$$[16] \quad A_{22} = [D_{21}\Delta m_{1\infty} + (D_{22} - D_1)\Delta m_{2\infty}]/(D_2 - D_1)$$

The steady-state molality differences

$$[17] \quad \Delta m_{1\infty} = m_1(a,\infty) - m_1(0,\infty)$$

$$[18] \quad \Delta m_{2\infty} = m_2(a,\infty) - m_2(0,\infty)$$

are established as $t \rightarrow \infty$. The gradient in NaOH, $\Delta m_{2\infty}/a$, is generated even though the solution is free of added NaOH; the cool end of the cell will contain more OH^- than HCO_3^- ions ($m_2 > 0$), while the warm end contains more HCO_3^- than OH^- ions ($m_2 < 0$).

If $\Delta m_{1\infty}$ and $\Delta m_{2\infty}$ can be measured, the heats of transport of Na_2CO_3(1) and NaOH(2) can be calculated from the expression (15)

$$[19] \quad H_1^* = -(T/\Delta T)\left[\Delta m_{1\infty}\frac{\partial\mu_1}{\partial m_1} + \Delta m_{2\infty}\frac{\partial\mu_1}{\partial m_2}\right]$$

$$[20] \quad H_2^* = -(T/\Delta T)\left[\Delta m_{1\infty}\frac{\partial\mu_2}{\partial m_1} + \Delta m_{2\infty}\frac{\partial\mu_2}{\partial m_2}\right]$$

for a ternary mixed electrolyte. μ_1 and μ_2 are the chemical potentials of the components at the mean cell temperature and composition.

$$[21]\quad \mu_1 = \mu_1^0 + RT \ln (m_{Na}^2 m_{CO_3} \gamma_{Na}^2 \gamma_{CO_3})$$

$$[22]\quad \mu_2 = \mu_2^0 + RT \ln (m_{Na} m_{OH} \gamma_{Na} \gamma_{OH})$$

γ_i is the activity coefficient of species i. Defining $\beta = m_{HCO_3}/m_1$ as the extent of hydrolysis, the ionic molalities are given by $m_{CO_3} = (1 - \beta)m_1$, $m_{HCO_3} = \beta m_1$, $m_{OH} = \beta m_1 + m_2$ and $m_{Na} = 2m_1 + m_2$. β can be calculated from the relation

$$[23]\quad K = \frac{\beta(\beta m_1 + m_2)}{1 - \beta} \frac{\gamma_{HCO_3}\gamma_{OH}}{\gamma_{CO_3}}$$

3. Experimental

Reagent grade sodium carbonate and bicarbonate were used as received. Carbonate-free sodium hydroxide solutions were standardized potentiometrically. Distilled, deionized water was used to prepare the solutions.

The two Harned-type Soret cells (13) (heights 0.912 and 1.219 cm) used in this work were operated with a 10 K temperature difference. Changes in the molalities of the Na_2CO_3 and NaOH components during thermal diffusion were followed by measuring the corresponding changes in electrical resistance across small platinum electrodes at levels $a/6$ and $5a/6$ along the solution columns. Details of the equipment, procedure, and cell calibration are given elsewhere (13, 14, 16).

The problem is to calculate $\Delta m_{1\infty}$ and $\Delta m_{2\infty}$ from the resistance measurements. The first step is to convert the absolute resistances to the differential quantity

$$[24]\quad Y(t) = \frac{R(5a/6, t) - R(a/6, t)}{R(5a/6, t) + R(a/6, t)}$$

to correct for small but unavoidable drifts in the mean cell temperature.

The series expression for $Y(t)$ converges very rapidly. For the pseudo-binary solutions, the truncated expression

$$[25]\quad Y(t) = Y_\infty + Y_1 \exp(-t/\theta)$$

is accurate provided $t/\theta > 0.15$, where θ is the characteristic time, $a^2/\pi^2 D$. The Soret coefficient is given by

$$[26]\quad \sigma = -\pi^2 Y_1 / 2\sqrt{3} B \Delta T$$

where

$$[27]\quad B = -\mathrm{d} \ln R/\mathrm{d} \ln m_1 = \mathrm{d} \ln \Lambda/\mathrm{d} \ln m_1$$

Least-squares values of Y_1 together with published (17) molar conductivities (Λ), diffusion coefficients (7, 8), and activity coefficients (18, 19), all evaluated at the mean cell temperature and composition, were used to calculate σ and H^* for the pseudo-binary Na_2CO_3 solutions.

Dilute solutions

At 0.05 mol kg^{-1} and below, plots of $\ln |Y(t) - Y_\infty|$ were curved, rather than linear, indicating measurable departures from pseudo-binary behavior (see Fig. 1). For these ternary $Na_2CO_3(1)$ + NaOH(2) solutions, $Y(t)$ decayed as (14)

$$[28]\quad Y(t) = Y_\infty + Y_1 \exp(-t/\theta_1) + Y_2 \exp(-t/\theta_2)$$

with characteristic times $\theta_1 = a^2/\pi^2 D_1$ and $\theta_2 = a^2/\pi^2 D_2$. D_1 and D_2, and hence θ_1 and θ_2, were calculated from published D_{ik} values (8). The parameters Y_∞, Y_1, and Y_2 were then calculated by using linear least squares to fit $Y(t)$ to the variables $\exp(-t/\theta_1)$ and $\exp(-t/\theta_2)$ according to eq. [28].

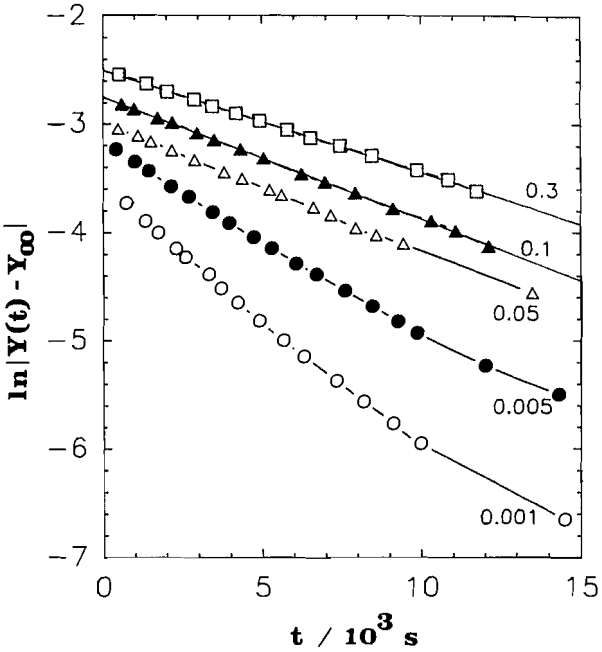

FIG. 1. Plots of $\ln |Y(t) - Y_\infty|$ against t for aqueous sodium carbonate at the molalities 0.001, 0.005, 0.05, 0.1, and 0.3 mol kg^{-1}.

TABLE 1. Soret coefficients and heats of transport of pseudo-binary aqueous $Na_2CO_3(\bar{m}_1)$ solutions at 25°C[a]

m_1	B	D	σ	$1 + \mathrm{d} \ln \gamma_\pm/\mathrm{d} \ln m_1$	H_1^*
0.10	0.833	0.943	8.46	0.774	14.5
0.30	0.758	0.834	7.56	0.707	11.9
0.50	0.706	0.745	8.21	0.654	11.9

[a]Units: m_1 in mol kg^{-1}, D in 10^{-9} m^2 s^{-1}, σ in 10^{-3} K^{-1}, H_1^* in kJ mol^{-1}.

$\Delta m_{1\infty}$ and $\Delta m_{2\infty}$ were evaluated by solving the linear equations

$$[29]\quad B_1'\Delta m_{1\infty} + B_2'\Delta m_{2\infty} = (\pi^2/2\sqrt{3})(Y_1 + Y_2)$$

$$[30]\quad [B_1'(D_{11} - D_{22}) + 2B_2'D_{21}]\Delta m_{1\infty} + [2B_1'D_{12} + B_2'(D_{22} - D_{11})]\Delta m_{2\infty} = (\pi^2/2\sqrt{3})(D_1 - D_2)(Y_1 - Y_2)$$

The parameters

$$[31]\quad B_i' = -(\partial \ln R/\partial m_i)_{T,m_k}$$

were measured by using an auxiliary conductance cell; B_1' was obtained from the conductivities of binary solutions of Na_2CO_3 above and below $\bar{m}_1$, while B_2' was obtained using solutions of composition $\bar{m}_1$ to which NaOH or $NaHCO_3$ had been added.

Finally, eqs. [19] and [20] gave the ternary heats of transport of the components. The ionic activity coefficients that were used were calculated from the expression (20)

$$[32]\quad \ln \gamma_{\pm i} = -1.17 z_i^2 I^{1/2}/(1 + I^{1/2})$$

which is sufficiently accurate for the present application. I, the ionic strength, equals $(3 - \beta)m_1 + m_2$.

The analysis of the data for the ternary $Na_2CO_3(1)$ + NaOH(2) solutions closely resembles the treatment (14) developed previously for ternary NaCl(1) + NaOH(2) solutions. In the present study, however, the mean cell molality of the NaOH component, $\bar{m}_2$, is zero. The equations have therefore been rewritten to replace indeterminate terms such as d ln R/d ln m_2 or d ln m_2/dT with d ln R/dm_2 and dm_2/dT.

4. Results and discussion

Thermal diffusion was measured at the mean cell temperature 25.0 ± 0.1°C and total sodium carbonate molalities from 0.001 to 0.5 mol kg^{-1}.

Table 1 gives the measured Soret coefficients and heats of transport for "pseudo-binary" Na_2CO_3 solutions at the molalities 0.1, 0.3, and 0.5 mol kg^{-1}. Each reported σ value is the average of values from six runs. The standard deviation of the σ values was about 2%.

The "short" and the "tall" cells gave identical results within experimental precision, which suggests that convection was not a serious source of error. Table 1 includes the auxiliary values of B, D, and 1 + d ln $\gamma_\pm$/d ln m that were used in the calculations.

Table 2 gives the steady-state molality gradients and the derived heats of transport for the dilute ternary $Na_2CO_3(\bar{m}_1)$ + NaOH($\bar{m}_2 = 0$) solutions. In this case eight runs were made at each composition and the $\Delta m_{i\infty}/a$ values were averaged. The supplementary values of D_{ik}, B_i', β, and $\partial\mu_i/\partial m_k$ are listed in Tables 2 and 3. The two cells gave identical results.

$\Delta m_{1\infty}/\Delta T$ and $\Delta m_{2\infty}/\Delta T$ are negative, indicating that both the Na_2CO_3 and NaOH components diffuse to the cold plate. At 0.05 mol kg^{-1}, where only about 5% of the carbonate ions are hydrolyzed, the gradient in the NaOH component is about 15% as large as the Na_2CO_3 gradient. At 0.001 mol kg^{-1}, hydrolysis is only 35% complete, yet the thermally-induced gradient in the NaOH component is $2\frac{1}{2}$ times larger than the Na_2CO_3 gradient! It should be emphasized that the NaOH gradients represent gradients in "excess" NaOH, over and above the NaOH present to balance the $NaHCO_3$ produced by hydrolysis.

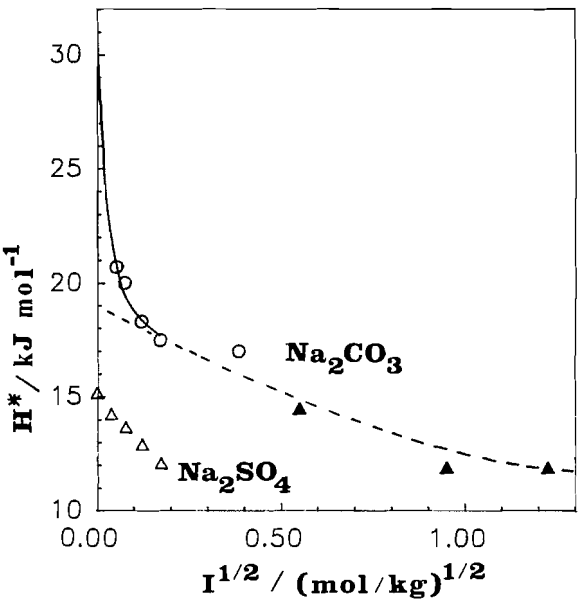

FIG. 2. Heats of transport of aqueous salts at 25°C plotted against the square root of the ionic strength. Na_2CO_3: ○, measured H_1^* values (this work); —, predicted values (eq. [33]); - - -, extrapolated pseudo-binary H_1^* values. Na_2SO_4: △, measured values (21).

The OH^- ions strongly seek the cooler parts of the solution because their heat of transport is so large. The substantial electric field that is generated to slow down these unusually mobile ions (and thereby maintain electroneutrality) will tend to drive the CO_3^{2-} ions in the opposite direction — to the warm plate. This may help account for the relatively small induced gradients in the Na_2CO_3 component at high dilution.

The results show that the gradient in the Na_2CO_3 component relative to that of the NaOH component decreases sharply with concentration. Below 0.001 mol kg^{-1} the Na_2CO_3 could conceivably change sign, signalling the reversed thermal diffusion of Na_2CO_3 to the warm plate. (Such behavior has been reported for NaCl in the analogous NaCl + NaOH solutions (14).) Unfortunately, reliable results could not be obtained at concentrations significantly below 0.001 mol kg^{-1} — the cell resistances were too large to be measured precisely.

In Fig. 2 the heat of transport of the Na_2CO_3 component, H_1^*, is plotted against the square root of the ionic strength, $I^{1/2}$. For comparison, the heat of transport of Na_2SO_4 (21) — a nonhydrolyzing 1:2 salt — is also plotted. The jump in $H_1^*(Na_2CO_3)$ at low ionic strength due to hydrolysis is evident.

0.050	0.892	1.158	4.03	0.909	5.42
0.100	0.876	1.132	3.74	0.884	4.89

[a]Units: m in mol kg^{-1}, D in 10^{-9} m^2 s^{-1}, σ in 10^{-3} K^{-1}, H^* in kJ mol^{-1}.

H_2^*, the ternary heat of transport of the NaOH component in aqueous Na_2CO_3 solutions, is plotted against $I^{1/2}$ in Fig. 3. The binary heat of transport of NaOH in pure water (5, 6, 14), H^*(NaOH), is also shown. Study of Fig. 3 shows that H_2^* and H^*(NaOH) become identical as the ionic strength drops. This result is hardly surprising in view of the additivity rule, but it does provide a valuable check that the experiments and the calculations were performed correctly.

To help interpret the results, a few thermal diffusion measurements were made on dilute aqueous $NaHCO_3$ solutions. Table 4 gives the results. In Fig. 3 the heat of transport of $NaHCO_3$ is plotted against $I^{1/2}$. Convection did not appear to be significant, as indicated by linear plots of $Y(t)$ against $\exp(-t/\theta)$. Although nonequilibrium $NaHCO_3$ solutions are strictly ternary systems owing to disproportionation ($NaHCO_3 = CO_2 + NaOH$), this feature was unimportant at the compositions that were used; no evidence was obtained for ternary thermal diffusion of this salt.

Although the theory of thermal diffusion with chemical reaction is well understood for binary solutions (22), the corresponding theory for ternary systems remains to be developed. In the meantime, the simple-minded expression

$$[33] \quad H_1^* = (1 - \beta)H^*(Na_2CO_3,unh) + \beta H^*(NaHCO_3) + \beta H^*(NaOH)$$

may provide a qualitative guide to the behavior of dilute aqueous Na_2CO_3 solutions. $H^*(NaHCO_3)$ and $H^*(NaOH)$ stand for the binary heats of transport of $NaHCO_3$ or NaOH in pure water (Fig. 3). $H^*(Na_2CO_3,unh)$, the hypothetical heat of transport per mole of *unhydrolyzed* sodium carbonate, may be obtained by extrapolation of H_1^* values from above 0.05 mol kg^{-1} where hydrolysis is unimportant (dashed curve, Fig. 2). The estimates of H_1^* obtained from eq. [33] are plotted in Fig. 2. Satisfactory agreement with the measured H_1^* values is obtained. The limiting heat of transport of infinitely dilute (and therefore completely hydrolyzed) aqueous Na_2CO_3, 31 ± 1 kJ mol^{-1}, equals the sum of the limiting heats of transport of aqueous $NaHCO_3$ and NaOH.

Received February 22, 1991

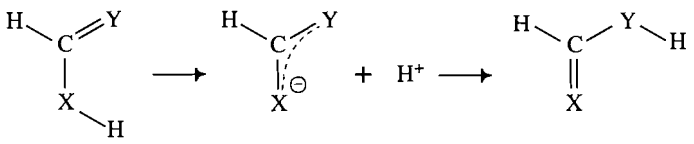
RAYMOND A. POIRIER, DAKE YU, and PETER R. SURJAN. Can. J. Chem. **69**, 1589 (1991).

Ab initio calculations are performed to investigate the effect of water on the 1,3-intramolecular hydrogen rearrangement in the HX—CH=Y ⇌ X=CH—YH isoelectronic series, for X, Y = CH_2, NH or O, by modeling with a single H_2O molecule. The geometries for the complexes are optimized at both the 3-21G and 6-31G** basis set levels. MP2 and some MP4 calculations are performed to take into account the correlation effects, and ZPV corrections are calculated at the MNDO level. The results show that the water molecule has a significant effect on the molecules in which hydrogen bonds can be formed or partially formed. The "solvent effects" are also examined using the self-consistent reaction-field (SCRF) approach. A combination of supermolecule and SCRF approach appears to work well at predicting the effect of solvent on relative stabilities and barriers.

Key words: tautomerism, *ab initio*, 1,3-hydrogen rearrangement, solvent effects.

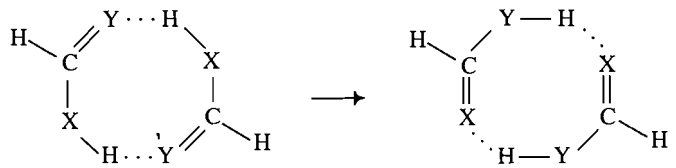
RAYMOND A. POIRIER, DAKE YU et PETER R. SURJAN. Can. J. Chem. **69**, 1589 (1991).

Utilisant un modèle impliquant une seule molécule de H_2O, on a effectué des calculs *ab initio* pour étudier l'effet de l'eau sur la réaction de transposition intramoléculaire-1,3 de l'hydrogène dans les séries isoélectroniques HX—CH=Y ⇌ X=CH—YH dans lesquelles X, Y = CH_2, NH ou O. On a optimisé les géométries des complexes aux niveaux des ensembles 3-21G et 6-31G**. On a aussi effectué des calculs MP2 et MP4 pour tenir compte des effets de corrélation et on a calculé les corrections ZPV au niveau MNDO. Les résultats montrent que la molécule d'eau a un effet important sur les molécules dans lesquelles il peut se former au moins partiellement des liaisons hydrogènes. On a aussi étudié les «effets de solvant» en utilisant une approche de champ de réaction auto-cohérent (SCRF). Il semble qu'une approche combinant une supermolécule et un champ de réaction auto-cohérent permet de bien prédire l'effet de solvant sur les stabilités relatives et sur les barrières des réactions.



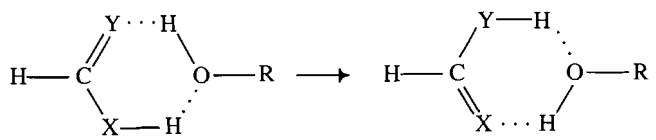
Mots clés : tautomérisme, *ab initio*, transposition-1,3 de l'hydrogène, effets de solvant.

[Traduit par la rédaction]



I. Introduction

Tautomerism is of interest to many areas of chemistry and biology (1–34). Understanding tautomerism is of great importance to chemistry and especially to biochemistry, where, for example, tautomerism of nucleic acid bases is relevant to the theory of spontaneous mutagenesis (1). Although there are, for example, many possible tautomeric forms of uracil, until recently only the diketo tautomer was known to exist. The keto–enol form of both uracil and thymine have now been detected by the fluorescence excitation method (11). For this reason and due to interest in the orbital symmetry rule a great deal of quantitative theoretical interest has also been given to tautomerism (13–34). Knowledge of the energetics of tautomerism in simple model molecules such as formamide – formamidic acid and amidine can provide useful information on the intrinsic stability of various tautomers of more complex molecules. These serve as prototypes for many biologically active molecules, a few of which have been tabulated in Table 1. Most of the calculations have focused on the relative stabilities of the tautomeric forms and have looked at barriers for the direct 1,3-intramolecular hydrogen rearrangement, which models the gas phase reaction. It is well known that the solvent plays an important role in both affecting the relative stabilities and the barriers, especially in protic solvents. In solution one can formulate a number of possible mechanisms (5):



Mechanism A: Deprotonation/reprotonation

Mechanism B: Dimerization (self-catalysed)

Mechanism C: Solvent-catalysed

Measurements of the relative stabilities and even more so the barriers to the hydrogen shift are difficult experimentally since the equilibrium concentration of one or some of the less stable isomers can be very small. Often these values can only be estimated. For example, the pK method was used to

estimate the relative free energies in solution of the diketo and keto–enol tautomers of uracil (2). Bensaude and Dubois (5, 6) have shown, using the T-jump relaxation technique, that 6-methoxy 2-oxopyridine in aqueous solvent undergoes a concerted 1,3-hydrogen rearrangement through a water bifunctional diffusion-controlled dimerization (Mechanism B). Under various other conditions competition between these mechanism can occur (6). The same authors (7) have also shown that the equilibria and therefore the relative stabilities can be significantly affected by the solvent. The keto/enol ratios of 6-chloro and 6-methoxy 2-oxopyridines, for example, have been shown to vary by several orders of magnitudes in going from polar

†Barriers for the forward/reverse reaction.

aprotic solvents to water. The relative energies of these tautomers in different environments can give some insight into the influence of solvent effects on molecular stability and on the barriers. Another difficulty which arises with determining the position of tautomeric equilibrium experimentally is that in order to eliminate solvation effects of polar solvents, dilute solutions in nonpolar solvents have to be used. It has been shown that for 2-oxopyridine, for example, that only in very dilute solution ($<10^{-7}$ M) and high temperatures (>100°C) did the equilibrium constant become comparable to the gas phase value and this was shown to be due to the formation of dimers (3). Therefore, both solvation and the formation of dimers can affect significantly the position of the equilibrium.

A theoretical description of solvation is particularly difficult. In general, both an accurate statistical treatment and an exact solution of the Schrödinger equation for the solute–solvent complex, representing a many body system, remain an insoluble problem. The studies on solvent effect within theoretical calculations are carried out in two different kinds of approximate approaches, namely the discrete (35) and the continuum (36, 37) models. In the former model, individual solvent molecules interact with a solute and are explicitly dealt with. The solvent effect is included into the calculations by considering a "supermolecule" system, *i.e.*, a complex consisting of the solute molecule surrounded by one or more solvent molecules. The discrete approach is often used when specific interactions are prevailing. On the other hand, the continuum model studies the properties of a molecule situated in a cavity embedded in a dielectric medium and it is associated with the reaction-field concept (37). In the SCRF (self-consistent reaction field) approximation (38), the dielectric field generated by the polarized environment is described by the so-called reaction-potential and the polarization potentials are incorporated into the Schrödinger equation. The cavity radius is selected in such a way that the limitations imposed by the van der Waals radii are met. The continuum model describes well the mean properties of the environment but it does not account for specific effects. Studies (39, 40) show that calculations using a modified reaction-field approach on a series of important reactions gives qualitatively the same results as those obtained using the supermolecular approach for reactions in which only one or two water molecules are involved mechanistically. The SCRF approximation has been used successfully to predict the effect on tautomeric equilibria (41) and on radical formation energies (42). The discrete-continuum approach involves a combination of the above two methods. In this model, the solvent molecules in the first layer are treated individually, whereas those of the outer sphere are represented by a continuous dielectric field. In many cases, a discrete plus continuum model is better suited for describing complex systems (43).

SCHEME 1

As illustrated by Tables 1 and 2, there are few systematic studies which look at the relative tautomeric stabilities and there are even fewer mechanistic studies (barriers). Due to the difficulties mentioned, a systematic experimental study which looks at a number of related systems, takes into account solvent effect and carefully investigates mechanism, would be very difficult. Such systematic study is more amenable to a computational approach.

As a first step in a systematic study we looked at the direct 1,3-intramolecular hydrogen rearrangement in the following isoelectronic series of small molecules (31), as shown in Scheme 1.

The results indicated, for one, that the relative stabilities and barriers were in excellent agreement whether calculated using the 3-21G or 6-31G** optimized geometries. For example, the 6-31G**/CISD results did not differ by more than 1 or 2 kJ/mol in using the 3-21G geometry instead of the 6-31G** optimized geometry, representing less than 1% error. The work also further revealed the advantage of treating a series of the same type of molecules is that it clearly shows that the trends, in barriers for example, are independent of the level of calculation, although the individual barriers may vary significantly. The trends in relative stabilities and in the barriers of these simple compounds was explained using simple proton affinity arguments and bond order concepts.

The barriers for the 1,3-intramolecular hydrogen rearrangement reactions tend to be high and would model tautomeric

equilibrium in the gas phase. In the present work a systematic study similar to that in ref. 31 is made for the 1,3-intramolecular hydrogen rearrangement reaction in water, modeled with a single H_2O molecule. Through the remaining text, the direct 1,3-intramolecular hydrogen rearrangement will be referred to as the gas phase case and the 1,3-intramolecular hydrogen rearrangement via a H_2O molecule will be referred to as the H_2O-mediated or supermolecule case. The H_2O-mediated tautomeric mechanism in formamide, formamidic acid, and amidine have been studied in the past, but using the 3-21G basis set only, which favors planar structures at nitrogen and fails qualitatively in predicting relative energies (31). The SCRF method is also used to investigate the interactions between "solvent molecules" and the supermolecule. The effect of the reaction-potential on energies are examined with a number of values for k, which is a combination of the macroscopic dielectric constant ϵ of the solvent, and the so-called "cavity radius" R (36). The importance of correlation and ZPV (zero-point vibration) on relative stabilities and barriers is also examined.

II. Computational details

Calculations were performed with the MUNGAUSS (44) program on the Newfoundland and Labrador Computer Services (NLCS) AMDAHL 5880 and GAUSSIAN86 (45) on the VAX 8800 of Memorial University of Newfoundland. Structures for the supermolecules were optimized using analytical energy gradients at the 3-21G split valence shell basis set level (46) and the 6-31G** polarized basis set level (47, 48). Single-point calculations at the 3-21G geometries were also performed at the 6-31G** level for comparison. All minima and symmetrical transition states were optimized with the OC method (ref. 49, the algorithm is described in ref. 49) and the nonsymmetrical transition states were optimized using the minimization of sum of squares gradient technique VA05AD (50). All the bond orders were calculated using Mayer's definition (51). GAUSSIAN86 was used for MP2/6-31G*//6-31G** calculations for all the molecules, including the gas phase model molecules and the supermolecules to investigate the correlation effects. MP2/6-31G**//6-31G** and MP4/6-31G*//6-31G** calculations were also performed for the smallest system, HO—CH=O(H_2O). For the SCRF calculations, the effective Fock operator is expressed as $F = F_0 - k\hat{\mu}\langle\hat{\mu}\rangle$, where k can be given by $2(\epsilon - 1)/(2\epsilon + 1)R^3$ bohr^{-3} in the SCRF model suggested by Tapia (36), $\hat{\mu}$ is the dipole moment operator and F_0 is the standard SCF Fock operator. In the present study we assume k is a purely empirical parameter. The SCRF energy is defined as $E(\text{SCRF}) = E_0 - \frac{1}{2}k\langle\hat{\mu}\rangle^2$. It should be emphasized that this work represents the first application of the SCRF approximation to estimate the effect of solvation on barriers for reactions of this type. We are assuming that the thermodynamic formulation of the transition state theory will apply to the solution phase, as described by the SCRF. This is a reasonable assumption in this case since the barriers are high (52) and the reaction is an intramolecular arrangement in which little solvent reorganization is expected. The ZPV corrections were calculated with MNDO (53) at the

6-31G** geometries. The gas phase model 3-21G//3-21G, 6-31G**//3-21G, and 6-31G**//6-31G** SCF results are from ref. 31.

III. Results and discussion

III.1 Geometries

The 3-21G and 6-31G** optimized structures for the supermolecules shown in Fig. 2 are summarized in Tables 3 and 4, respectively. The total energies corresponding to these structures, calculated with different basis sets at the SCF level and with MP2 corrections, are reported in Table 5.

For the 15 supermolecules studied in the present work, most of the optimized geometries yield "cyclic structures" for the reactants (**a**), transition states (**b**), and products (**c**). Except for the propene–H_2O case, which has a dipole moment of only 0.3 D compared with 1.0 to 4.1 D for other species, the cyclic structures show strong co-operative hydrogen bonding, indicated by the characteristic geometric parameter, the O—H_x and/or O—H_y distance, as shown in Fig. 2 and reported in Tables 3 and 4.

In all the unsymmetrical cases, the H_2O molecule in the supermolecules is preferentially bonded to the terminal atom which forms the double bond with the central carbon.

Similar to the results of the study on the gas model molecules (31), a number of trends appear when comparing some of the most important geometrical parameters of the 3-21G and 6-31G** optimized geometries. The C—X and C—Y 6-31G** bond lengths are generally shorter than the corresponding 3-21G bond lengths. The 3-21G and 6-31G** XCY bond angle differs by less than 1°, except for CH_3CHCH_2, in which the XCY angle changed by 1.2° in (**a**) and by 2.0° in (**b**). In contrast with the gas model molecule results, the supermolecule XCY angles decrease in going from 3-21G to 6-31G** (except for CH_2CHNH_2 (**a**), where 6-31G** XCY is larger than that of 3-21G by 0.4°). This reveals the role of polarization functions in cases where hydrogen bonding exists.

Comparing the optimized geometries for the reactants, transition states, and products, the most significant difference between the gas model molecules and the H_2O-mediated case is the change in the XCY angle in the transition state. For the H_2O-mediated case, the XCY angle increased only slightly (0.3 to 6°), compared to the 14 to 19° change for the gas model molecules (31). The changes in other geometric parameters from reactant to transition state and then to product are also smaller compared with those in the gas model molecules. This significant difference in the changes in geometry between the gas model molecules and the supermolecules is consistent with the lower barriers for the H_2O-mediated case.

III.2 Relative stabilities

Table 6 summarizes the relative stabilities for H_2O-mediated results for various levels of calculations, along with the direct

†I for gas phase molecule and II for H_2O-mediated case. Column 1, 3-21G//3-21G; col. 2, 6-31G**//3-21G; col. 3, 6-31G**//6-31G**; col. 4, 6-31G*//6-31G**; col. 5, MP2/6-31G*//6-31G**; col. 6, MP2/6-31G*//6-31G** + ZPV(MNDO); col. 7, 6-31G**//6-31G** at k = 0.001 bohr^{-3}; col. 8, 6-31G**//6-31G** at k = 0.006 bohr^{-3}.

1,3-intramolecular hydrogen shift results of ref. 31. In most cases, the largest change in relative stabilities for both the gas phase results and the H_2O-mediated results occurs in going from the 3-21G//3-21G level to the 6-31G**//3-21G level. The results at the 6-31G**//3-21G level and higher are in good agreement. For example, the 6-31G**//3-21G and 6-31G**//6-31G** relative stabilities differ by an average of only 3 kJ/mol.

For the methyl imine – vinyl amine case (CN), the methyl imine is predicted to be more stable by 48 kJ/mol at the highest level. This is the only case for which the 3-21G//3-21G level fails qualitatively. Both the addition of a water molecule and the SCRF increases the stability of the methyl imine tautomer.

For acetaldehyde – vinyl alcohol (CO), the only case for which experimental results are available, the acetaldehyde tautomer is predicted to be more stable by 74 kJ/mol at the highest level. For the H_2O-mediated case the SCRF increases slightly the stability of the vinyl alcohol (column 3 vs. columns 7 and 8), whereas the opposite occurs for the gas phase. The gas phase and the H_2O-mediated case give similar results, where the relative stability differs by only 2 to 3 kJ/mol with the vinyl alcohol being consistently stabilized by the addition of a water molecule. Experimentally the relative stability in acidic aqueous solution is estimated to be 36 kJ/mol (10), indicating that the SCRF does correctly reduce the relative stability, predicting 41 kJ/mol for a value of k = 0.006 bohr^{-3}.

For the formamide – formamidic acid case (NO), formamide is predicted to be more stable, by 59 kJ/mol at the highest level. The addition of a water molecule and the SCRF to the gas phase both result in an increase in the stability of formamidic acid. Addition of the SCRF to the H_2O-mediated case on the other hand increases the stability of the formamide tautomer. These results can be compared to related systems, such as *N*-phenylbenzamide for which a relative stability in the gas phase is predicted to be 60 kJ/mol, in excellent agreement with the calculated gas phase values. This is also in good agreement with the MBPT(2)/6-31G*//3-21G+ZPV results (34) for the relative stability kk-ke tautomers of uracil of 63 kJ/mol (cf. Table 1). These results suggest that the relative stability in related structures is fairly consistent. The exceptions to the rule, such as 2-oxopyridine and 2-oxopyrimidine, where the relative stability between the keto and enol form are about

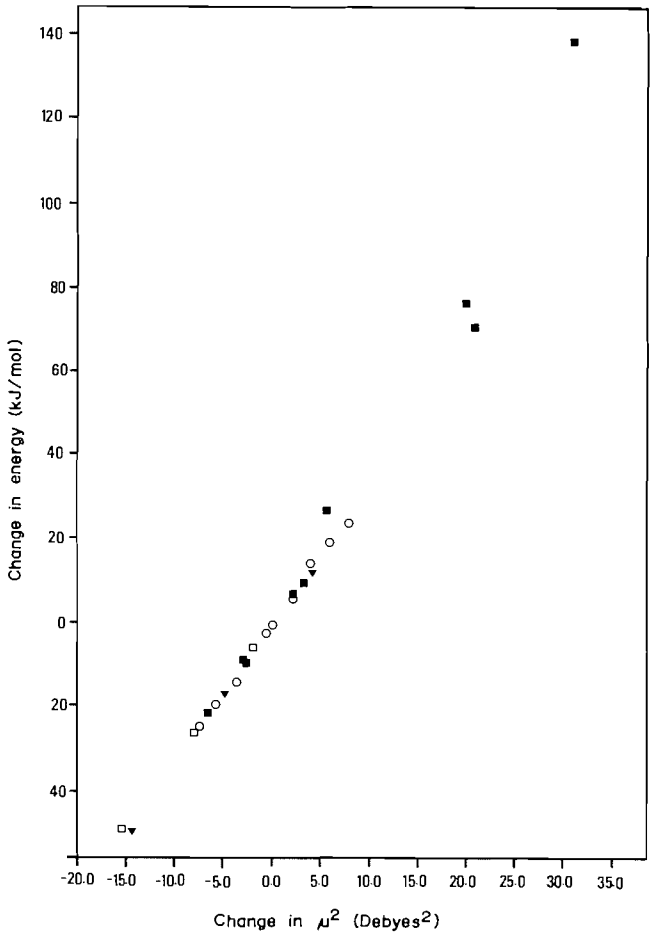

FIG. 3. The relationship between changes in barrier height and relative stability, and changes in the square of the dipole moment (○ gas phase barrier, ■ H_2O-mediated barrier, □ gas phase relative stability, and ▼ H_2O-mediated relative stability). The energies and dipole moment are for the 6-31G**//6-31G** level.

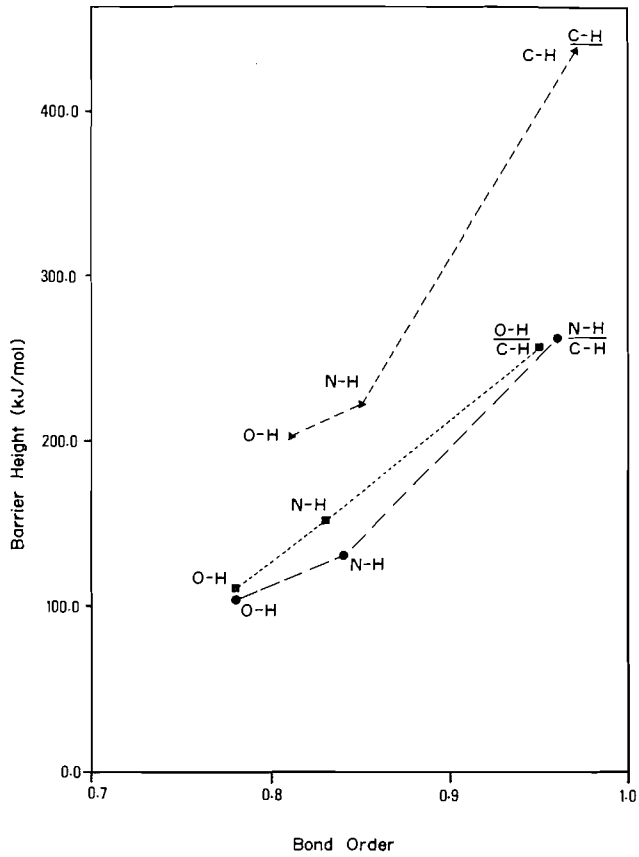

FIG. 4. The relationship between the barrier height and the bond order of the X—H bond being broken in going from reactant to transition state (6-31G**//6-31G**). The bonds beside the points are bonds being broken and the underlined bonds at the top of each curve are the bonds being formed.

−2.5 and −10 kJ/mol, respectively, can be explained by the increase resonance in the enol form relative to the keto form.

The effect of correlation on relative stability can be seen by comparing columns 4 and 5 of Table 6. For both the gas phase molecules and the supermolecules the change in relative stabilities due to correlation varies between 1.0 and 3.8 kJ/mol for MP2/6-31G*//6-31G**. Addition of ZPV correction represents a further change of between 4.0 and 8.8 kJ/mol.

Columns 3 and 7 or 8 represent the effect of a polar aprotic solvent. Addition of the SCRF consistently stabilizes the tautomer with the largest dipole (cf. Table 7 and Fig. 3). This is not too surprising since the SCRF adds a dipole–dipole interaction term to the Fock operator.

III.3 Barriers

Table 8 summarizes the barrier heights for the H_2O-mediated results for various levels of calculations, along with the direct 1,3-intramolecular hydrogen shift results of ref. 31. As can be seen from Table 2, no experimental results and few computational results are available in this case. As indicated in Table 8, the nine barriers predicted by 6-31G**//3-21G and 6-31G**//6-31G** only differ by an average of 6 kJ/mol. This encourages the use of 3-21G optimized structures on large systems for this kind of study.

The correlation has a much larger contribution on the transition states and therefore on the barriers. For the gas phase case, the lowering in the barriers heights at MP2 ranges from 54 to 65 kJ/mol compared to a range of 26 to 52 kJ/mol

at CISD-DQ/6-31G**//6-31G** (31). For the H_2O-mediated case MP2 lowers the barrier heights by 36 to 68 kJ/mol. Higher level calculations on formic acid at the MP2/6-31G**//6-31G** level further lowers the barrier by 7.3 kJ/mol, while MP4/6-31G*//6-31G** lowers the barrier by only 1.7 kJ/mol.

The SCRF term introduces both significant decreases and increases in the barrier heights. Again the species with the largest dipole is the most stabilized by the SCRF. This can be seen from Fig. 3, where the change in barrier is plotted against the change in the square of the dipole moment. When the transition state dipole increases relative to the reactant, the effect of a polar solvent (SCRF) is to lower the barrier and vice versa. Barrier heights should be further reduced by the addition of a second water molecule (cf. Table 2).

Figure 4 plots the barrier height as a function of the X—H bond order, which is being broken in going from reactant to product, and the lines connect the points with the same X. There is a general increase in barrier height in the order O—H, N—H, and C—H. This implies that the O—H bond is the easiest to break and that the C—H bond is the most difficult to break for a given series, when the terminal group Y is kept the same. For a group in which the bond being broken is held the same, the order of barrier heights are N—H, O—H, and C—H, that is, O—H and N—H is opposite to the gas phase results. These results indicate that the barriers in these systems are predominantly controlled by the type of bond being broken in the transition state and is consistent with product-like transition states (in this paper, we have chosen the more stable tautomers as the reactant (**a**)).

Table 8 shows that the barriers are reduced by 94 to 124 kJ/mol from the gas model molecules to the supermolecules except for X and Y = CH_2, where the barriers for both CH_3CHCH_2 and $CH_3CHCH_2(H_2O)$ are essentially the same, based on 6-31G** results.

IV. Conclusions

The results in this work indicate that for reliable results the lowest acceptable level is 6-31G*//3-21G. The water molecule plays a significant role in catalyzing the 1,3-intramolecular hydrogen rearrangement reaction for molecules in which some hydrogen bonding is possible. The combination of the supermolecule and self-consistent reaction field approach in predicting the effect of solvent on both relative stabilities and barriers appears to be quite promising. The results indicate that the effect of polar solvent can be qualitatively predicted based on changes in dipole moment.

Stereochemical requirements for the formation of vanadate complexes with peptides

JASWINDER S. JASWAL AND ALAN S. TRACEY[1]
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6
Received April 18, 1991

JASWINDER S. JASWAL and ALAN S. TRACEY. Can. J. Chem. **69**, 1600 (1991).

The condensation reactions occurring between vanadate and a number of amino acids and simple peptides have been studied by ^{51}V nuclear magnetic resonance. Vanadate and ligand stoichiometry has been established for the complexes formed and their formation constants determined. The amino acids were all found to undergo rather weak interactions with vanadate and in general provided two products with ^{51}V chemical shifts near −545 and −555 ppm. The peptides also gave minor products with NMR signals occurring with that of vanadate itself. However, in this case, the major products occur at approximately −510 ppm. These latter complexes are monovanadate, monoligand complexes which require the terminal amino, the carboxylate groups and an unsubstituted nitrogen in the peptide linkage in order for product formation to occur. Sidechains promote product formation, apparently by favouring a more readily complexed peptide conformation. Formation constants vary from about 20 to 50 M^{-1} depending on the sidechain. The carboxylate group can be replaced by a hydroxymethyl. This, however, leads to a significant decrease in product formation at pH 7. Hydrogen ion concentration studies showed that the complexes, when considered to be formed from $VO_4H_2^-$ and neutral peptide, did not require or give off protons. However, when the carboxylate was replaced by the alcohol functionality a proton was released. On the basis of this study the coordination of the vanadate/peptide complexes has been assigned.

Key words: peptide, vanadate, complexes, vanadium magnetic resonance.

JASWINDER S. JASWAL et ALAN S. TRACEY. Can. J. Chem. **69**, 1600 (1991).

Faisant appel à la rmn du ^{51}V, on a étudié les réactions de condensation qui se produisent entre le vanadate et un certain nombre d'acides aminés et de peptides simples. On a déterminé les stoechiométries du vanadate et du ligand dans les complexes formés ainsi que leurs constantes de formation. On a trouvé que tous les acides aminés n'établissent que des interactions faibles avec le vanadate et que, en général, ils conduisent à deux produits avec des déplacements chimiques du ^{51}V de près de −545 et −555 ppm. Les peptides fournissent aussi des produits mineurs avec des signaux de rmn apparaissant avec ceux du vanadate lui-même. Toutefois, dans ce cas, les produits majeurs présentent un signal près de −510 ppm. Ces derniers complexes sont des complexes monocoordinés du monovanadate qui ne peuvent se produire qu'en présence d'un groupement amino terminal, de groupements carboxylates et d'un azote non-substitué d'une liaison peptidique. Les chaînes latérales favorisent la formation du produit, apparemment en favorisant une conformation peptidique qui peut être complexée plus facilement. Les constantes de formation varient de 20 à 50 M^{-1} dépendant de la chaîne latérale. On peut remplacer un groupe carboxylique par un groupe hydroxyméthyle. À un pH de 7, cette modification conduit toutefois à une diminution importante dans la formation du produit. Des études sur la concentration en ions hydrogènes ont montré que, lorsqu'on considère que les complexes se forment à partir du $VO_4H_2^-$ et d'un peptide neutre, leur formation ne requière pas de protons et qu'elle ne donne pas lieu à une expulsion de protons. Toutefois, lorsqu'on remplace le carboxylate par une fonction alcool, il y a expulsion d'un proton. Sur la base de cette étude, on a attribué la coordination des complexes de vanadate/peptide.

Mots clés : peptide, vanadate, complexes, rmn du vanadium.

[Traduit par la rédaction]

Introduction

The past few years have seen an extraordinary expansion of interest in the aqueous chemistry and biochemistry of vanadium oxoanions, particularly of the V(IV) and V(V) oxidation states. Much of this interest has concentrated on the role of these ions as phosphate analogues principly because they are potent inhibitors of a variety of phosphate metabolizing enzymes and activators of a number of others (1, 2). Additionally, both vanadate (V(V)) and vanadyl (V(IV)) bind tightly to a number of proteins, particularly albumins (3, 4) and transferrins (5). Vanadium has a large number of other biochemical effects many of which have been discussed in a number of recent reviews concerning the biochemistry of vanadium. These have been published in the single volume referred to in ref. 1.

In view of the biological activity of vanadate, considerable work has gone into obtaining an understanding of the interactions of this ion with metabolites and other small molecules. Of particular interest in this regard is the interactions of vanadate with amino alcohols (6, 7), amino acids (8–10), and small peptides (9–12). A good understanding of the interactions of vanadate with such materials will provide a firm basis for extension into studies of more complex systems.

A study of the available information on vanadate/peptide interactions revealed a surprising lack in fundamental information concerning these systems and furthermore suggested that some reported results were not correct. In view of this it was decided to undertake a detailed investigation of vanadate interactions with a variety of amino acids and small oligopeptides. The main purpose of this study was to establish which functional groups were necessary for complex formation, whether complexes of differing coordination were formed, and the stoichiometry of and proton requirements for complex formation. This initial report concentrates mainly on the function of the peptide bond and the terminal groups in complex formation. An additional report will consider the role of functionalized side chains in complex formation.

Experimental section

Materials

All amino acids and peptides used in this study were purchased from Sigma Chemical Company except for the glycylglycine, gly-

TABLE 1. Table of reactants and chemical shifts of products of complex formation between vanadate and a selection of amino acids and peptides[a,b]

Ligand[a]	^{51}V chemical shift	Reference	Ligand	^{51}V chemical shift	Reference
Glycine[c]	−523, −546, −560	9, 10	Alanine	−547, −557	
Serine	−541, −554	9	Arginine	−555	
Asparagine	−545, −556		Valine	−552	
Glycinamide	NP				
Glygly	−505	9, 10	Glyglygly	−505	10
GlyglyOEt	NP		GlyglyglyOEt	NP	
CBZ-glygly	NP		CBZ-glyglygly	NP	
Glyglyglygly	NP		Glyglycinamide	NP	
Glyser	−494, −504, −507	9	GlyserOEt	−494, −501	
Glypro	NP	9	Progly	−493	9
Glyval	−510		Valgly	−506	
Glyasp	−509	9	Valasp[c]	−513	9
Leuleu	−512		Glysar	NP	9

[a]The standard three letter abbreviations for amino acids have been used: NP, no product; CBZ, carbobenzoxy.
[b]All ligands in this table have been studied in our laboratory under conditions of μ = 1.0 M KCl, 20 mM HEPES buffer, pH 7, and variable vanadate or ligand concentrations.
[c]The results of this study are not in agreement with previously published reports.

For personal use only.

cylglycylglycine, and glycylserine ethyl ester hydrochlorides which were prepared according to literature procedures (13). The latter compounds were characterized by ^1H NMR spectroscopy and by elemental analysis. ^1H NMR spectra of the purchased materials were obtained as deemed necessary; all were used as supplied. Vanadium pentoxide (99.99%) was purchased from Aldrich Chemical Company and the buffer, *N*-(2-hydroxyethyl)-piperazine-*N'*-ethane sulfonic acid (HEPES), was obtained from Boehringer Mannheim GmbH.

Solutions

The vanadate stock solution was prepared from vanadium pentoxide by adding 0.5 mol equiv. of V_2O_5 to a 1.0 M solution of NaOH and stirring until the solution became colourless (~24 h). The solution was then diluted with distilled water to provide a 0.1 M vanadate stock solution.

Except for leucylleucine and the tri- and tetraglycine final solutions, which were prepared by direct weighing, 1.0 M peptide stock solutions were prepared in distilled water. Suspensions were warmed slightly if needed for dissolution to occur. HEPES (1.0 M) and KCl (2.0 M) stock solutions were also prepared. As an intermediate step in the process, solutions containing peptide, vanadate, KCl, and HEPES were prepared so as to ascertain what pH the stock solutions needed to be adjusted to so that mixing them provided a resultant solution of pH about 6.0 to 6.5. For the final solutions the pH was adjusted upward with NaOH to pH 7.0. This process avoided the formation of decavanadate. The final solutions contained 20 mM HEPES, the appropriate amount of vanadate and peptide and the ionic strength was maintained at 1.0 M with KCl.

Freshly opened pH 10.0 and pH 4.0 standard buffer solutions were used for pH calibration and the calibration was confirmed using a pH 7 buffer.

Spectroscopy

All ^{51}V NMR spectra were obtained from a Bruker AMX-400 NMR spectrometer operating at 105 MHz and at ambient temperature (22 ± 1°C). Chemical shifts are relative to an external $VOCl_3$ reference assigned to 0.0 ppm. Spectral widths of 80 KHz, 60° pulse widths and 0.05 acquisition times were used throughout. A polynomial baseline correction was applied to all spectra before integrals were obtained.

Methods

The appropriate equilibria were considered as outlined in the text. The equations were put into their linear form and the results analyzed graphically. The slopes and, where non-zero, the intercepts were obtained by least-squares analysis. The errors in the parameters represent the 95% confidence levels (3σ).

Results

Vanadate tends to not react very strongly with amino acids. Products, however, are formed as indicated in Table 1. Apparently, there are three distinct types of products formed with ^{51}V chemical shifts near −525, −545, and −555 ppm. Chemical shifts near these positions are not observed for any of the peptides in this study. The peptides give rise to product NMR signals which are centred near −494, −506, and −511 ppm, depending on the peptide.

Under the conditions of this study, a number of peptides do not yield complexes with vanadate. These peptides fall into three classes. Peptides, which are protected at the *N*-peptide linkage as by the ring in proline or the methyl group of sarcosine do not give product complexes. This was observed for glycylproline and glycylsarcosine. Prolylglycine, however, does provide a product. Also, no products were observed if the terminal NH_2 group was protected with a carbobenzoxy (CBZ) group or if the carboxylate group was protected as the ethyl ester. These observations are in agreement with those of other workers (9).

In order to quantify the formation of the amino acid and peptide complexes it is necessary to take into account the formation of vanadate oligomers. The vanadate tetramer, V_4, in particular serves as a useful reference compound. The formation of the predominant products is represented in eqs. [1] through [3].

$$[1] \quad 4V_1 \overset{K_0}{\rightleftharpoons} V_4 \qquad [V_1]^4K_0 = [V_4]$$

$$[2] \quad 2V_1 \overset{K_1}{\rightleftharpoons} V_2 \qquad [V_1]^2K_1 = [V_2]$$

$$[3] \quad 5V_1 \overset{K_2}{\rightleftharpoons} V_5 \qquad [V_1]^5K_2 = [V_5]$$

It is of importance to establish whether any complexes are formed which are in rapid exchange with vanadate itself so that a time-averaged signal is being observed. This formation is given in eq. [4]. Tetravanadate can be used to examine this

TABLE 2. Formation constants for the vanadate complexes of selected amino acids[a,b]

Amino acid	^{51}V chemical shift	Formation constant	^{51}V chemical shift	Formation constant
Glycine[c]	−523	$0.5 \pm 0.2\ M^{-2}$	−560	$0.13 \pm 0.12\ M^{-1}$
	−546	$0.39 \pm 0.10\ M^{-1}$		
Alanine	−547	$0.19 \pm 0.14\ M^{-1}$	−557	$0.49 \pm 0.08\ M^{-1}$
Serine	−541	$0.75 \pm 0.24\ M^{-1}$	−554	$0.94 \pm 0.04\ M^{-1}$
Arginine			−555	$0.71 \pm 0.12\ M^{-1}$

[a]All formation constants were determined for $\mu = 1.0$ M KCl, pH 7.0, 20 mM HEPES buffer, and variable amounts of added vanadate or added amino acid.

[b]Single NMR spectra of asparagine and valine solutions were obtained and products observed to form. The ^{51}V chemical shifts were −545 and −556 ppm for the asparagine products and −552 ppm for that of valine.

[c]The formation constants determined in this study are two orders of magnitude smaller than those previously reported (10).

possibility so that combination of eq. [1] with eq. [4] and rearrangement gives eq. [5].

$$[4] \quad V_1 + l \overset{K_3}{\rightleftharpoons} Vl \qquad [V_1][l]K_3 = [Vl]$$

$$[5] \quad \frac{[V_1] + [Vl]}{[V_4]^{1/4}} = K_0^{-1/4} + K_0^{-1/4}K_3[l]$$

A graph of the term on the left of this equation versus the equilibrium concentration of the added ligand should give a straight line of intercept $K_0^{-1/4}$ and slope $K_0^{-1/4}K_3$. The possibility of formation of Vl was examined for the amino acids and for a variety of peptides, including glycylglycine, prolylglycine, glycylvaline, and glycylserine.

Of the amino acids studied, only with glycine was there an indication of formation of the Vl product. However, glycine does not give rise to a signal near −555 ppm. It is very likely that the Vl product observed for glycine corresponds to the −555 ppm products, perhaps occurring with the much more intense V_1 signal at −560 ppm by virtue of accidental degeneracy. This seems possible since the product formed with the closely related alanine has a chemical shift of −557 ppm, only 3 ppm from that of V_1. The formation constants that were determined are listed in Table 2. Of the products formed with glycine, the largest formation constant ($0.4\ M^{-1}$) is about a factor of 200 smaller than that determined under similar conditions by an enzyme assay technique (10). The reason for this discrepancy is not clear but the same assay procedure gave formation constants for di- and triglycine complexes which also were larger than those determined in this study; factors of 5 and 35, respectively. It may be that the amino acids or peptides interfere with the enzymic assay procedure. It is worth noting here that 3-hydroxybutanoic acid, ethanolamine, and 1,3-propanediol did not provide observable products which can be assigned to cyclic derivatives although, of course, vanadate esters will be formed at the hydroxyl positions (14).

Figure 1 shows a number of ^{51}V NMR spectra obtained from solutions containing glycylglycine or other peptides. In each case the formation of at least one product clearly is evident. Ligand and vanadate concentrations studies allowed the stoichiometry of the products to be established.

Initial examination of the results according to eq. [5] revealed that a product corresponding to Vl is formed as demonstrated in Fig. 2*A*. From the slope and intercept the constants $K_0^{-1/4} = (2.5 \pm 0.1) \times 10^{-3}\ M^{3/4}$ and $K_3 = 0.34 \pm 0.11\ M^{-1}$ were obtained. Values of K_3 similar to that for glycylglycine were measured for a number of dipeptides. They are given in Table 3 where the products are assigned a chemical shift of −560 ppm. They probably occur at this frequency by virtue of rapid exchange with vanadate. Glycylserine gives rise to the largest value for K_3 ($0.8 \pm 0.3\ M^{-1}$). However, this peptide has a hydroxyl group which will give rise to a vanadate ester with a formation constant of about $0.2\ M^{-1}$ (14). It is evident from these results that the formation of Vl must be taken into account when characterizing the other products.

Variation of the vanadate and ligand concentrations revealed that, for all cases studied, only one peptide and one vanadate were involved in product formation. Product formation can then be represented as in eq. [6] where the product is identified by its ^{51}V chemical shift (PPM) and V_1 is given by $[V_1] = K_0^{-1/4}[V_4]^{1/4}$ to allow for Vl formation or alternatively,

$$[6] \quad V_1 + l \overset{K_4}{\rightleftharpoons} PPM \qquad [V_1][l]K_4 = [PPM]$$

where $V_1 = (V_1 + Vl)/(1 + K_3[l])$. Having obtained V_1, K_4 can readily be obtained by plotting the relevant quantities of eq. [6]. The results obtained for glycylglycine are displayed in Fig. 2*B* from which it is evident that a good linear relationship is obtained. In this graph the open circles derive from fixed ligand studies with variable vanadate concentrations while the solid circles represent variable ligand concentration studies. Table 3 gives the formation constants obtained for the −505 ppm product of glycylglycine and the corresponding values for a number of other dipeptides. These studies with glycylglycine and the other peptides did not completely rule out the possibility of the formation of divanadobisligand products at high ligand concentrations. Such products, if they are formed, must be present in low concentrations for the conditions of this study. In this regard, it should, however, be noted that the studies with prolylglycine revealed some upward curvature in the plots. In view of the results obtained with the other peptides this curvature was attributed to non-ideal behaviour in solution, a result perhaps of attractive interactions between the hydrocarbon rings of different proline entities. Similar observations have been ascribed to based stacking interactions in the nucleoside/vanadate systems (15).

Unlike the other dipeptides studied, glycylserine gives rise to two major products, one occurring at −507 ppm the other at −494 ppm. Ligand and vanadate concentration studies clearly showed a 1:1 stoichiometry for both products. Good

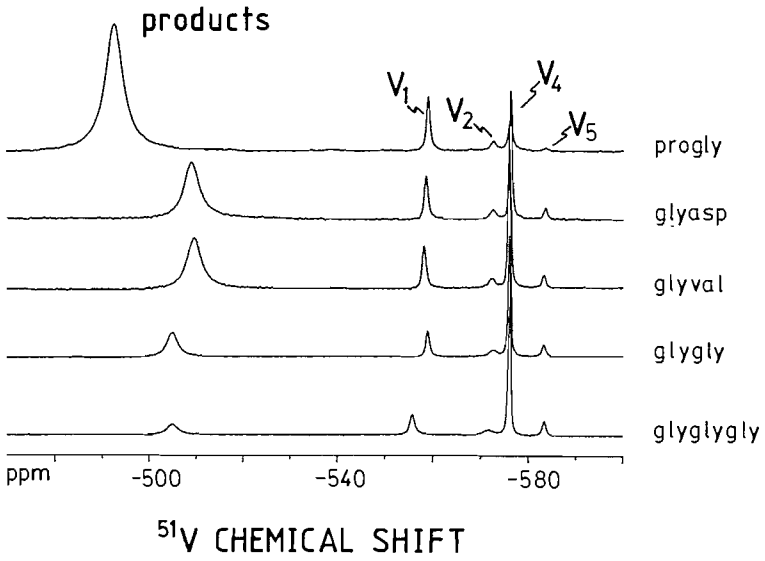

FIG. 1. ^{51}V NMR spectra showing the formation of various peptide complexes of vanadium (V). Conditions of the experiments were 3.0 mM vanadate, 20 mM HEPES buffer, μ = 1.0 M KCl, pH 7.0, 125 mM peptide.

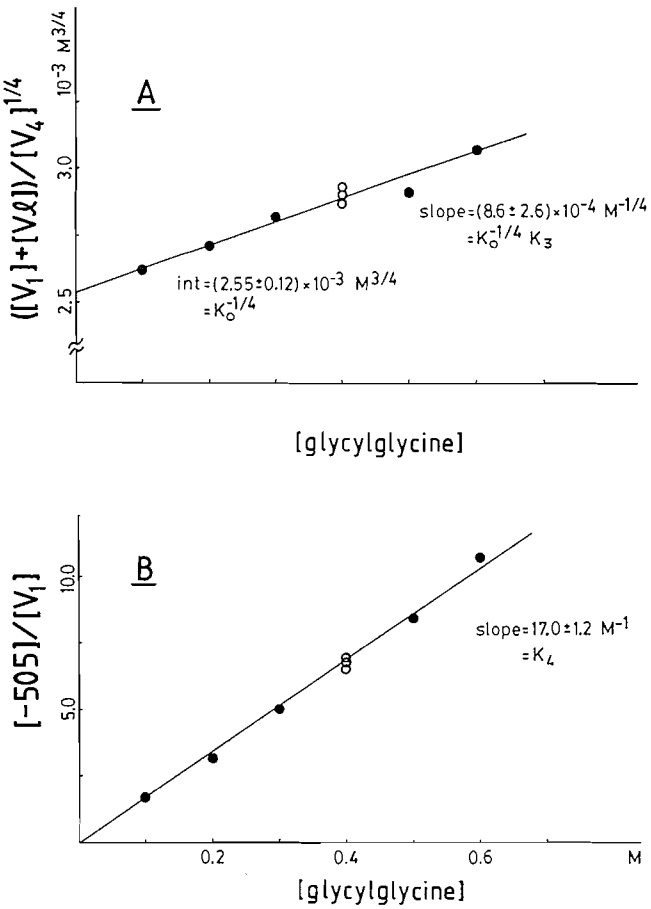

FIG. 2. Graphical display of the formation of glycylglycine/vanadate complexes plotted according to eq. [5] (top) and eq. [6] (bottom). Good linear relationships were obtained. The top graph indicates the presence of a product with an NMR signal occurring under that of vanadate. The bottom graph establishes the V_1l_1 stoichiometry of the −505 ppm product. Conditions of the experiments were pH 7.0, HEPES buffer 20 mM, μ = 1.0 M KCl; variable vanadate concentrations (○); variable glycylglycine concentrations (●).

linear plots were obtained for the products with the equilibrium constants being 7.5 ± 0.8 M^{-1} and 54 ± 3 M^{-1} for the −494 and −507 ppm products, respectively at pH 7.4.

The close correspondence between the −507 ppm signal of the glycylserine product compared to that of glycylglycine at −505 ppm suggests a similar structure for those products. Evidence in support of this was obtained from pH studies which allowed proton stoichiometry to be established. It was necessary to first determine the pK_a values for vanadate and the dipeptide under the conditions of the different pH studies which were 3.0 mM total vanadate, 20 mM HEPES buffer, μ = 1.0 M KCl, variable pH, 125 mM glycylserine or 400 mM glycylglycine. The chemical shift of the vanadate signal can be used to determine the second pK_a of vanadate

$$[7] \quad pH = pK_a + \log\left(\frac{\delta_L - \delta_0}{\delta_0 - \delta_H}\right)$$

according to eq. [7] where δ_0 is the observed chemical shift and δ_L = −560 ppm is the chemical shift of $VO_4H_2^-$ and δ_H = −537 ppm is that of VO_4H^{2-} (16–18). The values determined were 8.06 ± 0.08 and 7.90 ± 0.08, respectively, for the glycylserine and glycylglycine solutions. The first (18) and third (19) pK_a values of vanadate, approximately 3 and 12, respectively, are well outside the range of pH values utilized in this study. The pK_a's of glycylglycine and of glycylserine were determined by titration and found to be 8.1 ± 0.1 and 8.2 ± 0.1, respectively, for the conditions of this study. These pK_a values are for the equilibrium $RNH_3^+ \rightleftharpoons RNH_2 + H^+$ since only this is important for the present study.

Equation [6], when rewritten to take into account proton stoichiometry and the pK_a values of the reactants and products, gives eq. [8], where PPM is used to specify the product of interest by its chemical shift.

When the pH of a 3 mM vanadate 400 mM glycylglycine solution was increased in a stepwise manner from pH 6.5 to 9.5, it was found that product formation was increasingly disfavoured, while for the glycylserine only the formation of the −507 ppm product was disfavoured while the −494 ppm

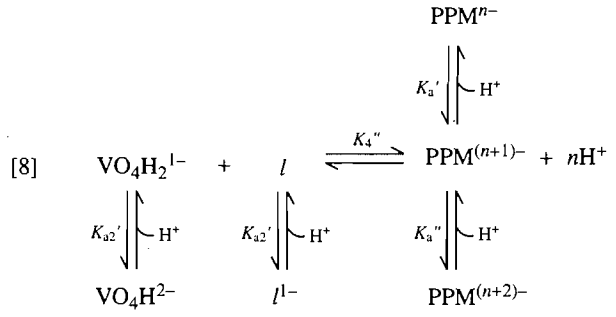
$Vglyser^{2-}$ ⇌ $Vglyser^{3-}$ + H^+	−494	(1.5 ± 0.5) × 10^{-10} M
$VO_4H_2^{1-}$ + glyser ⇌ $Vglyser^{2-}$ + H^+	−504	(5.3 ± 0.6) × 10^{-8}
$VO_4H_2^{1-}$ + $glyserOEt^{1+}$ ⇌ $VglyserOEt^{1-}$ + H^+	−504	(2 ± 1) × 10^{-7}
$VO_4H_2^{1-}$ + $glyserOEt^{1+}$ ⇌ $VglyserOEt^{1-}$ + H^+	−501	(39 ± 4) × 10^{-7}



[a]Products are identified by their vanadium chemical shifts and the errors quoted for the formation constants are at the 95% confidence level.

[b]Formation constants are reported for the following conditions: μ = 1.0 M KCl, 20 mM HEPES buffer, pH 7.0, variable vanadate and peptide concentrations.

[c]The values reported were calculated for pH 7.0 from the pH independent formation constants according to eq. [10], the ligand and vanadate concentration studies were done at pH 7.4.

[d]Equilibrium constants were determined under conditions of μ = 1.0 M KCl, 20 mM HEPES buffer, 0.125 M glycylserine or 400 mM glycylglycine and variable pH, from pH 6.5 to 9.6.

[e]Equilibrium constants for solutions containing no added KCl were glygly, 19 ± 2 M^{-1}; glyasp, 21 ± 5 M^{-1}; valgly, 60 ± 3 M^{-1}; progly, 73 ± 5 M^{-1}.

product was initially favoured, then disfavoured at the higher pH levels. The results of the pH study for glycylserine are shown in Fig. 3. This figure clearly reveals a different proton stoichiometry for the −494 and −507 ppm products and also shows that there is an additional product (−504 ppm) formed that apparently has a proton stoichiometry similar to that of the −494 ppm product. Evidently the −494 and −504 ppm products lose a proton as the product is formed while the −507 ppm product does not, thus *n* (of eq. [8]) = 1, 1, and 0, respectively, for the three. The remaining question is whether the product itself has a pK_a near the range of pH values of this study. The formation constant K_4' is related to K_4'' of eq. [8] as shown in eq. [9] where

$$[9] \quad K_4' = K_4''(1 + [H^+]/K_a' + K_a''/[H^+])$$

$K_4' = [PPM]/[VO_4H_2^{1-}][l^0]$ and [PPM] represents the total observed product at that chemical shift. Calculation of this last ratio as a function of pH of the solution revealed that it increased slightly with increase in pH. This suggested that a proton was being lost at high pH, indicating the occurrence of the dissociation K_a'' of eq. [8] so that the term $[H^+]/K_a'$ in eq. [9] can be neglected. A plot of K_4' vs. $1/[H^+]$ gave a line of intercept $K_4'' = 72 \pm 6$ M^{-1} and slope $K_4''K_a'' = (3.2 \pm 0.8) \times 10^{-8}$ for the −507 ppm product and an intercept of $(3.3 \pm 0.8) \times 10^{-7} = K_4''$ and slope of $(4.9 \pm 1.7) \times 10^{-17}$ M $= K_4''K_a''$ for the −494 ppm product. These correspond to the pK_a'' values 9.4 and 9.8, for the −507 and −494 ppm products, respectively. These pK_a values are at the upper limit

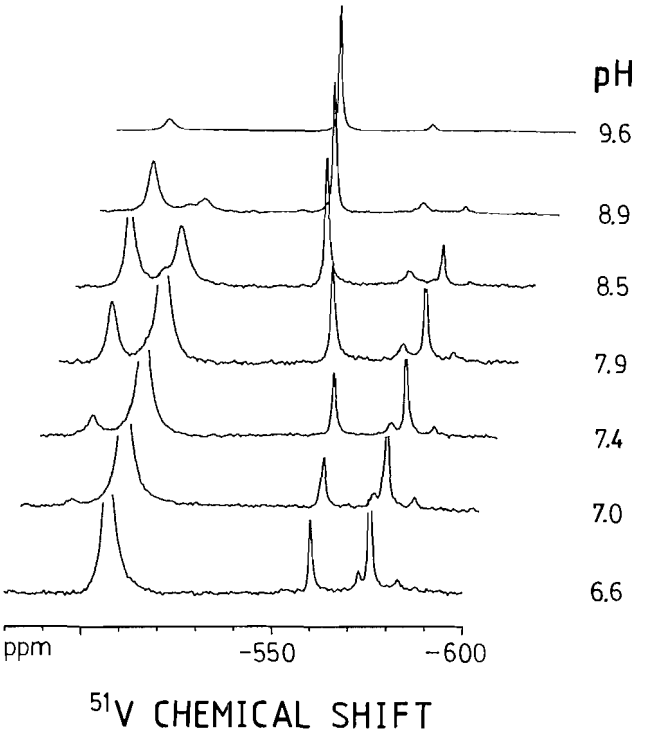


FIG. 3. ^{51}V NMR spectra of the vanadate/glycylserine system showing the dependence of product formation on the hydrogen ion concentration. The signals at −494 and −504 ppm are derived from the involvement of the hydroxymethyl in complex formation and that at −507 ppm results from the utilization of the terminal carboxylate. Conditions of the experiments were 3.0 mM vanadate, 125 mM glycylserine, 20 mM HEPES buffer, μ = 1.0 M KCl, variable pH.

of the pH levels of this study where little or no product is formed. At such high levels both $VO_4H_2^-$ and glyser^0 are lost to VO_4H^{2-} and glyser$^-$ because of their respective pK_a values. An additional proton would have to be given up as the product formed in order for product formation to be maintained. It did not prove possible to obtain a pK_a value for the −504 ppm product. Its value can not be significantly smaller than the pK_a's discussed above, therefore K_4'' can be assumed to be equal to the observed value of $K_4' = (5.3 \pm 0.6) \times 10^{-8}$ for pH values below about 9.

The pH variation studies of the glycylglycine/vanadate complex formation (−505 ppm) revealed that this product had a pH dependence similar to that of the −507 ppm product formed with glycylserine. This suggests a close structural analogy in agreement with very similar chemical shifts. On the other hand, the complexes formed with glycylserineOEt of chemical shifts −484 and −501 ppm had a pH dependence similar to that of the −494 and −504 ppm products formed with glycylserine. Table 3 provides all of the equilibrium constants determined in this study.

The pH independent formation constants, K_4'', of Table 3 can be used to calculate K_4 of eq. [6] for any pH value by utilizing eq. [10] which follows directly from eq. [8] with $n = 0$ or 1. This formula is useful if different equilibrium

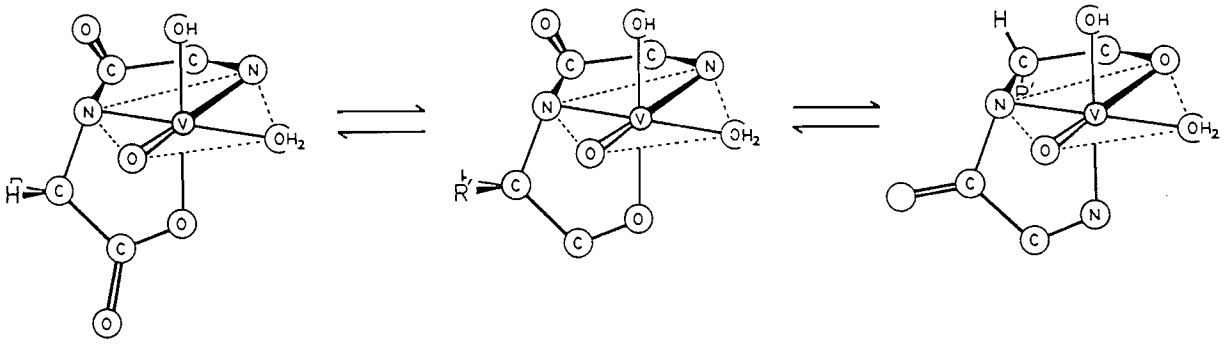
$$[10]\quad K_4 = \frac{K_4''(1 + K_a''/[H^+])}{[H^+]^n(1 + K_{a2}/[H^+])(1 + K_{a2}'/[H^+])}$$

studies have not been done at the same pH and a direct comparison is desired. It also provides an internal check on K_4 and K_4'' since these constants are determined in separate experiments utilizing a different procedure.

Discussion

Amino acids undergo rather weak interactions with vanadate to form three types of products with characteristic ^{51}V chemical shifts of about −523, −545, and −556 ppm. The three signals were not observed for all the amino acids studied. Glycine, alanine, and serine gave products at approximately −545 ppm. Only glycine provided an observable signal at −523 ppm while the alanine, serine, and arginine products gave signals at −556 ppm. Although glycine did not give signals near −556 ppm this frequency is close to that of vanadate, −560 ppm, and there may be signal overlap. Utilization of tetravanadate for a reference signal supported this and indicated that the V_1 signal was a composite signal for the case of glycine but not for the other amino acids where a separate signal near −556 ppm was observed.

The stoichiometry established for the products giving rise to the −523, −545, and −556 ppm products was Vl_2, Vl, and Vl, respectively. If the two ligands of Vl_2 complex in a bidentate manner than Vl_2 is probably octahedral. Picolinic acid, a structural analogue of amino acids, gives products with NMR signals at −513 and −529 ppm (20). These apparently correspond to octahedral products. Picolinic acid also gives a product with a ^{51}V chemical shift of −550 ppm. It seems likely that this corresponds to the −545 ppm signals of the amino acids. In the picolinate case the signal was tentatively assigned to a trigonal bipyramidal product. This coordination about vanadate has been found from X-ray studies of the picolinate derivative, $VO_2(pic)(OP(N(CH_3)_2)_3)$ (21). It seems likely that a similar coordination occurs with the amino acids.



The −556 ppm products possibly derive from anhydride formation with the carboxylate group of the various amino acids. These complexes arise from the acid form of the carboxylate (22). Calculations based on the pK_a of the amino acid and the formation constant determined for acetic acid suggest that the formation constant should be negligibly small ($\sim$0.03 M^{-1}). However, the adjacent ammonium group could well interact positively to stabilize products. On the other hand, the peptides studied also give rise to complexes with formation constants similar to those of the amino acids and chemical shifts which occur with the V_1 signal. It seems more likely then that all these products arise from complex formation with the amino group to give tetrahedrally coordinated products. In any event, with the peptides these are minor products compared to the much more favourable reactions involving the peptides as multidentate ligands.

It is evident from Table 1 that the formation of vanadate peptide complexes follow a simple pattern. Diglycine and triglycine form products, tetraglycine does not, or at best only exceedingly weakly. Protection of either the *N*-terminal or *C*-terminal position prevents complex formation. Furthermore, if the nitrogen of the peptide linkage is substituted as in glycylsarcosine or glycylproline there also is no product formation. In addition, prolylglycine forms a product while glycylglycinamide does not.

Evidently in the absence of functionalized side chains the requirements for complex formations are three-fold: (*1*) a terminal primary or secondary amine, (*2*) an unsubstituted nitrogen in the peptide bond, and (*3*) a carboxylate group.

Non-functionalized sidechains or sidechains which are functionalized at a remote site as in valylaspartate were not ob-

served to form products additional to those discussed above. The sidechains however, did promote product formation, doubling or trebling the formation constants compared to glycylglycine as is evident from Table 3. Even if the dipeptide has bulky substituents in the sidechains of both of the amino acid residues, as in valylaspartate or leucylleucine, there is no diminution in the formation of products (Table 3). This probably occurs because the sidechain interaction favour a peptide conformation which more readily complexes vanadate. In this respect, preliminary studies of the effect of ionic strength on the equilibria established in these systems suggests that lower ionic strength favours product formation for some, but not all, peptides. The behaviour seems to depend on the presence of sidechains and also may simply be related to changes in conformer populations.

There is no necessity for the carboxylate carbonyl functionality to be present. In glycylserine the sidechain, $—CH_2OH$, provides an alternative to the $—CO_2^-$ as the third functional group necessary for strong complexation to occur. Indeed, two products, in addition to that occurring with the carboxylate functionality, as formed. Furthermore, they are retained when the glycylserine ethylester is utilized instead of glycylserine as the ligand.

The proton requirements for product formation suggest that the different types of ligands coordinate, similarly. The product obtained from glycylglycine (−505 ppm) does not release a proton as products are formed, that from glycylserine (−507 ppm) also does not. These are the products formed from $H_3N^+(—)NH(—)CO_2^-$. Those formed from $H_3N^+(—)NH(—)CH_2OH$ (−494 ppm, −504 ppm) both release protons as complexation occurs. Thus the charge on the complex centre is the same in either case, the extra negative charge on the second set of products derives from a free side-chain carboxylate group and is not present if the glycylserine ethyl ester is the ligand. The pK_a values of the product glycylserine complexes are also similar, being 9.4 for the carboxylate product and 9.8 for the hydroxymethyl-derived product.

Replacement of the peptide hydrogen by an alkyl group prevents product formation. Evidently, this proton is required for water production. Presumably one, if not two, of the ammonium protons are also required for water formation as the final coordination geometry is established. The coordination about vanadate in these peptide complexes is one of conjecture, although octahedral coordination has been proposed (9, 12). Little compelling evidence for this has been presented since the products as well could be trigonal bipyramidal, as proposed for a series of aminoalcohol multidentate ligands (6). Ligand and proton stoichiometry as well as the ability to lose a proton at high pH are consistent with either coordination, the difference between the two coordinations being the presence of an aquo ligand for the octahedral geometry.

Triglycine forms a −505 ppm complex only if neither the amino nor the carboxylate groups are protected while tetraglycine does not yield a product. This suggests that triglycine is acting as a tetradentate ligand. Tetradentate complexation suggests the coordination is octahedral as, for instance, found for the complex formed between ethylenediamine tetraacetic acid and vanadate (23). Perhaps the most compelling evidence for octahedral coordination is the observation of three products with glycylserine. The two involving the hydroxymethyl are separated by 10 ppm (−494 and −504 ppm). The product utilizing carboxylate (−507 ppm) is only separated by 3 ppm from the −504 ppm product. These chemical shifts suggest a close structural correspondence between the various products.

The orientation of the carboxylate and amide groups in octahedral geometry can be expected to be strongly directed by the electronic factors deriving from the V=O bond, the tendency being towards a 90° orientation (see ref. 24 for a compilation of structures). This would lead to a single product since proton transfer between —OH and $—OH_2$ will be rapid. Actually, with glycylserine two products could be formed because of the asymmetric centre. However, since the coordination at the vanadium will be virtually identical in either case, the ^{51}V chemical shift separation would be expected to be small and not observable, perhaps contributing to the linewidth of several ppm. When the complex forms with the hydroxyl group of the hydroxymethyl rather than with the carboxylate, the strong directing influence of the V=O will be absent and the hydroxyl groups could complex in either a 90 or 180° orientation. Scheme 1 depicts a simple equilibrium scheme based on the above arguments. Interestingly enough, inspection of molecular models indicates that sterically the ethyl ester of glycylserine will favour a peptide conformation in which the $—CH_2OH$ is rotated to the position normally occupied by the $—CO_2^-$. The large increase in the formation constant of the −504 ppm product (a factor of 100) is in accord with this, and by implication, the carboxylate and hydroxymethyl groups occupy structurally similar positions in the product complexes as depicted in Scheme 1.

It is not possible to form three trigonal bipyramidal products since the three rings produced in each product are all 5-membered and too small to accommodate the 120° angle required for an equatorially oriented ring. However, trigonal bipyramidal geometry can not be completely ruled out. The 10–12 ppm separation in chemical shift between the two

types of products may represent a difference in coordination geometry rather than the difference in ligand orientation in Scheme 1. This could explain the observation that the rotationally restricted prolylglycine gives a product at −494 ppm (see Table 2). More likely though, this +10 ppm shift compared to glycylglycine is a result of complexing a secondary rather than a primary nitrogen. In support of this, it has been observed that the chemical shift of the complex formed with the tertiary amine, *N*-methyldiethanolamine, is shifted +7 ppm with respect to that formed with diethanolamine (6).

It is evident from this work that complexation of vanadate by serum albumins and other proteins can not occur by random binding at accessible peptide linkages since in the absence of both terminal amino and carboxylate groups no complexation occurs. These requirements are for the simple peptides and can be bypassed if an amino acid segment which is accessible to vanadate contains an appropriately functionalized sidechain as in glycylserine and other peptides (8, 11, 12). Clearly, different sidechain substituents will apply different constraints to complex formation and this is a topic of continuing interest. In the systems investigated here, no evidence for complexation by vanadate oligomers was obtained and this also points out the importance of extending studies similar to this to more complex peptides.

FT-IR transmission spectra of liquids in well-made and firmly held cells with KBr or NaCl windows are usually very reproducible except that their baselines often show unexpected variations. To obtain absolute absorption intensities from these spectra such baseline differences must be corrected. The problem is illustrated with absorbance spectra of the 1036 cm^{-1} band of benzene and the absorption index spectra calculated from them via the National Research Council of Canada program 46. Distinction is made between the experimental absorbance spectrum, the ideal experimental absorbance spectrum, and the absorbance spectrum, and a soundly-based method to correct the baselines is presented. We describe a modification of the NRC program 46 that effects the correction and calculates, on a laboratory computer, the complex refractive indices from a transmission spectrum of a liquid.

The method is applied to 15 transmission spectra of the 1036 cm^{-1} band of benzene. It improves the agreement between the 15 peak absorption index values obtained from these spectra from 4% to 2.5%, and improves the agreement between the baseline absorption index values from 5% to 0.01%, all percentages being of the peak value. A table of the average real and imaginary refractive indices and molar absorption coefficients is given. The average peak absorption index value and the area under the band agree closely with those obtained in 1980, and with earlier values from transmission or ATR measurements. These areas are all distinctly lower than those calculated from early measurements of dispersion. These results form the basis for a possible recommendation to the International Union of Pure and Applied Chemistry for a secondary intensity standard. We encourage others to measure this band to help ascertain that systematic errors do not significantly influence our results.

To summarise our numerical results at 25 ± 1°C and 1.0 cm^{-1} nominal resolution: The average peak absorption index is 0.0710 with a 95% confidence limit of 0.0004, which is within 0.0001 of the less precise value measured in 1980 with a dispersive instrument that was calibrated against a primary intensity standard. The area under the absorption index band between 1095.8 and 912.6 cm^{-1} is 1.358 cm^{-1} with a 95% confidence limit of 0.009 cm^{-1}, and that under the molar conductivity band is 3.69 ± 0.03 km/mol. These areas convert to 15.64 ± 0.1 km/mol and 6.79 ± 0.05 km/mol for the more commonly used measures of integrated absorption, the areas under the Naperian and decadic molar absorption coefficients, respectively.

Key words: infrared, absorption intensity, optical constants, FT-IR spectroscopy, benzene (liquid), intensity standard.

JOHN E. BERTIE, C. DALE KEEFE et R. NORMAN JONES. Can. J. Chem. **69**, 1609 (1991).

Les spectres de transmission IR-TF des liquides dans des cellules bien faites et bien fermées, avec des fenêtres de KBr ou de NaCl, sont généralement très reproductibles, à l'exception du fait que leurs lignes de base donnent souvent lieu à des variations inattendues. Afin d'obtenir des intensités d'absorption absolues à partir de tels spectres, ces différences dans les lignes de base doivent être corrigées. Le problème est illustré par le spectre d'absorption de la bande à 1036 cm^{-1} du benzène et du spectre d'indice d'absorption calculé à partir de ceux-ci par le biais du programme 46 du Conseil National de Recherches du Canada. On fait un distinction entre le spectre d'absorption expérimental, le spectre d'absorption expérimental idéal, et le spectre d'absorption et on présente une méthode bien fondée pour corriger les lignes de base. On décrit un modification du programme 46 du CNRC qui effectue la correction et qui calcule, sur un ordinateur de laboratoire, les indices de réfraction complexes à partir d'un spectre de transmission d'un liquide.

On a appliqué la méthode à 15 spectres de transmission de la bande du benzène à 1036 cm^{-1}. On peut ainsi améliorer de 4% à 2,5% la correspondance entre les valeurs des indices d'absorption des bandes obtenues à partir de ces spectres et on améliore aussi de 5% à 0,01% la correspondance entre les valeurs de l'indice d'absorption de la ligne de base; tous les pourcentages sont relatifs à la valeur maximale. On rapporte une table des valeurs moyennes réelles et imaginaires des indices de réfraction et des coefficients molaires d'absorption. La valeur de l'indice moyen d'absorption du pic ainsi que la surface sous la bande sont en bon accord avec les valeurs obtenues en 1980 et avec des valeurs antérieures obtenues à partir de mesures de transmission ou de ATR. Ces surfaces sont plus basses que celles calculées antérieurement sur la base de mesures de dispersion. Ces résultats forment la base d'une recommandation potentielle à l'Union Internationale de Chimie Pure et Appliquée pour un étalon secondaire d'intensité. On invite les autres chercheurs à mesurer cette bande afin de s'assurer que des erreurs systématiques n'influencent pas nos résultats d'une façon importante.

Pour résumer nos résultats numériques à 25 ± 1°C et 1,0 cm^{-1} résolution nominale, l'indice d'absorption moyen du pic est égal à 0,0710 avec une limite de confiance de 95% de 0,0004; cette valeur à 0,0001 de la valeur moins précise mesurée en 1980 à l'aide d'un instrument de dispersion qui avait été calibré à l'aide d'un étalon primaire d'intensité; la surface sous la bande d'indice d'absorption qui s'étend de 1095,8 à 912,6 cm^{-1} est égale à 1,358 cm^{-1} avec une limite de confiance de 95% de 0,009 cm^{-1} et cette sous la band de conductivité molaire est égale à 3,69 ± 0,03 km/mol. Ces surfaces correspondent à 15,64 ± 0,1 km/mol et 6,79 ± 0,05 km/mol pour les mesures plus couramment utilisées pour l'absorption intégrée, respectivement les surfaces sous les coefficients molaires d'absorption napériens et décadiques.

Mots clès : infrarouge, intensité d'absorption, constantes optiques, spectroscopie IR-TF, benzène (liquide), étalon d'intensité.

Introduction

In work reported in earlier papers in this series about 5 years ago (1–3) we recorded transmission spectra of liquid benzene at 25°C and converted them to imaginary refractive index spectra using methods developed in the 1970s by Jones and coworkers (4–11). Our objective was to determine whether our FT-IR spectrometer, which had not been calibrated for intensity accuracy, gave the same absolute intensitiés at the peaks of the imaginary refractive index bands as had been found by Goplen, Cameron, and Jones (4) using a dispersive infrared spectrometer which was calibrated using the primary standard provided by rotating sectors. For the 1036 cm^{-1} band of benzene, the average of all our measurements gave (1, 2) the maximum value of $k(\tilde{\nu})$, the imaginary refractive index, equal to 0.0718, with a 90% confidence limit of 0.0004, at 1036.0 cm^{-1}, compared with 0.0711 with an estimated error (4, 5) of 0.0014 given by Goplen, Cameron, and Jones. Our measurements were made at 1 cm^{-1} nominal resolution (in fact 0.8 cm^{-1} resolution with the triangular apodisation function that was used (1, 2)). The measurements of Goplen, Cameron, and Jones (4) were made at 0.7 to 1.0 cm^{-1} resolution.

Our earlier calculations (1–3) were done on a mainframe computer using the programs 22, 45, and 46 from the National Research Council of Canada Bulletins "Computer programs for infrared spectrophotometry" (10, 11), and the imaginary refractive indices were obtained from numerical computer output lists. No provision existed at that time for superimposing all of the input absorbance spectra or all of the output $k(\tilde{\nu})$, spectra for visual comparison.

Since then we have connected the Aspect 2000 computer on our Bruker IFS 113V spectrometer to a Dell System 220, a computer which runs Microsoft DOS, and we can transfer our spectra and manipulate them using Spectracalc (Galactic Industries Corporation, Salem, New Hampshire, U.S.A.). Spectracalc allows, *inter al,* many spectra to be loaded and compared on the monitor. Comparison of many experimental spectra, and of the imaginary refractive index spectra calculated from them, revealed that baseline inconsistencies existed in the experimental spectra (1, 2) that were not fully corrected by the NRC program 46 which transformed the experimental spectra to imaginary refractive index spectra.

In the present paper we describe how the Bruker 113V spectrometer is connected to our DOS computer and how the baseline inconsistencies in the absorbance spectra may be removed with confidence. We report here what we now believe to be the best imaginary refractive index spectrum and the best molar absorption coefficient spectrum of the 1036 cm^{-1} band of benzene. The average peak intensity from these spectra agrees to within 0.2% with the less precise result (4) that was estimated (5) via rotating sector calibration to be accurate to better than ±2%.

At the end of the paper, we summarise a procedure and a Fortran computer program that can be conveniently used on a computer running the DOS operating system with a 16 MHz Intel 80286 or 80386 cpu, preferably with a math co-processor, to correct an experimental absorbance or transmission spectrum of a full liquid cell for baseline and reflection effects. Reliable absolute intensity data may be obtained if such corrected spectra are accompanied by an absorbance or transmission spectrum of the same cell empty which shows the interference fringes due to multiple reflections between the windows from which the sample thickness can be calculated. The procedure described is of general use, but will be particularly applied in these laboratories to the establishment of infrared secondary intensity standards, under the IUPAC program described elsewhere (12). The potential use of the 1036 cm^{-1} band of benzene as a secondary standard of infrared intensity is discussed.

The absolute intensity may be described by the imaginary refractive index, $k(\tilde{\nu})$, which is more briefly called the absorption index (13, 14). It may be equally well described by any other equivalent measure of absorption intensity, including the quantity usually preferred by chemists, the molar absorption coefficient, $E_m(\tilde{\nu})$. This is more properly (13, 14) called the molar decadic absorption coefficient, to indicate the use of the decadic logarithm, and is defined as

$$E_m(\tilde{\nu}) = (Cd)^{-1}\{-\log_{10}[I_t(\tilde{\nu})/I_o(\tilde{\nu})]\}$$

where C is the molar concentration and d is the pathlength. This paper uses these quantities as well as the linear (decadic) absorption coefficient, which is defined (13, 14) as

$$K(\tilde{\nu}) = d^{-1}\{-\log_{10}[I_t(\tilde{\nu})/I_o(\tilde{\nu})]\}$$

Method

Data transfer and format

The Aspect 2000 computer of our Bruker 113V FT-IR spectrometer communicates with the Dell system 220 computer through its ports for the high-speed-paper-tape punch and reader. A digital direct memory access interface card (model PDMA–16 from the Metrabyte Corporation, Taunton, MA, U.S.A.) was fitted to the Dell computer to allow it to communicate with the Aspect, and the two computers are linked by a 60 ft long, 40 conductor cable. The data transfer is controlled by the programs ASTOPC for the Dell and the Aspect computers. A data file of 6000 points transfers in about 2 s. This system was developed for the aspect 2000 and Aspect 3000 computers in the Chemistry Department at the University of Alberta by R. E. D. McClung and G. Bigam. The software is available from Professor McClung.

The spectra are transferred as Bruker ".DATA" files in the "ATS" data format, and are imported into Spectracalc as ".SPC" files via a data converter supplied by Galactic Industries Corporation. The programs we use can read and write the Spectracalc ".SPC" files, and can also read and write the ASCII ".Y" files which contain, in sequence, the first wavenumber, the last wavenumber, the number of points, and the ordinate values.

The NRC programs 22 (10), 45 (11), and 46 (11) were modified in this laboratory to provide this facility under the names RNJ22A, RNJ45A, and RNJ46A. The Kramers–Kronig transform routine in NRC program 46 (11) was modified to increase its speed and to incorporate the MacLaurin formula method of handling the singularity that has been described by Ohta and Ishida (15). Details of this modification will be published elsewhere (16).

Absorbance spectra, apparent absorbance, experimental absorbance spectra, and ideal experimental absorbance spectra

The problem in detail

An experimentalist usually obtains an absorbance spectrum of a cell full of liquid by measuring the transmission spectrum of the full cell relative to the empty sample compartment and taking the negative decadic logarithm of the transmittance. In FT-IR spectroscopy, this is usually done by recording separate intensity spectra, which were traditionally called single beam

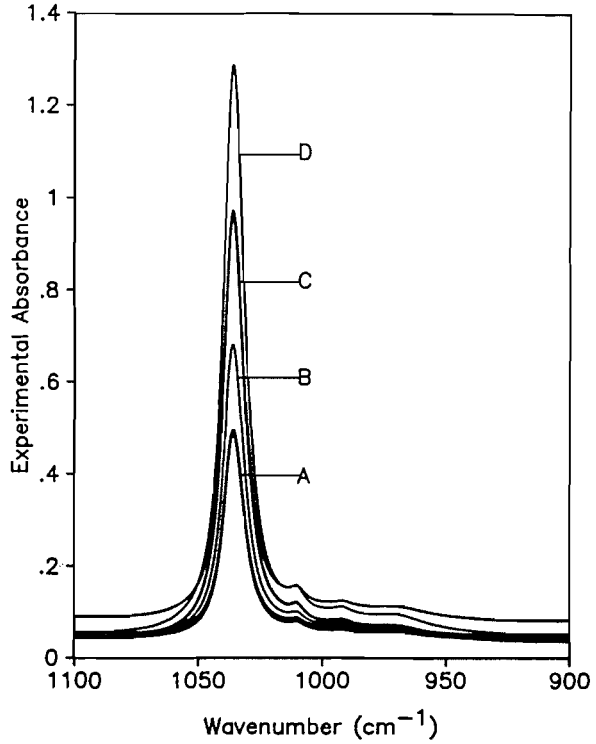

FIG. 1. Experimental absorbance spectra of C_6H_6(l) in cells with KBr or NaCl windows; 25°C and 1 cm^{-1} resolution. The number of spectra in each of the four groups of spectra labelled A to D and the approximate liquid layer thickness for each group are Group A, six spectra, 11 μm; Group B, one spectrum, 15 μm; Group C, seven spectra, 23 μm; Group D, one spectrum, 33 μm.

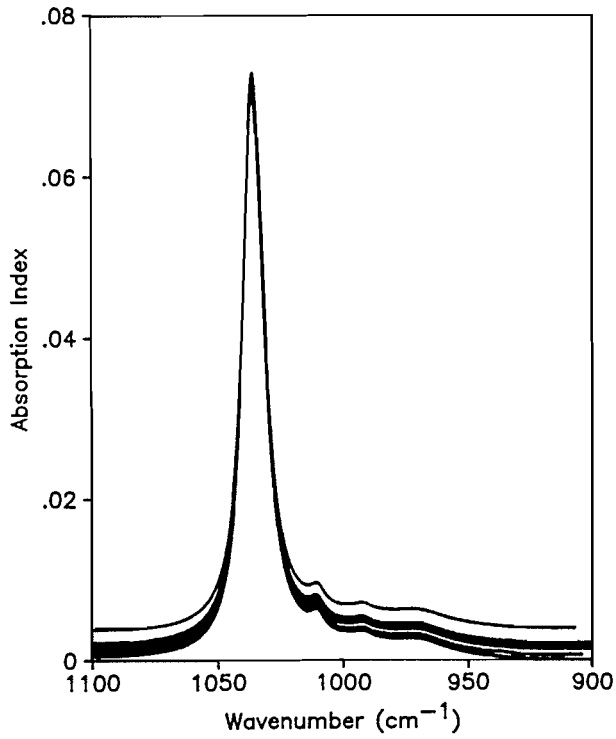

FIG. 2. The 15 absorption index spectra (imaginary refractive index spectra) calculated from the 15 spectra in Fig. 1.

spectra, of the full cell and of the empty sample compartment, ratioing them, and taking the negative logarithm. On a double-beam dispersive instrument, it is done by recording the spectrum of the full cell relative to that of the empty reference beam, and taking the negative logarithm.

It is important to note that neither method yields the absorbance spectrum as it is currently defined by IUPAC (13, 14). IUPAC defines *absorbance* to be a measure of the energy loss due only to absorption by the sample (13, 14). Absorbance does not include the energy loss due to reflection effects at the inner and outer window surfaces, nor does it include background energy loss due to attenuation by the cell or other mechanism. For this reason, we use the term *experimental absorbance spectrum* for the spectrum the experimentalist obtains by either of the above methods. We reserve the term *absorbance spectrum* for the spectrum that has been fully corrected for background effects and reflection losses so that it contains only the loss due to absorption. We use the term *apparent absorbance* for contributions to the experimental absorbance from effects other than absorption.

The *experimental absorbance* is, thus, the sum of the *absorbance* and the *apparent absorbance* due to reflection effects and other sources of energy loss.

Experimental absorbance spectra of liquid benzene and the absorption index, $k(\tilde{\nu})$, spectra calculated from them are shown in Figs. 1 and 2. These spectra are those reported earlier (1, 2), and will be further explored in this paper. Fifteen experimental absorbance spectra recorded in cells of four different path lengths are shown in Fig. 1. The inconsistencies in the baselines are clear, because the curves cross. In particular, two of the curves of set C clearly have very high baselines.

The NRC program 46, which transformed the experimental absorbance spectra to the $k(\tilde{\nu})$ spectra, corrects for reflection effects at the inner and outer window surfaces under certain ideal assumptions (7, 11) about the light beam, including the assumption of 90° incidence. All apparent absorbance due to reflection effects under these ideal assumptions should have been eliminated by the transformation of the experimental absorbance spectra to the $k(\tilde{\nu})$ spectra by the program, as should all effects of the different pathlengths. Thus the 15 spectra in Fig. 2 would be superimposed if the experimental absorbance spectra were recorded under the ideal conditions assumed by the NRC program 46. We define *ideal experimental absorbance spectra* as experimental absorbance spectra recorded under the ideal conditions assumed by NRC program 46.

The absorption index spectra, $k(\tilde{\nu})$ spectra, in Fig. 2 show the magnitude of the error. There is a spread at the peak of 4% and a spread at the baseline of 5%, both percentages of the peak k value. The spread at the baseline must result from differences between the real experimental conditions and the ideal ones assumed by the program, *i.e.* from differences between the experimental absorbance spectra and the ideal experimental absorbance spectra.

Differences in the baseline can arise from a variety of sources. A gross error occurs if the metal of the window holder blocks part of the beam. But even when, as usual, this is avoided, the angle of incidence of the infrared beam is very important, because marked variations are seen unless the cell is held very firmly in the infrared beam, and its position is very reproducible each time it is placed in the beam.

In the experiments we reported earlier (1, 2), the liquid cell was held by a leaf-spring in a massive brass holder which was pinned into holes in the bottom of the sample compartment.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

This ensured that the position of the cell was very reproducible each time it was inserted, much more reproducible than is provided by the cell holders supplied by most manufacturers. This improved the reproducibility of the spectra immensely, but the baseline variations evident in Figs. 1 and 2 resulted in spite of this. We speculated (2) that they may arise from differences in the exact position of the infrared beam in the sample compartment each time the interferometer module is aligned which cause small differences in the angle of incidence.

The solution

Whatever be the source of the baseline variations, the position of the baseline in the ideal experimental absorbance spectrum can be calculated accurately. Thus the spurious, or non-ideal, contribution to the experimental baseline can be calculated and removed from the experimental absorbance spectrum with good accuracy, to yield the ideal experimental absorbance spectrum.

The apparent absorbance due to reflection effects under the ideal conditions of NRC program 46 can be calculated via the logic of program 46. We call this the *ideal apparent absorbance.*

The ideal experimental absorbance is simply the sum of the ideal apparent absorbance and the absorbance of the sample.

The absorbance of the sample in a cell of known pathlength can be calculated for the spectral regions of very weak absorption if the linear absorption coefficient, $K(\tilde{\nu})$, of the sample is known for these regions. The linear absorption coefficient can be found from measurements using long pathlength cells for which the absorbance of the sample in these regions of very weak absorption sufficiently exceeds the apparent absorbance due to non-ideal effects that the latter can be neglected.

The ideal experimental absorbances in the wings of the band, at one wavenumber on each side of the band, are then calculated as the sum of the absorbance of the sample and the ideal apparent absorbance at these wavenumbers.

The differences between the experimental absorbances and the ideal experimental absorbances at these two wavenumbers are the desired corrections to the baseline at these two wavenumbers. The correction to the baseline at other wavenumbers is obtained as a straight line through these two points, yielding a linear correction spectrum.

The correction spectrum is subtracted from the experimental absorbance spectrum to yield the ideal experimental absorbance spectrum.

The ideal experimental absorbance spectrum is then converted to the absorption index spectrum via NRC program 46.

Results

The detailed solution

Calculation of the ideal apparent absorbance

The ideal apparent absorbance is the absorbance due to reflection effects in a transmission cell full of liquid under the ideal assumptions described by Jones and colleagues (7) in eq. [26] of their paper. These assumptions are normal incidence for the central ray, optically flat windows, and uniform intensity distribution across the beam.

It is noteworthy, in passing, that the intensity distribution across the beam is not an important factor. This is shown by using program 46 to calculate the optical constants for different values of the half-cone angle of the convergent light in the focussed beam. The calculated results are the same to better than 0.1% for half-angles of 5.5°, as on our Bruker 113V spectrometer, and for 0°. This could not be so if the spatial intensity distribution across the beam was important.

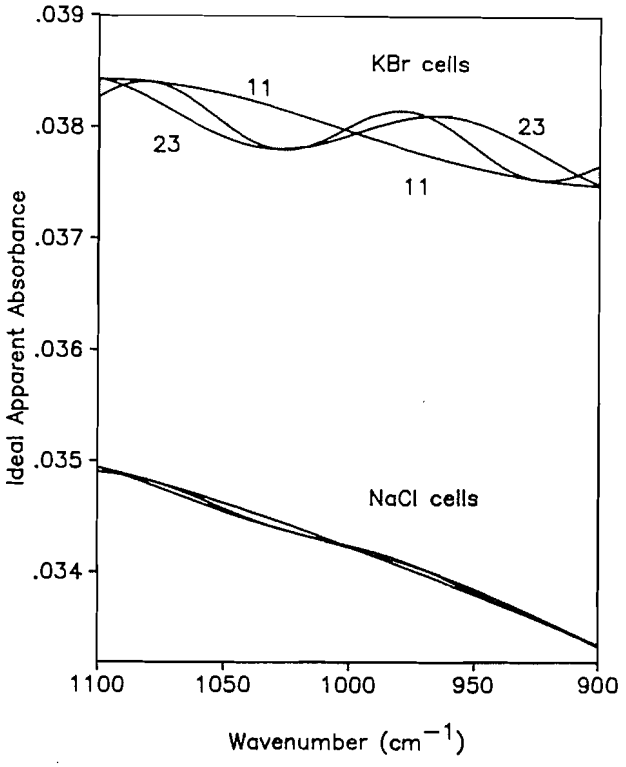

FIG. 3. Ideal apparent absorbance calculated by program Baseline for cells full of benzene. The window materials are shown and the pathlengths 11, 23, and 33 μm were used for each window material.

The Fortran programming to calculate the ideal apparent absorbance is provided as part of NRC program 46, and was extracted by us into a program BASELINE. The programs use the wavenumber-dependent real refractive index of the window material. They assume that the windows are sufficiently thick that interference fringes from within the windows are too closely spaced to be resolved, so that the effect of the multiple reflection can be calculated by neglecting the phases of the multiply reflected rays in each window (7).

The programs correctly calculate the interference fringes caused by multiple reflection within the thin liquid layer. For calculation of the baseline, absorption by the liquid was ignored, by assuming the absorption indices to be zero at all wavenumbers, and the real refractive index of the liquid was assumed constant at its value at the high wavenumber limit of the band. For the 1036 cm^{-1} band of benzene, the value at 1100 cm^{-1} was used, with $n = 1.475$.

Figure 3 shows the spectral baselines, i.e., the ideal apparent absorbance spectra, calculated by program BASELINE for benzene in cells fitted with KBr windows or with NaCl windows. The refractive index discontinuity at the window–benzene interface is so small that the amplitude of the interference fringes is small. It is clear that the baseline one would obtain by neglecting the fringes decreases in apparent absorbance from 1100 to 900 cm^{-1}. This is because the refractive indices of KBr (17, 18) and NaCl (19, 20) are larger at 1100 cm^{-1} than at 900 cm^{-1}, as is shown in Table 1. Table 1 also contains the numerical ideal apparent absorbances at 1100 and

TABLE 1. Infrared refractive index and apparent absorbance due to reflection effects for KBr and NaCl windows

	KBr windows		NaCl windows	
Wavenumber (cm^{-1})	1100	900	1100	900
Refractive index of windows				
	1.5282	1.5239	1.5006	1.4870
Apparent absorbance for pathlength				
(*a*) From BASELINE				
11 μm	0.0384	0.0375	0.0349	0.0333
23 μm	0.0384	0.0375	0.0349	0.0333
33 μm	0.0383	0.0377	0.0349	0.0333
(*b*) From eq. [1]				
Any pathlength	0.0379	0.0374	0.0348	0.0333

900 cm^{-1} for the KBr and NaCl windows and cells 11, 23, and 33 μm thick.

Alternatively this information can be obtained, with slightly lower accuracy, without invoking program BASELINE. To an accuracy of better than 0.0005 the ideal apparent absorbances calculated at 1100 and 900 cm^{-1} equal those expected from a single window in air. If the interference fringes are averaged by summing over the multiple reflections, the formulae for the apparent transmittance, $T = I_t/I_o$, at normal incidence which result from this treatment are (eq. [12] in ref. 7)

$$[1] \quad T = (1 - R)/(1 + R)$$

where $R = (n - 1)^2/(n + 1)^2$, therefore $T = 2n/(n^2 + 1)$. The ideal apparent absorbance due to these reflection losses is $-\log_{10}\{T\}$.

The values calculated from these equations are independent of the cell thickness. Equation [1] yields the ideal apparent absorbances shown at the bottom of Table 1. The agreement between these and the more accurate values given by program BASELINE ranges from 0.0001 to 0.0005.

The linear absorption coefficient of the liquid in the wings of the band

The true absorbance of the liquid at the extremes of a band is found from spectra of a liquid layer sufficiently thick that neglect of possible baseline inconsistencies has an acceptably small effect.

Figure 4 shows experimental absorbance spectra of benzene in nominally 500 μm thick KBr cells. The top spectrum, for example, was recorded in a 506.7 μm cell and shows experimental absorbances at 1095.8 and 912.2 cm^{-1} of 0.3430 and 0.3215. From program BASELINE, the ideal apparent absorbances are 0.0383 and 0.0376 at 1095.8 and 912.2 cm^{-1}. With the neglect of possible baseline inconsistencies, the difference between these two quantities at each wavenumber gives the absorbances of benzene as 0.3047 and 0.2839, and the *absorbances per cm path,* i.e., the linear absorption coefficients, as 6.01 cm^{-1} and 5.60 cm^{-1}. In fact, the average of 11 such spectra in 500 and 780 μm cells gave the linear absorption coefficients at 1095.8 and 912.2 cm^{-1} equal to 6.01 cm^{-1} and 5.57 cm^{-1} with 95% confidence limits of 0.09 cm^{-1}.

Ideal experimental absorbance, absorbance, and absorption index spectra

Table 2 summarises the calculation of the ideal experimental absorbances at 1095.8 and 912.2 cm^{-1} of a KBr cell full of 23 μm thickness of liquid benzene. The absorbance at 1095.8 cm^{-1} of a benzene layer 23.0 μm thick is $(6.01 \pm 0.09) \times 10^{-4}$ $\mu m^{-1} \times 23.0$ μm = 0.0138 ± 0.0002. The ideal apparent absorbance at 1095.8 cm^{-1} of a KBr cell filled with 23 μm thickness of benzene is 0.0384 ± 0.0001 from program BASELINE. The ideal experimental absorbance at 1095.8 cm^{-1} of this cell is the sum of these two numbers, 0.0522 ± 0.0003. At 912.2 cm^{-1}, the corresponding numbers are $(5.57 \pm 0.09) \times 10^{-4}$ $\mu m^{-1} \times 23.0$ μm = 0.0128 ± 0.0002, 0.0376 ± 0.0001 from BASELINE, and 0.0504 ± 0.0003.

Thus the ideal experimental absorbance at the extreme of the band can be calculated with a precision of about 0.6%.

The differences between these ideal experimental absorbances and the experimental absorbances must be removed before NRC program 46 is used.

To correct the experimental absorbance spectra to ideal experimental absorbance spectra, a straight line was interpolated between the differences found at 1095.8 and 912.2 cm^{-1} and was subtracted from the experimental absorbance spectrum. Program BASECORR performed this correction. The 15 ideal experimental absorbance spectra which resulted from this procedure are shown in Fig. 5, which should be compared with Fig. 1 to see the effect of the corrections.

The ideal experimental absorbance spectra were processed by our program RNJ46A to convert them to refractive index spectra by an iterative procedure (11). Once the absorption index spectrum is obtained, the true absorbance spectrum can be calculated from it by

$$\mathrm{Abs}(\tilde{\nu}) = \frac{4\pi\tilde{\nu}k(\tilde{\nu})d}{2.303}$$

Figure 6 shows for one sample the experimental absorbance spectrum, the ideal experimental absorbance spectrum, and the absorbance spectrum of benzene, the latter showing only energy loss due to absorption if our ideal assumptions are correct.

The absorption index spectra are shown in Fig. 7. They should be compared with those in Fig. 2 to see the marked improvement provided by this correction procedure. The spread of values at the peak is 2.5% of the peak value in Fig. 7 and 4% of the peak value in Fig. 2. At the edges of the band, the spread of values is 0.01% of the peak value in Fig. 7 and 5% in Fig. 2.

The average of the 15 absorption index spectra of Fig. 7 is presented in Fig. 8 with the real refractive index, $n(\tilde{\nu})$, spectrum calculated from it via Kramers–Kronig transformation and the value 1.475 for n at 1100 cm^{-1}. This value of n at 1100 cm^{-1} was found by the Kramers–Kronig transform of $k(\tilde{\nu})$ between 2131 and 804 cm^{-1}, using the value 1.474 for n at 2131 cm^{-1} which was taken from ref. 4. The spread of the 15 real refractive index spectra calculated from the absorption index spectra in Fig. 7 was ±0.045%, so the accuracy of the real refractive index values is largely determined by the value $n(1100\ cm^{-1}) = 1.475$.

Figure 8 also includes the molar absorption coefficient spectrum calculated from the absorption index spectrum. It is indistinguishable from the absorption index spectrum on the scale shown, and is defined by the right-hand ordinate scale.

Infrared intensities

The values of the real refractive indices, the absorption indices, and the molar absorption coefficients are tabulated in

[c]Ideal experimental absorbance = ideal apparent absorbance + absorbance.

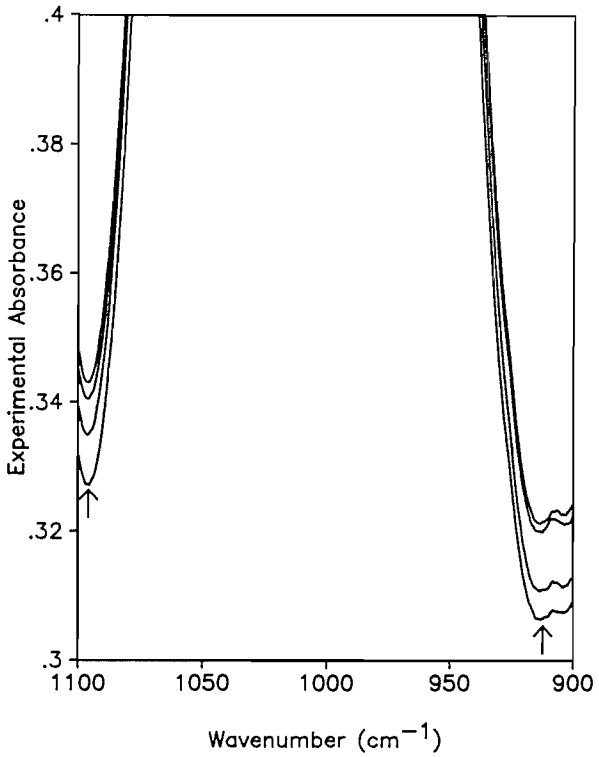

FIG. 4. Experimental absorbance spectra of C_6H_6(l) in KBr cells; 25°C and 1 cm^{-1} resolution. Pathlengths from top to bottom: 506.7, 506.9, 495.8, and 480.1 μm, all ±1 to 2 μm. The arrows are located at 1095.8 and 912.2 cm^{-1}.

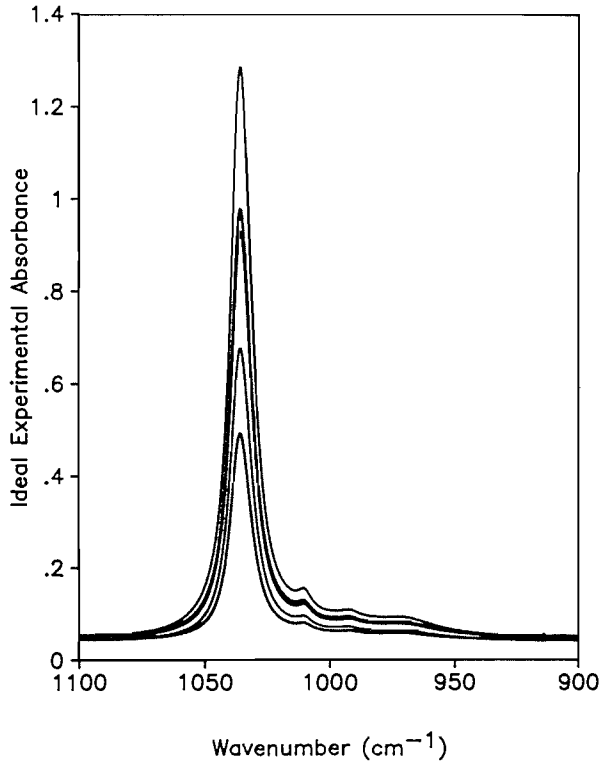

FIG. 5. The 15 ideal experimental absorbance spectra calculated from the experimental absorbance spectra in Fig. 1.

Table 3. The wavenumber intervals are 0.964 cm^{-1} rather than the 0.482 cm^{-1} intervals of the original spectrum to save space. The tabulated absorption index spectrum can be interpolated via a program that Fourier transforms, zero-fills, and inverse-Fourier transforms, such as INTERPOL in Spectracalc, to reproduce the original $k(\tilde{\nu})$ values to ≤0.00004. The instrumental resolution was 1 cm^{-1} and the temperature was 25°C.

The average absorption index value at the peak of the band is 0.0710 with a 95% confidence limit of 0.0003. Two points should be noted. First, this value is clearly to be preferred over our earlier (1, 3) value, 0.0718 with a 90% confidence limit of 0.0004, because the latter clearly includes baseline errors. Second, this result agrees to 0.0001 with the value given by Goplen, Cameron, and Jones (4) which was calibrated against a primary standard but is less precise. The average peak value of the molar absorption coefficient is 35.9 ± 0.2 L per mole-cm.

The area under the absorption index band between 1095.8 and 912.6 cm^{-1} is 1.358 ± 0.009 cm^{-1} where 0.009 is the 95% confidence limit. The area under the molar absorption coefficient band is 6.79 ± 0.05 km/mol. It is sometimes preferred to measure the area above a baseline through the data rather than above zero ordinate. We took a linear baseline through the average of 5 ordinates centered on 1095.8 cm^{-1} and the average of 5 ordinates centered on 912.6 cm^{-1}. The area between 1095.8 and 912.6 cm^{-1} above this baseline is 1.163 cm^{-1} for the absorption index and 5.84 km/mol for the molar absorption coefficient. The 6.79 ± 0.05 km/mol area under the molar absorption coefficient band will be used in the program IRYTRUE (12) as the secondary absolute intensity reference to facilitate the calibration of liquid cells for absolute intensities.

The molar conductivity spectrum is $V_m\tilde{\nu}\epsilon''(\tilde{\nu}) = 2V_m\tilde{\nu}n(\tilde{\nu})k(\tilde{\nu})$ where V_m is the molar volume and ϵ'' is the imaginary dielectric constant, also called the dielectric loss. The molar conductivity is used to calculate molecular properties, because the area under a molar conductivity band equals

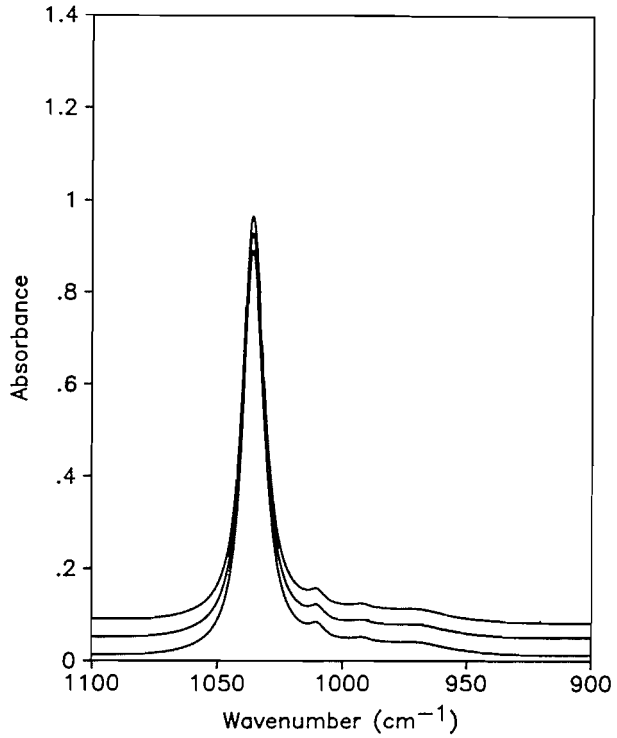

FIG. 6. From top to bottom, the experimental absorbance spectrum, the ideal experimental absorbance spectrum, and the absorbance spectrum of one sample of benzene.

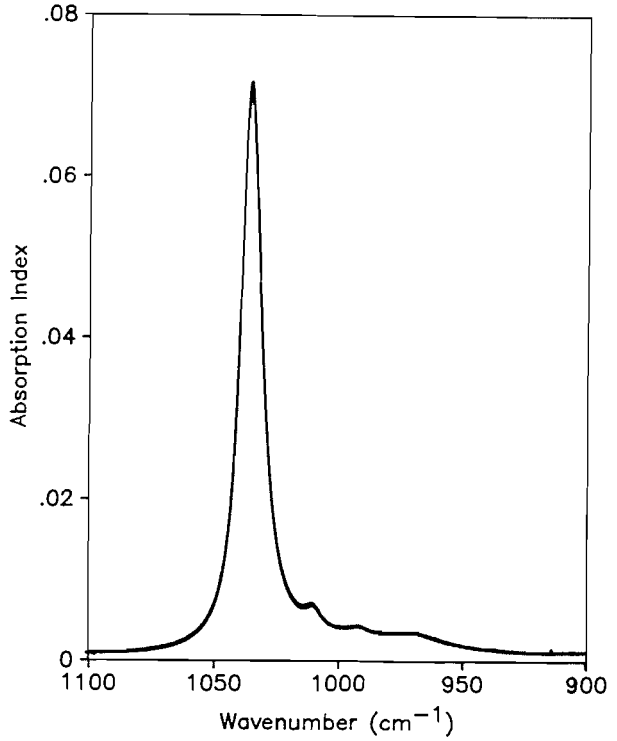

FIG. 7. The 15 absorption index (imaginary refractive index) spectra of benzene calculated from the spectra in Fig. 5.

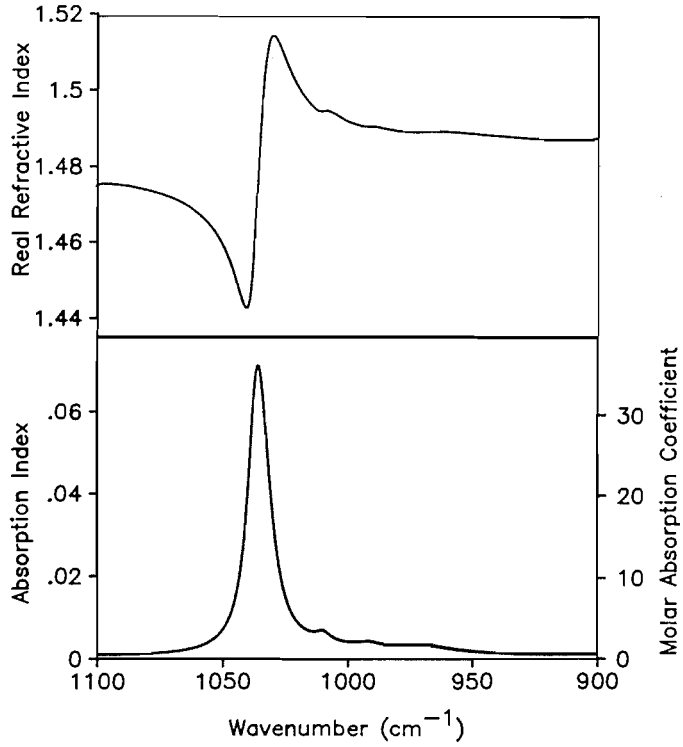

FIG. 8. Lower box, the average of the 15 absorption index spectra in Fig. 7 and, upper, the real refractive index spectrum calculated from it and $n(1100\ \text{cm}^{-1}) = 1.475$. The lower box contains the absorption index band defined by the left ordinate scale and also the molar absorption coefficient band defined by the right ordinate scale. The two curves are indistinguishable on this scale.

$(N_a/6c^2)\ (\partial\mu/\partial Q)_{eff}^2$, which equals $\{(0.1487)^{-1}\ (\partial\mu/\partial Q)_{eff}^2\}$ if $(\partial\mu/\partial Q)_{eff}^2$ is in (Debye/Å)^2/amu and the area is in km/mol. Here N_a and c are Avogadro's number and the velocity of light, respectively, and $(\partial\mu/\partial Q)_{eff}$ is the effective dipole moment derivative for a benzene molecule in the liquid. The area between 1095.8 and 912.6 cm^{-1} under the molar conductivity band is 3.69 km/mol above the zero ordinate, or 3.17 km/mol above the baseline described above. It is not clear which of these two areas should be used, because it is not clear to what extent the fundamental vibration contributes intensity to the baseline.

The 1036 cm^{-1} band of liquid benzene as a potential infrared secondary intensity standard

In a paper to be published elsewhere (12) we describe a project, set up under the auspices of the International Union of Pure and and Applied Chemistry, for the establishment of a set of calibration standards for quantitative infrared intensities. It is particularly desired that the standards be useful to the analytical community to facilitate quantitative infrared analysis of liquids. The 1036 cm^{-1} band of benzene is one of the bands to be included in this project, and the procedure described above will also be used to develop and evaluate the standard intensities.

The 1036 cm^{-1} band of benzene has been studied by many workers (1, 2, 4, 21–27) between 1960 and 1980 by different methods. Their values for the peak absorption index range from 0.069 to 0.072. The average of these values is 0.0705 ± 0.0015, so it seems clear that the absolute peak intensity of this

band is known to at least ±2%. In fact the most recent values are probably the best, partly because one value was measured against a primary standard (4), and also because of the great improvements in instrumentation over the past 15 years. Thus we believe the current value, 0.0710 with a 95% confidence limit of 0.0003, is the best available for 25°C and a nominal resolution in the range 0.8–1.0 cm^{-1}.

The area under the average molar absorption coefficient band between 1095.8 and 912.6 cm^{-1} is 6.79 ± 0.05 km/mol. When multiplied by 2.303 this converts to 15.64 ± 0.10 km/mol for A_j, the Napierian-logarithmic equivalent measure of the integrated absorption. Previous workers have found similar values, namely 15.34 (24), 15.4 ± 1.1 (23), and 15.82 (26) km/mol between 1080 and 920 cm^{-1}) (we obtain 15.3 between 1080 and 920 cm^{-1}) and 15 (22) between 1080 and 1000 cm^{-1} (we obtain 13.0 between 1080 and 1000 cm^{-1}). Other workers (28, 29) have deduced the integrated intensity from measurements of the real refractive index, and have all found values nearer to 19 km/mol. Again, we believe the value obtained in this work is the best currently available for 25°C, although it should be noted that our values of the real refractive index are about 1.5% higher than the literature (4, 21–27, 29) values.

To help assess the reliability of peak heights and areas recommended to IUPAC as secondary intensity standards, we seek the assistance of the spectroscopic community. We plan to explore the intensities of benzene in the regions 3820 – 3525, 3320 – 2915, 2260 – 2125, 1905 – 1720, 1565 – 1335, 1100 – 905, and 915 – 800 cm^{-1}. We seek spectra of cells full of benzene recorded in other laboratories with peak experimental absorbances between 0.5 and 1.5 in these wavenumber regions, together with spectra of the cell exactly as it was used for the benzene but recorded either before filling or after removing all of the benzene. The reference for these spectra should be the empty sample compartment, not the empty cell. A nominal resolution 1 cm^{-1} is preferred, but 2 cm^{-1} is useful. We will process such spectra with the program RNJ46A in order to test the reliability of our results.

It should be noted that the thermal expansion of benzene (30) is sufficient to change the value of the absorption index by 0.0004 per 5°C change in temperature, even if no change in molecular transition moment occurs, because the molar volume changes from 88.86 mL/mol at 20°C to 89.41 mL/mol at 25°C. It is important, therefore, to maintain the temperature constant to about ±1°C, and preferably at 25°C, in order to obtain results to test the values reported in this paper.

Computer programs

Until this work was finished the only changes to the NRC program 46 that were incorporated in program RNJ46A were to allow the input and output to be in Spectracalc format or ASCII ".Y" format, and to use Bertie and Zhang's (16) much faster modification of the original Kramers–Kronig transform subroutine. Thus the following three steps were necessary to convert an experimental absorbance spectrum to an ideal experimental absorbance spectrum and then to the real and imaginary refractive index spectra. (1) Select a reference wavenumber on each side of the band and determine the ideal experimental absorbance at these reference wavenumbers using the cell thickness, the linear absorption coefficient obtained from thick cell measurements, and the ideal apparent absorbance as calculated by BASELINE. (2) Correct the experimental absorbance spectrum to the ideal experimental absorbance spectrum with BASECORR, using the ideal experimental absorbances calculated in (1) at the two reference wavenumbers. (3) Use this ideal experimental absorbance spectrum in RNJ46A to calculate the $k(\tilde{\nu})$and $n(\tilde{\nu})$ spectra.

However, since the logic of BASELINE is contained in NRC program 46, the above procedure can be done automatically by the program if the baseline correction procedure (i.e., the logic of BASECORR) is added to it and if the user supplies the linear absorption coefficient at the two reference wavenumbers.

Our latest version of NRC program 46 (RNJ46A, version 04/91) incorporates these features. Further, to reduce the execution time, the complex variables and complex arithmetic operations contained in the original NRC program 46 have been replaced by real variables and real arithmetic. Further, Ohta and Ishida's (31) correction to the logic has been included, although it has negligible effect for the 1036 cm^{-1} band of benzene.

These modifications to program RNJ46A were made for compilation under Microsoft Fortran 5.0 running under Microsoft DOS, Version 3.3 or 4.1, and execution on moderately fast laboratory computers such as 16 to 20 MHz 286- or 386-based computers, preferably with a math co-processor. For a file of 416 data points, the current version of RNJ46A requires approximately 1 min to compute converged optical constants.

The program RNJ46A is available from J.E.B. on request.

This paper is dedicated to Dr. Richard Norman Jones

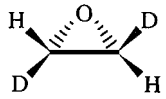
TERESA B. FREEDMAN, KEVIN M. SPENCER, N. RAGUNATHAN, LAURENCE A. NAFIE, JEFFREY A. MOORE, and JOHN M. SCHWAB. Can. J. Chem. **69**, 1619 (1991).

Vibrational circular dichroism (VCD) spectra of an exceptionally simple chiral three-membered ring molecule, (*S*,*S*)-[2,3-$^2H_2$]oxirane, have been obtained for samples in the gas phase and in C_2Cl_4 and CS_2 solution. The VCD band contours for the gas phase samples of this molecule with C_2 symmetry follow those of the absorption spectra, with the modes of *A* symmetry species giving rise to bands with two sharp Q-branch maxima on either side of a distinct minimum, and the modes of *B* symmetry species giving rise to bands with a strong central Q-branch. The signs and relative intensities of the VCD bands can be understood in terms of chiral perturbation by the deuterium substitution of the vibrational modes of the parent oxirane molecule, which mixes modes of A_1 and A_2 symmetry, and modes of B_1 and B_2 symmetry, thus introducing angular charge oscillation about the direction of linear charge oscillation.

Key words: vibrational circular dichroism, oxirane, chiral perturbation.

TERESA B. FREEDMAN, KEVIN M. SPENCER, N. RAGUNATHAN, LAURENCE A. NAFIE, JEFFREY A. MOORE et JOHN M. SCHWAB. Can. J. Chem. **69**, 1619 (1991).

Opérant en phase gazuese ainsi qu'en solutions dans le C_2Cl_4 ou le CS_2, on a déterminé les spectres de dichroïsme circulaire vibrationnel (DCV) d'une molécule cyclique chirale exceptionnellement simple, le (*S*,*S*)-[2,3-$^2H_2$]oxirane. Les bandes de contour du DCV des échantillons gazeux de cette molécule de symétrie C_2 sont semblables à celles du spectre d'absorption; les modes des espèces de symétrie *A* donnent lieu aux bandes comportant deux maxima aigus de la branche Q de chaque côté d'un minimum distinct alors que les espèces de symétrie *B* donnent lieu aux bandes qui possèdent une branche Q centrale forte. On peut comprendre les signes et les intensités relatives des bandes du DCV en fonction d'une perturbation chirale, causée par une substitution par du deutérium des modes vibrationnels de la molécule oxirane fondamentale, qui provoque un mélange des modes de symétrie A_1 et A_2 avec les modes de symétrie B_1 et B_2 et qui introduit une oscillation angulaire de charge autour de la direction de l'oscillation linéaire de charge.



Mots clés : dichroïsme circulaire vibrational, oxirane, perturbation chirale.

[Traduit par la rédaction]

Introduction

The evaluation of theoretical formulations (1–8) and calculational approaches (9–16) for determining vibrational circular dichroism (VCD) intensities (17–21) requires small rigid molecules for which testing of methodological variables is practical. Simple three-membered ring molecules that are chiral due to isotopic substitution are ideal for this purpose. Calculations on such species (9–15, 22) have outpaced the generation of experimental data (23–26) with which theoretical results can be compared and evaluated. In addition, these simple chiral molecules provide the opportunity to investigate mechanisms for generating VCD intensity that can be applied to the interpretation of VCD spectra of complex molecules, in order to obtain information on solution conformations when calculations are not practical or desirable.

The smallest chiral molecule in this category, (*S*,*S*)-[2,3-$^2H_2$]-oxirane, **1**, has been the focus of recent theoretical investigations (12, 14, 15) using three different approaches to calculating VCD intensities. We previously reported the CH- and CD-stretching VCD spectra of **1** in CCl_4 solution (23). Mid-infrared spectra were not possible at the time of that study due to sample impurities. With the availability of higher purity samples of the *trans*-[$^2H_2$]oxirane enantiomers, we have undertaken a more extensive investigation of the VCD spectra of gas-phase (25) solution samples, in order to provide experimental data for comparison to the calculational approaches, and to gain a better understanding of the mechanisms for generating the VCD features.

(*S*,*S*)-[2,3-$^2H_2$]oxirane

1

Experimental

The (*S*,*S*) and (*R*,*R*) antipodes of [2,3-$^2H_2$]oxirane were synthesized by a modification of the published procedure (27). The benzene contaminant that had prevented observation of the mid-infrared bands in our earlier study of solution-phase samples (23) was largely eliminated by decreasing (to 1.1 equivalents) the amount of tetraethylammonium fluoride used in the desilylation of labeled (trimethylsilyl)-oxirane. The oxirane thus generated was trapped in a collection vessel cooled to −196°C. The enantiomeric excess values of both labeled oxirane enantiomers were estimated at 94% by 500 MHz ^1H NMR analysis of the Mosher ester derivatives (28) of the antipodal 3-(triphenylsilyl)[2,3-$^2H_2$]oxiranemethanol precursors. Small amounts (<5%) of benzene and diethyl ether impurities were revealed by the infrared absorption spectra of the oxirane samples.

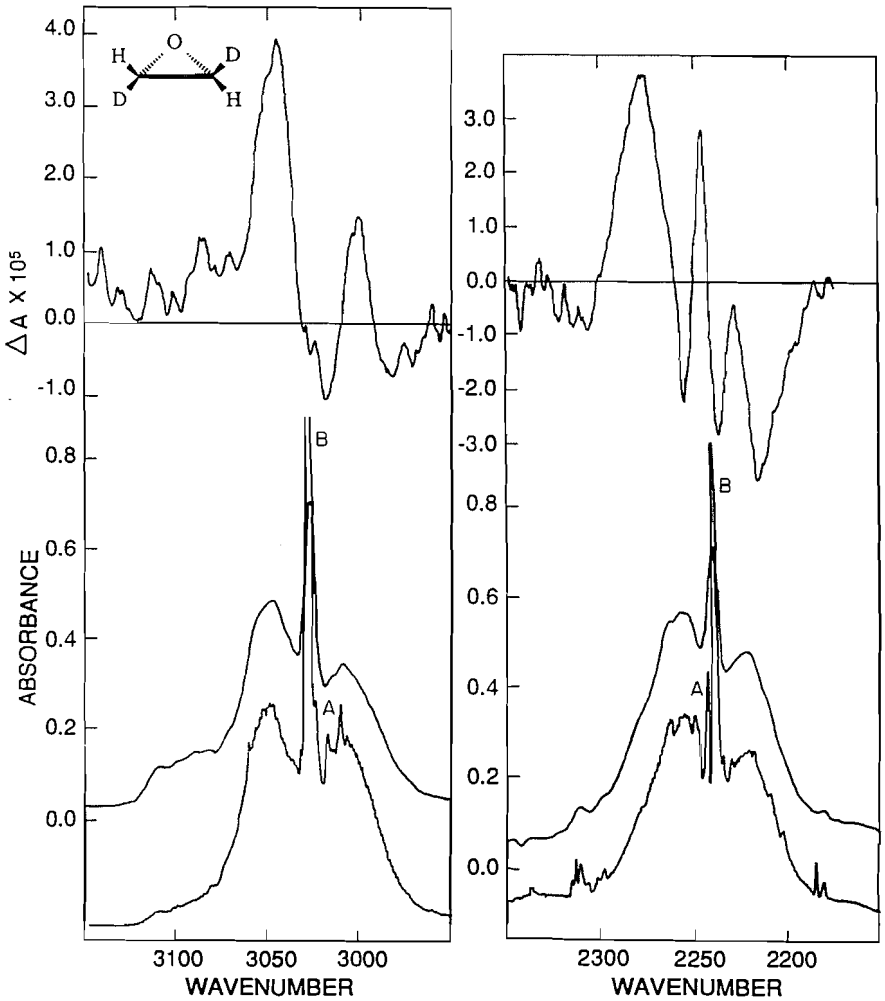

FIG. 1. Gas-phase absorption (middle traces) and VCD (upper traces) spectra of (*S,S*)-[2,3-$^2H_2$]oxirane in a 25.4-mL volume, 5-cm path length cell, in the (A) CH-stretching region, 7.2 cm^{-1} resolution, 8-mg sample and (B) CD-stretching region, 5.4 cm^{-1} resolution, 13-mg sample. Lower traces in both regions show spectra at 1 cm^{-1} resolution for a different sample (ordinate scale not displayed).

Infrared absorption and VCD spectra were obtained at Syracuse University for gas-phase samples in a 5-cm path length, 25.4-mL volume cell equipped with KBr windows and a sidearm for condensing the sample. For the solution-phase samples, a sealed cylindrical Pyrex cell (25 mm diameter and 8 mm path length) was constructed with BaF_2 windows, a sidearm for condensing the sample and solvent, and a vacuum line port. The amount of sample (or solvent) introduced into either cell was accurately determined by condensation from a known volume on a vacuum line equipped with a 1000-Torr High Accuracy Baratron gauge (MKS Instruments, Andover, MA) for measuring pressure (1 Torr = 133.3 Pa).

The CH- and CD-stretching VCD spectra for the gas-phase samples were recorded on a dispersive VCD instrument previously described (29), with resolutions of 7.2 cm^{-1} at 3000 cm^{-1} and 5.4 cm^{-1} at 2100 cm^{-1}. Prior to obtaining spectra of the solution-phase samples, this instrument was interfaced to an IBM XT computer equipped with a Data Translation 2811 data acquisition board and Spectra Calc software (Galactic Industries, Salem, NH), for data acquisition and manipulation. For the 1500–750 cm^{-1} region, VCD spectra were recorded on a modified Nicolet 7199FITIR spectrometer (30) at 4 cm^{-1} resolution with 12 288 AC and 800 DC scans (2.5 h per enantiomer) for the solution-phase sample. For the 4 cm^{-1} resolution gas-phase spectrum in this region, four sets of data at 4 cm^{-1} resolution, each consisting of 12 288 AC and 800 DC scans for each enantiomer, were collected on successive days and averaged. Absorption spectra were recorded on Nicolet 7199 or Bomem DA3 FTIR spectrometers. Sample sizes, ranging from 8 to 40 mg, were selected to maintain maximum absorbances below 0.8 in the region of interest. The final VCD spectra were obtained as one-half the difference between the spectra of the (*S,S*) and (*R,R*) enantiomers in order to remove baseline artifacts. Rotational and dipole strengths were determined by obtaining peak areas with the Spectra Calc curve-fitting software.

Results

Absorption and VCD spectra in the CH- and CD-stretching regions are shown in Fig. 1 for the gas-phase sample of (*S,S*)-[2,3-$^2H_2$]oxirane. The middle and upper traces show the absorption and corresponding VCD spectra at the maximum resolution obtainable with good signal quality on the dispersive instrument, 7.2 cm^{-1} in the CH-stretching region and 5.4 cm^{-1} in the CD-stretching region. The lower traces show the absorption spectra at 1 cm^{-1} resolution obtained for a different sample. The absorption intensity observed near 3100 cm^{-1} and extra intensity near 3050 cm^{-1} in the center trace of Fig. 1, which is absent in the lower trace, is due to some benzene contaminant in the sample of the (*R,R*)-[2,3-$^2H_2$]oxirane antipode used to obtain the absorption spectrum. The achiral benzene does not interfere with the VCD spectrum. The corresponding spectra for the sample in tetrachloroethylene (C_2Cl_4) solution with 8 cm^{-1} resolution are shown in Fig. 2. The CH-stretching spectra for a

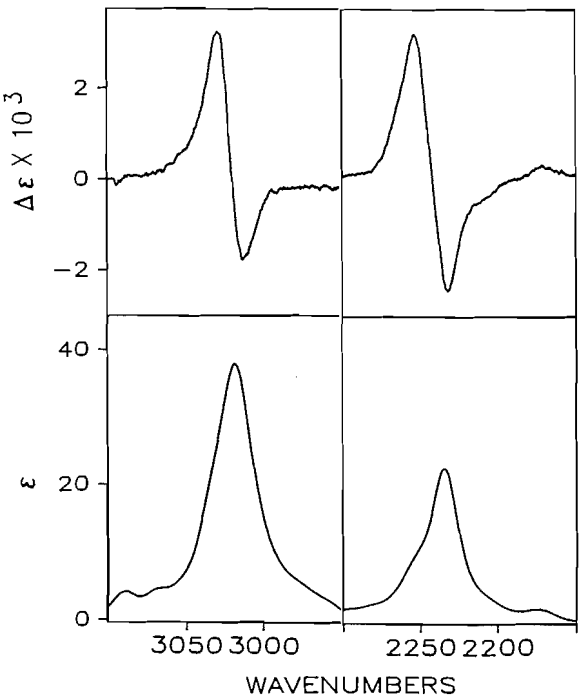

FIG. 2. CH- and CD-stretching absorption and VCD spectra of (*S,S*)-[2,3-$^2H_2$]oxirane 0.019 M in C_2Cl_4 solution, 0.8-cm path length, 8 cm^{-1} resolution.

sample at approximately the same concentration in carbon disulfide (CS_2) solution were nearly identical in anisotropy ratio to those in C_2Cl_4.

Spectra at 4 cm^{-1} resolution in the 700–1500 cm^{-1} region for a gas-phase sample (20 mg) are shown in Fig. 3. We previously presented gas-phase absorption and VCD spectra in the 1000–1500 cm^{-1} region for a larger sample (40 mg), with correspondingly improved signal-to-noise ratio for that region (25). The spectra shown in Fig. 3 include several bands below 1000 cm^{-1}, which could not be measured at the higher pressure. Mid-infrared spectra obtained at 1 cm^{-1} resolution displayed the expected sharper and more intense Q-branches, but did not exhibit any additional features (31). The lowest frequency band, observed at 673 cm^{-1} in the gas-phase absorption spectrum, is below the low frequency limit of our VCD instrument. The positive VCD signals for the 885 and 817 cm^{-1} modes occur at the Q-branch frequencies and are above the noise level, whereas any VCD for the 754 cm^{-1} could not be measured with our present detector. The spectra for a sample 0.052 M in CS_2 solution are presented in Fig. 4 for the 900–1350 cm^{-1} region; bands outside this region were obscured by interfering, intense solvent absorbance. The absorption feature at 1034 cm^{-1} and the shoulder at 1117 cm^{-1} are due to small amounts of benzene and diethyl ether impurities, respectively; these achiral impurities did not interfere with the VCD spectra.

The frequencies, absorption intensities, and VCD intensities are compiled in Table 1. The intensities are presented as dipole and rotational strengths, which were determined from the integrated band intensities.

Assignments

For gas-phase vibrational spectra, the rotational band contours provide information on the symmetry species of the vibrational modes (32). (*S,S*)-[2,3-$^2H_2$]Oxirane is an asymmetric top molecule in which the C_2 axis coincides with the intermediate moment of inertia. The smallest moment of inertia is approximately perpendicular to the plane of the three-membered ring, and the largest moment of inertia lies perpendicular to the C_2 axis approximately in the ring plane. The value of $\rho = B/A$ (where A and B are the rotational constants about the axes of the smallest and intermediate moments of inertia, respectively) is ~0.9. Calculations of band contours with these parameters (33) show that, under medium dispersion, the modes of A symmetry (dipole moment change along the C_2 axis) should have "type B" band contours, with two sharp Q maxima on either side of a distinct minimum, and weaker broad P- and R-branches. Modes of B symmetry (dipole moment change in the plane perpendicular to the C_2 axis) will have "type A" or "type C" band contours; for ρ near its limiting value of 1, "type A" and "type C" bands will both have a strong central Q-branch and weaker broad P- and R-branch maxima on either side. With the exception of some of the strongly overlapping bands, the absorption spectra of (*S,S*)-[2,3-$^2H_2$]oxirane display these types of band contours, and identical band contours are observed in the VCD spectra. The symmetry species of the normal modes listed in Table 1 were readily determined from the band contours.

To obtain additional information on the nature of the normal modes, a normal coordinate calculation was carried out in cartesian coordinates. The scaled *ab initio* force field (4-31G basis set) of Lowe *et al.* (34) and the experimental geometry of Hirose (35), both determined for the parent oxirane molecule, were employed. This force field yields normal mode frequencies quite close to those obtained with a 6-31G(ext) basis set (12); the latter force field is not yet available in the literature. The calculated cartesian displacement derivatives were then used to find distorted geometries at the two extremes of the vibrational cycle for each mode. These two geometries were overlaid, viewed from various angles, and plotted with ChemCad (C-Graph Software, Austin, TX). The 15 normal modes are shown in Figs. 5 and 6 as stereoprojections in a plane perpendicular to the C_2 axis.

The fundamental vibrational normal modes of the parent oxirane molecule can be described in terms of the 15 symmetry coordinates shown in Fig. 7. The symmetry species for this C_{2v} molecule can be characterized by the translation T_α along the α axis ($\alpha = x$, y, or z) and (or) rotation R_α about the α axis that transforms as that species. Oxirane has five modes of A_1 symmetry (T_z), three modes of A_2 symmetry (R_z), four modes of B_1 symmetry (T_x,R_y), and three modes of B_2 symmetry (T_y,R_x). Vibrational circular dichroism intensity is proportional to the rotational strength, $R = (\boldsymbol{\mu})_{01} \cdot (\boldsymbol{m})_{10}$, the scalar product of the electric dipole transition moment $\boldsymbol{\mu}$, which has the same transformation properties as a translation, and the magnetic dipole transition moment $\boldsymbol{m}$, which transforms like a rotation. In Fig. 7, the arrows designate the direction of displacement of the hydrogen or ring nuclei for one phase of the mode. We make the approximation that the nuclear displacement produces a local electric dipole transition moment, which we position along the hydrogen or oxygen displacement; electric or magnetic dipole transition moment contributions from charge flow away from the local nuclear displacement are ignored. For each coordinate, the $\oplus$ or $\ominus$ for T_α indicates the direction of the electric dipole transition moment, $\boldsymbol{\mu} = \boldsymbol{\mu}_\alpha$, along the α axis for the phase of nuclear displacement shown. In determining the electric dipole transition moment directions, we use the results of *ab initio* molecular orbital calculations, which show that for an aliphatic CH contraction, positive $\boldsymbol{\mu}$ is directed C → H, whereas for CH

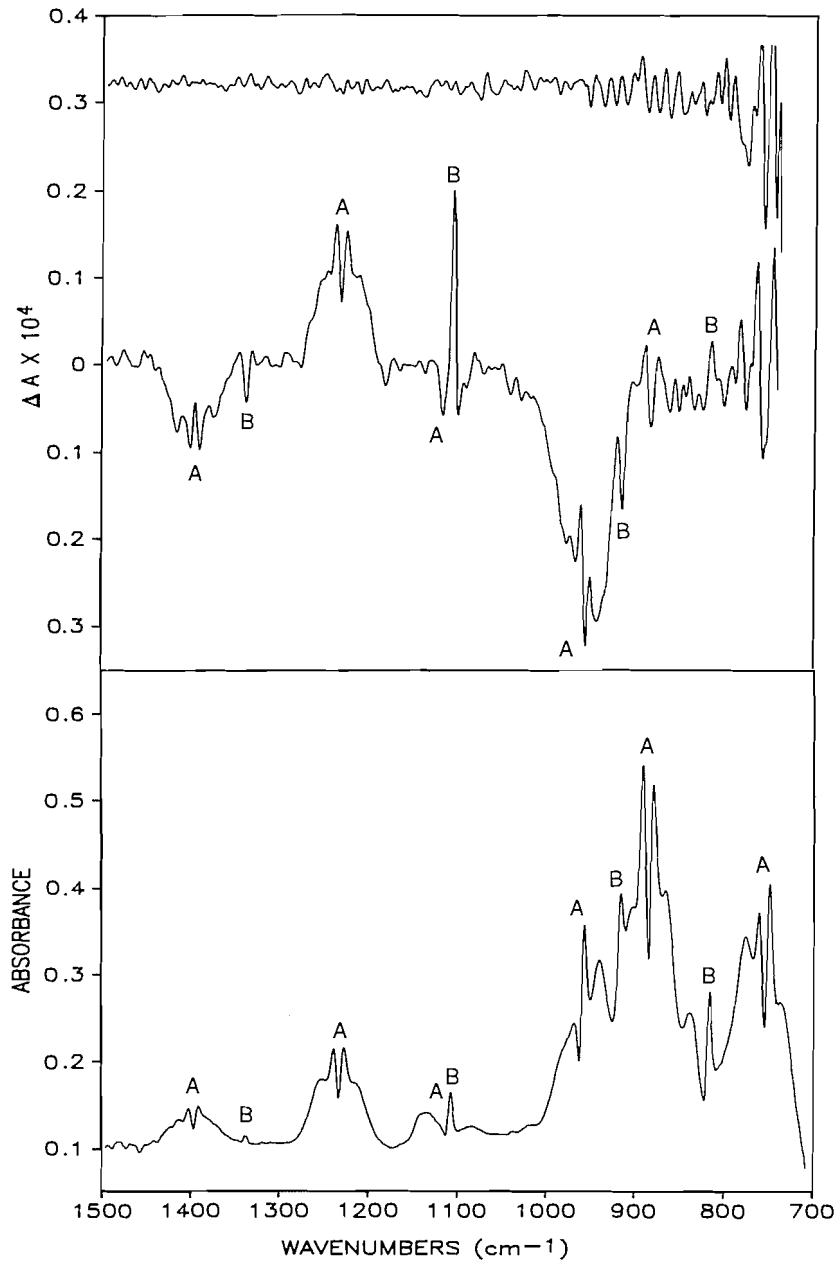

FIG. 3. Mid-infrared absorption and VCD spectra of a gas-phase sample of (*S,S*)-[2,3-$^2H_2$]oxirane; 20-mg sample, in a 5-cm path length, 25.4 mL volume cell, at 4 cm^{-1} resolution.

displacement perpendicular to the bond direction, positive μ is in the direction of hydrogen motion (36); for the ring modes, positive μ is in the direction opposite to that of the motion of the oxygen nucleus. The sign for each R_α indicates the direction of the magnetic dipole transition moment, $\boldsymbol{m} = \boldsymbol{m}_\alpha$, as determined by using the right-hand rule and the sense of circulation of positive charge. For the scissors, wag, rock, and twisting modes, the sense of charge circulation that defines the direction of $\boldsymbol{m}$ is readily determined from the sense of circulation of the displacement vectors, since the positive direction of each local electric dipole transition moment approximately coincides with the direction of the displacement vector for the hydrogen motion. For the CH stretches, the direction of $\boldsymbol{m}$ is deduced from the sense of circulation of the electric dipole transition moments (which are oposite in direction to the hydrogen displacements) about the coordinate axes placed at the center of mass. Although not forbidden by symmetry, the rotational character of the B_1 stretch and scissors modes (S_1 and S_8) is quite small and will be neglected. As expected for the achiral oxirane, none of the symmetry coordinates (or normal modes, which are linear combinations of coordinates of the same symmetry) can contribute to VCD intensity, since R_α and T_α, for the same direction α, do not transform as the same symmetry species.

Deuteriation of the *trans* CH bonds reduces the symmetry to the chiral point group C_2. The A_1 and A_2 species under C_{2v} symmetry both correlate to the A species (T_z,R_z) under C_2 symmetry; similarly, the B_1 and B_2 symmetry species both correlate to the B species (T_x,R_x,T_y,R_y). The normal modes of (*S,S*)-[2,3-$^2H_2$]oxirane can all be decomposed into linear combinations of the oxirane symmetry coordinates in Fig. 7. With this decomposition, the *trans* deuterium substitution can

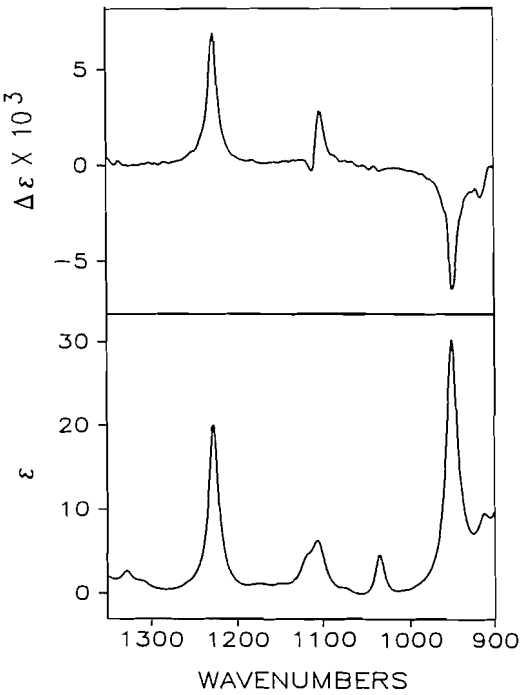

FIG. 4. Absorption and VCD spectra of (*S,S*)-[2,3-$^2H_2$]oxirane in the 900–1350 cm^{-1} region, 0.052 M in CS_2 solution, 0.8-cm path length, at 4 cm^{-1} resolution.

be considered as a chiral perturbation that mixes the A_1 and A_2 symmetry modes, or B_1 and B_2 symmetry modes, of the parent achiral oxirane. In Figs. 5 and 6, each (*S,S*)-[2,3-$^2H_2$]oxirane vibration is described by the oxirane symmetry coordinates, with relative phases indicated by + or −, that make the largest contributions to that mode. In addition, for each symmetry coordinate contribution, the translational and (or) rotational property and the directions of the electric and magnetic dipole transition moments are given. With this breakdown into translational (electric dipole) and rotational (magnetic dipole) contributions, the sign of the VCD for each (*S,S*)-[2,3-$^2H_2$]-oxirane mode is readily predicted from the directions of μ_α and m_α for each α, taking into account the relative sizes of opposing contributions. The decomposition of each mode into symmetry coordinate contributions can be deduced quantitatively from the calculated nuclear displacements. To assess opposing electric dipole moment contributions, we note that oxygen displacement results in a much larger electric dipole moment change than a comparable CH bending displacement. For unit displacements, the rocking displacement coordinates have larger projections than the twisting coordinates in the *xy* plane (Fig. 7) for the A_2 modes or in the *yz* plane for the B_2 modes, which result in a larger magnetic dipole transition moment due to local electric moment circulation from the rocking contributions to a mode, compared to a similar contribution from a twisting coordinate. In the following detailed descriptions, the modes are designated by our calculated frequencies.

The *B*-symmetry modes at 3040 and 2224 cm^{-1} arise from the in- and out-of-phase combinations of the B_1 and B_2 CH stretches, S_7 and S_{10}. The two modes are predicted to have similar VCD intensities of opposite sign, with the in-phase combination at 3040 cm^{-1} being positive. The *A*-symmetry modes at 3036 and 2239 cm^{-1} are the two linear combinations of the A_1 and A_2 symmetry coordinates S_1 and S_4. VCD intensities of similar magnitude but opposite sign, with the in-phase mode at 3036 cm^{-1} negative, are predicted. These predicted VCD intensity patterns agree with the observed CH- and CD-stretching spectra in Figs. 1 and 2.

The *A*-symmetry modes at 1397, 1235, and 947 cm^{-1} are found to be three linear combinations of the S_2 (A_1 CH_2-scissors) and S_5 (A_2 CH_2-rock), and either the S_{13} (A_1 in-phase ring stretch) or S_{14} (A_1 out-of-phase ring stretch) symmetry coordinates. In this case, the large electric dipole moment contribution from the ring stretch (due to the oxygen motion) dominates that from the CH_2-scissors. The A_2 CH_2-rock has a large rotational character. The modes at 1235 and 947 cm^{-1}, in which the electric dipole moment contributions from the ring stretch and CH_2-scissors are in the same direction, are predicted to have large absorption intensity (due to the ring motion) and large positive and negative VCD intensity (due to the relative phases of the ring stretch and CH_2-rock), respectively. In the mode at 1397 cm^{-1}, the electric dipole moment contributions from ring stretch and CH_2-scissors are in opposite directions, and the contribution from oxygen motion is smaller; these two factors reduce the magnitude of both the absorption and VCD intensity compared to the other two modes. The S_5 and S_{13} or S_{14} contributions have the same phase relationship in the 1397 and 947 cm^{-1} modes, and both are predicted to be negative. From Figs. 3 and 4, we observe that these three modes give rise to the three most dominant features in the VCD spectrum; the intensities follow the predicted sign and magnitude pattern, with the 1397 cm^{-1} mode being weaker than the other two.

The *B* mode at 1328 cm^{-1} is the in-phase combination of S_8 (B_1 CH_2-scissors) and S_{11} (B_2 CH_2-rock), and is predicted to have negative VCD intensity, as observed. This mode is much weaker in both absorbance and VCD than the *A* mode at 1397 cm^{-1} since there is no ring-stretching contribution. The S_8 and S_{11} symmetry coordinates contribute in small amounts to the lower frequency *B* modes; the lowest frequency mode at 646 cm^{-1} contains the out-of-phase combination of S_8 and S_{11}, in addition to a large contribution from S_{12} (B_2 CH_2-twist). With the assumption that the contributions from the rock dominate those from the twist, we predict weak positive VCD for the 646 cm^{-1} mode, which lies below the detection limit for our instrument. The absorption intensity is predicted to be small, since no oxygen motion is involved; the weak band observed at 673 cm^{-1} in the absorption spectrum (not shown) is comparable in intensity to the 1106 cm^{-1} band.

Four modes can be primarily described as linear combinations of CH_2 wag and twist. The pair of *A*-symmetry modes at 1123 and 726 cm^{-1} are the in- and out-of-phase combinations of S_3 (A_1 CH_2-wag) and S_6 (A_2 CH_2-twist), with the wag making the more dominant contribution to the higher frequency mode and the twist making the more dominant contribution to the lower frequency mode. When the modes are viewed as a projection in the *xz* plane, it is clear that the hydrogens are undergoing large displacement in the 1123 cm^{-1} mode, and the deuteriums in the 746 cm^{-1} mode. The 1123 cm^{-1} mode is predicted to be quite weak in absorbance, with negative VCD intensity, in agreement with observation. A contribution from S_{14} (A_1 ring stretch) to the 746 cm^{-1} mode should result in a large absorption intensity. This mode, predicted to have positive VCD, is observed as an intense absorption band at 754 cm^{-1}, at the detection limit of the VCD instrument where the VCD signal-to-noise ratio is poor. The pair of *B*-symmetry modes at 1117 and 918 cm^{-1} arise from in- and out-of-phase mixing of the S_9 (B_1 CH_2-wag) and S_{12} (B_2 CH_2-twist). The

[a]Calculated with *ab initio* force field of Lowe *et al.* (34) and experimental geometry of C. Hirose (35).

[b]Measured from integrated intensities for solution-phase sample for all bands except for values in parentheses, which were estimated from the relative intensities in the gas-phase spectrum.

[c]MFP = magnetic field perturbation, from ref. 12, with 6-31G(ext) basis; LMO(I) and LMO(II) = localized molecular orbital model, from ref. 14, with 6-31G(ext) and 6-31$\tilde{G}$(-2$\tilde{S}$,2$\tilde{P}$,2$\tilde{P}_H$) basis sets, respectively; VC = vibronic coupling, sum-over-states method, from ref. 15, 6-31$\tilde{G}$(-2$\tilde{S}$,2$\tilde{P}$,2$\tilde{P}_H$) basis.

[d]The dipole strength calculations are identified by the rotational strength method to which they correspond.

[e]C_2Cl_4 solution for CH- and CD-stretching modes; CS_2 solution for mid-infrared modes.

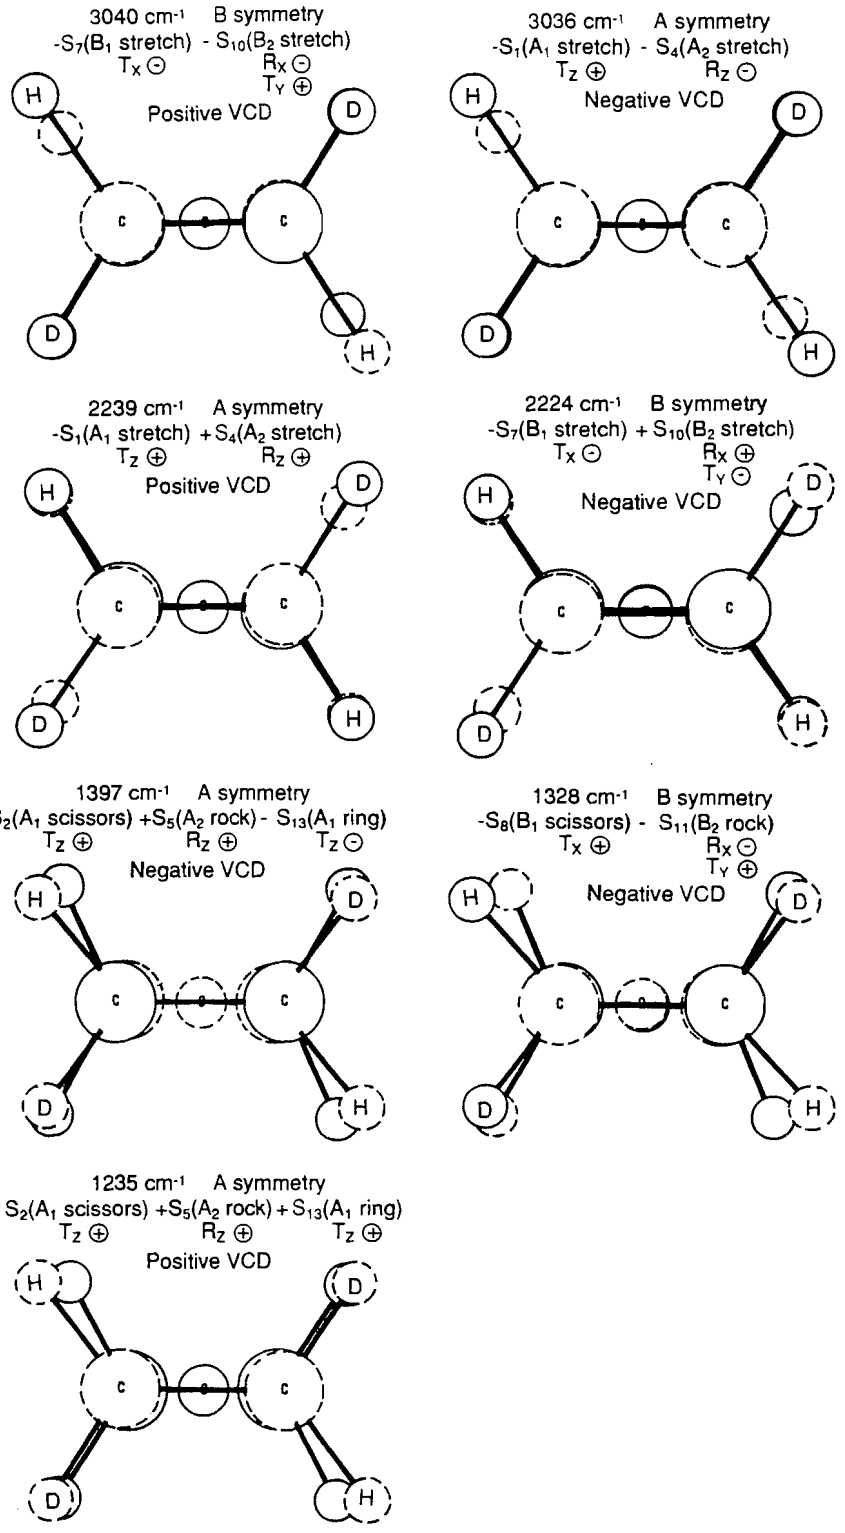

FIG. 5. Stereoprojections of the calculated vibrational normal modes of (*S*,*S*)-[2,3-$^2H_2$]oxirane between 3100 and 1200 cm^{-1}. Dotted and solid circles indicate nuclear positions at opposite extremes of the vibrational cycle. For each mode (in the phase of vibration from solid to dotted nuclear positions), the symmetry coordinates of the parent oxirane molecule (see Fig. 7), with phase indicated by + or −, that makes the largest contributions to the mode are identified. In addition, for each symmetry coordinate contribution, the translational (T_α) and (or) rotational (R_α) character is listed, and the direction of the electric dipole transition moment along the translational axis or magnetic dipole transition moment along the rotational axis is given.

modes are predicted and observed to be a positive–negative VCD pair, with moderate absorption intensity.

The final two modes are primarily ring stretches. The most intense mode at 885 cm^{-1} corresponds to the calculated *A* mode at 871 cm^{-1}. In addition to the large contribution from the S_{14} (A_1 ring stretch) symmetry coordinate, small contributions from S_2 (A_1 CH_2-scissors), S_5 (A_2 CH_2-rock), and S_6 (A_2 CH_2-twist) are present. The magnetic dipole transition moment contributions from the A_2 rock and twist are in opposite directions, but since the rotational character of the rock is larger than that of the twist, we predict weak positive VCD, in agreement with the observed weak positive VCD at 880 cm^{-1}. The *B* ring stretch at

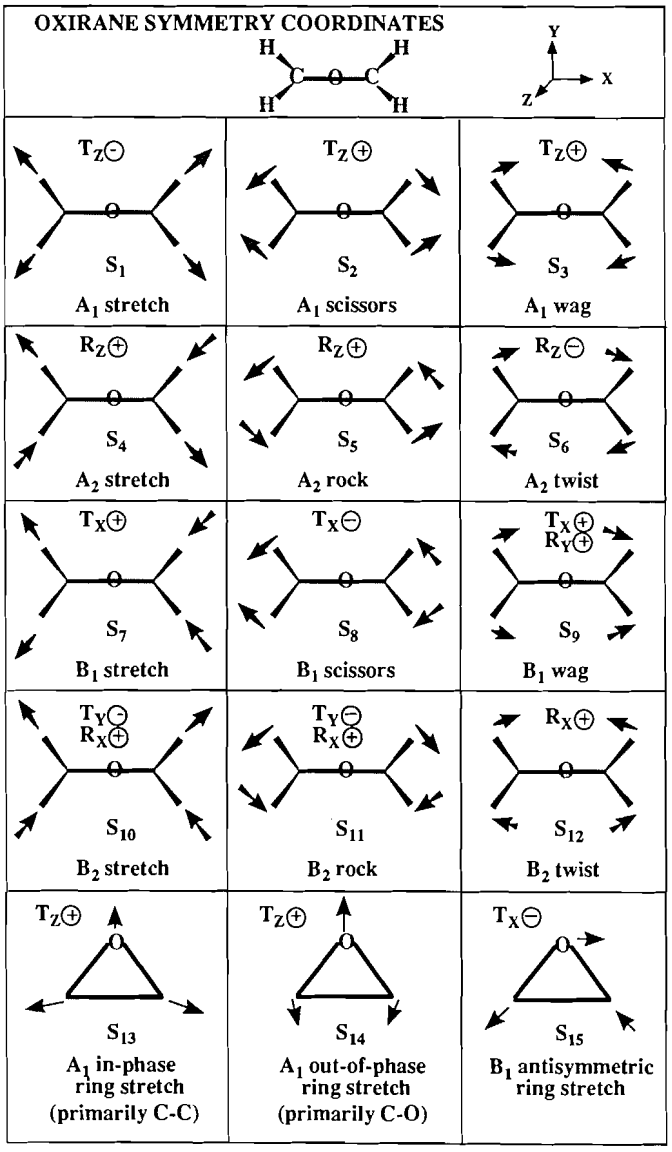

FIG. 7. Schematic diagram of symmetry coordinates for oxirane CH_2 stretch, scissors, wag, rock and twist, and ring stretching motion of symmetry species A_1, A_2, B_1, or B_2. T_α and R_α ($\alpha = x, y,$ or z) identify the translational and rotational character of the motion, respectively. The sign associated with T_α denotes the direction of the electric dipole transition moment due to linear displacement of positive charge along the α axis; the sign associated with R_α denotes the direction of the magnetic dipole transition moment due to positive charge circulation about the α axis.

820 cm^{-1}, primarily S_{15} (B_1 ring stretch), includes small amounts of S_9 (B_1 CH_2-wag) and S_{12} (B_2 CH_2-twist). Since S_{15} gives the predominant electric dipole transition moment contribution, weak positive VCD is predicted. Weak positive VCD intensity that coincides in frequency with the Q-branch of the 817 cm^{-1} mode is observed with signal-to-noise ratio ~2.

Discussion

Conceptualizing the vibrational modes of (*S,S*)-[2,3-$^2H_2$]-oxirane as arising from chiral perturbation of the modes of the parent oxirane molecule provides a lucid insight into the origin, sign, and relative magnitude of each VCD feature. With the vibrational force field employed here, and the approximation of local electric dipole moment contributions, we are able to predict all the observed VCD signs and relative intensities. The requirements for large VCD intensity are the presence of a large linear charge oscillation along an axis accompanied by a large amount of oscillating charge circulation about the same axis. For the most intense VCD features in (*S,S*)-[2,3-$^2H_2$]oxirane, the linear charge motion arises from oxygen displacement in the ring stretches; the charge circulation arises from the methylene group motions. The largest oxygen displacements occur in the mid-infrared modes of *A* symmetry, which are more intense than the *B*-symmetry modes. In contrast, in (*S,S*)-[1,2-$^2H_2$]-cyclopropane, where there is no oxygen in the ring, the *B* modes are more intense (24). The ring modes in (*S,S*)-[2,3-$^2H_2$]-oxirane at 885 and 817 cm^{-1}, which involve large oxygen displacement but only small contributions from angular methylene motion, exhibit small VCD anisotropy ratios. In the CH- and CD-stretching regions, the net linear charge oscillation is larger for the *B* modes, but the charge circulation is larger for the *A* modes. As a result, nearly conservative VCD couplets are observed in each region.

The approach taken in this study to understand the origin of the VCD features in molecules that are chiral due to isotopic substitution also serves to demystify the results of calculations of VCD intensities for (*S,S*)-[2,3-$^2H_2$]oxirane using various *ab initio* methods (12, 14, 15), and to provide insight into the discrepancies between observed and calculated VCD signs and intensities. Calculations on (*S,S*)-[2,3-$^2H_2$]oxirane using three different approaches have appeared in the recent literature: the magnetic field perturbation (MFP) method of Stephens and co-workers (6, 12, 13), the implementation for *ab initio* wavefunctions by Polavarapu and Bose (14) of the localized molecular orbital (LMO) method of Nafie and Walnut (1, 2), and the implementation by Dutler and Rauk (15) of the sum-over-states vibronic coupling formulation of Nafie and Freedman (3). In addition, the absorption and VCD intensities in the CH- and CD-stretching regions have been calculated with the random phase approximation (37), which gave results similar to, but slightly smaller than, the magnetic field perturbation method. We present in Table 1 a comparison of the observed intensities with the results of the three calculations (12, 14, 15) that reported all the normal modes. It must be noted that none of the three calculations or our analysis were carried out with precisely the same geometry and normal mode nuclear displacements. The LMO calculations were carried out with an unscaled force field, whereas both the MFP and VC calculations employed scaled force fields that give similar good agreement with experiment. Our analysis (4-31G basis set), and the MFP and LMO(I) calculation (6-31G(ext) basis) employed the experimental geometry; the LMO(II) and VC calculations employed the optimized geometry for the basis set used (6-31$\tilde{G}$(-2$\tilde{S}$,2$\tilde{P}$,2$\tilde{P}_H$)). In Table 1, we have identified each dipole strength calculation by the rotational strength calculational method with which it is associated. The dipole strength calculations are of course not model dependent; the differences in calculated dipole strength for a given mode reflect the differences in geometry, scaling, and basis set used.

Overall, all three calculations reproduce the VCD and absorption intensity patterns. There are some notable discrepancies. The *A* mode at 1112 cm^{-1} is calculated with the incorrect sign with all three approaches. Our analysis shows that this mode has a small electric dipole transition moment contribution from ring stretch that is opposite in direction to the contribution from S_3 (A_1 wag). The correct sign is obtained if the wag

contribution determines the net electric dipole moment direction. If the calculations are overestimating the contribution from oxygen motion, the incorrect sign would result. A comparison of the observed and calculated dipole strengths for the modes that involve ring stretches suggests that this may indeed be the case; for example, the calculated absorption intensity of the 961 cm^{-1} mode is much too large.

The rotational strengths for the two CH-stretching modes calculated with the MFP approach (12) are two to three times larger than both the observed values and those calculated by the other two methods, which agree well with experiment. Although a VCD couplet with the observed magnitude can be simulated from the MFP rotational strengths by decreasing the frequency separation between the two modes to allow extensive cancellation of two Lorentzian bands of opposite sign, the resulting band shapes in the simulated spectrum do not agree with the observed spectrum. In comparing the observed and calculated rotational strengths for (*S,S*)-cyclopropane-1,2-$^2H_2$, we have found a similar disagreement for the MFP calculations in the CH-stretching region.[2]

For the rotational strengths of the five lowest frequency modes, there are several differences in sign for the three calculations, and the magnitude for the 885 cm^{-1} ring mode calculated by the LMO method is much larger than that obtained by experiment. Unfortunately, our instrumentation does not allow observation of the VCD bands for the two lowest frequency modes, and the VCD features for the 885 and 817 cm^{-1} modes are only slightly above the noise level. From our analysis of the oxirane symmetry coordinate contributions to the (*S,S*)-[2,3-$^2H_2$]oxirane normal modes, we find that these five modes in general involve ring stretching and methylene motions that in some cases generate electric dipole transition moment contributions in opposite directions, and (or) two different methylene motions that produce magnetic dipole transition moment contributions in opposite directions. Since none of the calculations used precisely the same force field and geometry, some of the differences among the calculations may lie in the form of the normal modes used, reflected in differences among these opposing contributions to the modes. Alternatively, the three calculational approaches, as implemented, may place different importance on the various electronic contributions to the rotational strengths. Without employing the same normal mode nuclear displacement vectors with all three approaches, it is not possible to use the comparison with experiments as a way to rank the accuracy of the various calculational approaches.

The CH- and CD-stretching VCD couplets can also be calculated with the coupled oscillator model, $R^{\pm} = \mp\pi\nu_0 \boldsymbol{R}_{12} \cdot \boldsymbol{\mu}_1 \times \boldsymbol{\mu}_2$, where the + and − signs refer to the in- and out-of-phase modes, respectively; ν_0 is the unperturbed frequency of a single isolated oscillator; $\boldsymbol{R}_{12}$ is the separation vector between oscillators 1 and 2; and $\boldsymbol{\mu}_1$ and $\boldsymbol{\mu}_2$ are the electric dipole transition moments for the uncoupled oscillators. With $|\boldsymbol{\mu}_i| = (D/2)^{1/2}$, where D is the total dipole strength obtained from the integrated absorption intensity, we calculate $R^+ = -6.04 \times 10^{-44}$ esu^2 cm$_2$ for the *A*-symmetry CH stretch and $R^+ = -2.71 \times 10^{-44}$ esu^2 cm^2 for the *A*-symmetry CD stretch, if we assume that the electric dipole transition moment lies along the bond axis. These values agree in sign with the observed spectra, but are too small in magnitude. Stephens *et al.* (12) calculate an angle between the bond direction and electric dipole transition moment of 16.0° and 22.6° for the CH and CD stretch, respectively. Placing the electric dipole transition moment vector off the bond axis (which is reasonable for a charge flow contribution to the CH stretch from the adjacent CO bond) results in a larger coupled oscillator rotational strength, but introduces an uncertainty into the location of the separation vector (12). Although some adjacent *A* and *B* symmetry modes in the mid-infrared region appear to have in- and out-of-phase relationships between *trans* CH or CD motions (Figs. 5 and 6), these modes cannot be analyzed in terms of isolated coupled oscillators, due to the differing contributions from ring stretches.

The vibrational modes of (*S,S*)-[2,3-$^2H_2$]oxirane consist of coupled nuclear motion with translational and rotational characteristics. The electronic motion in this molecule for the most part appears to follow hae nuclear motion or to result in charge flow within a bond or two adjacent bonds. There is no extended region in the molecule for charge flow to occur in the absence of nuclear motion. It is reasonable, therefore, to obtain a satisfactory descriptive analysis of the VCD intensities based only on the arrangement of local electric dipole moment contributions as deduced from the nuclear displacements. For this type of normal mode, it is also reasonablle that all three calculational approaches should yield similar, satisfactory rotational strengths, since the calculated dipole strengths agree adequately with experiment. We previously postulated that the positive VCD intensity in the CH-stretching region of (*S,S*)-[2,3-$^2H_2$]oxirane resulted from vibrationally generated ring current in the three-membered ring (23). That proposal is not valid, The difference in intensity between the *A* and *B* symmetry CH stretches is adequately reproduced in the MFP and VC calculations and can be attributed to differences due to symmetry in the contributions from charge flow in the CO bonds (38).

This paper is dedicated to Dr. Richard Norman Jones

RATNAKAR K. GOSAVI, MANUEL TORRES, and OTTO P. STRAUSZ. Can. J. Chem. **69**, 1630 (1991).

The energies and geometries of the low-lying electronic states of formylmethylene have been calculated at the SCF and CI levels using 6-31G** basis set. In agreement with previous reports and accumulated experimental observations, the ground state is the carbenoid triplet with a planar geometry. Also, in agreement with all previous single configuration SCF and CI calculations, the lowest excited singlet state is computed to be the nonplanar closed shell carbenoid structure. In contrast, accumulated experimental evidence along with previously reported MC–SCF results require this state to be planar. The present calculation predicts the existence of a (σ–σ) 1,3-diradical $^1A'$ state, which appears to be identical to the MC–SCF lowest singlet state, but this state lies some 11 kcal/mol above the closed shell carbenoid ^1A state. Apparently, single configuration SCF methods are inadequate for the correct description of the electronic manifold of formylmethylene.

Key words: formylmethylene, singlet and triplet states, *ab initio* MO calculations, conformers, molecular structure.

RATNAKAR K. GOSAVI, MANUEL TORRES et OTTO P. STRAUSZ. Can. J. Chem. **69**, 1630 (1991).

On a calculé les énergies et les géométries des états électroniques inférieurs du formylméthylène à des niveaux SCF et CI, en utilisant un ensemble de base 6-31G**. En accord avec les données rapportées antérieurement et les observations expérimentales accumulées, l'état fondamental est le triplet carbénoïde avec une géométrie plane. De plus, en accord avec tous les calculs SCF et CI de configuration unique, on a calculé que l'état singulet excité le plus bas possède la structure carbénoïde non planaire, à couche fermée. Par ailleurs, les données expérimentales accumulées ainsi que les résultats MC–SCF rapportés antérieurement indiquent que cet état est plan. Les calculs rapportés ici prédisent l'existence d'un état (σ–σ) 1,3-radicalaire, $^1A'$, qui semble être identique à l'état singulet le plus bas du MC–SCF; toutefois, l'énergie de cet état est 11 kcal/mol plus élevée que celle de l'état carbénoïde à couche fermée, ^1A. Apparemment, les méthodes SCF à configuration unique sont inadéquates pour décrire correctement des divers états électroniques du formylméthylène.

Mots clés : formylméthylène, états singulet et triplet, calculs d'OM *ab initio*, conformères, structure moléculaire.

Introduction

Ketocarbenes and oxirenes have been postulated as intermediates in the Wolff rearrangement of α-diazoketones. There have been several theoretical studies reported in the literature (1–20) on the structures and electronic states of ketocarbenes and related oxirenes, and numerous attempts have been made to explain the mechanism of their reactions. All the *ab initio* molecular orbital calculations reported have been performed on the isomers of the parent C_2H_2O. All closed shell RHF–SCF geometry optimizations predicted a nonplanar geometry for the lowest singlet state of formylmethylene, with the hydrogen atom H_5 (Fig. 1a) on the carbene carbon, C_2, lying above the CCO plane. In contrast, photolysis and thermolysis studies (21–24) of α-diazoketones have shown that their ketocarbene decomposition products occur in geometric conformer pairs and therefore must have a planar geometry, and that the conformation of the more abundant conformer agrees with the conformation of the parent α-diazoketone and, thus, the conformation is maintained in the decomposition. The only *ab initio* calculation that has predicted the correct planar geometry for the lowest excited singlet state of formylmethylene is the recent multi-configuration SCF calculation by Robb and co-workers (15) indicating a σ–σ 1,3-diradical structure with an energy 5.5 kcal/mol higher than the cylic oxirene isomer.

After submission of the present article a paper by Schaefer and co-workers (20) came to our attention, reporting some coupled-cluster calculations on oxirene. The part of this paper that is relevant to the present work is the statement that in the b_2 ring deformation in oxirene leading in the direction of carbenoid closed shell singlet formylmethylene, where Radom and co-workers (11) were able to locate the transition state between oxirene and formylmethylene ^1A at the 4-31G SCF level of theory, Schaefer and co-workers found that formylmethylene is not a minimum at the double zeta plus polarization function with configuration interaction calculations involving single and double excitations.

ESR studies of several ketocarbenes (25–28) have shown that these carbenes have a triplet ground state with planar geometry and also that in most cases the conformation of the most abundant triplet ketocarbene is the same as that of the precursor diazoketone. Recently some highly strained ketocarbenes have been isolated in sufficiently high concentration so that their UV-visible and infrared spectra (27, 28) could be recorded. Earlier *ab initio* molecular orbital calculations (5) on formylmethylene with partially optimized geometry using STO-3G + 3*d* functions on the carbene carbon with the open shell RHF–SCF method predicted a planar triplet as the ground state. At the same level of calculations the closed shell lowest singlet state was 25 kcal/mol higher in energy than the triplet ground state.

Preliminary results of Tanaka and Yoshimine (9) have also shown that formylmethylene has a triplet ground state with a planar geometry and that the lowest singlet state, lying 20 kcal/mol above the triplet ground state, has a closed shell nonplanar geometry. Harding and Wagner (13) optimized the geometry for the low-lying $^3A''$ and $^3A'$ states of formylmethylene with double zeta plus polarization functions, at the RHF–SCF, CISD, and CISDQ levels and found that the $^3A''$ state is

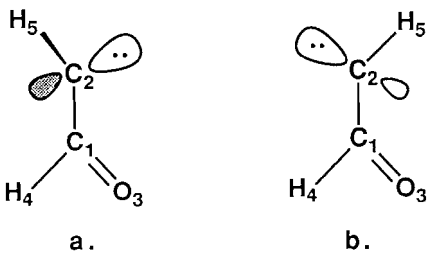

FIG. 1. Carbenoid closed shell structure of formylmethylene.

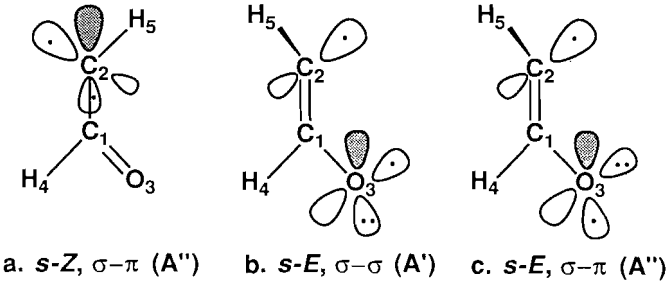

FIG. 2. Diradical structures of formylmethylene.

lower than the $^3A'$ state by 29 kcal/mol. The $^3A'$ state had a 1,3-diradical structure with a carbon–oxygen single bond and a carbon–carbon double bond, whereas the $^3A''$ state had a carbenoid structure with a carbon–oxygen double bond and a carbon–carbon single bond.

The MC–SCF computations (15) with 6-31G* basis set and complete geometry optimization, using reference space with only two active π orbitals and two active σ orbitals, predicted a σ–σ type diradical for the lowest singlet ($^1A'$) and triplet ($^3A'$) states. However, in calculations using five active orbitals (three π and two σ) the σ–π triplet ($^3A''$) state turned out to have a lower energy than the σ–σ triplet state, $^3A'$. These calculations also predicted the triplet to be the ground state for formylmethylene, and the σ–σ diradical ($^1A'$) singlet state to be the lowest singlet state, which is only 1.3 kcal/mol higher in energy than the $^3A'$ state.

Knowledge of the structure and conformation of the lowest singlet state of formylmethylene is important with respect to the interpretation of the mechanism of the decomposition of α-diazoketones and, as has recently been shown, to the reactivity of ketocarbenes (29). Since there are no calculations reported in the literature on the relative energies of the geometric conformers of singlet and triplet states of formylmethylene, we carried out a series of *ab initio* molecular orbital calculations on the conformer pairs of the low-lying electronic states of formylmethylene, including both the lowest singlet and triplet states.

Methods

The singlet state of formylmethylene can be represented either as a closed shell carbene, Fig. 1, or as an open shell diradical structure, Fig. 2. The open shell structures can be represented as either a carbene in which both unpaired electrons are localized on carbene carbon, C_2, with one electron in the σ and the other in the π orbital, giving an A'' state (Fig. 2a), or as a 1,3-diradical in which one electron is localized on the carbene carbon, C_2, in the σ orbital, and the other on the oxygen atom. Depending on the occupation of the single unpaired electron on the oxygen atom, namely, whether it is in the in-plane σ orbital, Fig. 2b, or in the perpendicular π orbital relative to the CCO plane, Fig. 2c, a (σ–σ) A' or (σ–π) A'' state will result, respectively. All molecular parameters were optimized at the SCF level by the energy gradient method with 6-31G** basis set (30). The RHF open shell SCF method was used for the lowest singlet and triplet-state energy calculations of the diradical isomers. It is known that the geometry optimization by the RHF–SCF open shell method tends to overestimate the stability of the extreme localized structures (31–33). This has been overcome by the geometry optimization at the CI level, which usually gives the delocalized structure with a global minimum. Configuration interaction calculations including singly and doubly excited configurations (CISD) with respect to the SCF configuration were performed using the direct CI method (34) at the SCF optimized geometry. Quadruple excitation correction was calculated by Davidson's formula (35) and added to the CI results (CISDQ). Only the lowest 30 orbitals ($24a' + 6a''$ in the C_s symmetry structures) were used in the CI calculations, with the lowest three orbitals corresponding to the carbon and oxygen 1*s* core orbitals kept doubly occupied and frozen. Partial optimization of the geometry at the CISDQ level was done by the stepwise method. All computations were performed with the modified version of the Gaussian 82 program (36), the Monstergauss Program (37).

Results and discussion

The optimized molecular parameters of all carbene and diradical isomers of formylmethylene at the SCF level are summarized in Table 1. Calculated total energies at the SCF and CI level of all isomers at the SCF optimized geometry are tabulated in Table 2, along with the relative energies at the CISDQ level with respect to the $^3A''$ ground state of the diradical structure of formylmethylene.

The computational results predict the triplet, $^3A''$, as the ground state of formylmethylene with an *s-Z* conformation and both unpaired electrons localized on the carbene carbon, C_2, one in the σ and the other in the π orbital (Fig. 2a). Earlier, Harding and Wagner (13) also reported a similar electronic structure for the $^3A''$ ground state and our optimized molecular parameters (Table 1) are in good agreement with their values optimized with double zeta plus polarization functions. The corresponding triplet *s-E* conformer with the same electronic configuration is only 1.4 kcal/mol higher in energy than the *s-Z* conformer. The energy barrier for *s-Z* to *s-E* isomerization in the triplet ground state is 9.0 kcal/mol, with the terminal H atom being linear with the C—C bond. The molecular parameters for the two conformers are quite similar (Table 1). The next excited triplet state has an A', σ–σ structure with the two unpaired electrons localized on different centers, C_2 and O, with an *s-Z* configuration, which is 26.1 kcal/mol above the ground state triplet ($^3A''$). The optimized molecular parameters (Table 1) are in good agreement with earlier reported values (13), and the $^3A'' - {}^3A'$ energy difference calculated at the CISDQ level with SCF optimized geometry (26.1 kcal/mol) is very close to the value of 29.1 kcal/mol obtained with the geometry optimization at the CISDQ level (13). The $^3A'$ *s-E* conformer is isoenergetic with the *s-Z* conformer, and their optimized molecular parameters are also very close to one another (Table 1) and in agreement with the MC–SCF optimized values (15). The energy barrier for the *s-Z* to *s-E* isomerization in the $^3A'$ state is 5.2 kcal/mol, which is smaller than in the $^3A''$ ground state. These results are consistent with the experimental (25–28) and earlier theoretical (5, 7, 9, 13, 15) prediction that formylmethylene and its substituted derivatives have a triplet ground state. MC–SCF calculations reported by Novoa *et al.* (15) also predicted that the lowest triplet state has a σ–π structure, but the authors did not report the total energy and electronic configuration of this state, nor the energies for the *s-Z* conformers. All the calculations they reported were for the *s-E* conformers with σ–σ structure (A' states).

The single configuration RHF–SCF level geometry optimization gives the close shell carbene with nonplanar structure as the lowest singlet state, which is 18.1 kcal/mol higher in energy than the $^3A''$ ground state at the CISDQ level. All the earlier closed shell RHF–SCF calculations (3–5, 7–9, 11) predicted the nonplanar geometry for the lowest singlet state, with the exception of the MC–SCF calculations of Novoa *et al.* (15), which gave the σ–σ 1,3-diradical planar structure ($^1A'$) as the lowest singlet state for formylmethylene. Since their calculations were performed to explore the role of the lowest triplet state of formylmethylene in the Wolff rearrangement and the ring closure reaction in the lowest singlet state formylmethylene to form the oxirene, they did not investigate the energies of other conformers of formylmethylene or of the A″ state.

Open shell RHF–SCF geometry optimization of the diradical configuration of formylmethylene gave three structures, Fig. 2, corresponding to three local minima, which were verified by the calculation of eigenvalues of the Hessian matrix. Of the three structures, the *s-E* conformer of the $^1A''$ 1,3-diradical state with the σ–π configuration is the lowest singlet state for the diradical structure and is 9.8 kcal/mol above the closed shell singlet with a nonplanar carbene structure, and 27.9 kcal/mol above the ground state $^3A''$ with an *s-Z* conformation. The $^1A'$ state *s-E* and *s-Z* conformers with a 1,3-diradical structure are close, 1.5 and 1.8 kcal/mol, respectively, above the $^1A''$ state. The *s-E* and *s-Z* conformers are nearly isoenergetic (Table 2), the *s-E* conformation being slightly more stable in both the $^1A''$ and $^1A'$ states with the 1,3-diradical structure. The third local minimum corresponds to the carbenoid $^1A''$ state. This state is also fairly close to the lowest $^1A''$ state with 1,3-diradical structure, only 5.2 and 4.1 kcal/mol above the respective conformers. In the carbenoid structure, the *s-Z* conformer is slightly more stable than the *s-E* conformer. For comparison, the planar closed shell carbene geometry (Fig. 1b) was optimized for the $^1A'$ state. But this turned out to be a saddle point on the surface with a critical point order of one. Recently, Schaefer and co-workers (20), in their study on the oxirene b_2 ring deformation leading to formylmethylene, did not find a minimum that corresponds to formylmethylene at the DZP–CISD level theory. Surprisingly, the total energy (Table 2) of this planar carbene structure at the CISDQ level is very close to those of the $^1A'$ 1,3-diradical conformers.

In the carbenoid structures, both closed shell as well as open shell, the SCF optimized bond distance (Table 1) and the calculated bond order (Table 3) show that the C—C bond distance is slightly shorter than the single bond value and the C—O bond distance is close to the C=O double bond value. In the 1,3-diradical structure, the C—C bond distance is close to the C=C double bond value and the C—O bond distance is close to the C—O single bond value. The $^1A'$ optimized molecular parameters (Table 1) are in good agreement with the MC–SCF optimized values (15).

It has been recognized (31–33) that in open shell molecules containing multiple bond(s), the geometry optimization at the RHF–SCF level tends to overestimate the stability of the extreme, localized structures. This problem is overcome by the geometry optimization at the CI level, which usually results in a delocalized structure with a global minimum. For this reason we carried out a partial geometry optimization at the CISDQ level with C_1—C_2 and C_1—O_3 bond distances and $C_2C_1O_3$ bond angle, on the closed shell carbene (^1A) and the lowest energy conformers of the $^3A''$, $^1A''$, and $^1A'$ states. Optimized molecular parameters with the CISDQ level energy are tabulated in Table 4. In the $^3A''$ state we obtained only one minimum

[a]The $^1A''$ (RHF optimized geometry) and both $^1A'$ and $^3A'$ states have a 1,3-diradical structure while the ^1A, $^1A''$ (UHF optimized geometry) and $^3A''$ states have a carbenoid structure.
[b]In kcal/mol.
[c]Energy value of closed shell carbene isomer.

corresponding to the carbenoid structure. Even the partial geometry optimization of the $^1A''$ state resulted in only one minimum corresponding to the 1,3-diradical structure. The minimum found in the RHF–SCF geometry optimization corresponding to the carbenoid structure (Fig. 2a) in the $^1A''$ state vanishes. The optimized bond distances at the CISDQ level are slightly longer that the SCF optimized values, and there is not much change in the total and relative energies.

The question of the low-lying electronic states of formylmethylene and their substituted derivatives is of primary importance in the photochemistry of α-diazoketones, the associated Wolff rearrangement reactions, and in the chemistry of ketocarbenes, oxirenes, and their isomeric structures. According to the results of the present calculations, in agreement with all previous *ab initio* SCF, CI, and MC–SCF calculations, the ground state of formylmethylene is the *s-Z* conformer of the planar ($\sigma-\pi$) carbenoid A″ state. The *s-E* conformer of this state lies 1.40 kcal/mol above the *s-Z* conformer. These theoretical results are supported by the experimental observation of a series of triplet state ketocarbenes in low-temperature crystals and matrices that, at sufficiently low temperatures, are stable indefinitely. Evidence for the existence of *s-Z*–*s-E* conformerism also comes from esr spectroscopy. It has been found that most ketocarbenes can assume two conformer geometries, one major and one minor, and their esr spectra suggest that these are *s-Z*–*s-E* conformers and therefore they must have a planar structure.

With regard to the nature of the lowest singlet state of formylmethylene, the theoretical results are not as concordant. All available *ab initio* single configuration SCF, SCF–CI calculations including the present results predict a closed shell, nonplanar carbenoid structure for the lowest singlet state. However, the prediction of the only available MC–SCF calculations is different in that it gives for the lowest singlet state the planar ($\sigma-\sigma$) 1,3-diradical A′ state. Yet according to the double zeta plus polarization function with CISD calculation by Schaefer and co-workers (20), formylmethylene is not a minimum on the C_2H_2O surface. The available experimental results on the chemistry of ketocarbenes suggest that the lowest state is indeed a planar ($\sigma-\sigma$) state that exists in two close-lying conformations. In the absence of complicating secondary effects, one of the conformers readily undergoes Wolff rearrangement while the other conformer prefers oxirene formation (29):

s-E *s-Z*

Thus, the accumulated experimental data support the MC–SCF result. Therefore, we can tentatively conclude that for formylmethylene, a small molecule with several available orbital occupancies and many close-lying electronic states, the single configuration SCF method is inadequate for the correct description of the electronic manifold of the molecule, and MC–SCF calculations must be employed. It must also be stated that the single configuration SCF–CI calculation produces a $^1A'$ state with the same geometry and orbital occupancy as the MC–SCF calculation but this state occurs as one of the low-lying excited singlet states and not as the lowest singlet state. Also, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

carbenoid ^1A state computed here must correspond to an excited singlet state, as probably does the diradical $^1A''$ state. Therefore, the main inadequacy of the SCF–CI method in the computing of the electronic manifold of formylmethylene does not appear to be the generation of spectroscopic states that do not correspond to physical reality but rather to the incorrect energy ordering of the generated states.

We further performed some UHF–SCF calculations with geometry optimization on a few diradical isomers, the results of which are tabulated in Table 5. Spin contamination is evident in both singlet and triplet states and the UHF–SCF total energies obtained are lower than the RHF–SCF values, which conforms to the known performance of the UHF calculations leading to low values for total energies. The UHF–SCF results also predict the carbenoid $^3A''$ state to be the ground state, as do the RHF results. But for the singlet state the calculations predict the carbenoid $^1A''$ state to lie lower in energy than the closed shell carbene structure, Table 5. These UHF–SCF results along with the calculated energies of the RHF–SCF optimized geometry of all planar conformers, which are very close to each other, clearly manifest the inadequacy of single configuration calculations for the singlet states.

The closed shell reaction surfaces for the interconversion of C_2H_2O isomers have been reported in the literature (4, 8, 9, 11–13, 18, 19). MC–SCF calculations (15) have been reported only for the reaction of the diradical form of formylmethylene to give oxirene along with the singlet–triplet state crossing in formylmethylene. The present results reveal the existence of other close-lying conformer pair singlet states in formylmethylene, which undoubtedly play some role in the photochemistry of α-diazoketones, in the Wolff rearrangement reactions, and in the chemistry of formylmethylene and its isomers.

Theoretical studies of peptidic structures. Conformation of the tetrapeptide *N*-acetyl-Asp-Glu-Lys-Ser-NH-CH_3

S. E. THORNTON AND S. FRAGA

Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received April 19, 1991

This paper is dedicated to Dr. Richard Norman Jones

S. E. THORNTON and S. FRAGA. Can. J. Chem. **69**, 1636 (1991).

The peptide Asp-Glu-Lys-Ser has been studied using the software package ALTA:maPS, with simulation of the pH conditions and the influence of the solvent, in order to investigate the possible stabilization of its structure by a hydrogen bond and a salt-bridge. The theoretical results confirm the existence of a salt-bridge, between the side chains of the Glu and Lys residues, in aqueous solution at neutral pH but not at acid pH, in agreement with the observation from NMR studies. On the other hand the calculations indicate that no hydrogen bond exists in aqueous solution at either pH. The fact that an in-vacuum simulation shows the existence of a hydrogen bond between the peptidic CO group of the Asp residue and the peptidic NH group of the Ser residue suggests that a molecular dynamics study might confirm that a small percentage (less than 25%) of the peptide molecules may exist as an H-bonded conformer, as postulated from the NMR results.

Key words: peptides, conformation, theoretical prediction.

S. E. THORNTON et S. FRAGA. Can. J. Chem. **69**, 1636 (1991).

Afin d'évaluer la possibilité de stabilisation de sa structure par une liaison hydrogène et un pont de sel, on a étudié le peptide Asp-Glu-Lys-Ser en utilisant le programme ALTA:maPS simulant les conditions de pH et l'influence du solvant. Les résultats théoriques confirment que, en solutions aqueuses, à des pH neutres mais non acides, il existe un pont de sel qui relie les chaînes latérales des portions Glu et Lys; ces conclusions sont en accord avec les observations faites par des études RMN. Par ailleurs, les calculs indiquent que, en solutions aqueuses, à tous les pH, il n'existe pas de liaisons hydrogènes. Le fait qu'une simulation sous vide démontre l'existence d'une liaison hydrogène entre le groupe CO peptidique du résidu Asp et le groupe NH peptidique du résidu Ser suggère qu'une étude de dynamique moléculaire pourrait confirmer qu'un faible pourcentage (moins que 25%) des molécules peptidiques peuvent exister sous la forme d'un conformère comportant une liaison hydrogène, comme on peut le déduire des résultats de RMN.

Mots clés : peptides, conformation, prédictions théoriques.

Introduction

The practical significance of being able to predict the spatial conformation of peptides "from scratch" (i.e., from their amino acid sequences or primary structure) has motivated the dedication of considerable efforts to this task. A variety of potentials have been developed for this purpose and implemented in corresponding software packages, such as AMBER, CHARMM, ECEPP, MMPEP, etc. (for details and references, see the recent works in ref. 1).

At this laboratory, work in this area was developed in various stages. First, a potential was proposed (2) for the study of molecular interactions and associations. This potential was expressed as a summation of all the atom–atom pair potentials (AAPP) for the two interacting molecules, with the AAPP's given as $1/R$ expansions (with terms in $1/R$, $1/R^4$, $1/R^6$, and $1/R^{12}$). The coefficients of those terms were obtained by fitting of the accurate self-consistent field results of Clementi and co-workers (3–5) for the interaction of biomolecules (amino acids, purines, and pyrimidines) with water, with some semi-empirical considerations and modification by inclusion of a dispersion contribution. Later on, the above potential was adapted to the study of protein structures (6). Independently of these developments, and taking into account the difficulties in the theoretical prediction of the tertiary structure of proteins from their amino acid sequences, some effort was dedicated to the prediction of secondary structures (7–9). Finally, the complete formulation for the prediction of secondary structures, the determination of tertiary structures, and the molecular interactions was implemented in the software package ALTA:maPS (hereafter abbreviated as maPS) for the modelling and analysis of protein structures, either by themselves or in interaction with other systems (10).

The theoretical study of protein structures is based on a minimum energy criterion, with the goal of determining the global minimum in the conformational energy hypersurface. The considerable number of degrees of freedom in large peptidic structures may pose serious difficulties, which is not the case for short peptides. An additional advantage in the study of the latter is the possible availability of more complete experimental information, which allows for a more detailed evaluation of the theoretical procedure and of its results.

The tetrapeptide Asp-Glu-Lys-Ser (hereafter denoted in short as DEKS) corresponds to the sequence positions 7 through 10 of the collagen type I α-1 chain *N*-telopeptide (16 amino acids long) (11). The interest in this peptide arises from the fact that its conformation may correspond to a β-I turn and that β-turns have been postulated to play a significant role in the initiation of protein folding (12). Consequently, DEKS represents a very appropriate system for the test of both experimental and theoretical techniques.

Recently, DEKS has been studied (13) under varying conditions of solvent and pH, using several one- and two-dimensional NMR techniques for both proton and ^{13}C (such as COSY, ROESY, proton–carbon shift correlation, and selective

COLOC). The experimental results were interpreted using the software package ECEPP/2 (14), checking for consistency with the patterns of ROE's and the coupling constants.

This work presents the results obtained in the theoretical study of DEKS.

Calculations

The calculations were performed, on an IBM RISC System/6000, using the software package maPS.

Crystallographic structures of the individual amino acids were used in the initial construction of the peptidic chain, whose N and C termini were then protected with the groups H_3C-CO- and -HN-CH_3, respectively, in order to simulate the experimental conditions (13). (It must be noted that in the experiments the C terminus was protected by an -NH_2 group. The protection groups used in the theoretical calculations were chosen and incorporated into the program in the belief that they better simulate the situation in the complete peptide, eliminating or at least reducing unwanted interactions between the extremes of the chain in such short, test peptides as the one considered in this work.) In all the calculations described below, the backbone dihedral angles ϕ and ψ as well as the first side-chain dihedral angles χ_1 were optimized to one degree under a minimum energy criterion; the peptidic dihedral angles, ω, however, were set to, and maintained at, 180°, as usual.

Two sets of calculations were first performed for the isolated peptide. The sequence $D^-E^-K^+S$ (i.e., with ionized carboxyl groups in the side chains of the Asp and Glu residues and with the amino group in the side chain of the Lys residue in protonated form) was used for the modelling of the conformation of the peptide at an approximately neutral pH. On the other hand, the sequence DEK^+S was used for the simulation of the conformation at a low (acid) pH.

In each case the isolated peptide was constructed by successive formation of each peptidic bond, with optimization in each case of the ψ angle of the residue preceding the peptidic bond and of the ϕ and χ_1 angles of the residue following it. After the tetrapeptide was constructed, its termini were then protected, with optimization of the first ϕ angle and the last ψ angle of the peptidic chain. Then, the tertiary structure just obtained was fully optimized until convergence to one degree was reached for each angle. As a representative example, Fig. 1 presents schematically the structure obtained for $D^-E^-K^+S$, showing the H-pattern postulated from the experimental work (13). (See below for the quantitative discussion of the results.)

The resulting, optimized structures were then re-optimized in the presence of the solvent. The procedure used in this study is as follows. A solvent molecule is placed in the presence of the peptide, whose conformation is then re-optimized with consideration of the interaction with the solvent molecule. The latter is then allowed to approach the peptide, in a controlled manner, along the path of decreasing energy for the molecular association; only a maximum, preset displacement is allowed in this procedure in order to permit the solute to fully adapt to the existence of the solvent. Next, the peptide is re-optimized again, and the process is repeated until both the conformation of the peptide and of the molecular association peptide–solvent have stabilized (with mimimum energy). The solvent molecule is then incorporated into the peptide, as if it formed part of the closest residue; that is, it is included in the listing of atoms of the peptide, with the coordinates it had at the moment of stabilization. The procedure is then repeated for successive solvent

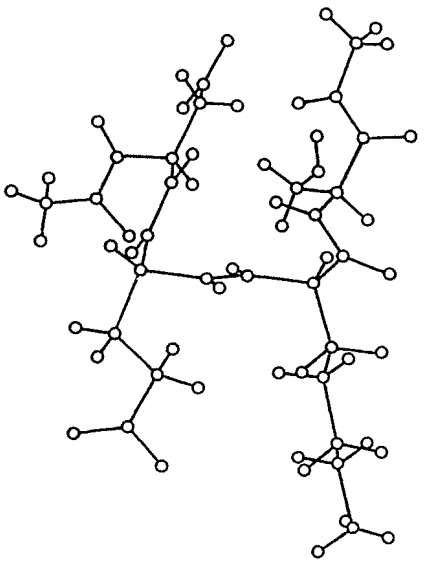

FIG. 1. Schematic representation of the structure obtained for *N*-acetyl-$D^-E^-K^+S$-NH-CH_3. The salt-bridge is established between the side chains of the Glu and Lys residues, which form the lower arms of the H-pattern. See, for comparison, the figure postulated from the experimental results (13).

molecules. As the number of solvent molecules added increases, their stabilization positions will lie farther and farther from the peptide, with less and less effect on its conformation. For that reason, the present calculations were carried out until a total of only six solvent molecules had been incorporated.

This simulation will allow for the consideration, to a certain extent, of the influence of the solvent on the conformation of the solute. Comparison of the resulting conformations for the peptide (structure $D^-E^-K^+S$, alone and in the presence of solvent, and structure DEK^+S, alone and in the presence of solvent) will yield the necessary information for a discussion of the effect of both the pH and solvent on the conformation of the peptide. It must be emphasized, however, that the procedure adopted in this work, with successive instead of simultaneous addition of the solvent molecules, will provide only an approximate simulation of the solvation process.

Although the experimental results were obtained in both aqueous and CD_3OH/H_2O (60:40) solutions, the calculations were performed only with water. It is expected that, in terms of molecular interactions, the situation will be very similar for both types of solutions, given the high percentage of water.

Results and discussion

The experimental observations of Otter *et al.* (13) yielded information on the possible existence of a salt-bridge and a hydrogen bond, depending on the experimental (pH and solvent) conditions.

In particular, a clear correlation was observed between the existence of the salt-bridge and the pH of the solution. At approximately neutral pH, both in aqueous and in CD_3OH/H_2O (60:40) solutions, the evidence indicated the existence of a salt-bridge between the side chains of the Glu and Lys residues (i.e., between the respective -COO^- and -NH_3^+ groups). At a pH below the pK_a of the carboxyl groups, in aqueous solution, no evidence was obtained for the existence of a salt-bridge.

It seems, however, that the H-bond does not constitute a fundamental characteristic of the peptide conformation. An

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

indication of the existence of such a bond between the peptidic -NH group of the Ser residue and the peptidic -CO group of the Asp residue was obtained only in CD_3OH/H_2O (60:40) solution, at about neutral pH, being estimated[1] that less than 25% of the peptide molecules may exist as an H-bonded conformer. No evidence of the H-bond was observed in the other two cases (i.e., in aqueous solution at about neutral pH and in CD_3OH/H_2O (60:40) solution at acid pH).

The existence of the salt-bridge (or, equivalently, the dependence of the conformation on the pH) is confirmed by the theoretical calculations. Inspection of the conformations obtained for the isolated peptides shows that the distance between the (hydroxyl) oxygen of the $-COO^-$ group of the Glu residue and the nitrogen of the $-NH_3^+$ group of the Lys residue is 4.86 Å (in $D^-E^-K^+S$) and 9.81 Å (in DEK^+S); that is, a salt-bridge exists in $D^-E^-K^+S$ (at neutral pH) but not in DEK^+S (at acid pH). The corresponding distances, in the conformations obtained in the calculations performed in the presence of solvent (with six molecules added as described above) are 4.81 Å (in $D^-E^-K^+S$) and 8.05 Å (in DEK^+S); that is, the solvent will not destroy the salt-bridge.

On the other hand, analysis of the conformations obtained for the isolated peptides shows that the distance between the oxygen in the peptidic -CO group of the Asp residue and the hydrogen of the peptidic -NH group of the Ser residue is 2.67 Å (in $D^-E^-K^+S$) and 1.82 Å (in DEK^+S); that is, an H-bond exists in the isolated DEK^+S molecules (at acid pH) and a close-to-H-bond exists in $D^-E^-K^+S$ (at neutral pH). The interesting fact, however, is that in the presence of solvent (see above) no H-bond is observed in either case; the corresponding distances are 5.41 Å (in $D^-E^-K^+S$) and 3.87 Å (in DEK^+S).

These results confirm that in aqueous solution the peptide adopts, at neutral pH, a conformation stabilized by a salt-bridge, which does not exist in acid pH. A static calculation, as the present one, indicates that no H-bond exists in solution but it is possible, taking into account the results obtained for the isolated peptide, that a molecular dynamics study would show the possible existence of an H-bonded conformer.

Regarding the possible existence of a β-I turn, the results show that such is not the case. The dihedral angles φ and ψ for the Glu and Lys residues should have in such a case the values −60, −30, −90, and 0°, respectively, but the values obtained in the calculations are as follows:

	Isolated peptide	Solvated peptide
DEK^+S	−63, −21, −70, −17	−97, −51, −99, −3
$D^-E^-K^+S$	−57, −28, −158, 28	−160, −44, −140, 34

[1]G. Kotovych. Private communication.

These results show, taking into account the confirmed existence of the salt-bridge, that stabilization by the latter may be obtained with a conformation that is not necessarily that of a β-I turn.

In concluding, it may be mentioned that the relevance of considering solvation effects, even though in an approximate manner, has been confirmed in this work, which in addition shows the usefulness of maPS in the study of protein structures.

Protein secondary structure from FT-IR spectroscopy: correlation with dihedral angles from three-dimensional Ramachandran plots[1]

MICHAEL JACKSON AND HENRY H. MANTSCH
Steacie Institute for Molecular Sciences, National Research Council Canada, Ottawa, Ont., Canada K1A 0R6
Received May 28, 1991
This paper is dedicated to Dr. Richard Norman Jones

MICHAEL JACKSON and HENRY H. MANTSCH. Can. J. Chem. **69**, 1639 (1991).

The frequency of the so-called "amide I" band (amide C=O stretching vibration, νC=O) of proteins is discussed in terms of the dihedral angles of the various secondary structures present within proteins. We propose that in the case of intra- or intermolecular hydrogen-bonded amide carbonyl groups the frequency of this absorption can be directly related to the ϕ, ψ angles of the amide moieties for the major secondary structures. Amide I bands at frequencies above those found for non-hydrogen bonded amide carbonyl groups are rationalized in terms of a change in the third dihedral angle, ω. Rotation around the amide C—N bond in sterically demanding structures, such as turns where ω deviates from 180°, is expected to cause an increase in the electron density of the amide carbonyl groups and so increase νC=O to frequencies greater than that seen for unperturbed carbonyl groups.

Key words: FT-IR spectroscopy, proteins, structure, dihedral angles.

MICHAEL JACKSON et HENRY H. MANTSCH. Can. J. Chem. **69**, 1639 (1991).

On discute de la fréquence de la bande dite « amide I » (vibration d'élongation C=O de l'amide, νC=O) des protéines en fonction des angles dièdres de diverses structures secondaires présentes dans les protéines. On suggère que, dans les cas de groupes carbonyles d'amides impliqués dans des liaisons intra- ou intermoléculaires, la fréquence de cette absorption peut être reliée directement avec les angles ϕ et ψ des portions amides des structures secondaires principales. Les bandes amide I observées à des fréquences situées au-dessus de celles que l'on retrouve pour des groupes carbonyles d'amides qui ne sont pas impliqués dans des liaisons hydrogènes peuvent être rationalisées en fonction d'un changement du troisième angle dièdre, ω. On s'attend à ce que des rotations autour de la liaison amide C—N dans des structures implicant de fortes demandes stériques, comme dans les cas où ω s'éloigne de 180°, vont provoquer une augmentation dans la densité électronique des groupes carbonyles des amides et par la suite une augmentation de νC=O vers des fréquences plus élevées que celles observées avec des groupes carbonyles non-pertubés.

Mots clés : spectroscopie FT-IR, protéines, structure, angles dièdres.

[Traduit par la redaction]

The amide I band

The amide groups of proteins give rise to a prominant infrared absorption band, νC=O, which involves the amide carbonyl stretching vibration and is commonly referred to as the amide I band; it covers the range 1600–1700 cm^{-1}. Elliot (1) first demonstrated an empirical correlation between the frequency of the maximum of the νC=O band and the secondary structure of a range of proteins as determined by X-ray diffraction. These studies were extended by Susi *et al.* (2) and together with theoretical predictions (3) identified infrared spectroscopy as a potentially powerful tool for the structural characterization of proteins and polypeptides. Two major problems restricted the application of IR spectroscopy to the conformational analysis of proteins. The first was the almost blanket absorption of water in the spectral regions of interest. This problem is alleviated by the use of short pathlengths and digital subtraction routines, and (or) the use of ^2H_2O as solvent. The second problem was more difficult to overcome. No naturally occurring protein contains only one secondary structural motif. Each protein is composed of varying proportions of a number of commonly occurring secondary structures, namely α-helices, β-sheets and turns, together with polypeptide segments having little order. Each of these structures gives rise to a νC=O band, and the relative widths and peak separations are such that these individual bands cannot be resolved by increasing the instrumental resolution. The result is a broad νC=O band, from which relatively little information (apart from the overall peak maximum) can be gained. Obviously, the substructure of the νC=O band could provide important structural information. To this end, a number of band narrowing (often also called resolution enhancement) methodologies have been developed.

Fourier self-deconvolution

The most widely used band narrowing technique in IR spectroscopy of biological materials is Fourier self-deconvolution (4). Any absorption in an IR spectrum can be considered to be the result of the convolution of a line that has position but no shape (i.e., the Dirac δ function) with a lineshape (which has width but no position), to produce an absorption with both position and shape. In the Fourier domain this may be expressed as the multiplication of a cosine wave, whose period is determined by the frequency of the line, and a decaying exponential, the rate of decay being determined by the width of the lineshape, to produce an exponentially decaying cosine function. The more rapid the rate of decay, the wider the absorption profile. Obviously, if we could reduce the rate of decay of the cosine function we would reduce the width of the IR absorption band. This is achieved by multiplying the Fourier transform of the absorption band with an increasing exponential function. The inverse Fourier transform of the product then yields an absorption band of reduced width. Successful application of Fourier deconvolution to overlapping absorption bands can significantly enhance peak separation.

The application of deconvolution to the amide I band of

For personal use only.

proteins reveals the existence of considerable fine structure for most proteins. The newly visualized bands may then be assigned to specific secondary structures within the protein.

Assignment of amide I bands to specific secondary structures

Although by now hundreds of papers have been published on the FT-IR spectroscopic analysis of protein secondary structure (see refs. 5–7 for reviews), correlations between the position of the νC=O bands and a particular type of secondary structure remain on a semi-empirical basis. A large number of proteins, polypeptides, and peptides whose structures have been determined by X-ray have been examined by FT-IR spectroscopy and correlations made between the frequency of νC=O and the principle components of the protein secondary structure deduced from X-ray diffraction.

Correlation of structure with νC=O is relatively straightforward for proteins which have a high β-sheet or α-helical character. Thus absorptions in the regions 1630–1640 cm^{-1} and 1648–1657 cm^{-1} are generally attributed to β-sheet and α-helices respectively. However, assignment of absorptions outside these ranges is highly variable. Particular problems are encountered in the 1660–1700 cm^{-1} region of the spectrum. Absorptions in this region are often attributed to turns although this is complicated by the presence of the high-frequency component of the anti-parallel β-sheet absorption, which arises as a result of coupling of neighbouring amide C=O transition dipoles (such coupling is only apparent for β-sheet structures and does not produce splitting of bands associated with other secondary structural motifs). Attributing absorptions above 1660 cm^{-1} on a semi-empirical basis to individual secondary structures has thus met with less success than the assignment of the major bands. Herein we propose a different approach to correlating νC=O with structure. The first step is to correlate relative hydrogen bond strengths, which may be correlated with the dihedral angles φ and ψ from the well-known two-dimensional Ramachandran plot, with νC=O. In addition, we suggest that the Ramachandran plot should be extended to include the third dihedral angle, ω. With reference to this three-dimensional Ramachandran plot, the effect of variations in ω upon νC=O is then considered.

Correlation of νC=O with dihedral angles

An example of a 2-D Ramachandran plot is shown in Fig. 1. Two features are immediately apparent. Firstly, the appearance of two main clusters on the plot indicates that certain sets of dihedral angles, corresponding to the commonly occurring protein secondary structres, are favoured. Secondly, although certain sets of dihedral angles are favoured, the areas between clusters are still relatively well populated, that is, there is a continuum. We shall now show that the major populations of dihedral angles may be related to specific νC=O frequencies.

Values of the dihedral angles φ,ψ of −180°,180° correspond to an extended polypeptide chain such as those found upon thermal denaturation of a protein. In such an extended structure intramolecular hydrogen bonding is not possible. However, a planar, extended chain will be able to align extremely well with neighbouring chains, which will allow the formation of strong intermolecular hydrogen bonds. The formation of such very strong hydrogen bonds would be expected to result in a low νC=O frequency. In Fig. 2a we show the spectrum of

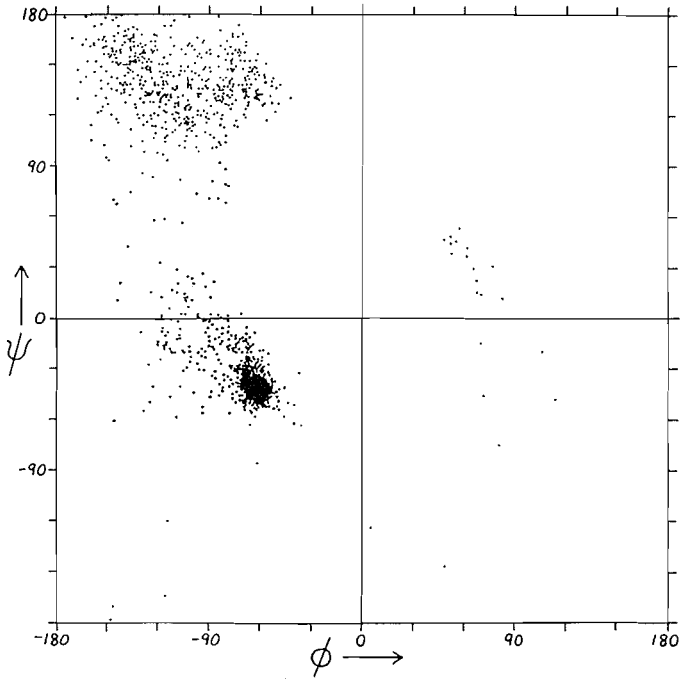

FIG. 1. Two-dimensional Ramachandran plot of the φ and ψ values found in a representative sample of X-ray structures (resolution 1.2–1.8 Å). Reproduced from J. S. Richardson and D. C. Richardson. *In* Prediction of protein structure and the principles of protein conformation. *Edited by* G. D. Fasman. Plenum Press, New York. 1990.

poly-L-lysine in its extended, intermolecularly hydrogen bonded form. As predicted, a low amide I maximum is seen (1612 cm^{-1}). Formation of strong intermolecular hydrogen bonds between extended strands (often referred to as an intermolecular β-sheet) has been suggested to account for the appearance of bands between 1610 and 1625 cm^{-1} in thermally and solvent denatured proteins (8, 9).

A reduction in φ,ψ to −120°,140° brings us to one of the more highly populated regions of the Ramachandran plot. Dihedral angles in this range still form structures of an extended type, although the reduction in the dihedral angles will now favour intramolecular hydrogen bonding between extended chains, forming the standard β-sheet structures. Packing constraints obviously mean that the strength of these intramolecular hydrogen bonds is less than those seen in the intermolecular β-sheet. We should therefore expect to see the νC=O for intramolecular β-sheet structures at a higher frequency, although still reflecting the presence of relatively strong hydrogen bonds. In Fig. 2b we show the spectrum of concanavalin A, a protein known from X-ray diffraction data to be predominantly β-sheet in structure. The νC=O maximum is indeed observed at a higher frequency than for poly-L-lysine, i.e., 1636 cm^{-1} compared to 1612 cm^{-1}.

Further changes in φ,ψ to −60°,−40°, bring us to the second main cluster of points in the 2-D Ramachandran plot. Successive φ,ψ angles of −60°,−40° produce a structure in which the C=O group of residue *n* is so aligned as to be able to form an almost linear hydrogen bond with the N—H group of residue *n* + 4, forming the well-known α-helix. The length of the hydrogen bond formed by this arrangement will be greater than that in intramolecular β-sheets, and we may expect to observe

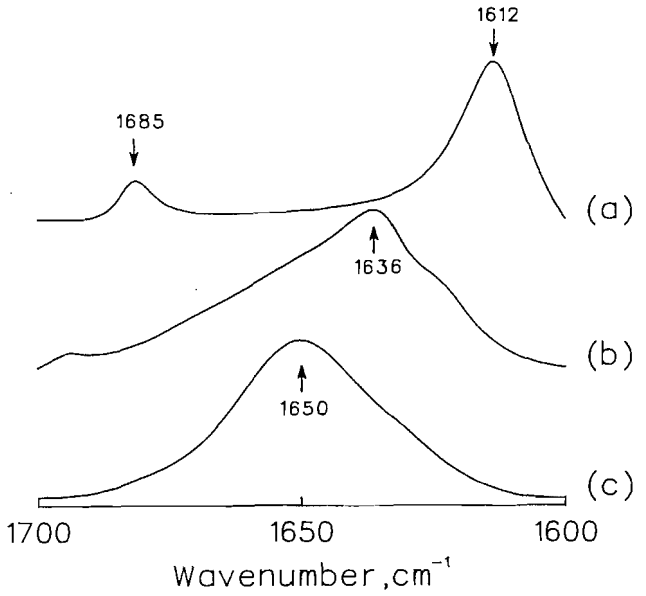

FIG. 2. FT-IR spectra in the νC=O region of poly-L-lysine in ^2H_2O, pD 12 at 60°C (a), of concanavalin A in ^2H_2O, pD 7.4 at 25°C (b), and of myoglobin in ^2H_2O pD 7.4 at 25°C (c).

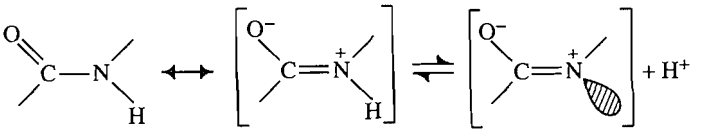

the νC=O maximum at a higher frequency. Examination of the spectrum of the α-helical protein myoglobin in Fig. 2c shows this to be the case, νC=O occurring at 1650 cm^{-1}. Other helical structures have been proposed, including the 3_{10}-helix and the α_{II}-helix. The 3_{10}-helix has φ,ψ angles of −70°,−5°, which results in the $^{\alpha}C$ atoms of residues *n* and *n* + 3 being exactly in line rather than the C=O and N—H groups. The result of this is that hydrogen bonds formed between C=O and N—H groups are nonlinear, which reduces their strength. We may therefore confidently expect distorted helical structures such as 3_{10}-helices to absorb at higher frequencies than α-helices. This has recently been demonstrated experimentally (10), 3_{10}-helices exhibiting an absorption band at 1660–1666 cm^{-1} in chloroform solution.

A non-repetitive sequence of φ,ψ angles for consecutive amino acid residues results in the formation of irregular hydrogen bonding patterns, that is, so-called random structures. As there exists a range of hydrogen bonding strengths and degrees of linearity, a broad absorption profile characterizes such structures; in ^2H_2O solution this is centered at 1644 cm^{-1}. This frequency is lower than that observed for hydrogen-bonded helical structures in the same solvent, which reflects the greater degree of hydrogen bond formation with solvent in disordered proteins.

Under certain circumstances, extended structures with a range of dihedral angles and no intramolecular hydrogen bonding are formed. We have recently shown this to be the case for all proteins and polypeptides dissolved in dimethyl sulfoxide (11). The νC=O band is observed at 1663 ± 2 cm^{-1} for every protein we have so far examined in this solvent. The appearance of this absorption is due to hydrogen bonding of the DMSO to all amide N—H groups, which totally disrupts the native structure of the protein. As all N—H groups are hydrogen bonded to the solvent and DMSO has no hydrogen bond donor capability, the amide carbonyl groups must be non-hydrogen bonded. We believe therefore that νC=O for free C=O groups in proteins and peptides occurs in the 1660–1665 cm^{-1} region of the spectrum.

We have shown above that absorptions appearing in the spectral region 1610–1665 cm^{-1} can be confidently assigned to intermolecular associations (1610–1625 cm^{-1}), β-sheet (1630–1640 cm^{-1}) and α-helical (1648–1652 cm^{-1}) structures, and free amide carbonyls (1660–1665 cm^{-1}), and that the frequencies of these various absorptions can be related to φ,ψ angles, which determine hydrogen bonding schemes. This still leaves a number of consistently reported (although relatively minor) absorptions between 1665 and 1695 cm^{-1} that are generally difficult to assign. It would not be expected that C=O bands should be seen at frequencies above that assigned to the free stretching C=O vibration, as any hydrogen bonding effects would tend to lower νC=O due to reductions in electron density of the C=O bond. To explain increases in frequency above that seen for the free C=O in DMSO, we envisage two mechanisms by which electron density in the C=O bond may be increased.

Firstly, a reduction in the dielectric constant of the environment will decrease the degree of polarization of the carbonyls and will result in an increase in electron density in the double bond. This will result in an increase in νC=O and may account for absorptions above 1665 cm^{-1}. The second way in which the electron density of the amide carbonyl can be increased relates to the planarity of the amide group. The amide group is planar due to resonance and tautomerism:

These structures are stabilized by hydrogen bonding and result in the C—N bond assuming partial double bond character due to a flow of electrons from the C=O to the C—N bond. Free rotation around this bond is therefore restricted, the planarity of the amide group is enforced, and the third dihedral angle, ω, is 180°. In other words the amide group is in a *trans* configuration. A reduction in the planarity of the amide groups will have the opposite effect, that is, electron flow from the C—N bond may restore the electron density in the carbonyl groups and so increase the νC=O maximum. Thus while we believe that free amide C=O groups in proteins and peptides generally exhibit an absorption in the range 1660–1665 cm^{-1}, this frequency may be increased by rotation around the C—N bond of the amide group. Such a situation may result from steric constraints imposed upon peptide groups in such rigid and conformationally restricted structures as turns.

In conclusion, we postulate herein that the major absorption bands arising from hydrogen-bonded amide C=O groups of proteins in the region 1610–1660 cm^{-1} are related to the dihedral angles φ,ψ, whereas we interpret absorptions above 1665 cm^{-1} as arising from non-hydrogen bonded amide C=O groups with distorted C—N bonds, in which the third dihedral angle, ω, deviates from 180°. In addition, a reduction in the dielectric constant of the environment of C=O groups may also increase the frequency.

The photoreduction of xanthone with diethylaniline in cyclodextrin cavities was studied at 77 K and room temperature by a time-resolved ESR technique. The radical pair observed in β- and γ-cyclodextrins showed inverted spin polarization compared to that of precursor excited triplet xanthone. This result is rationalized by taking account of the fixed orientation of the radical ion pair in the cyclodextrins. Frozen aqueous solutions and dried powder-like samples provided similar results. The spectrum of the radical pair was also detected in an aqueous solution of β-cyclodextrin at room temperature.

Key words: cyclodextrins, xanthone, spin polarization, radical ion-pair, time-resolved ESR.

Utilisant une technique de RPE résolue en fonction du temps et opérant à 77 K, on a étudié la photoréduction de la xanthone, par la diéthylaniline, dans des cavités de cyclodextrine. La paire de radicaux observée dans des β- et γ-cyclodextrines présente une polarisation de spin inversée par rapport à celle du triplet excité de la xanthone précurseur. On rationalise ce résultat en prenant en considération l'orientation déterminée de la paire d'ions radicalaire dans les cyclodextrines. Des solutions aqueuses congelées et des solutions séchées sous forme de poudre fournissent des résultats similaires. On a aussi détecté le spectre de la paire de radicaux dans une solution aqueuse de β-cyclodextrine, à température ambiante.

Mots clés : cyclodextrines, xanthone, polarisation de spin, paire d'ions radicalaire, RPE résolue en fonction du temps.

[Traduit par la rédaction]

Introduction

Cyclodextrins (CD) can be used to model enzymes, and their cavities provide unique reaction fields for specific physical and (or) chemical events (1). To explore these reaction fields, spin polarization transfer along with triplet–triplet energy transfer has been studied by a time-resolved ESR (TRESR) technique (2, 3). When xanthone and naphthalene were dissolved in γ-CD, excitation of xanthone led to the formation of the spin polarized triplet excited state of naphthalene. On the basis of this observation, a fixed conformation of the two molecules in the CD cavity was proposed. The chemical reaction in the CD cavity is of great interest and the observation of TRESR should provide important information about the reactivity and the conformation of the intermediate radical pair in the cavity.

In a series of TRESR studies of the excited states of aromatic compounds and intermediate radical pairs, low temperature organic glasses were employed as matrices (4–8). In glassy solution, an anisotropic dipole interaction between the two spins that are known to form a triplet state appears in the spectrum. The spin polarization pattern of the excited triplet state and the intermediate radical pair provides information about intersystem crossing and (or) polarization transfer during the reaction.

In glassy media, the photoreduction of benzophenone with *N*,*N*-diethylaniline produced a spin-polarized radical pair along with the excited triplet state of benzophenone (9). Both the radical pair and the excited triplet state showed a similar polarization pattern. Therefore, it was concluded that the hydrogen abstraction reaction took place from the excited triplet state of benzophenone and the direction of the active principal axis of the radical pair was nearly parallel to the C=O direction of precursor benzophenone. A similar study has been reported for the system acridine/acridan, where the TRESR spectrum of inverted spin polarization compared to the precursor excited triplet state of acridine appeared (10). The polarization of the radical pair is rationalized by taking account of the fixed relative conformation of the principal axes of the excited triplet state of acridine and that of the resultant radical pair.

In this paper, a TRESR study of the direct chemical reaction of photoexcited xanthone and *N*,*N*-diethylaniline inside β- and γ-CD cavities is reported, and its polarization transfer mechanism is briefly discussed. Dried CDs are shown to work as a good reaction field and an isolation matrix even at room temperature.

Experimental

A conventional X-band ESR spectrometer (Varian E-109), with minor modification, was used for the TRESR measurement. No field modulation was employed, so the TRESR spectra shown in the present paper are all given by the absorption and emission of the microwave signal (upward absorption and downward emission throughout). A nitrogen gas laser (Molectron UV24, $\lambda = 337.1$ nm) was used as the source of the excitation light pulse. The signals in several fixed time regions were accumulated by a boxcar integrator (NF, BX531) (3).

Commercially available xanthone (Xn) was recrystallized from ethanol and then purified by multiple zone refining. GR grade *N*,*N*-diethylaniline (DEA) was used immediately after distillation under reduced pressure. Commercially available GR grade α-, β-, and γ-CDs were used as received. The concentration of both Xn and DEA in aqueous solutions of CDs were 2×10^{-3} mol dm^{-3}. The concentration of CDs was changed from 2×10^{-2} to 2×10^{-3} mol dm^{-3} to investigate whether CDs possibly reveal an aggregated environment.

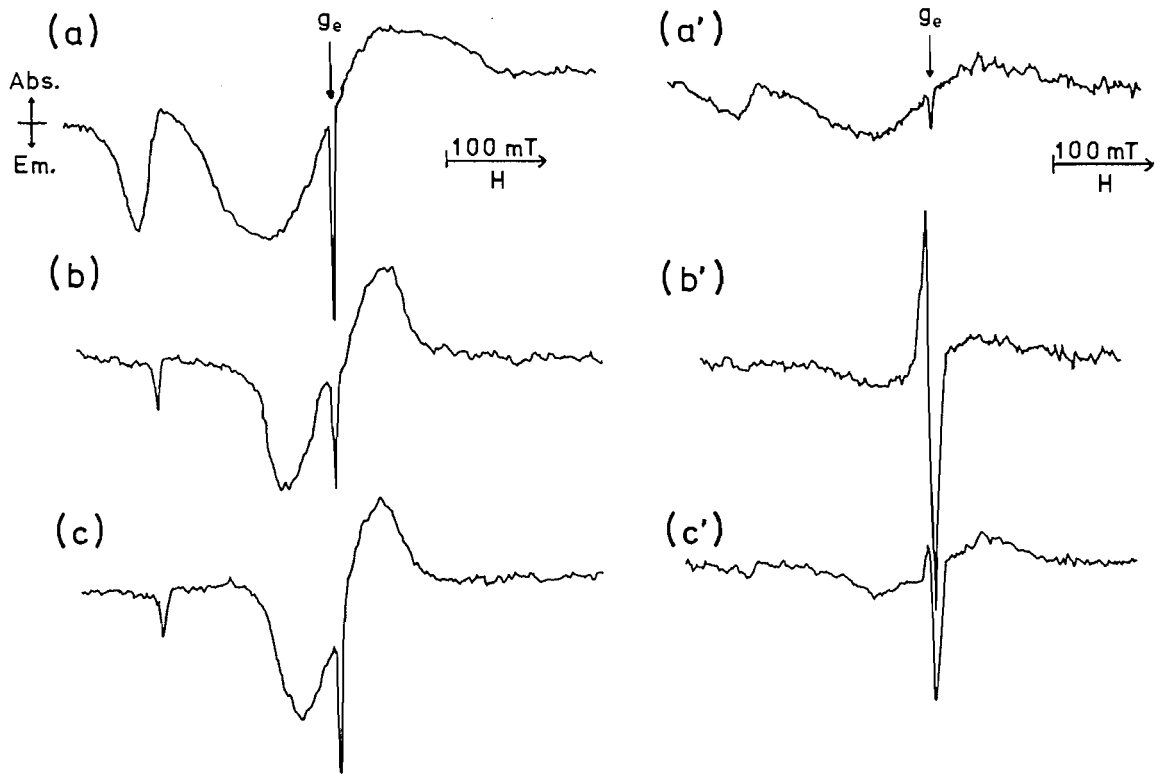

FIG. 1. Time-resolved ESR spectra observed for the systems of xanthone in (a) α-CD, (b) β-CD, and (c) γ-CD in the absence of DEA, and also in (a′) α-CD, (b′) β-CD, and (c′) γ-CD in the presence of DEA at 77 K. The observation time is 0.8–1.0 μs after laser excitation.

Measurement of the frozen aqueous solution of CDs was carried out at 77 K in a 5 mm o.d. quartz tube after degassing the sample. The powder sample was prepared by drying aqueous solutions of Xn, DEA, and CDs by passing dry nitrogen gas and degassing in vacuum. The TRESR measurements of the powder sample were carried out at 77 K and room temperature. The TRESR measurement of the liquid phase sample at the above concentration was performed by a flow method (11) at room temperature.

Results and discussion

Frozen solution of CDs

Figures 1a, b, and c show the TRESR spectra observed in the photolysis of the frozen aqueous solution of Xn and respective CDs at 77 K. These spectra were assigned to the excited triplet state of Xn (12). The differences in these spectra reflect the different environments in the respective CD cavities. The spectrum in α-CD is explained by the nonhydrated excited triplet state of Xn, while the spectra in β- and γ-CDs are explained by the hydrated Xn in the CD cavity. Especially in γ-CD, inclusion of two Xn molecules is possible. When DEA was added to the above solutions, either a similar or a different spectrum appeared, depending on the CD used. Figure 1a′ shows the spectrum observed for the system of Xn and DEA in α-CD. This spectrum is almost identical to that observed in the absence of DEA except for the signal intensity. This implies that the xanthone and the DEA molecules are not included in the same cavity or, if they are included, they do not interact. Figures 1b′ and c′ show the appearance of certain paramagnetic species with spin polarization in the presence of DEA, and the excited triplet state of Xn is still observed. The latter may be due to isolated Xn that does not interact with DEA under the influence of CDs.

Figure 2a shows the center portion of Fig. 1b′, which indicates that a spin-polarized radical pair is produced in the photolysis of Xn/DEA in β-CD. The computer-simulated TRESR spectrum of randomly oriented triplets (7) is shown in Fig. 2c for zfs (zero-field splitting) parameters $D = -9.7$ mT, $E = 0.8$ mT, with the highest population assumed to be in the middle spin-sublevel (Y′) which is located close to the lowest one. The use of a negative D value is rationalized by the assumption that a radical pair can be approximated in terms of a point dipole model. A small bump observed near the g_e field in Fig. 2a may be due to a small amount of stabilized radicals. The assignment of this radical pair and the cause of the spin polarization will be discussed later.

Figure 3a shows the center portion of the TRESR spectra observed in the photolysis of Xn/DEA in γ-CD (Fig. 1c′). The spectral line shape is asymmetrical compared to that observed in β-CD. The sharp emissive peak is located near the g_e field. This means that the spectrum is composed of both the radical pair and the product radical; in other words, there exist two different reaction modes in the γ-CD environment.

To see what happens for high concentrations of CDs, the following experiments were carried out. CD aggregate formation was confirmed for the β-CD system above a concentration of 2×10^{-3} mol dm^{-3} by observing the CD concentration dependence of the optical density of Xn. Therefore, aggregate formation must be the cause of the complication of the data. A quite interesting result was obtained when samples with low concentration of β- and γ-CDs (2×10^{-3} mol dm^{-3}) were passed through a micro-filter with 0.45 μm i.d. The observed TRESR spectra of the radical pairs were much clearer than those observed in high concentration CDs, that is, the spectra of excited Xn and stabilized radical had almost vanished. In the case of β-CD, no drastic spectral change of the radical pair occurred. There was only a slight decrease of the emissive signal of the radical near the g_e field as shown in Fig. 2b. In the case of γ-CD, however, the spectrum of the radical pair

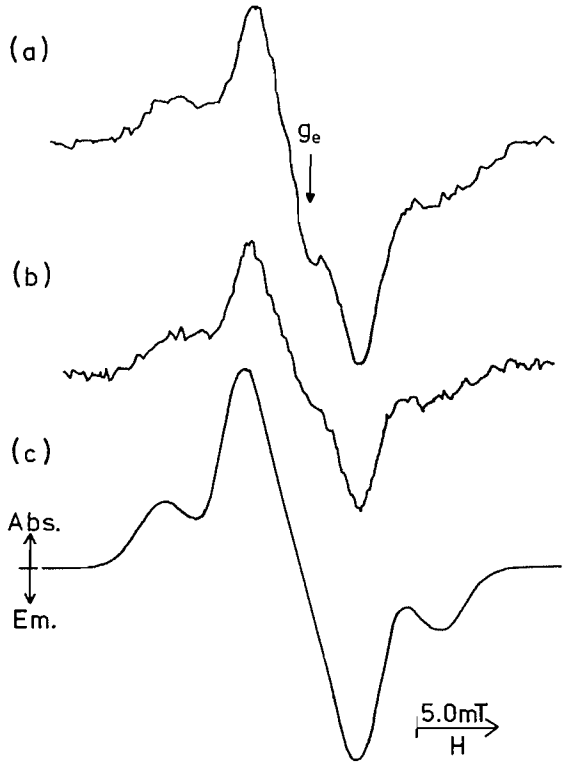

FIG. 2. Time-resolved ESR spectra observed at 0.8–1.0 μs after laser excitation for the system of xanthone/DEA in β-CD. (a) [β-CD] $= 2 \times 10^{-2}$ mol dm^{-3}, (b) [β-CD] $= 2 \times 10^{-3}$ mol dm^{-3} (see text), and (c) simulated spectrum (the relative population rates $P_{x'}/P_{y'}/P_{z'}$ = 0.1/0.9/0).

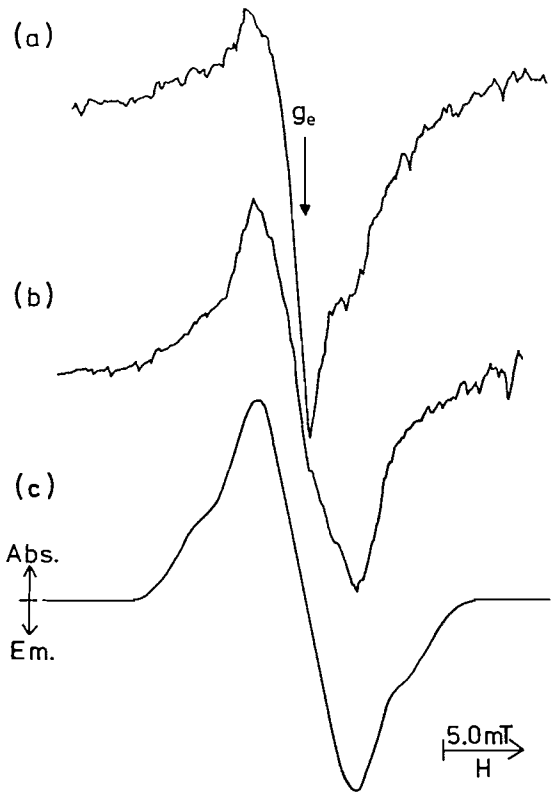

FIG. 3. Time-resolved ESR spectra observed at 0.8–1.0 μs after laser excitation for the system of xanthone/DEA in γ-CD. (a) [γ-CD] $= 2 \times 10^{-2}$ mol dm^{-3}, (b) [γ-CD] $= 2 \times 10^{-3}$ mol dm^{-3} (see text), and (c) simulated spectrum (the relative population rates $P_{x'}/P_{y'}/P_{z'}$ = 0.1/0.9/0).

became sharper and the emissive component of a stabilized radical was not observed. These results lead to an important conclusion. Most CD molecules exist as aggregates under high concentration conditions and the many xanthone molecules in the CD cavity are isolated in the aggregate. Under these conditions, the excited triplet state of xanthone is observable. Under low concentration conditions, the Xn molecule in the unaggregated CDs can react with DEA located close to, or included with, the Xn. In γ-CD, whose cavity size is larger than that of β-CD, the effect of CD aggregation is significant. The trapped Xn in the aggregate of γ-CD may react with γ-CD or DEA located nearby to produce a stabilized radical with an emissive polarization as in the triplet mechanism of CIDEP (Chemically Induced Dynamic Electron Polarization) (13).

Figures 3b and c show the observed and simulated TRESR spectra of Xn/DEA in the γ-CD system for low concentrations of γ-CD. From the simulated spectrum, zfs parameters of $D = -7.4$ mT and $E = 0.3$ mT are determined. The Y′ sublevel is also the most actively populated level in this system, just as in β-CD. The smaller D value, compared to that in β-CD, implies that the distance between two dipoles is larger. This may reflect the relative cavity sizes.

In the photolysis of the homogeneous solution of Xn in 2-propanol in the presence of DEA, a Xn anion radical with an emissive pattern was observed.[2] A similar experiment was carried out in an SDS micellar solution in the presence of DEA, and the emissive Xn anion radical was also observed in this special system.[2] These results suggest that charge transfer between photoexcited Xn and DEA takes place, and the excited triplet state of Xn with the highest population of the upper sublevel is the precursor of this reaction. In the present system of CDs, no clear evidence for the assignment of the radical species forming the radical pair was obtained. However, the photochemical reaction in the homogeneous and micellar systems shown above and the theoretical consideration that will be discussed later suggest the formation of a radical ion pair composed of a Xn anion radical and a DEA cation radical under the influence of β- and γ-CDs.

The inside diameters of α-, β-, and γ-CDs are known to be about 0.45, 0.7, and 0.85 nm, respectively (1). The different size of these CD cavities may be one of the crucial points that determine the inclusion conditions. In α-CD, only a single molecule can be included because of the small size of the cavity. In β- and γ-CDs, partial and (or) complete inclusion (see below) of the two molecules may be possible. The distances of the two spins of the radical pair in β- and γ-CDs are estimated to be 0.66 and 0.72 nm, respectively, in terms of the point-dipole approximation. This difference may reflect the diameters of the respective CD cavities.

In the experiment of triplet–triplet energy transfer in γ-CD reported previously, inclusion of two molecules, Xn and naphthalene, that keep their molecular plane parallel, was proposed to explain the spin polarization transfer (2, 3). In β-CD, the observation of a reproducible triplet–triplet energy transfer failed because of the smaller cavity size compared to γ-CD. In the present case, we assume that a similar inclusion of Xn and DEA to those in the energy transfer experiment occurs and that charge transfer takes place between the two molecules. The observation of the radical pair in β-CD implies that com-

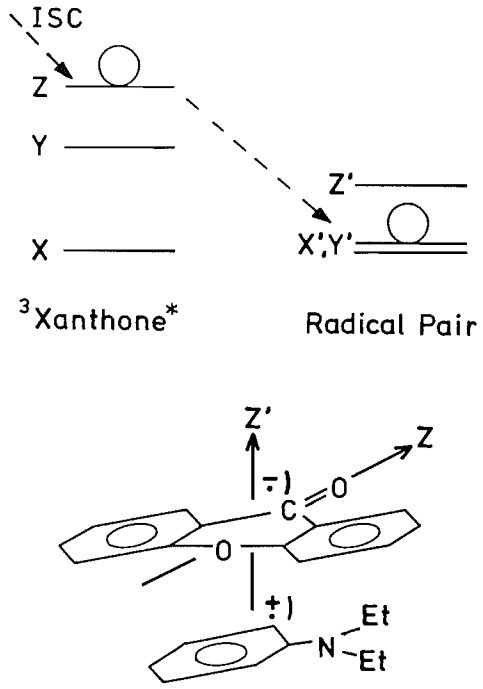

FIG. 4. Conceptual diagram of radical pair formation and polarization transfer in a CD cavity.

plete inclusion of the two molecules in the cavity is unlikely, but that partial inclusion of the coupled two molecules should occur. Observation and comparison of the optical absorption spectra of Xn in β-CD with and without DEA in aqueous solution showed no band shift of the absorption spectrum of Xn.[3] This indicates that there is no strong contribution of a charge transfer (CT) complex of Xn and DEA in β-CD.

The spin polarization of the radical pair is apparently inverted compared to that of the excited triplet state of Xn. To explain this, the following two mechanisms are postulated. (1) Excitation of a local electronic state of Xn, leading to the lowest excited triplet state by intersystem crossing (ISC) from the excited singlet state. This spin-polarized triplet state reacts with DEA located nearby to form a radical ion pair. (2) Excitation of the weak CT complex of Xn and DEA, which leads to the lowest excited triplet state of the complex by ISC from its excited singlet state, prior to charge separation. In the first model, the spin polarization is induced through ISC in locally excited Xn, and the conversion of the principal axes of the excited triplet state sublevels of Xn into those of the radical ion pair takes place during the very fast charge transfer reaction. The active Z-axis of the excited state of Xn becomes roughly perpendicular to the Z'-axis of the radical ion pair after the fast charge separation. This situation is illustrated in Fig. 4. This interpretation of the spin polarization transfer through the interconversion of the principal axes has been applied to T–T energy transfer (2, 3) and radical pair formation (8–10). In the second model, ISC of the excited CT complex may induce the characteristic spin polarization of the resultant radical pair. When the CT character of this excited complex is not strong enough, the local electronic state of Xn induces a similar spin polarization in the excited triplet state of the complex. Therefore, the same mechanism of inversion of the spin sublevel during the charge separation may be anticipated. In any case, the local excitation of Xn plays an important role for the induction of the spin polarization of the radical pair.

In addition, the use of triethylamine or diphenylamine or dimethylaniline instead of DEA did not provide a radical pair spectrum such as that observed in the system of Xn and DEA in β-CD.[3] They provided only an emissive spectrum without any special structure, probably because of the formation of the intermediate radical species or the radical pair, in which the two radicals involved are oriented randomly so that an exclusively emissive spectral pattern is expected just as for triplet–triplet energy transfer in glassy media (14). Therefore, the systems of Xn and DEA in β- and γ-CDs are very specific.

Powder condition of CDs

Figure 5 shows the TRESR spectra observed in the photolysis of a powdered β-CD sample at 77 K and room temperature. The spectrum observed at 77 K is almost identical to that of the frozen solution at 77 K (Fig. 2a). This indicates that the condition of Xn and DEA in the CD cavity and (or) in the CD aggregate is about the same as that in the frozen aqueous solution. The spectrum of the powdered sample at room temperature is very similar to that at 77 K. The spectral change with time indicates that the signal decay of this radical pair is almost independent of temperature. The polarization pattern gradually alters with time; that is, the intensity ratio of the center portion to the side peaks of the spectrum gradually decreases with time in favor of the totally emissive component. The decay of this signal is thought not to be due to ordinary spin lattice relaxation, but may be due to anisotropic ISC followed by a chemical reaction such as back charge transfer through the singlet manifold. The spectral change may be interpreted as depopulation of one of the spin sublevels of the in-plane principal axes and also the superposition of the signal due to the emissively polarized radicals.

Figure 6 shows the TRESR spectra similarly observed in the photolysis of the powdered γ-CD sample at 77 K and room temperature. The spectrum observed at 77 K is also similar to that observed in the γ-CD system of the frozen aqueous solution (Fig. 3a) except for the intensity of the emissive signal of the radical species near g_e. In this case, the spectrum at room temperature is a bit different from that observed for the same timing at 77 K, but similar to that observed at a later time at 77 K. This indicates that the spectrum of the radical pair deforms much faster at room temperature than that at 77 K. This difference may be ascribed to the larger diameter of the cavity and (or) the rough packing of the γ-CD aggregate compared to that of β-CD.

Since the powdered sample of β- and γ-CDs works like the frozen solution, the two molecules, Xn and DEA, are thought to be tightly restrained even without the aqueous medium. Therefore, it may safely be concluded that CD powders can be used for the observation of the excited molecules and (or) the intermediate radical pair even at room temperature.

Aqueous solution at room temperature

The TRESR measurement of the aqueous solution was carried out by the flow technique at room temperature. Only the β-CD solution provided a CIDEP-like A/E pattern as shown in Fig. 7. This spectrum seems to be easily assigned to some intermediate radical with the singlet precursor RPM (Radical Pair Mechanism) (13), but it is realized that it is almost identical to that observed in the frozen condition. In other words, the triplet-state radical pair is an apparent anomaly in aqueous solution at room temperature. We know that, for high concen-

trations of CDs, they form aggregates that may be too large to tumble freely under this condition. The restrained molecular motion makes it possible to observe the radical pair directly as a triplet state. In fact, the observation of this spectrum failed for low concentrations of β-CD (ca. 1×10^{-3} mol dm^{-3}) where no aggregate formation was expected.

Conclusion

The spin-polarized radical pair between the Xn anion and DEA cation radicals with a fixed orientation was produced under the influence of β- and γ-CDs in both frozen solution at 77 K, and dried powder at both 77 K and room temperature. The spin polarization patterns of these radical pairs were inverted compared to that in the excited triplet state of Xn. This inversion may be interpreted as the interconversion of the principal axes between the excited triplet state of Xn and the radical ion pair. The liquid sample of the β-CD system showed the same spectrum of the radical ion pair as that observed at 77 K, probably because of aggregate formation of β-CD in water.

The effect of added salts on carbon monoxide adsorption on platinum and palladium hydrosols: an FTIR study

MICHAEL R. MUCALO AND RALPH P. COONEY[1]

Chemistry Department, University of Auckland, Private Bag, Auckland, New Zealand

Received April 2, 1991

This paper is dedicated to Professor Richard Norman Jones

MICHAEL R. MUCALO and RALPH P. COONEY. Can. J. Chem. **69**, 1649 (1991).

Fourier transform infrared spectroscopy has been used to investigate the effect of added cations and anions on CO adsorption on platinum and palladium hydrosols. In general, anion effects on CO adsorption may be classified into three categories. In the first category, poisoning anions (*e.g.* CN^-, SH^-) block the surface against CO adsorption so that infrared spectra exhibit either no $\nu(CO)_{ads}$ bands or $\nu(CO)_{ads}$ bands at lower frequencies (<2070 cm^{-1}). In the second category, inert anions (*e.g.* the halides, citrate, $EDTA^{2-}$) have no apparent effect on $\nu(CO)_{ads}$. The third category is characterised by anions such as PO_4^{3-}, CO_3^{2-}, or stearate ion which affect $\nu(CO)_{ads}$ via the pH change that the dissolved anions cause in the metal hydrosol dispersion medium. Infrared spectra of platinum and palladium hydrosols in cyanide media were found to exhibit bands due to cyanate, tetracyanoplatinate(II), and tetracyanopalladate(II) arising from cyanide corrosion of the metal hydrosols. Ultraviolet/visible spectra of iodide ion in platinum hydrosols indicated that iodoplatinate(II) species had been produced. The band shape of $\nu(CO)_{ads}$ at 2070 cm^{-1} in platinum hydrosols is found to be sensitive to the state of dispersion of the hydrosol particles. Bands due to CO adsorbed on hydrosol particles in either a completely or partially aggregated state are weaker and broader with a decreased value of $\nu(CO)_{ads}$ relative to that of the unaggregated hydrosol.

Key words: platinum hydrosols, palladium hydrosols, CO adsorption, infrared spectroscopy, added salts.

MICHAEL R. MUCALO et RALPH P. COONEY. Can. J. Chem. **69**, 1649 (1991).

On a utilisé la spectrométrie infrarouge avec transformation de Fourier pour rechercher l'influence de l'addition des cations et des anions sur l'adsorption de la molécule de CO sur les hydrosols de platine et de palladium. En général, on peut classifier les effets des anions sur l'adsorption du monoxyde de carbone dans trois catégories. Dans la première catégorie se trouvent les anions empoisonnants (par exemple, CN^-, SH^-) qui bloquent la surface contre l'adsorption du CO en causant la disparition de la bande $\nu(CO)_{ads}$ du spectre infrarouge ou l'apparition de la bande $\nu(CO)_{ads}$ à une fréquence plus basse (<2070 cm^{-1} pour les hydrosols de platine). La catégorie secondaire se caractérise par des anions qui sont apparemment inertes (par exemple, les halogénures, le citrate et le tétra-acétate éthylènediamine). L'addition de ces anions aux hydrosols métalliques n'influencent pas la fréquence de la bande $\nu(CO)_{ads}$. Dans la troisième catégorie se trouvent les anions PO_4^{3-}, CO_3^{2-} et l'ion stéarate. L'influence de ces anions sur la bande $\nu(CO)_{ads}$ est le résultat du changement de pH qui est causé par la dissolution des anions dans le milieu de dispersion. Quand on introduit les hydrosols dans un milieu de cyanure, il est possible d'observer des bandes dans les spectres infrarouges de ces solutions, que l'on a assignées aux espèces cyanate, platinotétracyanure et palladotétracyanure. Ces espèces sont les produits formés par la corrosion des hydrosols dans le milieu de cyanure. Le spectre ultra-violet/visible de l'iodure dissous dans les hydrosols de platine a indiqué la présence du platinotétraiodure. On a noté que l'état de la dispersion du hydrosol de platine influe sur la forme de la bande $\nu(CO)_{ads}$ à 2070 cm^{-1}. Les bandes dues au CO adsorbé sur la surface des particules colloïdales dans un état complètement ou partiellement agrégé sont plus faibles et plus larges avec une valeur inférieure de $\nu(CO)_{ads}$ relative à celle de l'hydrosol non-agrégé.

