noise-decoupled ^{13}C nmr spectrum was obtained in the usual manner. The molar ratio of shift reagent to alcohols was determined by comparing the magnitude of the signal due to the methyl groups of the ligand with the signals due to **7** and **8**. More shift reagent was added until spectra were obtained for six molar ratios. Plots of lanthanide-induced shift versus molar ratio of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

lanthanide were linear. The magnitudes of the shifts, extrapolated to a 1:1 substrate-to-lanthanide ratio, were as follows: for the major alcohol (**7**): C-1, 4.0 ppm; C-2, 10.0 ppm; C-3, 6.5 ppm; C-4, 3.5 ppm; C-5, 3.0 ppm; C-6, 3.3 ppm; C-7, 3.4 ppm; C-2′, 11.0 ppm; C-3′, 14.0 ppm; C-4′, 58.7 ppm; and C-5′, 17.3 ppm; for the minor alcohol (**8**): C-1, 9.6 ppm; C-2, 12.2 ppm; C-3, 4.1 ppm; C-4, 4.2 ppm; C-5, 3.0 ppm; C-6, 5.0 ppm; C-7, 4.7 ppm; C-2′, 13.8 ppm; C-3′, 16.2 ppm; C-4′, 64.4 ppm; and C-5′, 17.5 ppm. Shift reagent was removed from the solution by passage through a silica gel column. This proved to be costly as much alcohol was not recovered.

*Spiro(bicyclo[2.2.1]heptane-2,1′-[2,4]cyclopentadiene) (**2**)*

A large excess of *para*-toluenesulfonyl isocyanate (0.5 mL) was added to a solution of **7** and **8** (40.0 mg, 0.244 mmol) in dry benzene. The mixture was stirred at room temperature for 0.5 h, then heated under reflux for 50 h. The benzene was evaporated, and the residue was immediatedly passed through a short silica gel column with hexane as the eluant to provide **2** as a clear colorless liquid (29.9 mg, 84%); ir ν_{max}: 2955, 2865, and 1455 (m) cm^{-1}; uv λ_{max} (hexane): 205 nm (ϵ = 1200) and 258.5 (ϵ = 960); ^1H nmr (360 MHz) δ: 6.379 (1H, ddd, J = 1.3, 2.0, 5.3 Hz), 6.299 (1H, ddd, J = 1.5, 2.0, 5.2 Hz), 6.237 (1H, ddd, J = 1.5, 1.7, 5.3 Hz), 6.121 (1H, ddd, J = 1.3, 1.7, 5.2 Hz), 2.43 (1H, m, $W_{1/2}$ = 9 Hz), 0.8–2.1 (complex m); ^{13}C nmr δ: 145.9 (=CH), 143.2 (=CH), 129.2 (=CH), 126.6 (=CH), 62.8 (C-2), 44.1 (C-1), 39.7 (C-7), 38.0 (C-4), 33.9 (C-3), 29.1 (C-5), and 28.6 (C-6); ms m/z (%, elemental composition): 146.1095 (100, M^+, $C_{11}H_{14}^+$ requires 146.1095), 131.0860 (6, $C_{10}H_{11}^+$), 117.0705 (49, $C_9H_9^+$), 105.0703 (7, $C_8H_9^+$), 91.0550 (10, $C_7H_7^+$), and 67.0555 (12, $C_5H_7^+$).

*Diels–Alder reactions with **2***

The commercially available dienophiles were purified before reaction. In order that the adduct ratios be undisturbed, 360 or 400 MHz ^1H nmr spectra were obtained on the crude reaction mixtures, which in every instance contained a small amount of unreacted dienophile but no unreacted **2**. Adduct ratios were determined by careful integration of the best resolved pairs of signals in these spectra.

Addition of para*-benzoquinone to **2**: (1*RS,2s,*4*SR,*1′*R,*4′*S,*4′a*R,*8′a*S)- and (1*RS,2r,*4*SR,*1′*R,*4′*S,*4′a*R,*8′a*S)-1′,4′,4′a,8′a-tetrahydrospiro(bicyclo[2.2.1]heptane-2,9′-[1,4]methanonaphthalene)-5′,8′-dione (**9**a and **9**b)*

A solution of *para*-benzoquinone (2.21 mg, 0.0205 mmol) in CH_2Cl_2 (1.1 mL) was added to a stirred solution of diene **2** (2.99 mg, 0.0204 mmol) in CH_2Cl_2 (2.5 mL). This mixture was heated under reflux for 15 h. The solvent was evaporated to provide 5.0 mg (96%) of pale yellow needles (which decomposed rapidly in light), composed of **9***a* and **9***b* in a ratio of 69:31, respectively; ir of mixture ν_{max}: 1750, 1730, 1705, and 1675 cm^{-1}; ^1H nmr (360 MHz) resolved signals from **9***a* in the mixture in $CDCl_3$ [C_6D_6] δ: 6.579 [6.072] (2H, s, C-6′H and C-7′H), 6.091 [5.806] (1H, ddd, J = 0.7, 3.1, 5.8 Hz, C-3′H), 6.034 [5.767] (1H, ddd, J = 0.8, 2.7, 5.8 Hz, C-2′H), and [0.565] (1H, dd, J = 2.6, 12.2 Hz, C-3H$_{endo}$); ^1H nmr (360 MHz) resolved signals from **9***b* in the mixture in $CDCl_3$ [C_6D_6] δ: 6.574 [6.072] (2H, s, C-6′H and C-7′H), 6.379 [5.78[5]] (1H, ddd, J = 0.8, 3.0, 5.8 Hz, C-3′H), 6.321 [5.710] (1H, ddd, J = 0.8, 3.1, 5.8 Hz, C-2′H), and [0.771] (1H, dd, J = 2.8, 12.9 Hz, C-3H$_{endo}$); ms of mixture m/z (%, elemental composition): 254.1307 (100, M^+, $C_{17}H_{18}O_2^+$ requires 254.1307), 226.1356 (23, $C_{16}H_{18}O^+$), 161.0966 (12, $C_{11}H_{13}O^+$), 146.1094 (27, $C_{11}H_{14}^+$ by *retro*-Diels–Alder), 117.0703 (31, $C_9H_9^+$), 110.0368 (31, $C_6H_6O_2^+$, some unreacted quinone, also), 91.0548 (27, $C_7H_7^+$), and 67.0555 (19, $C_5H_7^+$).

*Addition of maleic anhydride to **2**: (1*RS,2s,*4*SR,*3′a*R,*4′*S,*7′R,*7′a*S)- and (1*RS,2r,*4*SR,*3′a*R,*4′*S,*7′R,*7′a*S)-3′a,4′,7′,7′a-tetrahydro-1′,3′-dioxospiro(bicyclo[2.2.1]heptane-2,8′-[4,7]methanoisobenzofuran) (**10**a and **10**b)*

A solution of maleic anhydride (2.01 mg, 0.0205 mmol) in CH_2Cl_2 (1.0 mL) was added to a stirred solution of the diene **2** (2.99 mg, 0.0204 mmol) in CH_2Cl_2 (2.5 mL). This mixture was heated under reflux for 15 h. Evaporation of the solvent yielded 4.9 mg (98%) of a clear liquid (which solidified some days later) composed of **10***a* and **10***b* in a ratio of 72:28, respectively; ir of the mixture ν_{max}: 1815 (m), 1755 (s), 1080, and 910 cm^{-1}; ^1H nmr (360 MHz) resolved signals from **10***a* from the mixture in $CDCl_3$ [C_6D_6] δ: 6.361 [5.788[5]] (1H, ddd, J = 0.8, 2.7, 5.9 Hz, C-5′H), 6.309[5] [5.747[5]] (1H, ddd, J = 0.8, 3.1, 5.9 Hz, C-6′H), 3.575 [2.52] (1H, dd, J = 4.4, 8.1 Hz, C-3′aH), 3.545 [2.48[5]] (1H, dd, J = 4.2, 8.1 Hz, C-7′aH), 3.150[5] [2.46[5]] (1H, m, $W_{1/2}$ = 9 Hz, C-7′H), 3.006 [2.269] (1H, m, $W_{1/2}$ = 8 Hz, C-4′H), 2.275[5] [1.874] (1H, apparent br t, $W_{1/2}$ = 10 Hz, C-4H), 2.249[5] [1.796] (1H, apparent br d, $J \approx$ 3.9 Hz, C-1H), 0.994 [0.224] (1H, dd, J = 2.6, 12.6 Hz, C-3H$_{endo}$), and [0.524] (1H, ddd, J = 3.1, 4.4, 12.6 Hz, C-3H$_{exo}$); ^1H nmr (360 MHz) resolved signals from **10***b* from the mixture in $CDCl_3$ [C_6D_6] δ: 6.267[5] [5.78[5]] (1H, ddd, J = 0.9, 3.0, 5.8 Hz, C-5′H), 6.240 [5.703] (1H, ddd, J = 1.0, 3.0, 5.8 Hz, C-6′H), 3.695 [2.570] (1H, dd, J = 4.8, 8.0 Hz, C-3′aH), 3.486 [2.400] (1H, dd, J = 4.6, 8.0 Hz, C-7′aH), 3.17[5] [2.43[5]] (1H, m, C-7′H), 3.054 [2.336] (1H, m, $W_{1/2}$ = 10 Hz, C-4′H), 2.159 [1.768] (1H, apparent br t, $W_{1/2}$ = 10 Hz, C-4H), 1.818 (1H, apparent br d, $J \approx$ 3.9 Hz, C-1H), and 1.074 [0.575] (1H, dd, J = 2.8, 13.0 Hz, C-3$_{endo}$); ms of mixture m/z (%, elemental composition): (M^+ not apparent), 216.1148 (5, $M^+ - CO$, $C_{14}H_{16}O_2^+$ requires 216.1151), 171.1174 (100, $C_{13}H_{15}^+$), 117.0704 (14, $C_9H_9^+$), 104.0630 (19, $C_8H_8^+$), 91.0548 (28, $C_7H_7^+$), and 67.0054 (32, $C_5H_7^+$).

Addition of N*-phenylmaleimide to **2**: (1*RS,2s,*4*SR,*3′a*R,*4′*S,*7′R,*7′a*S)- and (1*RS,2r,*4*SR,*3′a*R,*4′*S,*7′R,*7′a*S)-3′a,4′,7′,7′a-tetrahydro-1′,3′-dioxo-2′-phenylspiro(bicyclo[2.2.1]heptane-2,8′-[4,7]methanoisoindole) (**11**a and **11**b)*

Thermal reaction

A solution of *N*-phenylmaleimide (3.54 mg, 0.0205 mmol) in CH_2Cl_2 (1.0 mL) was added to a stirred solution of the diene **2** (2.99 mg, 0.0204 mmol) in CH_2Cl_2 (2.5 mL). The mixture was heated under reflux for 15 h, then the solvent was evaporated to yield 6.7 mg (100%) of a mixture composed of **11***a* and **11***b* in a ratio of 69:31, respectively; ir ν_{max}: 1710 and 1600 cm^{-1}; ^1H nmr (360 MHz) resolved signals from **11***a* from the mixture in $CDCl_3$ [C_6D_6] δ: 6.273 [5.949] (1H, ddd, J = 0.8, 2.8, 5.9 Hz, C-5′H), 6.232[5] [5.911] (1H, ddd, J = 0.8, 3.0, 5.9 Hz, C-6′H), 3.454 [2.692] (1H, dd, 4.2, 7.5 Hz, C-3′aH), 3.423 [2.674] (1H, dd, 4.2, 7.5 Hz, C-7′aH), 3.183 [2.754] (1H, dddd, J = 0.8, 1.0, 3.0, 4.2 Hz,[6] C-7′H), 3.029 [2.560] (1H, dddd, J = 0.8, 1.0, 2.8, 4.2 Hz,[6] C-4′H), 2.174[5] [2.009] (1H, apparent br d, $J \approx$ 3.6 Hz, C-1H), 2.174[5] [1.976] (1H, apparent br t, $J \approx$ 3.9 Hz, C-4H), 1.434[5,7] (1H, dt, J = 3.9, 12.5 Hz, C-3H$_{exo}$), and 1.075 [0.505] (1H, dd, J = 2.7, 12.5 Hz, C-3H$_{endo}$); ^1H nmr (360 MHz) resolved signals from **11***b* from the mixture in $CDCl_3$ [C_6H_6] δ: 6.205[5] [5.91[5]] (1H, ddd, J = 0.7, 2.9, 5.5 Hz,[6] C-5′H), 6.180[5] [5.860] (1H, ddd, 0.7, 3.0, 5.5 Hz, C-6′H), 3.568 [2.843] (1H, dd, J = 4.7, 7.5 Hz, C-3′aH), 3.368 [2.599] (1H, dd, J = 4.6, 7.5 Hz, C-7′aH), 3.18[5] [2.73[5]] (1H, m, C-7′H), 3.080 [2.63] (1H, m, $W_{1/2}$ = 9 Hz, C-4′H), 2.154 [1.860] (1H, apparent br t, $J \approx$ 3.9 Hz, C-4H), 1.953 [1.399] (1H, apparent br d, $J \approx$ 3.6 Hz, C-1H), and 1.095 [0.778[5]] (1H, dd, J = 2.9, 13.0 Hz, C-3H$_{endo}$). Recrystallization of this product plus some of the product of the catalysed reaction (below) from ethyl acetate gave a colorless material free of unreacted *N*-phenylmaleimide. Anal. calcd. for $C_{21}H_{21}NO_2$: C 78.97, H 6.63, N 4.39; found: C 78.85, H 6.53, N 4.50.[8]

Catalysed reaction

A stirred solution of *N*-phenylmaleimide (3.54 mg, 0.0205 mmol) in CH_2Cl_2 (1.5 mL) as cooled in a Dry Ice – acetone bath, and 25 μL (0.020 mmol) of a 10% solution of BF_3 etherate in CH_2Cl_2 was added by syringe, followed by a solution of the diene **2** (2.99 mg, 0.0204

mmol) in CH_2Cl_2 (2.5 mL). After 2.5 h, the mixture was allowed to attain room temperature and H_2O (approx. 2 mL) was added. The H_2O was removed by Pasteur pipet, and the solution was washed in this way with 10% $NaHCO_3$ and H_2O again. The organic solution was passed through a short plug of anhydrous Na_2SO_4, then evaporated to yield 6.2 mg (95%) of a yellow solid composed of **11***a* and **11***b* in a ratio of 73:27, respectively.

Received July 4, 1990

L. Breau, N. K. Sharma, I. R. Butler, and T. Durst. Can. J. Chem. **69**, 185 (1991).

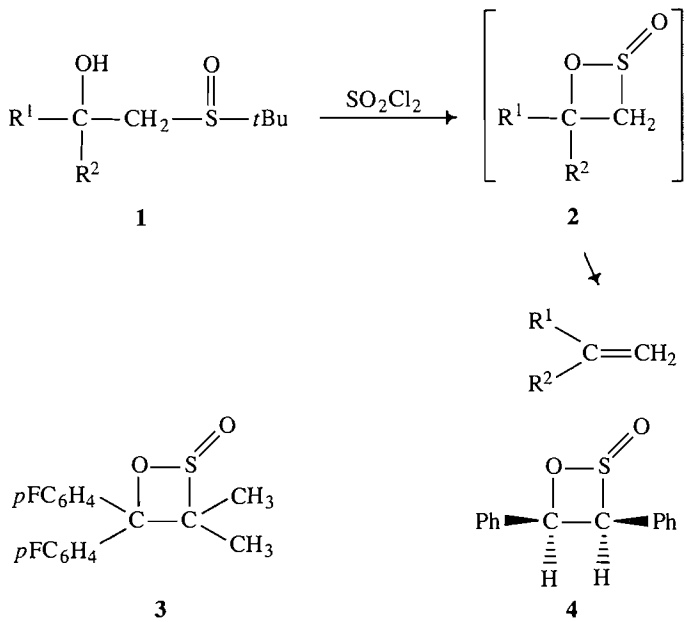
Erythro and *threo*-1,2-diphenyl-2-*tert*-butylsulfinylethanols **5** and **8** were prepared from the condensation of the α-lithio derivative of benzyl-*tert*-butyl sulfoxide with benzaldehyde. Reaction of **5** with sulfuryl chloride gave the title compound, (2*R**,3*S**,4*R**,6*R**)-3,4-diphenyl-6-(diphenylmethyl)-1,5-dioxa-2-thiane-2-oxide **6**, the first representative of a new heterocyclic ring system. Similar treatment of **8** resulted in the formation of **7**, a stereoisomer of **6**. This same compound was also obtained by photolysis of **6**. In both **6** and **7** the S=O bond is in an axial orientation.

Key words: sulfuryl chloride, reaction with β-hydroxy sulfoxides; 1,2-diphenyl-*tert*-butylsulfinylethanol; β-hydroxysulfoxides; β-sultines; *N*-chlorosuccinimide, reaction with β-hydroxysulfoxides.

L. Breau, N. K. Sharma, I. R. Butler et T. Durst. Can. J. Chem. **69**, 185 (1991).

On a préparé les *érythro*- et *thréo*-1,2-diphényl-2-*tert*-butylsulfinyléthanols (**5** et **8**) par condensation du dérivé α-lithien du sulfoxyde de benzyle et de *tert*-butyle avec le benzaldéhyde. La réaction du produit **5** avec le chlorure de sulfuryle fournit le composé mentionné dans le titre, le (2*R**,3*S**,4*R**,6*R**)-3,4-diphényl-6-(diphénylméthyl)-1,5-dioxa-2-thiane-2-oxyde (**6**), le premier représentant d'un nouveau système d'hétérocycles. Lorsqu'on soumet le produit **8** à un traitement semblable, il y a formation du produit **7**, un stéréoisomère du produit **6**. On a obtenu le même composé par photolyse du produit **6**. Dans les produits **6** et **7**, l'orientation de la liaison S=O est axiale.

Mots clés : chlorure de sulfuryle, réaction avec les sulfoxydes β-hydroxy; 1,2-diphényl-*tert*-butylsulfinyléthanol; sulfoxydes β-hydroxy; β-sultines; *N*-chlorosuccinimide, réaction avec les sulfoxydes β-hydroxy.



[Traduit par la revue]

Introduction

A number of years ago we reported that β-hydroxy-*tert*-butyl sulfoxides, **1**, reacted with SO_2Cl_2 or *N*-chlorosuccinimide (NCS) to yield alkenes (1). β-Sultines, **2**, were shown to be intermediates in this process. These compounds were generally unstable but we were able to isolate and characterize several tetrasubstituted derivatives (2); an X-ray structure determination was carried out on compound **3** (3). As part of a search for other examples of relatively stable β-sultines we attempted the isolation of *cis*-3,4-diphenyl-1,2-oxathietane-2-oxide, **4**. We had anticipated considerably increased stability for this compound compared to its *trans* isomer. Such a compound was expected to show a significantly puckered four-membered ring to relieve the interaction between the *cis*-phenyl substituents (2, 3), and a relatively slow loss of SO_2 to form *cis*-stilbene.

The expected precursor for **4**, the β-hydroxysulfoxide **5**, was prepared in an unambiguous manner from *trans*-stilbene oxide via the series of reactions shown in Scheme 1. Reactions of **4** with NCS in refluxing benzene gave the expected *cis*-stilbene, presumably via **4**, in 50% isolated yield; no trace of *trans*-stilbene was observed. Surprisingly, when **5** was reacted with SO_2Cl_2 at −78°C in CH_2Cl_2 in an effort to observe **4**, a crystalline product, mp 161–162°C, was obtained in up to 60% yield accompanied by diphenylacetaldehyde (35%).

This material analyzed for $C_{28}H_{24}O_3S$. The proton NMR showed four unique hydrogens, each as a doublet with J = 3.0 Hz, at δ 3.49, 4.53, 6.17, and 6.67 ppm, in addition to 20 aromatic hydrogens. The infrared spectrum revealed a strong band at 1125 cm^{-1} indicative of a sultine (4). Attempted structure determinations during our initial studies by chemical transformation carried out on this new material were frustrated by contradictory and ambiguous results (5). In the end the structure was shown by single crystal X-ray structure determination to be the unusual δ-sultine **6** (Fig. 1).[4] This compound, which can be considered as an acetal derived from diphenylacetaldehyde and a β-hydroxysulfinic acid, represents,

SCHEME 3

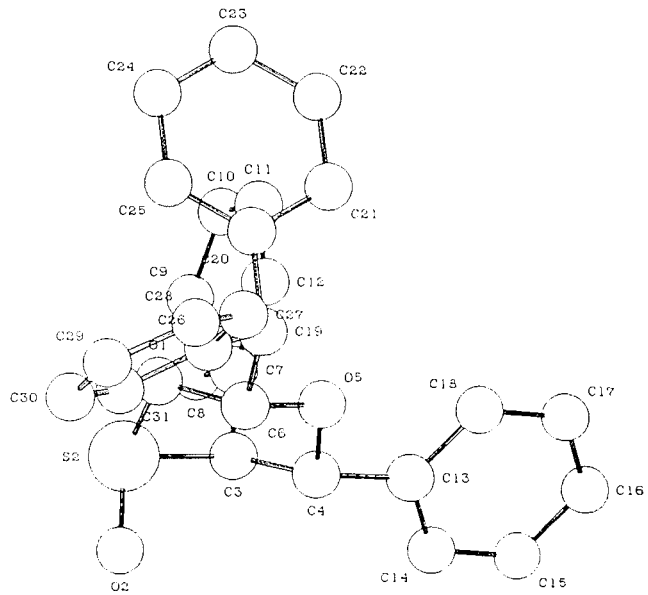

FIG. 1. The molecular structure of (2*R**,3*S**,4*R**,6*R**)-3,4-diphenyl-6-(diphenylmethyl)-1,5-dioxa-2-thiane-2-oxide **6** showing the atomic numbering. Hydrogen atoms have been omitted.

to the best of our knowledge, a new heterocyclic system, namely a 1,5-dioxa-2-thiane-2-oxide.

The X-ray structure of **6** (Fig. 1) shows a *cis* arrangement between the two phenyl groups on the six-membered ring with the C-3 substituent taking up an axial orientation. The 3 Hz coupling constant observed for the remaining hydrogens at C-3 and C-4 shows that a similar conformation exists in solution. The observed axial configuration of the S=O bond is preferred in δ-sultines (4, 6).

Photolysis of **6** in a quartz apparatus with a medium pressure mercury lamp gave an isomeric sultine **7** in quantitative yield. This same compound was obtained by reaction of the *erythro*-β-hydroxysulfoxide, **8**, prepared as shown in Scheme 2. In the latter reaction diphenylacetaldehyde was again a by-product; *trans*-stilbene was also formed.

The NMR spectrum for the isomeric sultine **7** (ir: 1120 cm^{-1}) shows a clear diaxial relationship for the C-3 and C-4 hydrogens (δ 4.02 and 5.86, J = 11 Hz); the remaining non-aromatic hydrogens appear as doublets at δ 4.43 and 6.67 (J = 4 Hz). These data together with the two modes of preparation secure the structure as **7**.

Examples of the photolability of benzylic carbon sulfur bonds in sulfoxides are known (7). Cleavage of this bond in **6** should lead to a diradical, which, after bond rotation, can recombine to give **7**. Complete isomerization of **6** to **7** is reasonable since this places all carbon substituents of the ring in the favorable equatorial position. The S=O bond continues to be axial.

The mechanism for the formation of these unusual heterocycles has not been investigated. A possible route to **6** is shown in Scheme 3.

Reaction of the hydroxysulfoxide **5** with SO_2Cl_2 should give the chlorooxosulfonium species **9** (6*c*). This species can react further in several possible ways: (i) cyclization to the β-sultine **4**, (ii) fragmentation to diphenylacetaldehyde and *t*-BuS(O)Cl, or (iii) loss of *t*-BuCl, or 2-methylpropene and HCl, to give the β-hydroxysulfinyl chloride **11**. Interaction of diphenylacetaldehyde or its enol with either **9** or **11** could lead to the oxonium ion **12**, or the related enol ether, either of which should cyclize to **6**. A similar pathway would hold for the conversion of **8** to **7**.

Experimental

Melting points were determined by use of a Gallenkamp digital melting point apparatus and are uncorrected. Infrared spectra were run as films on sodium chloride plates for oils, and in chloroform ($CHCl_3$) for solids using a Perkin Elmer 783 spectrophotometer. Mass spectra was recorded on an AEIMS 9025 instrument. Proton NMR spectra were recorded on either Varian EM-306-A or XL-300 spectrometers using $CDCl_3$ – 1% TMS solvent. ^{13}C spectra were obtained using a Varian XL-300 spectrometer. The chemical shifts for carbon and proton are reported in ppm downfield from TMS.

Column chromatography was accomplished using Baker or Terochem 60–200 mesh silica as the adsorbent. Purifications by radial, centrifugally accelerated thin-layer chromatography were performed on a Harrison Research Chromatotron model 7924 using silica gel coated rotors.

Benzyl tert-*butyl sulfide*

Benzyl chloride (70.0 g, 0.55 mol) was added dropwise, at room temperature, to a stirred methanolic solution ($MeOH/H_2O$ 1:1, 250 mL) of *tert*-butyl mercaptan (50.0 g, 0.55 mol) and potassium hydroxide (34 g, 0.60 mol). The mixture was heated under reflux for 16 h, then cooled. The resulting biphasic mixture was extracted into CH_2Cl_2 (300 mL), then washed twice with 5% NaOH (100 mL) and twice with H_2O (100 mL). The organic extract was dried with anhydrous calcium chloride, and removal of solvent gave the crude sulfide, which was further purified by distillation under reduced pressure, yielding benzyl *tert*-butyl sulfide (83.4 g, 84%); bp 80°C at 0.15 Torr (1 Torr = 133.3 Pa); ir ν_{max} (NaCl): 2800, 1600, 1495, 1450, 1362, 1168, 715, and 697 cm^{-1}; nmr: 1.35 (s, 9H), 3.75 (s, 2H), 7.1–7.4 (m, 5H).

Benzyl tert-*butyl sulfoxide.*

The purified sulfide was dissolved in ethyl acetate (150 mL), and stirred at −60°C while a solution of *m*-chloroperoxybenzoic acid 80% (28 g, 0.11 mol) in ethyl acetate (100 mL) was added dropwise. After the addition was completed, the solution was stirred at −30°C for 30 min and then at room temperature for 1 h. The reaction was washed with 10% sodium bisulfite solution (3 × 100 mL) followed by 5% sodium hydroxide solution (3 × 100 mL). The ethyl acetate layer was dried ($CaCl_2$) and evaporated under reduced pressure. The residual solid was purified by flash chromatography (gradient elution: CH_2Cl_2/hexane 75:25 to CH_2Cl_2/EtOAc 50:50 and finally with EtOAc), to yield the sulfoxide (15.7 g, 72%) as a white solid. The product was further purified by vacuum sublimation at 79°C (0.05 Torr); mp 74–75°C; ir ν_{max} ($CHCl_3$): 1050 cm^{-1}; nmr: 1.45 (s, 9H), 3.55 (d, J = 12 Hz, 1H), 3.84 (d, J = 12 Hz 1H), 7.28 (br s, 5H).

Threo *and* erythro-*1,2-diphenyl-2*-tert-*butylsulfinylethanol (8) and (5) (Scheme 2)*

From benzyl tert-*butyl sulfoxide.*

Benzyl *tert*-butyl sulfoxide (10.0 g, 51 mmol) was dissolved in THF (50 mL) and cooled to −78°C under N_2. This solution was stirred vigorously while a solution of lithium diisopropylamide (prepared from 2.5 N *n*-butyl lithium in hexanes (21 mL, 52 mmol) and diisopropylamine (7.2 mL, 51 mmol) in THF (150 mL) cooled to −70°C), was added by cannula. Stirring was maintained for a further 30 min, and then a solution of benzaldehyde (5.42 g, 51 mmol) in THF (50 mL) was added dropwise. The reaction mixture was then stirred for an additional 30 min at room temperature, quenched with water (100 mL), and the THF removed under reduced pressure. The aqueous phase was extracted with CH_2Cl_2 (3 × 100 mL). The combined organic extracts were dried ($CaCl_2$) and the solvent was evaporated. The crude product was purified by column chromatography (CH_2Cl_2/hexanes/EtOAc 35:35:30) to provide two products. The first to elute was *threo*-1,2-diphenyl-2-*tert*-butylsulfinylethanol (**8**) as a white solid (7.3 g, 47%); mp 167.5–168°C (dec.); ir ν_{max} ($CHCl_3$): 3500–3180, 1050, 1030, 1005, and 1000 cm^{-1}; nmr: 1.20 (s, 9H), 4.00 (d, J = 8 Hz, 1H), 5.27 (dd, J = 8 and 2 Hz, 1H), 6.08 (d, J = 2 Hz, 1H, -OH), 6.95 (br s, 10H); CIMS m/z: 303 (M^++1, 67%), 229(96), 197(91), 181(96), 180(100), 107(62), 105(60). Anal. calcd. for $C_{18}H_{22}O_2S$: C 71.50, H 7.33, S 10.68; found: C 71.27, H 7.36, S 10.47.

The second compound to elute (with gradient elution CH_2Cl_2/EtOAc 1:1 to 0:1) was the *erythro*-1,2-diphenyl-2-*tert*-butylsulfinylethanol (**5**) as a white solid (3.8 g, 25%); mp 165.5–166°C (dec.); ir ν_{max} ($CHCl_3$): 3340, 1058, 1030, 702 cm^{-1}; nmr: 1.15 (s, 9H), 4.01 (d, J = 3 Hz, 1H), 4.65 (d, J = 6 Hz, 1H, -OH), 5.72 (dd, J = 6 and 2 Hz, 1H), 6.8–7.3 (br s, 10H); CIMS m/z: 303 (M^++, 55%), 229(77), 197(100), 181(58), 180(71), 107(47), 105(41). Anal. calcd. for $C_{18}H_{22}O_2S$: C 71.50, H 7.33, S 10.68; found: C 71.27, H 7.03, S 10.24. This isomer was identical with the compound obtained as in Scheme 1.

From erythro-*1,2-diphenyl-2*-tert-*butylthioethanol (Scheme 1)*

trans-Stilbene oxide (1.96 g, 1 mmol), *tert*-butyl mercaptan (0.99 g, 1.1 mmol), and KOH (0.6 g, 1.1 mmol) were heated under reflux in 1-propanol (20 mL) for 8 h. The reaction mixture was cooled, poured into water, and extracted with dichloromethane (3 × 50 mL). The organic exctract was dried and evaporated. The crude product was distilled at 150–160°C (0.05 Torr) to give 2.2 g (75%) of a pale yellow oil, which solidified on standing to a pale yellow solid; mp 59–61°C; ir ν_{max} ($CHCl_3$): 3350 cm^{-1}; nmr: 1.20 (s, 9H), 2.5 (br s, 1H), 4.2 (d, J = 6 Hz, 1H), 5.0 (d, J = 2 Hz, 1H), 7.2 (m, 10H). The purified *erythro*-1,2-diphenyl-2-*tert*-butylsulfinylethanol (5.6 g, 20 mmol) was oxidized with *m*-chloroperoxybenzoic acid (4.4 g, 25.5 mmol) in dichloromethane (200 mL) to give 4.5 g (75%) of *erythro*-1,2-diphenyl-2-*tert*-butylsulfinylethanol (**5**).

cis-*Stilbene*

Hydroxysulfoxide **5** (604 mg, 2 mmol) and *N*-chlorosuccinimide (280 mg, 2.1 mmol) were refluxed in benzene (100 mL) for 1 h. The reaction mixture was cooled and the solvent removed on a rotary evaporator. The crude residue was purified by column chromatography (CH_2CH_2/hexane 1:1) to afford *cis*-stilbene (185 mg, 51%); nmr: 6.55 (s, 2H), 7.2 (s, 10H).

(2R, 3S*, 4R*, 6R*)-3,4-Diphenyl-6-(diphenylmethyl)-1,5-dioxa-2-thiane-2-oxide (6)*

The *erythro*-1,2-diphenyl-2-*tert*-butylsulfinylethanol (**5**) (0.50 g, 1.6 mmol) in dichoromethane (10 mL) was cooled to −78°C under an inert atmosphere. The solution was stirred vigorously while a 1.0 M solution of sulfuryl chloride in CH_2Cl_2 (1.85 mL, 1.85 mmol) was added dropwise by syringe. Stirring was maintained for a further 20 min at −78°C and the reaction mixture was quenched by addition of 10% $NaHSO_3$ solution (100 mL). Separation of the organic layer, extraction of the aqueous layer with dichloromethane (2 × 25 mL), drying ($CaCl_2$), and removal of solvent from the combined organic layers gave a pale yellow oil. The oily residue was purified on Chromatotron (gradient elution; hex/CH_2Cl_2 1:0 to 0:1) to provide diphenylacetaldehyde (85 mg, 26%), eluted first as a pale yellow oil, and then δ-sultine (**6**) (199 mg, 55%), eluted second as a viscous colourless oil that crystallized on standing; mp 160–162°C; ir ν_{max} ($CHCl_3$): 1125 cm^{-1}; nmr: 3.47 (d, J = 3 Hz, 1H), 4.52 (d, J = 3 Hz, 1H), 6.15 (d, J = 3Hz, 1H), 6.64 (d, J = 3 Hz, 1H), 6.72–7.44 (br m, 20H); ^{13}C nmr: 55.3, 66.3, 73.9, 94.3 132–139 (Ar-C). Anal. calcd. for $C_{28}H_{24}O_3S$: C 76.35, H 5.45, S 7.20, found: C 76.72, H 5.66, S 7.15.

(2R,3R*,4R*,6R*)-3,4-Diphenyl-6-(diphenylmethyl)-1,5-dioxa-2-thiane-2-oxide (7)*

Using the procedure described above, a solution of *threo*-1,2-diphenyl-2-*tert*-butylsulfinylethanol (**8**) (1.0 g, 33 mmol) was treated with SO_2Cl_2 (3.3 mL, 3.3 mmol) to yield *trans*-stilbene (410 mg, 69%), diphenylacetaldehyde (100 mg, 15%), and the δ-sultine (**7**) (49 mg, 7%), as a white solid; mp 162–163°C; ir ν_{max} ($CHCl_3$): 1120 cm^{-1}; nmr: 4.03 (d, J = 11 Hz, 1H), 4.42 (d, J = 5 Hz, 1H), 5.85 (d, J = 11 Hz, 1H), 6.68 (d, J = 4 Hz, 1H), 7.05–7.37 (br m, 20H). Anal. calcd. for $C_{28}H_{24}O_3S$: C 76.35, H 5.45, S 7.20; found: C 76.57, H 5.45, S 7.15.

Photoisomerisation of δ-sultine (6) to δ-sultine (7)

A solution containing sultine (**6**) (300 mg) in benzene: acetone (40 mL + 10 mL) was irradiated for 30 min using a 500-W Hanovia lamp and a Corex filter. The solvent was removed *in vacuo* and the residual material was crystallized from methylene chloride – pentane to

yield 295 mg of a fluffy white compound. All the physical data (mp, ir, nmr) were identical to those of **7**, above.

X-ray structure determination of (2R, 3S*, 4R*, 6R*)-3,4-Diphenyl-6-(1,1-diphenylmethyl)-1,5-dioxa-2-thiane-2-oxide (6)*

Crystal data: $C_{28}H_{24}O_3S$ fw = 440.55

Triclinic, $P\bar{1}$, $a = 9.1150(15)$, $b = 10.126(2)$, $c = 13.316(2)$ Å, $\alpha = 108.57(2)$, $\beta = 95.70(2)$, $\chi = 99.91(2)°$, $V = 1132.0(4)$ Å^3, $\rho_c = 1.293$ g cm^{-3}, $\mu = 1.44$ mm^{-1} (24°C, $CuK_{\alpha 1}$, $\lambda = 1.540562$ Å), $z = 2$. $F(100) = 464$.

Suitable crystals of **6** were obtained by slow diffusion of a diethyl ether top solvent layer into a concentrated solution containing **6** in dichloromethane. A crystal measuring approximately 0.15 × 0.25 × 0.35 mm was selected and mounted on a glass fibre. Intensity data were collected using a Picker diffractometer using the $\theta/2\theta$ scan mode. Unit cell dimensions were obtained from 26 reflections with 2θ between 100 and 117°. The calculated density assumes two molecules per unit cell. The data were collected to a maximum Bragg angle of 120°. Out of 5021 reflections measured, 3372 were unique; of these, 2500 were considered observed with $I_{net} > 2.5\sigma(I_{net})$. No absorption correction was made. The structural solution was made by direct methods followed by least-squares refinement using the NRCVAX series of programmes (8, 9). A Fourier difference map gave all non-hydrogen atoms. Hydrogen atoms were placed at calculated positions and refined. The final least-squares cycle was calculated with 56 atoms, 386 parameters using 2500 significant reflections. Weights based on counting statistics were used. The residuals on significant reflections were $R_F = 0.049$, $R_W = 0.055$, and $G_oF(S) = 2.01$. For all reflections $R_F = 0.070$, $R_W = 0.058$, where $R_F = \Sigma|F_o - F_c|/\Sigma(F_o)$, $R_W = [\Sigma(w(F_o - F_c)^2/\Sigma(wF_o^2)]^{1/2}$, and $G_oF(S) = [\Sigma(w(F_o - F_c)^2/((\text{number of reflections}) - (\text{number of parameters}))]^{1/2}$. The maximum shift-to-$\sigma$ ratio was 0.002. In the last D-map the deepest hole was -0.300 e Å^{-3} and the highest peak 0.430 e Å^{-3}, indicating an absence of solvent molecules.

Two 1*H*-naphtho[2,3-*c*]pyran-1-one metabolites from the fungus *Paecilomyces variotii*

WILLIAM A. AYER,[1] PETER A. CRAW, AND KOOHEI NOZAWA
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received June 28, 1990

WILLIAM A. AYER, PETER A. CRAW, and KOOHEI NOZAWA. Can. J. Chem. **69**, 189 (1991).

The fungus *Paecilomyces variotii* Bainier, isolated from larvae of *Dendroctonus ponderosa* Hopk. (mountain pine beetle), is antagonistic to *Ophiostoma clavigerum*, the fungus believed responsible for tree mortality caused by blue stain fungi. The metabolites produced by *P. variotii* when grown in liquid culture have been studied and two new 1*H*-naphtho[2,3-*c*]pyran-1-ones related to semi-vioxanthin (**4**) have been isolated. The structures of these two metabolites, semi-viriditoxin (**1**) and semi-viriditoxic acid (**2**), have been determined by chemical and spectroscopic methods.

Key words: fungal metabolites, blue stain disease, *Paecilomyces variotii*, semi-viridotoxin, semi-viridotoxic acid.

WILLIAM A. AYER, PETER A. CRAW et KOOHEI NOZAWA. Can. J. Chem. **69**, 189 (1991).

Le champignon *Paecilomyces variotii* Bainier, isolé des larves du *Dendroctonus ponderosa* Hopk. (des pins de montagne), est un antagoniste du *Ophiostoma clavigerum*, le champignon qui serait responsable de la mort des arbres causée par le champignon de coloration bleue. On a étudié les métabolites obtenus lorsqu'on a fait croître le *P. variotii* dans un milieu de culture liquide et on a isolé deux nouvelles 1*H*-naphtho[2,3-*c*]pyran-1-ones qui sont reliées à la semi-vioxanthine (**4**). Les structures de ces deux métabolites, la semi-viriditoxine (**1**) et l'acide semi-viriditoxique (**2**) ont été déterminées par des méthodes chimiques et spectroscopiques.

Mots clés : métabolites de champignon, maladie de coloration bleue, *Paecilomyces variotii*, semi-viridotoxine, acide semi-viridotoxique.

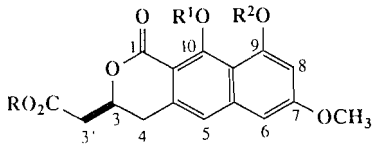
[Traduit par la revue]

Introduction

The blue stain disease of lodgepole pine (*Pinus contorta* Dougl. var *latifolia* Engelm.) is caused by a number of fungi vectored by the mountain pine beetle (*Dendroctonus ponderosae* Hopk.) (1). As part of our continuing investigation of fungi associated with this economically serious disease, we have examined the metabolites produced in liquid cultures of the fungus *Paecilomyces variotii* Bainier, which shows in vitro inhibitory activity towards *Ophiostoma clavigerum* (Robins.-Jeff. & Davids.) Harrington, a fungus strongly associated with tree mortality caused by blue stain fungi (2). We report herein the isolation and structure determination of two new 1*H*-naphtho[2,3-*c*]pyran-1-ones produced by *Paecilomyces variotii*.

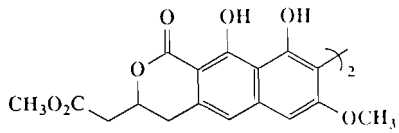
Results and discussion

Paecilomyces variotii Bainier was isolated from an egg gallery of mountain pine beetle in lodgepole pine at Invermere, British Columbia, in September 1986. The fungus was grown in still culture on a modified malt extract medium for 3 weeks. Extraction of the dried mycelium with chloroform and chromatography of the residue gave compound **1**. The filtered culture broth was extracted with dichloromethane and the extract crystallized from chloroform to afford crystals of compound **2**. Chromatography of the crystallization mother liquors gave further compound **2**.



An examination of the spectral data for compounds **1** and **2** suggested a close structural similarity to the 1*H*-naphtho[2,3-*c*]-pyran-1-one fungal metabolites viriditoxin (**3**), semi-vioxanthin (**4**), and vioxanthin (**5**). Semi-vioxanthin (**4**) and vioxanthin (**5**) have been isolated from *Penicillium citro-viride* (3), vioxanthin (**5**) from *Trichophyton violaceum* (4), and viriditoxin (**3**) from *Aspergillus viridi-nutans* (5). By analogy with the naming of these previously reported 1*H*-naphtho[2,3-*c*]pyran-1-ones, we have named compound **1** semi-viriditoxin as it represents the monomeric subunit of the symmetrical dimer viriditoxin (**3**). Compound **2**, semi-viriditoxic acid, is the corresponding carboxylic acid of semi-viriditoxin.

Semi-viriditoxin (**1**) was obtained as microcrystals, mp 168–170°C, and has the molecular formula $C_{17}H_{16}O_7$ as determined by high resolution electron impact mass spectrometry (hreims). The Fourier transform infrared (Ftir) spectrum displays characteristic hydroxyl (3428, 3382 cm^{-1}), aliphatic ester (1736 cm^{-1}), and dihydroisocoumarin carbonyl (1655 cm^{-1}) and C=C (1647, 1582 cm^{-1}) absorptions. The position of the dihydroisocoumarin carbonyl absorption reflects the presence of strong intramolecular hydrogen bonding between the carbonyl group and the C10 phenolic hydrogen. Removal of the effect of this hydrogen bonding as in the methyl ether (**6**) (*vide infra*) shifts the dihydroisocoumarin carbonyl absorption to 1713 cm^{-1}. The ultraviolet spectrum of semi-viriditoxin (**1**) has maxima at 260, 309, and 374 nm, which are very similar in position and intensity to those reported (3) for semi-vioxanthin (**4**).



The ^{1}H nmr spectrum of semi-viriditoxin (**1**) was readily assigned by first-order analysis in conjunction with comparisons to the reported spectra of viriditoxin (**3**) (5), and semi-vioxanthin (**4**) and vioxanthin (**5**) (3). The assignments of the aromatic hydrogen signals of semi-viriditoxin (**1**) were confirmed by the observation of large nuclear Overhauser enhancements (nOe) of the *meta*-coupled aromatic hydrogens (J 2.2 Hz) at δ 6.57 (16.6%) and δ 6.61 (13.2%) when the aromatic methoxyl hydrogen signal at δ 3.89 was irradiated. Irradiation of the other aromatic hydrogen signal at δ 6.90 (br s) resulted in a nOe to the doublet at δ 6.61 (H6, 13%) (hence the doublet at δ 6.57 must be due to H8) and a nOe to a doublet of doublets (J 15.8, 3.5 Hz) at δ 3.14 (H4, 3.4%). The signal due to H4β (δ 3.04) displays the expected geminal coupling (J 15.8 Hz) to H4α and vicinal coupling (J 10.0 Hz) to H3, as well as a small benzylic coupling (J 1.0 Hz) to H5. When the signal at δ 6.90 was irradiated, the signal due to H4β simplified to a doublet of doublets (J 15.8, 10.0 Hz). The ^{13}C nmr spectrum of semi-viriditoxin (**1**) was readily assigned by comparison with the reported spectrum (3) of semi-vioxanthin (**4**) (Table 1). The additional signals at

[a]In $CDCl_3$.
[b]In $(CD_3)_2SO$.

δ 170.7 and δ 52.2 in the spectrum of semi-viriditoxin (**1**) are typical of those expected for an aliphatic methyl ester (6).

Semi-viriditoxic acid (**2**) was obtained as pale yellow leaves, mp 172–175°C, and has a molecular formula of $C_{16}H_{14}O_7$ as determined by hreims. The differences between the spectra of **2** and **1** are as expected. Thus, a broad carboxylic absorption is observed from 3200 to 2400 cm^{-1} in the Ftir spectrum of **2**, the ^1H nmr spectrum of **2** contains only one singlet due to methoxyl hydrogens whereas the spectrum of **1** contains two such singlets, and the ^{13}C nmr spectrum correspondingly contains one less carbon resonance than observed in the spectrum of **1** (Table 1).

Brief exposure of semi-viriditoxic acid (**2**) to a solution of diazomethane resulted in methylation to give semi-viriditoxin (**1**) as well as dimethylation to give semi-viriditoxin 10-methyl ether (**6**). Zeeck *et al.* (3) reported that the C10 phenol of semi-vioxanthin (**4**) is also selectively methylated with diazomethane and both the Ftir and ^1H nmr spectra of semi-viriditoxin 10-methyl ether (**6**) compare favourably with those of semi-vioxanthin 10-methyl ether (**8**). In the absence of intramolecular hydrogen bonding the dihydroisocoumarin carbonyl absorption occurs at 1713 cm^{-1} in the Ftir spectrum of **6** (cf 1655 cm^{-1} in semi-viriditoxin). Methylation of the carboxylic acid and only the C10 phenol of **2** is consistent with a significant nOe (15.5%) to the phenol singlet at δ 9.84 when the C10 methoxyl singlet at δ 4.14 is irradiated. Complete methylation of semi-viriditoxic acid (**2**) was achieved using an excess of methyl iodide and potassium carbonate to give the dimethyl ether (**7**) to semi-viriditoxin.

The circular dichroism (cd) spectra of semi-viriditoxin (**1**) and semi-viriditoxic acid (**2**) are very similar to that reported for semi-vioxanthin (**4**), which has been shown to possess the *R* configuration at C3 (3). Accordingly, we have assigned semi-viriditoxin and semi-viriditoxic acid the absolute stereochemistries indicated in **1** and **2** respectively (*S* configuration at C3). Semi-viriditoxin (**1**) and semi-viriditoxic acid (**2**) both showed weak antibacterial activity against a number of bacteria, but neither compound showed antifungal activity against *Ophiostoma clavigerum*.

Experimental

For general experimental details see ref. 7. Low pressure liquid chromatography (lplc) was performed on an E. Merck silica gel 60 prepacked size A column using a Fluid Metering Inc. model RP-SY pump.

Growth of Paecilomyces variotii *and isolation of metabolites*

Slant tubes of *Paecilomyces variotii* Bainier (NOF-1232) were obtained from Dr. Y. Hiratsuka, Northern Forest Research Centre, Edmonton, and a specimen sample of the fungus was deposited with the University of Alberta Microfungus Collection (register number UAMH

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12

6353). Slant cultures of the fungus were maintained at 20°C on Weitzman and Silva–Hunter medium (10 g Pablum baby oatmeal, 10 g Hunt's tomato paste, 1.5 g KH_2PO_4, 1.0 g $MgSO_4 \cdot 7H_2O$, 1.0 g $NaNO_3$, 20 g Alphacel, 20 g agar, in 1 L water). Several slant tubes of potato dextrose agar (PDA, Difco) were then inoculated with the mature maintenance stock of the fungus, and grown at room temperature for 3 weeks. Five slant tubes of the PDA culture of the fungus were used to inoculate 10 2.8-L Fernbach flasks each containing 1 L of modified malt extract medium (20 g malt extract (Difco), 20 g D-glucose, 1.0 g bacto-peptone (Difco), 1 L water) and the still cultures were kept at room temperature for 3 weeks.

The mycelium was separated by filtration through cheesecloth, then air dried and ground to a coarse powder (50 g). Soxhlet extraction with chloroform gave a brown oil (3.1 g), which was subjected to flash chromatography. Elution with chloroform gave an oil (62 mg), which was subjected to lplc, eluting with benzene – ethyl acetate (7:1), to give semi-viriditoxin (**1**) (13 mg). Further elution with ethanol gave an oil (0.60 g), which was subjected to lplc using chloroform–ethanol – acetic acid (100:4:0.5) to give semi-viriditoxic acid (**2**) (17 mg).

The filtered culture broth was concentrated at reduced pressure to approximately 2 L and then extracted several times with dichloromethane. The combined dichloromethane extracts were evaporated to give a residue (0.90 g), which deposited crystals of semi-viriditoxic acid (**2**) (18 mg) from chloroform solutions. The mother liquors were flash chromatographed, eluting with chloroform containing increasing amounts of ethanol. Elution with chloroform–ethanol – acetic acid (100:20:0.5) gave an oil (62 mg), which was subjected to lplc, eluting with chloroform–ethanol – acetic acid (100:4:0.5), to give further semi-viriditoxic acid (**2**) (12 mg).

(*S*)-3,4-Dihydro-9,10-dihydroxy-7-methoxy-1*H*-naphtho[2,3*c*]pyran-1-one-3-acetic acid methyl ester (*Semi-viriditoxin*) (**1**) crystallized from benzene – Skellysolve B as off-white microcrystals, mp 168–170°C; $[\alpha]_D^{20}$ −9.0° (*c* 0.21, $CHCl_3$); cd (*C* 0.36 mM, dioxane) 28°C: $[\theta]_{360}$ +2000, $[\theta]_{320}$ +1300, $[\theta]_{270}$ −26 600; uv (CH_3OH) λ_{max} (log ε): 260 (4.62), 309 (3.64), 374 (3.97) nm; Ftir (KBr): 3428, 3382 (OH), 1736 (C=O), 1655 (lactone C=O), 1647, 1582 (C=C), 1160, 1132 (C—O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.78 (1H, dd, *J* = 16.0, 6.7 Hz, H3′), 2.98 (1H, dd, *J* = 16.0, 6.7 Hz, H3′), 3.04 (1H, ddd, *J* = 15.8, 10.0, 1.0 Hz, H4β), 3.14 (1H, dd, *J* = 15.8, 3.5 Hz, H4α), 3.76 (3H, s, CO_2CH_3), 3.89 (3H, s, 7-OCH_3), 5.06 (1H, dddd, *J* = 10.0, 6.7, 6.7, 3.5 Hz, H3), 6.57 (1H, d, *J* = 2.2 Hz, H8), 6.61 (1H, d, *J* = 2.2 Hz, H6), 6.90 (1H, br s, H5), 9.44 (1H, s, 9-OH), 13.58 (1H, s, 10-OH); ^{13}C nmr: see Table 1; hreims, *m/z* calcd. for $C_{17}H_{16}O_7$ (M^+): 332.0896; found: 332.0888 (100), 314 (19), 282 (35), 258 (26).

(*S*)-3,4-Dihydro-9,10-dihydroxy-7-methoxy-1*H*-naphtho[2,3-*c*]pyran-1-one-3-acetic acid (*Semi-viriditoxic acid*) (**2**) crystallized from chloroform as pale yellow leaves, mp 172–175°C; $[\alpha]_D^{20}$ 0° (*c* 0.10, $CHCl_3$); cd (*c* 0.63 mM, dioxane) 28°C: $[\theta]_{360}$ +5300, $[\theta]_{320}$ +2400, $[\theta]_{268}$ −31 800; uv (CH_3OH) λ_{max} (log ε): 219 (4.18), 260 (4.69), 309 (3.61), 323 (3.51), 368 (3.96), 374 (3.96) nm; Ftir (KBr): 3600–3250 (OH), 3200–2400 (br, CO_2H), 1710, 1646, 1583 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.73 (1H, dd, *J* = 16.0, 6.5 Hz, H3′), 2.93 (1H, dd, *J* = 16.0, 6.5 Hz, H3′), 3.01 (1H, ddd, *J* = 16.0, 10.5, 1.0 Hz, H4β), 3.15 (1H, dd, *J* = 16.0, 3.5 Hz, H4α), 3.86 (3H, s, 7-OCH_3), 5.06 (1H, dddd, *J* = 10.0, 6.7, 6.7, 3.5 Hz, H3), 6.50 (1H, d, *J* = 2.2 Hz, H8), 6.55 (1H, d, *J* = 2.2 Hz, H6), 6.88 (1H, br s, H5), 9.41 (1H, s, 9-OH), 13.60 (1H, s, 10-OH); ^{13}C nmr: see Table 1; hreims, *m/z* calcd. for $C_{16}H_{14}O_7$ (M^+): 318.0739; found: 318.0743 (100), 300 (14), 274 ($M^+ - CO_2$, 17), 256 (14), 230 (21).

Methylation of semi-viriditoxic acid (2) with diazomethane

An excess of an ethereal solution of diazomethane was added to a solution of **2** (7 mg) in methanol (2 mL) and the solution allowed to stand for 3 min before being evaporated to a yellow oil. Chromatography (lplc), eluting with benzene–acetone (20:1), gave semi-viriditoxin 10-methyl ether (**6**), which crystallized from benzene as colourless needles (3 mg), mp 175–180°C (dec.); Ftir (KBr): 3430, 3325, 1734, 1713, 1636, 1575, 1161 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.74 (1H, dd, *J* = 16.0, 7.0 Hz, H3′), 2.97 (1H, dd, *J* = 16.5, 7.0 Hz, H3′), 3.05 (1H, ddd, *J* = 16.0, 10.5, 1.5 Hz, H4β), 3.14 (1H, dd, *J* = 16.5, 3.5 Hz, H4α), 3.75 (3H, s, CO_2CH_3), 3.89 (3H, s, 7-OCH_3), 4.14 (3H, s, 10-OCH_3), 4.95 (1H, dddd, *J* = 10.5, 7.0, 7.0, 3.5 Hz, H3), 6.58 (1H, d, *J* = 2.5 Hz, H6 or H8), 6.61 (1H, d, *J* = 2.5 Hz, H6 or H8), 7.24 (1H, br s, H5), 9.84 (1H, s, OH); hreims, *m/z* calcd. for $C_{18}H_{18}O_7$ (M^+): 346.1053; found: 346.1047 (100), 315 (19), 268 (24), 244 (23), 229 (23).

Further elution with benzene–acetone (20:1) gave semi-viriditoxin (**1**) (1.5 mg) (correct tlc, ^1H nmr).

Methylation of semi-viriditoxic acid (2) with methyl iodide – potassium carbonate

A mixture of semi-viriditoxic acid (20 mg), potassium carbonate (0.10 g), and methyl iodide (0.10 mL) in dimethylformamide (1.0 mL) was stirred at room temperature for 16 h. Work-up in the usual manner provided a yellow oil, which was purified by flash chromatography. Elution with ethyl acetate – Skellysolve B (1:1) gave the dimethyl ether (**7**) (10.2 mg), which crystallized from ethyl acetate – Skellysolve B as flakes, mp 127–128°C; Ftir ($CHCl_3$ cast): 1730 (br), 1621, 1571 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.71 (1H, dd, *J* = 16.0, 6.7 Hz, H3′), 2.95 (1H, dd, *J* = 16.5, 6.5 Hz, H3′), 3.03 (1H, ddd, *J* = 15.5, 10.5, 1.0 Hz, H4β), 3.11 (1H, dd, *J* = 15.5, 3.2 Hz, H4α), 3.81 (3H, s, CO_2CH_3), 3.98 (3H, s, $ArOCH_3$), 4.04 (3H, s, $ArOCH_3$), 4.14 (3H, s, $ArOCH_3$), 4.87 (1H, dddd, *J* = 10.0, 6.5, 6.5, 3.0 Hz, H3), 6.50 (1H, d, *J* = 2.5 Hz, H6 or H8), 6.64 (1H, d, *J* = 2.5 Hz, H6 or H8), 7.22 (1H, br s, H5); hreims, *m/z* calcd. for $C_{19}H_{20}O_7$ (M^+): 360.1209; found: 360.1220 (100), 287 (17), 258 (20).

Photoresponses for various porphyrin films prepared by the electrolytic micelle disruption (EMD) method have been investigated in the indium–tin oxide/porphyrin/I_3^-, I^-/Pt cell. The EMD film of an n-type porphyrin, 5,10,15,20-tetra(4-pyridyl)porphyrin (T(4-Py)P), exhibited a clear optical filtering effect (OFE), while not for the EMD films of p-type porphyrins such as (5,10,15,20-tetraphenylporphyrinato)zinc(II) (ZnTPP). For the EMD-ZnTPP film, the photocurrents at 500–700 nm were remarkably enhanced by increasing the film thickness. These photoelectrochemical properties were explained in terms of the electrolyte-permeability of the EMD films, which were confirmed by the electrochemical measurements and electron microscopic observations. The high conversion efficiency of the EMD-ZnTPP film was explained on the same basis. The difference in the thickness dependence of OFE between T(4-Py)P films prepared by the EMD and physical vapor deposition method was elucidated by the differences in diffusion lengths of excitons and in widths of photoactive layers in the films. In addition, a modified version of the EMD method was described in conjunction with a morphology control of the porphyrin solids.

Key words: porphyrin, organic thin film, photoresponse, micelle, electrochemistry.

Opérant dans une cellule d'indium-oxyde d'étain/porphyrine/I_3^-, I^-/Pt, on a étudié les photoréponses de divers films de porphyrines préparés par le méthode des dislocations micellaires électrolytiques (DME). Le film de DME d'une porphyrine de type-n, la 5,10,15,20-tétra-(4-pyridyl)porphyrine (T(4-Py)P), présente un net effet de filtrage optique (EFO); ce n'est pas le cas avec les films des porphyrines de type-p, comme celui du (5,10,15,20-tétraphénylporphyrinato)zinc(II) (ZnTPP). Pour le film de DME du ZnTPP, les photocourants de la région allant de 500 à 700 nm augmentent d'une façon remarquable avec une augmentation de l'épaisseur du film. On explique ces propriétés photoélectrochimiques en fonction d'une perméabilité aux électrolytes des films de DME; cette explication est confirmée par des mesures électrochimiques et par des observations de microscopie électronique. La grande efficacité de conversion du film de DME du ZnTPP s'explique de la même manière. La différence observée dans les relations entre l'épaisseur et l'EFO des films de T(4-Py)P préparés soit par la DME ou par la méthode du dépôt de vapeurs physiques est attribuée aux différences dans les longueurs de diffusion des excitons et dans les largeurs des couches photoréactives des films. De plus, on décrit une version modifiée de la méthode de DME qui a été associée à un contrôle de la morphologie des porphyrines solides.

Mots clés : porphyrine; film organique mince; photoréponse; micelle; électrochimie.

[Traduit par la revue]

Introduction

Photoelectric and photoelectrochemical properties of organic solid films have been extensively studied, because the organic photoconductors are very promising functional materials applicable to devices such as photocell, TV vidicon tube, laser printer, etc. Usually, thin films of the organic molecules are prepared by using the physical vapor deposition (PVD) method and casting or spin-coating technique (1–5). Recently, however, a new method called an electrolytic micelle disruption (EMD) method has been developed, which is based on the electrolytic disruption of micelles containing dye particles (6–8). Previously, we have shown that the phthalocyanine (Pc) film prepared by the EMD technique is more efficient in photoactivity than the film prepared by the PVD method (9). A similar enhancement in conversion efficiency was observed with porphyrin films (10). Furthermore, we pointed out that the EMD-Pc film was so porous that the electrolyte solution could be penetrable through the EMD film (11).

In this paper, we present the details on spectroscopic and photoelectrochemical properties of porphyrin films prepared by the EMD and its modified methods compared with those for the films prepared by the PVD method, and discuss the conversion efficiencies in relation to the morphologies of the EMD and PVD films.

Experimental

Porphyrins used were 5,10,15,20-tetraphenylporphyrin (H_2TPP), MgTPP, and ZnTPP, which are characterized as p-type organic semiconductors, and 5,10,15,20-tetra(4-pyridyl)porphyrin (T(4-Py)P) which is an n-type organic semiconductor (12–14). These porphyrins were purchased from Strem Chem. Inc. The surfactant (11-ferrocenyl)undecyltridecaethyleneglycol ether (FPEG), was purchased from Wako Pure Chem. Co. MgTPP was purified by HPLC to remove the free base H_2TPP. Other chemicals were used without further purification. An indium–tin oxide (ITO) film, whose sheet resistance was about 20 ohm and transparency over 80%, was from Matsuzaki Shinku Co. The procedures in the production of a porphyrin film on an ITO substrate by the EMD method were as follows: (*1*) aqueous mixtures containing 1 mmol dm^{-3} (mM) FPEG, 5 mM porphyrin, and 0.1 M LiBr, were sonicated for 30 min and then stirred for 10–30 days, (*2*) the resulting solution was centrifuged for 30 min at 500 × *g*, where *g* is 9.8 m s^{-2}, (*3*) the supernatant solution, where a suitable amount of dye particles was involved as micelles with FPEG, was supplied for the potential-controlled electrolysis, which was carried out at 0.50 V vs. SCE in the three-electrode system. Thickness of the dye film could be controlled by the amount of electricity passing through the electrode (7, 10). A modified version of the EMD technique was also used to produce the dye films, which is abbreviated as mod-EMD method hereafter. The procedures were as follows: (*1*) given amounts of ZnTPP and FPEG were dissolved completely in ethanol, and evaporated to dryness, (*2*) the solid residue consisting of ZnTPP and FPEG was redissolved into distilled water and the solution filtrated through a filter whose pore size was 0.20 μm, (*3*) the filtrate was centrifuged for 15

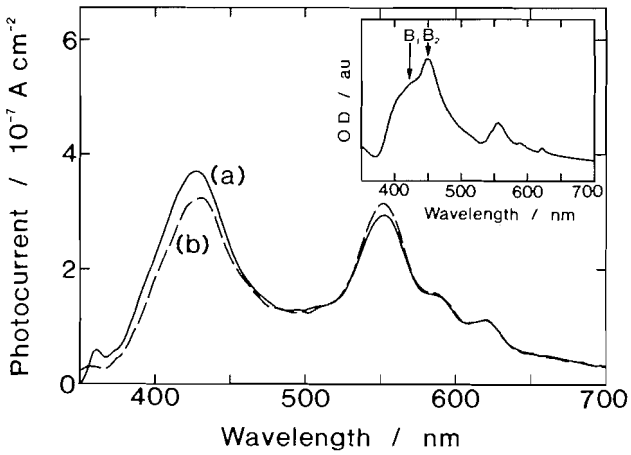

FIG. 1. Photocurrent action spectra for the ITO/EMD-ZnTPP/I_3^-, I^-/Pt cell. Illumination is done through (*a*) the ZnTPP/electrolyte interface and (*b*) the ITO electrode under short circuit conditions. The inset shows the absorption spectrum of the EMD-ZnTPP film.

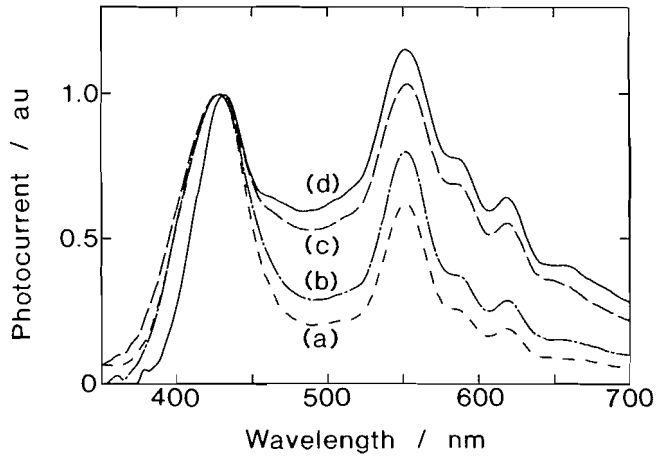

FIG. 2. Thickness dependence of the photocurrent action spectra for ITO/EMD-ZnTPP electrodes. The amount of electricity, which is a measure of a film thickness, was (*a*) 5, (*b*) 10, (*c*) 30, and (*d*) 40 mC cm^{-2}.

min at 16500 × *g* to sediment large particles, and (*4*) the supernatant solution was supplied for the electrolysis which was done in the same manner as described in the EMD method.

The electrolysis and cyclic voltammetry were carried out by a Hokuto-Denko HAB-151 potentiostat. Quantity of electricity (Q) was measured by a home-made coulometer. Thickness of an EMD film was monitored by Q or optical density (OD) of the film. The photocurrent action spectra were measured by a Jasco CT-10S monochromator with a 300W tungsten–halogen lamp and a Takeda Riken TR-8651 electrometer. The redox solution used consisted of 0.5 mM I_2 and 0.1 M KI in an acetate buffer (pH 4.7). The standard redox potential for the I_3^-/I^- couple was 0.29 V vs. SCE. The photocurrents were normalized in such a way that the photon flux of monochromatic light incident on the surface of the porphyrin electrode was constant at 2.5 × 10^{13} photons cm^{-2} s^{-1}. For light source, a 500 W xenon lamp was used with Toshiba ND filters, cut-off filters, or interference filters. The optical absorption spectra were measured by a Shimadzu UV-240 spectrophotometer. The experiments of X-ray diffraction were carried out by a Rigaku Denki RAD-1B diffractometer. All measurements were done at room temperature.

Results and discussion

Figure 1 shows the short-circuit photocurrent action spectra obtained on illumination of the ITO and electrolyte side in the ITO/EMD-ZnTPP/I_3^-, I^-/Pt cell. The inset depicts the optical absorption spectrum of the EMD-ZnTPP film used. The shapes of both action spectra closely resembled each other and all peaks coincided well with those for the ITO/PVD-ZnTPP electrode. No obvious optical filtering effect (OFE) was observed, although the thickness of the EMD porphyrin film was 200 nm, which was usually thick enough for the PVD film to exhibit the OFE (15). The result of the OFE for PVD-ZnTPP films indicated that the PVD-ZnTPP/electrolyte junction was a blocking contact, being stronger than the contact with ITO. It is worthy to note that a new absorption peak B_2 is observed at around 450 nm in addition to the peak B_1 which corresponds to the Soret peak of the PVD-ZnTPP film. The peak B_2 is attributable to the different morphology of ZnTPP crystallines, which may be formed in the course of preparing the micelle solution (10). As shown in Fig. 1, however, the light absorption process responsible for the component B_2 substantially does not contribute to generating a photocurrent, though now the reason is uncertain.

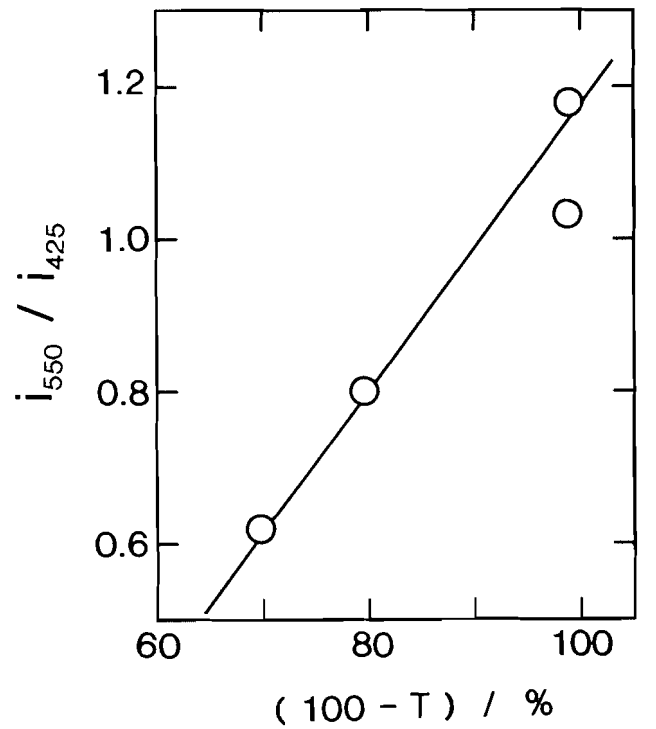

FIG. 3. Plot of the ratio of i_{550} to i_{425} as a function of the transmittance (T) at 550 nm for the EMD-ZnTPP film.

The dependence of film thickness on the photocurrent action spectrum of the EMD-ZnTPP electrode was noticeable as shown in Fig. 2, where illumination was done through the ITO electrode and all photocurrents were normalized with the photocurrent at the Soret band peak (425 nm). The photocurrents at 425 nm were almost independent of the film thickness (or quantity of electricity) in the range from 100 nm (5 mC cm^{-2}) to 800 nm (40 mC cm^{-2}). On the other hand, the photocurrents at wavelengths between 500 and 700 nm increase with the increase of film thickness. Figure 3 is a plot of the ratio (i_{550}/i_{425}) against (100 − T), where i_{550} and i_{425} are photocurrents at Q band and Soret band peaks (550 nm and 425 nm),

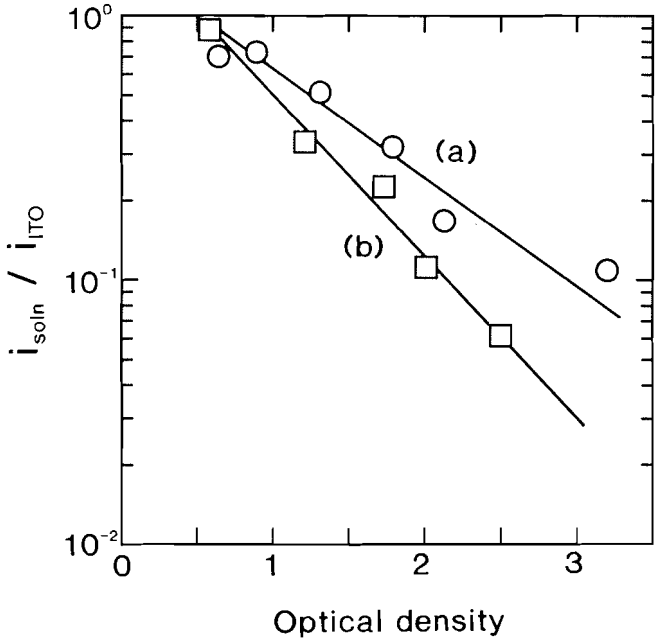

FIG. 4. Plot of i_{soln}/i_{ITO} against the optical density at the Soret band peak (430 nm) for the ITO/T(4-Py)P electrode prepared by (*a*) the EMD and (*b*) PVD methods.

respectively, and T is the transmittance (%) of an EMD-ZnTPP film at 550 nm. The abscissa ($100 - T$) is the percentage of photons absorbed by the ZnTPP films. Figure 3 shows that photocurrents at the Q band peak are proportional to the amount of photons absorbed by the ZnTPP film, since i_{425} is nearly constant. In view of the fact that the absorption coefficient at 425 nm is as high as 2.5×10^5 cm^{-1}, even the thinnest EMD-ZnTPP film (100 nm) can absorb more than 98% of photons incident on the ZnTPP film. Therefore, the photocurrent at the Soret peak must not depend upon the film thickness beyond 100 nm.

The thickness dependence of photocurrents for PVD-ZnTPP films differs from that for EMD-ZnTPP films: the photocurrents for PVD-ZnTPP films decrease with increasing the film thickness up to, at least, 400 nm, and the ratio of photocurrents at the Q band and Soret band peaks is constant at 0.35. The results on the PVD films imply that the photocurrents of PVD films do not correlate with the amount of photons absorbed by the films. In the PVD case, the photocurrents seem to be governed by other factors such as the amount of photons absorbed within the depletion layer formed near the surface of PVD-ZnTPP film, and carrier traps, etc. (15).

Figure 4 shows the OFE observed with T(4-Py)P films. The photocurrents of i_{soln} and i_{ITO} were obtained on illumination of the electrolyte and ITO side at Soret band peak (430 nm), respectively. For both EMD and PVD films, semilogarithmic plots of i_{soln}/i_{ITO} against OD decrease almost linearly with increasing the OD of each film. This is explicable by the OFE due to the T(4-Py)P layer. In other words, a blocking contact is formed at the ITO/T(4-Py)P junction and only photons absorbed near the ITO/T(4-Py)P interface contribute to the carrier generation and thus the photocurrent. On the other hand, the T(4-Py)P/electrolyte contact is ohmic or nearly ohmic. The slope of line (*b*) for the PVD film is slightly steeper than that of line (*a*) for the EMD film. According to the exciton model described previously (15), the gradient of a line becomes steep when the exciton diffusion length (L_{exc}) and/or the apparent

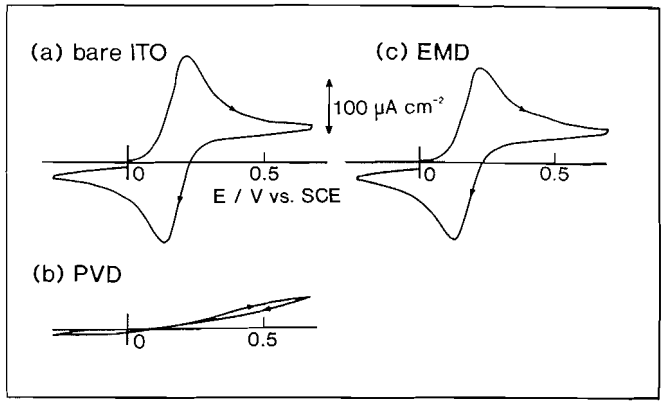

FIG. 5. Cyclic voltammograms of (*a*) bare ITO, (*b*) ITO/PVD-ZnTPP, and (*c*) ITO/EMD-ZnTPP electrodes in 0.1 M KCl solutions containing 1 mM $[Fe(CN)_6]^{4-}$. Potential sweep rate was 100 mV s^{-1}.

barrier width (W_{ap}) are small. It therefore derived from the result shown in Fig. 4 that the L_{exc} or W_{ap} for the EMD porphyrin film is greater than that for the PVD film. The density of the EMD film is likely to be lower than that of the PVD film. This would lead to a result inconsistent with the result in Fig. 4. In regard to L_{exc} and W_{ap}, which relate with the photocurrent and conversion efficiency, Fan and co-workers have demonstrated a very interesting view (16, 17), in that the photoactive region in the photovoltaic CuPc cell is restricted by the grain size of microcrystallines in the sublimed CuPc film, since the exciton diffusion length and the width of photoactive layer (W) being approximately equal to W_{ap} are influenced by the grain size. In our case, the grain size for the EMD-T(4-Py)P film seems to be fairly great compared with that of the PVD film. This inference is drawn from the X-ray diffraction study of the EMD and PVD films. The EMD-ZnTPP film showed a diffraction pattern similar to that of ZnTPP hydrate powders (18), although the diffraction of the former was very weak in comparison with the latter. On the other hand, no X-ray diffraction was observed with the PVD-ZnTPP film. Consequently, it is deduced that the grain size of microcrystallines constituting the EMD film is larger than that for the PVD film on assuming that both EMD and PVD films consist of microcrystallines. Namely, L_{exc} and W (or W_{ap}) for the EMD film are larger than those for the PVD film. This is consistent with the finding that the photocurrent for the EMD-T(4-Py)P film is 2–3 times greater than that of the PVD film, and that the EMD-ZnTPP film is more efficient than the PVD-ZnTPP film as shown before.

Electrochemical studies of the EMD- and PVD-ZnTPP film give important information on the morphologies of EMD and PVD films as shown in Fig. 5, illustrating the cyclic voltammograms of ions $[Fe(CN)_6]^{4-}$ at the bare ITO, ITO/PVD-ZnTPP (80 nm) and ITO/EMD-ZnTPP (300 nm) electrodes in 0.1 M KCl aqueous solutions. Well-defined redox waves were observed at the bare ITO and ITO/EMD-ZnTPP electrodes. This fact shows that the electrolyte solution can penetrate easily through the EMD film and come into contact with the ITO substrate, where $[Fe(CN)_6]^{4-}$ ions are oxidized reversibly. On the other hand, no obvious redox wave was observed at the ITO/PVD-ZnTPP electrode in the potential range studied, suggesting that the PVD-ZnTPP film was so dense that the electrolyte could not permeate in the PVD film and not reach the ITO electrode. Similar results were obtained with EMD films of other porphyrins including T(4-Py)P. The permeable feature of the EMD porphyrin film is also inferred from the scanning electron microscope

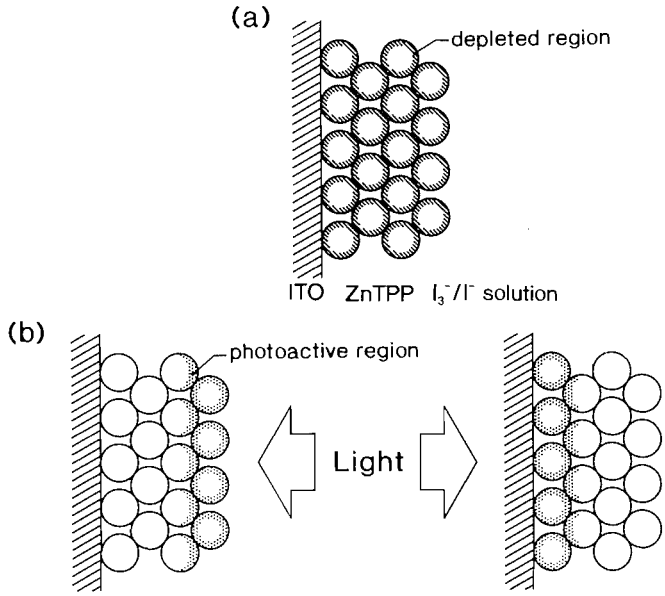

FIG. 6. Schematic illustration for the ITO/EMD-ZnTPP electrode in the I_3^-/I^- redox solution (*a*) in the dark and (*b*) under illumination. The arrows show the illumination direction.

(SEM) pictures in Fig. 9. On the bases of the SEM pictures and results of cyclic voltammograms, the morphological features of the EMD layer on ITO are represented schematically as in Fig. 6. When the ITO/EMD-ZnTPP electrode is dipped into the I_3^-/I^- redox solution, the electrolyte solution permeates the ZnTPP film. Thus a depletion layer can be formed near the surface of every ZnTPP particle contacting the electrolyte solution, because the ZnTPP/electrolyte contact is blocking (Fig. 6 (*a*)). Therefore, there may be no difference in the amount of photons absorbed in the depleted region irrespective of the direction of light illumination (Fig. 6 (*b*)). This explains the experimental finding that the OFE is not observed with the EMD-ZnTPP electrode. The thickness dependence of photocurrent may also be interpreted by the spread of photoactive sites over the entire film. Namely, the photocurrents are proportional to the amount of photons absorbed by the whole film. Similar photoresponses observed with the other p-type porphyrins such as MgTPP and H_2TPP are also understood on the basis of the electrolyte-permeable nature of the EMD films.

Figure 7 illustrates the absorption spectra of micelle solutions centrifuged with various accelerations. The absorption spectrum (*a*) for the non-centrifuged solution having an opaque purple color exhibits two Soret peaks of X_1 and X_2, and an appreciable background resulting from scattering of light due to large ZnTPP particles dispersed in the solution. With the increase in the centrifugal force the peak height of X_2 relative to X_1 decreases, indicating that ZnTPP particles responsible for the absorption X_2 are heavier than for X_1. In addition to this, the increased centrifugal force leads to a narrower half-peak width of X_1; the half-peak width of 20 nm in the spectrum (*e*) for 13000 × *g* is close to 12 nm for that of the Soret peak of ZnTPP molecules in benzene. These results denote that the micelle solution before the centrifugation consist of ZnTPP particles with widely-distributed sizes. In view of the principle of the EMD method, the results suggest a possibility of controlling morphologies of the porphyrin films by changing the size of ZnTPP particles dispersed in the micelle solution. The EMD films of ZnTPP prepared from micelle solutions centrifuged at

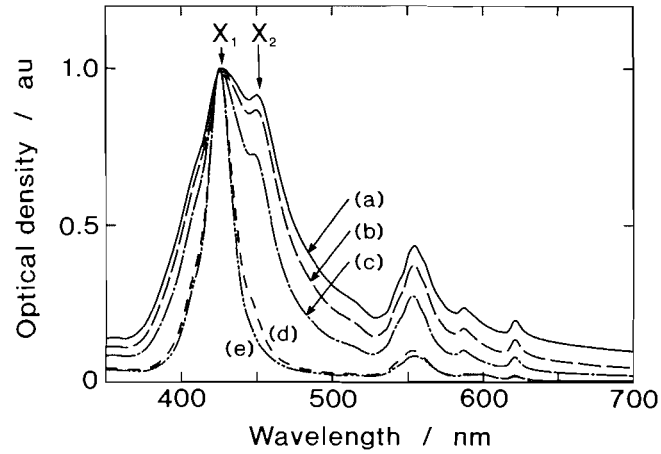

FIG. 7. Optical absorption spectra of the supernatant solutions (*a*) before and after the centrifugal treatments at (*b*) 500 × *g*, (*c*) 2000 × *g*, (*d*) 6800 × *g*, and (*e*) 13000 × *g*. All spectra were normalized at 425 nm.

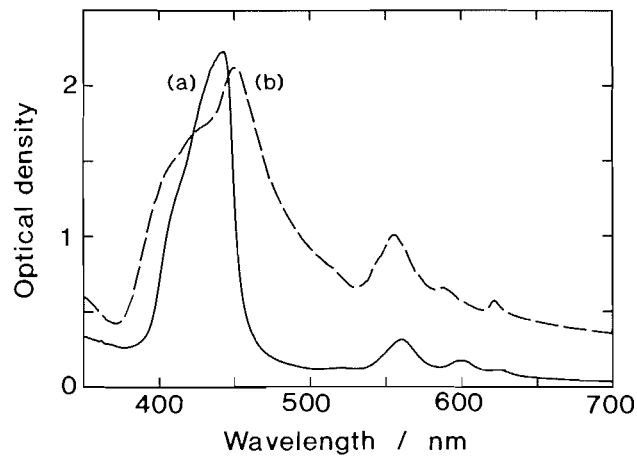

FIG. 8. Absorption spectra of ZnTPP films prepared by (*a*) the mod-EMD and (*b*) EMD methods.

accelerations below about 500 × *g* exhibited the absorption spectra similar with the one for the EMD-ZnTPP film shown in the inset of Fig. 1, where the absorption components of X_1 and X_2 correspond well to B_1 and B_2 for the EMD-ZnTPP film, respectively. On the other hand, an attempt to prepare EMD porphyrin films from the micelle solution treated at 13000 × *g* was unsuccessful, presumably due to the extremely small amount of fine ZnTPP particles in the solution. A successful preparation of EMD films from solutions containing very fine ZnTPP particles was attained only by preparing micelle solutions based on the modified EMD method as described in the Experimental section. Absorption spectrum (*a*) in Fig. 8 was obtained with the mod-EMD-ZnTPP film thus prepared, whose Soret peak was fairly sharp in comparison with that in spectrum (*b*) of the EMD-ZnTPP film. In addition, the absorption background in spectrum (*a*) was small. Comparing SEM pictures (*a*)–(*d*) in Fig. 9, it is clear that the morphology of the mod-EMD film is different from that of the EMD film. The mod-EMD film is studded with ZnTPP particles as large as 1–2 μm, which presumably grew during the electrolysis because the micelle solution supplied for the electrolysis was filtrated with a minipore (0.20 μm) filter before use. Furthermore, it is seen in picture (*b*) that the ITO substrate is covered with a very thin

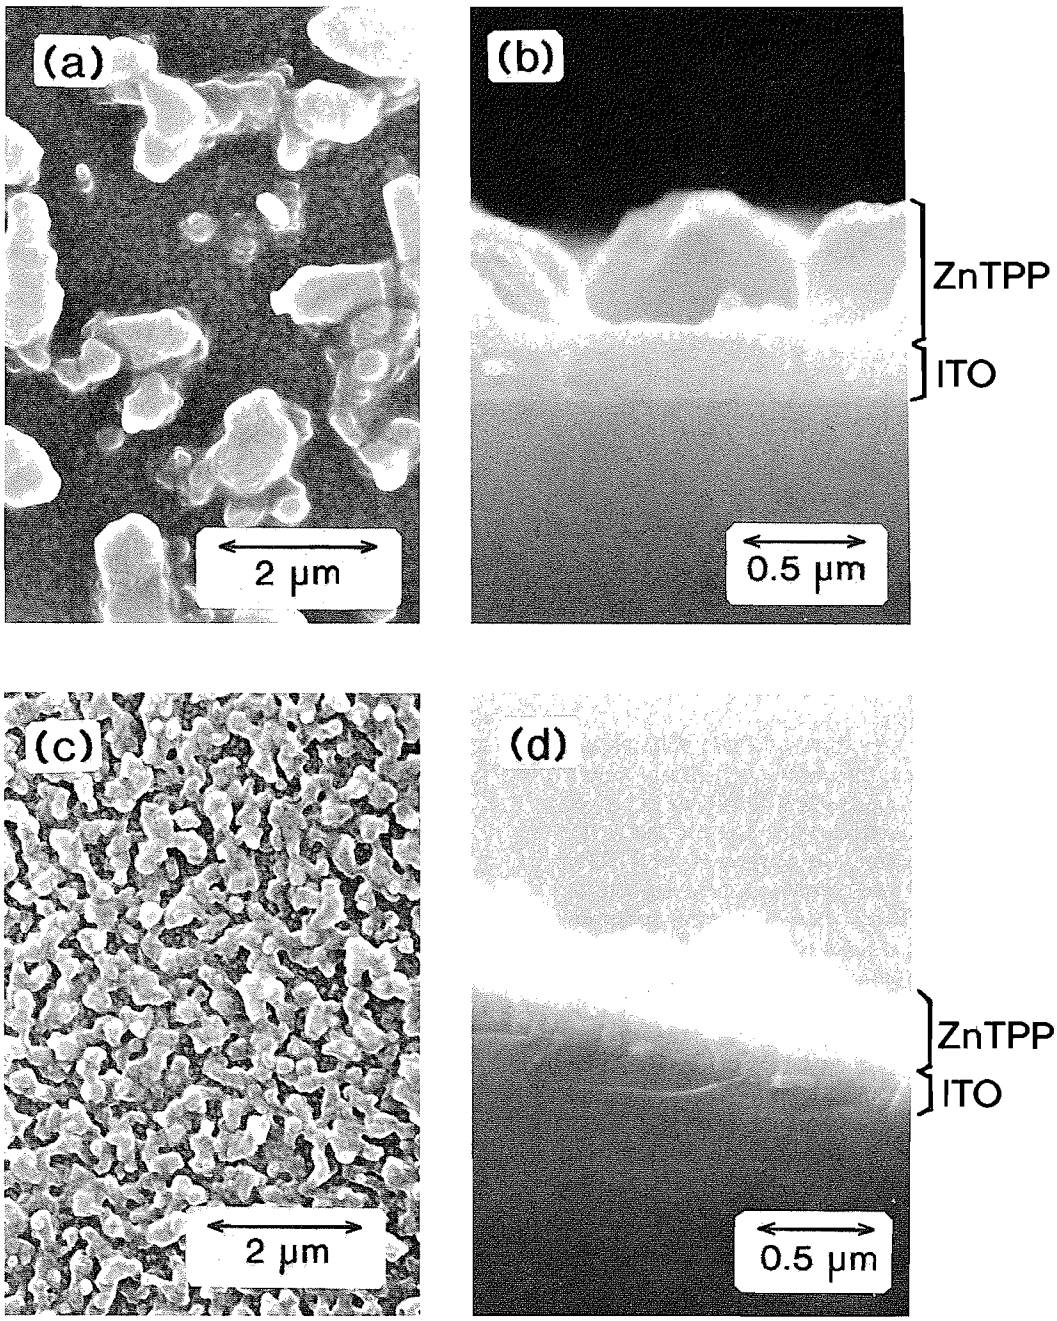

FIG. 9. Scanning electron microscope pictures of the ZnTPP films prepared by (*a*,*b*) the mod-EMD and (*c*,*d*) EMD methods.

ZnTPP layer. This ZnTPP layer seems to be enough not to allow an electrolyte permeation, because any clear redox waves for the $[Fe(CN)_6]^{4-/3-}$ couple were not observed at the ITO electrode coated with the mod-EMD film. It is noted that the transparency of the mod-EMD porphyrin film is superior to the EMD film and comparable to that of the PVD film.

Typical values of photoelectrochemical parameters such as short-circuit photocurrent (i_{sc}) and open-circuit photovoltage (V_{oc}) are summarized in Table 1. V_{oc} and fill factors were independent of the film thickness, irrespective of the film formation techniques. As the thickness increased, i_{sc} increased for the EMD film and was constant for the mod-EMD film, whereas i_{sc} decreased for the PVD film. The power conversion efficiency is about 0.0013% for the mod-EMD-ZnTPP film in the I_3^-/I^- redox system, showing that the mod-EMD-ZnTPP is not efficient compared with the EMD film. Such a small conversion efficiency might be attributed to the surfactants remaining in the mod-EMD film. The presence of FPEG in the mod-EMD film was confirmed indirectly by a determination of Fe atoms, coming from the ferrocenyl moiety of FPEG, by the atomic absorption spectroscopy. The surfactant remaining in the normal EMD films was much smaller than that in the mod-EMD film. The power conversion efficiency of the EMD-T(4-Py)P film was about 0.00018%, which was 3–4 times larger than that of the PVD-T(4-Py)P film.

In conclusion, the EMD porphyrin films were found to be more efficient than the PVD and mod-EMD porphyrin films. The high performance of the ITO/EMD-ZnTPP electrode was

attributable mainly to the morphological features of the film inferred from the results obtained by the cyclic voltammetry, scanning electron micrography, and X-ray diffractometry. The modified EMD technique provided an organic thin film with a unique morphology, although the photoactivity was comparable with that of a PVD film.

Acknowledgment

A new palladium-catalyzed coupling reaction of vinylic and allylic triflates with pyrimidine nucleosides

MOHAMED EZELDIN HASSAN
Chemistry Department, The African University, Aswan, Egypt

Received March 29, 1990

MOHAMED EZELDIN HASSAN. Can. J. Chem. **69**, 198 (1991).

Vinylic trifluoromethane sulfonates (triflates) form palladium intermediates that react with pyrimidine nucleosides to produce C-5 alkyl substituted nucleosides after hydrogenation of the vinylic coupling products with hydrogen and Pd/C in methanol. The reaction, which is run under mild conditions, appears to be a general one since both mono- and disubstituted vinylic triflates, as well as the cyclic ones, gave high yields of the corresponding C-5 alkyl-substituted nucleoside. The reaction with allyl triflate requires the use of the 5-chloromercurinucleoside.

Key words: nucleosides, triflates, palladium catalysis.

MOHAMED EZELDIN HASSAN. Can. J. Chem. **69**, 198 (1991).

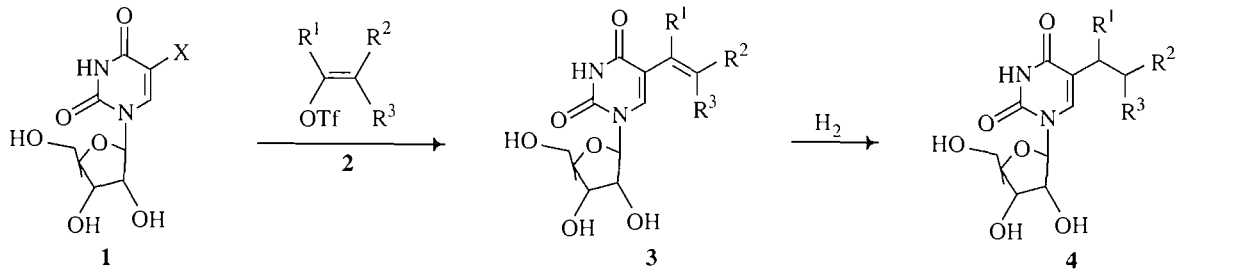
Les trifluorométhanesulfonates vinyliques forment des intermédiaires vinyliques que réagissent avec les nucléosides de pyrimidine pour conduire, après hydrogénation des produits de couplage vinyliques à l'aide d'hydrogène et de Pd/C, à des nucléosides substitués en position 5 par des groupements alkyles. Il semble que cette réaction, qui est réalisée dans des conditions douces, est générale puisque des triflates vinyliques mono- ou di-substitués, aliphatiques ou cycliques, donnent des rendements élevés des nucléosides correspondants, substitués en position 5 par des groupements alkyles. La réaction avec le triflate d'allyle nécessite l'utilisation du 5-chloromercurinucléoside.

Mots clés : nucléosides, triflates, catalyse par palladium.

[Traduit par la revue]

Introduction

The direct synthesis of 5-alkyl substituted pyrimidine nucleosides has been reported by two routes (1, 2). A photochemical approach through the generation of an initial reactive species from either a haloalkyl or 5-iodouridine derivative has been reported (1). Alternatively, an approach employing the palladium-catalyzed olefination reaction of 5-chloromercuriuridine derivatives (2) is a useful synthetic procedure, which allows for ready access to these potential antiviral and anticancer agents (3). However, the reaction of C-5 mercurated nucleosides with simple monosubstituted alkenes generally leads to complex product mixtures and in some instances is complicated by the formation of substantial amounts of C-5 methoxyalkyl nucleosides (2). While the palladium-catalyzed reaction of alkenes with vinyl halides has been practically limited to the reactions of vinylic bromides and iodides (4), the ease of preparation of vinylic trifluoromethanesulfonate (triflates) in high regioselective purity persuaded us to investigate the palladium-catalyzed coupling reaction of pyrimidine nucleosides with vinyl triflates.



When uridine **1***a* was refluxed for 48 h in tetrahydrofuran under nitrogen with 2-propenyl triflate (5) **2***a* in the presence of tetrakis(triphenylphosphine)palladium(0) and 3 equivalents of lithium chloride, the expected modified nucleoside 5-(2-propenyl)uridine **3***a* was isolated in a moderate yield (54%). The structure of **3***a* was established based on its ^{1}H NMR, mass spectrum, and its catalytic hydrogenation to 5-(2-propyl)uridine **4***a* (2). While alkyl substituted olefins are usually inert in the Heck olefination reaction (6), we observed that both mono- and dialkyl substituted vinyl triflate derivatives react well under these reaction conditions. Therefore, the reaction between uridine **1***a* and 2-methyl-1-propenyl triflate **2***b* (7) afforded 5-(2-methyl-1-propenyl)uridine **3***b* in 43% yield. Catalytic hydrogenation of **3***b* gave 5-(2-methyl-1-propyl)uridine **4***b*. The reaction also was extended to the coupling of uridine **1***a* with cyclic vinylic triflates. 5-(6-Methylcyclohexen-1-yl)uridine **3***c* was obtained from the reaction of **1***a* with 6-methylcyclohexen-1-yl-triflate **2***c* (8).

In an attempt to increase the yield of these reactions, we activated the nucleoside by its conversion to the 5-chloromercuri derivative **1***b*, prior to coupling with **2**. This, however, led to a complicated product mixture. Catalytic hydrogenation of the product mixture obtained from the reaction of **1***b* with **2***a* afforded 5-(2-propyl)uridine **4***a*, with identical melting point and ^{1}H NMR to that obtained from the hydrogenation of **3***a*. In the absence of lithium chloride or when bis(triphenylphosphine)palladium(II) dichloride was used instead of tetrakis palladium(0), a remarkable yield depression was observed. This may indicate that the vinylpalladium(II) triflate, which resulted from the oxidative addition of triflates to palladium, is incapable of entering a catalytic cycle as in the Heck olefination reaction (6). In the presence of lithium chloride, apparently a vinylpalladium(II) chloride complex is generated, which is then capable of undergoing further reaction with the nucleoside **1***a* to afford the coupled product and generate a palladium(0) species (Scheme 2).

It has been reported (9) that the organopalladium(II) complex formed from the transmetalation of the 5-chloromercurinucleoside and palladium chloride undergoes reaction with variously substituted allylic chlorides regioselectively and requires only catalytic amounts of palladium chloride. The difficulty in synthesizing and purifying the allylic chlorides limits this approach. Other allylic derivatives afforded poor yields and (or) additional side products (9). When allyl triflate **2***d* (10) was allowed to react with uridine **1***a* under the above conditions, only starting material was recovered. However, treatment of allyl triflate with 5-chloromercuriuridine **1***b* afforded the expected allylic uridine derivative **3***d* (52% yield). It seems that in this latter case the palladium exchanges initially for the nucleoside mercury to give the transient organopalladium intermediate **5**, which then forms another intermediate **6** with the allylic triflate. This then collapses to 5-allyluridine **3***d*.

Finally, we attempted to extend this reaction to the attachment of a simple unsubstituted alkyl side chain at C-5 of the pyrimidine nucleoside. In all cases these attempts were unsuc-

cessful. Upon treatment of nucleosides **1***a* or **1***b* with ethyl or propyl triflates (1, 2) under similar conditions, no alkyl substituted nucleoside could be detected. Most probably alkyl palladium triflates containing an sp^3 hydrogen β to the carbon bearing the palladium undergo a facile β-hydride elimination in preference to alkene insertion. It is also quite possible that this type of triflates does not undergo oxidative addition in the first place.

Experimental

Melting points were taken on a Fisher–Johns melting point apparatus and are uncorrected. IR spectra were measured with a Unicam S.P. 2006, and UV spectra with a Perkin–Elmer 554 recording spectrophotometer. ^{1}H NMR spectra were obtained on a Varian 56/69 A and mass spectra on a Varian CH5 mass spectrometer. Unless indicated, C, H, N analyses were ±0.4% of the calculated values, and were performed at the Microanalytical Center, Cairo University. High pressure liquid chromatography was performed using Partisile PXS 10/25 ODS-II, and preparative, Partisile M9-10/50 ODS-2 columns.

5-(2-Propenyl)uridine **3**a *and 5-(2-propyl)uridine* **4**a

Method A

To a stirred suspension of 2-propenyl triflate **2***a* (5) (836 mg, 4.4 mmol), lithium chloride (542 mg, 13 mmol), and $Pd(PPh_3)_4$ (110 mg, 4.4 mol %) in 50 mL of tetrahydrofuran, was added 500 mg of uridine **1***a* (2.05 mmol). The reaction mixture was refluxed under

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

nitrogen for 48 h, cooled, and filtered through a Celite pad. It was washed with 10% ammonium hydroxide solution (3 × 25 mL), then with water (2 × 25 mL), dried over magnesium sulfate, and the resulting solution was concentrated under vacuum. The residue was chromatographed (silica gel; 15% methanol in chloroform) to afford 5-(2-propenyl)uridine **3***a* (314 mg, 54% yield) as white crystals after crystallization from CH_3CN, mp 143°C. ^1H NMR (D_2O), δ: 1.91 (3H, s, Me), 3.89 (2H, m), 4.28 (3H, m), 5.30 (1H, d, J = 11 Hz), 5.36 (1H, d, J = 11 Hz), 6.21 (1H, m, anomeric proton), 7.80 (1H, s, C6 proton). Anal. calcd. for $C_{12}H_{16}N_2O_6$: C 50, 70, H 5.63, N 9.86; found: C 50.89, H 5.76, N 9.58.

The nucleoside **3***a* (284 mg, 1 mmol) in 100 mL of methanol was treated with 50 mg of 10% Pd/C and stirred under 24 psi of hydrogen for 10 h (1 psi = 6.9 kPa). The catalyst was removed by filtration and the filtrate evaporated under reduced pressure. The residue was chromatographed over silica gel, using 10% methanol in chloroform as eluent, to give 5-(2-propyl)uridine **4***a* (224 mg, 78.4% yield), mp 192°C (lit. (2) mp 191–193°C). ^1H NMR (D_2O), δ: 1.1 (6H, d, J = 6.2 Hz, 2Me), 2.78 (1H, m, Me-C*H*-Me), 3.9 (2H, s), 4.25 (3H, m), 6.1 (1H, d, J = 3 Hz, anomeric H), 7.8 (1H, s, C6 proton).

Method B

A mixture of 2-propenyl triflate **2***a* (836 mg, 4.4 mmol), lithium chloride (542 mg, 13 mmol), Pd $(PPh_3)_4$ (110 mg, 4.4 mol%), and 5-chloromercuriuridine **1***b* (980 mg, 2.0 mmol) was refluxed in THF under nitrogen for 48 h. Work-up as described above afforded a complicated mixture of vinylic uridines, as proved by ^1H NMR spectroscopy. However, catalytic hydrogenation of this mixture under the same conditions described for hydrogenation of **3***a* gave 5-(2-propyl)uridine **4***a* having a melting point and NMR identical to the product of method A.

5-(2-Methyl-1-propenyl)uridine **3**b

Uridine **1***a* (500 mg, 205 mmol) was added to a stirred mixture of 2-methyl-1-propenyl triflate **2***b* (7) (898 mg, 4.4 mmol), lithium chloride (542 mg, 13 mmol), and Pd $(PPh_3)_4$ (110 mg, 4.4 mmol%) in THF and refluxed under nitrogen for 48 h. Work-up as above afforded **3***b*, crystallizing from CH_3CN as white crystals, mp 168°C (264 g, 43% yield). ^1H NMR (D_2O), δ: 1.83 (6H, s, 2Me), 3.95 (2H, m), 4.20 (2H, m), 4.25 (1H, m), (1H, s, olefinic proton). Anal. calcd. for $C_{13}H_{18}N_2O_6$: C 52.35, H 6.04, N 9.40; found: C 52.29, H 6.26, N 9.63.

5-Isobutyluridine **4**b

Catalytic hydrogenation of 5-(2-methyl-1-propenyl)uridine **3***b*, prepared as in the previous synthesis, gave 5-isobutyluridine **4***b* (74% yield) as white crystals, mp 171°C. ^1H NMR (D_2O), δ: 1.2 (6H, d, 2Me), 1.67 (1H, m, Me-CH-Me), 2.3 (2H, t), 3.91 (2H, m), 4.32 (3H, m), 6.1 (1H, m, anomeric proton), 7.70 (1H, s, C6 proton). Anal. calcd. for $C_{13}H_{20}N_2O_6$: C 5.20, H 6.67, N 9.33; found: C 51.83, H 6.9, N 9.57.

5-(6-Methylcyclohexen-1-yl)uridine **3**c

6-Methylcyclohexen-1-yl triflate (8) (1.70 g, 4.4 mmol) was dissolved in THF (50 mL) and treated successively with lithium chloride (542 mg, 13 mmol), Pd $(PPh_3)_4$ (110 mg, 4.4 mol%), and uridine **1***a* (500 mg, 2.05 mmol) and refluxed under nitrogen for 48 h. Work-up as above afforded **3***c* (316 mg, 45.7% yield), mp 162°C. ^1H NMR (D_2O), δ: 1.89 (d, 3H, Me), 1.61 (4H, m), 2.1 (2H, m), 2.5 (1H, m), 3.9 (2H, m), 4.23 (3H, m), 5.96 (1H, m, anomeric proton), 6.09 (1H, t, J = 4.2 Hz), 7.82 (1H, s, C6 proton). Anal. calcd. for $C_{16}H_{22}N_2O_6$: C 56.80, H 6.50, N 8.28; found: C 56.55, H 6.23, N 8.40.

5-Allyluridine **3**d

5-Chloromercuriuridine, **1***b* (980 mg, 2.0 mmol), was added to a stirred mixture of allyl triflate (**2***d*, 863 mg, 4.4 mmol), Pd $(PPh_3)_4$ (110 mg, 4.4 mol%), and lithium chloride (542 mg, 13 mmol) in tetrahydrofuran and refluxed for 48 h. Work-up as above gave 5-allyluridine **3***d*, as white crystals, mp 176°C (lit. (13) mp 175–176°C) (295 mg, 52% yield). ^1H NMR (D_2O), δ: 3.1 (2H, d, J = 6 Hz), 3.9 (2H, m), 4.25 (3H, m), 5.19 (1H, d, J = 17 Hz), 5.21 (1H, d, J = 11 Hz), 5.95 (2H, m), 7.7 (1H, s).

An *ab initio* study of the structure and intramolecular proton transfer in tropolone

MIGUEL A. RÍOS[1] AND JESÚS RODRÍGUEZ

Departamento de Química Física, Facultad de Química, Universidad de Santiago de Compostela, Santiago de Compostela, Galicia, Spain

Received May 15, 1990

MIGUEL A. RÍOS and JESÚS RODRÍGUEZ. Can. J. Chem. **69**, 201 (1991).

An *ab initio* study of tropolone was carried out at the 3-21G level, with full optimization of the geometry, and the intramolecular proton transfer in the ground state was analysed. The two equivalent C_s structures can be converted to each other via a C_{2v} symmetry transition state with a double minimum potential. The splitting of the ground vibrational state generated by proton tunneling was determined by procedures of variable complexity and found to be in the range $\Delta = 0.1–0.15$ cm^{-1}, i.e., clearly smaller than experimental predictions.

Key words: tropolone, intramolecular hydrogen bond, proton transfer, *ab initio* calculations, molecular structure.

MIGUEL A. RÍOS et JESÚS RODRÍGUEZ. Can. J. Chem. **69**, 201 (1991).

On a réalisé des calculs *ab initio* sur la tropolone, au niveau 3-21G, avec optimisation complète de la géométrie et on a analysé le transfert intramoléculaire de proton dans l'état fondamental. Les deux structures C_s équivalentes peuvent se transformer l'une dans l'autre par le biais d'un état de transition de symétrie C_{2v} comportant un double minimum de potentiel. Le dédoublement de l'état vibrationnel fondamental provoqué par un effet tunnel a été déterminé par des procédures de complexité variable et on a trouvé qu'il est de l'ordre de $\Delta = 0{,}1–0{,}15$ cm^{-1}, soit une valeur beaucoup plus faible que celle prédites sur la base de données expérimentales.

Mots clés : tropolone, liaison hydrogène intramoléculaire, transfert de proton, calculs *ab initio*; structure moléculaire.

[Traduit par la revue]

Introduction

One of the major features of tropolone (2-hydroxy-2,4,6-cycloheptatrien-1-one) is the occurrence in its structure of a strong intramolecular hydrogen bond between the two oxygen atoms present in the molecule. As with other similar instances (e.g., the enol form of malonaldehyde), this situation may result in the occurrence of two equivalent C_s structures (Fig. 1(a)) that can be interconverted by a proton transfer, or in a single symmetrical C_{2v} structure where the H atom is equidistant from the two O atoms (Fig. 1(b)). This in turn implies obtaining either a double or single minimum potential curve, which seems to be determined, among other factors, by the distance between the two electronegative atoms involved in the hydrogen bond. In the case of tropolone, experimental results reported thus far (1–9) appear to confirm the occurrence of a double minimum with a proton transfer, both in the ground and in the excited states.

A double minimum potential curve and proton transfer by tunneling result in the splitting (Δ) of vibrational levels. Redington and Redington (1) reported the results of an IR absorption study of tropolone in neon matrices; however, their spectral data were perturbed by non-homogeneous environmental effects, so that they could not provide a detailed, consistent interpretation. Their average Δ(H) and Δ(D) values (2.2 and 3.0 cm^{-1}) reveal the inversion of the usual isotopic effect. Jackman *et al.* (2) used a straightforward procedure to estimate an upper limit for the rate of exchange of deuterium and postulated that it should be less than 10^{10} s^{-1}, corresponding to $\Delta(D) \leq 0.17$ cm^{-1} via the equation $\tau = h/2\Delta$ (ref. 3). Later, Tomioka *et al.* (4) used a one-dimensional theoretical model, which they fitted with the aid of some IR spectral data, to recalculate the Δ values, which they found to be 6.2 and 0.4 cm^{-1} for the hydrogen atom and deuterium, respectively; as can be seen, these values are quite different from those reported by Redington and Redington and, moreover, the Δ(D) values calculated by both authors exceed the Jackman upper limit.

In contrast to the Δ values, however, consistent results were obtained for the proton transfer barrier, namely 5600 (Redington and Redington) and 5890 cm^{-1} (Tomioka *et al.*).

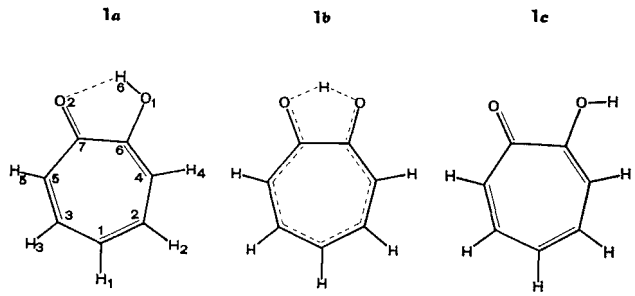

FIG. 1. Structures studied. (a) Stablest conformation: C_s with a hydrogen bond. (b) Structure with a C_{2v} symmetry. (c) C_s conformation with C—O—H angle rotated by 180° and no hydrogen bond.

This paper reports a theoretical *ab initio* study of tropolone with full optimization of its C_s and C_{2v} structures, including calculation of the potential barrier, the frequency of the intramolecular proton transfer by tunneling, and the splitting of the vibrational levels to which it gives rise.

Computation

All computations were made under no constraints by using the program GAUSSIAN 88 (10) and the 3-21G (11) basis set on a CONVEX C-120 computer.

According to our calculations, the intramolecular hydrogen bond in the enol form of malonaldehyde is properly reproduced by the 3-21G basis. Thus the calculated values of O---O = 2.607 Å and barrier height = 7.79 kcal/mol are in better agreement with experimental estimates (12) (2.56 Å and 4–5 kcal/mol) than those obtained with the following basis sets: 4-31G (13) (2.630 Å, 11.6 kcal/mol); C,O(9*s*5*p*/4*s*2*p*) H(4*s*/2*s*) + polarization functions (14) (2.685 Å, 11.4 kcal/mol); 6-31G[2] (2.680 Å, 12.6 kcal/mol); and 6-31G** (15) (2.684 Å, 10.3 kcal/mol). Only a slight improvement is reported for the

6-31G** basis by including electronic correlation at the MP2 level (15) (2.589 Å, 3.6 kcal/mol). However, this agreement between 3-21G calculations and experimental results is probably due to a cancellation of errors coming from basis set limitations and lack of correlation effect. There is no certainty that an analogous cancellation takes place in the tropolone case, so a confirmation of the results of this work by post-HF calculations with better basis set (e.g., 6-31G**MP2) would be desirable, which is not possible for us at present.

Results and discussion

Structural trends

We studied the structures depicted in Fig. 1 with full optimization; their most representative geometric and energetic parameters are listed in Table 1. The most stable (**1***a*) corresponds to one of the two equivalent C_s structures. The second (**1***b*) corresponds to the saddle point in the transition between the two equivalent C_s structures. As expected, we obtained a double minimum potential with a barrier of 4894.2 cm^{-1}, which is of about the same order as the previously mentioned experimental estimates.

Finally, we also optimized the conformation C_s involving no hydrogen bond (**1***c*); it turned out to be 11.23 kcal/mol less stable than **1***a*. This value is thus indicative of the strength of the hydrogen bond, the energy of which cannot be accurately determined for the intramolecular variety.

The most stable conformation C_s (**1***a*) yielded an O---O distance of 2.516 Å, i.e., significantly smaller than the value obtained for malonaldehyde with the same basis (2.607 Å). However, the energy barrier estimated for tropolone (13.99 kcal/mol) is significantly greater than the value obtained for malonaldehyde (7.79 kcal/mol), which shows the significance of factors other than the O---O bond length on the barrier height.

Our results for the C_s geometry are consistent with the experimental measurements made by Simanouchi and Sasada (5), especially the most interesting parameters related to the hydrogen bond: the experimental and calculated O---O distances were 2.53 and 2.52 Å, and those of the O---H bond were 1.98 and 1.93 Å, respectively. The agreement supports the reliability of the basis used in the reproduction of this kind of hydrogen bond, although no accurate comparisons can be made because the experimental data are referred to the solid phase.

All C—C bonds in the C_{2v} structure except C6—C7, which length is closer to that of a single bond, are virtually of the same length, thereby showing π electrons to be highly delocalized around the ring. The O---O distance (2.27 Å) is considerably shorter than in structure C_s so that the O—H bond can be established at a distance of 1.23 Å.

Finally, we studied the structural effect of the hydrogen bond by comparing structure **1***a* with the conformer **1***c* where no hydrogen bond is present. As expected, the O---O distance and the C—O—H angle decrease upon formation of the hydrogen bond, though only slightly, which appears to be due to the fact that the oxygen atoms are in such a position that the molecule is not compelled to adopt a strained structure for the intramolecular bond to be formed. Thus, the seven-membered ring is scarcely distorted and only the extent of conjugation is modified (increased), which shows in the lengthening of the double and the shortening of the single bonds in the structure **1***a*.

Proton transfer

We studied proton transfer by taking a one-dimensional approach to the process. Other methods (16, 17) involve calculations relying on two-dimensional estimates; however, their increased complexity results in no significantly improved results in treating the transfer process.

The potential energy curve was fitted to the following polynomial function

$$[1] \quad V = ax^4 + bx^2$$

which was used elsewhere by Rossetti and Brus (3) to study proton transfer in tropolone in the excited state. As in earlier work (18), we took the reaction coordinate as the position of the H atom with respect to the overall molecule throughout the transfer process. The pathway followed by the hydrogen atom, referred to the mass centre of the system, was estimated by fitting an arc to the three points defined by the H positions in the two C_s minima (**1***a*) and the C_{2v} transition state (**1***b*). Thus, the x coordinate in eq. [1] corresponds to the H atom position in the arc. The parameters in eq. [1] were obtained from R_0 (the length of the above-mentioned arc, which was found to be 1.0622 Å), V_0 (the energy difference between structures C_s and C_{2v}), and the curvature of the potential function at the singular points, which was estimated from the energy change resulting from the slight variation in the position of the H atom along the

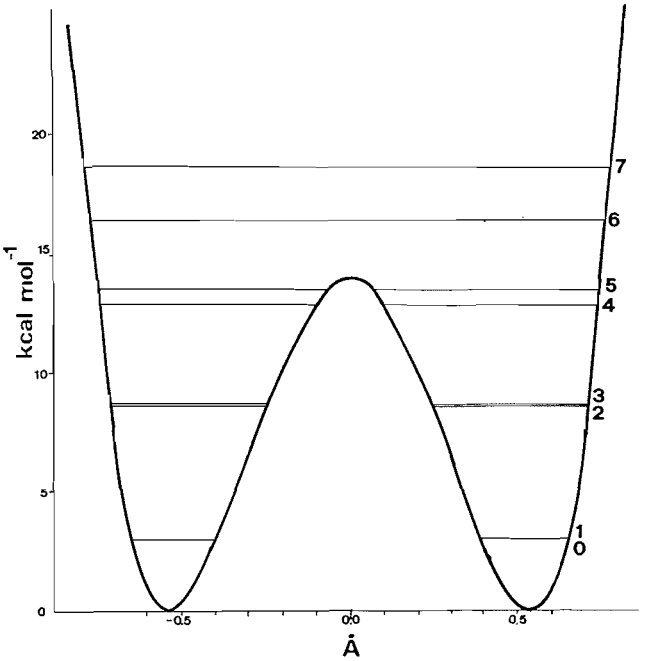

FIG. 2. Potential curve and vibrational levels obtained by fitting the potential curve to eq. [1].

reaction coordinate. Such parameters were found to be $a = 61\,514.4$ cm^{-1} Å^{-4} and $b = -34\,702.4$ cm^{-1} Å^{-2}.

Figure 2 shows the fitted curve and the vibrational levels obtained by the procedure developed by Laane (19), who reported numerical solutions to the Schrödinger vibrational equation obtained from the potential in eq. [1]. The reduced mass of H was taken as its nominal value, as there is evidence that the reduced mass in intramolecular proton transfers with tunneling is similar to that of a free proton (3). The ground vibrational level was found to be subject to a splitting of $\Delta = 0.12$ cm^{-1} (a value of 0.10 cm^{-1} was obtained by fitting the curve to a function defined by a sum of a parabola and a Gaussian (20)). The equation $\tau = h/2\Delta$ yielded a tunneling frequency of 7.2×10^9 s^{-1}.

For contrast, we also calculated Δ by the procedure recently employed successfully by Bicerano *et al.* (14) for the transfer in malonaldehyde, which required the prior calculation of the vibrational frequencies of the initial, final, and transition states. This procedure uses the Wentzel–Kramers–Brillouin (WKB) approximation to calculate the splitting resulting from tunneling at a double minimum potential, which for small splittings is given by (21)

$$[2] \quad \Delta = \frac{\hbar\omega_F}{\pi} e^{-\theta}$$

where ω_F is the classical vibrational frequency at one of the wells and θ is the WKB barrier penetration integral. If the barrier is approximated by the Eckart potential function (see, for example, ref. 22), then θ is given by

$$[3] \quad \theta = \frac{2\pi}{\hbar\omega_i}(V_{eff} - (E_0 V_{eff})^{1/2})$$

where V_{eff} is the effective height of the one-dimensional barrier, E_0 is the energy referred to the bottom of the potential wells, and ω_i is the imaginary frequency at the top of the barrier.

If tunneling is assumed to be an essentially one-dimensional process, the vibrational mode of the "reactant" (structure C_s) to be chosen should be representative of the reaction coordinate; obviously, this can only be the O—H stretching vibration, which will be designated as degree of freedom F, with an ω_F frequency. Thus, we are assuming that the other $(F - 1)$ vibrational modes contribute adiabatically (see, for example, ref. 23) to the determination of the effective one-dimensional barrier. For the ground state,

$$[4] \quad V_{eff} = V_0 + \sum_{k=1}^{F-1} \tfrac{1}{2}(\hbar\omega_k^{\neq} - \hbar\omega_k)$$

$$[5] \quad E_0 = \tfrac{1}{2}\hbar\omega_F$$

where ω_k and $\omega_k^{\neq}$ are the frequencies of the reagent, C_s, and transition state, C_{2v}, respectively, and V_0 is the potential barrier.

The frequencies, which were calculated analytically, are listed in Table 2; as can be seen, one of them for structure C_{2v} is imaginary, which is consistent with a transition state.

The imaginary frequency obtained was $\omega_i = 1778.13$ cm^{-1}, while the O—H stretching frequency for C_s was 3769.44 cm^{-1}. By using the frequencies listed in Table 2 we found the summation term in eq. [4] to be 970.37 cm^{-1}. This and the V_0 value obtained (4894.2 cm^{-1}) yielded $\Delta = 0.15$ cm^{-1}, i.e., quite similar to that obtained by using the polynomial approximation.

With the described procedure and the same basis (3-21G) we obtained a Δ of 22 cm^{-1} for the splitting in malonaldehyde, a value very close to the experimental one (12) (21 cm^{-1}).

In summary, the procedure based on the calculation of frequencies, at least in this case, does not modify significantly the results obtained by using the other potential functions mentioned, which involve less expensive calculations.

On the other hand, the Δ values obtained in this work (between 0.10 and 0.15 cm^{-1}) are indicative of smaller splitting, and hence a lower frequency for the transfer process, than those reported by Redington and Redington (1) and Tomioka *et al.* (4) from experimental estimates, notwithstanding the fact that the height of the calculated barrier is similar to that obtained by these authors.

It seems logical to assume that the Δ of tropolone must be

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

much smaller than that of malonaldehyde, as the experimental barrier of the former is three times as high as that of the latter and only slight differences in their R_0 values are expected according to the experimental O---O distances (2.53 versus $\simeq$2.56 Å). However, further experimental and more precise work and (or) more rigorous calculations will be required to clarify the discrepancy between the results reported here and the experimental estimates available.

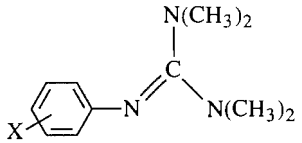
Received May 22, 1990

PRZEMYSLAW PRUSZYNSKI and KENNETH T. LEFFEK. Can. J. Chem. **69**, 205 (1991).

A series of 22 phenyl substituted derivatives of 2-phenyl-1,1′,3,3′-tetramethylguanidine were used as bases in the proton transfer reaction from bis(4-nitrophenyl)cyanomethane in acetonitrile solvent. Brønsted and Hammett type relationships are examined for this family of closely related substrates. The Brønsted relationship constructed from the pK_a values determined in acetonitrile shows $\beta = 0.55 \pm 0.03$. The best fit of the Hammett relationship, with special values for *p*-NO_2 and *p*-CN groups, gives the reaction constant $\rho = -1.39 \pm 0.1$. The kinetic isotope effect, k_H/k_D, increases from 9.6 to 12.4 at 25°C with decreasing base strength, i.e., when the reaction becomes more thermoneutral.

Key words: tetramethylguanidine, proton transfer, deuterium isotope effects.

PRZEMYSLAW PRUSZYNSKI et KENNETH T. LEFFEK. Can. J. Chem. **69**, 205 (1991).



On a utilisé une série de 22 2-phenyl-1,1′,3,3′-tétraméthylguanidines substituées par des groupements phényles comme bases dans des réactions de transfert de proton, à partir du bis(4-nitrophényl)cyanométhane dans l'acétonitrile comme solvant. On a examiné les relations du type de Brønsted et de Hammett pour cette famille de substances intimement apparentées. La relation de Brønsted, établie à partir des valeurs de pK_a déterminées dans l'acétonitrile, présente une valeur $\beta = 0{,}55 \pm 0{,}03$. La meilleure coïncidence de la relation de Hammett, avec des valeurs spéciales pour les groupements *p*-NO_2 et *p*-CN, conduit à une constante de réaction $\rho = -1{,}39 \pm 0{,}1$. Lorsqu'on fait diminuer la force de la base, l'effet isotopique cinétique, k_H/k_D à 25°C, augmente de 9,6 à 12,4; c'est-à-dire que la réaction devient plus thermoneutre.

Mot clés : tétraméthylguanidine, transfert de proton, effets isotopiques du deutérium.

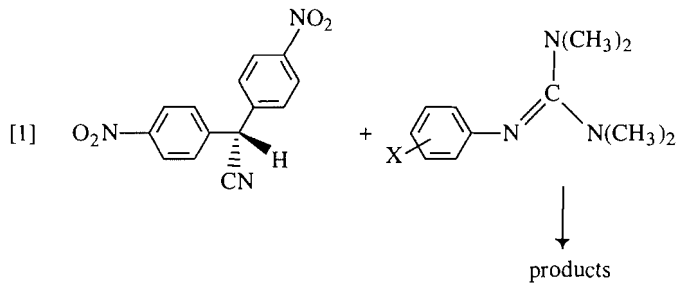
Introduction

The synthesis and pK_a measurements of a large series of phenyl substituted derivatives of 2-phenyl-1,1′,3,3′-tetramethylguanidines **1** (1–3) allow the proton transfer reactions



1

from a suitable carbon acid to be studied for a group of strong bases of closely allied structure. Carbon acids that belong to the group of pseudoacids are relatively weak and this creates the need for a series of stronger bases with known pK_a values. The well-known series of bases, such as anilines or pyridines, are much too weak to abstract the proton from most nitro, *p*-nitrophenyl, and cyano activated carbon acids. Previous studies (4, 5) of kinetic isotope effects and activation parameters of proton transfer reactions with respect to the identity of the base have involved bases of somewhat different skeletal structure, which hampered the interpretation of the results.

This paper presents the results of measurements of equilibrium constants and rate constants for the reaction of 24 phenyl substituted derivatives of **1** for the proton transfer reaction from bis(4-nitrophenyl)cyanomethane in acetonitrile solvent, shown in eq. [1]. Six of these reactions have been studied over a range of temperature, the activation parameters evaluated, and the primary deuterium isotope effects have been determined for four of them.