Mots clés : hydrosols de platine, hydrosols de palladium, adsorption du CO, spectrométrie infrarouge, sels ajoutés.

1. Introduction

The study of adsorption processes occurring at metal sol particles has been facilitated by Fourier transform infrared spectra of adsorbed carbon monoxide which serves as a convenient spectroscopic surface probe molecule for this purpose (1–3) since the vibrational spectra of CO adsorbed at electrode, catalyst, and single crystal surfaces are well-documented (4, 5). The application of electric double-layer theory to explain (6) the stabilisation achieved by metal hydrosols implies that the particles in such systems may be considered as microelectrodes. The addition of electrolytes to negatively charged metal hydrosols affects double-layer properties and hence hydrosol surface properties. For example, aggregation of the colloid may occur if, above a critical electrolyte concentration, the Debye length of the hydrosol particle double-layers is sufficiently diminished (6). Changes in the vibrational surface spectra of CO adsorbed on colloidal platinum surfaces reflect the effects of added electrolytes on the surface properties of the platinum hydrosols. Both linear and 2-fold bridging CO have been detected for colloidal platinum in dichloromethane (7) and for colloidal palladium in methylcyclohexane media (8). An *ab initio* SCF study (9) of the Pd–CO chemisorption system has demonstrated that bond weakening in CO due mainly to $d_\pi(Pd)—\pi^*(CO)$ backbonding, leads to a calculated frequency ($\nu(CO)$) reduction of -72 cm^{-1} with an increase in C—O bond length of *ca.* 0.7 pm. The band due to CO adsorbed linearly on platinum (at *ca.* 2070 cm^{-1}) is used to study surface processes in platinum hydrosols and the band due to the two-fold bridging mode, B_2, of adsorbed CO (at *ca.* 1950 cm^{-1}) is used in studies of palladium hydrosols. In X-ray photoelectron spectra of the deposited hydrosols (10), there is evidence for thin layers or patches of platinum(II) oxides on the platinum hydrosols and palladium(II) and palladium(IV) oxides on the palladium hydrosols. Observed $\nu(CO)_{ads}$ values for CO adsorbed on platinum and palladium hydrosols are characteristic of CO adsorbed on platinum and palladium metal (4) thus the oxide layer is not believed to intervene between adsorbed CO and the metal. However, the extent of surface oxidation may influence the amount of metal available for CO adsorption as illustrated in a recent FTIR study of the influence of pH on CO adsorption on

platinum and palladium hydrosols (2). In particular, increasing the pH of the medium was found to lead to a decrease in $\nu(CO)_{ads}$ caused by a reduction in CO coverage which was believed to result from oxide film growth on the platinum and palladium particles.

In the present study, the effect of the presence of added electrolytes (cyanide, halides, hydrosulfide, and others) on carbon monoxide adsorption on platinum and palladium hydrosols has been monitored by infrared spectroscopy.

2. Experimental

Reagents

Unprotected borohydride-generated platinum hydrosols were the principal colloidal substrates used in this study. Borohydride-generated palladium hydrosols were studied to a lesser extent since the unprotected sols are colloidally stable for only a few hours after preparation whereas the platinum sols are colloidally stable for an indefinite period under ambient conditions. The use of unprotected hydrosols over protected poly (vinyl alcohol) hydrosols is favoured since the protecting agent is found to influence CO adsorption (3). The preparation, purification, and characterisation of the hydrosols by densimetry, ultraviolet/visible and X-ray photoelectron spectroscopy have been described in previous studies (2, 10). The potassium cyanide, potassium chloride, cesium chloride, and barium chloride (all analytical reagents), sodium stearate, and disodium hydrogen citrate (both laboratory reagents) were all supplied by BDH Chemicals and the trisodium phosphate ($Na_3PO_4 \cdot 12H_2O$), lithium chloride, potassium bromide (laboratory reagent grade), sodium chloride, potassium iodide, and anhydrous potassium carbonate (all Pronalys analytical reagents) were supplied by May and Baker Chemicals. Potassium fluoride, rubidium chloride, and strontium chloride (analytical grade) were supplied by Reidel-De-Haën and the anhydrous sodium acetate, sodium hydrosulfide, and calcium chloride hexahydrate (analytical reagents) were supplied, respectively, by Merck Chemicals, Aldrich Chemicals, and Koch-Light Laboratories. Disodium EDTA (ethylenediamine tetraacetate) and magnesium chloride (analytical reagents) were supplied by Ajax Chemicals. These salts were used without further purification. Millipore water, obtained by passing singly distilled water through a Milli-Q Continental Water System, was used for the preparation of the stock solutions of inorganic salts. The CO gas used (minimum purity, 99.5%) was supplied by New Zealand Industrial Gases Ltd.

Spectroscopy

All infrared spectra were recorded at 4 cm^{-1} resolution using a Digilab FTS-60 Fourier transform infrared spectrometer. Ultraviolet/visible spectra were recorded on a Hewett Packard 8452A diode-array ultraviolet/visible spectrophotometer. Platinum or palladium sol/inorganic salt solutions for infrared analysis were usually prepared by adding 0.2 cm^3 of inorganic salt stock solution (in general, 10^{-3} to 2 mol dm^{-3}) to 1.8 cm^3 of platinum or palladium sol to yield a salt concentration that was ten times less than that of the stock solution (10^{-4} to 0.2 mol dm^{-3}). Samples (*ca.* 0.15 cm^3) of these solutions were saturated with CO gas in a gas-bubbling vessel for 10 min and then examined by infrared spectroscopy as a thin film between calcium fluoride windows using the spectrum of the windows as a background. A spectrum of water was then subtracted from the resultant spectrum until water bands in the vicinity of $\nu(CO)_{ads}$ were suppressed. Asymmetric $\nu(CO)_{ads}$ band profiles were subjected to smoothing (Savitsky-Golay) and sub-band analysis based on Gaussian sub-bands using Spectra-Calc (Galactic Industries) curve-fitting software. The sum of the sub-band absorbances ($\Sigma(A_{CO})_i$, $i = 1$–3) obtained from bandfitting was then used (2) to calculate the CO coverage given by $\theta(CO)_{ads}$.

3. Results and discussion

Stability of hydrosol towards added electrolytes

In general, the bulk of the infrared data arises from spectral analysis of platinum sol/inorganic salt solutions in which the concentration of the inorganic salt was less than 10^{-2} mol dm^{-3} and the platinum sol was colloidally stable. Monovalent salt concentrations exceeding 0.02 mol dm^{-3} in platinum sols usually induced aggregation. Salts containing divalent or trivalent anions (*e.g.* Na_3PO_4 and K_2CO_3) normally caused aggregation of the platinum sol at salt concentrations of ≥ 0.01 mol dm^{-3} whereas salts containing divalent cations like $MgCl_2$ caused aggregation at salt concentrations of $\geq$ *ca.* 10^{-4} mol dm^{-3}. The aggregation concentrations observed in this study for the various inorganic salts are in agreement with critical coagulation concentrations reported in the study of platinum sol stability toward salts by Furlong *et al.* (11). Palladium hydrosol samples, on the other hand, were already aggregated prior to adding the inorganic salt. However, CO treatment was found to cause colloidal redispersal (2) of the palladium, so that $\nu(CO)_{ads}$ which was observed for such systems was related to spectra of a dispersed colloid.

Effect of salt addition on $\nu(CO)_{ads}$

Previous studies of carbon monoxide adsorption on platinum and palladium hydrosols as a function (2) of pH have demonstrated that surface adsorption of anions (viz., OH^-) reduces CO coverage and hence the value of $\nu(CO)_{ads}$ by the effective loss of dipolar coupling between the adsorbed CO molecules on the surface. Figure 1 represents the $\nu(CO)_{ads}$–θ data accumulated in this study arising from the addition of electrolytes which come under three categories (see later discussion) to platinum hydrosols. In general, Fig. 1 demonstrates that $\nu(CO)_{ads}$ decreases with decreasing θ which confirms that a loss of dipolar coupling is responsible for the reduction in $\nu(CO)_{ads}$ values. Figure 2 illustrates how the various anions studied affected $\nu(CO)_{ads}$ for CO adsorbed on platinum hydrosols. Tables 1 and 2 give salt concentrations, $\theta(CO)_{ads}$, $\nu(CO)_{ads}$, and pH values for some selected platinum and palladium hydrosol/inorganic salt systems. In general, the effects of anions on CO adsorption on platinum and palladium hydrosols have been summarised into three broad categories: (*i*) anionic poisons which completely block CO adsorption on the sol particles, (*ii*) inert anions which have no apparent effect on $\nu(CO)_{ads}$, and (*iii*) anions which affect $\nu(CO)_{ads}$ via the pH change brought about in the sol dispersion medium by the introduction of dissolved anions. The influence of the alkali and alkaline earth cations on $\nu(CO)_{ads}$ was found to be negligible except where the cations induced sol aggregation.

(i) Poisoning anions (SH^-, CN^-)

Cyanide and hydrosulfide anions are known to exhibit strong specific adsorption on platinum and it is well documented that sulfides are catalyst poisons (12). It is therefore not surprising that CO adsorption is completely blocked by these anions. In the case of the Pt sol/NaSH system, $\nu(CO)_{ads}$ was not observed for the CO-treated hydrosols for a series of NaSH concentrations starting from 0.013 to 0.00013 mol dm^{-3} (pH = 7.90). At this lower concentration limit, $\theta(CO)_{ads}$ is reduced leading to a lower $\nu(CO)_{ads}$ value of *ca.* 2065 cm^{-1} (see Fig. 2(*b*) and Table 1), indicating that either the residual poisoning effect of the SH^- ion or the effect of dispersion pH may be the dominant factor (see later). Bonzel and Ku (13) have shown that pre-adsorbed sulfur affects both the adsorption energy and the total amount of CO adsorbed on Pt(111) surfaces. In the case of the Pd sol/SH^- (0.01 mol dm^{-3}) system, CO treatment of the flocculated sol did not result in sol redispersal and no $\nu(CO)_{ads}$ was observed in the infrared spectrum of the CO-treated flocculated palladium. This indicated that CO was not able to displace the strongly adsorbed hydrosulfide anion.

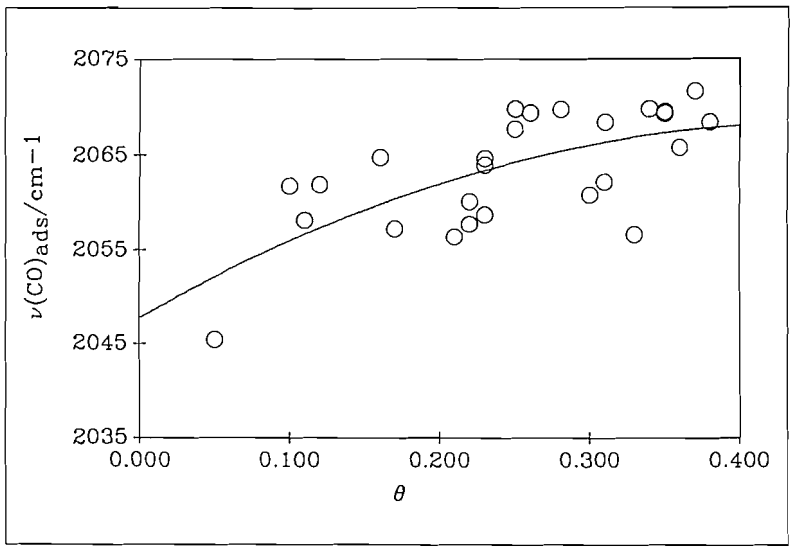

FIG. 1. Correlation of $\nu(CO)_{ads}$ with CO coverage (given by $\theta(CO)_{ads}$) for CO adsorbed on platinum sols in the presence of various added anions (collated data from many experiments).

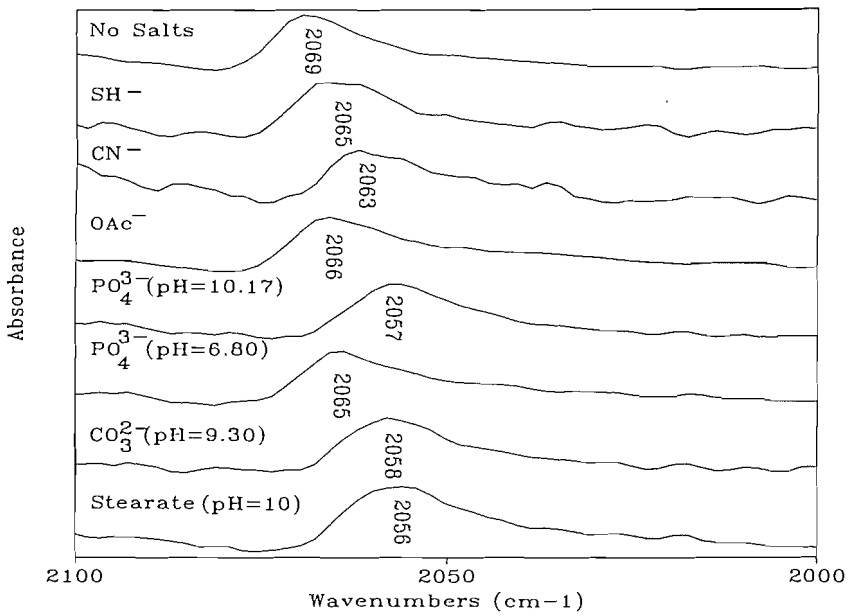

FIG. 2. Infrared spectra of CO adsorbed on a platinum hydrosol in the presence of various anions. Top to bottom: no anions added, 1.3×10^{-4} mol dm^{-3} NaSH, 1×10^{-4} mol dm^{-3} KCN, 1×10^{-2} mol dm^{-3} NaOAc, 2.2×10^{-3} mol dm^{-3} Na_3PO_4 (pH = 10.2), 2.2×10^{-3} mol dm^{-3} Na_3PO_4 (adjusted to pH = 6.8 using $HClO_4$), 2.2×10^{-3} mol dm^{-3} K_2CO_3 (pH = 9.3), and (*h*) 1 cm^3 of platinum sol saturated with sodium stearate (*ca.* 10^{-5} mol dm^{-3}, pH = 10.1).

Cyanide is recognised as being a better σ-donor ligand than carbon monoxide in the reactive and synthetic chemistry of discrete metal complexes. Infrared spectra of CO-treated Pt sol/KCN (0.1, 0.01, and 0.001 mol dm^{-3}) did not exhibit $\nu(CO)_{ads}$ bands, suggesting poisoning by preferential adsorption of cyanide. However, at a potassium cyanide concentration of 0.0001 mol dm^{-3} (pH = 7.28), $\nu(CO)_{ads}$ was detected at *ca.* 2063 cm^{-1} (see Table 1 and Fig. 2(*c*)) which is lower than the expected (2) value (*ca.* 2067 cm^{-1}) in the absence of cyanide at this pH (see later). This observation implies coverage of adsorbed CO as a result of surface poisoning by cyanide. The relatively low pH (7.28) of this system suggests that some cyanide ions may be removed from the solution hydrolysis equilibrium by adsorption. Infrared spectra of CO-treated palladium hydrosols in the presence of cyanide (0.1 mod dm^{-3}) also exhibited no $\nu(CO)_{ads}$ bands.

Infrared spectra of the aggregated Pt sol/KCN (0.1 mol dm^{-3}) samples revealed two relatively weak bands at 2133 and 2169 cm^{-1} in addition to the more intense band at 2080 cm^{-1} due to bulk solution cyanide (see Fig. 3(*b*), the 2133 cm^{-1} band is due (14) to the ν(CN) stretching mode of $[Pt(CN)_4]^{2-}$(aq) and the 2169 cm^{-1} band has been assigned (15–17) to the ν(CN) band of bulk cyanate (NCO^-)). These species are believed to arise from the enhanced corrosion of the platinum particles in the (pH ~ 11) cyanide medium. Indeed, this was confirmed when the same bands were observed for cyanide addition to platinum hydrosols from different preparations *viz.*, citrate- and electric-arc-generated (Bredig) sols. In contrast, spectro-

[a]Value in parentheses refers to the coverage of adsorbed CO on a platinum sol in the absence of added salts.
[b]Adjusted with 0.025 mol dm^{-3} $HClO_4$.

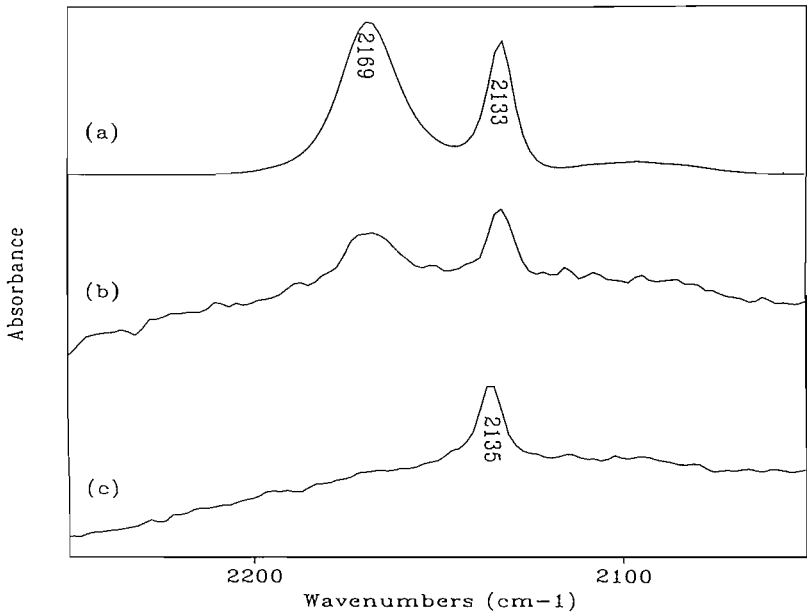

FIG. 3. Infrared spectra of the solution from (*a*) $PtO_2 \cdot xH_2O$ suspension in 0.1 mol dm^{-3} KCN, (*b*) platinum hydrosol (aggregated in 0.1 mol dm^{-3} KCN, and (*c*) clear solution arising from complete dissolution of palladium hydrosol in 0.1 mol dm^{-3} KCN. In all spectra the band due to bulk solution cyanide ($\nu(CN) = 2080\ cm^{-1}$) has been suppressed by subtraction.

electrochemical studies of cyanide corrosion of platinum electrodes have shown little (17) or no evidence (16) for tetracyanoplatinate(II) species. There was no evidence for bands due to $\nu(CO)_{ads}$ as reported in a spectroelectrochemical study of cyanide electrosorption at platinum electrodes (16). The infrared spectra of the species arising from cyanide corrosion of platinum hydrosols was found to be identical to that of platinum dioxide in the presence of cyanide (Fig. 3(*a*)) suggesting that the species observed in the spectra of the Pt sol/KCN system had arisen from cyanide interaction with an oxidised platinum surface.

In contrast, flocculated palladium sol particles dissolve quickly in 0.1 mol dm^{-3} KCN. The infrared spectrum of the resultant clear solution exhibits a single band (Fig. 2(C)) at *ca.* 2135 cm^{-1} which has been assigned (14) to the $\nu(CN)$ stretching mode of $[Pd(CN)_4]^{2-}(aq)$. The complete dissolution of platinum hydrosol particles in the 0.1 mol dm^{-3} KCN as opposed to the slow corrosion of the platinum hydrosol particles in the same medium supports the general observation that palladium is more reactive than platinum (18).

(ii) Inert anions (halides, citrate, acetate)

When platinum sol samples containing halide ions (F^-, Cl^-, Br^-, and I^-) in the concentration range 0.001 to 0.002 mol dm^{-3} were treated with CO, $\nu(CO)_{ads}$ was found to be insensitive to the presence of halide ion. Coverages given by $\theta(CO)_{ads}$ also show no clear trend (see Table 1). However, it was noted that the pH values of the platinum sol/KI samples were higher than for the iodide solution background whereas the other halides exhibited the opposite result. For example, the pH of a platinum sol/0.01 mol dm^{-3} KI solution was higher (7.62) than the pH of a straight 0.01 mol dm^{-3} KI solution prepared in the absence of the platinum hydrosol (6.25). This indicates a

possible reaction of iodide (see reaction [1]) with the surface layer of platinum(II) oxide:

[1] $Pt(OH)_2 + 4I \rightarrow [PtI_4]^{2-} + 2OH^-$

The surface hydroxide/oxide film has been detected (10) on the platinum sol surface by XPS (see Introduction). Indeed, when the concentration of KI in the dispersion medium is *ca.* 0.2 mol dm^{-3}, the platinum sol aggregates ($\nu(CO)_{ads}$, 2058 cm^{-1}), and an orange–pink colour is apparent in the clear solution after the flocculated particles have settled. Ultraviolet/visible spectra of this solution yielded bands at 338, 388, and 494 nm as well as a shoulder at 442 nm. The series of bands at 338 and 388 nm and shoulder at 442 nm agree approximately in position and relative intensity to those observed for the ultraviolet/visible spectrum of an aqueous solution (19) of $[PtI_4]^{2-}$(aq). The band at 494 nm has not been assigned as the wavelength does not correspond to any simple complex or polyiodide species (20). The ultraviolet/visible spectrum of the aquo complex $[PtI_3(H_2O)]^-$ has also been reported in the literature (19) but this species exhibits bands which differ from those observed in ultraviolet/visible spectra discussed in this study. It is possible that mixed iodohydroxo complexes ($[PtI_{4-x}(OH)_x]^{2-}$) contribute to the ultraviolet/visible spectrum.

Infrared spectra of a CO-treated platinum sol samples containing *ca.* 0.01 mol dm^{-3} sodium acetate exhibit $\nu(CO)_{ads}$ at *ca.* 2066 cm^{-1} at a pH in the range 6–7 (see Table 1). Thus the acetate ion appears to have a slight effect on CO adsorption, although the onset of aggregation of the hydrosol at the acetate concentration studied may be responsible for the decrease in $\nu(CO)_{ads}$ (see later). Radiotracer studies show that acetate adsorbs significantly on platinum electrode surfaces (21) at higher electrode potentials where appreciable oxidation of the electrode has occurred. The platinum sol is believed (10) to possess a thin oxide layer (*ca.* 2.07 nm) as measured from X-ray photoelectron spectroscopy so that acetate adsorption on this layer may be responsible for the slight decrease in $\nu(CO)_{ads}$. No bands due to adsorbed acetate were detected since the molar extinction coefficients (22) of carbonyl stretching frequencies ($\nu(CO)$) are in general smaller (by 2 to 6 times) than the value for CO adsorbed (23) on platinum (1200 dm^3 cm^{-1} mol^{-1}). The infrared spectrum of CO-treated palladium sol in 0.01 mol dm^{-3} sodium acetate (pH = 7.15) shows $\nu(CO)_{ads}$ to be at 1953 cm^{-1} (see Table 2) which is similar to $\nu(CO)_{ads}$ for this system in the absence of acetate (2) at pH 7.2.

When solutions of disodium hydrogen citrate are added to platinum sols, infrared spectra of the CO-treated sol samples show no anion-induced change in the position of $\nu(CO)_{ads}$ or in CO coverage (see Table 1). The result is not surprising since disodium hydrogen citrate is commonly used (11, 24) as a reductant for the preparation of metallic hydrosols from H_2PtCl_6 solutions. Moreover, infrared spectra of citrate-generated platinum hydrosols treated with CO have been reported by the authors (1) to exhibit $\nu(CO)_{ads}$ bands in the same region (2065–2070 cm^{-1}) as that observed for CO adsorbed on the borohydride-generated platinum hydrosols. Infrared spectra of CO-treated platinum sol solutions containing 0.001 mol dm^{-3} disodium EDTA and sodium oxalate also show negligible changes in the position of $\nu(CO)_{ads}$ (2070 cm^{-1}) and $\theta(CO)_{ads}$.

(iii) Anions affecting $\nu(CO)_{ads}$ via pH (PO_4^{3-}, CO_3^{2-})

Inorganic salts such as Na_3PO_4, K_2CO_3, and sodium stearate dissolved in platinum sols often cause significant pH changes in the dispersion medium. The increase in pH is thus believed to be the major factor responsible for the decrease in $\nu(CO)_{ads}$ observed when metal hydrosol samples containing these inorganic salts are treated with CO gas. This effect can be observed most clearly when frequency–pH data from anion addition to platinum or palladium hydrosols are superimposed on the $\nu(CO)_{ads}$ vs. pH plots reported (2) in an earlier publication (see Fig. 4) dealing with the influence of pH on CO adsorption on the hydrosols. For example, saturation of a 1.0 cm^3 sample of platinum sol with sodium stearate (pH = 10) was found to cause $\nu(CO)_{ads}$ to decrease from 2070 to *ca.* 2060 cm^{-1} (see Fig. 2(h)). The saturation of the sol was evident when further addition of solid sodium stearate led to no further increase in pH and no further decrease in $\nu(CO)_{ads}$. Therefore, dispersion pH appears to be a more important factor in the decrease in $\nu(CO)_{ads}$ than adsorption of stearate ion. This assumption is supported by Fig. 4, where the data relating to sodium stearate lies on the polynomial fitted to the frequency–pH data from ref. 2.

Trisodium phosphate concentrations of 0.001 to 0.002 mol dm^{-3} (pH = 10–11) in platinum hydrosols cause $\nu(CO)_{ads}$ to decrease to values in the range 2050–2060 cm^{-1} (see Fig. 2(*e*) and Table 1) while concentrations of 0.01 mol dm^{-3} lead to aggregation and to the appearance of $\nu(CO)_{ads}$ bands at 2038 cm^{-1}. For palladium sols in 0.01 mol dm^{-3} Na_3PO_4 (pH = 11.83, $\nu(CO)_{ads}$ decreases from 1953 cm^{-1} to 1944 cm^{-1} (see Table 2) as expected at this pH on the basis of earlier studies (2). Indeed, when a platinum sol in 0.002 mol dm^{-3} trisodium phosphate (pH = 10.2, $\nu(CO)_{ads}$ = 2057 cm^{-1}) is adjusted to pH 6.8 by perchloric acid addition, $\nu(CO)_{ads}$ increased to 2065 cm^{-1} (see Fig. 2(*f*) and Table 1) which illustrates the importance of pH in determining $\nu(CO)_{ads}$ in the platinum sol/phosphate ion system. This hypothesis is supported by the observation (Fig. 4) that phosphate systems appear to follow the frequency–pH curve closely. Platinum sol solutions containing 0.001–0.01 mol dm^{-3} potassium carbonate appear to cause similar decreases in $\nu(CO)_{ads}$ in infrared spectra as does phosphate (see Table 1 and Fig. 2(g)). Frequency–pH data for carbonate media also follow the curve in Fig. 4 except for some divergence at high pH. This may be attributable (23) to carbonate adsorption on a platinum oxide surface.

The frequency–pH data from the poisoning anions (CN^-, SH^-) and acetate have also been included in Fig. 4. In general, the poisoning of the platinum sol surface by cyanide is indicated

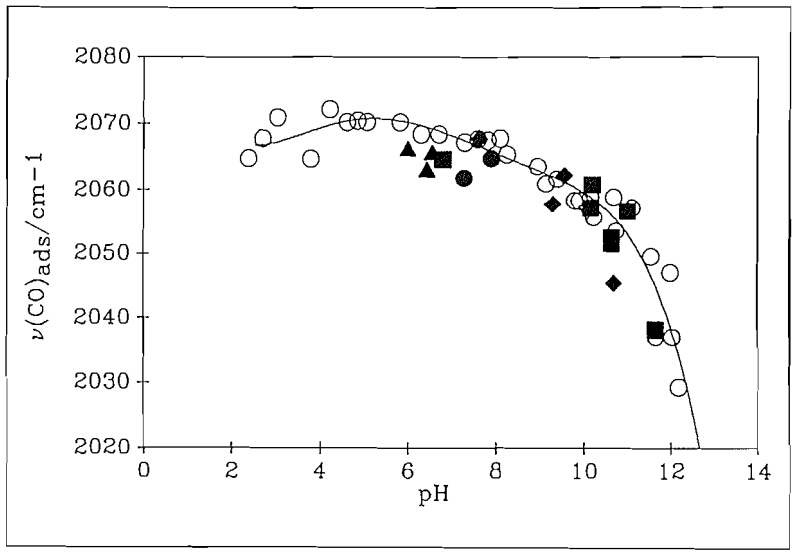

FIG. 4. $\nu(CO)_{ads}$–pH data from infrared spectra of CO adsorbed on platinum hydrosols in the presence of various anions superimposed on the frequency–pH data (open circles) for CO adsorbed on platinum hydrosols from ref. 2. Legend: phosphate (filled squares), carbonate (filled diamonds), acetate (filled triangles), cyanide, hydrosulfide (filled circles), and stearate (obscured by phosphate point at pH ~ 10).

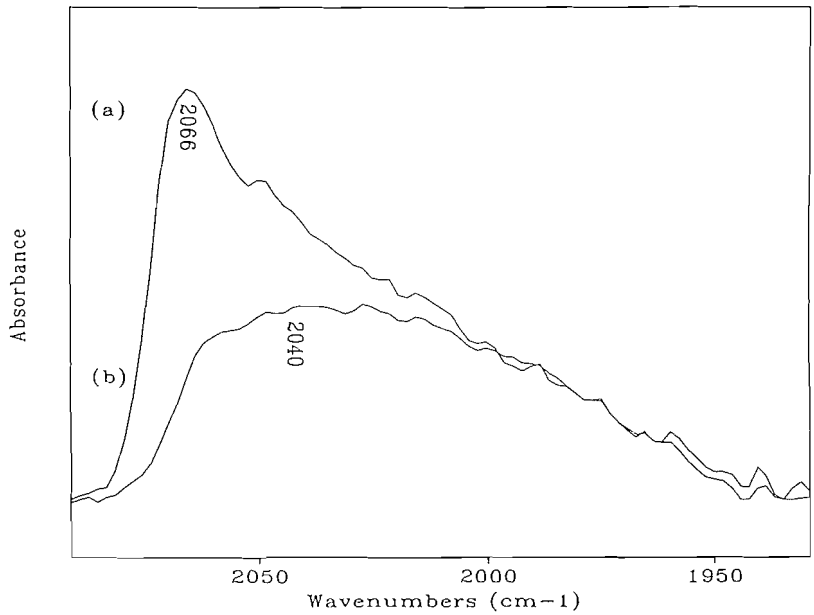

FIG. 5. Infrared spectra of CO adsorbed on a platinum hydrosol in the presence of calcium chloride: (*a*) 10^{-5} mol dm^{-3} $CaCl_2$ (hydrosol stable) and (*b*) 10^{-3} mol dm^{-3} $CaCl_2$ (hydrosol aggregated).

by the deviation of $\nu(CO)_{ads}$ observed for the 10^{-4} mol dm^{-3} cyanide system from the platinum sol frequency–pH curve. The decrease in $\nu(CO)_{ads}$ for the 1.3×10^{-4} mol dm^{-3} NaSH/platinum sol solution, in contrast, appears to yield a value of $\nu(CO)_{ads}$ which would be expected at a pH of 7.90. The absence of significant deviation of acetate frequency–pH data from the curve in Fig. 4 also reveals the insensitivity of CO adsorption on platinum sols in the presence of this anion.

Frequency–pH data relating to CO adsorption on palladium hydrosols in the presence of acetate and phosphate have been superimposed on the plot of $\nu(CO)_{ads}$ vs. pH (consisting of two straight lines) for the palladium hydrosol/CO system from ref. 2. The negligible deviation of this data from the plot supported the suggestion that these anions only exert a pH effect.

Effect of aggregation on the $\nu(CO)_{ads}$ band

In general, the shape of the $\nu(CO)_{ads}$ band is sensitive to aggregation processes in the platinum hydrosol. For CO adsorbed on platinum metal in a colloidally dispersed state, $\nu(CO)_{ads}$ is in general relatively narrow as depicted in Fig. 2(*a*) for CO adsorbed on platinum in the absence of added salts. However, CO treatment of platinum sols in the presence of inorganic salts close to critical coagulation concentrations leads to lower frequency $\nu(CO)_{ads}$ bands which are weaker and considerably broadened. For example, CO-treated solutions of platinum hydrosols in 0.01 mol dm^{-3} KCl have produced broad $\nu(CO)_{ads}$ bands at *ca.* 2055 cm^{-1} even though the colloid appears to be stable. The bulk solution from which the platinum sol/KCl (0.01 mol dm^{-3}) sample for infrared analysis was withdrawn was observed to aggregate on standing. The $\nu(CO)_{ads}$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/07/12
For personal use only.

band of a CO-treated platinum sol solution in 0.01 mol dm^{-3} sodium acetate appears weaker and broader than the $\nu(CO)_{ads}$ band for CO adsorbed on platinum in the absence of acetate. Given that the value for $\nu(CO)_{ads}$ is slightly lower than that expected at the dispersion pH (see Fig. 4), it is possible that the partial aggregation in the colloid sample induced by the concentration of sodium acetate used (*ca.* 0.01 mol dm^{-3}, see Effect of salt addition on $\nu(CO)_{ads}$) is responsible for the slight effect caused by acetate on CO adsorption (see earlier).

Presumably, the aggregation of the platinum sol induces surface heterogeneity and loss of surface area so that the $\nu(CO)_{ads}$ band broadens and weakens in intensity. Broadening of $\nu(CO)_{ads}$ for flocculated hydrosols has been noted in earlier work referring to aggregation of platinum hydrosols by $HClO_4$ (2) and by extraction of such sols into aliphatic alcohols (3).

The effects of cations on CO adsorption on platinum hydrosols have also been investigated. However, infrared spectra of CO adsorption on colloidally stable platinum hydrosols in the presence of the alkali (10^{-3} mol dm^{-3}) or alkaline earth metal chlorides (10^{-5} mol dm^{-3}) revealed no detectable differences in $\nu(CO)_{ads}$. Alkali and alkaline-earth metal chloride concentrations of 10^{-2} and 10^{-4} mol dm^{-3}, respectively, were observed to induce aggregation of the platinum sols. The difference in aggregation concentrations between the monovalent and divalent cations is indicative of the Schultze–Hardy Rule which states (6) that the valency of the cation is important in determining the critical coagulation concentration. Irrespective of the aggregating cation, CO-treatment of the flocculated platinum sol particles leads to the loss of the relatively sharp peak at 2070 cm^{-1} and the appearance of the expected broad $\nu(CO)_{ads}$ bands which are centered at *ca.* 2040 cm^{-1} (see Fig. 5). Other cations such as Pb^{2+} (as lead(II) acetate) added to platinum sols cause negligible changes in $\nu(CO)_{ads}$ for $[Pb^{2+}]$ in the dispersion medium below the coagulation concentration. Amphiphilic cations such as the cetyl trimethyl ammonium cation cause an initial decrease in $\nu(CO)_{ads}$ from 2070 to 2065 cm^{-1}. The invariance of $\nu(CO)_{ads}$ with further addition of CTAB suggests that a saturation limit for CTAB has been reached. The spectroscopic behaviour of this system is thus similar to that of the platinum sol/sodium stearate system although the pH (5.0) of platinum sol/CTAB samples differs negligibly from the natural pH of the hydrosol in the absence of CTAB. This is consequently reflected by the smaller deviation of $\nu(CO)_{ads}$ from 2070 cm^{-1}.

The following infrared spectroscopic study in this series will involve the adsorption of CO on rhodium hydrosols (25).

Introduction

Recent developments in laser techniques enable us to convert tunable visible dye laser light into tunable light in the IR region. Raman shifting in H_2 and differential frequency mixing are typical techniques for frequency conversion to the IR region. Though the bandwidth of the converted IR light is greater (typically $0.1 \sim 1\ cm^{-1}$) than that of a diode laser, it has a wider tunable range, higher peak power ($0.1 \sim 1$ MW) and shorter duration (<10 ns). These factors give us several possibilities in the study of the spectroscopy and dynamics of molecules. For example, pump–probe experiments with pulsed IR lasers allow ultrafast time-resolved spectroscopy in the IR region as the poor time resolution of typical IR detectors is overcome (1). The high peak power allows efficient generation of vibrationally excited molecules so that it is possible to observe their electronic transitions. Since with IR laser light we can populate particular vibrational levels that cannot be reached at room temperature, the observed electronic transitions may lead to new information on vibrational levels of the excited electronic state (2) and also to the study of the dissociation dynamics from high vibrational states of the excited electronic state (3–13). Another application of this type of laser is in photothermal spectroscopy (photoacoustic and thermal lensing spectroscopies). Since in photothermal spectroscopy a transition is detected by a thermal effect, this technique may be applied to nonemissive molecules and states. The high overtone vibrations of acetylene were observed by the photoacoustic spectroscopy with visible output of a dye laser (14). However, for IR transitions, the heat generated is small because of the small transition energy. It is desirable, therefore, to use a high sensitivity detection method and a tunable IR laser with high peak power. In this paper, we demonstrate the application of the pulsed tunable IR laser and photothermal spectroscopy to the measurement of the infrared spectrum of gaseous acetylene. The original aim of our study is the observation of electronic transitions of acetylene from particular vibrational levels of the electronic ground state rather than the observation of the infrared spectrum itself. The results obtained here provide an important step towards our final aim.

The following three techniques were used to generate pulsed IR laser light depending on the wavelength region: (I) 3100–3500 cm^{-1}: The difference wave produced by frequency mixing of the fundamental of a Nd^{3+}:YAG laser-pumped dye laser and the second harmonic of the Nd^{3+}:YAG laser (532 nm) with a $LiIO_3$ (LIO) crystal. (II) 5800–7700 cm^{-1}: The difference wave generation of (I), in which the 532 nm beam was replaced by the fundamental of the YAG laser (1.064 μm). (III) 7400–9700 cm^{-1}: The second Stokes stimulated Raman lines excited by the Nd^{3+}:YAG laser-pumped dye laser by using a H_2 Raman shifter.

Our experimental setup is shown in Fig. 1. A Nd^{3+}:YAG laser (Quantel YG 581-10) was operated at 10 Hz repetition rate. In method (I), the output of a dye laser was mixed with the 532 nm beam of the YAG laser in a LIO crystal mounted on an automatically tracked, angle-tuned stage (Inrad, IR Autotracker). In the case of (II), the setup was almost the same as (I) except that the dye laser beam was mixed with a fundamental of YAG laser. In method (III), the dye laser beam was passed through a H_2 Raman shifter which contained H_2 gas at a pressure of 20 atm. The IR laser light produced by these three methods was separated from the dye laser beam, 1.064 μm beam, or 532 nm beam by a visible-cut filter and a 1.064 μm reflection mirror. For photoacoustic spectroscopy, shown in Fig. 1(*a*), a cell was equipped with a home-made ribbon microphone and the sample gas pressure was ~200 Torr. For thermal lensing spectroscopy, shown in Fig. 1(*b*), the IR laser beam was passed through a 40 cm-long cell which contained sample gas at about 470 Torr. From the opposite side of the cell, a He–Ne laser beam was passed collinearly. The density of the transmitted He–Ne beam was monitored by a photodiode. The signal from the microphone or the photodiode was amplified by gains of 10 and 2000, respectively. The amplified signal was integrated by a digital boxcar integrator (PAR 4402/4420), and recorded on a microcomputer. Acetylene gas was used after passing through a Dry Ice/methanol trap for purification.

The observed spectra are shown in Fig. 2. Figure 2(*a*) shows the photoacoustic spectrum of ν_3 (CH anti-symmetric stretching 3287 cm^{-1}) region of gaseous acetylene. The IR laser light of 37 μJ energy per pulse was generated by method (I) using a DCM dye laser. The spectrum shows sharp rovibrational lines.

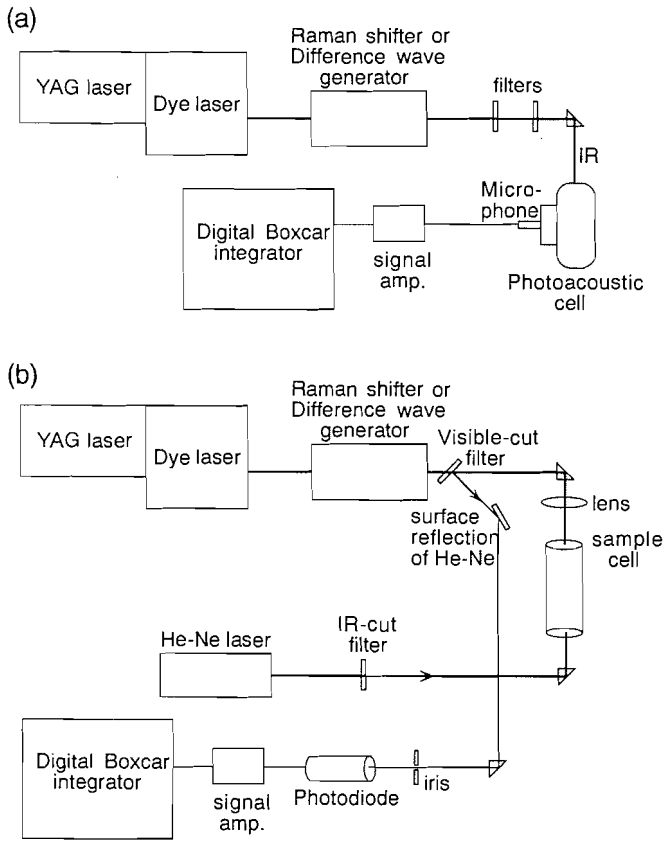

FIG. 1. Schematic diagram of the experimental setup for (*a*) photoacoustic spectroscopy and (*b*) thermal lensing spectroscopy.

The observed structures are complicated by Fermi resonance of ν_3 with several combination bands ($\nu_2 + \nu_4 + \nu_5$...see ref. 15). Figure 2(*b*) shows the photoacoustic spectrum of the $\nu_1 + \nu_3$ combination band (ν_1: CH symmetric stretching 3373 cm^{-1}). The IR laser light was generated by method (II) also using DCM. The energy of the IR laser was 1.0 mJ per pulse. The spectrum shows the regular rovibrational structure of a Σ–Σ transition. No extra lines due to vibrational mixing are observed. Assignments of the rotational lines are indicated in the figure. Both spectra are consistent with the known IR absorption spectrum of acetylene (15–20). The observation of well-resolved rovibrational structure is a good demonstration that the tunable IR laser is useful for detecting vibrational spectra with high sensitivity when combined with photoacoustic spectroscopy.

We have also used the tunable pulsed IR laser in thermal lensing spectroscopy. Figure 2(*c*) shows the thermal lensing spectrum of gaseous acetylene in the region of $\nu_1 + \nu_2 + \nu_3$ (ν_2: CC stretching 1974 cm^{-1}). Infrared laser light of 1.3 mJ per pulse was generated by method (III). The spectrum again shows the well-resolved rovibrational structure of a Σ–Σ transition, showing that combination of thermal lensing spectroscopy with a tunable IR laser is also useful for gaseous vibrational spectroscopy. We have also measured the photoacoustic spectrum for the same combination band, which yields a similar spectrum. The photoacoustic signal is about 100 times more intense than the signal from thermal lensing spectroscopy, giving a better signal-to-noise ratio for the photoacoustic spectrum. Despite the lower signal intensity, thermal lensing spectroscopy may still be useful because it does not require any special equipment such as a microphone or a specially designed cell.

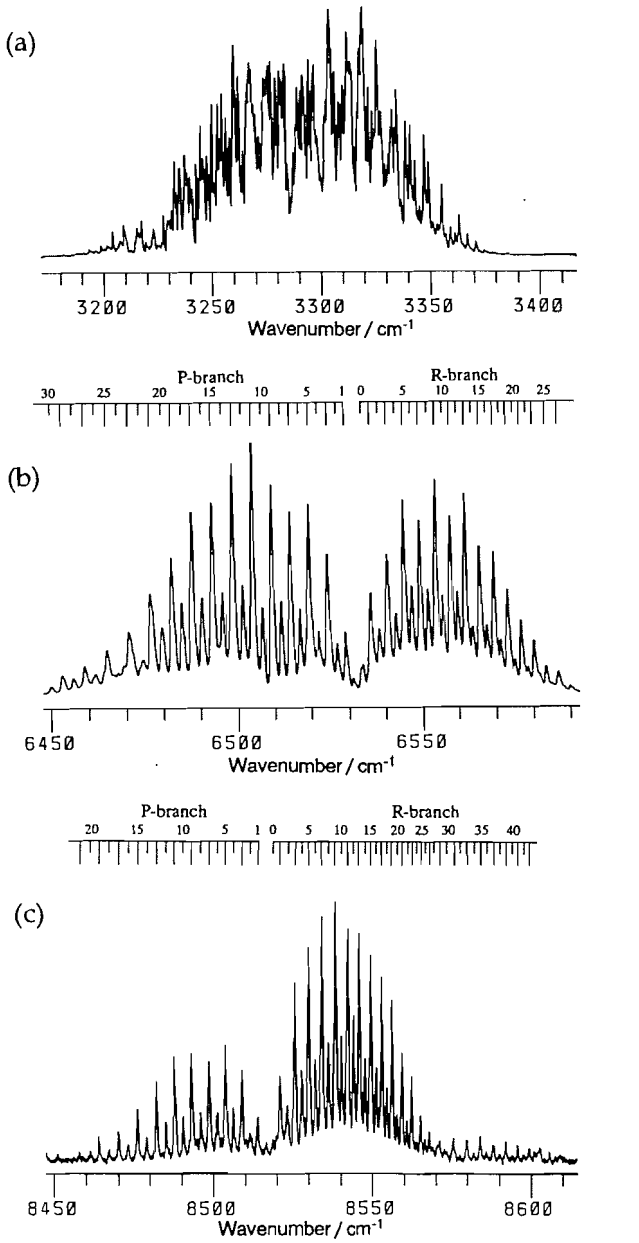

FIG. 2. Photoacoustic spectra of ν_3 (*a*), $\nu_1 + \nu_3$ (*b*) and a thermal lensing spectrum of $\nu_1 + \nu_2 + \nu_3$ (*c*) for gaseous acetylene.

In this paper, we have presented vibrational spectra of acetylene observed using a tunable pulse IR laser derived from a visible dye laser. The combination of this laser with photoacoustic and thermal lensing spectroscopies has proved useful for the measurement of vibrational spectra in the gas phase.

The infrared emission spectra of LiF and HF

H. G. HEDDERICH,[1] C. I. FRUM, R. ENGLEMAN, JR., AND P. F. BERNATH[1]
Department of Chemistry, The University of Arizona, Tucson, AZ 85721, U.S.A.
Received March 20, 1991
This paper is dedicated to Dr. Richard Norman Jones

H. G. HEDDERICH, C. I. FRUM, R. ENGLEMAN, JR., and P. F. BERNATH. Can. J. Chem. **69**, 1659 (1991).

The high resolution infrared spectrum of LiF has been measured in emission with the McMath Fourier transform interferometer at Kitt Peak. A total of 800 lines with $v = 1 \rightarrow 0$ to $v = 8 \rightarrow 7$ of the main isotopomer, ^{7}LiF, and 250 lines with $v = 1 \rightarrow 0$ to $v = 3 \rightarrow 2$ of the minor isotopomer, ^{6}LiF, were observed. These ro-vibrational transitions and the pure rotational transitions from the literature were fit to a set of Dunham coefficients Y_{ij} and a set of mass-reduced Dunham coefficients U_{ij}. The same spectrum shows 13 pure rotational emission transitions of HF in the vibrational ground state with $J = 13 \rightarrow 12$ to $J = 25 \rightarrow 24$. These transitions were used to determine an improved set of rotational constants for HF.

Key words: infrared spectra, LiF, HF.

H. G. HEDDERICH, C. I. FRUM, R. ENGLEMAN, JR. et P. F. BERNATH. Can. J. Chem. **69**, 1659 (1991).

On a mesuré les spectres d'émission infrarouge à haute résolution du LiF à l'aide d'un interféromètre à transformation de McMath Fourier au niveau Kitt Peak. On a observé 800 raies avec des valeurs de v allant de $v = 1 \rightarrow 0$ à $v = 8 \rightarrow 7$ pour l'isotopomère principal, ^{7}LiF, et on a observé 250 raies avec des valeurs de v allant de $v = 1 \rightarrow 0$ à $v = 8 \rightarrow 7$ pour l'isotopomère minoritaire. On a adapté ces transitions de vibration-ro et les transitions de rotation pure répertoriées dans la littérature à un ensemble de coefficients de Dunham Y_{ij} et à un ensemble de coefficients U_{ij} de masse réduite Dunham. Ces mêmes spectres montrent 13 transitions d'émission de rotation pure du HF dans l'état fondamental de vibration avec $J = 13 \rightarrow 12$ à $J = 25 \rightarrow 24$. On a utilisé ces transitions pour déterminer un ensemble amélioré de constantes de rotation pour le HF.

Mots clés : spectres infrarouge, LiF, HF.

I. Introduction

The infrared spectra of alkali halides have been of interest to spectroscopists for a long time (1, 2). However, high-resolution infrared data for these molecules have only become available after the introduction of diode laser and Fourier transform infrared spectrometers. Nevertheless, the first infrared data on LiF was obtained by Vidale (3) as early as 1959 with a Perkin-Elmer grating spectrometer. He observed the spectrum of LiF both in absorption and emission. However, the resolution was not high enough to obtain an unambiguous rotational assignment and, therefore, the correct band center. Vidale gave three possible assignments. Only after the microwave measurements on ^{6}LiF by Wharton *et al.* (4) did the correct assignment become apparent. Several additional papers report the infrared spectrum of LiF trapped in low temperature matrices (5–10).

The first high-resolution infrared data on LiF was published by Maki (11). He used a tunable diode laser system for the observation of ro-vibrational transitions with $v = 1 \leftarrow 0$ to $v = 8 \leftarrow 7$ for ^{7}LiF and ^{6}LiF. Diode lasers display many gaps in their spectral coverage. Therefore, only a few lines of each vibrational band were accessible. In this paper the complete emission spectra of ^{7}LiF and ^{6}LiF between 630 and 1030 cm^{-1} are published (Figs. 1, 2).

HF is an important gas for use as an absolute wavenumber standard. In 1987 Jennings *et al.* (12) published rotational constants for HF calculated from measurements in four different laboratories. Highly accurate data in the far infrared ($J = 1 \leftarrow 0$ to $J = 4 \leftarrow 3$) were obtained with a tunable far-infrared spectrometer at the National Bureau of Standards laboratory in Boulder. Transitions with $J = 5 \leftarrow 4$ to $J = 7 \leftarrow 6$ were measured with a commercial high-resolution Fourier transform spectrometer at the National Research Council, Ottawa, Canada. Lines with $J = 17$ to $J = 21$ were observed with a vacuum grating spectrograph (13) and lines with $J = 26$ to $J = 32$ with a tunable diode laser spectrometer at the University of Lille, France. In 1988 Jennings and Wells (14) remeasured the $J = 27 \leftarrow 26$ and $J = 33 \leftarrow 32$ transitions by using a tunable diode laser heterodyne spectrometer (15). Except for these two lines, the mid-infrared transitions are relatively inaccurate. Unfortunately the uncertainties in the molecular constants in this publication seem to be a factor of 10 too small. As a by-product of our work with LiF, we publish thirteen rotational transitions of HF in the range 500 to 900 cm^{-1}. A new fit including the far-infrared data and the diode laser measurements provide an improved set of rotational constants for HF.

II. Experimental

The high resolution infrared emission spectra of ^{6}LiF, ^{7}LiF, and HF between 500 and 1400 cm^{-1} were observed with the McMath Fourier transform spectrometer at Kitt Peak. The unapodized resolution was 0.0055 cm^{-1} with a liquid helium cooled As:Si detector and a KCl beamsplitter. The upper wavenumber limit was set by a wedged InSb filter while the lower limit was given by the transmission of the KCl beamsplitter and by the detector response. The spectrum of LiF was taken accidentally during an attempt to observe the infrared spectrum of MgF_2.

Solid MgF_2 was heated to about 1500 K in an alumina tube furnace. The apparatus used for the experiment was described in detail earlier (16). The heating rate was about 5 K/min. The temperature of the furnace was measured with a chromel–alumel thermocouple placed between the heating elements and the alumina tube. Deposition of solid material onto the windows was avoided by pressurizing the cell with 5 Torr of argon. A series of spectra were taken as the furnace heated up and then cooled down. Initially a globar was placed behind the tube furnace and its image was focused on the 8 mm aperture of the Fourier transform spectrometer. No absorption spectra were observed, but when the globar was shut off (at a temperature of about 1300 K) an emission spectrum was monitored. The inten-

[a]Numbers in parentheses are estimated uncertainties.

sities of the emission lines increased with higher temperature. The maximum temperature which is accessible with our current system is about 1500 K and it was at this temperature that the best emission spectrum was obtained. All emission signals decreased rapidly as the furnace cooled and disappeared at about 1200 K.

III. Results

The emission features were observed in the region where the infrared spectrum of MgF_2 was expected (Figs. 1, 2). However, the high resolution spectrum showed a pattern typical of a diatomic molecule. After some thought and a literature search we found that the emission spectrum belonged to LiF (11). The presence of Li in our system was puzzling but in a previous experiment the alumina tube was used to vaporize LiNC. Despite careful cleaning of the cell, some Li remained on the walls of the alumina tube. At higher temperatures the MgF_2 could react with water (which is always present in the system) and form HF. The HF can react with the Li impurities and produce LiF. Direct reduction of MgF_2 with Li is also possible but MgF was not detected. An additional reaction of HF with the alumina tube took place to form AlF. The emission of AlF was observed in the spectrum (17).

The spectral analysis program PC-DECOMP, developed by J. W. Brault, was used for data analysis. The rotational line profiles were fit to Voigt lineshape functions. The strong lines show a "ringing" caused by the $(\sin x/x)$ lineshape function of the Fourier transform spectrometer. The ringing was eliminated by using the "filter fitting" routine available in PC-DECOMP. The signal-to-noise ratio for the strong lines was better than 1000 and the resulting resolution-enhanced line width was 0.0005 cm^{-1}. The HF lines were used for absolute calibration (+/−0.0002 cm^{-1}) of the spectrum. For this calibration the HF absorption lines, taken in a spectrum at lower temperature, were calibrated against CO_2 (18).

The assignment of the vibrational bands of the main isotopomer ^{7}LiF was straightforward (Table 1). Data reduction was made by using Dunham's equation (19)

$$[1] \quad T(v,J) = \sum_{i,j} Y_{ij} \left(v + \frac{1}{2}\right)^i [J(J+1)]^j$$

Pure rotational transitions reported by Pearson and Gordy (20) were included in the fit. The Dunham coefficients obtained from this fit are shown in Table 2.

[a]Each isotopomer was fit independently. One standard deviation in parentheses.

The assignment of the vibrational bands of the minor isotopomer, ^{6}LiF, was carried out by comparing predicted line positions with the unassigned lines in the spectrum. The line positions for ^{6}LiF are also shown in Table 1. The mass-dependent Dunham coefficients Y_{ij} are listed in Table 2.

Finally, all infrared and microwave data for LiF was combined and fit to the mass-reduced Dunham expression including Watson's correction due to the breakdown of the Born–Oppenheimer approximation (21, 22)

$$[2] \quad Y_{ij} = \mu^{[(i+2j)/2]} U_{ij} \left[1 + \left(\frac{m_e}{m_{Li}}\right) \Delta_{ij}\right]$$

where μ is the reduced mass, U_{ij} are the mass-independent parameters, m_{Li} is the atomic mass of Li (23), m_e is the electron mass, and Δ_{ij} is the mass scaling factor for the Li atom. The

data required two Δ's, one for U_{10} ("ω_e") and one for U_{01} ("B_e"). The final mass-independent coefficients and the Δ's are listed in Table 3.

The energy levels of HF were fit to the expression (24)

$$[3]\quad E_v(J) = B_vJ(J+1) - D_v[J(J+1)]^2 + H_v[J(J+1)]^3 + L_v[J(J+1)]^4 + M_v[J(J+1)]^5$$

The fit includes all lines listed in Table 4 and Table 5 shows the determined constants.

IV. Conclusion

The high-resolution infrared emission spectra of LiF and HF were observed with a Fourier transform instrument. The ro-vibrational transitions of the fundamental band and of seven hot bands for ^{7}LiF and of three bands for ^{6}LiF were rotationally analyzed. Pure rotational transitions for HF were also observed and enabled us to calculate an improved set of molecular constants. The accuracy of the line positions allows the use of HF as an absolute wavenumber standard.

On vibrational force field calculations[1]

W. F. MURPHY

Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received April 22, 1991

This paper is dedicated to Dr. Richard Norman Jones

W. F. MURPHY. Can. J. Chem. **69**, 1672 (1991).

A series of computer routines for performing normal coordinate calculations of harmonic vibrational frequencies is described. These are designed for operation on current-generation computers having direct-access storage. Example results are given for the chain isomer of disulfur difluoride.

Key words: vibrational force field calculations, normal coordinate calculations, harmonic force fields.

W. F. MURPHY. Can. J. Chem. **69**, 1672 (1991).

On décrit une série de routines d'ordinateur permettant de calculer les coordonnées normales des fréquences vibrationnelles harmoniques. Elles ont été développées pour être utilisées avec les ordinateurs de la présente génération possédant un accès direct aux données enregistrées. On rapporte des résultats types obtenus avec la chaîne isomère du difluorure de disulfure.

Mots clés : calculs de champs de force vibrationnelle, calculs de coordonnées normales, champs de force harmonique.

Introduction

One of the principal themes of R. N. Jones' scientific career has been his interest in the development of computer programs for the analysis of vibrational spectroscopic data, and in making these programs available for the use of the spectroscopic community. Many of these have been distributed as N.R.C. Bulletins, in which some eight bulletins contain descriptions, operating instructions, and listings of over 55 programs implemented by Jones and his co-workers.

One of the more popular bulletins (1) describes the programs CART, GCALC, and FPERT, used for the calculation of vibrational frequencies and fitting harmonic vibrational potentials by means of the Wilson **GF** matrix procedure (2). These programs, implementations and improvements of earlier routines due to Hilderbrandt (3) and Schachtschneider (4), were designed for batch operation on the main frame computers used during the 1960's and 70's. Thus, each program's output was required as input for the succeeding program in the series, and the operator had to be concerned with incorporating this information correctly with the input data for the next program. However, with modern computers having on-line storage, this mode of operation is not very convenient.

In the past few years, I have developed a series of programs to perform vibrational force field and intensity calculations on such computer systems, and it seems appropriate to include a description of them in this special issue honoring Norman Jones. These routines are noteworthy in that output data are stored in machine readable form in auxiliary data files where they may be automatically accessed by subsequent programs. The force field program itself is designed explicitly to scale *ab initio* calculated force fields to fit vibrational wavenumbers (5). In addition, several enhancements have been incorporated in these programs, which should be of interest to others making such calculations. Among alternative routines are two available from the Quantum Chemistry Program Exchange: NORCRD (6), which carries out the calculation in cartesian coordinates, and a "General Vibrational Analysis System" (7), which can automatically exploit the molecular symmetry to simplify the calculation.

[1]Issued as NRCC No. 33243.

The procedures and background for normal coordinate calculations have been considered in detail in the book by Wilson, Decius, and Cross (2). There have been several more recent review articles treating various aspects of such calculations; among them refs. 8–11. In this article, I will assume that the reader is familiar with the general concepts of normal coordinate calculations as provided in these references.

The remainder of this paper includes a description of the utility DATIO routines, followed by a discussion of our implementation of programs for calculating the **B** and **G** matrices required for the kinetic term in the problem. Then the programs for calculating and fitting the potential are described. Finally, the operation of these programs is demonstrated by a sample calculation chosen to verify the operation in the case where the molecular coordinates include a torsional coordinate.

Method

These programs are implemented on the NRC VM/CMS system (IBM model 3090) in the FORTRAN 77 language. The IMSL mathematical subroutine library (12) has been used extensively for numerical routines. (Use of the current version of the IMSL library (Edition 10.0; IMSL MATH/LIBRARY Version 1.0) would require significant revision of several of the programs.) The underlying approach used in formulating these programs is that storage size is not an appreciable problem in modern machines, so that I have chosen to minimize the input/output carried out by the programs. The fundamental constants used in these routines are those given in the recent IUPAC compilation (13).

Auxiliary data routine: DATIO

This routine is used to store arrays calculated by one program for access and use by other programs at a later time. When the DATIO routine is used in a program, it is first initialized through a prologue entry. Here, the input/output file name is passed to the routine, where the file is opened and read into memory.

The stored information is as follows: the first record is a list of array labels, used to identify the stored arrays. The second record is an integer array that contains the dimensions of these arrays. The following records contain the arrays, in machine

readable IBM double precision words (FORTRAN unformatted I/O), in the order given by the labels. The current version is dimensioned for ten arrays, each having a maximum of 4000 elements. The dimensions are easily modified, if necessary.

To access an array from a program, the array label and the maximum dimensions of the target array are passed to DATIO. If the label matches one of the stored labels, and the dimensions are valid, the internal array is copied to the target in single or double precision, as requested. If the expected array dimensions are provided from the calling program, the actual dimensions are checked for validity; otherwise, the actual dimensions are passed back to the calling program.

To store an array, the label, dimensions, and array itself are passed to DATIO. If the array is not currently stored, the routine checks that free space is available; if it is stored, the new version will replace it. In either case, the dimensions are checked and, if valid, the single or double precision array elements are stored in double precision format.

When ending a program, a DATIO epilogue entry is called; if any changes have been made to the stored information, the entire data file is rewritten.

Two types of files are maintained: those containing data that are mass independent, such as the geometry; these files are designed as MOLECULE files in the following discussion. The ones containing mass dependent data are designated as SPECIES files.

Molecular geometry

There are several existing routines for converting molecular bond lengths and angles to cartesian coordinates, such as CART (1, 3), XYZ (6), EUCLID (14), and ATCOOR (15). We make use of one of these, as appropriate, or use the cartesian coordinates determined in an *ab initio* calculation. A simple routine reads the cartesian geometry, permutes the axes and atom numbering, if desired, and stores these coordinates in the DATIO MOLECULE file.

***B* matrix/*U* matrix:** *UBMAT*

The routine UBMAT, the first calculation routine of the group, reads the cartesian geometry from the designated MOLECULE file. Then, the various internal coordinates are defined as specified in the input data file: first the bond stretches, in terms of the atoms involved, and then the various types of deformations, in terms of the bonds involved. The deformation coordinates are implicitly normalized by a length of 1 Å to maintain consistent units for the force constant matrix.

Then, for each of the internal coordinates, the elements of the **B** matrix, relating the internal and cartesian coordinates, are generated. For bond stretches and nonlinear bond angle deformations, the relations given by Wilson, Decius, and Cross (2) are used. For several of the deformation coordinates, the displacement vectors s_{ti} (2), where t indicates the internal coordinate and i the atom, can be conveniently expressed in terms of the unit vector

$$[1] \qquad \hat{\boldsymbol{h}}_{12} = \frac{\hat{\boldsymbol{e}}_1 \times \hat{\boldsymbol{e}}_2}{\sin \phi_{12}}$$

where $\hat{\boldsymbol{e}}_1$ and $\hat{\boldsymbol{e}}_2$ are unit vectors directed toward the terminal atoms of bonds 1 and 2, away from their common atom, 3, and ϕ_{12} is the angle between the bonds, which have lengths of r_1 and r_2. The relation between the s_{ti} vectors and the **B** matrix elements is straightforward (2).

Thus, for a nonlinear bend coordinate

$$[2] \qquad \boldsymbol{s}_{t1} = \frac{\hat{\boldsymbol{e}}_1 \times \hat{\boldsymbol{h}}_{12}}{r_1}$$

$$\boldsymbol{s}_{t2} = \frac{\hat{\boldsymbol{e}}_2 \times \hat{\boldsymbol{h}}_{21}}{r_2}$$

and

$$\boldsymbol{s}_{t3} = -\boldsymbol{s}_{t1} - \boldsymbol{s}_{t2}$$

For the out-of-plane deformation of a bond with respect to the plane formed by two other bonds, the recommended coordinate (16) is equivalent to the change in the quantity

$$[3] \qquad \hat{\boldsymbol{e}}_1 \cdot \hat{\boldsymbol{e}}_2 \times \hat{\boldsymbol{e}}_3$$

where the three bonds, 1, 2, and 3, share a common atom, 4. This coordinate has the advantage that it is invariant, to within a change of sign, to permutation of the bond labels. It differs from the coordinate, θ, defined by Wilson, Decius, and Cross (2),

$$[4] \qquad \sin \theta = \hat{\boldsymbol{h}}_{23} \cdot \hat{\boldsymbol{e}}_1$$

by the factor $\sin \phi_{23}$. In terms of these quantities, the $\boldsymbol{s}$ vectors are for the out-of-plane deformation coordinate (eq. [3])

$$\boldsymbol{s}_{t1} = \frac{\sin \phi_{23}}{r_1 \cos \theta}(\hat{\boldsymbol{h}}_{23} - \sin \theta \hat{\boldsymbol{e}}_1)$$

$$[5] \qquad \boldsymbol{s}_{t2} = \frac{1}{r_2 \cos \theta}(\sin \phi_{31} \hat{\boldsymbol{h}}_{31} - \sin \theta \hat{\boldsymbol{e}}_3 \times \hat{\boldsymbol{h}}_{23})$$

$$\boldsymbol{s}_{t3} = \frac{1}{r_3 \cos \theta}(\sin \phi_{12} \hat{\boldsymbol{h}}_{12} + \sin \theta \hat{\boldsymbol{e}}_2 \times \hat{\boldsymbol{h}}_{32})$$

and

$$\boldsymbol{s}_{t4} = -\boldsymbol{s}_{t1} - \boldsymbol{s}_{t2} - \boldsymbol{s}_{t3}$$

For the torsional coordinate of two bonds 1 and 3, attached to either end of bond 2, the $\boldsymbol{s}$ vectors may be given in terms of the $\hat{\boldsymbol{h}}$ vectors by

$$\boldsymbol{s}_{t1} = \frac{\hat{\boldsymbol{h}}_{12}}{r_1 \sin \phi_{12}}$$

$$\boldsymbol{s}_{t2} = \frac{(r_1 \cos \phi_{12} - r_2)\hat{\boldsymbol{h}}_{12}}{r_1 r_2 \sin \phi_{12}} - \frac{\cos \phi_{32} \hat{\boldsymbol{h}}_{32}}{r_2 \sin \phi_{32}} \qquad [6]$$

$$\boldsymbol{s}_{t3} = \frac{(r_3 \cos \phi_{32} - r_2)\hat{\boldsymbol{h}}_{32}}{r_2 r_3 \sin \phi_{32}} - \frac{\cos \phi_{12} \hat{\boldsymbol{h}}_{12}}{r_2 \sin \phi_{12}}$$

$$\boldsymbol{s}_{t4} = \frac{\hat{\boldsymbol{h}}_{32}}{r_3 \sin \phi_{32}}$$

The torsional coordinates have been discussed several times in the literature, and the error in the standard reference (2) has been pointed out (17, 18). In our work, we have used the coordinate defined (16, 19, 20) as the sum of all of the three-bond combinations that involve the central bond, 2, where the (summed) **B** matrix elements are then divided by the total number of these combinations.

Finally, the linear bend coordinate **B** matrix elements are calculated as defined by Ferigle and Meister (21).

It is often convenient to consider the problem in terms of symmetry coordinates, made up of linear combinations of internal coordinates that transform according to the various representations of the molecular point group. The elements of the **U** matrix, which transforms the internal coordinates to symmetry coordinates, and labels for the various symmetry coordinates, used for convenience in the printed output, are read from the input file. The coefficients for each coordinate are normalized by the program, and then their orthogonality is checked. The redundancy relations, which may exist among internal coordinates, need not be removed by the operator at this step.

The **B**, **U**, and **UB** matrices, along with the symmetry coordinate labels, are stored in the MOLECULE file upon completion of this program.

G Matrix calculation: GCALC

This routine begins by retrieving the **UB** matrix from the MOLECULE file. Then, a list of symbols for the atoms is read from the input file, and the appropriate atomic masses (22) are obtained from a look-up table. If required, i.e., if the **G** matrix is being calculated for a lower symmetry isotopic species, an additional blocking matrix may be included in the input file, as well.

The procedure followed in this routine is governed by the method used for solving the **GF** matrix eigenvalue problem. The **G** matrix is conventionally obtained from

$$[7] \quad \mathbf{G} = (\mathbf{UB})\mathbf{M}^{-1}(\mathbf{UB})^T$$

where **M** is the diagonal mass matrix, and ^{T} denotes the matrix transpose. However, since the eigenvalue problem will be solved by means of the Choleski decomposition of $\mathbf{G}^{-1}$ (8), this latter matrix is the principal result calculated in this routine. A check is made whether symmetry coordinates have been used to block the **G** matrix and, if so, the calculations outlined here are carried out separately for each of the symmetry blocks. Also, a check is made for redundant coordinates and, optionally, they may be removed.

We proceed as follows: The **G** matrix may be given as eq. [7] above, or equivalently,

$$[8] \quad \mathbf{G} = (\mathbf{UBM}^{-1/2})(\mathbf{UBM}^{-1/2})^T$$

Then, the singular value decomposition (23) of $(\mathbf{UBM}^{-1/2})^T$ can be determined as

$$[9] \quad (\mathbf{UBM}^{-1/2})^T = \mathbf{PSV}^T$$

where **P** and **V** are orthogonal matrices, and **S** is diagonal. In terms of these matrices, **G** is given by

$$[10] \quad \mathbf{G} = (\mathbf{PSV}^T)^T(\mathbf{PSV}^T) = \mathbf{VS}^2\mathbf{V}^T$$

or

$$[11] \quad \mathbf{GV} = \mathbf{VS}^2$$

so the elements of the diagonal $\mathbf{S}^2$ matrix are the eigenvalues of **G**, and **V** are the eigenvectors. This provides a means of eliminating redundant coordinates, if any are present.

If **G** has zero eigenvalues, the corresponding eigenvectors give (combinations of) the redunancy relations, and the remaining eigenvectors are orthogonal combinations of the symmetry coordinates with the redundancies removed (24). By means of an interactive procedure, suitable orthogonal transformations are applied to the remaining eigenvectors, in order to generate symmetry coordinates of the desired structure. For example, deformation coordinates for methyl and methylene groups have been given (25), as well as a complete set of recommended coordinates (5). If redundancies are removed, the transformed eigenvector matrix, **V′**, is used to transform the **U** matrix to the new set of coordinates, and revised coordinate labels are requested from the operator. Finally, the revised **UB** product matrix is calculated.

For the solution of the **GF** eigenvalue problem, we require the Choleski decomposition of the inverse of **G**, i.e., the lower triangular matrix, **R**, satisfying

$$[12] \quad \mathbf{G}^{-1} = \mathbf{RR}^T$$

To accomplish this, note from eq. [10] that, since **V** is orthogonal,

$$[13] \quad \mathbf{G}^{-1} = \mathbf{VS}^{-2}\mathbf{V}^T$$

Thus, **R**, the Choleski factor of **G**, is obtained by applying the Givens' reduction (23) to transform $\mathbf{VS}^{-1}$ to triangular form.

The Choleski matrix, **R**, the atomic masses, and the auxiliary blocking matrix are stored in the SPECIES file and, if redundant coordinates have been removed, the revised **U** and **UB** matrices and the revised coordinate labels are stored in the MOLECULE file. Finally, the **G** matrix is calculated and printed out, for reference.

Normal coordinate calculation: FCALC

The **GF** eigenvalue problem can be expressed in the form of the generalized symmetric eigenvalue problem (23)

$$[14] \quad \mathbf{FL} = \mathbf{G}^{-1}\mathbf{L}\Lambda$$

As stated earlier, this problem may be transformed into a simple symmetric matrix eigenvalue problem, if the Choleski decomposition of the $\mathbf{G}^{-1}$ matrix (eq. [12]) is used.

$$[15] \quad (\mathbf{R}^{-1}\mathbf{FR}^{-T})(\mathbf{R}^T\mathbf{L}) = (\mathbf{R}^T\mathbf{L})\Lambda$$

or

$$[16] \quad \mathbf{ZW} = \mathbf{W}\Lambda$$

The symmetric matrix **Z** is obtained from **F** by two applications of the Choleski forward substitution routine (23) to obtain the intermediate matrix **Y**

$$[17] \quad \mathbf{RY} = \mathbf{F}$$

and then **Z**

$$[18] \quad \mathbf{ZR}^T = \mathbf{Y}$$

while the eigenvectors, **L**, are obtained from the eigenvectors of eq. [16] by Choleski back substitution (23)

$$[19] \quad \mathbf{R}^T\mathbf{L} = \mathbf{W}$$

The vibrational frequencies, ν_i, are obtained from the eigen-

values, λ_i, by means of

[20] $\nu_i = \lambda_i^{1/2}/2\pi c$

where the factors required for conversion of units have been suppressed.

Thus, to perform a calculation of the vibrational frequencies from a given force field, the program reads the **R** matrix from the SPECIES file, as well as the auxiliary blocking matrix, if needed. The **F** matrix, expressed in internal or symmetry coordinates, may be input in one of three formats: element by element, as blocks of a symmetrized **F** matrix, or the entire matrix may be read in from an additional file. The **U** matrix, if needed to transform the **F** matrix from internal to symmetry coordinates, is read from the MOLECULE file, along with the symmetry coordinate labels for use in the printed output.

The eigenvalue problem is solved as outlined above, and the phase of each eigenvector is arbitrarily adjusted so the largest element is positive. The potential energy distribution is calculated for the diagonal **F** matrix elements using the usual relations (1). The **L** matrix elements are expressed in the mass weighted representation (2), and also in the dimensionless representation (26). The vibrational frequencies and both representations of the **L** matrices are stored in the SPECIES file at the completion of the program.

Force field scaling: FFIT

In our recent work, we have not required a procedure for deriving an empirical force field by performing a best fit of observed vibrational frequencies, but such a routine could be easily implemented (8) by means of standard library routines. In general, however, such an approach is of limited value for larger molecules; the numerical system is often underdetermined, at least in a practical, if not a strict mathematical, sense (8). In our work, we have used extensively a routine to scale *ab initio* force fields (5) to fit observed frequencies, to compensate for basis set deficiencies and the neglect of electron correlation in the *ab initio* calculation. Such an empirical procedure will be needed until high-level *ab initio* force field calculations, including electron correlation, can be carried out for larger molecules of interest to chemical spectroscopists. If frequency data from a sufficient number of isotopic species are available, we have obtained better fits when relating scale factors to different types of symmetry coordinates (17, 28) (CH stretch, methyl symmetric deformation, methyl and methylene asymmetric deformation, methyl and methylene rocking, etc., for alkane molecules, for example). This behavior may be understood by noting that, for the molecules we have considered, the force constant matrix is more nearly diagonal when expressed in symmetry coordinates, as compared to internal coordinates. Thus, the empirical scaling procedure has a more limited effect upon the smaller interaction force constants in the symmetry coordinate representation. It is also important to allow for the correlation of anharmonic observed frequencies to harmonic ones (29).

On each iteration of the nonlinear fitting routine, the fitting parameters are allocated to appropriate elements of a diagonal scaling matrix, **D**, and then the scaled *ab initio* $\mathbf{F}_{sai}$ matrix is given by

[21] $\mathbf{F}_{sai} = \mathbf{D}\mathbf{F}_{ai}\mathbf{D}$

This procedure has the effect of multiplying diagonal force constants by the square of a scale factor, and off-diagonal ones by the product of the related scale factors. Thus, the scale factors determined in our work are the square of those used by other workers (5).

In the fitting procedure, $\mathbf{F}_{sai}$ is used to calculate vibrational eigenvalues, and the minimization routine then varies the scaling parameters to minimize the sum of squares of the weighted differences from the observed ones. The weights, w, for each eigenvalue, λ_{calc}, can be chosen to be

[22] $$w = \frac{1}{2\lambda_{obs}}$$

which is equivalent to fitting the percent frequency difference:

[23] $$w(\lambda_{calc} - \lambda_{obs}) = \frac{\nu_{calc}^2 - \nu_{obs}^2}{2\nu_{obs}^2} \simeq \frac{\nu_{calc} - \nu_{obs}}{\nu_{obs}}$$

or, alternatively,

[24] $$w = \frac{\nu_{obs}}{2\lambda_{obs}}$$

which is equivalent to fitting the frequency difference, itself:

[25] $$w(\lambda_{calc} - \lambda_{obs}) \simeq \nu_{calc} - \nu_{obs}$$

In fact, for the determination of the scaled *ab initio* force field, there is little difference between the fitted results with the two types of weights.

The fitting is carried out using the IMSL nonlinear least-squares routine ZXSSQ (12), with the convergence criterion that each parameter estimate agrees to a specified number of significant digits on successive iterations. The standard errors of the scale factors are calculated (30) from the standard error of the fit.

For each isotopic species considered in the calculation, the frequencies and the two forms of the **L** matrix are saved in the SPECIES file for use in subsequent calculations.

Auxiliary routines

Ab initio force field calculations normally yield a force constant matrix in cartesian coordinates, $\mathbf{F}_X$, which must be transformed to internal or symmetry coordinates for use in our calculations. This transformation requires either the generalized inverse of **B** or that of **UB** for these two cases. This inverse is the non-unique matrix that satisfies, for the symmetry coordinate case,

[26] $(\mathbf{UB})\mathbf{A} = \mathbf{E}$

where **E** is the unit matrix. In terms of quantities already calculated in our routines, a convenient form of **A** may be given as (5)

[27] $\mathbf{A} = \mathbf{M}^{-1}(\mathbf{UB})^T\mathbf{G}^{-1}$

The inverses of the **M** and **G** matrices are those for a selected parent isotopic species; the latter matrix, expressed in symmetry coordinates, can be obtained from the Choleski decomposition matrix, **R** (see eq. [12]). Then the $\mathbf{F}_S$ matrix, in symmetry coordinates, is given by

[28] $\mathbf{F}_S = \mathbf{A}^T\mathbf{F}_X\mathbf{A}$

Permutations can be applied to the cartesian axes and atom numbering, to maintain consistency with any such permutations performed earlier on the geometry.

Example

The operation of these routines has been demonstrated in several publications from our laboratory over the past few years, including force field determinations for hexafluoroacetone (31), propane (32), cyclohexane (33), trimethylphosphine (27), and *n*-butane (28), and the results of such calculations have also been used in our absolute Raman intensity studies (28, 33–36). For this reason, it is felt that there is no need to carry out a complete force field determination as part of this description of the computational capability of these programs.

However, when writing a program to carry out normal coordinate calculations, it is useful to have detailed example results available, for testing purposes. Such examples are contained in a IUPAC publication of test data for normal coordinate calculations (37). There, input data for testing normal coordinate analysis programs and the results of the calculation are given for four representative molecules. These data were used to verify the operation of the present routines.

There is one situation that is not checked in these examples: the proper consideration of the torsional coordinate. The sign error for the torsion **B** matrix elements, mentioned above, has

[a]Force constants taken from ref. 39. Units: **F** matrix elements in aJ $Å^{-1}$, eigenvalues in aJ $Å^{-1}$ u^{-1}, frequencies in cm^{-1}, the eigenvectors (**L** matrix elements) for the mass weighted normal coordinates in $u^{-1/2}$, the eigenvectors (**L** matrix elements) for the dimensionless normal coordinates in Å, and P.E.D. in percent.

no effect if the three bonds involved are in the same plane. In addition, if the torsional coordinate about a bond is defined in terms of all three-bond combinations involving the central bond, the sign errors cancel if the central bond lies in a plane of symmetry. Thus a torsional coordinate not satisfying such symmetry conditions should be considered in order to check the correct determination of the **B** matrix elements for this case.

Therefore, the present programs may be demonstrated by performing an example calculation for such a situation; the case of the FS—SF chain isomer of disulfur difluoride has been chosen. This is an interesting molecule; it rearranges to form a more stable pyramidal S=SF_2 isomer at room temperature (38). The vibrational analysis of this molecule was recently described (39). The atom numbering, geometry, and internal and symmetry coordinates are given in Table III of ref. 39. The output from the UBMAT routine is shown in Table 1, and from the GCALC routine in Table 2. If the sign error is present in the **B** matrix routine, the (x,y,z) elements for the torsional coordinate become (0.176027, 0.813478, 0) for atom 2, and (0.820382, 0.140376, 0) for atom 3. These values then give (−0.007388, 0, −0.013592, 0.087125) for row 4 of the **G** matrix. The output from the FCALC routine is shown in Table 3.

Conclusion

The program system outlined here has been used satisfactorily for several years in this laboratory for the calculation of vibrational force fields and normal coordinates. The ability to store intermediate results in auxiliary data files has proven to be very convenient, and has simplified the transfer of the results of one program for use in another. Several unique numerical procedures have been incorporated into these programs, to enhance their operation. Finally, the example calculation for disulfur difluoride should prove useful for anyone wishing to check other versions of routines for performing such calculations.

The infrared spectra and circular dichroism of bullfrog (*Rana catesbeiana*) skeletal muscle troponin C with and without Ca^{2+} have been measured in aqueous solution at temperatures between 24 and 80°C at pH 7.0. Infrared spectral changes with increasing temperature, particularly in the amide I region, have been extensively examined by using the techniques of thermal difference spectrum and deconvolution. Ca^{2+}-free troponin C seems to be denatured at about 70°C, but its denaturation proceeds gradually without an abrupt structural change. Ca^{2+} binding causes a considerable change in the secondary structure of the whole protein. Consequently, Ca^{2+}-bound troponin C has a higher α-helix content and is thermally more stable than the Ca^{2+}-free protein. Both the deconvolved amide I bands and circular dichroism data indicate that there are similarities between the secondary structure (and probably the tertiary structure as well) of the Ca^{2+}-bound protein at 80°C and that of the Ca^{2+}-free protein at room temperature.

Key words: bullfrog skeletal muscle troponin C, Fourier transform infrared and circular dichroism studies.

TATSUYUKI YAMAMOTO, MITSUO TASUMI et MASARU TANOKURA. Can. J. Chem. **69**, 1679 (1991).

Opérant en solutions aqueuses, à un pH de 7,0, en présence et en l'absence d'ions Ca^{2+} et à des températures allant de 24 à 80°C, on a mesuré les spectres infrarouges et le dichroïsme circulaire de la troponine C des muscles du squelette de la grenouille taureau (*Rana catesbeiana*). Utilisant les techniques de déconvolution et de différences spectrales causées par la chaleur, on a examiné avec attention les variations des spectres infrarouges avec une augmentation de la température, particulièrement dans la région amide I. Il semble que la troponine C sans ions Ca^{2+} soit dénaturée à environ 70°C; cette dénaturation se fait toutefois graduellement, sans changement structural abrupt. Une liaison avec le Ca^{2+} provoque un changement important dans la structure secondaire de la protéine dans son ensemble. On peut en déduire que la troponine C liée au Ca^{2+} soit plus riche en hélice α et thermiquement plus stable que la protéine sans Ca^{2+}. Les données tant du dichroïsme circulaire que des bandes amide I soumises à une déconvolution indiquent qu'il existe des similarités entre la structure secondaire (et probablement la structure tertiaire) de la protéine liée au Ca^{2+}, à 80°C, et celle de la protéine sans Ca^{2+} à la température ambiante.

Mots clés : troponine C des muscles du squelette de la grenouille taureau, spectres infrarouges et de dichroïsme circulaire.

[Traduit par la rédaction]

Introduction

Troponin C (abbreviated as TnC) is one of Ca^{2+}-binding proteins and is known to be involved in regulation of muscle contraction (1–3). A TnC molecule binds up to four Ca^{2+} ions in two kinds of Ca^{2+} binding sites called the high and low affinity sites (4, 5). Binding of Ca^{2+} by TnC removes inhibition of interaction between actin and myosin, thus causing muscle contraction (6, 7).

X-ray analyses of crystalline TnCs from skeletal muscles of turkey and chicken (8–11) have revealed a rather peculiar "dumbbell" like structure of the TnC molecule, which consists of two globular domains interconnected by an α-helical rod. Each globular domain contains two Ca^{2+} binding sites. The content of α-helix in the TnC molecule calculated on the basis of the structure determined by X-ray analysis is about 60% (8).

Although the amino acid sequence of bullfrog skeletal muscle TnC has not been determined yet, it is expected to be quite similar to that of TnC from another frog species *Rana esculenta* (12) because the amino acid compositions of TnCs from the two frog species are almost identical (13). Both frog and chicken skeletal muscle TnCs are composed of 162 amino acid residues, of which only 15 residues are different between them. The residues in the Ca^{2+}-binding loops are mostly preserved. Therefore, it is reasonable to assume that the three-dimensional structure of bullfrog TnC under study would be analogous to that of chicken TnC, if the former could be crystallized.

It has been pointed out from fluorescence measurements (14, 15) and an X-ray small-angle scattering study (16) that the three-dimensional structures in crystal (prepared from solutions at pH 5.5) may be different from those in aqueous solution at pH 7.0. Thermal denaturation processes of TnC in aqueous solution have been studied by ^1H nuclear magnetic resonance (17), circular dichroism (18), and calorimetric measurements (19–21). The results of these studies have indicated that, broadly speaking, thermal denaturation of TnC gradually occurs in contrast with globular proteins which usually have well-defined denaturation temperatures. All the above studies cited in this paragraph have been done by using rabbit skeletal muscle TnC. On the other hand, a group including one of the present authors has suggested that differences may exist in thermodynamic properties between rabbit and frog skeletal muscle TnCs (22). In the present paper, we have studied thermal denaturation processes of TnC from bullfrog skeletal muscle in H_2O solution

at neutral pH with and without Ca^{2+} by Fourier-transform infrared and circular dichroism (CD) measurements.

Experimental

Sample preparation

Bullfrog skeletal muscle TnC was prepared by the method described previously (22). Contaminating Ca^{2+} was removed by the trichloroacetic acid treatment. To obtain a Ca^{2+}-free sample, freeze-dried TnC (20 mg) was dissolved in an aqueous solution (2 mL) containing 0.1 M KCl and 10 mM EGTA. Similarly, a Ca^{2+}-bound sample was prepared by dissolving freeze-dried TnC in an aqueous solution containing 0.1 M KCl and 0.2 M $CaCl_2$. A small quantity of dithiothreitol (about 1 mM) was added to each solution to suppress aggregation of TnC. The pH value was adjusted to 7.0. These solutions were concentrated to about 10% (w/v) by centrifugation and were used for infrared measurements.

For circular dichroism measurements, a Ca^{2+}-free TnC sample was prepared by dissolving freeze-dried TnC into a solution containing 2 mM KCl, 1mM EGTA, and 1 mM PIPES buffer (pH 7.0). A Ca^{2+}-bound TnC sample was prepared by dissolving freeze-dried TnC in an aqueous solution, in which 0.5 mM $CaCl_2$ was contained instead of 1 mM EGTA. The concentration of TnC was adjusted to 46 mg/L in each solution. A small quantity of dithiothreitol was added in this case also.

Measurements of infrared spectra

Infrared spectra were observed on a JEOL JIR-100 Fourier-transform infrared spectrophotometer equipped with an MCT detector (Judson J15D12). Spectral measurements were carried out at 2 cm^{-1} resolution in a temperature range from 24 to 80°C at intervals of 4°C. Interferograms from 500 scans were averaged to obtain one spectrum. This required about 10 min. The temperature of the sample was changed with a ribbon heater wound around the cell holder, and monitored by a copper–constantan thermocouple inserted in the cell. The sample was kept at a constant temperature for 10 min before performing a spectral measurement at this temperature. Dry air was continuously flowed into the spectrophotometer during spectral measurements. About 10 μL of the protein solution was set between two CaF_2 disks using a 15 μm Teflon spacer. The gap between the two CaF_2 disks was sealed with glue to avoid evaporation of water. Infrared spectra of the buffer solutions were similarly observed at various temperatures. To eliminate the contribution of absorptions due to water from the spectrum of the protein solution, the spectrum of the buffer solution was subtracted, after multiplying an appropriate factor (approximately 0.9), from the spectrum of the protein solution observed at the same temperature (23).

No smoothing procedure was employed for the observed infrared spectra. Deconvolution was performed according to the method described by Jones and Shimokoshi (24). A Lorentz bandshape function and a triangle^2 apodizing function were used with deconvolving parameters as follows: $2\sigma = 28$ cm^{-1} and $L = 0.18$ cm. To examine the reproducibility, the same spectral measurements were repeated at least three times.

Measurements of circular dichroism spectra

Circluar dichroism spectra of Ca^{2+}-free and Ca^{2+}-bound TnC were observed on a JASCO J-600 CD spectropolarimeter. A cell of 2 mm path length was placed in a holder through which temperature-controlled water was circulated. The temperature of the sample, monitored by a thermometer directly fixed to the cell holder, was raised from 25 to 80°C at intervals of 5°C. Circular dichroism spectra were observed from 200 to 250 nm under continuous flow of nitrogen gas.

The α-helix content of TnC was estimated using the following equations (25–27). Even if the α-helix contents estimated in this way may not be completely reliable per se, their relative values are useful for confirming infrared results, as described later.

$$\alpha\text{-helix content} = \frac{4880 - [\Theta_{222}]}{45400}$$

$$[\Theta_{222}] = \frac{M\Theta_{222}}{100cl}$$

where Θ_{222} is the ellipticity observed at 222 nm, M is the mean molecular weight of the amino acid residues of the protein under study (112 for TnC), c is the protein concentration in g/mL, and l is the thickness in dm of the sample solution.

Results and discussion

Comparison of the infrared spectra of Ca^{2+}-free and Ca^{2+}-bound troponin C

The infrared spectra (2000–1000 cm^{-1}) of Ca^{2+}-free and Ca^{2+}-bound TnC at room temperature are shown in Fig. 1, where strong absorptions of solvent water have already been subtracted. At first glance, the spectra of the Ca^{2+}-free and Ca^{2+}-bound proteins are similar. It is noted, however, that the widths of the intense amide I and II bands at about 1650 and 1550 cm^{-1}, respectively, are different before and after Ca^{2+}-binding, although their peak positions remain almost unchanged. The full widths at half maximum of the amide I bands in Figs. 1*A* and 1*B* are 50 and 40 cm^{-1}, respectively. Since it is well known that the amide I bands due to α-helices and random coils are closely located (28–30), the present results suggest that both the Ca^{2+}-free and Ca^{2+}-bound proteins contain α-helices and random coils, but the Ca^{2+}-bound protein has a higher content of α-helix.

A closer look at the two spectra in Fig. 1 leads us to find small but nevertheless significant differences between them, particularly in the region around 1400 cm^{-1}. The band at 1402 cm^{-1} in the spectrum of Ca^{2+}-free TnC (Fig. 1*A*) is assignable to the symmetric stretch of the free carboxylate groups of aspartic and glutamic acid residues. In the spectrum of Ca^{2+}-bound TnC, on the other hand, two bands are observed at 1426 and 1404 cm^{-1} (Fig. 1*B*). A more extensive examination of the effects of Ca^{2+} binding on this region of the infrared spectrum may shed new light on the mechanism of Ca^{2+} binding and accompanying structural changes, to which a Raman study (31) has not given a definite answer. In the present study, however, we will confine

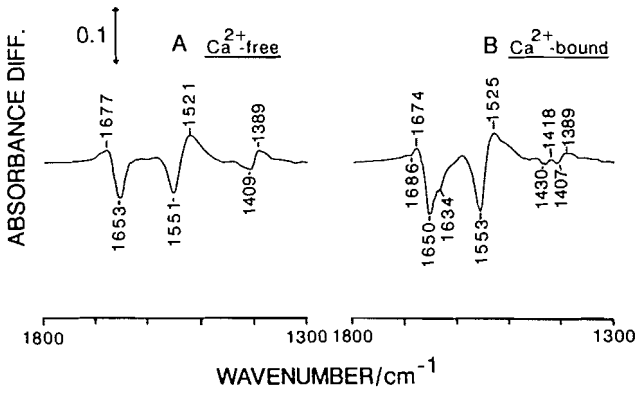

FIG. 2. Infrared thermal difference spectra of Ca^{2+}-free (*A*) and Ca^{2+}-bound (*B*) troponin C between 80 and 24°C; 2 cm^{-1} resolution.

our attention to temperature dependences of the infrared spectra of the Ca^{2+}-free and Ca^{2+}-bound proteins.

Infrared difference spectra

Differences between the infrared spectra observed at 80 and 24°C has been computed for both Ca^{2+}-free and Ca^{2+}-bound TnC without multiplying a factor to either of the spectra observed at the two temperatures, and the results are shown in Fig. 2. The strong negative bands are observed at 1653 and 1551 cm^{-1} in the difference spectrum of Ca^{2+}-free TnC (Fig. 2*A*), and likewise at 1650 and 1551 cm^{-1} in the difference spectrum of Ca^{2+}-bound TnC (Fig. 2*B*). These negative bands are reasonably assigned to α-helical parts, which are destroyed and converted into random coil as the temperature is raised. The random coil is considered to have very broad absorptions centering around 1660 and 1530 cm^{-1}, which should appear in the positive side but are largely cancelled by the overlapping negative bands. Therefore, the positive peaks at 1677 and 1674 cm^{-1} in Figs. 2*A* and 2*B*, respectively, should not be treated as true ones corresponding to a certain secondary structure.

In Fig. 2*B*, a small negative feature is observed at 1686 cm^{-1}. This negative feature is considered to arise from overlapping of a weak negative absorption and the tail of the broad positive absorption due to the random coil. The presence of this weak negative absorption at 1686 cm^{-1} is supported by the fact that a band located at about 1682 cm^{-1} in the deconvolved spectra (see below) seems to decrease in intensity at high temperatures. Moreover, in the case of ribonuclease A, a similar band has been observed at 1690 cm^{-1} and assigned to β-sheet (32, 33). An NMR study (34) has shown that a short β-sheet structure is formed in the C-terminal region of rabbit skeletal muscle TnC upon Ca^{2+} binding. According to X-ray diffraction studies (8–11), the TnC molecules from skeletal muscle of turkey and chicken have β-turns in the Ca^{2+}-binding loops. Since β-turns are also known to give rise to an absorption in the region of 1690–1680 cm^{-1} (30), it is highly probable that the negative 1686 cm^{-1} band of Ca^{2+}-bound TnC arises from the β-sheet and/or β-turns which are destroyed or become loose with increasing temperature. In the thermal difference spectrum of Ca^{2+}-free TnC (Fig. 2*A*), it is not clear whether a corresponding band exists.

From the absorbance difference of the negative band at 1653 cm^{-1} and the absorbance at 1651 cm^{-1} in Fig. 1*A*, the percentage absorbance change at 80°C for the amide I band of Ca^{2+}-free TnC can be calculated. The results of such calculation are plotted against temperature in Fig. 3, together with the results for the negative band of Ca^{2+}-bound TnC at 1650 cm^{-1}.

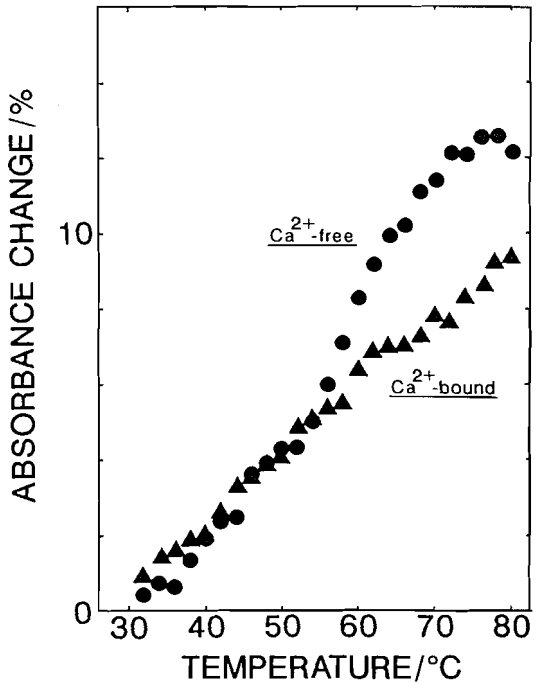

FIG. 3. Absorbance change vs. temperature plot for the amide I band at 1653 cm^{-1} of Ca^{2+}-free troponin C (●) and for that at 1650 cm^{-1} of Ca^{2+}-bound troponin C (▲).

Similar results for the amide II bands are shown in Fig. 4. The percentage absorbance changes thus calculated are always underestimated because, in measuring the absorbance difference of a negative band, an offset arising from the broad positive absorption due to the random coil is not taken into account. Then, the peak-to-peak differences (for example, the distance between the positive absorbance at 1677 cm^{-1} and the negative absorbance at 1653 cm^{-1} in Fig. 2*A*) are used to calculate the percentage absorbance changes. The results obtained in this way change the slopes of the curves (or lines), but do not change the shapes of the curves (or lines) which are most important in the following discussion.

The following points may be noted in Figs. 3 and 4. (*1*) No abrupt absorbance change occurs when the temperature is raised. This means that the secondary structure of the protein changes gradually with increasing temperature. The absorbance changes shown in Figs. 3 and 4 present a marked contrast with those observed for ribonuclease A, which shows an abrupt absorbance change corresponding to a cooperative structural change (32, 33). (*2*) In the case of Ca^{2+}-free TnC, the slope of the absorbance change of the amide I band becomes greater at about 55°C, and the change itself seems to level off in the temperature range above 75°C. The intensity of the amide II band changes almost linearly with temperature until about 75°C and then levels off. These results indicate that Ca^{2+}-free TnC is denatured at about 75°C. (*3*) In the case of Ca^{2+}-bound TnC, both amide I and II bands change in intensity almost linearly over the entire temperature range of 24–78°C, giving no sign of levelling off. Thus, Ca^{2+}-bound TnC, being thermally more stable than the Ca^{2+}-free proteins, is not fully denatured at 78°C.

The above three points are mostly in agreement with the results previously reported by ^1H nuclear magnetic resonance (17), circular dichroism (18), and calorimetric measurements (19–21), although there are minor deviations which are prob-

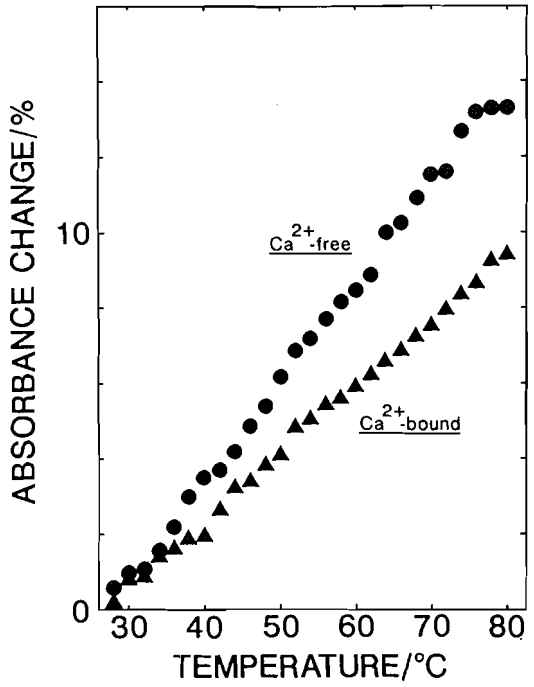

FIG. 4. Absorbance change vs. temperature plot for the amide II band at 1551 cm^{-1} of Ca^{2+}-free troponin C (●) and for that at 1553 cm^{-1} of Ca^{2+}-bound troponin C (▲).

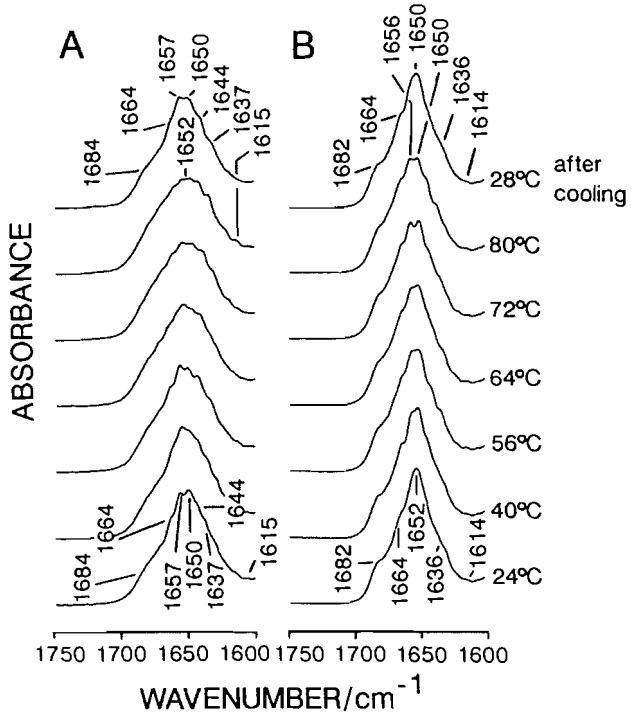

FIG. 5. Temperature dependence of the deconvolved amide I bands of Ca^{2+}-free (*A*) and Ca^{2+}-bound (*B*) troponin C; 2 cm^{-1} resolution.

ably due to differences in measuring conditions (concentration, etc.)

Deconvolved infrared spectra

The deconvolved infrared spectra in the amide I region of Ca^{2+}-free and Ca^{2+}-bound TnC are shown in Fig. 5. Compared with the deconvolved spectra of ribonuclease A (31, 32), the deconvolved spectra in Fig. 5 seem to have a broad background absorption extending from 1700 to 1600 cm^{-1}, which must be associated with more or less random structures. On top of this broad background absorption, each spectrum has peaks which are made less broad by the deconvolution procedure. For example, the spectrum of the Ca^{2+}-free protein at 24°C (Fig. 5*A*) has a doublet at 1657 and 1650 cm^{-1}, which undoubtedly corresponds to the negative band at 1653 $^{-1}$ in Fig. 2*A*. The spectrum of the Ca^{2+}-bound protein at 24°C (Fig. 5*B*) has a prominent single peak at 1652 cm^{-1}, which again corresponds to the negative band at 1650 cm^{-1} in Fig. 2*B*.

In the deconvolved spectrum of Ca^{2+}-bound TnC from rabbit sketetal muscle in D_2O solution, Trewhella *et al.* (35) have observed two intense peaks at 1647 and 1637 cm^{-1} (Fig. 4*a* of ref. 35). (In the text of ref. 35, the wavenumber of the former peak is referred to as 1644 cm^{-1}.) It is possible that both of these peaks derive upon deuteration from the 1652 cm^{-1} band of the Ca^{2+}-bound protein in Fig. 5*B*, although the sources of TnCs used by Trewhella *et al.* and in the present study are different. Trewhella *et al.* seem to assign the 1647 cm^{-1} band to "distorted" α-helix without touching on the origin of the 1637 cm^{-1} band. Our own data, which were obtained in H_2O solution, are not useful for discussing the validity of their band assignment.

Although it is not possible to make a definite assignment of each peak in the doublet of the Ca^{2+}-free protein, both of the two peaks are most probably associated with α-helical parts, because, as mentioned above, these peaks correspond very well to the negative band at 1650 cm^{-1} in Fig. 2*A*. The two peaks are merged into the prominent, rather sharp peak at 1652 cm^{-1} of the Ca^{2+}-bound protein (Fig. 5, 24°C). This spectral change upon Ca^{2+} binding is rather small in wavenumber but very clear in bandshape. Therefore, it is inferred that Ca^{2+} binding to the globular domains gives a significant perturbation to the three-dimensional structure of the whole protein, e.g., an increase in α-helix content (this point will be discussed later) and modifications of α-helical structures not only in the globular domains but also in the interconnecting rod. A ^1H nuclear magnetic resonance study (34) and an optical rotatory dispersion study (36) have also shown that the Ca^{2+} binding causes significant conformational changes to the rabbit skeletal muscle TnC molecule.

In the deconvolved spectrum of the Ca^{2+}-bound protein at 24°C, a shoulder exists at 1682 cm^{-1} (as mentioned earlier) but only a broad band is seen in the corresponding region (around 1684 cm^{-1}) of the Ca^{2+}-free protein.

With increasing temperature the doublet at 1657 and 1650 cm^{-1} of the Ca^{2+}-free protein becomes less apparent. On the contrary, the 1652 cm^{-1} band of the Ca^{2+}-bound protein gradually splits into a doublet as the temperature is raised. At 80°C this doublet appears to be quite similar to that of the Ca^{2+}-free protein at 24°C. Indeed, the overall spectral pattern of the Ca^{2+}-bound protein at 80°C resembles that of the Ca^{2+}-free protein at 24°C. This indicates that similarities exist between the three-dimensional structure of the Ca^{2+}-bound protein at 80°C and that of the Ca^{2+}-free protein at 24°C. It should be emphasized that Ca^{2+} is still bound to the apoprotein at 80°C, although the number of Ca^{2+} per apoprotein is not clear. If the protein has no Ca^{2+} at 80°C, the deconvolved spectrum at 80°C in Fig. 5*B* must be identical to that of the Ca^{2+}-free protein at 80°C in Fig. 5*A*.

The shoulder at 1682 cm^{-1} of the Ca^{2+}-bound protein at 24°C appears to become broader at higher temperatures. This is consistent with the presence of the negative feature at 1686 cm^{-1} in Fig. 2*B*.

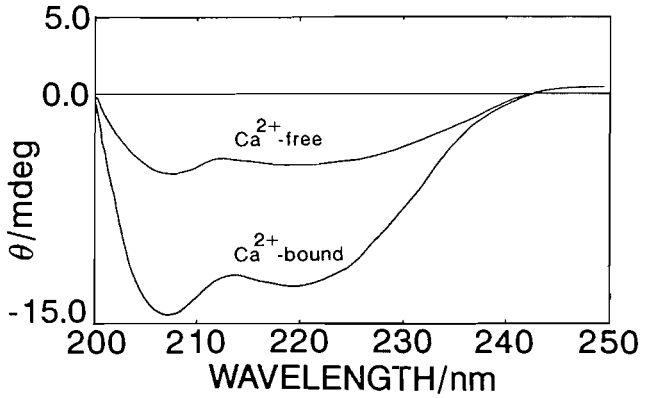

FIG. 6. CD spectra of Ca^{2+}-free (top) and Ca^{2+}-bound (bottom) troponin C at room temperature.

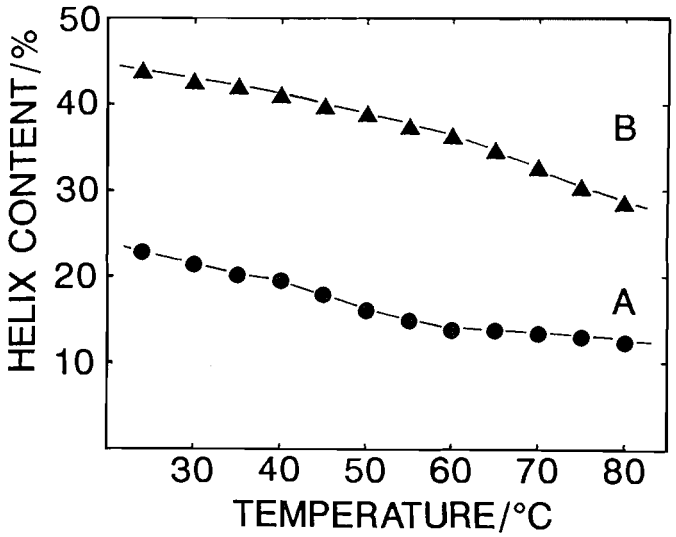

FIG. 7. Helix content vs. temperature plot for Ca^{2+}-free (●) and Ca^{2+}-bound (▲) troponin C.

Circular dichroism and the α-helix content

Circular dichroism (CD) spectra of Ca^{2+}-free and Ca^{2+}-bound TnC observed at 25°C are shown in Fig. 6. The α-helix contents calculated from the values of Θ_{222} using the equations given earlier are plotted against temperature in Fig. 7.

The α-helix contents thus estimated (44 and 23% for the Ca^{2+}-bound and Ca^{2+}-free proteins, respectively, at room temperature) are considerably lower than the value (60%) obtained for the Ca^{2+}-bound proteins in crystal, even if we admit that the accuracy of such estimation is not completely dependable. This is consistent with the existence of a very broad background absorption mentioned earlier for the deconvolved infrared spectra. Such spectral evidence suggests that the three-dimensional structure of TnC determined by X-ray analysis does not persist in aqueous solution, particularly for the Ca^{2+}-free protein. Such a view is consistent with the conclusion derived from fluorescence measurements (14, 15) and an X-ray small-angle scattering study (16) that the distance between the two globular domains in Ca^{2+}-bound TnC from rabbit skeletal muscle is smaller in aqueous solution at neutral pH than that in crystal. A higher α-helix content in Ca^{2+}-bound TnC than in the Ca^{2+}-free protein has been shown from optical rotatory dispersion measurements (36).

It is clearly seen in Fig. 7 that the α-helix contents of both the Ca^{2+}-free and Ca^{2+}-bound proteins decrease gradually with increasing temperature. The slope of the curve for the Ca^{2+}-free protein appears to change at about 60°C. This is consistent with the trend observed in the absorbance change of the amide I band in the difference spectra (Fig. 3) and also with the results obtained from CD measurements (18). However, the slope of the α-helix content vs. temperature relationship in Fig. 7 becomes smaller above 60°C, whereas that of the amide I absorbance change becomes larger in the same temperature range. The origin of this discrepancy is not clear.

In the case of the Ca^{2+}-bound protein, the helix content vs. temperature relationship in Fig. 7 has a moderate curvature over the entire temperature range. It should be noted the the α-helix content of the Ca^{2+}-bound protein at 80°C is about 28%, a value close to that of the Ca^{2+}-free protein at 25°C. This result obtained from the CD spectra is consistent with the above-mentioned similarity of the deconvolved infrared spectra between the Ca^{2+}-bound protein at 78°C and the Ca^{2+}-free protein at 24°C.

In going from 25 to 80°C, the α-helix content of the Ca^{2+}-free protein decreases from 23 to 13% (10% decrease), and that of the Ca^{2+}-bound protein from 44 to 28% (16% decrease). These decreases in α-helix content are not far from the percentage absorbance changes of the amide I and II bands in going from 24 to 78°C (Figs. 3 and 4), although the percentage absorbance change of the Ca^{2+}-free protein is greater than that of the Ca^{2+}-bound protein.

Thus, it may be said that, apart from some discrepancies in detailed aspects, there is a good correspondence between the results obtained independently from the infrared and CD spectra, despite the fact that these two kinds of spectra have been observed at very different concentrations.

Conclusion

Fourier-transform infrared techniques, viz., thermal difference spectrum and deconvolution, are useful for obtaining information on conformational changes occurring in thermal denaturation processess of Ca^{2+}-free and Ca^{2+}-bound TnCs.

The present infrared and circular dichroism studies have collectively shown the following points so far expressed separately by other authors. (*1*) Ca^{2+}-free TnC seems to be denatured at about 75°C, although the denaturation proceeds gradually without an abrupt structural change. Ca^{2+}-bound TnC is thermally more stable than the Ca^{2+}-free protein. (*2*) The secondary structure (and the tertiary structure as well) of Ca^{2+}-bound TnC in aqueous solution at neutral pH is different from either that in crystal or that of Ca^{2+}-free TnC. (*3*) Ca^{2+}-bound TnC in aqueous solution has a rather high α-helix content (about 44%) at room temperature. Its α-helix content decreases with increasing temperature. (*4*) The α-helix content in Ca^{2+}-free TnC in aqueous solution is much lower than that in the Ca^{2+}-bound protein at room temperature, and decreases further with increasing temperature.

In addition to the above points, it has been convinvingly shown that the secondary structure (and probably the tertiary structure also) of Ca^{2+}-bound TnC at 80°C resembles that of the Ca^{2+}-free protein at room temperature.

Acknowledgement

We are grateful to Dr. F. Inagaki, Tokyo Metropolitan Institute of Medical Science, for his cooperation in circular dichroism measurements.

We have made calorimetric measurements of the enthalpies of solution of gibbsite, $Al(OH)_3$(cr), in aqueous sodium hydroxide solutions at five temperatures from 100 to 150°C. Results of these measurements have been used to obtain the standard enthalpies of formation of Na^+(aq) + $Al(OH)_4^-$(aq) at the experimental temperatures. These results have also led to values of ΔC_p^0 for the reaction represented concisely by $Al(OH)_3$(cr) + OH^-(aq) = $Al(OH)_4^-$(aq), from which we have obtained standard state partial molar heat capacities of Na^+(aq) + $Al(OH)_4^-$(aq). Combination of our results with those from earlier investigations has permitted calculation of thermodynamic properties of Na^+(aq) + $Al(OH)_4^-$(aq) over a wide range of temperature and thence some generalizations about the usefulness of various equations for representing or predicting these thermodynamic properties.

Key words: gibbsite, enthalpy of solution; sodium aluminate (aqueous), thermodynamic properties; heat capacities, Na^+(aq) + $Al(OH)_4^-$(aq).

QIYUAN CHEN, YUMING XU et LOREN G. HEPLER. Can. J. Chem. **69**, 1685 (1991).

Nous avons mesuré, par calorimétrie, les enthalpies de solution de la gibbsite, $Al(OH)_3$(cr), dans des solutions aqueuses d'hydroxyde de sodium à 5 températures différentes allant de 100 à 150°C. Ces résultats ont permis d'obtenir les enthalpies standards de formation des ions Na^+(aq) + $Al(OH)_4^-$(aq) à ces températures. Ces résultats ont également permis d'obtenir les valeurs de ΔC_p^0 de la réaction représentée de façon concise par l'équation : $Al(OH)_3$(cr) + OH^-(aq) = $Al(OH)_4^-$(aq), à partir de laquelle nous avons obtenu les capacités molaires partielles de l'état standard des ions Na^+(aq) + $Al(OH)_4^-$(aq). En combinant nos résultats à ceux provenant d'études précédentes, nous avons pu calculer les propriétés thermodynamiques des ions Na^+(aq) + $Al(OH)_4^-$(aq) dans un large intervalle de températures et de faire une généralisation relative à l'utilité de diverses équations pour représenter ces propriétés thermodynamiques.

Mots clés : gibbsite, enthalpies de formation; $NaAl(OH)_4$(aq), les propriétés thermodynamiques; capacités calorifiques, Na^+(aq) + $Al(OH)_4^-$(aq).

[Traduit par la rédaction]

Introduction

The present calorimetric investigations of the enthalpy of solution of the mineral gibbsite, $Al(OH)_3$, in aqueous sodium hydroxide (several concentrations and several temperatures) have been carried out for two reasons. One specific reason has been to obtain thermochemical data that can be useful in connection with the Bayer process for treating gibbsite prior to processes leading directly to the production of metallic aluminum. A more general reason for the research described here has been to obtain thermodynamic data for the aqueous aluminate ion, $Al(OH)_4^-$, over a range of temperatures; these thermodynamic data can be useful in fields as varied as the geochemistry of aluminum-containing minerals and the corrosion of metallic aluminum. Results from these calorimetric measurements also permit testing earlier predictions of the temperature dependence of thermodynamic properties of $Al(OH)_4^-$(aq).

We already have some thermodynamic data for $Al(OH)_3$(gibbsite, cr), $Al(OH)_4^-$(aq), Al^{3+}(aq), and related species such as OH^-(aq) for 298 K. There are also some equilibrium data for higher temperatures. Most directly related to the results of this research are calorimetrically determined partial molar heat capacities for Na^+(aq) + $Al(OH)_4^-$(aq) over the temperature ranges 10–55°C (1) and 53–245°C (2).

In this work we have made calorimetric measurements of the enthalpy (ΔH) of the reaction represented by

[1] $Al(OH)_3$(gibbsite) + OH^-(aq) = $Al(OH)_4^-$(aq)

in which the non-reactive Na^+(aq) is not shown.

Experimental

Synthetic gibbsite was prepared according to a procedure established by Yin *et al.* (3). The procedure of Yin *et al.* involved dissolving certified (Fisher, Lot 765051) aluminum hydroxide in concentrated aqueous sodium hydroxide to obtain a solution with molar ratio Na/Al = 1.7. This solution was diluted with distilled water until the concentration of NaOH was 3.5 mol/L. Then this solution was seeded with small crystals of gibbsite (confirmed by X-ray analysis) that were kindly supplied by Yin. The seeded solution, initially at 32°C, was stirred slowly for 72 h while the temperature declined to 24°C. The resulting precipitate of gibbsite was washed with dilute sodium hydroxide and then with distilled water for several hours after the wash water became neutral. The washed $Al(OH)_3$ was dried at 60°C and then at 105°C to constant weight. Finally, sieving led to a sample of synthetic gibbsite that was 325–500 mesh to be used for analysis and calorimetric measurements. Heating to drive off all water led to 65.38 ± 0.05% Al_2O_3, as compared with 65.36% calculated from atomic masses.

Sodium hydroxide solutions were prepared from Assured Reagent (BDH, Lot 103769/14850) NaOH and distilled water, with care being taken to exclude CO_2. Weight titrations with standard potassium hydrogen phthalate led to the temperature-independent molalities (mol/kg) of the NaOH solutions. Separate titrations with hydrochloric acid solutions permitted establishment of the upper limit of carbonate contamination as 0.2% of the NaOH concentration.

A Tian-Calvet heat-flow calorimeter (Setaram, Model C-80) was used for our calorimetric measurements. Calibration and testing of this calorimeter has been described in detail by Xu (4). On the basis of Xu's testing and our own experience, we estimate that accuracy of the ΔH values reported here is about 0.5%.

Times required for complete reaction of gibbsite with excess NaOH ranged from about 45 to 75 min, depending on the temperature and the concentration of the NaOH solution.

To minimize thermal effects due to corrosion of the cells, four preliminary calorimetric measurements were carried out with concentrated NaOH (5 molal) at 150°C. These preliminary experiments led to formation of a "tight" layer of corrosion product on the cell walls and effectively stopped further corrosion. Blank runs with NaOH solutions (no gibbsite) confirmed the absence of a further thermal effect due to corrosion.

Results

Results (ΔH values) of all the calorimetric measurements of heats of solution of gibbsite in aqueous sodium hydroxide are reported in Table 1. Because the reaction, as represented concisely by equation [1], is electrically symmetrical, the initial molality of NaOH is equal to the final molal ionic strength of the solution as listed in Table 1.

It is possible to obtain ΔH^0 and $C_p{}^0$ values corresponding to infinite dilution as follows. First we recognize that ΔH (at any one temperature) of an electrically symmetrical reaction is independent of ionic strength in the Debye–Hückel range of concentration, and that initial dependence on ionic strength will be proportional to the ionic strength and also related to the composition of the constant ionic strength solution. The ΔH values in Table 1 are clearly dependent on temperature ($\Delta C_p \neq 0$), so we express the enthalpies of reaction as a quadratic function of temperature. All of this is summarized by the equation

$$[2] \quad \Delta H = (a_1 + a_2 m_{Al} + a_3 I + a_4 m_{Al} I) + (a_5 + a_6 m_{Al} + a_7 I + a_8 m_{Al} I)T + (a_9 + a_{10} m_{Al} + a_{11} I + a_{12} m_{Al} I)T^2$$

TABLE 2. Coefficients of eqs. [2]–[4]

$a_1 = -9.50987 \times 10^0$	$a_7 = -1.373631 \times 10^{-3}$
$a_2 = -1.105191 \times 10^1$	$a_8 = -5.852004 \times 10^{-3}$
$a_3 = +8.514732 \times 10^{-1}$	$a_9 = +2.715057 \times 10^{-5}$
$a_4 = +1.174895 \times 10^0$	$a_{10} = -6.544641 \times 10^{-5}$
$a_5 = +9.591291 \times 10^{-2}$	$a_{11} = -1.870039 \times 10^{-6}$
$a_6 = +5.439204 \times 10^{-2}$	$a_{12} = +6.80837 \times 10^{-6}$

TABLE 3. ΔH^0 and $\Delta C_p{}^0$ of reaction [1]

t (°C)	ΔH^0 (kJ mol^{-1})	$\Delta C_p{}^0$ (J K^{-1} mol^{-1})
100.1	30.07	116.2
112.9	31.56	116.9
125.7	33.06	117.6
138.6	34.59	118.3
150.3	35.97	118.9

Then we have

[3] $\Delta H^0 = a_1 + a_5 T + a_9 T^2$

and

[4] $\Delta C_p{}^0 = a_5 + 2a_9 T$

Values of the parameters in eqs. [2]–[4] are listed in Table 2.

We have used the values of the parameters listed in Table 2 to calculate the values of ΔH corresponding to each calorimetric measurement. The standard deviation, $S = [(y_i - y)^2/(n - 1)]^{1/2}$, associated with these calculated values is 0.14 kJ mol^{-1}.

Derived values of ΔH^0 and $\Delta C_p{}^0$ for the reaction represented by eq. [1] are listed in Table 3.

Thermodynamic calculations and discussion

A principal aim of this research has been to obtain thermodynamic properties of aqueous sodium aluminate: $Na^+(aq) + Al(OH)_4{}^-(aq)$. To obtain these thermodynamic properties, we combine our experimental results with the already known thermodynamic properties of gibbsite and aqueous sodium hydroxide as follows.

Hemingway *et al.* (5) have measured the heat capacities of gibbsite from 13 to 480 K. Their results lead to $S^0 = 68.44$ J K^{-1} mol^{-1} for $Al(OH)_3$(cr,gibbsite) at $T = 298.15$ K and also to values of $(H^0{}_T - H^0{}_{298.15})$ for this substance. Hemingway and Robie (6) have applied hydrofluoric acid calorimetry to determine $\Delta_f H^0 = -1293.13 \pm 1.19$ kJ mol^{-1} for gibbsite at $T = 298.15$ K. We have combined all of these properties with those of the elements (7) to obtain the thermodynamic properties of gibbsite that are listed in Table 4.

For NaOH(aq) at $T = 298.15$ K we select $\Delta_f H^0 = -470.355 \pm 0.072$ kJ mol^{-1} and $S^0 = 47.55 \pm 0.25$ J K^{-1} mol^{-1} from the CODATA critical compilation (8). Standard state partial molar heat capacities of NaOH(aq) have been selected from results of five calorimetric investigations (9–13). All of these results fit together smoothly and apparently reliably over the temperature range of interest to us. We have combined these properties with those of the elements (7) to obtain the thermodynamic properties of NaOH(aq) that are listed in Table 5.

We have combined our enthalpies of reaction (Table 3) of gibbsite with NaOH(aq) with the enthalpies of formation of gibbsite (Table 4) and aqueous NaOH (Table 5) to obtain the enthalpies of formation of aqueous sodium aluminate, $Na^+(aq) + Al(OH)_4{}^-(aq)$, listed in the second column in Table 6. The values of $\Delta_f(H^0{}_T - H^0{}_{298.15})$ listed in the third column in Table 6 are calculated from heat capacities of the elements (7) and the partial molar heat capacities of $NaAl(OH)_4$(aq) from this work as discussed in the following paragraphs. Finally, the fourth column in Table 6 lists our values for the standard state enthalpy of formation of aqueous sodium aluminate at $T = 298.15$ K: the average is $\Delta_f H^0 = 1743.11 \pm 0.24$ kJ mol^{-1}, where the $\pm$ indicates the *standard deviation*. The *uncertainty* in this $\Delta_f H^0$ is much larger than the standard deviation. Considerations of uncertainties in auxiliary data (other standard enthalpies of formation and heat capacities) and our measurements lead us to estimate that the *total* uncertainty in our $\Delta_f H^0$ values in Table 6 is about ± 1.5 kJ mol^{-1}.

To obtain values for the standard state partial molar heat capacities of aqueous sodium aluminate, we start with the $\Delta C_p{}^0$ values listed in Table 3 for the reaction represented by eq. [1]. Combinations of these $\Delta C_p{}^0$ values with heat capacities at the same temperatures for gibbsite (Table 4) and aqueous NaOH (Table 5) lead to the standard standard state heat capacities of $NaAl(OH)_4$(aq) that are list in the last column of Table 6.

In addition to our heat capacities of $NaAl(OH)_4$(aq) for five temperatures (100–150°C) listed in Table 6, we have experimental heat capacities at four temperatures (10–55°C) from Hovey *et al.* (1) and at five temperatures (53–245°C) from Caiani *et al.* (2). As our first step toward assessing and then using these standard state heat capacities for $NaAl(OH)_4$(aq) at 14 temperatures from 10 to 245°C, we have made a graph of $C_p{}^0$ against T (Fig. 1) and observed that 13 of the results fall on a reasonably smooth curve. We have therefore proceeded with analysis, omitting the $C_p{}^0$ from Caiani *et al.* (2) for 53°C, which seems to be inconsistent with the other 13 heat capacities from three independent investigations.

An equation proposed by Holmes and Mesmer (14) has been used by them and others for convenient representation of standard state heat capacities of aqueous electrolytes. We have fitted their equation to the results of Hovey *et al.* (1), Caiani *et al.* (2), and the present results to obtain

[5] $C_p{}^0 = -1451.041 - 7.758518/(T - 470) + 8.993519T - 1.235584 \times 10^{-2} T^2$

for $NaAl(OH)_4$(aq). For this fitting we have weighted the direct heat capacities (1, 2) twice as heavily as we have our own heat capacities (obtained by differentiation of ΔH^0 values). The standard deviation of the fit of eq. [5] is 12 J K^{-1} mol^{-1}, which is very good. We have also used the same heat capacities of $NaAl(OH)_4$(aq) for fitting the HKF equation (15) and find that the standard deviation of the fit is twice as large as the 12 J K^{-1} mol^{-1} found above for the Holmes–Mesmer equation.

The Holmes–Mesmer equation fits the experimental data better than does the HKF equation, but it should be noted that the former equation has more adjustable parameters than does the latter. Because the fit of the Holmes–Mesmer equation is better, we use this equation in some further calculations.

Although we are using the Holmes–Mesmer equation here, let us point out that the HKF equation has a substantial value.

*Average $\Delta_f H^0_{298.15} = -1743.11 \pm 0.24\ kJ\,mol^{-1}$.

Hovey *et al.* (1) used their heat capacities over the relatively narrow range from 10 to 55°C to evaluate the parameters in the HKF equation and thence estimated standard heat capacities of $NaAl(OH)_4$(aq) at much higher temperatures. Although the experimental results from the present investigation and from Caiani *et al.* (2) for high temperatures are to be preferred to the values estimated by Hovey *et al.* (1), it should be recognized that the estimated values are close enough to the better experimental values to be useful for a variety of thermodynamic calculations.

On the basis of the calculations summarized above and a few similar calculations for other electrolytes, we offer the following generalizations. (*i*) The Holmes–Mesmer equation is usually better than the HKF equation for accurate represen-

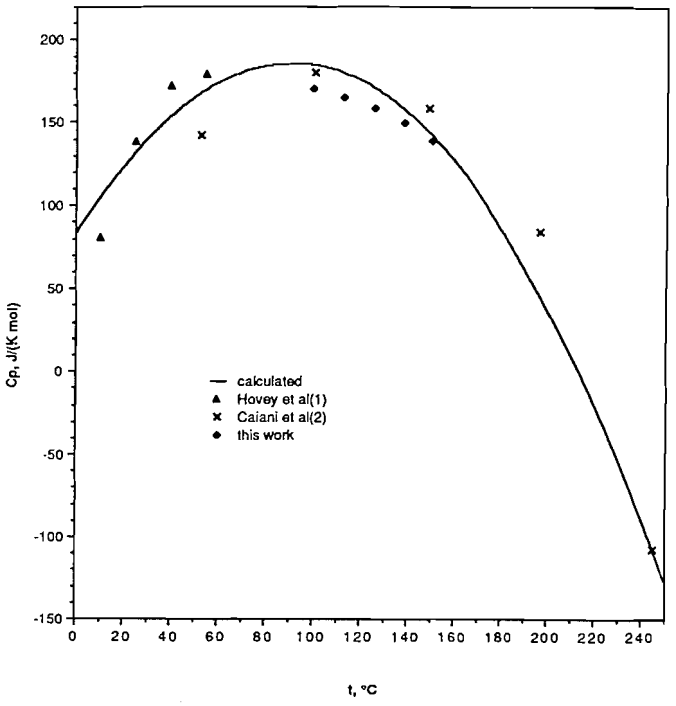

FIG. 1. Standard state partial molar heat capacities of $NaAl(OH)_4$-(aq) from various sources.

tation of experimental heat capacities of aqueous electrolytes over a wide range of temperatures. (*ii*) The HKF equation is most useful in the common case where one has heat capacities for a narrow range of temperatures (say 10–55°C) and wants to estimate heat capacities for higher temperatures.

In Table 7 we summarize the thermodynamic properties of $NaAl(OH)_4(aq)$. Calculations leading to the tabulated quantities have made use of properties already cited and the smoothed heat capacities obtained from the Holmes–Mesmer equation [5].

Next we use the thermodynamic properties for $NaAl(OH)_4$-(aq) that are listed in Table 7 with the thermodynamic properties of HCl(aq) and NaCl(aq) to calculate the conventional thermodynamic properties of $Al(OH)_4^-(aq)$ that are listed in Table 8. All of these tabulated properties are based on the commonly used convention that $\Delta_f G^0$, $\Delta_f H^0$, S^0, and C_p^0 of $H^+(aq)$ are zero at every temeprature. For these calculations we have used thermodynamic properties from this investigation and from refs. 8, 16–18.

Thermodynamic properties listed in Tables 7 and 8 are related to the earlier work by Chang (19, 20), Kuyunko *et al.* (21), and Apps *et al.* (22, 23). It is a convincing indication of thermodynamic consistency of a variety of experimental results that the Gibbs energies of $Al(OH)_4^-(aq)$ reported by Apps *et al.* (22, 23) are in good agreement with our values that are based on calorimetric measurements. It appears (24) that

consideration of all of these results together leads to selection of "best" $\Delta_f H^0$ and S^0 values that are closer to those we have selected here than to those selected earlier (23) by Apps *et al.*

Molecular orientation in thin Langmuir–Blodgett films of dipalmitoylphosphatidylcholine as studied by FTIR transmission and reflection–absorption spectroscopy

EMIKO OKAMURA, JUNZO UMEMURA, AND TOHRU TAKENAKA[1]
Institute for Chemical Research, Kyoto University, Uji, Kyoto-fu 611, Japan

Received April 19, 1991

This paper is dedicated to Dr. Richard Norman Jones

EMIKO OKAMURA, JUNZO UMEMURA, and TOHRU TAKENAKA. Can. J. Chem. **69**, 1691 (1991).

Langmuir–Blodgett (LB) films of DPPC were prepared by the horizontal lifting technique at various surface pressures encompassing the plateau region of its surface pressure (π) – area (A) isotherm. Molecular orientation in the LB films was quantitatively evaluated by a method recently proposed by Umemura *et al.* (J. Phys. Chem. **94**, 62 (1990)) using Fourier transform infrared (FTIR) transmission and reflection–absorption (RA) spectra. From the results obtained, it is apparent that (*i*) in the LB films deposited at higher surface pressures above the plateau, the hydrocarbon chains are of all-*trans* conformation and well oriented at the tilting angle of *ca.* 20° from the surface normal; (*ii*) at lower surface pressures below the plateau, the chain segments are almost randomly oriented (like in a liquid-crystalline state) with an increased amount of the *gauche* conformers; and (*iii*) in the films deposited within the plateau, the hydrocarbon chains are in an intermediate state between the above two states. It is therefore concluded that the plateau corresponds to a process of the reorientation of the hydrocarbon chains from an almost randomly-oriented state to a highly-oriented one with the increase in the number of the all-*trans* conformers.

Key words: dipalmitoylphosphatidylcholine, Langmuir–Blodgett film, molecular orientation, infrared reflection–absorption spectra, surface pressure–area isotherm.

EMIKO OKAMURA, JUNZO UMEMURA et TOHRU TAKENAKA. Can. J. Chem. **69**, 1691 (1991).

Utilisant la technique du soulèvement horizontal à diverse pressions superficielles couvrant la région du plateau de son isotherme de la pression superficielle (π) – surface (A), on a préparé des films de Langmuir–Blodgett (LB) de la DPPC. Utilisant la méthode proposée récemment par Umemura et ses collaborateurs (J. Phys. Chem. **94**, 62 (1990)) et basée sur les spectres infrarouges par transformation de Fourier de transmission (IRTF) et de réflexion–absorption (RA), on a évalué d'une façon quantitative l'orientation moléculaire dans les films de LB. À partir des résultats obtenus, il est apparent que, dans les films LB déposés : (*i*) à des pressions superficielles supérieures à celle du plateau, les chaînes hydrocarbonées possèdent toutes la conformation complètement *trans* et elles sont toutes orientées à un angle d'environ 20° par rapport à la surface normale; (*ii*) à des pressions inférieures à celles de la pression du plateau, les segments de chaînes sont pratiquement orientés au hasard (état semblable à celui d'un cristal-liquide) avec une quantité plus importante des conformères *gauches*; et (*iii*) à des pressions correspondant à celles du plateau, les chaînes hydrocarbonées sont dans un état intermédiaire entre les deux états mentionnés plus haut. On en conclut donc que le plateau correspond à un processus de réorientation des chaînes hydrocarbonées d'un état orienté pratiquement au hasard vers un état hautement orienté avec une augmentation du nombre des conformères complètement *trans*.

Mots clés : dipalmitoylphosphatidylcholine, film de Langmuir–Blodgett, orientation moléculaire, spectre infrarouge de réflexion–absorption; isotherme de la pression superficielle–surface.

[Traduit par la rédaction]

Introduction

Langmuir–Blodgett (LB) films of phospholipids have been of great interest as highly organized assemblies mimicking biomembranes. As far as we know, however, the structure and molecular orientation in the thin LB films have scarcely been investigated mainly for two reasons.

One reason is the difficulty of depositing phospholipid LB films on solid substrates by vertical dipping (or LB) technique. In the case of dipalmitoylphosphatidylcholine (DPPC), for example, only the single monolayer has so far been deposited with a transfer ratio of unity (1–3). Peng *et al.* (3) have overcome this difficulty by using an aqueous uranyl acetate solution as the subphase. However, the uranyl ion may affect the structure of the LB films of DPPC, since the surface pressure (π) – area (A) isotherm of the spread monolayer on this subphase differs from that on pure water (3). Another improvement of the film deposition of DPPC has recently been achieved by Okahata and co-workers (4). They have succeeded in depositing multibilayer LB films from pure water surface at higher surface pressures, using the horizontal lifting (HL) technique without a frame for removing the residual monolayer from the water surface at the pulling-up stage of the solid substrate. The transfer ratio was found to be 2.0 (4). Usefulness and characteristics of this technique for the deposition of the LB films of stearic acid have also been pointed out by our laboratory (5). Futhermore, in the present study, we found that the multilayer LB films of DPPC could be deposited by this technique from the water surface even at lower surface pressures, as will be described later in detail.

The other reason is that the convenient technique for quantitative analyses of molecular orientation in thin organic films has not been established. Recently, however, Umemura *et al.* have proposed a useful method for the quantitative evaluation of molecular orientation in thin LB films using infrared reflection–absorption (RA) and transmission spectroscopy (6).

In this paper, using the same method, we quantitatively evaluated the molecular orientation in thin LB films of DPPC deposited by the HL technique at various surface pressures. Since it has been known that the spread monolayer of DPPC on the water surface has a clear plateau region in the π–A isotherm ascribable to a liquid-expanded (LE) to liquid-condensed (LC) phase transition (7–11), special attention was paid to the difference in molecular structure and orientation in the LB films

prepared at the surface pressures below and above the plateau pressure.

Experimental

L-DPPC was purchased from Sigma Chemical Co. and used without further purification. Chloroform used as the spreading solvent was a specially prepared reagent from Nacalai Tesque, Kyoto. Water was purified as described previously (12). The DPPC monolayers were spread from a 1.3×10^{-3} M chlorofrom solution on water at 20°C. The surface pressure of the monolayers was measured by the Wilhelmy method using a Shimadzu model ST-1 surface tensometer equipped with a ground-glass plate. As the solid substrates for infrared transmission measurements, CaF_2 plates (25 mm in diameter) were employed. Glass slides on which a 100-nm thick silver film had been vacuum-evaporated were used for RA measurements. Since the surfaces of both substrates are hydrophilic, the first DPPC monolayer was transferred using the vertical dipping technique and the following monolayers were deposited by the HL technique without a frame for removing the residual monolayer from the water surface at the pulling-up stage of the solid substrates. The dipping speed of the substrates was 5 mm min^{-1}. The transfer ratios were found to be 1.0 ± 0.1 for the first monolayer and 1.9 ± 0.2 for the following monolayers at all the surface pressures examined.

The infrared spectra were recorded on a Nicolet model 6000C FTIR spectrophotometer equipped with an MCT detector with a resolution of 4 cm^{-1}. Five thousand interferograms were accumulated for both RA and transmission measurements. The accuracy of frequency readings was better than ± 0.2 cm^{-1}. For the RA measurements, a Harrick model RMA-00G reflection attachment was used at an angle of incidence of 85°. Two wire-grid polarizers were placed in parallel with each other just after the reflection attachment to improve the degree of polarization.

Results and discussion

The π–A isotherm of the DPPC monolayer on the water surface is given in Fig. 1, being in good agreement with those reported previously (9–13). There is a clear plateau region between *ca.* 0.6 and 0.8 nm^2 $molecule^{-1}$. The LB films were deposited at (*a*) 1.5, (*b*) 5.5, (*c*) 30, and (*d*) 45 mN m^{-1}, with points (*a*) and (*b*) being below and around the plateau pressure, respectively, and (*c*) and (*d*) being above it.

Infrared transmission and RA spectra of DPPC LB films

Figure 2 shows the infrared transmission spectra of the 9-monolayer LB films of DPPC deposited on a CaF_2 substrate at the above four points. In this figure, increase in band intensities, which is due to the surface-density increase of DPPC on the monolayer compression, was corrected and normalized to the value at 1.5 mN m^{-1}. Assignments of the absorption bands are summarized in Table 1. Frequency changes of the antisymmetric and symmetric CH_2 stretching (ν_aCH_2 and ν_sCH_2) bands on the monolayer compression are shown in Table 2. Both bands shift to lower frequencies with the increase in the surface pressure, suggesting the increase in the amount of all-*trans* conformers of the hydrocarbon chain (14–16). These frequency shifts are very similar to the recent results of FTIR external reflection spectroscopy by Dluhy *et al.* (17, 18) for DPPC monolayers spread on the water surface. This fact implies the similarity of the structure between the spread monolayer and the LB films. The CH_2 scissoring band of the DPPC LB films is observed at 1468 cm^{-1} irrespective of the surface pressure, indicating that the hydrocarbon chains are predominantly packed in the hexagonal subcell lattice (6, 14, 15).

As shown in Fig. 2, the intensities of the CH_2 stretching and scissoring bands are largely enhanced at 30 and 45 mN m^{-1}. Although the intensities of the polar group bands are relatively weak as compared to these hydrocarbon bands, the intensity

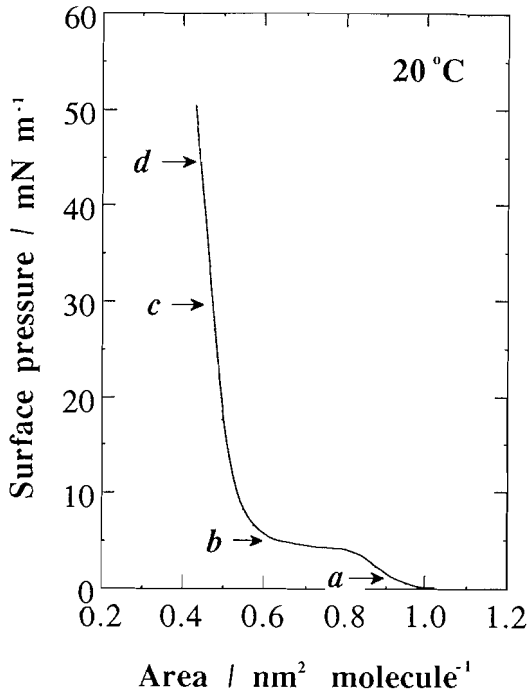

FIG. 1. Surface pressure (π) – area (A) isotherm of a DPPC monolayer at the air/water interface at 20°C. The arrows *a*, *b*, *c*, and *d* represent the surface pressures at which the LB films were transferred.

enhancements are also found for the C=O stretching (1737 cm^{-1}), antisymmetric and symmetric PO_2^- stretching (1257 and 1093 cm^{-1}), symmetric C—O—C stretching (1058 cm^{-1}), and asymmetric $N^+(CH_3)_3$ stretching (969 cm^{-1}) bands at 30 and 45 mN m^{-1}.

Figure 3 represents the infrared RA spectra of the 9-monolayer LB films of DPPC deposited on a Ag-evaporated glass slide at the points (*a*), (*b*), (*c*), and (*d*) in Fig. 1. Increase in intensities caused by the surface-density increase was also corrected. Evidently, the intensity of the ν_aCH_2 and ν_sCH_2 bands is decreased with increasing the surface pressure, being accompanied by the same frequency shifts as that shown in Table 2. The decrease in intensity of these bands makes a striking contrast to the above-mentioned fact for the transmission spectra (Fig. 2). This clearly indicates that the transition moments of these bands tend to orient parallel to the film surface at higher surface pressures above the plateau. In other words, the hydrocarbon chain of DPPC tends to orient perpendicular to the film surface at these pressures. This is also ascertained by the fact that the CH_2 wagging band at 1200 cm^{-1} appears at 30 and 45 mN m^{-1} in the RA spectra, while it is absent at the same pressures in the transmission spectra. The spectral change for the polar group bands is rather complex, but the intensities of the symmetric PO_2^- stretching and symmetric C—O—C stretching bands are enhanced at 30 and 45 mN m^{-1}. However, the asymmetric $N^+(CH_3)_3$ stretching band cannot be detected at these pressures.

Quantitative evaluation of the molecular orientation

Using our new method (6), the orientation of the hydrocarbon chain and the polar groups of DPPC in the LB films deposited at (*a*), (*b*), (*c*), and (*d*) points was quantitatively evaluated from the transmission and RA spectra shown in Figs. 2 and 3, under the confirmed condition of an uniaxial orientation with respect to the surface normal. The orientation

969	Asymmetric $N^+(CH_3)_3$ stretching

angles of the transition moments of the ν_aCH_2 and ν_sCH_2 bands (α and β, respectively) thus obtained are listed in Table 2, together with the orientation angle of the hydrocarbon chain axis (γ) calculated from the α and β values by the orthogonal relation (6)

$$\cos^2\alpha + \cos^2\beta + \cos^2\gamma = 1$$

In the 9-monolayer LB films deposited at 30 and 45 mN m^{-1} (above the plateau), the transition moments of both ν_aCH_2 and ν_sCH_2 bands are oriented with the angle of 76–78° from the surface normal. By using these values, the orientation angle of the hydrocarbon chain axis (γ) is calculated to be 18–20° from the surface normal, in a good agreement with that (19°) estimated by Akutsu *et al.* (1) from the transmission infrared dichroism for thick LB films of DPPC (~120 layers on each side of a ZnS substrate coated with a ferric stearate layer) deposited at 29.5 mN m^{-1}. From these γ values, the order parameter $f = (3\langle\cos^2\gamma\rangle - 1)/2$ of the hydrocarbon chain is calculated to be 0.8–0.9 at 30 and 45 mN m^{-1}, suggesting the highly ordered state of the chain.

TABLE 2. Frequencies and orientation angles α, β, and γ of DPPC in the 9-monolayer LB films deposited at various surface pressures

		ν_aCH_2		ν_sCH_2		
Point	π/mN m^{-1}	ν/cm^{-1}	α^a	ν/cm^{-1}	β^a	γ^b
d	45	2918	76°	2850	76°	20°
c	30	2918	77°	2850	78°	18°
b	5.5	2919	59°	2851	64°	42°
a	1.5	2922	56°	2853	57°	51°

[a]Tilt angle of the transition moments from the surface normal.
[b]Orientation angle of the hydrocarbon chain axis derived from the orthogonal relation.

At 1.5 mN m^{-1} (below the plateau), however, the hydrocarbon chain axis is found to be tilted with the angle of *ca.* 50°, which corresponds to the order parameter of *ca.* 0.1. These values mean that the hydrocarbon-chain segments are almost randomly oriented with large proportion of the *gauche* conformers (like in a liquid-crystalline state) below the plateau. The orientation angle and the order parameter of the chain axis ($\gamma \approx 40°$ and $f \approx 0.3$) at 5.5 mN m^{-1} (around the plateau) are the intermediates between the above two cases. This fact suggests that the hydrocarbon chain in the LB film prepared around the plateau region is in the gel to liquid-crystalline transition state. These results agree well with those of electron microscopic observations by Neuman *et al.* (13, 19) for the monomolecular DPPC films deposited on a mica substrate at the plateau surface pressure.

The orientation angles (φ's) were also calculated for the polar bands at 30 and 45 mN m^{-1}, as shown in Table 3. The intensity of these bands at 1.5 and 5.5 mN m^{-1} was very weak and the angles hard to estimate. The results in Table 3 are also compatible with those obtained at 29.5 mN m^{-1} by Akutsu *et al.* (64° for the C=O stretching band and 55–90° for the symmetric PO_2^- stretching band) (1); they mean that the transition moments of the polar bands lie rather parallel to the film surface. The weak intensities of these bands at 1.5 and 5.5 mN m^{-1} in the

transmission and RA spectra imply that a different type of orientation of the polar groups takes place at these low surface pressures.

Conclusions

Using the horizontal lifting technique, we deposited the multilayer LB films of DPPC on solid substrates from the water surface at various surface pressures. FTIR transmission and RA spectra were recorded for these LB films deposited on CaF_2 and Ag substrates, respectively. From the intensity ratio of the major absorption bands between the RA and transmission spectra, we quantitatively evaluated the molecular orientation in the LB films. The hydrocarbon-chain segments of DPPC in the LB films transferred at lower surface pressures below the plateau of the π–*A* isotherm were almost randomly oriented as in a liquid-crystalline state. The chains in the films transferred at higher surface pressures above the plateau were found to be highly oriented with the all-*trans* conformation. The orientation angle of the hydrocarbon chain axis was obtained to be *ca.* 20° from the surface normal. For the films transferred at the surface pressures around the plateau, the hydrocarbon chains were in the intermediate state between the above two cases. It is, therefore, concluded that the plateau in the π–*A* isotherm corresponds to a process of the reorientation of the hydrocarbon chains from an almost randomly-oriented state to a highly-oriented one with the increase in the number of the all-*trans* conformers.

Anomalous temperature-dependent Raman scattering in lithium hydrazinium sulfate

ROGER FRECH AND SCOTT H. BROWN
Department of Chemistry and Biochemistry, University of Oklahoma, Norman, OK 73019, U.S.A.

Received April 23, 1991

This paper is dedicated to Dr. Richard Norman Jones

ROGER FRECH and SCOTT H. BROWN. Can. J. Chem. **69**, 1695 (1991).

Results of a polarized Raman scattering study of single crystal lithium hydrazinium sulfate, $LiN_2H_5SO_4$, over a temperature interval from 11 to 300 K are discussed. Unusual temperature dependence of the band center scattering intensity is observed in a few intramolecular hydrazinium modes, intramolecular sulfate ion modes, and lattice modes. The intensity of these modes increases with increasing temperature from 11 K to about 175 K, then abruptly decreases over a small interval between 175 and 200 K. Above 200 K the band center intensity then exhibits normal behavior, slowly decreasing with increasing temperature. Possible explanations for this anomalous behavior are discussed.

Key words: lithium hydrazinium sulfate, proton conductor, Raman spectroscopy.

ROGER FRECH et SCOTT H. BROWN. Can. J. Chem. **69**, 1695 (1991).

On discute des résultats obtenus lors d'une étude de diffusion Raman polarisée sur un cristal unique du sulfate de lithium et d'hydrazinium, $LiN_2H_5SO_4$, réalisée dans l'intervalle de températures allant de 11 à 300 K. On a observé une relation inhabituelle entre la température et l'intensité de la diffusion du centre de la bande de quelques modes intramoléculaires de l'hydrazinium, de quelques modes intramoléculaires de l'ion sulfate et dans quelques modes du réseau. Les intensités de ces modes augmentent avec une augmentation de la température de 11 K à environ 175 K; elles diminuent alors rapidement sur un petit intervalle entre 175 et 200 K. Au-dessus de 200 K, l'intensité du centre de la bande se comporte normalement; elle diminue lentement avec une augmentation de la température. On discute de diverses explications possibles pour ce comportement anormal.

Introduction

The coarse features of the proton conductivity of lithium hydrazinium sulfate, $LiN_2H_5SO_4$, can be explained in part by the structure of a crystallographic unit cell. The crystal is orthorhombic (1–4) with a tetramolecular cell characterized by the space group $Pna2_1$ ($C_{2v}{}^9$). The sulfur and lithium atoms are tetrahedrally coordinated by oxygen atoms, forming a three-dimensional framework through which channels run parallel to the c axis. The hydrazinium ions, $N_2H_5{}^+$, lie in these channels and are linked by an extended hydrogen-bonded network between NH_2 groups with the N—N axis perpendicular to the channels, *i.e.* perpendicular to the c axis. The $NH_3{}^+$ ends of the hydrazinium ions are hydrogen bonded to the surrounding sulfate ions.

The protonic conductivity is anisotropic, with the highest value along the c axis (5). Therefore, it is assumed that the extended hydrogen-bonded network of hydrazinium ions is implicated in the ionic transport mechanism. Two models have been invoked to describe the mechanism of proton transport in this compound. In the first, a Grotthuss-like mechanism (6), proton transport is described (7) as a hop along the extended hydrogen-bonded network, perhaps assisted by tunneling, from a polyatomic donor to an adjacent polyatomic acceptor species. Following the hop, the donor ion reorients to receive another proton. In this model, the charge-carrying species is the proton and the donor/acceptor ions are part of a relatively rigid framework. Reorientational degrees of freedom of the donor/acceptor ions play a significant role in the proton transport mechanism. In the Vehicle Model (8) the charge-carrying species is a polyatomic species to which a proton is attached. The protonated species is mobile within the framework defined by other charged species occupying fixed lattice sites. Therefore in lithium hydrazinium sulfate, the mobile species is assumed to be the $N_2H_5{}^+$ hydrazinium ion (5).

The X-ray and neutron diffraction analyses describe the structural features of the unit cell of lithium hydrazinium sulfate and this, combined with the conductivity data, implicate the extended hydrogen-bonded network of the NH_2 portion of the hydrazinium ions as playing a role in the conductivity mechanism. However, dynamical measurements are required to extend this picture. To this end there have been few infrared (9) and Raman (10, 11) spectroscopic studies, as well as NMR studies (12–14). We recently reported the results of a temperature-dependent Raman study of an oriented single crystal (15); these data argued against the Vehicle mechanism as significantly contributing to the conductivity below room temperature. In the course of these and subsequent measurements, a pattern of anomalous behavior was noted in a number of vibrational modes. That behavior is the subject of this paper.

Experimental

Reagent grade $N_2H_6SO_4$ and Li_2CO_3 were mixed in a 2:1 molar ratio in water. Large single crystals of optical quality were obtained by slow evaporation of the aqueous solution at 40°C. Typical crystals were elongated along the c axis with prominent (010), (110), and (011) faces. The crystal used for the spectroscopic measurements was cut into a parallelpiped whose axes corresponded to the crystallographic axes as verified by X-ray diffraction measurements.

Polarized Raman spectra were recorded at a spectral bandpass of 3 cm^{-1} on a system based on a 0.85 meter Czerny-Turner double monochromator with a cooled C31034 photomultiplier tube. The incident radiation was provided by the 488.0 nm line of a Spectra Physics model 165/265 argon ion laser operating with an output power of 300 mW. The sample was cooled in an Air Products Displex model CSA-202E closed cycle helium refrigeration system equipped with a DMX-1E vacuum shroud sample chamber. The high optical quality of the sample prevented secondary laser emission lines from appearing in the Raman spectra, necessitating the use of a neon calibration lamp to calculate the frequencies of the various bands. The uncertainty in the band positions is estimated to be ± 1 cm^{-1}.

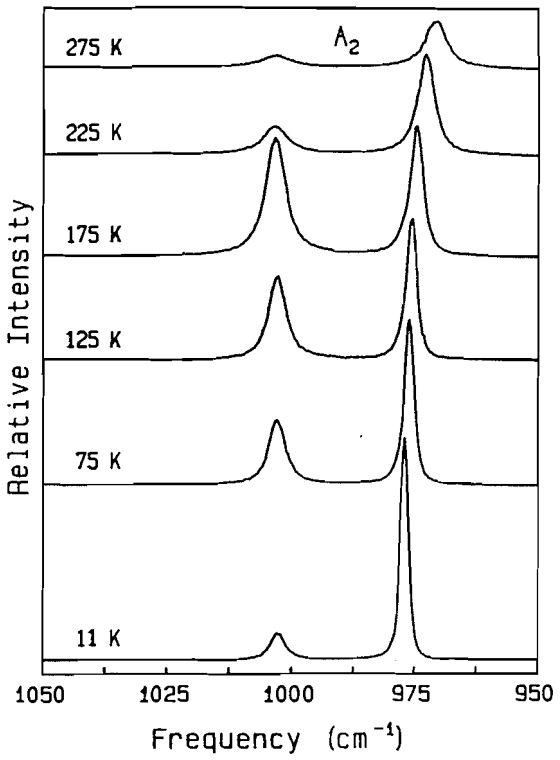

FIG. 1. Temperature-dependent Raman scattering spectra for the hydrazinium ion ν(N—N) mode and the anomalous sulfate ion ν_1 mode in an A_2 scattering geometry.

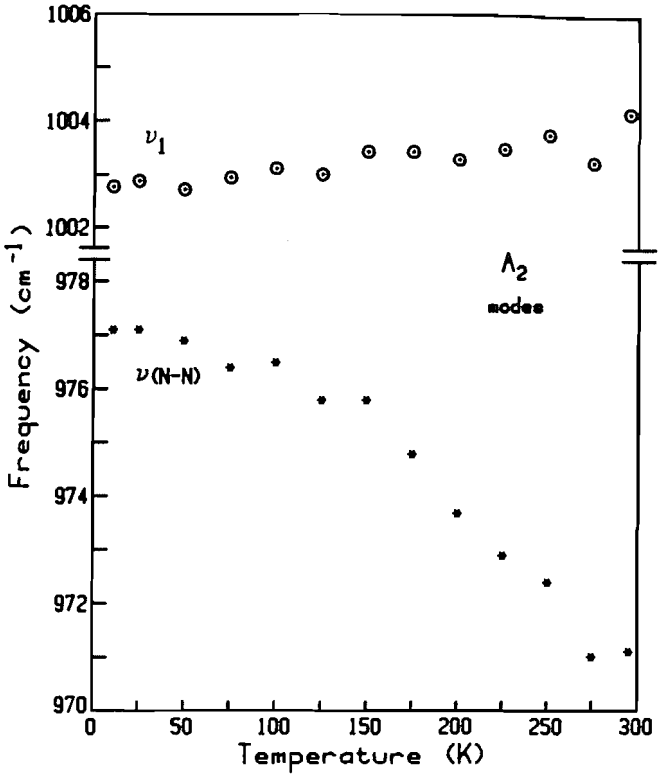

FIG. 2. The temperature dependence of the hydrazinium ion ν(N—N) and the anomalous sulfate ion ν_1 stretching frequencies.

Results

Figure 1 shows the temperature dependence of the ν(N—N) mode at 977 cm^{-1} and the $\nu_1(SO_4^{2-})$ at 1004 cm^{-1} in a scattering geometry which allows modes belonging to the A_2 irreducible representation. The ν(N—N) mode shows the expected trends in intensity, frequency, and bandwidth over the entire temperature range. In particular, the peak intensity slowly decreases with increasing temperature. By contrast, the $\nu_1(SO_4^{2-})$ component shows two distinct types of anomalous intensity behavior in this range. First, the intensity at the band center gradually *increases* with temperature over the range 11–175 K. Second, the intensity decreases dramatically and abruptly over the small temperature interval between 175 and 200 K. Then, above 200 K, the peak intensity gradually decreases with increasing temperature as expected for a typical vibrational mode.

The frequency and bandwidth behavior of this mode were carefully measured, primarily to examine these spectral parameters for breaks or anomalies which might coincide with the surprising intensity behavior. The spectral bandwidth (FWHM) was deconvoluted assuming a triangular instrumental slit function and was found to increase from 3.6 cm^{-1} at 11 K to 7.9 cm^{-1} at 295 K. The rate of increase of the bandwidth with temperature is small at low temperatures, but increases at about 100 K and appears to be linear from 100 to 300 K. This bandwidth behavior is quite similar to most of the other modes in lithium hydrazinium sulfate and is not unusual. The bandwidths of the ν_1 components belonging to other irreducible representations was also examined and the temperature dependence was found to be quite similar to the A_2 component.

The temperature dependence of the frequencies of both the

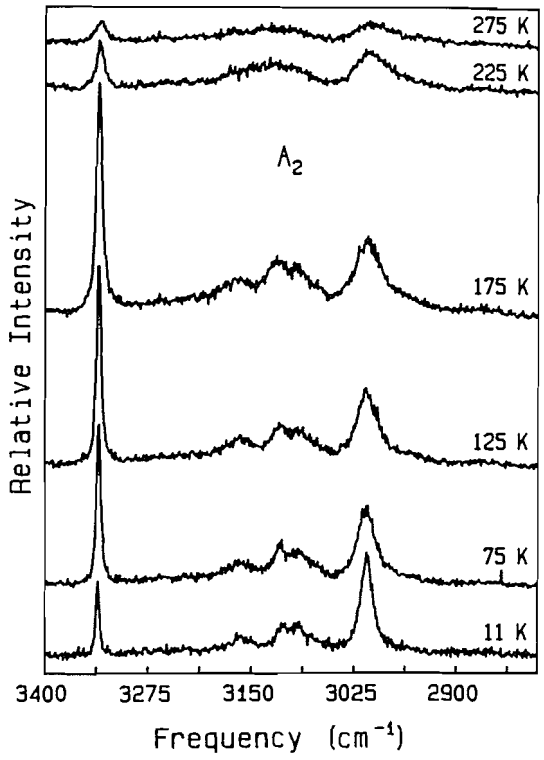

FIG. 3. Temperature-dependent Raman spectra for the NH stretching modes of the hydrazinium ion in an A_2 scattering geometry. Note the anomalous intensity behavior of the mode at 3336 cm^{-1}.

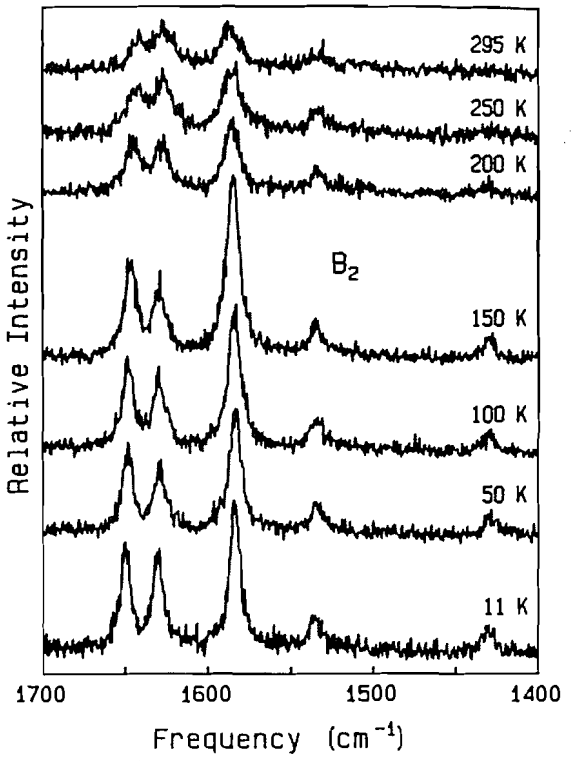

FIG. 4. Temperature-dependent Raman spectra of the HNH angle deformation modes of the hydrazinium ion in a B_2 scattering geometry, illustrating the anomalous mode at 1583 cm^{-1}.

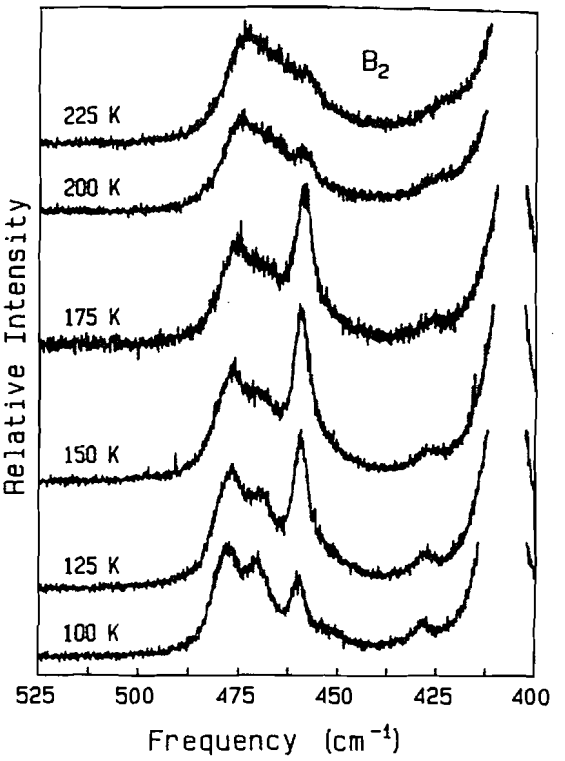

FIG. 5. Raman spectra of the sulfate ion ν_2 mode and the lithium ion lattice modes from 100 to 225 K, illustrating the anomalous mode at 461 cm^{-1}.

ν(N—N) mode and $\nu_1(SO_4^{2-})$ is shown in Fig. 2. The ν_1 mode is only slightly dependent on temperature, which is not unusual for the totally symmetric stretching motion of the sulfate anion. However, it is unusual that there is a slight increase of the frequency with increasing temperature. These data show that there are no abrupt changes in either the frequency or the bandwidth of the $\nu_1(SO_4^{2-})$ mode at 175–200 K in spite of the abrupt change in peak intensity.

Behavior similar to the A_2 component of $\nu_1(SO_4^{2-})$ is noted in a small number of other modes. Figure 3 shows the N—H stretching region in an A_2 scattering geometry. The symmetry-based assignments of these bands have been previously given (10). The mode at 3336 cm^{-1} shows exactly the same pattern of intensity dependence on temperatures as did the $\nu_1(SO_4^{2-})$ mode. It should be noted that all other N—H stretching modes show no unusual temperature dependent behavior.

Although the previous two bands displaying anomalous intensities occurred in an A_2 scattering geometry, such behavior is not restricted to that irreducible representation. Figure 4 shows a rather complicated spectral region containing bands primarily from the HNH angle deformation modes which belong to the B_2 symmetry species. The intensity of the band at 1583 cm^{-1} exhibits the previously described anomalous pattern with increasing temperature.

Another striking example is the B_2 mode at 461 cm^{-1} illustrated in Fig. 5. This mode is predominantly the ν_2 bending motion of the sulfate ion, although it is possible that there is some contribution from lithium ion translatory motion mixed in. It is particularly interesting that the other ν_2 components at slightly higher frequencies show no unusual temperature-dependent intensity behavior.

Finally the external optic modes from 320 to 20 cm^{-1} are shown in Fig. 6. Here the modes at 199, 126, and 115 cm^{-1} exhibit the previously described anomalous behavior. The latter two modes are especially striking, since at 25 K they appear as high and low frequency shoulders around the lattice mode at 121 cm^{-1}. As the temperature increases, the mode at 121 cm^{-1} slowly decreases in peak intensity, while the two flanking anomalous modes grow in intensity. Between 175 and 225 K these modes collapse into an asymmetric band whose peak intensity continues to decrease with increasing temperature.

Discussion

Abrupt intensity changes in the Raman scattering spectrum with temperature are often associated with phase transitions. Indeed there is evidence that Raman spectroscopy is more sensitive to minute displacements of atoms than are X-ray diffraction methods (16). In lithium hydrazinium sulfate, any structural change responsible for the anomalous modes would be expected to be small since such a small percentage of the modes is affected. No major structural phase transitions have been reported for lithium hydrazinium sulfate in the range of 11–300 K; in fact the temperature-dependent spectroscopic data in this study argue against any major transitions in this range.

One dynamical change in the lithium hydrazinium sulfate crystal which occurs in the temperature range of interest originates in the reorientational motions of the $—NH_2$ and $—NH_3^+$ ends of the hydrazinium ion. The oscillations of the $—NH_3^+$ entity are reported to increase in amplitude with temperature throughout the entire 11–300 K range (17, 18). It is conceivable that the changes in the dynamics of the hydrazinium ion

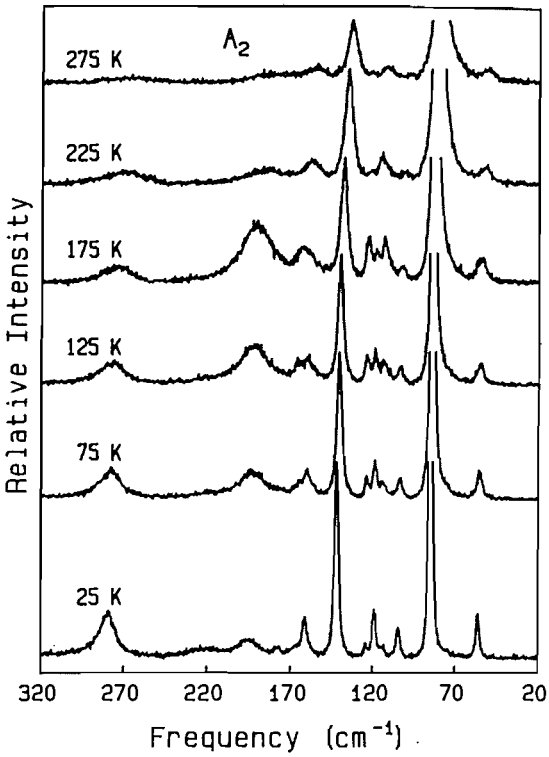

FIG. 6. Temperature dependence of the Raman active lattice modes in an A_2 scattering geometry. Note the anomalous modes at 199, 126, and 115 cm^{-1}.

could cause the intensities of several hydrazinium ion internal modes to correspondingly vary with temperature. However, using this picture to justify the anomalous behavior observed in several sulfate ion internal modes and lattice modes is difficult and would require a substantial degree of coupling between the hydrazinium modes and the other sulfate and lattice modes which display unusual temperature-dependent behavior. This degree of coupling seems unlikely since the sulfate internal modes are relatively unaffected by deuterium substitution, indicating a low degree of coupling between the hydrazinium and sulfate ion sublattices (11).

Though the structural change responsible for the anomalous mode behavior must be small, the fact that both intramolecular sulfate and hydrazinium ion modes and intermolecular lattice modes are involved suggests that the origin of this anomalous behavior is global in nature, *i.e.* associated with the entire unit cell. One possible origin for this behavior is the unusual temperature dependence of the unit cell dimensions. The thermal expansion coefficients for lithium hydrazinium sulfate have been measured (19) and are anisotropic in nature, with a very erratic coefficient along the *c* axis from 130 to 200 K. Possibly the anomalous behavior can be explained in terms of vibrational modes which are very sensitive to the anisotropic nature of the orthorhombic cell expansion. In the case of NH_4ReO_4, anomalous Raman spectroscopic and heat capacity data were determined to be due solely to changes in the unit cell parameters with temperature rather than a first or second order phase transition (20–22). This suggests that a careful study of the lithium hydrazinium sulfate lattice dimensions and unit cell structure as a function of temperature might afford some insight into the origin of the anomalous modes.

P. T. T. WONG. 1991. Can. J. Chem. **69**, 1699 (1991).

Hydrogen/deuterium (H/D) exchange rate constants in chymotrypsinogen have been determined at several pressures up to 28.9 kbar by FTIR spectroscopy. The secondary structure of the protein molecules was monitored simultaneously at the corresponding pressures by the intensity redistribution of the infrared amide I band at these pressures. As in other proteins, the labile protons on the amide groups in chymotrypsinogen can, to a good approximation, be separated into two classes, each with distinct first order H/D exchange rates constants in the time period from 10 min to ~24 h. The fast exchange rate constant increases while the slow exchange rate constant decreases with increasing pressure. The increase in the fast exchange rate constant at high pressure is largely associated with the pressure-induced unfolding of the protein molecules. At extremely high pressure (12.8 kbar), in addition to the unfolding of protein molecules, pressure induced a distortion and weakening of the hydrogen bonds of the fold protein segments also contribute to an increase in the overall H/D exchange rate. The present results confirm that when chymotrypsinogen is dissolved in D_2O, a considerable amount of D_2O molecules is bound to the protein molecules on the surface as well as in the interior cavities of the molecules. The H/D exchange takes place between these bound D_2O and the protons in the protein molecules. The mechanism of the H/D exchange and the interior dynamics in proteins are discussed on the basis of the present results.

Key words: hydrogen/deuterium exchange, exchange kinetics, rate constant, pressure effects, infrared spectroscopy, protein, conformation structure, bound water.

P. T. T. WONG. 1991. Can. J. Chem. **69**, 1699 (1991).

Faisant appel à la spectroscopie ir par transformation de Fourier, on a déterminé les constantes de vitesse d'échange hydrogène/deutérium (H/D) du chymotrypsinogène, à plusieurs pressions allant jusqu'à 28,9 kbar. En se basant sur la redistribution de l'intensité de la bande infrarouge amide I aux diverses pressions, on a déterminé simultanément la structure secondaire des molécules de protéines aux pressions correspondantes. Comme dans d'autres protéines, les protons labiles des groupes amides du chymotrypsinogène peuvent être séparés, en première approximation, en deux classes possédant chacune des constantes (allant de 10 min à environ 24 h) distinctes pour les vitesses d'échange H/D du premier ordre. Lorsqu'on augmente la pression, la constante de vitesse pour l'échange rapide augmente alors que celle de l'échange lent diminue. L'augmentation observée à des pression élevées de la constante de vitesse de l'échange rapide est principalement associée à un déploiement des protéines qui serait induit par la pression. À des pressions extrêmement élevées (12,8 kbar), la pression, en plus de provoquer un déploiement des molécules de protéines, induit aussi une distorsion et un affaiblissement des liaisons hydrogènes des segments repliés de la molécule qui contribuent à augmenter la vitesse globale de l'échange H/D. Les résultats présentés ici confirment que, lorsque le chymotrypsinogène est dissous dans du D_2O, il y a un grand nombre de molécules de D_2O qui sont liées aux molécules de protéines, tant à la surface que dans les cavités intérieures des molécules. L'échange H/D se produit entre ces molécules de D_2O liées et les protons des molécules de protéines. On discute du mécanisme d'échange H/D et de la dynamique intérieure des protéines en fonction des résultats obtenus dans cette étude.

Mots clés : échanges hydrogène/deutérium, cinétique des échanges, constante de vitesse, effets de pression, spectroscopie à l'infrarouge, protéine, structure de conformation, eau liée.

[Traduit par la rèdaction]

Introduction

The hydrogen/deuterium (H/D) exchange method has been widely used to investigate the internal dynamics of globular proteins (1–4). It has been shown from these studies that in general, exchange of labile protons of peptides and side chain protons which are located on the surface of the protein and are exposed to the bulk water is extremely rapid, whereas peptide and side chain protons in the interior of folded protein exchange with much slower rates.

Three distinct theories for the mechanism of H/D exchange in proteins have been proposed, i.e., (*1*) local unfolding, (*2*) solvent penetration, and (*3*) regional melting (2,5–8). The local unfolding model suggested that H/D exchange in proteins is controlled by the localized cooperative unfolding of segments of proteins, which leads to an extrusion of the chains with labile protons into the bulk solvent where exchange takes place. The penetration model assumes that H/D exchange takes place within the protein interior as a result of diffusion of solvent molecules into the buried exchangeable sites by small amplitude fluctuations or mobile defects in the protein packing. The regional melting mechanism suggests that H/D exchange takes place within solvent-filled clefts in the protein surface formed by localized disruption of the conformational structure arising from the cooperative breaking of several hydrogen bonds.

Hydrostatic pressure is known to enhance hydrogen bonding (9–11) and to damp molecular fluctuation (9–12). Pressure is also known to induce a dramatic change in conformational structure in globular proteins (10, 13, 14). Therefore, a study of

pressure effects on the H/D exchange rate in globular proteins would certainly shed some light on the mechanism of the H/D exchange and thus the interior dynamics of globular proteins. The conformational state of a globular protein is also altered by changes in temperature or pH. However, in addition to a change in the conformational structure, a kinetic energy change is associated with a change in temperature. The H/D exchange rate is also altered by different acid/base catalyzing mechanisms at different pHs (1–4).

Infrared spectroscopy is a classical technique for the study of H/D exchange in proteins (15), which became a powerful and rapid technique for this purpose after the development of Fourier transform infrared spectrometers. One of the advantages of infrared spectroscopy over other physical methods for the study of H/D exchange in proteins is that the conformational structure of the protein under study can be monitored concomitantly during the measurement of the H/D exchange rate constants.

In the present work, the H/D exchange rate constants of chymotrypsinogen at several pressures up to 28.9 kbar have been measured. The study of pressure effects on the structure of proteins has gained considerable interest in recent years (10, 13, 14, 16–28). A number of experimental techniques have been used. In most of these investigations, changes in the properties of proteins were observed below 5 kbar. Recent advances in the high pressure infrared spectroscopic technique for aqueous systems developed in our laboratory allows us for the first time to combine the pressure parameter with infrared spectroscopy to determine pressure effects on both the conformational structure and the H/D exchange rate constant simultaneously in a globular protein, chymotrypsinogen, in the pressure range up to 28.9 kbar. Consequently, the correlation between the H/D exchange rate and the conformational state of the protein can be established, which in turn may reveal the mechanism of H/D exchange and the internal dynamic properties in globular proteins.

Experimental methods

High-purity chymotrypsinogen A from bovine pancreas was purchased from Sigma Chemical Co. Solutions of 100 mg/mL were prepared in Tris-HCl D_2O buffer (pD = 7.6). Protein solutions were placed at room temperature together with powdered α-quartz in a 0.37 mm diameter hole on a 0.23 mm thick stainless steel gasket mounted on a diamond anvil cell. The α-quartz was used as internal pressure calibrant (29). All the protein solutions were prepared immediately prior to the infrared measurements. The maximum time required between the preparation of the solution and the recording of the first infrared spectrum is less than 10 min.

Infrared spectra of samples were measured as a function of time at room temperature and at a constant pressure on a Bomem model DA3.02 Fourier transform spectrometer using a liquid-nitrogen cooled mercury cadmium telluride detector. The infrared beam was condensed by a sodium chloride lens system onto the sample in the diamond anvil cell. For each spectrum 512 interferograms were co-added at a spectral resolution of 4 cm^{-1}.

For each pressure, infrared spectra of the protein solutions were measured at intervals of 10 min for the first 3 to 4 h and then at intervals of 30 min set by the computer of the spectrometer. The zero time of the H/D exchange was taken as the time when the solid protein was first mixed with D_2O buffer.

The H/D exchange rate in proteins were measured by following the decrease in the amide II peak at 1550 cm^{-1} with time (15), which takes advantage of the fact that this infrared absorption peak shifts to a frequency of about 1450 cm^{-1} when the proton atom is replaced by deuterium atom. The base line of the spectra was obtained from the spectrum of a fully exchanged sample which was prepared by three months incubation in D_2O followed by heating to 40°C for 6 h or alternately followed by pressurizing to 8 kbar. In the infrared spectrum of the fully exchange sample, the intensity of the amide II band is diminished and only the wings of the deuterated amide II band at 1450 cm^{-1} and the shoulder band of the side chains at 1570 cm^{-1} remain (13). Data reduction was performed with software developed in this laboratory.

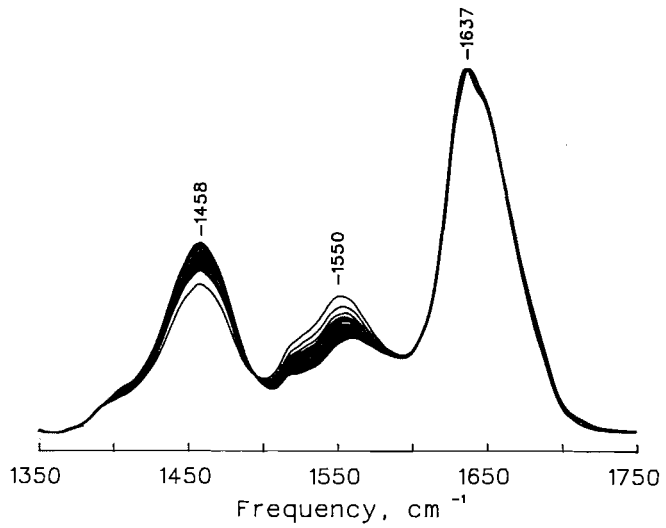

FIG. 1. A stack plot of the infrared spectra of chymotrypsinogen in the frequency region 1350–1750 cm^{-1} as a function of time up to 13 h.

Results and discussion

Infrared spectra of chymotrypsinogen solution in D_2O buffer (pD, 7.6) have been measured as a function of time at several pressures. Typical infrared spectra measured at 3.5 kbar and in a time period of 13 h are shown in Fig. 1. The strong amide I band at 1637 cm^{-1} is due to the in-plane C=O stretching vibration weakly coupled with C—N stretching and in-plane N—H bending and the band at 1550 cm^{-1} is due to the amide II mode which is a mixed vibration involving N—H in-plane bending and C—N stretching (30). It is evident from Fig. 1 that as a result of H/D exchange, the intensity of the amide II band at 1550 cm^{-1} decreases while that of the deuterated amide II band at 1447 cm^{-1} increases with increasing time. The peak intensity ratios between the amide II band and the amide I band ($A_{\text{amide II}}/A_{\text{amide I}}$) are plotted versus time for several pressures in Fig. 2. Taking this intensity ratio before exchange begins as 0.45 (15, 31) the percentage of the hydrogen exchanged in the protein can be calculated as a function of time for various pressures.

I. H/D exchange at ambient conditions

At atmospheric pressure, about 17% of the labile protons in chymotrypsinogen are exchanged within 10 min. It has been generally assumed that these extremely rapidly exchanging protons are those located on the surface of protein molecules and hence are in direct contact with the solvent (1–4). After 10 min, the exchange becomes slower and the $A_{\text{amide II}}/A_{\text{amide I}}$ ratio decreases exponentially with time. The decreasing rate of this intensity ratio and thus the H/D exchange rate becomes much slower after about 4 h. It has been shown that in a period of 17 days the H/D exchange in chymotrypsinogen is still far from completion (13). If those protons which do not exchange with solvent after 24 h are considered as the "hard to exchange" protons in the protein molecule, they represent more than 50% of the amide protons in chymotrypsinogen at atmospheric pressure (see Table 1).

TABLE 1. H/D exchange rate constants of two classes of labile protons in chymotrypsinogen and percentages of "hard-to-exchange" protons and extremely fast exchanging protons at several pressures

Pressure (kbar)	Hard-to-exchange protons (%)	Protons exchanged within 10 min (%)	Slow exchange k (min)	Fast exchange k (min)
0.001	52	17	4.3×10^3	3.7×10^{-2}
2.3	42	26	4.6×10^3	4.0×10^{-2}
3.5	31	30	2.1×10^3	4.8×10^{-2}
4.8	11	36	1.8×10^3	7.2×10^{-2}
12.8	1	75	1.3×10^3	1.9×10^{-1}
28.9	32	47	1.3×10^3	8.9×10^{-2}

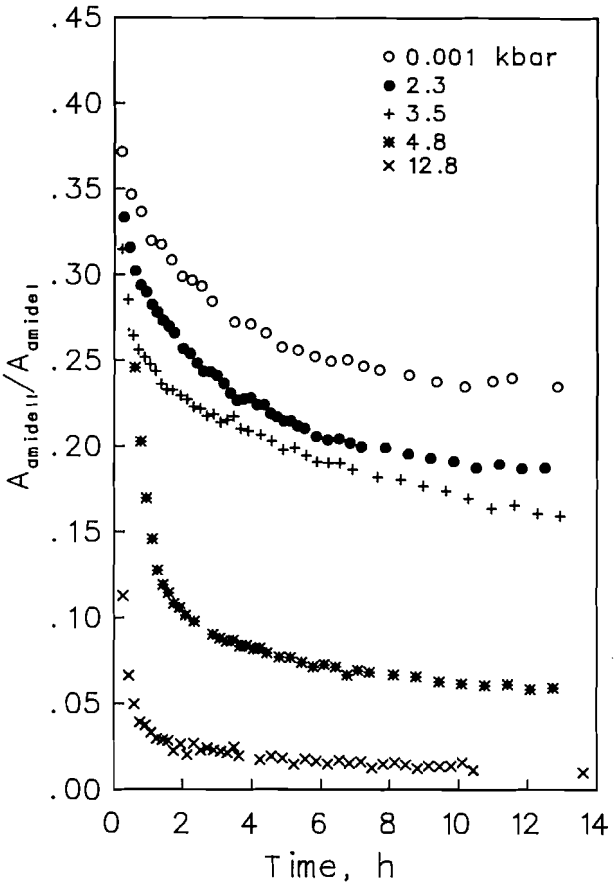

FIG. 2. Time dependences of infrared intensity ratio between the amide II band and amide I band of chymotrypsinogen at several pressures.

According to the graphic method (32, 33), in addition to the extremely fast exchange which occurs within 10 min, the first order H/D exchange rate can be distributed into two regions in many proteins, i.e., the fast and slow exchange regions. The semilogarithmic plots of the $A_{amide\ II}/A_{amide\ I}$ ratios of chymotrypsinogen at atmospheric pressure as well as at various pressures versus time in the time period between 10 min and 24 h also show two distinct portions which are related to the fast and slow exchange regions, each with distinct first order H/D rate constants. These fast and slow exchange rate constants of chymotrypsinogen at several pressures are given in Table 1. Therefore, according to the H/D exchange characteristics, labile protons in chymotrypsinogen can be classified into four categories: (*1*) extremely fast exchange (within 10 min) (*2*) fast exchange (in 10 min to ~4 h), (*3*) slow exchange (in ~4 to 24 h), and (*4*) hard to exchange (longer than 24 h).

II. Pressure effects on H/D exchange

As shown in Fig. 2 and Table 1, in general, the overall H/D exchange rate in chymotrypsinogen is increased by hydrostatic pressure. However, effects of pressure on the H/D exchange in chymotrypsinogen are significant different in three pressure ranges, i.e. below 3.5 kbar, between 3.5 and 12.8 kbar, and above 12.8 kbar.

Below 3.5 kbar, the pressure-induced changes in both the fast and slow exchange rate constants are very small (Table 1). However, the number of "hard-to-exchange" protons is significantly reduced by pressure (10% at 2.3 kbar). In the meantime, almost the same number of "extremely fast exchange" protons which exchange within 10 min is increased by pressure. These results suggest that the main pressure effect in the pressure range below 3.5 kbar is to convert small amount of labile protons (10% at 2.3 kbar) from the "hard-to-exchange" state to the "extremely fast exchange" state.

In the pressure range between 3.5–12.8 kbar, pressure induces a significant increase in the fast exchange rate constant (more than double at 4.8 kbar, see Table 1). On the other hand, pressure also induces a significant decrease in the slow exchange rate constant (more than half at 4.8 kbar, see Table 1). In this pressure range, not all those "hard-to-exchange" protons disappeared at high pressure are converted into "extremely fast exchange" protons. For instance, at 4.8 kbar only 11% of the total labile protons remain as "hard-to-exchange" protons, but the "extremely fast exchange" protons only increase slighly from 30% of the total labile protons at 3.5 kbar to 36% at 4.8 kbar (see Table 1). Apparently, some of the disappeared "hard-to-exchange" protons contribute to the increase in the fast exchange rate constant.

At 12.8 kbar, the "hard-to-exchange" protons have almost disappeared, the fast exchange rate constant increases more than double of that at 4.8 kbar, and the slow exchange rate constant again has decreased slightly. The most dramatic pressure effect at 12.8 kbar is that about 75% of the labile protons become "extremely fast exchange" protons which complete the H/D exchange within 10 min (Fig. 2 and Table 1).

III. Pressure effects on conformational structure in chymotrypsinogen

The infrared spectrum of the amide I band of chymotrypsinogen in D_2O buffer solution has been reported previously (13). Apparently, this amide I band consists of several overlap-

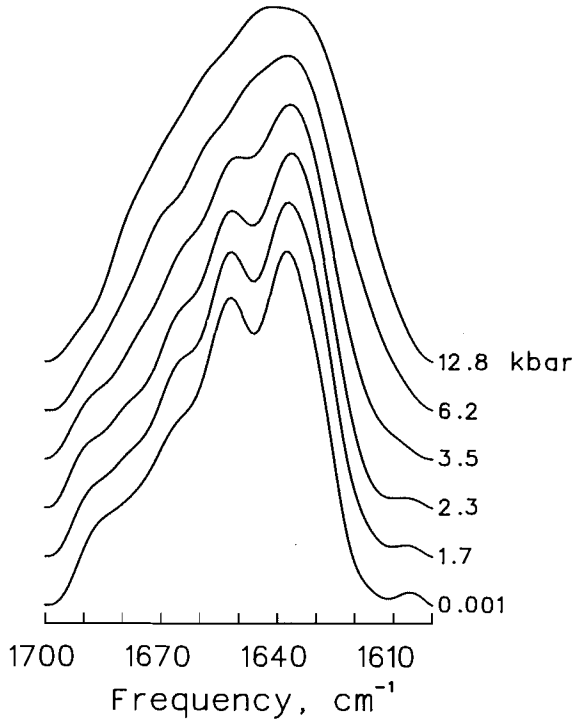

FIG. 3. Deconvolved infrared spectra of chymotrypsinogen in the amide I band region at several pressure using a band width of 15 cm^{-1} and a resolution enhancement factor of 1.7.

ping bands with maxima at 1636, 1654, 1667, and 1686 cm^{-1}, which are more clear in the slightly deconvolved spectra as shown in Fig. 3. It is well recognized that for various types of conformational structure of the amide backbone in polypeptides and proteins, the peak maxima of the amide I band are at different frequencies. Thus, the amide I band in the infrared spectra of polypeptides and proteins has been widely used for determination of the conformational structure in these systems (15, 30, 34). The infrared spectra of the amide I band in Fig. 3 clearly indicate that the amide backbone in chymotrypsinogen consists of segments in the β-sheet, α-helical, and unordered conformations, which give rise to the amide I bands at 1636 (1686), 1654, and 1667 cm^{-1}, respectively (15, 30, 34). The strongest component band is at 1636 cm^{-1}, which indicates that the β-sheet conformation of the amide groups predominates over other structures in chymotrypsinogen at atmospheric pressure.

It is known that considerable changes in conformational structure in globular proteins can be induced by external pressure in the pressure range above about 3 kbar (10, 13, 14). In chymotrypsinogen below 3.5 kbar no significant redistribution of intensity of the amide I band is induced by pressure (Fig. 3). Starting from 3.5 kbar, the intensities in the frequency region between 1640 and 1650 cm^{-1} (random coil) and that near 1667 cm^{-1} (turns) increase with increasing pressure. On the other hand, the intensities of the component bands at 1636, 1686 (β-sheet), and 1654 cm^{-1} (α-helix) decrease as pressure increases. These results indicate that a pressure-induced denaturation associated with changes in conformational structure in aqueous chymotrypsinogen starts at 3.5 kbar. In this denaturation process, the contributions of the unorderd random coil and turn structures increase at the expense of the β-sheet and α-helical structures. Moreover, in the denatured chymotrypsinogen the α-helical structure is largely distorted as evident from the broadening of the component band at 1654 cm^{-1}. This pressure-induced denaturation is irreversible as shown by the irreversible changes in the infrared spectrum.

IV. Effects of conformational changes on H/D exchange

Below 3.5 kbar, the fine features on the amide I band are the same as those at atmospheric pressure. Therefore, there is no significant change in conformational structure in chymotrypsinogen in this pressure range.

It is well known (35) that in the pressure range up to 3 kbar, globular proteins are subject to a pressure-induced dissociation from oligomers to monomers. In this process, some interacting side chains are ionized and the labile protons in these ionized side chain are in contact with bulk solvent. In the meantime, some of the interior labile protons of the amide backbone in oligomers become exposed to bulk solvent when they are dissociated into monomers. Consequently, some "hard-to-exchange" protons in oligomeric chymotrypsinogen become "extremely fast exchange" protons in monomers. The present results show that about 10% of the labile protons take part in this conversion at 2.3 kbar.

The conformational structure of chymotrypsinogen starts to change at 3.5 kbar. The amunt of random coil segments and unordered turns increase slightly at 3.5 kbar and further increase with increasing pressure at the expense of β-sheet and α-helical segments. It is well established that the rate of H/D exchange of random coil segments and unordered turns in protein molecules is the fastest, whereas that of β-sheet segments is the slowest (2, 5, 15, 36–38). Therefore, a 50% increase in the fast exchange rate constant at 4.8 kbar from that at 3.5 kbar is the result of pressure-induced conversion of a large portion of the amide backbone in the protein molecules from α-helical and β-sheet conformation into the unordered random coil and turns. The slow H/D exchange process must be involved in the exchange reaction of "hard-to-exchange" protons which are buried in the interior of the β-sheet segments of the protein molecules (5). This is further supported by the fact that the slow rate constant decreases slightly with decreasing amount of "hard-to-exchange" protons in the protein molecules as pressure increases (see Table 1).

At 12.8 kbar, chymotrypsinogen is almost completely denatured, most of the amide backbones of the protein molecules are in the random coil and unordered turn structure, and the remaining α-helical and β-sheet segments are distorted (13). The disappearance of the "hard-to-exchange" protons and the dramatic increase in the fast exchange rate constant at 12.8 kbar imply that at such a high pressure, pressure not only induces more protein segments into the fast exchange unordered state, it also gives rise to a significant distortion and a weakening of hydrogen bonds of the protein segments with "hard-to-exchange" conformation.

V. H/D exchange in the ice VII state

Figure 4 compares the time dependence of $A_{\text{amide II}}/A_{\text{amide I}}$ ratio of chymotrypsinogen between 28.9 and 12.8 kbar. Apparently the H/D exchange rate at 28.9 kbar becomes much slower than that at 12.8 kbar and is even slower than that at 4.8 kbar (Fig. 2 and Table 1). This abnormal trend of the pressure effect on the H/D exchange rate at 28.9 kbar is the result of a phase transition in the solvent. Liquid D_2O transforms into ice VII at about 25 kbar pressure (39). The mobility of D_2O molecules in the ice VII state is much smaller than that in the liquid state and thus the H/D exchange of labile protons in chymotrypsinogen with D_2O molecules in ice VII at 28.9 kbar is expected to be prohibited if the H/D exchange only takes place between labile protons and bulk D_2O. However, at 28.9 kbar even though the bulk D_2O is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/07/12

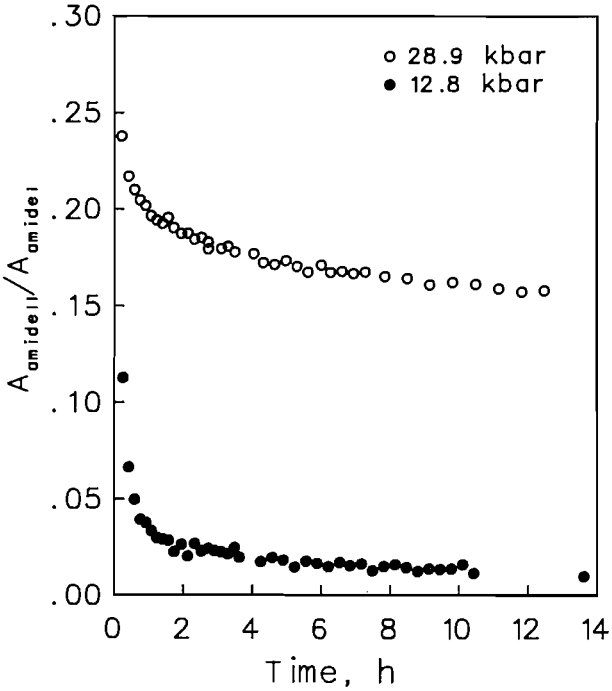

FIG. 4. Time dependences of infrared intensity ratio between the amide II band and amide I band of chymotrypsinogen at 12.8 and 28.9 kbar.

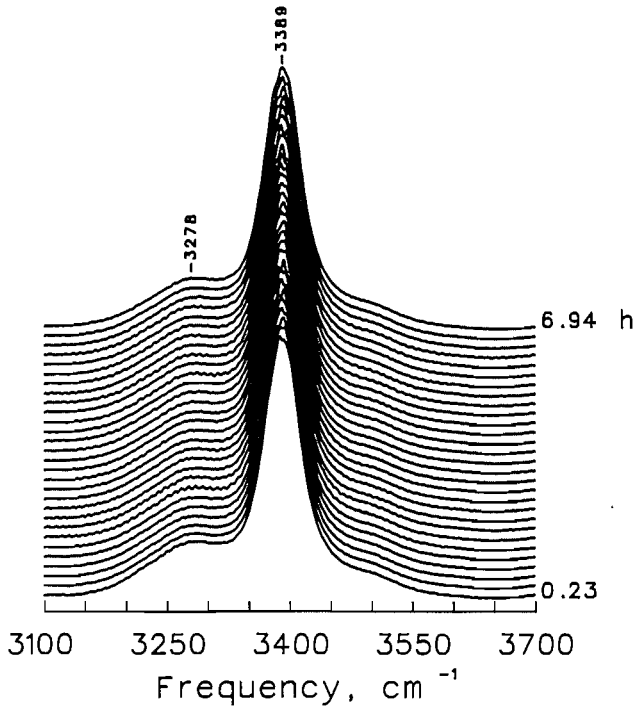

FIG. 5. A stack plot of the uncoupled OH stretching band of a D_2O solution of chymotrypsinogen at 28.9 kbar as a function of time.

in the ice VII state, the H/D exchange still takes place continuously with time, which is evident from the decrease in the $A_{amide\ II}/A_{amide\ I}$ ratio with increasing time (Fig. 4). The general pattern of the H/D exchange at low pressure, i.e., fast in the first several hours and then tapering off, still remains at 28.9 kbar. Therefore, there must be some D_2O molecules in chymotrypsinogen which do not take part in the formation of ice VII at 28.9 kbar and the H/D exchange at 28.9 kbar takes place between these D_2O molecules and the labile protons in chymotrypsinogen. Indeed, this is evident from the infrared spectrum at 28.9 kbar of the uncoupled OH stretching mode of HOD molecules which are present in the commercial D_2O samples as impurities as shown in Fig. 5. It is known that the uncoupled OH stretching mode of ice VII appears as a very sharp band at about 3390 cm^{-1} and that of the bound HOD molecules gives rise to a broad band extending from 3100 to 3700 cm^{-1} (40). As seen in Fig. 5, both the sharp ice VII band and the broad bound water band coexist in the infrared spectrum of the chymotrypsinogen solution in D_2O at 28.9 kbar. Since the integrated intensity of the broad band of bound HDO is comparable with that of the sharp ice VII band of bulk HDO at 28.9 kbar, a significant amount of D_2O molecules are bound to chymotrypsinogen when the protein is dissolved in D_2O. Therefore, in addition to the surface bound D_2O, some D_2O molecules penetrate into the interior cavities of the protein where they are separated from bulk D_2O, which is consistent with the results from X-ray study (5). All these surface and interior bound D_2O molecules do not take part in the formation of ice VII in bulk D_2O at 28.9 kbar and the H/D exchange takes place between labile protons of protein molecules and these bound D_2O molecules. The fact that about 70% of total labile protons are exchanged in about 7 h (see Fig. 4) also indicates that in this ice VII system quite a large amount of D_2O penetrates into the protein interior and binds to the protein molecules when solid chymotrypsinogen is dissolved in D_2O. These results indicate that the H/D exchange picture in chymotrypsinogen is close to that described by the regional melting mechanism (5). Apparently, no collective small amplitude fluctuations or mobile defects are required for this penetration process as suggested by the penetration mechanism of H/D exchange. Moreover, since the H/D exchange takes place in the interior of the protein molecules, no movement of the unfolded segment into bulk solvent on the surface of the protein molecules is necessary for the H/D exchange as suggested by the local unfolding hypothesis. At 28.9 kbar, chymotrypsinogen is denatured, and thus the H/D exchange should be fast and all the "hard-to-exchange" protons should be converted into "easy-to-exchange" protons similar to that observed at 18.9 kbar. However, the fast exchange rate constant at 28.9 kbar is smaller than that at 12.8 kbar and 32% of the labile protons remain unexchanged after 24 h (see Table 1). These results suggest that the availability of the exchangeable D_2O molecules decreases with time at 28.9 kbar and imply that the diffusion and exchange between bound D_2O and bulk D_2O which is in the ice VII state at 28.9 kbar is extremely slow.

Both amino-oxo and amino-hydroxy tautomeric forms of 9-methylguanine have been identified in approximately equal abundance in infrared studies of these molecules isolated in the hydrophobic environment of an argon matrix at 12 K. The amino-hydroxy tautomer occurs in two different rotamers correlated with the rotation of the OH group. The ratio of concentrations of the two rotamers is sensitive to UV irradiation, and this ratio then relaxes to an equilibrium value after irradiation is stopped. This sensitivity allows us to separate the experimental spectra related to the oxo tautomer and to each of the rotamers of the hydroxy tautomer. The relative concentrations of the amino-oxo and amino-hydroxy tautomers ([a-o]/[a-h] = K(o-h) = 1.0 ± 0.3) and of the two rotamers (K(h1-h2) = 0.31 ± 0.10 in an argon matrix at 12 K and about 30 ± 15 in the vapor at 470 K) are estimated from the observed relative infrared absorbances. From these relative concentrations the differences between the free energies of the tautomers (ΔG_{470} (o-h) = 0 ± 0.5 kJ mol^{-1}) and of the two rotamers (ΔG(h1-h2) = 0.12 ± 0.03 kJ mol^{-1} in the argon matrix at 12 K and ΔG_{470} between +2 and −13 kJ mol^{-1} in the vapor at 470 K) have been estimated. The electronic absorption spectrum of 9-methylguanine isolated in the argon matrix at 12 K and the effect of brief ultraviolet irradiation on it have also been studied. In an effort to interpret the experimental results, *ab initio* calculations of the infrared spectra have been made for 9-methylguanine at the 3-21G//3-21G level. Comparison with the experimental spectra is of some help with the assignment of the infrared spectra for the different tautomers.

Key words: 9-methylguanine, tautomerism, infrared and ultraviolet spectra, matrix isolation, *ab initio* calculation.

Des études infrarouges effectuées dans un environnement hydrophobe, dans une matrice d'argon, à 12 K, on permis de mettre en évidence des quantités pratiquement égales des formes tautomères amino-oxo et amino-hydroxy de la 9-méthylguanine. Le tautomère amino-hydroxy se retrouve dans deux rotamères différents reliés à la rotation du groupe OH. Le rapport des concentrations des deux rotamères est sensible à l'irradiation UV; ce rapport retourne vers une valeur d'équilibre lorsqu'on cesse l'irradiation. Cette sensibilité nous permet de séparer le spectre expérimental relié au tautomère oxo et à chacun des rotamères du tautomère hydroxy. En se basant sur les absorptions relatives observées dans l'infrarouge, on a évalué les concentrations relatives des tautomères amino-oxo et amino-hydroxy ([a-o]/[a-h] = K(o-h) = 1,0 ± 0,3) et deux rotamères (K(h1-h2) = 0,31 ± 0,10 dans une matrice d'argon à 12 K et d'environ 30 ± 15 en phase vapeur à 470 K). Sur la base de ces concentrations relatives, on a évalué les différences entre les énergies libres des tautomères (ΔG_{470}(o-h) = 0 ± 0,5 kJ mol^{-1}) et des deux rotamères (ΔG(h1-h2) = 0,12 ± 0,03 kJ mol^{-1} dans la matrice d'argon à 12 K alors que le ΔG_{470}, en phase vapeur à 470 K, se situe entre +2 et −13 kJ mol^{-1}). On a aussi étudié le spectre d'absorption électronique de la 9-méthylguanine isolée dans la matrice d'argon à 12 K ainsi que l'effet d'une brève irradiation avec de l'ultraviolet. Dans le but d'interpréter les résultats expérimentaux, on a effectué des calculs *ab initio* au niveau 3-21G//3-21G des spectres infrarouges de la 9-méthylguanine. Une comparaison des résultats de ces calculs avec les spectres expérimentaux est utile pour attribuer les spectres infrarouges des divers tautomères.

Mots clés : 9-méthylguanine, tautomérie, spectres infrarouge et ultraviolet, isolement dans une matrice, calculs *ab initio*.

[Traduit par la rédaction]

Introduction

There are at least two reasons for studying infrared (IR) spectra of nucleic acid bases isolated in an inert environment such as that provided by isolation in an argon matrix. First, such studies are necessary to obtain data for testing the reliability of predictions from quantum mechanical *ab initio* calculations with different basis sets of properties (particularly the vibrational spectra) for these molecules. Such calculations are at present possible only for individual isolated molecules, so that their predictions *must* be tested with data from studies of molecules unperturbed by intermolecular interactions. Matrix isolation studies of the nucleic acid bases provide uniquely such experimental data. If the quantum mechanical calculations with a given basis set predict accurate values for vibrational properties and relative energies of smaller isolated bases, one can hope that similar calculations might also successfully predict vibrational properties, energies, and conformations for the larger biomolecules.

The second reason for studies of the spectra of isolated molecules is to determine spectra, for non-interacting molecules, that serve as a reference for comparison with corresponding spectra of molecules incorporated in DNA or RNA from studies of solutions or solids where the vibrations of the nucleic acid bases are affected by their mutual interactions and by interactions with the solvent or in the crystal (e.g., see refs. 1–6

[1]We believe that our extensive use of the computer in analyzing the data for this paper makes it especially appropriate for this special issue dedicated to Dr. Norman Jones. We have certainly kept in mind his cautionary advice in our analysis, so that he has always been in our minds as we wrote it.

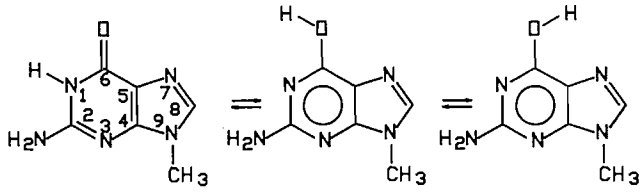
and references given there). Such comparisons are expected to provide valuable information concerning the nature of these interactions and their effects on the vibrations of molecules.

A number of studies of tautomerism have been made for nucleic acid bases and their analogues (see refs. 7*a*–*d* and references therein), including studies of molecules isolated in the gas phase (see ref. 8, and references therein) and in inert noble gas matrices (see refs. 9, 10, and references therein). In addition there have been several studies concerning the effect of UV irradiation on the matrix-isolated nucleic acid bases (see ref. 10, and references therein).



Guanine and 9-methyl- (or 9-ethyl) guanine are the only nucleic acid bases of biological significance for which high concentrations of the "rare" amino-hydroxy tautomer have been found to occur in the gas phase (8*h*) and in an inert hydrophobic environment formed by condensation of a thermal molecular beam of these molecules in a large excess of argon (i.e., in a low-temperature argon matrix held on a cold window at 12 K) (11–14). The most recent *ab initio* quantum mechanical calculations (15, 16) performed for guanine with a 6-31G (d, p) basis set at the MBPT2 level (single point calculation), with zero point vibrational energy included, confirm the results from the experimental observations that the energy of the amino-hydroxy (a-h) tautomer is nearly the same as that of the amino-oxo (a-o) tautomer ($E_{a\text{-}o} - E_{a\text{-}h} = -5.1$ kJ mol^{-1} (16*a*)). *Ab initio* calculations of the vibrational spectra of the a-o tautomer of guanine had been made before, using STO-3G (17) and 3-21G (12) basis sets. As far as we know there have been no published results from *ab initio* calculations of the vibrational frequencies and intensities for the amino-hydroxy tautomers of guanine or 9-methylguanine (9MG).

In our previous study (13) we showed that the relative concentration of the tautomers of 9MG can be changed by ultraviolet (UV) irradiation of the matrix over a long period of time (about 12 h), which probably causes photodecomposition of the a-o and a-h tautomers at different rates. In the present paper we report results of a recent experimental study of the infrared (IR) absorption spectra and rotational isomerism observed for the hydroxy tautomer as well as the effect of brief (2–5 min) UV irradiation on the relative concentrations of the rotational isomers. The results from our previous study (13) of the effect of long-lasting UV irradiation provided additional help with the analysis of the spectra of the different tautomers and rotamers and with the vibrational assignment of the experimentally observed bands to the normal modes of the a-o and a-h forms. The spectrum of the a-h tautomer discussed in ref. 13 corresponds to that of the hydroxy form in the relaxed state (a-h2) discussed here.

Methods

Experimental

The experimental procedure and conditions for preparing the low-temperature matrix and recording the IR spectra with the Nicolet model 740 FTIR spectrometer were the same as those described elsewhere (18). The spectra were studied at a spectral resolution of 1 cm^{-1}. The sample of 9MG was kindly provided to us by Professor Nelson Leonard of the University of Illinois (for a description of the synthesis see ref. 8*h*). It was additionally purified by vacuum sublimation in the process of preparing the matrix sample. The temperature of the sublimation was about 200°C, much below the melting point. There was no indication of any thermal decomposition of samples heated to this temperature, as shown by IR spectra from the solid films remaining on the window after evaporating the argon that were *identical* with spectra from KBr pellets of the original unheated solid 9MG sample.

SCHEME 1

The matrix sample was obtained by passing argon gas over the subliming sample and condensing the resulting gaseous mixture (with 9MG:Ar ratio of about 1:1000) onto a cold CsI window mounted in a closed cycle He cryostat (Displex model CSA 202E) and cooled to about 12 K.

The matrix sample was irradiated for 2–5 min by focussed UV light, which passed through a water filter 7 cm thick. The source of the UV light was a 100-W medium-pressure mercury lamp. The IR spectrum of a solid film of 9MG remaining after evaporation of the argon from the matrix after the UV irradiation (2–5 min) did not show any measurable new features when compared with the spectrum of solid 9MG (in KBr) that had not been irradiated with UV light. From this observation it follows that the *2–5 min* UV irradiation through this filter does not cause measurable photodecomposition of the matrix-isolated sample, as had been observed for long-lasting UV irradiation.

The electronic absorption spectrum of 9MG isolated in the argon matrix was studied using a Nicolet model 9420 UV/VIS spectrophotometer, with the same technique for forming the matrix-isolated sample and UV irradiation as described above for the infrared study.

Calculation

An *ab initio* LCAO calculation (19) was carried out using the GAUSSIAN 86 program (20) with a split valence 3-21G basis set (19). The geometries of the tautomers and rotamers were optimized by the gradient procedure (21). To simplify the calculation, it was assumed that all molecules were planar (C_s symmetry) and the geometry optimization was performed within this restriction. The calculated structures are shown in Scheme 1.

The force constants for the optimized structures gave positive frequencies for all modes except for the torsion of the methyl group about the CN9 bond, indicating that the conformation of the CH_3 group for our calculations did not correspond to the minimum energy value. It is expected that this error will have no effect on any of the other normal modes of the molecule. All optimized structures were characterized by analysis of the harmonic vibrational frequencies obtained by diagonalizing the force-constant matrices. To account for the errors due to the small basis set and for anharmonicity of the vibrations, the calculated frequencies for in-plane modes were multiplied by a scaling factor of 0.90 (22), the OH stretch by 0.918 (23), and those for the out-of-plane modes (excluding the modes involving the CH_3 group, which used the 0.9 factor) by a factor of 0.81 (see ref. 24) for comparison with the experimental spectra. The calculated intensities are compared with the relative intensities measured in the experimental spectra.

Results and discussion

Tautomerism and rotational isomerism of 9MG

The most easily derived information about hydroxy ↔ oxo tautomerism and about the rotational isomerism in the hydroxy tautomer of the 9MG molecule is obtained from the spectral region related to the characteristic stretching vibrations of the OH, NH, and CO bonds involved in these transformations. Other vibrational modes, although very important from the

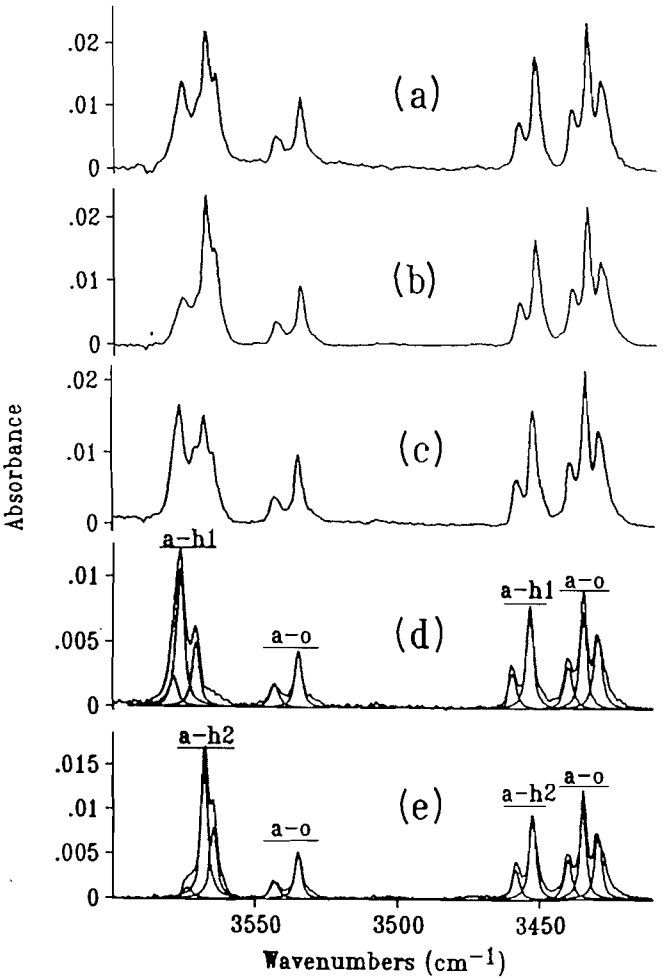

FIG. 1. The infrared spectrum in the OH and NH stretching region for 9MG isolated in an argon matrix at about 12 K. (a) Spectrum recorded just after deposition, recorded using only 5 scans to minimize the effect of relaxation during the scan time. (b) Spectrum of the same matrix as in (a), but after 2 hours relaxation, recorded using 200 scans. (c) Spectrum from the same sample as in (b) after 5 min of UV irradiation, recorded using 32 scans to mimimize relaxation during the scans. (d) The difference spectrum obtained from the subtraction (c − b = d). Spectrum (d) corresponds to that from a mixture of rotamer a-h1 and the a-o tautomer. (e) The difference spectrum obtained from the subtraction (b − c = e). Spectrum (e) corresponds to that from a mixture of rotamer a-h2 and tautomer a-o. Both spectra (d) and (e) show the separated components for the overlapping bands obtained from the deconvolution procedure. The weak band at 3572 cm^{-1} is due to the water dimer impurity.

spectroscopic and analytical points of view, provide much less straightforward information about these particular phenomena, especially because they are made up of strongly coupled motions of several atoms in the molecule. The entire experimental IR spectrum is discussed at the end of this paper where we propose a vibrational assignment base on *ab initio* calculations of different tautomers and rotamers of 9MG.

For now, let us focus on the IR spectrum of 9MG in the characteristic region related to the OH and NH stretching vibrations shown in Fig. 1.

The spectrum of the matrix sample of 9MG obtained immediately after deposition is shown in Fig. 1(a), while spectrum (b) is from the same matrix at the same temperature after a period of 2 hours relaxation. The only visible difference between these two spectra is the drastic change in the intensity distribution in the region between 3580 and 3560 cm^{-1}, where the OH and NH_2 asymmetric stretching modes occur (see ref. 11).

The original intensity distribution can be restored or even reversed by brief (2–5 min) irradiation of the matrix sample by UV light to produce the spectrum shown as (c) in Fig. 1. When the UV irradiated matrix sample is allowed to relax in the dark, the intensity distribution gradually changes until, after about 2 h, it returns to the same spectrum originally observed before UV irradiation (Fig. 1(b)). This process can be repeated over and over again. We interpret the changes in the intensity distribution in this region as due to changes in the relative concentrations of rotamers of the a-h tautomer: the high frequency band in the OH stretch due to a-h1 and the low frequency band to the a-h2 species. Our intuitive expectation for the conformation of these two rotamers was that indicated in Scheme 1 showing the conformations used in the *ab initio* calculations. The first rotamer (a-h1) was expected to have the OH group directed towards the C6—N1 bond (RN1) and the second rotamer (a-h2) to have the OH bond directed towards the C5—N7 bond (RN7). Here we use a different notation (a-h1 or a-h2) to describe the rotamers responsible for the changes in the experimental spectrum from that used to describe the rotamers considered in the calculation (RN1 or RN7) to stress the possibility that they might not be the same. As we shall see below in the discussion of the vibrational assignment of the IR spectrum, other possible conformations (for example with the OH bond out of the plane) might be responsible for the experimental spectra attributed to the rare a-h tautomer of 9MG.

The effect of the UV irradiation on the distribution of intensity in the spectrum from the different rotamers isolated in the low-temperature matrix and the relaxation in the dark observed here is very similar to observations for a number of other molecules reported previously (25–28).

To check whether the change in the intensity distribution during the relaxation process is induced by exposure of the matrix sample to irradiation by the infrared source in the spectrometer, as has been observed for rotational isomers of other smaller molecules isolated in low-temperature matrices (29–37), we observed the relaxation of the matrix in the IR beam as compared with that in the dark (i.e., with the sample cut off from the infrared and UV beams) for the same period of time after UV irradiation. There was no significant difference between the relaxation occurring in the dark and that occurring in the sample exposed to the infrared source.

The IR spectrum of matrix-isolated 9MG is a superposition of the spectra of three species: a-o, a-h1, and a-h2. To obtain the spectrum of each component separately, we utilized the selective effect provided by brief UV irradiation on the distribution of the intensity in the infrared spectra of rotamers a-h1 and a-h2, combined with the subroutines from the SpectraCalc (Galactic Industries Corp.) software for subtraction, multiplication, deconvolution, and integration of the overlapping bands of the multicomponent spectrum. This procedure and the level of uncertainty involved are demonstrated in Figs. 1(d) and 1(e) for that part of the spectrum related to the OH, NH, and NH_2 stretching modes.

Step 1 of the procedure is subtraction of the "relaxed" spectrum obtained before UV irradiation (shown in Fig. 1(b)) from that obtained after brief UV irradiation (shown in Fig. 1(c)) using a multiplication factor that reduces to zero in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

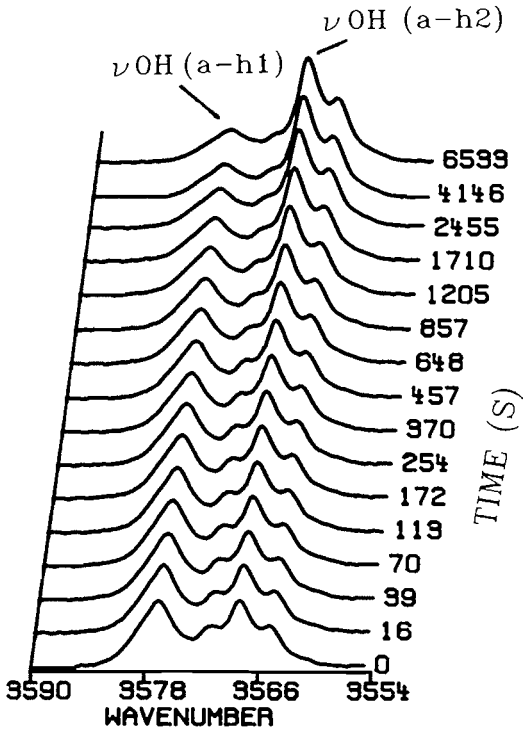

FIG. 2. Time dependence of the intensity distribution in the OH stretching region corresponding to rotamers a-h1 and a-h2 of 9MG isolated in an argon matrix at about 12 K. The spectrum at time $t = 0$ was obtained using 1 scan after UV irradiation of the matrix for 5 min. The number of scans for succeeding traces increases as $N + 1$ for the Nth scan, up to a maximum of 10 scans.

difference spectrum the absorbance of the low-frequency component of the OH stretch related to the a-h2 species. The resulting difference spectrum (Fig. 1(d)) contains only absorption bands due to the a-o and a-h1 species.

Step 2 of the procedure is to subtract the spectrum in Fig. 1(c) from that in Fig. 1(b) using a multiplication factor that reduces to zero the absorbance of the high frequency component of the OH stretch related to the a-h1 species. This difference spectrum (Fig. 1(e)) contains bands corresponding to the a-o and a-h2 species.

Step 3 now applies the band deconvolution subroutine for the bands that overlap in Figs. 1(d) and 1(e), using a band shape that is a mixture of Lorentzian (75%) and Gaussian (25%) functions and allowing the widths and intensities to be optimized, to give the separated absorption components related to the a-o, a-h1, and a-h2 species.

Figure 2 shows the time dependence of the intensity distribution in the OH stretching region for the two bands at 3568 and 3576 cm^{-1}. Because the absorbance, A, at 3576 cm^{-1} attributed to the a-h1 rotamer (and that at 3568 cm^{-1} for the a-h2 rotamer) is proportional to its concentration, the plot in Fig. 3(a) shows the kinetics of the relaxation process. A plot of $\ln(A_t - A_\infty)$, where A_t is the absorbance of either species at time t and A_∞ is the absorbance of that species extrapolated to infinite time, against time will be linear if the relaxation from one rotamer to the other follows first-order kinetics. As can be seen in Fig. 3(b) this plot is exactly linear both for the species whose concentration decreases in the relaxation process and for the species whose concentration increases.

The observed changes in the intensity distribution in the OH stretching region allow us to estimate the difference in the

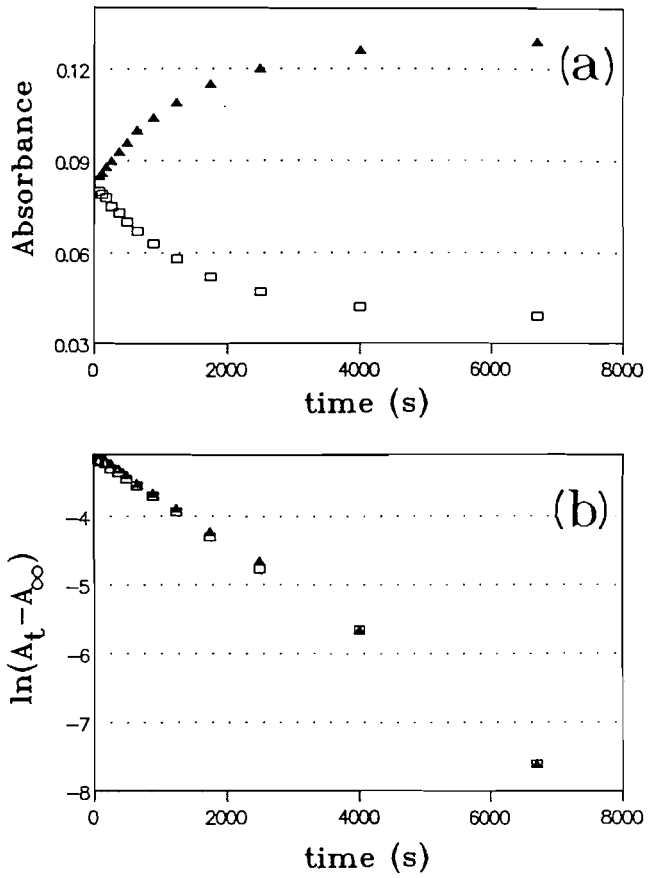

FIG. 3. (a) A graph showing the intensities of the OH stretching modes for the a-h1 and a-h2 rotamers of 9MG as a function of the time after UV irradiation of the matrix sample. (b) A graph showing the dependence of $\ln|A_t - A_\infty|$ on the time after UV irradiation of the matrix sample. Here A_t is the maximum absorbance for the band at time t, and A_∞ is the maximum absorbance of that band at infinite time. This correlation is for the band at 3576 cm^{-1} (Δ) for the a-h1 rotamer and for the band at 3568 cm^{-1} (□) for the a-h2 rotamer. The correlation is given by: $\ln|A_t - A_\infty| = 6.7 \times 10^{-4}t - 3.1$.

stabilization energies for the a-h1 and a-h2 rotamers. We believe that the spectrum of the relaxed matrix sample (shown in Fig. 1(b)) corresponds to the equilibrium concentrations of the rotamers at the matrix temperature (about 12 K). The ratio of the integrated absorbance of the OH band for the a-h1 rotamer at 3576 cm^{-1} to that of the a-h2 rotamer at 3568 cm^{-1} is measured to be $A_{h1}/A_{h2} = K_{12}(h1\text{-}h2) = [a\text{-}h1]/[a\text{-}h2] = 0.31 \pm 0.10$. The error is mainly due to the uncertainty of the decomposition of the overlapping bands. From this value of K, the standard free energy difference at 12 K can be obtained:

$$\Delta G_{12}^0 = -RT\ln K_{12}(h1\text{-}h2) = +0.12 \pm 0.03 \text{ kJ mol}^{-1}$$

with the a-h1 rotamer slightly *less* stable than the a-h2 rotamer. This standard free energy difference is between rotamers isolated in argon at equilibrium.

We have also estimated the free energy difference between rotamers in the vapor phase by looking at the intensity ratio of these same two bands in the spectrum of the "unrelaxed" sample recorded immediately after deposition (spectrum (a) in Fig. 1). For this unrelaxed sample the value of $K(h1\text{-}h2) = 0.62$. If this value of $K(h1\text{-}h2)$ is used as a measure of the equilibrium in the vapor at 470 K, $\Delta G_{470}^0 = +2$ kJ mol^{-1}. Since the deposition occurs over some period of time, the spectrum recorded

immediately after deposition contains contributions from molecules that have partially relaxed as well as from those that have just been deposited without time for any relaxation. We have corrected the absorbances shown in Fig. 1(a) using the relaxation parameters (the rate constant from the slope of the plot shown in Fig. 3(b)): slope = -6.7×10^{-4} and intercept = -3.1. Correction of the original intensity ratio ($A_{h1}/A_{h2} = 0.62$) by extrapolation to the time for the beginning of the deposition (about 39 min) gives an estimated upper limit for the equilibrium constant, for the vapor at 470 K, of K_{470}(h1-h2) = 30. If we use this value for K_{470} in the equation for ΔG^0, we find that our estimate for the standard free energy change from the a-h2 rotamer to the a-h1 rotamer in the gas phase is $\Delta G_{470}{}^0$ (h1-h2) = -13 kJ mol^{-1}. The "true" value of $\Delta G_{470}{}^0$(h1-h2) thus lies between +2 and -13 kJ mol^{-1}.

Finally, we should note here that we have remeasured the equilibrium constant for the hydroxy ↔ oxo tautomeric equilibrium in the same way as is described above for the rotameric equilibria. The result is K(o-h) = [a-o]/[a-h] = 1.0 ± 0.3, agreeing with our previous estimate (K(o-h) = 1.25 (ref. 13)) within the experimental error. Assuming that the appropriate temperature for this equilibrium is 470 K, the standard free energy change for this tautomerization is $\Delta G_{470}{}^0 = 0 \pm 0.5$ kJ mol^{-1}. There is no time "relaxation" effect on this equilibrium.

The experimental estimates of the values of ΔG, both for the tautomeric equilibrium and for the rotameric equilibrium, may be compared with the relative internal energy differences, ΔE (including zero point energies, ZPE). calculated at the HF/6-31G(d)//3-21G level for these equilibria:

$$\Delta E_1 = E_{a\text{-}o} - E_{RN7} = -9.8 \text{ kJ mol}^{-1}$$
$$\Delta E_2 = E_{a\text{-}o} - E_{RN1} = -5.2 \text{ kJ mol}^{-1}$$
$$\Delta E_3 = E_{RN1} - E_{RN7} = -4.6 \text{ kJ mol}^{-1}$$

These predictions are to be compared with the experimental estimates, at 470 K for the vapor:

$$G_{a\text{-}o} - G_{a\text{-}h} = 0 \text{ kJ mol}^{-1}$$
$$G_{a\text{-}h1} - G_{a\text{-}h2} = (\text{from } +2 \text{ to } -13) \text{ kJ mol}^{-1}$$

and in the matrix at 12 K:

$$G_{a\text{-}h1} - G_{a\text{-}h2} = 0.12 \text{ kJ mol}^{-1}$$

The calculated energy differences include the difference in zero point vibrational energies at the 3-21G level. We believe that the agreement between the experimental and theoretically predicted values may be within the uncertainty of the calculation, although it is possible that the equilibria studied experimentally are for different species than for the calculation (see below).

Vibrational assignment of the infrared spectra

Figure 4a shows the infrared spectrum (3600–400 cm^{-1}) measured for 9MG isolated in an Ar matrix recorded just after deposition and relaxation of the matrix. Figure 4b presents the spectrum of the same matrix after short (5 min) irradiation with the UV light. Comparison of these two spectra shows that brief UV irradiation causes changes in many spectral regions. The most clearly visible changes are observed in the 3580–3560 cm^{-1} and 1350–1150 cm^{-1} regions. When a UV-irradiated matrix is left for some time to relax, its spectrum converts back to the original one (Fig. 4a).

Subtracting the spectrum in Fig. 4(a) from that in Fig. 4(b) leads to the spectrum shown in Fig. 4(c). Here, the lower part (negative) shows all absorption bands (related to a-h1) that increase their absorbance as a result of UV irradiation, while the upper part (positive) indicates all bands (related to a-h2) for which the relative absorbance decreases with the UV irradiation. All bands that are not affected by UV irradiation cancel out and do not appear in the difference spectrum. Also bands with the same frequency for each rotamer cancel, as for example the bands at 3459 and 3453 cm^{-1}.

The main features of the difference spectrum in Fig. 4(c) are (1) a total absence of absorption from the C=O stretching mode (near 1740 cm^{-1}); and (2) the appearance of the well-resolved features in the positive and negative parts of the spectra in many regions, particularly in that of the OH stretching modes (near 3576 and 3568 cm^{-1}) and in the region of COH bending modes 1350–1150 cm^{-1}). These observations confirm the suggestion above based upon the changes in the OH, NH, and NH_2 region that this brief UV irradiation affects only the hydroxy tautomer of 9MG, and it seems most likely that this irradiation affects only the rotation of the OH group. Applying the subtraction procedure with different multiplication factors and the band decomposition procedure as described above for the OH and NH spectral region, we were able to obtain the separated spectra over the entire IR region for the two rotamers a-h1 and a-h2 of the amino-hydroxy tautomer and the amino-oxo tautomer (a-o).

These results are summarized in Table 1, where the first two columns collect "unprocessed" frequencies and maximum absorbances for all bands observed in the experimental spectrum of the relaxed matrix. The next six columns give the integrated intensities of the particular bands, obtained from the experimental spectrum using the subtraction, decomposition, and integration routines as mentioned above, together with the vibrational assignments of these bands.

Comparison of the experimental and calculated spectra

Table 2 summarizes the frequencies, intensities, and descriptions of the normal modes (potential energy distributions, PEDs) obtained from the *ab initio* calculations for the RN1 and RN7 rotamers of the a-h tautomer, and the results for the a-o tautomer. The definition of the symmetry coordinates needed to interpret the PEDs is given in Table 3.

Figure 5 shows a comparison of the experimental (a-o, a-h1, and a-h2) and calculated (a-o, RN1, and RN7) spectra. A more detailed comparison of the frequencies and intensities in the experimental and calculated spectra for each normal mode of each species can be obtained by comparing data listed in Tables 1 and 2. As seen in Table 1, there are several spectral regions where frequencies of the different tautomers and rotamers are very similar or even identical. In attempting to separate the absorption bands for the different species in these regions we rely strongly on the *relative intensities* of the bands in the difference spectra corresponding to the mixture of a-o and a-h1 and (or) of a-o and a-h2 species obtained after using the subtraction procedure described above and shown in Figs. 1(d), (e) so that we were able to identify which species was responsible for which absorption.

There could be several reasons for discrepancies between experimental and calculated spectra; some of these are suggested below.

1. The limitations involved in the calculation of spectra for this large molecule using this small 3-21G basis set are expected to cause discrepancies. This limitation might be particularly important in the vibrational assignment of ring modes, for which contributions from different atoms are known to depend relatively strongly on the basis set used, and it is known

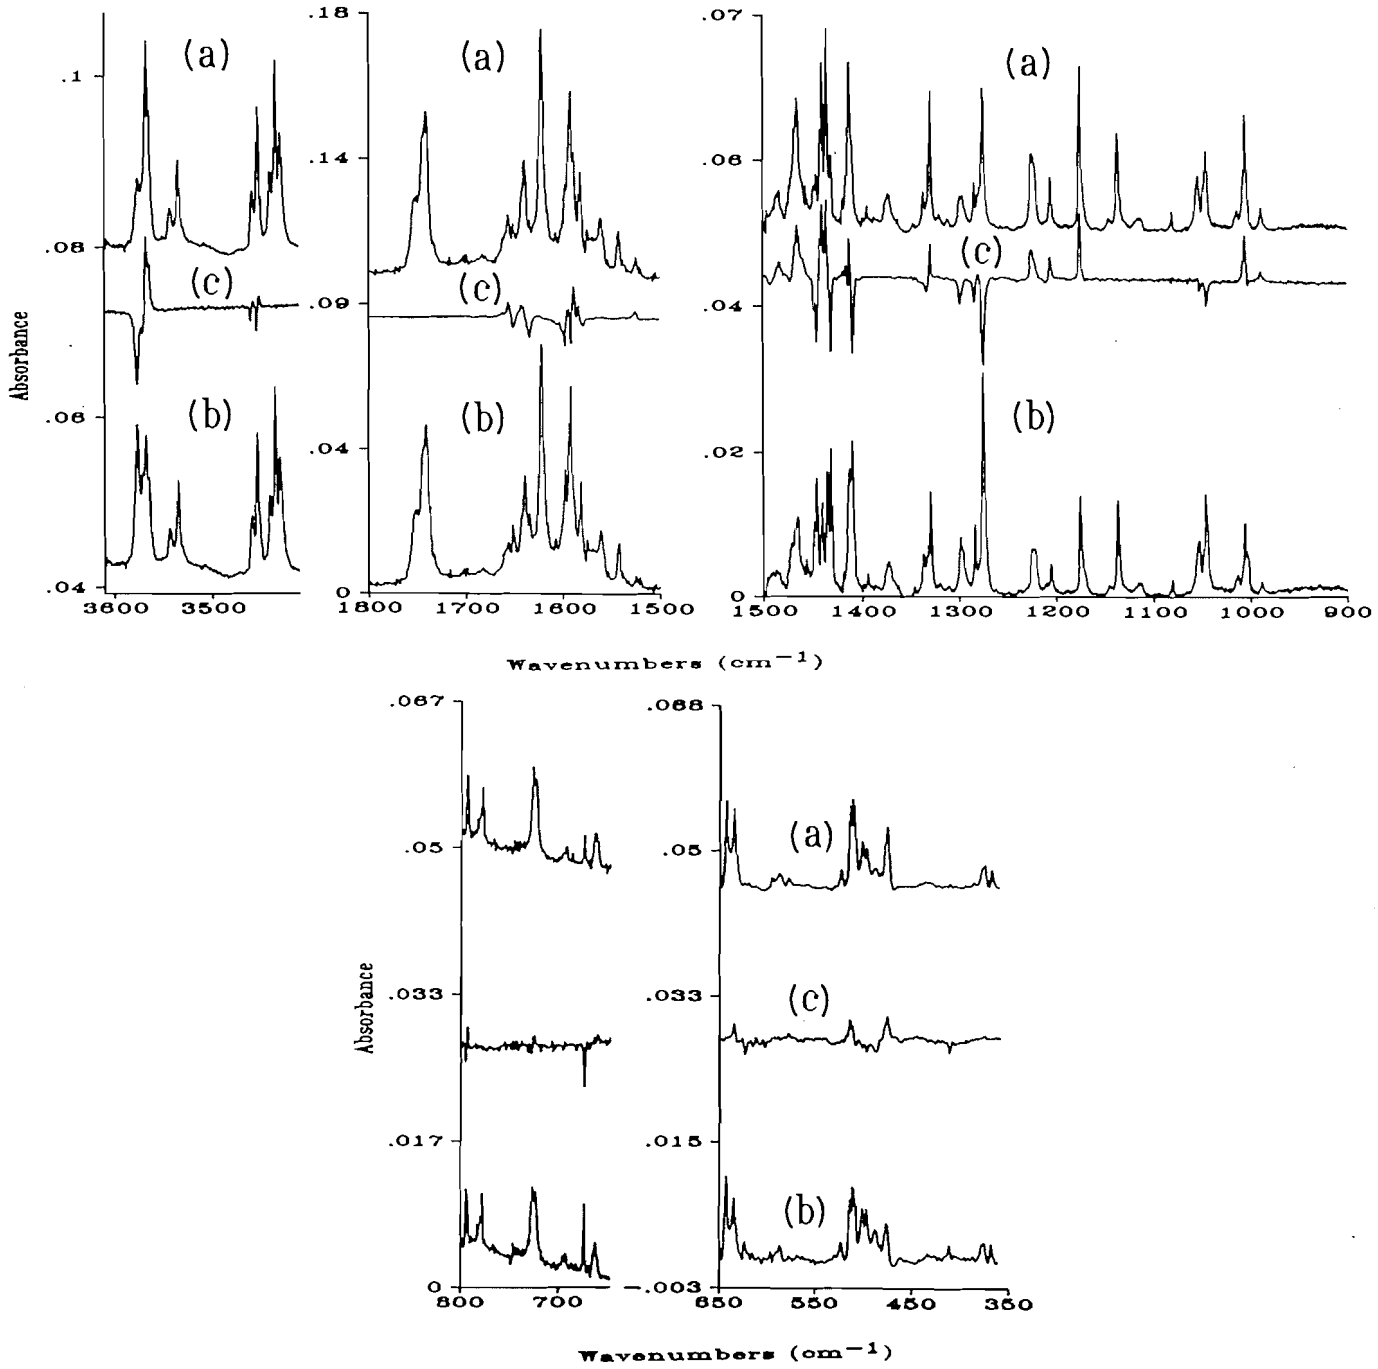

FIG. 4. Infrared spectrum of 9MG isolated in an argon matrix at about 12 K. (Regions where no (or only very low) absorption was observed are not shown.) (a) Spectrum obtained after the sample had relaxed for about 2 h after deposition, using 200 scans. (b) Spectrum obtained (using 32 scans) after sample a was irradiated by UV light for 5 min. (c) The difference spectrum (a − b) corresponding to the spectrum from a mixture of the a-h1 rotamer (negative bands) and the a-h2 tautomer (positive bands).

to be important for the out-of-plane modes (e.g., near 500–450 cm^{-1}) because these modes are predicted with intensities too high and also with frequencies too high after scaling by the factor of 0.9. The calculated frequencies for the out-of-plane modes are found to agree better with the experimental values when they are scaled by 0.81 rather than 0.9. This effect from the use of the 3-21G basis set is seen clearly in the comparison of the experimental spectra of uracil with the calculated vibrational spectra using 3-21G, 6-31G(d), and 6-31G(d,p) basis sets (38)).

2. The harmonic approximation made in calculating the spectra does not account for anharmonic effects, particularly Fermi resonance splittings, which are likely to be present in experimental spectra (e.g., in the carbonyl stretching region (40)).

3. Restricted rotation of the NH_2 group probably results in splitting each of the NH_2 stretching modes into two components (see the experimental spectra in Figs 1. and 4 in the region around 3540 and 3450 cm^{-1}, related, respectively, to the

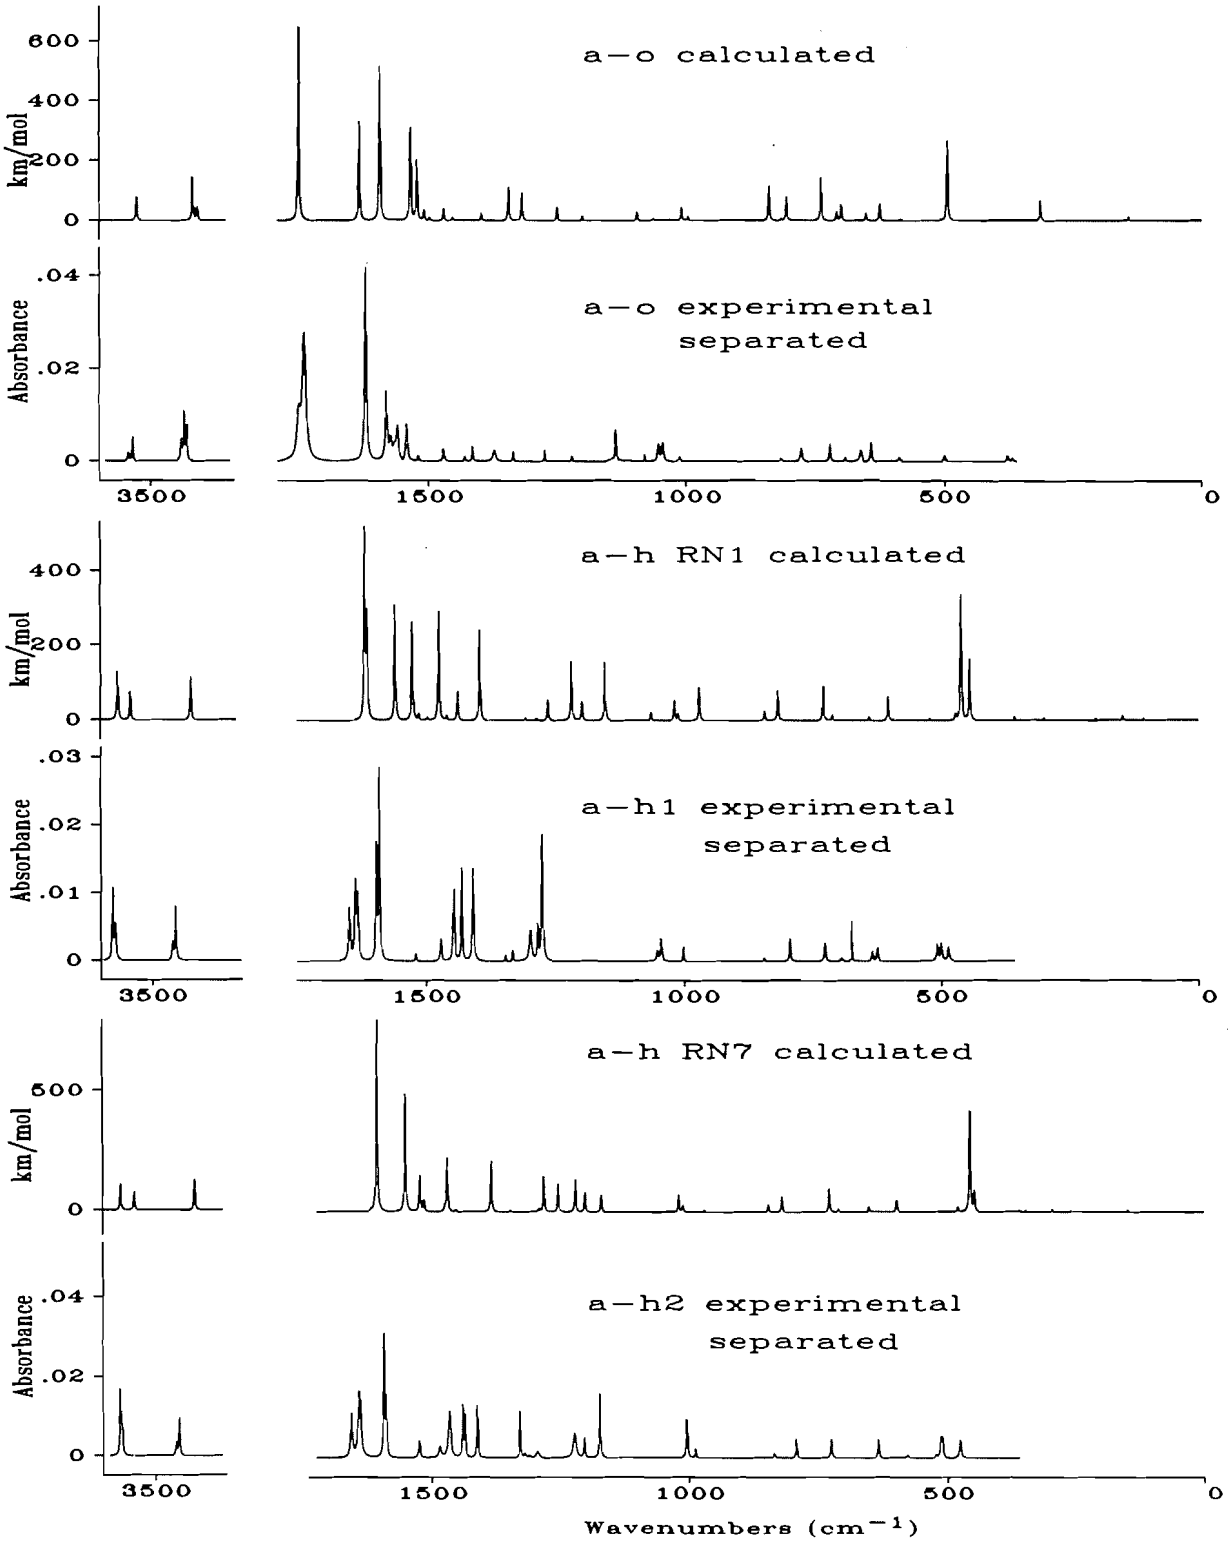

FIG. 5. Comparison of the separated experimental infrared spectra for the a-o tautomer and the a-h1 and a-h2 rotamers of 9MG isolated in an argon matrix at 12 K and with the spectra calculated using a 3-21G basis set for the a-o tautomer and for the RN1 and RN7 rotamers shown in Scheme 1. The simulation of the calculated spectra is made by setting the intensity at the maximum equal to the value of the calculated absolute intensity, choosing the band contour to be a mixture of Lorentzian (75%) and Gaussian (25%) shapes, and using a value of 3 cm^{-1} for the full width of the band at half the maximum intensity.

TABLE 1. Experimental frequencies (FREQ), absorbances at maxima (ABS), relative intensities (INT) and vibrational assignment for the amino-oxo tautomer (a-o) and for two rotamers of the amino-hydroxy tautomer (a-h1) and (a-h2) of 9-methylguanine isolated in Ar matrix at 12 K

[a]Absorbances at maxima in experimental spectrum of the 9MG in Ar before UV irradiation (relaxed sample).

[b]Relative integrated intensities obtained from the band separation and integration procedures (see description in text). The experimental integrated absorbance assigned to the well-separated C=O stretching vibration (marked by *) was assumed to be the same as the calculated intensity of this mode (see Table 2, for a-o).

[c]Normal mode according to numbering in Table 2 for this tautomer.

[d]Relative integrated intensity as in (*b*), only related to the calculated intensity of the vibration Am s st of the a-h1 tautomer (see Table 2, for RN1 tautomer).

[e]Abbreviations for description of vibrations as in Table 3. Note that de = De.

[f]Relative integrated intensity as in (*b*), only related to the calculated intensity of the vibration Am s st of the a-h2 tautomer (see Table 2, for RN7 tautomer).

[a]Numbering of the normal modes for the a-o tautomeric form, in order of the calculated unscaled frequencies.

[b]Frequencies scaled by a factor of 0.90, except for the OH stretch (0.918, based on studies of other systems (23)) and for the out-of-plane modes, which are scaled by a factor of 0.81 (all op modes except for the stretch, scissors bend, and rock of the CH_3 group). These scaling factors have been chosen because of experience with previous calculations for uracils (38) and thiouracils (24). The negative frequency for the Me tor is, of course, imaginary; it is the eigenvalue that is negative, indicating that calculated geometry is not correct for the orientation of the CH_3 group.

[c]The potential energy distributions (PEDs) are as defined by Morino and Kuchitsu (39*a*), using the procedure suggested by Keresztury and Jalsovszky (39*b*). Abbreviations and symmetry coordinates are defined in Table 3.

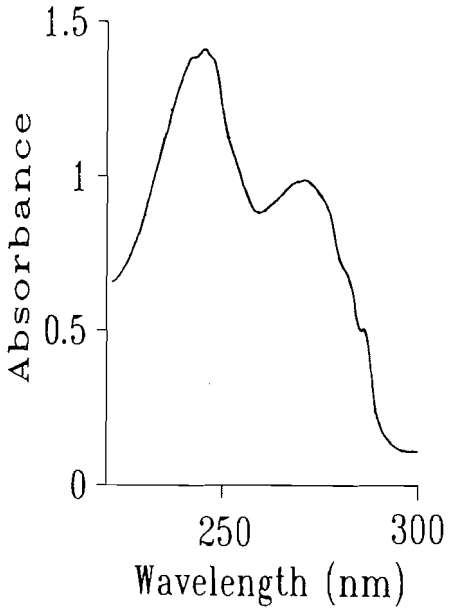

FIG. 6. Ultraviolet absorption spectra of 9MG isolated in an argon matrix at about 12 K, before and after a 5-min UV irradiation by the medium-pressure Hg lamp. Both spectra are identical and overlap exactly.

asymmetric NH_2 stretch of the a-o form and NH_2 symmetric stretch of the a-h1 and a-h2 rotamers).

As seen in Fig. 5, the agreement between the general patterns of the experimental and calculated spectra for the a-o tautomer is reasonably good, as can be expected for a calculation at this level of theory (see also Tables 1 and 2 for details).

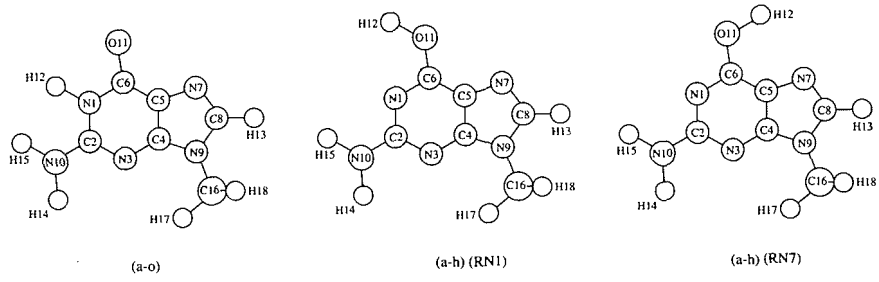
For the a-h1 and a-h2 rotamers the agreement is very poor, particularly for the intensities, as can be seen in Fig. 5. Although it is possible to find bands in the experimental spectra for a-h1 and a-h2 that correspond reasonably well in frequency to the calculated spectra for RN1 and RN7, the corresponding relative intensities found in the experimental spectra are often drastically different from those predicted by the calculation (compare data in Tables 1 and 2). For this reason we do not believe that a reliable detailed vibrational assignment of the experimental spectrum to the calculated modes can be made at this time for the a-h rotamers; consequently in Table 1 we have proposed very tentative and general assignment of the vibrational absorption bands observed for the a-h1 and a-h2 species. It should be pointed out, however, that we believe that the separation given in Table 1 between the bands due to the oxo tautomer and also between the bands from the two hydroxy rotamers is valid and useful, and that the correct assignment of the observed absorption bands for the hydroxy tautomers to the normal modes will not differ greatly from that given in Table 1.

These very large discrepancies between the experimental spectra for a-h2 and a-h1 and the spectra calculated for the RN7 and RN1 conformation of the a-h tautomer might indicate nonplanarity of the OH group for one or both rotamers in the experimental study. To be able to carry out the calculation at this level for such a large molecule, we were forced to assume planar RN1 and RN7 conformations, so that it is not possible at present to test whether calculated spectra for nonplanar conformations would, in fact, agree better with the experimental spectra. One may expect that a nonplanar configuration of the OH group might well result in a different spectrum than for a planar configuration, particularly in the intensity pattern.

Finally, we should comment on the hypothetical possibility that the hydroxy-imino tautomer might be present in our experimental spectrum, rather than the amino-hydroxy rotamers. The observed spectrum in the OH, NH stretching region is not totally inconsistent with such a tautomer instead of the amino-hydroxy form. Unfortunately, we do not have any idea at present what spectrum could be expected in other regions for the hydroxy-imino form.

To investigate the hypothesis concerning the possibility of the appearance of the hydroxy-imino tautomer we have optimized the geometry for this tautomer at the 3-21G level. This calculation predicts the energy of the hydroxy-imino tautomer to be 120 kJ mol^{-1} *higher* than that of the a-o form. The calculations at the same level quoted above predict the RN1 tautomer to be only 19 kJ mol^{-1} and RN7 only 22 kJ mol^{-1} less stable than the a-o tautomer. Although it is known that calculations with a 3-21G basis set do not predict stabilization energies well, the very high value predicted for the hydroxy-imino tautomer certainly indicates that this tautomer is less likely to be present in our experiment.

Additional support for the interpretation of the observed IR spectrum as due to the presence of the rotamers a-h1 and a-h2 and not due to the presence of additional tautomers, such as the imino-hydroxy tautomer, comes from the studies of the electronic absorption spectrum of the matrix-isolated 9MG sample and the effect on this spectrum of brief irradiation by UV light from a mercury lamp, similar to the study reported above for the IR spectrum.



The electronic absorption spectrum from this study is shown in Fig. 6. The spectra of the matrix sample before and after UV irradiation lasting the same period of time as in the IR experiment are identical. If the UV irradiation caused any changes in the equilibrium between tautomers, one might expect visible changes in the electronic absorption, as has previously been observed for the case of cytosines (see ref. 41).

Conclusion

In summary, the use of the changes induced by the UV irradiation, aided by the SpectraCalc computer analysis of our experimental IR spectra, has allowed us to separate the infrared spectrum observed for 9MG isolated in an argon matrix into contributions from three species. One species is surely the amino-oxo tautomer; the most likely interpretation of the other two species is that they are rotamers of the amino-hydroxy tautomer. However, the infrared spectra calculated with a 3-21G basis set for the two planar rotamers of the amino-hydroxy tautomer do not agree very well with the observed spectra attributed to these forms. Because spectra calculated at this level of theory for the amino-oxo tautomer of 9MG and for most other molecules in our experience generally have better resemblance in pattern to the experimental spectra than we found between the experimental spectra of a-h1 and a-h2 and the spectra calculated for RN1 and RN7, we suspect that the structures for the molecules a-h1 and a-h2 studied in our experiment may be different from those assumed for the calculation. We believe that the most likely explanation for the discrepancy between the 3-21G calculated spectra and the experimental spectra is the planar configuration assumed for the OH bond in the calculation for this tautomer. We cannot rule out the possibility that the 3-21G basis is simply much less adequate for calculations for the hydroxy tautomer than it is for the oxo

[a]The symmetry coordinates are the same for all three molecules (the a-o tautomer and the two rotamers (RN1 and RN7) of the a-h tautomer) except for those coordinates involved in the tautomerism (namely, the N1H bond in the a-o tautomer and the OH bond in the a-h form). These coordinates appear in pairs in the table and have the same numbers, but those for the a-h tautomer are designated by a prime: e.g., S_{12} and S'_{12} for the N1H st of a-o and for the OH st of the a-h forms, respectively.

[b]Unnormalized linear combinations of internal coordinates, defined to be orthogonal to the redundancy conditions, and with the appropriate symmetry (see Pulay *et al.* (42)). The Δr bond stretching internal coordinates are defined by their descriptions; the $\Delta\alpha_i$ bending coordinates describe the changes in the internal ring angles with apex at atom i (e.g., $\alpha_1 = <$C6N1C2, etc.); the $\Delta\beta_{ij}$ coordinates describe the bending of the external angles with apex at atom i and with the j subscript giving the ring atom on the other arm of the angle (e.g., $\beta_{65} = <$OC6C5, and $\beta_{61} = <$OC6N1, etc.); $\Delta\theta$ is defined by the description; $\Delta\phi_i$ (i = 1–3) are deformations of the angles in the NH_2 group (e.g., ϕ_1 is the HNH angle); $\Delta\phi_i$ (i = 4–9) are deformations of the angles in the CH_3 group; the $\Delta\gamma$ out-of-plane wagging coordinates are given by their descriptions; and the $\Delta\tau$ out-of-plane torsions are designated by a subscript that describes either the end bond that is being twisted out of plane or by two numbers that give the center bond in the ring about which the torsion is taking place. Definitions of the internal coordinates follow those given by S. Califano (43).

[c]Abbreviations are st, stretch; s, symmetric; a, asymmetric; Me, methyl; Am, amino; R6, the six-membered pyrimidine ring; De, deformation; R5, the five-membered imidazole ring; be, bend; ro, rock; sci, scissors bend; umb, umbrella; tor, torsion; and o, out-of-plane.

[d]The coefficients are $a = 0.80902$, $b = 0.30902$, $c = 1.11803$, and $d = 1.80902$.

form for this molecule. Possibly future calculations of the vibrational spectra for a nonplanar a-h tautomer of 9MG at the 3-21G level or with a better basis set may help to interpret further the experimental results obtained from this study.

Acknowledgements

We are extremely grateful to Professor Nelson Leonard and to Dr. S. Kumar of the University of Illinois for supplying the sample of 9-methylguanine. We also wish to thank Dr. Pierre LeBreton (University of Illinois, Chicago Circle) for valuable discussions. Support of the experimental study by NIH Research Grant No. GM32988 is gratefully acknowledged, as is support for the computing by the University of Alabama at Birmingham.

Amino acid/zwitterion equilibria II: vibrational and NMR studies of substituted thiazolidine-4-carboxylic acids

H. E. HOWARD-LOCK,[1] C. J. L. LOCK, AND M. L. MARTINS

Laboratories for Inorganic Medicine, Departments of Chemistry and Pathology, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received July 5, 1991

This paper is dedicated to Dr. Richard Norman Jones

H. E. HOWARD-LOCK, C. J. L. LOCK, and M. L. MARTINS. Can. J. Chem. **69**, 1721 (1991).

Infrared and Raman spectra (4000–100 cm) of solid samples of seven different 2-phenyl-, *N*-benzoyl-, and 2-ethyl-2 methyl derivatives of L-cysteine and D-penicillamine have been observed and assigned. Proton and ^{13}C nuclear magnetic resonance spectra for the compounds have also been measured. Amino acid/zwitterion equilibria are discussed with reference to p*K* values and the vibrational spectra

Key words: amino acid/zwitterion equilibria, thiazolidine carboxylic acids.

H. E. HOWARD-LOCK, C. J. L. LOCK et M. L. MARTINS. Can. J. Chem. **69**, 1721 (1991).

On a déterminé les spectres infra-rouge et Raman (4000–100 cm) d'échantillons solides de sept dérivés différents des 2-phényl-, *N*-benzoyl- et 2-éthyl-2-méthyl- de la L-cystéine et D-pénicillamine et on rapporte les attributions qui en découlent. On a aussi déterminé les spectres de résonance magnétique nucléaire du ^{1}H et du ^{13}C de ces composés. On discute des équilibres acide aminé/zwitterion par rapport aux valeurs de p*K* et aux spectres de vibration.

Mots clés : équilibres acide aminé/zwitterion, acides carboxyliques de thiazolidine.

[Traduit par la rédaction]

Introduction

The modes of action and adverse side effects of the drug D-penicillamine depend on several reactions, an important one being the condensation with aldehydes and ketones to form thiazolidine rings. Penicillamine might compete successfully with cysteine in vivo in this type of reaction (1). Both bind specifically to free aldehydes on collagen. Penicillamine inhibits cross-linking and depolymerizes incomplete cross-links of collagen, where these linkages are of the aldimine type. Thus, the effects of penicillamine are mainly upon skin collagen, giving rise to several side effects and some benefits (in scleroderma) as well.

The formation of thiazolidine rings is the basis for the suggested use of D-penicillamine as an alcohol detoxicant, and for treatment of scleroderma, morphea, keloid formation, and of vitreous and scleral scarring of the eye. Formation of thiazolidine rings is also the probable mode of action of D-penicillamine as vitamin B6 antagonist, and we have fully characterized the complex between pyridoxal and D-penicillamine (2).

Recently, we showed that methyl substitution at the C2 and C5 positions of thiazolidine-4-carboxylic acid affects the amino acid/zwitterion equilibrium (3). A downward shift of amino group p*K* and an upward shift of COOH group p*K* with increasing number of CH_3 groups was noted, although it was evident that other factors, such as the change in ring conformation and the degree of hydrogen bonding, played a role. The nature of the carbonyl-containing group affects the substitution at the C2 thiazolidine ring position and this in turn can affect the amino acid/zwitterion equilibrium and thus the hydrogen bonding behaviour in vivo.

A further process occurs in vivo, which may affect thiazolidine ring formation and which will affect zwitterion formation. This is substitution at the amine group. A new drug, which is used in the treatment of respiratory diseases, is *N*-acetylcysteine. This introduces a new variable, namely substitution at the N3 position. Thus we have extended our previous studies of how substitution affects these equilibria by considering a series of 2-phenyl, 2-methyl-2-ethyl-, and *N*-benzoyl-substituted thiazolidine-4-carboxylic acids.

Materials and methods

All the starting materials were reagent grade and were used as received, after checking the NMR spectrum. D-(−)-Penicillamine free base and L-(+)-cysteine hydrochloride monohydrate were supplied by Sigma Chemical Company, St. Louis, MO. Formaldehyde, 37% v/v, was supplied by Sargent–Welsh Scientific Co., Skokie, IL. Acetaldehyde was distilled from paraldehyde, reagent grade, supplied by BDH Chemicals, Toronto, Ont. Benzaldehyde was obtained from Eastern Chemical, Hauppauge, NY, acetone from BDH Chemicals, Toronto, Ont., 2-butanone from Aldrich Chemical Company, Milwaukee, WI, and benzoyl chloride from Eastman Kodak Company, Rochester, NY. Elemental analyses were provided by Guelph Chemical Laboratories, Guelph, Ont. Melting points were determined on a Gallenkamp capillary melting point apparatus, and are not corrected. The preparation of the various substituted thiazolidine-4-carboxylic acids was carried out as indicated schematically in Table 1 and outlined in detail as follows.

2-Phenylthiazolidine-4-carboxylic acid **1**

The method of Riemschneider and Hoyle (4) was followed with modification: 1.2 g (0.01) mol of L-cysteine hydrochloride monohydrate, A, was added to a mixture of 1.08 g (0.0105 mol) of benzaldehyde in 30 mL of water at pH 8.0. The mixture was stirred at room temperature and a precipitate started appearing within 30 min. The mixture was filtered to yield 1.35 g (65%) of white solid, $C_{10}H_{11}NO_2S$, mp 154–155°C (lit. (4) mp 159–160°C).

3-Benzoyl-2-phenylthiazolidine-4-carboxylic acid **2**

The method of Clarke *et al.* (5a) was followed with modification: 0.42 g (0.002 mol) of **1** was dissolved in 20 mL of pyridine. The solution was cooled on ice and it became a light suspension. Benzoyl chloride (0.3 g, 0.0025 mol) was added dropwise to the stirred mixture, which slowly turned yellow as the solid gradually dissolved. The reaction was allowed to proceed in the refrigerator overnight. The product was recovered as follows: The mixture was evaporated under reduced pressure to leave a yellow oil and some white solid. This was dissolved in 80 mL dichloromethane, then extracted twice with 20 mL water. The combined aqueous layers were extracted once with a small

TABLE 1. Nomenclature and preparation scheme for some substituted thiazolidine-4-carboxylic acids[a]

Reactants	Benzaldehyde	2-Butanone	Benzoyl chloride
L-Cysteine	**1**[b]	**3**	
1			**2**
3			**4**
D-Pencillamine	**5**	**6**	
6			**7**

Nomenclature: The products are secondary amino acids that are 5-membered heterocyclic rings containing a sulfur atom at position 1, a nitrogen atom at position 3, carbon atoms at 2, 4, and 5, and a COOH group attached to C4.

[a]Reflux overnight at room temperature or gentle heat (~80°C).

[b]**1**, 2-phenylthiazolidine-4-carboxylic acid; **2**, 3-benzoyl-2-phenylthiazolidine-4-carboxylic acid; **3**, 2-ethyl-2-methylthiazolidine-4-carboxylic acid; **4**, 3-benzoyl-2-ethyl-2-methylthiazolidine-4-carboxylic acid; **5**, 2-phenyl-5,5-dimethylthiazolidine-4-carboxylic acid; **6**, 2-ethyl-2,5,5-trimethylthiazolidine-4-carboxylic acid; **7**, 3-benzoyl-2-ethyl-2,5,5-trimethylthiazolidine-4-carboxylic acid.

volume of CH_2Cl_2. The combined organic layer was dried with anhydrous sodium sulfate, filtered, and evaporated in the rotoevaporator. The yellow solid recovered, which had only a faint pyridine odour at this stage, was dissolved in 20 mL methanol and was acidified to pH 2–3 with aqueous HCl. Water was added dropwise until the solution turned slightly cloudy. The mixture was allowed to stand at room temperature until crystals formed. These were recrystallized from hot methanol to give a pale yellow solid. Yield 0.35 g (60%), mp 128-129°C (lit. (5*a*) mp 153–154°C). Anal. calcd. for $C_{17}H_{15}NO_3S$: C 65.2, H 4.8, N 4.5, S 10.2, O 15.3; found: C 62.5, H 5.7, N 4.3, S 9.8, O 18.2. Anal. calcd. for **2**·0.7 H_2O: C 62.6, H 5.1, N 4.3, S 9.8, O 18.2.

2-Ethyl-2-methylthiazolidine-4-carboxylic acid 3

A published procedure (5*b*) was used as follows: 1.5 g (0.0125 mol) L-cysteine was added to 22 mL of 2-butanone and the mixture was refluxed for 5 h. The mixture was filtered while hot. Most of the cysteine remained undissolved and unreacted. White solid, 0.6 g, was recovered after evaporation of the filtrate, followed by recrystallization from hot 2-butanone; $C_7H_{13}NO_2S$, mp 130–132°C (lit. (5*b*) mp 132–133°C).

3-Benzoyl-2-ethyl-2-methylthiazolidine-4-carboxylic acid 4

Compound **3** (1.0 g, 0.006 mol), 30 mL of pyridine, and 0.8 g of benzoyl chloride were reacted in a flask cooled by an ice bath. Thirty minutes later a white solid started precipitating out of the pale yellow solution. The work-up procedure was identical to that reported in the preparation of **2**; 0.6 g (40%) of a white solid was obtained, mp 133–134°C. Anal. calcd. for $C_{14}H_{17}NO_3S$: C 60.2, H 6.1, N 5.0, S 11.5, O 17.2; found: C 60.5, H 6.3, N 4.8, S 11.3, O 17.2.

2-Phenyl-5,5-dimethylthiazolidine-4-carboxylic acid 5

A published procedure (5*a*) was followed: 1.0 g (0.0066 mol) of D-penicillamine was added to 1.0 mL benzaldehyde and 10 mL ethanol, and the mixture was heated for 30 min. The almost clear mixture was filtered while hot and as the filtrate cooled a white precipitate started separating. The cooled solution was filtered to obtain 1.3 g (80%) of a white solid, $C_{12}H_{15}NO_2S$, mp 141–142.5°C (lit. (5*a*) mp 145–146°C).

2-Ethyl-2,5,5-trimethylthiazolidine-4-carboxylic acid 6

To 1.5 g (0.01 mol) of D-penicillamine was added 25 mL 2-butanone and the mixture was refluxed for 4 h. The clear solution was allowed to cool but no crystallization occurred. Evaporation produced 1.5 g (70%) of white solid, recrystallized from 2-butanone, mp 117–119°C (lit. (5*c*) mp 183–183.5°C). Anal. calcd. for $C_9H_{17}NO_2S$: C 53.2, H 8.4, N 6.9, O 15.7, S 15.8; found: C 53.7, H 8.6, N 6.8, O 15.4, S 15.4.

3-Benzoyl-2-ethyl-2,5,5-trimethylthiazolidine-4-carboxylic acid 7

Compound **6** (0.20 g, 0.00125 mol) was dissolved in 15 mL pyridine and 0.15 g benzoyl chloride was added. The mixture was left in the refrigerator overnight. A yellow oil was recovered after evaporation and yielded a yellow crystalline solid after cyrstallization from methanol–water. The crystals were filtered and washed with ether to give a white solid, 0.15 g (40%), mp 182–183°C. Anal. calcd. for $C_{16}H_{21}NO_3S$: C 62.5, H 6.9, N 4.6, O 15.6, S 10.4; found: C 62.4, H 7.0, N 4.6, O 15.6, S 10.8.

Almost all of the compounds were purified by recrystallization and their melting points are close to the reported values, except for **2** and **6**. Elemental analyses were obtained for those compounds for which no mp was found in the literature, **4** and **7**. Most of these compounds had been previously prepared but very little is known about their structure and spectroscopic properties. Many of the thiazolidines known today were synthesized before 1949 from *dl*-penicillamine, so that the products obtained consisted of mixtures of stereoisomers. This might explain the melting point disparity between the published values and the values obtained here for 3-benzoyl-2-phenylthiazolidine-4-carboxylic acid **2** (128–129°C vs. 153–154°C). It is much more likely that the material described here is at least partly hydrated; the analytical figures are poor for the anhydrous material but agree fairly well with a 0.7 hydrate. An even larger disparity occurs for the melting point of **6**: 117–119°C versus 183–183.5°C published, for which no apparent explanation arises. The narrow range of observed mp's suggests the compounds are relatively pure; moreover, their proton and carbon-13 spectra were obtained and are consistent with the structure proposed, and the vibrational spectra agree with those of closely related structures.

No literature mp values could be found for 3-benzoyl-2-ethyl-2-methylthiazolidine-4-carboxylic acid **4** (mp 133–134°C) and 3-benzoyl-2-ethyl-2,5,5-trimethylthiazolidine-4-carboxylic acid **7** (mp 182–183°C), and we believe we are reporting their preparation and characterization for the first time. The elemental analyses of **4** and **7** indicate purity and stability.

Spectral measurements

Infrared spectra were recorded on both Nicolet 7199 FT-IR and Perkin–Elmer model 283 spectrophotometers. The samples were ground with KBr at a concentration of approximately 1% by weight and then pressed into pellets. Spectra were calibrated with polystyrene. Raman spectra were excited by means of λ5145 Å radiation from a Spectra-Physics model 164-02 argon ion laser and recorded on a Spex 14018 double monochromator. Solid samples were contained in glass melting point tubes, and solutions in NMR tubes. The spectrometer was calibrated regularly against an indene standard and had previously been calirtated with a neon lamp; the wavelength readout scale was found not to change (±1–2 cm).

Solutions for NMR studies were prepared in D_2O and concentrations were about 100 mg (solid)/mL of solvent. External tetramethylsilane was used as the reference. Proton NMR spectra were recorded on a Varian T60 spectrometer, and ^{13}C NMR spectra were recorded on a Bruker WP-80 spectrometer operating at 20.115 MHz.

The p*K* values of some of the water-soluble thiazolidine-4-carboxylic acids **3**, **6**, and **7** were obtained by titration of aqueous solutions with 0.01 N NaOH and 0.01 N HCl. The pH values were measured with a Corning model 130 pH meter, which was standardized with Scientific Products potassium hydrogen phthalate pH 4.00 buffer, BDH pH 7.00 buffer, and Scientific Products boric acid/potassium hydroxide pH 10.00 buffer. The pH measurements are reliable to ±0.03.

Results and discussion

The vibrational spectra

In the *N*-benzoyl compounds and in the thiazolidine compounds derived from benzaldehyde there are peaks that result from aromatic and C—H bond stretches. These give rise to multiple absorption peaks in the 3100–3000 cm region of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

the spectrum, while aliphatic C—H bond stretches occur at 3000 cm or lower. For a monosubstituted aromatic ring, carbon–carbon stretching frequencies have been assigned to bands in the regions 1608–1600, 1589–1580, 1495–1490, and 1452–1446 cm. Bands at 1240 ± 8, 1177 ± 6, 1156 ± 5, 1073 ± 4, and 1027 ± 3 cm have contributions from the bending vibrations of aromatic C—H bonds (6). We observe these bands and find that they are slightly sharper than neighbouring bands in the infrared spectra. Also we have allowed our assignments slightly wider frequency ranges than in benzene alone because of contributions from both phenyl and benzoyl groups. Medium strong bands at 751 ± 15 and 697 ± 11 cm are also characteristic of monosubstituted benzene rings. The frequency of these bands is variable because of the interaction with out-of-plane ring bending. Raman bands expected for monosubstituted benzene rings are 1620–1565, 1005–90 (very strong), 625–605, and 415–400 (very weak) cm (6).

The C—S stretching frequency has been assigned in D-penicillamine and β,β-dimethylcysteic acid to 548 cm, a very strong Raman band. In L-cysteine it has been assigned to 678 cm and it has been concluded that substituents on carbon atoms adjacent to sulfur cause a decrease in the stretching frequency of the C—S bond (7). Bands in the region of 680 and 600 cm, and 630 and 540 cm, are so assigned.

Thiazolidine ring modes have been assigned in the past as follows: 1150–1110 cm arise from CCN stretches; 380, 330, 280, and 191 cm bands result from CNC, CCS, NCS, and CSC deformations, respectively. Deformations involving sulfur usually have been found to be intense in the Raman, and showed isotopic shifts caused by the adjacent CD_3 groups in tetramethylthiazolidine-4-carboxylic acid prepared from deuterated acetone (7). The ring assignments are consistent with previous findings. The detailed spectra have been deposited.[2]

Table 2 shows selected vibrational bands that pertain to the amino acid/zwitterion equilibria, and we will discuss in detail only these features. Characteristic O—H stretching bands are present in the infrared at 3460–3400 cm for all compounds containing COOH functional groups. There are also fairly intense broad bands at about 3000 cm for some of the compounds as well as distinct bands between 2500 and 1940 cm. These broad absorptions at lower frequency are a result of moderately strong hydrogen bonds in some of these compounds. In cysteine and D-penicillamine the hydrogen bond absorptions are so strong that they mask the CH_2 and CH_3 absorptions almost completely (3).

Three types of hydrogen bonds can occur in thiazolidine-4-carboxylic acid derivatives: O—H...O, O—H...N, and N—H...O bonds. The first type can be much shorter than the other two: Hamilton and Ibers (8) have discussed correlations between the frequency of anti-symmetric stretching modes and the O...O or N...O distance in such bonds. A lowering of OH frequency correlates with a lower force constant and a longer OH bond. The O—H bond length actually increases as the O...O bond length decreases. Thus lower O—H stretching frequencies correlate with formation of stronger O—H...O hydrogen bonds. Increase of band width and intensity enhancement occur at the same time. Similar effects occur for the O—H...N and N—H...O bonds (8).

Hydrogen bonds of the type O—H...O are expected to have infrared bands between 3500 and 2600 cm for O...O distances of 2.90–2.60 Å. Hydrogen bonds between oxygen and nitrogen atoms have lower stretching frequency bands in the region of 2600–1900 cm (8).[3] All compounds in Table 2 show hydrogen bonding bands in the range 3450–3000 cm. Some compounds show splitting of bands and others have additional bands at lower wave numbers. These observations imply that there are moderate O...O hydrogen bonds, in the range of 2.88–2.65 Å (8). Hydrogen bonds of the O...N or N...O type only exist for the non-*N*-benzolyated compounds, and are characterized by two bands in the regions 2500–2350 cm and 1990–1900 cm, as observed by us for *S*-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid (7).

The two *N*-benzoyl derivatives of L-cysteine **2** and **4**, and the compounds **5**, **6**, and **7** in Table 2 are all amino acids, having C=O stretching frequencies around 1725 cm. Compounds **1**, 2-phenylthiazolidine-4-carboxylic acid, and **3**, 2-ethyl-2-methylthiazolidine-4-carboxylic acid, are zwitterions; there are no bands in the C=O region of 1740–1725 cm or in the C—O region (1215–1190 cm). COO^- stretching bands are very intense in the infrared at 1625 cm, and weaker in the Raman at 1630 and 1603 cm, for **3**, and at 1572 cm in the infrared for **1**. The latter is an unusually low frequency, but it is probaby caused by the proximity of the phenyl group, and there are three Raman bands between 1621 and 1580 cm. The symmetric vibrations of COO^- in both zwitterions are assigned to the bands at 1388–1376 cm. The amide C=O band was assigned to 1660–1620 cm, typical of disubstituted amides.

The NMR spectra

The proton NMR spectra of thiazolidine-4-carboxylic acids derived by condensation of D-penicillamine and L-cysteine with benzaldehyde and 2-butanone and their *N*-benzoyl derivatives are shown in Table 3 and the coupling constants in Table 4. Peaks at 7.42 ppm are assigned to the aromatic protons, a multiplet being observed because the protons are not equivalent. The protons on C4 have chemical shifts between 3.56 and 4.90 ppm depending on the overall structure of the molecule. The lowest chemical shift is caused by the C4 proton in 2-phenyl-5,5-dimethylthiazolidine-4-carboxylic acid, **5**, and the greatest deshielding of a C4 proton is in 3-benzoyl-2-phenylthiazolidine-4-carboxylic acid, **2**. In general the chemical shift of the C4 proton is higher in the *N*-benzoyl derivatives than in the other thiazolidine compounds. C5 protons are mostly unaffected by the presence of the benzoyl group, since they are spatially removed from the nitrogen atom, although some deshielding is noticed if there is a phenyl group on C2. Protons on C2 are markedly deshielded compared to protons on other ring carbon atoms, probably because of the presence of the phenyl ring on the same carbon atom. Deshielding is especially pronounced in the *N*-benzoyl-2-phenylthiazolidine compound, **2**, because of the proximity of the carbonyl of the amide, which attracts electron density from neighbouring atoms. The spectrum of the 2-phenylthiazolidine compound, **1**, is similar to that of the 2-methylthiazolidine compound in that both are mixtures of stereoisomers and each proton type in the molecule gives rise

[2]Tables containing the complete listing of infrared and Raman wave numbers and the approximate mode descriptions and assignments for compounds **1–7** may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

to two signals. The chemical shift difference is probably very small, however, since no splitting was observed. The three-line signal of the proton at C4 was expected to be a four-line signal.

Compound **2** had some new aromatic peaks in a multiplet at 7.30 ppm, and the downfield shift of the proton at C2 was increased significantly, probably because of the proximity of the amide carbonyl group, which attracts electron density from neighbouring atoms. Even though the compound is a mixture of diastereomers, only one signal was observed for each type of proton.

The C4 proton of 2-ethyl-2-methythiazolidine-4-carboxylic acid, **3**, gives a triplet at low field and the C5 protons cause overlapping doublets of doublets. A singlet at 1.62 ppm results from the resonance of the methyl protons on C2. The ethyl

group shows two set of peaks: the methyl group is a triplet, and the methylene protons are nonequivalent and form part of an ABC_3 system.

The spectrum of 3-benzoyl-2-ethyl-2-methylthiazolidine-4-carboxylic acid, **4**, is essentially the same as the previous one with additional aromatic peaks. Both NMR spectra show two closely spaced signals for each type of proton, like all the other compounds in this table, because of the presence of a new asymmetric center at C2.

The 2-phenyl-5,5-dimethylthiazolidine-4-carboxylic acid, **5**, has two methyl groups, each of which gives two singlets, since they can be in one of two possible positions that are nonequivalent. Otherwise the spectrum is similar to that of the L-cysteine analogue.

[a] pK_1 is pK of the carboxylic group.
[b] pK_2 is pK of the amino group.
[c] Calculated in kcal mol, from $\Delta G = -RT \ln (K_2/K_1)^{1/2}$.
[d] $(1/2)(pK_1 + pK_2)$.

The carbon-13 chemical shifts of the componds are shown in Table 5. Some of the peak assignments, especially those of the carbon atoms in the ring, were difficult to make. Spin-sorted spectra were obtained and compared, and it is believed the peaks are assigned correctly. Only general trends of the data listed in Table 5 will be noted here.

The carboxyl carbon atoms have very consistent chemical shifts, near 170 ppm, and thus this group is very little affected by other ring substituents. The next most deshielded carbon atom is in the amide carbonyl of the benzoylated compounds, the signal occurring at 138.7–145 ppm. The aromatic carbon atoms all have values between 125 and 137 ppm, with the two nearest the C=O being the most deshielded.

The carbon atom in the thiazolidine ring with the highest chemical shift is usually C4 except when C2 is doubly substituted. The highest-field ring carbon atom is C5, which has low chemical shift values unless there are methyl substituents directly bonded to it. Methyl groups on C5 give peaks around 30 ppm and those on C2 have slightly higher chemical shifts, 33–38 ppm. Ethyl group carbon atoms are not assigned specifically in Table 5, but the terminal methyl carbon atom gives a peak of higher field than the methylene carbon atom.

The amino acid/zwitterion equilibria

The amino acid/zwitterion equilibria are independent of the pH of solution and the presence of the cation and anion. The vibrational spectra, on the other hand, are capable of showing the presence of all three species — the cation, the neutral species, and the anion.

The pK values represent the extent of protonation of ionizable groups, and are presented in Table 6. There is a downward shift of amino group pK with increasing methyl group substitution, especially on C2. Increase of COOH group pK with methyl substitution is partly caused by inductive effects of the methyl group; also with increasing substitution the anion cannot be solvated so effectively. Thus the equilibrium $AH \rightleftarrows A^- + H^+$ is shifted to the left-hand side.

From the equation relating the Gibbs standard free energy to the equilibrium constant relationship for a given reaction in solution, we have calculated the free energy of conversion from the amino acid to the zwitterion form. The values of ΔG°, also shown in Table 6, vary between −4.23 and −1.83 kcal mol^{-1} for L-cysteine and *S*-2,2,5,5-tetramethylthiazolidine-4-carboxylic acid. The isoelectric point is the pH at which the concentration of the zwitterion is at a maximum, and the concentrations of anion and cation are equal. Below the isoelectric point, the molecule is positively charged; above it, negatively. Thus at physiological pH these thiazolidine-4-carboxylic acids would all be negatively charged.

Compounds **3** and **6** have the highest values for amino group pK in this series. The carboxyl group pK values of 2.7 and 2.9 are similar to the rest of the series. The ΔG° values of −3.50 and −3.07 are closer to the value for the unsubstituted thiazolidine-4-carboxylic acid, and higher than the values for the methyl-substituted compounds.

The pK values for some compounds could not be measured because of poor solubility, but their form in the solid state can be assigned as either amino acid or zwitterion from the vibrational spectra. The compounds that exist in the amino acid form in the solid are **2**, **4**, **5**, **6**, and **7** (which includes all the *N*-benzoyl derivatives). Compounds **1** and **3** are zwitterions in the solid. Although **6** has pK values typical of the zwitterion in solution, the solid shows the characteristic C=O and C—O infrared bands of the amino acid.

The ^{13}C NMR spectra show a correlation related to these equilibria: The chemical shifts of the carboxylate carbon atoms in **1** and **3** are greater than those for the other compounds, and are close to the values for the unsubstituted thiazolidine-4-carboxylic acid. These compounds are all zwitterions in the solid.

The zwitterion forms of D-penicillamine and L-cysteine become the amino acid forms in the thiazolidine complexes because of marked changes in the pK values of the amino and carboxylic acid groups.

The amino acid/zwitterion equilibria depend both on structural variations in the ring and on the number and type of substituents on the ring (with changes at the C2 position having greater effect than those at C5). In all cases, however, the changes are large enough that they will markedly affect the hydrogen bonding behaviour in vivo, and thus this is an important feature of thiazolidine formation in biological milieu.

Energy transfer between Langmuir–Blodgett monolayers of organic dyes

E. JOHNSON AND R. AROCA[1]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received May 28, 1991

This paper is dedicated to Dr. Richard Norman Jones

E. JOHNSON and R. AROCA. Can. J. Chem. **69**, 1728 (1991).

The Langmuir–Blodgett technique has been used to prepare multilayer structures in order to investigate the distance dependence of the nonradiative transfer of electronic energy from a donor plane of molecules to an acceptor plane. The distance between well-separated donor molecules and acceptor molecules was carefully controlled by spacer layers of arachidic acid. New systems for energy transfer studies are considered that use *N*-hexyl-*N'*-ethyl-3,4:9,10-perylenetetracarboxyldiimide (HPTCDE) and *N*-hexyl-3,4:9,10-perylenetetracarboxylmonoimide (HPTCO) as donors and lutetium diphthalocyanine ($LuPc_2$) as acceptor. The limitations of the Förster dipole theory of energy transfer from a donor monolayer of point dipoles to an acceptor layer are discussed.

Key words: energy transfer, Langmuir–Blodgett, diphthalocyanine, perylene.

E. JOHNSON et R. AROCA. Can. J. Chem. **69**, 1728 (1991).

Afin d'étudier la relation entre la distance et l'énergie électronique de transferts non-radiatifs de molécules d'un plan donneur à un plan accepteur on a préparé des structures multicouches à l'aide de la technique de Langmuir–Blodgett. Pour contrôler avec précision la distance entre des molécules de donneur et des molécules d'accepteur bien séparées, on a utilisé des couches d'acide arachidique. On a considéré de nouveaux systèmes pour les études de transfert d'énergie; ils utilisent le *N*-hexyl-*N'*-éthyl pérylène-3,4:9,10-tétracarboxyldiimide (HPTCDE) et le *N*-hexyl pérylène-3,4:9,10-tétracarboxylmonoimide (HPTCO) comme donneurs et le diphtalocyanine de lutécium ($LuPc_2$) comme accepteur. On discute des limitations de la théorie dipolaire de Förster du transfert d'énergie d'une monocouche de dipôles ponctuels agissant comme donneur à une couche agissant comme accepteur.

Mots clés : transfert d'énergie, Langmuir–Blodgett, diphtalocyanine, pérylène.

[Traduit par la rédaction]

Introduction

Langmuir–Blodgett (LB) monolayers of strongly absorbing and fluorescent dyes represent an important type of model systems where the increase and direction of photon absorption can be studied. The nontrivial transfer of electronic excitation energy between well-separated donor molecules and acceptor molecules occurs before the emission takes place. Förster's dipole theory of energy transfer (ET) predicts that when the corresponding optical transitions in both molecules are allowed, the probability of ET decreases with the sixth power of the distance (1). A parallel can be drawn between the trivial and nontrivial ET between molecules and the transfer of power in the far-zone and the near-zone fields of oscillating dipoles in classical electrodynamics (2). Hans Kuhn (3) applied the dipole–dipole model to a number of practical systems with restricted geometries. In particular, he derived the basic equations for the luminescence quenching of a dipole emitter by a monolayer of oriented dipoles. The latter approach has been used by several groups to explain the results for the distance dependence of nontrivial ET between well-separated monomolecular layers (4–6). Recently, the dynamics of the Förster-type energy transfer in organic systems of restricted geometries has been reviewed by Yamazaki *et al.* (7). There exists, however, a very limited amount of data for energy transfer between neat LB monolayers of strongly absorbing dye molecules. Only very recently, Penner reported steady-state energy transfer for donor and acceptor layers of concentrated J-aggregated cyanine dyes (5). In the present report, the excimer emissions of two perylene derivatives: *N*-hexyl-*N'*-ethyl-3,4:9,10-perylenetetracarboxyldiimide (HPTCDE) and *N*-hexyl-3,4:9,10-perylenetetracarboxylmonoimide (HPTCO), that were in resonance with the red absorption of lutetium bis-phthalocyanine ($LuPc_2$) were used to study the distance dependence of the energy transfer between LB layers. The separation between the two dye layers was controlled by interposing fatty acid layers. A critical discussion of the results and Kuhn's model is presented. The possibility of a competitive quenching from electron transfer processes has also been examined experimentally, and the perylene–phthalocyanine interactions were followed for a number of perylene derivatives.

[1]Author to whom correspondence may be addressed.

Experimental

The spectroscopic characterization of HPTCDE, HPTCO, and $LuPc_2$ has previously been reported (8, 9). Reproducible isotherms of all three dyes have been recorded at 20°C. Both perylene derivatives possess two limiting areas. HPTCO has limiting areas of 0.24 and 0.84 nm^2. HPTCDE has limiting areas of 0.64 and 0.94 nm^2. $LuPc_2$ has a limiting area of 0.75 nm^2. Moreover, all three dyes have collapse pressures above 35 mN/m. The acceptor layer of $LuPc_2$ was first deposited on to a Corning 7056 glass slide. Spacer layers of arachidic acid were then deposited on top of the acceptor layer. Finally, the desired perylene derivative was placed above the previously deposited matrix as well as on a bare glass section of the slide. The latter section of the slide was used as a fluorescence reference layer. Z deposition was used in all cases. All film materials were dissolved in chloroform for film spreading. HPTCO was the least soluble. Its final concentration in $CHCl_3$ was 1.9×10^{-4} M. The concentration of HPTCDE, $LuPc_2$, and arachidic acid was 1.2×10^{-4} M, 8.3×10^{-5} M, and 1.8×10^{-3} M respectively. Approximately 6×10^{16} chromophore molecules were spread onto an aqueous subphase containing $CdCl_2$ at a concentration of 2.5×10^{-4} M. Films were prepared in a Lauda Langmuir film balance equipped with an electronically controlled dipping device, Lauda Filmlift FL-1. Monolayers of the perylene dyes were transferred at a constant speed of 3 mm/min, and at surface pressures of 15 mN/m. Monolayers of $LuPc_2$ were transferred at 10 mN/m. In all cases, the transfer ratio was near unity. Spectra Physics model 2020 Kr^+ and Ar^+ ion lasers were used. Typical spectral bandpass and laser power were 5 cm^{-1} and 200 mW

For personal use only.

respectively. Raman shifts and steady-state fluorescence were measured with a Spex-1403 double monochromator and the Ramanor U-100 with microscope attachment. Electronic absorption spectra were recorded on a Response UV–VIS spectrophotometer interfaced with an IBM PC computer.

Results and discussion

Electronic spectra and excimer emission

The electronic absorption spectrum of $LuPc_2$ (in a 1:1 molar ratio solution of HPTCDE and $LuPc_2$ in $CHCl_3$), and the fluorescence spectrum of HPTCDE obtained from the same solution are shown in Fig. 1. A dip in the 650–680 nm region of the emission spectrum of HPTCDE is due to trivial and nontrivial energy transfer between the two dye molecules. It can be seen that the molecular monomer emission of perylene and perylene derivatives does not have a strong fluorescence band in resonance with the absorption Q (667 nm) band of the $LuPc_2$. However, perylene and perylene derivatives show a structureless band about 5000 cm^{-1} to the red of the lowest absorption band, which has been associated with excimer or exciplex emission (10, 11). The strong excimer emission in the 650-nm region is observed in crystal, thin solid evaporated films, pellets, and LB layers of perylene derivatives (12). The exciplex formation is well documented in Birks' book (9), and is obtained by dissolving a perylene derivative in certain aromatic solvents such as *N*,*N*-dimethylaniline (DMA). For instance, solution experiments with HPTCDE, HPTCO, and PDCI (*N*-octyl-3,4-perylenedicarboximide) in DMA provided a clear example of exciplex formation with a characteristic broad emission in the 600–700 nm region of the visible spectrum. Azumi and McGlynn (13) have explained the formation of stable excited perylene dimers (excimers) using molecular exciton and charge resonance states, and concluded that a number of excimers could be formed by perylene molecules in a geometrical arrangement where the molecular planes are parallel. It is the strong excimer emission of perylene derivatives in LB monolayers, which is in resonance with the Q-absorption band of the $LuPc_2$ molecule, that was used to monitor the energy transfer between the two LB monolayers. Typical results of steady-state measurements of the excimer fluorescence of an HPTCO LB monolayer of the neat material and separated from one LB of $LuPc_2$ by arachidic acid monolayers are illustrated in Fig. 2. The emitter monolayer was facing the collection optics to avoid the contribution of trivial emission–absorption transfer in the intensity measurements.

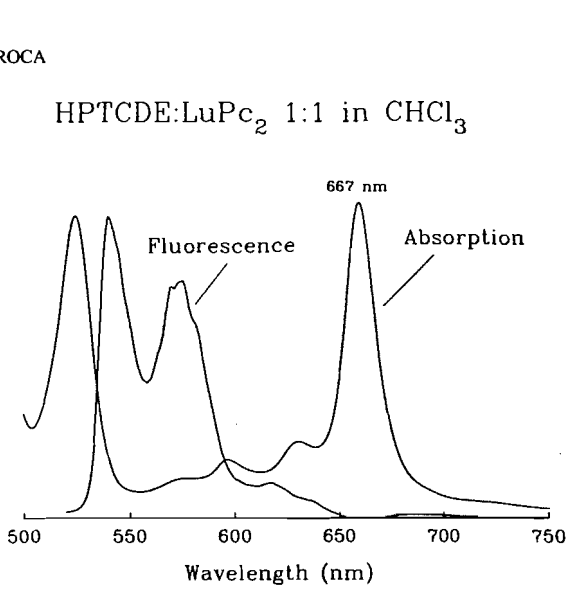

FIG. 1. Absorption spectrum of $LuPc_2$ and fluorescence spectrum of HPTCDE in a 1:1 molar ratio in $CHCl_3$.

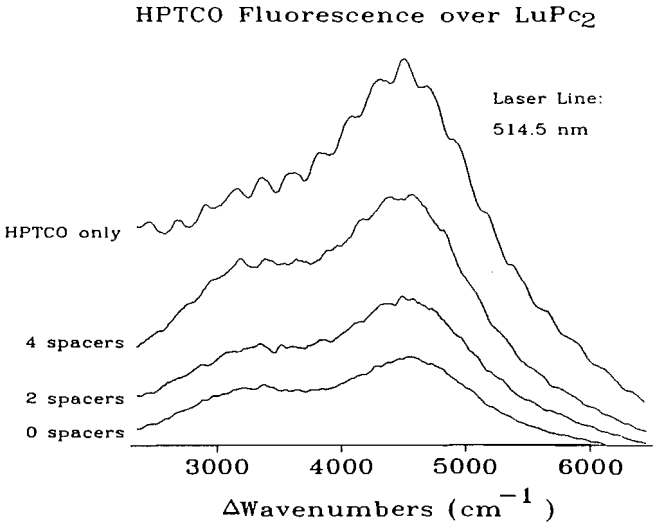

FIG. 2. Fluorescence intensity of the HPTCO excimer emission in a HPTCO/AA/$LuPc_2$ system.

Distance dependence of the energy transfer

The $LuPc_2$ monolayer is the acceptor layer and the perylene derivative forms the donor layer. The physical model in Förster's dipole theory of energy transfer is a donor monolayer of point dipoles interacting with an acceptor layer of dipoles, in a case where the corresponding electronic transitions are allowed. The limitations of the model have been recently discussed by Chang (14). It was found that the Förster dipole approximation for energy transfer would be applicable for donor–acceptor distances large compared to their sizes and when an angular average of the dipolar orientations may be taken. The latter condition implies that the approximation would not be suitable for ordered layers if the rotational relaxation time is greater than the fluorescence lifetime.

The quenching of luminescence of a dipole emitter in the donor layer by absorbing dipoles in the acceptor layer is proportional to the power of the electric field. In Kuhn's model the emitter is an oscillating dipole perpendicular to the donor layer plane located at a distance d from the acceptor layer with dipoles parallel to the layer plane (3). The power of the classical field contains three terms proportional to r^{-2}, r^{-4}, and r^{-6}, which after integration to calculate the power absorbed produces Kuhn's equation for the distance dependence of the energy transfer

$$[1]\quad q/q_d = 1 + (d_0/d)^4 + \eta(d_0/d)^2$$

where q is the quantum yield of the emitter in the absence of the acceptor layer, and q_d is the quantum yield for an acceptor layer at a distance d; d_0 is the critical transfer distance, or distance where the energy transfer and deactivation through other paths are equal. A simplification of eq. [1] is obtained by dropping the quadratic dependence, and the energy transfer decreases as the fourth power of the interlayer separation (5). Application of the latter approximation to the interpretation of experimental data has not always been successful, and Fromherz and Reinbold (15) have found that the dependence of the energy transfer on the distance of the dye layers, for their experiments, was better fit by a cubic power.

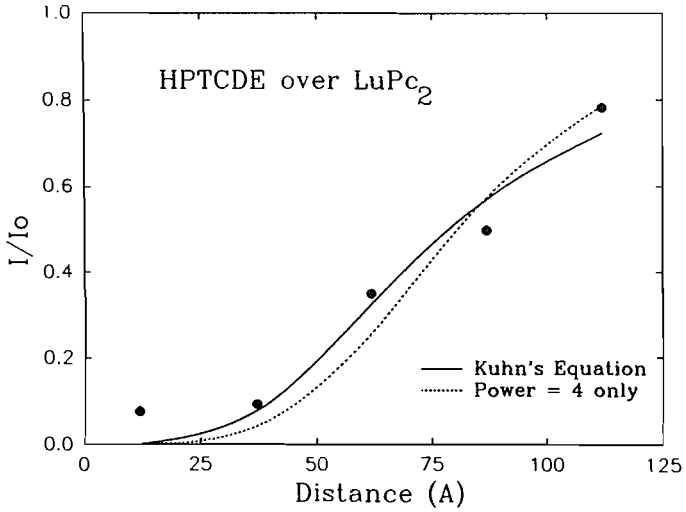

FIG. 3. Fluorescence intensity ratio I/I_0 of the HPTCDE excimer emission as a function of the distance from one LB of neat $LuPc_2$.

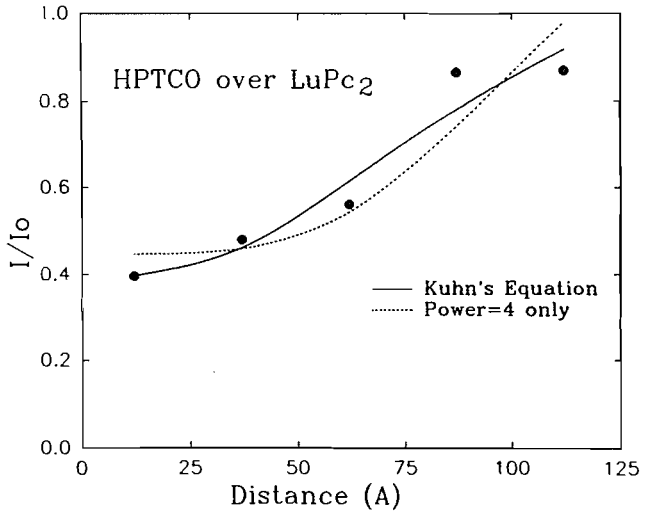

FIG. 4. Fluorescence intensity ratio I/I_0 of the HPTCO excimer emission as a function of the distance from one LB of neat $LuPc_2$.

In general, the information accumulated on ET between LB monolayers seems to indicate: (a) the fourth power term alone (in eq. [1]) may not provide a good fitting of the experimental results, (b) the most significant ET between LB layers (d_0 values) takes place on a scale of 10 nm.

Langmuir–Blodgett monolayer samples for the present study were prepared by Z deposition of the acceptor layer, spacer, and donor monolayer. The thickness of one spacer layer has been reported to be 2.7 nm (16). The results of the ET experiments for HPTCDE/spacer/$LuPc_2$ and HPTCO/spacer/$LuPc_2$ are presented in Figs. 3 and 4 respectively. Equation [1] gave the best fit for the present set of experimental points. The critical distance values obtained are given in Table 1, where the results produced by the fourth power fitting are also included for comparison. The d_0 values given by Kuhn's full equation gave results in agreement with Fromherz and Reinbold (15), who reported d_0 values between 6.2 and 6.4 nm for their monomethine–oxacyanine–monomethine–thiacyanine system. The fourth power approximation seems to overestimate the critical transfer distance. The η coefficient, which depends strongly on molecular orientation, changes considerably for the two molecules, 1 for HPTCDE and 3 for HPTCO. In this respect it would be interesting to carry out experiments with LB monolayers fabricated with well-defined molecular orientations to study the orientational effect on the energy transfer measurements.

Electron transfer versus energy transfer

Dr. R. O. Loutfy of the Xerox Research Centre of Canada was concerned with the extent of electron-transfer contribution to the fluorescence quenching of HPTCDE and HPTCO. To distinguish electron transfer from energy transfer, a number of experiments were carried out. First, solutions with different relative concentrations of HPTCO, HPTCDE, and $LuPc_2$ were prepared. The solution containing $LuPc_2$ mixed with HPTCDE showed no changes in any of the absorption bands of either component. However, at a high relative concentration of HPTCO with $LuPc_2$, a new band at 700 nm appears. This new band has been assigned in the literature to the Q-band of oxidized $LuPc_2$ (17). However, the 700-nm band was not observed for a HPTCO/$LuPc_2$ bilayer assembly or any other LB assemblies used in this study of energy transfer. The latter results would indicate that the electron transfer complex formed between $LuPc_2$ and HPTCO has geometric requirements that are not satisfied by the molecular arrangement in the LB films. The mixed solution of HPTCO/$LuPc_2$ in $CHCl_3$ was unique in forming aggregates that precipitated out of solution. This reaction is limited to the perylene derivatives containing an anhydride group, and was not observed in a series of solutions of perylene dicarboximide derivatives and $LuPc_2$. The absorption spectrum of the solution and that of the precipitate are shown in Fig. 5. In solution the absorptions of the HPTCO and $LuPc_2$ are clearly observed. The Q-band of $LuPc_2$ showed the presence of the 700-nm band, which corresponds to the oxidized form of $LuPc_2$. The spectrum of the precipitate indicated the formation of an aggregate with very broad bands of the phthalocyanine unit and a weak absorption in the spectral region of the HPTCO. The nature of the aggregate is not known. In a second set of experiments, an aliquot of an aqueous solution containing the strong electron acceptor, 1,1′-diheptyl-4,4′-bipyridinium dibromide (HBP) (18) was spread over 1 LB of $LuPc_2$. After the solvent had evaporated, the absorption spectrum of this slide was recorded. Again, no bands corresponding to either the reduced or oxidized form of $LuPc_2$ were observed. In conclusion, there was no evidence of electron transfer for the HPTCDE/$LuPc_2$ system. The HPTCO and $LuPc_2$ formed, in solution, aggregates or a change transfer complex that contains oxidized $LuPc_2$. However, the formation of these aggregates or the oxidation of $LuPc_2$ was not observed in LB bilayers with adjacent LB monolayers of each dye. Furthermore, the quenching of HPTCO for the latter system was less effective than in the HPTCDE/$LuPc_2$ case (see Figs. 3 and 4), ruling out the extra quenching due to electron transfer.

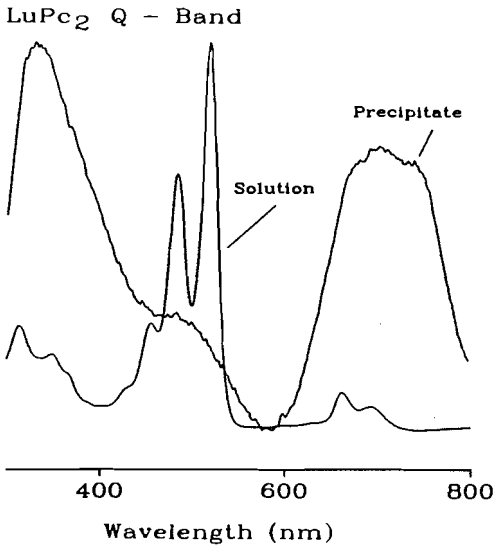

FIG. 5. Absorption spectrum of the HPTCO–LuP_2 mixture in $CHCl_3$, and absorption spectrum of the precipitate obtained from insoluble aggregates.

Conclusion

An important new system of perylene–phthalocyanine dyes has been used for energy transfer studies involving the excimer emission of the perylene derivative. The critical distance observed for energy transfer in the new system indicated that the ET occurs mainly on the 10-nm scale, which is in agreement with previous observations with different dyes. The possibility of electron transfer contributions to the fluorescence quenching was found to be negligible. Further studies of energy transfer between LB monolayers with well-defined molecular orientation could help to clarify the limitations of the equations obtained using the dipole theory.

Polarized and depolarized continuum resonance Raman scattering of molecular iodine: accurate determination of repulsive states

J. STREMPEL AND W. KIEFER

Institut für Physikalische Chemie der Universität Würzburg, Marcusstrasse 9-11, D-8700 Würzburg, Federal Republic of Germany

Received April 18, 1991

This paper is dedicated to Dr. Richard Norman Jones

J. STREMPEL and W. KIEFER. Can. J. Chem. **69**, 1732 (1991).

We have recorded high-resolution polarized and depolarized resonance Raman spectra of molecular iodine with excitation by argon-ion laser lines at 496.5, 488.0, and 476.5 nm up to the seventh, and with 457.9 nm up to the fifth, overtone. These spectra were also calculated numerically applying second-order perturbation theory. In contrast to earlier publications on this subject, special emphasis was put on obtaining highly reliable polarized and depolarized spectra. The variations of the spectral band shapes and depolarization ratios obtained at different excitation wavelengths could be explained by means of the specific contributions of the two excited electronic states $^3\Pi_{0^+u}$ and $^1\Pi_{1u}$. About 60 different experimentally obtained spectra were finally used to derive the positions of the two excited-state potentials involved in this type of light scattering. The derivation was done by comparison of the experimental and theoretically simulated spectra where parameters of the $^1\Pi_{1u}$ as well as of the $^3\Pi_{0^+u}$ state potentials were varied.

Key words: resonance Raman scattering, diatomic molecules, potentials, excited electronic states.

J. STREMPEL et W. KIEFER. Can. J. Chem. **69**, 1732 (1991).

Utilisant une excitation par les raies d'un laser ion-argon (à 496,5, 488,0 et 476,5 nm jusqu'à septième harmonique et par celle à 457,9 nm jusqu'à la cinquième harmonique), on a enregistré les spectres Raman de résonance polarisée et dépolarisée, à haute résolution, de l'iode moléculaire. On a aussi calculé ces spectres d'une façon numérique en appliquant la théorie du deuxième ordre de perturbation. Par opposition aux publications antérieures sur ce sujet pointu, on a mis l'accent sur l'obtention de spectres polarisés et dépolarisés très fiables. On peut expliquer les variations des formes des bandes des spectres et des rapports de dépolarisation avec les longueurs d'onde d'excitation à l'aide de contributions spécifiques des deux états électroniques excités $^3\Pi_{0^+u}$ et $^1\Pi_{1u}$. On a finalement utilisé 60 spectres expérimentaux différents pour évaluer les positions des potentiels des deux états excités impliqués dans ce type de diffusion de la lumière. On a réalisé cette évaluation en comparant les spectres expérimentaux et théoriques qui avaient été simulés en faisant varier les paramètres de $^1\Pi_{1u}$ ainsi que les potentiels de l'état $^3\Pi_{0^+u}$.

Mots clés : diffusion Raman de résonance, molécules diatomiques, potentiels, états électroniques excités.

[Traduit par la rédaction]

Introduction

Since the first observation of the resonance Raman effect in halogen gases (1) at the National Research Council in Ottawa, Canada, the molecules bromine and iodine have been extensively examined experimentally. Kiefer and Bernstein (2) measured the Raman spectra of iodine excited in the resonant region with high resolution and explained the various features of the fundamental and overtone bands by means of Fortrat parabolas and the thermal distribution of the states as S-, Q-, and O-branches. Theoretical calculations were performed in order to simulate the spectra (3–8). In the case of bromine, Baierl and Kiefer (6–8) showed that two excited electronic states, the repulsive $^1\Pi_{1u}$ and the bound $^3\Pi_{0^+u}$ state, have to be taken into account in order to calculate the spectra. The influence of these two states appears in very specific band shapes and depolarization ratios of the fundamental Q-branch for excitation with different laser frequencies. In the case of iodine, Williams and Rousseau (3) measured and calculated depolarized spectra with 488.0, 476.5, and 457.9 nm lines and $\Delta v = 3$ and $\Delta v = 8$ but neglected the contribution of discrete levels of the $^3\Pi_{0^+u}$ and the contribution of the $^1\Pi_{1u}$ state. No spectra were calculated for excitation with 496.5 nm where the intermediate Raman level is just above the dissociation limit of the $^3\Pi_{0^+u}$ state. In a further investigation Williams *et al.* (5) included, in their calculations of the $\Delta v = 3$ and 8 Raman transitions, the $^1\Pi_{1u}$ state as well as the discrete $^3\Pi_{0^+u}$ levels and measured polarized and depolarized spectra. With the new experimental data they optimized the potential position but they had difficulty in simulating the spectra excited with 496.5 nm. Furthermore the $^3\Pi_{0^+u}$ potential was held at a fixed position.

In this paper we report for the first time polarized and depolarized spectra with all vibrational transitions from $\Delta v = 1$–8 excited with the laser lines 496.5, 488.0, and 476.5 nm and with $\Delta v = 1$–6 excited with 457.9 nm. The theoretical calculations consider both the $^1\Pi_{1u}$ state as well as the continuous and discrete vibrational levels of the $^3\Pi_{0^+u}$ state. Both potentials have been varied in order to achieve a good agreement with all experimental spectra. The huge amount of experimental data allowed us to derive what we think to be very accurate data for the excited state potentials.

Theoretical calculation of continuum resonance Raman band intensities

Because the theory employed in this paper has been described earlier in detail (6, 8), only a short summary with the essential ideas is presented here.

The standard expression for the scattering intensity of a space-fixed scattering arrangement is given by

$$[1] \quad I_{\rho z}^{if} \propto \omega_f^4 N_i g_i |(\alpha_{\rho z})_{if}|^2$$

where i and f designate the initial and final states, respectively, and ρ the direction of polarization x or z of the scattered light. The incident light is chosen to be linearly polarized in the z-direction. ω_f is the frequency of scattered light. The population

of initial states N_i is calculated with the assumption of thermal equilibrium in the scattering region. The intensity dependence from the nuclear spin quantum number is expressed by the nuclear spin factor g_i.

$(\alpha_{\rho z})$ is the polarizability tensor, which can be calculated using second-order perturbation theory (Kramers–Heisenberg–Dirac relation) and the dipole approximation. In the case of resonance excitation one obtains

$$[2] \quad (\alpha_{\rho z})_{if} = \sum\!\!\!\!\!\!\int_r \frac{\langle f|\mu_\rho|r\rangle\langle r|\mu_z|i\rangle}{\hbar\omega_{ri} - \hbar\omega_0}$$

with the dipole operators μ_ρ, the incident energy $\hbar\omega_0$, and the energy difference $\hbar\omega_{ri}$ between the initial state i and the unperturbed eigenstates r. The sum sign stands for summation over discrete states and the integral sign for the integration over continuous levels. In the integral the density of states factor is omitted for clarity. The damping factor that would appear in the denominator of eq. [2] has been set to zero according to ref. 4.

The state of a diatomic molecule is characterized by the quantum numbers e (electronic), v (vibronic), J (total angular momentum), k (projection of J on the molecular axis), and m (magnetic). Because no external field is applied one has in addition to sum over the degenerate quantum numbers m_i and m_f.

The polarizability tensor is transformed into spherical space-fixed coordinates. This space-fixed frame is changed into a molecular-fixed frame by using the formula of rotation matrices. Now the rotational part is separated from the matrix elements. The matrix elements are calculated in the molecular rest frame by transforming the coordinate system to a molecular fixed cartesian one.

The Raman transitions occur between the rovibronic levels of the ground state $^1\Sigma_g^+$ ($e_f = e_i = 0$, $k_f = k_i = 0$) via excited electronic states and therefore one obtains for the polarizability tensor (without the rotational part):

$$[3] \quad (\bar{\alpha}_{\bar{\rho}\bar{z}})_{if} = \sum_{e,k} \sum\!\!\!\!\!\!\int_{v_r^e} \frac{\langle 0 v_f 0|\bar{\mu}_{\bar{\rho}}|e\, v_r^e\, k\rangle\langle e\, v_r^e\, k|\bar{\mu}_{\bar{z}}|0 v_i 0\rangle}{\hbar\omega_{ri} - \hbar\omega_0}$$

The overlined quantities are expressed in the molecular rest frame. The sum and (or) integration must be taken over the two upper excited electronic states $^3\Pi_{0^+u}$ (abbreviated as B) and $^1\Pi_{1u}$ (abbreviated as Π) with all their involved discrete and continuous vibronic levels and the possible orientations of the total angular momentum k. For the $^3\Pi_{0^+u}$ state there is only one orientation of J ($k = 0$) but the $^1\Pi_{1u}$ state is double degenerate with respect to k ($k = \pm 1$).

By applying the Born–Oppenheimer approximation one obtains for a single matrix element

$$[4] \quad \langle e'v'k'|\bar{\mu}_\xi|e\,v\,k\rangle \approx \langle e'k'|\bar{\mu}_\xi|ek\rangle\langle v'|v\rangle$$

Using only the first term of the Herzberg–Teller expansion, the electronic matrix element is calculated with the electronic wave functions at equilibrium distance of the nuclei and treated as a constant factor:

$$[5] \quad \langle e'k'|\bar{\mu}_\xi|ek\rangle \approx \langle e_0'k'|\bar{\mu}_\xi|e_0k\rangle = M_{e'e}$$

This approximation causes only a small error in the resulting Raman intensities because the change in the value of the electronic transition moment M_{B-X} for a fixed incident wavelength is only about 2% between the $v_i = 0$ and $v_i = 19$ states with respect to the value for the $v_i = 9$ state using the linear function given by Tellinghuisen (9)

$$[6] \quad M_{B-X}(\bar{R}) = 0.884\bar{R} + 1.388$$

With $\bar{R}$ as the R centroid. The units of M_{B-X} are debye (D) and $\bar{R}$ is in angstrom (Å). Because only the relative intensity ratios of the various bands within the Raman transitions belonging to the same Δv will be taken into account, and not the intensity ratios between the Raman bands excited with different wavelengths (where in fact the variation of M_{B-X} with the incident energy is remarkable), the error in neglecting the energy dependence of M_{B-X} is small compared to the error introduced through the uncertainty in determining the spectroscopic temperature.

Additionally, Tellinghuisen (9, 10) has assumed the electronic transition moment between the states $^1\Pi_{1u}$ and $^1\Sigma_g^+$ to be constant, which leads to correct theoretical results within experimental error in calculating the absorption coefficient. However, it has been mentioned (9) that this assumption is not absolutely correct. Since the contribution of the $^1\Pi_{1u}$–$^1\Sigma_g^+$ transition to the absorption coefficient in the region above 21 000 cm^{-1} is even greater than that of the $^3\Pi_{0^+u}$–$^1\Sigma_g^+$ transition, the error in treating M_{B-X} as a constant is even smaller and therefore negligible in our case. In addition it should be mentioned that the degeneracy of the $^1\Pi_{1u}$ state is contained in the rotational part and not involved in the electronic transition moment.

The selection rule of J for a single dipole transition is $\Delta J = \pm 1$. This results in a total selection rule $\Delta J = 0, \pm 2$ and gives rise to three different branches, which are designated by O ($\Delta J = -2$), Q ($\Delta J = 0$), and S ($\Delta J = +2$).

The polarizability tensor can now be written as

$$[7] \quad (\alpha_{\rho z})_{if} = \sum_{e=B,\Pi} M_e^2 D_e(J_i, \Delta J, \rho) \underbrace{\sum\!\!\!\!\!\!\int_{v_r^e} \frac{\langle v_f|v_r^e\rangle\langle v_r^e|v_i\rangle}{\hbar\omega_{ri} - \hbar\omega_0}}_{=:\ \chi_e^{v_f v_i}}$$

The factors M_e represent the electronic matrix elements between the ground state $^1\Sigma_g^+$ and the two excited electronic states $^3\Pi_{0^+u}$ and $^1\Pi_{1u}$. The factors $D_e(J_i, \Delta J, \rho)$ contain the change between the different coordinate systems. The second sum and integral is abbreviated by $\chi_e^{v_f v_i}$. It has the meaning of a scattering amplitude and is a complex function since the integral has to be calculated over the singularity at $\omega_{ri} = \omega_0$ (4).

After summation over the magnetic quantum numbers m_i and m_f, the intensity of a Raman transition between rovibronic levels of the ground state is now given by:

$$[8] \quad I_{\rho z}^{if} \propto \omega_f^4 g_i N_i \{ M_B^4 R_B(J_i, \Delta J, \rho)|\chi_B^{v_f v_i}|^2 + M_\Pi^4 R_\Pi(J_i, \Delta J, \rho)|\chi_\Pi^{v_f v_i}|^2 + 2M_B^2 M_\Pi^2 R_{B+\Pi}(J_i, \Delta J, \rho)|\chi_B^{v_f v_i}\chi_\Pi^{v_f v_i}| \}$$

where R_B, R_Π, and $R_{R+\Pi}$ are the rotational factors for the states B and Π and for the interference term, respectively, after summation over m_i and m_f.

Equation [8] clearly shows that the intensity of a rovibronic transition is composed of the contributions of the two excited states as well as an interference term. Each term involves an

electronic, a rotational, and a vibrational part. In the electronic part the ratio $\mathcal{R} = \frac{M_\Pi^2}{M_B^2}$ determines the relative electronic contribution of the two excited states. Because it is only possible to determine the ratio $\mathcal{R}$ and not the single electronic transition moments M_Π and M_B, we have set M_B^2 to unity. For the two directions of polarization, the three rotational branches, and the three intensity terms given in eq. [8] one has to calculate 18 algebraic rotational factors (6). The complex functions $\chi_e^{v_f v_i}$ are calculated numerically by iteration of the wavefunctions and integration of the product of the wavefunctions. The integral over the singularity is calculated using Cauchy's law of integration.

In the low energy region the $^1\Sigma_g^+$ ground state is known with satisfactory accuracy and corresponding data were therefore taken from the literature (11, 12). The RKR values of the $^1\Sigma_g^+$ ground state potential have been taken from Coxon (11). Between these values the ground state potential has been interpolated with cubic splines. The spectroscopic parameters have been taken from Barrow and Yee (12). From these data the line positions of the rovibronic transitions are calculated using the standard expression

$$[9]\quad \frac{E_{evJ}}{hc} = \omega_e\left(v+\frac{1}{2}\right) - \omega_e x_e\left(v+\frac{1}{2}\right)^2 + \omega_e y_e\left(v+\frac{1}{2}\right)^3 + \ldots + \left(B_e - \alpha_e\left(v+\frac{1}{2}\right)\right)(J+1)J + \ldots$$

where ω_e, $\omega_e x_e$, and $\omega_e y_e$ are the vibrational constants, B_e the rotational constant, and α_e the coupling coefficient. Higher order expressions can be neglected because the spectral resolution is only about 1 cm^{-1}.

In the experiment the absorption of the molecules leads to a high temperature in the laser focus, with the consequence that many rovibronic levels are populated. Therefore in a numerical calculation one has to consider a high number of rotational and vibrational occupied levels. We have used 400 rotational and 20 vibrational levels of the ground state. For three rotational branches a Raman band then consists of 24 000 rovibronic transitions. The δ-like intensities are folded with an appropriate gaussian function in order to simulate the restricted spectral conditions (resolving power of the spectrometer). The proportionality factor is used to scale the calculated intensity to the experimental data.

The specific appearance of a Raman band is determined, first, by the exact position of the electronic potential curves of the contributing states via the Franck–Condon factors and, second, parametrically by the rotational intensity factors, which depend only on the symmetry of the involved states and the ratio of the square of the two electronic transition moments.

The depolarization ratio ρ of a Raman signal is defined as the ratio between the depolarized and polarized intensity, I_{xz} and I_{zz}, respectively:

$$[10]\quad \rho = \frac{I_{xz}}{I_{zz}}$$

The depolarization ratio of O- and S-bands is 0.75 and depends neither on the excitation wavelengths nor on the different electronic transitions. Q-branches are polarized ($\rho < 0.75$) and the exact value depends on the square of the electronic transition moments as well as on the Franck–Condon factors of the different transitions (8). The depolarization of overlapping S- and Q-bands can be used to determine the ratio $\mathcal{R}$ although the Q-branches are not resolved. The latter lower the depolarization ratio of the combined band, depending upon their relative contributions.

Experimental

The continuum resonance Raman spectra of iodine were excited with an argon-ion laser (Spectra Physics, model 171). No foreign gas was added in the iodine cell. To achieve approximately the same spectroscopic temperature for different excitation wavelengths, the laser output power was set to 1 W for each of the laser lines used. The spectra were recorded with a Spex model 1403 double monochromator using a photon counting system. The polarized and depolarized Raman spectra were obtained simultaneously, applying the two-channel technique developed by Kiefer and Topp (13). The correct adjustment of the system with respect to polarization was checked first, by recording the polarized 459 cm^{-1} and depolarized 214 cm^{-1} and 318 cm^{-1} lines of liquid carbon tetrachloride.

The spectral resolution was chosen to about 0.3 cm^{-1} for the fundamental bands, and 1.0 cm^{-1} for lower, and 1.5 cm^{-1} for higher overtones.

The iodine cell was heated just above the melting point of iodine (≈387 K). This results in a vapor pressure of about 120 hPa. Kiefer and Bernstein (2) determined the spectroscopic temperature under similar conditions by the Stokes/Anti-Stokes ratio of the fundamental band and found a value of 1150 K. This method is acceptable for the case of iodine because the Franck–Condon factors vary only slightly between the Stokes and Anti-Stokes bands. Methods described elsewhere (3, 14) do not measure the rovibronic temperature directly. The relatively high spectroscopic temperature in the iodine cell in comparison to the temperatures reported elsewhere (3, 5) is due to the fact that no N_2 was added. Therefore no cooling effect due to collisions with the cold foreign gas N_2 occurs.

The influence of different spectroscopic temperatures on the band shape of an overtone (e.g., $\Delta v = 3$) can be seen in Fig. 1, where sharp S-band heads occur. In the calculated spectrum B a temperature of 1000 K was used and the S-band heads are sharp and high. With a temperature of 650 K (spectrum C), as reported by Williams and Rousseau (3), the calculated S-band heads are lower compared to spectrum B. The bands have an appearance similar to the data reported in ref. 3. This behaviour is due to the fact that at low temperatures the maximum of the Maxwell–Boltzmann distribution is far away from the maximum of the Fortrat parabola (2) and therefore only weak S-band heads are formed. There is no strong effect of the temperature on the intensity distribution for the various bands. Therefore all other spectra have been calculated with a temperature of 1000 K.

Results and discussion

Contribution from discrete levels of the $^3\Pi_{0^+u}$ state

The sum over states in eq. [7] contains the sum over the discrete levels of the $^3\Pi_{0^+u}$ state as well as the integrals over the continuum of the $^3\Pi_{0^+u}$ and $^1\Pi_{1u}$ states. The sum over states is weighted with the energy difference between incident energy and the energy difference between the initial and intermediate states. The discrete sum therefore makes a significant contribution to the scattering intensity only if the laser energy is very close to the dissociation limit of the $^3\Pi_{0^+u}$ state. In the case of the 496.5-nm excitation the laser energy added to the lowest initial ($v = 0$, $J = 0$) level of the ground state reaches the continuum of the $^3\Pi_{0^+u}$ state about 92 cm^{-1} above the dissociation limit. Therefore a non-negligible contribution of the discrete states to the scattering intensity has to be taken into account in the calculated spectra.

As an example of how the discrete levels contribute to the intensity of the $\Delta v = 1$ band excited with the 496.5-nm argon-

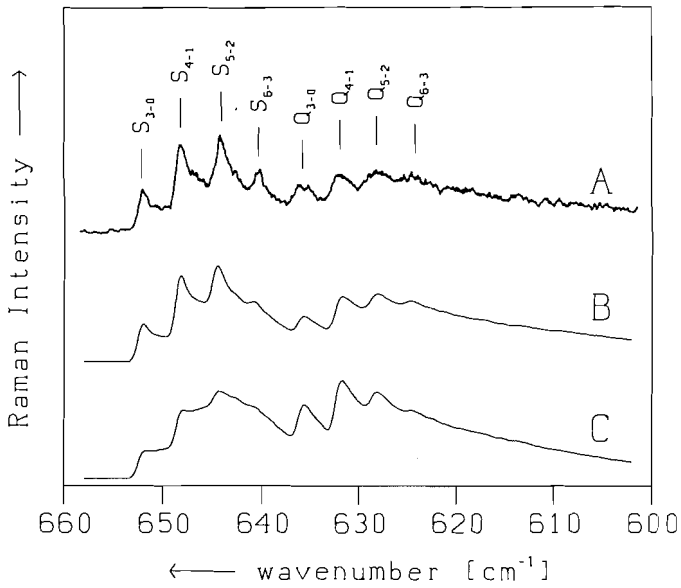

FIG. 1. Depolarized (I_{xz}) continuum resonance Raman spectrum of the second overtone region in iodine with excitation at $\lambda = 488.0$ nm. A: experimental; B: calculated using $T = 1000$ K; C: calculated using $T = 650$ K.

ion laser line, we show this band in Fig. 2 together with calculations in which the contributions of the discrete levels have been included (spectrum B) and excluded (spectrum C). The contribution of the discrete levels is significant only for the Q_{1-0}-band because here the energy dominators in the sum over the discrete levels are low enough. In this case the Q_{1-0}-band is decreased because the sign of the interference term is negative and the additional contribution from the discrete levels therefore lowers the overall intensity. The hot bands have a larger energy difference than the discrete levels and are therefore not influenced by these levels. For all spectra excited with higher energy the contribution of the discrete $^3\Pi_{0^+u}$ levels is very low and essentially can be neglected in the calculated spectra.

Contribution from the $^1\Pi_{1u}$ state

In most previous work (3, 7) the $^1\Pi_{1u}$ state was not taken into account because its square of the electronic transition moment is small relative to that for $^3\Pi_{0^+u}$ state. To achieve a better agreement between simulated and experimental spectra we also included the contribution from the repulsive $^1\Pi_{1u}$ state.

In Fig. 3 we clearly demonstrate this contribution for the case of $\Delta v = 8$ transitions excited with 496.5 nm. Including the $^1\Pi_{1u}$ state in the calculation, we observe a notable decrease of all Q-branch intensities and an increase of the S_{8-0} band intensity. This is a nice example of the interference being effected by the mixed term in eq. [8]. The interferences for the Q- and S-branches are in opposite directions because the rotational intensity factors in the interference term for I_{zz} have different signs for each branch while all other terms have the same signs.

In Fig. 4 (experiment) and Figs. 5 and 6 (theory) an example of nearly complete overlapping bands is shown. Here the S-band heads with $v_f \leftarrow v_i$ transitions overlap in frequency with $(v_f - 1) \leftarrow (v_i - 1)$ transitions of the Q-branches. Spectrum A of Fig. 4 was obtained for parallel laser and observation polarization (I_{zz}) whereas spectrum B represents I_{xz} where laser and observation polarization are perpendicular. Spectrum C is a direct recording (13) of the isotropically scattered Raman light

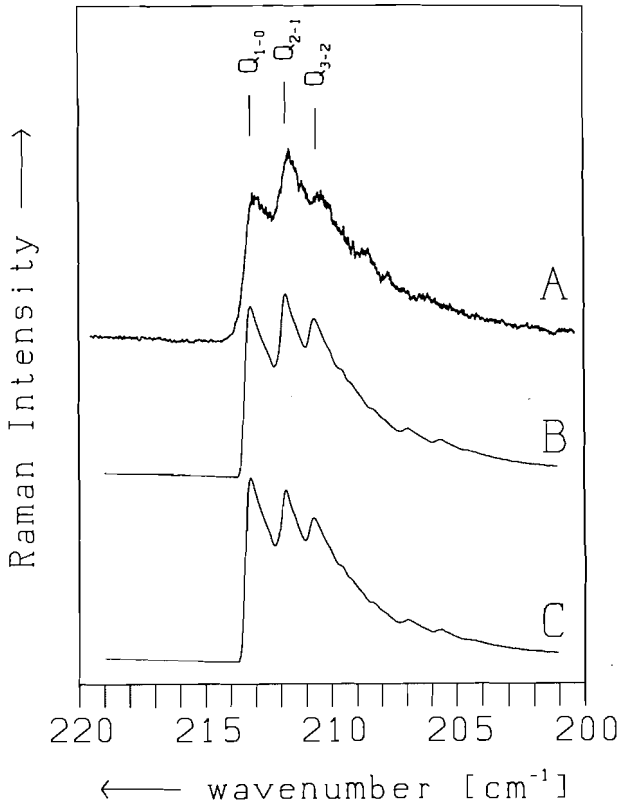

FIG. 2. Contributions from discrete levels of the $^3\Pi_{0^+u}$ state to the scattering intensity with excitation wavelength 496.5 nm demonstrated for the $\Delta v = 1$ transition in iodine. A: experimental spectrum (I_{zz}); B: calculated spectrum (I_{zz}) including the contributions from the discrete levels; C: same as B, but excluding the contributions from the discrete levels.

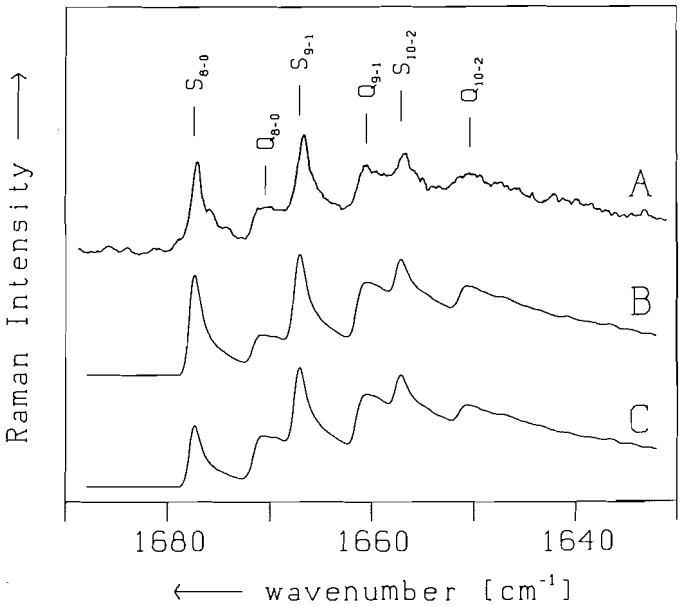

FIG. 3. Contributions from the $^1\Pi_{1u}$ state to the scattering intensity demonstrated for the $\Delta v = 8$, I_{zz} transitions in iodine excited with 496.5 nm. A: experimental spectrum (I_{zz}); B: calculated spectrum including the contribution of the $^1\Pi_{1u}$ state; C: same as B, but excluding the contribution of the $^1\Pi_{1u}$ state.

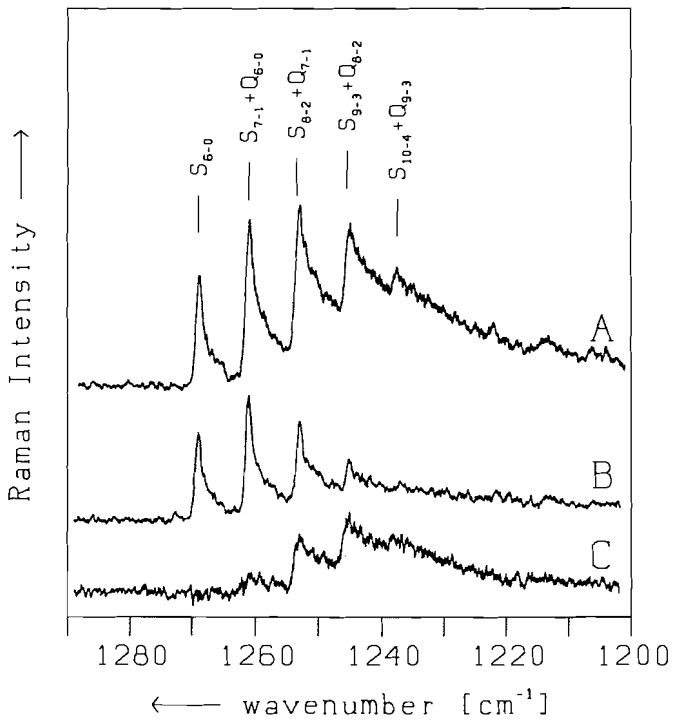

FIG. 4. Experimentally obtained continuum resonance Raman spectrum of the fifth overtone ($\Delta v = 6$) of iodine for 488.0-nm excitation. A: I_{zz}; B: I_{xz}; C: $I_{zz} - \frac{4}{3}I_{xz}$.

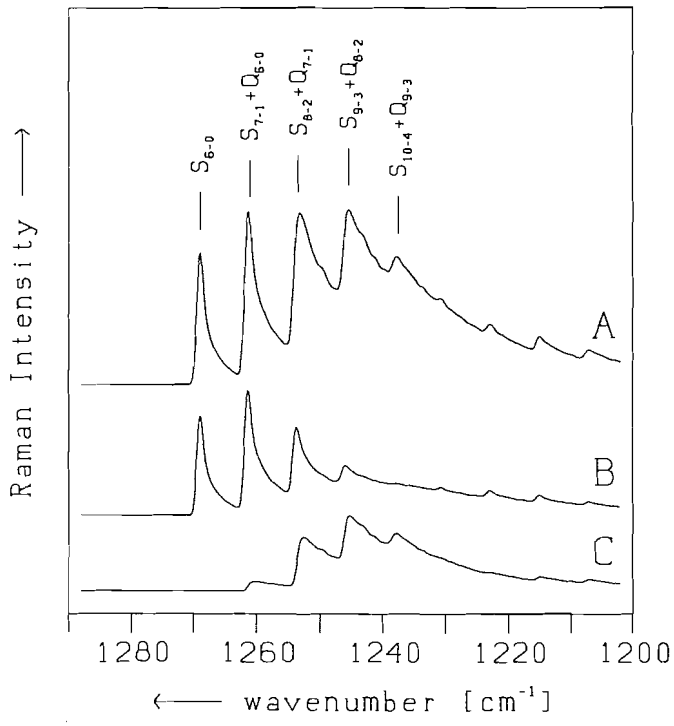

FIG. 5. Calculated continuum resonance Raman spectrum of the fifth overtone ($\Delta v = 6$) of iodine for 488.0-nm excitation. Contribution from the $^1\Pi_{1u}$ state are included. A: I_{zz}; B: I_{xz}; C: $I_{zz} - \frac{4}{3}I_{xz}$.

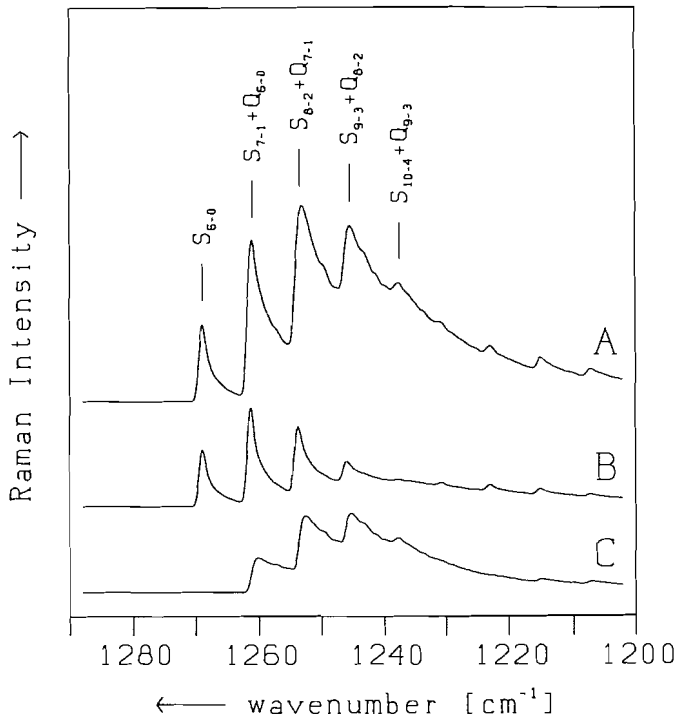

FIG. 6. Same as Fig. 5 but with exclusion of the $^1\Pi_{1u}$ state contributions.

($I_{zz} - \frac{4}{3}I_{xz}$). Spectrum C therefore contains only Q-branch scattering, while spectrum B shows the whole depolarized band intensity. The calculations including and excluding the $^1\Pi_{1u}$ state contribution, Figs. 5 and 6, respectively, reveal that the $^1\Pi_{1u}$ state cannot be neglected. Compare for instance the calculated S_{6-0} transition with the experiment: inclusion of the repulsive state reproduces the experimentally observed intensity much better. The same holds for the Q-bands. This fine comparison could only be made because of the experimental possibility of scanning directly the isotropically pure scattering, i.e., the Q-branches.

The influence of the $^1\Pi_{1u}$ state can be seen at overlapping Q- and S-bands by determining the depolarization ratios of the different bands, because the rotational intensity factors of the Q-branches and the scattering amplitudes for transitions via the two electronic states are different for the two states and the interference term. In Table 1 the calculated depolarization ratios for 488.0-nm excitation for the $\Delta v = 6$ transition with and without inclusion of the $^1\Pi_{1u}$ state for the $6 \leftarrow 0$ transition and various hot bands are compared with experimental data. The experimental values have an accuracy of about 10%. It is obvious that the $^1\Pi_{1u}$ state has a remarkable influence on the depolarization ratio although this is not clearly visible from the relative peak intensities. Again the $^1\Pi_{1u}$ contribution via the Q-branches is destructive and enhances the depolarization ratio because the depolarization ratios for the $^1\Pi_{1u}$ and interference terms alone are lower than for the single $^3\Pi_{0^+u}$ term.

We have found for the ratio $\mathcal{R}$ defined above a value of 0.16 with an uncertainty of about 25%, which has been estimated in the following way: first, the Raman spectra were calculated using temperatures associated with the maximum and minimum temperatures within the error limit. These spectra were compared to the observed ones. In a second calculation, which has been performed for $T = 1000$ K, we varied the ratio $\mathcal{R}$.

TABLE 1. Calculated and observed depolarization ratios for $\Delta v = 6$ transitions in iodine for 488.0-nm excitation

	S_{6-0}	$S_{7-1} + Q_{6-0}$	$S_{8-2} + Q_{7-1}$	$S_{9-3} + Q_{8-2}$
Experiment	0.75	0.73	0.53	0.36
Calculated including $^1\Pi_{1u}$	0.75	0.71	0.51	0.29
Calculated excluding $^1\Pi_{1u}$	0.75	0.61	0.40	0.26

For the extreme values of $\mathcal{R}$ we took the ones that led to a similar deviation from the observed spectra as was the case for the calculated spectra with the extreme values of temperature.

The values of $\mathcal{R} = 0.19$ and 0.20 as given by Tellinghuisen in refs. 9 and 10, respectively (which were derived for 470 nm), as well as the value (0.18) reported by Brith *et al.* (15) are within this error limit. The value 5.0 as reported by Williams *et al.* (5) is probably due to a printing mistake in the definition of $\mathcal{R}$. The reciprocal would be 0.2 and this value would be in good agreement with the others mentioned.

Sensitivity to position of excited state potentials

The spectral feature in continuum resonance Raman scattering is very sensitive to the relative position between ground and excited states. The ground state position was determined by Coxon (11) using the Rydberg–Klein–Rees (RKR) method. The accuracy of turning points for the $^1\Sigma_g^+$ state in the range of interest of low ($v < 40$) vibrational levels is below 2×10^{-14} m. The ground state potential was not varied because its position is very well known and therefore the error is much lower than that of the excited states. The potential in the bound region of the $^3\Pi_{0^+u}$ state was calculated by Barrow and Yee using the same method (12). In our case the important turning points are those near the dissociation limit and here the method is less accurate. The accuracy of turning points in this region has been estimated to be $\pm 2 \times 10^{-13}$ m (9). In a more recent analysis Gerstenkorn *et al.* (16) have given new values for the eigenenergies and turning points, which differ about 0.08 cm^{-1} and 5×10^{-14} m, respectively, from the values given in ref. 12 for high values of v. These new values are within the estimated error limit of the previous values.

The repulsive part of the $^3\Pi_{0^+u}$ state and the potential for the pure repulsive $^1\Pi_{1u}$ state have been determined from absorption data by Child and Bernstein (17) applying an exponential form. In the continuous region between 20 000 and 22 000 cm^{-1} both the $^3\Pi_{0^+u}$ and $^1\Pi_{1u}$ states show continuous absorption bands and the determination of potential functions is less accurate than in bound regions.

In this paper the repulsive parts of the potentials are calculated using an exponential function of the form

$$[11] \quad V(R) = V_e + Ce^{-\gamma(R-r_e)}$$

A set of parameters given by Child and Bernstein (17) was used as a first approximation. The final set of parameters was achieved by alternate variation of the single parameters and comparison of the resultant calculated spectra with the experimental data.

To demonstrate how the position of the excited potentials influences the intensities of the various bands in the continuum resonance Raman spectra, we demonstrate in Figs. 7–9 various calculations and compare them to the observed ones. Excellent agreement between calculation (spectra B) and experiment

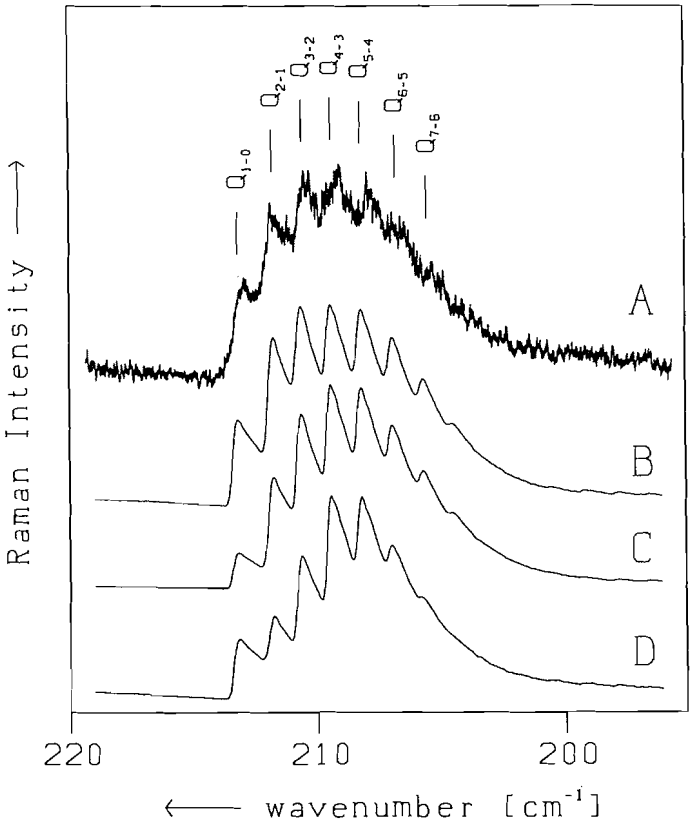

FIG. 7. Observed (A) and calculated (B–D) continuum resonance Raman spectra (I_{zz}) of the fundamental region ($\Delta v = 1$) of iodine for 457.9-nm excitation. B: calculated with optimized parameter using an exponential form given in eq. [11]; C: same as B, except that the $^3\Pi_{0^+u}$ and $^1\Pi_{1u}$ potentials have been shifted by -4×10^{-13} m and -3.25×10^{-12} m, respectively; D: same as B, except that the $^3\Pi_{0^+u}$ and $^1\Pi_{1u}$ potentials have been shifted by $+5 \times 10^{-13}$ m and $+2.75 \times 10^{-12}$ m, respectively.

(spectra A) has been obtained for the fundamental and all observed overtones for one set of parameters. Besides the fundamental vibrational region (Fig. 7), we show as additional examples the first ($\Delta v = 2$) and third ($\Delta v = 4$) overtones (Figs. 8 and 9, respectively). The set of parameters that led to the best agreement between experiment and theory is listed in Table 2. It was obtained by a combined variation of the parameters.

In Figs. 7–9 we show in addition calculated spectra C and D, where the excited-state potentials have been shifted by a small amount to either smaller (spectra C) or larger (spectra D) nuclear distances. For exact values see the caption for Fig. 7. Again these small shifts demonstrate the high sensitivity of continuum resonance Raman band shapes to the position of excited-state potentials.

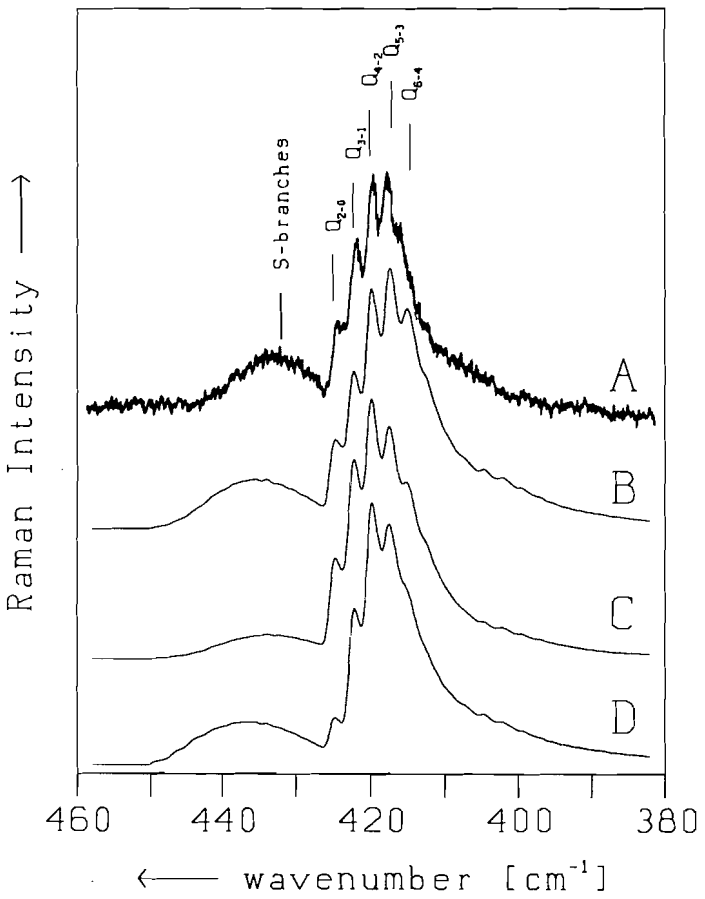

FIG. 8. Same as Fig. 7, except for $\Delta v = 2$ and excitation wavelength 476.5 nm.

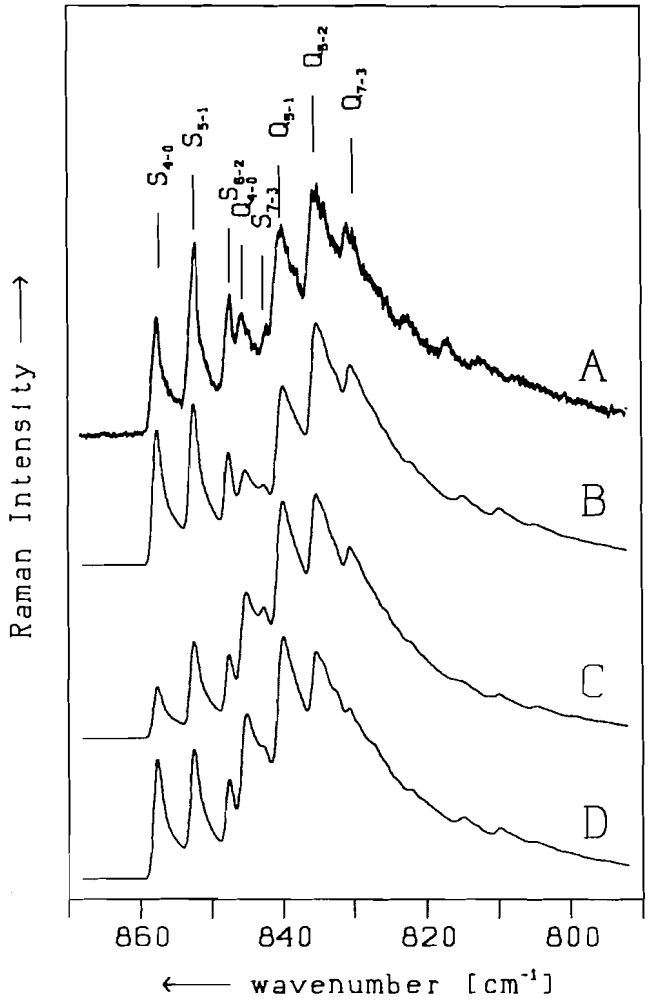

FIG. 9. Same as Fig. 7, except for $\Delta v = 4$ and excitation wavelength 488.0 nm.

Finally, we want to compare our potential curves with those obtained by means of other methods. The deviation of our $^1\Pi_{1u}$ potential curve at about 22 000 cm^{-1} from the curve obtained by Chapman and Bunker (18) by means of predissociation measurements is -2.4×10^{-12} m. The deviation in the same region of the $^1\Pi_{1u}$ potential curve given by Tellinghuisen (9) (obtained from absorption measurements) is -3.2×10^{-12} m. If we continue the pure repulsive $^3\Pi_{0^+u}$ potential curve into the bound region, it turns out that near the dissociation limit the repulsive turning points given by Barrow and Yee (12) as well as those from Gerstenkorn *et al.* (16) differ by about -2.3×10^{-12} m from the extrapolated repulsive values. To attach the bound potential curve to the repulsive part without discontinuity, we shifted the turning points of the bound part by this amount. The inaccuracy to the Raman band shapes involved in this procedure is not critical because the contribution of the bound states is significant but rather low only with the excitation wavelength 496.5 nm and can be neglected for higher incident energies. The reason for the different results obtained with absorption, predissociation, and continuum resonance Raman measurements is that in each method important simplifications, e.g., truncating of even low Herzberg–Teller terms, still have to be used in order to derive the potential data within acceptable computation time. Therefore one would expect some differences between the different methods. If one takes a look at the calculated absorption spectra in Fig. 2 of ref. 9, which were computed using two different sets of parameters having the same order of deviations as those mentioned above, one remarks that both absorption curves do not differ much more than the given experimental uncertainty. For this reason we conclude that the method of deriving potential data via the calculation of continuum resonance Raman band shapes serves as an additional approach with a similar accuracy to the conventional methods.

TABLE 2. Parameters for the excited states $^3\Pi_{0^+u}$ and $^1\Pi_{1u}$ of iodine as derived from the comparison of simulated to experimentally observed continuum resonance Raman spectra

State	M_e^2/M_B^2	C/cm^{-1}	γ/nm^{-1}	r_e/nm	V_e/cm^{-1}
$^1\Pi_{1u}$	0.16	7470	34.4	0.26825	12547.2
$^3\Pi_{0^+u}$	1.00	3340	63.5	0.26655	15769.1

Because our calculations refer only to the pure repulsive branches of the potential curves, we want to emphasize that the values given in this work are valid only above the dissociation limit of the $^3\Pi_{0^+u}$ state, that is, in the region of pure continuous absorption bands.

Conclusion

In this paper we have shown that continuum resonance Raman spectroscopy delivers a huge amount of spectroscopic data in the form of vibrational–rotational bands (fundamental,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

hot bands, overtones) that can be excited with various lines of ion lasers. The simulation of these bands using time-independent (perturbation) theory as applied in this paper or applying time-dependent theory (19, 20) allows the determination of positions of repulsive potentials or repulsive parts of bound states. To demonstrate the accuracy inherent in this method we have measured many polarized and depolarized continuum resonance Raman spectra in iodine. It turned out that the experimental method, where the isotropically scattered Raman light can be directly recorded (13), was of great help for this purpose. To improve the values of the potential curves it would be useful to undertake a sophisticated comparison between the calculations of continuous absorption coefficients and continuum resonance Raman spectra. Similar work on other (isotopically pure) halogen and interhalogen molecules is presently in progress in our laboratory.

Solubility of domoic acid in water and in non-aqueous solvents[1]

MICHAEL FALK, PING F. SETO, AND JOHN A. WALTER

Institute for Marine Biosciences, National Research Council of Canada, 1411 Oxford Street, Halifax, N.S., Canada B3H 3Z1

Received June 24, 1991

This paper is dedicated to Dr. Richard Norman Jones

MICHAEL FALK, PING F. SETO, and JOHN A. WALTER. Can. J. Chem. **69**, 1740 (1991).

The solubility of domoic acid (DA) in H_2O and D_2O, in aqueous NaCl solution and in several non-aqueous solvents was measured by NMR and UV spectroscopies. The solubility in water is comparable with that of aminoacids such as glutamic acid and aspartic acid. It is markedly pH-dependent, passing through a minimum at the isoelectric point, the increase towards both higher and lower pH values indicating that the anionic and cationic forms are more soluble than the neutral form. The effect of NaCl on the solubility of DA in water is negligible. The solubility of DA in alcohols is lower than in water but it is much higher than the solubility of glutamic acid or aspartic acid. The octanol–water partition coefficient for DA at pH 5.32, $K_{ow} = 0.0037$, was obtained by a direct UV measurement. The low value of K_{ow} indicates that aquatic organisms cannot take up DA directly from the water and bioaccumulation may proceed only through dietary intake.

Key words: solubility of domoic acid, NMR of domoic acid, UV spectra of domoic acid, octanol–water partition coefficient of domoic acid.

MICHAEL FALK, PING F. SETO et JOHN A. WALTER. Can. J. Chem. **69**, 1740 (1991).

On a determiné la solubilité de l'acide domoïque (AD) dans H_2O et D_2O, dans une solution aqueuse de NaCl et dans plusieurs solvents non-aqueux par les spectroscopies RMN et UV. La solubilité dans l'eau est comparable à celle des acides aminés tels que l'acide glutamique ou aspartique. Elle dépend du pH et passe par un minimum au point isoélectrique. L'accroîssement de solubilité lorsque le pH est supérieur ou inférieur au point isoélectrique indique que les formes anionique et cationique sont plus solubles que sa forme neutre. L'effet du NaCl sur la solubilité de l'acide domoïque dans l'eau est négligeable. La solubilité dans les alcools est moins grande que celle dans l'eau, mais elle est beaucoup plus grande que la solubilité de l'acide glutamique ou aspartique. Le coefficient de partition octanol–eau à pH 5,32, $K_{ow} = 0{,}0037$, a été determiné directement par la spectroscopie UV. La basse valeur de K_{ow} indique que les organismes aquatiques ne peuvent pas absorber l'acide domoïque dissous dans l'eau mais peuvent l'accumuler seulement par leur régime alimentaire.

Mots clés : solubilité de l'acide domoïque, spectre RMN de l'acide domoïque, spectre UV de l'acide domoïque, coefficient de partition de l'acide domoïque entre l'octanol et l'eau.

Introduction

The solubilities of domoic acid (DA, Fig. 1) in different media are important parameters for the understanding of the biological action and environmental behaviour of this newly discovered and seasonally dangerous marine toxin (1, 2). Knowledge of solubilities of DA is also important in the development of suitable conditions of separation, purification, and analysis. The objective of the present study was to determine the solubility of DA in water and in organic solvents and to compare it with the solubilities of related compounds.

A limited quantity of material, about 50 mg, was available for this study. This and the need to recycle it precluded the use of the very accurate classical gravimetric methods of solubility measurement (3, 4), necessitating the use of the somewhat less accurate spectroscopic methods, ultraviolet spectoscopy (UV) and ^1H nuclear magnetic resonance spectroscopy (NMR). These two methods are complementary: NMR works best at concentrations above 1 mM, and is well suited to studies of DA in water and methanol, in which DA has a relatively high solubility. The more sensitive UV method works best at lower concentrations and is well suited to studies of DA in such solvents as octanol or acetonitrile. The UV method enabled us to measure directly the octanol–water partition coefficient, a parameter widely used in estimating pollutant partitioning between water and sediments, bio-concentration factors and toxicity relationships (5, 6). The NMR measurements of DA solubility in water were performed

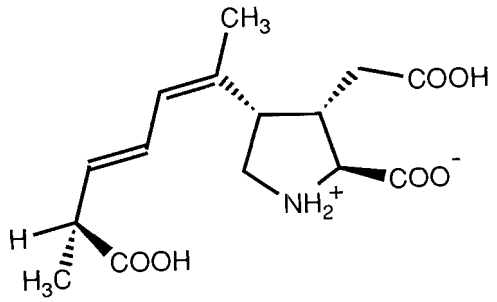

FIG. 1. Molecular structure of neutral domoic acid in its most stable zwitterion form.

both in H_2O and D_2O, the measurements in the latter being more accurate for reasons discussed below. The solubilities of DA in H_2O and in D_2O are expected to be almost the same, as are the solubilities of most organic molecules (7, 8).

Experimental

Materials

The same stock of crystalline DA dihydrate was used as in our earlier work (9, 10). The non-aqueous solvents were of spectroscopic grade and were thoroughly dried with molecular sieve. 1-Octanol was Aldrich HPLC grade, glass-distilled and filtered through 0.5 micron pore filters. The amount of water that could have entered these solvents by the dissolution of DA dihydrate crystals during the experiments was calculated to be about 66 ppm for methanol, 6 ppm for 1-octanol, and less than 1 ppm for the other solvents.

NMR spectroscopy

The experiments were performed at 20°C. DA crystals were added

[1]NRCC No. 33340. Presented in part at the Second Canadian Workshop on Harmful Marine Algae, Bedford Institute of Oceanography, Dartmouth, N.S., October 2–4, 1990.

to D_2O in a high-precision NMR tube (Wilmad 535-pp, nominal i.d. 4.200 to 4.213 mm; measured i.d. of 5 tubes 4.20 ± 0.01 mm) until the solution was saturated, as indicated by undissolved crystals remaining after vigorous agitation of the solution. This yielded the saturated solution at the isoelectric point. Thereafter, pD was adjusted by the addition of small amounts of 0.1 M NaOD or DCl. The pH and pD measurements were made with a Fisher Accumet model 610A pH meter and an Ingold 6030 combination electrode, calibrated with standard Anachemia buffers. Values of pD were obtained by adding 0.4 to the meter readings (11).

^{1}H NMR spectra of the solutions were recorded at 300.13 MHz on a Bruker MSL-300 spectrometer, care being taken to ensure that the probe tuning was optimized and that the degree of probe damping was not detectably altered by changes to the DA solution or by the use of a separate sucrose standard. Acquisitions used single 45° pulses separated by 10 s delays to ensure complete spin–lattice relaxation between transients. The average integrated intensity per proton type, I_D, of the DA resonances was calibrated by comparison with the average area I_S obtained under the same conditions from a standard 12.49 mM solution of sucrose contained in an identical NMR tube. The concentration of the DA solution was obtained as $C = 12.49 \times I_D/I_S$ (mM). This method allows a direct measurement of the saturation concentration of DA without the need to dilute an aliquot of the solution, and circumvents the possibility of errors due to the suspended small crystals in an aliquot, as the NMR spectrum of solid DA would be too broad to be detectable in these experiments. The validity of the method rests on the assumption that the physical distribution of the sample in the probe, the response of the probe, the excitation pulse, and the signal amplification are constant, and that complete relaxation occurs between transients. Ancillary experiments showed that errors resulting from these sources were not significant compared to those due to integration.

An identical procedure was used for the NMR determination of the solubility of DA in D_2O containing 3.5 wt% NaCl. Standard sucrose solutions for these experiments were prepared in D_2O having the same NaCl concentration. Similarly, measurements of DA solubility in CD_3OD utilized the same procedure and type of tube, the standard being an 18.3 mM solution of glucose in CD_3OD.

In the pD range 4.8 to 5.2, the solubility of DA in D_2O increased to the point where there was insufficient material to prepare a saturated solution in a 5 mm NMR tube. The measurement at pD 5.38, the highest pD for which a saturated solution was attainable with the amount of DA at our disposal, utilized a Wilmad 520-1 tube, which has a 2.5 mm o.d. portion containing *ca.* 80 μL of solution in the active region of the NMR probe. The same tube was used in successive measurements with identical volumes of DA or sucrose solution in D_2O, the tube being positioned reproducibly in the probe. It was not possible to use the pH meter with such a small amount of solution, so pD was determined from the chemical shifts of proton resonances which are sensitive to pD (10). Small but undetermined concentration dependences of chemical shifts reduce the accuracy of this method of pD determination: the pD measured by pH meter (11) on the solutions in the pD range 3.45 to 5.15, in a 5 mm tube, was 0.10 lower on the average than that calculated from the chemical shifts.

One set of measurements was also made at the isoelectric point in H_2O solution, in which case the prominent water resonance was presaturated before data accumulation. The level of irradiation used for presaturation was shown in preliminary experiments to have no influence on the intensity of the DA resonances. The need to presaturate with H_2O solution was the reason for our use of D_2O for the remainder of the experiments. Presaturation reduced the accuracy with which integrals could be measured, and was particularly difficult to perform satisfactorily with the small sample tube needed at high pD.

Ultraviolet spectroscopy

The experiments were performed at 20°C. Chloroform, tetrahydrofuran, and acetone were insufficiently transparent at 241 nm to observe the spectrum of dissolved DA. Water, alcohols, dichloromethane, acetonitrile, and cyclohexane did have sufficient transparency. Saturated solutions of DA in these solvents were prepared by placing a few small crystals of DA in a small quantity of solvent in a stoppered glass tube. After several days of equilibration, a small amount of the solution was drawn off (taking care to avoid including any of the crystals), diluted if necessary, and its absorbance at 241 nm measured in a 1-cm cuvette on a CA/McPherson EU-700 spectrophotometer as in ref. 9. The concentration of DA in non-aqueous solvents was determined by assuming its peak molar absorptivity at 241 nm to be $\epsilon_{max} = 2.44 \times 10^4$ L mol^{-1} cm^{-1}, the value for the uncharged molecule (9). In a preliminary experiment we have established that ϵ_{max} of neutral DA is the same to within about 2% in pure water and in a mixture of 100 parts methanol and 1 part water. We have thereupon assumed that ϵ_{max} is also the same for the other non-aqueous solvents. The uncertainty of this assumption is probably only a minor source of error, more likely sources being the possibly incomplete saturation of the non-aqueous solutions and the difficulties attending the many-fold dilutions necessary in the case of saturated aqeuous or methanolic solutions. For the saturated 1-octanol solutions, the peak absorbance A_{241}, too high to be measured directly, was calculated from the much lower absorbance at 260 nm, A_{260}, using the ratio $A_{241}/A_{260} = 4.57$, based on DA spectra of more dilute solutions.

TABLE 1. Solubility of domoic acid in H_2O and D_2O

pH or pD*	Solubility mmol/L	Solubility g/L
H_2O results		
UV, pH 3.09±0.01	22.8±3.0	7.1±1.0
NMR, pH 3.15±0.03	24.5±1.0	7.6±0.6

*A constant 0.4 has been added to pH meter readings in D_2O to provide the pD value (11).

†Estimated from the positions of the 5′- and 1′-CH_3 proton signals (1).

Measurement of K_{ow}

The octanol–water partition coefficient of DA, K_{ow}, was measured by placing in a tightly stoppered vial a lower layer of 4 mL of water initially containing about 2 μmol DA and an upper layer of 12 mL of 1-octanol. The initial concentration of DA in water corresponded to about 2% of its solubility limit and was chosen to be directly measurable in a 1-mm UV cuvette. The bottle was gently agitated on a mechanical shaker, stopped intermittently in order to measure A_o, the peak absorbance of the octanol layer at 241 nm in a 1-cm cuvette. When the A_o readings reached a stationary level, which took several days, the peak absorbance of the water layer, A_w, was measured in a 1-mm cuvette and its pH was determined. The octanol–water partition coefficient was obtained as $K_{ow} = A_o/10A_w$.

Results

The solubility of DA in H_2O at the isoelectric point was measured independently by NMR and UV. The NMR result, 24.5 ± 1.0 mM at pH 3.15 ± 0.03, was in good agreement with the mean UV result, 22.8 ± 3.0 mM at pH 3.09 ± 0.01. The solubility of DA in D_2O at different pD values is recorded in Table 1. At the isoelectric point, pD 3.45, the solubility of DA in D_2O, 24.3 ± 1.0 mM, is essentially the same as the NMR-measured value for H_2O. This close agreement and the general observation that solubilities of organic molecules in D_2O and in H_2O differ by only a few percent (7, 8) lead us to assume that the

variation of the solubility of DA in H_2O with pH and with salt content is essentially the same as for DA in D_2O, which we could measure more accurately. The solubility of DA in 3.5 wt.% NaCl solution in D_2O (which corresponds roughly to the salinity of seawater) was found to be 25.4 ± 1.0 mM, the same within the experimental error as in pure D_2O (Table 2). Table 2 also lists the measured solubilities of DA in non-aqueous solvents. The solubility in methanol could be measured by NMR or UV (NMR giving the more accurate value), but the solubility in the other organic solvents was too low for an NMR measurement. The solubility of DA diminishes in the series water – methanol – octanol–dichloromethane–acetonitrile–cyclohexane. The solubility in cyclohexane is too low to be measurable even by UV, signifying that it must be below 2.0×10^{-5} mM.

The value of the octanol–water partition coefficient was obtained by a direct UV measurement at pH 5.32 as K_{ow} = 0.00374, or $\log K_{ow} = -2.43$. Because of the marked variation of DA solubility with pH, the value of K_{ow} is likely to be pH-dependent and probably passes through a maximum near the isoelectric point. This does not affect the *order of magnitude* of K_{ow} or conclusions which we draw from it.

Discussion

Solubility in water at the isoelectric point

Solubilities of aminoacids in water at room temperature vary widely, from the highly soluble glycine (250 g/kg) and L-proline (162 g/kg) to the relatively insoluble L-tyrosine (0.45 g/kg) (12). The solubility of DA in water, 7.6 g/L, is intermediate between these extremes, and is comparable with the solubilities of the structurally related glutamic acid and of aspartic acid (Table 3). An aminoacid related even more closely to domoic acid is the neurotoxin kainic acid, occurring in marine algae (15). A recent measurement of the solubility of kainic acid in water at its isoelectric point (pH 3.27) yielded the solubility 11.0 g/L or 51.6 mmol/L at 20° (16). Thus, DA is slightly less soluble in water than kainic acid, probably due to the longer olefinic side-chain of DA.

Effect of pH

The solubility of aminoacids in water passes through a minimum near their isoelectric point but increases towards both lower and higher pH values, since both the anionic and cationic forms are more water-soluble than the uncharged form. This behaviour has been reported for tyrosine (17, 18), glycine (19), and phenylalanine (20), and has also been observed for glutamic acid (16). The solubility of DA in water follows the same pattern.

A simple linear model of DA solubility

We made an attempt to fit the pD-dependence of the solubility of DA in D_2O to an equation based on the following linear model. As discussed in our earlier paper (9), DA molecules occur in aqeuous solution in one of five possible protonation forms, whose proportions vary with pH: the fully protonated cation (**A**), the neutral molecule (**B**, see Fig. 1), the singly charged anion (**C**), the doubly charged anion (**D**), and the triply charged anion (**E**). In analogy with other physico-chemical parameters of DA (9), its total solubility S may be expressed at any pH as a linear combination of the individual solubilities of the five DA species, S_a to S_e:

$$[1] \qquad S = aS_a + bS_b + cS_c + dS_d + eS_e$$

where a to e are the mole fractions of the five species. At every pH, the mole fractions can be calculated from the known pK_a values of domoic acid (10), so that the data in Table 1 can be fitted to eq. [1] by optimization. Using an optimization technique previously used to fit the variation of UV and NMR spectral parameters of DA with pH and pD (9, 10), we have found that the data points between pD 2.26 and 5.15 could be fitted to the model (Fig. 2). On the other hand, attempts to include the very large value of solubility at pD 5.38 led to physically unacceptable negative values for some of the solubility parameters. The linear model is based on the assumption that the dissolved DA molecules function as independent entities and the failure of this model signals the occurrence of strong molecular interactions between DA molecules or ions in solution. Such interactions are also apparent from the observed variation of the NMR chemical shifts with DA concentration (10). At the moment, the molecular basis of these interactions is not clear, but since we have found that the analogous linear model similarly fails to fit the dependence of the solubility of glutamic acid with pH (16), the phenomenon is not specific to DA and could be of a more general nature. It is likely that strong interactions and a steep rise of solubility could also occur at low pH, so that extrapolation of the measured solubilities to the region below pD 2.26, based on the linear model, cannot be trusted.

Effect of temperature

We have no data for DA, but other aminoacids show only a very moderate increase of aqueous solubility with rising temperature. The rates of increase that have been reported vary from

0.3% per degree for phenylalanine to 1% per degree for glycine (21).

Effect of salinity

The effect of salinity on the solubility of DA in water, at levels corresponding to seawater, is small enough to be neglected in most practical considerations.

Solubility in alcohols

The solubility of DA in alcohols is less than in water. Though the data are very limited, it is clear that solubility diminishes with increasing length of the hydrocarbon chain: the solubility of DA in methanol and in 1-octanol is, respectively, 1/12 and 1/118 of its solubility in water at the isoelectric point. Aminoacids such as glutamic acid, aspartic acid, or glycine, appear to exhibit an even more drastic diminution of solubility with increasing length of hydrocarbon chain (Table 3). However, such comparisons are complicated by the uncertain degree of hydration of solvents used in such studies, which has led to serious discrepancies in the literature. For example, the solubility of glycine in ethanol at 25°C has been reported to be 0.39 mM by McMeekin *et al.* (22) and 8.5 mM by Dey and Lahiri (13).

Solubility in alcohol–water mixtures

The solubility of DA in alcohol–water mixtures was not investigated, but one should not assume that the solubility varies linearly or even monotonically as a function of alcohol concentration, complex behaviour having been observed for some aminoacids. For example, the solubility of phenylalanine in mixtures of water and 1-propanol increases at first, passes through a maximum at about 0.2 mole fraction alcohol, then decreases sharply at higher alcohol concentrations (23).

Bioaccumulation

Aquatic organisms, including molluscs, crustaceans, and fish, may take up organic chemicals either directly from the water or through the food chain (24). The tendency of such uptake for various substances is measured by bioconcentration factors, K_B, which have been found to correlate linearly with octanol–water partition coefficients, K_{ow} (25–27). The K_{ow}/K_B correlations have been specifically shown (28) to apply to the bioconcentration of many organic compounds by *Mytilus edulis*, the mussel responsible for the original human intoxications in 1987 that first led to the discovery of DA as the amnesic shellfish toxin (1, 2). The value of log $K_{ow} = -2.43$, obtained in the present work and the K_{ow}/K_B correlations of refs. 25–28 imply that log K_B is negative, i.e. K_B is less than unity, indicating little tendency of DA to be bioconcentrated.

While the low value of K_{ow} and K_B implies that passive transport of DA across biological membranes is negligible, active uptake of DA by the epithelial cells of the digestive system might be expected to occur, these cells being involved in the active uptake of aminoacids. However, it has been observed during toxic outbreaks that DA present in contaminated shellfish is found largely (or perhaps exclusively) in their digestive systems and not in muscles or other body tissues (29). It thus appears that DA does not efficiently pass across body membranes by either passive or active transport mechanisms.

Acknowledgments

A part of this research was carried out by Paul W. Wiseman, summer assistant at this Institute, 1988 and 1989. Some of the NMR measurements were carried out by D. M. Leek. We are

Measurements of far-infrared optical constants of liquids with a synchrotron radiation source

YOSHITAKA FUJITA, TETSUHIKO OHBA,[1] AND SHUN-ICHI IKAWA[2]
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060, Japan
Received April 17, 1991
This paper is dedicated to Dr. Richard Norman Jones

YOSHITAKA FUJITA, TETSUHIKO OHBA, and SHUN-ICHI IKAWA. Can. J. Chem. **69**, 1745 (1991).

The far-infrared optical constants of liquid acetonitrile, carbon disulfide, and carbon tetrachloride were determined from transmission measurements with a synchrotron radiation source at the Institute for Molecular Science (Okazaki). The small size of the synchrotron radiation source was of benefit to measurements of transmittances that were suited for an analysis based on an optical theory. From the transmittances of liquid acetonitrile at temperatures ranging from 238 to 343 K, both the absorption coefficients and the refractive indices were obtained by using the subtractive Kramers–Kronig relation proposed by Jones and co-workers. The dipole moment of liquid acetonitrile calculated from the optical constants, 4.5 ± 0.1 D, is nearly independent of temperature. The spectra of carbon disulfide and carbon tetrachloride were measured at pressures in the ranges 1–1800 bar and 1–1100 bar, respectively. The absorption coefficients were obtained from the transmittances by neglecting the dispersion of the refractive indices. The zeroth and second moments of the collision-induced absorption bands were obtained as a function of pressure, after resolving the overlap of intramolecular vibrational bands.

Key words: far-infrared, optical constants, pressure, liquid, synchrotron radiation source.

YOSHITAKA FUJITA, TETSUHIKO OHBA et SHUN-ICHI IKAWA. Can. J. Chem. **69**, 1745 (1991).

Utilisant des mesures de transmission effectuées avec une source de radiation synchrotron, à l'Institute for Molecular Science (Okazaki), on a déterminé les constantes optiques dans l'infrarouge lointain de l'acétonitrile, du disulfure de carbone et du tétrachlorure de carbone liquides. La petite taille de la source de radiation synchrotron était utile dans la mesure des transmissions appropriées pour une analyse basée sur une théorie optique. À partir des transmissions de l'acétonitrile liquide, à des températures allant de 238 à 343 K, et utilisant la relation soustractive de Kramers–Kronig proposée par Jones et ses collaborateurs, on a obtenu les coefficients d'absorption ainsi que les indices de réfraction. Le moment dipolaire de l'acétonitrile liquide calculé à partir des constantes optiques, 4,5 ± 0,1 D, est pratiquement indépendant de la température. On a mesuré les spectres du disulfure de carbone et du tétrachlorure de carbone à des pressions respectives de 1 à 1800 bar et de 1 à 1100 bar. On a obtenu les coefficients d'absorption à partir des coefficients de transmission, en négligeant la dispersion des indices de réfraction. Après avoir résolu le recouvrement des bandes vibrationnelles intramoléculaires, on a pu déterminer les moments d'ordre zéro et second des bandes d'absorption induites par les collisions en fonction de la pression.

Mots clés : infrarouge lointain, constantes optiques, pression, liquide, source de radiation synchrotron.

[Traduit par la rédaction]

Introduction

Band shapes of far-infrared absorption of liquids are informative about the dynamics and interactions of liquid molecules. If the molecules have permanent dipole moments, the absorption is caused primarily by the reorientational motion of the dipole moments, and the band shape, providing a spectral density of the motion, tells about how the orientation of the molecules fluctuates in the liquid state. On the other hand, non-dipolar liquids show far-infrared absorption that arises from transient dipole moments induced through molecular collisions. The band shape of this collision-induced absorption is given by the fluctuation of both the orientation and the magnitude of the induced dipole moments.

For analyzing the band shapes (1, 2), we need the optical constants or the complex refractive indices by which spectra of liquids are fully characterized. However, measurements of the optical constants of liquids in the far-infrared region are scarce. Most of them were performed by Dispersive Fourier-Transform Spectrometry (3), but the procedure for data analysis by this method is not straightforward. In the previous study (4, 5), we measured attenuated total reflection (ATR) of liquids with an optically pumped far-infrared laser as a source and obtained fairly precise values of the optical constants of some liquids. However, the precise measurements of ATR could be performed only at spot frequencies where strong laser lines were available.

The present paper reports the determination of continuous spectra of the optical constants of liquids from transmission measurements with the synchrotron orbital radiation (hereafter referred to as SOR) as a far-infrared source. The SOR facilities are usually intended to produce high-intensity photon beams in the range of extreme ultraviolet to X-ray. However, the SOR is also a promising light source in the far-infrared region (6–8) where intense broad-band sources are lacking. At present, the radiative intensity of the SOR in the far-infrared is not very remarkable. At a typical operating current of 100 mA, it is only in the region below 30 cm^{-1} (8) that the SOR provides a greater intensity than the high-pressure mercury lamp, the conventional far-infrared source. In spite of this, the SOR has advantages over the mercury lamp in its brightness, its high degree of polarization, and its pulsed nature. Particularly, the brightness of the SOR coming from its very small source and small beam divergence is of benefit for precise measurement of the optical constants. For instance, the source is about 0.5 mm in diameter and the acceptance angles are 60 (vertical) and 80 (horizontal) mrad (9) at the far-infrared beam line of the UVSOR facility of the Institute for Molecular Science (IMS, Okazaki). Therefore, the SOR makes it easier to obtain a par-

allel or near-parallel beam of a moderate diameter and to control the angle of incidence of light into the liquid cell within a small tolerance.

Though the transmission measurements are conventional and simple, we must carefully analyze observed transmittances, which are usually deformed by interference fringes due to multiple reflection inside a cell and by errors due to spread of incident angle of light and uncertainty in the sample thicknesses and so on. A good guide for dealing with these effects has been given by Jones and co-workers (10–12). They have established a standard way to control or treat the errors associated with the transmission measurements and to obtain the optical constants in the infrared region. In the present study, we have consulted their scheme of analysis, which is also applicable in the far-infrared region.

In this paper, we report two extreme cases of transmission measurements. One is measurement of a liquid film of acetonitrile of about 30 μm thickness. Acetonitrile is one of the most heavily absorptive liquids in the far-infrared region and its optical constants have been difficult to measure without large uncertainty (5). The other case concerns measurements of liquid carbon tetrachloride and carbon disulfide under pressure. The thicknesses of these liquid layers were 4–6 mm, since the collision-induced absorption (hereafter referred to as CIA) of the non-dipolar liquids is roughly two orders of magnitude smaller than that of liquid acetonitrile. To obtain the optical constants from the observed transmittances, we applied an optical theory in somewhat different ways to the thin and thick liquid layers.

Recently, after we started this study, Marteau *et al.* (13) reported measurements of the CIA of the same liquids under pressure. Their method of processing experimental data is different from ours and, we believe, it is worthwhile to compare the results of the two studies, since high-pressure measurements of CIA are very scarce, although they would provide an important clue to the mechanism of CIA and also to the local structure of the liquids.

Experimental method and results

Spectroscopic grade acetonitrile, carbon tetrachloride, and carbon disulfide from Nacalai Tesque were used as received. Spectral measurements were performed at the FIR beam line (BL6A1) of UVSOR by use of a SPECAC Martin–Puplett interferometer. The detectors used were Infrared Laboratories Ge and InSb bolometers operated at liquid helium temperature. Spectral resolution was 3 cm^{-1}. An observed interferogram was corrected for the time decay of the beam current before being transformed to a spectrum. Windows of the cell used for measuring thin liquid films of acetonitrile were hyper-pure silicon disks with thickness of 3 mm and the opening of the cell was 15 mm. Thicknesses of liquid films were adjusted to be about 30 μm with an aluminum spacer. The temperature of the cell was controlled by use of an electric heater and liquid nitrogen in the 238–343 K range, with a precision of ±0.5 K during a spectral scan. Figure 1 shows an example of apparent transmittances of liquid acetonitrile, which were obtained as a ratio of the transmission intensity of the filled cell to that of a silicon disk of 6 mm thickness as reference. Because of absorption by a quartz window used as a radiation shield in the detector housing, the signal-to-noise ratio is fairly low on the high frequency side. Two types of interference fringes are involved in the observed transmittance. Waving with a period of about 30 cm^{-1} is attributed to interference fringes arising from about a 50-μm difference in thickness between front and rear windows of the cell. This type of interference fringe has not been reported so far, to our knowledge, and indicates the uniformity of the angle of incidence. The collection angle of the optics used was less than 5°, which is several times smaller than that of conventional optics with a high-pressure

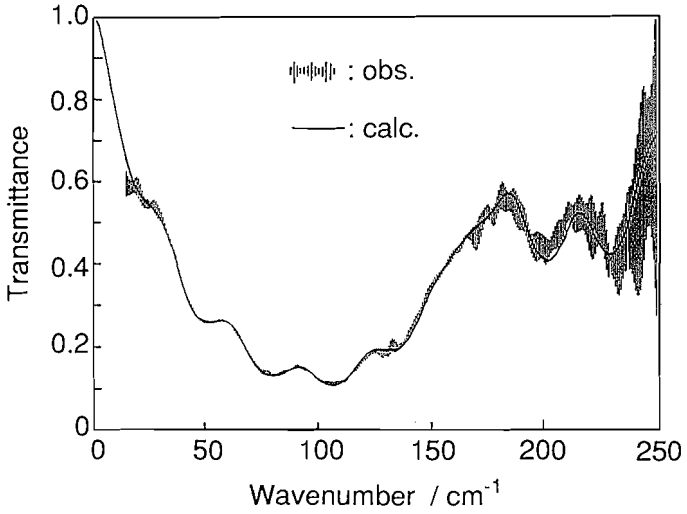

FIG. 1. Observed (||||||||||||) and calculated (—) transmittances of an acetonitrile liquid film of about 30 μm thickness at 298 K, obtained as a ratio of transmission intensity of a filled cell to that of a silicon disk as reference. The vertical bars of the observed transmittance indicate uncertainty estimated from standard deviation of the transmission intensities.

mercury lamp. Another type of interference fringe involved in Fig. 1, though not obvious, has about a 130-cm^{-1} period. This is due to the multiple reflection within the liquid film of about 30-μm thickness.

A schematic of the high-pressure cell used is shown in Fig. 2. The cell body is made of precipitation-hardened stainless steel SUS630; its effective aperture for optical transmission is 4 mm and the path length, including windows, is 30 mm. The windows are hyper-pure silicon crystals of 10 mm diameter and 10–14 mm thick, by which the path length of a sample can be adjusted in the 2–10 mm range. Oil pressure is generated by a hand pump and intensified by about 20 times to pressurize the liquid specimen. The pressure is measured by a semiconductor strain gauge with a precision of a few percent. Spectra of carbon tetrachloride were measured at pressures ranging from 1 to 1100 bar at 298 K and those of carbon disulfide in the range 1–1800 bar. The reference was taken to be transmission intensity of the empty high-pressure cell. Figure 3 shows examples of observed transmittances of carbon disulfide.

Theory of transmittance

We shall consider transmission of light through a three-layer (vacuum–window–vacuum) system and a five-layer (vacuum–window–liquid–window–vacuum) system. The transmittances are generally given by the method of the characteristic matrix (14) and, for the normal incidence of light, the results are

$$[1]\quad T_3(\nu) = \left| \frac{\hat{t}_{12}\hat{t}_{23}\exp(i\hat{\beta}_2)}{1+\hat{r}_{21}\hat{r}_{32}\exp(2i\hat{\beta}_2)} \right|^2$$

and

$$[2]\quad T_5(\nu) = \left| \frac{\hat{t}_{12}\hat{t}_{23}\hat{t}_{34}\hat{t}_{45}\exp[i(\hat{\beta}_2+\hat{\beta}_3+\hat{\beta}_4)]}{1+\hat{Q}} \right|^2$$

for the three- and five-layer systems, respectively, where

$$[3]\quad \hat{Q} = \hat{r}_{12}\hat{r}_{23}\exp(2i\hat{\beta}_2) + \hat{r}_{23}\hat{r}_{34}\exp(2i\hat{\beta}_3) + \hat{r}_{34}\hat{r}_{45}\exp(2i\hat{\beta}_4) + \hat{r}_{12}\hat{r}_{34}\exp[2i(\hat{\beta}_2+\hat{\beta}_3)] + \hat{r}_{23}\hat{r}_{45}\exp[2i(\hat{\beta}_3+\hat{\beta}_4)] + \hat{r}_{12}\hat{r}_{23}\hat{r}_{34}\hat{r}_{45}\exp[2i(\hat{\beta}_2+\hat{\beta}_3+\hat{\beta}_4)] + \hat{r}_{12}\hat{r}_{45}\exp[2i(\hat{\beta}_2+\hat{\beta}_3+\hat{\beta}_4)]$$

P: piston; S: liquid sample; W: silicon windows of 10 mm diameter and 10–14 mm thickness by which the path length of a sample is adjusted in the 2–10 mm range. Oil pressure is generated by a hand pump and intensified by about 20 times to pressurize the liquid sample.

Here, $\hat{r}_{ij}$ and $\hat{t}_{ij}$ are the complex coefficients of reflection and transmission, respectively, at an interface between layers i and j, and $\hat{\beta}_i$ is the complex propagation coefficient of the layer i. These coefficients are given by

$$[4] \quad \hat{r}_{ij} = \frac{\hat{n}_i - \hat{n}_j}{\hat{n}_i + \hat{n}_j}$$

$$[5] \quad \hat{t}_{ij} = \frac{2\hat{n}_i}{\hat{n}_i + \hat{n}_j}$$

$$[6] \quad \hat{\beta}_i = 2\pi\nu d_i \hat{n}_i$$

where $\hat{n}_i = n_i + ik_i$ is the complex refractive index of layer i and d_i its thickness. Equations [1] and [2] can be rewritten as

$$[7] \quad T_3(\nu) = \exp(-\alpha_W d_W)\left|\frac{1-\hat{R}_{VW}}{1-\hat{R}_{VW}\exp(2i\hat{\beta}_W)}\right|^2$$

$$[8] \quad T_5(\nu) = \exp[-\alpha_W(d'_W + d''_W) - \alpha_L d_L] \times \left|\frac{(1-\hat{R}_{VW})(1-\hat{R}_{WL})}{1+\hat{Q}}\right|^2$$

where suffixes V, W, L indicate vacuum, window, and liquid, respectively, and

$$[9] \quad \alpha_i = 4\pi\nu k_i$$

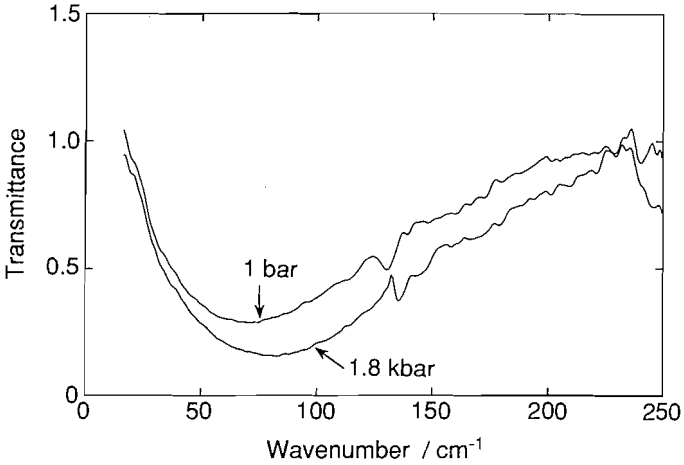

FIG. 3. Observed transmittances of liquid carbon disulfide at 1 bar and 1.8 kbar at 298 K, obtained as ratios of transmission intensities of a filled and an empty high-pressure cell.

is the absorption coefficient of layer i, and

$$[10] \quad \hat{R}_{ij} = \hat{r}_{ij}^2$$

Transmittances given by eqs. [7] and [8] would show complicated interference fringes. However, the fringes are largely smeared in the observed transmittance, which is given by a convolution of $T_n(\nu)$ with an instrumental line-shape (ILS) function, $F(\nu)$, as (15)

$$[11] \quad \langle T_n(\nu)\rangle_{ILS} = \int_0^\infty T_n(\nu')F(\nu-\nu')d\nu'$$

where $F(\nu)$ is given by the Fourier transform of an apodization function $f(x)$, x being the optical path difference between two arms of the interferometer (16). In the present experiment, we used $f(x) = \cos^2(\pi x/2L)$, where L is the maximum of x, and then

$$[12] \quad F(\nu) = \frac{1}{1-(2\nu L)^2}\cdot\frac{\sin\pi\nu L}{2\pi\nu L}$$

The measurements were performed with $L = 3.2$ mm, which provides 3.1 cm^{-1} full-width of $F(\nu)$. At this condition, the interference fringes of $T_3(\nu)$ are completely leveled out in $\langle T_3(\nu)\rangle_{ILS}$, which is given by

$$[13] \quad \langle T_3(\nu)\rangle_{ILS} = \exp(-\alpha_W d_W)\frac{|1-\hat{R}_{VW}|^2}{1-|\hat{R}_{VW}|^2\exp(-2\alpha_W d_W)}$$

On the other hand, the interference fringes will partially remain in $\langle T_5(\nu)\rangle_{ILS}$. In general, far-infrared absorption of liquids is very broad and featureless, and both n_L and k_L are slowly varying functions of ν. As a result, eq. [11] for $n = 5$ can be reduced to

$$[14] \quad \langle T_5(\nu)\rangle_{ILS} = \exp[-\alpha_W(d'_W + d''_W) - \alpha_L d_L] \times |(1-\hat{R}_{VW})(1-\hat{R}_{WL})|^2 N(Q)$$

where

$$[15] \quad N(Q) = \int_0^\infty \frac{F(\nu-\nu')}{|1+\hat{Q}(\nu')|^2}\,d\nu'$$

Optical constants of liquid acetonitrile at various temperatures

The observed apparent transmittance of liquid acetonitrile, $T^{obs}(\nu)$, shown in Fig. 1, is represented by a ratio of eq. [14] to eq. [13]. Since $d'_W + d''_W$ is approximately equal to d_W and absorption coefficients of hyper-pure silicon used for the windows are very small in the far-infrared region (17), the effects of absorption of the silicon windows are partially cancelled in $T^{obs}(\nu)$, which is given by

$$[16]\quad T^{obs}(\nu) = \exp(-\alpha_L d_L)|1 - \hat{R}_{WL}|^2 \times \{1 - |\hat{R}_{VW}|^2 \exp(-2\alpha_W d_W)\}N(Q)$$

$T^{obs}(\nu)$ is a function of the complex refractive indices of the liquid. To determine both the real and imaginary parts, we have used the subtractive Kramers–Kronig relation proposed by Jones and co-workers (10*b*),

$$[17]\quad n(\nu) - n(\nu_r) = \frac{2}{\pi} P \int_0^\infty \frac{\mu k(\mu)}{\mu^2 - \nu^2} d\mu - \frac{2}{\pi} P \int_0^\infty \frac{\mu k(\mu)}{\mu^2 - \nu_r^2} d\mu = \frac{2(\nu^2 - \nu_r^2)}{\pi} P \int_0^\infty \frac{\mu k(\mu)}{(\mu^2 - \nu^2)(\mu^2 - \nu_r^2)} d\mu$$

where P denotes the Cauchy principal value of the integral, frequency ν_r is called the anchor point, and the refractive index at this point, $n(\nu_r)$, is assumed to be known. The $n(\nu_r)$ value at 298 K was taken from the result of the laser ATR method (4) and values at other temperatures were calculated by utilizing the Lorenz–Lorentz equation (18).

For a practical calculation, we have assumed the following analytical expression for the absorption coefficient:

$$[18]\quad \alpha(\nu) = \frac{\nu^2}{P_0 + P_1\nu^2 + P_2\nu^4 + \cdots + P_N\nu^{2N}}$$

An advantage of using eq. [18] is that the integral in the subtractive Kramers–Kronig relation, eq. [17], can be analytically carried out by the following equation:

$$[19]\quad \frac{2}{\pi} P \int_0^\infty \frac{\mu k(\mu)}{\mu^2 - \nu^2} d\mu = \frac{1}{4\pi^2\nu} P \int_{-\infty}^\infty \frac{\alpha(\mu)}{\mu - \nu} d\mu = \frac{1}{4\pi\nu} \sum_{i=1}^{N} \mathrm{Re}\left\{ \frac{Z_i^2}{(Z_i - \nu)\mathrm{Im}(Z_i)} \prod_{j(\neq i)}^{N} \frac{1}{(Z_i - Z_j)(Z_i - Z_j^*)} \right\}$$

where Z_i is the ith pole of eq. [18] with a positive imaginary part and Z_i^* its complex conjugate. The parameters $\{P_n\}$ were adjusted by least-squares fitting of the theoretical transmittance to the observed spectrum. For the present spectra, $N = 6$ was found to be enough. The result of the least-squares fitting is shown by a solid curve in Fig. 1 and the resulting optical constants are plotted in Figs. 4 and 5.

Using the sum rule (19, 20), we can estimate the internal dipole moments of the liquid molecules from the optical constants. The dipole moment μ is given by

$$[20]\quad \mu^2 = \frac{3c^2 I_\perp}{2\pi\rho} \int_0^\infty n(\nu)\alpha(\nu)D(\nu)d\nu$$

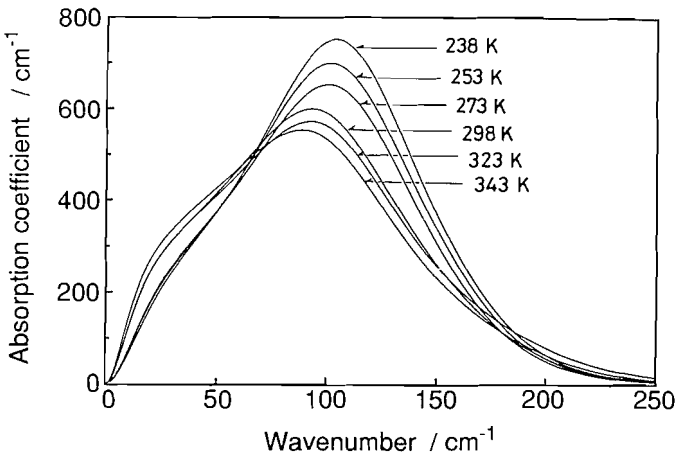

FIG. 4. Absorption coefficients of liquid acetonitrile at various temperatures.

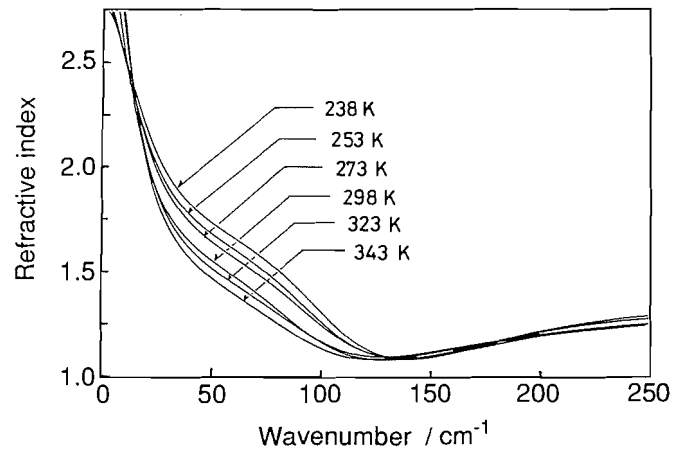

FIG. 5. Refractive indices of liquid acetonitrile at various temperatures.

where ρ is the number density of the molecules, $I_\perp$ the moment of inertia about the axis perpendicular to the dipole moment, and $D(\nu)$ a correction factor for the internal-field effect given by (21)

$$[21]\quad D(\nu) = 3\frac{2(n^2 + k^2)^2 + n_\infty^4}{(n_\infty^2 + 2)^2(n^2 + k^2)^2}$$

where n_∞ is the refractive index related to the molecular polarizability. The calculated dipole moments of liquid acetonitrile were 4.5 ± 0.1 D in the 238–343 K range and almost independent of temperature. This result supports the basic assumption that most of the far-infrared absorption of liquid acetonitrile comes from rotational motion of the dipole moments. An increase of the dipole moment from the gas-phase value, 3.92 D (22), is attributed to the intermolecular induction effect by the dipole–dipole interaction in the liquid state (23).

Absorption coefficients of liquid carbon disulfide and carbon tetrachloride under pressure

Transmittance of the empty high-pressure cell is given by eq. [14] with $\alpha_L = 0$ and $n_L = 1$, and the observed apparent transmittance of liquids, examples of which are shown in Fig. 3, is given by

$$[22]\quad T^{obs}(\nu) = \exp(-\alpha_L d_L)\frac{|1-\hat{R}_{WL}|^2 N(Q)}{|1-\hat{R}_{VW}|^2 N_{empty}(Q)}$$

All of the optical path lengths, $n_i d_i$, of the three layers in the high-pressure cell were thick enough and different from each other. Therefore, all the oscillating terms must disappear in the observed transmittances and $N(Q)$ is reduced to

$$[23]\quad N(Q) = \sum_k (QQ^*)^k$$

Since the aperture of the high-pressure cell is limited to 4 mm while its optical path length is considerably longer, components of multiple reflection are easy to lose from the optical axis owing to the spread of the angle of incidence and the possible wedge shape of the layers. In this case, the summation on the right-hand side of eq. [23] must be limited to a certain order. If we limit to the first order, eq. [22] is reduced to

$$[24]\quad T^{obs}(\nu) = \exp(-\alpha_L d_L)\left|\frac{1-\hat{R}_{WL}}{1-\hat{R}_{VW}}\right|^2 \times \frac{(1+|\hat{R}_{VW}\hat{R}_{WL}|)^2 + (|\hat{R}_{VW}| + |\hat{R}_{WL}|)^2 \exp(-2\alpha_L d_L)}{1+6|\hat{R}_{VW}|^2 + |\hat{R}_{VW}|^4}$$

where eqs. [3]–[6], [9], and [10] were used. For both hyper-pure silicon and non-dipolar liquids, the imaginary parts of the refractive indices are negligibly small as compared with the real parts, $k_W \ll n_W$ and $k_L \ll n_L$, in the far-infrared region, and the dispersion of both n_W and n_L will be very small. Therefore, $\hat{R}_{WL}$ and $\hat{R}_{VW}$ in eq. [24] can be approximated as real constants given by

$$[25]\quad R_{WL} = \left(\frac{n_W - n_L}{n_W + n_L}\right)^2$$

$$[26]\quad R_{VW} = \left(\frac{1-n_W}{1+n_W}\right)^2$$

The magnitude of the dispersion of the refractive index of hyper-pure silicon from 10 to 150 cm^{-1} is about 0.002 (24) and the value of n_W is taken to be the average in this range, 3.418. No refractive indices of carbon tetrachloride and carbon disulfide in the far-infrared region have been reported so far and the values of n_L were estimated from the static dielectric constants, ε_L, by the Maxwell relation

$$[27]\quad n_L^2 = \varepsilon_L$$

Using these values, we calculate the absorption coefficients of the liquid specimens from the observed transmittances by eq. [24]. The results from two kinds of measurement with the InSb detector and the Ge detector were joined at 30 cm^{-1} for carbon disulfide and 50 cm^{-1} for carbon tetrachloride where the lower frequency ranges were given by the InSb detector. The resulting absorption coefficients of liquid carbon disulfide and carbon tetrachloride are plotted in Figs. 6 and 7. Uncertainty at high frequencies is particularly large for the spectra of carbon tetrachloride. This is due to absorption by a thick quartz window for separating vacuums between the storage ring and the interferometer. The quartz window had been set

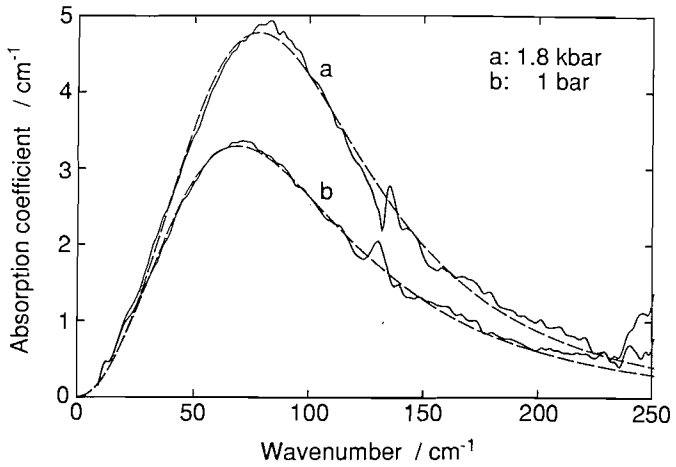

FIG. 6. Absorption coefficients of liquid carbon disulfide at 1 bar and 1.8 kbar at 298 K, obtained by applying eq. [24] to the observed transmittances. Broken lines represent calculated collision-induced absorption bands.

in place of a silicon window when carbon tetrachloride was measured.

For a test of the validity of the above method, we analyzed the transmittance observed at 1 bar (100 kPa) with an ordinary liquid cell, which had a sufficient opening of 15 mm diameter and shorter path length of 9–13 mm, including 3 and 4 mm thicknesses of the silicon windows. The transmittance was obtained as a ratio of transmission intensities at 2 and 6 mm thicknesses of the liquid layers. The absorption coefficients were obtained by applying eq. [22] with the expansion of eq. [23]. It was found that even when the expansion was limited to the first order, the result was within 1–2% of the convergent value, which was reached at expansion to the fourth order. The result agrees within a few percent to that obtained with the high-pressure cell at 1 bar, and also agrees well with the literature values (13, 25).

To analyze the band shape of the collision-induced absorption (CIA), we must resolve overlap of a few intramolecular vibrational bands on the high frequencies. However, the signal-to-noise ratio of the present high-pressure measurements was too low at the high frequencies. Therefore, we obtained a spec-

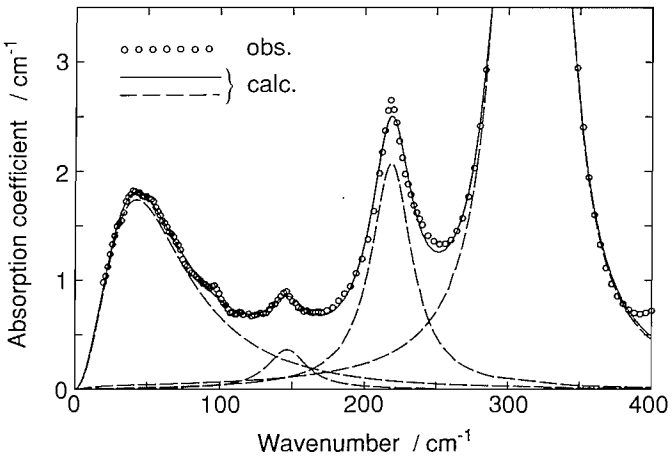

FIG. 8. A joined spectrum of carbon tetrachloride at 1 bar. (○○○): observed; (—): calculated total; and (– – –): calculated component bands.

trum at higher frequencies at 1 bar with a conventional FT-FIR spectrometer and joined this spectrum to that measured with the high-pressure cell at 1 bar. The resulting spectrum of carbon tetrachloride is shown in Fig. 8. Bands at 96, 147, 219, and 311 cm^{-1} are assigned to the ν_4–ν_2, ν_1–ν_4, ν_2, and ν_4 transitions, respectively (26). The overlap was resolved by least-squares fitting, where the CIA band was represented by eq. [18] with $N = 3$, while the intramolecular bands were given by Lorentzian functions that were modified so as to be zero at zero wavenumber, i.e.,

$$[28]\quad F(\nu) = \frac{hb^2}{b^2 + (\nu - \nu_0)^2} - \frac{hb^4}{(\nu^2 + b^2)(\nu_0^2 + b^2)}$$

Fairly good fit was obtained, as shown in Fig. 8. To analyze the spectra at the high pressures, the parameters of the intramolecular bands were fixed at values for 1 bar except for a correction of h for change in the density. The resulting bands of the CIA are shown by broken lines in Fig. 7.

For carbon disulfide, overlap of intramolecular bands is less heavy than that for carbon tetrachloride. The CIA band was separated from bands with peaks at 263 cm^{-1} (ν_1–ν_2) and 396 cm^{-1} (ν_2) in a similar way to the above for carbon tetrachloride. The results are shown by broken lines in Fig. 6.

Moments of the collision-induced bands calculated by the equations

$$[29]\quad A_0 = \int_0^\infty \frac{\alpha(\nu)}{\nu^2} d\nu$$

and

$$[30]\quad A_2 = \int_0^\infty \alpha(\nu) d\nu$$

are plotted against pressure in Figs. 9 and 10, for carbon tetrachloride and carbon disulfide, respectively. These moments are related to the molecular multipole moments that give the collision-induced dipole moments, and to the local structure of the liquids (27). The A_0 and A_2 values of carbon tetrachloride at 1 bar, i.e., 0.134 and 156 cm^{-2} respectively, are in good agreement with recent literature values, i.e., 0.148 (13), 0.189 (25), 0.145 (28), and 149 cm^{-2} (13), 145 cm^{-2} (25), and 154 cm^{-2} (28), respectively. The value of A_0 is only slightly dependent

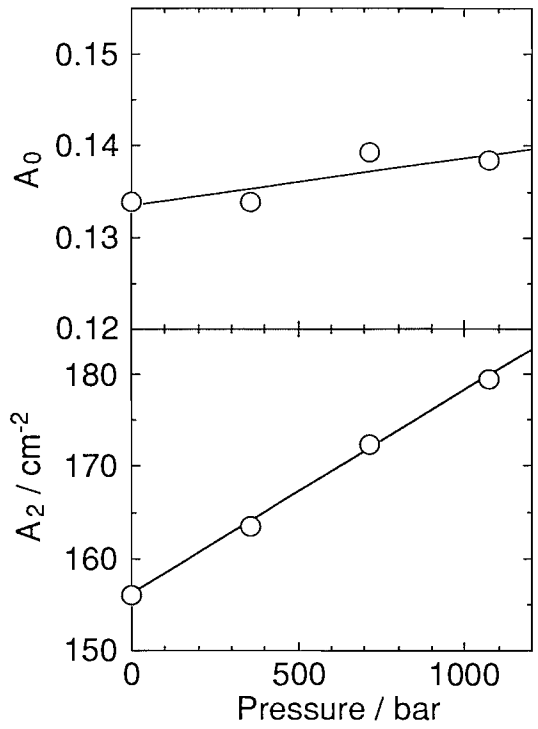

FIG. 9. The zeroth and second moments of the collision-induced absorption bands of carbon tetrachloride plotted against pressure.

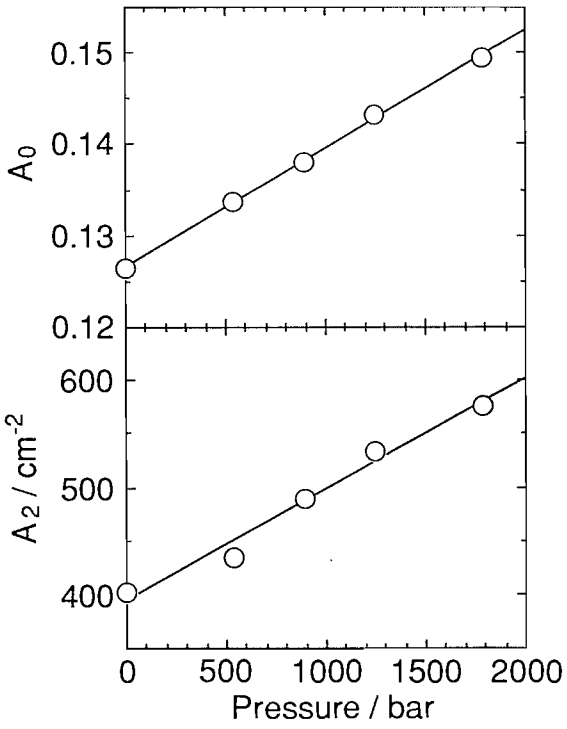

FIG. 10. The zeroth and second moments of the collision-induced absorption bands of carbon disulfide plotted against pressure.

on the pressure, while the A_2 value increases about 15% as the pressure increases from 1 bar to 1.1 kbar. On the other hand, the A_0 value calculated from the result by Marteau *et al.* (13) increased definitely with increasing pressure, and the rate of increase of their A_2 value was about double that of the present result. The discrepancy between the two studies is probably

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

due to the different ways of dealing with the high-frequency wing of the CIA band, where Marteau *et al.* assumed an exponential decay instead of separating the intramolecular bands. For carbon disulfide, the present A_0 value at 1 bar, 0.126, is distinctly smaller than the literature values, which are 0.190 (13) and 0.175 (28), while the A_2 value, 402 cm^{-2}, is somewhat larger than the previous values, which are 322 cm^{-2} (13), 357 cm^{-2} (28), and 386 cm^{-2} (29). This is probably also due to the difference in dealing with the high-frequency wing of the CIA band. In spite of this, the slopes of A_0 and A_2 against the pressure agree moderately well with those of Marteau *et al.* (13). Further studies are required to clarify the "true" property of the CIA. A molecular dynamics calculation, as well as further experiments, would be useful.

An average magnitude of the collision-induced dipole moment is calculated by (28)

$$[31] \quad \langle \mu^2 \rangle = (3\varepsilon_0 k_B T/\pi^2 \rho) n D_{pw} A_0$$

where ε_0 is the permittivity of free space, k_B the Boltzmann constant, and nD_{pw} the Polo–Wilson correction factor (30),

$$[32] \quad nD_{pw} = \frac{9n}{(n^2+2)^2}$$

where D_{pw} is given by eq. [21] with $k = 0$ and $n_\infty = n$. The value of n under pressure was calculated by the Tait equation (31). The calculated root-mean-square values of the induced dipole moments are 0.093 and 0.124 D for carbon tetrachloride and carbon disulfide, respectively, being almost independent of pressure. These values agree moderately well with the previous values (28, 29).

A fowl feather barb 10 μm in thickness was subjected to a polarized infrared spectroscopic measurement by the use of a microscopic device. Nearly 50% of its peptide groups were found to give the 1633 and 1684 cm^{-1} bands characteristic of the antiparallel-chain pleated sheet structure, and the remaining 50% gave the 1659 cm^{-1} band assignable to unordered polypeptide chains. The orientation of the pleated sheet was determined to be on average $\theta = 52°$ and $\chi = 39°$, where θ and χ are the angles for the transformation of the *XYZ* coordinate system fixed on the pleated sheet and the *abc* coordinate system fixed on the sample barb. The Raman spectra of the barb were also examined with another microscopic device and a 488.0-nm laser beam. A sharp *aa* component of the Raman scattering tensor was observed at 1667 cm^{-1}. Based on this fact, a revised set of parameters for the vibrational couplings among the peptide groups in the pleated sheet has been proposed. Some discussions have been made on the amide I Raman tensor of the antiparallel-chain pleated sheet.

Key words: fowl feather barb, Raman microscope, infrared microscope, antiparallel-chain pleated sheet, Raman scattering tensor.

MASAMICHI TSUBOI, FUMIKO KANEUCHI, TERUKI IKEDA et KISO AKAHANE. Can. J. Chem. **69**, 1752 (1991).

Utilisant un appareil microscopique, on a soumis la barbette d'une plume d'oiseau d'une épaisseur de 10 μm à une mesure de spectroscopie infrarouge polarisé. On a trouvé que près de 50% des groupes peptidiques donnent lieu à des bandes à 1633 et 1684 cm^{-1} caractéristiques de la structure à feuillets plissés avec des chaînes antiparallèles; l'autre 50% donne lieu à une bande à 1659 cm^{-1} que l'on peut attribuer à des chaînes de polypeptides qui ne sont pas ordonnées. On a déterminé que l'orientation du feuillet plissé est en moyenne $\theta = 52°$ et $\chi = 39°$, où θ et χ sont les angles de la transformation du système de coordonnées *XYZ* fixé sur le feuillet plissé et du système de coordonnées *abc* fixé sur l'échantillon de barbette. On a aussi examiné le spectre Raman de la barbette à l'aide d'un autre appareil microscopique et d'un faisceau de laser de 488,0 nm. On a observé une forte composante *aa* du tenseur de diffusion Raman à 1667 cm^{-1}. Sur la base de ce résultat, on propose un ensemble révisé des paramètres de couplages vibrationnels parmi les groupes peptidiques du feuillet plissé. On présente aussi quelques discussions du tenseur Raman de l'amide I du feuillet plissé avec des chaînes antiparallèles.

Mots clés : barbette d'une plume d'oiseau, microscope Raman, microscope infrarouge, feuillets plissés avec des chaînes antiparallèles, tenseur de diffusion Raman.

Introduction

Spectroscopic studies of feather keratin have so far been made mostly with samples prepared from the calamus or rachis section of avian feathers (1, 2). Their barbs, in which the crystallite alignment looks better under a polarizing microscope, are too thin for conventional infrared and Raman spectroscopic measurements. Due to recent developments in infrared and Raman microscopy (3, 4), however, even such a thin barb (10 μm in diameter, for example) can now be subjected to these vibrational spectroscopic examinations. If, in such spectroscopic examinations, a comparative study is possible of the infrared and Raman data for the same barb sample, it may yield additional benefits. For each polypeptide conformation, an infrared transition moment caused by its characteristic vibration (the amide I vibration, for example) is well understood as a vector sum of the localized transition moments at the constituent peptide groups. On the other hand, our knowledge of the corresponding Raman scattering tensor is still quite limited. For example, the amide I Raman tensor localized at a peptide group has not yet been established. The contribution of such a localized Raman tensor to the tensor of the antiparallel-chain pleated sheet has never been examined. Such an examination would be facilitated by structural knowledge derived from infrared data on the same sample.

In the present paper, the infrared and Raman spectra of a single barb from fowl feather are reported, and a combined interpretation is described.

Experimental

Fowl feathers were scoured with a dilute, non-ionic detergent solution, rinsed in tap water and then in distilled water, air-dried, and degassed repeatedly by soaking in fresh dry acetone and then air-drying again. These were refluxed with diethyl ether (50°C) for 48 h to remove waxes. A single barb from this was found to be a long cylinder with a diameter of 10 μm and with small lumps arranged at intervals of 75 μm along its elongation direction (see Fig. 1). Under a polarizing microscope it showed a marked positive birefringence. The retardation looked rather homogeneous all over the cylinder.

Its infrared spectra were observed with an infrared microscope,

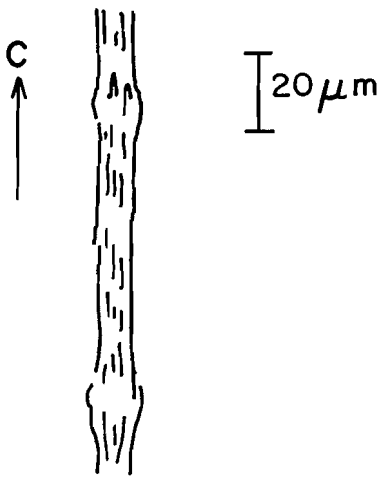

FIG. 1. Fowl feather barb.

Jasco Micro FTIR-100, in its transmission mode. By the use of four aperture plates, all the beams were cut except those going through a rectangular field of 10 × 120 μm, which covered the sample barb. By the use of an infrared polarizer placed in front of the detector, two spectra were recorded, with the electric vector of the infrared radiation both parallel and perpendicular to the elongation direction (*c* axis) of the barb. The results of these observations are shown in Fig. 2.

Raman spectra were observed with a Jasco R-MPS-11 Raman microscope connected with a Jasco NR-1100 Raman spectrophotometer system. For excitation, the 488.0-nm beam of an NEC GLG 3200 Ar ion laser was used. The exciting laser beam came down through the objective (50×) onto the sample barb placed on the microscope stage. First, its elongation direction (*c* axis) was placed parallel to the electric vector of the incident laser beam ($E \parallel c$). Raman scatterings with the *cc* and *ca* components from it were collected by the same objective (in a back-scattering mode), and sent through a beam splitter and a mirror system into the Raman spectrophotometer. The sample barb was found to be fluorescent, but irradiation with a relatively weak laser beam for 1 or 2 h rendered it less fluorescent to the extent that a Raman spectroscopic measurement became possible. The signal-to-noise ratio, however, did not yet become sufficiently high to observe the two components, *cc* and *ca*, separately with a polarizer. Thus, only the Raman scattering intensity, $I_{cc} + I_{ca}$, was obtained, and the result is shown in the upper portion of Fig. 3. Next, the sample barb was rotated on the stage by 90° around the vertical axis, so that the electric vector of the exciting laser beam was now perpendicular to the elongation direction of the barb. The Raman scattering intensity, $I_{aa} + I_{ac}$, was examined, and the result is given in the lower portion of Fig. 3.

Results and discussion

1. Interpretation of the infrared spectra

The observed spectra (Fig. 2) were analyzed by a least-squares procedure into component bands, each of which was assumed to have a Lorentz function profile. Both of the $E \parallel c$ and $E \perp c$ amide I bands were found to consist of three components, with peaks at 1684, 1659, and 1633 cm^{-1}. The 1659 cm^{-1} component is assignable to the unordered polypeptide chains, which probably involve a number of turns. This assignment is supported by the fact that its shape and height are exactly the same for the $E \parallel c$ spectrum as for the $E \perp c$ spectrum. Following Miyazawa's analysis (5), the two components at 1684 and 1633 cm^{-1} are assigned to the antiparallel-chain pleated sheet structure (6), whose unit cell contains four peptide groups (see Fig. 4). The 1684 cm^{-1} component must have a vector-sum transition moment along the *Z* axis (defined as the extending direction of the zigzag polypeptide chain; see Fig. 4), whereas the 1633 cm^{-1} component has a moment along the *Y* axis (perpendicular to *Z* in the sheet plane; nearly parallel to the C═O bond; see Fig. 4).

From the area–intensity measurements of these components of the amide I band, an estimate of the relative amounts of these polypeptide structures was made. It was found that (unordered polypeptide)/(antiparallel-chain pleated sheet) = 51:49.

2. Orientation of the antiparallel-chain pleated sheet

With its external appearance in mind, let us assume that the barb has a cylindrical symmetry, or that it is a uniaxial crystal. The crystal is considered to involve a number of antiparallel-chain pleated sheets as well as the unordered polypeptide chains. Let us next assume that one of these pleated sheets (*XYZ*) is oriented in the crystal (*abc*) as illustrated in Fig. 5. Then, other pleated sheets must be oriented so that all the sheets have the same θ and χ values, whereas the ϕ values are distributed evenly over 360° to keep the axial symmetry around the *c* axis.

The $E \parallel c / E \perp c$ intensity ratio of the 1684 cm^{-1} component is found to be 1.3 (from Fig. 2), and therefore the *Z* axis must be inclined from the *c* axis by $\theta = 52°$ (because $\parallel / \perp = 2 \cos^2 \theta / \sin^2 \theta$). The $E \parallel c / E \perp c$ intensity ratio of the 1633 cm^{-1} component is found to be 0.69, and therefore the *Y* axis must be inclined by 60° from the *c* axis. The set of these data determines uniquely the orientation angles: $\theta = 52°$, $\chi = 39°$.

3. Interpretation of the Raman spectra

As seen in Fig. 3, a sharp Raman peak is found to rise at 1667 cm^{-1} in the broad-background Raman scattering covering the 1690–1640 cm^{-1} range. This 1667 cm^{-1} Raman band is assigned the amide I vibration of the antiparallel-chain pleated sheet, in which all the peptide groups vibrate in-phase ($\nu(0,0)$, in the following section).

4. Proposed revision of the set of the vibrational coupling constants in the antiparallel-chain pleated sheet

Miyazawa and Blout (7) derived an equation for the frequency of the amide I vibration of the antiparallel-chain pleated sheet:

$$[1] \qquad \nu(\delta, \delta') = \nu_0 + D1 \cos \delta + D1' \cos \delta'$$

where the first term ν_0 is the unperturbed frequency, and the second and third terms are due to the intrachain and interchain vibrational interactions, respectively. δ is the phase angle between adjacent peptide group motions in the chain ((1) and (2), or (3) and (4) in Fig. 4) and $D1$ is determined by the potential and kinetic energy interactions between them; δ' and $D1'$ pertain to the interaction through interchain hydrogen bonds (between (1) and (4) in Fig. 4, for example) and have meanings similar to those of δ and $D1$. Miyazawa and Blout (7) gave the following set of values

$$[2] \qquad \nu_0 = 1658, \quad D1 = 8, \quad D1' = -18 \text{ cm}^{-1}$$

This leads to the following frequencies:

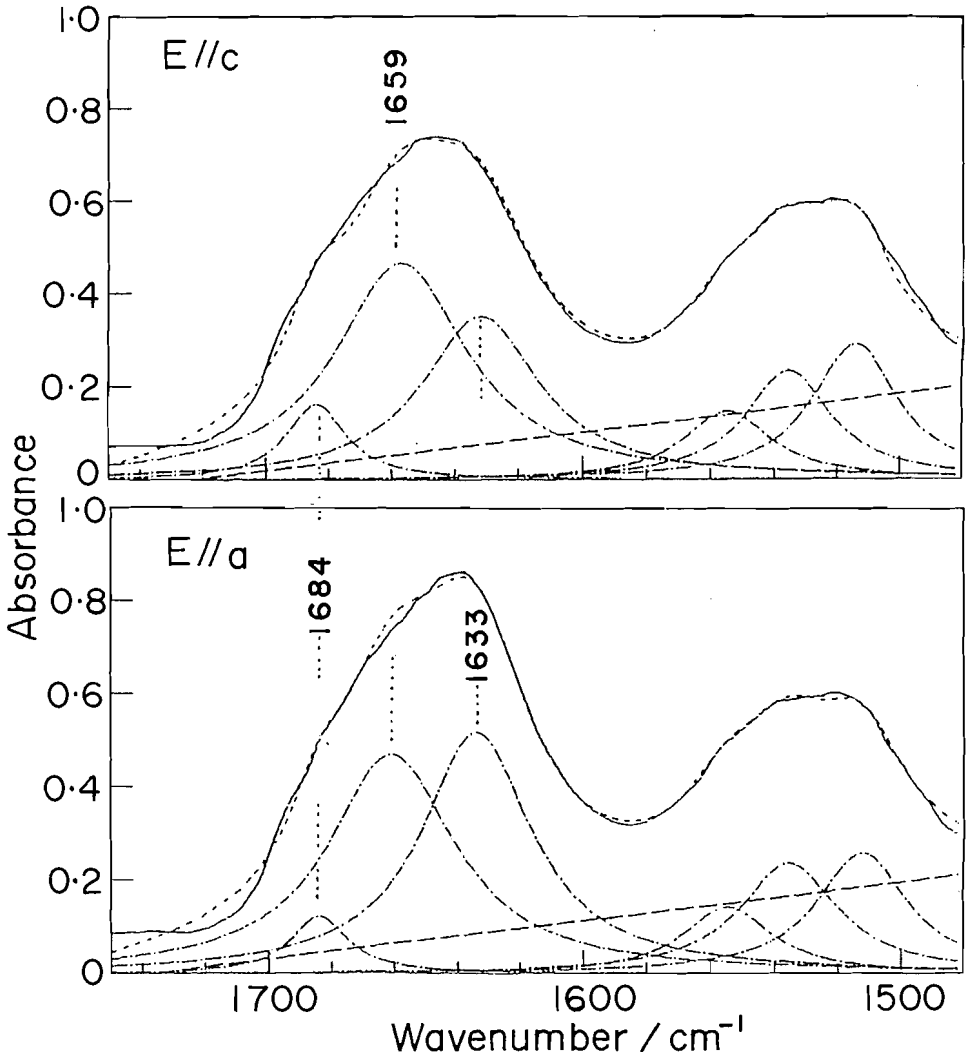

FIG. 2. Infrared absorption spectra (full line) of single barb from fowl feather. Upper spectra, electric vector (E) of the incident radiation is parallel to the elongation direction (c axis) of the barb. Lower spectra, E is perpendicular to the c axis. Resolved components of the amide I band around 1650 cm^{-1} are shown by the chain line (-·-·-·-). The broken line indicates the assumed background, and the dotted line gives the calculated spectrum, which is the sum of the resolved components, and which should fit the observed spectrum (full line).

$$[3]\quad \begin{cases} \nu(0,\pi) = \nu_0 + D1 - D1' = 1684\ cm^{-1}\ (1684\ cm^{-1})\ \text{IR-}Z \\ \nu(\pi,0) = \nu_0 - D1 + D1' = 1632\ cm^{-1}\ (1633\ cm^{-1})\ \text{IR-}Y \\ \nu(0,0) = \nu_0 + D1 + D1' = 1648\ cm^{-1}\ (1667\ cm^{-1})\ \text{Raman} \end{cases}$$

for the observed frequencies given in parentheses. Thus, the calculated frequency, 1648 cm^{-1}, for the Raman-active vibration, now in question, does not agree with the observed frequency (1667 cm^{-1}). To improve this point, we propose to change the set of parameters as follows:

$$[4]\quad \nu_0 = 1658,\quad D1 = 18,\quad D1' = -8\ cm^{-1}$$

This leads to the following frequencies:

$$[5]\quad \begin{cases} \nu(0,\pi) = \nu_0 + D1 - D1' = 1684\ cm^{-1}\ (1684\ cm^{-1})\ \text{IR-}Z \\ \nu(\pi,0) = \nu_0 - D1 + D1' = 1632\ cm^{-1}\ (1633\ cm^{-1})\ \text{IR-}Y \\ \nu(0,0) = \nu_0 + D1 + D1' = 1668\ cm^{-1}\ (1667\ cm^{-1})\ \text{Raman} \end{cases}$$

with nearly perfect agreement with the observed frequencies given in the parentheses.

5. Raman scattering tensor for the amide I vibration of the antiparallel-chain pleated sheet

On the basis of the Raman spectroscopic measurement on a single crystal of a dipeptide (aspartame), whose molecule involves only one peptide group, Tsuboi *et al.* (4) derived the shape and orientation of the amide I Raman tensor ($\boldsymbol{\alpha}'$) excited at 488.0 nm. The orientation of the principal axes, *x*, *y*, and *z*, of the tensor is reproduced in Fig. 6. The relative amounts of the tensor components are $\alpha'_{xx}/\alpha'_{xx} = 0.05$ ($= r_1'$) and $\alpha'_{yy}/\alpha'_{zz} = 0.2$ ($= r_2'$). If this tensor is placed at every peptide group (see Fig. 4), the Raman scattering tensor $\boldsymbol{\alpha}$ of an antiparallel-chain pleated sheet is given as

$$[6] \qquad \boldsymbol{\alpha} = \sum_{i=1}^{4} \tilde{\boldsymbol{L}}_i \boldsymbol{\alpha}' \boldsymbol{L}_i$$

$\boldsymbol{L}_i$ is calculated from the atomic coordinates given by Pauling and Corey (6) as

$$[7] \qquad L_1 = \begin{pmatrix} 0.0052 & -0.3735 & 0.9276 \\ 0.5877 & -0.7494 & -0.3051 \\ 0.8090 & 0.5468 & 0.2156 \end{pmatrix}$$

$$[8] \qquad L_2 = \begin{pmatrix} 0.0052 & 0.3735 & 0.9276 \\ -0.5877 & -0.7494 & 0.3051 \\ -0.8090 & 0.5468 & -0.2156 \end{pmatrix}$$

$$[9] \qquad L_3 = \begin{pmatrix} -0.0052 & 0.3735 & 0.9276 \\ -0.5877 & 0.7494 & -0.3051 \\ -0.8090 & -0.5468 & 0.2156 \end{pmatrix}$$

$$[10] \qquad L_4 = \begin{pmatrix} -0.0052 & -0.3735 & 0.9276 \\ 0.5877 & 0.7494 & 0.3051 \\ 0.8090 & -0.5468 & -0.2156 \end{pmatrix}$$

The principal axes of the synthetic Raman tensor $\boldsymbol{\alpha}$ come out to be the *X*, *Y*, and *Z* axes shown in Fig. 4, as expected, and its tensor components are calculated to be

$$[11] \qquad \alpha_{XX}/\alpha_{ZZ} = 0.2585 \qquad (= r_1)$$

$$[12] \qquad \alpha_{YY}/\alpha_{ZZ} = 1.7300 \qquad (= r_2)$$

6. Raman scattering intensities of the barb and the orientation of the antiparallel-chain pleated sheet in it

The relation of the polarized Raman spectra of a crystal and the orientation of the molecules in it is not as simple as the relation of its polarized infrared spectra and the molecular orientation. If the crystal is uniaxial, and if the molecule in it,

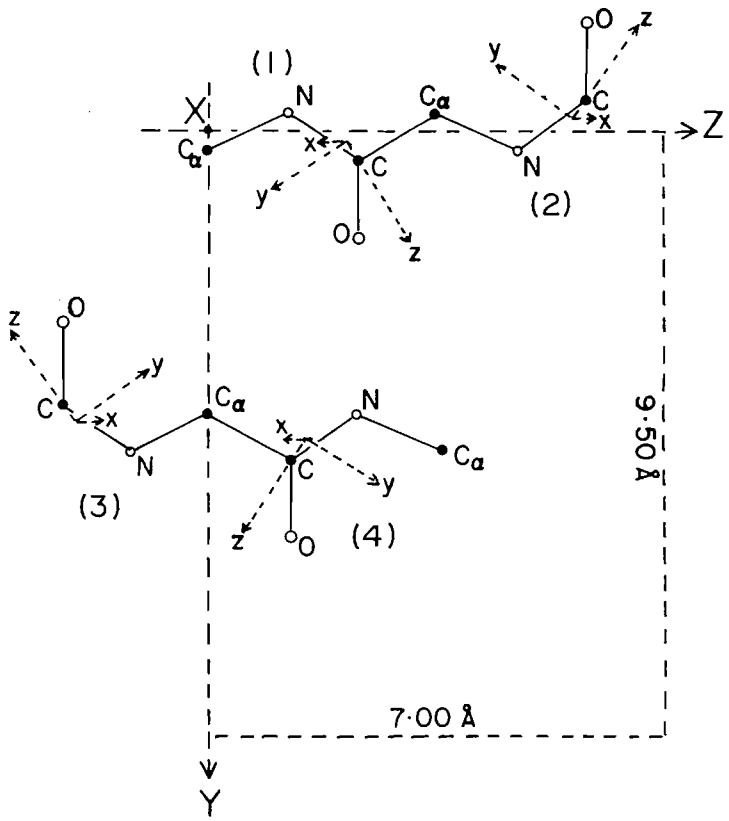

FIG. 4. Antiparallel-chain pleated sheet structure of polypeptide, drawn on the basis of the coordinates given by Pauling and Corey (6). Its X, Y, and Z axes are defined as given here. Its unit cell involves four peptide groups, and the principal axes, x, y, and z, of the amide I Raman tensor (for 488.0 nm excitation) localized on each peptide group are also shown here.

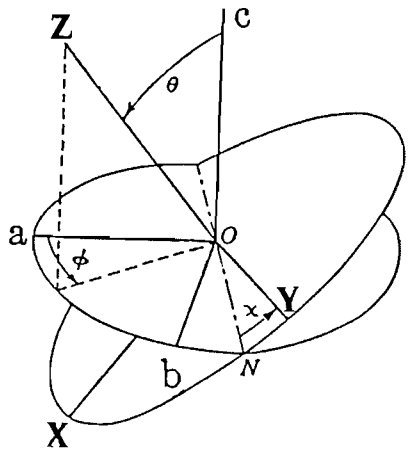

FIG. 5. Definitions of the angles, θ, φ, and χ. These angles are for designating the orientation of the XYZ rectangular axes system of the antiparallel-chain pleated sheet (see Fig. 4) with respect to the crystallographic abc rectangular axes system.

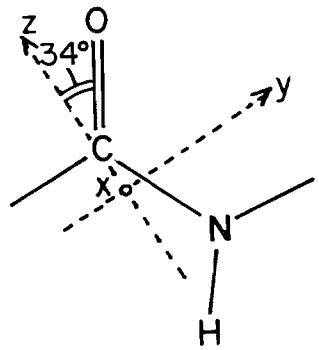

FIG. 6. Amide I Raman tensor (excited at 488.0 nm) of a single peptide group. Its principal axis x is perpendicular to the peptide plane, y and z axes are in the plane, and z axis makes a 34° angle from the C=O bond. $r_1 = \alpha_{xx}/\alpha_{zz} = 0.05$ and $r_2 = \alpha_{yy}/\alpha_{zz} = 0.2$, where α_{xx}, etc., are the Raman tensor components.

with the Raman tensor of $\alpha_{XX}/\alpha_{ZZ} = r_1$ and $\alpha_{YY}/\alpha_{ZZ} = r_2$, is placed with the orientation angles θ and χ (see Fig. 5), then the Raman scattering intensities I_{cc}, I_{aa}, and I_{ac} are given as (5)

$$[13]\quad \frac{I_{cc}}{I_{aa}} = \frac{I_{cc}}{I_{bb}} = 4\left(\frac{\sin^2\theta(r_1\cos^2\chi + r_2\sin^2\chi) + \cos^2\theta}{\cos^2\theta(r_1\cos^2\chi + r_2\sin^2\chi) + (r_1\sin^2\chi + r_2\cos^2\chi) + \sin^2\theta}\right)^2$$

$$[14]\quad \frac{I_{ac}}{I_{aa}} = \frac{I_{bc}}{I_{bb}} = 2\,\frac{\sin^2\theta\cos^2\theta(r_1\cos^2\chi + r_2\sin^2\chi - 1)^2 + \sin^2\theta\sin^2\chi\cos^2\chi(r_1 - r_2)^2}{(\cos^2\theta(r_1\cos^2\chi + r_2\sin^2\chi) + (r_1\sin^2\chi + r_2\cos^2\chi) + \sin^2\theta)^2}$$

In our present case of antiparallel-chain pleated sheet, it has been concluded that $r_1 = 0.2585$ and $r_2 = 1.7300$ (Sect. 5). By replacing these values in eqs. [13] and [14], I_{cc}/I_{aa} and I_{ac}/I_{aa} have been calculated for various θ and χ values. The results are shown in Fig. 7. By the help of such a diagram one should be able, in principle, to determine the orientation (θ and χ) of the antiparallel-chain pleated sheet in the barb from Raman data alone. In the present case, however, the ac component cannot be resolved from the aa component, and the spectral separation of the unordered portion of the polypeptide chain from the antiparallel-chain pleated sheet portion also seems difficult (see Fig. 3). In addition, the orientation has already been determined from the infrared data (in Sect. 2). Let us therefore examine whether this orientation is consistent with the Raman data now in question.

The set of angles, $\theta = 52°$ and $\chi = 39°$, corresponds to $I_{cc}/I_{aa} = 0.75$ and $I_{ac}/I_{aa} = 0.15$ (from Fig. 7), and therefore $(I_{cc} + I_{ca})/(I_{aa} + I_{ac}) = 0.78$. The actually observed Raman spectra (Fig. 3) definitely indicate that $(I_{cc} + I_{ca})/(I_{aa} + I_{ac}) < 1$ at 1667 cm^{-1}, and hence it is concluded that the orientation predicted from the infrared data is qualitatively consistent with the Raman data. A slightly more quantitative examination, however, suggests that χ is smaller than 39° because $(I_{cc} + I_{ca})/(I_{aa} + I_{ac})$ seems smaller than 0.7. In this connec-

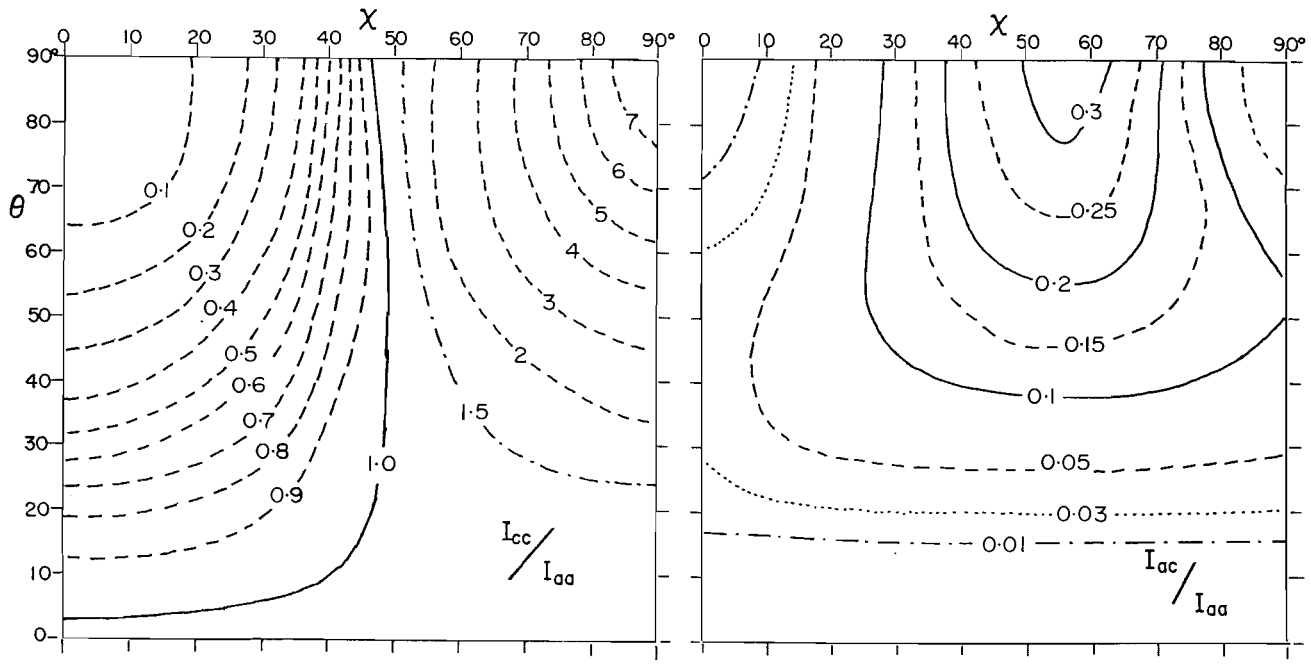

FIG. 7. The Raman scattering intensity ratios, I_{cc}/I_{aa} and I_{ac}/I_{aa}, expected from the orientations (θ and χ) of the antiparallel-chain pleated sheet whose principal axes are X, Y, and Z as shown in Fig. 4. Here, it was assumed that $\alpha_{XX}/\alpha_{ZZ} = 0.2585$ and $\alpha_{YY}/\alpha_{ZZ} = 1.7300$, as calculated in Sect. 5 in the text.

tion, we should pay attention to the following two conditions in our experiments: First, we are observing a much greater area (10 × 120 μm) of the sample barb in the infrared microscopy than in the Raman microscopy (a circle only 2 μm in diameter). Second, we are rotating the sample barb on going from the Raman spectroscopic measurement of the $I_{cc} + I_{ca}$ component to that of the $I_{aa} + I_{ac}$ component, which does not ensure that exactly the same area of the barb sample is subjected to the $I_{cc} + I_{ca}$ measurement as to the $I_{aa} + I_{ac}$ measurement. In the infrared dichroism measurement, on the other hand, the sample barb was never moved, and therefore it is certain that our $E \parallel c$ spectrum came from exactly the same sample area as the $E \perp c$ spectrum. Taking these two factors into account, we may conclude that, in our sample barb, there is an appreciable heterogeneity (with a scale of 2 μm) in the orientation of the pleated sheet, and that the values derived from the infrared data ($\theta = 52°$, $\chi = 39°$) represent the average of such a heterogeneous orientation.

Phase transitions in adamantane derivatives: 1-fluoroadamantane

NANCY T. KAWAI, DENIS F. R. GILSON,[1] AND IAN S. BUTLER[1]

Department of Chemistry, McGill University, 801 Sherbrooke St. W., Montreal, P.Q., Canada H3A 2K6

Received April 23, 1991

This paper is dedicated to Dr. Richard Norman Jones

NANCY T. KAWAI, DENIS F. R. GILSON, and IAN S. BUTLER. Can. J. Chem. **69**, 1758 (1991).

The solid-state phase behaviour of 1-fluoroadamantane (1-$C_{10}H_{15}F$) has been investigated by differential scanning calorimetry, and by infrared and Raman spectroscopy. The phase transition occurs at 227 K on cooling and at 231 K upon heating, with average ΔH_t and ΔS_t of 1.65 kJ mol^{-1} and 7.3 J K^{-1} mol^{-1}. The transition was also apparent in the low-temperature IR and Raman spectra by a sudden line narrowing, and characteristic spectral features of each phase were identified. Both phases I and II were disordered, and further cooling of phase II resulted in the formation of a glass. Attempts to induce a glass transition (predicted to occur at ~90 K) by slow heating were unsuccessful. Vibrational spectroscopic studies at high pressures showed a phase transition at 3.3 ± 1.0 kbar, upon compression. The phases formed under pressure were the same as those induced by lowering temperature.

Key words: high-pressure infrared and Raman spectroscopy, phase transition, plastic crystal, orientational disorder.

NANCY T. KAWAI, DENIS F. R. GILSON et IAN S. BUTLER. Can. J. Chem. **69**, 1758 (1991).

Faisant appel à la calorimétrie de balayage différentiel et aux spectroscopies infrarouge et Raman, on a étudié le comportement de phase de l'état solide du 1-fluoroadamantane (1-$C_{10}H_{15}F$). La transition de phase se produit à 227 K lors du refroidissement et à 231 K lors du chauffage; les valeurs moyennes du ΔH_t et du ΔS_t sont 1,65 kJ mol^{-1} et 7,3 J K^{-1} mol^{-1}. On peut aussi détecter la transition dans les spectres IR et Raman à basses températures grâce à un amincissement soudain des raies; on a identifié les caractéristiques spectrales de chaque phase. Les phases I et II sont toutes les deux désordonnées et un refroidissement plus poussé de la phase II conduit à la formation d'un verre. Aucun des essais tentés pour induire une transition de verre (qui devrait se produire à environ 90 K) par un chauffage lent n'a été couronné de succès. Des études de spectroscopie vibrationnelle à pressions élevées ont montré que, lors de la compression, il se produit une transition de phase à 3,3 ± 1,0 kbar. Les phases qui se forment sous pression sont les mêmes que celles qui sont induites par un abaissement de la température.

Mots clés : spectroscopies infrarouge et Raman à haute pression, transition de phase, cristal plastique, désordre orientationnel.

Introduction

A large number of organic cage compounds exhibit orientational disorder in the solid state (1–3), and investigations of many derivatives of adamantane, tricyclo[3.3.1.1]decane, have been reported with the aim of correlating phase behaviour with molecular structure. There are two positions on the adamantane cage where single substitution can occur: the 1-position, where the molecule retains a threefold rotation axis, and the 2-position, where a plane of symmetry remains intact. The phase behaviour of the 1-adamantanes varies according to the substituent. Among the halo-adamantanes, 1-chloro and 1-bromoadamantane exhibit one- and two-phase transitions, respectively, to ordered phases (4). The 1-iodo derivative also exhibits a solid–solid phase transition; however, the high-temperature phase is not plastically crystalline (4, 5). The behaviour of 1-cyanoadamantane is drastically different from the halo derivatives (6). Upon cooling, the plastic crystal, phase I, undergoes a transition to phase II, which can be quenched to a glassy crystal, phase I_g. Upon heating, this glassy phase can be annealed to form a metastable phase, phase I′, which will then undergo an irreversible transition to phase II.

Several studies have been reported specifically on the phase behaviour of 1-fluoroadamantane. Differential scanning calorimetric measurements (4) revealed a phase transition at 222 K, with an enthalpy and entropy of transition of 1.50 kJ mol^{-1} and 6.77 J K^{-1} mol^{-1}, respectively. The melting temperature in a sealed tube was measured to be 525 K, but the entropy of fusion was not measured. Single-crystal X-ray diffraction (7)

1-fluoroadamantane

was used to determine the structure of the high-temperature phase as face-centred cubic (*Fm3m*), with four molecules per unit cell, with a = 9.535(4) Å. Although the entropy of fusion is not known, the cubic structure suggests that the high-temperature phase of fluoroadamantane is plastic. The molecular motions in this phase were investigated by ^{1}H, ^{19}F, and ^{13}C NMR spectroscopy, by measuring T_1 relaxation times (8), by incoherent quasielastic neutron scattering (9), from dielectric properties (10), and by Raman scattering from a single crystal (11). The reorientational motions of fluoroadamantane could be separated into two components: rotation about the threefold molecular axis, and a tumbling motion of the molecular axis about eight distinguishable equilibrium orientations along the ⟨111⟩ directions of the cubic lattice. The results of the different techniques agreed very well with each other; the correlation times of the motions could be described by Arrhenius laws (9):

[1] $\tau_{C4} = 9.3 \times 10^{-13} \exp(2960/T)$ s

[1]Authors to whom correspondence may be addressed.

[2] $\tau_{M3} = 5.9 \times 10^{-13} \exp(1560/T)$ s

where τ_{C4} is the correlation time of the tumbling motion, and τ_{M3} is that of molecular rotation. The activation energies for the tumbling and rotational motions are therefore 24.6 and 13.0 kJ mol^{-1}, respectively. These barriers are comparable to those in the plastic phase of 1-chloroadamantane (12), reflecting the structural similarities of the two solids. Only the ^{1}H wideline NMR and dielectric experiments were successfully carried out below the phase transition temperature. According to proton second-moment measurements, the phase transition does not qualitatively change the reorientational motions, which slow down progressively until a rigid lattice is formed near 80 K (8). The crystal structure of the phase below 222 K could not be determined precisely because the single crystals cracked upon cooling through the transition; however, the low-temperature phase was shown to be non-cubic even at 4 K (10). The dielectric measurements suggested that the low-temperature lattice is tetragonal, as in adamantane (13, 14), with one of the ⟨001⟩ directions of the cubic lattice remaining as a fourfold axis. The barriers to reorientation below and above the phase transition were determined by dielectric relaxation to be 29.1 and 19.0 kJ mol^{-1}, respectively. The knowledge of the structure and the degree of order of fluoroadamantane below 222 K, therefore, remains elusive.

Recently, a "symmetry departure" model was used to explain glass transitions in molecular crystals such as cyclohexanol and 1-cyanoadamantane (15), and an analysis of the available data on fluoroadamantane led to the prediction of a glass transition, upon heating, near 90 K. The IR spectrum, measured in solution, has been reported, but with virtually no assignments (16), and, except for the few bands measured from the single crystal (11), the full Raman spectrum has yet to be described. The behaviour of fluoroadamantane under pressure also remains unexplored, and, due to the apparent disorder down to 4 K, the effect of pressure may be different from the effects that result from lowering the temperature. Thus, as an extension of previous studies on the chloro and bromo derivatives (17–19), the phase behaviour of fluoroadamantane was investigated by low-temperature and high-pressure vibrational spectroscopy.

Experimental

Sublimed crystals of 1-fluoroadamantane were provided by Ms. K. Khougaz and Professor P. G. Farrell (McGill University). Proton NMR analysis (200 MHz) did not reveal the presence of any impurities, and the sample was used without additional purification.

Differential scanning calorimetry (DSC) was performed on a Perkin–Elmer DSC-7 calorimeter with liquid nitrogen as the coolant. Both the temperature and enthalpy of the calorimeter were calibrated by using the phase transition of cyclohexane (Aldrich, Gold Label). The sample, typically 5–10 mg, was weighed on a Cahn microbalance and hermetically sealed in an aluminium pan. Thermograms were obtained on cooling and on heating at a scanning rate of 5 K min^{-1}.

Infrared spectra were acquired on a Nicolet 6000 FT-IR spectrometer with a liquid nitrogen cooled MCT-B (mercury cadmium telluride) detector. A spectral resolution of 1 cm^{-1} was employed. Raman spectra were recorded on an Instruments S.A. spectrometer with a Jobin–Yvon Ramanor U-1000 double monochromator, with an IBM PS/2 model 60 computer for data collection and processing. The excitation source was the 514.532-nm line of a Spectra Physics model 165-5W argon ion laser. In the variable-temperature experiments, the sample temperature was maintained with a Cryodyne Cryocooler model 21 cryostat (Cryogenics Technology Inc.) and measured using a silicon diode thermocouple attached to a Cryophysics model 4025 controller. Infrared and Raman spectra were measured over a wide temperature range (60–295 K) on both cooling and heating, and at every 5 K near the phase transition. In the Raman spectroscopic experiments, the sample was sealed in a glass capillary tube and mounted onto the cold finger in the cryostat with indium foil as a conducting junction. Typically, the laser power at the sample was 300 mW and a resolution of between 1 and 2.5 cm^{-1} was obtained. For the IR spectra, the sample was sublimed onto a KBr window attached to the cold finger. The sample was then annealed through the phase transition until the spectra of the two phases remained consistent. Although the cryostat was usually operated under vacuum, a nitrogen atmosphere was also used to prevent sublimation of phase I from the window.

Variable-pressure Raman spectra were obtained using a diamond anvil cell (DAC) from Diacell Products, Leicester, England, equipped with type IIA diamonds. The sample, together with a ruby chip as a pressure calibrant (20), was placed in the 300-μm hole of a 380 μm thick stainless steel gasket between the diamonds. The DAC was placed under the 4× objective of the Nachet optical microscope coupled to the spectrometer. Typically, a resolution of 4 cm^{-1} was employed and about 50 mW of laser power at the sample were used. Spectra were measured upon compression every 1–5 kbar up to 60 kbar (1 bar = 100 kPa).

The DAC used in the IR experiments was from High Pressure Diamond Optics (Tucson, Arizona), and was also equipped with type IIA diamonds. A 200 μm thick stainless steel gasket was used between the diamonds. The pressure calibrant chosen was the antisymmetric stretching mode of NO_3^- in $NaNO_3$ diluted in a NaBr matrix (0.1–0.3 wt.%) (21). The DAC was mounted onto an XYZ stage, which was aligned on a Spectra-Bench 4× beam condenser (Spectra-Tech). Infrared spectra were obtained upon compression and decompression at 1–3 kbar intervals up to 22 kbar.

Results and discussion

Differential scanning calorimetric measurements of fluoroadamantane confirmed the presence of a single phase transition (phase I ⟶ phase II) at 227 K on cooling, with enthalpy and entropy changes of 1.7 kJ mol^{-1} and 7.6 J K^{-1} mol^{-1}. Upon heating, the transition displayed a slight hysteresis, occurring at 231 K, with ΔH_t and ΔS_t of 1.6 kJ mol^{-1} and 6.9 J K^{-1} mol^{-1}. This transition temperature is higher than the value of 222 K (on heating) reported in the literature (4). No other phase transitions were observed by DSC, and repeated cycling of the sample between 298 and 123 K did not affect the phase I ⟶ phase II transition temperature.

Variable-temperature IR and Raman spectra were measured at every 5 K on cooling and on heating between 250 and 200 K, i.e., through the phase I ⟶ phase II transition temperature. Spectra of each phase are shown in Figs. 1 and 2. Upon comparison of these spectra, very few differences are apparent, but a definite narrowing of peaks did occur suddenly at the transition point. Figure 3 is a plot of linewidths (FWHH) of two isolated bands versus temperature, in the cooling direction. In both cases, there is a distinct decrease in the linewidths at the phase transition, and the C–H stretching region showed the most pronounced changes. In both the IR and Raman spectra, phase I is characterized by a peak at 2857 cm^{-1} and then a broad envelope of peaks centred at about 2928 cm^{-1}. In phase II, the narrowing of peaks is sufficient to resolve the band at 2891 cm^{-1}, and the other higher-frequency C—H stretching bands appear as a more rounded band centred at about 2930 cm^{-1}. The Raman spectra of both phase I and phase II do not contain any discrete peaks below 100 cm^{-1}, indicating that, on the timescale of the Raman measurements, the molecular motions are isotropic. This agrees well with the reorientational correlation times reported in the literature

(17). Further cooling of phase II down to 60 K did not induce any other observable phase transitions. To see if the glassy crystalline structure would anneal to an ordered crystal, the temperature of the sample was increased from 60 to 120 K by approximately 5 K every hour. If the glassy phase transformed to an ordered, crystalline phase, line narrowing and the appearance of sharp external modes would be expected. Such effects, however, were not observed in the Raman spectrum.

The vibrational peaks of phases I and II of fluoroadamantane are listed in Table 1. Raman polarization measurements were measured in CS_2 solution. While the spectra of adamantane itself have been assigned according to force-field calculations (22), other 1-substituted derivatives have been assigned simply by comparison with other molecules. The vibrational spectra of fluoroadamantane, $C_{10}H_{15}F$, should contain 72 normal modes. Under C_{3v} molecular symmetry, however, these transform as $\Gamma_{vib}{}^{int} = 17a_1 + 7a_2 + 24e$, where only the a_1 and e modes are IR and Raman active, and the a_2 modes are totally inactive. These can be separated into 15 C—H stretching modes ($\Gamma_{\nu(CH)} = 4a_1 + a_2 + 5e$), and 57 non-CH modes ($\Gamma_{non\text{-}CH} = 13a_1 +$

$6a_2 + 19e$). Therefore, there should be a total of 41 peaks coincident in the IR and Raman spectra, with nine of these in the C—H stretching region. A total of 50 bands were observed in the IR and Raman spectra of phase II, which should not display any solid-state effects, but where the linewidths are narrowed sufficiently to resolve close-lying bands. The vibrational spectrum was assigned with the aid of assignments for adamantane (23, 26) and other 1-substituted derivatives (23), and seven a_1 bands could be identified from the polarization measurements. Although C—F stretching bands usually occur between 1000

and 1400 cm^{-1} (24), it has been reported that, when adjacent to a C—C single bond, the C—F and C—C stretching vibrations become mixed and the lower frequency band is higher in C—F character (25). For example, in $(CH_3)_3CF$, the C—F stretching band occurs at 751 cm^{-1} whereas the symmetric and antisymmetric C—C stretches are observed at 892 and 1260 cm^{-1}, respectively (26). From comparisons with other 1-substituted adamantanes, the symmetric cage-breathing mode was assigned to the strong, polarized band at 774 cm^{-1}. Therefore, the C—F stretching vibration could be assigned to the polarized band at 730 cm^{-1}, and the peak at 1265 cm^{-1} is probably a skeletal stretching mode having *e* symmetry. As a consequence of the cage structure, the majority of the other bands between 800 and 1400 cm^{-1} are coupled, and involve contributions from skeletal stretching, and from methylene and methine C—C—H deformations. Based on valence force-field calculations for adamantane (22), the symmetric and antisymmetric methine C—H stretching modes are assigned to the bands occurring at 2891 and 2911 cm^{-1}, respectively. The remaining C—H stretches were assigned to the methylene hydrogens, and their symmetries were determined according to the polarization measurements.

In the cases of adamantanone (27), 2-chloroadamantane (17), and 1-chloroadamantane (17), the behaviour of the compounds under pressure mimicked their low-temperature results. These molecules, however, all displayed phase transitions to ordered, crystalline solids. The effects of pressure on fluoroadamantane, therefore, may or may not be analogous to the low-temperature experiments. Initially, Raman spectra were measured over a wide pressure range of 59 kbar. Figure 4 shows the C—H stretching region through a range of moderate pressures. Below 1.7 kbar, the spectrum resembles those observed for phase I in the variable-temperature experiments. Between 1.7 and 4.5 kbar, however, the shoulder at about 2945 cm^{-1} becomes better separated from the remainder of the higher-frequency C—H bands. This is analogous to the observations of the phase I → phase II transition under low-temperature conditions. The additional application of pressure,

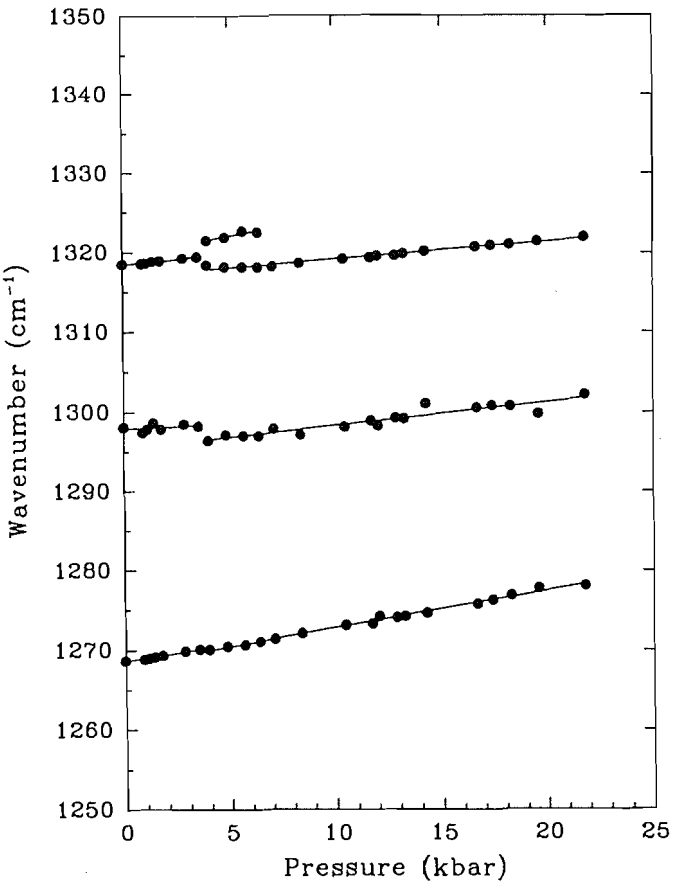

FIG. 7. Pressure dependences of selected IR bands of 1-fluoroadamantane.

even as high as 59 kbar, did not induce any other phase transitions. It is concluded, therefore, that the glassy phase also forms upon compression, and will not spontaneously crystallize even under very high pressure.

High-pressure IR experiments were performed, but at smaller pressure increments and over a narrower range of pressures. Figure 5 shows the C—H stretching region of the IR spectrum at various pressures. Although the line-narrowing effect is not as obvious as in the Raman spectra, the phase I → phase II transition can be observed between 2.8 and 3.9 kbar. The IR experiments were also used to measure the spectral changes that occur to the peak at 1318 cm^{-1}, which is a combination of C—C stretching and various C—C—H and CH_2 bending modes. In Fig. 6(A), the splitting of this peak into two due to sudden line narrowing is observed between 2.8 and 3.9 kbar, which is analogous to the effect that occurred upon lowering the temperature (Fig. 6(B)), and offers further proof of the occurrence of the phase transition at 3.3 ± 1.0 kbar. In another attempt to induce the second phase transition, the sample was left under 22 kbar of pressure for a period of 36 h, and then left at 18 kbar for an additional 36 h. From our experience, these pressures correspond roughly to cooling the sample at 20 K and then around 80 K, respectively. As in the low-temperature experiments, a crystalline phase of fluoroadamantane did not form.

The pressure dependences of several modes were measured in both the IR and Raman spectra. Since more points were obtained in the IR spectra at moderate pressures, the dv/dp values were measured from the IR rather than the Raman spectra whenever possible. Figure 7 shows the pressure dependences of selected peaks in the IR spectrum, and Table 2 lists the pressure dependences of all the vibrational bands measured. Overall, the dln ν/dp values of both phases are quite high, which is consistent with the disordered nature of phases I and II. The pressure dependences of several Raman bands of adamantane itself have been reported (28), and these dln ν/dp values are also very high, ranging from −0.5 to 14×10^{-4} $kbar^{-1}$ for the skeletal modes, and from 1.1 to 3.2×10^{-4} $kbar^{-1}$ for the C—H stretching vibrations. The totally symmetric, cage-breathing vibration in adamantane, occurring at 759 cm^{-1}, has the highest pressure dependence of 14×10^{-4} $kbar^{-1}$. These pressure dependences can be compared to the dln ν/dp values for the 773 cm^{-1} peak of fluoroadamantane (9.2×10^{-4} and 7.0×10^{-4} $kbar^{-1}$ in phases I and II, respectively). The disordered phases of these adamantanes belong to the same space group, *Fm3m*, $Z = 4$, where $a = 9.445$ Å for adamantane (29), and $a = 9.53$ Å for fluoroadamantane (7). From these unit cell dimensions, the densities of these solids are calculated to be 1.07 and 1.18 g cm^{-3}, respectively. It is reasonable, therefore, that the pressure dependence of the cage-breathing mode of fluoroadamantane has a lower value compared to that in adamantane, because its crystal density is higher, and its lattice should be less compressible.

Upon examination of the pressure dependences within the fluoroadamantane molecule, those of the 729 and 773 cm^{-1} peaks are particularly high. This is expected since these bands have been assigned in the variable-temperature section as the symmetric C—F and C—C stretching modes, respectively, and stretching vibrations generally have higher pressure dependences than bending motions (30, 31). The C—C stretching mode has a higher pressure dependence compared to the C—F stretch in both phases I and II; the C—F bond length in fluoroadamantane was reported to be 1.370 ± 0.004 Å by microwave spectroscopy (32), and the C—F stretching force constant is typically 6.0×10^{-5} dyn cm^{-1} (33). Thus, the higher force constant causes the C—F bond to be less compressible, and the pressure dependence is slightly lower than that of C—C vibrations, even though the former also has a shorter bond length. The peaks at 814, 904, and 1045 cm^{-1} also have relatively large pressure dependences, and these bands can therefore be assigned to modes that also have significant contributions from skeletal stretching vibrations. The peaks that have very low dln ν/dp values are largely deformation modes, i.e., those at 1316 and 1354 cm^{-1} are CH_2 twisting or wagging vibrations. Although the C—H stretching region could not be fully explored, due to the extensive overlap of these peaks, the two bands that were measured suggest that their pressure dependences are relatively low, compared with, for example, the data obtained for the smaller cage molecules norbornadiene (30) and norbornylene (31). This can be attributed to the absence of ring strain in the fluoroadamantane molecule.

Conclusion

The phase behaviour of 1-fluoroadamantane has been explored by DSC, and by vibrational spectroscopy at low temperatures and at elevated pressures. The phase transition which occurs under pressure is the same as that which occurs upon lowering the temperature. Below the phase transition temperature, or above the corresponding transition pressure, the formation of a glassy-crystalline phase was observed. This behaviour is similar to that of cyanoadamantane, and it sets 1-

fluoroadamantane apart from the other halo derivatives. It is interesting to note that, upon changing the halogen substituent from F to Cl to Br to I, the number of ordered and disordered phases also changes. This trend may be due to differences in dipole moment, size of the substituent, or other molecular properties. This substituent effect may be further expanded by considering the halo-adamantanes substituted at the 2-position. In this case, the bromo derivative exhibits one phase transition, whereas the chloro derivative undergoes two solid–solid transitions (17). No investigations of the solid-state phase behaviour of either 2-fluoro or 2-iodoadamantane have been reported up to the present time.

The structure of the solvated lithium cation in methyl acetate (MA) solutions has been investigated using Raman spectroscopy. Two bands at 844 and 864 cm^{-1} have been assigned to two different types of MA: the former is from the bulk solvent and the latter arises from MA molecules solvating the lithium cation. From measurement of changes in intensity of these bands with increasing salt concentration a solvation number of four for Li^+ in MA has been inferred. Changes in the Raman bands at ca. 1740 cm^{-1} suggest that solvation occurs through the carbonyl group. Evidence for contact ion pairing between Li^+ and AsF_6^- is also presented. An equilibrium between solvent-shared ion pairs and contact ion pairs is proposed for which an equilibrium constant is estimated. The system $LiAsF_6$/methyl formate (MF) is similar in structure.

Key words: Raman, ion pair formation, lithium and hexafluoroarsenate ions, methyl acetate and formate, lithium ion solvation.

ZHONGYI DENG et DONALD E. IRISH. Can. J. Chem. **69**, 1766 (1991).

Faisant appel à la spectroscopie Raman, on a étudié la structure du cation de lithium solvaté dans des solutions d'acétate de méthyle (AM). On a attribué les deux bandes observées à 844 et à 864 cm^{-1} à deux types différents d'AM; la première est attribuée à la masse de la solution alors que la deuxième est attribuée à l'AM solvaté par le cation lithium. En se basant sur des mesures de changement dans l'intensité de ces bandes avec une augmentation de la concentration du sel, on peut déduire que le nombre de solvatation du Li^+ dans l'AM est égal à quatre. Des changements dans les bandes Raman aux environ de 1700 cm^{-1} suggèrent que la solvatation se produit par le biais du groupe carbonyle. On présente aussi des données suggérant l'existence de paires d'ions de contact entre le Li^+ et le AsF_6^-. On suggère qu'il existe un équilibre entre les paires d'ions partagées par le solvant et les paires d'ions de contact; on en a évalué la constante d'équilibre. La structure du système $LiAsF_6$/formiate de méthyle (FM) est semblable.

Mots clés : Raman, formation des paires d'ions, ions de lithium et hexafluoroarsénate, acétate et formiate de méthyle, solvatation du ion de lithium.

Introduction

The search for new electrolyte–solvent systems capable of providing improved performance of both primary and secondary lithium cells and batteries is ongoing. Aprotic solvents, such as ethers, esters, amides carbonates, nitriles, and dimethyl sulfoxide, either alone or mixed, have received extensive study (1). Effort has been focused on overcoming the inferior conductivity of the electrolyte, relative to aqueous systems. Recently methyl formate (MF) and methyl acetate (MA) were identified as possible solvents (2–5). Conductance measurements (3–5) and, for MA/$LiAsF_6$ and MA/$LiClO_4$, microwave relaxation spectroscopy and some infrared spectra (5) have been reported. Solutions of MA have a surprisingly high conductance over a wide temperature range. Despite evidence for ion pairing, strong ion–solvent interactions were also suggested in these studies.

Raman spectroscopy has proved to be a powerful technique for probing ion–ion and ion–solvent interactions. Recently Hyodo and Okabayashi studied local structure in $LiClO_4$/EC (ethylene carbonate) and mixed solvent systems (6). We have reported Li^+ solvation in CH_3CN solutions, and adsorption of the species at silver electrode surfaces (7). In anticipation of surface Raman studies of the electrode systems Ag/MA, $LiAsF_6$ and Li/MA, $LiAsF_6$, the present investigation was undertaken to gain knowledge of the solvation number of Li^+ in MA (and MF), the extent of ion pair formation, and the spectral changes that could be expected because of such phenomena. $LiAsF_6$ has been regarded favourably as an electrolyte salt because of its high conductivity and apparent stability towards lithium (8). We chose $LiAsF_6$ for this study because of the previous work done with $LiAsF_6$/MA (5). Future work will focus on the new class of imide and methide salts (9).

Experimental

Reagents and solution preparation

The following chemicals were used without further purification: lithium hexafluoroarsenate ($LiAsF_6$) electrochemical grade (Lithco, Lithium Corp. of America); methyl acetate (MA) and methyl formate (MF) anhydrous, 99+% (Aldrich Chemical Co.); 18-crown-6, 99% (Aldrich Chemical Co.). Solutions were prepared by weight and concentrations are expressed as moles per kilogram of solvent. The lithium salt was slowly added to the solvent in a dry-box with an argon atmosphere.

Raman spectra

All Raman spectra were recorded using a Jarrell–Ash 25-100 1.0-m Czerny–Turner monochromator equipped with a model 129 digital cosecant stepping drive, an RCA 31034 selected photomultiplier tube, and an SSR model 1104/1120 photon-counting system. This spectrometer operates under microcomputer control. Data can be transmitted to a DEC PRO 380 microcomputer, interfaced to a VAX 11/785. On this system programs for baseline correction and spectral bandfitting are available; the program used is an adaptation of the one developed by Pitha and Jones (10) and subsequently modified by Murphy and Bernstein (11).

Results and discussion

Raman spectra of pure MA and $LiAsF_6$/MA

The Raman spectrum of pure methyl acetate in the 150–1850 cm^{-1} range is presented in Fig. 1(a). The observed Raman frequencies and assignments are given in Table 1. The Raman

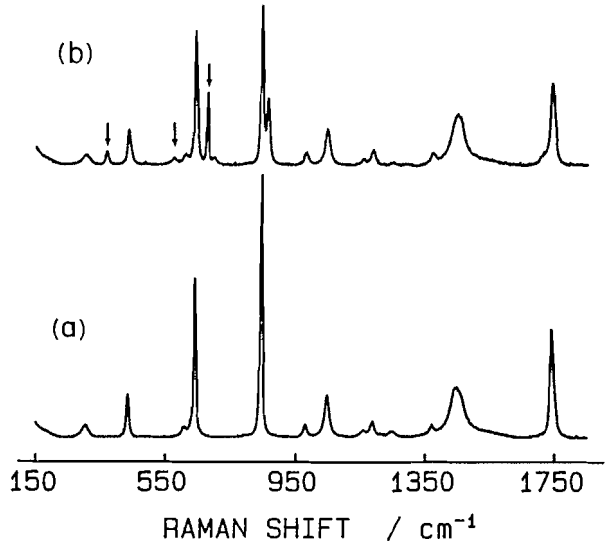

FIG. 1. Raman spectra of (a) pure MA and (b) 1 *m* $LiAsF_6$/MA in the 150–1850 cm^{-1} region. Arrows designate bands of AsF_6^-. Here and hereafter the vertical axis indicates the intensity in arbitrary units unless otherwise specified.

spectrum of 1 *m* $LiAsF_6$/MA is shown in Fig. 1(b). Raman bands of AsF_6^- are marked by arrows. The Raman bands of methyl acetate show little change of frequency or shape on addition of $LiAsF_6$, except for Raman bands at ca. 844 cm^{-1} and at ca. 1740 cm^{-1}. The Raman band at 844 cm^{-1} has been assigned to the C—C symmetric stretching mode (12, 13). A second band at 864 cm^{-1} increases in intensity as the concentration of solute increases. The Raman band at about 1740 cm^{-1} has been assigned to the C=O stretching vibration (12–14). A shoulder at 1720 cm^{-1} also increases with the increase of concentration of solute.

The AsF_6^- anion has octahedral symmetry (O_h) and thus its 15 normal modes of vibration span the representation:

$$\Gamma = A_{1g} + E_g + 2F_{1u} + F_{2g} + F_{2u}$$

Of these $\nu_1(A_{1g})$, $\nu_2(E_g)$, and $\nu_5(F_{2g})$ are Raman active, $\nu_3(F_{1u})$ and $\nu_4(F_{1u})$ are infrared active, and the F_{2u} mode is inactive. The Raman and infrared spectra of AsF_6^- in polycrystalline $CsAsF_6$ have been reported (15). Raman bands at 685, 576, and 372 cm^{-1} have been assigned to ν_1, ν_2, and ν_5, respectively. Infrared bands at 699 and 392 cm^{-1} were assigned to ν_3 and ν_4, respectively. The ν_6 band position was estimated as 322 cm^{-1} (15); it has been observed at 252 cm^{-1} for $O_2^+AsF_6^-$ (16), in which the O_h symmetry is lowered to T_h.

In MA the Raman bands of AsF_6^- occur at 676, 572, and 366 cm^{-1}. A shoulder at about 696 cm^{-1} can be seen in Fig. 1(b). Farber *et al.* (17) attributed this weak band to the Raman forbidden ν_3 mode, made active by perturbations from the solvent.

Inoue *et al.* (18) have studied the ν_3 infrared band region of $LiAsF_6$ in several organic solvents. They observed three bands in this region. A band at 702 cm^{-1} was assigned to the "spectroscopically free" AsF_6^-, including solvent-separated ion pairs $Li^+SAsF_6^-$ (and possibly dimers). A band at 717 cm^{-1} was

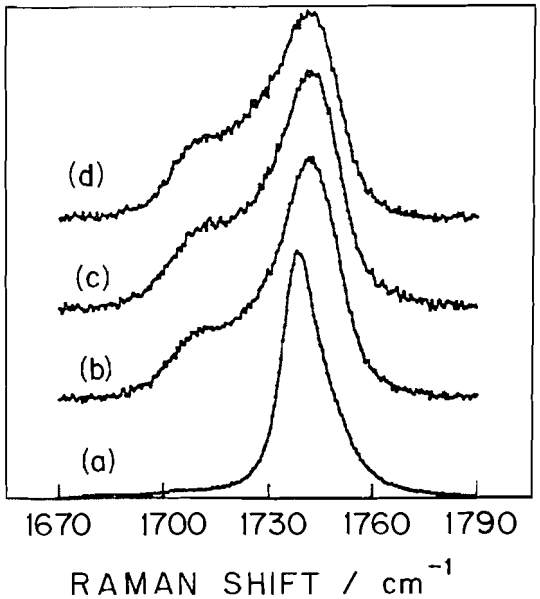

FIG. 2. The dependence on the concentration of $LiAsF_6$ of the Raman intensity in the C=O stretching region, 1670–1790 cm^{-1}. Concentrations are (a) 0; (b) 1.5; (c) 2.8; (d) 4.1 *m* respectively.

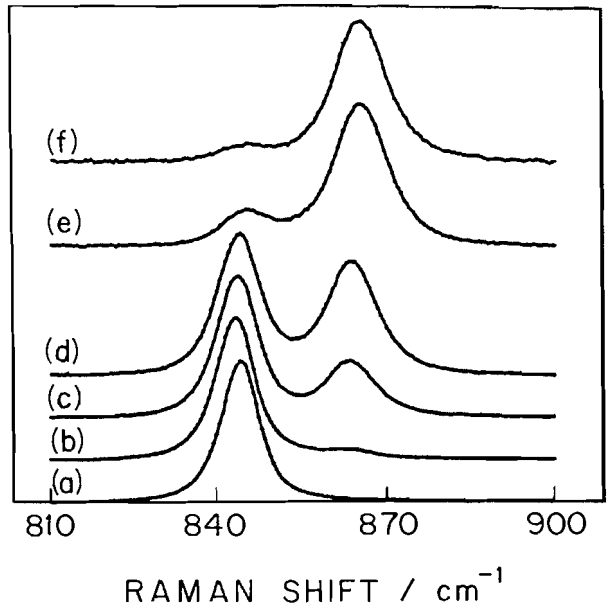

FIG. 3. The dependence on the concentration of $LiAsF_6$ of the Raman intensity in the H_3C—C stretching region, 810–900 cm^{-1}. Concentrations are (a) 0; (b) 0.2; (c) 1.0; (d) 1.5; (e) 2.8; (f) 4.1 *m* respectively.

assigned to a contact ion pair $Li^+AsF_6^-$, and the 676 cm^{-1} band was assigned to a combination $\nu_5 + \nu_6$.

We shall discuss the new features in the spectra in detail.

The C=O stretching mode spectral region of methyl acetate

Three new bands occur in addition to the Raman-active bands of methyl acetate and lithium hexafluoroarsenate in Fig. 1(b). First we discuss the shoulder (1720 cm^{-1}) of the C=O stretching vibration mode of methyl acetate ($\nu_5 \cong 1740$ cm^{-1}). Figure 2 illustrates how the Raman spectra in the C=O stretching vibration region of MA change as the concentration of $LiAsF_6$ increases. Figure 2(a) is the spectrum of pure MA; Figs. 2(b), (c), and (d) are the spectra of 1.5 *m*, 2.8 *m*, and 4.1 *m* $LiAsF_6$/MA, respectively. The band of pure MA is asymmetrical on the high-wavenumber side of the peak maximum but otherwise it has a simple contour. For the electrolyte solution there is obviously a new band at ca. 1720 cm^{-1}, which increases in intensity when the concentration of $LiAsF_6$ increases. These bands suggest that two kinds of methyl acetate coexist in the electrolyte solution. One kind, from the bulk solvent, described as "free", generates the 1740 cm^{-1} band. The other kind solvates the lithium cation and gives the 1720 cm^{-1} band. The lithium cation probably binds through the carbonyl functional group of methyl acetate, because the C=O stretching vibration has been very strongly affected by solvating with lithium cation. None of the other vibrational modes, except the C—C stretching vibration (to be discussed below) of methyl acetate, was significantly affected by the solvation.

The C—C stretching mode spectral region of methyl acetate

Raman spectra in the 810–900 cm^{-1} region of methyl acetate (a) and $LiAsF_6$/MA solutions ((b)–(f)) are presented in Fig. 3. As the concentration of $LiAsF_6$ increases from 0.2 to 4.1 *m*, a new band at 864 cm^{-1} increases in intensity at the expense of the 844 cm^{-1} band.

The ratio of the intensity of the Raman band at 864 cm^{-1} (I_{864}) to the intensity of the Raman band at 844 cm^{-1}, ν_{14} of methyl acetate (I_{844}), I_{864}/I_{844}, changes from 0.059 for 0.2 *m* to 12.19 for 4.1 *m* $LiAsF_6$. The relative intensities of these two bands depend

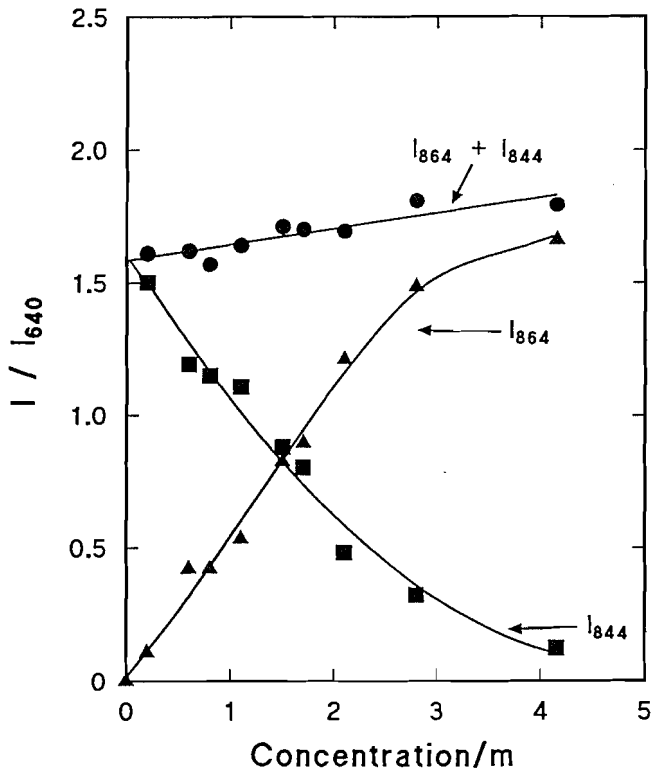

FIG. 4. Relative integrated intensities of the 844 and 864 cm^{-1} bands and their sum versus the concentration of $LiAsF_6$.

on the concentrations of the solutions, but the total combined intensity of these two bands ($I_{864} + I_{844}$) is almost constant, as shown in Fig. 4. The band at 844 cm^{-1} is assigned to the C—C stretching vibration of "free" methyl acetate and the band at 864 cm^{-1} is assigned to the C—C stretching vibration of the species solvating the lithium cations. It may be significant that the 864 cm^{-1} band has a larger full width at half-peak maximum (FWHM) than the 844 cm^{-1} band. The difference diminishes

from about 3.7 cm^{-1} for 0.2 *m* solution to about 0.8 cm^{-1} for 4.1 *m* solution. The larger FWHM for the band from MA molecules in the lithium ion solvation sphere suggests a shorter lifetime for MA in the solvation shell of Li^+; such lability is expected for a solvent complex. The enhanced FWHM decreases as the amount of bulk solvent decreases.

In the discussion above, the ν_{14} mode has been described as C—C stretch, in accordance with an early assignment by Wilmshurst (13). The normal coordinate analysis of Matzke *et al.* (19) suggests that this is a mixed mode with 39.5% H_3C—C stretch, 24.3% C—O stretch, 16.7% O—C—O bend, and 11.5% C=O stretch. In a later report by George *et al.* (14) the ν_{14} mode is assigned to the CH_3—O stretch. In recent publications dealing with metal ion – acetate ion complexing (20, 21) we have observed that the C—C stretch of acetate ion is sensitive to the addition of a cation; it shifts from 926 cm^{-1} to 939 cm^{-1} on binding to Mg^{2+}, Pb^{2+}, or Zn^{2+}. The present shift for the ester–lithium interaction is somewhat comparable. In the absence of more extensive normal coordinate calculations we shall continue to designate ν_{14} as a C—C stretch but recognise the probability that there can be a significant contribution from the C—O stretch in the normal mode. Probably in solution and particularly when binding to a cation the ester would adopt the *cis* conformation.

The addition of crown ethers

Crown ethers and cryptands are good macrocyclic ligands for alkali-metal cations (22–24). It has also been reported that charge transport of a lithium salt in a solid electrolyte is enhanced by addition of crown ethers (25, 26). It is interesting to observe the effect of adding a crown ether or cryptand to the present system. In view of the cavity size of the macrocyclic ligands, the most suitable for sequestering the lithium ion should be 12-crown-4 and Kryptofix 211. Unfortunately, white precipitates formed when these were added to concentrated $LiAsF_6$/MA solutions. A precipitate also formed when 15-crown-5 was added to the system. Surprisingly, no precipitate formed when 18-crown-6 was added to the system, even at a concentration equal to half of the concentration of $LiAsF_6$.

The effect of addition of 18-crown-6 is illustrated in Fig. 5 and Table 2. Figures 5(a), (b), and (c) show Raman spectra of 2 *m* $LiAsF_6$/MA, 2 *m* $LiAsF_6$/MA + 1 *m* 18-crown-6, and 1.1 *m* $LiAsF_6$/MA, respectively. It is clear that the intensity of the C—C stretching vibrational mode, 844 cm^{-1}, is lower than that of the solvation band, 864 cm^{-1}, for 2 *m* $LiAsF_6$/MA. The reverse is true for 2 *m* $LiAsF_6$/MA + 1 *m* 18-crown-6. The ratio of the intensities of the two bands I_{844}/I_{864} in 2 *m* LiAsF6 + 1 *m* 18-crown-6 is almost the same as that in 1.1 *m* $LiAsF_6$/MA (Fig. 5 and Table 2). Also note that the intensity of the new band at 696 cm^{-1} in Fig. 5(b) is much lower than the intensity in 5(a). I_{696} in the former system is almost the same as that in 1.1 *m* $LiAsF_6$/MA. The intensity data are listed in Table 2.

The interpretation of these results is as follows. One molecule of 18-crown-6 sequesters one lithium cation, thus lowering the concentration of $Li^+(CH_3CO_2CH_3)_x$ and so reducing the intensity of the 864 cm^{-1} band to that of a 1.1 *m* solution. Thus the observation supports the assignment of the 864 cm^{-1} band to molecules in the first solvation sphere of Li^+. The observation of diminished intensity of the 696 cm^{-1} band will be dealt with below.

The determination of the solvation number of lithium cation

To calculate the concentrations of the free methyl acetate and the complexed species from the measured Raman intensities of different salt concentrations, an intensity standard is required. An internal standard should ideally be sufficiently soluble in the solvent, should not have Raman bands that interfere with the bands being measured, and should not compete by complexation. We found the band of methyl acetate (solvent of the system) at 640 cm^{-1} (the O—C—O bend) to be satisfactory. It retained a single, symmetrical band profile on addition of the salt to MA and its integrated intensity appears to be a faithful measure of the total MA concentration.

One band that was studied at 696 cm^{-1} is quite weak when the concentration of $LiAsF_6$ is less than 1 *m*. To measure its intensity it was desirable to have an internal standard with comparable intensity; thus the 610 cm^{-1} band (the CH_3—CO_2 out-of-plane bend) was chosen. The ratio of the intensities I_{610} to I_{640} was found to be essentially constant over the concentration range 0.2–2.8 *m* $LiAsF_6$; the value was 0.0596 ± 0.0058. Thus both of these bands can serve as standards to obtain relative integrated intensities.

In Fig. 4 the relative intensities I_{844}/I_{640}, I_{864}/I_{640}, and $I_{total}/I_{640} = (I_{864} + I_{844})/I_{640}$ are plotted versus the concentration of $LiAsF_6$. The intensity of the band at 864 cm^{-1} increases and the intensity of the band at 844 cm^{-1} decreases as the concentration of salt increases. The total intensity, $(I_{864} + I_{844})/I_{640}$, remains almost constant over a quite wide concentration range. The increase of the intensity of the 864 cm^{-1} band with increasing concentration

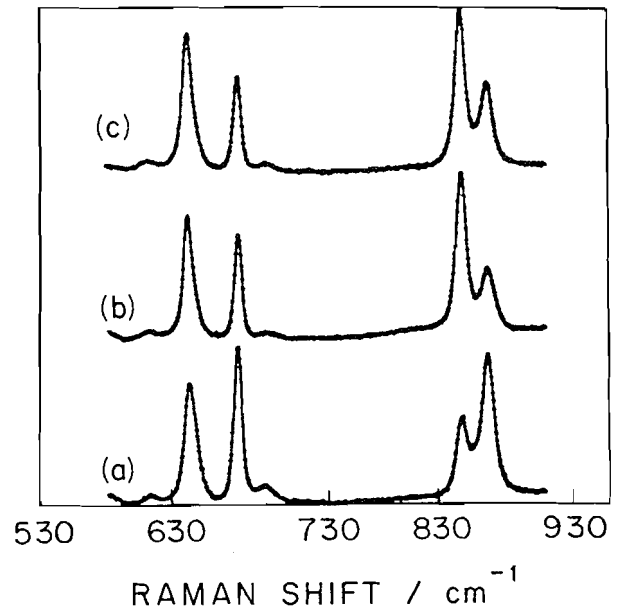

FIG. 5. Raman spectra of (a) 2 *m* $LiAsF_6$/MA; (b) 2 *m* $LiAsF_6$/MA + 1 *m* 18-crown-6, and (c) 1.1 *m* $LiAsF_6$/MA in the 590–900 cm^{-1} region.

TABLE 2. Raman intensity ratios for the system of $LiAsF_6$/MA with and without 18-crown-6

System	I_{676}/I_{640}	I_{696}/I_{640}	I_{844}/I_{640}	I_{864}/I_{640}
2.0 *m* $LiAsF_6$/MA	0.81	0.256	0.628	1.21
2.0 *m* $LiAsF_6$/MA +1.0 *m* 18-crown-6	0.53	0.063	1.21	0.52
1.06 *m* $LiAsF_6$/MA	0.44	0.058	1.06	0.67
1.5 *m* $LiAsF_6$/MA	0.53	0.081	0.085	0.77
1.5 *m* $LiAsF_6$/MA +0.5 *m* 18-crown-6	0.48	0.052	1.19	0.56

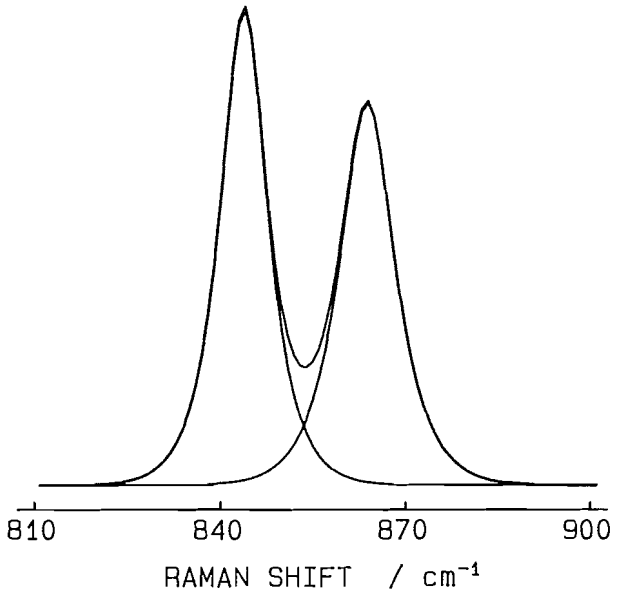

FIG. 6. The application of BNDFT to the spectrum of 1.5 *m* $LiAsF_6$/MA in the 810–900 cm^{-1} region.

of lithium cations is consistent with the assignment of the band to molecules in the primary solvation sphere of Li^+. The decrease in the intensity of the 844 cm^{-1} band is consistent with the assignment to the "free" methyl acetate molecules. The greater the concentration of lithium cations, the less is the amount of free methyl acetate left in the system. This fact supports the assignment of the two bands to the two different classes of solvent, viz., bulk (or free) and solvating.

Figure 6 illustrates the result of applying the BNDFT program to the spectrum of 1.5 *m* $LiAsF_6$/MA solution.

We designate the relative integrated intensity of the free species as I_f and its concentration as C_f; similarly for the bound species we define I_b and C_b. Assuming proportionality between intensity and concentration we can write

$$[1] \quad I_f = J_f C_f$$

and

$$[2] \quad I_b = J_b C_b$$

where J_f and J_b are the molar scattering coefficients for the two species.

Material balance requires that

$$[3] \quad C_{MA} = C_f + C_b$$

The total intensity is given by

$$[4] \quad I_T = I_b + I_f = J_b C_b + J_f C_f$$

If the molar scattering coefficients of the 864 and the 844 cm^{-1} bands are equal, and are set equal to J, then eq. [4] becomes

$$[5] \quad I_T = J(C_b + C_f) = JC_{MA}$$

On a molality scale of concentration, C_{MA} is constant and thus I_T should be independent of the concentration of salt. As Fig. 4 illustrates, this is not quite true; the slope of I_T vs. C_{Li} is not quite zero. There is indication that J_b may be somewhat larger than J_f.

Equation [4] can be rearranged to give

$$[6] \quad I_T = (J_b - J_f)C_b + J_f C_{MA}$$
$$= (1 - J_f/J_b)I_b + J_f C_{MA}$$

TABLE 3. Composition, relative integrated intensities, and solvation numbers of lithium

$LiAsF_6$/mol kg^{-1}	I_b	I_T	C_b/mol kg^{-1}	$\bar{n}_s$
4.1	1.551	1.678	12	2.8
2.8	1.485	1.808	11	3.9
2.2	1.333	1.866	9.8	4.5
1.7	0.8962	1.700	6.6	3.9
1.5	0.8264	1.708	6.1	4.1
1.3	0.7198	1.719	5.3	4.1
1.1	0.5854	1.645	4.3	3.9
0.79	0.4424	1.644	3.3	4.1
0.64	0.4227	1.616	3.1	4.9
0.18	0.1064	1.608	0.79	4.4

A plot of I_T versus I_b should be linear with a slope of $(1 - J_f/J_b)$ and an intercept of $J_f C_{MA}$, where C_{MA} is known and constant. The data give the equation

$$[7] \quad I_T = 0.129\, I_b + 1.59$$

with a correlation coefficient of 0.755. Thus $J_f = 0.118$ and $J_b = 0.135$, where $C_{MA} = 13.5$ mol kg^{-1}.

The solvation number of the lithium cation, equivalent to the average ligand number of lithium, $\bar{n}_s$, is defined as

$$[8] \quad \bar{n}_s = C_b/C_{Li} = I_b/(C_{Li}J_b)$$

This value is tabulated in Table 3 for each concentration of $LiAsF_6$. A solvation number of four for the lithium cation is suggested. This value is commonly found for the lithium cation in ionic crystals (27, 28) and aqueous solutions (29), and it has also been reported for solutions of $LiClO_4$ in ethylene carbonate (6). The lower values at higher salt concentrations are attributed to some ion pairing between Li^+ and AsF_6^-. At concentrations of salt greater than 3.4 *m* there is insufficient solvent to allow for a complete solvation sphere of four molecules of MA and thus some ion pairing and solvent-shell distortion must occur. Other evidence for ion pairing is presented below.

Raman spectral evidence for contact ion pairing in $LiAsF_6$/MA

Shown in Fig. 7 are Raman spectra of five concentrations of $LiAsF_6$/MA solutions in the 580–720 cm^{-1} region. The band with a maximum at ca. 610 cm^{-1} is ν_{24}, the $H_3C—O_2$ out-of-plane bending vibration mode of MA, a very weak band. The band with a maximum at 640 cm^{-1} is ν_{15}, the O—C—O bending mode of MA, which has been chosen as an internal standard as discussed above. The two bands at 676 and 696 cm^{-1} originate from the AsF_6^- ion. In this spectral region the infrared spectrum contains three bands at 717, 703, and 677 cm^{-1} (5). The assignments must rationalize both the Raman and infrared spectra. The Raman band at 676 cm^{-1} corresponds closely to the ν_1 (A_{1g}) mode of AsF_6^- (Table 4). For a 2.5 *m* aqueous solution of $LiAsF_6$ we observe this band at 682 cm^{-1}. Ion pairs are unlikely in aqueous solution and thus it is reasonable, based solely on spectroscopy, to assign this band to the "free" anion. However, from microwave dielectric relaxation and electrical conductivity measurements Salomon *et al.* (5) concluded that virtually no free ions exist in $LiAsF_6$/MA solutions, because of the low permittivity (6.67); solvent-separated ion pairs and possibly dimers, referred to as "spectroscopically free" because their vibrational signals are essentially indistinguishable from those of free ions, and contact ion pairs were proposed (5). Thus we will assign the 676 cm^{-1} Raman band to the ν_1 (A_{1g}) mode of solvent-shared ion

pairs. The 703 cm^{-1} infrared band is assigned to the ν_3 (F_{1u}) mode of the same species.

The 696 cm^{-1} Raman band is assigned to the ν_1 (A_{1g}) mode (under O_h symmetry and selection rules) of a contact ion pair. This band increases in intensity relative to the 676 cm^{-1} band as the concentration of $LiAsF_6$ increases. Shown in Fig. 8 is a typical example of the result of bandfitting the 580–720 cm^{-1} region for 2.8 *m* $LiAsF_6$/MA. The relationship between the intensity of the 676 cm^{-1} band and the 696 cm^{-1} band is illustrated in Fig. 9. The corresponding F_{1u} mode of the ion pair must be the 717 cm^{-1} infrared band. Its intensity increases with salt concentration in a manner analogous to the intensity of the 696 cm^{-1} Raman band, although it was only studied in dilute solutions (5). There is no trace of this band in the Raman spectrum, and it is forbidden by selection rules.

The remaining band to be assigned is the 676 cm^{-1} infrared band. Salomon *et al.* (5) assigned this band to the ($\nu_5 + \nu_6$) combination ($F_{2g} \times F_{2u} = A_{1u} + E_u + F_{1u} + F_{2u}$; active in infrared, inactive in Raman). We place the ν_5 (F_{2g}) mode at 366 cm^{-1}. Thus the forbidden F_{2u} mode would occur at ca. 311 cm^{-1}. This position is consistent with the estimate of Begun and Rutenberg

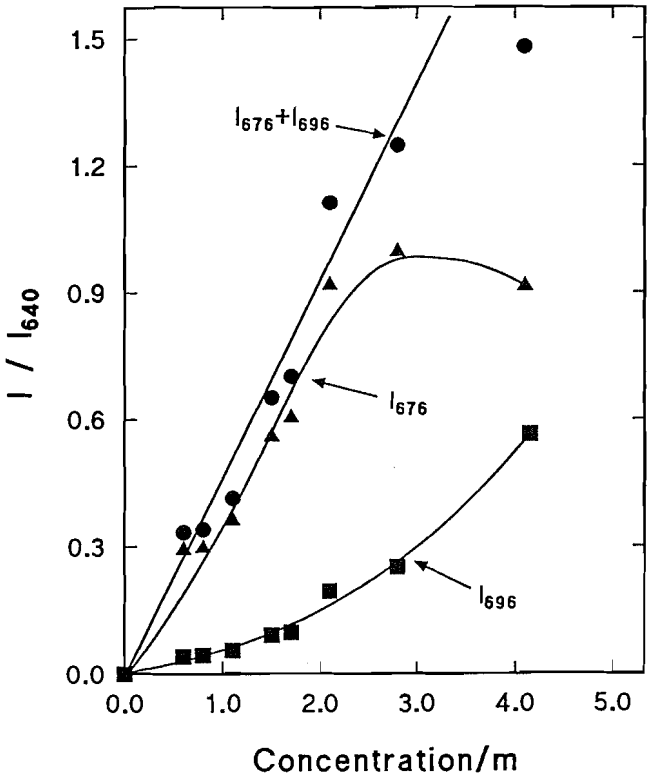

FIG. 9. Concentration versus the relative integrated intensities, I_{676}/I_{640} (▲) of the ν_1 band of the AsF_6^-, I_{696}/I_{640} (■) of the 696 cm^{-1} band attributed to the contact ion pair, and $(I_{676} + I_{696})/I_{640}$ (●).

(15). Because it is forbidden in the Raman spectrum and because combinations have weak Raman intensity, no contribution from this combination is expected under the intense 676 cm^{-1} Raman band. The assignments are summarized in Table 5.

Further evidence that the 696 cm^{-1} band originates from a contact ion pair is presented in Fig. 5 and Table 2. For a MA solution containing $LiAsF_6$ (2 *m*) and 18-crown-6 (1 *m*) the intensity of the 696 cm^{-1} band decreased markedly. Thus when

lithium is made unavailable such that ion pairing is diminished, the band intensity is diminished; the conclusion is that the band arises from ion pairing. An equilibrium of the following type is proposed:

[9] $Li(MA)_4^+AsF_6^- = Li(MA)_3^+AsF_6^- + MA$

Inoue *et al.* (18) have reported infrared spectra for $LiAsF_6$ in several organic solvents: acetone, 1,2-dimethoxyethane, tetrahydrofuran, 2-methyltetrahydrofuran, and dimethyl carbonate. In all cases three infrared bands were observed for AsF_6^-, and their assignments are as described above. The intensity of the 717 cm^{-1} band was found to be dependent on the permittivity of the solvent and the concentration. It was very weak in the case of acetone, a result also confirmed by our Raman measurements. Acetone has a permittivity of 20.7 compared to values of less than 7 for the other solvents. Thus the evidence for contact ion pairs in solvents of low permittivity from both Raman and infrared spectra is strong, despite the fact that experience has shown that the perturbations of the highly symmetrical anions (with T_d or O_h symmetry) by ion association are rarely sufficient to alter the symmetric vibrations significantly.

An estimate of the value of the equilibrium constant for process [9] can be arrived at from the intensity data in Fig. 9 if the following assumptions are made: the molar scattering factor of the 676 cm^{-1} band is equal to that of the 696 cm^{-1} band (this is probably true within 10% if the mode of vibration is the same and only the environment has changed); the concentration of free MA is given by

[10] $C_{MA} = C_{MA(TOTAL)} - 4(C_{MA,ssip}) - 3(C_{MA,cip})$

Here ssip refers to solvent-shared ion pair and cip refers to contact ion pair. The concentration quotient for process [9] is then

[11] $K = C_{cip}C_{MA}/C_{ssip}$

where the mole fraction of the contact ion pair is $X_{cip} = I_{696}/(I_{696} + I_{676})$ and $C_{cip} = X_{cip}C_{salt}$. The value of K is 1.2 ± 0.3 over the concentration range 0.64–2.8 *m* (average of seven values). In an independent experiment using reagents that were not dried, a value of K equal to 1.1 ± 0.2 was obtained over the concentration range 0.86–2.5 *m* (average of nine points). Thus a value of 1.2 ± 0.3 at ca. 25°C is within the present accuracy for the given model.

Extensions to the methyl formate (MF)/$LiAsF_6$ system

Methyl formate has also been identified as a possible battery electrolyte, despite its limited liquid range (mp −99°C; bp 34°C). Spectra of 4.4 *m* and 1.0 *m* solutions of MF/$LiAsF_6$ were measured for comparison with those of methyl acetate. Shown in Fig. 10 are spectra of pure MF and the 4.4 *m* $LiAsF_6$ solution in the 150–1850 cm^{-1} range. Three Raman-active bands of the AsF_6^- ion were observed (Table 4), contrary to the report of Venkatasetty (30) who observed only the ν_1 and ν_5 bands at 678 and 344 cm^{-1} respectively. In addition, the 696 cm^{-1} band, attributed to the ion pair, is clearly visible as a shoulder on the 675 cm^{-1} band.

The Raman band at 1718 cm^{-1}, assigned to the ν_4 C=O stretching vibration of MF (31), develops a distinct shoulder on the low-frequency side when $LiAsF_6$ is present (Fig. 10). This shoulder can be attributed to those MF molecules which are solvating the lithium cation, by analogy to the MA case. Because of the weakness of this shoulder, quantitative study was not undertaken.

Summary

From Raman spectra of $LiAsF_6$ in MA, a solvation number of four for the lithium cation has been inferred. Bonding through the carbonyl group is suggested. As the concentration of salt increases, the concentration of a contact ion pair also increases. An equilibrium between solvent-shared ion pairs and contact ion pairs is proposed. The equilibrium constant has been estimated as 1.2 ± 0.3 at 25°C. Spectral comparisons suggest that similar chemistry occurs in $LiAsF_6$/MF solutions.

This paper is dedicated to Dr. Richard Norman Jones

A. M. HEYNS, K.-J. RANGE, and K. MÜLLER. Can. J. Chem. **69**, 1774 (1991).

KHCOO II is orthorhombic at ambient conditions and it is shown that traces of moisture affect the polymorphism of these very hygroscopic crystals. Dry KHCOO II transforms into phase I at 417 K (144°C), and this phase can be supercooled to room temperature, remaining metastable for several days before transforming back to the orthorhombic phase II. The Raman spectra of phases I and II, as well as of supercooled phase I, are reported in the present study. The absence of some prominent translational modes in the Raman spectra of KHCOO II, compared to NaHCOO II, can be explained on the basis of a group-theoretical treatment. From the temperature dependence of the linewidths of various Raman-active librational and internal modes, activation energies are obtained for intramolecular motions of the formate ions. Fermi resonance occurs between the overtone of the bending mode $2\nu_5$ and the C—H stretching mode ν_1 in KHCOO II and the coupling constant W increases with temperature. The Raman and X-ray data show that KHCOO I is structurally different from NaCHOO I, but it is not possible to assign a definite structure to this phase on the basis of a Raman spectrum alone.

Key words: Potassium formate, phase transition, Raman spectra.

A. M. HEYNS, K.-J. RANGE et K. MÜLLER. Can. J. Chem. **69**, 1774 (1991).

À la température ambiante, le KHCOO II est orthorhombique; on a montré que des traces d'humidité affectent le polymorphisme de ces cristaux très hygroscopiques. À 417 K (144°C), le KHCOO II sec se transforme en phase I que l'on peut surgeler jusqu'à la température ambiante; il peut être maintenu dans cette forme métastable pendant plusieurs jours avant sa retransformation en phase II orthorhombique. Dans ce travail, on a mesuré les spectres Raman des phases I et II ainsi que de la phase surgelée. Pour expliquer l'absence de modes translationnels remarquables dans le spectre Raman de la phase II du KHCOO, par comparaison avec celui de la phase II du NaHCOO, on fait appel à un traitement théorique des groupes. Sur la base de la relation entre la température et les largeurs de bande des divers modes librationnels et internes actifs en spectroscopie Raman, on a déterminé les énergies d'activation des mouvements intramoléculaires des ions formiates. Dans le KHCOO II, il se produit de la résonance de Fermi entre l'harmonique du mode de vibration angulaire $2\nu_5$ et le mode d'élongation C—H ν_1; la constante de couplage W augmente avec la température. Les spectres Raman et les données de la diffraction des rayons-X démontrent que le KHCOO I est structurellement différent du NaHCOO I; il n'est toutefois pas possible d'attribuer un structure définie à cette phase uniquement sur la base d'un spectre Raman.

Mots clés : formiate de potassium, transition de phase, spectre Raman.

[Traduit par la rédaction]

Introduction

The polymorphism of NaHCOO (1–3), $LiHCOO \cdot H_2O$, and LiHCOO (4) has been investigated in our laboratories and it was found that these alkali metal formates exhibit complex behaviour as far as the variety of phases and their crystal structures are concerned. NaHCOO, in particular, undergoes a series of phase transitions upon the application of pressure (1) as well as upon heating to 500 K (227°C) at ambient pressures (2). Upon cooling the high-temperature phase I of NaHCOO, an intermediate phase is obtained that can be supercooled to room temperature, requiring an induction period of several days before transforming back to phase II, the modification stable at ambient conditions (3).

KHCOO has not been studied so thoroughly. It is known to be orthorhombic, belonging to the space group $Cmcm$ (D_{2h}^{16}) (5, 6). It undergoes a first-order phase transition at 418 K (145°C) with $\Delta H_{tr} = 0.1$ kcal mol^{-1} and $\Delta S_{tr} = 0.4$ cal mol^{-1} K^{-1} and melts at 441 K (168°C) (7). The Raman spectra of KHCOO have been reported at ambient temperatures (1); however, in the present paper we report the temperature dependence of its Raman spectra and these results are supplemented by DTA/DTG and X-ray powder diffraction measurements of the changes that occur at the phase transition and melting point temperatures during heating and cooling cycles.

Experimental

KHCOO has been prepared according to the equation:

$$2HCOOH + K_2CO_3 \rightarrow 2KHCOO + CO_2 + H_2O$$

Accordingly, formic acid was added to K_2CO_3 and the product formed was filtered off. The KHCOO so obtained was handled in a glove-box under an argon atmosphere. The crystals were heated at 423 K to remove the excess of formic acid. The product was then recrystallized from methanol and long, transparent needles were obtained. These crystals were dried under vacuum and kept in a desiccator under dry P_2O_5.

The Raman spectra were recorded on a Dilor Z-24 spectrometer using the 514.5-nm line of Coherent Innova-5 Ar^+-laser to excite the spectra. The samples of KHCOO were sealed in glass capillary tubes and were then placed in a heating oven obtained from Dilor Industries, Lille, France, for Raman measurements at ambient and higher temperatures. The resolution of the Raman bands quoted in this study is approximately 2 cm^{-1}.

Powder diffraction patterns at variable temperatures have been obtained on an Enraf–Nonius Delft Guinier–Simon camera, model FR 553. For these measurements the KHCOO samples were sealed in

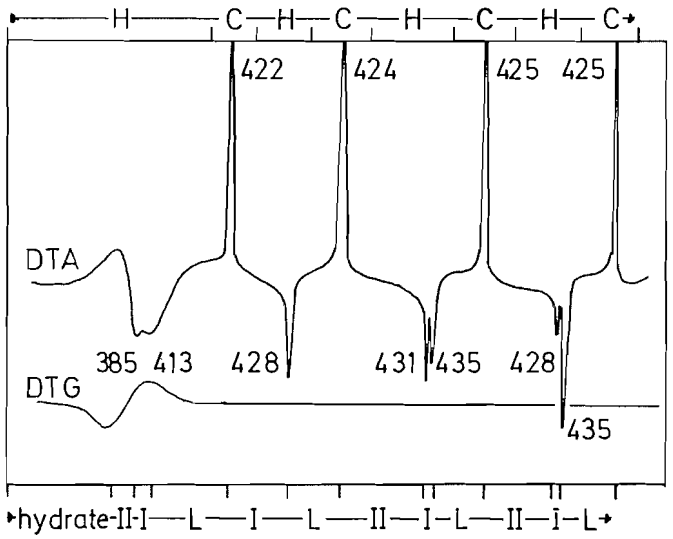

FIG. 1. DTA/DTG recordings of a KHCOO sample that has absorbed moisture during the sample preparation. The heating (H) and cooling (C) cycles are indicated at the top of the figure. At the bottom the two phases (I and II), and the liquid (L) are shown.

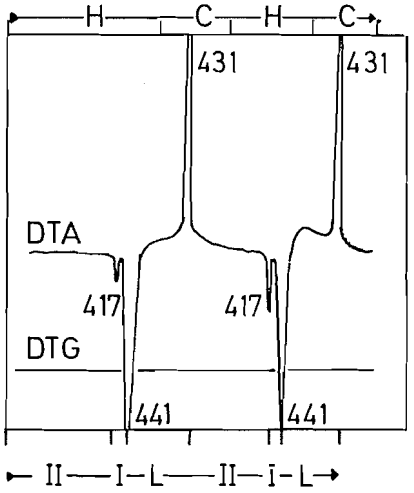

FIG. 2. DTA/DTG recordings of a dry sample of KHCOO. The heating (H) and cooling (C) cycles are indicated, as well as the temperature stability regions of phases I and II and those of the melt (L).

Lindemann tubes. A heating or cooling rate of 3 K min^{-1} was used in these experiments.

The DTA-TG recordings were made on a thermogravimetric-differential thermal analyser obtained from Rigaku, model 8076 D1. Great care had to be exercised to prevent the absorption of any moisture by the very hygroscopic KHCOO crystals, and the samples were thus sealed from the atmosphere after the containers and sampling area had been thoroughly dried and kept under a dry argon atmosphere. The heating and cooling rate in these experiments was approximately 10 K min^{-1}.

Results

The polymorphism of KHCOO

The influence of traces of moisture on the polymorphism of KHCOO is shown in Fig. 1. Upon heating a sample that was exposed to the atmosphere for a very short time, a mass loss, starting at 346 K (73°C) was observed. This can be attributed to the loss of water. Two peaks are further evident at 385 K (112°C) and 413 K (140°C), the latter being the melting point and the former the phase transition temperature in KHCOO. Upon cooling, the melt solidifies at 422 K and, upon heating, the solid melts at 428 K. When the melt is cooled down once again, the freezing point shifts to 424 K and a new heating cycle shows two peaks at 431 and 435 K respectively. They once again represent the phase transition and the melting points respectively.

However, upon using a thoroughly dried sample of KHCOO and taking the necessary precautions to exclude moisture during the experiments, the results shown in Fig. 2 are obtained. The phase transition occurs at 144°C (417 K), agreeing very well with the temperature of 145°C (418 K) reported elsewhere (7). The melting point occurs at 168° (441 K). As is evident in Fig. 2, these temperatures could be reproduced, within experimental error, in subsequent measurements.

Powder diffraction patterns that were obtained of KHCOO at various temperatures indicate that, from 300 K up to approximately 415 K, the spectrum obtained is of the room temperature phase only. Then, until the solid melts at 441 K, the lines of the high-temperature modification (phase I) are obtained. After the melt has been kept at a temperature of ca. 448 K for approximately 1 h, freezing occurs at 432 K and the spectrum of the room temperature phase is obtained upon further cooling. However, when the samples are heated to temperatures just below that of the melting point, KHCOO I is obtained and, upon cooling, the high-temperature phase I remains metastable, even at room temperature for several days, before it transforms into the room temperature phase II. When the supercooled phase I at room temperature was heated again to the melting point, only the room temperature phase II of KHCOO was obtained upon cooling. It must also be noted that heating to its melting point does not always ensure the formation of phase II upon solidification; in some cases the high-temperature modification was observed in this process as well.

To summarize, the high-temperature modification of KHCOO (phase I) can be supercooled, sometimes from the melt, and this metastable phase then takes up to 5 days before it is transformed completely to the room temperature phase II. The powder diffraction patterns that were obtained of KHCOO I could be indexed by means of the programmes GUIN and VISSER and indicate a possible monoclinic crystal system for this phase with $a = 10.145(7)$, $b = 12.781(5)$, and $c = 7.581(3)$ Å and $\beta = 103.893(2)°$. However, exact structural details of this phase can only be obtained from a single-crystal X-ray diffraction analysis.

Vibrational selection rules and Raman spectra (Phase II)

The different fundamental vibrations of the formate ion are as follows: $\nu_1(A_1)$, the symmetric C—H stretching mode, occurs at 2750–2850 cm^{-1}, $\nu_2(A_1)$, the symmetrical C—O stretching mode, occurs at 1380–1410 cm^{-1}, $\nu_3(A_1)$, the symmetric O—C—O bending mode, occurs at 750–800 cm^{-1}; ν_4, the asymmetric C—O stretching mode, occurs at 1530–1600 cm^{-1}; $\nu_5(B_1)$, the in-plane C—H bending mode, is usually observed between 1330 and 1380 cm^{-1}; and ν_6, the out-of plane bending mode, occurs at 1050–1080 cm^{-1} (1). Under *Cmcm* (D_{2h}^{17}) symmetry, the formate groups are located on the sites of C_{2v} symmetry and the following splitting of fundamental modes can be expected, viz. $\nu_1(A_1)$, $\nu_2(A_1)$, and $\nu_3(A_1)$ under C_{2v} will split into $A_g(R) + B_{2u}(ir)$ mode under D_{2h}; $\nu_4(B_1)$ and $\nu_5(B_1)$ will split into $B_{3g}(R) + B_{1u}(ir)$; and, finally, $\nu_6(B_2)$ will split into $B_{1g}(R) + B_{3u}(ir)$ components. In other words, each fundamental vibrational mode will split into a Raman- and an infrared-active component. The vibrational spectra of KHCOO are summarized in Table 1. (It should be noted that the correct

correlation between the C_{2v} site group and the D_{2h} factor is obtained by choosing the $C_{2(y)}$ axis to correlate C_{2v} with D_{2h} under *Cmcm* symmetry. Our results therefore differ from those of Mentzen and Oddon (6) who used a different correlation.) The K^+ ion is eightfold coordinated to oxygen atoms as shown in Fig. 3, and this polyhedron is of C_{2h} symmetry (6). Under this symmetry, the A_u and $2B_u$ translational modes of the K^+ ions split into $A_u(—)$ + $B_{3u}(ir)$ + $2B_{1u}(ir)$ + $2B_{2u}(ir)$ modes. The

A_1, B_1, and B_2 translational modes of the $HCOO^-$ groups under C_{2v} symmetry split into $A_g(R)$ + $B_{2u}(ir)$ + $B_{3g}(R)$ + $B_{1u}(ir)$ + $B_{1g}(R)$ + $B_{3u}(ir)$ modes under D_{2h}. Subtracting the acoustic modes B_{1u} + B_{2u} + B_{3u}, the following translational modes are predicted for KHCOO, viz. $\Gamma_{transl} = A_g(R) + B_{1g}(R) + B_{3g}(R) + A_u(-) + 2B_{1u}(ir) + 2B_{2u}(ir) + B_{3u}(ir)$.