Results and discussion

Many proton transfer reactions from carbon acids to nitrogen bases in acetonitrile have been shown to give an ion-pair product

[1] 

by the application of the Hildebrand–Benesi method (6) of determining the equilibrium constant. However, in a recent publication, Galezowski and Jarczewski (7) have shown that for the reactions of 1-nitro-1-(4-nitrophenyl)alkanes with 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in acetonitrile solvent, the ion-pair products are at least 97% dissociated into free ions at the concentrations typically used in kinetic measurements. For proton transfer reactions with large equilibrium constants the Hildebrand–Benesi plots do not easily distinguish between ion-pair products and separated ion products, with both equations showing high correlation coefficients (7).

For a reaction of the type shown in eq. [2],

[2] $$AH + B \rightleftharpoons \underset{\text{ion pair}}{A^-BH^+} \rightleftharpoons \underset{\text{free ions}}{A^- + BH^+}$$

it may be assumed that the interconversion of ions and ion pairs is fast. If the overall equilibrium constant is large, the reverse reaction may be neglected and the overall forward second-order rate constant (k_2) may be determined by measuring the pseudo-first-order rate constants (k_{obs}) at a series of large base concentrations and fitting to eq. [3].

[3] $$k_{obs} = k_2[B]$$

Most of the phenyltetramethylguanidine bases are so strong that the equilibrium constants for the proton transfer reactions are very high. In these cases it is very difficult to determine the

TABLE 1. Equilibrium constants for the reaction of bis(4-nitrophenyl)cyanomethane and substituted 2-phenyl-1,1',3,3'-tetramethylguanidines in acetonitrile solvent at 25°C

Substituent in base	ϵ ($dm^3\ mol^{-1}\ cm^{-1}$)	K_{ip} ($dm^3\ mol^{-1}$)	Corr. coeff. (ion pair)	K_i	Corr. coeff. (ions)
4-CN	58 000 ± 200	10 500 ± 100	0.9946	$(9.5 \pm 0.5) \times 10^{-2}$	0.9955
4-NO_2	69 000 ± 1000	4 100 ± 600	0.9724	$(3.7 \pm 0.6) \times 10^{-3}$	0.9727

equilibrium constant quantitatively and this was done only for the two weakest bases, the *p*-nitro and *p*-cyano derivatives. The equilibrium absorptions of the product peak at 645 nm for a series of base concentrations at constant acid concentration were fitted to the Hildebrand–Benesi equations (6) derived for an ion-pair product, eq. [4], and for separated ion products, eq. [5]. *A* is the absorbance at equilibrium, *a* and *b* are the initial

$$[4]\quad a/A = \frac{1}{K_{ip} b \epsilon} + \frac{1}{\epsilon}$$

$$[5]\quad a/A = \frac{A}{K_i b \epsilon^2} + \frac{1}{\epsilon}$$

concentrations of the acid and base respectively, ϵ is the molar extinction coefficient, K_{ip} is the equilibrium constant assuming an ion-pair product, and K_i is the overall equilibrium constant for the reaction yielding separated ions as products. The base was always in large excess over the acid and was varied in the range (1×10^{-3})–(5×10^{-2}) M. Linear plots were obtained for both a/A vs. $1/b$ (eq. [4]) and for a/A vs. A/b (eq. [5]) for both reactions. The results are summarized in Table 1, and the equilibrium constants are sufficiently high that eq. [3] should be obeyed, even if the products are indeed essentially fully ionized.

The pseudo-first-order rate constants, k_{obs}, were determined at a series of base concentrations always in large excess. The second-order rate constants, k_2, were calculated by a least-squares fit to eq. [3] and are collated in Table 2, together with the pK_a values previously determined (3). The plots of the k_{obs} values versus base concentration do pass through the origin, with the possible exception of the *p*-NO_2 derivative, and therefore yield k_2 values that are a very good approximation to the true second-order rate constants for the reaction [1]. The data in Table 2 for the *para* and *meta* substituted bases may be used to construct Brønsted and Hammett correlations, and the *ortho* substituted bases allow the influence of steric factors on the rate of the reaction to be assessed.

The Brønsted relationship between log k_H at 25°C and pK_a of the conjugate acid of the base is shown in Fig. 1 and yields a Brønsted β coefficient of 0.55 ± 0.03 when calculated using only the solid points that represent the various *para* and *meta* substituted bases. This is the same within experimental error as the value of 0.53 reported (5) for the acid 4-nitrophenylphenylcyanomethane reacting with various nitrogen bases in acetonitrile, and also the same as the average value found by Bordwell and Boyle (8) for several arylnitromethanes reacting with bases in water. More O'Ferrall (9) lists values of the Brønsted exponent that vary between 0.38 and 0.79 for the ionization of ketones and nitroalkanes.

The bases containing *ortho* substituents on the phenyl group are shown with open circles in Fig. 1. The points for 2-OMe and 2,4-di-OMe derivatives (points 11 and 12) show a positive deviation from the general relationship for *meta* and *para* substituted bases. This behaviour may be explained by a possible stabilization of the positive charge developed on the base in the transition state by interaction with an oxygen of the *ortho* methoxy group. All the other *ortho* derivatives show a negative deviation, which is most likely caused by simple steric hindrance. This effect is especially pronounced for *ortho* alkyl derivatives (points 19–24).

A Hammett plot, shown in Fig. 2 for nine of the bases, using σ^- values (10) for the *para*-nitro, *para*-cyano, and *para*-trifluoromethyl groups in recognition of the important resonance structures of these bases, gives a ρ value of -1.39 ± 0.10 with a correlation coefficient of 0.987. If σ^0 values (10) are used for all the substituents, the correlation coefficient is almost as good at 0.985 and ρ is -1.94 ± 0.13. These values are consistent with the fact that the positive charge developing on the nitrogen atom directly bonded to the phenyl ring is partially redistributed onto the two other nitrogen atoms and apparently shifted away from the phenyl ring. The Hammet ρ values reported previously for the equilibrium constants of this series of bases (2, 3) were -1.84 ± 0.05 and -2.18 ± 0.16 in water and acetonitrile respectively. These were values determined using σ^- constants where appropriate, and therefore are to be compared with $\rho = -1.39$ for the proton transfer rate constants. This value might be expected to be higher since it is the nitrogen atom directly bonded to the phenyl ring which undergoes protonation. Delocalization of the positive charge, the same effect that is responsible for the unique strength of the guanidine bases, must also lower the sensitivity of this strength to the substituent effect. When the ρ value of -1.39 for $\log_{10} k$ is compared to -2.18 for pK_a, the conclusion may be drawn that the transition state of the reaction comes early on the reaction coordinate. This conclusion is consistent with a Brønsted β value of 0.55 and is also consistent with a Hammett correlation study (11) of cyanocarbon acids reacting with tetramethylguanidine in acetonitrile solvent in which the substituent on a phenyl group in the acid was varied.

The activation parameters for the six reactions studied over a range of temperature are shown in Table 3. The enthalpies of activation are all very low and show no discernable trend. They differ from one another by barely more than the standard deviations, with the slowest reaction of the *p*-NO_2 substituted base yielding the smallest enthalpy of activation. The entropies of activation show a slightly larger variation with the largest negative value found with the *p*-NO_2 substituted base. The stronger electron-withdrawing groups, *p*-NO_2 and *p*-CN, give larger negative entropies of activation but the four weaker groups all yield values between -29 and -30 cal $mol^{-1}\ deg^{-1}$. Negative entropies of activation of this magnitude are typical of proton transfer reactions to carbon acids in acetonitrile solvent. If a major part of the barrier to reaction is the breaking of the initial state solvation shell (12, 13), the small enthalpies of activation are consistent with a transition state that is reached early along the reaction coordinate.

The primary deuterium isotope effects for four of the

$\Delta\Delta S^{\ddagger}$ (cal mol^{-1} K^{-1})		1.2 ± 0.7	0.2 ± 0.6	0.1 ± 0.3	−0.1 ± 0.3

reactions are given in Table 4. The rate ratios decrease with increasing temperature almost exactly as required for the entire isotope effect to be in the enthalpy of activation, and three of the bases show a $\Delta\Delta H^{\ddagger}$ effect corresponding to the loss of a C–H (or C–D) stretching frequency. The *p*-NO_2 base shows a slightly larger effect, indicating a possible contribution from proton tunnelling. There is a small but clear variation of k_H/k_D with the pK_a of the base. The weakest base, the *p*-nitro derivative, shows the largest isotope effect, in keeping with the theory (14–16) that the maximum isotope effect will occur in the more thermoneutral process.

Experimental

The 2-phenyl-1,1,3,3-tetramethylguanidines were synthesized by the method of Bredereck and Bredereck (17) from 1,1,3,3-tetramethylurea (Aldrich) and the appropriate aniline, in the presence of $POCl_3$. The detailed synthesis including modifications in the work-up procedure was described earlier (2, 3). The purity of these compounds

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

was assessed by GC–MS analysis using Hewlett–Packard 5890 A/5970 MSD apparatus.

Bis(4-nitrophenyl)cyanomethane was synthesized by nitration of diphenylcyanomethane according to the procedure described in the paper of Haskelberg and Larie (18). The reaction was performed using fuming nitric acid at −40°C. The crude reaction product was first purified by converting it into the salt by washing with NaOH, extracting the water phase with ether, and reprecipitating the product using acetic acid. The product was further crystallized from benzene and acetic acid until it gave a single spot on a TLC (mp 93–94.5°C exactly as reported earlier by Hojatti and Leffek (11), confirming the validity of this measurement in the light of the earlier reported value of 40–45°C (19)). ^{1}H NMR ($CDCl_3$), δ: 5.4 (1H, s), 7.5 (4H, d, J = 9.0 Hz), 8.2 (4H, d, J = 9.0 Hz).

Bis(4-nitrophenyl)cyanomethane-*d* was prepared by OD^- catalyzed isotopic exchange in a D_2O–dioxan mixture. The neutralization of the anion by DCl/D_2O was followed by evaporation of the solvents. The residue, consisting of the deuterated compound and NaCl, was not separated but dissolved in a new portion of D_2O–dioxan and the procedure was repeated. After five such cycles the residue, after evaporation, was extracted with dry $CHCl_3$ followed by its evaporation. The degree of deuteration was found to be 98% based on ^{1}H NMR and MS spectrometry.

Equilibrium measurements were done using a Cary 219 spectrophotometer at 25°C. The absorbance was measured for the series of solutions with constant acid concentration (in the range of (5×10^{-6})–(2×10^{-5}) M) and varying base concentrations. For stronger bases the change in absorbance due to the increase of their concentration was too small to be reliably measured.

The reaction rate constants were measured using a Durrum –Gibson stopped-flow spectrophotometer, equipped with a computerized data acquisition system, using acid concentrations in the range of (5×10^{-6})–(1×10^{-5}) M with the base concentration high enough to allow for pseudo-first-order kinetics. The rate constants were calculated using the Guggenheim method (20) and the activation parameters obtained by a least-squares fit to the transition state theory equation.

Sedum alkaloids. XI. Synthesis of sedinone and sedacrine by application of anodic oxidation

FRANK DRIESSENS AND CLAUDE HOOTELÉ[1]

Service de chimie organique, Faculté des sciences, Université Libre de Bruxelles, B-1050 Bruxelles, Belgium

Received April 13, 1990

FRANK DRIESSENS and CLAUDE HOOTELÉ. Can. J. Chem. **69**, 211 (1991).

α-Methoxycarbamate **12**, synthetic precursor of the 2,6-disubstituted alkaloids of *Sedum acre*, was obtained in high yield from 2-phenacylpiperidine **5**; the key step of the synthesis rests on the anodic methoxylation, which allows the functionalization of carbon 6. Nucleophilic substitution of the methoxy group by an acetonyl chain leads, after the required transformations, to sedinone **23**. Bromomethoxylation of the enecarbamate **19** followed by dehydrohalogenation and nucleophilic substitution of the methoxy group leads to sedacrine **33**. In both cases, the nucleophilic substitution of the methoxy group leads to a *cis* 2,6-disubstituted piperidine derivative.

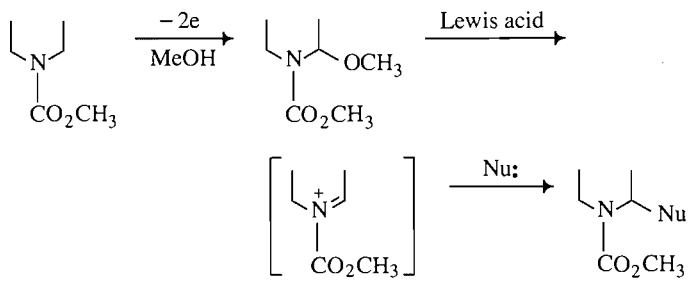
Key words: synthesis, piperidine alkaloids, anodic methoxylation.

FRANK DRIESSENS et CLAUDE HOOTELÉ. Can. J. Chem. **69**, 211 (1991).

L'α-méthoxycarbamate **12**, précurseur synthétique des alcaloïdes 2,6-disubstitués de *Sedum acre* a été obtenu avec un rendement élevé au départ de la 2-phénacylpipéridine **5**; l'étape clé de la synthèse est la méthoxylation anodique qui permet la fonctionnalisation du carbone 6. La substitution nucléophile du groupe méthoxy par une chaîne acétonyle conduit, après aménagement fonctionnel, à la sédinone **23**. La bromométhoxylation du ènecarbamate **19** suivie d'une déhydrohalogénation et de la substitution du groupe méthoxy permet d'accéder à la sédacrine **33**. Dans les deux cas, la substitution du groupe méthoxy conduit à un dérivé pipéridinique *cis* 2,6-disubstitué.

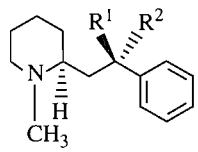
Mots clés : synthèse, alcaloïdes pipéridiniques, méthoxylation anodique.

[Traduit par la revue]



Introduction

Piperidine alkaloids constitute a large family of compounds, many of which exhibit a wide range of physiological activities. Because of this aspect, intense activity has been devoted to the isolation and structure determination of bases of this class and to the development of general routes for their synthesis (1). In this context, during the last few years, several methods were developed for the synthesis of 2,6-disubstituted piperidine alkaloids and especially for the bases isolated from *Solenopsis* species (2). Although electrochemical methoxylation emerged recently as a powerful method for the synthesis of piperidine derivatives (3, 4), no application to the synthesis of 2,6-disubstituted piperidine alkaloids has yet been recorded. Our interest in *Sedum* and related alkaloids prompted us to evaluate the potentiality of anodic methoxylation as a key step for the synthesis of members of this subgroup.



Anodic methoxylation allows the easy preparation of α-methoxyamides and α-methoxycarbamates. These compounds constitute interesting synthetic intermediates because of their facile conversion into the corresponding *N*-acyliminium ions, which have been shown to be versatile electrophiles. The combination of anodic methoxylation and nucleophilic substitution, e.g., with silyl enol ethers, appears to be a choice method for the introduction of a new C—C bond α to the nitrogen atom of cyclic amides and carbamates (Scheme 1).

The electrochemical preparation and the synthetic usefulness of α-methoxycarbamates were investigated by T. Shono in particular, who developed the syntheses of several alkaloids based on the sequence of Scheme 1. In the field of 2-alkylpiperidine alkaloids, application of this sequence leads, *inter alia*, to the synthesis of sedamine **1** and allosedamine **2** (5, 6).

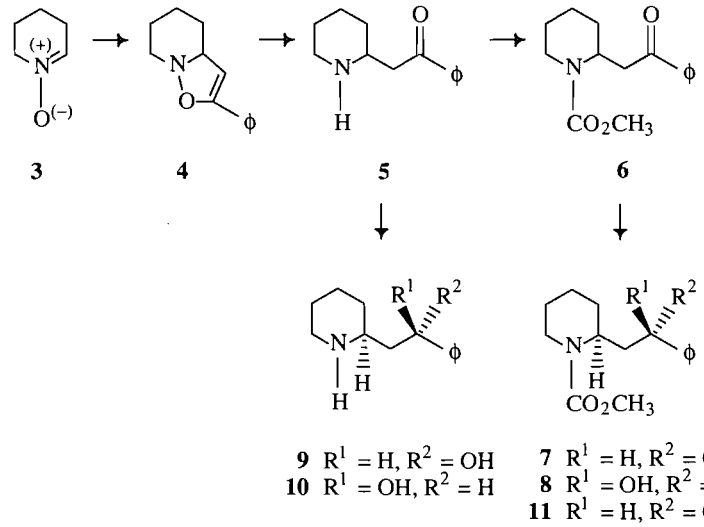
We pointed out, in a preceding communication, that all the 2,6-disubstituted alkaloids isolated from *Sedum acre* contain a (−)-sedamine moiety (7). This feature allows their synthesis to be based on the alkylation at C-6 of a common 2-substituted piperidine derivative. In this respect, the anodic methoxylation process seemed promising because it was observed that the least

SCHEME 1

1 $R^1 = H, R^2 = OH$
2 $R^1 = OH, R^2 = H$

substituted α-carbon atom of *N*-acylpiperidines is oxidized specifically (5); a rationalization of this observation has been offered (8).

Results and discussion



We wish to report here the synthesis of the alkaloids sedinone **23** and sedacrine **33** via the precursor **12** using anodic methoxylation methodology.

Preparation of the precursor 12

2-Phenacylpiperidine **5** was obtained (70% overall yield) by the method we described earlier (9) via hydrogenolysis (H_2, Pd/C) of the isoxazoline **4** resulting from the cycloaddition between the nitrone **3** and phenylacetylene (Scheme 2). Acylation of the nitrogen atom of **5** with methyl chloroformate under

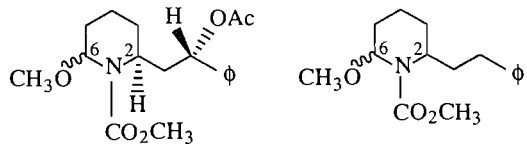


SCHEME 2

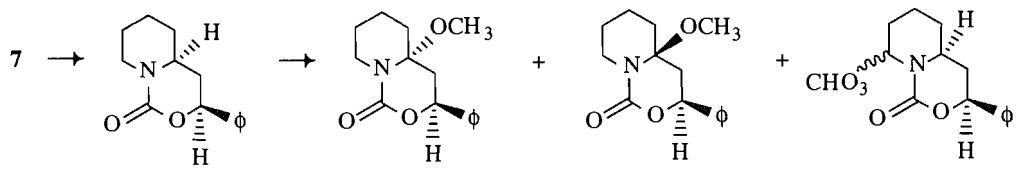
Schotten–Baumann conditions yielded quantitatively the carbamate **6**. The same compound had previously been obtained in comparable yield through the sequence anodic methoxylation – nucleophilic substitution (6). Reduction of the keto group of **6** with $NaBH_4$ in MeOH furnished a 70:30 mixture of the diastereoisomeric alcohols **7** and **8**. However, a 98:2 mixture of **7** and **8** was obtained when the reduction was performed with lithium tri-*tert*-butoxyaluminium hydride in THF. Under the same conditions, 2-phenacylpiperidine **5** was transformed into a 35:65 mixture of **9** and **10**. The high selectivity observed for the reduction of the ketone function of the carbamate **6** with $Li(tBuO)_3AlH$ is worthy of note because the sequence described above constitutes a simple and efficient route for the synthesis of sedamine-type derivatives. Thus, norsedamine **9** and sedamine **1** were obtained by basic ethanolysis and by $LiAlH_4$ reduction of **7** respectively. Another efficient stereoselective synthesis of sedamine-type derivatives was described recently (10). On the other hand, it had been established previously that allosedamine-type derivatives are accessible in high yield and with a high stereoselectivity via cycloaddition between nitrone **3**, or derivatives of **3**, and styrene (11).

Acetylation of the alcohol **7** yielded quantitatively **11**, which was submitted to anodic oxidation.

All anodic oxidations performed in this study were carried out at room temperature in methanol containing Et_4NOTs as a supporting electrolyte, in an undivided cell equipped with two vitreous carbon electrodes; a constant potential of 8.00 V was applied. After 8 F/mol of electricity was passed, the oxidation of the acetyl derivative **11** was complete and yielded quantitatively the 6-methoxylated compound **12**. In agreement with structure **12**, the ^{13}C nmr spectrum showed the presence of only 4 methylene groups. In the ^1H nmr spectrum ($CDCl_3$; 250 MHz) of **12**, H-2 and H-6 appeared as broad signals centered at 4.28 and 5.40 ppm respectively; a broadening of signals, due to the "slow" rotation around the N—CO_2CH_3 bond, is observed for all the compounds of this series. The broad signals at 3.28 and 3.72 ppm are attributed to the methoxy group at C-6 and to the N—CO_2CH_3 group, respectively, by comparison with the spectrum of the trideutero derivative obtained after anodic methoxylation of **11** in CD_3OD. When the ^1H nmr spectrum of **12** was recorded at 57°C, sharp signals were observed for the three methyl groups; there was no indication of the presence of another isomer. The configuration at C-6 was, however, not established.

12 **13**

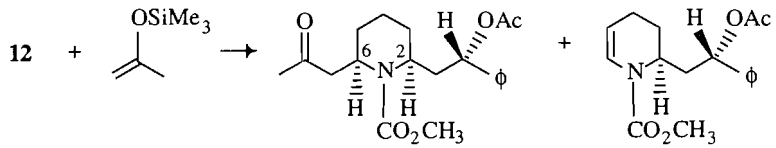
In the same experimental conditions, oxidation of the ketone **6** in methanol furnished regiospecifically the α-methoxycarbamate **13** in 96% yield. On the other hand, anodic methoxylation of the bicyclic derivative **14** (Scheme 3), obtained by transesterification from **7**, gave a mixture of isomers **15**, **16**, and **17** in a 1:1:1 ratio. In this case, the lack of regioselectivity can be ascribed to the strain induced in the less substituted iminium intermediate by the presence of the lactam cycle.



Synthesis of sedinone 23

The replacement of the methoxy group of **12** by an acetonyl side chain was carried out by treatment of **12** with 2-trimethylsilyloxypropene **20** in CH_2Cl_2 in the presence of $TiCl_4$, as a Lewis acid (Scheme 4). After column chromatography only one isomer, the 2,6-disubstituted derivative **18**, was isolated in 70% yield, along with the enecarbamate **19** (10% yield), which results from the elimination of methanol from **12**.

The *cis* configuration of **18** was not established at this stage but rests on the isolation of sedinone **23** as the major isomer after the steps described below (Scheme 5).



Protection of the keto group of **18** with ethylene glycol yielded quantitatively the dioxolane **21** whose carbomethoxyl and acetyl groups were reduced with $LiAlH_4$ to give the *N*-methyl derivative **22** (82% yield). Deprotection of **22** was carried out in boiling 0.1 N aqueous hydrochloric acid; a 90:10 mixture of sedinone **23** and 6-episedinone **24** was isolated (96% yield). The acetal **21** being a pure compound, the presence of **24** in the hydrolysis mixture must result from a partial epimerization of C-6 during the basic work-up after the deprotection step. While β-aminoketones such as **23** and **24** epimerize readily in basic medium, or simply in methanol, their salts are stereochemically stable. The epimerization therefore involves the nitrogen lone pair and may be accounted for by the path depicted in Scheme 6, as described for pelletierine and related compounds (23). As sedinone **23** is the major compound of the

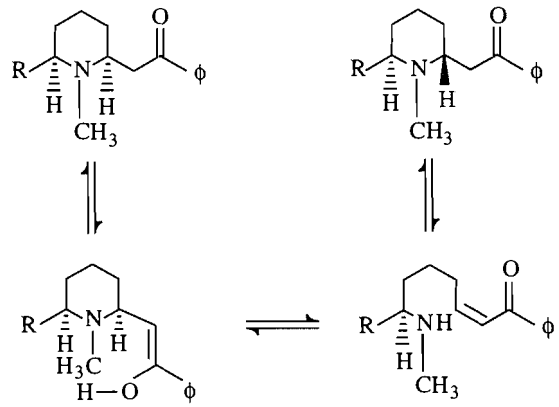
SCHEME 5

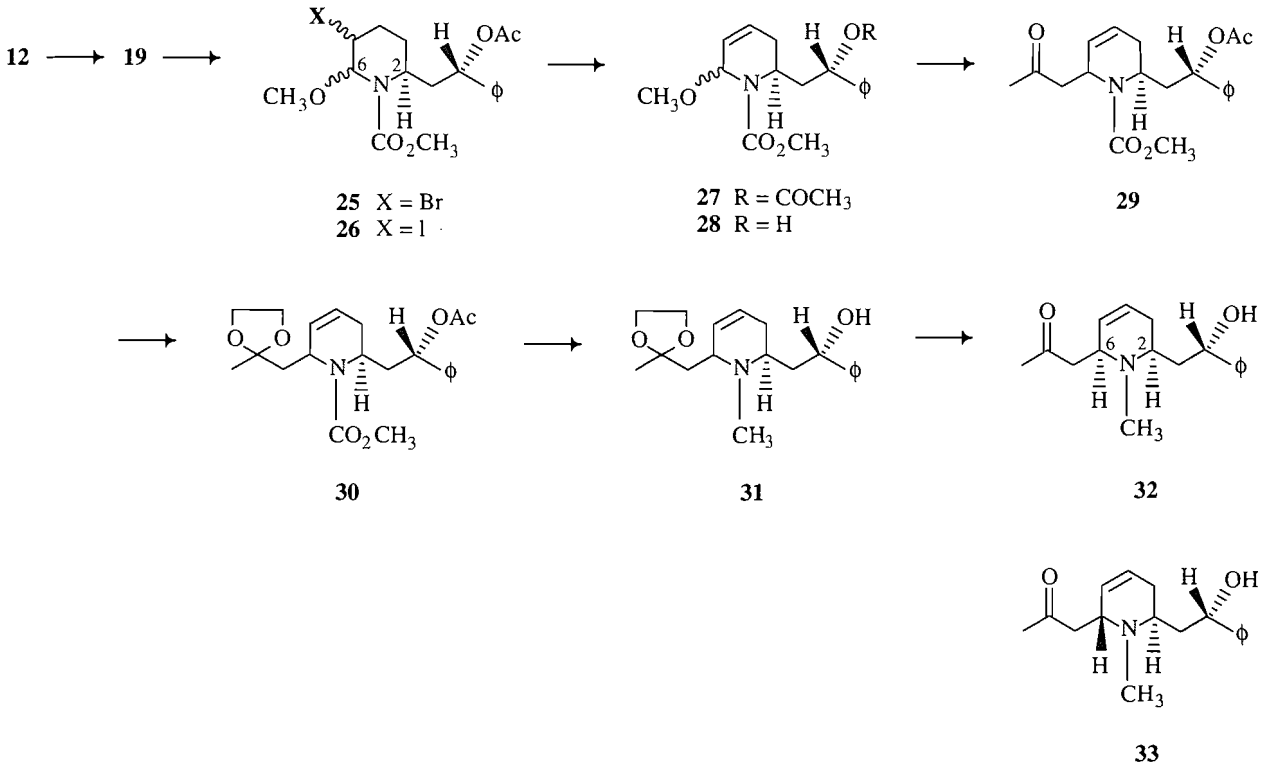


mixture, which is not the equilibrium mixture (8), the relative 2,6 configuration of **18** has to be *cis*.

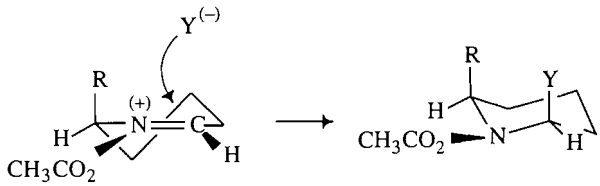
The same sequence of reactions was applied to (−)-norsedamine **9** (12) as the starting material. After hydrolysis of the optically active acetal **22**, (−)-sedinone hydrochloride was isolated by fractional crystallization from the mixture of the hydrochlorides. The physical properties of the synthetic sample, including the optical rotation, were identical with those of the hydrochloride prepared from a natural sample of (−)-sedinone **23**.

Synthesis of sedacrine 33

The synthesis of sedacrine **33** from the precursor **12** (Scheme 7) requires the introduction of a C=C double bond in position 4. Recently, Shono *et al.* (13) and Torii *et al.* (14) reported that enecarbamates, which are easily obtained from α-methoxycarbamates (15), are suitable precursors of 2-alkyl-6-methoxy-1,2,3,6-tetrahydropyridine derivatives via halomethoxylation followed by dehydrohalogenation. Consequently, the enecarbamate **19** was prepared by treatment of **12** with *p*-toluenesulfonic acid in benzene at room temperature (yield 96%).



Quantitative bromomethoxylation of **19** was carried out by addition of bromine to a methanolic solution of **19** in the presence of sodium methoxide to give **25**, which is likely to be a mixture of diastereoisomers. The 5-bromo derivative **25** was then subjected to dehydrohalogenation conditions (DBU in



SCHEME 6

toluene at 87°C for 3 h). However, no elimination of HBr occurred. On the other hand, similar treatment of the corresponding 5-iodo derivative **26** (prepared from **19** in 85% yield) furnished a mixture of **27** and the corresponding alcohol **28**; the presence of the alcohol **28** is not surprising since DBU is known as a deprotective agent for acetyl groups (16). Treatment of the crude reaction mixture with acetic anhydride in pyridine led to the isolation of **27** in 93% yield from **26**. The nmr spectra did not allow us to establish whether **27** is a pure compound or a mix-

SCHEME 7

SCHEME 8

ture of diastereoisomers. The nucleophilic substitution of the methoxy group of **27** by an acetonyl chain was carried out in CH_2Cl_2 at −78°C in the presence of $TiCl_4$; after chromatography, the substitution product was isolated in 64% yield. The stereochemistry at C-6 was not established at this stage but the product must contain at least 90% of the *cis* compound **29**, as can be inferred from the isolation of a 9:1 mixture (by ^1H nmr) of episedacrine **32** and sedacrine **33** (84% overall yield) after a sequence of reactions identical with that described above for the synthesis of sedinone **23**: i.e., protection of the keto group of **29**, $LiAlH_4$ reduction of the acetal **30**, and deacetalization. After equilibration in methanol, a 6:1 mixture (by ^1H nmr) of **33** and **32** was obtained.

When the same sequence was applied to (−)-**12** as the starting material, (−)-sedacrine **33**, identical in all respects with the natural compound, was obtained.

In the two examples discussed above, the nucleophilic substitution of the methoxy group leads with high stereoselectivity to the *cis* 2,6-disubstituted piperidine derivative; this stereochemical control of the C-6 configuration is worthy of note and results from the stereoelectronically preferred axial attack of the nucleophile (8, 17) on the *N*-acyliminium intermediate, whose favoured conformation has an axial alkyl group at C-2 (18, 19) (Scheme 8). Other examples of *cis* stereoselectivity in the substitution of a methoxy group by a nucleophile have already been reported (24, 25).

Experimental

Melting points were determined on a Kofler microscope and are uncorrected. Mass spectral data were obtained on a Micromass 7070 spectrometer. Nuclear magnetic resonance spectra were recorded in $CDCl_3$ with TMS as internal standard on a Bruker WM 250 spectrometer. Optical rotations were measured on a Perkin Elmer 141 polarimeter.

Preparation of the carbamate **6**

K_2CO_3 (5.805 g) and methyl chloroformate (3.9 mL) were successively added to a stirred solution of 2-phenacylpiperidine **5** (3.870 g) in water (100 mL). After 15 h, NH_4OH was added and the basic solution was extracted with $CHCl_3$ (2 × 100 mL). The combined $CHCl_3$ layers were evaporated and the residue was filtered through a short column of alumina to afford quantitatively the carbamate **6** (4.966 g), mp 92°C after crystallization from hexane/ethyl acetate 5:1 (lit. (6) mp 89.2°C); ^1H nmr δ: 7.98 (2H), 7.5 (3H), 4.86 (1H, m, H2), 4.06 (1H, m, H6e), 3.62 (3H, s, CO_2CH_3), 3.29 (1H, dd, J = 9 and 15 Hz, H7), 3.15 (1H, dd, J = 6 and 15 Hz, H7′), 2.93 (1H, dt, H6a), 1.69–1.38 (6H, m); ^{13}C nmr δ: 198.3 (C8), 156.0 (NCO), 137.0, 133.1, 128.7, 128.2, 52.4 (CH_3), 48.3 (C2), 40.0 and 39.3 (C6 and C7), 28.0 and 25.3 (C3 and C5), 18.9 (C4); ms, *m/z*: 261 (11%), 230 (2), 202 (39), 156 (6), 142 (100), 141 (35), 105 (47), 77 (31), 70 (11).

Reduction of **6** *with Li(tBuO)$_3$AlH*

The carbamate **6** (152 mg) was dissolved in THF (15 mL) and Li(*t*BuO)$_3$AlH (1.480 g) was added. The mixture was then refluxed for 4 h. After cooling, some drops of water were added and the mixture was filtered through Celite and evaporated to dryness. The residue was dissolved in water (70 mL), basified with NH_4OH, and extracted with $CHCl_3$ (2 × 70 mL). Evaporation of the solvent gave a mixture (153 mg) of **7** and **8** (98:2 by ^1H nmr). **7** and **8** were separated by chromatography on alumina ($CHCl_3$); **7** (oil): ^1H nmr δ: 7.3 (5H, m), 4.74 (1H, m, H8), 4.43 (1H, m, H2), 3.92 (1H, m, H6e), 3.66 (3H, s), 2.80 (1H, m, H6a), 2.17 (1H, m, H7), 1.89 (1H, m, H7′), 1.61–1.36 (6H, m); ^{13}C nmr δ: 156.5 (NCO), 144.7, 128.3, 127.4, 125.8, 72.4 (C8), 52.5 (CH_3), 48.7 (C2), 39.9 and 39.6 (C6 and C7), 29.0 (C3), 25.4 (C5), 19.1 (C4); ms, *m/z*: 263 (7%), 186 (3), 142 (100). **8** (oil): ^1H nmr δ: 7.3 (5H, m), 4.60 (1H, m), 4.47 (1H, m), 4.05 (1H, m), 3.75 (3H, s),

.85 (1H, m, H6a), 2.22 (1H, m, H7), 2–1.3 (7H, m); ms, *m/z*: 263 (7%), 186 (3), 142 (100).

*Reduction of **6** with $NaBH_4$*

The carbamate **6** (131 mg) was dissolved in methanol (5 mL) and $NaBH_4$ (100 mg) was added. After 2 h at room temperature, the solvent was evaporated and water was added to the residue; extraction with $CHCl_3$ afforded, after evaporation of the solvent, 132 mg of a 70:30 mixture (by ^1H nmr) of **7** and **8**.

*Reduction of 2-phenacylpiperidine **5** with $Li(tBuO)_3AlH$*

2-Phenacylpiperidine **5** (143 mg) was treated with $Li(tBuO)_3AlH$ (358 mg) in refluxing THF (10 mL) for 15 h. After addition of some drops of water, the mixture was filtered through Celite and the solvent was evaporated. The residue was dissolved in water (50 mL), basified with NH_4OH, and extracted with $CHCl_3$ (3 × 50 mL). Evaporation of the combined organic layers gave a mixture (140 mg) of norsedamine **9** and norallosedamine **10** (35:65 by ^1H nmr (20)).

*Preparation of norsedamine **9** from **7***

A solution of **7** (144 mg) and KOH (750 mg) in EtOH (7.5 mL) was heated under reflux for 6 h. After evaporation of the solvent, the residue was dissolved in water (15 mL), basified with NH_4OH, and extracted with $CHCl_3$ (2 × 15 mL). Evaporation of the combined organic layers afforded norsedamine **9** (98 mg, 87% yield), whose ^1H nmr and mass spectra were identical with those reported in the literature (20).

*Preparation of sedamine **1** from **7***

To a solution of the carbamate **7** (120 mg) in THF (15 mL) was added $LiAlH_4$ (115 mg) and the mixture was refluxed for 6 h. Some drops of AcOEt and water were added and the mixture was filtered through Celite and evaporated to dryness. The residue was dissolved in 0.2 N aqueous HCl (50 mL) and extracted with $CHCl_3$ (2 × 3 mL). The aqueous phase was then basified with NH_4OH and extracted with $CHCl_3$ (3 × 50 mL). Evaporation of the combined $CHCl_3$ phases and filtration through a short column of alumina afforded homogeneous sedamine **1** (95 mg); the mass and ^1H nmr spectra of the base are identical with those reported in the literature (20).

*Acetylation of the alcohol **7***

The alcohol **7** (1.560 g) was treated at room temperature for 15 h with a mixture of pyridine (7 mL) and Ac_2O (7 mL). After evaporation of the solvent, filtration of the residue through a short column of alumina ($CHCl_3$) yielded **11** quantitatively (1.805 g; oil); ^1H nmr δ: 7.3 (5H), 5.73 (1H, dd, J = 6 and 8 Hz, H8), 4.32 (1H, m, H2), 4.04 (1H, m, H6e), 3.65 (3H, s), 2.93 (1H, m, H6a), 2.37 (1H, m, H7), 2.04 (3H, s), 1.89 (1H, m, H7′), 1.62–1.37 (6H, m); ^{13}C nmr δ: 170.1, 156.0 (NCO), 140.7, 128.5, 128.1, 126.7, 74.3 (C8), 52.4, 48.3 (C2), 39.4 and 36.7 (C6 and C7), 28.6 (C3), 25.5 (C5), 21.1, 19.1 (C4); ms, *m/z*: 305 (1%), 262 (2), 245 (17), 186 (10), 142 (100).

*Preparation of the bicyclic derivative **14***

A solution of the carbamate **7** (169 mg) and KOH (17 mg) in methanol (10 mL) was heated under reflux for 3.5 h. After the solvent was evaporated, the residue was dissolved in water (15 mL), basified with NH_4OH, and extracted with $CHCl_3$ (2 × 15 mL). Evaporation of the $CHCl_3$ and crystallization from hexane afforded **14** (127 mg, 86% yield); mp 97–98°C; ^1H nmr δ: 7.32 (5H), 5.17 (1H, dd, J = 2 and 12 Hz, H8), 4.54 (1H, m, H6e), 3.46 (1H, ddt, J = 2.5 and 11 Hz, H2), 2.73 (1H, dt, J = 3 and 13 Hz, H6a), 2.29 (1H, ddd, J = 2.5 and 14 Hz, H7), 1.97–1.20 (7H, m); ms, *m/z*: 231 (34%), 187 (16), 186 (24), 127 (28), 104 (100).

Anodic methoxylations

All anodic methoxylations were carried out at room temperature in methanol (analytical grade) containing Et_4NOTs as a supporting electrolyte, in an undivided cell equipped with two vitreous carbon electrodes, an exit tube (containing $CaCl_2$) for venting purposes, and a magnetic stirring bar. The carbon electrodes (0.3 cm in diameter, immersed 3.5 cm into the solution) were spaced 1.0 cm apart. The potentiostat was a homemade apparatus. I_0 is the current intensity at the beginning of the anodic oxidation.

*Preparation of **12** by anodic methoxylation*

Into the electrolysis cell were placed **11** (313 mg), Et_4NOTs (80 mg), and 15 mL of methanol. The solution was stirred for 10 min and a constant potential of 8.00 V was applied. After 8 F/mol of electricity was passed (15.5 h, I_0 = 17.1 mA), some drops of NH_4OH were added to the solution and the solvent was evaporated; the residue was dissolved in water (70 mL), basified with NH_4OH, and extracted with $CHCl_3$ (2 × 70 mL). The combined $CHCl_3$ layers were evaporated and the residue was filtered ($CHCl_3$) through a short column of alumina to afford quantitatively the 6-methoxylated derivative **12** (oil, 343 mg); ^1H nmr δ: 7.3 (5H, m), 5.80 (1H, dd, H8), 5.40 (1H, m, H6), 4.28 (1H, m, H2), 3.72 (3H, s, NCO_2CH_3), 3.28 (3H, br, C6-OCH_3), 2.08 (3H, s), 2.4–1.4 (8H, m); ^{13}C nmr δ: 170.3, 156.7, 82.5 (C6), 73.9 (C8), 55.4 (C6-OCH_3), 52.6, 47.9 (C2), 40.0 (C7), 30.5 (C5), 27.5 (C3), 21.2 ($OCOCH_3$), 13.7 (C4); ms, *m/z*: 303 ($M^{+\cdot} - CH_3OH$, 4%), 275 (12), 260 (2), 243 (5), 214 (11), 172 (54), 140 (58), 71 (100).

*Preparation of **13** by anodic methoxylation*

Ketone **6** (82 mg) and Et_4NOTs (45 mg) in 15 mL of methanol were electrolyzed as described above to afford, after 8F/mol of electricity was passed (8.5 h, I_0 = 11.0 mA), the 6-methoxylated derivative **13** (oil, 88 mg, 96% yield), ^1H nmr δ: 8.1–7.3 (5H), 5.44 (1H, m, H6), 4.84 (1H, m, H2), 3.73 (3H, m, NCO_2CH_3), 3.34 (3H, m, C6-OCH_3); ^{13}C nmr δ: 198.7 (C8), 156.8, 137.2, 133.1, 128.6, 82.6 (C6), 55.5 (C6-OCH_3), 52.7, 47.4 (C2), 42.0 (C7), 30.1 and 27.6 (C3 and C5), 13.6 (C4); ms, *m/z*: 259 ($M^{+\cdot} - CH_3OH$, 17%), 172 (21), 154 (60), 140 (43), 105 (52), 77 (28), 75 (16), 71 (100).

*Anodic methoxylation of **14***

The bicyclic compound **14** (296 mg) and Et_4NOTs (150 mg) in 15 mL of methanol were electrolyzed as described above. After 7 F/mol of electricity was passed (9.5 h, I_0 = 28.1 mA) the mixture was treated in the usual way. Fractionation of the residue by chromatography on alumina ($CHCl_3$) afforded four fractions. The first fraction contained the pure 2-methoxylated derivative **15** (or **16**) (oil, 59 mg); ^1H nmr δ: 7.35 (5H, m), 5.11 (1H, dd, J = 2 and 12 Hz, H8), 4.12 (1H, m, H6e), 3.15 (3H, s, OCH_3), 2.93 (1H, dt, J = 3 and 13 Hz, H6a), 2.48 (1H, dd, J = 12 and 14 Hz, H7a), 1.96 (1H, dd, J = 2 and 14 Hz, H7e); ms, *m/z*: 261 (2%), 260 (4), 230 (56), 216 (19), 186 (100), 105 (76), 104 (55), 82 (69), 77 (48), 71 (51), 55 (58). The second fraction (85 mg) was a mixture of the same 2-methoxylated derivative **15** (or **16**) and the 6-methoxylated derivative **17** (1:3 by ^1H nmr); ms *m/z*: 261. **17**: ^1H nmr δ: 7.35 (m), 5.70 (m, H6), 5.18 (dd, J = 2 and 12 Hz, H8), 3.36 (s, OCH_3). The third fraction (34 mg) was a mixture of **17** and the other 2-methoxylated derivative **16** (or **15**) (1:1 by ^1H nmr). The last fraction contained the pure 2-methoxylated derivative **16** (or **15**) (oil, 71 mg): ^1H nmr δ: 7.35 (5H, m), 5.35 (1H, dd, J = 2 and 12 Hz, H8), 4.28 (1H, m, H6e), 3.31 (3H, s, OCH_3), 3.09 (1H, dt, J = 3 and 13 Hz, H6a), 2.45 (1H, dd, J = 2 and 15 Hz, H7e), 1.94 (1H, dd, J = 12 and 15 Hz, H7a); ms, *m/z*: 261 (4%), 260 (2), 230 (73), 186 (100), 105 (30), 104 (75), 82 (63), 77 (29), 55 (48).

*Nucleophilic displacement of the methoxy group of **12***

To a stirred solution of $TiCl_4$ (638 mg) in dichloromethane (10 mL) at −78°C, under an atmosphere of nitrogen, was added dropwise a solution of **12** (1012 mg) in the same solvent (10 mL). After the mixture was stirred for 5 min, a solution of 2-trimethylsilyloxypropene (21) (770 mg), contaminated by ca. 25% of $(CH_3)_3SiOSi(CH_3)_3$) in dichloromethane (10 mL), was added dropwise. The resulting reaction mixture was stirred for 2 h at −78°C and then allowed to reach room temperature (2 h). Cold water (100 mL) was then added and the solution was stirred for 10 min. After basification with NH_4OH, the mixture was extracted with $CHCl_3$ (3 × 100 mL). The combined organic layers were evaporated and the residue was fractionated by chromatography on alumina ($CHCl_3$) to afford **18** (oil, 766 mg, 70% yield) and the enecarbamate **19** (oil, 90 mg, 10% yield). **18**: ^1H nmr δ: 7.3 (5H, m), 5.77 (1H, dd, J = 4 and 10 Hz, H8), 4.67 (1H, m, H6), 4.30 (1H, m, H2), 3.69 (3H, s), 2.65 (2H, m, H9 and H9′), 2.16 and 2.10 (2 × 3H), 2.07–1.5 (8H, m); ^{13}C nmr δ: 206.5, 170.3, 156.2, 140.6, 128.6, 128.1, 126.5, 73.7 (C8), 52.6, 48.4 (C9), 47.5 and 46.4 (C2 and C6), 41.3 (C7), 30.0 (C11), 28.0 and 27.3 (C3 and C5), 21.2,

13.9 (C4); ms, *m/z*: 361 (<0.5%), 318 (0.5), 301 (15), 242 (10), 212 (4), 198 (19), 154 (10), 140 (100), 85 (11), 83 (18), 75 (6), 43 (16). **19**: ^{1}H nmr δ: 7.29 (5H, m), 6.72 (1H, m, H6), 5.84 (1H, dd, J = 4 and 9 Hz, H8), 4.88 (1H, m, H5), 4.38 (1H, m, H2), 3.75 (3H, s), 2.06 (3H, s), 2.26–1.55 (6H, m); ^{13}C nmr δ: 170.4, 153.8, 140.9, 128.7, 128.2, 126.7, 124.0 (C6), 105.9 (C5), 73.4 (C8), 53.0, 47.7 (C2), 37.7 (C7), 24.2 (C3), 21.3, 17.7 (C4); ms, *m/z*: 303 (8%), 260 (2), 243 (11), 186 (4), 184 (8), 142 (16), 141 (38), 140 (100), 139 (81), 138 (90), 124 (15), 43 (28).

*Preparation of **21** from **18***

A solution of **18** (117 mg), ethylene glycol (128 mg), and $TsOH \cdot H_2O$ (3 mg) in 20 mL of benzene was heated under reflux for 20 h in a Dean–Stark apparatus. After evaporation of the solvent, the residue was dissolved in water (20 mL), basified with NH_4OH, and extracted with chloroform ((2 × 20 mL). The combined organic layers were evaporated and the residue was filtered through a short column of alumina ($CHCl_3$) to yield quantitatively **21** (oil, 131 mg) after evaporation: ^{1}H nmr δ: 7.3 (5H), 5.76 (1H, dd, J = 4 and 10 Hz, H8), 4.4 and 4.3 (2H, m, H6 and H2), 3.92 (4H, m, OCH_2CH_2O), 3.70 (3H, s), 2.09 (3H, s), 1.37 (3H, s), 2.1–1.4 (10H, m); ^{13}C nmr δ: 170.3, 156.1, 140.8, 128.0, 126.5, 109.4 (C10), 73.8 (C8), 64.6 and 64.1 (OCH_2CH_2O), 52.4 (NCO_2CH_3), 47.6 and 47.1 (C2 and C6), 43.1 and 41.3 (C7 and C9), 28.3 and 27.4 (C3 and C5), 23.8 (C11), 21.1 (CH_3COO), 14.0 (C4); ms, *m/z*: 405 (0.5%), 345 (3), 242 (12), 154 (3), 143 (4), 140 (100), 87 (55), 43 (24).

*Preparation of **22** from **21***

To a solution of **21** (125 mg) in THF (15 mL) was added $LiAlH_4$ (117 mg). The mixture was then heated under reflux for 17 h. Some drops of AcOEt and then water were added and the mixture was filtered through Celite and evaporated to dryness. The residue was dissolved in 0.2 N aqueous HCl (30 mL) and extracted with $CHCl_3$ (3 × 7 mL). The organic phases were discarded and the aqueous phase was basified with NH_4OH and extracted with chloroform (2 × 30 mL). Evaporation of the chloroform afforded **22** (oil, 81 mg, 82% yield): ^{1}H nmr δ: 7.25 (5H, m), 4.94 (1H, dd, J = 3 and 11 Hz, H8), 3.92 (4H, m), 3.24–3.04 (2H, m, H2 and H6), 2.26 (3H, s, NCH_3), 1.36 (3H, s), 1.99–1.30 (10H, m); ^{13}C nmr δ: 145.3, 128.2, 126.9, 125.6, 109.5 (C10), 76.1 (C8), 64.9 (C6), 64.6 and 64.3 (OCH_2CH_2O), 59.1 (C2), 43.0 (C9), 40.7 (C7), 26.2 (NCH_3), 24.1 (C11), 25.3, 24.0, and 23.2 (C3, C4, C5); ms, *m/z*: 319 (7%), 276 (8), 218 (47), 198 (100), 98 (17), 96 (34), 87 (50), 43 (21).

*Hydrolysis of the acetal **22***

A solution of the acetal **22** (93 mg) in 0.12 N aqueous HCl (20 mL) was heated under reflux for 30 min. The mixture was then cooled, basified with NH_4OH, and extracted with $CHCl_3$ (2 × 30 mL). Evaporation of the combined organic layers afforded a mixture (77 mg) of sedinone **23** and 6-episedinone **24** (9:1 by ^{1}H nmr).

*Preparation of (−)sedinone **23** from (−)-norsedamine **9***

K_2CO_3 (600 mg) and methylchloroformate (0.4 mL) were successively added to a stirred solution of (−)-norsedamine **9** (401 mg) in water (30 mL). After 4 h, NH_4OH was added and the solution was extracted with $CHCl_3$ (2 × 30 mL). The combined organic layers were evaporated and the residue was filtered through a short column of alumina ($CHCl_3$) to afford quantitatively (−)-**7** (oil, 512 mg) after evaporation of the solvent; acetylation of the alcohol (−)-**7**, as described for racemic **7**, yielded (−)-**11** (oil), $[\alpha]_D$ −98° (*c* 1.7, MeOH), Anodic methoxylation of (−)-**11** afforded (−)-**12** (oil), $[\alpha]_D$ −96° (*c* 1.9, MeOH).

Starting from (−)-**12**, the sequence described for the racemic compound (nucleophilic displacement, acetalization, $LiAlH_4$ reduction, and hydrolysis) afforded a 90:10 mixture (by ^{1}H nmr) of (−)-sedinone **23** (^{1}H nmr, NCH_3 δ: 2.26) and 6-episedinone **24** (^{1}H nmr, NCH_3 δ: 2.33); 184 mg of the above mixture was dissolved in ether (25 mL) and treated with gaseous HCl. Crystallization of the precipitate from 2-butanone afforded (−)-sedinone hydrochloride (138 mg), mp 175–177°C; $[\alpha]_D$ −79° (*c* 2, MeOH) (lit. (22) mp 175°C; $[\alpha]_D$ −79.4° (*c* 1, MeOH)). The mass and ^{1}H nmr spectra of the free base were identical with those reported in the literature (7, 22).

*Preparation of the enecarbamate **19** from **12***

A mixture of **12** (655 mg) and $TsOH \cdot H_2O$ (68 mg) in benzene (50 mL) was stirred for 30 min at room temperature. The solvent was then evaporated and the residue was filtered through a short column of alumina ($CHCl_3$) to afford, after evaporation, the enecarbamate **19** (oil, 570 mg, 96% yield). The spectra of **19** are described above.

*Bromomethoxylation of the enecarbamate **19***

To a mixture of **19** (101 mg) and sodium (8.4 mg) in anhydrous methanol (8 mL) was added dropwise a solution of bromine (68 mg) in anhydrous methanol (7 mL). The mixture was then stirred for 15 min at room temperature. After evaporation of the solvent, the residue was dissolved in dilute NH_4OH (70 mL) and extracted with $CHCl_3$ (2 × 70 mL). The combined organic layers were evaporated and the residue was filtered through a short column of alumina ($CHCl_3$) to yield quantitatively the bromo derivative **25** (oil, 139 mg): ^{1}H nmr δ: 7.3 (5H, m), 5.75 (1H, dd, H8), 5.5 (1H, m, H6), 4.35 (2H, m, H2 and H5), 3.7 (3H, s, $NCOOCH_3$), 3.4 and 3.3 (3H, 2s, C6-OCH_3), 2.1 (3H, s), 2.6–1.4 (6H, m); ms, *m/z*: 383 (18%), 381 (18), 323 (17), 321 (17), 220 (77), 219 (100), 218 (>100), 217 (95), 216 (63), 204 (26), 202 (26), 140 (65), 94 (57), 43 (69).

*Iodomethoxylation of the enecarbamate **19***

To the enecarbamate **19** (288 mg) and sodium (24.2 mg) in anhydrous methanol (10 mL) was added dropwise a solution of iodine (271 mg) in anhydrous methanol (10 mL). After stirring for 1 h, the mixture was treated as described above to afford the 5-iodo derivative **26** (oil, 374 mg, 85% yield): ^{1}H nmr δ: 7.32 (5H, m), 5.79 (1H, dd, J = 5 and 9 Hz, H8), 5.64 and 5.48 (1H, 2m, H6), 4.5–4.2 (2H, m, H2 and H5), 3.76 (3H, s, $NCOOCH_3$), 3.34 (3H, m, C6-OCH_3), 2.09 (3H, s), 2.4–1.6 (6H, m); ms, *m/z*: 430 (2%), 401 (22), 302 (8), 274 (19), 266 (21), 261 (24), 242 (25), 197 (75), 170 (40), 140 (83), 138 (51), 43 (78).

*Dehydroiodation of **26***

(a) A mixture of **26** (154 mg) and DBU (161 mg) in anhydrous toluene (0.5 mL) was heated at 87°C for 4 h. After cooling, pyridine (1 mL) and acetic anhydride (1 mL) were added and the solution was allowed to stand for 16 h at room temperature. Water and NH_4OH were then added and the mixture was extracted with chloroform (2 × 50 mL). The combined $CHCl_3$ layers were evaporated and the residue was filtered through a short column of alumina ($CHCl_3$). Evaporation of the solvent afforded **27** (oil, 103 mg, 93% yield): ^{1}H nmr δ: 7.30 (5H, m), 5.90–5.73 (3H, H4, H5, and H8), 5.47 (1H, m, H6), 4.40 (1H, m, H2), 3.73 (3H, m), 3.40 (3H, m, C6-OCH_3), 2.05 (3H, s), 2.5–1.7 (4H, m); ^{13}C nmr δ: 170.1, 156.5, 140.4, 128.4, 128.0, 126.9, 125.8 and 124.8 (C4 and C5), 80.0 (C6), 73.9 (C8), 56.4 (C6-OCH_3), 52.8, 44.9 (C2), 39.8 (C7), 28.2 (C3), 21.2; ms, *m/z*: 333 (<0.5%), 302 (3), 273 (8), 242 (5), 241 (5), 170 (18), 138 (100), 94 (25), 43 (16).

(b) The iodo derivative **26** (687 mg) in anhydrous toluene (1.5 mL) was treated with DBU (717 mg). After 4 h at 87°C, fractionation of the mixture by chromatography on alumina ($CHCl_3$) afforded the acetyl derivative **27** (oil, 213 mg, 43% yield) and the alcohol **28** (oil, 99 mg, 23% yield): ^{1}H nmr δ: 7.3 (5H), 5.80 (2H, m, H4 and H5), 5.16 (1H, m, H6), 4.77 (1H, dd, J = 3 and 12 Hz, H8), 4.46 (1H, m, H2), 3.82 (3H, m, $NCOOCH_3$), 3.60 (3H, m, C6-OCH_3), 2.5–1.6 (4H, m); ms, *m/z*: 291 (<0.5%), 259 (13), 170 (13), 153 (21), 139 (89), 138 (100), 94 (30).

*Nucleophilic displacement of the methoxy group of **27***

To a stirred solution of $TiCl_4$ (54 mg) in dichloromethane (5 mL) at −78°C, under an atmosphere of nitrogen, was added dropwise a solution of **27** (85 mg) in dichloromethane (5 mL). After the mixture was stirred for 5 min, a solution of 2-trimethylsilyloxypropene (65 mg, contaminated by ca. 25% of $(CH_3)_3SiOSi(CH_3)_3$) in dichloromethane (5 mL), was added dropwise. The solution was stirred for 2 h at −78°C and then allowed to reach room temperature (2 h). Cold water (40 mL) was added and the mixture was stirred for 10 min, basified with NH_4OH, and extracted with $CHCl_3$ (3 × 40 mL). After evaporation of the solvent, chromatography on alumina ($CHCl_3$) of the residue yielded **29** (oil, 59 mg, 64% yield): ^{1}H nmr δ: 7.33 (5H), 5.9–5.7 (3H, m, H4,

H5, and H8), 4.8–4.2 (2H, m, H2 and H6), 3.70 and 3.69 (3H, 2s, $NCOOCH_3$), 2.9–2.6 (2H, m, H9 and H9′), 2.17 and 2.16, 2.11 and 2.09 (2 × 3H, 4s), 2.5–1.8 (4H, m); ms, *m/z*: 302 (7%), 299 (39), 242 (12), 195 (75), 194 (99), 152 (39), 140 (47), 138 (100), 94 (58), 43 (92).

*Preparation of the acetal **30***

A solution of **29** (57 mg), ethylene glycol (62 mg), and $TsOH \cdot H_2O$ (1.5 mg) in benzene was heated under reflux for 16 h in a Dean–Stark apparatus. The solvent was then evaporated and the residue was dissolved in water, basified with NH_4OH, and extracted with $CHCl_3$ (2 × 40 mL) to yield quantitatively the acetal **30** (oil, 64 mg): ^1H nmr δ: 7.3 (5H), 5.98–5.65 (H3, H4, H5, and H8), 4.51 (2H, m, H2 and H6), 3.94 (4H, m), 3.70 (3H, m, $NCOOCH_3$), 2.08 (3H, m, CH_3COO), 1.42 (3H, m), 2.3–1.6 (6H, m); ms, *m/z*: 403 (<0.5%), 344 (3), 343 (2), 302 (7), 242 (7), 194 (9), 140 (39), 138 (100), 87 (91), 43 (43).

*Reduction of **30** with $LiAlH_4$*

To a solution of the acetal **30** (63 mg) in THF (15 mL) was added $LiAlH_4$ (58 mg); the mixture was refluxed for 16 h. Some drops of AcOEt and water were added and the mixture was filtered through Celite and evaporated to dryness. The residue was dissolved in 0.2 N aqueous HCl (50 mL) and extracted with $CHCl_3$ (2 × 3 mL). The aqueous phase was then basified with NH_4OH and extracted with $CHCl_3$ (3 × 50 mL). Evaporation of the combined $CHCl_3$ phases afforded **31** (oil, 43 mg, 86% yield): ^1H nmr δ: 7.3 (5H, m), 5.78–5.56 (2H, m, H4 and H5), 4.95 (1H, dd, J = 2 and 11 Hz, H8), 3.96 (4H, m, OCH_2CH_2O), 3.83 (1H, m, H6), 3.43 (1H, m, H2), 2.21 (3H, s, NCH_3), 1.38 (3H, s), 2.5–1.35 (6H, m); ms, *m/z*: 317 (5%), 216 (72), 196 (28), 98 (71), 96 (81), 94 (100), 87 (93).

*Hydrolysis of the acetal **31***

A solution of the acetal **31** (38 mg) in 0.1 N aqueous HCl (20 mL) was heated under reflux for 30 min. After cooling, NH_4OH was added and the mixture was extracted with $CHCl_3$ (2 × 30 mL) to afford a 9:1 mixture (by ^1H nmr) of 6-episedacrine **32** and sedacrine **33** (32 mg). The mixture was then dissolved in methanol (15 mL) and left at room temperature for 16 h. Evaporation of the solvent yielded a 1:6 mixture (by ^1H nmr) of **32** and **33** (32 mg).

*Synthesis of (−)-sedacrine **33***

Starting from (−)-**12**, the sequence described above afforded a 1:6 mixture of 6-episedacrine **32** and (−)-sedacrine **33**. This mixture was dissolved in 2-butanone and a solution of perchloric acid in acetone was added until neutralization. The solvent was evaporated and fractional crystallizations of the residue from 2-butanone yielded pure (−)-sedacrine perchlorate, mp 168–169°C; $[\alpha]_D$ −114° (*c* 1.7, MeOH) (lit. (7) mp 169°C; $[\alpha]_D$ −115° (*c* 2, MeOH)). The nmr and mass spectra of the free base are identical with those reported in the literature (7, 22).

Structure of the O-antigen of *Actinobacillus pleuropneumoniae* serotype 12 lipopolysaccharide[1]

LINDA M. BEYNON, MALCOLM B. PERRY,[2] AND JAMES C. RICHARDS
Division of Biological Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received July 18, 1990

LINDA M. BEYNON, MALCOLM B. PERRY, and JAMES C. RICHARDS. Can. J. Chem. **69**, 218 (1991).

The structure of the O-antigen of *Actinobacillus pleuropneumoniae* serotype 12 was determined by 1D and 2D NMR spectroscopic methods, methylation analysis, and partial hydrolytic degradation. The O-polysaccharide was shown to consist of a trisaccharide repeating unit having the structure

$$\begin{array}{l}\rightarrow 5)\text{-}\beta\text{-D-Gal}f\text{-}(1\rightarrow 6)\text{-}\beta\text{-D-Gal}f\text{-}(1\rightarrow \\ \quad\quad\quad\

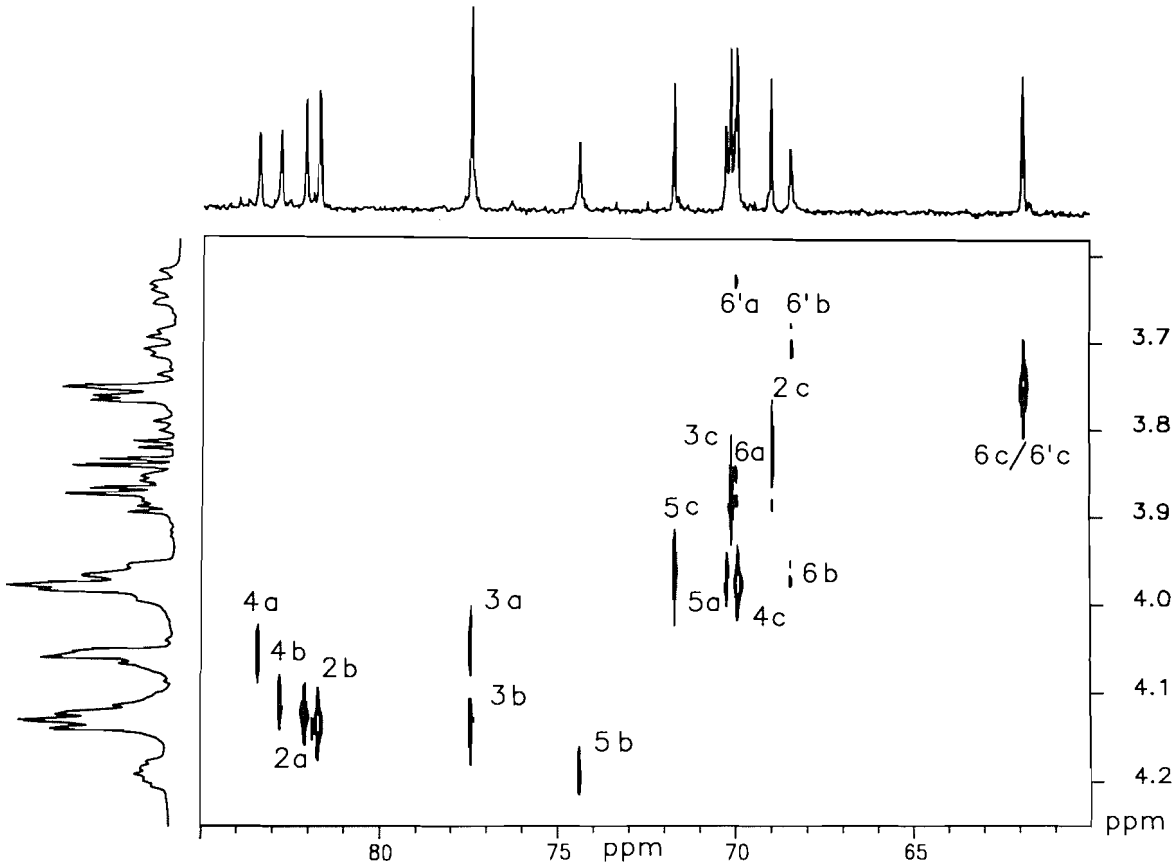

FIG. 1. Heteronuclear $^{13}C-^{1}H$ chemical shift correlation map, for the spectral regions F_2 (85–60 ppm) and F_1 (4.30–3.58 ppm), of the *A. pleuropneumoniae* serotype 12 LPS O-polysaccharide. The respective ^{13}C and ^{1}H 1D projections are displayed along the F_2 and F_1 axes, respectively, and the correlated resonances are labelled.

TABLE 1. Methylation analyses data for *A. pleuropneumoniae* serotype 12 O-antigen and degradation products

Methylated sugar[a] (as alditol acetates)	T_{MG}[d]	Molar ratios[b,c]			
		I	II	III	IV
1,2,3,4,5-Gal	0.7		0.3	0.4	0.5
2,3,5,6-Gal	0.9				0.2
2,3,4,6-Gal	1.0	1.0	1.0	1.0	1.0
2,3,5-Gal	1.4	0.6		0.5	
2,3-Gal	1.7	0.9			

[a]2,3,4,6-Gal represents 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methylgalactitol, etc.

[b]I, O-polysaccharide; II, α-D-Gal$_p$-(1 → 6)-D-Gal-ol; III, α-D-Gal$_p$-(1 → 6)-β-D-Gal$_f$-(1 → 6)-D-Gal-ol; IV, reduced disaccharide fraction.

[c]Uncorrected, fid response.

[d]Retention times relative to that of 1,5-di-*O*-acetyl-2,3,4,6-tetra-*O*-methylgalactitol.

the three sugars in the repeating unit were 6-linked. A third methylene resonance at 61.9 ppm could be attributed to the primary hydroxyl carbon of the galacto*pyranosyl* residue (16).

Methylation and hydrolysis of the O-chain afforded a product that, after reduction ($NaBH_4$) and acetylation, gave GLC–MS results (Table 1) that indicated the polysaccharide to be composed of branched trisaccharide repeating units in which the D-galactopyranosyl residues were present as the non-reducing end groups. Thus, the combined analytical results indicated that the trisaccharide repeating unit consists of a terminal α-D-galactopyranosyl, a 6-*O*-substituted β-D-galactofuranosyl, and a 5,6-di-*O*-substituted β-D-galactofuranosyl residue.

NMR studies of the O-polysaccharide

The structure of the trisaccharide repeating unit was determined by a combination of 1D and 2D NMR methods. A complete assignment of the ^{1}H NMR spectrum was achieved via COSY and relay COSY, followed by subsequent assignment of the ^{13}C resonances from a 2D $^{13}C-^{1}H$ chemical shift correlation experiment (Fig. 1). The three galactosyl residues were labelled **a**, **b**, and **c** according to the order of decreasing anomeric ^{1}H chemical shifts. The resonances corresponding to the terminal α-D-galactopyranosyl residue (residue **c**) were well resolved and the corresponding sub-spectrum was readily identified on the basis of the observed proton coupling constants (Table 2).

Identification of the sub-spectra corresponding to the two β-D-galactofuranosyl residues **a** and **b** was more difficult. The resonances associated with these residues were not well resolved and strong coupling between H-3**a** and H-4**a**, and between H-2**b**, H-3**b**, and H-4**b**, precluded measurement of the related vicinal coupling constants. Fortunately, the H-6 and H-6′ resonances for **a** and **b** could be easily identified, from connectivities to the corresponding methylene carbon (C-6) resonances in the $^{13}C-^{1}H$ chemical shift correlation map (Fig. 1), which permitted additional points of entry into the respective ^{1}H spin-systems. In this way, the resonance associated with H-5**b** (4.19 ppm) was easily assigned from the corresponding cross-peaks to H-6**b** (3.98 ppm) and H-6′**b** (3.70 ppm). In the COSY contour plot, cross-peaks relating the H-4**b**/H-5**b**,

H-5	3.97	4.19	3.97
H-6 ($J_{5,6}$)	3.87 (3.4)	3.98 (5.5)	3.76 (—)
H-6′ ($J_{5,6'}$)	3.63 (7.2)	3.70 (3.6)	3.76 (—)
($J_{6,6'}$)	(10.8)	(10.8)	(—)

[a]Measured at 27°C in ppm from internal acetone (δ 2.225).
[b]First-order coupling constants measured in hertz (Hz).
[c]Unresolved coupling.

H-5**b**/H-6**b**, and H-5**b**/H-6′**b** proton pairs were apparent along a line at the chemical shift value of H-5**b** (4.19 ppm) (Fig. 2). Similarly, it was possible to identify H-4**a** (4.05 ppm), H-5**a** (3.97 ppm), H-6**a** (3.87 ppm), and H-6′**a** (3.63 ppm) from the related cross-peaks in the COSY spectrum. That the resonances of H-2**b** (4.14 ppm) and H-3**b** (4.13 ppm) overlapped was obvious from the relay COSY spectrum, which showed only a single cross-peak relating H-1**b** and both H-2**b** and H-3**b**. The overlapping of the ring proton resonances in β-D-galactofuranosyl residues has been observed previously (17).

The apparent deshielding (17) of resonances corresponding to H-5 and H-6 for residue **b** and H-6 for residue **a** (Table 2) is diagnostic of glycosidation at the respective C-5 and C-6 positions.

The ^{13}C NMR spectrum of the O-polysaccharide contained 17 discrete signals, which were assigned via 2D heteronuclear ^{13}C–^{1}H chemical shift correlation (Fig. 1) and by reference to published data (12, 13, 16) (Table 3). The low-field positions for C-4 and C-2 (81–83 ppm) of residues **a** and **b** are characteristic of galactofuranose residues (12, 13) and, since the chemical shifts of C-1**c** → C-6**c** correlate closely with those published (16) for methyl α-D-galactopyranoside, **c** was identified as a non-reducing terminal sugar.

The arrangement of the three galactose residues within the repeating unit was determined from ^{1}H–^{1}H nOe measurements and selective INEPT experiments.

Saturation of each of the three anomeric protons showed *intra*-residue nOe to the H-2 resonances within the respective ring systems. In addition, significant *inter*-residue effects between H-1**a** and H-5**b**, between H-1**b** and the H-6**a**/H-6′**a** pair, and between H-1**c** and the H-6**b**/H-6′**b** pair indicate the arrangement of the residues within the polysaccharide to be

$$\rightarrow \mathbf{a} \rightarrow \mathbf{b} \rightarrow \mathbf{a} \rightarrow$$
$$\uparrow$$
$$\mathbf{c}$$

Confirmation of this sequence was obtained from selective INEPT experiments. Due to the inherent flexibility of the furanose ring systems (18) within the polymer, it was possible to employ this technique (19) to establish connectivities between the anomeric protons and the aglyconic carbons of adjacent residues. A truncated version of the selective INEPT pulse sequence was employed without broad-band proton decoupling (20), and the ^{13}C NMR spectra obtained from pulsing the

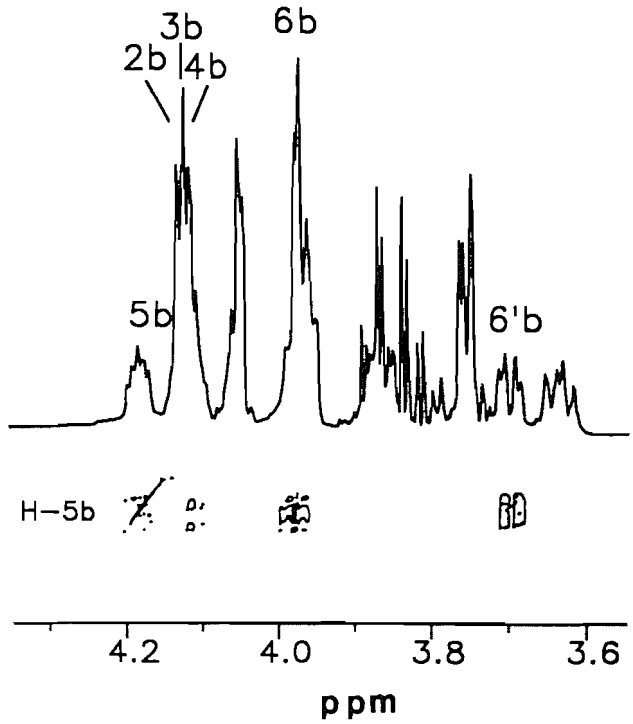

FIG. 2. Cross-peaks relating the H-4, H-5, H-6, and H-6′ resonances belonging to the residue **b** sub-spectrum in the COSY contour plot of the serotype 12 O-polysaccharide at the H5**b** chemical shift value. Resonance assignments associated with residue **b** are indicated in the 1D projection.

anomeric proton resonances of each of the three galactosyl residues are shown in Fig. 3.

The intensity of the ^{13}C signals in the selective INEPT spectra is a function of the efficiency of polarization transfer through a $^3J_{H,C}$ coupling pathway and is conformationally dependent (21). The spectra obtained from pulsing the anomeric protons of the β-D-galactofuranosyl residues (Figs. 3a and 3b) showed intense doublets for C-4 arising from the efficient transfer of polarization within the furanosyl ring systems via H-1 → C-1 → O-4 → C-4, whereas polarization transfer to C-3 via H-1 → C-1 → C-2 → C-3 was absent (Fig. 3a) or very weak (Fig. 3b). Polarization transfer across the respective glycosidic linkages from H-1**a** to C-5**b** (d, 74.4 ppm, Fig. 3a), and from H-1**b** to

For personal use only.

C-6**a** (t, 70.0 ppm, Fig. 3b) confirmed the sequence of the galactofuranosyl disaccharide backbone unit, → **a** → **b** →. Verification that the terminal α-D-galactopyranosyl residues **c** are 1,6-linked to the galactofuranosyl residues **b** was obtained from pulsing H-1**c** where the selective INEPT experiment (Fig. 3c) showed the connectivity to the methylene carbon triplet from C-6**b** (68.5 ppm) together with proton-coupled signals from C-3**c** (70.2 ppm) and C-5**c** (71.8 ppm) of the α-D-pyranoside.

In the spectrum obtained by pulsing H-1**b** (Fig. 3b), a ^{13}C doublet was observed (70.2 ppm) overlapping the C-6**a** triplet (70.0 ppm). This doublet could only be assigned to C-3**c**, and most likely arises from partial saturation of H-1**c** due to the proximity of the H-1**b** and H-1**c** resonances (ca. 25 Hz separation). Correspondingly, in the spectrum obtained by pulsing H-1**c** (Fig. 3c), the signal from C-4**b** (82.8 ppm) could be attributed to partial saturation of H-1**b**.

Depolymerization of the O-polysaccharide

Depolymerization of the polysaccharide with 48% aqueous hydrogen fluoride for 24 h (4°C), followed by fractionation of the product on Bio-Gel P2, afforded a disaccharide **1** (K_{av} 0.84) which had $[\alpha]_D$ +91.7 (*c* 0.8, water) and showed a single spot on TLC (R_f 0.20). The ^1H NMR spectrum of reduced **1** contained a single doublet ($J_{1,2}$ 3.3 Hz), for the anomeric proton at 4.98 ppm, indicating the presence of an α-linked residue. The ^{13}C NMR spectrum was consistent with the disaccharide alditol possessing a terminal α-D-galactopyranosyl residue (Table 3). GLC–EI–MS of reduced methylated **1** gave a single peak (T_{MS} 1.28) with fragment ions at *inter alia* *m/z* 219, 235, 249, and 133 (Fig. 4). Methylation analysis of reduced **1** gave 2,3,4,6-tetra-*O*-methylgalactitol and 1,2,3,4,5-penta-*O*-methylgalactitol (Table 1). These results permit **1** to be assigned the structure

α-D-Gal$_p$-(1 → 6)-D-Gal
1

In a second experiment depolymerization of the polysaccharide with 48% aqueous hydrogen fluoride for 6 h (0°C), followed by fractionation of the product on Bio-Gel P2, afforded a trisaccharide **2** (K_{av} 0.68) and a disaccharide fraction (K_{av} 0.81). The trisaccharide **2** showed predominantly one spot on TLC analysis (R_f 0.12). The ^1H NMR spectrum of reduced **2** contained two signals, for the anomeric protons, at 5.06 ($J_{1,2}$ 1.7 Hz) and 4.97 ppm ($J_{1,2}$ 2.0 Hz). The presence of two signals at 99.5 and 108.6 ppm (Table 3) in the ^{13}C NMR spectrum indicated that **2** contained both α-D-galactopyranose and β-D-galactofuranose residues. GLC–EI-MS analysis of reduced, methylated **2** gave a major peak (T_{MS} 5.30) with fragment ions at *m/z* 219, 393, 235, and 423 (Fig. 5) as well as a minor peak (7.5%, T_{MS} 1.25) that had a mass spectrum identical to that of reduced methylated **1**. Methylation analysis of the reduced sample gave 1,2,3,4,5-penta-*O*-methylgalactitol, 2,3,4,6-tetra-*O*-methylgalactitol, and 2,3,5-tri-*O*-methylgalactitol (Table 1), which allowed **2** to be assigned the structure

α-D-Gal$_p$-(1 → 6)-β-D-Gal$_f$-(1 → 6)-D-Gal
2

TLC analysis of the disaccharide fraction showed it to be a mixture of two oligosaccharides (R_f 0.17 and 0.29). GLC–EI-MS analysis of the reduced methylated fraction gave two peaks (T_{MS} 1.28 and 1.31, respectively) in the ratios of 1.0:0.28, each having a mass spectrum nearly identical to that of reduced methylated **1** (*m/z* 219, 187, 155, and 235). However, the fragment ion at *m/z* 88 in the mass spectrum of the minor component was of only low intensity (10%), suggesting that this disaccharide contained a non-reducing terminal galacto-

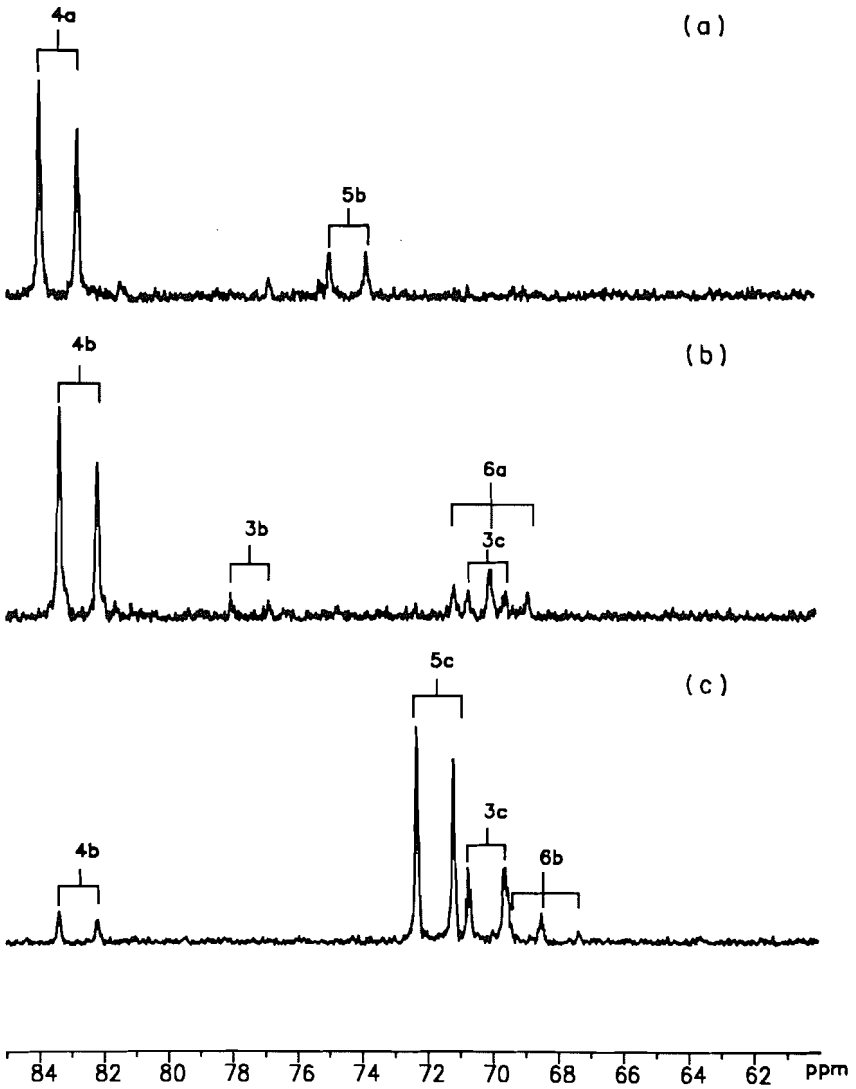

FIG. 3. Proton-coupled selective INEPT ^{13}C NMR spectra obtained from pulsing the H-1 resonances of (a) residue **a**; (b) residue **b**; and (c) residue **c**. Assignments are indicated.

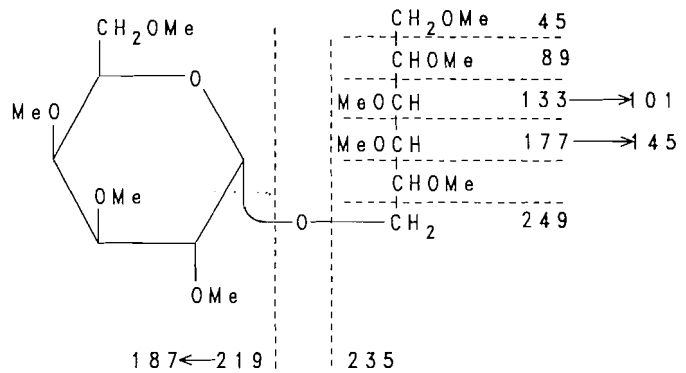

FIG. 4. GLC–EI-MS fragmentation ions from reduced methylated **1**.

furanosyl residue (22). The methylation analysis (Table 1) was in agreement with the major component of the disaccharide fraction having the same structure as **1** and the minor component having a non-reducing terminal galactofuranosyl residue. The lack of a second reducing residue, other than 1,2,3,4,5-penta-*O*-methylgalactitol, suggested that the minor component had the structure

$$\text{Gal}_f\text{-}(1 \rightarrow 6)\text{-Gal}$$

3

and arose from cleavage of the O-polysaccharide at the terminal galactopyranosidic and the 1,5-galactofuranosidic linkages.

Thus, the combined NMR spectroscopic and chemical evidence permits the branched trisaccharide repeating unit of the O-chain polysaccharide of *A. pleuropneumoniae* serotype 12 to be identified as

$$\begin{array}{l}\rightarrow 5)\text{-}\beta\text{-D-Gal}_f\text{-}(1\rightarrow 6)\text{-}\beta\text{-D-Gal}_f\text{-}(1\rightarrow \\ \qquad\qquad\quad 6 \\ \qquad\qquad\quad | \\ \qquad\qquad\quad \alpha\text{-D-Gal}p\end{array}$$

4

A number of other bacteria have been reported (20, 23–28) to possess LPS O-antigen polysaccharides that are composed solely of D-galactose residues. It is noteworthy, in this context, that the galactose content of the LPS from a virulent strain of *A. pleuropneumoniae* serotype 5 is 13 times that of an avirulent strain (28). The serotype 5 LPS O-polysaccharide consists of a homopolymer of 1,6-linked β-D-galactopyranosyl residues (23).

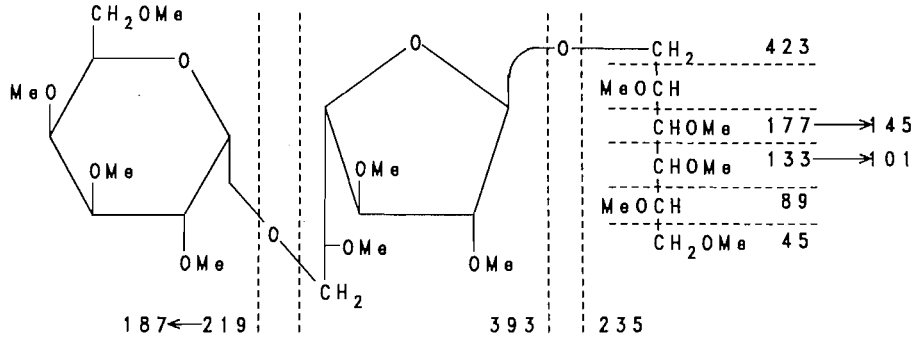

FIG. 5. GLC–EI-MS fragmentation ions from reduced methylated **2**.

Experimental

Production of lipopolysaccharide and O-polysaccharide

Actinobacillus pleuropneumoniae (NRCC 4267) serotype 12 was grown in Bacto PPLO broth (yield 260 g, wet weight) and LPS was isolated by the aqueous-phenol extraction procedure (9). A solution of LPS (0.35 g) in aqueous 1% acetic acid (100 mL) was kept at 100°C for 1.5 h, and the O-polysaccharide recovered by gel filtration on Sephadex G-50 and DEAE–Sephacel as previously described (29).

Analytical methods

Analytical methods were essentially as previously described (30). The following conditions were employed using a Hewlett–Packard 5885B GLC–MS system fitted with a flame ionization detector and an OV-17 fused silica capillary column (Quadrex Corp.): *A* (for alditol acetates), 180°C for 2 min then 4°C/min to 240°C; *B* (for partially methylated alditol acetates), 180°C for 2 min than 2°C/min to 240°C; *C* (for (*R*)-2-butyl acetate derivatives), 180°C for 4 min then 2°C/min to 240°C; *D* (for methylated disaccharide alditols), 220°C for 1 min then 7°C/min to 280°C; *E* (for methylated trisaccharide alditols), 240°C for 1 min then 10°C/min to 280°C. For methylated oligosaccharide alditols, retention times are quoted relative to that of methylated sucrose (T_{MS}).

Methylation of samples (2 mg) was carried out using the methods of either Hakomori (31) or Ciucanu and Kerek (32) and the products were isolated by partition between dichloromethane and water. Methylated oligosaccharide alditols were analysed directly by GLC–MS (programs *D* and *E*), followed by hydrolysis and conversion of the partially methylated glycoses to their alditol acetates, as previously described (33), and analysis by GLC–MS.

TLC was performed on silica gel (Merck) with 6:3:1 (v/v) propanol – conc. NH_3 – water. Sodium dodecyl sulphate (SDS)– PAGE was made under the same conditions as previously recorded (10).

NMR spectroscopy

Measurements were made at 27°C, on solutions in D_2O, using a Bruker AM-500 spectrometer equipped with an Aspect 3000 computer, operating in the pulsed Fourier transform mode with quadrature detection using standard Bruker software.

Proton NMR spectra (500 MHz) were recorded using a spectral width of 1.9 kHz, a 16 K data block, and a 90° pulse width. Chemical shifts are expressed relative to internal acetone (δ, 2.225 ppm). The nOe difference spectra were obtained by using a selective low-power presaturation pulse applied to the proton resonance for 200 ms, in which each line of a multiple resonance was irradiated sequentially for 20 ms, followed by a 90° observation pulse (34).

Broad-band proton-decoupled ^{13}C NMR spectra (125 MHz) were obtained using a spectral width of 31 kHz, a 32 K data block, and a 90° pulse width employing WALTZ decoupling (35). Heteronuclear $^1J_{C,H}$ values were measured using gated decoupling (36) and DEPT spectra (37) were obtained with broad-band proton decoupling, a 135° proton pulse width, and a 3.3 ms delay between pulses.

Homonuclear 2D COSY and relayed coherence transfer experiments were carried out employing conventional pulse sequences (38–40). Spectra were measured using data sets ($t_1 \times t_2$) of 512 × 2048 points for a spectral width of 1319 Hz, with a recycle delay of 1.2 s, and 32 transients were collected for each value of the incrementable delay (t_1). The data were zero-filled to give 1024 × 2048 points and, following resolution enhancement in both dimensions by unshifted sine-bell-window functions, the data were processed to give magnitude spectra with symmetrization.

The 2D ^{13}C–^1H chemical shift correlated spectrum was recorded with proton decoupling in the F_2 domain (41). The initial data matrix ($t_1 \times t_2$) of 128 × 4096 points was zero-filled and Fourier transformed to give a final matrix of 512 × 4096 points. Spectral widths of 7575 and 552 Hz for the respective ^{13}C (F_2) and ^1H (F_1) chemical shift domains and a recycle delay of 1.4 s were employed. Fixed delays τ_1 and τ_2 were set at 3.30 and 1.70 ms, respectively, to select for all multiplicities. Resolution enhancement was applied in both dimensions by means of a Lorentz-to-Gauss transformation and the data were processed to give a power spectrum.

Selective INEPT experiments were carried out without broad-band proton decoupling as described previously (20).

Depolymerization of the O-polysaccharide

O-Polysaccharide (20 mg), dissolved in 48% (w/v) aqueous hydrofluoric acid (1 mL), was kept at 4°C for 24 h. The reaction was quenched by pouring the mixture into a slurry of solid CO_2 – calcium carbonate – dichloromethane (42). The mixture was allowed to warm to room temperature and, after the addition of water, the precipitate and dichloromethane were removed by centrifugation. Disaccharide **1** (yield 6.3 mg), obtained by Bio-Gel P2 gel permeation chromatography, was reduced ($NaBH_4$, 20°C, 3 h). A sample (2 mg) of reduced **1** was methylated (32), analysed by GLC–MS, hydrolysed (4 M TFA, 1 h, 125°C), and the partially methylated glycoses converted to their alditol acetates.

O-Polysaccharide (24 mg) was treated with 48% (w/v) aqueous hydrofluoric acid (1 mL) for 6 h at 0°C and the product worked up as above. The products **2** (yield 2.8 mg) and a disaccharide fraction (yield 3.3 mg) were reduced and methylated (31), analysed by GLC–MS, hydrolysed (4 M TFA, 45 min, 125°C), and the partially methylated glycoses converted to their alditol acetates.

General methods

Concentrations were made under reduced pressure at <40°C. Optical rotations were measured at 20°C in 10-cm microtubes, using a Perkin Elmer 243 polarimeter.

Acknowledgments

We thank Dr. S. Lariviere, University of Montreal, Saint Hyacinthe, for the bacterial culture, Mr. F. P. Cooper for the GLC–MS analyses, and Mr. D. W. Griffith for the large-scale production of bacterial cells.

1,*n*-Radical ions. Photosensitized (electron transfer) carbon–carbon bond cleavage. Formation of 1,6-radical cations[1]

DONALD R. ARNOLD,[2] LAURIE J. LAMONT, AND ALLYSON L. PERROTT
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

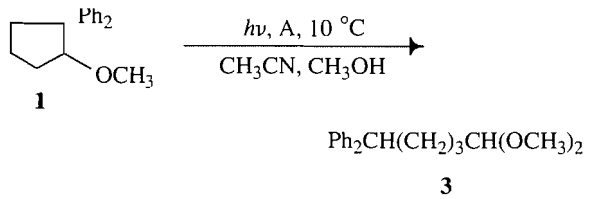
Received July 13, 1990

DONALD R. ARNOLD, LAURIE J. LAMONT, and ALLYSON L. PERROTT. Can. J. Chem. **69**, 225 (1991).

The reactivity of the radical cations of methyl 2,2-diphenylcyclohexyl ether (**7**), 6,6-diphenyl-1,4-dioxaspiro[4.5]decane (**8**), methyl *cis*- and *trans*-2-phenylcyclohexyl ether (**9***cis* and *trans*), and 6-phenyl-1,4-dioxaspiro[4.5]decane (**10**), generated by photosensitized (electron transfer) irradiation, has been studied. Solutions of the ethers and acetals in acetonitrile–methanol (3:1), with 1,4-dicyanobenzene (**2**) serving as the electron acceptor, were irradiated with a medium-pressure mercury vapour lamp through Pyrex. The diphenyl derivatives **7** and **8** were reactive; **7** gave 6,6-diphenylhexanal dimethyl acetal (**11**) and **8** gave 2-methoxy-2-(5,5-diphenylpentyl)-1,3-dioxolane (**12**). These are the products expected from the intermediate 1,6-radical cation, formed upon carbon–carbon bond cleavage of the cyclic radical cation. The monophenyl derivatives **9***cis* and *trans* and **10** were stable under these irradiation conditions. The mechanism for the carbon–carbon bond cleavage and for the *cis–trans* isomerization is discussed. An explanation, based upon conformation, is offered for the lack of reactivity of **9** and **10**. Molecular mechanics (MM2) calculations were used to determine the preferred conformation of **9***cis* and *trans*, and **10**.

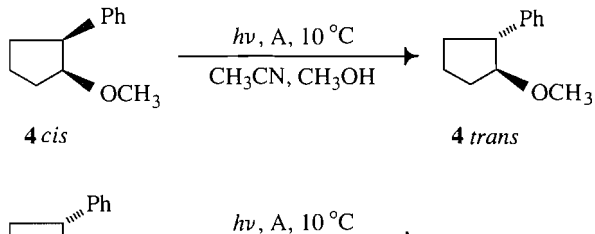
Key words: photosensitization, electron transfer, radical cation, carbon–carbon bond cleavage, conformation.

DONALD R. ARNOLD, LAURIE J. LAMONT et ALLYSON L. PERROTT. Can. J. Chem. **69**, 225 (1991).



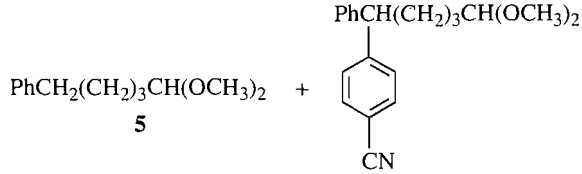
On a étudié la réactivité des cations radicalaires du méthoxy-2,2,-diphénylcyclohexane (**7**), du 6,6-diphényl-1,4-dioxaspiro[4,5]décane (**8**), des *cis*- et *trans*-méthoxy-2-phénylcyclohexane (**9***cis* et *trans*) et du 6-phényl-1,4-dioxaspiro[4,5]décane (**10**) générés par une irradiation photosensibilisée (transfert d'électron). Utilisant une lampe à vapeur de mercure de pression moyenne opérant à travers du Pyrex, on a irradié les éthers et les acétals en solution dans un mélange d'acétonitrile–méthanol (3:1), en présence de 1,4-dicyanobenzène (**2**) servant comme accepteur d'électrons. Les dérivés diphénylés **7** et **8** sont réactifs; **7** conduit à l'acétal diméthylique du 6,6-diphénylhexanal (**11**) alors que **8** fournit le 2-méthoxy-2-(5,5-diphénylpentyl])-1,3-dioxolane (**12**). Ce sont les produits que l'on peut attendre à partir de l'intermédiaire du cation radicalaire-1,6, formé par clivage de la liaison carbone–carbone du cation radicalaire cyclique. Les dérivés monophénylés **9***cis* et *trans* et **10** sont stables dans ces conditions d'irradiation. On discute du mécanisme de clivage de la liaison carbone–carbone ainsi que de l'isomérisation *cis–trans*. On offre une explication, basée sur la conformation, pour le manque de réactivité des dérivés **9** et **10**. On a utilisé des calculs de mécanique moléculaire (MM2) pour déterminer les conformations privilégiées des produits **9***cis* et *trans* et **10**.

Mots clés : photosensibilisation, transfert d'électron, cation radicalaire, clivage d'une liaison carbone–carbone, conformation.
[Traduit par la rédaction]



Introduction

Photosensitized (electron transfer) carbon–carbon bond cleavage of five-membered cyclic compounds generates 1,5-radical cations (**2**). When the irradiation is carried out in the presence of a nucleophile, often the solvent, further reaction of these intermediates proceeds by nucleophilic attack on the cationic site, and reduction of the radical site by electron transfer from the radical anion of the photosensitizer, followed by protonation of the resulting anion (**2**). A typical example is shown in reaction [1]: irradiation of an acetonitrile–methanol (3:1) solution of methyl 2,2-diphenylcyclopentyl ether (**1**) and 1,4-dicyanobenzene (**2**) (an electron-accepting photosensitizer) gives the dimethyl acetal of 5,5-diphenylpentanal (**3**) in good yield (>60%) (*2a*).



The monophenyl analogue (**4**) behaves similarly (*2b*). In this case, irradiation of the *cis* isomer (**4***cis*) under identical conditions leads to relatively efficient isomerization to a mixture of the *cis* and *trans* isomers. Continued irradiation leads to formation of the expected cleavage product (**5**) and the product (**6**) resulting from attack of the intermediate radical at the *ipso* position of the 1,4-dicyanobenzene radical anion (reaction [2]) (*2b*).[3] It was not clear from this initial report which isomer (*cis*

[3]Substitution products such as **6** are expected when the reduction potential of the intermediate radical is greater (more negative) than the reduction potential of the photosensitizer (1,4-dicyanobenene, −1.66 V (sce)) (*2b*, 3). Under these conditions, addition of the radical to the radical anion competes with electron transfer.

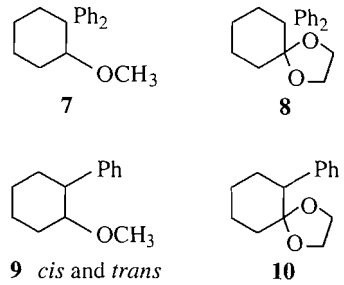
SCHEME 1. The mechanism for the photosensitized (electron transfer) carbon–carbon bond cleavage and deprotonation.

or *trans*) was involved in the carbon–carbon bond cleavage reaction, or whether both isomers were participating in this reaction.



The *cis–trans* isomerization was explained by a mechanism involving deprotonation of the radical cation (**4***cis*$^{+\cdot}$), followed by reduction of the radical by the radical anion of the photosensitizer and reprotonation of the resulting anion. Support for this mechanism came from the observation that deuterium was incorporated at the benzylic position of **4***cis* and *trans* when the irradiation of **4** *cis* was carried out in acetonitrile–methanol-d_4.

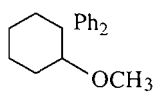
The proposed mechanism for the carbon–carbon bond cleavage and for the *cis–trans* isomerization is shown in Scheme 1 (2*b*).

The main objective of this programme is to identify the factors that need to be considered in order to be able to predict whether a particular radical cation will undergo the carbon–carbon bond cleavage reaction. There are few, if any, reports of reactions involving the intermediate formation of 1,6-radical cations.[4] If these intermediates could be formed generally and predictably, reactions involving their formation could have significant synthetic utility. We have extended our investigation to cyclic systems containing six-membered rings in the hope of generating 1,6-radical cations. The compounds chosen for study were similar to those that have been shown to react in the five-membered ring series: methyl 2,2-diphenylcyclohexyl ether (**7**), 6,6-diphenyl-1,4-dioxaspiro[4.5]decane (**8**), methyl *cis*- and *trans*-2-phenylcyclohexyl ether (**9***cis* and *trans*), and 6-phenyl-1,4-dioxaspiro[4.5]decane (**10**) (Chart 1).

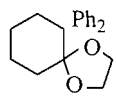
The irradiation conditions used in this study were the same as those used previously (2). It is reasonable to expect that the first three steps in the proposed mechanism (Scheme 1, steps 1–3) will proceed as well with these six-membered ring compounds

[4]Griffin and co-workers have reported the formation of a 1,6-radical cation (4). Irradiation of racemic 9,10-dimethoxy-9,10-dimethyl-9,10-dihydrophenanthrene and 1,4-dicyanonaphthalene (an electron-accepting photosensitizer) in acetonitrile solution results in isomerization of the dihydrophenanthrene to a mixture of the diastereomers. The 1,6-radical cation (cleavage of the 9,10 bond of the radical cation of the dihydrophenanthrene) was proposed as an intermediate; however, in this case both the radical and carbocation centres are conjugatively coupled through the π-system. The mechanism may be different.

7 **8**



9 *cis* and *trans* **10**



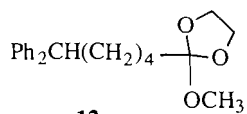


CHART 1

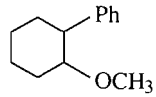

as with those that have a five-membered ring. Two important limitations for step 4 in the proposed mechanism have been identified: (1) Both the nascent fragments, the carbocation and the radical, must be relatively stable, that is, the bond dissociation energy of the radical cation cannot be greater than ca. 55 kJ mol^{-1} or cleavage will not occur (3). (2) A favoured conformation of the radical cation must allow overlap of the singly occupied molecular orbital (SOMO) and the incipient radical or carbocation (2*a*). There was no reason to doubt that all of the compounds chosen for study would satisfy these criteria and carbon–carbon bond cleavage was anticipated. Therefore, it was a surprise to find that **9***cis* and *trans*, and **10**, were stable to irradiation under these conditions. Clearly, additional criteria are required in order to be able to make reliable predictions regarding reactivity in this reaction. As is true for all attempts to define the scope and limitations of any reaction, examples of molecules that do not react are just as informative as examples of those that do.

Results

Solutions of the ether or acetal and photosensitizer, 1,4-dicyanobenzene (**2**), in acetonitrile–methanol (3:1) were degassed and irradiated through a Pyrex filter using a medium-pressure mercury vapour lamp. The results of the irradiations are summarized in Table 1 and in reactions [3]–[6] below. The struc-

[b]No products due to carbon–carbon bond cleavage were observed.
[c]Irradiation at 80°C. No volatile products were detected by gc/ms.

TABLE 2. Summary of the oxidation potential measurements

Compound	E_p(V)[a]	$E_p - E_{p/2}$(mV)
Methyl *trans*-2-phenylcyclopentyl ether (**4***trans*)	2.05	160
Methyl *cis*-2-phenylcyclopentyl ether (**4***cis*)	2.05	120
Methyl 2,2-diphenylcyclohexyl ether (**7**)	2.16	200
6,6-Diphenyl-1,4-dioxaspiro[4.5]decane (**8**)	2.14	210
Methyl *trans*-2-phenylcyclohexyl ether (**9***trans*)	2.25	230
6-Phenyl-1,4-dioxaspiro[4.5]decane (**10**)	2.11	200

[a]The estimated error is ±0.03 V. The oxidation potential ($E_{1/2}^{ox}$) can be taken as 0.03 V less than the anodic peak potential (ref. 19).

tures assigned to the products (**11** and **12**) from reactions [3] and [4] rest firmly on an analysis of the ^1H and ^{13}C nmr spectra.

Deuterium incorporation studies were carried out on the *cis* and *trans* isomers of methyl 2-phenylcyclohexyl ether (**9**), and on 6-phenyl-1,4-dioxaspiro[4.5]decane (**10**). These compounds were irradiated under the usual conditions, except that the solvent was acetonitrile–methanol-d_4 (3:1). Analyses of the photolysate by capillary column gas chromatography with a mass selective detector (gc/ms), using selected ion monitoring, showed that less than 1% of one deuterium had been incorporated in the recovered starting material.

The reactivity of methyl *cis*- and *trans*-2-phenylcyclopentyl ether (**4***cis* and *trans*) was reinvestigated in greater detail. Irradiation of methyl *trans*-2-phenylcyclopentyl ether (**4***trans*) under the usual conditions showed that this isomer undergoes carbon–carbon bond cleavage; the acetal (**5**) and the substitution product (**6**) were detected. There was no evidence for isomerization of **4***trans* to **4***cis*. In marked contrast, no cleavage products were observed during the initial phase of the irradiation of the *cis* isomer; instead, **4***cis* was isomerized to **4***trans*.

The oxidation potentials of the ethers and acetals were measured by cyclic voltammetry (Table 2). All of the anodic waves were typical of irreversible oxidation.

The calculated structures of the *cis* and *trans* isomers of methyl 2-phenylcyclopentyl ether (**4***cis* and *trans*), of methyl 2-phenylcyclohexyl ether (**9***cis* and *trans*), and of 6-phenyl-1,4-dioxaspiro[4.5]decane (**10**) were optimized with the 1987 force field of the MM2 program (5). The dihedral driver option of the program was used to rotate first the methoxy group and then the phenyl group; several energy minima were identified for each compound. The calculated lowest-energy conformers, the global minima, are shown in Figs. 1–5.

Discussion

Based upon the known reactivity of several similar acyclic and five-membered cyclic analogues, it was reasonable a priori to predict that all of the compounds studied (Chart 1) would cleave under these photosensitized (electron transfer) conditions. Therefore, the observed reactivity of **7** and **8** (reactions [3] and [4]) is unexceptional.[5] The cleavage products **11** and **12** were formed in good yield. The proposed mechanism (Scheme 1, steps 1–7), involving the formation of a 1,6-radical cation intermediate in both cases, accounts for these results. The complete lack of reactivity of both **9***cis* and *trans* and **10**, even at the higher temperature (80°C), is surprising and the existing mechanistic criteria do not provide a satisfactory explanation.

There is sufficient evidence to suggest that the first three steps in the proposed mechanism (Scheme 1, steps 1–3) will occur with all of the compounds studied. The free-energy change (ΔG) for the initial electron transfer step (Scheme 1, step 2), calculated using the Weller equation, is exergonic by at least 38 kJ mol^{-1} in every case and the rate should be diffusion controlled (7). Step 3, deactivation by back-electron transfer from the radical anion of the electron acceptor to the radical cation, is the main competing process in every case. There is no reason to expect that this step will be exceptionally rapid in the reactions involving **9** and **10**. The obstacle to reaction must lie within step 4, the crucial carbon–carbon bond cleavage of the radical cation.

The factors that are known to inhibit step 4 of the proposed

[5]There was no evidence for cyclization of the intermediate 1,6-radical cation into the terminal phenyl group in either reaction. This cyclization has been observed only in the case of the 1,4-radical cation where the process 6-*endo*-trig may be relatively favoured (6).

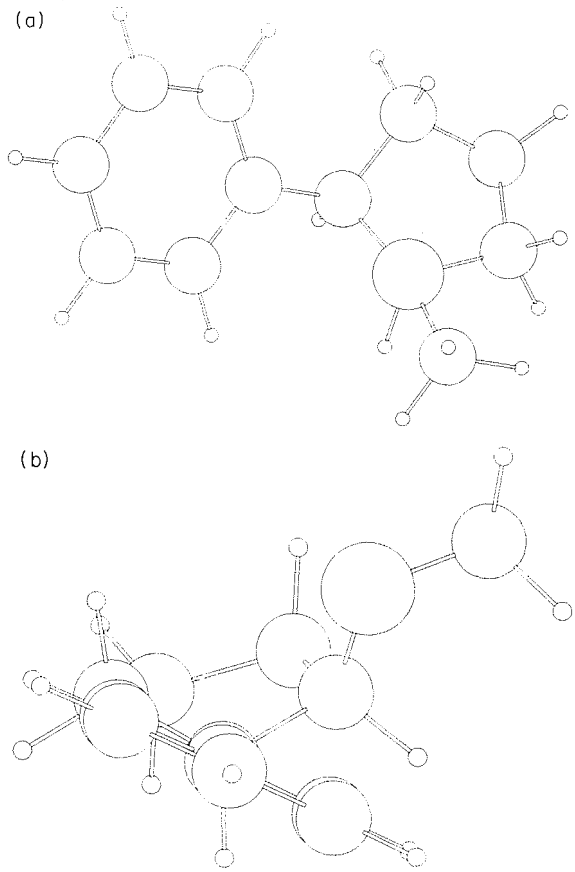

FIG. 1. The global minimum conformer of methyl *cis*-2-phenylcyclopentyl ether (**4***cis*): (a) Looking down the oxygen–carbon bond. The dihedral angle between the benzylic carbon–carbon bond and the oxygen–carbon (methyl) bond is 166°. (b) Viewed along the plane of the phenyl ring. The angle between the plane of the phenyl ring and the benzylic carbon–hydrogen bond is 66°.

mechanism cannot explain the lack of reactivity of $\mathbf{9}^{+\cdot}$ or $\mathbf{10}^{+\cdot}$. The fact that similar 2-phenylalkyl ethers, including **4***trans*, do cleave under these conditions makes it unlikely that the carbon–carbon bond dissociation energy of the radical cation of either **9** or **10** is above the threshold (55 kJ mol^{-1}) for cleavage (2). However, the benzylic carbon–carbon bond dissociation energy for these monophenyl derivatives will be at least 17 kJ mol^{-1} greater than that for the diphenyl derivatives. This is a consequence of the additional delocalization of the bis-benzylic radical relative to the benzylic radical. The bond dissociation energy for the radical cation of the monophenyl derivatives will therefore be closer to the energy threshold and cleavage may demand more stabilization of the incipient carbocation by the methoxy group. The preferred conformation of phenylcyclohexane has the plane of the phenyl ring perpendicular to the cyclohexane (8). This conformation should allow overlap of the SOMO, which is largely associated with the phenyl ring, with the benzylic carbon–carbon bond, sufficient for cleavage to occur. Clearly neither of these considerations can account for the lack of reactivity of **9** or **10**; an additional limitation must be identified.

Perhaps with the monophenyl derivatives, the alkoxy group must provide maximum stabilization of the incipient carbocation fragment for cleavage to occur. One of the nonbonding lone pairs of electrons on the oxygen atom must overlap with the carbon–carbon anti-bonding (σ^*) orbital in order to stabilize the transition state for cleavage. Figure 6b shows the orientation of the alkoxy group, aligned for maximum stabilization, as a Newman projection along the oxygen–carbon bond. Maximum stabilization occurs when the dihedral angle between the nonbonding pair of electrons of the oxygen and the adjacent carbon–carbon anti-bonding (σ^*) orbital is 0°. When this dihedral angle is 90°, stabilization is at a minimum; intermediate dihedral angles provide stabilization as a $\cos^2$ function (9). **Hypothesis**: If a preferred conformation of the ether does not have the alkoxy group oriented in such a way that a lone pair of electrons on the oxygen can overlap with the adjacent carbon–carbon anti-bonding orbital, cleavage may be inhibited.

The fact that neither **9***cis* nor *trans* was isomerized, or incorporated deuterium upon photosensitized (electron transfer) irradiation, must also be explained. For isomerization or deuterium incorporation to occur, the radical cation must deprotonate from the benzylic position (Scheme 1, step 8). It is well established that the acidity of a radical cation is greatly enhanced relative to the neutral molecule (10). However, the conformation of the benzylic carbon–hydrogen bond relative to the SOMO is also important for deprotonation. The SOMO must overlap with the adjacent carbon–hydrogen bond in order for deprotonation to occur (11).

The lowest energy conformer of methyl *cis*-2-phenylcyclohexyl ether (**9***cis*), calculated using the MM2 program, is shown in Fig. 3. The absolute value of the dihedral angle between the methyl group bonded to the oxygen and the carbon–carbon bond to be cleaved was calculated to be 170°. The dihedral angle of the plane of the phenyl group with respect to the benzylic hydrogen was calculated to be 26°. Although the phenyl group is well aligned for carbon–carbon bond cleavage, the orientation of the methyl group on the oxygen prevents interactions of the nonbonding pairs of electrons on oxygen with the carbon–carbon anti-bonding orbital. The search for a conformer with the phenyl and alkoxy groups suitably aligned for cleavage identifies one, but this conformer has a calculated heat of formation that is 24.9 kJ mol^{-1} above that of the global minimum.

The most stable conformation of **9***cis* is also poorly aligned for deprotonation. When the angle between the plane of the phenyl ring and the benzylic carbon–hydrogen bond is 26°, overlap with the SOMO is only 19% effective; deprotonation is inhibited. The conformer next in energy above the global minimum was calculated to have a dihedral angle between the phenyl ring and the benzylic carbon–hydrogen bond of 61°. Deprotonation from this conformer is feasible; however, this structure has a calculated heat of formation that is 7.2 kJ mol^{-1} above that of the global minimum. The equilibrium concentration of this conformer is too small for it to participate in the reactivity of this isomer.

The global minimum structure calculated for methyl *trans*-2-phenylcyclohexyl ether (**9***trans*) (Fig. 4) is similarly consistent with the observed lack of reactivity toward both carbon–carbon bond cleavage and deprotonation. The most stable conformer with both the phenyl and alkoxy groups favourably aligned for carbon–carbon bond cleavage is 8.1 kJ mol^{-1} above the global minimum, and the lowest energy conformer that could conceivably deprotonate is 18.0 kJ mol^{-1} less favourable.

The structure of the lowest energy conformer of methyl *cis*-2-phenylcyclopentyl ether (**4***cis*) is shown in Fig. 1. The orientation of the methoxy group prevents interaction of the nonbonding electrons on oxygen with the carbon–carbon anti-bonding orbital, inhibiting carbon–carbon bond cleavage of the radical cation. However, the preferred orientation of the

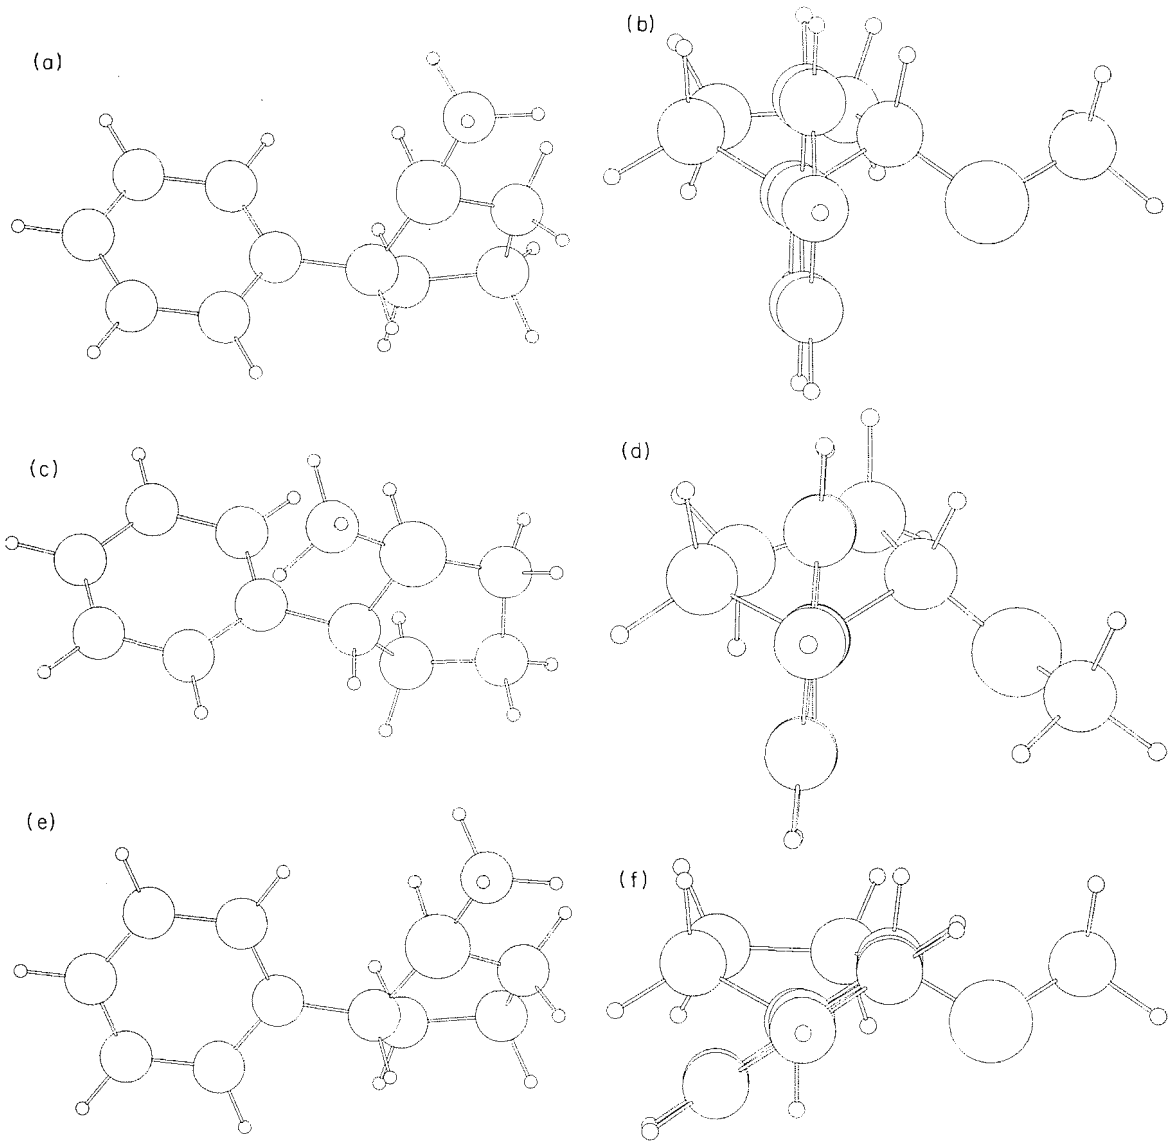

FIG. 2. The low-energy conformers of methyl *trans*-2-phenylcyclopentyl ether (**4***trans*): (a) The global minimum conformer ($\Delta H_f = -93.35$ kJ mol^{-1}). Looking down the oxygen–carbon bond. The dihedral angle between the benzylic carbon–carbon bond and the oxygen–carbon (methyl) bond is 173°. (b) The global minimum conformer. Viewed along the plane of the phenyl ring. The angle between the plane of the phenyl ring and the benzylic carbon–hydrogen bond is 0°. (c) The reactive conformer ($\Delta H_f = -93.14$ kJ mol^{-1}). Looking down the oxygen–carbon bond. The dihedral angle between the benzylic carbon–carbon bond and the oxygen–carbon (methyl) bond is 65° (the optimum angle is 60°). (d) The reactive conformer. Viewed along the plane of the phenyl ring. The angle between the plane of the phenyl ring and the benzylic carbon–hydrogen bond is 5°. (e) An unreactive conformer ($\Delta H_f = -93.14$ kJ mol^{-1}). Looking down the oxygen–carbon bond. The dihedral angle between the benzylic carbon–carbon bond and the oxygen–carbon (methyl) bond is 173°. (f) The same conformer as pictured in (e). Viewed along the plane of the phenyl ring. The angle between the plane of the phenyl ring and the benzylic carbon–hydrogen bond is 56°.

phenyl group should allow sufficient overlap of the SOMO with the benzylic carbon–hydrogen bond to permit deprotonation and, subsequently, isomerization and deuterium incorporation. The angle between the plane of the phenyl ring and the benzylic carbon–hydrogen bond is 66°. An angle of 66° provides 83% effective overlap for the deprotonation reaction. The lowest energy conformer that could participate in the carbon–carbon bond cleavage was calculated to be 5.8 kJ mol^{-1} above the global minimum.

The structural analysis of the *trans* isomer of methyl 2-phenylcyclopentyl ether (**4***trans*) was more complicated. Instead of one clearly recognizable global minimum, structure optimization revealed three conformers with comparable energy minima (Fig. 2). The "global" minimum does not have a conformation favourable for either reaction. However, there are two other conformers within 0.2 kJ mol^{-1} energy, and in one of these conformers the methyl group is not antiperiplanar to the carbon–carbon bond to be cleaved. The dihedral angle between the benzylic carbon–carbon bond and the oxygen–carbon (methyl) bond is 65°, close to the optimum arrangement (Fig. 6b). The nonbonding pair of electrons on oxygen can provide the stabilization of the incipient carbocation required for the cleavage. Experimentally, the radical cation of this isomer does undergo carbon–carbon bond cleavage.

The calculated lowest energy conformer of 6-phenyl-1,4-dioxaspiro[4.5]decane (**10**) is shown in Fig. 5. The orientation of the phenyl group should allow sufficient overlap of the SOMO with the carbon–carbon bond. However, again in this

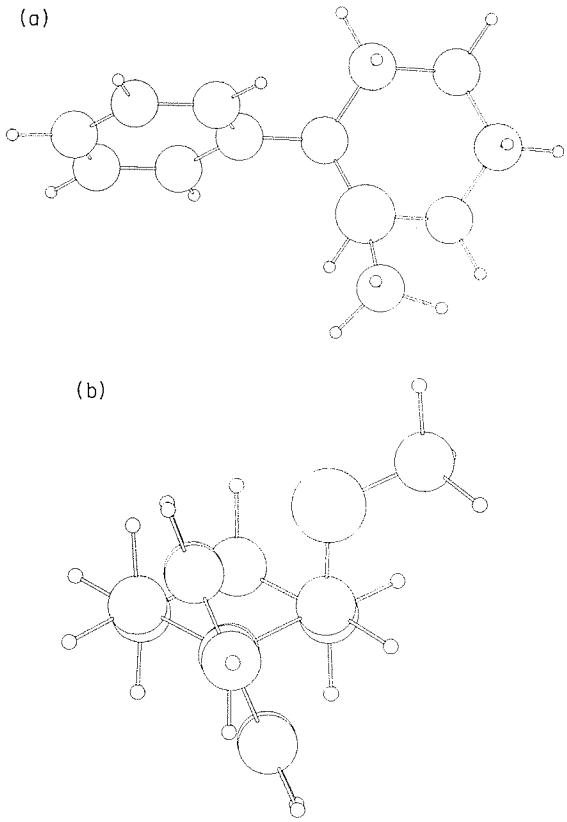

FIG. 3. The global minimum conformer of methyl *cis*-2-phenylcyclohexyl ether (**9***cis*): (a) Looking down the oxygen–carbon bond. The dihedral angle between the benzylic carbon–carbon bond and the oxygen–carbon (methyl) bond is 170°. (b) Viewed along the plane of the phenyl ring. The angle between the plane of the phenyl ring and the benzylic carbon–hydrogen bond is 26°.

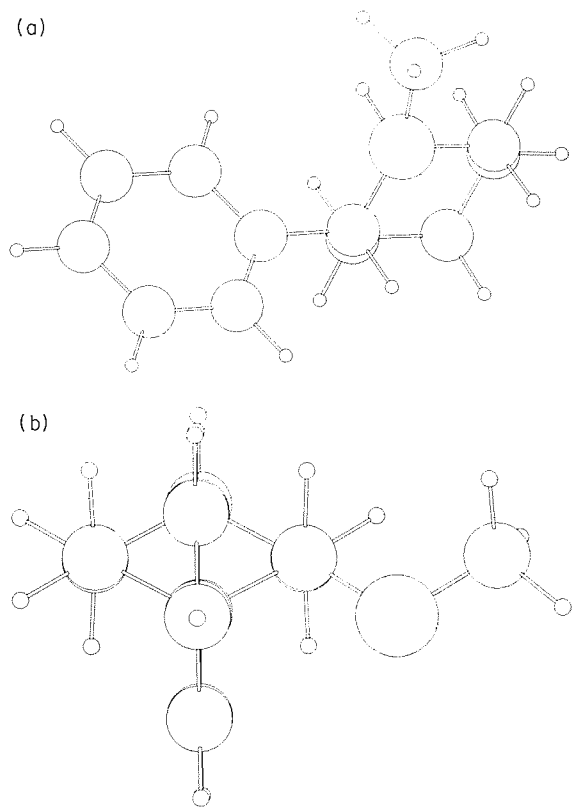

FIG. 4. The global minimum conformer of methyl *trans*-2-phenylcyclohexyl ether (**9***trans*): (a) Looking down the oxygen–carbon bond. The dihedral angle between the benzylic carbon–carbon bond and the oxygen–carbon (methyl) bond is 164°. (b) Viewed along the plane of the phenyl ring. The angle between the plane of the phenyl ring and the benzylic carbon–hydrogen bond is 1°.

case, the dihedral angle between the nonbonding pair of electrons on oxygen and the carbon–carbon σ^* orbital deviates considerably from the optimum and cleavage does not occur.

Conclusions

The reactivity of radical cations, generated by the photosensitized (electron transfer) technique, can be conformationally dependent. Knowledge of the preferred conformation of the neutral molecule, based upon MM2 calculations, has proven to be valuable in explaining the reactivity of radical cations. Not only can the carbon–carbon bond cleavage of the radical cation be predicted, but also the likelihood of deprotonation.