The symmetry operators (R/t) of *Cmcm* and their effect on the K and C atoms in KHCOO are shown in Table 2.

Using the information in Table 2, schematic representations of the translatory lattice modes can be made as is shown in Fig. 4 (the acoustic modes are not included in this figure). It can be noted that no modes involving motions of the K^+ ions are Raman active in KHCOO and that the Raman-active translatory vibrations therefore involve motions of the $HCOO^-$ groups only. "Molecular" translational modes, the term used by Maas

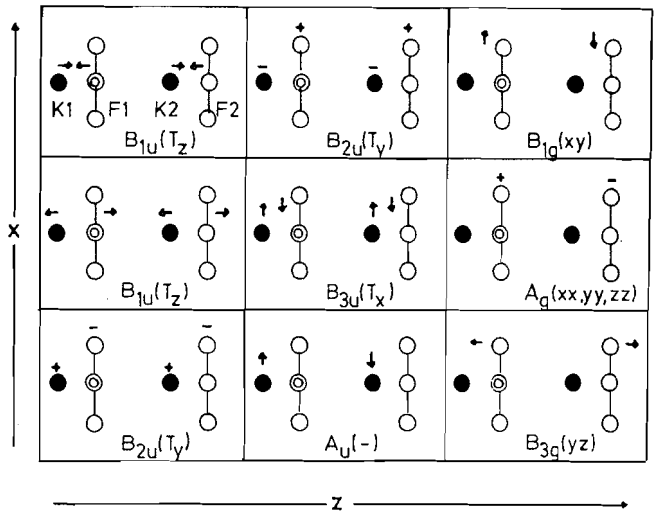

FIG. 4. A schematic representation of the translatory lattice modes in KHCOO in the $x-z$ plane. K1,F1 and K2,F2 denote the potassium and formate ions 1 and 2 respectively.

(8, 9) to describe motions in which the Na^+ and $HCOO^-$ groups of one molecule in NaHCOO move in the same direction, while the second molecule moves in an opposite direction, are not allowed in KHCOO.

In addition to the above-mentioned lattice modes, the $A_2 + B_1 + B_2$ rotational modes of the $HCOO^-$ groups under C_{2v} site group symmetry in KHCOO will split into $B_{1g}(R) + B_{2g}(R) + B_{3g}(R) + A_u(-) + B_{1u}(ir) + B_{2u}(ir)$ components under D_{2h} symmetry.

As far as the internal formate vibrations are concerned, the infrared and Raman bands of KHCOO are in agreement with the group-theoretical predictions. Each fundamental mode is split into a Raman- and an infrared-active component. These bands are summarized in Table 1. The assignment of the bands is rather obvious and has been discussed elsewhere in detail for the Raman-active modes (1).

The low-frequency Raman spectrum of KHCOO II is shown in Fig. 5 at various temperatures. At ambient conditions, the bands at 206, 131 (shoulder), and 125 cm^{-1} can be assigned to the $R_x(B_{3g})$, $R_y(B_{2g})$, and $R_z(B_{1g})$ rotational modes, by analogy to NaHCOO II (9). These bands closely resemble their counterparts in NaHCOO II, as far as their frequencies, bandshapes, and relative intensities are concerned. The sequence of frequencies of the rotational bands is in agreement with the magnitude of the moments of inertia of the formate ion, which vary in the order of $I_x << I_y \simeq I_z$. A weak shoulder at 156 cm^{-1} and a very weak feature at ~100 cm^{-1} once again resemble bands that have been observed in NaHCOO II (1, 8, 9). These features can be assigned to translational modes involving the formate groups.

The major difference between the Raman spectra of KHCOO II and NaHCOO II is the absence of the most intense Raman band at ~75 cm^{-1} in NaHCOO II in the spectrum of KHCOO II. This vibration has been assigned (8, 9) to a molecular vibration in NaHCOO in which the two molecular units move in opposite directions along the x-axis. It is not allowed for KHCOO II, as is evident from Fig. 4, but is, however, activated in phase I of KHCOO, as can be seen in Fig. 5.

Temperature dependence of modes, II–I phase transition

The temperature dependence of the major bands of KHCOO is shown in Fig. 6. The occurrence of the II–I phase transition at

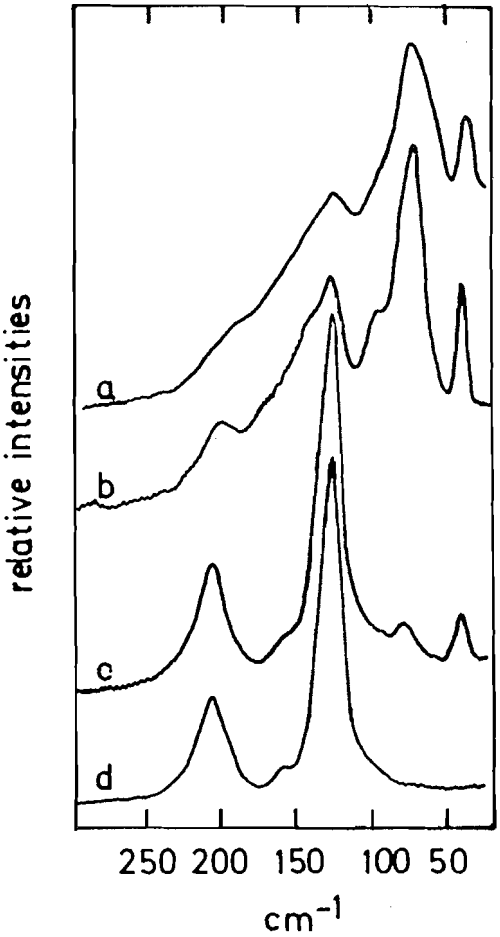

FIG. 5. The Raman-active lattice modes of KHCOO at (a) 425 K (phase I); (b) 300 K (phase I at 300 K); (c) supercooled phase I at 300 K after 72 h; (d) phase II at 300 K.

417 K in this compound is clearly evident. The results shown in Fig. 6 have been obtained during heating cycles only and do not reflect the results obtained during the cooling cycles. It was already shown in Fig. 5 that phase I can be supercooled, the room-temperature phase only being recovered after the elapse of a few days. Hysteresis, as shown by KHCOO I, is a common feature of first-order phase transitions (10) and was also observed in the cases of NaHCOO (1, 2) and LiHCOO (4). It is controlled by the strain energy stored in hybrid crystals and (or) kinetic barriers preventing nucleation (10). The magnitude of the hysteresis width is affected by factors such as particle size, rate of heating, and impurities (10). As was already shown, the presence of traces of moisture affects the polymorphism of KHCOO and, although the crystals were carefully dried and sealed in glass tubes, it is possible that traces of moisture were present and could affect the hysteresis width in the Raman measurements.

The majority of frequencies of the Raman modes graphically represented in Fig. 6 show downward shifts upon an increase in the sample temperature. A few modes, like ν_3, ν_2, and ν_5 are only marginally affected by an increase in the sample temperature. The rotational modes are particularly sensitive towards temperature. Figure 6 shows the variation in the frequencies of Raman modes; many of them also show a decrease in their half-widths with temperature. The linewidth can be expressed by the equation $\Delta = \Delta_0 + A_0 e^{-E/RT}$, where Δ is the linewidth of a band at a particular temperature T and Δ_0 is the linewidth at a

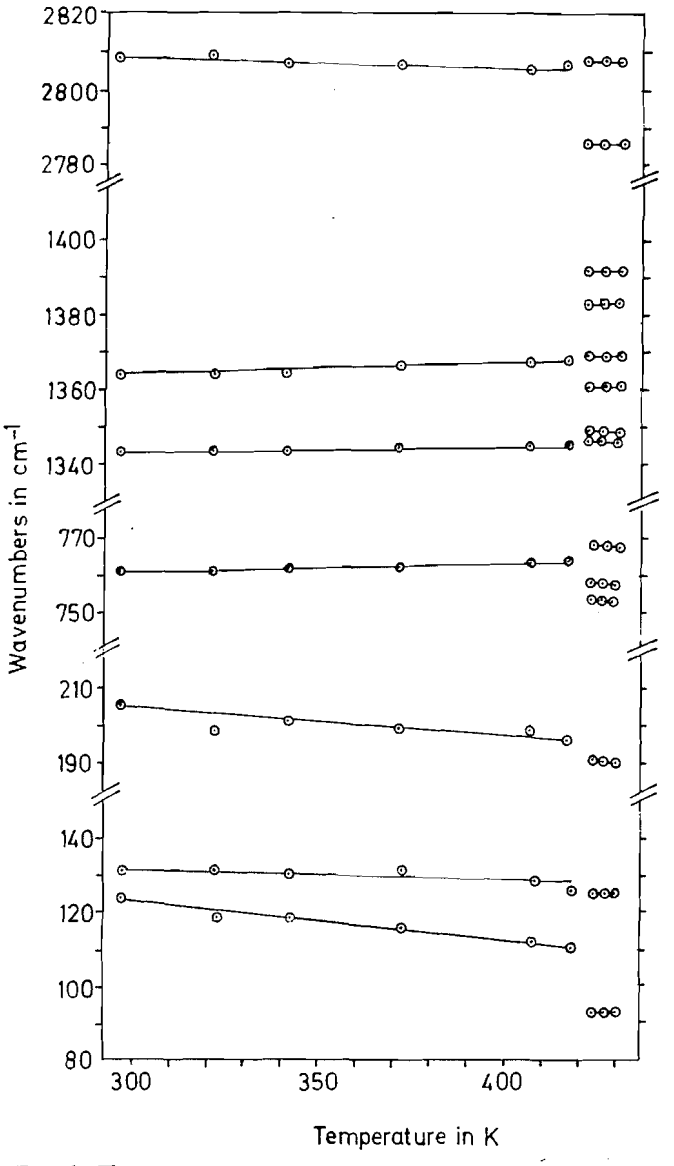

FIG. 6. The temperature dependence of the major Raman bands of KHCOO. The occurrence of the phase transition at 417 K is clearly evident.

very low temperature where molecular motions no longer influence the linewidth; A_0 is a constant and E is the activation energy (11). A plot of $\ln(\Delta-\Delta_0)$ vs. $1/T$ should give rise to a straight line with a slope of $-E/R$. The result of such a plot for the librational mode ν_{R_z} at 125 cm^{-1} is shown in Fig. 7. An activation energy of 5.6 kJ mol^{-1} is accordingly obtained. The activation energies calculated from other bands are summarized in Table 3.

It is known that the formate ion has several resonance structures and it was shown that in the case of NaHCOO these structures contribute towards the final one (12). It was also shown that both internal and external bands of KHCOO are broadened at high temperatures and the activation energy of 6.0 kJ mol^{-1} or less represents a low barrier to molecular motions that cannot be ascribed to rapid reorientations of the formate ions. Calculations involving the moments of inertia of the formate ions show that these orientations have much higher activation energies than 6.0 kJ mol^{-1}, and the well-defined librational bands observed in the Raman spectra of KHCOO are

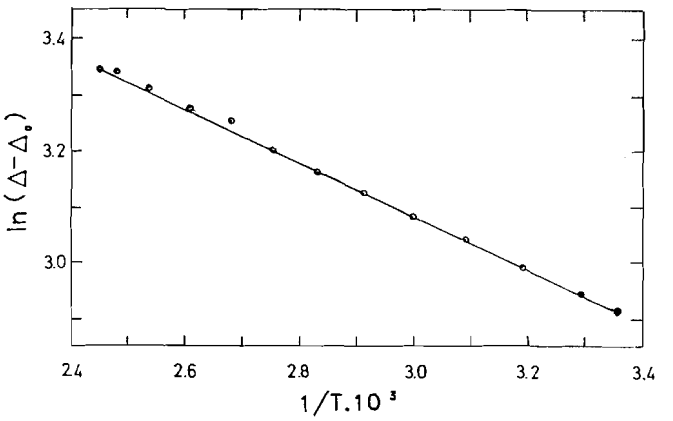

FIG. 7. The variation of $\ln(\Delta-\Delta_0)$, where Δ is the half-width at a particular temperature T and Δ_0 the very value at a very low temperature, against $1/T$ for the librational band ν_{R_x} at 206 cm^{-1}.

TABLE 3. Activation energies for the reorientational motions of the formate groups in KHCOO

Mode	cm^{-1}	E, kJ/mol^{-1}
ν_1	2810	5.7±0.10
ν_{R_z}	125	5.6±0.10
ν_{R_x}	206	4.0±0.05
ν_2	1345	6.0±0.20

also not in accordance with a great deal of reorientational freedom for the formate ions. There are, therefore, other motions that must affect the linewidths of the Raman-active formate groups, which could possibly be ascribed or partly ascribed to intramolecular motions reflecting the various structures that the formate ion can adopt.

It was shown that ν_5 is of $B_{3g}(R) + B_{1u}(ir)$ symmetry, and $2\nu_5$ should split into $2A_g(R) + 2B_{2u}(ir)$ components under D_{2h} symmetry. $2\nu_5$ occurs at 2713 cm^{-1} in the Raman spectrum of KHCOO II, showing that only one of the predicted A_g components is observed. ν_1 is also of A_g symmetry and occurs at 2809 cm^{-1} and it could therefore be expected that Fermi resonance will occur between these modes. It can be assumed that the ratio of the intensities of ν_5 and ν_1 are related by the equation (13)

$$R = I_a/I_b = \frac{\Delta\nu - \Delta\nu^0}{\Delta\nu + \Delta\nu^0}$$

where $\Delta\nu$ is the observed frequency separation between $2\nu_5$ and ν_1, and $\Delta\nu^0$ is the frequency separation between the unperturbed modes. $\Delta\nu^0$ can be obtained accordingly. R was found to vary linearly with temperature for KHCOO II and the variation of $\Delta\nu^0$ with temperature could therefore be determined. If the intensity of the unperturbed overtone, $2\nu_5$, is assumed to be neglible with respect to ν_1, the Fermi coupling constant, W, can be calculated from the following equation (ref. 13):

$$W^2 = \frac{(\Delta\nu)^2 - (\Delta\nu^0)^2}{4}$$

W has been calculated accordingly and its value at various temperatures are summarized in Table 4.

It can be seen from these results that the unperturbed energy

TABLE 4. The variation of W, the Fermi resonance coupling constant, with temperature for $2\nu_5$ and ν_1 in KHCOO

373	41.63
408	42.71

levels of ν_1 and $2\nu_5$, which are separated by 56 cm^{-1} at ambient conditions, will be coupled by Fermi resonance, pushing the energy levels further apart. W increases slightly with temperature, as is evident in Fig. 8 where the perturbed and unperturbed energy levels of ν_1 and $2\nu_5$ are graphically represented against temperature. These corrected values of $2\nu_5$ can also be used to calculate harmonic frequencies for ν_5 and it becomes evident immediately that this fundamental mode is largely harmonic in nature. This is also reflected by its temperature dependence, as is shown in Fig. 6.

At a first glance, the Raman spectra of phase I in KHCOO and NaHCOO are identical, as has already been reported (1). However, a closer scrutiny reveals a number of differences between these spectra. Firstly, KHCOO I has a Raman band at 38 cm^{-1}, which is not present in NaHCOO I (this feature does, however, develop in the intermediate phase I′ of NaHCOO (3)). No intermediate phase has been observed upon cooling down KHCOO; either the metastable phase I is obtained or the room temperature phase II forms directly. It is, however, difficult to say whether the supercooled phase I of KHCOO does not invariably contain traces of phase II since so many Raman bands of these two phases occur at identical frequencies (this is evident in Fig. 6). ν_3, which is observed in a frequency range where other bands do not occur, is split into two components in NaHCOO I and into three components in KHCOO I (Table1). Then, finally, six components are observed in the frequency range of 1300–1400 cm^{-1} and three, viz. the ones at 1346, 1348, and 1360 cm^{-1}, can be assigned to the C—O stretching mode ν_2, and the ones at 1369, 1387, and 1396 cm^{-1} are most probably due to components of the C—H bending mode ν_5.

It is more difficult to identify all of the individual components of the lattice modes of supercooled KHCOO I at room temperature. It is abundantly clear, however, that the bands are much broader than the ones of KHCOO II at the same temperatures (Fig. 5). For example, the half-width of the librational mode ν_{R_x} at 201 cm^{-1} in KHCOO I is 43 cm^{-1} compared to 23 cm^{-1} of the corresponding band in KHCOO II. It is also clear from Fig. 5 that the librational band ν_{R_z} at 125 cm^{-1} in KHCOO I could have several components that are not clearly resolved at room temperature. It is also clear from Fig. 5 that the "molecular" translation mode at ~70 cm^{-1} in phase I of KHCOO is the most intense band in the Raman spectra of both phase I at 423 K and the supercooled phase at 300 K. If this mode does indeed represent the motions of the molecules in the x-direction, then the band at 39 cm^{-1}, which is also rather prominent in the Raman spectrum of KHCOO I, can be assigned to the corresponding mode in either the y- or z-directions of the crystals. This mode has previously been assigned to a difference band in NaHCOO, viz. 112–74 cm^{-1} (1), but its temperature dependence shows that this assignment is highly unlikely in the case of KHCOO I.

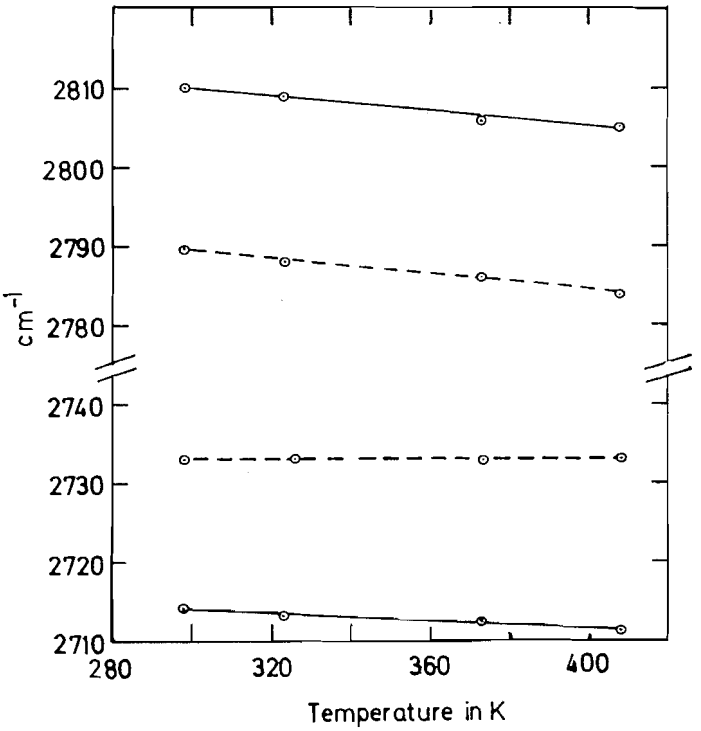

FIG. 8. The temperature dependence of the observed frequencies of ν_1 and $2\nu_5$ (solid lines) and the corrected frequencies for Fermi resonance (broken lines) in KHCOO.

The structural differences between NaHCOO I and KHCOO I were also evident from the powder diffraction patterns of these two compounds. The pattern obtained for NaHCOO I could be indexed on the basis of an orthorhombic unit cell with $a = 10.715$, $b = 13.007$, and $c = 3.4477$ Å compared to the monoclinic system of KHCOO I mentioned earlier. Not too much value can be attached to these assignments and only an exact crystal structure determination of single crystals will give an unambiguous assignment to the correct space group. But in view of the results obtained with both Raman spectroscopy and X-ray crystallography, there is little doubt that the crystal structures of these two compounds in phase I are indeed different.

Monoclinic structures are known for the alkali metal formates. NH_4HCOO belongs to the monoclinic space group Pc (C_s^2) with $Z = 2$ (14) and each internal formate mode is split into A' (ir,R) and A'' (ir,R) components. This space group can therefore be excluded as a possible candidate for KHCOO I. The monoclinic high-temperature phase of LiHCOO belongs to the space group $C2/c(C_{2h}^6)$ with $Z = 32$ (15). In this structure there are four independent formate groups and each formate mode can theoretically be split into four components. This will, of course, depend on the extent of differences in the bond lengths and angles. For example, the C—H bond lengths are equal to 1.03, 1.01, 1.00, and 0.99 Å in LiHCOO and four closely spaced C—H symmetric stretches (ν_1) have indeed been observed in the Raman spectra of this compound (4). On the other hand, only two C—O stretching modes have been observed in its Raman spectra (4), and it is obvious that the C—O bond lengths of 1.232, 1.235, 1.237, 1.238, 1.239, 1.241, 1.243, and 1.245 Å (15) are not sufficiently different to give rise to separate components for each bond length. A possible explanation for this is that the C—O stretching modes are broader in this compound than the C—H modes. This could

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

be due to molecular motions in the crystal. However, it was impossible to resolve all the predicted C—O components, even using a resolution of less than 0.5 cm^{-1}. It can therefore lead to serious misconceptions if the number of modes in the Raman spectra are simply counted and a structure is assigned accordingly. It can also be noted that the number of lattice modes and their frequencies closely correspond in LiHCOO I and KHCOO I. The structure of LiHCOO I can therefore not be excluded as a possible candidate for the structure of KHCOO I.

Computers and infrared spectroscopy: evolution and revolution[1]

D. J. MOFFATT, J. K. KAUPPINEN,[2] AND H. H. MANTSCH

Steacie Institute for Molecular Sciences, National Research Council of Canada, Ottawa, Ont., Canada K1A 0R6

Received May 28, 1991

This paper is dedicated to Dr. Richard Norman Jones

D. J. MOFFATT, J. K. KAUPPINEN, and H. H. MANTSCH. Can. J. Chem. **69**, 1781 (1991).

A brief history of the relationship between computer and infrared spectroscopist is given with emphasis on the use of the Fourier transform. Subsequently, an algorithm is developed that may be used to devise an objective Fourier self-deconvolution procedure which depends only on the input data and is not subject to the biases that are often introduced in such subjective techniques.

Key words: deconvolution, Fourier transform, maximum entropy method.

D. J. MOFFATT, J. K. KAUPPINEN et H. H. MANTSCH. Can. J. Chem. **69**, 1781 (1991).

Mettant l'accent sur l'utilisation de la transformation de Fourier, on présente un résumé de l'histoire de la relation entre les ordinateurs et les practiciens de la spectroscopie infrarouge. Par la suite, on propose un algorithme qui peut être utilisé pour développer une méthode objective d'auto-déconvolution de Fourier qui ne dépend que sur les données fournies et qui n'est pas sujette aux déviations qui sont souvent introduites dans de telles techniques subjectives.

Mots clés : déconvolution, transformation de Fourier, méthode d'entropie maximale.

Preamble

Shortly after the digital computer became available to scientists some 30 years ago, enterprising spectroscopists started to harness it to the task of solving problems in infrared spectroscopy. One such spectroscopist was Dr. R. Norman Jones, who was among the first to utilize computers for processing of IR spectral data. As Norman put it then to his friend, he was out "to marry the computer to infrared spectroscopy", and what a successful marriage it became! He began the production of computer software in the early 60s here in Ottawa and, along with a number of dedicated co-workers, produced a compilation of modular computer programs that are still in use today in many laboratories throughout the world. They were collated into the National Research Council of Canada Bulletin series entitled "Computer programs for infrared spectroscopy" (1), and were disseminated to the spectroscopic community at large for a token fee that barely covered the cost of the magnetic tape on which they were distributed.

The 50 individual programs cover such diverse areas as (*i*) organization, sorting and error-checking of raw spectral data; (*ii*) simple conversion and scale changes (e.g., transmittance/absorbance and wavenumber/wavelength); (*iii*) basic analysis of spectral curves including smoothing, differentiation, peak and valley location, integration; (*iv*) band simulation and band contour analysis including the damped harmonic oscillator model and Cauchy (Lorentzian)–Gauss functions; (*v*) instrument calibration including wavenumber calibration, correction for slit width distortion and evaluation of cell path length; (*vi*) programs for normal coordinate analysis; (*vii*) calculation of optical properties including determination of optical constants from transmission and ATR measurements. Some of the former programs will appear somewhat rudimentary by today's standards but at that time the spectroscopist who wished to work with digitized data was forced to write his own programs for virtually *everything*. Moreover, it was the era of the punched card, when a gust of wind or an unfortunate slip of the hand could undo hours of tedious data encoding. Careful attention to error-checking and data organization was necessary to limit the extent of such catastrophies.

The bond between computer and spectroscopist that was fomented by Norman Jones is totally consummated today. The keypunch has been replaced by the keyboard, paper tape by the floppy disk, and endless columns of numbers have given way to lines of glowing phosphor on computer monitors. Few of us foresaw the explosive advances that were to become the hallmark of the computer industry, but thanks to men like Norman Jones we were well prepared to embrace them.

Revolution

In the period 1975–1985 the infrared spectroscopist saw the quality of his instrumentation increase by roughly three orders of magnitude[3] with the introduction of the Fourier transform infrared (FT-IR) spectrometer. Fortunately for the spectroscopist, there grew in tandem a technology that was ideally suited to manage the enormous amount of information flowing from this instrumentation — the microcomputer industry. It would be lamentable indeed were we forced to record as traces of ink on paper spectra having a signal-to-noise (S/N) ratio exceeding 10 000.

The many characteristics of the Fourier transform IR spectrometer that brought about this revolution have been detailed elsewhere (2–4), so only a few major ones will be noted here: (*i*) higher energy throughput (no slits) and multiplexed data, both leading to significant improvements in S/N; (*ii*) an abscissa scale linear in wavenumber, constant in resolution, and accurate to within 0.01 wavenumber (and even better in high resolution instruments); (*iii*) perforce, the collection of raw data in *digitized* form on a relatively powerful computer, eliminating the laborious hand-digitization process that had to be applied to data from older instruments.

---

[2]On leave of absence from the University of Turku, Department of Applied Physics, Turku, Finland.

[3]It may be argued that it is the quality of the data and not the instruments themselves that had undergone this dramatic improvement.

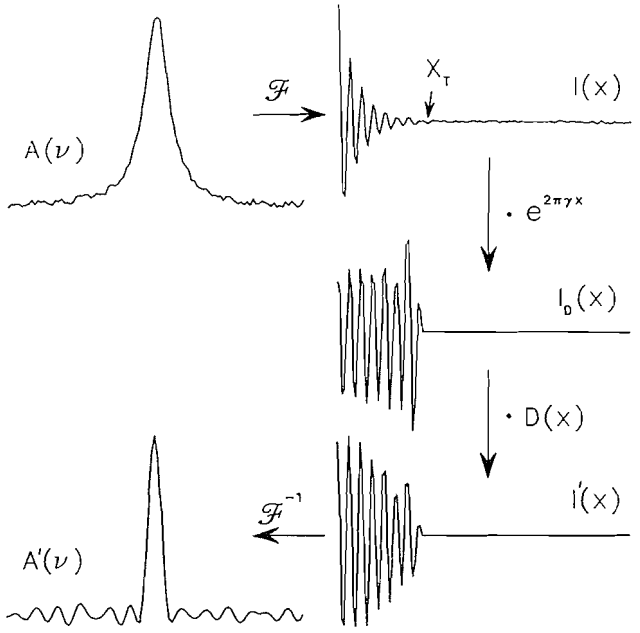

FIG. 1. Illustration of the FSD procedure applied to a single noisy Lorentzian band. In this illustration $D(x)$ is the Fourier transform of a Bessel function, the output lineshape of $A'(\nu)$.

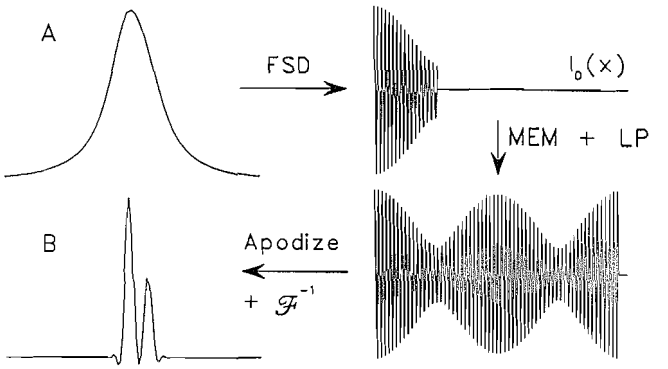

FIG. 2. Illustration of the LOMEP procedure applied to a Lorentzian doublet.

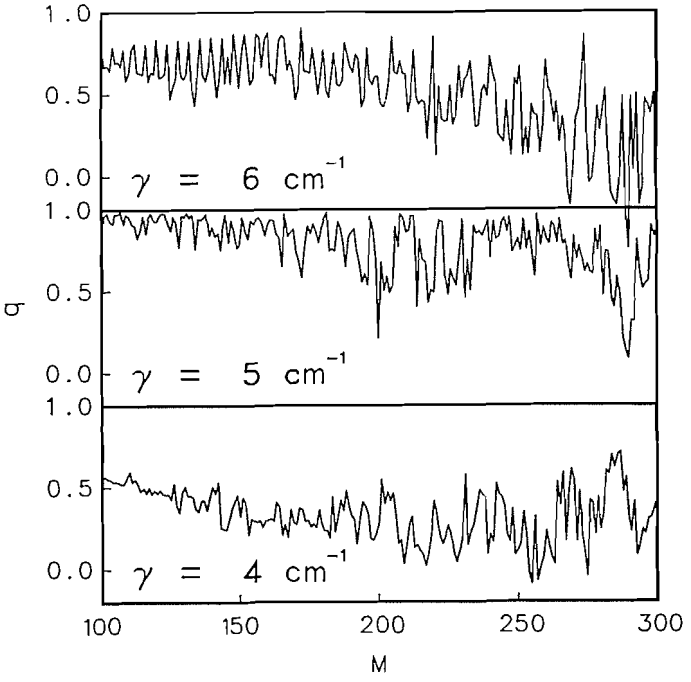

FIG. 3. Behavior of q as a function of M for three values of γ in the FSD step of LOMEP.

The Fourier transform — a digression

Apart from the pragmatic advantages, another perhaps less recognized benefit of the FT-IR technology was that it forced many spectroscopists to familiarize themselves with a mathematical tool that has found an application in virtually all fields of scientific investigation (5, 6), the Fourier transform. Like the NMR spectroscopist a decade earlier, the IR spectroscopist who made the effort to learn the relationship between data in the frequency and time domains gave himself a powerful new perspective in interpreting the data presented by his spectrometer. With a mastery of the Fourier transform comes a *clear* understanding of such common and useful data processing procedures as smoothing, interpolation, differentiation, apodization, and data sampling. A good example of this is the process of digital smoothing involving convolution with a set of coefficients, e.g., the method of Savitzky and Golay (7). Viewed in the time domain, this conceptually complicated procedure of convolution is reduced to the trivial multiplication by a weighting function (8).

Another common problem in IR spectroscopy that may benefit from the use of the Fourier transform is the choice of "optimal resolution", *i.e.*, the lowest instrumental resolution that may be used without degrading the spectrum. The choice of this value has been the source of some controversy, with many spectroscopists choosing to err on the side of caution using a higher resolution than necessary and paying a price in terms of computation time, data storage/transfer and, above all, signal-to-noise ratio. The Fourier transform is quite useful in this context; for a given spectrum, the point in the time domain where signal falls below the noise level can be used to accurately calculate this resolution value.

Evolution

With the widespread availability of digitized spectra came a demand for software to process this large quantity of data. Programs initially made available by the instrument manufacturers performed such mundane tasks as data collection, plotting/display, scaling, baseline correction, and addition/subtraction. Shortly thereafter more sophisticated routines appeared including smoothing, interpolation, differentiation, integration, and interactive subtraction (digital spectral stripping). Then there evolved programs directed at specific applications. The analytical spectroscopist in particular benefited from routines that performed quantitative analysis on multi-component samples. Also developed were libraries containing thousands of digitized spectra that could be scanned in a matter of seconds. Such customized software became more and more commonplace as spectroscopists became familiar with this new technology and became aware of what the computer could (and could not) do for them.

While the software tools evolved, so too did the tools accessible for spectroscopy itself. The new technology made possible such low energy techniques as photoacoustic, diffuse reflectance, and aqueous solution studies. However, there was somewhat of a dilemma with the more routine high energy spectra, i.e. neat liquids, KBr pellets, or organic solutions. Such spectra were being routinely obtained with an S/N of 4000 or more while for

most applications 400 was utterly sufficient. How to make use of the excess S/N, i.e. *information*? Once again as we shall see the computer comes to the rescue.

Deconvolution

One of the NRC computer programs mentioned above (9) deals with corrections for the distortion introduced by the finite slit width of a dispersive spectrometer, which is accomplished by deconvolving this distortion from the experimental data. In 1981, this procedure was taken a step further with the introduction of the technique of Fourier Self-Deconvolution (FSD) to IR spectroscopy (10). Essentially this was an attempt to correct for a "distortion" that nature imposes on infrared absorption bands — the Lorentzian lineshape.

To illustrate the principles of FSD let us consider a single infrared absorbance band, $A(\nu)$, with a Lorentzian lineshape. The absorbance value, A, at a given wavenumber, ν, is given by:

$$[1] \qquad A(\nu) = A_0\gamma^2/[\gamma^2 + (\nu - \nu_0)^2]$$

where A_0 is the maximum absorbance, ν_0 is the wavenumber corresponding to A_0, and γ is the half-width at halfheight (HWHH) of the band. The cosine Fourier transform of $A(\nu)$ is given by

$$[2] \quad I(x) = \mathcal{F}\{A(\nu)\} = \int_{-\infty}^{+\infty} A(\nu)\cos(2\pi\nu x)d\nu = A_0\gamma\pi\cos(2\pi\nu_0 x)e^{-2\pi\gamma|x|}$$

where x has the unit of cm with ν given in wavenumbers. The

For personal use only.

exponential decay term, $\exp(-2\pi\gamma|x|)$, in eq. [2] is controlled by γ, that is, the wider the band, the more rapidly its Fourier transform decays. A point, x_T, in the time domain is then chosen beyond which the data are set to zero; this is often the point where the signal falls below the noise level. (In practice, this position is arrived at empirically, based on the noise level that may be tolerated in the deconvolution result.) Then, for a Lorentzian bandshape, FSD is performed by multiplying eq. [2] by the quantity $\exp(2\pi\gamma|x|)$ yielding an undamped cosine wave. This time domain function, $I_D(x)$, may then be multiplied by one of several suitable weighting functions, $D(x)$ (11), to yield a new signal, $I'(x)$, before inverse Fourier transformation to give the deconvolved band $A'(\nu)$. A typical choice for $D(x)$ is $(1 - (x/x_T)^2]^2$ which becomes a Bessel function on Fourier transformation. Figure 1 illustrates the steps involved in the FSD procedure.

FSD accomplishes a narrowing of all individual lines in a given spectrum with subsequent improvement of the information content to the spectroscopist, i.e., line positions, intensities and, most importantly, number. The practical restrictions on the method are non-uniform distribution of lineshape in the spectrum and the signal-to-noise ratio (note the higher noise level in $A'(\nu)$ compared to $A(\nu)$. Thus it is evident that this technique provides a practical use for the excess S/N made available to us by the FT-IR spectrometer.

Though it has found a niche in the spectroscopist's array of data processing tools, a major drawback of FSD has been its subjectivity (12); the output of the method depends somewhat on the practitioner since the values of γ and x_T have to be estimated and can greatly affect the output $A'(\nu)$.

Beyond deconvolution

Recently (13), we introduced a procedure of line-narrowing which we named LOMEP (from Lineshape Optimized Maximum Entropy linear Prediction), a combination of the procedures of Fourier Self-Deconvolution (FSD), Maximum Entropy Method (MEM), and Linear Prediction (LP). Given a spectrum consisting of lines all having the same (known) lineshape with only their position and intensity changing (a situation to which we refer as the LOMEP criterion), FSD is first performed but is stopped at step 2 ($I_D(x)$ in Fig. 1), which leads, in the time domain, to a signal consisting of undamped cosine waves. The impulse response of a prediction error filter (required by LP) is then computed using Burg's MEM and this time domain signal is extrapolated using LP. The Fourier transform of this extended signal leads to higher resolution in the frequency domain, hence to narrower lines in the output spectrum. Figure 2 illustrates this procedure applied to a synthetic double of Lorentzian lines (A in Fig. 2). The lines have a separation of 4 cm^{-1} with intensities 1.0 and 0.5, respectively; both lines have halfwidths at half height of 5.0 cm^{-1} and an S/N (peak-to-peak) of ~500. Application of the LOMEP procedure leads ot the separation of the two lines as per B in Fig. 2.

In a subsequent study (14), in which we explored the practical application of LOMEP, we introduced a value q, the quality factor, for estimating the accuracy of the linear prediction step in LOMEP. The q factor uses the property of a signal consisting only of undamped cosine waves that LP should work equally well in both directions. A corollary to this observation is that the data used in the calculation of the a_k coefficients (in the MEM step of LOMEP) should accurately predict themselves. This value, q, essentially gives an indication of how well the time domain signal can be modelled with a small number of undamped cosine waves.

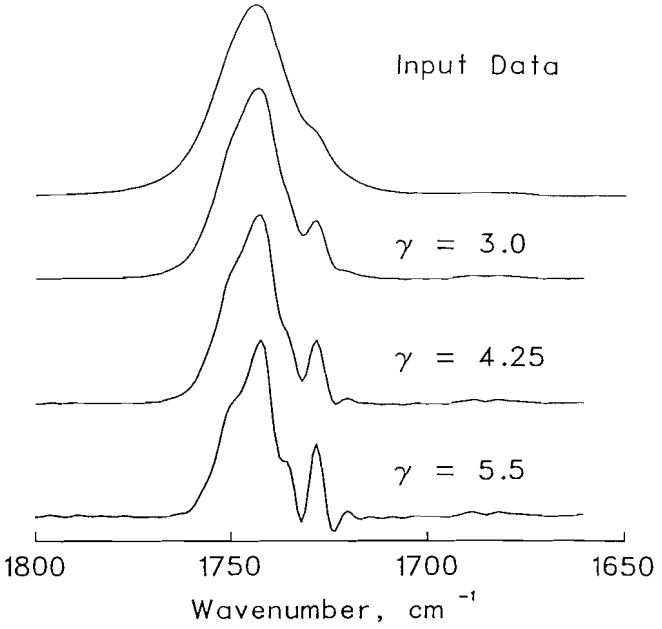

FIG. 6. FSD, at three γ values, applied to the C=O stretching region of the infrared spectrum of dairy cream (neat).

Hence, a by-product of the development of the LOMEP procedure is the feasibility of developing an objective FSD algorithm the output of which depends only on the input data. In theory, one merely varies the FSD halfwidth parameter, γ, to maximize q. The present study investigates such a procedure applied to a model system of Lorentzian lines containing random noise (trace A in Fig. 2).

In LOMEP the value of q depends not only on the FSD lineshape parameters, but also, and rather chaotically, on the number of points, M, used in the MEM part of the LOMEP procedure. Figure 3 illustrates this problem for three FSD halfwidth values when LOMEP is applied to the Lorentzian doublet in Fig. 2. There are various solutions to this difficulty; in this study we will take the simple approach of merely averaging the value of q between certain values of M, i.e., $M_1 \leq M \leq M_2$. Hence we can define

$$[3] \quad q_{av} = \frac{\sum_{i=M_1}^{M_2} q_i}{M_2 - M_1 + 1}$$

Figure 4 illustrates a plot of q_{av} versus FSD halfwidth when LOMEP is applied to the model doublet. In this example $M_1 \geq 100$, $M_2 \geq 300$. It is apparent that the q value goes through a distinct maximum at the halfwidth of the input Lorentzian lines.

Figure 5 shows the result of same procedure applied to some experimental IR spectroscopic data — the region of the carbonyl stretching band of a sample of commercial table cream. The maximum q_{av} occurs at approximately $\gamma = 4.25$ cm^{-1}. Figure 6 illustrates the results of applying FSD to the same data using this value for γ, along with two other γ values that differ by approximately ±30%. A sampling of the literature will reveal this to be a reasonable value for the range of FSD halfwidths applied to similar experimental spectroscopic data. Because of the subjective nature of FSD, any of the traces in Fig. 6 can be argued as a correct FSD result. The power of this new procedure, then, is to remove this ambiguity, by limiting the range of γ halfwidths applied to a set of data in the FSD procedure.

Epilog

The algorithm presented above is a symbolic product of the "marriage" that Norman Jones had arranged several decades ago. This marriage has now become a synergy as one is often hard-pressed today to decide where the spectrometer ends and the computer begins. The challenge is, as infrared spectrometers present us with yet better spectra, to find new approaches that allow us to extract additional information from the experimental spectra by means of data processing.

This paper is dedicated to Dr. Richard Norman Jones

K. H. MICHAELIAN, W. I. FRIESEN, S. YARIV, and A NASSER. Can. J. Chem. **69**, 1786 (1991).

Diffuse reflectance infrared spectra of kaolinite and binary mixtures of this clay with alkali halides have been analysed using curve-fitting and deconvolution. For caesium chloride and caesium bromide, decomposition of the hydroxyl stretching region has made it possible to correlate the positions and intensities of bands due to structural hydroxyl groups of kaolinite, or to intercalated water, with the degree of intercalation. One of these bands, arising from uncoupled inner surface OH stretching in kaolinite, is not identifiable in spectra of the uncomplexed clay or mixtures where intercalation did not occur. A new band revealed by curve-fitting spectra of intercalated samples is attributed either to water at the interface between the clay and the alkali halide, or to an FeO—H impurity in the kaolinite.

Key words: kaolinite, infrared, curve-fitting.

K. H. MICHAELIAN, W. I. FRIESEN, S. YARIV et A. NASSER. Can. J. Chem. **69**, 1786 (1991).

Faisant appel à un ajustement de courbes et à la déconvolution, on a analysé les spectres infrarouges de réflexion diffuse de la kaolinite et de mélanges binaires de cet argile avec des halogénures alcalins. Pour le chlorure ainsi que le bromure de césium, il a été possible de décomposer la région d'élongation de l'hydroxyle afin d'établir une corrélation entre les positions et les intensités des bandes dues aux groupes structuraux hydroxyles ou à l'eau intercalée et le degré d'intercalation. Il n'a pas été possible d'identifier l'une de ces bandes, provenant de l'élongation du OH non couplé de la surface interne de la kaolinite, dans l'argile non complexée ou dans les mélanges où il ne s'est pas produit d'intercalation. On attribue une nouvelle bande, révélée par l'ajustement des bandes des spectres des échantillons intercalés, soit à l'eau qui se trouve à l'interface entre l'argile et l'halogénure alcalin ou à une impureté de FeO—H qui serait présente dans la kaolinite.

Mots clés : kaolinite, infrarouge, ajustement de courbes.

Introduction

Curve-fitting and deconvolution (resolution enhancement) are two of the many numerical methods for the analysis of infrared spectra to which Dr. R. Norman Jones has contributed during his distinguished career. Many spectroscopists now use these techniques on a daily basis in order to increase the amount of information discernible in their data: as an example, this paper describes an infrared study of clay intercalation, where the identification of several bands would not have been possible without the use of both curve-fitting and deconvolution. In addition, second-derivative calculations were carried out using a program derived from one published in the NRC bulletins on infrared spectrophotometry.

Recently, we described diffuse reflectance ("DRIFT") and photoacoustic infrared spectra of binary mixtures of kaolinite, $Al_2Si_2O_5(OH)_4$, with several alkali halides (1). These spectra show that caesium chloride intercalates kaolinite when the two are either mixed, ground in air, or ground in the presence of a small amount of water. The data may be interpreted in terms of a complex in which a water molecule is hydrogen bonded to both a siloxane oxygen and an inner surface hydroxyl group, while being coordinated to the Cs^+ and Cl^- ions. For caesium bromide, intercalation occurred only when the mixture of the two solids was kept moist during grinding.

The OH stretching region of the DRIFT spectra of these complexes shows substantial changes with respect to that of kaolinite (Figs. 1a and 2a, ref. 1). Four new bands are visible: two arise from the symmetric (ν_1) and the antisymmetric (ν_3) vibrations of the intercalated water; one is due to uncoupled stretching vibrations of inner surface hydroxyl groups; and the remaining band arises from a new AlO—H stretching vibration. Moreover, the positions and relative intensities of the four well-known hydroxyl stretching bands of kaolinite are also modified as a result of the intercalation. The complexity of these spectra makes it desirable to separate the individual bands numerically so that the spectra can be fully characterized. To achieve this objective, we have performed curve-fitting and deconvolution calculations, the results of which are presented in this paper.

Spectra and calculations

Details regarding sample preparation and measurement of spectra have been reported previously (1). Before the curve-fitting was carried out, the spectra were baseline-linearized using standard software of the infrared spectrometer (Bruker IFS 113v). This adjustment to the data creates a horizontal baseline by subtracting a straight line from the spectrum over the selected region. The OH stretching region was arbitrarily assumed to extend from 3500 cm^{-1} to 3800 cm^{-1} for kaolinite and the mixtures whose spectra resemble that of the natural clay. The lower limit was changed to 3200 cm^{-1} for spectra displaying a broad low-frequency tail.

Our treatment of the spectra incorporated curve-fitting and deconvolution in the three-step approach previously employed for analysis of infrared spectra of coal (2, 3). According to this strategy, the measured spectrum is first deconvolved to increase the resolution of the bands, thereby providing better initial estimates of their number and peak

positions. After curve-fitting is completed, the resulting synthesized spectrum is also deconvolved. Consistency between the two deconvolved spectra is then made the essential criterion for accepting the curve-fitting parameters. In cases where doubt about the validity of certain features remained after these calculations, second derivatives of the observed spectra were computed; the results supported our conclusions regarding the existence of the bands.

Results and discussion

Our results are summarized in Figs. 1–5 and Table 1, and discussed in detail for kaolinite, kaolinite/CsCl, and kaolinite/CsBr in the following paragraphs.

The kaolinite bands A, B, C, D, Z, and A′ were fit satisfactorily with Lorentzian functions. Both Lorentzian and Gaussian shapes were tried for the water ν_1 and ν_3 bands, with Gaussian bands producing the superior fit. This observation is not surprising, as Gaussian bands generally reproduce both infrared and Raman spectra of water more accurately than Lorentzian bands.

Kaolinite

Figure 1 shows the results obtained for natural kaolinite from Makhtesh Ramon, Israel. Curve a represents the fitted spectrum, while b shows the individual bands making up the spectrum. Curve c is the difference between the fitted and measured (baseline-linearized) spectra.

The positions of the individual bands are listed in Table 1, together with their assignments and accepted symbols (4). According to the results of intercalation and deuteration studies (5), it is generally accepted that bands A, B, and C arise from inner surface hydroxyl groups, whereas D is due to the less accessible inner hydroxyl. In contrast, the 3596 cm^{-1} band occurs only for kaolinites that contain iron (6), but is not relevant in the following discussion of alkali halide mixtures because it is masked by another, much stronger, band.

The only ambiguity regarding the interpretation of the kaolinite spectrum involves the possible existence of band Z, which is observed in Raman (7–9) and photoacoustic infrared (10, 11) spectra of kaolinite, and arises from uncoupled inner surface hydroxyl stretching (12, 13). Deconvolution of the measured spectrum only hinted at a band at the appropriate frequency (3686 cm^{-1}). To check whether this band might contribute to the measured spectrum, the curve-fitting calculation

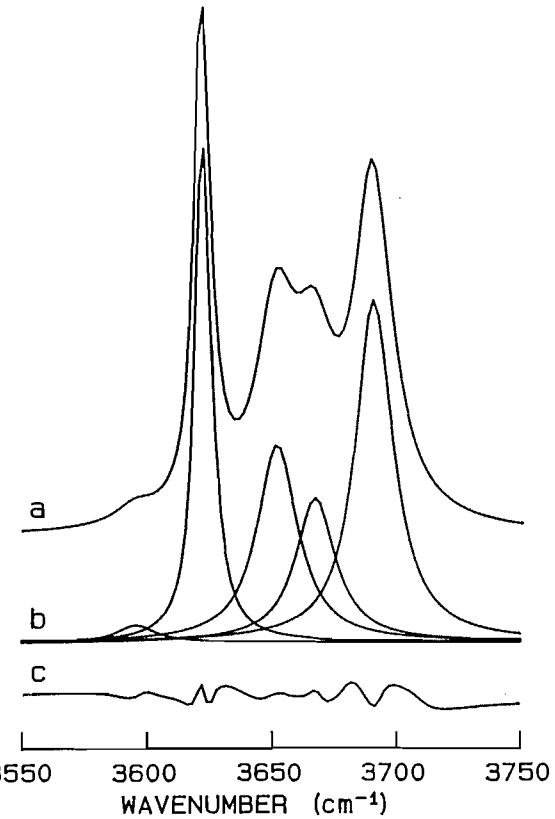

FIG. 1. Curve-fitting results for natural kaolinite. Curve a: fitted spectrum; curve b: component bands (cf. Table 1); curve c: difference between fitted and measured spectra.

was repeated by adding it to the five shown in Fig. 1. The resulting calculated spectrum was in slightly better agreement with the measured one; however, deconvolution of this new fitted spectrum did not verify the presence of the extra band. Moreover, the fitted intensity and width of the band varied with the starting values of these parameters. Since we require consistency between the results of the curve-fitting and deconvolution calculations, the occurrence of band Z is not confirmed. There-

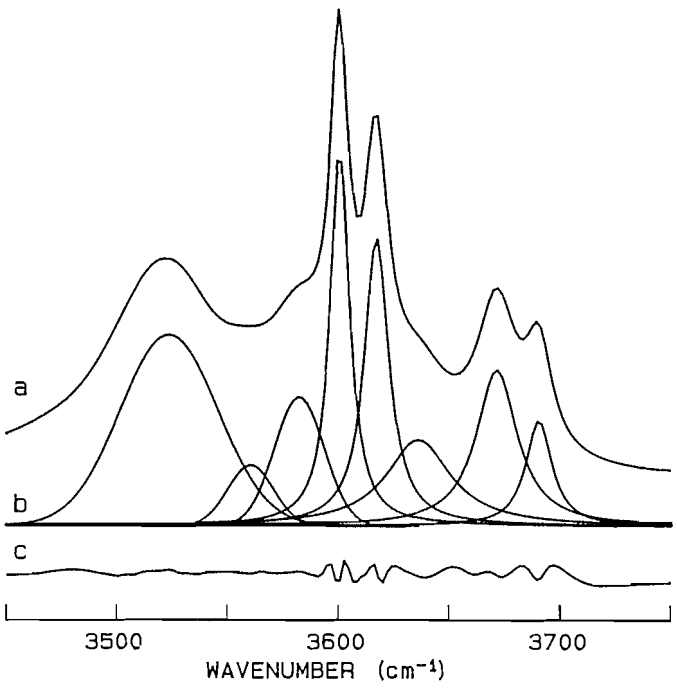

FIG. 2. Curve-fitting results for mixed kaolinite/CsCl. a–c as in Fig. 1.

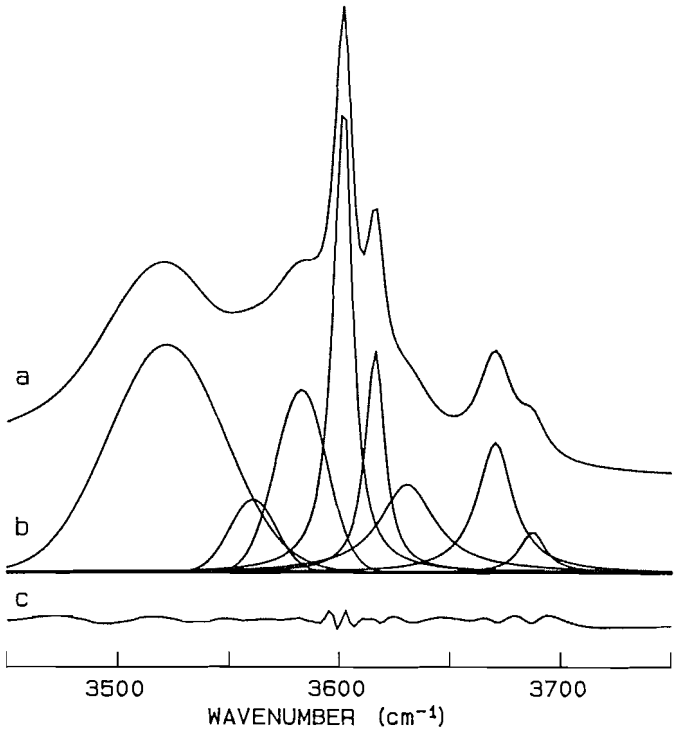

FIG. 3. Curve-fitting results for air-ground kaolinite/CsCl. a–c as in Fig. 1.

fore, we conclude that it contributes little or no intensity to the DRIFT spectrum of kaolinite.

Kaolinite/CsCl

All of the kaolinite/CsCl mixtures yield spectra that differ substantially from that of kaolinite. As shown in our previous work (1), the degree of intercalation in these mixtures varies in the sequence: mixed < air ground < wet ground. A qualitative indication of the different degrees of intercalation is provided by comparing the fitted spectra in Figs. 2–4 (corresponding to the measured spectra in Fig. 2a, ref. 1). The availability of three samples also makes it possible to monitor trends in frequencies and (or) intensities of individual bands and to achieve a consistent set of assignments.

Considering first the structural hydroxyl groups of kaolinite, the calculations reveal a progressive decrease in the frequencies and intensities of bands A, C, D, and Z as intercalation increases. Some of the weaker bands in the fitted spectra are not visible in the measured spectra, with the result that Table 1 in this work is more complete than Table 2 in ref. 1 with regard to hydroxyl stretching frequencies. Furthermore, the frequencies obtained from curve-fitting can be considered to be more accurate than the apparent maxima in the original spectra. It should also be emphasized that the curve-fitting results in no way contradict our previous conclusions (1).

The occurrence of band D in the spectra of the air-ground and wet-ground mixtures deserves further comment. Because this band is due to inner OH groups (5), it should not be affected by the intercalation. However, the peak positions listed in Table 1 indicate that band D shifts to slightly lower frequency as the degree of intercalation increases. As discussed previously (1), this frequency shift might be attributable to delamination of the tactoid and reduction of the symmetry of the alumino-silicate layer (perhaps through curling, which also occurs in halloysite). Such structural changes could also cause some reduction in the intensity of this band. This appears to be the case according to Figs. 2–4 but, since the intensity scale in each figure depends on the maximum of the sharp, narrow band A′, comparisons of absolute intensities for a particular band are difficult.

The OH stretching frequencies of the intercalated water also decrease systematically as the degree of intercalation increases. These bands are noticeably broader than those of kaolinite, reflecting greater participation of the hydroxyl groups of water in hydrogen bonding; as mentioned above, they are Gaussian, whereas the bands due to kaolinite are all Lorentzian. Intuitively, the water bands in the spectrum of the wet-ground sample (Fig. 4) should be more intense than those for the air-ground sample (Fig. 3). This expectation seems to be supported by the fact that the H_2O bands account for a greater proportion of the integrated intensity in Fig. 4, although it must be reiterated that the intensity scale differs from one figure to the next.

An unexpected result of the curve-fitting calculations is their prediction of a third Gaussian component between the ν_1 and ν_3 water bands: a satisfactory fit could not be obtained in the region below 3600 cm^{-1} until a band was introduced near 3560 cm^{-1}. Its existence is also suggested by the second-derivative spectra, particularly for the wet-ground kaolinite/CsCl complex. As shown in Table 1, the behaviour of this band is similar to that of bands of both kaolinite and intercalated water, thus providing at least circumstantial support for its authenticity. Therefore, it is plausible that this newly detected band arises from an intercalated water molecule in an environment different from that described previously (1), i.e., one where coordination to both alkali halide ions does not occur. One candidate is the water, possibly located at the interface between kaolinite and the alkali halide, that yields the endothermic DTA peak near 100°C (14). If the band is due to the ν_3 vibration of such a water molecule, then the ν_1 band would fall below 3500 cm^{-1} and contribute to the broad low-frequency wing that extends to the beginning of the OH stretching region.

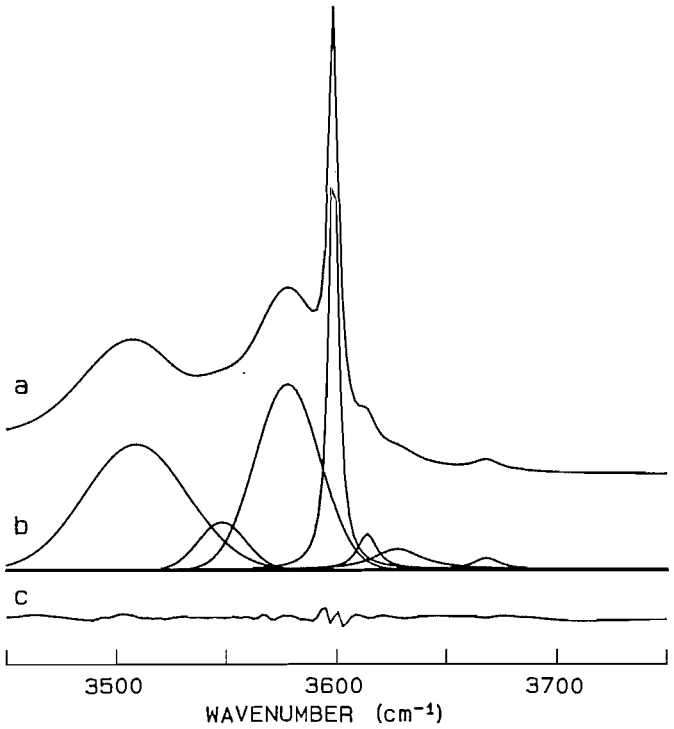

FIG. 4. Curve-fitting results for wet-ground kaolinite/CsCl. a–c as in Fig. 1.

Another explanation of the third Gaussian band is that it arises from FeO—H stretching. To check this possibility, we recently recorded the infrared spectrum of a freshly prepared wet-ground mixture of the Fe-free Georgia kaolinite with CsCl (the absence of Fe is inferred from the lack of a 3596 cm^{-1} band in the spectrum of the uncomplexed clay). Because this mixture had not been aged like the others (1), its spectrum differed from that in Fig. 4, resembling instead the result for the mixed sample in Fig. 2. The curve-fitting results indicate that three Gaussian bands are present, although no band appears in the vicinity of 3560 cm^{-1}. Hence this experiment does not permit a definite assignment of the third Gaussian band to either intercalated water or FeO–H stretching. The spectrum of this sample will be measured after a suitable period for intercalation, in a further attempt to establish the origin of this band.

The remaining band in these rather complex spectra, designated A′, arises from a new inner surface hydroxyl stretching vibration (1) that does not occur in kaolinite. Unlike many of the bands discussed above, its frequency hardly varies with the extent of intercalation. The clear definition of band A′ in the original spectra is such that curve-fitting yields no significant new information about it.

Kaolinite/CsBr

The results for the wet-ground mixture of kaolinite and caesium bromide are plotted in Fig. 5 and summarized in the last column of Table 1. Bands A and D are visible in the measured spectrum, which also appears to contain very weak bands corresponding to B and C; with regard to the latter two bands, however, our curve-fitting analysis yielded only a single band at 3658 cm^{-1}. Since A and D have frequencies about the same as those of the natural clay, the fact that the 3658 cm^{-1} frequency is intermediate between bands B and C suggests that it contains contributions from both. More importantly, these results imply the existence of some uncomplexed kaolinite in the mixture.

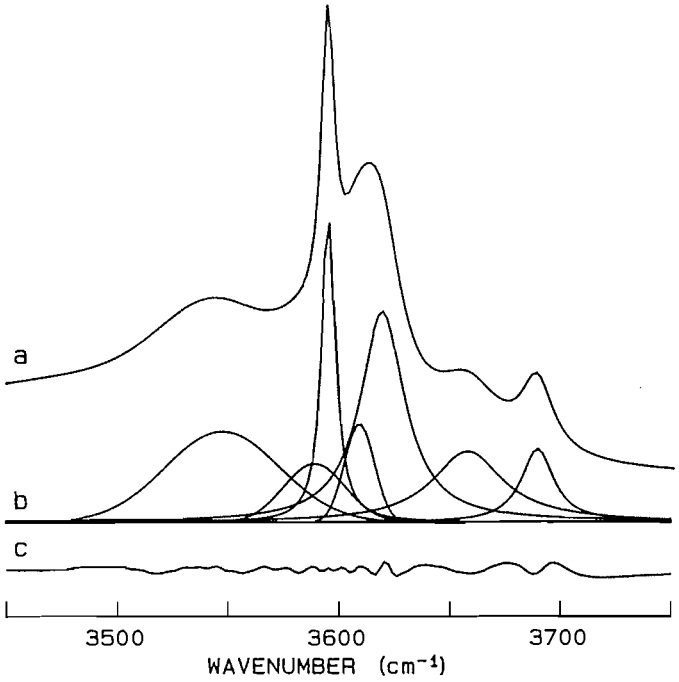

FIG. 5. Curve-fitting results for wet-ground kaolinite/CsBr. a–c as in Fig. 1.

The ν_1 and ν_3 vibrations of the intercalated water in kaolinite/CsBr occur at higher frequencies than for any of the caesium chloride mixtures (cf. Table 1). Taken together with the fact that band A′ occurs at slightly lower frequency in the CsBr complex, the result is that ν_3 now falls on the high-frequency side of A′. Curve-fitting for this spectrum suggested a third Gaussian band between ν_1 and ν_3, similar to that found for kaolinite/CsCl; as discussed above for kaolinite/CsCl, this can be attributed either to a second type of water molecule or to an FeO—H group.

Other mixtures

Finally, we mention results for three other air-ground mixtures: kaolinite/CsBr, kaolinite/KBr, and kaolinite/KI. All three yielded spectra similar to that of uncomplexed kaolinite (Fig. 1); hence the only pertinent question again concerns the presence of band Z. In fact, the curve-fitting results for these three mixtures were also inconclusive: the parameters of the fitted bands depended on their initial values, and the fit was only marginally improved by adding the extra band. These results lead to the conclusion that band Z is so weak that its contribution to the spectra cannot be verified by these calculations.

Conclusions

This paper has described the use of curve-fitting and other numerical methods for the analysis of diffuse reflectance infrared spectra of mixtures of kaolinite and alkali halides. Progressive decreases in the frequencies (and, in some cases, the intensities) of the hydroxyl stretching bands of kaolinite or intercalated water were monitored for kaolinite/caesium chloride mixtures. Furthermore, a new band was identified in the spectra of kaolinite/CsCl and kaolinite/CsBr mixtures, and attributed either to a water molecule at the clay/alkali halide interface or to FeO—H stretching. For kaolinite and its mixtures where intercalation does not occur, the presence of the band arising from uncoupled inner surface hydroxyl stretching was not confirmed by curve-fitting and deconvolution.

NOTE ADDED IN PROOF: The spectrum of the wet-ground mixture of Georgia kaolinite and CsCl, measured after an ageing period of 3 months, was fit using Gaussian bands at 3524, 3565, and 3592 cm^{-1}. These results support the assignment of the 3565 cm^{-1} band to intercalated water rather than to FeO—H.

Received April 23, 1991

This paper is dedicated to Dr. Richard Norman Jones

YIXIAN LIU, J. A. KONINGSTEIN, and Y. YEVDOKIMOV. Can. J. Chem. **69**, 1791 (1991).

Relative values have been obtained for the cross section of fluorescence of tetrakis(4-*N*-methylpyridyl)porphine and the zinc(II) complex with DNA. Time-resolved fluorescence spectra have been used to assign fluorescence of porphyrins which intercalate at or are externally bound to DNA. The experimental data suggest that an equilibrium distribution for intercalated and externally groove-bound to DNA of porphyrin is reached for $r \simeq 200$ complexes. Radiative lifetimes of the various porphyrin species have been determined and evidence is found suggesting the contribution of non-linear effects to the intensity of laser induced fluorescence of $r > 1000$ complexes.

Key words: cross section, fluorescence, porphyrin–DNA complexes, intercalation, outside bound.

YIXIAN LIU, J. A. KONINGSTEIN et Y. YEVDOKIMOV. Can. J. Chem. **69**, 1791 (1991).

On a déterminé les valeurs relatives des sections efficaces de fluorescence de la tétrakis(4-*N*-méthylpyridyl)porphyrine et du complexe du zinc(II) avec l'ADN. On a utilisé les spectres de fluorescence résolus en fonction du temps pour attribuer la fluorescence des porphyrines intercalées à ou liées à l'extérieur de l'ADN. Les données expérimentales suggèrent qu'on atteint une distribution à l'équilibre entre les porphyrines intercalées à ou liées à l'extérieur de l'ADN lorsqu'on approche de $r \simeq 200$ complexes. On a déterminé les temps de radiation des diverses espèces de porphyrines et on a trouvé des données suggérant la contribution des effets non-linéaires à l'intensité de la fluorescence induite par un laser des complexes avec $r > 1000$.

Mots clés : section transversale, fluorescence, complexes porphyrine–ADN, intercalation.

I. Introduction

There is a large body of information available in the literature on the complexation of water-soluble, substituted, and cationic porphyrins and metalloporphyrins with nucleic acids in solution (1–10). These studies indicate that tetrakis(4-*N*-methylpyridyl)porphine [H_2TMpyP] and its zinc derivative display different affinities for GC and AT rich regions of DNA. Various spectroscopic techniques, including absorption, circular and linear dichroism have been employed in the past to study the complexation and it is well known that intercalation takes place in H_2TMpyP at the GC sites while in addition this molecule can also attach itself to the AT sites of DNA. The Zn–porphyrin molecule does not intercalate but is believed to bind externally (5, 10).

The porphyrins exhibit fluorescence in the red part of the spectrum between 580 and 800 nm (9) (Fig. 1). The emission spectrum of H_2TMpyP changes upon the addition of DNA to the solution, in particular the width of the bands. Such changes, however, are not observed for the zinc(II) derivative molecule.

In this paper we discuss the results of a spectroscopic study of the emission spectra of H_2TMpyP and ZnTMpyP in a buffer solution with and without DNA. We have taken advantage of an experimental situation that the fluorescence signal of the porphyrin molecule and that due to the Raman shift of water at ~3500 cm^{-1} are separated if these emissions are induced with laser radiation of an argon ion laser tuned to a wavelength at 476.5 nm (Fig. 1). The intensity of the Raman band of water can be used as an internal standard and the relative value for the cross section of fluorescence can be determined as a function of the concentration of porphyrin molecules in solution. These results, in combination with those of a picosecond time-resolved fluorescence study which includes polarization anisotropy measurements, permit the assignment of spectra that belong to two sites where the H_2TMpyP molecules are either intercalated or externally bound to DNA.

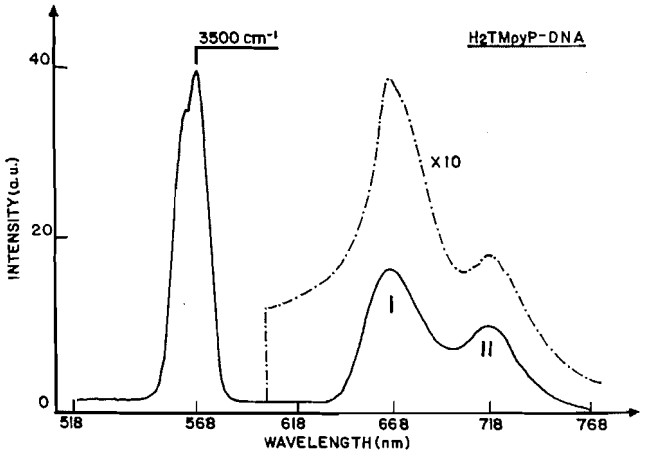

FIG. 1. Typical Raman and fluorescence spectra of water and H_2TMpyP–DNA complexes; — fresh sample; ····· used sample after 20 days; $r = 800$.

From the concentration-dependent value of the cross section for molecular fluorescence, the distribution of the H_2TMpyP molecule over the two sites of DNA as a function of r number of the porphyrin–DNA complexes has been determined (r is the concentration of base pairs of DNA/total concentration of porphyrins).

II. Experimental

A. Instrumental

Emission spectra (Raman and fluorescence) of buffer solutions (pH = 7) of H_2TMpyP and its zinc derivative, together with those of such solutions to which DNA was added, were recorded with a Raman spectrometer. The spectra were dispersed with a Jovin-Yvon double monochromator and the signals emerging from the exit slit were detected with a cooled RCA 31034 A photomultiplier tube. The output of this tube was processed by a photon counting system, spectral data could also be stored in a PC.

Raman and fluorescence spectra were excited with radiation of 476.5 nm of an argon ion laser (power level ~ 30 mW). A typical experimental run is displayed in Fig. 1, and the intensity of the polarized Raman shift at ~3500 cm^{-1} of water is proportional to $45\alpha^2 + 7\beta^2$. Because the integrated intensity of the fluorescence band of the porphyrin molecule is compared to that of the intensity of the Raman band of water (internal standard), one could in principle obtain an absolute value for the cross section of fluorescence band if the cross section for the Raman band of water would be known. The cross section for the Raman shift has recently been determined for excitation wavelength in the uv and vuv but a disagreement exists in the literature (12, 13) on the exact value of the intensity. Extrapolation of these results by intensity calculations for the spectrum of water excited with 476.5 nm is at present thought to yield only approximate results.

Of importance to this work is the ratio $I(fl)/I(Raman)$ where $I(fl)$ and $I(Raman)$ are the integrated intensity of the red fluorescence bands of the porphyrin and the integrated intensity of the Raman shift of water, see Fig. 1. For the solutions used in the present experiments we found that the ratio $I(fl)/I(Raman)$ was proportional to the cross section for fluorescence of the porphyrins and is therefore referred to as the cross section for fluorescence.

Time-resolved spectra were obtained using a 6 ps dye laser as an excitation source where the wavelength could be tuned to the region of 560–650 nm. If tuned to 590 nm one finds that this wavelength is in resonance with a weak absorption band of the porphyrins in solution. The molecular emission was detected by a cooled Hamamatsu R 1564U multichannel plate photomultiplier which is attached to a Jarrell-Ash double monochromator. This monochromator operates in the subtractive mode. The signal generated by the multichannel photomultiplier was processed by a time correlated single photon counting system with the time response of the optical detection system being 42 ps (11).

B. Sample handling

Emission spectra were measured from solutions which were prepared from stock buffer solutions containing H_2TMpyP or its zinc derivative and of a stock buffer solution of chicken blood erythrocytes DNA (B-form), the O.D. = 1.0 at 256 nm. The pH = 7 buffer solutions contained 0.01 M sodium phosphate and 0.3 M NaCl and the concentration of H_2TMpyP and ZnTMpyP was 1.47×10^{-3} and 1.096×10^{-3} M, respectively. Fresh samples were made before each series of measurements and the spectra were taken from solutions in air-tight Raman cells.

III. Results

A. Cross sections for molecular emission of H_2TMpyP and its zinc derivative in buffer solutions

Figures 2*A* and *B* show the concentration-dependent value of the cross section of the red fluorescence band of H_2TMpyP and its zinc derivative in a buffer solution. The fluorescence band extends from about 600 to 780 nm and the signal is well separated from the Raman shift of water at ~3500 cm^{-1} and this shift occurs at ~568 nm, see also Fig. 1. The signal/noise of fluorescence for solutions containing the Zn–porphyrin is higher than that of the H_2TMpyP molecule and fluorescence cross sections could be determined for Zn–porphyrin solutions which are $< 3 \times 10^{-7}$ M. The value of the cross section of

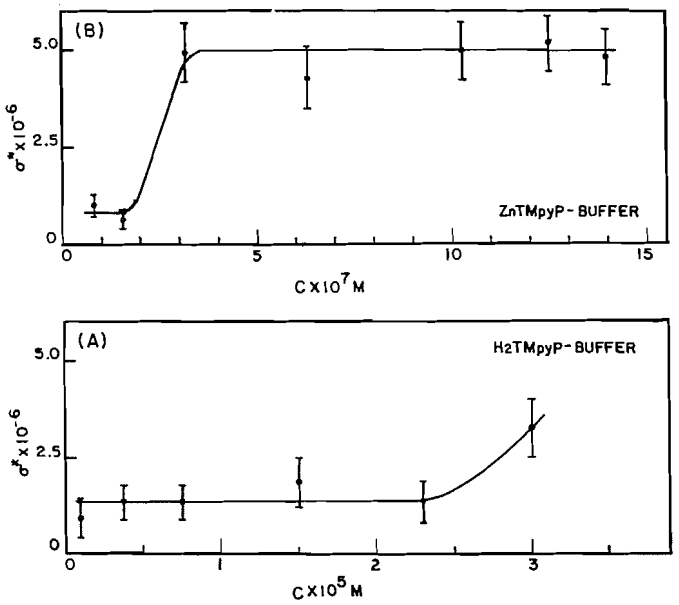

FIG. 2. Relative cross section σ* of fluorescence of H_2TMpyP and ZnTMpyP in buffer solution versus concentration C of H_2TMpyP and ZnTMpyP, respectively; (*A*) H_2TMpyP in buffer solution; (*B*) ZnTMpyP in buffer solution.

TABLE 1. A comparison of relative cross section and radiation lifetime for fluorescence of porphyrin complexes

Compounds	Cross section† $\sigma^* \times 10^{-6}$	Lifetime τ (ns)	Remarks
H_2TMpyP	1.5±0.3	5.0±0.5	Monomer in buffer
H_2TMpyP	>3	<4.5	Aggregate in buffer
H_2TMpyP–DNA	‡	1.7±0.3	Porphyrin binding site I
H_2TMpyP–DNA	‡	10±0.5	Porphyrin binding site II
ZnTMpyP	5.0±0.5	1.3±0.3	Monomer
ZnTMpyP–DNA	70±5	1.8±0.5	Bound externally

†Relative to the cross section of the Raman of H_2O at 3500 cm^{-1} excited with λ = 476.5 nm.
‡σ^*(site I) >> σ^*(site II).

fluorescence for the H_2TMpyP porphyrin molecules is independent of concentration for solutions which are $< 2.5 \times 10^{-5}$ M. The cross section increases in value for solutions which are $> 2.5 \times 10^{-5}$ M. The rotational correlation time of monomeric H_2TMpyP is ~300 ps, but if measured for solutions which are $> 7.4 \times 10^{-5}$ M, the rotational relaxation time increases suggesting that the concentration of aggregates of this molecule increases (14).

The data shown in Fig. 2*B* are for the Zn–porphyrin molecule in the buffer solution. For solutions which are $< 3 \times 10^{-7}$ M one finds that the cross section decreases. The decrease in the value of the cross section for concentrations $< 3 \times 10^{-7}$ M is the result of effective population saturation of the electronic excited state in which the spontaneous fluorescence originates. The fluorescence intensity for solutions $< 3 \times 10^{-7}$ M is non-linear in laser intensity. In Table 1 are given the relative values of the cross section for emission of fluorescence of aggregates of H_2TMpyP and its zinc derivative.

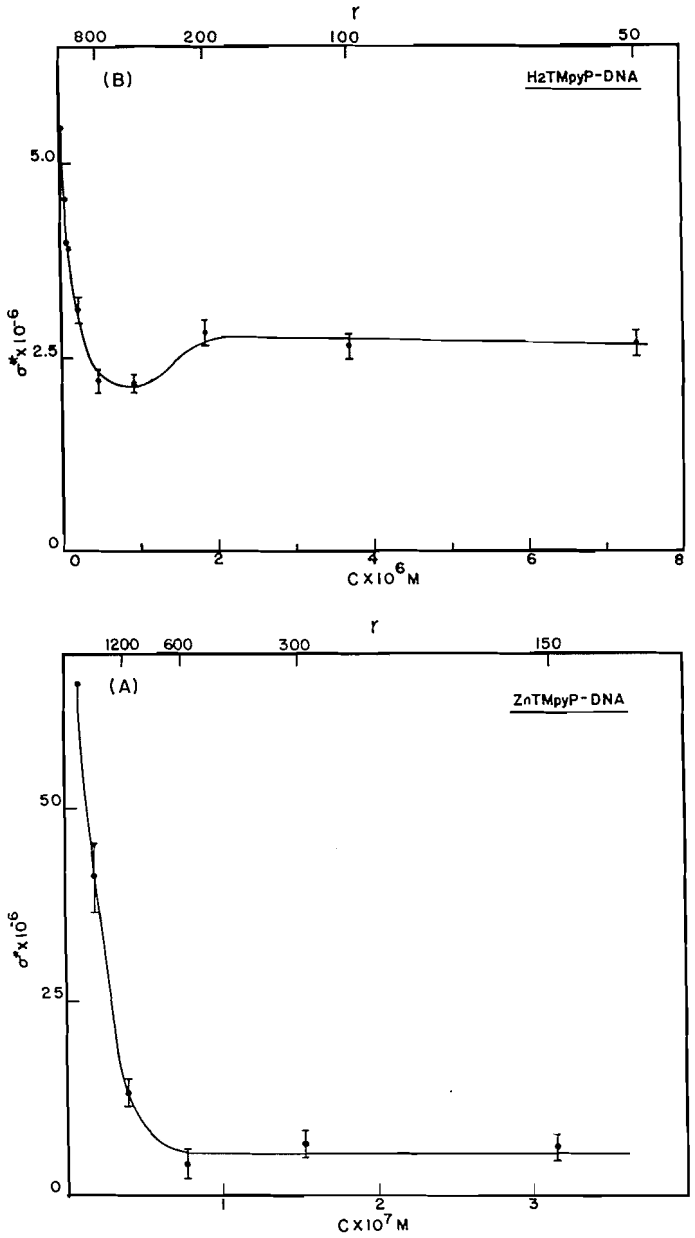

FIG. 3. Relative cross section σ^* of fluorescence of H_2TMpyP–DNA and ZnTMpyP–DNA complexes in buffer solution versus concentration C of H_2TMpyP and ZnTMpyP respectively; (*A*) ZnTMpyP–DNA in buffer solution; (*B*) H_2TMpyP–DNA in buffer solution.

B. Fluorescence of porphyrin–DNA complexes

In Fig. 3*A* is shown the concentration-dependent value of the cross section of fluorescence originating in the Zn–porphyrin molecule complexed to DNA with r values between 5000 and 150. For $r < 600$ complexes, the value of the cross section of fluorescence is within experimental error and equals the value for the cross section of emission of Zn–porphyrin, see Fig. 2*B*.

A sharp increase occurs for the cross section of fluorescence of ZnTMpyP–DNA and H_2TMpyP–DNA complexes takes place in solutions with $r > 600$, see Fig. 3*A* and 3*B*. It is shown in section IV that the sharp increases are the result of the onset of non-linear effects. If the increases are neglected, the data points (Fig. 3*B*) indicate that the cross section for fluorescence for $r > 800$ complexes approaches a value which could be close to the cross section for emission of monomeric H_2TMpyP. On the other hand, for $200 > r > 50$ complexes, the value of the cross section is independent of the concentration of the porphyrin molecule.

IV. Assignment of fluorescence of H_2TMpyP–DNA complexes

The interpretation of the concentration-dependent value of the cross section of fluorescence of H_2TMpyP–DNA complexes in terms of concentration of fluorescence of various species is facilitated if the results (11) of a time-dependent fluorescence study are considered. In these experiments, fluorescence from the porphyrin–DNA complexes are induced with a 6 ps pulse at 590 nm. An analysis of the fluorescence decay at 668 and 718 nm of solutions with $r = 50$ complexes shows that to a first approximation this decay is biexponential with decay times of 2.0 ± 0.5 and 10.0 ± 0.5 ns. There is evidence that another fluorescence process contributes to the overall intensity for solution with $r = 5$ complexes. The decay time of this process is estimated to be 5.0 ± 1.5 ns and the fluorescence is assigned to that of the porphyrin molecule unbound to DNA because the value of the decay time is within the experimental error equal to the decay of 5.0 ± 0.5 ns measured for fluorescence of H_2TMpyP in the buffer solution which does not contain DNA. The presence of fluorescence from unattached porphyrin becomes more clear if the value of r decreases. The rotational relaxation time of monomeric H_2TMpyP in the buffer solution, obtained from time-resolved polarization anisotropy measurements, is 300 ± 50 ps.

The rotational correlation times of the two species for fluorescence with decay time of 2.0 ± 0.5 and 10.0 ± 0.5 ns, within experimental error, are the same and longer than 10 ns. The long rotation time indicates that the emissions originate in excited states of the H_2TMpyP molecule which occupy different sites, designated by site I (nonintercalation) and II (intercalation), respectively (see also section V) for porphyrin molecules attached to DNA. The time-resolved spectrum of the two different sites is shown in Fig. 4, see also Table 1.

In the fluorescence experiments, the laser radiation is focussed on a cell with a 10 cm lens and the path length of the beam inside the cell is 1 cm. For a 10^{-7} M solution, there are $\sim 2 \times 10^7$ porphyrin molecules in the irradiated volume. Assuming a diameter of $d = 200$ μm for the focussed blue laser beam, these molecules are exposed to a flux of $\sim 10^{17}$ photons/s for a power level of 40 mW. Assuming that 10% of the photons are absorbed by H_2TMpyP molecules with the longer lifetime (site II) of the excited state from which the fluorescence originates, we find that during one lifetime of 10 ns, the ratio of photons/porphyrin molecules $\simeq 5$. This suggests that conditions are favorable for effective population saturation of an excited state of porphyrin and hence stimulated emission may contribute to the intensity of the fluorescence. Also, the excited state absorption spectrum of porphyrin molecules may replace in part that of the ground state and the intensity of the Raman band of water could change as a result of absorption of the Raman emitted light by the excited state of porphyrin molecule (15). The observed behaviour of the value of the cross section for ZnTMpyP and H_2TMpyP–DNA complexes with $r \geq 800$ is thought to be mainly caused by the onset of stimulated emission. The results obtained for ZnTMpyP in the buffer solution and for ZnTMpyP–DNA complexes suggest that differences exist in their energy level diagrams and value of transition moments for transition from the ground and (populated) first excited state in the spectral region of 580–720 nm.

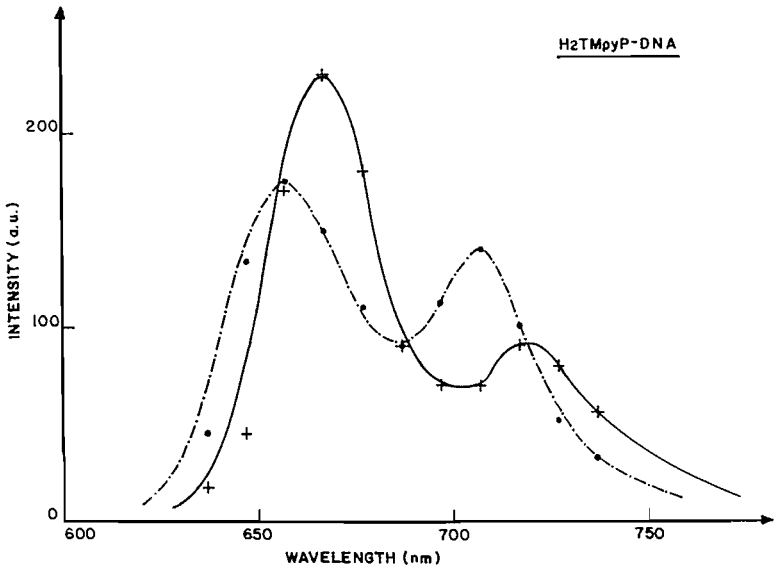

FIG. 4. Time-resolved fluorescence spectra of H_2TMpyP–DNA in buffer solution; — lifetime 1.7 ± 0.3 ns and bound to site I of DNA; ----- lifetime is of 10 ± 0.5 ns and bound to site II of DNA.

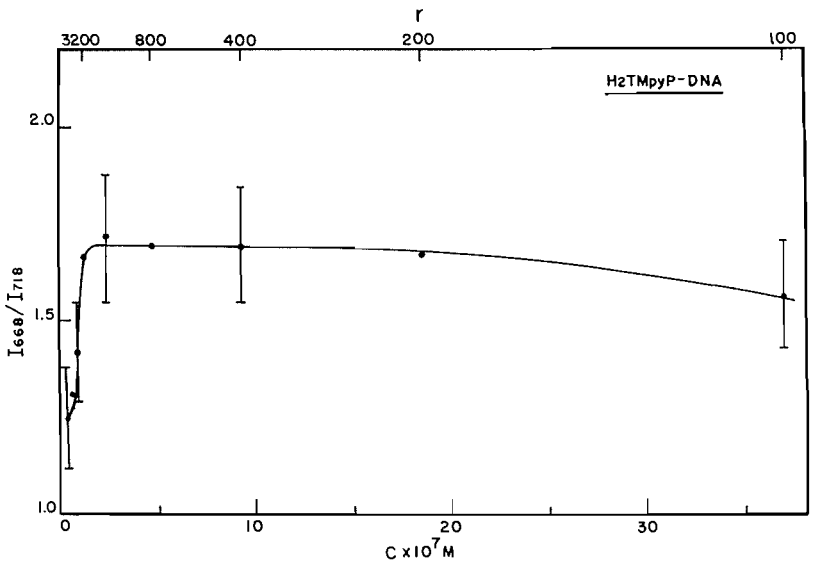

FIG. 5. Amplitude ratio I_{668}/I_{718} of fluorescence peaks of H_2TMpyP–DNA in buffer solution versus concentration C of H_2TMpyP.

Shown in Fig. 5 is the concentration-dependent value for the intensity ratio $I(668)/I(718)$ for peak intensities at 668 and 718 nm. The ratio decreases for solutions with $r > 800$ complexes and approaches the value for fluorescence observed in the time-resolved spectrum of site II.

From the discussion above, the increase in the value of the cross section for fluorescence (Fig. 3*B*) for $r > 800$ complexes is associated with the onset of non-linear effect of porphyrin molecules which occupy site II. This information, combined with the observation (Fig. 3*B*) that the cross section for emission of H_2TMpyP–DNA decreases for $800 > r > 200$ complexes, suggests that for $r > 200$ complexes preferential occupation of site II over site I takes place. For the $r = 200$ complexes, however, an equilibrium distribution has been reached.

Assuming that for $r > 200$ all porphyrin molecules are attached to the DNA, the ratio of molecules occupying site II/site I = 3.0 ± 0.3 as determined from the data points of Figs. 4 and 5. However, for the $r < 200$ complexes, the concentration of unattached porphyrin to the fluorescence signal becomes more evident.

V. Conclusions

Shown in Table 1 are the values of the cross section for emission of the various species. The (relative) values of the cross section were obtained from the data displayed in Figs. 3, 4, and 5. It is well known from circular (3) and linear dichroism (10) and absorption spectra, that H_2TMpyP molecules intercalate at the GC sites of DNA for $r = 200$. Our results suggest that H_2TMpyP molecules binding to DNA are intercalating dominantly for the $r \geq 3200$. For smaller r values another species contributes to the absorption signal and this species has been identified in terms of H_2TMpyP which is externally bound to DNA. Thus the emission spectrum of site II is due

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

to the intercalated H_2TMpyP molecules while the porphyrin molecules occupying site I are externally bound to DNA. Upon storage of solutions containing porphyrins which are intercalated and externally bound to DNA it is observed that fluorescence originating in the intercalated porphyrin gradually disappears while that of externally bound porphyrin remains observable, although the intensity of the fluorescence has decreased in time, see Fig. 1. The disappearance of the spectrum of intercalated H_2TMpyP is thought to be the result of splitting of the DNA sugar–phosphate chains.

Solution of ZnTMpyP–DNA complexes reveals the emission of a complex with a decay time which, within the experimental error, equals that of externally groove-bound H_2TMpyP. The Zn complex is $5 \sim 6$ coordinated with H_2O which has led in earlier work to the suggestion that steric hindrance prevents intercalation (4, 5).

We believe that the results given above can be used in any study of the drug molecules — DNA complexes as long as the position of the Raman shift of water, used as an internal standard for intensity measurements, does not overlap with that of the fluorescence spectrum of the drug molecules. However, by using the radiation of tunable lasers, experimental conditions can always be found to satisfy this requirement. This is particularly true if the molecular emission is induced with laser light tuned to the position of the strong Soret band of porphyrin molecules in solution.

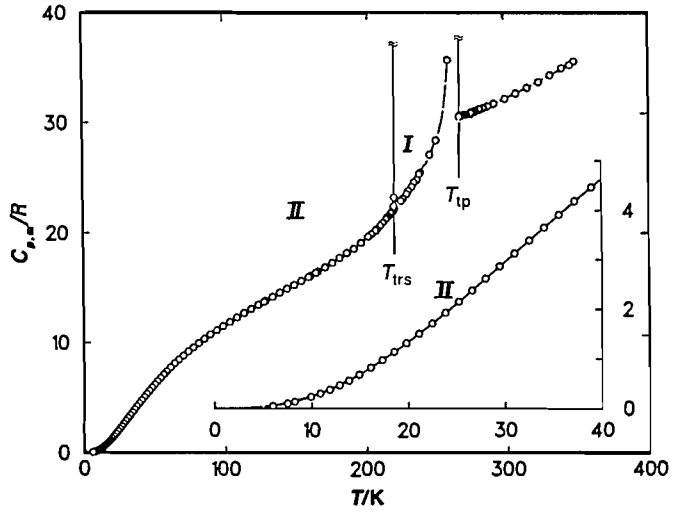

FIG. 1. Heat capacity versus temperature curve of heptanoic acid. Phase designations are given by Roman numbers.

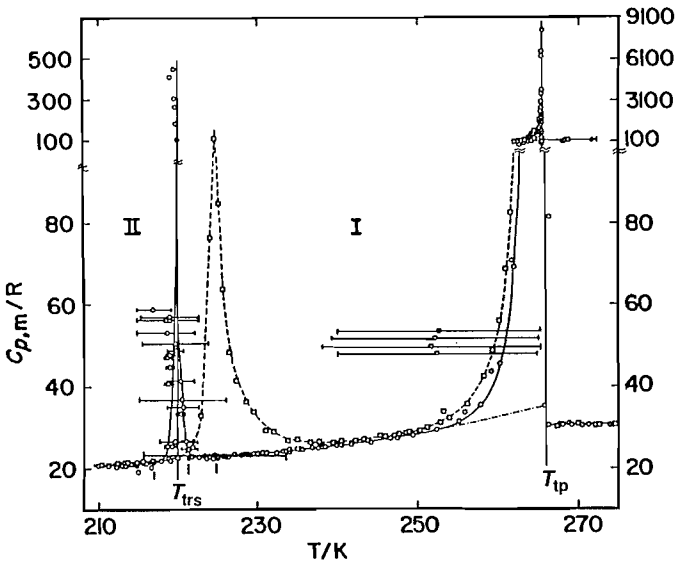

FIG. 2. Expanded heat-capacity curve of heptanoic acid in the transition/fusion regions. —○—, this work; ---□--- ref. 3. Lattice heat-capacity contributions are indicated by dashed line. The three undercooled (metastable) Phase I points of Series XIV are indicated by ●. Horizontal bars designate the temperature range of enthalpy-type determinations.

tion, is presumably occasioned by their failure to cool their sample low enough to convert between enantiotropic forms of the acid.

In our measurements on cooling slowly to 212 K (Series II), no excess transitional enthalpy was observed on an enthalpy determination. Subsequently, we cooled rapidly to 215 K (Series XIV) and were able to make heat capacity measurements on the Phase I over its region of metastability below the transition. These (three) metastable values are displayed in Fig. 2. These values coincide with those of Phase II and hence provide a firm basis for devising a lattice heat-capacity trend smoothly through the transition region despite the fact that the transition by its sharpness, high heat-capacity values ($\approx 400R$), and undercooling phenomena is characteristically first-order. The sharpness of our transition is noticeably more pronounced than that of Schaake *et al.* (3) as seen in Fig. 2.

Fusion

Five sets of runs were made through the melting region; these results also are shown in Table 2. The lattice line for Phase I, drawn through the transition region in Series XIV, is extrapolated to continue the lattice curve to T_{tp}. The enthalpy of fusion is $(1820 \pm 1)R$ K and corresponds to an entropy of fusion $(6.891 \pm 0.004)R$.

Fractional fusion

The nonlinearity of the curve of equilibrium melting temperatures from the Series II determinations (Table 1) as further delineated in Table 3 versus the reciprocal of the fraction melted ($1/F$) are treated by the approach of Mastrangelo and Dornte (10) for solid-soluble/liquid-soluble contaminates. The curvature of the T versus $1/F$ plot for this sample, shown in Fig. 4, suggests that at least part of the impurities are certainly present to some extent in solid solution with heptanoic acid. The form of the melting equation suitable in the presence of solid solution formation is (10):

$$T = T_{tp} - x_2 R T_{tp}^2 \{\Delta_{fus} H_m^0 [F + K(1 - K^{-1}]\}^{-1}$$

in which x_2 is the mole fraction of impurity, T_{tp} is the triple-point temperature, T is the equilibrium temperature of the determinations, $\Delta_{fus}H_m^0$ is the enthalpy of fusion, F is the fraction melted, and K is the partition coefficient. The $K(1 - K)^{-1}$ factor corrects the upward concavity of the otherwise linear plot of T versus $1/F$ (if $K = 0$) in the absence of solubility of the impurity in the solid phase and rectifies the plot for $0 < K < 1$. To determine K, values at $T_{1.00}$, $T_{0.50}$, and $T_{0.25}$

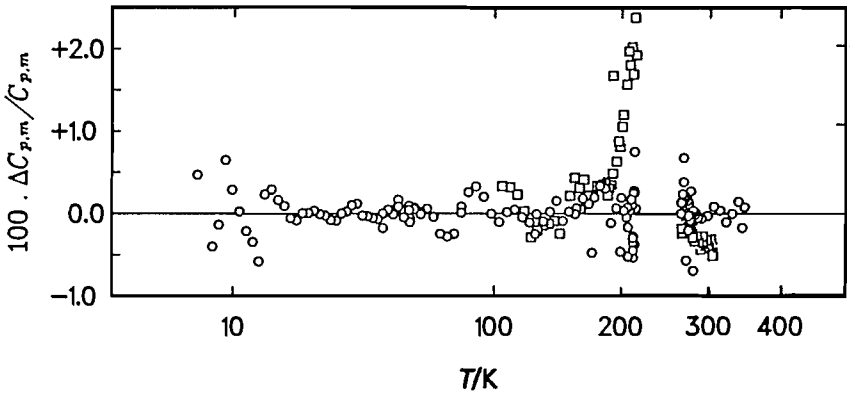

FIG. 3. Deviation plot for heptanoic acid sample with respect to our smoothed curve. ○, this work; □, ref. 3 (a $T^{1/3}$ scale was used to arbitrarily spread the individual data points.)

[a]Equilibrium temperature.
[b]F = fraction melted.

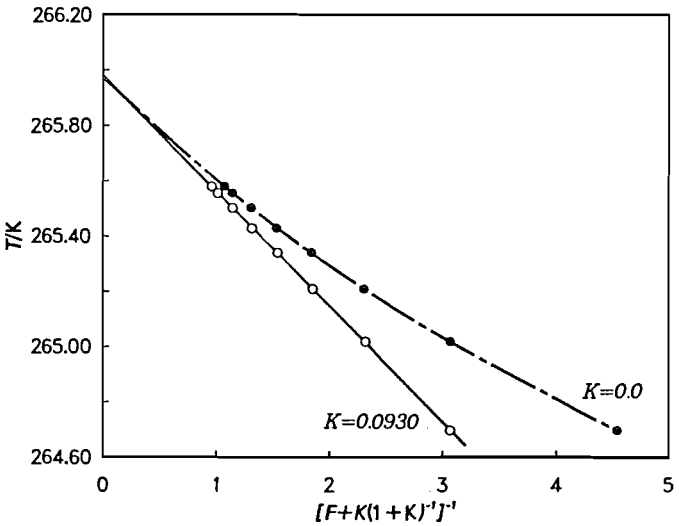

FIG. 4. Plot of the equilibrium temperature versus functions of the fraction melted for heptanoic acid. F is the fraction melted and K is the partition coefficient. The experimental values with $K = 0$ are represented by ● 's and the - - - line. The same values with $K = 0.0930$ for the solid-solution approach are shown as ○ 's with a continuous line.

are read off the ordinary curve at $1/F$ values of 1, 2, and 4 and are then substituted in the expression for K and the process is reiterated until K and T_{tp} values converge.

In this treatment, the T_{tp} and x_2 values obtained from the expressions $T_{tp} = T_{1.00} + (T_{1.00} - T_{0.50})(1 + K)(1 - K)^{-1}$ and $x_2 = (\Delta_{fus}H_m^0)/(RT_{tp}^2)(T_{1.00} - T_{0.50})(1 + K)(1 - K)^{-2}$ are $K = 0.093 \pm 0.003$, $x_2 = 0.0103 \pm 0.0003$, and $T_{tp} = (265.98 \pm 0.01)K$. The literature values for the triple point of **C7H** are 265.83 K (3), 261.75 K (1, 2), 266.02 K (5), 266.05 K (12), and 265.69 K (13).

The summary of fractional melting data is shown in Table 4. In Table 5, a comparison of observed transition and fusion temperatures and thermodynamic property increments with literature values is provided. Although our sample is purer than that of Schaake *et al.* (3) the similarity of the K values suggests similarity in the nature of the impurities.

The solubility of the impurity in the solid phase revealed by the value of K and the somewhat higher purity of our sample judged by the same criterion may explain the observed slightly higher fusion temperature and the much lower transition temeprature than those reported by Schaake *et al.* (3).

As noted by previous investigators (2–4) the thermodynamic sums of thermophysical enthalpies (or entropies) of fusion and solid/solid transition for odd n n-alkanoic acids (neglecting small temperature effects) nearly match the trend of the same properties of fusion for the even acids. Since our Phases II and I are identified as α- and β-phases, respectively, in earlier literature, it can be seen readily in Fig. 5 (in which the solid lines essentially represent the $\Delta_{trs}H_m^0$) that the enthalpies of fusion of the even compounds are well represented by the sums for the odd compounds. The trends as n gets small are attributed to hydrogen bonding (11).

In Fig. 6, the enthalpies of fusion of the odd acids and those of transition for the odd acids are plotted separately against the total number n of carbon atoms. The increment in the entropies of fusion of odd members with increasing length of the carbon chain is probably related to the packing of the methylene groups in the crystalline Phase I state (1, 2), but the magnitude of enthalpies of transition of the Phase I to the Phase II form of the odd acids are not as smoothly dependent on n as are the enthalpies of fusion at the triple point. This

This paper is dedicated to Dr. Richard Norman Jones

ABDUL KARIMEH LABBAN, EDGAR FRANCIS WESTRUM, JR., and JOSE ANTONIO RODRIGUEZ. Can. J. Chem. **69**, 1796 (1991).

The sub-ambient heat capacity of heptanoic acid is characterized by a first order transition at 219.99 K which shows a $C_{p,m}$ maximum greater than $400R$ and $\Delta_{trs}S_m^0$ of $1.132R$. The acid melts at the triple point 265.98 K and shows a $C_{p,m}$ maximum greater than $8200R$ and $\Delta_{fus}S_m^0$ of $6.891R$. At 298.15 K the values of $\Delta_0^{T\ K}S_m^0$, $\Delta_0^{T\ K}H_m^0$, and $\Phi_m(T,0)$ are $38.89R$, $6737R$ K, and $16.29R$. Prior measurements by Adriaanse *et al.* (1964) with a micro calorimeter between 173 and the melting point did not reveal the transition, nor did the method-of-mixtures ("drop") calorimetry of Garner *et al.* (1924) between 213 K and the melting point although they claim to have confirmed the presence of both distinct crystalline phases. The somewhat greater measurement range of Schaake *et al.* (1982) — from 104 to 304 K — by adiabatic calorimetry on a characterized sample did reveal the transition albeit at a temperature 4.8 K higher and with 4% less entropy of transition (double the combined estimated standard deviation).

Key words: *n*-heptanoic acid, heat capacity, transitions, triple point.

ABDUL KARIMEH LABBAN, EDGAR FRANCIS WESTRUM, JR. et JOSE ANTONIO RODRIGUEZ. Can. J. Chem. **69**, 1796 (1991).

La capacité calorifique de l'acide heptanoïque à des températures inférieures à la température ambiante est caractérisée par une transition du premier ordre à 219,99 K qui présente un $C_{p,m}$ maximum qui est supérieur à $400R$ et un $\Delta_{trs}S_m^0$ de $1,132R$. L'acide fond au point triple de 265,98 K et présente un $C_{p,m}$ supérieur à $8200R$ et du $\Delta_{fus}S_m^0$ de $6,891R$. À 298,15 K, les valeurs du $\Delta_0^{T\ K}S_m^0$, $\Delta_0^{T\ K}H_m^0$ et $\Phi_m(T,0)$ sont égales à $38,89R$, $6737R$ K et $16,29R$. Des mesures antérieures effectuées par Adiaanse *et al.* (1964), à l'aide d'un microcalorimètre, à des températures allant de 173 au point de fusion, n'ont pas permis de détecter la transition; il en a été de même pour la calorimétrie des méthodes de mélange («abaissement») de Garner *et al.* (1924) réalisée entre 213 K et le point de fusion, même s'ils ont affirmé avoir confirmé la présence des deux phases cristallines distinctes. Les résultats de Schaake *et al.* (1982), obtenus à partir de mesures s'étalant de 104 à 304 K effectuées à l'aide de la calorimétrie adiabatique sur un échantillon caractérisé, ont révélés la transition même si sa transition est 4,8 K plus élevée et que l'entropie de transition est 4% plus faible (deux fois les écarts types combinés calculés).

Mots clés : acide *n*-heptanoïque, capacité calorifique, transitions, point triple.

[Traduit par la rédaction]

Introduction

Heptanoic acid — $CH_3(CH_2)_5COOH$ hereafter (**C7H**) — has special relevance in biology, industry, and environmental pollution and its fusion and the transition processes in the acid have been previously studied. The heat capacity of heptanoic acid was studied by Garner *et al.* (1, 2) by drop (method of mixtures) calorimetry from 213 K to its melting point, but no transition was found below the melting point. They claim, however, to have confirmed the presence of two (α- and β-) enantiotropic forms seen in the other odd acids of this series. These forms have different enthalpies of crystallization as a consequence of the differences in the crystal structure. Schaake *et al.* (3, 4) studied several odd- and even-linear alkanoic acids and the low-temperature heat capacity of heptanoic acid from 104 to 304 K by equilibrium adiabatic calorimetry and found a solid/solid transition at 224.8 K. The heat capacity of a 99.9% pure heptanoic acid has been measured from 173 K to the melting point by Adriaanse *et al.* (5) with a microcalorimeter; they found no transition between 173 K and the melting point.

Although the prevailing discrepancy in the thermophysical properties of heptanoic acid in the region of the transition can possibly be explained by the failure of both Garner and Adriaanse to cool the sample to a temperature low enough to convert it to the α-enantiotropic form stable at lower temperatures, our heat-capacity measurements are extended to cover the entire range between 5 and 350 K, to complete the morphology of heat capacity curve, to provide more reliable thermodynamic values, to explore the nature of the transition, and to provide data for comparison with planned subsequent measurements on the acid (**C7H**)/salt(**C7Tl**) complex (6, 7).

A sharp solid/solid, first-order, phase transition is observed in this study (the phases designated here as II and I correspond to α-, β-forms in the literature) and new and more precise values of the transition temperature and increments T_{trs}, $\Delta_{trs}H^0$, $\Delta_{trs}S^0$, and the corresponding values for the triple point (tp) are determined as well as the thermophysical properties derived from smoothed values C_p from 5 to 350 K.

Experimental

Sample provenance

The sample used in this study was prepared from commercial (Fluka Company) heptanoic acid; their assay of the purity indicated 98%. The acid was subsequently purified by the following procedure. First it was freed from neutral and basic impurities by dissolving it in aqueous KOH and extracting with dry diethyl ether. The aqueous phase was acidified with HCl, again extracted with dry diethyl ether, and the extract washed several times with distilled water. The basifi-

cation and acidification processing was done on an equimolar basis. This extract was dried over magnesium sulphate for several days and the diethyl ether removed by distillation. Then the acid was fractionally distilled at 1.8 kPa; the boiling point at this pressure is 337 K.

The acid was stored under an argon atmosphere to prevent the absorption of water. The purity determined by gas–liquid chromatography with mass spectrometric sensor technique (University of Michigan, Mass Spectrometry Laboratory) indicated a value of (99.72 ± 0.02)% purity, and about (0.30 ± 0.02)% of organic impurities, such as 0.1% in each of the following: acetate, diethyl ether, and hexanoic acid or isomeric heptanoic acids. In addition, the sample analyzed by d.s.c. indicated a value of 99.5% purity. The loading process was done in a dry He atmosphere to avoid contamination and absorption of water.

Calorimetric technique

The sample (mass = 49.637 g) was loaded into a gold-plated, OFHC copper calorimeter, laboratory designation W-AB. This corresponds to an amount-of-substance factor of 2.62287 mol^{-1} with a molar mass of 130.1090 g mol^{-1} on the basis of the 1978 IUPAC relative atomic masses. The buoyancy corrections were calculated assuming a density of 0.916 g cm^{-3}. Following evacuation, 5.1 kPa of purified helium were added to the calorimeter to enhance thermal equilibration. The calorimeter was sealed within the vacuum chamber by a screw cap (activated by a remotely operating hexagonal wrench) which pressed a gold gasket against the circular knife edge on the stainless-steel neck of the calorimeter.

The calorimetric measurements were made in the Mark XIII cryostat described previously (8). This calorimeter uses intermittent-heating, adiabatic, equilibrium methods. The programming, data logging, and calorimetry were done by computerization as described elsewhere (9). All measurements of mass, time, resistance, etc., were referred to calibrations of the National Bureau of Standards.

To achieve approximate thermal equilibration in mapping runs, the sample was kept for at least two hours after the heating periods at each determination in the region of transition and fusion for Series XII and II; even so, at best semi-equilibration was achieved. The enthalpy increments are, however, based on (equilibrium) enthalpy-type runs across the entire transition region.

The thermal history of the C7H sample is shown by the linear array (solid arrows indicate cooling and dashed arrows indicate data acquisition ranges for various series of heat capacity or enthalpy increment measurements when so specified or more rarely simply a heating period):

Results and discussion

Heat capacity

The values of $C_{p,m}/R$ at the mean temperature of each measurement (arranged in chronological order so the magnitude of ΔT employed usually can be inferred from the increments in mean temperatures) are listed in Table 1 and diagrammed in Fig. 1. Details of the heat capacity peaks are shown in Fig. 2. Apart from transition and melting regions, the numerical data have been fitted to appropriate orthogonal polynomials on the basis of which the relevant smoothed heat capacities were calculated at selected temperatures. The heat capacity of the sample at low temperature ranged from 93% of that of sample plus calorimeter at 10 K, to a minimum of 78% at 118 K, and gradually increased to 86% above 300 K, except in the transition and melting regions. The standard deviations in the heat-capacity values are 3.0% at 6 K and decrease to 0.2% at 20 K and to less than 0.1% above 50 K.

Schaake *et al.* (3) reported the heat capacity of heptanoic acid only from 104 to 304 K. The deviation of their data from the smoothed curve of the present measurement is shown in Fig. 3. No significant difference below the transition and above the melting point between our sample and their relatively less pure sample is observed, except in the region near transition and fusion as shown in Figs. 2 and 3.

II–I transition

In the present measurements, the II–I transition in the heat capacity was observed at 219.99 K, a temperature substantially lower than the 224.8 K value observed by Schaake *et al.* (3). The magnitude of $\Delta_{trs}H_m^0$ is (260.2 ± 1)R K for the present work, and about 6% higher than the reported value of (245.1 ± 4.6)R K for the previous work (3). These differences can be attributed to the higher purity of the sample in the present work. The enhanced maximum heat capacity observed at the peaks in our measurements, as well as the more nearly isothermal nature of our transition further reinforce this point. The solid/solid transition occurs reproducibly at equilibrium (on heating) at a temperature lower by 4.8 K than their reported value.

In the course of the measurements eight sets of heat-capacity and enthalpy-type determinations were made through the anomalous region from an initial temperature, T_1, to a final temperature, T_2, as summarized in Table 2. Series I, III, IV, and V are not included in the average even though the measurements were taken at different cooling rates through the transition, and some (Series I, III, and V) to relatively low temperatures. The low results found are probably accounted for by some inadequacy in the phase conversion. That Garner *et al.* (1, 2) and Adriaanse *et al.* (5) did not find the transi-

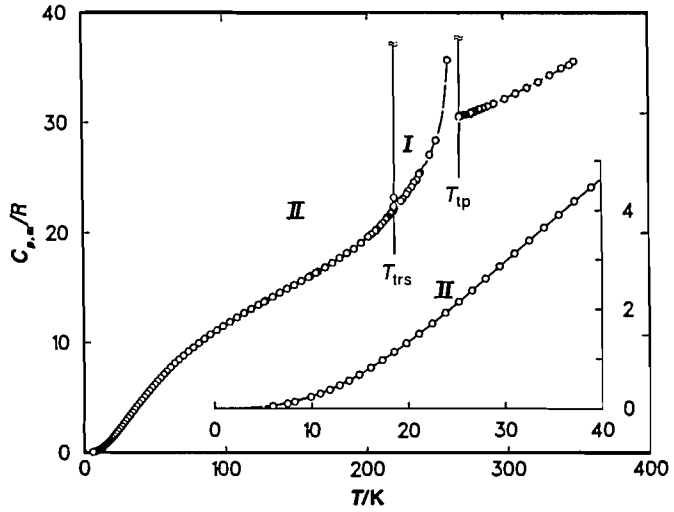

FIG. 1. Heat capacity versus temperature curve of heptanoic acid. Phase designations are given by Roman numbers.

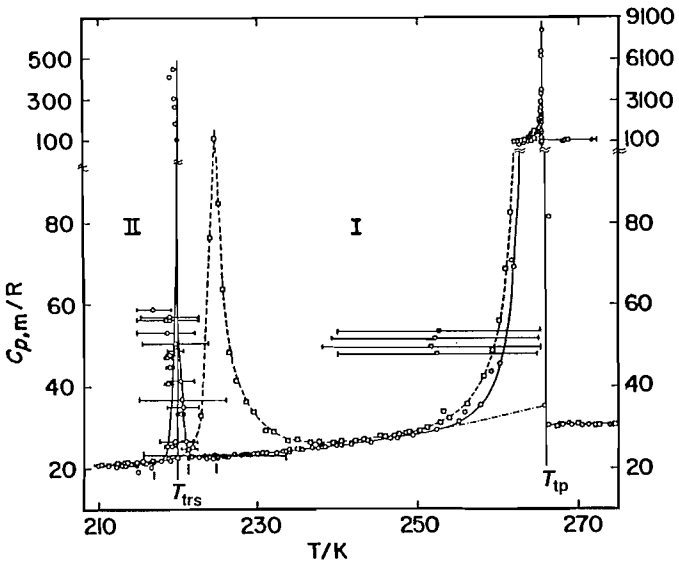

FIG. 2. Expanded heat-capacity curve of heptanoic acid in the transition/fusion regions. —○—, this work; ---□--- ref. 3. Lattice heat-capacity contributions are indicated by dashed line. The three undercooled (metastable) Phase I points of Series XIV are indicated by ●. Horizontal bars designate the temperature range of enthalpy-type determinations.

tion, is presumably occasioned by their failure to cool their sample low enough to convert between enantiotropic forms of the acid.

In our measurements on cooling slowly to 212 K (Series II), no excess transitional enthalpy was observed on an enthalpy determination. Subsequently, we cooled rapidly to 215 K (Series XIV) and were able to make heat capacity measurements on the Phase I over its region of metastability below the transition. These (three) metastable values are displayed in Fig. 2. These values coincide with those of Phase II and hence provide a firm basis for devising a lattice heat-capacity trend smoothly through the transition region despite the fact that the transition by its sharpness, high heat-capacity values ($\approx 400R$), and undercooling phenomena is characteristically first-order. The sharpness of our transition is noticeably more pronounced than that of Schaake *et al.* (3) as seen in Fig. 2.

Fusion

Five sets of runs were made through the melting region; these results also are shown in Table 2. The lattice line for Phase I, drawn through the transition region in Series XIV, is extrapolated to continue the lattice curve to T_{tp}. The enthalpy of fusion is $(1820 \pm 1)R$ K and corresponds to an entropy of fusion $(6.891 \pm 0.004)R$.

Fractional fusion

The nonlinearity of the curve of equilibrium melting temperatures from the Series II determinations (Table 1) as further delineated in Table 3 versus the reciprocal of the fraction melted ($1/F$) are treated by the approach of Mastrangelo and Dornte (10) for solid-soluble/liquid-soluble contaminates. The curvature of the T versus $1/F$ plot for this sample, shown in Fig. 4, suggests that at least part of the impurities are certainly present to some extent in solid solution with heptanoic acid. The form of the melting equation suitable in the presence of solid solution formation is (10):

$$T = T_{tp} - x_2 R T_{tp}^2 \{\Delta_{fus} H_m^0 [F + K(1 - K^{-1}]\}^{-1}$$

in which x_2 is the mole fraction of impurity, T_{tp} is the triple-point temperature, T is the equilibrium temperature of the determinations, $\Delta_{fus}H_m^0$ is the enthalpy of fusion, F is the fraction melted, and K is the partition coefficient. The $K(1 - K)^{-1}$ factor corrects the upward concavity of the otherwise linear plot of T versus $1/F$ (if $K = 0$) in the absence of solubility of the impurity in the solid phase and rectifies the plot for $0 < K < 1$. To determine K, values at $T_{1.00}$, $T_{0.50}$, and $T_{0.25}$

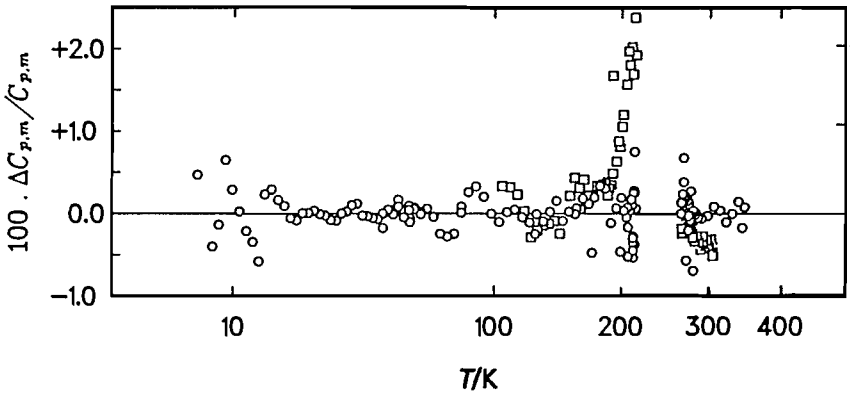

FIG. 3. Deviation plot for heptanoic acid sample with respect to our smoothed curve. ○, this work; □, ref. 3 (a $T^{1/3}$ scale was used to arbitrarily spread the individual data points.)

[a]Equilibrium temperature.
[b]F = fraction melted.

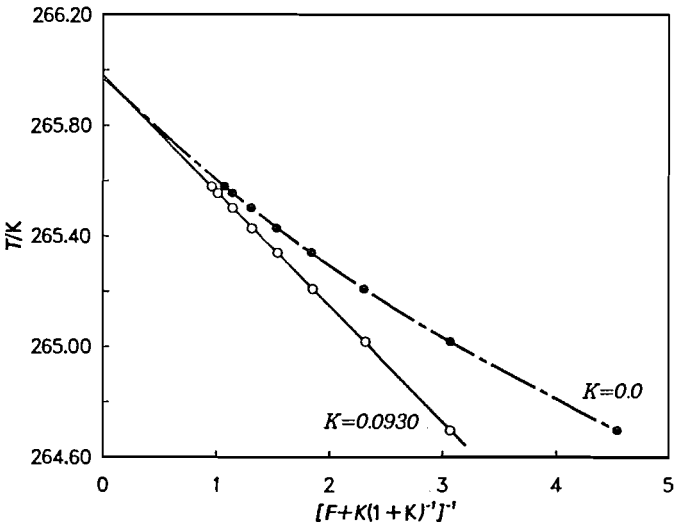

FIG. 4. Plot of the equilibrium temperature versus functions of the fraction melted for heptanoic acid. F is the fraction melted and K is the partition coefficient. The experimental values with $K = 0$ are represented by ● 's and the - - - line. The same values with $K = 0.0930$ for the solid-solution approach are shown as ○ 's with a continuous line.

are read off the ordinary curve at $1/F$ values of 1, 2, and 4 and are then substituted in the expression for K and the process is reiterated until K and T_{tp} values converge.

In this treatment, the T_{tp} and x_2 values obtained from the expressions $T_{tp} = T_{1.00} + (T_{1.00} - T_{0.50})(1 + K)(1 - K)^{-1}$ and $x_2 = (\Delta_{fus}H_m^0)/(RT_{tp}^2)(T_{1.00} - T_{0.50})(1 + K)(1 - K)^{-2}$ are $K = 0.093 \pm 0.003$, $x_2 = 0.0103 \pm 0.0003$, and $T_{tp} = (265.98 \pm 0.01)K$. The literature values for the triple point of **C7H** are 265.83 K (3), 261.75 K (1, 2), 266.02 K (5), 266.05 K (12), and 265.69 K (13).

The summary of fractional melting data is shown in Table 4. In Table 5, a comparison of observed transition and fusion temperatures and thermodynamic property increments with literature values is provided. Although our sample is purer than that of Schaake *et al.* (3) the similarity of the K values suggests similarity in the nature of the impurities.

The solubility of the impurity in the solid phase revealed by the value of K and the somewhat higher purity of our sample judged by the same criterion may explain the observed slightly higher fusion temperature and the much lower transition temeprature than those reported by Schaake *et al.* (3).

As noted by previous investigators (2–4) the thermodynamic sums of thermophysical enthalpies (or entropies) of fusion and solid/solid transition for odd n n-alkanoic acids (neglecting small temperature effects) nearly match the trend of the same properties of fusion for the even acids. Since our Phases II and I are identified as α- and β-phases, respectively, in earlier literature, it can be seen readily in Fig. 5 (in which the solid lines essentially represent the $\Delta_{trs}H_m^0$) that the enthalpies of fusion of the even compounds are well represented by the sums for the odd compounds. The trends as n gets small are attributed to hydrogen bonding (11).

In Fig. 6, the enthalpies of fusion of the odd acids and those of transition for the odd acids are plotted separately against the total number n of carbon atoms. The increment in the entropies of fusion of odd members with increasing length of the carbon chain is probably related to the packing of the methylene groups in the crystalline Phase I state (1, 2), but the magnitude of enthalpies of transition of the Phase I to the Phase II form of the odd acids are not as smoothly dependent on n as are the enthalpies of fusion at the triple point. This

This paper is dedicated to Dr. Richard Norman Jones

KIM D. TRUONG, CLAUDE PÉPIN, ANDRÉ D. BANDRAUK, MARC DROUIN, ANDRÉ MICHEL, and MARCEL BANVILLE. Can. J. Chem. **69**, 1804 (1991).

The donors dipropylamine (DPA), methyldipropylamine (MDPA), and ethyldipropylamine (EDPA) from 1:2 charge transfer complexes with the acceptor tetracyanoquinodimethane (TCNQ). All crystals in the above series are semiconductors and undergo a first-order phase transition at the temperature around 210 K as obtained from conductivity measurements. The X-ray structure of DPA–$(TCNQ)_2$ was obtained as a function of temperature, and shows a distinct order–disorder transition in the hydrogen-bond network between donors and acceptors. Polarized reflection spectra on single crystals of these compounds were measured as a function of temperature in the frequency range from 400 to 4000 cm^{-1}. A detailed study of the C≡N modes of TCNQ indicates this mode is strongly influenced by the transition due to it being hydrogen bonded to the donors. The reflection coefficients of the IR active A_g modes of TCNQ also undergo a sharp discontinuity at the transition temperature. These results are interpreted as due to a cooperative order–disorder and electronic spin – Peierls transition.

Key words: organic semiconductors, X-ray structure, polarized reflection spectra, phase transition, cooperative order–disorder transition, spin–Peierls transition.

KIM D. TRUONG, CLAUDE PÉPIN, ANDRÉ D. BANDRAUK, MARC DROUIN, ANDRÉ MICHEL et MARCEL BANVILLE. Can. J. Chem. **69**, 1804 (1991).

La dipropylamine (DPA), la méthyldipropylamine (MDPA) et l'éthyldipropylamine (EDPA) agissent comme donneurs pour former des complexes de transfert de charge 1 : 2 avec le tétracyanoquinométhane (TCNQ) qui agit comme accepteur. Tous les cristaux des séries sus-mentionnées sont des semi-conducteurs et, d'après les mesures de conductivité, ils subissent une transition de phase du premier ordre à une température d'environ 210 K. Faisant appel à la diffraction des rayons-X, on a déterminé la structure du complexe DPA–$(TCNQ)_2$ en fonction de la température; on observe une transition distincte ordre/désordre dans le réseau des liaisons hydrogènes entre donneurs et accepteurs. On a mesuré le spectre de réflexion polarisée de cristaux uniques en fonction de la température entre 400 et 4000 cm^{-1}. Une étude détaillée des modes C≡N du TCNQ indique que ce mode est fortement influencé par la transition; cet effet est dû au fait que cette liaison est impliquée dans une liaison hydrogène avec les donneurs. Les coefficients de réflexion des modes A_g du TCNQ actifs en infrarouge subissent aussi une discontinuité importante au niveau de la température de transition. On interprète ces résultats en fonction d'une transition coopérative ordre/désordre et spin électronique/Peierls.

Mots clés : semiconducteurs organiques, structure aux rayons-X, spectres de polarisation, transition de phase, transition coopérative ordre–désordre, transition spin–Peierls.

[Traduit par la rédaction]

Introduction

Organic low-dimensional materials attract much attention due to the extensive π-electron delocalization along 1D or 2D stacks of anions or cations. Some of these materials become superconductors. In general these materials exhibit Peierls or spin–Peierls transitions that strongly affect the optical, magnetic, and electrical properties of such systems (1, 2). Recently, these materials were examined for large optical nonlinearities (3).

In previous papers we examined the effect of hydrogen bonding between donors and acceptors (4–6). In particular, a 1:2 charge transfer series of crystals with dipropylamine (DPA) and its derivatives as donors and 7,7′,8,8′-tetracyanoquinodimethane (TCNQ) as acceptor exhibited unique electric, magnetic, and thermoelectric power (TEP) behaviour (7, 8). A dominant transition around the temperature T_c = 210 K showed an abrupt change of these properties. Measurements of the electrical conductivity and magnetic properties suggested the occurrence of an "inverse spin – Peierls" transition (8) because the lower temperature phase exhibited an increase in conductivity. Preliminary infrared (IR) spectra showed that A_g modes of the TCNQ anion became IR active and split into multiplets below the phase transition temperature T_c (7).

In the present paper we present both X-ray data and polarized reflection spectra in order to elucidate the nature of the transition in single crystals of these materials. The crystal structure of DPA–$(TCNQ)_2$ was obtained above and below T_c, leading to the conclusion that an order–disorder transition occurs in the hydrogen-bond network between donors

and acceptors as the temperature is lowered below T_c. Detailed reflection spectra are presented for single crystals of DPA–$(TCNQ)_2$, MDPA–$(TCNQ)_2$, and EDPA–$(TCNQ)_2$, as a function of polarization. The changes in the reflectivity connected with the phase transition around 210 K are examined as a function of temperature. Transverse and longitudinal frequencies in the TCNQ anion stacks have been determined from the reflectance spectra by means of a Kramers–Kronig analysis. Correlation of the structural and spectral data suggests a cooperative order–disorder transition in the H-bond network and an electronic spin – Peierls transition in the conduction stack of TCNQ anions.

Experimental

Preparation and spectra

Single crystals of the materials were prepared by methods described elsewhere (7). Chemical analysis showed 1:2 stoichiometry. The crystals are triclinic (see below) and form in needles, the needle axis being *a*, the stacking axis of the TCNQ chains. In our spectral measurements, the light was polarized parallel and perpendicular to the TCNQ stacks. All measurements were taken as total reflectance, the standard used being evaporated aluminium. An FT-IR spectrometer BOMEM model DA3 was used for spectral measurements with a cooled detector of Ge doped with Cu in the frequency range 400 to 4000 cm^{-1}. A Perkin–Elmer polarizer (gold grid on AgBr) was used for polarization experiments. All measurements were done on single crystals a few mm long and up to 0.5 mm wide, with a very good S/N ratio for polarization parallel to the *a* axis.

Low-temperature spectra were obtained by thermally anchoring the sample to a controlled cold finger. The temperature was measured with thermocouples (Au chromel) with an accuracy of ±3 K.

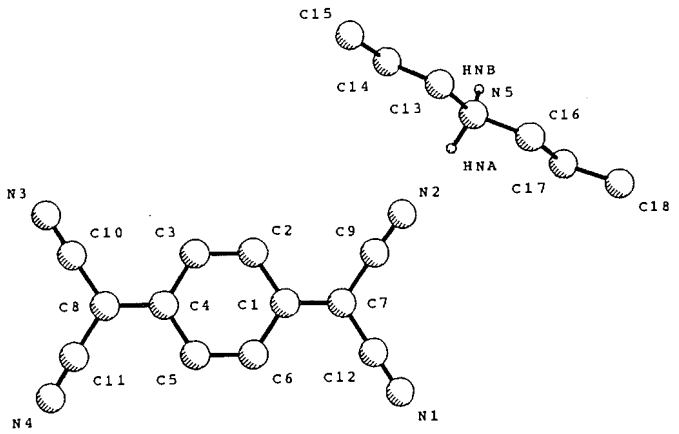

FIG. 1. TCNQ and DPA atom labelling.

X-ray crystallography[2]

The crystal data and experimental details are given in Table 1. The cell parameters were determined by least-squares refinement of the

diffraction geometry of 24 accurately centered reflections. Data were collected at 293 and 193 K on an Enraf–Nonius CAD4 automated diffractometer using $\omega/2\theta$ scan technique. Two standard reflections were monitored every 60 min without significant deviation. The data were corrected for Lorentz and polarization effects. No correction was made for absorption. The structure was solved using direct methods. At 293 K, the DPA molecule is disordered. The N5 atom (Fig. 1) is located near the center of symmetry. The four hydrogens on the TCNQ molecule were located by Fourier difference, whereas those on the DPA that could not be located were geometrically placed. We decided to keep fixed the atomic parameters x, y, z, and u of DPA H atoms, since refinement gives unrealistic distances and angle values. All non-H atoms of the TCNQ were refined anisotropically and treated isotropically for the DPA. The structure at 193 K shows no disorder on the DPA. All hydrogens were geometrically placed and refined. The final cycles of the refinement process were carried out by full-matrix least squares on F, minimizing the function $\Sigma\omega\,(|F_o| - |F_c|)^2$ where ω is defined as $1/\sigma^2$ (F).

The NRCVAX system was used for all calculations (9). Scattering factors were those of Cromer and Waber (10). The highest peaks of residual electron density were respectively 0.28 and 0.18 e/Å^3 at 293 and 193 K. The secondary extinction coefficient was 0.23(3) and 0.14(2) at 293 and 193 K respectively (11, 12). Full detailed structures will be published in Acta Crystallographica (Sect. C).

X-ray structure of DPA–TCNQ$_2$

Above the critical temperature $T_c = 210$ K, the acceptor TCNQ's are stacked along the a(A) axis at equal distances of 3.27(3) Å. The donor DPA molecules are disordered by the thermal motions. Each DPA shares its two hydrogen bonds with four equivalent TCNQ's (Fig. 2). The N(5) atom (Fig. 1) is located at the inversion center. The two cyanide nitrogens N(2) and N(4) are H-bonded to N(5). Table 2 shows the H-bond distances and angles at two different temperatures, 293 and 193 K.

Below T_c, the DPA donor molecule is ordered. The asymmetric unit is doubled as well as the unit cell. The inversion center located at N(5) is lost because of the nonsymmetric DPA (Fig. 3). The TCNQ's are not equivalent as in the phase above T_c. The acceptor molecules stack as NMMN·NMMN tetramers. The MM planes are parallel. The distances separating MM and NN are 3.20(3) and 3.30(3) Å respectively. The former are H-bonded, the latter are not. The NM planes are not parallel, forming an angle of 2.22(5)°. In the unit cell, the two DPA's are oriented in such a way to H-bond only the M-TCNQ's. The M planes are linked together via two H-bonds from separate DPA's. Each DPA links two separate M-TCNQ's, so that two neighbouring sheets of H-bonded TCNQ's and DPA's are separated by two adjacent sheets of non H-bonded (isolated) N-TCNQ's. The DPA H-bonds in neighbouring sheets point towards each other, whereas in the high-temperature, disordered phase, these are randomly distributed.

Reflectance spectra

In Fig. 4 we present the reflectance spectra of DTA–(TCNQ)$_2$ for polarization parallel to the a stacking axis as a function of temperature. The broad features at 295 K are identical to those found in many other TCNQ organic conductors (13–16). We observe five distinct large TCNQ vibration bands around 700, 1200, 1300, 1600, and 2200 cm^{-1}, which are usually associated with IR active A_g modes of the TCNQ anion (4, 14). These bands appear at almost the same frequency in the case of the deuterated compound DPA$_d$–(TCNQ)$_2$, and the derivatives MDPA–(TCNQ)$_2$ and EDPA–(TCNQ)$_2$ (Figs. 5–7). For cations of bigger size, such as MDPA and EDPA, we observe that at 210 K the bands seem larger than in the case of DPA. The coefficient of reflection at this polarization is almost 40% in the case of DPA–(TCNQ)$_2$, diminishing to 18% for EDPA and 30% for DPA$_d$ and MDPA. For the electric field polarized perpendicular to the a stacking axis, the reflectivity is much lower, thus confirming the free electron delocalization along the stacking axis.

The low reflectivity along the a axis indicates a markedly high electron–phonon scattering rate, which is related to the low electrical conductivity observed at room temperature in these complexes (7). Below 210 K, the spectra of all these complexes change dramatically, many bands splitting below T_c as in the case of TEA–(TCNQ)$_2$ (14, 17). In Tables 3 and 4 we report all the vibrational frequencies of DPA–(TCNQ)$_2$ above and below the phase transition, $T_c \sim 212$ K. These were calculated from the conductivity obtained from the reflectance spectra by a Kramers–Kronig inversion. This spectral con-

ductivity is fitted with the dielectric factorized function model (18),

$$[1] \quad \epsilon(\omega) = \epsilon(\infty)\prod_j \frac{(\omega_{Lj}^2 - \omega^2 - i\gamma_j\omega)}{(\omega_{Tj}^2 - \omega^2 - i\gamma_j\omega)}$$

Formula [1] describes transverse (T) and longitudinal (L) phonons where ω_{Tj} is the transverse frequency, ω_{Lj} the longitudinal frequency, and γ_j a general damping parameter, assumed to be the same for the j'th mode. These frequencies are obtained from a least-squares fitting procedure. The oscillator strength parameters S_j (proportional to the square of effective charges) reported in Tables 3 and 4 are calculated from a generalized Lyddane–Sachs–Teller relation (18).

$$[2] \quad S_j' = \epsilon(\infty)\left[\left(\frac{\omega_{Lj}}{\omega_{Tj}}\right)^2 - 1\right]\prod_{M\neq j}\frac{(\omega_{LM}^2 - \omega_{Tj}^2)}{(\omega_{TM}^2 - \omega_{Tj}^2)}$$

In general, we observe that the IR active A_g broad vibrations at 220 K appear as multiplets at 210 K. These results suggest that the symmetry at low temperatures is lower, in accordance with a loss of inversion symmetry. We calculated the oscillator strength parameter S (Tables 3 and 4) and found out that at 210 K, the S values are generally higher than those at 220 K for most vibrations. These results indicate that the effective charges increase in the low-temperature phase, in accordance with the thermoelectric power results (8) at the low temperatures. The phase transition also clearly affects the C≡N stretch (Fig. 10) and deformation vibrations (Fig. 11). With the polarization parallel to the a axis, the C≡N in-plane stretching vibration at 2198 cm^{-1} appears as a strong band at the phase transition temperature T_c = 210 K (Fig. 10). The same results were obtained with MDPA–$(TCNQ)_2$ and EDPA–$(TCNQ)_2$. We can explain this result as a strong interaction between the conduction electrons along the a axis with the C≡N vibrations at the lower temperature due to the large electronegativity of these groups. Similarly in Fig. 11, the C≡N in-plane deformation at 700 cm^{-1} becomes more intense in the low-temperature phase. We reiterate that in this phase there is a higher conductivity due to a lower activation energy for the electron hopping. Thus increased conductivity correlates here with stronger C≡N IR activity. The appearance of this C≡N stretching mode at 2198 cm^{-1} for polarization parallel to the conduction (stacking) axis a has been previously associated with dimerization in TCNQ salts (19). We are thus observing the same phenomenon here. Conversely, in Fig. 11, the C—C—N out-of-plane deformation at 486 cm^{-1} disappears at 210 K, indicating a reduction of electron vibration interaction for this mode below the phase transition. The same effect occurs for the 820 cm^{-1} CH out-of-plane bend. We conclude that *in-plane* vibrations acquire intensity in the low-temperature phase, whereas *out-of-plane* vibrations become much less intense in this new phase.

In general, with the polarization parallel to the a axis, the coefficients of reflection of TCNQ A_g modes are around 30%. This coefficient is very small (about 3%) for the polarization perpendicular to the stacking a axis, confirming thus that TCNQ A_g modes

gain intensity via coupling to the delocalized charge density at the TCNQ site in these complexes.

Discussion

Previously reported electrical and magnetic properties of these semiconductors (7, 8) pointed to an unusual phase transition, which we termed an inverse spin – Peierls transition. Sharp decreases in resistivity, thermoelectric power, and magnetic susceptibility all occurred simultaneously at around 210 K for the DPA and its derivative series.

The X-ray structure, Figs. 2 and 3, reveals that these discontinuities in physical properties are manifestations of the disorder-to-order phase transition occurring in the hydrogen-bond network to be found in these materials. The donor molecules have two protons accessible for hydrogen bonding, with the highly electronegative C≡N groups of the stacked acceptor TCNQ's responsible for the conductivity. In the high-temperature phase, all TCNQ's are equivalent, with an approximate 1/2 charge by stoichiometry. This corresponds to the 1/4-filled band, which in the limit of weak electronic correlation can be expected to undergo an electronic spin – Peierls transition, a tetramerization in this case, leading to a metal–semiconductor phase transition upon lowering the temperature (1, 2). The transition observed at 210 K is of the semiconductor–semiconductor type since only a change in the activation energy occurs. Both electron–electron repulsion and the disorder induced by the H-bonds scatter the conduction electron sufficiently to maintain the high-temperature phase semiconducting (20).

The tetramerization expected for the present compounds, which is a signature of an electronic spin – Peierls, is strongly coupled to the order–disorder H-bond transition upon lowering the temperature. Two different types of TCNQ dimers are formed in the stack: hydrogen-bonded M-TCNQ dimers and nonhydrogen-bonded N-TCNQ dimers (Fig. 3), resulting

in a NMMN tetrameric system. This is therefore a cooperative order–disorder and electronic spin – Peierls transition. In the ordered phase, the protons induce an extra electrostatic potential of periodicity $4k_F$, where k_F is the Fermi wave vector, which therefore reinforces the Peierls transition, i.e., tetramerization of the TCNQ's. The increase in complexity of the IR active A_g mode spectrum also correlates strongly with this picture. In particular, the increase in oscillator force of these vibrations is now explainable as an increase in electron-vibration coupling in the tetramer (21). Furthermore, the C≡N vibrations show the greatest spectral change in crossing the phase transition (Figs. 10 and 11). These changes corroborate this interpretation, which is reflected in the abrupt increase in H-bonding to these highly electronegative groups upon lowering the temperature to $T_c = 210$ K.

We conclude by reiterating that the present results point to a cooperative disorder–order proton transition and an electronic spin – Peierls transition enhancing the tetramerization of these 1/4-filled band organic conductors as one lowers the temperature to $T_c = 210$ K.

An infrared spectroscopic study of 2-methylpropene (isobutene) adsorbed on a Pt/SiO_2 catalyst before and after hydrogenation

GULERANA SHAHID[1] AND NORMAN SHEPPARD
School of Chemical Sciences, University of East Anglia, Norwich NR4 7TJ, U.K.

Received April 22, 1991

This paper is dedicated to Dr. Richard Norman Jones

GULERANA SHAHID and NORMAN SHEPPARD Can. J. Chem. **69**, 1812 (1991).

The infrared spectrum from 2-methylpropene (isobutene) adsorbed at room temperature on a Pt/SiO_2 catalyst is interpreted, with the help of the metal-surface selection rule, in terms of the presence of a mixture of π-bonded, di-σ, and alkylidyne (2-methylpropylidyne) surface species. Heating and evacuation at 100°C retains the original alkylidyne, which occurs together with another surface species probably containing multiple $-CH_2Pt$ groups. Heating to 200 and then to 300°C leads to progressive and strong reductions in the absorptions from alkyl-type surface species, which are replaced by increasing absorptions at ca. 3060 cm^{-1} from unsaturated alkene groups. Hydrogenation at room temperature, after the removal of gas-phase and physically adsorbed 2-methylpropane (isobutane) by evacuation, leaves a methyl-rich spectrum, probably from a partially hydrogenated surface species. Hydrogenation and evacuation at 100°C give a much weaker residual spectrum from saturated hydrocarbon surface species. Subsequent hydrogenation at 200°C gives a spectrum suggesting the presence of a surface *n*-butyl group, clearly the result of a skeletal surface isomerisation. At 300°C in hydrogen the surface species is from a longer *n*-alkyl chain and occurs together with gas-phase methane implying the operation of a disproportionation reaction on the surface. Evacuation of hydrogen at 200 or 300°C leads to virtually total removal of the *n*-alkyl absorptions, which are, however, completely restored by re-addition of H_2. In agreement with a similar study by Avery on a Pd/SiO_2 catalyst, we conclude that after evacuation C—H bonds are largely replaced by C—Pt bonds at stepped-type surface sites.

Key words: 2-methylpropene adsorbed on Pt/SiO_2, infrared spectrum.

GULERANA SHAHID and NORMAN SHEPPARD Can. J. Chem. **69**, 1812 (1991).

Faisant appel à la règle de sélection des surfaces métalliques, on interprète le spectre infrarouge du 2-méthylpropène (isobutène) adsorbé à la température ambiante sur un catalyseur de Pt/SiO_2 en fonction de la présence à la surface d'un mélange d'espèces avec des liaisons-π, des adsorptions di-σ et d'alkylidyne (2-méthylpropylidyne). Par chauffage et mise sous vide à 100°C, l'alkylidyne original est conservé avec une autre espèce présente à la surface qui contient probablement plusieurs groupes $-CH_2Pt$. Par chauffage à 200°C, puis à 300°C, il y a une forte perte progressive des espèces alkyles présentes à la surface; elles sont remplacées par des absorptions croissantes aux environs de 3060 cm^{-1}, causées par des groupes alcènes. Après une hydrogénation à la température ambiante, suivie d'une élimination de la phase gazeuse et du 2-méthylpropane (isobutane) adsorbé, on observe un spectre riche en groupes méthyles qui est probablement dû à une espèce partiellement hydrogénée présente à la surface. Une hydrogénation, suivie d'une élimination des espèces par chauffage à 100°C, fournit un spectre contenant, à la surface, un résidu contenant une quantité beaucoup plus faible d'hydrocarbures saturés. Une hydrogénation subséquente à 200°C donne un spectre suggérant la présence à la surface d'un groupe *n*-butyle qui serait la résultat d'une isomérisation du squelette à la surface. À 300°C, en présence d'hydrogène, l'espèce à la surface est due à une chaîne carbonée beaucoup plus longue et elle se retrouve en même temps que du méthane dans la phase gazeuse; ces résultats suggèrent qu'il se produit une réaction de dismutation sur la surface. L'évacuation de l'hydrogène à 200 ou à 300°C conduit à une élimination pratiquement complète des absorptions de groupes *n*-alkyles qui sont toutefois complètement réintroduits par une ré-addition de H_2. En accord avec les conclusions d'Avery, basées sur une étude semblable impliquant un catalyseur de Pd/SiO_2, on conclut que, après l'évacuation, les liaisons C—H sur des sites superficiels à gradin sont en grande partie remplacées par des liaisons C—Pt.

Mots clés : 2-méthylpropène adsorbé sur Pt/SiO_2, spectre infrarouge.

[Traduit par la rédaction]

Introduction

In a previous paper we interpreted the infrared spectra of propene adsorbed on a silica-supported platinum Pt/SiO_2 catalyst as a function of temperature and hydrogenation in terms of the structures of the adsorbed species present under the various conditions (1). As the Pt/SiO_2 catalyst had fairly large metal particles, typically 5–15 nm in diameter, the use of the metal-surface selection rule (MSSR) gave effective insight in the interpretive process (1). A similar study, confined to straight adsorption at room temperature, has also been described for the three linear butenes, but-1-ene and *cis*- and *trans*-but-2-ene, adsorbed on Pt/SiO_2 (2). The latter results were compared with those obtained by reflection–absorption infrared spectroscopy (RAIRS) from the same alkenes adsorbed on the Pt(111) face of a metal single crystal (2). In the present paper we describe the spectra from 2-methylpropene (isobutene) adsorbed on Pt/SiO_2 over a wide range of temperature and hydrogenation conditions. Comparisons are made with the results of 2-methylpropene adsorbed on Pt(111) as a function of temperature as studied by RAIRS[2] and by vibrational electron energy loss spectroscopy (VEELS) (3).

Earlier room temperature studies of 2-methylpropene adsorbed on silica-supported Ni (4), Pd (5), Pt (4), and Ir (6) catalysts gave similar spectra, dominated by absorptions from methyl-rich species, to those obtained in the present study before and after the addition of hydrogen.

Experimental

The detailed procedure for the preparation of the Pt/SiO_2 discs for infrared transmission study from $H_2PtCl_6 \cdot xH_2O$ and finely-divided Cabosil (SiO_2) by reduction with hydrogen has been reported else-

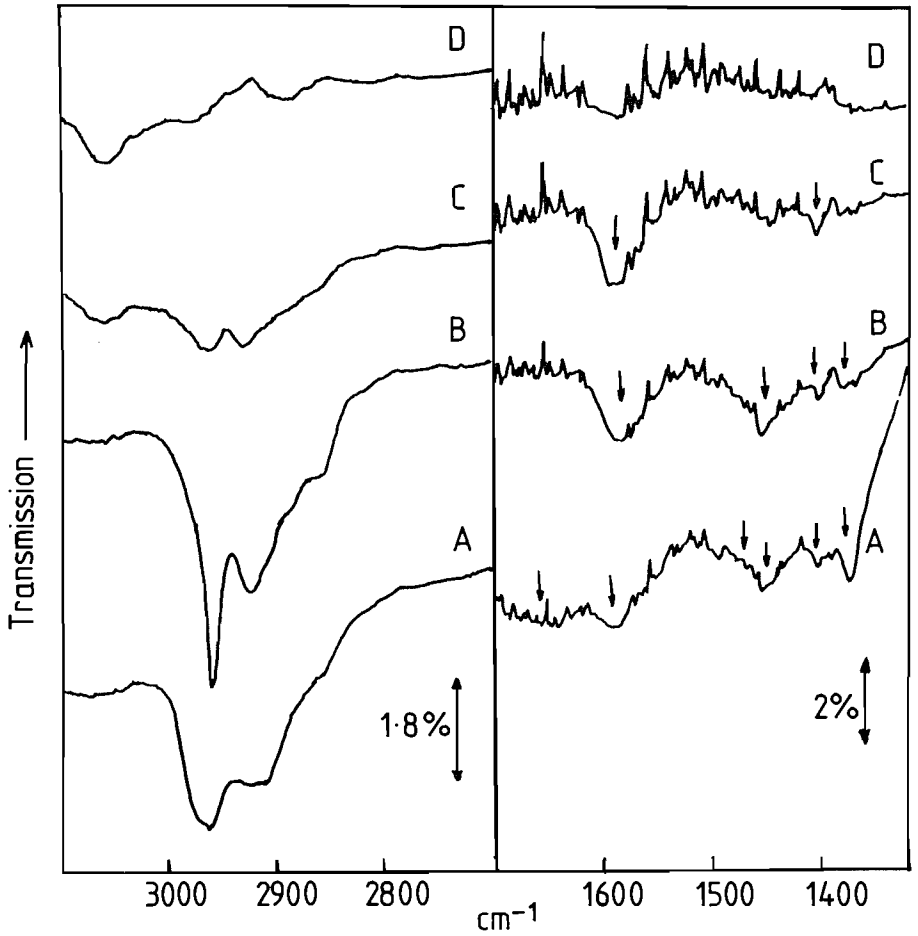

FIG. 1. Infrared spectra in the $\nu CH_3/\nu CH_2$ and $\delta CH_3/\delta CH_2$ regions after adsorption of 2-methyl propene on Pt/SiO_2 at room temperature (A); followed by successive heating to (B) 100°C; (C) 200°C; and (D) 300°C. All spectra were recorded at room temperature after evacuation of the gas phase at the temperatures indicated, and are ratioed against the spectrum of the catalyst in vacuum prior to the adsorption of propene. Sharp features in the 1700–1320 cm^{-1} region additional to those indicated by arrows and discussed in the text are due to poor cancellation of absorption from water vapour in the optical path.

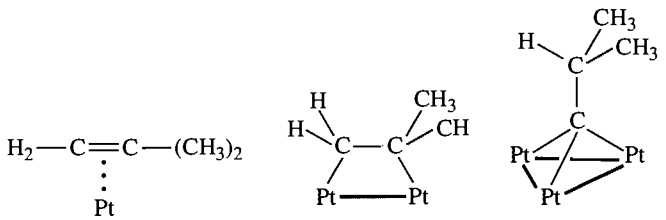
where (1). All infrared spectra were measured *at room temperature* at 4 cm^{-1} resolution using a Digilab FTS 20V Fourier-transform spectrometer. Transmission spectra were ratioed against that of a clean Pt/SiO_2 disc obtained prior to carrying out the adsorption experiments and, where appropriate, against the gas-phase spectrum obtained by lifting the Pt/SiO_2 disc out of the infrared beam.



2-Methylpropene (isobutene), stated purity of 99.0%, was obtained from Messer Griesheim of Germany.

Results and discussion

Room temperature adsorption and evacuation

The spectrum obtained after adsorption at ca. 300 K followed by evacuation is shown in the starting spectra, labelled A, of Figs. 1, 2, and 3. There was some variability of the relative intensities of absorption bands, showing that more than one species is present. The positions, in cm^{-1}, and relative intensities of the absorption bands are as follows: ca. 2970 (m, sh), 2960 (s), ca. 2925 (w to m), 2910 (m), 2865 (mw), ca. 1660 (m, vbd), 1600 (m, bd), 1475 (mw), 1450 (m), 1405 (mw), 1375 (m), where the abbreviations are s, strong; ms, medium strong; m, medium; mw, medium weak; w, weak; sh, shoulder; bd, broad; vbd, very broad. The ca. 2970 and 2925 cm^{-1} absorptions were strongest in Fig. 1A, and only that spectrum possibly had a very broad and weak absorption at ca. 3070 cm^{-1}. Figures 1A and 3A showed the very broad absorption between 1700 and 1620 cm^{-1}, centred at about 1660 cm^{-1}. No sharp absorptions were present that could be attributed to 2-methylpropene adsorbed on the silica support (7).

Following our successful analysis of the spectra from ethene (8–10) and propene (1) adsorbed on the same type of Pt/SiO_2 catalyst, we shall consider the spectra of the initially adsorbed species in terms of possible contributions from the π-bonded species (**1**), the di-σ adsorbed species (**2**), and the 2-methylpropylidyne (isobutylidyne) surface species (**3**). Each

1 **2** **3**

of these surface complexes could retain a plane of symmetry to give an overall symmetry of C_s. In the case of the di-σ species this requires the atoms in the C_2M_2 ring to be coplanar: if this is not the case the symmetry is C_1. The metal-surface selection rule (MSSR) (11, 12) states that only the completely symmetrical A′ vibrational modes will be infrared active through

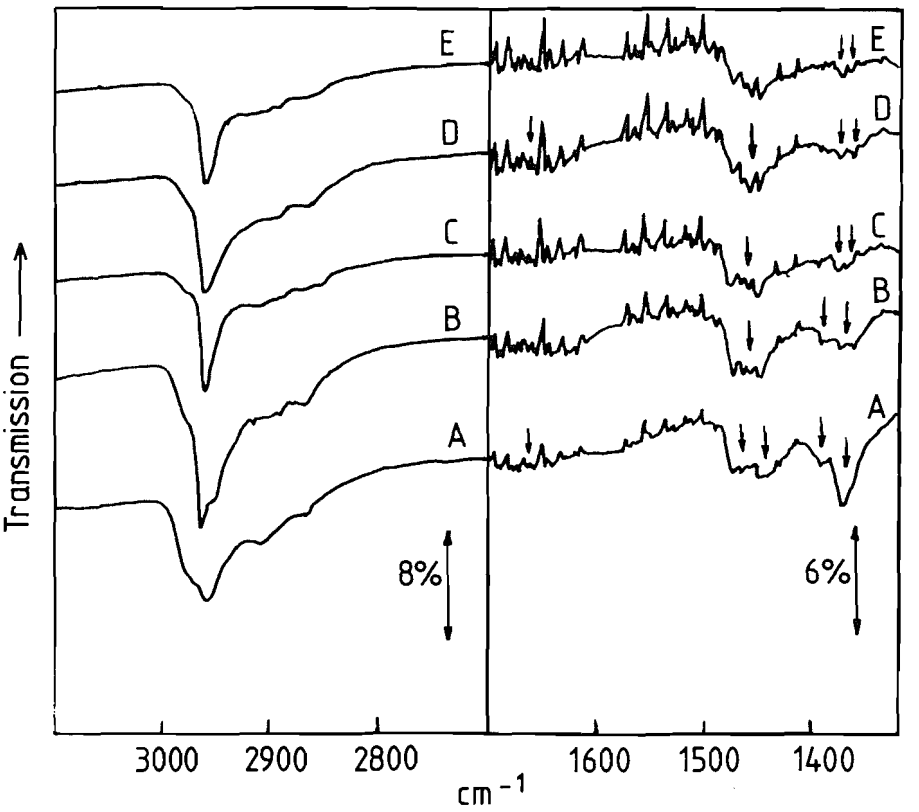


FIG. 2. Infrared spectra of 2-methyl propene (A) adsorbed at room temperature on Pt/SiO_2; followed in succession by (B) addition of 1 Torr H_2; (C) evacuation; (D) addition of 2 Torr H_2; and (E) evacuation. All spectra are ratioed against that of the evacuated catalyst prior to propene adsorption.

having components of their vibrational dipole moments perpendicular to the surface. The A″ antisymmetric modes have dipole changes parallel to the surface and are therefore MSSR-forbidden. For each of the structures **1–3** we identify below the expected strongest allowed A′ modes that could occur down to 1300 cm^{-1}. The latter is the experimental cut-off limit due to effectively black-out absorption by the SiO_2 lattice modes of the catalyst. The intensity predictions take into account the expected directions of the vibrational dipoles with respect to the surface, and also the relative intensities of the functional-group absorptions in the absence of preferred molecular orientations, as measured in the liquid state.

The approximate wavenumbers to ±20 cm^{-1} and relative intensities of some relevant group modes in the absence of the MSSR are as follows (13): 2965, νCH_3as (s); 2915, νCH_3s in $CH_3CH{=}C$ (s); 2870, νCH_3s in alkanes (m); 1450, δCH_3as (m); 1375, δCH_3s (s); 2890, νCH in alkanes (w); 1340, δCH in alkanes (m).

The values for the absorptions of other relevant groups as actually measured on metal surfaces, i.e., also incorporating the effects of the MSSR, are as follows (9, 10): 3015, νCH_2s in $C{=}CH_2$ (mw); 1600–1500, νC=C in π-complexes (mw); 1415, δCH_2 in $C{=}CH_2$ (m); 2920, νCH_2s in $-CH_2M$ (M = metal) (m); 1430, δCH_2 in $-CH_2M$ (w,bd).

Taking into account the above data, modified where necessary by the requirements of the MSSR (allowed vibrational dipoles approximately perpendicular to the surface strong, and those near parallel to the surface weak) we can predict the following positions for the most prominent absorptions from structures **1–3**.

1, The π-complex: 2965, νCH_3as and 1450, δCH_3as.

2, The di-σ complex: 2920, νCH_2s; 2870, νCH_3s; 1375, δCH_3s. In the RAIR spectrum of this complex[2] on Pt(111) at 90 K, the strongest absorption at 2895 cm^{-1} probably is from the νCH_3s mode.

3, 2-Methylpropylidyne (isobutylidyne): 2965, νCH_3as and 1450 δCH_3as. The strongest absorptions in the RAIR spectrum at room temperature on Pt(111), where this species is expected to predominate, are at 2968 and 1445 cm^{-1},[2] in very good agreement with the above predictions.

It is seen that on the above criteria alone it is not possible to distinguish between the π-complex and the alkylidyne. No strong absorptions occur in Figs. 1A, 2A, or 3A that can be attributed to $\nu H_2C{=}C$ or νC=C modes of a π-complex, although a pair of weak absorptions at ca. 3070 and 1600 cm^{-1} in Fig. 1A may denote the presence of a small amount of this surface species. In general, however, we shall assume, as also in the propene case (1), that the νCH_3 and δCH_3 absorptions from the 2-methylpropylidyne predominate in the spectrum. We hence assign the absorption bands of the initially adsorbed species as set out in Table 1. It is noted that the MSSR restricts the number of split-degeneracy CH_3 modes that can be observed.

The great breadth of the ca. 1660 cm^{-1} absorption in Figs. 1A, 2A, and 3A is such that it is unlikely to be attributable to a νC=C mode. At elevated temperatures, as shown in Figs. 1B and 1C, another strong absorption occurs at 1590 cm^{-1}. This persists in Fig. 1C where the absorptions from surface hydrocarbon species are much weakened. Based on the band positions (14) and breadths we tentatively assign the ca. 1660 and the 1590 cm^{-1} absorptions to νPtHPt*s* modes from adsorbed hydrogen on 2-fold bridged sites, possibly on different crystalline facets. Further work with the perdeutero hydrocarbon is needed to confirm this structural assignment. The adsorbed hy-

2910 (m)	νCH_3s	2	1405 (mw)	δCH_2 of CH_2M	2
2865 (mw)	νCH_3s	3	1375 (m)	δCH_3s	2

[a] **1** the π-bonded species; **2** the di-σ species; **3** 2-methylpropylidyne (isobutylidyne). s, strong; ms, medium strong; m, medium; mw, medium weak; w, weak; sh, shoulder; bd, broad; vbd, very broad.

drogen at room temperature could arise from the dissociative adsorption of 2-methylpropene as 2-methylpropylidyne and at elevated temperatures from further CH-bond dissociation.

Heating and evacuation at elevated temperatures

Figure 1B shows the spectrum obtained after heating and evacuation at 100°C followed by cooling to room temperature. A strong spectrum is retained but with a greatly modified profile relative to that obtained at room temperature. The absorptions were observed at ca. 2970 (w,sh); 2960 (vs); 2922 (s); ca. 2910 (w,sh); 2890 (w,sh); 2860 (m); 1590 (ms,bd); 1450 (ms); 1405 (m); 1375 (m). Compared with the room temperature spectrum, the weakening of the 2970 and 1475 cm^{-1} absorptions is consistent with the removal of some of the π-species on heating. Likewise the substantial weakening of the 2910 and 1375 cm^{-1} absorptions can be interpreted in terms of a reduction in the amount of the di-σ species present. Conversely the strengthening of the 2960 and 1450 cm^{-1} absorptions suggests an increase in the amount of the 2-methylpropylidyne species. The alkylidyne species are frequently found to persist to higher temperatures than the others (3, 16). In the specific case of ethene on Pt/SiO_2 (10) and Pt/Al_2O_3 (17), di-σ com-

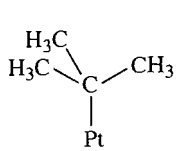
plexes were found to be converted to ethylidyne on heating from lower temperatures to room temperature.

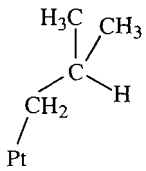
Additional to the expected absorptions of 2-methylpropylidyne, there remain prominent hydrocarbon bands in the spectrum of Fig. 1B at ca. 2920 and 1405 cm^{-1}. In the case of ethene on Pt/SiO_2, nearby νCH_2s absorptions were observed from two distinct di-σ species, presumably occurring on different surface sites or crystal facets, only one of which was converted to ethylidyne at room temperature. The persistence of the 2920 and 1405 cm^{-1} absorption could therefore be attributed to a remaining more stable di-σ species, of which the 2920 cm^{-1} band represents νCH_2s and the 1405 cm^{-1} δCH_2 of CH_2M. The considerable strength of the 2920 cm^{-1} band, however, suggests the possibility of the presence of alternative structures containing multiple CH_2M groups (which are expected to absorb at ca. 2920 cm^{-1} (νCH_2s) and ca. 1430 cm^{-1} (δCH_2) (10) derived from further dehydrogenation of CH_3 groups.

After heating to 200°C followed by evacuation and then cooling, a much weakened spectrum occurs in the region 3000–2800 cm^{-1} characteristic for alkane-type groups, but a broad new absorption occurs at ca. 3060 cm^{-1}, which is typical of alkene absorption of the C═CH or C═CH_2 types (13). Clearly a mixture of saturated and unsaturated species now occurs on the surface. The great weakening of the νCH_3as absorption, now shifted to ca. 2965 cm^{-1}, is paralleled by a strong reduction in intensity of the δCH_3as absorption near 1450 cm^{-1}. The second alkane absorption, shifted to ca. 2930 cm^{-1}, is also weakened by at least a factor of two relative to the spectrum of Fig. 1B. The ca. 1405 cm^{-1} band retains its intensity but the δCH_2 mode of a C═CH_2 group could now also be contributing intensity at this position (13). The ca. 1590 cm^{-1} absorption retains its intensity, but is now accompanied by a weak absorption at ca. 2200 cm^{-1} (not illustrated), which can be attributed to a νPtH vibration of a "linear" or "on-top" PtH group. On a bare Pt/SiO_2 surface such modes absorb at 2130 cm^{-1} (15, 18, 19), but the coadsorption of hydrocarbon species may well cause a wavenumber shift.



After heating to 300°C the 3060 cm^{-1} absorption becomes more prominent and the alkane absorptions weaker again, showing that the one replaces the other. The "negative" features at ca. 2920 and 2850 cm^{-1} may well arise from weak features from hydrocarbon contamination in the spectrum of the Pt/SiO_2 background used for ratioing purposes. Although the earlier VEEL study of 2-methylpropene was not taken to such a high temperature, such spectra from propene, but-1-ene, and pent-1-ene, taken in the range 230–330°C, all showed a single νCH absorption between 3050 and 3070 cm^{-1} (3). These absorptions were accompanied by strong low-energy loss features between 850 and 830 cm^{-1}, which are found in many high-temperature VEEL spectra from hydrocarbon adsorption residues. They are usually attributed to C_2H or CH surface species (3, 20). The low wavenumber feature is suggestive of an out-of-plane δCH deformation mode of a substituted ethylene (13), or of a tilted CH group interacting with several metal atoms by a combination of σ and π bonding (3). The considerable strength of the 3060 cm^{-1} νCH absorption suggests that the CH bond is oriented at an angle to the surface of the metal particles so as not to be weakened by the operation of the MSSR (3). Overall there is very satisfactory agreement between the results on Pt/SiO_2 and the VEELS evidence on Pt(111) about the general types of hydrocarbon species present on the Pt surface in the different temperature ranges.

After heating at 300°C both the absorptions at 2200 cm^{-1} (νPtH) and 1590 cm^{-1} ($\nu PtHPt$) have gone in agreement with a second burst of hydrogen desorption in this temperature range from 2-methylpropene adsorbed on Pt(111) (3). The only absorptions additional to those shown in Fig. 1 are at 2020 and 1820 cm^{-1}, which can clearly be assigned to the presence of small proportions of adsorbed CO on on-top (linear), and bridging, sites respectively (21). The bridging CO species occurs at an early stage but does not subsequently grow, whereas the linear species gradually increases in amount during the consecutive experiments at higher temperatures.



Hydrogenation at room temperature

The effect of the addition of 1 Torr H_2 (1 Torr = 133.3 Pa) at room temperature (ca. 25°C) on the spectrum obtained on initial adsorption, Fig. 2A, is shown in Figs. 2B and 2C before and after evacuation respectively. The substantial reduction of intensity between Figs. 2B and 2C on evacuation, and particularly the weakening of absorptions at 2950, 1465, and near 1370 cm^{-1}, implies the removal of physically adsorbed species formed by the hydrogenation. These absorptions are consistent with the presence of the expected hydrogenation product, 2-methylpropane (isobutane), which is also detected in the gas phase. However, after evacuation (Fig. 2C) a substantial methyl-rich spectrum is retained, showing that there are stable chemisorbed species that resist hydrogenation. Essentially the same spectra were obtained after addition of 2 Torr H_2 followed by evacuation, Figs. 2D and 2E.

The two likely partially hydrogenated surface species are **4** and **5** below. Possibly one of these is hydrogenated to isobutane while the other stays chemisorbed at room temperature. The absorptions in Fig. 2C occur at ca. 2980 (w,sh); 2960 (s); 2910 (w,bd,sh); 2870 (w); ca. 1470 (m,bd); ca. 1380 (w); and 1365 (w). Taking into account the MSSR, the intensity distribution suggests the structural assignment to the adsorbed species of either residual 2-methylpropylidyne or the partially hydrogenated structure **5**. Of these two alternatives, **5** is preferred because of the occurrence of two δCH_3s absorptions at 1380 and 1365 cm^{-1}. These are typical of the presence of $(CH_3)_2CH$- groups, but for the more rigid 2-methylpropylidyne structure one of these would be forbidden by the MSSR. Structure **5** could be most readily produced by hydrogenation of the 2-methylpropylidyne adsorbed species and **4** from the di-σ or π initial species.

4

5

Further addition of gas-phase hydrogen leads, Fig. 2D, to only minor changes in the spectrum of the adsorbed species, mainly a thickening of the 2960 cm^{-1} absorption on the low wavenumber side and some background intensification in the 2930 cm^{-1} region. It seems that there is a minor proportion of adsorbed species that are susceptible to hydrogenation on the surface. Further evacuation and rehydrogenation cycles lead to no further changes so the surface species in question are very stable at room temperature.

No appreciable ca. 1600 cm^{-1} absorptions occur in the spectra of Figs. 1A, 2A, and 3A, but the very broad band

centred near 1660 cm^{-1} occurs more consistently. It persists after hydrogenation but is weaker in intensity in spectra obtained after evacuation, which is consistent with its association with hydrogen chemisorption.

Hydrogenation at elevated temperatures

The spectra are illustrated in Fig. 3 and all were obtained at room temperature after the higher temperature treatments. Spectra were taken in both the presence and absence, i.e., after evacuation, of gas-phase hydrogen.

Addition of hydrogen at 100°C led to 2-methylpropane (isobutane) in the gas phase and, on cooling, a larger amount of the physically adsorbed species compared with hydrogenation at room temperature. This is shown by the greater strength of absorptions at 2950 and 1470 cm^{-1} and is confirmed by evacuation at 100°C, Fig. 3C, where only a weak residual spectrum is retained with bands at 2960, 2915, 2870, 2855, 1580, ca. 1450, and 1380 cm^{-1}. However, subsequent addition of hydrogen at 200°C led to a much stronger spectrum of an *n*-alkyl species and the relative intensities within the 2950/2915 and 2870/2850 cm^{-1} band-pairs is close to what would be expected from the CH_3/CH_2 ratio of an *n*-butyl group bonded to the surface (5, 22). This provides clear evidence that isomerisation of the C_4 skeleton to a straight chain has occurred under the influence either of the high temperature or hydrogenation, or both.

On evacuation at 200°C this spectrum virtually disappears, Fig. 3E, but is restored in a modified form on rehydrogenation at 300°C, Fig. 3F. Such a very remarkable loss of intensity of all the bands from the adsorbed species on evacuation was observed previously at lower temperatures by Avery (5) for alkyl groups bonded to Pd/SiO_2 catalysts. As the removal of CH bonds from the substituted alkane is accompanied by the appearance of only an extremely weak absorption band (if any), in the 3100–3000 cm^{-1} characteristic of alkenes, it seems that CH bonds must be largely replaced by CPt bonds on evacuation. Avery has suggested that this may occur for the linear alkane groups that can become multiply CPt-bonded on evacuation along the edges of steps in the surfaces of the metal particles. For geometrical reasons, some sort of grooved metal surface feature seems to be necessary for the formation of many CPt bonds. A notable difference between the Pt/SiO_2 and Pd/SiO_2 cases is that in the former the phenomenon occurs above 100°C, but in the latter case at room temperature.

The addition of hydrogen at 300°C, Fig. 3F, again indicates the presence of *n*-alkyl groups bonded to the surface, but with much weaker relative absorptions from CH_3 groups at ca. 2940 (shoulder) and near 1380 cm^{-1}, implying the presence of longer alkyl chains. At the same time a weak and sharp gas-phase absorption at ca. 3020 cm^{-1} denotes the presence of gas-phase methane. Overall, compared with the results at 200°C, a disproportionation reaction has clearly occurred. Finally, evacuation at 300°C, Fig. 3G, leads once again to the disappearance of all the alkyl hydrocarbon absorptions. At 300°C the spectra are indistinguishable from those obtained either before or after evacuation from the adsorption of any of the linear butenes (15).

The absorptions assigned to the PtHPt groups alternate in position between 1620 and 1590 cm^{-1} in the presence or absence respectively of hydrogen in the gas phase. When hydrogen is present, weak absorption bands at 2130 cm^{-1} from surface PtH species are also present (18, 19). Absorption bands from adsorbed CO increase in intensity with increasing high-temperature treatments of the sample, giving a weak doublet at ca. 1890 and 1850 cm^{-1} in the CO-bridging region, and stronger absorptions from the linear adsorbed species moving from ca. 1980 to 2030 cm^{-1}.

Conclusions

Through application of the MSSR for vibrational spectra on these Pt/SiO_2 catalysts with fairly large metal particles it has proved possible to account for the room temperature infrared spectrum from the adsorption of 2-methylpropene in terms of the presence of π-, di-σ adsorbed, and 2-methylpropylidyne species. At higher temperatures, up to 300°C, the adsorbed species gradually transform from alkane to alkene in type.

Hydrogenation at room temperature leads some of the adsorbed species to leave the surface as 2-methylpropane and others, of a branched alkyl type, to remain chemisorbed. Hydrogenations at high temperatures up to 300°C provide spectroscopic evidence for isomerisation of the C_4 skeleton to a straight chain and for surface disproportionation reactions leading to gas-phase methane with longer alkyl chains remaining on the surface. The alkyl-type spectra in the presence of hydrogen virtually completely disappear on evacuation but are regenerated by a renewed dose of hydrogen. As suggested earlier for such spectroscopic adsorption phenomena on Pd/SiO_2 (5), this must imply the replacement of many CH groups by CPt bonds to the surface. This probably occurs along steps or similar features in the surfaces of the metal particles.

NOTE ADDED IN PROOF: A recent paper (23) has reported the VEEL spectra of 2-methyl propene adsorbed on Ni(111) between 80 and 150 K. The di-σ form is found at low temperatures, decomposing to a di-σ/π adsorbed species. This could be a precursor of room temperature 2-methyl propylidene.

Semiclassical model calculations of weak, strong, and short O—H···O H-bonds

WERNER A. P. LUCK AND THOMAS WESS
Universität Marburg, D-W-3550 Marburg, Germany

Received March 8, 1991

This paper is dedicated to Dr. Richard Norman Jones

WERNER A. P. LUCK and THOMAS WESS. Can. J. Chem. **69**, 1819 (1991).

The OH potentials of the complexes $(HOH\cdots OH)^-$ are calculated by an *ab initio* MO-LCAO-SCF-CISD method with a 6-31G** basis set for 30 different O···O distances. The resulting OH vibration levels are calculated by the so-called semiclassical Planck–Sommerfeld phase integral. The experimental H-bond effects on vibration spectra, and their anomalies, could be established by calculations of H-bond energies, OH frequencies, anharmonicities, the Badger–Bauer rule, correlation between OH and O···O distances, isotopic effects, and the Ubbelohde effect. For very short H-bonds new properties could be predicted. There seem to exist three classes of H-bond: (1) weak or medium-strong, (2) strong, and (3) very short. The simple phase integral method could demonstrate the anomalous effects of strong H-bonds solely by the transition from two separated minima to one, without necessarily assuming tunnel effects.

Key words: strong H-bonds, IR spectra and theory, tunnel effects.

WERNER A. P. LUCK et THOMAS WESS. Can. J. Chem. **69**, 1819 (1991).

Utilisant une méthode MO-LCAO-SCF-CISD *ab initio* avec un ensemble de base 6-31G** et 30 distances O···O différentes, on a calculé les potentiels OH des complexes $(HOH\cdots OH)^-$. On a calculé les niveaux vibrationnels OH qui en découlent par la méthode semi-classique d'intégrale de phase de Planck–Sommerfeld. Grâce à ces calculs, on a pu déterminer les effets des liaisons hydrogènes expérimentales sur les spectres de vibration ainsi que leurs anomalies, comme : les énergies des liaisons H, fréquences des OH, les anharmonicités, la règle de Badger–Bauer, la corrélation entre les distances OH et O···O, les effets isotopiques et l'effet Ubbelohde. Pour des liaisons H très courtes, on a prédire de nouvelles propriétés. Il semble qu'il existe trois classes de liaisons H : (1) des liaisons faibles ou moyennement fortes; (2) des liaisons fortes et (3) des liaisons très courtes. La méthode simple d'intégrale de phase permet de démontrer les effets anormaux des liaisons H fortes grâce à la transition de deux minima séparés vers un, sans pour cela faire l'hypothèse de l'existence d'effets tunnels.

Mots clés : liaisons H fortes, spectres et théorie IR, effets tunnels.

[Traduit par la rédaction]

Introduction

In our group, Schiöberg (1, 2) recently demonstrated again, for the H-atom, Morse potentials, and harmonic oscillators, the agreement of quantized energy levels of known potentials between the modern Schrödinger method and the older Planck–Sommerfeld phase integral (3, 4).

$$[1] \qquad \oint p_v(r)\,\mathrm{d}r = (v + 1/2)\,h \qquad v = 0, 1, 2, \cdots$$

where $p_v(r) = (2\mu\ E_{\mathrm{kin},v}(r))^{1/2} = (2\mu)^{1/2}\ (E_v - V(r))^{1/2}$; p_v: momentum; $E_{\mathrm{kin},v}$, E_v, and $V(r)$: kinetic, total, and potential energies; and μ: reduced mass.

The Schrödinger method should include eq. [1], which is related to the de Broglie equation. For instance, for the H-atom with mv = constant, and assuming a periodic orbit $\oint \mathrm{d}q = 2\pi r$ at wavelength λ, eq. [1] is parallel to the de Broglie relation $\lambda = h/mv$. Applying eq. [1] means that the areas between the potential curve and the vibration levels have to be set as multiples of h. This requires only short computer times. It gives the possibility of intuition as a supplement to quantum mechanical calculations. Colleagues who like it may find consolation in the word of the Nobel prize winner Max Born (5): "Renouncing such interpretations would make impossible every insight and bring to a standstill the intuition as a basis of research." With this method we were recently able to demonstrate (6) nearly quantitatively the temperature (T) constancy of the density $\rho = \rho_0$ of rare gas crystals from $T = 0$ K to a limiting temperature T_g, and the experimental linear relation $\rho = \rho_0 - bT$ for $T > T_g$. This simple approximation not only brings a deep understanding of intermolecular interactions in the condensed phase up to the T-linearity of the heat of vaporization but can also give intuitive understanding of the continuum of Debye's quantized specific heat frequencies or Planck's black body radiation (6). Equation [1] could also be applied with some success to H-bonds $(ClH\cdots Cl)^-$ (7).

There is some interest in applying eq. [1] to important problems in the mechanism of proton transfer. Certain anomalous behaviour of strong H-bonds has been interpreted as caused by tunnel effects. We were interested in testing whether the properties of strong H-bonds are a conclusive and unique argument for tunnel effects. We were also interested in testing whether this simple method of eq. [1] could give a consistent model of the complicated results of H-bond spectroscopy. Surprisingly, this seems to be possible.

It was of special interest to determine if the semiclassical approximation would be able to calculate experimental isotope ratios $(OH\cdots O)/\nu(OD\cdots O)$ significantly lower than 1, which wave-mechanics calculations did not do (8–12). Also it would be interesting to find out if a result of quantum mechanics (9–12) could be established that a small disturbance of a symmetric double-well potential induces strong different transitions.

1. Results

1. Calculation of the OH potential

Lippincott and Schroeder (13) described OH···O complexes with a double minimum potential. Other authors used different polynomials (8–15), namely Morse potentials (16), exponential functions (9), parabolic functions (9), etc. Janoschek, Weidemann, Zundel, *et al.* (17–19) and Scheiner (20, 21) used quantum chemical energies of models $(H_2O—H\cdots OH_2)^+$ of $(H_3N—H\cdots NH_3)^+$. Our model $(HOH\cdots OH)^-$ was calculated with the *ab initio* MO-LCAO-SCF-CISD method with a 6-31G** basis set using a CONVEX C230 computer. The Cl procedure is extensive but it is necessary to take into account the electron–electron correlations for the potential in strong

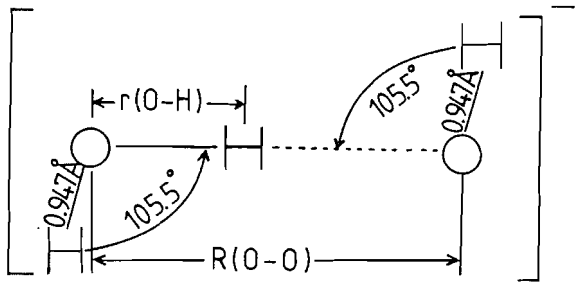

FIG. 1. Assumed geometry of a linear H-bonded $(HOH\cdots OH)^-$ complex. (Geometry of the monomer H_2O optimized with the Hartree–Fock method).

H-bonds (22–26). The geometry of the H_2O monomer has been estimated with the simple Hartree–Fock method neglecting the electron–electron correlations, which are less important for the geometry. We assume the geometry of $(HOH\cdots OH)^-$ to be as shown in Fig. 1.

Figure 2 shows some examples of OH potentials obtained by the *ab initio* method (black points in Fig. 2). The whole potential curve has been represented between points 1 and 2 by polynomials $ar^2 + br^3 + cr^4$ determined by points 1–3 and in the next step between points 2 and 3 by a similar polynomial with varying a, b, and c determined by points 2–4, etc. It was necessary to add r^3 terms to get normal potential curves. The zero point of the potential scale in Fig. 2 is the potential minimum of the monomeric OH group (Fig. 2 on the left). Starting at $R_{O\cdots O} = 3.8$ Å, the potential of the complex is noticeably negative on this scale as a consequence of H-bond interaction (Fig. 2 on the right). Potential curves have been calculated for 30 different $R_{O\cdots O}$ distances in the region $3.8 \text{ Å} \geq R_{O\cdots O} \geq 2.2$ Å (47).

The maximum of the H-bond interaction (the most negative value of V in curves in Figs. 2–5) has been found as 120.65 kJ mol^{-1} at $R_{O\cdots O} = 2.44$ Å, in a region where the double minimum changes to a single one. In this region the distance of the centred H-atom is going to be equal to both O-atoms and is called a symmetric H-bond.

2. Semiclassic calculation of the OH vibration levels

The 30 different potentials described in the last section have been treated with eq. [1], integrating from the smallest OH distance r_{OH} to the largest one along the potential curves and multiplying for a full oscillation by a factor 2 to get the allowed vibration levels with the whole phase integral. The value of the integral, calculated by iterations with a DEC VAX 11/750 computer, increases monotonically with increasing energy level. After about 10–20 steps the quantized vibration levels and the values of the two turning amplitudes were obtained. These levels are given as full lines in Figs. 2–5. The same procedure was repeated for OD (dotted lines in Figs. 2–5). We calculated H or D oscillations assuming non-moving O-atoms. This means we took $\mu(H) = 1.008$ g mol^{-1} or $\mu(D) = 2.014$ g mol^{-1}.

Our monomer OH model ($R_{O\cdots O} = \infty$ gives an OH frequency $\nu = 3740.4$ cm^{-1} in fairly good agreement with $\nu(HOD_{vapour}) = 3707$ cm^{-1} (27). The frequencies with H-bond interactions will be discussed later in Figs. 7–10.

At large $R_{O\cdots O}$ distances with a double minimum the phase integral obviously has to be applied to just one minimum. Two possibilities could be discussed for H-bond cases near a *symmetric H-bond:*

1. In a double minimum potential with oscillations below the potential barrier between the two minima we apply the phase integral to only one minimum. Near symmetric H-bonds at some $R_{O\cdots O}$ (for instance 2.76 Å and $\upsilon = 1, 2$; 2.72 Å, $\upsilon = 1$; 2.66 Å, $\upsilon = 1$) it happens that the admitted value $(\upsilon + 1/2)h$ is, on the one hand, too large compared with the area of one minimum to allow oscillations within only one potential well, but on the other hand too small for oscillations above the potential barriers including the two minima in eq. [1]. In such cases certain quantum numbers υ could be impossible. This effect is mass dependent and could therefore induce the anomalous isotope effect for $\nu(OH)/\nu(OD)$. $\upsilon = 1$ could be possible for OD at 2.76 and 2.72 A (Fig. 3).

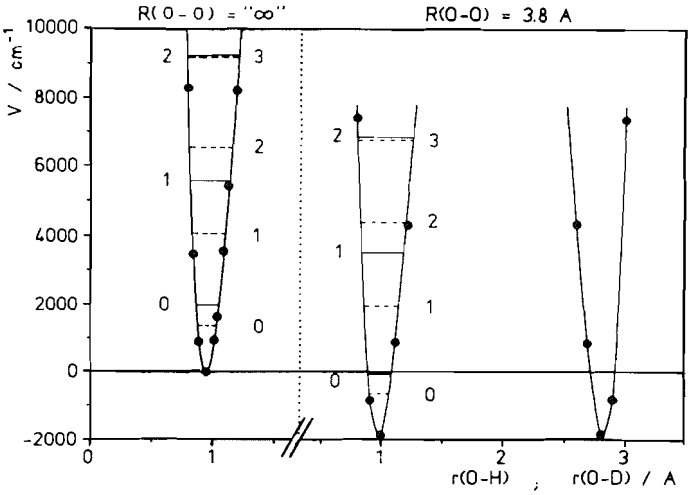

FIG. 2. (●) Potential V values calculated with the 6-31G** basis set. (—) Allowed OH vibration levels υ_H calculated with the phase integral on one minimum (υ_H values on the left side). (----) Allowed OD vibration levels υ_D calculated with the phase integral (υ_D values on the right side). From left to right: $R(O\cdots O)$/Å: ∞; 3.8.

2. We admit total "tunneling" and apply the phase integral immediately to both minima, integrating both areas. For the region $3.8 \text{ Å} > R_{O\cdots O} > 2.52$ Å eq. [1] has therefore also been applied to both minima (corresponding allowance of unlimited tunneling). Figure 5 for example shows the results for $R_{O\cdots O}$: 2.76, 2.72, and 2.66 Å. For 2.76 Å, vibrations up to $\upsilon = 2$ are possible below the potential barrier and for $R_{O\cdots O} = 2.72$ Å, $\upsilon_H = 1$ is included in oscillations below the potential well. All calculations are done only for $\upsilon \leq 4$, excluding high T.

As an approximation, we decided to exclude case 2 (quantization including areas of two partial potential minima). But, if the theoretical vibration level is not far from the potential barrier, $O\cdots O$ vibrations or environmental influences could change the height of the barrier a little for the proton transfer and also change the condition of quantization. Therefore the following discussion for such selected cases is based on the results of such calculations as the examples of Fig. 5 (integrating over the two minima of the double minimum). Case 2 has been assumed for all $R_{O\cdots O} < 2.66$ Å as well (Fig. 4). This procedure could also be an indication of a tunnel effect in such cases.

The theoretical coupling with $O\cdots O$ vibrations is neglected in our method, studying the head lines on a first approximation. This seems to be possible in regard to the large change of $\nu(OH)$ from 3740 to 700 cm^{-1} in Fig. 7, etc.

As one result, Figs. 3–5 demonstrate that the allowed level distances increase with the quantum number υ in case of an overlapping of two minima with vibration levels in symmetric potential parts. That means they are neither harmonic with constant level distances nor anharmonic with decreasing distances but "superharmonic" with increasing distances (negative

$x_e\omega_e$ in Fig. 9). We had found (6) a similar superharmonic case with the sum of intermolecular Lennard–Jones potentials of nearest neighbours in condensed phases, and Millen and co-workers were able to establish this effect experimentally with H-bond vibrations (57). The first, meanwhile more or less forgotten, theoretical "superharmonic" example was given by Pöschel and Teller (58) in 1933.

2. Discussion

1. H-bond energies

Figure 6 shows the energy levels $E(v_{H,min})$ and $E(v_{H,min} + 1)$ in units of cm^{-1} of all 30 cases calculated at a certain constant $R_{O\cdots O}$ ($v_{H,min}$: smallest allowed level of our procedure discussed above). These levels would correspond to the zero-point vibrations. The calculated black points in Fig. 6 are connected with a polynomial $ax^2 + bx^3 + cx^4$. The two curves of Fig. 6 correspond as energies for different $R_{O\cdots O}$ to potential curves of the O···O vibrations. Applying the phase integral of eq. [1] to these curves yields information about the possible vibrational levels of the H-bond stretching ($\mu_{(0)} = 8$ g mol^{-1} is used). We define them by the quantum numbers v'. The minimum of the lower "potential curve" of the O···O vibrations was found at $R_{O\cdots O} = 2.46$ Å with $E(v_{H,min}) = -139.58$ kJ mol^{-1}. If we similarly plot V_{min} for the 30 curves of the types in Figs. 2–5, and assuming, as in Fig. 2, V_{min} of the monomer as the zero point, we get the minimum of the O···O potential curve at $R_{O\cdots O} = 2.44$ Å and $V_{min}(O\cdots O) = -120.65$ kJ mol^{-1} (see above). In a first approximation this value would be the calculated H-bond dissociation energy. Our value is similar to the quantum-mechanics calculation (24): -118.07 kJ mol^{-1} at 2.465 Å. Experimental data give values of -94.2 kJ mol^{-1} (28), -100 kJ mol^{-1} (29), and -144 kJ mol^{-1} (30). A comparison between these experimental values and the theoretical value has to take into account corrections for the zero-point energies of other vibrations and rotations or librations, respectively (22, 24, 31). The shortest known strong H-bonds are given in the literature (32) as 2.44 Å, a value not far from our model, minimum value 2.46 Å in Fig. 6. H-bond energies ΔU_H for the strongest O—H···O H-bonds (33) are given as about -130 kJ mol^{-1}, similar to our prediction. These comparisons are extended to different types of O···O H-bonds, not only the same type as our model, with different charge distributions (HOH···OH)$^-$, so these could be only half-quantitative comparisons of the size of order.

The limited comparison of our charged model complex with medium strong uncharged H-bonds is demonstrated by the H-bond energy value $\Delta U_H = -85$ kJ mol^{-1} (7100 cm^{-1}) of Fig. 3 at $R_{O\cdots O} = 3$ Å, a region in which the known $\nu(OH) = f(R_{O\cdots O})$ diagrams (32) already give $\nu(OH)$ values not far from monomers. Therefore, comparisons between our charged model and real neutral H-bonds seem to give mainly theoretical $R_{O\cdots O}$ values that are a little too large. That means the potential of real non-charged H-bonds corresponding to Fig. 6 would be expected to become a little steeper at larger $R_{O\cdots O}$ values. But the general view of our theoretical results seems to be quite good.

For the strong H-bonded equilibrium configuration of our model complex (HOH···OH)$^-$ around $R_{O\cdots O} = 2.46$ Å, Fig. 6 indicates, for $\nu(OH)$, for the O···O quantum state $v' = 0$ a value of 1109.1 cm^{-1}, and for $v' = 1$ a value of 1141.6 cm^{-1}. OH transitions with a change of the quantum number v' of the O···O vibrations are not very probable for strong H-bonds (1, 2).

The minimum in Fig. 6 corresponds to a change of this potential curve in Figs. 2–5 from two minima into one; the "kink" around 2.6 Å corresponds to the change of vibration levels with areas in only one potential minimum to levels containing both minima.

2. The OH stretching frequencies

Figure 7 compares the experimental values (32) of $\nu(OH) = f(R_{O\cdots O})$ with the result of our changed model complex (HOH···OH)$^-$. The experimental curve for mainly neutral OH···OH bonds has a similar relation, but a shift to smaller $R_{O\cdots O}$. The theory predicts a minimum at about 2.6 Å. This distance corresponds to the case of a $v_H = 0$ near the potential barrier in Fig. 4; therefore case 2 (Sect. 1.2) has been assumed. The smallest $\nu(OH)$ in the theoretical minimum of Fig. 7 is about 750 cm^{-1}, which is in good agreement with the smallest experimental value (720 cm^{-1}) in Novak's (32) review. The appearance of the predicted minimum is unknown; perhaps it could be proved by high pressure measurements, which often show red shifts in a similar way in not too large pressure regions, for ROH systems, as the decreasing temperature corresponds to shorter distances (36, 37). In the case of self-association of 2,2,3,3,4,4,4-heptafluoro-1-butanol (HFB) in perfluoroheptane (PFHP) as solvent, our research group found (37) really experimental OH ν-minima. But they do have much smaller

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

depth at pressures $p \approx 3$ GPa. This p corresponds to a density increase of about 55%. We found a similar ν-minimum for the OH vibration of perfluoro-*tert*-butanol (PFTB) H-bonded to dioxane or to tetrahydrofuran (37) with poly-monochlorotrifluoroethene (PCFE) as solvent. In this case the minimum of the density change is about 30%.

Similarly, we observed small OH ν-minima at $p \approx 2$–3 GPa for monomeric OH (36) induced by van der Waals interactions between OH and solvents. Such minima could be observed for the systems HFB/PFHP/PCFE or PFTB/PFHP/PCFE. In these cases we could also calculate these minima at 3.8 Å (HFB/PFHP), at 3.6 Å (PFTB/PFHP), at 3.55 Å (HFB/PCFE), or at 3.4 Å (PFTB/PCFE) with the semiclassical phase integral method, overlapping the Morse potential with the Lennard–Jones potential. We were able to establish similar minima with other methods (60, 61) as well. This is another example of the efficiency of the phase integral method.

With the assumption of a correlation (34) between the half-width $\Delta\nu_{1/2}$ and a thermal distribution of O···O distances, the theoretical curve in Fig. 7 would predict a proportionality between $\Delta\nu_{1/2}$ and the H-bond induced shift $\Delta\nu$, as it is observed in many experiments (35, 37). In the region of short H-bonds (minimum in Fig. 7) $\Delta\nu_{1/2}$ could be reduced. There are also some indications of the reality of these predictions (14, 32). High pressure spectroscopy (36, 37) has also shown an increase of $\Delta\nu_{1/2}$ (OH) with increasing pressure p. It has been difficult to understand these effects until now, but they could be related to the curve of Fig. 7 in the sense that smaller $R_{O\cdots O}$ values are induced by high p. On the other hand $\Delta\nu_{1/2}$ decreases with reduced T (reduced $R_{O\cdots O}$ distribution) and does not change much at a low T. ν becomes nearly constant at $T \leq 90$ K (59).

3. *The anharmonicity $x_e\omega_e$ of the OH stretching vibration in dependence on the O···O distance*

The calculated frequencies of our model complex for the fundamental vibration $\nu_{min} \rightarrow (\nu_{min} + 1)$ and the first and second overtones $\rightarrow(\nu_{min} + 2)$ and $\rightarrow(\nu_{min} + 3)$ are plotted in Fig. 8.

The irregularities near the minimum depend on uncertainties in our calculations at higher transitions of the O—H excitations. Here in the critical region we could not decide clearly whether the quantization for the higher quantum numbers ($\nu = 2, 3\ldots$) must be done within only one minimum of the double minimum potential or whether areas of both minima have to be considered in the sense of an effect induced by O···O vibrations or tunneling. In the region of strong H-bonds near $R_{O\cdots O} \approx 2.8$ Å the overtone frequencies come near to the fundamental ones (Fig. 8). This could be related to the broad bands of strong H-bonds, called "continuum" by Zundel (17–19, 38–41). This "continuum" could not really be a continuum because the more precise overtone spectra of acids (34, 42) or NaOH (43, 44) show the broad absorption only at the low frequency sides of the OH bands (42, 43). The presented results also make improbably the assumption that the broad bands of strong acids could be induced by an H_3O^+ absorption region (44, 45). This conclusion has already been questioned because OH^- solutions show similar broad bands in the liquid state (42, 43).

Instead of the continuum, we would prefer the nomenclature: very broad OH band or "partial continuum". The increasing $\Delta\nu_{1/2}$, meaning uncertain spectroscopic results, vindicates the use of approximate calculations also for strong H-bonds.

The calculated strong reduction of overtone frequencies (Fig. 8) could also be related to the discussed "triplet structure" of

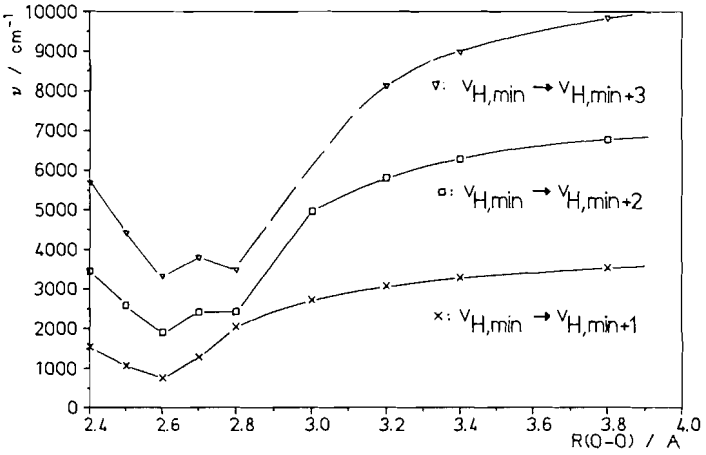

FIG. 8. Calculated OH frequencies based on Figs 2–5 of the fundamental, first, and second overtones (from the bottom to the top).

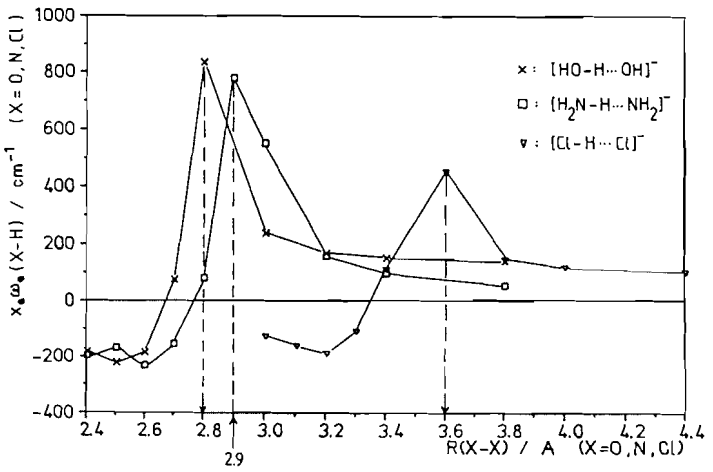

FIG. 9. Anharmonicities $x_e\omega_e$ calculated with the theoretical fundamental and first overtone. OH, NH, and ClH bands calculated with the same method (47) in dependence on the H-bond lengths.

strong OH bands. This effect has been interpreted occasionally by tunnel effects (8). As Fig. 8 demonstrates, this conclusion seems not to be necessary in this case.

In the case of medium-strong H-bonds, $\Delta\nu$ of the first overtone has been observed to be nearly double compared with $\Delta\nu_{(fundamental)}$ (46). This is in agreement with the calculated results but this rule may be not valid for strong H-bonds, a region that is not so easy to measure by the strong increase in $\Delta\nu_{1/2}$.

The strong change of the anharmonicity in the case of strong H-bonds is demonstrated in Fig. 9, which is based on the comparison between the first overtone and fundamental frequencies. Figure 9 includes similar calculations for NH···N and ClH···Cl H-bonds (47). For the predicted behaviour of very short H-bonds, $R_{O\cdots O} < 2.7$ Å, the anharmonicity becomes superharmonic already for the first overtone, an effect that has already been recognized for higher overtones as shown in Figs. 2–5.

4. *H-bond energies and frequency shifts (Badger–Bauer rule)*

Figure 10 shows the relation between the OH stretching frequencies calculated in our approximation in dependence on the potential minima V_{min} (minima in the series of Figs. 2–5).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

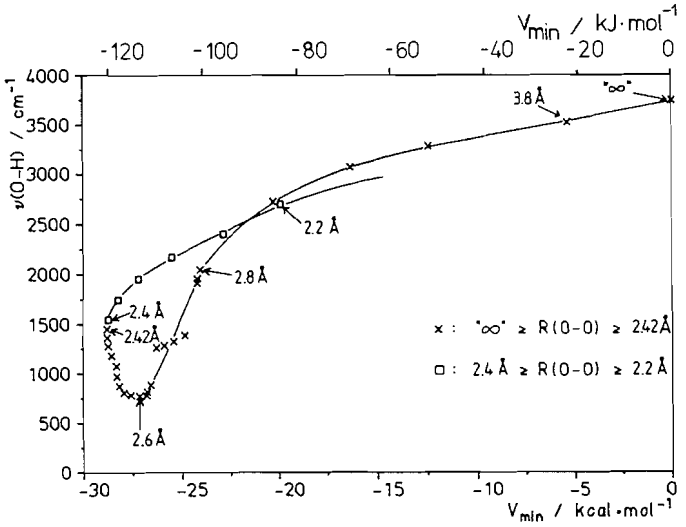

FIG. 10. Calculated fundamental OH stretching frequency of the $(HOH\cdots OH)^-$ complex as a function of the potential minimum V_{min} in the series of Figs. 2–5.

For weak H-bonds the diagram demonstrates an approximate proportionality between $\Delta\nu$ and V_{min}, a relation often discussed by experimentalists as the Badger–Bauer rule. Sometimes this relation has been questioned by theoreticians because of the relation claimed by Buckingham (48): $\Delta\nu \sim \partial V/\partial R$. Both relations could be true if $V_{min} \sim \partial V/\partial R$ is valid (36, 49).

Figure 10 demonstrates strong anomalies at very short O···O distances. Because of the decrease of V_{min} at very short H-bond length, we propose the following nomenclature: 1. long H-bonds, 2. short H-bonds, and 3. very short H-bonds or 1. weak, 2. strong, and 3. short H-bonds. Very short H-bonds are not necessarily strong H-bonds. In this region the repulsion forces have more influence on V_{min}. In the region of strong H-bonds, small influences by the environment (solvent effect, temperature or pressure changes) could induce in addition fairly strong frequency shifts and changes of $\Delta\nu_{1/2}$. This has to be taken into account in discussions of the so-called "continuum" of strong H-bonds.

The minimum in Fig. 10 at about 2.6 Å corresponds to an $R_{O\cdots O}$ at which the zero-point level is extended on both potential minima (Fig. 4); $R_{O\cdots O} \approx 2.4$ Å corresponds to a transition from a flat minimum (as in Fig. 4), which appears for 2.46 Å $> R_{O\cdots O} >$ 2.42 Å, to a more parabola-like potential curve (47).

5. *Correlation between OH distances r_{OH} and O···O distances $R_{O\cdots O}$*

Hamilton and Ibers (50) have given collected neutron-scattering data for the relation $r_{OH} = f(R_{O\cdots O})$. Figure 11 shows these data with a jump in the $R_{O\cdots O}$ region at about 2.48 Å, while cases with angle deviations >10° from a linear H-bond are excluded. In Fig. 11 theoretical results of our calculation for the $(HOH\cdots OH)^-$ complex under discussion are included. These results are in good agreement with the experimental data for neutral OH···O H-bonds with the exception of a change of the shift to higher O···O distances similar to that discussed in Fig. 7. In cases of calculated minima, the position of the lower one of the two minima nearest to oxygen has been taken for r_{OH}. In cases of symmetric potentials of the OH vibration, r_{OH} has been taken at $0.5R_{O\cdots O}$. At about $R \lesssim 2.55$ Å the double minimum changes to one in the series of Figs. 1–5 (47).

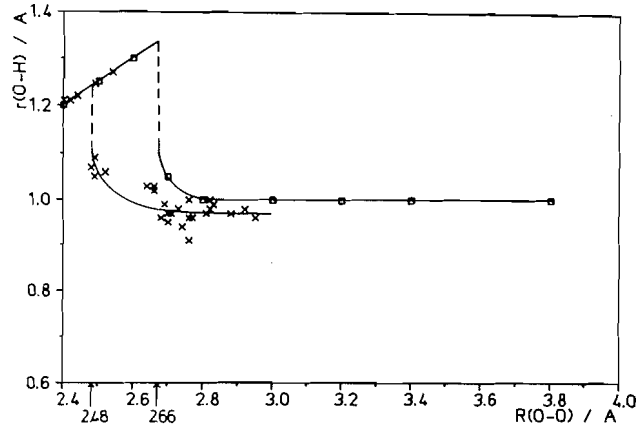

FIG. 11. (×) Neutron scattering results for $r_{OH} = f(R_{O\cdots O})$ (50). (□) Our theoretical values.

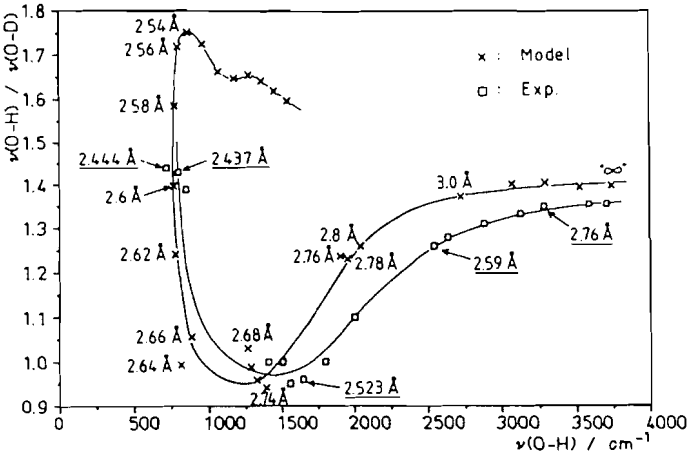

FIG. 12. Experimental (□) and theoretical (×) model isotope ratio $y = \nu(OH)/\nu(OD)$ of the fundamental stretching vibrations in different frequency ranges.

6. *Ratio of the frequencies* $\nu(OH)/\nu(OD)$

The experimental ratio $y = \nu(OH)/\nu(OD)$ of the fundamental OH band gives experimental anomalies in the region of the transition between the double minima to a single minimum (8–13, 32, 51–54) (Fig. 12, squares). Our calculated values of the charged complex agree with these results but give again a shift of the minimum position (Fig. 12). The curves in Fig. 12 consist of three parts:

1. Weak H-bonds with $R_{O\cdots O} >$ 2.76 Å (theory) or >2.6 Å (experiments) with $1.2 \lesssim y \lesssim 1.4$ and $r_{OH} = 1$ Å (Fig. 11).

2. Strong H-bonds with 2.74 Å $\gtrsim R_{O\cdots O}$ (theory) $\gtrsim$ 2.68 Å or 2.55 Å $\gtrsim R_{O\cdots O}$ (exp.) $\gtrsim$ 2.5 Å with a sharp decrease of y from about 1.2 to 0.9 and a kink in r_{OH} (Fig. 11).

3. Short OH-bonds with $R_{O\cdots O} \leq$ 2.68 Å (theory), $R_{O\cdots O}$ (exp.) < 2.5 Å with a sharp increase of y experimentally up to about $(2)^{1/2}$ or theoretically predicted to about 1.75 for very short H-bonds.

Papers on wave mechanics describe the second region with low y-values as caused by tunneling effects (8, 16). The three regions of Fig. 12 are caused in our model calculation by the three regions of Fig. 11: 1. weak H-bonds with constant r_{OH} distance; 2. small increase of r_{OH} from 1 to 1.1 Å; 3. short H-bonds with enlarged r_{OH}. The anomalous isotope ratio (case 2) does not require tunnel effects in our description.

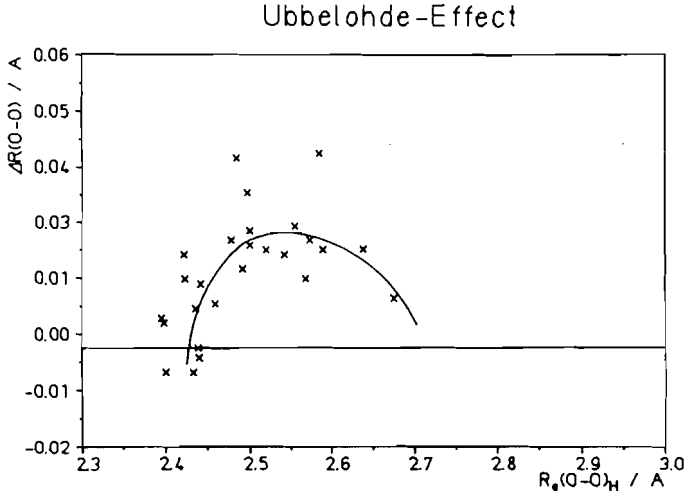

FIG. 13. The increase $\Delta R_{O\cdots O}$ of the O···O distances by deuteration (Ubbelohde effect) (56).

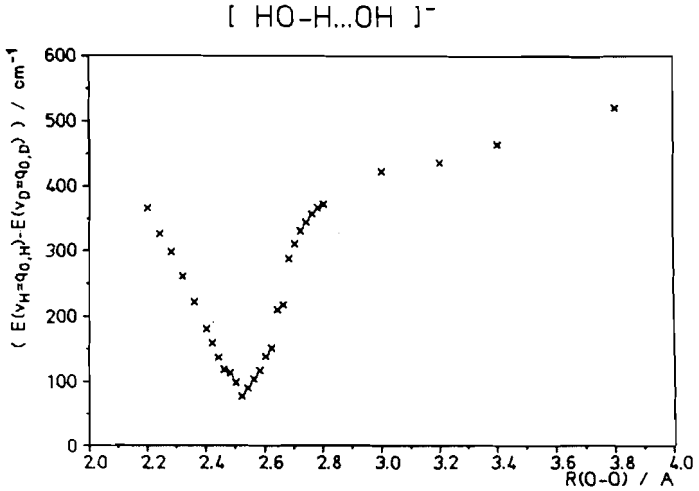

FIG. 14. The difference of the calculated zero-point energy levels of OH and OD as $f(R_{O\cdots O})$.

7. *The Ubbelohde effect, the increase of O···O distances in OD complexes*

The larger vibration amplitudes of OH compared with OD would lead one to expect smaller O···O distances after deuteration. But on the contrary, Ubbelohde (55) demonstrated that deuteration increases the O···O distances in the region between about 2.43 and 2.7 Å (Fig. 13). For shorter H-bonds, $R_{O\cdots O} < 2.43$ Å, the O···O distance may decrease for OD.

We now consider our model complex $(HO—H\cdots OH)^-$ in equilibrium (RO···O = 2.46 Å) as example of an O—H···O bond where the Ubbelohde effect is still to be expected with regard to Fig. 13. Varying the O···O distance, the OD vibration levels are below the OH levels (see Figs. 2–5). The difference of the lowest allowed zero-point energy level for OH minus OD is given in Fig. 14 (data Fig. 2, etc.). Starting at a large O···O distance for our model complex $(HO—H\cdots OH)^-$, this difference decreases with decreasing $R_{O\cdots O}$ to at least a minimum of about 60 cm^{-1} and increases again for shorter O···O distances. The cause of the so-called Ubbelohde effect for our model complex is based on the O···O vibration around its equilibrium distance 2.46 Å, which is near the maximum of the observed Ubbelohde effect at $R_{O\cdots O} = 2.5$ Å: If we discuss the H-bond potential as $f(R_{O\cdots O})$ (Fig. 6) the corresponding OD curve for our calculation would be obtained by subtracting, for every $R_{O\cdots O}$, the values of Fig. 14. As a result the OD curve would become more flat (higher anharmonicity) than the OH curve. Consequently the mean value of $R_{O\cdots O}$ averaged on one O···O oscillation would be larger for OD than for OH and the Ubbelohde effect could be understood based on the calculation for Fig. 14.

$R_{O\cdots O} \approx 2.52$ Å in Fig. 14 corresponds to the case in which the second possible vibration level ($v = 1$) for OH starts to contain areas of both potential minima (Fig. 3) (47) but the second level for OD contains an area of just one potential minimum (Fig. 3). The maximum of about 2.54 Å corresponds to the first potential area in which the zero-point level contains areas of the two minima.

3. Conclusion

The discussed charged H-bond complex $(HOH\cdots OH)^-$ applying the simple semiclassical Planck–Sommerfeld phase integral gives a consistent picture of many anomalous spectroscopic H-bond observations. For mainly O—H···O neutral H-bond complexes experimental anomalies appear only at smaller O···O distances of about 0.2 Å compared with the calculated charged complex. The anomalies are based mainly on the transition from a double-minimum potential to a single-minimum one. They appear even without taking a tunnel effect into account. The calculations can be discussed with the separation of three different types of H-bonds: weak, strong, and short. For short H-bonds some predictions can be given. Experiments with the high pressure technique should be done in this region of repulsion forces for testing the given predictions. Analogous calculations done of $(HN—H\cdots NH_2)^-$ and $(Cl—H\cdots Cl)^-$ give similar results, except that the H-bond distances for the anomalous effects increase (47).

Conformational stability, barriers to internal rotation, *ab initio* calculations, and vibrational assignment of 2-butanone

J. R. DURIG,[1] F. S. FENG, AIYING WANG, AND H. V. PHAN[2]
Department of Chemistry, University of South Carolina, Columbia, SC 29208, U.S.A.

Received July 9, 1991

This paper is dedicated to Dr. Richard Norman Jones

J. R. DURIG, F. S. FENG, AIYING WANG, and H. V. PHAN. Can. J. Chem. **69**, 1827 (1991).

The Raman (3200–10 cm^{-1}) and infrared spectra (3200–30 cm^{-1}) have been recorded for 2-butanone (ethyl methyl ketone), $CH_3CH_2C(O)CH_3$, for the gas and solid. Additionally, the Raman spectrum and qualitative depolarization ratios have been obtained for the liquid. Evidence for the existence of two conformations in the gas and liquid is observed, with the *trans* form (the two CH_3 moieties oriented *trans* about the central C—C bond) much more abundant than the high-energy form, presently identified tentatively to be the *gauche* rotamer. The *trans* form is the only form remaining in the spectrum of the solid. A very weak infrared band at 65 cm^{-1} has been assigned to the asymmetric torsion of the *trans* conformer. Using this frequency, ΔH, and the dihedral angle of the *gauche* rotamer, a potential function is proposed for the conformational interchange. Spectral features observed at 195.5 and 181.0 cm^{-1} in the far infrared spectrum of the gas have been assigned to the $1^{\mp} \leftarrow 0^{\pm}$ and $2^{\mp} \leftarrow 1^{\pm}$ of the methyl torsion of the ethyl group of the *trans* form, from which a barrier of 868 ± 3 cm^{-1} (2.48 ± 0.01 kcal/mol) is calculated. Similarly, the fundamental CH_3—C(O) torsion has been observed at 94.5 cm^{-1} for the *trans* conformer from which a threefold barrier to internal rotation has been calculated to be 233 cm^{-1} (666 cal/mol). Utilizing the rotational constants for two isotopic species, which were reported in an earlier microwave study, the heavy atom r_0 structural parameters have been determined. A complete vibrational assignment is proposed, which is supported with the results from a normal coordinate analysis performed with the force fields calculated with the 3-21G basis set. Full geometry optimizations have been carried out at the 6-31G* basis set for both the *trans* and *gauche* conformations as well as for the transition states to determine the structural parameters, energy difference, and barriers to internal rotation about the central C—C bond.

Key words: 2-butanone, vibrational spectrum; *ab initio* calculations, 2-butanone; conformational stability, 2-butanone.

J. R. DURIG, F. S. FENG, AIYING WANG et H. V. PHAN. Can. J. Chem. **69**, 1827 (1991).

On a déterminé les spectres Raman (3200–10 cm^{-1}) et infrarouge (3200–30 cm^{-1}) de la butan-2-one (éthyl méthyl cétone), $CH_3CH_2COCH_3$, tant à l'état gazeux que solide. On a aussi déterminé le spectre Raman et les rapports qualitatifs de dépolarisation du liquide. On a obtenu des données qui suggèrent l'existence de deux conformations tant en phase gazeuse que liquide; l'abondance de la forme *trans* (dans laquelle les deux portions CH_3 sont orientées en *trans* par rapport à la liaison C—C centrale) est beaucoup plus grande que celle de la forme plus riche en énergie que l'on croit être le rotamère *gauche*. La forme *trans* est la seule présente dans le spectre du solide. On a attribué une très faible bande, présente à 65 cm^{-1} du spectre infrarouge, à une torsion asymétrique du conformère *trans*. Utilisant cette fréquence, le ΔH et l'angle dièdre du rotamère *gauche*, on propose une fonction de potentiel qui permet de déterminer le changement conformationnel. On a observé des caractéristiques spéciales à 195,5 et 181,0 cm^{-1} dans le spectre infrarouge lointain du produit gazeux; on les a attribuées aux torsions $1^{\mp} \leftarrow 0^{\pm}$ et $2^{\mp} \leftarrow 1^{\pm}$ du méthyle présent dans la forme *trans* du groupe éthyle; à partir de ces données, on a pu calculer que la barrière à cette torsion est égale à 868 ± 3 cm^{-1} (2,48 ± 0,01 kcal/mol). De la même manière, on a observé la torsion fondamentale CH_3—C(O) à 94,5 cm^{-1} pour le conformère *trans*; on en a déduit que la barrière triple à la rotation interne est égale à 233 cm^{-1} (666 cal/mol). Utilisant les constantes rotationnelles des deux espèces isotopiques qui ont été antérieurement sur la base d'une étude par micro-ondes, on a déterminé les paramètres structuraux r_0 de l'atome lourd. On propose une attribution vibrationnelle complète qui est en accord avec les résultats obtenus à partir d'une analyse des coordonnées normales réalisée avec des champs de force calculés avec un ensemble de base 3-21G. Dans le but de déterminer les paramètres structuraux, les différences d'énergie et les barrières à la rotation interne autour de la liaison centrale C—C et utilisant un ensemble de base 6-31G*, on a effectué une optimisation complète de la géométrie des conformations *trans* et *gauche* ainsi que des états de transition.

Mots clés : butan-2-one, spectre vibrationnel; calculs *ab initio*, butan-2-one; stabilité conformationnel, butan-2-one.

Introduction

We recently completed investigations on the rotational isomerism in a series of compounds having the general formula $CH_3CH_2C(O)X$, where X is F (1), Cl (2), and Br (3) utilizing Raman and infrared spectroscopy. All of these molecules were shown to exist in *trans/gauche* equilibria in the gaseous and liquid phases, with the *trans* conformer (CH_3 moiety is *trans* to the halogen atom) being the more stable form in both of these phases and the only conformer present in the annealed solid. While exclusive evidence for the existence of the second conformer in these molecules was abundantly observed with Raman and infrared spectroscopy (1–3), microwave spectroscopy proved to be useful in the observation of the high-energy rotamer only in the case of propionyl fluoride (4), although the electron diffraction technique has been utilized to determine the structure of the *gauche* form of propionyl bromide (5). As a continuation of our studies of this series of compounds, we extend our investigation to 2-butanone (ethyl methyl ketone), $CH_3CH_2C(O)CH_3$, where the CH_3 moiety rather than the halogen atom is the substituent.

Although ethyl methyl ketone has been studied by microwave spectroscopy (6, 7), the detection of the second conformer has not been made with this technique. In the first (6) of these two microwave investigations of the *trans* form,

the barrier of the methyl group attached to the sp^2 carbon was determined to be 518 ± 1 cal/mol (181 ± 0.3 cm^{-1}) and 497 ± 1 cal/mol (174 ± 0.3 cm^{-1}) for the normal and the $CH_3CD_2C(O)CD_3$ species, respectively. Additionally, the total dipole moments of 2.779 ± 0.015 and 2.771 ± 0.015 D were determined for the normal and d_5 species, respectively. In the second microwave investigation (7), a similar value of 183 cm^{-1} was determined for the internal rotation barrier for the same methyl group for the *trans* form. For the other CH_3 group, the authors of the second microwave investigation obtained a value of 795 ± 10 cm^{-1} for the barrier to internal rotation. A rough estimate of 5500 cm^{-1} was proposed for the barrier of the asymmetric torsional rotation, which, according to the authors (7), would yield a fundamental frequency of 80.4 cm^{-1} for this vibration. In neither of these two microwave studies were structural parameters determined, although in the first study (6) parameters were suggested that were transferred from acetone and propane.

The electron diffraction technique has also been utilized to study rotational isomerism in ethyl methyl ketone (8). With a *trans/gauche* equilibrium in the gas, the population of the *trans* form was estimated to be 95 ± 3%, which corresponds to a ΔG of 2.1 ± 0.4 kcal/mol. The r_α structure was given with the *gauche* form having a dihedral angle of 110°, which was estimated from that of 2-methyl-1-butene (the *trans* is presently defined to be at 0°).

Infrared spectra of ethyl methyl ketone in various phases have been studied (9) previously. With the results of a normal coordinate analysis, the authors concluded that the *gauche* rotamer was the higher energy form. Values of 1070 ± 100 and 2020 ± 100 cal/mol, respectively, were obtained for enthalpy differences for the liquid and gas from variable-temperature studies of the infrared bands.

Ab initio calculations have also been utilized to investigate the barriers to internal rotation about the C—C bond in ethyl methyl ketone (10–12). In the first study (10), however, complete geometry optimizations were carried out only with the RHF/STO-3G and RHF/3-21G basis sets, and energies at higher basis set levels (RHF/6-31G* and MP3/6-31G*) were obtained using RHF/3-21G geometries. The energies so obtained at the RHF/6-31G* basis set failed to predict a second conformer, although an abundance of evidence was previously observed in the infrared spectra (9) for the second conformer. In a subsequent study (11), full optimizations were carried out at the RHF/6-31G*//6-31G*, MP2/6-31G*//6-31G*, MP3/6-31G*//6-31G*, and MP4/6-31G*//6-31G* levels. However, the authors again performed calculations at fixed conformations rather than searching for the "true" *gauche* minimum and *trans*-to-*gauche* transition state. This method once again failed to locate the *gauche* conformation with basis sets higher than RHF/3-21G. The similar procedure was employed in the third investigation (12) where the 4-21G basis set was used. The calculations were carried out for conformations at 30° intervals and from the calculated energies a second stable conformer was not predicted.

We are presently utilizing Raman spectroscopy along with infrared data as a means to study rotational isomerism in $CH_3CH_2C(O)CH_3$. In addition, we also carry out restricted Hartree–Fock *ab initio* calculations with the 3-21G and 6-31G* basis sets with complete geometry optimizations at all maxima and minima on the potential surface. These results are compared to those obtained for the propionyl halides and also to the corresponding quantities of some other similar molecules.

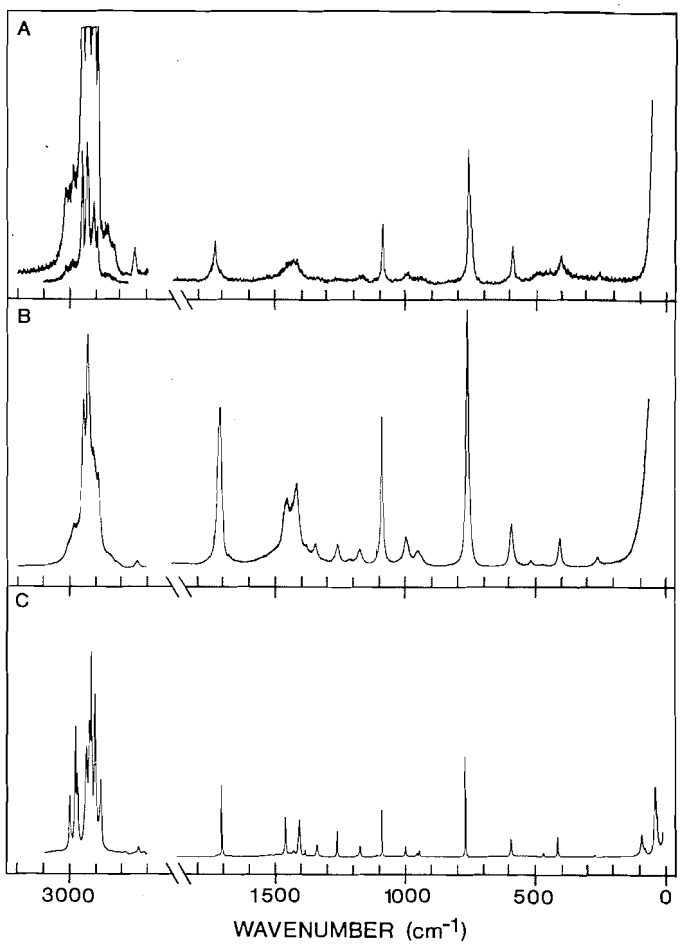

FIG. 1. Raman spectra of (A) gaseous, (B) liquid, and (C) solid ethyl methyl ketone.

Experimental

A sample of ethyl methyl ketone was obtained commercially from Fisher Scientific (Fair Lawn, NJ). Further purification was accomplished by using a low-temperature vacuum fractionation column. The pure sample was stored under vacuum and in a slush of *n*-propanol and Dry Ice. All sample handling and manipulation was carried out under vacuum racks.

The Raman spectra (Fig. 1) were recorded on a Cary model 82 spectrophotometer. This instrument is equipped with a Spectra-Physics model 171 argon ion laser operating on the 5145 Å line. The spectrum of the vapor (Fig. 1A) was recorded with the standard Cary multipass accessory. The spectrum of the liquid (Fig. 1B) was obtained with the sample sealed in a spherical cell (13). The spectrum of the solid (Fig. 1C) was recorded by depositing the sample onto a blackened brass block that was housed in a cell fitted with quartz windows and cooled by boiling liquid nitrogen. The annealing process was accomplished by repeatedly warming and freezing the sample until the line observed at 519 cm^{-1} completely disappeared.

The mid-infrared spectra of the gas (Fig. 2A) and annealed solid (Fig. 2B) were recorded on a Digilab model FTS-14C Fourier transform interferometer equipped with a Ge/KBr beamsplitter and a TGS detector. For the spectrum of the gas, the sample was contained in a 12-cm cell fitted with CsI windows. The spectrum of the solid was obtained by depositing the sample onto a CsI plate, which was cooled by boiling liquid nitrogen and housed in a cell fitted with CsI windows. The annealing process was the same as described above.

The far infrared spectrum of the gas (Fig. 3A) was collected with a Nicolet model SVX 200 Fourier transform interferometer from a sample contained in a 1-m cell fitted with polyethylene windows. The instrument was equipped with a vacuum bench and a liquid

helium cooled Ge bolometer containing a wedged sapphire filter and a polyethylene window. The resolution was 0.10 cm^{-1} and a 25-μm Mylar beamsplitter was used. The spectrum of the annealed solid (Fig. 3B) was obtained with a Digilab model FTS-15B Fourier transform interferometer equipped with a 6.25-μm Mylar beamsplitter and a TGS detector. The sample was deposited onto a silicon plate cooled by boiling liquid nitrogen and contained in a cell fitted with polyethylene windows.

Asymmetric and methyl torsions

Asymmetric torsion

In our recent studies of propionyl halides (1–3) and fluoroacetone (14) an abundance of evidence was found in the far infrared spectra of the gas for the asymmetric torsional mode of the stable conformers. In some cases, Q-branches were observed arising from transitions near the top of the potential wells, and these prominent Q-branches allowed the determination of an accurate potential function from which barriers to internal rotation were obtained. Therefore, it was hoped that the corresponding spectrum of gaseous ethyl methyl ketone would contain Q-branches for the asymmetric torsion arising from both the *trans* and *gauche* conformers so that a potential function could be calculated.

Unfortunately, even at very high vapor pressure, no prominent Q-branches were observed in the appropriate region (100–30 cm^{-1}) in our spectrum (Fig. 3A) that could be definitively

assigned to the asymmetric torsion. However, there is a weak band occurring at about 65 cm^{-1} and we confidently assigned it to the asymmetric torsional mode of one of the conformers. Since the *trans* conformer is so much more abundant, we assigned it to this conformer.

Utilizing this frequency, along with the ΔH (706 $cm^{-1} \cong \Delta E$) for the gas (9) as a forbidden transition between the lowest energy levels in each of the conformer wells and the dihedral angle for the *gauche* conformer from the *ab initio* calculation, we have calculated the first three terms of the potential function for the conformational interchange. The barriers to internal rotation may be obtained by using the sum of cosine functions for the potential energy:

$$V(\phi) = \frac{1}{2}\sum_{i=1}^{3} V_i(1 - \cos i\,\phi)$$

Since the structural parameters are different for the two conformers, the calculations for the kinetic energy term, which is also a function of the dihedral angle, ϕ, of the rotating top, included "relaxation" of the structural parameters. Therefore, the structural parameters obtained from the *ab initio* calculations with the 6-31G* basis set were utilized to calculate the kinetic energy term, or the "*F*-series", of the Hamiltonian according to:

$$F(\phi) = F_0 + \sum_{i=1}^{6} F_i \cos i\,\phi$$

With this calculated "*F*-series" and the potential coefficients given in Table 1, a reasonable fit of the observed transition was obtained with a *gauche* dihedral angle of 102.8° and an energy difference of 565 ± 66 cm^{-1}. Although the fundamental asymmetric torsion of the *trans* conformer has been assigned, the corresponding vibration of the high-energy *gauche* form was not observed in our far infrared spectrum of the gas, and an attempt to locate the $1^{\mp} \leftarrow 0^{\pm}$ and $2^{\mp} \leftarrow 0^{\pm}$ transitions in the Raman spectrum of the gas proved to be unsuccessful. In the calculations of the potential function, we used the frequency of 59.5 cm^{-1} for the *gauche* form. This rough estimate for this quantity was based on the separation of about 4 cm^{-1} between the fundamental frequencies for the asymmetric torsions for the two conformers for fluoroacetone (14) (the only ketone for which we have observed the asymmetric torsional mode for both rotamers). It should be noted that a dihedral angle less than 102.8 leads to a *gauche* well with a barrier too low to accommodate a torsional energy level with the zero point energy. Similarly, a ΔH ($\sim \Delta E$) greater than 565 cm^{-1} leads to a well with a barrier lower than the zero point energy (Table 1). This calculation initially gave a V_2 term of 3 cm^{-1} with an uncertainty of about 10 times the value so the V_2 term was dropped.

A second calculation (Table 1, calc. 2) was carried out utilizing the energy difference obtained from the *ab initio* calculation with the 6-31G* basis set and the *gauche* dihedral angle estimated in the electron diffraction study (8). The torsional frequency for the *gauche* conformer was put into the calculation with a very low weight. This calculation gives a more realistic *gauche*-to-*trans* barrier of 88 ± 10 cm^{-1} but the predicted *gauche*-to-*gauche* barrier is about 100 cm^{-1} higher than the value predicted from the *ab initio* calculations with the 6-31G* basis set. Also, the asymmetric torsional frequency for the *gauche* conformer is predicted at 44.5 cm^{-1}, which seems very low compared to the predicted *ab initio* value. Nevertheless, it appears that this potential function is a more realistic one than that of calculation 1. However, since the *ab initio* calculation gives a *gauche* torsional frequency of 55 cm^{-1}, which implies a zero point level of approximately 23 cm^{-1}, the first potential function is physically satisfactory.

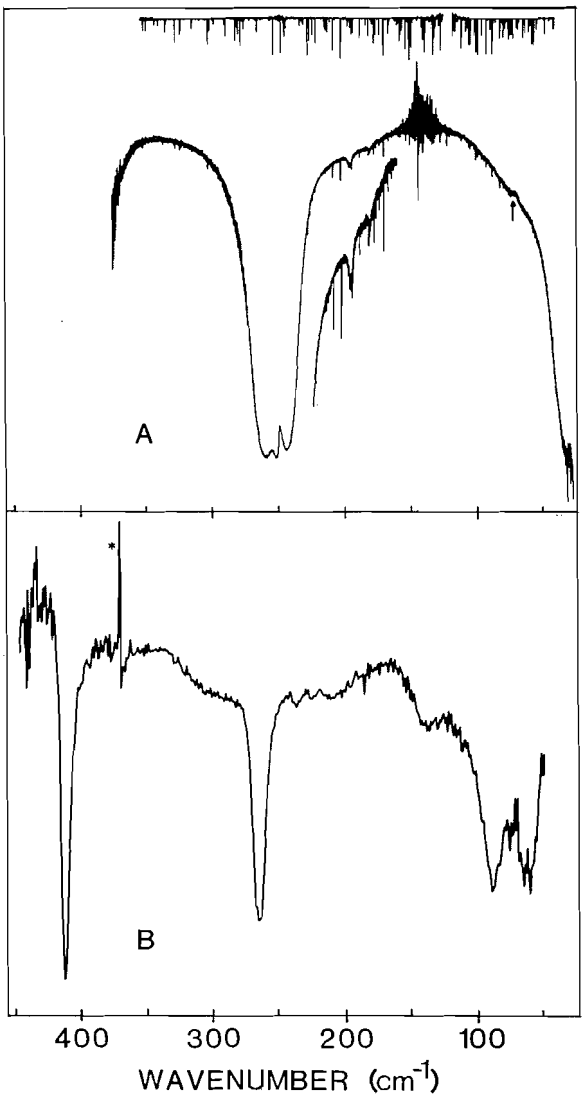

FIG. 3. Far infrared spectra of (A) gaseous and (B) solid ethyl methyl ketone. The top spectrum in (A) is the spectrum of water in the vapor phase. The sharp line indicated with an asterisk (*) is an instrumental artifact.

Methyl torsions

In the far infrared spectrum of the gas (Figs. 3A and 4) there are two weak bands of apparent C-type band contour. Based on the microwave study (7) and our recent investigations of propionyl halides (1–3), the higher frequency feature at 195.5 cm^{-1} is assigned to the fundamental transition of the CH_3—CH_2 torsional mode of the *trans* conformer. Using an *F* number of 5.613 cm^{-1} this frequency was fitted to a threefold potential and the preliminary results indicated that the C-type band at 181.0 cm^{-1} was due to the first excited state transition. With the inclusion of this second feature in the calculations, the barrier to internal rotation of the CH_3—CH_2 torsion was

CH_3—C(O)	181 ± 0.3	183	233	324(303)	248(283)	493(506)	520(504)

[a]Value taken from ref. 6. This value is for the d_0 isotopic species. Value of 184 ± 0.3 cm^{-1} was reported for $CH_3CD_2C(O)CD_3$.
[b]Values taken from ref. 7.
[c]This study.
[d]Values in parentheses were obtained with hydrogens in each moiety reoptimized as equivalent to each other. See text.

determined to be 868 ± 3 cm^{-1}. Our present value is about 10% higher than the value of 795 ± 10 cm^{-1} previously determined in the microwave study (7). For the corresponding fundamental of the *gauche* form we could not find any infrared band in the appropriate region, despite a very extensive search.

Values of 181 ± 0.3 and 183 cm^{-1} have been determined for the barrier to internal rotation of the CH_3—C(O) torsion of the *trans* form in the microwave investigations (6, 7). With the latter value the authors (7) in the second study proposed a value of 85 cm^{-1} for the fundamental torsional vibration. There appears to be no such feature in this region of our infrared spectrum of the gas. However, there appears to be a very weak band at 94.5 cm^{-1} and this feature is tentatively assigned to the $1^{\mp} \leftarrow 0^{\pm}$ transition of the CH_3—C(O) torsion of the *trans* form. Again using a threefold periodic cosine-

[a]Abbreviations used: s, strong; m, moderate; w, weak; sh, shoulder; bd, broad; p, polarized; dp, depolarized; P, Q, and R refer to vibrational–rotational branches. A, B, and C refer to infrared band contours.
[b]ν' denotes assignment modes for the *gauche* conformer.

based function and an F number of 5.488 cm^{-1}, a value of 233 cm^{-1} was obtained. Although the observed feature is very weak, and hence the assignment tentative, the calculated value of 233 cm^{-1} for the barrier is very reasonable based on the barrier of 292 cm^{-1} determined (15) for acetone, and a lower barrier is expected for ethyl methyl ketone. The presently determined barriers for the CH_3 rotors are compared to those obtained with microwave spectroscopy and *ab initio* calculations in Table 2.

Vibrational assignment

With the results obtained from the normal coordinate analysis, the assignment of the carbon–hydrogen stretching modes of the *trans* rotamer is straightforward, with all of the antisymmetric stretches predicted and assigned to frequencies higher than those of the symmetric stretches. However, the depolarization ratios of the two lines observed at 3000 and 2978 cm^{-1} in the Raman spectrum of the liquid necessitate the assignment of the former to ν_{21} and ν_{22} as degenerate and the latter to ν_{23}, respectively. This assignment does not agree entirely with the order predicted by *ab initio* calculations. Infrared bands observed as shoulders at 3022 and 3014 cm^{-1} in the spectrum of the gas are found to be absent from the spectrum of the solid. Based on the calculated frequencies, we tentatively assign these to the CH_3 antisymmetric stretch (ν'_1) and CH_2 antisymmetric stretch (ν'_{23}), respectively, of the *gauche* form. All of the carbon–hydrogen bending fundamentals are assigned as predicted from the *ab initio* calculations, with the exception of the CH_2 rocking mode of the *trans* form. This particular bending fundamental is calculated to occur at a higher frequency than the $C_1C_2C_3$ symmetric stretch; however, we observe a strong line at 768 cm^{-1} and a very weak feature at 743 cm^{-1} in the Raman spectrum of the solid. The relative intensity of these features necessitates the present assignment of the higher frequency line to the $C_1C_2C_3$ symmetric stretching mode and that at 743 cm^{-1} to the CH_2 rocking fundamental. A similar situation was also encountered in the study of propionyl fluoride (1).

The C=O stretching vibration (ν_6) of ethyl methyl ketone is observed to occur, as expected, at a much lower frequency at 1739 cm^{-1} in the infrared spectrum of the gas than the corresponding vibration in the propionyl halides (1–3). The observation of the only B-type band indicates that the C=O stretches of the *trans* and *gauche* conformers are degenerate or nearly degenerate. The carbon–carbon stretches of the *trans* form are assigned to intense infrared bands at 995 ($C_1C_2C_3$ antisymmetric stretch, ν_{15}), 950 (C_1C_4 stretch, ν_{16}), and 768 cm^{-1} ($C_1C_2C_3$ antisymmetric stretch, ν_{17}). For the *gauche*, the shoulder of medium intensity occurring at 748 cm^{-1} in the Raman spectrum of the gas is observed for the $C_1C_2C_3$ symmetric stretch.

The present assignment of the low-frequency skeletal bending modes of both isomers is very much in agreement with that proposed in the previous study (9). For the *trans* form, prominent features are observed at 594, 411, and 265 cm^{-1} for the CO in-plane bend (ν_{18}), CC(O)C deformation (ν_{19}), and CCC (ν_{20}) bend, whereas the weak line at 471 cm^{-1} in the Raman spectrum of the solid is assigned to the CO out-of-plane bend (ν_{30}). For the *gauche* conformation, weak featureless bands are observed at 644 (CO out-of-plane bend), 520 (CO in-plane bend), and 442 cm^{-1} (CC(O)C deformation) in the spectrum of the gas. The details of the complete assignment of ethyl methyl ketone are listed in Table 3.

Ab initio calculations

As mentioned above, *ab initio* calculations have previously been carried out for ethyl methyl ketone (10–12); however, full geometry optimizations for fixed conformations failed to predict a higher energy form. This failure is undoubtedly due to lack of relaxation of the structural parameters. In other words, the values of the structural parameters of ethyl methyl ketone at the RHF/6-31G* basis set, for example, must be at least slightly different from the corresponding quantities with the RHF/3-21G basis set. Therefore, we have carried out full optimizations at the RHF/6-31G* basis set for the *trans* and *gauche* forms, as well as for the transition states, in order to obtain better determination of the energy differences and barriers to internal rotations.

The LCAO-MO-SCF restricted Hartree–Fock calculations were performed with the GAUSSIAN-86 program (16) using Gaussian-type basis functions. The calculations were carried out wtih the 3-21G and 6-31G* basis sets. Based on the results of the microwave investigations (6, 7) and our own studies of propionyl halides (1–3), we initially performed optimization

for the *trans* conformation having a plane of symmetry containing all of the heavy atoms. The structural parameters for this form are given in Table 4. To make good predictions on the form of the high-energy conformation, a potential surface scan was carried out by only varying the dihedral angle $OC_1C_2C_3$ from 0° (*trans* position) to 180° (*cis* position) and keeping the remaining parameters at the optimized values obtained for the *trans* form. The resulting potential surface obtained with the 6-31G* basis set is given by the dashed line in Fig. 5. The potential surface obtained in this manner predicts a second stable form at about 100° and 712 cm^{-1} higher in energy than the *trans* form. At the 3-21G basis set level the *gauche* form is also at 100° and 904 cm^{-1} less stable. From the potential surface at the 6-31G* basis set, values of 727 and 917 cm^{-1}, respectively, are calculated for the *trans*-to-*gauche* and *gauche*-to-*gauche* barriers. It can be seen that the *gauche*-to-*trans* barrier is calculated extremely low at 15 cm^{-1}. With the 3-21G basis set, values of 958 and 1227 cm^{-1} were obtained for the *trans*-to-*gauche* and *gauche*-to-*gauche* barriers, respectively, and a small value of 53 cm^{-1} for the *gauche*-to-*trans* barrier was calculated.

In addition to the *gauche* minimum, the *trans*-to-*gauche* and *gauche*-to-*gauche* transition states were further optimized by relaxation of all geometric parameters to produce more meaningful potential surfaces. The potential surface obtained with the 6-31G* basis set is indicated by the solid line curve in Fig. 5. Structural parameters for the *gauche* conformer are also given in Table 4. With these additional calculations, the *trans*-to-*gauche*, *gauche*-to-*gauche*, and *gauche*-to-*trans* barriers are 527, 491, and 3 cm^{-1}, respectively, with the larger

TABLE 5. Symmetry coordinates for ethyl methyl ketone

Species	Approximate description	Symmetry coordinate[a]
A′	CH_3 antisymmetric stretch[b]	$S_1 = 2a_1' - a_2' - a_3'$
	CH_3 antisymmetric stretch	$S_2 = 2a_1 - a_2 - a_3$
	CH_3 symmetric stretch	$S_3 = a_1 + a_2 + a_3$
	CH_3 symmetric stretch[b]	$S_4 = a_1' + a_2' + a_3'$
	CH_2 symmetric stretch	$S_5 = r_1 + r_2$
	C=O stretch	$S_6 = T$
	CH_3 antisymmetric deformation	$S_7 = 2\alpha_1 - \alpha_2 - \alpha_3$
	CH_3 antisymmetric deformation[b]	$S_8 = 2\alpha_1' - \alpha_2' - \alpha_3'$
	CH_2 deformation	$S_9 = (\sqrt{6}+2)\delta - (\sqrt{6}-2)\mu - \sigma_1 - \sigma_2 - \varepsilon_1 - \varepsilon_2$
	CH_3 symmetric deformation	$S_{10} = \alpha_1 + \alpha_2 + \alpha_3 - \beta_1 - \beta_2 - \beta_3$
	CH_3 symmetric deformation[b]	$S_{11} = \alpha_1' + \alpha_2' + \alpha_3' - \beta_1' - \beta_2' - \beta_3'$
	CH_2 wag	$S_{12} = \sigma_1 + \sigma_2 - \varepsilon_1 - \varepsilon_2$
	CH_3 in-plane rock[b]	$S_{13} = 2\beta_1' - \beta_2' - \beta_3'$
	CH_3 in-plane rock	$S_{14} = 2\beta_1 - \beta_2 - \beta_3$
	$C_1C_2C_3$ antisymmetric stretch	$S_{15} = d_1 - d_2$
	C_1C_4 stretch	$S_{16} = d_3$
	$C_1C_2C_3$ symmetric stretch	$S_{17} = d_1 + d_2$
	CO in-plane bend	$S_{18} = \omega - \theta$
	CC(O)C deformation	$S_{19} = 2\phi - \omega - \theta$
	$C_1C_2C_3$ bend	$S_{20} = (\sqrt{6}-2)\delta - (\sqrt{6}+2)\mu + \sigma_1 + \sigma_2 + \varepsilon_1 + \varepsilon_2$
	CH_3 redundancy[b]	$S_{1R} = \alpha_1' + \alpha_2' + \alpha_3' + \beta_1' + \beta_2' + \beta_3'$
	CH_3 redundancy	$S_{2R} = \alpha_1 + \alpha_2 + \alpha_3 + \beta_1 + \beta_2 + \beta_3$
	CH_2 redundancy	$S_{3R} = \delta + \mu + \sigma_1 + \sigma_2 + \varepsilon_1 + \varepsilon_2$
	CO redundancy	$S_{4R} = \phi + \omega + \theta$
A″	CH_3 antisymmetric stretch	$S_{21} = a_2 - a_3$
	CH_3 antisymmetric stretch[b]	$S_{22} = a_2' - a_3'$
	CH_2 antisymmetric stretch	$S_{23} = r_1 - r_2$
	CH_3 antisymmetric deformation	$S_{24} = \alpha_2 - \alpha_3$
	CH_3 antisymmetric deformation[b]	$S_{25} = \alpha_2' - \alpha_3'$
	CH_2 twist	$S_{26} = \sigma_1 - \sigma_2 - \varepsilon_1 + \varepsilon_2$
	CH_3 out-of-plane rock	$S_{27} = \beta_2 - \beta_3$
	CH_3 out-of-plane rock[b]	$S_{28} = \beta_2' - \beta_3'$
	CH_2 rock	$S_{29} = \sigma_1 - \sigma_2 + \varepsilon_1 - \varepsilon_2$
	CO out-of-plane bend	$S_{30} = \eta$
	CH_3 torsion	$S_{31} = \tau_1$
	CH_3 torsion[b]	$S_{32} = \tau_2$
	Asymmetric torsion	$S_{33} = \tau_3$

[a]Not normalized.
[b]These fundamentals belong to the CH_3 moiety closest to the carbonyl moiety.

6-31G* basis set and 776, 708, and 24 cm^{-1}, respectively, with the 3-21G basis set. The total energies for the *trans* and *gauche* conformers were calculated at the 6-31G* basis set to be −230.9980483 and −230.9956588 hartrees, respectively, which corresponds to an energy difference of 524 cm^{-1}. The energies obtained from the smaller basis set give a larger difference of 752 cm^{-1} also with the *trans* conformer as the low-energy form.

In our investigations of propionyl chloride (2) and propionyl bromide (3), the barrier to internal rotation of the CH_3 group was reproduced very well by *ab initio* calculations (within 20% in the worst case). Therefore, for the present case of ethyl methyl ketone, similar agreement is also expected and similar calculations were performed. Using the optimized structural parameters obtained for the *trans* and *gauche* forms at both the 3-21G and 6-31G* basis sets, the CH_3 moieties were rotated 60° with no additional optimizations. With this procedure, the barrier for the CH_3—CH_2 torsion of the *trans* conformer is calculated to be 860 and 1030 cm^{-1} at the 3-21G and 6-31G* basis sets, respectively. The corresponding quantities for the *gauche* rotamer are much higher at 1220 and 1247 cm^{-1}. The same procedure was carried out for the CH_3—C(O) torsion and values of 324 and 248 cm^{-1}, respectively, with the 3-21G and 6-31G* basis sets were obtained for the *trans* form, whereas barriers of 493 and 520 cm^{-1} were calculated for the *gauche* conformer. These values are listed and compared to those obtained experimentally in Table 2.

A comparison of the barriers for the CH_3 moieties for the *trans* form calculated with *ab initio* calculations and those derived from experimental data shows conflicting results. For example, the value of 860 cm^{-1} at the 3-21G basis set for the CH_3—CH_2 torsion is in excellent agreement with the value of 868 ± 3 cm^{-1} calculated with our far infrared data. However, the value of 1030 cm^{-1} obtained with the 6-31G* basis set is almost 20% too high (compared to the value of 868 ± 3 cm^{-1}). The opposite trend is obtained for the CH_3—C(O) torsion, with the 6-31G* basis set giving a value in much better agreement than the 3-21G basis set.

Subsequently, the conformations were reoptimized with hydrogen atoms in each moiety being held equivalent to each other in order to have a "true" threefold potential. As before, each CH_3 moiety was then rotated 60° to determine the

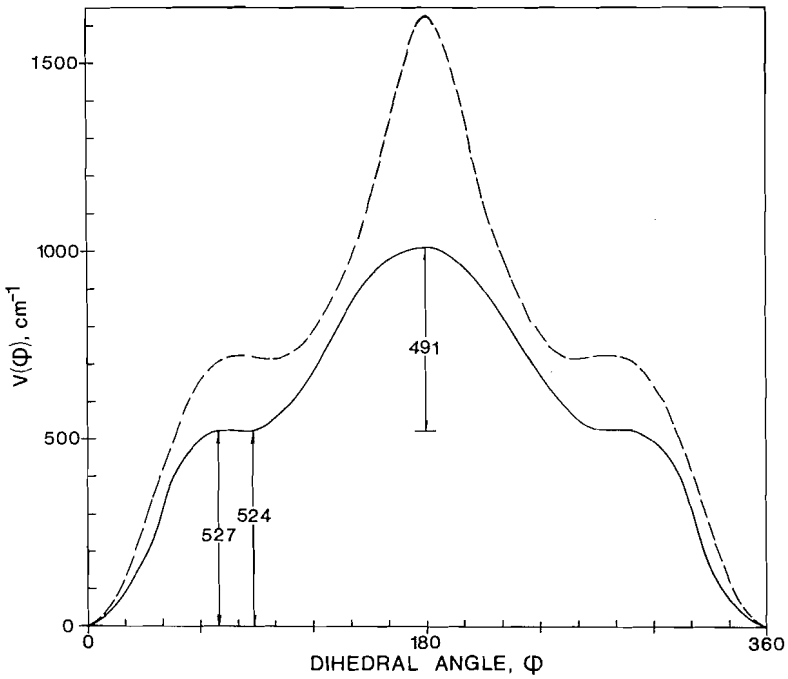

FIG. 5. Potential function governing internal rotation about the central C—C bond in ethyl methyl ketone as determined by *ab initio* calculations with the 6-31G* basis set. The potential surface given by the dashed line was obtained by allowing the torsional dihedral angle to vary by 10° increments from the *trans* position (0°) to the *cis* position (180°) while all other structural parameters were held fixed at the optimized values obtained for the *trans* conformer. The potential surface given by the solid line was obtained by additional optimizations at the *gauche* minimum and at the transition states by relaxation of all the geometric parameters.

barrier. With the exception of the value for the CH_3—CH_2 torsion with the 6-31G* basis set, the barriers show significant effects of forcing the hydrogen atoms to be equivalent, as seen in Table 2. For the *gauche* conformation, the barriers are essentially non-sensitive to the levels of calculations and the calculated values appear to be too large in all cases, although one can only speculate in the absence of derived values from experimental data.

Normal coordinate analysis

Normal coordinate analyses for both the *trans* and *gauche* conformers of ethyl methyl ketone were carried out using the force fields calculated with the GAUSSIAN-86 program (16) with the RHF/3-21G basis set. The optimized structural parameters (Table 4) and the symmetry coordinates (Table 5) were used to calculate the *G* and *B* matrices according to the Wilson method (17) and the computer programs written by Schachtschneider (18). The *B* matrix was then utilized to convert the force fields in cartesian coordinates into the force fields in internal coordinates (Fig. 6). The force fields in internal coordinates are given in Tables 6 and 7 for the *trans* and *gauche* conformers, respectively. The *G* matrix was used along with the force fields in internal coordinates to calculate the "pure" *ab initio* vibrational frequencies with scaling factors of 1.0. These frequencies, as well as the potential energy distribution (P.E.D.), are summarized in Tables 8 and 9 for the *trans* and *gauche* conformers, respectively.

A comparison of the calculated frequencies and the observed values for both conformers shows that the calculated frequencies are overestimated by 10.7 and 9.3% overall average error for the *trans* and *gauche* conformers, respectively. Subsequently, we scaled the force constants for the stretching coordinates by 0.90, those for the bending coordinates by 0.80,

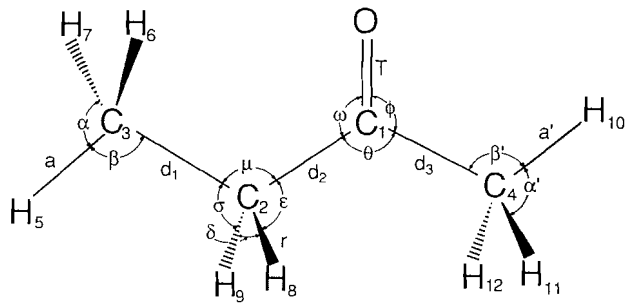

FIG. 6. Internal coordinates for ethyl methyl ketone. Torsional internal coordinates are not included.

those for the torsional coordinates by 1.0, and those for the interaction coordinates by geometric averages. With this procedure, we obtained overall average errors of 3.8 and 3.5%, respectively, for the *trans* and *gauche* rotamers. These "fixed scale" frequencies are also summarized in Tables 8 and 9.

Discussion

For all of the compounds with the general formula CH_3CH_2-C(O)X, where X is F, Cl, Br, and CH_3, a *trans/gauche* equilibrium is observed in the gas and liquid, with the *trans* conformer being the more stable form in both states. It is also the *trans* form that exists in the solid. One can assume that substitution on the sp^2 carbon does not affect significantly the conformational behavior. We have just completed similar studies on haloacetones, $XCH_2C(O)CH_3$, where X is F (14), Cl (19), and Br.[3] For these latter molecules, it is the *cis* (in fluoroacetone) or *gauche* (in chloroacetone and bromoace-

tone) conformer that is thermodynamically more stable than the *trans* form. However, in the liquid phase the abundance of the *trans* form increased and it becomes the lower energy species. Then in the solid phase, the *gauche* isomer completely disappeared upon annealing of the samples and the *trans* conformer exclusively remained. The increased stability of the *trans* isomeric form upon condensation can be attributed to dipole–dipole interactions, which can be at least in part correlated with the total dipole moment (20, 21). Therefore, it is evident that for these simple molecular systems it is not only the degree of substitution that affects the conformational behavior, but the positions of substitution also play a major role in the equilibrium between the stable forms. It would be interesting to investigate the conformational composition and behavior of the compounds with the general formulas $CH_3CX_2C(O)Y$ and $YCX_2C(O)CH_3$, where X and Y are halogen atoms.

The presently proposed potential function governing the asymmetric torsion for ethyl methyl ketone must be considered as tentative. However, it is worthwhile to note that in our studies of propionyl halides (1–3), excellent agreement was achieved between the values determined from *ab initio* calculations and those derived from the asymmetric potential functions. Therefore, in view of these points, the uncertainties in the barriers to internal rotation (Table 1) may be underestimated. Nevertheless, the barriers are in fair agreement with those calculated theoretically. Lastly, the *gauche*-to-*trans* barrier for ethyl methyl ketone is very small compared to the corresponding quantities for the propionyl halides (1–3). It is not surprising that in the earlier studies (10–12) the authors "missed" the *gauche* potential minimum as well as the *trans*-to-*gauche* transition state at the 6-31G* basis set because of their procedures in carrying out the calculations. In several cases we found that the smaller 3-21G basis set gives better predictions on conformational stabilities than the larger 6-31G* basis set.

Among the structural parameters determined by *ab initio* calculations only four are significantly different between the two conformers of ethyl methyl ketones: $r(C_2—C_3)$, $\angle(C_1C_2C_3)$, $\angle(C_1C_2C_9)$, and $\angle(H_8CH_9)$. With the 6-31G* basis set, the $C_2—C_3$ distance increases by about 0.01 Å from 1.524 Å in the *trans* form to 1.535 Å in the *gauche* form. In the electron diffraction study (8), this parameter was held fixed at

1.531 Å for both conformers, which is not quite the average of our 6-31G* *ab initio* predicted values. For the $C_1C_2C_3$ angle, a difference of 2.81° was calculated with the 6-31G* basis set with that of the *trans* being larger. The difference in the $\angle(C_1C_2C_3)$ of the two forms was not observed in the case of the halides (1, 2). The decrease in the value of this parameter when the molecule rotates from the *trans* to the *gauche* conformation is probably at the expense of the $\angle(C_1C_2H_9)$ and $\angle(H_8CH_9)$ angles, both of which increase significantly from the values of the *trans* to those for the *gauche* conformation.

With the 6-31G* basis set, the C—H and C=O bonds are expected to be about 0.010 and 0.02 Å too short, respectively. Using the microwave (6) rotational constants obtained for the *trans* conformer of $CH_3CH_2C(O)CH_3$ and $CH_3CD_2C(O)CD_3$, we calculated the r_0 parameters by adjusting $r(C_1—C_2)$, $r(C_2—C_3)$, and $r(C_1—C_4)$, and $\angle(C_2C_1O)$, $\angle(C_2C_1C_4)$, and $\angle(C_1C_2C_3)$. As initial values, we utilized structural parameters predicted with the 6-31G* basis set with the above adjustment for the C—H and C=O bond lengths. Excellent reproducibility of the experimental rotational constants was obtained, as evident in Table 10. However, the values of the $C_1—C_2$ and $C_1—C_4$ distances, which were varied, decreased, and the $C_1—C_4$ distance is essentially equal to the value for acetone (22) (1.507 ± 0.003 Å). The reported (22) C=O distance in acetone is 1.222 ± 0.003 Å. Since the C=O distance is expected to have the same value for both acetone and ethyl methyl ketone we used the electron diffraction (8) value of 1.218 Å, which is, within experimental error, the same value as that for acetone. The difference in the $C_1—C_2$ and $C_1—C_4$ distances is larger than expected since the *ab initio* results indicate the difference should be 0.003 Å, but $r(C_1—C_2)$ and $r(C_2—C_3)$ are strongly correlated so the final results are somewhat dependent on the initial starting values for these parameters. The determined angles are in good agreement with those predicted with the 6-31G* basis set except for $\angle C_2C_1O$, which is 0.8° larger than the *ab initio* value. The r_0 structural parameters obtained from the microwave data are compared to those obtained experimentally and theoretically in Table 4. It is believed that the r_0 parameters obtained are closer to the actual ones than any of those previously proposed.

Of the three bond distances between heavy atoms that are common in propionyl fluoride, propionyl chloride, and ethyl methyl ketone, only the C=O bond distance in both conformations is affected by the substitution of the CH_3 moiety for a halogen atom. The value for this parameter calculated with the 6-31G* basis set increases from about 1.168 Å in the two halides (1, 2) to 1.192 Å in the ketone. This sharp increase is accompanied by a significant decrease in the C_2C_1O bond angle, which goes from 128.7° (*trans*) and 128.5° (*gauche*) for propionyl fluoride (1), to 127.4° (*trans*) and 126.8° (*gauche*) in propionyl chloride (2), and finally to 122.1° (*trans*) and 121.0° (*gauche*) in ethyl methyl ketone. Presumably, these changes are due to the electron-withdrawing ability of the substituents in $CH_3CH_2C(O)X$. These trends were also observed in our studies of fluoroacetone (16) and chloroacetone (19).

Finally, the *ab initio* dihedral angle for the *gauche* form is as much as 25° smaller than the value estimated from 2-methyl-1-butene and kept constant in the electron diffraction study (8). The deviation of this structural parameter from the expected value of 120° reflects the repulsive interactions between the two methyl groups.

Among the diagonal force constants, only four force constants are different between the two conformers, with values of 1.082 and 0.797 mdyn/Å calculated for the $C_1C_2C_3$ bending coordinate for the *trans* and *gauche* form, respectively. The difference reflects the difference in the calculated values for the $\angle C_1C_2C_3$ angle. However, the corresponding calculated frequencies for this motion are not significantly affected by these different force constants. Likewise, the force constants for both of the CH_3 torsional coordinates increase by 41% from the *trans* to the *gauche* form, but the calculated frequencies for the torsions change only slightly. Similarly, the asymmetric torsional force constants of 0.011 and 0.015 mdyn/Å are calculated for the *trans* and *gauche* conformer, respectively, which represent a 36% difference, but the asymmetric torsional fundamental frequencies for both forms are predicted to have the same value of 55 cm^{-1}.

As evident from Tables 8 and 9, extensive mixing of the normal modes are predicted for fundamental frequencies below 1500 cm^{-1}. For the *trans* form, mixing is calculated between the C—C stretching and the in-plane skeletal bending vibrations in the A′ symmetry block, whereas the carbon–hydrogen rocking modes are predicted to be coupled in the A″ block. For the *gauche* conformer, mixing occurs among the same normal modes as those for the *trans* conformer. The degree of mixing in both conformers made it difficult to assign several of the spectral features observed in the spectra of the gas and liquid, especially those arising from the *gauche* rotamer, because the bands are already nondescript, featureless, and weak. In several instances the assignment could not have been made without the calculated potential energy distributions among the symmetry coordinates.

The vibrational data clearly show that there is a substantial well at the *gauche* conformation. To obtain a better theoretical value for the relative barriers for conformational interchange a very large basis set must be used with electron correlation. We plan to carry out such a calculation in the near future.

The vibrational spectrum, barrier to internal rotation, and *ab initio* calculations of 2-chloropropane[1]

J. F. SULLIVAN,[2] AIYING WANG, MEI-SHIOW CHENG, AND J. R. DURIG
Department of Chemistry, University of South Carolina, Columbia, SC 29208, U.S.A.

Received July 15, 1991

This paper is dedicated to Dr. Richard Norman Jones

J. F. SULLIVAN, AIYING WANG, MEI-SHIOW CHENG, and J. R. DURIG. Can. J. Chem. **69**, 1845 (1991).

The Raman spectra (3200–50 cm^{-1}) of gaseous, liquid, and solid 2-chloropropane-d_3 (isopropyl-d_3 chloride), $CH_3(CD_3)$-CHCl, and the infrared spectra (3200–50 cm^{-1}) of the gas and solid have been recorded. The torsional transitions observed in the far infrared spectrum of the gaseous sample recorded at a resolution of 0.10 cm^{-1} between 265 and 135 cm^{-1} were analyzed in terms of the semirigid rotor model. An effective barrier of 1378 ± 4 cm^{-1} (3.94 ± 0.01 kcal/mol), cosine–cosine coupling term of 166 ± 10 cm^{-1} (0.47 ± 0.03 kcal/mol), and sine–sine coupling term of −173 ± 1 cm^{-1} (−0.49 ± 0.01 kcal/mol) were determined by fitting ten observed frequencies arising from the CH_3 and CD_3 torsions. The assignment of the 27 fundamentals is given and discussed. A complete equilibrium geometry, barrier to internal rotation, and vibrational frequencies have been determined by *ab initio* Hartree–Fock gradient calculations employing either 3-21G* or 6-31G* basis sets for both the d_0 and d_3 species. These calculated results are compared to the experimental values as well as to the corresponding quantities for some similar molecules.

Key words: 2-chloropropane, vibrational spectrum; *ab initio* calculations; barrier to internal rotation.

J. F. SULLIVAN, AIYING WANG, MEI-SHIOW CHENG et J. R. DURIG. Can. J. Chem. **69**, 1845 (1991).

On a enregistré les spectres Raman (3200–50 cm^{-1}) d'échantillons gazeux, liquide et solide du 2-chloropropane-d_3 (chlorure d'isopropyle-d_3), $CH_3(CD_3)CHCl$, ainsi que les spectres infrarouges (3200–50 cm^{-1}) du gaz et du solide. On a analysé les transitions de torsion, observées dans le spectre infrarouge lointain de l'échantillon gazeux enregistré à une résolution de 0,10 cm^{-1} entre 265 et 135 cm^{-1}, en fonction du modèle du rotor semi-rigide. On a déterminé une barrière effective de 1378 ± 4 cm^{-1} (3,94 ± 0,01 kcal/mol), terme de couplage cosinus/cosinus de 166 ± 10 cm^{-1} (0,47 ± 0,03 kcal/mol) et un terme de couplage sinus/sinus de −173 ± 1 cm^{-1} (−0,49 ± 0,01 kcal/mol) en ajustant dix fréquences observées pour les torsions de CH_3 et de CD_3. On fait les attributions de 27 fondamentales et on en discute. En se basant sur des calculs *ab initio* de gradient de Hartree–Fock utilisant des ensembles de base soit 3-21G* ou 6-31G* tant pour les espèces d_0 et d_3, on a déterminé une géométrie d'équilibre complète, la barrière à la rotation interne et les fréquences de vibration. On compare les résultats de ces calculs avec les valeurs expérimentales ainsi qu'avec les valeurs correspondantes pour des molécules semblables.

Mots clés : 2-chloropropane, spectre vibrationnel; calculs *ab initio*; barrière à la rotation interne.

[Traduit par la rédaction]

Introduction

The barriers to internal rotation of two methyl groups bonded to a common carbon atom have been the subject of a number of investigations. Recently, the microwave and far-infrared spectra, structure, and barriers to internal rotation for 2-fluoropropane were reported (1). Based on the magnitude of the sine–sine ($V'_{33} = -92$ cm^{-1}) and cosine–cosine coupling terms ($V_{33} = 107$ cm^{-1}) determined for the parent and two isotopic species of 2-fluoropropane, it was concluded that top–top coupling is significant in this molecule. A similar study (2) has also been carried out on 2-chloropropane (isopropyl chloride) where the average effective V_3 barrier was found to be 1380 ± 3 cm^{-1} (3.95 ± 0.01 kcal/mol) based on the observation of six Q-branches observed between 270 and 230 cm^{-1} in the infrared spectrum, and a second series of double jumps observed in the Raman spectrum and assigned to the lower energy series. Because the structure of this molecule results in *B*-type infrared band contours for the A″ methyl torsion, no Q-branches were observed in the far-infrared spectrum for this series. Consequently, only two double-jump transitions from the Raman spectrum could be used in the calculations. Because of the uncertainty in the assignment of the A″ methyl torsional series, we decided to record the far-infrared spectrum of the 2-chloropropane-d_3 molecule, $(CH_3)(CD_3)CHCl$, as deuteration of one of the methyl groups would lower the symmetry to trivial C_1, where all fundamentals would give rise to $A/B/C$ hybrid bands. Deuteration in this position would also shift the CD_3 methyl torsion out of the region of the CH_3 torsion, which should aid in the assignment.

For comparison with the previous vibrational assignment (3) for the 2-chloropropane-d_0 molecule, the infrared and Raman spectra of the -d_3 molecule have also been recorded, and *ab initio* Hartree–Fock gradient calculations employing both 3-21G* and 6-31G* basis sets were carried out to obtain the equilibrium geometry and potential energy distributions. The r_0 structure has also been calculated based on the rotational constants for eight isotopic species from the previously reported microwave study (4) from which r_s structural parameters were determined. The results of this study are reported herein.

Experimental

The sample of 2-chloropropane-d_3 was synthesized via the reaction of isopropanol-d_3 (Merck, Sharp and Dohme, Quebec, Canada) with phosphorus trichloride at a ratio of 3:1. It was then purified by a low-temperature, low-pressure fractionation column.

Mid-infrared spectra of the gas and solid from 3200 to 400 cm^{-1} were obtained with a Digilab model FTS-14C Fourier transform interferometer equipped with a Ge/KBr beamsplitter and a TGS detector. Far-infrared spectra (480–50 cm^{-1}) of the gas and solid were obtained with a Digilab model FTS-15B Fourier transform interfero-

meter equipped with a 6.25-μm beamsplitter and a TGS detector. The gaseous sample was contained in a 1-m cell fitted with polyethylene windows for the far-infrared studies and in a 10-cm cell equipped with CsI windows for the mid-infrared study. For the gas phase, the data were collected at a resolution of 0.5 cm^{-1}. For the solid phase, the sample was condensed onto a silicon or cesium iodide plate, which was maintained under vacuum and cooled with liquid nitrogen. The resolution used for the solid phase was 1 cm^{-1}. The far-infrared spectra at a resolution of 0.1 cm^{-1} below 270 cm^{-1} were also recorded on a Nicolet model 200 SXV Fourier transform interferometer equipped with a vacuum bench and a liquid helium cooled Ge bolometer containing a wedged sapphire filter and polyethylene windows.

The Raman spectra were recorded on a Cary model 82 spectrophotometer equipped with a Spectra-Physics model 171 argon ion laser operating on the 5145 Å line. The spectrum of the gas was recorded by using a standard Cary multipass accessory and the laser power at the sample was 1 W. The spectrum of the liquid was recorded from the sample sealed in a glass capillary. The spectrum of the solid was obtained by annealing the sample sealed in a glass capillary using a Cryogenic Technologies, Inc. cryostat connected to a Lake Shore Cryogenics Inc. model DTC-500 temperature controller. Reported frequencies are expected to be accurate to ±2 cm^{-1}.

Results

Methyl torsion

The infrared spectrum of gaseous 2-chloropropane-d_3 recorded at 0.10 cm^{-1} resolution between 265 and 135 cm^{-1} is shown in Fig. 1. Though the water absorption bands exist at relatively the same intensity as the torsional transitions, there is no difficulty in recognizing either the $-CH_3$ or the $-CD_3$ torsional transitions. The strongest Q-branch at 250.2 cm^{-1} is assigned to the $1 \leftarrow 0$ transition for the methyl torsion whereas the second strongest Q-branch at 178.9 cm^{-1} is assigned to the $1 \leftarrow 0$ transition for the CD_3 torsion. The other three Q-branches with medium intensity at 237.2, 172.7, and 166.5 cm^{-1} were assigned to be the $2 \leftarrow 1$ transition for the $-CH_3$ torsion, and the $2 \leftarrow 1$ and $3 \leftarrow 2$ transitions for the $-CD_3$ torsion, respectively.

The torsional problem in 2-chloropropane may be treated on the basis of the semi-rigid $C_{3v}(T)$-$C_s(F)$-$C_{3v}(T)$ or $C_s(e)$ model (T = top; F = frame; e = two equivalent tops). Its internal Hamiltonian was derived by Groner and Durig (5) and is given by

$$H_1 = \tfrac{1}{2}[g^{44}\hat{p}_0^2 + 2g^{45}\hat{p}_0\hat{p}_1 + g^{55}\hat{p}_1^2] + \tfrac{1}{2}[V_{30}(1 - \cos 3\tau_0) + V_{06}(1 - \cos 6\tau_0) + V_{03}(1 - \cos 3\tau_1) + V_{06}(1 - \cos 6\tau_1) + V_{33}(\cos 3\tau_0 \cos 3\tau_1 - 1) + V'_{33} \sin 3\tau_0 \sin 3\tau_1]$$

with symmetry restrictions $V_{30} = V_{03}$ and $V_{60} = V_{06}$. The symmetry group of this internal Hamiltonian is of order 18, $C_3 \otimes \Theta_3$, and is isomorphous to the direct product of cyclic group, C_3, of order 3 with dihedral group Θ_3, of order 6. Its character table has been given by Durig *et al.* (6) and is available elsewhere in the same notations. The high barrier torsional energy levels split into sublevels according to:

$$\Gamma^{00\sigma} \otimes \Gamma^{10} \otimes \Gamma^{11} \otimes \Gamma^{12\sigma}$$

where σ is + or − for $\bar{v}$ even or odd, respectively, and where $\bar{v}$ is the limiting vibrational quantum number of the antisymmetric mode in the C_s point group with respect to the symmetry plane of the molecular frame. $\Gamma^{00\sigma}$ are one-dimensional representations and Γ^{11} is the two-dimensional representation. $\Gamma^{12\sigma}$ are the symbols for two complex conjugate pairs of one-dimensional representations. Γ^{10} represents a complex conjugate pair of two-dimensional representations and, thus, leads to fourfold degenerate energy levels. The selection rules have been derived and summarized elsewhere (6).

[a]Calculated by using the potential coefficients in Table 2.

As shown by Groner and Durig (5), the potential parameter set commonly used for this potential function presented above is not the best one in terms of determinability since some of the coefficients are strongly correlated. There exist linear combinations that are considerably less correlated than V_{30}, V_{03}, and V_{33}. These new parameters have generally lower

$$\begin{bmatrix} V_{3s} \\ V_{3d} \\ V_{\text{eff}} \end{bmatrix} = \begin{bmatrix} \frac{1}{2} & \frac{1}{2} & 0 \\ \frac{1}{2} & -\frac{1}{2} & 0 \\ \frac{1}{2} & \frac{1}{2} & -1 \end{bmatrix} \begin{bmatrix} V_{30} \\ V_{03} \\ V_{33} \end{bmatrix}$$

dispersions than the original ones. In the case of the potential function for equivalent tops, $V_{3s} = V_{03} = V_{30}$ and $V_{3d} = 0$, and the effective barrier is given directly by V_{eff}.

The initial calculations were carried out by using five of these transitions together with the potential constants for the

2-chloropropane-d_0 compound provided earlier (2). Five more weak transitions were located, based on the calculated eigenvalues and eigenfunctions from the output of the initial calculations. The observed bands and their assignments are listed in Table 1. The calculations were continued as an iterative process until the difference between the observed and calculated frequencies, as well as the dispersions in the potential constants, were minimized. The final fit of the calculation gives rise to an average effective barrier of 1378 ± 4 cm^{-1} (3.94 ± 0.01 kcal/mol) for 2-chloropropane-d_3. This result is in excellent agreement with the value of 1380 ± 3 cm^{-1} (3.95 ± 0.01 kcal/mol) obtained for 2-chloropropane-d_0 by Durig and Guirgis (2). In addition to the effective barrier, both the cosine–cosine coupling term, V_{33}, and the sine–sine coupling term, V'_{33}, were evaluated and these constants were found to have values of 166 ± 10 cm^{-1} and −173 ± 3 cm^{-1}, respectively. The values should be contrasted with the values of V_{33} = 209 ± 12 cm^{-1} and V'_{33} = −171 ± 2 cm^{-1} for the d_0 molecule (2). The torsional potential constants and kinetic coefficients for the -d_3 compound are listed in Table 2.

Vibrational assignment

The 2-chloropropane-d_3 has C_1 symmetry and the 27 normal modes should show $A/B/C$ hybrid-type infrared band contours. The Raman spectra, mid-infrared, and far-infrared spectra of this compound are shown in Figs. 2, 3, and 4, respectively. The proposed vibrational assignment is listed in Table 3. In the CH stretching region, five bands with relatively consistent intensity and frequencies are observed for both the -d_3 and -d_0 compounds, whereas only four fundamental modes are expected for the -d_3 compound in this region. The band at 2888 cm^{-1} is assigned as an overtone of the fundamental frequency at either 1464 or 1455 cm^{-1}. This band was assigned as a fundamental mode in the previous study by Klaboe (3). The *ab initio* calculations predict the CH stretch to be higher in frequency than the two CH_3 antisymmetric stretches, and was, thus, initially considered to be at 2996 cm^{-1}, which is the highest observed frequency. However, this assignment is not consistent with that given by McKean *et al.* (7) for $(CD_3)_2CHCl$ where a band at 2962 cm^{-1} had to be assigned to the CH stretch. Since an isolated CH stretch provides a definitive assignment for this mode, we likewise assign the band at 2958 cm^{-1} to the secondary CH stretch.

There are two CD_3 antisymmetric stretches and one CD_3 symmetric stretch to be assigned around 2000 cm^{-1}. They

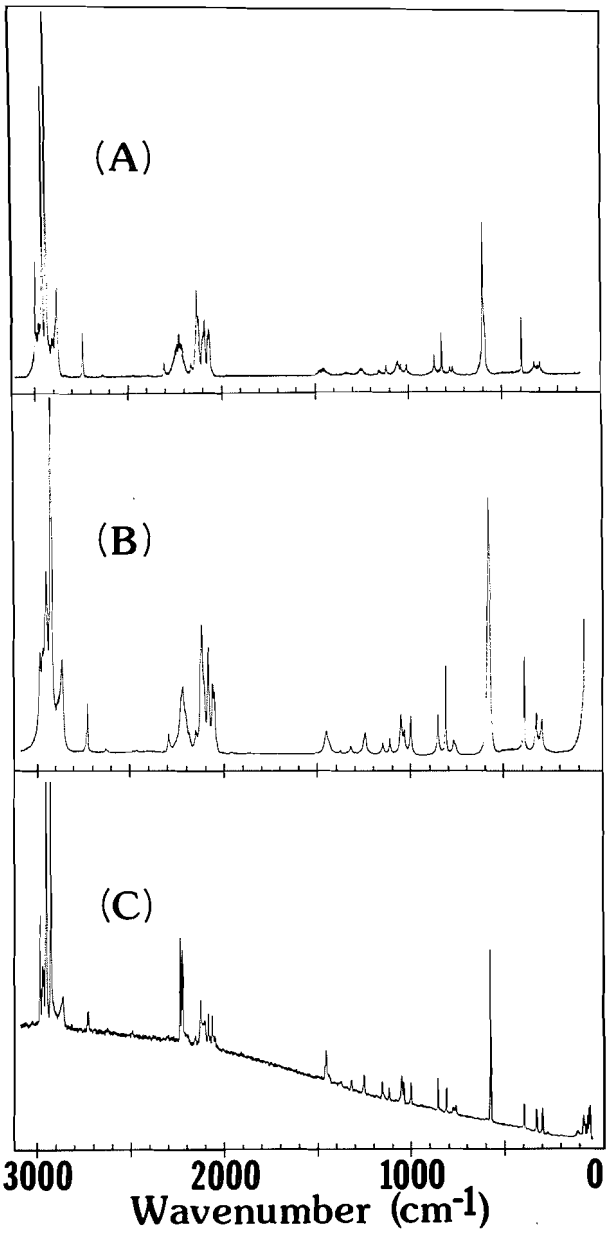

FIG. 2. Raman spectra of CH_3CD_3CHCl: (A) gaseous phase; (B) liquid phase; (C) solid phase.

were assigned at 2242, 2231, and 2130 cm^{-1}, respectively, in the mid-infrared spectrum of the gas. There are two more peaks with medium intensity in the Raman spectra of both the gas and liquid around 2000 cm^{-1}. Since they are too low in frequency to be CD_3 stretching fundamentals, they are assigned as overtone bands.

The two CH_3 antisymmetric deformations, CH_3 symmetric deformation, two HCCl bends, one of the CH_3 rocks, and the CCC antisymmetric stretch are assigned to bands that are close in frequencies to the similar fundamentals of the -d_0 compound. The comparison between the fundamental frequencies from experiments (3) and *ab initio* calculations for the -d_0 compound is given in Table 4. The CH_3 deformations occur around 1400 cm^{-1} as expected, whereas the CD_3 deformations shift to much lower frequencies around 1000 cm^{-1}, which is close to the CH_3 rocking region. The CH_3 rock of the -d_3 compound is forced down to 1010 cm^{-1} from 1066 cm^{-1} for

[a]Abbreviations used: s, strong; m, medium; w, weak; v, very; sh, shoulder; bd, broad; P, Q, and R refer to vibrational–rotational branches.
[b]This is the same numbering used in Table 4, which is consistent with the numbering for the d_0 compound.

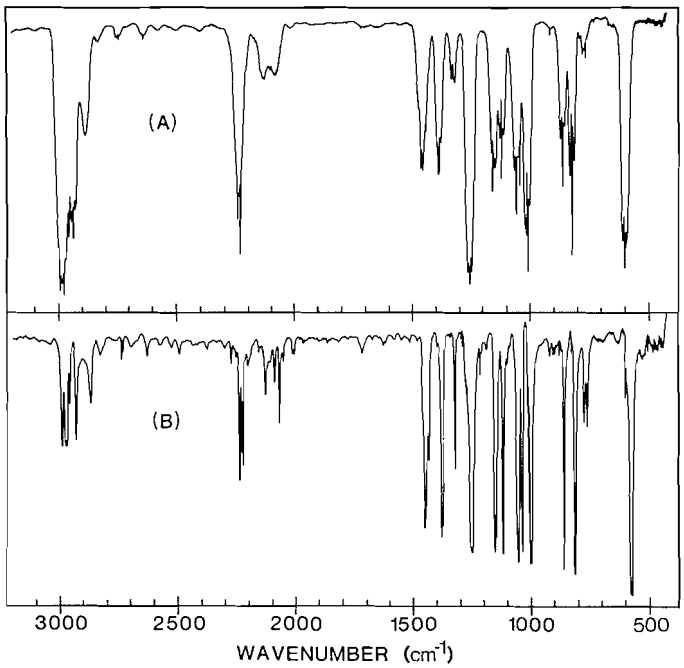

FIG. 3. Mid-infrared spectra of CH_3CD_3CHCl: (A) gaseous phase; (B) solid phase.

the CH_3 rock in the -d_0 compound by three CD_3 deformations. It should be noted that the band at 1010 cm^{-1} has extensive mixing with other normal modes that are higher in frequency. The CD_3 symmetric deformation is calculated to be higher in frequency than two of the CD_3 antisymmetric deformations whereas the CH_3 antisymmetric deformations are almost always higher than the CH_3 symmetric deformation. Deuteration of the BH_3 group shows the same tendency (8, 9).

The two CD_3 rocks are assigned at 822 and 764 cm^{-1}. The shift factors of 1.10 and 1.23, respectively, appear too low but these two modes mix with the CH_3 rocking and CC stretching modes, which should not shift with deuteration of the methyl group. Presumably, this is part of the reason for the low shift factors for these two modes.

All the skeletal modes are assigned in agreement with the assignment of these modes made by Klaboe (3). The assignment of the -CH_3 and -CD_3 torsions has already been addressed. The antisymmetric (A″) methyl torsion for 2-chloropropane-d_0 should have a *B*-type band contour and a depolarized Raman line. Unfortunately, the methyl torsions for this compound were not observed in the Raman spectrum. From the far-infrared spectrum previously reported (2), along with the present *ab initio* calculations, it can be concluded that the A′ methyl torsion should be assigned higher in frequency than the A″ methyl torsion for the 2-chloropropane-d_0 species. This is the exact opposite of the previously proposed (2, 3) assignments for these two fundamentals. The comparison of the assignment by Klaboe (3) with the present normal coordinate analysis will be discussed in detail in the Discussion.

Ab initio *calculations*

The program GAUSSIAN-82 using Gaussian-type basis functions (10) was utilized to perform the LCAO-MO-SCF restricted Hartree–Fock calculations. The energy minima with respect to nuclear coordinates were obtained by simultaneous relaxation of all geometric parameters using the gradient method of Pulay (11, 12). The calculated structural parameters for 2-chloropropane determined with both the 3-21G* and 6-31G* basis sets are listed in Table 5.

To obtain a more complete distribution of the molecular motions involved in the normal modes of 2-chloropropane, we carried out normal coordinate analyses. The force field obtained from the *ab initio* program (10) is in cartesian coordinates. Basis sets typically used for this purpose are at the 3-21G, 3-21G*, 4-21G, or 4-21G* level, but from previous studies it has been found that for most molecules the values in the force constants and frequencies are not significantly different when a smaller, as opposed to a larger, basis set is used. For this study the 3-21G* basis set was used to obtain the force field, and the normal coordinate analysis was performed by using the Wilson matrix method (13) and the computer program written by Schachtschneider (14).

The following procedure was followed for the normal coordinate analysis. The cartesian coordinates obtained for the optimized structure were input into the *G*-matrix program together with the complete set of 30 internal coordinates (Fig. 5). This set of internal coordinates was used to form the 27 symmetry coordinates with the three redundancies that are given in Table 6. With the deuteration of one of the methyl groups, the

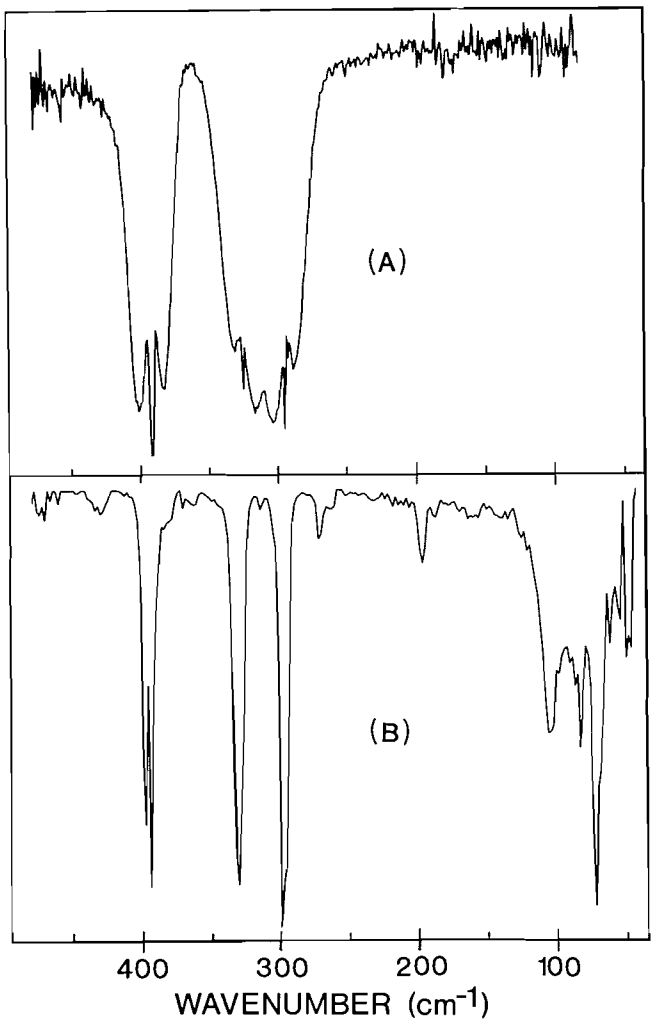

FIG. 4. Far infrared spectra of CH_3CD_3CHCl: (A) gaseous phase; (B) solid phase.

$-d_3$ molecule does not possess a symmetry plane as the $-d_0$ compound does. Therefore, there may be less coupling between the two rotors in the $-d_3$ molecule compared to that in the $-d_0$ species. The output of this *G*-matrix program consists of the *B* matrix as well as the unsymmetrized and symmetrized *G* matrices. The *B* matrix was used to convert the force field in cartesian coordinates from the *ab initio* calculations to a force field in terms of the desired internal coordinates. The resulting force field for 2-chloropropane is given in Table 7. This force field was then input, along with the unsymmetrized *G* matrix and scaling factors, into the perturbation program by Schachtschneider (14). All diagonal elements of the obtained force fields in internal coordinates were assigned scaling factors. Initially all scaling factors were kept fixed at a value of 1.0 to produce the pure *ab initio* calculated vibrational frequencies. Subsequently, scaling factors of 0.9 for stretching coordinates, 0.8 for bending coordinates, and 1.0 for torsional coordinates, and the geometric average of scaling factors for the interaction force constants were used to obtain the "fixed scaled" force field and resultant frequencies. A total of 30 symmetry coordinates were used to determine the potential energy distributions (P.E.D.), which are given in Table 4 for the $-d_0$ and $-d_3$ species, respectively.

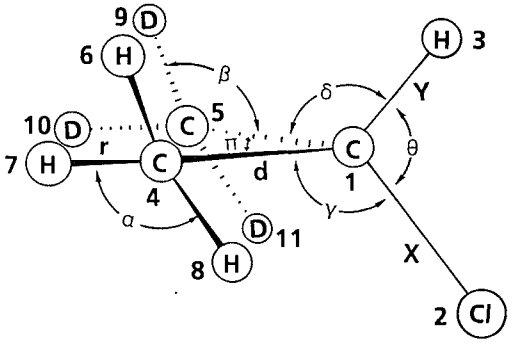

FIG. 5. Internal coordinates of CH_3CD_3CHCl.

Structure

The r_0 structure for the 2-chloropropane molecule has been determined with the previously reported (4) rotational constants using a program (15) developed in our laboratory. It consists of direct iterative adjustments of structural parameters to the observed rotational constants. With the availability of 24 moments of inertia determined for 2-chloropropane from the assignment of the microwave spectrum (4), the calculation of the r_0 structure presents no difficulties.

As input to the program, we utilized the *ab initio* calculated parameters with an adjustment of 0.010 Å added to the calculated methyl C—H distances from the 6-31G* basis set. The secondary C—H distance was fixed at 1.095 Å according to the experimentally determined value (7). With only these adjusted C—H distances fixed, we then calculated the heavy atom bond distances and all bond angles and dihedral angles. The determined values agree well with the previously reported r_s structures (Table 5), with the exception of the C—Cl bond distance. Our value of 1.806 ± 0.003 Å for the C—Cl bond distance is larger than the r_s value of 1.798 ± 0.006 Å; however, considering the uncertainty on the r_0 and r_s values for this parameter, the two values are within experimental error of each other. Nevertheless, the discrepancy between the r_0 and r_s values is greater than expected although the *ab initio* results indicate that the C—Cl distance should be longer than the reported r_s value.

The rotational constants are readily reproduced with only four of the 24 parameters having errors a little larger than 0.5. The weighted least-squares fit of the rotational constants gives relatively small uncertainties for most of the parameters. Only the $<H_3C_1C_4$ angle, which is equal to the $<H_3C_1C_5$ angle for the $-d_0$ compound, is calculated to have an uncertainty of 0.3° and the C—Cl distance has a relatively larger uncertainty of 0.003 Å. The relatively large uncertainty on the $H_3C_1C_4$ angle may be accounted for by the relatively larger calculated uncertainty on the rotational constant *A* of the $-H_3$ substituted species, $CH_3CDClCH_3$. However, this angle had the exact same value as that from the r_s structure, and most of the other HCC angles agreed with the *ab initio* calculated and r_s values except for the $<H_6C_4H_8$, which is off by more than 1.0°.

To determine the reliability of the resultant r_0 structures, we attempted a few more similar calculations. The r_0 values listed in Table 5 were obtained by inputting uncertainties of 0.015 Å for bond distances and 1.5° for bond angles. We tried a similar iterative calculation by changing the uncertainties to 0.030 Å and 3.0° for the bond distances and angles. The resultant bond angles are only different from those listed in Table 5 by ±0.1°.

[a]Bond lengths in Å, angles in degrees, rotational constants in MHz, dipole moments in debye, and energy in hartrees.
[b]For atom numbering, see Fig. 5.
[c]From ref. 4. The rotational constants listed in this column are presently calculated using the r_s structure.
[d]Calculated using the rotational constants given in ref. 4 with an adjustment of 0.010 Å added to the calculated methyl C—H distances from the 6-31G* basis set. The C—H distance for $C_1—H_3$ is fixed at 1.095 which was determined from ref. 7. Microwave determined values, A = 8069.09, B = 4570.82, and C = 3207.57 MHz.
[e]Calculated using only the rotational constants of molecules with heavy atom substitution.

The two heavy atom bond distances are strongly correlated with each other for all of the r_0 calculations. With the larger input uncertainty, the C—C distance increased by 0.001 Å whereas the C—Cl distance decreased by the same amount.

We tried another calculation in which we utilized only the rotational constants reported (4) for the heavy atom isotopic species. Twelve moments of inertia of this type were used to calculate only the heavy atom structures with all the bond distances and angles associated with the carbon–hydrogen bonds held fixed. The results of this calculation were dramatically different, i.e., the carbon–carbon distance increased to 1.521 ± 0.001 Å and the carbon–chlorine distance was reduced to 1.801 ± 0.002 Å. The fit to the rotational constants was excellent and this value for the C—Cl distance agrees very well with the r_s value of 1.798 ± 0.008 Å for this bond.

For the 2-chloropropane-d_0 compound, the two methyl tops are equivalent. The two hydrogens, -H_6 and -H_9, which are oriented approximately 180° to the chlorine atom, are calculated to have longer CH bond distances than the other hydrogens. The corresponding angles, $<H_6C_4C_1$ and $<H_9C_5C_1$, are calculated to be smaller than the other HCC angles from all the methods, i.e., *ab initio*, r_s, and r_0 structural calculations. Compared to the other hydrogens, these two are further away from the chlorine atom, which is a weak electron donor. This may then partially account for the unique property of the two hydrogens. All the bond angles from the r_0 structural calculations are in excellent agreement with those from the r_s structural determination and *ab initio* calculations. We believe the determined r_0 structural parameters should be within the listed uncertainties of the actual values.

Discussion

The barriers to internal rotation of the methyl rotors are essentially the same for the two isotopic species of 2-chloropropane, i.e., for CH_3CD_3CHCl, V_3 = 1378 ± 4 cm^{-1}, and for $(CH_3)_2CHCl$, V_3 = 1380 ± 3 cm^{-1} (Table 2). This value is considerably larger than the V_3 value of 1149 ± 69 cm^{-1} (3.29 ± 0.12 kcal/mol) for the corresponding fluoride molecule (1), $(CH_3)_2CHF$. However, it is consistent with the methyl barriers of other chlorine-substituted hydrocarbons compared to the corresponding fluorine-substituted molecules. The chlorine-containing compounds always have much larger methyl barriers than the fluorides.

The values for the sine–sine coupling term for the two isotopomers are essentially identical where $V'_{33} = -173 \pm 3$ cm^{-1} for CH_3CD_3CHCl and −171 ± 2 cm^{-1} for $(CH_3)_2CHCl$. Because of the agreement this potential constant appears to be well determined. However, for the cosine–cosine coupling term there is a difference of approximately 15% between the two values, i.e., V_{33} = 166 ± 10 cm^{-1} for CH_3CD_3CHCl and V_{33} = 209 ± 12 cm^{-1} for $(CH_3)_2CHCl$. Since the cosine–cosine coupling term is expected to have essentially the same value

as the sine–sine coupling term except opposite in sign, we believe the lower value of 166 ± 10 cm^{-1} obtained in the present study is probably a better value than the larger value reported (2) earlier.

In the recent study (1) of 2-fluoropropane, the V_{33} and V'_{33} values for the d_0 and d_7 isotopic species are about 95 and −95 cm^{-1}, respectively, whereas for the d_3 molecule the values are more than twice these values. Since the potential coupling is expected to be smaller in the fluoride, it is probable that the lower values are closer to the actual values. However, it would be of interest to determine these potential coupling parameters by *ab initio* calculations for the fluoride. Similarly there have not been any determinations of these parameters for the corresponding bromide and the determination of these potential terms from the low frequency data would be of interest for comparison to the values for the chlorides.

Initially we did not expect the 6-31G* basis set to give such a poor prediction for the C—Cl bond distance. For example this basis set gives (16) a value for the C–Cl bond of 1.785 Å for the CH_3Cl molecule with the experimental value determined (17) to be 1.775 ± 0.002 Å. Therefore, one would expect the calculated value of 1.815 Å to be too large by 0.010 Å but probably not by 0.014 Å. Nevertheless, we believe the smaller C—Cl distance is closer to the actual value. The fact that the C—D distance is shorter by 0.007 Å than the corresponding C—H distance may skew the results to a longer C—Cl distance when the rotational constants for the deuterium-substituted molecules are used. To determine the correct value for the C—Cl distance it would be useful to carry out *ab initio* calculations for chloroethane and compare the calculated parameters to the experimental ones (18). Similar *ab initio* calculations for tertiary butyl chloride could be used to see if the theoretical results reproduce the observed elongation of the C—Cl bond with substitution of an increased number of methyl groups on the carbon atom (19).

In Table 8, the structural data for propane and 2-halopropanes are listed for comparison. Definite trends exist among the parameters considered, despite the differences between the method of least-squares fitting of the present study and the isotopic substitution method of Kraitchman (20) used to calculate the r_s structural parameters of the remaining molecules listed in Table 8. The progressive increase in the CCX angle and the C—X bond distance from propane to 2-iodopropane parallels the systematic increase in the size of X. The trend in the CCC angle is not so well defined and, in fact, this parameter appears to be relatively constant for the 2-halopropane molecules. The difference in the C—C distance in propane and that for 2-fluoropropane is within the experimental uncertainties but, based on data from the other 2-halopropanes, it is clear that the C—C distance is shorter for the halosubstituted molecules than in propane. In fact, a slight decrease in the C—C distance is found with an increase in the size of the

halogen atom in the halopropanes. A similar trend is observed in other haloalkanes (21–25).

The vibrational assignment for the -d_3 species was supported by the *ab initio* calculations and the Teller–Redlich product rule. The theoretical value for the entire A block is 18.47 whereas the experimental value is 17.92, which leads to an acceptable error of 3%. For many compounds (26, 27) containing the CD_3 group, frequently the CD_3 symmetric deformation and the CD_3 rock have a smaller shift factor compared to the expected value, ~1.37, whereas the CD_3 antisymmetric deformations have relatively large shift factors. The skeletal modes in the region below 650 cm^{-1} shift down for the -d_3 compound and are mainly due to the change in mass of the methyl groups from 15 amu to 18 amu for the perdeuterated methyl group. Results from the fixed scale *ab initio* calculations of the low frequency skeletal modes are in excellent agreement with the observed bands. The light and heavy methyl torsions are calculated within 1 and 2 cm^{-1}, respectively, of the calculated values. It is interesting that even though the CD_3 torsion shifts only by a factor of 1.3, when it is multiplied by the shift factor of the CH_3 torsion, 1.05, the product is the expected shift factor of 1.37 for the CD_3 methyl group.

For the -d_0 species, the 27 fundamentals span the irreducible representations 15A′ + 12A″. The 15A′ modes should give rise to polarized Raman lines and A/C-type band contours in the infrared spectrum of the gas, whereas the 12A″ fundamental vibrations should have depolarized Raman lines and show B-type band contours in the infrared spectrum of the gas. The assignments made by Klaboe (3) according to the band contours and depolarization ratios are in fair agreement with the calculated results from the present study with a few exceptions.

In the C—H stretching region, we expect three A″ fundamentals and they are thus assigned to two depolarized lines and one B-type band as previously proposed (3) even though it is not totally consistent with the frequency order from the *ab initio* calculations. For the four A′ carbon–hydrogen stretches, however, the CH_3 symmetric stretch (ν_4) was misassigned at 2878 cm^{-1}, which is too low to be a fundamental. This mode is assigned to a strong band at 2927 cm^{-1}, which was previously assigned (3) to the CH stretching motion. The corresponding C—H stretch (ν_3) and CH_3 antisymmetric stretch (ν_2) are assigned to a weak band at 2955 cm^{-1} and a strong band at 2989 cm^{-1}. Similar to the assignment for the -d_3 compound, the C—H stretch is assigned as the third frequency even though it is calculated as the highest frequency. It is interesting that by adding 0.010 Å to the *ab initio* calculated value for this secondary carbon–hydrogen distance, one would obtain a distance of 1.090 Å, whereas the experimental value is 1.095 ± 0.001 Å. Therefore, the *ab initio* calculations give a considerably shorter distance for this C—H bond than those for the C—H bonds of the methyl group. This significant difference in the calculated distance is the apparent reason why the *ab initio* predicted frequency for this C—H bond is the highest predicted value.

The A′ and A″ CH_3 torsions are calculated to occur at 261 and 236 cm^{-1}, respectively, and they are thus assigned at 276 and 253 cm^{-1}. As mentioned earlier, these two torsions have been (2, 3) assigned just the opposite. Similarly, the HCCl rock (ν_{13}) is assigned at 418 cm^{-1}, which is higher than the skeletal bend (ν_{14}) at 336 cm^{-1}. These two fundamentals were in the opposite order. It should be mentioned that these two modes mix extensively according to the P.E.D. from *ab initio* cal-

culations. For the -d_3 compound, the one at higher frequency (380 cm^{-1}) has more skeletal bend (39%) than the HCCl rock (27%) from the P.E.D. predictions.

One can also note that the A″ skeletal stretch is calculated lower in frequency than the two A″ CH_3 rocking modes before scaling. Since we scale the stretching modes by 0.9 and bendings by 0.8, the A″ skeletal stretch then occurs higher in frequency at 1121 cm^{-1} than the two CH_3 rocks (956 and 949 cm^{-1}) after scaling. This frequency order is consistent with that proposed by Klaboe (3), who assigned the stretch and the two CH_3 rocks at 1123, 972, and 936 cm^{-I}, respectively. The switching after scaling is also the case for the -d_3 species for the antisymmetric skeletal stretch with the CD_3 symmetric deformation.

Finally it should be noted that the determined force constants (Table 7) are very similar in value to those obtained for the corresponding fluoride (1) except for those associated with the C—X bond. It should be possible to use these force constants with adjustment for the C—Br or C—I bonds to predict the normal frequencies for 2-bromo- and 2-iodopropane.

Vibrational spectra and force field studies of $[PtCl_3(CO)]^-$ anion labelled with $^{13}C^{16}O$, $^{12}C^{18}O$, and radioactive $^{14}C^{16}O$

J. MINK

Institute of Isotopes of the Hungarian Academy of Sciences, H-1525 Budapest, P.O.B. 77, Hungary

AND

P. L. GOGGIN

Department of Inorganic Chemistry, University of Bristol, Bristol BS8 1TS, United Kingdom

Received April 29, 1991

This paper is dedicated to Dr. Richard Norman Jones

J. MINK and P. L. GOGGIN. Can. J. Chem. **69**, 1857 (1991).

Detailed infrared and Raman studies are reported for $[PtCl_3(^{12}C^{16}O)]^-$, $[PtCl_3(^{13}C^{16}O)]^-$, $[PtCl_3(^{12}C^{18}O)]^-$, and $[PtCl_3(^{14}C^{16}O)]^-$ together with assignments. Bands observed for the $^{14}C^{16}O$ species at 2005, 483, 507, and 466 cm^{-1} are assigned to CO and PtC stretching, PtCO in-plane and out-of-plane linear bending modes, respectively. Force constants have been calculated using a modified valence force field, with constrained off-diagonal force constants based on $[PtCl_4]^{2-}$ and $[PtX_3(CO)]^-$ (X = Br, I). The effective **G**-matrix method (EGM) has been used for approximate calculation of CO and PtC stretching force constants for some other square-planar platinum–carbonyl complexes. The results are discussed with the assistance of stretching force constants for some of the simpler complexes.

Key words: vibrational spectra, force constant calculation, ^{13}C, ^{14}C, and ^{18}O labelled $[PtCl_3(CO)]^-$.

J. MINK et P. L. GOGGIN. Can. J. Chem. **69**, 1857 (1991).

On a réalisée des études ir et Raman détaillées des anions $[PtCl_3(^{12}C^{16}O)]^-$, $[PtCl_3(^{13}C^{16}O)]^-$, $[PtCl_3(^{12}C^{18}O)]^-$ et $[PtCl_3(^{14}C^{16}O)]^-$ et on rapporte les attributions qui en découlent. Les bandes observées à 2005, 483, 507 et 466 cm^{-1} pour l'espèce $^{14}C^{16}O$ sont attribuées respectivement aux modes de d'élongation du CO et du PtC et aux modes de déformation angulaire linéaire dans le plan et hors-du-plan du PtCO. On a calculé les constantes de force en utilisant un champ de force de valence modifié avec des constantes de force contraintes, décalées par rapport à la diagonale et basées sur les anions $[PtCl_4]^{2-}$ et $[PtX_3(CO)]^-$ (X = Br, I). On a utilisé la méthode de matrice-**G** effective (MGE) pour faire des calculs approximatifs des constantes de force pour l'élongation du CO et du PtC dans quelques autres complexes plans carrés du platine-carbonyle. On discute des résultats à l'aide de constantes de force d'élongation de quelques complexes plus simples.

Mots clés : spectres vibrationnels, calculs de constantes de force, $[PtCl_3(CO)]^-$ marqué avec du ^{13}C, du ^{14}C et du ^{18}O.

Introduction

Carbon monoxide is known to form complexes with almost every transition element. The bonding in metal carbonyls has attracted a number of experimental and theoretical scientists. Important information about the nature of bonding lies in the value of the force constants. Apart from the fact that the vibrational spectra of isotopic species give additional data for force constant calculation, the isotope shifts provide a great help in the assignment of the vibrational bands.

The CO stretching bands observed in the infrared and Raman spectra are usually strong, sharp, and sensitive to the environment. The vibrational spectra outside the CO stretching region are also informative though their interpretation is less easy. The M—C stretching and M—CO bending modes are usually very close to each other (near 600–400 cm^{-1}) and it is difficult to assign them without additional information. That is another important reason for studying the vibrational spectra of metal carbonyls labelled with carbon or oxygen isotopes. Labelled carbon monoxide, $^{14}C^{16}O$, has not — until now — been used in metal carbonyls for studying vibrational spectra and structure.

We have made extensive studies by means of rotational and vibrational spectroscopy of carbon-14 labelled compounds, involving pure rotational spectra of $^{14}C^{16}O$ (1), rotational–vibrational spectra of $^{14}C^{16}O$ (2), $^{14}C^{16}O_2$ (3, 4), $^{14}C_2H_2$ (5, 6), $^{14}C_2H_6$ (7), $^{14}C^{12}CH_2$ (7), and $^{14}C_6H_6$ (3).

Vibrational spectral measurements and in most of the cases force field studies of simple square-planar carbonyl complexes of platinum metals have been carried out for $[M_2X_4(CO)_2]^{2-}$ (M = Pt(I), Pd(I), X = Cl, Br) (8, 9); *cis*-$[MX_2(CO)_2]^{n-}$ (for $n = 0$, MX = PtCl, PtBr (8, 9); for $n = 1$, MX = RhCl, RhBr, or IrCl) (10, 11). Infrared and Raman spectra of $[MX_3(CO)]^-$ (MX = PdCl, PdBr, PtCl, PtBr, or PtI) (10) and force constants for planar vibrations (12) have been reported.

In this paper we report the results of detailed analysis of the vibrational spectra of $[PtCl_3(^{13}C^{16}O)]^-$, $[PtCl_3(^{12}C^{18}O)]^-$, and $[PtCl_3(^{14}C^{16}O)]^-$ and force constant calculations involving out-of-plane vibrations as well.

Experimental

The salts $[NPr_4^n][PtCl_3(CO)]$ were prepared as previously reported (10). The $^{13}C^{16}O$ and $^{12}C^{18}O$ gases used for the preparation were purchased from the Prochem division of BOC in the U.K. The $^{14}C^{16}O$ gas was prepared on a usual vacuum line equipped with mercury manometer, liquid N_2 traps, and a Töppler pump for gas manipulation. The starting material for producing $^{14}C^{16}O$ was $Ba^{14}CO_3$ and $^{14}CO_2$ was eliminated by adding H_2SO_4 and then carbon dioxide was reduced on a Zn catalyst at 385°C to carbon monoxide.

The infrared spectra were recorded partly on a Digilab FTS-20C spectrometer equipped with TGS detector and KBr supported Ge-beamsplitter and on a Perkin-Elmer 580 B spectrometer. Far-infrared spectra were measured with a Grubb-Parsons I.R.I.S. interferometer using 0.01 and 0.04 mm Mylar beam splitters.

The Raman spectra of solid and dissolved samples of ^{14}C-labelled species were produced with a Jobin Yvon Ramanor HG-25 spectrom-

[b]Infrared spectra measured in CH_2Cl_2 or in $CHCl_3$, Raman spectra in C_6H_6 solution. More precise frequency values are listed in Table 4.
[c]Spectral range is not measured.

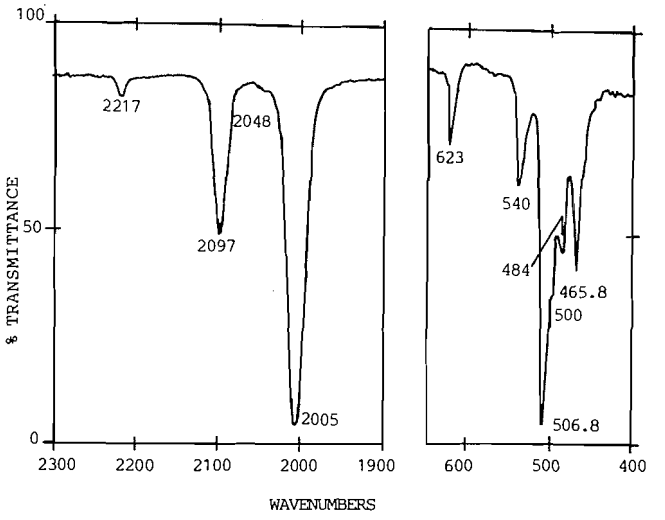

FIG. 1. Selected ranges of infrared spectrum for $[NBu_4^n][PtCl_3(^{14}C^{16}O)]$ measured in CH_2Cl_2 solution. The extra bands belong to the following species: 2217 w, $^{14}CO_2$ dissolved in CH_2Cl_2; 2097 m, $^{12}C^{16}O$ stretching; 2048 vw, sh, $^{13}C^{16}O$ stretching of natural abundance; 623 w, cation band; 540 m, ~500 sh band of $Pt^{12}C^{16}O$.

eter by using the 488 and 514.5 nm lines of an ILA 120 Ar^+ laser (Karl Zeiss, Jena). The other isotope derivatives were measured on a Coderg T800 triple monochromator spectrometer with excitation from Coherent Radiation Laboratories model 52 krypton- or argon-ion lasers.

Assignment of the spectra

The spectra features in the 2300–1700 and below 650 cm^{-1} regions recorded for solutions as well as the solid state are presented in Table 1. The infrared spectrum of $[PtCl_3(^{14}C^{16}O]^-$ in CH_2Cl_2 solution is shown in Fig. 1, whilst its Raman spectrum of the solid in the 550–25 cm^{-1} region is given in Fig. 2. The largest isotope shifts ever observed for metal carbonyls have been detected, namely 92, 33, 31, and 14 cm^{-1} for CO stretching, PtCO in-plane, PtCO out-of-plane bendings, and PtC stretching modes, respectively. The relative integrated intensities of the two CO stretching bands (2097 and 2005 cm^{-1}) in Fig. 1 correspond exactly to 86% isotopic purity calculated from the specific activity of the starting $Ba^{14}CO_3$.

The assignment discussed below is generally based on our earlier publications (10, 12), although additional experimental data of three isotopic species have led to slight modifications of the previous assignments.

For C_{2v} symmetry there should be three vibrations in the 600–400 cm^{-1} region: PtC stretching, in-plane and out-of-plane PtCO deformations. The polarized Raman line must relate to the PtC stretching mode and the strong infrared band can be assigned to the PtCO in-plane deformation which is close to those of *cis*-$[PtCl_2Me(CO)]^-$ where it was observed as a polarized Raman line (13). Fortunately, the carbon isotope sensitivity of the PtCO out-of-plane mode produces 16 and 31 cm^{-1} isotope shifts for $^{13}C^{16}O$ and $^{14}C^{16}O$ species, respectively, which is considerably stronger than those for the PtC stretching mode (6 and 14 cm^{-1}, respectively). Therefore, the accidentally degenerate PtC stretching and PtCO out-of-plane modes of $[PtCl_3(^{12}C^{16}O)]^-$ appear as well-separated pairs at 499/481 and 483/466 cm^{-1} for the $^{13}C^{16}O$ and $^{14}C^{16}O$ species, respectively. It is interesting to note that for $C^{18}O$ the PtC mode is lower than either of the PtCO bending modes.

The assignments of PtCl stretching vibrations basically

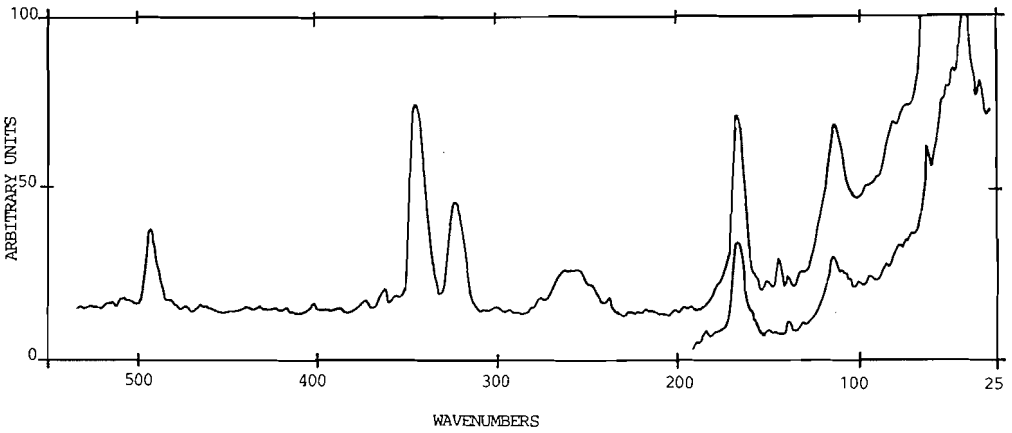

FIG. 2. Raman spectrum of $[NBu_4^n][PtCl_3(^{14}C^{16}O)]$ in solid state. Excitation by 40 mW at 514.5 nm line of argon laser.

follow from the patterns that we have previously established for $[PtCl_3L]^-$ (14, 15). For all isotope species only two Raman lines were observed around 345 and 320 cm^{-1}, and two infrared bands basically at the same positions. Since both were polarized in the Raman spectra the assignment for a_1 species is obvious. Therefore, the more intense infrared band was assigned to $PtCl_2$ asymmetric stretching of b_1 species at 343 cm^{-1}.

The in-plane and out-of-plane deformation modes below 170 cm^{-1} are assigned on the basis of $[PtCl_4]^{2-}$ (16). The strong infrared feature at 131 cm^{-1} in solution is probably an out-of-plane deformation related to b_2, which coincides with CPtCl in-plane deformation mode of b_1 species, whilst the lowest feature (105 cm^{-1}) is close to the frequency calculated for the inactive b_{2u} mode of $[PtCl_4]^{2-}$ (16). The feature near 150 cm^{-1}, which is possibly polarized in the Raman, corresponds to the e_u in-plane vibration of $[PtCl_4]^{2-}$ and maybe to the a_1 mode for the carbonyl complex. The remaining highest frequency band at about 170 cm^{-1} can be related to the b_{2g} mode of $[PtCl_4]^{2-}$ appearing at 172 cm^{-1}. The above discussed correlation is summarized in Table 2.

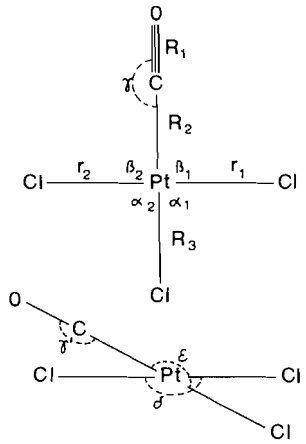

FIG. 3. Internal coordinates of the square-planar $[PtCl_3(CO)]^-$ complex.

Calculation of force constants

Force constant calculation of $[PtCl_3(CO)]^-$ was first performed by Norton (17). Reinvestigation of the vibrational spectra with a slightly modified assignment and the evaluation of ^{13}C isotopic species in the CO stretching region (in natural abundance) gave a reason for recalculating the force constants for planar modes (12).

Now we have spectroscopic data for four pure or highly enriched isotopic species of CO and we are able to extend our force field studies.

The ten in-plane and three out-of-plane internal coordinates are defined with reference to Fig. 3. Square-planar molecular geometry with linear PtCO bonding has been assumed. The equilibrium interatomic distances (pm) are in CO, 114; PtC, 176; PtCl(*cis*), 230; PtCl(*trans*), 232. These values were adopted from the molecular parameters of similar structures, e.g. from $[PtCl_4]^{2-}$. The *trans*-PtCl bond of the CO group was estimated to be 2 pm longer than in the *cis*-ClPtCl bonds (18). The program system used for normal coordinate treatment and force constant calculations is described elsewhere (19).

The $[PtCl_3(CO)]^-$ anion belongs to the C_{2v} symmetry group. The non-redundant internal valence symmetry coordinates were used as published earlier (12), and the additional out-of-plane species (b_2) involve $S_{10} = \gamma'$, $S_{11} = \delta$, and $S_{12} = \epsilon$ symmetry coordinates. The relationship between the force constants in symmetry coordinate terms and those in internal coordinate terms is shown in Table 2 of ref. 12.

There are nine in-plane vibrations, $5a_1 + 4b_1$, and three out-of-plane modes, $3b_2$. For four isotopic species we have formally 48 frequencies, but a number of them are not carbon- or oxygen-isotope sensitive (they are not independent). We are restricted to determining 12 diagonal and one non-diagonal terms. Initially we ignored all interaction constants of the CO group and thus entries F_{12}, F_{13}, F_{14}, F_{15}, F_{67}, F_{68}, F_{69}, and $F_{10,11}$ are set to zero. This constraint is identical to that used

earlier (12). Six other interaction constants were taken from ref. 12 without further refinement.

Initial values for the force constant refinements were taken from previous calculations (12). The final refined values in symmetry coordinate terms are listed in Table 3. The agreement between the wavenumbers calculated from the force constants and the experimental assignments is evident from Table 4. It can be seen that the wavenumber correspondence is good for the available experimental frequencies. We have used estimated experimental wavenumbers for ν_{11} and ν_{12} for some of the isotopic species so the force field for the out-of-plane vibrations must be considered as a preliminary result: the evidence from the $^{12}C^{16}O$ and $^{14}C^{16}O$ cases shows little wavenumber sensitivity to isotopic substitution.

When comparing the force constants in Table 3 with earlier ones (12) it is important to mention that from the isotope-sensitive frequencies we were able to determine more accurate force constants F_{11}, F_{22}, F_{66} but the others are close to the earlier results. The PtCl (*trans* to CO) stretching mode, ν_4, showed some carbon and oxygen isotope sensitivity, that is why the new value of F_{44} slightly differs from the earlier one. The PED and eigenvector calculations proved that there is some contribution from the PtC stretching mode in this PtCl stretching one.

For the ν_1 and ν_2 frequencies we have eight independent isotope-sensitive wavenumbers. Taking into account that $F_{12} = 0$, we have eight experimental data for three force constants (F_{11}, F_{12}, and F_{22}). The results of this calculation are presented in Table 5. The stretching force constants of the PtCO group are very much distorted by introducing an extra F_{12} interaction term, especially for the calculation based on experimental data only for two ^{12}CO and ^{13}CO isotopes (last column in Table 5). It should be pointed out that there is no reason for introducing an extra force constant for the stretch–stretch interaction of the PtCO group. The fit was found better for $F_{12} = 0$ and the force constants became more comparable with the literature results.

Discussion

Table 6 lists the internal coordinate force constants which may be evaluated from Table 3. All diagonal in-plane terms have been fitted with low dispersion except the PtCO linear bending mode. The relatively high inaccuracy of the H(PtCO) in-plane force constant can be explained by the bad fit of ν_6 for the $^{14}C^{16}O$ isotope species. The observed isotope shift (33 cm^{-1}) for this molecule is much higher than the calculated one (24 cm^{-1}).

The relatively high dispersion of the out-of-plane force constants (b_2 species) is not surprising since only the ν_{10} mode shows carbon and oxygen isotope sensitivity in our series. This picture did not change significantly by the introduction of additional $F_{10,12}$ and $F_{11,12}$ force constants into the refinement.

The *trans*-influence of the CO ligand can be clearly recognised by slight lowering of the *trans*-PtCl force constant.

We have already reported results of force constant calculation for *cis*-$[PtX_2(CO)_2]$ (X = Cl, Br) (11) and $[PtX_3(CO)]^-$ (X = Br, I) (12). Some characteristic spectroscopic data for these molecules are presented in Table 7.

Since the coupling of PtC and especially CO stretching modes to other motions in these molecules should not significantly differ in a series of platinum monocarbonyls, these stretching force constants can be approximately reproduced by the following so-called effective **G**-matrix (EGM) method.

Using the experimental CO and PtC stretching frequencies (ν in cm^{-1}) and the corresponding force constants (K in N cm^{-1}) obtained from the full solution of the vibrational problem for $[PtX_3(CO)]^-$ series (where X = Cl, Br, I) and with the simplified relation:

$$\Lambda = 0.5891(\nu/1000)^2 \sim G_e K$$

where Λ is the eigenvalue, the effective **G** matrix elements (G_e) have been calculated.

Using the averaged G_e values obtained for $[PtX_3(CO)]^-$ anions, the expressions for approximate calculation of force constants of related molecules have been obtained:

$$[1] \quad K(^{12}CO) = 3.7404(\nu/1000)^2$$

$$[2] \quad K(^{13}CO) = 3.9191(\nu/1000)^2$$

$$[3] \quad K(PtC) = 15.8280(\nu/1000)^2$$

where ν is the corresponding stretching frequency in wavenumbers and the parameters 3.7404, 3.9191, and 15.8280 refer to the relation $0.5891/G_e$. On the basis of the above approximate expressions, CO and PtC stretching force constants (in N cm^{-1}) can be predicted for other platinum monocarbonyls without performing full normal coordinate treatment for all of them, as listed in Table 7.

The calculated CO stretching force constants for different isotopic species can be slightly different (e.g. for *cis*-$[PtCl_2(CO)(PMe_3)]$ 16.61/16.55 N cm^{-1} for ^{12}CO and ^{13}CO, respectively), therefore averaged values are listed in Table 7.

It is well known that for CO stretching force constants the factored force field parameter referring to eq. [1] is 4.0383 calculated on the basis of the isolated diatomic approximation. It is important to note that the EGM method presumably gives more comparable approximate force constants with the refined

values obtained from the full solution. The other advantage of the EGM method is that PtC stretching force constants can also be predicted by eq. [3].

The relationship between the square of CO stretching frequencies and force constants is presented in Fig. 4. Basically all monocarbonyls (one CO group per platinum atom) lie close to a line but the two dicarbonyls, namely *cis*-$[PtX_2(CO)_2]$ (X = Cl, Br), are out from this relation.

The relationship between CO and PtC stretching force constants is presented in Fig. 5.

Of course, the PtC stretching mode is more strongly coupled with other vibrations of the complex and so we cannot expect the almost linear correlation as in Fig. 4. In spite of the slightly scattered picture, it is clearly seen that the type of halide ligands always determines the metal–carbon bond strengths in the order: iodide < bromide < chloride, independent of the sequence of CO stretching frequency or force constant. Generally, it can be concluded that the PtC force constants are more sensitive to the coordination sphere, oxidation state, or overall charge of platinum.

The force constants calculated for PtC stretching in *cis*-$[PtX_2(CO)_2]$ are the lowest for the series presented in Table 7. In mononuclear dicarbonyls the two CO ligands have to share the back donation from the in-plane d orbital of the metal, consequently the Pt—C bond is weakened. The lower (zero) charge of the complex enhances the trend in the same direction. Conversely, the CO stretching force constants show the opposite trend, being at their highest in $[PtX_2(CO)_2]$. This

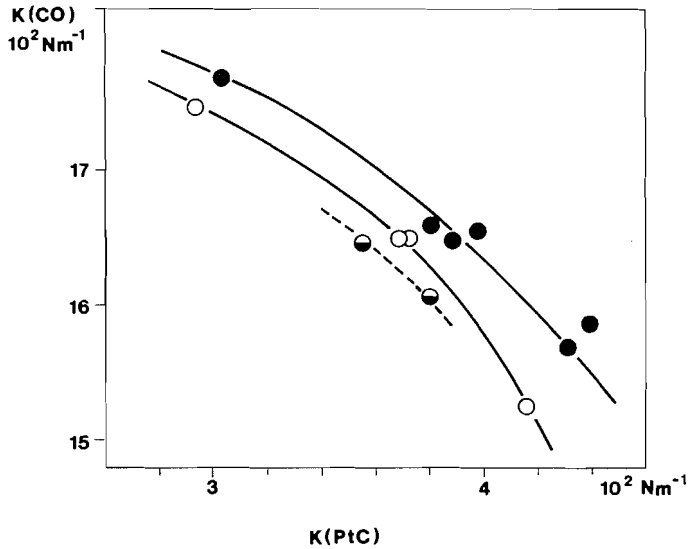

FIG. 5. Relationship between CO and PtC stretching force constants for square-planar platinum carbonyls (see Table 7): ●, chlorides; ○, bromides; ◒, iodides.

is presumably the consequence of the lower σ-overlap of the metal in the uncharged complex.

The other zero-charged representatives are the *cis*-$[PtX_2(CO)(PMe_3)]$ compounds, but the PMe_3 ligand is a strong electron donor; on this basis the PtC stretching force constant increases by about 25%, as compared to those in dicarbonyls.

Among the negative charged complexes the strongest PtC bond is formed in *cis*-$[PtX_2R(CO)]^-$ anions (where R = Me, Bu^n) indicating again a strong electron donor character of alkyl ligands.

The charge independence and close similarity of PtC force constants in $[PtX_3(CO)]^-$, *cis*-$[PtX_2(CO)(PMe_3)]$, and $[PtX(CO)(PMe_3)_2]^+$ can result from the superposition of several effects. As the number of X decreases the metal becomes more positive as a consequence of the decrease in overall charge, but this effect is compensated by the strongly electron donor PMe_3 ligand, and the π-component of the metal—carbon bond remains relatively constant, as does the strength of the Pt—C bond.

The relatively large PtC force constants for Pt(I) dimer complexes agree with the very low CO stretching force constants. The trend of averaged PtC force constants for

$$[PtX_2(CO)_2]^0 \quad [PtX_3(CO)]^- \quad [Pt_2X_4(CO)_2]^{2-}$$
$$3.1 \quad < \quad 3.8 \quad < \quad 4.2 \text{ N cm}^{-1}$$

shows that changes in overall charge of the complex and changes in oxidation state affect the Pt—C bond strength in the same way.

Étude potentiométrique de la stabilité de complexes tensioactif–β-cyclodextrine

D. JEZEQUEL, A. MAYAFFRE ET P. LETELLIER[1]

Laboratoire d'énergétique et réactivité aux interfaces, Université Pierre et Marie Curie, Bât. F, 8, rue Cuvier, 75231 Paris CEDEX 05, France

Reçu le 22 février 1991

D. JEZEQUEL, A. MAYAFFRE et P. LETELLIER. Can. J. Chem. **69**, 1865 (1991).

Les valeurs des constantes de dissociation des complexes formés entre la β-cyclodextrine (β-CD) et 13 agents tensio-actifs cationiques de type alkylammonium ont été déterminées par potentiométrie au moyen d'électrodes sélectives aux amphiphiles. Les résultats suggèrent, pour les plus longues chaînes (C12, C14 et C16), l'existence de deux complexes successifs (β-CD)M^+ et (β-CD)$_2M^+$, dont les valeurs relatives des constantes de dissociation sont dans un rapport voisin de 600. Ce comportement n'est pas modifié lorsque l'on change la nature de la «tête polaire», les valeurs des constantes de dissociation étant très peu influencées par ce paramètre. Pour les chaînes carbonées alkyles comportant moins de 12 atomes de carbone, on constate une stabilisation des complexes 1 : 1 lorsque la chaîne s'allonge. Jusqu'à $n = 12$, les valeurs des pK_1 des complexes 1 : 1 varient linéairement avec le nombre de carbones, n, de la chaîne alkyle. Ensuite, pour $n = 14$ et $n = 16$, l'augmentation de pK_1 est moins importante et parallèlement l'intervention d'un deuxième complexe s'avère indispensable pour décrire convenablement le comportement des surfactifs en solution. La connaissance des valeurs des constantes de dissociation de ces complexes permet d'envisager la constitution de «solutions tampons» formées d'agents tensio-actifs permettant de maintenir une concentration fixe de l'amphiphile en solution, lors d'une réaction.

Mots clés : agent tensio-actif, β-cyclodextrine, électrodes sélectives, constantes de complexation, potentiométrie.

D. JEZEQUEL, A. MAYAFFRE, and P. LETELLIER. Can. J. Chem. **69**, 1865 (1991).

The complexation constants K of β-cyclodextrine with 13 ammonium surfactants were determined by a potentiometric method using electrodes selective to amphiphilic ions. Especially for C12, C14, and C16 tails, a model that provides for the formation of a second complex (β-CD)$_2M^+$, with a K_1/K_2 ratio of about 600, provides a good fit with the experimental curves. Results show a poor influence of the polar group, for example in the case of the dodecyl chain. On the other hand, the pK_1 values and the hydrophobic tail length are linked by a linear relation up to $n = 12$ carbon atoms; beyond, pK_1 tends to be proportionally smaller and pK_2 more important.

Key words: surfactant, β-cyclodextrin, selective electrodes, complexation constants, potentiometric study.

Introduction

Les propriétés complexantes des cyclodextrines vis-à-vis des agents tensio-actifs (surfactifs) neutres ou chargés (anioniques et cationiques) ont été mises en évidence et étudiées par de nombreux auteurs (1–9). Les valeurs des constantes de complexation ont été le plus souvent mesurées pour les espèces chargées par une méthode conductimétrique et leur précision dépend essentiellement de l'estimation de la différence de mobilité entre l'espèce tensio-active monomère et celle du complexe formé (4–9). Si dans le cas des surfactifs anioniques cette différence est notable, il faut constater que pour les cationiques elle est faible, et souvent insuffisante pour obtenir des valeurs précises des constantes d'équilibre. Pour cette raison, nous avons abordé l'étude de la complexation des tensio-actifs cationiques par une voie *potentiométrique*, en utilisant des *électrodes sélectives indicatrices de surfactif.*

Nous avons borné notre étude aux propriétés de la β-cyclodextrine (CD) vis-à-vis de six surfactifs cationiques dont les têtes polaires sont des ammonium totalement substitués :

décyltriméthylammonium	DTA
dodécyltriméthylammonium	DDTA
tétradécyltriméthylammonium	TDTA
hexadécyltriméthylammonium	HDTA
hexadécylpyridinium	HDP
dodécyldiméthylallylammonium	DDDAA

et de sept ammonium acides obtenus par la protonation d'une amine à longue chaîne aliphatique :

octylammonium	OA
décylammonium	DA
dodécylammonium	DDA
tétradécylammonium	TDA
hexadécylammonium	HDA
dodécyldiméthylammonium	DDDA
cyclododécylammonium	CDDA

On cherchera donc, dans cette étude, à comparer les valeurs des constantes de dissociation des complexes selon la nature de leur groupement polaire, la longueur et la nature de leur chaîne aliphatique.

Partie expérimentale

1. Produits

La β-cyclodextrine est un produit Orsan. Les bromure d'alkyltriméthylammonium ainsi que ceux d'hexadécylpyridinium et de cyclododécylammonium sont des produits Aldrich. Le bromure de dodécyldiméthylallylammonium a été synthétisé selon la procédure décrite dans la référence 10.

Nous avons préparé les chlorure et acétate d'alkylammonium et de dodécyldiméthylammonium, à partir des amines correspondantes (produits Fluka (C_{10}); Janssen (C_{12}, C_{14}); Aldrich (C_{16}, cycloC_{12}). On neutralise par de l'acide chlorhydrique ou acétique, un système hétérogène constitué d'amine pure en présence de sa solution aqueuse saturée.

Les chlorure d'ammonium peu solubles dans l'eau précipitent à froid. Ils sont lavés et recristallisés dans l'eau en dessous de la température de Kraft. Les solutions d'acétate correspondant à la solution neutralisée ramenée à un pH légèrement acide par ajout d'une très faible quantité d'acide acétique, sont lyophilisées (l'acide acétique en excès est éliminé au cours de la lyophilisation).

2. Technique expérimentale

2.1. Électrodes sélectives de surfactif

Pour les alkyltriméthyl ammonium : Les électrodes indicatrices d'alkyltriméthylammonium mettent en jeu des membranes polymériques rendues sélectives à l'amphiphile cationique. Elles ont été réalisées au laboratoire (11) selon une méthode proche de celle décrite dans la littérature par différents auteurs (12, 13).

La membrane polymérique a été préparée en effectuant la suite d'opérations suivantes : (*a*) 0,4 g de PVC de très haut poids moléculaire (Janssen) et 1,6 g de dinonylphtalate, DNP (Merck), sont dissous dans 10 mL de tétrahydrofurane, THF (R.P. Prolabo); (solution *a*). (*b*) L'ion tétraphénylborure (TPB) est utilisé comme «transporteur» de l'amphiphile cationique dans la membrane polymérique. On prépare le tétraphénylborure du surfactif cationique par précipitation dans l'eau en mélangeant en quantités stoechiométriques du tétraphénylborure de sodium et du bromure de l'amphiphile cationique. Le précipité est lavé et purifié par, au minimum, trois extractions successives liquide–liquide (eau–CH_2Cl_2). Le sel est ensuite recristallisé deux fois dans un mélange éther éthylique – dichlorométhane. On prépare une solution 0,01 mol dm^{-3} du complexe TPB–amphiphile dans du THF. (*c*) On mélange 0,5 mL de la solution précédente à 3 mL de la solution contenant le PVC et le plastifiant. (*d*) La solution est mise à évaporer à l'atmosphère ambiante pendant 24 h dans un récipient à fond plat (aire = 25 cm^2).

La membrane ainsi obtenue, d'une épaisseur de 0,2 mm environ, est découpée et collée sur un embout en verre préalablement trempé dans la solution *a*.

La référence interne est constituée par la chaîne électrochimique suivante :

électrode calomel, solution de KCl saturée dans l'eau	KCl aq saturé	gel de KCl : $C = 2$ mol dm^{-3}	solution d'amphiphile cationique : $C = 10^{-3}$ mol dm^{-3}

Pour les alkylammonium : Nous avons réalisé des électrodes indicatrices d'ions alkylammonium en employant une méthode de préparation identique à la précédente, l'ion transporteur étant également l'ion tétraphénylborure. Pour un milieu donné, ces électrodes présentent en général une réponse nernstienne convenable au surfactif étudié. Cependant, le groupement ammonium étant acide, le complexe tétraphénylborure d'alkylammonium est susceptible de se dissocier à la surface de la membrane selon le niveau d'acidité de son environnement. Il en résulte que les électrodes ainsi constituées sont sensibles au pH du milieu, ce qui constitue un inconvénient majeur lorsque les espèces à doser possèdent par elles-mêmes des propriétés acides. Ces électrodes n'ont donc été utilisées que dans des milieux de pH fixé.

Il est connu que la spécificité des électrodes indicatrices de surfactifs vis-à-vis de composés possédant des groupements chargés hydrophiles *de nature voisine et de chaînes de longueurs comparables* reste très faible (14), alors qu'elle est excellente par rapport aux ions inorganiques. Si cette caractéristique limite généralement l'emploi de ces électrodes indicatrices aux milieux qui ne contiennent qu'un seul surfactif, elle présente également l'avantage de permettre le dosage de différents surfactifs avec une réponse nernstienne dans une certaine zone de concentration. Nous avons ainsi utilisé des électrodes incluant des complexes d'alkyltriméthylammonium (indépendantes du pH) pour doser des alkylammonium, après avoir déterminé leur domaine de réponse linéaire. Les valeurs des concentrations des ammonium suivants ont pu être mesurées au moyen d'électrodes indicatrices d'alkyltrimélthylammonium, incluant un complexe

de DA	pour doser le	CDDA
de DTA	pour doser le	DDA
de DDTA	pour doser le	DDDA
de TDTA	pour doser le	TDA, HDA et DDDAA

Pour les autres surfactifs, l'électrode indicatrice faisait intervenir un complexe de l'amphiphile dosé.

2.2. Pile de mesure

L'électrode spécifique est opposée à une électrode de référence :

Ag | AgCl | KCl gel 2 mol dm^{-3} |

protégée de la diffusion de l'amphiphile par un pont salin (KCl 2 mol dm^{-3}) gélifié contenu dans un fin tuyau en Téflon. Cette configuration a été adoptée pour retarder au maximum la diffusion rapide du surfactif dans l'électrode. Il est important de renouveler très souvent le gel en contact avec la solution. On réalise donc la chaîne électrochimique suivante :

référence interne | membrane | solution étudiée | référence

dont la f.é.m. peut s'écrire sous la forme :

$$[1] \quad \Delta E = \Delta E^0 + 2{,}3\,\frac{RT}{F}\log(M^+) = \Delta E^0 - 2{,}3\,\frac{RT}{F}\,\mathrm{p}M$$

Les mesures de f.é.m. ont été effectuées à l'aide d'un millivoltmètre Tacussel, Minisis 8000, la température des solutions étant maintenue constante et égale à (298 ± 0,1) K par un bain thermostaté.

À titre d'exemple, les courbes d'étalonnage pour les surfactifs DDTA, HDA et CDDA sont reportées sur la figure 1. On observe sur les courbes la présence de points anguleux (exemple des courbes DDTA et HDA, figure 1) correspondant aux concentrations micellaires critiques (cmc), dont les valeurs sont regroupées dans le tableau 1.

Ces électrodes présentent une réponse nernstienne (pente égale à 0,059 V par décade) pour une gamme de concentrations en surfactif (obtenues par dilution d'une solution concentrée) pouvant aller de $5\cdot10^{-7}$ mol dm^{-3} jusqu'à la cmc. Cet étalonnage permet également d'obtenir le paramètre ΔE^0 de l'équation [1]. Les f.é.m. sont stables à ±0,1 mV.

Par ailleurs, ces graphes montrent que pour une concentration inférieure à la cmc, les amphiphiles se trouvent essentiellement sous la forme monomère et que l'on ne peut mettre en évidence la présence d'éventuels dimères (15, 16). Pour des solutions de titre inconnu en surfactif, on détermine le pM correspondant :

$$[2] \quad \mathrm{p}M = \frac{\Delta E^0 - \Delta E}{0{,}059}$$

La technique que nous mettons en oeuvre conduit à une excellente reproductibilité des courbes expérimentales. Ceci prouve la fiabilité de la chaîne électrochimique utilisée et, en conséquence, le bon fonctionnement de ses éléments constitutifs. Cependant, un tel résultat ne peut être obtenu que si l'on apporte un soin particulier à protéger l'électrode de référence de la diffusion du surfactif.

3. Détermination des constantes de complexation des surfactifs

3.1. Conditions expérimentales

La détermination potentiométrique des constantes de complexation a été effectuée à 298 K à partir des courbes de titrage de l'amphiphile par une solution de β-cyclodextrine

TABLEAU 1. Valeurs des concentrations micellaires critiques des acétates d'alkylammonium, et d'alkyltriméthylammonium, dans l'eau à 298 K, déterminées par potentiométrie. Le nombre de carbones de la chaîne aliphatique est n

Acétates d'alkylammonium							
Composé	OA	DA	DDA	TDA	HDA	DDDA	CDDA
Carbones, n	8	10	12	14	16	12	12
cmc/mol dm^{-3}	$1{,}75\cdot10^{-1}$	$4\cdot10^{-2}$	$1{,}4\cdot10^{-2}$	$3{,}4\cdot10^{-3}$	$8\cdot10^{-4}$	$1{,}6\cdot10^{-2}$	—

Acétates d'alkyltriméthylammonium						
Composé	DTA	DDTA	TDTA	HDTA	HDP	DDDAA
Carbones, n	10	12	14	16	16	12
cmc/mol dm^{-3}	$6\cdot10^{-2}$	$1{,}4\cdot10^{-2}$	$3{,}5\cdot10^{-3}$	10^{-3}	$7\cdot10^{-4}$	$1{,}1\cdot10^{-2}$

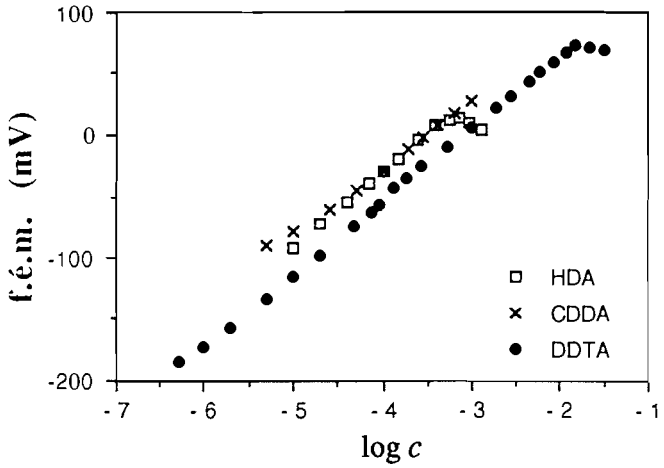

FIG. 1. Exemples d'étalonnages d'électrodes indicatrices de surfactifs.

10^{-2} mol dm^{-3}. Nous avons exploité ces courbes à partir de la fonction $\Delta E = f(r)$, où r est, pour chaque point de la courbe, défini comme le rapport du nombre total de moles de cyclodextrine n_{CD} ajoutées, au nombre total de moles de surfactif n_M introduites :

$$[3] \quad r = \frac{n_{CD}}{n_M}$$

Les concentrations de surfactif utilisées ont toujours été choisies inférieures à la concentration micellaire critique. Les solutions d'acétate d'alkylammonium ont été acidifiées par une faible quantité d'acide acétique afin d'éviter une éventuelle dissociation du sel acide. L'ensemble de ces dosages a été réalisé par pilotage automatique permettant l'obtention d'un grand nombre de points expérimentaux (pilote Tacussel TT-P2 couplé à un micro-ordinateur).

3.2. *Résultats expérimentaux*

À titre d'exemple nous présentons dans les tableaux 2–5 une série de résultats caractéristiques des différents comportements observés que nous commenterons dans la discussion. ΔE (mV) est la valeur de la f.é.m. mesurée, ΔE_1 et ΔE_2 sont les valeurs de f.é.m. calculées à partir des modèles présentés dans le paragraphe suivant.

3.3. *Modèles de complexation*

L'exploitation des fonctions $\Delta E = f(r)$ exige que l'on se fixe un modèle de complexation du surfactif par la cyclodextrine. On peut ainsi envisager deux possibilités :

TABLEAU 2. Titrage de DTA$^+$ (ΔE^0 = 205,0 mV)

r	pM	ΔE (mV)	ΔE_1 (mV)	ΔE_2 (mV)
0,000	3,00	28,0	28,0	28,0

3,805	4,11	−38,0	−37,7	−37,8
3,992	4,14	−39,0	−39,1	−39,2

(a) Modèle à un complexe

On suppose que la cyclodextrine CD et le surfactif M$^+$ conduisent à un complexe 1 : 1 (CDM$^+$). L'équilibre de dissociation du complexe s'écrit :

$$[4] \quad CDM^+ \Longleftrightarrow CD + M^+$$

La constante d'équilibre est égale à :

$$[5] \quad K = \frac{[CD][M^+]}{[CDM^+]}$$

en faisant intervenir les valeurs des concentrations des espèces en solution. On supposera que l'on se place toujours en solution suffisamment diluée pour ne pas avoir à tenir compte de l'intervention des coefficients d'activité. La conservation des masses s'écrit :

$$[6] \quad \begin{aligned} [M^+]_{total} &= [M^+] + [CDM^+] = C \\ [CD^+]_{total} &= [CD] + [CDM^+] = rC \end{aligned}$$

Pour chaque point du dosage, on calcule la valeur de la constante de complexation par la relation :

$$[7] \quad K = \frac{10^{-2pM} + C(r-1)10^{-pM}}{C - 10^{-pM}}$$

8,359	5,55	−124,5	−119,2	−124,1
8,991	5,59	−127,0	−121,3	−126,5

On détermine ainsi une valeur moyenne de pK à ±0,05 unité sur l'ensemble des points expérimentaux. Cette valeur étant connue, on peut alors recalculer la concentration de M^+ en fonction de r en résolvant l'équation du second degré :

$$[8] \quad [M^+]^2 + (K + C(r-1))[M^+] - KC = 0$$

puis calculer à l'aide de la relation [1] la f.é.m. ΔE_1 de la pile (cf. tableaux 2–5). Ce modèle simple permet de décrire parfaitement les résultats expérimentaux pour le traitement des courbes relatives aux surfactifs de C8–C12.

En revanche en ce qui concerne les composés en C14 et C16, on constate que l'expression [7] conduit à des valeurs de pK qui varient avec r principalement lorsque ce paramètre prend des valeurs élevées. Les valeurs de ΔE_1 calculées à partir d'une valeur moyenne de pK obtenue sur le domaine $1 < r < 2$ par exemple, s'écartent nettement des valeurs expérimentales pour le domaine où $r \geq 3$ (tableaux 4 et 5, et figure 2, courbe E1).

TABLEAU 5. Titrage de $HDTA^+$ (ΔE^0 = 273,2 mV)

r	pM	ΔE (mV)	ΔE_1 (mV)	ΔE_2 (mV)
0,000	3,13	88,5	88,5	88,5
0,099	3,18	86,5	85,7	85,7
0,664	3,58	64,5	61,8	61,9
0,980	3,99	42,5	36,9	37,6
1,232	4,33	22,0	16,4	17,4
1,518	4,60	3,0	1,2	1,9
1,949	4,85	−12,0	−12,8	−12,8
2,504	5,05	−25,0	−24,1	−25,1
3,144	5,22	−35,5	−32,9	−35,0
3,872	5,37	−43,5	−40,3	−43,5
4,695	5,49	−51,0	−46,7	−51,0
5,549	5,60	−57,5	−52,0	−57,3
6,413	5,69	−63,0	−56,4	−62,7
7,312	5,77	−67,5	−60,3	−67,4
8,212	5,84	−71,5	−63,7	−71,6
9,112	5,91	−75,0	−66,7	−75,3
10,041	5,96	−78,5	−69,5	−78,7
11,020	6,02	−81,5	−72,1	−81,9
11,977	6,07	−84,5	−74,4	−84,8
12,421	6,09	−85,5	−75,5	−86,1

Ceci suggère la présence d'un complexe d'ordre supérieur, à deux cyclodextrines, dont l'existence a été déjà signalée par J. W. Park et H. J. Song dans le cas de surfactifs anioniques (2) pour la β-CD, et par R. Palepu et V. C. Reinsborough (8) pour la α-CD et la β-CD. Nous avons donc envisagé cette hypothèse et effectué l'analyse de nos résultats à partir du système d'équations suivant :

(b) Modèle à deux complexes

$$[9] \quad CDM^+ \Longleftrightarrow CD + M^+ \qquad K_1 = \frac{[CD][M^+]}{[CDM^+]}$$

$$CD_2M^+ \Longleftrightarrow CDM^+ + CD \qquad K_2 = \frac{[CDM^+][CD]}{[CD_2M^+]}$$

La conservation des masses s'écrit alors :

$$[10] \quad [M^+]_{total} = [M^+] + [CDM^+] + [CD_2M^+] = C$$

$$[CD]_{total} = [CD] + [CDM^+] + 2[CD_2M^+] = rC$$

soit :

$$[11] \quad C = [M^+]\left(1 + \frac{[CD]}{K_1} + \frac{[CD]^2}{K_1K_2}\right)$$

et

$$[12] \quad rC = [CD] + [M^+]\left(\frac{[CD]}{K_1} + \frac{2[CD]^2}{K_1K_2}\right)$$

À partir de ce système d'équations, on ajuste les valeurs de pK_1 et pK_2 de manière à obtenir le meilleur accord possible entre les courbes expérimentales et calculées. On constate que les valeurs de pK_1 restent voisines de celles que l'on obtient pour le domaine où $r < 3$, en supposant l'existence d'un seul complexe, ce qui confirme la prédominance du complexe 1 : 1.

Les résultats expérimentaux sur l'ensemble des valeurs de r sont parfaitement décrits pour les C14 et C16 à l'aide du

TABLEAU 6. Valeurs des constantes de dissociation des complexes formés entre la cyclodextrine et les amphiphiles cationiques

[a]Pour les composés en C8, C10 et C12, le modèle à un complexe permet de décrire correctement les courbes expérimentales, en particulier lorsque les concentrations en surfactif restent faibles. Cependant l'exploitation des résultats à l'aide du modèle à deux complexes est également possible de manière aussi satisfaisante pour C8 et C10. L'introduction du deuxième complexe devient indispensable pour C12, lorsque les concentrations en surfactif sont supérieures à 10^{-2} mol L^{-1}.

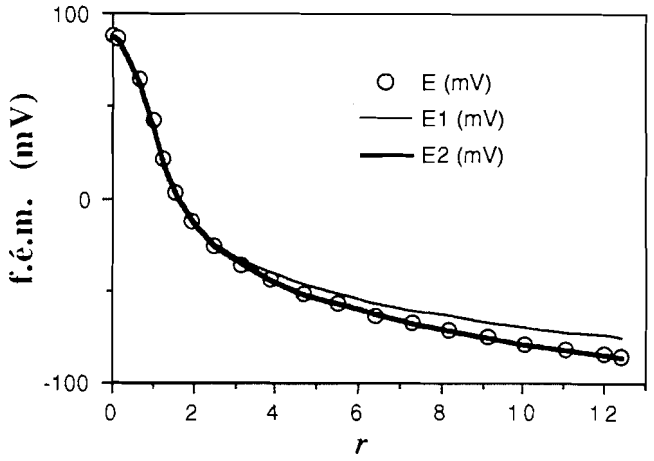

FIG. 2. Courbes de titration de HDTABr par la β-cyclodextrine. La courbe calculée au moyen du modèle à deux complexes (ΔE2) passe par l'ensemble des points expérimentaux. La courbe calculée au moyen du modèle à un complexe (ΔE1) ne parvient pas à décrire le comportement du surfactif en présence de cyclodextrine.

modèle à deux complexes (cf. valeurs de ΔE_2 dans les tableaux 4 et 5, et la courbe E2 sur la figure 2).

Les valeurs de pK_1 et pK_2 pour tous les amphiphiles étudiés sont regroupées dans le tableau 6 et sont données avec une incertitude absolue de l'ordre de 0,05 unité logarithmique.

(c) Influence de la concentration du surfactif

Pour l'écriture et le calcul des constantes d'équilibre K_1 et K_2, nous avons toujours considéré que les solutions étaient suffisamment diluées pour ne pas avoir à tenir compte des coefficients d'activité. Si l'on considère leur intervention dans l'expression de ces constantes (équations [5] et [9]), on obtient :

$$[5'] \quad K_1 = \frac{[CD][M^+]}{[CDM^+]} \frac{\gamma_{CD}\gamma_{M^+}}{\gamma_{CDM^+}}$$

$$[9'] \quad K_2 = \frac{[CDM^+][CD]}{[CD_2M^+]} \frac{\gamma_{CDM^+}\gamma_{CD}}{\gamma_{CD_2M^+}}$$

Les coefficients d'activité sont définis alors dans le modèle des solutions diluées. La cyclodextrine étant une espèce électriquement neutre, de concentration maximum de 10^{-2} mol L^{-1}, il est raisonnable de poser $\gamma_{CD} = 1$. En ce qui concerne les rapports $\gamma_{M^+}/\gamma_{CDM^+}$ et $\gamma_{CDM^+}/\gamma_{CD_2M^+}$, même en admettant qu'individuellement les valeurs des coefficients sont différents de 1, on peut supposer en se référant au modèle de Debye et Hückel, que leur rapport doit être très proche de l'unité, et ceci quelle que soit la force ionique du milieu.

En revanche, la mise en évidence d'un éventuel deuxième complexe doit s'avérer d'autant plus aisée que la concentration du surfactif est plus grande. Afin de vérifier ces hypothèses, nous avons effectué le dosage du DDTA à plusieurs concentrations de surfactif. Pour les concentrations élevées ($C = 10^{-2}$ mol dm^{-3}) l'introduction d'une deuxième constante (pK_2 de l'ordre 1,4) s'avère effectivement indispensable pour décrire avec précision le comportement du surfactif. On vérifie d'autre part que les valeurs de pK_1 et pK_2 sont indépendantes de la force ionique du milieu.

4. Discussion

Comme on peut le constater sur le tableau 6, les valeurs de pK déterminées au moyen de mesures conductimétriques sont dans la littérature, selon les auteurs, très différentes les unes des autres. Ceci tient au fait que les conductivités équivalentes des amphiphiles et des complexes sont relativement proches pour les surfactifs cationiques et que l'analyse des courbes exige que l'on détermine simultanément la conductivité du complexe et sa constante de dissociation.

Il n'en est pas de même pour les mesures potentiométriques. Dès lors que l'on dispose d'une chaîne électrochimique fiable (voir partie expérimentale), on peut déterminer avec précision pM, *pour tous les points expérimentaux*, et en conséquence, calculer à l'aide de l'équation [7] autant de valeurs de pK que

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

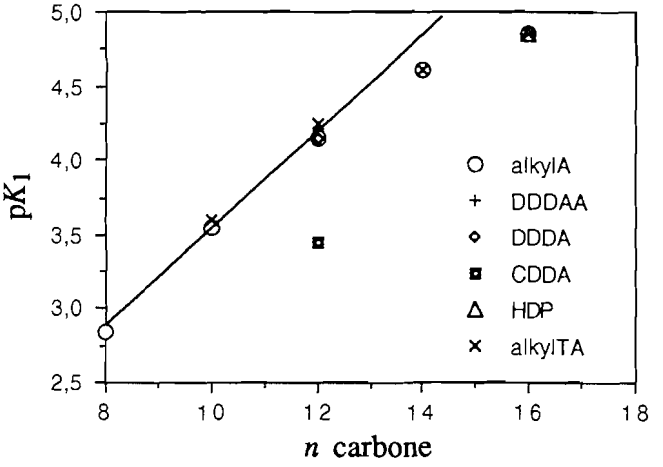

FIG. 3. Valeurs de pK_1 en fonction de la longueur de la chaîne carbonée.

de points. La constance des valeurs obtenues et leur dispersion autour d'une valeur moyenne permet alors de conclure sans ambiguïté sur la valeur du pK retenue ainsi que sur la validité du modèle utilisé pour exploiter les courbes. C'est une démarche de ce type qui nous a conduit à proposer une exploitation des résultats à l'aide d'un modèle à deux complexes dans les cas où, au lieu d'observer une distribution *aléatoire* des valeurs de la constante autour d'une valeur moyenne, on observe une variation continue en fonction de r, de la constante calculée avec le modèle à un complexe.

À titre de comparaison, nous avons introduit les valeurs de constantes trouvées par conductimétrie dans les équations des courbes de dosage potentiométriques. Nous avons constaté que, pour nombre d'entre elles, il est impossible de décrire convenablement les résultats expérimentaux. À l'inverse, les valeurs que nous proposons permettent de retrouver les courbes de conductimétrie publiées, en modifiant légèrement les paramètres de conductivité. Il semble donc qu'il faille considérer avec prudence les valeurs d'un certain nombre de constantes de dissociation des complexes surfactif–cyclodextrine publiées dans la littérature.

L'analyse des valeurs de constantes de dissociation déterminées par potentiométrie confirme et précise un certain nombre de propriétés déjà mises en évidence par différents auteurs pour d'autres complexes β-cyclodextrine–surfactif (4, 5, 7–9).

Importance de la nature du groupement polaire

On constate (tableau 6 et figure 3) que les valeurs des constantes de dissociation des complexes pour les alkyltriméthylammonium et alkylammonium diffèrent très peu pour des longueurs de chaînes identiques. Ainsi, on trouve un pK_1 de 4,20 ± 0,05 pour les quatre surfactifs possédant une chaîne linéaire à 12 carbones. Le groupement ionique constituant la tête polaire du surfactif ne semble donc pas influencer notablement le phénomène de complexation (6). Seul le cyclododécylammonium possède un comportement particulier, dû, bien évidemment, à la présence du cycle dans la molécule.

En revanche, si l'on compare ces valeurs à celles publiées dans la littérature concernant les complexes de surfactifs anioniques de même longueur de chaîne (détermination par conductimétrie (5)), on remarque qu'elles sont différentes et que l'on devrait en conclure que les complexes anioniques, à même longueur de chaîne, sont plus dissociés que les complexes cationiques. Une telle affirmation est cependant téméraire car on ne peut pas affirmer que cette différence est totalement attribuable à une spécificité des interactions surfactif anionique – cyclodextrine, et qu'elle n'est pas due plus simplement à une incertitude sur les constantes de dissociation inhérente à la méthode employée.

Complexation en fonction de la longueur de la chaîne

On remarque que les valeurs des pK de dissociation augmentent de façon sensiblement linéaire avec la longueur de la chaîne jusqu'à $n = 12$, ce qui implique que les complexes deviennent de plus en plus stables au fur et à mesure que la chaîne s'allonge. L'accroissement moyen de pK_1 par carbone est de 0,33 unité environ.

En revanche, pour les composés en C14 et C16, on observe que la variation de pK_1 par carbone devient moins importante que pour les surfactifs de chaîne plus courte. Ceci est à mettre sur le compte de l'apparition du complexe 1:2 qui implique une seconde molécule de cyclodextrine.

Ce comportement diffère de celui observé pour les surfactifs anioniques, comme les alcanesulfonates pour lesquels les valeurs des constantes de dissociation (complexes 1:1) deviennent invariantes dès que le nombre de carbones de la chaîne linéaire dépasse 10 (5). L'accroissement moyen de pK est inférieur à celui que nous observons pour les alkylammonium (0,2 unité pour les alcanesulfonates). Là encore, il est difficile de conclure sur cette différence de comportement basée sur des valeurs de constantes obtenues par des techniques expérimentales différentes qui ne conduisent pas aux mêmes analyses. Ainsi, on peut s'interroger sur l'éventuelle formation d'un complexe à deux cyclodextrines pour les surfactifs anioniques où $n \geq 14$.

Conclusion

Les résultats qui viennent d'être exposés montrent l'intérêt de la mise en oeuvre d'une méthode potentiométrique basée sur la fabrication d'une électrode indicatrice de surfactif pour étudier la stabilité des complexes entre la β-cyclodextrine et les surfactifs.

La possibilité de déterminer précisément des valeurs de constantes de dissociation dans l'eau, mais également dans des milieux réactionnels complexes, permet d'envisager différents types d'applications aux complexes surfactif–cyclodextrine et en particulier la réalisation de «solutions tampons». En général, les surfactifs sont utilisés au cours d'opérations industrielles, dans des milieux comportant de nombreux solutés susceptibles d'interagir avec eux, et entre autres de les précipiter. Il se pose donc très souvent le problème du maintien à une concentration donnée et fixe du surfactif en solution tout au long de l'opération envisagée. Ceci est rendu possible par l'utilisation de solutions tampon de surfactifs dont la fabrication et l'utilisation peut être calquée strictement sur celles des «solutions tampon de protons». Les valeurs reportées dans le tableau 6 montrent que selon le surfactif employé, il est possible de maintenir la concentration d'un surfactif dans la gamme 10^{-4}–10^{-5} mol dm^{-3}. L'utilisation d'autres formes de la cyclodextrine permet sans aucun doute d'étendre encore ce domaine. Un travail sur ce thème est en cours au laboratoire.

Remerciements

Nous remercions particulièrement C. Tribet pour la synthèse de l'allyldiméthyldodécylammonium (DDDAA) ainsi que la société Orsan pour la fourniture de la β-cyclodextrine et sa contribution générale à nos travaux de recherches.

Metallometallation of allenes: an exploratory study[1]

SHANKAR M. SINGH AND ALLAN C. OEHLSHLAGER
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6
Received March 11, 1991

SHANKAR M. SINGH and ALLAN C. OEHLSHLAGER. Can. J. Chem. **69**, 1872 (1991).

Reaction of either *n*-$Bu_3SnCu(CN)Li$ (**8**) or $(n\text{-}Bu_3Sn)_2Cu(CN)Li_2$ (**9**) with 1,2-undecadiene gave 71–92% of a (*Z*/*E*) mixture of 1-tri-*n*-butylstannyl-2-undecene (**27**) accompanied by 8–32% of a mixture of (*E*)-2-tri-*n*-butylstannyl-2-undecene (**28**) and 2-tri-*n*-butylstannyl-1-undecene (**29**). When the above reactions were warmed to 0°C, **28** and **29** were the major products. The mixed cuprates, **10–14**, gave the mixtures rich in vinylstannanes, **28** and **29**, along with **27**. Addition of Sn—Al reagents, **15** and **16**, or Sn—B reagents, **18** and **19**, to 1,2-undecadiene in the presence of 5 mol% of CuCN or $CoCl_2\cdot(PPh_3)_2$ provided mixtures rich in vinylstannanes, **28** and **29**. However, with 1 equiv. of CuCN, mixtures rich in allylstannanes **27** were obtained. Reaction of 5-hydroxy-1,2-pentadiene with the Sn—Al reagents, **15** and **16**, gave 53–61% of a single 5-hydroxy-2-tri-*n*-butylstannyl-1-pentene (**32**) in the presence of 5 mol% of $CoCl_2\cdot(PPh_3)_2$. The stannylcopper adducts generated in the reaction of 1,2-undecadiene and **8** or **9** were treated with iodomethane to give 55–78% of a (*Z*/*E*: 67/33) mixture of 1-tri-*n*-butylstannyl-2-methyl-2-undecene (**33**). Addition of mixed silylcuprates, **21**, **22**, and **23**, to 1,2-undecadiene gave mixtures rich in (*E*)-2-dimethylphenylsilyl-2-undecene (**35**) and 2-dimethylphenylsilyl-1-undecene (**36**). A rationale for the putative adducts' formation is also presented.

Key words: Sn—Cu, Sn—Al, Sn—B reagents; putative adducts.

SHANKAR M. SINGH et ALLAN C. OEHLSHLAGER. Can. J. Chem. **69**, 1872 (1991).

La réaction du *n*-$Bu_3SnCu(CN)Li$ (**8**) ou du $(n\text{-}Bu_3Sn)_2Cu(CN)Li_2$ (**9**) avec le undéca-1,2-diène fournit de 71 à 92% d'un mélange (*Z*/*E*) de 1-tri-*n*-butylstannylundéc-2-ène (**27**) accompagné de 8 à 32% d'un mélange de (*E*)-2-tri-*n*-butylstannylundéc-2-ène (**28**) et de tri-*n*-butylstannylundéc-1-ène (**29**). Les cuprates mixtes, **10–14**, fournissent des mélanges riches en vinylstannanes (**28** et **29**) aux côtés du produit **27**. L'addition des réactifs Sn—Al, **15** et **16**, ou des réactifs Sn—B, **18** et **19**, au undéca-1,2-diène, en présence de 5 mol% de CuCN ou de $CoCl_2\cdot(PPh_3)_2$ conduit à des mélanges riches en vinylstannanes, **28** et **29**. Toutefois, avec un équivalent de CuCN, on obtient des mélanges riches en allylstannanes **27**. La réaction du 5-hydroxypenta-1,2-diène avec les réactifs Sn—Al, **15** et **16**, en présence de 5 mol% de $CoCl_2\cdot(PPh_3)_2$, fournit de 53 à 61% d'un seul 5-hydroxy-2-tri-*n*-butylstannylpent-1-ène (**32**). Les adduits de stannylcuivre générés au cours de la réaction du undéca-1,2-diène avec **8** ou **9** ont été traités avec l'iodométhane pour fournir de 55 à 78% d'un mélange (*Z*/*E*: 77/33) de 1-tri-*n*-butylstannyl-2-méthylundéc-2-ène (**33**). L'addition de silylcuprates mixtes, **21**, **22** et **23**, au undéca-1,2-diène fournit des mélanges riches en (*E*)-2-diméthylphénylsilylundéc-2-ène (**35**) et 2-diméthylphénylsilylundéc-1-ène (**36**). On présente aussi une rationalisation pour la formation des adduits putatifs.

Mots clés : Sn—Cu, Sn—Al, Sn—B réactifs; adduits putatifs.

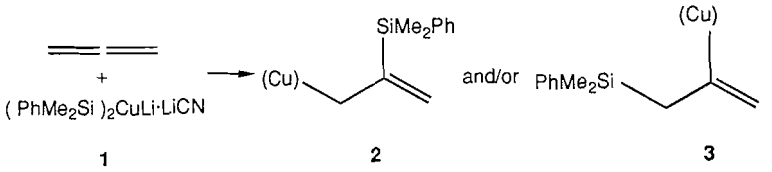
Introduction

Metallometallations of unsaturated organic compounds proceed well for silyl and stannyl containing dimetallic reagents (e.g. Sn—M; Al, Zn, B, Mg, Mn, Sn, Si and Si—M; Al, Zn, B, Mg, Sn). These reactions are catalyzed by transition metals and copper(I) has emerged as a catalyst of choice (1). The reactions are presumed to involve silyl- or stannylcupration followed by transmetallation of the vinyl copper bond by the electrophilic metal accompanying the silyl or stannyl anion. When conducted under controlled conditions these processes can proceed with high regio- and stereospecificity to provide easily functionalized dimetallic intermediates (2).

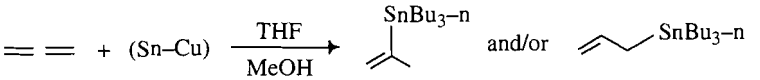
Recently Oshima and co-workers reported the copper(I)- or palladium-catalyzed addition of Si—M (M = Mg, Al, Zn) reagents to symmetrical allenes (3). Silylcuprations of allene as well as mono-, di-, and trisubstituted allenes with **1** have been reported by Fleming and co-workers (4). The products were either vinylsilanes, **2**, or allylsilanes, **3**, depending on the degree of substitution of the allenes (Scheme 1).



Recent work by Barbero and co-workers (5), summarized in the Table 1, has shown that the regiochemistry of the reaction depends upon the temperature and the nature of the stannylcuprate reagents. Stannylcupration of 1,2-propadiene gave only vinylstannane, **6**, in the presence of LiCl at −76 to 0°C (Table 1, entry 1) while at −100°C only allylstannane, **7**, was formed (Table 1, entry 2). The formation of **6** at the higher temperature and **7** at the low temperature suggests that the former is a product of thermodynamic control and the latter is a product of kinetic control. Effects of salts were also studied. When the halide-free stannylcuprate was reacted with allene at −78°C, only **7** was obtained (Table 1, entry 5) whereas the stannylcuprate in the presence of LiCl (*in situ*) gave **6** as the major product at this temperature (Table 1, entry 3).

Both vinyl and allylstannanes are important intermediates in organic synthesis due to their ability to undergo stereospecific C—C bond formation under mild conditions (6). Our continuing interest in the metallometallations led us to explore the reactions of dimetallic reagents with allenes. In this paper, we describe the reactions of Sn—Cu, Sn—Al, and Sn—B as well as Si—Cu reagents with allenes. We also have briefly investigated the mechanism of these reactions.

Results and discussion



Tri-*n*-butylstannyllithium (**5**) was prepared by deprotonation of Bu_3SnH with lithium diisopropylamide or by cleavage of *n*-Bu_3Sn—$SnBu_3$-*n* with alkyllithium (7). Treatment of 1 equiv. of *n*-Bu_3SnLi (**5**) with 1 equiv. of CuCN gave the lower order cuprate, *n*-$Bu_3SnCu(CN)Li$ (**8**), while 2 equiv. of **5** gave the higher order cuprate, $(n\text{-}Bu_3Sn)_2Cu(CN)Li_2$ (**9**). Reaction of **5** with CuCN in the presence of 2-thienyllithium gave *n*-Bu_3Sn(2-thienyl)$Cu(CN)Li_2$ (**10**). Reaction of **5** with

[1]This paper is dedicated to Professor Herbert C. Brown on the occasion of his 80th birthday.

CuBr·DMS in the presence of lithium diisopropylamide or lithium dicyclohexylamide gave *n*-Bu_3Sn(N-*i*-Pr_2)CuLi (**11**) and *n*-Bu_3Sn(N-Cy_2)CuLi (**12**), respectively. Mixed stannylalkylcuprates, *n*-Bu_3Sn(*n*-Bu)Cu(CN)Li_2 (**13**) and *n*-Bu_3Sn(*sec*-Bu)Cu(CN)Li_2 (**14**) were prepared by the reaction of **5** with CuCN followed by the addition of the appropriate alkyllithium.

Addition of Et_2AlCl or Me_3Al to **5** at −78°C gave *n*-Bu_3Sn—$AlEt_2$ (**15**) and *n*-Bu_3Sn—$AlMe_3^-Li^+$ (**16**), respectively. Similarly, reaction of *B*-methoxy-9-BBN (**17**) or tri-*n*-butylborane with **5** provided *n*-Bu_3Sn—$BBN^-(OMe)Li^+$ (**18**) and *n*-Bu_3Sn—$BBu_3^-Li^+$ (**19**), respectively.

Silylcuprates $PhMe_2SiCu(CN)Li$ (**20**), $(PhMe_2Si)_2Cu(CN)Li_2$ (**1**), $PhMe_2Si$(*n*-Bu)Cu(CN)Li_2 (**21**), $PhMe_2Si$(*sec*-Bu)Cu(CN)Li_2 (**22**), and $PhMe_2Si$(*t*-Bu)Cu(CN)Li_2 (**23**) were prepared by reaction of $PhMe_2SiLi$ (**24**) with solutions containing 1 equiv. each of CuCN and the appropriate lithium reagent. 1,2-Undecadiene (**25**) was chosen as a substrate because of its low volatility that facilitated detection of unreacted starting material. It was prepared by alkylation of allene with 1-octylbromide (8). 5-Hydroxy-1,2-pentadiene (**26**) was employed to determine if the polar functional group would exhibit a directive effect on the regiochemistry of the additions.

Reaction of 2 equiv. of *n*-$Bu_3SnCu(CN)Li$ (**8**) with 1,2-undecadiene (Scheme 2) in tetrahydrofuran (THF) at −78°C followed by quenching with aqueous NH_4Cl/MeOH gave 91% of a (*Z*/*E*:65/35) mixture of 1-tri-*n*-butylstannyl-2-undecene (**27**) accompanied by 9% of a mixture of (*E*)-2-tri-*n*-butylstannyl-2-undecene (**28**) and 2-tri-*n*-butylstannylstannyl-1-undecene (**29**) (Table 2, entry 1). Structures of **27**, **28**, and **29** were determined by analysis of their ^1H nmr spectra.

Thus, in the ^1H nmr spectrum of *Z*-**27**, signals in between 5.31 and 5.39 ppm (dtt, 1 H, J = 10, 7, 1 Hz) were assigned to

SCHEME 2

the vinyl hydrogen attached to C-3 while the vinyl hydrogen at C-3 in *E*-**27** gave signals between 5.43 and 5.51 ppm (dtt, 1 H, J = 15, 7, 1.5 Hz). The signals between 5.71 and 5.85 ppm in the spectrum of *Z*-**27** (dtt, 1 H, J_{trans} = 15, 7, 1.5 and J_{cis} = 10, 7, 1 Hz) were attributed to a vinyl hydrogen at C-2 of this isomer. The ^1H nmr spectrum of **28** exhibited a signal at 5.85 ppm (tq, 1 H, J = 7, 1 Hz and $^3J_{Sn—H}$ = 64 Hz) attributed to the vinyl hydrogen attached to C-3. The Sn—H coupling (64 Hz) indicates these two nuclei possess a *cis* arrangement (1 h). The *Z*- and *E*-vinyl hydrogens of **29** resonated at 5.36 ppm (dt, 1 H, J = 2.9, 1 Hz and $^3J_{Sn—H}$ = 64 Hz) and 5.91 ppm (dt, 1 H, J = 2.9, 1.5 Hz and $^3J_{Sn—H}$ = 146 Hz), respectively.

Reaction of homostannylcuprates **9** and **8** with **25** (Table 2, entries 1–6) revealed that these reagents gave mixtures rich in allylstannane, **27**.[2] To improve the stereoselectivity of allylstannane formation we examined a variety of proton sources

[2]THF solutions containing 2 equiv. of trialkylstannyllithium and 1 equiv. of CuCN have been shown by NMR to contain nearly equivalent amounts of $(R_3Sn)_2CuCNLi_2$, $(R_3Sn)_3CuLi_2$, and $(R_3Sn)_3Cu_2Li$, ref. 9.

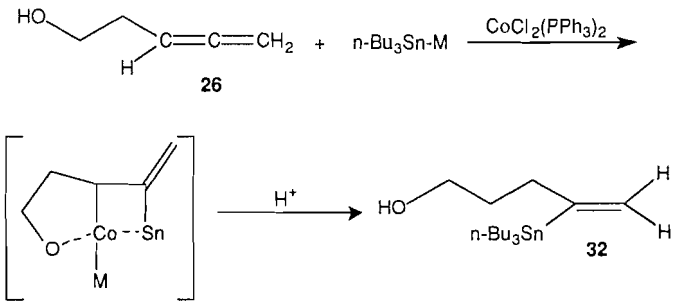
[b]The ratios were determined by capillary gc.
[c]Yields refer to gc, *n*-dodecane was used as the internal standard.

to quench the presumptive stannylcopper intermediates. On the assumption that neither aqueous NH_4Cl nor MeOH provide products of kinetic control (e.g. *Z*-**27**), we employed more active hydrogen ion sources such as acetic and trifluoroacetic acids. These did not alter the stereochemistry of **27**, but decreased yields of the stannyl products to 63–65% and nearly 30% of **25** was recovered. No undecenes were detected in these reaction mixtures. Reaction of 1 equiv. of cuprate **8** with **25** required 18 h to yield **27** which was a mixture of *E* and *Z* isomers (Table 2, entry 2). In contrast, reaction of **9** with **25** gave *Z*-**27** stereospecifically. Thus, reaction of 2 equiv. of $(n$-$Bu_3Sn)_2Cu(CN)Li_2$ (**9**) with **25** provided 75% of *Z*-**27**, along with 25% of **28** and **29** (Table 2, entry 3). Use of HMPA as a coordinating solvent did not alter the regioselectivity of the reaction (Table 2, entry 4). However, when **9** was treated with **25** at −100°C the regioselectivity of the reaction improved significantly (Table 2, entries 5, 6). Thus reaction in THF/HMPA gave 92% of **27** along with 8% of **28** and **29**. Quenching the above reactions after warming to 0°C gave 56% of **28** and **29** together with 44% of **27** (Table 2, entry 7). While our work was in progress, Barbero and co-workers (5) reported that presence of the salts in these reactions catalyzes the isomerization of the initially formed adduct to a more stable isomer (Table 1). We studied the effect of the salt and found that it had little effect on the regioselectivity of the reaction (Table 2, compare entries 7 and 8). Thus, it appears that the stannylcuprations that occur at higher temperature yield vinylstannanes, **28** and **29** (e.g. thermodynamic control), while at low temperature the reactions yield allylstannane, **27** (e.g. kinetic control).

Homostannylcuprates, **8** and **9**, are inherently unstable and their reactions with **25** are accompanied by the formation of numerous stannyl-containing byproducts due to the excess of reagent required to achieve complete consumption of allene (even in the presence of methanol). To circumvent these problems we examined the reactions of several heterostannylcuprates with **25**. Heteroalkylcuprates containing phosphido, amido and 2-thienyl groups react with organic substrates via exclusive transfer of the alkyl group (10). Furthermore, both 2-thienyl (10*c*) and alkylstannylcuprates (11) exclusively transfer trialkylstannyl ligands. Fleming and Newton have shown an identical preference for the transfer of silyl with $PhMe_2Si(Me)Cu(CN)Li_2$ (12). Stannylcuprates containing 2-thienyl (**10**) or amino ligands (**11** and **12**) react with **25** to give nearly equal amounts of vinyl and allyl stannane products (Table 2, entries 9–11). Mixed alkylstannylcuprates, **13** and **14**, gave mixtures rich in vinylstannanes, **28** and **29** (Table 2, entries 12, 13).



It is evident from recent work in our laboratory that dialkylaluminum and boron cations act as *in situ* transmetallation agents in stannylcuprations to provide intermediates containing reactive C—Al and C—B bonds in place of relatively unreactive C—Cu bonds (1 h, ref. 2). These transmetallations can be achieved by the copper-catalyzed addition of preformed reagents such as n-$Bu_3Sn—AlEt_2$ (**15**), n-$Bu_3Sn—AlMe_3^-Li^+$ (**16**), n-$Bu_3Sn—BBN^-(OMe)Li^+$ (**18**) or n-$Bu_3Sn—BBu_3^-Li^+$ (**19**). Alternatively, addition of Et_2AlCl or *B*-methoxy-9-BBN (**17**) to stannylcuprations will result in C—Cu transmetallation (2). Reaction of n-$Bu_3Sn—AlEt_2$ (**15**), n-$Bu_3Sn—AlMe_3^-Li^+$ (**16**), n-$Bu_3Sn—BBN^-(OMe)Li^+$ (**18**) or n-$Bu_3Sn—BBu_3^-Li^+$ (**19**) with **25** in the presence of 5 mol% CuCN gave mixtures rich in vinylstannane, **29** (Table 3, entries 1, 4, 7, 10). With 1 equiv. of catalyst mixtures rich in allylstannane, **27**, were obtained (Table 3, entries 2, 5, 8, 11). Use of $CoCl_2 \cdot (PPh_3)_2$ as a catalyst gave mixtures of allyl and vinylstannanes, **27** and

SCHEME 3

29, respectively (Table 3, entries 3, 6, 9, 12). Regioselectivity of these reactions depends upon the temperature and the nature of Sn—Al and Sn—B reagents. With 1 equiv. of catalyst, reactions conducted at −78°C provided mixtures rich in **27** while with 5 mol% of the catalyst higher temperatures were required to complete the reaction and gave mixtures rich in **28** and **29**.

Metallometallation of hydroxyallene, **26**, was studied in the hope that the hydroxyl group would direct the regiochemistry of addition of Sn—M reagents (Scheme 3). Addition of both lower and higher order homostannylcuprates (**9** and **8**) gave mixtures of allyl and vinylstannanes, **30–32** (Table 4, entries 9 and 10). Addition of Sn—Al and Sn—B reagents in the presence of CuCN also gave mixtures (Table 4, entries 2, 4, 6, 8). Only use of oxyphilic $CoCl_2 \cdot (PPh_3)_2$ as a catalyst with **15–19** gave a single vinylstannane product (**32**) in high regiochemical purity (Table 4, entries 1, 3, 5, 7). The ^1H nmr spectrum of **32** in the vinyl region was very similar to that of **29**.

Stannylcopper adducts generated in the reactions of **8** and **9** with **25** were reacted with MeI, Et_2AlCl, and *B*-Br—BBN in the hope that electrophilic capture would provide single isomers. Indeed, the adducts generated from either **8** or **9** and **25** reacted with MeI to give only allylstannane, **33** (Table 5, entries 1 and 2). The isomer distribution obtained is, within experimental error, that obtained upon quenching with a solution of MeOH and aq. NH_4Cl (Table 2, entries 1 and 4). The structure of **33** was confirmed by NMR spectroscopy. A signal at 1.73 ppm was assigned to the hydrogens of *E*-methyl carbon while the hydrogens of *Z*-methyl carbon resonanted at 1.81 ppm. Signals at 1.91 ppm (bs) and 1.93 ppm (bs) were attributed to the hydrogens at C-1 of *Z*- and *E*-isomers, respectively. The hydrogen on the *Z*-vinylic carbon resonated at 5.12 ppm (bt, $J = 7$ Hz) while the hydrogen of the *E*-vinylic carbon resonated at 5.26 ppm (bt, $J = 7$ Hz). Irradiation of the signals at 5.12 ppm resulted in enhancement of the signal at 1.81 ppm. Hence, the hydrogen of the vinylic carbon and the hydrogens of the methyl carbon at 1.81 ppm are *cis*. The reaction with the higher order cuprate provides a higher yield of product in a shorter time than reaction with the lower order cuprate. Quenching the reaction of **8** or **9** and **25** by addition of Et_2AlCl or B-Br-9-BBN followed by protonolysis gave allylstannane, **27**, and vinylstannanes, **28** and **29** (Table 5, entries 3–6). Yields of stannanes are again higher from the reaction with the higher order cuprate.

We also studied silylcupration of **25** with $PhMe_2SiCu(CN)Li$ (**20**), $(PhMe_2Si)_2Cu(CN)Li_2$ (**1**), $PhMe_2Si(n\text{-}Bu)Cu(CN)Li_2$ (**21**), $PhMe_2Si(sec\text{-}Bu)Cu(CN)Li_2$ (**22**), and $PhMe_2Si(t\text{-}Bu)Cu(CN)Li_2$ (**23**). Reaction of homosilylcuprates **1** and **20** gave

mainly allylsilane, **34**, while mixed silylalkylcuprates, **21–23**, provided vinylsilanes, **35** and **36** (Table 6).

In reactions in which cuprous ion is present in catalytic quantities the higher order stannyl or silylcuprates are considered to be the active species regardless of the presence of electrophilic aluminum or boron counter ions (1 h). A catalytic role for cuprous ion in the additions of Sn—M reagents to allenes is described in Scheme 4 (1 h) in which the first step is the oxidative addition (*a*) of the Sn—M reagent to Cu^+ to generate a three-coordinate Cu^+ species. This is followed by complexation (*b*) and stannylcupration (*c*) of the allene. Another equivalent Sn—M reagent oxidatively adds (*d*) to the vinyl copper species to give a higher order cuprate which undergoes reductive elimination with the assist of solvent (*e*) to regenerate the initial complex and a Sn—M adduct. The oxidative state of copper remains +1 throughout the reaction sequence. Examination of Tables 3 and 5 reveals that the outcome of stannylmetallations of **25** is not influenced by the order of addition of reagents. Essentially the same compositions of allylstannane **27** are obtained from reactions in which aluminum or boron reagents are added before or after the allene.

Addition of Sn—M reagents to the least substituted double bond of 1,2-allenes would give intermediates **37** and **38**, while

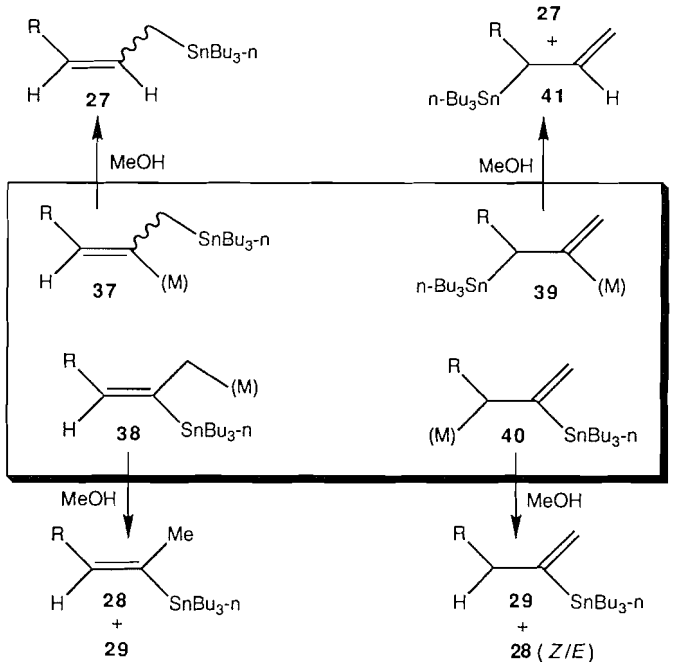
[a]Reactions were conducted in THF.
[b]The ratios were determined by capillary gc.
[c]Yields refer to isolated products.



addition to the internal double bond would give intermediates **39** and **40**. The formation of allylstannanes is undoubtedly via **37** and **39**. Allylstannane, **27**, derived from most additions of Sn—Cu, Sn—Al, and Sn—B reagents is predominantly, but not exclusively, *Z*. Notable exceptions (Table 2, entries 2 and 9) in which *E*-**27** predominated were reactions quenched after warming above 0°C. Intermediate, **37**, would be expected to give predominantly *Z*-**27** since stannylcupration should occur in *cis* fashion (13) from the least hindered side of the allene. To rule out the involvement of **39** as an intermediate we conducted the work-up and isolation of **27** under conditions which would be expected (14) to allow the isolation of **41**. Under carefully controlled work-up conditions and using ^1H nmr analysis we found no evidence of **41**.[3] This militates against the involvement of **39** as an intermediate in the formation of **27** and suggests **37** as the intervening species. The formation of both *E*- and *Z*-**27** in the reactions described in Tables 2 and 3 is thus due to either *Z* to *E* isomerization during workup or nonstereoselective attack of **25** by the organometallic reagents. Allylstannane, **27**, was shown to be stable under both work-up and analysis conditions (14). Intermediates **38** and **40** are presumptive precursors of vinylstannanes, **28** and **29**. *In situ* transmetallation of the C—Cu bonds of **38** and **40** by electrophilic aluminum or boron followed by the protonolysis of allylmetal increases the proportion of **29** relative to **28**. This course of events requires that **38** (M = Al, B) be converted to **29** by SE′ protonolysis. Indeed, it is known that both allylaluminums (16) and allylborons (17) undergo protonolysis by SE′ processes. Thus it appears that the vinylstannanes are formed via **38** and not **40**. Overall the weight of evidence suggests stannylcupration of 1,2-allenes occurs at the external olefin linkage to yield **37** and **38** which ultimately give rise to **27–29**. The relative proportions of allyl to vinylstannane

SCHEME 4

[3]Crotyltrimethylstannanes undergo facile equilibration between the 1-stannyl and 3-stannyl isomers with the latter being sufficiently unstable in polar solvents that it is difficult to isolate. Kinetically controlled isomerization of 1-buten-3-yltrimethylstannane in methanol gives a 3:1 mixture of *Z*- and *E*-2-butenyltrimethylstannanes which equilibrates to an approximate 1:1 mixture upon standing, ref. 14. However, in non-polar aprotic solvents allylstannanes are stable to 1,3 shift, ref. 15.

SCHEME 5

products are thus a function of the regiochemistry of addition. Homocuprates **8** and **9** give **37** while heterostannylcuprates, **10–12**, and mixed alkylstannylcuprates favor **38**. Only in the case of an allene containing a proximal polar functional group **26** are the reactions clean (Table 4).

Reaction of **25** with homosilylcuprates, **20** and **1**, gave predominantly allylsilane (*Z*-**34**, Table 6). This result parallels the stannylcuprations of this allene (Table 2). Addition of mixed silylalkylcuprates, **21–23**, to give **25** gave mixtures rich in vinylsilane, again paralleling the stannyl system. It is attractive to attribute the products formed in these reactions to the intermediacy of the silyl analogs of **37** (M = Cu) and **38** (M = Cu).

Experimental

Gas–liquid chromatographic analyses were conducted on either a Hewlett-Packard 5880A or 5890A gas chromatographs fitted with capillary inlet systems, flame-ionization detectors and WCOT columns (7, 15, and 30 m × 0.25 mm i.d.) of glass or fused silica. Columns were coated with OV-101, SP-2100, or DB-1 liquid phases. Injection port and detector temperatures were 260 and 275°C, respectively. Helium was the carrier gas. Dodecane was used as the internal standard for quantitative analyses.

Low resolution mass spectra were obtained on a Hewlett-Packard 5985B gas chromatograph – mass spectrometer and high resolution mass spectra were recorded with Kratos/AEI MS 50 or MS 902 spectrometers. ^{1}H nmr spectra were recorded in $CDCl_3$ or C_6D_6 Bruker 100 or 400 WM spectrometers. Signal positions are given in δ units and the tin–hydrogen coupling constants ($J_{Sn—H}$) are given as an average of the ^{117}Sn and ^{119}Sn values. Infrared spectra were determined on a Perkin-Elmer 599B spectrometer.

All reactions requiring anhydrous and/or oxygen-free conditions were conducted with a positive pressure of argon or nitrogen in flame-dried glassware. Tetrahydrofuran (THF) was freshly distilled from sodium or potassium metal with benzophenone as an indicator. CuCN, 9-BBN, *n*-Bu_3SnCl, $(n\text{-}Bu_3Sn)_2$, $PhMe_2SiCl$, and Et_2AlCl were purchased from Aldrich Chemical Co.

*Preparation of 1,2-undecadiene (**25**)*

This was prepared in 93% yield by the method of Brandsma (8); bp 55°C (3 Torr); ir (film): 2959, 2928, 2872, 1957.9, 1660.8, 1466, 1377.5, 1093.7, and 841 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.86 (3 H, t, *J* = 6 Hz), 1.2–1.62 (12 H, m), 1.86–2.21 (2 H, m), 4.62–4.86 (2 H, dt, *J* = 6, 3 Hz), 5.0–5.32 (1 H, tt, *J* = 6, 6 Hz).

*Preparation of 5-hydroxy-1,2-pentadiene (**26**)*

Ethyl 3,4-pentadienoate (18) (6.3 g, 50 mmol) in 10 mL of ether was added dropwise to a suspension of LAH (2 g, 50 mmol) in 50 mL of ether at 0°C. The mixture was stirred for 1.5 h. Ice-cold 2 N HCl was added to hydrolyze excess LAH. The aq. layer was extracted with ether (3 × 30 mL) and the etheral layer was washed with brine, dried ($MgSO_4$), and concentrated *in vacuo* to give a crude product which was distilled to give 3.1 g of **26** (74%), bp 50–53°C at 12 Torr; ir (film): 3346.7, 2957.1, 2928.2, 2854.8, 1957.9, 1735.4, 1466, 1377.3, 1180.5, 1093.7, and 841 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 1.67 (1 H, bs), 2.10–2.43 (2 H, m), 3.72 (2 H, bs), 4.62–4.89 (2 H, dt, *J* = 6, 3 Hz), 5.99–5.27 (1 H, tt, *J* = 6, 6 Hz).

*Preparation of tri-*n*-butylstannyllithium (**5**)*

From n-*Bu_3SnH*: To a mixture of diisopropylamine (0.7 mL, 5 mmol) in 10 mL of THF was added *n*-BuLi (2.1 mL, 5 mmol) at −40°C. After 30 min, *n*-Bu_3SnH (1.35 mL, 5 mmol) was added and the solution was stirred for 40 min to give 5 mmol of *n*-Bu_3SnLi.

From n-*Bu_3SnH—$SnBu_3$*-n: *n*-Butyllithium (2.1 mL, 5 mmol) was added to a solution of bis tri-*n*-butylstannane (2.53 mL, 5 mmol) in 10 mL of THF and the reaction mixture was stirred for 20 min to yield *n*-Bu_3SnLi (5 mmol).

Preparation of n-*$Bu_3SnCu(CN)Li$ (**8**)*

Copper(I) cyanide (0.45 g, 5 mmol) was added to a THF solution of tri-*n*-stannyllithium (prepared as above) (5 mmol) at −78°C to give **8**.

Preparation of $(n\text{-}Bu_3Sn)_2Cu(CN)Li_2$ (**9**)

CuCN (0.225 g, 2.5 mmol) was added to **5** (5 mmol) at −78°C to afford **9**.

*Preparation of mixed cuprates, **10–14***

Addition of lithium 2-thienylcyanocuprate (20 mL, 5 mmol) to **8** (5 mmol) in THF at −78°C gave the mixed cuprate, **10**. Similarly, other mixed cuprates were prepared by mixing 1 equiv. of the organolithium with an equivalent of **8** in THF at −78°C.

Preparation of n-*$Bu_3Sn—AlEt_2$ (**15**) and* n-*$Bu_3Sn—AlMe_3^-Li^+$ (**16**)*

Diethylaluminum chloride (5 mmol) was added to a THF solution of *n*-Bu_3SnLi (5 mmol) at −78°C and the mixture was stirred for 30 min to give **15**. Similarly, reaction of trimethylaluminum with **5** at −78°C gave **16**.

Preparation of n-*$Bu_3Sn—BBN(OMe)^-Li^+$ (**18**) and* n-*$Bu_3Sn—BBu_3^-Li^+$ (**19**)*

Addition of B-methoxy-9-BBN (5 mmol) to a THF solution of 5 mmol of tri-*n*-butylstannyllithium (**5**) at −78°C provided **18**. Similarly, reaction of tri-*n*-butylborane with **5** gave **19**.

*Preparation of dimethylphenylsilyllithium (**24**)*

Small pieces of lithium wire (0.45 g, 64 mmol) were added to dimethylphenylsilyl chloride (3.6 g, 21 mmol) in 20 mL of THF at −5°C. The mixture was stirred overnight at 0°C and the reagent was titrated by following the method of Fleming *et al.* (19).

*Preparation of $PhMe_2SiCu(CN)Li$ (**20**) and $(PhMe_2Si)_2Cu(CN)Li_2$ (**1**)*

Addition of 1 equiv. of $PhMe_2SiLi$ in THF as prepared above to 1 equiv. of CuCN at −78°C gave **20** whereas reaction of 2 equiv. of $PhMe_2Si$ with 1 equiv. of CuCN at −78°C gave **1**.

Preparation of $CoCl_2{\cdot}(PPh_3)_2$

This complex was prepared according to the reported method (20). A solution of triphenylphosphine (38 g, 145 mmol) in 250 mL of benzene was refluxed with anhydrous cobalt chloride (8.64 g, 66 mmol) for 1 h. The blue precipitate which formed melted at 100–102°C (lit. (21) mp 102°C).

Reaction of n-*$Bu_3SnCu(CN)Li$ (**8**) with 1,2-undecadiene (**25**) (Table 2, entry 1)*

The following procedure is representative: To a mixture of 10

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

mmol of **8** in 20 mL of THF was added allene **25** (0.95 mL, 5 mmol) at −78°C. After the addition, the mixture was stirred for 1 h and quenched by the addition of a solution of MeOH and aq. NH_4Cl. The aqueous layer was extracted with hexanes (4 × 50 mL). The combined organic layer was washed twice with brine (30 mL), dried ($MgSO_4$), and the solvent removed *in vacuo* to give crude products (3.7 g). The crude isolate was treated with silver acetate (2.8 g, 16 mmol) in 100 mL of ethyl acetate in the open air at room temperature. After 13 h, the mixture was filtered through Celite, then washed with ice-cold water (2 × 50 mL) and brine (2 × 50 mL), dried ($MgSO_4$), and the solvents removed. The crude products were purified on silica gel (pretreated with Et_3N) by elution with hexanes to give a mixture of **27**, **28**, and **29** in 91% yield (2 g). Isomer ratios were determined by gc analysis.

Attempted isolation of ***41*** *under the control experiment*

To a suspension of **9** (2.5 mmol) in 20 mL of THF, was added allene **25** (0.2 mL, 1.25 mmol) at −78°C. After I h the reaction mixture was quenched with saturated $NaHCO_3$ at −78°C and work up as usual. The products obtained were subjected to nmr analysis immediately.

(E)- and (Z)-1-Tri-n-*butylstannyl-2-undecene (27)*

^{1}H nmr ($CDCl_3$) δ: 0.9–1.08 (18 H, m), 1.25–1.51 (18 H, m), 1.56–1.66 (6 H, m), 1.89 (2 H_{trans}, d, J = 7 Hz, $J_{Sn—H}$ = 49.95, 66.6 Hz), 1.96 (2 H_{cis}, d, J = 7 Hz, $J_{Sn—H}$ = 53.28, 59.94), 2.16 (2 H_{trans}, dt, J = 7, 6.5 Hz), 2.24 (2 H_{cis}, dt, J = 7, 6.5 Hz), 5.31–5.39 (1 H_{cis}, dtt, J = 10, 7, 1 Hz), 5.43–5.51 (1 H_{trans}, dtt, J = 16, 7, 1.5 Hz), 5.71–5.85 (1 H_{trans} and 1 H_{cis}, dtt, J_{trans} = 16, 7, 1.5 and J_{cis} = 10, 7, 1 Hz); gc/ms, m/e (%, rel. int.): 387 (M^+ − 57, 30.3%). Exact Mass calcd. for $C_{19}H_{39}Sn$ (M^+ − Bu): 387.2073; found: 387.2080.

(E)-2-Tri-n-*butylstannyl-2-undecene (28)*

^{1}H nmr (C_6D_6) δ: 0.85–1.25 (18 H, m), 1.28–1.56 (18 H, m), 1.59–1.84 (6 H, m), 2.02 (3 H, d, J = 1.5 Hz and $J_{Sn—H}$ = 49.95 Hz), 2.29 (2 H, dt, J = 7, 6.5 Hz), 5.85 (1 H, tq, J = 7, 1.5 Hz and $J_{Sn—H}$ = 70 Hz); gc/ms, m/e (%, rel. int.): 387 (M^+ − 57, 92.85%). Exact Mass calcd. for $C_{19}H_{39}Sn$ (M^+ − Bu): 387.2073; found: 387.2080.

2-Tri-n-*butylstannyl-1-undecene (29)*

^{1}H nmr (C_6D_6) δ: 0.9–1.08 (18 H, m), 1.25–1.51 (20 H, m), 1.56–1.83 (6 H, m), 2.46 (2 H, t, J = 6.5 Hz), 5.36 (1 H, d, J = 2.9 Hz and $J_{Sn—H}$ = 65 Hz), 5.91 (1 H, dt, J = 2.9, 1.5 Hz and $J_{Sn—H}$ = 140 Hz); gc/ms, m/e (%, rel. int.): 387 (M^+ − 57, 66.66%). Addition of (n-$Bu_3Sn)_2Cu(CN)Li_2$ ***(9)*** *to* ***25*** *(Table 2, entry 3)*

The following method is representative: Allene **25** (0.45 mL, 2.5 mmol) was added to a mixture of **9** (5 mmol) in 20 mL of THF at −78°C. The reaction mixture was stirred for 1.5 h and quenched by the addition of a solution of MeOH and aq. NH_4Cl. The organic layer was separated and the aqueous solution was extracted with hexanes (4 × 50 mL) and dried ($MgSO_4$). Removal of the solvents gave the crude products which were treated with silver acetate and purified as above to give a mixture of **27**, **28**, and **29** in 86% yield (0.95 g).

Addition of n-$Bu_3Sn(2\text{-}Th)Cu(CN)Li_2$ ***(10)*** *to* ***25*** *(Table 2, entry 9)*

The following method is representative: To a solution of *n*-$Bu_3Sn(2\text{-}Th)Cu(CN)Li_2$ (5 mmol, prepared as above) in THF was added 1,2-undecadiene (0.45 mL, 2.5 mmol) at −78°C. The reaction was warmed to 10°C over a period of 12 h. Gas chromatographic (quantitative, dodecane as the internal standard) analysis of an aliquot revealed the product distribution given in Table 2 in an overall 69% yield.

Reaction of n-$Bu_3Sn—AlEt_2$ ***(15)*** *with* ***25*** *(Table 3, entry 1)*

The following procedure is representative: To reagent **15** (5 mmol) prepared as above in 20 mL of THF was added **25** (0.45 mL, 2.5 mmol) followed by CuCN (0.025 g, 0.27 mmol) at −40°C. The reaction mixture was warmed to room temperature over a period of 16 h and quenched by addition of a mixture of MeOH and aq. NH_4Cl. After the usual work-up as above, the crude product was treated with silver acetate and subjected to flash chromatography to yield allylstannane **27** and vinylstannane **29** in 80% yield (0.83 g).

Reaction of n-$Bu_3Sn—AlMe_3^-Li^+$ ***(16)*** *with* ***25*** *(Table 3, entry 5)*

The following method is representative: 1,2-Undecadiene (0.34 g, 2.3 mmol) and CuCN (0.45 g, 5 mmol) were added to a solution of **16** in 20 mL of THF at −78°C. After 2 h, the mixture was hydrolyzed by addition of an ice-cold solution of MeOH and aq. NH_4Cl. The aq. solution was extracted with hexanes (4 × 30 mL). The combined organic layer was washed with brine (2 × 30 mL), dried ($MgSO_4$), and concentrated *in vacuo* to provide crude product which was purified by flash chromatography to give **27** and **29** in 90% yield (0.9 g).

Addition of n-$Bu_3Sn—AlEt_2$ ***(15)*** *to 5-hydroxy-1,2-pentadiene* ***(26)*** *in presence of* $CoCl_2{\cdot}(PPh_3)_2$ *(Table 4, entry 1)*

The following procedure is representative: To a solution of **15** (5 mmol) in 20 mL of THF was added allene **26** (0.22 mL, 2.5 mmol) followed by $CoCl_2{\cdot}(PPh_3)_2$ (0.163 g, 5 mol%) at −78°C. The mixture was warmed to room temperature over a period of 18 h and quenched by addition of an ice-cold solution of MeOH and aq. NH_4Cl. After the usual work-up, the crude product was flash chromatographed (ethyl acetate:*n*-hexane, 1:9) to provide 5-hydroxy-2-tri-*n*-butylstannyl-1-pentene (**32**) in 53% yield (0.5 g).

Addition of n-$Bu_3Sn—AlEt_2$ ***(15)*** *to 5-hydroxy-1,2-pentadiene* ***(26)*** *in presence of CuCN (Table 4, entry 2)*

The following method is representative: To a solution of **15** (5 mmol) in 20 mL of THF was added **26** (0.2 mL, 2.5 mmol) followed by CuCN (0.026 g, 5 mol%) at −78°C. The mixture was warmed to room temperature over a period of 15 h and hydrolyzed by the addition of a mixture of MeOH and aq. NH_4Cl. After the extractive work-up with ether, the crude product was purified as above to give (*E*)- and (*Z*)-5-hydroxy-1-tri-*n*-butylstannyl-2-pentene (**30**), (*E*)-5-hydroxy-2-tri-*n*-butylstannyl-2-pentene (**31**) and **32** in 57% yield (0.54 g).

The adsorption of several aromatic nitro compounds and the ion-exchange of heavy metal ions on electro-oxidized carbon fibres have been investigated using cyclic voltammetric and polarographic techniques. Electro-oxidation is performed by potentiostatic double pulse application. This procedure results in the generation of many functional —OH and —COOH groups with adsorptive and ion-exchanging properties.

Multimolecular layers of adsorbed substances may be formed through a procedure of successive adsorption of the nitro-compound and electro-reduction to the corresponding amine, resulting in the attachment of considerable amounts of the nitro-compound to the carbon fibres.

The ion-exchange capacity is estimated to be ca. 1 mequiv. g^{-1} and with slight deviations it follows the rank Ag, Cu, Cd, Pb, Hg. After the electro-reduction of the exchanged metal ions, the ion-exchange process can be repeated several times. This procedure is of importance for the removal of significant amounts of heavy and toxic metals from industrial waste waters.

Key words: electro-oxidized carbon fibres, adsorption of aromatic nitro compounds, cation-exchange of heavy metals.

E. THEODORIDOU, A. D. JANNAKOUDAKIS, P. D. JANNAKOUDAKIS et S. ANTONIADOU. Can. J. Chem. **69**, 1881 (1991).

Faisant appel à des techniques de polarographie et de voltampérométrie cyclique, on a étudié l'adsorption de plusieurs composés aromatiques nitrés et l'échange ionique d'ions de métaux lourds sur des fibres de carbone électro-oxydées. On a réalisé l'électro-oxydation en appliquant une double pulsation potentiostatique. Cette méthode permet de générer plusieurs groupes fonctionnels —OH et —COOH possédant des propriétés d'adsorption et d'échange ionique.

Si on utilise une technique d'adsorptions successives des composés nitrées suivies d'électroréductions en amines correspondantes, on peut former des couches multimoléculaires de substances adsorbées; il en résulte un attachement de quantités considérables de composés nitrés sur les fibres de carbone.

On a évalué que la capacité d'échange ionique est d'environ 1 mequiv. g^{-1} et, avec des déviations légères, l'ordre est le suivant : Ag, Cu, Cd, Pb et Hg. Après l'électroréduction des ions métalliques échangés, on peut répéter le processus d'échange ionique plusieurs fois. Cette procédure est importante pour l'enlèvement de quantités importantes de métaux lourds et toxiques d'eaux usées industrielles.

Mots clés : fibres de carbone électro-oxydées, adsorption de composés nitrés aromatiques; échange cationique de métaux lourds.

[Traduit par la rédaction]

Introduction

Carbon fibre sorption materials represent a species of carbonaceous adsorbents. They are in many respects similar to activated charcoal (1).

Studies on the application of carbon fibres as adsorbents for several gases (such as NO, NH_3, CH_3NH_2, and benzene vapour) have been reported in the literature. It was found that the adsorption ability of the carbon fibre material is enhanced through activation with metal or metal salt additives (2–4).

PAN-based activated carbon fibres pretreated with sulfuric acid and annealed at 350°C have been used for the adsorption of NO_x (5).

Activated carbon fibres have also been used for the removal of organic molecules of a comparatively large size from liquid media. For this purpose, adsorbents with a developed supermicro- and mesopore structure proved to be the most effective (6). As it has been reported in the literature (7), commercial carbon fibre adsorbents are very effective for the removal of toxic chlorine compounds from aqueous solutions.

Carbon fibres have also been used for the preparation of ion-exchangers. Oxidative treatment of the fibres is the most frequently used approach for this purpose. Various reagents have been used as oxidizers: solutions of nitric acid at different concentrations (8), mixtures of concentrated nitric and sulfuric acid (8, 9), hydrogen peroxide (10), and $K_2Cr_2O_7$ or $KMnO_4$ in concentrated acidic solutions (11). However, chemical pretreatment of the carbon fibres reduces their mechanical stability and electronic conductivity and therefore restricts their application in electrochemical procedures.

On the contrary, electrochemically oxidized PAN-based carbon fibres are characterized by good mechanical stability, high electronic conductivity, and a porous hydrophilic structure (12). These fibres bear hydroxylic and carboxylic groups and show remarkable ability for the attachment of several species dissolved in solutions. This property enables the use of the electro-oxidized fibres for chromatographic determinations and ion-exchange procedures.

The application of repetitive anodic oxidation and cathodic reduction by potentiostatic double pulses favours the generation of numerous —OH and —COOH groups on the carbon fibre surface without affecting the mechanical properties and electronic conductivity of the graphitic material (12–14).

The effective area of pulse oxidized fibres is of the order of $m^2\ g^{-1}$. These fibres have already been employed as supports for noble metal catalysts (12, 14, 15), for metalloporphyrin redox mediators (16–18), and for chemically modified electrodes (19).

The present study is focused on the adsorptive and ion-exchanging properties of the electrooxidized fibres and their utility as convenient substrates for the attachment of several

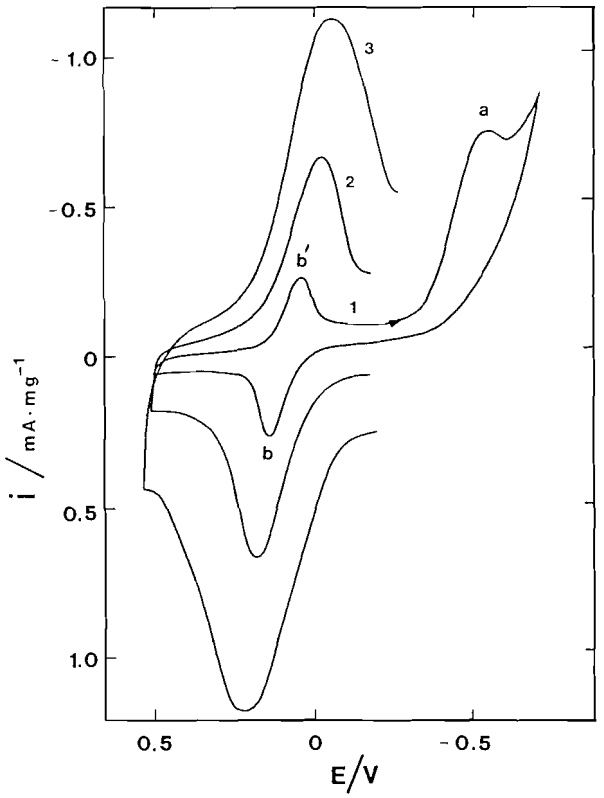

FIG. 1. Cyclic voltammograms (v = 10 mV s^{-1}, pH = 4) of 2-nitro-1-naphthol adsorbed on electrooxidized carbon fibres. (*1*), (*2*), and (*3*): first, second, and third successive adsorption procedure. Start potential: −0.1 V vs. SCE.

substances dissolved in solutions. The adsorption experiments were carried out with various nitro and nitroso compounds, while for the ion-exchange processes heavy and toxic metals have been used. The choice of these substances was based on our previous knowledge on their electrochemical behaviour on pristine, not electro-oxidized fibres (20–24) and especially on the possible ecological demand for their removal from technical waste waters.

Experimental

The PAN-based carbon fibres used in this study were produced by Celanese Corp. (type GY-70). They are formally arranged in bundles containing an average of 384 filaments. These fibres are highly oriented and mechanically stable with the following technical characteristics: density 2 g cm^{-3}, filament diameter 7 μm, specific resistance 7×10^{-4} Ω m, and Young modulus 5.15×10^{11} N m^{-2} (25).

The oxidation of the fibres was performed by potentiostatic double pulse application for a 6-min period in aqueous 0.05 M Na_2SO_4 solution. The applied potential range extended from +2.3 up to −0.3 V vs. S.C.E. and the duration of the oxidative pulse was six times longer than that of the reductive pulse (12). The effective area of the pristine bundle of fibres is 1.7 cm^2 mg^{-1}, while the corresponding value for the electro-oxidized fibres is 6.8 cm^2 mg^{-1}, i.e., four times larger (16). The electro-oxidation procedure enhances the widening of the fibres and thus facilitates inner planes of the bundles to be directly accessible to the solution.

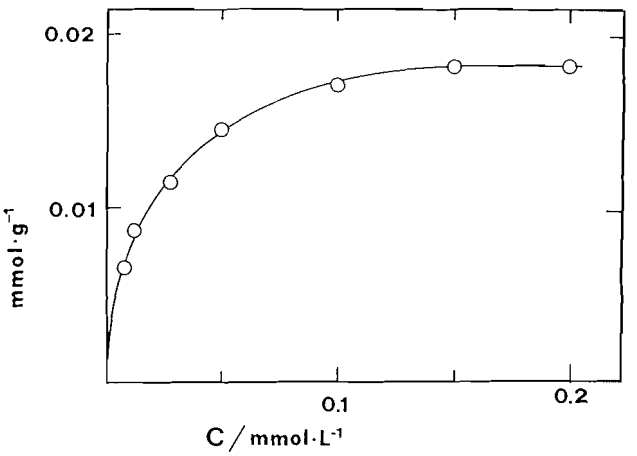

FIG. 2. Adsorption isotherm of 2-nitro-1-naphthol on electro-oxidized carbon fibres, for the first adsorption procedure (T = 25°C).

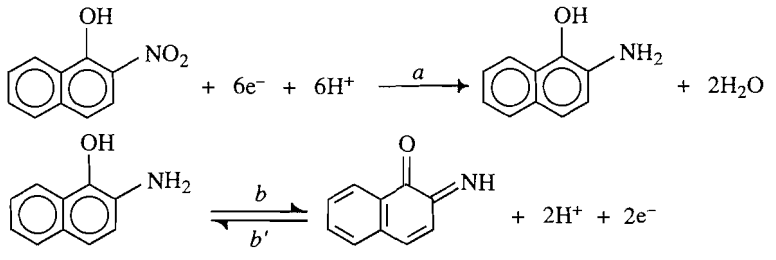
The electrical connection is performed by pressing one end of the fibre bundle painted with conductive carbon paste between two platinum sheets, which are then put to a metallic conjunction plugged into the electrical circuit.

The adsorption of nitro compounds was accomplished by dipping the electro-oxidized fibre bundles in aqueous methanolic solutions (50% v/v in methanol) of these compounds. The adsorption equilibrium was attained approximately after 3 h. The quantity of the nitro compound adsorbed on the fibres was estimated from the data obtained by cyclic voltammetric measurements on these fibres in aqueous buffered solutions. The same series of experiments were repeated on large bundles of carbon fibres. After the adsorption of the nitro compound, polarographic measurements were taken to estimate the remaining unadsorbed quantity of nitro compound in the solution. The results verified the values obtained from the cyclic voltammetric measurements.



The ion-exchange of the heavy metal ions was accomplished by dipping the electrooxidized fibres in aqueous solutions of varying metal salt concentrations. The equilibrium was attained in a 2-h period. The ion-exchanged quantity of the metal was determined by cyclic voltammetric measurements of the carbon fibres bearing metal ions in aqueous buffered solutions. By means of cyclic voltammetry on a hanging mercury electrode the amount of the unexchanged metal remaining in solution after the establishment of equilibrium was also estimated.

Results and discussion

(a) Adsorption of nitro compounds

Figure 1 (curve *1*) presents, as an example, the cyclic voltammogram of carbon fibres bearing adsorbed 2-nitro-1-naphthol (2N1N). The adsorption was carried out in a 10^{-3} M 2N1N solution and the adsorption procedure follows a typical adsorption isotherm as shown in Fig. 2.

Peaks *a*, *b*, and *b'* in Fig. 1 correspond to the following reactions (20):

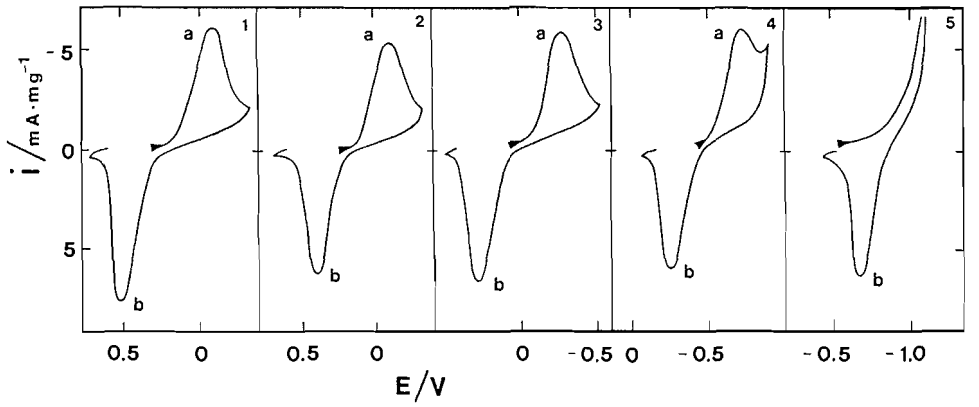


FIG. 3. Cyclic voltammograms (v = 20 mV s^{-1}, pH = 4) of electro-oxidized carbon fibres after ion-exchange with Ag^+ (*1*), Hg^{2+} (*2*), Cu^{2+} (*3*), Pb^{2+} (*4*), and Cd^{2+} (*5*).

The charge under peak *a* is almost three times larger than that under peak *b*, supporting the reaction scheme presented above. The peak currents depend linearly on the potential scan rate as it is expected for species immobilized on the electrode surface (26). The shape of peaks *b* and *b'* is unaffected through successive potential scans. This means that the reduction product, *i.e.*, aminonaphthol, remains strongly adsorbed on the electro-oxidized carbon fibres.

The amount of the adsorbed 2N1N was accurately evaluated from the charge under peak *b* more preferably than under peak *a*, since the reduction of 2N1N to the corresponding amine (peak *a*) is followed by the reduction of the surface functional groups (13, 14). The estimated values were used in Fig. 2. Figure 2 indicates that the maximum amount of 2N1N adsorbed on the electro-oxidized fibres during the first adsorption procedure is 0.018 mmol g^{-1}.

After the electro-reduction of the adsorbed 2N1N to the corresponding amine, it was found that the carbon fibres retain the ability to adsorb considerable amounts of additional nitro compound. This procedure can be performed repeatedly and the product of the electro-reduction (*i.e.* the corresponding aminonaphthol) still remains adsorbed on the electro-oxidized fibres. This is schematically presented in Fig. 1, where curves *2* and *3* refer to the 2nd and 3rd successive adsorption procedure, respectively.

The deposition of the limiting amount of 2N1N on the electro-oxidized fibres is achieved after four successive adsorption experiments, and measures 0.3 mmol g^{-1}. This indicates that the attached quantity of 2N1N is almost 17 times larger than that in the first adsorption procedure. Taking into account that 1 g of electro-oxidized fibres exhibits 6800 cm^2 of effective electrode area, it is estimated that the total amount of 2N1N deposited on the fibres is 4.4×10^{-8} mol cm^{-2}. Since it is known that in the case of electro-sorption of β-naphthol from aqueous solution onto graphite powder, the monolayer coverage is 2.5×10^{-10} and 6.4×10^{-10} mol cm^{-2} for planar and perpendicular orientation, respectively (27), it is concluded that the entire amount of 2N1N deposited on the fibres corresponds to a multilayer coverage.

The stable multimolecular layer that is finally formed indicates that during the successive adsorption procedures the nitro compound is attached to the previously subdeposited layers of the corresponding amino compound. This fact suggests that the reduced form of the nitro compound exhibits intensive adsorption properties.

After the series of experiments, it was found that dipping a 50 mg bundle of electro-oxidized fibres in 30 mL of a 10^{-3} M 2N1N solution, 90% of the total amount of the dissolved nitro compound could be withdrawn from the solution. This argument resulted from cyclic voltammetric measurements on the fibres as well as from polarographic determination of the remaining unadsorbed nitro compound in the solution.

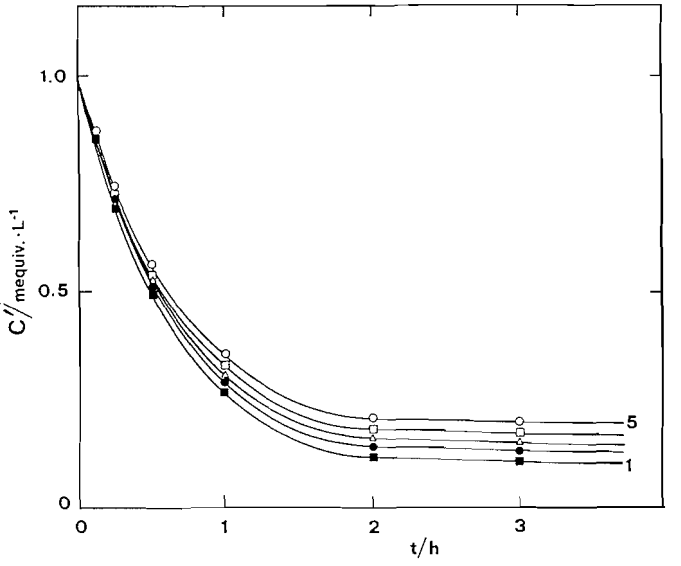

FIG. 4. Concentration of the metal ions remaining in the solution after the ion-exchange of electrooxidized carbon fibres with Ag^+ (*1*), Cu^{2+} (*2*), Cd^{2+} (*3*), Pb^{2+} (*4*), and Hg^{2+} (*5*) as a function of time.

Similar experiments for various nitro and nitroso compounds confirmed that adsorption on electro-oxidized fibres somewhat follows chemisorption, resulting in the formation of multimolecular layers. This conclusion implies that considerable amounts of the nitro compound can be attached to the fibres.

In the case of 1-nitro-2-naphthol, 1-nitroso-2-naphthol, and 2-nitroso-1-naphthol, the total amount adsorbed is approximately the same as in the case of 2-nitro-1-naphthol. As for the dinitrobenzene isomers, the adsorbed amount varies between 0.05 and up to 0.08 mmol g^{-1}.

(b) Ion-exchange of heavy metals

Figure 3 presents the cyclic voltammogram of electro-oxidized carbon fibres after the ion-exchange of heavy metal ions, accomplished in a rather concentrated solution of the corresponding metal salt (c = 10^{-2} M).

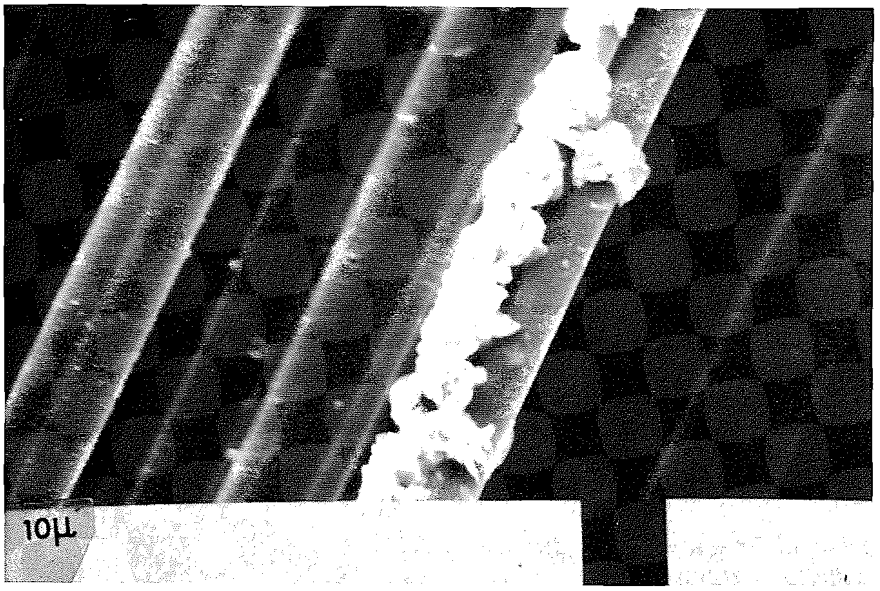

FIG. 5. SEM-micrograph of electrooxidized carbon fibres bearing Ag clusters after 25 successive ion-exchange procedures with Ag^+.

This figure shows that the electrochemical reduction of Ag^+, Hg^{2+}, Cu^{2+}, and Pb^{2+} ions (peak *a*) occurs before the reduction of the functional groups of the electro-oxidized fibres, whereas the reduction of Cd^{2+} takes place concurrently with the reduction of the functional groups. In all cases the ion-exchanged quantity was estimated from the integrated area under peak *b*, which corresponds to the dissolution of the respective ion-exchanged metal quantity. These results were confirmed by ion-exchange experiments on large bundles of electro-oxidized fibres under stationary conditions and further polarographic determination of the quantity not ion-exchanged in the solution. The values obtained in correlation with the time required for the ion-exchange equilibrium resulted in a plot in Fig. 4, which implies that 85–95% of the dissolved metal ions can be attached to 30 mg of electro-oxidized fibres dipped in 30 mL of a 10^{-3} M solution for a period of approximately 2 h.

The ion-exchange capacity is of the order of 1 mequiv. g^{-1} and with slight variations follows the order Ag, Cu, Cd, Pb, Hg. Similar range was obtained for heavy metal ion-exchange on natural cellulose (28).

After a quantitative electro-reduction of the ion-exchanged metal on the adsorptive material, further repetitive attachment of additional quantities is possible. This fact is of great importance for the removal of significant quantities of heavy and toxic metal ions from industrial waste waters. The total quantity of the metal ion that can be ion-exchanged using repeatedly the same electro-oxidized fibre bundle exceeds the primarily estimated value (1 mequiv. g^{-1}) during the first ion-exchange procedure.

Figure 5 illustrates a SEM-micrograph of electro-oxidized fibres after 25 successive Ag^+ ion-exchange procedures. It shows that large metal clusters are sparsely situated on the carbon fibre surface, while functional groups of the oxidized carbon matrix are directly exposed to metal ions of the solution, indicating that Ag^+ ion-exchange may still occur.

Cadmium ion-exchange experiments were carried out in addition to the experiments under stationary conditions, using a column filled with trimmed electro-oxidized fibres as adsorptive material. The most favourable conditions for the attachment of 90% of the metal ions dissolved in a 10^{-3} M solution as follows were: flow velocity 5 mL min^{-1}, column diameter 12 mm, and column height 60 cm.

For these experiments carbon fibres electro-oxidized for periods larger than 6 min were also used, since they exhibit enhanced ion-exchange properties because of an increased number of —OH and —COOH groups. It was found that carbon fibres oxidized for 15 min have ion-exchange capacity 2.5 mequiv. g^{-1}. The prolonged oxidation reduces the conductivity of the fibres; however, this fact does not interfere in their application as adsorptive material.

From our series of experiments it was found that the fibres exhibit ion-exchange capacity parallelling the electrooxidation time.

Ion-exchange capacity of heavy metal ions proved to be independent on pH in the range 4 to 8, and unaffected by significant concentrations of NaCl (up to 0.5 M).

The displacement of heavy metal ions is successfully accomplished through relatively concentrated solutions of $Ca(NO_3)_2$ (0.1–0.5 M), confirming the ion-exchanging properties of the oxidized graphitic material.

Blank measurements were performed on unelectro-oxidized fibres. The results showed that the amount of the attached nitro compound is ca. 15 times less than the corresponding amount on electro-oxidized fibres during the first adsorption procedure. The primary deposited quantity on the pristine fibres is not increased upon successive adsorption experiments due to the absence of functional groups.

The ion-exchange of heavy metals on initial carbon fibres was negligible.

Physical characteristics and polarographic reduction mechanism of some oxazolones

M. I. ISMAIL

Department of Chemistry, Faculty of Science, Ain-Shams University, Abbassia, Cairo, Egypt

Received April 12, 1990

M. I. ISMAIL. Can. J. Chem. **69**, 1886 (1991).

The redox potential ($\Delta E_{1/2}$), electron affinity (EA), ionization potential (IP), coulomb repulsion integral (J_{12}), and electronic transition energy (E_{CT}) of several oxazolone derivatives in DMF were computed. A linear correlation was shown to exist between $\Delta E_{1/2}$ and E_{CT}. The polarographic reduction was investigated in ethanolic-Theil buffer solutions. At pH $\leq$ 7.2, two waves were obtained representing the uptake of 2- and 4-electron steps respectively. In alkaline media, a third wave appeared seemingly a result of the hydrolysis of oxazolones. The rate of hydrolysis was determined and the electrode mechanism was elucidated and confirmed via spectrophotometric and coulometric analysis.

Key words: oxazolones, polarography, electrochemistry, electrode reaction, spectrophotometry, redox potential.

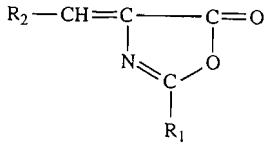
M. I. ISMAIL. Can. J. Chem. **69**, 1886 (1991).

On a calculé le potentiel rédox ($\Delta E_{1/2}$), l'affinité électronique (AE), le potentiel d'ionisation (PI), l'intégrale de répulsion coulombique (J_{12}) et l'énergie de transition électronique (E_{CT}) de plusieurs dérivés de l'oxazolone dans le DMF. On a démontré qu'il existe une corrélation linéaire entre $\Delta E_{1/2}$ et E_{CT}. On a étudié la réduction polarographique dans des solutions éthanoliques du tampon de Theil. À des pH inférieurs à 7,2, on a observé deux vagues correspondant respectivement à l'absorption de 2 et de 4 électrons. En solutions alcalines, une troisième vague apparaît; elle semble être causée par une hydrolyse des oxazolones. On a déterminé les vitesses d'hydrolyse des oxazolones, on a élucidé le mécanisme à l'électrode et on l'a confirmé par analyses spectrophotométriques et coulométriques.

Mots clés : oxazolones, polarographie, électrochimie, réaction à l'électrode, spectrophotométrie, potentiel rédox.

[Traduit par la rédaction]

Introduction



Numerous studies have been devoted to the chemistry, electrochemistry, and spectroscopy of heterocyclic compounds, specially those exhibiting applications in biological and medicinal researches (1, 2). On the other hand, the polarographic behaviour of the oxazole ring, structurally a heterocyclic system, has attracted only minor attention in literature (3, 4) as compared to major spectroscopic investigations (5–10). Consequently, in the present investigation our attention was devoted mainly to oxazolones possessing wide applications in the electrosyntheses of various amino alcohols, thiamine, and amino acids (11, 12). The study was focussed on the polarographic behaviour of some oxazolones (1–15), in Thiel buffer – ethanolic solutions of different pH values as well as in DMF. The electrode reaction mechanism and various physical properties of these compounds were also investigated.

An ultimate goal of this investigation was to establish the relationship between the spectroscopic data (E_{CT}) and the absolute difference in the electrochemical oxidation and reduction potentials ($\Delta E_{1/2}$) for the studied compounds. The study was extended to estimate the true $E^{OX}_{1/2}$ and/or $E^{R}_{1/2}$ as well as the coulomb repulsion integral J_{12}.

Experimental

Oxazolones (1–15) were prepared according to recommended procedure (13). The purity and structures of the compounds were checked by measurements of mp, nmr, mass spectra, and elemental analysis. The polarograms were recorded by Radiometer PO_4 type recording polarograph using a dropping mercury electrode with $m = 2.12$ mg/s and $t = 3.65$ s at h = 52 cm Hg. Depolarizer concentrations studied were 5×10^{-4} M in 50% (v/v) ethanolic – Theil buffer mixtures and in DMF – 0.1 M of *N*-tetrabutylammonium perchlorate. The electrolytic cell used was the same as that described by Peltier *et al.* (14).

The UV absorption spectra of oxazolones reaction in 50% ethanol – 0.1 M acid or base solution and in DMF were recorded on a Pye Unicam SP 1800 spectrophotometer attached to a temperature regulated cell holder.

Results and discussion

1. The polarographic behaviour and spectrophotometry of 2-alkyl (aryl)-4-arylidene-oxazolin-5-one (1–15)

Figure 1 represents the polarographic reduction of 5×10^{-4} M of compound **1** in Theil buffer – 50% ethanolic solution of varying pH as a typical representative example for the studied series. At pH $\leq$ 7.2, the polarogram consists of two waves (A and B) with a height ratio 1:2. The limiting current (i_l) of the two waves is sustained constant and the whole polarogram shows a marked shift to more negative potentials throughout this pH range. When the pH is increased up to 7.5–7.9, the limiting current of the two waves starts to decrease while the second wave (B) becomes characterized by a small maximum. At pH $\geq$ 8.2, a third wave (C) starts to appear at more negative potential (−1.68 V) where its limiting current shows an increase by increasing the pH value (or by increasing the time at a constant pH). At these pH values, the current of waves A and B seems to be unstable and consequently an irregular shaped-polarogram is produced. This can be attributed to a change in the concentration of the electroactive species near the electrode surface with time. Such a change may be caused by hydrolysis of the oxazolones being catalysed by the alkali to form the corresponding acid (3, 9, 10, 15).

The effect of time on the electroreduction of compound **1** in 50% ethanol – 0.1 M NaOH is shown in Fig. 2. At zero time, two waves A and B are observed. As the time increases, the total limiting current decreases, followed by the formation of wave C. The limiting current of wave C increases with time; after 25 min, the produced polarogram shows only one well developed wave C where its i_l is quite similar to that of wave A.

Figure 3 represents the UV spectra of 1×10^{-4} M of compound **1** in presence of 50% ethanol – 0.1 M HCl (Fig. 3*a*) and 50% ethanol – 0.1 M NaOH (Fig. 3*b*). It is quite clear that this class of compounds shows a reasonable stability in acidic medium up to 35 min whereas in the basic medium, the hydrolysis starts a few minutes after the addition. In acidic conditions, hydrolysis tends to complete in 130 min and in basic conditions it takes only 15 min. These findings reflect the minor catalytic hydrolyzing effect of the acid as compared to that of the alkali. This indicates the stability of the compounds under study in acidic solutions within the time of polarographic measurements. It is known that oxazolones exhibit an absorption band at 366 nm which decreases in intensity with time with the appearance of a new band at 280 nm, representing the corresponding acid (during hydrolysis) or its ester (during alcoholysis). The composition of the medium used favours the hydrolysis of oxazalones but not alcoholysis since the latter requires a higher percentage of the alcohol and a lower concentration of the catalyst (10). The previously reported data (15–18) revealed that these compounds are

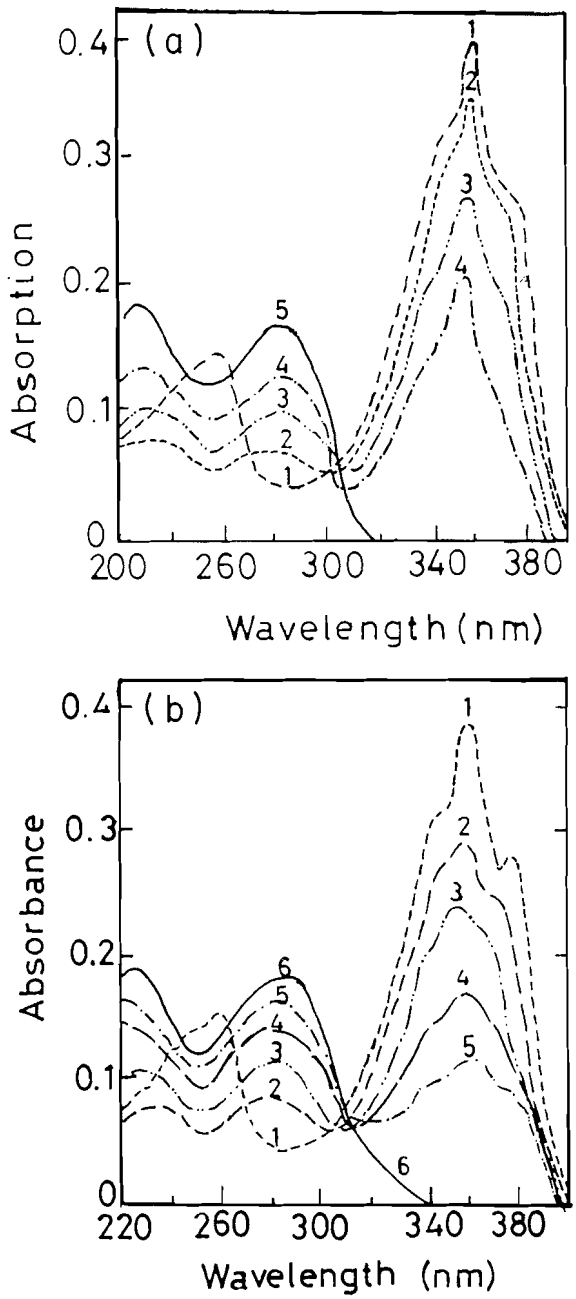

FIG. 3. (*a*) Ultraviolet absorption spectra of 1×10^{-4} M of **1** in 50% ethanol – 0.1 M HCl after various times: (*1*) 2 min; (*2*) 38 min; (*3*) 55 min; (*4*) 75 min; (*5*) 130 min. (*b*) Ultraviolet absorption spectra of 1×10^{-4} M of **1** in 50% ethanol – 0.1 M NaOH after various times: (*1*) 2 min; (*2*) 4 min; (*3*) 6 min; (*4*) 8 min; (*5*) 10 min; (*6*) 15 min.

considered the most stable oxazolones, resisting hydrolysis in cold water. The presence of phenyl group in position 2 was assumed to increase their stability towards acids.

The measurement of the polarographic reduction and the UV spectra of 2-benzoylaminocinnamic acid becomes essential to confirm that wave C represents the reduction of the hydrolysis product of the oxazolone studied. The experimental polarogram of this compound exhibited only one wave at −1.67 V, and its spectrum in ethanol displayed only one band at 280 nm. These results indicate that wave C does not represent a stepwise reduction of oxazolones moiety but may reflect the electroreduction of the hydrolysis product. Moreover, the

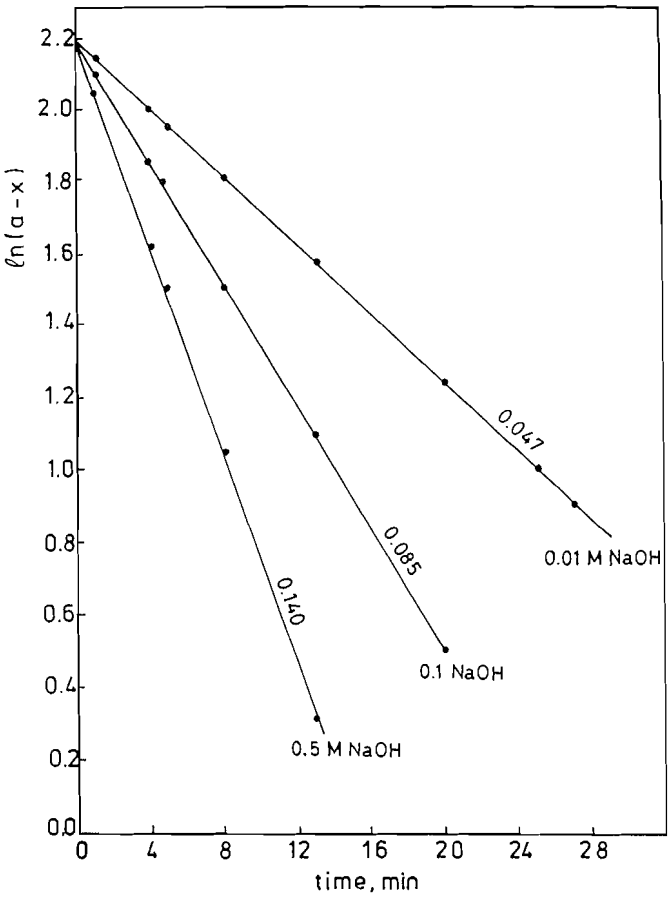

FIG. 4. First order Plots for the hydrolysis of (1) in 50% ethanol – NaOH at 25°C.

hydrolysis of oxazolones in alkaline ethanolic solution is found to be first order with respect to oxazolones (Fig. 4). The rate constant k increases *viz.*, 0.047, 0.085, and 0.14 min^{-1} as the concentration of NaOH is increased from 0.01, 0.1, to 0.5 M, respectively. In other words, the reaction rate is accelerated by the presence of OH^- ions.

2. Nature of waves

Coulometric analysis of compound **1** was carried out under controlled potential, *viz.* −1.1 V at ionic strength of 0.1 M in 50% ethanol – 0.05 M HCl as well as in ethanolic buffer solution of pH 3.2. The two solutions are the proper media since the compound studied showed reasonable stability. The total number of electrons transfered in the electrode process was found to be approximately six. From the height ratio of the two waves (1:2), one may assume that wave A represents a two-electron reduction step, whereas wave B corresponds to the uptake of four electrons. Using the Ilkovic equation the number of electrons could also be evaluated. The number of electrons obtained by both approaches were quite close. The diffusion coefficient (D) of the depolarizer was determined experimentally (19) by applying the Stokes–Einstein equation [1]. The obtained values are listed in Table 1.

$$[1] \quad D_0 = 3.31 \times 10^{-5}(D/M)^{1/3}/\eta \text{ cm}^2/\text{s}$$

The effect of mercury pressure on limiting current at pH < 7.2 reveals that the two waves are diffusion controlled. The applicability of Ilkovic equation at different pH shows that the values of i_l/C obtained at pH > 7 are not constant, evidently

[d]Wave B.

due to the hydrolysis of the oxazolones. An excellent linear relationship passing through the origin is obtained for the total limiting current of the two waves at pH < 7. Accordingly, it seemed that the polarographic determination of oxazolone derivatives should be performed only in acidic media.

The thermodynamic reversibility (20) of the waves can be tested from the correlation of E with log $(i/i_l - i)$ at pH < 7.5. The results show straight lines with somewhat varying slopes. The listed data in Table 1 indicate that the waves proceed irreversibly and this trend increases as the pH is increased. This is substantiated by a shift of $E_{1/2}$ towards more negative values as the concentration of the depolarizer is increased (21).

For personal use only.

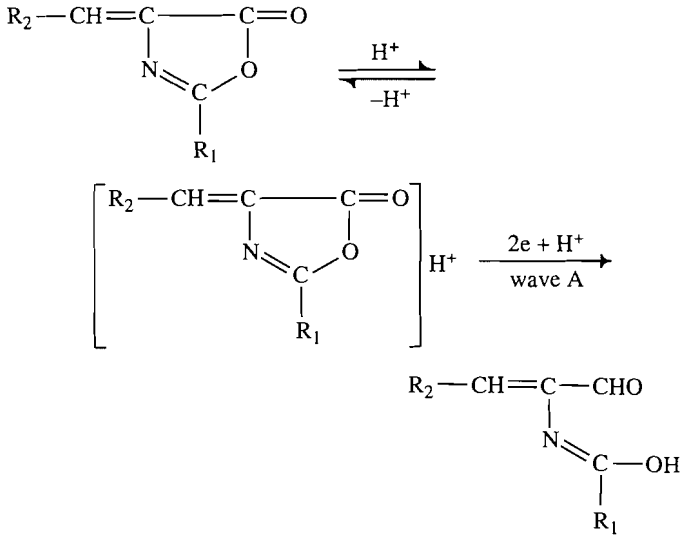
The irreversibility is further supported by the lower values of the electron rate constant, K_e^0, and the higher values of the free energy of activation, ΔG^*; both being calculated by applying the Delahay (22, 23) and Koutecky (24) equations as modified by Issa and Tharwat (25) for irreversible waves;

$$[2] \quad \log K_e^0 = \left(\frac{i_{irr}}{i_{rev} - i_{irr}}\right)_{E=0} + \log \frac{1}{0.886}\left(\frac{d}{t}\right)^{1/2}$$

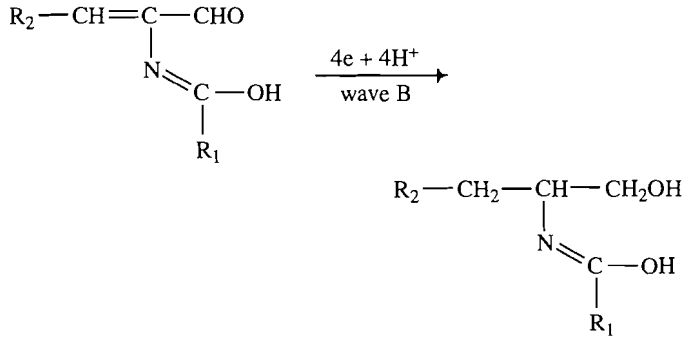
$$[3] \quad \Delta G^* = 5778.8\left(5.097 + \frac{\alpha n_a}{0.059}E - \log K_e^0\right)$$



The correlation between limiting current of waves A, B, and C and pH is shown in Fig. 5. The first two waves (A and B) show dissociation curves (26). For wave C, however, i_l increases as pH is increased. The relationship between $E_{1/2}$ (for waves A and B) and pH gives straight lines (Fig. 5), the slope of each indicates the consumption of hydrogen ions (Z_{H^+}) in the reduction process (20). For wave C, $E_{1/2}$ is practically pH independent.

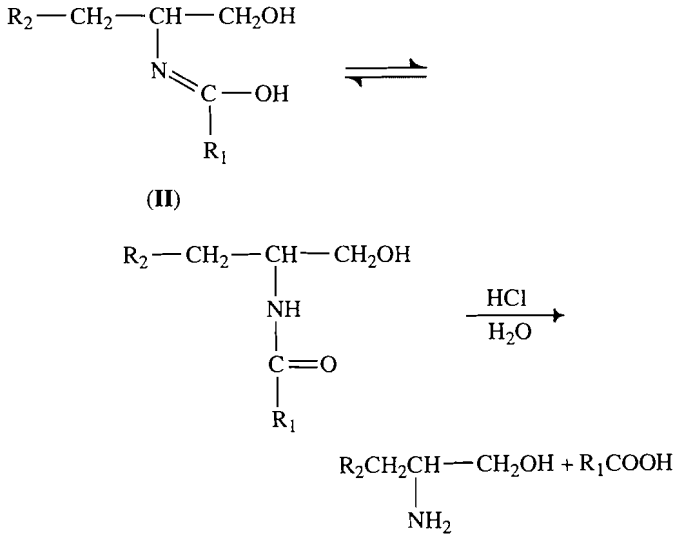
3. Reduction mechanism

The available data in the present study allow the following conclusions:



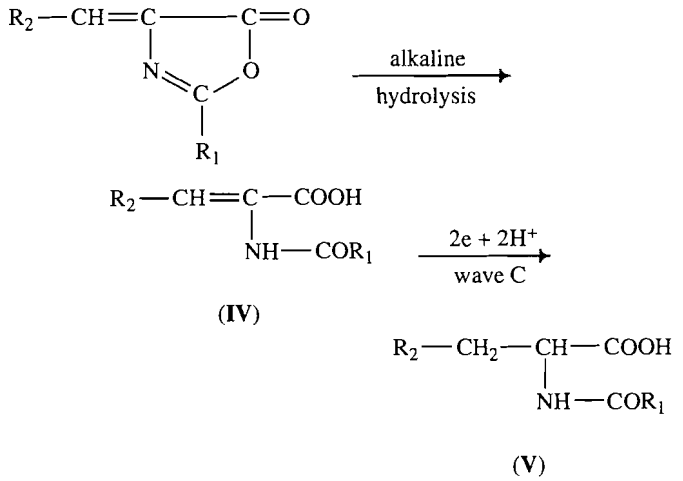
(a) At pH ≤ 7.2 (waves A and B)

Wave A represents the uptake of two electrons corresponding to the cleavage of the protonated oxazolone ring-oxygen (4) to give the corresponding aldehyde (**I**)



(**I**)

Wave B corresponds to a 4-electron reduction step, representing the reduction of α,β-unsaturated aldehyde (27, 28) to produce the corresponding saturated alcohol (**II**),



(**II**)

The proposed reduction mechanism was further supported by coulometric analysis of compound **1** in 50% ethanol – 0.05 M HCl carried out on the total limiting current. The main electrolysis product, 2-amino-3-phenylpropanol (**III**) could be identified by its mp and IR spectra (4, 11). Such electrolysis product can only be obtained through acid hydrolysis of benzoyl derivative of 2-amino-3-phenylpropanol (**II**) which is formed along wave B.

(b) At pH > 7.2 (wave C)

Based on the foregoing findings, oxazolones undergo hydrolysis in alkaline medium to form 2-benzoylaminocinnamic acid (**IV**) which is reduced at the DME via a two-electron step to form benzoyl derivative of phenyl alanine (**V**) (3).

4. Determination of electron affinities and ionization potentials of oxazolones

The half-wave reduction ($E_{1/2}^R$) and oxidation ($E_{1/2}^{OX}$) potentials for oxazolone derivatives under investigation were measured in DMF vs. SCE. The $E_{1/2}^R$ of the first wave A was taken as a measure of the electron affinity (EA) of the compound according to eq. [4] (29–31):

$$[4] \quad EA = -E_{1/2}^R + 2.49 \pm 0.26$$

The ($E_{1/2}^{OX}$) of organic compounds were directly related to the ionization potentials (IP) according to eq. [5] (32, 33):

$$[5] \quad IP = (1.478 \pm 0.027)E_{1/2}^{OX} + (5.821 \pm 0.009)$$

[a]Calculated using eq. [6].
[b]Values taken from ref. 9.

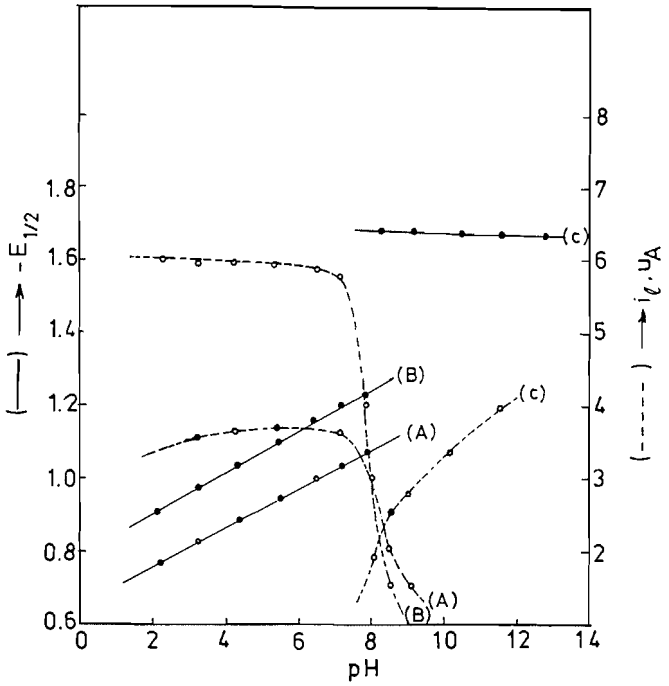

FIG. 5. The correlation of $E_{1/2}$ (—) and i_1 (···) with pH.

The values of $E^{R}_{1/2}$, $E^{OX}_{1/2}$, EA, and IP are listed in Table 2. It is worthy to mention that the polarographic behaviour of oxazolones in DMF, which is an aprotic solvent exhibiting no interaction with the oxazolones, is close to that in ethanolic buffer solutions at pH < 7.2 (Tables 1, 2). This may confirm that the obtained polarographic data in acidic media are confined to the compounds of interest and certainly not related to the hydrolytic product.

5. Effect of molecular structure on $E^{R}_{1/2}$ *and* E_{CT}

The electronic transition band (E_{CT}) of the studied oxazolones were measured in DMF (Table 2). From the obtained half-wave reduction potentials ($E^{R}_{1/2}$) and E_{CT} of oxazolone derivatives, one can conclude that the electron-donating substituents render the reduction process difficult and shifts the $E^{R}_{1/2}$ to more negative values and decreases the value of E_{CT}. However, the electron-attracting groups facilitate the reduction process leading to a decrease in delocalization within the oxazolone ring. On the other hand, the electroreduction of those compounds, when R_1 is the phenyl group, requires more energy than the electroreduction of the compounds containing a methyl group linked to a phenyl ring with donor character and steric effect. Thus, the $E^{R}_{1/2}$ of the former compounds should occur at more negative values and possess lower E_{CT} than the latter compounds.

The use of electrochemical redox potential data to interpret photochemical reactions, where the excited states undergo electron or charge transfer processes, was developed only recently (34–36). Accordingly, it was found interesting to correlate E_{CT} with the absolute difference between $E^{OX}_{1/2}$ and $E^{R}_{1/2}$. This runs in good harmony with the general correlation reported in literature for other types of molecules (36, 37). Analysis of our experimental data of $\Delta E_{1/2}$ and E_{CT} by the least-square sequential simplar method results in a linear equation [6], with an excellent correlation coefficient of 0.994.

$$[6]\quad \Delta E_{1/2}(E^{OX}_{1/2}-E^{R}_{1/2}) = -0.23(\pm 0.03)+0.279(\pm 0.009)E_{CT}$$

The validity of eq. [6] was tested by measuring and calculating either $E^{R}_{1/2}$, $E^{OX}_{1/2}$, or E_{CT} for some other oxazolone derivatives. The results show a good agreement between the calculated values and those measured experimentally as illustrated in Table 2. A trail was also made to compute the coulomb repulsion integral (36, 38) J_{12} according to eq. [7] (adopting the derived values of E_{CT} and $\Delta E_{1/2}$ in our present work),

$$[7]\quad E_{CT} = \Delta E_{1/2} - J_{12}$$

The data obtained are summarized in Table 2. It seems that the method of estimation of the parameter J_{12} given in this work

is much more direct and easier than the known complicated method based on semi-empirical molecular orbital theories.

Concerning the distant polar interaction in free energies of transfer. An explanation and an estimation procedure

J. Peter Guthrie

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received December 20, 1990[1]

J. Peter Guthrie. Can. J. Chem. **69**, 1893 (1991).

For polyfunctional compounds, free energies of transfer from gas to aqueous solution require corrections for the interactions of polar groups (Distant Polar Interactions). These corrections can be made with very few adjustable parameters by using a model of the solvation process assuming hydrogen bonding is the major source of the effect on free energy of transfer for polar groups, and that hydrogen bonding is perturbed by polar effects, measured by Taft σ^*. Parameters evaluated for polyfluoro, polychloro, and polybromo compounds successfully predicted the free energies of transfer for mixed polyhalogen compounds. Preliminary parameters have been evaluated for ethers, amines, phenyl groups, nitriles, and esters.

Key words: free energy of transfer, distant polar interaction, hydrogen bonding, solvation.

J. Peter Guthrie. Can. J. Chem. **69**, 1893 (1991).

Avec les composés polyfonctionnels, il est nécessaire de corriger les énergies libres de transfert de la phase gazeuse à des solutions aqueuses pour les interactions des groupements polaires (Interactions dipolaires à distance). On peut effectuer ces corrections avec un nombre limité de paramètres ajustables en utilisant un modèle du processus de solvatation basé sur l'hypothèse que les ponts hydrogènes sont la source principale de l'effet sur l'énergie libre de transfert pour les groupes polaires et que ces ponts hydrogènes sont perturbés par les effets polaires que l'on peut mesurer par le σ^* de Taft. Les paramètres évalués pour les composés polyfluorés, polychlorés et polybromés ont permis de prédire correctement les énergies de transfert de composés contenant un mélange d'halogènes. On a évalué les paramètres préliminaires pour les éthers, les amines, les groupes phényles, les nitriles et les esters.

Mots clés : énergie libre de transfert, interaction dipolaire à distance, liaison hydrogène, solvatation.

[Traduit par la rédaction]

Introduction

A longstanding goal of physical organic chemistry has been to explain chemical reactivity in terms of the structures of the reacting molecules. One way of approaching this goal is to look for ways to estimate enthalpies and free energies of formation of the species involved in reaction, so that the thermodynamics of the reaction can be used as a starting point for the explanation and prediction of reactivity. It has been found that thermodynamic quantities can be estimated quite reliably in terms of structural additivity (1–3). However, these quantities are estimated for the gas phase, and most organic reactions are carried out in solution. It was a major step forward when Hine and Mookerjee showed that free energies of transfer from the gas phase to aqueous solution could also be estimated in terms of structural additivity (4). A remaining problem, to which Hine and Mookerjee called attention, was that their scheme was only satisfactory for monofunctional compounds, because calculated free energies of transfer for polyfunctional compounds generally deviated from the experimental values by amounts much larger than were found for monofunctional compounds. This was attributed to distant polar interactions (DPI), which it was proposed were determined by hydrogen bonding interactions (4), but no way was suggested to estimate these interactions. Thus a large number of empirical corrections appeared necessary, and the usefulness of the estimation procedure for molecules of interesting complexity was severely restricted.

We wish now to report that a straightforward application of the assumption that the DPI is a linear function of the electron-withdrawing properties of other substituents on the molecule leads not only to a reliable way to estimate the DPI corrections, but allows an important reduction in the number of parameters needed to estimate the free energy of transfer. At least for the class of molecules with no hydrogens directly bonded to electronegative atoms, this means that the DPI problem is solved.

Results

We begin with an examination of the implications of the assumption that free energies of transfer are determined by relatively small and constant (i.e., independent of environment) contributions from hydrophobic solvation of the hydrocarbon moieties of a molecule and relatively large contributions from solvation of the electronegative atoms, by hydrogen bonding or other polar interactions. These polar contributions to solvation are assumed to be sensitive to the environment. In support of this analysis we quote the group contributions reported by Hine and Mookerjee for groups which can be represented by $[CH_2(X)_2]$, $[CH(X)_3]$, and $[C(X)_4]$, together with a few additional contributions based on measurements since this work. The values in Table 1 show that for X = C, in various bonding states, or for no more than one X being an electronegative atom, the group contribution is essentially constant, while if more than one X is an electronegative atom, the contributions are drastically different. This is a consequence of making the standard assumption, namely that all $[O(C)_2]$ groups are the same. This pushes all effects of the presence of more than one electronegative atom into the $[CH_n(X)_{4-n}]$ group contribution. We list the group contributions both as contributions to log γ ($\gamma = c_w/c_g$ (4)) and as contributions to ΔG_t (the free energy of transfer from gas at 1 atm (1 atm = 101.3 kPa) to aqueous solution at 1 M), which is directly applicable to the problem of calculating free energies of formation in solution. It is necessary to allow for the change in concentration units from gas to aqueous solution, so the calculation is:

$$\Delta G_t = 1.90 + \Sigma(\text{group contributions}) + \Sigma(\text{DPI})$$

First we examined the available data for haloalkanes to see

[i]Extrapolated from data at 10 and 15°C. These points defined a reasonable ΔH; if the data at 5°C were used as well, both ΔH and ΔC_p were needed and the values were not in reasonable accord with those for CF_4 and CF_3CF_3.

[j]Based on solubility data at a temperature other than 25°C; not included in the final least-squares fit.

whether such a treatment would work. Halocarbon data are relatively abundant because of the interest in their effects on the environment (5), and provide a convenient test set. We have found that what is, in effect, a two-parameter correlation for each halogen is sufficient. The two parameters were the number of halogen atoms and the sum of the Taft σ* values for substituents on the carbon bearing each halogen. Here we have in effect altered the parameterization from that used by Hine and Mookerjee, who made the normal assumption that univalent substituents should be incorporated into the group for the carbon bearing the substituents, as for example $[CHF_2(C)]$. If we assume that each halogen will affect the solvation of the other halogens or polar groups in the molecule, then we must treat each halogen as a group with a contribution, and a perturbation caused by the DPI. Here we are using the term DPI even for interactions of halogens bonded to the same carbon: while this is not really distant it allows us to continue using the accepted descriptor rather than inventing a new one. Thus in place of $[CHF_2(C)]$ we will use $2[F(C)] + [CH(X)_3]$. For each compound we calculated the sum of the contributions from the groups for C and H only, and then fitted the difference between this and the observed value to:

$$\delta\Delta G_t = n_F[F] + r_F\Sigma_F\sigma^*$$

The data are found in Table 2 and the quality of the fit is shown in Fig. 1. For other halogens analogous fits were obtained: chlorine, Table 3 and Fig. 2; bromine, Table 4 and Fig. 3; iodine, Table 5 and Fig. 4. For iodo compounds there are not enough data for a reliable determination of r_I.

A test of the general validity of these correlations is possible by examination of compounds with more than one kind of halogen. What we did was to use the parameters evaluated for compounds containing only fluorine, or only chlorine, or only bromine, along with the literature parameters for carbon groups, $[CH_n(X)_{4-n}]$, and calculate the free energy of transfer

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/07/12

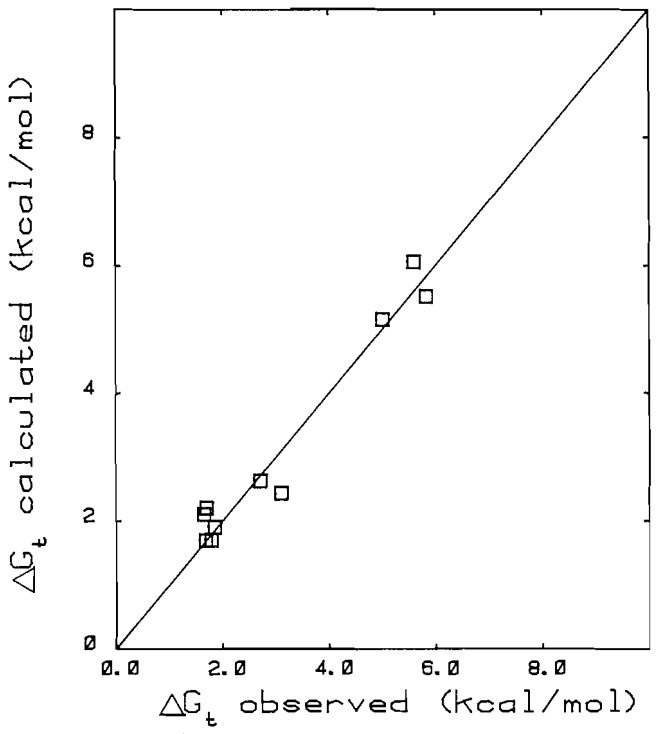

FIG. 1. Calculated vs. observed free energies of transfer for fluorine compounds.

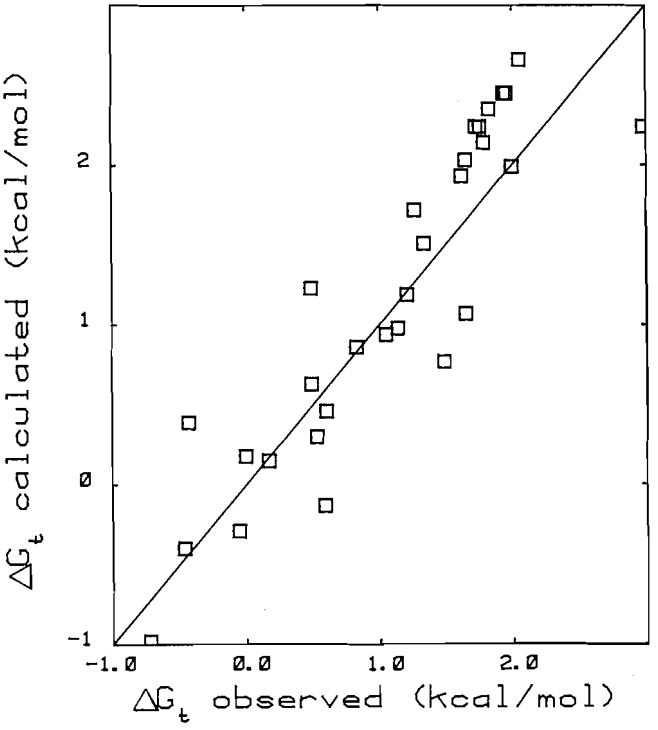

FIG. 2. Calculated vs. observed free energies of transfer for chlorine compounds.

for the mixed halogen compounds, with no adjustment of parameters.

The equation used to calculate these free energies of transfer is

$$\Delta G_t = n_3[CH_3(X)_1] + n_2[CH_2(X)_2] + n_1[CH_1(X)_3] + n_0[C(X)_4] + n_F[F] + r_F\Sigma_F\sigma^* + n_{Cl}[Cl] + r_{Cl}\Sigma_{Cl}\sigma^* + n_{Br}[Br] + r_{Br}\Sigma_{Br}\sigma^*$$

The quality of the match of calculated to experimental data, shown in Table 6 and Fig. 5, shows that we are indeed able to describe the free energies of transfer in terms of our DPI treatment with no additional parameters beyond those needed for compounds with only one kind of halogen. The rms deviation is 0.77, and as we will see when we consider possible sources of the larger deviations, in the Discussion, this may be higher than the true value.

Having demonstrated that the approach we are using provides not just a suitable correlation but also has good predictive powers, we now turn to other functional groups. For these the available body of data is more restricted. There has been, to date, insufficient motivation for gathering these data, which could not be satisfactorily correlated, even though polyfunctional molecules are likely to be the sorts of compounds where free energies of formation will be most useful.

The available body of data for non-halogen functional groups is collected in Table 7. We have limited ourselves to compounds where the interactions are through at least one sp^3 carbon. The problems of polysubstituted arenes or alkenes remain to be solved. To make maximum use of the meagre body of data, we have fitted all of the compounds at once, except for the iodo compounds where there is no overlap, since no free energies of transfer could be found for compounds containing iodine and another functional group. We have included the

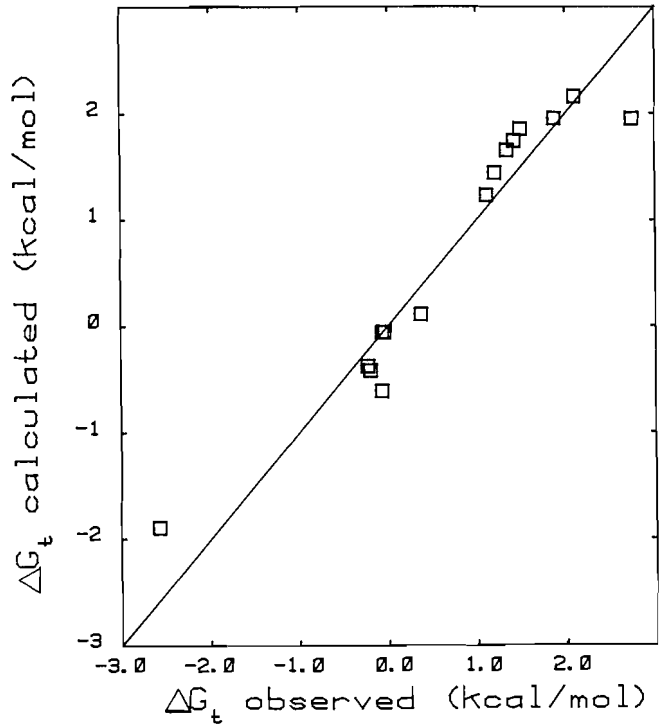

FIG. 3. Calculated vs. observed free energies of transfer for bromine compounds.

phenyl group in this treatment, using the published group contributions for aromatic C and H (4), but correcting for the effect of polar substituents. Obviously this can only apply for non-conjugated and unsubstituted phenyl substituents. The contributions from carbon groups, $[CH_n(C)_{4-n}]$, and from $[C_BH]$ and $[C_B(C)]$ were subtracted, and the remainders fitted by least

squares to:

$$\delta\Delta G_t = n_F[F] + r_F\Sigma_F\sigma^* + n_{Cl}[Cl] + r_{Cl}\Sigma_{Cl}\sigma^* + n_{Br}[Br] + r_{Br}\Sigma_{Br}\sigma^* + n_O[O(C)_2] + r_O\Sigma_O\sigma^* + n_N[N(C)_3] + r_N\Sigma_N\sigma^* + r_{Ph}\Sigma_{Ph}\sigma^* + n_{CN}[CN] + r_{CN}\Sigma_{CN}\sigma^* + n_{COO}[COO] + r_{CO_{COO}}\Sigma_{CO}\sigma^* + r_{O_{COO}}\Sigma_{O_{COO}}\sigma^*$$

where [ ] are the fixed contributions for the different groups and $\Sigma_X\sigma^*$ are the sums of the Taft σ^* values for the substituents on the carbon bonded to X. The ester group was initially assigned two polar contributions, the sums of the Taft σ^* values for the substituents on the carbon bonded to the carbonyl, and of the Taft σ^* values for the substituents on the carbon bonded to the oxygen. Least-squares evaluation of these parameters gave a good fit with only one deviation more than 1 kcal/mol, and an rms deviation of 0.539, but $r_{CO_{COO}}$ was undefined, i.e., the calculated uncertainty of the parameter was greater than its value. The least-squares fit was repeated with this parameter deleted from the model, and the resulting fit was essentially as good, but all parameters were now defined. The rms deviation was now 0.542. The revised model is

$$\delta G = n_F[F] + r_F\Sigma_F\sigma^* + n_{Cl}[Cl] + r_{Cl}\Sigma_{Cl}\sigma^* + n_{Br}[Br] + r_{Br}\Sigma_{Br}\sigma^* + O(C)_2]n_O + r_O\Sigma_O\sigma^* + N(C)_3]n_N + r_N\Sigma_N\sigma^* + r_{Ph}\Sigma_{Ph}\sigma^* + r_{CN}\Sigma_{CN}\sigma^* + COO]n_{COO} + r_{O_{COO}}\Sigma_{O_{COO}}\sigma^*$$

The quality of the fit is shown in Table 7 and Fig. 6.

All the σ^* values used in these correlations are given in Table 8. The final set of parameters is given in Table 9. It should be noted that the DPI can be quite large relative to the observed ΔG_t. For instance, from Table 2, $CF_3CF_2CF_3$, $\Sigma_F\sigma^*$ = 70.74, ΔG_t = 5.60; since r_F = 0.217 (Table 9), the DPI is 15.35, while the sum of group contributions (including the term for standard state adjustment) is −9.00, for a calculated value of 6.35. Clearly the DPI can have a major impact on the observable value, though it is often relatively small.

Discussion

We tested our model for the DPI by calculating values for mixed halogen compounds using only the parameters evaluated for compounds containing only fluorine or only chlorine or only bromine. This test was successfully passed, in that the observed and calculated values showed an rms deviation of 0.77. Nonetheless there were some disturbingly large deviations and we have examined these carefully. In most cases it seems likely that there are problems with the experimental results, because the values reported do not seem to be consistent with other data in the literature. Our approach in this examination is based on the assumption that one should have relatively smooth changes in ΔG_t for simple successive replacements of one halogen by another.

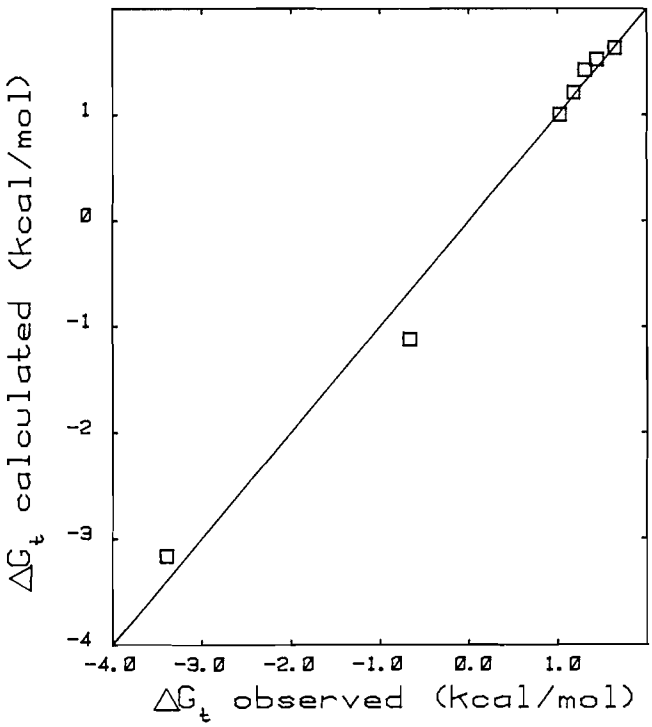

FIG. 4. Calculated vs. observed free energies of transfer for iodine compounds.

The first deviating compound was $CBrClF_2$. We look for a simple pattern in the series $CBrF_3$, $CBrClF_2$, $CBrCl_2F$, $CBrCl_3$, but cannot directly test the idea because values are only reported for the first two (Table 6) and the second is being examined. We can try the assumption that the series $CClF_3$, CCl_2CF_2, CCl_3F, CCl_4 should be similar, and here we have values of 4.17, 3.54, 2.85, and 2.00 respectively, for

[e]Calculated from the solubility of the gas at a total pressure of 1 atm (5).

[f]Calculated from the solubility of the liquid (5), and the vapor pressure (26).

[g]Reference 24.

[h]Calculated from the solubility of the liquid (5), and the vapor pressure (27).

[i]Calculated from the solubility of the gas at a total pressure of 1 atm (5); the solubility was measured at 30°C.

[j]Calculated from the solubility of the gas at a total pressure of 1 atm (5); the solubility was measured at 37°C.

[k]Calculated from the solubility of the liquid (5), and the vapor pressure (27). Horvath (5) gives two values for the solubility; we have used the value from a report by Imperial Chemical Industries (28); the value from Dreisbach (26) seems 10 times too high by comparison with solubilities of $Cl(CH_2)_3Cl$ and $Br(CH_2)_3Br$.

[l]$\Delta G_t = \Sigma[CH_n(X)_{4-n}] + [F]n_F + r_F\Sigma_F\sigma^* + [Cl]n_{Cl} + r_{Cl}\Sigma_{Cl}\sigma^* + [Br]n_{Br} + r_{Br}\Sigma_{Br}\sigma^*$; $[F] = -1.065$, $r_F = 0.221$, $[Cl] = -1.244$, $r_{Cl} = 0.170$, $[Br] = -1.525$, $r_{Br} = 0.155$, halogens only; $[F] = -1.095$, $r_F = 0.228$, $[Cl] = -1.221$, $r_{Cl} = 0.170$, $[Br] = -1.388$, $r_{Br} = 0.135$, all compounds.

[m]Based on solubility data at a temperature other than 25°C; not included in the final least-squares fit.

an increment, on replacing F by Cl, of −0.63, −0.69, and −0.85 respectively. Then from the value for $CBrF_3$, ΔG_t = 3.18 kcal/mol, one expects that ΔG_t for $CBrClF_2$ will be about 2.55 rather than the value of 1.28 derived from published data. The value calculated by the least-squares parameters is 2.78.

The next one to be examined is $CHBrF\text{-}CF_3$. The literature value for $CHBrCl\text{-}CF_3$ is 1.80 kcal/mol; using the increment for replacement of Cl by F deduced above we get an expected value of about 2.4 kcal/mol instead of the value of 3.63 derived from literature data. The value calculated using the least-squares parameters is 2.18.

Next we examine $CClF_2CF_3$. In the series CF_3CF_3; $CClF_2\text{-}CF_3$; $CClF_2CClF_2$; CCl_2FCF_3; CCl_2FCClF_2; CCl_2FCCl_2F; CCl_3CCl_3; we observe only one exception to a monotonic decrease in ΔG_t as F is replaced by Cl, namely $CClF_2CF_3$. The increment by which ΔG_t decreases as F is replaced by Cl gets larger as the replacement process continues, but clearly we expect a ΔG_t value closer to 5 than to 6 kcal/mol for $CClF_2CF_3$. This in fact is also predicted by our model.

Now we turn to $CH_2Br\text{-}CH_2Br\text{-}CH_2Cl$. We observe that the change from $CH_2Cl\text{-}CH_2Cl$ (ΔG_t = 0.17 kcal/mol) to $CH_2Br\text{-}CH_2Br$ (ΔG_t = −0.20 kcal/mol) is accompanied by a change in ΔG_t of −0.37 kcal/mol. Similarly the change from $CH_3\text{-}CHCl\text{-}CH_2Cl$ (ΔG_t = 0.60 kcal/mol) to $CH_3\text{-}CHBr\text{-}CH_2Br$ (ΔG_t = −0.04 kcal/mol) is accompanied by a change in ΔG_t of −0.64 kcal/mol. Thus we expect that ΔG_t will decrease on going from $CH_2Cl\text{-}CHCl\text{-}CH_2Cl$ (ΔG_t = −0.72 kcal/mol) to $CH_2Br\text{-}CH_2Br\text{-}CH_2Cl$ to perhaps −1.2 kcal/mol, and not to be 0.50 as calculated from the solubility and vapor pressure data in the literature. The value calculated using the least-squares parameters is −1.32 kcal/mol.

We conclude that the literature data are in many cases imprecise, and that errors have been propagated from one compilation to another, in considerable measure because there has

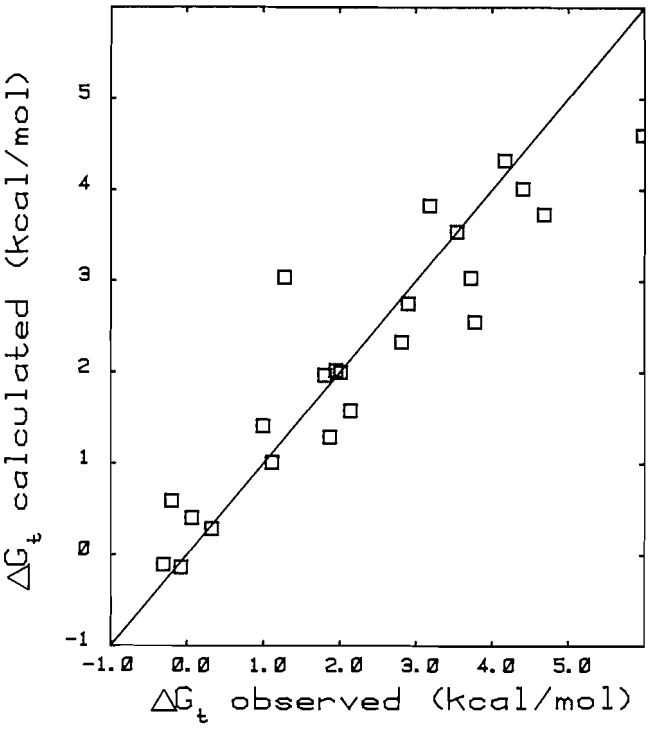

FIG. 5. Calculated vs. observed free energies of transfer for mixed halogen compounds.

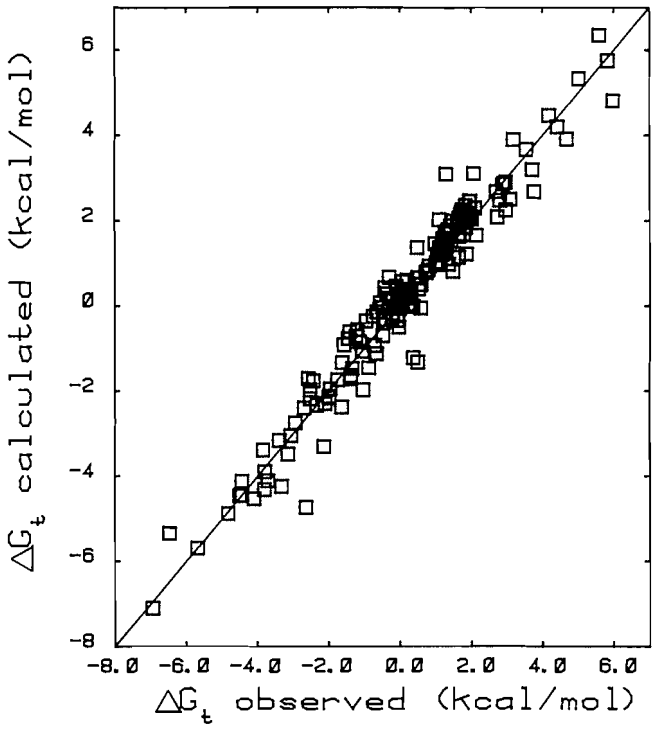

FIG. 6. Calculated vs. observed free energies of transfer for all compounds considered in this paper.

been no easy way to test values for reasonableness. Such a test is now feasible and it should be possible to avoid this class of errors in future.

Our treatment requires 17 parameters to fit 151 free energy of transfer values, with only 4 deviations greater than 1 kcal/mol. Three of these serious deviations represent compounds examined above, with the conclusion that the values reported are probably incorrect. Hine's treatment (4) would require 36 group contributions and 35 distant polar interactions (many based on only one compound) to fit the same set of data, and 32 compounds would have to be excluded as being unique within the group contributions framework. Cabani *et al.* published a different group contribution scheme (24), which for our set of 151 free energy of transfer values would require 14 group contributions and 70 corrections for polar interactions, most of them based on only one compound. The advantage of our treatment seems obvious.

There have been previous attempts, in addition to the schemes of Hine and Mookerjee (4) or Cabani *et al.* (24), to predict either solubility or free energies of transfer of organic compounds. Since, for sparingly soluble compounds, the solubility and vapor pressure permit the calculation of the free energy of transfer, and vapor pressures are relatively accessible (6–8), a reliable way to estimate solubility would be almost as valuable as a reliable way to estimate free energies of transfer. There would remain the problem of estimating the free energy of transfer for highly soluble compounds. Solubility has been successfully correlated with partition coefficient (9), with atomic and structural contributions (for halogenated hydrocarbons) (10), and with the surface areas of the polar groups (11, 12). Free energies of transfer have been fitted to the solvatochromic model (13). In the present context the deficiency in all of these efforts is in treating compounds with more than one nearby polar functional group. Although the partition coefficient is an additive constitutive property (14–16) it too is subject to distant polar interactions (17), for which there is not a good predictive method. Solubilities could be predicted successfully using surface areas and dipole moments, but the compounds fitted included few that were polyfunctional. Similarly the use of the solvatochromic method has concentrated on monofunctional compounds and it may be non-trivial to obtain values of the input parameters π, α, and β.

Recently there have been reports of calculational methods that hold promise of still more general solutions to the problem of calculating free energies of formation (18, 19). Both methods are computationally intensive, and although the algorithms are described, the programs to carry out the calculations are not widely available. Furthermore the data set used for initial testing has included almost entirely monofunctional compounds, so that at present it is not clear whether the promise of a general solution will be realized.

One advantage of our method is that it allows us to estimate, with some confidence, free energies of transfer for molecules for which direct measurement is not possible, because the compound of interest reacts rapidly with water. This is a problem that we have encountered (20, 21), and continue to encounter, in our research on analogs of tetrahedral intermediates and other metastable reaction intermediates.

Our treatment successfully handles ethers and tertiary amines, but does not fit alcohols or primary or secondary amines. These are, in polyfunctional compounds, likely to engage in intramolecular hydrogen bonding in the gas phase, and this will strongly perturb the free energy of transfer. Our approach could be used if one could calculate the equilibrium constant for formation of such intramolecular hydrogen bonds in the gas phase, but this is not yet possible.

The results presented above show that we have been able to account for DPI in substituted alkanes in terms of a simple

O_{COO}	0.309 ± 0.093

[a]All at 25°C; free energies of transfer from ideal gas at 1 atm to ideal 1 M aqueous solution with an infinitely dilute reference state. Unless otherwise noted, parameters were evaluated by least squares as described in the text.
[b]Calculated from the parameters in ref. 4.
[c]Contribution for the phenyl substituent, calculated from the contributions for the groups making it up as $5[C_BH] + [C_B(C)]$.

model with a very limited number of parameters. Moreover, we have been able to diminish very markedly the number of parameters required to predict ΔG_t for this class of compounds. The parameterization scheme proposed by Hine and Mookerjee was very successful in fitting the available data for monofunctional compounds, for which 22 group contributions were evaluated, but less successful for di- or polyfunctional compounds, where it was clear that a large number of DPI parameters would be needed; 13 could be evaluated from the data available then. However, this scheme included only a small fraction of the parameters that would be needed to cover all possible types of compound with 1, 2, 3, or 4 substituents on a central carbon, the substituents being C, N, O, F, Cl, Br, or I; in fact 336 group contributions would be needed, and a very large number of DPI terms. This combinatorial explosion makes some simpler method for estimating ΔG_t very important.

Hine and Mookerjee (4) suggested that DPI were often attributable to effects on hydrogen bonding, and we used hydrogen bonding as the mental model for the DPI in developing our approach. It must be remembered that, particularly for the polyhalogenated compounds, this may not be the correct description; by the empirical test of successful prediction there exists some polar effect upon the free energy of transfer. Jencks has suggested that hydrogen bond strength should follow basicity measured by pK_a with a Brønsted slope of approximately 0.2 (22). Since basicity depends on substituent effects at the carbon bearing the basic atom with a Taft ρ* of approximately 1.8 (23), we expect a slope of free energy of hydrogen bonding vs. Σσ* of $1.366 \times 0.2 \times 1.8 = 0.49$, which is approximately the value found: see Table 9. The behavior that we observe seems consistent with expectation for hydrogen bonds. That the DPI for halogens have some hydrogen bonding component may be indicated by the decreasing sensitivity to polar effects as the atom becomes larger.

We explored the possibility that the solvent-accessible surface area for the functional groups in a molecule would provide a measure of steric hindrance to solvation. It seemed plausible

that such hindrance might modulate the solubilizing effect of polar groups. However, we found that the coefficients for such areas were all undetermined when this more elaborate parameterization was used for least-squares fitting, i.e., the errors calculated by the least-squares program were larger than the parameters. Thus there was no advantage to including solvent-accessible surface areas, which required some computational effort to determine.

We conclude that it is now possible to estimate the free energy of transfer for a wide range of polyfunctional organic compounds that are derivatives of alkanes, with phenyl treated as a special kind of univalent substituent. Although the predictions are not as precise as were achieved for monofunctional compounds by the schemes of Hine and Mookerjee (4) or Cabani *et al.* (24), the ability to treat polyfunctional compounds with confidence and with a much smaller set of parameters more than compensates. Further efforts should lead to improved predictive schemes.

Dihydroxyacids from the chlorination of ketones: an unexpected process

J. PETER GUTHRIE,[1] JOHN COSSAR, AND JINQIAO LU
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

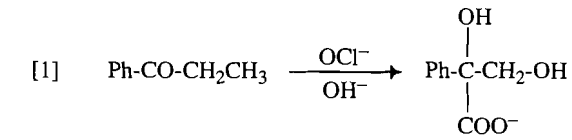
Received January 18, 1991

J. PETER GUTHRIE, JOHN COSSAR, and JINQIAO LU. Can. J. Chem. **69**, 1904 (1991).

Chlorination of propiophenone in aqueous alkali at room temperature, with low concentrations of hypochlorite, leads to 2-phenylglyceric acid as the major product. This acid is formed by further oxidation of 1-phenyl-1,2-propanedione, which is an intermediate in the oxidation of propiophenone. Formation of this acid is reasonable in the light of other halogenation chemistry. Analogous reactions are observed for butyrophenone, which yields 2,3-dihydroxy-2-phenylbutanoic acid, and for cycloheptanone, which yields 1,2-dihydroxycyclohexanecarboxylic acid.

Key words: 2-phenylglyceric acid, propiophenone, chlorination, hydrolysis, rearrangement, cycloheptanone, 1,2-dihydroxycyclohexanecarboxylic acid.

J. PETER GUTHRIE, JOHN COSSAR et JINQIAO LU. Can. J. Chem. **69**, 1904 (1991).



La chloration de la propiophénone, en solution aqueuse alcaline, à température ambiante, à faibles concentrations d'hypochlorite, conduit à la formation d'acide 2-phénylglycérique comme produit principal. Cet acide se forme par une oxydation subséquente de la 1-phényl-propane-1,2-dione qui se forme comme intermédiaire lors de l'oxydation de la propiophénone. La formation de cet acide peut être attendue à la lumière d'autres résultats obtenus dans la chimie des halogénations. Des réactions analogues ont été observées avec la butyrophénone qui conduit à l'acide 2,3-dihydroxy-2-phénylbutanoïque et avec la cycloheptanone qui conduit à l'acide 1,2-dihydroxycyclohexanecarboxylique.

Mots clés : acide 2-phénylglycérique, propiophénone, chloration, hydrolyse, réarrangement, cycloheptanone, acide 1,2-dihydroxycyclohexanecarboxylique.

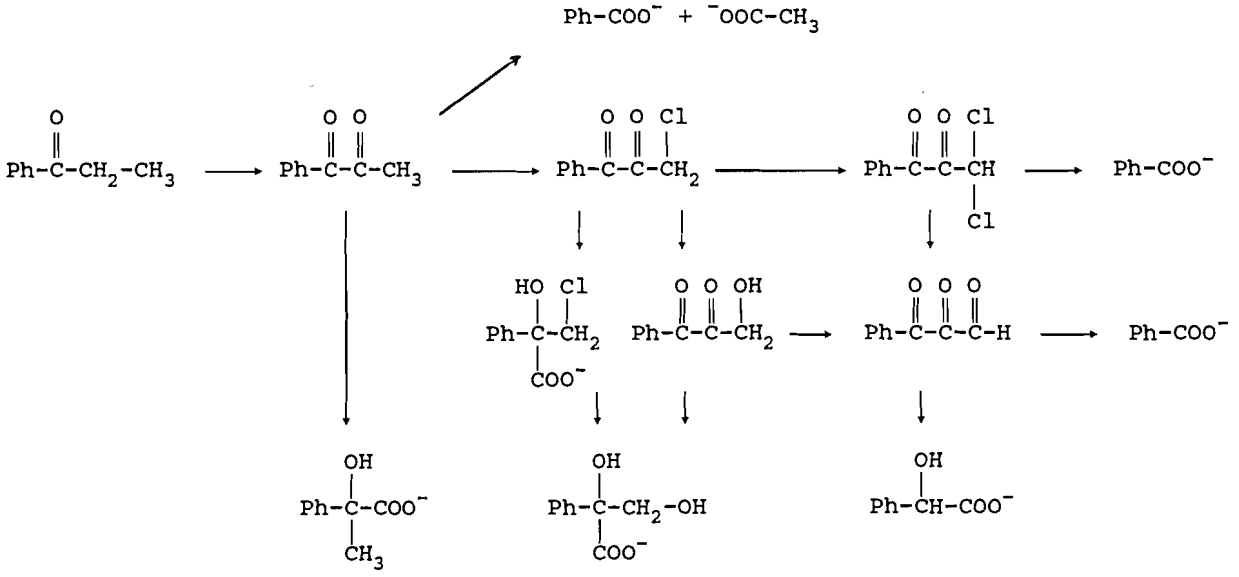
Chlorination of ketones is a well-known reaction, which has been used for many years. Nevertheless it can still give rise to unexpected products even with simple ketones: for example, acetone can give major amounts of lactic acid (1). The halogenation of propiophenone has been reported to give rise to benzoic acid (2, 3) and acetic acid (3). We wish to report that under some conditions the major product of the chlorination of propiophenone is 2-phenylglyceric acid, reaction [1], and that this appears to be a general reaction.

Results

2-Phenylglyceric acid was the major product when propiophenone in 1 M aqueous NaOH was treated with 4.05 equivalents of NaOCl solution. The hypochlorite was added slowly over 5 h, then excess oxidant was destroyed by adding $NaHSO_3$ solution. Acidification and extraction gave a product mixture shown by NMR analysis to contain small amounts of benzoic, mandelic, and atrolactic acids, but to be principally 2-phenylglyceric acid. This identification is based on comparison of NMR spectra with those of an authentic sample prepared by the literature route (4–6). ^1H NMR spectra in D_2O (Na salt) or CD_3OD were identical for both samples. The crude product mixture upon crystallization from 1:1 ethyl acetate – petroleum ether gave phenylglyceric acid of mp 146.5–148°C (lit. mp 145–146°C (7), 149°C (8), 146–148°C (9); mixture mp with an authentic sample, 148°C). The yield of 2-phenylglyceric acid was 75% by NMR analysis, 64% based on crystalline product.

In the early stages of the investigation, before yields had been improved by rational variation of the reaction conditions, we found that formation of the methyl ester and acetylation gave material that was better suited to column chromatography and separation of the various products.



The reaction appears to be general. When we used butyrophenone as substrate, the major product crystallized from the acid extract, mp 125–133°C. The yield based on NMR analysis was 51%, and 32% based on crystalline material. This product had a 200 MHz ^1H NMR consistent with a mixture of diastereomeric 2,3-dihydroxy-2-phenylbutyric acids.

Oxidation of cycloheptanedione by lead tetraacetate has been reported to give, as a minor by-product, a compound identified as 1,2-dihydroxycyclohexanecarboxylic acid, although no rigorous structure proof was reported (10). We have found that chlorination of cycloheptanone by aqueous alkaline hypochlorite, with a high ratio of $[HO^-]$ to $[OCl^-]$, gives a useful yield of 1,2-dihydroxycyclohexanecarboxylic acid in one step. This reaction is more complex than the oxidations of alkyl aryl ketones, because of the possibility of Favorskii rearrangement, and the greater likelihood of aldol condensations because of the inherently greater reactivity of dialkyl ketones (11). Although the yield of 1,2-dihydroxycyclohexanecarboxylic acid was improved by lowering the hypochlorite concentration, preferably by use of a motor-driven syringe to add sodium hypochlorite solution, too low a concentration of hypochlorite led to decreased yields of acidic products, and a greater yield of neutrals, presumably the result of coupling reactions. Favorskii rearrangement leading to cyclohexanecarboxylic acid was a major side reaction, as was cleavage to pimelic acid. Nonetheless, under the best conditions that we found (1 g of cycloheptanone in 1 L 1 N aqueous NaOH, to which 60 mL "Javex" was added at a rate of 0.15 mL/min), 1,2-dihydroxycyclohexanecarboxylic acid would crystallize from the crude reaction product.

Discussion

We believe that the reaction of propiophenone proceeds via 1-phenyl-1,2-propanedione as an intermediate: see Scheme 1. That this dione is an intermediate in the halogenation of propio-

[1]Author to whom correspondence may be addressed.

SCHEME 1

phenone has been proposed before (2). Consistent with this mechanistic proposal, 1-phenyl-1,2-propanedione also gives 2-phenylglyceric acid upon chlorination in alkali. Reaction in 0.5 N NaOH, 0.012 N NaOCl, leads to 2-phenylglyceric acid in 67% yield based on NMR analysis, 48% based on crystalline product.

We propose that 1-phenyl-1,2-propanedione undergoes halogenation followed by a benzilic acid rearrangement to give 3-chloro-2-hydroxy-2-phenylpropanoate, which then undergoes hydrolysis to form 2-phenylglycerate. Consistent with this proposal, the yield of 2-phenylglyceric acid is increased by raising the hydroxide concentration, and lowering the hypochlorite concentration, i.e., by increasing the $[OH^-]/[OCl^-]$ ratio: see Table 1. This could be done by lowering the initial hypochlorite concentration or by adding the hypochlorite slowly rather than all at the start of the reaction. The competing pathways, whether the key intermediate is the hydroxy- or chloro-phenylpropanedione, are further chlorination or rearrangement. Chlorination will be first order (or zero order) in hydroxide (1) because the enolate reacts with hypochlorite ion; rearrangement may be first or second order in hydroxide depending on whether the mono- or di-anion of the tetrahedral adduct rearranges. Thus raising the ratio $[OH^-]/[OCl^-]$ should give more rearrangement and improve the yield, which it does.

Initially we suspected that the rearrangement involved the α-hydroxy derivative of the dione, i.e., 3-hydroxy-1-phenyl-1,2-propanedione. We now favor the involvement of the precursor to this hydroxy compound, i.e., 3-chloro-1-phenyl-1,2-propanedione, as the key intermediate which rearranges. A chloro substituent is likely to be better at stabilizing a "methide" migrating group than is a hydroxyl. In any event, it seemed of interest to determine whether 3-hydroxy-1-phenyl-1,2-propanedione would give rise to 2-phenylglyceric acid. 3-Hydroxy-1-phenyl-1,2-propanedione has been reported (12) but never purified; we thought it plausible that 3-hydroxy-1-phenyl-1-propanone might give rise to 3-hydroxy-1-phenyl-1,2-propanedione and that in alkaline solution 3-dimethylamino-1-propanone might give rise to 3-hydroxy-1-phenyl-1-propanone. In the event, reaction of 3-dimethylamino-1-phenyl-1-propanone with alkaline hypochlorite gave rise to phenylglyceric acid. This is a permissive rather than a conclusive experiment, but certainly suggests that 3-hydroxy-1-phenyl-1,2-propanedione is capable of forming 2-phenylglyceric acid under our reaction conditions.

TABLE 1. Effect of reagent concentrations upon 2-phenylglycerate yield[a]

$[OH^-]$	$[OCl^-]$	$[OH^-]/[OCl^-]$	Yield of 2-PGA (%)

[a]Reactions carried out in water at 25°C.

[b]NaOCl solution added gradually: concentration would have been 0.01 M had it been added all at once.

Atrolactic acid is known to form by hydroxide-catalyzed rearrangement of phenylpropanedione (3). Benzoic acid can arise in various ways, including direct oxidative cleavage of phenylpropanedione by hypochlorite. Extensive oxidation of phenylpropanedione can also plausibly lead to benzoic acid. Mandelic acid is likely to arise from phenylglyoxal (13), which in turn might arise in various ways, most plausibly from phenylpropanetrione; see Scheme 1. Further investigations to unravel this complicated network of reactions are currently underway.

The stereochemistry of the 1,2-dihydroxycyclohexanecarboxylic acid produced from cycloheptanone is not rigorously defined by the ^{13}C NMR although comparison of the observed chemical shifts with values calculated from those for cyclohexanecarboxylic acid by additivity rules (14) suggest that the two OH groups are *trans*. Mechanistic arguments, assuming rearrangement of the chloride, suggest that the product should have the OH groups *trans*. If the conversion of CH-Cl to CH-OH takes place after rearrangement, then it must involve displacement of axial Cl by an internal nucleophile. If this is OH (or O^-), then diaxial opening leads to the isomer with the two OH groups *trans*. If the internal nucleophile is COO^-, then for it to have been axial while Cl was also axial requires the OH on carbon 1 to have been *cis* to the Cl. After internal displacement the OH will be *trans* to the oxygen of the β-lactone. This will open by

SCHEME 2

$B_{AC}2$ attack on the carbonyl, leading to the isomer with the OH groups *trans*.

The reaction of cycloheptanone with alkaline hypochlorite has numerous possible paths, Scheme 2, and it is not surprising that a number of products are formed. Complete optimization would require considerable investigation, but we have been able to demonstrate that the yield of the dihydroxyacid can be increased to the point of being useful with a modest amount of rational variation.

The reaction reported here represents the simplest preparation of either 2-phenylglyceric acid or 1,2-dihydroxycyclohexanecarboxylic acid reported to date, and appears to be a general way to effect the unusual transformation:

$$\text{R-CO-CH}_2\text{-CH}_2\text{-R'} \longrightarrow \text{R-C(OH)(COOH)-CH-R'}$$

An important restriction on the generality of this process is the requirement that the rest of the molecule be resistant to attack by alkaline hypochlorite, which is a powerful oxidant.

Experimental

Materials

Propiophenone (Aldrich), butyrophenone (Aldrich), cycloheptanone (Aldrich), 1-phenyl-1,2-propanedione (Aldrich), and cyclohexanecarboxylic acid (Eastman) were commercial materials. β-Dimethylaminopropiophenone · HCl was prepared by the literature route (15). Sodium hypochlorite solution was either Baker 5% reagent or Javex.

Methods

The presence of hypochlorite in a reaction mixture was tested for, using starch–iodide paper. Carboxylic acid products were detected on TLC plates by spraying with bromocresol green solution. Preparative layer chromatography of acids was carried out using solvents containing acetic acid to prevent tailing. The solvent was driven off after development by heating the plate at 50°C for 16 h. Bands could then be visualized by spraying with bromocresol green solution.

Propiophenone to 2-phenyl-2,3-dihydroxypropanoic acid

Propiophenone, 204 mg (1.50 mmol), was dissolved in a small amount of methanol (5 mL) and added with stirring to 1 L of 0.46 M NaOH, 0.54 M KCl, 0.01 M NaOCl and allowed to react at room temperature for 3 h. Reaction was stopped by the addition of $NaHSO_3$ (1.1 g) and the basic solution was extracted with ether (3 × 100 mL). Drying (Na_2SO_4) and evaporation gave 2 mg of oil, which had no distinct signals in proton NMR. The aqueous solution was cooled in ice, made acidic with concentrated HCl (45 mL), and extracted with ether (3 × 200 mL). Drying and evaporation gave 116 mg of oil, which partially crystallized on standing. Since only about 60% of the expected product had been recovered it was assumed that the remainder might be extracted by a more polar solvent. A further extraction with ethyl acetate (400 mL) yielded 62 mg of a colorless oil, which crystallized on standing and which was not soluble in chloroform. A third extraction of the aqueous solution with ethyl acetate (2 × 250 mL) gave another 60 mg with a proton spectrum similar to the second extract. Analysis by ^{1}H NMR, using integration of appropriate peaks, after the major product had been identified as 2-phenylglyceric acid, showed that the combined crude product consisted of 15% benzoic, 24% mandelic, and 57% phenylglyceric acids.

A similar product study starting with mandelic acid exposed for 1 h to aqueous 0.5 M OH^-, 0.03 M OCl^-, treated with sulphite, acidified and extracted with EtOAc resulted in 92% recovery of mandelic acid with no other products detectable by ^{1}H NMR (1:3 CD_3OD–$CDCl_3$), δ (TMS): 5.14 (s, -C*H*(OH)-COOH), 5.13 (s, -O*H*), 7.32 (m, C_6H_5).

Propiophenone to 2-phenyl-2,3-dihydroxypropanoic acid

Propiophenone, 643 mg (4.79 mmol), was dissolved in a small

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

amount of methanol (15 mL) and added with stirring to 1 L of 0.46 M NaOH, 0.54 M KCl, 0.03 M NaOCl and allowed to react at room temperature for 3 h. Reaction was stopped by addition of $NaHSO_3$ (4.5 g) and the basic solution was extracted with ether (3 × 100 mL) to remove any neutral products.

The aqueous solution was concentrated to 350 mL, cooled in ice, made acidic with concentrated HCl (45 mL) and extracted with ethyl acetate (5 × 100 mL), dried (Na_2SO_4), and evaporated, yielding 915 mg white solid. ^1H NMR analysis revealed a similar composition to the first product study. Aromatic signals for benzoic acid at 8.02 and 8.06 ppm made up only 11.5% of the total of aromatic signals, indicating only 29 mol% benzoic acid in the product mixture. A signal at 5.20 indicated 18 mol% mandelic acid, and the pair of doublets at 3.76 and 4.29 (J = 11) indicated 41 mol% (assuming 1H per doublet) of 2-phenylglyceric acid.

The UV spectrum in water showed short-wavelength absorption with no pronounced maximum. From the absorption at 225 nm (λ_{max} for benzoate in water, ϵ_{max} = 10 000) we calculated a maximum yield of 32 wt.% of benzoate in the crude product. Since ^1H NMR revealed 29 mol% benzoic acid, the other products cannot have much absorbance at this wavelength.

The entire product (915 mg) was refluxed in methanol containing 5 vol.% H_2SO_4 for 90 min, poured into ice water (100 mL), and extracted with ethyl acetate (3 × 100 mL). The extract was dried (Na_2SO_4) and evaporated, yielding 849 mg liquid. TLC with 15% EtOAc – petroleum ether gave four spots (UV-active), R_f's 0.7, 0.6, 0.3, and 0.25. The fastest moving spot had the same R_f as methyl benzoate.

The entire batch of methyl ester was treated with excess Et_3N – acetic anhydride (3 mL, 2.5 mL) with 15 min heating on a steam-bath followed by addition of methanol (3 mL) and extraction, drying, and evaporation as before, yielding 866 mg. Column chromatography (silica, 40 g; 0–25% EtOAc–hexanes) on the esterification mixture gave the following fractions: 104 mg methyl benzoate; 144 mg methyl *O*-acetylmandelate; 425 mg material later identified as methyl 3-acetoxy-2-hydroxy-2-phenylpropanoate. This material was crystallized from ether – petroleum ether, mp 59.5–60°C; ^1H NMR ($CDCl_3$), δ: 2.07 (3H, s, CH_3-CO), 3.82 (3H, s, CH_3O), 4.0 (1H, br, O*H*), 4.38 and 4.71 (2H, doublets of an AB quartet, J = 11 Hz, CH_2), 7.32–7.63 (5H, C_6H_5); ^{13}C NMR, δ: 20.71 (CH_3-CO), 53.46 (CH_3-O), 68.83 (CH_2-OAc), 77.63 (quaternary C), 125.60, 128.52, 128.58 (aromatic), 170.60 (CH_3-*CO*), 173.14 (*CO*-OCH_3). A 200 MHz proton spectrum in $CDCl_3$ revealed one *O*-methyl (3H, s) at 3.82 ppm, one *O*-acetyl group (3H, s) at 2.07, one broad OH group signal at 4.0 ppm, two doublets (J = 11.4) centred at 4.71 and 4.38 ppm, 3H aromatic (m) 7.32–7.40, and 2H aromatic (m) 7.58–7.63 ppm.

O-*Acetylmandelic acid methyl ester* (ref. 16)

Mandelic acid, 1.3 g, was refluxed 90 min in 5% H_2SO_4 in methanol, 50 mL, the solution poured into 150 mL ice water, and extracted with ethyl acetate, 3 × 100 mL. After evaporation, the product was treated with a mixture of 3 mL acetic anhydride, 3 mL Et_3N, heated on a steam bath 15 min, diluted with methanol, 5 mL, washed into a separatory funnel with water, 100 mL, and extracted with ethyl acetate, 300 mL. The organic layer was washed first with dilute acid (0.1 M H_3PO_4), then with dilute base (0.1 M NaOH) dried (Na_2SO_4), and evaporated, yielding 0.86 g oily liquid (48%). ^1H NMR spectrum ($CDCl_3$), δ (TMS): 7.40–7.48 (2H, m), 7.32–7.40 (3H, m), 5.93 (1H, s), 3.69 (3H, s), 2.17 (3H, s).

Propiophenone to 2-phenyl-2,3-dihydroxypropanoic acid

Propiophenone, redistilled, 647 mg (4.82 mmol), was dissolved in 5 mL methanol and added to 500 mL deoxygenated 1 M aqueous NaOH with vigorous stirring. A solution of NaOCl (0.3 M) was slowly added (65 mL, (19.5 mmol) over a period of 5 h). In the first 30 min, 35 mL was added, whereupon all of the ketone dissolved and the solution became deep yellow. In the second 30 min, 5 mL was added, followed by 10 mL the second hour, 5 mL after 4 h, and another 10 mL after 5 h. The reaction temperature was 28°C. The yellow colour began to fade after the last addition of hypochlorite. After 8 h, OCl^- was still present (iodide test), and was destroyed by reaction with $NaHSO_3$ (0.5 g). An ether extract of the basic solution (3 × 100 mL) yielded 20 mg brown oil (3%).

Half the water was evaporated from the basic solution before acidifying with concentrated HCl (45 mL). The ethyl acetate extract (4 × 200 mL) yielded 852 mg, which by ^1H NMR analysis was estimated to contain: 75% 2-phenylglyceric acid, doublets at 3.73 and 4.26 ppm; 7% atrolactic acid, singlet at 1.78 ppm; 7% benzoic acid, multiplets at 8.0–8.05 ppm; 9% mandelic acid, singlet at 5.18 ppm. The presence of atrolactic acid was confirmed by addition of 5 mg of authentic sample, which caused the sharp singlet at 1.78 ppm to double in intensity, thus confirming the proton assay.

Crystallization from 1:1 ethyl acetate – petroleum ether gave 564 mg 2-phenylglyceric acid (3.10 mmol, 64%), mp 146.5–148°C (lit. mp (7) 145–147°C; (8) 149°C; (9) 146–148°C; mixture mp with an authentic sample, 148°C). ^1H NMR (CD_3OD), δ (TMS): 3.73 and 4.26 (AB quartet), 7.24–7.66 (multiplet), and comparison with an authentic sample prepared by the literature route (4–6). ^1H NMR spectra in D_2O (Na salt) or CD_3OD were identical for both samples.

1-Phenyl-1,2-propanedione to 2-phenyl-2,3-dihydroxypropanoic acid

1-Phenyl-1,2-propanedione, 710 mg (4.79 mmol), was dissolved in a small amount of methanol (5 mL) and added with stirring to 1 L of 0.50 M NaOH, 0.5 M KCl, 0.012 M NaOCl and allowed to react for 3 h at room temperature. The initial yellow colour disappeared within 2 min. Reaction was stopped by addition of $NaHSO_3$ (1.1 g) and the basic solution was extracted with ether (3 × 100 mL). Evaporation gave no detectable products by TLC. The aqueous solution was cooled in ice, made acidic with concentrated HCl (45 mL), and extracted with ethyl acetate (3 × 200 mL). Drying and evaporation gave 933 mg of oil, which partially crystallized on standing. TLC (2% AcOH, 10% MeOH, 88% $CHCl_3$) showed a spot with the same R_f, 0.6, as benzoic acid. A 200 MHz proton spectrum of the acid extract (in $CDCl_3$ – 10% CD_3OD) indicated 22% benzoic, 14% mandelic, and 58% phenylglyceric acids by integration. The mixture of acids was dissolved in a minimum amount of methanol and crystallized from 88% benzene, 10% hexanes, 2% methanol, yielding 416 mg of almost pure 2-phenylglyceric acid (2.28 mmol, 47.6%), mp 143–145.5°C. ^1H NMR (CD_3OD), δ: 3.71 (1H, d, J = 11.3), 4.23 (1H, d, J = 11.3), 4.98 (4H, b, OH), 7.3–7.4 (3H, m), 7.6–7.7 (2H, m). A recrystallization from 1:1 ethyl acetate – pet. ether gave 279 mg (32%), mp 147–148.5°C (lit. mp (7) 145–147°C; (8) 149°C; (9) 146–148°C). The acids from the mother liquor were esterified with methanol – 5% H_2SO_4 (50 mL) with 3 h refluxing, diluted with ice-water (50 mL), and extracted with ethyl acetate (3 × 50 mL), yielding 490 mg (85–90% of expected), which was estimated by proton NMR to contain 41% benzoate (signals at 8.0–8.05), 21% mandelate (singlet at 5.19), and 38% 2-phenylglycerate (doublet at 4.32). Total assay: 2-phenylglyceric acid, 3.23 mmol (67%); benzoic acid, 1.03 mmol (21%); mandelic acid, 0.53 mmol (11%).

β-Dimethylaminopropiophenone · HCl to 2-phenyl-2,3-dihydroxypropanoic acid

β-Dimethylaminopropiophenone · HCl (15), 450 mg (2.11 mmol), was dissolved in a small amount of water (5 mL) and added to 500 mL 1 M NaOH, 0.02 M NaOCl with rapid stirring at room temperature. Initially, organic material began to oil out but redissolved within 1 min. A yellow colour appeared in the first minute but disappeared within 5 min. An acrid odour, probably of *N*-chlorodimethylamine, was produced. The vapors above the reaction solution produced a quick reaction with starch–iodide paper. Reaction was stopped after 3 h by addition of $NaHSO_3$ (1.0 g) and the solution brought to pH 7 by addition of 4 M H_3PO_4 (100 mL). The neutral solution was extracted with ether (3 × 100 mL); the evaporated ether extracts (15 mg) gave no signals in the proton NMR corresponding to likely products. The aqueous solution was acidified with 6 M HCl (100 mL) and extracted with ethyl acetate (4 × 200 mL). The extract was dried (Na_2SO_4) and evaporated, yielding 283 mg of a mixture of benzoic, mandelic, and 2-phenylglyceric acids (2-PGA). ^1H NMR spectrum (70:30 $CDCl_3$–CD_3OD), δ (TMS): 1.99 (s, acetic acid), 3.76 (d, J = 11.4, CH_2 of 2-PGA), 4.30 (d, J = 11.2, CH_2 of 2-PGA), 5.19 (s, CH of mandelic acid), 6.1 (s, b, OH), 7.2–7.7 (m, aromatic), 8.0–8.1 (m, aromatic *ortho* to COOH). Assay based on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

integration: 28% benzoic; 44% mandelic; 28% 2-phenylglyceric acids. Based on the proton assay and the weight of product, the acids recovered represent 1.86 mmol, 89% of starting material.

Butyrophenone to 2,3-dihydroxy-2-phenylbutanoic acid

Butyrophenone, 744 mg (5.02 mmol) was dissolved in methanol (5 mL) and added with stirring to an aqueous solution of 1 M NaOH, 0.03 M NaOCl, 1 L (30 mmol, sixfold excess). After 3 h with vigorous stirring, the ketone was completely dissolved and most of the hypochlorite was gone. Hypochlorite solution (0.3 M), 20 mL (6 mmol), was added, and after an additional 2 h hypochlorite was still present. The excess was destroyed by addition of $NaHSO_3$ (2.0 g) and the basic solution was extracted with ether (3 × 200 mL), yielding 15 mg semi-solid, which had only one spot by TLC (10% EtOAc – 90% petroleum ether) with R_f value 0.24, not the same as butyrophenone, R_f 0.54. No further attempt was made to identify this product.

After acidifying with concentrated HCl (45 mL), the solution was extracted with ethyl acetate (4 × 150 mL), which, after drying (Na_2SO_4) and evaporation, yielded 684 mg colorless syrupy liquid. Crystallization from CCl_4 (20 mL) yielded 311 mg (1.59 mmol, 31.6%), mp 125–133°C; 200 MHz ^1H NMR ($CDCl_3$ – 10% CD_3OD), δ (TMS): 0.97 and 1.26 (3H, 2 methyl doublets indicating two diastereomers, J = 6.4 Hz and J = 6.2 Hz, with an integral ratio of 3.0:1.0), 4.58 (q, J = 6.4 Hz), larger, near 4.5, smaller and partly hidden under the OH signal (a pair of quadruplets, C*H*(OH)(CH_3)), 7.35 (3H, m), 7.69 (2H, m, aromatic protons); lit. (17) (mixture of diastereomers, ratio not stated) mp 158–165°C, ^1H NMR (acetone-d_6), δ: 0.9 and 1.2 (3H, 2d), 4.5 (1H, q, CH), 7.3 (3H, m, aromatic), 7.7 (2H, m, aromatic).

The mother liquor from crystallization, 373 mg, was dried and analysed by proton NMR (10% CD_3OD – 90% $CDCl_3$): 2,3-dihydroxy-2-phenylbutanoic acid was still present; a singlet at 5.15 indicated the presence of mandelic acid and the downfield aromatic signals of benzoic acid (8.04, 8.08) were clearly present. A proton assay indicated 32% benzoic, 25% mandelic, and 43% 2,3-dihydroxy-2-phenylbutanoic acid.

The total assay, based on both crystalline product and NMR analysis of the mother liquors is as follows: 2,3-dihydroxy-2-phenylbutanoic acid, 51.4%; benzoic acid, 14.7%; and mandelic acid, 11.5%, for a total yield of acids of 77.6%.

Cycloheptanone to 1,2-dihydroxycyclohexanecarboxylic acid

Cycloheptanone, 0.245 g (2.1 mmol), was added to 0.5 M aqueous NaOH solution, 500 mL, to which was added, at 0, 18, and 22 h, three equal portions of NaOCl solution, 5 mL, 0.44 M, 2.2 mmol each. Nearly all of the hypochlorite had been consumed before the second and third addition. The reaction was stopped after 42 h. No significant amount of material was recovered from extraction of the basic reaction solution. Acidification followed by extraction with ether (4 × 75 mL) gave 200 mg of light-yellow viscous liquid. Preparative layer chromatography, developed with 10% AcOH – 90% $CHCl_3$, gave cyclohexanecarboxylic acid, 43.6 mg, 0.34 mmol (16%), R_f 0.69; pimelic acid, 55.2 mg, 0.34 mmol (16%), R_f 0.51, mp 104–105°C (lit. (18) mp 106°C); 1,2-dihydroxycyclohexanecarboxylic acid, 28.0 mg, 0.175 mmol (8%), R_f 0.16, mp 113–114°C (lit. (10) mp 104–105°C); unidentified: 18.3 mg, R_f 0.38 and 0.58.

The apparent yield of cyclohexanecarboxylic acid may be lower than in the actual product mixture because it is sufficiently volatile to have evaporated during evaporation of solvent at 0.2 Torr[2] and during drying of the preparative layer plate at 50°C for 16 h after development. A control experiment in which 100 mg of the pure acid was put through the same procedure (dissolving in ether, evaporating to 0.2 Torr, running on a preparative layer plate, oven drying, extracting with ether, and evaporating again) yielded 81% by weight by the acid.

The identification of purified 1,2-dihydroxycyclohexanecarboxylic acid, mp 112–113°C, depends upon its spectroscopic properties. Exact Mass calcd. for $C_7H_{12}O_4$: 160.7386; found: 160.7361. ^1H NMR (90% $CDCl_3$ – 10% CD_3OD), δ (TMS): 1.6 (br m, 8H, CH_2), 3.88 (d of d, 1H, CH(OH)). ^{13}C NMR (CD_3OD), δ (TMS): 178.98 (COOH), 77.75 (quaternary, C-1), 73.34 (methyne, C-2), 34.93 (methylene, C-6), 30.44 (methylene, C-3), 25.08 (methylene, C-5), 20.76 (methylene, C-4). The acid was converted to the methyl ester using diazomethane. ^{13}C NMR (CD_3OD), δ (TMS): 176.67 (COOR), 76.89 (quaternary, C-1), 72.26 (methyne, C-2), 52.96 (*O*-methyl), 34.22 (methylene, C-6), 30.01 (methylene, C-3), 24.10 (methylene, C-5), 19.86 (methylene, C-4). The methyl ester was acetylated using acetic anhydride – pyridine to give methyl 2-acetoxy-1-hydroxycyclohexanecarboxylate. ^{13}C NMR (CD_3OD), δ (TMS): 175.34 (COOR), 169.96 (acetyl CO), 75.45 (C-1), 75.01 (C-2), 52.96 (*O*-methyl), 34.05 (C-6), 26.37 (C-3), 23.77 (C-5), 20.98 (acetyl methyl), 19.47 (C-4).