The conformation of the initially formed radical cation must reflect the equilibrium concentration of conformers of the neutral molecules: the electron transfer process (Scheme 1, step 2) is diffusion controlled. The competing deactivation process, back-electron transfer (Scheme 1, step 3), is known to be rapid, 10^7–10^9 s^{-1} (7*b*). The rate of the carbon–carbon bond cleavage and deprotonation (Scheme 1, steps 4 and 8) must be more rapid than back-electron transfer; and the rate of change in conformation, rotation around a carbon–oxygen bond, must be slower than back-electron transfer under these conditions.

In these cyclic ether systems, the carbon–carbon bond dissociation energies of the radical cations are low; the bond cleavage reaction competes with deprotonation. If the alkoxy group were replaced with an alkyl group, the bond dissociation energy would be increased to the point that carbon–carbon bond cleavage will not occur. This leads us to suggest that photosensitization (electron transfer) can be used to isomerize chiral molecules at the saturated centre. This reaction has synthetic utility. It can be used to convert a mixture of diastereomers to a single isomer.

Experimental

General information

The ^1H nmr and ^{13}C nmr spectra were recorded on a Nicolet Magnetics Corporation NB-360 spectrometer. Chemical shifts are reported in parts per million downfield from tetramethylsilane. Infrared spectra were recorded on a Perkin Elmer 180 or a Perkin Elmer 283B spectrometer, as noted. Frequencies are reported in wavenumbers, relative to polystyrene film (1601.8 cm^{-1}). Gas chromatography (gc/ms) was done on a Hewlett Packard 5890A gc equipped with a model 5970 mass selective detector interfaced with a Hewlett Packard 9816 microcomputer. The column used was 25 m × 0.2 mm, 5% phenyl methyl silicone on fused silica with a film thickness of 0.25 μm. Quantitative gas chromatography was done on a Hewlett Packard 5890A equipped with a flame ionization detector (gc/fid). This chromatograph was fitted with a 25 m × 0.25 mm, OV-1701 fused silica column. Melting points were taken on a Thermolyne melting point apparatus and are corrected. Combustion analyses were done by Canadian Microanalytical Service Limited.

Oxidation potentials were obtained by cyclic voltammetry using a three-electrode cell that has been described previously (12). The reference electrode was a saturated calomel electrode (sce). The electrolyte was tetraethylammonium perchlorate (TEAP) (0.1 M) in acetonitrile.

Irradiations were carried out in Pyrex tubes using a Canadian General Electric Co. 1-kW medium-pressure mercury vapour lamp with a

quartz cooling jacket immersed in a constant temperature bath at either 10°C or 80°C, as noted. Samples were degassed by nitrogen ebullition for 5 min prior to irradiation.

Solvents were distilled prior to use. Acetonitrile and 1,4-dicyanobenzene (**2**) (Aldrich Chem. Co.) were purified as described previously (13). Synthesis and purification of the isomers and methyl 2-phenylcyclopentyl ether (**4**) have been described previously (*2b*). 1-Phenylcyclohexene and 2-phenylcyclohexanone were obtained from Aldrich Chem. Co.

The MM2 calculations were carried out on a VAX 8800 mainframe computer. Structures of the methyl 2-phenylcycloalkyl ethers (**9***cis*

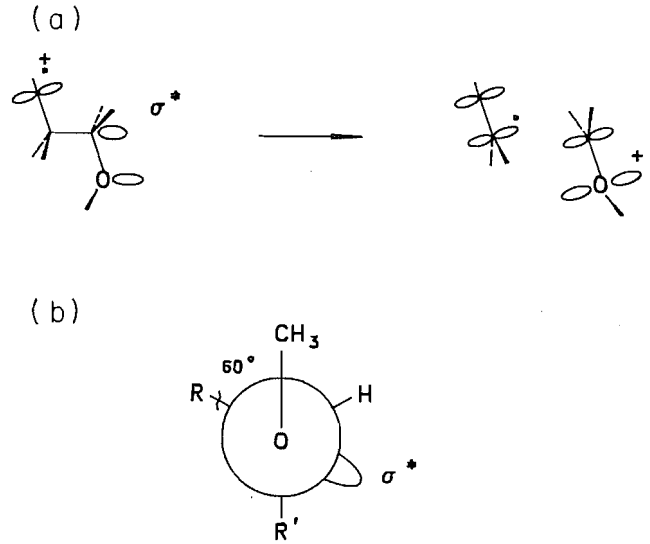

FIG. 6. Carbon–carbon bond cleavage of the radical cation is favoured when the SOMO overlaps with the bonding orbital (σ), and when a non-bonding pair of electrons on the oxygen overlaps with the anti-bonding orbital (σ*). The preferred conformation for carbon–carbon bond cleavage of the radical cation illustrated, (a) with the dashed–wedged line notation, and (b) with the Newman projection.

and *trans* and **4***cis* and *trans*) and **10** were optimized (steric energies were minimized) with the 1987 force field (Quantum Chemistry Program Exchange). For each of the isomers of **4** and **9**, four initial starting conformations were considered. Three conformations of **10** were optimized.

Preparation of compounds

Preparation of methyl 2,2-diphenylcyclohexyl ether (9)

Methyl 2,2-diphenylcyclohexyl ether (**9**) was prepared from 2,2-diphenylcyclohexanone, a known compound (14), by a two-step synthesis. The ketone (3.23 g, 1.29×10^{-2} mol) was reduced, using lithium aluminum hydride (0.35 g, 9.22×10^{-3} mol), to 2,2-diphenylcyclohexanol. The ether was then prepared from this alcohol using NaH (3.0 g, 0.12 mol) and dimethyl sulphate (2.4 mL, 3.2 g, 2.5×10^{-2} mol). The overall yield of **9** for the two steps was 65%; mp 65.6–66.1°C (lit.(15) mp 64–65°C); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.25(m, 10H), 4.04(m, 1H), 3.11(s, 3H), 2.42(m, 2H), 1.91–1.37 (m, 6H).

Preparation of 6,6-diphenyl-1,4-dioxaspiro[4.5]decane (8)

6,6-Diphenyl-1,4-dioxaspiro[4.5]decane (**8**), a new compound, was synthesized from 2,2-diphenylcyclohexanone (1.56 g, 6.25×10^{-3} mol) by a known procedure (16) using chlorotrimethylsilane (5.1 mL) in ethylene glycol (50 mL). The acetal (**8**) was obtained in quantitative yield by flash column chromatography, eluting with 60% methylene chloride and 40% hexanes; mp 113.5–117.1°C; ir (PE 180) KBr: 3020(w), 2960(s), 2920(s), 2880(s), 2860(s), 1590(m), 1490(s), 1440(s), 1340(m), 1270(m), 1260(m), 1210(s), 1180(s), 1150(s), 1130(s), 1080(s), 1070(s), 1020(s), 940(s), 825(m), 740(s), 680(s); ^{1}H nmr (360 MHz) in $CDCl_3$ (−10°C): 7.63(d, 2H), 7.16(m, 8H), 3.82(dd, 1H, J = 6.6 Hz, J = 13.5 Hz), 3.61(dd, 1H, J = 6.6 Hz, J = 12.0 Hz), 3.36(dd, 1H, J = 5.89 Hz, J = 12.0 Hz), 2.74(m, 2H), 2.46(m, 1H, J = 13.5 Hz), 2.29(m, 1H), 1.67(m, 5H); ^{13}C nmr (90 MHz) in $CDCl_3$: 145.2, 130.0, 127 ($W_{1/2}$ = 105 Hz), 125.5, 112.3, 56.7, 65 ($W_{1/2}$ = 260 Hz), 35.1, 34.2, 24.4, 21.4. Anal. calcd. for $C_{20}H_{22}O_2$: C 81.60, H 7.53; found: C 81.74, H 7.71.

Preparation of methyl cis- *and* trans*-2-phenylcyclohexyl ether (9*cis *and* trans*) (17)*

Methyl *cis*- and *trans*-2-phenylcyclohexyl ether (**9**) were prepared by the photosensitized (electron transfer) addition of methanol to 1-phenyl-1-cyclohexene (0.35 g, 2.22×10^{-3} mol) using 1,4-dicyanobenzene (**2**) (0.19 g, 1.48×10^{-3} mol) as an electron-accepting

photosensitizer and acetonitrile–methanol (3:1) as solvent (18). At 90% conversion (23 h irradiation), a mixture of the *cis* and *trans* ethers (70:30, 75% yield) was obtained by column chromatography on silica gel (Kieselgel 60), using methylene chloride and hexanes as eluent. The *cis* and *trans* isomers were separated by preparative gas chromatography. **9***cis*: ^{1}H nmr (360 MHz) in $CDCl_3$: 7.28(m, 5H), 3.50(m, 1H), 3.09(s, 3H), 2.65(m, 1H, J = 12.9 Hz), 2.11(m, 1H, J = 12.9 Hz), 2.03(m, 1H, J = 3.7 Hz), 1.35–1.86(m, 6H); ^{13}C nmr (90 MHz) in $CDCl_3$: 145.0, 128.0, 127.8, 125.8, 79.8(d), 56.9(q), 48.0(d), 29.1(t), 26.3(t), 19.8(t). **9***trans*: ^{1}H nmr (360 Hz) in $CDCl_3$: 7.29(m, 2H), 7.21(m, 3H), 3.26(ddd, 1H, J = 4.05 Hz, J = 10.23 Hz, J = 10.32 Hz), 3.10(s, 3H), 2.51(m, 1H, J = 10.4 Hz, J = 11.95 Hz), 2.24(m, 1H, J = 12.07 Hz), 1.86(m, 2H), 1.74(m, 1H), 1.24–1.49(m, 4H); ^{13}C nmr (90 MHz) in $CDCl_3$: 144.9, 128.2, 127.5, 126.0, 83.2(d), 56.7(q), 51.1(d), 34.5(t), 31.4(t), 26.1(t), 25.0(t).

*Preparation of 6-phenyl-1,4-dioxaspiro[4.5]decane (**10**)*

6-Phenyl-1,4-dioxaspiro[4.5]decane (**10**), a new compound, was prepared from 2-phenylcyclohexanone according to a known procedure (16). The acetal was purified by column chromatography using silica gel (Kieselgel 60) with methylene chloride and hexanes as the eluent. Pure **10** was obtained in 95% yield; ir (PE 283B) neat: 3040(w), 2940(s), 2880(s), 2860(s), 1600(w), 1500(m), 1450(m), 1340(w), 1260(m), 1220(m), 1155(s), 1140(m), 1095(s), 1045(m), 1030(m), 930(s), 760(m), 700(s); ^{1}H nmr (360 MHz) in $CDCl_3$: 7.32(m, 2H), 7.22(m, 3H), 3.68(m, 2H), 3.43(m, 1H), 2.91(m, 1H), 2.80(dd, 1H, J = 13.2 Hz, J = 3.5 Hz), 2.03(m, 1H), 1.83–1.35(m, 7H); ^{13}C nmr (90 MHz) in $CDCl_3$: 141.4(s), 129.5, 127.7, 126.2, 110.2(s), 65.1(t), 64.7(t), 52.1(d), 36.9(t), 30.5(t), 25.7(t), 24.3(t). Anal. calcd. for $C_{14}H_{18}O_2$: C 77.03, H 8.31; found; C 76.96, H 8.28.

Irradiations

Irradiation of methyl cis- *and* trans-*2-phenylcyclopentyl ether (**4**cis and* trans*)*

A solution of **4***trans* and 1,4-dicyanobenzene (**2**) in acetonitrile–methanol (2 mL, 3:1) was irradiated at 10°C. Progress of the reaction was monitored by gc/fid. After 3 h of irradiation, analysis showed that the product, 5-phenylpentanal dimethyl acetal (**5**), was present; no **4***cis* was detected.

A similar solution of the *cis* isomer was irradiated. After 6 h, analysis of the solution showed two products: **4***trans* and 5-phenylpentanal dimethyl acetal (**5**).

*Irradiation of methyl 2,2,-diphenylcyclohexyl ether (**7**)*

A solution of methyl 2,2-diphenylcyclohexyl ether (**7**) (0.22 g, 8.3×10^{-4} mol) and **2** (0.14 g, 1.1×10^{-3} mol) in acetonitrile–methanol (30 mL, 3:1) was irradiated at 10°C for 5 days. The yield of 6,6-diphenylhexanal dimethyl acetal (**11**) was 94% at 87% conversion, ^{1}H nmr (360 MHz) in $CDCl_3$: 7.23(m, 10H), 4.29(t, 1H, J = 5.66 Hz), 3.87(t, 1H, J = 7.78 Hz), 3.26(s, 6H), 2.04(m, 2H), 1.54(m, 2H), 1.23–1.41(m, 4H); ^{13}C nmr (90 MHz) in $CDCl_3$: 145.1, 128.3, 127.8, 126.0, 104.5, 52.6, 51.2, 35.6, 32.3, 27.8, 24.5.

*Irradiation of 6,6-diphenyl-1,4-dioxaspiro[4.5]decane (**8**)*

A solution of **8** (0.21 g, 7.3×10^{-4} mol) and **2** (0.09 g, 7.3×10^{-4} mol) in acetonitrile–methanol (30 mL, 3:1) was irradiated for 14 h. The *ortho* ester **12** was identified in the reaction mixture by ^{1}H nmr; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.24(m, 10H), 4.08(m, 2H), 3.93(m, 2H), 3.88(t, 1H, J = 7.98 Hz), 3.23(s, 3H), 2.04(m, 2H, J = 7.8 Hz, J = 15.6 Hz), 1.75(m, 2H), 1.47(m, 2H), 1.27(m, 2H). The reaction mixture was added to methanol (5% HCl) and refluxed for 1 h. 2,2-Diphenylcyclohexanone (13%) was recovered and methyl 6,6-diphenylhexanoate was isolated in 50% yield; ^{1}H nmr (360 MHz) in $CDCl_3$: 7.23(m, 10H), 3.88(t, 1H, J = 7.8 Hz), 3.62(s, 3H), 2.26(t, 2H, J = 7.57 Hz), 2.05(m, 2H, J = 7.8 Hz), 1.66(m, 2H), 1.28(m, 2H); ^{13}C nmr (90 MHz) in $CDCl_3$: 174.0, 145.0, 128.4, 127.8, 126.1, 51.4, 51.1, 35.3, 33.9, 27.5, 24.9.

*Irradiation of methyl 2-phenylcyclohexyl ether (**9**)*

A solution of **9***cis* (23 mg, 1.2×10^{-4} mol) and **2** (20 mg, 1.6×10^{-4} mol) in acetonitrile–methanol (2 mL, 3:1) was irradiated at 80°C for 40 h. Neither carbon–carbon bond cleavage nor isomerization products were observed (gc/ms).

A solution of **9***trans* (22 mg, 1.2×10^{-4} mol) and **2** (12 mg, 9.3×10^{-5} mol) in acetonitrile–methanol (2 mL, 3:1) was irradiated at 80°C for 40 h. No products were detected (gc/ms).

A solution of **9***cis* (49 mg, 2.6×10^{-4} mol) and **2** (39 mg, 3.0×10^{-4} mol) in acetonitrile–methanol-d_4 (2 mL, 3:1) was irradiated at 10°C for 4 days. The ratio of the m/m + 1 peaks due to the molecular ion of **9***cis* in the gc/ms was the same before and after irradiation. No deuterium incorporation was observed by selected ion monitoring (SIM).

A solution of **9***trans* (20 mg, 1.1×10^{-4} mol) and **2** (10 mg, 7.8×10^{-5} mol) in acetonitrile–methanol-d_4 (2 mL, 3:1) was irradiated at 10°C for 24 h. No incorporation of deuterium was observed (SIM).

*Irradiation of 6-phenyl-1,4-dioxaspiro[4.5]decane (**10**)*

A solution of **10** (87 mg, $3.7 \times 10^{-}$ mol) and **2** (51 mg, 4.0×10^{-4} mol) in acetonitrile–methanol (3:1) was irradiated at 10°C for 3 days. No product resulting from carbon–carbon bond cleavage was detected (gc/ms).

A solution of **10** (41 mg, 1.9×10^{-4} mol) and **2** (34 mg, 2.7×10^{-4} mol) in acetonitrile–methanol (2 mL, 3:1) was irradiated at 80°C for 25 h. No product resulting from carbon–carbon bond cleavage was observed (gc/ms).

A solution of **10** (48 mg, 2.2×10^{-4} mol) and **2** (32 mg, 2.5×10^{-4} mol) in acetonitrile–methanol-d_4 (2 mL, 3:1) was irradiated at 10°C. Progress of the reaction was followed by gc/ms using SIM. After 35 h of irradiation, less than 1% deuterium incorporation had occurred.

Received April 4, 1990

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **69**, 234 (1991).

The condensation of *N,N'*-bis(1-cyano-1-methylethyl)-*N,N'*-dihydroxymethanediamine and mesitylboronic acid gives 4,6-bis(1-cyano-1-methylethyl)-2-mesityl-1,3-dioxa-4,6-diaza-2-boracyclohexane in good yield. Crystals of the latter compound are orthorhombic, a = 15.825(1), b = 17.958(1), c = 14.014(1) Å, Z = 8, space group *Pbca*. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.037 and R_w = 0.051 for 2844 reflections with $I \geq 3\sigma(I)$. The molecule has a six-membered cycloboronate structure featuring the first structurally characterized BONCNO ring. The ring was found to have a *C*-envelope conformation in the solid state. Bond lengths include: O—B(sp^2) = 1.356(2) and 1.370(2), and C(aryl)—B = 1.560(2) Å.

Key words: organoboron compound, boron compound, crystal structure.

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **69**, 234 (1991).

La condensation de la *N,N'*-bis(1-cyano-1-méthyléthyl)-*N,N'*-dihydroxyméthanediamine et de l'acide mésitylboronique fournit le 4,6-bis(1-cyano-1-méthyléthyl)-2-mésityl-1,3-dioxa-4,6-diaza-2-boracyclohexane avec un bon rendement. Les cristaux de ce dernier composé sont orthorhombiques, groupe d'espace *Pbca*, avec a = 15,825(1), b = 17,958(1) et c = 14,014(1) Å et Z = 8. On a résolu la structure par des méthodes directes et on l'a affinée par là méthode des moindres carrés (matrice entière) jusqu'à des valeurs de R = 0,037 et R_w = 0,051 pour 2844 réflexions avec $I \geq 3\sigma(I)$. La molécule possède un cycloboronate à six chaînons comprenant le premier cycle BONCNO à être caractérisé. On a trouvé que, à l'état solide, le cycle existe dans une conformation *C*-enveloppe. Les longueurs des liaisons observées comprennent : O—B(sp^2) = 1,356(2) et 1,370(2) et C(aryl)—B = 1,560(2) Å.

Mot clés : composés organoboriques, composés boriques, structure cristalline.

Introduction

N,N'-Dihydroxy-*N,N'*-dialkylaminals **1** react with arylboronic acids to give bicyclic pyroboronates **3** with transannular N—B coordination (1, 2). The bicyclo[3.3.0]octane skeletal structure of these compounds has been established by an X-ray crystallographic analysis of the *N*-methyl/*B*-phenyl-substituted derivative **3***a* (3).

Reaction of **1** and arylboronic acid in various molar ratios (including 1:1) leads to type **3** products, rather than the six-membered "diol boronate" **4**. Cyclic esters derived from 1,3-alkanediols similar to **4** are well-known in the literature (4). The structures of several arylboronates of 1,3-diols have been elucidated by X-ray crystallographic analyses (5–8). To achieve the formation of a type **4** boronate with the "diol" compound **1** we reduced the basicity of the aminal nitrogen atom by incorporation of an α-cyano group into the *N*-alkyl substituent. The decrease in basicity should weaken the dative N—B interaction which is possible in the hypothetical intermediate **2** leading to the bicyclic 2:1 condensate **3**. In addition, steric hindrance of the boronic acid by *ortho* substitution in the aryl residue could impede an extension of the coordination at boron from trigonal planar sp^2 to tetrahedral sp^3. Indeed, the condensation of a *N*-(α-cyanoalkyl)aminal **1** (R = $C(CH_3)_2CN$) and mesitylboronic acid (Ar = 2,4,6-$(CH_3)_3C_6H_2$) gave a crystalline 1:1 condensation product, according to elemental analyses and spectroscopic data. Although mass spectral data were consistent with a monomeric condensate, it was not possible to decide unambiguously between the expected six-membered cycloboronate structure **4** and the less probable *N*-oxide form **5** or its rearrangement product **6**, its dimer **7**, and possible oligomers like **8** (n = 2, 3, or higher). Thus an X-ray crystallographic analysis has been undertaken to determine the molecular structure of the condensate and to provide data on the conformation of the new heterocyclane ring, at least in the solid state.

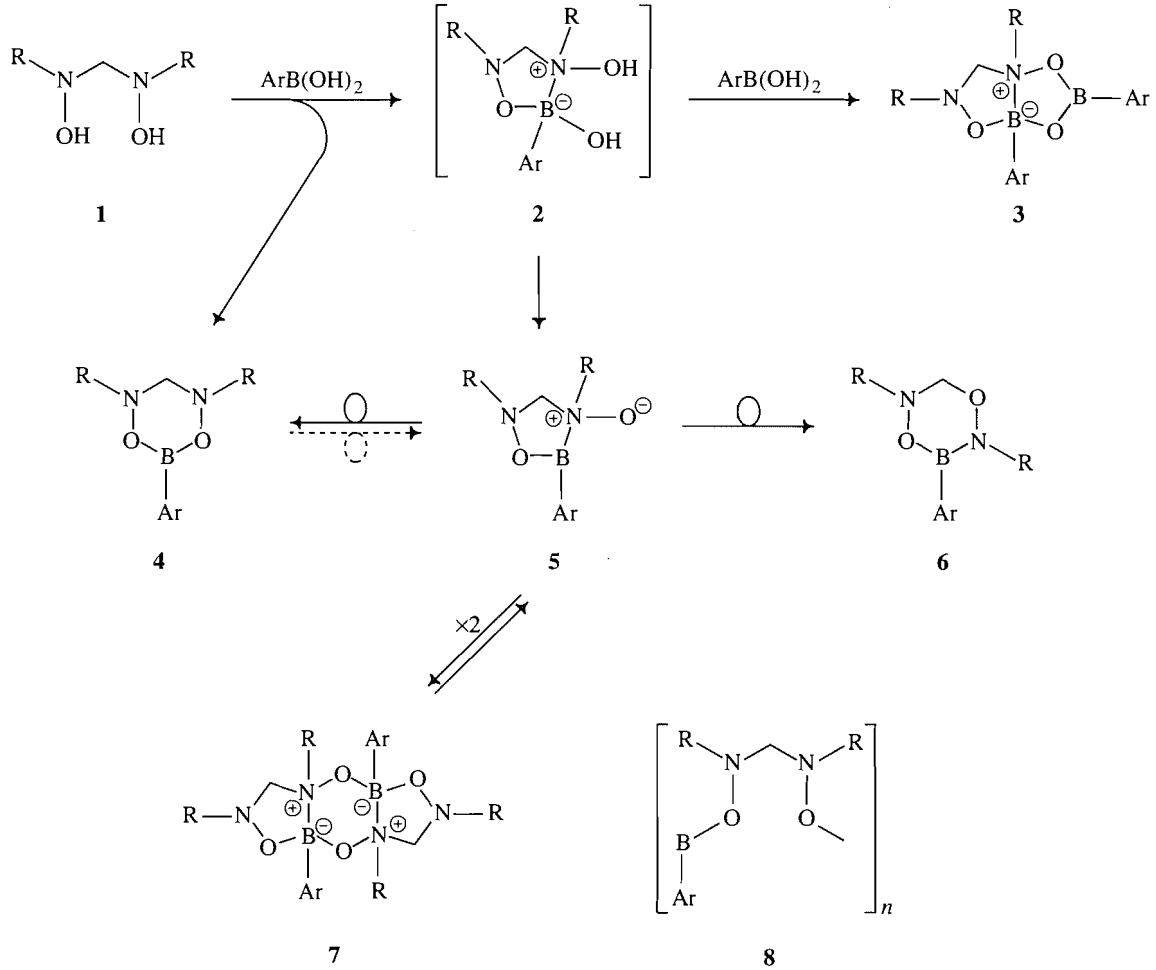
Experimental



*4,6-Bis(1-cyano-1-methylethyl)-2-mesityl-1,3-dioxa-4,6-diaza-2-boracyclohexane, **4**a (R = $C(CH_3)_2CN$, Ar = 2,4,6-$(CH_3)_3C_6H_2$)*

N,N'-Bis(1-cyano-2-methylethyl)-*N,N'*-dihydroxymethanediamine **1** (R = $C(CH_3)_2CN$) (9) (0.64 g, 3 mmol) and mesitylboronic acid (0.49 g, 3 mmol) are dissolved in 20 mL of benzene and refluxed for 1 h with continuous removal of water. After partial evaporation *in vacuo* colorless crystals formed upon cooling. Yield: 0.83 g (81%). Melting point (decomp.) 158–160°C (from benzene). *Anal.* calcd. for $C_{18}H_{25}BN_4O_2$: C 63.54, H 7.41, B 3.18, N 16.47; found: C 63.55, H 7.59, B 3.20, N 16.47. Infrared (KBr): 2230 (C≡N), 1610 cm^{-1} (aryl-C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ(ppm) = 1.67 (s, 2 $C(CH_3)_2$), 2.27 (s, *p*-CH_3), 2.43 (s, 2 *o*-CH_3), 4.35 (s, N—CH_2—N), 6.78 (s, 2 aromatic H). Mass spectrum (70 eV, 60°C): m/z = 340 (56%, M^+), 298 (14%), 272 (8%, M − $C(CH_3)_2CN$), 241 (14%), 227 (36%, M − H_2C=N(OH)$C(CH_3)_2CN$), 161 (15%), 147 (41%, $(CH_3)_3C_6H_2$), 133 (26%), 113 (76%, H_2C=N(OH)$C(CH_3)_2CN$), 97 (10%), 85 (26%), 68 (100%, $C(CH_3)_2CN$), 56 (8%), 45 (64%, CH_2NOH). Crystals suitable for X-ray analysis were obtained by recrystallization from dry benzene.

*X-ray crystallographic analysis of **4**a*

A crystal *ca.* 0.25 × 0.25 × 0.35 mm in size was mounted on a glass

fiber. Unit-cell parameters were refined by least squares on setting angles for 25 reflections ($2\theta = 92.4$–$118.1°$) measured on a diffractometer with Cu-K_α radiation ($\lambda = 1.54178$ Å). Crystal data at 21°C are as follows

$C_{18}H_{25}BN_4O_2$ f.w. = 340.23

Orthorhombic, $a = 15.825(1)$, $b = 17.958(1)$, $c = 14.014(1)$ Å, $V = 3982.6(5)$ Å^3, $Z = 8$, $\rho_c = 1.135$ Mg m^{-3}, $F(000) = 1456$, μ(Cu-K_α) = 5.66 cm^{-1}. Absent reflections: $0kl$, k odd, $h0l$, l odd, and $hk0$, h odd, uniquely indicate the space group *Pbca* (No. 61).

Intensities were measured with graphite-monochromated Cu-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of $(1.10 + 0.30 \tan\theta)°$ in ω (with up to eight rescans, background/scan time ratio = 0.5) was employed. Data were measured to $2\theta = 155°$. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random variations. After data reduction,[2] an empirical absorption correction, based on azimuthal scans for three reflections, was applied. Transmission factors range from 0.909 to 1.00. Of the 4294 independent reflections measured, 2844(66.2%) had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.035F^2)^2]/\mathrm{Lp}^2$ with S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were refined with isotropic thermal parameters. A correction for secondary extinction was applied, the final value of the extinction coefficient being 8.35×10^{-6}. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 10. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix least-squares refinement of 327 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.037$ and $R_w = 0.051$ for 2844 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.15σ. The mean error in an observation of unit weight was 2.09. The final difference map showed maximum fluctuations of ±0.15 e Å^{-3}. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, bond lengths and angles involving hydrogen, and structure factors have been deposited.[3]

Results and discussion

The X-ray analysis shows that compound **4***a* has the expected six-membered cycloboronate structure of the type **4** (Fig. 1), and represents (to the best of our knowledge) the first heterocyc-

lane with a BONCNO ring skeleton to be structurally characterized. The structure is comparable to that of a simple 1,3-diol boronate and possesses a "semi-planar" (C(1)—sofa) conformation for the six-membered heterocyclic ring, similar to those postulated for and established by X-ray analyses of several crystalline phenylboronates of 1,3-diols **9** (5–7) and **10** (8) as well as related ethylboronates (11, 12) and a simple boric acid ester of a 1,3-diol (13).

The essential planarity (to within 0.026 Å) of the N—O—B—O—N moiety in the boronate portion of **4***a* results, as does that of corresponding ring fragments in compounds **9**, **10**, and other known six-membered cyclic esters of ethylboronic or boric aid, from the partial double bond character of the O—B bonds caused by O—B $pp(\pi)$ back donation. This is supported by the relatively short O—B distances in **4***a* (1.356(2) and 1.370(2) Å). Corresponding O—B distances in the related compounds mentioned above range from 1.354 to 1.398 (average 1.373 Å) (5–8,11–13). Correlation of these O—B bond lengths with O—B π-bond order (14) yields a value of around 50%. Thus, a mean bond order of 1.5 is characteristic of the O—B bonds in the cycloboronate **4***a*.

In contrast to phenylboronates like **9** and **10**, in which the phenyl rings lie approximately coplanar with the C—O—B—O—C moieties of the boronate rings (suggesting at least some π-interaction between the aromatic system and the unoccupied boron p_z-orbital), the mesityl group of **4***a* is oriented perpendicular (dihedral angle between normals to the aromatic ring and boron coordination mean planes = 87.2°) to the boronate ring. This is apparently due to the steric hindrance of the ortho methyl substituents. The B—C(aryl) distance in **4***a* (1.560(2) Å) is nearly equal to those in **9***b* (6) (1.564 Å) and **9***c* (7) (1.561 Å), marginally longer than that in **10** (8) (1.554 Å), and distinctly longer than the reported (5) value for **9***a* (1.506 Å). The similarity of the above-mentioned distances suggests that for the B(sp^2)-C(aryl) bonds, in contrast to the O—B(sp^2) bonds, $p\pi-p\pi$ interactions appear to play a relatively minor role.

Compared to the bicyclic pyroboronate **3***a*, the monocyclic boronate **4***a* requires a different configuration at one of the aminal nitrogen atoms. Whereas **3***a* has the same configuration at both amine centres (*R,R* or *S,S*),[4] compound **4***a* has opposite configurations (*R,S*) at the two amine centres. Both of the bulky *N*-cyanoalkyl substituents are found in equatorial positions, resembling the similar influence of *tert*-butyl substituents on the geometry of cyclohexane ring systems (15). Considering the bond lengths and the conformational arrangement of both cyanoalkylamine groups in **4***a*, an anomeric effect (16) seems to contribute to the stabilization of the molecular geometry: the antiperiplanar orientation of both non-bonding electron pairs with respect to the adjoining geminal cyano groups allows the overlap of the nitrogen *n*-orbital with the antibonding σ* orbital of the C—C(cyano) bond. This is supported by relatively short C—N(amine) and long C—C(cyano) bonds within the cyanoalkylamine moiety of **4***a*. The mean C—N distance of 1.481 Å is somewhat shorter than comparable C—N bonds in *N-t*-butyl hydroxylamine derivatives: 1.497 Å (17), 1.496 Å (18). Correspondingly, the mean C—C(cyano) distance of 1.486 Å in **4***a* is longer than the comparable C—C(cyano) distance of 1.460 Å in Me_3C—CN (19) and the average value of 1.469 Å reported for C(sp^3)—C(cyano) bonds (20). An even longer C—C(cyano) bond (1.51 Å) has been reported for the *N*-cyanoalkylpiperidine **11** (21) which has the same *N*-substituent as **4***a* and an analogous conformation of the cyanoalkylamine moiety. Stereoelectronic effects on the geometry of the α-cyanoalkylamine group, similar to those deduced from bond lengths and conformations of both the hydroxylamine derivative **4***a* and the amine derivative **11** (21), have been postulated for α-cyanohydroxylamine derivatives of the general formula **12** (with a preferred axial orientation of the cyano group) on the basis of ^{1}H nmr data (22, 23).

The mean C≡N bond length of 1.140 Å in **4***a* is in good agreement with the average value 1.137 Å reported for cyano groups (20), and is slightly shorter than the values of 1.15 Å in **11** (21) and 1.158 Å in Me_3C—CN (19). The mean C—N and N—O distances in the aminal group (O—N—CH_2—N—O) of 1.460 and 1.461 Å, respectively, are equal within experimental error to the corresponding values of 1.461 and 1.458 Å reported

[4]Equal numbers of enantiomers are found in the crystal (3); formula **3***a* depicts the (1*R*,5*S*,7*R*)-enantiomer.

Study of the protonation of simple Schiff bases in solvents of various polarity by means of Raman spectroscopy

S. ALEX, P. TURCOTTE, R. FOURNIER, AND D. VOCELLE[1]

Département de chimie, Université du Québec à Montréal, PO Box 8888, Station A, Montréal (Québec), Canada H3C 3P8

Received August 15, 1989[2]

S. ALEX, P. TURCOTTE, R. FOURNIER, and D. VOCELLE. Can. J. Chem. **69**, 239 (1991).

In this study, the protonation of simple Schiff bases by organic acids in various solvents is investigated by Raman spectroscopy and the spectral response of the C=N$^+$ stretching mode is correlated with the macroscopic properties of the medium surrounding the imine. Upon protonation, the unperturbed C=N stretch increases in frequency due to the combination of the coupling with the C=N$^+$H bend and a partial rehybridization of the C=N bond. Depending on the proton location relative to that of its counterion, one mechanism may prevail over the other. Intensity measurements show that protonation is mostly controlled by the hydrogen bonding properties of the solvent and by the polarity of the medium. However, whatever the solvent, full proton transfer cannot be achieved with organic acids with pK_a similar to the COOH of amino acids found in visual or bacterial pigments, meaning that the protonation mechanism may depend upon particular properties of the protein.

Key words: imines, protonation, Raman spectroscopy, rhodopsin, Schiff base.

S. ALEX, P. TURCOTTE, R. FOURNIER et D. VOCELLE. Can. J. Chem. **69**, 239 (1991).

Cet article porte sur l'étude de la protonation des bases de Schiff simples avec des acides carboxyliques dans divers solvants par spectroscopie Raman. Nous avons établi qu'il est possible d'identifier la nature du milieu entourant l'imine, à partir des réponses spectrales obtenues sur le lien C=N$^+$. Une fois protonée, la vibration d'élongation C=N augmente en fréquence suite à la combinaison d'un couplage avec le mode de déformation C=N$^+$H et d'une rehybridation partielle du lien C=N. Dépendant de la position du proton vis-à-vis de son contre-ion, un des deux mécanismes peut être favorisé au dépend de l'autre. Quant aux mesures des intensités, elles montrent que la protonation de la base de Schiff est principalement contrôlée par la capacité de solvolyse du solvant et par la polarité du milieu. Cependant, quel que soit le milieu choisi, il a été impossible d'obtenir une protonation totale du groupe C=N avec des acides organiques dont l'acidité est comparable à celle rencontrée chez les fonctions COOH des acides aminés présents dans les pigments. Aussi, le mécanisme de transfert du proton semble nécessiter des propriétés particulières de la protéine.

Mots clés : imines, protonation, spectroscopie Raman, rhodopsine, base de Schiff.

Introduction

Bacteriorhodopsin and rhodopsin are proteins able to absorb light in the visible range between 500 and 600 nm. When they are exposed to light, they undergo their respective photocycles, which have been fully investigated and described in the literature (for example, see ref. 1–4 and refs. cited therein for reviews and recent developments). Even if their roles are not essentially the same, they both contain a chromophoric molecule of retinal covalently bound to a lysine residue via a protonated Schiff base linkage. Recently, a large number of articles aimed at finding the proton source and characterizing the local environment of the chromophore have been published (see reviews already quoted).

The work reported here is related to this field of research, and its main objective is to discuss the protonation of the simple Schiff bases and its effect on the C=N and C=N$^+$ stretching vibrations. So far, Raman spectroscopy has been widely used for such systems as pigments and model chromophores and has given valuable information (5–14). We also propose to investigate the influence of protonation and of the environment with the same technique. We decided to use a saturated imine to address this question even if the model is far removed from the visual or bacterial chromophores, since with retinal derivatives the presence of double bonds strongly weakens, or overlaps with, the Raman signal derived from either the C=N or the C=N$^+$ stretching vibration. The results reported are comparable to the early work done by Lussier *et al.* (15) on the state of protonation on similar systems in apolar solvents, using FT-IR. Lussier's data have been used as a basis of comparison and to calibrate the Raman results, Raman spectroscopy being more convenient for this type of study. This work was then extended to other solvents. Finally, the spectral behavior of these models is related to the more general case of the visual and bacterial rhodopsins.

The selected model system is built around mineral or organic acids used as proton sources, and an imine. The acids are chosen either to bracket the pK_a of amino acid residues met in the pigments and (or) to obtain the full protonation of the imine. The following acids have been used: hydrochloric acid (HCl, pK_a = −6.9 in water), trichloroacetic acid (TCA, pK_a = 0.66 in water), dichloroacetic acid (DCA, pK_a = 1.26 in water), monochloroacetic (MCA, pK_a = 2.85 in water), and propionic acid (PRO, pK_a = 4.87 in water).

Experimental section

Preparation of the samples

All the imines were prepared according to the method reported in ref. 15. The preparation and the purity control of these compounds were also described in this article. The following imines were investigated, fully or in part, according to our needs: $(CH_3)_2CHCH{=}NC(CH_3)_3$ (I_1), $(CH_3)_2CHCH{=}NCH(CH_3)_2$ (I_2), $(CH_3)_3CCH{=}NC(CH_3)_3$ (I_3), and $(CH_3)_3CCH{=}NCH(CH_3)_2$ (I_4). Their pK_a's have been evaluated by Favrot *et al.* (16, 17) and fall in the range 6–8 in $CHCl_3$ solution. Most of the investigations were carried out on I_2. These molecules promptly undergo hydrolysis, especially in acidic medium, so great care has been taken to avoid the presence of moisture. All the solvents were Spectrograde and were purchased from the Aldrich Chemical Company, Milwaukee, WI, U.S.A. Most were used without further purification, except chloroform, which was passed at least three times over an activated basic alumina column in order to remove traces of acids, ethanol, and water. The acids used were purchased from the same company and dried over P_2O_5 in a desiccator under vacuum. All liquid acids and solvents were stored over molecular sieves (3Å). The

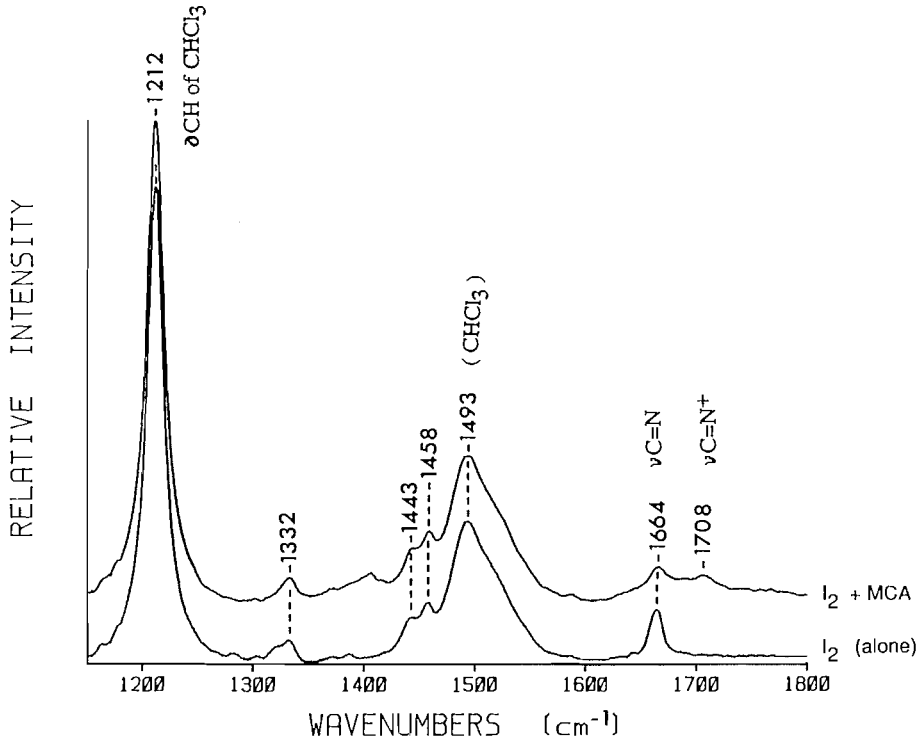

FIG. 1. Raman spectra of a 0.2 M solution of isobutylidene isopropylamine (I_2) in $CHCl_3$ (A) and of an equimolar solution of I_2 – 0.2 M MCA (B). The solvent bands are not substracted (excitation wavelength 488.0 nm).

complexes were synthesized by mixing an equimolar (unless otherwise stated) quantity of the acid with the proper imine in the appropriate solvent. The experiments were run in two types of solvents, the first being apolar, namely chloroform (refractive index or $n_D = 1.443$, dielectric constant or $D = 4.81$), and the second including both protic (methanol, $n_D = 1.3288$, $D = 32.80$) and aprotic (dimethyl sulfoxide or DMSO, $n_D = 1.478$, $D = 46.70$) polar solvents. Tentative experiments were carried out in a low dielectric constant medium, but in this situation the complexes are insoluble and are readily precipitated from solution. Raman spectra of these latter compounds were of little help, as they exhibit strong fluorescence background under laser exposure either in the solid state or from the centrifuged residue (not isolated from the solution).

For the deuteration of acids, the product of interest was dissolved in D_2O (Aldrich Chemical Company) and crystallized under inert atmosphere. This step was repeated as often as necessary, and the purity of the acids as well as the degree of hydrogen exchange were checked by NMR and IR spectroscopy. Then the imine–acid complexes were synthesized and dissolved in the proper solvents.

The Raman spectra were recorded on a Spex Triplemate spectrograph coupled with an EG & G Princeton Applied Research detector, model 1422, and were excited with ca. 100–200 mW of the 488 nm laser line (Spectra Physics CW Ar^+ laser, model 2016) in order to minimize the fluorescence of the sample. The sealed capillary was mounted on a thermally regulated sample holder and maintained at a temperature of 5°C. The spectra were recorded with a 3 cm^{-1} resolution at ca. 1600 cm^{-1} during 15 min. The fluorescence background was routinely subtracted with an appropriate nth order polynomial when necessary. All the Raman intensities reported in this work are normalized to the CH deformation mode of $CHCl_3$ at ca. 1212 cm^{-1}, whatever the solvent used. This is performed by first normalizing the imine bands to a particular peak P of the solvent present, and then, this latter band (P) is converted, by using a suitable factor, to a value related to the deformation mode of $CHCl_3$. In the text this procedure is called renormalization of the intensities. The scaling factors are deduced from Raman spectra of solutions of both solvents mixed in various proportions. Raman bands generated by organic solvents are usually very intense; the linearity of the detector response was also checked for the given laser power and no saturation effect was detected.

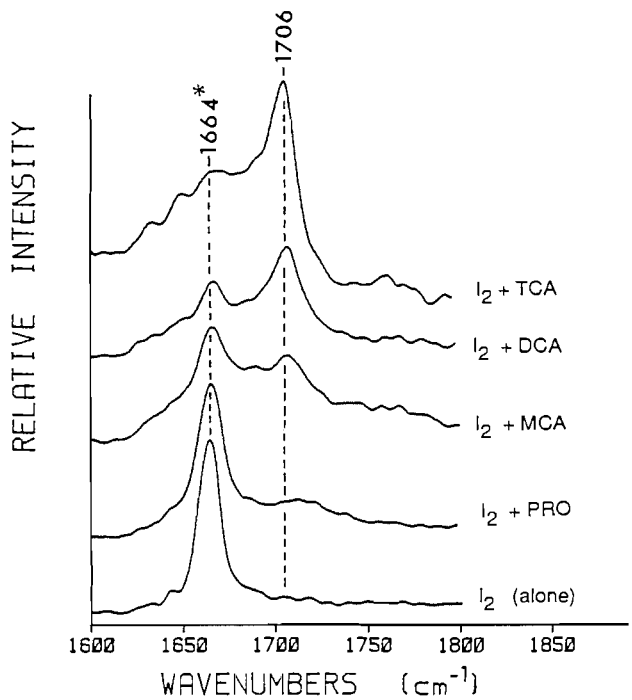

FIG. 2. Raman spectra of a 0.2 M solution of I_2 and its complexes in $CHCl_3$ solution in the region 1500–1800 cm^{-1}. The spectrum are solvent subtracted (excitation wavelength 488.0 nm).

The FTIR spectra were monitored on a Digilab FTS 50 spectrometer using a 2 cm^{-1} resolution and a recording time of about 5 min. The sample was held between two CaF_2 windows of a 0.1 mm optical path.

Results and discussion

The evaluation of the degree of protonation of the Schiff base by an organic or mineral acid is easily achieved by Raman spectroscopy because the signal derives mostly from the imines,

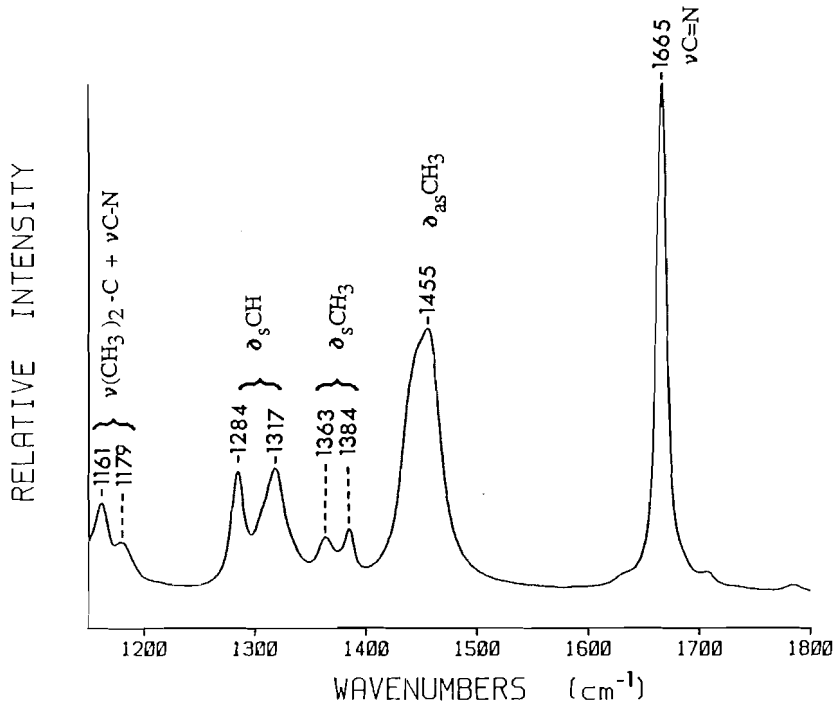

FIG. 3. Raman spectrum of neat isobutylidene isopropylamine (I_2) in the region 1200–1800 cm^{-1}.

since no additional contribution is seen from the unavoidable presence of acids. The complex under investigation can be represented as follows, using symbolic notation:

$$C{=}N + HOOC\text{-}R \rightleftharpoons C{=}N^{+}H\cdots\cdots{}^{-}OOC\text{-}R$$

Raman spectra of these imines mixed with organic acids are shown in Figs. 1 and 2. Only the data collected in chloroform are plotted, the results with other solvents being essentially similar. The discussion is focussed on the 1500–1800 cm^{-1} region where only the $\nu_{C=N}$ or $\nu_{C=N^+}$ stretching vibrations are observed, depending on the protonation state of the molecule. This is always true except in the case of TCA, where a broad emission deriving from the $\nu_{as\ COO^-}$ mode at ca. 1669 cm^{-1} overlaps with these modes; this is indicated by the asterisk in Fig. 2. No particular attention will be given to the rest of the spectra since only the two vibrations $\nu_{C=N}$ and $\nu_{C=N^+}$ are good probes to monitor the local environment and the state of hydrogen bonding (18–22). However, an example of a spectrum of the neat imine I_2 (pK_a = 7.15 in $CHCl_3$) is given in Fig. 3 and the main features pointed out (*vide infra*).

The text is organized as follows: in Sect. I, a frequency analysis of the $\nu_{C=N}$ and $\nu_{C=N^+}$ stretching is reported. In Sect. II, intensity measurements of these modes as a function of the protonation state are discussed. Finally, in Sect. III, some implications for bacterial and visual pigments are mentioned.

I. Frequency analysis of the $\nu_{C=N}$ and $\nu_{C=N^+}$ stretching vibrations in solvents of various polarity

Inspection of Tables 1–3 shows that when a simple imine is dissolved in various solvents both the frequency position and intensity of the $\nu_{C=N}$ mode are modified, compared to its unsolvated state. This is particularly true when the solvent is able to form hydrogen bonds with the imine. This is illustrated with methanol where the $\nu_{C=N}$ peak position is shifted by ca. 4 cm^{-1}. Since methanol or other alcohols are known to form strong hydrogen bonds with C=N (20, 23, 24), the results might be explained accordingly: that is, hydrogen bonding could better localize the π electrons on the C=N group and contributes to increase its vibrational frequency. This might also explain the increase in intensity of the band although this enhancement is probably only related to the variation of the dielectric constant. However, this explanation runs contrary to the usual effect of hydrogen bonding, which shifts stretching vibrations to lower frequencies as is effectively noted in chloroform, where a downward frequency shift of ca. 2 cm^{-1} is monitored upon solvation of imines like I_1 or I_4. This first observation demonstrates that, depending on the solvent, H bonding is differently expressed. For a solvent like dimethyl sulfoxide (DMSO), the $\nu_{C=N}$ position is not affected, meaning that interactions are limited. With imines substituted with *tert*-butyl instead of isopropyl groups, the result is almost similar except that the intensity of the $\nu_{C=N}$ band is split by a factor of 2 due to intensity borrowing through Fermi resonance from a side band at ca. 1653 cm^{-1} (15).

Upon protonation, the $\nu_{C=N}$ mode at ca. 1664 cm^{-1} disappears at the expense of a $\nu_{C=N^+}$ mode detected between 1698 and 1712 cm^{-1} in $CHCl_3$ depending on which kind of acid is used (see Table 1). For this new vibration, the frequency range is not so widely distributed in MeOH (see Table 2) and the average position of this vibration is located at almost the same position (1700–1703 cm^{-1}). In DMSO (see Table 3), lack of significant protonation severely limits the discussion, $\nu_{C=N^+}$ being very weak or absent.

The upward frequency shift observed on the $\nu_{C=N^+}$ (compared to the $\nu_{C=N}$) is not consistent with normal expectations. Protonation of the C=N group should rather shift its stretching mode to lower wavenumbers. This anomaly is, however, well documented in the literature (18–22, 24, 25) and the behavior can be explained by invoking a mixing of the $\nu_{C=N}$ mode and the $C{=}N^{+}H$ bend (19–22), thus propelling the $\nu_{C=N^+}$ Raman vibration to higher frequency. This explanation was based in part on the experimental fact that downward isotopic shifts of ca. 25 cm^{-1} have been noted on substituting hydrogenated acids (HX) by deuterated ones (DX). Using a diatomic oscillator model, Deng and Callender (26) showed that indeed the upward shift on Schiff bases, upon protonation, originated from such a

[c]These values are estimated from the loss of intensity monitored on the $\nu_{C=N}$ mode.

coupling since deuteration reduced it greatly. However, even if there has been general agreement about this coupling, Lòpez-Garriga *et al.* (18, 25) have recently cautioned that this should not be taken for granted. They stressed that a redistribution of the electronic density in such a system is conceivable and consequently will give the same spectral response without requiring any coupling. In support of this theory these authors invoked a rehybridization of the C=N bond upon protonation, leading to a shortening of its length by 0.007 Å and a stiffening of its force constant. This raises the question as to which of the two theories is the more valid for our study.

From Tables 1 and 2, it is seen that the frequency differences (between the neat imine and its complexes) appear *a priori* inversely proportional to the acid strength. With weak acids (PRO, MCA, and DCA), the difference is of the order of 48–44 cm^{-1} while from much stronger acids (TCA and HCl), it is around 42–34 cm^{-1}. This means either that the C=N/C=N^+H stretch–bend interaction is reduced with strong acids or that upon protonation the C=N bond is weakened, this compensating for the action of coupling. This latter hypothesis has been ruled out because acids are expected to form fairly strong H-bonds with the imines, at least similar to the ones created with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

the use of methanol, with the same effect on the C=N link. Hence, the frequency distribution of $\nu_{C=N^+}$ seems rather a function of the nature of the counterion. This is consistent with the limited effect of the anion on the $\nu_{C=N^+}$ vibration position in MeOH, where the hydrogen bond network around the chromophore is known to play a buffer electrostatic role (or a levelling effect) (23). The negative charge probably defines the proton position and, in this kind of complex, the proton can be found close to the nitrogen atom (i.e., forming a front H-bond), or close to its counterion (involving a back H-bond), or again hesitating between both moieties (3, 15). Keeping this picture in mind, it is interesting to look at its effect on the $C{=}N^+$ oscillator.

First, the importance of the coupling can be revealed by using deuterated acids, considering that the C=N stretching mode will receive much smaller contributions from the $C{=}N^+D$ bend than from the $C{=}N^+H$ bend. Therefore, as stated before, the isotopic shift between the deuterated and the protonated imines will emphasize the importance of the coupling. This being so, we tested the proposal by using deuterated acids. Results given in Table 4 show that the deuterated Schiff bases have $\nu_{C=N^+}$ at higher frequencies than the unprotonated Schiff bases. If it is assumed that, with deuterium, the coupling between the stretch and the bend is slight, then the upward shift can only be attributed to a rehybridization of the C=N function as in the Lopez–Garriga theory since there exists no other proposal but the two already described. In Table 4, it is also possible to note that the isotopic shifts found in our work are almost the same as those found by Deng and Callender (25 cm^{-1}) in their study (26). So we are dealing with two facts: deuteration indicates that rehybridization is present in our Schiff bases upon protonation, while the isotopic shifts of ca. 25 cm^{-1} indicate that stretch–bend interactions are also important. One way of solving this question is simply to invoke the presence of *both* effects and, from this, try to analyze how both theories could explain our results obtained by using different acids in different solvents.

Let us start with HCl (and DCl). The isotopic shift found is 22 cm^{-1}, a lower value that the one found for the upward frequency shift of the C=N stretching band upon protonation and which is probably due to rehybridization and stretch–bend interaction, the latter being somewhat reduced. However, in methanol, the isotopic shift returns at 26 cm^{-1}. This reduced contribution in $CHCl_3$ could possibly be explained by invoking the high electronegativity of the Cl^- ion and its small ionic radius, both favoring the back H-bond (viz. $N\cdots H^+\cdots Cl^-$) (15, 20). As a consequence, the contribution of δ_{N^+H} to $\nu_{C=N^+}$ should be lower in this context, the -NH link becoming longer and more directional and harder to bend (27).[3] This point of view is consistent with the fact that back H-bridges appear weaker in complexes containing halides such as bromides and iodides as counterions, as described by Lussier *et al.* (15).

For organic acids like TCA, there is no change in the isotopic shift whatever the solvent used. In this case, one can imagine that the front H-bond is favored (viz. $N^+\cdots H\cdots {}^-OOC$), this being justified by the different electronegativity and larger size of the carboxylate anion. In this context, the isotopic shift should be important since the proton, being closer to the nitrogen atom, should allow a strong stretch–bend interaction. This is actually the case since an isotopic value of 26 cm^{-1} is registered.

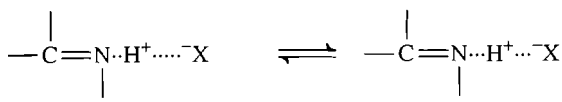
There is no way here to measure the relative importance of rehybridization and stretch–bend coupling. One can only

[3] δ: deformation mode.

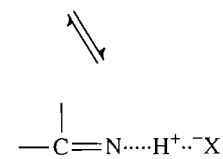
TABLE 4. Effect of isotopic substitution on the frequency positions of the $\nu_{C=NH^+}$ stretching vibrations of I_2 complexes with mineral and organic acids in chloroform and in methanol

	$CHCl_3$		MeOH or MeOD	
Complexes	$\nu_{C=NH^+}$ (cm^{-1})	Δd^a (cm^{-1})	$\nu_{C=NH^+}$ (cm^{-1})	Δd^a (cm^{-1})
I_2–HCl	1698	—	1700	—
I_2–DCl	1676	(22)	1676	(24)
I_2–TCA	1706	—	1704	—
I_2–TCA-*d*	1679–1680	(27–26)	1678	(26)

[a] Δd represents the isotopic shift between $\nu_{C=N^+H}$ and $\nu_{C=N^+D}$.



predict that rehybridization will be quite important when the positive charge sits mainly on the nitrogen atom, as shown below:



This is the case for the unconjugated Schiff bases (the present work) while for conjugated Schiff bases a somewhat different picture arises:

But acids can protonate the azomethine function in different ways, i.e., the proton could be more or less close to the nitrogen atom as shown below:

(A) (B)

(C)

Thus, the proton could be nearer to the nitrogen atom (A), closer to the counterion (C), or more or less in the middle (B). We have seen that in the stretch–bend theory, structures A and B should give maximal stretch–bend interaction, provided that the coincidence of the energy levels of the two modes is not broken as has been observed on similar complexes (20, 21, 24, 26). It should also give maximal rehybridization, so that both theories are affected the same way. The question of protonation will be discussed in Sect. II.

II. Analysis of the state of protonation of the imine complexes

Besides the frequency modulation, the intensity changes of both vibrations (viz. $\nu_{C=N}$ and $\nu_{C=N^+}$) are also of interest because they can be used to monitor the extent of proton transfer. The intensities needed for the calculations are normalized to a selected band of solvent present and are reported in Tables 1–3. For convenience, they have been renormalized to the $\delta_{C=H}$ mode of $CHCl_3$ (see experimental section for detail). The degree of protonation is estimated either from the intensity of the $\nu_{C=N}$ or of the $\nu_{C=N^+}$, depending upon which mode is the more intense. Their Raman signals being linear with respect to concentration, the percentage of protonation is easily calculated using basic algebra.

The extent of protonation obtained is summarized in Tables 1–3 for $CHCl_3$, MeOH, and DMSO, respectively. The given percentages are comparable to the data of Lussier *et al.* (15) acquired for chloroform. Clearly, none of the carboxylic acids used are able to completely protonate the Schiff base, and a significant proton transfer appears only with acids having pK_a's lower than ca. 2 units in water (that is, for very strong acids). This situation deteriorates when the imine is less basic. For instance, a drop of 1 unit in the pK_a of the imine group leads to a loss of 10% in proton transfer. Protonation is improved by a factor of approximately 20 percent when the dielectric constant of the solvent is increased from ca. 5 to ca. 33 units (see Tables 1 and 2). These comments only apply when the medium strongly interacts with the analyte, because with a non-interacting but polar solvent like DMSO, protonation is simply absent (see Table 3). This can be understood by looking at the factors affecting imine – carboxylic acid complexes. They generally obey the following equations (written using symbolic notation) (28–30):

[1] $C{=}N + HOOC{-}R \rightleftharpoons C{=}N\cdots\cdots HOOC{-}R$

I II

$C{=}N^+H\cdots\cdots{}^-OOCR$

III

From an experimental point of view, the protonated species quoted in this work correspond to complex III. The protonation is driven by the force associated with the energy gradient corresponding to the pK_a difference between the imine and the acid functions. From one solvent to another, pK_a's are modified by both the electrostatic properties of the medium and its solvation capacity.

This makes it difficult to predict the extent of protonation based solely on this physical factor alone (viz. grad(pK_a) in water). A better analysis can be carried out by separating the electrostatic forces and by using a grad(pK_a) related to a particular solvent (i.e., water, this being more convenient as pK_a's do not have a clear meaning in nonaqueous solvents). Qualitatively, proton transfer occurs when it abides by the following inequality:

[2] $\text{Grad}(pK_a) - (F_c + F_s) > 0$

The position of the balance between the terms in expression [2] will locate the proton. This equation shows that protonation is significant when the driving term grad(pK_a) is not overcome by the attractive electrostatic (or coulombic) force F_c, which tends to retain the proton near its anion in a low dielectric medium. Besides, the solvation capacity of the medium F_s severely reduces the proton motion towards nitrogen. This term (F_s) represents the solvent ability to create a tight ion pair or to solvate charge, this being equivalent to the reaction $RCOOH \rightleftharpoons RCOO^-\cdots H^+$. In other words, only a solvent with a good hydrogen bonding capacity is able to polarize the acid, that is, to make it an ion pair (viz. A^-H^+), this being followed by a total ionization of $RCOO^-\cdots H^+$ (viz. $RCOO^-\cdots H^+ \rightleftharpoons RCOO^- + H^+$) if the medium happens to be sufficiently polar. Using this definition, F_s will be small when the solvent is able to create ion pairs such as $RCOO^-\cdots H^+$ and will tend to infinity otherwise. This image fits the protonation pattern obtained in chloroform and methanol (where F_s and F_c are moderate), as well as in DMSO where F_s is infinite and F_c ineffective. Now, it is clear that for a given grad(pK_a) and polarity of the medium, proton transfer will occur only when ion pairs are present, this being the limiting factor.

III. Implications for bacterial and visual pigments

As reported in Sect. I, the imine–HCl system in $CHCl_3$ is characterized by a reduced isotopic shift resulting from a H^+ located near the counterion (viz. $N^+\cdots\cdots H\cdot\cdot X^-$), thus forming a less ionic complex (15, 20, 31). However, the literature (20, 21, 24, 32) shows that a reduced isotope effect could also be explained in term of a weaker interaction between the protonated Schiff base and its counterion (viz. $N^+\cdot\cdot H\cdots\cdots X^-$), which leads to a less effective C=N/N—H coupling owing to the modification of their vibrational level energy proximities (20, 21, 27). This last statement implies that the counterion is separated by a large gap from the protonated imine and, consequently, the positive charge rests mainly on the nitrogen atom, while in our case the positive charge is located on the proton, which is supposed to be distant from the imine. These facts illustrate that reduced deuterium effect may indicate that the proton is located at either end of the $N^+\cdots H\cdots X^-$ axis, and the $\nu_{C=N^+H}$ frequency position is best explained by the rehybridization model because it assumes a minimal role for the C=N/N—H coupling. As a consequence, for cases where H^+ is located more or less at midpoint along the $N^+\cdots H\cdots X^-$ bridge, the $\nu_{C=N^+}$ frequency position could be explained by both coupling and rehybridization as already demonstrated by Baasov *et al.* (20), and this situation is the most commonly encountered in models.

Intensity measurements may help to solve the protonation problem in rhodopsins. At present protonation of the Schiff base in pigments is believed to involve complex paths. For instance, evidence that aspartic acids 85, 96, 115, and 212 in bacteriorhodopsin are affected in this protonation process has been reported (33). From data for our carboxyl–imine complexes, it is clear that the medium around the chromophore should exhibit strong interactions with the proton source in order to insure full protonation. This statement derives from eq. [2], where the role of these interactions is to minimize the forces F_c and F_s, both factors reducing the effectiveness of grad(pK_a). In other words, the chromophore pocket should be at least chloroform-like or, even better, methanol-like. This idea is not new and has already been widely suggested (see refs. 3 and 4 and refs. therein) and, as an example, the presence of water has been often invoked to suit this requirement (34).

This hypothesis can be tested by mixing an imine with an acid having a protonating capacity similar to aspartic or glutamic acid, and then by adding a water-like molecule in various proportions. This was done in our laboratory by solubilizing an

imine–PRO system in a $CHCl_3$ matrix and adding quantities of methanol ranging from 1 to 20% (v/v). Upon addition of 1, 5, 10, 20% of MeOH by volume to this apolar matrix, an increase in protonation can be observed. Duplicating the same experiments with twice the amount of acid compared to the imine again improves the proton transfer. Even so, this excess of acid is not enough to fully protonate the imine. Therefore the presence of a water-like medium could only partially explain the whole protonation mechanism.

Nevertheless, these model systems should be accepted with reservations for two reasons: first, the model cannot integrate all the factors met in the proteins and, second, the literature (35, 36) reports a pK_a value of 13.3 for the chromophore in bacteriorhodopsin. Similarly, a value of about 2.5 units (33) has been suggested for some aspartic acid residues in the pigments instead of the usual 3.8 units, this giving a grad(pK_a) that cannot be reproduced by our models. In spite of these two weaknesses, our examples prove that the protein has to provide to the chromophore a medium able to "solvate" COO^- and H^+ groups, this condition being fundamental.

Conclusion

Frequency changes experienced by a Schiff base and isotopic substitution on protonated imines may be correlated to the Schiff base – counterion interaction. With regard to protonation, it is clear that this will be eased only if the chromophore cavity is protic and fairly polar. These conditions can be fulfilled in the pigments by invoking the presence of water. This raises the question of how Schiff bases, sensitive to hydrolysis, will be able to survive in pigments? Some explanations suggest that either H_2O molecules have different physical or chemical properties in the proteins, or hydrolysis may be triggered only when a sufficiently large concentration of water is present inside the chromophore pocket. So far no work has been done in this sense and the question remains open.

Calculation of the vertically excited singlet $n \rightarrow \pi^*$ state of *trans*-N_2H_2 carried out in C_s symmetry at the RHF and RHF-CISD levels results in a broken symmetry solution in which the wave function does not reflect the C_{2h} symmetry of the molecular framework. The excited state RHF energy computed in C_s symmetry is lower than the corresponding energy computed in C_{2h} symmetry, but the single-reference CISD energy based on the C_s RHF configuration is higher than the corresponding C_{2h} result. The symmetry breaking leads to difficulties in the description of the excited state potential energy surface, including the location of stationary points and the calculation of vibrational frequencies, and in the treatment of complexes of excited N_2H_2 with other molecules. The molecular symmetry of the vertically excited state can be restored in C_s calculation by the use of a four-configuration MCSCF wave function. The MCSCF procedure provides consistent data and leads to the prediction that the relaxed excited state has C_2 molecular symmetry. Unlike the RHF case, the UHF wave function does not display symmetry breaking at the C_{2h} geometry, and agrees with the MCSCF model in predicting an equilibrium structure of C_2 symmetry. A low-energy structure of C_2 symmetry has also been found with the UMP2 model, although it could not be positively confirmed that it corresponds to an equilibrium structure. The symmetry-breaking dilemma is not unique to the excited $n \rightarrow \pi^*$ state of N_2H_2, but arises in other molecules in which the two chromophores are similarly symmetry related.

Key words: symmetry breaking, excited state, MCSCF, N_2H_2.

JANET E. DEL BENE, KYUNGSUN KIM et ISAIAH SHAVITT. Can. J. Chem. **69**, 246 (1991).

Des calculs effectués aux niveaux RHF et RHF-CISD, sur l'état singulet excité verticalement $n \rightarrow \pi^*$ de la *trans*-N_2H_2 calculée dans la symétrie C_s, conduisent à une solution avec discontinuité dans la symétrie dans laquelle la fonction d'onde n'est pas un reflet de la symétrie C_{2h} du cadre moléculaire. L'énergie RHF de l'état excité, calculée dans la symérie C_s, est inférieure à l'énergie correspondante calculée dans la symétrie C_s est inférieure à l'énergie corrrespondante calculée dans la symètrie C_{2h}; toutefois l'énergie CISD à référence simple, calculée sur la base de la configuration RHF C_s, est supérieure à la valeur C_{2h} correspondante. La discontinuité dans la symétrie conduit à des difficultés dans la description de la surface d'énergie potentielle de l'état excité, y compris dans la localisation des points stationnaires, dans les calculs des fréquences de vibration ainsi que dans le traitement de complexes du N_2H_2 excité avec d'autre molécules. La symétrie moléculaire de l'état excité verticalement peut être restaurée dans les calculs C_s par l'utilisation d'une fonction d'onde MCSCF à quatre configurations. La méthode MCSCF fournit des données cohérentes et conduit à faire la prédiction que l'état excité relaxé possède une symétrie moléculaire C_2. Par opposition avec le cas RHF, la fonction d'onde UHF ne présente pas de discontinuité dans la symétrie de la géométrie C_{2h} et elle est en accord avec le modele MCSCF pour prédire une structure d'équilibre pour la symérie C_2. Avec le modèle UMP2, on a aussi trouvé une structure de basse énergie de symétrie C_2, même si on n'a pas pu confirmer positivement qu'elle correspond à une structure en équilibre. Le dilemme de la discontinuité dans la symétrie n'est pas unique à l'état excité $n \rightarrow \pi^*$ de la N_2H_2; c'est une situation que l'on retrouve dans d'autres molécules dans lesquelles les deux chromophores sont aussi reliés par la symétrie.

Mots clès : discontinuité dans la symmétrie, état excité, MCSCF, N_2H_2.

[Traduit par la rédaction]

Introduction

In a study of $n \rightarrow \pi^*$ transitions in molecules containing lone pairs of electrons, we have encountered a symmetry-breaking problem in the single-determinant description of the lowest singlet excited state of N_2H_2. In this case, the wave function produced from a restricted Hartree–Fock (RHF) calculation carried out in C_s symmetry fails to reflect the full C_{2h} symmetry of the molecular framework. This symmetry-breaking problem gives rise to discontinuities on the potential energy surface, preventing the correct location of stationary points and the calculation of reliable vibrational frequencies and other properties of excited N_2H_2. In particular, it causes difficulties in the calculation of binding energies of complexes of excited N_2H_2, because these complexes generally possess lower symmetry than N_2H_2 itself. This type of problem, first referred to by Löwdin (1) as the "symmetry dilemma", has been investigated extensively (see, e.g., Čížek and Paldus (2), McKelvey and co-workers (3), Jackels and Davidson (4), Seeger and Pople (5), Paldus and co-workers (6), Englebrecht and Liu (7), Davidson and co-workers (8), McLean *et al.* (9), and Szalay *et al.* (10), and references therein), primarily for the ground doublet state of allyl and other radicals. Interestingly (and similar to the case of the allyl radical (8)), the unrestricted Hartree–Fock (UHF) wave function of singlet-excited N_2H_2 does not break symmetry at the C_{2h} geometry (though the lowest-energy C_{2h} geometry is unstable with respect to asymmetric a_u and b_u distortions of the molecule on the UHF potential energy surface). In an effort to investigate the symmetry-breaking problem for excited N_2H_2, we have used several *ab initio* models and different symmetry contraints to compute the energy of the vertically excited molecule and to search the excited-state potential energy surface for stationary points.

Methods

All the calculations were carried out with the 6-13+G(*d*,*p*) basis set (11, 12). The ground state structure of *trans*-N_2H_2 was

fully optimized with correlation at second-order Møller–Plesset perturbation theory (13–16) (MP2) with this basis. This molecule has C_{2h} symmetry, with a closed-shell ^1A_g ground state. Single-configuration restricted open-shell Hartree–Fock calculations followed by configuration interaction with all single and double excitations (17) (CISD) were carried out to obtain the energy of the vertically excited $n \rightarrow \pi^*$ state. These calculations were done in both C_{2h} symmetry, where the excited state is ^1B_g, and in C_s symmetry, where the excited state is $^1A''$, always maintaining the C_{2h} molecular framework. Similar calculations were done for the UHF and unrestricted second-order Møller–Plesset (UMP2) models. Multiconfigurational SCF (MCSCF) and multireference CISD calculations of the vertically excited state were carried out using C_s symmetry.

Geometry optimizations to determine the structure of the relaxed excited state were carried out using the RHF, UHF, UMP2, and MCSCF models in C_{2h}, C_s, and C_2 symmetries. The UHF and UMP2 optimized structures and vibrational frequencies were calculated using the GAUSSIAN 88 system of computer programs (18). The RHF, MCSCF, and CI calculations were done with the COLUMBUS system of programs (19, 20). The location of stationary points on the RHF and MCSCF potential energy surfaces from computed values of the energy and the energy gradient was accomplished with the MINPT program (21).

The occurrence of symmetry-broken solutions greatly complicates the characterization of symmetrically constrained stationary points and the determination of the corresponding vibrational frequencies, at least when analytically computed second derivatives are not available. On the one hand, if the wave function calculations are carried out without symmetry constraints, the symmetric points usually represent cusps on the complete potential energy surface in symmetry breaking cases. On the other hand, if the calculations at the symmetric points are symmetry constrained, it is not unusually possible to carry out equivalent calculations at asymmetrically distorted geometries. However, it has been found (3, 6, 7) that the symmetrically constrained Hartree–Fock wave function can often be obtained as an unstable solution, presumably a saddle point on the orbital optimization surface (not to be confused with the potential energy surface), of the unconstrained Hartree–Fock equations for the symmetric point, and that corresponding unstable solutions which connect smoothly with it can even be found at slightly distorted geometries (6, 7).

In the RHF calculations described here, it was found possible to find such solutions and to obtain a complete set of frequencies corresponding to symmetrically constrained stationary points using just energies and gradients. First, the orbitals obtained in the symmetrically constrained calculation at the symmetric stationary point were reexpressed in a format appropriate for lower symmetry calculations and were used as starting orbitals in symmetry unconstrained calculations at the same point. These orbitals were found to satisfy the symmetry-unconstrained RHF equations, and produced the same energy as in the constrained calculation. Then, the same starting orbitals were used in calculations on slightly asymmetrically distorted geometries, and were found to produce solutions which connected quite smoothly with the solution at the symmetric point. This procedure can be regarded as an analytical continuation of the symmetry-constrained solution into the asymmetric region of the potential energy surface.

The UHF frequencies were computed with the GAUSSIAN 88 programs using analytical second derivatives, and were not subject to instability problems. However, the UMP2 frequency determinations use energies and gradients only, and require calculations at asymmetrically distorted geometries around the stationary point. Some of these distorted geometries have no symmetry at all, and the UHF solutions at these points collapsed to the ground state (since the excited and ground-state UHF determinants could not be distinguished in this case by differences in the occupancy of spin orbitals of different symmetry or spin), preventing the reliable determination of the UMP2 frequencies and the characterization of the stationary points.

All calculations reported in this work were carried out on the AMDAHL 5868 computer at Youngstown State University and the CRAY Y-MP8/864 at the Ohio Supercomputer Center.

Results and discussion

Vertical excitation energies

The RHF and CISD energies of N_2H_2 in the ground and the first vertically excited $n \rightarrow \pi^*$ state are reported in Table 1, along with the Mulliken gross atomic populations. In C_{2h} symmetry the RHF excited state has ^1B_g symmetry and lies 3.54 eV above the ground state. However, if the RHF calculation is done in C_s symmetry (while maintaining the molecular framework in C_{2h}), a lower energy for the $^1A''$ $n \rightarrow \pi^*$ state is found and the excitation energy decreases to 3.39 eV. This lowering of energy is accompanied by a symmetry breaking of the wave function

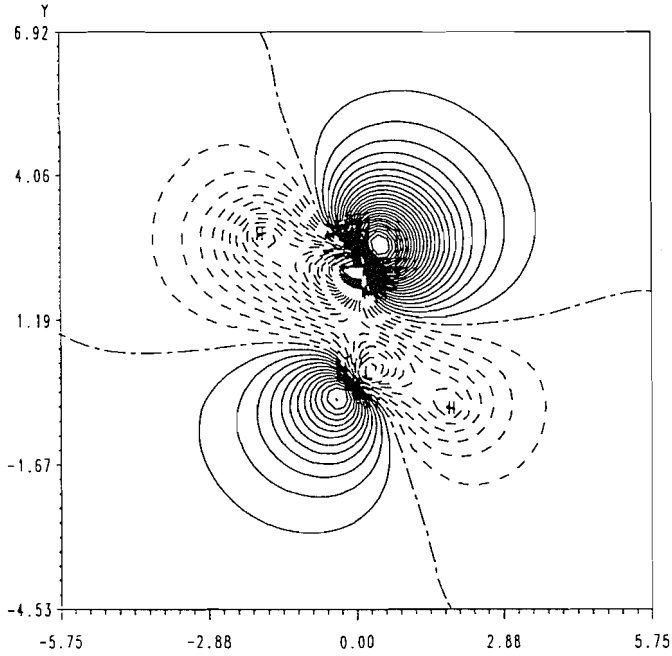

FIG. 1. Cross-section, in the molecular plane, of the singly-occupied $7a'$ RHF orbital for vertically-excited N_2H_2, computed in C_s symmetry. Countour lines range from -0.5 to $+0.5$ in steps of 0.02. Solid lines indicate positive values, dashed lines negative values, and nodes are designated by short–long dashed lines. The nitrogen atoms are located at the origin and on the positive Y axis. The coordinate scales are in units of Bohr radii (a_0).

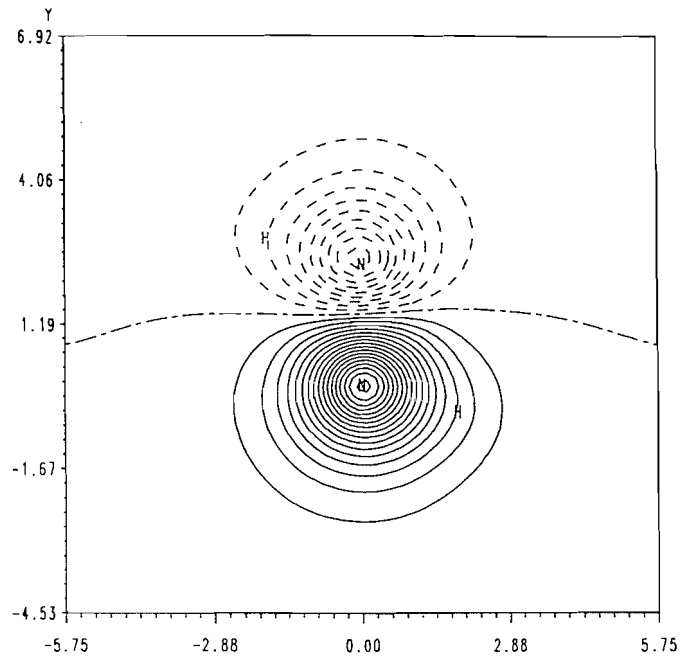

FIG. 2. Cross-section, in a plane 1 a_0 above the molecular plane, of the singly-occupied $2a''$ RHF orbital computed in C_s symmetry. Line values and other details are the same as in Fig. 1.

which makes the two N—H groups nonequivalent, as indicated by the Mulliken population data. Configuration interaction does not restore the equivalency of the two N—H groups in C_s symmetry. Furthermore, the CISD energy based on the C_s single-configuration reference function is now higher than the CISD energy based on the C_{2h} single-configuration reference function. Thus, neither the single-configuration RHF wave function nor the CISD wave function based on it provide an appropriate description of the $n \rightarrow \pi^*$ excited state of N_2H_2.

The restricted open-shell Hartree–Fock calculation in C_s symmetry gives rise to the configuration

$$(1a')^2(2a')^2(3a')^2(4a')^2(5a')^2(6a')^2(1a'')^2(7a')^1(2a'')^1$$

Both the doubly-occupied $6a'$ and singly-occupied $7a'$ orbitals (the two lone-pair orbitals in the ground state) have different contributions from the two N—H groups. Likewise, the two nitrogen atoms make different contributions to the doubly-occupied $1a''$ (π) and the singly-occupied $2a''$ (π^*) orbitals. The singly-occupied $7a'$ orbital is polarized toward one N—H group, while the singly-occupied $2a''$ orbital is polarized toward the other. This is shown in Fig. 1 and 2, respectively, which present contour diagrams of the $7a'$ orbital in the molecular plane and of the $2a''$ orbital in a plane 1 a_0 above the molecular plane.

The symmetry dilemma is resolved when a suitable multiconfiguration wave function is used for the calculation of the excited-state energy. (Obviously, an equivalent multiconfiguration function for the ground state is required for the determination of the excitation energy in this case.) The active space required to make the two NH groups equivalent in C_s-symmetry calculations for the excited state consists of the two highest-energy σ orbital, $6a'$ and $7a'$, and the two lowest-energy π orbitals, $1a''$ and $2a''$. This active space requires that three electrons be distributed in $6a'$ and $7a'$ and three electrons in $1a''$ and $2a''$, and generates four configurations. It is evident from the Mulliken populations shown in Table 1 that the resulting four-configuration MCSCF wave function restores the equivalence of the two N—H groups in C_s symmetry. The MSCSF energy, is of course, lower than any single-configuration energy. The four-reference CISD energy is also lower than any single-reference CISD energy for the excited state. The CI coefficients of the four reference configurations in the multireference CISD wave function are

$\ldots(6a')^2(1a'')^2(7a')^1(2a'')^1$	0.935
$\ldots(6a')^2(1a'')^1(7a')^1(2a'')^2$	0.000
$\ldots(6a')^1(1a'')^2(7a')^2(2a'')^1$	0.000
$\ldots(6a')^1(1a'')^1(7a')^2(2a'')^2$	0.192

The UHF and UMP2 energies and UHF gross atomic populations for the ground and excited state of N_2H_2 are displayed in Table 2. The ground state solutions are identical to the corresponding RHF and MP2 solutions. The excited state calculations produce identical results in C_{2h} and C_s symmetries, displaying no spatial symmetry breaking (though they do not represent a pure singlet spin state).

Excited state geometries

The discrepancy between the RHF and CISD energies computed for excited N_2H_2 in C_{2h} and C_s symmetries suggests that there are discontinuities on the excited state potential energy surface associated with symmetry breaking. To further investigate this surface, we have attempted to optimize the geometry of relaxed N_2H_2 in the first excited singlet state using various theoretical methods and imposing different symmetry constraints. The resulting structures and energies are reported in Table 3.

Using the RHF model, geometry optimizations were done in C_{2h}, C_s, and C_2 symmetries. The C_s structure has two inequivalent N—H groups and a significantly longer N—N bond than in the C_{2h} and C_2 structures. The C_{2h} structure has

[a]Bond lengths in ångströms and angles in degrees; energies in hartrees.
[b]Number of imaginary frequencies.
[c]The frequencies could not be determined reliably in this case (see text).

one imaginary frequency which corresponds to out-of-plane distortion toward a C_2 structure. Both the C_s and C_2 optimized structures are predicted to be true minima, with no imaginary frequencies, but the C_s structure has the lower energy. As seen below, no other model predicts a stable minimum of C_s symmetry.

Though the UHF solution for the excited state at the ground-state geometry does not display symmetry breaking, there is a UHF stationary point of C_s symmetry lower in energy than the UHF C_{2h} stationary point. However, neither of these two points is a true minimum on the UHF potential energy surface, having one and two imaginary frequencies, respectively, and there is a true minimum of lower energy having C_2 symmetry. Although it is not expected that there would be a global minimum of C_1 symmetry, this possibility could not be pursued because of our inability to prevent the collapse of the UHF calculation to the ground state in this case.

Geometry optimization of excited N_2H_2 at the UMP2 level of theory produced just two stationary points. Optimization in C_s symmetry encountered difficulties, but appeared to be converging toward a C_{2h} structure, with equivalent N—H groups. The optimized nonplanar C_2 structure has a lower energy than the optimized C_{2h} structure. It was not possible to obtain consistent frequencies for either of these structures for reasons discussed in the previous section.

The fourth method used to locate the global minimum on the N_2H_2 potential surface was the multiconfigurational MCSCF procedure. At this level of theory only two stationary points were found. The C_{2h} structure has one imaginary frequency corresponding to an out-of-plane twist. The optimized C_2 structure has a lower energy, and with no imaginary frequencies appears to be the global minimum and equilibrium structure for singlet excited N_2H_2.

In summary, while RHF, UHF, UMP2, and MCSCF all exhibited stationary points of C_2 symmetry lower in energy than C_{2h}, the RHF point was not the global minimum, and the UMP2 point could not be reliably confirmed to be a minimum rather than a saddle point. The symmetry-breaking problem has been investigated in detail in this work only for the excited $n \rightarrow \pi^*$ state of N_2H_2, but similar problems are anticipated in other

molecules, such as glyoxal and the diazines, in which the two chromophores are similarly symmetry related.

The direct electrochemical synthesis of the novel copper(I) complex $Cu_2[OC_6Cl_4(OH)]_2[(C_6H_5)_2PCH_2P(C_6H_5)_2]_2$

THEODORE A. ANNAN, JAMES E. KICKHAM, AND DENNIS G. TUCK[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received February 8, 1990[2]

THEODORE A. ANNAN, JAMES E. KICKHAM, and DENNIS G. TUCK. Can. J. Chem. **69**, 251 (1991).

The electrochemical oxidation of copper in an acetonitrile solution of an aromatic diol ($R(OH)_2$ = catechol, tetrachloro-1,2-dihydroxybenzene, 2,2′-dihydroxybiphenyl) gives soluble copper(I) products which are reduced to copper at a platinum cathode. In the presence of $R(OH)_2$ + L (L = 2,2′-bipyridine, triphenylphosphine, bis(diphenylphosphino)methane (= dppm)), the products are adducts of copper(I) species in which the anionic ligand is $[R(O)OH]^-$. The crystal structure of $Cu_2[OC_6Cl_4(OH)]_2(dppm)_2$ is triclinic, with a = 22.418(5) Å, b = 11.784(4) Å, c = 13.492(4) Å, α = 61.63(2)°, β = 86.66(2)°, γ = 80.61(2), V = 3093(2) Å^3, Z = 2, and space group $P\bar{1}$. The molecule consists of a Cu—P—C—P—Cu—P—C—P ring, with copper ligated by $[R(O)OH]^-$ groups external to this. Intramolecular O—H---O hydrogen-bonding contributes to the stabilization of this novel complex.

Key words: Copper, electrochemical synthesis, hydrogen bonding, aromatic diols, crystal structure.

THEODORE A. ANNAN, JAMES E. KICKHAM et DENNIS G. TUCK. Can. J. Chem. **69**, 251 (1991).

L'oxydation électrochimique du cuivre en solution avec un diol aromatique ($R(OH)_2$ = catéchol, tétrachloro-1,2-dihydroxybenzène, 2,2′-dihydroxybiphényle) dans de l'acétonitrile conduit à des produits solubles du cuivre(I) qui sont réduits en cuivre à une cathode de platine. En présence de $R(OH)_2$ + L (L = 2,2′-bipyridine, triphénylphosphine, bis(diphénylphosphino)-méthane (= dppm), les produits sont des adduits d'espèces du cuivre(I) dans lesquels le ligand anionique est le $[R(O)OH]^-$. La structure cristalline du $Cu_2[OC_6Cl_4(OH)]_2(dppm)_2$ est triclinique avec a = 22,418(5), b = 11,784(4) et c = 13,492(4) Å, α = 61,63(2), β = 86,66(2) et γ = 80,61(2)°, V = 3093(2) Å^3, Z = 2 et groupe d'espace $P\bar{1}$. La molécule comprend un cycle Cu—P—C—P—Cu—P—C—P dans lequel le cuivre est lié au groupe externe par des groupements $[R(O)OH]^-$. La liaison hydrogène intramoléculaire O—H---O contribue à la stabilisation de ce nouveau complexe.

Mots clés : cuivre, synthèse électrochimique, liaison hydrogène, diols aromatiques, structure cristalline.

[Traduit par la rédaction]

Introduction

One of the advantages of direct electrochemical synthesis is that in producing compounds by oxidising a metallic element in non-aqueous solution, the formation of lower oxidation state species is often favoured. Some examples include the synthesis of $Sn(SPh)_2$ (1), $Pb(SPh)_2$ (1), salts of $Ga_2X_6^{2-}$ (X = Cl, Br, I) (2), $Sn(O_2R)$ (R = catecholate, etc.) (3), InSPh (4), and the unusual indium(I) species In[OR(OH)] ($R(OH)_2$ = 1,2-$C_6H_4(OH)_2$, 2,3-dihydroxynaphthalene, 2,2′-dihydroxybiphenyl, 1,2-dihydroxytetrabromobenzene) (5), and In[SR(SH)] (R = 1,2-C_2H_4, 1,2-C_3H_6, 1,3-C_3H_6, 1,4-C_4H_8, 2,3-C_4H_8, 1,5-C_5H_{10}, 1,6-C_6H_{12}) (6). Similarly investigation of various copper–thiol systems in non-aqueous electrochemical synthesis gave rise to a number of CuSR compounds and their adducts, and some interesting cage structures were identified by X-ray crystallography (7–11). These latter form part of a large group of copper(I)-thiolato and -dithiolato species which illustrate the wide range of stereochemical possibilities in such molecules (12–14).

We now report an unusual copper(I) compound obtained in the extension of earlier work on the electrochemical synthesis of derivatives of aromatic 1,2-diols (3, 5, 15), where the product is the dppm adduct (dppm = bis(diphenylphosphino)methane) of the copper(I) derivative of 2-hydroxy-3,4,5,6-tetrachlorophenolate. The structure of this dimeric species has been established.

Experimental section

General

Copper anodes, in the form of sheets approximately 1 cm × 2 cm × 0.5 mm, were washed successively with dilate nitric acid, water, and acetone before use. Acetonitrile was distilled from calcium hydride immediately before use. All other materials were used as supplied.

Copper analysis was performed by atomic absorption spectrophotometry, using an IL-251 instrument. Microanalysis was by Guelph Chemical Laboratories Ltd. Infrared spectra were run as KBr discs on a Nicolet 5DX instrument; ^1H and ^{13}C nmr spectra were recorded on a Bruker 300 L spectrometer.

Electrochemical synthesis

The experimental techniques were essentially those used in earlier work, with cells of the type

$$Pt_{(-)}/CH_3CN + R(OH)_2 + L/Cu_{(+)}$$

and the diols investigated were catechol (1,2-dihydroxybenzene), tetrachloro-1,2-dihydroxybenzene, 4-*t*-butyl-1,2-dihydroxybenzene, and 2,2′-dihydroxybiphenyl. The neutral ligands used were 2,2′-bipyridine (bpy), triphenylphosphine, and dppm. Not all of these systems gave rise to identifiable products (see below). The composition of the solutions used are given in Table 1. Each experiment was run for 3 h at room temperature in an atmosphere of dry nitrogen, and the solution phase was stirred mechanically at regular intervals. Observations on specific systems are given below.

(*i*) Catechol, etc. When cells containing *ca.* 2.2 mmol of diol and no neutral ligand were used as the electrolyte, copper was dissolved from the anode, but deposition of metal on the cathode became increasingly apparent as the experiment proceeded. The electrochemical efficiency (E_F) for the anodic dissolution of copper, defined as moles Cu dissolved per Faraday of charge, was 1.10 mol F^{-1} for both catechol and tetrachlorocatechol. These experiments were not pursued further.

(*ii*) $Cl_4C_6(OH)_2$ + dppm. As electrolysis proceeded, the colour of the solution turned from pale brown through pink to orange, and after about 90 min, colourless crystals began to deposit and continued to form as current flowed. At the end of the experiment, these crystals were collected by filtration *in vacuo*, washed with acetone (10 mL), dried *in vacuo*, and identified as $Cu[OC_6Cl_4(OH)]$dppm (*Anal.* calcd. C 53.7, H 3.31, Cu 9.14; found C 53.3, H 3.40, Cu 9.25). The material

$(C_6H_4)_2(OH)_2$-2,2′	0.42	dppm	0.86	25	160	1.12
$C_6H_4(OH)_2$	0.37	Ph_3P	1.77	8	228	1.07

[a]Dissolved in 50 mL CH_3CN containing ca. 30 mg Et_4NClO_4.
[b]bpy = 2,2′-bipyridine; dppm = bis(diphenylphosphino)methane.
[c]Voltage to give an initial current of 20 mA.

used in the X-ray studies was obtained by recrystallizing the initial product from *N*,*N*-dimethylformamide. The ^1H nmr spectrum consists of a multiplet in the aromatic region, a singlet at 2.08 (d_6-dmso) or 1.64 ($CDCl_3$), which is assigned to CH_2 of dppm, and weak broad resonances at 3.75 (d_6-dmso) or 3.99 ($CDCl_3$) indicative of hydrogen bonding between solvent and the OH of the $[C_6Cl_4O(OH)]^-$ ligand. The ^{13}C spectrum (in dmso; Me_4Si = 0) shows two groups of resonances in the aromatic region; those at 132.4, 129.8, and 128.1 ppm are assigned to the phenyl carbons of dppm, shifted from 138.6, 132.6, and 128.5 ppm in the free ligand, while the remaining features at 150.0, 117.9, and 116.9 arise from Cl + C2, C3 + C6, and C4 + C5 of tetrachlorocatecholate, and are close to the values reported for indium(III) (16) and tin(IV) (17) complexes of this ligand. In addition, a triplet at 25.75, 25.47, 25.18 ppm arises from the CH_2 of dppm. The ^{31}P spectrum of the complex in dmso shows a singlet at −6.26 ppm (relative to external 85% H_3PO_4), shifted from −18.61 ppm for dppm itself in the same solvent.

(*iii*) 2,2′-Dihydroxybiphenyl + dppm. During electrolysis, the solution became deep yellow, but no precipitation occurred. The solvent was subsequently removed by evaporation *in vacuo* to give a pale brown oil (*ca.* 15–20 mL) which was triturated overnight with diethyl ether, in which the oil is insoluble. The ether was decanted away, and the residual oil redissolved in CH_3CN (20 mL); addition of Et_2O (70 mL) precipitated a brown solid, which was washed with Et_2O (5 mL) and dried; yield 0.28 g, 21% on the basis of metal dissolved. Analysis agreed with the formula $Cu[O(C_6H_4)_2OH].0.5dppm.2CH_3CN$ (*Anal.* calcd. C 65.4, H 5.01; found C 65.3, H 4.75). Melting point 185–190°C. The infrared spectrum has a medium intensity band at 2225 cm^{-1}, corresponding to $\nu(C{\equiv}N)$ of CH_3CN. The ^1H spectrum ($CDCl_3$) shows resonances at 7.3–6.5 (phenyl), 2.83 (br) (H-bonding), 2.33 (s) (CH_2 of dppm), and 1.24(s) (CH_3CN): the presence of trace quantities of $CHCl_3$, and the low solubility, did not allow for meaningful integration.

(*iv*) 2,2′-Dihydroxybiphenyl + 2,2′-bipyridine. The solution obtained by dissolving equimolar quantities of these compounds in acetonitrile was deep orange in colour. During electrolysis, this changed to deep red, and a steady increase in the current at constant voltage was observed, implying the formation of charged species; the voltage was decreased at intervals to keep the current at 20 mA. At the end of the electrolysis, small quantities (60 mg) of a brown–red solid were removed by filtration, and the red filtrate was slowly evaporated to dryness over 3 days. The resultant solid was dissolved in CH_3CN (15 mL), and diethyl ether (100 mL) added to precipitate a brown solid which was collected and dried *in vacue*; yield 0.41 g, 41% on the basis of metal dissolved. Analysis agreed with the formula $Cu[O(C_6H_4)_2OH].bpy$ (*Anal.* calcd.: C 65.3, H 4.23, N 6.92, Cu 15.7; found: C 64.7, H 4.25, N 6.54, Cu 15.4). Melting point > 300°C. The infrared spectrum confirmed the presence of 2,2′-bipyridine (18). Attempts to run the nmr spectrum of this compound failed because of the presence of paramagnetic species.

(*v*) Other systems which gave rise to solid products included 4-*t*-butylcatechol + dppm, and catechol + Ph_3P. In the former system, the product of the electrolysis was isolated as a heavy orange oil, but this became deep purple after being kept at 0°C for 3 days, and a purple–blue solid was obtained when this material was taken to dryness *in vacuo*. (Found: C 65.5, H 5.42, Cu 10.8.) Similarly, for catechol + PPh_3, the product of the electrolysis was a dark green solid, which on recrystallization (CH_3CN + Et_2O) gave an unstable green solid; Found: C 67.4, H 4.97, Cu 12.6. In neither case could a satisfactory stoichiometry be established, and no further studies were carried out on these compounds.

TABLE 2. Summary of crystal data, intensity collection, and structural refinement for $Cu_2[OC_6Cl_4(OH)]_2(dppm)_2$, $C_{62}H_{46}Cl_8Cu_2O_4P_4$

Largest shift/esd in final cycle	0.03

Crystallographic analysis

A colourless crystal of $Cu_2[OC_6Cl_4(OH)]_2(dppm)_2$ (**1**) was mounted along its longest dimension on a Syntex $P2_1$ diffractometer, and data collected at room temperature (*ca.* 25°C) by procedures described previously (19). The intensities of three check reflections were monitored regularly, but no significant decay was observed during the

[a] $U_{eq} = \frac{1}{3}[\Sigma_i\Sigma_j U_{ij} a_i^* a_j^* \mathbf{a}_i \cdot \mathbf{a}_j]$

time required for data collection. The cell parameters were measured and refined from 30 strong high angle ($15° < 2\theta < 25°$) reflections. Data used in the structure determination were corrected for Lorentz and polarization effects, and analytically for absorption. Density was measured by the flotation method in carbon tetrachloride – benzene mixtures. No symmetry or extinctions were observed, and the crystal was assigned to the space group $P\bar{1}$.

The structure was solved by first locating the Cu atoms by direct methods using the program SHELX (20), and then proceeding with the usual heavy atom Fourier technique. The structure was refined by block-matrix least-squares methods, using 271 parameters in one block and 115 in the other. The two copper atoms Cu(1) and Cu(2) were common to each block, one of which also contained Cl(1)—Cl(4), P(1)—P(4), O(1)—O(4), C(01), C(02), and C(1)—C(6), while the other contained the remaining carbon atoms (C(11)–C(86). Convergence was achieved at $R = 0.1169$. The anistropic treatment of the atomic thermal vibrations showed several non-positive definite parameters for the carbon atoms of the phenyl rings of dppm, and this treatment was therefore restricted to Cu, Cl, P, O, C(01), C(02), and C(1)—C(6) (see Figs. 1 and 2 for numbering). Geometrical constraints were applied to all the aromatic rings, imposing identical C—C bond lengths of 1.395 Å and bond angles of 120°. The rings bonded through C(11) and C(21) showed unacceptably high thermal vibrations at some of the carbon atoms, indicating disorder in these phenyl groups. Several attempts were made to correct this disorder problem but none of them led to convergence in our refinement, and this uncorrected disorder problem therefore accounts for the residual electron density of 1.1 e/Å^3 located around the phenyl rings in question.

Hydrogen atoms were included on all carbon atoms in idealized position (r(C—H) = 0.95 Å and ∠ CCH = 109.5°), with isotropic thermal parameters assigned values 0.01U (Å^2) greater than those for the appropriate carbon atoms. The hydrogen atoms bonded to O(2) and O(4) were constrained, with bond distances of 1.10 Å. After several cycles of refinement, convergence was achieved, with the final $R = 0.0719$ and $R_w = 0.0844$ for 4730 unique "observed ($I > 3\ \sigma(I)$)" reflections. The function minimized during least-squares calculation was $\Sigma_w(|F_o| - |F_c|)^2$ with $w = (\sigma_2(F) + \rho F^2)$ and final $\rho = 0.00001$.

Details of the crystal size, intensity data collection, and structure refinement are summarized in Table 2. Table 3 gives the atomic coordinates for the non-hydrogen atoms, and Table 4 presents the interatomic distances and angles. Atomic positions of hydrogen atoms, equivalent isotropic temperature factors, the unit cell diagram, and observed and calculated structure factor amplitudes are available as

supplementary data.[3] The molecular structure is shown in Fig. 1; Fig. 2 isolates the core of the molecule.

Stability of $Cu_2[OC_6Cl_4(OH)]_2(dppm)_2$(1)

This compound darkens on heating, turning brown at *ca.* 200°C; the melting point is not sharp (211–214°C), and a brown liquid is formed above this range.

In an attempt to remove the proton of the $[OC_6Cl_4(OH)]^-$ ligand, a sample of **1** (0.77 g, 0.55 mmol) in acetonitrile (50 mL) was treated with Et_3N (0.1 mL, 0.073 g, 0.71 mmol). The solution, which became pale green, was refluxed for 1.5 h, after which minor solid impurities were removed by filtration and the filtrate taken to dryness to give a colourless powder which was identified as the starting material **1**.

Results and discussion

The structure of $Cu_2[OC_6Cl_4(OH)]_2(dppm)_2$

There are a number of interesting features to this molecule, which can be simply described as two copper(I) units, $Cu[OC_6Cl_4(OH)]$, held together by bridging dppm units (see Fig. 1). One immediate conclusion is that the Cu—Cu distance, 2.946(1) Å, appears to preclude any metal–metal bonding interaction (see refs. 20 and 21 for a discussion of this subject). The absence of any Cu–Cu interaction is also in keeping with the bond angles in the Cu—P—CH_2—P—Cu bridge, in which the phosphorus atom is essentially tetrahedral (sum of all angles 654.3°), and in which the P—C—P angles of 112.9(6)° and 112.7(5)° imply the absence of any strain in this ligand. The sums of the bond angles at copper are 359.4° (Cu(1)) and 358.2° (Cu(2)), establishing a quasi-trigonal planar stereochemistry at these atoms. The core of the molecule is an eight-membered ring, folded along the Cu—Cu axis, as shown in Fig. 2.

The most striking difference between this structure and those of copper(I)—thiolate cages, is that in the latter the thiolate ligand bridges copper atoms to give a range of Cu_2S_2, Cu_4S_4, etc., rings. Neutral monodentate or bidentate ligands then bond to the copper, and may also serve as additional bridges which cap the Cu_nS_n ring. In the present structure, the oxy ligand is monodentate, and external to the central eight-membered Cu—P—C—P—Cu—P—C—P feature. It would be interesting to see if one aspect of this argument, namely, that the softer (S,P) atom bridges while the harder atom (O,N) is external to the ring system, applies in other structures involving low oxidation state d^{10} metal ions.

The Cu—P bond distances (ave. 2.246 Å) are close to those in other copper(I)–dppm complexes with bridging dppm ligands (*e.g.* ave. Cu—P value 2.295 Å in $[Cu_2S_2C_3H_6(dppm)_2]_2$ (11); 2.290 Å in $Cu_4(PPh_2)_4(dppm)_2$ (22)), and the P—C distances and angles equally are very close in all these compounds. An interesting comparison for the Cu—O bond

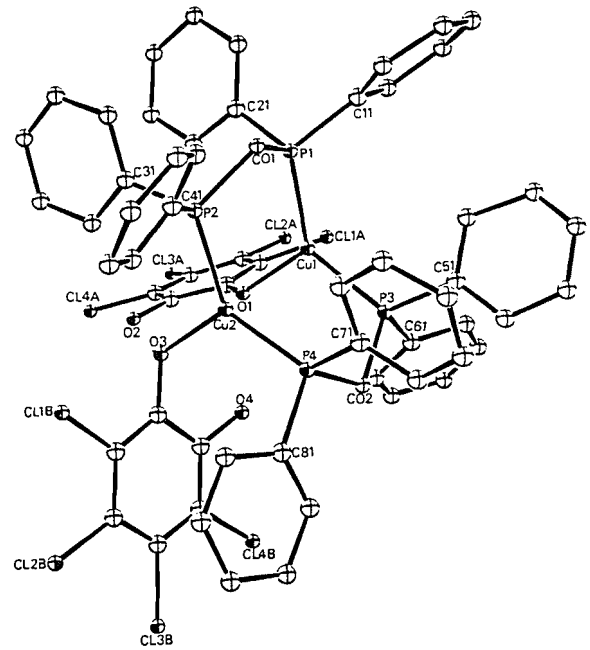

FIG. 1. ORTEP diagram of $Cu_2[OC_6Cl_4(OH)]_2(dppm)_2$; all atoms are shown isotropically, with 30% probability. Hydrogen atoms have been omitted for clarity.

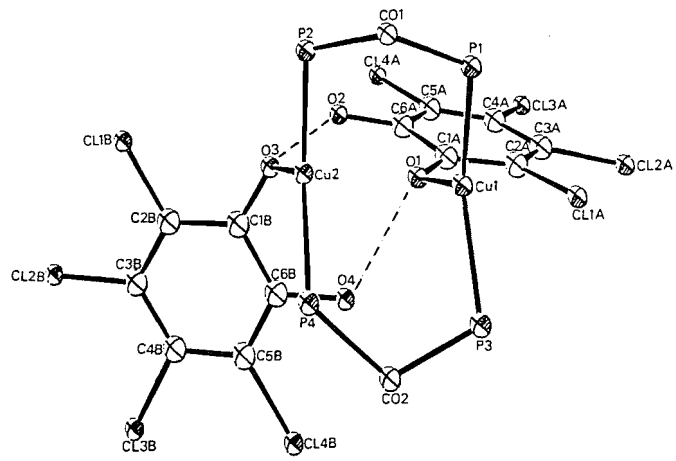

FIG. 2. The core of the structure of $Cu_2[OC_6Cl_4(OH)]_2(dppm)_2$, identifying the intramolecular hydrogen-bonding.

distance (1.986(5) Å) is with the unusual $L_3Cu_4OCl_6(OH)_2.L$ (L = *N*-methylpyrrolidin-2-one) (23), in which Cu—O within the Cu_4OCl_6 core is 1.896 Å (ave), that to the oxygen atom of the external L is 1.918 Å (ave), and that to the aquo ligand is 1.936(6) Å. The Cu—O bond is shorter than that in the compound formed in the oxidation of a phenoxo-bridged binuclear copper(I) species with $Cl_4C_6O_2$-*o* (24); in this product,

two copper(II) atoms are bridged by $Cl_4C_6O_2^{2-}$, with Cu—O distances of 1.995(9) Å.

The final point to be addressed is the nature of the 2-hydroxy-3,4,5,6-tetrachlorophenolate ligand. The loss of only one of two acidic protons from the parent substituted catechol is surprising, since the pK values for the two dissociations do not differ in any unusual degree; the values for $Cl_4C_6(OH)_2$ do not appear to be available, but for catechol itself, pK_1 = 9.45 and, pK_2 = 12.8 (25). It therefore seems unlikely that the presence of one residual acidic hydrogen in the ligand is the result of differences in the pK values, or the energy changes which they represent. Rather one should look for some stabilizing factors in the final complex, and in the case of the present structure this is to be found in the intramolecular hydrogen-bonding which is identified from the crystallographic results. In the crystallographic refinement, the hydrogen atoms were reasonably assumed to be bonded to O(2) and O(4), since O(1) and O(3) are coordinated to copper atoms. The final results show that the distances O(1)—O(4) (2.713(3) Å) and O(2)—O(3) (2.750(3) Å) are well within the range identified for O—H---O distances in hydrogen-bonded solid state structures (26, 27). The stability of this compound in the solid state therefore owes more to these hydrogen bonds than to the energy implicit in the retention of one proton in $[C_6H_4O(OH)]^-$. The failure to deprotonate **1** by reaction with Et_3N, in contrast to the behaviour of In[OR(OH)] (5) and In[SR(SH)] (6), is clearly also due to this intermolecular hydrogen-bonding.

Electrochemical synthesis

For each of the systems studied, the value of the electrochemical efficiency, defined as the number of moles of copper dissolved per Faraday of charge, is in the range 1.11 ± 0.04 mol F^{-1}. This is higher than the value of 1.00 mol F^{-1} which would be required by the sequence

[1] cathode: $R(OH)_2 + e \rightarrow R(O)OH^- + H_2(g)$

[2] anode: $R(O)OH^- + Cu \rightarrow Cu[OR(OH)] + e$

and this deviation is probably related to the problem of maintaining a constant current during E_F measurements because of the deposition of small amounts of copper on the anode in these experiments. An alternative scheme to reactions [1] and [2], involving the formation of RO_2^{2-} anions which subsequently interact with $R(OH)_2$ to give $2R(O)OH^-$ anions, does not affect the conclusion that these copper(I) species are formed in the initial anodic oxidation process [2], and are not the product of the disproportionation of an initially-formed copper(II) product. The systems in Table 1 are clearly further examples of the usefulness of direct electrochemical oxidation of metals in producing low oxidation state complexes as noted in the Introduction.

General conclusions

Given the varied stability and crystallinity of the products described in the Experimental section, it is clear that the synthesis of $Cu_2[OC_6Cl_4(OH)]_2(dppm)_2$ was indeed fortuitous. Equally, given the significance of hydrogen bonding in this structure, it is not surprising that changes in either substituted catechol or in neutral ligand produce structural changes that allow oxidation to copper(II) to occur. It would clearly be imprudent to speculate on the number of structures similar to that shown in Fig. 1 which might be stabilized by suitable variation in the ligands used.

It is shown that the primary ionization, under conditions of liquid-assisted secondary ionization mass spectrometry (LSIMS), of neutral complexes of the type $[(\eta^5\text{-}C_5Me_4R')Rh(SCN)_2(CNR)]$, involves the loss of a thiocyanate ligand. The processes leading to the observed spectra have been elucidated using techniques of accurate mass measurement and tandem mass spectrometry, so that the molecular weight and elemental composition of the isocyanide ligand RNC can be deduced with confidence. The greatest sensitivity was found when 3-nitrobenzyl alcohol was used as the matrix. Bimolecular reactions are shown to occur under LSIMS conditions, yielding ions containing two rhodium atoms but not the isocyanide. The implications of these results for the characterization and analysis of isocyanide metabolites of *Trichoderma hamatum* are discussed and illustrated.

Key words: isocyanides, mass spectrometry, rhodium complexes, *Trichoderma hamatum*.

R. K. BOYD, D. J. EMBREE, A. J. MCALEES et A. TAYLOR. Can. J. Chem. **69**, 257 (1991).

On démontre que l'ionisation primaire de complexes neutres du type $[(\eta^5\text{-}C_5Me_4R')Rh(SCN)_2(CNR)]$, dans des conditions de spectrométrie de masse avec ionisation secondaire assistée par un liquide SMISAL), implique la perte d'un ligand thiocyanate. Les processus conduisant aux spectres observés ont été élucidés à l'aide des techniques de mesure des masses exactes et de la spectrométrie de masse en tandem; on a donc pu déduire la masse moléculaire et la composition élémentaire du ligand isocyanure, RNC, avec confiance. On a trouvé que la meilleure sensibilité est obtenue lorsque l'alcool 3-nitrobenzylique est utilisé comme matrice. On a démontré que, dans les conditions de SMISAL, il se produit des réactions bimoléculaires conduisant à des ions qui contiennent deux atomes de rhodium, mais pas d'isocyanure. On discute et on illustre les implications de ces résultats pour la caractérisation et l'analyse des métabolites du *Trichoderma hamatum* qui contiennent de l'isocyanure.

Mots clés : isocyanures, spectrométrie de masse, complexes du rhodium, *Trichoderma hamatum*.

[Traduit par la rédaction]

Interest in the isocyanide metabolites (*e.g.* **1***a*) of *Trichoderma hamatum* lies in their unusual inhibition of growth of functionally important rumen bacteria, *e.g.*, *Fibrobacter succinogenes*, and thus being implicated in poor performance of ruminant animals on pasture (1, 2). Isolation and structural characterization of these isocyanide metabolites has been hampered by their sensitivity to light and their marked tendency to polymerise. The most unstable isocyanides (*e.g.* **1***a*) can be converted to their relatively stable esters **1***b* (3), thus permitting structural studies by X-ray crystallography, nmr spectroscopy, and mass spectrometry (4). We have shown (3, 5) that isocyanides RNC are readily converted into stable crystalline rhodium complexes of the type $[\eta^5\text{-}(C_5Me_4R')Rh(SCN)_2(CNR)]$ **2**, by reaction with the dirhodium complex reagent $[\eta^5\text{-}(C_5Me_4R')\text{-}Rh(SCN)_2]_2$ (R′ = Me, **2***a*; R′ = Et, **2***b*); such complexes prepared from naturally occurring mixtures of isocyanides can be separated (6) by two-dimensional thin layer chromatography (tlc).

Liquid-assisted secondary ion mass spectrometry (LSIMS) of η^5-cyclopentadienylrhodium(III) complexes is well-known (7, 8), and LSIMS analysis of spots on tlc plates has been reported (9). It therefore seemed possible to utilize the inherent sensitivity of the mass spectrometer to explore and characterize the isocyanide metabolites of *T. hamatum*, usually present in low concentration. As a first step towards this goal we have prepared a number of complexes **2** of well-characterised isocyanides RNC, *viz.* cyclohexyl isocyanide (10), phenyl isocyanide, benzyl isocyanide, methyl 2-isocyano-2-methylpropionate (NC—CMe_2—CO_2Me), phenyl 2-isocyano-2-methylpropionate (NC—CMe_2—CO_2Ph), and **1***b*, and studied their LSIMS spectra.

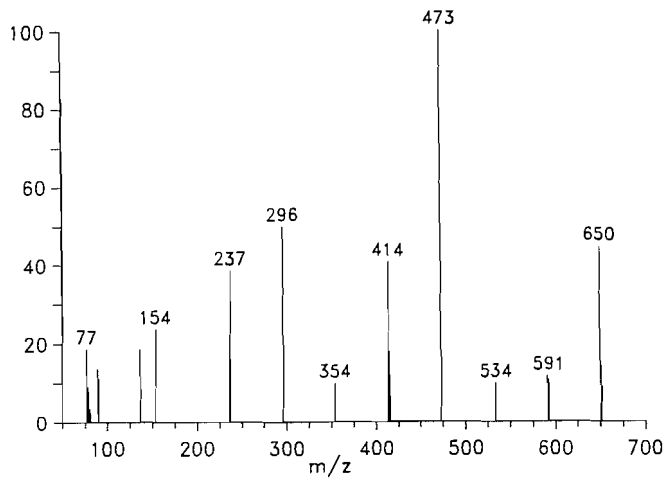

FIG. 1. Positive ion LSIMS spectrum of $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2\text{-}(RNC)]$ with RNC = **1** (R″ = Me). Peaks below *m/z* 200 may be attributed to the matrix (3-nitrobenzyl alcohol). The primary beam was Cs^+ at 25 keV (17 keV at the sample, maintained at 8 kV); static resolving power (10% valley definition) 1500, scan speed 5s/decade.

Results and discussion

The positive ion LSIMS spectrum of the neutral complex **2***a* with RNC = **1***b* is shown in Fig. 1. In Table 1 a summary of the sample-derived ions in this spectrum, and in analogous spectra of other complexes **2***a* of known structures, is given. In Table 1 only those ions with *m/z* values less than the molecular weight of the neutral complex **2***a* are reported. Ions at *m/z* 650, 592, 591, and 534 (Fig. 1) were observed in the spectra of all

TABLE 1. Major ions in the positive ion LSIMS spectra of neutral rhodium complexes **2***a*, $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2(RNC)]$, of known isocyanides RNC[a]

Isocyanide	*M*(RNC), u	*M*(**2**), u	*m/z*, observed
C_6H_5—NC	103	457	399, 341, 340, 296, 238, 237
$C_6H_5CH_2$—NC	117	471	413, 355, 354, 296, 238, 237
cyclo-C_6H_{11}—NC	109	463	405, 347, 346, 296, 238, 237
MeO_2C—$C(Me_2)$—NC	127	481	423, 365, 364, 296, 238, 237
$C_6H_5O_2C$—$C(Me_2)$—NC	189	543	485, 427, 426, 296, 238, 237
1, R″ = Me	177	531	473, 415, 414, 296, 238, 237

[a]Ions observed at *m/z* values greater than *M*(**2**) have been omitted (see text).

TABLE 2. Accurate mass measurements (from manual peak matching at 8 000 resolving power, 10% valley definition); precision of measurements 3–5 ppm

Assigned atomic composition	Mass		Deviation (ppm)
	Calculated	Measured	
$Rh(CH_2.C_5Me_4)$	237.0151	237.0144	3
$Rh(C_5Me_5)(SCN)$	295.9980	295.9965	5
$Rh_2(C_5Me_5)_2(SCN)$	534.0209	534.0199	2
$Rh_2(C_5Me_5)_2(SCN)_3$	649.9711	649.9736	4
$Rh(C_5Me_5)(SCN)(C_6H_5CH_2NC)$[a]	413.0559	413.0552	2
$Rh(C_5Me_5)(SCN)$ (**1**, R″ = Me)[b]	473.0770	473.0782	3

[a,b]$(M - CNS)^+$ ions from complexes **2** of known constitution, for RNC = benzyl isocyanide and **1** (with R″ = Me), respectively.

complexes **2***a* (R′ = Me) investigated in the present work, and thus do not contain the isocyanide moiety. The identities of these ions, as well as of the common low-mass ions at *m/z* 237, 238, and 296 (Table 1), are discussed below.

The same peaks were observed no matter which LSIMS matrix was used, although matrices incorporating thiol groups gave additional peaks corresponding to displacement of ligands by matrix-derived species; these extra peaks were intense in some cases, so such matrices were not suitable. However, use of glycerol, perdeuteroglycerol, and 3-nitrobenzyl alcohol gave simple spectra which were identical to one another, apart from mass peaks readily identifiable as derived directly from the matrix. Use of 3-nitrobenzyl alcohol yielded an ionization efficiency which was at least an order of magnitude greater than that achievable using glycerol, and most of the spectra reported here were obtained using the former matrix. The corresponding negative ion LSIMS spectra were dominated by thiocyanate anion, and did not provide information on the nature of the isocyanide ligand.

The monoisotopic molecular weight of the compound **2***a* with RNC = **1***b* is 531.0521, but the ion at *m/z* 534 (Fig. 1) is not a protonated molecular ion with an additional ligand H_2 (11) since the measured accurate mass (Table 2) is much too low. In addition, as noted above, this ion was observed in the spectra of *all* the complexes **2***a* studied in the present work, and therefore does not contain the RNC ligand. However, the accurate mass of the ion at *m/z* 473 (Table 2) of 473.0782 ($C_{21}H_{26}N_2O_2RhS$ requires 473.0770), corresponds to **3** with RNC = **1***b*, generated by the loss of the thiocyanate ion from the corresponding neutral complex **2***a*. This reaction was observed in the LSIMS spectra of all the model compounds studied (Table 1). The peak at *m/z* 354 in Fig. 1 corresponds to ionization of the neutral complex by expulsion of a $(RNC)^-$ anion (loss of 177 u in this case); this was the only example for which this process was observed to compete with the loss of thiocyanate (as the leaving group), and the process was not investigated further.

Further fragmentations of the $(M - SCN)^+$ ions were complex. Accurate mass measurements on the common fragment ions at *m/z* 296, 238, and 237 (Table 2) were not sufficient, in the absence of any other information, to uniquely specify the atomic compositions. However, if it is specified that these ions contain sub-structures comprised of Rh atoms, SCN^- groups, and (C_5Me_5) ligands, the results summarised in Table 2 do establish the atomic constitutions unambiguously. This question of the sub-structures in these ions, and related questions, were approached by exploiting techniques of tandem mass spectrometry and collision-induced dissociation (CID). Mass-selected ions were transmitted to the RF-only quadrupole *q* of the BEqQ tandem hybrid instrument; the experimental conditions thus involved low-energy collisional activation with a laboratory frame collision energy in the range 30–50 eV. For argon collision gas and the precursor ions studied, this translates into maximum ("elastic-limit") center-of-mass energies 2–7 eV. Multiple collision conditions were used to promote formation of lower mass fragments.

Figure 2 is the CID spectrum of the ion at *m/z* 473 (Fig. 1), the $(M - SCN)^+$ ion **3** (RNC = **1***b*). The most intense fragmentation provided the common (Table 1) fragment ion at *m/z* 296; the accurate mass of such ions formed in the ionization source (Table 2) agreed with an assigned structure $[(C_5Me_5)Rh(SCN)]^+$, and this was consistent with the CID spectrum of these ions (not shown) which comprised an intense peak at *m/z* 237 and a weaker one at *m/z* 238. Hence the fragmentation of the $(M - SCN)^+$ ions to form fragments at *m/z* 296 involves the loss of the neutral organic isocyanide ligand. This ion at *m/z* 296 and its homologue (at *m/z* 310) derived from complexes **2***b* with R′ = Et are of diagnostic importance because the molecular weights and elemental

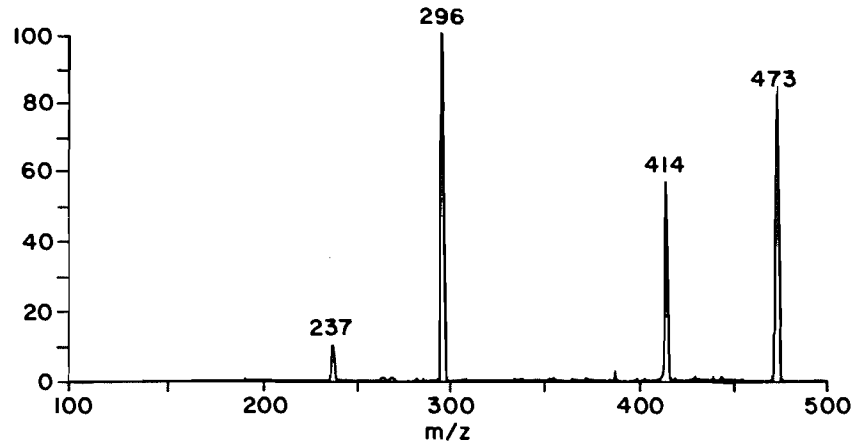

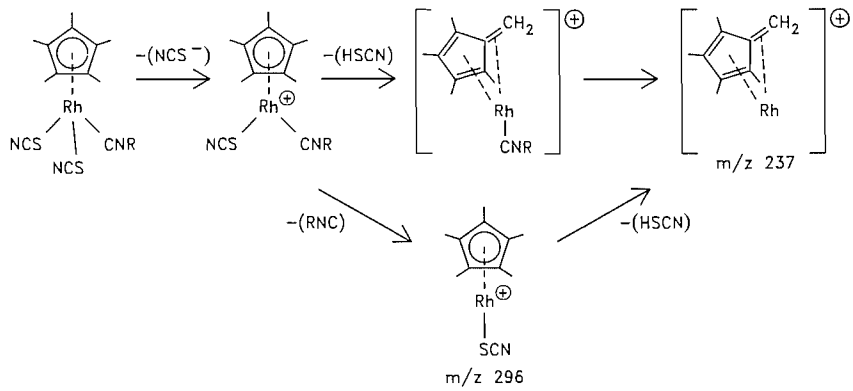

FIG. 2. Low-energy CID spectrum of the ion at m/z 473 in Fig. 1, formed as the $[M - (SCN)]^+$ ion by LSIMS of the rhodium complex **2** with RNC = **1** (R″ = Me). Laboratory-frame collision energy 30 eV, argon collision gas, 60% attenuation of intensity of precursor ion.

SCHEME 1

compositions of the isocyanide ligands can be deduced from the differences between the m/z values of these ubiquitous fragments and those of their $(M - SCN)^+$ precursors.

A competing fragmentation reaction of the $(M - SCN)^+$ ions, shown in Fig. 2, involves the loss of the elements HSCN (59 u). Similar reactions have been reported in the fast atom bombardment (FAB) mass spectra of compounds such as **4**, in which fragment ions observed to correspond to loss of a protonated ligand were formulated (8) as the *ortho*-metallated triphenylphosphine, **5**. In the reactions studied in this work the proton lost can originate only from the isocyanide or the cyclopentadienyl ligands. The former is less likely on the basis of the geometry of the Rh—C≡N—R system in the neutral complex **2***a* in the crystalline state (5), but evidence shown below (Fig. 4) suggests that the proton lost from the $(M - SCN)^+$ ions can originate from either the RNC or (C_5Me_5) ligand. The sequence shown in Scheme 1 is dominant at lower energies (Fig. 2), and is consistent with the accurate mass measurements (Table 2). The structure proposed for the fragment ion at m/z 237 (Scheme 1), incorporating a tetramethylfulvene ligand, suggests a related structure **6** for the fragment ion originally (8) assigned the formula **5**.