Pimelic acid and cyclohexanecarboxylic acid were identified by comparison of ^1H NMR spectrum and TLC behavior with authentic samples.

Cycloheptanone to 1,2-dihydroxycyclohexanecarboxylic acid

Cycloheptanone, 1.00 g, was dissolved in ice-cold water, 500 mL, and then a solution of NaOH, 40 g, in ice-cold water, 500 mL, was added slowly. Then Javex, 60 mL, was added using a motor-driven syringe at a rate of 0.15 mL/min. The solution was stirred for a further 70 h after the addition of all the Javex, and then excess hypochlorite was destroyed by adding $NaHSO_3$, 2.2 g. The solution was extracted (ether, 3 × 400 mL) and the extracts were evaporated to 50 mL, then washed (aqueous 2 N HCl, 2 × 50 mL; water, 2 × 50 mL), dried (Na_2SO_4), and evaporated to dryness: 40 mg. The aqueous product solution was acidified using concentrated HCl, 100 mL; NaCl was added, 250 g, and the resulting solution was extracted using ethyl acetate (5 × 400 mL). The extract was evaporated to 200 mL, washed with water (2 × 50 mL), dried (Na_2SO_4), and evaporated: 829 mg. From 671 mg of this crude product, crystallization (ether–hexane) gave 107 mg of 1,2-dihydroxycyclohexanecarboxylic acid, mp 112–114°C. Preparative layer chromatography on the mother liquor from crystallization gave cyclohexanecarboxylic acid, 236 mg; pimelic acid, 56 mg; unknown, 43 mg; and further 1,2-dihydroxycyclohexanecarboxylic acid, 110 mg.

Synthesis of (+/−) arthrographol[1]

WILLIAM A. AYER[2] AND PETER A. CRAW
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 8, 1991

WILLIAM A. AYER and PETER A. CRAW. Can. J. Chem. **69**, 1909 (1991).

A total synthesis of (+/−) arthrographol (**1**) in seven steps from vanillin is reported. Key steps in the synthesis are a single-step conversion of 5-allylvanillin (**2**) into the benzofuranmethanol **6**, alkylation of the chloride **25** with the lithium anion of crotyl phenyl sulfide to give the sulfide **26**, and formation of the 1(*E*),3(*E*)-1,3-pentadienyl side chain of arthrographol (**1**) via oxidation of the sulfide **26** and subsequent elimination of phenylsulfenic acid. The synthetic (+/−) arthrographol (**1**) inhibits the growth of *Ophiostoma clavigerum* (Robin.-Jeff. & Davids.) Harrington, the most pathogenic of the fungi associated with the blue stain disease of lodgepole pine (*Pinus contorta* Dougl. var *latifolia* Engelm.).

Key words: arthographol, alkylation, 2-butenyl phenyl sulfide, polyketide.

WILLIAM A. AYER et PETER A. CRAW. Can. J. Chem. **69**, 1909 (1991).

On rapporte une synthèse totale du (+/−)-arthrographol (**1**) impliquant sept étapes à partir de la vanilline. Les étapes clés de la synthèse sont une conversion en une étape de la 5-allylvanilline (**2**) en benzofuraneméthanol **6**, une alkylation du chlorure **25** avec le sel de lithium de l'anion du sulfure de crotyle et de phényle qui conduit au sulfure **26** et la formation de la chaîne latérale 1(*E*),3(*E*)-penta-1,3-diènyle de l'arthrographol (**1**) par oxydation du sulfure **26** et l'élimination subséquente de l'acide phénylsulfénique. Le (+/−)-arthrographol (**1**) de synthèse inhibe la croissance du *Ophiostoma clavigerum* (Robins.-Jeff & Davids.) Harrington, le plus pathogène des champignons associés avec la maladie de la teinte bleue du pin (*Pinus contorta* Dougl. var *latifolia* Engelm.).

Mots clés : arthographol, alkylation, sulfure de 2-butényle et de phényle, polyketide.

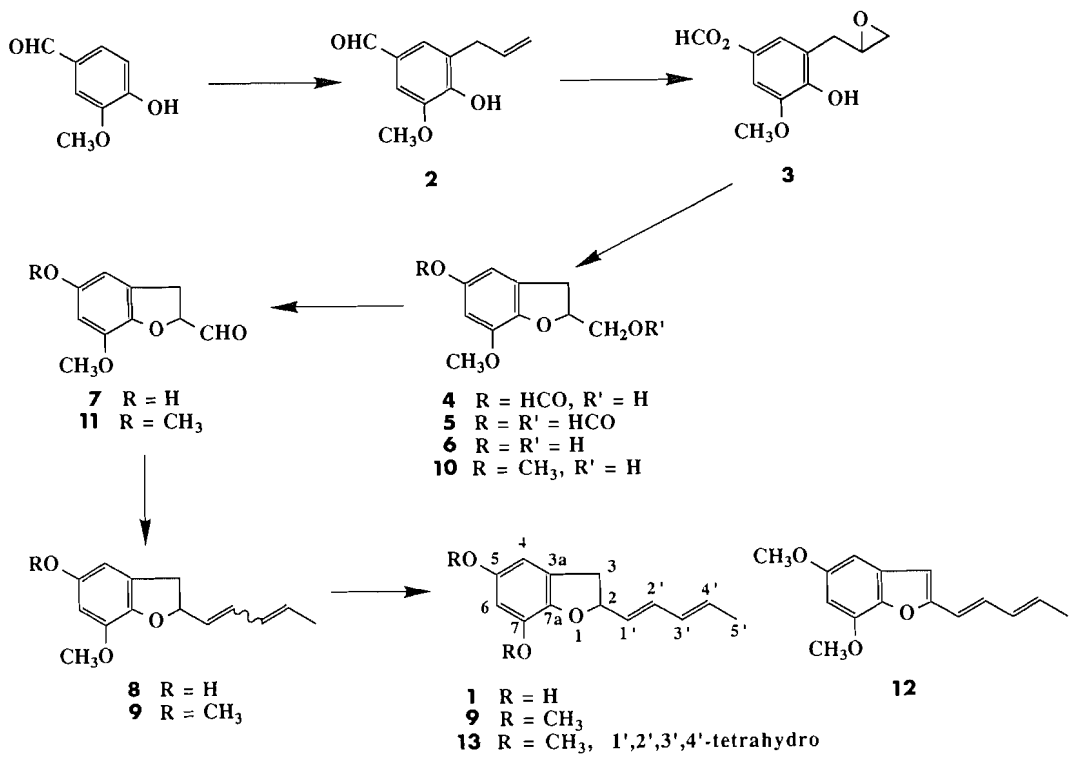
[Traduit par la rédaction]

Introduction

The blue stain disease of lodgepole pine (*Pinus contorta* Dougl. var *latifolia* Engelm.) is caused by a number of fungi vectored by the mountain pine beetle (*Dendroctonus ponderosae* Hopk.) (1). Recently we examined the metabolites produced in liquid cultures of the fungus *Arthrographis pinicola* Sigler and Yamaoka (2), which shows inhibitory activity against *Ophiostoma clavigerum* (Robin.-Jeff. & Davids.) Harrington, a fungus strongly associated with tree mortality caused by the blue stain fungi. Our investigations with *Arthrographis pinicola* led to the isolation of (−) arthrographol (**1**), which we believe to be responsible for the strong inhibitory activity of this fungus. Since (−) arthrographol (**1**) is produced in very small amounts (~0.2 mg/L) in liquid cultures, an efficient total synthesis of this compound was desirable to permit further testing of **1** as a potential control agent for the blue stain fungi. We report herein the results of our synthetic investigations, which culminated in a successful synthesis of (+/−) arthrographol (**1**).

Discussion

The successful synthesis of (+/−) arthrographol (**1**) began with *O*-allylation of vanillin and subsequent thermal Claisen rearrangement to give 5-allyl-4-hydroxy-3-methoxybenzaldehyde (**2**) (3). Epoxidation of **2** with 2.5 equivalents of *m*-chloroperbenzoic acid gave the unstable epoxyformate **3** resulting from concomitant epoxidation of the 5-allyl group and Baeyer–Villiger oxidation of the benzaldehyde (Scheme 1). The epoxyformate **3** suffered considerable decomposition when exposed to silica gel for any longer than brief periods during chromatography. Intramolecular cyclization (4) to give the benzofuran formate **4** occurred readily when the epoxyformate **3** was distilled at reduced pressure in a Kugelrohr oven. Cyclization to give **4** was also accompanied by some *trans*-esterification to give the bisformate **5** and decarbonylation to give the phenolic benzofuran **6**. If the epoxyformate **3** was not chromatographed, attempted thermal cyclization to give the benzofuran **4** gave only polymeric material. The combined yield of **4**–**6** for the two steps from **2** was 63%. A more efficient synthesis of the benzofuran **6** was achieved by epoxidation/Baeyer–Villiger oxidation of **2** and subsequent brief treatment of the crude, unchromatographed epoxyformate **3** with potassium carbonate in methanol. This procedure gave the benzofuran **6** in 71% yield.



We now anticipated that oxidation of the primary alcohol of **6** to give the aldehyde **7** and subsequent Wittig reaction with the lithium anion of (2-butenyl)triphenylphosphonium bromide would give the diene **8**, which bears the C2-(1,3-pentadienyl) side chain of arthrographol (**1**). However, all attempts to oxidize the alcohol **6** using either pyridinium chlorochromate or dichromate in dichloromethane, or Swern conditions (5), failed to give the aldehyde **7**, possibly due to the low solubility of **6** in dichloromethane. Since it would be necessary to deprotect the C8-methoxy group of **8** in order to complete the synthesis of (+/−) arthrographol (**1**), we felt that the conditions for monodemethylation of **8** would equally well be applicable to bis-demethylation of a dimethyl ether of (+/−) arthrographol (**9**). In the event, **6** was methylated to give the dimethyl ether **10**, which was readily oxidized under Swern conditions to the aldehyde **11**. Interestingly, the Ftir spectrum of a chloroform cast of **11** displayed only a very weak $\nu_{C=O}$ band at 1732 cm^{-1} and a strong ν_{O-H} band at 3400 cm^{-1}, which suggests that **11** exists, at least when cast on a NaCl plate, as an equilibrium mixture of aldehyde and enol tautomers. The ^{13}C nmr spectrum of pure **11** contained the expected 10 signals for the aldehyde tautomer (δ_{CO} 201.6, δ_{C2} 85.0) and additional weaker and somewhat broadened signals that might be due to the enol tautomer.

The aldehyde **11** was converted into a mixture of dienes **9** upon reaction with the lithium anion of crotyl triphenylphosphonium bromide. However, ^1H nmr analysis indicated that the

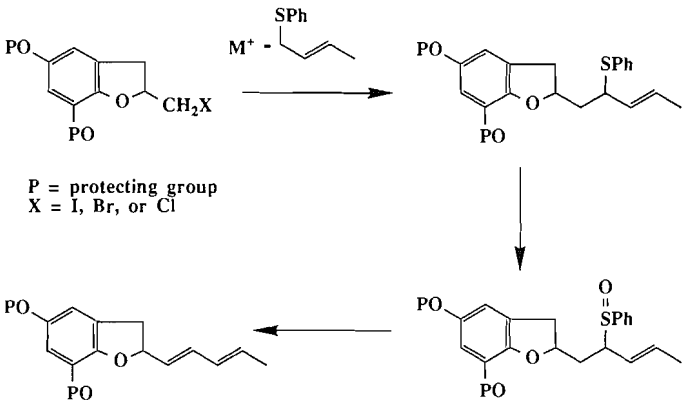
SCHEME 1

desired (*E,E*)-diene, as in arthrographol (**1**), was only a minor component of the inseparable mixture of dienes. The major diene in the mixture displayed signals in the ^{1}H nmr spectrum ($J_{H1'-H2'}$ = 10.0 Hz, $J_{H3'-H4'}$ = 14.9 Hz) that suggested it was the 1(*Z*),3(*E*)-pentadiene isomer arising from an unstabilized betaine formed by reaction of the crotyl triphenylphosphonium anion with the aldehyde **11**, and subsequent elimination of triphenylphosphine oxide to generate mainly a *Z* double bond. The mixture of dienes was isomerized to predominantly the 1(*E*),3(*E*)-diene (>80% by ^{1}H nmr) by refluxing with a catalytic amount of iodine (6) in carbon tetrachloride. The reaction with iodine also gave a small amount of the corresponding furan **12** (*m/z* 244 (M^+), δ_{H3} 6.47, s) possibly arising from dihydrofuran iodination (either benzylic or allylic) and subsequent dehydroiodination. Crystallization of the mixture of dienes containing mainly the (*E,E*) isomer gave the pure (*E,E*)-diene whose ^{1}H nmr spectrum was identical with that of dimethylarthrographol prepared by methylation of natural (−) arthrographol. Hydrogenation of the mixture of dienes obtained from the Wittig reaction gave tetrahydrodimethylarthrographol (**13**), which was identical (^{1}H nmr) with the product of methylation and hydrogenation of natural (−) arthrographol (**1**).



To complete the synthesis of (+/−) arthrographol (**1**) it was now necessary to address the anticipated difficult problem of demethylation of (+/−) dimethylarthrographol **9**. This was not expected to be an easy transformation as the (+/−) dimethyl ether **9** also contains a reactive *O*-allyl ether. Thus, we were not completely surprised when attempted demethylation with either trimethylsilyl iodide (7), boron tribromide (8), or lithium diphenylphosphide (9) failed to give any (+/−) arthrographol (**1**), and instead led to extensive decomposition of the starting material.

As a result of the inability to demethylate (+/−) dimethylarthrographol **9** we decided to investigate the possibility of unmasking the offending 3-methoxy group derived from vanillin prior to formation of the 1,3-pentadiene side chain at C2 of the benzofuran. Initially we were encouraged when 5-allyl vanillin (**2**) was smoothly demethylated with boron tribromide in dichloromethane to give 5-allyl-3,4-dihydroxybenzaldehyde. However, attempted epoxidation/Baeyer–Villiger oxidation and cyclization of this catechol did not give any 2,3-dihydro-5,7-dihydroxy-2-benzofuranmethanol (**14**), presumably due to facile oxidation to an *o*-benzoquinone, which then decomposed. As a result our attention shifted to cleavage of the methoxy group of the phenolic benzofuran **6**. At this stage we also wished to investigate an alternative procedure of forming the C2-1,3-pentadienyl side chain of arthrographol (**1**) in which alkylation of a C2-halomethylbenzofuran with the anion of crotyl phenyl sulfide followed by sulfur oxidation and elimination of phenylsulfenic acid would generate predominantly an (*E*)-1,2-double bond in the pentadienyl side chain (Scheme 2). A similar alkylation–oxidation–elimination sequence was used to form the (*E,E*)-1,3-pentadienyl unit of the sex pheromone of the codling moth, 8(*E*),10(*E*)-dodecadien-1-ol, from 8-bromo-1-octanol (10).

Cleavage of the methoxy group of **6** with boron tribromide failed to give a good yield of the desired resorcinol **14**. Accordingly, we converted the alcohol into the corresponding iodide **15**, bromide **16**, and chloride **17**. The iodide **15** and chloride **17** were prepared in high yield from reaction of the alcohol **6** with iodine–imidazole–triphenylphosphine in benzene (11) and acetonitrile,[3] and *N*-chlorosuccinimide–triphenylphosphine in tetrahydrofuran (THF) (12), respectively. Attempts to form the bromide **16** with either *N*-bromosuccinimide–triphenylphosphine in THF or carbon tetrabromide – triphenylphosphine in THF or dichloromethane (13) did not give more than 40%

SCHEME 2

conversion to the bromide **16** even after prolonged reaction or use of excess of the brominating reagent.

Attempts to convert the iodide **15** into the resorcinol **18** with boron tribromide in dichloromethane led to decomposition, while the bromide **16** gave a low yield of the corresponding resorcinol **19** but this material was contaminated with considerable amounts of dibromo impurities (hreims, cims). Finally, cleavage of the methyl ether of the chloride **17** was investigated and it was found that reaction with 2 equivalents of boron tribromide in dichloromethane at room temperature gave nearly quantitative yields of the resorcinol **20**. Attention now turned to protection of the two phenolic groups in **20** prior to alkylation with the anion of crotyl phenyl sulfide. Initially we chose to protect the resorcinol **20** as its bismethoxymethyl ether **21** (74% yield), as the MOM protecting groups should be easily removable by mild acid treatment (14). Next, alkylation of the bismethoxymethyl ether **21** with the lithium anion of crotyl phenyl sulfide was investigated. After several attempts it was found that the allyl phenylsulfide **22** could be prepared in good yield using an excess of the lithium anion of crotyl phenyl sulfide in the presence of sodium iodide in a solvent mixture of tetrahydrofuran and 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (DMPU) (15). The absence of either or both sodium iodide and DMPU from the reaction led to poor yields of **22** and many unwanted by-products. The allyl phenyl sulfide **22** was oxidized with *m*-chloroperbenzoic acid to the sulfoxide **23**. The sulfoxide **23** readily eliminated phenylsulfenic acid when refluxed in benzene containing triethylamine to give a mixture of bismethoxymethyldienes **24** (46% from sulfide **22**), which contained mainly the desired (*E,E*) isomer (>80% by ^{1}H nmr). Unfortunately, deprotection of the bismethoxymethyl ether **24** to give (+/−) arthrographol (**1**) using HCl (cat.) – *i*PrOH–THF–H_2O, HCl (cat.) – CH_3OH, pyridinium-*p*-toluenesulfonate (cat.) – CH_2Cl_2–H_2O, trifluoroacetic acid (cat.) – CH_2Cl_2, or silica gel – CH_2Cl_2–H_2O either failed to give any reaction or led to decomposition.

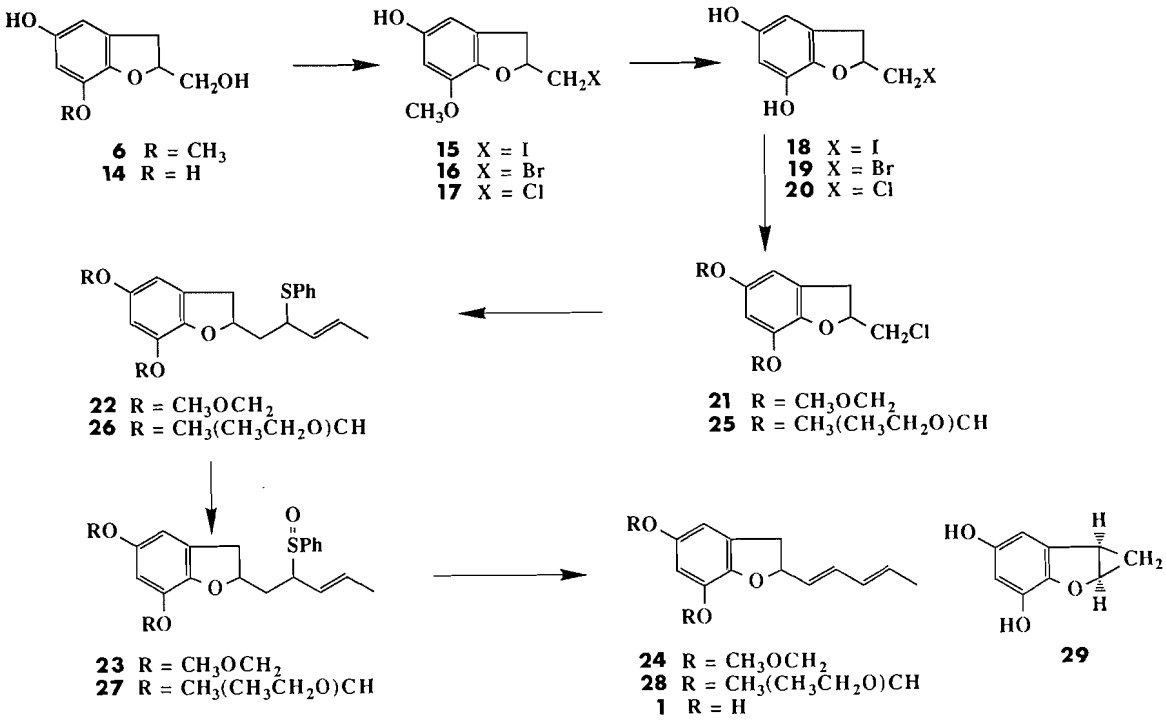
As an alternative to the use of MOM protecting groups for the resorcinol **20** we prepared the bistrimethylsilyl, and bis-*tert*-butyldimethylsilyl ethers of **20** but neither of these compounds underwent successful alkylation with the lithium anion of crotyl phenyl sulfide in the presence of sodium iodide – DMPU, probably due to iodide-promoted desilylation. Finally, the bisethoxyethyl ether **25** was prepared in high yield from resorcinol **20**. The ethoxyethyl group has been used extensively as a protecting group for alcohols, but not for phenols. Before proceeding with the alkylation of **25** we briefly examined the conditions for deprotection of the two bisethoxyethyl protecting groups and found that the bisethoxyethyl ether **25** could be deprotected in high yield to the resorcinol **20** using a mixture of acetic acid – methanol–water (1:50:50).

The bisethoxyethyl ether **25** was alkylated with the lithium anion of crotyl phenyl sulfide in THF–DMPU containing sodium iodide to give the allyl phenyl sulfide **26**, which was a complex mixture of diastereoisomers (^{1}H nmr) due to the additional asymmetric centres of the ethoxyethyl groups, in 71% yield. However, the ^{1}H nmr and hreims of **26** fully support the structure of this compound. The allyl phenyl sulfide **26** was oxidized with *m*-chloroperbenzoic acid to the sulfoxide **27**, which in turn was refluxed in benzene–triethylamine, and to our pleasure the crude diene **28** so obtained was readily deprotected with acetic acid in aqueous methanol to give (+/−) arthrographol (**1**) in 32% yield from the sulfide **26**. The reaction also gave a lesser amount (18%) of a by-product to which we have provisionally assigned the cyclopropane structure **29** on the basis of ^{1}H nmr and hreims data.

The synthetic (+/−) arthrographol (**1**) was contaminated with minor amounts of other diene isomers but these were readily removed by fractional crystallization to give pure (+/−) arthrographol (**1**). The ^{1}H nmr, Ftir, hreims, tlc behaviour, and mp of this material were in excellent agreement with those of natural (−) arthrographol (**1**). The synthetic (+/−) arthrographol (**1**) inhibited the growth of the blue stain fungus *Ophiostoma clavigerum* at concentrations of 50 and 100 μg in the filter paper disc bioassay (2).

Experimental

For general experimental details see ref. 16. The following solvents were distilled immediately prior to use: tetrahydrofuran (THF) and benzene were distilled under argon from sodium – benzophenone ketyl; 1,3-dimethyl-3,4,5,6-tetrahydro-2(1*H*)-pyrimidinone (DMPU) was distilled from calcium hydride at reduced pressure (85–90°C, 3 Torr (1 Torr = 133.3 Pa); dichloromethane, triethylamine, and diisopropylamine were distilled from calcium hydride under argon. Imidazole and triphenylphosphine were purified by sublimation at reduced pressure. *N*-Chlorosuccimide was recrystallized from benzene. *N*-Bromosuccinimide was recrystallized from water and dried *in vacuo* over silica gel. Sodium iodide was dried *in vacuo* at 100°C for 4 h and stored in a desiccator. *m*-Chloroperbenzoic acid was purified according to Fieser and Fieser (17). Crotyl phenyl sulfide was prepared according to Babler and Haack (10), and crotyl triphenylphosphonium bromide according to Bohlmann and Mannhardt (18). All other solvents and liquid reagents were distilled prior to use.



4-Allyloxy-3-methoxybenzaldehyde (3)

A mixture of vanillin (12.2 g, 80.3 mmol), potassium carbonate (10.0 g, 72.5 mmol), and allyl bromide (6.8 mL, 78.6 mmol) in dimethyl formamide (20 mL) was stirred under an argon atmosphere for 44 h, then further allyl bromide (0.5 mL) and potassium carbonate (1.0 g) were added and stirring continued for a futher 24 h. The mixture was poured into water (200 mL) and acidified to pH 5–6 (litmus) with 2 M hydrochloric acid. The aqueous mixture was extracted with ether (3 × 100 mL) and the combined extracts were washed successively with saturated sodium hydrogen carbonate solution and brine. The dried ether extract was evaporated to a pale yellow oil, which was chromatographed on silica gel, eluting with ethyl acetate – Skellysolve B (1:5) to give 4-allyloxy-3-methoxybenzaldehyde as a clear liquid (15.06 g, 98%); Ftir ($CHCl_3$ cast): 1684, 1594, 1585, 1508, 1276, 1136 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 9.84 (1H, s), 7.40–7.46 (2H, m), 6.96 (1H, d, J = 8.1 Hz), 6.02–6.13 (1H, m), 5.43 (1H, d, J = 17.0 Hz), 5.33 (1H, d, J = 10.5 Hz), 4.69 (2H, d, J = 5.2 Hz), 4.00 (3H, s).

5-Allyl-4-hydroxy-3-methoxybenzaldehyde (2)

4-Allyloxy-3-methoxybenzaldehyde (0.63 g) was heated under an

For personal use only.

SCHEME 3

atmosphere of argon at 195–205°C in a Kugelrohr oven for 15 min. The resulting orange-brown liquid, which crystallized upon cooling, was chromatographed on silica gel. Elution with ethyl acetate – Skellysolve B (1:4) gave 5-allyl-4-hydroxy-3-methoxybenzaldehyde (0.50 g, 79%), which crystallized from Skellysolve B as needles, mp 81–82°C (lit. (3) mp 83–84°C); Ftir ($CHCl_3$ cast): 3185, 1670 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 9.82 (1H, s), 7.31 (2H, br s), 6.29 (1H, s), 5.94–6.06 (1H, m), 5.13 (1H, ddd, J = 3.6, 1.5, 1.5 Hz), 5.09 (1H, br s), 3.96 (3H, s), 3.46 (2H, d, J = 6.8 Hz).

2,3-Dihydro-5-hydroxy-7-methoxy-2-benzofuranmethanol (6)

A solution of 5-allyl-4-hydroxy-3-methoxybenzaldehyde (**2**) (1.00 g, 5.21 mmol) and *m*-chloroperbenzoic acid (80–85% assay, 2.5 g, 11.6–12.3 mmol) was stirred in dichloromethane (100 mL) under argon for 18 h, then transferred to a separatory funnel and washed with a 1:1 mixture of 10% w/v sodium sulfite and saturated sodium hydrogen carbonate. Evaporation of the dried dichloromethane solution gave an oil, which was dissolved in methanol (10 mL) and added to a stirred suspension of potassium carbonate (2.0 g, 14.5 mmol) in methanol (90 mL). The brown mixture was stirred for 1 h, then concentrated at reduced pressure to approximately 20 mL and diluted with water (100 mL). The aqueous mixture was extracted with ethyl acetate (5 × 50 mL) and the combined extracts were dried and evaporated to a brown oil. Flash chromatography, eluting with ethyl acetate – Skellysolve B (2:1), gave the benzofuran **6** as a pale brown oil (0.724 g, 71%), which crystallized on standing. Recrystallization from ethyl acetate gave small prisms, mp 126–127°C; Ftir (KBr): 3362, 3139, 3134, 1626, 1613, 1499, 1201, 1146, 1094 cm^{-1}; ^1H nmr (CD_3OD) δ: 6.13 (2H, s, H4, H6), 4.59–4.69 (1H, m, H2), 3.64 (3H, s, OCH_3), 3.54 (2H, d, J = 4.5 Hz, CH_2OH), 3.01 (1H, dd, J = 15.5, 9.5 Hz, H3), 2.80 (1H, dd, J = 15.8, 7.7 Hz, H3); ^{13}C nmr (CD_3OD) δ: 153.0, 145.5, 142.3, 129.2, 104.7, 101.0, 84.7, 65.0, 56.5, 33.3; hreims (probe 120°C), m/z calcd. for $C_{10}H_{12}O_4$ (M^+): 196.0736; found: 196.0740 (100), 165 ($M^+ - CH_2OH$, 30), 153 (22), 152 (24).

Epoxidation of 5-allyl-4-hydroxy-3-methoxybenzaldehyde (2)

A solution of 5-allyl-4-hydroxy-3-methoxybenzaldehyde (1.00 g, 5.21 mmol) and *m*-chloroperbenzoic acid (80–85% assay, 2.6 g, 12.0–12.8 mmol) was stirred in dichloromethane (100 mL) under argon for 25 h, then transferred to a separatory funnel and washed with a 1:1 mixture of 10% w/v sodium sulfite and saturated sodium hydrogen carbonate. Evaporation of the dried dichloromethane solution gave an oil, which was quickly flash chromatographed. Elution with ethyl acetate – Skellysolve B (2:3) gave the crude epoxyformate **3** (0.918 g), which was used in the next step without further purification; Ftir ($CHCl_3$ cast): 3445, 1738, 1620, 1600, 1496, 1466, 1438, 1360, 1290, 1234, 1185, 1152, 1102 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.23 (1H, s), 6.56 (2H, br s), 6.08 (1H, s), 3.80 (3H, s), 3.16–3.21 (1H, m), 2.89 (1H, dd, J = 14.0, 5.0 Hz), 2.83 (1H, dd, J = 14.1, 6.0 Hz), 2.75 (1H, dd, J = 4.5, 3.5 Hz), 2.56 (1H, dd, J = 5.0, 2.6 Hz); hreims (probe 120°C), m/z calcd. for $C_{11}H_{12}O_5$ (M^+): 224.0685; found: 224.0687 (100), 196 (29), 181 (19), 177 (17), 168 (22), 166 (19), 165 (19), 153 (31), 152 (28), 135 (17), 123 (20), 107 (15).

Thermal rearrangement of the epoxyformate 3

The crude epoxyformate **3** (0.918 g) was distilled in a Kugelrohr oven (155–160°C, 1.0 Torr) and the distillate chromatographed on silica gel. Elution with ethyl acetate – Skellysolve B (1:1) gave successively the bisformate **4** (49.7 mg, 4% from **2**), then the hydroxy formate **5** (0.547 g, 42% from **2**). Further elution with ethyl acetate – Skellysolve B (2:1) gave the phenolic alcohol **6** (0.172 g, 17% from **2**). The bisformate **4** was obtained as an oily solid; Ftir ($CHCl_3$ cast): 1750 (sh), 1728, 1627, 1600, 1496, 1466, 1322, 1201, 1153, 1104, 1086 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.25 (1H, s, HCO_2), 8.09 (1H, s, HCO_2), 6.58 (1H, d, J = 1.8 Hz, H4 or H6), 6.51 (1H, d, J = 2.2 Hz, H4 or H6), 5.06–5.14 (1H, m, H2), 4.43 (1H, dd, J = 12.5, 3.6 Hz, CH_2O_2CH), 4.34 (1H, dd, J = 12.2, 6.3 Hz, CH_2O_2CH), 3.83 (3H, s, OCH_3), 3.34 (1H, dd, J = 15.8, 9.7 Hz, H3), 3.05 (1H, dd, J = 16.0, 8.0 Hz, H3); ^{13}C nmr ($CDCl_3$) δ: 160.6, 159.7, 145.6, 144.4, 143.9, 127.0, 109.6, 105.1, 80.6, 64.7, 56.1, 32.4; hreims (probe 120°C), m/z calcd. for $C_{12}H_{12}O_6$ (M^+): 252.0634; found: 252.0631 (100), 224 (67), 178 (48), 177 (36), 165 (28), 152 (17), 137 (15), 135 (28), 107 (15), 77 (16). The hydroxy formate **5** crystallized on standing as fine needles, mp 91–92°C; Ftir ($CHCl_3$ cast): 3335, 1703, 1692, 1630, 1613, 1496, 1220, 1201, 1146 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.07 (1H, s, HCO_2), 6.30 (1H, d, J = 2.5 Hz, H4 or H6), 6.28 (1H, d, J = 2.5 Hz, H4 or H6). 5.52–5.63 (1H, m, OH), 4.97–5.05 (1H, m, H2), 4.38 (1H, dd, J = 12.2, 3.9 Hz, CH_2OH), 4.32 (1H, dd, J = 12.2, 6.2 Hz, CH_2OH), 3.78 (3H, s, OCH_3), 3.24 (1H, dd, J = 16.0, 9.6 Hz, H3),

2.72 (1H, dd, J = 15.8, 7.7 Hz, H3); ^{13}C nmr ($CDCl_3$) δ: 161.1, 150.8, 144.3, 141.0, 126.8, 103.4, 99.7, 79.8, 65.0, 55.8, 32.6; hreims (probe 100°C), m/z calcd. for $C_{11}H_{12}O_5$ (M^+): 224.0685; found: 224.0683 (100), 178 (47), 177 (33), 165 (21), 153 (12), 152 (12), 137 (14), 135 (27), 107 (14), 77 (13), 65 (12), 39 (19). The phenolic alcohol **6** crystallized from ethyl acetate as prisms, mp 126–127°C (correct ^{1}H nmr spectrum).

*2,3-Dihydro-5,7-dimethoxy-2-benzofuranmethanol (**10**)*

Iodomethane (1.5 mL, 24.1 mmol) was added to a suspension of the phenol **6** (0.50 g, 2.55 mmol) and potassium carbonate (4.0 g) in acetone (25 mL). The mixture was stirred at room temperature under argon for 3 h, then further iodomethane (0.5 mL) was added and stirring continued for a further 17 h. The mixture was diluted with water and extracted with dichloromethane (3 × 30 mL). Evaporation of the dried combined extracts and flash chromatography of the oily product, eluting with ethyl acetate – Skellysolve B (3:2), gave an oily forerun followed by the dimethyl ether **10** (0.511 g, 95%), which crystallized as an amorphous solid on standing, mp 66–68°C; Ftir ($CHCl_3$ cast): 3400, 1618, 1606, 1499, 1203, 1148 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.35 (2H, br d, J = 2.0 Hz, H4, H6), 4.88–4.96 (1H, m, H2), 3.89 (1H, dd, J = 12.4, 3.1 Hz, CH_2OH), 3.84 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 3.73 (1H, dd, J = 12.3, 6.0 Hz, CH_2OH), 3.21 (1H, dd, J = 15.8, 9.6 Hz, H3), 3.08 (1H, dd, J = 15.5, 8.0 Hz, H3); ^{13}C nmr ($CDCl_3$) δ: 154.7, 144.2, 141.5, 127.5, 101.1, 98.9, 83.6, 64.3, 55.8, 55.7, 32.1; hreims (probe 110°C), m/z calcd. for $C_{11}H_{14}O_4$ (M^+): 210.0891; found: 210.0891 (100), 182 (16), 179 (25), 167 (27), 166 (21).

*2,3-Dihydro-5,7-dimethoxy-2-benzofurancarboxaldehyde (**11**)*

Dimethyl sulfoxide (0.20 mL, 2.82 mmol) was added dropwise to a stirred solution of oxalyl chloride (0.15 mL, 1.72 mmol) in dichloromethane (5 mL) at −78°C under argon. The solution was stirred at −78°C for 5 min, then a solution of the alcohol **10** (0.242 g, 115 mmol) in dichloromethane (2 mL) was added dropwise. The resulting slurry was stirred at −78°C for 30 min, then triethylamine (1.0 mL, 7.2 mmol) was added and the mixture stirred at 0°C for 10 min. The slurry was transferred to a separatory funnel using dichloromethane and washed successively with 0.5 M hydrochloric acid and brine. Evaporation of the dried extract and flash chromatography of the product, eluting with ethyl acetate – Skellysolve B (1:1), gave the aldehyde **11** as a pale yellow oil (0.225 g, 94%); Ftir ($CHCl_3$ cast): 3400, 1732 (w), 1622, 1610, 1499, 1201, 1148 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 9.88 (1H, d, J = 1.2 Hz, CHO), 6.38 (1H, d, J = 2.6 Hz, H4 or H6), 6.35 (1H, d, J = 2.6 Hz, H4 or H6), 5.04 (1H, ddd, J = 10.8, 6.5, 1.2 Hz, H2), 3.88 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 3.44 (1H, dd, J = 16.0, 10.5 Hz, H3), 3.33 (1H, dd, J = 16.0, 6.5 Hz, H3); ^{13}C nmr ($CDCl_3$) δ: 201.6, 155.6, 144.6, 141.1, 125.8, 100.9, 99.6, 85.0, 55.9, 55.8, 32.3; hreims (probe 150°C), m/z calcd. for $C_{11}H_{12}O_4$ (M^+): 208.0736; found: 208.0731 (100), 180 (13), 179 (99), 151 (24), 121 (23), 77 (12), 51 (10).

2,3-Dihydro-5,7-dimethoxy-2-[1-(1,3-pentadienyl)]benzofuran

n-Butyllithium (0.46 mL of a 1.6 M solution in hexanes) was added to a suspension of crotyl triphenylphosphonium bromide (0.29 g, 0.74 mmol) in THF (10 mL) at 0°C to give an orange-red solution of the phosphonyl anion. The solution was cooled to −78°C and a solution of the aldehyde **11** (57.6 mg) in THF (1.2 mL) was added dropwise. The mixture was stirred at −78°C for 2 h, then warmed to room temperature and quenched with water. The solution was transferred to a separatory funnel and diluted with water, acidified with 1 M hydrochloric acid, and extracted with dichloromethane (3 × 25 mL). Evaporation of the dried combined extracts and flash chromatography of the product, eluting with ethyl acetate – Skellysolve B (1:10), gave an inseparable mixture of the isomeric dienes (60.8 mg, 89%), which crystallized on standing; ^{1}H nmr ($CDCl_3$, major diene) δ: 6.35 (2H, br s, H4, H6), 6.11 (1H, dd, J = 11.0, 11.0 Hz, H2′), 5.80 (1H, dq, J = 14.9, 6.9 Hz, H4′), 5.67–5.80 (1H, m, H3′), 5.67 (1H, br dd, J = 9.0, 9.0 Hz, H2), 5.54 (1H, br dd, J = 10.0, 10.0 Hz, H1′), 3.83 (3H, s, OCH_3), 3.74 (3H, s, OCH_3), 3.36 (1H, dd, J = 15.5, 8.9 Hz, H3), 2.98 (1H, dd, J = 15.2, 8.9 Hz, H3), 1.79 (3H, dd, J = 7.0, 1.4 Hz, H5′); ^{13}C nmr ($CDCl_3$, major diene) δ: 154.6, 144.3, 141.7, 132.3, 131.4, 127.6, 127.3, 126.2, 101.0, 99.1, 79.2, 55.7 (2), 37.0, 18.1; hreims (probe 100°C), m/z calcd. for $C_{15}H_{18}O_3$ (M^+): 246.1256; found: 246.1260 (100), 231 (15), 191 (32), 167 (30), 166 (33).

*Isomerization to 1′(E),3′(E)-2,3-dihydro-5,7-dimethoxy-2-[1-(1,3-pentadienyl)]benzofuran (**9**)*

A very small crystal of iodine (<1 mg) was dissolved in carbon tetrachloride (2 mL) and 0.1 mL of the iodine solution was added to a stirred solution of the isomeric dienes (50.0 mg) in carbon tetrachloride (5 mL). The solution was refluxed under argon for 18 h, then evaporated to dryness and the product flash chromatographed. Elution with ethyl acetate – Skellysolve B (1:10) gave the furan (1.5 mg) followed by a mixture of the isomeric dienes (48.0 mg), which consisted mainly (^{1}H nmr) of the desired (*E,E*) isomer. Recrystallization of the mixture of dienes from dichloromethane – Skellysolve B gave the pure (*E,E*)-diene **9** as flaky needles, mp 101–103.5°C; ^{1}H nmr ($CDCl_3$,(*E,E*)-diene) δ: 6.35 (2H, br s, H4, H6), 6.28 (1H, dd, J = 15.0, 10.2 Hz, H2′), 6.05 (1H, ddq, J = 15.0, 10.2, 1.5 Hz, H3′), 5.76 (1H, dq, J = 15.0, 7.0 Hz, H4′), 5.74 (1H, dd, J = 15.0, 7.5 Hz, H1′), 5.21 (1H, br ddd, J = 8.5, 8.5, 8.5 Hz, H2), 3.83 (3H, s, OCH_3), 3.74 (3H, s, OCH_3), 3.31 (1H, dd, J = 15.6, 9.2 Hz, H3), 2.99 (1H, dd, J = 15.4, 8.8 Hz, H3), 1.76 (3H, dd, J = 6.8, 1.5 Hz, H5′); ^{13}C nmr ($CDCl_3$) δ: 154.7, 144.4, 141.9, 132.9, 131.1, 130.5, 129.0, 127.7, 101.2, 99.2, 84.1, 55.97, 55.92, 37.2, 18.1. The furan **12** was obtained as a pale yellow solid; ^{1}H nmr ($CDCl_3$) δ: 6.96 (1H, dd, J = 15.5, 10.5 Hz, H2′), 6.54 (1H, d, J = 2.5 Hz, H4 or H6), 6.47 (1H, s, H3), 6.41 (1H, d, J = 2.5 Hz, H4 of H6), 6.27 (1H, br d, J = 16.0 Hz, H1′), 6.20 (1H, br ddq, J = 15.0, 10.5, 1.0 Hz, H3′), 5.92 (1H, dq, J = 15.0, 7.0 Hz, H4′), 3.98 (3H, s, OCH_3), 3.82 (3H, s, OCH_3), 1.83 (3H, dd, J = 7.0, 1.0 Hz, H5′); hreims (probe 140°C), m/z calcd. for $C_{15}H_{16}O_3$ (M^+): 244.1099; found: 244.1098 (100), 229 (54), 214 (10), 115 (15).

Methylation of natural (−) arthrographol

Iodomethane (30 μL) was added to a suspension of (−) arthrographol (2.5 mg) and potassium carbonate (0.10 g) in acetone (1 mL). The mixture was stirred at room temperature under argon for 36 h, then diluted with dichloromethane and washed with water. Evaporation of the dried dichloromethane solution gave an oil, which was filtered through a plug of silica gel using ethyl acetate – Skellysolve B (1:5). Removal of the solvents gave the dimethyl ether of (−) arthrographol (2.8 mg); ^{1}H nmr ($CDCl_3$) δ: 6.35 (2H, s, H4, H6), 6.29 (1H, dd, J = 15.1, 10.5 Hz, H2′), 6.06 (1H, ddq, J = 15.0, 10.5, 1.5 Hz, H3′), 5.76 (1H, dq, J = 15.0, 7.0 Hz, H4′), 5.74 (1H, dd, J = 15.0, 7.5 Hz, H1′), 5.21 (1H, ddd, J = 8.5, 8.5, 8.5 Hz, H2), 3.83 (3H, s, OCH_3), 3.74 (3H, s, OCH_3), 3.31 (1H, dd, J = 15.5, 9.0 Hz, H3), 2.99 (1H, dd, J = 15.5, 8.5 Hz, H3), 1.76 (3H, dd, J = 7.0, 1.0 Hz, H5′).

Hydrogenation of the dimethyl ether of (−) arthrographol

5% Palladium – charcoal (5 mg) was added to a solution of (−) arthrographol dimethyl ether (2.8 mg) in ethyl acetate (0.5 mL) and the mixture was stirred under an atmosphere of hydrogen for 2 h. The mixture was filtered and the catalyst washed with ethyl acetate. The filtrate was evaporated and the product filtered through a plug of silica gel using ethyl acetate – Skellysolve B (1:20) to give 2,3-dihydro-5,7-dimethoxy-2-pentylbenzofuran (**13**) (*tetrahydrodimethoxyarthrographol*) as an oil (1.9 mg); ^{1}H nmr ($CDCl_3$) δ: 6.36 (2H, s, H4, H6), 4.79 (1H, ddt, J = 9.0, 9.0, 6.8 Hz, H2), 3.84 (3H, s, OCH_3), 3.75 (3H, s, OCH_3), 3.23 (1H, dd, J = 15.5, 9.2 Hz, H3), 2.85 (1H, dd, J = 15.6, 8.8 Hz, H3), 1.25–2.00 (8H, m), 0.89 (3H, t, J = 6.5 Hz, H5′); hreims (probe 140°C), m/z calcd. for $C_{15}H_{22}O_3$ (M^+): 250.1568; found: 250.1565 (100), 168 (24), 167 (46), 166 (20), 161 (14).

Hydrogenation of the mixture of synthetic dimethoxy dienes

Hydrogenation of a mixture of the dienes (5.2 mg) obtained from the Wittig reaction of the aldehyde and crotyl triphenylphosphonium bromide as for hydrogenation of the dimethyl ether of (−) arthrographol

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

(see above) gave (+/−) tetrahydrodimethoxyarthrographol (**13**) (4.5 mg) (^{1}H nmr ($CDCl_3$) identical with that above).

*2,3-Dihydro-5-hydroxy-2-iodomethyl-7-methoxybenzofuran (**15**)*

Iodine (56 mg, 0.221 mmol) was added in one portion to a suspension of triphenylphosphine (75 mg, 0.286 mmol) and imidazole (20 mg, 0.294 mmol) in acetonitrile (0.7 mL). The resulting yellow solution was stirred under argon at 10°C for 15 min, then benzene (2 mL) was added to give a pale yellow suspension to which was added a solution of the alcohol **6** (20 mg, 0.111 mmol) in acetonitrile (0.3 mL). The mixture was stirred under argon at room temperature for 21 h (tlc indicated the reaction was almost complete after 2 h). The mixture was diluted with dichloromethane and washed successively with 1 M sodium sulfite and brine. Evaporation of the dried solution gave an oil, which was flash chromatographed, eluting with ethyl acetate – Skellysolve B (1:3) to give the iodide **15** (29.6 mg, 87%), which crystallized on standing. Recrystallization from ethyl acetate – Skellysolve B – dichloromethane gave fine needles, mp 146.5–147.5°C; Ftir ($CHCl_3$ cast): 3350, 1622, 1605, 1510, 1492, 1467, 1451, 1435, 1335, 1195, 1140, 1087 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.30 (1H, d, J = 2.2 Hz, H4 or H6), 6.28 (1H, d, J = 2.2 Hz, H4 or H6), 4.88 (1H, dddd, J = 10, 9, 7, 4 Hz, H2), 4.53 (1H, s, OH), 3.83 (3H, s, OCH_3), 3.49 (1H, dd, J = 10.0, 4.0 Hz, CH_2I), 3.36 (1H, dd, J = 16.1, 9.0 Hz, H3), 3.33 (1H, dd, J = 10.0, 10.0 Hz, CH_2I), 3.04 (1H, dd, J = 16.1, 7.0 Hz, H3); ^{13}C nmr ($CDCl_3$) δ: 150.5, 144.4, 141.7, 127.0, 103.5, 99.8, 82.1, 56.0, 36.9, 8.8; hreims (probe 120°C), m/z calcd. for $C_{10}H_{12}O_3I$ ($M^+ + H^+$): 306.9831; found: 306.9819 (15); m/z calcd. for $C_{10}H_{11}O_3$ ($M^+ - I$): 179.0708; found: 179.0708 (100), 147 (32), 127 (HI, 4), 126 (I, 4), 119 (30), 91 (19); cims: 324 ($M^+ + NH_4^+$, 100).

*2,3-Dihydro-2-bromomethyl-5-hydroxy-7-methoxybenzofuran (**16**)*

A solution of triphenylphosphine (0.267 g, 1.02 mmol) in THF (2 mL) was added dropwise to a stirred solution of *N*-bromosuccinimide (0.182 g, 1.02 mmol) in THF (10 mL) under argon to give a sticky precipitate. After 5 min a solution of the alcohol **6** (100 mg, 0.51 mmol) in THF (3 mL) was added and the resulting pale orange mixture was stirred for 26 h. The mixture was diluted with dichloromethane and washed with 1 M sodium sulfite. Evaporation of the dried solution and flash chromatography of the resulting red-brown oil, eluting with ethyl acetate – Skellysolve B (1:2), gave the bromide **16** (40.6 mg, 30.7%). Further elution with ethyl acetate – Skellysolve B (2:1) gave unreacted alcohol **6** (68.8 mg, 68.8%). The bromide crystallized from ethyl acetate as prisms, mp 126–127°C; Ftir ($CHCl_3$ cast): 3400, 1628, 1609, 1494, 1458, 1341, 1185, 1140, 1088, 948, 840 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.30 (2H, br s, H4, H6), 5.07 (1H, br s, OH), 4.98 (1H, m, H2), 3.81 (3H, s, OCH_3), 3.62 (1H, dd, J = 10.4, 4.5 Hz, CH_2Br), 3.47 (1H, dd, J = 10.5, 7.6 Hz, CH_2Br), 3.31 (1H, dd, J = 15.8, 9.2 Hz, H3), 3.09 (1H, dd, J = 15.9, 7.2 Hz, H3); hreims (probe 120°C), m/z calcd. for $C_{10}H_{11}O_3{}^{81}Br$ (M^+): 259.9872; found: 259.9873 (75.2); m/z calcd. for $C_{10}H_{11}O_3{}^{79}Br$ (M^+): 257.9892; found: 257.9894 (73.2), 180 (13), 179 (M^+ − Br, 100), 151 (15), 149 (17), 147 (43), 119 (35), 91 (21), 77 (14), 65 (17), 53 (11), 51 (11).

*2,3-Dihydro-2-chloromethyl-5-hydroxy-7-methoxybenzofuran (**17**)*

A solution of triphenylphosphine (0.67 g, 2.56 mmol) in THF (4 mL) was added to a stirred solution of *N*-chlorosuccinimide (0.34 g, 2.55 mmol) in THF (10 mL) at room temperature under argon. The thick cream-colored suspension was stirred for 5 min, then a solution of the alcohol **6** (0.245 g, 1.25 mmol) in THF (6 mL) was added dropwise. The suspension was stirred for 7.5 h, then poured into water and extracted with dichloromethane (3×) (a small amount of 1 M hydrochloric acid (approx. 0.5 mL) was added to disperse an emulsion that formed upon shaking). Evaporation of the dried combined extracts gave an oil, which was flash chromatographed. Elution with ethyl acetate – Skellysolve B (1:2) gave unreacted triphenylphosphine, and further elution with ethyl acetate – Skellysolve B (1:1) gave the chloride **17** (0.265 g, 99%), which crystallized on standing. Recrystallization from ethyl acetate – Skellysolve B gave needles, mp 112.5–113°C; Ftir ($CHCl_3$ cast): 3360, 1628, 1610, 1495, 1457, 1342, 1196, 1140, 1090 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.30 (2H, m, H4, H6), 5.01 (1H, m, H2), 3.83 (3H, s, OCH_3), 3.78 (1H, dd, J = 11.1, 5.0 Hz, CH_2Cl), 3.65 (1H, dd, J = 11.1, 6.9 Hz, CH_2Cl), 3.32 (1H, dd, J = 15.9, 9.1 Hz, H3), 3.12 (1H, dd, J = 16.1, 6.9 Hz, H3); ^{13}C nmr ($CDCl_3$) δ: 150.6, 144.3, 141.4, 126.9, 103.5, 99.8, 81.7, 55.9, 45.7, 34.2; hreims (probe 120°C), m/z calcd. for $C_{10}H_{11}O_3Cl$ (M^+): 214.0397; found: 214.0398 (100), 216/214 (100:32), 179 (16), 165 (33), 147 (53).

*2,3-Dihydro-2-chloromethyl-5,7-dihydroxybenzofuran (**20**)*

Boron tribromide (2.94 mL of a 1.0 M solution in dichloromethane) was added to a stirred solution of the chloride **17** (0.315 g, 1.47 mmol) in dichloromethane (30 mL) and the initially blue solution stirred under argon at room temperature for 6 h. The solution was poured into ethyl acetate (100 mL) and the organic layer washed successively with water, saturated sodium hydrogen carbonate, and brine. Evaporation of the dried solution and flash chromatography of the resultant brown oil, eluting with ethyl acetate – Skellysolve B (2:3), gave the resorcinol **20** (0.293 g, 99%), which crystallized on standing. Recrystallization of a portion of this material from dichloromethane gave fine needles, mp 117–118°C; Ftir (KBr): 3526, 3382, 1634, 1618, 1505, 1485, 1187, 1127, 854 cm^{-1}; ^{1}H nmr ($CDCl_3/CD_3OD$) δ: 6.25 (2H, br d, J = 2.0 Hz, H4, H6), 4.90 (1H, m, H2), 3.67 (1H, dd, J = 11.7, 6.2 Hz, CH_2Cl), 3.58 (1H, dd, J = 11.7, 6.2 Hz, CH_2Cl), 3.23 (1H, dd, J = 16.2, 9.0 Hz, H3), 2.96 (1H, dd, J = 16.2, 6.5 Hz, H3); ^{13}C nmr ($CDCl_3$) δ: 150.9, 140.2, 139.6, 127.0, 103.2, 102.8, 81.7, 45.9, 34.1; hreims (probe 150°C), m/z calcd. for $C_9H_9O_3Cl$ (M^+): 200.0240; found: 200.0242 (100), 202/200 (100:32), 165 (20), 163 (20), 151 (25), 147 (36), 138 (59), 123 (22), 19 (21).

*Bis(methoxymethyl) ether of 2,3-dihydro-2-chloromethyl-5,7-dihydroxybenzofuran (**21**)*

Methoxymethyl chloride (0.28 mL, 3.50 mmol) was added to a stirred solution of the resorcinol **20** (0.172 g, 0.86 mmol) and di-(isopropyl)ethylamine (0.61 mL, 3.50 mmol) in dichloromethane (15 mL). The solution was stirred at room temperature under argon for 22 h, then transferred to a separatory funnel and washed successively with 0.01 M hydrochloric acid and saturated sodium hydrogen carbonate. Evaporation of the dried dichloromethane solution and flash chromatography, eluting with ethyl acetate – Skellysolve B (1:3), gave the bis(methoxymethyl) ether **21** as a clear oil (0.184 g, 74%); Ftir ($CHCl_3$ cast): 1621, 1607, 1488, 1152, 1135, 1061, 1018 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.71 (1H, d, J = 2.6 Hz, H6), 6.61 (1H, ddd, J = 2.4, 1.0, 1.0 Hz, H4), 5.20 (2H, s, OCH_2O), 5.08 (2H, s, OCH_2O), 5.02 (1H, dddd, J = 9.4, 6.8, 6.3, 4.5 Hz, H2), 3.78 (1H, dd, J = 11.5, 4.5 Hz, CH_2Cl), 3.66 (1H, dd, J = 11.5, 6.3 Hz, CH_2Cl), 3.50 (3H, s, OCH_3), 3.49 (3H, s, OCH_3), 3.36 (1H, br dd, J = 15.5, 9.4 Hz, H3), 3.16 (1H, br dd, J = 15.5, 6.8 Hz, H3); ^{13}C nmr ($CDCl_3$) δ: 152.3, 143.4, 141.3, 127.3, 106.7, 105.8, 95.5, 95.4, 81.9, 56.3, 55.9, 45.7, 34.2; hreims (probe 150°C), m/z calcd. for $C_{13}H_{17}O_5Cl$ (M^+): 288.0765; found: 288.0765 (24), 290/288 (24:8), 45 (100). Further elution gave a mono-(methoxymethyl) ether of the resorcinol (25 mg, 12%); ^{1}H nmr ($CDCl_3$) δ: 6.53 (1H, d, J = 2.2 Hz), 6.37 (1H, ddd, J = 2.2, 1.0, 1.0 Hz), 5.19 (2H, s), 4.95 (1H, dddd, J = 9.1, 7.0, 7.0, 4.5 Hz), 4.61 (1H, s), 3.77 (1H, dd, J = 11.5, 5.0 Hz), 3.66 (1H, dd, J = 11.2, 6.9 Hz), 3.50 (3H, s), 3.33 (1H, br dd, J = 16.0, 9.1 Hz), 3.14 (1H, dd, J = 16.0, 7.0 Hz).

Alkylation of the bis(methoxymethyl) ether of 2,3-dihydro-2-chloromethyl-5,7-dihydroxybenzofuran

n-Butyllithium (0.40 mL of a 1.6 M solution in hexanes) was added to a stirred solution of diisopropylamine (90 μL, 0.643 mmol) in THF (6 mL) at 0°C under argon. The solution of lithium diisopropyl amide was cooled to −78°C and crotyl phenyl sulfide (10) (107 μL, 0.652 mmol) was added. The yellow solution was stirred at −78°C for 25 min, then a solution of sodium iodide (20 mg, 0.133 mmol) and the bis(methoxymethyl) ether **21** (46 mg, 0.16 mmol) in THF (1 mL) and DMPU (0.5 mL) was added slowly via a cannula. The flask containing the bis(methoxymethyl) ether and sodium iodide was rinsed into the reaction vessel using further THF (0.5 mL) and the resulting orange

For personal use only.

solution was stirred at −78°C for 1.5 h. The solution was then brought to 0°C, quenched with water, diluted with ethyl acetate, and washed successively with 0.05 M hydrochloric acid, water, and saturated sodium hydrogen carbonate. Evaporation of the dried solution and flash chromatography of the product, eluting with ethyl acetate – Skellysolve B (1:5), gave successively unreacted crotyl phenyl sulfide, the bis(methoxymethyl) ether of 2,3-dihydro-5,7-dihydroxy-2-[1-(2-phenylthio-3-pentenyl)]benzofuran **22** (52.1 mg, 95% based on recovered **21**), and unreacted bis(methoxymethyl) ether **21** (8.3 mg).

The alkylation product **22** was obtained as an oil; ^{1}H nmr ($CDCl_3$) δ: 7.36–7.43 (2H, m, PhS), 7.18–7.33 (3H, m, PhS), 6.68 (1H, d, J = 2.3 Hz, H6), 6.58 (1H, dd, J = 2.5, 1.3 Hz, H4), 5.26–5.51 (2H, m, H3′, H4′), 5.19, 5.202, 5.205 (2H, 3 s, OCH_2O), 5.06 (2H, s, OCH_2O), 4.81–5.04 (1H, m, H2), 3.90 (<1H, ddd, J = 9.5, 8.7, 5.0 Hz, H2′), 3.74 (<1H, dd, J = 15.0, 7.5 Hz, H2′), 3.47, 3.49, 3.51 (6H, 3 s, OCH_3), 3.25, 3.26 (1H, 2 br dd, J = 15.5, 9.0 Hz, H3), 2.82, 2.83 (1H, 2 dd, J = 15.5, 8.0 Hz, H3), 2.18–2.32 (1H, m, H1′), 1.94 (<1H, ddd, J = 13.8, 6.9, 6.9 Hz, H1′), 1.84 (<1H, ddd, J = 14.5, 9.8, 4.7 Hz, H1′), 1.72 (<1H, br dd, J = 5.0, 5.0 Hz, H1′), 1.59, 1.62 (3H, 2 dd, J = 6.4, 1.0 Hz, H5′); hreims (probe 150°C), m/z calcd. for $C_{23}H_{28}O_5S$ (M^+): 416.1658; found: 416.1658 (36), 306 (M^+ − PhSH, 2), 262 (7), 239 (36), 45 (100).

*2,3-Dihydro-5,7-bis[(methoxy)methyleneoxy]-2-[1-(1,3-pentadienyl)]benzofuran (**24**) ((+/−)Bismethoxymethylarthrographol)*

A solution of *m*-chloroperbenzoic acid (27 mg, 0.133 mmol) in dichloromethane (1.5 mL) was added to a solution of the sulfide **22** (52.1 mg, 0.125 mmol) in dichloromethane (5 mL) and the reaction mixture stirred at 0°C for 2.5 h. The solution was then diluted with ethyl acetate, washed with saturated sodium hydrogen carbonate, and evaporated to give an oil. Flash chromatography, eluting with ethyl acetate – Skellysolve B (1:1), gave the sulfoxide **23** (45.2 mg), which was used in the next step without further purification; hreims (probe 150°C), m/z calcd. for $C_{17}H_{24}O_6$ (M^+ − C_6H_5S): 324.1573; found: 324.1575 (3), 306 (M^+ − PhSOH, 21), 126 (PhSOH, 10), 125 (10), 78 (17), 45 (100). A solution of the sulfoxide **23** (45.2 mg, 0.104 mmol) and triethylamine (0.15 mL, 1.08 mmol) in benzene (5 mL) was stirred and refluxed under argon for 27 h. Removal of solvents and chromatography of the resulting pale brown oil, eluting with ethyl acetate – Skellysolve B (1:5), gave the diene **24** as a clear oil (17.8 mg, 46% from the sulfide **22**); ^{1}H nmr ($CDCl_3$, major diene) δ: 6.70 (1H, br d, J = 2.5 Hz), 6.60 (1H, br s), 6.28 (1H, dd, J = 15.0, 10.5 Hz, H2′), 6.05 (1H, br ddq, J = 15.0, 10.5, 1.5 Hz, H3′) 5.75 (1H, dq, J = 15.0, 7.0 Hz, H4′), 5.72 (1H, dd, J = 15.3, 7.5 Hz, H1′), 5.23 (1H, ddd, J = 8.2, 8.2, 8.2 Hz, H2), 5.19 (2H, s, OCH_2O), 5.07 (2H, s, OCH_2O), 3.47 (3H, s, OCH_3), 3.45 (3H, s, OCH_3), 3.31 (1H, dd, J = 15.5, 9.5 Hz, H3), 2.98 (1H, dd, J = 15.5, 8.6 Hz, H3), 1.76 (3H, br d, J = 7.0 Hz, H5′); ^{13}C nmr ($CDCl_3$, major diene) δ: 151.9, 143.7, 141.2, 133.0, 131.2, 130.5, 128.8, 106.7, 105.8, 95.6, 95.4, 84.3, 56.2, 55.9, 37.0, 18.1 (1 signal obscured); hreims (probe 150°C), m/z calcd. for $C_{17}H_{22}O_5$ (M^+): 306.1467; found: 306.1474 (24), 229 (11), 207 (8), 45 (100).

*Bis(ethoxyethyl) ether of 2,3-dihydro-2-chloromethyl-6,8-dihydroxybenzofuran (**25**)*

A solution of ethyl vinyl ether (0.25 mL, 2.6 mmol), the resorcinol **20** (50 mg, 0.25 mmol), and a small crystal of pyridinium *p*-toluenesulfonate in dichloromethane (5 mL) was stirred under argon for 20 h, then filtered through a short (2 cm) plug of silica gel, eluting with ethyl acetate – Skellysolve B (1:5, 100 mL). Removal of solvents gave the bis(ethoxyethyl) ether of 2,3-dihydro-2-chloromethyl-6,8-dihydroxybenzofuran (**25**) (86 mg, 99%) as a clear oil; Ftir ($CHCl_3$ cast): 1607, 1482, 1382, 1192, 1152, 1135, 1110, 1076, 1052 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.64, 6.62 (1H, 2 m), 6.55 (1H, m), 5.40, 5.39 (1H, 2 overlapping q, J = 5.5 Hz, $OCH(CH_3)OCH_2CH_3$), 5.29 (1H, q, J = 5.4 Hz, $OCH(CH_3)OCH_2CH_3$), 4.98 (1H, m, H2), 3.94–3.74 and 3.72–3.52 (6H, 2 m, CH_2Cl, and OCH_2CH_3), 3.34 (1H, br dd, J = 16.0, 9.0 Hz, H3), 3.12 (1H, ddd, J = 16.0, 6.6, 2.9 Hz, H3), 1.48, 1.47 (3H, 2 d, J = 5.3 Hz, $OCH(CH_3)OCH_2CH_3$), 1.43 (3H, d, J = 5.3 Hz, $OCH(CH_3)CH_2CH_3$), 1.21, 1.20, 1.19 (6H, 3 t, J = 7.0 Hz, OCH_2CH_3); hreims (probe 150°C), m/z calcd. for $C_{17}H_{25}O_5Cl$ (M^+): 344.1390; found: 344.1390 (3), 299 (3), 272 (4), 227 (5), 202 (33), 201 (11), 200 (100), 73 (39).

Alkylation of the bis(ethoxyethyl) ether of 2,3-dihydro-2-chloromethyl-5,7-dihydroxybenzofuran

n-Butyllithium (0.54 mL of a 1.12 M solution in hexanes, 0.605 mmol) was added to a stirred solution of diisopropylamine (85 μL, 0.608 mmol) in THF (6 mL) at 0°C under argon. The solution of lithium diisopropyl amide was cooled to −78°C and crotyl phenyl sulfide (95 μL, 0.579 mmol) was added dropwise. The yellow solution was stirred at −78°C for 35 min, then a solution of sodium iodide (90 mg, 0.60 mmol) and the bis(ethoxyethyl) ether **25** (100 mg, 0.291 mmol) in THF (1 mL) and DMPU (1.0 mL) was added slowly via a cannula. The flask containing the bis(ethoxyethyl) ether and sodium iodide was rinsed into the reaction vessel using further THF (0.5 mL) and the resulting orange solution was stirred at −78°C for 35 min. The solution was then brought to 0°C, quenched with water (1 mL), diluted with ethyl acetate, and washed successively with 0.05 M hydrochloric acid, water, and saturated sodium hydrogen carbonate. Evaporation of the dried solution and flash chromatography of the product, eluting with ethyl acetate – Skellysolve B (1:10), gave unreacted crotyl phenyl sulfide, followed by the bis(ethoxyethyl) ether of 2,3-dihydro-5,7-dihydroxy-2-[1-(2-phenylthio-3-pentenyl)]benzofuran (**26**) (97.6 mg, 71%); ^{1}H nmr ($CDCl_3$) δ: 7.15–7.50 (5H, m, PhS), 6.57–6.65 (1H, m), 6.54 (1H, br s), 5.26–5.51 (2–3H, m), 5.19 (1H, q, J = 5.5 Hz), 4.97–5.10 (<1H, m), 4.76–4.92 (<1H, m), 3.71–3.97 (2H, m), 3.50–3.64 (2H, m), 3.20–3.32 (1H, m), 2.76–2.90 (1H, m), 2.14–2.30 (1H, m), 1.77–2.05 (1H, m), 1.63 (<3H, br d, J = 6.3 Hz), 1.58 (<3H, br d, J = 6.5 Hz), 1.47–1.51 (6H, m), 1.43 d, J = 5.5 Hz), 1.21 (6H, br t, J = 7.5 Hz); hreims (probe 160°C), m/z calcd. for $C_{27}H_{36}O_5S$ (M^+): 472.2284; found: 472.2274 (6), 329 (14), 328 (65), 219 (37), 218 (100), 189 (14), 163 (30), 151 (89), 150 (19), 139 (21), 110 (11), 73 (51), 45 (92), 44 (14), 43 (15).

1′(E),3′(E)-2,3-Dihydro-5,7-dihydroxy-2-[1-(1,3-pentadienyl)] benzofuran ((+/−) arthrographol)

A solution of *m*-chloroperbenzoic acid (63 mg, 95% assay, 0.346 mmol) in dichloromethane (4 mL) was added to a solution of the sulfide **26** (150 mg, 0.318 mmol) in dichloromethane (10 mL) and the reaction mixture stirred at 0°C under argon for 30 min. The solution was then diluted with further dichloromethane and washed with saturated sodium hydrogen carbonate. Evaporation of the dried solution gave the crude sulfoxide **27** (153.6 mg), which was used immediately without further purification. A solution of the crude sulfoxide **27** and triethylamine (0.50 mL, 3.59 mmol) in benzene (10 mL) was stirred and refluxed under argon for 4 h, then allowed to stand at room temperature overnight. The mixture was diluted with ethyl acetate and washed successively with 1 M hydrochloric acid, water, and saturated sodium hydrogen carbonate. Evaporation of the dried solution gave an oil, which was chromatographed, eluting with ethyl acetate – Skellysolve B (1:5), to afford a mixture of the bis(ethoxyethyl) ethers of 2,3-dihydro-5,7-dihydroxy-2-[1-(1,3-pentadienyl)]benzofuran (**28**) as an oil; hreims (probe 120°C), m/z calcd. for $C_{21}H_{30}O_5$ (M^+): 362.2093; found: 362.2116 (4), 219 (15), 218 (100), 163 (11), 138 (20), 73 (37), 45 (71). The mixture of bis-(ethoxyethyl) ethers **28** was stirred in a solution of acetic acid – methanol–water (1:50:50, 10 mL) for 1 h, then poured into saturated sodium hydrogen carbonate. The aqueous mixture was extracted (3×) with ethyl acetate and the combined extracts were dried and evaporated to an oil, which was flash chromatographed. Elution with ethyl acetate – Skellysolve B (1:3) gave an oily forerun that was discarded, followed by (+/−) arthrographol (22.2 mg, 32% from the sulfide **26**), which was contaminated with minor amounts of other diene isomers. The impure (+/−) arthrographol was recrystallized from ethyl acetate – Skellysolve B – dichloromethane to give pure (+/−) arthrographol (**1**) as needles (13.2 mg), mp 124–126°C (lit. (2) mp of (−)-**1**, 122°C); Ftir (KBr): 3440, 3420, 1660, 1641, 1615, 1503, 1489, 1471, 1163, 1130, 1047, 991, 850, 838, 810 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 6.30 (1H, dd, J = 15.5, 10.5 Hz, H2′), 6.27 (1H, d, J = 2.5 Hz, H6), 6.25 (1H,

distorted dd, J = 2.0, 1.0 Hz, H4), 6.08 (1H, ddq, J = 15.0, 10.5, 1.5 Hz, H3′), 5.79 (1H, dq, J = 15.1, 7.0 Hz, H4′), 5.72 (1H, dd, J = 15.0, 7.8 Hz, H1′), 5.20 (1H, ddd, J = 8.3, 8.3, 8.3 Hz, H2), 4.90 (1H, s, OH), 4.43 (1H, s, OH), 3.30 (1H, dd, J = 15.5, 8.8 Hz, H3), 2.98 (1H, br dd, J = 15.5, 8.5 Hz, H3), 1.77 (3H, dd, J = 7.0, 1.5 Hz, H5′); hreims (probe 120°C), m/z calcd. for $C_{13}H_{14}O_3$ (M^+): 218.0943; found: 218.0941 (100), 203 (17), 185 (11), 164 (11), 163 (65), 139 (30), 138 (57), 91 (12), 80 (11), 79 (16), 77 (16), 65 (10), 41 (12), 39 (16).

Further elution of the column with ethyl acetate – Skellysolve B (1:1) gave the cyclopropane **29** as an oil (9.3 mg, 18%); ^{1}H nmr ($CDCl_3$–CD_3OD) δ: 6.34 (1H, d, J = 2.5 Hz, H4 or H6), 6.13 (1H, d, J = 2.5 Hz, H4 or H6), 4.71 (1H, ddd, J = 5.5, 5.5, 2.0 Hz, H2), 2.47 (1H, ddd, J = 9.0, 5.5, 4.0 Hz, H3), 0.89 (1H, ddd, J = 9.0, 5.5, 5.5 Hz, CH_2), 0.28 (1H, ddd, J = 5.5, 4.2, 2.0 Hz, CH_2); hreims (probe 80°C), m/z calcd. for $C_9H_8O_3$ (M^+): 164.0474; found: 164.0463 (100), 165 (67), 163 (47), 136 (10), 121 (10), 108 (10), 93 (10), 80 (14), 79 (13), 78 (10), 77 (15), 67 (13), 65 (11), 43 (15), 39 (13).

The proton affinities and deprotonation enthalpies of β-D-fructopyranose and α-L-sorbopyranose

ROBERT J. WOODS, WALTER A. SZAREK,[1] AND VEDENE H. SMITH, JR.[1]
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received June 4, 1990[2]

This paper is dedicated to Professor Ross Stewart on the occasion of his 65th birthday

ROBERT J. WOODS, WALTER A. SZAREK, and VEDENE H. SMITH, JR. Can. J. Chem. **69**, 1917 (1991).

The proton affinities (PAs) and deprotonation enthalpies (DPEs) were calculated for the pyranoid forms of two naturally occurring sugars, D-fructose and L-sorbose. In both molecules the PAs of the primary hydroxyl group (HO-1), the anomeric hydroxyl group (HO-2), and the ring-oxygen atom (O-6) were calculated, as were the DPEs of HO-1 and HO-2. The stabilities of the conjugate acids and bases of these sugars are enhanced by the presence of intramolecular hydrogen bonding, a feature that is significant in explaining the differences in sweetness and the rates of mutarotation of the title compounds, as well as the differences in the rates of acid-catalyzed hydrolysis of ketopyranosides.

Key words: proton affinity, deprotonation enthalpy, *ab initio* calculations, AM1, hexuloses.

ROBERT J. WOODS, WALTER A. SZAREK et VEDENE H. SMITH, JR. Can. J. Chem. **69**, 1917 (1991).

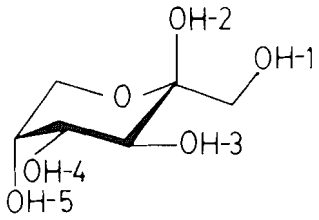
On a calculé les affinité protoniques (AP) et les enthalpies de déprotonation (EDP) des formes pyranoïdes de deux sucres naturels, le D-fructose et le L-sorbose. Dans les deux molécules, on a calculé les AP du groupe hydroxyle primaire (OH-1), du groupe hydroxyle anomérique (OH-2) et de l'atome d'oxygène du cycle (O-6) ainsi que les EDP du HO-1 et du HO-2. Les stabilités des acides et des bases conjugués de ces sucres sont augmentées par la présence d'une liaison hydrogène intramoléculaire, une caractéristique qui est importante pour expliquer les différences dans la douceur et les vitesses de mutarotation des composés mentionnés dans le titre ainsi que dans les vitesses d'hydrolyses acido-catalysées des cétopyranosides.

Mots clés : affinité protonique, enthalpie de déprotonation, calculs *ab initio*, AM1, hexyloses.

[Traduit par la rédaction]

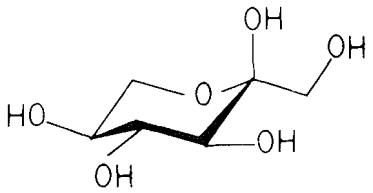
Introduction

The most direct computational approach to the measurement of atomic and molecular acidities and basicities is through evaluation of the deprotonation enthalpies (DPEs) and proton affinities (PAs) of the acids and bases, respectively. *Ab initio* computational methods are well suited for the evaluation of the PAs and DPEs of small molecules, and have been employed extensively for such calculations (1). Del Bene (2) has reported the effects of basis set choice and electron correlation on *ab initio* calculations of the PAs of several oxygen and nitrogen bases, consisting of compounds containing no more than two non-hydrogen atoms. The most accurate results reported by her were within 1–3 kcal/mol of the experimental values, and were obtained from calculations employing a triple-split valence basis set (6-311G) with two sets of polarization functions and one set of diffuse functions on all non-hydrogen atoms, and one set of polarization functions on the hydrogen atoms. It should be noted that it has been recently reported (3) that the 6-311G basis set is actually of valence double-zeta (ζ) quality. Corrections for electron correlation and zero-point vibrational energy were included by Del Bene (2), and the calculations were performed on geometries optimized with a 6-31G* basis set. It has been reported that the inclusion of electron correlation may lead to an incorrect prediction of the sign of the correlation contribution (4), unless a sufficiently large basis set is employed. Calculations performed without diffuse functions, such as at the 6-31G* level, have been shown to predict proton affinities less accurately by 1–3 kcal/mol (2). As might be expected, smaller basis sets do not predict absolute PAs satisfactorily; however, estimates of relative PAs may be made with some success, even with minimal STO-3G level calculations (5).



The calculation of accurate DPEs is somewhat more challenging, as it is necessary to allow the extra electrons, associated with the deprotonated species, to be distributed farther from the nuclei than are the electrons in the neutral species. Consequently, it has been reported that the use of basis sets incorporating diffuse functions is required (5).

Unfortunately, in calculations of the energies of larger molecules such as monosaccharides, it is often unfeasible to perform full geometry optimizations at the *ab initio* level. Moreover, to obtain meaningful values it would be necessary to choose a basis set that could not only provide the required accuracy in the calculation of the PAs and DPEs, but could reproduce also the energies associated with intramolecular hydrogen bonding and the stereoelectronic *exo*-anomeric effect (6). With current computational limitations, such calculations are not practical at the *ab initio* level; however, in a study of the conformational preferences of hexuloses, such as β-D-fructopyranose (**1**) and α-L-sorbopyranose (**2**), we (7) found that the AM1 semi-empirical molecular orbital method (8) performed well. Moreover, Dewar and Dieter (9) recently reported an examination of the application of AM1 in the calculation of the PAs and DPEs of a large selection of carbon, nitrogen, and oxygen bases and acids.



In the case of the PAs, Dewar and Dieter compared the AM1 results to experimental values, and to *ab initio* values calculated using a 6-31G* basis set employing geometries optimized at the 3-21G level. In the case of the DPEs, the AM1 results were compared to experimental values, and to *ab initio* values calculated at the 4-31+G level with, and without, second-order Møller–Plesset electron correlation, using geometries optimized at the 4-31+G level. The average error in the AM1-calculated PAs of the oxygen bases was reported to be 6.8 kcal/mol, while for the oxygen acids the average error in the DPEs was 7.6 kcal/mol. Those authors reported also that, for

β-D-Fructopyranose (**1**)

α-L-Sorbopyranose (**2**)

the oxygen bases, experimental trends in PAs were reproduced accurately by AM1. However, in the case of some of the oxygen acids, for example, the aliphatic alcohols, the calculated DPEs failed to reproduce the experimental trends, largely because of an observed increase in the error associated with the DPEs as a function of both the size of the alkyl group and the localization of the negative charge. Of relevance is the finding by those authors that, in the case of bifunctional bases, high PAs were obtained, in agreement with experiment, when intramolecular hydrogen bonds were able to stabilize the conjugate acids, and, moreover, that AM1 effectively reproduced this intramolecular hydrogen bonding.

For monosaccharides **1** and **2** it was not practical to perform *ab initio* calculations, and AM1 was selected as an alternative computational method for estimating the PAs and DPEs of these hexuloses.

Hydroxyl groups HO-1 and HO-2 in **1** and **2** are believed to bind to the sweet taste receptor through hydrogen bonding, in which the anomeric hydroxyl group has been considered to act as a proton donor (AH) group while the primary hydroxyl group has been considered to act as a proton acceptor (B) group (10). However, previous work by us indicated that the traditional assignment of the AH and B functionalities in **1** should be reversed (11, 12). A calculation of the PAs and DPEs of HO-1 and HO-2 was undertaken to address this question as well as to help explain the observation (10, 13) that **1** is significantly sweeter than **2**.

Presented in this paper are the calculated PAs of the primary hydroxyl group (HO-1), the anomeric hydroxyl group (HO-2), and the ring-oxygen atom (O-6), as well as the DPEs of HO-1 and HO-2, for both **1** and **2**. The errors associated with the DPEs were minimized in this study by limiting the calculations to molecules that had identical molecular formulas and differed in configuration at only one of the carbon nuclei. Furthermore, the anomeric effect (6) (in the case of deprotonation of HO-2) and intramolecular hydrogen bonding (in the cases of deprotonation of HO-1 and HO-2) should serve to delocalize the anionic charge.

Methodology

All calculations reported in this article were performed using the AM1 method, as provided in the AMPAC[3] package of computer programs, employing the keywords PRECISE, to lower all calculational tolerances by a factor of 100, and PULAY, to invoke Pulay's method (15) for achieving SCF convergence.

Starting geometries were defined using standard bond lengths and angles (16), and staggered torsion angles. Initially all of the C—O—H bond angles were defined, through the use of dummy atoms, as being linear. We found that optimization of these starting geometries consistently leads to low-energy, chemically reasonable, conformations, which often correspond to global energy minima (7). Other intramolecular hydrogen bond patterns were generated through manipulation of the hydroxyl groups in these optimized conformations, followed by reoptimization. While we found AM1 to perform well in the case of intramolecular hydrogen bonding, weaknesses associated with the AM1 calculated intermolecular hydrogen bonds were noted (17). In the case of the starting geometries of the protonated species, the protons were located about the oxygen atoms so as to generate planar trigonal geometries. For each structure the three staggered rotamers of the hydroxymethyl group (+gauche, *G*+; −gauche, *G*−; and anti-periplanar, *AP*; O-1 to O-2) were examined.

Discussion

Proton affinities

The calculated PAs of **1** and **2** are listed in Tables 1 and 2, respectively. The value reported by Stull and Prophet (18) for the heat of formation of H^+ (367.2 kcal/mol) was used in the calculation of all of the PAs and DPEs. Included for comparison

[3]AMPAC (QCPE Program No. 527) is described in the Quantum Chemistry Program Exchange newsletter (14).

[c]Values taken from ref. 7.

are the PAs of methanol (9) and methanediol.[4] The average PA of the anomeric oxygen atom (O-2) for the three rotamers of **1** was calculated to be 188 kcal/mol, whereas the average PA of O-1 for the same conformers was 183 kcal/mol. In each of the conformers of **1** the PA of O-2 was consistently higher than that of O-1. However, in both the case of protonation at O-1 and protonation at O-2, the *G*+ and *G*− rotamers gave rise to PAs that were approximately 5.5 kcal/mol higher than those calculated for the *AP* rotamers. This dependence of the PAs on the orientation of the hydroxymethyl group may be explained by an examination of the heats of formation of **1** and its protonated forms (see Table 1). The protonated *G*+ and *G*− rotamers of **1** were calculated to be more stable than the *AP* rotamers by approximately 6.5 kcal/mol for protonation at O-1 or O-2 whereas, in the case of the neutral species, the *G*+ and *G*− rotamers were calculated to be more stable than the *AP* rotamers by approximately 1 kcal/mol. Thus, the increased PAs for the *G*+ and *G*− conformations of **1** arise from corresponding increases in the stabilities of the protonated forms of these conformers. Methanediol has been studied (20) as a simple model for the anomeric effect (see ref. 6), and it is noteworthy that the PA of methanediol as calculated using AM1 is slightly lower than that of methanol. In the cases of HO-1 and HO-2 in **1** and **2**, the reverse trend in PAs is found, namely, the PA of the anomeric hydroxyl group is higher than that of the primary hydroxyl group.

The calculated PAs of **2** listed in Table 2 indicate the same general trends as observed for **1**. The PA of O-2 (185.6 kcal/mol) is higher on average than the PA of O-1 by approximately 3.5 kcal/mol. The *G*+ and *G*− rotamers again have the highest PAs, being higher by approximately 6 kcal/mol for protonation at O-1 or O-2 than calculated for protonation of the *AP* rotamers. Analogously to the case of **1**, the trends in the PAs of **2** reflect trends in stabilities of the protonated species. Of relevance is the observation that, for all conformers of **1** and **2**, the PA of O-2 in **1** was calculated to be higher than the PA of O-2 in **2** by 1–4 kcal/mol, whereas, the PAs of O-1 in both **1** and **2** are approximately equal for each corresponding rotamer, the difference in the average PAs being approximately 1 kcal/mol.

The average PAs for protonation at O-6 in both **1** and **2** were calculated to be approximately equal to the corresponding average PAs for protonation at O-1. However, unlike the case of protonation at O-1 or O-2, the lowest PAs calculated for O-6 occurred for conformations of **1** and **2** in which the hydroxymethyl groups adopted *G*− orientations. The PAs of the *G*− conformations were found to be lower by approximately 6 kcal/mol than those calculated for the *G*+ conformers. The *G*+ conformers were found to exhibit the highest PAs, which were higher by approximately 2 kcal/mol than predicted for the *AP* conformers.

The AM1 optimized geometries of the protonated forms of **1** and **2** are presented in Figs. 1 and 2, respectively. A summary of the intramolecular hydrogen bond geometries predicted for **1** and **2** is given in Tables 3 and 4, respectively. An examination of Figs. 1 and 2 indicates that the *G*+ and *G*− rotamers of **1** and **2**, when protonated at either O-1 or O-2, exhibit stabilizing interactions between the protonated hydroxyl groups and neighboring oxygen atoms. In the case of protonation at O-1 in the *G*+ rotamers, stabilizing interactions between $H(HO\text{-}1)^+$ and both O-2 and O-6 are present. The interaction of $H(HO\text{-}1)^+$ with O-2 in the *G*+ conformers of both **1** and **2** is facilitated by an orientation of HO-2 such that HO-2 adopts a torsion angle with respect to the ring-oxygen atom (O-6) of approximately 180°. We have previously used the term "anti-*exo*-anomeric" to describe this orientation of HO-2 (7). In this orientation hydrogen bonds extend between HO-2 and O-3, HO-3 and O-4, and HO-4 and O-5. In the case of **1**, HO-5 may be hydrogen bonded to the ring oxygen atom O-6, an interaction that was found also to be present in the neutral species (7). However, in the protonated form, the interaction between $H(HO\text{-}1)^+$ and O-6 has the effect of destabilizing any interaction between HO-5 and O-6, as indicated by the energy difference of approximately 1 kcal/mol between structures $\mathbf{1H}_{1g+}$(ii), which contains an interaction between HO-5 and O-6, and $\mathbf{1H}_{1g+}$(i), in which this interaction is absent.

Protonation of O-1 in **1** and **2**, in conformers in which O-1 adopts a *G*− orientation, led to the formation of hydrogen bonds between $H(HO\text{-}1)^+$ and both O-2 and O-3. An *exo*-anomeric orientation of HO-2 enabled the formation of a hydrogen bond between $H(HO\text{-}1)^+$ and O-2, and was accompanied by the formation of hydrogen bonds extending between HO-3 and O-4, HO-4 and O-5, and between HO-5 and O-6. Unlike the case of the *G*+ conformers of **1**, the most stable orientation of HO-5 in the *G*− conformers was that in which a hydrogen bond was present between HO-5 and O-6.

In the *AP* conformers of **1** and **2**, protonation of O-1 led to the generation of structures containing bifurcated hydrogen bonds between $H(HO\text{-}1)^+$ and O-6. In both **1** and **2**, an *exo*-anomeric orientation of HO-2 was preferred, with hydrogen bonds predicted between HO-3 and O-2. In the case of **2**, hydrogen bonds were predicted to exist also between HO-4 and O-3, and

[4]The values of the PA and DPE of methanediol were generated through protonation and deprotonation of the lowest energy conformer of methanediol as defined by constraining the H—O—C—O torsion angles to values of 60°. Details of these and related calculations at the *ab initio* level have been reported (19).

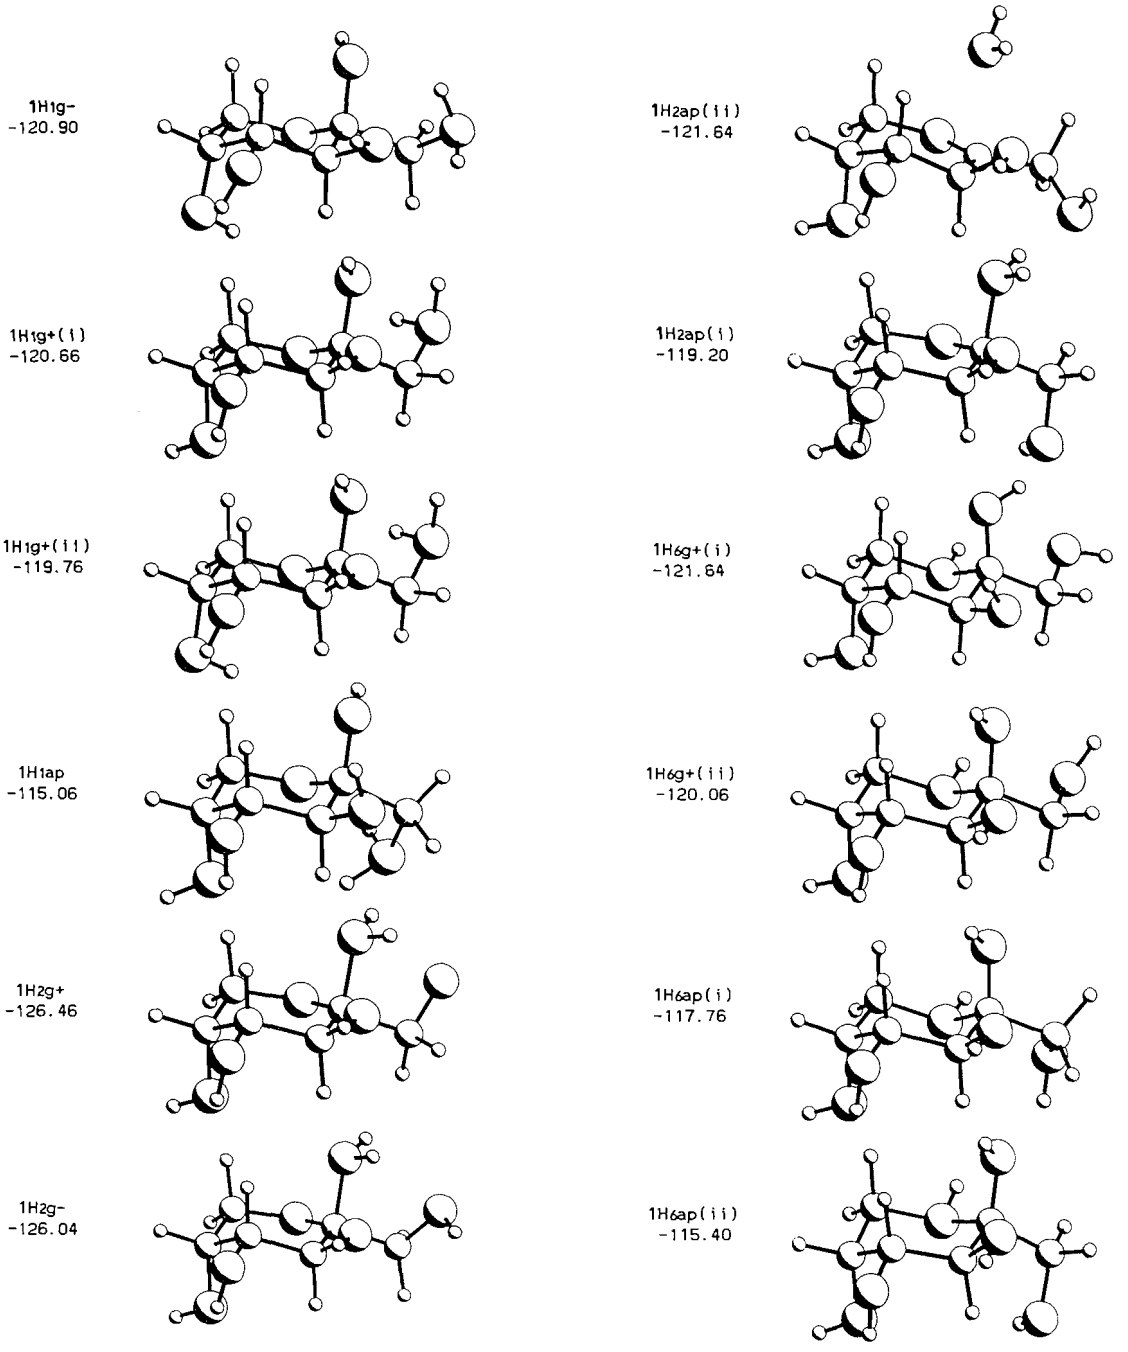

FIG. 1. AM1 optimized geometries and heats of formation (kcal/mol) of protonated β-D-fructopyranose (**1H**). Structures are listed in order of increasing energy for protonation at O-1, O-2, and O-6, respectively. Protonated species are indicated by "**H**" after the symbol for the neutral molecule, whereas deprotonated species are indicated by "−". Sites of protonation or deprotonation are indicated by a subscript numeral, indicating the relevant oxygen atom. The three staggered orientations of the hydroxymethyl groups are indicated by the symbols "g+" (+gauche), "g−" (−gauche), and "ap" (anti-periplanar), O-1 to O-2.

HO-5 and O-4 whereas, in the case of **1**, a hydrogen bond between HO-4 and O-5 was formed. These hydrogen bond patterns were predicted also to be present in the neutral forms of **1** and **2** (7). In the case of **1** protonated at O-1, the interaction between $H(HO\text{-}1)^+$ and O-6 precludes the possibility of hydrogen bonding between HO-5 and O-6.

Protonation of O-2 in both **1** and **2** led to structures in which hydrogen bonds were predicted to exist between $H(HO\text{-}2)^+$ and O-3, HO-3 and O-4, and HO-4 and O-5, regardless of the orientation of the hydroxymethyl group. In the case of **1**, there were no instances in which a hydrogen bond was predicted between HO-5 and O-6, an observation that is reflective of a reduced negative charge at O-6, presumably owing to a transfer of charge through the anomeric center to O-2. Moreover, the ring conformations of **1** and **2**, in conformers protonated at O-2, approach that of a half chair, as would be expected to arise from a depletion of electron density at C-2.

Both the *G*+ and *G*− conformers of **1** and **2**, when protonated at O-2, were found to exhibit hydrogen bonds between $H(HO\text{-}2)^+$ and O-1. Furthermore, in the *G*− conformers of both

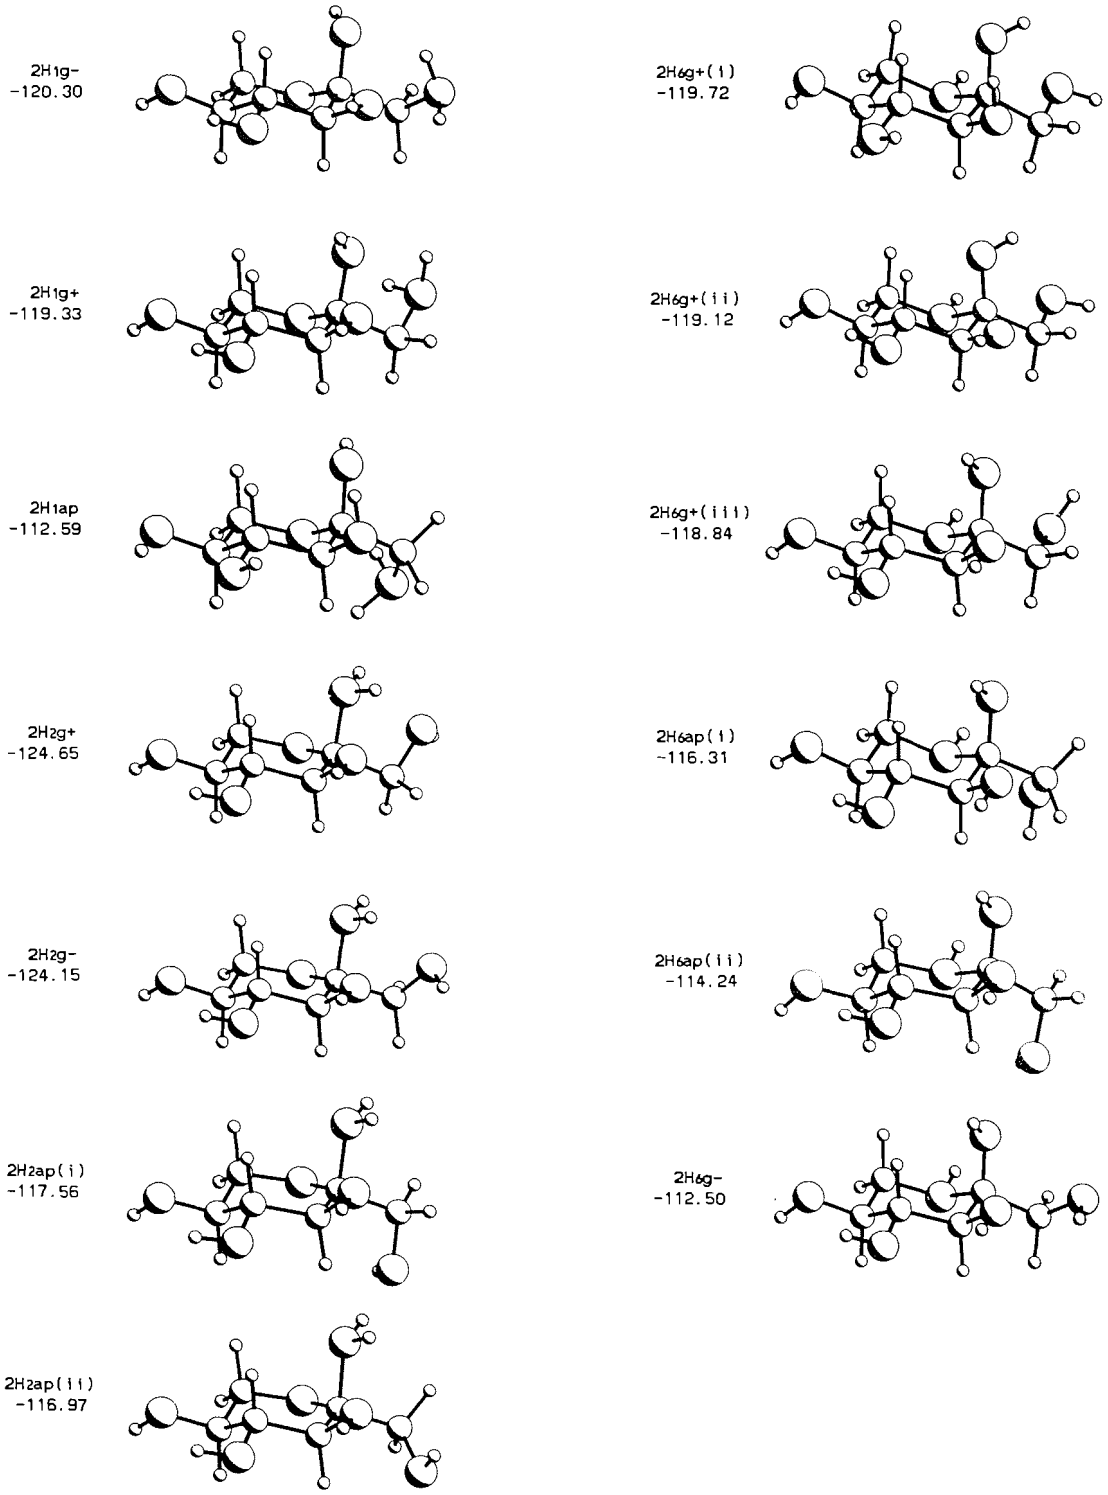

FIG. 2. AM1 optimized geometries and heats of formation (kcal/mol) of protonated α-L-sorbopyranose (**2H**). Structures are listed in order of increasing energy for protonation at O-1, O-2, and O-6, respectively. The definition of the symbols is given in the legend for Fig. 1.

1 and **2**, HO-1 was found to form a hydrogen bond with O-3. Weak hydrogen bonds between HO-1 and O-6 were predicted to form in the *AP* conformers of **1** and **2** when these conformers were protonated at O-2. The average HO-1—O-6 separation in structures $\mathbf{1H}_{2ap}$(i) and $\mathbf{2H}_{2ap}$(i) was 2.86 Å (see Tables 3 and 4), which may be compared to a corresponding value (7) of 2.34 Å for the neutral species. Lacking the ability to form hydrogen bonds between H(HO-2)$^+$ and O-1, the *AP* rotamers were predicted to be less stable by approximately 7 kcal/mol than the corresponding *G*+ or *G*− rotamers.

While conformer $\mathbf{2H}_{2ap}$(ii) indicated the possibility of a hydrogen bond existing between HO-1 and O-3, this structure was predicted to be slightly less stable than conformer $\mathbf{2H}_{2ap}$(i), in which a hydrogen bond existed between HO-1 and O-6. No conformer analogous to $\mathbf{2H}_{2ap}$(ii) was found for **1**, but rather, upon optimization, the corresponding rotamer of **1** gave rise

[c]Intermolecular hydrogen bond.

to a cyclic oxocarbenium ion – water complex, **1**H_{2ap}(ii) (see Fig. 1). While this complex was predicted to be more stable than **1**H_{2ap}(i) by approximately 2.5 kcal/mol, it was still less stable than the *G*+ and *G*− species by approximately 5 kcal/mol. Similar oxocarbenium ions have been shown to be produced during the gas-phase decomposition of protonated methyl 2,3,4,6-tetra-*O*-methyl-α- and β-D-galactopyranosides (21) and permethylated deoxyhexopyranosides (22), and are believed to be intermediates in glycoside hydrolysis (23, 24). The spontaneous generation of a cyclic oxocarbenium ion resulting from protonation of O-2 in **1** may be relevant to the mechanism of the mutarotation of ketopyranoses, in that protonation of the anomeric oxygen atom, rather than of the ring oxygen atom, may be the first step; however, it is recognized that mutarotation is a solution phenomenon. The mechanism by which aldopyranoses mutarotate has been well studied, and is believed to proceed through an acyclic aldehyde intermediate arising from protonation of the ring oxygen atom (25, 26). However, in the cases of both the acid-catalyzed anomerization and hydrolysis of aldopyranosides, a cyclic oxocarbenium ion, derived from protonation of the anomeric oxygen atom, has been indicated as an intermediate (26). That this cyclic oxocarbenium ion was found in the present study for **1** and not for **2** may be of relevance as regards both the rates of mutarotation of **1** and **2** and the rates of acid-catalyzed hydrolysis of the corresponding glycosides. It is well known that **1** exhibits rapid mutarotation while **2** does not (27), and that methyl β-D-fructopyranoside is hydrolyzed at a significantly faster rate than is methyl α-L-sorbopyranoside (28, 29). The implications of these calculations, as concerns the mechanisms of mutarotation of ketopyranoses and of ketopyranoside hydrolysis, will be the subject of a future study.

Arguments analogous to those presented above may be used to explain the differences in the PAs for protonation at O-6. Both the *G*+ and *AP* rotamers of **1** and **2** were predicted to provide stabilizing interactions between O-1 and $H(O\text{-}6)^+$, in the cases of protonation at the ring oxygen atom. No corresponding interactions were possible in the *G*− rotamers. These stabilizing interactions had the effect of lowering the heats of formation of the protonated *G*+ and *AP* conformers, relative to that of the *G*− species, by approximately 3.5 kcal/mol. Thus, for both **1** and **2** the difference between the PAs of O-6 in the *G*+ and *AP* rotamers, and the PA of O-6 in the *G*− rotamers, is related to the additional stabilizations present in the *G*+ and *AP* conformers.

The PAs given in Tables 1 and 2, and discussed above, indicate that the anomeric hydroxyl groups in **1** and **2** are more basic than either the hydroxymethyl groups or the ring oxygen atoms in these sugars, and may be assigned to the proton acceptor (B) unit of the saporous group (10). Moreover, the PA of HO-2 in **1** was found to be higher than the PA of HO-2 in **2**, by an average value of approximately 2.5 kcal/mol.

Deprotonation enthalpies

The calculated DPEs for HO-1 and HO-2 in **1** and **2** are listed in Tables 5 and 6, respectively. Included for comparison are the DPEs of methanol (9) and methanediol.[4] The average DPE for the anomeric hydroxyl groups in **1** and **2** is 352 kcal/mol, while that for the hydroxymethyl groups is 360 kcal/mol, features that confirm the expected trends in the acidities of these hydroxyl groups. The absolute values of the DPEs for HO-1 in both **1** and **2** do not differ significantly from one another, regardless of the orientations of the hydroxymethyl groups. Similarly, the DPEs for HO-2 in **1** and **2** are approximately equal for all conformers. The higher acidity of the acetal hydroxyl proton than the primary hydroxyl proton was further confirmed by the values for the DPEs of methanediol (378.8 kcal/mol) and methanol (385.4 kcal/mol).

It is noteworthy that fewer stable conformations of the deprotonated structures were found than of either the neutral or protonated species. The hydrogen bond geometries for the AM1 optimized geometries of deprotonated **1** and **2** are given in Tables 7 and 8, respectively. In the case of deprotonation at HO-1, in both **1** and **2**, only the *G*− rotamers formed stable structures, a feature likely arising from repulsions between O-6 and $(O\text{-}1)^-$. In structures **1**$-_{1g-}$ and **2**$-_{1g-}$, hydrogen bonds were predicted to exist between HO-2 and $(O\text{-}1)^-$, HO-3 and $(O\text{-}1)^-$, and HO-3 and O-2 (see Figs. 3 and 4). The two conformers differed in the orientations preferred by HO-4 and HO-5. In **1**$-_{1g-}$, hydrogen bonds were formed between HO-4 and O-5, and between HO-5 and the ring oxygen atom, O-6, while in rotamer **2**$-_{1g-}$, hydrogen bonds were found between HO-4 and O-3, and between HO-5 and O-4. This reversal in the direction of the intramolecular hydrogen bonds in the cases of **1** and **2** was predicted to be present in the neutral molecules (7).

Only in the case of **1** was a stable *AP* rotamer found in the species deprotonated at O-1, namely **1**$-_{1ap}$ (see Fig. 3). In this structure the pyranose ring was found to prefer a $^{3,6}B$(D) boat conformation, stabilized by the formation of hydrogen bonds

were predicted for the neutral and protonated species all have exhibited preferences for intramolecular hydrogen bonding in which O-1 acted as a proton acceptor. However, in the case of the deprotonated species, this rotamer would be expected to contain an unfavorable O-1···$(O\text{-}2)^-$ interaction that would inhibit the formation of stable *G*− conformations. In the *G*+ conformers hydrogen bonds were predicted to exist between HO-1 and $(O\text{-}2)^-$ and between HO-3 and $(O\text{-}2)^-$ for both **1** and **2**. In the case of **1**, further hydrogen bonding was observed between HO-4 and O-5, and HO-5 and O-6, whereas in the case of **2**, hydrogen bonds between HO-4 and O-3, and HO-5 and O-4, were preferred.

The *AP* conformers of **1** and **2**, deprotonated at O-2, gave rise to similar hydrogen bonding involving HO-3, HO-4, and HO-5, as seen in the *G*+ rotamers. Hydrogen bonds in the *AP* conformers, **1**−$_{2ap}$ and **2**−$_{2ap}$, were predicted to exist between HO-1 and O-6 as found in the neutral molecule (7).

Neither the geometries, nor the energies, of the conformers

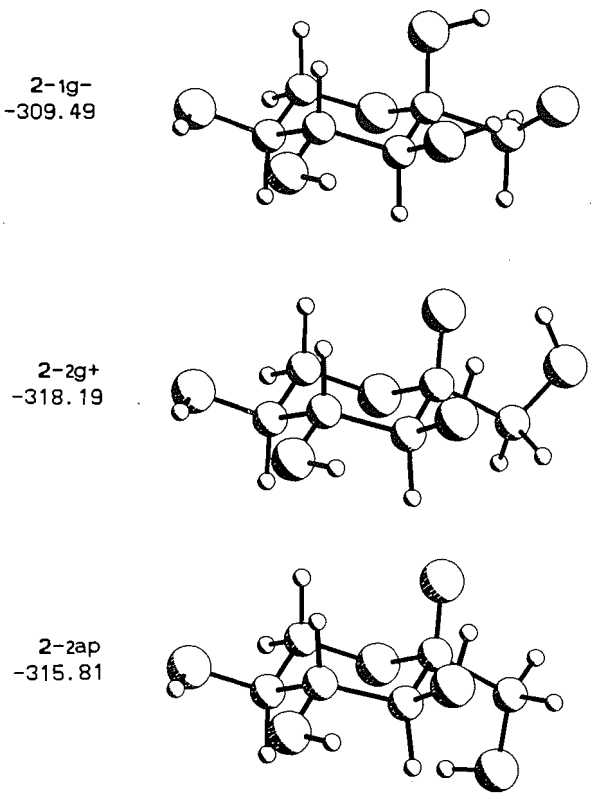

FIG. 4. AM1 optimized geometries and heats of formation (kcal/mol) of deprotonated α-L-sorbopyranose (**2**−). Structures are listed in order of increasing energy for deprotonation at O-1, O-2, respectively. The definition of the symbols is given in the legend for Fig. 1.

of the deprotonated forms of **1** and **2** exhibited any significant differences (with the exception of the formation of boat conformer $\mathbf{1}-_{1ap}$), an observation that indicates it is unlikely, at least in the gas phase, that the acidities of HO-1 or HO-2 in **1** and **2** are reflective of the different sweetness of these two sugars. However, the DPEs given in Tables 5 and 6, and discussed above, do indicate that, for both **1** and **2**, the anomeric hydroxyl group is more acidic than the hydroxymethyl group, HO-2 having an average DPE that was lower by approximately 8 kcal/mol than that of HO-1.

Conclusions

Based on the above analysis of the PAs and DPEs of **1** and **2**, it appears that the anomeric hydroxyl group is both more basic and more acidic than the hydroxymethyl group, and more basic than the ring heteroatom. The difference between the PAs of HO-1 and HO-2 was predicted to be approximately 5 kcal/mol in favor of the protonation of HO-2, whereas the difference between the DPEs of these groups was calculated to be approximately 8 kcal/mol in favor of the deprotonation of HO-2. Although these energies are not identical, their similarity indicates that the anomeric hydroxyl groups in **1** and **2** may be viewed as being amphiprotic. The higher acidity of HO-2 arises from a delocalization of the negative charge on O-2 in a manner equivalent to that responsible for the anomeric effect, namely, through an ($n_{O\text{-}2}$–$\sigma^*_{C—O\text{-}6}$) interaction, and results in an enhanced stabilization of the conjugate base. However, in the case of protonation, the basicity of HO-2 is enhanced by the presence of intramolecular hydrogen bonds in the conjugate acid between $H(HO\text{-}2)^+$ and other suitably located hydroxyl groups. The extent to which the conjugate acid is also stabilized through an ($n_{O\text{-}6}$–$\sigma^*_{C—O\text{-}2}$) anomeric interaction is not known; however, it has been reported that the protonation of sugars, in which the anomeric hydroxyl group is replaced by an amino group, leads to an attenuation of the anomeric effect, which is known as the "reverse anomeric effect" (6). Unlike the anomeric effect, in which an axial orientation is preferred at the anomeric center, the reverse anomeric effect is characterized by a preference for an equatorial orientation at that center.

The difference in the PAs of HO-2 in **1** and **2** suggests an explanation for the difference in the rates of mutarotation of these sugars and, moreover, may have broad implications as concerns the analysis of the rates of acid-catalyzed hydrolysis and anomerization of glycosides, it being recognized that these processes are solution phenomena.

The high PAs of HO-2 in both **1** and **2** indicate that the traditional assignment (10) of the proton donor (AH) unit to hydroxyl group HO-2, and the proton acceptor (B) unit to hydroxyl group HO-1, of the saporous group, should be reversed. That is, the anomeric hydroxyl group (HO-2) may be viewed as the proton acceptor unit, while the primary hydroxyl group (HO-1) may be the proton donor unit. Furthermore, the difference in the sweetness of **1** and **2** may be related to the difference in the PAs of the anomeric hydroxyl groups. The sugar is believed to bind to the taste receptor through a reciprocal hydrogen bond between the proton acceptor unit (B, HO-2) (11) and a proton donor unit in the receptor, and between the proton donor group (AH, HO-1) (11) and a proton acceptor unit in the receptor (10). The sweetness of the sugar would depend in part on the strength of this binding, a feature that would be reflected by the PA of HO-2 and the DPE of HO-1. In **1** and **2**, the DPEs of HO-1 were predicted to be approximately equal; however, the high PA of HO-2 in **1** would be expected to enhance the binding of **1** to the receptor, and may be responsible for the higher sweetness of **1**. The availability of low energy orientations of HO-2, which could facilitate hydrogen bond formation with the receptor, must be assumed to also play a significant role.

An NMR study of the structure and reactivity of phosphonium ylides stabilized by a carbonyl function

MARGARET M. KAYSER[1] AND KRISTA L. HATT
Department of Chemistry, University of New Brunswick, P.O. Box 5050, Saint John, N.B., Canada E2L 4L5
AND
DONALD L. HOOPER
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received March 26, 1991

MARGARET M. KAYSER, KRISTA L. HATT, and DONALD L. HOOPER. Can. J. Chem. **69**, 1929 (1991).

The structures of five stabilized phosphonium ylides **1–5** were studied by ^1H, ^{13}C, and ^{31}P NMR. Various trapping experiments were followed by investigation of the relative reactivities of these ylides vis-à-vis benzaldehyde. A novel effect of some significance, the influence of acidic contaminants (conjugate acids, H_2O, etc.) on the structure and reactivity of these compounds, is discussed.

Key words: stabilized phosphoranes, Wittig condensations, acid catalysis.

MARGARET M. KAYSER, KRISTA L. HATT et DONALD L. HOOPER. Can. J. Chem. **69**, 1929 (1991).

Faisant appel à la RMN du ^1H, du ^{13}C et du ^{31}P, on a étudié les structures de cinq ylures de phosphonium stabilisés (**1–5**). Après diverses expériences de piégeage, on a aussi examiné les réactivités relatives des ces ylures vis-à-vis du benzaldéhyde. On discute d'un nouvel effet qui a une certaine importance : l'influence des contaminants acides (acides conjugués, H_2O, etc.) sur la structure et la réactivité des ces composés.

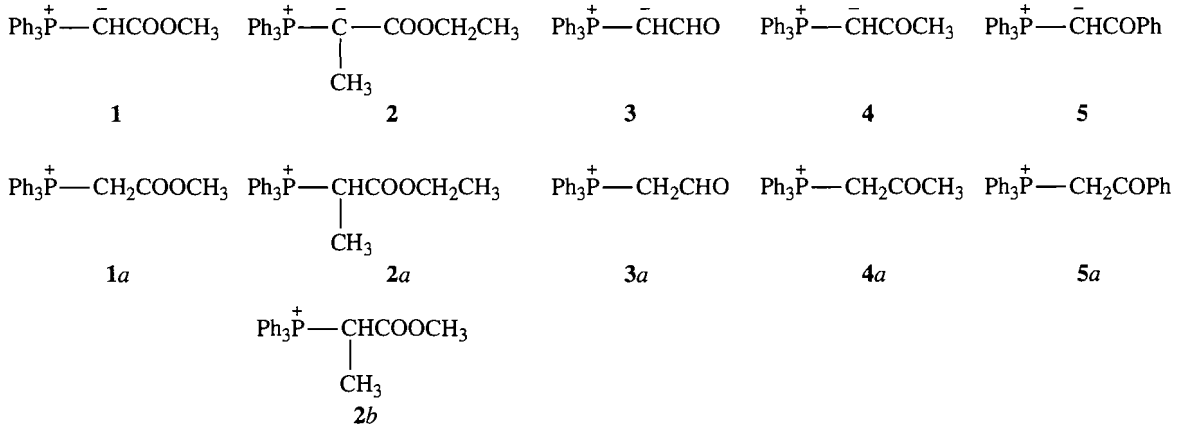
Mots clés : phosphoranes stabilisés, condensations de Wittig, catalyse acide.

[Traduit par la rédaction]

Introduction

Stabilized phosphoranes such as methyl (triphenylphosphoranylidene)acetate **1** or 1-triphenylphosphoranylidene-2-propanone **4** derive much of their importance from their utility in the synthesis of α,β-unsaturated esters and ketones. As a result, numerous studies on the mechanism and stereochemistry of these condensations have been conducted over the years (1, 2). In spite of considerable efforts no experimental evidence of any, even transient, intermediates has so far been reported, and the course of these reactions still remains largely speculative (3).

In the course of our studies of the condensations of stabilized phosphoranes with various cyclic anhydrides by ^{31}P NMR, we noted small but persistent downfield drifts of ylide signals. As it was not clear whether the drifts were related to the temperature variation or to some transformation of the ylide during the reactions, we decided to conduct a background study of the temperature-related behaviour of selected stabilized ylides prior to the investigation of their condensations with carbonyl compounds.

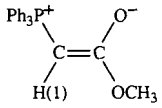


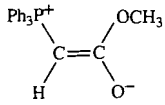
This paper reports a variable-temperature ^1H, ^{13}C, and ^{31}P NMR study of five commonly used ylides **1–5**, the subsequent investigation of their structures, and a base-line comparison of their reactivities vis-à-vis benzaldehyde.

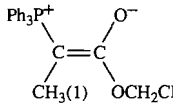
Results

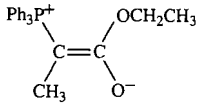
Our ^1H NMR study of ylide **1**, discussed extensively in the previous communication (7), supported the earlier findings (4–6). More complete data on the ^1H, ^{13}C, and ^{31}P chemical shifts and nuclear spin coupling constants for the five ylides under investigation are listed in Tables 1 and 2.

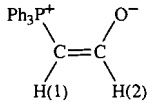
Methyl (triphenylphosphoranylidene)acetate 1

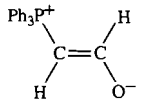


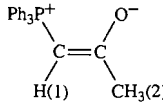


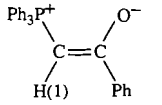












As the spectroscopic data for ylide **1** have been discussed previously (7) only the main points are reiterated here. The ^1H NMR spectrum of phosphorane **1** at room temperature shows two sharp signals corresponding to the protons of the methoxy group at 3.50 ppm and the methine proton at 2.95 ppm. No proton–phosphorus coupling is observed since the highly labile proton exchanges rapidly with traces of acidic contaminants

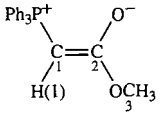
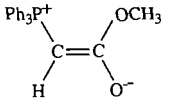
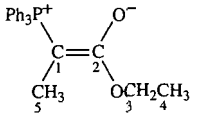
(conjugate acid, atmospheric water, traces of DCl from solvent) at room temperature. When care is taken to minimize atmospheric moisture, both signals broaden significantly. When the ylide and the solvent $CDCl_3$ are treated to remove traces of water, and the spectra recorded under anhydrous conditions, further broadening is observed. At low temperatures, proton exchange slows sufficiently for the phosphorus–hydrogen coupling to be observable; moreover, as the proton exchange is slowed it becomes evident that the ylide exists in two distinct isomeric forms, *cis* (*E*) and *trans* (*Z*).

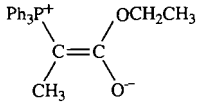
When a trace amount of BuLi is added to the $CDCl_3$ solution of the ylide, to remove conjugate acid and all other sources of acidic protons, the two isomeric structures become sharply distinct even at room temperature, their stability increased by the complexation of the enolate ions **1**-*cis* and **1**-*trans* (in the ratio 3:1) with available lithium cations.

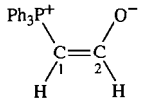
It should be pointed out, however, that the lithium cation, although apparently stabilizing, is not essential for the room temperature stability of **1**-*cis* and **1**-*trans*. When other "proton sponges" such as CaH_2 or 1,1,1,3,3,3-hexamethyldisilazane are employed, the spectra of **1** are very similar to those obtained after treatment with BuLi. The ^{13}C and ^{13}P NMR studies of ylide **1** confirm the above findings (7).

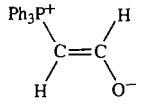


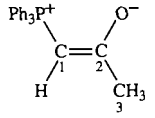


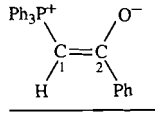












(Carboethoxyethylidene) triphenylphosphorane **2**

At −40°C ylide **2** also exists in two isomeric forms, with the **2**-*trans* (*Z*) configuration being the more abundant (75%) according to Crouse *et al.* (8). At this temperature the signals for the methylene protons (-OCH_2CH_3) show as two sharp quartets at 3.73 ppm *trans* and 4.07 ppm *cis* and the two methyl triplets are at 0.37 ppm *trans* and 1.28 ppm *cis*, Fig. 1. On warming to +35°C the methylene protons collapse to a single distinct quartet while the methyl group gives a broad poorly defined triplet. The two isomeric forms, however, become clearly distinguishable at this temperature when the sample is treated with a drop of BuLi.

The ^{13}C shift and coupling data for **2** at −40°C indicate the presence of a mixture of *cis* and *trans* structures. At room temperature, only a single form is observable, with chemical shifts corresponding closely to those described by Gray (9). This spectrum resolves to that of the two forms upon addition of BuLi.

In the low temperature ^{31}P spectrum, a commercial sample of ylide **2** gives a broad peak at 23.48 ppm, and a small signal corresponding to its conjugate acid, **2***a*, at 26.29 ppm. Even on treatment with BuLi, which removes the conjugate acid, the peak at 23.48 ppm ($\nu_{\frac{1}{2}}$ = 65 Hz) is not resolved, indicating that the ^{31}P signals of the two isomers overlap. This is confirmed by the fact that as the temperature is raised to +20°C the signal becomes considerably narrower ($\nu_{\frac{1}{2}}$ = 34 Hz).

(Triphenylphosphoranylidene)acetaldehyde 3

NMR shows that a sample of ylide **3**, dried but not treated with BuLi, is a mixture of isomeric forms **3**-*cis* (*Z*) and **3**-*trans* (*E*) in the ratio 3:2 even at room temperature. Coalescence of the signals occurs above 80°C, which, along with the low temperature limiting frequency difference, corresponds well to the $\Delta G^{\neq}$ = 17.6 kcal/mol calculated by Snyder and Bestmann (10).

At low temperature (−40°C), spectra of **3** are identical to those run at room temperature, Fig. 2. When precautions are not taken to prevent the exposure of ylide **3** to air and moisture, the ^{1}H NMR spectrum at +30°C shows broad singlets without distinguishing features for all protons. The conjugate acid **3***a* is unstable; we were unable to prepare it or even to observe its signals in the NMR spectra.

1-Triphenylphosphoranylidene-2-propanone 4

Only a single structure is discernible for ylide **4** in NMR spectra at −40°C, as well as at room temperature. In the ^{1}H spectrum the methine proton is a doublet centered at 3.70 ppm with J_{PH} = 26 Hz. Methyl protons show as a doublet at 2.10 ppm with the coupling constant to ^{31}P of 3 Hz. In the presence of traces of conjugate acid both methine and methyl signals collapse to singlets. The ^{31}P spectra of **4** at room temperature and at −40°C show only a sharp singlet at 13.23 ppm ($\nu_{\frac{1}{2}}$ = 4.96 Hz).

Benzoylmethylene triphenylphosphorane 5

In a room temperature ^{1}H spectrum of a commercial sample of ylide **5**, the methine proton shows as a broad doublet. On adding a drop of butyl lithium the two peaks sharpen, but with no significant shift in the position of the doublet centered at 4.55 ppm with J_{PH} = 25 Hz. The spectrum corresponding to a single structural form is temperature invariant between +25 and −40°C. ^{13}C and ^{31}P spectra confirm that only one structural form can be detected by NMR. These results are in agreement with the earlier reports (4, 11–14).

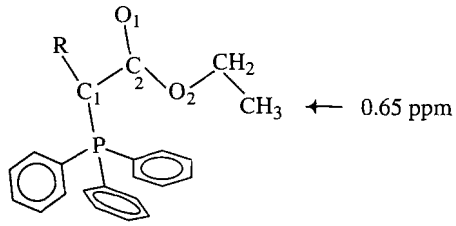
The geometries of isomeric conformers in stabilized ylides

Assignment of the preferred *cisoid* conformation for ylides **1**, **3**, **4**, and **5** was based on the patterns of methine proton absorptions and the effects of diamagnetic shielding on the chemical shifts of the -OCH_3 or -OCH_2CH_3 groups in the *cis* form (4). The latter effect was invoked also to assign the *trans* conformation to the predominant isomeric structure in ylide **2** (8).

We confirmed these assignments in a series of trapping experiments. In general, triethyloxonium tetrafluoroborate was used for trapping reactions at low temperatures (−78 to −30°C), while trimethyloxonium tetrafluoroborate, which is insoluble in organic solvents at low temperatures, was reserved for the reactions carried out at room temperature. The ^{1}H and ^{13}C NMR shifts for the trapped ylides are shown in Table 3.

Ylide **1** trapped with triethyloxonium tetrafluoroborate at −78°C gave a mixture of two isomeric products **6**-*cis* and **6**-*trans* corresponding to the original ratio of **1**-*cis* (*E*) and **1**-*trans* (*Z*) observed at low temperatures. The major product showed a highly shielded methyl triplet (-OCH_2CH_3) with δ 0.728 indicating that the newly introduced ethyl group was in the region of diamagnetic shielding of the phenyl substituent on the phosphorus atom.

When the trapping experiment was carried out with trimethyloxonium tetrafluoroborate at 0°C, no *O*-alkylation could be detected in the crude reaction mixture; the product obtained consisted of a mixture of *C*-alkylated compound **2***b* and the conjugated acid **1***a*. The identities of the two products were confirmed by the two-dimensional $^{1}H/^{13}C$ chemical shift correlation spectrum shown in Fig. 3.



By analogy with phosphorane **1**-*cis* (*E*) and **1**-*trans* (*Z*), the assignment of the *trans* (*Z*) configuration to the predominant structure in **2** was based on the fact that the major isomer possessed a highly shielded methyl triplet at 0.373 ppm. When **2** was treated with triethyloxonium tetrafluoroborate at −78°C, the two ethoxy groups became clearly visible, with the methyl of the new ethoxy group appearing at the lower field (1.469 ppm), **7**, Table 3.

Ylide **3**, which exists in two forms at room temperature, was trapped with triethyloxonium tetrafluoroborate at 0°C. The ratio of salts **8**-*cis* and **8**-*trans* was found to correspond exactly to the ratio of isomeric forms **3**-*cis* and **3**-*trans* observed at room temperature. The major isomeric form **3**-*cis* gave the major compound **8**-*cis* with the more highly shielded methyl of the ethoxy group (methyl triplet at 0.937 ppm).

The NMR spectra of anhydrous **4** in $CDCl_3$ were invariant over the range of −30 to +40°C. This suggested that ylide **4** is essentially biased toward one conformation **4**-*cis* (*Z*), according to the trapping experiment with triethyloxonium tetrafluoroborane. The ^{1}H spectrum of the trapped product showed a highly shielded methyl triplet at 0.685 ppm belonging to an ethoxy group *cis* to the phosphorus atom.

Ylide **5** was trapped cleanly with triethyloxonium tetrafluoroborate at 0°C to give only one vinylic ether identified as **10**-*cis*. The methyl group of the new ethoxy group is diamagnetically shielded by the phenyl rings on the phosphorus (0.60 ppm), confirming the original structural assignment.

Additional support for geometry assignments for the two forms of ylides comes from the crystallographic study of a related ylide **11** (15). In **11** the ethoxy group *cis* to the phosphorus atom is located within the shielding region of one of the phenyl rings. In the ^{1}H NMR spectrum its methyl triplet appears, as expected, at higher field with δ 0.65 (16), suggesting that in the solution as in the crystalline state the same conformation is preferred energetically.

11, R = —CCH_2CH_2COOH (O)

Reactions of ylides with benzaldehyde

A low-temperature condensation monitored by ^{31}P NMR showed that when a solution of benzaldehyde in $CDCl_3$ cooled to −30°C was added to a frozen $CDCl_3$ solution of **1** and the temperature was subsequently maintained at −30°C the ylide's

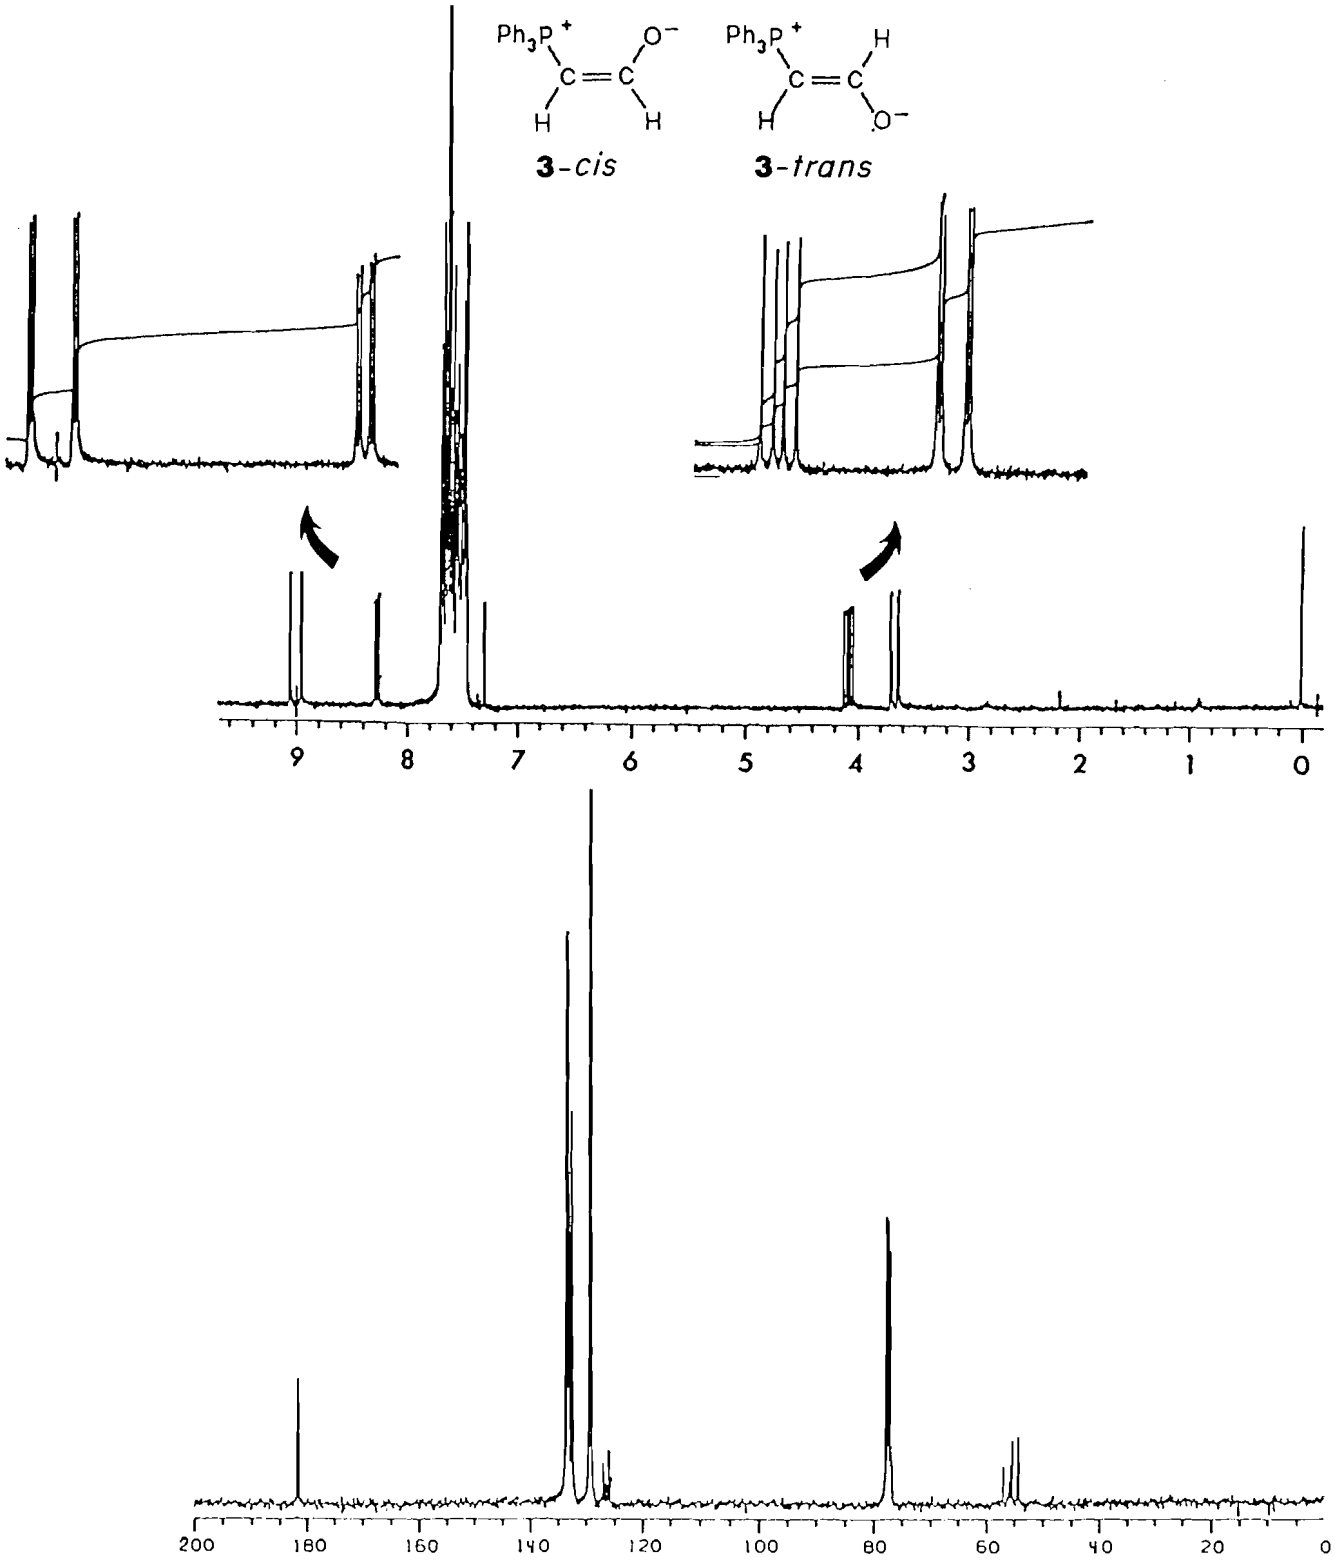


FIG. 2. ^{1}H and ^{13}C room temperature NMR spectra for ylide **3**.

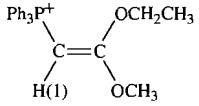

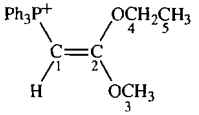

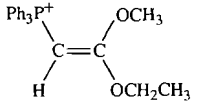

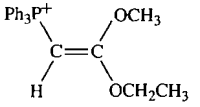

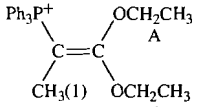

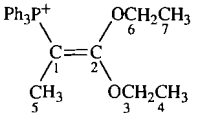

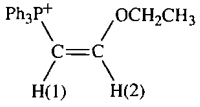

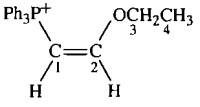

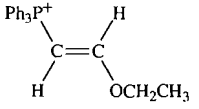

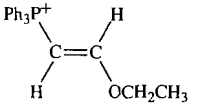

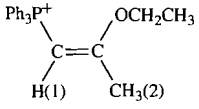

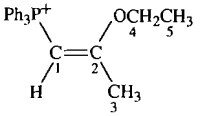

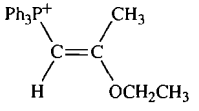

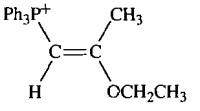

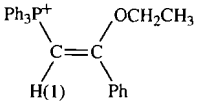

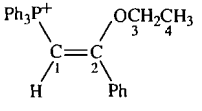

two signals at 17.99 and 16.43 ppm collapse instantaneously to a sharp singlet at 17.87 ppm. As the temperature was raised to −20°C the product (triphenylphosphine oxide) peak appeared. The reaction proceeded rapidly and after 90 min most of benzaldehyde was consumed, as shown by proton NMR. The product, methyl cinnamate, was contaminated with some conjugate acid **1***a*, indicating that acidic impurities originally present in the reaction mixture converted part of the ylide into its conjugate acid.

In the course of the reaction the new signal at 17.87 ppm corresponding to the "reactive" ylide diminished as the product peak grew. It also drifted slightly toward lower field. We

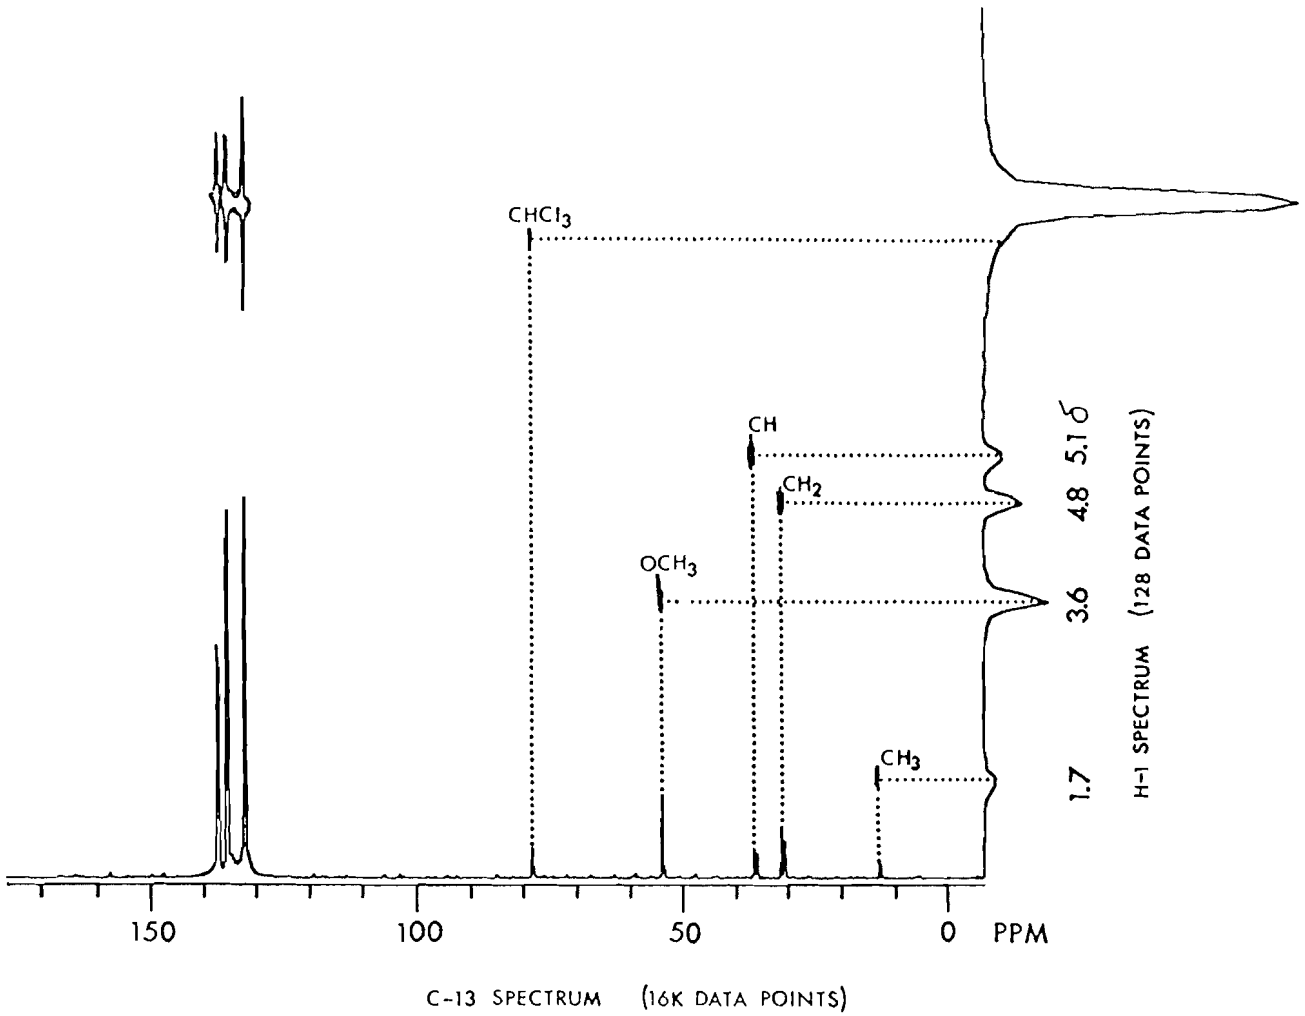

FIG. 3. Two-dimensional $^{1}H-^{13}C$ chemical correlation spectrum for the product of the reaction of the ylide **1** with trimethyloxonium tetrafluoroborate at 0°C.

suppose that the observed downfield drift is due to the continuously changing proportion of the rapidly exchanging ylide – conjugate acid pair as the ylide is consumed during the reaction. This view is supported by the fact that if a reaction, containing an excess of the ylide, is allowed to stand for several days at room temperature, the remaining ylide is slowly hydrolyzed by traces of atmospheric moisture and the only peak observable, other than that of the product, is the signal for the conjugate acid **1***a* at 21.42 ppm.

When the $CDCl_3$ solution of the ylide was treated with BuLi prior to the reaction with freshly distilled benzaldehyde at −30°C, the *cis* and *trans* signals persisted throughout the reaction, which was, in this case, quite slow. After 90 min at −20°C, less than 5% triphenylphosphine oxide showed in the ^{31}P spectrum. After standing for over 15 h at room temperature, the two signals of the ylide were small but clearly distinct, while a trace of benzaldehyde could be still be detected in the proton spectrum of the reaction mixture.

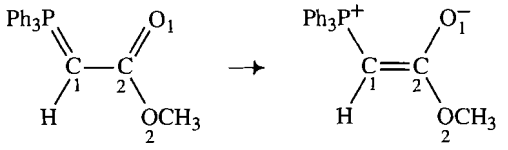
Phosphorane **2** is comparable in behaviour and reactivity to **1**. Both ylides react faster with benzaldehyde in the presence of traces of acidic contaminants and are significantly slower when a proton sponge is added to the reaction mixture.

Ylides **1** and **2** are considerably more reactive than **3**, **4**, and **5**. To illustrate this we compared room temperature condensations of the five phosphoranes, recrystallized but not otherwise treated, with freshly distilled benzaldehyde. Starting with a 1:1 ratio of the two reactants dissolved in $CDCl_3$, we monitored the time required to consume 50% of the ylide. Under the identical experimental and atmospheric conditions[2] the reactions with ylides **1** and **2** reached a half-time within 5 to 8 min, the reaction with **4** took 100 min, while the reaction with **5** required approximately 4 h. The condensation of benzaldehyde with **3** was much slower and no appreciable progress could be detected even after 4 h.

Room temperature condensations of benzaldehyde with ylides **1**, **4**, and **5** in presence of a small quantity of a proton sponge (hexamethyldisilazane) were noticeably slower, taking roughly twice as much time to reach the 50% point as the reactions described above.

Discussion

In an effort to better understand the structure/reactivity relationship in stablized ylides, we attempted to correlate the



[2]It should be pointed out that since the rates of these reactions are highly variable, depending on how anhydrous are the reaction conditions, the same condensations carried out with highly purified ylides on a very dry day would all take a longer time, but their relative rates would be comparable.

results from our NMR study with available crystal structures. A search of the literature showed that although many phosphoranes have been investigated by X-ray crystallography (17), only two of the ylides included in our study, **1** and **5**, are among them (18, 19). Pertinent bond lengths, ^{13}C chemical shifts, and pK_a values for a series of ylides are listed in Table 4.

X-ray analysis of **1** showed the $PCHC(O)CH_3$ fragment to be almost planar, with both a short P—C bond and a significant double bond character in the C—C bond, Table 4. Thus, it was suggested that the best representation for ylide **1** appears to be a resonance hybrid between forms **1**-"ylide" and **1**-*cis* (18).

1-"ylide" **1**-*cis*

Although in ylides **1**, **5**, and **11** the P—C1 bonds are quite short (20), the ^{13}C chemical shifts show that there is a considerable negative charge localized on the C1 carbon of each ylide. Hence, the small P—C1 separation may be largely due to an important electrostatic attraction between P^+ and C^-. This conclusion is supported by the ^{31}P spectra of the ylides, which show P atoms highly deshielded, with chemical shifts very similar to those of their conjugate acids.[3]

Extended Hückel calculations for model compounds H_3PCH_2 and $CH_2PH_3CH_2$ show that, although including the 3*d* orbitals on phosphorus results in reduction of charge separation and an increase in P–C overlap population, there is essentially no barrier to rotation of the PH_3 group, and the ylide carbon remains quite negative (21).

In view of the high negative charge concentration on the carbon atom of the ylide, one might expect that in stabilized ylides an important charge delocalization should occur toward the electron-attracting or conjugating groups substituted on the carbon.

The fact that in several stabilized ylides two isomeric forms are observable by NMR, and the facility with which these ylides can be trapped as vinylic ethers, provides experimental evidence for the concentration of a significant negative charge on the carbonyl oxygen atom, particularly in compounds such as **3**, **4**, and **5** that are so easily *O*-alkylated.

The bond lengths from the crystal structures confirm an important contribution from the enolate forms in ylides **1** and **5**, Table 4. Thus, in **1** the C1—C2 bond is closer in length to a normal C_{sp2}—C_{sp2} double bond (1.34 Å) than to a C_{sp2}—C_{sp2} single bond (1.46 Å), while the C2—O1 bond seems to be largely a single bond. In compound **5** the length of the corresponding C1—C2 bond also suggests significant double bond character, but the C2—O1 bond is somewhat shorter. The apparent C2—O1 single bond character in **1** is enhanced by electron delocalization within the carboalkoxy group. Since such delocalization diminishes the contribution of enolate forms in compound **1**, it thereby increases the relative contribution of the $Ph_3P^+C^-HCOOCH_3$ form,[4] making it a more reactive ylide, and more difficult to trap as an enolate.

These conclusions are in agreement with the pK_a values and ^{13}C chemical shifts for C1 atoms. Thus, it is the ylide with the highest negative charge on its C1 carbon atom that has the lowest barrier to rotation and the highest reactivity.

Alkyl triphenylphosphonium salts are deprotonated only by very strong bases such as lithium alkyls or aryls or sodium amide in liquid ammonia. In phosphonium salts substituted with electron-attracting or conjugating groups, the acidity of the α-protons is considerably increased and the corresponding ylides are much weaker bases. Within the series of ylides studied, **1** is a stronger base (pk_a 8.8) than either **4** (pK_a 6.6) or **5** (pK_a 6.0). Kinetic studies have demonstrated that the rate of the reaction between benzaldehyde and a series of stabilized ylides increases logarithmically with their basicity (22). It may be anticipated, therefore, that ylide **1** (and the related ylide **2**) exchanges with protic acids more rapidly than **4** or **5**. This, in fact, is the key to their structure as well as their reactivity.

In view of the above, we propose the scenario illustrated, for ylide **1**, in Scheme 1. In the absence of a catalytic amount of acidic protons, ylide **1** is best represented by slowly (on the NMR time scale) interconverting *cis* and *trans* enolate forms. The observed 3:1 ratio reflects the relative stabilities of the two structures. When a source of acidic hydrogen atoms is introduced, proton exchange between the ylide and the protic acid occurs. This rapid exchange involves the reactive ylide, i.e., the form best represented by the resonance structure in which the negative charge is highly concentrated on the carbon atom of the ylide during the rotation about the C1—C2 bond. If a reactive carbonyl compound such as an aldehyde or a cyclic anhydride is available, addition to the carbonyl can occur instead of proton exchange. At low temperatures the coexistence of the two enolate forms is due to a slower rate of methine proton exchange (7).

Addition of BuLi removes all traces of acids, including the conjugate acid, and hence the low-energy route for the conversion of the two isomers. As a result, even at room temperature on the NMR time scale each of the isomers becomes more stable, further fixed in its enolate form by complexation with lithium cations. It should be pointed out that the complexation of the enolate(s) by Li cations has no effect on the ^{13}C chemical shifts. There is no increase in the enolate's contribution to the hybrid, it simply becomes more stable. An ylide "trapped" as an enolate will react preferentially with "hard acids" at the oxygen atom.

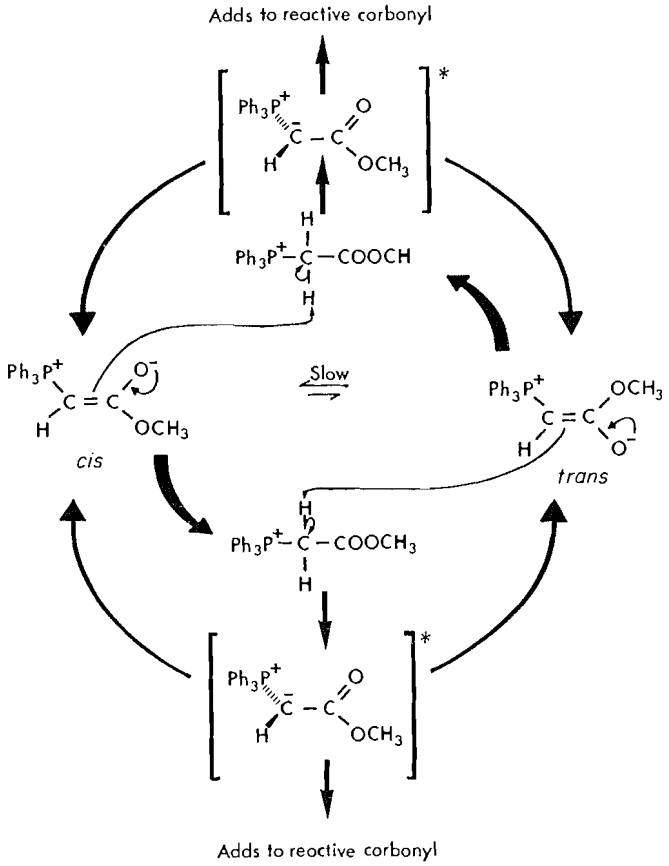
The less basic ylides **3**, **4**, and **5** are not nearly as sensitive to traces of acidic protons and under reasonably anhydrous conditions exist at room temperature in largely delocalized form(s). However, here also, addition of excess acid and (or) raising the temperature promotes proton exchange and faster rotation about the C1—C2 bond.[5]

The conclusions derived from this study may be summarized as follows:

1. The general description of stabilized ylides is not adequately represented by the resonance hybrid shown in **1**-"ylide"/**1**-*cis*. Depending on the nature of the ylide, the possibility of having two isomeric forms, each a hybrid in its own right, must be examined. This is important not only to the understanding of the structure of stabilized ylides, but also to the understanding of their reactivities.

2. Within a series of stabilized ylides, ^{13}C chemical shifts for

[3]Chemical shifts for conjugate acids vary slightly depending on the counterions present. However, in all cases the signals in these salts are quite close to those of the corresponding ylides. For example, the chemical shift for $Ph_3PCH_2COOCH_3Br$ **1***a* ia 21.42 versus 17.99 ppm in **1**.



[4]This view is supported by the fact that Ph_3P-CH-C(O)-NH_2 is considerably more basic (pK_a 11) and more reactive than **1** (22, 23).

[5]Ylide **3** is moisture and light sensitive, hence it should be recrystallized from acetone and used under reasonably anhydrous conditions.

TABLE 4. Comparison of ^{13}C chemical shifts (ppm), bond lengths (Å), and pK_a values for a series of four ylides

SCHEME 1

Cl atoms serve as an excellent indicator of the ylides' reactivity, as do the pK_a values of the corresponding conjugate acids.

3. It is not necessary to carry out condensations with stabilized ylides under strictly anhydrous conditions or with highly purified ylides, since traces of moisture or conjugate acid actually catalyze these reactions. The presence of "hard" cations such as Li^+ stabilizes the unreactive enolate forms, thus slowing the addition of an ylide to the reactive carbonyl groups. On the other hand, large excesses of moisture or other proton sources convert ylides into their conjugate acids, hence lowering the yields.[6]

[6]In the presence of moisture, ylide **1** is converted into its conjugate acid **1***a*, which slowly decomposes to Ph_3PO and methyl acetate.

Experimental

Nuclear magnetic resonance spectra were recorded at 361 MHz (^1H), 91 MHZ (^{13}C), and 146 MHz (^{31}P) on the Nicolet 360NB spectrometer of the Altantic Region Magnetic Resonance Centre, and some ^{31}P spectra were recorded at 81 MHz on the Varian XL-200 spectrometer of the University of New Brunswick. All spectra were recorded for $CDCl_3$ solutions. Calibration of the spectra was done with respect to TMS as the internal reference (^1H and ^{13}C) or 85% H_3PO_4 as external standard (^{31}P). Temperature control was by the usual Nicolet method. Calibration of the thermocouple showed an estimated error of less than 1° in the temperature range used. Line widths were measured by the Nicolet LF routine.

All the ylides used in this study were obtained from Aldrich or Lancaster Chemical Companies. For the reactions carried out under anhydrous conditions the ylides were dried by azeotropic treatment with benzene while $CDCl_3$ was dried over molecular sieves. The NMR tubes were heated at 150°C for at least 3 h and cooled under dry nitrogen. The reactions were run under argon.

General procedure for low temperature alkylation with triethyloxonium tetrafluroborate

Ylide (1.5 mmol) dissolved in 10 mL CH_2Cl_2 (dried over CaH_2 and distilled) was placed in an oven-dried 25-mL three-necked round bottom flask equipped with a dropping funnel and maintained under dry nitrogen. The stirred solution was cooled to −78°C and triethyloxonium tetrafluoroborate (1.5 mmol, 1.0 M in CH_2Cl_2) was added dropwise over 5 min to the vigorously stirred solution. The solution was stirred for an additional hour at −30°C, then allowed to warm slowly to room temperature. The solvent was removed under reduced pressure. The resulting reaction mixture was analyzed by ^1H and ^{13}C NMR.

General procedure for 0°C alkylation with trimethyloxonium tetrafluoroborate

Ylide (1.5 mmol) in 10 mL CH_2Cl_2 (dried over CaH_2 and distilled) was placed in an oven-dried 50-mL three-necked round bottom flask equipped with a dropping funnel and maintained under dry nitrogen. The solid trimethyloxonium tetrafluoroborate (1.6 mmol) was suspended in 20 mL CH_2Cl_2 and transferred into the dropping funnel. The suspension was added slowly to the stirred solution of the ylide cooled to 0°C. The stirring was continued for an additional hour and then the reaction mixture was allowed to warm to room temperature. Upon removing the solvent under reduced pressure the reaction product was analyzed by ^1H and ^{13}C NMR.

*Trapping of methyl (triphenylphosphoranylidene)acetate **1** at −78°C with triethyloxonium tetrafluoroborane*

The crude product was composed of the two isomers **6**-*cis* and **6**-*trans* in the ratio of 3:1. The major product **6**-*cis*: ^1H NMR δ: 0.728 (t, 3H, OCH_2CH_3), 4.023 (q, 2H, OCH_2CH_3), 4.138 (s, 3H, OCH_3),

4.282 (d, 1H, PC*H*, $^2J_{PH}$ = 11 Hz), 7.810–7.416 (aromatic H's); ^{13}C NMR δ: 13.77 (C5), 47.50 (C1, $^1J_{PC}$ = 115.5 Hz), 59.12 (C4), 65.20 (C3), aromatic, 172 (C2); the minor product **6**-*trans*: ^{1}H NMR δ: 1.479 (t, 3H, OCH_2CH_3), 3.550 (s, 3H, OCH_3), 4.249 (d, 1H, PC*H*, $^2J_{PH}$ = 11.2 Hz), 4.463 (q, 2H, OCH_2CH_3), 7.810–7.416 (aromatic H's); ^{13}C NMR δ: 23.07 (C5), 48.0 (C1, $^1J_{PC}$ = 117 Hz), 55.26 (C3), 68.94 (C4), aromatic, 168 (C2).

Trapping of methyl (triphenylphosphoranylidene)acetate ***1*** *at 0°C with trimethyloxonium tetrafluoroborane*

The crude mixture consisted of two products, *C*-alkylated ylide **2***b* and the conjugate acid **1***a*. Compound **2***b*: ^{1}H NMR δ: 1.67 (dd, 3H, $PCCH_3$, $^3J_{PH}$ = 18.4 Hz, $^3J_{HH}$ = 7.2 Hz), 3.55 (s, 3H, OCH_3), 5.06 (m, 1H, PC*H*), 7.58–7.84 (aromatic H's); ^{13}C NMR δ: 12.93, 36.06, 53.34, aromatic, 164.45; ^{31}P NMR δ: 28; conjugate acid **1***a*: ^{1}H NMR δ: 3.57 (s, 3H, OCH_3), 4.58 (d, 2H, PCH_2, $^2J_{PH}$ = 13.8 Hz), 7.58–7.84 (aromatic H's); ^{13}C NMR δ: 30.79, 53.34, aromatic, 164.45, ^{31}P NMR δ: 21.6.

Trapping of (carboethoxyethylidene) triphenylphosphorane ***2***

Ylide **2** (571 mg, 1.6 mmol) was dissolved in 20 mL CH_2Cl_2 (distilled from CaH_2) and cooled to −78°C in a dry, three-necked flask under nitrogen. Triethyloxonium tetrafluoroborate (300 mg, 1.6 mmol) was previously dissolved in a minimum amount of CH_2Cl_2. The ethylating agent was added to the ylide solution at −78°C and the mixture was stirred for 30 min before it was allowed to slowly warm to room temperature. The solvent was evaporated to give compound **7** containing some conjugate acid **2***a*. Trapped ylide **7**: ^{1}H NMR δ: 0.490 (t, 3H, OCH_2CH_3-A), 1.469 (t, 3H, OCH_2CH_3-B),1.727 (d, 3H, $PCCH_3$, $^3J_{PH}$ = 14.7 Hz), 3.569 (q, 2H, OCH_2CH_3-A), 4.439 (q, 2H, OCH_2CH_3-B), 8.10–7.60 (aromatic H's); ^{13}C NMR δ: 15.20 (C7), 19.90 (C4),30.47 (C5), 65.33 (C6), 67.34 (C1, $^1J_{PC}$ = 99.9 Hz), 70.89 (C3), aromatic, 168.72 (C2, J_{PC} = 11.1 Hz).

Trapping of triphenylphosphoranylidene acetaldehyde ***3***

Ylide **3** (240 mg, 0.8 mmol) was dissolved in 25 mL CH_2Cl_2 (distilled from CaH_2) at room temperature in a dry, three-necked flask under nitrogen. Triethyloxonium tetrafluoroborate (150 mg, 0.8 mmol) was previously dissolved in a minimum amount of CH_2Cl_2. The ethylating agent was added to the ylide solution at room temperature and the mixture was stirred for 30 min before the solvent was evaporated to give a mixture of two isomers **8**-*cis* and **8**-*trans* in the ratio 2:1. The major isomer **8**-*cis*: ^{1}H NMR δ: 0.937 (t, 3H, OCH_2CH_3), 4.093 (q, 2H, OCH_2CH_3), 5.367 (dd, 1H, PC*H*, $^2J_{PH}$ = 16.0 Hz, $^3J_{HH}$ = 6.9 Hz), 7.87–7.51 (aromatic H's); ^{13}C NMR δ: 14.89 (C4), 66.14 (C3), 78.70 (C1, $^1J_{PC}$ = 105.8 Hz), aromatic, 170 (C2); the minor isomer **8**-*trans*: ^{1}H NMR δ: 1.377 (t, 3H, OCH_2CH_3), 4.336 (q, 2H, OCH_2CH_3), 5.909 (dd, 1H, PC*H*, $^2J_{PH}$ = 13.3 Hz, $^3J_{HH}$ = 12.1 Hz), 6.779 (dd, 1H, PCC*H*, $^3J_{PH}$ = 13.2 Hz, $^3J_{HH}$ = 12.0 Hz), 7.87–7.51 (aromatic H's); ^{13}C NMR δ: 14.54 (C4), 68.82 (C3), 77.86 (C1, $^1J_{PC}$ = 93.9), aromatic, 168.67 (C2, $^2J_{PC}$ = 19.1 Hz).

Trapping of 1-triphenylphosphoranylidene-2-propanone ***4***

Ylide **4** (503 mg, 1.6 mmol) was dissolved in 20 mL of CH_2Cl_2 (distilled from CaH_2) and cooled to 0°C in a dry, three-necked flask under nitrogen. Triethyloxonium tetrafluoroborate (300 mg, 1.6 mmol) was previously dissolved in a minimum amount of CH_2Cl_2. The ethylating agent was added to the ylide solution at 0°C and the mixture stirred for 30 min before it was allowed to slowly warm to room temperature. The solvent was evaporated to give **9**-*cis*: ^{1}H NMR δ: 0.685 (t, 3H, OCH_2CH_3), 2.416 (s, 3H, CH_3), 3.985 (q, 2H OCH_2CH_3), 5.193 (d, 1H, PC*H*, $^1J_{PH}$ = 18.1 Hz), 7.85–7.50 (aromatic H's); ^{13}C NMR δ: 13.84 (C5), 19.83 (C3, $^3J_{PC}$ = 11.0 Hz), 65.84 (C4), 75.61 (C1, $^1J_{PC}$ = 101.5 Hz), aromatic, 178.85 (C2).

Trapping of benzoylmethylene triphenylphosphorane ***5***

Ylide **5** (609 mg, 1.6 mmol) was dissolved in 15 mL of CH_2Cl_2 (distilled from CaH_2) and cooled to 0°C in a dry, three-necked flask under nitrogen. Triethyloxonium tetrafluoroborate (300 mg, 1.6 mmol) was previously dissolved in a minimum amount of CH_2Cl_2. The ethylating agent was added to the ylide solution at 0°C and the mixture stirred for 30 min before it was allowed to warm to room temperature. The solvent was evaporated to give the trapped ylide **10**-*cis*: ^{1}H NMR δ: 0.603 (t, 3H, OCH_2CH_3), 3.636 (q, 2H, OCH_2CH_3), 5.485 (d, 1H, PC*H*, $^2J_{PH}$ = 17.7 Hz), 7.827–7.340 (aromatic H's); ^{13}C NMR δ: 13.88 (C4), 68.38 (C3), 83.16 (C1, $^1J_{PC}$ = 94.7 Hz), aromatic, 178.28 (C2); ^{31}P NMR δ: 17.38.

The conjugate acid **1***a* was purchased from Aldrich as the bromine salt. The other conjugate acids were prepared by treating the $CHCl_3$ solution of the corresponding ylide with concentrated HCl, drying, and evaporating the solvent. To introduce BF_4^- as the counterion, the solution of conjugate acid was treated with a slight excess of $AgBF_4$. The silver halide salt was removed by filtration and the solvent was evaporated to the new phosphonium salt, **1***a*: ^{1}H NMR δ: (PCH_2) 5.531 ($^2J_{PH}$ = 13.6 Hz) (Br^-) and 4.60 ($^2J_{PH}$ = 14.0 Hz) (BF_4^-); ^{13}C NMR δ: (PCH_2) 32.33 ($^1J_{PC}$ = 59.0 Hz) (Br^-) and 31.07 ($^1J_{PC}$ = 58.61 Hz) BF_4^-); **2***a*: ^{1}H NMR δ: ($PCHCH_3$) 6.850 (dq) (Cl^-) and 5.047 (dq) (BF_4^-); ($PCHCH_3$) 1.682 ($^3J_{PH}$ = 18.6 Hz, $^3J_{HH}$ = 7.1 Hz) (Cl^-) and 1.662 ($^3J_{PH}$ = 18.2 Hz, $^3J_{HH}$ = 7.1 Hz) (BF_4^-); ^{13}C NMR δ: (PC*H*) 36.11 ($^1J_{PC}$ = 52.2 Hz), ($PCHCH_3$) 12.91; **3***a*: ^{1}H NMR δ: (PCH_2) 6.10 ($^1J_{PC}$ = 11 Hz) (Cl^-) and 4.977 ($^2J_{PC}$ = 11.8 Hz); ^{13}C NMR δ: (PC*H*) 38.27 ($^1J_{PC}$ = 60.3 Hz), (CH_3) 31.10 (BF_4^-).

A kinetic and ultraviolet–visible study of a series of thermo- and photochromic dyes is reported. Ultraviolet irradiation of the indolino-benzospiropyran derivatives **1′–4′** leads to their transformation to the open-chain, colored merocyanine forms, which undergo thermal ring closure into the colorless spiro forms. The rate of this ring closure has been determined in different solvents. Plots of log (rate) vs. the solvent parameter E_T are linear but are dependent on the nature of the substituent in the phenyl moiety, which yields information on the electronic character of the ground state (IIa ↔ IIb) and the transition state. The ring-closure process is characterized by a zwitterionic type transition state, TS_3. The merocyanine dyes exhibit a significant solvatochromic effect, which unexpectedly shows sensitivity to substituents on the phenyl group. This observation finds explanation through semi-empirical molecular orbital (MOPAC) calculations. The MOPAC calculations also predict that the most stable configurational isomer of the merocyanines is the CTTC form.

Key words: indolino-benzospiropyran–merocyanine interconversion, photochromic–solvatochromic dyes.

SAM-ROK KEUM, MUN-SUK HUR, PETER M. KAZMAIER et ERWIN BUNCEL. Can. J. Chem. **69**, 1940 (1991).

On rapporte une étude basée sur la cinétique ainsi que sur l'UV–VIS d'une série de colorants thermo- et photochromiques. Une irradiation par l'UV des dérivés indolino-benzospiropyranes **1′–4′** conduit à leur transformation en chaînes ouvertes, des formes colorées de la mérocyanine qui subissent une cyclisation thermique conduisant aux formes spiro incolores. On a déterminé la vitesse de cette cyclisation dans différents solvants. Les courbes du log (vitesse) vs. le paramètre E_T du solvant sont linéaires, mais elles dépendent de la nature des substituants présents sur la portion phényle; cete dépendance fournit de l'information sur le caractère électronique de l'état fondamental (IIa ↔ IIb) et de l'état de transition. Le processus de cyclisation est caractérisé par un état de transition de type zwitterionique. ET_3. Les colorants mérocyanines présentent un effet solvatochromique important qui présente d'une façon inattendue une sensibilité vis-à-vis des substituants présents sur le groupe phényle. Cette observation peut être expliquée à l'aide de calculs semi-empiriques d'orbitales moléculaires (MOPAC). Ces calculs permettent aussi de prédire que l'isomère des mérocyanines configurationnellement le plus stable est la forme CTTC.

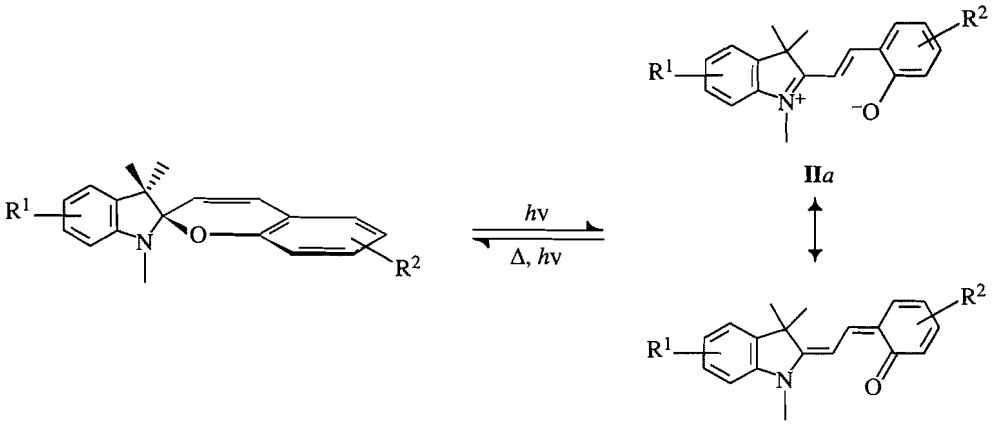
Mots clés : interconversion indolino-benzospiropyrane–mérocyanine, colorants photochromiques–solvatochromiques.
[Traduit par la rédaction]

Introduction

Thermo- and photochromic compounds (1–3) are among the most interesting of functional dyes, since they form colored species upon heating or irradiation with ultraviolet light. A typical example of an organic thermo- and photochromic compound currently being studied is the spiropyran derivative, 6′-nitro-1,3,3-trimethylspiro-(indolino-2,2′-benzopyran), **4′**.

Spiropyran–merocyanine transformations have been studied extensively since these reversible photo processes were first discovered by Fischer and Hirshberg in 1952 (5), and independently by Chaude and Rumpf in 1953 (6). Basically, the spiropyran dyes consist of two π-systems linked by a tetrahedral spiro carbon, while substituents modify the stability of the spiropyran as well as the long wavelength absorption associated with the π-system. Spiropyrans are known to be in equilibrium with their metastable colored forms (2). Absorption of ultraviolet light shifts the equilibrium towards the merocyanine colored form, **II**, while the reverse process to the colorless form, **I**, is induced by visible light, heat, or can occur spontaneously.

A number of authors (7–10) have reported important advances towards understanding the detailed photochemical processes involved in the photochromism and the reverse photochromism of spiropyrans. As well, various practical applications, such as in recording, copying, and display materials, have highlighted the potential usefulness of such compounds (11–16).



It is generally assumed that a thermo- and photo-sensitive equilibrium exists between the spiropyran (**I**) and a planar, colored, metastable, species resulting from scission of the bond between the spiro carbon and the pyran oxygen. Many unsolved problems remain, however, such as the identity and exact structure of the photochemically produced colored species, the formation of reaction intermediates, and the detailed mechanistic processes involved in the equilibrium between the two species. The colored species is generally accepted to have the electronic configuration of a resonance hybrid, i.e., zwitterionic (**II***a*)↔ quinoidal (**II***b*), depending on structure, substituents, solvent environment, etc. (17).

Our prime interest in these materials was the potential application for color imaging on synthetic materials. Use of the

State **I**
Colorless spiro form

State **II**
Colored merocyanine form

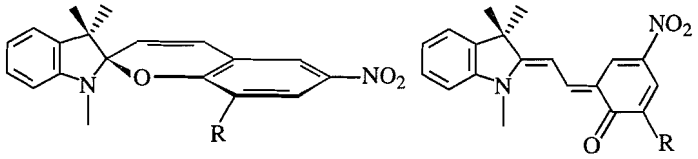
photochemical system for these materials requires that states **I** and **II** should be reasonably stable at ordinary temperatures, in the absence of exciting illumination, and that the photochemical interconversion of states **I** and **II** should be feasible at ordinary temperatures. A number of studies are proceeding to develop spiropyrans that are photochemically active at room temperature and above. It has been found in our work that the thermal stability of state **II** can be markedly affected by careful choice of substituents on the photochemical process.

Continuing our studies of these thermo- and photochromic indolino-benzospiropyrans (4), in this paper we describe various UV–VIS spectroscopic studies to determine the influence of solvent on the equilibrium. Thus the aim of the present work is to evaluate the influence of solvent on UV–VIS spectral absorption (solvatochromism) (18), the electronic effects of substituents on thermo- and photochromism, and the kinetics of spiro ring formation of the open-chain merocyanine form of the indolino-benzospiropyrans. The influence of substituents in the benzopyran ring on the kinetics of the ring-closure reaction in different solvent systems is of particular interest since it could yield mechanistic information on the nature of the spiro ring formation process.

Experimental section

Materials and solvents

All compounds in this work have been prepared by literature procedures (2). Acetone and chloroform were dried over calcium sulfate and calcium chloride, respectively, and distilled. Dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) were dried over molecular sieves (Type 4A) and calcium hydride, respectively, and distilled under reduced pressure. All other solvents were of spectroscopic grade.



UV–VIS spectroscopy and kinetic measurements

The thermo- and photochromic spiropyran was dissolved in dry DMSO ($(1.0–10) \times 10^{-2}$ M) and kept in the dark. An aliquot (1–10 μL) was delivered to a quartz cuvette containing the solvent and allowed to come to thermal equilibrium. After half an hour, the cell was exposed to UV light from a 4-W "Blak-Ray" (Ultra-violet Products Inc., San Gabriel, CA) for 4–5 min and immediately placed in a Perkin–Elmer Lambda 5 or Perkin–Elmer 552 spectrophotometer. The disappearance of the colored form of the spiropyran was followed at the wavelength of maximum absorption (500–600 nm). The absorbance at equilibrium, A_e, was taken as the absorbance after 10 half-lives. First-order rate constants (k_{obs}) were calculated from linear log $(A_t - A_e)$ vs. time plots.

Results and discussion

Analysis of UV–VIS and kinetic data

The electronic absorption spectra of the spiropyrans in state **I** show no absorbance in the visible region, while in state **II**, formed on irradiation, a strong absorption at 500–600 nm with high extinction coefficients is observed. The rate of reversion to the colorless spiro ring (**II** → **I**) was measured after UV irradiation in various solvents for four 8′-substituted-6′-nitro-1,3,3-trimethylindolino-benzospiropyrans (**1′–4′**) by following the

1′–4′ **1–4**

1′, 1; R = H
2′, 2; R = Br
3′, 3; R = I
4′, 4; R = OMe

disappearance of the absorption band in the 500–600 nm region. A sample kinetic run for the ring closure reaction of **1**, the open-chain form of **1′**, in dimethyl sulfoxide after irradiation with UV light is shown in Fig. 1, while the corresponding absorbance vs. time data are given in Table 1.[4] The decay rate of the photoinduced colored transients obeyed good first-order kinetics for all substrates examined in this work.

The kinetic data for the ring-closure reactions of the four spiropyrans after UV irradiation are given in Table 2. The rate constants are independent of the initial spiropyran concentration in the range of 10^{-3} M to 5×10^{-5} M. The data in Table 2 demonstrate that the rate of the spiro ring formation is drastically reduced as the solvent polarity is increased.

Rate constants vs. solvent polarity parameters

Various attempts have been made to find a relationship between rate processes and solvent polarity parameters in related systems (18). Flannery (19) observed rather poor linearity on plotting log(rate) versus Kosower's *Z* or Brownstein's *S*

[4]Although only one configuration is shown for **1–4** it is understood that several conformers would be in equilibrium (*vide infra*).

parameters (20) for the ring-closure reaction of **2**. However, the choice of these scales is somewhat arbitrary and a more general solvent parameter would seem to be more appropriate.

In the present work, on plotting log(rate) versus the solvent parameter E_T (21) reasonably good linear plots were obtained (Fig. 2). It is apparent that the rate of the ring closure from the open-chain merocyanine form depends markedly on the substituents present in the series **1–4**. The sensitivity of rate on medium polarity is highest (slope = 0.17) for compounds **2** and **3**, which are halogen substituted in the 8′-position, whereas it is lowest (slope = 0.10) for **4**, which has a methoxy group in the 8′-position. The results for the latter are comparable to the sensitivity of **1** for which the slope value is 0.16. The slope and correlation-coefficient parameters on plotting log(rate) versus E_T for **1–4** are given in Table 3.

Another interesting observation is that there is a crossover in the lines for **1** and **4**, while the series **1**, **2**, and **3** exhibit practically parallel lines. This implies that reactivity comparison studies could be misleading. Thus the order of reactivity will be different in the region below and above E_T = 41–42. If a solvent

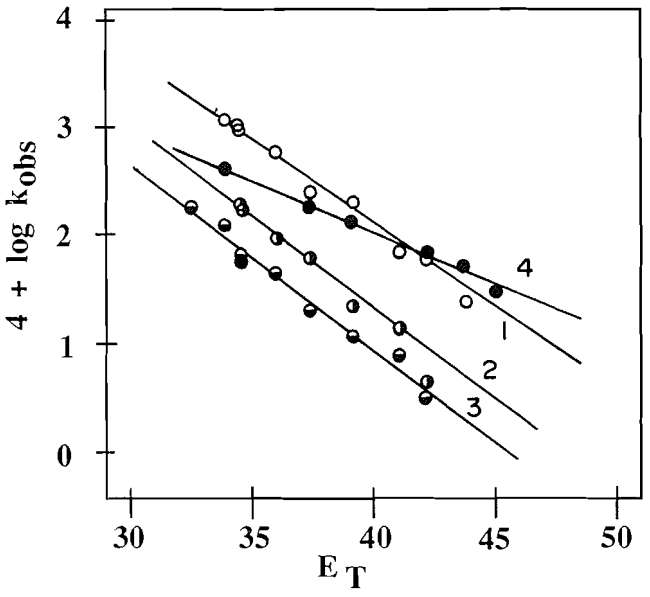

FIG. 2. Plots showing correlation between k_{obs} and E_T for the ring-closure reactions of merocyanines from UV irradiation of 8′-substituted 6′-nitro-1,3,3-trimethylindolino-benzospiropyrans in various solvents: **1**, (○); **2**, ◑; **3**, (◒); **4** (●).

TABLE 3. Slope and correlation-coefficient parameters in plotting −log (rate) versus E_T for ring closure after UV irradiation of spiropyrans **1′–4′**

Spiropyran	Slope	Corr. coeff.
1′	0.16±0.01	0.998
2′	0.17±0.01	0.988
3′	0.17±0.01	0.978
4′	0.10±0.01	0.998

of relatively low value of E_T is used for the reaction, the reactivity order is **1** > **4** > **2** > **3**, whereas for a solvent of higher E_T value the order could be changed to **4** > **1** > **2** > **3**.

Solvent effect on LFER for reaction rate vs. substituents

The Hammett linear free energy correlation between reaction rate and the substituent parameter $\Sigma\sigma$ (22) as a function of solvent polarity is of interest. Such a relationship was found previously in absolute ethanol (19) and is now extended to two solvent systems other than alcohols, namely to acetone and dimethylformamide.

The rate constants of the thermal ring-closure reaction of the open form of spiropyrans in the two solvent systems as a function of σ value are given in Table 4 and plotted in Fig. 3. The slopes derived from Fig. 3 are given in Table 5, including the literature data for ethanol (23). An interesting aspect is that the sensitivity (absolute value of slope) increases as the medium polarity is decreased (Fig. 4), which implies that a charge–dipole interaction is important in the reaction.

Mechanism of spiro ring closure

Three different mechanisms involving three corresponding transition states have been suggested for the thermal ring-closure reaction of the merocyanine open form of spiropyrans. TS_1 applies to a concerted electrocyclic process as suggested by Dürr

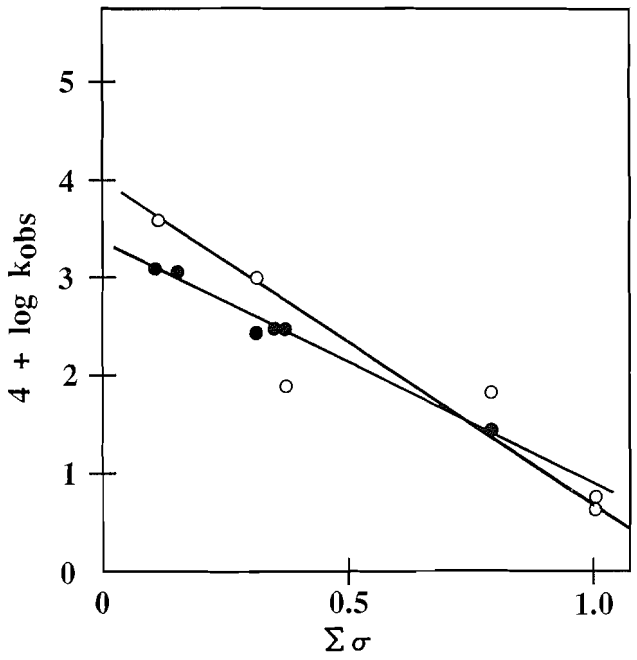

FIG. 3. Plots of log k_{obs} vs. $\Sigma\sigma$ for the ring-closure reactions of merocyanines from irradiation of substituted 1,3,3-trimethylindolino-benzospiropyrans in different solvents: acetone (○); DMF (●).

[a]Double peaks at 550 and 570 nm.

It is apparent that the electrocyclic reaction is not expected to show marked sensitivity to medium polarity, in accordance with an isopolar, six-membered activated complex (ref. 2, pp. 160–170). The free-radical mechanism had been ruled out on the grounds that the colored solutions were unchanged on treatment with oxygen, hydrogen, and hydroquinone (27), although Sueishi (26) recently favored this from a pressure study of **1**. As well, a radical mechanism would not be expected to exhibit appreciable sensitivity to substituents, unlike the findings in the present study.

TS_I TS_2 TS_3

The large decrease in rate on increasing the solvent polarity (Fig. 2) is in accord with a process in which charge is dissipated on going from the ground state to the transition state. Clearly this supports TS_3 as the transition state which is operative in our system.

It is also interesting that the sensitivity of the reaction rate to solvent effect, i.e., the slope of the log k_{obs} vs. E_T plots in Fig. 2, is dependent on the nature of the substituent R; the slope is higher for electron-withdrawing substituents (Cl, Br) than for electron-releasing (OCH_3). This finds explanation in that an electron-withdrawing group will stabilize the dipolar structure **II***a* in the ground state. The more dipolar the character, the greater the sensitivity to solvent polarity of the reaction rate, and conversely for electron-donating substituents. Thus the observed trends of the slopes in Fig. 4 (see Table 5) provide further support for the dipolar structure of the merocyanines formed on ring opening of the spiropyrans.

Solvatochromism

The UV–VIS spectral data of the open form of the spiropyrans **1'**, **2'**, and **4'** in various solvents are collected in Table 6, while

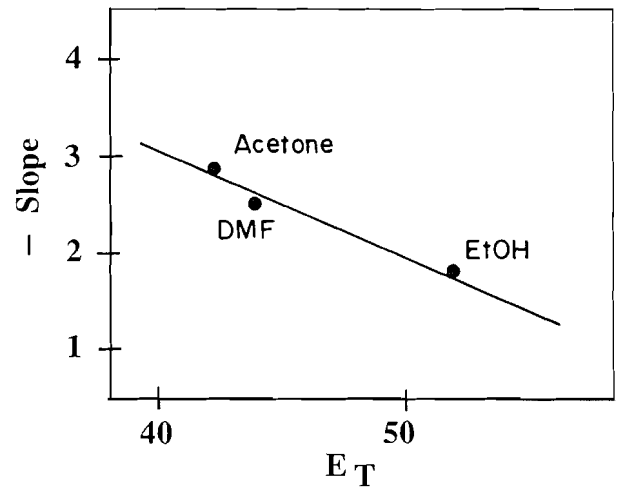

FIG. 4. Plot of slope parameter in log k_{obs} vs. $\Sigma\sigma$ plots vs. the solvent polarity parameter E_T for the thermal ring-closure reaction of the merocyanines formed on irradiation of 1,3,3-trimethylindolino-benzospiropyrans.

in Fig. 5 the results are plotted as frequency (ν) versus the solvent polarity parameter E_T.

The results show that a marked solvatochromism (18, 28–32) is exhibited by the merocyanines derived from spiropyrans **1'**, **2'**, and **4'**. As the solvent polarity is increased, a hypsochromic shift is observed. Figure 5 shows that there is a fairly good relationship between ν_{max} and the solvent polarity parameter E_T, with the following relationships:

[1] Compound **1**: $\nu_{max} = 113\ E_T + 12\ 800$ $r = 0.987$; $n = 13$

[2] Compound **2**: $\nu_{max} = 135\ E_T + 12\ 300$ $r = 0.985$; $n = 11$

[3] Compound **4**: $\nu_{max} = 94\ E_T + 12\ 900$ $r = 0.976$; $n = 7$

The striking feature about the present results, as displayed in Table 6 and Fig. 5, is the marked hypsochromic shift that is exhibited with increasing solvent polarity (i.e., negative solvato-

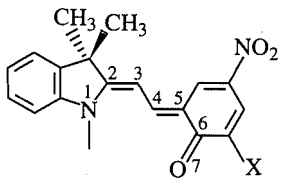
[b]In kcal/mol.

chromism). It is known that the nature of the observed solvent effect for a given dye molecule, i.e., bathochromic or hypsochromic shift with increasing solvent polarity, depends largely on the change in dipolar characteristics between ground and excited states (18). For a weakly polar molecule, with low polarity in the ground state and increased polarity in the excited state, a bathochromic shift results. Conversely, for a highly polar molecule in the ground state and reduced polarity in the excited state, a hypsochromic shift is observed.

In principle, a merocyanine dye could exhibit either a bathochromic or a hypsochromic shift since the ground state could have an electronic configuration corresponding largely to the nonpolar quinoid form **II***b*, or to the dipolar, zwitterionic form **II***a*, or an in-between character. The observation of a hypsochromic shift (negative solvatochromism) in the present system is hence indicative of a highly polar ground state, i.e., approaching the configuration of the zwitterionic form **II***a*, and an excited state with decreased polarity.

In general terms, we may represent the ground state of the merocyanines as a polyene-like structure **A** and the excited state as a polymethine-like structure **B**, a situation that will result in a hypsochromic shift. Conversely, a bathochromic shift would have resulted if the ground state had the quinoidal structure **C** and the excited state the dipolar structure **B**.

MOPAC calculations of structural effects on solvatochromism



Since the solvatochromic evidence described above clearly showed a stabilization of the dipolar form as the aromatic ring substituents were varied from methoxy to bromo, i.e., **4** to **2**, it was of interest to see if molecular orbital calculations could provide additional insight into the origin of this substituent effect. Semi-empirical calculations have proven useful in interpreting the behavior of merocyanines (29, 34) and thus the question of substituent effects appeared tractable in light of the past success of calculations at this level of sophistication.

Accordingly, calculations have been performed to analyze the substituent effects observed for the solvatochromic behavior of merocyanines **1**, **2**, and **4**. To investigate the effect of ring substituents on the electronic configuration of the ground state, it was first necessary to calculate the predicted minimum energy configuration for this system, which is structurally different from those considered in earlier work (34). Figure 6 describes the configurations in the ring-open form that were considered, and the energy for each was fully optimized using MOPAC 5.0 (35) incorporating the AM1 Hamiltonian. Table 7 summarizes the results on the energies of the isomers investigated. Clearly, from a consideration of the energies, the CTTC stereoisomer is predicted to be the most stable for compounds **1**, **2**, and **4**. Table 8 summarizes the atomic charges, total bond orders, π bond orders, and bond lengths predicted for **1**, **2**, and **4**.

The results of the MOPAC-AM1 calculations are shown in Table 8. From a consideration of both the bond orders and the π

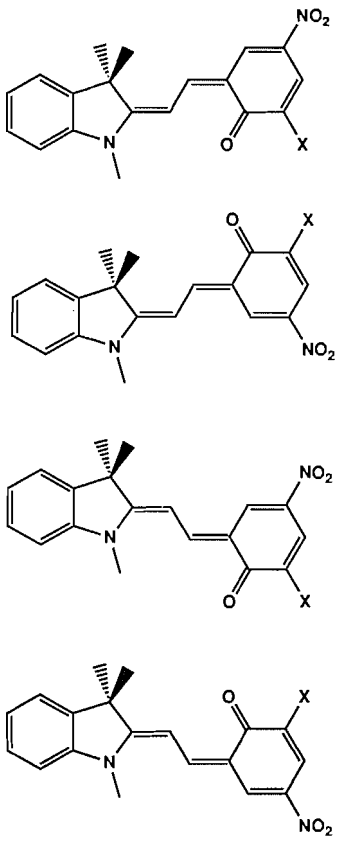

FIG. 6. Geometrical configurations of the indolino merocyanines. The TTCC, etc., designations refer to the geometry (*trans*, T, or *cis*, C) about the 2–3, 3–4, 4–5, and 5–6 bonds (see Table 8).

bond orders, it is clear that our calculations predict a quinoid ground state for **1**, **2**, and **4**. This is in agreement with other theoretical investigations (29, 34) applicable to the isolated molecules in the gas phase and in the absence of specific solute–solvent interactions. However, it is noteworthy that as the substituent on the chromophore is changed from an electron-donating group (**4**) to an electron-withdrawing group (**2**), the bond orders reflect a shift to a more dipolar electronic configuration. For example, the π bond order for the carbon–nitrogen bond is 0.2421 for the methoxy substituent while it is 0.2712 for the bromo substituent. Thus the consequence of chromophore substitution (**4** → **2**) is to stabilize the zwitterionic form.

Typically, solvatochromic compounds can be described by two extreme resonance-contributing structures: one a quinoidal, nonpolarized, formally nonaromatic structure; the other a zwitterionic, polarized, formally aromatic structure. The change in absorption band with solvent arises from a variation in the contribution of these canonical forms to the overall resonance hybrid (18, 29, 36). The present work shows that, just as increasing solvent polarity predisposes the ground state toward the zwitterionic contributing structure, progressively more powerful electron-withdrawing substituents also perturb the electronic ground state in the same direction and the observed solvatochromic effect is the superposition of these two perturbations. This is in agreement with the change in slope observed for the three merocyanines as shown in Fig. 5.

A second interesting consequence of the molecular orbital calculations on **1**, **2**, and **4** is the observation that the π bond order of the C15—C17 bond is very low. It has generally been assumed that aromaticity is an important contributor to the stability of the zwitterionic form. The π bond order for the C15—C17 bond only increases from 0.0942 for R = H to 0.0959 for R =

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

OCH_3 and this trend (π bond order (R = OCH_3) > (R = Br) > (R = H)) does not follow the trend observed for the substituent effect on the solvatochromism ((R = Br) > (R = H) = (R = OCH_3)). The implication of this result is that the substituent effect observed is stabilizing the zwitterionic form directly by enhancing the electron-accepting capacity of the oxygen anion and not by increasing the aromatic stabilization energy of the phenyl group.

In conclusion, substituents affect the solvatochromic behavior of merocyanine dyes by increasing the sensitivity of the chromophore to solvation effects. The molecular orbital calculations show that substituents introduce perturbations into the chromophore that are very similar, but not identical, to the perturbations caused by solvent effects themselves. The ultimate solvatochromic behavior is a superposition of these two effects. Although electronegative substituents increase the relative contribution of the dipolar canonical form to the overall ground state resonance hybrid, substituents do so without increasing the aromaticity of the aromatic pendent group.

Preparation and characterization of a series of bromodiphenyl(*N*,*N*-dialkyldithiocarbamato)tellurium(IV) compounds where R = Me, Et, *i*-Pr, Bu, and of chlorodiphenyl(*N*,*N*-dibutyldithiocarbamato)tellurium(IV) and diphenylbis(*N*,*N*-dibutyldithiocarbamato)tellurium(IV). Crystal structure of $Ph_2TeBr[S_2CNEt_2]$ and $Ph_2Te[S_2CNBu_2]_2$

JANE H. E. BAILEY, JOHN E. DRAKE, and MARIA L. Y. WONG

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont., Canada N9B 3P4

Received April 18, 1991

JANE H. E. BAILEY, JOHN E. DRAKE, and MARIA L. Y. WONG. Can. J. Chem. **69**, 1948 (1991).

The series $Ph_2TeBr[S_2CNR_2]$, where R = Bu, Pr, *i*-Pr, Et, and Me, as well as $Ph_2TeCl[S_2CNR_2]$ and $Ph_2Te[S_2CNR_2]_2$, where R = Bu, Pr, have been synthesized and characterized by elemental analysis and vibrational spectroscopy. Comparisons of the effect of changing R groups and halogen atoms can be made based on the two crystal structures determined herein along with earlier work. The geometry about tellurium is consistent with that of a distorted sawhorse structure where the dithiocarbamate groups are monodentate (or anisobidentate). The crystal structures of $Ph_2TeBr[S_2CNEt_2]$, **4**, and $Ph_2Te[S_2CNBu_2]_2$, **7**, were completed. The cell parameters for **4** are $a = 11.204(3)$ Å, $b = 14.106(11)$ Å, $c = 13.867(10)$ Å, $\alpha = 99.62(6)°$, $\beta = 102.76(5)°$, $\gamma = 87.73(4)°$, $V = 2107$ Å^3, $Z = 4$, $R = 0.0448$, and $R_w = 0.0489$ and for **7** are $a = 19.392(6)$ Å, $b = 9.622(2)$ Å, $c = 19.089(6)$ Å, $\beta = 104.70(2)°$, $V = 3445(2)$ Å^3, $Z = 4$, $R = 0.0397$, and $R_w = 0.0439$. Nuclear magnetic resonance spectra are not simple and indicate that several species are present in solution, as rearrangements and reductive elimination take place.

Key words: structure, tellurium, bromo, diphenyl, dialkyldithiocarbamato.

JANE H. E. BAILEY, JOHN E. DRAKE et MARIA L. Y. WONG. Can. J. Chem. **69**, 1948 (1991).

On a synthétisé la série $Ph_2TeBr[S_2CNR_2]$ dans laquelle R = Bu, Pr, *i*-Pr, Et et Me ainsi que les séries $Ph_2TeCl[S_2CNR_2]$ et $Ph_2Te[S_2CNR_2]_2$, dans lesquelles R = Bu et Pr et on les a caractérisées par leurs analyses élémentaires et les spectres de vibration. On peut faire des comparaisons de l'effet provoqué par le changement des groupes R et des atomes d'halogène en se basant sur des structures cristallines déterminées antérieurement ainsi que sur deux autres déterminées dans ce travail. La géométrie autour de tellure est en accord avec celle d'une structure en dent de scie déformée dans laquelle les groupes dithiocarbamates sont monocoordonnés (ou anisobicoordonnés). On a déterminé complètement les structures des composés $Ph_2TeBr[S_2CNEt_2]$ **4**, et $Ph_2Te[S_2CNBu_2]_2$ **7**. Pour le composé **4**, les paramètres sont $a = 11{,}204(3)$, $b = 14{,}106(11)$ et $c = 13{,}867(10)$ Å, $\alpha = 99{,}62(6)$, $\beta = 102{,}75(5)$ et $\gamma = 87{,}73(4)°$, $V = 2107$ Å^3, $Z = 4$, $R = 0{,}0448$, et $R_w = 0{,}0489$ alors que pour le composé **7**, les paramètres sont $a = 19{,}392(6)$ $b = 9{,}622(2)$ et $c = 19{,}089(6)$ Å, $\beta = 104{,}70(2)°$, $V = 3445(2)$ Å^3, $Z = 4$, $R = 0{,}0397$ et $R_w = 0.0439$. Les spectres rmn ne sont pas simples et ils indiquent que plusieurs espèces sont présentes en solution alors qu'il se produit des transpositions et des réactions d'éliminations réductrices.

Mots clés : structure, tellure, bromo, diphényle, dialkyldithiocarbamato.

[Traduit par la rédaction]

Introduction

Dithiocarbamate complexes have experienced extensive study (1–7). Dithiocarbamate groups usually act in a bidentate fashion (3–7); typical examples that have been observed range from transition metal complexes such as $Co[S_2CNMe_2]_2NO$, where the Co atom is at the centre of a square pyramid (8), and $Cu_4[(S_2CNEt_2)_2]_4$, where the dithiocarbamate group coordinates form the faces of the Cu_4 tetrahedron (9), to main group compounds such as $C_4H_9Sn[S_2CNEt_2]$, where the geometry around the tin atom is that of a pentagonal bipyramid (10). There are fewer examples of monodentate linkages, which usually occur in mixed ligand complexes such as $Pt[S_2CN\textit{i}\text{-}Bu_2]_2$-$[PMe_2Ph]_2$ (11).

Monodentate (or anisobidentate) bonding is consistently found in several, previously reported, dithiocarbamates of germanium (12–15). In some cases it has been noted that changes in the mode of attachment occur with the variation of the alkyl group of the dithiocarbamate ligand. Thus in $Zn[S_2$-$CNMe_2]_2$ (16), the dithiocarbamate groups are bidentate and bridging, whereas in $Zn[S_2CNEt_2]_2$ both dithiocarbamate groups are bidentate and the molecule is monomeric (17).

Previously, we reported the reactions of diphenyltellurium dichloride with the sodium salts of *N*,*N*-dimethyl-, *N*,*N*-diethyl-, and *N*,*N*-diisopropyldithiocarbamate in which the crystal structures, $Ph_2Te[S_2CNMe_2]_2$, $Ph_2Te[ClS_2CNEt_2]$, and Ph_2TeCl-$[S_2CN\textit{i}\text{-Pr}]$, were discussed (18). We now extend this study to include the series of bromo derivatives $Ph_2TeBr[S_2CNR_2]$, where R = Bu, Pr, *i*-Pr, Et, and Me, as well as $Ph_2TeCl[S_2CNR_2]$ and $Ph_2Te[S_2CNR_2]$ where R = Bu, Pr to complete the chloro- and bis-series of derivatives. Compounds were characterized by elemental analysis, vibrational and NMR spectroscopy, and two structural determinations were completed by X-ray crystallography. Studies were made by ^1H, ^{13}C, and ^{125}Te NMR spectroscopy of the mode of decomposition of these and related species in solution.

Experimental

Materials

$TeCl_4$, Ph_4Sn, Me_3SiBr, diisopropylamine, dipropylamine, dibutylamine, toluene, diethyl ether, and petroleum ether were obtained from Aldrich. All but toluene, which was distilled, were used as purchased. Carbon disulfide (BDH) was distilled from P_4O_{10} prior to use, whereas ethanol and methylene chloride were used as supplied by BDH. Both NaS_2CNMe_2 and NaS_2CNEt_2, obtained from Aldrich as hydrated salts, were dried in vacuum for 4–5 days prior to use.

Synthesis of NaS_2CNi-Pr_2, NaS_2CNPr_2, and NaS_2CNBu_2

An equimolar mixture of sodium hydroxide (3.96 g) and carbon disulphide (3.66 g) was mixed in ethanol (20 mL). Diisopropylamine was slowly added at 3 drops/s and the mixture was then heated for 1.5 h under a continuous N_2 stream of approximately 1–2 bubbles/s. The solid formed was washed with diethyl ether and dried under vacuum for 4–5 days. The butyl and propyl dithiocarbamate salts were similarly made with the substitution of dibutylamine and dipropylamine for diisopropylamine. The products were obtained in 60–80% yields.

Synthesis of Ph_2TeCl_2

An equimolar solution of tetraphenyltin (4.56 g) and tellurium tetrachloride (2.87 g) in toluene (20 mL) was refluxed at 60°C for 12 h and worked up in the manner previously described (19).

Synthesis of Ph_2TeBr_2

Diphenyltellurium dichloride (0.35 g) was dissolved in CS_2 (5 mL) and the system kept in an ice bath and purged under nitrogen. Bromotrimethylsilane (0.30 g) was added slowly to the mixture. Once addition was complete the mixture was stirred at ambient temperature for 3–4 h. The solution was then filtered and placed in the refrigerator to allow crystallization of Ph_2TeBr_2; 0.35 g; 80% yield; mp 196–198°C (lit. mp 196–198°C).

Synthesis of diphenylbis(N,N-*dialkyldithiocarbamato)tellurium(IV)*

Typically, sodium *N,N*-dibutyldithiocarbamate (1.02 g), previously dried *in vacuo* for 4–5 days, was added to a solution of Ph_2TeCl_2 (0.62 g) in CS_2 (15 mL). A continuous stream of N_2 at a rate of 3 bubbles/s was maintained throughout the procedure. The mixture was refluxed at 45°C for 3 h. The product solution was filtered to remove NaCl and any unreacted material. A couple of drops of petroleum ether were added and the solution was left in the refrigerator at −6°C until crystals formed. The crystals of $Ph_2Te[S_2CNBu_2]_2$ were washed with *n*-hexane and dried in vacuum for 2–3 days; 0.93 g; 77% yield; yellow crystals; mp 127–128°C. Anal. calcd. for $C_{30}H_{46}N_2S_4Te$: C 52.18, H 6.71, N 4.26; found: C 52.22, H 6.83, N 3.95. Similarly *N,N*-diphenylbis(*N,N*-dipropyldithiocarbamato)tellurium(IV) was prepared in 83% yield; yellow crystals; mp 76–77°C. Anal. calcd. for $C_{26}H_{38}N_2S_4Te$: C 49.24, H 6.04, N 4.42; found: C 48.88, H 5.97, N 4.23.

Synthesis of chlorodiphenyl(N,N-*dialkyldithiocarbamato)tellurium(IV)*

Typically, an equimolar mixture of sodium *N,N*-dibutyldithiocarbamate (0.57 g), previously dried, and Ph_2TeCl_2 (0.87 g) was refluxed in excess methylene dichloride or CS_2 (10 mL) at 45°C for 3 h. N_2 gas was bubbled through at a rate of 3 bubbles/s. The solution was then filtered to remove any solid materials and left in the refrigerator to crystallize. $Ph_2TeCl[S_2CNBu_2]$, 0.84 g; 65% yield; pale yellow crystals; mp 88–90°C. Anal. calcd. for $C_{21}H_{28}ClNS_2Te$: C 48.35, H 5.41, N 2.69; found: C 47.88, H 5.47, N 2.69.

Similarly prepared were $Ph_2TeCl[S_2CNR_2]$, R = Me, Et, Pr, and *i*-Pr for subsequent conversion to the four corresponding bromides.

Synthesis of bromodiphenyl(N,N-*dialkyldithiocarbamato)tellurium(IV)*

Typically, $Ph_2TeCl[S_2CNBu_2]$ (0.29 g) was dissolved in CS_2 (5 mL) and the system kept in an ice bath and purged under nitrogen. An equimolar amount of bromotrimethylsilane (0.075 mL) was added slowly to the mixture. Once addition was complete the mixture was stirred at ambient temperature for 3–4 h. The solution was then filtered and placed in a refrigerator to allow the crystallization of $Ph_2TeBr[S_2CNBu_2]$, 0.19 g; 60% yield; yellow crystals; mp 97–98°C. Anal. calcd. for $C_{21}H_{28}BrNS_2Te$: C 44.56, H 4.79, N 2.49; found: C 45.23, H 5.06, N 2.49. Similar methods were used to prepare pale lime-green crystals of $Ph_2TeBr[S_2CNPr_2]$, mp 93–94°C; of $Ph_2TeBr[S_2CNi\text{-}Pr_2]$, mp 143–147°C; $Ph_2TeBr[S_2CNEt_2]$,$\frac{1}{2}CS_2$, mp 192°C; and $Ph_2TeBr[S_2CNMe_2]$, mp 97°C.

Alternate synthesis of $Ph_2TeBr[S_2CNR_2]$

Typically, diphenyltellurium dibromide (0.82 g) was stirred in dried methylene chloride or CS_2 (10 mL) in a two-necked flask. The solution was cooled with an ice bath and purged under N_2. Sodium *N,N*-dibutyldithiocarbamate (0.53 g), previously dried *in vacuo* for 4–5 days, was added from a finger tube attached to the flask. The solution was stirred in an ice bath under nitrogen for 30 min. At this time the mixture was allowed to reach ambient temperature and stirred for 3–4 h. The product solution was filtered and placed in a refrigerator at −6°C until crystals formed. Crystals of $Ph_2TeBr[S_2CNBu_2]$ were washed with *n*-hexane and dried *in vacuo* for 2–3 days; 0.94 g; 71% yield; pale green crystals; mp 98°C. Anal. calcd. for $C_{21}H_{28}BrNS_2Te$: C 44.56, H 4.79,. N 2.49; found: C 44.29, H 4.78, N 2.21.

Physical measurements

All solvents were dried and distilled prior to use. Elemental analyses were performed by Galbraith Laboratories in Knoxville, TN, or M-H-W Laboratories in Phoenix, AR. Density measurements were performed by the flotation method in CCl_4/C_6H_6. The infrared spectra were recorded on a Nicolet 5DXFT spectrometer as KBr pellets and far infrared spectra on a Bohmem IR Spectrometer between polyethylene films. Samples for Raman spectroscopy were sealed in capillary tubes and the spectra recorded on a Ramanor U-1000 spectrometer using the 4880 Å exciting line. The ^1H NMR spectra were recorded on a Bruker AC300 spectrometer in CS_2 or $CDCl_3$ solutions using tetramethylsilane as the internal reference for CS_2 solutions. The same instrument was used to record the $^{13}C\{^1H\}$ NMR spectra. A Bruker AC200 spectrometer was used to record ^{125}Te spectra, referenced to dimethyl tellurium. The melting points were determined on a Fisher-Johns apparatus.

X-ray crystallographic analysis

X-ray diffraction data were collected on a Syntex P_21 diffractometer by the procedure already described in detail (13). In each case the crystal was sealed in a capillary and mounted along the largest dimension. The least-squares refinement of the setting angles of 35 reflections ($15 > 2\theta > 30$) led to the cell dimensions given in Table 1. The appropriate space group was used in both cases and later assumed correct because of successful refinement of the data. During data collection, the intensities of three monitor reflections measured after 200 reflections decreased in the range approximately 2–4% and the appropriate scaling factor was employed. Each set of data was corrected for Lorentz and polarization effects, and an empirical absorption correction was applied but resulted in no significant changes in refinement. The ranges of absorption correction factors were 0.92–0.90 for **4**, and 0.98–0.96 for **7**. A summary of crystal and refinement data are given in Table 1.

The position of the tellurium was determined by a sharpened Patterson synthesis. The remaining atoms were revealed using SHELX and difference maps. Te, S, N, and where appropriate Br were refined anisotropically. Limitations on data in one case allowed only the anisotropic refinement of carbon atoms other than those in the phenyl rings in which the carbon atoms were fixed as a hexagon and so we completed both refinements with the same restrictions. Hydrogen atoms were included at the idealized positions (C—H = 0.95 Å; HCH (for ethyl and butyl) = 109.5°; CCH = 120° (for phenyl rings)) with isotropic *U* values set at approximately 0.01 Å greater than the corresponding carbon atom. Complete refinement by full-matrix least-squares methods minimizing the function $\Sigma w(|F_o| - |F_c|)^2$ converged satisfactorily in both cases at $R = 0.0448$ and $R_w = 0.0489$ for **4**; and $R = 0.0397$ and $R_w = 0.0439$ for **7**. A weighting scheme of the form $w = 1/[\sigma(F) + \rho F^2]$ was employed with final ρ values of 0.00007 for **4** and 0.00012 for **7**, respectively. No evidence was found of reflections being affected by secondary extinctions. We also refined both structures without fixing the rings, which resulted in a NP/P of only 6.9 for **4** with convergence at $R = 0.0439$ and $R_w = 0.485$ for **4** and $R = 0.0391$ and $R_w = 0.0426$ for **7**. No bond distances or bond angles were significantly altered with the exception of those involving the connection of tellurium to the phenyl ring which changed marginally. Also because the phenyl rings were not fixed, the uncertainty on the Te—C bond lengths increased very slightly along

with the bond length: for **4**, Tel-C6 = 2.14(1) and Te2—C23 = 2.12(1) and for **7**, Te—C10 = 2.136(5).

The final fractional coordinates for non-hydrogen atoms of **4** and **7** are listed in Tables 2 and 3 respectively. Both molecules were subjected to the same degree of refinement and in both cases NP/P was greater than 10. Important bond lengths and angles are given in Tables 4 and 5. The molecular structures of both the compounds are given in Figs. 1 and 2. Tables of anisotropic Te, S, N, Br, and all C atoms not in the phenyl rings, final fractional coordinates and thermal parameters of hydrogen atoms, as well as tables of observed and calculated structure factors have been deposited.[1]

Results and discussion

The diphenylbromo(*N*,*N*-dialkyldithiocarbamato)tellurium-(IV) derivatives are made by either an essentially quantitative conversion of the corresponding chloro derivatives by an exchange reaction using bromotrimethylsilane or by direct reaction with diphenyltellurium dibromide. The chloro derivatives and diphenylbis(*N*,*N*-dibutyldithiocarbamato)tellurium-(IV) were made by the procedures described earlier (18). One typical method of characterizing such compounds is by NMR spectroscopy. However, it soon became apparent that although these species could all be recrystallized and their molecular formulation confirmed by analysis, they dissociated rapidly in solution. Thus assignments of NMR spectra to particular compounds (see Table 7) depended on selecting peaks in sequences of spectra which were changing with time. In this context it seemed appropriate to at least confirm the solid state structures of the new compounds when crystals of sufficient quality could be formed.

The crystal structure of $Ph_2Te[S_2CNBu_2]_2$, 7

Unlike that which was found for the analogous methyldithiocarbamate derivative, the compound crystallizes in the space group $P2/c$. However, the geometry around tellurium is again best described as a sawhorse structure typical of tellurium(IV) compounds based on a distorted trigonal bipyramid in which the lone-pair occupies an equatorial position. The organo substituent in the dithiocarbamate is a relatively long-chain alkane compared with other compounds of this type whose structures are known, namely, $Ph_2Te[S_2CNMe_2]_2$ (18) and $Ph_2Te[S_2CNEt_2]_2$ (20). Nevertheless, the structures are similar with the C—Te—C angles in the equatorial position being 95.3(2)° for **7** and 94.23(13) and 94.07(7)° for the two crystalline forms of $Ph_2Te[S_2CNEt_2]_2$ (20) and 99.4(1)° for $Ph_2Te[S_2CNMe_2]_2$ (18), and with the Te—C bond lengths being essentially identical in all three compounds. The exact length determined for the Te—C bond may vary depending on whether the structure is determined using fixed phenyl rings or not. Thus, with fixed rings, the value of the Te—C bond length in **7** is calculated to be 2.125(4) Å, which is close to the reported average value for tellurium – aryl carbon bonds (21). If, as was the case for $Ph_2Te[S_2CNMe_2]_2$, the carbon atoms in the ring are

not fixed then the Te—C bond length is calculated as 2.136(5) for **7** and 2.140(5), 2.143(2), and 2.142(2) for the methyl analogue (18) and the two forms of the ethyl analogue, respectively. The distortion from linear for the two axial S atoms bonded to tellurium is similar with an angle of 173.2(1)° for **7**, 175.11(3) and 178.94(2)° for the ethyl analogues, and 172.0(1)° for the methyl analogue. The Te—S distances are essentially identical, being 2.622(2) Å for **7**, 2.62(1) Å for $Ph_2Te[S_2CNMe_2]_2$ (18), and 2.6303(9) for $Ph_2Te[S_2CNEt_2]_2$ (20). Furthermore, not surprisingly, the positions of the non-bonded or partially "bonded" sulfur atoms are essentially the same, with distances of 3.195(2) Å for **7** and 3.186(2) Å and 3.1103(9) Å for the analogues; the sum of the van der Waals radii being ca. 4.0 Å (22). The similarity extends to the bite angles for the ligand of 61.0(2)° for **7** and 61.84(2)° for the *C*2/*c* form of $Ph_2Te[S_2CNEt_2]_2$ (20). If the longer tellurium–sulfur bonds are considered as part of the coordination shell about tellurium, then tellurium has an effective coordination number of seven and has close to a 1:2:2:2 geometry (23) as was described for the ethyl analogue (20) and $C_8H_8Te[S_2CNEt_2]_2$ (24). Presumably, the molecules are packed together in sufficiently discrete units so that the longer chains of the butyl groups provide no hindrance to crystallization in essentially identical arrangements, although it is notable that the nearest neighbour contact for tellurium is a terminal methyl group of a butyl chain.

The crystal structure of $Ph_2TeBr[S_2CNEt_2]\cdot\frac{1}{2}CS_2$, ***4***

This bromo derivative crystallizes out with CS_2 contained in the lattice as triclinic *P*1 and is essentially identical to that previously reported for the chloro derivative (18). The same distorted sawhorse structure is present around tellurium with the Te—Br bond now replacing an axial Te—S bond. The Te—Br bonds of 2.743(2) and 2.779 Å for the two asymmetric units are longer than the Te–Br bonds reported for Ph_2TeBr_2 of 2.682(3) Å (25) but by a lesser amount than was noted between Ph_2TeCl_2 and $Ph_2TeCl[S_2CNEt_2]$ (18). Other bond lengths and bond angles involving tellurium are essentially the same for the bromo and chloro derivatives. The similarity between $Ph_2TeCl[S_2CNEt_2]\cdot\frac{1}{2}CS_2$ and $Ph_2TeBr[S_2CNEt_2]\cdot\frac{1}{2}CS_2$ even ex-

[a]Symmetry-equivalent positions: prime indicates -*x*, *y*, 0.5-*z*.

tends to the location of the closest interaction between Te and an atom containing lone-pairs on an adjacent atom, the Te--S′ distances being 3.678(3), 3,865(3), 3.656(2), and 3.825(2), respectively, for **7** and its chloro analogue. By contrast, the packing in $Ph_2TeCl[S_2CN(i\text{-}Pr)_2]$ is such as to make the closest such interaction Te---Cl′ at a distance of 3.607(2) Å (18).

In all of these dithiocarbamates, as for the methyl and ethyl analogues, the S_2C—N bond clearly has partial double-bond character as it is considerably shorter (1.331(8) for **4** and 1.34(1) for **7**) than the shortest N—C bond to an organic group (1.469(8) for **4** and 1.47(2) for **7**). The similarity of the environment of the ligand itself is further emphasized by the short C—S(terminal) and long C—STe bonds in the two compounds which span the range 1.66(1)–1.69(1) for **7** and 1.681(6) for **4** for C=S and 1.74(1)–1.75(1) for **7** and 1.764(6) for **4** for C—STe. This situation is generally the case for all the ligands for the compounds reported or discussed herein. Thus the ligand is essentially unchanged whether it is in a bis-substituted compound or a chloro- or bromo-substituted derivative.

Infrared and Raman spectra

As has been mentioned, these compounds all have a tendency to decompose when dissolved. Consequently, the vibrational spectra (Table 6) become more important in providing a characterization in the solid state. However, it soon becomes evident that those features attributed by previous workers to ν(C—NR_2), νC=S), and ν(C—SM) stretches in the regions 900–1500 cm^{-1} all occur in the same area as strong features in both the Raman and IR spectra of phenyl and alkyl groups so that their assignment is only possible by essentially circular arguments. Thus the infrared spectra, at least in this region, can provide little information to confirm the nature of the compound. However, the Raman spectrum shows a distinctive peak in the range 947–980 cm^{-1}, attributable to the NCS_2 group, close to and usually of comparable intensity to the definitive *p* and *b* phenyl vibrations (26) which are always seen at 998 ± 1 and 1018 ± 1 cm^{-1}. Another peak of comparable intensity appears consistently in all of these compounds in the 360–390 cm^{-1} region which is typical of many M—S containing compounds, and so it is assigned to the Te—S stretching mode. By contrast, in Ph_2TeCl_2, the two Te—Cl stretching vibrations are seen at 287 and 267 cm^{-1} (27) which is markedly to lower wave number than ν(Te—S), particularly as the Te—S bond is longer than the Te—Cl bond in Ph_2TeCl_2 of 2.48–2.54 Å (28). Another surprising feature is that in the bromo derivatives there is no very strong band in the region below 200 cm^{-1} in the Raman spectrum. This is in marked contrast to the Raman spectrum of Ph_2TeBr_2 where the band at 159 cm^{-1}, attributed to the symmetric Te—Br stretching vibration, is at least an order of magnitude more intense than any other feature in the whole spectrum (27). The most intense peak in this lower region of the Raman spectrum varies considerably from compounds **1**–**5** so that, rather disappointingly, ν(Te—Br) is not a distinctive Raman feature. However, in the far ir spectrum of compounds **1**–**5** there is a peak centred at ca. 169 cm^{-1} which is clearly more intense than any feature in this region in the spectra of compounds **6**–**8**. This is therefore assigned to ν(Te—Br) which places it at approximately the average value of the asymmetric (185 cm^{-1}) and symmetric (159 cm^{-1}) Te—Br stretching modes in Ph_2TeBr_2 (27).

Nuclear magnetic resonance spectra

The ^1H and ^{13}C NMR spectra recorded in Table 7 give the chemical shifts of compounds **1**–**8** recorded immediately after dissolution in $CDCl_3$ solution. Carbon disulfide was also used as solvent but in all cases the spectra recorded after a matter of days, in some cases only hours, showed no more than trace amounts of the original compound. The chemical shifts for all of the phenyl groups are very similar for all compounds **1**–**8** regardless of the nature of the attached dithiocarbamate or whether it is a bis-, chloro-, or bromo-substituted derivative. The shifts in the ^1H NMR spectrum are also close to those for Ph_2TeCl_2 and Ph_2TeBr_2 and significantly different from those of Ph_2Te, whose values are included for comparative purposes. The chemical shifts related to the alkyl groups of the dithiocarbamates are also virtually the same for a given ligand in the bis, chloro, or bromo derivatives, which is not surprising in view of the similarities within the X-ray structures that we report herein and that have been reported by us and others (18, 20). The typical H—H coupling associated with first-order spectra is clearly evident for the ethyl group and the terminal methyl groups in the isopropyl, propyl, and butyl compounds. For all of

*Also have peaks in the Raman at ~174 cm^{-1} but none corresponding in the IR spectra.

the propyl and butyl compounds, the -CH_2 group attached to nitrogen has the expected triplet from H—H coupling, while the middle -CH_2 groups can be readily assigned as overlapping doublets of triplets in the case of propyl groups. For the butyl groups, the central -CH_2 groups are seen as doublets of triplets and doublets of quartets with very similar values of the coupling constants. It should be noted that in the diligands, e.g., $(CH_3CH_2CH_2CH_2)_2NCS_2S_2CN(CH_2CH_2CH_2CH_3)_2$, the NMR spectra indicate that the alkyl groups which are chemically equivalent are magnetically non-equivalent. Their NMR data are included in Table 7 for comparison.

While ^1H and ^{13}C NMR spectra can be obtained sufficiently rapidly to provide at least one spectrum that has essentially no extraneous peaks, the accumulation times involved in recording ^{125}Te NMR spectra of reasonable quality are such as to rarely show the presence of only the sample of compound **1–8** that was initially dissolved. In Table 8, the additional chemical shifts that are observed in the spectra of compounds **1–8** and other related derivatives are included to provide the background to indicate the mode of dissociation and/or rearrangement.

In the ^{125}Te NMR spectra of all bis compounds, $Ph_2Te[S_2CNR_2]_2$ peaks are seen in the range 703–712 ppm, compared to 765–780 ppm for all bromo-substituted compounds, $Ph_2TeBr[S_2CNR_2]_2$, and 918, 885, and 691 ppm respectively for Ph_2TeCl_2, Ph_2TeBr_2, and Ph_2Te. Based on the crystal structures and the similarities in the ^1H NMR spectra, the chemical shifts of $Ph_2Te[S_2CNR_2]_2$ species might well have been expected to be similar to those of the tellurium(IV), Ph_2TeX_2 (X = Cl, Br) species rather than the tellurium(II) species, Ph_2Te. Also, if the NMR is re-recorded after solutions of the bis compounds have been held at room temperature for more than 48 h, the only peak observed in the ^{125}Te NMR spectrum is that contributable to Ph_2Te. Thus, the overall reductive-elimination indicated for $Ph_2Te[S_2CNBu_2]_2$ [1] is a facile reaction for all $Ph_2Te[S_2CNR_2]_2$ species.

[1] $Ph_2Te[S_2CNBu_2]_2 \rightarrow Ph_2Te + Bu_2NCS_2S_2CNBu_2$

The presence of $Bu_2NCS_2S_2CNBu_2$ is readily confirmed by increases in the features attributable to it at 3.91 and 1.89, 1.72 ppm for NCH_2 and $NCCH_2$, respectively, in the ^1H NMR spectra and 57.82, 53.64 and 30.63, 28.55 ppm for NCH_2 and $NCCH_2$, respectively, in the ^{13}C NMR spectra of a solution of $Ph_2Te[S_2CNBu_2]_2$ as the corresponding peaks attributable to the bis compound decrease in intensity. Typically, if $CDCl_3$ is distilled onto freshly prepared $Ph_2Te[S_2CNBu_2]_2$ and held at liquid N_2 temperature until the solution is allowed to warm up in the spectrometer, all peaks can be initially assigned to the presence of only $Ph_2Te[S_2CNBu_2]_2$. However, these peaks progressively decrease in intensity until after 3 days the spectrum is dominated by peaks attributable to Ph_2Te and $Bu_2CNS_2NCBu_2$ although weak peaks are still present at room temperature at 134.5, 130.1, 129.7, ~54, and ~30 ppm which are similar to, but do not correspond to, those of the original compound but which are at least consistent with the presence of a second form of $Ph_2Te[S_2CNBu_2]_2$. The same general pattern is observed for all $Ph_2Te[S_2CNR_2]_2$ compounds so examined.

Thus, it seems reasonable to suppose that the bis compounds do exist in two forms in solution, one of which would be the favoured form at low temperature and so resembles the crystal structure with Te—S bonds at ca. 180° to each other (a "*trans*" form) and in which the closest approach of S-atoms on adjacent ligands would be approximately 5.50 Å even allowing for free rotation. The second form would be one in which at least one of the anisobidentate S-atoms of the crystal structure has become the more tightly bound S-atom of the ligand resulting in the presence of two dithiocarbamate groups with Te—S bonds at approximately 90° to one another (a "*cis*" form) and free rotation about these bonds would readily bring the pendant sulfur atoms into close contact leading to the ready formation of the diligand, as is demonstrated diagrammatically in Fig. 3*a*. The existence of S-ligands "*cis*" to one another is clearly seen in the structure of the dimeric species $\{Ph_3Te(S_2CNi\text{-}Pr)\}_2$ (29) although intramolecular monodentate–bidentate dithiolate exchange is an equally probale initiation step. The reductive-elimination might be expected to be reversible but if so the equilibrium must be very strongly towards the right hand side and we have been unable to obtain any unequivocal evidence of the formation of bis compounds from the reaction of diligand and Ph_2Te in solution.

The ^{125}Te NMR chemical shifts of the $Ph_2TeBr[S_2CNR_2]$ species, as mentioned earlier, are all in the range of 765–780 ppm and are approximately mid-way between those of Ph_2TeBr_2 and the bis compounds or Ph_2Te, again consistent with the thiocarbamate groups having a surprisingly small influence on the

value of the chemical shift. It can be seen from Table 7 that the spectra of these halogenated derivatives also display features attributable to Ph_2TeX_2 and Ph_2Te.

Typically, the disappearance of the initial peak attributable to $Ph_2TeX[S_2CNR_2]$ species decreases at a much slower rate than was the case for the bis species. As the intensity of the initial peak decreases, so the intensities of those attributable to Ph_2TeX_2 and Ph_2Te increase. It is reasonable to assume that exchange takes place in accord with route [2] and that the bis species decompose as they form too rapidly for their presence to be picked up in these NMR spectra.

The transformation to Ph_2TeX_2 and $Ph_2Te[S_2CNR_2]_2$ could be by exchange involving the halide groups or the dithiocarbamate (as indicated in Fig. 3*b*) or both. Because of the propensity for bis compounds to undergo rapid reductive-elimination, it is difficult to obtain evidence of their ability to exchange. However, the presence of the dithiocarbamate as a bridging ligand in $\{Ph_3Te(S_2CNi\text{-}Pr)\}_2$ (29) with Te—S bond lengths of approximately 3.1 Å indicates that such a process is feasible, as does the crystal packing in $Ph_2TeCl[S_2CNEt_2]$, $Ph_2TeCl[S_2$-

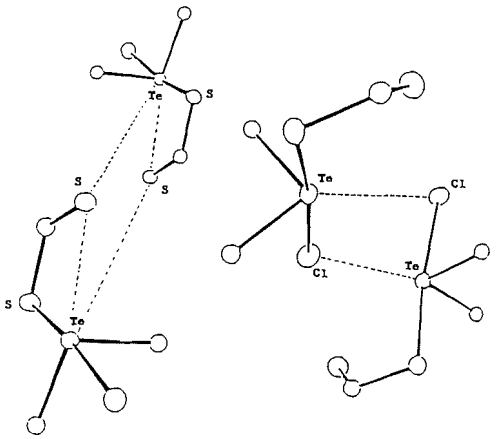

FIG. 4. Possible intermediates as suggested by a section of the packing diagrams of $Ph_2Te[S_2CNR_2]_2$ (*a*) and $Ph_2TeX[S_2CNR_2]_2$ (*b*) species showing the intermolecular interactions.

$CNi\text{-}Pr_2$] (18), and $Ph_2TeBr[S_2CNEt_2]$, which gives Te---S distances between molecules of ca 3.6 Å (Fig. 4*a*). Similarly, the crystal structure of $Ph_2TeCl[S_2CNi\text{-}Pr_2]$ also shows a Te---Cl′ interaction with an adjacent molecule of only ca. 3.6 Å (18) (Fig. 4*b*) and although no such interaction is observed between Cl or Br atoms in the crystal structures of the $Ph_2TeX[S_2CNEt_2]$ analogues, it is reasonable to suppose it is possible in solution. Indeed, the ^{125}Te NMR spectrum of a solution of Ph_2TeCl_2 and Ph_2TeBr_2 confirms that halogen exchange readily occurs with the formation of a peak at 905 ppm attributable to $Ph_2TeClBr$.

A molecular mechanics study of conformational isomerism in 1- and 3-aryl hydantoins and 3-aryl-2-thiohydantoins

LAWRENCE D. COLEBROOK
Department of Chemistry and Biochemistry, Concordia University, 1455 de Maisonneuve Blvd. W., Montreal, P.Q., Canada H3G 1M8

Received November 2, 1990

LAWRENCE D. COLEBROOK. Can. J. Chem. **69**, 1957 (1991).

Energy profiles for internal rotation about the C—N pivot bond in a series of 1- and 3-aryl hydantoins and 3-aryl-2-thiohydantoins have been computed using the MMX molecular mechanics force field. Rotational ground and transition states have been identified and their energies calculated. Conformational preferences of diastereomeric rotamers have been investigated. Computed rotational energy barriers generally are within ±2 kcal/mol of the experimentally determined values.

Key words: conformational isomerism, hindered rotation, hydantoins, thiohydantoins, molecular mechanics.

LAWRENCE D. COLEBROOK. Can. J. Chem. **69**, 1957 (1991).

Utilisant des champs de force de la mécanique moléculaire MMX, on a calculé les profiles d'énergie pour la rotation interne autour de la liaison C—N d'une série de 1- et de 3-aryl hydantoïnes et de 3-aryl-2-thiohydantoïnes. On a identifié les états rotationnels fondamentaux et de transition et on a calculé leurs énergies. On a étudié les préférences conformationnelles des rotamères diastéréoisomères. Généralement les valeurs calculées pour les barrières à l'énergie de rotation sont à ±2 kcal/mol des valeurs expérimentales.

Mots clés : isomérie conformationnelle, rotation empêchée, hydantoïnes, thiohydantoïnes, mécanique moléculaire.

Introduction

We have previously reported ^1H and ^{13}C nmr and X-ray crystallographic studies of a variety of aryl-substituted N-heterocyclic compounds which exhibit biphenyl-like isomerism. At equilibrium, these compounds form a mixture of enantiomeric or diastereomeric rotational isomers resulting from restricted internal rotation of the aryl and heterocyclic moieties about the C—N pivot bond connecting the two ring systems. The studies have included 1-arylhydantoins (1, 2), 3-arylhydantoins (1, 2), and 3-aryl-2-thiohydantoins (1, 3–5), with a number of different aryl group substituents and with various substitution patterns on the heterocyclic group.

It was shown that those compounds with diastereomeric rotational isomers usually exhibit room temperature nmr spectra that are the superimposition of the spectra of the two rotamers. The majority of the spectra are temperature dependent, collapsing to a single, time-averaged spectrum at sufficiently high temperature. Those compounds with enantiomeric rotational isomers (which have identical spectra in an achiral solvent) were synthesized with an internal chirality-sensitive probe that exhibited a spectrum dependent on the rate of internal rotation. Activation parameters for hindered rotation were obtained from the temperature-dependent ^1H nmr specrtra, from the coalescence points or by complete lineshape analysis when this proved feasible. Some of the rotational barriers were sufficiently high that time-averaged spectra could not be obtained at the highest attainable temperatures. In certain cases, the rotational barriers of compounds with diastereomeric rotational isomers were sufficiently high that a single rotational isomer could be isolated by careful crystallization, and its rate of isomerization followed by nmr methods. An X-ray crystallographic structure determination was carried out on one such isomer (5).

In the majority of cases in which the rotational isomers were disastereomers, it was observed that the isomers were present in unequal concentration at equilibrium. Although, in principle, this should always be the case for diastereomers, the mechanism by which stereochemical information was transmitted from one unsymmetrically substituted part of the molecule to another was not always clear. It was suggested that an unsymmetrical solvent shell could provide such a mechanism (5). The origin of ground state stereochemical preferences has been further investigated in the present study.

The temperature-dependent spectra of these compounds were originally interpreted in relation to conformational preferences and exchange processes with the aid of physical molecular models, using organic chemists' qualitative stereochemical intuition. There remained some uncertainty in the identification of the stereochemistry of the rotational ground states and the transition states, since two interconversion pathways are potentially available. We have now investigated the same structures using molecular mechanics calculations (6) to gain further insight into the ground and rotational transition state conformations, and to test the utility of these calculations to provide quantitative information on these systems. Energy profiles for rotation of the two ring systems about the central C—N bond have been computed, and the conformational isomers and possible rotational transition states have been identified. This quantitative treatment has led to a more complete understanding of the conformational preferences and the rotational transition states of these compounds.

Results and discussion

Rotational energy profiles and activation energies for rotation may readily be calculated using molecular mechanics methods. The parameters for molecular mechanics force fields are mainly derived from gas-phase results, so solute–solvent interactions are not evaluated. The experimental data reported for the compounds that are considered in this paper suggest that solvation influences rotational barriers and ground state conformations. Nevertheless, molecular mechanics calculations may provide insight into the conformational behaviour of these compounds, and aid our understanding of the significance of solvation.

The experimental measurements provided activation parameters for hindered rotation. In certain cases, it was only possible to measure $\Delta G^{\neq}$, but in others the complete set of Eyring

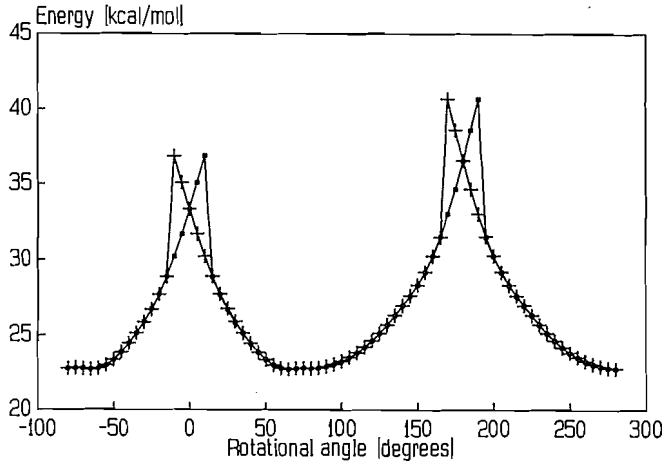

FIG. 1. Computed rotational energy profile for **1***b*, calculated at 5° intervals. The C2—N--C—C(CH_3) dihedral angle was driven. ■, increasing dihedral angle; +, decreasing dihedral angle.

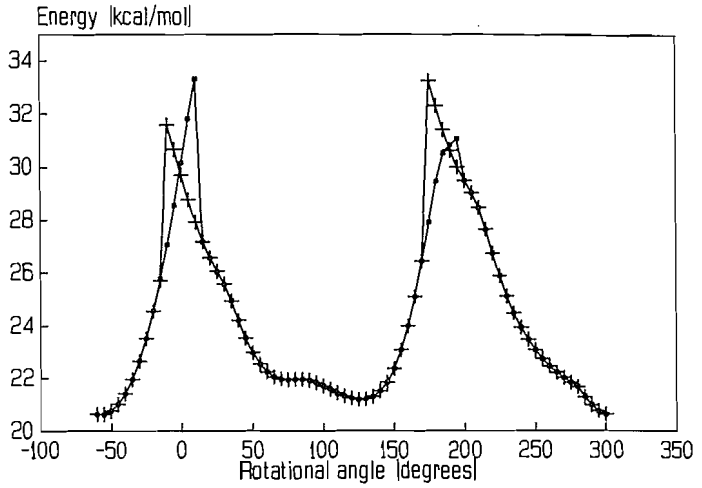

FIG. 2. Computed rotational energy profile for **1***i*, calculated at 5° intervals. The C2—N--C—C(CH_3) dihedral angle was driven. ■, increasing dihedral angle; +, decreasing dihedral angle.

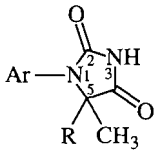
activation parameters, $\Delta G^{\neq}$, $\Delta H^{\neq}$, and $\Delta S^{\neq}$, were calculated. The activation parameters obtained from molecular mechanics calculations correspond most closely to the enthalpy term, $\Delta H^{\neq}$.



The dihedral driver option of PCMODEL 3.0, which was used to calculate the rotational energy profiles, writes an output file containing the coordinates of the energy-minimized structures corresponding to each selected dihedral angle about the C—N pivot bond. It is instructive to view the structures on the computer graphics screen in the vicinities of the energy minima (to identify the preferred conformations) and the energy maxima (the rotational transition states). The molecular mechanics calculations predict quite severe bond distortion near the rotational transition states of the more highly hindered compounds. The computed geometry of the distorted molecule near a transition state reflects the history of the molecule, i.e., the geometry depends on the geometries of the immediately preceding states. One aspect of this distortion is that there is a hysteresis effect in passing a high maximum: the computed energy maximum lags the change in dihedral angle, and the profiles differ depending on whether the dihedral angle is increasing or decreasing in passing through a maximum (the profiles are identical except near an energy maximum) (Figs. 1 and 2). This appears to be an artefact of the computational procedure. A further effect of the bond distortion is that the computed energy tends to increase relatively slowly as the maximum is approached, but it collapses rapidly as the maximum is passed. Examination of the predicted molecular structures at the rotational transition state shows the bulky *ortho*-aryl substituent bent away from the region of steric strain, out of the general plane of the ring, so that it lags behind the change in dihedral angle. At the energy maximum the *ortho* hydrogen atom has passed the general plane of the heterocyclic group, so that both *ortho*-aryl substituents lie on the same face of the molecule, which is very distorted. Further change in dihedral angle produces a sudden relief of steric strain, the bulky *ortho* substituent and the aryl group attaining a more normal geometry.

For those compounds which have enantiomeric rotational isomers, the skewed profiles in the vicinity of the energy maxima for increasing and decreasing dihedral angle are mirror images (Fig. 1). However, the 1-aryl-5-methylhydantoins, which have diastereomeric rotational isomers, show skewed profiles in the vicinity of the maxima that are not mirror images. Further, the corresponding increasing and decreasing computed maxima are not identical, since the rotational pathways remain diastereomeric up to, and including, the transition state maxima (Fig. 2). In effect, the computations predict that there are different (diastereomeric) rotational transition states (with different molecular geometries) in the directions of increasing and decreasing rotational angle, a consequence of the calculations following different (diastereomeric) pathways in the forward and the reverse directions. This prediction appears to violate the principle of microscopic reversibility. Similar problems have been noted in other force-field studies involving the interconversion of diastereomeric conformational isomers (7). Because of difficulties in interpretation, only a limited quantitative consideration of rotational barriers of the 1-aryl-5-methylhydantoins has been included in the discussion.

The 1-aryl-5-methylhydantoins have a strong steric interaction between the fixed chiral centre (at C-5) and the atropisomeric centre associated with the substituted biphenyl-like ring systems. In the 3-aryl-5-methylhydantoin series, the diastereomeric interactions between the aryl and heterocyclic moieties are much smaller, and the skewing of the profiles in the vicinity of the energy maxima does not show significant deviation from a mirror image relationship.

In this study, all of the rotational energy profiles were calculated starting near an energy minimum, where bond distortion should be negligible, with equal incrementation of the dihedral angle, so that the calculations approach and pass an energy maximum in a smooth progression of states. In addition, the energies near the maxima of **1***b* and **3***e* were investigated by starting with the molecules minimized to an unstrained low-energy conformation, rotating and then fixing the dihedral angle at a position near the energy maximum, then minimizing with a single dihedral angle constraint. In each case, the energy minimized to the corresponding point on the lower energy dihedral driver hysteresis curve (see figures), thus missing the hysteresis effect and finding a lower energy maximum than the dihedral driver procedure. Comparison of the energy barriers calculated by these two procedures with the experimental $\Delta H^{\neq}$ value for **3***e* showed that the dihedral driver method gave much better agreement. It was concluded that the dihedral driver method is the more realistic approach.

1-Aryl-5,5-dimethylhydantoins

Studies of 1-aryl-5,5-dimethylhydantoins in both achiral (DMSO-d_6 and pyridine) and chiral (*S*-(+)-trifluoromethylphenylethanol) solvents have been reported (1,2).

The 5,5-dimethyl compounds have enantiomeric rotational isomers, which have indistinguishable spectra in an achiral solvent. However, the molecules contain a probe, the geminal dimethyl group, with a spectrum that is sensitive to the mean lifetimes of the conformational isomers. Reported activation parameters for restricted internal rotation were calculated from mean lifetimes obtained by complete lineshape analysis of the temperature-dependent ^{1}H nmr spectra of **1***b*, **1***c*, **1***f*, and **1***g*, and from the coalescence temperatures of signals of **1***d*–**1***e* in DMSO-d_6 solution. Free energies and enthalpies of activation for the 2-methylphenyl, 2,3-dimethylphenyl, 2,4-dimethylphenyl, 2,5-dimethylphenyl, 2-chlorophenyl, and α-naphthyl compounds (**1***b*–**1***g*) in various solvents are in the range 17.4–21.2 kcal/mol and 13.7–16.0 kcal/mol, respectively (Table 1) (1, 2, 8).

The computed rotational energy profile of 1-phenyl-5,5-dimethylhydantoin, **1***a*, shows a double energy minimum, with dihedral angles of 55° and 125° with respect to C-2, separated by a small barrier (0.4 kcal/mol) at a dihedral angle of 90°. The calculated rotational barrier is 2.8 kcal/mol. The computed rotational energy profiles of the substituted 1-aryl series show a broad, single potential well at a dihedral angle of 65–80°, with the *ortho* substituent inclined towards C-2. Compounds with substituted aryl groups are predicted to have less librational freedom than the phenyl compound, and to have much higher rotational barriers. There are two possible transition states for rotation, the *ortho*-aryl substituent passing either the substituents in the 5-position or the 2-carbonyl group. In the report of the experimental study (1), it was suggested, using a qualitative argument based on examination of Dreiding molecular models, that the bulky *ortho* substituent passes the 5-position in the preferred transition state. However, computation for the 5,5-dimethyl series predicts that the rotational transition state in which the more bulky 1-aryl group *ortho* substituent passes the carbonyl group in the 2-position rather than the geminal dimethyl group is preferred (by 0.6–3.9 kcal/mol). This prediction is supported by examination of the van der Waals surfaces of the carbonyl and geminal dimethyl groups, using molecular graphics.

Comparison of the computed rotational barriers of **1***b* and **1***c* supports the inferences that have been made on the buttressing effects of *ortho*-methyl groups. The 2,3-dimethylphenyl compound, **1***c*, has a higher computed and experimentally determined rotational enthalpy barrier than the 2-methyl compound, **1***b* (by 0.4 and 0.3 kcal/mol, respectively). This difference, which was originally observed during racemization studies of optically active biphenyls (9), has been attributed to the reduced ability of the 2-methyl group to bend in the rotational transition state because of steric interference from the 3-methyl group. Compounds **1***d* (2,4-dimethylphenyl) and **1***e* (2,5-dimethylphenyl), which lack this buttressing effect, have similar experimental and computed rotational energy barriers.

In the experimental paper, it was noted that the 2-methylphenyl compound, **1***b*, has a higher rotational barrier than the 2-chlorophenyl compound, **1***f*. Computation predicts a small difference in the opposite sense. Neglect of the influence of a polar solvent (DMSO-d_6) may be responsible for this discrepancy.

The computed rotational barriers (Table 1) show quite close agreement (within 1.0–2.4 kcal/mol) with the experimentally determined values of $\Delta H^{\neq}$ considering that the measurements may be subject to error (10), that solvation is not taken into account, and that further refinements in the force-field parameters used in the calculations are possible.

1-Aryl-5-methylhydantoins

The four compounds in this series, **1***i*–**1***l*, have diastereomeric rotational isomers, present in unequal concentration at equilibrium (equilibrium constants range from 1.1 to 1.3). The reported experimental rotational barriers are much lower than in the 5,5-dimethyl series ($\Delta G^{\neq}$ = 11.1–14.6 kcal/mol), so that time-averaged spectra are observed in the ^{1}H nmr spectra at normal temperatures. At sufficiently low temperatures, the separate spectra of the diastereomeric rotamers may be observed (1, 8).

1-Phenyl-5-methylhydantoin, **1***h*, shows a narrow computed energy minimum, the phenyl group being inclined away from the 5-methyl group at an angle of 35° (with respect to C-2). The computed rotational energy profiles of the substituted aryl compounds are complex, particularly in the range where the *ortho* substituent passes the substituents in the 5-position. In the predicted low-energy conformation of the preferred conformer of all the compounds examined, the aryl group is inclined at an angle of 60–70° (with respect to the *ortho* substituent and the 2-carbonyl group) to the plane of the hetero ring, the *ortho* substituent lying towards the 2-carbonyl group, on the same face of the molecule as the 5-methyl group. In the preferred conformation of the energetically less favoured conformer, the aryl group is inclined at an angle of 115–125°, with the *ortho* substituent lying towards the 5-hydrogen atom, on the face opposite the 5-methyl group. These computational predictions are of interest, since they indicate that the conformer with the bulky aryl substituent and the 5-methyl group *cisoid* is more stable (by 0.6–1.0 kcal/mol) than the conformer with these groups *transoid*. Inferences based on the use of physical molecular models led to the opposite conclusion in the experimental study (8). The similar placement of the aryl group in the two conformers is consistent with the observed small 5-methyl group ^{1}H nmr chemical shift difference, since the methyl groups experience similar deshielding effects from the aromatic ring current. Positive identification of the rotamers by ^{1}H nmr NOED measurements appears to be precluded by the very short rotamer lifetimes of these compounds, even at low temperatures.

Barriers to rotation by the lower energy path out of each of the two diastereomeric potential wells were calculated for **1***i*–**1***l*, using the energy profiles derived for increasing and decreasing

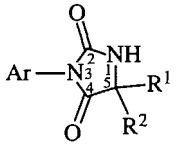
[a]Temperature at which $\Delta G^{\neq}$ was calculated (°C).
[b]Measured activation parameter (kcal/mol).
[c]Calculated rotational barrier from the lowest energy conformation to the lower maximum (kcal/mol). For **1***i*–**1***l*, the rotational barrier from each of the diastereomeric minimum energy rotamers to the lower barrier is quoted.
[d]Measured free energy difference between rotamers (kcal/mol).
[e]Measured rotational equilibrium constant.

dihedral angles (Table 1). The computed rotational barriers are much lower in the 1-aryl-5-methylhydantoin series than for the corresponding compounds in the 5,5-dimethyl series, in agreement with the experimental observations. Because of experimental difficulties in obtaining reliable values for $\Delta H^{\neq}$, quantitative comparisons of the computed and experimentally determined barriers are not available.



3-Aryl-5,5-dimethylhydantoins

Activation parameters for hindered internal rotation in the 3-aryl-5,5-dimethylhydantoin series (**2***b*–**2***d*) were obtained by complete lineshape analysis of the temperature-dependent 5-methyl spectra over a range of temperatures in pyridine or 2-chloropyridine solutions (1, 2, 11). All of the compounds were in the slow exchange region at ambient temperature. Free energies and enthalpies of activation are in the range 18.2–21.3 kcal/mol and 13.1–18.3 kcal/mol, respectively.

The computed rotational energy profile of 3-phenyl-5,5-dimethylhydantoin, **2***a*, shows the phenyl group inclined towards C-2 at a dihedral angle of 45° in the conformational ground state. The profiles of the 3-aryl-5,5-dimethyl series compounds (**2***b*–**2***d*) show two almost identical energy minima for each enantiomeric rotamer, with dihedral angles of about 60° and 120° from C-2, separated by a small barrier at 90° (about 1 kcal/mol). Hence there exists a broad range of dihedral angles available for librational motion between the two energy barriers to interconversion. Computation predicts that motional freedom in all of the aryl hydantoins and thiohydantoins is much more restricted in the rotational transition states than in the ground states, consistent with the large negative entropies of activation that have been measured (2, 11).

The original study was unable to provide detailed information on the nature of the conformational ground states or the transition states. In particular, it was not possible to make any inferences concerning the interconversion pathways, which involve apparently similar carbonyl groups. Interconversion of

2

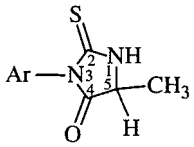
a Ar = phenyl, $R^1 = R^2 = CH_3$
b Ar = 2-methylphenyl, $R^1 = R^2 = CH_3$
c Ar = 2-chlorophenyl, $R^1 = R^2 = CH_3$
d Ar = 2-bromophenyl, $R^1 = R^2 = CH_3$
e Ar = 2-methylphenyl, $R^1 = H$, $R^2 = CH_3$
f Ar = 2,3-dimethylphenyl, $R^1 = H$, $R^2 = CH_3$
g Ar = 2-chlorophenyl, $R^1 = H$, $R^2 = CH_3$
h Ar = 2-trifluoromethylphenyl, $R^1 = H$, $R^2 = CH_3$
i Ar = 2-methylphenyl, $R^1 = H$, $R^2 = C_6H_5$
j Ar = 2-chlorophenyl, $R^1 = H$, $R^2 = C_6H_5$

the enantiomeric rotational isomers could proceed via two possible transition states, in which the 3-aryl group *ortho* substituent passes either the 2- or the 4-carbonyl group oxygen atom. Computation indicates that these rotational transition states are very similar in energy, so that a distinct preference for one pathway over the other is unlikely.

The computed rotational barriers are in the order: phenyl << 2-methylphenyl < 2-chlorophenyl < 2-bromophenyl. There is satisfactory agreement with the computed barriers and the experimentally determined values of $\Delta H^{\neq}$ (Table 1).

3-Aryl-5-methyl- and 3-aryl-5-phenylhydantoins

Compounds **2***f*–**2***j*, with diastereomeric rotamers, have rotational barriers that are similar to those of the correspondingly substituted 5,5-dimethyl compounds, with reported (1, 11, 12) free energies of activation within the range 18.7–20.8 kcal/mol. Equilibrium constants range from about 1.0 to about 1.6, with the 5-phenyl compounds showing a somewhat greater deviation from unity than the 5-methyl compounds. The 2-chlorophenyl compounds have higher experimental rotational barriers ($\Delta G^{\neq}$), by 0.7–2.1 kcal/mol, than the corresponding 2-methylphenyl compounds. No significant differences between the rotational barriers of the 5-methyl and the 5-phenyl compounds were observed.



The computed rotational energy profiles of the 3-aryl-5-methyl- or 3-aryl-5-phenylhydantoins show two shallow minima of almost identical energy, separated by a barrier of less than 1 kcal/mol, for each rotational isomer, with dihedral angles of about 60° and 120°. The molecules are, therefore, free to undergo librational motion of large amplitude in their rotational ground states. Computation predicts that the diastereomeric rotamers have different ground state energies, so that the rotamers will be present in unequal concentration at equilibrium. Ground state energy differences between the rotamers are larger for the 5-phenyl compounds (0.29–0.35 kcal/mol) than for the 5-methyl compounds (0.10–0.11 kcal/mol), consistent with experimental data. The *ortho* aryl substituents are *cisoid* to the C-5 substituent (methyl or phenyl) in the energetically preferred rotamers.

The rotational barriers by the two available pathways (the *ortho* substituent passing either the 2- or the 4-carbonyl group) are very similar in energy, with perhaps a slight preference (≤0.5 kcal/mol) for the pathway past the 4-carbonyl group.

The computed rotational barriers are in the order 2-methylphenyl < 2,3-dimethylphenyl < 2-chlorophenyl < 2-trifluorophenyl. Computed barriers and experimental values of $\Delta H^{\neq}$ are close (Table 1).

3-Aryl-2-thiohydantoins

We previously reported (3, 5) that the equilibrium ratio of the diastereomeric rotational isomers of the 3-aryl-substituted 2-thiohydantoins, **3***e* and **3***g*, is non-unity, an observation that has been repeated for a number of other examples of 3-arylhydantoins and thiohydantoins unsymmetrically substituted at C-5 (1, 11–13). Equilibrium constants are in the range 1.2–1.9 for this series, the compound with the largest equilibrium constant, **3***e*, also having the largest rotational barrier. This observation was of particular interest since the sites of unsymmetrical substitution on the aryl and heterocyclic moieties are too far apart for a direct interaction that could transmit stereochemical information (5).

3

a Ar = phenyl
b Ar = 2-methylphenyl
c Ar = 2-fluorophenyl
d Ar = 2-chlorophenyl
e Ar = 2-bromophenyl
f Ar = 2-methoxyphenyl
g Ar = α-naphthyl
h Ar = β-naphthyl

With the exceptions of the 2-fluorophenyl (**3***c*) and the β-naphthyl (**3***h*) compounds, all of the members of this series have rotational barriers that are too high to measure by lineshape methods, so activation parameters were measured by equilibration in pyridine solution of one rotamer, isolated by careful crystallization (5, 13). Equilibration rates of **3***e* and **3***g* were measured over a range of temperatures so that $\Delta H^{\neq}$ could be calculated. Free energies of activation for rotation of **3***c* and **3***h* were measured for DMSO-d_6 solutions at the coalescence temperatures, 86° and 97.5°C, respectively (4, 13).

In the computed minimum energy conformation of 3-phenyl-5-methyl-2-thiohydantoin, **3***a*, the dihedral angle with respect to C-2 is 50°. There is a 7.4 kcal/mol rotational barrier at 0° and a 1.5 kcal/mol librational barrier at 90°. The computed profile for 3-(β-naphthyl)-5-methyl-2-thiohydantoin, **3***h*, is similar to that of the phenyl compound, with dihedral angles of 50° and 130°. The α-naphthyl compound shows a broad, flat minimum between about 50° and 130°, but the remaining compounds are predicted to have a stronger conformational preference, near 65°, in their conformational ground states.

An X-ray crystallographic study (5) of the thermodynamically *less* stable rotamer of **3***e*, isolated in >99% isomeric purity by careful crystallization, revealed that the bromine atom and the C-5 methyl group were *transoid*. The heterocyclic ring was found to be planar to within experimental error, while the dihedral angle between the heterocyclic rings was 82°, the bromine atom lying closer to the carbonyl oxygen atom than to the sulphur atom. This crystallographic study provided no evidence on how the unsymmetrically substituted aryl group could sense the stereochemistry at C-5 so that one rotamer is preferred. It was postulated that, in solution, the steric effect of the 5-methyl group might be transmitted to the bromine atom via an unsymmetrical solvent shell around the carbonyl and thiocarbonyl groups (5).

Computation of the rotational energy profile of **3***e* predicted

that the two rotational energy barriers differ by about 4.7 kcal/mol, the lower barrier, which is presumably involved in the interconversion process, requiring passage of the bromine atom past the oxygen rather than the sulphur atom. In the experimental study, the complete set of activation parameters was derived from rate constants for equilibration, measured over a range of temperatures. The computed barrier (from the less stable rotamer) of 18.9 kcal/mol is in good agreement with the 17.6 ± 1.7 kcal/mol experimental value of $\Delta H^{\neq}$.

Computation predicts ground state energies of the two rotamers differing by 0.16 kcal/mol, the isomer with the bromine atom and the 5-methyl group *cisoid* being the more stable. This is in complete agreement with experiment. Although the heterocyclic group was found to be planar to within the limits of refinement in the crystallographic study, the computational study predicts small deviations from planarity that transmit stereochemical information between C-5 and the aryl group. Assuming that the entropies of the two rotational isomers are very similar, the predicted equilibrium ratio is about 1.3 at normal temperatures, close to the observed value of 1.9 ± 0.1. Hence the computation suggests that it is not necessary to invoke an unsymmetrical solvent shell to explain that the equilibrium ratio differs from unity.

The dihedral angle at the energy minimum of the less stable (*transoid*) rotamer is predicted to be 113°. The energy trough is broad (with an additional shallow minimum at 80°) so that the angle is not well defined, and the angle determined crystallographically, 98°, falls within this range. The dihedral angle at the energy minimum of the preferred rotamer (*cisoid*) is 111°, with the bromine atom lying towards the 2-carbonyl group.

Overall, similar computed and solid state conformations of the thermodynamically less favoured isomers are predicted. The computed profiles of **3***b*, **3***c*, **3***d*, and **3***f* predict similar conformational behaviour to that of **3***e*.

We have reported (4) that 3-(β-naphthyl)-5-methyl-2-thiohydantoin, **3***h*, shows a ^{1}H nmr spectrum consisting of the superimposed spectra of two diasteromeric rotational isomers at room temperature, and a single, time-averaged, spectrum at higher temperatures. A value for $\Delta G^{\neq}$ of 21.7 kcal/mol was reported for the coalescence point (97.5°C, DMSO-d_6 solution).

Computation indicates no rotational ground state energy difference between the two diastereomeric rotational isomers of **3***h*, consistent with the experimental observation, and expected since the *ortho* substituents of the 3-aryl group are both hydrogen atoms. Further, no significant difference between the energies of the two rotational transition states is predicted, although a difference could be visualized as a result of buttressing of one of the *ortho* hydrogens of the 3-aryl group by the adjacent fused ring. This buttressed hydrogen atom must pass either a sulphur or an oxygen atom in the transition states. If buttressing effects exist, they are more likely to be seen in the strained transition states than in the ground states. Two, almost equal energy, conformational ground states for each diastereomeric rotamer are predicted, with dihedral angles of 49° and 131°, and separated by a barrier of 1.5 kcal/mol at a dihedral angle of 90°.

The rotational energy profile of 3-phenyl-5-methyl-2-thiohydantoin, **3***a*, was calculated for reference purposes. This was almost identical in appearance to that of 3-(β-naphthyl)-5-methyl-2-thiohydantoin, but the computed rotational barrier was slightly lower, 7.4 vs. 7.7 kcal/mol. It was earlier suggested (4) that the steric requirements of one of the *ortho* hydrogen atoms in β-naphthyl-substituted compounds might be increased by buttressing with the adjacent fused ring. These calculations indicate that such an effect is likely to be small. The large difference between the experimentally determined $\Delta G^{\neq}$ and the calculated rotational barrier of **3***h* is at present unexplained, but the role of the solvent (DMSO-d_6) may be important.

The computed rotational barriers are in the order: phenyl < β-naphthyl << 2-fluorophenyl < 2-methoxyphenyl < 2-methylphenyl < 2-chlorophenyl < α-naphthyl ≃ 2-bromophenyl (Table 1).

Computed rotational enthalpy barriers about 3 kcal/mol higher in the thiohydantoin series than in the corresponding oxygen analogues are predicted. The experimental free energy differences in corresponding compounds are about 5.5 kcal/mol.