Some information on the question of the origin of the hydrogen atom, in the HSCN expelled from the $(M - SCN)^+$ ions, can be obtained from Figs. 3 and 4 which compare the CID spectra of the $[M - 2(SCN)]^+$ and $[M - (SCN) - (HSCN)]^+$ ions at m/z 415 and 414 (Fig. 1), respectively. According to the proposed interpretation these ions correspond to $[(C_5Me_5)Rh(RNC)]^+$ and $\{[(C_5Me_5)Rh(RNC)] - H\}^+$. The CID spectrum of $[(C_5Me_5)Rh(RNC)]^+$ (m/z 415) is shown in Fig. 3. As anticipated the dominant reaction corresponds to expulsion of the intact RNC ligand (177 u in this case) to form a fragment ion at m/z 238, presumably $[(C_5Me_5)Rh]^+$; only a trace of the ion at m/z 237 was observed. However, the situation is not entirely simple, since a fragment ion corresponding to loss of $CH_3\cdot$ is also observed (Fig. 3).

The CID spectrum of $\{[(C_5Me_5)Rh(RNC)] - H\}^+$ (m/z 414) is shown for comparison in Fig. 4. Now the product ion corresponding to the loss of intact RNC (at m/z 237 in this case) is of intensity comparable to that at m/z 238, arising from expulsion of (RNC − H). One possible rationalisation of this observation suggests that, in formation of m/z 414 by expulsion of HSCN from $[(C_5Me_5)Rh(SCN)(RNC)]^+$ ions (m/z 473), some of the expelled hydrogen atoms originated from the RNC moiety, and some from the C_5Me_5 ligand. Expulsion of (RNC − H), *i.e.* 176 u, from the former type of ions at m/z 414 would give the m/z 238 fragments, while expulsion of the intact RNC from the latter type would give the ions at m/z 237 (Fig. 4). Thus the fragment ion at m/z 238 is assigned as $[(C_5Me_5)Rh]^+$, consistent with mass shifts in the corresponding spectra (not shown) of ions derived from a homologous neutral complex **2** with RNC = **1** (R″ = Et); however, the fragmentation route shown in Scheme 1 was the dominant one in all examples studied here. The mass spectra of all the other model compounds (Table 1) can be rationalized by similar analyses.

All LSIMS spectra of the model compounds contained ions of

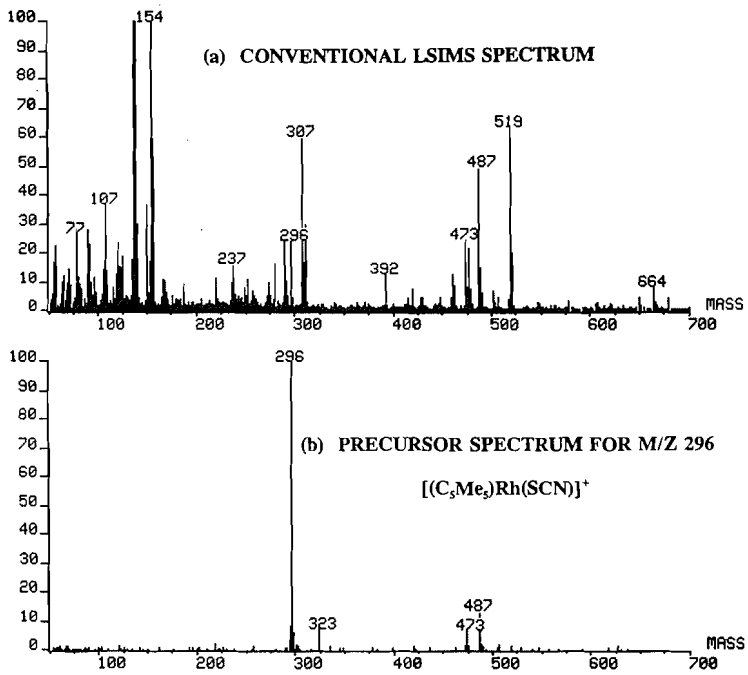

FIG. 5. Positive ion LSIMS spectra of the crude esterified ethyl acetate extract of a fermentation of *T. hamatum*, treated with excess $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2]_2$. (*a*) Conventional mass spectrum (magnet scan), with detection immediately following double-focus (BE) stage. (*b*) As (*a*), but quadrupole mass filter set to transmit *m/z* 296 and detection after the entire BEqQ train, *i.e.* a precursor scan for *m/z* 296. Conditions in the RF-only quadrupole collision cell *q* were laboratory-frame collision energy 30 eV, argon collision gas, 60% attenuation of intensity of precursor ion.

high abundance at *m/z* values greater than the molecular weight of the complex under study. Similar species have been reported (8) in the cases of other Rh and Ir coordination complexes, where they have been attributed to reactions of the complexes with components of the matrix. In the work reported here such an explanation is untenable because ions of the same mass were observed in spectra when four different matrices were used. The species *m/z* 650, 591, and 534 (Fig. 1) were present in the LSIMS spectra of all the compounds listed in Table 1 and hence did not contain an isocyanide ligand. In the LSIMS spectra of complexes **2***b*, with R′ = Et, a similar triad was observed at *m/z* 678, 619, and 562, *i.e.*, 28 u greater, implying the presence of two cyclopentadienyl groups. The accurate mass measurements (Table 2) of the ions at *m/z* 534 and 650 are consistent with the formulations $[(C_5Me_5)_2Rh_2(SCN)]^+$ and $[(C_5Me_5)_2Rh_2(SCN)_3]^+$, respectively. The same groups of ions were observed in the LSIMS spectra of the reagents $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2]_2$ and $[(\eta^5\text{-}C_5Me_4Et)Rh(SCN)_2]_2$, and thus the ions at *m/z* 650 and *m/z* 678 may be assigned to $[M - (SCN)]^+$ ions of these dirhodium reagents. Their appearance in the LSIMS spectra of the monorhodium complexes **2***a* implies that bimolecular reactions were proceeding in the ionization source under LSIMS conditions; this conclusion agrees with the observation that the intensities of these dirhodium ions, relative to that of the $(M - SCN)^+$ ions of **2***a*, increased markedly with increasing concentration of sample in the matrix. This hypothesis was also confirmed by examining the LSIMS spectrum of a mixture of the two homologous complexes **2***a* and **2***b* of the same isocyanide. In this case ions at *m/z* 534, 591, 650 and 562, 619, 678 were observed, exhibiting the expected 28 u shifts. In addition, however, a third group of ions at 548, 605, and 664 (*i.e.* 14 u shifts) were present, clearly indicating the occurrence of cross-reactions producing species containing one (C_5Me_5) and one (C_5Me_4Et) ligand.

The question of whether these cross-reactions occurred in the liquid matrix, or in the gas phase immediately above the matrix, was explored using a dual-target sample probe (VG Analytical). Complex **2***a* was loaded on one target, and **2***b* on the other, both in 3-nitrobenzyl alcohol as matrix. The primary beam of Cs^+ ions was adjusted (defocussed) so that both of the targets were activated simultaneously. No cross-reaction products were observed in the secondary ion mass spectrum under these conditions. Thus it is unlikely that the dimerization occurs in the gas phase, though it is possible that the reaction proceeds in the "selvedge" region immediately above the irradiated surface.

The complexes **2** of the model isocyanide compounds were easily separated on analytical tlc plates, where quantities of about 0.5 μg could be detected by sight and 0.05 μg detected by reflected ultraviolet light at 254 nm. Such spots could be eluted by treatment with 3-nitrobenzyl alcohol as described in the Experimental section and excellent mass spectra obtained (*e.g.* Fig. 1) by transferring 1–2 μL of the solution to the probe. An alternative procedure for analysis of isocyanide mixtures, eliminating a chromatographic step, was also investigated. In a mixture of isocyanide complexes **2***a* all provide the daughter ion at *m/z* 296. Thus a scan of the ion reactions leading to *m/z* 296 should reveal parent ions whose masses correspond to the $[(\eta^5\text{-}C_5Me_5)Rh(SCN)(NCR)]^+$ ions for various isocyanide ligands. Figure 5(*a*) is an LSIMS spectrum of the crude esterified ethyl acetate extract of a fermentation of *T. hamatum*, treated with excess $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2]_2$, while Fig. 5(*b*) is a precursor scan for *m/z* 296 conducted on the same extract. Useful information is difficult to detect in Fig. 5(*a*) but Fig. 5(*b*) shows signals at *m/z* 473 and 487, corresponding to the

metabolite methyl esters **1***b* and **7** (R″ = Me). Further work on this rapid screening analytical method is envisaged.

The present work has shown that positive ion LSIMS spectra of complexes **2**, exemplified by Fig. 1, are interpretable in a self-consistent manner to yield the nominal mass of the isocyanide ligand RNC. Indeed mass measurements on the $(M - SCN)^+$ ions give, after subtracting the mass (295.9980) of the $[(\eta^5\text{-}C_5Me_5)Rh(SCN)]$ moiety, the accurate mass and thus information concerning the atomic constitution of RNC; experimental uncertainties in such mass differences will be of the order of 10 ppm. Identification of the $(M - SCN)^+$ ions can be made via the spectral clues discussed in relation to Table 1, and if necessary confirmed by simple tandem mass spectrometry experiments (Fig. 2). The present work also confirms the remarkable properties of 3-nitrobenzyl alcohol as a matrix for LSIMS of transition metal complexes (12).

Experimental

Melting points are not corrected. Infrared spectra were measured on a Perkin-Elmer 283 instrument, and ^1H and ^{13}C nmr spectra in 5 mm tubes on a Bruker MSL-300 instrument at 300 and 75 MHz, respectively. Chemical shifts are given in ppm downfield from the signal of tetramethylsilane. Mass spectra were obtained using a hybrid tandem instrument of BEqQ configuration (ZAB-EQ, VG Analytical, Manchester, U.K.) with a VG 250J data system. A VG Analytical cesium ion gun, operated at a beam energy of 25 keV (and thus an effective energy of 17 keV at the sample probe maintained at 8 kV) was used to provide the primary ion beam for LSIMS. Four liquid matrices were used: dithioerythritol–dithiothreitol (5:1), glycerol, glycerol[$^2H_8$], and 3-nitrobenzyl alcohol. The first three were used as received, the last was distilled under reduced pressure and the middle-third fraction used. Accurate mass measurement (8×10^3 resolving power, 10% valley definition, precision 3–5 ppm) were made by the peak matching method, using either matrix-derived ions or ions derived from alkali iodides added to the matrix as standards. Tandem mass spectrometry involved the selection of precursor ions by the double-focussing (BE) analyser followed by collision-induced dissociation of mass-selected ions in the RF-only quadrupole (q), using a laboratory frame collision energy in the range 30–50 eV and argon collision gas at a pressure sufficient to attenuate the intensity of the precursor ion beam to 50–60% of its initial value.

Mass spectrometry of isocyanide complexes from analytical tlc plates was achieved as follows. The yellow (or orange) spot on the chromatogram was scraped from the plate into a vial and the mixture treated with 3-nitrobenzyl alcohol (50 μL). The mixture was agitated for 2 min, the silica allowed to settle under gravity, and 2 μL of the supernatant liquid transferred to the tip of the direct introduction probe using a syringe; the probe was inserted into the source immediately. In general there was sufficient material for a LSIMS spectrum and for a mass measurement of the $M - 58^+$ ion in a spot containing *ca.* 0.5 μg of the complex. Tetrahydrofuran (THF) was distilled from lithium aluminum hydride immediately before use.

Reaction of phenyl isocyanide with $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2]_2$

A solution (20 mL) of the rhodium complex (72 mg) in dichloromethane was treated with phenyl isocyanide (ref. 13, 20 mg). After 1 h the solution was concentrated and the concentrate (0.5 mL) applied to two preparative layer chromatography (plc) plates (20 × 20 × 0.1 cm). The plates were developed with methyl alcohol – dichloromethane (1:39) and the main orange band eluted from the silica with THF. The eluate was evaporated and the *complex* ($\eta^5\text{-}C_5Me_5Rh(SCN)_2.CNC_6H_5$) separated from ethyl acetate as stout rods, mp 160–162°C. *Anal.* calcd. for $C_{19}H_{20}N_3RhS_2$: C 49.9, H 4.4, N 9.2, Rh 22.5, S 14.0; found: C 49.6, H 4.4, N 9.4, Rh 22.4, S 13.8. δ_C 130.7, 129.7, 127.3, 121.75 (2CNS), 103.4 (5C $J_{^{13}C,Rh}$ 5 Hz), 9.3 (5C).

Preparation of $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2(CNCH_2C_6H_5)]$

A solution of the dirhodium complex reagent (ref. 5, 210 mg) in dichloromethane (15 mL) was treated dropwise with a solution (2 mL) of benzyl isocyanide (Aldrich, 30 mg) in dichloromethane. After 2 h at room temperature the reaction solution was concentrated to 2 mL and the concentrate applied to a Florisil (25 g) column (20 × 2 cm). The column was eluted successively with dichloromethane (100 mL), and dichloromethane – methyl alcohol mixtures as follows: 99:1 (100 mL), 49:1 (200 mL), 19:1 (1200 mL), 9:1 (100 mL), and 4:1 (100 mL, containing 1% NaSCN). The product was eluted in the dichloromethane – methyl alcohol (49:1) fraction, and excess reagent appeared in the final fraction. The eluate (49:1) was concentrated to 5 mL, diethyl ether (15 mL) added, and the orange–yellow precipitate (93 mg) collected. The complex separated from ethyl acetate as orange needles, mp 135–136°C. *Anal.* calcd. for $C_{20}H_{22}N_3RhS_2$: C 50.96, H 4.7, N 8.9, Rh 21.8, S 13.6; found: C 51.0, H 4.7, N 9.0, Rh 21.4, S 13.3. Infrared ν_{max} (CH_2Cl_2) 2210, 2102 cm^{-1}; δ_H (C^2HCl_3) 7.5–7.3 (m, 5H), 5.1 (s, 2H), 1.81 (s, 15H).

Preparation of the cyclohexylisocyanide complex of $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2]$

This complex was prepared from cyclohexylisocyanide (10) on the same scale and in the same way as the benzyl isocyanide complex. The crude product was purified by plc. The major orange band that separated on developing the plate with methyl alcohol – dichloromethane (1:49) was eluted with THF, the eluate evaporated, and the residue recrystallized from ethyl acetate giving the complex as glistening orange leaflets, mp 132–134°C. Anal. calcd. for $C_{19}H_{26}N_3RhS_2$: C 49.2, H 5.7, N 9.1, Rh 22.2, S 13.8; found: C 49.2, H 5.7, N 9.0, Rh 21.8, S 13.5. Infrared ν_{max} (CH_2Cl_2) 2205, 2105 cm^{-1}; δ_C 121.75 (*C*NS), 102.44 (d, $J_{^{13}C,Rh}$ 6 Hz), cyclopentadienyl ring carbons), 55.7 (cyclohexyl methine carbon atom), 32.2, 24.67, 22.82 (cyclohexyl methylene carbons), 9.13 (5 *C*H_3). The isocyanide carbon atom bonded to rhodium was not detected in the proton decoupling experiments (*cf.* ref. 14).

Phenyl 2-N-benzyloxycarbonylamino-2-methylpropionate

2-*N*-Benzyloxycarbonylamino-2-methylpropionic acid (ref. 15, 11.8 g) was suspended in dichloromethane (75 mL) and phenol (5 g) added. When all the solids had dissolved, dicyclohexylcarbodiimide (10.5 g) was added. The mixture was stirred at room temperature for 18 h, when the precipitated urea was removed by filtration, the filtrate evaporated, and the oily residue taken up in toluene (30 mL). The toluene solution was filtered, the filtrate washed with sodium bicarbonate solution (1%, 3 × 100 mL), dilute HCl (*N*, 50 mL) and finally with water. The solution was dried over Na_2SO_4, filtered, and evaporated to give an oil (16 g) which crystallised on standing. The majority of this product was dissolved in boiling petroleum ether (bp 60–80°C, 600 mL). The filtered solution was cooled very slowly, seeded at the first sign of opalescence, and maintained at 4°C for 24 h. The *phenyl ester* separated as colorless rods, mp 61–62°C. *Anal.* calcd. for $C_{18}H_{19}NO_4$: C 69.0, H 6.1, N 4.5, O 20.4; found: C 69.0, H 6.2, N 4.6, O 20.2. Infrared ν_{max} (CCl_4) 3450, 3430, 1760, 1730, 1460, 1280, 1125 cm^{-1}.

Preparation of the phenyl 2-isocyano-2-methylpropionate complex of $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2]$

The phenyl ester (3.6 g, see preceding paragraph) was dissolved in ethyl formate (75 mL) and formic acid (0.1 mL) added. The solution was treated with palladium on carbon (10%, 0.12 g) and the mixture shaken with hydrogen at 3 atm pressure for 18 h. The shaking should start as soon as possible to prevent crystallisation of the formate on the carbon, thus rendering the catalyst ineffective. Methanol (100 mL) was then added to the reaction mixture, which was filtered through a bed of Celite 545 (1 cm thick), and the filtrate evaporated. The crystalline residue was taken up in hot ethyl acetate (90 mL) and the filtrate kept at 4°C for 24 h. *Phenyl 2-N-formylamino-2-methylpropionate* separated as colorless needles, mp 133–135°C (some sublimation above 110°). *Anal.* calcd. for $C_{11}H_{13}NO_3$: N 6.7, found: N 6.4. This ester (0.25 g) was treated with a solution (3 mL) of triethylamine (6.05 mL) in dichloromethane (25 mL). The solution was introduced into a flame-dried, nitrogen-filled vessel and was stirred and cooled to −5°C. A solution (0.5 mL) of phosphorus oxychloride (2.17 g) in dichloro-

methane (5 mL) was added to the reaction solution with a syringe over a period of 40 min, while maintaining the temperature at −5°C. After a further 1 h at −5°C the reaction mixture was allowed to warm to room temperature and was stirred under nitrogen for 18 h. The mixture was treated with a solution (5 mL) of sodium bicarbonate (0.52 g) and was then diluted with 5 mL of dichloromethane. The phases were separated and the aqueous phase extracted with dichloromethane (2 × 5 mL). The extracts were combined and freeze–dried at −15°C for 18 h. The ice was filtered off, the filtrate treated with $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2]_2$ (100 mg), and the reaction mixture kept at ambient temperature for 3 h. The resulting solution was concentrated to 3 mL and the concentrate applied to two plc plates, which were developed with dichloromethane–methyl alcohol (19:1). The orange band of greatest R_F was eluted with THF and the eluate evaporated. The residue (70 mg) was chromatographed as before, and the crystalline residue remaining after evaporation of the THF collected (30 mg, mp 149–152°C). The *complex* separated from butyl acetate – isopropyl ether (1:3) as orange needles (mp 150–152°C). *Anal.* calcd. for $C_{23}H_{26}N_3O_2RhS_2$: C 50.8, H 4.8, N 7.7, Rh 18.9, S 11.8; found: C 50.5, H 4.8, N 7.8, Rh 18.4, S 11.8. Infrared ν_{max} ($CHCl_3$) 2205, 2114, 1769, 1725 cm^{-1}; δ_H (C^2HCl_3), 7.1–7.5 (m, 5H), 2.04 (s, 6H), 1.88 (s, 15H); *m/z* 485.0767 ($(M - SCN)^+$, $C_{22}H_{26}N_2O_2RhS$ requires 485.0770).

Preparation of the methyl 2-isocyano-2-methylpropionate complexes of $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2]$ and $[(\eta^5\text{-}C_5EtMe_4)Rh(SCN)_2]$

Methyl 2-isocyano-2-methylpropionate (ref. 16, 63 mg) was dissolved in dichloromethane (5 mL) and treated with a solution (10 mL) of $[(\eta^5\text{-}C_5Me_5)Rh(SCN)_2]_2$ (170 mg) in dichloromethane. The resulting orange solution was kept at room temperature overnight, then concentrated to 1 mL and the concentrate applied to two plc plates which were developed with dichloromethane – methyl alcohol (93:7). The main orange band was eluted with THF. The complex separated from butyl acetate as yellow needles, mp 138–139°C. *Anal.* calcd. for $C_{18}H_{24}N_3O_2RhS_2$: C 44.9, H 5.0, N 8.7; found: C 44.7, H 5.0, N 8.9. δ_H 3.86 (3H), 1.86 (15H), 1.83 (6H). The homologous complex (R′ = Et) was prepared in exactly the same way using $[(\eta^5\text{-}C_5EtMe_4)Rh(SCN)_2]_2$ (200 mg) and methyl 2-isocyano-2-methylpropionate (60 mg). The complex separated from butyl acetate – isopropyl ether (1:3) as orange needles, mp 74°C. *Anal.* calcd. for $C_{19}H_{26}N_3O_2RhS_2$: C 46.1, H 5.3, N 8.5; found: C 45.9, H 5.3, N 8.3. δ_H 3.85 (s, 3H; ester methyl protons), 2.36 (q, *J* 7.7 Hz, 2H; methylene protons on cyclopentadienyl ring), 1.88 (s, 12H; protons on methyl groups directly bonded to cyclopentadienyl ring), 1.86 (s, 6H; methyl protons on isopropyl moiety), 1.14 (t, *J* 7.7 Hz, 3H; methyl protons on ethyl substituent on cyclopentadienyl ring).

Received June 28, 1990

YING MU, CLARE AITKEN, BRUNO COTE, JOHN F. HARROD, and EDMOND SAMUEL. Can. J. Chem. **69**, 264 (1991).

A systematic comparison between the dimethylzirconocene (DMZ) and dimethyltitanocene (DMT) catalyzed dehydrocoupling of organosilanes is reported. The polymerization rates of primary silanes are about ten times faster for DMZ than for DMT, but the characteristics of the polymers produced are essentially identical. Variations of molecular weight and molecular weight distribution with varying monomer and reaction time, and the relative amounts of linear and cyclic polymer are also essentially the same for the two catalysts.

Oligomerizations of phenylmethylsilane, diphenylsilane, and 1,2-diphenyldisilane are described. The compound Cp_2Zr-(SiPhMeH)(μ-H)$_2$(SiPhMe$_2$)ZrCp_2 (**1***b*) is isolated from the reaction of phenylmethylsilane with DMZ and its structure confirmed by crystallography and ^{1}H-NMR spectroscopy. The compound $Cp_2Zr(Me)(\mu\text{-}H)_2(SiPh_2H)ZrCp_2$ (**1***d*) is isolated from the reaction of diphenylsilane with DMZ and its structure assigned by NMR spectroscopy. A number of other hydride bridged species are observed by ^{1}H-NMR in the reactions of DMZ with phenylmethyl-, diphenyl-, and *n*-butylmethylsilanes and their structures are tentatively assigned. The implications of these observations on the mechanism of transformation of DMZ into active catalyst and our current views of the polymerisation mechanism are also discussed.

Key words: silanes, dehydrocoupling, titanocene, zirconocene, polysilanes.

YING MU, CLARE AITKEN, BRUNO COTE, JOHN F. HARROD et EDMOND SAMUEL. Can. J. Chem. **69**, 264 (1991).

On a effecté une comparaison systématique du déshydrocouplage des organosilanes, catalysé par le diméthylzirconocène (DMZ) et par le diméthyltitanocène (DMT). Les vitesses de polymérisation des silanes primaires sont environ dix fois plus rapides avec le DMZ qu'avec le DMT; toutefois, les caractéristiques des polymères obtenus sont essentiellement identiques. Les variations des masses moléculaires et des distributions des masses moléculaires en fonction du monomère et du temps de réaction ainsi que les quantités relatives des polymères linéaires et cycliques sont aussi essentiellement les mêmes pour les deux catalyseurs.

On décrit les oligopolymérisations du phénylméthylsilane, du diphénylsilane et du 1,2-diphényldisilane. On a isolé le composé Cp_2Zr(SiPhMeH)(μ-H)$_2$(SiPhMe$_2$)ZrCp_2 (**1***b*) de la réaction du phénylméthylsilane avec le DMZ et on a confirmé sa structure par cristallographie et par RMN du ^{1}H. On a isolé le composé $Cp_2Zr(Me)(\mu\text{-}H)_2(SiPh_2H)ZrCp_2$ (**1***d*) du mélange réactionnel du diphénylsilane avec le DMZ et on a attribué sa structure à l'aide de la spectroscopie RMN. En se basant sur la rmn du ^{1}H, on a observé un certain nombre d'autres espèces pontées par de l'hydrure dans les mélanges réactionnels du DMZ avec les phénylméthyl-, diphényl- et *n*-butylméthylsilanes et on leur a attribué des structures provisoires. On discute aussi des implications de ces observations sur le mécanisme de transformation du DMZ en catalyseur actif et sur nos vues actuelles concernant le mécanisme de polymérisation.

Mots clés : silanes, déshydrocouplage, titanocène, zirconocène, polysilanes.

[Traduit par la rédaction]

Introduction

In earlier papers we have described the exceptional activity of bis(cyclopentadienyl)dialkylzirconium complexes for the catalytic dehydrocoupling of silanes (1–4). Since our original report, a number of other groups have made important observations on this reaction. Tilley and co-workers have developed general methods for synthesis of silylzirconium complexes and shown how these complexes can generate Si—Si bonds through σ-bond metatheses with other Si—H compounds (5–9). Corey *et al.* have demonstrated catalytic oligomerizations of secondary silanes at higher temperatures with catalysts generated in situ by reaction of zirconocene(IV) chloride with butyl lithium (10–12). Campbell *et al.* have provided unequivocal evidence for the predominant production of cyclic oligosilanes by polymerization of *n*-butylsilane with dimethylzirconocene (13).

In this paper we present the results of a detailed comparison between dimethylzirconocene (DMZ) and dimethyltitanocene (DMT) (14–16) as catalysts for the polymerization of some primary and secondary silanes. The structures and NMR spectra of some important intermediates in these catalytic reactions are also discussed.

Results and discussion

Polymerization of primary organosilanes

DMZ exhibits almost identical behavior to DMT in catalyzing the polymerization of primary organosilanes. The only dramatic differences between the two systems are the pronounced induction period for the titanium catalyzed reaction and the essentially complete reduction of the titanium to Ti(III) at the onset of polymerization. The zirconium catalyzed reaction exhibits a slight autoacceleration in the course of the reaction at low catalyst, or monomer, concentrations, but no obvious induction period. In addition, although paramagnetic Zr(III) species are observable in reaction mixtures by EPR spectroscopy, most of the zirconium remains in the form of NMR-observable Zr(IV) species throughout the reaction. A typical reaction profile for a DMZ-catalyzed polymerization of phenylsilane is shown in Fig. 1*b*.

The evolution of the reaction products may be followed by ^{1}H-NMR spectroscopy. Although 1,2-diphenyldisilane is

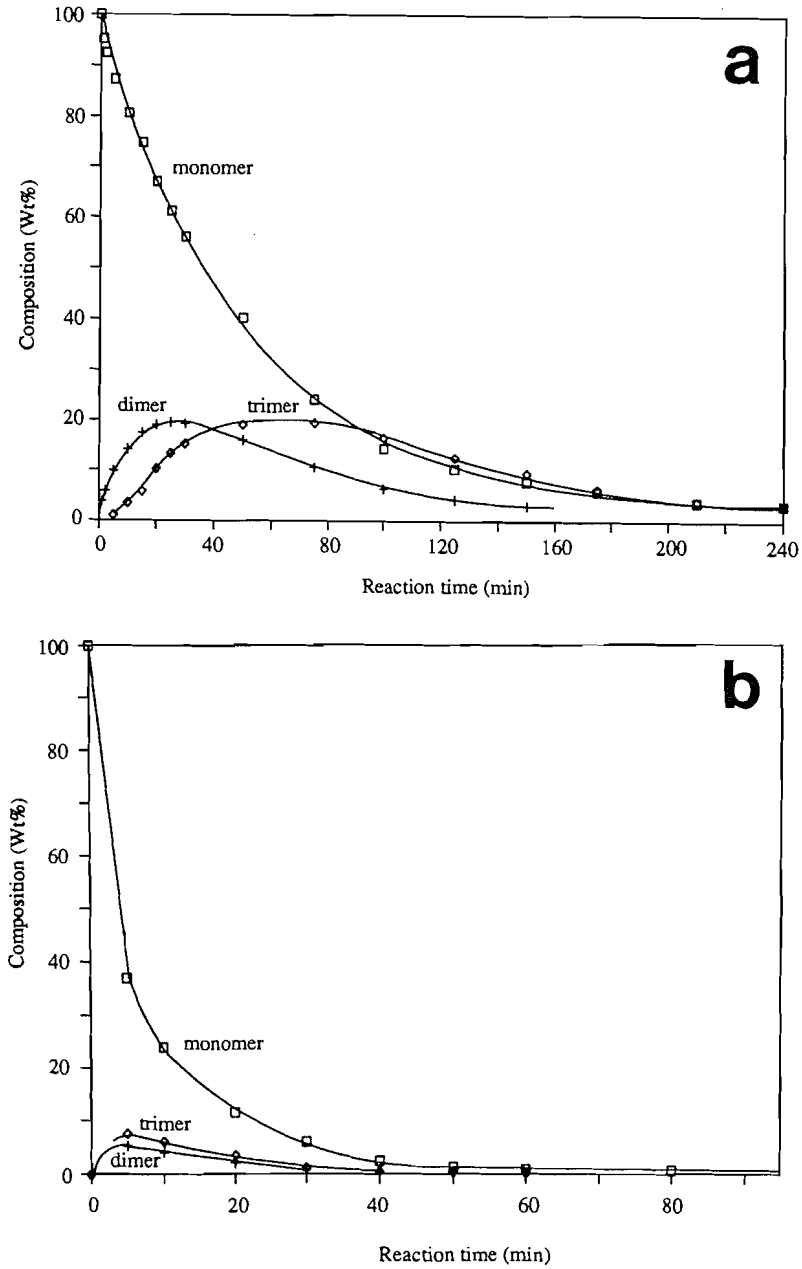

FIG. 1. Reaction rate profile for the polymerisation of phenylsilane catalysed by (*a*) DMT. $[DMT]_i$ = 0.08 M, neat $PhSiH_3$; (*b*) DMZ: $[DMZ]_i$ = 0.04 M, $[PhSiH_3]_i$ = 3.0 M. T = 20°C in both cases.

observable as a product of the reaction, its concentration never rises to more than about 5% of the initial monomer concentration with the DMZ catalyst. We had earlier claimed that no dimer is produced in the DMT-catalyzed reaction (14). This incorrect claim was based on our failure to observe dimer (or any other identifiable oligomer) during the polymerization reaction. More recently we have found that the NMR signals for the dimer are greatly broadened in the presence of the active titanium catalyst, probably as a result of a rapid equilibrium between disilane and the catalyst, and the catalyst must either be destroyed by oxidation, or removed, in order to observe the dimer and trimer at room temperature. Even in the presence of catalyst, these species can be observed at lower temperature (ca. −20°C). Using such procedures it was established that the DMT-catalyzed polymerization leads to a maximum accumulation of about twenty per cent of dimer in the initial stages of the reaction, as illustrated in Fig. 1*a*.

The complex, and different, reaction rate profiles make absolute comparison of the reactivities of the two catalysts difficult. The use of either maximum rates, or times to achieve 80% conversion, lead to the same conclusion: that the DMZ-catalyzed polymerization of phenylsilane is about an order of magnitude faster than the DMT reaction under ambient conditions. The results of a comparison of relative rates for three different primary silanes, shown in Table 1, reveal little difference between the two catalyst systems. No significance can be attached to the small numerical differences since the titanium data were based, in this particular case, on initial rates of reactions where the hydrogen product was completely scavenged by co-hydrogenation of cyclohexene (17), while

TABLE 1. Relative rates of polymerization of some primary organosilanes with DMT[a] and DMZ[b]

Monomer	Relative rates		
	$PhSiH_3$	$BzSiH_3$	$HxSiH_3$
DMT	13	1	1
DMZ	100	15	5

[a]Data from ref. 16.
[b][DMZ] = 0.020 M; $[silane]_i$ = 1.20 M; in C_6D_6 at 20°C.

the zirconium data are maximum rates. The co-hydrogenation technique could not be applied to the DMZ system since the zirconium is much less active as a hydrogenation catalyst and hydrogen scavenging is only about 50% efficient.

On the basis of their broad, poorly resolved NMR spectra all of the polymers produced with these catalysts may be assumed to be atactic and, within the limits of accuracy of NMR integration, to have the average composition (RSiH). The extreme broadness and lack of resolution of the NMR peaks is attributed to the atacticity of the polymers. The ^{29}Si(DEPT) spectra, with suitable pulse angles for the detection of SiH and SiH_2, reveal the presence of SiH_2 units in the polyphenyl- and polyhexylsilane samples synthesised with DMZ, but no SiH_2 was detected in the polybenzylsilanes. It may therefore be concluded that the phenyl and *n*-hexyl polymers contain at least some linear species, while the benzyl polymer consists uniquely of cyclics. Essentially the same behaviour was reported previously for the DMT catalysed reactions (16).

The molecular weights and molecular weight distributions of the polymers produced by the two catalysts are also remarkably similar. Unfortunately, for both systems, the average degrees of polymerization fall in an awkward range (ca. 10 to 20), where the molecules are a bit too small to be adequately described in purely statistical terms, yet a bit too large to achieve separations of stereoisomers and define exact structures. Nevertheless, the application of a number of different physico-chemical techniques allows some reasonably firm conclusions regarding the structures and compositions of the products.

The phenyl and hexyl polymers give bimodal GP chromatograms with a very narrow distribution low molecular weight fraction and a somewhat broader distribution higher molecular weight fraction. A number of representative chromatograms are illustrated in Fig. 2. Two features of these chromatograms should be noted. In the first place, the formation of the higher molecular weight fraction is favoured by high monomer concentrations. Secondly, very long contact times with the catalyst lead to a reversion of the higher molecular weight fraction to lower molecular weight species. Both of these patterns of behaviour are what would be expected if the lower molecular weight fraction consists of cyclics. In the first case, the formation of cyclics is favoured by low monomer concentration since intramolecular ring closure will be favoured relative to a linear propagation effected via an intermolecular reaction of monomer with the propagating species. In the second case the cyclics result from a classical back-biting depolymerization reaction whose rate becomes more and more significant relative to propagation as the concentration of SiH decreases. These observations also conform with the observation that the polybenzylsilane, which ^{29}Si-NMR indicated to contain no linear species, gives a monomodal chromatogram of narrow dispersity. The polydispersities of the samples in Fig. 2 range from 1.3 to 1.7.

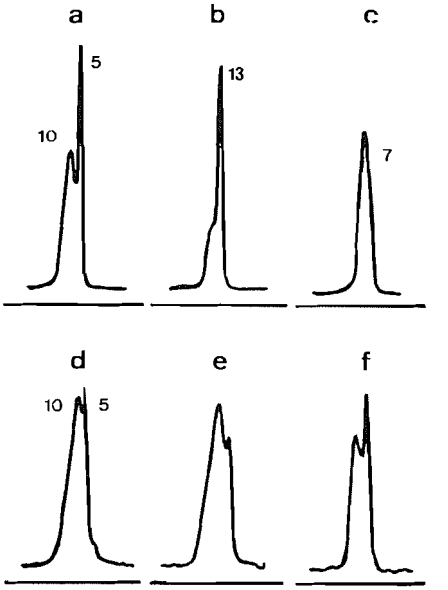

FIG. 2. Some representative chromatograms for polysilanes produced with DMZ catalyst, $[DMZ]_i$ = 0.075 M; toluene solvent; 20°C. (*a*) Poly(phenylsilane), $[PhSiH_3]_i$ = 4.0 M, 20 days; (*b*) poly(*n*-hexylsilane), $[HxSiH_3]_i$ = 3.1 M, 20 days; (*c*) poly(benzylsilane), $[BzSiH_3]_i$ = 3.7 M, 20 days; (*d*) poly(phenylsilane), $[PhSiH_3]_i$ = 4.0 M, 1 day; (*e*) poly(phenylsilane), $[PhSiH_3]_i$ = 4.0 M, 3 days; (*f*) poly(phenylsilane), $[PhSiH_3]_i$ = 2.0 M, 1 day. The figures next to the peaks are the calculated peak maximum degrees of polymerization.

Oligomerization of secondary silanes

We have recently described the stoichiometric reactions of secondary silanes with DMT in some detail (18). Secondary silanes react readily with DMT, in the presence of coordinating ligands, to give titanocene(III)silyl complexes, analogous to those obtained with primary silanes (18). They do not, however, give the binuclear titanocene(III)silyl complexes, readily obtained with primary silanes (15, 18), in the absence of coordinating ligands. In addition, the secondary silanes show very low reactivity under conditions where primary silanes are rapidly dehydrocoupled by catalytic amounts of dialkyltitanocenes. Structural evidence suggests that steric hindrance may prevent formation of both the titanocene(III)silyl dimer and the necessary transition state for dehydrocoupling in the case of secondary silanes (18).

DMT does not couple secondary silanes at an appreciable rate at room temperature. At temperatures in the range of 60–80°C, with the use of relatively high catalyst concentrations, and in the absence of solvent, diphenyl- and phenylmethylsilanes can be coupled. In the case of diphenylsilane, only the dimer is produced, but with sufficiently long reaction times the reaction goes eventually to completion. In the case of phenylmethylsilane the rate of dehydrocoupling is slightly faster than that for diphenylsilane and both the dimer and trimer are produced. At very long reaction times, conversions of up to 70% of trimer have been obtained, but no tetramer has been detected. A typical reaction profile for DMT catalysed phenylmethylsilane oligomerisation is shown in Fig. 3*a*.

We have previously reported the dimerization of secondary silanes with DMZ (1). More recently Corey *et al.* have shown that catalysts generated *in situ* by reaction of dichlorozircono-

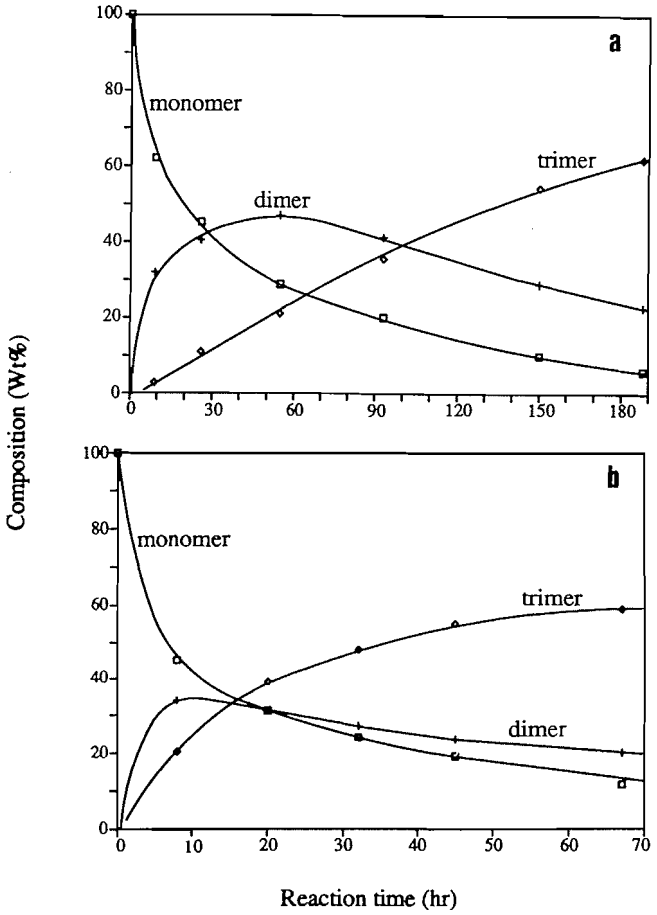

FIG. 3. Evolution of reaction products for oligomerizations of phenylmethylsilane catalyzed by (*a*) DMT, $[DMT]_i = 0.22$ M; (*b*) DMZ, $[DMZ]_i = 0.20$ M. $T = 80°C$ and reactions in neat $PhMeSiH_2$ in both cases.

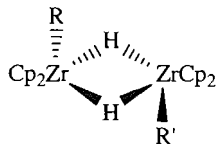
cene with butyl lithium can oligomerise secondary silanes to products containing several silicon atoms (12). Except for a slightly higher catalytic activity (ca. ×5), DMZ gives essentially the same results with diphenyl and phenylmethylsilanes (see Fig. 3*b*) as obtained with DMT. In particular, we note the failure of the DMZ catalyst to give any oligomers higher than the dimer for diphenylsilane and the trimer for phenylmethyl silane. It is possible that the difference between the results of Corey *et al.* and ours, with regard to the observation of higher oligomers, is due to the effect of excess alkyl lithium in the *in situ* generated catalyst system. In work to be described elsewhere, we have found that excess methyl lithium can have a large effect on the molecular weight of polyphenylsilanes produced with *in situ* generated dimethyltitanocenes.

Neither DMT nor DMZ catalysed the coupling of butylmethylsilane under any condition of concentration, or temperature that were tried.

A dramatic exception to the general behavior described above is the oligomerisation of 1,2-diorganodisilanes. Although formally secondary silanes, these compounds polymerise even more rapidly than their analogous monomers, with both titanium and zirconium based catalysts. It is this behavior which prevents the build up of dimer in the system when starting from monomer and which seems to put the group 4-metallocenes in a category apart from catalysts derived from other transition groups. In all cases of the latter, there is a clear stepwise polymerisation passing from monomer to dimer to trimer etc. (2, 19).



A reaction profile for the polymerization of 1,2-diphenyldisilane is shown in Fig. 4. No trimer was detected in this reaction. Since the NMR resonances of the tetramer and of higher oligomers overlap, it is not possible to estimate the concentration of these species accurately. However, it is clear, from both GPC and ^{29}Si-NMR measurements, that the main initial product is the tetramer and that the reaction is proceeding by dehydrocoupling. The small amount of monomer produced is perhaps due to a catalytic disproportionation reaction, such as shown in reaction [1]. The small amount of trimer, which should also result from such a disproportionation, could have escaped detection because of the greater linewidth of the Si—H resonance relative to that of the dimer and monomer.

[1] $$n H_2PhSiSiPhH_2 \rightarrow (n-1)PhSiH_3 + H_2PhSi(SiPhH)_nH$$

The greater reactivity of the disilane can be attributed, at least in part, to the lower bond energy of a silicon substituted SiH species, relative to one that has no Si—Si bond (20). The bond energy argument is not sufficient to explain the peculiar activity of the group 4 catalysts, since the same effect would be expected to apply to other catalysts, such as vanadocene, which in fact are less active towards the dimer than to the monomer and which produce trimer, rather than tetramer, as the secondary product (2).

Products of reactions of silanes with DMZ

In a preliminary communication we reported the isolation and characterization of the unusual bimetallic silylzirconocene-hydride complex **1***a* from the reaction of DMZ with phenylsilane (1). NMR studies of both stoichiometric and catalytic reactions of phenylsilane and DMZ showed **1***a* to be produced almost quantitatively (ca. 90%) in the early stages of the reaction, and with the passage of time appreciable quantities of other species, both diamagnetic and paramagnetic, were produced. The structural assignment of **1***a* was based on ^{1}H- and ^{29}Si-NMR data and on a single crystal X-ray structure. The quality of the X-ray structure was poor due to a severe disorder problem, resulting from the ordered superposition of the two enantiomers of **1***a* in the crystal, but was sufficiently good to confirm the structure assignment. We have now isolated compound **1***b* from the reaction of methylphenylsilane with DMZ. The compound appeared to give excellent single crystals, but attempts to resolve the X-ray structure were again frustrated by the same type of disorder as encountered in **1***a*. The manner

in which the two superposed enantiomers lead to a symmetric electron density map is illustrated in Scheme 1. Crystal data, collection and refinement parameters are listed in Table 2. A listing of atomic coordinates and isotropic thermal parameters is given in Table 3. Although the residuals are at the margin of acceptability, the X-ray data confirm the structure assignment based on NMR data. The ^{1}H-NMR spectrum is shown in Fig. 5.

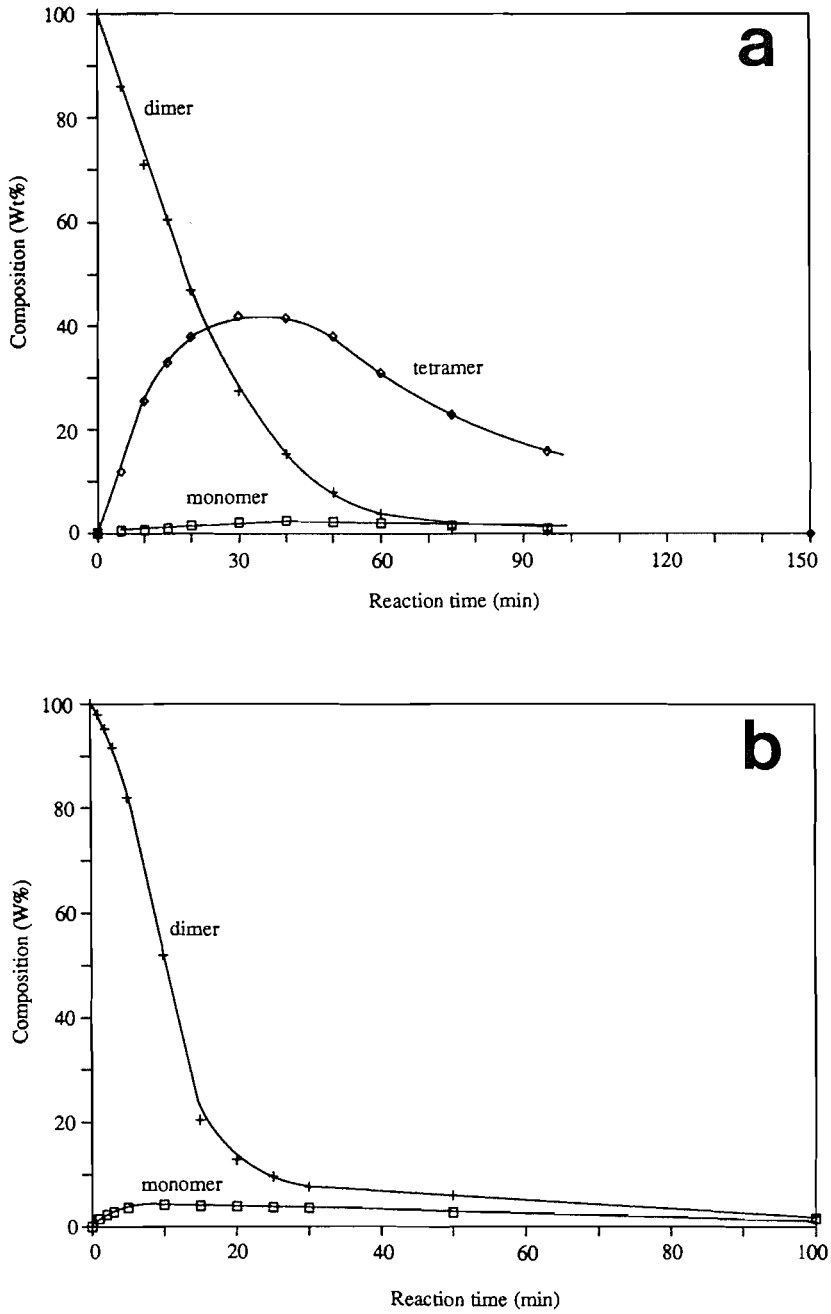

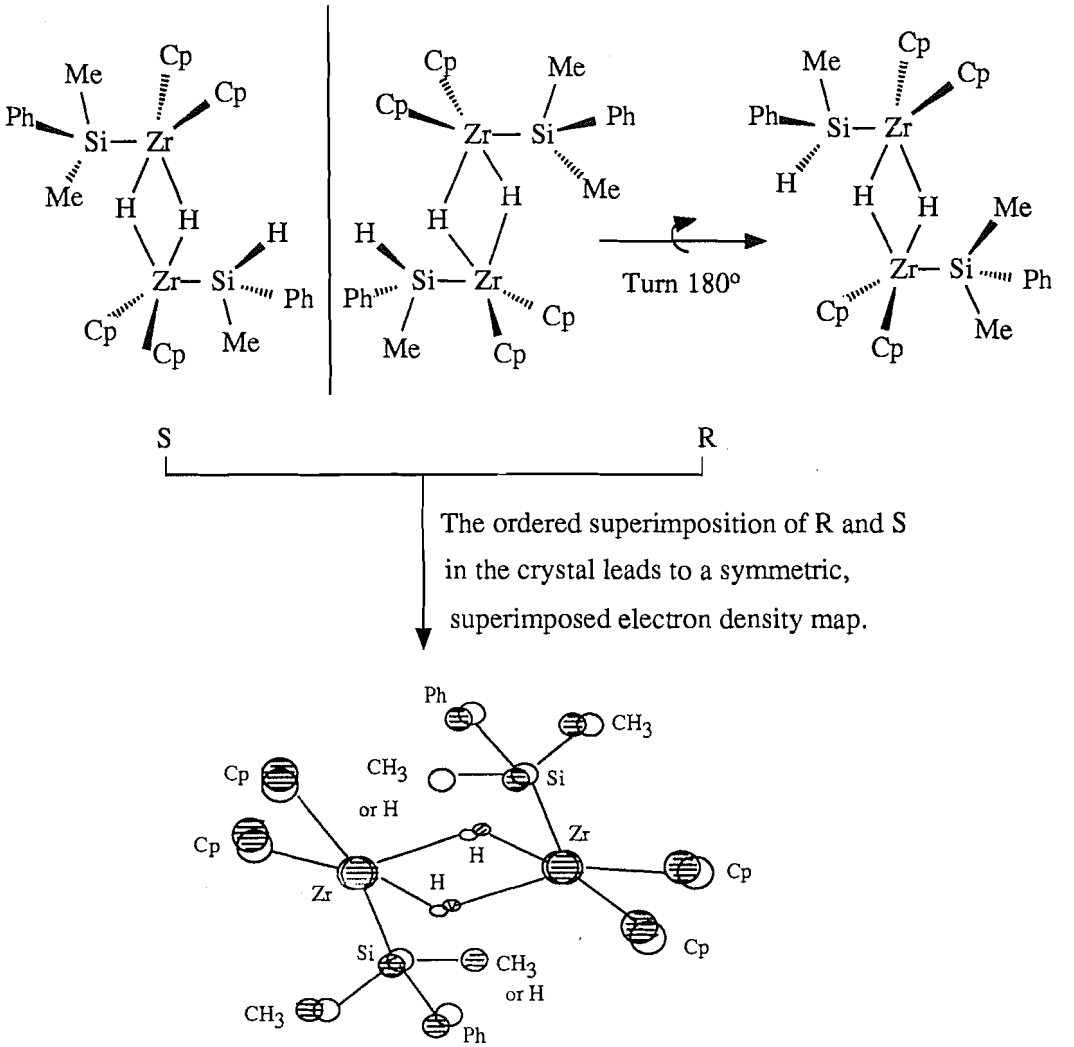

FIG. 4. Catalytic oligomerization of 1,2-diphenyldisilane by (*a*) DMT, $[DMT]_i = 0.02$ M in neat disilane (concentrations estimated by GPC); (*b*) DMZ, $[DMZ]_i = 0.025$ M; $[Ph_2Si_2H_4]_i = 2.5$ M in C_6D_6 solvent (concentrations estimated by ^{1}H-NMR). Both reactions at 20°C.

Homonuclear decoupling confirms that the Si—H resonance (4.88 ppm) is coupled to the weaker methyl resonance at 0.596 ppm. A ball and stick structure showing the atomic numbering scheme is shown in Fig. 6 and an ORTEP diagram of the $[SiZrH]_2$ fragment of **1***b*, showing thermal ellipsoids and relevant molecular parameters, is presented in Fig. 7.[2]

Because of the relatively poor precision of the molecular parameters, detailed comparison with other related structures is of questionable utility. Suffice it to say that the structural parameters are certainly in line with those reported for other bridged Zr(IV) hydrides (22) and Zr(IV) silyl complexes (7, 23). The compounds **1***a* and **1***b* are more remarkable for their overall structure than for the details of their molecular parameters. The presence of two different silyl groups, one derived directly from the starting silane and another derived from methyl transfer to the starting silane, raises two important questions. Firstly, why is the unsymmetrical, rather than the symmetrical, compound preferentially formed? Secondly, is the formation of this particular structure a direct consequence of the mechanism whereby the silanes transform DMZ to active catalyst?

[2]Complete tables of molecular parameters, heavy atom anisotropic thermal parameters, H atom coordinates and isotropic thermal parameters, and observed and calculated structure factors have been deposited. Before attempting to answer these questions, it is helpful to consider the results of an ^{1}H-NMR study of the reactions of several different silanes with DMZ.

The reactions of $PhSiH_3$, $PhMeSiH_2$, Ph_2SiH_2, and $BuMeSiH_2$ with DMZ

In Fig. 8, the ZrH resonances of the reaction products of several silanes with DMZ are shown. It is evident from these spectra that different silanes exhibit dramatically different reactivity towards DMZ. As noted previously, $PhSiH_3$ reacts rapidly and completely at room temperature to give **1***a* and a few other trace products containing bridging Zr—H bonds. The stoichiometry of this reaction is as shown in reaction [2]. Methane was detected by ^{1}H-NMR as CH_4 when the silane was $PhSiH_3$ and CH_3D when $PhSiD_3$ was used. In contrast to the reaction of DMT, only a trace amount of $PhMeSiH_2$ was produced in this reaction. Also, at the time of complete conversion of the DMZ to **1***a*,

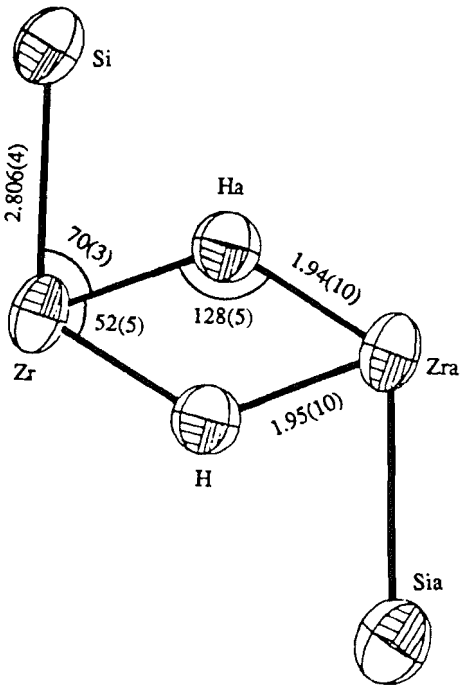

FIG. 7. ORTEP diagram of the $[SiZrH]_2$ fragment of **1***b*.

in contrast to the secondary silanes described below, no hydride signal was evident at −12 ppm.

The reactions of $PhMeSiH_2$ and Ph_2SiH_2 are much slower than that of $PhSiH_3$, requiring 1 to 2 days to go to completion under the same conditions that lead to complete reaction of $PhSiH_3$ in ca. 1–2 h. In the case of $PhMeSiH_2$, the major product is still the unsymmetrical silyl, **1***b*, but this product now only accounts for about 55% of the total observable Zr—H species. The NMR spectrum of the $PhMeSiH_2$ reaction products is more complicated than that of the $PhSiH_3$ products and that of the Ph_2SiH_2 is more complicated still. In the last case, the unsymmetrical silyl complex, **1***c*, only accounts for ca. 10% of the total observable Zr—H species and the major products are the mixed methyl/silyl dimers **1***d* and **1***e*, which are produced in comparable amounts. **1***d* was isolated as a pure product from the reaction of diphenylsilane with DMZ and its structure is assigned on the basis of its NMR spectrum, shown in Fig. 9.

A further feature of the spectra of the secondary silane products is the appearance of a hydride resonance in the region of −12 ppm. This resonance is at unusually high field for a Zr—H resonance and is almost certainly due to a diamagnetic zirconocene(III) species; most likely a zirconium analogue of the previously reported titanocene(III)silyl dimer (15). Unfortunately, these products have thus far resisted our attempts at isolation and characterization in the pure state.

n-Butylmethylsilane is much less reactive than phenylmethyl- or diphenylsilane and it requires heating to achieve reasonable reaction rates. However, the reaction products are very simple. The unresolved multiplet at −5.70 ppm is due to a

symmetrical hydride-bridged dimer, the most likely candidate being **1***f*. The second resonance, at −12 ppm, is assigned tentatively to the symmetrical zirconocene(III)silyl dimer.

The above results, insofar as they concern phenyl-, phenylmethyl-, and diphenylsilane, show a consistent pattern which suggests that in these cases there is an initial production of $Cp_2Zr(SiRR'H)Me$ (**2***a*) by reaction [3]. There is precedent for

[3] $Cp_2ZrMe_2 + RR'SiH_2 \rightarrow Cp_2Zr(SiRR'H)Me + CH_4$

2*a*

this type of complex, produced by an alternative synthetic route (9). Production of the various hydride species must then be accounted for by reactions which do not produce free RR'MeSiH. The latter constraint precludes formation of $Cp_2Zr(H)Me$, **2***b*, by a metathesis in the reverse sense to [3]. A more likely route to **2***b* is a metathesis between **2***a* and silane as shown in [4], since it is known that compounds of this type react with hydrogen more rapidly via the Zr—Si bond than the Zr—C bond (9).

[4] $Cp_2Zr(SiRR'H)Me + RR'SiH_2 \rightarrow Cp_2Zr(H)Me + HSiRR'SiRR'H$

2*b*

A similar constraint applies to the formation of methylated silyl ligands. The low reactivity of secondary relative to primary, and tertiary relative to secondary silanes, excludes any process which involves formation and subsequent rapid reaction of the free methylated silane. The most likely candidate for the methylation step is a σ-bond metathesis between a ZrMe and a ZrSiRR'H species (reaction [5]). Such reactions can account

[5] $ZrMe + ZrSiRR'H \rightarrow ZrH + ZrSiRR'Me$

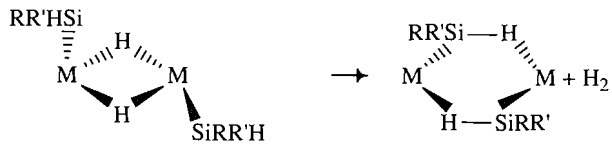
for the formation of all the observed hydride and methylsilyl species in the dimers **1** in simple one-step reactions. In the context of [5], one of the main roles of the metal is the activation of the α-Si—H bond of the silyl ligand towards σ-bond metathesis. For such a reaction to be thermodynamically possible, the greater strength of the Zr—H bond, relative to Zr—C bond, must outweigh the loss of stability of the Zr—Si bond resulting from increased steric encumbrance about the silicon (5, 7). This condition is surely satisfied given the generally greater stability of M—H as opposed to M—C bonds.

From the above arguments we conclude that the formation of the unsymmetrical dimers **1***a* and **1***b* is due to the prevalence of reactions [4] and [5] in the early stages of the reaction, during which DMZ is abundant. After the DMZ is exhausted, conversions of **2***a* and **2***b* to the silyl hydride species can occur by analogues of [3] and [5]. In the case of diphenylsilane, conversion of **2***b* to silyl hydride is apparently too slow and dimerization of **2***b* with silylhydrides predominates to give species **1***d* and **1***e*.

Extension of [5] to the propagation reactions suggests [6] and [7] as likely processes. In particular, [7] provides a rationalisation

[6] $ZrSiRR'H + ZrSiRR'H \rightarrow ZrH + ZrSiRR'SiRR'H$

[7] $ZrSiRHSiRH_2 + ZrSiRHSiRH_2 \rightarrow ZrSiRH_2 + ZrSiRHSiRHSiRH_2$



for the redistribution of 1,2-disubstituted disilanes. A precedent for [6] has been reported by Woo and Tilley (6).

The hydrogen evolving step, required to close the dehydrocoupling cycle, presents some problems in terms of simple σ-bond metathesis. It is not clear whether or not the reaction shown in [8] is thermodynamically allowed. We have recently

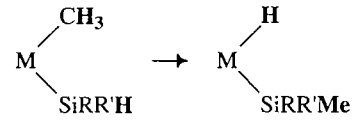
[8] $M—H + Si—H \rightarrow M—Si + H_2$

calculated the Ti—H and Ti—Si bond energies for the compound $Cp_2Ti(H)(SiH_3)$, **3**, to be ca. 60 and 30 kcal/mol, respectively (25). Assuming a typical Si—H bond energy to be ca. 90 kcal/mol (21, 24) and the bond energy for H_2 to be 104 kcal/mol, the reaction of **3** with a silane in the sense of [8] would be endothermic by ca. 15 kcal/mol. This appears to be far too high to account for the observed reactivities. In addition, the extremely facile reaction of the Zr—Si bond with H_2 in the reverse sense of [8] (9) supports the contra-thermodynamic character of [8]. On the other hand, Woo and Tilley have observed the direct reactions of zirconocene hydrides with silanes, with evolution of hydrogen, in what appears to be a simple bimolecular reaction (6). It is very possible that these seeming contradictions arise from fairly large differences in the thermodynamics, depending on the degree of substitution of the silyl group. It is well established that both silyl metathesis (5) and catalytic dehydrocoupling (3, 4) have rates that vary greatly with the substitution at silicon.

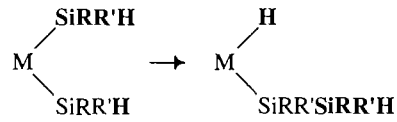
An interesting speculation is that the hydrogen evolution reaction may occur via dimeric species, such as **1**. In a pathway of this type, shown in [9], the energy sacrificed in the cleavage

[9] 

4



of the M—H bond can be compensated by the formation of a M—H—Si bridge and by the additional strength of a M—Si bond which involves d_π—p_π bonding to the d^1 metal centre. Species such as **4** are well established in titanium chemistry (15) and there is a strong possibility that the high field resonances in the spectra shown in Fig. 8 are due to species of the type **4**.



We are continuing our studies of the chemistry of the compounds **1** in an effort to obtain evidence in support of this speculation.

Conclusions

The sum of the observations reported above lead us to two primary conclusions. Firstly, the mechanisms of Si—H activation by the DMT and DMZ catalyst systems are very closely related, since both catalysts give essentially the same kinds of polymer and the molecular weights and molecular weight distributions of the polymers vary in the same way with varying reaction conditions. Secondly, all of the experimental observations can be accommodated within the context of the σ-bond metathesis mechanism proposed by Woo and Tilley (5, 6). These conclusions require the assumption that the obligatory titanium(IV) species be readily available by some kind of rapid equilibrium process such as that previously suggested to explain kinetic results (17), since no titanium(IV) intermediates have been detected in titanocene based reactions, subsequent to the initial reduction of the DMT.

Despite our present preference for the M(IV) σ-bond metathesis mechanism, we still believe that these systems are too poorly understood to prematurely discard several other plausible mechanisms. Among these are the intermediacy of silylene complexes (4, 19), σ-bond metathesis involving M(III) as opposed to M(IV) complexes, intramolecular σ-bond metathesis, as exemplified in reactions [10] and [11], and ligand transfer processes between M(III) and M(IV) species.

[11] 

Experimental

The general experimental techniques for purifying solvents, synthesis of reactants and catalysts, and carrying out reactions are the same as described in earlier publications (2, 15, 16). 1,2-Diphenyldisilane was synthesised using the vanadocene catalyzed dimerization of phenylsilane (2).

Polymer characterization

Details of the various experimental methods of polymer characterization have been published elsewhere (16).

Reaction of primary and secondary silanes with DMZ

All these reactions were followed by ^{1}H-NMR. The standard conditions for stoichiometric reactions of DMZ with different silanes were DMZ (5 mg) dissolved in a mixture of degassed benzene-d_6 (0.5 mL) and the appropriate silane (0.06 mmol). Reaction mixtures were sealed in NMR tubes, placed in the temperature controlled cavity of a 200 or 300 MHz FT-NMR spectrometer, and the concentrations of the various species with the passage of time were estimated by integration of ^{1}H spectra. The concentrations of monomer, dimer, and trimer in catalytic oligomerization reactions of phenyl- and diphenylsilanes can usually be followed easily due to the simplicity and sharpness of the spectra and the good separation of the resonances (2). In the case of methylphenylsilane, the dimer and the trimer have more complicated spectra due to the presence of geometric isomers and due to the coupling between the Si—H and C—H protons. The ^{1}H-NMR spectra of these species are as follows: dimer: ∂_{Si-H} = 4.625 (q) and 4.638 (q); ∂_{C-H} = 0.337 (d) and 0.347 (d). Trimer: ∂_{Si-H} = 4.711 (q), 4.718 (q), 4.726 (q), and 4.734 (q); ∂_{C-H} (ter) = 0.343 (d), 0.347 (d), 0.378 (d) and 0.381 (d); ∂_{C-H} (mid) = 0.417 (s), 0.427 (s) and 0.446 (s). From these data it is evident that the dimer and trimer can be monitored by integration of their Si—H resonances.

The oligomerization/redistribution of diphenyldisilane was carried out in a Schlenk tube. DMZ (20 mg, 0.155 mmol)) was rapidly dissolved in a mixture of benzene-d_6 (2 mL), diphenyldisilane (1.0 mL), and cyclohexane (0.10 mL for calibration). Gas evolution commenced immediately and the colour of the solution slowly turned to orange. The reaction mixture was periodically sampled and analyzed by ^{1}H-NMR.

The oligomerization of phenylmethylsilane was studied using neat phenylmethylsilane. The reaction mixture was prepared in a Schlenk tube and placed in a constant temperature oil bath. The progress of the reaction was monitored by periodic sampling and analysis by ^{1}H-NMR.

Synthesis of compounds **1**a, **1**b, *and* **1**d

These three compounds were prepared by the same method. DMZ (200 mg, 0.80 mmol) was dissolved in degassed benzene (**1***a*) or *n*-hexane (**1***b*,*d*) (4.0 mL) containing the silane (2.4 mmol). The solution slowly changed from colourless to orange with a slow gas evolution and the formation of orange crystals over a period of several hours. The crystals were filtered, washed several times with *n*-hexane and dried under vacuum. Yields: **1***a*, 155 mg, 58%; **1***b*, 119 mg, 44%; **1***d*, 54 mg, 21%. **1***a* and **1***b* were obtained as well-formed crystals, **1***d* as a microcrystalline powder.

The crystal structure of compound **1**b

A crystal of dimensions 0.1 × 0.2 × 0.4 mm was sealed in a thin-walled capillary. Diffraction measurements were carried out on a Nicolet R3M/E diffractometer.[3] Computations were performed using the SHELXTL system[4] adapted to an Eclipse S/140 computer. Crystal data and collection parameters are listed in Table 2. The space group $P2_1/c$ was established by systematic absences in the complete data set ($0k0$, $k = 2n + 1$ and $h0l$, $l = 2n + 1$). The intensity data were corrected for absorption and Lorentz-polarization effects. The positions of the independent zirconium and silicon atoms were deduced from the *E*-map. The positions of all other independent non-hydrogen atoms were determined from difference Fourier synthesis and the dimeric structure of the compound was confirmed at this point. After a refinement of the positional and thermal parameters of the non-hydrogen atoms by least squares, all of the hydrogen atoms were calculated from difference Fourier synthesis and refined with isotropic thermal parameters. The largest peak corresponded to the bridging hydrides. Finally, all non-hydrogen atoms were refined by full-matrix least-squares with anisotropic thermal parameters. All atoms other than silicon and zirconium were severely distorted and the electron density for C_{42} showed 1/2 occupancy at the two sites of the dimer, indicating that the crystal contains a pair of enantiomers of **1***b* and the disorder problem results from the ordered superposition of the two enantiomers. The final atomic coordinates are listed in the supplementary material. The final least squares refinement converged with the residuals shown in Table 2.

Received August 8, 1990

JING-LONG DU, STEVEN J. RETTIG, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **69**, 277 (1991).

The synthesis of the β and γ forms of $M(Ph_2PO_2)_2$ where M = Co and Mn are described and the compounds are characterized by infrared spectroscopy, differential scanning calorimetry, X-ray powder diffraction, and low-temperature (2–80 K) magnetic susceptibility studies. Single crystal X-ray diffraction studies are reported on the γ forms. Crystals of the γ forms of poly-bis(μ-diphenylphosphinato)cobalt(II) and poly-bis(μ-diphenylphosphinato)manganese(II) are isomorphous, crystallizing with 4 formula units per unit-cell in the monoclinic space group $P2_1/c$. Lattice constants are a = 8.080(2), 8.161(1), b = 23.550(6), 23.751(1), c = 11.726(3), 11.6946(6) Å, and β = 92.88(2), 93.026(8)° for the Co and Mn derivatives respectively. The structures were solved by heavy atom methods and were refined by full-matrix least-squares procedures to R = 0.039 and 0.045 for 4041 and 2878 reflections with $I \geq 3\sigma(I)$, respectively. Both crystal structures consist of double phosphinate-bridged chain polymers containing tetrahedrally coordinated metal atoms: Co—O = 1.950(2)–1.963(2) Å, O—Co—O = 104.81(8)–117.77(9)°, Mn—O = 2.016(3)–2.033(3) Å, O—Mn—O = 103.2(1)–114.7(1)°. All four compounds exhibit antiferromagnetic coupling and magnetic susceptibilities have been analyzed according to two Heisenberg models for linear chains of metal ions with S = 3/2 for cobalt and S = 5/2 for manganese. The Weng model (with values for the Wagner and Friedberg model in parentheses) gives $-J$ = 0.25 (0.26) cm^{-1} and 0.55 (0.60) cm^{-1} for the β and γ forms, respectively, of $Co(Ph_2PO_2)_2$, and 0.34 (0.36) cm^{-1} and 0.17 (0.17) cm^{-1} for the β and γ forms, respectively, of $Mn(Ph_2PO_2)_2$.

Key words: crystal structure, diphenylphosphinates of cobalt(II) and manganese(II), magnetic properties.

JING-LONG DU, STEVEN J. RETTIG, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **69**, 277 (1991).

On décrit la synthèse des formes β et γ des $M(Ph_2PO_2)_2$ dans lesquels M = Co et Mn et on a caractérisé les composés par spectroscopie infrarouge, par calorimétrie à balayage différentiel, par diffraction des rayons-x par des poudres et par des études de susceptibilité magnétique à basse température (2–80 K). On rapporte des études de diffraction des rayons-X effectuées sur des cristaux uniques des formes γ. Les cristaux des formes γ du poly-bis(μ-diphénylphosphinato)cobalt(II) et du poly-bis(μ-diphénylphosphinato)manganèse(II) sont isomorphes et ils cristallisent, avec 4 unités de formule par maille, dans le groupe d'espace monoclinique $P2_1/c$, avec a = 8,080(2) et 8,161(1), b = 23,550(6) et 23,751(1) et c = 11,726(3) et 11,6946(6) Å et β = 92,88(2) et 93,026(8)° respectivement pour les dérivés du Co et du Mn. On a résolu les structures par les méthodes aux atomes lourds et on les a affinées par la méthode des moindres carrés jusqu'à des valeurs respectives de R = 0,039 et 0,045 pour 4041 et 2827 réflexions avec $I \geq 3\sigma(I)$. Les deux structures comportent des doubles chaînes de polymères, liées par des groupements phosphinates, qui contiennent des atomes métalliques coordonnés d'une façon tétraédrique: Co—O = 1,950(2)–1,963(2) Å; O—Co—O = 104,81(8)–117,77(9)°; Mn—O = 2,016(3)–2,033(3) Å; O—Mn—O = 103,2(1)–114,7(1)°. Les quatre composés présentent un couplage antiferromagnétique et on a analysé les susceptibilités magnétiques suivant deux modèles de Heisenberg pour des chaînes linéaires d'ions métalliques avec S = 3/2 pour le cobalt et S = 5/2 pour le manganèse. Le modèle de Weng (avec les valeurs pour le modèle de Wagner et de Friedberg entre parenthèses) conduit à des valeurs respectives de $-J$ = 0,25 (0,26) cm^{-1} et 0,55 (0,60) cm^{-1} pour les formes β et γ du $CO(Ph_2PO_2)_2$, respectivement, et 0.34 (0.36) cm^{-1} et 0.17 (0.17) cm^{-1} pour les formes β et γ, respectivement du $Mn(Ph_2PO_2)_2$.

Mots clés : structure cristalline, diphénylphosphinates du cobalt(II) et du manganèse(II), propriétés magnétiques.

[Traduit par la rédaction]

Introduction

Coates and Golightly first described the preparation of cobalt(II) diphenylphosphinate, $Co(Ph_2PO_2)_2$, and on the basis of its solubility properties and color they suggested a polymeric structure with tetrahedrally coordinated cobalt(II) ions linked in chains by double phosphinate bridges (1). Rose and Block later reported studies on the compound prepared by a different route. This work, which included X-ray powder diffraction and thermogravimetric analysis supported the original proposed structure and, moreover, showed the compound to be isomorphous with the β crystalline modification of zinc(II) diphenylphosphinate (2). Although a second, γ, modification of the zinc compound has been reported (3), no evidence for the γ modification of $Co(Ph_2PO_2)_2$ was found in this earlier work. We report here the synthesis of two forms of both $Co(Ph_2PO_2)_2$ and $Mn(Ph_2PO_2)_2$ which on the basis of X-ray powder diffraction studies appear to be isomorphous with the β and γ forms of $Zn(Ph_2PO_2)_2$. Sufficiently large crystals of the γ forms of both compounds were obtained to permit single crystal X-ray diffraction studies. These reveal tetrahedral metal centres linked by double phosphinate bridges as proposed in the early studies (1). The β forms were obtained only as microcrystalline powders and hence their detailed structures remain uncertain.

Our interest in binary metal phosphinates stems from the fact that such compounds often provide interesting examples of low-dimensional magnetic exchange. For example, copper(II) diphenylphosphinate, a polymeric chain compound in which square planar metal ions are linked by double phosphinate bridges (4) exhibits weak ferromagnetism (5). In the present work, low temperature magnetic susceptibility studies reveal weak antiferromagnetism in all of the materials studied.

Experimental

Preparations

Poly-bis(μ-diphenylphosphinato)cobalt(II), $Co[(C_6H_5)_2PO_2]_2$ (γ form)
Cobalt(II) chloride hexahydrate (1.19 g, 5.00 mmol) was dissolved

in 30 mL of dimethylformamide and this solution was mixed with a solution containing 2.18 g (10 mmol) of diphenylphosphinic acid and ~1.2 mL of triethylamine dissolved in 50 mL of dimethylformamide. A clear solution was obtained; on standing over 3 months, blue needle-like crystals formed. The crystals were collected by filtration, washed with acetone, and air-dried. *Anal.* calcd. for $CoC_{24}H_{20}P_2O_4$: C 58.44, H 4.09; found: C 58.26, H 4.05.

$Co[(C_6H_5)_2PO_2]_2$ (β form)

Cobalt diphenylphosphinate was prepared according to the method of Coates and Golightly (1). Cobalt(II) chloride hexahydrate (2.67 g, 11.2 mmol) was dissolved in 50 mL of water, then added dropwise to a stirring solution of sodium diphenylphosphinate which was prepared by neutralizing diphenylphosphinic acid (5.27 g, 24.2 mmol) in 100 mL water with sodium hydroxide. Initially a red solution formed and as more of the metal salt solution was added a blue precipitate formed. After addition was complete the mixture was heated gently on a hot plate then filtered. The pink filtrate was heated at 60°C for 2 days during which time product in the form of a blue precipitate formed. This was collected by filtration, washed with warm water then air dried. *Anal.* found: C 58.45, H 4.07. The first precipitate obtained in this synthesis was redissolved in cold water and heating this solution for two days at 60°C yielded more analytically pure product.

Poly-bis(μ-diphenylphosphinato)manganese(II), $Mn[(C_6H_5)_2PO_2]_2$ (γ form)

Diphenylphosphinic acid (2.18 g, 10.0 mmol) was dissolved in 40 mL aqueous methanol (1:3 methanol:water, v/v) and neutralized with potassium carbonate. To this stirring solution was added dropwise, over about 30 min, manganese sulfate monohydrate (0.845 g, 5.00 mmol) in 35 mL of water. A precipitate in the form of a fine white microcrystalline powder formed and the mixture was stirred for an additional 45 min. The powder was then removed by filtration, washed with a 50:50 methanol:water mixture and then air-dried overnight. *Anal.* calcd. for $MnC_{24}H_{20}P_2O_4$: C 58.91, H 4.12; found: C 59.07, H 4.34.

Attempts to prepare a formamide adduct of $Mn[(C_6H_5)_2PO_2]_2$ led instead to the synthesis of the γ form of the binary phosphinate in a crystalline form suitable for single crystal X-ray diffraction studies. The neutralized acid and manganese(II) sulfate solutions were prepared as above. These were then mixed and 60 mL of formamide was added immediately before any precipitate formed. Over a period of 3 months pale-green crystals were collected, washed with water, and dried under vacuum at 60°C for 6 h. That these crystals are the same material as the microcrystalline powder sample described above was confirmed by a detailed comparison of the spectroscopic and other physical properties of the two samples as described later. All of the data (other than the single crystal X-ray data) reported in this experimental section for γ-$Mn[(C_6H_5)_2PO_2]_2$ were obtained on the microcrystalline powder sample.

$Mn[(C_6H_5)_2PO_2]_2$ (β form)

Diphenylphosphinic acid (2.19 g, 10.0 mmol) was dissolved in 70 mL of dimethylformamide and neutralized by the addition of 1.7 mL of triethylamine. To this stirring solution was added dropwise, over about 30 min, a solution of manganese(II) chloride tetrahydrate (1.00 g, 5.06 mmol) in 50 mL of dimethylformamide. A white precipitate formed and the mixture was left stirring overnight. The product was collected by filtration, washed well with acetone, and air-dried. *Anal.* found: C 58.8, H 4.25.

Infrared spectroscopy

Infrared spectra (4000 to 250 cm^{-1}) were recorded using a Perkin-Elmer Model 598 spectrophotometer. Samples were mulled in Nujol and pressed between KRS-5 plates (Harshaw Chemical Co.). Frequencies are considered accurate to within ± 3 cm^{-1}. Bands observed in the range of 1600 to 250 cm^{-1} are given (w = weak, m = medium, s = strong, sh = shoulder, v = very, numbers in parentheses refer to split bands):

γ-$Co(Ph_2PO_2)_2$: 1593 w, 1439 m, 1212 m, 1180 wsh, 1135 vs, 1069 wsh, 1049 vs, 1026 s, 1001 m, 760 wsh, 755 w, 723 s, 700 s, 696 wsh, 576 s, 546 s, 440 w, 420 w, 335 wsh, 324 w, 308 w.

β-$Co(Ph_2PO_2)_2$: 1593 w, 1438 m, 1210 w, 1138 vs, 1070 wsh, 1056 vs, 1025 s, 1001 m, 757 m, 731 s, 696 s, 575 s, 545 s, 470 w, 439 w, 408 w, 400 w.

γ-$Mn(Ph_2PO_2)_2$: 1595 w, 1443 m, 1211 m, 1183 w, (1143, 1150) vs, 1072 w, 1053 vs, 1026 s, 1002 m, (757, 761) w, 727 s, 701 s, 698 wsh, 578 wsh, 572 s, 549 s, 438 w, 415 w, 318 w, 310 w.

β-$Mn(Ph_2PO_2)_2$: 1593 w, 1440 m, 1310 w, 1210 w, 1185 wsh, (1152, 1140) vs, 1073 wsh, 1060 vs, 1028 s, 1002 m, 758 m, 733 s, 696 s, 570 s, 544 s, 466 w, 426 w, 403 w, 390 w.

Differential scanning calorimetry

Differential scanning calorimetry, DSC, measurements were made with a Mettler DSC 20 cell and a Mettler TC10 TA processor operating over the temperature range 35 to 400°C. The β and γ forms of $Co(Ph_2PO_2)_2$ exhibit single endothermic peaks at 366°C (ΔH = 23 J g^{-1}) and 368°C (ΔH = 18 J g^{-1}), respectively. The β form of $Mn(Ph_2PO_2)_2$ shows a single endotherm at 357°C (ΔH = 24 J g^{-1}) while the γ form of this compound exhibits three endothermic peaks at 213°C (ΔH = 29 J g^{-1}), 238°C (ΔH = 4 J g^{-1}), and 356°C (ΔH = 26 J g^{-1}).

X-ray powder diffractometry

X-ray powder diffraction patterns were recorded in the range 2θ = 5–60° using a Rigaku Rotaflex rotating anode X-ray powder diffractometer (Ni filtered Cu-K_α radiation). The powder patterns are depicted for the four compounds in Fig. 1.

Electronic spectroscopy

Electronic spectra of samples of the β and γ forms of $Co(Ph_2PO_2)_2$ mulled in Nujol and smeared on filter paper were obtained on a Shimadzu UV-2100 spectrometer and the spectra are shown in Fig. 2.

Magnetic susceptibility measurements

Magnetic susceptibilities were measured from 2 to 80 K using a PAR model 155 vibrating sample magnetometer, VSM, as described previously (6). Measurements were made at a field of 7501 G. The diamagnetic corrections used were -14, -12, and -127×10^{-6} cm^3 mol^{-1} for Mn^{2+}, Co^{2+}, and $(C_6H_5)_2PO_2^-$, respectively. The magnetic susceptibility values for the cobalt compounds were corrected for temperature independent paramagnetism using a value for TIP of 560×10^{-6} cm^3 mol^{-1} calculated as described below. Values of magnetic susceptibilities and magnetic moments are included as supplementary material.[2]

X-Ray crystallographic analyses of γ-$Co(Ph_2PO_2)_2$ and γ-$Mn(Ph_2PO_2)_2$

Crystallographic data for both compounds appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 20.1–30.4° for the cobalt and 66.8–84.8° for the manganese derivative. The intensities of three standard reflections, measured every 200 reflections throught the data collections, were essentially constant for both compounds. The data were processed[3] and corrected for Lorentz and polarization effects, and absorption (empirical, based on azimuthal scans for three reflections).

The structure of the Co complex was solved by heavy atom methods, the Co and P atoms being positioned from the Patterson function and the remaining non-hydrogen atoms from a subsequent difference Fourier synthesis. The refinement of the isomorphous Mn complex was initiated using the non-hydrogen atom positions from the γ-$Co(Ph_2PO_2)_2$ stucture (with the origin shifted by -0.5 along z). The non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were refined with isotropic thermal parameters for the Co

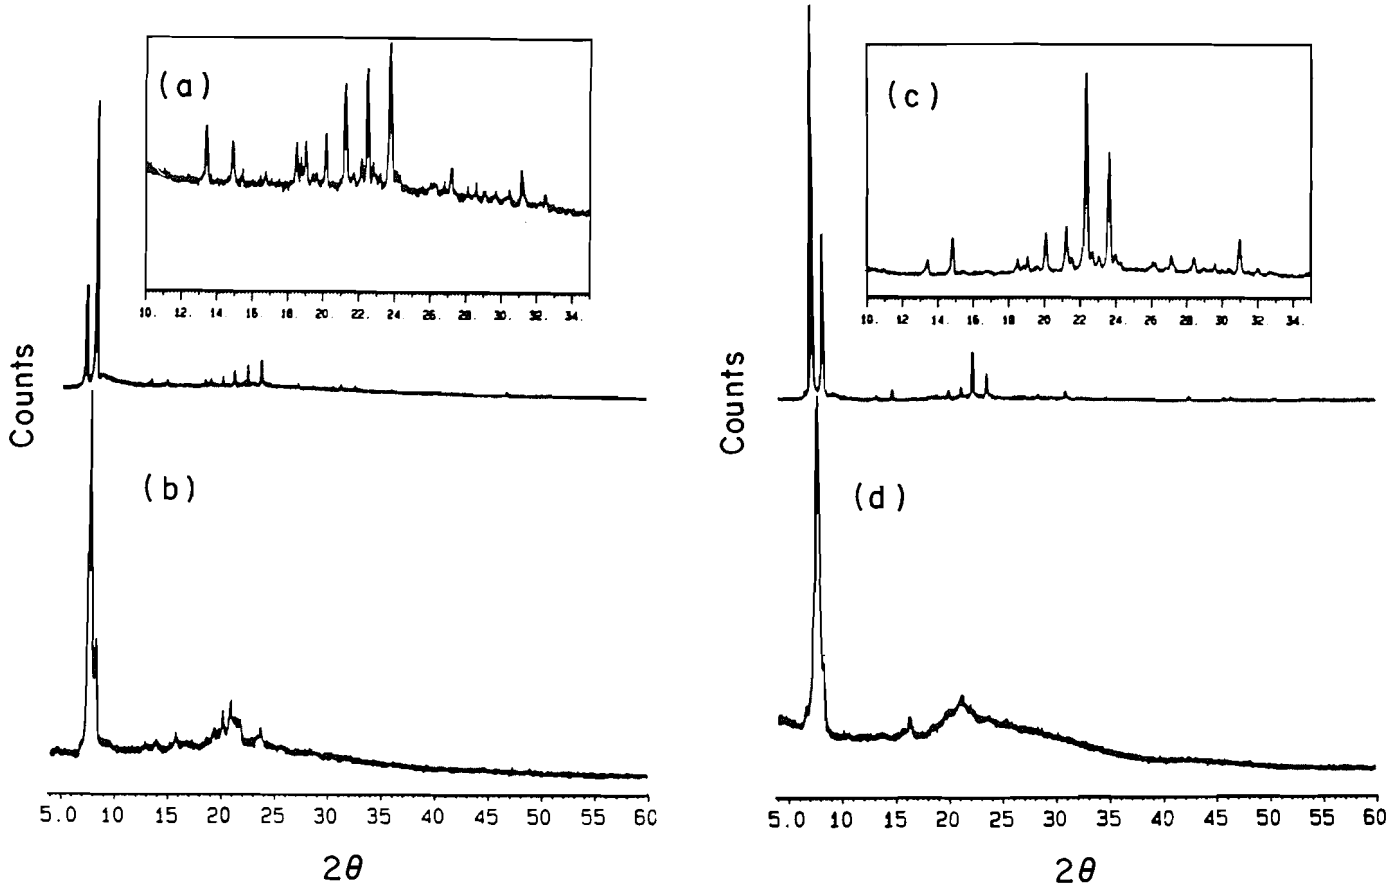

FIG. 1. X-Ray powder diffraction patterns for $M(Ph_2PO_2)_2$: (*a*) γ-Co, (*b*) β-Co, (*c*) γ-Mn, (*d*) β-Mn.

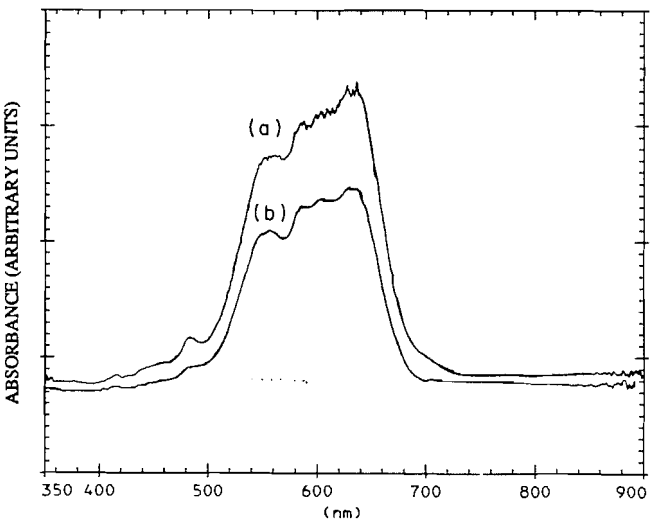

FIG. 2. Electronic spectra for $Co(Ph_2PO_2)_2$: (*a*) γ form, (*b*) β form.

complex and were fixed in idealized positions (C—H = 0.98 Å, $B_H = 1.2B_{\text{bonded atom}}$) for the Mn complex. Secondary extinction corrections were applied, the final values of the extinction coefficient being 1.08×10^{-7} for γ-$Co(Ph_2PO_2)_2$ and 3.63×10^{-6} for γ-$Mn(Ph_2PO_2)_2$. Neutral atom scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (7). Final atomic coordinates and equivalent isotropic thermal parameters are given in Table 2 and bond lengths and angles appear in Tables 3 and 4, respectively. Hydrogen atom parameters, anisotropic thermal parameters, bond lengths and angles involving hydrogen, general torsion angles, intermolecular distances, least-squares planes, and measured and calculated structure factor amplitudes for both structures are included as supplementary material.[2]

Results and discussion

Cobalt(II) diphenylphosphinate

Two crystalline modifications of $Co(Ph_2PO_2)_2$ were obtained which, based on their X-ray powder diffraction patterns (Fig. 1), appear to be isomorphous with the β and γ modifications of $Zn(Ph_2PO_2)_2$ (3, 8). The β form of the cobalt compound was reported previously by Rose and Block (2) who used a different synthetic route from that employed here, the latter being similar to that described by Coates and Golightly (1). The powder patterns we observed for our β samples showed broad line features at the higher θ values suggesting a lower degree of crystallinity than in the γ samples. The γ form of $Co(Ph_2PO_2)_2$ has not been reported previously; we obtained this in crystalline form suitable for a single crystal X-ray diffraction study.

The crystal structure of γ-$Co(Ph_2PO_2)_2$ consists of fused eight-membered rings, each ring consisting of two cobalt ions bridged by two phosphinate groups (Fig. 3). The coordination about each cobalt is approximately tetrahedral with O—Co—O bond angles ranging from 104.81(8) to 117.77(9)° (Fig. 4). This contrasts with the situation for the dialkylphosphinates of copper(II) where the CuO_4 chromophore is a compressed tetrahedron (O—Cu—O bond angles range from 92.74(5) to 149.85(6)° in the diethylphosphinate, for example) (6, 9) and for copper(II) diphenylphosphinate where the coordination

[a]Temperature 294 K, Rigaku AFC6S diffractometer, Mo-K_α radiation (λ = 0.71069 Å) or Cu-K_α (λ = 1.54178 Å), graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1, up to eight rescans), $\sigma^2(F^2) = [S^2(C + 4B) + (pF^2)^2]/Lp^2$ (S = scan rate, C = scan count, B = normalized background count, $p = 0.03$ for the Co complex and 0.045 for the Mn complex). Function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma(|F_o| - |F_c|)^2/(m - n)]^{1/2}$. Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

about the metal is square-planar (4). There is nothing remarkable about the internal phosphinate geometry in the cobalt compound with bond angles and distances being typical for metal phosphinate compounds. A unique feature of the present structure, however, involves the conformation of the Co—O—P—O—Co unit. Here, the two bridged metals are on opposite sides of the plane formed by the O—P—O atoms and, as a consequence, the eight-membered rings are linked in a folded or stepped fashion along the direction of the chain. The two crystallographically unique, centrosymmetric, eight-membered $(Co—O—P—O)_2$ rings have very similar conformations with cross ring Co···Co contacts of 4.329(1) and 4.363(1) Å. In the copper(II) diphenylphosphinate and dialkylphosphinate structures the bridged copper atoms are on the same side of the plane formed by the bridging O—P—O atoms and a more extended linear chain structure results. In copper(II) dihexylphosphinate, for example, the cross ring (Cu···Cu contacts are 4.9277(8) and 4.9310(8) Å (6). It is possible that β-$Co(Ph_2PO_2)_2$, for which we have no detailed structural information, has a chain structure more like that of the copper polmers.

[a]Here and elsewhere in the report the symbols ′ and ′′ refer to symmetry operations: $1-x, 1-y, 1-z$ and $-x, 1-y, 1-z$ for the Co complex and $1-x, 1-y, -z$ and $-x, 1-y, -z$ for the Mn complex.

Spectroscopically there is relatively little difference between the β and γ forms of $Co(Ph_2PO_2)_2$. The visible spectra are virtually identical (Fig. 2), indicating little difference in the CoO_4 chromophores. The infrared spectra of the two forms are also very similar (see experimental section). Both forms show two strong bands which may be assigned to the antisymmetric and symmetric PO_2 stretching frequencies, the former occurring at 1138 cm^{-1} in both forms and the latter at 1049 and 1056 cm^{-1} in the β and γ forms, respectively. These band frequencies and separations are similar to those observed for the phosphinates of copper(II) (5, 6, 9) and are consistent with relatively symmetrical phosphinate bridging as shown by the X-ray structure determination of the γ form. The most distinctive feature in the infrared spectra which distinguishes the β and γ forms is a band at about 1210 cm^{-1} which is moderately strong in the γ form and appears only very weakly in the β form. There are also some differences in the weak bands which occur below 500 cm^{-1} and which may be ascribed to Co—O or lattice vibrations. The DSC thermograms are very similar for both forms (experimental section). The single endothermic bands observed correspond closely to the β → ϵ (paracrystalline phase) transition reported for $Zn(Ph_2PO_2)_2$ (345°C, ΔH = 21 J g^{-1}, ref. 8) and may be assigned to a similar event.

We have examined the magnetic properties of both forms of $Co(Ph_2PO_2)_2$ at low temperatures (2–82 K) and the data have been deposited.[2] The susceptibilities have been corrected for temperature independent paramagnetism, TIP, calculated from the expression TIP = $8N\beta^2/10Dq$. The value of 10 Dq was estimated from the spectrum of $Co((C_8H_{17})_2PO_2)_2$ (form I), a phosphinate compound previously reported to contain tetrahedral cobalt(II) (10). This compound exhibits broad structured absorptions centred near 6 500 and 16 500 cm^{-1} assigned to $^4A_2(F) \rightarrow 4T_1(F)$ and $^4A_2(F) \rightarrow {}^4T_1(P)$ transitions, respectively (10). From this it is possible to calculate 10 Dq as 3740 cm^{-1} and hence TIP as 560×10^{-6} cm^3 mol^{-1}.

The magnetic moment of cobalt(II) ($^4A_2$ ground state in T_d) in a regular or slightly distorted tetrahedral environment is expected to be temperature independent except possibly at very low temperatures where zero-field splitting (ZFS) effects may impart some temperature dependence (11). The magnetic moments for both the β and γ forms of $Co(Ph_2PO_2)_2$ decrease significantly with decreasing temperature (deposited material). Attempts to fit the experimental magnetic susceptibilities calculated assuming zero-field splitting (11) show that ZFS alone cannot account for the magnetic properties of these materials. The susceptibility data for the γ form pass through a maximum at 3.6 K indicative of antiferromagnetic behavior. The magnetic data for this compound have been analyzed according to two Heisenberg models for linear chains, the scaling model of Wagner and Friedberg with $S = 3/2$ (12) and the Weng model (13) with coefficients generated by Hiller *et al.* (14) for $S = 3/2$. The magnetic parameters generated for the best fits between experiment and theory are given in Table 5. The Weng model reproduced the position of the maximum in the susceptibility better and gave an overall better fit than the other model. The best fit curve using the Weng model is shown in Fig. 5*a*. There is no maximum in the susceptibility data of the β form of $Co(Ph_2PO_2)_2$; nonetheless, the data may be analyzed assuming antiferromagnetic coupling which is somewhat weaker than that in the γ form. In this case there is little difference in the quality of the fit between the two models; the best fit parameters are given in Table 5 and the best fit curve employing the Weng model is shown in Fig. 5*b*.

Manganese(II) diphenylphosphinate

In our investigations on manganese(II) diphenylphosphinate complexes we established synthetic routes to two forms of $Mn(Ph_2PO_2)_2$ which, on the basis of their X-ray powder diffraction patterns, infrared spectra and, in one case, a single crystal X-ray diffraction study, are isomorphous with the β and γ forms of $Co(Ph_2PO_2)_2$ just described. The preparation of the bis(dimethylformamide) complex of manganese(II) diphenylphosphinate is described in the literature (16). We found the complex formed in this preparation to be very susceptible to the loss of dimethylformamide such that, on washing well with acetone followed by drying in air, all of the amide ligand is lost and anhydrous $Mn(Ph_2PO_2)_2$ is obtained. The infrared spectrum (experimental section) and X-ray powder diffraction pattern (Fig. 1) for this material indicate isomorphism with β-$Co(Ph_2PO_2)_2$. The DSC thermogram, like that of the cobalt analog, also shows just one endothermic peak which for the manganese compound is at 357° (ΔH = 24 J g^{-1}).

The preparation of $Mn(Ph_2PO_2)_2$ from aqueous methanol solution gives a microcrystalline powder which, on the basis of

its infrared spectrum (experimental section) and X-ray powder diffraction pattern (Fig. 1), is isomorphous with γ-$Co(Ph_2PO_2)_2$. The DSC thermogram for the manganese compound, however, is more complex than that of the cobalt analog (experimental section). γ-$Mn(Ph_2PO_2)_2$ exhibits a peak at 356°C which may be ascribed, as in the case of the other compounds studied here, to a transition to a paracrystalline phase. However, in addition it shows another major endotherm at 213°C and a minor event at 238°C. On cooling the sample from the paracrystalline phase to 35°C and reheating, the event at 213°C disappears while the weak peak at 235°C and the 356°C event are retained. A possible explanation for these observations is that the γ form converts

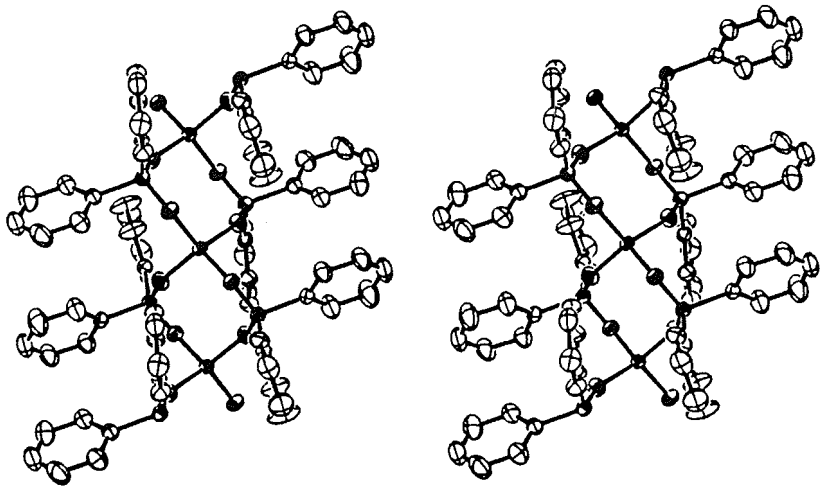

FIG. 3. Stereoview of the γ-$Co(Ph_2PO_2)_2$ structure showing a section of the linear double phosphinate bridged chain structure. γ-$Mn(Ph_2PO_2)_2$ is isomorphous and isostructural.

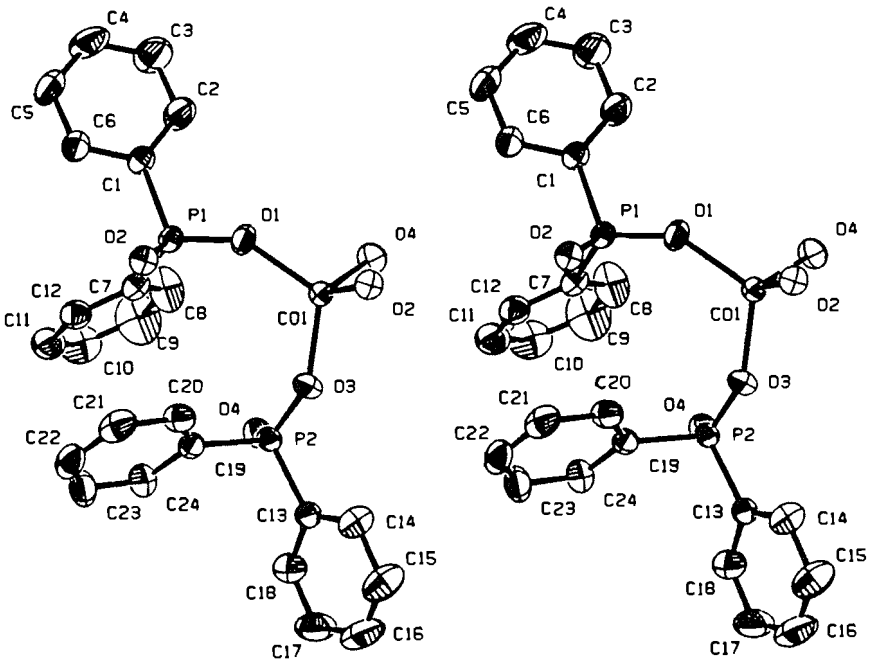

FIG. 4. Stereoview of the asymmetric unit of the γ-$Co(Ph_2PO_2)_2$ structure showing atom labelling and the coordination about the metal atom. 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. γ-$Mn(Ph_2PO_2)_2$ is isomorphous and isostructural.

irreversibly to a third form at 213°C which in turn converts to the β form at 238°C. The transition from β to the paracrystalline phase then occurs at 356°C as observed for an independently prepared sample of β-$Mn(Ph_2PO_2)_2$. Complex thermal behaviour of this type is not uncommon for metal phosphinate polymers (see, for example, ref. 8); it is interesting though that it is seen in γ-$Mn(Ph_2PO_2)_2$ but not in any of the other compounds studied here.

Attempts to prepare a formamide adduct of $Mn(Ph_2PO_2)_2$ by adding formamide to the methanol solution prior to the formation of a precipitate led instead to the slow crystallization of the γ form. Confirmation that these crystals were of the γ form came from a variety of studies. The infrared spectrum and the magnetic susceptibilities of ground samples of these crystals are the same to within experimental error as observed for the microcrystalline powder samples as reported here. The X-ray powder diffraction pattern of powdered samples of these crystals is identical to that shown in Fig. 1 with the exception that some of the relative peak intensities differ. This likely arises from differences in preferred orientation in the powdered samples. Powdered samples of the crystals show only small differences in the DSC thermogram from that of the microcrystalline powder. Three events occur at 210°C (ΔH = 25 J g^{-1}), 240° (ΔH = 7 J g^{-1}), and 358°C (ΔH = 27 J g^{-1}). The irreversibility of the event at 210°C was confirmed in this sample also. Crystals obtained from this preparation were large enough for a single crystal X-ray structure determination.

The crystal structure of γ-$Mn(Ph_2PO_2)_2$ shows the compound to be isomorphous and isostructural with the γ form of cobalt(II) diphenylphosphinate. The Mn—O distances are longer than those in the cobalt complex, ranging from 2.016(3) to 2.033(3) Å (average 2.027 Å), and the angles about the Mn

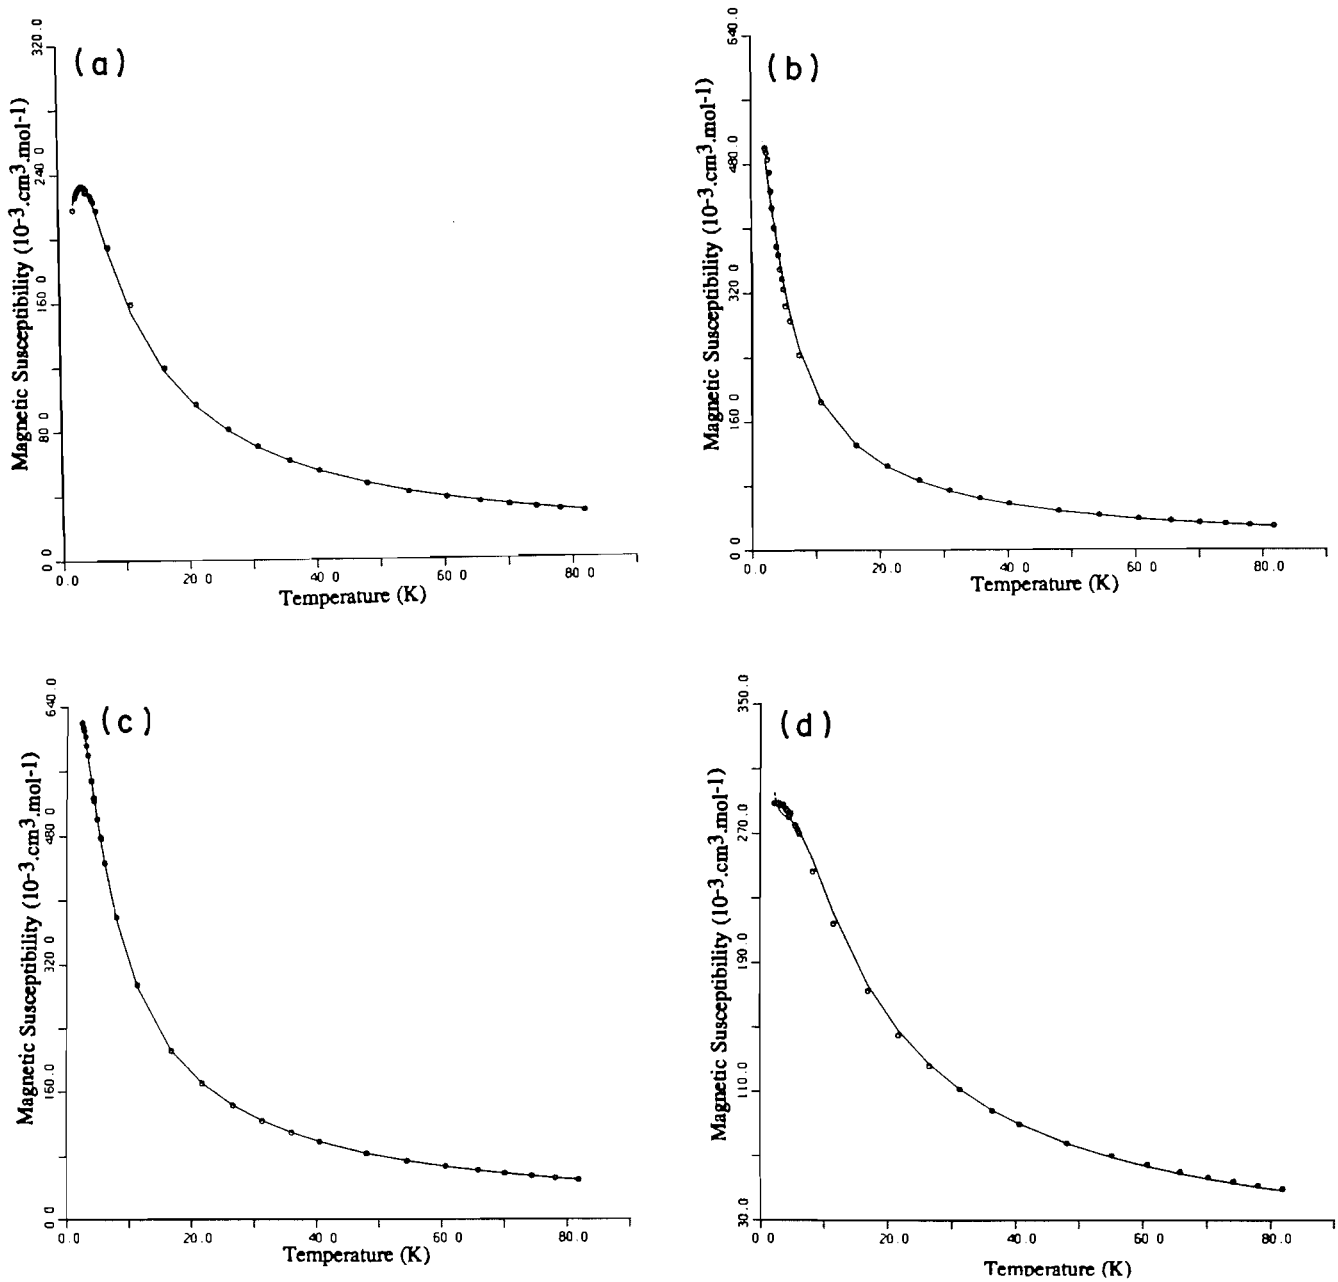

FIG. 5. Magnetic susceptibility versus temperature plots for $M(Ph_2PO_2)_2$: (*a*) γ-Co, (*b*) β-Co, (*c*) γ-Mn, (*d*) β-Mn. Circles are experimental data and solid lines are calculated as described in the text.

atom range from 103.2(1) to 114.7(1)°. The Mn...Mn distances along the chain are 4.417(1) and 4.446(1) Å. All other features of the structure are as described above for γ-$Co(Ph_2PO_2)_2$.

Tetrahedral manganese(II) complexes by virtue of their $^6A_1$ ground state should, in the absence of magnetic exchange, exhibit a temperature independent spin-only magnetic moment of 5.92 μ_B, with possibly small deviations at the lowest temperatures due to weak zero-field splitting effects. Both forms of $Mn(Ph_2PO_2)_2$ exhibit lower than spin-only moments over the entire range studied and, moreover, the moments decrease significantly with temperature (deposited data)[2] thus indicating the presence of antiferromagnetic coupling. The coupling appears to be greater in the case of the β form where the magnetic moment values are lower at all temperatures than those obtained for the γ form and the onset of a maximum in the susceptibility is observed at the lowest temperatures studied. Fits to the Wagner–Friedberg and Weng models for $S = 5/2$ were obtained and the best fit parameters are given in Table 5. For these manganese compounds a better fit between experiment and theory is obtained if allowance is made for a paramagnetic component as was described in an earlier study on manganese(II) monophenylphosphinate (17). The improvement in fit is particularly noticed near the susceptibility maximum in β-$Mn(Ph_2PO_2)_2$. The best-fit parameters, including allowance for the paramagnetic component, are also given in Table 5 and the theoretical curves obtained from the Weng model and employing these parameters are compared with experiment in Fig. 5*c* for the γ form and Fig. 5*d* for the β form.

In summary, β and γ forms of both $Co(Ph_2PO_2)_2$ and $Mn(Ph_2PO_2)_2$ have been synthesized and characterized. All

four materials show antiferromagnetic behavior which can be analyzed according to Heisenberg models for linear chains. Single crystal X-ray diffraction studies on the γ forms confirm the presence of extended chains in which tetrahedrally coordinated metal atoms are linked by double phosphinate bridges. The magnetic exchange which likely proceeds by a superexchange mechanism via the bridging O—P—O groups is of the same order of magnitude in the γ forms of the cobalt and manganese compounds, which is perhaps not too surprising considering the similarities in structural parameters in the two compounds. On the other hand, it is interesting to note that, whereas the exchange coupling is greater for the γ form of $Co(Ph_2PO_2)_2$ compared to its β form, the opposite is true for the $Mn(Ph_2PO_2)_2$ pair. Whether such a finding is a result of differences in the detailed structures of the two β forms or a consequence of the different metal ion electron configurations and therefore magnetic orbitals involved is something which is difficult to answer without a detailed knowledge of the structures of the β forms.

Finally, it should be noted that earlier studies by Ripamonte and co-workers (18, 19) on zinc(II) and beryllium(II) phosphinate polymers led these authors to suggest that coordination polymers involving bridging phosphinate groups and tetrahedral metal atoms have alternate single and triple phosphinate bridges, rather than the double phosphinate bridge, regardless of the organic side group. That this is not the case is shown by the work presented here as well as the recently reported X-ray structure determination of zinc(II) monophenylphosphinate which also reveals tetrahedral metal centres combined with the double phosphinate bridge system (20).

A microstratigraphic investigation of iron ion migration in some ancient Egyptian wall paintings using PIXE Analysis

GEORGE BURNS AND K.M. WILSON-YANG[1]

Lash Miller Chemical Laboratories, University of Toronto, 80 St. George Street, Toronto, Ont., Canada M5S 1A1

Received May 28. 1990

GEORGE BURNS and K. M. WILSON-YANG. Can. J. Chem. **69**. 286 (1991).

The painted murals in the tombs at Beni Hasan (*circa* 2100 B.C.) are obscured by a rock-like grey surface layer. Its formation involves subsurface removal of slightly soluble calcite ($CaCO_3$) under the action of surface-condensed water. To study the mechanism of surface layer formation and the effect of mural cleaning during recent restorations, the PIXE microprobe was used. Iron depth profiles in red-painted samples taken from the murals, both uncleaned and cleaned, have been obtained over depths of 80 μm (the cleaned sample) and 100 μm (the uncleaned sample). It has been found that the uncleaned sample has more Fe at all depths than does the cleaned sample and that portions of the uncleaned pigment appear to be pure Fe_2O_3. The shapes of depth profiles of Fe in the cleaned and uncleaned samples are similar to the shapes of diffusion curves; this finding is in agreement with the mechanism of surface layer formation proposed in our earlier papers. Apparent diffusion coefficients for the ion migration of Fe, D_{Fe}, in the limestone painting substrate have been determined, assuming constant temperature diffusion over 4 000 years: $D_{Fe(u)} = (1.4 \pm 0.5) \times 10^{-16}$ cm^2/s for the uncleaned sample and $D_{Fe(c)} = (0.7 \pm 0.4) \times 10^{-16}$ cm^2/s for the cleaned sample, where errors are given as the 95% C.I. based on standard deviations of the slope of the fitted curve. These coefficients are consistent with the mechanism of slow migration of Fe in the painting substrate in an arid environment. The difference between D_{Fe} values secured for the cleaned and uncleaned samples is attributed to a partial removal of the paint layer in the cleaned sample during the restoration efforts. Thus, if it is assumed that either 20 or 40 μm of paint layer was removed during HCl-cleaning of murals, $D_{Fe(c)} = (1.0 \pm 0.4) \times 10^{-16}$ and $D_{Fe(c)} = (1.4 \pm 0.6) \times 10^{-16}$ cm^2/s, respectively, are obtained. Removal of the top 40 μm of the mural corresponds to elimination, during the restoration, of the order of 60% of the uncleaned paint layer.

Key words: Egypt, PIXE, ancient murals deterioration.

GEORGE BURNS et K. M. WILSON-YANG. Can. J. Chem. **69**, 286 (1991).

Les murales des tombes trouvées à Beni Hasan (environ 2100 BC) sont obscurcies par des couches superficielles grises qui ressemblent à du roc. Leur formation implique l'enlèvement, sous la surface, de calcite ($CaCO_3$) partiellement soluble sous l'action d'eau qui se condense à la surface. Afin d'étudier le mécanisme de formation de la couche superficielle ainsi que l'effet du nettoyage de ces peintures effectué dans le cadre de restaurations récentes, on a fait appel à des microprobes PIXE. On a déterminé les profils de concentration du fer en fonction de la pofondeur (jusqu'à 80 μm pour des échantillon nettoyé et jusqu'à 100 μm pour l'échantillon non-nettoyé) pour des échantillons peints en rouge prélevés sur les murales. On a trouvé que, à toutes les profondeurs, l'échantillon qui n'a pas été nettoyé contient plus de fer que celui qui a été nettoyé et que des portions du pigment non-nettoyé semblent être du Fe_2O_3 pur. Les formes des profils des concentrations du Fe en fonction de la profondeur dans les échantillons nettoyé et non-nettoyé ressemblent aux formes des courbes de diffusion; ce résultat est en accord avec le mécanisme de formation de la couche superficielle qui a été proposé dans nos communications antérieures. Faisant l'hypothèse que la température de diffusion a été constante au cours des derniers 4 000 ans, on a déterminé les coefficients de diffusion apparents pour la migration de l'ion Fe dans le substrat qu'est le calcaire peint; $D_{Fe(u)} = (1,4 \pm 0,5) \times 10^{-16}$ cm^2/s pour l'échantillon qui n'a pas été nettoyé et $D_{Fe(c)} = (0,7 \pm 0,4) \times 10^{-16}$ cm^2/s pour l'échantillon qui a été nettoyé alors que les erreurs sont égales à 95% de l'I.C. basé sur les déviations standard de la pente de la courbe. Ces coefficients sont en accord avec le mécanisme d'une migration lente du Fe dans le substrat peint, dans un environnement aride. Les différences observées pour les valeurs de D_{Fe} obtenues pour les échantillons nettoyés et non-nettovés sont attribuées à un enlèvement partiel de la couche de neinture dans l'échantillon nettoyé qui se serait produit au cours des efforts de restauration. Donc, si on fait l'hypothèse que 20 ou 40 μm de la couche de peinture a été enlevé au cours du nettoyage des muales avec du HCl, on obtient des valeurs respectives de $D_{Fe(c)} = (1,0 \pm 0,4) \times 10^{-16}$ et $D_{Fe(c)} = (1,4 \pm 0,6) \times 10^{-16}$ cm^2/s. L'enlèvement de 40 μm de la surface de la murale correspond à l'élimination, durant la restauration, d'environ 60% de la couche de peinture qui n'a pas été nettoyée.

Mots clés : Égypte, PIXE, détérioration de murales anciennes.

Introduction

Eco-archaeological chemistry

Extensive degradations of ancient monuments throughout the world, and specifically in Egypt (see, for example, ref. 1), cause considerable concern not only in the scientific community but also to the public at large (1). Study of such processes by chemical means provides an unusual opportunity for elucidation of fundamental physicochemical processes which occur over a very long period of time, of the order of millennia, which is of the order of 10^{11} s. While modern chemical methods now make possible studies of processes down to the order of 10^{-13} s, studies of very slow processes have been difficult to conduct because there are but few systems of well-defined age if this age is of the order of a few millennia. Even if the age can be determined, it is rare to find a system which existed under sufficiently uniform conditions over such a long period of time. However, some archaeological systems satisfy both of these requirements. In addition, such studies are important because prevention of degradation of ancient monuments and development of reliable conservation and restoration methods require, as a first step, an adequate understanding, at a rather fundamental level, of the physicochemical processes responsible for these deteriorations (2).

Without such understanding, even the most conscientious conservation or restoration effort may not only simply fail, but may even augment the existing damage. These questions are the domain of eco-archaeological chemistry, sometimes considered to be a part of a more general field of eco-archaeometry (2), which combines methods of analytical and physical chemistry and associated (2) fields. In this paper, an attempt is made to study, using some tools of eco-archaeological chemistry, the deteriorating murals of the ancient tombs of Beni Hasan.

Degradation at the Beni Hasan Tombs

The tombs at Beni Hasan, Egypt, contain artistically significant painted murals which constitute important records of First Intermediate Period and Middle Kingdom (*circa* 2100 B.C. to 1800 B.C.) life. These paintings were executed on the tomb walls using the tempera technique (3) on the polished limestone which constitutes the painting substrate. A thin layer (3, 4) of whitewash (5) may have been employed to prepare the rock surfaces for painting; however, in our work, no conclusive evidence has been found to verify this point.

The Beni Hasan wall paintings are now obscured by a rock-like grey deposit (3, 6, 7) and evidence accumulated from historic sources suggests (7) that the development of this surface degradation product has accelerated over the past 150 years.

Investigations of the grey degradation layer and its formation have been conducted (5, 8) on a small collection of fragments, coloured with the yellow and the red iron-based pigments assembled by the authors on site from the Beni Hasan tomb paintings. The first few nanometres of the surface deposit have been analyzed earlier by the X-ray photoelectron spectroscopy (8). The results of this analysis made it possible to propose a mechanism (8) for the formation of the degradation layer which required that, in addition to dust deposition, surface layer formation involves ion migration within and throughout the paint layers and subsurface regions. According to the proposed mechanism (8), it is this ion migration that led to formation of the $CaCO_3$ surface layer in which sand and dust particles are now imbedded. It is this ion migration that also led to eventual subsurface removal of slightly soluble material, mainly $CaCO_3$, from the substrate upon which the murals were painted and the subsequent deposition of this material on the surface. The migration of this material appeared to be possible under the action of surface-condensed water (5).

Although all these predictions could not have been verified from the XPS observations (8), some of them were subsequently confirmed using light microscopy and electron microprobe analyses (5): painted fragments, examined in cross-section, showed some subsurface depletion and associated formation of dendritic structures within the substrate, below the painted layers (5). Such confirmation provides qualitative support for the proposed (8) mechanism; however, this work (8) provided no direct evidence for ion migration within the murals.

The degradation process which results in the subsurface depletion below the paint layer has been suspected also to act directly on the paint layers (5): in the depleted yellow-painted samples, degradation was so extensive that a clear demarcation of the paint layer could not be seen. However, the subsurface degradation associated with the surface layer formation was seen in only one red-pigmented sample (5), although not at the same depth as in the yellow samples. Furthermore, the red paint layer-substrate separation line can be seen both under the microscope and by the electron microprobe (5).

During continuing cleaning endeavour by chemists and conservators of the Egyptian Antiquities Organization, the obscuring grey layer which covers the painted surface at Beni Hasan is being removed from some murals (3). This restoration effort involves use of fairly concentrated HCl on the encrusted painted surface, normally applied with a papier maché poultice, and then rinsing the surfaces with water applied in the same manner. However, Egyptian scientists expressed a continuous concern (the late Professor Z. Iskander, private communication) that during this cleaning, disruption of the both the iron-based paint layer and the limestone substrate may accompany removal of the disfiguring surface layer with HCl.

To further investigate the mechanism of the physicochemical processes responsible for the formation of grey deposits at Beni Hasan and to study the effects of strong acid on wall paintings, a proton-induced X-ray emission (PIXE) microprobe has been used. This technique yields iron concentration and its depth distribution in the red painted samples. In earlier electron microprobe studies (5), the equipment proved to be not sufficiently sensitive for quantitative analysis of iron.

Experimental section

A red-painted, uncleaned sample from Beni Hasan Tomb 15 (the First Intermediate Period), and a red-painted, HCl-cleaned fragment from Beni Hasan Tomb 2 (the Middle Kingdom), were investigated using the PIXE analyses. Representative photographs of pigmented samples assembled in Beni Hasan tombs were reproduced elsewhere (5, 8).

PIXE sample preparation

The samples were grain-mounted in an epoxy resin of low curing temperature (Metaserv Metset SW). Cross-sections were exposed by cutting the sample perpendicular to the surface with a diamond saw (Buehler Isomet) using ethanol as coolant. The exposed surfaces were ground by hand with 600 and 1000 mesh carborundum on plate glass with spectroscopic grade methanol (Fisher ACS) as a lubricant. The surfaces were then polished using, in succession, 9, 3, 1, and 1/4 μm particle-size diamond pastes. Samples were observed at 100× magnification after 1000 mesh grinding, and reexamined after final polishing. When the paint and surface crust strata were clearly visible and no surface irregularities were seen under the microscope, the polishing was judged complete. The final exposed cross-sectional areas were approximately 1 mm^2. The specimens were mounted in 28 mm × 9.5 mm × 1.6 mm aluminum sample holders.

To quantify PIXE results,[2] a pellet whose composition imitates the paint layer composition was prepared. The red paint layer in the wall paintings at Beni Hasan has been found, from microprobe analyses (5), to be a mixture of iron oxide, silica, and calcium sulphate as well as phosphates and calcium carbonate.[3] The standard pellet was prepared from three components: (*1*) 0.3561 g Fe ore, National Bureau of Standards Standard Reference Material, NBS SRM 27e, (*2*)

[2]Quantification in PIXE and related techniques is difficult for thick samples of heterogeneous materials, a category in which most archaeological material falls. In provenance studies of obsidian, peak intensity ratios have been used without correction, see ref. 9*a*. Fundamental parameter methods, similar to those used routinely in electron microprobe analyses (9*b*) have been employed on ceramics (9*c*) and special consideration has been given to the development of computer-based quantification procedures for thick samples (9*d*).

[3]In ancient Egypt, anhydrous iron oxide, Fe_2O_3, has been found mixed with $CaSO_4.2H_2O$ (10*a*). The presence of calcite, quartz, gypsum, and haematite was reported in red pigments from the Tomb of Horemheb (*circa* 1350 B.C.) (10*b*).

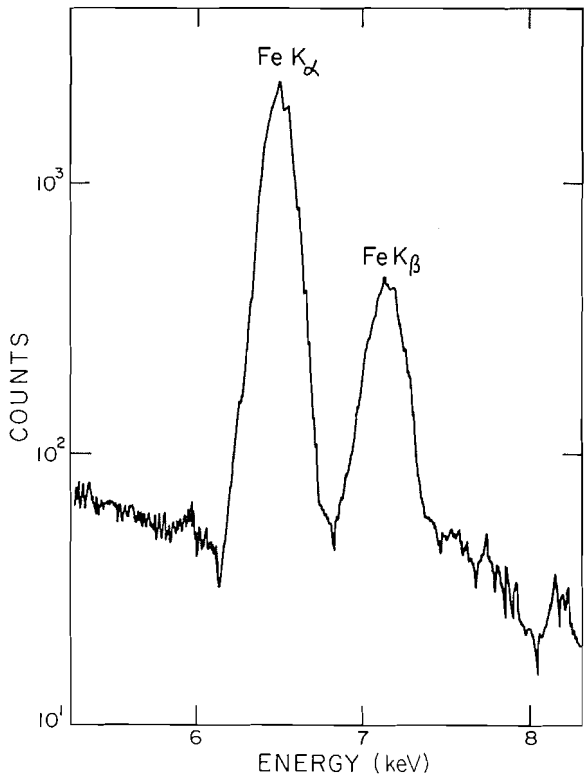

FIG. 1. An example of PIXE spectrum of Fe obtained in the present work.

0.2851 g Opal glass NBS SRM 91, and (*3*) 0.2735 g reagent grade $CaSO_4.2H_20$ (Fisher ACS). This standard contained 26.72% Fe. The three components were mixed by grinding in a mortar and pestle. The mixture was shaken twice in a WIG-L-BUG^R automatic mixer for 15 s a time. A pellet was formed by applying a pressure of 104 kg/cm^2 for 3 min using a Barnes Engineering pellet press. Upon removal, the 9 mm diameter pellet was also mounted on an aluminum sample holder. Both samples and standard were coated with an approximately 10 μm thick layer of carbon, deposited by sublimation in vacuum, to reduce charging and heating effects (11).

PIXE analyses

PIXE spectra were collected at the van de Graaff accelerator, Los Alamos National Laboratories. The superconducting solenoid magnet used as a final lens on this PIXE microprobe provides a finely-focused beam. The instrumentation has been described elsewhere (12). A 3 MeV, 4 namp, proton beam with an approximate diameter of 5 μm was employed to generate the spectra. An aluminum filter was placed in front of the Si:Li detector to reduce the intensity of the spectral background. A piece of Cu foil was placed on each sample to act as a positional reference and a conductive pathway. For the uncleaned sample, a depth profile was assembled from six spectra which were collected in 20 μm steps starting at an Fe maximum. In the cleaned sample, the depth profiles were assembled from five spectra which were collected starting from a point within the limestone substrate and extending into the paint layer as far as it was possible. An example of Fe PIXE spectrum is shown in Fig. 1.

PIXE data reduction

Data reduction was performed in Toronto: Fe concentrations have been calculated from the Los Alamos raw spectral data. The mixed-oxide pellet standard was used to reduce the background-subtracted peak areas to elemental concentrations. Backgrounds were calculated by linear extrapolation under individual peaks. It was assumed that a peak existed when the net count under the peak was greater that 2.3 times the standard deviation of the background.[4]

[4]This is the critical level for detection, $L_c = 1.64$ (2σ background) at 95% significance level (13).

TABLE 1. Concentration of Fe (%wt.) versus distance (μm)

Distance (μm)	[Fe]*	
	Cleaned sample	Uncleaned sample
0	37.9±0.4 (1.1%)	79.9±0.3 (0.4%)
20	27.5±0.3 (1.1%)	79.1±0.3 (0.4%)
40	13.6±0.2 (1.5%)	58.8±0.2 (0.3%)
60	11.9±0.2 (1.7%)	35.4±0.2 (0.5%)
80	5.6±0.1 (1.8%)	28.5±0.1 (0.4%)
100	—	20.1±0.1 (0.5%)

*The errors are the standard deviation compounded from the counting error on the background subtracted counts for each element and the error associated with the calibration standard. Relative standard deviations in percent.

Partially resolved K_a and K_b peaks from Ca were seen also, as well as three well-defined peaks due to elements lighter than calcium. None of these lighter elements was investigated in the present studies: they were expected to be due to elements which have a smaller atomic number than Ca, such as oxygen and silicon; the latter two elements can normally be investigated using the electron microprobe technique since their concentrations are relatively large.

Results

Depth and distributions

Iron concentrations from cleaned and uncleaned samples are summarized in Table 1 and plotted against depth in Fig. 2. The starting point of the scans, 0 μm, is defined as a point closer to the surface than all other points, but inside the paint layer of a sample; at this point a maximum Fe concentration was observed.

Error assessment

In a similar stratigraphic investigation of thick samples of heterogeneous materials (14) where the standards closely mimicked the samples, the error in concentration, due to the method of analysis as a whole, was estimated to be ±5%. This error can be considered, therefore, the lower limit in the present work. In investigations described below, a single standard was used; however, a single standard cannot anticipate all matrix effects in the wide range of compositions which can be encountered in a stratigraphic analysis. The proton stopping-power, the degree of enhancement by secondary X-rays and the sample absorption coefficients all change with composition.

The maximum percentage of Fe in pure Fe_2O_3 is 69.9%. The concentrations of Fe at the first two distances in the uncleaned sample (Table 1) are higher than that possible for pure Fe_2O_3 by 10% by weight or 14% relative error. Therefore, for the present analyses, 14% is assumed to be the relative method error for results whose relative standard deviation (Table 1) is less than 14%. For all other results, the relative method error is estimated by the reported relative standard deviation (Table 1). The difference between two individual results was taken to be significant if it was equal to or larger than 1σ, where σ is estimated by the relative method error as defined above; in our case $\sigma \geq 14\%$, and corresponds to a 68% level of confidence.

Discussion

The most evident findings of this work are that (*i*) the uncleaned paint layer contains appreciably more iron than the cleaned sample and that (*ii*) at least some of the analyzed

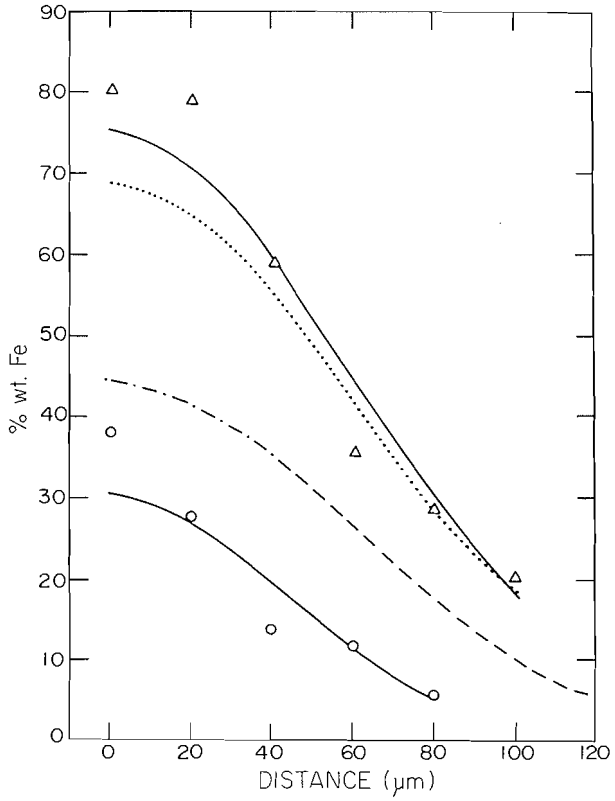

FIG. 2. Iron percentage versus distance in μm. Errors in abundance are given in Table 1; error in distance is 2.5 μm. △, uncleaned sample; upper solid curve, uncleaned sample diffusion curve, $D^{4000y}_{(Fe(u)} = (1.4 \pm 0.5) \times 10^{-16}$ cm²/s. ○, cleaned sample; lower solid curve, cleaned sample diffusion-like curve, $D^{4000y}_{Fe(c)} = (0.7 \pm 0.3) \times 10^{-16}$ cm²/s. These curves were calculated by least-squares fits to experimental data. The dashed-dotted curve was calculated from cleaned sample data plotted, using the assumption that 40 μm of the surface of the cleaned mural were removed during recent restorations; dotted line, see text. The dashed curve is identical to the lower solid curve, but displaced by 40 μm to the right; it extrapolates directly into the dashed- dotted curve.

portion of the uncleaned paint layer is almost pure Fe_2O_3. At 0 μm the Fe content of the cleaned sample is less than that of the uncleaned sample by 42% by weight; this difference is 53% of the Fe content of the uncleaned sample. Indeed, the uncleaned sample has more Fe than the cleaned sample at all distances (Table 1).

Apart from the data in Table 1, and the approximate composition of the pigment layer found in electron microprobe analyses (5), only a few analyses of ancient Egyptian red iron oxide pigments appear in the literature (10). It is suspected that, generally, the range of compositions is broad: in medieval usage, the raw materials from iron oxide red pigments ranged from as little as 20% Fe_2O_3 (14% Fe) to as much as 95% Fe_2O_3 (66% Fe) with clay and quartz making up the balance (14*a*) Two main types of red pigments are known to be used in ancient Egypt: anhydrous oxide of iron, and hydrated oxides of iron, usually referred to as red ochre (14*b*) The present work yields evidence that ancient Egyptians, as early as *circa* 2100 B.C., indeed used pigments which were, at least in part, fairly pure Fe_2O_3. Even if we were to assume that the relative error is 14% (as was done above), the pigment samples analyzed would be 100% pure. However, if the error is larger than 14% purity, purity of sample below 100% would be possible. Red pigments analyzed previously (14*c*) yielded 79.11 and 81.34 pure Fe_2O_3. We are not aware of any analyses which yield purity higher than 81.34. Red ochre, being hydrated ferric oxides, contain smaller concentrations of Fe and hence less Fe_2O_3 than pure Fe_2O_3.

Migration of Fe in uncleaned and cleaned samples

The PIXE depth profiles for Fe extend beyond 30 ± 10 μm, which is the red paint film thickness measured by optical microscopy and seen in electron microprobe depth scans (5). The subsurface depletion and dendrite formation, visible under the light microscope in yellow-painted fragments also extends beyond 30 μm; the dendrites have been found to extend 55 to 230 μm below the surface layer (5). However, these subsurface effects are not as extensive in red-painted samples (5). The depth profiles of iron concentration (Fig. 2) obtained from the PIXE analyses of the red-painted samples are similar to distributions which would arise if changes in Fe concentrations in depth were due to diffusion. Therefore, the Fe depth profiles (Fig. 2) suggest that the red-painted samples are also affected by the subsurface presence of solvent; specifically, they imply that transport of iron away from the paint layer has occurred. This finding had not been detected previously (5) in earlier electron microprobe work.

To calculate apparent diffusion coefficients for Fe ion migration, one can assume that the depth profiles of Fe in both samples are the result of a constant diffusion-like ion migration which has occurred either over 4 000 years, *i.e.*, the approximate age of these paintings, or over 150 years (7), the approximate time of the acceleration of the growth of the surface degradation layer. Then, apparent diffusion coefficients for Fe ion migration in the painting substrate can be calculated from the experimental data (Table 1, Fig. 2) for these two time periods. If it is assumed that diffusion-like migration has occurred from a film of uniform composition into the limestone-based substrate, then the concentration distribution can be described by (15)

$$[1] \qquad C(x) = K \exp(-x^2/4Dt)$$

where D is the apparent diffusion coefficient and concentration at distance x is represented by $C(x)$.[5] The pre-exponential factor, K, is equal to $M/(\pi Dt)^{1/2}$, where M is the initial mass of diffusing substance per unit area in the thin film. Apparent diffusion coefficients can be calculated from the least-squares fitted curve of ln $C(x)$ versus x^2. Error in the diffusion coefficient is reported throughout as the 95% C.I. based on the standard deviation of the slope of the fitted curve.

The apparent diffusion coefficient for Fe in the uncleaned sample, $D^{4000y}_{Fe(u)}$, is $(1.4 \pm 0.5) \times 10^{-16}$ cm²/s assuming constant temperature diffusion over approximately 4 000 years. The dotted line (Fig. 2) was plotted using the assumption that at 0 μm, the Fe weight percent is equal to 69.9%; its diffusion coefficient over 4 000 years, being $(1.5 \pm 0.4) \times 10^{-16}$ cm²/s, did not differ significantly from $D_{Fe(u)}$ reported above. Using

[5]The use of this equation assumes that migration occurs from the thin film in the positive direction x, in our case into the limestone. In a semi-infinite boundary condition, it is implicit that C(0) does not change when $x = 0$; this condition may also be accommodated by the immobilization of pigment in the paint layer. However, it is necessary that the source of the diffusing material exceed some minimum thickness. A minimum layer thickness for the assumption of the semi-infinite boundary condition can be calculated from the expression: $l_{(min)} = 4.3(Dt)^{1/2}$; ref. 15(*a*). Using the estimates of the diffusion coefficient found here, $l_{(min)}$ is approximately 130 μm: the thickness of the paint film is about one quarter of this value.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

the same method of calculation for the diffusion coefficient of Fe in the limestone painting substrate in the cleaned sample, $D^{4000y}_{Fe(c)} = (0.7 \pm 0.3) \times 10^{-16}$ cm^2/s. For diffusion over 150 years, $D^{150y}_{Fe(u)} = (4 \pm 1) \times 10^{-15}$ cm^2/s and $D^{150y}_{Fe(c)} = (2 \pm 1) \times 10^{-15}$ cm^2/s. Note that these apparent diffusion coefficients in the cleaned sample are approximately half of those found for the uncleaned sample. At first sight, these calculations may suggest that Fe in the cleaned sample moved a shorter distance over the equivalent time period as did Fe in the uncleaned sample only because the sample was recently cleaned with HCl. However, this explanation cannot be accepted: it would be unreasonable to suggest a mechanism which would require that apparent diffusion coefficients, obtained from calculations based on diffusion over millennia, are affected by recent HCl cleaning. Furthermore, such a mechanism should account for the fact that the concentration of Fe in the cleaned sample is lower than that of the uncleaned sample at each distance (Table 1). One would expect that the apparent diffusion coefficients in the cleaned and uncleaned samples be the same, if the pigment does not interact chemically with HCl during cleaning. If, on the other hand, one is to assume that red pigment is somewhat soluble in HCl, cleaning should promote migration of iron into the substrate; then the inequality $D_{Fe(c)} > D_{Fe(u)}$ would be predicted. Dissolution of pigment in HCl is indeed possible: it has been reported that 50% HCl has been used to dissolve iron oxides in limestone fractionation experiments (16). However, the inequality $D_{Fe(c)} < D_{Fe(u)}$ is observed.

To explain the differences in Fe ion apparent diffusion coefficients in the cleaned and uncleaned samples, it is first assumed that 20 to 40 μm of paint layer has been removed during restorations. Then, apparent diffusion coefficients were recalculated by translating the cleaned Fe depth profile by 20 μm and by 40 μm (Fig. 2). This yields $D^{4000y}_{Fe(c)}(20\ \mu m) = (1.0 \pm 0.4) \times 10^{-16}$ cm^2/s and $D^{4000y}_{Fe(c)}(40\ \mu m) = (1.4 \pm 0.6) \times 10^{-16}$ cm^2/s. The $D^{4000y}_{Fe(c)}$ calculated in this manner, and especially $D^{4000y}_{Fe(c)}(40\ \mu m)$, are comparable to the apparent diffusion coefficient calculated for the uncleaned sample. Thus, the lower value of the $D^{4000y}_{Fe(c)}$, *i.e.* $D^{4000y}_{Fe(c)} = (0.7 \pm 0.4) \times 10^{-16}$ cm^2/s, from the cleaned sample data, may be attributed to the removal of the paint layer during recent *in situ* cleaning. The removal of 40 μm of paint layer is equivalent to the removal of 60% of the Fe pigment; the latter estimate is deduced by comparing the areas under the two solid % Fe *versus* distance curves for the cleaned sample (Fig. 2). This conclusion should be considered with a measure of caution: apparent diffusion coefficients just overlap at 95% confidence interval. Furthermore, there is no reason to believe that the original thickness of the pigment layers was the same for both samples investigated. Therefore, the 60% number has more qualitative than quantitative significance: the percent of pigment removed by cleaning may have been smaller or larger than 60% depending upon the original thickness of the pigment of the cleaned sample. Nonetheless, present findings suggest that a removal of some 60% of the pigment is possible. Such a removal would constitute major damage to the painted surfaces and should not be considered acceptable. If one were to accept a loss of pigments in order to restore the beauty of the original mural, one would have to face an even graver consequence of current restoration practices: one may expect that a cleaned surface will develop again, relatively quickly, its own new grey crust of dust imbedded in $CaCO_3$. This time it will not be possible to remove the crust with HCl, without removing practically all the remaining pigment.

It is difficult for a technician who is responsible for the cleaning of murals to estimate the amount of pigment removal which occurs during the restoration. His primary responsibility is to produce a good product, *i.e.*, a well-cleaned, fresh-looking mural surface; and indeed visual inspection of restored murals by an interested visitor entice admiration of a beautiful restoration effort. Murals do look lighter in colour, as indeed they should because fresh layers of pigments are exposed and because they contain now an appreciable amount of white calcium carbonate. However, low percent concentrations of Fe_2O_3 in red pigments have often been used in Egypt and elsewhere (10, 14*a*); therefore, the quality of colour may not be questioned. On the other hand, HCl washing using papier-maché sponges yields loose $CaCO_3$ deposits which contain appreciable quantities of sand, an efficient abrasive of an already damaged pigment. Therefore, removal of large quantities of pigments may not be totally unexpected.

A mechanism for Fe migration

Using kinetic parameters found in high temperature diffusion studies for Fe in single Fe_2O_3 crystals[6] (17), a diffusion coefficient of 4×10^{-40} cm^2/s at 25°C has been calculated for Fe, assuming a temperature-independent pre-exponential factor. This number is 10^{25} times smaller than the observed apparent diffusion coefficients. This mechanism for explanation of diffusion-like data (Fig. 2) can therefore, be neglected. The mechanism for solid state diffusion in single crystals involves substitutional and interstitial migration of ions through the crystal lattice, which is indeed a relatively slow process.

For solid state diffusion in a less-ordered system, for example, ground calcite, the diffusion coefficient is considerably higher. Using kinetic parameters obtained elsewhere[7] (18), the diffusion coefficient for the self-diffusion of ^{14}C in ground calcite has been calculated as 2×10^{-28} cm^2/s at 25°C. This represents an increase of 10^{12} over the diffusion coefficient of Fe in single crystals; a change of this magnitude is apparently due to increased migration along calcite microcrystal boundaries. (The factor of 10^{12}, *i.e.* 10^{-40} *vs.* 10^{-28} is probably still too small because the diffusion of ^{14}C may be expected to occur in conjunction with movement of CO_3^{2-}; its diffusion coefficient in single crystals is expected to be considerably smaller than that of iron. Since the diffusion coefficient for ^{14}C in ground calcite is still smaller by a factor 10^{12} than that found for Fe in the painting substrate at Beni Hasan, it can be concluded that this type of self-diffusion process is also too slow to account for apparent diffusion coefficients observed in this work.

On the other hand, diffusion coefficients for ions in free solution are of the order of 10^{-5} cm^2/s. This diffusion process is some 10^{11} times faster than the diffusion in Beni Hasan samples. Therefore, the observed apparent diffusion coefficients cannot be attributed to free diffusion in solution.

Ion migration within solvent-saturated pores, *i.e.*, within rock (19), decreases diffusion coefficients by one to three orders of magnitude from the solution value depending, in part, on the degree of porosity and tortuosity. Room temperature diffusion coefficients for the movement of $Na^+$and Cl^- in unconsolidated sediments are of the order of 10^{-5} cm^2/s in sediments with 80% porosity to 10^{-6} cm^2/s in sediments with

[6] $D_{Fe} = A \times 10^{-9} \exp(-B/k_bt)$ for $T < 1173$ K, $A = 2.8$ eV, $B = 1.8$ eV (17).

[7] $D = D_0 \exp(-E_a/k_bt)$ for 250 – 550°C, $D_0 = 4.6 \times 10^{-16}$ cm^2/s, $E_a = 71$ kJ mol^{-1} (18).

20% porosity. Room temperature diffusion coefficients of the order of 10^{-7} to 10^{-8} cm^2/s have been reported for 2-propanol in wet portland cement with 21% porosity to 1.2% porosity, respectively (20).[8] Thus, the observed apparent diffusion coefficients cannot be attributed to ion migration in solvent-saturated pores.

Diffusion coefficients measured in some porous materials may be smaller by a factor of 10^6 than those found for the free movement of ions in porous media because the interaction on, or ion exchange with, pore-wall material is slow. For example, in sodium ion/water leaching experiments on powdered silicate-based glasses, apparent ion diffusion coefficients range from 10^{-14} to 10^{-17} cm^2/s at 40°C. The 10^3 spread in the apparent diffusion coefficients is due predominantly to variation in composition of the mixed oxides which were incorporated in the silica lattice of the glasses tested (21). These numbers compare reasonably well with the apparent diffusion coefficients for iron found in this work, which are of the order of 10^{-15} to 10^{-16} cm^2/s.

The magnitude of the Fe ion apparent diffusion coefficients, over the period of 4 000 years, are of the same order of magnitude as those obtained (22) for Ca ion migration across accurately dated clay—cement interfaces. Thus, the apparent diffusion coefficient for Ca ion was found to be 1.34×10^{-16} cm^2/s to 9.77×10^{-17} cm^2/s in masonry samples ranging in age from 68 years to approximately 4 000 years (22). The 150 year Fe-ion apparent diffusion coefficients are only one order of magnitude larger than the Ca-ion apparent diffusion coefficients. It thus appears that the Beni Hasan system is fairly well mimicked by diffusion in clay cement systems.

It thus can be concluded that in the heterogeneous matrix of the limestone painting substrate at Beni Hasan, movement of Fe ions in the limestone can be most appropriately considered in terms of ionic diffusion, with active sites for the migrating ions located on the walls of the rock pores. This movement involves the presence of a solvent (water) which intimately interacts with the active sites. Substrate porosity, and intermittent water (solvent) availability in these arid tombs, appear to be the major factors responsible for the magnitude of the apparent diffusion coefficients found in the Beni Hasan samples.

Since the magnitudes of the 4 000 year and the 150 year Fe-ion apparent diffusion coefficients are both consistent with ionic diffusion within rock pores, it is not possible, on the basis of available data, to establish which of these diffusion times is more appropriate in the description of ion-migration in the painting substrate at Beni Hasan.

Ionic diffusion processes for dating purposes

Diffusion-related phenomena have been studied in ancient materials such as metals (23), obsidians (24), masonry (17) and papers (25). Dating of archaeological and historical materials has been attempted using diffusion-like phenomena and it was shown that it may be appropriate in narrowlydefined situations.[9] Present results indicate, however, that although it may be possible to obtain apparent diffusion coefficients, it is much more ambiguous to establish the reliable age of ancient materials from these diffusion coefficients alone. This latter point is relatively easy to demonstrate using such well-dated ancient materials such as the Beni Hasan murals. For example, it could not be established from the Fe-ion apparent diffusion coefficients found here whether the Fe migration took place predominantly over 4 000 years or over 150 years. The mechanism of ion migration in murals would have to be defined in much greater detail before a reasonably accurate dating would become feasible. Nonetheless, metal ion depth profiles such as found here may prove to be a means of diagnosing and monitoring the effects of industrially generated acid condensation on exposed rock and building materials.

Validity of the approach used

Results and their interpretations discussed above suggest that it is appropriate to conduct scientific studies such as these, to a large extent because they form a technical background for further restoration and conservation initiatives. Nonetheless, it should be stressed that one of the difficulties of the approach is that the samples studied, being taken from irreplaceable ancient historic records some 4 000 years old, have to be small in size and in number. Consequently, only two samples were studied here. Yet, it can also be noted that it is encouraging that much information can be obtained using such a small number of small samples. Efforts, now in progress, are directed toward expanding this work, using a larger number of samples. Generally, it is clear that more work should be done, and although the approach is clearly useful, extrapolation to other colours, murals and tombs is at best risky, if not impossible, at least for the present.

[8]2-Propanol was used to displace water in wet portland cement.

[9]In the dating of obsidian by hydration rind thickness, it has been recognized that composition, chemical reaction, and concurrent diffusion all play roles in the kinetics of hydration (24). The migration of ink in historical papers has been correlated with age, but the mechanism for the movement of Fe-based inks down paper fibrils was not determined (25).

Acknowledgements

The authors wish to thank the Egyptian Antiquities Organization for permission to take samples from the tombs at Beni Hasan. Special thanks are extended to Dr. Ali el Khouli and Mr. Mottawi Balboosh. Mr. George Taylor, Geology Department, University of Toronto, gave useful advice on sample preparation and provided the polishing and grinding compounds. Dr. C.J. Maggiore of the van de Graaff accelerator Laboratory at Los Alamos ran the PIXE spectra. This work was supported in part by the Natural Sciences and Engineering Research Council of Canada and in part by the University of Toronto.

Colloidal molybdoantimonic acids as ion exchangers

M. KONÉ, P. COURTIN, AND J. LEMERLE

Laboratoire de chimie des polymères inorganiques, Université P. et M. Curie, 4 place Jussieu, 75252 Paris, Cedex 05, France

Received November 28, 1989[1]

M. KONÉ, P. COURTIN, and J. LEMERLE. Can. J. Chem. **69**, 293 (1991).

Colloidal particles with a c.c.p. structure were obtained from mixtures of antimonic and molybdic acids through a polymerization process. These particles were octahedral and their sizes fits the log-normal distributions. The mean size decreases and the polydispersity increases with increasing Mo content in the particles. The stability of the aqueous dispersions was due to the surface charge density of the particles which was enhanced when increasing the Mo content. Ion exchange reactions can occur with the dispersions. Two different routes lead to Ag^+ fixation: substitution of core H^+ without flocculation of the dispersion or cancellation of external charges with flocculation.

Key words: inorganic exchangers, colloids, antimonic acid, molybdic acid.

M. KONÉ, P. COURTIN et J. LEMERLE. Can. J. Chem. **69**, 293 (1991).

Des particules colloïdales ayant la structure c.f.c. de l'acide antimonique sont préparées par polymérisation de mélanges d'acides antimonique et molybdique. Les liaisons en taille de ces particules octaédriques satisfont une loi log-normale. La taille moyenne diminue et la polydispersité augmente quand la teneur en Mo augmente. La stabilité des dispersions est due aux charges de surface dont la densité est augmentée par la teneur en Mo. Les dispersions de ces particules peuvent être le siège de réactions d'échange d'ions. Ag^+ peut être fixé selon deux processus : substitution des protons de la structure sans floculation de la dispersion ou annulation des charges externes causant la floculation.

Mots clés : échangeurs inorganiques, colloïdes, acide antimonique, acide molybdique.

Introduction

Inorganic ion exchangers are used in large quantities for separation processes, substitution of polyphosphates in detergents, and as inert matrices for catalyst application. Their cavities are responsible for their activities. Inorganic ion exchangers like zeolites are usually manufactured through a sol–gel process involving the mixing of aluminate and silicate solutions. Particles of inorganic oxides of colloidal size can be prepared by spontaneous polymerization of inorganic acids in aqueous solution. This route leads to particles whose composition and size can be controlled.

In previous work (1), inorganic polymers including both molybdic and antimonic acids have been prepared. In this paper we describe the nature and physicochemical properties of the particles.

Experimental

The particles were isolated by preparative ultracentrifugation from aged mixtures of antimonic and molybdic acids (1). The starting mixtures had a constant antimony concentration (6×10^{-2} mol L^{-1}) and variable molybdenum concentration ($0 < Mo/Sb < 1.88$). The preparative centrifugation was performed after 10 months. The particles were packed down to the bottom of the centrifugation tube and obtained after discarding the supernatant liquid. The particles were dried for solid state study or redispersed in water for sol study.

Preparative ultracentrifugations were carried out with a Beckman Microfuge at 10000 rpm for 1 h. In this centrifuge the tube axis is colinear with the centrifugal field.

The Mo and Sb contents of the particles were measured by atomic absorption with an air–acetylene flame for antimony and a nitrous acetylene flame for molybdenum (1). In this paper, r stands for the Mo/Sb ratio in the particles.

The solid particles were studied by electron microscopy with a Jeol 100 CX II microscope. Samples were prepared by deposition of the dilute sol containing the particles on a grid. Analytical electronic microscopy was carried out with Link equipment. X-ray powder patterns were obtained from diffractometry with a CGR Theta 60 diffractometer using CuK_α radiation. Analytical grade NaCl was added to the powders as an internal standard to yield accurate mean crystal size (2).

Analytical ultracentrifuge experiments were carried out with a Beckman model E ultracentrifuge equipped with schlieren and absorption optics. Double sector cells manufactured in Kel F were used. The rotation speed was 8000 rpm. To avoid the effects of electric charges, an electrolyte (LiCl 5×10^{-2} mol L^{-1}) was added to the samples just before the runs. Specific volumes were measured by density measurements carried out with a PAAR automatic densimeter.

Photon correlation spectroscopy (PCS) was made with a Brookhaven BI90 correlator. The samples were clarified through Millipore filters prior to the measurements.

Ion exchange (Ag^+/H^+) experiments were performed using a Methrom pH stat to keep the pH at a constant value of 6.5. $AgNO_3$ was added to the dispersion of particles. The amount of base added to keep the pH constant is recorded simultaneously with the silver electrode potential in the medium. Ion exchange experiments were also performed without addition of base. The silver electrode potential in the dispersion was measured under these conditions.

Viscosity measurements were carried out with an Ubelhode capillary viscosimeter.

Results

The composition of the particles was homogeneous as shown by analytical electron microscopy (standard deviation = 0.007 for Mo/Sb = 0.085). Electronic micrographs (TEM) of the particles showed different shapes: hexagonal, square, or diamond (Fig. 1). These shapes can be considered projections of an octahedron onto a plane. This assumption was confirmed by STEM micrographs. The particles had a tendency to associate, even if the sol is ultrasonically dispersed prior to the grid making. Association of the particles increased with increasing Mo content. Accurate size measurements could not be made for $r > 0.32$. For low Mo content ($r = 0.085$), the particles were ordered. High resolution micrographs showed ordered lattice planes with d spacings = 5.98 Å (Fig. 2). The octahedron edges (e) were measured on the micrographs to give the particle size distributions for each sample (Fig. 3). For each sample about 500 particles were measured. The experimental values fit into the log-normal distributions as are particles obtained by

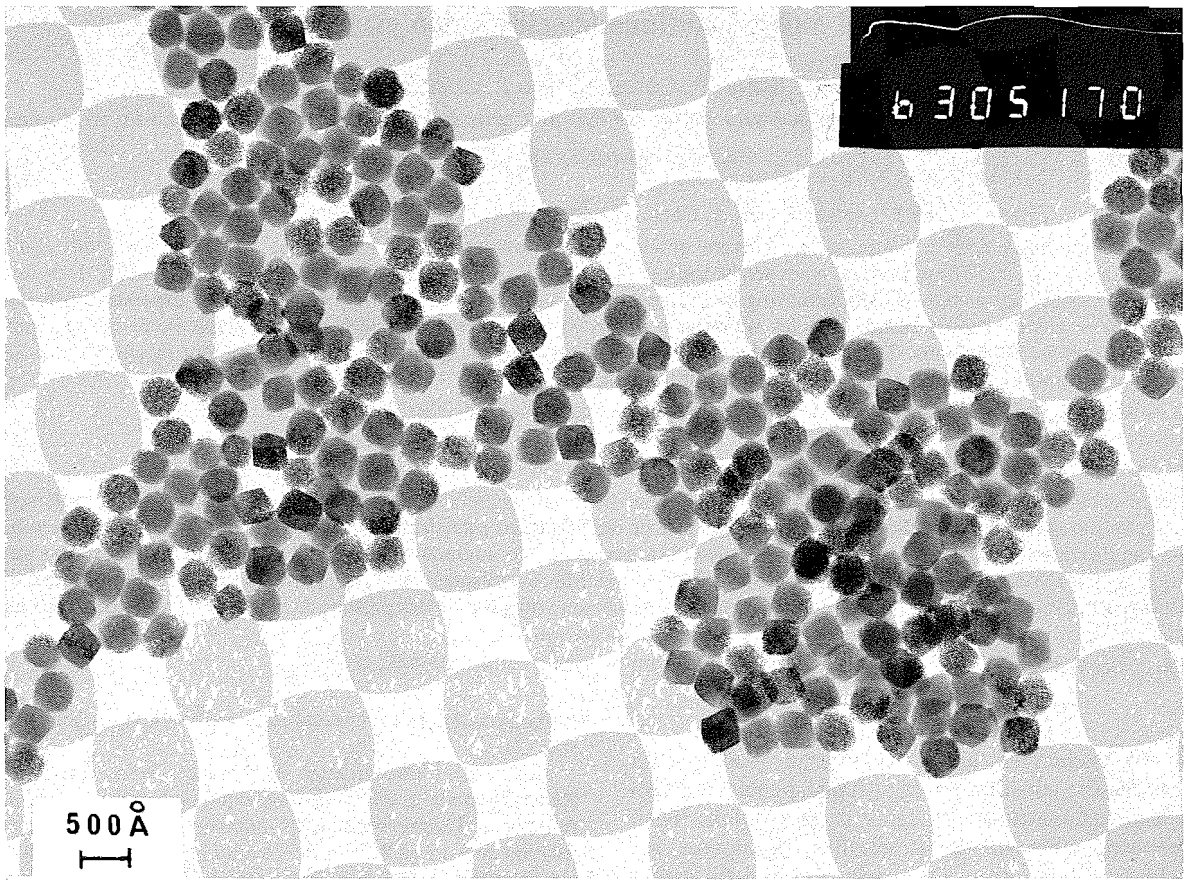

FIG. 1. Electron micrograph (TEM): composition of the particles. r = Mo/Sb = 0.085.

crystallization and/or sol gel process (3, 4). The samples were characterized by the following parameters (Table 1).

Geometric mean size $\bar{e}$:

$$\bar{e} = \sqrt[n]{e_1 e_2 \ldots e_n}$$

Standard deviation σ

$$\ln \sigma = \sqrt{\frac{\Sigma n_i (\ln e_i - \ln \bar{e})^2}{\Sigma n_i}}$$

and e_m corresponds to the maximum value on the distribution curve.

For a given ageing time of the starting mixtures before the preparative centrifugation, the size of the particles decreased when r increased. Moreover, for a given r, the particle size increased when the starting mixture aged.

Powder diffraction patterns agree with a cubic close packing (c.c.p.) structure (pyrochlore type), as in β antimonic acid (5). The unit cell decreased slightly from 10.38 to 10.33 Å when r increases from 0 to 0.32 (Table 2). Such changes have been seen in mixed oxides with a pyrochlore structure (6, 7). The d spacings corresponding to 111 planes are the same as those measured on high resolution micrographs, thus the octahedral faces correspond to 110 planes.

The peak width gave the mean crystal sizes (2) (Table 3). These mean crystal sizes are greater than the mean particle sizes measured by microscopy. Such differences are generally observed. These two measurements may be correlated using the Tronc and Bonnin (8) relationship:

$$e_{RX} = e_{\mu E} \exp [2.5(\ln \sigma)^2]$$

where e_{RX} and $e_{\mu E}$ are the sizes measured by diffractometry and electronic microscopy, respectively.

Aqueous dispersions of the particles were studied by ultracentrifugation and PCS. For a given particle concentration, the measured sedimentation coefficient was dependent on the optics used. Using absorption optics the sedimentation coefficient was about twice that using schlieren optics. With absorption optics, the light scattered is measured by the detector. Thus the heavier particles which scatter the light much more than the others were more heavily weighted in sedimentation coefficients. This artefact does not exist with schlieren optics. Nevertheless, S was independent of the concentration with UV optics ($2 \times 10^{-4} \leq C \leq 2.7 \times 10^{-3}$) and schlieren optics ($2 \times 10^{-3} \leq C \leq 10^{-1}$). As these concentration ranges overlap, S is independent of the concentration in the whole range ($2 \times 10^{-4} \leq C \leq 10^{-1}$). The distribution curves of sedimentation coefficient were calculated from ultracentrifugation patterns (9) (Fig. 4).

The sols had a reduced viscosity which was slightly dependent on the concentration.

The PCS measurements gave apparent diameters of equivalent spheres which are close to the other values (Table 4, Fig. 5).

Molybdoantimonic acids were dispersed in aqueous solutions of tetramethylammonium chloride of various concentrations (tetramethylammonium is not specifically adsorbed (10)). HCl or $N(CH_3)_4OH$ were added to these sols and after equilibrium the pH was measured. Blank solutions were made by adding HCl or $N(CH_3)_4OH$ to solutions of the same electrolyte at the same concentration and the pH measured. In the sols the negative charges (surface charges SO^-, Cl^-, and OH^-) must

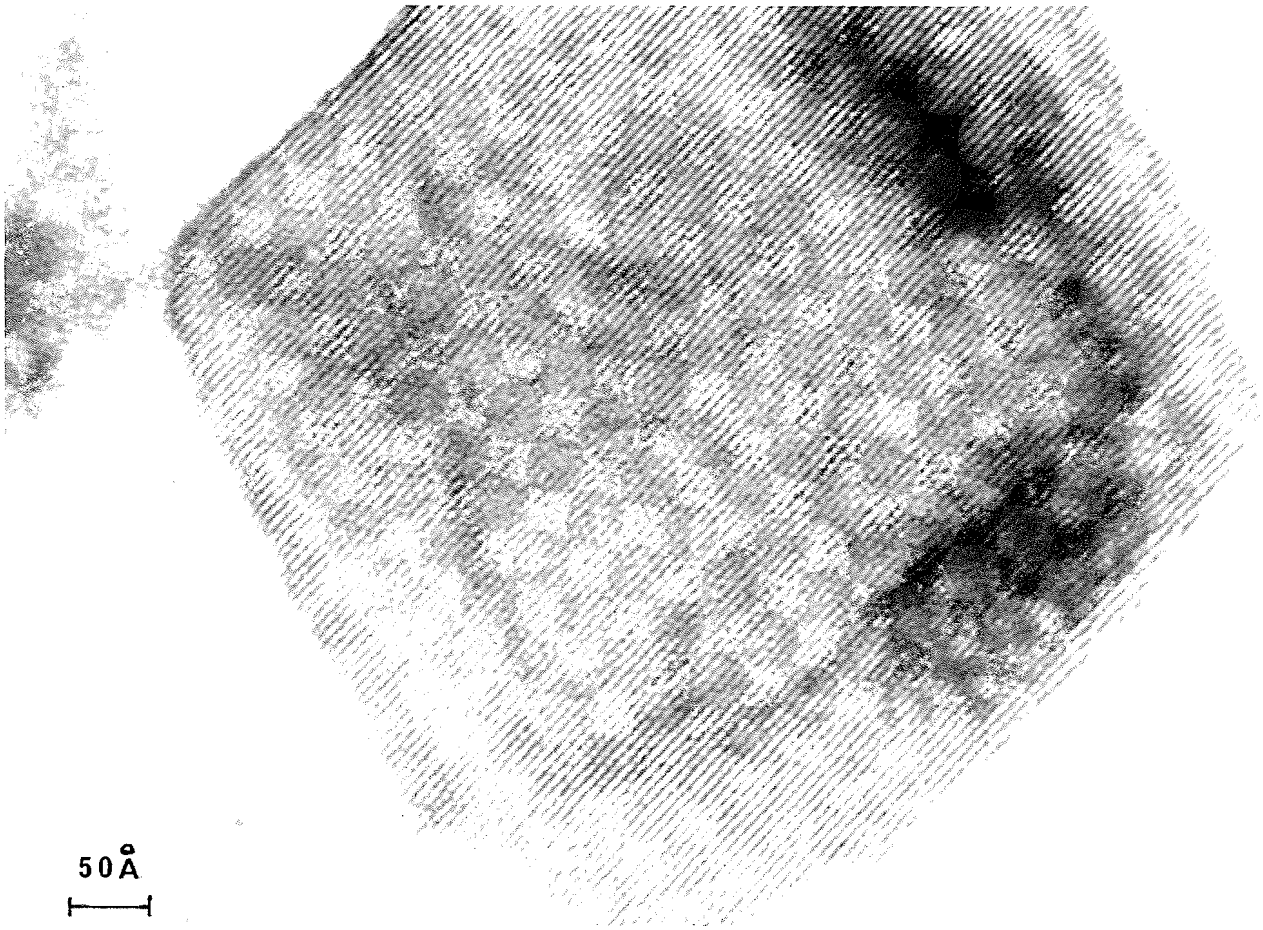

FIG. 2. High resolution electron micrograph (TEM): composition of the particle. r = Mo/Sb = 0.085.

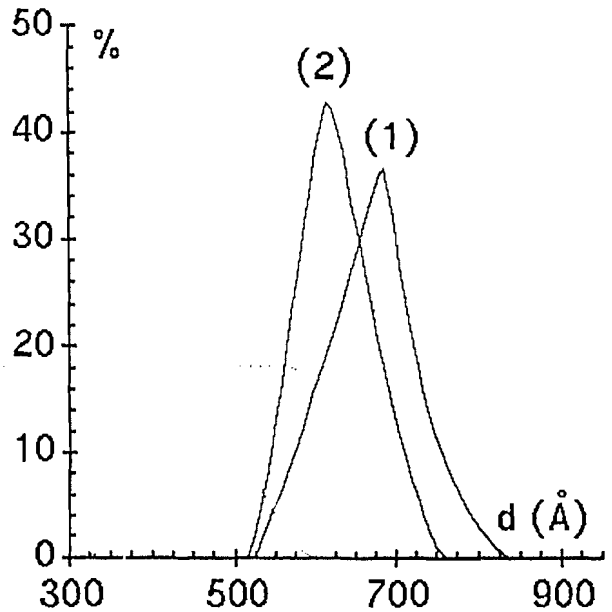

FIG. 3. Distribution curves of particles size measured by electron microscopy, (*1*) Mo/Sb = 0.085, (*2*) Mo/Sb = 0.165.

be balanced by positive charges:

$$[SO^-] + [OH^-] + [Cl^-] = [H^+] + [N(CH_3)_4{}^+]$$

Here $[Cl^-]$ and $[N(CH_3)_4{}^+]$ are known quantities, and $[H^+]$ and $[OH^-]$ were obtained from pH measurements on the sols and the corresponding blank solutions. Thus $[SO^-]$ can be obtained.

TABLE 1. Mean particle size measured by electronic microscopy

$r = \frac{Mo}{Sb}$	$\bar{e}$ (Å)	σ	e_m (Å)
0.085	686	1.065	686
0.165	635	1.074	618
0.32	538	1.112	484

These values are plotted in Fig. 6. The values obtained with different electrolyte concentrations are very close. The intersection point of these curves corresponds to $[SO^-] = 0$ for pH ~ 0.88, corresponding to the PZC of the molybdoantimonic acid (19). In a colloidal dispersion in pure water, H^+ is the cation in the diffuse layer.

The dispersions were titrated by rapid addition of tetramethylammonium hydroxide (maximum addition time 10 s). These protometric titrations were made at constant ionic strength using tetramethylammonium chloride (0.1 mol L^{-1}). The number of H^+ titrated is almost independent of the ionic strength. Under these conditions (fast protometric titrations) the surface of the particles is not modified. The concentration of H^+ in the diffuse layer corresponds to the $[H^+]$ measured and is the same as that from pH measurements, after standardization of the glass electrode for the same ionic strength. The results are reported in Table 5.

The sizes and structure of the particles were not modified (no changes in ultracentrifugation measurements and powder

diffraction patterns) when the addition of base was stopped at pH reaches 7.

The particles had the same structure as β antimonic acid which is an ion exchanger (H^+ in the core particles can be removed by other cations) (5, 11), and they can also have ion exchange properties. In the first experiment, small amounts of Ag^+ were added to a dispersion of particles at constant ionic strength (tetramethylammonium nitrate 0.1 mol L^{-1}). The curve which represents the variation of the silver electrode potential exhibited two steps (Fig. 7). Before the first step the sol is homogeneous. The potential at the Ag-sensitive electrode indicates a low Ag^+ concentration in the solution: Ag is in or on the particles. As the sol is not flocculated during this step, Ag is not quantitatively fixed onto the SO^- sites located at the surface. At higher Ag^+ ratios, addition of Ag to molybdoantimonic acid induces flocculation of the sol. The peptization can only be obtained if the pH is risen to the higher values near 7.5. In the second experiment, the addition of silver nitrate was done at pH = 6.5. After each addition of Ag^+, the pH was kept constant to 6.5 by adding a strong base ($N(CH_3)_4OH$). The concentration of free Ag^+ in solution was measured potentiometrically with a silver electrode. Figure 8 shows the variation of the amount of base added to keep the pH constant versus the amount of Ag^+ added. This curve exhibits three segments of different slopes. Along the segment AB, one H^+ is titrated when one Ag^+ is added. The dispersion remains homogeneous. Along the segment BC, the dispersion flocculates. During this section

the number of titrated protons is lower than the number of added Ag^+. Between A and C, Ag^+ obtained from electrode measurements is negligible. After C, Ag^+ does not react. The ratios corresponding to C are reported in Table 6.

These Ag^+/Sb ratios and that corresponding to the composition of the flocculated materials are the same. The amount of Ag fixed in the particles is higher at pH 6.5. than that in acidic medium. The structure of the flocculated materials was that of silver antimonate (c.c.p. pyrochlore type) corresponding to r = 0 (Table 2) (11). The unit cell dimension of the antimonates with a pyrochlore structure is generally decreased when H is substituted by Ag (6, 11, 12).

Discussion

The octahedral particles can be assumed to have approximately the same hydrodynamic behaviour as spheres. Under this condition, their frictional coefficient in the aqueous phase can be estimated from Stokes' law. Assuming the particles are not solvated, the diameter of the rigid sphere (D) can be obtained from the sedimentation velocity S (Table 4) from the following relationship.

$$D = 2\sqrt{\frac{9S\eta}{2(\rho - \rho_0)}}$$

where η is the solvent viscosity, ρ the particle density (Table 4), and ρ_0 the solvent density. The diameter D_m, corresponding

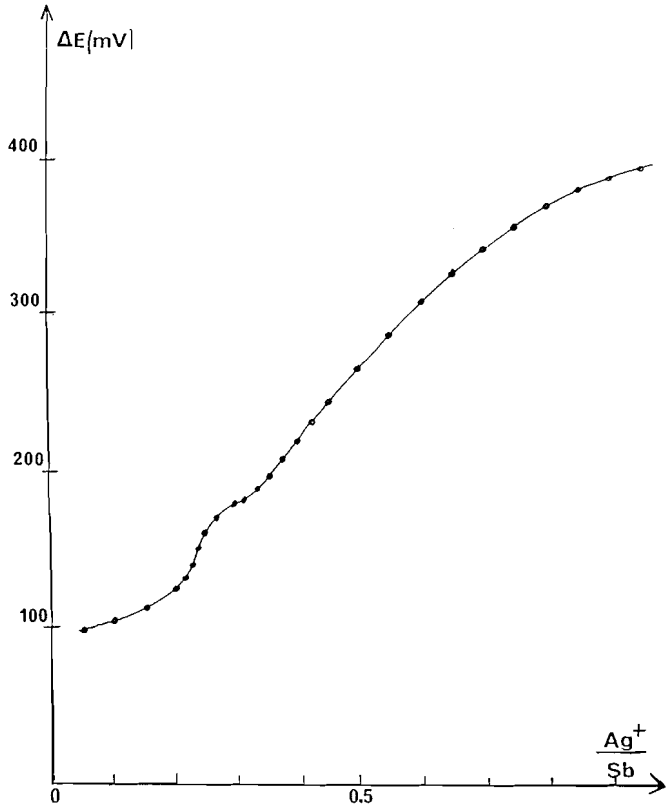

FIG. 7. Ion exchange experiment in acidic medium, $r = 0.085$.

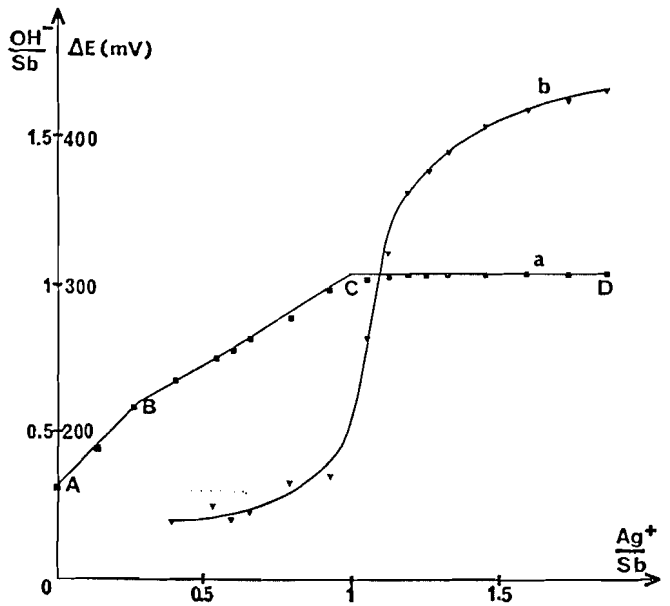

FIG. 8. Ion exchange experiment at pH 6.5; $r = 0.32$; curve a $(OH^-/Sb) = f(Ag^+/Sb)$, curve b, $\Delta E_{Ag} = f(Ag^+/Sb)$.

to the maximum on the distribution curve of sedimentation coefficient, and the geometric mean size are reported in Table 4. The particle sizes measured by different methods are in good agreement. The dispersed phase had the same sedimentation coefficient as the high polymers in the starting mixture before preparative centrifugation (1). Ultracentrifuge and PCS measurements give the hydrodynamic diameter while diffractometry and electronic microscopy give the diameter in the solid state. As these values are close, the solid crystalline particles pre-exist in the dispersed phase.

TABLE 6. Ion exchange properties of the particles

$r = \frac{Mo}{Sb}$	$\frac{Ag^+}{Sb}$	$\frac{H^+}{Sb}$
0	1	1
0.069	1	0.99
0.32	1.04	1.04
0.47	0.795	0.80
0.60	0.66	0.66

The reduced viscosity also leads to the hydrodynamic diameter of the spheres. With our experimental results ($[\eta] = 1.1$ cm^3 g^{-1} for $r = 0.085$), the Stokes–Einstein law or the Hiltner and Krieger formula (13) (suspensions of charged spherical particles) give results which are close. This hydrodynamic diameter is higher than the core diameter measured from electronic micrographs and leads too high a value for the thickness of a water shell. This abnormally high hydrodynamic diameter can be attributed to the electroviscous effects which have not been taken into account in the calculation. Such deviations have already been seen for charged spheres at low ionic strength and low shear rates (14, 15).

The stability of the particle dispersions arises from electric charges located at the surface of the particles (16, 17). The pH at which the surface charge is zero (PZC) is about 0.88. The pH of the dispersions is near 2. The reaction at the surface can be summarized as following.

$$[1]\quad \overline{SOH} \Leftrightarrow \overline{SO}^- + H^+, \qquad k_1 = \frac{\bar{a}_{SO^-}\, a_{H^+}}{\bar{a}_{SOH}}$$

where a_i is activity of species i, and bars refer to values in the dispersed phase. $[H^+]$ can be measured from fast protometric titrations or from pH measurements. This value depends on the pH of the sol.

The number of negative charges (z) per particle is $z = [\overline{SO}^-]/C_0$ where $[SO^-] = [H^+]$, C_0 is number of particles per unit volume, $C_0 = C_1/m$, $C_1 = [Sb + Mo]$, and m = number of atoms in a particle. In a pyrochlore structure the unit cell contains 16 atoms. The number of atoms in a particle is:

$$m = \frac{16V}{v_0}$$

where V, v_0 represents the volume of a particle and a unit cell, respectively. The number of electric charges per unit of surface area σ_S, can be calculated from:

$$\sigma_S = \frac{1.6 \times 10^{-19} z}{S}$$

where S is area of the particle surface, and

$$\sigma_S = \frac{1.6 \times 10^{-19} \times 16[H^+]}{v_0 C_1}\frac{V}{S} = \frac{2.56 \times 10^{-18}[H^+]}{v_0 C_1}\frac{V}{S}$$

For an octahedron

$$V = e^3\frac{\sqrt{2}}{3}$$

$$S = 2e^2\sqrt{3}$$

where e is the octahedron edge.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

Taking into account the log normal distribution of the particle size, these expressions become

$$V = \int_0^\infty \frac{\sqrt{2}}{3} e^3 f(e)\mathrm{d}e$$

$$S = \int_0^\infty 2\sqrt{3} e^2 f(e)\mathrm{d}e$$

with

$$f(e) = \frac{1}{\sqrt{2\pi}\ln\sigma} \exp\left[-\left(\frac{\ln(e/\bar{e})}{\sqrt{2}\ln\sigma}\right)^2\right]$$

We obtain

$$\frac{V}{S} = \frac{\bar{e}\sqrt{2}}{6\sqrt{3}} \exp\left[\frac{7}{2}(\ln\sigma)^2\right]$$

If the particles are spheres

$$\frac{V}{S} = \frac{\bar{e}}{6} \exp\left[\frac{7}{2}(\ln\sigma)^2\right]$$

Antimonic acid particles are spheres and molybdoantimonic acid particles are octahedral. Accurate values for V/S are used according to the shape of the particles. The surface charge of the particles depends on the pH of the sol. The influence of Mo content on σ_S can be shown in two ways: (*i*) σ_S is calculated at the same pH for all samples. Under these conditions $[H^+]$ is measured from the number of protons released from the surface when pH increased from PZC to the fixed value. (*ii*) σ_S is calculated at the pH of the dispersion of molybdoantimonic acids. In this case the concentration in antimony and pH of the sol must be given.

The results are reported in Table 5. When Mo is included in antimonic acid, σ_S is roughly increased. When the Mo content increases, the size of the particles decreases, leading to small changes in σ_S values but an increase in $[SO^-]$.

Ag fixation in the particles can be made through two routes: (*i*) ion exchange in the whole particles (core and surface) as for zeolites (18) antimonates (11, 12).

[2] $\overline{H^+} + Ag^+ \Leftrightarrow H^+ + \overline{Ag^+}$

$$k_2 = \frac{a_H \bar{a}_{Ag}}{\bar{a}_H a_{Ag}}$$

(*ii*) fixation of Ag on the SO^- sites located at the surface

[3] $\overline{SO^-} + Ag^+ \Leftrightarrow \overline{SOAg}$

$$k_3 = \frac{\bar{a}_{SOAg}}{\bar{a}_{SO^-} a_{Ag^+}}$$

The general formulae of these compounds correspond to $Sb_{1-x}Mo_xO_3H_{1-x}$. The protons and antimony atoms are present in the same quantity in the particles. The protons displaced by Ag at pH 6.5 are almost all of the protons present in the particles. Thus both routes have to be taken into account.

If $k_2 > k_3$, ion exchange in the core of particles can occur prior to fixation onto the SO^- sites located at the surface. Under these conditions, if Ag is added in small quantities, no flocculation occurs. Ag can be fixed at the surface if it is added in great quantities. As the concentration of H^+ in solution increases, Ag cannot be exchanged quantitatively according to equilibrium [2]. The concentration of Ag in solution increases, leading to a kick on the curve representative of Ag potential.

In the experiments performed at pH = 6.5, equilibrium [2] is displaced towards the right. The amount of Ag exchanged is increased. During the first step (AB) (Fig. 7), only ion exchange (equilibrium [2]) takes place. During the second step (BC) two equilibria take place. As exchange is favored by increasing pH, the concentration of Ag in solution is kept very low and the representative curve of the Ag potential does not exhibit a step before all the H^+ are removed and all the Ag^+ fixed onto the whole SO^- sites.

The particles are formed through a polymerization process (1) involving water elimination between two adjacent monomers. In acidic medium Mo and Sb are six-coordinated and approximately the same size. MoO_6 octahedra can easily substitute SbO_6 octahedra when building the c.c.p. structure. Mo atoms limit the extension of the polymerization. For $r > 0.32$ the particles are associated and the crystallinity is decreased; therefore the particle size could not be accurately measured. For Mo-rich particles ($r > 0.32$) there is not enough Sb to build defect-free pyrochlore structure. The ion exchange properties of the pyrochlore structure are modified and the amount of H^+ removed from the particle core must decrease.

Conclusion

Colloidal particles with a narrow size distribution were formed through a polymerization process and no noticeable aggregation occurs in the solid state. These particles are ion exchangers. The fixation of cations is done through two different reactions: substitution of protons in the structure or cancellation of the external charges. The relative occurrence of these two processes is monitored by the Mo content of the particles which controls their charge surface density.

Au cours d'un travail de synthèse de dérivés de l'acide quinique, régulateurs potentiels de la biosynthèse des acides aminés aromatiques, nous avons préparé un intermédiaire 1,5-diacétoxy-3,4-bis(bicyclophosphoranylato)quinate de méthyle **7**. Ce dernier a été caractérisé par RMN ^1H, ^{31}P, infrarouge, analyse élémentaire et spectrométrie de masse. Sa structure moléculaire a été déterminée par diffraction des rayons X et une étude conformationnelle complète a été effectuée. Le cycle quinique adopte une forme chaise presque parfaite. Les deux groupements bicyclophosphoranes présentent une géométrie bipyramidale trigonale avec une annelation axiale–équatoriale–axiale. Les cycles pentagonaux adoptent une forme enveloppe avec l'atome de carbone tétrasubstitué à la pointe du rabat.

Mots clés : voie de l'acide shikimique, 1,5-diacétoxy-3,4-bis(bicyclophosphoranylato)quinate de méthyle, analyse conformationnelle, RMN ^1H et ^{31}P, structure cristalline.

MICHEL BALTAS, LATIFA CHAHOUA, LILIANE GORRICHON, PIERRE TISNÈS, DOURAID HOUALLA, ROBERT WOLF, and JOËL JAUD. Can. J. Chem. **69**, 300 (1991).

In connection with our work on quinic acid derivatives, which are supposed to regulate the biosynthesis of aromatic amino acids, we have prepared the methyl 1,5-di-*O*-acetyl-3,4-bis-*O*-(bicyclophosphoranylato)quinate **7**. The compound obtained has been characterized by NMR (^1H and ^{31}P), IR, elemental analysis, and mass spectrometry. Its molecular structure has been determined by X-ray diffraction and an exhaustive conformational study has been accomplished. The quinic ring adopts an almost perfect chair form. Both bicyclophosphoranyl groups present a trigonal bipyramidal geometry with an axial–equatorial–axial type annelation. The pentagonal rings adopt an envelope form in which the tetrasubstituted carbon atom is at the top of the fold.

Key words: shikimic acid pathway, methyl 1,5-di-*O*-acetyl-3,4-bis-*O*-(bicyclophosphoranylato)quinate, conformational analysis, ^1H and ^{31}P NMR, crystal structure.

Récemment, nous nous sommes intéressés à la formation d'acétals et de borates dérivés des acides shikimique et quinique (1–3). Ces acides interviennent dans la biosynthèse des acides aminés aromatiques, un processus fondamental et spécifique des végétaux et des microorganismes (4–6) (schéma 1).

Nous abordons maintenant l'étude de la phosphorylation de l'acide quinique. En effet, si l'importance de l'acide shikimique et des dérivés ou analogues phosphorés est bien établie et largement étudiée (7, 8), le rôle de l'acide quinique reste mal connu.

L'acide quinique n'apparaît que chez les végétaux mais il peut constituer une source de carbone chez les microorganismes (9); sa présence permet d'observer, ou d'induire, une régulation de la voie de l'acide shikimique (10). Cependant, la formation de l'acide quinique en quantités importantes, dans certains cas plus de 5% du poids du végétal sec, suggère d'autres activités métaboliques encore indéterminées et (ou) d'autres interférences avec la voie de l'acide shikimique, par exemple par le biais des dérivés phosphorylés de l'acide quinique.

La synthèse des dérivés phosphorylés de l'acide quinique fait intervenir deux étapes principales :

(i) La protection sélective des fonctions hydroxylées qui ne doivent pas être touchées lors de la phosphorylation.

(ii) Le choix de la réaction de phosphorylation et des réactifs pouvant permettre selon le cas l'accès à des dérivés mono-, di- ou poly-phosphorylés sur le squelette quinique.

La synthèse des dérivés phosphorylés de l'acide quinique relève du procédé général de phosphorylation des alcools. Jusqu'à une date récente celle-ci était réalisée soit par action d'un dérivé du phosphore tétracoordonné possédant un groupement phosphoryle et un groupement partant X (méthode de Khorana et coll. (11))

$$ROH + \underset{\underset{O}{\|}}{>P—X} \rightarrow HX + RO—\underset{\underset{O}{\|}}{P<}, \quad X = Cl, NR_2..$$

soit par action d'un dérivé du phosphore tricoordonné (phosphitation) suivie d'une oxydation (méthode de Letsinger *et al.* (12*a*), Caruthers (12*b*))

$$ROH + X—P< \rightarrow HX + RO—P< \xrightarrow[\frac{1}{2}O_2]{} RO—\underset{\underset{O}{\|}}{P<}$$

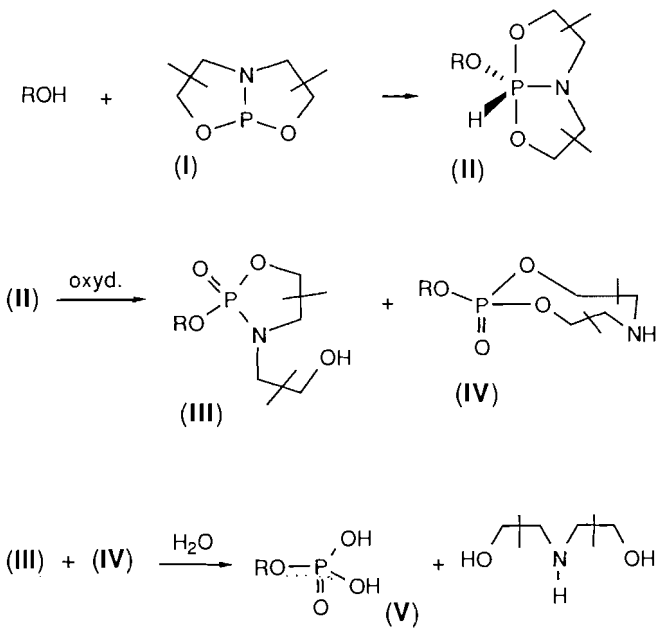
SCHÉMA 1

En 1988, Duthu *et al.* (13) ont décrit un autre procédé de phosphorylation qui exploite l'aptitude des bicyclophosphanes (**I**) à subir l'addition oxydante des alcools pour conduire à un bicyclophosphorane à liaison P—H (**II**). L'oxydation de ce dernier fournit les dérivés du phosphore tétracoordonné (**III**) et (**IV**) dont l'hydrolyse aboutit au monoester phosphorique recherché (**V**) (schéma 2):



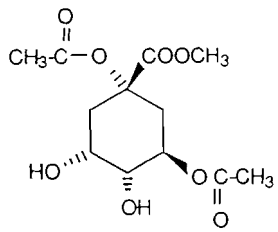


SCHÉMA 2

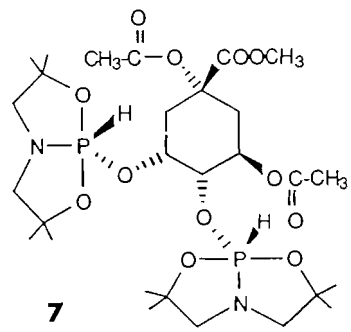

Dans les deux premiers procédés, la présence des fonctions alcools sur deux atomes de carbone vicinaux conduit en cas de non protection à un fort taux de cyclisation. Par contre dans le cas de la phosphoranylation une telle cyclisation n'a jamais été observée. Nous avons donc choisi cette dernière méthode de phosphorylation.

L'approche expérimentale de ce problème nous a amené à choisir dans un premier temps le composé **6** comme produit de départ.

Dans ce premier article nous rapportons la synthèse du bicyclophosphorane **7**, son analyse conformationnelle par RMN ainsi que sa structure moléculaire par diffraction des rayons X.

6

7

Résultats et discussion

Le diol **6** a été obtenu suivant le schéma 3. L'action de l'acide D(−)quinique **1'** avec le benzaldéhyde conduit à l'acétal lactonique **8**. Il est connu (14) que cette méthode ne conduit pas à des produits de racémisation de l'acide D(−)quinique. La méthanolyse de **8** en présence de méthylate de sodium, puis l'acylation des fonctions hydroxy en C4 et C6 en présence de 4-*N*,*N*-diméthylaminopyridine (DMAP) et d'anhydride acétique conduit à l'ester complètement protégé **10**. Le diol **6** est alors obtenu par déprotection acide de la fonction acétal avec un rendement global de 65%. Il a été identifié par RMN ^{1}H et ^{13}C, IR, analyse élémentaire et spectrométrie de masse.

La synthèse du bicyclophosphane **11** a été effectuée suivant la méthode décrite dans la littérature (13).

Enfin le dérivé **7** a été obtenu par action de deux équivalents du bicyclophosphane **11** sur le diol **6**. Après recristallisation dans le toluène il est obtenu sous forme de cristaux blancs avec un rendement de 62% par rapport à **6**.

Le composé **7** a été caractérisé par spectrométrie de masse, analyse élémentaire et spectroscopies IR, RMN ^{1}H et ^{31}P (cf. partie expérimentale). Sa structure moléculaire a été établie par diffraction des rayons X.

Étude de RMN

Attribution des signaux

Le spectre RMN ^{31}P{^{1}H} (fig. 1a) du composé **7** contient deux pics à $\delta = -40{,}4(5)$ ppm et $\delta = -41{,}9(1)$ ppm alors que sans découplage de proton (fig. 1b) chacun de ces pics se présente comme un doublet avec un écart entre les branches égal à $^1J_{P-H} = 815$ Hz et $^1J_{P-H} = 809$ Hz. Chacun des membres des doublets présente une structure fine ou un élargissement lié

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

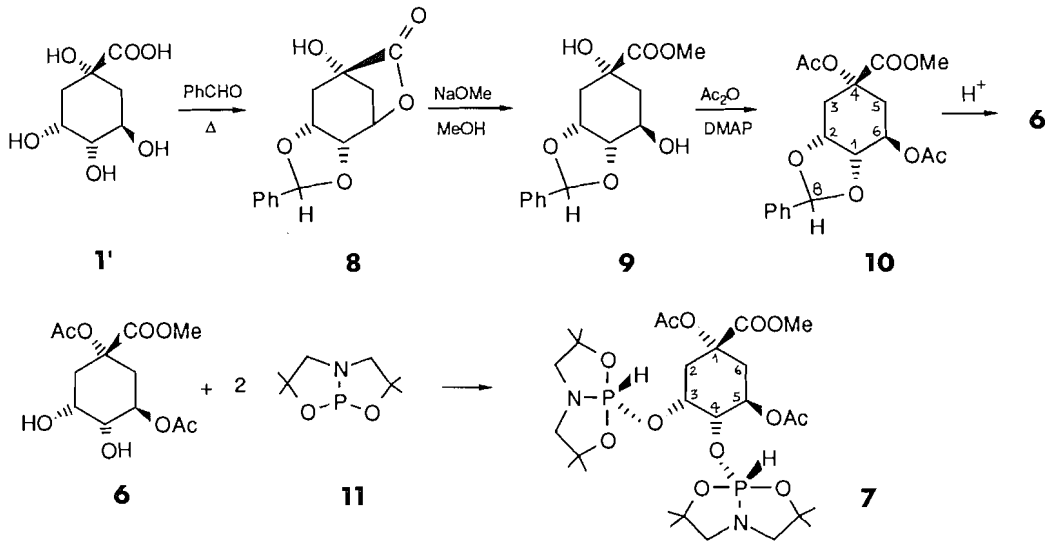

SCHÉMA 3

à des couplages ^3J avec d'autres protons. Les déplacements chimiques des noyaux de ^{31}P ainsi que les grandes constantes de couplage montrent qu'on est en présence d'un composé à deux atomes de phosphore pentacoordonné ayant chacun un atome d'hydrogène directement lié au phosphore (bis-phosphorane à liaison P—H).

Le spectre RMN ^1H du composé **7** enregistré à une radiofréquence de 250 MHz (dans C_6D_6) (fig. 2) confirme la présence de deux protons liés chacun à un phosphore. Ces protons résonnent à $\delta = 7{,}35$ ppm et $\delta = 7{,}30$ ppm et se présentent sous la forme de deux doublets avec des écarts entre les branches de 815 Hz et 809 Hz respectivement.

L'analyse spectrale du cycle quinique a été effectuée après irradiation des deux noyaux de ^{31}P.

Les troix protons méthine H3, H4 et H5 donnent naissance à trois massifs bien séparés entre 4,7 et 5,8 ppm. Lorsque les noyaux ^{31}P sont irradiés les deux massifs les plus blindés, centrés respectivement à 4,81 et 5,30 ppm, sont perturbés (fig. 3). On peut donc les attribuer aux protons H3 ou H4 et par conséquent le massif le plus déblindé ($\delta = 5{,}70$ ppm) au proton H5.

Le proton H4 doit présenter un doublet dédoublé par couplage avec H3 et H5 et il correspond au massif le plus blindé (4,81 ppm). Cette attribution est confirmée par l'irradiation du massif du proton H5 à 5,70 ppm qui le simplifie en un doublet.

Outre les signaux correspondants au groupe méthoxy à $\delta = 3{,}37$ ppm et aux deux CH_3 des fonctions acétyles à $\delta = 1{,}89$ et $\delta = 1{,}72$ ppm on distingue à $\delta = 2{,}90$ et $\delta = 2{,}10$ ppm deux massifs représentant chacun un proton. Ils sont attribuables aux protons méthyléniques portés par les carbones C2 ou C6. L'irradiation du proton H5 entraîne seulement la modification du massif à $\delta = 2{,}10$ ppm alors que l'irradiation du proton H3 entraîne celle du massif à $\delta = 2{,}90$ ppm. Ceci permet d'attribuer le premier à un des protons H6 et le massif à $\delta = 2{,}90$ ppm à un des protons H2. Les deux autres protons donnent naissance à des signaux qui se trouvent confondus avec ceux des protons NCH_2 des cycles pentagonaux phosphoraniques ($\delta = 2{,}76$–$2{,}40$ ppm; 10 protons). Pour terminer nous trouvons un ensemble de pics entre 1,5 et 1,1 ppm attribuables aux groupements méthyles des groupes bicyclophosphoraniques (24 protons).

Conformation du cycle quinique

La conformation du cycle quinique a été établie à partir de l'analyse des constantes de couplage entre les différents protons du cycle. L'accès à ces paramètres a été facilité par l'irradiation des deux noyaux de phosphore et dans certains cas par des découplages homonucléaires proton–proton. Les spectres obtenus ont été analysés dans les conditions du premier ordre. Les déplacements chimiques des protons du cycle quinique ainsi que les constantes de couplages sont rassemblés dans le tableau 1.

Les valeurs des constantes de couplage mesurées sur les différents massifs sont en accord avec la stéréochimie relative des différents carbones asymétriques C3, C4, C5 en série quinique. En les comparant avec celles déterminées par Corse *et al.* (15) d'une part et Haslam et Turner (16) d'autre part dans cette même série quinique, elles permettent d'établir une conformation chaise pour le composé **7** où le substituant carboxylate de méthyle du carbone C1 est en position équatoriale. En effet le proton H4 possède une constante de couplage de 7,8 Hz avec le proton H5 typique dans cette série d'un couplage axial–axial; l'autre valeur de couplage de 3,4 Hz conduit à attribuer au proton H3e l'orientation équatoriale. Les valeurs trouvées sur les massifs des protons H3 et H5 vérifient cette stéréochimie et permettent de plus d'attribuer les massifs à 2,90 et 2,10 ppm respectivement aux protons H2a et H6a. La valeur de 14,8 Hz du couplage $^2J_{2a-2e}$ est plus grande que celle observée habituellement dans cette série. Elle pourrait être interprétée par un aplatissement de la forme chaise au niveau de l'enchaînement C1–C2–C3 qui a été reconnu comme responsable de l'augmentation d'une telle constante (17). Cette déformation serait également responsable du fait que le proton H2a résonne à champ plus faible que H2e, ce qui constitue une inversion de la règle de Lemieux (18). Le massif à 2,10 ppm du proton H6a présente des constantes de couplage de 13,5 et 7,8 Hz proches de celles habituellement rencontrées. Cette observation ainsi que le fait que δH6a < δH6e en accord avec la règle de Lemieux montrerait qu'il n'y a pas de déformation dans le fragment C5–C6–C1 du cycle quinique.

Stéréochimie des groupes bicyclophosphoraniques

La stéréochimie sera déduite de l'analyse des paramètres de RMN des substituants CH_3 et des protons NCH_2.

Les déterminations structurales par diffraction des rayons X effectuées sur des bicyclophosphoranes comparables ont montré que ces composés adoptent généralement une géométrie bipyra-

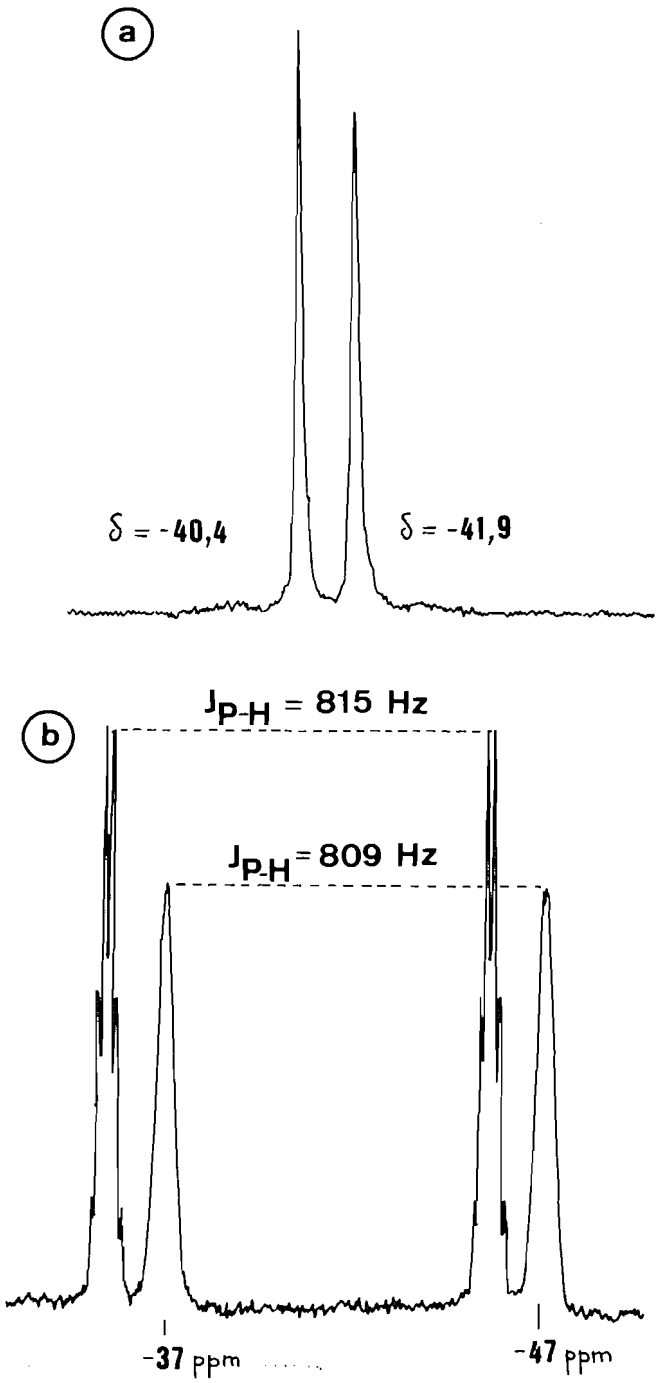

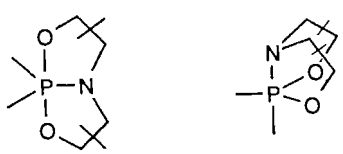

FIG. 1. Spectre RMN ^{31}P (81,01 MHz) du composé **7** dans C_6D_6 (a) spectre découplé du proton; (b) spectre couplé du proton.

midale trigonale avec soit une annelation axiale–équatoriale–axiale (a-e-a) soit une annelation équatoriale–axiale–équatoriale (e-a-e) (19). Dans l'une comme dans l'autre il existe un élément de symétrie qui permute les deux cycles pentagonaux symétriquement substitués. La présence sur l'atome de phosphore de deux substituants différents rend diastéréotopes les groupes CH_3 portés par le même atome de carbone ainsi que les protons NCH_2. Quelle que soit la géométrie effectivement adoptée par les groupes bicyclophosphoraniques on peut s'attendre à ce que dans chaque bicyclophosphorane les quatre substituants CH_3 ainsi que les quatre protons NCH_2 soient deux à deux équivalents. On devrait donc observer quatre signaux correspondant aux substituants CH_3 et deux systèmes ABX pour les protons NCH_2.

Pour le composé **7** ceci n'est pas le cas. En effet, l'examen du domaine spectral à $\delta = 1,5$ et $\delta = 1,1$ ppm où l'on attend les signaux correspondants aux substituants CH_3 montre la présence de cinq pics (fig. 2) dont les intensités sont comme 3 : 3 : 6 : 9 : 3. Il en résulte que les groupements méthyles de deux bicyclophosphoranes ne sont plus permutés par l'élément de symétrie locale propre à chaque bicycle : ils sont tous distincts. Ce fait traduit l'existence d'un centre chiral C3 et C4 en β de chaque atome de phosphore qui différencie l'environnement spatial des cycles pentagonaux. Le même effet est observé sur les protons NCH_2 (fig. 4). En effet le massif correspondant à ces protons ($\delta = 2,76$–$2,40$ ppm) ne comporte pas les 16 pics attendus pour les deux parties AB des deux systèmes ABX (X = P) mais présente une multiplicité bien plus grande confirmant ainsi la différenciation des quatre groupes de protons NCH_2 (fig. 5).

L'analyse du spectre enregistré à 250 MHz comme à 300 MHz ne nous a pas permis la détermination complète des constantes de couplage et en particulier celles attribuables à $^3J_{H-C-N-P}$. Nous avons pu établir toutefois, par irradiation des deux atomes de phosphore, que le massif résiduel s'analyse comme un ensemble de trois systèmes AB et d'un système AM (tableau 2). Ainsi nous obtenons quatre groupes de protons NCH_2 distincts dont un se trouve beaucoup plus différencié que les trois autres. À notre sens celà doit traduire l'existence d'un effet d'anisotropie dû au reste de la molécule qui s'exerce préférentiellement sur un seul des quatre cycles pentagonaux. L'étude de la structure moléculaire par diffraction des rayons X nous permettra de confirmer cette proposition.

Étude cristallographique

Les paramètres atomiques finaux issus de l'analyse structurale par diffraction des rayons X sont rassemblés dans le tableau 3,[2] et certaines données utiles de géométrie moléculaire dans les tableaux 4–6. La figure 5 représente une vue perspective de la molécule où sont indiqués les numéros des différents atomes. Dans un souci de clarté, les atomes d'hydrogène n'ont pas été représentés. Nous commenterons d'abord les données relatives au cycle quinique puis celles concernant les deux groupes bicyclophosphoraniques.

La conformation du cycle quinique est celle d'une chaise presque parfaite. Les atomes de carbone C3, C4, C6, C1 sont dans un plan alors que les atomes de carbone C2 et C5 se trouvent de part et d'autre de ce plan à des distances de 0,602 Å et −0,670 Å respectivement (tableau 6). L'écart entre les

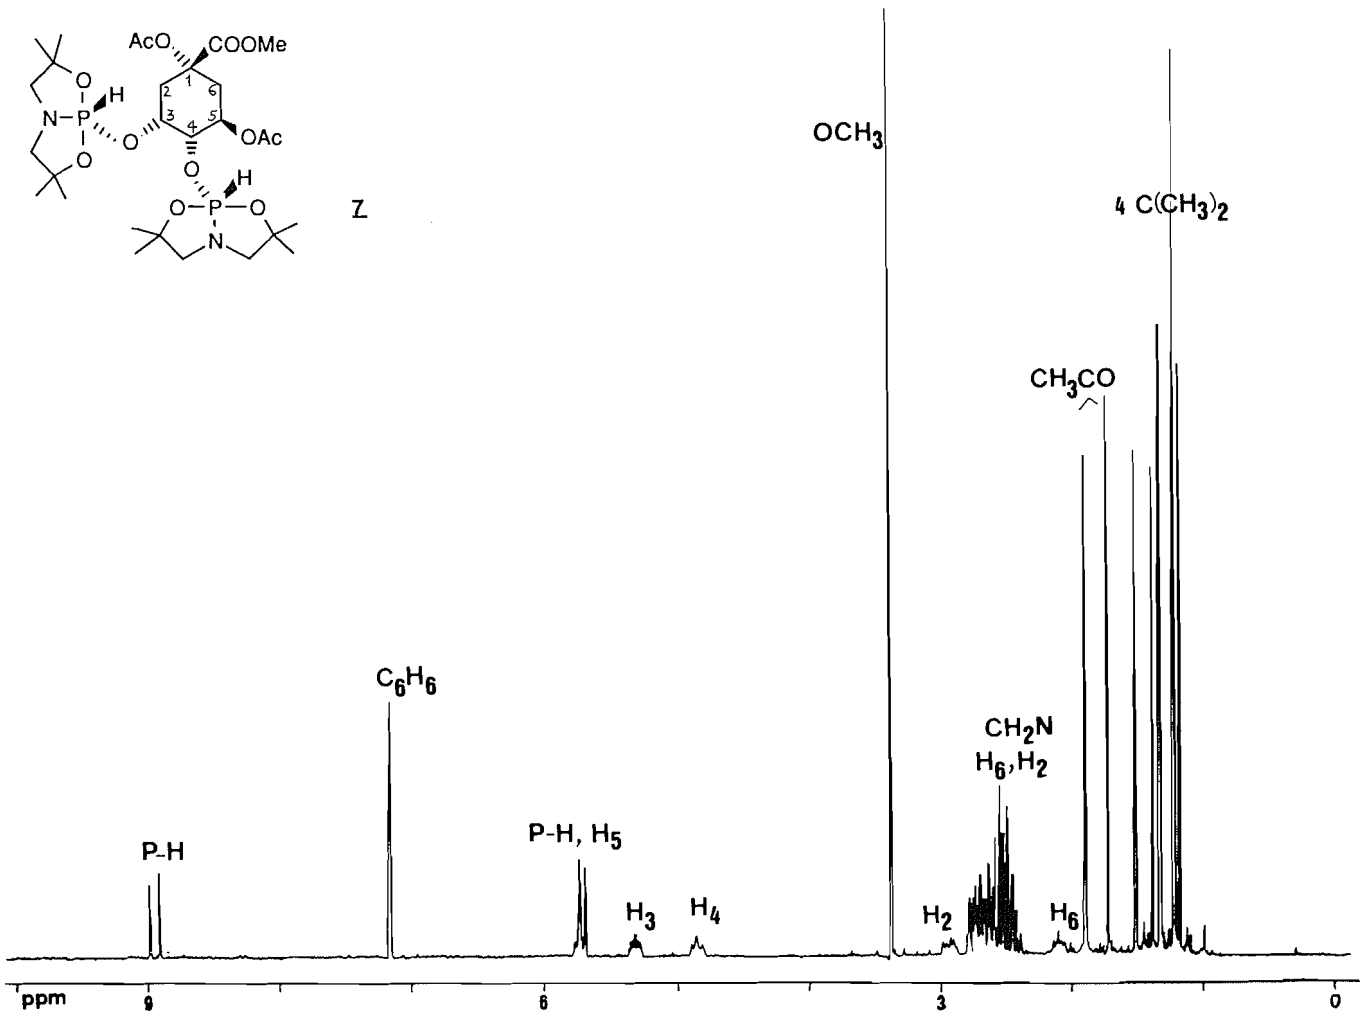

FIG. 2. Spectre RMN ^1H (250 MHz) du composé **7** dans C_6D_6.

TABLEAU 1. Données spectrales en RMN ^1H du composé **7** (250 MHz, $CDCl_3$)

Proton	δ (ppm)	*J* (Hz)	Proton	δ (ppm)	*J* (Hz)
P-H	7,35 (d) 7,30 (d)	815 809	H2a	2,90 (m)	J_{2a-3e} = 6,7 J_{2a-2e} = 14,8
H5	5,70 (m)	J_{5-6a} = 7,8 J_{5-6e} = 4,0 J_{5-4a} = 4,8	NCH_2, H2e,[a] H6e	2,76–2,40	
H3	5,29 (m)	J_{3e-4a} = 3,4 J_{3e-2a} = 6,7 J_{3e-2e} = 3,4	H6a	2,12 (m)	J_{5-6a} = 7,8 J_{6a-6e} = 13,5
H4	4,81 (m)	J_{4a-3e} = 3,4 J_{4a-5a} = 7,8	O=C—CH_3	1,89 (s) 1,72 (s)	
OCH_3	3,41 (s)		$(CH_3)_2C$<	1,50 1,32 (6H) 1,18	1,38 1,21 (9H)

[a]L'analyse de ce massif est donnée dans le tableau 2.

distances des atomes C2 et C5 par rapport à ce plan pourrait être dû à un léger applatissement de la chaise du côté de C2 qui le rapprocherait du plan indiqué ci-dessus. La valeur moyenne absolue des angles de torsion intraannulaire est égale à 54,07° (tableau 5). Cette valeur est comparable à celle correspondante à l'acide D(−)quinique (54,9°) (20) ainsi qu'à celle obtenue pour un cyclohexane libre par un calcul théorique après minimisation de l'énergie (55,5°) (21). Une analyse plus fine montre que les angles de torsion d'un côté du cycle (C4–C5–C6) sont plus grands que ceux de l'autre côté (C1–C2–C3) rejoignant ainsi la différence observée quant à la position des carbones C2 et C5 par rapport au plan moyen du cycle. Cette distorsion pourrait

[a]Les atomes affinés anisotropiquement sont donnés sous la forme d'équivalents isotropiques définis ainsi au moyen des paramètres de la maille : $B_{eq} = 4/3[a^2B(1,1) + b^2B(2,2) + c^2B(3,3) + ab(\cos\gamma)B(1,2) + ac(\cos\beta)B(1,3) + bc(\cos\alpha)B(2,3)]$.

être le résultat des interactions diaxiales entre le groupement acetoxy en C1 et le groupement phosphoranique en C3. En outre les angles C2—C1—O4 et C6—C1—O4 ont des valeurs sensiblement différentes de celles observées dans l'acide quinique (20) (C2—C1—O4 = 113,6° et C6—C1—O4 103,4° contre 107,9° et 111° respectivement). Cette variation pourrait très bien s'expliquer par l'interaction diaxiale signalée ci-dessus.

L'atome d'oxygène O7 (C=O) de la fonction acetoxy en C1 se trouve dans le même plan que l'atome de carbone C1 (C1–O4–C9–O7 = −2°), le plaçant ainsi dans une position

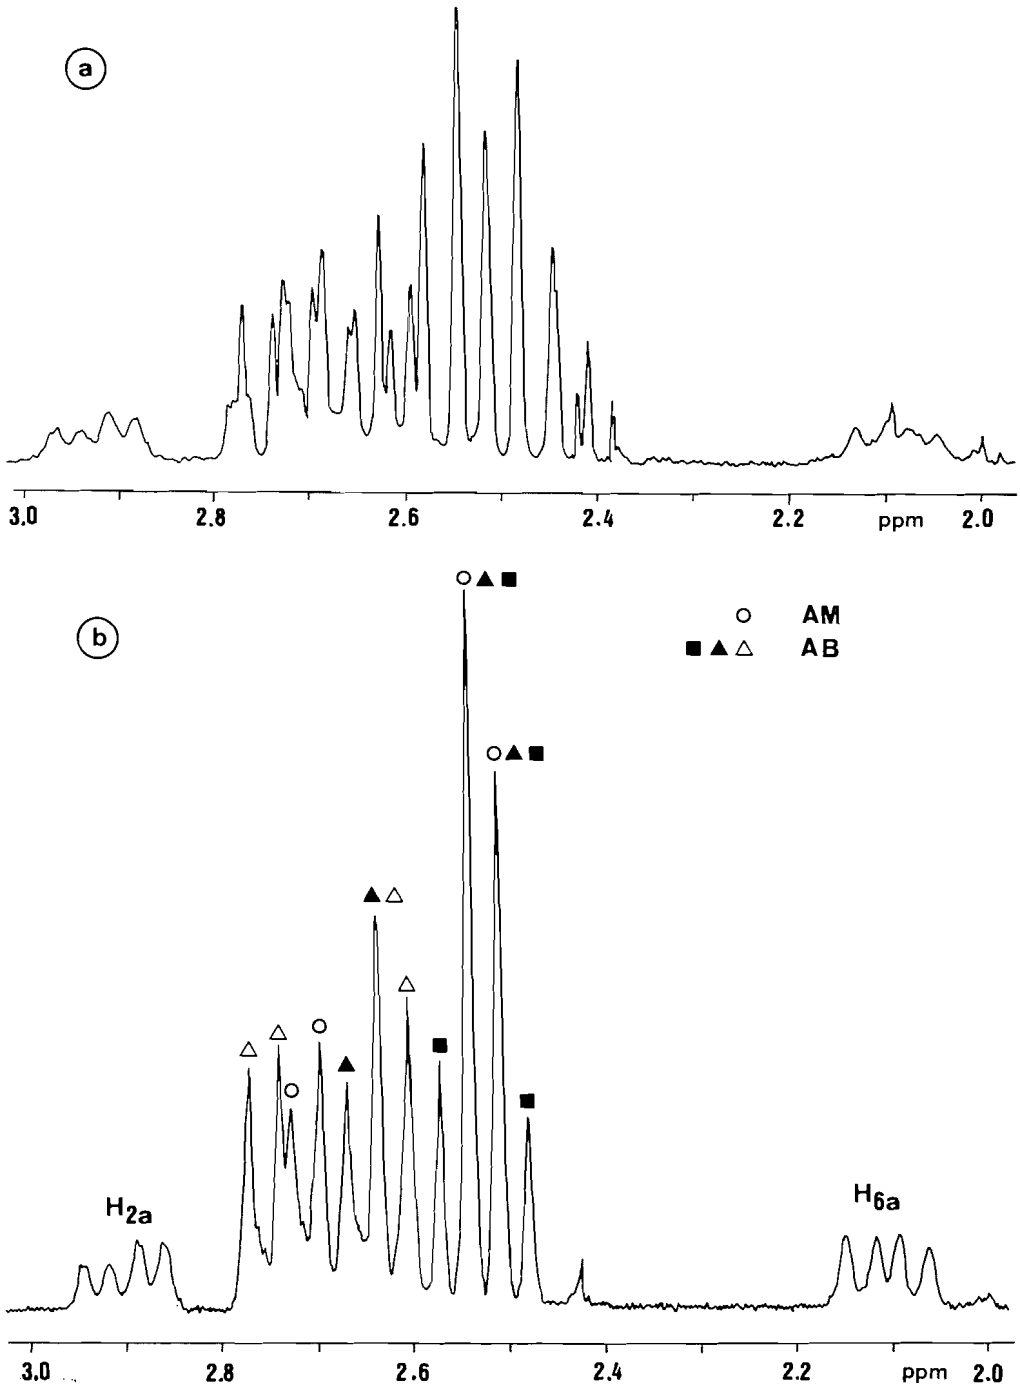

FIG. 4. Région de δ = 2–3 ppm du spectre RMN ^1H (250 MHz) du composé dans C_6D_6 (a) avant découplage des deux atomes de phosphore et (b) après irradiation.

eclipsée. L'atome d'oxygène O5 de la fonction acétate en C1 est orienté du côté C5–C6 du cycle quinique. Enfin, le carbonyle du groupement acetoxy en C5 est orienté vers l'intérieur du cycle quinique avec l'atome d'oxygène O8 (C=O) dans le même plan que C5 (C5–O3–C11–O8 = 1,91°) (tableau 5).

Les deux bicyclophosphoranes adoptent une géometrie bipyramidale trigonale avec une annelation axiale–équatoriale–axiale. Les atomes d'oxygène des cycles pentagonaux sont bien en position axiale : O9–P1–O10 = 174,9° et O11–P2–O12 = 172° alors que les atomes d'oxygène O1, O2 liés au cycle quinique ainsi que les atomes d'azote N1, N2 sont dans le plan équatorial (tableau 4). Dans chaque cycle oxazaphospholane les atomes de phosphore, d'oxygène, d'azote et de carbone NCH_2 sont dans un plan, l'atome de carbone tétrasubstitué étant en dehors de ce plan. Il en résulte que ces cycles adoptent la conformation d'une enveloppe, l'atome de carbone lié à l'oxygène étant à la pointe du rabat. Ce résultat confirme les conclusions précédemment obtenues à partir de l'étude RMN de bicyclophosphoranes comparables (22). Les orientations des deux bicyclophosphoranes par rapport au cycle quinique sont différentes. Le plan moyen du bicyclophosphorane lié à C3 (P1–O10–C16–N1–C14–O9) est quasiment perpendiculaire au plan moyen du cycle quinique (O9–P1–O1–C3 = −170,41° et O10–P1–O1–C3 = 9,65°) alors que celui du bicyclophos-

phorane en C4 (P2–O11–C18–N2–C20–O12) est légèrement incliné par rapport au même plan (O11–P2–O2–C4 = 20,77 et O12–P2–O2–C4 = −157,28°).

L'examen d'un modèle moléculaire reproduisant ces données structurales et tenant compte du fait que le groupement carbonyle du substituant acetoxy porté par l'atome de carbone C5 (C11O8) pointe vers l'intérieur du cycle quinique complète les observations faites en RMN ^{1}H concernant les protons méthyléniques NCH_2. En effet les protons CH_2 portés par le carbone C18 du bicyclophosphorane lié en C4 du cycle quinique peuvent se trouver dans le cône d'anisotropie du carbonyle C11O8 (le cône est défini par un angle de 43° entre la verticale menée de l'atome d'oxygène au plan du carbonyle C=O et l'axe de ce dernier (23)). Les autres protons CH_2 des bicyclophosphoranes portés en C3 ou en C4 du cycle quinique sont tout à fait en dehors du cône d'anisotropie des groupements carbonyles en C5 ou en C1 (C7O5, C9O7). Cet effet d'anisotropie peut se traduire par une augmentation de l'écart entre les déplacements chimiques des protons CH_2 en C18. Ainsi de ce fait ces protons se présentent en RMN comme un système AM, alors que les autres protons NCH_2 sont des systèmes AB.

Enfin la structure cristalline est stabilisée par un ensemble des liaisons hydrogènes intermoléculaires faisant intervenir l'atome d'oxygène des groupements carboxylate en C1 (O5) avec un des protons portés par C20 (C20H220...O5 d = 2,61 Å; C2—H220—O5 : 162°) et l'atome d'oxygène O7 de l'acetoxy en C1 avec les protons portés par les atomes de carbone C18 et C24 :

C18H118..O7 = 2,58 Å et C18—H118—O7 153°

C24H124..O7 = 2,76 Å et C24—H124—O7 151°

Partie expérimentale

Méthodes spectroscopiques

Les spectres de RMN ^{1}H, ^{13}C et ^{31}P ont été enregistrés avec différents appareils Bruker : WP-60, AC-80, WH-90, WM-250 et AM-300 WB.

Les déplacements chimiques, exprimés en parties par million du

champ inducteur (ppm) sont mesurés avec une précision de ± 0,005 ppm pour ^{1}H, ± 0,03 ppm pour ^{31}P et ^{13}C (références : TMS pour ^{1}H et ^{13}C, H_3PO_4 à 85% pour ^{31}P). Les constantes de couplage, exprimées en Hz, sont mesurées avec une précision de ± 0,2 Hz.

Les spectres infrarouge ont été effectués sur un appareil Perkin–Elmer 783, les spectres de masse sur Nermag R10-10. La chromatographie haute performance est réalisée sur un appareil Jobin–Yvon avec de la silice 6–35 μm Amicon.

*(1S,2R,4R,6R,8S)-4(Méthoxycarbonyl)-8 phenyl-7,9 dioxabicyclo-[4.3.0]nonane-2,4-diol (**9**)*

Ce composé a été préparé comme indiqué par Lesuisse et Berchtold (14).

*(1S,2R,4R,6R,8S)-2,4-Diacétoxy 4-(méthoxycarbonyl)-8 phenyl-7,9 dioxabicyclo[4.3.0]nonane (**10**)*

À une solution de **9** (1,6 g; 5,71 mmol) dans le chlorure de méthylène (40 mL) on ajoute successivement 12 mmol (1,4 g) de 4-*N,N*-dimethylaminopyridine (DMAP) et 12 mmol (1,08 mL) d'anhydride acétique. Après 2 h d'agitation à la température ambiante, on lave à l'eau, on extrait la phase organique, on sèche sur $MgSO_4$ et on évapore le solvant. Le produit désiré **10** est obtenu sous la forme de cristaux blancs (1,79 g, rendement = 83%); F = 132–133°C; ν_{max} ($CHCl_3$, cm^{-1}) : 1740 (C=O). RMN ^{1}H ($CDCl_3$) δ : 7,50 (m, 2H, Ar), 7,37 (m, 3H, Ar), 5,83 (s, 1H, C8-H), 5,33 (m, 1H, C6-H, J_{6-5} = 11,10, $J_{6-5'}$ = 4,50, J_{6-1} = 6,75), 4,50 (m, 1H, C2-H, J_{2-1} = 6,50, J_{2-3} = 3,15, $J_{2-3'}$ = 5,00 Hz), 4,24 (dd, 1H, C1-H, J_{1-6} = 6,75, J_{1-2} = 6,50), 3,71 (s, 3H, OCH_3), 2,87 (m, 1H, C3-H, $J_{3-3'}$ = 16,0, J_{3-2} = 3,15, J_{3-5} = 2,30), 2,46 (m, 1H, C3-H', $J_{3-3'}$ = 16,0, $J_{3'-2}$ = 5,0), 2,43 (m, 1H, C5-H, $J_{5-5'}$ = 13,50, J_{5-6} = 4,50, J_{5-3} = 2,30 Hz), 2,06 (s, 3H, CH_3CO), 2,05 (s, 3H, CH_3CO), 1,88 (m, 1H, C5-H', $J_{5'-5}$ = 13,50, $J_{5'-6}$ = 11,10). RMN ^{13}C ($CDCl_3$) δ : 171,44 (C=O), 170,07 (C=O), 136,99, 129,59, 128,42, 126,86 (C_6H_5), 104,43 (C8), 78,11 (C4), 75,97 (C6), 74,99 (C1), 70,96 (C2), 52,77 (OCH_3), 34,50 (C5), 30,74 (C3), 21,05 (CH_3CO), 20,86 (CH_3CO). SM *m/e* (intensité relative) : 378 M^+ (17), 136 (12), 105 (53), 43 (100). Anal. calc. pour $C_{19}H_{22}O_8$: C 60,31, H 5,86; trouvée : C 60,33, H 5,82.

Anal. calc. pour $C_{28}H_{50}N_2O_{12}P_2$: C 50,29, H 7,48, N 4,19; trouvée : C 49,69, H 7,53, N 4,21.

Étude cristallographique et collection des données

Le monocristal du composé **7** a été obtenu par évaporation lente sous atmosphère inerte et à température ambiante d'une solution de bicyclophosphorane **7** dans le toluène. Le cristal transparent choisi pour l'étude se présente sous la forme approximative d'un cube de 0,3 mm de côté.

Les mesures ont été effectuées à l'aide d'un diffractomètre automatique Enraf–Nonius de type CAD4. Le composé cristallise dans le système orthorombique, le groupe spatial étant $P2_12_12_1$. L'affinement de 25 réflexions *hkl* réparties aléatoirement dans l'espace réciproque conduit aux paramètres de la maille cristalline suivants : *a* : 10,853 (9) Å; *b* : 16,971 (6) Å; *c* : 19,326 (5) Å; *V* 3560 Å^3.

L'ensemble des calculs a été effectué sur un ordinateur Digital Vax 730; la chaîne SDP a été utilisée. L'intensité des réflexions *hkl* a été corrigée des facteurs de Lorentz et de la polarisation. Aucune décroissance des tâches de contrôle d'intensité n'étant observée, cette correction n'a pas été nécessaire. Une correction d'absorption expérimentale a également été effectuée malgré une valeur faible (1,73 cm^{-1}) du coefficient d'absorption. Ceci a conduit à des coefficients de transmission variant de 0,93 à 1,0.

La détermination de la structure cristalline a été effectuée par l'utilisation des méthodes directes (programme MULTAN). L'affinement des positions atomiques et de l'agitation thermique de tous les atomes exceptés les hydrogènes nous a conduit à un facteur de reliabilité $R = 0{,}15$ puis $R = 0{,}07$ après introduction de l'agitation thermique anisotrope. À ce stade d'affinement une série de Fourier-différence nous a permis de localiser les atomes d'hydrogène à l'exception des deux hydrogènes liés aux atomes de phosphore. Un calcul théorique nous a permis de confirmer nos observations et de fixer les longueurs entre atomes de carbone et hydrogène à 0,97 Å. La contribution des atomes d'hydrogène a été introduite dans le dernier affinement mais ni leurs positions ni leurs agitations thermiques n'ont été affinées.

L'affinement final incluant également l'extinction secondaire ($3{,}17 \times 10^{-7}$) conduit à un facteur de reliabilité final $R = 0{,}046$. Le tableau 3 donne les coordonnées atomiques. Les paramètres angulaires et de liaison ainsi que les valeurs de torsion les plus significatives sont données dans les tableaux 4 et 5. Les tableaux des plans moyens caractéristiques de la molécule sont regroupés dans le tableau 6. Enfin, les données cristallines du composé sont consignées dans le tableau 7.

The boiling point data for the binary liquid mixtures of 1-bromobutane with 1,2-dichloroethane, 1,1,1-trichloroethane, and 1,1,2,2-tetrachloroethane were obtained over the entire composition range by using a standard Swietoslawski type ebulliometer at 715 Torr. The experimental t–x data were used to estimate Wilson parameters and also to calculate the equilibrium vapor compositions for these systems. These Wilson parameters were used to calculate activity coefficients and these in turn were used to compute excess Gibbs free energy.

Key words: Wilson parameters, 1-bromobutane + chloroethane systems.

K. RAMBABU, P. VENKATESWARLU, G. K. RAMAN et Y. V. L. RAVI KUMAR. Can. J. Chem. **69**, 311 (1991).

Opérant à une pression de 715 Torr et utilisant un ébulliomètre standard de type Swietoslawski, on a déterminé les données relatives aux points d'ébullition de mélanges liquides binaires du 1-bromobutane avec le 1,2-dichloroéthane, le 1,1,1-trichloroéthane et le 1,1,2,2-tétrachloroéthane couvrant l'ensemble des compositions. On a utilisé les données expérimentales t–x pour évaluer les paramètres de Wilson ainsi que pour calculer les compositions des vapeurs à l'équilibre de ces systèmes. On a utilisé ces paramètres de Wilson pour calculer les coefficients d'activité et on a utilisé ces derniers pour calculer l'énergie libre de Gibbs en excès.

Mots clés : paramètres de Wilson, systèmes de 1-bromobutane + chloroéthane.

[Traduit par la rédaction]

Introduction

Distillation has been used as an effective means of separation in chemical processing. Evidently an accurate and complete knowledge of vapor–liquid equilibrium data for the mixture under consideration is necessary for the design of separation equipment. Generally, vapor–liquid equilibrium data are obtained under two fixed conditions, namely, isothermal and isobaric. Most distillation processes are carried out at constant pressure rather than at constant temperature, so that the temperature–composition curves are more practical in making such calculations as the number of plates, although for theoretical consideration the pressure–composition curves are preferable. Hence, an attempt is made to determine the isobaric boiling points and to calculate vapor compositions, activity coefficients, and excess Gibbs free energies for the systems of 1-bromobutane with chloroethanes at 715 Torr (1 Torr = 133.3 Pa).

Experimental

A Swietoslawski ebulliometer (Hala *et al.*, ref. 1) was used to measure the boiling points of the mixtures. The ebulliometer was connected to a vacuum system. Pressure was measured with a mercury manometer with an accuracy of ±1 Torr. The temperatures were measured with a PT 100 thermometer, which gave an accuracy of ±0.1°C. The detailed procedure was described previously (1).

Isobaric binary systems

The isobaric boiling points of the systems 1-bromobutane with 1,2-dichloroethane, with 1,1,1-trichloroethane, and with 1,1,2,2-tetrachloroethane were determined over the entire range of compositions. Mixtures of different compositions were made by taking suitable quantities (by weight) of the pure materials. The equilibrium compositions were not determined gravimetrically. The liquid compositions were assumed from the gravimetric compositions of the mixture. Vapour compositions were estimated by using the Wilson model. The boiling points for the known binary compositions were measured at 715 Torr.

Purification of materials

All materials were purified by the methods described by Riddick and Bunger (2). 1-Bromobutane, Fluka (AG 99%, GC pure), was used without further purification. 1,2-Dichloroethane (BDH) was purified as described by Choudary and Naidu (3). 1,1,1-Trichloroethane (Koch–Light) was washed with concentrated hydrochloric acid, followed by 10% potassium carbonate solution, and then with 10% sodium chloride solutions. It was dried over calcium chloride, distilled twice, and the middle fraction collected. During the distillation about 0.5 g of phenol was added as a stabilizer. 1,1,2,2-Tetrachloroethane (Riedel) was shaken with concentrated sulphuric acid for 10 min. The operation was repeated until the acid developed no more colour. The chloroalkane was then washed with water, steam distilled, dried with potassium carbonate, and finally fractionated.

The purity of the samples was checked by comparing the measured densities and boiling points of the compounds with those reported in the literature (4, 5). Densities were determined using a bicapillary type pycnometer that offered an accuracy of 2 parts in 10^5.

Results

Isobaric t–x measurements are used for the data reduction. The model for expressing the composition and temperature dependence is chosen to be the Wilson equation (6):

$$[1]\quad \ln \gamma_1 = -\ln [X_1 + \Lambda_{12}X_2] + X_2\left[\frac{\Lambda_{12}}{X_1 + \Lambda_{12}X_2} - \frac{\Lambda_{21}}{X_2 + \Lambda_{21}X_1}\right]$$

$$[2]\quad \ln \gamma_2 = -\ln [X_2 + \Lambda_{21}X_1] + X_1\left[\frac{\Lambda_{21}}{X_2 + \Lambda_{21}X_1} - \frac{\Lambda_{12}}{X_2 + \Lambda_{12}X_1}\right]$$

The Wilson parameters Λ_{12} and Λ_{21} are given by

$$[3] \quad \lambda_{12} = \frac{V_2^L}{V_1^L} \exp\left[-\frac{\lambda_{12} - \lambda_{11}}{RT}\right]$$

$$[4] \quad \lambda_{21} = \frac{V_1^L}{V_2^L} \exp\left[-\frac{\lambda_{12} - \lambda_{22}}{RT}\right]$$

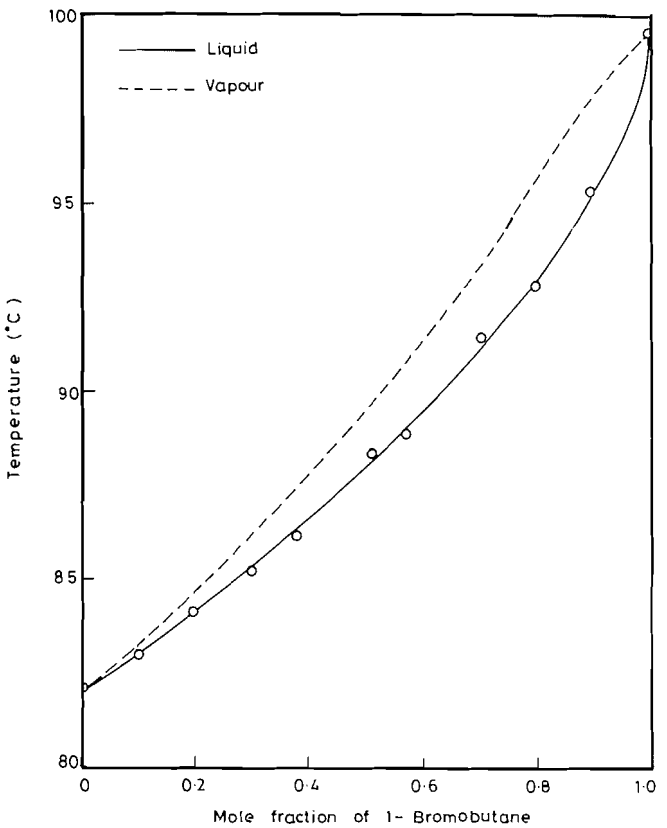

FIG. 1. 1-Bromobutane + 1,2-dichloroethane (○) at 715 Torr.

where V_1^L and V_2^L are liquid molar volumes, and $(\lambda_{12} - \lambda_{11})$ and $(\lambda_{12} - \lambda_{22})$ are temperature independent (to some extent) Wilson parameters. λ's are the energies of interaction between the molecules designated in the subscripts.[3]

Discussion

The optimum Wilson parameters λ_{12} and λ_{21} are obtained by minimizing the objective function ϕ, using Nelder–Mead optimization techniques (7), and the values are presented in Table 1 along with the standard deviation of the fit.

$$[5] \quad \phi = \Sigma(P_{calc}/P_{exp} - 1.0)^2$$

Since the prediction of vapor–liquid equilibrium data involves the vapor pressure data of the pure compounds, these same data have been determined for 1-bromobutane, 1,2-dichloroethane, 1,1,1-trichloroethane, and 1,1,2,2-tetrachloroethane.

[3] *Glossary*: *A*,*B*,*C*: Antoine constants; *P*: pressure, Torr; *t*: temperature, °C; X_1: mole fraction in liquid phase; *Y*: vapor composition; γ activity coefficients; Λ Wilson parameter. Subscript 1 refers to 1-bromobutane, and subscript 2 to the chloroethanes.

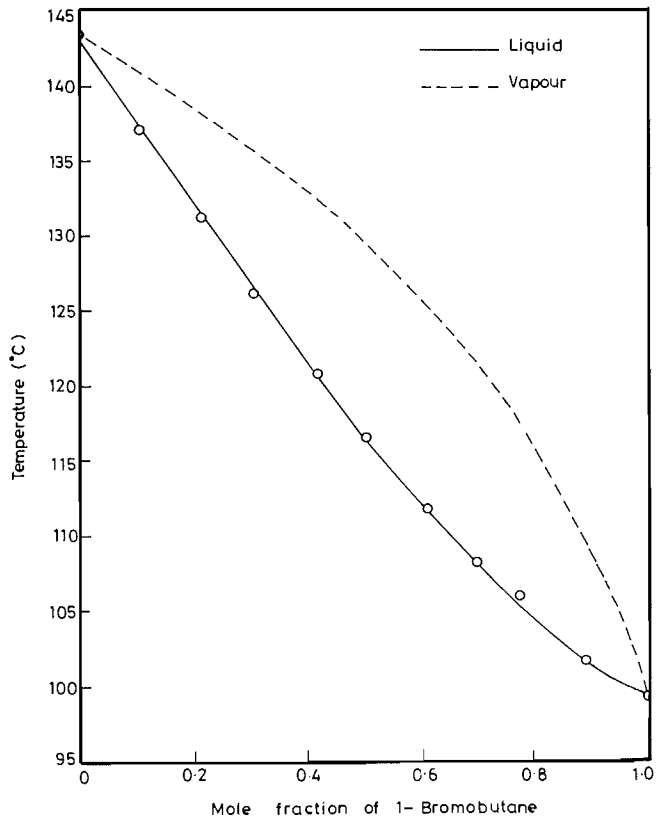

FIG. 3. 1-Bromobutane + 1,1,2,2-tetrachloroethane (○) at 715 Torr.

The Antoine constants for the pure compounds were obtained by non-linear regression analysis of the experimental data (8). The observed Antoine constants are presented in Table 2. The liquid composition, measured boiling points, vapour compositions, and activity coefficients using the Wilson equation are presented in Table 3 and shown in Figs. 1–3. If vapor-phase non-idealities are neglected, which is justified at these low pressures, the vapor compositions can be calculated by using the following equation.

$$[6] \quad Y_1 = \frac{X_1 P_1^S \gamma_1^S}{P_{calcd}}$$

The excess Gibbs free energies at 25°C for the three systems were also calculated with these model parameters by using

Synthesis, electrochemical and spectroscopic investigations of 2,2′:4,4″-terpyridine and 2,2′:4,4″:6,2″-quaterpyridine ligands for metal complex photoelectrochemistry

L. PERSAUD[1] AND G. BARBIERO

Department of Chemistry, University of Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received August 13, 1990

L. PERSAUD and G. BARBIERO. Can. J. Chem. **69**, 315 (1991).

The synthesis of 2,2′:4,4″:6,2‴-quaterpyridine and 2,2′:4,4″-terpyridine was accomplished by a reverse aldol condensation reaction of the appropriate aldehyde with alkyl and pyridyl acetyls. A selective quaternization method in toluene is described. In this method the 1,1′ nitrogens survive alkylation and are free to coordinate with metals to form metal complexes. The electrochemical behaviour of the neutral ligands as well as the monoquaternized cations was established by linear sweep cyclic voltammetry. Spectroelectrochemical techniques were used to establish the electronic spectral behaviour and stability of the radicals obtained upon reduction.

Key words: 2,2′:4,4″-terpyridine, quaterpyridine, selective quaternization.

L. PERSAUD et G. BARBIERO. Can. J. Chem. **69**, 315 (1991).

Les aldéhydes appropriés soumis à des réactions de retroaldolisation avec les acétyles d'alkyle de pyridine fournissent la 2,2′:4,4″:6,2‴-quaterpyridine et la 2,2′:4,4″-terpyridine. La formation sélective des sels quaternaires est favorisée dans le toluène où les azotes 1,1′ sont libres pour donner des complexes avec des ions métalliques. Par voltampérométrie à balayage cyclique, les caractéristiques électrochimiques des espèces neutres ainsi que celles des cations monoquaternaires ont été établies. Les caractéristiques spectrales UV et la stabilité des radicaux anions ont été déterminées par spectroélectrochimie.

Mots clés : 2,2′:4,4″-terpyridine, quaterpyridine, quaternisation sélective.

Introduction

The diimine ligand, 2,2′-bipyridine, continues to find extensive usage in the preparation of metal complexes for photochemical and photophysical studies. It has been modified by a number of substituents in an effort to tune and control excited states behaviour. Reviews by Kalyanasundaram (1), Juris *et al.* (2), and more recently by Krause (3) have summarized a number of substituted 2,2′-bipyridines and their metal complexes along with some of their excited states behaviour. Most of the modifications were accomplished by adding the same group to both rings to obtain disubstituted derivatives. Small and simple groups such as chloride as well as the larger and strongly interacting aromatic phenyl rings were used. Among these groups the latter appear to be particularly interesting.

Metal complexes of 4,4′-diphenyl-2,2′-bipyridine were shown to exhibit an enhanced absorbance in the MLCT band (4). In addition, their excited states lifetimes are longer than others in which the substituent is nonaromatic. This behaviour was also observed for other molecules derived from the closely related 1,10-phenanthroline ligand with phenyl substituents in the 4 and 7 positions (5). The phenyl ring appears to be the factor that is responsible for this behaviour. The aromatic nature and its ability to undergo resonance isomerism have been suggested as the explanation (6). These groups are in conjugation with the π system of the parent ligand and extend it away from the metal center. This affects the dipole transition, which in turn influences the absorptivity.

Pyridine groups are similar to the phenyl rings. They are aromatic and can undergo conjugation. 2,2′-Bipyridine with a pyridine substituent in the 4 position is therefore an interesting ligand since it can exhibit behaviour similar to the phenyl derivatives. In addition, a quaternized pyridine substituent can undergo redox reaction and thereby provide a site away from the metal center, but in conjugation with it, for the acceptance or donation of an electron. The combined features of a redox site and electronic conjugation effects in this molecule make it a new and different ligand system for excited states electron transfer studies. In spite of this, such a system was only recently prepared when Morgan and Baker (7) catalytically coupled two molecules of 4,4′-bipyridine to produce a 2,2′:4,4″:4′,4″-quaterpyridine.

As part of the general effort to develop new ligands and new modifications of known ligands for the preparation of molecular complexes to investigate photoelectrocatalysis and photoinduced electron transfer we have successfully synthesized 2,2′:4,4″-terpyridine (**1**) and 2,2′:4,4″:6,2‴-quaterpyridine (**2**). These molecules were selectively quaternized at the N″ nitrogen to give the corresponding *N*″-methylterpyridinium (**3**) and *N*″-methylquaterpyrindium (**4**) cations. Their preparation and electrochemical and spectroscopic behaviour are described.

Experimental

Reagents

4-Pyridinecarboxaldehyde, 2-acetylpyridine, pyruvic acid, tetrabutylammonium hexafluorophosphate, and ammonium hexafluorophosphate were purchased from Aldrich. *N*,*N*-Dimethylformamide was either spectrophotometric or anhydrous sure/seal grade, also from Aldrich. Other solvents and chemicals were reagent grade obtainable from commercial sources.

Apparatus

Cyclic voltammetry and other electrochemical measurements were done on a PAR 273 potentiostat/galvanostat in conjugation with an EG&G model RE0089 X–Y recorder. The working electrode was a platinum disk, the counter electrode was a platinum wire, and the reference electrode was a Ag/Ag^+ (0.1 M $AgNO_3/CH_3CN$) the potential of which was measured as −0.31 vs. the standard calomel electrode. For cyclic voltammetric measurements millimolar quantities of samples were used in anhydrous sure/seal grade DMF with 0.1 M tetra-*n*-butylammonium hexafluorophosphate as supporting electrolyte. The latter was recrystallized from ethanol and dried under vacuum at 80°C. Spectroelectrochemical measurements were obtained by electrolyzing the solution in a locally made cell with a 1-cm spectrophotometric cuvette that fitted directly in the path of the light beam. The counter electrode was separated from the bulk solution by a fritted glass disk.

[a]Solution in $CDCl_3$.
[b]Solution in DMSO-d_6.

Spectrophotometric measurements were recorded on an HP 8452A diode array spectrophotometer. NMR data were collected on a Bruker 250 MHz spectrometer with an Aspect 2000 computer. The ionic compounds or salts were taken in deuterated DMSO while the neutral materials were measured in deuterated chloroform. Molecular mass information was obtained on a 70 eV V.G. Micromass ZAB-1F spectrometer.

*Preparation of 2,2′:4,4″ terpyridyl (**1**) [Terpy]*

To a stirring solution of 4-pyridinecarboxaldehyde (0.1047 mol) in 40 mL of methanol cooled at −25°C, pyruvic acid (28 mL) neutralized at 0°C with 84 mL of 20% aqueous NaOH and 20 mL of 20% aqueous NaOH were simultaneously added dropwise over a 30 min period. A solution of 2-acetylpyridine (0.0891 mol) in 25 mL of methanol was cooled to −25°C and added dropwise to the reaction mixture over a 40 min period, followed by the dropwise addition of 40 mL of 20% aqueous NaOH over a 90 min period while always maintaining the reaction temperature between −15 and −20°C. The reaction mixture was stirred for an additional 4 h, warmed to room temperature, filtered, and washed with water. The precipitate was dissolved in methanol and treated at reflux with ammonium acetate to yield 7.25 g (54%) of the quaterpyridine. The original filtrate solution was heated with stirring to 80°C with ammonia gas bubbling through. After 1 h the mixture was filtered hot and washed with hot water. The filtrate was cooled to room temperature and treated with concentrated HCl to induce precipitation. The crude precipitate was reprecipitated twice from a saturated aqueous NaOH/concentrated HCl solution system, to give 4.7 g (23%) of 6-carboxyl-2,2′:4,4″ terpyridine acid as a white precipitate; MS, *m/e* 277.

*Preparation of 2,2′:4,4″:6,2‴-quaterpyridine (**2**) [Qpy]*

To a stirring solution of 4-pyridinecarboxyaldehyde (0.1047 mol) in 40 mL of methanol cooled to −15°C, 2-acetylpyridine in 20 mL of methanol and 40 mL of 20% aqueous NaOH were simultaneously added dropwise over a 20 min period. The reaction mixture was stirred for 3 h maintaining a temperature of −10 to −15°C, warmed to room temperature, and filtered. The filtrate solution was refluxed with 40 g of ammonium acetate for 4 h, filtered, and washed several times with hot water and hot ethanol, yielding 10.31 g of crude product, which was recrystallized from a minimum quantity of 15% DMF in methanol to give 9.46 g (69%) of **2** as white crystals, mp 216°C. The ^{13}C and ^1H nuclear magnetic resonance values are summarized in Tables 1 and 2 respectively. Anal. calcd. for $C_{20}H_{14}N_4$: C 77.40, H 4.55, N 18.05; found: C 77.42, H 4.58, N 18.04.

The carboxylic acid mentioned above (1.2 g) was heated to 280°C for 10 min to give a brown oil, which solidified upon cooling. The precipitate was purified twice, once in hot toluene and secondly by suspending the product in 10% aqueous NaOH and extracting with toluene. The organic extract was treated with charcoal, filtered, evaporated to dryness, and kept under reduced pressure overnight, to give 2,2′:4,4″-terpyridine (0.71 g, 59%) as white microcrystals, mp 84–85°C. The ^{13}C and H NMR are summarized in Tables 1 and 2 respectively. Anal. calcd. for $C_{15}H_{11}N_3$: C 77.23, H 4.75, N 18.01; found: C 77.28, H 4.65, N 18.03.

*Preparation of N″-methyl-2,2′:4,4″-terpyridinium iodide (**3**) [TerpyMe]$^+(I^-)$ and hexafluorophosphate (salts of **1**)*

To a solution of 2,2′:4,4″-terpyridine (300 mg) in 300 mL of toluene maintained at 50°C with stirring, methyl iodide (1 mL) in 10 mL of toluene was added dropwise and left to react for 24 h. The mixture was filtered hot, washed with hot toluene, and dried under vacuum. The crude iodide salt was recrystallized from ethanol to give *N″*-methyl-2,2″:4,4″-terpyridinium iodide salt (433 mg, 90%). The ^{13}C and ^1H chemical shifts are summarized in Tables 1 and 2 respectively. Anal. calcd. for $C_{16}H_{14}N_3$: C 51.22, H 3.76, N 11.20; found: C 51.24, H 3.76, N 11.27.

The hexafluorophosphate salt was prepared by dissolving 200 mg of the iodide salt **2** in 22 mL of water, followed by excess addition of a saturated aqueous ammonium hexafluorophosphate solution. The white slurry solution was filtered, washed with water, and recrystallized from methanol to give 189 mg of the hexafluorophosphate salt.

Preparation of N″*-methyl-2,2′:4,4″:6,2‴-quaterpyridinum iodide (4) [QpyMe]$^+$(I$^-$) and hexafluorophosphate (salts of 2)*

The selective monoquaternization of the N″ of quaterpyridine (**2**) was synthesized in the same manner as the terpyridine compound to give *N*″-methyl-2,2′:4,4″:6,2‴-quaterpyridinium iodide salt (90%). The ^{13}C and ^1H resonance values are summarized in Tables 1 and 2 respectively. Anal. calcd. for $C_{21}H_{17}N_4$: C 55.77, H 3.79, N 12.39; found: C 55.72, H 3.74, N 12.37. The exchange of the iodide ion for hexafluorophosphate was achieved in the same manner as mentioned above.

Results and discussion

Synthesis

The coupling methods (8, 9) known for preparing bi-, ter-, and other pyridines were not chosen because of the anticipated difficulty that may incur in product separation.

We initially contemplated using the route described by Krohnke (10) to obtain compounds **1** and **2** by first preparing the 4-pyridyl-2′-acetylpyridine from 4-pyridinecarboxaldehyde and 2-acetylpyridine and then using this unsaturated pyridyl ketone in the reaction with Ortoleva–King reagent (11). Despite repeated attempts, the desired unsaturated ketone was not successfully isolated. It appears that the pyridine aldehyde undergoes a condensation reaction with two molecules of the acetylpyridine to give a diketone. Reactions of this type in which two molecules of methyl ketone react with one molecule of an aldehyde have been reported (12). A similar reaction is inferred here since the product of the reaction between the 4-pyridinecarboxaldehyde and 2-acetylpyridine always produces the quaterpyridine **2** when refluxed with ammonium acetate or ammonia gas. The isolation of 6-carboxy-2,2′:4,4″-terpyridine when pyruvic acid is present in the reaction mixture also supports the 1:2 ratio aldehyde/acetyl reaction.