Conclusions

This computational study has provided insight into the conformational ground and transition states of these compounds that was not available in the experimental studies. In the 3-aryl-5-methyl- or 3-aryl-5-phenylhydantoin and thiohydantoin series, with diastereomeric rotamers, it has shown that stereochemical information may be transmitted between the 3-aryl and the unsymmetrically substituted C-5 centre via small deviations from planarity of the ring systems, leading to unequal energies of the conformational ground states. It predicts that the bulky *ortho* substituent and the C-5 substituent prefer to be *cisoid* in the diastereomeric conformational ground states of both the 1-aryl and the 3-aryl series, contrary to what might be expected from a study of physical molecular models. It predicts the preferred conformational transition states where these are significantly different in energy. It predicts activation energies for conformational interconversion that are close to the experimentally determined enthalpy values, despite neglect of solvation effects. Molecular mechanics computation, therefore, provides a useful tool in interpreting the experimental data on these conformationally mobile molecules.

Computation

Molecular mechanics calculations were carried out on a Silicon Graphics, Inc., Personal IRIS 4D/25G workstation, using PCMODEL 3.0 software (Serena Software, Inc., Bloomington, IN, U.S.A.). Structures were minimized using the MMX force field (derived from the MM2 force field of Burkert and Allinger (6)) in combination with VESCF molecular orbital calculations on the aromatic π-electron systems. PCMODEL uses generalized force-field parameters if no standard MM2 parameters are available. Some generalized parameters were required in the calculations reported here. Absolute calculated energies will be less accurate if generalized, rather than exact, parameters are used, but geometries should be close. The default value was used for the dielectric constant.

Following identification of a low-energy conformation of each molecule, the dihedral driver software option was used to calculate a rotational energy profile. The dihedral angle about the C—N pivot bond between the two ring systems was driven in a stepwise fashion, with energy minimization at each step. Profiles were calculated for 5° increments (or decrements) in dihedral angle. Where knowledge of the transition state energies was important, the profiles in the immediate vicinity of the rotational transition states were calculated for 1° increments.

A plot of the minimized energy versus dihedral angle yielded a rotational energy profile. When the rotational ground state energies of diastereomeric rotamers were to be compared, the energies were minimized without constraints starting from dihederal angles corres-

ponding to the mimima established from the profiles. Dihedral angles are defined between C-2 and the *ortho* aryl carbon carrying a substituent.

G. W. BUCHANAN, C. MORAT, R. A. KIRBY, and J. S. TSE. Can. J. Chem. **69**, 1964 (1991).

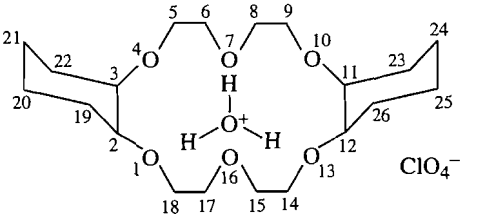
From 100.6-MHz ^{13}C NMR coalescence temperature measurements, the title complex is shown to undergo a single degenerate ring inversion process with a free energy barrier of 49.4 ∓ 1.6 kJ/mol. This is ca. 5 kJ/mol higher than the barrier in the free crown. The solid state ^{13}C CPMAS spectrum is indicative of a totally unsymmetrical conformation and the shift trends in the solid are analyzed in terms of local torsional angle variations. Comparisons of experimental vs. calculated (GIAO) ^{13}C chemical shift ranges for the CH_2O carbons in the solid are made and satisfactory agreement with respect to the overall range and magnitude of the ^{13}C shielding differences is obtained.

Key words: crown ethers, stereochemistry, NMR.

G. W. BUCHANAN, C. MORAT, R. A. KIRBY et J. S. TSE. Can. J. Chem. **69**, 1964 (1991).

En se basant sur des mesures de température de coalescence en RMN du ^{13}C, à 100,6 MHz, on peut démontrer que le complexe mentionné dans le titre subit un seul processus dégénéré d'inversion de cycle avec une barrière d'énergie libre de 49,4 ∓ 1,6 kJ/mol. Cette valeur est environ 5 kJ/mol plus élevée que celle observée avec les éthers couronnes. Le spectre CPMAS du ^{13}C à l'état solide suggère l'existence d'une conformation complètement non-symétrique et on peut analyser les variations dans les déplacements dans le solide en fonction de variations locales de l'angle de torsion. On a effectué des comparaisons entre les plages des déplacements chimiques expérimentaux et calculés (GIAO) du ^{13}C des carbones CH_2O à l'état solide; on a obtenu une bonne correspondance pour l'ensemble des plages ainsi que pour l'amplitude des différences entre les blindages des ^{13}C.

Mots clés : éthers couronnes, stéréochimie, RMN.



[Traduit par la rédaction]

Introduction

The hydroxonium perchlorate complex of *cis-syn-cis*-dicyclohexano-18-crown-6 (**1**) was first reported in the literature almost 20 years ago (1). More recently (2) the X-ray crystallographic structure was published. This material is of interest for several reasons, not the least of which is its hydrogen bonding characteristics involving three oxygens of the crown ether and the three H's of the H_3O^+ entity. Such stable hydrogen bonds might be expected to lead to increased stereochemical rigidity relative to the uncomplexed crown ether. In view of our general interest in the solution and solid phase stereochemical dynamics of 18-crown-6 systems (3–7), we now report the results of a 100.6 MHz ^{13}C NMR study of **1** as a function of temperature, as well as its solid phase ^{13}C NMR spectrum at 45.3 MHz. Results are compared with earlier findings on related systems.

Results and discussion

The structure and numbering scheme for **1** is illustrated in Fig. 1. The disposition of the cyclohexane rings is consistent with that determined by X-ray crystallography (2). In Fig. 2 are presented a series of 100.6 MHz ^{13}C spectra for **1** as a function of temperature, while Fig. 3 shows the solid phase spectrum. Table 1 contains the ^{13}C NMR chemical shift data in solution (at the limits of fast and slow conformational exchange) as well as the solid phase chemical shifts for **1**.

1

FIG. 1. Structure and numbering scheme for **1**.

The assignments of the solution ^{13}C shifts in the fast exchange limit are consistent with those reported earlier for the free *cis-syn-cis* isomer of dicyclohexano-18-crown-6 (8). There are only minor (less than 1.5 ppm) effects due to complexation of the H_3O^+ in the cavity. As the temperature is reduced, broadening begins to occur first in the low-field resonance (due to C2,3,11,12) since this is the site with the largest chemical shift difference (9.41 ppm or 936.8 Hz) in the slow exchange spectrum. Indeed, the spectrum at 295 K shows substantial evidence for this broadening effect. From coalescence temperatures (T_c) and the chemical shift differences in the slow exchange limit, one can use the Eyring equation to calculate $\Delta G^{\neq}$, the free energy of activation for ring reversal. In the present case, all five resonances in the fast exchange limit undergo coalescence behaviour, each at a unique temperature. Data are collected in Table 1. The similarity of $\Delta G^{\neq}$ values at different temperatures suggests that $\Delta S^{\neq}$ for the conformational processes involved cannot be substantially different

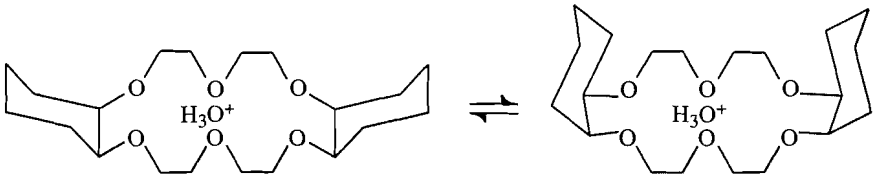
from zero. Hence one can calculate an average $\Delta G^{\neq}$ value of 49.4 kJ/mol with a standard deviation of 1.4 kJ/mol.



This value represents the free energy of activation for the degenerate double cyclohexane ring inversion process depicted below. The observation of 10 ^{13}C resonances in the slow exchange limit in solution is consistent with a conformation having a plane of symmetry that bisects O7 and O16. Of course the 18-membered central ring must also change its conformation as the cyclohexyl moieties invert; however, the rate-limiting process is almost certainly degenerate cyclohexane ring inversion since the activation energy for ring inversion of 18-crown-6 itself in solution is too low to be accessible via present NMR methods (6), while that for *cis*-1,2-disubstituted cyclohexanes is ca. 45 kJ/mol (9).

The value of $\Delta G^{\neq}$ for **1** is ca. 5 kJ/mol higher than the ring inversion barrier for disubstituted cyclohexanes as well as that for the free crown of **1** (3, 4), indicating that complexation with H_3O^+ indeed increases the effective rigidity of **1** relative to the free crown and hence renders the cyclohexane ring inversion process more difficult. Interestingly, the duality of conformational processes observed for the uncomplexed case is absent in the present H_3O^+ complex as well as the KOPh complex studied previously (3).

The chemical shift differences for the cyclohexyl carbons of **1** at 173 K are within 0.8 ppm of those for related molecules at low temperature (3) and reflect the now well-documented influence of axial vs. equatorial oxygen on the ^{13}C chemical shifts of carbons bearing α, β, and γ relationships to the oxygen atoms (10). Hence the C3,11 positions bearing axial oxygen are shielded (in this case by 9.31 ppm) relative to the C2,12 pair, which bear equatorial oxygen. The C21,24 sites, which bear *gauche*-γ relations to the axial oxygens O4 and O10 respectively, are shielded by 5.11 ppm relative to the C20,25 pair, which are *trans*-γ to the equatorial O1 and O13 sites respectively. Only small (0.69 ppm) β stereochemical differences are found for the C22,23 vs. C19,26 pairs of **1**.

The solid phase ^{13}C NMR spectrum of **1** (Fig. 3) shows the presence of a nonsymmetrical conformation in the solid in accord with the results from X-ray crystallography (2). Although some resonance overlap is present, there are 11 resolved oxygenated carbon resonances (out of 12 possible) in the range of 67–82 ppm. Since the torsional angles in the macrocyclic portion of **1** have been published (2), it is instructive to attempt an analysis of the 18-membered ring carbon shift pattern in terms of torsional angle influences on ^{13}C shieldings.

To this end, the experimental torsional angle data for these carbons of **1** are presented in Table 2. Using the Gauge Invariant Atomic Orbital (GIAO) approach (11, 12),

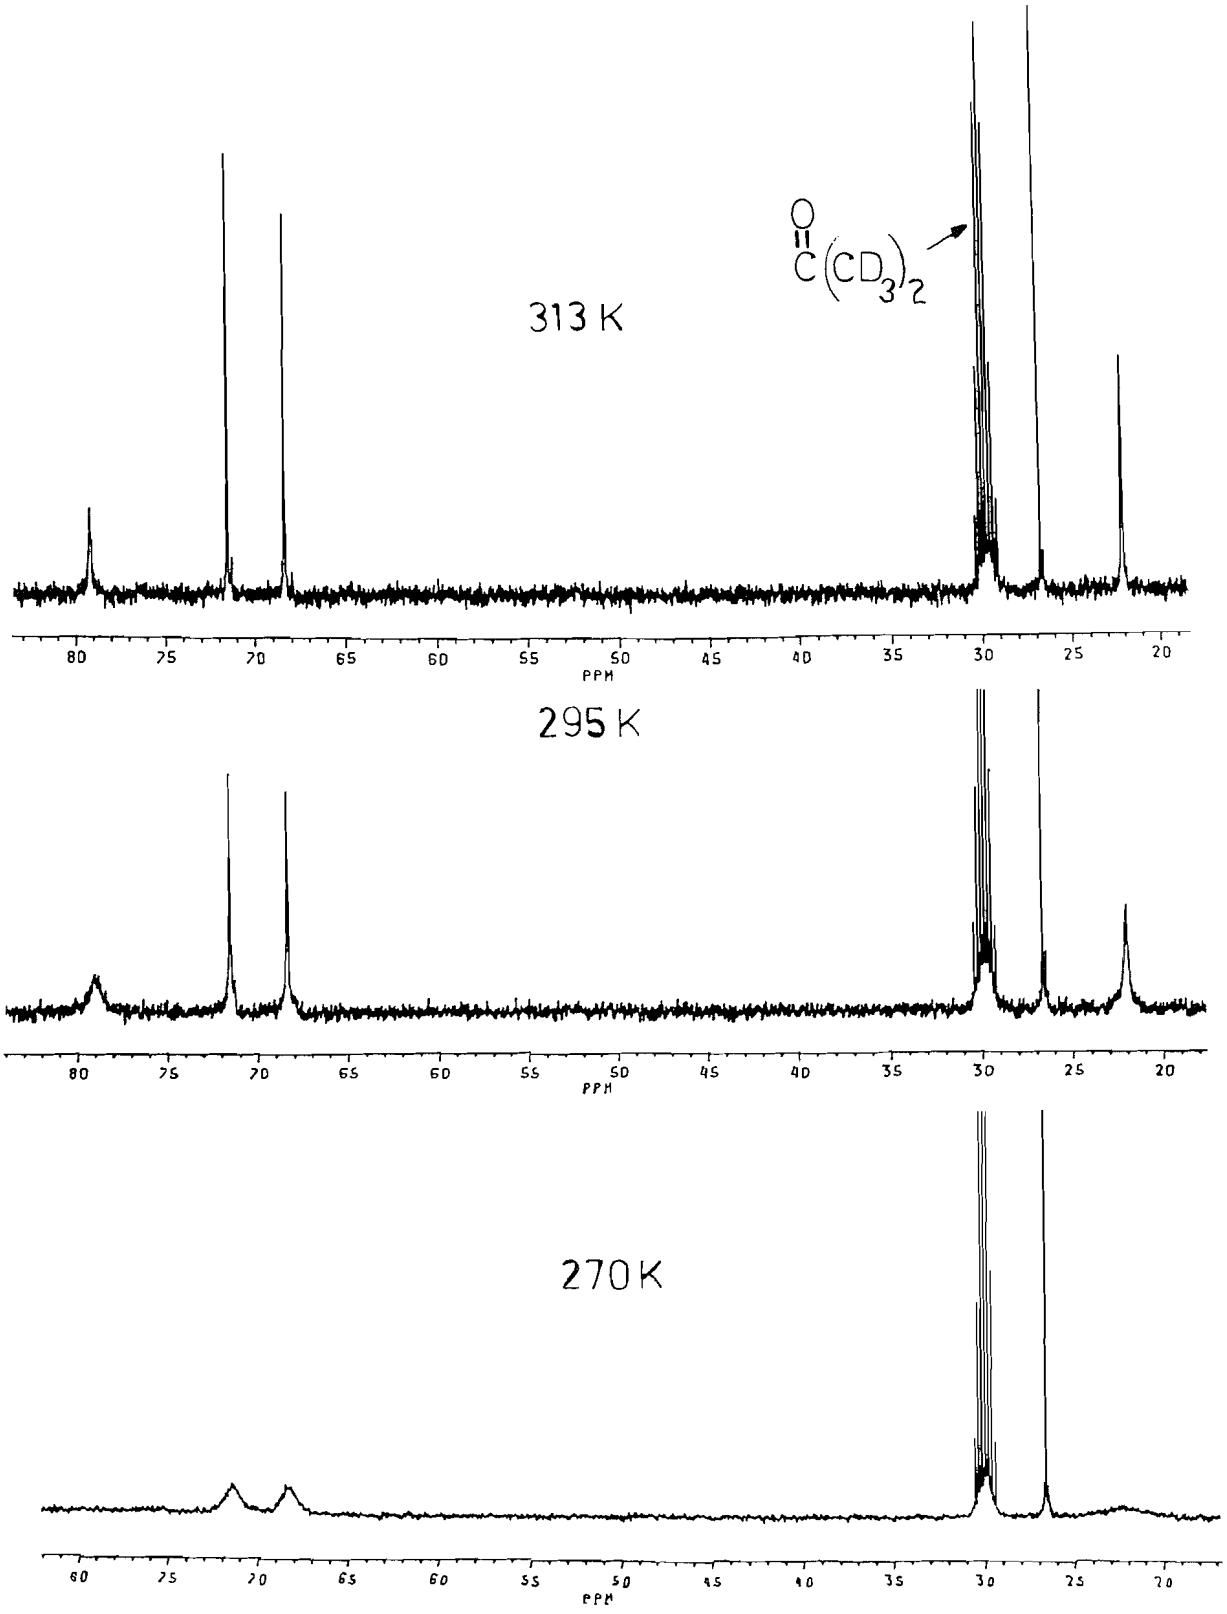

FIG. 2. 100.6 MHz ^{13}C NMR spectra of **1** as a function of temperature.

the ^{13}C NMR shielding for the O—C*—C—O network as a function of dihedral angle has been calculated using ethylene glycol as a model (Fig. 4) while shifts for the C*—C—O—C, C—O—C*—C, and C*—O—C—C networks as a function of dihedral angle are shown in Fig. 5. For the latter three networks, ethylmethyl ether was employed as a model compound. In these calculations, the absolute scale is employed wherein chemical shifts increase with increasing shielding. On this scale, CH_4 occurs at 221.0 ppm, whereas on the usual TMS scale it appears at −2.1 ppm.

For the latter three networks, the calculated dependence of the shielding on dihedral angle bears some similarity to the

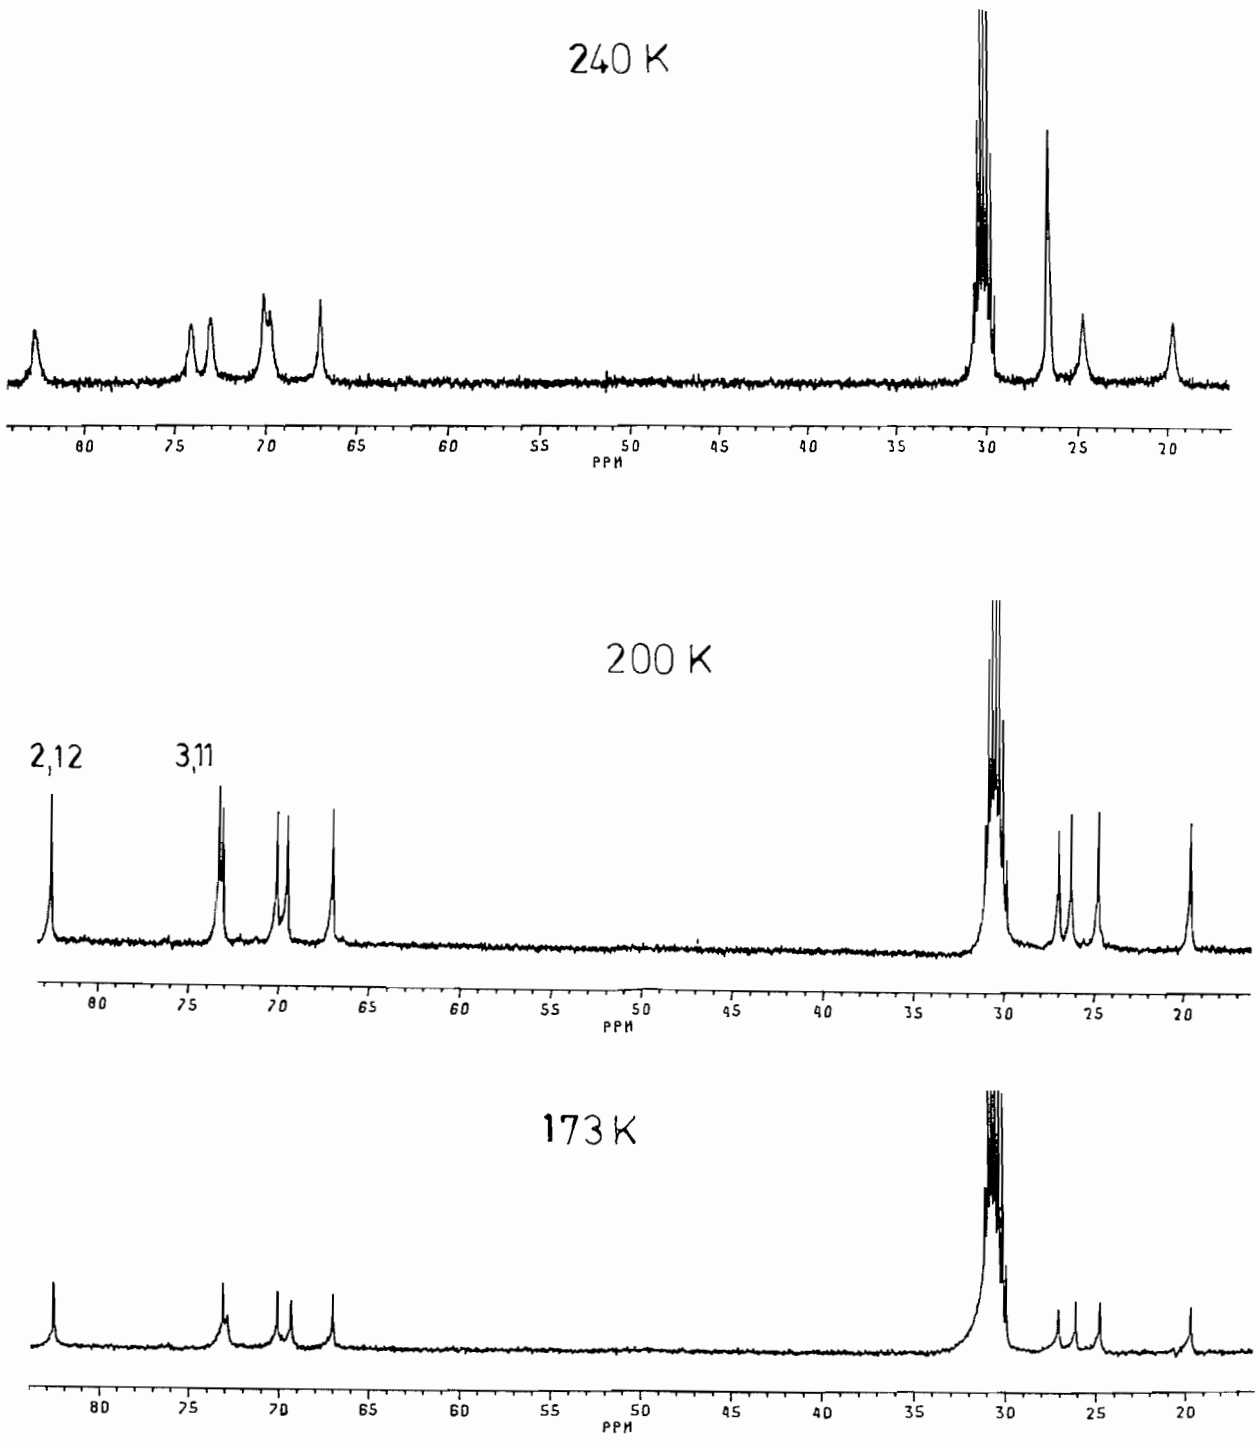

FIG. 2. (*concluded*)

INDO results for butane (13) in that maximum deshielding occurs near $\theta = 120°$ in each instance. A number of discussions have appeared in the literature (14, 15) regarding possible linear correlations between dihedral angle and experimental ^{13}C chemical shifts for terminal carbons of materials in which γ-steric shifts exist. The present calculations suggest that such correlations may indeed exist, but only in narrow ranges of dihedral angles.

To calculate the relative shielding for each of the CH_2-O carbons, the sum (Σ) of the four absolute chemical shifts was calculated using the four torsional network contributions as depicted in Figs. 4 and 5. The calculated range of Σ values was from 641.2 to 647.1. Hence a relative shielding for each carbon can be calculated by subtraction of the value of 641.2 from each Σ calculated. Using this approach, the C14 site is predicted to be the most shielded and has a relative shielding of 5.9 ppm. The most deshielded site is C17.

Accordingly, the most shielded CH_2-O resonance at 67.34 ppm in the ^{13}C CPMAS spectrum is attributed to C14. The next most shielded CH_2-O site is calculated to be C18 with a relative shielding of 5.6 ppm. Presumably this carbon is part of the intensity two resonance at 68.25 ppm. In a similar

fashion one can tentatively assign the remainder of the CH_2-O resonances of the solid as listed in Table 1.

The observed range of chemical shifts for these carbons in solid **1** is 4.3 ppm, while the range calculated from the GIAO treatment is 5.9 ppm. Given the fact that influences other than torsional environment (i.e., steric and electronic effects of the guest) may also play a significant role in determining the chemical shift, this level of agreement is deemed acceptable. Crystal packing forces may also be significant. In solution at 173 K, the range of CH_2-O ^{13}C shifts observed (5.9 ppm) is exactly that calculated via the GIAO approach.

One should, however, exercise some caution in strict application of the results of such theoretical chemical shift calculations for molecules in the gas phase to solution or solid phase spectra. Presently, efforts are underway in these laboratories to obtain experimental verification of these calculated, angularly dependent, ^{13}C shifts, especially in the case of ethylene glycol and some substituted derivatives.

Experimental

Materials

The complex **1** was prepared according to the published procedure (1). In acetone-d_6, there is no evidence of dissociation of the complex. The ^1H NMR chemical shift for the H_3O^+ protons of **1** is 9.858 ppm in acetone-d_6 solution.

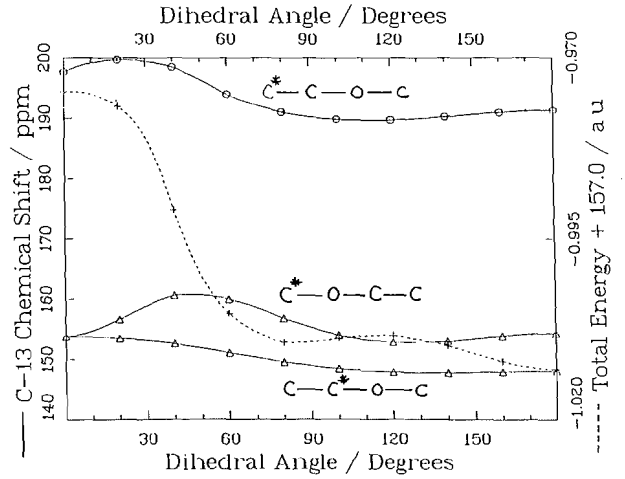

FIG. 5. GIAO calculated angular dependence of the isotropic ^{13}C NMR chemical shifts for the three carbons of ethylmethyl ether (—). Total conformational energy as a function of dihedral angle (- - - -).

Spectra

The solution phase ^{13}C NMR spectra were recorded at 100.6 MHz using a Bruker AM-400 spectrometer via techniques described previously (4). The ^{13}C CPMAS solid phase spectra were obtained on a Bruker CXP-180 instrument at 45.3 MHz. Experimental details have been described earlier (5, 6).

Computations

^{13}C chemical shifts were calculated using the NRC IBM-3090 computer system. For the GIAO calculations, standard geometries (16) were employed. The GAUSSIAN 86 program (17) was used to generate wavefunctions using a double zeta (DZ) basis set.

M'HAMED ESSEFFAR, MOHAMED EL MOUHTADI, JOSÉ-LUIS M. ABBOUD, JOSÉ ELGUERO et DANIEL LIOTARD. Can. J. Chem. **69**, 1970 (1991).

Des calculs semi-empiriques au moyen de la méthode AM1, ont été utilisés pour discuter de l'affinité protonique des molécules poly-oxygénées (dioxane, glymes et éthers couronne). Les valeurs calculées, bien que systématiquement plus faibles que les expérimentales, sont corrélées linéairement avec elles ($r = 0{,}993$). Étant donné les profondes modifications conformationnelles que subissent ces molécules quand on les protone, le résultat est très satisfaisant; il permet d'estimer les affinités protoniques, AP, du 9-éther-couronne-3 (206,5 kcal mol^{-1}) et du glyme-5 (231,1 kcal mol^{-1}). En plus, ce travail justifie le fait qu'à nombre égal d'atomes d'oxygène, les glymes sont plus basiques que les éthers couronne. Pour ces derniers l'affinité protonique dépend des tensions angulaires dans la base et des liaisons hydrogènes intramoléculaires dans le cation.

Mots clés : protonation, réactivité, glymes, éthers couronnes, coordination.

M'HAMED ESSEFFAR, MOHAMED EL MOUHTADI, JOSÉ-LUIS M. ABBOUD, JOSÉ ELGUERO, and DANIEL LIOTARD. Can. J. Chem. **69**, 1970 (1991).

Semi-empirical calculations at the AM1 level have been used to study the proton affinity (PA) of polyether compounds (dioxane, glymes, and crown ethers). The calculated values, although systematically lower than the experimental ones, are linearly correlated with eight experimental PA's ($r = 0.993$). Taking into account the considerable conformational changes that take place upon protonation, the result is highly satisfactory and provides an estimate of proton affinity for 9-ether-crown-3 (206.5 kcal mol^{-1}) and glyme-5 (231.1 kcal mol^{-1}). Moreover, this work provides a rationale for the fact that, for the same number of oxygen atoms, glymes are more basic than crown ethers. For the crown ethers, the proton affinity depends on angular strain in the base and on intramolecular hydrogen bonds in the cation.

Key words: protonation, reactivity, glymes, crown ethers, coordination.

Introduction

Les éthers macrocycliques $(CH_2CH_2O\text{-})_n$ originalement synthétisés par Pedersen (1) en 1967, ont connu une attention particulière au cours de ces deux dernières décenies. Ils présentent des propriétés aussi variées qu'intéressantes et sont susceptibles d'applications en catalyse, en synthèse organique et en biologie (2–4). À ce sujet un certain nombre de mises au point ont été publiées (5–8). Nous citons à titre d'exemple les structures cristallines du 18-éther-couronne-6 et ses complexes avec les sulfocyanures de divers métaux alcalins (9–14). Du point de vue théorique, peu d'études ont été réalisées. Seules les études structurales, du 12-éther-couronne-4 (15), la complexation du 18-éther-couronne-6 et du 12-éther-couronne-4 par NH_4^+, Na^+ et K^+, en CNDO/2 (16–18) sont connues.

Dans le but d'apporter une contribution exhaustive à ce sujet, nous nous proposons une étude quantitative de la protonation en phase vapeur de dix polyéthers : 6-éther-couronne-2, glyme-1, 9-éther-couronne-3, glyme-2, 12-éther-couronne-4, glyme-3, 15-éther-couronne-5, glyme-4, 18-éther-couronne-6 et glyme-5. La complexation de ces systèmes par les ions Li^+, Na^+ et K^+ sera examinée dans un prochain article.

Méthode de calcul et procédure

Pour obtenir des affinités protoniques bien précises, les méthodes *ab initio* avec des bases raisonablement étendues, constituent un moyen efficace et parfois inévitable. Mais souvent de telles méthodes ne peuvent pas être appliquées à des molécules organiques d'intérêt chimique et biologique. De ce fait, les méthodes semi-empiriques sont alors de grand intérêt dans l'approche de la réactivité de ces molécules. C'est dans ce cadre que nous avons fait appel à la méthode AM1. Cette méthode développée par le groupe de Dewar a trouvé des applications très variées aussi bien dans le domaine de la recherche fondamentale que dans le domaine de la recherche appliquée. Cette procédure implantée dans le programme AMPAC (19), s'est révélée d'une efficacité considérable. L'introduction d'une pseudodiagonalisation rapide au niveau des itérations SCF (20) et la précision des résultats obtenus rend cette méthode largement utilisée dans plusieurs domaines de la chimie.

Les affinités protoniques sont déterminées par différence des

chaleurs de formations de la molécule neutre et de la molécule protonée de la réaction [1] en phase vapeur :

[1] $B + H^+ \rightarrow BH^+$

[2] $AP = -\Delta H = -[\Delta H_f(BH^+) - \Delta H_f(B) - \Delta H_f(H^+)]$

Dans le formalisme AM1, $\Delta H_f(H^+)$ est définie par la valeur paramétrisée U_{ss}, intégrale monocentrique électronique, choisie pour mieux reproduire les chaleurs de formation des hydrocarbures (21). Cette procédure conduit à une valeur empirique de U_{ss} qui diffère considérablement de celle appropriée à un atome d'hydrogène isolé. Par conséquent $\Delta H_f(H^+)$ calculée en AM1 (314,9 kcal mol^{-1}) est très faible devant la valeur expérimentale (367,2 kcal mol^{-1}) (22). Pour ce faire, nous avons basé nos calculs des AP sur la valeur expérimentale. L'utilisation de cette valeur est en accord avec la philosophie semi-empirique de la méthode et a l'avantage de limiter les erreurs des AP calculées uniquement aux erreurs dues aux chaleurs de formations des bases neutres et protonées. La méthode AM1 décrit alors de façon satisfaisante le phénomène de protonation des molécules oxygénées, tant sur le plan énergétique que conformationel (23).

Résultats et discussion

(a) Analyse des structures géométriques

Les molécules neutres et protonées présentent plusieurs conformations d'énergies très proches et les algorithmes d'optimisation convergent vers l'une d'entre elle, mais pas nécessairement la plus basse. Ce problème ne semble pas crucial pour les glymes dans la mesure où les minima sont probablement très voisins en énergie. Par contre les tensions de cycle dans les couronnes peuvent introduire des écarts énergétiques importants.

Une étude conformationnelle exhaustive (24) du dioxane et du glyme-1, dans les cas neutres et protonés, nous a fourni les motifs de base pour bâtir plusieurs conformations plausibles qui ont servi de points de départ pour les algorithmes d'optimisation. Les différentes conformations neutres ainsi obtenues ont, à leur tour, servi de points de départ pour les formes protonées, par ajout systématique du proton successivement placé sur les deux sites de protonation envisageables pour chaque oxygène.

Compte tenu de la taille des molécules envisagées et du nombre important des paramètres géométriques, nous ne décrirons dans cet articles que les structures géométriques les plus stables des éthers couronne (formes neutres et protonées). La stabilité de ces structures a été vérifiée par le procédé LTRD (25) implanté dans le programme AMPAC. Ce procédé permet de s'assurer de la fiabilité et de la nature de la structure. Si la structure correspond à un minimum sur la surface de potentiel, le nombre de valeurs propres négatives de la matrice des constantes de force (matrice de Hessien) est égal à 0.

9-Éther-couronne-3

Dans le 9-éther-couronne-3, bien qu'il soit supérieur au dioxane, la tension du cycle est encore non négligeable; ce qui réduit le nombre de possibilités conformationnelles. La structure la plus stable est celle représentée sur la figure 1(a) où les oxygènes s'alternent en dessus et en dessous du plan moyen du cycle. Les paramètres géométriques montrent que ces derniers sont disposés à environ 3 Å, les uns des autres réduisant ainsi les répulsions électroniques des paires libres. La protonation de cette molécule se fait sur l'un des trois oxygènes (les trois sites sont équivalents). La figure 1(b) montre que la protonation conduit à une déformation de la molécule par rapport à son état neutre. En effet, les motifs (OCH_2CH_2O) qui étaient disposés de façon à minimiser les interactions entre les paires libres, sont maintenant orientés de manière à favoriser la dicoordination du proton. La distance H^+–O calculée (1,01 Å) indique que le proton, bien qu'il

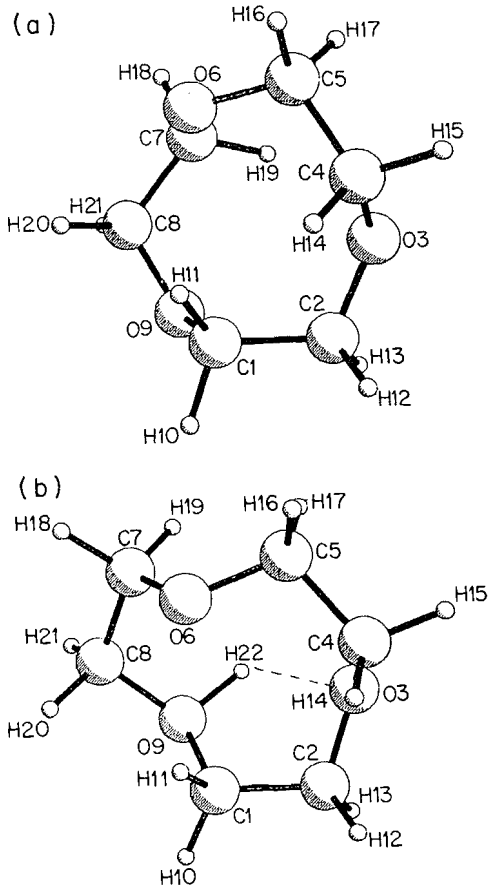

FIG. 1. (a) Structure du 9-éther-couronne-3; (b) structure du 9-éther-couronne-3 protoné.

soit lié à O_9 par une liaison covalente, crée une liaison hydrogène avec l'atome d'oxygène voisin (O_3) où la distance H^+—O_3 est de 2,08 Å.

12-Éther-couronne-4

Plusieurs conformations ont été mises en évidence pour cette molécule. La conformation la plus stable est celle qui présente une alternance plus ou moins régulière du motif chaise (OCH_2CH_2O) bien qu'on note l'apparition d'un motif à 120° pour fermer le cycle (figure 2(a)). Les longueurs de liaison C—C (1,52 Å) et C—O (1, 42 Å) sont pratiquement les mêmes, alors que les angles plans sont plus ou moins déviés de la valeur optimale (109°). Les angles dièdres qui sont caractéristiques de chaque conformation, montrent des déviations importantes des valeurs idéales (0°, 120° ou 180°). Ces valeurs présentent une alternance du motif chaise (OCH_2CH_2O) à ±60° à l'exception d'un seul qui apparaît à 116° rompant la symétrie de la molécule.

La fixation d'un proton sur chacun des sites actifs conduit à quatre conformations différentes du 12-éther-couronne-4 protoné et cela pour chacune des configurations probables de la molécule neutre. La conformation la plus stable est celle qui présente une liaison hydrogène intramoléculaire. Il est à signaler que la protonation depuis la conformation la plus stable de la molécule neutre ne conduit pas forcément au minimum le plus stable de la molécule protonée. En effet, parmi les différentes conformations de la molécule neutre, seule la protonation depuis l'optimum de symétrie C_{2v} conduit au minimum le plus stable représenté sur la figure 2(b). Il apparaît clairement que le proton est dicoordiné entre les oxygènes O_1 et O_2 formant ainsi une couronne bicyclique à huit chaînons. La liaison hydrogène ainsi obtenue

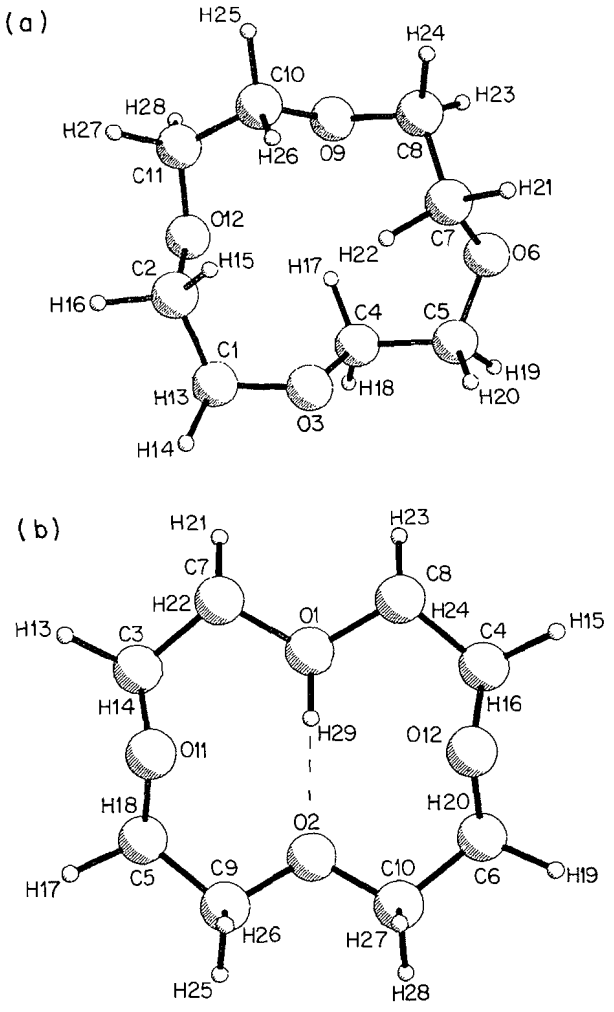

FIG. 2. (a) Structure du 12-éther-couronne-4; (b) structure du 12-éther-couronne-4 protoné.

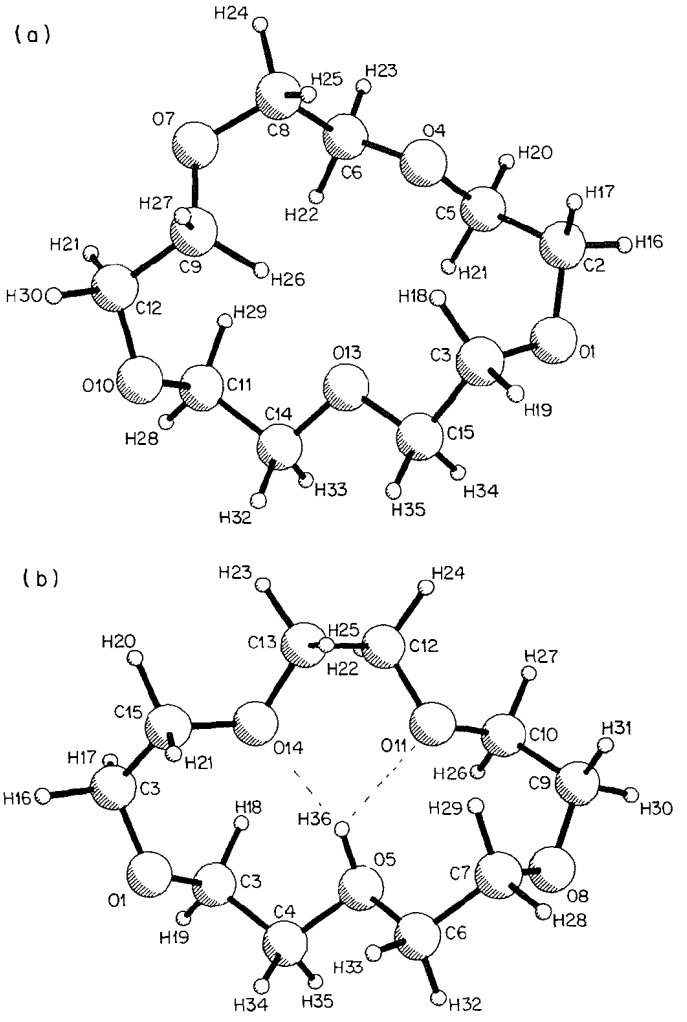

FIG. 3. (a) Structure du 15-éther-couronne-5; (b) structure du 15-éther-couronne-5 protoné.

n'est pas idéalement linéaire (O_1—H_{29}—$O_2 \cong 150°$). Cette faible déviation de la linéarité est imposée par la tension du cycle formé. Cette dicoordination peut être constatée également au niveau des angles plans des oxygènes en interactions ($C_7O_1C_8$) et ($C_9O_2C_{10}$) qui diminuent d'environ 3° par rapport aux autres. Il est à signaler également que contrairement à la conformation la plus stable de la molécule neutre où les motifs (OCH_2CH_2O) s'alternent de part et d'autre du plan moyen du cycle, tous les oxygènes sont du même côté et orientés de façon favorable à la dicoordination. Les deux oxygènes non impliqués dans la liaison hydrogène intramoléculaire sont à 4,3 Å l'un de l'autre.

15-Éther-couronne-5

Contrairement au 12-éther-couronne-4, le 15-éther-couronne-5 est beaucoup plus flexible et la régularité des motifs chaise et bateau n'est pas tout à fait respectée. La conformation la plus stable représentée sur la figure 3(a), montre que l'alternance des motifs (OCH_2CH_2O) chaise est très perturbée.

Les longueurs des liaisons et les angles plans sont identiques à ceux du 12-éther-couronne-4. Les angles dièdres des motifs (OCH_2CH_2O) sont alternés autour du plan moyen du cycle suivant la séquence (+ − + −) mais sont largement déformés par rapport aux valeurs idéales (±60° ou ±120°). Par conséquent, la structure du 15-éther-couronne-5 semble indiquer que les cinq sites basiques ne sont pas équivalents. La conformation protonée la plus stable est celle où l'orientation des dipôles (OCH_2CH_2O) permet une interaction par liaison hydrogène intramoléculaire. La structure représentée sur la figure 3(b) montre, encore une fois, que la dicoordination se fait préférentiellement entre les oxygènes opposés formant ainsi un cycle à huit membres à l'intérieur de la couronne. Les distances H^+–O indiquent qu'un faible pontage est possible entre le proton et les oxygènes O_{11} et O_{14} conduisant à une tricoordination. Cette interaction du proton avec les trois oxygènes empêche la linéarité connue de la liaison hydrogène. L'angle O_{14}—H—O_5 (155°) n'est que faiblement dévié de la valeur optimale, tandis que l'angle O_{11}—H—O_5 (120°) est franchement affecté. Les deux autres oxygènes (O_1 et O_8) sont dans des positions défavorables pour interagir avec le proton. Il est à noter que les distances H^+–O_{11} et H^+–O_{14} de 2,14 et 2,06 Å respectivement sont du même ordre de grandeur que dans le cas du 12-éther-couronne-4 protoné.

18-Éther-couronne-6

Le 18-éther-couronne-6 est la molécule la plus flexible de toute la série envisagée. Toutes les études rapportées sur cette molécule indiquent que sa structure la plus stable est de symétrie C_i (26). Celles effectuées au moyen de la mécanique moléculaire indiquent que les structures de symétrie C_i et D_{3d} sont de stabilité comparable (27). Le résultat de nos calculs réalisés au moyen de la méthode AM1 indique que la structure la plus stable est de symétrie D_{3d} (figure 4(a)). Sur cette structure, les motifs chaises

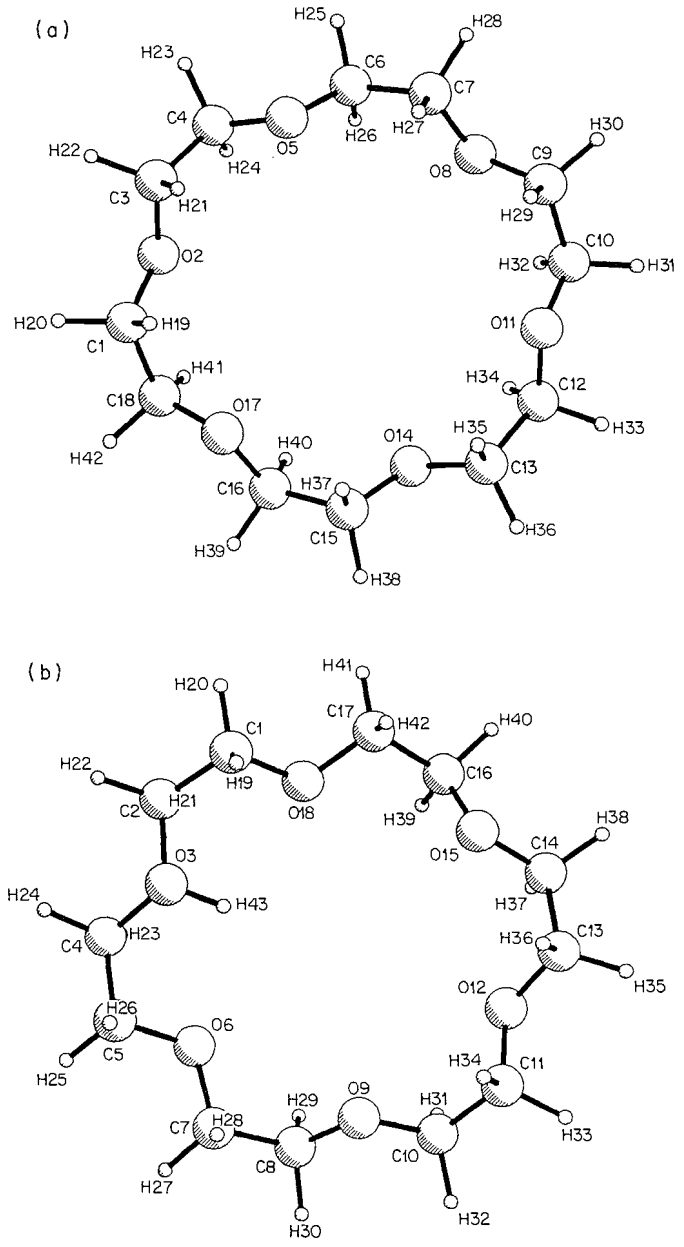

FIG. 4. (a) Structure du 18-éther-couronne-6; (b) structure du 18-éther-couronne-6 protoné.

sont bien alternés à ±0,3 Å autour du plan moyen du cycle. Les angles de torsion de ces motifs ne s'éloignent des valeurs optimales (120°) que d'environ 15°. Les oxygènes les plus proches sont ceux en position γ (3,2 Å). Les autres distances sont supérieures à 5 Å. Les plus éloignés sont à 6 Å l'un de l'autre déterminant ainsi le diamètre de la cavité de cette couronne.

La structure protonée la plus stable, parmi toutes les configurations, est celle représentée sur la figure 4(b). Bien que tous les motifs (OCH_2CH_2O) soient orientés de façon favorable, aucune des conformations mises en évidence n'a montré l'existence d'une liaison hydrogène intramoléculaire. Les distances H^+–O sont toutes supérieures à 2,5 Å, valeur optimale pour former une liaison hydrogène, excepté les oxygènes O_6 et O_{18} en position γ qui montrent une très faible interaction avec le proton (H^+–O_6 = 2,42 Å et H^+–O_{18} = 2,47 Å). Ceci est confirmé par le fait que la distance entre le proton et l'oxygène qui le fixe est inférieure à celle rencontrée dans les autres cas. Cette faible interaction par liaison hydrogène n'est sûrement pas suffisante pour stabiliser davantage la molécule protonée.

TABLEAU 1. Affinités protoniques expérimentales et calculées en AM1 des glymes et des éthers couronne[a]

N°	Composé	AP (AM1)[b]	AP (exp)[c]

(b) Affinités protoniques

L'étude de la fixation d'un proton à l'intérieur d'un éther couronne, n'est qu'une première étape qui sera suivie par la complexation avec d'autres ions d'intérêt chimique pouvant conduire à des interactions au-delà de la dicoordination.

Les données expérimentales disponibles jusqu'à présent, concernant ces composés macrocycliques, sont celles de Meot-Ner (28) et de Kebarle et coll. (29). Les moyennes des valeurs de ces auteurs sont résumées dans le tableau 1.

L'énergie de complexation des polyéthers avec le proton est composée de deux contributions essentielles : électrostatique et covalente. Si la première est due à l'interaction ion–dipôle se produisant à grandes distances, la seconde est due au transfert de charges du ligand au cation. Dans les chaînes linéaires tels que les glymes, la protonation du premier groupe O-CH_3 est souvent suivie par une cyclisation induite par la formation d'une liaison hydrogène interne dans laquelle le proton est dicoordiné entre deux groupes basiques. À différence de la basicité, l'affinité protonique n'est pas affectée par le facteur entropique. L'examen des données du tableau 1 montre que l'AP des éthers couronne et des glymes croît régulièrement avec la taille de la molécule. Ceci traduit les effets stabilisateurs de la polarisation du squelette moléculaire (aussi bien à travers les liaisons qu'à travers l'espace) et de la liaison hydrogène intramoléculaire.

Une comparaison des AP (calculées et expérimentales), des glymes et des éthers couronne homologues indique que, sans exception, les glymes sont favorisés. La différence est maximale pour le dioxane et le 9-éther-couronne-3, atteint un minimum pour le 12-éther-couronne-4, puis augmente lentement avec la taille du cycle.

Le dioxane, relativement à son homologue ouvert, présente une tension du cycle importante. La protonation de ce dernier se fait préférentiellement sur la conformation bateau (24). Les répulsions dipolaires entre les oxygènes, qui sont importantes dans les formes neutres, ont disparu et l'orientation des groupes CH_2OCH_2 stabilise la charge positive beaucoup plus que dans la forme chaise. Le dipôle de ce motif, dans le cas de son homologue ouvert, le glyme-1, est dans une position encore plus favorable. Ce qui conduit à une forte AP relativement au dioxane bateau. La grande stabilité observée en passant du glyme-1 au glyme-2 est attribuée principalement à l'allongement de la

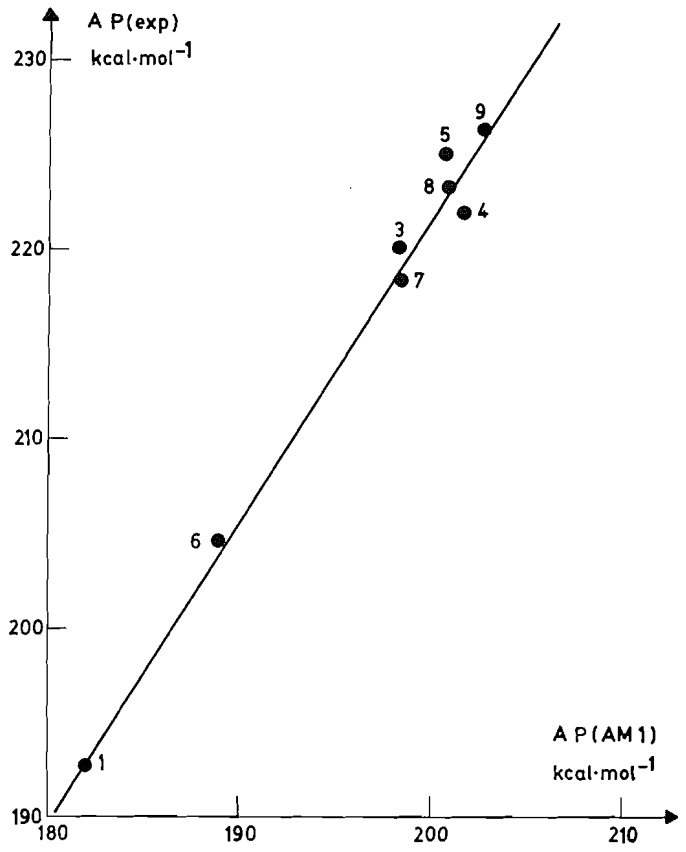

FIG. 5. Corrélation entre les affinités protoniques calculées et les valeurs expérimentales.

chaîne entre les deux oxygènes terminaux. La flexibilité de la chaîne linéaire est un facteur favorable à la dicoordination bien que l'oxygène du milieu défavorise la stabilisation dans certains cas.

La stabilité des couronnes est aussi très importante bien qu'elle soit inférieure à celle de leurs homologues ouverts. Dans le cas du 12-éther-couronne-4 protoné, deux oxygènes opposés dans le cycle peuvent atteindre une distance et une orientation favorables à la dicoordination. Les deux autres sont forcés être à des distances plus grandes. Le 15-éther-couronne-5 permet plus de flexibilité et une meilleure orientation dipolaire. En effet, les distances entre le proton et les cinq oxygènes de la molécule laissent supposer qu'une interaction au-delà de la dicoordination est possible. L'introduction du sixième groupe CH_2OCH_2 pour former le 18-éther-couronne-6 rend les distances entre les oxygènes relativement plus grandes. Seule l'interaction conduisant à un cycle hexagonal est possible, du moins dans le cadre de la méthode AM1. Ce qui explique probablement la faible AP de cette molécule par rapport à celle du 15-éther-couronne-5. Les différences entre les valeurs des AP calculées et mesurées varient entre 11 et 25 kcal mol^{-1}. Néanmoins, l'ordre de basicité est très bien reproduit, comme le montre la figure 5.

La relation entre AP(AM1) et AP(exp) est donnée par l'équation [3] :

$$[3] \quad AP(exp) = (-98{,}4 \pm 15{,}5) + (1{,}60 \pm 0{,}08)AP(AM1)$$

en kcal mol^{-1}; $n = 10$; $r^2 = 0{,}986$; d.s = 1,5 kcal mol^{-1}.

La pente de cette relation linéaire est importante (1,60). Ceci est à rapprocher des résultats obtenus dans une étude antérieure portant sur les effets de substituant sur l'affinité protonique des alcools et des éthers aliphatiques (23).

La qualité de la corrélation définie par l'équation [3] est cependant assez élevée pour montrer que la méthode AM1 est capable de décrire l'évolution de l'AP au sein de ces familles de composés d'une façon très satisfaisante et de conduire à des estimations fiables.

Conclusion

Dans ce travail nous avons présenté les structures géométriques les plus stables de quelques polyéthers sous leur forme neutre et protonée. Nous avons montré que la protonation à partir de la structure préférée de la molécule neutre ne conduit pas forcément à la conformation la plus stable de la molécule protonée. La dicoordination du proton n'apporte de stabilisation significative que si le pont hydrogène est formé entre deux oxygènes opposés conduisant à un cycle à huit membres. Dans le cas des glymes, la protonation de l'un des oxygènes des groupes extrêmes $-OCH_3$, est suivie d'une cyclisation par liaison hydrogène impliquant une stabilisation importante du système moléculaire.

La structure du 15-éther-couronne-5 protoné montre qu'une interaction par liaison hydrogène au-delà de la dicoordination, même en phase vapeur, n'est pas exclue. Ce comportement est probablement l'un des facteurs qui contribue à l'augmentation de l'AP de cette molécule par rapport à celle du 18-éther-couronne-6. La protonation de cette dernière n'a montré qu'un faible pontage entre deux oxygènes adjacents. La bonne corrélation obtenue entre nos valeurs calculées en AM1 et les valeurs expérimentales fournit une justification satisfaisante de nos résultats.

Ces résultats peuvent être utiles pour l'interprétation du phénomène de la protonation dans des solvants faiblement basiques où la stabilisation par tri- et tétra-coordination est fortement possible.

A quantitative ion exchange/atomic absorption method is described for measuring the fraction of free calcium in solution at millimolar levels. Sample solutions are equilibrated with a micro-column of strong-acid type cation-exchange resin under electrolyte concentrations (0.75 mol/L $NaNO_3$) high enough to provide conditions where the calcium sorbed on the resin is proportional to the free calcium in solution. After a water wash, the sorbed calcium is eluted from the resin with nitric acid directly into an atomic absorption spectophotometer. Free calcium levels were estimated using calibration curves obtained over the range 0–5 mM calcium with a precision of ±0.05 mM. The effect of magnesium, at concentrations twice that of calcium, on measured calcium levels is negligible. The method is pH insensitive over the range 5–7. Selectivity for free calcium in the presence of complexing ligands such as citrate and phosphate is high. The method shows promise for the determination of ionized calcium in biological systems.

Key words: ion exchange, atomic absorption, free calcium determination, ion speciation.

AMITHA K. HEWAVITHARANA, VASANTHA MUTUCUMARANA et BYRON KRATOCHVIL. Can. J. Chem. **69**, 1976 (1991).

On décrit une méthode quantitative d'échange ionique/absorption atomique permettant de mesurer le calcium libre, en solution à des niveaux millimolaires. On place les solutions d'échantillon dans une micro-colonne de résine échangeuse de cations de type acide fort, avec des concentrations d'électrolyte suffisamment élevées (0,75 mol/L de $NaNO_3$) pour qu'elles fournissent des conditions telles que la quantité de calcium adsorbé sur la résine est proportionnelle à la quantité de calcium à l'état libre dans la solution. Après un lavage à l'eau, le calcium adsorbé est élué de la résine à l'aide d'acide nitrique directement dans un spectrophotomètre d'absorption atomique. On évalue les niveaux de calcium en se basant sur des courbes de calibration obtenues entre 0 et 5 mM de calcium avec une précision de ± 0,05 mM. L'effet du magnésium sur les niveaux de calcium mesurés est négligeable jusqu'à des concentrations doubles de celles du calcium. Entre 5 et 7, la méthode n'est pas sensible au pH. En présence de ligands complexants comme le citrate et le phosphate, la sélectivité pour le calcium libre est élevée. La méthode est prometteuse pour la détermination de calcium ionisé dans des systèmes biologiques.

Mots clés : échange ionique, absorption atomique, détermination du calcium libre, spéciation ionique.

Introduction

There is continuing interest in the measurement of ionized as opposed to total metal in environmental and clinical fields. Ionized calcium, in particular, is important in clinical applications (1–3) where it typically occurs at millimolar levels.

Calcium ion-selective electrode (ISE) potentiometry (4–6) and spectrophotometry with color-forming ligands (7, 8) are frequently used to measure ionic calcium at millimolar levels. ISE's are subject to several interferences, however, and require careful matching of samples and standards, while colorimetric methods have limitations in pH range and in application to colored samples. Another recently developed approach to ion speciation, an ion-exchange column-equilibration technique, has been used to determine free copper ion concentrations in natural waters (9) and free nickel ion concentrations in sewage (10). This method requires constant cation levels in the test solutions at concentrations such that the amount of analyte ion sorbed onto the resin is small compared to total sorbed cation. Under these conditions, called "trace conditions", the amount of analyte ion sorbed on the resin is directly proportional to the analyte ion concentration in solution.

In this paper the use of the ion-exchange column-equilibration technique for the determination of free calcium ion concentrations at millimolar levels is investigated. An ideal method for measuring individual species of a metal ion in solution will introduce little or no perturbation of the system. The ion exchange column equilibration method used here allows the column to come to equilibrium with fresh sample solution, so the concentration of calcium in the sample is not biased by sorption from the sample. The method does require that the fraction of resin in the calcium form be of the order of one percent or less. For the work described here this has been accomplished by making the samples to be analyzed about 0.75 mol/L in sodium nitrate.

Experimental

Apparatus

A microcomputer-controlled data-acquisition/processing system, developed previously in this laboratory for ion speciation studies using the ion-exchange/atomic-absorption method (11), was used. The major components consist of a peristaltic multichannel pump and a Perkin Elmer model 4000 atomic absorption spectrophotometer, with data acquired by an IBM PC via an AST A to D converter. The construction of the micro resin column is described elsewhere (12). For this study a column containing 4.8 mg of resin was employed. pH measurements were made with a Fisher model 520 digital pH/ion meter and Fisher glass-calomel electrodes calibrated with Fisher standard buffers at pH 4 and 7.

Reagents

All chemicals used were reagent grade or better. The resin in the column was analytical grade 100–200 mesh Dowex 50W X8 strong-acid type cation exchanger (J. T. Baker Chemical Co.) treated as described in the literature (13). The ion exchange capacity of this resin is 5.1 mequiv./g on a dry basis.

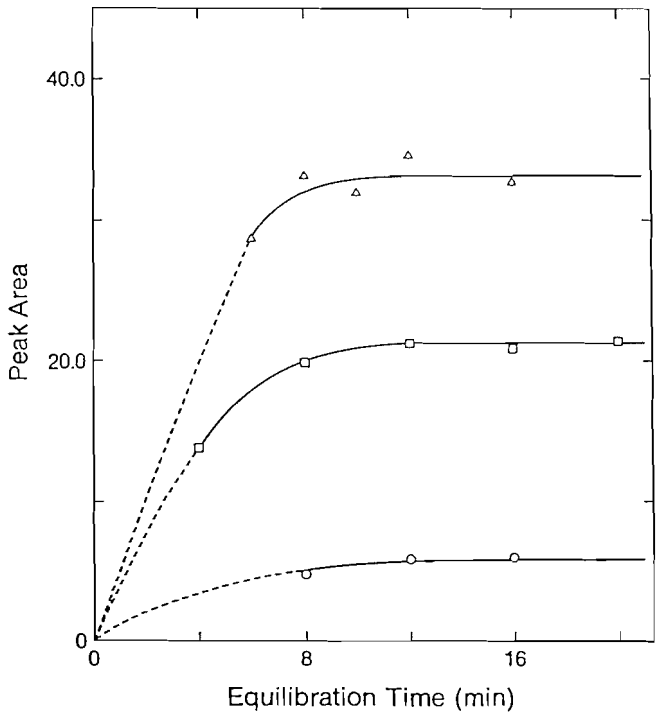

FIG. 1. Column equilibration curves at 0.1 mol/L Na^+: ○, 0.013 mM (0.5 mg/L) Ca^{2+}; □, 0.025 mM (1.0 mg/L) Ca^{2+}; △, 0.125 mM (5.0 mg/L) Ca^{2+}. Note: AA sensitivity was changed for the different solutions, so peak areas among plots are not directly comparable.

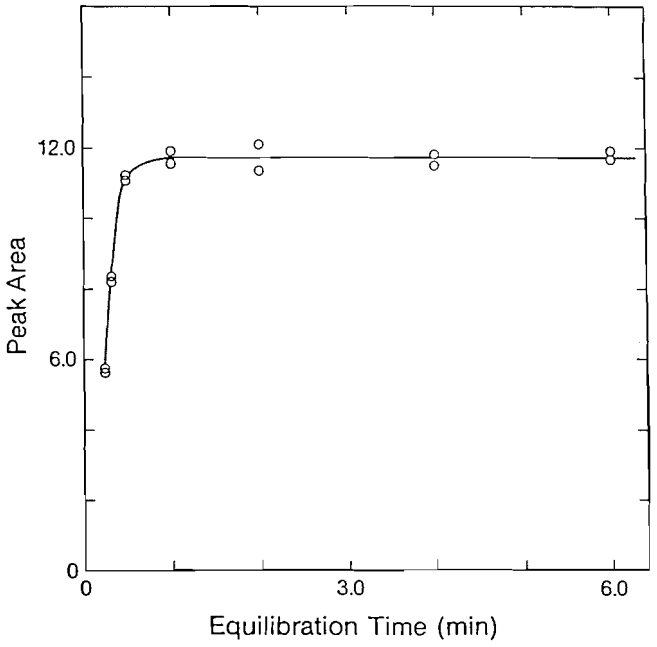

FIG. 2. Column equilibration curve for 0.625 mM (25 mg/L) Ca^{2+} solution in 0.75 mol/L Na^+.

Procedure

Standard solutions were prepared containing known concentrations of calcium as calcium nitrate (from calcium carbonate and HNO_3) and swamping electrolyte, $NaNO_3$. Some solutions were adjusted to pH 5 using HNO_3 or NaOH as required, others to pH 7 using HEPES buffer.

The column was thermostatted at 25 ± 1°C and the flow rate through it maintained at 4.5 mL/min with a peristaltic pump. A computer-controlled valve system described earlier (11) was used to perform the following operations.

The column was first washed by pumping water through it for 1 min. Next the solution of interest was passed through the column to waste until complete breakthrough was achieved (12). At breakthrough the composition of the column influent and effluent are the same and the resin is in equilibrium with the test solution. After the loading cycle, the column was backwashed with water for 3 min to remove any interstitial test solution. This washing cycle was followed by a 30 s elution of the sorbed ions with 2 M HNO_3 directly into the atomic absorption spectrophotometer. The column was washed with water before introduction of the next test solution. The data acquired from the AAS were stored in an IBM PC microcomputer, then processed to obtain peak heights and areas.

Results and discussion

Effect of calcium concentration on the time of equilibration

The time period required to achieve complete equilibration of resin with solution was examined with three concentrations of calcium at a constant electrolyte concentration of 0.1 mol/L and pH 5. The results, Fig. 1, show that the time required to achieve complete equilibration does not significantly change with the concentration of calcium at a constant electrolyte concentration. It was also determined that the time of equilibration was not affected by replacing sodium with potassium or by the presence of at least 4.1 mM (100 mg/L) magnesium or 0.65 mol/L of urea. For 0.1 mol/L electrolyte concentrations, the equilibration time is about 12 min. Therefore, for a series of Ca standards prepared with the same electrolyte concentration, measurement of the equilibration time of one standard is adequate to determine the equilibration time for the entire set.

Effect of electrolyte concentration on the time of equilibration

The equilibration time for 0.625 mM (25 mg/L) calcium solution in 0.75 mol/L sodium nitrate as electrolyte was found to be less than 1 min (Fig. 2). The corresponding time for 0.5 mol/L sodium nitrate was about 3 min. These data and the value of 12 min for 0.1 mol/L sodium nitrate reported in the previous section indicate that the time required for equilibrium between solution phase and resin phase decreases as the electrolyte concentration is increased.

Effect of electrolyte concentration on calibration curves

The effect on calibration plots for calcium of concentrations of $NaNO_3$ electrolyte ranging from 0.1 to 0.75 mol/L are shown in Fig. 3. The linearity of the plot depends on the closeness of the experimental conditions to trace conditions. The increase in the linear region with increasing concentration of electrolyte suggests that at lower levels of electrolyte the column is not operating under trace conditions. Table 1 gives the fraction of calcium present on the resin at equilibrium with sodium ion concentrations of 0.1 and 0.75 mol/L. The data show that the column is not operating at trace conditions at 0.1 mol/L electrolyte concentration, and explains the curvature of the calibration curve. A sodium ion concentration of 0.75 mol/L was found to provide a calibration curve which can be used to determine Ca^{2+} concentrations up to 5 mM (200 mg/L) with a standard deviation of the order of ±0.05 mM.

Tables of the affinity of DOWEX 50W X8 for cations show K^+ favored over Na^+ by a factor of about 1.5 (14). These affinities were measured at low ionic strengths, however. At the higher ionic strengths used here selectivity reversal is observed, such that sodium is better than potassium in providing trace conditions for calcium concentrations in the millimolar range. Therefore all subsequent measurements of calcium were made using 0.75 mol/L $NaNO_3$ as electrolyte.

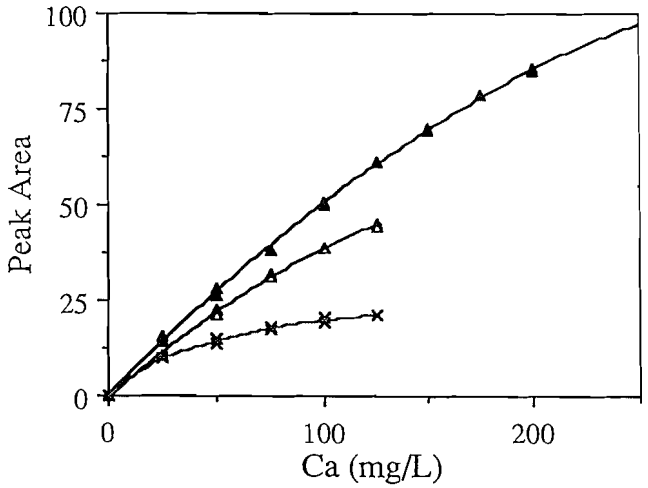

FIG. 3. Calibration curves for standard Ca^{2+} solutions. ×, at 0.1 mol/L Na^+; △, at 0.5 mol/L Na^+; ▲, 0.75 mol/L Na^+. Note: AA sensitivity was changed for different calibration curves, so peak area values are not directly comparable from plot to plot. All points were measured in duplicate.

TABLE 1. Fraction of resin in calcium form at equilibrium with 0.1 and 0.75 mol/L sodium ion in solution

Total Ca^{2+} mg/L (mM) in solution	Fraction resin in Ca form at	
	0.1 mol/L Na^+	0.75 mol/L Na^+
25 (0.625)	0.102	0.014
50 (1.25)	0.184	0.027
75 (1.88)	0.286	0.037
100 (2.50)	0.348	0.046
125 (3.13)	0.409	0.055

Effect of magnesium and pH on precision and accuracy of calcium measurements

The effect of magnesium, which often occurs at significant concentrations with calcium in biological systems (15), was evaluated by adding amounts ranging from 0 to 4.1 mM (100 mg/L) to a 1.87 mM (75 mg/L) solution of calcium and determining the free calcium levels. Although magnesium can be expected to sorb onto the resin, calcium peak areas are not significantly changed, indicating that magnesium does not interfere at these levels. This result suggests that column equilibrium between sodium and magnesium does not affect to any significant extent the equilibrium between calcium and sodium over the concentration range investigated.

The effect of pH over the range 5–7 on the calcium signal was also investigated. A solution of 1.87 mM (75 mg/L) calcium was taken as before, the pH adjusted to a value of 5, 6, or 7, and the sorbed calcium measured. The calcium signal was not affected, which suggests that the method is insensitive to pH over this range.

Selectivity of the method for free over bound calcium

The presence of complexing ligands results in the binding of metal ions and thereby lowers free metal ion concentrations in solution. Depending on ligand charge, the metal ligand complexes may be cationic, anionic, or neutral. In the ion-exchange column-equilibration method employed here, it is assumed that only free, hydrated, metal is sorbed onto the resin. However, sorption of cationic or neutral complexes might also occur (9), giving rise to falsely high free calcium values. To assess the extent to which this process occurs, the free calcium in solutions containing known concentrations of citrate and phosphate was measured by the ion exchange method. The fractions of free calcium in the solutions were also calculated from equilibrium-constant data by computer, using the program COMICS (16).

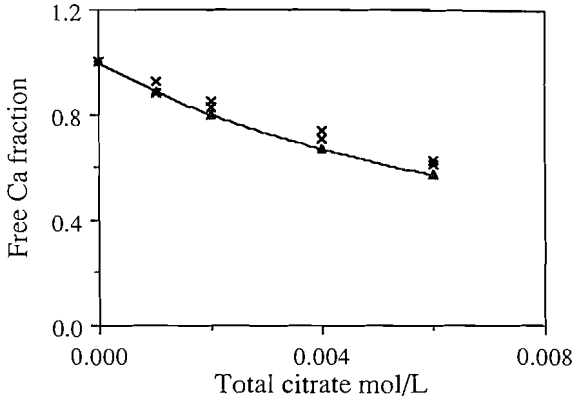

FIG. 4. Variation in fraction of free calcium with added citrate. ×, measured values; ▲, calculated values.

Results obtained for the fraction of free calcium in the presence of varying amounts of total citrate at pH 5 are shown in Fig. 4. Calculated values are based on complexes of the type $CaCit^-$, CaHCit, and CaH_2Cit^+ (Cit denotes the triply charged citrate anion). The stability constants at 0.1 ionic strength (17) were recalculated for 0.75 ionic strength using the Davies equation. Corrections were also made for the formation of $NaCit^{2-}$ (17) and $NaHCit^-$ (18) complexes. The agreement between the calculated and the measured calcium fractions is satisfactory, especially in light of uncertainties in equilibrium constants as a function of ionic strength. The results indicate that the column selectively sorbs free calcium in the presence of calcium–citrate species.

The variation of free calcium fraction in the presence of varying amounts of total phosphate at pH 5 is shown in Fig. 5. Calculated values are based on formation of the complexes $CaPO_4^-$, $CaHPO_4$, and $CaH_2PO_4^+$ (17) and ionic strength corrections were carried out as for the citrate system. Corrections were also made for the formation of $NaPO_4^{2-}$, $NaHPO_4^-$, and NaH_2PO_4 complexes (19). Here, too, agreement between the calculated and measured values is satisfactory. The small differences may be due to one or more of the following: (*1*) In the case of citrate, the possible formation of a neutral NaH_2Cit complex, which would also tie up citrate. A stability constant value for this species has not been reported. If such a complex were present, it would cause the calculated values of free calcium to be higher than shown in Fig. 4. (*2*) In the case of phosphate, stability constant values for $NaPO_4^{2-}$ and NaH_2PO_4 are reported for 37°C only (19), whereas all other stability constants used in these calculations were measured at 25°C. The stability constant for $NaHPO_4^-$, which has been measured at both temperatures, shows a slightly lower value for 25°C than for 37°C. The use of two stability constants measured at 37°C could cause calculated values of free calcium to be slightly higher than the actual ones. (*3*) The calculated values shown are for a pH of 5. Even small deviations in pH will cause a difference between calculated and observed free calcium values. (*4*) Small errors may be introduced in correction of activities to the high ionic strength used.

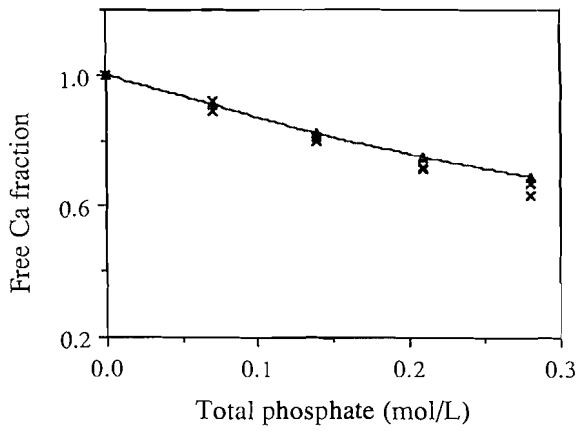

FIG. 5. Variation in fraction of free calcium with added phosphate. ×, measured values; ▲, calculated values.

TABLE 2. Results for the determination of free and total calcium in the urine of seven normal individuals; total measured by flame atomic absorption ($n = 3$), free by the ion exchange column equilibration method ($n = 2$) described in this study; uncertainties are ± one standard deviation

Free Ca^{2+}, mM	Total Ca, mM	% Free Ca
0.73±0.10	1.37±0.02	53
1.30±0.02	2.00±0.02	65
3.08±0.12	6.00±0.03	51
2.78±0.02	4.50±0.04	62
4.35±0.07	8.00±0.03	54
2.20±0.09	4.50±0.03	49
0.75±0.04	1.25±0.02	62

Despite these uncertainties, the method appears highly selective for free calcium. In the citrate system the fraction of neutral calcium-ligand species can be as high as 0.12, while in the phosphate system the fraction of neutral calcium-ligand species can be as high as 0.1 and that of the positively charged calcium-ligand species can be as high as 0.2. Thus even though, as mentioned earlier, the resin might be expected to sorb cationic and neutral calcium-ligand complexes, under the conditions studied such sorption processes appear to be negligible.

To provide a preliminary test of the method, the free urine calcium levels of seven normal individuals were determined by the procedure described. Total calcium levels were also measured by flame atomic absorption after 50-fold dilution of the urine samples. Percentages of free calcium in the range of 49–65% were found (Table 2). These levels are similar to those previously estimated for percent free calcium in urine (6).

In summary, this work describes a procedure for the estimation of free calcium at the millimolar level in the presence of ligands such as citrate and phosphate. The method can be used over the pH range normally seen in biological systems, and is unaffected by concentrations of magnesium twice that of calcium. It therefore shows promise for the estimation of ionized calcium in biological systems in the presence of a variety of ligands and interfering metal ions.

A comparison of acetone and poly(propylene glycol) as solvents for lithium triflate and lithium perchlorate

JAMES R. STEVENS[1] AND PER JACOBSSON
Department of Physics, Chalmers University of Technology, S-412 96 Gothenburg, Sweden

Received March 18, 1991

JAMES R. STEVENS and PER JACOBSSON. Can. J. Chem. **69**, 1980 (1991).

Solutions of $LiCF_3SO_3$ and $LiClO_4$ in acetone and in poly(propylene glycol) (PPG 400 and PPG 4000) have been compared by studying the nondegenerate, symmetric stretch (A_1,SO_3) and (A_1,ClO_4) Raman modes. The Raman spectra contain bands due to the symmetric stretching motion of the "free" anion and due to the symmetric stretching motion of anions in ion aggregates. It is concluded that "free" ions, ion pairs, triplets, and aggregates are present. Although PPG has a much lower dielectric constant, it is a better solvent for these salts than the dipolar aprotic acetone. These findings have ramifications on the current controversy of whether "free" ions are present at all in polyether–salt complexes such as PPG 4000/$LiCF_3SO_3$.

Key words: acetone, poly(propylene glycol), lithium triflate, lithium perchlorate, Raman.

JAMES R. STEVENS et PER JACOBSSON. Can. J. Chem. **69**, 1980 (1991).

On a comparé des solutions de $LiCF_3SO_3$ et de $LiCl_4$ dans l'acétone et dans le poly(propylène glycol) (PPG 400 et PPG 4000) en étudiant les modes d'élongation symétrique non-dégénérés (A_1,SO_3) et (A_1,ClO_4) observés en spectroscopie Raman. Les spectres Raman contiennent des bandes qui sont dues au mouvement d'elongation symétrique de l'anion "libre"et d'autres qui sont dues au mouvement d'élongation symétrique des anions dans les agrégats d'ion. On en conclut que des ions "libres", des paires d'ions, des triplets et des agrégats sont présents. Pour ces sels, on observé que, même si la constante diélectrique du PPG est beaucoup plus faible, c'est un meilleur solvant que l'acétone aprotique et dipolaire. Ces observations ont des implications sur la question actuellement controversée concernant la présence des ions "libres" dans tous les complexes polyéther/sel, comme PPG 4000/$LiCF_3SO_3$.

Mots clés : acétone, poly(propylène glycol), triflate de lithium, perchlorate de lithium, Raman.

[Traduit par la rédaction]

Introduction

There has been an extensive study of the ion solvation and association of alkali and alkali earth metal perchlorates in a range of dipolar aprotic solvents using infrared and Raman spectroscopy. This was prompted, in large part, by the wide current interest in using these salts as dopants in polyethers and similar polymers to produce solid polymeric electrolytes for such applications as electrochromic devices, batteries, and fuel cells.

The most extensive studies have been carried out by Perelygin *et al.* (1–10). Raman studies are reported for perchlorates in acetone, acetonitrile, pyridine, and dimethylsulphoxide (1). Infrared studies are reported for perchlorates in propylene carbonate (2), ethyl acetate (3), tetrahydrofuran (4), dimethylformamide (5), dimethyl sulphoxide (6), acetone (7, 8), and acetonitrile (9, 10).

Generally the picture that emerges from the work of Perelygin and associates is that in an ion association equilibrium, we find such species as "free" ions, contact ion pairs (monodentate and bidentate), charged and neutral triplets, quadrupoles, and higher aggregates. In solvents with electron donicity (Gutmann's DN_{SbCl_5}, kcal mol^{-1}) values > 25 and relative permittivity (ϵ_r) values > 37 (e.g., dimethylformamide (5) and dimethyl sulphoxide (6)), the perchlorate salts are completely dissociated. (See Reichardt (11) for values of ϵ_r, DN, and dipole moments (μ)). For a series of solvents which have values of DN in the 15–35 range but values of ϵ_r in the range 8–37 (acetonitrile, acetone, pyridine, and tetrahydrofuran) "free" ions are found in equilibrium with associated species for the perchlorates (1, 4, 7–10). Ion association decreases in going from acetonitrile (ϵ_r = 35.9, DN = 14.1) to propylene carbonate (2) (ϵ_r = 64.9, DN = 15.1). In ethyl acetate (3) (ϵ_r = 6.0, DN = 17.1, $\mu = 6.1 \times 10^{-30}$ C m), the ions of these salts are completely associated even in dilute solutions with the largest assortment of different forms of associated ionic species being observed (3). In dilute solutions of $LiClO_4$ and $NaClO_4$ in ethyl acetate contact ion pairs are reported to be the most common species (3).

Wong *et al.* (12) carried out infrared, Raman, and NMR studies on solutions of various lithium and sodium salts in acetone. Cation–acetone vibrational bands were identified but were found to be independent of the anion for alkali metal salts with polyatomic anions. In disagreement with Perelygin *et al.* (1–10), Wong *et al.* (12) found that the symmetric stretch $\nu_1(A_1,ClO_4)$ band centred at 935 cm^{-1} remains unchanged when the acetone/$LiClO_4$ mole ratio is ≥4 but that below this ratio the band progressively broadens, shifting to higher frequency with increase in concentration.

By studying the splitting of the isotropic and anisotropic components of the Raman CO stretching vibration in acetone/perchlorate systems, Bukowska (13) identified both cation solvation and cation–acetone transient cross-links. Lalic *et al.* (14) studied the Raman spectra of solutions of $LiClO_4$ and $Sr(ClO_4)_2$ in acetone and acetonitrile with, in some cases, varying amounts of NaSCN. They observed a band at a lower frequency (911.5 cm^{-1}) than the ClO_4^- symmetric stretch and interpreted it as a $2\nu_2(A_1+E)$ overtone in Fermi resonance with $\nu_1(A_1)$. Lalic *et al.* (14) observed split bands related to the $\nu_1(A_1,ClO_4)$ symmetric stretch at 933, 939, and 948 cm^{-1} and citing the earlier Raman studies of Frost *et al.* (15) and Mayes *et al.* (16) of perchlorates in aqueous solutions (15) and in acetone (16) assigned these to, respectively, "free" anions, solvent separated ion-pairs, and contact ion pairs. Neither of these authors (13, 14) was, apparently, aware of the work of Perelygin and co-workers (1–10).

The solvation of $LiCF_3SO_3$ and $LiClO_4$ in polyethers is important in the synthesis of solid electrolytes. However, there

is a current controversy as to the nature of the charge carrying ion species in these systems. Gray (17) and MacCallum *et al.* (18) argue, based on the Fuoss triple ion interpretation (19), that charged triple ions are the mobile species which contribute to the ionic current for concentrations above 0.01 M. It should be noted that two adjustable parameters, the pair and triple ion formation constants, are used in fitting the "triple-ion" theory (19) to conductivity data. Cameron *et al.* (20) and Schanz (21) support the concept of the redissociation of ion pairs formed at low concentrations and argue that "free" ions are responsible for charge transport. The general contention of those in favour of the triple ion interpretation is that polyethers like poly(propylene oxide) have such a low dielectric constant that similar to ethyl acetate (3) and methyl acetate (22) ($\epsilon_r = 6.7$, DN = 16.5, $\mu = 7.9 \times 10^{-30}$ C m), for example, no free ions should be present for salt concentrations of the order of 1 M (also see ref. 18). They concur with Petrucci and co-workers (22) that salts like $LiClO_4$ and $LiAsF_6$ in low dielectric constant solvents can only be "spectroscopically free", by which they mean solvent separated (or loose) ion pairs.

This paper examines this contention by comparing the solubility of $LiClO_4$ and $LiCF_3SO_3$ in acetone and in PPG ($\epsilon_r = 4.7$ (23), $\mu = 28.0 \times 10^{-30}$ C m (24) for PPG 4000) as inferred from a study of the nondegenerate symmetric stretch (A_1,ClO_4) and (A_1,SO_3) modes in Raman spectra.

Acetone was selected since it is a dipolar, aprotic, electron-pair, oxygen donor solvent ($\epsilon_r = 20.6$, DN = 17.0, $\mu = 9.0 \times 10^{-30}$C m). According to Reichardt (11), both free and associated ions should exist in equilibrium for salts dissolved in acetone; the ratio between free and associated ions depends upon, *inter alia*, the solvent, ion sizes, charge distribution, and specific ion solvation. Persson *et al.* (25) have proposed a donor strength scale for hard acceptors (Li^+, Na^+) based on the Gibbs free energy of transfer of the sodium ion from a solvent to the same reference solvent as is used in the Gutmann DN scale. This scale indicates that hard oxygen donor solvents like acetone solvate hard acceptors particularly well (25). Although the electrostatic factor ($\mu \cdot \epsilon_r$) places acetone in the highest solvent classification, i.e., dipolar, non-hydrogen bond donor solvents (11), it is dangerous to rely totally on these macroscopic parameters since they are really unsuitable measures of microscopic molecular interactions. The state conditions which apply in these electrolytes are very complex. Potentials of higher order than ion–dipole or dipole–dipole are important (26).

Experimental

The preparation of poly(propylene glycol) (PPG) (Polyscience Inc.) included filtering through a 1 μm Millipore filter, heating in a vacuum oven for about 3 days at 120°C, and drying under a vacuum at pressures $<10^{-4}$ Torr using a freeze–thaw method. Anhydrous $LiCF_3SO_3$ and $LiClO_4$ (Ventron Division, Alpha) were vacuum dried at 125°C for 24 h and then at room temperature for 24 h. The salts were dissolved directly into the dried polyethers in a dry argon atmosphere using temperatures between 65 and 80°C. The prepared samples were stored under vacuum and measurements were made in a helium atmosphere. The PPG–$LiCF_3SO_3$ and PPG–$LiClO_4$ complexes were made for ether oxygen to lithium (O:Li) = 16:1 and molecular weights of 4000 and 400. The value of the ionic conductivity peaks for concentrations between O:Li = 16:1 and 30:1 (23). Karl Fischer titration (Metrohm 684) showed the water content to be of the order of 0.1% by weight.

We have measured the donicity of PPG 4000 using the ^1H NMR chloroform chemical shift technique of Hahn *et al.* (27). The observed shift of 0.1 M chloroform in PPG 4000 relative to tetramethylsilane (TMS) in *d*-chloroform was 8.00 ppm. The shift of pure chloroform relative to TMS in *d*-chloroform was 7.27 ppm. The observed shift of chloroform in PPG 4000 was corrected for the difference in the volume magnetic susceptibilities (K) of chloroform ($K = -0.740 \times 10^{-6}$ cgs (28)) and PPG 4000 ($K = -0.706 \times 10^{-6}$ cgs) giving a value of DN = 21. The K for PPG 4000 was estimated using Pascal's magnetochemical method (29).

Solutions of acetone/$LiCF_3SO_3$ (16:1) and acetone /$LiClO_4$ (16:1 and 1000:1) were prepared under a dry argon atmosphere by mixing pure anhydrous salt (dried as above) with dried reagent grade acetone. Since the acetone is completely miscible with water, great care was taken to dry the acetone using a freeze drying procedure under vacuum until there was no evidence of the infrared absorption bands of the valence vibrations of water molecules (3000–3600 cm^{-1}). Karl Fischer titration showed the water content to be less than 0.1% by weight.

The experimental setup includes an argon-ion laser operating at 488 nm, a Spex double monochromator (model 1403) with 1800 lines/mm holographic gratings, and a liquid nitrogen cooled charge coupled device (CCD) low signal to noise detector which gives a "readout" resolution of about 0.2 cm^{-1} with rapid recordings. The overall instrumental resolution, mainly restricted by the slitwidths, was set to give a value of 0.9 cm^{-1}. At all temperatures (250 K, 300 K, 350 K), a continuous flow cryostat (Oxford CF1204) with a temperature stability better than 0.1 K was used. The Raman spectrum of the pure dry acetone or pure dry PPG was subtracted from the spectra of the solutions. The remaining Raman profiles were then deconvoluted from the instrumental function using Jansson's method (30). The combination of better instrumental resolution, better samples, and much improved signal to noise ratios results in a standard error for the deconvoluted spectra which is an order of magnitude better than previous reports (15, 16).

Results and discussion

We begin with a brief report on the ν(A_1,ClO_4) symmetric stretch region of the ClO_4^- anion in acetone in order to relate to the previous work mentioned in the Introduction. The usual T_d symmetry of the ClO_4^- anion is reduced to C_{3v} and C_{2v} in association with cations and the symmetric stretch bands are observed for "free" anions and anions in ion aggregates, distinct band components indicating different ClO_4^- environments. Figures 1(*a*) and 1(*b*) show, respectively, the raw data and the deconvoluted spectra with fitted components at 300 K for those bands for acetone/$LiClO_4$ mole ratios of 1000 and 16. In agreement with Perelygin and Mikhailov (1), the feature at 911 cm^{-1} is attributed to an overtone of the deformational vibration $\nu_2(E)$ of the perchlorate ion; it is independent of concentration and is symmetric over a range of temperatures from 250 to 450 K. The feature at 938 cm^{-1} is attributed to contact ion pairs, $Li^+ClO_4^-$, monodentately coordinated; the frequency of this component is reported to shift on changing cations (1). We disagree with Frost *et al.* (15) and James *et al.* (16) who assigned this vibration to loose ion pairs for 1 M $LiClO_4$ (≈O:M = 16:1). The separation of the loose ion pair peak from the "free" ion peak at 932 cm^{-1} would not be as great as 6 cm^{-1}. As the temperature is increased, the relative intensity of the 938 cm^{-1} component for the 16:1 sample increases from 0.2 at 250 K to 0.3 at 350 K and the intensity of the 932 cm^{-1} component decreases. For an acetone/$LiClO_4$ mole ratio of 1000, we still find these 932 cm^{-1} and 938 cm^{-1} components present, the relative intensity of the contact ion pair component changing from 0.04 at 250 K to 0.1 at 350 K.

The feature at 932 cm^{-1} is independent of the cation (1) and is attributed to the "free" ClO_4^- anion. This assignment is justified in the following. James *et al.* (16) find the lowest (A_1ClO_4) band frequency to be 934 cm^{-1} for $LiClO_4$ in acetone. This group obtained the same frequency for $LiClO_4$ and $NaClO_4$ in aqueous solutions (>1 M) (15). These features are reported as narrow

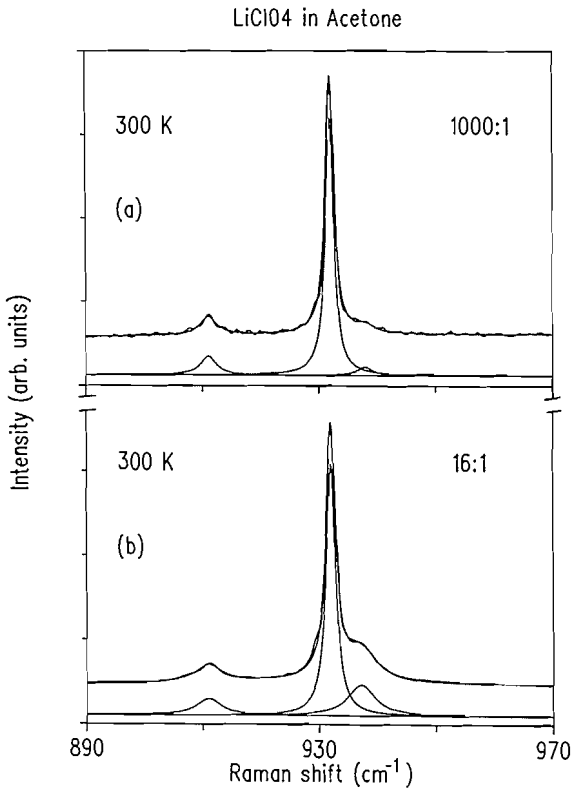

FIG. 1. (*a*) Acetone/$LiClO_4$ mole ratio 1000 at 300 K: raw Raman (A_1,ClO_4) spectrum above and deconvoluted, fitted Raman (A_1,ClO_4) spectra below. (*b*) Acetone/$LiClO_4$ mole ratio 16 at 300 K: raw spectrum above and deconvoluted, fitted Raman (A_1,ClO_4) spectra below.

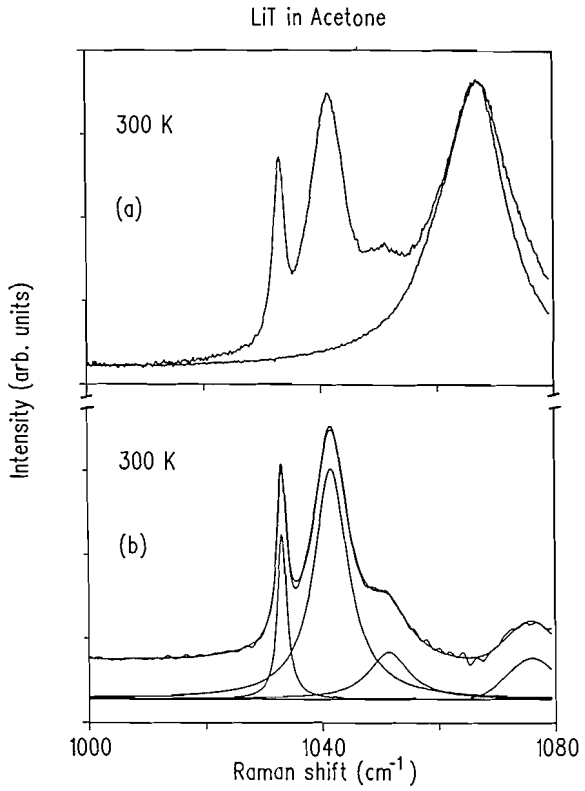

FIG. 2. (*a*) Acetone/$LiCF_3SO_3$ (LiT) mole ratio 16 at 300 K: raw Raman (A_1,SO_3) spectrum showing the acetone background. (*b*) Acetone/$LiCF_3SO_3$ mole ratio 16 at 300 K: background subtracted, deconvoluted, fitted Raman (A_1SO_3) spectrum.

Lorentzians (15). In a high permittivity solvent such as water, one should expect that a very high percentage of the salt is completely dissociated. We have observed this feature at 932 cm^{-1} with full width at half maximum (FWHM) = 1 cm^{-1}. In comparison with the Cary 82 used by Frost *et al.* (15) and James *et al.* (16), the signal-to-noise ratio of the CCD is much better and the resolution is also improved. Further, Perelygin *et al.* (1) have studied the $\nu_1(A_1,ClO_4)$ Raman spectra for the $(C_4H_9)_4NClO_4$ salt in acetone. They conclude that because the voluminous cation $(C_4H_9)_4N^+$ does not distort the symmetry of the anion even with incomplete dissociation, the 932 cm^{-1} feature must be attributed to vibrations of the free perchlorate ion of symmetry T_d (1). Finally, the hard oxygen donor acetone is an excellent solvent for a hard acceptor like Li^+ (25).

Figure 2(*a*) shows the raw data for the symmetric stretch Raman bands for an acetone/$LiCF_3SO_3$ mole ratio of 16 at 300 K. Figure 2(*b*) is the same band group with the background subtracted and the instrumental function deconvoluted. The fitted components are shown. The low frequency component is best fit with a Lorentzian at 1033 cm^{-1} with FWHM = 1 cm^{-1}. Schantz (21) studied a dilute (0.1 M) aqueous solution of $NaCF_3SO_3$ in which the $\nu_1(A_1SO_3)$ mode was detected as a one component band at 1033 cm^{-1} with FWHM = 5 cm^{-1} (Lorentzian). With a dilute salt concentration in such a high permittivity solvent almost all the ions should be "free". The component is not influenced by the change in cation from Na^+ to Li^+ and is assigned to "free" anions. The next band component (Gaussian) at 1042 cm^{-1} is shifted to higher frequencies by 9 cm^{-1} compared to the 5 cm^{-1} shift for the corresponding component for $NaCF_3SO_3$ in acetonitrile (31), a similar dipolar aprotic solvent. The fact that this component is sensitive to the cation suggests that it arises, at least in part, from contact ion pairs as was discussed by Perelygin and Mikhailov (1). The next highest frequency component (Lorentzian, Fig. 2(*b*)) at 1051 cm^{-1} is suggested to be due to $Li^+CF_3SO_3^-Li^+$ triplets. With Perelygin and Mikhailov (1), we infer from this the presence of the other triplet species $CF_3SO_3^-Li^+CF_3SO_3^-$ with an SO_3^- symmetric stretch vibration approximately the same as for contact ion pairs (1042 cm^{-1}). Finally, a broad (Gaussian) component is observed at 1076 cm^{-1} which we attribute to aggregates of ions. To confirm this we performed a Raman backscattering measurement on a compressed pellet of dried $LiCF_3SO_3$ and observed a narrower band centered at the same frequency. Although the amount of water contained in these complexes is extremely low, what is there may influence these ion associations.

Figure 3(*a*) shows the variation in the relative intensities of three of the four components in the $\nu_1(A_1,SO_3)$ region as a function of temperature for an acetone/$LiCF_3SO_3$ mole ratio of 16. Most of the ions are associated; only ~12% are "free". The concentration of "free" ions and aggregates decreases with increasing temperature. The proposed contact ion pair-triplet component at 1042 cm^{-1} is ~60% and increases very slightly with temperature. The overall triplet concentration is higher than the "free" ion concentration and increases with increasing temperature. Figure 3(*b*) shows that the frequencies on which these components are centered do not shift with changes in temperature.

Figure 4(*a*) shows the raw data and fitted components for the $\nu_1(A_1,SO_3)$ mode at 350 K for PPG 400/$LiCF_3SO_3$ (O:Li = 16:1). As for acetone/$LiCF_3SO_3$, the Lorentzian peak at

TABLE 1. The relative intensities of "free" ions and associated ions for $LiClO_4$ and $LiCF_3SO_3$ in PPG

PPG	Salt O:Li = 16:1	T (K)	Fraction "Free" ions	Contact pairs triplets	Triplets
400	$LiCF_3SO_3$	250	0.75	0.12	0.13
		350	0.75	0.20	0.05
	$LiClO_4$	250	~1.00		No triplets
		350	0.98	0.02	No triplets
4000	$LiCF_3SO_3$	250	0.41	0.44	0.15
		350	0.28	0.53	0.19
	$LiClO_4$	250	0.94	0.06	No triplets
		350	0.80	0.20	No triplets

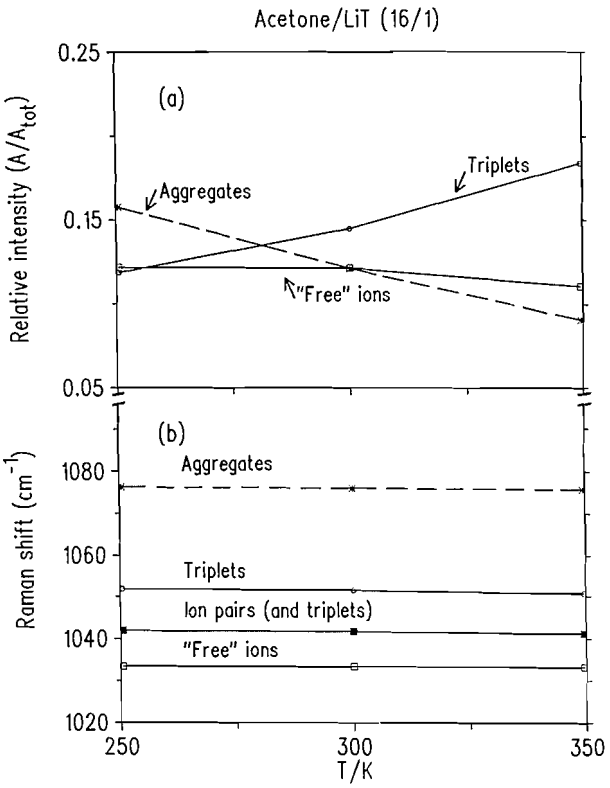

FIG. 3. (*a*) Acetone/$LiCF_3SO_3$ (LiT): relative intensities of the band profile of the Raman (A_1SO_3) spectrum as a function of temperature for "free" ions, triplets ($Li^+CF_3SO_3^-Li^+$) and aggregates. (*b*) Acetone/$LiCF_3SO_3$: peak frequencies of the band profile of the Raman (A_1, SO_3) spectrum as a function of temperature.

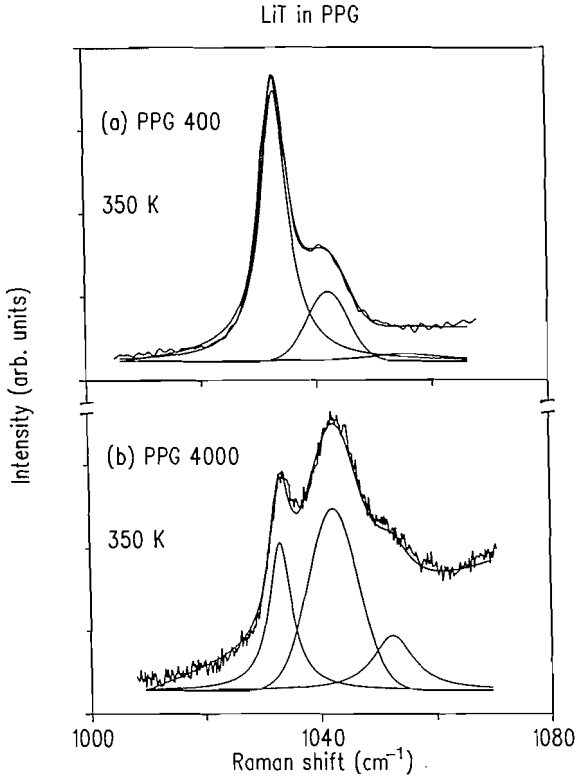

FIG. 4. (*a*) PPG 400/$LiCF_3SO_3$ (LiT) (O:Li = 6:1): Raman (A_1,SO_3) profile at 350 K; raw data above and background subtracted, deconvoluted below showing fitted components. (*b*) PPG 4000/$LiCF_3SO_3$ (O:Li = 16:1): Raman (A_1SO_3) profile at 350 K; raw data above and background subtracted, deconvoluted below showing fitted components.

1033 cm^{-1} (FWHM = 3 cm^{-1}) is suggested to be due to "free" ions. The Gaussian peak at 1042 cm^{-1} is assigned to contact ion pairs and $CF_3SO_3^-Li^+CF_3SO_3^-$ triplets and the very weak Lorentzian peak at 1055 ± 5 cm^{-1} is suggested to be due to $Li^+CF_3SO_3^-Li^+$ triplets. Figure 4(*b*) shows the $\nu_1(A_1,SO_3)$ profile at 350 K for PPG 4000/$LiCF_3SO_3$ (O:Li = 16:1). In Fig. 4(*b*) the lowest (Lorentzian, "free" ion) component peaks at 1032 cm^{-1} (FWHM = 2 cm^{-1}), the second (Gaussian) component at 1041 cm^{-1}, and the highest frequency (Lorentzian, triplet) component at 1052 cm^{-1}. As in Fig. 3(*b*), there is no change in these frequencies with temperature. Table 1 lists the relative intensities at 250 and 350 K for $LiCF_3SO_3$ and $LiClO_4$ in PPG 400 and PPG 4000 (O:Li = 16:1). The "free" ion component in $\nu_1(A_1,ClO_4)$ for the PPG/$LiClO_4$ complex peaks at 931 cm^{-1}.

From the experimental evidence (i.e., more "free" ions in PPG than in acetone for the same salt concentration), it is concluded that PPG is a better solvent for these salts than acetone, which is a very good solvent. This means that PPG should not be included in the class of apolar aprotic solvents like methyl acetate (22) and ethyl acetate (3) although they have about the same ϵ_r values as PPG (but much lower DN and μ values). (See Reichardt's Fig. 3.3 for defiinitions (11)). An explanation for this result is difficult; comments using values of ϵ_r, DN, and μ can be made but as pointed out above, probably gloss over the complex explanation. ϵ_r increases with

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/07/12
For personal use only.

salt concentration in these PPG–salt complexes (23) as it does for most organic solvent/salt systems (≤0.3 M) (22). For PPG, DN is higher and μ is quite a bit higher. The orientation of dipolar aprotic solvent molecules around ions in the absence of specific ion–solvent interactions is determined largely by dipole moment (11). Here we also have the specific donor–acceptor relationship between the solvent and the cation. Since PPG is such a good solvent for these salts, since our spectral resolution is very good, and since there is good agreement between the frequencies of the low frequency peaks in the (A_1,ClO_4), and (A_1SO_3) Raman modes in water/salt solutions and solvent/salt solutions, we believe that these low frequency peaks are due to essentially free anions and not to solvent separated (or loose) ion pairs.

Conclusions

We conclude that "free" ions are present in PPG/$LiClO_4$ and PPG/$LiCF_3SO_3$ complexes and that PPG is a better solvent for these salts than acetone. Triple ions were not detected in PPG/$LiClO_4$ complexes but are suggested to be present in PPG/$LiCF_3SO_3$ and acetone/$LiCF_3SO_3$ systems. For PPG/$LiCF_3SO_3$ complexes, the fraction of "free" ions at room temperature is much greater than the fraction of triplets.

Solvation of the proton and the trifluoromethanesulfonate ion in eight solvents

ROBERT L. BENOIT AND DANIEL FIGEYS

Département de chimie, Université de Montréal, C.P. 6128, Succ "A", Montréal (Qué.), Canada H3C 3J7

Received February 25, 1991

ROBERT L. BENOIT and DANIEL FIGEYS. Can. J. Chem. **69**, 1985 (1991).

The enthalpies of solution of a sterically hindered aromatic diamine, 1,8-bis(dimethylamino)naphthalene (proton sponge, PS) and of its trifluoromethanesulfonate salt, and of trifluoromethanesulfonic acid have been determined in water, methanol (MeOH), ethanol (EtOH), pyridine (Py), dimethyl sulfoxide (Me_2SO), dimethylformamide (DMF), acetonitrile (MeCN), and sulfolane (Sul). Single ion enthalpies of transfer for $CF_3SO_3^-$ and H^+, from Me_2SO to the other solvents, have been calculated using two extrathermodynamic assumptions, namely the tetraphenylarsonium–tetraphenylborate one and the recently proposed assumption based on the equality of transfers of uncharged PS and its conjugated cation PSH^+. While both sets of transfer enthalpies using each assumption, for $CF_3SO_3^-$ and H^+, differ by some 12 kJ mol^{-1} for water and MeOH, the values are in satisfactory agreement for Py, DMF, Me_2SO, and Sul. These results support the validity of both extrathermodynamic assumptions for the nonprotogenic solvents, thus putting on firm ground the solvent basicity scale based on the enthalpy of transfer of H^+ (in kJ mol^{-1}): Py(−63) > DMF(−32) > Me_2SO(−27) > EtOH(−1) ~ H_2O(0) ~ MeOH(+2) > PC(+44) > MeCN(+55) > Sul(+68). These values correlate well with the enthalpies of complex formation with boron trifluoride.

Key words: solvation, proton, trifluoromethanesulfonate ion, proton sponge, extrathermodynamic assumption.

ROBERT L. BENOIT et DANIEL FIGEYS. Can. J. Chem. **69**, 1985 (1991).

On a déterminé les enthalpies de solution d'une diamine aromatique encombrée stériquement, la 1,8-bis(dimethylamino)-naphtalène (PS) et de son trifluorométhanesulfonate, et de l'acide trifluorométhanesulfonique dans l'eau, le méthanol (MeOH), l'éthanol (EtOH), la pyridine (Py), le diméthylformamide (DMF), le diméthylsulfoxyde (Me_2SO), l'acétonitrile (MeCN) et le sulfolane (Sul). On a calculé les enthalpies de transfert des ions $CF_3SO_3^-$ et H^+, du Me_2SO aux autres solvants, en utilisant deux hypothèses extrathermodynamiques, l'hypothèse tétraphénylarsonium–tétraphenylborate et l'hypothèse proposée récemment et basée sur l'égalité des transferts de la base neutre PS et de son cation conjugué PSH^+. Si les deux séries d'enthalpies de transfert utilisant chaque hypothèse pour $CF_3SO_3^-$ et H^+, différent d'environ 12 kJ mol^{-1} avec H_2O et MeOH, l'accord des valeurs est satisfaisant avec Py, DMF, Me_2SO and Sul. Ces résultats confirment la validité des deux hypothèses extrathermodynamiques pour les solvants non-protogéniques et permettent d'établir une échelle de basicité de solvants basée sur l'enthalpie de transfert de H^+ (en kJ mol^{-1}) : Py(−63) > DMF(−32) > Me_2SO(−27) > EtOH(−1) ~ H_2O(0) ~ MeOH(+2) > PC(+44) > MeCN(+55) > Sul(+68). Ces valeurs donnent une bonne corrélation avec les enthalpies de formation des complexes avec le trifluorure de bore.

Mots clés : solvatation, proton, trifluorométhanesulfonate, proton sponge, hypothèse extrathermodynamique.

Introduction

Single ion thermodynamics is a subject of considerable interest in its relation to the study of solvent effects on physicochemical properties and reactivity parameters. Efforts are currently being made to rationalize thermodynamic transfer functions of single ions (for example, the enthalpy of transfer) from a reference solvent to another solvent, in terms of properties of the ions and solvents (1). However, single ion transfer values can only be obtained with the help of a so-called extrathermodyamic assumption. Among the proposed assumptions (2) the tetraphenylarsonium–tetraphenylborate (TATB) assumption is widely preferred. It assumes the equality of the transfer functions, such as the enthalpy, for the related large symmetrical cation $As\Phi_4^+$ and anion $B\Phi_4^-$, $\Delta H_t^0(As\Phi_4^+) = \Delta H_t^0(B\Phi_4^-) = \frac{1}{2}\Delta H_t^0(As\Phi_4B\Phi_4)$. This assumption has nevertheless been criticized, mainly on spectroscopic grounds (3). It is clear that the validity of the TATB assumption would be considerably strengthened if a different assumption could be shown to give comparable values for the transfer functions of selected ions.

We have recently proposed and discussed (4) the basis and merits of such an assumption which calls, this time, for the equality of the transfer functions for an uncharged base, PS, and its conjugate cation, PSH^+, so that for example $\Delta H_t^0(PS) = \Delta H_t^0(PSH^+)$, where PS (proton sponge) stands for 1,8-bis(dimethylamino)naphthalene.

We are now reporting enthalpy data which lead us to compare values of the enthalpies of transfer between solvents for the ions $CF_3SO_3^-$ and H^+, as obtained using both the TATB assumption and the new PS/PSH^+ assumption. Our results demonstrate that both of these quite different hypotheses are compatible for transfers between five nonprotogenic solvents.

Experimental

Chemicals

Proton sponge (Aldrich) was recrystallised according to the procedure of De Groot and Sikkema (5). 1,8-Bis(dimethylamino)naphthalenium trifluoromethanesulfonate[1] was prepared by adding either an ethanol solution or pure trifluoromethanesulfonic acid[1] to an ethanol solution of 0.1–0.3 M proton sponge to reach the 1:1 equivalent point, as determined potentiometrically. The fine salt precipitate formed was filtered, washed with cold ethanol, and dried. pH measurements in water and Me_2SO showed the salt to be free of acidic or basic impurities. $SbCl_5$ (Aldrich 99.99%) and anhydrous HCl (Alpha gas 99.0%) were used as received. Acetonitrile (Fisher Scientific, optima grade, water ≤ 0.01%), pyridine (A&C reagent), dimethyl sulfoxide (BDH, analytical reagent), dimethylformamide (ACP, reagent), methanol (A&C, spectrograde), and ethanol (Anachemia) were used as received. Sulfolane (Aldrich) was vacuum distilled twice, the first time with CaH_2 (~3–5 g/L). Trifluoromethanesulfonic acid (Aldrich) was distilled under reduced pressure before use. The preparation of tetraethylammonium trifluoromethanesulfonate has already been described (6).

[1]Written as CF_3SO_3PSH rather than $PSHCF_3SO_3$ for easier comparison of data with trifluoromethanesulfonic acid which is written, as is customary, CF_3SO_3H.

Apparatus and procedure

Heats of solution were measured at 25.00 ± 0.01°C (30.00 ± 0.01°C for sulfolane) with an L.K.B. model 8721-1 isoperibol calorimeter as previously described (4). The calorimeter was connected to a home-made digital-analog circuit and a Zenith computer. A program was written in Basic to process the resistance–time signals of the calorimeter (7). The performance of the calorimeter was checked by determining the solution enthalpy of dried tris(hydroxymethyl)aminomethane (Aldrich) in 0.1 M aqueous HCl at 25.00 and 30.00°C. The values obtained were within 1% from literature data (8). This accuracy, although moderate, was adequate for our purpose. For each solute at least three measurements were made at different concentrations. Because of the unavoidable presence of some acidic or basic impurities at the 10^{-3} M level (3) in a few solvents, some measurements were made in these solvents using successive, instead of independent, additions of solutes and neglecting the first value. For example, with pyridine the heat of solution of CF_3SO_3PSH was found to be abnormally exothermic up to 5×10^{-3} M and this concentration corresponded exactly to the concentration of a strongly basic NH_3 impurity which neutralized PSH^+. With Me_2SO from Anachemia which contained a 1.9×10^{-3} M moderately strong acid (possibly HNO_3 since NO_2 is used as catalyst in the gas phase synthesis of Me_2SO) abnormal values were obtained for the enthalpies of solution of PS. Me_2SO from BDH had only 2×10^{-4} M acid and the enthalpy of solution of PS above this concentration was constant within the experimental errors. The possible influence of small concentrations of water present in some solvents on the enthalpy of solution of PS was also considered. This influence should be minimal since the enthalpies of solution of PS in water and the other solvents are not too different (Table 1) and the hydrolysis reaction of PS in solvent–water corresponds to $k_b \sim 10^{-1.8}$ and $\Delta H^0 \sim -11$ kJ mol^{-1} (4). Nevertheless, some experiments were carried out using the solvent MeCN, where the activity of water is high (20), and adding water up to 0.4 M. The solution enthalpy of PS, at the 5×10^{-3} M concentration level, was found to be +24.8 ± 0.4 kJ mol^{-1} (5 measurements) to be compared with +24.5 ± 0.3 kJ mol^{-1} (Table 1) so that the influence of water, if any, is well within our experimental errors.

Results

The molar enthalpies of solution of proton sponge (PS) and of its trifluoromethanesulfonate salt CF_3SO_3PSH, and of trifluoromethanesulfonic acid were determined in water, methanol (MeOH), ethanol (EtOH), pyridine (Py), dimethyl sulfoxide (Me_2SO), dimethylformanide (DMF), acetonitrile (MeCN), and sulfolane (Sul). Then, the enthalpies of transfer of PSH^+, $CF_3SO_3^-$, and H^+ were calculated.

1. Enthalpies of solution

Proton sponge

The plots of the heat of solution of PS against the number of moles dissolved (concentration range 0.8–7.5 $\times 10^{-3}$ M) are linear and the least-square slopes gave the molar enthalpy of solution of PS, which corresponds to reaction [1]:

[1] $\quad PS(c) = PS(s)$

The ΔH^0_{cs} values for the solvents, with their standard deviations, are given in Table 1 together with the value for water obtained indirectly (4).

Trifluoromethanesulfonate salt

The heats of solution of the salt CF_3SO_3PSH were plotted against the number of moles dissolved. The least-square slopes of the linear plots led to the molar enthalpy of solution $\Delta H_{csi}(CF_3SO_3^-\ PSH^+)$ for reaction [2].

[2] $\quad CF_3SO_3^-\ PSH^+(c) = PSH^+(s) + CF_3SO_3^-(s)$

In the concentration range studied ((0.8–5.3) $\times 10^{-3}$ M) the concentration dependence of the enthalpy of solution for a uni-univalent electrolyte is small (9) and masked by experimental errors. Possible ion-pairing effect at these low concentrations was also neglected on account of the nature of both anion and cation. The ΔH^0_{csi} values are listed in Table 1.

Trifluoromethanesulfonic acid

In the most basic solvents, H_2O, MeOH, EtOH, Me_2SO, and DMF, CF_3SO_3H is a strong electrolyte so that its solution corresponds to reaction [3] with its ΔH^0_{lsi}

[3] $\quad CF_3SO_3H(l) = H^+(s) + CF_3SO_3^-(s)$

However, in less basic MeCN and Sul the ionization of CF_3SO_3H is only partial, the pK's being respectively 2.5 (MeCN) (10) and 3.6 (Sul) (6) so that the solution of CF_3SO_3H involves both reactions [4] and [5] with their respective enthalpy changes ΔH^0_{ls} and ΔH^0_{si}.

[4] $\quad CF_3SO_3H(l) = CF_3SO_3H(s)$

[5] $\quad CF_3SO_3H(s) = H^+(s) + CF_3SO_3^-(s)$

Then we observe

[6] $\quad \Delta H_{obs} = \Delta H^0_{ls} + \alpha \Delta H^0_{si}$

where α the degree of ionization of CF_3SO_3H is obtained from the above pK values.

In order to calculate the enthalpy of transfer of the anion–cation pair $CF_3SO_3^-H^+$, we need to know the enthalpy change ΔH^0_{lsi} for reaction [3],

[7] $\quad \Delta H^0_{lsi} = \Delta H^0_{ls} + \Delta H^0_{si}$

We have already found that for moderately strong acids (chloroacetic acids in water (11)) it is not practical to determine ΔH^0_{ls} and ΔH^0_{si} from eq. [6] and values of ΔH_{obs} for different values α, i.e., of total acid concentrations. We have therefore determined ΔH^0_{ls} and ΔH^0_{si} separately. First, we approximate ΔH^0_{ls} by measuring the heat of solution of $CF_3SO_3H(l)$ in a 0.2 M CF_3SO_3H solution in MeCN or Sul. The correction for $\alpha \Delta H^0_{si}$ (eq. [6]) is negligible because α is small and $\Delta H^0_{si} < \Delta H^0_{ls}$. Second, we approximate $-\Delta H^0_{si}$. as the difference between the heat of solution of $CF_3SO_3NEt_4(c)$, first in the solvent containing 0.2 M HCl–$SbCl_5$, a strong acid (6), then in the solvent alone. This procedure, which has already been used in the case of sulfolane (6), was used for MeCN.

Values of ΔH^0_{lsi} for CF_3SO_3H in the most basic solvents of the series were obtained directly as described for $CF_3SO_3^-PSH^+$ and are reported in Table 1. For pyridine, with a 12.3 dielectric constant, although CF_3SO_3H is certainly a strong acid, like ClO_4H and HI (12), the ion-pair $CF_3SO_3^-PyH^+$ dissociation constant is estimated to be $\sim 10^{-3}$ (12). Since we did not observe a variation of the heat of solution of CF_3SO_3H between 0.009 and 0.05 M, we concluded that the enthalpy of dissociation of the ion-pair could be neglected.

2. Enthalpies of transfer

The enthalpy of transfer ΔH^0_t of a solute from a reference solvent (r) to a solvent (s) is equal to the molar enthalpy of solution of the solution in solvent (s) minus its enthalpy of solution in solvent (r). Thus for PS we have, from eq. [1],

TABLE 1. Enthalpies of solution of proton sponge PS, CF_3SO_3PSH, and CF_3SO_3H at 25°C

Solvent	ΔH_s^0 (kJ mol^{-1})			
	PS(c)[a]	CF_3SO_3PSH(c)[b]	$CF_3SO_3H(l)$[c]	$CF_3SO_3H(l)$[d]

[b] From data in ref. 13 using the TATB assumption.
[c] From data in ref. 14 for the transfer of H^+Cl^- and using the TATB assumption.
[d] From data in Table 1 for the transfer of $H^+CF_3SO_3^-$ and $\Delta H_t^0(CF_3SO_3^-)$ (column b) from ref. 13 using the TATB assumption.
[e] See text.

[8] $$\Delta H_t^0(PS) = \Delta H_{rs}^0(PS) = \Delta H_{cs}^0(PS) - \Delta H_{cr}^0(PS)$$

While water is usually selected as the reference solvent, particularly when dealing with ionic transfers (1), we found it more convenient here to take Me_2SO as the reference solvent (r) in part because the heat of solution of PS in water has a high ±5 kJ mol^{-1} margin of error.

Similarly, for the transfer of the salt CF_3SO_3PSH we have, according to eq. [2],

[9] $$\Delta H_{rs}^0(CF_3SO_3^-) + \Delta H_{rs}^0(PSH^+) = \Delta H_{csi}^0(CF_3SO_3PSH) - \Delta H_{cri}^0(CF_3SO_3PSH)$$

Using the extrathermodynamic assumption

[10] $$\Delta H_{rs}^0(PS) = \Delta H_{rs}^0(PSH^+)$$

we obtain

[11] $$\Delta H_{rs}^0(CF_3SO_3^-) = \Delta H_{csr}^0(CF_3SO_3PSH) - \Delta H_{cri}^0(CF_3SO_3PSH) - [\Delta H_{cs}^0(PS) - \Delta H_{cr}^0(PS)]$$

[12] $$\Delta H_{rs}^0(H^+) = \Delta H_{lsi}^0(CF_3SO_3H) - \Delta H_{lri}^0(CF_3SO_3H) - \Delta H_{rs}^0(CF_3SO_3^-)$$

The calculated enthalpies of transfer of PSH^+, $CF_3SO_3^-$, and H^+ with their corresponding errors are given in Table 2 together with the transfer values obtained from literature data with the TATB assumption (13, 14).

Discussion

The transfer enthalpies of $CF_3SO_3^-$ and H^+, derived from both extrathermodynamic assumptions (Table 2), can be compared for two hydroxylic solvents and three nonprotogenic solvents. First, we note that for H_2O and MeOH, the $\Delta H_{rs}^0(CF_3SO_3^-)$ or $\Delta H_{rs}^0(H^+)$ values corresponding to the PS/PSH^+ and TATB assumptions differ by some 12 kJ mol^{-1}. Second, for the solvents DMF and MeCN, the difference is now reduced to some 2 kJ mol^{-1}. We also see differences between the $\Delta H_{rs}^0(H^+)$ values obtained with the same TATB assumption but different experimental data, either based on the ionization of CF_3SO_3H or on that of HCl (14). Such differences, which come from experimental errors resulting from the many steps involved in the various thermochemical paths, give an idea of the margin of error on the transfer values. On this basis the agreement between the transfer values obtained with the PS/PSH^+ and TATB assumptions for the solvents Me_2SO, DMF, MeCN, and Sul can be considered satisfactory.

Both extrathermodynamic assumptions used here are quite different, assuming the equality of transfers either for a neu-

For personal use only.

tral and a cation (PS/PSH^+) or for an anion and a cation ($B\Phi_4^-/As\Phi_4^+$) so that the agreement gives credence to both assumptions and the values obtained. The question remains as to why both assumptions are not compatible when considering hydroxylic solvents. We may assume that the PS/PSH^+ hypothesis is the faulty one with this solvent class. A possibility which comes to mind is that weak H-bonding may take place between these solvents and PS through the weakly basic $-NMe_2$ group. We are now making additional measurements of the heat of solution of PS in a larger number of solvents to try to isolate some H-bonding contributions on the basis of the correlation equation using the solvatochromic parameters of the solvents.

It is worth pointing out that the enthalpies of transfer of $CF_3SO_3^-$ obtained by combining the values obtained with the TATB and PS/PSH^+ assumptions (the latter for Py and Sul) are consistently low: using now H_2O as the reference solvent we have for ΔH^0_{ws}(kJ mol^{-1}), H_2O (0), MeOH (+4.4), Py (+6.2), Me_2SO (+1.2), DMF (−3.4), MeCN (+2.5), Sul (+3.9). This observation has an interesting consequence in that the enthalpy of transfer of CF_3SO_3H(l) can be used to approximate the enthalpy of transfer of H^+ for solvents when no data are available for the transfer of $CF_3SO_3^-$

$$[13]\quad \Delta H^0_{rs}(H^+) = \Delta H^0_{rs}(CF_3SO_3H) - \Delta H^0_{rs}(CF_3SO_3^-) \sim \Delta H^0_{rs}(CF_3SO_3H)$$

Thus for EtOH we estimate $\Delta H^0_{rs}(H^+) \sim +26$ kJ mol^{-1}. This latter value indicates that the basicities of bulk EtOH, and of MeOH and H_2O are indeed very close, a valuable result since there are apparently no $\Delta H^0_{ws}(H^+)$ data available for EtOH and MeOH (15).

By combining the TATB and PS/PSH^+ results in Table 2 (using the sixth column for H_2O, MeOH, EtOH, and averaging for the other solvents), the following basicity order for the solvents is deduced form the $\Delta H^0_{ws}(H^+)$ values in kJ mol^{-1} Py (−63) > DMF (−32) > Me_2SO (−27) > EtOH(−1) ~ H_2O(0) ~ MeOH(+2) > PC[2](+44) > MeCN(+55) > Sul(+69). We tried to correlate these enthalpies of transfer of H^+ with the solvents' solvatochromic parameters as was done before (1) but with, in our opinion, more reliable values. The correlation was poor but the number of solvents is still too limited for a good statistical evaluation of the data using the three relevant solvatochromic parameters, Π^*, α, and β.

The following interesting correlation has been found between the above enthalpies of transfer of H^+ and the enthalpies of complex formation with BF_3(g), which have been used as a measure of nonprotogenic solvent Lewis basicity (16):

$$[14]\quad \Delta H^0_{ws}(H^+) = (1.72 \pm 0.03)\Delta H^0_{gs}(BF_3) + (157 \pm 3)$$
$$N = 6, \qquad r = 0.999, \qquad \text{sd} = 2.2 \text{ kJ mol}^{-1}$$

The ranges covered for $\Delta H^0_{ws}(H^+)$ and $\Delta H^0_{gs}(BF_3)$ are, respectively, 132 and 77 kJ mol^{-1}. Considering that H^+ is a Brønsted acid and BF_3 a Lewis acid, although both may be considered "hard" acids, the results of the correlation are surprisingly good. As a matter of fact, the correlation is much better than that between $\Delta G^0_{ws}(H^+)$ and $\Delta H^0_{gs}(BF_3)$($N = 6, r = 0.891$, sd = 18 kJ mol^{-1}), one of the many relationships involving BF_3 already examined by Maria and Gal. Over and above its intrinsic interest (16), this correlation adds further support to the validity of our reported $\Delta H^0_{ws}(H^+)$ values for the nonprotogenic solvents.

Finally, it should be pointed out that conjugated B/BH^+ systems similar to PS/PSH^+ could also be used as the basis of related extrathermodynamic assumptions provided that BH^+ is a large cation with non-specific solvation (4), thus excluding for example Hammett-type bases (2). Macrocyclic ligands are clearly good candidates for such assumptions, and indeed they have been used to evaluate single-ion transfer parameters for ions such as Ag^+, Tl^+, K^+, Na^+ (see for example refs. 17 and 18). However, the present authors are not aware of any report on the use of macrocylic ligands to evaluate directly $\Delta H^0_t(H^+)$. It may be that the encapsulation of small species like H^+ in such ligands presents some particular problems (19).

[2]PC for propylene carbonate, value in ref. 14.

Microbial oxidation of benzyl sulfides and bibenzyl by *Mortierella isabellina* and *Helminthosporium* species

HERBERT L. HOLLAND, CYNTHIA G. RAND, PETER VISKI, AND FRANCES M. BROWN
Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received April 25, 1991

HERBERT L. HOLLAND, CYNTHIA G. RAND, PETER VISKI, and FRANCES M. BROWN. Can. J. Chem. **69**, 1989 (1991).

The biotransformation of 1,2-diphenylethane by the fungus *Mortierella isabellina* ATCC 42613, and that of a series of alkyl benzyl sulfides by the fungi *M. isabellina* and *Helminthosporium species* NRRL 4671 have been studied. *Mortierella* hydroxylates 1,2-diphenylethane in low yield, giving (*S*)-1,2-diphenylethanol with an enantiomeric purity of 33%. Bioconversions of deuterium-labelled and racemic 1,2-diphenylethanol by *M. isabellina* demonstrate that this organism performs reversible oxidation/reduction of the alcohol. Biotransformations of *n*-alkyl benzyl sulfides by *H.* species give predominantly the (*S*) enantiomer of sulfoxide, with no sulfone formation, but *M. isabellina*, although showing a general preference for the oxidation of alkyl benzyl sulfides to (*R*) sulfoxides, also generates sulfones from *n*-alkyl benzyl sulfides in a time-dependent manner that suggests a stereoselective removal of (*R*) sulfoxide. The latter microorganism can be used, however, for the production of (*R*)-benzyl methyl and benzyl isopropyl sulfoxides, and gives (*S*)-benzyl *tert*-butyl sulfoxide in low yield.

Key words: biotransformation, enzymes, sulfoxides.

HERBERT L. HOLLAND, CYNTHIA G. RAND, PETER VISKI et FRANCES M. BROWN. Can. J. Chem. **69**, 1989 (1991).

On a étudié la biotransformation du 1,2-diphényléthane par le champignon *Mortierella isabellina* ATCC 42613 et celle d'une série de sulfures d'alkyle et de benzyle par les champignons *M. isabellina* et *Helminthosporium* NRRL 4671. Le *M. isabellina* provoque une hydroxylation du 1,2-diphényléthane avec un faible rendement conduisant au (*S*)-1,2-diphényléthanol, avec une pureté énantiomérique de 33%. Les bioconversions, par le *M. isabellina*, des 1,2-diphényléthanols racémiques et marqués au deutérium démontrent que cet organisme provoque une oxydoréduction réversible de l'alcool. Les biotransformations, par les espèces *H.*, des sulfures de *n*-alkyles et de benzyle conduisent principalement aux énantiomères (*S*) des sulfoxydes, sans formation de sulfone. Par ailleurs, même si le *M. isabellina* montre une préférence générale pour l'oxydation des sulfures d'alkyles et de benzyle en (*R*)-sulfoxydes, il conduit aussi à la formation de sulfones; la quantité de sulfone qui se forme en fonction du temps suggère qu'il y a un enlèvement stéréosélectif du sulfoxyde (*R*). On peut toutefois utiliser ce dernier micro-organisme pour produire, avec de faibles rendements, les sulfoxydes (*R*) de benzyle et de méthyle (ou de benzyle et d'isopropyle) et le sulfoxyde (*S*) de benzyle et de *tert*-butyle.

Mots clés : biotransformation, enzymes, sulfoxides.

[Traduit par la rédaction]

Introduction

Microbial biotransformation is now generally recognized as the simplest and most direct method for the preparation of a range of optically active sulfoxides of moderate to high enantiomeric purity (1), the most frequently studied group of substrates for this reaction being diaryl or alkyl aryl sulfides (1). Biotransformations or bioconversion has also been used as a method for the direct introduction of the hydroxyl group at the benzylic position of a range of unsubstituted and substituted aromatic hydrocarbons (2–4). Among the microorganisms most commonly employed for sulfoxidation are the fungi *Mortierella isabellina* NRRL 1757 (ATCC 42613), and *Helminthosporium* species NRRL 4671 (1, 5–7); the former organism has also been extensively examined for its ability to perform the benzylic hydroxylation reaction (2–4).

In spite of the widespread application of these fungi for asymmetric sulfoxidation, and the early demonstration that benzyl sulfides are good substrates for biotransformation by other organisms (8), and in the light of a renewed interest in the production of chiral benzyl sulfoxides (9), it is surprising that there has been no systematic study of the use of *M. isabellina* or *H.* species for the bioconversion of benzyl sulfides. We now present the results of the biotransformation of the series of benzyl sulfides **8**–**15** by both these microorganisms. An additional reason for this study was to assess the degree of competition (if any) between S and C oxidation when both atoms are in a benzylic position, and to this end we have also studied the biotransformation of the cyclic sulfide **16**, diphenyldisulfide **17**, and 1,2-diphenylethane (**1**) by *M. isabellina*.

Bioconversions of 1,2-diphenylethane (**1**) by *M. isabellina* (summarized in Table 1) proceeded very slowly, giving only a low yield of the corresponding alcohol **2** of moderate enantiomeric purity, assigned the (*S*) configuration on the basis of optical rotation measurements.

It was our intention to use the deuterium-labelled substrate **4** to study the intramolecular deuterium kinetic isotope effects associated with the benzylic hydroxylation reaction, but control experiments in which the expected product of such a reaction, the labelled alcohol **5**, was used as a substrate revealed that deuterium geminal to the hydroxyl group was lost to the extent of 75% over a 3-day period. That this loss was due was due to oxidation to the ketone **3** and subsequent reduction of the latter was confirmed following incubation of **3**, when a moderate yield of alcohol **2** was obtained. In confirmation of this, the use of racemic **2** as a substrate resulted in the isolation of the (*S*) enantiomer of **2** in high yield following 3 days in contact with *M. isabellina*.

The enantiomeric purity of **2** produced by carbonyl reduction (91%) is considerably higher than that obtained from biotransformation of the racemate (68%), or from hydroxylation of **1** (33%), a phenomenon attributable to incomplete processing of the racemic alcohol and an unknown stereoselectivity in the hydroxylation reaction, respectively. In the case of the labelled substrate **5** it was possible to assess both the overall optical purity of the product (by optical rotation), and the optical purity of that portion of the product which had lost deuterium (by ^{1}H nmr analysis in the presence of chiral shift reagent using the C*H*OH resonance). The results, listed in Table 2, clearly

illustrate that the portion of the product which has undergone oxidation/reduction (and hence lost deuterium) has an enantiomeric purity (88%) identical (within experimental error) to that produced by carbonyl reduction (91%), confirming that the loss of label does indeed result from an oxidation/reduction process. The bioconversion of labelled substrate **7** without any loss of deuterium confirmed that no loss of label occurs from the α position (for example by carbonyl enolization), but in view of the potential complexity of the analysis of any results which might follow from biotransformation of **4**, this substrate was not investigated further.

The results obtained from biotransformation of the sulfides **8**–**16** are listed in Tables 2 and 3. Table 2 presents product yields and enantiomeric excesses, from which it is apparent that, although yields are reasonable in most cases, sulfoxides are rarely formed with high enantiomeric purity. The absolute configurations of the sulfoxides listed in Tables 2 and 3 were determined by comparison of the sign of rotation values with those in the literature. This correlation is well established for benzyl alkyl sulfoxides, the relevant references being those listed in Table 3.

Helminthosporium species failed to oxidize the aryl benzyl sulfides **8** and **9**, the low isolated yields of racemic sulfoxide being possibly the result of autooxidation, but gave consistently the (*S*) enantiomer of alkyl benzyl sulfoxides, with the exception of benzyl isopropyl sulfoxide (**13**), which was formed as the racemate. In the case of oxidation of benzyl *n*-propyl sulfide (**12**), the low yield of close to racemic material prompted us to carry out a control incubation using autoclaved fungus, but no autooxidation was apparent. The ability of *H.* species to convert alkyl aryl sulfides to (*S*) sulfoxides is well documented (1), so that the formation of (*S*) alkyl benzyl sulfides by this microoganism is not unexpected.

Oxidations of benzyl sulfides by *H.* species were characterized by the absence of sulfone products, unlike many of the bioconversions of these substrates by *M. isabellina*, which were complicated by the formation of sulfone in a time-dependent manner. Although no sulfones were produced from the aryl benzyl sulfides **8** and **9**, the biotransformation of alkyl benzyl sulfides resulted in the formation of sulfone from all substrates except benzyl *tert*-butyl sulfide (**15**). *Mortierella isabellina* rarely produces sulfone products from bioconversion of alkyl aryl sulfides (1).

The absolute stereochemistry of the sulfoxides produced from *n*-alkyl benzyl sulfides was found to be dependent upon both the biotransformation time and the amount of sulfone produced. This dependence suggests that, although the initial oxidation of sulfide to sulfoxide may occur with a slight preference for the production of the (*R*) enantiomer (see Table 2, for example **11** after 10 h), consistent with the observation that alkyl aryl sulfides were converted predominantly to (*R*) sulfoxides by this fungus (1), subsequent oxidation of sulfoxide to sulfone involves a substantial preference for removal of the (*R*) enantiomer. After long bioconversions (e.g., 48 h for **11**), sulfoxide enriched in the (*S*) enantiomer remains, and in the case of substrates **12** and **14** this phenomenon is manifested as an increase in the proportion of the (*S*) enantiomer as the bioconversion period (and hence the production of sulfone) is increased.

In an attempt to investigate the stereochemistry of the sulfoxide–sulfone oxidation, racemic sulfoxides derived from the *n*-alkyl benzyl sulfides **10**–**12** and **14** were prepared and used as substrates for bioconversion by *M. isabellina*. In all cases the only isolable material consisted of racemic sulfoxide, recovered in almost quantitative amount: no sulfone products were detected. We considered that this may be attributable to the inability of sulfoxide to induce the necessary oxidative enzymes in *M. isabellina*, and therefore performed a series of incubations of sulfoxides in which the microorganism had been grown in the presence of a small amount of the corresponding sulfide, but again no sulfoxide oxidation was observed.

[a]Solvent EtOH unless otherwise stated.

This inability of *M. isabellina* to convert sulfoxides to sulfones distinguishes this microorganism from many others (e.g., *Aspergillus niger*) that can be used to perform this bioconversion in a stereoselective manner (1). We were also unable to detect any sulfide products that may have arisen from sulfoxide reduction, a mode of biotransformation which is expressed by *M. isabellina* with other substrates (1).

We attribute the inability of *M. isabellina* to oxidize the sulfoxides used in this study to the failure of these sulfoxides to be accepted into the fungal cell, the location of the oxidative enzymes concerned (1). In this context it is noteworthy that, during sulfide biotransformation, the sulfoxide products are recovered exclusively from the aqueous bioconversion medium, suggesting that these materials, once excreted from the cell, do not reenter, and hence are not reoxidized from this environment. Oxidation of sulfoxide to sulfone during the biotransformation of sulfides must therefore occur immediately after formation of the former, and may take place even before dissociation of the sulfoxide from the enzyme's active site.

The general preference of *M. isabellina* for the production of (*R*) sulfoxides, established for the bioconversion of alkyl aryl sulfides (1), is seen in the bioconversion of benzyl isopropyl sulfide (**13**), where the (*R*) sulfoxide is obtained in an enantiomeric excess of 59%. Benzyl *tert*-butyl sulfide (**15**) is, however, oxidized to give predominantly the (*S*) enantiomer. This stereoreversal of benzyl sulfide oxidation in the presence of a *tert*-butyl substituent has also been observed for bioconversions carried out by *A. niger* (8), and oxidation by sodium metaperiodate in the presence of bovine serum albumin (13), and is rationalized by the assumption that the stereopreference for oxidation of benzyl alkyl sulfides is controlled by the relative sizes of the two substituents. Whereas the benzyl group is considered to be bulkier than *n*-alkyl or isopropyl substituents, the opposite holds in the case of benzyl *tert*-butyl sulfide (11).

It is interesting to note that in cases where the substrate presents the possibility of competitive benzylic S vs. C oxidation (e.g., **8**, **9**, and **16**) only the products of sulfoxidation were detected. In this respect, the oxidative enzymes of *M. isabellina* differ from those obtained from mammalian

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

sources, where both modes of oxidative metabolism are observed (14).

The final substrate used in the present study, diphenyldisulfide (**17**), was remarkable in that its biotransformation by *M. isabellina* represents a new type of bioconversion reaction. The only isolable product, formed in low yield, was **18**, the sulfoxide of thioanisole. This product was obtained predominantly as the (*R*) enantiomer, with an enantiomeric purity (48%) close to that obtained from the *M. isabellina* catalyzed oxidation of thioanisole (55%) (15), suggesting a route for the formation of **18** involving reductive cleavage and methylation of **17**, although the order in which these processes occur is not clear.

It is therefore apparent that, although *Helminthosporium* species NRRL 4671 can be used for the production of (*S*) *n*-alkyl benzyl sulfoxides of moderate enantiomeric purity, the corresponding (*R*) sulfoxides cannot be obtained routinely from sulfide bioconversions using *M. isabellina*. The latter microorganism can be used, however, for the production of (*R*)-benzyl methyl and benzyl isopropyl sulfoxides, and gives (*S*)-benzyl *tert*-butyl sulfoxide in low yield.

Experimental

Apparatus, materials, and methods

Melting points were determined on a Kofler heating stage. Infrared spectra were recorded with an Analect 6260FX spectrometer. The nmr spectra were recorded at 200 MHz (^{1}H) or 50 MHz (^{13}C) with a Bruker AC200 spectrometer, using $CDCl_3$ as solvent and $CHCl_3$ as internal standard. Enantiomeric ratios were determined where possible by ^{1}H nmr analysis in the presence of tris[3-(heptafluoropropylhydroxymethylene)-*d*-camphorato]europium(III). Mass spectra were obtained with a Kratos Concept 1S instrument. Thin-layer chromatography was performed on Merck silica gel 60F-254 and flash column chromatography used silica gel, Merck 9385, or equivalent. Optical rotations were obtained at 20°C with a Rudloph Autopol III polarimeter.

Maintenance of microorganisms

Mortierella isabellina ATCC 42613 (equivalent to NRRL 1757) and *Helminthosporium* species NRRL 4671 were maintained on malt agar slopes.

Preparation of substrates

With the exception of those listed below, the substrates used in this study were commerical samples. All substrates gave satisfactory spectral data (^{1}H nmr, ^{13}C nmr, ms, and ir).

1,2-Diphenylethane, 1,1-d_2 *(**4**)*

This was prepared from 1,2-diphenylethanol (**5**) (see below), via conversion using thionyl chloride to the chloride **6** and treatment of the latter with lithium triethylborodeuteride as described elsewhere (3). The reactions were carried out as described with the exception of the $LiEt_3BD$ treatment of **6**, which needed a reaction time of 7 days under refluxing conditions in order to achieve acceptable conversion. Under these conditions, **4** was obtained in an overall yield of 70% from alcohol **5**, and identified by comparison with authentic unlabelled material. Deuterium content ≥99% d_2 by ms and ^{1}H nmr.

*1,2-Diphenylethanol, 1-*d *(**5**)*

This was prepared in 85% isolated yield by lithium aluminum deuteride reduction of 1,2-diphenylethanone (**3**) as described elsewhere (3), and identified by comparison with authentic unlabelled material. Deuterium content ≥99% d_1 by ms and ^{1}H nmr.

1,2-Diphenylethanol-2,2-d_2 *(**7**)*

A solution of 1,2-diphenylethanone (**3**, 2 g) in dry toluene (100 mL) was treated with a solution of sodium deuteroxide in deuterium oxide as described (16). The mixture was stirred and refluxed for 3 days, and the toluene layer then separated, dried, and evaporated to give labelled 1,2-diphenylethanone having the following isotopic composition (by ms): d_2 85%, d_1 8%, d_0 7%. This material was subsequently treated without loss of deuterium label with lithium aluminium hydride as described (5) to give alcohol **7**, identified by comparison with authentic unlabelled material.

Benzyl p-*tolyl sulfide (**9**)*

This was prepared by adding 1 equivalent of benzyl chloride to a solution of 1 equivalent of *p*-thiocresol and 1 equivalent of potassium hydroxide in ethanol, and refluxing the mixture overnight. The product was obtained in high yield following a conventional work-up procedure, and gave satisfactory analytical data.

*Benzyl alkyl sulfides **11–14***

These compounds were prepared from benzyl mercaptan and the corresponding alkyl halide by the procedure described (17), and gave satisfactory analytical data.

Benzyl tert-*butyl sulfide (**15**)*

This was prepared from *tert*-butyl methyl sulfide and phenyl magnesium bromide by the route described (18). The final product had bp 130°C (24 Torr; 1 Torr = 133.3 Pa) (lit.(18) bp 129–131°C (21 Torr)) and exhibited satisfactory spectral data.

*Thiochroman (**16**)*

A mixture consisting of thiochromanone (5 g), potassium hydroxide (5 g), hydrazine (85%, 4 mL), and ethylene glycol (50 mL) was heated under reflux for 1.5 h, and then raised in temperature to 195°C and maintained at that temperature for a further 4 h. The reaction was then cooled, poured onto water, and the mixture extracted with ether. The extract was dried and evaporated to give a residue that was purified by chromatography (benzene/silica gel) to give **16** (1.8 g) as an oil, identified by comparison of spectral data with those reported (19, 20).

Preparation of sulfoxide standards

Sulfoxide standards were prepared from the corresponding sulfides using sodium metaperiodate as oxidant by the procedure described (21), and exhibited spectral and physical properties in accord with those reported.

Biotransformations

These are summarized in Table 1 for bibenzyl hydroxylations and Table 2 for sulfoxidations.

Mortierella isabellina: Two slopes of *M. isabellina* were used to inoculate 15 1-L Erlenmeyer flasks each containing 200 mL of a medium composed of glucose (40 g), yeast extract (5 g), sodium chloride (5 g), dibasic potassium phosphate (5 g), and soya flour (5 g) per litre of distilled water. The flasks were allowed to stand overnight at 27°C and then placed on a rotary shaker at 180 rpm, and growth continued for a further period of 72 h at 27°C. The fungus was then harvested by centrifugation, and resuspended in 15 1-L Erlenmeyer flasks each of which contained 200 mL of distilled water. Substrate (1 g in 30 mL 95% ethanol) was then distributed over the flasks, which were incubated at 180 rpm and 27°C for the time specified in the tables. The fungus and aqueous medium were then separated by centrifugation, and the latter extracted with dichloromethane (continuous extraction for 3–4 days). Concentration of this extract gave the crude material, which was examined as outlined below.

Helminthosporium species: The procedures were carried out exactly as described above, with the following modifications. The growth medium was composed of V-8 juice and calcium carbonate (200 mL and 3 g, respectively, per litre of water), adjusted to pH 7.2 by addition of 1 M sodium hydroxide, and separation of the fungus from its growth and incubation media was carried out by vacuum filtration.

Incubations with autoclaved fungus

These were performed as described above, with the exception that the fungal material was sterilized by autoclaving in distilled water at 121°C for 20 min, and then allowed to cool prior to addition of the substrate.

Attempted induction of sulfoxidizing enzymes in M. isabellina

This was performed by the addition of a solution of benzyl ethyl sulfide (**11**) (300 mg) in ethanol (95%, 15 mL) to a 48 h old growth of *M. isabellina* (15 1-L flasks), followed by growth for a further period of 24 h. Subsequent procedures were performed exactly as described above.

Isolation and characterization of products

The crude biotransformation extracts obtained as outlined above were examined by tlc, and submitted to flash chromatography using a benzene–ether 10% stepwise gradient, followed by an ether–methanol 10% stepwise gradient in the case of sulfoxides derived from **10–14**. The yields and ee values quoted in the tables refer to purified, homogeneous material, and arise from the combination of (only) homogeneous column fractions without further purification (e.g., crystallization) that could lead to alteration of stereochemical enrichment values. Products were identified by a combination of nmr, mass spectral, infrared, and optical rotation analysis. Specific rotation values for sulfoxides of Table 2, and references to values for homochiral sulfoxides, are listed in Table 3. Typical procedures are outlined below for 1,2-diphenylethane hydroxylation and for a sulfide biotransformation.

*Biotransformation of 1,2-diphenylethane (**1**) by* M. isabellina

Incubation of **1** (4 g) with 60 flasks of *M. isabellina* for a period of 72 h, followed by removal of the fungus by centrifugation and continuous extraction of the aqueous medium, resulted in an extract (0.54 g) that on chromatography afforded recovered 1,2-diphenylethane (0.4 g) followed by 1,2-diphenylethanol (80 mg), identified by comparison with authentic material, and having $[\alpha]_D$ −21 (*c* 0.5, EtOH) (lit. (22) $[\alpha]_D$ +60.6 (*c* 1.54, EtOH), lit. (23) $[\alpha]_D$ +52.8 (*c* 5.0, (EtOH)).

Biotransformation of benzyl methyl sulfide by H. *species*

Incubation of **10** (1 g) with *H.* species for a period of 30 h, followed by filtration and extraction of the aqueous medium, gave an extract (0.88 g) that on chromatography afforded benzyl methyl sulfoxide (0.76 g, 68%), identified by comparison with authentic racemic material, $[\alpha]_D$ +59.8 (*c* 1.08, EtOH) (lit. (11) $[\alpha]_D$ +96 (EtOH)).

*Biotransformation of diphenyldisulfide (**17**)*

Incubation of **17** (1 g) with 15 flasks of *M. isabellina*, followed by extraction and chromatography as described above, gave as the only isolable product thioanisole sulfoxide (**18**) (20 mg), identified by comparison with an authentic sample, $[\alpha]_D$ +85.25 (*c* 0.6, $CHCl_3$), ee 48%.

Received April 22, 1991

GRACIELA M. ESCANDAR and LUIS F. SALA. Can. J. Chem. **69**, 1994 (1991).

The equilibrium reactions between rutin, 3-[6-O-(6-deoxy-α-L-mannopyranosyl)-(β-D-glucopyranosyl)oxy]-2-(3,4-dihydroxyphenyl)-5,7-dihydroxy-4*H*-1-benzopyran-4-one, and quercetin (rutin aglycone) with iron(III), copper(II), cobalt(II), and nickel(II) have been studied by potentiometric and spectrophotometric methods in aqueous solution. All measurements were carried out at $t = 20°C$ and $\mu = 0.10$ M, and the corresponding stability constants were calculated by applying computational methods. The interactions between the proposed cations with both biological ligands and other related ones are compared, with simultaneous postulation of the probable structures.

Key words: chelate stability constants of rutin, chelate stability constants of quercetin, transition metal ion interaction with flavonoids, stability constant determinations, potentiometric and spectrophotometric studies.

GRACIELA M. ESCANDAR et LUIS F. SALA. Can. J. Chem. **69**, 1994 (1991).

Opérant en solutions aqueuses et faisant appel à des méthodes potentiométriques et spectrophotométriques, on a étudié les réactions d'équilibre de la rutine, 3-[6-O-(6-désoxy-α-L-mannopyranosyl)-(β-D-glucopyranosyl)oxy]-2-(3,4-dihydroxyphényl)-5,7-dihydroxy-4*H*-1-benzopyran-4-one, et de la quercétine (aglycone de la rutine) avec le fer(III), le cuivre(II), le cobalt(II) et le nickel(II). Toutes les mesures ont été effectuées à 20°C et à $\mu = 0{,}10$ M; on a calculé les constantes de stabilité correspondantes à l'aide de méthodes de calculs par ordinateurs. On a comparé les interactions des cations mentionnés plus hauts avec les deux ligands biologiques ainsi qu'avec d'autres substances apparentées; on a fait des hypothèses simultanées concernant leurs structures probables.

Mots clés : constantes de stabilité des chélates de la rutine, contantes de stabilité des chélates de la quercétine, interactions de ions des métaux de transition avec les flavonoïdes, déterminations des constantes de stabilité, études potentiométriques et spectrophotométriques.

[Traduit par la rédaction]

Introduction

Flavonoids are structures of recognized biological activity (1). Rutin (Scheme 1), one of the typical glucosides in the flavonoids series widely distributed in natural plants, is a potent inhibitor of lens aldose reductase (potentially useful for prevention of diabetic cataracts) (2). Pharmacologically, rutin as well as quercetin has a direct constructor action on the capillary bed and decreases the permeability and fragility of the vessels (3). We thought it of value to determine the stability constants of rutin and quercetin metal-ion complexes of biological interest, which have not yet been reported in the literature. The study was performed with the intention of applying the results to possible clinical and biological situations. For these reasons the chelate stability constants of rutin and quercetin with common divalent and trivalent metal ions have been determined.

Experimental section

Ligands

Rutin and quercetin were obtained commercially from Fluka. The purity of the ligands was checked by potentiometric titration. The ligand solutions were prepared just before each determination under nitrogen atmosphere to avoid oxidation of the ligand at high pH.

Reagents

Stock solutions of about 0.010 M of reagent grade metal nitrates were prepared in doubly distilled water, and their exact concentrations were determined by titration with previously standardized ethylenediaminetetraacetic acid (EDTA) solution in the presence of appropriate indicators (4). Fe(III) nitrate solution was prepared with 0.050 M HNO_3 to avoid the hydrolysis of this metal ion in the stock solution. The exact amount of excess acid was checked by the procedure used by Harris and Martell (5). Solutions of carbonate-free NaOH and HNO_3 were standardized against potassium hydrogen phthalate and sodium carbonate, respectively.

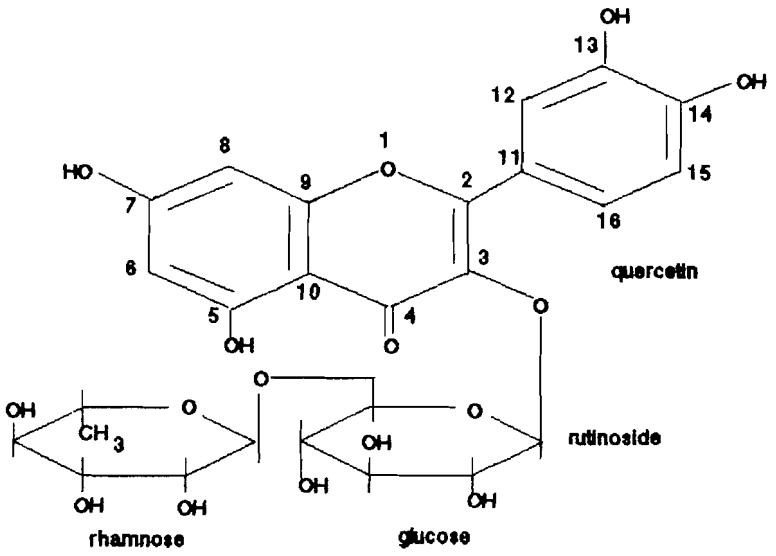
Potentiometric and spectrophotometric measurements

The procedures and apparatus used for potentiometric measurements have been described previously in detail (6). Briefly, measurements were made at 20.0 ± 0.1°C and 0.10 M ($NaNO_3$) ionic strength. The pH meter was standardized by titrations of HNO_3 and acetic acid to read $-\log [H^+]$ rather than hydrogen ion activity.

Since the acid form of the ligands is not sufficiently soluble, it was necessary to dissolve the ligands in standard base and develop the lower end of the equilibrium curves from a back titration, by stepwise addition of standard acid.

The spectrophotometric measurements were carried out with a Shimadzu UV-140-02(DB).

Competition equilibria



Since the rutin and quercetin–Fe(III) chelates are completely formed at low pH, spectrophotometric ligand–ligand competitions were performed by using a 1:1:1 molar ratio of the metal ion, ligand, and EDTA (reference ligand), employing a general method described on the literature (5). The pH and the wavelength for each competition had to be chosen so that only one ferric species absorbed. Protonation equilibria involving the free ligands and the ferric complexes were included in the calculations by using the protonation constants determined here or the literature values reported for EDTA. Duplicate reactions were run.

K_4	6.95	7.1	6.95	7.1
K_5	5.54	5.7		

Computations

The proton association constants for ligands, the protonation constants, and the stability constants of chelates were determined by using the FORTRAN program BEST (7).

Results and discussion

Protonation constants of ligands

The results of the equilibrium determinations on rutin and quercetin are presented in Table 1. The first protonation reaction of both ligands occurs above pH 10 where potentiometric measurements become insensitive. Therefore the high pH range was investigated spectrophotometrically. The absorption spectra of the ligands at several pH values are shown in Figs. 1 and 2. To calculate spectrophotometrically the protonation constants we performed a non-linear least-squares regression analysis on eq. [1], in the appropriate pH ranges.

$$[1] \quad A = T_L[(\epsilon_3\beta_3[H]^3 + \epsilon_2\beta_2[H]^2 + \epsilon_1\beta_1[H] + \epsilon)/(\beta_3[H]^3 + \beta_2[H]^2 + \beta_1[H] + 1)]$$

where A = absorbance, T_L = analytical concentration of ligand, ϵ_n = extinction coefficient, β_n = cumulative protonation constant.

Metal–ligand interaction

Due to the fact that the ligands under study present several positions where the selected metal ions can coordinate, different metal ion – ligand relationships were tried.

Iron(III) systems

Iron quercetin

The potentiometric equilibrium profile of pH vs. a (a: mol of NaOH added per mol of ligand or metal ion) for a 1:1 system shown in Fig. 3 has two breaks, one at $a = 3$ and the second one at $a = 6$. In the first buffer zone a fine precipitate was produced (probably the neutral species FeH_2L) and dissolved when the pH was increased. The equilibria are represented by eqs. [2]–[6]:

$$[2] \quad Fe^{3+} + L^{5-} + 2H_2O \rightleftharpoons Fe(OH)_2L^{4-} + 2H^+$$

$$[3] \quad Fe(OH)_2L^{4-} + H^+ \rightleftharpoons Fe(OH)L^{3-}$$

$$[4] \quad Fe(OH)L^{3-} + H^+ \rightleftharpoons FeL^{2-}$$

$$[5] \quad FeL^{2-} + H^+ \rightleftharpoons FeHL^-$$

$$[6] \quad FeHL^- + H^+ \rightleftharpoons FeH_2L$$

Of the three neutralized protons at the beginning of the potentiometric determination two of them were attributed to the catechol hydrogens and the third one to the deprotonation of the C-3 OH. It is facilitated by inductive presence of iron(III) through the conjugated network. We postulate the coordination to the catechol group by comparison of the absorption spectrum of our system with similar known simple models: catechol, tiron, salicylaldehyde. At pH = 4 the 1:1 Fe–quercetin system showed on its spectrum a smooth peak at λ 625–630 nm in the same zone in which 1:1 Fe–catechol (λ_{max} 680 nm) and 1:1

Fe–tiron (λ_{max} 670–676 nm) absorb (8). The 1:1 Fe–salicylaldehyde system does not absorb at such wavelengths, a fact that allows us to assume the possibility of no coordination at the bottom of the molecule. All these results indicated that the coordination to the catechol group is the strongest possibility, in agreement with the high affinity of this bidentate group for Fe(III) (9). Due to the spatial constraints on the quercetin molecule, there is no opportunity for any other OH group to coordinate Fe(III) even if one dissociation does occur. The coordination number of this ion is fulfilled with water molecules with high polarization effect and consequent deprotonation of two water molecules, producing hydroxy complexes. The species diagram distribution of the system under study (Fig. 4) shows that the complex FeH_2L is completely formed at low pH. Its stability constant was calculated through a spectrophotometric competitive method, employing EDTA, at pH = 3.70, λ 625 nm (ϵ_{MH2L} 1883 cm^{-1} M^{-1}) working with dilute solutions to avoid complex precipitation. The metal chelate stability constant and the corresponding chelate protonation constants (calculated in the soluble region of the potentiometric curve) are listed in Table 2.

The potentiometric curve of the 2:1 iron–quercetin system (Fig. 3) showed the formation of the stable chelates with different degrees of protonation, with the neutral species being insoluble.

The coordination of the second Fe(III) to the quercetin molecule might be produced between the carbonyl oxygen and either the C-5 OH group or the C-3 OH group (Scheme 2). Although we are not able to decide between the two possible structures employing potentiometric data, the formation of a stable six-member chelate ring would suggest that 2a is the most likely structure.

SCHEME 2

ratio could not be detected, and only 1:1 chelates were found in systems containing 1:2 ratio of reactants.

Iron rutin

The potentiometric curve of the 1:1 system (Fig. 6) could be explained with the formation of the same complexes proposed before for quercetin, with the difference that one less hydroxyl group was neutralized, the one involved on the glycosidic linkage. The first complex detected at low pH was the non-hydrolyzed species FeH_2L^+ whose formation constant was evaluated employing a competitive method with EDTA (pH = 3.00, λ 500 nm, ϵn_{MH2L} 2000 cm^{-1} M^{-1}). A relationship (2:1) M/L showed the existence of binuclear complexes. The coordination of the Fe(III) to the ligand would be established through the catechol group and between the carbonyl group and the free C-5 OH. The proposed equilibria for the 1:1 and 2:1 systems together with the corresponding equilibrium constants are shown in Table 3.

Cu(II) system

Cu quercetin

In the 1:1 solution the precipitation of the neutral species CuH_3L was observed at the beginning of the titration (Fig. 3). On increasing the pH the precipitate was dissolved with the production of a hydroxyl complex. The flattening of the curve after $a = 5$ suggests an additional equilibrium produced by the formation of the fully deprotonated complex. The proposed equilibria are

[7] $Cu^{2+} + L^{5-} + H_2O \rightleftharpoons Cu(OH)L^{4-} + H^+$

[8] $Cu(OH)L^{4-} + H^+ \rightleftharpoons CuL^{3-}$

[9] $CuL^{3-} + H^+ \rightleftharpoons CuHL^{2-}$

[10] $CuHL^{2-} + H^+ \rightleftharpoons CuH_2L^-$

The potentiometric curve of the 2:1 copper–quercetin system (Fig. 3) showed the formation of binuclear chelates. The

complex produced at high pH with two hydroxyl groups coordinated at each Cu atom could explain the tendency of this metal to fulfill its coordination number producing square-planar complexes. Table 4 shows the equilibrium constants calculated from the 1:1 and 2:1 systems.

The treatment of the data for the 1:2 Cu–quercetin system did not show the existence of such complexes. It is likely that the open coordination sites on the metal ion can react with other partially coordinated ligand molecules.

Cu rutin

1:1 ratio: At the beginning of the titration the solution was clear, becoming turbid as the pH was increased (Fig. 6). The observed result could be explained as the early production of a 1:1 complex followed by a disproportionation process to produce $Cu(OH)_2$ and the 1:2 Cu–rutin complex. The above statement was confirmed through the absence of precipitate along the potentiometric curve of the 1:2 system. Table 5 shows the equilibrium constant value.

2:1 metal ion – ligand ratio: The potentiometric curve showed similar behavior to the 1:1 system up to an a value of 2.5, where a disproportionation process took place before the binuclear complexes could be detected. At pH above 9.30 the precipitate was dissolved to produce a mixture of stable complexes but in this narrow pH range measurements of useful potentiometric data were not possible.

Ni(II) and Co(II) systems

The potentiometric behavior of both cations with the ligands investigated in the 1:1 systems was found to be similar. The

only difference lies in that the Co(II) complexes are stable enough to avoid the precipitation of the hydroxide. The analysis of the potentiometric curves (Figs. 3 and 6) showed a high coincidence with the potentiometric curves of the free ligands until $a \approx 1$. Precipitation of nickel(II) hydroxide took place at high pH, after the Ni(II) complexes were produced. Table 6 shows the stability constant values.

The ligands under study interact strongly with Fe(III), as shown through the stability constant values, with predominance of insoluble species at low pH values, and production of soluble hydroxo complexes at high pH. There are no possibilities of formation of complexes with several molecules of ligands such as catechol, probably due to the steric hindrance and the great hydrolytic tendency of the Fe(III) linked to rutin or quercetin which allow the production of very stable hydroxo complexes.

The interaction of rutin and quercetin is less strong with divalent ions of the transition series, the stability constant value of the complex produced between rutin and Cu(II) for a 1:2 M/L relationship being prominent.

The rigidity of these ligands would prevent simultaneous participation of other chelating donor groups within the ligand molecule. Therefore, it was decided to check the existence of binuclear complexes. The main coordination site was obviously the catechol group which was verified for the Fe(III)–L system by comparing the visible spectra with model systems. Moreover, the stability constant values were compared with those for the complexes with tiron and salicylaldehyde which appear at the end of each table.

Through the obtained results it can be observed that if the dissacharide present on the rutin molecule shows a possible interaction with the studied metal ions, it should be very weak, and its major influence should lie in increasing the solubility of the ligand.

Ion–molecule reactions of transition-metal ions with nitriles in the gas phase: competitive formation of both "end-on" and "side-on" coordination

LIN-ZHI CHEN AND JACK M. MILLER[1]

Department of Chemistry, Brock University, St. Catharines, Ont., Canada L2S 3A1

Received March 6, 1991

LIN-ZHI CHEN and JACK M. MILLER. Can. J. Chem. **69**, 2002 (1991).

First field-free region B/E linked scan studies of metastable and particularly collision-induced dissociations show that two competitive coordination processes ("end-on" and "side-on") exist in the complexation of metal ions (Ni^+, Co^+, Fe^+, and Mn^+) with alkanenitriles in the FAB source of an E/B configuration mass spectrometer. Analysis of the B/E linked scan CA spectra gives approximate percentages of the end-on coordination mode in the reactive complexes. An unusual β-methyl migration, involved in the elimination of CH_4 from end-on complexes, may be in competition with β-H migration/elimination of H_2 and β-C—C bond cleavage/elimination of alkene. For the side-on complexes, the metal ions can insert into various C—C bonds followed by β-H transfer/competitive elimination of alkene and alkane or by a direct C—M^+ bond cleavage to give an alkyl radical.

Key words: FAB mass spectroscopy, metal-ion/nitrile reactions, collisional activation, coordination modes, ion–molecule reactions.

LIN-ZHI CHEN et JACK M. MILLER. Can. J. Chem. **69**, 2002 (1991).

Des études de dissociations unimoléculaires, en particulier des dissociations induites par des collisions, effectuées dans la première région sans champ d'un spectromètre de masse de configuration E/B, à l'aide de balayages couplés E/B, démontrent l'existence de deux processus compétitifs de coordination ("par le bout" et "par le côté") dans la complexation d'ions métalliques (Ni^+, Co^+, Fe^+ et Mn^+) par les nitriles aliphatiques. L'analyse des spectres d'activation fournit des pourcentages approximatifs du mode de coordination par le bout les espèces réactives. Il est possible qu'une migration inhabituelle β d'un méthyle, impliqué dans l'élimination de CH_4 à partir des complexes de coordination formés par le bout, soit en compétition avec une migration/élimination β d'un H de H_2 ainsi que le bris en β d'une liaison C—C avec élimination d'alcène. Dans les complexes formés par une attaque de côté, les ions métalliques peuvent subir des insertions dans diverse liaisons C—C, suivies par un transfert d'un H en β avec élimination compétitive d'alcène ou d'alcane ou par un bris direct d'une liaison C—M^+ conduisant à un radical alkyle.

Introduction

Ion–molecule reactions of transition-metal ions (both positive and negative, including cluster ions) with organic molecules in the gas phase have received considerable attention during the last decade (1). Ion cyclotron resonance (ICR), Fourier-transform ICR, quadrupole, and sector mass spectrometers have been successfully applied to this field. The discovery that selective functionalization of remote C—H and C—C bonds is caused by transition-metal ions in "end-on" complexes (1*a*, 2) is of particular importance, since they display a similarity to enzymes. This remote functionalization has also been found in other systems such as isonitriles (3), amines (4), alcohols (4*b*, 5), alkynes (6), allenes (6*e*), and ketones (7). In fact, the selective C—H or C—C bond activation is a reflection of the reactivity and coordination of the complexed metal ions. Another important reaction mechanism involves the insertion of a metal ion into a C—C (or C—H) bond followed by β-H transfer and the competitive elimination of the ligands (1*c*). This mechanism can explain reactions of metal ions in "side-on" complexes.

Recently, we demonstrated (8) a coexistence of both end-on and side-on coordinated complexes of short-chain alkanenitriles (**1** and **2**) with transition-metal ions, Ni^+, Co^+, Fe^+, and Mn^+. That is interesting because the results indicate a competition between the coordination processes. Further study of the system might give insight into the nature of the coordination process. In this paper we will present additional experimental evidence for the competition in the case of longer chain nitriles **3**–**7** with the transition-metal ions (Ni^+, Co^+, Fe^+, Mn^+). We will also discuss the distribution of both coordination modes. Finally, an unusual β-methyl migration is also proposed and discussed.

Experimental

A Kratos Concept IS double-focusing mass spectrometer of E/B configuration (Kratos Analytical, Urmston, Manchester, UK) was used in this work. The instrument was controlled by a Kratos DS 90 Data General Eclipse based computer system. A Kratos Mach 3 data system running on a SUN SPARCstation was used for further data work-up. Ion–molecule adducts were prepared in a modified FAB source containing a small hole to accept the ligand vapour from a heated reservoir probe inserted via the EI/CI probe lock. A detailed description of the modified instrument, closed FAB source, and operating conditions are given elsewhere (8). Briefly, the instrument was fitted with an Ion Tech saddle field atom gun and xenon was used as the fast-atom source. The fast-atom-beam energy was 8 keV with a density corresponding to an emission current of about 1 mA. The source was operated at a temperature of 25°C, a pressure of about 10^{-5} Torr (measured in the source housing — not in the reaction region), and an accelerating voltage of 6 kV. We used a resolving power of 1000 for recording normal mass spectra. Metastable ion (MI) or

[1]For unknown reasons, complexation of Co^+ with valeronitrile was not observed by Schwarz and co-workers in their modified CI/FAB source coupled to a ZAB-HF-3F triple-sector mass spectrometer (2*b*), though we clearly detected the adduct in our system.

collision-induced dissociation (CID) in the first field-free region collision chamber behind the source slit was monitored by B/E linked scans. The collision gas was helium and its pressure in the collision chamber was maintained to reduce the main beam by 20% (corresponding to 1.1 collisions (9)). Since there was diffusion of gas from the source into the collision chamber region, metastable ions for recording the MI spectra might have been partially activated.

"Naked" metal ions were generated by sputtering from the solid salts, $FeSO_4\cdot 7H_2O$, $CoCl_2\cdot 6H_2O$, $NiCl_2\cdot 6H_2O$, and $MnCl_2\cdot 4H_2O$, which had been deposited by evaporation onto the FAB probe tip. Nitriles were introduced into the source via the reservoir probe. A 3-μL sample of the liquid reagent was typically injected into the reservoir probe whose temperature was 100°C. All samples were commerically available and used directly without further purification.

Results and discussion

Ion–molecule monoadducts, RCN—M^+, are the dominant products of the reactions between the transition-metal ions (Ni^+, Co^+, Fe^+, and Mn^+) and nitriles (**3**–**7**) in the closed FAB source.[1] We also observed diadduct ions, $(RCN)_2M^+$, and some fragments of the monoadducts. Stepnowski and Allison (10) have investigated these reactions in an ICR instrument. In most cases, however, the ion–molecule adducts were not dominant products. The fact that losses of small neutral species such as H_2, CH_4, and C_2H_2 remained significant may be due to the longer reaction time in ICR instruments vs. that in sector spectrometers. No reaction between acetonitrile and Co^+ and no diadduct ions, $(RCN)_2M^+$, were found in the ICR experiments.

I **II**

Fragmentations of adducts

In order to elucidate the structure and reaction mechansim of the monoadducts, metastable and collision-induced fragmentations of these species in the first field-free region were investigated using B/E linked scans (Table 1). Most of the fragments also exist in the normal mass spectra. Detailed description of the MI and CID fragmentations of **1** − M^+ and **2** − M^+ have been previously reported (8). Compared with the MI spectra of metal/nitrile (**3**–**7**) complexes, collisional activation induces additional fragmentation, consistent with the results obtained from **5** − M^+ and **7** − M^+ by Schwarz and co-workers (2). Schwarz's group described the most important processes, i.e. the losses of H_2 and C_2H_4, in terms of remote functionalization. However, the CA-induced fragmentations are of interest because they cannot be simply attributed to remote functionalization (see below). We will discuss these additional fragmentation processes and propose possible complexation modes.

By CA studies of the complexes of **5**, **7**, and unbranched longer-chain nitriles with Fe^+ and Co^+, Schwartz and co-workers demonstrated that the reactions of the end-on complexes involved an insertion of a metal ion into the C—H bond of a terminal methyl group of the nitrile, followed by both a β-hydrogen transfer to the metal centre and a β-C—C bond cleavage that produced, respectively, H_2 and C_2H_4 (2). Recently, however, a study combining FT-ICR and sector mass spectrometry suggested (11) that the reaction of **5**—M^+ is different from other long-chain nitrile complexes, and involved a degenerate isomerization to form a ferracyclobutane intermediate prior to any losses of neutral species. While the loss of one hydrogen was due to remote functionalization, ethylene was produced from internal chain positions. Loss of propene was

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

also observed in very low abundance. The difference was probably due to the ring strain in the intermediate formed during remote functionalization by **5**—Fe^+. Because of this special case, little of the following discussion relates to the **5**—M^+ complexes.

Remote functionalization reactions are also observed for complexes of **3** and **7** in our B/E linked scan experiments (MI and CA). These reactions are dominant and can be the sole reactions except for detachment in the metastable dissociations of RCN—M^+. For the complexes of **4** and **6** with branched alkyl chain, loss of propene instead of ethylene occurs (Table 1). Upon CA, however, some intense fragments due to losses of C_nH_{2n}, $\cdot C_nH_{2n+1}$, and C_nH_{2n+2} are observed. Figure 1 shows the MI and CA spectra of **7** − Ni^+. Compared with the MI spectrum, CA induces the losses of CH_4 (peak at *m/z* 139, 5% relative to losses of C_2H_4), C_2H_6 (*m/z* 125, 4%), C_3H_8 (*m/z* 111, 15%), C_3H_6 (*m/z* 113, 8%), C_4H_8 (*m/z* 99, 32%), C_5H_{10} (*m/z* 85, 12%), $\cdot C_2H_5$(*m/z* 126, 1%), $\cdot C_3H_7$ (*m/z* 112, 5%), $\cdot C_4H_9$ (*m/z* 98, 28%), and $\cdot C_5H_{11}$ (*m/z* 84, 2%).

In the end-on complex **I**, the approximately linear combination of atoms keeps M^+ so far from the nitrile chain that it attacks only the C—H or C—C bonds further out than the δ-position. Clearly, the end-on mode cannot account for the additional collision-induced fragments from RCN—M^+. One may suggest that an attack of the available C—H or C—C bonds by an electronically excited metal ion or a direct C—C bond cleavage contributes to these fragments. Although electron-impact ionization generates electronically excited M^+ ions (12), the FAB method generates ground-state metal ions (13, 14). Moreover, loss of alkane, alkyl radical, or alkene was found for other nitrile–metal complexes in sector (15), Fourier-transform ICR (2*d*, 16), and ICR (10) instruments, and described in terms of C—C bond insertion/C—M^+ bond cleavage sequence. Complexation of the metal ion with an organic substrate prior to insertion into a C—H or C—C bond is expected to be more favorable in energy and occurs in most ion–molecule reaction systems (1). If the initial complex is sufficiently long-lived, preferred coordination may play an important role in determining the final products (10). We thus suggest another coordination mode, which is in competition with the end-on mode, for the formation of the additional fragments from RCN—M^+.

The other coordination mode is probably the side-on, because side-on complexed metal ions are close enough to the α- and β-carbon to be able to insert (8). In fact, side-on coordination has been suggested by Schwarz *et al.* for the complexation of transition-metal ions with alkenenitriles (17), phosphaalkynes (18), and for the reaction of Cu^+ with nitriles (2*d*, 3*b*, 19). Moreover, the coordination mode of RNC—M^+ varies with the chain length of isonitrile. The side-on mode accounts for the complexes of short-chain isonitriles, corresponding to the losses of C_2H_4 and $\cdot C_2H_5$, while the end-on becomes competitive as the chain gets longer and even dominates when the methylene number in the chain is up to 5 (3). For α-branched nitrile (15, 16) and dinitrile (20), complexed metal ions insert into adjacent α-, β,- or γ-C—C bonds. These findings have led Schwarz *et al.* to propose the presence of the side-on coordination in addition to the end-on.

The traditional reaction mechanism of a side-on complex involves C—C bond insertion followed by β-H shift and competitive ligand elimination, as first suggested by Allison and Ridge (21, 22). A similar reaction mechanism has been established for the side-on complexes of RCN—Cu^+ (19). This also holds true for our side-on complexes RCN—M^+ (M = Ni, Co, Fe). When the metal ions insert into various C—C bonds, corresponding alkenes or alkanes are produced after hydrogen migration. Direct C—M^+ bond cleavage gives the alkyl radicals. In most cases, the loss of alkenes is much more intense than the loss of alkanes. This behavior has been interpreted by Schwarz *et al.* as due to a significant activation barrier and (or) a smaller frequency factor for the reductive elimination of alkanes (18). For complexes of **3**–**7** with the metal ions (Ni^+, Co^+, and Fe^+), almost all probable losses of alkenes and radicals except $CH_3\cdot$ are observed. The losses of the highest alkenes and radicals are accompanied by the formation of $[H,M,C,N]^+$ and M^+CN ions.[2] Ni^+ ions form $[H,M,C,N]^+$ rather than $M(CN)^+$ while the opposite case is observed for Fe^+. Co^+ behaves in a mode falling between Fe^+ and Ni^+. α-Disubstituted nitriles were also shown to give M^+/[H,C,N] ions (15, 23).

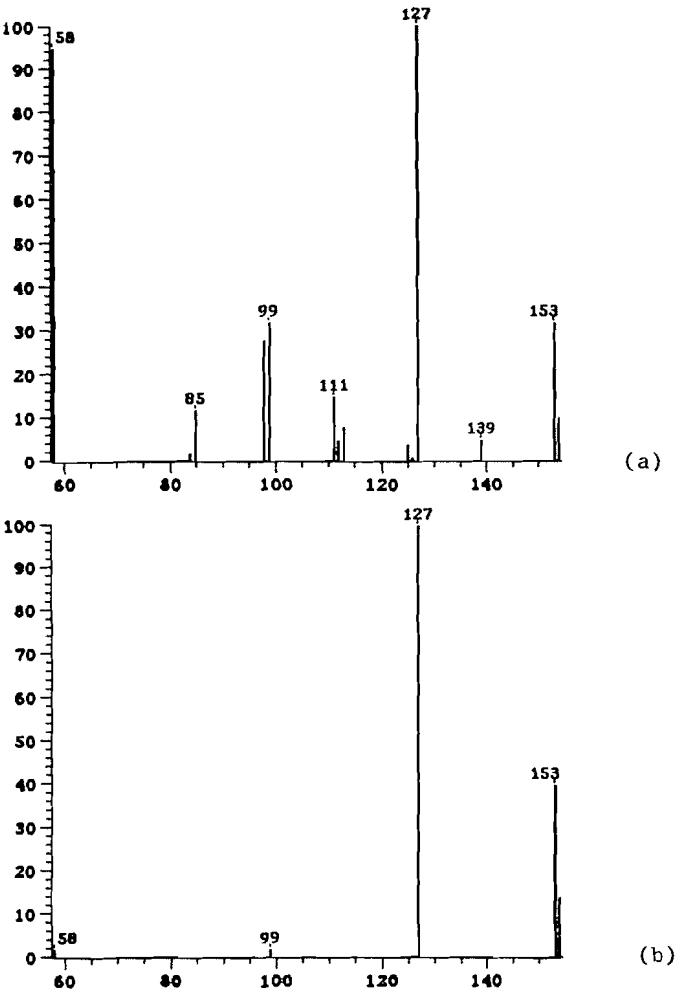

FIG. 1. B/E linked scan MI (*b*) and CA (*a*) spectra of **7**—Ni^+.

Most of the products generated by MI fragmentation of RCN—M^+ are expected from end-on coordination. This indicates that reaction from a side-on complex involves a higher activation energy than from an end-on complex, or that an activation energy is required for isomerization from "end-on" **I** to "side-on" **II** complexes prior to the dissociations.

The fragmentation of complexes formed from branched nitriles (**4**—M^+ and **6**—M^+) produces a considerable amount of methane. Figure 2 shows the MI and CA spectra of **6**—Co^+.

[2]In the experiment, we are unable to identify the structure of $[M,H,C,N]^+$ ions.

For personal use only.

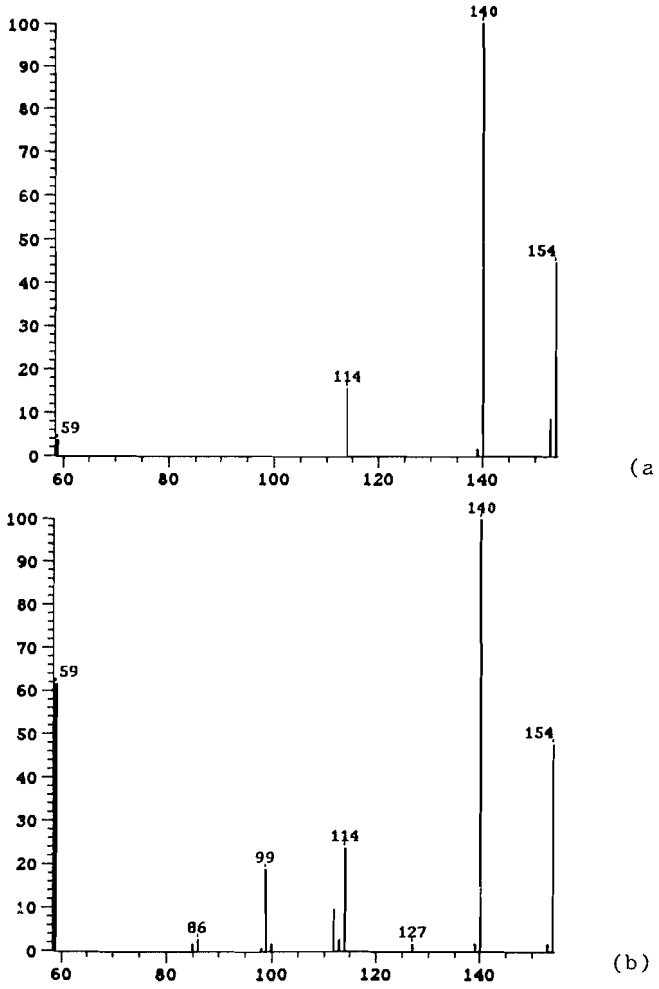

FIG. 2. B/E linked scan MI (*a*) and CA (*b*) spectra of **6**—Co^+.

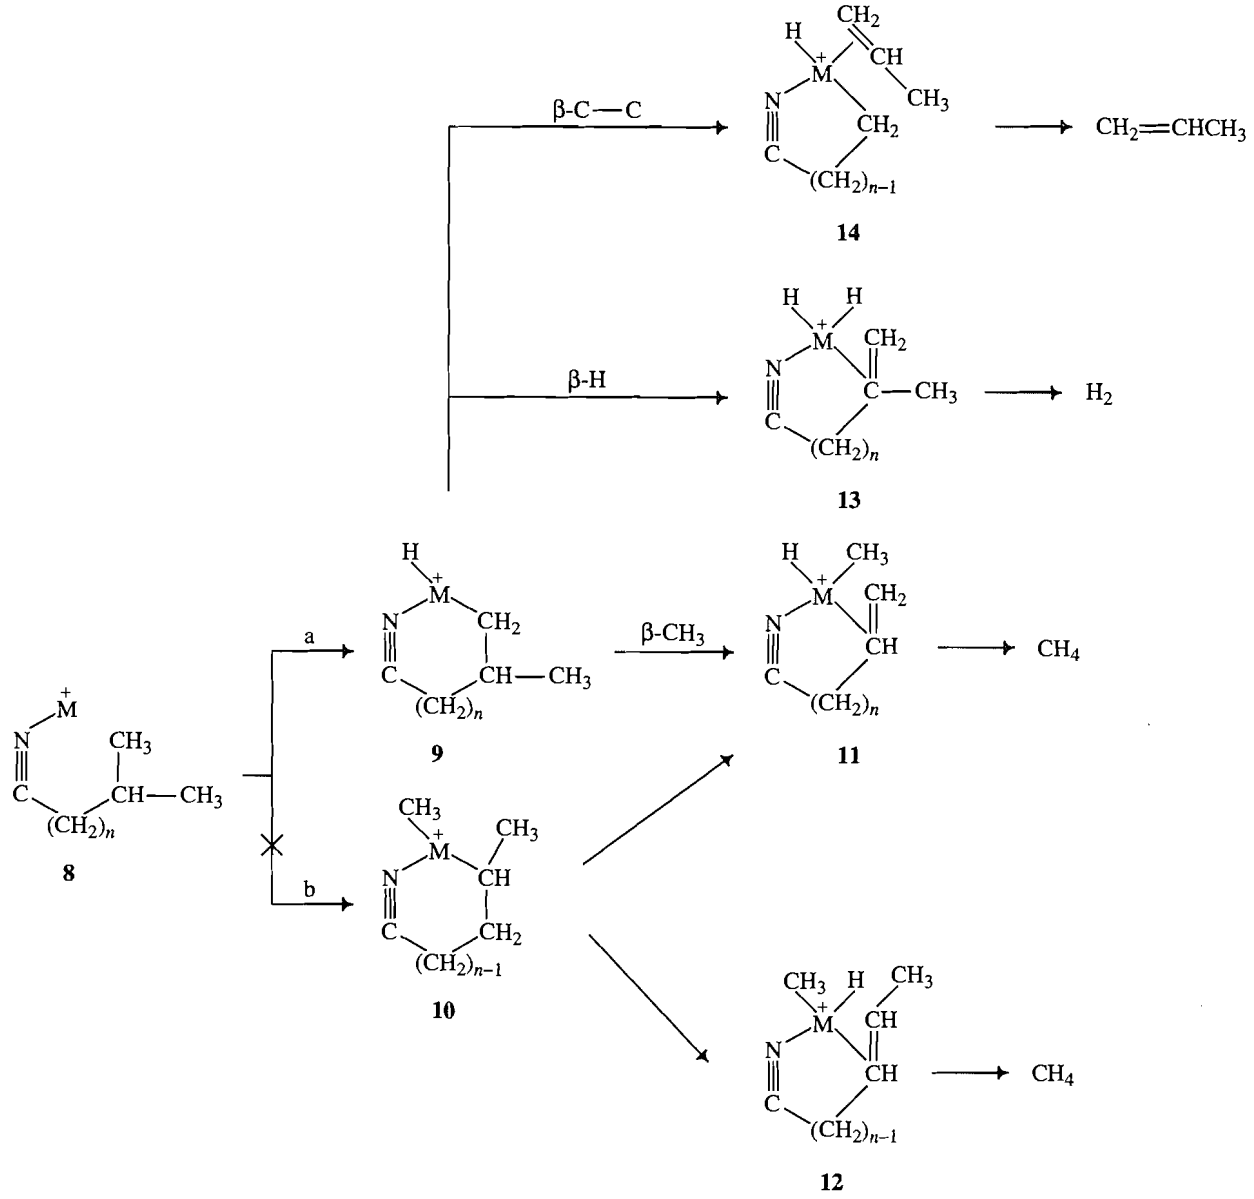
The MI spectrum shows the fragment peaks at m/z 154 ($-H_2$, 45%), m/z 140 ($-CH_4$, base peak), m/z 114 ($-C_3H_6$, 16%), and m/z 59 (Co^+, 5%); more fragments are produced by collisional activation. For Ni^+ and Co^+, the loss of CH_4 corresponds to the base peaks. Uncertainties may still arise, e.g. which of the coordination modes is involved in the methane loss and by what mechanism. However, we postulate that the methane is produced from the terminal methyl groups, because corresponding unbranched nitriles give quite low intensities for the methane loss (<6% relative to the corresponding base peaks). Side-on coordination seems unreasonable for the methane loss for the following reasons: (*i*) it is expected that a methyl group attached to a primary or secondary carbon cannot make as much difference for the metal ion insertion in a π-complex; (*ii*) since internal C—C bonds are weaker than terminal C—C bonds and the strength of the M^+—R bond formed increases as R gets larger (24, 25), metal ions prefer to insert into an internal C—C bond (24); (*iii*) the CH_4 loss is present in the MI spectra of **6**—M^+ and **4**—M^+, whereas the corresponding unbranched nitrile complexes **3**—M^+ show only the products of the end-on coordination, C_2H_4 and H_2. Thus, the methane loss may be ascribed to the end-on complex. Two possible routes are depicted in Scheme 1.

Path *b* in Scheme 1 involves an initial insertion of the metal ion into the terminal C—C bond (**8–10**) followed by a β-hydrogen transfer to the metal centre (**10–11** and (or) **10–12**) and reductive elimination of CH_4. However, using labeled unbranched nitriles, Schwarz and co-workers (2*b*,*c*) have demonstrated that the CH_4 loss commenced with hexanenitrile for Ni^+ and Co^+ and with octanenitrile for Fe^+ after the insertion into the terminal C—C bond. Even for **7**—Co^+, a very low intensity for CH_4 loss (6% relative to H_2 elimination) was observed. Moreover, reactions involving an insertion of the bare metal ion (Ni^+, Co^+, or Fe^+) into a C—CH_3 bond is a minor process because of the high ionization energy of $\cdot CH_3$ (26).

Thus the initial step is more likely the insertion of the metal ions into the terminal C—H bond to give an intermediate **9** (path *a*) followed by β-methyl transfer (**9–11**)/elimination of CH_4. It has been reported that in certain cases the insertion of a complexed metal ion into a C—H bond in the gas phase preceded insertion into C—C bonds (27, 6*b*), although insertion of Fe^+ into C—C bonds occurred to a greater extent than attack of C—H bonds (28). β-Alkyl migration was found in solution for a few organometallic systems (29). This is rare in the gas phase but has been observed (30). It should be noted that by this method, C—C insertion/β-H transfer vs. C—H insertion/β-$CH_3\cdot$ migration for the elimination of CH_4 could not be clearly distinguished (31).

In fact, the initial step (**8–9**) is a selective functionalization of a remote C—H bond by the metal ion, as already described for the losses of H_2 and C_2H_4 from RCN − M^+ (2). Competition can thus be expected for the elimination of H_2, C_3H_6, and CH_4. For **6**—M^+, elimination of H_2 and CH_4 are more prominent than C_3H_6. Furthermore, Ni^+ and Co^+ ions prefer CH_4 loss over H_2 loss, whereas the opposite case is true for Fe^+. A high preference for the loss of CH_4 over H_2 (3:1, calculated from the CA spectrum) exists for Ni^+. However, a different situation is observed in the case of **4**—M^+. The relative intensity of the neutral loss is $C_3H_6 > CH_4 > H_2$ for Ni^+ and Co^+, while it is approximately equal for Fe^+. It can be seen that the relative kinetic yields of the three neutrals depend on both the metal ions and nitriles. Detailed descriptions of the competition may need further kinetic studies using labeled nitriles and related thermochemical data, which are very sparse at the moment.

Since an α-alkyl shift has been suggested in the reactions of Co^+ with labeled ketones to give CH_4 (32), one may suggest a third mechanism for the loss of CH_4 from **4**—M^+ and **6**—M^+, which involves an initial insertion of the metal ions into the $R(CH_3)_2C$—H bond followed by an α-$CH_3\cdot$ migration to produce CH_4. However, it seems unlikely because internal C—H insertion started at the position C(7) of the nitrile for Co^+ and Ni^+ and C(8) for Fe^+ (2). Moreover, α-methyl transfer was found to be unfavourable in the loss of 42 mass units from Fe^+/phosphaalkynes (18).



The fragmentations of diadduct ions, $(RCN)_2M^+$, have also been investigated. B/E linked scan MI spectra of the diadduct ions show monoadduct peaks. A few additional low intensity peaks may be observed only in the presence of collision gas. We are interested in these results because they indicate that diadducts with different ligands, R^1CN—M^+—NCR^2, may be useful to measure relative metal ion affinity of the nitriles.[3] This is one of our current projects (34).

Competitive coordinating processes

As we discussed above, products from either side-on or

[3]CI/MS/MS has been demonstrated to be successful in determining the relative PA of organic bases using the dimer ions B_1—H^+—B_2. See, for example, ref. 33. Our current work shows that a similar method can give at least a qualitative sequence of the metal ion affinity of nitriles.

SCHEME 1. Proposed mechanisms for methane loss from **4**—M^+ or **6**—M^+

TABLE 2. Relative percentage of end-on coordination in the reactive monoadduct[a]

RCN—M^+	Fe^+	Co^+	Ni^+
6—M^+	88	80	68
7—M^+	86	87	57

[a]The side-on adducts of **3** and **4** which may also give both H_2 and C_2H_4 (or C_3H_6) are not collected in this table. We think that the abundance of the detached metal ion may be attributed to both coordinations in a distribution approximately equal to the ratio of the abundance sum of fragments from each coordination mode.

end-on complexes may be approximately distinguished except for **5**—M^+; the end-on adduct produces H_2, C_2H_4 (C_3H_6 for **4**—M^+ and **6**—M^+) and CH_4 (**4**—M^+, **6**—M^+, and **7**—M^+ except for **7**—Fe^+) while most other fragments such as radicals may be ascribed to the side-on complexes. We are thus able to get the percentage of the end-on complex in the monoadduct, which is expressed as the ratio of the abundance sum of fragments from end-on complexes over the sum of the total product ions in the CA spectra (Table 2). The percentages reported below correspond to the reactive complexes. Non-dissociating complexes are not readily observable in these experiments.

It is clear that for Fe^+ and Co^+, end-on coordination dominates in the initial complexation (see Table 2) whereas Ni^+ shows a slight preference for end-on coordination. This may reflect the stability of the complex with different coordination modes and (or) the insertion ability of the metal ions. For RCN—Mn^+, almost all fragmentations are due to dissociative detachment. This indicates that the insertion ability of Mn^+ is much lower than the three other metal ions. In this case, it is impossible to estimate the portion of either end-on or side-on coordination.

There are a few experimental (35, 36) and theoretical (37) studies reported so far on the coordination of nitriles to metal ions but detailed descriptions of the potential surface of both coordination processes seem impossible for the moment.

Conclusion

Competitive formation of side-on and end-on coordinated adducts probably exists in the ion–molecule complexation of

transition-metal ions (Ni^+, Co^+. Fe^+ and Mn^+) with alkanenitriles. Approximate percentages of the end-on coordination can be obtained by analyzing the B/E linked scan spectra. Although β-CH_3· transfer is rare in the gas phase, it may occur for the loss of CH_4 from end-on RCN—M^+ complexes, and is in competition with β-H migration and β-C—C cleavage. For the side-on complexes, metal ions can insert into various C—C bonds, followed by β-H transfer and alkene or alkane loss or by direct C—M^+ bond cleavage to give alkyl radicals.

An essentially "analytical" mass spectrometer with slight modification has been shown to provide comparable results to those obtained from "reverse geometry" sector instrument or FT-ICR spectrometer usually used for such studies.

Efficient addition of cerium(III) enolate of ethyl acetate to ketones: application to the synthesis of β-ethoxycarbonylmethyl α, β-unsaturated ketones

HSING-JANG LIU[1] AND BING-YAN ZHU
Department of Chemistry, The University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received May 31, 1991

HSING-JANG LIU and BING-YAN ZHU. Can. J. Chem. **69**, 2008 (1991).

The cerium(III) enolate derived from ethyl acetate was shown to undergo facile addition with ketones. With conjugated enones, 1,2-addition products were formed exclusively. Oxidative 1,3-oxygen transportation of these products provides an efficient route to synthetically useful β-ethoxycarbonylmethyl α,β-unsaturated ketones.

Key words: cerium(III) ester enolate, addition, ketones.

HSING-JANG LIU et BING-YAN ZHU. Can. J. Chem. **69**, 2008 (1991).

On montre que l'énolate de cérium(III) dérivé de l'acétate d'éthyle s'additionne facilement sur les cétones. Il se forme des produits d'addition 1,2 exclusivement avec les énones conjuguées. Le transfert oxydant d'oxygène-1,3 de ces produits fournit une voie d'accès efficace aux cétones α,β insaturées synthétiques très utiles β-éthoxycarbonylméthyles.

Mots clés : cérium(III), énolate d'ester, addition, cétones.

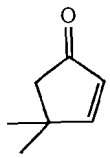
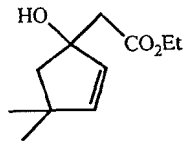
Introduction

In a projected total synthesis of pentalenolactone G (**1**) (1), enone ester **2** was required as an intermediate. Initial attempts to prepare this compound via the corresponding saturated ketone met with little success. Consequently, a synthetic approach involving addition of the enolate of ethyl acetate to enone **3** followed by oxidative 1,3-oxygen transportation of the resulting allylic alcohol **4** was explored. Although the addition of the lithium enolate of ethyl acetate to 2-cyclopentenone was found to proceed quite readily, giving the corresponding 1,2-adduct in 76% yield, the desired compound **4** could not be generated from enone **3** in more than 50% yield, regardless of the amount of reagent used, the reaction time, and temperature applied. This poor result could be attributed to the competing proton exchange process, which is an often encountered synthetic problem in aldol condensation reactions. To circumvent this problem, a reagent of lower basicity and (or) greater nucleophilicity is highly desirable. With regard to these properties, it has been demonstrated that organocerium(III) reagents in general are superior to the corresponding organolithium and magnesium reagents (2) that are commonly used. Under these considerations, the addition of the cerium(III) enolate of ethyl acetate to enone **3** was investigated. To our delight, treatment of enone **3** with slightly more than two equivalents of the cerium reagent under very mild conditions gave the desired 1,2-adduct **4** exclusively in virtually quantitative yield. Other than the reaction of the cerium enolate of *tert*-butyl acetate with acetophenones (3), the addition of the cerium(III) ester enolate to carbonyl is little known. The high efficiency observed for the transformation of **3** to **4** in terms of the yield (virtually quantitative) and regioselectivity (100% 1,2-addition) warranted further investigation on the addition of the cerium(III) ester enolate to conjugated enones, particularly in the context of preparation of β-alkoxycarbonylmethyl α,β-unsaturated ketones (e.g., **2**), which are useful synthetic intermediates for which efficient methods of preparation are rather limited.



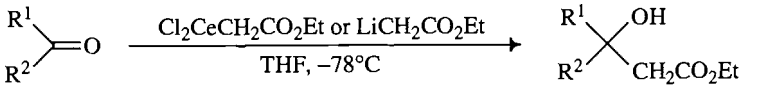
To determine the generality of the addition, a number of structurally diverse ketones were subjected to treatment with the cerium enolate, derived from the transmetallation reaction (3) of lithio ethyl acetate with anhydrous cerium(III) chloride (4). As



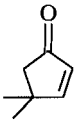
1

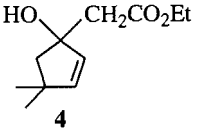
2

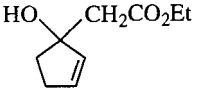
3

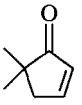


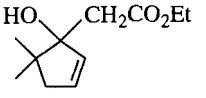
4

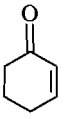


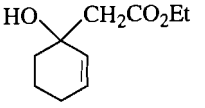


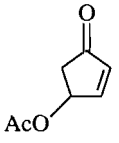


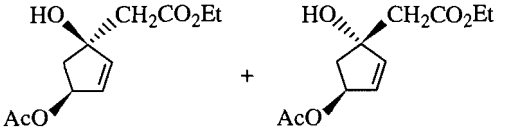


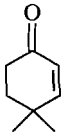


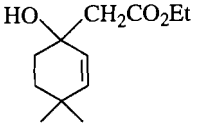


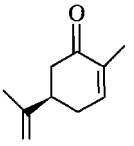


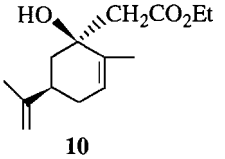


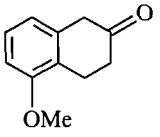


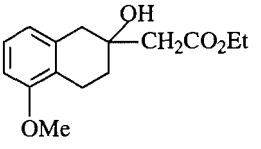












illustrated in Table 1, which summarizes the results, the addition reaction proceeded smoothly in all the cases examined and, without exception, products were obtained in yields greater than 90%. Several additional observations are noteworthy. (*i*) A minimum amount of two equivalents of the cerium(III) enolate is required in order to induce complete reaction. This is in agreement with the general observation for nucleophilic addition of cerium(III) reagents (3, 5). (*ii*) The addition of the cerium(III) enolate to conjugated enones (entries 1, 3, 5, 7, 9, 10, and 11) was shown to proceed with complete 1,2-regioselectivity. On the other hand, when the corresponding lithium reagent was applied in parallel experiments (entries 2, 4, 6, and 8), inferior yields of 1,2-adducts were obtained partly due to the formation of 1,4-addition product and recovery of the starting material. (*iii*) High yields of the desired addition products were also obtained from 4-acetoxy-2-cyclopentenone (entry 9), a highly unstable enone,[2] and 5-methoxy-β-tetralone (entry 12), a highly enolizable ketone. These results could be attributed to the mildness of reaction conditions applied, and to the low basicity and high nucleophilicity of the cerium(III) reagent. (*iv*) A high degree of stereoselectivity was observed for 4-acetoxy-2-cyclopentenone (entry 9), which gave an insepar-

[1]Author to whom correspondence may be addressed.

[2]This compound deteriorates readily on exposure to base or acid.

able mixture of two diastereomers **8***a* and **8***b* in a ratio of 9:1 as determined by ^{1}H NMR analysis. The stereochemistry of the major isomer **8***a* was confirmed by the nuclear Overhauser effect (NOE) detected as diagrammatically summarized in Fig. 1. The predominant formation of **8***a* could be attributed to the preferential addition of the cerium reagent from the sterically less hindered side of the starting enone. (*v*) The reaction of (−)-carvone (entry 11) gave rise to a single isomer **10**, presumably as a result of the stereoelectronically favored axial addition (6) of the cerium enolate to the carbonyl. The stereochemical assignment and the preferred conformation[3] depicted in Fig. 2 follow from several pieces of key information provided by the spin–spin decoupling, ^{1}H–^{13}C correlation 2D NMR and NOE studies, including the observed W-coupling

[3]The presence of an intramolecular hydrogen bonding was also indicated by the IR spectrum showing diagnostic absorption bands at 3509 and 3505 cm^{-1}.

TABLE 2. Oxidative 1,3-oxygen transportation of allylic alcohols

Entry	Allylic alcohol	Product	Time (h)[a]	Yield (%)
1	 **4**	 **2**	12	60
2	 **5**	 **12**	2.5	72
3	 **6**	 **13**	15	53
4	 **7**	 **14**	2	74
5	 **9**	 **15**	2	63
6	 **10**	 **16**	50	81

[a]All reactions were carried out in methylene chloride at room temperature using pyridinium chlorochromate.

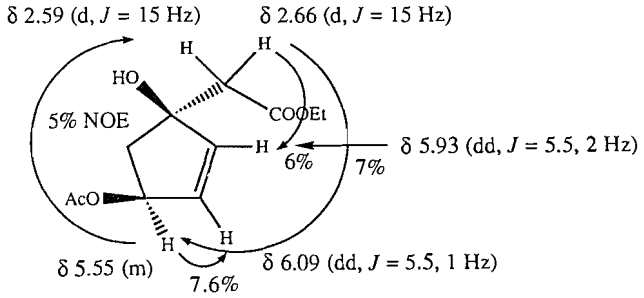

FIG. 1. NOE data for β-hydroxy ester **8***a*

(J = 1.5 Hz) between Ha and Hc, and a profound enhancement (10.9% NOE) of the multiplet at δ 2.28 due to Hd upon irradiation of the doublet at δ 2.58 for Hb (Fig. 2).

Oxidative 1,3-oxygen transportation was carried out on a large number of the allylic alcohols obtained in order to study the viability of using such a reaction in the formation of β-ethoxycarbonylmethyl α,β-unsaturated ketones. Treatment of alcohol **4** with pyridinium chlorochromate (2 mol. equiv.) in CH_2Cl_2 for 12 h at room temperature (7) gave a 60% yield of enone ester **2** required for our synthetic approach to pentalenolactone G (**1**). Similar treatment of several other allylic alcohols also resulted in their rearrangement to give the desired enone esters (Table 2). Thus, the combination of addition of the cerium(III) enolate of ethyl acetate to a conjugated enone and subsequent oxidative rearrangement provides an efficient means for the construction of β-ethoxycarbonylmethyl α,β-unsaturated ketones, useful synthetic intermediates that are otherwise difficult to prepare.

Experimental

General

All melting points were determined on a Köfler hot stage apparatus and are uncorrected. Elemental analyses were performed by the microanalytical laboratory of this department. Infrared spectra (IR) were recorded on a Perkin–Elmer model 457 or Nicolet 7-119 FT-IR spectrophotometer and were normally obtained in chloroform cast unless otherwise stated. High resolution mass spectra (HRMS) were

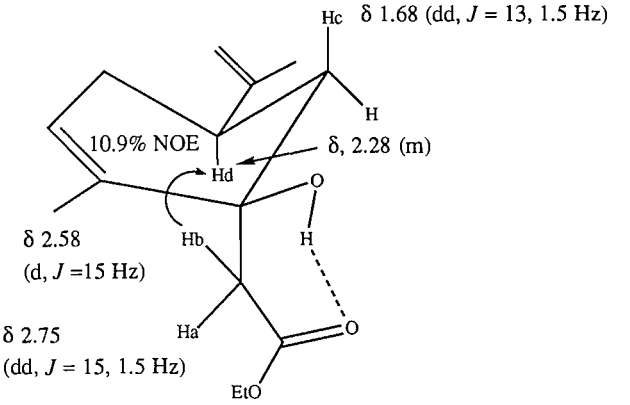

FIG. 2. The preferred conformation of alcohol **10**.

obtained using a Kratos AEI MS-50 high resolution mass spectrometer. Proton nuclear magnetic resonance specrtra (^{1}H NMR) were recorded on Bruker WH-300 (300 MHz) and WH-400 (400 MHz) spectrometers and were obtained on $CDCl_3$ solutions using tetramethylsilane as an internal reference. Carbon-13 nuclear magnetic resonance spectra (^{13}C NMR) were recorded on a Bruker WH-300 (75 MHz) spectrometer. The multiplicity of ^{13}C NMR signals was derived from off-resonance or Carr–Purcel–Meiboom–Gill spin echo J-modulated experiments (APT or Attached Proton Test) (8). Methyl and methine groups are shown as signals possessing an antiphase (doublet, quartet) with respect to the deuteriochloroform signal, whereas methylene groups, quaternary carbon atoms, and carbonyl groups appear in phase (singlet, triplet) with it. Nuclear Overhauser effects (NOE) were determined in the difference mode, in which a control (undecoupled) spectrum was computer-subtracted from the irradiated spectrum after Fourier transformation. Positive enhancements are defined as signals possessing an antiphase with respect to the irradiated signal. Samples for NOE measurements were deoxygenated with helium gas for 5 min prior to use. Optical rotations were otained on a Perkin–Elmer 24 polarimeter at the sodium D line using a 1.0 dm cell with a total volume of 1 mL.

All reactions were carried out under a positive pressure of argon gas. Argon was passed through a column of 4A molecular sieves and self-indicating silica gel. Reactions requiring anhydrous conditions were performed in oven-dried glassware that had then been assembled and allowed to cool while being purged with an inert gas. All reactions were monitored by analytical thin-layer chromatography (TLC). Analytical TLC was carried out on aluminium sheets precoated (0.20 mm layer thickness) with Merck silica gel 60F-254 containing a fluorescent indicator. Visualization was effected either by iodine or by dipping into an ethanol solution of vanillin (5%, w/v) in sulfuric acid (50%, v/v) followed by charring on a hot plate. Alternatively, an aqueous solution of phosphomolybdic acid (3%, w/v) containing ceric sulfate (0.5%, w/v) in sulfuric acid (3%, v/v) was used, followed by careful charring on a hot plate. Ultraviolet-active materials were detected by visualization under a UV lamp (254 or 350 nm). Flash chromatography (9) was used routinely for purification and separation of product mixtures using Merck silica gel of 230–400 mesh.

All solvents were distilled under an argon atmosphere prior to use. Tetrahydrofuran (THF) and diethyl ether were freshly distilled from a blue solution of sodium benzophenone ketyl. Diisopropylamine was distilled from sodium. Dichloromethane was distilled from calcium hydride. Hexane and ethyl acetate were purified by simple distillation. Cerium(III) chloride heptahydrate and pyridinium chlorochromate (PCC) were obtained from Aldrich. The following compounds were prepared according to the procedures in the literature: 5,5-dimethyl-2-cyclopenten-1-one (10), 4-acetoxy-2-cyclopenten-1-one (11), and 4,4-dimethyl-2-cyclohexen-1-one (12).

General procedure for the addition of cerium ester enolate to carbonyl compounds

(a) Anhyrdous cerium(III) chloride

Cerium(III) chloride heptahydrate (1.36 g, 3.64 mmol) was ground to a powder in a 30-mL round-bottomed flask with a magnetic stirring bar. The flask was heated gradually to 100°C under reduced pressure (ca. 0.1 Torr; 1 Torr = 133.3 Pa) in a Kugelrohr distillation apparatus. After 2 h at 100°C, the oven temperature was gradually increased to 150°C and cerium chloride was heated *in vacuo* for an additional 4–5 h. After the dried cerium chloride was cooled to room temperature under vacuum, argon and then THF (12 mL) were introduced. The resulting suspension was stirred for 2 h at room temperature prior to use for the prepartion of cerium ester enolate.

(b) Preparation of lithio ethyl acetate

To a stirred solution of diisopropylamine (405 mg, 4.0 mmol) in THF (5 mL), was added *n*-butyllithium (2.5 M in hexane, 1.6 mL, 4.0 mmol) dropwise at −78°C. The resulting solution was stirred at the same temperature for 20 min. A solution of ethyl acetate (326 mg, 3.7 mmol) in THF (2 mL) was then added and the reaction mixture stirred for 25 min at −78°C.

(c) Generation of cerium(III) enolate of ethyl acetate

The above suspension of cerium(III) chloride in THF was cooled to −78°C with stirring. The lithium ester enolate prepared from ethyl acetate was quickly transferred to this suspension via a cannula. The resulting mixture was vigorously stirred at −78°C for 2 h.

(d) Addition of cerium(III) ester enolate to carbonyl compounds

The carbonyl compound dissolved in a small amount of THF was added to the cerium ester enolate by syringe at −78°C. The reaction mixture was stirred at the same temperature until the starting material was no longer present as shown by TLC analysis. The reaction mixture was quenched with aqueous saturated NH_4Cl at −78°C and extracted with ether–hexane (1:1) (3 × 15 mL). The combined extracts were washed with water and brine and dried with magnesium sulfate. After filtration and concentration, the residue was subjected to flash chromatography on silica gel or bulb-to-bulb distillation under reduced pressure to afford the addition product.

*1-Carbethoxymethyl-4,4-dimethyl-2-cyclopenten-1-ol (**4**)*

According to the general procedure, 4,4-dimethyl-2-cyclopenten-1-one (170 mg, 1.55 mmol) was treated with the cerium(III) ester enolate (3.64 mmol) for 2 h. Flash chromatography of the crude product, using a solution of 15% ethyl acetate in hexane as an eluant, gave alcohol **4** (300 mg, 98% yield) as a colorless oil: IR: 3500 (OH), 1733, 1718 (C=O) cm^{-1}; ^{1}H NMR (300 MHz) δ: 5.70 (d, J = 5.5 Hz, 1H, CH=), 5.60 (d, J = 5.5 Hz, 1H, CH=), 4.19 (q, J = 7 Hz, 2H, OCH_2), 3.63 (s, 1H, OH), 2.68 (d, J = 16 Hz, 1H, C*H*HCO$_2$), 2.64 (d, J = 16 Hz, 1H, CH*H*CO$_2$), 1.92 (d, J = 14 Hz, 1H, C*H*H), 1.81 (d, J = 14 Hz, 1H, CH*H*), 1.29 (t, J = 7 Hz, 3H, CH_2CH_3), 1.19 (s, 3H, CH_3), 1.09 (s, 3H, CH_3); ^{13}C NMR δ: 172.81 (s, C=O), 144.97 (d, =CH), 131.70 (d, =CH), 83.35 (s, COH), 60.75 (t, OCH_2), 52.98 (t, CH_2), 45.89 (s, *C*Me$_2$), 44.78 (t, CH_2), 30.05 (q, CH_3), 29.19 (q, CH_3), 14.25 (q, CH_3); HRMS M$^+$: 198.1249 (calcd. for $C_{11}H_{18}O_3$: 198.1256). Anal. calcd. for $C_{11}H_{18}O_3$: C 66.67, H 9.09; found: C 66.60, H 9.02.

*1-Carbethoxymethyl-2-cyclopenten-1-ol (**5**)*

Following the general procedure, 2-cyclopenten-1-one (164 mg, 2.0 mmol) was reacted with the cerium(III) enolate (4.0 mmol) for 3.5 h. Alcohol **5** was isolated as a colorless oil in 96% yield (326 mg) after purification by flash chromatography on silica gel (15% EtOAc in hexane): IR: 3499, 3478 (OH), 1735 (C=O) cm^{-1}; ^{1}H NMR (300 MHz) δ: 5.92 (dt, J = 5.5, 2.2 Hz, 1H, C*H*=CH), 5.78 (dt, J = 5.5, 2.2 Hz, 1H, CH=C*H*), 4.20 (q, J = 7 Hz, 2H, OCH_2CH_3), 3.61 (s, 1H, OH), 2.66 (d, J = 15 Hz, 1H, C*H*HCO$_2$), 2.62 (d, J = 15 Hz, 1H, CH*H*CO$_2$), 2.50 (m, 1H), 2.30 (m, 1H), 2.00 (m, 2H), 1.28 (t, J = 7 Hz, CH_2CH_3); ^{13}C NMR δ: 172.72 (s, C=O), 135.07 (d, CH=), 134.13 (d, =CH), 83.15 (s, COH), 60.66 (t, OCH_2), 44.49 (t, CH_2CO_2), 37.76 (t, CH_2), 30.92 (t, CH_2), 14.16 (q, OCH_2CH_3); HRMS M$^+$: 170.0943 (calcd. for $C_9H_{14}O_3$: 170.0943). Anal. calcd. for $C_9H_{14}O_3$: C 63.53, H 8.24; found C 63.36, H 8.45.

*1-Carbethoxymethyl-5,5-dimethyl-2-cyclopenten-1-ol (**6**)*

Treatment of 5,5-dimethyl-2-cyclopenten-1-one (334 mg, 3.00 mmol) with the cerium(III) enolate (6.7 mmol) in THF for 4 h gave alcohol **6** as a colorless oil in 97% yield (576 mg) after purification by

1-Carbethoxymethyl-2-cyclohexen-1-ol (7)

Using the above standard procedure, 2-cyclohexen-1-one (196 mg, 2.04 mmol) was reacted with the cerium(III) enolate (4.5 mmol) in THF at −78°C for 4 h. Alcohol **7** was obtained as a colorless oil in 100% yield (376 mg) after bulb-to-bulb distillation (40°C, 0.1 Torr). IR: 3500 (OH), 1732, 1716 (C=O) cm^{-1}; ^1H NMR (300 MHz) δ: 5.84 (dt, J = 10, 4 Hz, 1H, C*H*=CH), 5.68 (br dt, J = 10, 1.3 Hz, 1H, CH=C*H*), 4.19 (q, J = 7 Hz, 2H, OCH_2), 3.60 (s, 1H, OH), 2.56 (d, J = 16 Hz, 1H, C*H*HCO_2), 2.52 (d, J = 16 Hz, 1H, CH*H*CO_2), 1.6–2.1 (m, 6H, $CH_2CH_2CH_2$), 1.30 (t, J = 7 Hz, CH_2CH_3); ^{13}C NMR δ: 172.54 (s, C=O), 131.00 (d, CH=), 130.29 (d, =CH), 68.20 (s, C-OH), 60.66 (t, OCH_2), 45.52 (t, CH_2CO_2), 35.78 (t, CH_2), 25.05 (t, CH_2), 18.96 (t, CH_2), 14.21 (q, OCH_2CH_3); HRMS M^+: 184.1101 (calcd. for $C_{10}H_{16}O_3$: 184.1098). (1S,4S*)- (8a) and (1R*,4S*)-4-Acetoxy-1-(carbethoxylmethyl)-2-cyclopenten-1-ol (8b)*

4-Acetoxy-2-cyclopenten-1-one (322 mg, 230 mmol) was treated with the cerium(III) enolate (8.00 mmol) for 7 h according to the general procedure. After the usual work-up and flash chromatography on silica gel (40% EtOAc in hexane), an inseparable mixture of diastereoisomeric alcohols **8*a*** and **8*b*** (9:1) was isolated as a colorless oil in 98% yield (514 mg). IR: 3494, 3488, 3479, 3468 (OH), 1733 (C=O) cm^{-1}; ^1H NMR (300 MHz), major diastereomer **8*a***, δ: 6.09 (dd, J = 5.5, 1 Hz, 1H, CHC*H*=CH), 5.93 (dd, J = 5.5, 2 Hz, 1H, CHCH=C*H*), 5.55 (m, 1H, AcOCH), 4.19 (q, 2H, J = 7 Hz, OCH_2), 3.84 (s, 1H, OH), 2.66 (d, J = 15 Hz, 1H, C*H*HCO_2), 2.59 (d, J = 15 Hz, 1H, CH*H*CO_2), 2.55 (dd, J = 14, 7.5 Hz, 1H, CHC*H*H), 2.05 (s, 3H, CH_3CO_2), 2.00 (dd, J = 14, 4 Hz, 1H, CHCH*H*), 1.28 (t, J = 7 Hz, 3H, CH_2CH_3); minor diastereomer **8*b***, δ: 5.96 (dd, J = 6, 4.5 Hz, 1H, C*H*=CH), 5.76 (m, 1H, AcOCH), 3.89 (s, 1H, OH), 2.79 (d, J = 16 Hz, 1H, C*H*HCO_2), 2.72 (d, J = 16 Hz, 1H, CH*H*CO_2), 2.45 (dd, J = 12, 7 Hz, 1H, CHC*H*H), 2.04 (s, 3H, CH_3CO_2), other peaks were overlapped with those of the major diastereomer; ^{13}C NMR, major diastereomer **8*a***, δ: 172.22 (s, C=O), 170.84 (s, C=O), 140.22 (d, CH=), 131.87 (d, =CH), 80.99 (s, C-OH), 76.97 (d, *C*HOAc), 60.97 (t, OCH_2), 44.99 (t, CH_2CO_2), 44.36 (t, CH_2), 21.44 (q, CH_3CO_2), 14.15 (q, OCH_2CH_3); minor diastereomer **8*b***, δ: 173.80 (s, C=O), 140.94 (d, CH=), 132.13 (d, CH=). 78.32 (d, *C*HOAc), 45.15 (t, CH_2CO_2), other peaks were overlapped with those of the major diastereomer; HRMS M^+ was not observed; m/z: 211.0964 (M^+ − OH, calcd. for $C_{11}H_{15}O_4$: 211.0970). Anal. calcd. for $C_{11}H_{16}O_5$: C 57.89, H 7.01; found: C 58.30, H, 7.06.

1-Carbethoxymethyl)-4,4-dimethyl-2-cyclohexen-1-ol (9)

4,4-Dimethyl-2-cyclohexen-1-one (250 mg, 2.01 mmol) was treated with the cerium(III) enolate (5.60 mmol) at −78°C for 3.5 h, giving alcohol **9** as a colorless oil in 96% yield (405 mg) after flash chromatography (15% EtOAc in hexane): IR: 3500 (OH), 1732, 1717 (C=O) cm^{-1}; ^1H NMR (300 MHz) δ: 5.52 (s, 2H, CH=CH), 4.20 (q, J = 7 Hz, 2H, OCH_2), 3.58 (s, 1H, OH), 2.56 (d, J = 15 Hz, 1H, C*H*HCO_2), 2.54 (d, J = 15 Hz, 1H, CH*H*CO_2), 1.6–1.9 (m, 3H), 1.4–1.5 (m, 1H), 1.29 (t, J = 7 Hz, 3H, CH_2CH_3), 1.06 (s, 3H, CH_3), 0.98 (s, 3H, CH_3); HRMS M^+: 212.1413 (calcd. for $C_{12}H_{20}O_3$: 212.1413).

(1S,5R)-1-(Carbethoxymethyl)-2-methyl-5-(1-methylethenyl)-2-cyclohexen-1-ol (10)

Following the standard procedure, (−)-5*R*-carvone (300 mg, 2.00 mmol) was reacted with the cerium(III) enolate (4.02 mmol) in THF at −78°C for 4 h. After the usual work-up and flash chromatography (10% EtOAc in hexane), the optically active alcohol **10** was obtained as a colorless oil in 100% yield (476 mg): $[\alpha]_D^{22}$ −31.4 (*c* 1.46, $CHCl_3$); IR: 3509, 3505 (OH), 1715 (C=O), 1645 (C=C) cm^{-1}; ^1H NMR (300 MHz) δ: 5.48 (m, 1H, CH=C), 4.73 (m, 2H, CH_2=C), 4.20 (m, 2H, OCH_2), 3.86 (s, 1H, OH), 2.75 (dd, J = 15, 1.5 Hz, 1H, C*H*HCO_2), 2.58 (d, J = 15 Hz, 1H, CH*H*CO_2), 2.28 (m, 1H, CH_2CHCH_2) 1.90–2.14 (m, 3H, C*H*HCHCH_2), 1.73 (m, 6H, 2 × CH_3), 1.68 (dd, J = 13, 1.5 Hz, 1H, CH*H*$CHCH_2$), 1.29 (t, J = 7 Hz, 3H, CH_2CH_3); ^{13}C NMR δ: 172.73 (s, C=O), 148.31 (s, *C*=CH), 136.82 (s, *C*=CH_2), 124.30 (d, CH=), 109.08 (t, CH_2=), 72.54 (s, C-OH), 60.63 (t, OCH_2), 41.82 (t, CH_2CO_2), 40.94 (t, CH_2), 39.56 (d, CH_2CHCH_2), 30.74 (t, CH_2), 20.32 (q, CH_3), 16.92 (q, CH_3), 14.06 (q, OCH_2CH_3); HRMS M^+: 238.1570 (calcd. for $C_{14}H_{22}O_3$: 238.1569). Anal. calcd. for $C_{14}H_{22}O_3$: C 70.59, H 9.24; found: C 70.79, H 9.44.

2-(Carbethoxymethyl)-1,2,3,4-tetrahydro-5-methoxy-2-naphthol (11)

5-Methoxy-2-tetralone (400 mg, 2.27 mmol) was treated with the cerium(III) enolate (8 mmol) in THF at −78°C for 15 h. After work-up in the usual manner and purification by flash chromatography (20% EtOAc in hexane), alcohol **11** was obtained in 92% yield (551 mg) as a white solid: mp 25–30°C; IR: 3500 (OH), 1728, 1715 (C=O), 1578 (Ph) cm^{-1}; ^1H NMR (300 MHz) δ: 7.10 (dd, J = 8, 8 Hz, 1H, ArH), 6.68 (d, J = 8 Hz, 2H, ArH), 4.19 (q, J = 7 Hz, 2H, OCH_2), 3.80 (s, 3H, OCH_3), 3.74 (s, 1H, OH), 2.86 (m, 3H), 2.62–2.70 (m, 1H), 2.58 (d, J = 16 Hz, 1H, C*H*HCO_2), 2.54 (d, J = 16 Hz, 1H, CH*H*CO_2), 1.90–2.00 (m, 1H), 1.84 (m, 1H), 1.28 (t, J = 7 Hz, 3H, CH_2CH_3); ^{13}C NMR δ: 172.90 (s, C=O), 157.20 (s, Ph), 135.44 (s, Ph), 126.51 (d, Ph), 123.88 (s, Ph), 121.64 (d, Ph), 107.32 (d, Ph), 69.21 (s, C—OH), 60.75 (t, OCH_2), 55.24 (q, OMe), 43.42 (t, CH_2CO_2), 41.81 (t, CH_2), 33.60 (t, CH_2), 20.83 (t, CH_2), 14.22 (q, OCH_2CH_3); HRMS M^+: 264.1366 (calcd. for $C_{15}H_{20}O_4$: 264.1362). Anal. calcd. for $C_{15}H_{20}O_4$: C 68.18, H 7.58; found: C 67.92, H 7.44.

General procedure for the oxidation of tertiary allylic alcohols with PCC in CH_2Cl_2

To a magnetically stirred slurry of PCC (2.00 mmol) in CH_2Cl_2 (5–8 mL), was added in one portion a solution of tertiary allylic alcohol (1.00 mmol) in CH_2Cl_2 (2 mL) at room temperature. The resulting dark red-black mixture was stirred for several hours at room temperature. The progress of the reaction was monitored by the analytical TLC on silica gel. After the complete consumption of the starting material, the reaction mixture was diluted with Et_2O (15 mL). The ethereal solution was decanted from the black resinous residue, which in turn was washed with Et_2O (3 × 10 mL). The combined ethereal solutions were passed through a short column (ca. 10 cm) of Florisil to remove any black polar material. The column was washed with diethyl ether (3 × 10 mL) and the combined ethereal solutions were concentrated on a rotary evaporator. The residue was subjected to flash chromatography (EtOAc in hexane) to afford the desired enone.

3-Carbethoxymethyl-5,5-dimethyl-2-cyclopenten-1-one (2)

Treatment of allylic alcohol **4** (210 mg, 1.06 mmol) with PCC (457 mg, 2.12 mmol) in CH_2Cl_2 (5 mL) for 12 h according to the general procedure followed by flash chromatography (20% ethyl acetate in hexane) gave enone ester **2** (125 mg, 60% yield) as a light yellow liquid: IR: 1739 (C=O, ester), 1708 (C=O, ketone), 1622 (C=C) cm^{-1}; ^1H NMR (300 MHz) δ: 6.04 (m, 1H, CH=), 4.20 (q, J = 7 Hz, 2H, OCH_2), 3.42 (br d, J = 1 Hz, 2H, CH_2CO_2), 2.56 (m, 2H, CH_2), 1.29 (t, J = 7 Hz, 3H, CH_2CH_3), 1.12 (s, 6H, 2 × CH_3); ^{13}C NMR δ: 213.75 (s, C=O, enone), 169.35 (s, C=O, ester), 168.82 (s, *C*=), 129.82 (d, CH=), 61.35 (t, OCH_2), 48.17 (t, CH_2CO_2), 44.54 (s, O=C*C*), 38.85 (t, CH_2), 24.97 (q, CH_3), 24.77 (q, CH_3), 14.16 (q, CH_2CH_3); HRMS M^+: 196.1099 (calcd. for $C_{11}H_{16}O_3$: 196.1099). Anal. calcd. for $C_{11}H_{16}O_3$: C 67.35, H 8.16; found: C 67.30, H 8.04.

3-Carbethoxymethyl-2-cyclopenten-1-one (**12**)

Following the standard procedure, alcohol **5** (330 mg, 1.94 mmol) was treated with PCC (835 mg, 3.88 mmol) in CH_2Cl_2 (20 mL) at room temperature for 2.5 h. The enone ester **12** was obtained as a light brown oil in 72% yield (235 mg) after flash chromatography (20% EtOAc in hexane): IR: 1735 (C=O, ester), 1714 (C=O, enone), 1676, 1620 (C=C) cm^{-1}; ^1H NMR (300 MHz) δ: 6.12 (br s, 1H, CH=), 4.20 (q, J = 7 Hz, 2H, OCH_2), 3.47 (br s, 2H, CH_2CO_2), 2.70 (m, 2H, CH_2), 2.46 (m, 2H, CH_2), 1.30 (t, J = 7 Hz, OCH_2CH_3); ^{13}C NMR δ: 209.02 (s, C=O, ketone), 172.55 (s, C=O, ester), 168.59 (s, C=), 132.23 (d, CH=), 61.13 (t, OCH_2), 38.62 (t, CH_2), 35.25 (t, CH_2), 31.41 (t, CH_2), 13.95 (q, CH_3); HRMS M^+: 168.0785 (calcd. for $C_9H_{12}O_3$: 168.0786). Anal. calcd. for $C_9H_{12}O_3$: C 64.29, H 7.14; found: C 64.18, H 7.17.

3-Carbethoxymethyl-4,4-dimethyl-2-cyclopenten-1-one (**13**)

Treatment of allylic alcohol **6** (210 mg, 1.06 mmol) with PCC (457 mg, 2.12 mmol) in CH_2Cl_2 (10 mL) for 15 h afforded enone ester **13** in 53% yield (110 mg) as a light brown oil after purification by flash chromatography (15% EtOAc in hexane): IR: 1739 (C=O, ester), 1718 (C=O, enone), 1693, 1618 (C=C) cm^{-1}; ^1H NMR (300 MHz) δ: 6.04 (br t, J = 1.2 Hz, 1H, CH=), 4.20 (q, J = 7 Hz, 2H, OCH_2), 3.33 (d, J = 1.3 Hz, 2H, CH_2CO_2), 2.32 (s, 2H, CH_2C=O), 1.29 (t, J = 7 Hz, 3H, OCH_2CH_3), 1.22 (s, 6H, 2 × CH_3); ^{13}C NMR δ: 207.05 (s, C=O, ketone), 179.09 (s, C=O, ester), 169.28 (s, C=), 130.35 (d, CH =), 61.32 (t, OCH_2), 51.26 (t, CH_2CO_2), 43.17 (t, O=CCH_2), 33.98 (s, CMe_2), 26.66 (q, 2 × CH_3), 14.07 (q, CH_3); HRMS M^+: 196.1101 (calcd. for $C_{11}H_{16}O_3$: 196.1100). Anal. calcd. for $C_{11}H_{16}O_3$: C 67.35, H 8.16; found: C 67.15, H 8.22.

3-Carbethoxymethyl-2-cyclohexen-1-one (**14**)

Using the standard procedure, allylic alcohol **7** (340 mg, 1.85 mmol) was treated with PCC (997 mmol, 4.63 mmol) in CH_2Cl_2 (10 mL) for 2 h. The crude product was purified by flash chromatography on silica gel (15% EtOAc in hexane) to afford enone ester **14** as a light brown oil in 74% yield (250 mg): IR: 1736 (C=O, ester), 1673 (C=O, enone), 1631 (C=C) cm^{-1}; ^1H NMR (300 MHz) δ: 5.94 (br t, J = 1.2 Hz, 1H, CH=), 4.19 (q, J = 7 Hz, 2H, OCH_2), 3.22 (br s, 2H, CH_2CO_2), 2.40 (m, 4H), 2.04 (m, 2H), 1.28 (t, J = 7 Hz, 3H, OCH_2CH_3); ^{13}C NMR δ: 199.22 (s, C=O, ketone), 169.28 (s, C=O, ester), 157.18 (s, C=), 128.64 (d, CH =), 61.12 (t, OCH_2), 43.31 (t, CH_2CO_2), 37.03 (t, O=CCH_2), 29.50 (t, CH_2), 22.46 (t, CH_2), 14.05 (q, CH_3); HRMS M^+: 182.0943 (calcd. for $C_{10}H_{14}O_3$: 182.0943). Anal. calcd. for $C_{10}H_{14}O_3$: C 65.93, H 7.69; found: C 65.66, H 7.89.

3-Carbethoxymethyl-6,6-dimethyl-2-cyclohexen-1-one (**15**)

Treatment of alcohol **9** (330 mg, 1.58 mmol) with PCC (850 mg, 3.95 mmol) in CH_2Cl_2 (8 mL) at room temperature for 2 h gave the enone ester **15** as an oil in 63% yield (210 mg) after purification by flash chromatography (5% EtOAc in hexane): IR: 1737 (C=O, ester), 1673 (C=O, enone), 1637 (C=C) cm^{-1}; ^1H NMR (300 MHz) δ: 5.86 (br t, J = 1.2 Hz, 1H, CH=), 4.18 (q, J = 7 Hz, 2H, OCH_2), 3.20 (br s, 2H, CH_2CO_2), 2.42 (br t, J = 6 Hz, 2H, CH_2), 1.84 (t, J = 6 Hz, 2H, CH_2), 1.29 (t, J = 7 Hz, 3H, OCH_2CH_3) 1.10 (s, 2 × CH_3); ^{13}C NMR δ: 204.04 (s, C=O, ketone), 169.46 (s, C=O, ester), 154.90 (s, C=), 127.19 (d, CH=), 61.10 (t, OCH_2), 43.03 (t, CH_2CO_2), 40.37 (s, CC=O), 36.07 (t, =CCH_2), 27.04 (t, CH_2), 23.94 (q, 2 × CH_3), 14.09 (q, OCH_2CH_3); HRMS M^+: 210.1257 (calcd. for $C_{12}H_{18}O_3$: 210.1257). Anal. calcd. for $C_{12}H_{18}O_3$: C 68.57, H 8.57; found: C 68.25, H 8.53.

(+)-(5S)-3-Carbethoxymethyl-5-(1-methylethenyl)-2-methyl-2-cyclohexen-1-one (**16**)

Alcohol **10** (280 mg, 1.17 mmol) was oxidized with PCC (760 mg, 3.53 mmol) in CH_2Cl_2 (8 mL) for 50 h. Since the oxidation was quite slow, a large excess (3.0 mol. equiv.) of PCC was used in this case. After flash chromatography (10% EtOAc in hexane), the optically active enone **16** was obtained in 81% yield (224 mg) as a colorless oil: $[\alpha]_D^{22}$ +66.33 (*c* 1.71, $CHCl_3$); IR: 1736 (C=O, ester), 1671 (C=O, enone), 1639 (C=C) cm^{-1}; ^1H NMR (400 MHz) δ: 4.81 (m, 1H CHH=), 4.76 (m, 1H, CHH=), 4.19 (q, J = 7 Hz, 2H, OCH_2), 3.33 (d, J = 15 Hz, 1H, CHHCO$_2$), 3.28 (d, J = 15 Hz, 1H, CHHCO$_2$), 2.68 (m, 1H), 2.60 (ddd, J = 16, 4, 1.5 Hz, 1H, $CH_{eq}H_{ax}C$=O), 2.47 (m, 2H), 2.34 (dd, J = 16, 13 Hz, 1H, $CH_{eq}H_{ax}C$=O), 1.81 (br t, J = 2 Hz, 3H, CH_3C=CH_2), 1.76 (br s, 3H, CH_3C=C), 1.28 (t, J = 7 Hz, 3H, OCH_2CH_3); ^{13}C NMR δ: 198.99 (s, C=O, ketone), 169.63 (s, C=O, ester), 148.92 (s, =CCH_2CO_2), 146.51 (s, CH_3C=C), 133.35 (s, CH_3C=CH_2), 110.58 (t, CH_2=C), 61.18 (t, OCH_2), 42.51 (t, CH_2CO_2Et), 41.28 (d, CH_2CHCH_2), 40.70 (t, CH_2), 36.61 (t, CH_2), 20.50 (q, CH_3), 14.19 (q, CH_3), 11.01 (q, CH_3); HRMS M^+: 236.1415 (calcd. for $C_{14}H_{20}O_3$: 236.1412). Anal. calcd. for $C_{14}H_{20}O_3$: C 71.19, H 8.47; found: C 71.35, H 8.31.

Silylation de dérivés *gem*-dihalogénés bicycliques : synthèse de dihydro- et tétrahydro-oxépines siliciées

MICHELINE GRIGNON-DUBOIS,[1] MICHELLE FIALEIX ET CLAUDE BIRAN

Laboratoire de chimie organique et organométallique, Unité de recherche associée n° 35 du Centre national de la recherche scientifique, Université Bordeaux I, 351, Cours de la Libération, 33405 Talence CEDEX, France

Reçu le 1er mai, 1991

MICHELINE GRIGNON-DUBOIS, MICHELLE FIALEIX et CLAUDE BIRAN. Can. J. Chem. **69**, 2014 (1991).

La silylation du 2-oxa-7,7′-dichloronorcarane au moyen des systèmes $Me_3SiCl/Li/THF$ ou $Me_3SiCl/Mg/HMPT$ permet selon la nature du métal et du solvant d'accéder aux dérivés bicycliques siliciés correspondants ou à des dihydro- et tétrahydro-oxépines siliciées.

Mots clés : silylation, hydro-oxépines.

MICHELINE GRIGNON-DUBOIS, MICHELLE FIALEIX, and CLAUDE BIRAN. Can. J. Chem. **69**, 2014 (1991).

The silylation of 2-oxa-7,7′-dichloronorcarane has been studied. According to the reagent ($Me_3SiCl/Li/THF$ or $MeSi_3Cl/Mg/HMPT$), we observed significant differences in the reactivity, and silyloxabicyclonorcaranes or silylhydrooxepines were obtained. The influence of solvant and experimental conditions is discussed.

Key words: silylation, hydrooxepine skeleton.

Les cycles à sept chaînons occupent une place importante dans la chimie des produits naturels et en thérapeutique (1). En série oxygénée, ils sont bien répandus et se rencontrent tant dans des médicaments (doxépine, oxétorone, scopoline ... (1*a*)) que dans des phéromones (brevicomine, frontaline (1*b*)) ou des métabolites de végétaux inférieurs (palisadines (1*c*, 1*d*)). Ceci nous a conduits à nous intéresser au squelette de l'oxépine dont les dérivés ne sont pas toujours faciles d'accès. Nous avons tenté de l'obtenir à partir du dihydropyrane, via l'addition de dihalocarbène suivie d'une silylation. En effet, nous avions précédemment constaté que la silylation de systèmes bicycliques tendus pouvait s'accompagner d'une extension de cycle (2) et il est connu que la présence d'un atome d'oxygène en α d'un cyclopropane fragilise ce dernier (3); de plus, la présence d'un groupe triméthylsilyle sur la molécule permet d'envisager une fonctionnalisation ultérieure du composé cyclique obtenu (4).

Résultats et discussion

Afin de favoriser l'extension de cycle et d'apprécier l'effet de l'oxygène sur la réactivité des squelettes bicycliques, nous avons effectué la silylation des composés **1-3** avec le système $Me_3SiCl/Mg/HMPT$ (5) qui nécessite un chauffage prolongé à 80°C; le dérivé oxygéné **3** a également été soumis au réactif $Me_3SiCl/Li/THF$ à 0°C.

Silylation par $Me_3SiCl/Mg/HMPT$

La réaction est conduite à 80°C pendant 24 h avec 2 équivalents de magnésium et 2,6 équivalents de Me_3SiCl. La comparaison des résultats obtenus avec les substrats **1** et **2** (fig. 1) à ceux précédemment observés avec le système $Me_3SiCl/Li/THF$ (2) montre l'influence du solvant et du métal.

La silylation du 7,7′-dichlorobicyclo[3,1,0]hexane, **1**, est ici univoque et conduit au 2,6-bis(triméthylsilyl)cyclohexène (**4**, rdt 90%) résultant de l'extension de cycle. Ceci constitue une excellente méthode de préparation de ce dérivé qui n'était isolé jusqu'ici qu'avec 25% de rendement et dont nous avions montré les potentialités synthètiques (2).

De même, le 7,7′-dichloronorcarane **2** a un comportement différent selon l'agent silylant puisque le 7,7′-bis(triméthylsilyl)norcarane, précédemment isolé avec 80% de rendement (2), est ici absent du mélange réactionnel; cependant, la structure bicyclique est dans ce cas conservée et on isole le 7-chloro-7-triméthylsilylnorcarane (**5**, rdt 55%, *exo/endo* 90 : 10) et le 7-triméthylsilylnorcarane (**6**, rdt 15%, *exo/endo* 60 : 40); ce dernier provient de la réduction du composé **5** au sein du milieu, ce qui est à rapprocher des résultats décrits par Shimuzu et Tsuno (6) à partir du 7,7′-dibromonorcarane et de ceux observés par Oku *et al.* (7), par action du système $Me_3SiCl/K/NH_3$. Signalons que le composé chlorosilicié **5** avait également été isolé avec 62% de rendement par Seyferth et Hanson (8), mais par un procédé beaucoup plus long et délicat de mise en oeuvre.

Le 2-oxa-7,7′-dichloronorcarane, **3**, présente une réactivité intermédiaire puisque l'on isole un mélange de dérivés mono- et disiliciés bicycliques (**7** et **9**) et à sept chaînons (**8** et **10**), tous originaux. Le 2-oxa-7-triméthylsilylnorcarane (**7**, rdt 20%, isomère *exo*) et la 2,3-dihydro-6-triméthylsilyloxépine (**8**, rdt 40%) sont les produits principaux de la réaction. Le 2-oxa-7,7′-bis(triméthylsilyl)norcarane **9** et la 2,3,4,5-tétrahydro-5,6-bis(triméthylsilyl)oxépine **10** sont isolés avec un rendement global de 18% mais dans des proportions **9/10** variant de 40 : 60 à 5 : 95 selon les essais. Ceci suggère que la 2,3,4,5-tétrahydro-5,6-bis(triméthylsilyl)oxépine, **10**, proviendrait de l'ouverture de son isomère **9** au sein du mélange réactionnel, hypothèse qui est étayée par les observations suivantes : (*i*) la prolongation du chauffage (48 h au lieu de 24) favorise la formation du composé **10**, qui est alors isolé avec 25% de rendement; (*ii*) à l'état pur, le 2-oxa-7,7′-bis(triméthylsilyl)norcarane, **9**, évolue lentement, même à température ambiante, pour donner la tétrahydrooxépine **10** correspondante. L'addition de chloroforme accélère cette évolution qui devient totale en 3 jours; (*ii*) chauffé dans l'HMPT pendant 24 h à 80°C, l'oxadichlorononorcarane, **3**, conduit exclusivement à la 2,3-dihydro-6-chlorooxépine, **11**, et nous n'avons jamais isolé ainsi de 2,3,4,5-tétrahydro-5,6-dichlorooxépine dont la silylation aurait pu rendre compte de l'obtention du dérivé **10**.

Par contre, l'oxanorcarane silicié **7**, constitué du seul isomère *exo*, est thermiquement stable et ne donne pas lieu à un agrandissement de cycle qui conduirait au composé **8**; ceci suggère que ces deux dérivés se forment selon des processus différents et que la relative fragilité de l'oxanorcarane disilicié **9** est due à la gène stérique introduite par le groupe silyle en position

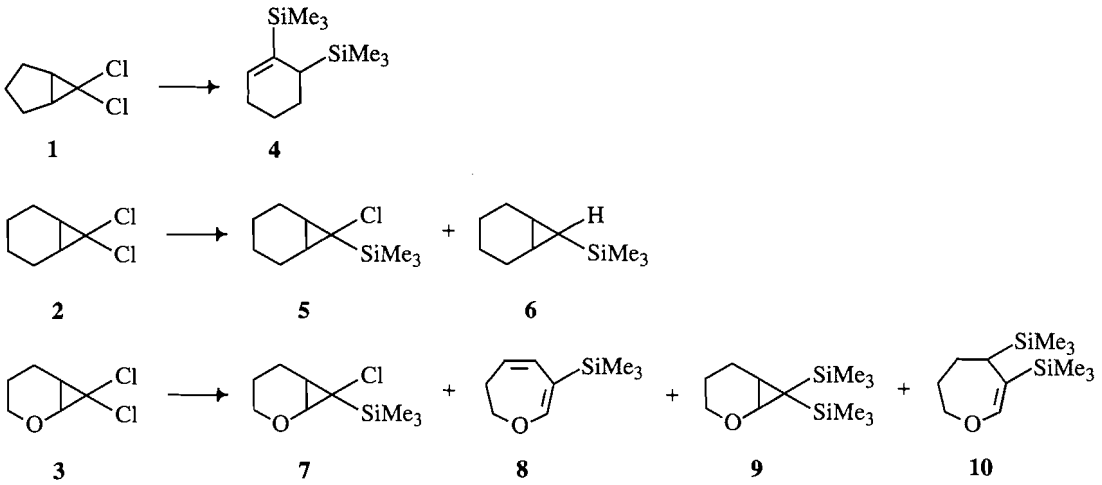

FIG. 1

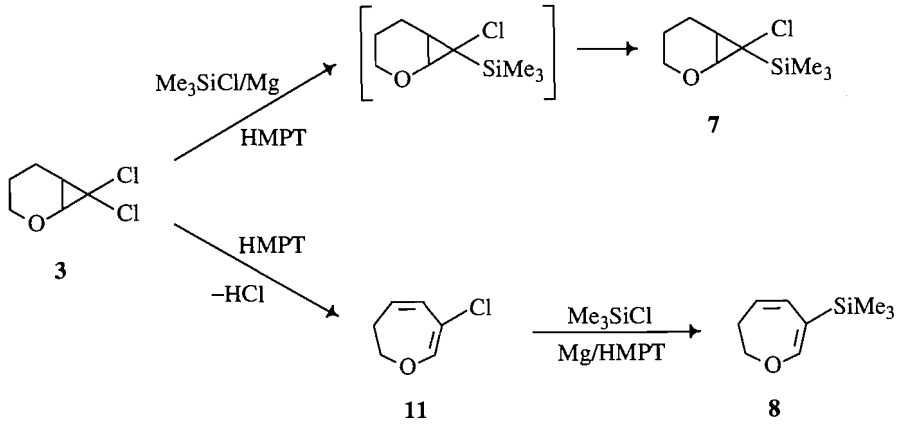

FIG. 2

endo. La 2,3-dihydro-6-triméthylsilyloxépine, **8**, résulterait de la silylation du dérivé chloré correspondant **11** (fig. 2); ce dernier proviendrait de la déchlorhydratation du substrat sous l'action de l'HMPT. En effet, lorsque la silylation est conduite avec la quantité stoechiométrique de magnésium, soit un équivalent, seule la 2,3-dihydro-6-chlorooxépine, **11**, est isolée. De plus, la silylation de cette dernière, préparée selon la référence 9, conduit dans les mêmes conditions (1 équiv. de Mg, 3 équiv. de Me_3SiCl, 24 h à 80°C) à l'oxépine siliciée **8**, isolée avec 65% de rendement.

La comparaison de ces résultats avec ceux observés à partir des dichlorobicycloalcanes **1** et **2** montre l'influence de l'atome d'oxygène puisqu'en son absence on n'isole pas de produit résultant d'une déchlorhydratation avec silylation. On note cependant l'analogie structurale entre les composés **7** et **5**–**6** d'une part et **10** et **4** d'autre part.

Silylation par $Me_3SiCl/Li/THF$

Le système $Me_3SiCl/Li/THF$ est un agent de silylation plus puissant que $Me_3SiCl/Mg/HMPT$ (4*c*, 5). La comparaison des résultats obtenus avec ces deux réactifs à partir du *gem*-dichloronorcarane en est une confirmation.

La silylation du 2-oxa-7,7′-dichloronorcarane, **3**, effectuée à 0°C avec 4 équivalents de lithium et 2,6 équivalents de Me_3SiCl, conduit, à côté des oxanorcaranes siliciés précédemment obtenus **7** (rdt 5%) et **9** (rdt 25%), aux 3-(triméthylsiloxy-3′-propyl)-1,2-bis(triméthylsilyl)cyclopropane (**12**, rdt 15%) et 3-(triméthylsiloxy-3′-propyl)-1,1,2-tris(triméthylsilyl)cyclopropane (**13**, rdt 5%) qui sont originaux (fig. 3). L'utilisation d'un excès de réactif (12 équiv. de Li, 6 équiv. de Me_3SiCl) permet d'augmenter le rendement en produits d'ouverture qui atteint alors 40% (**12**/**13** = 3 : 1). Ils résultent de la silylation de la liaison C(1)—O des composés **7** et **9** : elle s'effectue simultanément sur la face *endo* et *exo* du squelette bicyclique conduisant à un mélange d'isomères cyclopropaniques (proportion 70 : 30), qui ont été mis en évidence par chromatogra-

phie en phase gazeuse reliée à un spectromètre de masse. La complexité des spectres RMN ^1H ne permet pas de préciser la nature de l'isomère prépondérant; cependant, il est vraisemblable qu'il s'agit dans les deux cas du 2,3-*trans*, stériquement moins encombré que le *cis*. En milieu acide, le composé **13** conduit quantitativement à l'alcool **14**, également constitué de deux isomères et qui résulte de l'hydrolyse de la liaison O—Si.

Composé **14**

L'extension de cycle n'intervient donc plus, ce qui confirme le mécanisme proposé pour rendre compte de la formation des oxépines : en effet, la déchlorhydratation de l'oxadichloronorcarane ne se produit pas à 0°C dans le THF.

L'ouverture du cycle oxygéné conduisant à la formation des composés **12** et **13** est comparable à celle décrite par ailleurs (10) dans le cas du benzofurane et du benzothiophène. Afin de limiter cette réaction secondaire, nous avons utilisé le système $Me_3SiCl/Li/Et_2O$ qui est un agent de silylation moins puissant, mais, dans ces conditions, aucune silylation n'intervient même si l'on prolonge le temps de contact entre les différents réactifs.

Conclusion

Cette étude montre l'influence de la structure du substrat et des conditions expérimentales sur l'orientation de la silylation en série bicyclique. Ainsi le 2-oxa-7,7′-dichloronorcarane réagit avec le système $Me_3SiCl/Mg/HMPT$ pour conduire à des hétérocycles oxygénés siliciés bicycliques ou heptagonaux tous originaux. L'enchaînement «addition de dichlorocarbène – silylation dans l'HMPT» permet donc de passer du squelette du dihydropyrane à celui des oxépines. La généralisation de cette méthodologie devrait ouvrir de nouvelles voies d'accès à d'autres hétérocycles siliciés à 7 chaînons.

Cette extension de cycle n'intervient pas lorsque la réaction met en jeu le lithium dans le THF. Par contre, on assiste alors à l'ouverture partielle du cycle oxygéné.

Partie expérimentale

Le THF est préalablement distillé sur sodium et benzophénone, l'HMPT sur CaH_2 et le Me_3SiCl sur Mg en poudre.

Les composés **1–3** ont été synthétisés par addition de dichlorocarbène respectivement sur le cyclopentène, le cyclohexène et le 2,3-dihydropyrane selon le procédé de Julia et Girebreda (11). Le composé **11** a été préparé selon la référence 9.

Silylation par le système $Me_3SiCl/Mg/HMPT$

À une suspension de 0,25 at.g de magnésium en poudre dans 60 mL d'HMPT et 0,25 mol de Me_3SiCl, on ajoute, goutte à goutte, le substrat (0,1 mol de **1–3** ou 0,2 mol de **11**), puis on porte le mélange à 90°C pendant 24 h. Après refroidissement, le produit réactionnel est versé sur un mélange pentane/eau glacée acidifiée. La phase organique est ensuite lavée jusqu'à neutralité et séchée sur Na_2SO_4 et les produits formés sont isolés par distillation à l'aide d'une colonne à bande tournante. Les proportions de réactifs sont indiquées dans la partie Résultats.

Silylation par le système $Me_3SiCl/Li/THF$

À une suspension de 0,4 at.g de lithium, finement granulé, dans 150 mL de THF et 0,26 mol de Me_3SiCl fraîchement distillé, on ajoute, goutte à goutte, 0,1 mol du composé **3**, en refroidissant de telle manière que la température du milieu réactionnel soit maintenue entre 0 et 5°C. L'addition terminée, l'agitation est poursuivie pendant 24 h en maintenant la température entre 0 et 5°C. Le mélange réactionnel est alors filtré pour éliminer LiCl qui a précipité et le filtrat est évaporé sous le vide de la trompe à eau. Dans le cas (fréquent) où LiCl précipite à nouveau, on effectue une deuxième filtration après addition de 50 mL de cyclohexane. Après élimination du solvant à la trompe à eau, on obtient une huile jaune clair, dont les constituants sont séparés par distillation à l'aide d'une colonne à bande tournante.

Caractéristiques physico-chimiques des produits siliciés obtenus

Les analyses centésimales ont été effectuées au service central d'analyse du CNRS (F-69390 Vernaison). Les spectres de masse (SM) ont été enregistrés sur un appareil VG micromass 16 F (70 eV) et les spectres IR sur un spectromètre Perkin–Elmer 1420; tous les dérivés siliciés isolés présentent en IR des bandes de très forte intensité à 1250 et 850 cm^{-1} caractéristiques des groupes $SiMe_3$ et qui peuvent masquer le reste du spectre. Les spectres de RMN ont été enregistrés sur un appareil Bruker AC 250 fonctionnant à 250 MHz dans le cas du proton et 62,9 MHz pour le ^{13}C (solvant, $CDCl_3$; C_6H_{12} ref. int. à 1,4 ppm (^1H) ou 27,08 ppm (^{13}C)).

Les cycloalcanes siliciés **4–6** sont identiques aux échantillons que nous avons isolés par ailleurs (2, 12).

2-Oxa-7-triméthylsilylnorcarane (7): il est isolé par distillation : Eb 102°C/30 Torr (1 Torr = 133,3 Pa), rdt 20%. IR (film NaCl, cm^{-1}) : 3020, 2960, 2900, 2860, 1250, 860, 850. Kinetics and mechanism of oxidation of DL-α-alanine by permanganate ion in acid perchlorate media

REFAT M. HASSAN
Department of Chemistry, Faculty of Science, Assiut University, Assiut, Egypt

Received June 22, 1990[1]

REFAT M. HASSAN. Can. J. Chem. **69**, 2018 (1991).