NMR measurements and assignments

^{13}C NMR assignments were based on spectral models of pyridine, bipyridine, and their substituted derivatives (13–17), while the proton chemical shifts were analyzed with the aid of 2D carbon–proton correlation data and by comparison with literature values (18–23).

Reaction with ferrous sulfate

In addition to the NMR data, the reaction with ferrous sulfate is a simple chemical indicator test to show the α-diimine nitrogens do not undergo alkylation in the quaternization reaction. Ligands **1**–**4** readily form a red to purple coloration with this metal ion. For ligands **1** and **3** the absorbance maxima in the visible are 532 and 562 nm respectively while a shift to lower wavelength was observed for **2** and **4**.

Electrochemical measurements

Molecules **1**–**4** are designed for the preparation of metal complexes that are to be used as catalytic materials in photoelectrochemical studies. It is therefore important that the energetics of the free ligands be established in order to aid in the redox characterization of the more complicated metal complex systems. The half-wave potentials were obtained by linear sweep cyclic voltammetry. All the potentials referred to herein are experimental room temperature values referenced to the Ag/Ag^+ electrode referred to above. Scan speeds were 100 mV/s unless otherwise mentioned.

The redox behaviour of 2,2′:4,4″-terpyridine (**1**) is depicted in the voltammogram of Fig. 1A. There are three redox couples within the potential range of −0.5 to −3.5 V. For convenience the waves of each couple are numbered. Within the scan range

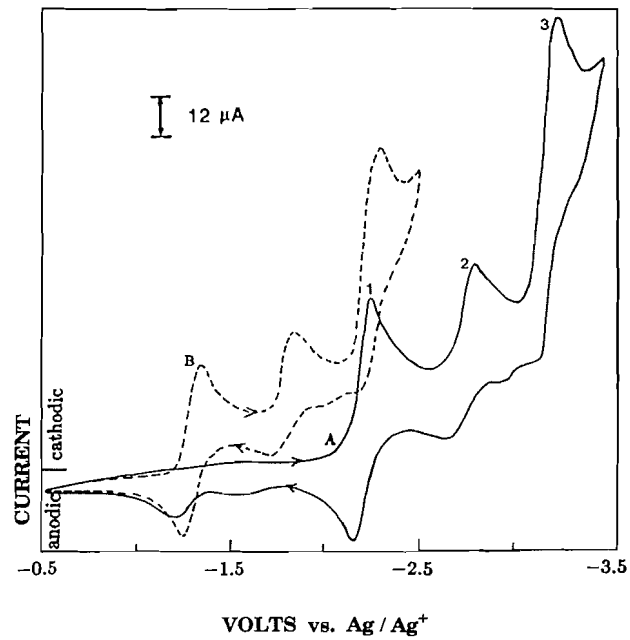

FIG. 1. Cyclic voltammograms of 2,2′:4,4″-terpyridine in 0.1 M $TBAPF_6$/DMF solution at 100 mV/s. (A) Fresh solution −0.5 to −3.2 V; (B) after electrolysis at −2.3 V vs. Ag/Ag^+.

of −0.5 to −2.3 V one reversible couple with a half-wave potential of −2.047 V was found. The profile, ratio of cathodic to anodic peak current, and peak to peak separation would suggest that this is one-electron transfer process. Beyond −2.3 V a quasi reversible wave at $E_{1/2}$ −2.507 V and an irreversible cathodic wave at −2.99 V were found. Successive scans in the potential range of −0.5 to −2.3 V revealed a small anodic wave at −1.503 V as well as a pre-wave at the foot of the ascending portion of the cathodic wave. There was no other change in the voltammogram and it remained this way after a number of repeated scans. Scans covering the first and second redox couples within the potential range of −0.5 to −2.8 V revealed another small anodic wave at −1.155 V. This wave increased as the scan encompassed the third cathodic wave at −2.970 V. Multiple scans did not indicate any increase in these peaks. The voltammogram remained unchanged. At 30 mV/s these small anodic waves were not seen but when the electrode was polarized beyond the second redox couple they showed up with an increase in current. To determine the origin of these transient waves the solution was electrolyzed at −2.3 V. A green coloration resulted, and the voltammogram of this solution is shown in Fig. 1B. A new reversible couple with $E_{1/2}$ at −1.201 V and a quasi reversible one at $E_{1/2}$ −1.621 V were observed. They are in the potential range where the anodic transients were found. These findings are indications that a slow chemical reaction follows the reduction process. At fast scan speeds the reaction product cannot completely diffuse away from the electrode interface and reacts with the electrode at the appropriate potential. At slow scan speeds there is adequate time for it to diffuse far enough from the electrode for any reaction to occur.

The voltammogram for 2,2′:4,4″:6,2‴-quaterpyridine (**2**) is given in Fig. 2. There are four major redox waves in the potential range −1.0 to −3.5 V. Scans taken within the potential range −1.8 to −2.5 V showed the first couple to be electrochemically reversible with characteristic one-electron transfer behaviour. The $E_{1/2}$ value was determined as −2.181 V and

[b]Refers to cathodic peak potentials for irreversible process.

the ratio of peak currents as 0.98. Successive scans at 100 mV/s showed only a very slight decrease in the peak currents. When the scan range was extended from −1.0 to −2.5 V a small anodic wave at −1.545 V and a pre-wave at the foot of the cathodic wave was observed. After the first few successive scans these transient waves did not increase and the voltammogram showed no further change. Between −1.0 and −2.85 V a second redox couple with $E_{1/2}$ of −2.654 V was observed. This is a quasi reversible couple with ΔE of 119 mV and an obvious larger cathodic wave. Further in the cathodic region quasi reversible and irreversible couples are seen at potentials of −2.993 V, and a broad wave between −3.2 and −3.4 V. When the scan is taken over the potential range of −1.0 to −3.5 V two additional small anodic waves in the reverse direction were observed at −1.178 and −1.670 V. These appear to be associated with the third and fourth redox processes. Multiple scans over this range do not indicate any changes in the voltammogram. Polarizing the electrode beyond the third redox couple resulted in an increase in the peaks in the region −1.178 to −1.670 V. At a scan rate of 30 mV/s these waves were absent. This behaviour is identical to that described for 2,2′:4,4″-terpyridine and the same explanation is applicable. From Table 3 it can be seen that the $E_{1/2}$ values of the first redox couple of 4,4-bipyridine, 2,2′:4,4″-terpyridine, and 2,2′:4,4″:6,2‴-quaterpyridine are very close within the potential range of −2.015 to −2.181 V. The latter are ca. 368 and 181 mV more positive than the half-wave potentials of 2,2′-bipyridine and 2,2′:4,4″:6,2‴-terpyridine, respectively. Unsubstituted pyridine and 2,2′-bipyridine are known to be more difficult to reduce (24, 25). The added electron is localized in the 4 position of the pyridine ring and an electron-withdrawing substituent in this position makes the reduction process easier. This may explain the more positive redox potential of the 4-substituted derivatives.

The electrochemical behaviour of the *N*″-methyl-monoquaternary cations **3** and **4** is different from that of their corresponding neutral compounds. No redox couple is detected at the extreme negative potentials. Figure 3 shows the voltammograms of both cations. Voltammogram A is that of the quaternized terpyridinium ion while B depicts the behaviour of the *N*″-quarternized quaterpyridinium moiety. The $E_{1/2}$ values are set out in Table 3. The current ratios of the cathodic to anodic waves are very close to unity. The peak to peak separations are slightly larger than the 60 mV value for an electrochemically

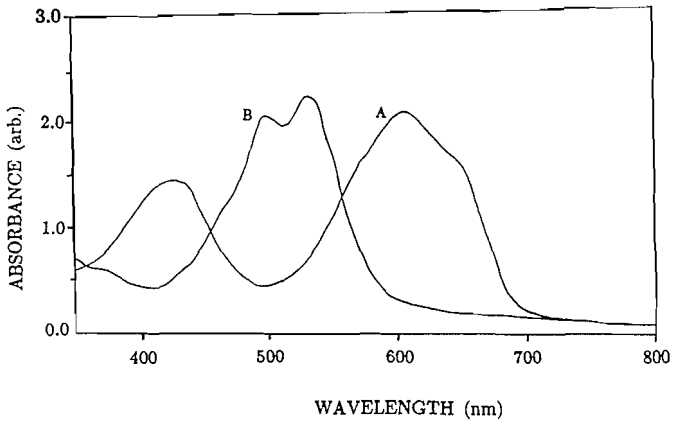

FIG. 5. Visible spectra of radical ions of (A) 2,2′:4,4″-terpyridine; (B) 2,2′:4,4″:6,2‴-quaterpyridine, obtained upon reduction at −2.2 and −2.45 V vs. Ag/Ag^+ respectively.

reversible process but this is normal for organic solvents. Successive scans do not introduce any changes in the voltammograms, indicating that on this time scale the reduced species are stable and can be reversibly generated at the electrode.

The electrochemical behaviour of these monoquaternary cations is similar to that of *N*-alkylpyridinium species bearing an electron-withdrawing substituent in the 4 position (24, 26). Voltammetric reduction of *N*′-methyl-4,4′-bipyridine was recorded and supports this suggestion. Half-wave values are given in Table 3 and are in close agreement with those obtained for the monoquaternary compounds **3** and **4**. The primary reduction process results in the formation of a neutral electron septet (24). For the *N*′-methyl-4,4-bipyridinium and monoquaternized compounds **3** and **4**, this septet is stable and undergoes further reduction at $E_{1/2}$ −2.014, −2.041, and −2.039 V respectively. These values are very nearly identical to that of the first redox couple of the 4,4′-bipyridine, which is 534, and 347 mV more positive than the corresponding couple of 2,2′-bipyridine and 2,2′:6,2″-terpyridine. The difference of 500 mV is large enough to suggest that the septet of 2,2′:4,4″-terpyridine is behaving more as a 4,4′-bipyridine than a 2,2′-bipyridine.

Electronic spectra

The electronic absorption spectra for compounds **1**, **2**, **3**, and **4** were determined in methanol. For these measurements the positive charge on the quaternized molecules was balanced by a perchlorate anion. The spectrum of 2,2′:4,4″-terpyridine is shown in Fig. 4A and it consists of three major band systems at 208, 240, and 276 nm. The profile of the long wavelength band may suggest more than one transition. The 2,2′:4,4″:6,2″-quaterpyridine shows spectral features similar to those of the terpyridine with an additional band clearly resolved at the long wavelength region. The spectrum is shown in Fig. 4B. It consists of four bands, positions of which are given in Table 4.

The spectral profiles of the perchlorate salts of the quaternized molecules are different from their corresponding neutral counterparts. The spectrum of the *N*″-methyl-2,2′:4,4″-terpyridinium cation, Fig. 4C, shows three major bands at 206, 252, and 318 nm with a clearly discernable shoulder on the higher energy portion of the 252 nm band. This shoulder is assigned at 272 nm. It appears that the long wavelength transition referred to in the neutral compound has now been resolved by shifting to lower energy. The *N*″-methyl-quaterpyridinium cation shows similar shifts in the spectrum when compared to the neutral molecule. The long wavelength band is shifted by 24

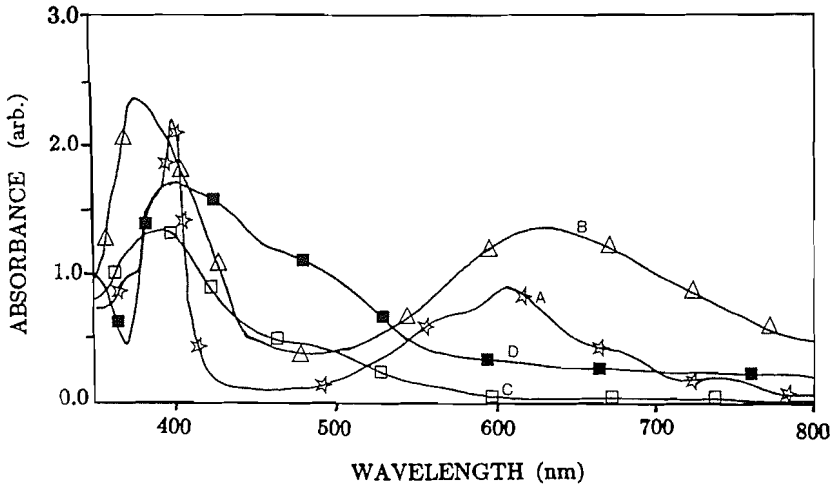

FIG. 6. Visible spectra of radicals of (A) *N*″-methylterpyridinium (**3**), and (B) *N*″-methylquaterpyridinium (**4**), obtained upon reduction at −1.6 V vs. Ag/Ag^+; (C) and (D) are the respective decomposition products.

nm to the red while the 242 nm band is displaced to 254 nm. The spectral profile is given in Fig. 4D.

Assignments of each absorption band cannot be made with certainty but, as in the case of the bipyridines (23), the lowest energy transition is long-axis polarized. The positions and apparent extinction coefficients are summarized in Table 4 while the spectra are shown in Fig. 4.

The electronic spectra of the first reduced species were obtained by spectroelectrochemical means. Each spectrum was generated by reduction beyond the cathodic wave of the redox couple. Figure 5A shows the visible spectrum of 2,2′:4,4″-terpyridine obtained upon controlled potential reduction at −2.2 V in DMF. As the reduction proceeds, the colorless solution becomes blue green with absorption bands at 425 and 606 nm. The latter bears a shoulder at 650 nm. The spectrum is different from the radical anion of 2,2′-bipyridine (25, 27–29) but appears to be similar to the radical anion of 4,4′-bipyridine. The latter was reduced at −2.2 V and spectral changes were compared in the 400 and 600 nm regions. This radical anion was found to be unstable over long periods. The solution turned yellow with an absorbance maximum at 406 nm. Reduction of similar molecules is known to form dimers (24, 26, 30–32). This is also likely to occur here. The close similarity in the spectral changes accompanying reduction of the terpyridine suggests that this molecule is behaving as a 4,4′-bipyridine rather than a 2,2′-bipyridine. This is in agreement with the suggestion deduced from the electrochemical results.

Figure 5B shows the spectrum of 2,2′:4,4″:6,2‴-quaterpyridine obtained upon electrolysis at −2.45 V. Two major bands, not far apart, are seen at 496 and 532 nm. A shoulder is discernable on the higher energy slope of the 496 nm band at approximately 460 nm. This spectrum is closely identical to that of the 2,2′-bipyridine radical anion (25, 27, 28) and not that of 4,4′-bipyridine. This indicates that the quaterpyridine is more likely to behave as a 2,2′-bipyridine than a 4,4′-bipyridine. The electronic influence of pyridine groups in both the 2 and 6 positions appears to outweigh the effects of the one in the 4 position.

The spectra of the reduced monoquaternized compounds **3** and **4** are different from those of the neutral species. The spectrum of the *N*″-methyl-terpyridinium cation obtained upon reduction at −1.6 V is presented in Fig. 6A. Major bands are found at 374, 570, 670, and 744 nm. The spectral changes are in agreement with those obtained upon reduction of *N*-alkylpyridinium salts (26). The spectrum of the radical of monoquaternary 4,4′-bipyridinium was generated by reduction at −1.5 V in order to verify this. Two characteristic absorption bands are found at 602 and 394 nm. The other features are identical to the radical species of *n*-alkylpyridinium and diquaternary 4,4′-bipyridinium cations (32, 33). The radical of 2,2′:4,4″-terpyridinium is not stable over long periods. It gave a yellow coloration, spectrum C, Fig. 6, upon standing.

Quaternization of the *N*″ nitrogen of the quaterpyridine also produces a radical with a different spectrum than that derived from the neutral compound. This is shown in Fig. 6B and was obtained after controlled potential reduction of the quaternized cation at −1.6 V. Two broad bands with maxima at 376 and 630 nm are obvious. The former has a shoulder at 422 nm. The absorption in the 600 nm region is similar to that of the reduction products of *N*″-methyl-4,4″-bipyridinium and *N*″-methyl-2,2′:4,4″-terpyridinium cations except for a shift in the peak maximum by 30 nm and some loss of fine structure. As in the case of the others, this radical is not stable over long periods. The blue color initially seen upon reduction is replaced by yellow. The spectrum of this yellow solution is given in Fig. 6D and is assigned to a dimeric species.

All the radicals obtained by electrochemical reduction were stable enough to obtain reliable spectral profiles. They undergo a slow chemical reaction. This is in agreement with the electrochemical observations. The question of the actual solution composition is an important one and, since the possibility exists that not only the desired species is in solution but that others may be present in small quantities, no extinction coefficients are included at this time.

Conclusion

Two new structural modifications of 2,2′-bipyridine were successfully prepared by condensation and cyclization procedures. The synthetic route is straightforward and does not require expensive catalytic materials as in the coupling reactions. A selective quaternization method was established in which the 1,1′ nitrogens survive the process and remain free to coordinate to metal ions for the preparation of metal complexes. The electrochemistry and spectroelectrochemistry are influenced by the position and degree of substitution. These results have indicated that the behaviour of the parent 2,2′-bipyridine ligand

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

is altered by the structural modifications. These changes are expected to be reflected in the chemistry of ground and excited states of metal complexes, to be investigated shortly.

Chemical state detection of dibutyl phosphate using ^{31}P NMR chemical shift change

NAOHITO UETAKE
Energy Research Laboratory, Hitachi, Ltd., Hitachi-shi, Ibaraki-ken 316, Japan

Received January 29, 1990

NAOHITO UETAKE. Can. J. Chem. **69**, 322 (1991).

Chemical shift changes of ^{31}P NMR were investigated for dibutyl phosphate (DBP) in several polar solvents and compared with tributyl phosphate (TBP). The chemical shift differences between DBP and TBP in the same solvents were found to reflect only the intermolecular interaction on P—OH in DBP, a moiety that is not present in TBP. Acid dissociation constants, K_a, in several polar solvents were determined using such chemical shift differences of DBP. The K_a determined in pure water is in good agreement with the literature value. The intermolecular interaction between alkaline ions and DBP was also investigated using a similar method. No interactions with Na^+ ion and K^+ ion were detected from chemical shift change. However, ion association between the tetramethylammonium ion and the DBP^- ion was detected and the complex formation constant was determined as $K_c = 0.49 \pm 0.02\ M^{-1}$.

Key words: Fourier transform nuclear magnetic resonance spectrometry, dibutyl phosphate, chemical shift, acid dissociation, intermolecular interaction.

NAOHITO UETAKE. Can. J. Chem. **69**, 322 (1991).

On a étudié les changements de déplacements chimiques dans les spectres RMN du ^{31}P du phosphate de dibutyle (PDB) en solution dans plusieurs solvants polaires et on les a comparés avec ceux obtenus avec le phosphate de tributyle (PTB). On a trouvé que les différences dans les déplacements chimiques entre PDB et PTB, dans les mêmes solvants, ne sont que le reflet de l'interaction intramoléculaire avec le P—OH présent dans de PDB, une portion qui n'est pas présente dans le PTB. Utilisant ces différences dans les déplacements chimiques du PDB, on a déterminé les constantes de dissociation acide, K_a, dans plusieurs solvants polaires. Utilisant une méthode semblable, on a aussi étudié l'interaction intermoléculaire entre les ions alcalins et le PDB. Sur la base des changements dans les déplacements chimiques, on n'a pas détecté d'interactions ioniques avec le Na^+ et le K^+. Toutefois, on a détecté une association ionique entre l'ion tétraméthylammonium et l'ion PDB^- et on a déterminé que la constante de formation du complexe, K_c, est égale à $0{,}49 \pm 0{,}02\ M^{-1}$.

Mots clés: spectrométrie de résonance magnétique nucléaire par transformation de Fourier, phosphate de dibutyle, déplacement chimique, dissociation acide, interaction intermoléculaire.

[Traduit par la rédaction]

Introduction

The chemical shifts of NMR spectra reflect the chemical state of the measured nuclei. The formation of chemical bonds changes the electron densities on the nuclei and gives different chemical shift values. Intermolecular interactions also contribute to the chemical shift change, but the degree of change is much smaller than for a true chemical bond. Neighboring molecules that have an intermolecular interaction in solution commonly exchange rapidly with each other. When the exchange frequency between two states is rapid, the NMR spectrum is observed in the averaged chemical shift, which depends on the relative population of the different states (1). If chemical states A and A·B are assumed to exchange very rapidly ($> 50|\nu_A - \nu_{A\cdot B}|$),

[1] $$A + B \leftrightarrows A\cdot B$$

the chemical equilibrium describes the relation between two states. The observed chemical shift is expressed in the equation

[2] $$\nu_{ob} = P_A\nu_A + P_{A\cdot B}\nu_{A\cdot B}$$

where ν_{ob} is the observed chemical shift, ν_A and $\nu_{A\cdot B}$ are chemical shifts of measured nuclei in A and A·B, respectively, and P_A and $P_{A\cdot B}$ are relative populations of A and A·B. Then, the equilibrium constant, K, for eq. [1] is defined by

[3] $$K = \frac{[A\cdot B]}{[A][B]}$$

The equilibrium constant K expresses the strength of the interaction between A and B. It is often difficult to determine the concentrations of A and A·B individually when they exchange rapidly with each other. Chemical shift measurements should offer a powerful method to detect and measure the K values. There must be suitable magnetic nuclei in the molecule in order to use NMR for such a purpose. Phosphorus is one such common element and it has a magnetic nucleus, ^{31}P ($I = 1/2$), that has a 100% natural abundance, relatively high sensitivity, and a wide chemical shift range (2). Since these properties of phosphorus are convenient for NMR study of weak intermolecular interactions, dibutyl phosphate (DBP), which is an organic acid containing phosphorus, was used and its intermolecular interactions in aqueous solutions and other polar solvents were investigated. DBP is one of the main degradation products of tributyl phosphate (TBP), which is used as an extraction solvent in nuclear fuel reprocessing. Therefore, the molecular structure of DBP resembles that of its precursor TBP. The main differences are the number of butyl groups and the existence of OH in DBP, which can undergo acid dissociation. In actual solvents, there are various contributions to the chemical shift and these cannot readily be separated. Thus an alternative is to consider chemical shift differences between two similar molecules, such as DBP and TBP. Therefore, DBP chemical shifts were measured and compared with those of TBP to evaluate the chemical state of DBP.

Experimental

Samples

Dibutyl phosphate (DBP) was obtained from Tokyo Chemical Industries. The ^{31}P NMR spectrum of the reagent DBP showed no other peaks from phosphorus compounds. Therefore, the purity of the reagent DBP was determined as 99.0% based on chemical analysis of the total phosphorus content. The TBP and solvents were of analytical reagent grade and obtained from Wako Chemical Industries. Tetramethylammonium hydroxide (TMAH) solution was also obtained from Wako Chemical Industries. Saturated tetramethylammonium hydroxide

Printed in Canada / Imprimé au Canada

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

solution was prepared by dissolving tetramethylammonium hydroxide pentahydrate (Kodak Organic Chemicals) in pure water.

The DBP was added to several polar solvents and alkaline solutions to give a concentration of 30 g/L. The TBP was also added to the polar solvents to give a concentration of 30 g/L and to one alkaline solution to give a saturated solution. Both DBP and TBP dissolve in pure water only below 30 g/L and so their saturated solutions were prepared for the experiments.

Procedures

All spectra were obtained on a Hitachi R-90H FT-NMR spectrometer with ^2D external lock operating at 36.4 MHz for ^{31}P and 22.6 MHz for ^{13}C in a field of 2.114 T. All spectra were measured at 32°C in a sample tube of 8 mm diameter. The ^1H decoupling procedure was adopted for ^{13}C. ^{31}P chemical shifts were measured relative to external P_4O_6 and ^{13}C shifts were relative to internal TMAH.

Since FT-NMR produces a high magnetic field by using a permanent magnet in a thermostat controlled at 35°C, the magnetic field applied to the sample is very stable. Moreover, room temperature was controlled at 22 ± 0.5°C in order to get even better magnetic field stability.

The P_4O_6 external standard was sealed in a capillary tube and placed in the sample tube. Free induction decays (FIDs) for a spectral width of 200 ppm were collected with 90° pulse angle for 16K data points. Fourier transformation was performed on the FID accumulated 100 times, giving a digital resolution of 0.02 ppm per data point. Sensitivity enhancement filters were not used.

The chemical shifts measured were corrected for the values for the pure water magnetic susceptibility condition using the equation

$$[4] \quad \delta_{corr} = \delta_{obs} - \frac{2}{3}\pi \times 10^6 (K_R - K_S)$$

where δ_{corr} and δ_{obs} are corrected and observed chemical shifts respectively, and K_R and K_S are magnetic susceptibilities of pure water and sample, respectively. The magnetic susceptibilities of pure solvents were obtained from the literature (3). The magnetic susceptibilities of TMAH solutions were determined from the ^{13}C NMR chemical shift of TMAH.

Results and discussion

Dissociation of DBP in polar solvents

The DBP is partially dissociated in polar solvents such as water and the following equilibrium is established:

$$[5] \quad HDBP \leftrightarrows H^+ + DBP^-$$

where HDBP is undissociated DBP and DBP^- is the dissociated DBP ion. The equilibrum of eq. [5] is described by the acid dissociation constant, K_a, which is defined in the following equation.

$$[6] \quad K_a = \frac{[H^+][DBP^-]}{[HDBP]}$$

HDBP and DBP^- interact with solvent molecules or solute molecules other than those of eq. [5] in the actual polar solvents. DBP can be categorized as having three parts when such interactions are considered. One of them is P—OBu, in which the butyl group contacts the other molecules. However, as the alkyl group is hydrophobic, it is expected to have few interactions with polar molecules such as water. Another is the P=O moiety, which acts as a base. The third is P—OH, which can dissociate and release a H^+ ion. Intermolecular interactions must be considered for each individual part. The effects of each part affect the ^{31}P nuclei in DBP.

TBP also has P=O and P—OBu in common with DBP, but does not have the P—OH group. Therefore, ^{31}P NMR chemical shifts of DBP and TBP in several polar solvents were measured

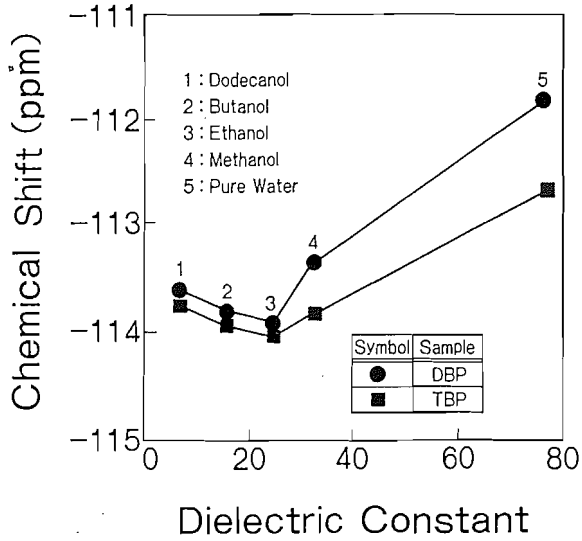

FIG. 1. ^{31}P chemical shifts of DBP and TBP in pure water and alcohols.

in order to evaluate the contributions from each part. The results in a group of normal alcohol solvents are shown in Fig. 1. The chemical shifts of DBP and TBP indicate the similar dependency on the solvent dielectric constant. The chemical shift difference between DBP and TBP is constant, 0.14 ppm from dodecanol to ethanol. This result indicates that the chemical shift of DBP depends on the intermolecular interaction of P=O or P—OBu in these solvents.

On the other hand, the chemical shift difference becomes larger as the dielectric constant becomes higher than that of ethanol. When the dielectric constant of solvent becomes higher and close to that of water, HDBP also begins to dissociate as shown in eq. [5]. If the intermolecular interactions on the P=O and P—OBu parts are the same as in DBP and TBP, the increase in chemical shift above ethanol in Fig. 1 is considered to be caused by dissociation of DBP. The fact that the chemical shift difference between DBP and TBP is constant in lower dielectric constant solvents supports the above assumption, in which the effects of intermolecular interactions on P=O and P—OBu are the same for both DBP and TBP. As TBP has one more butyl group than DBP and the resultant effect from the interaction on P—OBu is considered to be different for DBP and TBP, the main contribution to chemical shift change of HDBP or TBP is considered to be due to solvent–solute interaction on the part of P=O, of which there is only one moiety in each molecule. Hydrogen bonding between P=O and OH in alcohols seems to be the main interaction.

Therefore, adopting the chemical shift difference $\delta_{DBP} - \delta_{TBP}$, one can eliminate the contribution from the P=O part and determine the degree of dissociation of DBP. The chemical shift differences $\delta_{HDBP} - \delta_{TBP}$ and $\delta_{DBP^-} - \delta_{TBP}$ are required for such a calculation. Then, $\delta_{HDBP} - \delta_{TBP}$ can be determined from the value in the lower dielectric constant alcohol:

$$[7] \quad \delta_{HDBP} - \delta_{TBP} = 0.14 \pm 0.04 \text{ ppm}$$

The value of $\delta_{DBP^-} - \delta_{TBP}$ can be determined in 1 M NaOH solution, in which DBP dissociates completely as described in the next section.

$$[8] \quad \delta_{DBP^-} - \delta_{TBP} = 1.18 \pm 0.04 \text{ ppm}$$

As the total DBP concentration is already known, the concentra-

Pyridine	12.3	1.07	−0.03
Ethylene glycol	37.7	0.36	2.09
Formamide	111.0	0.76	0.90

tions of HDBP and DBP^-, respectively, can be determined using eq. [2]. The concentration of H^+ is equal to that of DBP^- in pure solvent. The equilibrium constant, K_a, can be calculated using eq. [6]. Measured $\delta_{DBP} - \delta_{TBP}$ and calculated pK_a's in several solvents are listed in Table 1. Dyrssen (4) reported a value $pK_a = 1.00 \pm 0.01$ from the distribution of DBP between hexene and a $HClO_4$–$NaClO_4$ solution. This value is in good agreement with the value in pure water in Table 1, which indicates that the above mentioned method can lead to proper pK_a values.

There are no reported values except for aqueous solution, so the values in Table 1 cannot be compared with those from other methods. If $\delta_{DBP} - \delta_{TBP}$ expresses only acid dissociation of DBP as for normal alcohols, the values in Table 1 become reliable. Since the main solvent–solute interactions are considered to be hydrogen bonding on P=O in these solvents, it seems to be a reasonable assumption.

Acid dissociation in solvents can be divided into two steps. The first step is ionization, as described by

[9] $$HDBP + S + \leftrightarrows HS^+ \cdot DBP^-$$

where S is solvent.

The second step is dissociation of the ion pair, as described by the following equation:

[10] $$HS^- \cdot DBP^- \leftrightarrows HS^- + DBP^-$$

Since eq. [9] depends on basicity or acidity of the solvent and eq. [10] depends on the dielectric constant (5), K_a depends on both basicity or acidity and dielectric constant of the solvent. The obtained dissociation constants, in Table 1, reflect such a relationship. It is important for the evaluation of specific intermolecular interactions to remove the contribution from the other interactions using adequate reference. Gutowsky and Saika (6) used ^1H NMR chemical shifts for determination of dissociation constants. However, their method is useful only for high concentration solutions because hydrogen exchanges between solute and solvent. Moreover, the atom located on the outer surface of molecules, like hydrogen, is directly affected by contact solvent molecules, and such interactions are complex. Their method can be applied for aqueous solution, because solute molecules are always solvated by water molecules and protected for other intermolecular interactions in aqueous solutions. However, application for other solvents is doubtful.

Intermolecular interaction in alkaline solutions

Since TBP is a base and mainly coordinated by water molecules in alkaline solutions, its chemical shift in alkaline solution is estimated to be constant and does not depend on concentration and alkaline species. The P=O moiety in DBP also has a base functionality and is mainly coordinated by water molecules in alkaline solutions. On the other hand, the P—OH functionality is acid in character and may interact with cations in alkaline solutions. Therefore, the chemical shift of DBP was measured in several alkaline solutions in order to detect solute–solute interactions. The chemical shift of TBP in 1 N NaOH, Na_2CO_3, and TMAH solutions is evaluated as −112.65 ppm, the same as in pure water. Therefore, the evaluation of intermolecular interactions of DBP can be discussed using the absolute chemical shift value instead of the difference between TBP and DBP. This reduces errors caused by taking the difference between two values obtained by individual measurements.

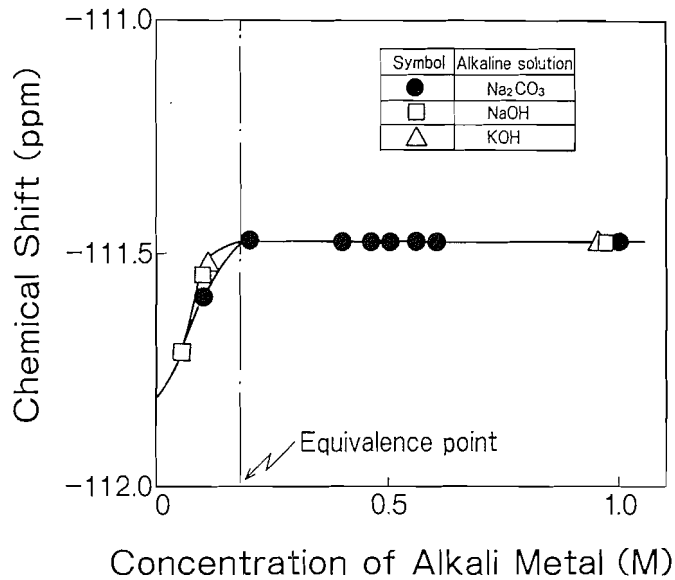

FIG. 2. ^{31}P chemical shifts of DBP in alkaline solutions.

The chemical shift measurement results of DBP in NaOH, Na_2CO_3, and KOH solutions are shown in Fig. 2. Chemical shifts of DBP become higher as alkaline concentration increases from pure water to the equivalent concentration for DBP. Above the equivalence point for DBP, chemical shifts of DBP become constant ($\delta_{DBP} = -111.47$ ppm). This chemical shift value does not depend on the kind of alkaline solution. Since HDBP is dissociated in alkaline medium and only DBP^- can exist above the equivalence point, the chemical shift value, −111.47 ppm,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12

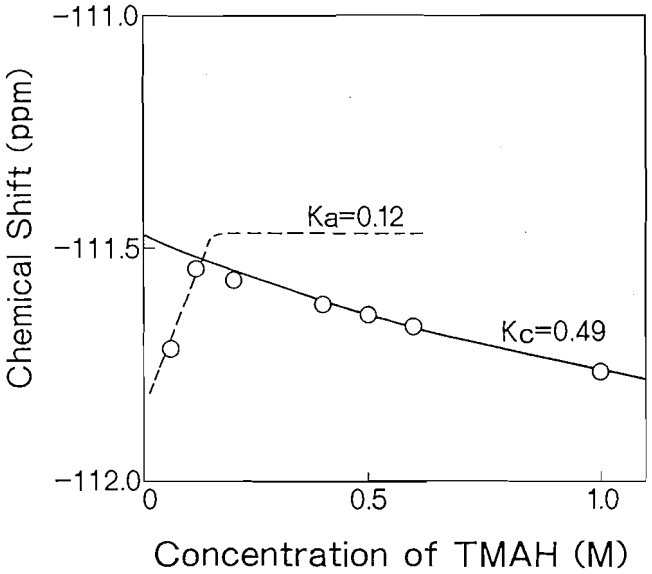

FIG. 3. ^{31}P chemical shifts of DBP in TMAH solutions.

is estimated to be that of DBP^-. The ^{31}P NMR spectra of DBP indicate no differences between NaOH and KOH solution and so it is concluded that any interaction of DBP with Na^+ ion and K^+ ion is too small to be detected by ^{31}P NMR.

Regarding alkaline concentration below the equivalence point for DBP, the chemical shift of DBP in Na_2CO_3 solution is slightly lower than that in NaOH and KOH. Carbonate ion in Na_2CO_3 solution reduces the hydroxide ion concentration and prevents the dissociation of DBP, resulting in a relatively lower chemical shift. However, the chemical shift agrees with that in NaOH and KOH above the equivalent Na_2CO_3 concentration for DBP. This indicates that there are no intermolecular interactions between carbonate ion and DBP.

Although TMAH is strongly alkaline, like NaOH and KOH, the chemical shift change of DBP in TMAH solution is different from that in other alkaline solutions, as shown in Fig. 3. Regarding the equivalence point for DBP, chemical shifts of DBP in TMAH solution are quite similar to those in NaOH and KOH solution. However, the chemical shift of DBP in TMAH solution decreases as TMAH concentration increases. This result indicates that DBP has some intermolecular interactions with TMAH. Since such an intermolecular interaction confirms the above equivalent TMAH concentration for DBP, it is not HDBP but also DBP^- that interacts with TMAH in solution. The following chemical equilibrium must be established:

[11] $DBP^- + TMA^+ \leftrightarrows DBP \cdot TMA$

Such a reaction can be considered as a kind of complex formation and its complex formation constant, K_c, is expressed by the following equation:

$$[12] \quad K_c = \frac{[DBP \cdot TMA]}{[DBP^-][TMA^+]}$$

Here, K_c expresses the strength of the intermolecular interaction (1).

To determine K_c using eq. [2], chemical shift values of DBP^- and DBP·TMA are needed. The former has already been determined and the latter can be determined by measuring the chemical shift of DBP in a TMAH saturated solution. The results are

$$\delta_{DBP \cdot TMA} = -112.39 \pm 0.02 \text{ ppm}$$
$$\delta_{DBP^-} = -111.47 \pm 0.02 \text{ ppm}$$

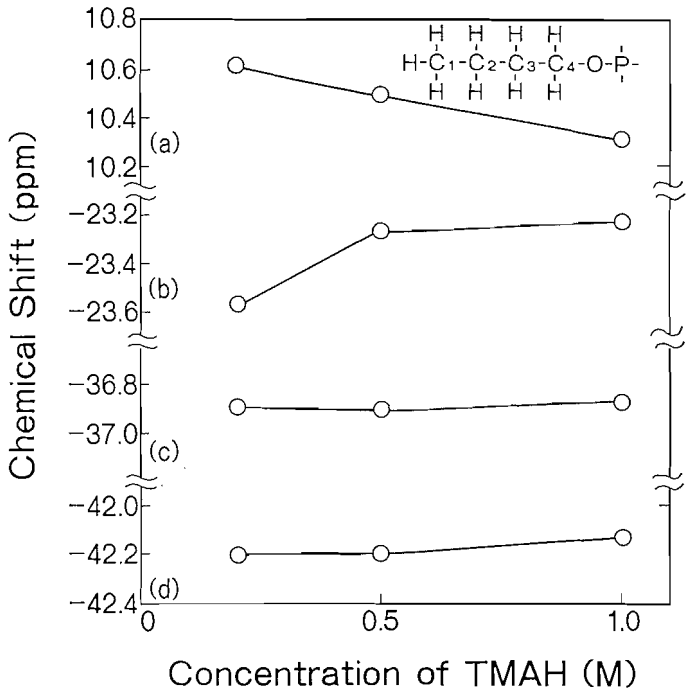

FIG. 4. ^{13}C chemical shifts of DBP in TMAH solution: (a) C_4, (b) C_3, (c) C_2, (d) C_1.

The K_c was determined using chemical shift values in TMAH concentrations between 0.1 and 0.4 M, and the following averaged value was obtained:

$$K_c = 0.49 \pm 0.02 \text{ M}^{-1}$$

To date, the intermolecular interaction between TMA^+ ion and DBP^- ion has not been reported. Larsen and Wahl (7) reported that there is an ion association between TMA^+ and hexacyanoferrate ion and that the complex formation constant (K_c) is 21 M^{-1}. On the other hand Lindman *et al.* (8) found an intermolecular interaction between tetraalkylammonium and bromine ions. They did not determine the K_c values, but did suggest such a intermolecular interaction was caused by an "iceberg structure" around the alkyl groups of the tetraalkylammonium ion. These reports indicate that alkylammonium ions have relatively stronger interactions with inorganic anions than alkali metal ions.

However, the K_c value for DBP·TMA is considerably lower than that for ion association between TMA^+ ion and the hexacyanoferrate ion. The origin of the intermolecular interaction may not always be similar for different species. Therefore, ^{13}C NMR chemical shift measurements were performed in order to investigate the interaction mechanism. The results were compared with those of ^{31}P NMR in order to clarify the effects of the location of measured nuclei.

The ^{13}C NMR chemical shift change is shown in Fig. 4 for each carbon in the butyl group of DBP in TMAH solution. The carbons C_1 and C_2, located on the outer surface of the DBP molecule, show little change. On the other hand, C_3 and C_4, located near the phosphorus atom of DBP, show a relatively larger chemical shift change. However, the chemical shift of C_3 changes in the opposite direction from that of C_4. Alkyl chains are easily distorted by intermolecular interactions and the relative location of each carbon changes in comparison with the non-interacting state. Therefore, secondary intermolecular interaction effects for the chemical shift will appear on alkyl carbons, adding to the effect expressed by eq. [2]. As C_4 is fixed

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

by the C—O bond and cannot change its location, the chemical shift change of C_4 corresponds to that of ^{31}P. A large secondary effect caused by the alkyl chain distortion is observed on C_3. These results suggest that P—O^- or P=O of the DBP^- ion is the main contributor to the intermolecular interaction. Large chemical shift changes of C_3 and C_4 are considered to be caused by the change in electron state of the oxygen that is bonded to phosphorus. As the ^{31}P chemical shift value of HDBP in alkaline solution estimated from eq. [7] is -112.51 ± 0.06 ppm and resembles that of DBP·TMA, the electronic states of phosphorus in these two species are considered to be similar. The kind of intermolecular interaction seems to be ion association through the P—O^-. As the K_c value is small and the intermolecular interaction is very weak, it is considered difficult to detect such an interaction using methods other than NMR. Although such a detection is possible by ^{13}C NMR as well as ^{31}P NMR, the secondary effect caused by the alkyl chain distortion makes quantitative evaluation using the ^{13}C NMR chemical shift difficult. It is important to select nuclei that cannot have such a molecular structure distortion when quantitative evaluation of intermolecular interaction using eq. [2] is required.

Conclusion

Intermolecular interactions of DBP were investigated for DBP in polar solvents using the ^{31}P NMR chemical shift. The adoption of chemical shift differences, $\delta_{DBP} - \delta_{TBP}$, could eliminate the effects on P=O, and allowed detection of the intermolecular interaction on P—OH separately. Acid dissociation constants in several polar solvents were determined using $\delta_{DBP} - \delta_{TBP}$. The K_a determined in pure water is in good agreement with that obtained by a conventional method. The intermolecular interaction of DBP in alkaline solution was also investigated. No intermolecular interactions with Na^+ and K^+ ions were detected by ^{31}P NMR chemical shift data. However, intermolecular interaction, possibly as an ion association between TMA^+ ion and DBP^- ion, was detected and the complex formation constant was determined as $K_c = 0.49 \pm 0.02\ M^{-1}$. The NMR chemical shift should be a powerful method of evaluating intermolecular interactions if careful attention is paid to the origin of the chemical shift.

Polar trifluoromethylation reactions: the formation of bis(trifluoromethyl)iodine(III) compounds and trifluoromethyl iodine(III) cations and anions[1]

WIELAND TYRRA AND DIETER NAUMANN[2]

Institut für Anorganische Chemie, Universität zu Köln, Greinstr. 6, D-5000 Köln 41, Federal Republic of Germany

Received May 23, 1990

WIELAND TYRRA and DIETER NAUMANN. Can. J. Chem. **69**, 327 (1991).

IX_3 (X = Cl, $OCOCF_3$, ONO_2) reacts with $Cd(CF_3)_2$ complexes or $Bi(CF_3)_3$ to yield the corresponding CF_3IX_2 derivatives. ^{19}F nuclear magnetic resonance spectroscopic evidence is found for $[I(CF_3)_2]^+$ and $I(CF_3)_2X$ (X = Cl, $OCOCF_3$) in the reactions of CF_3IX_2 with $Cd(CF_3)_2$ complexes. During the reaction of CF_3IF_2 and $Hg(CF_3)_2$ the new species $I(CF_3)_2F$ and *cis*-$[I(CF_3)_2F_2]^-$ are identified by nuclear magnetic resonance spectroscopy. The reactions proceed under polar conditions and can be accelerated by the addition of a Lewis acid such as BF_3, $B(OCOCF_3)_3$, or Sb(V) compounds. Difluoromethyl compounds are formed as by-products.

Key words: polar trifluoromethylations, trifluoromethyl iodine(III) compounds, difluoromethyl group formation.

Le IX_3 (X = Cl, $OCOCF_3$, ONO_2) réagit avec les complexes du $Cd(CF_3)_2$ ou avec le $Bi(CF_3)_3$ pour conduire aux dérivés CF_3IX_2 correspondants. Utilisant la résonance magnétique nucléaire du ^{19}F, on a mis en évidence la présence de $[I(CF_3)_2]^+$ et de $I(CF_3)_2X$ (X = Cl, $OCOCF_3$) lors des réactions du CF_3IX_2 avec les complexes du $Cd(CF_3)_2$. Dans les réactions du CF_3IF_2 et du $Hg(CF_3)_2$, on a identifié les nouvelles espèces $I(CF_3)_2F$ et *cis*-$[I(CF_3)_2F_2]^-$ par spectroscopie de résonance magnétique nucléaire. Les réactions se produisent dans des conditions polaires et on peut les accélérer par l'addition d'un acide de Lewis, comme les composés BF_3, $B(OCOCF_3)$ ou Sb(V). Les composés difluorométhylés se forment comme produits secondaires.

Introduction

While organoiodine(III) and non-fluorinated diorganoiodonium compounds are well-characterized versatile synthetic reagents, especially in organic reactions, only a few examples of fluorinated diorganoiodine(III) compounds with perfluoroalkyl groups are known in the literature. The mixed arylperfluoroalkyliodonium salts $[C_6H_5IR_f]^+[BF_4]^-$ (2) and $[C_6H_4(CH_3)IR_f]^+Cl^-$ (3) (R_f = C_3F_7, C_6F_{13}) have been described by Yagupolskii and co-workers and $[C_6H_5I(CF_2)_nF]^+X^-$ (n = 2, 3, 6, 7, 8, 10; X = $OCOCF_3$, OSO_2CF_3) by Umemoto *et al.* (4). Frohn *et al.* (5) have reported on the existence of the $[I(C_6F_5)_2]^+$ cation.[3] We have also prepared this cation from the reactions of C_6F_5I with $[XeC_6F_5]^+$ and of $C_6F_5IF_2$ with $B(C_6F_5)_3$, respectively (6). Christe and co-workers (7, 8) characterized the compounds i-$C_3F_7I(OSO_2F)_2$ and $R_fI(OClO_3)_2$ (R_f = i-C_3F_7, C_7F_{15}). Based on Raman spectra, they postulated the ionic structures $[I(R_f)_2]^+[IX_4]^-$ and were first to point out the existence of bis(perfluoroalkyl)iodonium salts. These authors also postulated for $CF_3I(ONO_2)_2$ the ionic structure $[I(CF_3)_2]^+$-$[I(ONO_2)_4]^-$, based on the observed decomposition reaction (9).

During our investigations of polar trifluoromethyl transfer reactions, the preparation of bis- and tris(trifluoromethyl)iodine(III) compounds was studied. In this paper we wish to report spectroscopic evidence for the successful preparation of these compounds.

Experimental

Materials

All commercially available compounds were purified by common methods. The following compounds were prepared according to literature procedures: $Cd(CF_3)_2 \cdot 2D$ (D = CH_3CN or diglyme) (10); $I(OCOCF_3)_3$ (11); $I(ONO_2)_3$ (12); $Bi(CF_3)_3$ (13); CF_3IF_2 (14); $CF_3I(OCOCF_3)_2$ (15); CF_3ICl_2 (16); $Zn(CF_3)Br$ (17); $Hg(CF_3)_2$ (18).

Nuclear magnetic resonance spectra were recorded with the Bruker FT NMR spectrometer AM 300; ^{19}F nmr 282.4 MHz (CCl_3F, ext.); ^{113}Cd 66.5 MHz (50 vol% $(CH_3)_2Cd$ in $CDCl_3$, ext.); negative values indicate high field shifts. The ^{19}F nmr chemical shifts and coupling constants for some of the new iodine derivatives are summarized in Table 1.

General procedure

All reactions were carried out in a dry nitrogen atmosphere. Carefully dried 25 mL glass Schlenk tubes were used as reaction vessels. Yields were determined by ^{19}F nmr spectroscopy.

Method A

The iodine component was dissolved or suspended in the appropriate solvent. The non-dissolved trifluoromethyl metal compound was added.

Method B

The solid iodine compound was added to a solution of the trifluoromethyl metal derivative in the appropriate solvent.

Method C

The iodine derivative and the trifluoromethyl metal compound were dissolved or suspended in the appropriate solvent. The solutions were combined.

Method D

The iodine derivative was dissolved or suspended in the appropriate solvent. The Lewis acid was added. Colour effects were observed after adding BF_3 or SbF_5. Solid bis(trifluoromethyl)cadmium complexes were added after approximately 12 h.

The reactions are summarized in Tables 2–4; the products are listed in order of decreasing yields (intensities of the nmr signals). Main products are printed in bold letters.

Results and discussion

Reactions of iodine(III) compounds with trifluoromethyl cadmium compounds and tris(trifluoromethyl)bismuth in pyridine and acetonitrile

Bis(trifluoromethyl)cadmium complexes are excellent reagents for the syntheses of many new or otherwise not readily available trifluoromethyl element compounds (13).

These reactions proceed via an ionic mechanism. A solvent stabilized cation reacts with the cadmium complex to form the

[d]$^4J(^{19}F-^{19}F) \approx 4$ Hz.

new trifluoromethyl species and a cadmium cation (eq. [1]).

[1*a*] $$EX_n \rightleftharpoons [EX_{n-1} \cdot D]^+ + X^-$$

[1*b*] $$[EX_{n-1} \cdot D]^+ + Cd(CF_3)_2 \cdot D' \longrightarrow CF_3EX_{n-1} \cdot D + [Cd(CF_3) \cdot D']^+$$

E: e.g., Sb, Bi; X: Cl, Br; D: e.g., Et_2O, MeCN;
D': 2 MeCN, glyme, diglyme

The dissociation shown in eq. [1*a*] is established by conductivity measurements. Iodine trichloride shows a molar conductivity of 76 Ω^{-1} cm^2 mol^{-1} (22) in acetonitrile solution, which can be attributed to an equilibrium according to eq. [2].

[2] $$2ICl_3 \rightleftharpoons ICl_2^+ + ICl_4^-$$

This amphoteric behaviour explains the existence of many salts containing ICl_2^+ and ICl_4^- units (23–26). Therefore we reacted ICl_3, $I(OCOCF_3)_3$, and $I(ONO_2)_3$ with bis(trifluoromethyl)cadmium complexes or tris(trifluoromethyl)bismuth at low temperature in various aprotic solvents.

In all cases we obtained the monotrifluoromethyl iodine derivatives; no evidence for a further substitution could be found.

[3] $$IX_3 + Cd(CF_3)_2 \cdot D \longrightarrow CF_3IX_2 + Cd(CF_3)X \cdot D$$
$$IX_3 + Cd(CF_3)X \cdot D \longrightarrow CF_3IX_2 + CdX_2 \cdot D$$
$$IX_3 + Bi(CF_3)_3 \longrightarrow CF_3IX_2 + Bi(CF_3)_2X$$
$$IX_3 + Bi(CF_3)_2X \longrightarrow CF_3IX_2 + Bi(CF_3)X_2$$
$$IX_3 + Bi(CF_3)X_2 \longrightarrow CF_3IX_2 + BiX_3$$
$$X = Cl, OCOCF_3, ONO_2$$

This behaviour is similar to that observed during reactions with tellurium tetrachloride (27). The reactions of $Cd(CF_3)$ complexes with $TeCl_4$ yielded only the bis(trifluoromethyl)tellurium species. No evidence was found for tris- or tetrakis(trifluoromethyl)tellurium compounds. However, $Te(CF_3)_4$ is formed when $Te(CF_3)_2Cl_2$ is reacted with the cadmium complex in a second separate reaction (28).

[4] $$Te(CF_3)_2Cl_2 + Cd(CF_3)_2 \cdot D \rightarrow Te(CF_3)_4 + CdCl_2 \cdot D$$

In analogy to these results, we studied the reactions of CF_3IX_2 (X: F, Cl, $OCOCF_3$) with $Cd(CF_3)_2$ complexes in acetonitrile and pyridine solutions. The results of reactions in the less polar solvents $CHCl_3$ and CH_2Cl_2 are described later.

When CF_3IF_2 is reacted with $Cd(CF_3)_2 \cdot D$ in pyridine or acetonitrile solution, ^{19}F nmr spectroscopic evidence is found for more highly trifluoromethyl-substituted iodine derivatives, but an assignment of the resonances could not be made. A number of by-products were identified: 2-, 3-, and 4-trifluoromethyl pyridine were formed during these reactions in addition to traces of 2,6-bis(trifluoromethyl)pyridine. The pyridine derivatives can be identified by their ^{19}F nmr spectra compared with data published earlier (19). Similar results were obtained when the reaction was carried out under modified conditions in CH_3CN solution. When CF_3ICl_2 in CH_3CN/CH_2Cl_2 mixtures is used as a starting material instead of CF_3IF_2, ^{19}F nmr spectroscopic evidence is found for $[I(CF_3)_2]^+$ and $I(CF_3)_2Cl$ as well as CF_3IF_2; the presence of CF_3IF_2 is indirect evidence for $I(CF_3)_3$. The large number of CF_2 products and the formation of CF_3IF_2, together with the absence of higher trifluoromethylated intermediates such as the sufficiently stable $I(CF_3)_2F$, allow the conclusion that $I(CF_3)_3$ must have been formed as an intermediate.

Thus, tris(trifluoromethyl)iodine can decompose via two possible pathways, either by the elimination of hexafluoroethane to yield CF_3I or by an elimination of two difluorocarbene units to form CF_3IF_2.

$I(CF_3)_2Cl$ can undergo a reductive elimination of CF_3Cl.

[5] $$CF_3ICl_2 + Cd(CF_3)_2 \cdot D \longrightarrow "I(CF_3)_3" + "I(CF_3)_2Cl"$$

[6] $$"I(CF_3)_2Cl" \longrightarrow CF_3I + CClF_3$$

[7] $$"I(CF_3)_3" \longrightarrow CF_3I + CF_3CF_3$$

[8] $$"I(CF_3)_3" \longrightarrow CF_3IF_2 + 2\,CF_2$$

One of the by-products formed during these reactions was

$CHClF_2$. This compound can be explained by an insertion of CF_2 into HCl, which has been formed by solvolysis of the starting material CF_3ICl_2. Insertion reactions into trifluoroacetic acid or trifluoromethylsulfonic acid are known (29) and will be discussed later.

Whether a reaction occurs or not, depends on the basicity of the solvent. The stronger the basicity of the solvent, the more the reactivity decreases. In solvents such as pyridine or DMF, the starting material CF_3ICl_2 forms adducts as also does $Cd(CF_3)_2$, and both reaction partners lose reactivity. The highest reactivity has been found in CH_3CN solution.

Similar results could be obtained using $CF_3I(OCOCF_3)_2$ instead of the dichloride. We also found spectroscopic evidence for $I(CF_3)_2OCOCF_3$ and CF_3IF_2. The by-products from difluorocarbene reactions could also be identified by their nmr spectra.

Although $Cd(CF_3)_2 \cdot D$ is an excellent precursor for CF_2 generation (30, 31) at ambient temperature or above, we never found evidence for CF_2 generated from the Cd complexes under these mild conditions. Identified products are trifluoroacetic acid difluoromethyl ester, $CF_3CO_2CF_2H$, and (difluoro(trifluoroacetato)methyl)trifluoromethyl cadmium, $CF_3CO_2CF_2CdCF_3$. These compounds could easily be identified by ^{19}F nmr and the latter also by ^{113}Cd nmr spectra. A detailed description of these nmr spectra is given later.

These results show that it is very difficult to obtain bis- or tris(trifluoromethyl)iodine(III) derivatives. The complexity of these systems can be confirmed by reactions of CF_3IF_2 with mercury, cadmium, and zinc compounds in less coordinating solvents.

Reactions of trifluoromethyliodine difluoride with trifluoromethyl zinc, cadmium, and mercury compounds in chloroform and dichloromethane

Trifluoromethyliodine difluoride forms 1:1 adducts with acetonitrile, pyridine, and quinoline (32) as well as with CsF.[4] In polar solvents such as DMF, CH_3CN, or pyridine the trifluoromethyliodine derivatives CF_3IX_2 (X = Cl, $OCOCF_3$) also form stable adducts with the solvent. This behaviour proves that a fourfold coordination of iodine is preferred. Because some anions containing the trifluoromethyl group are very stable (33, 34), we decided to carry out reactions to achieve fourfold coordination of the iodine central atom by an additional CF_3 group. Therefore, the reactions of $ZnBr(CF_3) \cdot 2DMF$, $Cd(CF_3)_2 \cdot$diglyme, and $Hg(CF_3)_2$ with CF_3IF_2 in non-coordinating solvents were investigated. In the following section the ^{19}F nmr spectra of the reactions of CF_3IF_2 and $Hg(CF_3)_2$ are

The splitting of the signals in the ^{19}F nmr spectrum strongly depends on the spatial arrangement of the ligands. The observed multiplicities indicate an A_6X spin system for $I(CF_3)_2F$. Therefore the structure of the molecule may be T-shaped with an axial arrangement of the CF_3 groups or it can be trigonal-planar. An arrangement with one CF_3 group in the axial and one in the equatorial position would cause an $A_3A_3'X$ spin system and can therefore be excluded.

Two conformers are possible for the anionic species $[I(CF_3)_2F_2]^-$. A square-planar arrangement of the four ligands is the most probable structure according to the VSEPR model.

cis conformer

trans conformer

The ^{19}F nmr spectra of this anion favour the *cis* conformer. In the *cis* conformer the F ligands are magnetically nonequivalent due to different couplings to the *cis* and *trans* CF_3 groups. The same arguments apply for the CF_3 groups. Therefore the trifluoromethyl groups split into doublets of doublets resulting from the spin–spin interactions with the *cis* and *trans* fluorine atoms. By analogy, the fluorine signals split into quartets of quartets ($A_3A_3'XX'$ spin system).

Fluorine exchange equilibria in solution could not be observed by ^{19}F nmr spectroscopy because $I(CF_3)_2F$ as well as $[I(CF_3)_2F_2]^-$ decompose in solution at approximately −10°C to give CF_4 and CF_3I.

It should be pointed out that the $CdCF_3$ and $ZnCF_3$ compounds are used as complexes. Therefore, an interaction of the iodine compound with the donor molecules must also be taken into consideration. A decomplexation of the cadmium species, for example, would lead to a naked $Cd(CF_3)_2$. This compound is stable up to 0°C (35). Uncomplexed $Zn(CF_3)_2$ decomposes at approximately −40°C.

[9] $Cd(CF_3)_2 \cdot \text{diglyme} + CF_3IF_2 \rightleftharpoons Cd(CF_3)_2 + CF_3IF_2 \cdot \text{diglyme}$

[10] $Cd(CF_3)_2 \longrightarrow$ dec.

Because Cd and Zn compounds are stronger Lewis-base acceptors than iodine(III) derivatives, the equilibrium [9] should strongly be shifted to the left side.

Polar trifluoromethylation reactions in the presence of a Lewis acid

We have previously shown that trifluoromethyliodine(III) derivatives are extremely stable in a pseudo-octahedral environment (16, 32). It is also known that diorgano iodonium cations (36) and dihalo iodonium cations (23–25) are stable species. Due to the VSEPR model we assume maxima in stability for disubstituted iodine cations with two identical ligands, because neither Yagupol'skii (2, 3) nor Umemoto (4) were able to prepare aryl-trifluoromethyl iodonium salts.

It is known that $Cd(CF_3)_2 \cdot D$ reacts with boron trifluoride or tantalum pentafluoride to form the cation $Cd(CF_3)^+$ (33). Therefore we can suggest that, if BF_3 is used, the anion $[B(CF_3)F_3]^-$ might be formed as an intermediate. This anion could interact with CF_3IF_2 to form $[I(CF_3)_2]^+$ and $[BF_4]^-$ as well as CdF_2.

[11] $Cd(CF_3)_2 \cdot D + BF_3 \longrightarrow [Cd(CF_3)]^+ + [B(CF_3)F_3]^-$

[12] $CF_3IF_2 + [B(CF_3)F_3]^- \longrightarrow [I(CF_3)_2]^+ + [BF_4]^- + F^-$

[13] $[Cd(CF_3) \cdot D]^+ + F^- \rightleftharpoons Cd(CF_3)F \cdot D$

Another reaction is possible as well. The short-lived species $[CF_3IF]^+[BF_4]^-$ may react directly with the cadmium complex to form $[I(CF_3)_2]^+[BF_4]^-$ and $Cd(CF_3)F \cdot D$. Unfortunately, these attempts failed. The Lewis acidity of BF_3 is obviously too high to form either $[CF_3IF]^+$ or $[B(CF_3)F_3]^-$ under the conditions applied. Both intermediates rapidly decompose to give CF_4, CF_3I, $[BF_4]^-$, and CF_2, which can be identified from its subsequent reactions. The low temperature at which we had to work may not have supplied the activation energy necessary for a trifluoromethyl transfer by the cadmium complex. Similar results were obtained using the Lewis acid SbF_5. Therefore, we studied the reactions of CF_3IF_2 and $CF_3I(OCOCF_3)_2$ with $Cd(CF_3)_2 \cdot D$ in the presence of $B(OCOCF_3)_3$, in order to make use of the increased stability of a $[CF_3I(OCOCF_3)]^+$ cation.

[14] $CF_3IF_2 + B(OCOCF_3)_3 \longrightarrow [CF_3I(OCOCF_3)]^+[BF_{4-x}(OCOCF_3)_x]^-$

[15] $[CF_3I(OCOCF_3)]^+ + Cd(CF_3)_2 \cdot D \longrightarrow [I(CF_3)_2]^+ + Cd(CF_3)(OCOCF_3) \cdot D$

We found ^{19}F nmr spectroscopic evidence for the bis(trifluoromethyl)iodine cation in the reaction mixture if sulphur dioxide or dichloromethane were used as solvents. No evidence was found for $[I(CF_3)_2]^+$ in CH_3CN or SO_2ClF. Although we could not isolate $[I(CF_3)_2]^+[BF_4]^-$ from the reaction mixtures, we could easily identify the cation by its ^{19}F nmr resonance. The ^{13}C satellites of $[I(^{12}CF_3)(^{13}CF_3)]^+$ form an $A_3A_3'X$ spin system in the ^{19}F nmr spectrum; they are split into quartets proving that two CF_3 groups are bound to iodine. The nmr data obtained are comparable to those of the isoelectronic bis(trifluoromethyl)tellurium (37).

During these reactions a great number of by-products were formed. Most of them could easily be identified by their nmr spectra.

Description and identification of the by-products formed during the reactions of $CF_3I(OCOCF_3)_2$ with $Cd(CF_3)_2 \cdot 2CH_3CN$

Many by-products were formed during the reactions of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

$CF_3I(OCOCF_3)_2$ and $Cd(CF_3)_2 \cdot 2CH_3CN$ in CH_3CN or SO_2 solution, as mentioned above.

The by-products that could be identified from the reaction in acetonitrile solution were CF_3IF_2, CF_3COOCF_2H, $Cd(CF_3)(CF_2OCOCF_3)$, and $Cd(CF_2OCOCF_3)_2$. Evidence was found for further compounds containing CF_2H groups but a conclusive assignment of the ^{19}F nmr resonances was impossible.

Because "$I(CF_3)_3$" and $Cd(CF_3)_2$ complexes undergo difluorocarbene eliminations under distinct conditions we propose a carbene or carbenoid mechanism.

Trifluoroacetic acid difluoromethyl ester shows two signals in the ^{19}F nmr spectrum: a singlet at δ −75.11 ppm, which can be assigned to the CF_3 group, and a doublet at δ −91.88 ppm, $^2J(^{19}F-^1H) = 68.7$ Hz, $^1J(^{19}F-^{13}C) = 252.3$ Hz, $^1\Delta = 0.1531$ ppm, which can be assigned to the CF_2H group (29).

$Cd(CF_3)(CF_2OCOCF_3)$ can be identified by its ^{19}F nmr and ^{113}Cd nmr spectra. The compound shows three different ^{19}F resonances. The CF_3 group is detected as a singlet at δ −36.58 ppm, $^2J(^{111/113}Cd-^{19}F) = 459.9/480.7$ Hz. The CF_2 group, directly bound to the cadmium atom, gives a resonance at δ −57.42 ppm, $^2J(^{111/113}Cd-^{19}F) = 318.3/332.7$ Hz, and the $OCOCF_3$ group is observed at δ −75.80 ppm. A spin–spin interaction between the CF_3 group and the CF_2 group bound to cadmium could not be observed. The existence of this structural element is proven by its ^{113}Cd nmr resonance. This signal is split into a quartet of triplets caused by the spin–spin interaction of the ^{113}Cd nucleus with three equivalent fluorine atoms of the CF_3 group and two of the CF_2 group. The coupling constants $^2J(^{113}Cd-^{19}F)$ have the absolute values of 483 Hz and 332 Hz, respectively, and are identical to those obtained from the ^{19}F nmr spectra within experimental error.

The chemical shift δ (^{113}Cd) −492 ppm is nearly identical to that of the bis(trifluoromethyl)cadmium complex (33), indicating similar electronic effects for these compounds.

These studies on trifluoromethyl iodine(III) derivatives clearly show the complexity of the system. We have been able to show that it is possible to generate bis(trifluoromethyl)iodine derivatives as neutral, cationic, and anionic species by varying the conditions, and to identify the new derivatives by their ^{19}F nmr spectra.

Further work is being done to isolate these compounds and to obtain more information about the mechanism that leads to by-products containing the CF_2H group.

Nucleic acid related compounds. 63. Synthesis of 5′-deoxy-5′-methyleneadenosine and related Wittig-extended nucleosides[1]

STANISLAW F. WNUK AND MORRIS J. ROBINS[2]

Departments of Chemistry, Brigham Young University, Provo, UT 84602, U.S.A., Academy of Agriculture, 60625 Poznań, Wojska Polskiego 75, Poland, and University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received August 1, 1990

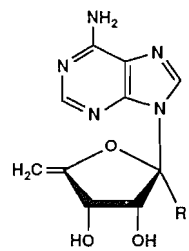
STANISLAW F. WNUK and MORRIS J. ROBINS. Can. J. Chem. **69**, 334 (1991).

Treatment of the purified 5′-aldehyde (**2***a*) (derived from 6-*N*-benzoyl-2′,3′-*O*-isopropylideneadenosine (**1***a*)) with methylenetriphenylphosphorane and successive deprotection with ammonia and acid gave 9-(5,6-dideoxy-β-D-*ribo*-hex-5-enofuranosyl)adenine (5′-deoxy-5′-methyleneadenosine) (**4**). Oxidation of **1***a* or 2′,3′-*O*-isopropylideneadenosine (**1***b*) and treatment of the crude 5′-aldehydes (**2***a* or **2***b*) with (*p*-toluenesulfonylmethylene)triphenylphosphorane gave high yields of the 5′-deoxy-5′-tosylmethylene derivatives (**5***a* or **5***b*). Removal of the tosyl group from **5***b* to give **3***b* was effected with tributylstannyllithium, but sulfone cleavage by the usual reductive methods failed. Reduction and deprotection of **5***a* or **5***b* gave 9-[5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-*ribo*-hexofuranosyl]adenine (**6***b*). Isomerization of the vinyl tosyl (**5***b*) to a 4′,5′-unsaturated allylic tosyl derivative (**7**) occurred under cleavage conditions and in solutions of aqueous or organic bases.

Key words: adenosine, 5′-deoxyadenosine, 5′-methylene-5′-deoxyadenosine, nucleosides.

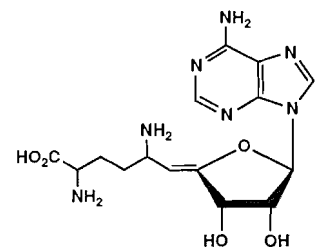
STANISLAW F. WNUK et MORRIS J. ROBINS. Can. J. Chem. **69**, 334 (1991).

La réaction du 5′-aldéhyde purifié (**2***a*) (obtenu à partir de la 6-*N*-benzoyl-2′,3′-*O*-isopropylidèneadénosine (**1***a*)) avec le méthylènetriphénylphosphorane, suivie d'une déprotection à l'aide d'ammoniac et d'acide, conduit à la 9-(5,6-didésoxy-β-D-*ribo*-hex-5-énofuranosyl)adénine (5′-désoxy-5′-méthylèneadénosine) (**4**). L'oxydation de **1***a* ou de la 2′,3′-*O*-isopropylidèneadénosine (**1***b*)), suivie d'une réaction des 5′-aldéhydes bruts (**2***a* ou **2***b*) avec le (*p*-toluènesulfonylméthylène)triphénylphosphorane fournit les dérivés 5′-désoxy-5′-tosylméthylènes (**5***a* ou **5***b*) avec d'excellents rendements. On a effectué l'enlèvement des groupements tosyles du produit **5***b* à l'aide de tributylstannyllithium et on a obtenu le produit **3***b*; toutefois le clivage de la sulfone par les méthodes réductrices habituelles s'est avéré inefficace. La réduction et la déprotection des produits **5***a* ou **5***b* a fourni la 9-[5,6-didésoxy-6-(*p*-toluènesulfonyl)-β-D-*ribo*-hexofuranosyl]adénine (**6***b*). L'isomérisation du dérivé vinyl tosyl (**5***b*) en un dérivé tosylé allylique 4′,5′-insaturé (**7**) se produit dans les conditions de clivage ainsi qu'en solutions aqueuses ou organiques de bases.



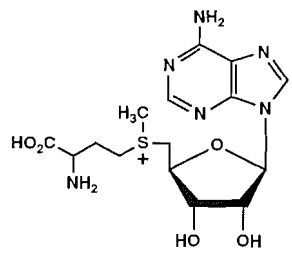
Mots clés : adénosine, 5′-désoxyadénosine, 5′-méthylène-5′-désoxyadénosine, nucléosides.

[Traduit par la rédaction]



Introduction

Examples of naturally occurring 4′,5′-unsaturated nucleosides include the antibiotics angustmycin A (decoyinine) (**A**) (1–3) and A9145C (**C**), a 4′,5′-didehydrosinefungin derivative (4). Synthetic 5′-deoxy-4′,5′-didehydroadenosine (**B**) (3) was found to be accepted by *S*-adenosylhomocysteine hydrolase as an alternative substrate (5). Sinefungin and antibiotic A9145C (**C**) are inhibitors of methyl transferase enzymes, and this inhibition can be reversed by the addition of *S*-adenosylmethionine (**D**) (4). We are developing inhibitors of enzymes utilized in pathways involving *S*-adenosylmethionine metabolism and wanted to examine nucleoside analogues with unsaturated groups at C5′.



Chain extensions and other carbon–carbon bond-forming reactions at C5′ of nucleosides have generally involved oxidation to 5′-aldehyde derivatives and treatment with Wittig-type reagents, or conversions with 5′-deoxy-5′-halonucleosides (6). Wittig-type reactions of nucleoside 5′-aldehydes with electronegatively substituted ylides have provided several 6′-substituted-5′,6′-unsaturated hexofuranosyl nucleosides (7–11). However, direct introductions of alkylidene groups (particularly the methylene group) at C5′ have met with limited success, presumably owing to the instability of the 5′-aldehyde (or intermediates/products) under the experimental conditions (8, 10). Ueda and co-workers reported successful Wittig reactions of 3′,5′-*O*-(1,1,3,3-tetraisopropyldisiloxan-1,3-diyl)-2′-keto adenosine (12) and uridine (13) derivatives with methylene-

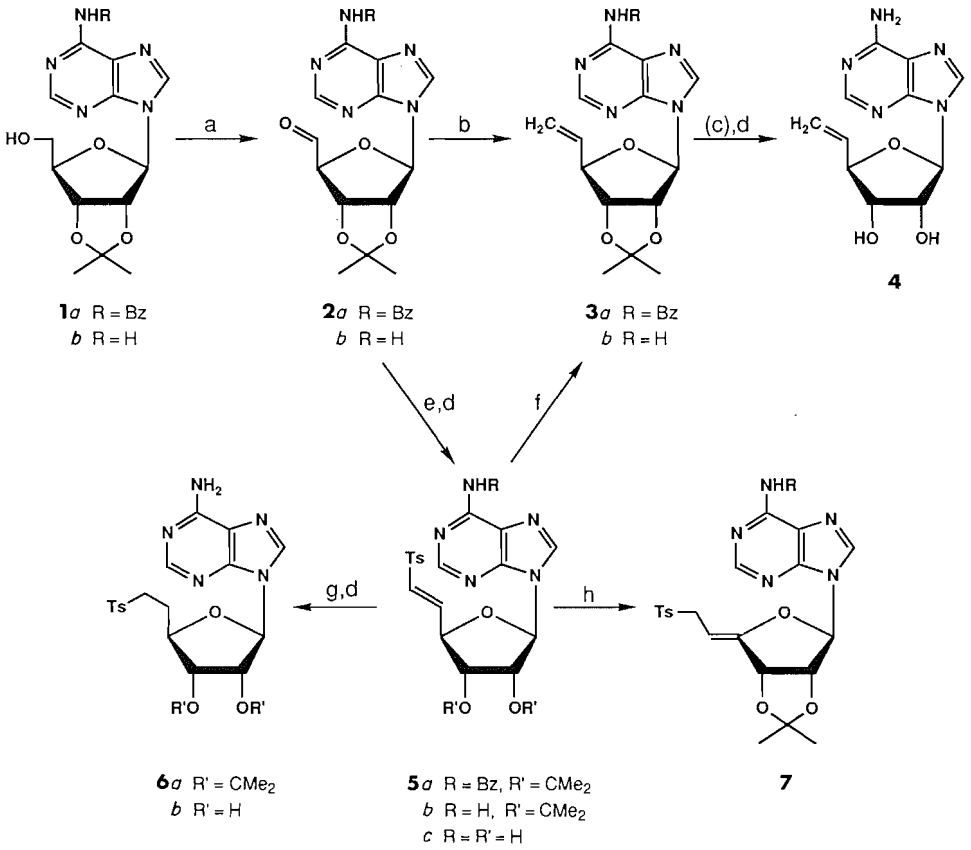
D



triphenylphosphorane to give 2′-deoxy-2′-methylene nucleosides. We also have developed efficient procedures for syntheses of purine and pyrimidine 2′-deoxy-2′-methylene and 3′-deoxy-3′-methylene nucleoside analogues with direct Wittig reactions (14). Seebach's silyl nitronate (nitro-aldol) methodology has been used in an efficient variation of the Henry reaction for chain extension of aldehydo sugars including a uridine 5′-aldehyde derivative (15). Barton *et al.* have developed a radical-mediated strategy that has been applied to the synthesis

of chain-lengthened nucleoside phosphonates and vinyl sulfonates (16).

A multistep synthesis of 5′-deoxy-5′-methyleneadenosine (9-(5,6-dideoxy-β-D-*ribo*-hex-5-enofuranosyl)adenine) (**4**) (Scheme 1) by conversion of D-allose to methyl 2,3-di-*O*-benzoyl-5,6-dideoxy-β-D-*ribo*-hex-5-enofuranoside, activation, coupling with the chloromercury salt of 6-benzamidopurine, and deprotection was reported in 1978 (17). We now describe two Wittig-based syntheses of **4** from adenosine, and transformations of related vinyl sulfone intermediates.

Results and discussion

Adenosine was protected, oxidized, and purified as described (18) to give the 6-*N*-benzoyl-2′,3′-*O*-isopropylidene-5′-aldehyde derivative (**2***a*). Treatment of **2***a* with methylenetriphenylphosphorane (generated (14, 19) from methyltriphenylphosphonium bromide and sodium 2-methyl-2-butoxide in benzene/ether) in tetrahydrofuran at −20°C resulted in formation of 6-*N*-benzoyl-9-(5,6-dideoxy-2,3-*O*-isopropylidene-β-D-*ribo*-hex-5-enofuranosyl)adenine (**3***a*) in 58% yield. The ^{1}H nmr spectrum of **3***a* had characteristic peaks for H6′ and H6″ at δ 5.17 and 5.27 as doublets of triplets with $J_{6'-6''} = J_{6'/6''-4'} =$ 1.3 Hz, $J_{6'-5'} = 10.4$ Hz (*cis*), and $J_{6''-5'} = 17.2$ Hz (*trans*). Removal of the benzoyl group from **3***a* with methanolic ammonia, treatment of the resulting **3***b* with aqueous trifluoroacetic acid, and purification on a column of Dowex 1 × 2 (OH^-) resin gave **4** in 36% overall yield from **2***a*.

Our second approach utilized the Wittig reaction of **2***a* with a stabilized ylid, (*p*-toluenesulfonylmethylene)triphenylphosphorane (20, 21), to give the vinyl sulfone product (**5***a*) in 85% yield. The large vinyl coupling constant ($^3J_{6'-5'} = 15$ Hz) indicated an *E* configuration for **5***a*. Treatment of crude **2***a* (from Moffatt oxidation (7, 22) of 6-*N*-benzoyl-2′,3′-*O*-isopropylideneadenosine (**1***a*)) with (*p*-toluenesulfonylmethylene)triphenylphosphorane gave the same high yield (86%) of **5***a*. Analogous oxidation of 2′,3′-*O*-isopropylideneadenosine (**1***b*) and treatment of crude **2***b* with the stabilized Wittig reagent gave **5***b* in 63% yield. It was hoped that removal of the sulfone group from **5***a* or **5***b* could be readily effected to provide a more efficient route to 5′-deoxy-5′-methyleneadenosine (**4**).

Methods for the reductive cleavage of carbon–sulfur bonds in saturated (23, 24) and α,β-unsaturated (25–27) sulfones have been reported. Unfortunately, our attempted application of these procedures to remove the *p*-toluenesulfonyl group from **5***a* or **5***b* failed to give significant quantities of **3***a* or **3***b*. The Corey sulfone cleavage (23) with sodium (24) or aluminum (25) amalgam, and the sodium dithionite procedure of Julia (26, 27) resulted primarily in rearrangement of the vinyl to allylic sulfones and recovery of starting material. Formation of more complex mixtures was observed under more vigorous conditions. Isomerization of the vinyl sulfone **5***b* to a single allylic sulfone (**7**, tentatively assigned the *Z* configuration with a less-hindered exocyclic 4′–5′ double bond) occurred under basic conditions. Formation of the allyl sulfone **7** was conveniently monitored by ultraviolet absorption spectroscopy. A major bathochromic shift and hypochromic effect were observed as the conjugated vinyl sulfone **5***b* (λ_{max} 236 nm (ε 23 500)) was converted into the allylic sulfone **7** (λ_{max} 258 nm

(ε 15 200)) in solutions of aqueous sodium hydroxide or 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in acetonitrile or THF.

Desulfonylation of **5***b* was effected (61% yield) via conjugate addition of tributylstannyllithium (28). However, ^{1}H nmr spectra of the crude product showed contamination by the allylic sulfone **7** (5–10%). Treatment of this mixture with aqueous trifluoroacetic acid and purification on a column of Dowex 1 × 2 (OH^-) resin gave pure **4** (39%). The contaminating allylic sulfone **7**, with 4′–5′ unsaturation, suffers acid-catalyzed decomposition as expected (3) from its exocyclic vinyl ether skeleton.

Treatment of **5***b* with sodium borohydride in aqueous methanol resulted in conjugate reduction of the vinyl sulfone to give **6***a* (~75% yield). Deprotection of **6***a* with aqueous trifluoroacetic acid gave 9-[5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-*ribo*-hexofuranosyl]adenine (**6***b*, 83%). Parallel treatment of the 6-*N*-benzoyl derivative (**5***a*) gave an equivalent yield of **6***b*. Deprotection of **5***b* proceeded without incident in aqueous trifluoroacetic acid to give 9-[5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-*ribo*-hex-5(*E*)-enofuranosyl]adenine (**5***c*, 89%).

Thus, direct Wittig treatment of the protected adenosine 5′-aldehyde (**2***a*) with methylenetriphenylphosphorane provided the most efficient sequence to 5′-deoxy-5′-methyleneadenosine (**4**). This route circumvented complications inherent in the multistep preparation of unsaturated sugar derivatives and coupling with a nucleobase (17). A sulfonyl-stabilized Wittig reagent gave high yields of protected vinyl sulfone intermediates, but removal of the *p*-toluenesulfonyl group proved to be difficult.

Experimental

Uncorrected melting points were determined on a microstage block. The uv spectra were recorded on a Beckman Acta M IV spectrophotometer. The ^{1}H nmr spectra were recorded on Bruker WH-200 or Varian Gemini-200 spectrometers. Mass spectra (ms) were obtained with AEI MS-12 or Jeol JMS-D-100 instruments. Elemental analyses were determined by the microanalytical laboratories of the University of Alberta or Adam Mickiewicz University, Poznań. Reagents and solvents were of commercial reagent quality. Diethyl ether and tetrahydrofuran (THF) were dried by distillation from sodium benzophenone ketyl. Acetonitrile was dried by distillation from P_4O_{10}. (*p*-Toluenesulfonylmethylene)triphenylphosphorane (73% (crystallized from CH_2Cl_2/hexane), mp 182–183°C (lit. (20) mp 186–187°C; (21) mp 182–184°C) was prepared (20) from bromomethyl *p*-tolyl sulfone (21) and triphenylphosphine. Tributylstannyllithium was prepared by treatment of tributyltin chloride with excess lithium in anhydrous THF under N_2 at ambient temperature (29). 6-*N*-Benzoyl-2′,3′-*O*-isopropylideneadenosine 5′-aldehyde (**2***a*, 55%, as the dehydrated aldehyde) was prepared from 6-*N*-benzoyl-2′,3′-*O*-isopropylideneadenosine (**1***a*) with isolation of the crystalline 1,3-diphenylimidazolidine intermediate (18). Sodium 2-methyl-2-butoxide was prepared by refluxing *tert*-amyl alcohol with excess sodium beads in benzene under N_2 for 10 days (30).

*6-*N*-Benzoyl-9-(5,6-dideoxy-2,3-*O*-isopropylidene-β-D-*ribo*-hex-5-enofuranosyl)adenine* **3***a*

To a magnetically stirred suspension of methyltriphenylphosphonium bromide (464 mg, 1.3 mmol) in dry Et_2O (75 mL) in a flame-dried flask under N_2 was added a solution of sodium 2-methyl-2-butoxide (1.115 mL of a 1.13 M solution in benzene, 1.26 mmol). The bright yellow solution was stirred for 1.5 h at ambient temperature and cooled to −40°C. Dehydrated **2***a* (18) (258 mg, 0.63 mmol) in anhydrous THF (50 mL) was added by syringe and stirring continued at −20°C for 2 h and overnight at ~0°C. NH_4Cl/H_2O was added, the layers separated, and the aqueous layer extracted with $CHCl_3$. The two organic fractions were washed separately with $NaHCO_3/H_2O$ and $NaCl/H_2O$, dried (Na_2SO_4), and evaporated. The combined residues were purified by silica column chromatography (EtOAc). Evaporation of appropriately pooled fractions gave 149 mg (58%) of **3***a* as a white solid foam: uv (MeOH): max 278, 229 nm (ε 20 100, 14 100), min 246 nm (ε 12 200); ^{1}H nmr ($CDCl_3$) δ: 1.43 and 1.57 (s,s; 3,3; CH_3's), 4.71–4.78 (m, 1, H4′), 5.04 (dd, $J_{3'-2'}$ = 6.2 Hz, $J_{3'-4'}$ = 3.4 Hz, 1, H3′), 5.17 (dt, $J_{6'-4'}$ = 1.3 Hz, $J_{6'-5'}$ = 10.4 Hz (*cis*), $J_{6'-6''}$ = 1.3 Hz, 1, H6′), 5.27 (dt, $J_{6''-4'}$ = 1.3 Hz, $J_{6''-5'}$ = 17.2 Hz (*trans*), 1, H6″), 5.58 (dd, $J_{2'-1'}$ = 2 Hz, 1, H2′), 5.90 (ddd, $J_{5'-4'}$ = 6.9 Hz, 1, H5′), 6.20 (d, 1, H1′), 7.5–7.7 (m, 3, Bz), 8.05–8.16 (m, 2, Bz), 8.12 (s, 1, H2), 8.82 (s, 1, H8), 9.15 (s, 1, NH); ms *m/z*: 407 (34, M^+), 378 (100), 277 (79). Anal. calcd. for $C_{21}H_{21}N_5O_4$ (407.4): C 61.91, H 5.20, N 17.19; found: C 61.82, H 5.32, N 17.28.

*9-(5,6-Dideoxy-β-D-*ribo*-hex-5-enofuranosyl)adenine (5′-deoxy-5′-methyleneadenosine)* **4**

Removal of the benzoyl group

Saturated NH_3/MeOH (15 mL) was added to a solution of **3***a* (203 mg, 0.5 mmol) in MeOH (15 mL) and stirring was continued at ~4°C overnight. Thin-layer chromatography (tlc) ($MeOH/CHCl_3$, 7:93) showed a new polar compound and the absence of **3***a*. Evaporation of the solution gave 198 mg of crude **3***b*, which can be deprotected directly in the next step. For spectroscopic characterization this material was purified by chromatography on silica ($MeOH/CHCl_3$, 1:49) to give 140 mg (92%) of **3***b* as a white solid foam: ^{1}H nmr ($CDCl_3$) δ: 1.40 and 1.65 (s,s; 3,3; CH_3's), 4.64–4.72 (m, 1, H4′), 5.00 (dd, $J_{3'-2'}$ = 6.2 Hz, $J_{3'-4'}$ = 3.2 Hz, 1, H3′), 5.13 (dt, $J_{6'-4'}$ = 1.3 Hz, $J_{6'-5'}$ = 10.4 Hz (*cis*), $J_{6'-6''}$ = 1.2 Hz, 1, H6′), 5.25 (dt, $J_{6''-4'}$ = 1.3 Hz, $J_{6''-5'}$ = 17.2 Hz (*trans*), 1, H6″), 5.50 (dd, $J_{2'-1'}$ = 1.8 Hz, 1, H2′), 5.75 (br s, 2, NH_2), 5.90 (ddd, $J_{5'-4'}$ = 6.2 Hz, 1, H5′), 6.10 (d, 1, H1′), 7.89 (s, 1, H2), 8.35 (s, 1, H8); ms *m/z*: 303 (12, M^+), 277 (100).

Removal of the isopropylidene group

A solution of crude **3***b* (198 mg) in CF_3CO_2H/H_2O (17:3) was stirred for 20 min at ~0°C and evaporated. The residue was dissolved in EtOH, evaporated, dissolved in MeOH (5 mL), and applied to a column of Dowex 1-X2 (OH^-) resin. Elution was effected with $MeOH/H_2O$ (3:7, 500 mL; followed by 1:1, 500 mL). Evaporation of appropriately pooled fractions gave a colorless product that was recrystallized from Et_2O/EtOH to give 87 mg (62% from **3***a*) of **4**: mp 185–187°C (lit. (17) mp 190–191°C); uv (MeOH): max 259 nm (ε 15 300), min 226 nm (ε 2350); ^{1}H nmr (Me_2SO-d_6) δ: 4.10 (ddd, $J_{3'-2'}$ = 5.0 Hz, $J_{3'-4'}$ = 4.6 Hz, $J_{3'-OH3'}$ = 5.6 Hz, 1, H3′), 4.28–4.34 (m, 1, H4′), 4.65 (ddd, $J_{2'-1'}$ = 5.2 Hz, $J_{2'-OH2'}$ = 5.7 Hz, 1, H2′), 5.17 (dt, $J_{6'-4'}$ = 1.5 Hz, $J_{6'-5'}$ = 10.6 Hz (*cis*), $J_{6'-6''}$ = 1.5 Hz, 1, H6′), 5.28 (dt, $J_{6''-4'}$ = 1.5 Hz, $J_{6''-5'}$ = 17.3 Hz (*trans*), 1, H6″), 5.35 (d, 1, OH3′), 5.52 (d, 1, OH2′), 5.90 (d, 1, H1′), 6.07 (ddd, $J_{5'-4'}$ = 6.8 Hz, 1, H5′), 7.30 (br s, 2, NH_2), 8.15 (s, 1, H2), 8.30 (s, 1, H8); ms *m/z*: 263 (12, M^+), 178 (26), 104 (45), 136 (67), 135 (100), 108 (44). Anal. calcd. for $C_{11}H_{13}N_5O_3$ (263.3): C 50.19, H 4.98, N 26.60; found: C 50.32, H 5.11, N 26.49.

*6-*N*-Benzoyl-9-[5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-*ribo*-hex-5(*E*)-enofuranosyl]adenine* **5***a*

Method A

A solution of **1***a* (411 mg, 1 mmol) and dicyclohexylcarbodiimide (DCC, 619 mg, 3 mmol) in anhydrous Me_2SO (2.5 mL) was stirred with cooling (ice bath) while Cl_2CHCO_2H (0.041 mL, 65 mg, 0.5 mmol) was added. Stirring was continued at ambient temperature for 90 min and then (*p*-toluenesulfonylmethylene)triphenylphosphorane (20, 21) (516 mg, 1.2 mmol) was added. After stirring overnight, tlc indicated complete conversion to a product that migrated faster than **1***a*. Oxalic acid dihydrate (252 mg, 2 mmol) in MeOH (5 mL) was added (to hydrolyze excess DCC) and, after 20 min, *N,N′*-dicyclohexylurea was filtered and the filtrate evaporated *in vacuo*. The residue was partitioned ($EtOAc/H_2O$) and the organic layer washed with H_2O (3 × 50 mL, to remove Me_2SO), $NaHCO_3/H_2O$, and $NaCl/H_2O$, dried ($MgSO_4$), and evaporated to give a slightly yellow foam. Silica column chromatography ($MeOH/CHCl_3$, 1.25:98.75) and "diffusion

For personal use only.

crystallization" (31) from EtOH/pentane/hexanes gave 482 nm (86%) of **5***a*: mp 106–108°C; uv (MeOH): max 279, 234 nm (ε 19 500, 29 700), min 256 nm (ε 12 800); ^{1}H nmr (Me_2SO-d_6) δ: 1.34 and 1.56 (s,s; 3,3; CH_3's), 2.38 (s, 3, $PhCH_3$), 4.95 (ddd, $J_{4'-3'}$ = 3.2 Hz, $J_{4'-5'}$ = 5.6 Hz, $J_{4'-6'}$ = 1.5 Hz, 1, H4′), 5.26 (dd, $J_{3'-2'}$ = 6.2 Hz, 1, H3′), 5.58 (dd, $J_{2'-1'}$ = 1.8 Hz, 1, H2′), 6.40 (d, 1, H1′), 6.77 (dd, $J_{6'-5'}$ = 15 Hz, 1, H6′), 6.91 (dd, 1, H5′), 7.40 (d, $J_{H_A-H_B}$ = 8.5 Hz, 2, aromatic H_A), 7.55–7.68 (m, 5, Bz), 8.07 (d, 2, aromatic H_B), 8.60 (s, 1, H2), 8.63 (s, 1, H8), 11.2 (s, 1, NH); ms (CI, NH_3) *m/z*: 562 (22, M + 1). Anal. calcd. for $C_{28}H_{27}N_5O_6S$ (561.6): C 59.88, H 4.85, N 12.47, S 5.71; found: C 60.18, H 4.86, N 12.71, S 5.58.

Method B

(*p*-Toluenesulfonylmethylene)triphenylphosphorane (537 mg, 1.25 mmol) in dry CH_3CN (20 mL) was added dropwise to a stirred solution of dehydrated **2***a* (18) (0.41 g, 1 mmol) in dry CH_3CN (5 mL) under N_2 and stirring was continued at ambient temperature for 10 h. The solution was evaporated to give a white solid that was purified by silica column chromatography and crystallized as in Method A to give 477 mg (85%) of **5***a* with identical physical and spectral data.

*9-[5,6-Dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-*D*-*ribo*-hex-5(*E*)-enofuranosyl]adenine* **5**b

Treatment of **1***b* (307 mg, 1 mmol) by Method A (as described above for **5***a*) gave 288 mg (63%) of **5***b* (after diffusion crystallization (31) from EtOAc/hexanes): mp 114–116°C; uv (MeOH): max 257, 236 nm (ε 16 600, 23 500), min 252, 222 nm (ε 16 000, 16 500); ^{1}H nmr (Me_2SO-d_6) δ: 1.32 and 1.53 (s,s; 3,3; CH_3's), 2.40 (s, 3, $PhCH_3$), 4.88 (ddd, $J_{4'-3'}$ = 3.3 Hz, $J_{4'-5'}$ = 6.0 Hz, $J_{4'-6'}$ = 1.25 Hz, 1, H4′), 5.20 (dd, $J_{3'-2'}$ = 6.0 Hz, 1, H3′), 5.49 (dd, $J_{2'-1'}$ = 2.0 Hz, 1, H2′), 6.26 (d, 1, H1′), 6.74 (dd, $J_{6'-5'}$ = 15 Hz, 1, H6′), 6.90 (dd, 1, H5′), 7.34 (s, 2, NH_2), 7.39 (d, $J_{H_A-H_B}$ = 8.5 Hz, 2, aromatic H_A), 7.58 (d, 2, aromatic H_B), 8.01 (s, 1, H2), 8.27 (s, 1, H8); ms *m/z*: 457.1406 (0.4, M^+ (calcd. for $C_{21}H_{23}N_5O_5S$ = 457.1419)), 442.1172 (1.8, M − CH_3), 302.1254 (100, M − Ts). Anal. calcd. for $C_{21}H_{23}N_5O_5S$ (457.5): C 55.13, H 5.07, N 15.13; found: C 55.27, H 5.11, N 15.37.

Desulfonylation of **5**b *to give 9-(5,6-dideoxy-2,3-*O*-isopropylidene-β-*D*-*ribo*-hex-5-enofuranosyl)adenine* **4**

A solution of **5***b* (183 mg, 0.4 mmol) in anhydrous THF (6 mL) was added to a stirred solution of tributylstannyllithium (29) (1.2 mL of a 1 M solution in anhydrous THF, 1.2 mmol) under N_2 at −78°C. After 1 h, $CHCl_3$ (10 mL) and silica gel (0.9 g; Merck 60, 200–400 mesh) were added and the resulting mixture stirred at ambient temperature for 20 h. The silica gel was filtered, washed with $CHCl_3$ (2 × 10 mL), and the combined mother liquors shaken with NH_4Cl/H_2O (15 mL) and $CHCl_3$ (10 mL). The organic layer was washed with $NaHCO_3/H_2O$ and $NaCl/H_2O$, dried ($MgSO_4$), and evaporated to give a yellow foam. Silica column chromatography (MeOH/$CHCl_3$, 1.75:98.25) of this material gave 74 mg (61%) of **3***b* as a white solid foam. The ^{1}H nmr spectrum of this tlc-homogeneous product had peaks identical to those noted above for **3***b*, but also had other peaks (5–10% integrated intensity) corresponding to the allyl-tosyl compound **7**. Deprotection of this material and purification (as described above for pure **3***b*) gave 41 mg (39%) of **4** with identical physical and spectral data.

*9-[5,6-Dideoxy-6-(*p*-toluenesulfonyl)-β-*D*-*ribo*-hex-5(*E*)-enofuranosyl]adenine* **5**c

A solution of **5***b* (137 mg, 0.3 mmol) in CF_3CO_2H/H_2O (17:3, 5 mL) was stirred for 20 min at ~0°C, evaporated, and coevaporated with EtOH. Crystallization and recrystallization of the residue from EtOH/hexanes gave 111 mg (89%) of **5***c*: mp 128–130°C; uv (MeOH): max 259, 239 nm (ε 16 700, 22 800), min 256, 223 nm (ε 16 500, 14 800); ^{1}H nmr (Me_2SO-d_6) δ: 2.38 (s, 3, $PhCH_3$), 4.26 (ddd, $J_{3'-2'}$ = 5.1 Hz, $J_{3'-4'}$ = 4.1 Hz, $J_{3'-OH3'}$ = 5.6 Hz, 1, H3′), 4.57 (dd, $J_{4'-5'}$ = 4.7 Hz, 1, H4′), 4.74 (ddd, $J_{2'-1'}$ = 5.4 Hz, $J_{2'-OH2'}$ = 5.5 Hz, 1, H2′), 5.58 (d, 1, OH3′), 5.60 (d, 1, OH2′), 5.94 (d, 1, H1′), 6.92 (d, $J_{6'-5'}$ = 15.1 Hz, 1, H6′), 7.07 (dd, 1, H5′), 7.43 (d, $J_{H_A-H_B}$ = 8.8 Hz, 2, aromatic H_A), 7.72 (d, 2, aromatic H_B), 7.91 (br s, 2, NH_2), 8.08 (s, 1, H2), 8.43 (s, 1, H8); ms *m/z*: 417 (1, M^+), 358 (3), 278 (10), 156 (14), 139 (32), 135 (100). Anal. calcd. for $C_{18}H_{19}N_5O_5S$ (417.4): C 51.79, H 4.59, N 16.78; found: C 51.66, H 4.39, N 16.61.

*9-[5,6-Dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-*D*-*ribo*-hexofuranosyl]adenine* **6**a

To a magnetically stirred solution of **5***b* (274 mg, 0.6 mmol) in $MeOH/H_2O$ (2:1, 30 mL) was added sodium borohydride (45 mg, 1.2 mmol). After stirring for 16 h at ambient temperature, the solution was concentrated to one-half volume and $CHCl_3$ (20 mL) and H_2O (10 mL) were added. The organic layer was separated and the aqueous layer washed with $CHCl_3$ (10 mL). The combined organic phase was washed with $NaCl/H_2O$ and H_2O, dried ($MgSO_4$), and evaporated to give a slightly yellow solid foam that was purified by silica column chromatography (MeOH/$CHCl_3$, 1.5:98.5). Evaporation of appropriately pooled fractions gave 208 mg (76%) of **6***a* as a tlc-homogeneous white solid that could be deprotected directly in the next step; ^{1}H nmr (Me_2SO-d_6) δ: 1.20 and 1.42 (s,s; 3,3; CH_3's), 1.80–1.98 (m, 2, H5′,5″), 2.33 (s, 3, $PhCH_3$), 3.10–3.45 (m, 2, H6′,6″), 4.08–4.16 (m, 1, H4′), 4.83 (dd, $J_{3'-2'}$ = 6.0 Hz, $J_{3'-4'}$ = 3.0 Hz, 1, H3′), 5.36 (dd, $J_{2'-1'}$ = 2.2 Hz, 1, H2′), 5.99 (d, 1, H1′), 7.27 (s, 2, NH_2), 7.31 (d, $J_{H_A-H_B}$ = 8.5 Hz, 2, aromatic H_A), 7.50 (d, 2, aromatic H_B), 7.97 (s, 1, H2), 8.16 (s, 1, H8); ms *m/z*: 459 (4, M^+), 444 (12), 401 (36), 304 (100).

Compound **5***a* was reduced with $NaBH_4$ by the same procedure to give **6***a* in the same yield.

*9-[5,6-Dideoxy-6-(*p*-toluenesulfonyl)-β-*D*-ribo-hexofuranosyl]adenine* **6**b

A solution of **6***a* (161 mg, 0.35 mmol) in CF_3CO_2H/H_2O (17:3, 5 mL) was stirred for 25 min at ~0°C, evaporated, and coevaporated with EtOH to give an amorphous glass. Crystallization and recrystallization from MeOH gave 122 mg (83%) of **6***b* (two crops): mp 158–160°C; uv (MeOH): max 261, 223 nm (ε 15 400, 15 600), min 240 nm (ε 7300); ^{1}H nmr (Me_2SO-d_6) δ: 1.90–2.03 (m, 2, H5′,5″), 2.38 (s, 3, $PhCH_3$), 3.20–3.43 (m, 2, H6′,6″), 3.88–3.98 (m, 1, H4′), 4.09 (dd, $J_{3'-2'}$ = 5.6 Hz, $J_{3'-4'}$ = 4.0 Hz, 1, H3′), 4.59 (dd, $J_{2'-1'}$ = 4.8 Hz, 1, H2′), 5.30 (br s, 2, OH2′, OH3′), 5.84 (d, 1, H1′), 7.41 (d, $J_{H_A-H_B}$ = 8.5 Hz, 2, aromatic H_A), 7.76 (d, 2, aromatic H_B), 8.26 (s, 1, H2), 8.50 (s, 1, H8), 8.52 (s, 2, NH_2); ms *m/z*: 419 (0.5, M^+), 278 (8), 246 (100), 157 (18), 139 (30), 135 (42). Anal. calcd. for $C_{18}H_{21}N_5O_5S$ (419.5): C 51.54, H 5.05, N 16.70; found: C 51.29, H 4.96, N 16.79.

*9-[5,6-Dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-*D*-erythro-hex-4(*Z*)-enofuranosyl]adenine* **7**

To a stirred solution of **5***b* (183 mg, 0.4 mmol) in CH_3CN/H_2O (4:1, 10 mL) was added 1 M $NaOH/H_2O$ (1 mL). (Alternatively, THF (10 mL) as solvent and DBU (0.06 mL, 60 mg, 0.4 mmol as base can be used.) After 4 h at ambient temperature, the solution was concentrated to one-half volume and EtOAc (10 mL) and HCl/H_2O (0.05 M, 2 mL) were added. The organic layer was separated and the aqueous layer washed with EtOAc (2 × 10 mL). The combined organic phase was washed with $NaHCO_3/H_2O$, $NaCl/H_2O$, and H_2O, dried ($MgSO_4$), and evaporated to a white foam that was crystallized from EtOH/hexanes to give 163 mg (89%) of **7**: mp 115–116°C; uv (MeOH): max 258, 227 nm (ε 15 200, 13 900), min 240 nm (ε 9700); ^{1}H nmr ($CDCl_3$) δ: 1.39 and 1.48 (s,s; 3,3; CH_3's), 2.35 (s, 3, $PhCH_3$), 3.83 (d, $J_{6'/6''-5'}$ = 8 Hz, 2, H6′,6″), 4.81 (t, 1, H5′), 5.19 (d, $J_{3'-2'}$ = 6 Hz, 1, H3′), 5.62 (d, 1, H2′), 6.02 (s, 2, NH_2), 6.14 (s, 1, H1′), 7.16 (d, $J_{H_A-H_B}$ = 8.5 Hz, 2, aromatic H_A), 7.67 (d, 2, aromatic H_B), 7.74 (s, 1, H2), 8.14 (s, 1, H8); ms *m/z*: 442.1178 (1.7, M − CH_3 [$C_{20}H_{20}N_5O_5S$] = 442.1185), 302.1257 (100, M − Ts). The aldol condensation of acetophenone with acetone

J. PETER GUTHRIE[1] AND XIAO-PING WANG
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received January 26, 1990[2]

J. PETER GUTHRIE and XIAO-PING WANG. Can. J. Chem. **69**, 339 (1991).

The kinetics and equilibria involved in the aldol condensation of acetophenone, acting as carbon acid, and acetone have been studied in aqueous alkaline solution. The reactions are all first order in hydroxide, with rate and equilibrium constants (defined for enone as initial compound) of: $k_{12} = 3.3 \times 10^{-4}\ M^{-1}\ s^{-1}$, $k_{21} = 3.2 \times 10^{-5}\ M^{-1}\ s^{-1}$, $K_{12} = 10.2$, $k_{23} = 8.0 \times 10^{-2}\ M^{-1}\ s^{-1}$, $k_{32} = 3.3 \times 10^{-4}\ M^{-2}\ s^{-1}$, $K_{32} = 4.1 \times 10^{-3}\ M^{-1}$. The series methylbutenal, mesityl oxide, and 3-methyl-1-phenyl-2-buten-1-one can now be compared with regard to regularities and deviations from regularity. The related series cinnamaldehyde, benzalacetone, and chalcone also provides insights into the behaviour of this system.

Key words: aldol, dehydration, equilibrium, acetophenone, acetone.

J. PETER GUTHRIE et XIAO-PING WANG. Can. J. Chem. **69**, 339 (1991).

Opérant en solution aqueuse alcaline, on a étudié la cinétique et l'équilibre impliqué dans la condensation aldolique de l'acétophénone, agissant comme acide carboné, et de l'acétone. Les réactions sont du premier ordre en ion hydroxyde; les constantes de vitesse et d'équilibre (définies pour l'apparition de l'énone) sont $k_{12} = 3{,}3 \times 10^{-4}\ M^{-1}\ s^{-1}$, $k_{21} = 3{,}2 \times 10^{-5}\ M^{-1}\ s^{-1}$, $K_{12} = 10{,}2$, $k_{23} = 8{,}0 \times 10^{-2}\ M^{-1}\ s^{-1}$, $k_{32} = 3{,}3 \times 10^{-4}\ M^{-2}\ s^{-1}$, $k_{32} = 4{,}1 \times 10^{-3}\ M^{-1}$. On peut maintenant comparer la série méthylbuténal, oxyde de mésityle et 3-méthyl-1-phénylbutèn-3-one-1 et déterminer les régularités ainsi que les déviations de la régularité. La série apparentée du cinnamaldéhyde, de la benzalacétone et de la chalcone éclaire aussi le comportement de ce système.

Mots clés : aldol, déshydratation, équilibre, acétophénone, acétone.

Introduction

We have studied various examples of simple aldol condensations (1–7). Although previously studied cases include both conjugated (5–9) and non-conjugated enones (2–4), there has been no detailed study of a cross-conjugated system where a ketone such as acetophenone acts as carbon nucleophile towards an unconjugated aldehyde or ketone in the aldol reaction. Chalcone has been studied (5, 9) but in this case there is through-conjugation by the phenyl derived from benzaldehyde as well as cross-conjugation for the phenyl derived from acetophenone. The present case allows us to assess the effects of cross-conjugation uncomplicated by competing through-conjugation. This system was also of interest to us in connection with enzyme model studies (10, 11), so it seemed appropriate to investigate it carefully. We also wished to compare a series of related enones, which have now been studied, namely 3-methyl-2-butenal, mesityl oxide (4-methyl-3-penten-2-one), and 3-methyl-1-phenyl-2-buten-1-one, the present compound. We have already seen effects of crowding on the rates and equilibria of the steps in the overall condensation in the series propenal, 2-butenal, and 3-methyl-2-butenal. One would expect similar but larger effects in the present series.

Results

The retroaldol cleavage of 3-methyl-1-phenyl-2-buten-1-one is expected to involve two stages, hydration of the enone followed by retroaldol cleavage of the ketol. This mechanism frequently leads to biphasic kinetics. In the present case the observed behavior was deceptively simple.

[1] $\text{Ph-CO-CH=C(CH}_3)_2 \rightleftharpoons \text{Ph-CO-CH}_2\text{-C(OH)(CH}_3)_2 \rightleftharpoons \text{Ph-CO-CH}_3 + \text{CO(CH}_3)_2$

The kinetics of the retroaldol reaction of the enone, 3-methyl-1-phenyl-2-buten-1-one, could be followed conveniently by UV spectroscopy. The reaction exhibited simple first-order behavior, with no sign of the two-phase behavior that might have been expected for a reaction proceeding by an addition, retroaldol cleavage sequence. The rate constants that we measured are found in Table 1(a). The apparent rate constants showed a first-order dependence on hydroxide concentration, leading to a second-order rate constant of $(3.26 \pm 0.30) \times 10^{-4}\ M^{-1}\ s^{-1}$.

The kinetics of the breakdown of the ketol, 3-hydroxy-3-methyl-1-phenyl-1-butanone, were also studied in hopes of being able to detect formation of the enone and so determine the partitioning ratio for the ketol. However, we found that the ketol also showed only simple first-order kinetics behavior, with no detectable formation of the enone. The rate constants that we measured are also found in Table 1(b). Here too the apparent rate constants were first order in hydroxide concentration, leading to a second-order rate constant of $(8.04 \pm 0.71) \times 10^{-2}\ M^{-1}\ s^{-1}$.

Clearly, dehydration of the ketol is slow relative to retroaldol cleavage. Since we see no sign of biphasic kinetics with either enone or ketol as starting material, we cannot evaluate k_{21} directly.

To evaluate k_{21}, we determined the equilibrium constant for hydration of the enone in acid where retroaldol cleavage is slow relative to establishment of hydration equilibrium. This shift in relative rates was expected on the basis of several literature analogies (12–14).

For the kinetic model

$$A_1 \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} A_2 \xrightarrow{k_{23}} A_3$$

where A_1 = enone, A_2 = ketol, A_3 = acetone + acetophenone, we may derive (15) the following rigorously correct equation for the absorbance A as a function of time for reaction starting with

[a]In aqueous solution at 25°C, ionic strength 0.1 (KCl) unless otherwise noted. Absorbance–time data were fitted to $A = \alpha + \beta \exp(-\lambda_i t)$ by non-linear least squares. We use λ_2 for the faster process, and λ_3 for the slower one to emphasize that the two kinds of experiment measure different phases of the expected double exponential integrated rate law. Standard deviations for the parameters are calculated by the least-squares procedure. Average values are weighted means.

[h]Followed at 255 nm.

the enone:

$$[2]\quad A = [A_1]\epsilon_1 + [A_2]\epsilon_2 + [A_3]\epsilon_3$$
$$= \{[A_1]^0 k_{12}/\lambda_2\}\{\epsilon_1(\lambda_2 - k_{23})/(\lambda_2 - \lambda_3) - \epsilon_2 + \epsilon_3 k_{23}/(\lambda_2 - \lambda_3)\}\exp(-\lambda_2 t) + \{[A_1]^0 k_{12}/(\lambda_2 - \lambda_3)\}\{\epsilon_1(k_{23} - \lambda_3)/\lambda_3 + \epsilon_2 - \epsilon_3 k_{23}/\lambda_3\}\exp(-\lambda_3 t) + \epsilon_3[A_1]^0$$

where $\lambda_2 = (p + q)/2$, $\lambda_3 = (p - q)/2$, $p = k_{12} + k_{21} + k_{23}$, $q = (p^2 - 4k_{12}k_{23})^{1/2}$.

There are two interesting special cases. The first pertains to reaction in acid where the hydration–dehydration equilibrium is established rapidly with respect to retroaldol cleavage. Then if k_{23} (and λ_3) are negligible relative to k_{12}, k_{21} and $\lambda_2 \approx k_{12} + k_{21}$, eq. [1] can be simplified to

$$A = \epsilon_1\{[A_1]^0 k_{21}/\lambda_2\} + \epsilon_2\{[A_1]^0 k_{12}/\lambda_2\} + (\epsilon_1 - \epsilon_2)\{[A_1]^0 k_{12}/\lambda_2\}\exp(-\lambda_2 t)$$
$$= \alpha + \beta \exp(-\lambda_2 t)$$

Defining K_{12} as the equilibrium constant for hydration, $K_{12} = k_{12}/k_{21}$, we see that

$$\alpha = [A_1]^0\{\{\epsilon_1 k_{21}/\lambda_2\} + \{\epsilon_2 k_{12}/\lambda_2\}\}$$
$$= [A_1]^0\{\epsilon_1/(1 + K_{12}) + \epsilon_2/(1 + 1/K_{12})\}$$

$$[3]\quad K_{12} = (\epsilon_2[A_1]^0 - \alpha)/(\alpha - \epsilon_2[A_1]^0)$$
$$\beta = [A_1]^0(\epsilon_1 - \epsilon_2)/(1 + /K_{12})$$
$$\alpha + \beta = \epsilon_1[A_1]^0$$
$$[A_1]^0 = (\alpha + \beta)/\epsilon_1$$

$$[4]\quad K_{12} = 1/[(\alpha/\beta)(1 - \epsilon_2/\epsilon_1) - \epsilon_2/\epsilon_1]$$

The second special case pertains to reaction in base where $k_{23} \gg k_{12}$, k_{21}. Under these circumstances, $\lambda_2 \approx k_{23}$, $\lambda_3 \approx k_{12}$, and eq. [1] becomes

$$A = [A_1]^0\epsilon_3 + (\epsilon_1 - \epsilon_3)\exp(-\lambda_3 t)$$
$$= \alpha + \beta \exp(-\lambda_3 t)$$

which is the equation one would derive for a single step reaction starting with A_1. Only the exponential in λ_3 is observable because the pre-exponential term for λ_2, approximately $[A_1]^0 k_{12}(\epsilon_1 - \epsilon_2)/k_{23}$, is very small. Thus the experimental data lead directly to k_{12}.

Similarly we may derive a rigorously correct equation for the absorbance as a function of time starting with the ketol:

$$[5]\quad A = \epsilon_1[A_1] + \epsilon_2[A_2] + \epsilon_3[A_3]$$
$$= \{[A_2]^0/(\lambda_2 - \lambda_3)\}\{-\epsilon_1 k_{21} - \epsilon_2(k_{12} - \lambda_2) + \epsilon_3(\lambda_3 - k_{23})\}\exp(-\lambda_2 t) + \{[A_2]^0/(\lambda_2 - \lambda_3)\}\{\epsilon_1 k_{21} + \epsilon_2(k_{12} - \lambda_3) - \epsilon_3(\lambda_2 - k_{23})\}\exp(-\lambda_3 t) + [A_2]^0\epsilon_3$$

Here also there are two special cases of interest. In the case of acid-catalyzed reactions, where $k_{23} \ll k_{21}$, k_{12}, and $\lambda_2 \approx k_{12} + k_{21}$, eq. [4] can be simplified to

$$A = [A_2]^0(\epsilon_1 k_{21} + \epsilon_2 k_{12})/\lambda_2 + [A_2]^0(\epsilon_2 - \epsilon_1)(k_{21}/\lambda_2)\exp(-\lambda_2 t)$$
$$= \alpha + \beta \exp(-\lambda_2 t)$$

and

$$K_{12} = (\epsilon_2[A_2]^0 - \alpha)/(\alpha - \epsilon_2[A_2]^0)$$
$$[A_2]^0 = (\alpha + \beta)/\epsilon_2$$

K_{12} was calculated from the least-squares parameters, using eq. [4].

In the case of base-catalyzed reactions, where $k_{23} \gg k_{12}$, k_{21}, $\lambda_2 \approx k_{23}$, $\lambda_3 \approx k_{12}$, and eq. [5] becomes

$$A = [A_2]^0\epsilon_3 + [A_2]^0\epsilon_1 k_{21}/k_{23} + [A_2]^0(\epsilon_2 - \epsilon_3 - \epsilon_1 k_{21}/k_{23})\exp(-\lambda_2 t)$$

For this condition the major reaction path for ketol is breakdown to acetone and acetophenone (k_{23}) with dehydration being a very minor side reaction. Thus the second phase controlled by λ_3 is both slow and of very small amplitude; the pre-exponential term for λ_3 is approximately $[A_2]^0\epsilon_1 k_{21}/k_{23}$. Provided that $\epsilon_1 k_{21}/k_{23} \ll \epsilon_1$, ϵ_2 we can further simplify the equation to

$$A = [A_2]^0\epsilon_3 + [A_2]^0(\epsilon_2 - \epsilon_3)\exp(-\lambda_2 t)$$
$$= \alpha + \beta \exp(-\lambda_2 t)$$

Substitution of the values derived from our analysis shows that the approximations employed are valid. For reactions starting with the ketol, the experimental data lead directly to k_{23}.

We measured rates of approach to hydration equilibrium in

[g]Experiments at 25.0°C.

acidic solutions and demonstrated by HPLC analysis that at the end of the initial kinetics process, as followed by UV spectroscopy, there was only a small amount of acetophenone present. Furthermore, the proportions of enone and ketol were the same whether reaction started with the enone or the ketol. The kinetics data are found in Table 2. The hydration reaction went to equilibrium, following first-order behavior, with a rate constant in 1 N HCl of $(3.74 \pm 0.81) \times 10^{-5}$ s^{-1} (starting from ketol), or $(3.72 \pm 0.007) \times 10^{-5}$ s^{-1} (starting from the enone). Combining all the data we obtain $(3.72 \pm 0.12) \times 10^{-5}$ s^{-1}. There was a slower subsequent change in absorbance. The equilibrium constant, K_{12} = [ketol]/[enone] is 10.72 ± 1.17 using data for reactions starting with the ketol, 9.58 ± 2.01 starting with the enone, and 10.24 ± 1.68 using all of the data. Then, since K_{12} must be the same in acid or base, and $K_{12} = k_{12}/k_{21}$, we may calculate the hydroxide-catalyzed rate constant, $k_{21} = (3.18 \pm 0.60) \times 10^{-5}$ M^{-1} s^{-1}.

To complete the description of this aldol reaction, we have measured the kinetics and equilibrium constants for enone formation from acetone and acetophenone. Although the HPLC peak assigned to 3-methyl-1-phenyl-2-buten-1-one in reaction mixtures of acetone plus acetophenone is small, and there are other small peaks, we are confident of our assignment because it corresponds to the major peak found for authentic samples of 3-methyl-1-phenyl-2-buten-1-one and because the rate constant for formation of this peak (starting from acetophenone at

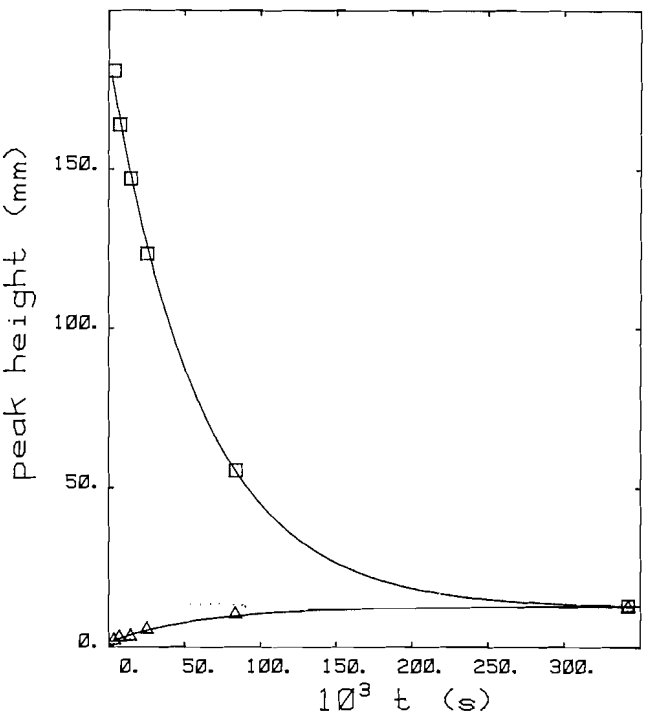

FIG. 1. Kinetics for cleavage and formation of 3-methyl-1-phenyl-2-buten-1-one, followed by HPLC. Initial conditions were as follows: cleavage, [enone] = 0.0013 M, [acetophenone] = 0.0122 M, [acetone] = 1.054 M, [OH^-] = 0.10 M; formation, [acetophenone] = 0.010 M, [acetone] = 0.972 M, [OH^-] = 0.10 M. The points for the formation reaction are corrected by the factor (1.054 × 0.0122)/(0.972 × 0.010) = 1.32, as described in the text.

various concentrations of acetone) and the rate constant for loss of this peak (starting from 3-methyl-1-phenyl-2-buten-1-one) are the same. The kinetics results are found in Table 3.

The rate constant for approach to equilibrium is the sum of the rate constants for the forward and reverse reactions (15). When, as in the present case, formation is much slower than breakdown, the same apparent rate constant, equal to the rate constant for breakdown, is found starting from either direction. Initial experiments to develop the analytical method were carried out at room temperature, 20–25°C, and included reactions followed from both directions; see Fig. 1. Since the equilbrium concentration of enone depends on the product [acetone][acetophenone] and the conditions were not exactly the same for the two reactions, we have corrected the points for the formation run by the ratio $[acetone]_1[acetophenone]_1/[acetone]_2[acetophenone]_2$. As would be expected, the equilibrium constant is relatively insensitive to the small temperature changes involved, but the rates of reaction are quite sensitive, and were faster for reactions thermostatted at 25°C. The rate constant for approach to equilibrium is $(3.06 \pm 0.33) \times 10^{-4}$ $M^{-1}\,s^{-1}$ (weighted mean of rate constants at 25°C, Table 3). Kinetics of breakdown studied by UV led to a rate constant of $(3.1 \pm 0.09) \times 10^{-4}\,M^{-1}\,s^{-1}$. The equilibrium constant for the overall reaction is $K_{31} \times$ [enone]/[acetone][acetophenone] = $(3.99 \pm 0.56) \times 10^{-4}\,M^{-1}$, based on all the experiments, including those at "room temperature", or $(4.04 \pm 0.81) \times 10^{-4}\,M^{-1}$, based on the four reactions carried out at 25°C. Since $K_{31} = K_{32}/K_{12}$, we can now calculate $K_{32} = (4.14 \pm 1.07) \times 10^{-3}\,M^{-1}$. Furthermore, since $K_{32} = k_{32}/k_{23}$, we can calculate $k_{32} = (3.33 \pm 0.91) \times 10^{-4}\,M^{-2}\,s^{-1}$.

Discussion

Examination of the data for two sets of aldol condensations in Table 4 shows both regularities and unexpected deviations from regularity. The reactions included are two sets of reactions of a common carbonyl compound combining with three different carbon acids in the aldol sense: acetone and benzaldehyde with acetaldehyde, acetone, or acetophenone.

For k_{12}, the rate constant for base-catalyzed addition of water to the unsaturated carbonyl compound, we see that the enals are always more reactive then enones. Addition to a cross-conjugated enone derived from acetophenone is faster by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

threefold than addition to the enone derived from acetone. This suggests that there is no extra steric relief upon hydration of an enone with two β-methyls relative to one with a β-phenyl, which can be in the *E* stereochemistry and out of the way. As we have argued previously (4), crowding in the enone (or enal) will not be relieved in the transition state for hydration, but relief of this crowding will affect the overall equilibrium constant for hydration.

For k_{21}, the rate constant for dehydration, the aldehydes are much faster than the ketones. The more dramatic effect is for methylbutenal, where k_{21} is 20 000 times faster than for mesityl oxide, while for cinnamaldehyde, k_{21} is only 60 times faster than for benzalacetone. The change from methyl to phenyl as carbonyl substituent is more regular, with the phenyl compound being 3–4 times faster.

For K_{12}, the equilibrium constant for hydration, the interesting effect is that the aldehydes show a marked preference for dehydration relative to the corresponding ketones. This can be seen to be an effect quite aside from any steric interactions by comparing cinnamaldehyde with benzalacetone or chalcone. Where there is a steric interaction as well, comparing methylbutenal with mesityl oxide or 3-methyl-1-phenyl-2-buten-1-one, the difference between enal and enone is almost 10 times larger. Conjugation clearly favors dehydration, with phenyl as β-substituent favoring dehydration by 30- to 200-fold relative to two β-methyl substituents. There is clearly no major effect of cross-conjugation; K_{12} values for mesityl oxide and 3-methyl-1-phenyl-2-buten-1-one are very similar as are K_{12} values for chalcone and benzalacetone.

For k_{23}, the actual retroaldol step, expulsion of acetone is always slowest, but relative leaving tendencies of acetaldehyde and acetophenone vary. Both are more acidic, hence better leaving groups, than acetone: acetaldehyde, pK_a 16.9 (16), 16.73 (17); acetophenone, 18.4 (18), 18.24 (19); acetone, 19.4 (20), 19.27 (21).

The aldol addition step, k_{32}, is the most surprising; relative rates for attack by the anions of acetaldehyde and acetone are the same for both series, but acetophenone anion is the most reactive nucleophile of the three towards benzaldehyde and the least reactive towards acetone. Part of the reason for this unexpected behavior may be a stabilization of the transition state for the attack of acetophenone on benzaldehyde because of favorable contacts between the aromatic rings. Part of the reason is the less favorable equilibrium constant for the addition step.

Experimental

Materials

3-Hydroxy-3-methyl-1-phenyl-1-butanone, "ketol"

Attempts to prepare this compound by directed aldol condensation of the lithium enolate of acetophenone with acetone led to mixtures containing 4-hydroxy-4-phenyl-2-pentanone, which could not be separated. A less direct synthesis gave pure material. Sodium borohydride (98%, Metal Hydrides Inc.), 0.6 g (15.5 mmol), dissolved in aqueous 0.005 M NaOH, 50 mL, was added to a solution of ethyl benzoylacetate, 2.0 g (10.4 mmol), in 95% ethanol, 100 mL. The reaction was followed by monitoring the UV absorbance at 250 nm in a 1-cm cell, and stopped after 1 h when the absorbance was 0.245. Ice, 50 g, was added to the reaction mixture and 4 M H_3PO_4, 3 mL, was added to adjust the pH to less than 7 (gas evolution). Extraction (chloroform, 1 × 200 mL, 2 × 50 mL), drying (Na_2SO_4), and evaporation gave 1.80 g, 90% crude ethyl 1-hydroxy-1-phenylpropionate. Following the procedure of Wroblewski (22), this crude hydroxy ester was reacted with excess methyl magnesium iodide to give 3-methyl-1-phenyl-1,3-butanediol, which was immediately oxidized to give 3-hydroxy-3-methyl-1-phenyl-1-butanone. The crude product was purified by column chromatography on silica gel, eluting with a linear gradient (0–10%) of ethyl acetate in petroleum ether. Fractions containing only ketol (judged by TLC) were pooled; UV (H_2O): λ_{max} 247.5, ϵ_{max} 12 800, ϵ_{260} 4440, ϵ_{255} 11 100, ϵ_{243} 11 800; ^{1}H NMR (200 MHz, $CDCl_3$) δ (TMS): 1.35 (6H, s) $(CH_3)_2C$, 3.16 (2H, s) CH_2-CO, 4.19 (1H, br s) O*H*, 7.47–7.60 (3H, complex) and 7.93–7.98 (2H, complex) C_6H_5-. Literature (22) ^{1}H NMR (90 MHz, $CDCl_3$) δ (TMS): 1.25 (6H, s), 3.05 (2H, s), 3.75 (1H, s), 7.25–8.1 (5H, m).

3-Methyl-1-phenyl-2-buten-1-one, "enone"

3-Hydroxy-3-methyl-1-phenyl-1-butanone (0.2 g, 1.25 mmol) was added to a crucible containing silica gel (4 g), a few drops of 12 N HCl and a small amount of methanol were added, and the mixture was heated (steam bath) for 1 h. Then the mixture was filtered and washed thoroughly with ethyl acetate. TLC analysis showed approximately 95% enone and 5% ketol. Two column chromatographies on silica gel, the first with a linear gradient (0–20%) of ethyl acetate in petroleum ether, the second with a linear gradient (0–10%) of ethyl acetate in CCl_4, gave pure material; UV (H_2O, 0.1 M KCl): λ_{max} 266 nm, ϵ_{max} 16 500, ϵ_{255} 13 300, $\epsilon_{247.5}$ 9920, ϵ_{243} 7550; ^{1}H NMR (200 MHz, $CDCl_3$) δ (TMS): 2.02 (3H, d, J = 1.4 Hz) CH_3—C=C, 2.22 (3H, d, J = 1.3 Hz) CH_3—C=C, 6.76 (1H, m, J = 1.3 Hz) *H*—C=C, 7.26–7.50 and 7.91–7.96 (5H, complex) C_5H_6-. Literature (23) ^{1}H NMR ($CDCl_3$) δ (TMS): 2.0 (s, 3H), 2.25 (s, 3H), 6.75 (br s, 1H), 7.2–8.0 (m, 6H).

Methods

The procedure for UV kinetics was as previously described (3, 4). Reactions followed by UV were carried out in 10-cm cells, so that low concentrations, ensuring complete solubility, could be used. For reactions followed by HPLC, reactions were carried out in thermostatted flasks, from which samples were removed at suitable intervals and quenched by addition of phosphoric acid. Analysis was carried out using Waters C-18 Radial-Pak columns, with aqueous methanol as eluting solvent. The concentration of materials eluted was monitored at suitable wavelengths: enone, 260 nm; ketol, 248 nm; acetophenone, 245 nm. For equilibrium constant (K_{31}) determinations, calibrations were carried out using suitable stock solutions of pure enone.

NMR spectra were recorded using Varian EM360 or XL200 spectrometers. TLC was carried out using Analtech Silica gel GF uniplates. Column chromatography was carried out using Terochem silica gel 1918.

The VCD spectrum of 2-methylthietane: measured (800–1500 cm^{-1}) and computed with semi-empirical models

R. A. SHAW, N. IBRAHIM, AND H. WIESER[1]

Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received September 12, 1990

R. A. SHAW, N. IBRAHIM, and H. WIESER. Can. J. Chem. **69**, 345 (1991).

The vibrational circular dichroism (VCD) spectrum (800 to 1500 cm^{-1}) is reported for 2-methylthietane (2MT). Fixed partial charge (FPC), atomic polar tensor (APT), and charge flow (CF) methods are used to compute the VCD spectra for both stable conformers (CH_3 in the axial or equatorial orientation) for the complete range of fundamental vibrations, based on 3-21G and 6-31G* harmonic force fields. The experimental and computed absorption and VCD spectra of *R*-(+)-2MT are compared to the previously reported spectra of *R*-(−)-2-methyloxetane. The success of the APT and CF models for reproducing the dominant ring stretching IR and VCD features of that compound is rationalized by a comparison of APT and FPC intensity expressions. Further comparison of the APT and FPC calculated electric dipole moment derivatives are interpreted to suggest values for the diagonal CS and CH stretching charge flow terms for 2MT. These investigations then provide a rationale for previously reported successes of the FPC model, and permit identification of specific vibrational modes of 2MT that are amenable to FPC-VCD modeling. The previously established conformational mixture of ~30% axial and 70% equatorial is shown to be in accord with FPC-VCD predictions for the most appropriate (β-CH_2 wagging) mode.

Key words: vibrational circular dichroism, 2-methylthietane, fixed partial charge, atomic polar tensor, charge flow.

R. A. SHAW, N. IBRAHIM et H. WIESER. Can. J. Chem. **69**, 345 (1991).

On a déterminé le spectre de dichroïsme circulaire vibrationnel (DCV) (de 800 à 1500 cm^{-1}) du 2-méthylthiétane (2MT). On a utilisé les méthodes des charges partielles fixes (CPF), des tenseurs polaires atomiques (TPA) et de l'écoulement des charges (EC) pour calculer le spectre de DCV des deux conformères stables (CH_3 dans les orientations axiale et équatoriale) de l'ensemble complet des vibrations fondamentales, basé sur les champs de force harmonique 3-21G et 6-31G*. On a comparé les absorptions expérimentale et calculée ainsi que le spectre de DCV du *R*-(+)-2MT avec le spectre rapporté antérieurement pour le *R*-(−)-méthyloxétane. Le succès des modèles des TPA et de l'EC à reproduire les caractéristiques principales des élongations en IR et en DCV est rationalisé par comparaison des expressions des intensités des TPA et des CPF. On croit qu'une autre comparaison des dérivées des moments dipolaires électriques, calculées à l'aide des TPA et des CPF, suggère des valeurs pour les termes d'écoulement des charges des élongations diagonales du CS et du CH du 2MT. Ces études ont fourni une base d'interprétation pour les succès rapportés antérieurement par le modèle CPF et elles permettent d'identifier des modes vibrationnels spécifiques du 2MT qui pourraient être examinés par le modèle des CPF-DCV. On montre que, pour le mode le plus approprié de la vibration de balancement du β-CH_2), le mélange conformationnel (d'environ 30% axial et 70 équatorial) qui a été mis en évidence antérieurement est en accord avec les prédictions de la CPF-DCV.

Mots clés : dichroïsme circulaire vibrationnel, 2-méthylthiétane, charges partielles fixes, tenseurs polaires atomiques, l'écoulement des charges.

[Traduit par la rédaction]

Introduction

Vibrational circular dichroism (VCD) spectroscopy measures the differential absorption of left versus right circularly polarized light in the infrared region (for reviews, see for example, ref. 1). The spectrum complements the conventional infrared absorption spectrum, displaying in principle either a positive or negative feature accompanying each vibrational transition. Measurement of VCD is currently feasible to a lower limit of about 600 cm^{-1}, with one of the present challenges being the extraction of structural and conformational details from the observed spectrum. One important theme involves measuring the spectra of small chiral molecules, both to provide a basis for testing theoretical models and to permit identification of spectral features which show a consistent correlation with common structural characteristics. Of particular interest are three- and four-membered rings which, owing to their limited conformational freedom, can serve as effective test cases for model calculations.

We present here the VCD spectrum of 2-methylthietane (2MT, Fig. 1) in the 800–1500 cm^{-1} range, and a series of model calculations based upon the scaled *ab initio* force fields reported earlier (2). This molecule is of particular interest since skeletal flexibility allows inversion between an equatorial and axial orientation of the methyl group, separated by a potential barrier of 341 cm^{-1} (3). The two conformers are suggested to exist in the ratio of approximately 70 to 30%, respectively, at ambient temperatures (2). The influence of ring inversion on the VCD signals may be assessed directly whenever corresponding transitions of the two conformers are resolved in the spectrum.

The 3-21G and 6-31G* force fields reported previously (2) are used here as the basis for calculating the VCD and infrared absorption intensities with the fixed partial charge (FPC), atomic polar tensor (APT), and charge flow (CF) models (4–6). While neither the FPC nor the APT model is universally applicable, even FPC as the simplest reproduces the observed VCD spectrum for certain molecules remarkably well, the most striking examples being *trans*-1,2-dideuteriocyclobutane (DDCB) and *trans*-1,2-dideuteriocyclopropane (DDCP) (7, 8). In the FPC approximation each atom is assigned a net charge which does not vary as the nuclei are displaced from the equilibrium positions. The success of the model for these two saturated hydrocarbons may thus be rationalized by suggesting that vibrational displacements do not induce significant redistribution of electronic charge such as might be anticipated for molecules containing readily polarizable bonds or heteroatoms. FPC calculations for molecules that do contain such groups

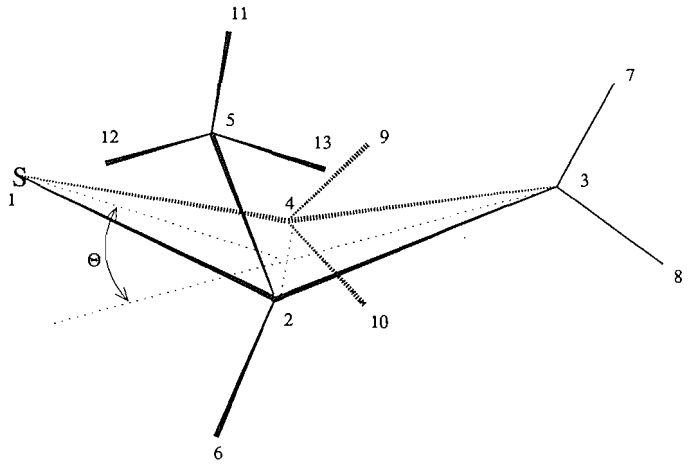

FIG. 1. *R*-(+)-2-methylthietane.

might then be expected to serve as a guide for understanding and modeling, by means of charge flow, such charge rearrangements as do occur.

In a recent report we employed both the FPC and APT models to predict the VCD and infrared absorption intensities of 2-methyloxetane (2MO) (9). From 800 to 1500 cm^{-1} FPC was found to reproduce the signs of nearly all VCD bands; however, the relative intensities were not accurate. The absorption intensities were adequately predicted only for the $CH/CH_2/CH_3$ bending modes in the 1100 to 1500 cm^{-1} range. These observations prompted a detailed comparison of the FPC and APT calculations, with emphasis focussed on attempts to rationalize similarities and differences between the two sets of calculated electric dipole moment derivatives with respect to local symmetry coordinates. This comparison suggested that for FPC the discrepancies in ring stretching absorption intensities might be diminished by including a term reflecting a flow of negative charge along the CO bond from carbon to oxygen as the bond elongates. The resulting improvement toward better agreement between computed and observed absorption and VCD intensities was taken as evidence to indicate that the heteroatom, oxygen in this case, may be viewed as a perturbation upon the otherwise saturated hydrocarbon structure. In this view, charge flow parameters are required to model electronic redistributions that occur solely as a consequence of the heteroatom, and it might be expected readily that the intensities of deformation modes localized at positions remote from the heteroatom can be modeled with FPC just as accurately as for DDCB and DDCP. The β-CH_2 wagging mode in particular was identified as being amenable to FPC modeling, enabling us to establish that the equatorial conformer predominates in solution.

The present study extends this approach, first examining the accuracy of the FPC and APT calculations, and then comparing the two in order to rationalize their strengths and weaknesses in reproducing the observed spectra of 2-methylthietane. We present evidence to suggest that CS stretching leads to charge flow along the CS bonds, allowing us to further assess the influence of a corresponding charge flow parameter on the calculated absorption and VCD intensities. In addition, we examine the effect of charge flow in the CH stretching region by including a diagonal term of the type $\partial\xi_{CH}/\partial R_{CH}$. Finally, we compare in detail the theoretical and experimental VCD spectra of 2MT to those of 2-methyloxetane, stressing in particular the correspondence between both calculated and observed features arising from normal modes that most closely resemble one another.

Theoretical background

The expressions for the dipole and rotatory strengths,

$$[1] \quad \mathcal{D}_i = |\langle 0|\mu|i\rangle|^2$$

$$[2] \quad \mathcal{R}_i = \mathrm{im}\{\langle 0|\mu|i\rangle\cdot\langle i|m|0\rangle\}$$

illustrate the role of the electric and magnetic dipole transition moments governing the calculated infrared absorption and VCD intensities for a transition from the ground state (0) to an excited vibrational state (i). While the former may be evaluated in a straightforward fashion, exact and tractable expressions for the latter have been derived and tested only recently.[2] The FPC, APT, and localized molecular orbital (LMO) (11) models account for the electronic contributions to the magnetic dipole transition moment with progressively less severe approximations in that order, each giving at the same time a clear physical interpretation for the underlying source of the VCD intensities. The CF model extends FPC to include the influence of vibrationally induced charge flow along bonds.

The following discussion rationalizes the success of the charge flow term $\partial\xi_{CO}/\partial R_{CO}$ introduced for 2-methyloxetane (9), while demonstrating simultaneously certain relationships among the FPC, CF, and APT. The expressions for the rotatory strength $\mathcal{R}_i$ are:

$$[3] \quad \mathcal{R}_i^{\mathrm{FPC}} = \frac{e^2\hbar}{4c}\left[\sum_n Z_n\left(\frac{\partial X_n}{\partial Q_i}\right)\right]\cdot\left[\sum_n X_{n,0}\times Z_n\left(\frac{\partial X_n}{\partial Q_i}\right)\right]$$

$$[4] \quad \mathcal{R}_i^{\mathrm{CF}} = \frac{e^2\hbar}{4c}\left[\sum_n Z_n\left(\frac{\partial X_n}{\partial Q_i}\right) + \sum_\alpha Y_\alpha\left(\frac{\partial \xi_\alpha}{\partial Q_i}\right)\right]\cdot \left[\sum_n X_{n,0}\times Z_n\left(\frac{\partial X_n}{\partial Q_i}\right) + \sum_\alpha X_\alpha \times Y_\alpha\left(\frac{\partial \xi_\alpha}{\partial Q_i}\right)\right]$$

$$[5] \quad \mathcal{R}_i^{\mathrm{APT}} = \frac{e^2\hbar}{4c}\left[\sum_n \frac{\partial\mu}{\partial X_n}\left(\frac{\partial X_n}{\partial Q_i}\right)\right]\cdot\left[\sum_n X_{n,0}\times\frac{\partial\mu}{\partial X_n}\left(\frac{\partial X_n}{\partial Q_i}\right)\right]$$

where Z_n and ξ_α denote the net equilibrium atom and bond charges, $X_{n,0}$ and X_α the position vectors for atom n and bond α (note that for the latter the bond position may be specified at any point along the line connecting the two atoms defining the bond), Y_α is a vector running from atoms A to B defining bond α (6), and Q_i the ith normal coordinate.

While several applications of APT and FPC expressions have been reported, the CF model remains largely unexplored. This is due primarily to the difficulty in obtaining reliable values for the charge flow parameters $\partial\xi_\alpha/\partial R_j$, *i.e.* the charge flow along bond α in response to a displacement in the internal (or local symmetry) coordinates R_j. The observed infrared absorption intensities have been successfully reproduced for a number of molecules by least squares adjustments of the formally equivalent electro-optical parameters (EOPs) (for a review, see ref. 12). Simplifying assumptions are inevitably required to reduce the number of variables in such refinements, and hence it is not assured that the corresponding charge flow terms reflect genuine electronic redistributions contributing to the observed

[2]For development of the exact theoretical expressions, see ref. 10*a*,*b*; for calculated results, see ref. 10*c*, *d*, and *e*.

intensities. A preferable approach may be to evaluate EOPs from first principles, as was suggested by Gribov and co-workers over several years with the MINDO/3 molecular orbital method (13).

In this paper, we examine the influence of diagonal charge flow terms involving the CS and CH bonds only, *i.e.* terms of the type $\partial\xi_{CX}/\partial R_{CX}$, X = S and H. The following discussion demonstrates certain relationships among the CF, FPC, APT, and LMO models, leading to a method for rationalizing these charge flow terms. To illustrate we write the rotatory strength $\mathcal{R}_i$ in the general form:

$$[6] \quad \mathcal{R}_i = \text{constant}[\text{E}]\cdot[\text{M}]$$

where E and M represent, respectively, the electric and magnetic dipole transition moment terms in square brackets in eqs. [3] to [5]. The contribution of *stretching* displacements R_j to the E term can be written for the APT model, and respectively for the CF model assuming only diagonal terms, as follows:

$$[7] \quad \sum_j \frac{\partial\mu}{\partial R_j}\frac{\partial R_j}{\partial Q_i}$$

$$[8] \quad \sum_j \left(Y_\alpha \frac{\partial\xi_\alpha}{\partial R_j} + Z_A^\alpha \frac{\partial X_A}{\partial R_j} + Z_B^\alpha \frac{\partial X_B}{\partial R_j} \right) \frac{\partial R_j}{\partial Q_i}$$

In the second expression, the letters A and B refer to the atoms defining the bond α. The first term denotes the diagonal charge flow upon displacement in R_j, while the last two are the fixed partial charge terms. Provided that the dipole moment derivative $\partial\mu/\partial R_j$ lies along the direction of the bond, as implied by the assumption of only diagonal charge flow contributions, these two expressions may be equated by choosing an appropriate value for $\partial\xi_\alpha/\partial R_j$. Under these conditions,

$$[9] \quad \frac{\partial\mu}{\partial R_j} \approx Y_\alpha \frac{\partial\xi_\alpha}{\partial R_j} + Z_A^\alpha \frac{\partial X_A}{\partial R_j} + Z_B^\alpha \frac{\partial X_B}{\partial R_j}$$

This approximate equality demonstrates that one way of assessing the possible role of charge flow, and of assessing the physical significance of such terms, is to compare the electric dipole moment derivatives as determined by APT given on the left with the fixed partial charge term augmented by charge flow given on the right. Assuming that the atomic polar tensors determined by *ab initio* means give essentially correct values for the dipole moment derivatives, discrepancies in direction and magnitude with the FPC values may be attributed to the neglect of charge flow in the FPC model. Consequently, for bond stretches the diagonal term $\partial\xi_\alpha/\partial R_j$ may be adjusted to best satisfy eq. [9].

The same reasoning for the magnetic dipole moment M lead to the corresponding approximate equality between APT and CF, again limiting R_j to stretching coordinates,

$$[10] \quad X_{A,0} \times \frac{\partial\mu}{\partial R_j} \approx X_{A,0} \times \left(Y_\alpha \frac{\partial\xi_\alpha}{\partial R_j} + Z_A^\alpha \frac{\partial X_A}{\partial R_j} + Z_B^\alpha \frac{\partial X_B}{\partial R_j} \right)$$

where all moment arms X_α, $X_{B,0}$, and $X_{A,0}$ have been moved to a common vector, $X_{A,0}$. These shifts are possible provided that the two contributions $(\partial\mu/\partial X_{A,0})(\partial X_{A,0}/\partial R_j)$ and $(\partial\mu/\partial X_{B,0})(\partial X_{B,0}/\partial R_j)$ to the electric dipole moment derivative for the APT expressions (left side of the equation) both follow the bond direction, and the three contributions to the right side of the equation, arising separately from the diagonal charge flow parameter $\partial\xi_\alpha/\partial R_j$ and the fixed partial charges on the two atoms, lie along the same inter-bond axis.

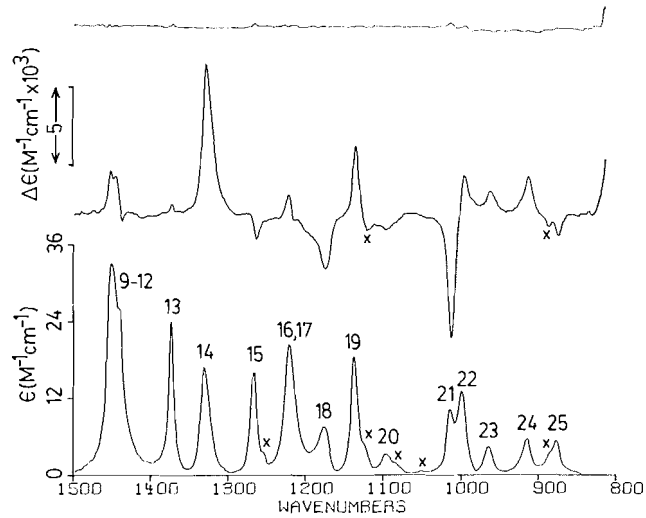

FIG. 2. Experimental infrared absorption (lower trace) and VCD (middle trace) spectra of *R*-(+)-2-methylthietane. The top trace is an estimate of the noise level in the VCD spectrum, i.e. one half of the difference between two separate VCD spectra that are averaged to give the spectrum displayed here. The symbol "×" denotes minor impurities in one of the enantiomers (*R*-(+)) and resulting absorption dependent artifacts in the VCD spectrum.

Analogous arguments may also be applied to the LMO model, assuming all localized molecular orbitals either follow the displaced nuclei exactly if the LMOs are tightly bound to an associated nucleus, or follow the displacement, *e.g.* the direction of bond stretching, if they are bonding molecular orbitals. In that case, expressions identical to APT are obtained.

The above arguments suggest that the APT model, and the CF model incorporating only diagonal charge flow terms, might be anticipated to yield similar intensities, and to reproduce the experimental VCD for those stretching modes involving bonds which are electrically independent, *i.e.* are not linked by charge flow coupling terms. For 2-methyloxetane the FPC value for $\partial\mu/\partial R_{CO}$ matched the APT derived dipole moment derivative in direction, namely parallel to the CO bond, but underestimated the magnitude (9). The discrepancy in absorption intensities for modes containing appreciable CO stretching was largely removed by including the charge flow parameter $\partial\xi_{CO}/\partial R_{CO} = 0.35$ e/Å transferring negative charge from carbon to oxygen as the bond stretches. For the rotatory strength the inclusion of this parameter, while relatively less effective, also leads to closer agreement with observed VCD intensities.

Experimental and computational details

R-(+)- and *S*-(−)-2-methylthietane were made from commercial *R*-(−)- and *S*-(+)-1,3-butanediol (Aldrich, $[\alpha]_D = -24.6°$ and $+25.0°$), respectively, following procedures published for the racemic compounds (14, 15). The methods involved the consecutive syntheses of the *R*-(−)- and *S*-(+)-dimesylates ($[\alpha]_D = -33.0°$ and $+32.6°$ crude, 97% and 96% yield, respectively), and *S*-(+)- and *R*-(−)-dibromides ($[\alpha]_D = +89.9°$ and $-89.0°$ crude, 85% and 90% yield, respectively). After fractional distillation with a Vigreux column from CaH_2 the final products were obtained in about 15% yield in the final step and 98% chemical purity. Chiral complexation chromatography using a Ni-Nop column (CC&CC, FRG) showed an enantiomeric excess of 80% for both enantiomers. The VCD spectrum of *R*-(+)-2-methylthietane is displayed in Fig. 2. It represents one half of the difference of the average of 20 000 scans for each enantiomer, obtained with 4 cm^{-1} resolution on the VCD spectrometer described previously (9).

For each conformer we have computed the VCD and absorption

intensities with the APT, FPC, and CF models based on the scaled 3-21G and 6-31G* force fields reported earlier (2). The atomic charges (Table 1) were derived by scaling the 6-31G* Mulliken values to give an average charge on hydrogen of +0.06 e, chosen to be in accord with the average of the STO-3G charges on the hydrogen atoms of 2-methyloxetane which reproduce qualitatively the experimental absorption intensities over the CH bending region 1100–1500 cm^{-1} (9). The atomic polar tensors were evaluated analytically for both basis sets as described previously (2).

Table 2 compares the electric dipole moment derivatives calculated with the FPC and APT expressions. The most prominent differences occur for the CH and CS stretching vibrations. For the former the direction of the dipole moment derivative is almost exactly opposite for FPC than for APT. This anomaly has been resolved in the framework of electro-optical parameters by introducing the term $\partial\xi_{CH}/\partial R_{CH} \approx 0.2$ e/Å carrying positive charge from hydrogen to carbon as the CH bond is stretched (12). The present charge flow computation includes this parameter. Although the value of 0.2 e/Å is probably not optimal for 2MT, it demonstrates the general influence of the term as discussed in the following section. For the stretching of the CS bonds FPC underestimates the dipole moment derivative $\partial\mu/\partial R_{CS}$. The charge flow term $\partial\xi_{CS}/\partial R_{CS} = 0.2$ e/Å optimizes the agreement between the CF and APT values of $\partial\mu/\partial R_{CS}$. Clearly the diagonal charge flow term cannot reproduce the difference between the APT values for the two distinct CS bonds, *i.e.* $\partial\mu/\partial R_{C(2)S}$ and $\partial\mu/\partial R_{C(4)S}$, but it does give the average value.

The calculated dipole and rotatory strengths for all calculations are listed in Tables 3 to 6. The experimental rotatory strengths reported in Table 7 were determined from the observed integrated VCD band areas derived from full width at half height measured by means of the band fitting program CAPR supplied by Nicolet. These values, however, are not true rotatory strengths for individual modes since the contributions from the two conformations were not separated. Theoretical spectra, reflecting the 7 to 3 ratio of equatorial to axial conformers deduced previously (2), are compared to the experimental spectra in Figs. 3 to 6.

Results and discussion

Empirical correlations

Two VCD features are of particular interest compared with the spectra of related molecules. Most striking is the strong positive band (for the *R*-(+) enantiomer) observed at 1329 cm^{-1}, arising from the C*—H out-of-plane deformation (peak 14 in Fig. 2). The absolute configuration at the chiral centre and the observed VCD sign for this mode are the same as for propylene sulfide (16), where this band is also the strongest observed feature ($\Delta\epsilon/\epsilon = 4.3 \times 10^{-4}$), and for the oxygen analogues 2-methyloxetane (9) and propylene oxide (17), providing further evidence confirming the C*—H out-of-plane deformation VCD band as a useful probe of the absolute configuration of the X—C*H(CH_3)—CH_2 fragment. It is of further interest to note that the VCD signal of this mode is insensitive to conformational change, *i.e.* ring inversion in this case; the observed and calculated absorption peaks arising from the equatorial and

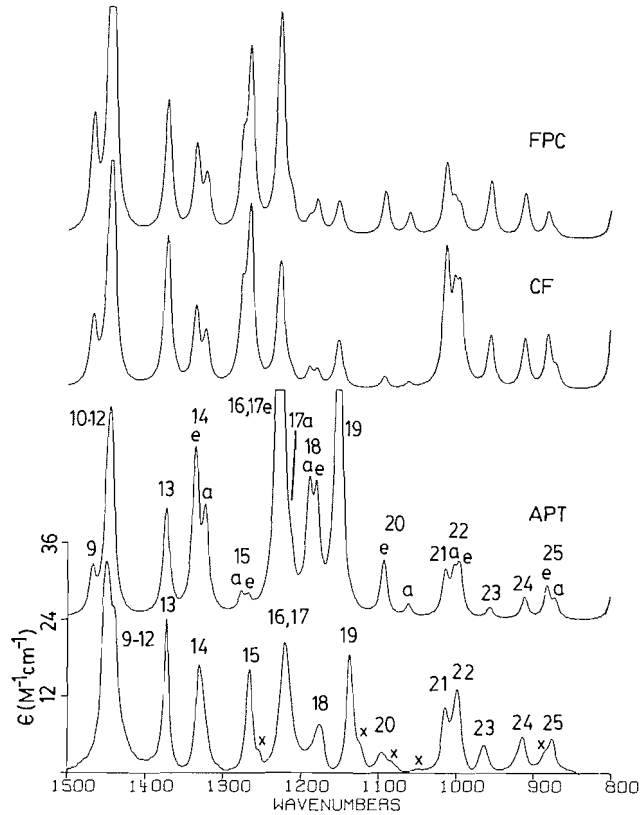

FIG. 3. Experimental (bottom trace) and theoretical absorption spectra (remaining traces) of 2-methylthietane computed with the models as indicated and based on the **6-31G*** force field.

axial conformers are sufficiently separated that a change in sign would be distinctly visible in the VCD spectrum (14.5 cm^{-1} in the vapour phase and 12.8 cm^{-1} by 6-31G*, respectively (2)).

The VCD band corresponding to the methyl symmetric deformation is very weak, as was found also for propylene sulfide (16). In contrast, both 2-methyloxetane (9) and propylene oxide (17) give strong positive VCD bands for the *R* configuration. The different intensities for the sulfur and oxygen analogs cannot be ascribed to changes in the nature of the normal mode which is essentially a pure umbrella motion coupled weakly with the C*—H out-of-plane bend. With the similarity in structure and the normal modes, the difference in the VCD intensities can be attributed, therefore, to electronic influences beyond the FPC model. One possible mechanism involving ring currents has been described qualitatively for 2-methyloxetane (9). It should be noted also that calculations using Stephens' exact formalism (10*b*) do reproduce the observed trend, yielding rotatory strengths of 3.8×10^{-44} (6-31G*) and 11.5×10^{-44} (6-31G**) esu² cm^2 for (*R*)-propylene sulfide (18) and (*R*)-propylene oxide (10*e*), respectively.

Comparison with the VCD spectrum of 2-methyloxetane

For two molecules with common sets of local symmetry coordinates, the normal coordinates of one may be used as the basis for describing the normal modes of the other (2):

$$\mathbf{Q}_2 = \mathbf{L}_2^{-1}\mathbf{L}_1\mathbf{Q}_1$$

where $\mathbf{L}_1$ is the matrix of eigenvectors for molecule **1**, comprised of elements of the type $\partial R_k/\partial Q_{j,1}$. With structural and/or conformational differences between the two molecules,

[c]Angle between $\partial\mu/\partial R_i$ calculated by FPC and CF vs. 6-31G* APT.

this relationship is not rigorously correct since the local symmetry coordinates (the **B** matrix) may not be exactly equivalent. The physical interpretation of this relationship is still clear, however. A diagonal product matrix $\mathbf{L}_2^{-1}\mathbf{L}_1$ implies that the displacements in the local symmetry coordinates comprising the normal modes are identical for the two compounds, while off-diagonal elements express the extent of mixing that occurs. The column vectors of this product matrix then give the normal modes of molecule **1** as a linear combination of a set of coordinates describing the normal modes of molecule **2**.

Having previously reported scaled force fields for 2-methyloxetane at the 3-21G and 6-31G* levels (2, 19), we may use this technique to estimate quantitatively the similarities between the normal modes of the oxygen and sulfur analogues. In Table 7 the calculated frequencies (6-31G*) of 2MO and 2MT are paired according to the most closely matched normal modes (*cf.* Table V, ref. 19, and Table 6, ref. 2, respectively), and the mixing is expressed as the normal modes of the former in terms of those of the latter. Given the flexibility of the four-membered rings and the possibility of two stable conformers in each case, there is some ambiguity in this comparison. We have chosen to compare the vibrational displacements of the optimized 6-31G* structure of 2MO, which is equatorial with a dihedral angle of about 7°, to those of the equatorial conformer of 2MT with a dihedral angle of about 21°.

Several points of interest emerge from this comparison. Although there are exceptions it is generally the case that the leading coefficient in each column vector of the matrix $\mathbf{L}_2^{-1}\mathbf{L}_1$ is double or nearly double the next largest term. This suggests that the majority of normal modes retain much the same character in 2MO as in 2MT. The FPC-VCD calculations are in accord with this conclusion, as the corresponding modes of 2MO and 2MT are predicted with the same sign in 26 of 33 instances despite changes in both the charge distribution and the structure. Differences with respect to corresponding APT-VCD intensities may then be assumed in general to arise from changes in the electronic environment (and hence APTs), with changes in the normal coordinates playing a less important role. Perhaps most interesting is the comparison of the *observed* VCD intensities for *matched* normal coordinates. Most features

[e]APTs calculated using 3-21G.

contain contributions from both the equatorial and axial conformers. The experimental values listed in Table 7 do not represent true rotatory strengths of the two molecules, but serve as measures of the total integrated intensity of possibly overlapped bands. Nevertheless, there is a close correspondence between signs of observed VCD features that correspond to the matched normal modes. For example, mode 20 in 2MO (1136 cm^{-1}) resembles a combination of modes 22 and 24 in 2MT (996 cm^{-1}), and the corresponding VCD features are both positive. We interpret this correspondence as providing experimental evidence supporting both a similarity in the normal modes and a common mechanism dominating the observed VCD intensities.

Calculated spectra 800–1500 cm^{-1}

Considering first the absorption spectra (Figs. 3 and 4, computed at the 6-31G* and 3-21G levels, respectively, and Tables 3 and 4), we note that with few exceptions FPC reproduces qualitatively the observed intensities in the entire range of 800–1500 cm^{-1} at both levels. The most striking discrepancy occurs for ν_{19} at 1137 cm^{-1} (CH_3 rock and α-CH_2 wag (2)) for which both force fields predict a relatively low intensity. This exception aside, the overall picture of stronger bands above and weaker ones below 1150 cm^{-1} is reproduced by all three models.

Since the charge flow calculations include only diagonal parameters for the CH and CS stretches, the CF spectral features might be anticipated to differ from those of FPC only in the CH stretching region, and for the CS stretching absorptions at 630 and 700 cm^{-1}. All of these transitions lie outside the VCD range presently available and therefore cannot be considered here. The corresponding calculated intensities are discussed separately below. The major unexpected changes relative to FPC absorption intensities occur for the bands observed at 999 and 1015 cm^{-1} (ν_{21} and ν_{22}, Figs. 3 and 4), arising largely from combinations of methyl rock (in-plane) and α-CH_2 twist in both conformers (2). The 6-31G* spectra show three features in this

[a–e] See Table 3.

region, the central band representing ν_{22} of the axial conformer. For 3-21G this axial absorption coincides with the lower wavenumber equatorial peak. For both levels of theory the intensities calculated for ν_{21} and ν_{22} are significantly enhanced by the inclusion of charge flow (see Tables 3 and 4) resulting in an exaggeration of the computed bands. We believe the effect of the C—S charge flow term $\partial\xi_{CS}/\partial R_{CS}$ may require compensation by other parameters of the type $\partial\xi_{CS}/\partial R_i$ involving one or several other modes, in this case in-plane methyl rocking and/or α-CH_2 twisting. The need for additional parameters is demonstrated further by ν_{20} arising primarily from the H_3C—C stretch, for which the intensity is significantly reduced from FPC to CF. Finally, we note that the 3-21G CF calculation provides good overall agreement with the corresponding APT intensities (see Fig. 4 and Table 4), which is not the case for 6-31G* (Fig. 3 and Table 3).

The APT calculated absorption spectra (6-31G* and 3-21G) were reported previously (2). As noted on that occasion, the former surprisingly is not clearly more accurate than the latter. In each case the intensities are reasonably accurate below 1150 cm^{-1}, whereas major discrepancies are apparent above. Transitions which are exaggerated most conspicuously at both levels of theory are ν_{16}, ν_{17}, and ν_{19}, modes involving C*—H in-plane bend, α-CH_2 wag, β-CH_2 twist, and CH_3 out-of-plane rock. In addition, ν_{15} arising primarily from the β-CH_2 wagging motion is conspicuously underestimated by 6-31G* and overestimated by 3-21G. The APT spectra are not clearly more accurate in terms of overall agreement with experiment than those of either FPC and CF. Major differences occur for ν_{15} (6-31G* only), ν_{16}, ν_{17}, and ν_{19} for which the APTs generally predict dipole strengths greater by at least a factor of two (Tables 3 and 4).

In contrast to the qualitative success in reproducing absorption intensities, none of the VCD models considered here agree in general with all the observed VCD features. Nevertheless, several points of interest emerge, particularly where agreement may be interpreted to suggest a genuine strength of a model.

If the success of FPC for DDCB does imply a general strength of the model for predicting the VCD spectra of saturated hydrocarbons, as mentioned in the Introduction, then equally good agreement might be anticipated in heteroatom substituted hydrocarbons for modes structurally removed and vibrationally isolated from the point of substitution. For 2MT this should be true for the methyl asymmetric deformation and the methylene

[e]APTs calculated using 3-21G.

scissors, and they would thus be expected to exhibit VCD features as predicted by FPC. It is therefore disconcerting that the VCD signals observed for these modes in the 1430–1470 cm^{-1} region (Figs. 5 and 6 and Tables 5 and 6) are not reproduced in any of the computed spectra. The discrepancies may be due in part to the force field not quite reproducing the correct spacing and/or ordering among the eight transitions (*i.e.* four equatorial and four axial) in this narrow range. Related to this are relatively large changes in the calculated displacements which may result from minor uncertainties in the force field. The agreement or disagreement between the observed and calculated VCD spectra in this region may therefore be unreliable as a guide for assessing the accuracy of the models.

The VCD signs of the bands observed at 1373, 1331, and 1266 cm^{-1}, arising from ν_{13}, ν_{14}, and ν_{15}, respectively (Figs. 5 and 6), and corresponding to CH_3 symmetric deformation, C*—H out-of-plane bend, and β-CH_2 wag (2), are reproduced by all but one of the calculations. The exception occurs for ν_{15} with the 6-31G* APTs. In this instance, the calculated absorption intensity is also in significant error, indicating that inaccuracies in the APTs are likely responsible and fortuitously magnified for this model in particular. All of the other computations yield opposite VCD signs for ν_{15} for the two conformers, negative for equatorial and positive for axial; the negative observed sign is reproduced only by assuming that the equatorial conformer predominates at the measurement temperature. This behaviour is analogous to that of 2-methyloxetane where the same mode was interpreted to also suggest a preference for the equatorial conformation (9). For the CH_3 symmetric deformation and C*—H bending modes the observed and calculated VCD signs for 2MT also match those of the corresponding modes in 2MO, although the VCD signals are relatively insensitive to conformation in these cases. The large difference in intensity for the CH_3 symmetric deformation between 2MO to 2MT is not reproduced by FPC or APT, suggesting that vibrationally induced electronic displacements likely play an important role governing the observed intensity. For the C*—H out-of-plane deformation (ν_{14}) the equatorial and axial transitions are well separated in the vapour phase absorption spectrum

[a]Calculated with scaled 6-31G* force field at the optimized (~6° equatorial) 6-31G* structure (ref. 2).

[b]Expresses normal coordinates of 2MO in terms of those of 2MT according to $Q_i^{2MO} = c_{i,j}Q_j^{2MT} + c_{i,k}Q_k^{2MT}$, $c_{i,j}$ and $c_{i,k}$ are the dominant elements in the product matrix $\mathbf{L}_{2MO}^{-1}\mathbf{L}_{2MT}$, derived from the eigenvectors in local symmetry coordinates. See text.

[c]Compares 6-31G* APT and FPC VCD intensities. FPC intensities of 2MO were calculated with the charges in ref. 9 and the force field in ref. 2. 6-31G* APTs were calculated in ref. 2.

[d]Compares observed VCD intensities for corresponding modes of 2MT (this work) and 2MO (ref. 9). Experimental values are not true rotatory strengths, since each observed band is a superposition of the equatorial and axial conformers.

(2), and the 6-31G* force field reproduces this splitting (Figs. 3 and 5). The width of the observed bands in solution must therefore arise from the equatorial and axial transitions, the former occurring at higher wavenumber with greater intensity, and both having the same VCD sign. The axial bands emerge as distinct shoulders upon Fourier self-deconvolution.

These examples illustrate the distinction between VCD configurational and conformational marker bands, the signs of the former being relatively insensitive to conformational change, while the latter strongly depend on it. The C*—H out-of-plane bending and β-CH_2 wagging modes, respectively, demonstrate this behaviour, as seen here for 2-methylthietane in the observed as well as all the model spectra, and earlier for 2-methyloxetane (9).

The 1050–1250 cm^{-1} region contains several heavily mixed bending modes. Four features are clearly visible in the VCD spectrum, occurring at 1222 (+), 1175 (−), 1137 (+), and 1097 (−) cm^{-1} (ν_{16}, ν_{18}, ν_{19}, and ν_{20}, respectively). All FPC and CF calculations predict precisely the opposite sign pattern. The 6-31G* APTs predict the correct sign for only two of the four (namely, ν_{18} and ν_{20}), while those of 3-21G provide better overall agreement in this region with but one exception (ν_{19}). The weak couplet labelled ν_{16} and ν_{17} in Fig. 6 appears to be well modeled by 3-21G APTs (the negative lobe of ν_{17} showing faintly in the observed spectrum is clearly evident upon Fourier self-deconvolution). This agreement may be fortuitous, since the computed ordering of the dominant transitions, namely ν_{16} and ν_{17} of the equatorial conformer, is opposite to that predicted by the 6-31G* force field (see Tables 3 and 4). Finally, the negative band observed at 1096 cm^{-1} (ν_{20} in Figs. 5 and 6) corresponds to the negative band predicted by 3-21G APTs for the equatorial conformer at 1125 cm^{-1} (Table 6 and Fig. 6). The

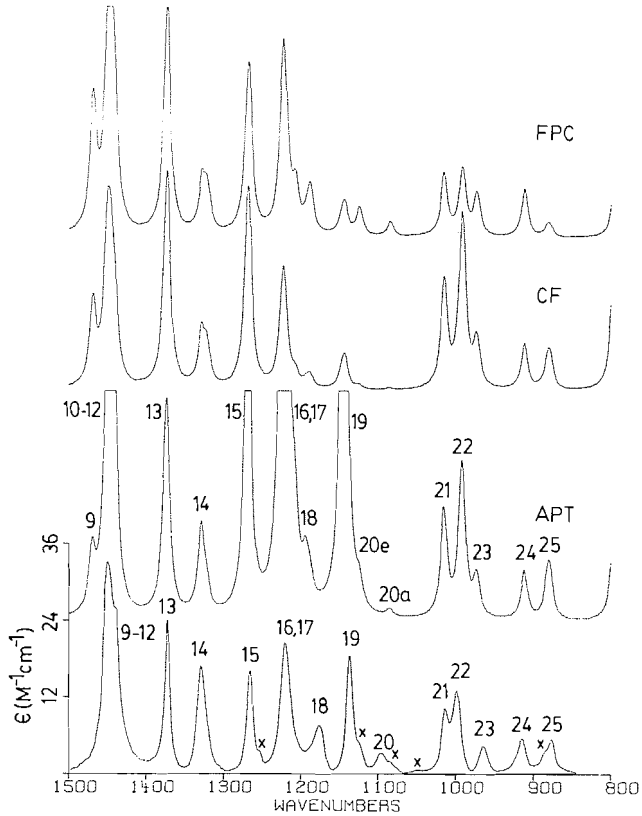

FIG. 4. Experimental (bottom trace) and theoretical absorption spectra (remaining traces) of 2-methylthietane computed with the models as indicated (remaining traces) and based on the **3-21G** force field.

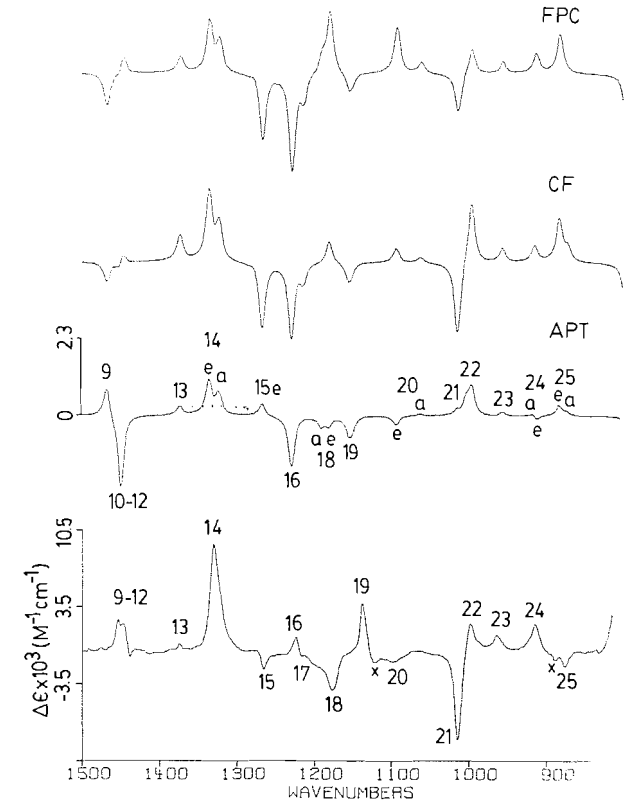

FIG. 5. Experimental (bottom trace) and theoretical VCD spectra (remaining traces) of *R*-(+)-2-methylthietane computed with the models as indicated and based on the **6-31G*** force field.

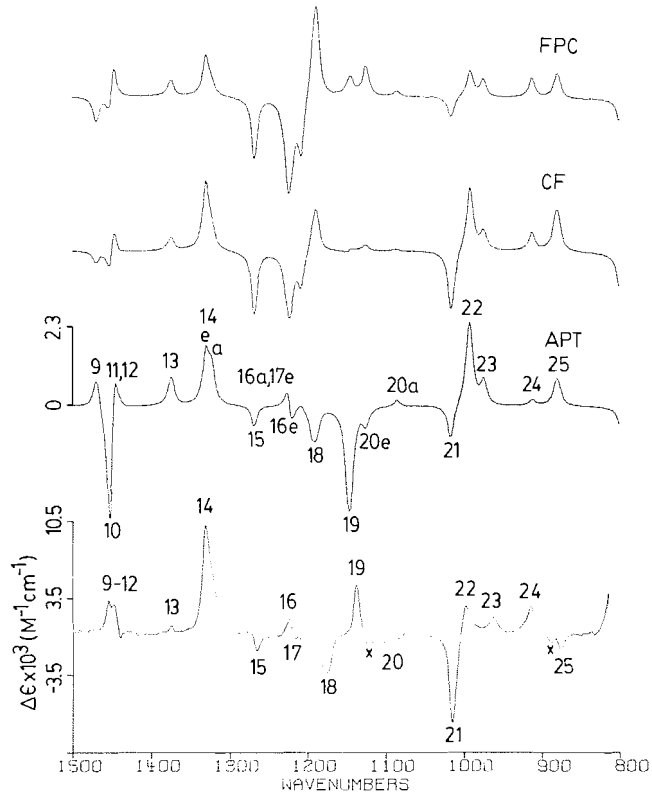

FIG. 6. Experimental (bottom trace) and theoretical VCD spectra (remaining traces) of *R*-(+)-2-methylthietane computed with the models as indicated and based on the **3-21G** force field.

positive VCD feature predicted at 1085 cm^{-1} arises from the same mode of the axial conformer. Both transitions show as clear vapour phase bands at 1101.4 and 1061.5 cm^{-1} (2) and are very well matched by the 6-31G* force field (Tables 3 and 4).

In the 800–1050 cm^{-1} range all of the calculations except 6-31G* APT are remarkably accurate, reproducing four of the five observed VCD signs (ν_{21} to ν_{24} and ν_{25}, respectively). These bands arise from combinations of CH_3 rocking and α-CH_2 twisting (ν_{21} and ν_{22}), H_2C—C stretching (ν_{23}), combination of methyl and methylene rocking (ν_{24}), and CH_3C—C stretching (ν_{25}). The enhancement of the absorption intensities for ν_{21} and ν_{22} upon introducing C—S charge flow with both force fields (3-21G and 6-31G*) was noted earlier in this section. The influence of the C—S stretching charge flow parameter on the intensity of the corresponding VCD couplet is even more striking, improving remarkably the agreement with the observed contour. Although this enhancement does not provide conclusive evidence, it does suggest strongly that the limited charge flow represented by the single parameter improves the physical description of the electronic response to these vibrations.

Calculated spectra in the CH and CS stretching regions

As demonstrated earlier (2), the 6-31G* APTs give a good reproduction of the CH stretching absorptions, whereas FPC underestimates essentially all of these intensities. By including the diagonal charge flow term $\partial\xi_{CH}/\partial R_{CH} = 0.2$ e/Å tranferring positive charge from hydrogen to carbon as the C—H bond is stretched, the discrepancies between FPC and APT are diminished appreciably (Table 3). For FPC the electric dipole moment derivative $\partial\mu/\partial R_{CH}$ is lower by a factor of three or four on average compared to 6-31G* APTs, and the direction is almost exactly *opposite* (see Table 2). The charge flow term

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

reverses the direction of $\partial\mu/\partial R_{CH}$ and increases its magnitude to about the 6-31G* APT value.

The computed CF-VCD intensities of the CH stretching modes similarly approach the APT values in most cases (Table 5). Both models reflect similar VCD mechanisms, *i.e.* the disymmetric coupling of separate oscillating moments. The electric moments in each case follow the direction of the bond stretching displacements, as inferred by eqs. [9] and [10]. The FPC model implies a fundamentally different source of VCD intensity for these modes in that the bond dipole moment derivatives lie in the opposite direction to both CF and APT. The fortuitous agreement in sign between FPC and CF is due to the fact that for a given normal coordinate displacement *both* the electric and magnetic dipole moments are reversed in sign for FPC relative to the CF and APT models. The predicted VCD sign is thus unaffected, as the rotatory strength is given by the product of these derivatives. This further explains the reported successes of the FPC model in qualitatively reproducing a number of CH stretching VCD spectra, and the paradox that a set of atomic charges optimized to fit the mid-infrared absorption and VCD features inevitably underestimates the CH stretching VCD intensities. The single charge flow parameter $\partial\xi_{CH}/\partial R_{CH} = 0.2$ e/Å both resolves this paradox and provides a model of electronic behaviour that is in close accord with the requirements dictated by *ab initio* calculations.

The charge flow parameter $\partial\xi_{CS}/\partial R_{CS}$ is most important for the two CS stretches ν_{27} and ν_{28}, as well as ν_{29}, a ring deformation mode that includes some CS stretching. The value of $\partial\mu/\partial R_{CS}$ increases from 0.04 to 0.34 and 0.35 e for the two stretches, compared to the 6-31G* APT values of 0.26 and 0.42 e, respectively, and reduces the orientation of the $\partial\mu/\partial R_{CS}$ vector with respect to APT from 117 and 123° to 2 and 19°, respectively (Table 2). The calculated absorption intensities for all three modes and for both conformers are markedly improved, although the relative intensities for the CS stretches are interchanged relative to APT (Table 3). Most striking are the changes in the VCD intensities for the three modes. Whereas FPC predicts signs opposite from APT in five of the six instances, ν_{27}^{eq} being the exception, CF matches APT in all but one case, namely ν_{29}^{eq} (Table 5). This convergence of CF and APT results suggests that a predominant source of VCD intensity is the coupling of the stretching coordinates, each of which gives rise to a change in dipole moment that is localized along the bond axis. This mechanism is analogous to that discussed above for the CH stretches, and the similarity between the CF and VCD intensities is rationalized by the arguments presented in the Theoretical background section.

In our previous study of the VCD spectrum of 2MO (9) it was demonstrated that by including the analogous charge flow parameter $\partial\xi_{CO}/\partial R_{CO}$ the calculated absorption and VCD intensities, compared with the experimental spectra, are improved relative to FPC for each of the four ring stretching modes. Although the corresponding CS bands lie below the accessible range of our present instrumentation, the computed spectra for 2MT show precisely the same trend as for 2MO. We believe, therefore, that the mechanism discussed in the Theoretical background section plays an important role in generating VCD intensity for the ring stretching modes, and that the CF and APT models represent this mechanism with comparable accuracy.

Summary and conclusions

In this report we present the experimental VCD spectrum of 2-methylthietane (2MT) in the region of 800 to 1500 cm^{-1}, and theoretical VCD spectra in the complete fundamental region. We have tested the approximate models of fixed partial charge (FPC), charge flow (CF) using only two charge flow parameters, one for each of the C—H and C—S bonds, and atomic polar tensors (APT), based on scaled 3-21G and 6-31G* *ab initio* harmonic force fields, against the measured absorption and VCD spectra, and compared the success of each model against one another.

The relatively poor performance of FPC may be traced to significant induced charge displacements that do not follow the direction of nuclear displacements. Morever, FPC generally fails to replicate the APT calculated magnitudes and orientation of the electric dipole transition moments, $\partial\mu/\partial R_i$. This is true even for many of the CH, CH_2, and CH_3 deformations, *i.e.* modes that closely follow FPC behaviour for the saturated hydrocarbons *trans*-1,2-dideuteriocyclobutane and *trans*-1,2-dideuteriocyclopropane. The same analysis for 2-methyloxetane indicated that the β-CH_2 and CH_3 deformations are amenable to FPC modeling based on relatively good agreements among the electric dipole transition moments both in magnitude and direction. The larger discrepancies for 2-methylthietane may be ascribed to polarization induced in the sulfur atom or the CS bond by the motion of fixed partial charges on the hydrogen atoms that are constant throughout the vibrational cycle. Within the charge flow formalism such influences would be reflected in significant terms of the type $\partial\xi_{CS}/\partial R_X$, where ξ_{CS} is the C—S bond charge and X may represent CH, CH_2, or CH_3 deformations.

Despite the generally poor performance of FPC it has been shown that the β-CH_2 wagging mode satisfies the criteria that we have deduced earlier for revealing FPC-like behaviour (9). Namely, (*1*) the FPC model calculation provides a dipole moment derivative $\partial\mu/\partial R_i$ (i = β-CH_2 wag) that closely matches the *ab initio* value, and (*2*), the β-CH_2 moiety is well removed from the sulfur atom and hence deformations such as the wag and localized at this point would be expected to reflect FPC-like behaviour as was found for saturated hydrocarbons. The observation of a negative VCD feature corresponding to the β-CH_2 wag is thus in accord with a preponderance of the equatorial conformer, with both FPC calculations predicting negative and positive features, respectively, for the equatorial and axial conformers. This analysis demonstrates that models such as FPC that are not uniformly accurate may nevertheless prove useful for stereochemical purposes when more elaborate calculations are not practical.

Earlier in the text we described an indirect method with which the dominant diagonal stretching charge flow terms may be determined by constraining the resulting dipole moment derivative to reproduce the *ab initio* value, 6-31G* in the present case (see eq. [9]). This procedure suggested appropriate values for $\partial\xi_{CH}/\partial R_{CH}$ and $\partial\xi_{CS}/\partial R_{CS}$. It also led to the close agreement between the resulting CF and APT intensities, rationalized by showing that for pure stretching modes the two models are formally equivalent with the constraint that each bond stretch contributes to the overall dipole moment change through a term that follows the bond axis exactly. This observation further explains why both the APT and CF methods should reproduce successfully the ring stretching VCD signs for 2-methyloxetane (9) and suggests that similar accuracy might be anticipated for the as yet unmeasured VCD features associated with the CS stretches of 2-methylthietane. The large CH stretching parameter has been recognized previously (12) as being necessary to resolve the fact that charges optimized to best reproduce the mid-infrared absorption intensities provide CH stretching inten-

For personal use only.

sities markedly lower than observed. We have demonstrated here the effectiveness of this term in resolving the corresponding discrepancies in the VCD spectrum, and have further rationalized previous successes of FPC calculations in the CH stretching region by showing that the charge flow and APT models provide essentially the same sign pattern.

A technique, exploited previously as a means of quantitatively estimating the similarities between normal coordinates of isotopically ($10d$) and conformationally (2, $10d$) distinct isomers, has been adopted here to provide a correlation between the normal coordinates of 2-methylthietane and 2-methyloxetane. The computed VCD intensities were then compared for each pair of matched normal coordinates, demonstrating close similarity in the FPC-VCD signs. Most significantly, this analysis permitted correlation between experimental VCD features measured for the two molecules, revealing a nearly unanimous matching of VCD signs observed for common modes and hence implying similar mechanisms underlying the VCD spectra of both compounds. This technique shows promise as a means of separating purely dynamic factors, *i.e.* changes or similarities in normal coordinates, from other influences affecting both computed and experimental spectra of structurally similar molecules ($10d$).

It is clear from this and other studies that the FPC and APT-VCD models are accurate only in favorable circumstances. Close analysis of such calculations has nevertheless proven useful in that they have confirmed the expectation that an extension of the charge flow model incorporating additional terms might lead to systematic improvements in the calculated absorption and VCD spectra. Both this study and that of 2-methyloxetane (9) strongly indicate that the limited set of parameters examined to date, viz. $\partial\xi_{CH}/\partial R_{CH}$, $\partial\xi_{CO}/\partial R_{CO}$, and $\partial\xi_{CS}/\partial R_{CS}$, reflect genuine contributions to the observed vibrational absorption and VCD spectra. Methods are being developed in our laboratory to provide *ab initio* estimates for complete sets of charge flow parameters (20), with preliminary results entirely consistent with this and previous (9) work.

NOTE ADDED IN PROOF. The accuracy of the FPC and APT models for calculating rotatory strengths and hence predicting VCD spectra has been questioned on several occasions, as indeed we emphasize here also for 2-methylthietane. As one of the referees has pointed out in the proof stage, Stephens and co-workers have recently compared in explicit detail the FPC and APT (and also the coupled oscillator) equations to Stephens' rigorous theory of vibrational rotatory strengths for a number of small chiral molecules, with the conclusion that the simple models, APT in particular, omit a magnetic moment contribution, namely the so-called $\mathbf{P}\cdot\mathbf{M}$ term (21). Stephens *et al.* further recommend against the use of the simple semi-empirical models for computing VCD intensities in the future, although they concede, though not believe, that for larger size molecules the $\mathbf{P}\cdot\mathbf{M}$ term may assume less dominance. According to our thinking, which largely coincides with that of Stephens' group, we are attempting to identify systematically those vibrational modes that are amenable to VCD intensity predictions by the simpler models, and extend this experience to larger molecules. In this manner we expect to gain a qualitative appreciation of the VCD mechanism which in the long run may contribute to improving theoretical formalisms. Our recent efforts to interpret the VCD spectrum of 6,8-dioxabicyclo[3.2.1]octane demonstrate this approach (22).

Lewis acidic titanium species: the synthesis, structure, bonding and molecular modelling considerations of the complexes $Ti(NR_2)_3Cl$ (R = Me, Et)

DAVID G. DICK, ROGER ROUSSEAU, and DOUGLAS W. STEPHAN[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received June 29, 1990

DAVID G. DICK, ROGER ROUSSEAU, and DOUGLAS W. STEPHAN. Can. J. Chem. **69**, 357 (1991).

Reaction of simple amides with $TiCl_4$ affords mixed amido-chloride species $Ti(NR_2)_{4-n}Cl_n$. The trisamide-chloride species $Ti(NR_2)_3Cl$ can be prepared directly employing three equivalents of amide or by reaction $Ti(NR_2)_4$ with $TiCl_4$. The compound $Ti(NMe_2)_3Cl$, **1**, crystallizes in the trigonal space group $R\bar{3}c$, with $a = 11.525(5)$, $c = 14.939(3)$ Å, $Z = 6$, and $V = 1718(1)$ Å^3. The compound $Ti(NEt_2)_3Cl$, **2**, crystallizes in the monoclinic space group $P2_1/c$, with $a = 8.385(2)$ Å, $b = 15.958(2)$ Å, $c = 14.230(4)$ Å, $\beta = 107.79(1)°$, $Z = 4$, and $V = 1813(1)$ Å^3. The geometry of the Ti coordination sphere in these complexes is best described as pseudo-tetrahedral. The structural data are consistent with Ti—N multiple bonding. Preliminary results of EHMO calculations are consistent with d_π—p_π Ti—N bonding. Attempts to replace the halides with phosphides ($LiPR_2$, R = Me, Et, Ph) led not to the Ti(IV) phosphido species, but rather to redox chemistry yielding Ti(III) amides and P_2R_4. The barrier to rotation about the Ti—N bonds has been considered. Variable temperature ^1H NMR studies reveal that the barrier is small. Extended Hückel total energy minimization calculations have been performed. In addition, MMX calculations of the barrier to Ti—N rotation are reported. The results of these calculations imply that the rotational barrier is dominated by steric effects.

Key words: titanium amides, structures, Ti—N bonding.

DAVID G. DICK, ROGER ROUSSEAU et DOUGLAS W. STEPHAN. Can. J. Chem. **69**, 357 (1991).

Les réactions d'amides simples avec du $TiCl_4$ fournissent des chlorures d'amides mixtes, $Ti(NR_2)_{4-n}Cl_n$. On peut préparer directement le chlorure de tris(amide), $Ti(NR_2)_3Cl$, en utilisant trois équivalents d'amide ou par réaction du $Ti(NR_2)_4$ avec du $TiCl_4$. Le composé $Ti(NMe_2)_3Cl$, **1**, cristallise dans le groupe d'espace trigonal $R\bar{3}c$, avec $a = 11,525(5)$ et $c = 14,939(3)$ Å, $Z = 6$ et $V = 1718(1)$ Å^3. Le composé $Ti(NEt_2)_3Cl$, **2**, cristallise dans le groupe d'espace monoclinique $P2_1/c$, avec $a = 8,385(2)$, $b = 15,958(2)$, $c = 14,230(4)$ Å, $\beta = 107,79(1)°$, $Z = 4$ et $V = 1813(1)$ Å^3. Un pseudo-tétraèdre est la meilleure façon de décrire la géométrie de la sphère de coordination de ces complexes. Les données structurales sont en accord avec une liaison Ti—N multiple. Les résultats préliminaires de calculs d'OMHE sont en accord avec une liaison Ti—N du type d_π—p_π. Lorsqu'on a voulu remplacer les halogénures par des phosphures ($LiPR_2$, R = Me, Et, Ph) on n'a pas obtenu les espèces Ti(IV)phosphido, mais plutôt une chimie rédox fournissant des amides du Ti(III) et du P_2R_4. On a considéré la barrière à la rotation autour des liaisons Ti—N. Des études de rmn du ^1H à température variable révélent que la barrière est faible. On a effectué des calculs de minimisation de l'énergie totale par le méthode du Hückel étendu. De plus, on a réalisé des calculs MMX de la barrière de rotation Ti—N. Les résultats de ces calculs impliquent que la barrière à la rotation est dominée par des effets stériques.

Mots clés : amides du Ti, structure, liaison Ti—N.

[Traduit par la rédaction]

Introduction

Our interest in Lewis acidic, early metal species stems from our studies of early/late heterobimetallic (ELHB) complexes (1–15). Investigation of such compounds are motivated by the potential for Lewis acid activation of small molecule substrates like CO or CO_2. In initiating efforts to synthesize more reactive ELHB complexes, we are exploring the incorporation of early metal fragments which exclude Cp ligands and offer effective Lewis acidity. To this end, it may be possible to derivatize the species $Ti(NR_2)_3Cl$, and thus incorporate this early metal moiety into an ELHB complex. In this, our initial report on these efforts, we have prepared and structurally characterized two complexes of the form $Ti(NR_2)_3Cl$. Conformational aspects and the nature of the bonding in these Lewis acidic, early metal species are considered. Preliminary attempts to derivatize these species are described and the implications for incorporation in ELHB complexes are discussed.

Experimental section

All preparations were done under an atmosphere of dry, O_2-free N_2 in a Vacuum Atmospheres' Inert Atmosphere glove box. The quality of the atmosphere was maintained employing a 5 cfm blower, a deoxygenation/drying catalyst column and a molecular sieve prepurifier canister. Solvents were reagent grade, distilled from the appropriate drying agents under N_2, and degassed by the freeze–thaw method at least three times prior to use. ^1H and $^{13}C\{^1H\}$ NMR experiments were performed using a Bruker AC-300 MHz spectrometer employing trace amounts of protio solvent as the internal reference. Chemical shifts are reported relative to $Si(CH_3)_4$. $^{31}P\{^1H\}$NMR experiments were performed using a Bruker AC-200 MHz spectrometer. The spectral data were referenced to external 85% H_3PO_4 in D_2O. Combustion analyses were performed by Galbraith Laboratories Inc., Knoxville, TN. Crystalline samples were shipped in ampoules sealed under an atmosphere of N_2. The compounds $Ti(NR_2)_4$ (R = Me, Et) were synthesized employing literature methods (16).

*Preparation of $Ti(NR_2)_3Cl$ (R = Me, **1**; Et, **2**)*

(a) From $Ti(NR_2)_4$

These compounds were prepared in a similar manner and thus only one description is given. To a 50 mL hexane solution $Ti(NEt_2)_4$ (2.00 g, 5.95 mmol) was added $TiCl_4$ (6.0 mL of a 0.33 M solution in benzene, 1.98 mmol) at −65°C. The mixture was allowed to warm to 25°C. The solution was stirred for 2 h. The solvent was removed *in vacuo* and the residue was distilled to give a yellow oil (bp 105°C, 0.1 Torr), yield (0.880 g, 37%).

(b) Direct synthesis

These compounds were prepared in a similar manner and thus only one description is given. To a 50 mL hexane solution $HNEt_2$ (14.80 mL, 0.143 mol) was added *n*-BuLi (57.2 mL, 2.5 M, 0.143 mol) at −65°C. To this solution was added a hexane solution (50 mL) containing $TiCl_4$ (5.25 mL, 0.0477 mol). The addition was performed at −65°C and the mixture was allowed to warm to 25°C. The solvent was removed *in vacuo* and the residue was distilled to give a yellow oil (bp 105°C, 0.1 Torr) yield (11.3 g, 79%). **1**: ^1H NMR (d_8-toluene): δ

Reactions of $Ti(NEt_2)_3Cl$ with $LiPR_2$ (R = Me, Et, Ph)

To a hexane solution of **1** (0.400 mg, 1.350 mmol) was added an equivalent of the Li salt of the phosphide (*i.e.*, $LiPMe_2$, $LiPEt_2$, or $LiPPh_2$). The solution becomes orange brown in colour on stirring. Monitoring the reaction via $^{31}P\{^1H\}$ shows the growth of the resonance attributable to the appropriate P_2R_4 species.

X-ray data collection and reduction

Diffraction experiments were performed on a four-circle Syntex $P2_1$ diffractometer with graphite-monochromatized Mo Kα radiation (λ = 0.71069 Å). The initial orientation matrices were obtained from 15 machine-centred reflections selected from rotation photographs. These data were used to determine the crystal systems. Partial rotation photographs around each axis were consistent with a trigonal crystal system for **1** and a monoclinic crystal system for **2**. The final lattice parameters and the orientation matrices were determined from 30 and 29 high-angle data ($20° < 2\theta < 25°$) for **1** and **2**, respectively. The observed extinctions were consistent with the space groups $R\bar{3}c$ for **1** and $P2_1/c$ for **2**. $-h, +k, +l$ were collected ($4.5° < 2\theta < 45.0°$) for **1**, and $\pm h, +k, +l$ data were collected ($4.5° < 2\theta < 40.0°$) for **2**. In each case, three standard reflections were recorded every 197 reflections. The intensities of the standards showed no statistically significant change over the duration of the data collection. The data were processed using the SHELX-76 program package.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (17–19). The heavy atom positions were determined using direct methods. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinement was carried out by using full-matrix least squares techniques on F, minimizing the function $w(|F_o| - |F_c|)^2$ where the weight, w, is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of each refinement, the titanium, chlorine, nitrogen, and carbons were assigned anisotropic temperature factors. The hydrogen atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. The hydrogen atom contributions were calculated, but not refined. The residual electron densities, in each case, were of no chemical significance. Crystal data and data collection parameters are summarized in Table 1. Tables of positional parameters (Table 2) and selected bond distances and angles (Table 3) are reported. Thermal parameters (Table S1), hydrogen atom parameters (Table S2), and calculated and observed structure factors (Table S3) have been deposited.[2]

Molecular modelling considerations

Energy minimization calculations were performed employing the MMX and MM2 options of the program package PC-MODEL[3] operating on a PC equipped with a 80386 processor and a 80387 numerical coprocessor. Initial molecular coordinates were taken from the X-ray structural studies.

Molecular orbital calculations

These calculations and plotting were performed employing the TRIBBL program package (20) operating on a VAX 3520 workstation. Extended Hückel calculations were performed employing the EHT option of TRIBBL. Geometry optimizations were done using the OPT9 routine. Cartesian coordinates of the various models were derived from the perturbations of the crystallographic data presented herein, employing PC-MODEL.

Results and discussion

The complexes $Ti(NR_2)_3Cl$ (R = Me **1**, Et **2**) were initially prepared by the reaction of $Ti(NR_2)_4$ and $TiCl_4$ employing the appropriate ratio to afford the desired product (reaction [1]). In both cases, the orange–yellow distillate crystallizes on standing in an inert atmosphere. Alternatively, these compounds can be prepared by the direct reaction of three equivalents of the

appropriate amide salt with $TiCl_4$ (reaction [2]). The ^1H NMR spectrum of **1** shows the a single resonance attributable to the methyl groups on the amide while the spectrum of **2** confirmed the presence of ethyl groups in the product. The results of combustion analyses were consistent with the formulations of **2** as $Ti(NEt_2)_3Cl$. These formulations were further confirmed by X-ray crystallographic studies (*vide infra*). Similar synthetic routes to these compounds were previously established by Benzing and Kornicker (21) and Chandra and Lappert (22). However, this report is the first to describe the isolation of **2** as a crystalline solid. Small amounts of either other $Ti(NR_2)_{4-n}Cl_n$ species or oxidation or hydrolysis products may account for the oils obtained by previous workers.

[1] $3Ti(NR)_4 + TiCl_4 \rightarrow 4Ti(NR_2)_3Cl$

[2] $3M(NR_2) + TiCl_4 \rightarrow 4Ti(NR_2)_3Cl + 3MCl$

Reactions with phosphides

Attempts to effect substitution reactions in which phosphido groups replace the chloride in **1** or **2** met with failure. Employing lithium disubstitutedphosphides where the substituents were phenyl, methyl, or ethyl groups led not to substitution, but rather to reduction of the Ti, presumably to $Ti(NR_2)_3$. In the case of R = Me this product is known to be dimeric (22). The phosphorus containing oxidation products in these reactions are of the form P_2R_4 where R = Ph, Me, Et. These species were identified by $^{31}P\{^1H\}$ NMR and were the only diamagnetic phosphorus containing products of the reactions. Related results have shown that other Ti(IV) species are reduced by phosphides to Ti(III) compounds. These results do not auger well for the synthesis of Ti(IV) phosphide derivatives and their subsequent use as synthons for ELHB complexes. However, bulkier substituents on the either the amides or the phosphide may inhibit bimolecular redox processes involved in electron transfer and thus stabilize complexes of the form $Ti(NR_2)_3(PR'_2)$. Current efforts are directed at this proposition.

Structural studies

The X-ray crystallographic study of **1** showed that the molecule crystallizes in the space group $R\bar{3}c$ with six independent molecules in the unit cell. An ORTEP drawing of **1** is shown in Fig. 1. The closest approach between molecules is 2.551 Å (H1B—H1B). The symmetry of the space group dictates that the Ti and Cl atoms sit on a crystallographically imposed threefold axis. Thus, the asymmetric unit is comprised of a single dimethylamido group, and one third of the Ti and Cl atoms.

Crystallographic study of **2** shows that the compound crystallizes in the space group $P2_1/c$ with four molecules in the unit cell. An ORTEP drawing of **2** is shown in Fig. 2. The closest approach between molecules is found to be 2.452 Å (H12A—H6C). In this case, no crystallographic symmetry is imposed on the individual molecules and thus, the contents of the asymmet-

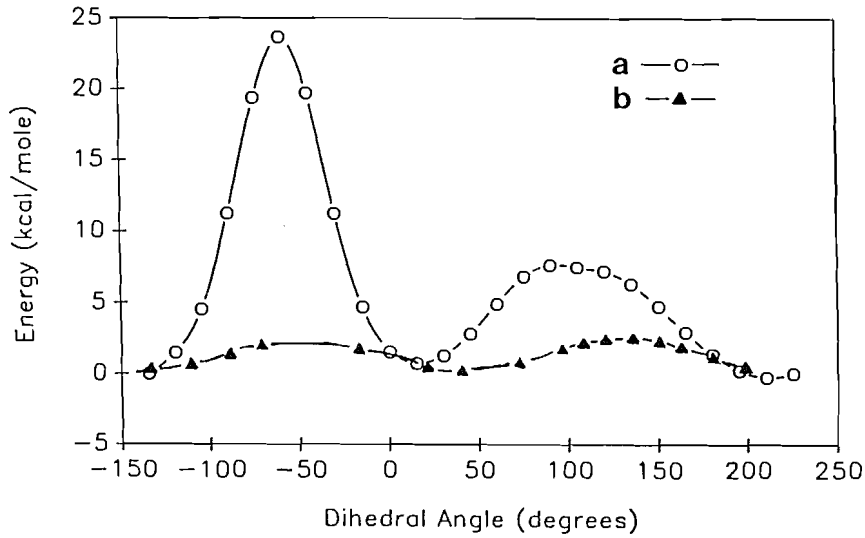

FIG. 4. (*a*) Plot of the energy barrier to Ti—N rotation for $Ti(NH_2)_3Cl$ derived from MMX calcualtions. (*b*) Plot of Extended Hückel total energy minimization curve for Ti—N rotation for $Ti(NH_2)_3Cl$ obtained employing OPT9 of TRIBBLE.

ric unit is a single molecule of **2**. The mononuclearity of the present compounds is in contrast to the tetrameric aggregates formed by $(Me_2N)_2TiF_2$ units (23) and the infinite chain structure formed by $(Et_2N)TiCl_3$ fragments (24).

For both **1** and **2**, the geometry of the Ti atoms of these monomeric species are best described as pseudo-tetrahedral, each being bonded to three nitrogen atoms and a chlorine. The Ti—Cl distances were found to be 2.300(3) Å in both molecules **1** and **2**. This compares to the Ti—Cl distances of 2.360, 2.708, and 2.251 Å found in $[(Et_2N)TiCl_3]_n$ (24). The Ti—Cl distance found in **1** and **2** is slightly shorter than that found in $Cp_2TiCl(C_5H_3N_4)$ (2.338 Å) (25) consistent with the Lewis acidity of the Ti centres in the present compounds. The Ti—N distances are similar being 1.866(4) Å in **1** and averaging 1.861(7) Å in **2**. In comparison, the Ti—N distance found in $[(Et_2N)TiCl_3]_n$ was 1.852(4) Å (25). In $[(Me_2N)_2TiF_2]_4$, the Ti—N distances of 2.14(3) and 2.19(3) Å correspond to the bridging amido groups while the Ti—N distances for terminal amido groups was found to be 1.99(3) Å (23). Similarly, the terminal Ti—N distances in the dimer $[Ti(NMe_2)_2(\mu\text{-N-}t\text{-Bu})]_2$ (1.914(2) Å) (26) were found to be slightly longer than those observed for **1** and **2**. Ti—N distances comparable to those in **1** and **2** were found in $Ti(OC_6H_2(t\text{-Bu})_3)_2(NMe_2)_2$ (1.878(5) Å) (27), $Ti(NMe_2)_2(O_2CNMe_2)_2$ (1.882(5) Å) (28) as well as the metallated Ti species $CpRu(CO)_2Ti(NMe_2)_3$ (1.885 (6) Å) (29). The N—Ti—N′ angle in **1** was found to be 105.4(2)° and ranged from 106.7(2) to 108.2(2)° in **2**. The Cl—Ti—N angle in **1** is 113.3(2)° whereas in **2** it averaged 111.4°. The angles about the nitrogen atoms sum to 360° indicative of the planarity at nitrogen, and suggestive of multiple bond character between the Ti and N. Such bonding is intuitively attributable to the Lewis acidity of the early metal centre. The C—C bond distances and angles within the ethyl moieties of **2** are as expected and precipitate no further comment.

Bonding considerations

The results of preliminary Extended Hückel calculations on the model compound $Ti(NH_2)_3Cl$ were considered. The calculated molecular orbital σ bonding framework of the molecule is as expected. Among the higher energy filled molecule orbitals are those attributable to Ti—N d_π—p_π bonding. One perspective of such bonding is shown in Fig. 3. The HOMO is a nonbonding orbital comprised of *p* orbital contributions from the N atoms. The LUMO is primarily titanium d_{z^2} in character. A more detailed treatment of the bonding in Lewis acidic early metal compounds will be forthcoming.[4]

Conformational considerations

The implication of Ti—N multiple bonding on the basis of structural and theoretical data for **1** and **2** raises the question regarding inhibited rotation about the Ti—N bonds. Variable temperature ^1H NMR studies of **1** and **2** over the temperature range 25 to −95°C were performed. In both cases, no change other than a slight changes in linewidth occurred on cooling to −95°C. This is in contrast to the temperature dependent spectra exhibited by $Zr(N(SiMe_3)_2)_3Cl$, **3** (ref. 30 and footnote 5). In the case of **3**, the spectra are interpreted in terms of the temperature dependence of rotation of the Zr—N bonds. It is intuitively expected on the basis of simple steric considerations, that rotation of the M—N bonds in **1** and **2** would occur more readily than in **3**.

One approach to questions of steric and conformational effects is offered by molecular mechanics calculations. Although this technique is best suited for applications in organic chemistry, it is of interest to examine the utility of these calculations in simple inorganic systems where the metal centre is approximately tetrahedral. Energy minimization calculations were performed on the model compound $Ti(NH_2)_3Cl$. The geometry of the initial model was derived from the crystallographic data. A total energy profile was calculated as a function of rotation of one of the Ti—N bonds. The energy barrier to rotation calculated was to be 25 kcal/mol for $Ti(NH_2)_3Cl$. Geometry optimization based on Extended Hückel energy calculations were also performed. The total energy was calculated as a function of rotation about a single Ti—N bond. The calculated barrier is small, on the order of 2–3 kcal/mol. These calculated energy profiles are shown in Fig. 4. The variable temperature NMR studies indicate that the barrier for **1** and **2** is less than 10 kcal/mol. It is clear from these results that molecular mechanics overestimates the barrier to rotation as this

approach does not model the cogwheel-like rotation of the three amido-groups. The EHMO calculation suggest that electronically the barrier to rotation is small. This implies that for substituted analogs of the model $Ti(NH_2)_3Cl$ steric factors will dominate the barrier to rotation of Ti—N bonds.

An ICR mass spectrometry study of ion/molecule reactions between ethyl chloride and alkylamines

GUOYING XU and JAN A. HERMAN
Département de chimie, Université Laval, Québec (Qué.), Canada G1K 7P4

Received July 5, 1990

GUOYING XU and JAN A. HERMAN. Can. J. Chem. **69**, 363 (1991).

Ion/molecule reactions in mixtures of ethyl chloride with C_1–C_4 alkylamines were studied by ICR mass spectrometry. Ethyl cation transfer to C_1–C_4 alkylamines proceeds mainly through diethylchloronium ions with rate constants $\sim 3 \times 10^{-10}$ cm^3 s^{-1}. In the case of *s*-butylamine the corresponding rate constant is 0.5×10^{-10} cm^3 s^{-1}.

Key words: ICR mass spectrometry, ion/molecule reactions, ethylchloride, methylamine, ethylamine, propylamines, butylamines.

GUOYING XU et JAN A. HERMAN. Can. J. Chem. **69**, 363 (1991).

Faisant appel à la spectrométrie de masse ICR, on a étudié les réactions ions/molécules des mélanges du chlorure d'éthyle avec les alkylamines C_1–C_4. Le transfert du cation éthyle vers les alkylamines C_1–C_4 se produit prinicpalement par le biais d'ions diéthylchloroniums avec des constantes de vitesse d'environ 3×10^{-10} cm^3 s^{-1}. Dans le cas de la *s*-butylamine, la constante de vitesse correspondante est $0{,}5 \times 10^{-10}$ cm^3 s^{-1}.

Mots clés : spectrométrie de masse ICR, réactions ion/molécule, chlorure d'éthyle, méthylamine, éthylamine, propylamines, butylamines.

Introduction

It is well established that the end-product ions formed in ion/molecule reactions of pure ethylchloride are the diethylchloronium ions, $(C_2H_5)_2Cl^+$, and their solvates, $[(C_2H_5)_2Cl^+\text{-}(C_2H_5Cl)_n]$. Since these products are unreactive toward ethyl chloride neutrals they are found to accumulate in the system with almost 90% yield at a pressure of one Torr in a high pressure mass spectrometer (1, 2).

Dialkylhalonium ions have been used as alkylating agents in both gas and liquid phase reactions (3–7), and it is expected that diethylchloronium ions will react similarly. Such alkylation processes are bimolecular nucleophilic displacement reactions and are usually highly exothermic for bases such as dimethyl ether, ethanol, ammonia, and many aromatic bases (5, 7, 8). The observed relative rates for many of these reactions (5, 7) reveal a negative temperature dependence, which strongly supports evidence for a double well potential model as summarized by Magnera and Kebarle (9).

Our intention was to study the alkylation processes between ethyl chloride and C_1–C_4 monoalkylamines to compare the importance of each of the following two reaction channels for the formation of $(C_2H_5)RNH_2^+$ species: (*a*) ethyl cation transfer from diethylchloronium ion, or (*b*) ethyl radical transfer from ethyl chloride to protonated alkylamine. The first channel being highly exothermic is expected to be the main reaction pathway, but the second channel, even if exothermic by <40 kJ/mol only, might contribute to the formation $(C_2H_5)RNH_2^+$ species especially at low concentration of ethyl chloride in the mixture.

Experimental

The pulsed ICR mass spectrometer used in this work has already been described (10, 11). The usual pulse sequence was started with a 2 ms ionizing pulse of 70 eV electrons followed by a variable delay (5–500 ms) during which ion/molecule processes take place. Then a 2 ms resonant RF frequency excitation pulse of 0.5 V, followed immediately by a 4 ms detection pulse, terminate the measured events. The pulse sequence is ended by a quenching pulse which sweeps out all remaining ions in the ICR cell. The magnetic field was set at 0.8 Tesla allowing to scan ions within a frequency range of 80 to 450 kHz which corresponds to a mass range of 26 to 150 amu. Due to the proximity of one of the trapping plates to the emission filament the temperature of the cell was not uniform. We estimate the average temperature of the cell to be around 50°C.

The pressure at which all experiments were performed was $(1.0 \pm 0.1) \times 10^{-5}$ Torr (1.33×10^{-5} mbar), as measured by an ionization gauge. At that pressure range ions can be kept in the ICR cell for about 2 s, but practical measurements of the intensities of ions limited this time to 0.5 s.

Ethyl chloride and methylamine from Matheson were of the best available purity (~99%). An analysis of methylamine has shown an impurity of 0.4% of dimethylamine. If trimethylamine is present as an impurity in methylamine it should be less than 0.1% which is the sensitivity limit of our analysis. Ethylamine from Matheson and the propyl-, isopropyl-, and butylamines from Aldrich were better than 99% pure and were used without further purification.

The mixtures of ethyl chloride with alkylamines were prepared in a known ratio in a separate high vacuum manifold, which was baked each time between preparation of gaseous samples.

Results and discussion

Since the ionization potential of ethyl chloride (IP = 10.97 eV) is higher than those of alkylamines (RNH_2), an efficient charge transfer from $C_2H_5Cl^+$ to RNH_2 will occur. Consequently, mixtures having a small content (<30%) of ethyl chloride will show peaks, if any, of low intensity of diethylchloronium ions (m/z = 93, 95), and therefore, these mixtures cannot be used to follow in the mass spectrum alkylation processes. For this reason we have measured the time evolution of mass spectra in $EtCl/RNH_2$ mixtures of concentration ratios 1:1 and 1:2. In such mixtures ion/molecule reaction sequences for each of the pure compounds is occurring and any new ion species originating from cross reactions between mixture components are easily observed and their relative rates of formation can be evaluated.

Mixtures of ethyl chloride (EtCl) with methylamine ($MeNH_2$)

Figure 1 shows the time evolution of fractional intensities of major ion species formed in the mixture $EtCl/MeNH_2$ = 1:1. We do not include the disappearance of the fragment ions of methylamine (m/z = 28, 29, and 30) as a function of time,

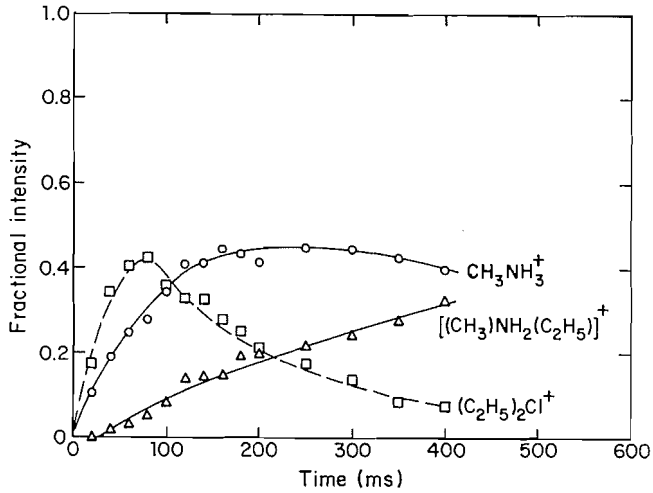

FIG. 1. Time evolution of fractional intensities of some ions of interest in C_2H_5Cl/CH_3NH_2 = 1:1 mixture.

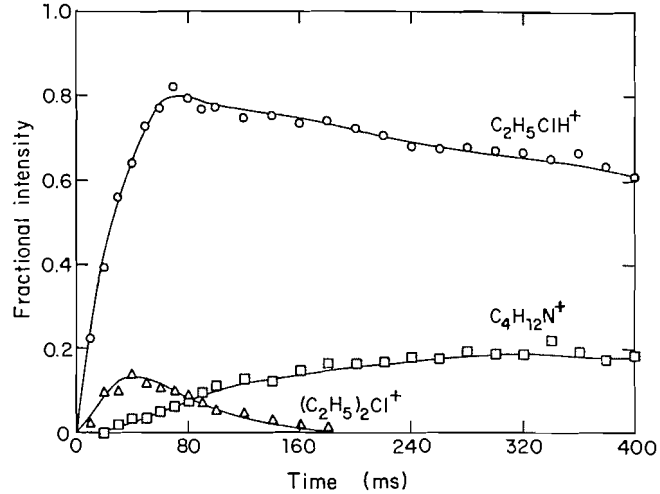

FIG. 2. Time evolution of fractional intensities of some ions of interest in $C_2H_5Cl/C_2H_5NH_2$ = 1:1 mixture.

because all these species vanish very quickly (<40 ms) in the proton transfer processes to form protonated methylamine, $CH_3NH_3^+$ (m/z = 32). Similarly we do not include the disappearance curves of the primary and fragments ions of ethyl chloride, nor the decay of the protonated species, $C_2H_5ClH^+$ (m/z = 65, 67), because within 40 ms the diethylchloronium ions are practically the sole species originating from ethylchloride left in the mass spectrum.

The m/z = 46 ion present in the mass spectrum is assumed to be $(CH_3)_2NH_2^+$ and could be accounted for totally by the presence of the dimethylamine impurity in the mixture, and is therefore omitted from Fig. 1. In the mass spectrum there are also small quantities of ion species of m/z = 56, 57, and 58 (<2% each) wich are usually seen in the high pressure mass spectrum of ethyl chloride. They are assumed to be $C_4H_8^+$, $C_4H_9^+$, and $C_4H_{10}^+$ species (2, 7). These ions do not intervene in any significant ion/molecule reactions with the mixture of neutral components, and therefore, will be systematically ignored in the present figures.

The only possible cross-product ion in the $EtCl/MeNH_2$ system is the m/z = 60 species, which is formed at longer times (>30 ms) and which is assumed to be $[C_2H_5NH_2CH_3]^+$.

[1] $(C_2H_5)_2Cl^+ + CH_3NH_2 \rightarrow [C_2H_5NH_2Cl_3]^+ + C_2H_5Cl$

$\Delta H_4 = -143$ kJ mol^{-1}

In calculating the enthalpy changes the values are taken from ref. 7 for the diethylchloronium ion and from ref. 12 for the other species.

Another possible structure could be $(CH_3)_3NH^+$, originating either from a proton transfer to the trimethylamine impurity, or a methyl group transfer to the protonated dimethylamine:

[2] $CH_3NH_3^+ + (CH_3)_3N \rightarrow (CH_3)_3NH^+ + CH_3NH_2$

$\Delta H_4 = -46.3$ kJ mol^{-1}

[3] $(CH_3)_2NH_2^+ + CH_3NH_2 \rightarrow (CH_3)_3NH^+ + NH_3$

$\Delta H_r = -46.9$ kJ mol^{-1}

As for reaction [2] the low concentration of this impurity (<0.1%) should give at 400 ms a contribution to the fractional intensity of approximately 0.04 (13), which is small compared to the experimental value of 0.33 in Fig. 1. Reaction [3] would contribute to the fractional intensity by around 0.11 if the assumed rate constant for this reaction is 1×10^{-10} cm^3 s^{-1} (14).

An additional argument in favour of an ethyl–methyl–ammonium structure might be inferred from the behaviour of the fractional intensities of the diethylchloronium and the m/z = 60 ions. After an initial rapid growth in intensity of the diethylchloronium ions with a maximum achieved at 40 ms the next systematic decrease in intensity coincides with a corresponding intensity increase of the m/z = 60 species, while the intensity of $CH_3NH_3^+$ ions remains constant, Fig. 1.

Mixtures of ethyl chloride with ethylamine ($EtNH_2$)

The time evolution of fractional intensities of the major species formed in the mixture $EtCl/EtNH_2$ = 1:1 are displayed in Fig. 2. The expected cross-product ion, $(C_2H_5)_2NH_2^+$ (m/z = 74), is clearly seen in the mass spectrum. However, this species can be formed via at least four reaction channels: (*a* and *b*) ethyl group transfer in exothermic processes from either ethylamine or ethylchloride to protonated ethylamine, (*c*) $C_2H_5^+$ transfer from the diethylchloronium species to ethylamine, and (*d*) from the diethylamine impurity. The present experimental data cannot unravel between the four possibilities, and any simulation of the rates would be a hopeless exercise. Therefore, we will not discuss this particular system.

Mixtures of ethyl chloride with n*-propylamine (ProNH2)*

The experimental data for ion-products formed in the mixture $EtCl/ProNH_2$ = 1:1 are shown in Fig. 3. The ion of interest is m/z = 88, which is assumed to be the ethylated propylamine ion: $[(C_3H_7)NH_2(C_2H_5)]^+$, and which is also found with small intensity in pure propylamine (~3% at 400 ms) (14). The intensity of m/z = 88 signal decreases as the concentration of ethyl chloride in the mixtures decreases. In a 4:1 mixture of $C_3H_7NH_2$:C_2H_5Cl, the intensity of this ion is too low to be detected. This suggests that ethyl chloride plays an important role in the formation of m/z = 88 ions:

[4] $(C_2H_5)_2Cl^+ + C_3H_7NH_2 \rightarrow [(C_3H_7)NH_2(C_2H_5)]^+ + C_2H_5Cl$

The heat of formation of $[(n\text{-}C_3H_7)NH_2(C_2H_5)]^+$ is not known, but it should not differ much (a few kJ/mol) from that of the value of 474 kJ mol^{-1} measured for its isomeric species $[(i\text{-}C_3H_7)NH_2(C_2H_5)]^+$ (12). In that case the enthalpy change for reaction [4] would be $\Delta H_r \approx -174$ kJ mol^{-1}.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

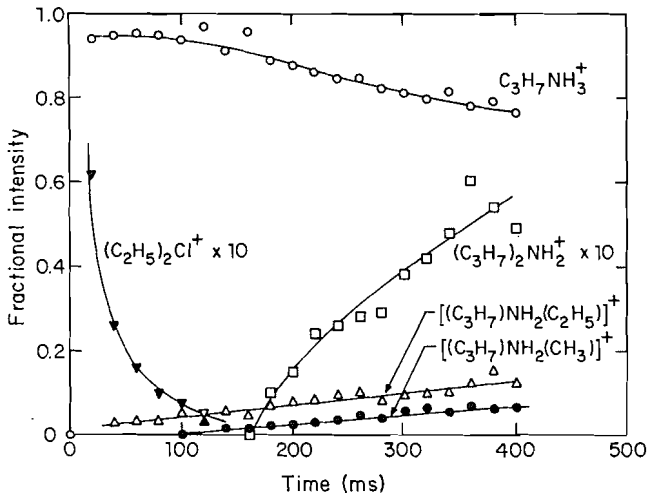

FIG. 3. Time evolution of fractional intensities of some ions of interest in $C_2H_5Cl/n\text{-}C_3H_7NH_2$ = 1:1 mixture.

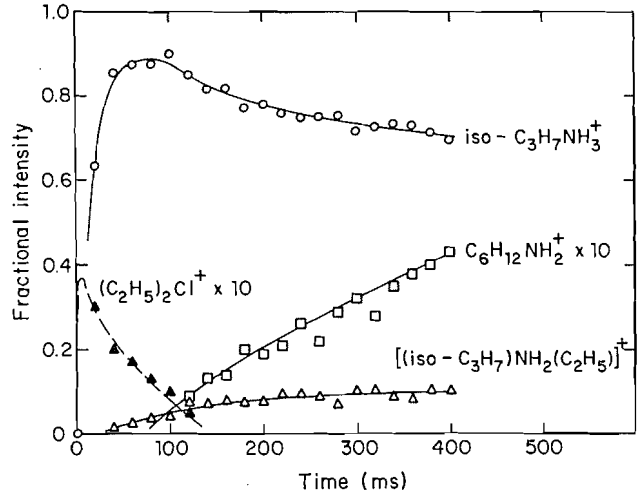

FIG. 4. Time evolution of fractional intensities of some ions of interest in $C_2H_5Cl/iso\text{-}C_3H_7NH_2$ = 1:1 mixture.

On the other hand, the intensity of diethylchloronium ions (m/z = 93, 95) approaches zero within 100 ms, while the intensity of m/z = 88 ions continues to increase long after, Fig. 3. It appears that to some extent the formation of m/z = 88 also corresponds to the consumption of the protonated propylamine (m/z = 60) in the two following reactions:

[5] $C_3H_7NH_3^+ + C_2H_5Cl \rightarrow [(C_3H_7)NH_2(C_2H_5)]^+ + HCl$

[6] $C_3H_7NH_3^+ + C_3H_7NH_2 \rightarrow C_5H_{14}N^+ + CH_3NH_2$

Assuming that $\Delta H_f[(C_3H_7)NH_2(C_2H_5)]^+$ is comparable to that of its isopropyl group containing isomer, the enthalpy of reaction [5] would be around -54 kJ mol^{-1} (12). On the other hand, the enthalpy change of reaction [6] depends on the structure of the $C_5H_{14}N^+$ species, but if it corresponds to $[(C_3H_7)NH_2(C_2H_5)]^+$, which is likely, then the heat of reaction would be slightly exothermic by ≈ -21 kJ mol^{-1}. As mentioned previously, reaction [6] which occurs in pure propylamine with a low rate constant ($<10^{-12}$ cm^3 s^{-1}) (14) might be real, or may reflect the presence of small amounts of impurities. Thus, the contribution from reaction [5] must be quite significant in this system.

The ion with m/z = 74 is assumed to be the methylated propylamonium ion: $[(CH_3)NH_2(C_3H_7)]^+$. It is observed in the mass spectrum of pure propylamine. It probably originates in a decomposition ion/molecule reaction between $C_3H_7NH_3^+$ and $C_3H_7NH_2$, (14) or from some impurity.

Mixtures of ethyl chloride with iso*-propylamine (*iso*-ProNH$_2$)*

In Fig. 4 is shown the time evolution of the fractional intensities of ions of interest formed in a $EtCl/iso\text{-}ProNH_2$ = 1:1 mixture. It is assumed that ions with m/z = 60, 88, and 100 are $[(CH_3)_2CHNH_3]^+$, $[(iso\text{-}C_3H_7)NH_2(C_2H_5)]^+$, and $C_6H_{12}NH_2^+$. The last ion is the main product-ion observed in the high pressure mass spectrum of pure *iso*-propylamine and is formed in a condensation-rearrangement reaction with elimination of ammonia and molecular hydrogen. This ion is not observed in the high-pressure mass spectrum of *n*-propylamine, and conversely the $[(C_3H_7)_2NH_2]^+$ (m/z = 102) ion present in the spectrum of *n*-propylamine is not observed in pure *iso*-propylamine. In pure *iso*-propylamine the ion with m/z = 88 is not observed, but becomes detectable when sufficient amounts of ethylchloride are present in the system. In the $EtCl/iso\text{-}ProNH_2$ = 1:1 mixture the ions with m/z = 88 are more abundant than the ions with m/z = 100 (Fig. 4). In 1:4 mixture these two ions have almost the same fractional intensities, and in 1:8 mixture the m/z = 100 ion species become the major product. This trend indicates that ethyl chloride is an essential compound for the formation of $C_5H_{14}N^+$ (m/z = 88) species, and the main channel for the formation of this ion is reaction [7]:

[7] $(C_2H_5)_2Cl^+ + iso\text{-}C_3H_7NH_2 \rightarrow [(C_3H_7)NH_2(C_2H_5)]^+ + C_2H_5Cl$

$\Delta H_r = -174$ kJ mol^{-1}

Mixtures of ethyl chloride with butylamines (BuNH$_2$)

Mixtures of ethylchloride with *n*-butylamine, *s*-butylamine, and *tert*-butylamine were studied.

In the mass spectrum of $EtCl/n\text{-}BuNH_2$ mixture the ion with m/z = 102, $C_6H_{16}N^+$, which might correspond to the cross-product ion, is also observed in the mass spectrum of pure 1-butylamine and accounts already for ~15% at 400 ms. In this case the probable formation process for this ion is a proton transfer to an unidentified impurity.

In the mass spectrum of $EtCl/n\text{-}BuNH_2$ mixtures the m/z = 102 ion is observed in variable amounts depending on neutral component ratios, but its fractional intensity is smaller than that for the pure *n*-butylamine. The occurrence of reaction [8]

[8] $(C_2H_5)_2Cl^+ + 1\text{-}C_4H_9NH_2 \rightarrow (C_4H_9NH_2C_2H_5)^+ + C_2H_5Cl$

in competition with a possible formation (as mentioned above) of an unidentified impurity with m/z = 102 does not allow us to make an unambiguous assessment of the importance of these two reaction channels. For this reason we did not simulate kinetics for this system as it would be only an arbitrary exercice.

In contradistinction to the previous system the formation of the cross-product ion with m/z = 102 can be unambiguously followed in the $EtCl/s\text{-}BuNH_2$ mixtures. In pure *s*-butylamine the ion with m/z = 102 is not formed, or its amount is within the background (~2%) of the mass spectrum, Fig. 5*a*. In Fig. 5*b* are shown the fractional intensities of the ions of interest in the $EtCl/s\text{-}BuNH_2$ = 1:2 mixture. As mentioned previously we did not draw the time evolution of primary and fragment ions, which disappear very quickly (<50 ms) to form the protonated butylamine and the diethylchloronium ions. In this figure an increase

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

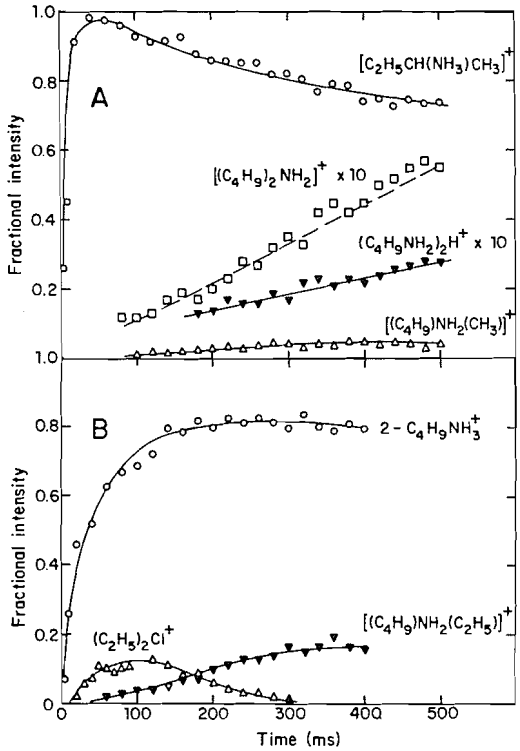

FIG. 5. Time evolution of fractional intensities of some ions of interest: (*A*) in pure *s*-$C_4H_9NH_2$, and (*B*) in C_2H_5Cl/*s*-$C_4H_9NH_2$ = 1:2 mixture.

in the intensity of m/z = 102 species coincides with a decrease of the intensity of the $(C_2H_5)_2Cl^+$ peak. It also seems that the formation of the m/z = 102 species does not correspond to the consumption of the protonated 2-butylamine ions (m/z = 74). Moreover, the relative intensities of the cross-product ion with m/z = 102 decrease to zero in mixtures richer in *s*-butylamine. Therefore the alkylation process is thought to proceed mainly through diethylchloronium ion consumption:

[9] $(C_2H_5)_2Cl^+ + s\text{-}C_4H_9NH_2 \rightarrow [(C_4H_9)NH_2(C_2H_5)]^+ + C_2H_5Cl$

The ΔH_f of butylethylammonium ion is unknown, but the dialkylamine ions of the same formula, $C_6H_{16}N^+$, have heats of formation between 101 and 111 kJ mol^{-1} (12), and it might be assumed that a comparable value characterizes the $[(C_4H_9)NH_2(C_2H_5)]^+$ species. If such is the case, then ΔH_r = -148 ± 10 kJ mol^{-1} for reactions [8] and [9].

Finally in the case of mixtures of *tert*-butylamine and ethyl chloride no cross-product ions with m/z = 102 were observed.

Rates of reaction

The reactivities of alkylamines with $(C_2H_5)_2Cl^+$ ions and chloroethane with RNH_3^+ species (R = CH_3, C_3H_7, and C_4H_9) are shown in Table 1. These values were obtained by numerical simulation by the procedure outlined in ref. 15. In these calculations the available rate constants for diethylchloronium ions formation (5), and those for the protonation of alkylamines in pure amines (14) were used. However, the results of numerical simultion in these complex systems are to be considered cautiously. Usually more than one reaction channel contributes to the formation of the studied species, and in these cases some arbitrariness is expected in assuming the relative importance of each reaction channel, even as in these calculations only exothermic ion/molecule processes were taken into account. Nevertheless, the simulated rate constants in Table 1 compare

TABLE 1. The rate constants of ethyl cation transfer

Reaction	$k \times 10^{10}$ cm^3 s^{-1}
$(CD_3)_2Cl^+ + CH_3NH_2$	145. ± 1.5
$(C_2H_5)_2Cl^+ + CH_3NH_2$	2 ± 1.5
$(C_2H_5)_2Cl^+ + C_2H_5NH_2$	n.d.[a]
$(C_2H_5)_2Cl^+ + n\text{-}C_3H_7NH_2$	3.1 ± 0.6
$(C_2H_5)_2Cl^+ + iso\text{-}C_3H_7NH_2$	3.3 ± 0.6
$(C_2H_5)_2Cl^+ + n\text{-}C_4H_9NH_2$	n.d.
$(C_2H_5)_2Cl^+ + s\text{-}C_4H_9NH_2$	0.5 ± 0.2
$(C_2H_5)_2Cl^+ + tert\text{-}C_4H_9NH_2$	< 0.005

[a]n.d. = not determined.

favourably with those already available for ethylation reactions with ammonia or trimethylamine (5), which are

[10] $[(C_2H_5)Cl(CH_3)]^+ + NH_3 \rightarrow C_2H_5NH_3^+ + CH_3Cl$

$k = 1.6 \times 10^{-10}$ cm^3 s^{-1}

[11] $[(C_2H_5)Cl(CH_3)]^+ + (CH_3)_3N \rightarrow [(CH_3)_3N(C_2H_5)]^+ + CH_3Cl$

$k = 4.0 \times 10^{-10}$ cm^3 s^{-1}

We also present in Table 1 the rate constant for the unambiguous reaction:

[12] $(CD_3)_2Cl^+ + CH_3NH_2 \rightarrow [CH_3NH_2CD_3]^+ + CD_3Cl$

measured on a FT-ICR instrument.[1] The rate constant for reaction [12] (Table 1) is about 20% higher than the rate coefficient for the following similar reaction (7):

[13] $(CH_3)_2Cl^+ + (CH_3)_3N \rightarrow (CH_3)_4N^+ + CH_3Cl$

$k = 11.7 \times 10^{-10}$ cm^3 s^{-1}

which seems reasonable.

The comparison of rate constant values show that the rates of methylation or ethylation of C_1–C_3 alkylamines (reactions [1], [4], [7], and [9]) are comparable, being around 1/5 of the collision rate estimated by trajectory calculation (16). The high uncertainty of the rate constant of reaction [1] results from the occurrence of reactions [2] and [3] the contributions of which are not easy to estimate. In the case of *s*-butylamine (reaction [9]) this rate constant diminishes by a factor of 6, probably due to the size and structure of the amine.

According to Sen Sharma and Kebarle's observation $C_2H_5^+$ transfer from methyl–ethyl–chloronium ion, $CH_3ClC_2H_5^+$, to benzene, toluene, and isopropylbenzene is faster at 305 K than the transfer of CH_3^+ from dimethylchloronium ions, $(CH_3)_2Cl^+$ (5). They suggested that the internal barrier is smaller for the transfer of the more weakly bound $C_2H_5^+$ to a given aromatic. In contrast, Mathews and Stone reported that the $C_2H_5^+$ transfer from diethylchloronium ion, $(C_2H_5)_2Cl^+$, to these aromatics is slower than CH_3^+ transfer from dimethylchloronium species (7). Our results are in agreement with those of Mathews and Stone (7).

The major channels for ethylation of alkylamine by ethyl chloride proceed through reactions [1], [4], [7], and [9] involving diethylchloronium ions. A similar behaviour was found in alkylamine/methyl chloride systems, where methylation occurs mainly in reactions between d_6-dimethylchloronium ions, $(CD_3)_2Cl^+$, and neutral alkylamines.[2]

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

The other possible methyl group transfer reaction channel:

[14] $RNH_3^+ + CD_3Cl \rightarrow [RNH_2CD_3]^+ + HCl$

where R = CH_3, C_2H_5, C_3H_7, and C_4H_9, is observed, but with very low rate constant values ($\leq 5 \times 10^{-13}$ cm^3 s^{-1}).[3] We expect that processes similar to reaction [14] between protonated alkylamines and ethyl chloride will proceed also at very low rates ($\sim 10^{-13}$ cm^3 s^{-1}), and therefore will not greatly contribute to the formation of ethylated alkylamines, $(C_2H_5)RNH_{2+}$.

Conclusion

In mixtures of alkylamine with ethyl chloride, ethyl cation transfer to methylamine, propylamines, 2-butylamine and most probably also to ethylamine, proceeds mainly through diethylchloronium ion, with rate constants $\sim 3 \times 10^{-10}$ cm^3 s^{-1}. Only *s*-butylamine reacts slower (Table 1). The second competitive pathway of ethylation occurring between protonated alkylamines and neutral ethylchloride, although slightly exothermic or thermoneutral, does not seem to proceed with sufficient rate to contribute evidently.

Excess properties for binary liquid mixtures of propionic acid with aniline derivatives

BEGOÑA GARCÍA,[1] RAFAEL ALCALDE, AND JOSÉ M. LEAL
Universidad de Valladolid, Departamento de Química Física, Colegio Universitario Integrado, 09001 Burgos, Spain
Received December 21, 1989

BEGOÑA GARCÍA, RAFAEL ALCALDE, and JOSÉ M. LEAL. Can. J. Chem. **69**, 369 (1991).

Excess viscosities, excess volumes, and excess free energies of activation for flow of the binary mixtures containing propionic acid with aniline, *o*-toluidine, *o*-anisidine, and *o*-chloroaniline were determined at five different temperatures from density and viscosity measurements. Based on the Regular Solutions Theory, the empirical parameter θ was calculated; this parameter is related to the viscosity, and also denotes the extent of the non-ideality of the system. The results obtained suggest the existence of acid–base interactions, as well as the formation of 1:2 complexes for the three first mixtures, and 2:1 complexes for *o*-chloroaniline + propionic acid. The extent of the specific interaction decreases with an increase in the strength of the base, and increases with an increase in the dipole moments. The equation $V = V_1^{X_1} \cdot V_2^{X_2}$ is proposed for predicting the mole volume of the mixtures, V, at any composition, X_i, as a function of the mole volumes of the pure components, V_i.

Key words: binary mixture, excess properties, predicting mole volumes, propionic acid.

BEGOÑA GARCÍA, RAFAEL ALCALDE et JOSÉ M. LEAL. Can. J. Chem. **69**, 369 (1991).

En se basant sur des mesures de densité et de viscosité obtenues à cinq températures différentes, on a déterminé les viscosités en excès, les volumes en excès et les énergies libres d'activation en excès pour l'écoulement de mélanges binaires contenant de l'acide propionique et de l'aniline, de l'*o*-toluidine, de l'*o*-anisidine et de l'*o*-chloroaniline. En se basant sur la théorie des solutions idéales, on a calculé le paramètre empirique θ; ce paramètre est relié à la viscosité et il est le reflet de la non-idéalité du système. Les résultats suggèrent qu'il existe des interactions acide–base ainsi qu'il y a formation de complexes 1 : 2 dans les trois premiers mélanges et de complexes 2 : 1 dans le cas de l'*o*-chloroaniline + l'acide propionique. L'importance de ces interactions spécifiques diminue avec une augmentation de la force de la base et elle augmente avec les moments dipolaires. On propose l'équation pour prédire le volume molaire, $V = V_1^{X_1} = V_2^{X_2}$, V, des mélanges à toute composition, X_i, et en fonction des volumes molaires, V_i, des produits purs.

Mot clés : mélange binaire, propriétés en excès, prédiction des volumes molaires, acid propionique.

[Traduit par la rédaction]

Introduction

In previous papers (1–3), the behaviour of binary mixtures containing polar liquids was investigated. Continuing the study of this type of mixtures, we report here excess molar volumes V^E, excess viscosities η^E, and excess free energies of activation for flow ΔG^{*E}, at five different temperatures of binary mixtures containing propionic acid + aniline, + *o*-toluidine, + *o*-anisidine, and + *o*-chloroaniline. From the values of the ionization constants of the *o*-substituted anilinium ions (4–6), an important role of the acid–base interactions may be inferred. The results obtained suggest the existence of proton transfer processes in the three first systems, as well as the probable existence of other interactions responsible for complex formation among the components of the mixtures. A detailed analysis of the relationships existing between η, V, and the empirical parameter θ is made and compared with those reported by other authors. From the proper definition of the magnitude ΔG^{*E}, a simple equation is deduced that permits predicting the molar volume of the mixtures at any composition using the molar volumes of the pure components.

Experimental

The solvents used were commercially available (Merck); aniline and *o*-toluidine were purified by distillation; *o*-anisidine and *o*-chloroaniline were recrystallized according to methods already described (7). The improvement in purity was followed by GC, UV–VIS spectroscopy, and density and viscosity measurements.

Measurements

Densities were measured with a double levelling pycnometer; it was calibrated at the five working temperatures. Viscosities were measured with a Cannon–Fenske viscometer calibrated with distilled water at different temperatures, with the density and viscosity values taken from the literature (8). Temperature was kept constant within ±0.01°C. Densities and viscosities were accurate within ±0.0001 and 0.004 units, respectively.

The purity of the reactants was assessed with a Perkin Elmer 990 gas chromatograph and Perkin Elmer 554 UV–VIS spectrophotometer, since absorptivities of these species had previously been determined (4, 6, 10). Analysis of the data was carried out with an Olivetti M 240 computer.

Results and discussion

In the investigation on binary mixtures of propionic acid with benzene, methylbenzene, ethylbenzene, and propylbenzene, Subha and Rao (11) found that viscosities decreased to a greater extent with the initial addition of hydrocarbons to propionic acid. Although this behaviour was interpreted by Johari (12) as characteristic of systems where at least one of the components exhibits intramolecular hydrogen bonding, Subha and Rao (13) reported maximum values for viscosities around $X = 0.35$ at 25°C for three acid–base mixtures, including aniline – propionic acid, in agreement with our own results. A table containing values of densities and viscosities obtained for the four binary mixtures at different temperatures has been deposited.[2]

In the present paper, the variation of viscosities with mole fraction at different temperatures fitted a polynomial equation for aniline derivatives fairly well. Strong deviations from linearity, characteristic of ideal behaviour, are apparent. According to Fort and Moore (14), such deviations may be attributed to specific interactions arising from the formation of complexes among the mixing molecules.

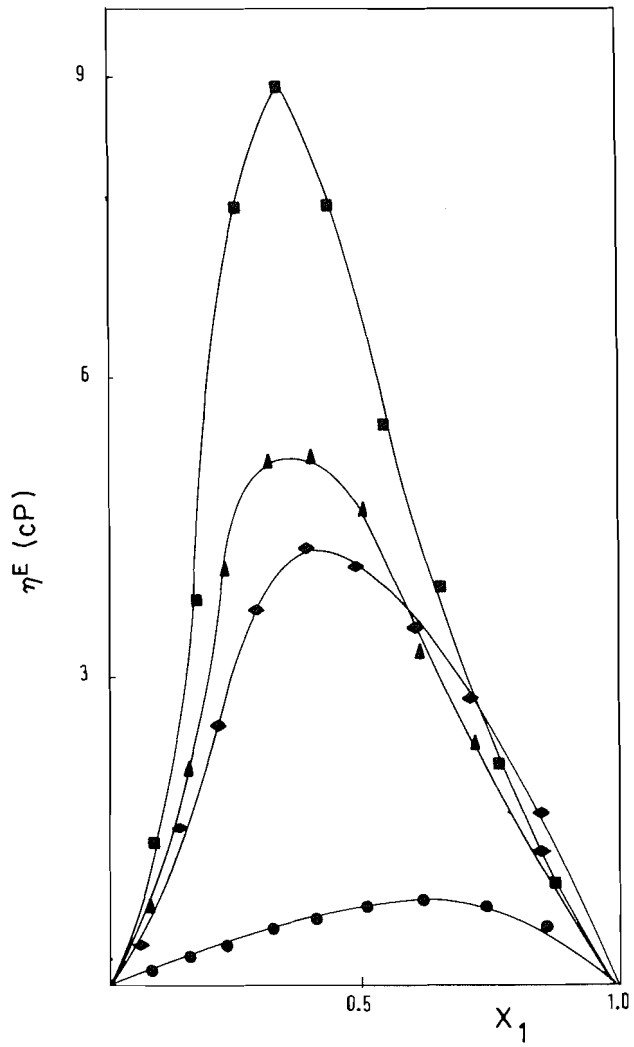

FIG. 1. Variation of the excess viscosity η^E (cP) with aniline derivative mole fraction for mixtures of propionic acid + *o*-chloroaniline (●), + *o*-anisidine (◆), + *o*-toluidine (▲), and + aniline (■); T = 293 K.

The values η^E, V^E, and ΔG^{*E} were fitted, at each temperature for each of the four mixtures studied, to a Redlich–Kister polynomial function. The excess viscosities of the four mixtures exhibited maxima against the mole fraction, these maxima decreasing with an increase in temperature, located at about X = 0.35 for aniline, *o*-toluidine, and *o*-anisidine, and at about X = 0.65 for *o*-chloroaniline (Fig. 1). This behaviour is also observed in liquid mixtures capable of forming complex species by intermolecular hydrogen bonding. The four mixtures showed negative excess volumes with well-defined minima (Fig. 2). Excess free energies of activation for flow behaved similarly to the excess viscosities, with maxima around X = 0.35, except for *o*-chloroaniline (Fig. 3). The solid lines in the figures were generated with the aid of the polynomial coefficients. Tables of the least-squares coefficients of the polynomial regressions for these excess quantities are available from the Depository of Unpublished Data.[2]

The results obtained for the thermodynamic properties of the mixtures indicate that the extent of the interaction increases according to the strength of the base: aniline (pK = 4.60) > *o*-toluidine (pK = 4.40) > *o*-anisidine (pK = 4.38) > *o*-chloroaniline (pK = 2.71), K being the ionization constant of the corresponding anilinium ions according to $RNH_3^+ \rightleftharpoons RNH_2 + H^+$ (4–6). At mole fractions corresponding to η^E maxima, the amount of protons required for the acid–base reactions may be supplied by the acid component of the mixtures (pK = 4.87) (9) in all cases except for *o*-chloroaniline, since its basicity is much lower than the acid strength of propionic acid. Nevertheless, the excess properties of the binary mixtures with *o*-toluidine and *o*-anisidine evidence behaviour less similar than would be expected from the strength of the bases. This fact indicates the existence of interactions, different from hydrogen bonding, responsible for the complex formation; to a first approximation (15), the stoichiometry of these complexes can be determined from the ratio of mole fractions corresponding to the maxima η^E, yielding the values 2:1 for *o*-chloroaniline and 1:2 for the other three mixtures.

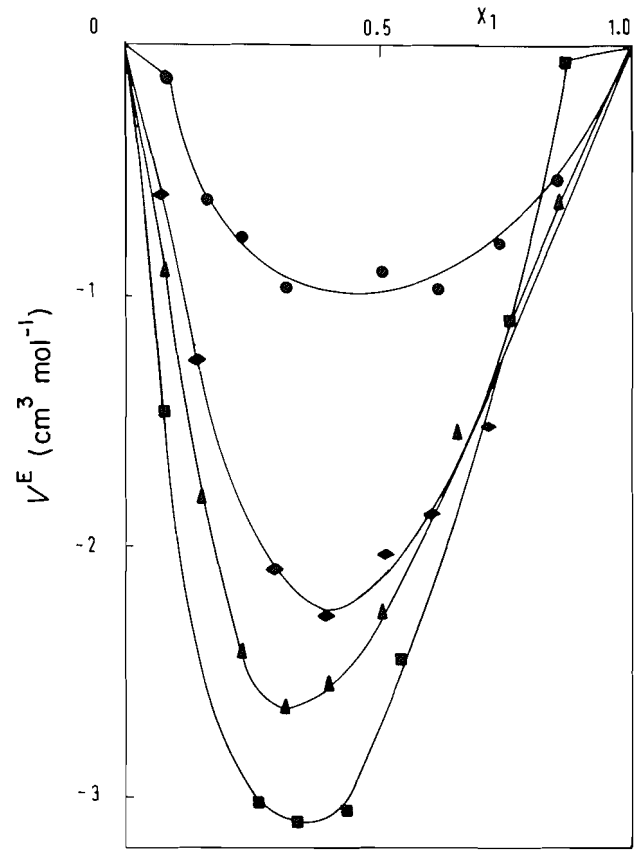

FIG. 2. Variation of the excess volumes V^E (cm^3 mol^{-1}) with aniline derivative mole fraction at 293 K (symbols as in Fig. 1).

Based on the ideas of the Regular Solutions Theory (16, 17), Grunberg and Nissan (18) proposed an empirical expression for viscosities of real liquid mixtures:

$$[1] \quad \ln \eta_{obs} = \ln \eta_{id} + X_1 X_2 \theta$$

where θ denotes the extent of non-ideality of the system, and

$$[2] \quad \ln \eta_{id} = X_1 \ln \eta_1 + X_2 \ln \eta_2$$

The variation of θ with temperature and composition is in the order (a) aniline > *o*-toluidine > *o*-anisidine > *o*-chloroaniline at constant temperature and composition; (b) θ decreases with an increase in temperature for all systems. Values of θ at different temperatures and mole fractions, obtained from eq. [1] have been placed in the Depository of Unpublished Data.[2] These results are in good agreement with those arising from the excess properties.

Prolongo *et al.* (19) reported positive values of θ correspond-

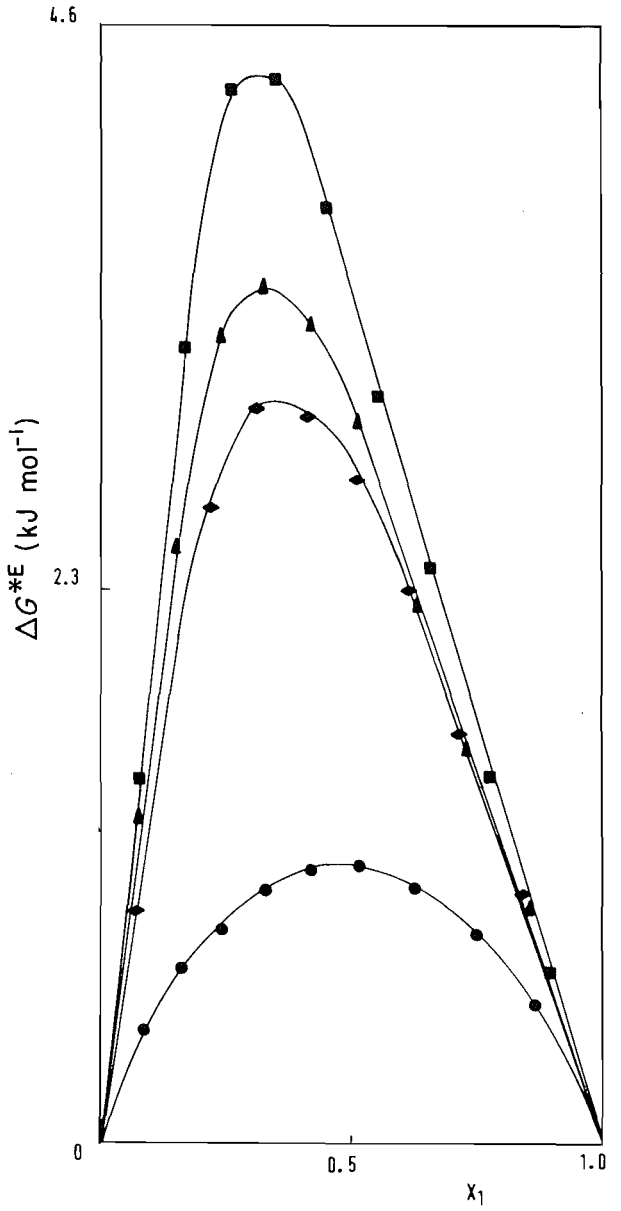

FIG. 3. Variation of the excess free energies of activation for flow ΔG^{*E} (kJ mol^{-1}) with aniline derivative mole fraction at 293 K (symbols as in Fig. 1).

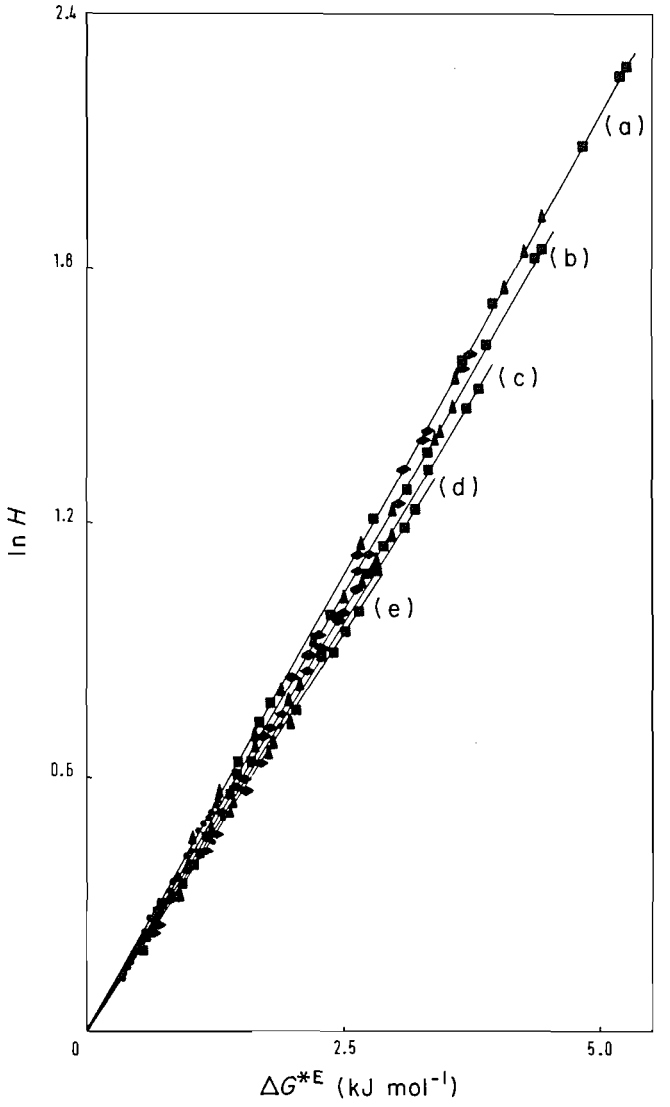

FIG. 4. Plot of ln H against ΔG^{*E} according to eq. [7]; (a) 283 K; (b) 293 K; (c) 303 K; (d) 313 K, and (e) 323 K.

ing to systems with negative excess volumes, which is in agreement with our own results, but the opposite effect was observed by Anantamaran (20).

In view of the different meaning of θ and V^E, it is difficult to establish a general correlation between the two magnitudes. Nevertheless, to pursue the suggested connection between the excess viscosity and the (negative) excess volume, the following correlation was proposed by Stairs (21):

$$[3] \quad H_{max}^{-1} = 0.570 + 1.035\, V_r^E(\max)$$

where

$$[4] \quad \ln H = -(W/RT)\, X_1X_2 = \theta X_1X_2 = \ln \eta_{obs} - \ln \eta_{id}$$

$$[5] \quad V_r^E = 100\,(V^E/V)$$

and where W denotes an interspecific interaction energy.

According to this proposal, the fractional change in the free volume at each composition should be related to our quantity H. Given that the mole fractions of the maxima η^E (plots η^E vs. X_1) and the minima V^E (plots V^E vs. X_1) do not coincide for our mixtures, values of H_{max} experimental and those calculated with eq. [3] also will not coincide. On the other hand, nonlinear plots of H_{max}^{-1} against V_{max}^E were obtained in the present study. This behaviour was also observed by Palepu *et al.* (22) in binary mixtures of *m*-cresol with substituted anilines; they reported a single straight line when ln H was plotted against ΔG^{*E}. This type of result is not unexpected, since the expression for ΔG^{*E} takes into account both viscosity and volume:

$$[6] \quad \Delta G^{*E} = RT\,(\ln \eta V - X_1 \ln \eta_1 V_1 - X_2 \ln \eta_2 V_2)$$

where η, η_1, and η_2 are the viscosities of the mixture and pure components, and V, V_1, and V_2 the molar volumes of the mixture and pure components. Palepu noted that systems with positive η^E and negative V^E led to straight lines, with zero intercept, when ln H was plotted against ΔG^{*E}; this intercept, however, was different from zero for binary mixtures of *m*-cresol with substituted anilines. From eqs. [4] and [6], it is deduced that

$$[7] \quad \ln H = m\, \Delta G^{*E} - \ln D$$

TABLE 1. Experimental and calculated values of the slope m (mol J^{-1}) according to eq. [7]; $S(y)$ = standard deviation; r_{xy} = linear correlation coefficient

T/K	m_{calcd}	m_{expt}	r_{xy}	$S(y)$
283	0.4250	0.4266	0.9999	0.004
293	0.4105	0.4120	0.9999	0.007
303	0.3969	0.3975	0.9999	0.002
313	0.3843	0.3847	0.9999	0.001
323	0.3724	0.3732	0.9999	0.002

where

[8] $$\ln D = \ln V - (X_1 \ln V_1 + X_2 \ln V_2)$$

At constant temperature a straight line should be obtained, with slope $m = 1/RT$ (Fig. 4). Table 1 collects the experimental and theoretical values determined for the slopes m, as well as the linear correlation coefficients, 36 being the number of data points for each of the straight lines; the standard error was estimated to be less than 0.007, and ln D was always less than 0.002. Thus the following equation can be derived from eq. [8]:

[9] $$V = V_1^{X_1} \cdot V_2^{X_2}$$

The percentage of error in V (calculated with eq. [9]) with respect to experimental measurements was always lower than 1%, at any temperature and for any composition of the mixtures.

Sense of sequential 1,5-sigmatropic rearrangements of dimethyl-3,3-dialkyl-3*H*-pyrazole-4,5-dicarboxylates. Crystal and molecular structures of two dimethyl-4,5-dialkyl-1*H*-pyrazole-1,3-dicarboxylates

CHRISTOPHER S. FRAMPTON,[1] MICHAEL W. MAJCHRZAK, AND JOHN WARKENTIN[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

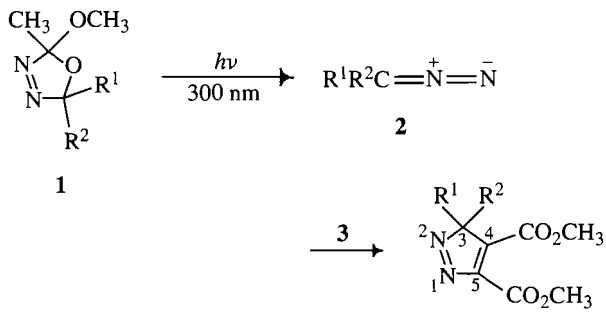
Received April 18, 1990[2]

CHRISTOPHER S. FRAMPTON, MICHAEL W. MAJCHRZAK, and JOHN WARKENTIN. Can. J. Chem. **69**, 373 (1991).

3,3-Dialkyl-3*H*-pyrazole-4,5-dicarboxylic acid dimethyl esters (**4**), obtained by cycloaddition of $R^1R^2C{=}N^+{=}N^-$ ($R^1 = R^2 = CH_3$; $R^1 = CH_3$, $R^2 = CH_2CH_3$) to $CH_3O_2CC{\equiv}CCO_2CH_3$, rearrange thermally by 1,5-sigmatropic alkyl shifts to both N and C. The latter rearrangement is followed by two successive 1,5-sigmatropic shifts of a methoxycarbonyl group. Final products of the threefold rearrangement were shown to be 4,5-dialkyl-1*H*-pyrazole-1,3-dicarboxylic acid dimethyl esters (**6**), rather than the isomeric 3,4-dialkyl-1*H*-pyrazole-1,5-dicarboxylic acid dimethyl esters (**7**), by means of single crystal X-ray diffraction. Those products therefore result from alkyl migration to C-4 of **4**, followed by sequential migration of the methoxycarbonyl group, initially at C-4, to C-3 and then to N-2 of **4**. In the initial alkyl migration step, ethyl migrates in preference to methyl, and in subsequent migration steps the methoxycarbonyl group migrates faster than the ethyl or methyl group. Crystals of 4-ethyl-5-methyl-1*H*-pyrazole-1,3-dicarboxylic acid dimethyl ester (**6***b*) are monoclinic, of space group $P2_1/n$, with $a = 7.907(1)$ Å, $b = 11.087(2)$ Å, $c = 13.199(3)$ Å, $V = 1124.9(4)$ Å^3, $D_c = 1.34$ g cm^{-3}, $D_m = 1.33$ g cm^{-3} for $Z = 4$, and $R_1 = 0.0772$ ($R_2 = 0.0626$) for 1474 reflections ($R_1 = 0.0428$, $R_2 = 0.0422$ for 903 reflections with $I > 3\sigma(I)$. The structure of **6***a* is similar.

Key words: 3,3-dialkyl-3*H*-pyrazoles, 1,5-sigmatropic rearrangements of; 4,5-dialkyl-1*H*-pyrazoles, crystal and molecular structures; 1,5-sigmatropic rearrangements of pyrazoles, sense of.

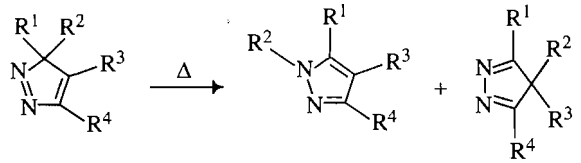
CHRISTOPHER S. FRAMPTON, MICHAEL W. MAJCHRZAK et JOHN WARKENTIN. Can. J. Chem. **69**, 373 (1991).



Les esters diméthyliques des acides 3,3-dialkyl-3*H*-pyrazole-4,5-dicarboxyliques (**4**), obtenus par cycloaddition des $R^1R^2C{=}N^+{=}N^-$ ($R^1 = R^2 = CH_3$); $R^1 = CH_3$, $R^2 = CH_2CH_3$) au $CH_3O_2CC{\equiv}CCO_2CH_3$, se réarrangement thermiquement par des transpositions 1,5-sigmatropiques d'alkyles vers le N ainsi que le C. Cette dernière transposition est suivie par deux transpositions 1,5-sigmatropiques successives d'un groupement méthoxycarbonyle. Faisant appel à la diffraction des rayons-X par un cristal unique, on a montré que les produits finaux de ces transpositions ternaires sont les esters diméthyliques des acides 4,5-dialkyl-1*H*-pyrazole-1,3-dicarboxyliques (**6**) plutôt que les esters diméthyliques isomères des acides 3,4-dialkyl-1*H*-pyrazole-1,5-dicarboxyliques. Ces produits sont donc formés par une migration d'un groupement alkyle vers la position C-4 du produit **4**, suivie par la migration séquentielle du groupement méthoxycarbonyle, initialement vers la position C-4, puis C-3 et finalement N-2 du produit **4**. Dans l'étape initiale de migration des groupements alkyles, l'éthyle migre de préférence au méthyle et, dans les étapes subséquentes de migration, le groupement méthoxycarbonyle migre plus rapidement que les groupements éthyle ou méthyle. Les cristaux de l'ester diméthylique de l'acide 4-éthyl-5-méthyl-1*H*-pyrazole-1,3-dicarboxylique (**6***b*) sont monocliniques, groupe d'espace $P2_1/n$, avec $a = 7{,}907(1)$, $b = 11{,}078(2)$ et $c = 13{,}199(3)$ Å, $V = 1124{,}9(4)$ Å^3, $D_c = 1{,}34$ g cm^{-3}, $D_m = 1{,}33$ g cm^{-3}, $Z = 4$ et $R_1 = 0{,}0772$ ($R_2 = 0{,}0626$) pour 1474 réflexions ($R_1 = 0{,}0428$, $R_2 = 0{,}0422$ pour 903 réflexions avec $I \geq 3\sigma(I)$). La structure du composé **6***a* est semblable.

Mots clés : 3,3-dialkyl-3*H*-pyrazoles, transpositions 1,5-sigmatropiques; 4,5-dialkyl-1*H*-pyrazoles, structures cristallines et moléculaires; signification des transpositions 1,5-sigmatropiques des pyrazoles.

[Traduit par la rédaction]



Introduction

Diazoalkanes (**2**), generated conveniently by photolysis of 5,5-dialkyl-2-methoxy-2-methyl-Δ^3-1,3,4-oxadiazolines (**1**) (1), are trapped efficiently, *in situ*, by dimethyl acetylenedicarboxylate (**3**) to afford 3,3-dialkyl-3*H*-pyrazole-4,5-dicarboxylic acid dimethyl esters (**4**), eq. [1].

[1] 

a: $R^1 = R^2 = CH_3$; *b*: $R^1 = CH_3$, $R^2 = CH_2CH_3$

Compounds **4** are of the 1,3-cyclopentadiene type and, as such, are prone to 1,5-sigmatropic rearrangement (2, 3). Examples of thermal rearrangement in the 3,3-dialkyl-3*H*-pyrazole skeleton are known (4–8) and include the reactions illustrated with eq. [2] (8).

[2] 

We found that **4***a* and **4***b* rearranged at 160°C in benzene solution by a mechanism more complicated than the simple competition between the two migration pathways depicted with eq. [2]. The 1*H*-pyrazole products of migration to nitrogen were obtained in each case but the second product was also a 1*H*-pyrazole, not a 4*H*-pyrazole. Although the possible structures of the unexpected products could readily be narrowed down to **6** or **7**, eq. [3], the choice between those two could not be made unambiguously by means of spectroscopy, in the absence of authentic samples.

(*a*: $R^1 = R^2 = CH_3$; *b*: $R^1 = CH_3$, $R^2 = CH_2CH_3$)

We now report that the crystal and molecular structures identify the unexpected materials obtained from **4** as **6**, rather than **7**.

Experimental

Syntheses

The pyrazole starting materials (**4***a*, **4***b*) were prepared by photolysis of the appropriate oxadiazoline precursors in the presence of **3**, as described previously (1).

Rearrangements

Thermal rearrangement was carried out by heating a solution (ca. 0.25 M) of the appropriate pyrazole in benzene to 160°C in a sealed nmr tube. Progress of the rearrangement was monitored by ^{1}H nmr spectroscopy. After 8 h at 160°C, rearrangement was complete (>95%).

*4,5-Dimethyl-1H-pyrazole-1,3-dicarboxylic acid dimethyl ester (**6**a)*

Yield 83%; ^{1}H nmr (500 MHz, C_6D_6, residual H at δ 7.15), δ: 2.04 (s, 3H, C-4Me), 2.09 (s, 3H, C-5Me), 3.38 (s, 3H, N-1 ester), 3.51 (s, 3H, C-3 ester); ^{13}C nmr (125.76 MHz, C_6D_6, at 128.0), δ: 8.59, 11.5, 51.3, 53.8, 111.0, 119.7, 141.7, 151.0, 163.2; ms (high resolution), m/z: 212.081; calcd. for $C_9H_{12}N_2O_4$: 212.079.

*4-Ethyl-5-methyl-1H-pyrazole-1,3-dicarboxylic acid dimethyl ester (**6**b)*

Yield 67%; ^{1}H nmr (500 MHz, C_6D_6, residual H at δ 7.15), δ: 1.08 (t, 3H), 2.12 (s, 3H), 2.59 (q, 2H), 3.36 (s, 3H, N-1 ester), 3.50 (s, 3H, C-3 ester).

*1-Ethyl-5-methyl-1H-pyrazole-3,4-dicarboxylic acid dimethyl ester (**5**b)*

Yield 33%; ^{1}H nmr (500 MHz, C_6D_6, TMS), δ: 0.84 (t, 3H), 1.91 (s, 3H), 3.25 (q, 2H), 3.57 (s, 6H); ^{13}C nmr (125.76 MHz, C_6D_6), δ: 9.86, 14.4, 44.1, 51.1, 51.7, 112.0, 142.5, 144.3, 163.6, 163.7.

X-ray crystallography

Crystals of **6***b* were grown from $CHCl_3$/petroleum ether. The density was determined by suspension in an aqueous solution of $ZnCl_2$. Clear parallelepiped crystals were examined under a polarizing microscope for homogeneity. A small well-formed crystal, 0.15 × 0.15 × 0.20 mm, was selected and sealed in a Lindemann capillary. Unit cell parameters were obtained from a least-squares fit of χ, φ, and 2θ for 15 reflections in the range 12.0° < 2θ < 24.2° recorded on a Nicolet P3 diffractometer with use of graphite monochromated MoKα radiation (λ = 0.71069 Å at 22°C). Intensity data were also recorded on a Nicolet P3 diffractometer with a coupled θ(crystal)–2θ(counter)

scan, for 1690 reflections in the quadrant h, k, $\pm l$ with $2\theta \leq 45°$. The methods of selection of scan rates and initial data treatment have been described (9, 10). Corrections for Lorentz–polarization effects were applied to all reflections. Two standard reflections (−1, −1, 0; 1.46% and 1, −1, 0; 1.60%) monitored every 48 reflections showed no sign of crystal decomposition or instrument instability. Systematically absent reflections (104) were excluded and 184 symmetry-equivalent data were then averaged (R_{int} = 0.0079) to give 1402 unique reflections. The data collection parameters for **6***a* were similar. A summary of crystal data is given in Table 1.

Solution of the structure

The structure was solved by direct methods on 299 reflections with $|E| > 1.2$ and 50 sets of starting phases with use of the program SHELXS-86 (11). Full-matrix least-squares refinement of the coordinates of all the non-hydrogen atoms followed by a three-dimensional electron density synthesis revealed the positional parameters for most of the hydrogen atoms. The temperaure factors of the non-hydrogen atoms, which were previously isotropic, were made anisotropic and further cycles of refinement and a difference synthesis revealed more hydrogen atoms. These were included, along with calculated positions for the rest of the hydrogen atoms, in subsequent cycles of refinement (U fixed at 0.08 Å^2). Futher refinement using full-matrix least squares minimizing $\Sigma w(|F_o| - |F_c|)^2$ was terminated when the maximum shift/error reached 0.003. Correction for secondary extinction was not necessary. Throughout the refinement, scattering curves were taken from ref. 12. The structure of **6***a* was solved in a similar manner. All calculations were performed on a VAX 8650 computer. Programs used: XTAL (13), data reduction; SHELX-86 (11), structure solution; SHELX-76 (14), structure refinement; MOLGEOM (15) and SNOOPI (16), diagrams. Final atomic positional parameters are given in Tables 2 and 3, selected bond lengths and bond angles are given in Tables 4 and 5. Tables listing full crystal data, least-squares mean planes and dihedral/torsional angles, hydrogen atom positional parameters, bond lengths and bond angles involving hydrogen atoms, and anisotropic temperature factors are available as supplementary material.[3]

[3]This material may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of full crystal data, hydrogen atom positional parameters, and bond lengths and angles involving hydrogen atoms have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

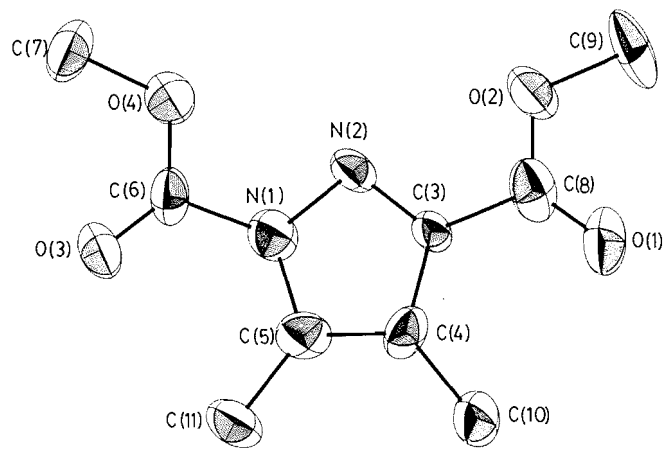

FIG. 1. View of molecule **6***a*.

Results and discussion

Views of molecules **6***a* and **6***b*, with atom numbering schemes, are depicted in Figs. 1 and 2. The molecular structures of **6***a* and **6***b* are similar to those of 1-nitropyrazole (17) and *N*,*N*′-carbonyldipyrazole (18) and do not have any remarkable features. The only reason for determining those structures was to discriminate, unambiguously, between the isomers **6** and **7** (Scheme 1). For that purpose, the best refinement was not necessary and the high *R*-value for **6***a*, which was the result of a large number of reflections with $I < 3\sigma(I)$, is not of great concern. The rearrangement products belong to the family **6**, not **7** (Scheme 1). With the identities of the products firmly established, those rearrangements can now be described in considerable detail.

Thermal isomerizations of conjugated pentadienyl systems are believed to occur, with few exceptions (3), by a concerted process known as a suprafacial 1,5-sigmatropic rearrangement (2). The term denotes an intramolecular shift of a group or atom from one position to another on the same face of a π-system that, at the transition state, has six π-electrons. The migrating entity remains continuously and covalently bonded to the rest of the structure during its migration. Such rearrangements are characterized by low migratory aptitudes for saturated groups

(e.g., alkyl) and high migratory aptitudes for unsaturated groups such as phenyl or ester (8*b*).

Although thermal 1,5-sigmatropic rearrangements of 3*H*-pyrazoles had been reported (8), the systems studied did not include any with alkyl groups at C-3 and with ester groups at both C-4 and C-5. The major questions at the outset were the following. First, would alkyl migration occur under thermodynamic control to form **5** (Scheme 1) following the sense of migration of ester, acyl, and cyano groups (5*b*) from C-3 to N-2? Second, if 4*H*-pyrazoles were formed preferentially, would they be isolable (8*a*) or would subsequent rearrangement be too fast? Third, in what sense would **8** rearrange under conditions where **8** are unstable? Although it was predictable that the ester groups of **8** would migrate to the exclusion of R^2 ($R^2 = CH_3$ or C_2H_5) it was not clear whether that group would migrate to form **9** or **10**, or both.

SCHEME 1

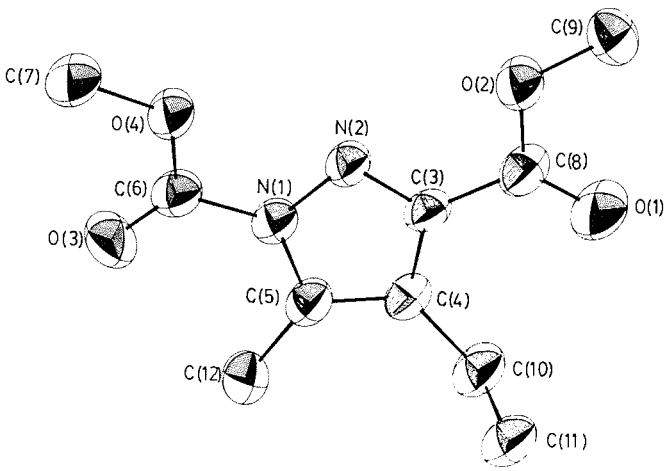

FIG. 2. View of molecule **6***b*.

The results of this study provide clear answers to those three questions. Methyl and ethyl group migrations are largely under kinetic control, **4***a* yielding only 9% of the aromatic product **5***a* and **4***b* leading to only 33% of **5***b*. In each case the major product comes from alkyl group migration to carbon. In this respect compounds **4** are similar to 4,5-diaryl-3,3-dimethyl-3*H*-pyrazoles (8*a*) and 5-methyl-3,3-dialkyl-3*H*-pyrazoles (8*b*); the ester groups of **4** do not have a pronounced effect (relative to H or aryl groups) on the preference for migration under kinetic control. The identity of the migrating group does appear to have a large effect on the site selectivity, on the other hand. Phenyl migrates about seven times faster to N-2 than to C-4 of ethyl and methyl-3,3,5-triphenyl-3*H*-pyrazole-4-carboxylates at 140°C (6), while ester, acyl, and cyano groups migrate exclusively to N-2 of 3-methyl-3-R-3*H*-pyrazole-4,5-dicarboxylic acid dimethyl esters (R = CO_2CH_3, $COCH_3$, CN) (5*b*).

Although the formation of 4*H*-pyrazoles (**8**) is required to account for the major products of rearrangement of **5**, accumulation of **8** to detectable levels did not occur under the reaction conditions. That result was not predictable, despite the fact that the CO_2CH_3 group migrates 19 000 and 826 times faster, respectively, than methyl and ethyl from C-3 of 3*H*-pyrazoles (8*b*). The reason why a prediction could not be made is that some 4*H*-pyrazoles are more stable than 3*H*-pyrazoles.[4] In fact, in many instances (6, 8*a*, 8*b*), 4*H*-pyrazoles have been isolated readily from the thermal rearrangement of their 3*H*-pyrazole isomers. In the present cases, **8** appears to rearrange faster than **4** in spite of the greater stability expected of the ring system **8**, with two CN double bonds.

Finally, the question of the sense of rearrangement of **8** is answered. The ester group migrates to the alkyl-bearing sp^2-carbon only, to form **9**, and as a result the net effect of two sigmatropic shifts is to interchange an alkyl group at C-3 of **4** with the ester group at C-4. Presumably this happens with overall inversion at C-3 because those sigmatropic shifts must be suprafacial. In the new 3*H*-pyrazole (**9**), the migration competition is again between CO_2Me and primary alkyl, and only ester migration, to form **6**, occurs. Presumably **9** also reverts to **8** but that rearrangement would have been invisible in the present study.

With the sense of the second of three sequential sigmatropic rearrangements firmly established by means of X-ray crystallography, it should be easier, in the future, to distinguish between rearrangement products of types **6** and **7** by means of ^1H and ^{13}C nmr spectroscopy.

Transformation of resin abietic acid into a pregnane-type steroid

ANTONIO ABAD,[1] CONSUELO AGULLO, MANUEL ARNO,[1] LUIS R. DOMINGO, JOSÉ ROZALEN, AND RAMON J. ZARAGOZA

Departamento de Química Orgánica, Universidad de Valencia, Dr. Moliner 50, 46100 Burjasot, Valencia, Spain

Received July 13, 1990

ANTONIO ABAD, CONSUELO AGULLO, MANUEL ARNO, LUIS R. DOMINGO, JOSÉ ROZALEN, and RAMON J. ZARAGOZA. Can. J. Chem. **69**, 379 (1991).

Abietic acid (**1***a*) has been converted into the pregnane analogue steroid **10** via a sequence of transformations involving as key step the acetylene-cation cyclization of **9**.

Key words: abietic acid, pregnane steroids, acetylene-cation cyclization.

ANTONIO ABAD, CONSUELO AGULLO, MANUEL ARNO, LUIS R. DOMINGO, JOSÉ ROZALEN et RAMON J. ZARAGOZA. Can. J. Chem. **69**, 379 (1991).

L'acide abiétique (**1***a*) a été converti en un stéroïde analogue du pregnane (**10**) via une séquence de transformation englobant comme étape clé la cyclisation du cation acétylénique **9**.

Mots clés : acide abiétique, steroïdes analogues du pregnane, cyclisation par cation acétylénique.

Introduction

The synthesis of the steroid skeleton from resin acids has attracted the attention of many research groups over the years. In recent years, the conversion of tricyclic diterpenes with pimarane (1), isopimarane (2), podocarpane (3), and abietane (4) skeleton into steroid compounds has been reported, but hitherto none of these syntheses has resulted in the preparation of a pregnane-type steroid structure.

We have recently reported the conversion of dehydroabietic acid into a C-aryl-18-norpregnane steroid (5) and we wish to report in this paper the conversion of the most abundant resin acid, abietic acid (**1***a*), into a pregnane analogue steroid (**10**).

Results and discussion

Since synthesis of the steroidal D-ring possessing the 13-methyl group by the use of the carbon units of the isopropyl group of abietane-type diterpenes had proved to be difficult (4, 6), our strategy for the above-mentioned conversion (**1** to **10**) was founded on the initial deisopropylation of abietic acid, then to build an acetylene alcohol (**9**), which might undergo a stereocontrolled acid-promoted cyclization, through the well-known acetylene-cation cyclization (7), to afford the 20-keto-steroid **10**.

On the basis of the above considerations, methyl abietate (**1***b*) was transformed into enone **3** by a previously described procedure, which involves conversion of **1***b* to diene **2** and subsequent cleavage of the C13—C15[2] double bond (8).

The required side chain at C-14 was introduced by alkylation of the dienolate anion of **3**. Thus, reaction of **3** with 1 equivalent of lithium diisopropylamide (LDA) at −78°C afforded the corresponding lithium dienolate, which was coupled to 1-iodo-3-pentyne[3] at −78°C in the presence of added hexamethylphosphoric triamide (HMPA) for 2 h (−78°C to room temperature) to give the monoalkylated product **4** in 42% yield (82% based on recovered starting material, which could be recycled) along with a small amount of dialkylated product **5** (5%). The monoalkylated product **4** was isolated as a mixture of epimers at C-14, according to the evidence obtained from the gc–ms data and ^{1}H and ^{13}C nmr spectra (see experimental section). Despite numerous attempts, we were unsuccessful in finding conditions to increase the low percent conversion of this reaction. Attempts to improve its efficiency by prolonging the reaction time, or by using a larger excess of the iodide or a different base–solvent system (e.g., $(CH_3)_3$ COK/$(CH_3)_3$COH, CH_3SOCH_2Na/CH_3SOCH_3) resulted in a lower yield of **4**. Presumably, the low percent conversion obtained in this reaction under all attempted conditions reflected the facile elimination of IH from the homopropargylic iodide.

On treatment with hydrochloric acid in methanol, the mixture of C-14 epimeric ketones (**4**) was converted into the α,β-unsaturated ketone **6** in 92% yield. Chemoselective double bond reduction of **6** with lithium in liquid ammonia by inverse addition at −78°C afforded the acetylenic ketone **7** in 74% yield. Although partial reduction of the 4α-methoxycarbonyl function occurred under these conditions (a 5–10% yield of **8** was obtained), the lithium–ammonia reduction of the conjugated double bond took place with no observable reduction of the acetylene group.

The synthesis of the desired acetylenic alcohol **9** was completed by reacting the acetylenic ketone **7** with methyllithium to give, in a 9:1 ratio, the isomeric alcohols **9***a* and **9***b*, which were easily separated by column chromatography. Probably due to steric hindrance towards carbonyl addition, α deprotonation was a serious competition reaction and only 60% conversion took place. By repeated addition of methyllithium to the hydrolysed product, 93% conversion could be achieved. The assigned stereochemistry at C-13 of **9***a* and **9***b* followed from a comparison of their ^{1}H and ^{13}C nmr spectra. Of particular significance was the chemical shift of the methyl group at C-13; this carbon resonates 8.4 ppm upfield in the 13α-alcohol (**9***b*) compared with the epimeric β-alcohol (**9***a*) (20.75 and 29.13 ppm, respectively) due to the cooperative γ-interactions with the two axial hydrogens on C-8 and C-11.

The final step in the synthesis of the pregnane analogue steroid **10** involved the acetylene-cation cyclization of **9**. Both epimeric acetylenic-carbinols (**9***a* and **9***b*) were cyclized as described for related cases (10) by treatment with a mixture of trifluoroacetic acid and trifluoroacetic anhydride at −23°C followed by hydrolysis of the initially formed enol trifluoroacetates with 10% ethanolic potassium hydroxide.[4] Chromatog-

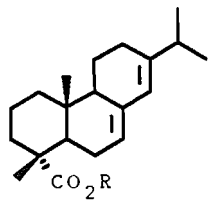
[2]Usual diterpene and steroid nomenclature and numbering are used for all tricyclic and tetracyclic compounds respectively.



[3]Prepared from 3-pentyn-1-ol as in ref. 9.

[4]The use of higher temperatures had only a small effect on the product distribution. Specifically, the ratio **10**/**11** was 4:1 when the cyclization reaction was conducted at room temperature.

raphy of the cyclization product afforded a 4.5:1 mixture (80% yield from alcohol **9***a*)[5] of desired 4α-methoxycarbonyl-4β-methyl-5α-pregnan-20-one (**10**, the major product) and its 13α (C/D *cis*) isomer (**11**), together with a small amount (less than 6%) of the six-membered annulated product (**12**). The mixture of 13-epimeric ketones **10** and **11** was separated by preparative high-pressure liquid chromatography (hplc). The stereochemistry assignments of both compounds were based on a comparison of the C-13 methyl group nmr signals at 0.56 ppm and 0.76 ppm for **10** and **11**, respectively, with the C-13 methyl frequencies of analogous structures.[6] The nmr signal of the methine proton of C-17, which appears at 2.49 ppm in **10** and at 2.96 ppm in the C-13 diastereoisomeric compound **11**, also substantiates the assigned stereochemistries. None of the 17α and 17β epimers of **10** and **11**, respectively, was detected in the ^1H nmr spectrum of the crude cyclization mixture.[6] It is worthwhile mentioning that the results obtained in the above cyclization of **9** seem to be at variance with those previously reported for the cyclization reaction of related acetylene-carbinols (10) for which the formation of C/D-*cis* fused compounds has not been detected. The formation of **12** was also surprising in that no detectable formation of six-membered annulated products took place during the cyclization of bicyclic carbinols (7).

Experimental

Melting points were determined on a Kofler apparatus and are uncorrected. The ir spectra were recorded on a Perkin–Elmer model 281 spectrometer. The ^1H and ^{13}C nmr spectra were measured in deuteriochloroform at 200.13 and 50.32 MHz, respectively, on a Bruker AC-200 spectrometer. Signals multiplicities in the ^{13}C nmr data were determined by DEPT experiments. Mass spectra were run by electron impact (70 eV) on a Varian MAT-311A spectrometer. Elemental analyses were performed by Servicio de semimicroanálisis del CSIC (Barcelona); final purification of all products for microanalysis was done by preparative hplc on a μ-Porasil column. Optical rotations were measured with a BS model A-PI polarimeter. Thin-layer chromatography was carried out on Merck 0.25 mm silica gel 60 HF_{254} analytical aluminium plates. Column chromatography refers to flash chromatography and was performed on Merck silica gel 60, 230–240 mesh. All reactions involving moisture- or air-sensitive materials were executed under an atmosphere of dry argon using oven-dried glassware and freshly distilled and dried solvents.

Methyl 13-oxo-podocarp-8-en-18-oate (3)

Enone **3** was obtained from abietic acid or commercial colophony as described in ref. 8; ^{13}C nmr, δ: 15.71 (C-19), 17.41 (C-2), 18.85 (C-20), 20.58 (C-6), 23.11 (C-11), 30.55 (C-7), 34.54 (C-12), 36.64 (C-10), 38.57 (C-1), 38.87 (C-3), 43.77 (C-14), 45.48 (C-5), 46.78 (C-4), 51.12 (OCH_3), 124.16 (C-8), 138.20 (C-9), 177.97 (C-18), 209.98 (C-13) ppm.

Methyl 13-oxo-14-(3-pentynyl)-podocarp-8-en-18-oate (4)

A stirred solution of the enone **3** (661 mg, 2.28 mmol) in anhydrous tetrahydrofuran (4 mL) containing a few crystals of anhydrous phenanthroline was treated dropwise with a stock solution of lithium diisopropylamide in tetrahydrofuran at −78°C until persistence of the characteristic rust colour of LDA-phenanthroline (approximately 3.9 mL, 0.6 M, 2.34 mmol). The stirring was continued at the same temperature for an additional 5 min. Hexamethylphosphoric triamide (1.2 mL, 6.9 mmol), followed by 1-iodo-3-pentyne (1.33 g, 6.85 mmol), was added and the resulting solution was allowed to warm to room temperature during 2 h. Water was added and the mixture was extracted with ether. The combined extracts were washed with brine until neutral, dried, and filtered. Evaporation of the solvent gave an oily residue, which was purified by flash chromatography (hexane–ether 9:1 as eluent) to give, in order of elution:

Dialkylated ketone 5 (50 mg, 5.2%) as an oil; $[\alpha]_D$ +98.8° (*c* 0.8, $CHCl_3$); ir (film) ν_{max}: 2940, 2860, 1730, 1715, 1465, 1445, 1260,

[5]A similar yield was obtained from the epimeric alcohol **9***b*, but in this case the ratio of **10** to **11** was ca. 9:1.

[6]Reported chemical shifts observed for the 13-Me group of related structures are δ 0.60 ppm in the case of 17β-acyl C/D *trans*-fused compounds (0.90 ppm for 17α epimers) and δ 0.80 ppm in the case of 17α-acyl C/D *cis*-fused isomers (1.20 ppm for 17β epimers). See, for example, refs. 7 and 10.

*Unreacted starting material **3*** (320 mg, 48.2%).

*Methyl 13-oxo-14-(3-pentynyl)-podocarp-8(14)-en-18-oate (**6**)*

To a solution of the ketone **4** (256 mg, 0.72 mmol) in methanol (10 mL) was slowly added concentrated hydrochloric acid (1.5 mL) and the mixture was stirred at room temperature for 1 h. Brine was then added and the mixture was extracted with ether. The combined organic layers were washed with aqueous $NaHCO_3$ and brine, dried, and evaporated to yield a yellowish oil. Chromatography with hexane–ether (8:2) as eluent gave the enone **6** (236 mg, 92%) as a solid: mp 62–62.5°C (from hexane); $[\alpha]_D$ +12° (*c* 0.8, $CHCl_3$); ir (film), ν_{max}: 2940, 2880, 1730, 1670, 1620, 1460, 1440, 1265, 1160 cm^{-1}; ^1H nmr ($CDCl_3$), δ: 0.91 (s, 3H, CH_3-10β), 1.19 (s, 3H, CH_3-4β), 1.71 (t, *J* 2.6 Hz, 3H, ≡C—CH_3), 2.02 (dd, *J* 12.2 and 3.2 Hz, 1H, H-5α), 1.87–2.20 (m, 1H, H-7α), 2.21 (dd, *J* 12 and 5.5 Hz, 1H, H-9α), 2.4 (dt, *J* 15.3 and 4.5 Hz, 1H, H-12β), 3.01 (ddd, *J* 15.5, 4.5, and 2.2 Hz, 1H, H-7β), 3.65 (s, 3H, CO_2CH_3); ^{13}C nmr, δ: 3.41 (C-5′), 15.04 (C-20), 16.76 (C-19), 17.85 (C-2), 18.50 (C-2′), 19.66 (C-11), 24.25 (C-6), 24.77 (C-1′), 31.02 (C-7), 36.63 (C-12 and C-3′), 38.87 (C-10), 37.79 (C-1), 47.08 (C-4), 48.20 (C-5), 51.83 (OCH_3), 52.25 (C-9), 75.38 (C-4′), 78.85 (C-3′), 133.75 (C-14), 158.21 (C-8), 198.74 (C-13); mass spectrum, *m/e* (relative intensity, %): 357 (M^+ +1, 23), 356 (M^+, 100), 341 (10), 297 (12), 296 (7), 281 (10), 227 (17), 176 (74), 175 (58), 161 (23), 121 (97). *Methyl 13-oxo-14β-(3-pentynyl)-podocarpan-18-oate (**7**)*

A solution of lithium (10 mg, 1.4 mmol) in liquid ammonia (5 mL) contained in a cooled (−78°C) addition funnel was slowly added to a well-stirred solution of enone **6** (236 mg, 0.66 mmol) in a mixture of ether (6 mL) and ammonia (10 mL), also at −78°C. After addition of solid ammonium chloride, followed by evaporation of the ammonia, water was added and the resulting mixture was extracted with ether. The organic layer was washed with brine and dried. After removal of the solvent, the residue was chromatographed on silica gel with hexane–ether (8:2) as eluent to give **7** (175 mg, 74%) as a solid: mp 102–102.5°C (from hexane); $[\alpha]_D$ −14.5° (*c* 1.6, $CHCl_3$); ir (KBr disc), ν_{max}: 2960, 2860, 1730, 1715, 1460, 1398, 1265, 1185 cm^{-1}; ^1H nmr, δ: 0.82 (s, 3H, CH_3-10β), 1.16 (s, 3H, CH_3-4β), 1.73 (t, *J* 2.55 Hz, 3H, ≡C—CH_3), 3.64 (s, 3H, CO_2CH_3); ^{13}C nmr, δ: 3.34 (C-5′), 14.27 (C-20), 16.56 (C-19), 16.71 (C-2′), 17.94 (C-2), 24.05 (C-6), 24.80 (C-11), 26.04 (C-1′), 32.75 (C-7), 36.64 (C-10), 36.85 (C-3), 38.26 (C-1), 41.63 (C-12), 42.48 (C-8), 47.30 (C-4), 49.18 (C-5), 51.75 (OCH_3), 54.49 (C-9), 54.68 (C-14), 75.48 (C-4′), 79.06 (C-3′), 179.03 (C-18), 211.90 (C-13); mass spectrum, *m/e* (relative intensity, %): 359 (M^+ +1, 2), 358 (M^+, 8), 343 (1), 299 (2), 293 (19), 292 (100), 274 (10). Anal. calcd. for $C_{23}H_{34}O_3$: C 77.05, H 9.56; found: C 77.19, H 9.30.

Further elution with hexane–ether 6:4 afforded *13-oxo-14β-(3-pentynyl)-podocarpan-18-ol (**8**)* (17.4 mg, 8%) as a foam; $[\alpha]_D$ −4.05° (*c* 1.0, $CHCl_3$); ir (KBr disk), ν_{max}: 3460, 2940, 2880, 1720, 1460 cm^{-1}; ^1H nmr, δ: 0.75 (s, 3H, CH_3-10β), 0.82 (s, 3H, CH_3-4β), 1.73 (t, 3H, *J* 2.5 Hz, ≡C—CH_3, 3.07 and 3.40 (each d, *J* 10.9 Hz, 1H each, 2 × H-18); ^{13}C nmr, δ: 3.43 (C-5′), 14.57 (C-20), 16.75 (C-2′), 17.54 (C-19), 18.10 (C-2), 21.29 (C-6), 24.80 (C-11), 26.40 (C-1′), 32.92 (C-7), 35.19 (C-3), 37.00 (C-10), 38.79 (C-1), 41.81 (C-12), 42.47 (C-8), 37.48 (C-4), 47.61 (C-5), 54.63 (C-9 and C-14), 71.77 (C-18), 75.53 (C-4′), 79.17 (C-3′), 212.57 (C-13); mass spectrum, *m/e* (relative intensity, %): 331 (M^+ +1, 3), 330 (M^+, 11), 315 (1), 299 (1), 266 (2), 265 (18), 264 (100), 246 (7), 234 (11), 233 (61), 216 (21), 215 (42).

*Methyl 13β-hydroxy-13α-methyl-14β-(3-pentynyl)-podocarpan-18-oate (**9**a) and C-13 epimer (**9**b)*

A crystal of 1,10-phenanthroline was added to a solution of acetylenic ketone **7** (110 mg, 0.31 mmol) in dry tetrahydrofuran (2 mL); the mixture was cooled to −78°C and then ca. 0.22 mL of a 1.6 M solution of methyllithium in ether was slowly added until a yellow-brown color persisted. The mixture was stirred for 5 min and then excess methyllithium was destroyed by careful addition of water. The resulting mixture was diluted with water and extracted with ether. The combined organic layers were washed with brine and dried. The ether was distilled off and the residue was dissolved in anhydrous tetrahydrofuran (2 mL). This solution was treated again with methyllithium and worked up as described above. After repeating this procedure once more, ^1H nmr analysis showed the presence of a small amount of **7** (about 5%). The crude product was chromatographed on silica gel, using hexane – ethyl acetate (9:1) as eluent, to afford, in order of elution:

*Starting compound **7*** (6.8 mg, 6.2%)

*Compound **9**a* (89.3 mg, 77.9%)) as a solid, mp 113–115°C (from hexane); $[\alpha]_D$ −34.6° (*c* 1.15, $CHCl_3$); ir (KBr disk), ν_{max}: 3520, 2930, 2860, 1720, 1440, 1395, 1260, 1180 cm^{-1}; ^1H nmr, δ: 0.85 (s, 3H, CH_3-10β), 1.14 (s, 3H, CH_3-4β), 1.18 (s, 3H, CH_3-13α), 1.73 (t, *J* 2.55 Hz, 3H, ≡C—CH_3), 1.93 (dd, *J* 12.6 and 3.4 Hz, 1H, H-5α), 3.62 (s, 3H, CO_2CH_3); ^{13}C nmr, δ: 3.39 (C-5′), 14.58 (C-20), 16.64 (C-19), 18.03 (C-2), 19.02 (C-2′), 19.41 (C-11), 24.36 (C-6), 27.86 (C-1′), 32.09 (C-7), 36.87 (C-3), 37.14 (C-8), 38.08 (C-1 and C-10), 40.50 (C-12), 47.47 (C-4), 49.49 (C-5), 51.05 (C-14), 51.72 (OCH_3), 55.49 (C-9), 71.37 (C-13), 75.55 (C-4′), 79.69 (C-3′), 179.35 (C-18); mass spectrum, *m/e* (relative intensity, %): 374 (M^+, 4), 359 (32), 356 (11), 341 (3), 316 (3), 290 (56), 121 (92), 81 (63), 43 (100). Anal. calcd. for $C_{24}H_{38}O_3$: C 76.96, H 10.22; found: C 77.18, H 10.10.

*Compound **9**b* (10.3 mg, 8.9%) as a clear foam that could not be induced to crystallize; ir (film), ν_{max}: 3500, 2925, 2860, 1720, 1245 cm^{-1}; ^1H nmr, δ: 0.81 (s, 3H, CH_3-10β), 1.02 (s, 3H, CH_3-13β), 1.14 (s, 3H, CH_3-4β), 1.73 (t, *J* 2.55 Hz, 3H, ≡C—CH_3), 3.62 (s, 3H, CO_2CH_3); ^{13}C nmr, δ: 3.42 (C-5′), 14.49 (C-20), 16.64 (C-19), 18.06 (C-2), 20.43 (C-2′), 21.97 (C-11), 24.32 (C-6), 27.85 (C-1′), 32.30 (C-7), 36.27 (C-10), 36.83 (C-3), 38.11 (C-1), 40.22 (C-8), 42.25 (C-12), 47.45 (C-4), 49.49 (C-5), 51.86 (OCH_3), 53.20 (C-14), 55.52 (C-9), 72.89 (C-13), 76.02 (C-4′), 79.95 (C-3′), 179.37 (C-18); mass spectrum, *m/e* (relative intensity, %): 374 (M^+, 1), 359 (17), 356 (4), 290 (22), 281 (4), 243 (5), 231 (10), 180 (19), 121 (62), 81 (49), 43 (100).

*Cyclization of **9**. 4α-Methoxycarbonyl-4β-methyl-5α-pregnan-20-one (**10**) and 13α-(C/D* cis*) isomer (**11**)*

To a mixture of trifluoroacetic acid (1.5 mL) and trifluoroacetic anhydride (0.75 mL) at −23°C was added the alcohol **9***a* (41 mg,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

0.12 mmol) and the resulting mixture was allowed to stand overnight at the same temperature. After evaporation of the solvent under reduced pressure, the residual oil was dissolved in ethanol (3 mL) and was treated with 10% ethanolic potassium hydroxide (1 mL). After stirring at room temperature for 1 h, the mixture was diluted with water and extracted with ether. The combined organic layers were washed with brine, dried, filtered, and evaporated to afford the crude material, which was chromatographed, using hexane – ethyl acetate (95:5) as eluent, to give an epimeric mixture of **10** and **11** (32.7 mg, 79.8%). Further elution gave *4α-methoxycarbonyl-4β,17aβ-dimethyl-D-homo-5α-androstan-17-one (12)* (2.3 mg, 5.6%) as a solid; mp 155–157°C (from hexane – ethyl acetate); ir (KBr disk), ν_{max}: 2930, 2850, 1730, 1715, 1460, 1390, 1250 cm^{-1}; ^1H nmr, δ: 0.60 (s, 3H, CH_3-18β), 0.85 (s, 3H, CH_3-10β), 0.89 (d, *J* 6.7 Hz, 3H, CH_3-17aβ), 1.15 (s, 3H, CH_3-4β), 3.63 (s, 3H, CO_2CH_3); ^{13}C nmr, δ: 7.10 (CH_3-17a), 13.18 (C-18), 14.51 (C-19), 16.64 (CH_3-4β), 18.07 (C-2), 19.88 (C-11), 24.24 (C-6), 26.04 (C-15), 29.68 (C-13), 31.70 (C-7), 35.63 (C-8), 36.28 (C-10), 36.85 (C-3), 38.01 (C-12), 38.45 (C-1), 41.36 (C-16), 47.50 (C-4), 49.42 (C-5), 51.16 (C-14), 51.85 (OCH_3), 55.79 (C-17a), 58.08 (C-9), 179.44 (CO_2), 213.58 (C-17); mass spectrum, *m/e* (relative intensity, %): 375 (M^+ +1, 3), 374 (M^+, 11), 346 (2), 315 (4), 302 (12), 290 (5), 287 (10), 242 (6), 229 (4), 147 (12), 55 (100).

Isomers **10** and **11** were separated from the above mixture by preparative hplc on a μ-Porasil column, with hexane – ethyl acetate (9:1) as eluent, to give pure **10** (26.3 mg, 64.1% from **9***a*) and its 13α(C/D-*cis*)-17β*H*-isomer **11** (5.8 mg, 14.1% from **9***a*).

Compound **10** was a solid; mp 116–116.5°C (from methanol); $[\alpha]_D$ +59.6° (*c* 1.14, $CHCl_3$); ir (KBr disk), ν_{max}: 2930, 2850, 1730, 1715, 1460, 1270 cm^{-1}; ^1H nmr, δ: 0.56 (s, 3H, CH_3-13β) 0.86 (s, 3H, CH_3-10β), 1.14 (s, 3H, CH_3-4β), 2.08 (s, 3H, $COCH_3$), 2.49 (t, *J* 9 Hz, 1H, H-17α), 3.62 (s, 3H, CO_2CH_3); ^{13}C nmr, δ: 13.37 (C-18), 14.60 (C-19), 16.63 (CH_3-4β), 18.08 (C-2), 20.38 (C-11), 22.73 (C-16), 24.18 (C-15), 24.36 (C-6), 31.55 (C-21), 32.34 (C-7), 35.29 (C-8), 36.23 (C-10), 36.92 (C-3), 38.17 (C-12), 38.88 (C-1), 44.08 (C-13), 47.63 (C-4), 50.02 (C-5), 51.83 (OCH_3), 56.28 (C-9), 56.75 (C-14), 63.73 (C-17), 179.47 (CO_2), 209.74 (C-20); mass spectrum, *m/e* (relative intensity, %): 375 (M^+ +1, 7), 374 (M^+, 29), 315 (30), 314 (57), 291 (92), 229 (32), 175 (40), 84 (100). Anal. calcd. for $C_{24}H_{38}O_3$: C 76.96, H 10.22; found: C 76.89, H 10.12.

Compound **11** was a solid; mp 202–202.5°C (from methanol); $[\alpha]_D$ −78.2° (*c* 0.55, $CHCl_3$); ir (KBr disk), ν_{max}: 2935, 2855, 1720, 1700, 1245, 1170 cm^{-1}; ^1H nmr, δ: 0.76 (s, 3H, CH_3-13α), 0.84 (s, 3H, CH_3-10β), 1.14 (s, 3H, CH_3-4β), 2.08 (s, 3H, $COCH_3$), 2.96 (t, *J* 9 Hz, 1H, H-17β), 3.62 (s, 3H, CO_2CH_3); ^{13}C nmr, δ: 14.60 (C-19), 16.70 (CH_3-4β), 18.05 (C-2), 19.42 (C-11), 24.04 (C-16), 24.36 (C-6), 25.46 (C-18), 25.92 (C-15), 31.72 (C-21), 33.13 (C-7), 34.55 (C-12), 36.38 (C-10), 36.87 (C-3), 37.29 (C-8), 38.02 (C-1), 45.33 (C-13), 47.56 (C-4), 49.61 (C-5), 51.83 (OCH_3), 54.25 (C-17), 55.01 (C-9), 55.95 (C-14), 179.44 (CO_2), 210.88 (C-20); mass spectrum, *m/e* (relative intensity, %): 375 (M^+ +1, 1), 374 (M^+, 4), 359 (1), 356 (3), 315 (3), 314 (6), 291 (9), 229 (4), 84 (24), 43 (100).

2-*S*-Methyl-5,5-dimethylimidazolin-4-one can be crystallized as Δ^1 or Δ^2 tautomers, depending on the solvent polarity. The structure, solved on crystals obtained from benzene, showed it to be the Δ^1 tautomer in the *anti* configuration. Δ^1-2-*S*-Methyl-5,5-dimethylimidazolin-4-one is monoclinic, space group $P2_1/c$, *with* a = 8.347(1), b = 10.121(1), c = 9.996(3) Å, β = 107.20(2)°, R = 0.037 for 1395 independent reflections with $I > 1\sigma(I)$. The quantum mechanical (MNDO, PM3, and AM1) calculations indicate that among the four conformers the *anti*-Δ^1 tautomer has both the lowest dipole moment and the lowest enthalpy of formation. The ultraviolet spectrum of the title compound has been recorded in solvents with different dielectric constants. The infrared spectra of the Δ^1 and Δ^2 solid samples are discussed relative to the ν(NH) and ν(CO) absorptions and in comparison with those recorded in carbon tetrachloride and in chloroform solution. Its acid–base behaviour has been studied by determining the pK_a in aqueous solutions and the results are compared with those obtained for some related hydantoins.

Key words: 2-*S*-methyl-5,5-dimethylimidazolin-4-one, tautomerism, hydantoin derivatives, crystal structure.

Le 2-*S*-méthyl-5,5-diméthylimidazoline-4-one peut être cristallisé comme tautomères Δ^1 ou Δ^2, selon la polarité du solvant. La structure, qui a été résolue sur des cristaux obtenus d'une solution benzénique, a mis en évidence que la tautomère Δ^1 possède une configuration *anti*. Δ^1-2-*S*-Méthyl-5,5-diméthylimidazoline-4-one est monoclinique, groupe spatial $P2_1/c$, avec a = 8,347(1), b = 10,121(1), c = 9,996(3) Å, β = 107,20(2)°, R = 0,037 pour 1395 réflections indépendantes avec $I > 1\sigma(I)$. Les résultats des calculs de mécanique quantique indiquent que le tautomère *anti*-Δ^1 a le moment dipolaire et l'enthalpie de formation les plus bas parmi les quatre conformères. Les spectres ultraviolets du composé dissous dans des solvants ayant des constantes diélectriques différentes ont été enregistrés. Les spectres infrarouges des tautomères sont discutés par rapport aux absorptions ν(NH) et ν(CO) et en comparaison avec ceux enregistrés dans le tétrachlorure de carbone et le chloroforme. Le comportement acide–base du composé a été étudié par la détermination du pK_a en solution aqueuse et les résultats ont été comparés à ceux obtenus pour certaines hidantoïnes apparentées.

Mots clés : 2-*S*-méthyl-5,5-diméthylimidazoline-4-one, tautomérie, dérivés hydantoïnes, structure cristalline.

Introduction

S-Methylation of 5,5-dimethyl-2-thioxoimidazolidin-4-one (L = ligand) yields Δ^1- or Δ^2-2-*S*-methyl-5,5-dimethylimidazolin-4-one tautomers (**I** or **II**), i.e.,

Δ^1(I) Δ^2(II)

This tautomerism, defined as annular desmotropy, was studied by ir and uv spectroscopies in several hydantoin derivatives (1, 2). Lempert *et al.* (2) determined the X-ray structures of the two desmotropes of 2-*S*-methyl-5,5-diphenylimidazolin-4-one in 1973, and showed that the polarity of the solvent is crucial in obtaining one of the two tautomers. Apolar solvents, such as carbon tetrachloride or benzene, stabilize the Δ^1 tautomer, while solvents such as water stabilize the Δ^2.

Since our main interest is in the coordination chemistry of the **I**/**II** mixture, our main goals will be to ascertain which factors can induce the ligand to coordinate a metal as **I** or **II** and to find out if the nature of the metal is important in determining the coordination by **I** or **II**. For instance, the reaction of 2-*S*-methyl-5,5-dimethylimidazolin-4-one with $CuCl_2$ in Pr^{i}OH at room temperature yielded a complex whose crystal structure was solved as $[CuL_4 \cdot H_2O]^{2+}[CuCl_4]^{2-}$ with the ligand N-coordinated as **II**.[3]

To clarify the chemical behaviour of the ligand, we have carried out a study on 2-*S*-methyl-5,5-dimethylimidazolin-4-one, by several techniques, both in the solid state and in solutions of different solvents.

Experimental section

2-S-Methyl-5,5-dimethylimidazolin-4-one

2-*S*-Methyl-5,5-dimethylimidazolin-4-one was prepared as previously described (3). Its recrystallization from benzene yields **I**, whereas from water **II** is obtained.

Spectroscopic measurements

The ir spectra (3500–3050 cm^{-1} and 1800–1600 cm^{-1}) were recorded in CCl_4 solutions in variable temperature liquid cells Specac P/N 21000 of NaCl with a pathlength of 0.1 cm using a Perkin–Elmer 983 instrument connected with a Perkin–Elmer 7500 data station. The ir spectra (3500–200 cm^{-1}) on the solid samples were recorded as KBr discs.

The uv spectra were recorded in several solvents using a Cary 2300 instrument, connected with a DS15.

X-ray data collection and structure determination of I

The solid obtained from benzene yielded crystals suitable for an X-ray structure determination. Crystal data and other experimental details are summarized in Table 1. The diffraction experiment was carried out on a Enraf–Nonius CAD-4 diffractometer at room temperature using monochromated Mo-K_α radiation (λ = 0.71073 Å). The calculations were performed on a PDP 11/73 computer using the SDP-Plus structure determination package (4). The diffracted intensities were corrected for Lorentz, polarization, and absorption (empirical correction) (5). Scattering factors for all the atomic species and anomalous dispersion corrections for scattering factors of non-hydrogen atoms were taken from ref. 6.

The structure was solved by direct methods (MULTAN), and refined by full-matrix least squares, minimizing the function $\Sigma w(F_o - k|F_c|)^2$. All the hydrogen atoms were located by a difference Fourier synthesis.

Anisotropic thermal factors were refined for all the non-hydrogen atoms, and isotropic temperature factors for the hydrogen atoms. The final difference Fourier synthesis showed maximum residuals of 0.2 e/Å^3. The atomic coordinates of the structure model are listed in Table 2.[4]

Potentiometric measurements

Potentiometric measurements were carried out using a Metrohm E 654 meter equipped with a Metrohm 6.0203 combined glass electrode. The potentiometer was connected with a PC IBM XT controlling the addition of the titrant (KOH) delivered from a Metrohm digital dispenser (model Dosimat E 665); the titrations on 2-*S*-methyl-5,5-dimethylimidazolin-4-one both alone and in presence of an excess of mineral acid (HCl) were performed automatically.

The electrode was standardized on the pH = $-\log C_{H^+}$ scale by titrating HNO_3 (0.01–0.005 mol dm^{-3}) with KOH at 25°C and I = 0.1 mol dm^{-3} (KNO_3). The titrations were carried out over a range of concentrations of 2-*S*-methyl-5,5-dimethylimidazolin-4-one between 0.001 and 0.01 mol dm^{-3}. All titrations were performed in triplicate.

The calculations of the E^0 of the electrode system, the purity of the compound, and the excess of HCl were performed by the least-squares computer program SUPERQUAD (7). The calculations of the ionization constants were performed by SUPERQUAD as well as by PSEQUAD (8). The latter program was modified to obtain a graph of the titration curve.

Conformational calculations

The calculations of the most stable conformations were done using the semiempirical quantum mechanical methods MNDO, AM1, and PM3 (9–12). The first two have been very useful in many chemical applications and AM1, in particular, is gaining major attention because of its ability to correct for the excessive long-range repulsions in the core–core repulsion terms occurring in the original MNDO method. The third, a newly parameterized MNDO method, has been added for comparison; it differs from the parent MNDO in that all two-electron one-center integrals have been optimized and, according to the author, it leads to better estimates of both heats of formation and molecular geometries (12). In the AM1 calculations the parameters of the sulphur atom were taken from the MNDO calculations, as implemented in the MOPAC 5.0 quantum mechanical package (13). The final geometries

Starred atoms were refined isotropically. Anisotropically refined atoms are given in the form of the isotropic equivalent thermal parameter defined as: $(4/3)*[a^2*B(1,1) + b^2*B(2,2) + c^2*B(3,3) + ab(\cos\gamma)*B(1,2) + ac(\cos\beta)*B(1,3) + bc(\cos\alpha)*B(2,3)]$.

[4]Tables of observed and calculated structure factor amplitudes, interatomic distances and angles, and temperature factors may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

Tables of interatomic distances and angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

[c]In the AM1 and MNDO approximations the *syn*-Δ^1 tautomer does not correspond to a minimum of energy and the calculation converges to the *anti* tautomer.

of the most stable conformers were refined using the PRECISE keyword, which increases the criteria for terminating electronic and geometric optimization by a factor of 100. Final force constant calculations on the optimized geometries were run with the FORCE keyword to locate ground and (or) transiton states in the potential energy hypersurface.

Results and discussion

For a better understanding of the chemical behaviour of 2-*S*-methyl-5,5-dimethylimidazolin-4-one, we carried out conformational computations both on the Δ^1 and Δ^2 monomers at the MNDO, PM3, and AM1 quantum mechanical level (9–13). Tables 3 and 4 summarize respectively some molecular properties and the optimized geometries of the four most stable conformations of the two monomers obtained with the different calculations. From the values of the enthalpies of formation (ΔH_f), at all levels of quantum mechanical approximations, it is evident that the *anti*-Δ^1 tautomer is the most stable compound, since it has a dipole moment (μ) close to that of the *syn*-Δ^1 and lower than both the Δ^2 conformers and its energy is 3 kcal/mol lower than that of its *syn* analogue and even lower than those of the Δ^2 compounds (see Table 3). It is also evident that the two Δ^2 conformers differ strongly in dipole moment and in spite of the difference in formation energy it is very probable that the solid obtained from water is the *syn*-Δ^2 tautomer. Unfortunately, these crystals are not suitable for an X-ray analysis.

As far as the *syn*-Δ^1 conformer is concerned, we point out that the AM1 and MNDO calculations gave no evidence that it is a stable compound. In fact, on optimization the *syn*-Δ^1 geometry converged to that of *anti*-Δ^1, this being due to the occurrence of a shallow minimum. This was not the case with the PM3 calculation by which a deeper minimum was found. Table 4 also collects the bond lengths and angles of the hydantoin rings found by an X-ray study of crystals obtained from benzene. The

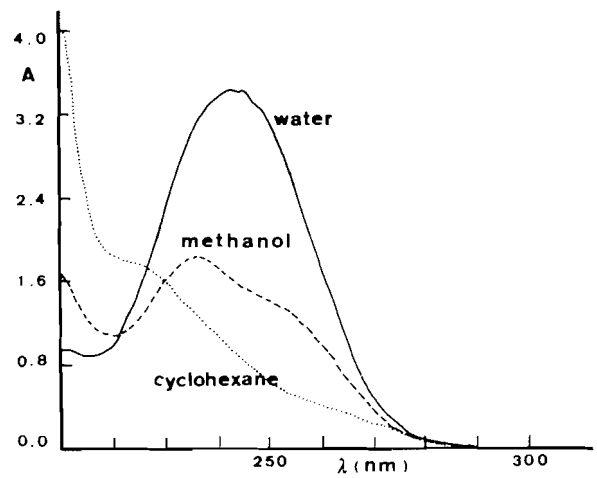

FIG. 1. Ultraviolet spectra of 2-*S*-methyl-5,5-dimethylimidazolin-4-one in solvents at different polarities.

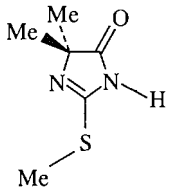

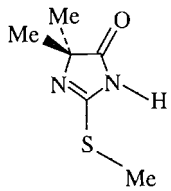

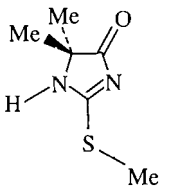

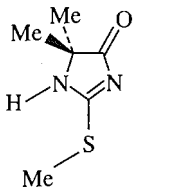

optimized geometry of *anti*-Δ^1 agrees fairly well with the experimental; in particular, this structure is found to be the most planar among the four; the major differences are seen in the C(2)—N(3) and N(3)—C(4) bond lengths. These are almost certainly due to the occurrence in the solid state of hydrogen bonds that were not accounted for in the quantum mechanical calculations. In fact PM3 calculations, carried out not on an isolated molecule but on a doubly hydrogen bonded molecule, have shown a consistent shortening of these two bonds, which become 1.429 and 1.437 Å respectively. However, packing forces in the solid state occur that are not reproduced by the calculations, as suggested by the differences in the dihedral angle N(3)—C(2)—S(6)—C(61).

As regards the comparison of the three quantum mechanical

methods, while the data in Tables 3 and 4 indicate a similar ability in giving relative formation enthalpies and molecular electric dipoles, they clearly show a better agreement between the geometries obtained by the AM1 and PM3 methods. In particular, with the PM3 method the calculated C—S bond lengths are very close to the experimental values.

Solution studies

Ultraviolet spectra

The spectra were recorded in solvents with various dielectric constants. They are independent of the starting sample (**I** or **II**) but undergo very large changes on passing from water to MeOH and cyclohexane (see Fig. 1). These changes agree well with those found for similar molecules, and previously assigned on the basis of the spectra of the *N*-methylated derivatives (1). In water, the absorption at higher wavelengths indicates that the conjugated structure **II** is the predominant tautomer (1, 2); vice versa, the unconjugated **I** is predominant in cyclohexane (as a non-polar solvent). The mixture of the two tautomers is clearly evident in a solvent with intermediate polarity such as MeOH.

Infrared spectra

In carbon tetrachloride, as expected, **I** and **II** show the same infrared spectrum. In particular, four ν(NH) stretching vibrations have been identified: one falling at 3442 cm^{-1} due to the free molecule, and three overlapped bands at 3086, 3171, and 3211 cm^{-1} due to the associated hydrogen bonding molecules. Figure 2a reports the spectra recorded between 3500 and 3000

cm^{-1} at three temperatures in the same solution. This solution shows only two peaks at 1760 and 1730 cm^{-1} in the ν(CO) region, attributable to the free and associated hydrogen bonding molecules (Fig. 2b). Both figures show very clearly the influence of temperature on the monomer–dimer equilibrium.

In chloroform, the ν(NH) absorptions show the same pattern as in carbon tetrachloride, except for a broadening of $\nu(NH)_{free}$ (the half-band width, $\Delta\nu_{1/2}$, is 19 cm^{-1} in carbon tetrachloride and 31 cm^{-1} in chloroform). However, this broadening, which could be due to the presence of two overlapped bands attributable to the $\nu(NH)_{free}$ of **I** and **II**, can also be explained on the basis of the different polarities of the two solvents. In the ν(CO) region, the bands due to both the free and associated molecules contribute to one broad absorption at 1738 cm^{-1} ($\Delta\nu_{1/2}$ = 40 cm^{-1}).

Acid–base behaviour

To obtain information on the aqueous solutions, where 2-*S*-methyl-5,5-dimethylimidazolin-4-one is present prevalently as the Δ^2 tautomer, we determined its pK_a both alone and in the presence of hydrochloric acid. The results obtained by the two methods are collected in Table 5, together with those obtained for 5,5-dimethyl-2-thioxo-imidazolidin-4-one (sox), and for its N(1)-methyl (mesox) and N(3)-methyl (soxme) derivatives.

pK_1 and pK_2 arise from the equilibria that involve as acids the LH^+ and L species respectively.

As can be seen, the results obtained from the two different programs practically coincide, as well as the pK_2 values obtained both in the presence and absence of mineral acid. Moreover, it appears very clear that 2-*S*-methyl-5,5-dimethyl-imidazolin-4-one in strong acidic medium is protonated,[5] whereas 5,5-dimethyl-2-thioxoimidazolidin-4-one and the *N*-methylated derivatives are not. The difference of about two pH units between mesox and soxme is due to the fact that mesox loses the hydrogen bonded to N(3), whereas soxme loses the hydrogen that is bonded to N(1). The comparison of pK_2 for sox and mesox clearly shows that the methyl group does not affect the pK values. The calculated value for our compound is exactly intermediate between those for soxme and mesox.

[5]We recently reported the crystal structure of LH^+ with I_3^- as a counterion, obtained by reacting L with I_2 in CH_2Cl_2 solution (14).

TABLE 5. pK_a values measured on 2-*S*-methyl-5,5-dimethylimidazolin-4-one (**I**/**II**), 5,5-dimethyl-2-thioxoimidazolidin-4-one (sox), 1,5,5-trimethyl-2-thioxoimidazolidin-4-one (mesox), and 3,5,5-trimethyl-2-thioxoimidazolidin-4-one (soxme)

Solid state studies

Structure of I

The structure of 2-*S*-methyl-5,5-dimethylimidazolin-4-one, solved for a crystal obtained from benzene, shows that it is the Δ^1 tautomer, i.e., **I** in the *anti* configuration (Fig. 3). Bond distances and angles are collected in Table 6. It is interesting to observe that the hydantoin skeleton is substantially unchanged on *S*-methylation; the major changes involve the variation of (i) the N(1)—C(2) bond, which undergoes a strong shortening (1.280(2) in **I** and 1.325(2) in 2-thiohydantoin); (ii) the C(2)—S(6) bond (1.741(1) in **I** and 1.648(2) in 2-thiohydantoin), which still has a significant double-bond character; and (iii) the

Ref.	Present work	14	3	3	3	3

Triiodide = 5,5-dimethyl-2-methylthio-4-oxoimidazolidinium triiodide.
ss = 5,5-dimethylimidazolidine-2,4-dithione.
seox = 5,5-dimethyl-2-selenoxoimidazolidin-4-one.
sse = 5,5-dimethyl-4-selenoxoimidazolidine-2-thione.

N(1)—C(2)—N(3) angle, which undergoes a sensitive increase (115.5(1) in **I** and 106.8(1) in 2-thiohydantoin). To this purpose, it is also interesting to compare the angles around C(2) in the title compound and in some related hydantoin derivatives. Table 7 collects the bond distances and angles of **I**, 5,5-dimethyl-2-methylthio-4-oxoimidazolidinium triiodide (14), 5,5-dimethylimidazolidine-2,4-dithione (3), 5,5-dimethyl-2-selenoxoimidazolidin-4-one (3), 5,5-dimethyl-2-selenoxoimidazoline-2-thione (3), and 2-thiohydantoin (3). The differences in the angles around the C(sp^2) for all these compounds can be easily interpreted in terms of the VSEPR model. As shown in the table, the α values are always greater than the β, as a consequence of the higher conjugation of the lone pair of N(1) with respect to N(3), with a consequent increased repulsion

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

between the N(1)—C(2) and C(2)=X bonds. The greater the difference in the repulsion, the higher the difference ($\alpha - \beta$) in the angles.

As expected, the value for this difference of 11.9° found in **I** is the highest among the compounds considered, since only in this compound is N(1)—C(2) practically a double bond. On the other hand, as a consequence of this double bond, the value of the angle γ, internal to the ring, is also the highest. The protonation of **I** on the N(1), observed in the 5,5-dimethyl-2-methylthio-4-oxoimidazolidinium triiodide (14), shifts the angles towards those verified in the hydantoin derivatives.

One of the most interesting features in the structure is that the oxygen atom is not involved in the hydrogen bonding and that the molecules are bound together in the crystal by hydrogen bonds involving only the N(1) and N(3) atoms. Hence, the molecular packing is realized by this hydrogen bond and by some weak van der Waals contacts (see Table 6).

The least-squares planes through the molecule show that the five-membered ring is not rigorously planar, with a deviation of −0.029(2) Å from the "best plane" for C(5).

Infrared spectra

Contrary to what was found in solution, **I** and **II** show two different ir spectra in the solid state, as shown in Fig. 4. It is very interesting to point out the differences in ν(NH) and ν(CO) absorptions. As said above, **I** (full line), obtained from benzene and whose structure has been solved, exhibits a ν(NH) band envelope at about 2800 cm^{-1} and a ν(CO) absorption at 1744 cm^{-1}; while **II** (dotted line) shows the ν(NH) band at 3100 cm^{-1} and ν(CO) at 1670 cm^{-1}.

The low value of ν(NH) found for **I** agrees with the crystallographic results. In fact, by introducing the value of 2.912 Å for the N(1)···N(3) distance R in the equation of Pimentel and Sederholm (15), $\Delta\nu_S = 1.05 \times 10^3 (3.38 - R)$, a shift of about 500 cm^{-1} from $\nu(NH)_{free}$ measured in CCl_4 is calculated, which is not very different from the experimental results.

The infrared spectrum of **II** in the solid state shows a ν(NH) absorption at 3100 cm^{-1}, which indicates a different hydrogen bonding pattern, attributable to an N—H···O interaction. Conversely, the N—H···O hydrogen bonding has been found in both the structures of the Δ^1 and Δ^2 tautomers of 2-*S*-methyl-5,5-diphenylimidazolin-4-one (2). This fact can explain the difference of 74 cm^{-1} between the ν(CO) frequencies of Δ^1 and Δ^2 tautomers of the title compound, a value very high if compared with those of 20 cm^{-1} in the two tautomers of 2-*S*-methyl-5,5-diphenylimidazolin-4-one (2) and 25 cm^{-1} in the two N(1)- and N(3)-methyl isomers of 2-*S*-methyl-5,5-pentamethyleneimidazolin-4-one (1).

Conclusions

The ir spectra of the two tautomers differ mainly in the ν(NH) and ν(CO) frequencies, as seen in Fig. 4. The low value of the ν(NH) frequency (around 2800 cm^{-1}) for **I** in the solid state agrees well with the data obtained from the crystal structure.

As regards the carbon tetrachloride or chloroform solutions, **I** and **II** show the same spectrum, which, on the basis of the position of the ν(CO) absorption, of the uv spectrum, and of the results of the theoretical calculations, must be attributed to the prevailing presence of **I**. Moreover, the calculations indicate that of the two possible tautomers in each of the possible configurations *anti* or *syn* with respect to the N-H hydrogen, the more stable in nonpolar solvent is the *anti*-Δ^1. Contrary to what was found in the solid state, in carbon tetrachloride solutions the more stable hydrogen bonds involve the oxygen atom.

In aqueous solutions, where 2-*S*-methyl-5,5-dimethylimidazolin-4-one is present mainly as the Δ^2 tautomer, the pK_a value clearly shows that proton detachment from N(1) occurs more easily than in the case of the N(3)-alkyl substituted hydantoins. This can be explained on the basis of a high contribution of the oxygen atom to the dispersion of charge of the anion (note the difference in the ν(CO) values between the two desmotrops).

The crystal and molecular structure of gold tris(fluorosulfate)

H. WILLNER,[1] S. J. RETTIG, J. TROTTER, AND F. AUBKE[2]

Department of Chemistry, The University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received September 24, 1990

H. WILLNER, S. J. RETTIG, J. TROTTER, and F. AUBKE. Can. J. Chem. **69**, 391 (1991).

Single crystals of gold(III) tris(fluorosulfate) are obtained by recrystallization from bis(fluorosulfuryl) peroxide, $S_2O_6F_2$, under O_2 pressure. The crystals of $[Au(SO_3F)_3]_2$ are monoclinic, $a = 9.700(4)$, $b = 9.222(2)$, $c = 10.810(4)$ Å, $\beta = 94.43(3)°$, $Z = 2$, space group $P2_1/a$. The structure was solved by heavy atom methods and was refined by full-matrix least-squares procedures, $R(F) = 0.038$ and $R_w(F) = 0.050$ for 1491 reflections with $I \geq 3\sigma(I)$. The structure consists of centrosymmetric $[Au(SO_3F)_3]_2$ dimers containing two bidentate, symmetrically bridging and four monodentate, terminal SO_3F ligands. The Au(III) ions have square-planar coordination geometry with bridging Au—O = 2.020(7) and 2.016(6) Å, and terminal Au—O = 1.959(7) and 1.956(9) Å. The dimeric $[Au(SO_3F)_3]_2$ units are linked in the solid state by weak Au—O interactions (2.757(8) and 2.960(7) Å), resulting in a distorted octahedral coordination geometry about each gold atom.

Key words: gold(III) tris(fluorosulfate), crystal structure.

H. WILLNER, S. J. RETTIG, J. TROTTER et F. AUBKE. Can. J. Chem. **69**, 391 (1991).

On a obtenu des cristaux uniques du tris(fluorosulfate) d'or(III) par recristallization de peroxyde de bis(fluorosulfuryle), $S_2O_6F_2$, sous pression d'O_2. Les cristaux de $[Au(SO_3F)_3]_2$ sont monocliniques, groupe d'espace $P2_1/a$, avec $a = 9{,}700(4)$, $b = 9{,}222(2)$ et $c = 10{,}810(4)$ Å, $\beta = 94{,}43(3)°$ et $Z = 2$. On a résolu la structure par la méthode des atomes lourds et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R(F) = 0{,}038$ et $R_w(F) = 0{,}050$ pour 1491 réflexions avec $I \geq 3\sigma(I)$. La structure comprend des dimères centrosymétriques de $[Au(SO_3F)_3]_2$ contenant deux ligands SO_3F bidentates, formant un pont symétrique, et quatre ligands monodentates terminaux. Les ions d'Au(III) possèdent une géométrie de coordination plan-carré dans laquelle les liaisons Au—O (pont) = 2,020(7) et 2,016(6) Å et Au—O (terminales) = 1,959(7) et 1,956(9) Å. À l'état solide, les unités de $[Au(SO_3F)_3]_2$ dimères sont liées par de faibles interactions Au—O (2,757(8) et 2,960(7) Å) qui conduisent à une géometrie de coordination octaédrique déformée autour de l'atome d'or.

Mots clés : tris(fluorosulfate) d'or, structure cristalline.

[Traduit par la rédaction]

Introduction

Gold tris(fluorosulfate), $Au(SO_3F)_3$, first reported by Cady and co-workers (1), is one of the few well-characterized binary gold(III) oxyacid derivatives (2). The compound is conveniently synthesized by the oxidation of gold powder with bis(fluorosulfuryl) peroxide (3), $S_2O_6F_2$, in fluorosulfuric acid, HSO_3F, as reaction medium.

Solid $Au(SO_3F)_3$ redissolved in HSO_3F is one of the strongest monoprotonic superacids (3, 4). The ability of $Au(SO_3F)_3$ to act as a SO_3F^- acceptor is evident from the formation and isolation of a number of tetrakis(fluorosulfato)aurate(III) salts with a variety of cations (3).

Vibrational spectra and the observed diamagnetism of pure $Au(SO_3F)_3$ have suggested an approximately square planar environment of gold, and the presence of both bidentate bridging and monodentate fluorosulfate groups (3). A low degree of intermolecular association is inferred from the appreciable solubility of $Au(SO_3F)_3$ in HSO_3F, and from a recent computer modelling study of electrical conductivity data on the HSO_3F–$Au(SO_3F)_3$–KSO_3F system (5).

We want to report on the molecular structure of gold(III) fluorosulfate, obtained by single crystal X-ray diffraction. Gold(III) fluorosulfate in the solid state consists of weakly associated dimeric $[Au(SO_3F)_3]_2$ units. Its structure reported here is of interest for the following reasons: (*i*) It is the first structure obtained for a binary metal fluorosulfate, other than the ionic fluorosulfates KSO_3F (6*a*) and $LiSO_3F$ (6*b*). (*ii*) Unprecedentedly, solid $[Au(SO_3F)_3]_2$ shows the presence of two distinctly different fluorosulfate groups in the same molecule. (*iii*) A detailed discussion of the dimeric structure will shed some light on the observed high Lewis acidity of gold(III) fluorosulfate, which makes its solution in fluorosulfuric acid one of the strongest, monoprotonic superacid systems (3–5). (*iv*) We have very recently generated defects of the highly unusual (2) cation Au^{2+} in solid $[Au(SO_3F)_3]_2$ (7). Knowledge of the structure of gold(III) fluorosulfate allows a better interpretation of the ESR spectra obtained for Au^{2+} defects (7). (*v*) As recently shown (8), the superacid system HSO_3F–$Au(SO_3F)_3$ has an interesting redox chemistry. Interaction with gaseous CO results in the formation of $[Au(CO)_2]^+$ and $Au(CO)SO_3F$, where an unusual type of CO bonding to gold is encountered.

Experimental

(a) Preparation of single crystals

Gold tris(fluorosulfate) is prepared from gold powder, oxidized by bis(fluorosulfuryl) peroxide, $S_2O_6F_2$ (9) in solution of fluorosulfuric acid, HSO_3F, as reported previously (3*a*). About 100 mg of the polycrystalline powder, obtained after removal of all volatiles, are filled inside an inert atmosphere box into a glass ampul, about 100 mm long with 10 mm o.d. Approximately 1 g $S_2O_6F_2$ are added *in vacuo* and O_2 gas is admitted, to give at room temperature an internal pressure of about 3 atm in the sealed-off ampul. The suspension of $[Au(SO_3F)_3]_2$ in $S_2O_6F_2$ is submersed in a bath of halocarbon wax (Halocarbon Products Corp.) and heated to 80°C for about 2 weeks. During this period orange–red crystals are formed above the $S_2O_6F_2$ level. The ampul is opened *in vacuo*, using an "ampul key", as described previously (10) and all O_2 and $S_2O_6F_2$ are distilled off. Suitable crystals are filled into carefully dried quartz capillaries of 0.5 mm diameter, again inside an inert atmosphere box (Vacuum Atmosphere Corp. Dri Lab. Model HE-493, filled with dry N_2 and equipped with a HE-493 Dri Train).

(b) Crystallographic details

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25

[a]Temperature 294 K, Rigaku AFC6S diffractometer, graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1), $\sigma^2(F^2) = [S^2(C + 4B) + (0.04F^2)^2]/Lp^2$ (S = scan rate, C = scan count, B = normalized background count), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, and gof = $[\Sigma(|F_o| - |F_c|)^2/(m - n)]^{1/2}$. Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

reflections with $2\theta = 41.8$–$45.7°$. The intensities of three standard reflections, measured every 150 reflections throughout the data collection, decayed uniformly by 4.5%. The data were processed[3] and corrected for Lorentz and polarization effects, decay, and absorption (empirical, based on azimuthal scans for four reflections). A total of 2478 reflections was collected on a Rigaku AFC6S diffractometer, of these 2347 were unique ($R_{int} = 0.081$) and those 1491 having $I \geq 3\sigma(I)$ were employed in the solution and refinement of the structure.

The structure was solved by conventional heavy atom methods, the coordinates of the Au and S atoms being determined from the Patterson function and those of the remaining atoms from a subsequent difference Fourier synthesis. All atoms were refined with anisotropic thermal parameters. The thermal parameters of the terminal O and F atoms bonded to S(3) suggest a possible rotational disorder about the S(3)—O(7) bond but no attempt was made to model this disorder, these atoms being refined with full occupancy. Neutral atom scattering factors and anomalous dispersion corrections for all atoms were taken from the International tables for X-ray crystallography (11). A correction for secondary extinction was applied, the final value of the coefficient being 0.645×10^{-6}. Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and bond angles appear in Tables 2–4, respectively. Anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor amplitudes are included as supplementary material.[4]

Results and discussion

(a) Single crystal preparation

The method used to obtain suitable single crystals, heating microcrystalline $Au(SO_3F)_3$, suspended in bis(fluorosulfuryl) peroxide, $S_2O_6F_2$, in an O_2-atmosphere for 2 weeks at 80°C was found during an unsuccessful attempt to synthesize a dioxygenyl salt according to

[1] $2O_2 + 2Au(SO_3F)_3 + S_2O_6F_2 \rightarrow 2O_2[Au(SO_3F)_4]$

It is unclear if O_2 is necessary for the preparation of single crystals. Obviously the boiling point of $S_2O_6F_2$, reported to be

67.1°C at 1 atm (9, 12*a*), is raised beyond the bath temperature of 80°C, and glass attack by $SO_3F\cdot$ radicals in the gas phase (12*b*) is now largely prevented.

The presence of $S_2O_6F_2$, on the other hand, appears to be important. Attempts to sublime solid $[Au(SO_3F)_3]_2$ *in vacuo*, or heating the compound to 125°C *in vacuo* results in the formation of Au^{2+} defects in the solid, presumably with release of $S_2O_6F_2$ (7). The gradual dissociation of $Au(SO_3F)_3$ at 80°C appears to be prevented by the presence of $S_2O_6F_2$. An extension of the method to grow single crystals of other metal fluorosulfates is presently being attempted.

It is interesting to note, that in addition to the plate-like crystals used in this study, one of the synthetic attempts yielded needle-like crystals, which were not investigated further.

(b) Description of the molecular structure of $Au(SO_3F)_3$

An ORTEP view of the molecular structure is shown in Fig. 1 and the packing of molecules in the unit cell is shown in Fig. 2. As can be seen, gold(III) fluorosulfate is dimeric in the solid state, quite in contrast to polymeric AuF_3 (13). On the other hand, there is a structural similarity to the other halides $AuCl_3$ (14) and $AuBr_3$ (15), which are also both dimeric.

The presence of bidentate, symmetrically bridging fluorosulfate groups widens the four-membered metallocycle, found for the two halides $AuCl_3$ and $AuBr_3$ (14, 15), to an eight-membered, centrosymmetric ring, which adopts a chair configuration. The two gold atoms are found in transannular positions with a cross ring distance of 4.510(2) Å, and are linked by two SO_2 moieties from the bridging bidentate fluorosulfate groups.

Both gold(III) centers are found in identical, nearly square coordination environments. The mean deviation from planarity is found to be 0.020 Å, and the maximal displacement is 0.053(7) Å, found for O(4). The close approach to a square planar geometry is evident also from the relevant bond angles (O—Au—O = 87.4(3)–93.2(3), 177.1(3), and 177.7(3)°).

The AuO_4-squares are slightly distorted, because the terminal, monodentate fluorosulfate groups bond more strongly to gold ($Au—O_{av.}$ = 1.957 Å) than do bridging, bidentate groups

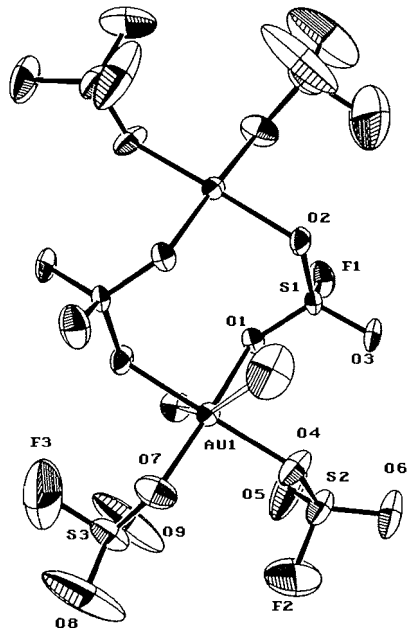

FIG. 1. View of the $[Au(SO_3F)_3]_2$ dimer; 50% probability thermal ellipsoids are shown. Labeled atoms comprise the asymmetric unit.

($Au—O_{av.}$ = 2.018 Å). Similar, slightly larger discrepancies between distances to bridging and terminal halides are reported for the gold–halogen distances in the gold(III) halides, AuF_3 (13), $AuCl_3$ (14), and $AuBr_3$ (15).

In the dimeric molecule, the two AuO_4-planes are positioned parallel to each other transposed by 2.124 Å and connected by bidentate SO_3F groups. The disposition of the four SO_3F groups about the gold(III) ion is interesting. As seen in Fig. 1, the terminal SO_3F groups coordinated to Au(1) are bent below the AuO_4 plane, while the bidentate SO_3F groups are pointing up. For Au(1)* the opposite, pairwise disposition of coordinated fluorosulfate groups is noted, thus generating the chair configuration of the metallocycle. A similar pairwise arrangement of coordinated monodentate nitrate groups is reported for the

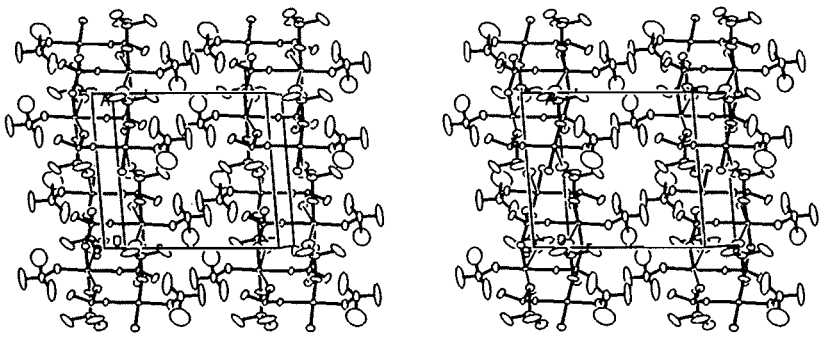

FIG. 2. Stereoview of the packing arrangement of gold(III) tris(fluorosulfate) viewed along the ***b*** axis.

$[Au(NO_3)_4]^-$ anion (16), where for the potassium salt a space group identical to the one found for $[Au(SO_3F)_3]_2$, $P2_1/a$, is reported. Hence the symmetry of the two $Au(SO_3F)_4$ moieties and of the $[Au(NO_3)_4]^-$ anion corresponds approximately to the point group C_{2h}.

Besides the short Au—O bonds, there are two, somewhat longer intermolecular Au···O contacts, Au(1)—O(6)′ at 2.757(8) Å and Au(1)—O(3)″ at 2.960(7) Å, above and below the Au(1)—O_4 plane. They give rise to a very distorted octahedral arrangement about gold(III), with the distortion also reflected in the O(6)′—Au(1)—O(3)″ bond angle, found to be 158.6(3)° rather than the expected 180°. A more regular, tetragonally elongated example for 4:2 coordination is reported for AuF_3 (13*b*), while for $AuCl_3$ (14), $AuBr_3$ (15), and Au_2O_3 (17*a*) several rather long Au···X, X = halogen or oxygen, contacts are found for each gold atom resulting in complex and highly distorted polyhedral geometries. Likewise in the $[Au(NO_3)_4]^-$ anion (16), four relatively short Au···O contacts of ~2.85 Å are observed, but these are intramolecular in nature and involve oxygen atoms of the bonded nitrate groups.

Thus only AuF_3 (13) and $[Au(SO_3F)_3]_2$ may be regarded as examples of 4:2 coordination with the regular arrangement in AuF_3 seemingly a consequence of the compact helical chain structure adopted by this compound. The denser packing in AuF_3 is reflected in the calculated density (13) of 6.78 g cm^{-3} while for $[Au(SO_3F)_3]_2$ a value of 3.404 g cm^{-3} is found, and in the Au···Au distances of 3.461 Å in AuF_3 versus 4.510 Å in $[Au(SO_3F)_3]_2$. The looser packing in $[Au(SO_3F)_3]_2$ and the low degree of intermolecular association contribute in our view to the fairly high solubility in HSO_3F and the acidity of the resulting monoprotonic superacid system.

(c) Discussion of bond parameters

Two aspects remain to be discussed: (*i*) The Au—O bond distances compared to values obtained for other gold(III) oxygen compounds (16–23) and (*ii*) the SO_3F bond parameters, viewed in comparison to relevant precedents. The structural chemistry of gold(III) (18) provides a number of relevant examples, in addition to the binary halides, AuF_3 (13), $AuCl_3$ (14), and $AuBr_3$ (15) already discussed. Nearly square planar AuO_4-groups are found in Au_2O_3 (17*a*), and $[Au(OH)_4]^-$ (17*b*), the selenite-oxide $Au_2(SeO_3)_2O$ (19*a*) and -chloride $Au(SeO_3)Cl$ (19*b*), the tetrakis(nitrato)aurate(III) anion found in $K[Au(NO_3)_4]$ (16), and in aurate(III) anions of various types found in Li_5AuO_4, $KAuO_2$, and $RbAuO_2$, according to X-ray powder data (20), and in $Na_6Au_2O_6$ (21) where a discrete $Au_2O_6^{2-}$ ion is present according to a single crystal diffraction study. A dimeric structure is suggested for $Au(OTeF_5)_3$ (22); however, the structure is disordered. A sulfonate group bonded to Au(III) is found in the organometallic compound $(CH_3)_2Au(H_2O)$-SO_3CF_3 (23). In most instances an approximately square planar coordination environment is found for gold(III).

As can be seen in Table 5, comparable short average Au—O distances of about 2.00 ± 0.02 Å are found for Au_2O_3 (17*a*) and the anion $[Au(OH)_4]^-$ (17*b*) and the oxyacid derivatives $Au_2(SeO_3)_2O$ (19*a*), $Au(SeO_3)Cl$ (19*b*) (considering here distances in the AuO_4 group only), in $[Au(NO_3)_4]^-$ (16) and in $[Au(SO_3F)_3]_2$. The reported crystal structure of dimeric $[Au(OTeF_5)_3]_2$ (22) would normally present a direct analogy and allow a good comparison to the structure of $[Au(SO_3F)_3]_2$. However, the structure is disordered and reported bond parameters, in particular Au—O distances of 1.78(4) and 1.82(3) Å, respectively, are unprecedentedly short and most likely incorrect. Differences within this group are small and probably not overly significant. On the other hand, Au—O distances are longer in the various alkali metal aurates (20, 21) by at least 0.1 Å and also longer in the organogold compound $(CH_3)_2Au(H_2O)OSO_2CF_3$ (23).

The short Au—O bonds are comparable to Au—F distances found in AuF_3 (13) and in $K[AuF_4]$ (24), where average values of 1.975 and 1.95 Å, respectively, are reported with esd's of 0.02 to 0.04 Å. The covalent single bond radius of fluorine is slightly shorter than that of oxygen (25), resulting in shorter Au—F bonds.

Hence it is probable that relativistic effects, which are reportedly at a maximum for gold and its compounds (26), are involved. While no relativistic calculations appear to have been done on AuO_4-containing systems, a recent study (27) on the stability of AuX_4^-, X = F, Cl, Br, or I is available using pseudopotentials, and a calculated Au—F equilibrium distance of 1.93 Å is suggested.

Only a limited number of crystal structures of inorganic fluorosulfates has been reported previously. These examples fall into four groups: (*i*) Ionic fluorosulfates: this group includes examples where the SO_3F-group has approximately C_{3v} symmetry, with S—O distances either the same or only slightly different from one another on account of weak cation–anion contacts. The examples consist of KSO_3F (6*a*), $LiSO_3F$ (6*b*), and NH_4SO_3F (6*c*), $S_4N_4(SO_3F)_2$ (28*a*), $(S_6N_4)(SO_3F)_2$ (28*b*), $Se_{10}(SO_3F)_2$ (28*c*), and 3-methyl-4,5-diphenyl-1,2,3-thiadiazolium fluorosulfate (28*d*); (*ii*) hydrogen bonded fluorosulfates like a 1:1 complex between acetic and fluorosulfuric acid (29) and the mono-solvated anion $[H(SO_3F)_2]^-$ (30), where no bond parameters are reported; (*iii*) non-metal fluorosulfates: $FXeSO_3F$ (31) and $[I(SO_3F)_2]I$ (32), both with monodentate fluorosulfate groups and $[(XeF)_2SO_3F][AsF_6]$ (33) where a

[a]Reference 32.
[b]Reference 34.
[c]The subscripts used in the table refer to coordinated oxygen, $O_{(b)}$, and terminal oxygen, $O_{(t)}$.

bidentate bridging SO_3F group is found, and (*iv*) organometallic fluorosulfates, with $(CH_3)_2Sn(SO_3F)_2$ (34) with bidentate, symmetrically bridging SO_3F groups as the sole example. In all instances, only a single bonding mode for the fluorosulfate group is observed.

A meaningful comparison to previous work is somewhat more difficult for the bond parameters of the SO_3F group on two accounts: (*i*) due to thermal motion of the non-bonded O and F atoms in the terminal SO_3F groups of $[Au(SO_3F)_3]_2$, only the parameters for bidentate SO_3F-groups are known with a high degree of accuracy and (*ii*) as summarized above most reported structures have ionic SO_3F^- groups with rather small differences in S—O distances for coordinated and non-coordinated oxygen within the fluorosulfate group.

This leaves the two xenon(II) fluorosulfato derivatives $FXeSO_3F$ (31) and the cation $[(FXe)_2SO_3F]^+$ (33) as the most

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

reasonable choices for a comparison. The former exhibits a monodentate, and the latter a bidentate bridging fluorosulfate group. The pertinent S—O and S—F distances, as well as some selected SO_2 bond angles for both compounds (31, 33), as summarized in Table 6 and compared to the data for $[Au(SO_3F)_3]_2$. While it may appear that SO_3F bonds are slightly shorter in $[Au(SO_3F)_3]_2$, the differences are either rather small, observed primarily for the monodentate SO_3F-groups, or within the quoted estimated standard deviations. The strong similarity between $Au(SO_3F)_3$ and both xenon-SO_3F derivatives (31, 33) extends also to the pertinent bond angles, and again the largest differences are found for the monodentate fluorosulfate groups in $FXeSO_3F$ (31) and $[Au(SO_3F)_3]_2$.

Summary

The structure of gold(III) fluorosulfate features a dimeric molecule, short Au—O bonds, a distorted example of 4:2 coordination for gold, and two distinctly different fluorosulfate groups. However, neither the Au—O distances nor the SO_3F bond parameters suggest an unprecedented, strong Au—O interaction in $[Au(SO_3F)_3]_2$ as the cause for the observed superacidity of the HSO_3F–$Au(SO_3F)_3$ system (3, 4). The reason for the reported superacidity must be seen in two other structural features: (*a*) the loose packing observed appears to permit sufficient solubility of $[Au(SO_3F)_3]_2$ in fluorosulfuric acid, and (*b*) the dimeric structure suggests, in agreement with computer modelling studies (5), two principle equilibria to be responsible for the high acidium ion concentration (4):

[2] $2HSO_3F + [Au(SO_3F)_3]_{2(solv.)} \rightarrow H_2SO_3F^+ + [Au_2(SO_3F)_7]^-_{(solv.)}$

[3] $2HSO_3F + Au(SO_3F)_{3(solv.)} \rightarrow H_2SO_3F^+ + [Au(SO_3F)_4]^-_{(solv.)}$

In contrast, for the recently reported superacid systems HSO_3F–$Nb(SO_3F)_5$ and HSO_3F–$Ta(SO_3F)_5$ (4) a higher degree of intermolecular association of the Nb- and Ta-species is suggested (5) and lower acidity is observed (4).

FERNANDE D. ROCHON, ROBERT MELANSON, and PI-CHANG KONG. Can. J. Chem. **69**, 397 (1991).

The reaction of NH_4TcO_4 with PPh_3 in DMF solution in the presence of HCl produces *mer*-$Tc^{III}(PPh_3)_2Cl_3(DMF)\cdot 2PPh_3$ (**1**). When the reaction is done in acidic DMA, the yellow product isolated was identified as $NH_2(CH_3)_2^+DMAH^+[TcCl_6]^{2-}\cdot PPh_3O$ (**2**). The dimethylammonium cation was produced from the reaction of the solvent (DMA) with aqueous HCl. The reaction of NH_4TcO_4 with PPh_3 in acidic acetone solution produces yellow $(PPh_3H)_2[TcCl_6]$ (≈15% yield) and some orange crystals (≈65% yield) identified by X-ray diffraction as $[Ph_3P\text{-}C(CH_3)_2\text{-}CH_2\text{-}CO\text{-}CH_3]^+[Tc(PPh_3)Cl_5]^-$. The cation was produced from the reaction of acetone used as solvent with HCl and PPh_3. The crystals of **1** are monoclinic with $P2_1/m$ space group, a = 11.393(4), b = 24.993(11), c = 12.398(4) Å, β = 106.98(3)°, Z = 2. The structure was refined to R = 0.072 and wR = 0.058. The Tc—O bond distance is 2.115(12) Å while the Tc—P bond lengths are 2.496(5) and 2.499(5) Å and the Tc—Cl are 2.399(5) and 2.342(3) Å. The C atoms of the DMF ligand are disordered. The crystals of **2** are triclinic, $P\bar{1}$ space group with a = 8.627(5), b = 13.308(7), c = 14.401(9) Å, α = 97.62(5), β = 91.31(5), γ = 106.42(5)°, and Z = 2. The structure was refined to R = 0.060 and wR = 0.076. The proton on $DMAH^+$ is hydrogen bonded to the oxygen of PPh_3O with a distance O···O = 2.48(1) Å.

Key words: technetium, DMF, triphenylphosphine, dimethylacetamide.

FERNANDE D. ROCHON, ROBERT MELANSON et PI-CHANG KONG. Can. J. Chem. **69**, 397 (1991).

La réaction de NH_4TcO_4 avec PPh_3 en solution dans le DMF, produit en présence de HCl, *mer*-$Tc^{III}(PPh_3)_2Cl_3(DMF)\cdot 2PPh_3$ (**1**). Lorsque la réaction est faite dans le DMA, le produit est le sel mixte $NH_2(CH_3)_2^+DMAH^+[TcCl_6]^{2-}\cdot PPh_3O$ (**2**). Le cation diméthylammonium a été produit par la réaction du solvant (DMA) avec HCl aqueux. La même réaction en milieu acétone produit le sel jaune $(PPh_3H)_2[TcCl_6]$ (rendement ≈15%) et des cristaux oranges identifiés par diffraction des rayons-X comme $[Ph_3P\text{-}C(CH_3)_2\text{-}CH_2\text{-}CO\text{-}CH_3]^+[Tc(PPh_3)Cl_5]^-$ (rendement ≈65%). Le cation a été produit par la réaction du solvant (acétone) avec HCl et PPh_3. Les cristaux de **1** sont monocliniques, groupe d'espace $P2_1/m$, a = 11,393(4), b = 24,993(11), c = 12,398(4) Å, β = 106,98(3)° et Z = 2. La structure a été affinée jusqu'à R = 0,072 et wR = 0,058. La distance Tc—O est 2,115(12) Å, tandis que les liens Tc—P = 2,496(5) et 2,499(5) Å et Tc—Cl = 2,399(5) et 2,342(3) Å. Les atomes de C du DMF sont désordonnés. Les cristaux de **2** sont tricliniques, $P\bar{1}$, avec a = 8,627(5), b = 13,308(7), c = 14,401(9) Å, α = 97,62(5), β = 91,31(5), γ = 106,42(5)°, Z = 2, R = 0,060 et wR = 0,076. Le proton sur $DMAH^+$ est lié par pont hydrogène à l'oxygène du PPh_3O avec une distance O···O = 2,48(1) Å.

Mots clés : technécium, DMF, triphénylphosphine, diméthylacétamide.

Introduction

The chemistry of technetium has recently become very important, especially in relation to the use of the isotope 99m in nuclear medicine. This nucleus is a γ-emitter with a half-life of 6.02 h and decays to its isomer technetium-99, which is a β-emitter with a long half-life of 213 000 years. The quantity of ^{99m}Tc needed in radiopharmacy is a few nanograms and for this reason its toxicity is negligible. It is therefore an ideal nucleus for diagnostic studies in nuclear medicine. It has been used for several years for bone scanning and recently it has been used to study the heart, the brain, the kidneys, the liver and other organs, and also tumor tissue. A good review on medical diagnostic imaging with complexes of ^{99m}Tc was published by Clarke and Podbielski in 1987 (1).

We recently started a project on the synthesis of new technetium compounds. The ultimate aim of our research project is to synthesize Tc complexes that could be of some interest for nuclear cardiology. The best heart agent that is being tested at the moment on humans is a Tc(I) hexacoordinated complex with an isonitrile ligand (2, 3). This compound accumulates rapidly in the heart and has a long retention time. But it also accumulates in other organs, which partly limits its use. Therefore, a search for more specific agents is continuing. These studies seem to indicate that such an agent should be charged +1 with a low oxidation state ≤3 for Tc. Other types of ligands producing Tc compounds that accumulate in the heart are phosphines, especially di(alkyl)phosphinoethane (4–6). We have therefore chosen to start a project on the synthesis of mixed-ligand compounds with isonitrile and phosphine derivatives. The synthetic methods must be very simple and adaptable to the use of "kits" (containing $[TcO_4]^-$ as starting material), which are used in nuclear medicine for preparing the ^{99m}Tc compounds. The number of intermediate Tc compounds must also be reduced to a minimum. The use of reducing agents was rejected since they produce secondary products that are difficult to eliminate in the preparation of the radiopharmaceuticals.

The synthesis of $[Tc(isonitrile)_6]^{3+}$ has been reported (7, 8). We first tried to synthesize compounds of the type $[Tc(isonitrile)_xCl_{6-x}]^{y+}$ but without success. We obtained either the hexacoordinated isonitrile compound or decomposition products. Since a few compounds of this type with phosphines $[Tc(phosphine)_xCl_{6-x}]^{y+}$ have been reported in the literature (9, 10), we decided to synthesize this type of compound with monodentate and bidentate phosphines and eventually study the reactions with isonitriles. We started this study with triphenylphosphine. The disubstituted compound $Tc^{IV}(PPh_3)_2Cl_4$ (9) has

been reported but no Tc–PPh_3 complex has been prepared yet with a lower oxidation state (≤ 3). The results obtained in our study are discussed below.

Experimental section

Ammonium pertechnetate ($NH_4{}^{99}TcO_4$) was obtained from Oak Ridge National Laboratory. It was recrystallized in nitric acid (**Caution**: ammonium pertechnetate in acid medium will produce some radioactive volatile compound) and dissolved in water. A 0.286 M solution was prepared. All manipulations were made in a laboratory approved for low-level radioactive material (^{99}Tc is a β-emitter with a particle energy of 0.292 MeV and a half-life of 2.13×10^5 years). Triphenylphosphine was bought from Aldrich.

The magnetic susceptibility measurements of the Tc compounds were done by the Faraday method on a Cahn instrument equipped with a millibalance. Corrections were made for diamagnetism. The infrared spectra were measured in the solid state as Nujol mulls on a FT-50 Digilab instrument equipped with a CsI beamsplitter. The microanalyses were performed by Galbraith.

mer-$Tc(PPh_3)_2Cl_3(DMF)\cdot 2PPh_3$

Ammonium pertechnetate (1 mL, 0.286 M) was added to a solution containing 1 mL of concentrated HCl and 0.84 g of triphenylphosphine dissolved in 16 mL of dimethylformamide (DMF). The clear red solution was left overnight and the next day the red crystals were filtered and washed with ethanol and ether. The compound is not soluble in ethanol, ether, or CCl_4, but is slightly soluble in acetone. Yield: ≈70%. IR (cm^{-1}): ν(C=O) 1649, ν(Tc–Cl) 330, 302; main other bands: 1087, 752, 745, 695, 519, 514, and 492. Magnetic moment μ = 3.1 BM.

$NH_2(CH_3)_2{}^+DMAH^+[TcCl_6]^{2-}\cdot PPh_3O$

A solution containing 0.52 g of PPh_3 and 1 mL of NH_4TcO_4 (0.286 M) dissolved in 8 mL of dimethylacetamide (DMA) was added to a second solution containing 1 mL of concentrated HCl dissolved in 6 mL of DMA. A clear red solution was obtained and set aside for crystallization. Ten days later, 6 mL of HCl (6 M) was added to the solution, which became slightly cloudy. About 2 mL of acetone was added to obtain a clear solution, which was covered and left at room temperature. A month later, yellow crystals suitable for X-ray diffraction methods were obtained. Yield: ≈40%. IR (cm^{-1}): ν(N—H) 3125, ν(C=O) 1671, ν(Tc–Cl) 315 (br); main other bands: 1122, 1082, 1070, 995, 722, 695, 544, and 539. Magnetic moment μ = 3.6 BM.

$(PPh_3H)_2[TcCl_6]$ and $(Ph_3P\text{-}C(CH_3)_2\text{-}CH_2\text{-}CO\text{-}CH_3)^+[Tc(PPh_3)Cl_5]^-$

A solution containing 1 mL of NH_4TcO_4 (0.286 M) and 1.5 mL of concentrated HCl dissolved in 30 mL of acetone was added to a second solution containing 0.57 g of PPh_3 dissolved in 20 mL of acetone. The mixture was stirred and refluxed immediately for 15 min. A light yellow precipitate was observed. The precipitate is $(PPh_3H)_2[TcCl_6]$ while $(Ph_3P\text{-}C(CH_3)_2\text{-}CH_2\text{-}CO\text{-}CH_3)[Tc(PPh_3)Cl_5]$ is in solution. The mixture was cooled to room temperature and the precipitate was filtered and washed. Yield of $(PPh_3H)_2[TcCl_6]$: ≈15%. IR (cm^{-1}): ν(P–H) 2440, ν(Tc–Cl) 318 (br); main other bands: 1114, 870, 748, 719, 691, and 498.

The above filtrate was concentrated to 15 mL and placed in a refrigerator to recrystallize. The next day, orange crystals suitable for X-ray diffraction studies were obtained. Yield of $(Ph_3P\text{-}C(CH_3)_2\text{-}CH_2\text{-}CO\text{-}CH_3)[Tc(PPh_3)Cl_5]$: ≈65%. IR (cm^{-1}): ν(C=O) 1718, ν(Tc–Cl) 345, 336, 326, 292; main other bands: 1102, 1087, 996, 748, 722, 692, 524, and 496. Magnetic moment μ = 4.06 BM.

Crystallographic measurements and structure resolution

The two crystals $Tc(PPh_3)_2Cl_3(DMF)\cdot 2PPh_3$ (**1**) and $NH_2(CH_3)_2{}^+\text{-}DMAH^+[TcCl_6]^{2-}\cdot PPh_3O$ (**2**) were selected after examination under a polarizing microscope for homogeneity. The unit cell parameters were obtained by least-squares refinement of the angles 2θ (10–25°), ω, and χ for 15 well-centered reflections on a Syntex $P\bar{1}$ diffractometer using graphite-monochromatized MoKα radiation. Crystal data and other information are summarized in Table 1. Scan rates and data treatment have already been described (12). Corrections were made for Lorentz–polarization effects and, for $Tc(PPh_3)_2Cl_3(DMF)\cdot 2PPh_3$, corrections were made for absorption (11 faces, transmission factors 0.933–0.961).

The anomalous dispersion terms of Tc, P, and Cl were included in the calculations (13).

The coordinates of the Tc atom were determined from the three-dimensional Patterson maps and the positions of all the other non-hydrogen atoms were found by the usual Fourier methods. The refinements of the structures were done by block-diagonal least-squares analysis, minimizing $\Sigma w(F_o - F_c)^2$. The atoms of the DMF molecule were found to be disordered. The three C atoms were clearly disordered on the two sides of the mirror plane. The N and O atoms are also probably slightly disordered by different amounts around the mirror. When their y coordinates were varied, the refined value was 0.250. Therefore they were placed on the mirror for the remaining refinements. Most H atoms could be located, but they were fixed at their calculated positions with a $U_{eq} = 0.076$. For the methyl H atoms, at least one H was obtained from a difference Fourier map and the positions of the remaining atoms were calculated. A hydrogen atom was clearly seen at 1.02 Å from the O atom in DMA, confirming the protonation of DMA. The H atoms were not refined. Isotropic secondary extinction corrections (14) were included in the calculations. Individual weights $w = 1/\sigma^2(F)$ were applied. The refinement of the scale factor, coordinates, and anisotropic temperature factors of all the non-hydrogen atoms converged to $R = 0.072$ and $wR = 0.058$ for **1**, to $R = 0.060$ and $wR = 0.076$ for **2**. There were a few residual peaks (<0.33 (for **1**) and <0.7 (for **2**) e Å^{-3}) in the close environment of the Tc atom.

The scattering curves of Cromer and Waber (15) were used except for the hydrogen atoms (16). The calculations were done on a Cyber 830 with programs already described (12).[2]

Results and discussion

We synthesized the Tc(IV) compound $Tc(PPh_3)_2Cl_4$ according to the published method (9). Its reaction with *tert*-butylisonitrile was studied in ethylene glycol following the method described in the literature to synthesize $Tc^{i}(CO)_3(PMe_2Ph)_2Cl$ (17). We obtained only decomposition products. A few trisubstituted compounds of Tc(III) with less crowded ligands have been prepared (9). These compounds were prepared by the reaction of NH_4TcO_4 with PR_3 in ethanol in the presence of HCl. In a 1 to 5 ratio (Tc:PR_3), the disubstituted Tc(IV) compound was prepared, while with a 1 to 15 ratio the trisubstituted Tc(III) complex was obtained. A few complexes of Tc(III) were prepared but not with PPh_3. We assumed that one factor was the solvent, since the disubstituted compound with PPh_3 is very insoluble in the reacting medium (ethanol with HCl). Therefore we decided to study the same reaction but in other solvents. We started the study in DMF with experimental conditions similar to those used to prepare $Tc(PPhMe_2)_3Cl_3$ (9) in an attempt to isolate PPh_3 complexes of Tc(≤III). In these reactions, PPh_3 acts as the reducing agent.

Reaction in DMF

When the reaction was done in acidic DMF, we isolated red crystals. The IR spectrum showed the presence of PPh_3, some ν(Tc–Cl) vibrations at 330 and 302 cm^{-1}, and a ν(C=O) band at 1649 cm^{-1}. The results of the crystal structure analysis showed that it was a Tc(III) compound with a coordinated DMF molecule bonded through its O atom. It is the isomer *mer*-$Tc(PPh_3)_2(DMF)Cl_3 \cdot 2PPh_3$ (**1**) with 2 non-coordinating PPh_3 molecules. This is the first example of a Tc–DMF compound. Molecular models have shown that $Tc(PPh_3)_3Cl_3$ cannot be prepared because the PPh_3 ligand is too bulky. The magnetic susceptibility measurement of *mer*-$Tc(PPh_3)_2(DMF)Cl_3 \cdot 2PPh_3$ showed that it was a low spin d^4 Tc(III) compound with 2 unpaired electrons ($\mu = 3.1$ BM). The preparation of a similar compound with acetonitrile (18) has recently been reported, but the compound is unstable in solution and its crystal structure was not reported. The compound $TcCl_3(PPh_3)_2(CH_3CN)$ was prepared from the reaction of $(n\text{-}Bu_4N)[Tc^{v}OCl_4]$ with PPh_3 in acetonitrile. The DMF compound, which has the advantage of being synthesized directly from $[Tc^{vii}O_4]$, could be an important intermediate for the synthesis of mixed-ligand Tc compounds of low valency.

The refined atomic parameters of the structure are listed in Table 2. A labelled diagram of the molecule is shown in Fig. 1. Several atoms are located on the mirror plane: Tc, Cl(1), P(1), P(2), O(1), N, and four C atoms. The DMF ligand, which is located *trans* to a Cl ligand, is disordered. O(1) and N are on the mirror (probably slightly disordered), while the three C atoms are disordered on the two sides of the mirror plane. The two bonded PPh_3 ligands are located *trans* to each other, as expected, to reduce steric hindrance and the three chlorine atoms are meridional. The structure of **1** is similar to that of $TcCl_3(PPh_3)_2(CO)$ reported recently (18).

The bond distances and angles of crystal **1** are shown in Table 3. The distance Tc—Cl(1) (2.399(5) Å) is significantly longer than the Tc—Cl(2) (2.342(3) Å) distance, which could indicate that DMF has a high *trans* influence. In $TcCl_3(PPh_3)_2(CO)$, the Tc—Cl bond *trans* to CO is also longer (2.397(2) Å) than the other Tc—Cl bonds (2.322(2) Å) (18). The Tc—P are 2.496(5) and 2.499(5) Å, which are very similar to the values (2.46(1) to 2.48(1) Å) obtained for the two Tc—P bonds *trans* to each other in the two independent molecules of *mer*-$Tc(Me_2Ph)_3Cl_3$ (19), but slightly shorter than the value of 2.525(2) Å observed in $TcCl_3(PPh_3)_2(CO)$ (18). The distance Tc—O(1) is 2.115(12) Å. The angles around Tc are close to 90 and 180° except the angle Cl(2)—Tc—Cl(2)′ = 168.5(1)°. This angle is 169.43(8)° in $TcCl_3(PPh_3)_2(CO)$ (18). The P—C distances are normal and vary from 1.81(1) to 1.85(1) Å while the average C—C distance is 1.38(15) Å for the bonded PPh_3 and 1.40(25) Å for the lattice PPh_3. All the non-hydrogen atoms in DMF are coplanar as observed in other DMF compounds (20, 21) and the angles around N are close to 120°.

The crystal consists of layers of Tc complexes located at $b = \frac{1}{4}$ and $\frac{3}{4}$ and parallel to the *ac* plane, separated by the PPh_3 layers located at $b \approx 0$ and $\approx\frac{1}{2}$. The different layers are held together only by van der Waals forces.

Reaction in DMA

A Tc–DMA compound was expected when the reaction was studied in DMA. A larger quantity of acid was used to prevent slow decomposition of the product. We isolated some yellow crystals. The IR spectrum of the compound showed a ν(N–H) stretching band at 3125 cm^{-1}, a carbonyl band at 1671 cm^{-1}, and a broad ν(Tc–Cl) band at 315 cm^{-1}. The product was studied by crystallographic methods. The results have shown that it is a Tc(IV) compound identified as $NH_2(CH_3)_2^+DMAH^+$-

[2]The following tables are available: anisotropic temperature factors (Table S1), hydrogen coordinates (Table S2), bond distances and angles (Table S3), stereoscopic view of the unit cell in the crystal *mer*-$Tc(PPh_3)_2Cl_3(DMF) \cdot 2PPh_3$, stereoscopic view of the packing in the unit cell for the crystal $NH_2(CH_3)_2^+DMAH^+[TcCl_6]^{2-} \cdot PPh_3O$, and observed and calculated structure amplitudes (Table S4). The complete set of tables may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen coordinates, bond distances and angles, and stereoscopic views of the unit cells have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW, U.K.

[a] $U_{eq} = \frac{1}{3}\Sigma_i\Sigma_j U_{ij} a_i^* a_j^* a_i \cdot a_j$.

$[TcCl_6]^{2-}\cdot PPh_3O$. The crystal contained a molecule of triphenylphosphine oxide, a protonated DMA cation, and finally a dimethylammonium cation. The DMA solvent reacted with HCl to produce dimethylamine and some organic carbonyl compound. Triphenylphosphine was oxidized to triphenylphosphine oxide from the reduction of Tc(VII) to Tc(IV) and (or) from the reaction with the carbonyl compound. This kind of oxidation is known in phosphorus chemistry (22). In this experiment, we had to use more acid than in the previous experiment with DMF, since there was decomposition in more dilute solution. The results of the magnetic susceptibility have shown a magnetic moment of 3.6 Bohr magnetons for 3 unpaired electrons, indicating a d^3 configuration for a Tc(IV) compound.

A labelled diagram of the compound $NH_2(CH_3)_2^+DMAH^+$-$[TcCl_6]^{2-}\cdot PPh_3O$ (crystal **2**) is shown in Fig. 2. The bond distances and angles are listed in Table 3. The Tc—Cl bond distances vary from 2.324(2) to 2.379(2) Å with *cis* angles of 88.34(7)–91.68(6)° and *trans* angles of 176.03(7)–179.94(7)°. The P—O(2) bond length is 1.492(5) Å and the average P—C distance is 1.800(6) Å. The angles around the P atom are close to the tetrahedral value (107.2(3)–111.2(3)°). The N(2)—C distances in the dimethylammonium cation are 1.49(1) Å. The bond distances and angles in protonated DMA are normal. All the non-hydrogen atoms are in a plane as expected because of the resonance in the N—C—O segment. The deviations from the best plane are O(1), 0.013(6); N(1), −0.020(6); C(1), −0.002(9); C(2), −0.006(7); C(3), 0.000(10); and C(4), 0.015(11) Å. The angles are also close to 120°. We were able to see the proton on the DMA molecule, which was located at 1.02 Å from O(1) (of DMA) and at 1.48 Å from O(2) of triphenylphosphine oxide. The short distance O(1)···O(2) (2.481(7) Å) clearly indicates hydrogen bonding between the two O atoms. The angles are O(1)—H···O(2) = 168.2 and

C(2)—O(1)···O(2) = 118.8(4)°. The structure is also stabilized by hydrogen bonding between the dimethylammonium cation and the chloride ligands with four distances N(2)···Cl ranging from 3.327(6) to 3.468(7) Å and H···Cl from 2.640 and 2.819 Å, slightly shorter than the sum of the van der Waals radii. The angles N(2)—H···Cl vary from 133.6 to 138.0°.

Reaction in acetone

The reaction of ammonium pertechnetate with triphenylphosphine in acidic acetone produced two compounds, a yellow powder in a low yield (≈15%) and some orange crystals in ≈65% yield. The IR spectra of the two compounds were clearly very different. The yellow compound showed a broad stretching ν(Tc–Cl) vibration at 318 cm^{-1}. The results of the elemental analysis have shown that it was the $(PPh_3H)_2[TcCl_6]$ ionic compound, which has already been reported by Bandoli, Clemente, Mazzi, and Roncari (11). These authors synthesized their compound by refluxing $[AsPh_4][TcO_4]$ with PPh_3 in ethanol and HCl.

The IR spectrum of the orange crystals showed a ν(C=O) band at 1718 cm^{-1}, and two ν(Tc–Cl) bands at 292 and 326 cm^{-1} with shoulders at 336 and 345 cm^{-1}. To identify the compound, the orange crystals were studied by X-ray diffraction methods. The results have shown that it is an ionic compound with $[Tc(PPh_3)Cl_5]^-$ as anion and a surprising cation $[Ph_3P\text{-}C(CH_3)_2\text{-}CH_2\text{-}CO\text{-}CH_3]^+$ produced from the reaction of PPh_3 with acetone in acid medium. The magnetic moment of 4.06 BM confirmed the d^3 configuration of Tc(IV) with three unpaired electrons. The crystal structure of this compound has been published by Bandoli *et al.* (11) who synthesized this compound by the following method:

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12

The authors isolated and characterized the intermediate compound $[NH_3\text{-}C(CH_3)_2\text{-}CH_2\text{-}CO\text{-}CH_3]^+[TcO_4]^-$, which in the presence of PPh_3 in acetone produced $[PPh_3C(CH_3)_2\text{-}CH_2\text{-}CO\text{-}CH_3]^+[Tc(PPh_3)Cl_5]^-$. We were able to prepare the same final product without the presence of NH_4OH, just by refluxing ammonium pertechnetate with PPh_3 for 15 min in acidic acetone.

Received June 22, 1990

G. W. BUCHANAN, S. MATHIAS, Y. LEAR, and C. BENSIMON. Can. J. Chem. **69**, 404 (1991).

For the title systems, single crystal X-ray data indicate the presence of totally asymmetric structures. These features are reflected in the multiplicity of resonances in the solid phase ^{13}C NMR spectra. Some of the ^{13}C chemical shift trends are analyzed in terms of torsional angle influences. In solution, resonance assignments have been made with the aid of 2D methods. Stereochemical inferences are drawn from NOESY spectra and ^{1}H–^{1}H couplings. Low temperature solution experiments indicate that conformational interconversions in both the free ligand and the NaNCS complex are rapid on the NMR timescale down to 163 K.

Key words: crown ethers, NMR, stereochemistry.

G. W. BUCHANAN, S. MATHIAS, Y. LEAR et C. BENSIMON. Can. J. Chem. **69**, 404 (1991).

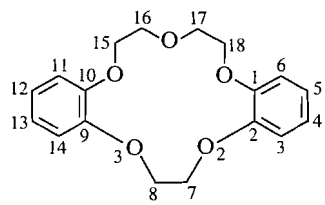
Pour les systèmes mentionnés dans le titre, les données de la diffraction des rayons-X par un cristal unique indiquent la présence de structures totalement asymétriques. La multiplicité des bandes de résonance dans les spectres RMN du ^{13}C, en phase solide, est le reflet de ces caractéristiques structurales. On a analysé quelques unes des tendances observées dans les déplacements chimiques du ^{13}C en fonction des influences des angles de torsion. En solution, on a fait les attributions des résonances à l'aide de méthodes en 2D. On a tiré des déductions stéréochimiques à partir des spectres COSY et des couplages ^{1}H–^{1}H. Des expériences en solution, à basses températures, indiquent que, jusqu'à 163 K, les interconversions conformationnelles, tant dans le ligand libre que dans le complexe NaNCS, sont rapides à l'échelle de temps de la RMN.

Mots clés : éthers couronne, RMN, stéréochimie.

[Traduit par la rédaction]

Introduction

The 15-crown-5 ether system is of interest because its cavity size (effective radius 1.35 Å) is most suited for complexation of the sodium ion. The original pioneering work of Pedersen (1) described the synthesis of benzo-15-crown-5 and subsequently a series of articles have appeared dealing with the crystal structure (2) and complexation features of this molecule (3–9), as well as 15-crown-5 ether itself (10–14). Also the solid phase ^{13}C NMR features of benzo-15-crown-5 have been reported (15).



In view of our interest in the dynamic stereochemistry of related systems (16–18), we present herein the preparation of dibenzo-15-crown-5 ether and its NaNCS complex as well as the characterization of their stereochemical features in the solid phase and in solution using X-ray and NMR methods.

Results and discussion