The kinetics of permanganate oxidation of DL-α-alanine in aqueous perchloric acid solution at a constant ionic strength of 2.0 mol dm^{-3} has been investigated spectrophotometrically. The reaction was found to show second-order kinetics overall with respect to each of the reactants in the slow initial stage; the second-order kinetics are not, however, maintained throughout the relatively fast final stage of reaction. The added salts lead to the prediction that Mn(III) and (or) Mn(IV) play a very important role in the reaction kinetics. A tentative mechanism consistent with the kinetics is discussed.

Key words: kinetics, oxidation, reduction, amino acids, permanganate.

REFAT M. HASSAN. Can. J. Chem. **69**, 2018 (1991).

Faisant appel à une méthode spectrophotométrique et opérant en solution aqueuse d'acide perchlorique à une force ionique constante de 2,0 mol dm^{-3}, on a étudié la cinétique de l'oxydation de la DL-α-alanine par le permanganate. On a trouvé que, dans sa phase initiale lente, la réaction est globalement du deuxième ordre impliquant chacun des réactifs; toutefois, cette cinétique n'est pas maintenue dans la phase finale, relativement rapide, de la réaction. L'effet des sels ajoutés laisse croire que les ions Mn(III) et (ou) Mn(IV) jouent des rôles très importants dans la cinétique de la réaction. On discute d'un mécanisme qui serait en accord avec la cinétique observée.

Mots clés : cinétique, oxydation, réduction, amino-acides, permanganate.

[Traduit par la rédaction]

Introduction

Although the extent of oxidation of organic compounds by permanganate ion depends on the nature of the substrate, the reactive species having the main role as the potential oxidant depends on the acidity of the medium (1).

The oxidation of DL-alanine by permanganate ion has been studied by Verma *et al.* (2) in concentrated solutions of sulphuric and perchloric acids (3–5 mol dm^{-3}). The mechanism proposed by them could not explain some of the experimental observations. Our preliminary experiments on this reaction at moderate $[H^+]$ suggested that the reaction mechanism is different from that proposed by Verma *et al.* The reaction was, therefore, reinvestigated in detail in an effort to put forward rate laws consistent with the experimental data, with a view to shedding more light on the mechanism of oxidation of amino acids by this oxidant as part of a series of investigations on amino acids carried out in our laboratory (3, 4).

Materials and method

Crystalline DL-α-alanine and potassium permanganate used were from Analar (BDH). All other reagents were of analytical grade and their solutions were prepared by dissolving the requisite amounts of the samples in doubly distilled conductivity water. The temperature is controlled within ±0.1°C.

The preparation and analysis of the stock solutions and the procedure for the kinetic runs were the same as described earlier (3, 4).

All kinetic measurements were conducted under pseudo-first-order conditions where the amino acid was maintained in a large excess over the permanganate ion concentration. The course of reaction was followed by monitoring the decrease in absorbance of permanganate ion at its absorption maximum, 525 nm, as a function of time. It was verified that there is no interference from other reagents at this wavelength.

Results

Stoichiometry and product analyses

The reaction mixtures containing varying ratios of the amino acid to MnO_4^- ion were mixed in the presence of 1.0 mol dm^{-3} $HClO_4$ adjusted to a constant ionic strength of 2.0 mol dm^{-3}, then equilibrated for 24 h at room temperature. Estimation of the unreacted $[MnO_4^-]$ showed that 1 mol of MnO_4^- consumed 2.5 ± 0.1 mol of the amino acid. Verma *et al.* (2) and Rao *et al.* (5) indicated that ammonia and acetaldehyde are two of the reaction products for the oxidation of DL-alanine by MnO_4^- ion. This result has been substantiated here by simple qualitative analyses (3, 6, 7) of the products conforming to the stoichiometric equation

$$[1]\quad 5CH_3CH(NH_2)COOH + 2MnO_4^- + 11H^+ = 5CH_3CHO + 5NH_4^+ + 2Mn^{2+} + 5CO_2 + 3H_2O$$

Similar reaction products have been observed during the oxidation of amino acids by MnO_4^- ion (3, 8–10) or by other oxidants (11, 12).

Reaction–time curves

The reaction–time curves were found to be of inverted S-shape throughout the entire range of reaction. The initial rates were relatively slow in the early stages, followed by an increase in the reaction rate over longer time periods. As the reaction is of autocatalytic nature, the oxidation obeys the rate expression $(A_t - A_\infty) = B_0 e^{-k_s t} + P_0 e^{-k_f t}$. Here, k_s and k_f are the first-order rate constants for the slow and fast reactions, while B_0 and P_0 represent the absorbance change for the slow and the fast reacting species, respectively. The rate constants, presented in Table 1, were obtained by drawing a straight line through the slow-time linear portion (k_s) of the first-order plot and extrapolating the line back to zero time (B_0). The rate of oxidation, k_f, for the fast oxidation reaction was obtained from plots of the form $-\ln [(A_t - A_\infty) - (A'_t - A_\infty)]$ vs. time. The quantity $(A_t - A_\infty)$ represents the experimental point and $(A'_t - A_\infty)$ represents the extrapolated point at time t' (13, 14) as shown in Fig. 1.

Dependence of reaction rate on $[MnO_4^-]$ and [amino acid]

The log (absorbance) – time plots for the initial stages of reaction indicate that the reaction is first order with respect to

TABLE 1. Rates of oxidation of DL-alanine by permanganate ion. $[MnO_4^-] = 2.8 \times 10^{-4}$ mol dm^{-3}; $[H^+] = 1.0$ mol dm^{-3}; $I = 2.0$ mol dm^{-3}; temperature = 25°C

10^2 [amino acid] (mol dm^{-3})	$10^4 k_s$ (s^{-1})	$10^4 k_f$ (s^{-1})	$10^3 k_s'$ (dm^3 mol^{-1} s^{-1})	$10^2 k_f'$ (dm^3 mol^{-1} s^{-1})
4.5	2.58	4.58	5.67	10.17
6.0	3.35	5.83	5.50	9.67
7.5	4.27	7.02	5.67	9.33
10.0	5.68	9.00	5.67	9.00
12.5	6.88	10.63	5.50	8.50
15.0	8.50	12.33	5.67	8.17

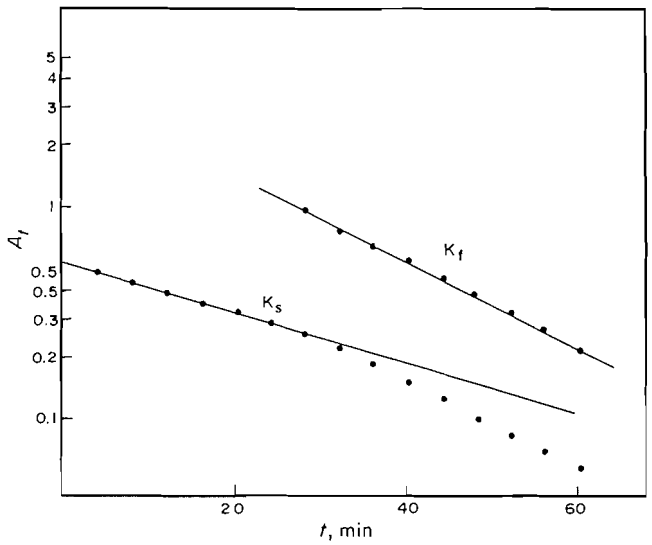

FIG. 1. Semi-log plot of A_t vs. time. $[MnO_4^-] = 2.8 \times 10^{-4}$; [DL-alanine] = 6×10^{-2}; $[H^+] = 1.0$; $I = 2.0$ mol dm^{-3}; temperature = 25°C.

permanganate ion. The order with respect to the amino acid in this initial stage was found from the measurements of the rates of several ratios of amino acid and fixed permanganate concentrations. The constancy of the second-order rate constants, k_s', derived from dividing k_s by [amino acid], indicates that the rate of oxidation is also first order in amino acid. The results are summarized in Table 1.

The second-order kinetics are, however, never maintained as the reaction proceeds throughout the autoacceleration period, and this behaviour is followed by a more complex kinetics.

Dependence of reaction rate on added salts

It is well known that acidified MnO_4^- is reduced by Mn^{2+} to give Mn^{3+} and Mn^{4+} ions (15)

$$[2] \quad MnO_4^- + 3Mn^{2+} + 8H^+ = 3Mn^{3+} + Mn^{4+} + 4H_2O$$

which are removed by fluoride ions through complex formation (16). If MnO_4^- ions are primarily responsible for the oxidation, a reduction in the initial rate should be observed in the presence of added Mn^{2+} ions, which reduce the concentration of MnO_4^- ions (17). If, on the other hand, intermediate manganese ions are the active oxidizing species, the addition of Mn^{2+} should cause an acceleration of the reaction rate. Similarly the addition of F^- ions should retard the reaction if the intermediate manganese ions are mainly responsible for the oxidation, but should cause no significant change if MnO_4^- ions are the principal oxidizing entities (3, 18).

TABLE 2. Effect of added salts on the autoacceleration rate of oxidation of DL-alanine by permanganate ion. $[MnO_4^-] = 2.8 \times 10^{-4}$ mol dm^{-3}; [DL-alanine] = 0.1 mol dm^{-3}; $[H^+] = 1.0$ mol dm^{-3}; $I = 2.0$ mol dm^{-3}; temperature = 25°C

10^3 [NaF] (mol dm^{-3})	$10^4 k_f$ (s^{-1})	10^3 [Mn^{2+}] (mol dm^{-3})	$10^4 k_f$ (s^{-1})
0.0	9.00	0.0	9.00
2.5	7.22	2.5	12.18
5.0	5.35	5.0	20.17
10.0	3.73	7.5	34.05

The experimental observations indicated that the reaction rate increased on increasing the Mn^{2+} ion, with the complete disappearance of the induction period even at low [Mn^{2+}], while a decrease in the rate was observed on addition of F^- ion. The results are summarized in Table 2.

Dependence of reaction rate on ionic strength

No primary effect was observed within the concentration limits demanded for the application of the Brønsted–Bjerrum equation. At higher concentrations of added $NaClO_4$, the values of k_s and k_f were found to increase with increasing ionic strength. The values of k_s and k_f at $I = 3.0$ and 4.0, and fixed values of $[H^+] = 1.0$, $[MnO_4^-] = 2.8 \times 10^{-4}$, and [DL-alanine] = 0.1 mol dm^{-3} at 30°C, are 6.83×10^{-4} and 7.83×10^{-4}, and 1.02×10^{-3} and 1.12×10^{-3} s^{-1}, respectively.

Dependence of reaction rate on [H^+]

To examine the influence of [H^+] on the rate of reaction, some kinetic runs were performed in $HClO_4$ solutions of 0.75–2.0 mol dm^{-3}. The ionic strength was kept constant at 2.0 mol dm^{-3} by adding sodium perchlorate as an inert electrolyte. It was found that the rate of oxidation increased with increasing [H^+]. The results are summarized in Table 3.

Oxidation of DL-alanine by manganese(III)

Manganese(III) perchlorate solutions are known to be reasonably stable in the presence of an excess of manganese(II), otherwise the Mn^{3+} disproportionates with the precipitation of manganese dioxide (7, 19).

Manganese(III) perchlorate solutions were prepared by addition of acid permanganate solution to sufficient acidified manganese(II) as described elsewhere (19). The prepared solutions were usually stable for a few days even when subsequently diluted so that the hydrogen ion concentration became about 1.5 mol dm^{-3}.

The kinetics of oxidation of DL-alanine by manganese(III)

TABLE 4. Rate constants for the oxidation of DL-alanine by manganese(III). $[Mn^{2+}] = 0.1$; $[Mn^{3+}] = 5.3 \times 10^{-4}$; $[H^+] = 1.0$; I = 2.0 mol dm^{-3}; temperature = 25°C

10^2[DL-alanine] (mol dm^{-3}):	5.00	7.50	10.00	15.00	20.00
$10^3 k_{obs}$ (s^{-1}):	2.35	3.22	4.10	5.35	6.18
$10^2 k$ (dm^3 mol^{-1} s^{-1}):	4.70	4.29	4.10	3.57	3.09

NOTE: k_{obs} is the observed pseudo-first-order rate constant and k is the second-order rate constant.

ion were followed spectrophotometrically under a nitrogen atmosphere at a wavelength of 290 nm, the absorption maximum of Mn^{3+} ion as a function of time. These kinetic measurements were carried out under pseudo-first-order conditions where the amino acid was present in a large excess over that of $[Mn^{3+}]$. The experimental results showed that the reaction was first order with respect to manganese(III) concentration, indicated by the linearity of log (absorbance) – time plots for more than three half-lives of reaction completion, while a fractional order was observed in [DL-alanine]. The results are summarized in Table 4.

Discussion

In acid solutions, amino acids tend to exist predominantly as the protonated species according to the following equilibria (20):

[3] $RCHNH_2CO_2H \rightleftharpoons RCH\overset{+}{N}H_3CO_2^-$ (zwitterion)

[4] $RCH\overset{+}{N}H_3CO_2^- + H^+ \overset{K_1}{\rightleftharpoons} RCH\overset{+}{N}H_3CO_2H$

By analogy with the chemistry of potassium permanganate under our experimental conditions (21), it is reasonable to assume that $HMnO_4$ species are generated as follows:

[5] $MnO_4^- + H^+ \overset{K_2}{\rightleftharpoons} HMnO_4$

where K_2 is the protonation constant (2.99×10^{-3} dm^3 mol^{-1} at 25°C) (21).

The hydrogen ion dependency of the reaction rate (non-integral order) suggests that at least one reaction path involving the protonated species is present in the slow stage of the reaction. Again, the positive salt effect further indicates that the reaction is between an ion and a neutral molecule (22).

In view of these facts and the experimental observations, a consistent mechanism involving two competitive reactions in the rate-determining step may be suggested for the induction period as follows:

[6] $MnO_4^- + LH^+ \xrightarrow{k_a} [*]$

[7] $HMnO_4 + LH^+ \xrightarrow{k_b} [*]$

where LH^+ represents the protonated species of DL-α-alanine. Hence the variation of the rate constant with change of the substrate and $[H^+]$ can be expressed by the following equation

$$[8] \quad \text{Rate} = \frac{k_a K_1 + k_b K_1 K_2 [H^+][LH^+][MnO_4^-]_T}{1 + K_2[H^+]}$$

where $[MnO_4^-]_T$ is the analytical total concentration of permanganate ion. Assuming that $K_2[H^+] \ll 1$ in eq. [8] under our experimental conditions, the second-order rate constant of the initial induction period can be rewritten as follows:

$$[9] \quad k_s' = k_a' + k_b'[H^+]^n$$

where $k_a' = k_a K_1$, $k_b' = k_b K_1 K_2$, and $n = 0.5$. Equation [9] requires that the plot of k_s' against $[H^+]^{0.5}$ be linear. The existing data satisfied this requirement, as shown in Fig. 2. The values of k_a' and k_b' were calculated by the least-squares method.

Unfortunately, the values of k_a and k_b could not be evaluated due to the non-availability of the protonation constants K_1 and K_2 at the various temperatures. Although some attempts were made to evaluate these constants at various temperatures from the experimental data, the results were not encouraging. The activation parameters of the k_a' and k_b' paths of the induction period were evaluated using Eyring's equation. The values calculated by the method of least squares are summarized in Table 5.

Several factors, such as the charge and the ordering of the solvent molecules around the activated complexes, may be responsible for the negative entropy of activation. In general, this ordering is affected by the charge on the activated complex. When the activated complex has zero charge, the ordering of the solvent molecules around the activated complex should be less than around the separate reactant ions; this will tend to make the entropy of activation less negative, and vice versa for the activated complex, which has a positive charge. It seems quite likely that the entropies of activation for the k_a' and k_b' paths are not consistent with this behaviour. Consequently, the less negative entropy of activation for the k_b' path compared with that for the k_a' path may be interpreted as the contribution of the positive ΔS^0 for the protonation of MnO_4^- ion in the former path, but not in the latter one, since $\Delta S^{\neq}$ values are composite quantities of entropy terms.

Moore and Hicks observed that the entropy of activation, $\Delta S^{\neq}$, for a group of MnO_4^- reactions, is negative for the reactions that proceed via complex formation, i.e., the inner-sphere mechanism (23, 24); while the $\Delta S^{\neq}$ values for the outer-sphere reactions tend to be more positive (25). The activation parameters for the oxidation of some organic substrates by MnO_4^- ion are summarized in Table 6. The entropy of activation for the MnO_4^-–DL-alanine reaction falls within the observed range of the former case. Again, Leffler and Grunwald (26) have pointed out that many reactions show an isokinetic relationship $\Delta H^{\neq} = C + B\Delta S^{\neq}$. As shown in Fig. 3, a plot of $\Delta H^{\neq}$ versus $\Delta S^{\neq}$ for the oxidation of some organic compounds by MnO_4^- ion (via similar reaction mechanisms) is fairly linear, with $C = 85$ kJ mol^{-1} and $B = 341$ K. The linearity and the slope of the curve obtained may confirm that the kinetics of these reactions follow similar reaction mechanisms, as previously suggested.

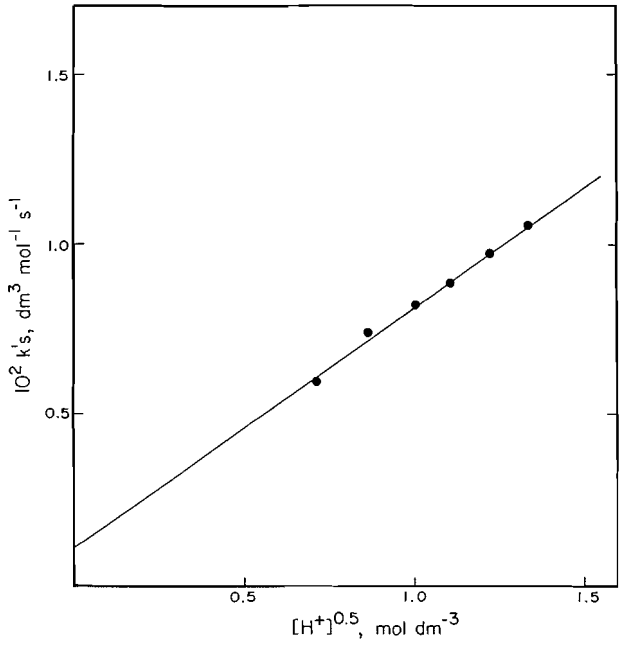

FIG. 2. Hydrogen ion dependency for the induction period. [MnO_4^-] = 2.8×10^{-4}; [DL-alanine] = 7.5×10^{-2}; I = 2.0 mol dm^{-3}; temperature = 30°C.

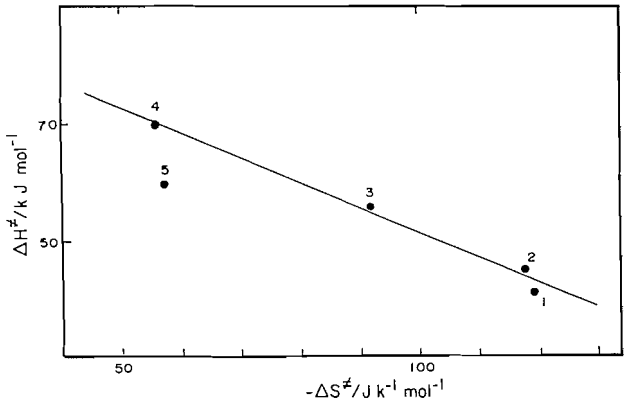

FIG. 3. Isokinetic relationship, $\Delta H^{\neq}$ vs. $\Delta S^{\neq}$, for oxidation of some organic substrates by MnO_4^- ion. (1) Glycol; (2) tartaric acid; (3) glycolic acid; (4) DL-alanine; (5) lactic acid.

Although the oxidation of DL-alanine by permanganate ion showed second-order overall kinetics, first order with respect to each of the reactants for the initial induction period, these kinetics are not maintained throughout the final, autoacceleration stage of reaction. Again, the complete disappearance of the induction period even at low [Mn^{2+}] and the decrease in the reaction rate on the addition of F^- ion may suggest that Mn^{3+} and (or) Mn^{4+} are the principle reactive species in the relatively fast final stage. But the oxidation of DL-alanine by manganese(III), as well as the continuous increase in oxidation rate with increasing the Mn^{2+} added to the MnO_4^-–alanine reaction mixture, indicates conclusively that Mn^{3+}, but not Mn^{4+}, is the sole oxidant throughout the autoacceleration stage.

Attempts were made to allow spectrophotometric detection of the Mn^{3+} ion intermediate as the reaction proceeded in the oxidation of DL-alanine by MnO_4^- ion. Unfortunately, the low concentration of the Mn^{3+} intermediate obtained under our experimental conditions made the detection unsuccessful.

Consequently, the most likely reaction mechanism that can be suggested for the autoacceleration period of the reaction involves the two competitive reactions [10] and [11]

$$[10] \quad Mn^{3+} + LH^+ \underset{}{\overset{K_3}{\rightleftharpoons}} MnL^{3+} + H^+ \xrightarrow[\text{slow}]{k_1} \text{product}$$

$$[11] \quad MnL^{3+} + LH^+ \overset{K_4}{\rightleftharpoons} MnL_2^{3+} + H^+ \xrightarrow[\text{slow}]{k_2} \text{product}$$

The intermediate complex ions, MnL^{3+} and MnL_2^{3+}, are formed and subsequently undergo further decomposition to give the reaction products. The variation of the rate constant either for the autoacceleration period or for the oxidation of

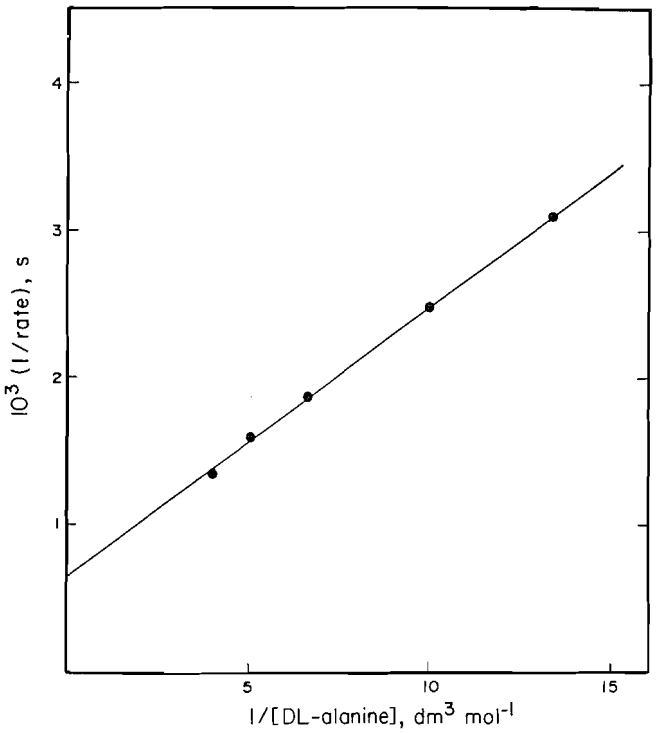

FIG. 4. Plot of 1/rate vs. 1/[DL-alanine] in the oxidation of DL-alanine by manganese(III). $[Mn^{3+}] = 5.3 \times 10^{-4}$; $[Mn^{2+}] = 0.1$; $[H^+] = 1.0$; $I = 2.0$ mol dm^{-3}; temperature = 25°C.

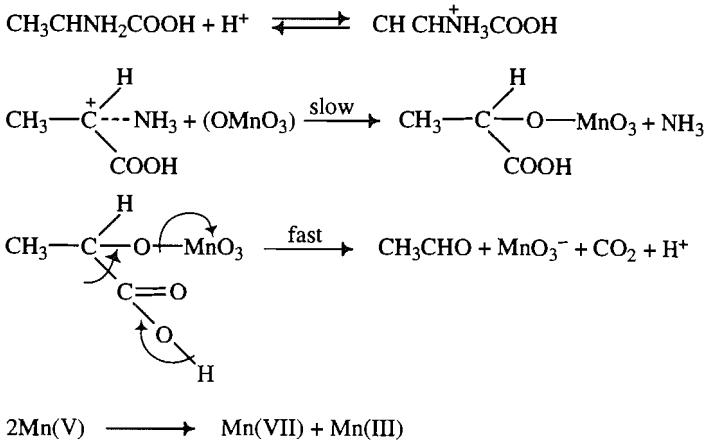
DL-alanine by manganese(III) with the change of the substrate and hydrogen ion concentrations may be expressed by the following relationship:

$$[12] \quad \text{Rate} = \frac{(k_1K_3[H^+]^{-1} + k_2K_3K_4[H^+]^{-2}) \cdot [LH^+][Mn^{3+}]_T}{1 + K_3[H^+]^{-1}[LH^+] + K_3K_4[H^+]^{-2}[LH^+]^2}$$

where $[Mn^{3+}]_T$ denotes the analytical total concentration of manganese(III)



$$[13] \quad [Mn^{3+}]_T = [Mn^{3+}] + [MnL^{3+}] + [MnL_2^{3+}]$$

Under our experimental conditions of low $[LH^+]$, the factor $K_3K_4[H^+]^{-2}[LH^+]^2 \ll (1 + K_3[H^+]^{-1}[LH^+])$, and hence reaction [11] may be neglected. Then, reaction [10] is considered as the sole rate-determining step, and eq. [12] can be recast as

$$[14] \quad \text{Rate} = \frac{k_1K_3[H^+]^{-1}[LH^+][Mn^{3+}]}{1 + K_3[H^+]^{-1}[LH^+]}$$

According to eq. [14], at constant $[H^+]$ a plot of 1/rate versus 1/[DL-alanine] should be linear, as shown in Fig. 4. The good linearity obtained, in addition to the positive intercept on the 1/rate axis, may be considered as kinetic evidence for the formation of an intermediate complex ion in accordance with Michaelis–Menten kinetics (27). Again, the plot of 1/rate against $[H^+]$ at constant substrate should give a straight line, as is observed experimentally with respect to the oxidation of DL-alanine by MnO_4^- ion. Unfortunately, the latter plot could not be examined with respect to the oxidation of DL-alanine by manganese(III). Similar reaction mechanisms for the oxidation of some organic substrates by MnO_4^- have been reported elsewhere (28–30).

The positive catalytic effect of Mn^{2+} on the rate of reaction

SCHEME 1

may reflect the one-electron transfer mechanism. However, this pathway is not favoured from the energetic point of view for the Mn(VII)/Mn(VI) (+0.56 V) and Mn(VII)/Mn(V) (+1.1 V) couples (31). The protonation of permanganate ion shifts the Mn(VII)/Mn(VI) couple to a more positive value (+1.3 V), which makes $HMnO_4$ a stronger oxidizing agent than MnO_4^- ion.

In view of these facts and the experimental observations, it may be possible to suggest that the oxidation of DL-alanine by permanganate ion proceeds by a successive one-electron transfer mechanism of inner-sphere nature throughout two distinct stages. In the initial slow stage, manganese(III) is formed as a transient species. Then, the Mn(III) formed is attacked by the substrate to give the reaction products via intermediate complex formation throughout the autoacceleration period. The mechanism of oxidation is illustrated in Scheme 1.

It unfortunately does not appear possible to obtain direct evidence for detection of the intermediate complex ions; this failure is, however, not contrary to the proposed mechanism of this reaction since the subsequent oxidation of the intermediates is slow in comparison with their formation.

Structural studies on 6-ethoxytetrahydropyrylium cations; stereoelectronic control in the reactions of lactonium salts

RONALD F. CHILDS,[1] MARIANNE D. KOSTYK, COLIN J. L. LOCK, AND MAILIVAGANAM MAHENDRAN
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1
Received April 20, 1990[2]

RONALD F. CHILDS, MARIANNE D. KOSTYK, COLIN J. L. LOCK, and MAILIVAGANAM MAHENDRAN. Can. J. Chem. **69**, 2024 (1991).

The structures of 6-ethoxy-2,3,4,5-tetrahydropyrylium, **1**, 6-ethoxy-2-methyl-2,3,4,5-tetrahydropyrylium, **2**, and 2-ethoxy-3,4,4a,5,6,7,8,8a-octahydro-1-benzopyrylium, **3**, hexachloroantimonates have been determined by X-ray crystallography. In each case the tetrahydropyrylium rings exist in shallow half-chair conformations with the cationic centers C(6), C(5), O(1), and O(6) having a planar arrangement. The cations all have a *Z* conformation about the O(6)—C(7) bonds and it is shown that this conformation is also preferred in solution by comparison of narrow-line ^{13}C NMR spectra in the solid state and solution. The O(1)—C(2) and O(6)—C(7) bond distances in **1–3** are significantly longer than those of comparable bonds in neutral esters. The length of the O(1)—C(2) bond is very dependent on substitution at C(2) suggesting a considerable fraction of the positive charge resides on this carbon as well as C(7). The closest cation/anion interactions present in the crystal lattices of these salts are between the chlorine atoms of the anion and the cationic center, C(6). These interactions provide information on the origin of the stereoselectivity observed in nucleophilic attack on these cations. The conformations, details of the C—O bonding, and closest contacts between cation and anion are discussed in terms of the concept of stereoelectronic control.

Key words: 6-ethoxytetrahydropyrylium cations, lactonium salts, structure, X-ray, stereoelectronic control.

RONALD F. CHILDS, MARIANNE D. KOSTYK, COLIN J. L. LOCK et MAILIVAGANAM MAHENDRAN. Can. J. Chem. **69**, 2024 (1991).

Les structures des hexachloroantimonates des 6-éthoxy-2,3,4,5-tétrahydropyrylium (**1**), 6-éthoxy-2-méthyl-2,3,4,5-tétrahydropyrylium (**2**) et 2-éthoxy-3,4,4a,5,6,7,8,8a-octahydro-1-benzopyrylium (**3**) ont été déterminées par diffraction des rayons-X. Dans chaque cas, les cycles tétrahydropyrylium existent dans des conformations demi-chaises peu profondes dans lesquelles les centres cationiques C(6), C(5), O(1) et O(6) sont dans un arrangement planaire. Les cations possèdent tous une conformation *Z* autour des liaisons O(6)—C(7); par comparaison des bandes fines des spectres RMN du ^{13}C à l'état solide et en solution, on a aussi démontré que cette conformation est aussi la conformation privilégiée en solution. Les longueurs des distances O(1)—C(2) et O(6)—C(7) des composés **1–3** sont beaucoup plus longues que celles des liaisons comparables des esters neutres. La longueur de la liaison O(1)—C(2) dépend beaucoup de la substitution en C(2); ce résultat suggère qu'une fraction importante de la charge positive se trouve sur ce carbone ainsi que sur celui en C(7). Les interactions cation/anion le plus proches observées dans les réseaux cristallins de ces sels se retrouvent entre les atomes de chlore de l'anion et le centre cationique C(6). Ces interactions fournissent de l'information sur l'origine de la stéréosélectivité observée lors des attaques nucléophiles sur ces cations. On fait appel au concept de contrôle stéréoélectronique pour discuter des conformations, des détails de la liaison C—O et des contacts les plus près entre le cation et l'anion.

Mots clés : cations 6-éthoxytétrahydropyrylium, sels de lactonium, structure, rayons-X, contrôle stéréoélectronique.

[Traduit par la rédaction]

Introduction

Carbenium ions with two oxygen substituents (OR and (or) OH) at the positive center are commonly encountered intermediates in organic chemistry (1). They are formed, for example, during the acid-catalyzed reactions of carboxylic acids and esters, reactions that are fundamental transformations of these important functional groups. Collapse of these cations with solvent leads to the formation of tetrahedral intermediates such as ortho or hemi-ortho esters with three oxygen-containing substituents on a tetrahedral carbon (2).

The reaction of dialkoxy/hydroxy cations with nucleophiles and the corresponding ionization of the tetrahedral intermediates to form these cations can occur with remarkable selectivity. Deslongchamps and co-workers suggested that the ease in cleavage of a C—O bond of one of these tetrahedral intermediates is governed by the relative orientation of the lone pairs of electrons on the remaining oxygen atoms and they coined the term stereoelectronic control to describe this electronic effect (3–7). The concept of stereoelectronic control has become widely accepted as a result of a great deal of work particularly involving cyclic systems where the relative conformations of oxygen substituents are well defined (8). The operation of microscopic reversibility means that the reactions of a dialkoxy carbenium ion with nucleophiles should be governed by the same principles as the ionization reactions. Indeed this assumption has been made to account for the stereo- and regio-selectivities encountered in the reactions of these cations (4–7, 9, 10).

To fully understand these reactions, particularly those involving collapse of the cation with a nucleophile, it is important to know the structures of these intermediary ions. With the appropriate choice of conditions it is possible to generate alkoxy/hydroxy substituted carbenium ions as long-lived intermediates (1, 11). Despite the large number of studies describing the properties of these cations, there have been few reports of the determination of their structures using direct methods.[3] The conformational preferences of some acyclic dialkoxy/hydroxy carbenium ions have been determined by NMR studies (17), but, this methodology cannot be extended to the types of cyclic systems used in establishing the concept of stereoelectronic control.

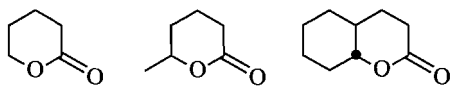
In this paper we describe the determination of the crystal structures of three dialkoxy carbenium ion salts derived by the alkylation of six-membered ring lactones.[4,5] These structures firmly establish the conformation of these cations and support the assumptions that have been made by previous workers.



Results

The salts selected for study in this work were **1–3**. These materials were prepared by treatment of the corresponding lactones, **4–6** respectively, with triethyloxonium hexachloroantimonate (11). The salts **1** and **2** were characterized by comparison of their ^1H and ^{13}C NMR spectra in CD_2Cl_2 solutions with those previously reported (6).[6] Narrow-line ^{13}C NMR spectra of **1** and **2** as crystalline solids were obtained with use of magic angle spinning techniques. The NMR spectra of **3** were fully consistent with the assigned structure, Table 1. Single crystals of the three salts were obtained on recrystallization from CH_2Cl_2 at low temperature.

1 **2** **3**

The crystal structures of the three cations were determined by X-ray diffraction techniques. The diffraction data for **1** and **2** were collected at low temperatures while those for **3** were collected at room temperature with the samples being kept in sealed tubes to prevent reaction with atmospheric moisture.

4 **5** **6**

[4]A preliminary structure of **3** has previously been reported in a review, ref. 18.

[5]A variety of names have been used for these salts including "lactonium" and "dioxenium". In this paper the Chemical Abstracts names and numbering system have been used for **1** and **2**. The numbering system used for **3** is non-systematic, to allow easy comparison between the corresponding bonds of all three cations.

[6]Cation **1** was previously prepared as its BF_4^- salt, ref. 6.

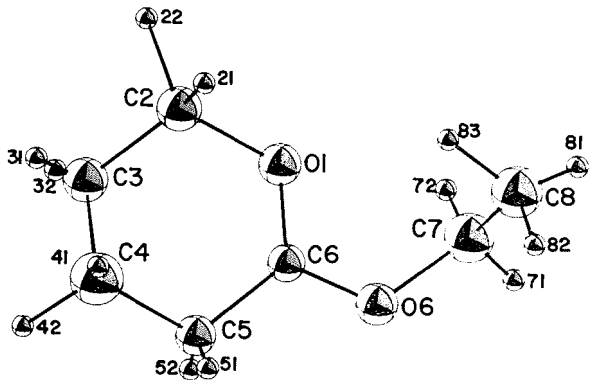


FIG. 1. The cation $C_7H_{13}O_2^+$ in compound **1**, showing the atom numbering. Hydrogen atoms are indicated by affixes only, in smaller print.

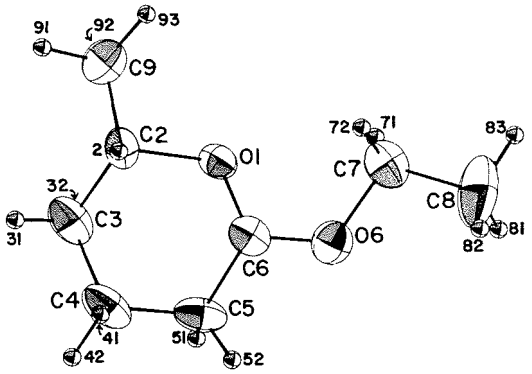

FIG. 2. The cation $C_8H_{15}O_2^+$ in compound **2**, showing the atom numbering. Hydrogen atoms are indicated by affixes only, in smaller print.

Selected bond distances and angles and atomic positional parameters of the three salts are given in Tables 2 and 3–5, respectively. The structures of **1–3** are shown in Figs. 1–3. Data on important planes in these cations are summarized in Table 6. Full details of the structure solutions are given in the experimental section and the supplementary material deposited with this paper.[7]

Discussion

Examination of the structures shown in Figs. 1–3 shows that in each case alkylation of the carbonyl oxygen atom of the lactone has taken place and that the structures are correctly represented as **1–3**. This alkylation is accompanied by a substantial change in the geometry of the salt with the C(6)–O(6) bond distance being significantly elongated and the O(1)—C(2) bond distance shortened as compared with those found

for six-membered ring lactones (19). There is no significant difference in the lengths of the O(1)—C(2) and C(6)—O(6) bonds of **1–3**, Table 2. Comparable C—O bond distances that are intermediate in length between C—O single and double bond lengths have been found in other oxygen-substituted carbenium ions (12–15, 18, 20, 21).

The geometry at the positively charged center of these salts is such that in each case atoms O(1), C(5), C(6), and O(6) lie in a plane, Plane A. Atoms C(2) and C(7) in **1** (−0.02(1) and 0.13(1) Å) and **3** (−0.06(1) and 0.06(1) Å) are also positioned close to Plane A. The C(2)—O(1)—C(6) and C(6)—O(6)—C(7) angles in each of these cations are close to 120°, as would be expected for sp^2-hybridized oxygen atoms. Overall, the structures are consistent with positive charge being delocalized over the O(1)C(6)O(6) fragment in these cations.

As a result of the near planar arrangement of the dialkoxy carbenium ion center, the six-membered rings of these cations are also forced to adopt relatively planar conformations. This can be seen, for example, on inspection of the edge view of **1**, shown in Fig. 4. The six-membered ring in **1** exists in a shallow pseudo-chair conformation with C(4) being above (−0.31(2) Å) and C(3) being below (0.43(2) Å) the plane defined by O(1), C(2), C(5), and C(6), Plane B. Cations **2** and **3** adopt similar pseudo-chair conformations with the C(2)-methyl group in **2** and the *trans*-fused six-membered ring in **3** occupying pseudo-equatorial positions on the lactonium ring.

The C(5)—C(6)—O(1) bond angles in these cations are significantly larger (125.2(6), 125.8(6), and 123.9(6)° in **1–3**, re-

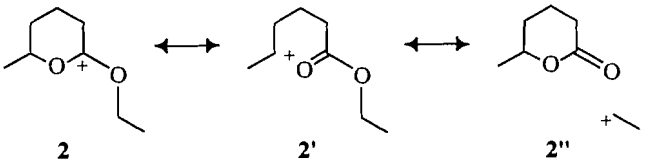
spectively) than is normally expected for a six-membered ring lactone (118.4(1.7)°) (19), (differences 3.8σ, 4.1σ, and 3.1σ respectively, where $\sigma = \sqrt{(\sigma_1^2 + \sigma_2^2)}$). Protonation of a ketone has been shown to result in an expansion of the C—C(=OH$^+$)—C bond angle from that encountered in the corresponding neutral ketone (21). Such an effect would seem to be unlikely in cations **1–3** where there are two oxygen substituents at C(6). Rather, the expansion in the C(5)—C(6)—O(1) bond angle is likely caused by the strain in the six-membered ring associated with the conformational requirements imposed by the planar arrangement of the four ring atoms.

It is interesting to consider the distances found for the O(1)—C(2) and O(6)—C(7) bonds in these structures and compare them with what normally would be expected for the corresponding O—C bonds in esters. In the first place the O—CH_2 bonds in **1–3** (O(1)—C(2) in **1** and O(6)—C(7) in **1–3**) are similar in length with an average distance of 1.489(5) Å.[8] This is significantly longer than the O—CH_2 distance (1.452(2) Å) found by Allen and Kirby in their detailed analysis of the structures of esters (22). It is clear that the presence of the positive charge in these lactonium salts causes an elongation of this O—CH_2 bond.[9] In **2** and **3** the O(1)—C(2) bonds are even longer (1.520(7) and 1.538(8) Å, respectively) than those of the O—CH_2 bonds and they represent some of the longest known C—O bonds. The difference between the O(1)—C(2) bonds in **2** and **3** as compared to **1** is that C(2) in the former cations has an extra carbon substituent. Within the ester series such a change in substitution at the carbon of a C—O bond leads on average to a small expansion of its length (1.460(2) as compared to 1.452(2) Å) (22). The elongation observed here is much larger than can be expected just on the basis of steric effects resulting from substitution at the carbon atom.

Allen and Kirby have shown that a C—O bond is lengthened as electron-withdrawing groups are attached to the O atom. This effect has been attributed to enhanced involvement of the ionic resonance contributor shown in eq. [1] (22, 24).



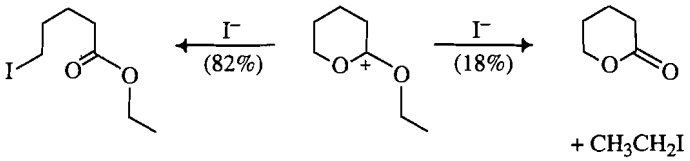
[1] R_3C—O—substituent ⟷ R_3C^+ O^--substituent

[8]The errors for mean bond lengths are given by

$$\sigma_D = \sqrt{(\Sigma_n (D - d_n)^2 / n(n-1))}$$

where D is the mean bond distance of n independent variables and d_n is the nth bond length.

[9]Corresponding O—C bond distances are found in the ethoxy group of the 1-ethoxyhomotropylium cation, ref. 23.



SCHEME 1

In the systems examined here the presence of the positive charge on C(6) means that there is a strongly electron-withdrawing group attached to O(1) and O(6). The elongation of the O(1)–C(2) and O(6)–C(7) bonds can be thought of as involving the structures shown in Scheme 1 with the transfer of the charge onto carbon atoms C(2) and C(7). Alkyl substitution at C(2), as in **2** and **3**, will enhance the contribution of the resonance form **2'** and cause a further elongation of this bond as compared to O(6)—C(6).

Examination of the bond angles at C(2) of **2** supports the suggestion of an enhanced ionic contribution to the O(1)—C(2) bond. Neglecting the bond angles involving hydrogen due to the large errors associated with them, it can be seen from the data in Table 2 that the C(3)—C(2)—C(9) and O(1)—C(2)—C(9) angles, 116.0(6) and 104.0(5)°, respectively, are significantly distorted from those expected for a carbon atom with a tetrahedral geometry. This distortion implies that the hybridization of C(2) is intermediate between sp^2 and sp^3 as would be expected to result from an elongation of the O(1)—C(2) bond and transfer of charge to C(2). Similar changes in bond angles as a function of the length of an O—C bond have been reported by Edwards, Jones, and Kirby in their mapping of the structural changes associated with the ionization of 1-arylethanol derivatives (25).

The $SbCl_6^-$ anions show no unusual features. They are very close to octahedral in all three compounds. In compound **1** there are two independent $SbCl_6^-$ anions, both sitting on inversion centres (000,00$\frac{1}{2}$). Although there are significant differences in the bond lengths and angles (Sb—Cl, ave. 2.367 Å, range 2.363(2)–2.378(1); *cis*-Cl—Sb—Cl, range 89.7(1)—91.3(1)), the differences are small and of no importance. In **2** there are again two independent $SbCl_6^-$ anions, both with the Sb atom and four chlorine atoms in the mirror planes at $\frac{1}{4}$,y,z and $\frac{3}{4}$,y,z. The variation in *cis* angles is similar to **1** (*cis*-Cl—Sb—Cl, range 89.4(1)–90.6(2)°) but the variation in Sb—Cl bond lengths is greater. In particular, the bonds out of the plane are longer than those in the plane (2.385(2) Å vs. a range of 2.339(2)–2.366(2) Å and 2.380(2) Å vs. a range of 2.344(2)–2.355(2) Å, although the average is very similar to

SCHEME 2

1 (2.363 Å). The $SbCl_6^-$ anion in **3** lies on a general position. The bond lengths and angles are similar to **1** and **2** (Sb—Cl ave. 2.363 Å, a range of 2.355(2)–2.373(2) Å; *cis*-Cl—Sb—Cl 88.3(1)–91.3(1)).

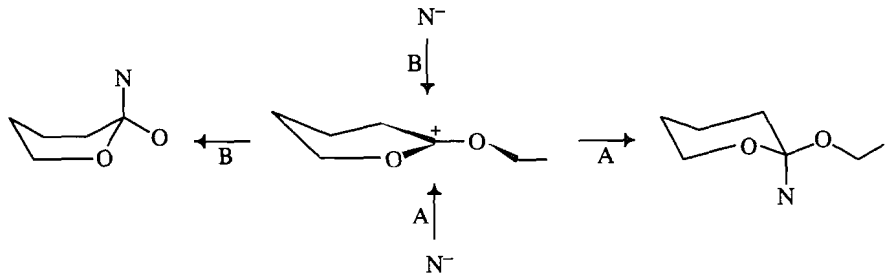
The large downfield shifts ($\Delta\delta$) observed for the solution ^{13}C chemical shifts of the C(2) resonances of **1–3** that occur on alkylation of these lactones indicates the presence of positive charge on these carbons in the cations, Table 1. Thus the downfield shifts of C(2) that accompany the conversion of **4** to **1** and **5** to **2** (18.5 and 24.5 ppm, respectively) are the largest shifts observed for any of the carbon atoms in these lactones. The downfield shift of C(2) resulting from the conversion of **5** to **2** is larger than that attending the formation of **1**, as would be expected on the basis of the greater C(2)—O(1) bond distance of **2**. A similar transfer of positive charge to the alkyl carbon atoms has been observed with the dioxolan-2-ylium cations (15).

The transfer of charge to C(2) and C(7) in these cations should be accompanied by contraction of the C(2)—C(3), C(2)—C(9), and C(7)—C(8) bonds (26). The errors associated with the structure determinations of **1–3** make this difficult to assess. For example, the average distance of the CH_2—CH_3 bond in these cations (1.486(12) Å) is not significantly different from the comparable bond in an ethyl group of an ester (1.503(2) Å) (difference 1.4σ) (22). It is clear that any contraction of this bond is small.

Beaulieu and Deslongchamps have shown that the reaction of **1** with iodide gives a high proportion of the ring-opened product as compared to cleavage of the ethyl group of the lactone, Scheme 2, and have accounted for this, at first sight surprising, regioselectivity on the basis of stereoelectronic effects (5). It was suggested that cleavage of the O(1)—C(2) or O(6)—C(7) bond would be facilitated when this breaking bond is anti-periplanar to the C(6)—O(6) or C(6)—O(1) bond, respectively. It was assumed that **1** existed in the *Z* conformation, Scheme 2, and, as such, cleavage of the O(1)—C(2) bond would be a low energy process.

The structures of **1–3** determined in this work fully support the assumption that these ions have a *Z* conformation about the C(6)—O(6) bond. As can be seen from Figs. 1–3, in each case these cations have adopted a *Z* conformation about this bond. Within each cation the -CH_2CH_3 group has a bisected arrangement with respect to the C(6)—O(6) bond. However, the CH_3 group of the ethyl substituent would seem to be able to adopt a variety of conformations, with it being closer to the plane of the ring (Plane B) in **2** (0.45(2) Å) and **3** (0.75(3) Å) than in **1** (−1.22(2) Å). The constraints imposed by the six-membered rings ensure that they have an *E* conformation about the C(6)—O(1) bonds. Acyclic dialkoxy carbenium ions have been shown to exist preferentially in an *E,Z* conformation about the two C^+—OR bonds. The present study demonstrates for the first time that this *E,Z* conformation is also preferred for cyclic cations.

It should be noted that the C(6)—O(6) *Z* conformational preference observed here for the cations **1–3** is for materials in their crystalline states. Reactions of these ions take place in solution and it could be argued that solvation might change the conformational preference about the C(6)—O(6) bond. While the occurrence of such a change in conformational preference in the two phases is extremely unlikely, given the uniformity in conformation found in the three separate examples of these cations studied here, this possibility is eliminated by the essentially identical ^{13}C NMR spectra observed for **1** and **2** in CD_2Cl_2 solution and in the solid state, Table 1. Overall, *the close similarity of the individual carbon atom resonances indicates that the conformation and charge distribution of these carbon atoms of the cation are the same in solution and the solid state.*



While the conformations found here for these cations fully support the assumptions made in explaining the regioselectivity of their reactions, examination of the various C—O bond distances fails to show evidence for the operation of stereoelectronic effects. It was suggested by Deslongchamps *et al.* that the reason for the *Z* conformation having a lower energy than the *E* form is due to the presence of a secondary electronic effect in which the lone pair of electrons on O(6) in the *Z* conformation is placed so as to interact with the antibonding orbital of the C(6)—O(1) σ bond. No such interaction is possible with the lone pair of electrons on O(1). As a result, the C(6)—O(6) bond should be shorter than the C(6)—O(1) bond. Examination of the data given in Table 2 shows no significant difference in the lengths of the C(6)—O(6) and C(6)—O(1) bonds in any of the cations. It is clear that any structural effect of the relative alignment of a lone pair and a C—O bond must be small. Similarly, one notes that attack at either C(2) or C(7) (Scheme 2) would be facilitated by the presence of positive charge on these carbon atoms and the lengthening and consequent weakening of the C(2)—O(1) and C(7)—O(6) bonds. However, the distances of these two bonds in each of the cations are the same within the error limits of the structure determinations (differences of 1.4σ, 2.5σ, and 3.0σ for **1–3** respectively) and as such there is no reason on this basis to expect a preference for attack at the C(2) position.

Crystal packing

It is of interest to consider the various cation/anion contacts present in the crystal lattices of these salts to see if the placement of the chlorine atoms of the $SbCl_6^-$ groups might correspond to the various types of reactions these cations can undergo with a nucleophile. For example, the long C(2)—O(1) and C(7)—O(6) bonds and positive charge on C(2) and C(7) could result from the presence of a chlorine atom in close proximity to these carbon atoms, situated to correspond to the commencement of nucleophilic attack as shown in Scheme 3 (27). However, examination of the long-range contacts in the crystal lattices of **1–3** shows that in each case the closest contacts occur at C(6) and that no other specific interactions seem to be present.

Cations **2** and **3** each have a chlorine atom above and below the O(1), C(5), C(6), O(6) plane. In **2** these chlorine atoms, Cl(21) and Cl(11), are situated 3.323(4) and 3.495(3) Å respectively from C(6), at internuclear distances that are less than the sum of the van der Waals radii of neutral C and Cl atoms (3.50 Å) (25). These Cl atoms are oriented as if they were undergoing a nucleophilic addition at C(6). The Cl(21)—C(6)—O(6) and Cl(21)—C(6)—O(1) angles are 93.7(5) and 94.1(5)°, respectively. In **3**, chlorine atoms Cl(4) and Cl(5) are found 3.279(7) and 3.766(7) Å respectively from C(6) and are sit-

SCHEME 3

uated approximately 90° to both the C(6)—O(6) and C(6)—O(1) bonds. The Cl(4)—C(6)—O(6) and Cl(4)—C(6)—O(1) angles are 83.0(7) and 91.3(7)°, while those corresponding to Cl(5) are 107.8(7) and 80.8(7)° respectively. The presence of counterions above and (or) below the carbonyl plane of a protonated or alkylated carbonyl group would seem to be a general phenomenon of the crystal packing of this type of organic salt (20).

Only one chlorine atom, Cl(21), is situated in close proximity to C(6) in the crystal lattice of **1**, Fig. 4. The C(6)—Cl(21) distance (3.200(6) Å) is significantly less than the sum of the van der Waals radii of the two atoms and the Cl(21)—C(6)—O(6) and Cl(21)—C(6)—O(1) angles are 88.5(3) and 97.3(4)°, respectively. In the other two known cases where only a single anion or other Lewis base is in close contact with the central carbon atom of a protonated or alkylated carbonyl group, this carbon atom is moved out of the carbonyl plane towards the Lewis base (20, 21). However, in **1** C(6) is not significantly displaced from the O(1), C(5), O(6) plane.

The addition of a nucleophile to C(6) of these tetrahydropyrylium salts takes place stereoselectively (2, 9). It has been suggested that the important feature of the reaction is that attack occurs on that face of the cation that leads directly to a chair, path A, rather than initially to a boat conformation, path B, of the six-membered ring, Scheme 3.

In the cations studied here both of these approaches are seen in the crystal lattice. With **1**, Cl(21) is situated in a position as if it were approaching by Path A, Scheme 3, to give the chair conformation. With both **2** and **3** the situation is more complicated, with two corresponding chlorine atoms perpendicular to C(6). However, the closest chlorine atom to C(6) in **2**, Cl(21), shows an approach angle corresponding to Path A. It should be noted that this path would give a chair conformation in which the C(2) methyl substituent would be in an equatorial position. Conversely, the closest chlorine atom contact in **3** is situated so as to approach by Path B.

It is perhaps not surprising that the cation/anion interactions present in the lattices of these salts show no clear preference for attack by Path A, Scheme 3, given the relatively low nucleophilicity of $SbCl_6^-$ and the consequent long C(6)—Cl distances involved.[10] However, as models for the cation in solution they are informative. It is clear that the environment of these cations in solution will be similar to that encountered in the crystal lattice. The near identity of the solid state and solution ^{13}C NMR spectra of **1** and **2** clearly demonstrates this point as does the general uniformity in relative anion–cation positions not only in the salts studied here, but also in the range of other known structures of alkoxy-substituted cations. In solution the anions could be replaced by solvent molecules depending on the nature and degree of ion-pairing present. However, the solvent molecules would in general be oriented in such a way that there would be interaction of a Lewis base in the solvent with C(6) as is found here within the crystal lattices. The results obtained here suggest that when the surrounding Lewis base atoms of anions, solvent, or nucleophiles are separated from C(6) by distances corresponding to somewhat less than the sum of the van der Waals radii of the two atoms involved, then no preference for attack by either of the two paths shown in Scheme 3 will be observed. For the chair/boat explanation shown in Scheme 3 to be correct, differentiation between Paths A and B must occur later in the reaction coordinate than those found here in the crystal lattices. However, the scope for delaying the transition states of these exothermic reactions is limited and relatively early transition states would be expected.

To examine these questions further it would be attractive to synthesize additional examples of these cations in which there is a closer, more specific interaction between the cationic center and a Lewis base. Such systems, while not easy to prepare and crystallize, offer the prospect of being able to map out the bonding changes associated with these reactions and would answer some of the questions raised in this work regarding the origin of the stereoselectivity of the reactions.

Experimental

NMR spectra were obtained on Varian EM-390, Bruker WM-250, WM-500, and MSL-100 spectrometers. All solution spectra were referenced with CD_2Cl_2. X-ray diffraction data for the crystals studied were collected on a Syntex $P2_1$ automatic diffractometer equipped with a low-temperature apparatus. Intensity measurements for **1** and **2** were made at low temperature (−65°C). The crystals were kept at low temperature by a stream of dry nitrogen, which had been cooled in a liquid nitrogen heat exchanger. Those for **3** were made at room temperature with the use of graphite monochromated MoK_α radiation ($\lambda = 0.71069$ Å).

Preparation of lactones

δ-Valerolactone (**4**) was commercially available and was distilled before use. Lactone **5** was obtained by Baeyer–Villiger oxidation of commercially available 5-methylcyclopentanone (28). *trans*-Octahydrocoumarin (**6**) was prepared according to the procedure of Graham and co-workers (29).

Preparation of hexachloroantimonate salts

Salts **1–3** were prepared from the corresponding lactones according to the procedure of Deslongchamps *et al.* (6). The salts were extremely hygroscopic and all manipulations were done under a controlled atmosphere. The salts were recrystallized from CH_2Cl_2 at −20°C to give single crystals suitable for X-ray diffraction studies.

6-Ethoxy-2,3,4,5-tetrahydropyrylium hexachloroantimonate, 1: mp 108–110°C (dec.). The ^1H NMR spectrum of **1** in CD_2Cl_2 at room

[10]While a chlorine atom remains in the nucleophile it is unlikely that examples of systems with extremely short C...Cl distances will be found.

temperature consisted of peaks at δ 1.40 (3H, t, J = 7.0 Hz, -CH_2-CH_3), 2.00 (4H, m, protons at C3 and C4), 3.42 (2H, m, protons at C5), 4.70 (2H, q, J = 7.0 Hz, -CH_2-CH_3), 5.04 (2H, m, protons at C2).

6-Ethoxy-2-methyl-2,3,4,5-tetrahydropyrylium hexachloroantimonate, 2: mp 127–128°C (dec.). The ^{1}H NMR spectrum of **2** in CD_2Cl_2 at room temperature displayed peaks at δ 1.44 (3H, t, J = 7.1 Hz, -CH_2-CH_3), 1.77 (3H, d, J = 6.5 Hz, -CH-CH_3), 2.0–2.5 (4H, m, protons at C3 and C4), 3.21 (2H, m, protons at C5), 4.90 (2H, dq, J = 7.1 Hz, $J_{H_aH_b}$ = 3.5 Hz, -CH_2-CH_3), 5.55 (1H, m, -CH-CH_3).

2-Ethoxy-3,4,4a,5,6,7,8,8a-octahydro-1-benzopyrylium hexachloroantimonate, 3: mp 120–122°C (dec.). The ^{1}H NMR spectrum of **3** in CD_2Cl_2 at room temperature displayed peaks at δ 1.45 (3H, t, J = 7.0 Hz, -CH_2-CH_3), 2.0–2.4 (13H, m, ring protons), 2.4–3.4 (1H, m, proton at C2), 4.90 (2H, q, J = 7.0 Hz, -CH_2-CH_3).

Crystallography

All crystals were handled under a dry nitrogen atmosphere at all times. Suitable single crystals were sealed in 0.3 mm diameter Lindemann capillary tubes with the use of a dry box equipped with a microscope. Buerger-type precession photographs were used to determine potential space groups and to establish approximate unit cell dimensions before the crystal was transferred to a Syntex $P2_1$ diffractometer. Crystal data for salts **1–3** are summarzed in Table 6.[11] For all crystals only reflections with $I > 0$ were used in the refinement. Scattering curves were taken from the International Tables and anomalous dispersion corrections applied to the curves for Sb and Cl. No absorption corrections were applied because the crystals were sealed in glass tubes.

6-Ethoxy-2,3,4,5-tetrahydropyrylium hexachloroantimonate, 1

Triclinic unit cell parameters for **1** were determined from a least-squares fit of χ, φ, and 2θ at −65°C for 15 reflections in the range 20° ≤ 2θ ≤ 29°. Intensity data were collected at low temperature in the space group $P\bar{1}$ by use of a coupled θ(crystal)–2θ(counter) scan. The XRAY76 (30) package and the XTAL program suite (31) were used for preliminary data treatment. The intensity data were corrected for Lorentz and polarization effects but not for absorption. This would lead to a maximum error on F_o of 3.6%.

The SHELX (32) program was used for structure determination and refinement. The antimony atom was found by direct methods with use of 2674 reflections with $|E| \geq 1.5$ and 20 sets of starting phases. Subsequent electron density difference maps revealed the positions of the remaining atoms. Temperature factors of all non-hydrogen atoms were made anisotropic and refined before hydrogen atom positions were located. Hydrogen atom positions and isotropic temperature factors were then varied through four full-matrix least-squares cycles before being fixed. Full-matrix least-squares refinement, which used a variable weighting scheme, minimized $\Sigma w(|F_o| - |F_c|)^2$ and was terminated when the maximum shift/error was ≤0.010.

6-Ethoxy-2-methyl-2,3,4,5-tetrahydropyrylium hexachloroantimonate, 2

The unit cell parameters for **2** were obtained at −65°C by a least-squares fit of χ, φ, and 2θ for 15 reflections in the range 20° ≤ 2θ ≤ 26°. The unit cell was found to be orthorhombic and intensity data were collected in the uniquely defined non-standard space group *Pmnb* by use of a coupled θ(crystal)–2θ(counter) scan. The XRAY76 (30) package and the XTAL program suite (31) were used for preliminary data treatment. Corrections were made for Lorentz and polarization effects but not for absorption. This would lead to a maximum error on F_o of 7.1%.

The position of the antimony atom was revealed by direct methods with use of 1633 reflections with $|E| \geq 1.5$ and 20 sets of starting phases. The remaining atoms were located from subsequent electron density difference maps. Temperature factors of all non-hydrogen atoms were made anisotropic and refined before hydrogen atoms were located. Hydrogen atom positional parameters and isotropic temperature factors were refined through four full-matrix least-squares cycles before being fixed. Full-matrix least-squares refinement, which employed a variable weighting scheme, minimized $\Sigma w(|F_o| - |F_c|)^2$ until the maximum shift/error was ≤0.011.

2-Ethoxy-3,4,4a,5,6,7,8,8a-octahydro-1-benzopyrylium hexachloroantimonate, 3

Unit cell parameter determination, data collection, and reduction were carried out as described above. The unit cell was found to be orthorhombic and data were collected in the uniquely defined space group $Pca2_1$. Corrections for Lorentz and polarization effects were applied to the measured intensities but not for absorption. This would lead to a maximum error on F_o of 8.4%. A SHELX (32) three-dimensional Patterson synthesis revealed the position of the antimony atom. All remaining atom positions were determined by subsequent electron density difference maps in conjunction with full-matrix least-squares refinement cycles. Hydrogen atoms were located once all non-hydrogen atoms had been anisotropically refined. Hydrogen atoms were given fixed positions and isotropic temperature factors. Full-matrix least-squares refinement with a variable weighting scheme minimized $\Sigma w(|F_o| - |F_c|)^2$ and refinement was terminated when the maximum shift/error was ≤0.001.

[11]Bond angles for the anions, anisotropic temperature factors, hydrogen atom positional parameters, isotropic temperature factors, bond lengths, and angles involving hydrogen atoms, and F_o and F_c tables are available as supplemental material, see footnote 7.

Crystal packing diagrams for **1–3** and tables of bond lengths and angles and hydrogen atom positional parameters have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

The crystal structure of $W(CO)_5$piperidine: Implications for photoreactivity of $W(CO)_5L$ complexes

CAROL MORALEJO, COOPER H. LANGFORD, AND PETER H. BIRD
Department of Chemistry and Biochemistry, Concordia University, 1455 de Maisonneuve Blvd. W., Montreal, P.Q., Canada H3G 1M8

Received November 19, 1990[1]

CAROL MORALEJO, COOPER H. LANGFORD, and PETER H. BIRD. Can. J. Chem. **69**, 2033 (1991).

The X-ray crystal structure of $W(CO)_5$piperidine is reported and assignments are given for the LF and CT band of $W(CO)_5$piperidine and $W(CO)_5$pyridine. The W---N, W---C (axial), and W---C (equatorial) bond lengths for $W(CO)_5$pip are 2.330(5), 1,963(6), and 2.04(7), respectively. The longer W---N bond length in $W(CO)_5$pip compared to $W(CO)_5$pyr corresponds to greater photoreactivity observed under LF triplet excitation for $W(CO)_5$pip but cannot account for the reverse trend observed under LF singlet irradiation. The structure also fails to support a model based on differences in π back donation from W. It is concluded that differences between singlet and triplet photoreaction originate in the relative rates of radiationless decay.

Key words: $W(CO)_5$piperidine, photoreactivity, crystal structure.

CAROL MORALEJO, COOPER H. LANGFORD et PETER H. BIRD. Can. J. Chem. **69**, 2033 (1991).

On a déterminé la structure cristalline du complexe $W(CO)_5$.pipéridine par diffraction des rayons-X et on a fait l'attribution des bandes LF et CT des complexes $W(CO)_5$.pipéridine et $W(CO)_5$.pyridine. Les longueurs des liaisons W---N, W---C(axial) et W---C(équatorial) du complexe $W(CO)_5$.pip sont respectivement 2,330(5), 1,963(6) et 2,04(7) Å. Le fait que la liaison W---N soit plus longue dans le complexe $W(CO)_5$.pip que dans le complexe $W(CO)_5$.pyr correspond à la plus grande photoréactivité observée lors de l'excitation LF du triplet du $W(CO)_5$.pip; elle ne peut toutefois pas expliquer le renversement de la tendance observée lors de l'irradiation LF du singulet. La structure ne permet pas non plus d'expliquer un modèle basé sur des différences dans la rétrocession d'électrons π par le W. On en conclut que les différences entre les photoréactions singlulet et triplet trouvent leur origine dans les vitesses relatives de la dégénérescence non radiative.

Mots clés : $W(CO)_5$.pipéridine, photoréactivité, structure cristalline.

[Traduit par la rédaction]

Introduction

Tutt and Zink (1) have elucidated the bond length changes characteristic of the vibrationally equilibrated low lying ^3E ligand field excited state of $W(CO)_5L$ (L = piperidine (pip) or pyridine (py)) using Heller's semi-classical time dependent theory of molecular spectroscopy (2). This provided an approach to the photochemical reactivity of the complexes, substitution of the L ligand. Recent results (3) show that the theoretical discussion of photoreactivity should include an appraisal of singlet behavior as well. In our recent work (3), we have observed that significant differences exist in the relative reactivities of $W(CO)_5$pyridine and $W(CO)_5$piperidine upon excitation into the LF singlet and triplet states. As a contribution to the understanding of the differences in reactivities between these two compounds, we have obtained a spectrum and a structure to evaluate the role of π back-donating in the pyridine complex. In this paper, the crystal structure of $W(CO)_5$pip is reported. The bond lengths are compared with reported bond lengths for $W(CO)_5$py and $W(CO)_6$ in an attempt to clarify whether a significant π back-bonding exists between W and pyridine which may account for observed differences in photochemical behavior between these two complexes under LF singlet irradiation. Other physical evidence such as the infrared frequencies and derived force constants for CO, and the positions of the LF bands in the deconvoluted electronic spectra do not support a very significant difference in W—N bonding between the py and pip complexes.

Experimental

Materials

$W(CO)_5$pip was prepared using a modification of the procedure proposed by Strohmeier and Gerlich (4). $W(CO)_6$ (0.65 g) and 5 mL of piperidine were mixed in 30 mL of THF. The solution was irradiated by exposure to cool-white fluorescent lab lights ($\lambda > 350$ nm) for 72 h. Prepurified N_2 was passed through a solvent bubbler into the solution to prevent solvent evaporation and to sweep out displaced CO. The reaction was monitored for unreacted $W(CO)_6$ by TLC on alumina plates. After 72 h, the THF was removed by rotary evaporation. The yellow residue was dissolved in benzene and mixed with 1–2 g of alumina. The benzene was evaporated overnight to encourage adsorption of the product onto the alumina. The adsorbed product was added to a column of neutral alumina in isoctane. Isooctane eluted unreacted $W(CO)_6$ and benzene eluted the product. Ethanol was used to elute the unreacted ligand. The crystals of $W(CO)_5$piperidine were grown by slow evaporation (2 weeks) in benzene/isooctane (2:1 v/v). $W(CO)_5$py (py = pyridine) was obtained as described in ref. 1.

The X-ray crystal structure determination

The chosen crystal was subjected to a preliminary photographic survey to check its quality and to determine the space group and approximate unit cell measurements. It was then transferred to a Picker Facs-1 diffractometer where more precise cell dimensions were obtained from 25 automatically centered reflections, and then intensity data were collected. Lorentz polarization and general absorption corrections were applied. The tungsten atom was located from a Patterson synthesis and the structure completed and refined routinely using anisotropic thermal parameters in the final stages. No attempt was made to include the hydrogen atoms. Details may be found in Table 1. Table 2 contains a listing of the final atomic coordinates, while listings of the anisotropic thermal parameters, observed and calculated structure factors, and a complete table of bond lengths and angles, are available as supplementary data.[2] All programs used for the data collection, structure solution, and refinement are part of the

TABLE 1. Crystallographic data for $W(CO)_5$pip

(*a*) Crystal parameters

Formula: $C_{10}H_{11}NO_5W$	fw = 409.05
Crystal system: Monoclinic	Space group: $P2_1/c$
a = 11.127(6) Å	α = 90 deg
b = 10.269(4) Å	β = 110.51(5) deg
c = 12.325(9) Å	γ = 90 deg
V = 1319.01 Å^3	Z = 4
D_{calcd} = 2.060 g cm^{-1}	μ(Mo Kα) = 89.53 cm^{-1}
Colour: yellow	Transmission 33–43%
Crystal size: 0.2 × 0.1 × 0.5 mm	Temp = 21°C

(*b*) Data collection and structure refinement*

Diffractometer: Picker FACS-1	Radiation: Mo Kα
Monochromator: graphite	Scan method: $\theta/2\theta$
Scan speed: 2°/m	Data limits: $3.5 < 2\theta < 50°$
Octants collected: $\pm h, +k, +l$	Total reflections collected: 2316
Independant reflections collected: 2316	Unique data $F_0 > 3\sigma F_0$: 1865
Least-squares method: block diagonal	Absorption correction: yes
Parameters refined: 154	Data/parameter ratio = 12.1
R_1 = 0.028	R_2 = 0.046
Goodness of fit = 0.81	

*$R_1 = \Sigma[||F_0| - |F_c||]/\Sigma|F_0|$; $R_2 = [\Sigma w(||F_0| - |F_c||)^2/\Sigma w|F_0|^2]^{1/2}$, where $w = 1/\sigma(F_0)$; goodness of fit = $[\Sigma w(|F_0| - |F_c|)^2/(N_{obs} - N_{parm})]^{1/2}$.

X-ray crystallographic system for the PDP-8 minicomputer by Larson and Gabe (5).

Spectral band deconvolution

The electronic spectra of $W(CO)_5L$ (L = py, pip) in all solvents used in this study were deconvoluted using a Gaussian band least-squares minimization routine (6) employing a Marquardt algorithm (7). The program allows the band positions to be fixed and the best Gaussian fits for the W → pyr CT, ^1A and ^1E bands were determined when the band maxima of the ^3E bands were initially fixed between 446 and 448 nm, depending on the solvent.

Results and discussion

Electronic spectra

The band maxima determined from the curve-fitting program for different solvents are given in Table 3. The uv–vis absorption spectra of $W(CO)_6$, $W(CO)_5$py, and $W(CO)_5$pip in alkane solvents display characteristics which have been well documented (8–12). For $W(CO)_6$ in cyclohexane, the lowest energy absorption band at ~28 570 cm^{-1} (350 nm) is assigned as the spin-forbidden $^3T_{1g} \leftarrow {}^1A_{1g}$ transition (8, 9). The first LF (ligand field) singlet transition, $^1T_{1g} \leftarrow {}^1A_{1g}$ is observed at 32 258 cm^{-1} (310 nm) as a shoulder on the more intense M → π^* CO charge-transfer absorption at 34 485 cm^{-1} (290 nm). A higher energy absorption band observed as a shoulder at 37 037 cm^{-1} (270 nm) is assigned as the second LF $^1T_{2g} \leftarrow {}^1A_{1g}$ transition. The highest absorption observed at ~43 000 cm^{-1} (233 nm) is assigned as the second component of the M → π^* CO charge-transfer transition.

Substitution of a CO in $W(CO)_6$ by a pyridine or piperidine molecule reduces the symmetry of the complex from octahedral to C_{4v}. Reduction of the symmetry results in a splitting of the T_{1g} and T_{2g} states. The electronic spectra of $W(CO)_5$py and $W(CO)_5$pip exhibit similar features in alkane solvents. In isooctane, each compound exhibits a low energy band, near 22 625 cm^{-1} (442 nm) which has been previously assigned as a LF $^3E \leftarrow {}^1A_1$ transition and which appears as a shoulder on the more intense LF ^1E transition centered near 26 180 cm^{-1}

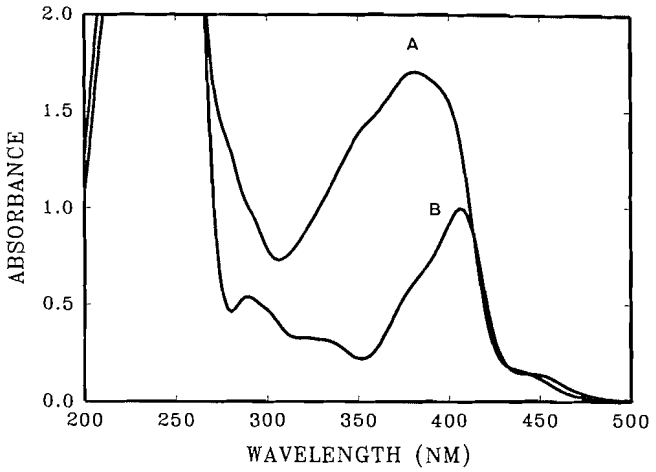

FIG. 1. Electronic spectra of (*a*) $W(CO)_5$pyridine and (*b*) $W(CO)_5$piperidine in isooctane. The concentration for both was 2.8 × 10^{-4} M.

(382 nm) for pyridine and 24 350 cm^{-1} (404 nm) for piperidine (Fig. 1) (10–12). Higher energy transitions have not been definitively assigned. The asymmetry of the band observed for piperidine at ~26 180 cm^{-1} (382 nm) suggests the presence of a second band. Based on the splitting of the $^1T_{1g}$ state from octahedral to C_{4v} symmetry, this asymmetry is probably due to a contribution from the orbitally forbidden, equatorially directed $^1A \rightarrow {}^1A_2$ transition (13). The intense absorption at 36 040 cm^{-1} (270 nm) observed for both complexes, by analogy to the MLCT assignment for $W(CO)_6$ is assigned as the W → π^* CO CT transition (8, 9). For $W(CO)_5$py in polar solvents, the asymmetry of the band observed near 28 570 cm^{-1} (350 nm) in non-polar solvents splits to reveal an absorption band which blue shifts and is resolved from the LF singlet band in more polar media (Fig. 2). This band has been assigned as a W → pyridine CT transition (14). Resolution of the CT and LF bands in the pyridine complex further reveals another transition at ~370 nm indicated by the asymmetry of the LF band.

Based on these assignments, the curve-fitting program previously described was used to deconvolute the bands in the 300–500 and 350–500 nm regions of the electronic spectra of $W(CO)_5$py and $W(CO)_5$pip, respectively. Four bands were assigned for the $W(CO)_5$py complex and three bands for the $W(CO)_5$pip complex. For $W(CO)_5$pyr, in order of decreasing energy, the four bands represent transitions to the W → pyr CT, ^1A, ^1E, and ^3E states, respectively. For $W(CO)_5$pip, the three bands represent, in order of decreasing energy, transitions to the ^1A, ^1E, and ^3E states, respectively.

X-ray data

Figure 3 shows the molecular structure. The important bond lengths for the $W(CO)_5$piperidine complex determined in this work are given in Table 4 together with the reported bond lengths for $W(CO)_6$ and $W(CO)_5$pyridine for comparison.

Photoreactivity

$W(CO)_5L$ (L = py, pip) are d^6 C_{4v} complexes which undergo efficient photochemical substitution of L by suitable donor molecules in solution (14–17). In mixed alkane/alkene solvents, LF singlet irradiation gives efficient substitution of L by alkene (3, 14–17) and the quantum yield is wavelength dependent for these complexes as was first reported by Wrighton, Hammond, and Gray (16). LF singlet excita-

tion (365, 436 nm) produces larger photosubstitution quantum yields for $W(CO)_5$py than $W(CO)_5$pip (Table 5) (3). Quantum yields on irradiation into the LF triplet states of both complexes are lower than for LF singlet irradiation (3). Under direct LF triplet irradiation (488 nm), the quantum yields are larger for $W(CO)_5$pip than for $W(CO)_5$py. In solvents such as benzene and dichloromethane which resolve the W → pyr CT and LF states in $W(CO)_5$pyridine, the quantum yields decrease relative to solvents in which the W → pyr CT and LF states are mixed. There is a corresponding decrease for $W(CO)_5$pip as well, indicating the presence of a general solvent effect, not a role for charge transfer. In all solvents we have studied, the photochemical behavior is similar for both complexes. Under direct LF singlet irradiation, the photosubstitution quantum yields are greater for pyridine than for piperidine. Under direct LF triplet irradiation, the trend is reversed. The only significant difference between the two complexes is the presence of

low-lying π^* orbitals on the pyridine in $W(CO)_5$py which may π-bond with the t_{2g} orbitals of W. In complexes where metal $d\pi$ – ligand π^* back-bonding is present, simultaneous depopulation of the $d\pi$-orbitals and population of a σ antibonding orbital may lead to enhanced photoreactivity.

Zink and Tutt have determined the excited state distortions of both complexes under LF triplet excitation using fluorescence, preresonance Raman spectroscopy, and time-dependent theory (1, 2). They observe that the W---N bond length in the piperidine complex is increased by as much as 0.3 Å while the W---N bond length in the pyridine complex is increased by 0.18 Å(1). This information may be used to interpret our photosubstitution results on the basis of bond strengths since quantum yields are higher for the piperidine complex than for the pyridine complex under LF triplet excitation (3). Reported CO stretching frequencies are lower for the monosubstituted complexes than they are for the hexacarbonyl, indicating more extensive metal-to-carbonyl π-bonding and stronger metal carbonyl bonds for the monosubstituted complexes (18, 19). Comparison of the W---C bond lengths of all three complexes confirms this (Table 4). The X-ray data obtained in this study shows that the W---N bond is longer in the piperidine complex than in the pyridine complex. The difference in bond lengths between these two complexes may be attributed to differences in the hybridization of the orbitals which are responsible for bonding in these complexes. The N orbitals in the pyridine complex are sp^2 hybridized due to the aromatic nature of the pyridine N. The N orbitals in the piperidine complex are sp^3 hybridized. Values obtained for the CO force constants of the pyridine complex do not differ significantly from those obtained for the piperidine complex (19). This suggests that no appreciable π-bonding exists between tungsten and the pyridine.

This appears to eliminate π back-bonding which is reduced in the excited state as a cause of enhanced photoreactivity in the pyridine complex upon LF singlet irradiation. It raises the question as to what other variable may account for both the observed differences under LF singlet irradiation and the reverse trend observed under LF triplet irradiation. Both the LF singlet and LF triplet reactive states have the same orbital configuration. As a consequence, MO arguments must lead to similar conclusions regarding the reactivity.

The structure reported in this paper is consistent with assignment of the difference between W---N bond distances in $W(CO)_5$py and $W(CO)_5$pip to differences in N hybridization. There is little reason to posulate π acceptor character for the py ligand. The lesser distortion of the W---N bond in the pyridine complex on excitation to the ^3E state with σ^* character cannot be attributed to residual π-bonding.

Tutt and Zink (1) have pointed out that the greater extension of the W---N bond in the pip complex can be seen as "explaining" the greater quantum yield for photosubstitution from the ^3E states. Unfortunately, no similar bonding factor is available to explain the reversal of reactivity from the ^1E states. This serves to emphasize that quantum yields are determined by a competition between reactive and non-reactive radiationless decay. The reactivity change between the ^1E and ^3E states must originate in the changes in the dynamics of the relaxation to the ground state. In a subsequent paper (21), an analysis of some solvent effects will hint as to the mechanisms of such relaxation processes.

JAN A. HERMAN, KAZIMIERA HERMAN, and TERRY B. MCMAHON. Can. J. Chem. **69**, 2038 (1991).

The formation of $C_6H_7^+$ species in ion/molecule reactions in gaseous vinyl chloride was studied in a high pressure photoionization mass spectrometer and in a Fourier transform ion cyclotron resonance (FT-ICR) spectrometer. Collision-induced dissociation (CID) mass spectra of $C_4H_5Cl^+$, $C_4H_6Cl^+$, and $C_6H_7^+$ species suggest a "butadiene-like" structure for the two former ions, and a non-benzenium structure for the last species. The $C_6H_7^+$ ions are formed in a two-step mechanism involving $C_4H_5^+$ as intermediate ions. These processes are in competition with condensation reactions leading to the formation of $C_6H_{7-9}Cl^+$ species.

Key words: ion–molecule reactions, gaseous vinyl chloride, collision-induced dissociation.

JAN A. HERMAN, KAZIMIERA HERMAN et TERRY B. MCMAHON. Can. J. Chem. **69**, 2038 (1991).

Utilisant un spectromètre de masse à photo-ionisation à haute pression et un spectromètre de résonance cyclotronique ionique par transformation de Fourier (FT-ICR), on a étudié la formation de l'espèce $C_6H_7^+$ dans des réactions ion/molécule du chlorure de vinyle gazeux. Les spectres de masse des dissociations induites par des collisions (DIC) des espèces $C_4H_5Cl^+$, $C_4H_6Cl^+$ et $C_6H_7^+$ suggèrent la présence d'une structure « ressemblant à un diène » pour les deux premiers ions et une structure qui ne correspond pas à un benzénium pour la dernière espèce. Les ions $C_6H_7^+$ se forment par un mécanisme en deux étapes impliquant les ions $C_4H_5^+$ comme intermédiaires. Ces processus sont en compétition avec les réactions de condensation conduisant à la formation d'espèce $C_6H_{7-9}Cl^+$.

Mots clés : réactions ion–molécule, chlorure de vinyle gazeux, dissociation induite par collision.

[Traduit par la rédaction]

Introduction

Ion/molecule reactions in gaseous vinyl chloride have been studied extensively. Both high pressure mass spectrometry (HPMS) and ion cyclotron resonance spectrometry (ICR) were used to unravel the complex ion/neutral processes occurring in this system (1–8). The main difference between the results found by these two techniques is the extent to which these ion/neutral processes can be followed. In HPMS the ion/neutral sequences up to the fourth generation of product ions could be followed (9). Moreover, the multiple collision conditions at high pressure allow a stabilization of excited collision complexes in three-body processes and formation of stabilized ion clusters. However, the increasing number of ion products formed in successive ion/molecule reactions which react in competition with the neutral constituent makes kinetic studies quite difficult due to the complexities of many processes taking place simultaneously in the system. On the other hand, the low pressure ($<10^{-5}$ Torr) in ICR experiments favours the study of events on a collision-by-collision time scale. However, this usually limits the measurements to the first generation of product ions. However, the capabilities characteristic of ICR spectrometry include the ability to carry out multiple-stage experiments involving the isolation of chosen ion species and the subsequent study of bimolecular ion/molecule reactions with the neutral gas target. Therefore, in order to unravel the complex details of the later ion/molecule reaction sequences in vinyl chloride it is desirable to prepare chosen product ions at high pressure, to selectively isolate them, and to allow them to react with neutrals at low pressure. In this manner the observed ion processes are unequivocally established without interferences from competing reaction channels.

The first sequence of ion/molecule reactions ([1] to [3]), providing the formation of $C_4H_5Cl^+$, $C_4H_6Cl^+$, and $C_3H_4Cl^+$ species has been observed both in HPMS or ICR experiments and is apparently well established (1–6):

$$[1]\quad C_2H_3Cl^+ + C_2H_3Cl \rightarrow [(C_2H_3Cl)_2]^{+*} \rightarrow C_4H_5Cl^+ + HCl$$

$$[2]\quad \rightarrow C_4H_6Cl^+ + Cl\cdot$$

$$[3]\quad \rightarrow C_3H_4Cl^+ + CH_2Cl\cdot$$

Ausloos and co-workers have reported the observation of the stabilized ion-dimer of vinyl chloride before its decomposition in reactions [1]–[3] (5), but this was not clearly substantiated in similar experiments by Neagu-Plesu (9). At higher pressure the next condensation step is observed with the formation of $C_6H_7Cl^+$, $C_6H_8Cl^+$, $C_6H_9Cl^+$, and $C_5H_6Cl^+$ species:

$$[4]\quad C_4H_5Cl^+ + C_2H_3Cl \rightarrow C_6H_7Cl^+ + HCl$$

$$[5]\quad \rightarrow C_6H_8Cl^+ + Cl\cdot$$

$$[6]\quad C_4H_6Cl^+ + C_2H_3Cl \rightarrow C_6H_8Cl^+ + HCl$$

$$[7]\quad \rightarrow C_6H_9Cl^+ + Cl\cdot$$

$$[8]\quad C_3H_4Cl^+ + C_2H_3Cl \rightarrow C_5H_6Cl^+ + HCl$$

In Fig. 1 the evolution of fractional intensities of these ion species as a function of pressure in experiments performed in a photoionization HPMS is shown. However, in addition to these ions, and with a far larger fractional intensity, is the formation of the $C_6H_7^+$ species, which seems to reach a steady state within the system (Fig. 1*A*). Evidently, this ion is formed in ion/molecule reactions involving C_4 ion species, and the reaction channel leading to its formation should reflect its structure. In order to elucidate the reaction channel through which the $C_6H_7^+$

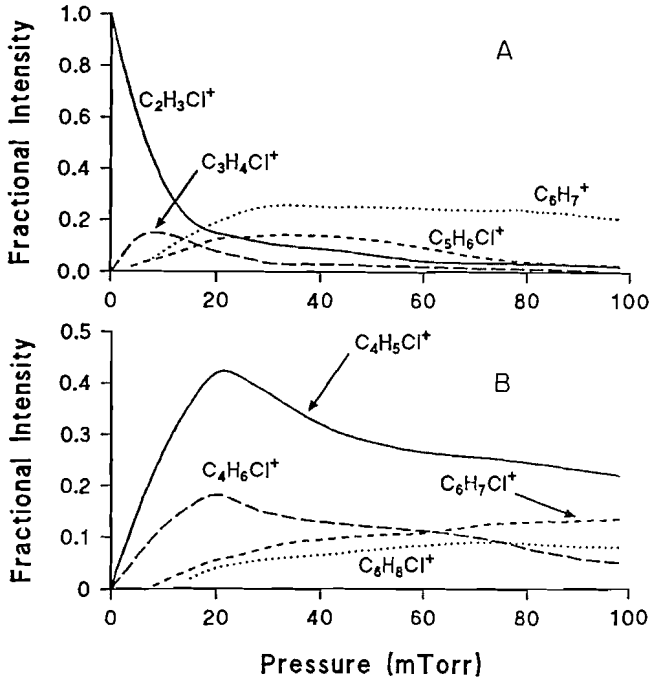

FIG. 1. Evolution of fractional intensities of ions in photoionized vinyl chloride at 10.64 eV as a function of pressure in high pressure mass spectrometer experiments.

is formed we have used the ICR ability to individually isolate the C_4 ion species and to react them with neutral vinyl chloride. An additional collision-induced dissociation (CID) experiment allowed the structure of this ion to be studied and, consequently, led to a proposal for the reactions sequence leading to its formation.

Experimental

The pressure dependence of fractional ion intensities was investigated in the photoionization high-pressure mass spectrometer already described (10, 11) A krypton resonance lamp very similar to those described by Ausloos and co-workers (12) was used as a photoionization source. The emitted light consists mainly of the 10.03 eV (~85%) and 10.64 eV (~15%) resonance lines. In these conditions about 70% of vinyl chloride ions are produced by absorption of 10.64 eV photons. The measurements were made under field-free conditions inside the collision chamber with an electric field of low intensity (~5 V cm^{-1}) applied in the ion optics. The distance in the collision chamber between the plane of formation of the parent ions by photon impact and the exit slit was 4.2 mm. The experiments were done at room temperature, 25 ± 2°C, as indicated by a thermocouple connected to the collision chamber.

The time evolutions of fractional intensities of selectively isolated $C_4H_5Cl^+$ and $C_4H_6Cl^+$ species and CID experiments on $C_6H_7^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$ ions were carried out at ambient temperature (~23°C) on a Spectrospin CMS 47 FT-ICR spectrometer (13, 14). Pure vinyl chloride was introduced into the ICR cell through a heated inlet controlled by a manual precision leak valve. The pressure of vinyl chloride in the cell was maintained at ~3×10^{-8} mbar. After the ionizing electron pulse a delay of 4 s allowed for the formation of $C_4H_5Cl^+$ and $C_4H_6Cl^+$ ions. Thereafter the application of the radio-frequency resonance ejection technique to all undesired ion species allowed the isolation of a single ionic species, and the subsequent measurement of its disappearance rate through a variable time delay. The pulse sequence used in the present experiments is shown in Fig. 2. In Fig. 3 the selectivity of the ejection technique to isolate the $C_4H_5Cl^+$ species from all ions formed in the ICR cell is shown.

The collision-induced dissociation (CID) experiment on $C_6H_7^+$, $C_4H_5Cl^+$, and $C_4H_6Cl^+$ ions was also performed on the same FT-ICR spectrometer using argon gas at 3×10^{-8} mbar as the neutral target.

The gaseous vinyl chloride from Matheson was of the best available (>99.5%) and was used as such.

Results

HPMS experiments

Vinyl chloride photoionized by absorption of 10.64 eV photons fortunately does not fragment into $C_2H_3^+$ ion, which requires higher energy (A.P. = 12.4 ± 0.1 eV) (15, 16). Therefore, the mass spectrum obtained at low pressure (<2 mTorr) contains only $C_2H_3Cl^+$, $C_4H_5Cl^+$, $C_4H_6Cl^+$, and $C_3H_4Cl^+$ species. With increasing pressure (>10 mTorr) the next generation of ions starts to build up according to reactions [4]–[8]. However, it is important to note that the $C_6H_7^+$ species becomes visible at very short times, simultaneous with the chlorinated C_6 species, and its fractional intensity exceeds the intensities of these ions (Fig. 1). Moreover, the fractional intensity of $C_6H_7^+$ ions rapidly reaches a constant value around 0.25, while the intensities of the chlorinated C_6 ion species are still increasing. At pressures above 80 mTorr the intensity of $C_6H_7^+$ decreases and a new species $C_8H_9^+$, not shown on Fig. 1, starts to build up.

FT-ICR experiments

The time evolutions of isolated $C_4H_5Cl^+$ and $C_4H_6Cl^+$ species reacting with neutral vinyl chloride were followed in FT-ICR experiments and are shown in Figs. 4 and 5, respectively. In each case the only ion products found in the mass spectrum were $C_6H_7^+$ ions and, in very small amount (<3%), $C_4H_5^+$ species. The initial disappearance rates of $C_4H_5Cl^+$ and $C_4H_6Cl^+$ ions are relatively rapid but decrease markedly with time to reach more or less constant values when their fractional intensities drop to ~0.75. However, there are some differences in the behaviour of these two ions. The $C_4H_5Cl^+$ species reacts more slowly to form $C_6H_7^+$ ions and both ions do not reach true fractional intensity plateau values, while $C_4H_5^+$ ions do not disappear completely with time (Fig. 4). On the other hand, $C_4H_6Cl^+$ ions react more rapidly, attain well-characterized plateau intensity values for both primary and $C_6H_7^+$ species and the $C_4H_5^+$ ions disappear completely after 15 s (Fig. 5). It is also worthwhile to note that in these measurements $C_6H_7Cl^+$, $C_6H_8Cl^+$, and $C_6H_9Cl^+$ species were not formed at any time. This suggests, in relation to the results of HPMS experiments (Fig. 1), that a third-order process is probably required to stabilize the condensation products formed in reactions [4]–[7]. If that is the case, then these ions will not be formed in ICR experiments due to the very low pressure.

From the initial slopes of the plots of fractional intensities for disappearance of $C_4H_5Cl^+$ and $C_4H_6Cl^+$ ions one can calculate initial rate constants for the reactions with vinyl chloride neutrals (Figs. 4 and 5):

[9] $C_4H_5Cl^+ + C_2H_3Cl \rightarrow C_6H_7^+ + \text{neutrals}$

$k_{9,\text{init}} = 2.3 \times 10^{-11}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$

[10] $C_4H_6Cl^+ + C_2H_3Cl \rightarrow C_6H_7^+ + \text{neutrals}$

$k_{10,\text{init}} = 4.4 \times 10^{-11}\ \text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$

At longer time (>40 s) the rate constant for disappearance of $C_4H_5Cl^+$ ions decreases 10-fold to a value $k_9' = 2.0 \times 10^{-12}$ $\text{cm}^3\ \text{molecule}^{-1}\ \text{s}^{-1}$, while that for $C_4H_6Cl^+$ (k'_{10}) becomes unmeasurably slow.

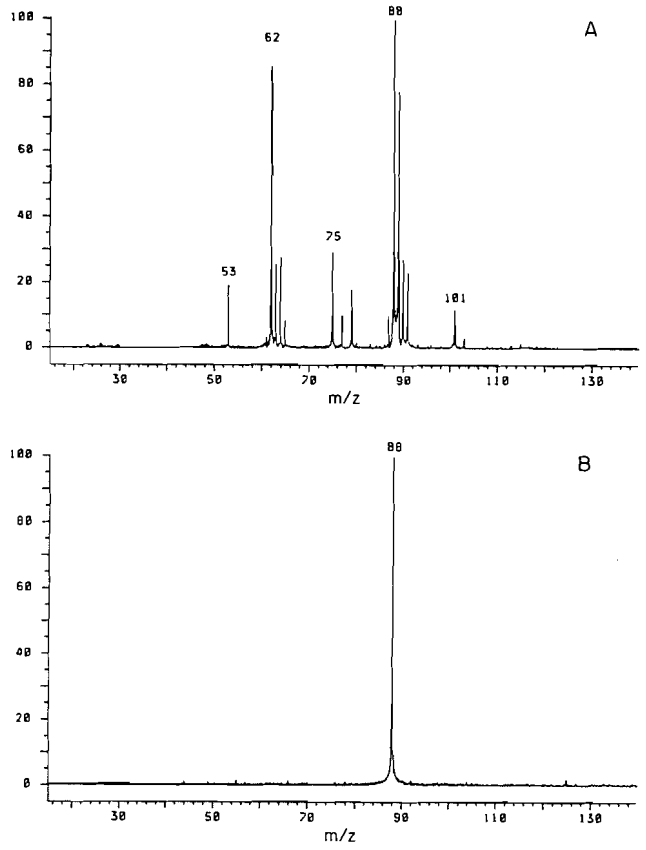

FIG. 3. The mass spectrum of selectively isolated $C_4H_5Cl^+$ ions: (*A*) before the isolation and (*B*) after selection.

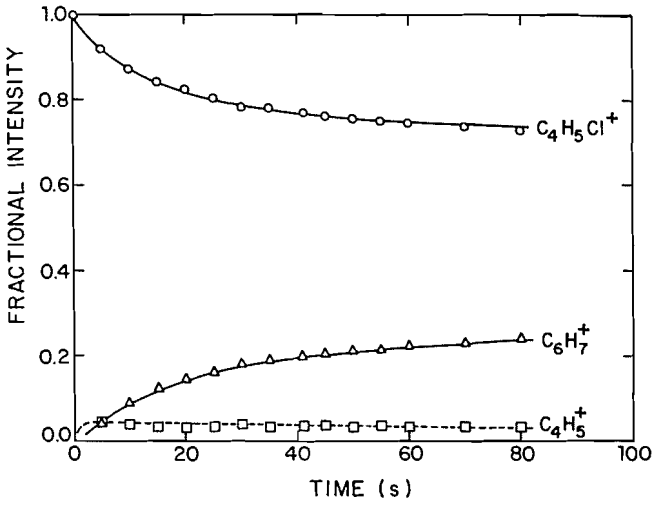

FIG. 4. Time evolution of fractional intensities of ions formed between $C_4H_5Cl^+$ and vinyl chloride in FT-ICR experiments.

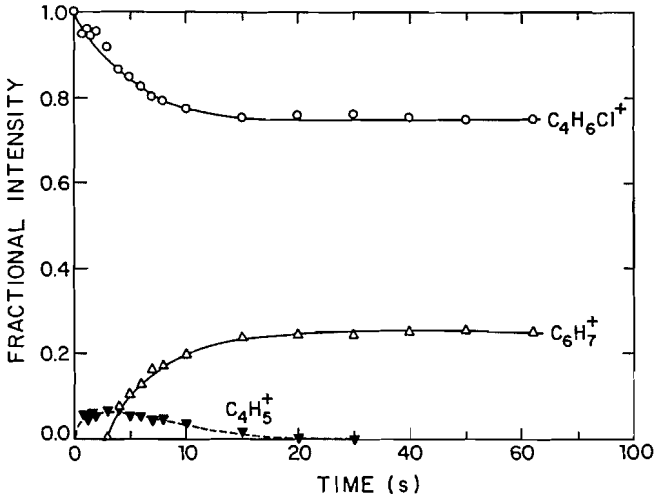

FIG. 5. Time evolution of fractional intensities of ions formed between $C_4H_6Cl^+$ and vinyl chloride in FT-ICR experiments.

CID experiments

Both $C_4H_5Cl^+$ and $C_4H_6Cl^+$ ions were examined in CID experiments. They were prepared in the same manner as in the above kinetic measurements and, after isolation, they were translationally excited by a RF pulse to ~16 eV energy and then allowed to collide with argon. In Fig. 6 the CID mass spectra of these ions under these conditions are shown. Both decomposition patterns are very similar with the main fragment being $C_4H_5^+$ (m/z 53) with two smaller $C_2H_3^+$ (m/z 27) and $C_3H_3^+$ (m/z 39) peaks. Other low intensity peaks (m/z 66 and 78) are probably ions formed in reaction with residual gases in the ICR cell.

In CID experiments $C_6H_7^+$ was prepared in the same manner as in the kinetic measurements, then selectively isolated and accelerated by a suitable RF pulse to an energy of ~16 eV and allowed to collide with argon atoms during a 0.15 s delay. The resulting CID mass spectrum is shown in Fig. 7*A*. It can be seen that the main fragment ions formed after collision are m/z 77 and 51, which correspond to $C_6H_5^+$ and $C_4H_3^+$ species. The origin of the low intensity m/z 67 peak is not clear. Formally it corresponds to a loss of one carbon atom from $C_6H_7^+$ species, but such a process seems unlikely at these low energies. It might be formed from some impurities present in the ICR cell.

In order to compare the structures of $C_6H_7^+$ ions with the same ions from different origin additional CID experiments were performed, the first on the protonated benzene ion (m/z 79) formed by reaction of benzene with CH_5^+ and $C_2H_5^+$:

[11] CH_5^+ (or $C_2H_5^+$) + $C_6H_6 \rightarrow C_6H_7^+ + CH_4$ (or C_2H_4)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12

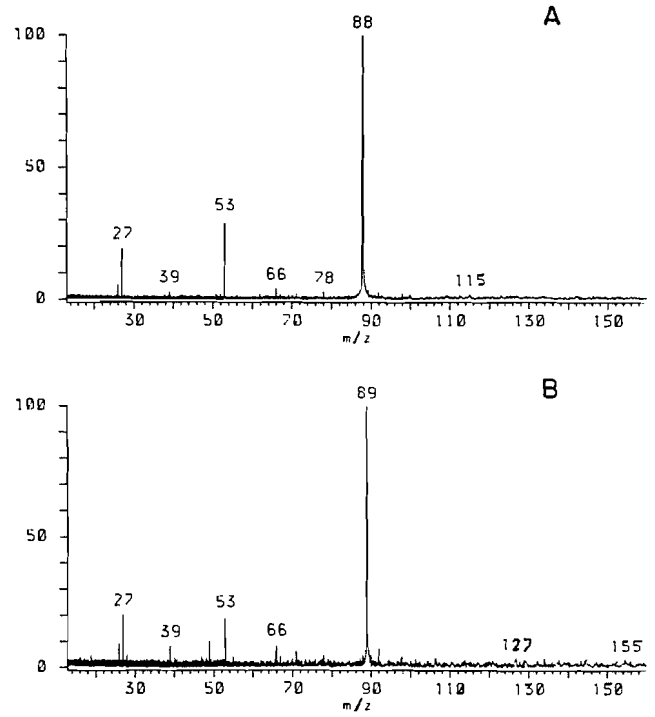

FIG. 6. Mass spectrum from collision-induced decomposition (CID) experiments of (*A*) $C_4H_5Cl^+$ and (*B*) $C_4H_6Cl^+$ ions.

and the second on the $(M - 1)^+$ fragment ion (m/z 79) of the 1,3,5-hexatriene formed in hydride abstraction with $C_2H_5^+$:

[12] $C_2H_5^+ + C_6H_8 \rightarrow C_6H_7^+ + C_2H_6$

In order to do this methane was introduced through a pulsed valve, ionized at the maximum pressure in the ICR cell, and allowed to form CH_5^+ and $C_2H_5^+$ species, and, after evacuation of the excess of methane, allowed to react with gaseous benzene or hexatriene at low pressure ($\sim 10^{-8}$ Torr) in the ICR cell. Once the $C_6H_7^+$ formed it was selectively isolated, activated, and allowed to collide with argon introduced to the ICR cell at 3×10^{-8} mbar.

Fig. 7*B* and *C* show the CID mass spectra on protonated benzene and on the $(M - 1)^+$ fragment ion of 1,3,5-hexatriene performed in the same conditions as for vinyl chloride system.

There are some differences between these three mass spectra: intensities of m/z 77 are not the same, and the absence of $C_2H_3^+$ (m/z 27) in Fig. 7*A*.

Discussion

The proposed reaction sequences leading to the $C_6H_7^+$ species formation must take into account the structure of this ion. The CID mass spectra experiments on $C_6H_7^+$ species formed, respectively, in vinyl chloride, benzene, or 1,3,5-hexatriene systems (Fig. 7), show distinct features to enable one to consider that the $C_6H_7^+$ from vinyl chloride compared to those formed in reactions [11] and [12] correspond to different structures.

The CID mass spectra of $C_6H_7^+$ formed in benzene or in 1,3,5-hexatriene are sufficiently similar to assume that to a large extent they may correspond to the same ion structure (Figs. 7*B* and *C*). Lias and Ausloos have shown that the $C_6H_7^+$ species formed in 1,3,5-hexatriene are a mixture of two ion populations composed of benzenium (~87%) and non-benzenium (~13%) isomers (19). This might account for the quantitative differences in peak intensities in Figs. 7*B* and *C*. On the other hand, the important m/z 77 peak and the absence of m/z 27 in the CID mass spectrum of $C_6H_7^+$ from vinyl chloride (Fig. 7*A*) point to another fragmentation pattern resulting from a different ion structure.

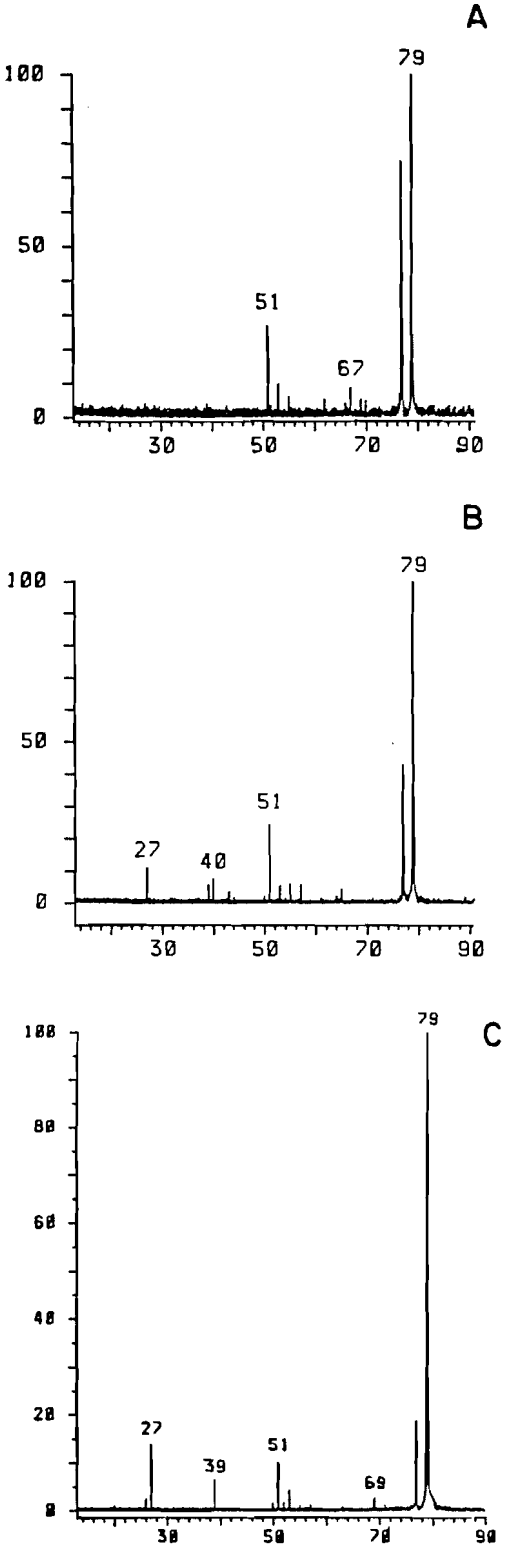

FIG. 7. Mass spectrum from collision-induced decomposition (CID) experiments of $C_6H_7^+$ ions: (*A*) formed in vinyl chloride system, (*B*) protonated benzene ion, and (*C*) from 1,3,5-hexatriene.

It is reasonable to assume that $C_6H_7^+$ ion species will react

with neutral bases in proton transfer processes only if their proton affinities (PA) are higher than that of the conjugate bases of the reactant ions. The PA of vinyl chloride is uknown, but it can be estimated to be ~172 kcal/mol (~719 kJ/mol) from the known heats of formation $\Delta H_f(H^+)$, $\Delta H_f(C_2H_3Cl)$, and $\Delta H_f(C_2H_4Cl^+)$ (20):

[13] $PA = \Delta H_f^0(C_2H_3Cl) + \Delta H_f(H^+) - \Delta H_f(C_2H_4Cl^+)$

The PA of benzene is 181.3 kcal/mol (21), while the PA of a "fulvene-like" structure of the same composition is estimated to be in the range 191–206 kcal/mol, and those of linear structures are PA = 196 kcal/mol (19). Therefore the absence of reactivity of $C_6H_7^+$ ions towards neutral vinyl chloride can be understood, and it is not surprising to see that this ion accumulates in the system with varying time and pressure (Fig. 1).

Whatever $C_6H_7^+$ structure is formed in the vinyl chloride system, its formation requires an ion-precursor species having a protonated butadiene structure. This ion is not observed in the HPMS experiment, but its transient presence is noted in the ICR mass spectrum (Figs. 4 and 5). The CID experiments for the $C_4H_5Cl^+$ and $C_4H_6Cl^+$ ions formed in reactions [1] and [2] suggest that the m/z 53 peak is an unsaturated four-carbon chain with the chlorine atom bound either on the first or second carbon atom (Fig.6). This is contrary to the condensation ion structures formed in ion/molecule reactions of alkyl chlorides which are those of the dialkylchloronium ions (17). The formation of such a carbon chain structure can be expected for the unsaturated radical ions, where condensation processes similar to those in addition polymerization might be operating. Ausloos *et al.* suggested that vinyl chloride ions may play the role of the chain initator in ionic polymerization of gaseous vinyl chloride (5).

FT-ICR experiments indicate clearly that $C_6H_7^+$ ions are originating from $C_4H_5Cl^+$ and $C_4H_6Cl^+$ species (Figs. 4 and 5). On the other hand, HPMS measurements suggest strongly that $C_6H_7Cl^+$, $C_6H_8Cl^+$, and $C_6H_9Cl^+$ ions also originate from the same chlorinated C_4 ion precursors (reactions [4]–[7]). It is not very likely that the collisional complexes, $(C_6H_{8\text{-}9}Cl_2)^+*$, will dissociate into $C_6H_7^+$ ions with elimination of two neutrals:

[14] $[C_6H_8Cl_2]^{+\cdot} \not\longrightarrow C_6H_7^+ + HCl + Cl^\cdot$

[15] $[C_6H_9Cl_2]^{+\cdot} \not\longrightarrow C_6H_7^+ + 2\,HCl$

It is, however, more likely that the formation of $C_6H_7^+$ species proceeds in two steps involving the $C_4H_5^+$ ions as intermediates. The first step probably involves thermoneutral or slightly endothermic reactions [16] and [17]:

[16] $C_4H_5Cl^+ + C_2H_3Cl \rightarrow [C_6H_8Cl_2]^+* \rightarrow C_4H_5^+ + C_2H_3Cl_2\cdot$

[17] $C_4H_6Cl^+ + C_2H_3Cl \rightarrow [C_6H_9Cl_2]^+* \rightarrow C_4H_5^+ + C_2H_4Cl_2$

followed by an exothermic reaction [18]:

[18] $C_4H_5^+ + C_2H_3Cl \rightarrow C_6H_7^+ + HCl$

The exothermicity of reaction [18] depends on the structures of $C_4H_5^+$ and $C_6H_7^+$ species. The available thermochemical data (19, 20) show that, if $C_4H_5^+$ ions have a "butadiene-like" structure and $C_6H_7^+$ is a benzenium ion, the reaction enthalpy might be as high as −70 kcal/mol, while for a $C_6H_7^+$ "fulvene-like" structure the heat of reaction drops to a range between −45 and −60 kcal/mol. On the other hand, if $C_4H_5^+$ has a methylcyclopropene structure, the reaction enthalpy is between −30 and −60 kcal/mol.

Reaction [18] has previously been observed, but at the same time it was shown that the formation of $C_4H_5^+$ ion requires the presence of vinyl ion, $C_2H_3^+$ (1):

[19] $C_2H_3^+ + C_2H_3Cl \rightarrow C_4H_5^+ + HCl$

However, in our HPMS experimental conditions the vinyl ion is not formed and in the FT-ICR experiment it is ejected. Therefore, we conclude that here $C_4H_5^+$ species originate in reactions [16] and [17].

In agreement with Bowers *et al.* the rate constant of $C_4H_5Cl^+$ in reaction [1] is 5.5×10^{-11} cm^3 molecule^{-1} s^{-1} (18), which is twice the measured rate constant of reaction [9]. This suggests, in relation to Figs. 4 and 5, that reactions [16] and [17] are slow processes determining the overall reaction rate. It follows that reaction [18] must be fast.

We believe that the mechanism of formation of $C_6H_7^+$ species in vinyl chloride is more closely related to those of formation of $C_6H_7^+$ isomers generated in propyne and allene than those in cyclohexadiene or hexatriene systems where only a loss of one hydrogen atom is involved. If this analogy holds, then it might be expected that an important fraction of $C_6H_7^+$ species has a non-benzenium structure. Moreover, the process leading to non-benzenium isomers increases in importance with increasing energy (19). Several different non-benzenium $C_6H_7^+$ isomers can be formed in the present conditions. In propyne and allene systems an examination of the energetics of proton transfer from the possible non-benzenium isomers, and the estimations of the proton affinities of possible C_6H_6 conjugate bases, point out that the most likely structures are the two protonated fulvenes **I** and **II** (19). It is probable that in vinyl chloride similar conditions prevail in order to form "fulvene-like" isomers, whose dissociation in CID experiments might possibly explain the absence of the $C_2H_3^+$ (m/z 27) and $C_3H_3^+$ (m/z 39) fragments.

I **II**

Experimental data from FT-ICR experiments indicate that only ~25% of the $C_4H_5Cl^+$ and $C_4H_6Cl^+$ species react to give $C_6H_7^+$ ions (Figs. 4 and 5). It is, therefore, tempting to assume that the above chlorinated C_4 ions are formed in different isomeric forms, one of which reacts to form $C_6H_7^+$ non-benzenium species (reactions [16] and [17]). The position of the chlorine atom on the first or the second carbon might determine the ability of the $C_4H_5Cl^+$ and $C_4H_6Cl^+$ ions to react either in addition processes [4]–[7] or in dissociation processes [16]–[17]. During the life-time of the collision complexes, $[H_{5,6}C_4Cl^+\cdot\cdot C_2H_3Cl]$, the chlorine atom in head (or tail) positions seems to be more accessible to transfer the chlorine atom or hydrogen chloride on the C=C double bond of the added neutral vinyl chloride with elimination of the $C_4H_5^+$ ion. On the other hand, the chlorine atom fixed on the second carbon atom seems to be less available, and the addition reactions to form $C_6H_{7-9}Cl^+$ species are more likely.

Conclusion

The CID mass spectra show evidence that the $C_6H_7^+$ species formed in the vinyl chloride system have predominantly non-benzenium structures. Owing to their higher proton affinities than vinyl chloride, they do not react further in proton transfer processes and accumulate in the system. The $C_6H_7^+$ species are formed from $C_4H_5Cl^+$ and $C_4H_6Cl^+$ precursor-ions in processes involving the $C_4H_5^+$ as intermediate species. These processes

are in competition with condensation reactions leading to $C_6H_{7-9}Cl^+$ ion products.

The rate constants of $C_6H_7^+$ formation and addition reactions to form higher condensation ion species are comparable and are of the order of 2×10^{-11} to 5×10^{-11} cm^3 molecule^{-1} s^{-1}. They are slow reactions.

The CID mass spectra of $C_4H_5Cl^+$ and $C_4H_6Cl^+$ species suggest that these ions have a "butadiene-like" structure. The time evolution of these ions points out that these species are formed in at least two isomeric forms, one of which reacts to form $C_6H_7^+$ species, while the other leads most probably to formation of $C_6H_7Cl^+$, $C_6H_8Cl^+$, and $C_6H_9Cl^+$ ions.

Mechanical and electrical anharmonicities of the linear hydrogen cyanide H-bonded trimer

WAGNER B. DE ALMEIDA[1]

Department of Chemistry, UMIST, P.O. Box 88, Manchester M6O 1QD, United Kingdom

Received March 8, 1991

WAGNER B. DE ALMEIDA. Can. J. Chem. **69**, 2044 (1991).

The anharmonicity of the hydrogen-bonded (N...H) and proton-donor (C—H) stretching modes of the linear $(HCN)_3$ species are calculated at the SCF level with the 4-31G and 6-31G** basis sets. Third and fourth energy derivatives and second and third dipole moment derivatives, which are needed to calculate the anharmonic terms, were evaluated by means of the one-dimensional Chebyshev polynomial fitting to the calculated *ab initio* points. Frequencies and intensities of overtone bands are reported and the effect of geometry relaxation on the polynomial fitted derivatives as well as mechanical anharmonicity on the vibrational intensities discussed.

Key words: H-bonding, anharmonicity, vibrational frequencies, intensities.

WAGNER B. DE ALMEIDA. Can. J. Chem. **69**, 2044 (1991).

Opérant au niveau auto-cohérent avec des ensembles de base 4-31G et 6-31**, on a calculé l'anharmonicité des modes d'élongation (N...H) impliqués dans une liaison hydrogène et (C—H) agissant comme donneur de proton des espèces linéaires $(HCN)_3$. Les troisième et quatrième dérivés de l'énergie et les deuxième et troisième moments dipolaires dérivés, nécessaires pour calculer les termes anharmoniques, ont aussi été évaluées en faisant appel à un ajustement unidimensionnel de polynôme de Chebyshev pour calculer les points *ab initio*. On a déterminé les fréquences et les intensités des harmoniques et on discute de l'effet de relaxation de géométrie sur les dérivés du polynôme ajusté ainsi que l'anharmonicité mécanique sur les intensités vibrationnelles.

Mots clés : liaison hydrogène, anharmonicité, fréquences vibrationnelles, intensités.

[Traduit par la rédaction]

Introduction

The subject of mechanical and electrical anharmonicity has increasingly attracted the attention of both theoreticians and experimentalists. The importance of the anharmonicity terms to our understanding of the infrared spectra of H-bond systems has been stressed by Sandorfy (1, 2). In ref. 1 anharmonicity constants have been determined for H-bonded complexes of the type dimethylether.....HX, X = F, Cl, from the measured overtones and combination bands. Also, the influence of mechanical and electrical anharmonicity on the intensity of X—H stretching vibrations (X = O or N in the most important cases) along with frequency and intensity of overtone bands, on the basis of the experimentally measured spectra, has been investigated (3–7).

Most theories of H-bonding have as their starting point the interaction of the fast X–H stretching motion (ν_1) and the slow X—H...Y bridge stretching motion (ν_σ),

$$\underset{\nu_1}{\text{X—H}}\text{.....}\underset{\nu_\sigma}{\text{Y}}$$

where X is a proton donor and Y is a proton acceptor. However, there are other low frequency H-bond vibrations with which ν_1 can interact. The X—H stretching is the most studied among the vibrations of the H-bonded species, its fundamental being characterized by its high intensity and great breadth compared to the free band. Anharmonicity plays an important role, with ν_1 in many cases being accompanied by a number of overtones and combination tones of vibrations of lower frequency whose intensity is boosted by Fermi resonance with ν_1. Ammonium and amine salts (8–11) and carboxylic acid dimers (12) are well-known examples of this. All available evidence from gas and solution spectra shows that H-bond formation increases the anharmonicity of the X—H stretching vibration and introduces appreciable anharmonic coupling between ν_1 and ν_σ modes. The importance of anharmonic coupling is highlighted by the appearance of combination bands. The great breadth of the infrared X—H stretching bands is thought to be due to combination bands of the type $(\nu_1 \pm \nu_\sigma)$ and $(\nu_1 \pm \nu_\beta)$, where ν_β is the H-bond bending mode X—H.....Y which accompanies ν_1 and under low resolution convolutes to it. Anharmonic coupling plays an essential role in making it possible for all these combination bands to appear. Sandorfy (1) has affirmed that both mechanical and electrical anharmonicity are needed to explain the observed intensities. It is also of interest to know the extent to which the anharmonicity of ν_1, χ_{11}, is affected by H-bond formation. It has been shown by Bernstein and co-workers (see ref. 1, table 3, p. 63) that, for a series of ethers, the χ_{11} values undergo a substantial increase upon H-bond formation, except for the weakest H-bonds.

The double harmonic approximation, in which terms higher than second energy and first dipole derivative in the energy and dipole moment expansion are respectively neglected, yields satisfactory values for frequency and intensity of fundamental bands. However, for the determination of overtones and combination bands which are forbidden in the harmonic approximation, the anharmonicity of the energy and dipole moment functions, determined through the anharmonicity of the wave function, need to be taken into account. A natural way of evaluating the anharmonic corrections consists of expanding the energy and dipole moment as a power series of the normal coordinates, Q, and then of calculating the higher energy and dipole derivatives, i.e., the expansion coefficients, by a polynomial fitting procedure or analytically (which means higher accuracy). The polynomial fitting approach has been applied for studying anharmonic effects on the vibrational spectra of the species $(HCN)_n$, $n = 1, 2, 3$ (14), HCN...HF and HF...HCN (15), and C_2H_2 (16). In the case of the hydrogen cyanide multimers and hydrogen cyanide – hydrogen fluoride complexes a least-squares one-dimensional Chebyshev polynomial fitting to the

calculated *ab initio* points has been done, while for the acetylene molecule a two-dimensional polynomial fitting in $r_{C—H}$ and $r_{C—C}$ has also been carried out.

The linear H-bonded hydrogen cyanide trimer has been much investigated. Most of the experimental and theoretical work can be found respectively in refs. 17–21 and 22–25, and references cited therein. However, the only study dealing with anharmonicity reported so far refers to the *ab initio* calculation of the anharmonicity of the ν_σ (H-bonding) stretching vibration, using the frozen monomer geometry approach (FMG), from ref. 14. In ref. 14 the effect due to geometry relaxation on the frequency and intensity parameters was examined for the HCN dimer. It was found that to keep the monomer geometry unchanged under complexation had considerable effect on higher dipole moment derivatives and, therefore, also on the intensity of the overtone bands. Moreover, the very high value found for the harmonic intensity for the H-bonded stretching mode of the HCN trimer, as compared to the value calculated using the dipole derivative evaluated analytically in ref. 25, suggested that geometry relaxation may be very important in large hydrogen-bonded clusters.

This work reports the calculation of higher energy and dipole moment derivatives along with mechanical and electrical anharmonic terms for the proton donor C—H (ν_1) and H-bonded N...H (ν_σ) stretching vibrations of the linear HCN trimer. A one-dimensional Chebyshev polynomial fitting to the 4-31G and 6-31G** *ab initio* points for the stretching coordinates ($r_{C—H}$ and $R_{N...H}$), with all other geometrical parameters being optimised in each case, has been performed. Frequency and intensity of the first and second overtone bands are given and the validity of the FMG approach in connection to the evaluation of the anharmonic terms discussed.

Method of calculation

The intensity of the kth non-degenerate vibrational normal mode of a molecule can be written as (26)

$$[1] \qquad \alpha_k = (8\pi^3 \nu_A N_A/3hc)|\langle v|\mu|v'\rangle|^2$$

where α_k is the intensity, ν_A the vibrational frequency, $\langle v|\mu|v'\rangle$ the matrix element between the two vibrational states v and v', and constants π, h, c, and N_A having their usual values. To express the intensity in km mol^{-1}, the unit in use here, eq. [1] may be rewritten as (14)

$$[2] \qquad A_k{}^T = K_a g_k |\langle v|\mu|v'\rangle|^2$$

where $A_k{}^T$ is the total vibrational intensity in km mol^{-1}, K_a is the conversion factor (in units of km mol^{-1} kg C^{-2}), g_k is the degeneracy, and $\langle v|\mu|v'\rangle$ the transition dipole moment (in units of C kg$^{-1/2}$). For convenience the vibrational frequency ν_A has been included in the term $|\langle v|\mu|v'\rangle|^2$. The total vibrational intensity, $A_k{}^T$, may be decomposed into the harmonic and anharmonic contributions.

$$[3] \qquad A_k{}^T = A_k[0;\, v \rightarrow v'] + A_k[1;\, v \rightarrow v']$$

the second term being ignored in the harmonic approximation.

To evaluate the matrix element $\langle v|\mu|v'\rangle$ the dipole moment is usually expanded as a Taylor series of the normal coordinates Q_k

$$[4] \qquad \mu = \mu^0 + (\partial\mu/\partial Q_k)_{eq} Q_k + (1/2!)(\partial^2\mu/\partial Q_k{}^2)_{eq} Q_k{}^2 + (1/3!)(\partial^3\mu/\partial Q_k{}^3)_{eq} Q_k{}^3$$

The dipole moment as given by eq. [4] is assumed to be a scalar quantity, i.e., only its magnitude has been considered. In this way the total intensity of the ν_k fundamental band, $v = 0 \rightarrow v' = 1$, acquires anharmonicity through the second and third dipole moment derivatives. By combining eqs. [2]–[4] it is found that for the fundamental band:

$$[5] \qquad A_k[0;\, 0 \rightarrow 1] = K_a g_k |(\partial\mu/\partial Q_k)_{eq} \langle 0|Q_k|1\rangle|^2$$

$$[6] \qquad A_k[1;\, 0 \rightarrow 1] = K_a g_k \{|(\partial^3\mu/\partial Q_k{}^3)_{eq} \langle 0|Q_k{}^3|1\rangle|^2 + 2(\partial\mu/\partial Q_k)_{eq} (\partial^3\mu/\partial Q_k{}^3)_{eq} \langle 0|Q_k|1\rangle\langle 0|Q_k{}^3|1\rangle\}$$

and for the overtones

$$[7] \qquad A_k[1;\, 0 \rightarrow 2] = K_a g_k |(\partial^2\mu/\partial Q_k{}^2)_{eq} \langle 0|Q_k{}^2|2\rangle|^2$$

$$[8] \qquad A_k[1;\, 0 \rightarrow 3] = K_a g_k |(\partial^3\mu/\partial Q_k{}^3)_{eq} \langle 0|Q_k{}^3|3\rangle|^2$$

The nth dipole moment derivative with respect to the normal coordinate Q, $\partial^n\mu/\partial Q^n$, is denoted $P^n{}_Q$ and, analogously, the corresponding derivative in internal coordinates is $P^n{}_R$. The relationships between the dipole derivatives in normal (Q) and internal (R) coordinates are given by (27).

$$[9] \qquad P_Q = P_R \mathbf{L}$$

where the $\mathbf{L}$ matrix is found by solving the well-known secular equations (28)

$$[10] \qquad \mathbf{GFL} = \mathbf{L}\lambda$$

and the $\mathbf{L}$ matrix is normalized according to

$$[11] \qquad \mathbf{L}\mathbf{L}^+ = \mathbf{G}$$

Values for $P^2{}_Q$ and $P^3{}_Q$ are obtained by taking successively the derivatives of eq. [9].

The mechanical anharmonicity is usually taken into account by expanding the vibrational potential energy as a Taylor series around the equilibrium position R_e

$$[12] \qquad U(R) = U_e + (1/2!)(\partial^2 U/\partial R_e{}^2)(R—R_e)^2 + (1/3!)(\partial^3 U/\partial R_e{}^3)(R—R_e)^3 + (1/4!)(\partial^4 U/\partial R_e{}^4)(R—R_e)^4$$

The transformation between internal and normal coordinates ($\partial^n U/\partial R^n \rightarrow \partial^n U/\partial Q^n$) follows the same procedure as in the case of dipole moment derivatives.

The vibrational energy of the kth vibrational mode may be written as

$$[13] \qquad E_{vib} = \omega_e(v_k + 1/2) + \chi_{kk}(v_k + 1/2)^2 + \alpha_e(v_k + 1/2)J_k(J_k + 1)$$

and the rotational contribution is

$$[14] \qquad E_{rot} = B_e J_k(J_k + 1) - \bar{D}_e J_k{}^2(J_k + 1)^2$$

where ω_e is the harmonic frequency, χ_{kk} the anharmonicity constant, α_e the vibration–rotation coupling constant, B_e the equilibrium rotational constant, and $\bar{D}_e$ the centrifugal-distortion constant. v_k and J_k are the vibrational and rotational quantum numbers for the kth mode respectively. For reasons of simplicity higher terms have been omitted in eqs. [13] and [14]. By neglecting vibration–rotation interaction and off-diagonal terms the observed frequency of the fundamental band and the first and second overtones can be written as (14)

$$[15] \qquad \nu^{01}{}_k = \omega_{ek} + 2\chi_{kk}$$

$$[16] \qquad \nu^{02}{}_k = 2\omega_{ek} + 6\chi_{kk}$$

$$[17] \qquad \nu^{03}{}_k = 3\omega_{ek} + 12\chi_{kk}$$

The spectroscopic parameters χ_{kk}, α_e, B_e, and $\bar{D}_e$, were

evaluated with the relationships derived by Levine (29) using second-order perturbation theory.

The energy and dipole moment derivatives with respect to the internal coordinates, R, were obtained via a one-dimensional Chebyshev polynomial fitting to the *ab initio* points calculated with an 4-31G (30) and 6-31G** (31) basis sets.

$$[18] \qquad E(r) \text{ or } \mu(r) = \sum_{k=1}^{n+1}{}' a_{k-1}T_{k-1}(r)$$

where a_{k-1} is a numerical coefficient which is found in a least-square fitting procedure of eq. [18] and $T_{k-1}(r)$ is a Chebyshev polynomial of degree $k-1$ (32).

The stretching variables used in the fitting procedure are shown below.

$$N_1—C_1\overset{r_1}{—}H_1\overset{R_1}{\text{-----}}N_2—C_2\overset{r_2}{—}H_2\overset{R_2}{\text{-----}}N_3—C_3—H_3$$

Four individual fittings (r_1, r_2, R_1, R_2) have been done. In each case 21 points were used with a grid of 2 pm (1 pm = 10^{-2} Å), which has been shown to give very good fitting results (14). In the one-dimensional fitting procedure a stretching coordinate, r_i^j, was varied as follows: r_i^1, r_i^2, ..., r_i^{21}. For each r_i^j value all the other geometrical parameters were optimised. This approach assures that the stretching coordinate r_i is varied along a one-dimensional minimum energy path in a multidimensional potential energy surface (PES). The full configurational space $|R^N$ may be decomposed into the components N internal coordinates and so, the process of optimising the $N-1$ variables, allowing one single stretching variable to assume distinct values (r_i^1, r_i^2, ..., r_i^{21}), appears to be a natural way of dealing with a multivariable problem. Perhaps this will give a more realistic picture than just freezing the other $N-1$ geometrical parameters. The energy and dipole derivatives were then evaluated by taking the derivative of the least-square fitted eq. [18] with respect to r_1, r_2, R_1, R_2 stretching coordinates.

In evaluating the dipole moment matrix elements, $<o|Q_k^n|v>$, $n = 1, 2, 3$ and $v = 1, 2, 3$, the harmonic oscillator wave functions (Hermite polynomials) have been used, a procedure which has been encouraged earlier (33). Another approach in which the wave functions Ψ_v and $\Psi_{v'}$ are written as linear combinations of the unperturbed harmonic oscillator wave functions, $\Psi^0_{v''}$, with the expansion coefficients $C_{v,v''}$ and $C_{v',v''}$ determined via second-order perturbation theory has been used for the CO molecule (34). In that approach the expansion coefficients depend on the energy derivatives, $\partial^n E/\partial Q_k^n$, which introduces a dependence between electric and mechanical anharmonicities.

The influence of mechanical anharmonicity on the intensity

of fundamental and overtone bands for the linear HCN trimer has also been examined in the present study. The expressions for $R_{v,v'}$, evaluated over anharmonic wave functions, derived by Herman and Shuler (34) using second-order perturbation theory were employed. The relationships for the fundamental band, $R_{1,0}$, first-overtone, $R_{2,0}$, and second-overtone, $R_{3,0}$, are as follows:

$$[19a]\quad R_{1,0} = (1/\sqrt{2})(1 - 3g/2 + 11b^2/4)P_q + (1/\sqrt{2})(-5b + 88bg - 715b^3/12)P^2{}_q + (3/\sqrt{2})P^3{}_q$$

$$[19b]\quad R_{2,0} = \sqrt{2}(b/2 - 111bg/8 - 71b^3/48)P_q + (1/\sqrt{2})(1 - 15g/4 + 3b^2/8)P^2{}_q + OP^3{}_q$$

$$[19c]\quad R_{3,0} = \sqrt{3}(g/4 + 3b^2/8)P_q + (\sqrt{3}/2)(2b - 84bg + 6573b^3/144)P^2{}_q + (\sqrt{3}/2)P^3{}_q$$

with $b = K_3/\omega_e$ and $g = K_4/\omega_e$, where K_3 and K_4 are, respectively, the third and fourth energy derivatives with respect to the normal coordinates in units of cm^{-1} and ω_e the harmonic frequency in cm^{-1}. $P^n{}_q$ are the dipole moment derivatives with respect to the dimensionless normal coordinates q, according to the dipole expansion.

$$\mu = P^0{}_q + P_q q + P^2{}_q q^2 + P^3{}_q q^3 + \ldots .$$

q is defined as

$$q = \alpha^{1/2}(r - r_e)$$

with $\alpha = 4\pi^2\omega_e cm/h$ in Å^{-2}, where ω_e is the harmonic frequency, m the reduced mass, and π, c, h have their common known values. The $P^n{}_q$ can be obtained from the dipole derivatives with respect to internal coordinates, P_R, using the relationship

$$P^n{}_q = P^n{}_R/(\alpha^{n/2}n!)$$

and P_Q may also be evaluated through eq. [9].

The transition dipole moments for the fundamental band, first and second overtone neglecting mechanical anharmonicities,

Due to the nature of the polynomial fitting used here, off-diagonal energy and dipole moment derivatives have been neglected. Certainly the inclusion of off-diagonal terms (like crossing energy/dipole derivatives and anharmonicity constants) will improve the values of the spectroscopic parameters calculated. However, it is believed that the gross features may be satisfactorily predicted by the diagonal terms alone (14, 16).

It is worth saying that the interaction between ν_1(XH) and ν_σ(HY), which is very much wanted by spectroscopists, cannot be obtained from a one-dimensional treatment. It involves the calculation of cross-derivatives of the type $\partial^n E/\partial XH^s \partial Hy^t$ and $\partial^n \mu/\partial XH^s \partial HY^t$ with $s + t = n$. This may be achieved by expanding the energy and dipole moment functions as a two-dimensional polynomial in XH and HY. Also, for the calculation of the frequency and intensity of the bending mode ν_β (X—H...Y bending angle) a three-dimensional polynomial in XH, HY, and β would be needed. The evaluation of these stretching/bending energy and dipole derivatives would enable the calculation of frequencies and intensities of overtones and combination bands for vibrational modes relevant to hydrogen-bonded complexes. The procedure reported in this article is being extended to accommodate two- and three-dimensional expansions.

Results and discussion

The quality of the fitting procedure can be assessed by the root-mean-square residual values, S_n (35), from Table 1. It is seen that the degree of fitting varies considerably for each stretching coordinate. The best value for n in eq. [18] is given below.

	4-32G				6-31G**	
	r_1	r_2	R_1	R_2	r_1	R_1
E n	6	6	4	4	5	4
μ n	4	4	3	2	3	3

Energy and dipole moment derivatives are reported in Tables 2 and 3 along with other theoretical and experimental results available. These derivatives were previously evaluated (14) by means of a one-dimensional Chebyshev polynomial fitting of the H-bonded stretching coordinate R, using the frozen monomer geometry approach (FMG). It is seen that the FMG fitted derivatives are noticeably exaggerated and the present results, using the fully optimised geometry approach (FOG), are in satisfactory agreement with the experimental values available as well as with the *ab initio* calculations reported by Kofranek *et al.* (23). It is also noted that the dipole derivatives for the proton-donor C—H mode in the HCN trimer are considerably larger than the respective values for the free monomer unit. This reflects the fact that the C—H modes in the hydrogen cyanide trimer probably acquire part of their high intensity through electrical anharmonicity. Furthermore, concerning the H-bonded stretching mode, it is found that geometry relaxation affects significantly both energy and dipole derivatives and, in this sense, the FMG approach is of little value.

Tables 4 and 5 contain frequencies and intensities of the fundamental bands along with mechanical and electrical anharmonic contributions. The harmonic frequencies calculated with the FOG polynomial-fitted derivatives compare well with the other results available, which supports the validity of the approach used here. The present intensities of the fundamental band appear to be satisfactorily represented. The deviations from the values reported by Kofranek *et al.* (23) including electron correlation at the CPF (Coupled Pair Functional approach) level can be attributed to the small basis set employed rather than the methodology applied here.

The electrical anharmonic contribution to the intensity of the fundamental band can be assessed by eq. [6]. It is found that the non-linear behaviour of the dipole moment function accounts for ~7% of the intensity of the C—H proton-donor mode and ~6% of the intensity of the N...H hydrogen-bonded fundamental stretching vibration.

Frequencies and intensities of overtones are in Table 6. There

[a]Intensity evaluated by adding the electrical anharmonic term (A'_σ [1; 0→ 1]), from Table 5, to the harmonic term $A^0_{\sigma,0}$.

are no experimental results available or other *ab initio* calculations reported, apart from ref. 14 for comparison. However, it is seen that the first overtone of the proton-donor C—H mode should be the most easily assigned in the spectra of the $(HCN)_3$ species.

Table 7 reports the equilibrium geometries and rotational and vibrational–rotational terms. The effect of geometry relaxation is clearly seen. The present spectroscopic constant values are in closer agreement with the experiment than the previous calculation using the FMG approach (14).

It has been pointed out earlier (ref. 1, Table 3, p. 63) that the χ_{11} values increase substantially upon H-bond complexation except for weakly bound species. The change in χ_{11}, $\Delta\chi_{11} = (\chi_{11})_{assoc} - (\chi_{11})_{free}$, predicted for the weakest species in ref. 13 was $\Delta\chi_{11} = -12$ cm^{-1}. In this study a value of $\Delta\chi_{11} = 3.5$ cm^{-1} is reported for $(HCN)_3$ using the anharmonic constant for the free HCN monomer unit, $(\chi_{11})_{free}$, calculated at the 6-31G** level.

Tables 8 and 9 report the effect of mechanical anharmonicity on the intensity of the C—H proton donor and N...H H-bonded modes. $A^0_{v,v'}$ is the intensity value neglecting the mechanical anharmonicity contribution and $A_{v,v'}$ the intensity evaluated with transition dipole moments given by eqs. [19*a*]–[19*c*], which include mechanical anharmonic terms. The transition dipole moment is a more useful quantity than the intensity itself, since the experimental spectroscopic studies in general report

values for $R_{v,v'}$. Unfortunately, there are no other values for the transition moments reported so far for comparison. The values from Tables 8 and 9 exhibit a quite regular pattern with the $R_{v,v'}$, values decreasing in the sequence of transitions: $v = 1 \rightarrow v' = 0$; $v = 2 \rightarrow v' = 0$; $v = 3 \rightarrow v' = 0$, as would be expected.

The effects of including mechanical anharmonicity, through second-order perturbation theory, in the calculation of intensities of fundamental and overtone bands are as follows. For the C—H mode the intensity of the $(1 \rightarrow 0)$ fundamental is increased by ~27%, the $(2 \rightarrow 0)$ overtone decreased by a factor of ~6, and the $(3 \rightarrow 0)$ decreased by ~10%. For the N...H hydrogen-bonded stretching mode the situation is quite different. The intensity of the $(1 \rightarrow 0)$ fundamental is increased by ~7%, the $(2 \rightarrow 0)$ overtone increased by a factor of ~3, and the $(3 \rightarrow 0)$ overtone increased by a factor of ~5. The values in Tables 8 and 9 quoted in parentheses correspond to the intensity of the fundamental band including electrical anharmonic contribution alone. It is seen that for the C—H mode the electrical anharmonicity accounts for ~7% of the increase of the intensity value while for the N...H mode the non-linear behaviour of the dipole moment function accounts for 7% of the intensity of the fundamental band (which is the same amount as obtained taking into account mechanical anharmonicity) and therefore, in this case, the mechanical anharmonic correction appears not to be important. It is opportune to say that the decrease in the C—H $(2 \rightarrow 0)$ overtone intensity with the inclusion of mechanical anharmonicity appears to be counterintuitive. However, this result may be understood as a consequence of the relative contribution of each term in eq. [19*b*].

From Tables 8 and 9 it can be seen that the effect due to mechanical anharmonicity on the intensity values is more pronounced for the overtone bands. Moreover, the enhancement of the intensity of fundamental and overtone bands for the C—H proton-donor mode upon complexation can be seen from Tables 5 and 6. The intensity of the $(1 \rightarrow 0)$, $(2 \rightarrow 0)$, and $(3 \rightarrow 0)$ vibrational transitions of the C—H stretching mode of the HCN subunit upon complexation is increased respectively by factors of ~5, ~339, and ~387, as calculated with the 6-31G** basis set.

The problem of using a small (less expensive) basis set has been addressed. It is seen from Tables 2 and 3 that the 6-31G** basis set (including polarization function in both first and second row atoms) generally yields lower values for the polynomial fitted derivatives than the split-valence 4-31G, and agreement with the CPF and experimental values reported previously is improved when polarization functions are added. Also, the 6-31G** frequencies and intensities of the fundamental and overtone bands are significantly lower than the corresponding 4-31G ones. If electron correlation is added a further decrease in the frequency and intensity values would be expected, as it has been extensively reported in the literature.

In the light of the gas-phase experimental results reported so far for H-bonded complexes it can be seen that the approach used here for the determination of anharmonic terms yields satisfactory results, although anharmonic experimental data are not yet available for the hydrogen cyanide H-bonded trimer for comparison. The difficulties encountered for the assigning of the experimental spectra of H-bonded complexes in the gas phase have already been emphasized by Sandorfy (1).

For the determination of frequency and intensity of combination bands as well as anharmonic coupling between ν_1 and ν_σ, which are very much sought after by experimentalists, crossed derivatives need to be introduced in eqs. [4] and [12], which imply that a two-dimensional polynomial fitting is required. In addition, the matrix element $<v|\mu|v'>$ will have a more complex form, with a large number of interaction terms. Therefore the use of linear combinations of the unperturbed harmonic oscillator wave functions determined via second-order perturbation theory appear not to be a straightforward approach.

Finally, it is worthwhile to say that a two-dimensional polynomial fitting to the $r_{X—H}$ and $R_{H...Y}$ stretching coordinates of the $(HCN)_2$ H-bonded dimer has been carried out (13), with frequencies and intensities of overtones and combination bands along with anharmonic coupling been reported.

Conclusions

A least-square polynomial fitting procedure has been applied for the determination of the energy and dipole moment derivatives with respect to the internal stretching coordinates of the linear hydrogen cyanide H-bonded trimer, using the 4-31G and 6-31G** basis sets, making possible the evaluation of the mechanical and electrical anharmonic terms. The validity of the FMG approach has been investigated and, in the case of electrical anharmonicity, geometry relaxation was shown to be important. The agreement with the few experimental and theoretical results available was satisfactory, giving confidence to the approach used here.

The effect of the mechanical anharmonicity on the intensity of fundamental and overtone bands has been investigated. It is found that the mechanical contribution to the intensity is more pronounced for the overtone bands. The calculations revealed that the inclusion of mechanical anharmonicity, through second-order perturbation theory, decreases the intensity of the C—H overtone and increases the intensity of the N...H overtone bands.

Mechanical and electrical anharmonicity are doubtless of fundamental importance for the understanding of the spectra of H-bonded complexes. With regard to the intensity of overtones and combination bands, there is a shortage of data still to be supplied and the results reported in this work will, hopefully, help fill the gaps in our present knowledge concerning the spectra of H-bonded clusters.

The photochemistry of several methyl-substituted *p*-methoxy-β-phenylpropiophenones (**1–5**) has been examined by nanosecond laser flash photolysis using 337-nm laser excitation. The ketone triplets decay by intramolecular β-aryl quenching of the carbonyl in a well-known process that is believed to involve charge transfer. Surprisingly, methyl substitution at the β-methylene group, which is not a participant in the deactiviation mechanism, causes a dramatic decrease in the triplet lifetime; the effect is attributed to different conformational preferences in ketones **1–3** and is rationalized on the basis of MMX calculations. Methyl substitution in the β-aryl ring affects the ease of oxidation of this ring and as a result induces changes in the kinetics for intramolecular charge transfer. This conclusion is further supported by electrochemical studies of ketones **1**, **4**, and **5**.

Key words: laser flash photolysis, triplet ketones, intramolecular quenching, charge transfer.

R. Boch, C. Bohne, J. C. Netto-Ferreira et J. C. Scaiano. Can. J. Chem. **69**, 2053 (1991).

Faisant appel à la photolyse éclair au niveau de la nanoseconde utilisant une excitation laser de 337 nm, on a étudié la photochimie de plusieurs *p*-méthoxy-β-phénylpropiophénones substituées par des groupes méthyles (**1–5**). Les triplets des cétones décroissent par un piégeage intramoléculaire du carbonyle par un β-aryle par un processus bien connu qui impliquerait une transfert de charge. Il est surprenant qu'une substitution par un méthyle sur le groupe méthylène en β qui ne participe pas au mécanisme de désactivation provoque une diminution dramatique du temps de vie du triplet; on attribue l'effect à des préférences conformationnelles différentes dans les cétones **1–3** et on les rationalise à l'aide de calculs MMX. Une substitution par un groupement méthyle sur le cycle β-aryle affecte la facilité avec laquelle on peut oxyder ce cycle et, par conséquence, induit des changements dans la cinétique du transfert de charge intramoléculaire. Cette conclusion est en accord avec les études électrochimiques des cétones **1**, **4** et **5**.

Mots clés : photolyse éclair utilisant une excitation laser, triplets des cétones, piégeage intramoléculaire, transfert de charge.

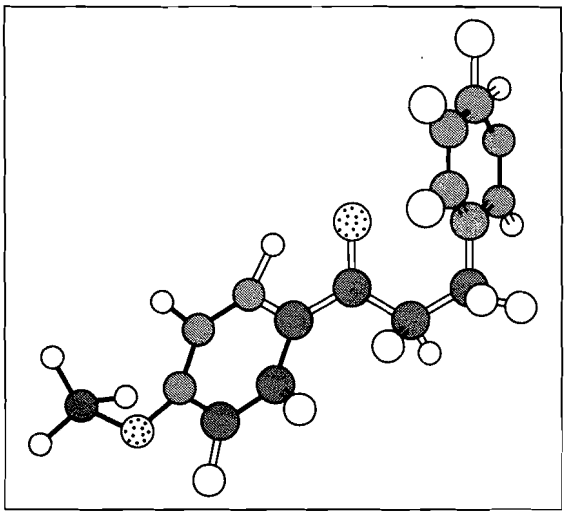
Introduction

Triplet states of ketones having aryl rings in the β-position, such as *p*-methoxy-β-phenylpropiophenone (**1**), decay through an intramolecular deactivation process involving the β-phenyl ring (1–6). This internal quenching mechanism has been known for over 20 years and is believed to involve the conformation shown in Chart 1. There has been extensive work using these ketones in mobility studies (7–10), taking advantage of the measurable slower deactivation when geometrical constraints are imposed on the movement of the β-phenyl ring. The mechanism of deactivation is not completely understood but it is generally accepted to involve movement of the phenyl ring above the carbonyl oxygen followed by charge transfer quenching involving the carbonyl n,π^* triplet state (1–4, 6), which may either be the lowest state, or be thermally populated (as in the examples herein).

Preliminary experiments with **2** indicated that methyl substitution away from the reaction centre had dramatic effects on the triplet lifetime compared to the unsubstituted ketone (**1**).



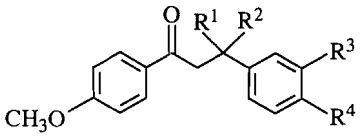


Chart 1

This observation prompted us to investigate various other methyl-substituted derivatives (**3–5**) in an attempt to understand the effects of methyl substitution on the triplet lifetimes. Substitutions were made either in the β-position or on the β-

phenyl ring to explore the influence of steric and redox properties.

A previous study (6) using various ring-substituted β-arylpropiophenones indicated that triplet lifetimes were rather insensitive to substituent effects on the β-phenyl ring. The ketone triplets examined had short lifetimes (between 10 and 60 ns), which reflects their low-lying n,π^* triplet states. It is believed that movement of the β-phenyl ring into the correct orientation for quenching becomes the rate-determining step, rather than the dynamics for the charge transfer process (6). Thus, the corresponding analogs for **1**, **4**, and **5**, without the methoxy group, show essentially no differences in their triplet lifetimes (6). In constrast, compounds in the present study have β-phenyl ring substituents, but also contain a *p*-methoxy group on the chromophore side that serves to increase the triplet lifetime by leading to a low-lying π,π^* triplet state, thus facilitating readily observable substituent effects.

In this paper we report a combination of the results of photochemical studies employing laser flash photolysis techniques, electrochemical measurements, and molecular modelling calculations that, combined, allow us to rationalize the observed variations in triplet lifetimes.

Experimental

Materials

Solvents used for flash photolysis and synthesis (benzene, acetonitrile, cyclohexane, methanol) were obtained from BDH (Omnisolve, glass distilled) and were used without further purification.

Ketones **1** and **2** were prepared following a synthetic procedure (11) involving conversion of the corresponding carboxylic acids (from Aldrich) into the acid chlorides by reaction with thionyl chloride. After removal of excess thionyl chloride, a Friedel–Crafts reaction (11) was carried out on the acid chlorides using anisole (Aldrich). Removal of excess anisole under reduced pressure followed by recrystallization from ethanol gave the desired product. No *ortho*-substituted product — another possible product of the reaction — was observed.

Synthesis of ketone **3** involved the initial synthesis of neophyl chloride from 3-chloro-2-methylpropene (Aldrich) following a literature procedure (12). A standard Grignard reaction was then carried out, converting the neophyl chloride into its corresponding carboxylic acid (11). The remainder of the synthesis is the same as for ketones **1** and **2**. After removal of excess anisole, the crude yellow liquid was purified by TLC on a silica gel spinning plate (Chromatotron model 7924T).

Ketones **4** and **5** were synthesized from *p*-methoxyacetophenone and 3-methylbenzyl alcohol (for **4**) or 4-methylbenzyl alcohol (for **5**) by the method of Pratt and Evans (13).

Laser flash photolysis

The samples, contained in 3 × 7 mm^2 Suprasil quartz cuvettes, were excited by pulses (337 nm; <10 mJ; ~8 ns) from a Molectron UV-24 nitrogen laser. Transient signals, initially acquired by a R-7912 Tektronix transient digitizer, were processed by a PDP-11/23+ computer, which also controlled the experiment and provided suitable storage and hardcopy facilities. Further details have been given elsewhere (14, 15).

Molecular modelling calculations

These calculations were carried out using a molecular modelling software program (PCMODEL version 4 from Serena Software) for the Macintosh II series of computers. The force field used is called MMX and is derived from the MM2 force field and MMP1 pi-VESCF routine of Allinger (16). A dihedral driver was utilized for the rotation of bonds and calculation of energies.

Cyclic voltammetry

Cyclic voltammograms were generated using an air-tight cell under nitrogen atmosphere and a Bioanalytical Systems CV-1B voltammograph instrument utilizing both platinum working (1 mm disk) and auxiliary electrodes and a silver/silver nitrate (0.1 M) reference electrode. Voltammograms were recorded on a calibrated Hewlett Packard X–Y recorder. The solutions for study consisted of 50 mL purified acetonitrile (passed through an activated alumina column), tetrabutylammonium perchlorate (1.71 g, 0.1 M) recrystallized 3 times from 90% ethyl acetate/10% hexane, and a mass of analyte equalling 1 mM. The solutions were degassed with nitrogen prior to the measurements. A standard solution of sublimed ferrocene gave a reversible signal with a potential of 0.05 V.

Results

Triplet lifetimes were determined at room temperature, employing laser flash photolysis techniques, as mentioned above. The decays showed clean monoexponential behavior, although a small amount of residual absorption was frequently observed following the completion of the triplet decay. Figure 1 shows a representative transient spectrum for **2** and a decay trace for the triplet monitored at 400 nm. The triplet spectra were virtually identical regardless of methyl substitution in the β-phenyl ring or in the methylene chain, and agree well with literature spectra for ketones with the *p*-methoxybenzoyl chro-

[b]Typical errors are about 5% for lifetimes of 50 ns or longer and ca. 10% for the shorter values.

mophore (6, 17). The triplet lifetimes recorded for ketones **1**–**5** are given in Table 1. The introduction of methyl groups in the β-position in ketones **2** and **3** had dramatic effects on the triplet lifetimes compared to the unsubstituted ketone **1**. We reasoned that since the mechanism of deactivation involves the interaction of the β-phenyl ring with the carbonyl oxygen, the introduction of methyl substituents may have induced changes in conformation and (or) the ring's freedom of movement. We note that since ketones **2** and **3** have γ-hydrogens, they can undergo the Norrish Type II reaction; Wagner *et al.* (2) showed that this process occurs with very low quantum yields in β-phenylbutyrophenone, thus supporting that the lifetimes are determined by β-phenyl quenching, and not chemical reactions.

Methyl substitutions in the *meta* and especially *para* positions on the β-phenyl ring also shorten the triplet lifetime (see Table 1). Shorter lifetimes could be the result of changes in the oxidation potential of the ring through methyl substitution, thereby facilitating easier transfer of electrons to the carbonyl n,π^* triplet during charge transfer. Electrochemical measurements (*vide infra*) were carried out in order to address this question.

While our studies center on methanol as solvent, a few exploratory measurements in acetonitrile and benzene (see Table 1) clearly suggest that our observations are quite general. The shorter lifetimes in non-hydroxylic solvents are believed to be due to entropic restrictions in hydroxylic media and have been discussed elsewhere (6).

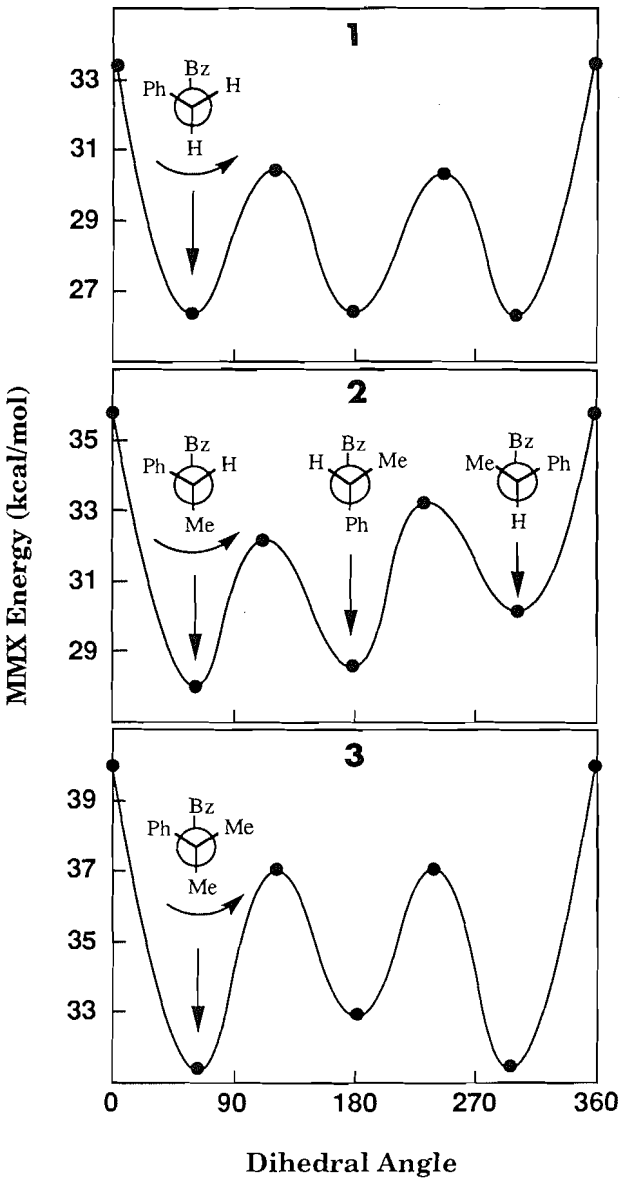

FIG. 2. Energy barriers calculated for key conformations using MMX (absolute MMX energies for different compounds are not comparable; only energy barriers can be compared). The energies were obtained by fixing the dihedral angle but minimizing the rest of the structure. "Bz" represents the *p*-methoxybenzoyl group; note that these are ground state structures.

Molecular mechanics calculations

In an attempt to understand the differences in triplet lifetimes (see Table 1), molecular mechanics calculations were performed using PCMODEL software to estimate the effects of conformational and steric factors of methyl substitution in the β-position. Dihedral drivers were used in which minimizations were performed for angle increments around 3° on ketones **1**–**3** for rotation about bond **b** as shown in the structure below. At the minimum and maximum energies the dihedral angle was fixed and the structure was reminimized; these positions were always very close (±2°) to the multiples of 60°. Figure 2 shows the results of these calculations. For example, ketone **1** has three lowest energy conformers having dihedral angles of about 60°, 180°, and 300° with respect to the car-

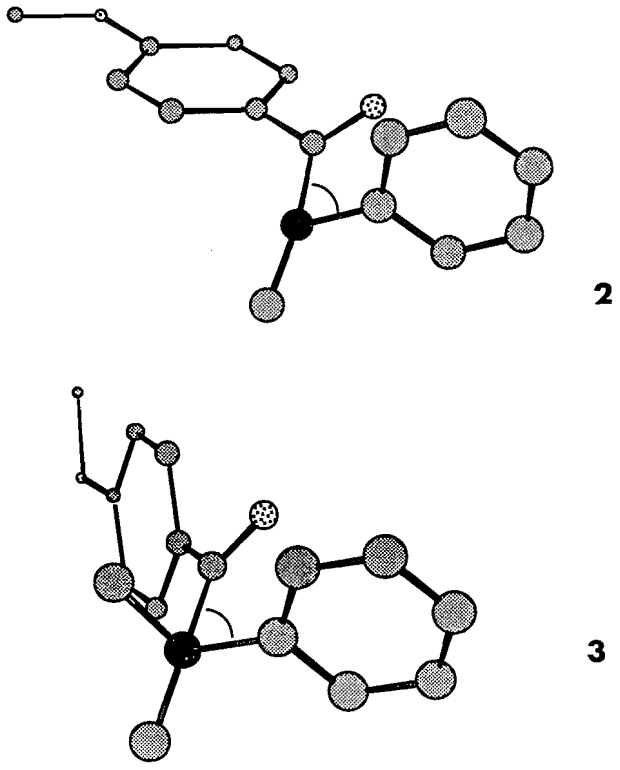

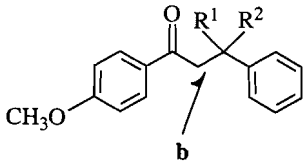

FIG. 3. Minimum energy conformations for **2** and **3** obtained using MMX calculations. Note that these are ground state structures. The solid black center displays two overlapping carbon atoms (as in a Newman projection) and the arc shows the angle displayed in Fig. 2.

bonyl group, each having approximately equal energies (180° being slightly higher). For ketone **2** the lowest energy conformer has a dihedral angle of about 60°. The preferred position of the deactivating phenyl ring in **2** now lies closer to the carbonyl (Fig. 3); this explains the reduction in lifetime between ketones **1** and **2**. For ketone **3**, the situation is quite similar; the β-phenyl ring now prefers to lie at either a 60° or 300° angle with respect to the carbonyl group. Combined with these conformational effects, increased methyl substitution in the β-position raises energy barriers of rotation, thus hindering movement of the phenyl group away from the carbonyl. Our calculations also suggested that in the case of **3** the distance

1–3

between the carbonyl oxygen and the ring (as measured by the distance to the *ortho*-carbons) was smaller than for **2**. However, it was clear that small changes in the position or tilt of the β-phenyl ring are not predicted very accurately at this level of calculation and any argument based on variations in this distance would be highly speculative.

Cyclic voltammetry

The electrochemistry of ketones **1**, **4**, and **5** was investigated in an attempt to establish to what degree different methyl substitutions on the phenyl ring can affect its electron-donating character. The oxidative properties of aromatic rings can be

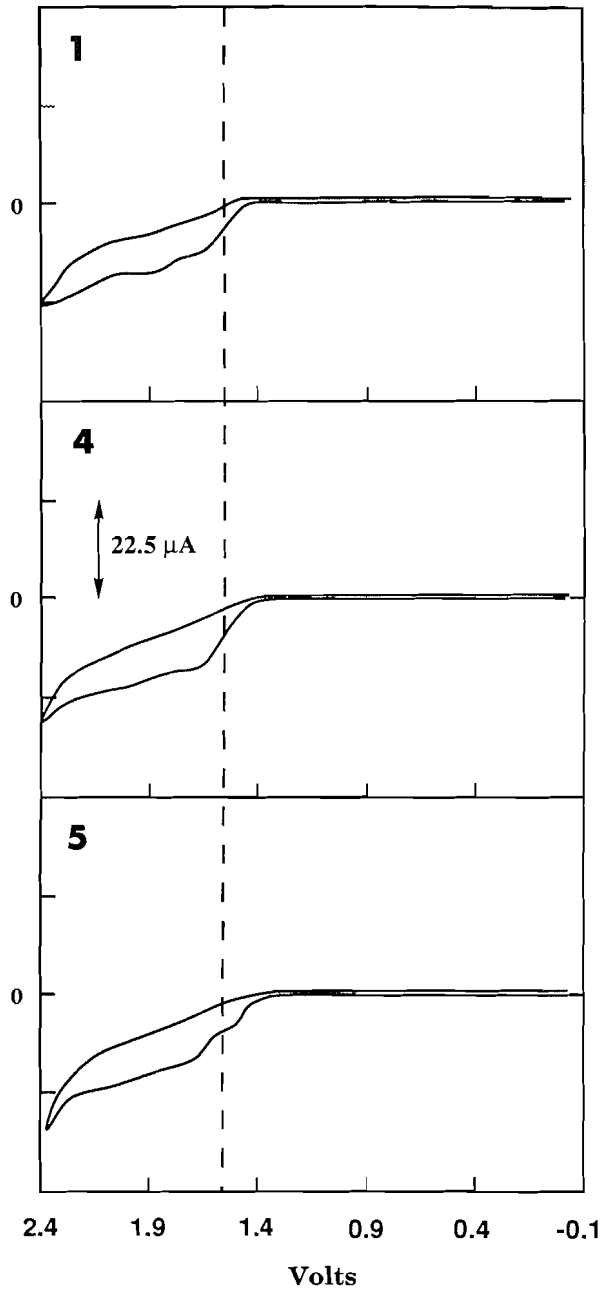

FIG. 4. Irreversible cyclic voltammograms of **1**, **4**, and **5** (the dashed line was added to facilitate comparison).

substantially altered by methyl substitution. In a related piece of work, differences in standard oxidation potentials for various alkylbenzene derivatives were reported by Kochi and coworkers (18), who recorded voltammograms under acid conditions with very fast scan rates and used microvoltammetric electrodes to measure the reversible reduction of the arene cation radicals. In our work, a more traditional cyclic voltammetry setup was sufficient since only relative irreversible oxidation voltammograms are adequate for our analysis.

Ketone **1**, **4**, and **5** all gave irreversible oxidative cyclic voltammograms, as expected. Representative voltammograms are shown in Fig. 4. For ketone **5**, which had the shortest triplet lifetime, the onset of oxidation was at a lower potential than for **1** or **4**. The same trend of oxidation potentials is also observed when comparing toluene to *m*- and *p*-xylene

(18). This lower potential is thought to be due to the *para*-substituted β-phenyl ring. Conclusions about oxidation potential differences concerning the β-phenyl ring for ketones **1** and **4** could not be easily drawn since the *p*-methoxyacetophenone moiety is oxidized at roughly the same potential as the β-phenyl ring, causing overlap of the signals. The faster onset of oxidation of ketone **5** suggests that the β-aryl ring is a better electron donor, thus resulting in the shorter triplet lifetime.

Discussion

It is well established that the mechanism for intramolecular β-aryl quenching of carbonyl triplets, like the Norrish Type I and II reactions (19), requires n,π^* triplet character (6) and adequate mobility so that the conformation for quenching can be achieved (see Chart 1). Conformational restrictions, imposed either by changes in the molecular structure (4), or by media (e.g., by inclusion in zeolite channels (7) or cyclodextrins (9, 10)) can lead to significant increases in triplet lifetime. All the ketones examined in this work have low-lying π,π^* triplets as a result of *p*-methoxy substitution of the benzoyl chromophore; this leads to triplet lifetimes that are sufficiently long to be amenable for study by nanosecond laser photolysis techniques. In addition, the lifetimes are sufficiently long that conformational and electronic factors can now lead to variations in these lifetimes. In contrast, in the case of β-phenylpropiophenone derivatives with no substitute on the benzoyl chromophore, the lifetimes are very short and are predominantly controlled by bond rotation (6).

Our initial work with **2** was motivated by our interest in systems with asymmetric centers. We were initially surprised by the unexpected shortening of the triplet lifetime upon introduction of a methyl group in the methylene chain. With hindsight we rationalize these results on the basis of conformational preferences. We note that earlier work comparing the lifetimes of β-phenylpropiophenones and α-phenoxyacetophenones also led to the conclusion that steric interactions involving the linkage between the chromophore and quencher can play a crucial role in determining the triplet lifetime (20, 21). Similarly, when the α- or β-carbon atoms in the linkage are part of a small ring system the triplet lifetimes are also increased significantly (4). In addition, conformational constraints imposed by substitution at the α-carbon of β-arylpropiophenones lead to reactivity differences towards triplet state intramolecular ϵ-hydrogen abstraction, which were interpreted as resulting from preferential population of the conformations necessary for reaction (22).

Our present studies reflect two distinct types of effects. In the case of compounds **1**, **2**, and **3**, the effects are of a conformational nature, since neither the properties of the chromophore nor those of the deactivating ring should be significantly affected by methyl substitution on the $-CH_2CH_2-$ link. Figures 2 and 3 show the results of MMX calculations, which even at this rather basic level illustrate the conformational preferences of these molecules. For ketone **1**, there are three preferred conformations with essentially the same predicted energy, whereas in the case of **2**, our MMX calculations indicate that the preferred conformation (see Figs. 2 and 3) places the β-phenyl ring at ~60° with respect to the carbonyl chromophore. The case of **3** is similar; now there are two energetically equivalent lowest energy conformations at 60° and 300°, increasing the probability of finding the β-phenyl ring close to the carbonyl. Besides analysing the preferred lowest energy conformations, one also has to take into account the energy barriers to approaching an eclipsed conformation. In a first approximation we assume that a fully eclipsed conformation (corresponding to the vertical axis in Fig. 2) between the β-phenyl and the carbonyl groups is required for quenching. The probability of obtaining the conformation required for quenching is a function of the energy barrier to obtain this eclipsed conformation but is also a function of the barriers observed for the other substituents. An increase of the rotational energy barrier required to move away from the preferred conformation is observed when substituting the β-hydrogens for methyl groups; this increase leads to a higher probability of the β-phenyl ring remaining close to the eclipsed conformation necessary for quenching. Clearly, not only are the chromophore and quencher closer in the case of **2** and **3**, but also the energy barriers predict easier quenching for these compounds, as observed.

It is generally believed that the mechanism for β-aryl quenching involves charge transfer from the quencher group to the excited carbonyl. Not surprisingly, in systems with low-lying π,π^* states quenching involves the more electrophilic and thermally populated n,π^* state (6). We reasoned that methyl substitution at the β-aryl ring should make oxidation easier and therefore result in a reduction of the triplet lifetimes. This prediction proved correct, as shown by the lifetimes for **4** and **5** given in Table 1. Cyclic voltammograms (see Fig. 4) also confirm this expectation, the largest effect on both the lifetime and the oxidation potential being induced by *para*-methyl substitution. It is interesting that, in the case of **5**, *p*-methyl substitutions essentially reverse the kinetic effect due to the low-lying π,π^* triplet in the *p*-methoxybenzoyl chromophore (compare the data in Table 1 with the unsubstituted substrate (6)); it is possible that, in the case of **5**, rotational control may play a role in determining the lifetime.

In conclusion, laser photolysis studies of the triplet states of **1–5** demonstrated the importance of conformational and redox properties in determining the kinetics for intramolecular charge transfer quenching in these molecules. The effects of substitution in the $-CH_2CH_2-$ link are quite dramatic but readily explained by MMX molecular modelling calculations. The results also confirm the earlier proposal (6) that in the absence of the *p*-methoxy substituent the lifetimes are too short to be amenable for direct study with nanosecond techniques and are largely controlled by bond rotation; this tends to mask other effects that are readily observable in the series studied herein.

Received April 2, 1991

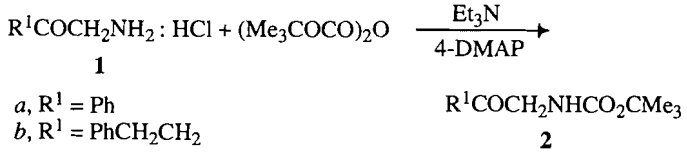
ANGEL GUZMAN, CLARA QUINTERO, and JOSEPH M. MUCHOWSKI. Can. J. Chem. **69**, 2059 (1991).

A versatile synthesis of α-alkyl-α-amino ketones **5** and cyclic α-amino ketones **7** based on the selective mono-α-alkylation and $C(\alpha),N$-cycloalkylation of α-*tert*-butoxycarbonylamino ketones **2** and subsequent acidic hydrolysis is described.

Key words: α-*tert*-butoxycarbonylamino ketones, α-alkyl-α-amino ketones, 2-acylpyrrolidines, and 2-acylpiperidines.

ANGEL GUZMAN, CLARA QUINTERO et JOSEPH M. MUCHOWSKI. Can. J. Chem. **69**, 2059 (1991).

On décrit une synthèse versatile des α-alkyl-α-amino cétones de type **5** et des α-amino cétones cycliques de type **7**; ces synthèses sont basées sur la mono-α-alkylation sélective et la $C(\alpha),N$-cycloalkylation des α-*tert*-butoxycarbonylamino cétones de type **2**, suivie d'une hydrolyse acide subséquente.



Mots clés : α-*tert*-butoxycarbonylamino cétones, α-alkyl-α-amino cétones, 2-acylpyrrolidines et 2-acylpipéridines.

[Traduit par la rédaction]

α-Amino ketones and the protected versions thereof are widely utilized as precursors of heterocyclic systems, ethanolamine derivatives of physiological interest, and peptidic natural products and congeners thereof. Numerous syntheses of these important starting materials have been devised (1) and new developments in this field continue apace (2–8). We recently demonstrated (9) that the monoanions of *N*-formylated α-amino ketones, like those of benzamidoacetone (10), are regioselectively alkylated on the α-carbon atom and that acidic hydrolysis of these products provided access to α-alkyl-α-amino ketones with satisfactory efficiency. A particular advantage of this process is that one substrate can serve as the progenitor of many new α-alkyl-α-amino ketones. This desirable characteristic is also found in the generation of such compounds based on the reaction of alkyl Grignard or alkyllithium reagents with N-protected α-amino acids (11–14) or with N-protected *O*,*N*-dialkyl-α-amino acid hydroxamates (15, 16) but is absent in many previously reported syntheses (e.g., see ref. 1 pp. 420–422, 431–432, 440–441, and 467). This paper describes studies on the mono- and dialkylation of α-*tert*-butoxycarbonylamino ketones, which show that they are also very useful substrates for the preparation of a variety of substituted α-amino ketone derivatives.

The *N*-*tert*-Boc-α-amino ketones **2** were prepared (Scheme 1) from the α-amino ketone hydrochlorides **1** and di-*tert*-butyl dicarbonate in the presence of a slight excess of triethylamine containing a catalytic amount of 4-dimethylaminopyridine.

As expected from the previous study with α-formamido ketones (9), reaction of **2** with an equivalent of sodium hydride in anhydrous dimethylformamide (DMF) generated the presumably thermodynamic, dipole-stabilized (10, 17) ketone enolates **3** (Scheme 2),[4] which on reaction with alkyl bromides or iodides led to the mono-α-alkyl derivatives **4** (Table 1) as the major products. In every case, a less polar by-product[5] was isolated and usually some starting material was recovered as well.

[4]A referee has stated that "The structure of the α-*tert*-Boc-amino ketone enolate proposed in Scheme 2 (i.e., **3**) is virtually an impossible structure since the acidity of the NH there is very likely to be much higher than the activated methylene." The referee also suggests that alkylation is more likely to occur via a reactive dianion (i.e., $[R^1COCHNCO_2CMe_3]^{2-}$). While it is probable that such a dianion would undergo *C*-alkylation (18), and we have no evidence to exclude the presence of a small amount of this species, it is most instructive to note the following points. The monoanion **3** is undoubtedly formed under conditions of thermodynamic control. Bordwell and Algrim (19) have reported that the pK_a's of CH_3COCH_3 and CH_3CONH_2 in DMSO are 26.5 and 25.5, respectively. The inductive effect of the *N*-*t*-Boc moiety would increase the acidity of the methylene hydrogens. It is thus clear that the acidity of the NH is not likely to be "much higher" than that of the methylene hydrogens. Secondly, the pK_a of ketone enols is ca. 11 (20), which guarantees that the monoanion of **2** has structure **3** and not $R^1COCH_2NCO_2CMe_3$. Thus, there is no need to invoke the presence of a small amount of the dianion to rationalize the monoalkylation reactions described herein.

[5]For example, the alkylation of **2** (R^1 = Ph) with methyl iodide gave material which had ^1H nmr absorptions at δ 1.46, 1.53 (singlets, total ~9H), 3.26, 3.57 (singlets, total ~3H), 7.27 (s, ~4H), and 8.08 (q, ~1H) and infrared peaks at 3440 and 1700 cm^{-1}. Acidic hydrolysis under mild conditions (0.5 N HCl, room temperature) was without effect; more vigorous conditions (3 N HCl, reflux) caused resinification.

[a]Yield of product after column chromatographic purification.
[b]ND = not determined.

SCHEME 2

Removal of the *t*-Boc group from **4** was effected slowly with excess trifluoroacetic acid at ambient temperature or rapidly with excess methanolic hydrochloric acid at reflux temperature. The salts of the α-alkyl-α-amino ketones **5** were thus obtained in overall yields quite comparable to those reported for the α-formamido ketone process (Table 2).

The dialkylation of **2** was examined using an equivalent of a 1,3-dihalopropane or a 1,4-dihalobutane derivative in the presence of two equivalents of sodium hydride. The second alkylation took place on nitrogen to give the corresponding 2-acylpyrrolidine (**6**, $n = 3$, Scheme 3) or 2-acylpiperidine (**6**, $n = 4$). The efficiency of this cyclization was dependent, to a certain extent, on the α,ω-dihalide used (Table 1) but it was not improved by addition of the sodium hydride in two separate one-equivalent portions (i.e., stepwise alkylation). In the phenethyl series, the pyrrolidine derivative **6** (R^1 = $PhCH_2CH_2$, $n = 3$) was accompanied by appreciable amounts of the α-allyl compound **4** (R^1 = $PhCH_2CH_2$, R^2 = CH_2-$CH{=}CH_2$), which was presumably formed by dehydrohalogenation of the monoalkylated intermediate. The successful formation of the cyclic α-amino ketone derivatives **6** is not unique to the α-*tert*-butoxycarbonylamino ketones **2** since *N*-formylphenacylamine gave analogous cyclic products in comparable yields under conditions identical to those described herein.[6] Whereas *C*,*N*-cycloalkylation in these systems is synthetically useful, dialkylation in the intermolecular sense is not. For example, *N*-formylphenacylamine on attempted dialkylation with benzyl bromide gave a 1:2:3 mixture of α-mono-, α,α-di, and α,α,*N*-trialkylated compounds (9).

Deprotection of **6** with hot methanolic hydrochloric acid gave the cyclic α-amino ketones **7** (Table 2). Given the ready

[6]A. Guzman, C. Quintero, and J. M. Muchowski. Unpublished observations.

[a]N-*t*-Boc compounds measured in $CHCl_3$; HCl salts obtained as dispersions in KBr.
[b]N-*t*-Boc compounds measured in $CDCl_3$; HCl salts in DMSO-d_6. Spectra measured at 200 MHz unless indicated otherwise.
[c]Measured at 90 MHz.

availability of **2**, this process constitutes a very useful route to such compounds for which few syntheses have been reported (21–23).

In summary, α-*tert*-butoxycarbonylamino ketones **2** are readily transformed into α-alkyl-α-amino ketones, 2-acylpyrrolidines, and 2-acylpiperidines. In this respect, they (i.e., **2**) are as synthetically useful as the corresponding formamido compounds and this fact adds flexibility to synthetic sequences in which the use thereof is contemplated.

SCHEME 3

Experimental

The melting points were determined in a Buchi model 510 melting point apparatus and are not corrected. The infrared spectra were measured with Perkin–Elmer 1720-X, 1420, or 197 infrared spectrophotometers. The ^1H nmr spectra were obtained with a Varian EM-390 or a Varian Gemini-200 nmr spectrometer and are expressed as parts per million (δ) from internal tetramethylsilane. The high-resolution mass spectra were obtained with a Finnigan MAT 311A mass spectrometer.

Phenacylamine hydrochloride (**1**, R^1 = Ph) and 1-amino-4-phenyl-2-butanone hydrochloride (**1**, $R^1 = PhCH_2CH_2$) were synthesized by the method of Ackrell *et al.* (9).

*2-N-tert-Butoxycarbonylaminoacetophenone (**2**, R^1 = Ph)*

Di-*tert*-butyl dicarbonate (10.36 g, 49.5 mmol), triethylamine (12.2 mL, 8.84 g, 87.5 mmol), and 4-dimethylaminopyridine (0.48 g, 3.9 mmol) were added to a stirred suspension of 2-aminoacetophenone hydrochloride (6.80 g, 39.6 mmol) in acetonitrile (100 mL). The mixture was stirred at room temperature for 0.5 h, the solvent was removed *in vacuo*, and the residue was subjected to column chromatographic purification on silica gel. The product (5.86 g, 63% yield) was eluted with hexane – ethyl acetate (95:5). After crystallization from dichloromethane–hexane it had mp 56–57°C; ir ($CHCl_3$): 3508, 3408, 1711, 1691 cm^{-1}; nmr ($CDCl_3$, 90) δ: 1.48 (s, 9H, *t*-Bu), 4.63 (d, 2H, J = 4.8 Hz, singlet after D_2O exchange, CH_2), 5.51 (bs,

1H, exchanged with D_2O, NH), 7.37–7.71 (m, 3H), 7.91–8.01 (m, 2H). Anal. calcd. for $C_{13}H_{17}NO_3$: C 66.38, H 7.23, N 5.95; found: C 66.29, H 7.25, N 5.93.

*1-N-tert-Butoxycarbonylamino-4-phenyl-2-butanone (**2**, $R^1 = PhCH_2CH_2$)*

This compound was prepared in the manner described above. It was obtained in 46% yield as an oil; ir ($CHCl_3$): 3434, 1703 cm^{-1}; nmr ($CDCl_3$, 90) δ: 1.43 (s, 9H, *t*-Bu), 2.59–2.99 (m, 4H, CH_2CH_2), 3.91 (d, 2H, J = 4.5 Hz, singlet after D_2O exchange, CH_2), 5.11 (s, 1H, exchanged with D_2O, NH), 7.08–7.24 (m, 5H, C_6H_5); *m/e*: 263.1521 (calcd. for $C_{15}H_{21}NO_3$: 263.1522).

*Monoalkylation of the α-tert-butoxycarbonylamino ketones **1***

A solution of the α-*tert*-butoxycarbonylamino ketone (2.0 mmol) in anhydrous DMF (5 mL) was added to a stirred suspension of sodium hydride (prepared from 0.10 g (2.1 mmol) of a 50% dispersion in mineral oil by washing with dry hexane) in dry DMF (5 mL) maintained in a nitrogen atmosphere at 0°C. After the addition was completed, stirring at 0°C was continued until hydrogen evolution was complete (0.25 h) and then the alkyl halide (2.4 mmol) was added. After a further 1 h at 0°C the reaction mixture was poured into saturated aqueous ammonium chloride solution, the product was extracted into ethyl acetate, the extract was washed with saturated salt solution, and then it was dried over sodium sulfate. The solvent was removed *in vacuo* and the residue was subjected to column chromatography on silica gel using hexane – ethyl acetate (95:5) as the eluting solvent. The less polar product of unknown structure was removed first, followed by the desired product and the starting material. The product yields are found in Table 1 and the physical constants in Table 3. The nmr and infrared spectra of selected compounds are found in Table 4. The remaining spectral data (Table 5) can be obtained from the Depository of Unpublished Data.[7]

*Alkylation of the α-tert-butoxycarbonylamino ketones **1** with α,ω-dihalides*

This alkylation reaction was carried out as described above except that 2.1 equivalents of sodium hydride were used.

*Synthesis of the alkylated α-amino ketone hydrochlorides of **5** and **7***

A solution of the alkylated α-*tert*-butoxycarbonylamino ketone (0.3 mmol) in methanol (15 mL) containing concentrated hydrochloric acid (0.14 mL, ~1.5 mmol) was heated at reflux temperature for 1 h. The solvent was removed *in vacuo* and the solid residue was crystallized from methanol – ethyl acetate. The product yields are found in Table 2 and the physical constants in Table 3. The spectroscopic data are compiled in Tables 4 and 5.

*Synthesis of the alkylated α-amino ketone trifluoroacetates of **5** and **7***

A solution of the alkylated α-*tert*-butoxycarbonylamino ketone (0.4 mmol) in dichloromethane (15 mL) containing trifluoroacetic acid (0.15 mL, 0.23 g, 2 mmol) was left at room temperature for 24 h. A further 2 mmol of the acid was added and after an additional 24 h the solvent was removed *in vacuo*. The solid residue was crystallized from ethyl acetate. The product yields are found in Table 2 and the physical constants are given in Table 3.

Kinetics and mechanism of the hydrolysis of a (5,6)-spirophosphorane. Thermodynamics of the hydrolysis of cyclic five-membered and six-membered phosphonium ions

GLENN H. MCGALL AND ROBERT A. MCCLELLAND
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 27, 1991

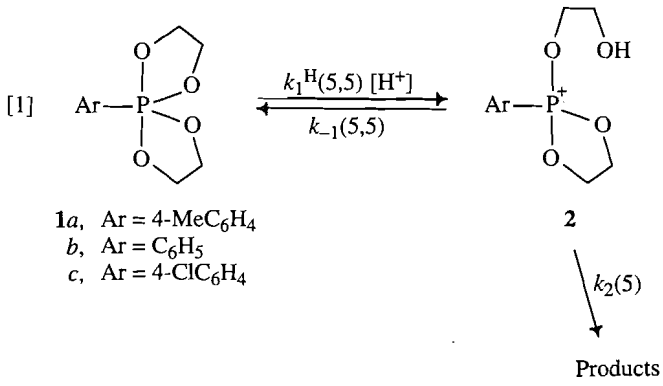
GLENN H. MCGALL and ROBERT A. MCCLELLAND. Can. J. Chem. **69**, 2064 (1991).

The cyclic five-membered phosphonium ion **2***b* (2-(2′-hydroxyethoxy)-2-phenyl-1,3,2-dioxaphospholan-2-ylium) derived from ring-opening of the (5,5)-spirophosphorane **1***b* (5-phenyl-1,4,6,9-tetraoxa-5-phosphaspiro[4,4]nonane) has been observed in neat CF_3SO_3H and at >85% H_2SO_4. The cation undergoes hydrolysis in the latter solutions, and an extrapolation has been carried out to obtain an estimate for reactivity in 100% water. Hydrolysis rate constants for phenyltrialkoxyphosphonium ions in water are 10^7, 10^0, and 5×10^{-3} s^{-1} for cyclic five-membered, cyclic six-membered, and acyclic derivatives respectively; these show an excellent correlation with rate constants for a similar series of phosphate esters. An investigation of the hydrolysis of the (5,6)-spirophosphorane **5** (5-phenyl-8,8-dimethyl-1,4,6,10-tetraoxa-5-phosphaspiro[4,5]decane) provides a clue as to the origins of these rate differences. This phosphorane can in principle hydrolyze via two isomeric cyclic phosphonium ions, the six-membered **14** and the five-membered **15**. The former is thermodynamically more stable, being the only cation observed under equilibrating conditions of strong acid. However, the hydrolysis of the spirophosphorane, as well as the hydrolysis of fully formed **14**, channels through the cyclic five-membered **15**. A thermodynamic breakdown reveals that the 9.5 kcal mol^{-1} difference in activation free energy for the hydrolysis of five- and six-membered cyclic phosphonium ions is due to a combination of a *higher* free energy (2.5–4.5 kcal mol^{-1}) for the five-membered cation, and a *lower* free energy (7–5 kcal mol^{-1}) for the pentacoordinate transition state with the five-membered ring. This analysis also shows that a (5,6)-spirophosphorane is 6–8 kcal mol^{-1} more stable than a (6,6)-spirophosphorane. Thus, a five-membered ring has a significant stabilizing effect on a pentacoordinated phosphorus structure. The accelerated hydrolysis of cyclic phosphonium ions and phosphate esters with five-membered rings is caused by a combination of this stabilizing effect in the transition state and a destabilizing effect in the ground state associated with ring strain.

Key words: phosphorane, hydrolysis, phosphate, phosphonium.

GLENN H. MCGALL et ROBERT A. MCCLELLAND. Can. J. Chem. **69**, 2064 (1991).

L'ion phosphonium cyclique à cinq chaînons **2***b* ((2-(2′-hydroxyéthoxy)-2-phényl-1,3,2-dioxaphospholan-2-ylium), formé par une ouverture de cycle du (5,5)-spirophosphorane **1***b* (5-phényl-1,4,6,9-tétraoxa-5-phosphasiro[4,4]nonane), a pu être observé tant du CF_3SO_3H à l'état pur que dans du H_2SO_4 à >85%. Le cation subit une hydrolyse dans ces dernières solutions et on a effectué une extrapolation pour obtenir une évaluation de la réactivité dans de l'eau à 100%. Dans l'eau, les constantes de vitesse des réactions d'hydrolyse des ions phényltrialkoxyphosphonium cyclique à cinq chaînons, cyclique à six chaînons et aliphatique sont respectivement égales à 10^7, 10^0 et 5×10^{-3} s^{-1}; ces valeurs présentent une excellente corrélation avec les constantes de vitesse pour une série similaire d'esters de l'acide phosphorique. Une étude de l'hydrolyse du (5,6)-spirophosphorane **5** (5-phényl-8,8-diméthyl-1,4,6,10-tétraoxa-5-phosphaspiro[4,5]décane) fournit des indications sur les origines de ces différences dans les vitesses. En principe, ce phosphorane peut s'hydrolyser par le biais de deux ions phosphonium cycliques isomères, l'ion à six chaînons **14** et l'ion à cinq chaînons **15**. Le premier est thermodynamiquement plus stable; il est le seul cation à être observé dans des conditions fortement acides équilibrantes. Toutefois, l'hydrolyse du spirophosphorane, de même que l'hydrolyse de l'ion **14** complètement formé, passe par l'ion cyclique à cinq chaînons **15**. Une attribution thermodynamique révèle que la différence de 9,5 kcal mol^{-1} qui existe entre énergies libres d'activation pour les hydrolyses des ions phosphonium cycliques à cinq et à six chaînons est due à une combinaison d'une énergie libre *plus élevée* (2,5–4,5 kcal mol^{-1}) pour le cation à cinq chaînons et une énergie libre *plus faible* (7–5 kcal mol^{-1}) pour l'état de transition pentacoordiné du cycle à cinq chaînons. Cette analyse permet aussi de montrer qu'un (5,6)-spirophosphorane est de 6–8 kcal mol^{-1} plus stable qu'un (6,6)-spirophosphorane. Un cycle à cinq chaînons a donc comme effet de stabiliser une structure phosphorée pentacoordinée. L'hydrolyse plus rapide des ions phosphonium cycliques et des esters de l'acide phosphorique comportant des cycles à cinq chaînons est causée par une combinaison de cet effet stabilisant de l'état de transition et un effet déstablisant de l'état fondamental associé avec la tension de cycle.



Mots clés : phosphorane, hydrolyse, phosphate, phosphonium.

[Traduit par la rédaction]

Oxyphosphoranes are the P=O analogs of acetals and ortho esters, and also model hydroxyphosphoranes, the pentavalent intermediates/transition states of phosphoryl group transfer. A variety of oxyphosphoranes have now been prepared, and their structural and fluxional characteristics subjected to considerable examination (1). However, kinetic and mechanistic studies of their hydrolysis reactions are limited (2–5), in marked contrast to the situation with acetals and ortho esters, which have been well studied in this respect (6, 7). With the initial objective to compare the carbonyl and phosphoryl derivatives, we have been studying mechanistic details of the hydrolysis of spirotetraalkoxyphosphoranes.

Our initial investigations focussed on (5,5)-spiro systems **1**, and revealed that there was hydrolysis throughout the pH range, with catalysis by H^+ and OH^-, as well as general acids and bases (8). The base reaction was proposed to follow an associative mechanism, with the base reacting at phosphorus to give a hexacoordinated intermediate. The acid reaction, on the other hand, appeared to involve a dissociative mechanism, with the formation of a phosphonium ion intermediate **2** and subse-

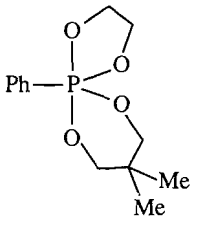
1*a*, Ar = 4-MeC_6H_4
b, Ar = C_6H_5
c, Ar = 4-ClC_6H_4

quent reaction with water. Analogous associative and dissociative mechanisms had previously been suggested by Archie and Westheimer, based upon observations with pentaaryloxyphosphoranes (2). The dissociative reaction is obviously analogous to the acid-catalyzed hydrolysis of acetals and ortho esters (6, 7).

With (6,6)-spirophosphoranes (9), no base reaction was observed, even at high pH. However, there was a very efficient dissociative reaction occurring throughout the pH range, with the ring-opened phosphonium ion **4** actually being observed as an intermediate in solutions with pH < ~8. The kinetic analysis revealed that this cation forms reversibly from the phosphorane in the hydrolysis, with an equilibrium constant, [**3***a*][H^+]/[**4***a*], of 3 × 10^{-9} M. The rate-limiting step in the



3*a*, R = H
b, R = Me

hydrolysis is the second step, the reaction of the cation with water, or at pH > 11, hydroxide ion. The reversibility results because the intramolecular reaction reforming the six-membered ring occurs with a rate constant $k_{-1}(6,6)$ 12 times greater than the rate constant $k_2(6)$ for the reaction of the cation with water.

Reversibility of the ring-opening step was considered for the acid hydrolysis of the (5,5)-spiro **1***a–c*, since this is consistent with the experimental data. This reaction exhibits a slightly positive entropy of activation, and this was originally taken as an indication of rate-limiting cation formation (8). A later study, however, demonstrated that, under non-hydrolytic conditions, addition of acid results in a rapid and reversible equilibrium (10). The phosphorane remains highly favored in the equilibrium, but the presence of small amounts of the phosphonium ion is indicated by an acid-catalyzed coalescence of ring protons in the ^1H NMR spectrum of the phosphorane associated with rapid opening and closing of the ring. A similar phenomenon is observed during the actual hydrolysis of an octamethyl analog of **1***b*, with the kinetic analysis showing that, with the octamethyl compound, $k_2(5)$ of eq. [1] is at least 2.5 × 10^6 smaller than $k_{-1}(5,5)$ (11). Moreover, this phosphorane also exhibits a positive entropy of activation for its overall hydrolysis, so that our use of this criterion to rule out reversibility with **1** had been incorrect. In consequence, our current interpretation is that ring-opening is probably reversible in the acid hydrolysis of **1***a–c* also (12).

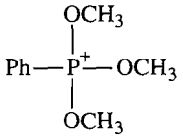
In this paper we report the observation of the cyclic five-membered phosphonium ion **2***b* in strong acids, and extrapolate to arrive at an estimate of the rate constant $k_2(5)$ in 100% aqueous solution. This phosphonium ion is orders of magnitude more reactive than its cyclic six-membered analogs **4** as well as acyclic analogs, the same situation as observed in the hydrolysis of cyclic and acyclic phosphate esters (13). Rate constants for the phenyltrialkoxyphosphonium ions are in fact excellently correlated with rate constants for the hydrolysis of phosphate esters, with the conclusion that the same factors are determining reactivity in both series.

We then report an analysis of the hydrolysis of the (5,6)-spirophosphorane **5** that provides an evaluation of the relative

5

effects of five- and six-membered rings at stabilizing both reactant phosphonium ions and the transition states for their reactions with water. This phosphorane was originally chosen to see if the hydrolysis is similar to that of the (5,5)-spiro **1** or the (6,6)-spiro **3**. In fact it exhibits the interesting behavior of thermodynamically opening its 5-atom ring to give a cyclic six-membered phosphonium ion, while the overall hydrolysis proceeds essentially exclusively by way of the cyclic five-membered cation obtained on opening the (6)-atom ring. The two phosphonium ions and their transition states for reaction with water are isomers of each other, and it is this feature that allows free energies to be directly compared. What emerges is that there is a *higher* free energy of a cyclic five-membered cation but a *lower* free energy of the five-coordinate transition state, and it is the combination of the two factors that gives rise to the enormously accelerated hydrolysis of the five-membered system. That a five-membered ring has relative stabilizing effects in opposite directions in four-coordinated and five-coordinated phosphorus was suggested previously, based upon examination of crystal structures (14). However, most explanations for the enhanced reactivity of cyclic five-membered phosphates have focused on the starting state, and the relief of ring strain in the transition state for the cyclic five-membered compound (13, 15). The potential discrepancy between enthalpic strain energy and observed rate constants has, however, been noted (15).

Results



Observation of the cyclic five-membered phosphonium ion 2b

These experiments were carried out in an attempt to observe a cyclic five-membered phosphonium ion. Previously

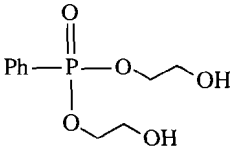
we had found that, whereas addition of a strong acid to a solution of (6,6)-spirophosphoranes **3** in CD_2Cl_2 or $CDCl_3$ leads to quantitative formation of cyclic six-membered phosphonium ions **4** (9), there is no observable reaction with (5,5)-spirophosphoranes other than the coalescence in the ^1H NMR spectrum (10). We now find that when dissolved in neat CF_3SO_3H **1***b* does exhibit NMR spectra consistent with the ring-opened phosphonium ion **2***b*. The most compelling evidence is the ^{31}P NMR chemical shift, which changes from −20.0 ppm in $CDCl_3$ to +59.7 ppm in the acid. The latter value is some 30 ppm more positive than the ^{31}P shifts of other phenyltrialkoxyphosphonium ions such as **4** (9) and **6** (16, 17). This is consistent with the formation of **2***b*, since a tetracoordinated phosphorus compound containing a five-membered ring is expected to exhibit a ^{31}P signal that is significantly downfield relative to acyclic and six-membered analogs (18–20). An example involving phosphonium ions involves a comparison of **7** (^{31}P = +12 ppm) and **8** (^{31}P = −18 ppm), where there is also a 30 ppm downfield shift caused by the presence of the five-membered ring (21).

6

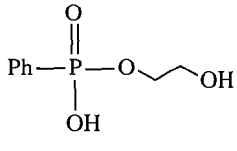
7

$(PhO)_4P^+$



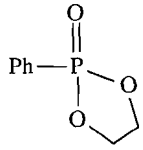
8

The cation **2***b* is not indefinitely stable in CF_3SO_3H, the ~60 ppm ^{31}P signal being completely replaced over 2–3 days by a cluster of signals around +34 ppm. The new products are likely oligomeric protonated phosphonate esters, forming by ring-opening of the cation in a reaction with an OH group of a second cation. Similar oligomerizations of spirophosphoranes under acidic conditions have been described previously (22).



The cation **2***b* is also observed in concentrated sulfuric acid where it displays a ^{31}P resonance at +58.2 ppm. Decomposition also occurs here, with the half-life being about 30 min. This reaction is a hydrolysis, since the rate increases in more dilute acids, and the ^{31}P NMR of the product mixture shows two closely spaced signals near +35 ppm due to the two products of hydrolysis (see next section). These phosphonate esters are protonated under these strong acid conditions, and slowly undergo further hydrolyses themselves. First-order rate constants for the hydrolysis of the cation **2***b* were measured in three acids, 96.0, 90.0, and 85.0% H_2SO_4, as 4.8×10^{-4} s^{-1}, 1.0×10^{-2} s^{-1}, and 3.5×10^{-2} s^{-1} respectively.

*Products of the acid hydrolysis of the (5,5)-spirophosphorane 1*b



In our previous study, the hydrolysis of this phosphorane was found to give two phosphonate esters, **9** and **10**, plus ethylene glycol (8). The monoester **10** was presumed to arise from hydrolysis of the initially formed cyclic ester **11**. This has now

9

10

11

been confirmed by the direct observation of **11** in solutions where its hydrolysis is relatively slow. In 1:1 CD_3CN:D_2O containing a 1:1 mixture of CD_3COONa:CD_3COOD (0.01 M each) **1***b* rapidly hydrolyzes, producing a solution with two ^{31}P resonances, one at +21.3 ppm and a second at +39.3 ppm. The former is characteristic of phenylphosphonate diesters and corresponds to **9** (8). The latter is very similar to a literature shift reported for **11** (23). When this solution is acidified with a few drops of 6 M DCl, the downfield peak is completely replaced by a peak at +18.6 ppm, indicating that **11** has rapidly reacted to produce the ring-opened **10**. A small UV absorbance decrease accompanies this hydrolysis, thereby permitting rate measurements. This hydrolysis exhibits catalysis by both H^+ and OH^- with second-order rate constants of 0.37 M^{-1} s^{-1} and 6.0×10^2 M^{-1} s^{-1} respectively.

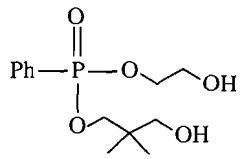


TABLE 1. Relative amount of the bis-phosphate ester **9** produced in the hydrolysis of the phosphorane **1***b*

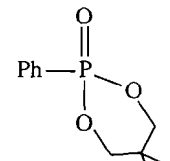
Solution	pH	Percent **9**
3 M HCl	−1.0 (H_0)	53
1 M HCl	−0.25 (H_0)	58
0.1 M HCl	1.0	63
0.01 M HCl	2.0	67
Biphthalate buffer	3.0	84
Biphthalate buffer	4.0	90
Acetate buffer	5.0	99
Phosphate buffer	7.0	100
Phosphate buffer	8.0	100



We have also investigated the pH dependency of the relative amounts of these products. As shown in Table 1 approximately 50% of the cyclic ester **11** or its hydrolysis product **10** is formed in acidic solutions, but this decreases as the pH is increased until at pH 7 the bis-ester **9** is the exclusive product (less than 1% **11**/**10**).

Products of the acid hydrolysis of the (5,6)-spirophosphorane 5

Hydrolysis of this phosphorane under acidic conditions yields two phosphonate esters, the bis-ester **12** and the monoester **10**, as well as 2,2-dimethyl-1,3-propanediol in an amount equivalent to the latter compound. The monoester **10** is also observed starting with the (5,5)-spirophosphorane **1***b*, and, as discussed in the previous section, arises from the cyclic ester **11**, which can be also observed with **5** in weakly acidic solutions. Two other products that could possibly have formed from the (5,6)-spirophosphorane are the cyclic six-membered phosphonate **13** and ethylene glycol. These were not detected

12

13

(less than 1%) in the ^{31}P and ^1H NMR spectra, as verified by the addition of authentic samples of these materials.

Yields of the bis-ester **12** as determined by integration of ^{31}P NMR signals were 80%, 3 M DCl; 83%, 1 M DCl; 85%, 0.1 M DCl; and 100%, pD 6 buffer.

Kinetics of the hydrolysis of the (5,6)-spirophosphorane 5

Kinetic studies were performed in aqueous solution at 25°C, with the ionic strength maintained at 1. First-order rate constants were measured between pH 12 and pH 5, the rates in

TABLE 2. Second-order rate constants for catalysis of the hydrolysis of the phosphorane **5** in aqueous solution at 25°C and an ionic strength of 1.0

Catalyst	k, M^{-1} s^{-1}
H_3O^+	$(3.65 \pm 0.05) \times 10^7$
$(CH_3)_2AsO_2H$	29 ± 4
$H_2PO_4^-$	9 ± 3
H_3BO_3	0.39 ± 0.02
HCO_3^-	0.005 ± 0.001
CO_3^{-2}	0.03 ± 0.01
OH^-	0.446 ± 0.001

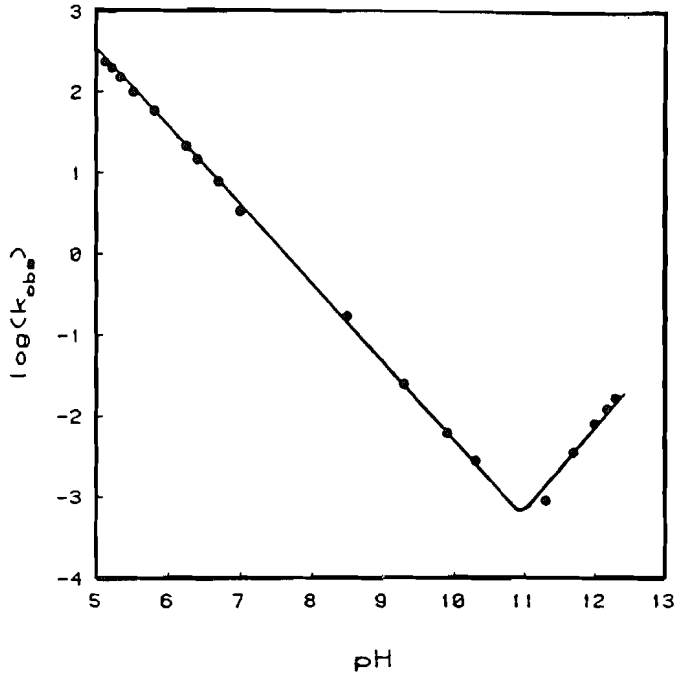


FIG. 1. Rate–pH profile for the hydrolysis of the (5,6)-spirophosphorane **5** in aqueous solution (25°C, ionic strength = 1.0).

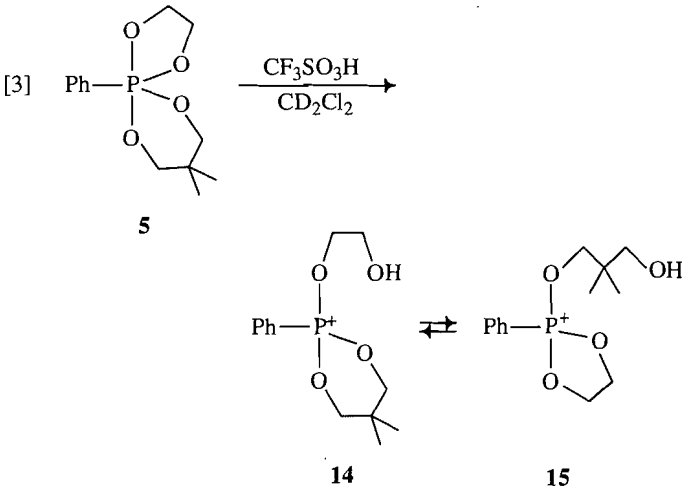
more acidic solutions being too fast even for stopped-flow spectroscopy. These rate constants could be fit by the equation



$$k(\text{obs}) = k_H[H^+] + k_{OH}[OH^-] + k_{HA}[HA] + k_B[A^-]$$

with catalysis by all acids and bases present in solution. Second-order rate constants are given in Table 2. This same kinetic pattern is observed with the (5,5)-spirophosphoranes **1** (8) and, as in the latter case, there is no pH-independent region with **5**, just a sharp break in the rate–pH profile at pH 11 from H_3O^+ to OH^- catalysis (Fig. 1). A Brønsted plot (not shown) for the four acid catalysts including H_3O^+ is linear, with a slope of 0.78 ± 0.05.

Phosphonium ions produced with the (5,6)-spirophosphorane 5

In behavior reminiscent of (6,6)-spirophosphoranes, treatment of **5** with one equivalent of CF_3SO_3H in CD_2Cl_2 quantitatively forms a phosphonium ion. This can be identified as the cyclic six-membered **14** from the ^1H NMR spectrum (see Fig. 2 and peak assignments indicated there) and the ^{31}P signal at +29.5 ppm. The latter is particularly indicative, being similar to the shift at +30.5 ppm observed with the analogous **4***b* (9). An isomeric cyclic five-membered phosphonium ion **15** can also form with this phosphorane but, as discussed previously, its ^{31}P signal is expected near +60 ppm, and no peak was observed in this region. Previous studies have shown that a spirophosphorane and a ring-opened phosphonium ion rapidly equilibrate under acidic conditions (9–11). Thus, the two cations **14** and **15** will be present in equilibrium amounts in this experiment, with equilibration occurring by way of the neutral phosphorane. Since a ^{31}P signal for the five-membered cation would have been detected if it were present in a 1% amount, we conclude that the equilibrium constant relating the two isomeric phosphonium ions ([**14**]/[**15**]) is greater than 100.

When a solution of **14** generated in acetonitrile with CF_3SO_3H is added to a weakly basic aqueous buffer, the phosphorane **5** is rapidly reformed. This is indicated by the observation of an absorbance *increase* characteristic of the hydrol-

ysis of the phosphorane, with a rate identical to that obtained starting with the phosphorane. Hydrolysis of the phosphonium ion would have appeared as an absorbance *decrease* (9, 17).

In acids with pH < 5, the hydrolysis of **5** is complete within 2 ms of mixing on a stopped-flow spectrophotometer, and in no solution up to and including 1 M HCl is there any indication of a phosphonium ion intermediate. The cation **14** is observed (and characterized by NMR) in concentrated H_2SO_4 solutions. It undergoes hydrolysis in these solutions with rate constants of 0.064, 0.011, 0.0016, and 0.000072 s^{-1} in 64.0, 70.0, 74.5, and 80.0% H_2SO_4 respectively.

Discussion

Lifetimes of phosphonium ions in water

With both phosphoranes **1** (8) and **5** the phosphonium ion intermediate cannot be detected during the hydrolysis in the normal pH range. This observation holds even under conditions where the overall hydrolysis of the phosphorane is complete within 2 ms, with the implication that the lifetime of the cation is shorter than this. We have described previously an approach for the oxocarbocation intermediates of acetal and ortho ester hydrolysis, where rate constants measured in strong acids were extrapolated to water with the assumption that differences between pairs of cations remain constant as the acidity is changed (24). This procedure was supported by observation of the required parallelism, albeit over a limited range in many cases, and through agreement with rate constants independently estimated by a "clock" approach (25). More recently, its validity

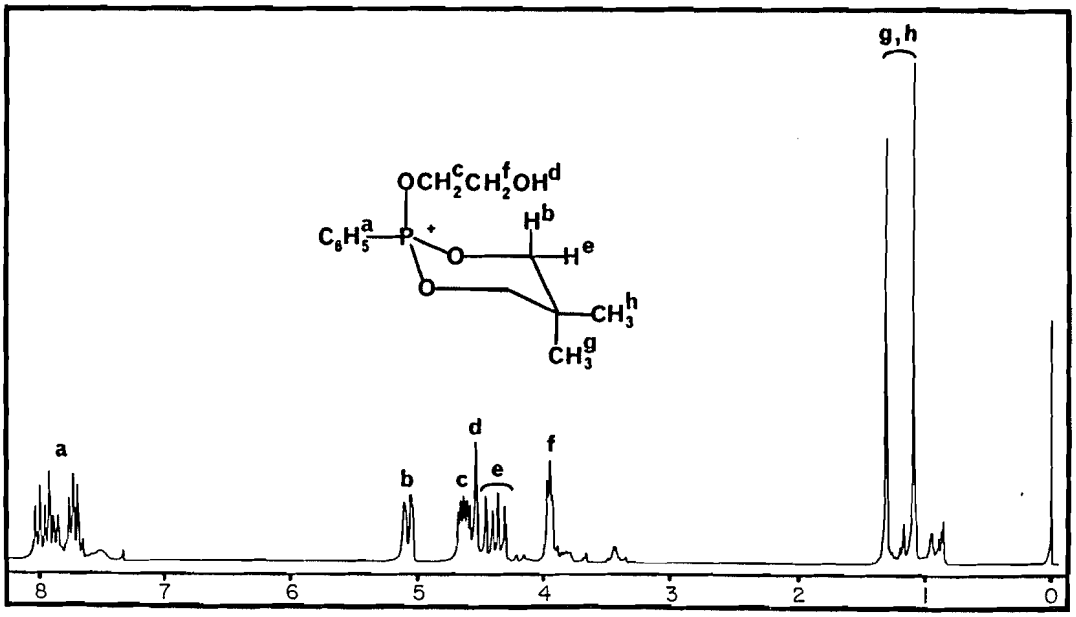

FIG. 2. ^{1}H NMR spectrum (200 MHz) of the cation **14** formed on the addition of CF_3SO_3H (0.11 M) to the phosphorane **5** (0.10 M) in CD_2Cl_2. The other unidentified small peaks in this spectrum are associated with impurities in the starting spirophosphorane.

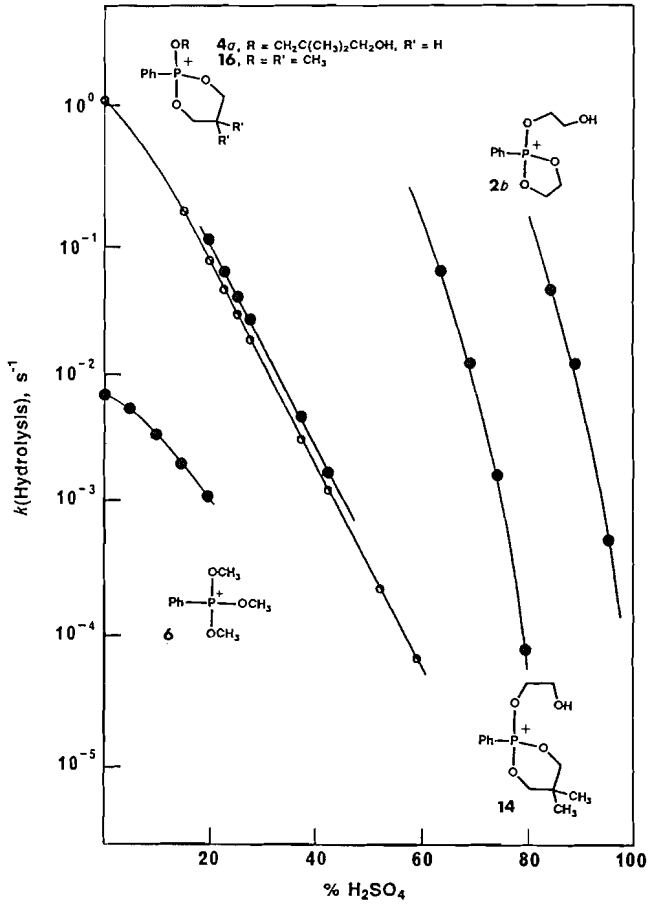

FIG. 3. Rate constants for the hydrolysis of phosphonium ions in sulfuric acid solutions (25°C). Data for **6** are from ref. 17, the point in water for **4***a* is from ref. 9, and the data for **4***a* and **16** in sulfuric acid solutions are from ref. 12.

has been conclusively established through direct measurement in water using the technique of laser flash photolysis (26, 27).

Figure 3 shows data for phosphonium ions that allow for such an extrapolation. For the acyclic **6** (17) and the cyclic six-membered **4***a* (9) rate constants have been measured directly in 100% aqueous solution, as 6.0×10^{-3} s^{-1} and 1.1 s^{-1} respectively. There is overlap of **4***a* and the more reactive **14** in 60–65% H_2SO_4, with a $10^{3.5}$ rate difference, and this leads to an estimate for the latter in water of $10^{3.5}$ s^{-1}. The assumption that is made is that the log k – acidity curve for this cation remains parallel to that of **4***a* on proceeding from solutions of this acidity to water. The cations **14** and **2***b* then overlap in 80–85% H_2SO_4, with a similar $10^{3.5}$ difference, and this leads to an estimate of 10^7 s^{-1} for the latter in water.

Incorporation of a ring into a trialkoxyphosphonium ion clearly has a significant effect, with the cyclic six-membered and five-membered cations being 200 times and 10^9 times more reactive than their acyclic analog. The accelerating effect of a five-membered ring in a phosphonium ion was observed previously, for the reaction of phenyltrialkylphosphonium salts with hydroxide ion (28). However, the rate enhancement, a factor of about 10^3, was considerably smaller than that observed in the present study, and there was no difference between the cyclic six-membered and acyclic cations. The trend with the phenyltrialkoxyphosphonium ions more closely parallels that seen in the hydrolysis of phosphate esters. Indeed, as shown in Fig. 4, there is an excellent quantitative correlation of rate constants for the three cations with rate constants for the base hydrolysis of similar phosphates (29). The phosphonium ions in fact show a slightly greater sensitivity to the structural change in this comparison, the slope of the correlation line being 1.3. Difference nucleophiles are, however, involved, and this could be part of the reason. What is apparent is that the very great reactivity of the five-membered cyclic system is observed in both the phosphonium ion and the phosphate

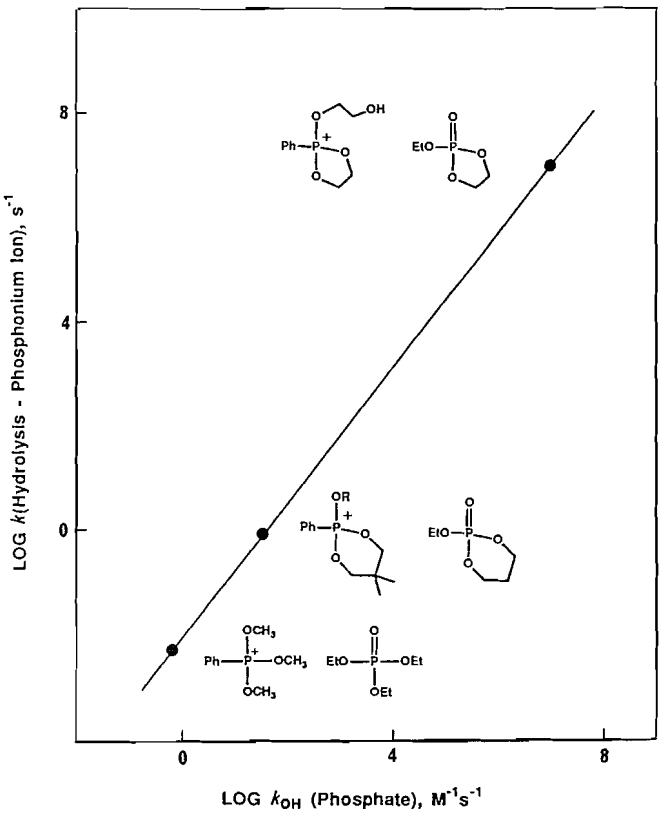

FIG. 4. Linear free energy correlation of rate constants for the hydrolysis of phosphonium ions with rate constants for phosphate esters reacting with hydroxide ion. Rate constants for the acyclic and cyclic six-membered phosphonium ions are directly measured in water (refs. 17 and 9 respectively). The rate constant for the cyclic five-membered phosphonium ion is based upon extrapolation from concentrated acid solutions. Data for the phosphates from ref. 29.

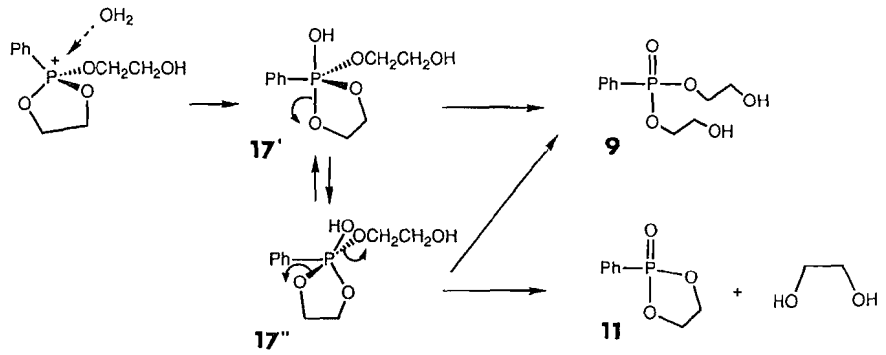
ester and, as demonstrated by the excellent linear free energy correlation, there must be a similar reason behind this.

The cation **14** is also interesting, since it reacts over three orders of magnitude more rapidly than **4***a* and **16**. This cannot represent a simple substituent effect since the three cations are very similar, and signals some unusual behaviour with **14**.

*Products of the acid hydrolysis of the (5,5)-spirophosphorane **1***

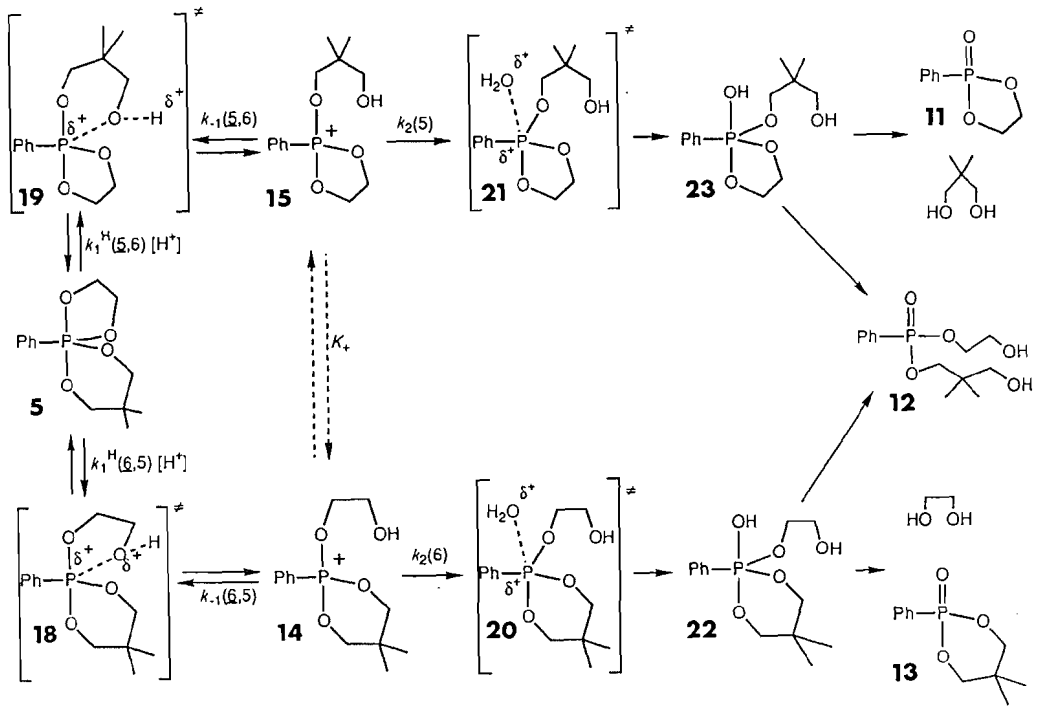
The analogy between cyclic five-membered phosphonium ions and phosphate esters is further illustrated by the pH dependency of the products obtained in the hydrolysis of each. Thus, the former, as an intermediate in the hydrolysis of **1**, exhibits a trend of giving only the bis-ester **9** in neutral solutions, with increasing amounts of the cyclic ester **11** as the acidity is increased (Table 1). This is exactly the same pattern as observed in the hydrolysis of methyl ethylene phosphate (30). In the latter case the explanation was advanced that the initially formed pentavalent intermediate can only undergo endocyclic cleavage, while a pseudorotation is required for exocyclic cleavage. The pH dependency was explained by a variation in the lifetime of the intermediate, with a very short lifetime at neutral pH so that breakdown occurs before pseudorotation. This same explanation must apply to the hydrolysis of the cyclic phosphonium ion. Here also the pentavalent intermediate **17′** that is formed initially on the addition of water would have a ring oxygen and an OH group in apical positions, so that only the bis-ester **9** derived from endocyclic cleavage can form. The cyclic ester **11** results only after pseudorotation to **17″** places the 2-hydroxyethoxy group in an apical position such that it also can be cleaved. As with methyl ethylene phosphate, the implication is that at neutral pH breakdown of **17′** occurs more rapidly than pseudorotation, so that only **9** is observed.

*Products of the acid hydrolysis of the (5,6)-spirophosphorane **5***



This phosphorane has aspects of the behaviour of both the (5,5)-spiro- and the (6,6)-spirophosphoranes. Like the latter, it reacts with strong acids in methylene chloride to quantitatively form a cyclic six-membered phosphonium ion. However, like the former, no phosphonium ion intermediate is observed during the hydrolysis in aqueous solutions. Moreover, the products **10** and **12** resemble those obtained from the (5,5)-spiro system, both in their nature and in their pH dependence. This suggests that these are forming by way of the cyclic five-membered phosphonium ion **15**, despite the fact that the six-membered isomer **14** is the more stable. The latter in fact can be ruled out as being the intermediate responsible for the final products, since its further reaction with water would result in significant quantities of the cyclic ester **13** and ethylene glycol, and these are not observed. This conclusion is supported by previous results with the (6,6)-spirophosphoranes **3**, where a cyclic six-membered phosphonium ion is the only intermediate that can form. With this system the appropriate cyclic six-membered phosphonate, and in this case a 1,3-diol, are indeed found as products (9).

*Thermodynamic analysis of the hydrolysis of the (5,6)-spirophosphorane **5***



The general scheme for the acid-catalyzed hydrolysis of this phosphorane is given in Scheme 2, while a diagram depicting free energies of various species, including transition states, is shown as Fig. 5. The arguments behind this figure are somewhat complex, since the exact identity of rate-limiting steps cannot be stated unambiguously. Despite this uncertainty, however, relative free energies of a number of important species can be defined within a fairly narrow range.

This figure was based upon the following: (a) In aqueous solution in the range from pH 5 to 10, the phosphorane **5** undergoes hydrolysis with a strict dependency on H^+ concentration with a second-order rate constant, $k_H(5,6) = 3.7 \times 10^7$ M^{-1} s^{-1}. A phosphonium ion intermediate is not observed in the overall hydrolysis. (b) We assume that the hydroxyphosphoranes **22** and **23**, once formed, rapidly go on to products. This will be particularly true in less acidic solutions where there is an efficient base catalysis of this process (30). (c) The value for $k_H(5,6)$ corresponds to a $\Delta G^{\neq}$ of 7.1 kcal mol^{-1}. With assumption (b), this represents the free energy difference between **5** and either the transition state **19** or **21**, since the products demonstrate that more than 99% of the overall hydrolysis proceeds by way of the cyclic five-membered cation. (d) The equilibrium constant [**14**]/[**15**] is greater than 100, so that **15** is more than ~2.5 kcal mol^{-1} higher in energy than **14**. This result was obtained in CD_2Cl_2 and in strongly acidic solution, but it must also be true in 100% water, since these cations will have very similar solvation. (e) On addition to a slightly basic aqueous solution, the fully formed phosphonium ion **14** forms the phosphorane. This indicates that the

SCHEME 1

SCHEME 2

intramolecular cyclization in this cation is faster than its reaction with water. (f) In more concentrated acids, **14** reacts $10^{3.5}$ times faster than cyclic six-membered analogs that hydrolyze by a direct reaction with water. This is a key observation, since, coupled with the demonstration of reversibility and the product analysis, it indicates that the hydrolysis pathway followed by **14** must involve recyclization to the phosphorane, and reaction by way of **15**. The $10^{3.5}$ rate acceleration associated with this pathway indicates that its transition state is ~5 kcal mol^{-1} lower in energy than the transition state for the direct reaction of the cation **14** with water. (g) We assume that the rate constants $k_2(6)$ and $k_2(5)$ of Scheme 2 are 10^0 s^{-1} and 10^7 s^{-1} respectively, as with analogous cyclic phosphonium ions. These correspond to $\Delta G^{\neq}$ values of 17.5 and 8 kcal mol^{-1} respectively.

Figure 5 was then constructed in the following manner, with the cation **14** being assigned a relative ΔG of zero for comparison purposes. (h) From point (g), the free energy of the transition state **20** for the direct hydration of this cation is at +17.5 kcal mol^{-1}. (i) From point (f), the transition state for the actual hydrolysis of this cation is at +12.5 kcal mol^{-1}. This transition state is one of **18**, **19**, or **21** and, although it is not known which, *none of these can be higher in energy than this*. Thus the dashed line A in Fig. 5 represents the maximum position for each of these three transition states. (k) Point (d) permits the assignment of a minimum ΔG for the cation **15** at +2.5 kcal mol^{-1}, and this in turn places a minimum of +10.5 kcal mol^{-1} for the transition state **21**, which from point (g) is always 8 kcal mol^{-1} higher in energy than **15**. (l) From argument (i) the maximum for the transition state **21** is at +12.5 kcal mol^{-1}. This in turn means that the maximum for the cation **15** is 8 kcal mol^{-1} below this, i.e., at +4.5 kcal mol^{-1}. (m) The phosphorane **5** is 7 kcal mol^{-1} lower in energy than either the transition state **19** or **21** (point (c)), and since these cannot be higher than +12.5 kcal mol^{-1} (argument (i)), the maximum for **5** is +5.5 kcal mol^{-1}. (n) A minimum of +3.5 kcal mol^{-1} for **5** can also be assigned, based upon the minimum for **21** and the argument that **5** cannot be more than 7 kcal mol^{-1} lower in energy than this transition state. (o) Minimum positions for the transition states **18** and **19** cannot be unambiguously assigned.

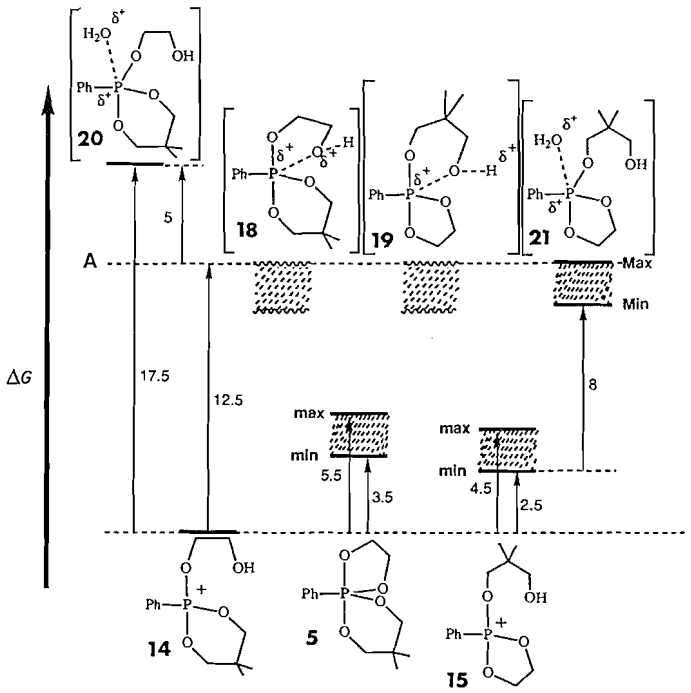

FIG. 5. Free energies for the hydrolysis of phosphonium ions. ΔG or ranges of ΔG have been determined as discussed in the text, and refer to 1 M H^+ as the standard state. In constructing this diagram, the values of ΔG have been rounded off to ± 0.5 kcal mol^{-1}.

Kinetic analysis of the hydrolysis of the phosphorane **5**

We consider in this section various possibilities for the rate-limiting steps in Scheme 2, and the consequences for the free energy diagram of Fig. 5.

(i) Cation **14** *and phosphorane* **5** *are rapidly equilibrating*

This is the model that we favor (see later), and it corresponds to a situation where the transition state **18** is lower in energy than the transition state **19**, or in kinetic terms $k_1^H(6,5) > k_1^H(5,6)$. With $k_{-1}(6,5)$ also greater than $k_2(6)$, **14** and **5** will therefore exist in a pH-dependent pseudo acid–base type of equilibrium during the hydrolysis, governed by an equilibrium constant that we define as before as $K_a(6,5) = [\mathbf{5}][H^+]/[\mathbf{14}]$. With the assumption that **15** is a steady-state intermediate, the following general rate expression is then obtained.

$$[4] \quad k(\text{obs}) = \left(\frac{k_1^H(5,6)\cdot k_2(5)[H^+]}{k_{-1}(5,6)+k_2(5)}\right) \times \left(\frac{K_a(6,5)}{K_a(6,5)+[H^+]}\right)$$

This derivation ignores any direct reaction of **14** with water, and makes no assumption as to the relative magnitudes of $k_{-1}(5,6)$ and $k_2(5)$. This equation describes two limiting conditions, phosphorane favored in the equilibrium ($K_a(6,5) > [H^+]$), with a linear dependency on $[H^+]$

$$[5] \quad k_H(5,6) = \left(\frac{k_1^H(5,6)\cdot k_2(5)}{k_{-1}(5,6)+k_2(5)}\right)$$

and phosphonium ion **14** favored in the equilibrium ($K_a(6,5) < [H^+]$), with k(obs) independent of pH

$$[6] \quad k(\text{cation}) = \left(\frac{k_1^H(5,6)\cdot k_2(5)}{k_{-1}(5,6)+k_2(5)}\right) K_a(6,5)$$

The former obviously represents the situation in the range from pH 10 to 5, where the required linear dependency on $[H^+]$ is observed, while the latter represents the situation in the concentrated sulfuric acid solutions where the cation is fully formed. Taking k(cation) as $10^{3.5}$ s^{-1}, the value obtained upon extrapolation from the latter solutions, $K_a(6,5)$ is calculated as 9×10^{-5} M by dividing eq. [6] by eq. [5]. Such a value is consistent with the observation that there is a linear dependency of k(obs) on $[H^+]$ in solutions with pH > 5. The value is also consistent with the observation that there are essentially *no* products derived from the direct reaction of **14** with water. For such a mechanism,

$$[7] \quad k(\text{obs}) = k_2(6) \times \left(\frac{K_a(6,5)[H^+]}{K_a(6,5)+[H^+]}\right)$$

and the second-order rate constant k_H in solutions where $K_a(6,5) > [H^+]$ is equal to $k_2(6)/K_a(6,5)$. Thus for this mechanism k_H can be calculated to be around 10^4 M^{-1} s^{-1}, using $k_2(6) = 1$ s^{-1} and the above $K_a(6,5)$. This number is over three orders of magnitude smaller than the observed k_H, which we have argued represents hydrolysis via **15**. In other words, the overall contribution to the products from a direct hydrolysis of **14** is less than 0.1%.

It can be noted that this model accurately defines the relative free energies of **14** and **5**, since it provides a numerical value for the equilibrium constant relating these species. This corresponds to $\Delta G = 5.5$, or the situation described in Fig. 5 by the maximum difference in free energy between **14** and **5**. The positions of the transition states **19** and **21** and the cation **15** then depend upon the relative magnitudes of $k_2(5)$ and $k_1(5,6)$.

(ia) Reaction of cation **15** *with water is rate limiting.* This corresponds to a situation where transition state **21** is higher in energy than transition state **19**, or $k_2(5) > k_1(5,6)$. In this sub-case of (i), transition state **21** represents the barrier in the overall hydrolysis of both **5** and **14**, and it has its free energy at the maximum position, +12.5 kcal mol^{-1}, in Fig. 5. Equations [5] and [6] simplify to

$$[8] \quad k_H(5,6) = \left(\frac{k_2(5)}{K_a(5,6)}\right)$$

$$[9] \quad k(\text{cation}) = \left(\frac{k_2(5)K_a(6,5)}{K_a(5,6)}\right)$$

where $K_a(5,6)$ is $[\mathbf{5}][H^+]/[\mathbf{15}]$, the equilibrium constant relating cation **5** and **15**. For this model, $K_a(5,6)$ is calculated as 3×10^{-1}, by substituting $k_2(5) = 10^7$ into eq. [8]. The equilibrium constant $[\mathbf{14}]/[\mathbf{15}]$ is also accurately determined as 3×10^3, from the ratio $K_a(5,6)/K_a(6,5)$. Thus these conditions also fix the free energy of the cation **15**, and this is at the maximum position indicated in Fig. 5.

(ib) Formation of cation **15** *from phosphorane* **5** *is rate limiting.* This corresponds to the opposite situation where $k_2(5) > k_{-1}(5,6)$, so that once **15** forms it proceeds on to products. For this sub-case, $k_H(5,6)$ is directly equal to $k_1^H(5,6)$ and the position of the transition state **18** lies at the maximum position in Fig. 5. The positions of the transition state **21** and the cation **15** are not precisely defined, although they must lie lower than the maximum indicated in the figure.

Although there is no unambiguous piece of experimental evidence distinguishing the two possibilities represented by

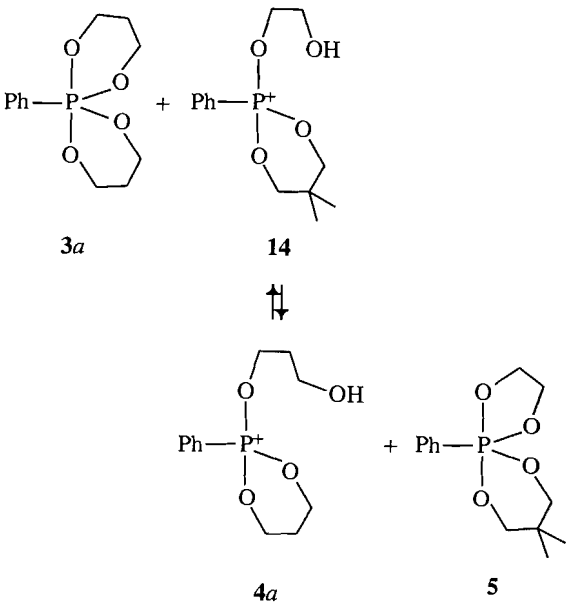
(ia) and (ib), consideration of the results with the (6,6)-spirophosphoranes suggests that the former is more likely. With the (6,6) compounds, there was the same competition, a ring closure at 3-hydroxypropoxy forming a six-membered ring versus a reaction with water, and the former was favored by more than one order of magnitude. The difference in the present case is that a much more reactive phosphonium ion is involved. This may attenuate the difference in the reactivity, but it would appear probable that ring closure would still be the faster process.

(ii) Ring closure to ***5*** *is rate limiting in the hydrolysis of preformed* ***14***

For this case, transition state **18** lies at its maximum position and both **19** and **20** are lower in energy. The cation **15** and the phosphorane **5** will also lie at positions lower than their maxima in Fig. 5, and $K_a(6,5)$ will be greater than the value obtained above since **14** and **5** will be closer in energy. In experiments that start with the phosphorane **5**, the cation **14** is never accessed since there is a lower barrier for overall hydrolysis through **15**. Starting with the cation **14**, reaction proceeds via the cation **15** but the initial cyclization step forming the phosphorane is rate limiting.

For this model, the rate constant for the reaction of the fully formed cation **14** is directly equal to the rate constant for cyclization $k_{-1}(6,5)$. At first glance, the number obtained, $10^{3.5}$ s^{-1}, is not unreasonable, since it signifies that the intramolecular reaction forming the five-membered ring is $10^{3.5}$ times faster than a reaction with a solvent water molecule. Similar comparisons have been well studied in 2-hydroxyethyl phosphate esters, and differences of this sort of magnitude are observed (31). However, in the following paper exactly the same competition arises in the phosphonium ion **24**, and the analysis conclusively establishes that cyclization is around 10^6 times faster than the reaction with water (32).

24



We believe that a similar difference is also likely to exist with **12**, and that $k_{-1}(6,5)$ is therefore greater than $10^{3.5}$. If this is true, **14** and **5** will exist in equilibrium and the arguments presented in case (i) apply.

In summary, the most likely situation is that described by case (ia). This has the phosphorane and the two cations in equilibrium in the overall hydrolysis, with the rate-limiting step the reaction of the five-membered cation with water, whether the starting point is the phosphorane or the cation **14**. For this situation the free energies of **5**, **15**, and **21** lie at the maximum position indicated in Fig. 5.

A five-membered ring stabilizes a spirophosphorane relative to a six-membered ring

One result that emerges from this analysis is that the equilibrium constant $K_a(6,5)$ is at least 10^4 times larger than the constant $K_a(6,6)$ for the similar equilibrium in a (6,6)-spirophosphorane (eq. [2]). This can be considered by placing the ions and phosphoranes that are involved into an isodesmic reaction.

This has an equilibrium constant that is the ratio of these two K_a values, and therefore lies in the range $3 \times 10^4 - 1 \times 10^6$.

[10] 

3a **14**

4a **5**

In other words, as written in this direction, the products are strongly favored in this equilibrium, with a ΔG of -6 to -8 kcal mol^{-1}. This cannot be due to a difference in thermodynamic stability of the reagent and product phosphonium ions, since these have very similar structure, both being cyclic six-membered phenyltrialkoxyphosphonium ions differing only in the presence or absence of remote methyl substituents and the length of the alkoxy chain. In consequence, the origin of the free energy change must lie in the relative energies of the two spirophosphoranes, with the conclusion that the (5,6)-spirophosphorane is considerably more stable, of the order of 6–8 kcal mol^{-1}, when compared to the (6,6)-spirophosphorane. This offers dramatic experimental confirmation that a five-membered ring has a significant stabilizing effect in a phosphorane structure.

Thermodynamics of the hydrolysis of cyclic phosphonium ions

A cyclic five-membered phosphonium ion is 10^7 times more reactive than a six-membered analog, a rate difference corresponding to a $\Delta\Delta G^{\neq}$ of 9.5 kcal mol^{-1}. Figure 5 shows how this $\Delta\Delta G^{\neq}$ is broken down into contributions from ground state and transition state. The cyclic five-membered phosphonium ion is indeed of higher energy than the six-membered cation. This is probably due to ring strain in the former (13), and it obviously provides for part of the accelerated hydrolysis of this cation. However, the free energy difference, 2.5–4.5 kcal mol^{-1}, is small and accounts for less than half of the overall $\Delta\Delta G^{\neq}$. The factor of greater importance is the lower free energy of the transition state having the five-membered ring. This difference, 5–7.5 kcal mol^{-1}, is in fact approaching the level of that observed between (5,5)- and (5,6)-spirophosphoranes, as discussed in the last section. The argument is normally made that the transition state for nucleophilic addition to tetracoordinated phosphorus resembles the pentacoordinate hydroxyphosphorane (13–15).

As noted in the introduction, there has been a previous suggestion that the accelerated hydrolysis of cyclic five-membered phosphates is due to a combination of destabilization in the starting phosphate and stabilization in the transition state (14), with the argument that ring strain is more important at tetracoordinated phosphorus, while intramolecular steric crowding is the principal factor at pentacoordinated phosphorus. While not pinpointing the actual origins of the effects, the data ob-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

tained in the present study clearly provide strong support for a model of differential stabilization. In fact with the phenyltrialkoxyphosphonium ions the transition state stabilization is the more important factor.

Experimental section

Materials

5 - Phenyl - 8,8 - dimethyl - 1,4,6,10 - tetraoxa - 5 - phosphaspiro-[4,5]decane (**5**) was prepared by the reaction of 2-phenyl-1,3,2-dioxaphospholane (33), 2,2-dimethyl-1,3-propanediol, and *N*-chlorodiisopropylamine according to the method of Trippett and co-workers (34). The crude product was obtained as a colorless liquid, which, after distillation at 25°C, 0.5 Torr (1 Torr = 133.3 Pa), crystallized on standing. Recrystallization from hexane gave colorless crystals, mp 36–37°C; ^{31}P NMR δ : −34.9. The ^{1}H NMR spectrum of this compound has been reported (35).

5-Phenyl-1,4,6,9-tetraoxa-5-phosphaspiro[4.4]nonane (*1*b) was prepared in the same way as **5** using ethylene glycol. Physical data were in agreement with those obtained for a sample prepared by a different technique (8).

5,5 - Dimethyl - 2 - (2' - hydroxyethoxy) - 2 - phenyl - 1,3,2 - dioxaphosphorinan-2-ylium (*14*) *trifluoromethanesulfonate* was prepared by slowly adding 1 equivalent of trifluoromethanesulfonic acid to the phosphorane **5** in methylene chloride (or CD_2Cl_2) at −78°C under nitrogen. The mixture was then allowed to warm to room temperature. Attempts to obtain solid salt by adding dry ether resulted in the separation of an oil. The phosphonium ion in CD_2Cl_2 had ^{31}P NMR δ : +29.5; ^{1}H NMR δ : 8.05–7.65 (5H, mult.), 5.08 (2H, broad doublet of doublets, J_{P-H} = 2.4 Hz and J_{H-H} = 10.7 Hz), 4.64 (2H, doublet of triplets, J_{P-H} = 4.2 Hz and J_{H-H} = 3.7 Hz), 4.54 (1H, s), 4.39 (2H, doublet of doublets, J_{P-H} = 18.9 Hz and J_{H-H} = 10.7 Hz), 3.96 (2H, broad triplet, J_{H-H} = 3.7 Hz), 1.31 (3H, s), 1.10 (3H, s).

2-(2'-Hydroxyethoxy)-2-phenyl-1,3,2-dioxaphospholan-2-ylium (2b) *trifluoromethanesulfonate* was prepared by adding the phosphorane **1***b* to neat trifluoromethanesulfonic acid in an NMR tube under nitrogen at −10°C. In a similar manner **1***b* was added to 96% sulfuric acid-d_2 in an NMR tube at 5°C.

5,5-Dimethyl-2-oxo-2-phenyl-1,3,2-dioxaphosphorinane ***13*** was prepared as previously described (36).

Products

In general, hydrolyses were carried out under conditions very similar to those employed in the kinetic studies. Products were identified primarily by ^{31}P and ^{1}H NMR. Since complex and variable mixtures were usually obtained, no attempts were made to isolate or purify individual products, although in a few cases authentic samples were prepared by unambiguous routes. The relative amounts of individual products were determined by integration of ^{1}H and ^{31}P NMR spectra. For FT NMR spectra, a delay of 0.5 s between pulses was employed to minimize signal saturation effects. In cases where both ^{1}H and ^{31}P NMR were employed, the results agreed, within experimental error.

For the phosphorane **1***b*, NMR spectra were recorded directly on the aqueous solution employed for the hydrolysis, deuterated solvent and buffer being employed in the case where analysis involved ^{1}H NMR. The ^{1}H NMR spectra of products obtained in acidic D_2O have been reported elsewhere (8). Products are bis(2-hydroxyethyl) phenylphosphonate **9** (^{31}P +22.7 ppm), mono-(2-hydroxyethyl) phenylphosphonate **10** (^{31}P +18.4 at pH <2 and +16.3 at pH >3), and ethylene glycol. That **10** derives from an initially formed cyclic ester, 2-oxo-2-phenyl-1,3,2-dioxaphospholane **11**, was established by adding **1***b* to 1:1 CD_3CN:D_2O containing 0.01 M each of CD_3COOD and CD_3COONa, pD ~ 6. Two ^{31}P NMR signals were observed, one at +21.3 corresponding to **9**, and a second at +39.3 ppm. A synthetic sample of **11** has been reported to have a ^{31}P shift at +38.4 ppm (23).

For the phosphorane **5**, ^{31}P NMR were obtained directly in H_2O, and ^{1}H NMR specta were obtained in $CDCl_3$, after hydrolysis in D_2O and removal of the solvent by lyophilization. The major product, identified as the mixed diester 2-hydroxyethyl-(2,2-dimethyl-3-hydroxypropyl) phenylphosphonate **12**, had ^{31}P NMR δ : +22.2; ^{1}H NMR δ : 7.9–7.4 (5H, mult.), 4.15–4.05 (2H, mult.), 3.89 (1H, d, J_{P-H} = 7.0 Hz), 3.78 (2H, broad triplet, J_{H-H} = 4 Hz), 3.67 (1H, d, J_{P-H} = 7.0 Hz), 3.41 (1H, d, J_{H-H} = 11.4 Hz), 3.34 (1h, d, J_{H-H} = 11.3 Hz), 0.88 (3H, s), 0.87 (3H, s). Minor products were mono-(2-hydroxyethyl) phenylphosphonate **10** (^{31}P +18.1) and 2,2-dimethyl-1,3-propanediol. The former was identified by comparison with the same product obtained from **1***b*, the latter by direct comparison with an authentic sample. The absences of 5,5-dimethyl-2-oxo-2-phenyl-1,3,2-dioxaphosphorinane **13** and ethylene glycol were established by the addition of authentic materials.

Kinetics

Conventional kinetic measurements were carried out on a Cary 2390 spectrophotometer linked with an Apple IIe microcomputer. Stopped-flow kinetic measurements were conducted on a Durrum–Gibson apparatus linked to a Tektronix 4050 microcomputer. The cell compartments of both instruments were thermostated at 25.0 ± 0.1°C, unless otherwise noted. Rate constants slower than 0.10 s^{-1} were obtained on the Cary spectrophotometer, by adding a small quantity (1–2 μL) of a concentrated stock solution of the substrate in dichloromethane to a UV cuvette containing the solution of interest, pre-equilibrated at the desired temperature. Absorbance versus time data were transferred to the Apple IIe microcomputer, and the data fit by an iterative procedure to the general equation for an exponential reaction. Faster reactions were studied on the Durrum stopped-flow spectrometer, by first dissolving the substrate in a solution in which the substrate was fairly stable, and then mixing this with an appropriate solution to give the desired pH. Rate constants were calculated using a Tektronix microcomputer, by linear regression of plots of $\ln(A_\infty - A_t)$ or $\ln(A_t - A_\infty)$ versus time. Final concentrations of substrate in both types of experiments were of the order of 1 mM.

Rate constants for the hydrolysis of **5** in aqueous solution were obtained as previously described for the phosphoranes **1** (8), by following an absorbance increase at 265 mm. From pH 11 to pH 8.5, measurements were made with the Cary spectrometer. Below pH 8, the stopped-flow apparatus was employed, with the phosphorane dissolved in 1 mM NaOH being mixed with an appropriate buffer. In solution with pH > 11, where further hydrolysis of products complicates simple kinetic analysis, a pH jump method (8) was employed.

The kinetics of the hydrolysis of **11** were studied by first forming the cyclic ester *in situ* by hydrolyzing **1***b* in a dilute neutral buffer, and then mixing this solution with an appropriate HCl or NaOH solution on the stopped-flow spectrophotometer.

Rate constants for the hydrolysis of the phosphonium ion **2***b* in concentrated H_2SO_4 were obtained by following an absorbance decrease at 232 nm following addition of the phosphorane **2***b*. First-order kinetic plots were slightly nonlinear, probably due to further hydrolysis reactions.

Rate constants for the hydrolysis of the phosphonium ion **14** in 60–80% H_2SO_4 were measured by following an absorbance decrease at 275 nm following addition of the phosphorane **5**.

Hydrolysis of a monocyclic oxyphosphorane containing a five-membered ring

GLENN H. MCGALL AND ROBERT A. MCCLELLAND
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received March 27, 1991

GLENN H. MCGALL and ROBERT A. MCCLELLAND. Can. J. Chem. **69**, 2075 (1991).

A kinetic study is reported for the hydrolysis of 2,2-diphenyl-2-methoxy-1,3,2-dioxaphospholane **1**. This phosphorane exists in aqueous solution in a pseudo acid–base equilibrium with an observable phosphonium ion, the ring-opened (2′-hydroxyethoxy)diphenylmethoxyphosphonium ion **5**. The equilibrium constant K_a ([**1**][H^+]/[**5**]) is 9×10^{-9}, values determined by kinetic and spectroscopic methods being in good agreement. This phosphonium ion is, however, not involved in the overall hydrolysis reaction, which proceeds via the thermodynamically less stable cyclic five-membered phosphonium ion derived by loss of the exocyclic methoxy group from the phosphorane, the 2,2-diphenyl-1,3,2-dioxaphospholan-2-ylium ion **6**. This route for the overall hydrolysis is established by analysis of the products, and by the observation that the rate constant for the disappearance of **5** in acid solutions is 40 000 times greater than that for an analog that differs only in not being able to cyclize, the (2′-methoxyethoxy)diphenylmethoxyphosphonium ion **7**. At all pH, the phosphorane **1** and the ring-opened phosphonium ion **5** exist in equilibrium, and the rate-limiting step in the overall hydrolysis is the cleavage of the exocyclic methoxy group to give the cyclic phosphonium ion **6**, which is rapidly converted to products by reaction with water. The actual equilibration reaction involving **1** and **5** cannot be observed at any pH, even with stopped-flow spectroscopy. The non-catalyzed ring closure of the phosphonium ion **5** reforming the phosphorane **1** occurs with a rate constant of 200–500 s^{-1}, corresponding to an effective molarity of (2–5) $\times 10^7$ M for the intramolecular hydroxy group in this reaction. The rate-limiting exocyclic cleavage is assisted by H^+, with a very large rate constant 2×10^9 M^{-1} s^{-1}. Catalysis by general acids is also observed. The Brønsted plot has a slope α of 1.0 for the weaker acids, with a break for acids with $pK_a < 3$. This "Eigen"-type behavior is proposed to arise from a transition state with little phosphonium ion character, in which the proton is almost completely transferred for the weaker acids.

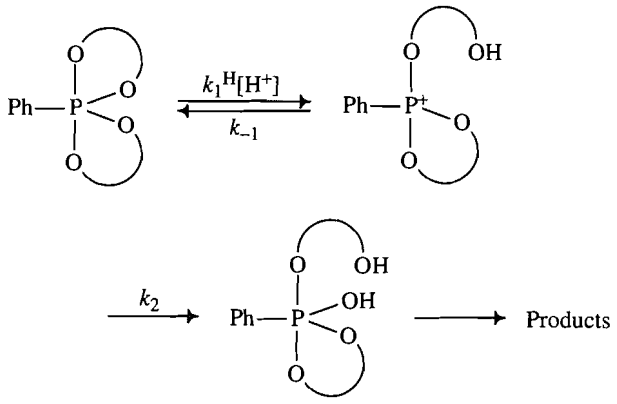
Key words: phosphorane, phosphate, phosphonium, hydrolysis.

GLENN H. MCGALL and ROBERT A. MCCLELLAND. Can. J. Chem. **69**, 2075 (1991).

On a effectué une étude cinétique de l'hydrolyse du 2,2-diphényl-2-méthoxy-1,3,2-dioxaphospholane, **1**. En solution aqueuse, ce phosphorane existe sous forme d'équilibre pseudo acide–base avec un ion phosphonium qui peut être observé, l'ion à cycle ouvert (2′-hydroxyéthyl)diphénylméthoxyphosphonium, **5**. Les valeurs de la constante d'equilibre K_a = [**1**][H^+]/[**5**] = 9×10^{-9} qui ont été déterminées par des méthodes cinétiques et spectroscopiques sont en bon accord. Toutefois, cet ion phosphonium n'est pas impliqué dans la réaction globale d'hydrolyse qui se produit par le biais de l'ion 2,2-diphényl-1,3,2-dioxaphospholan-2-ylium, **6**, comportant un cycle à cinq chaînons, qui est thermodynamiquement moins stable et qui est formé par la perte d'un groupe méthoxy exocyclique du phosphorane. On a établi que l'hydrolyse globale suit cette voie en examinant la nature des produits et en observant que la constante de vitesse pour la disparition du produit **5** en milieux acides est 40 000 fois plus grande que celle d'un analogue, l'ion (2′-méthoxyéthoxy)diphénylméthoxyphosphonium, **7**, qui ne diffère que par le fait qu'il ne peut pas se cycliser. À tous les pH, le phosphorane **1** et l'ion phosphonium à cycle ouvert **5** existent en équilibre et l'étape qui détermine la vitesse de la réaction de l'hydrolyse globale est la scission du groupement méthoxy exocyclique pour donner l'ion phosphonium cyclique **6** qui est transformé rapidement en produits par réaction avec l'eau. À aucun pH, même en faisant appel à la spectroscopie à flux stoppé, il n'est pas possible d'observer la réaction d'équilibre impliquant **1** et **5**. La clôture de cycle non-catalysée de l'ion phosphonium **5** pour redonner le phosphorane **1** se produit avec une constante de vitesse de 200–500 s^{-1} qui correspond à une molarité effective de (2–5) $\times 10^7$ M pour le groupe hydroxyle intramoléculaire impliqué dans cette réaction. La scission exocyclique qui détermine la vitesse de la réaction est aidée par les H^+ et la constante de vitesse est très élevée, 2×10^9 M^{-1} s^{-1}. On a aussi observé une catalyse générale par les acides. La pente α de la courbe de Brønsted est égale à 1,0 pour les acides plus faibles; on note un bris pour les acides avec un $pK_a < 3$. On propose que ce comportement de type « Eigen » est causé par un état de transition n'impliquant qu'un faible caractère d'ion phosphonium dans lequel le proton est pratiquement complètement transféré aux acides plus faibles.

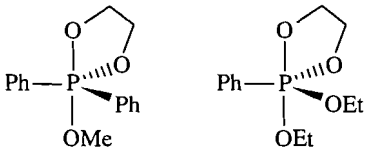
Mots clés : phosphorane, phosphate, phosphonium, hydrolyse.

[Traduit par la rédaction]



Introduction

In previous papers we have discussed the hydrolysis of spirotetraalkoxyphosphoranes comprising two five-membered rings (1, 2), two six-membered rings (3), and one five- and one six-membered ring (4). Throughout most of the pH region, these compounds undergo an acid-catalyzed dissociative hydrolysis involving a ring-opened phosphonium ion intermediate. This cation can be observed during the aqueous hydrolysis of the (6,6)-spirophosphoranes (3), while concentrated sulfuric acids are required to observe a cation with the other two. With all three types of phosphorane, ring-opening to the phosphonium ion is probably reversible. This has been unambiguously demonstrated with the (6,6)-spiro compound (3), with the (5,6)-spiro compound for ring-opening in one direction (4), and with an octamethyl-(5,5)-spiro derivative (2). Significant effects of ring size are observed on the thermodynamic and kinetic stabilities of phosphoranes and phosphonium ions, a cyclic five-membered phosphonium ion being 10^7 and 2×10^9 more reactive towards water than cyclic six-membered and acyclic analogs respectively (4). An analysis of the thermodynamics associated with the hydrolysis of the (5,6)-spirophosphorane revealed that part of the reason for the very much larger rate with the five-membered phosphonium ion is destabilization in the ground state, probably associated with ring strain (5). However, stabilization of the pentacoordinated transition state by the five-membered ring, probably due to relief of steric crowding (6), is equally, if not more important.



In this paper we discuss the hydrolysis of a phosphorane **1** that contains a single five-membered ring in addition to an exocyclic alkoxy group. A phosphorane of the type **2** had in fact been our

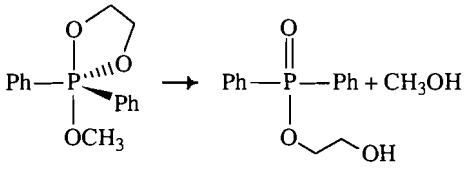
[1] 

first choice since this is a direct analog of the spiro compounds previously investigated. However, it proved difficult to maintain this compound in a pure state, since on standing it underwent disproportionation to phenyltetraethoxyphosphorane and the corresponding (5,5)-spirophosphorane. The contaminating material made analyses difficult, and **1**, which cannot disproportionate, was chosen for detailed studies.



1 **2**

Results

Products

Phosphorane **1** undergoes hydrolysis at all pH to give 2-hydroxyethyl diphenylphosphinate **3** and methanol as the only observable products. Authentic samples of other possible products, methyl diphenylphosphinate **4** and ethylene glycol, were added to the product mixtures to ensure their absence. The esters **3** and **4** are easily distinguished by their ^{31}P NMR chemical shifts (+35.5 and +33.2 ppm respectively). There was no observable peak in the hydrolysis mixture at the latter position, and we conclude that there is less than one percent of **4** formed. A sample of **3** was in fact isolated after hydrolysis and evaporation of the solvent (and methanol) in essentially pure form, and, with no further purification, had the same melting point as one previously reported for this compound (7).

Kinetics

Because of solubility problems in 100% aqueous media, kinetic experiments were carried out in 1:3 acetonitrile:water, with the temperature at 25°C and the ionic strength of 1.0 maintained with NaCl. Absorbance changes in the UV region between 260 and 280 nm were monitored. These changes were similar to ones previously observed with the spirophosphoranes (1–4). As illustrated in Fig. 1, addition of acid to a solution of phosphorane under anhydrous conditions is accompanied by a large absorbance increase, typical of the formation of a phosphonium ion (see NMR recorded under these conditions later). Addition of water to this solution results in an absorbance decrease, with the final spectrum corresponding to that of the phosphinate **3** lying intermediate between the spectra of the phosphonium ion and the phosphorane.

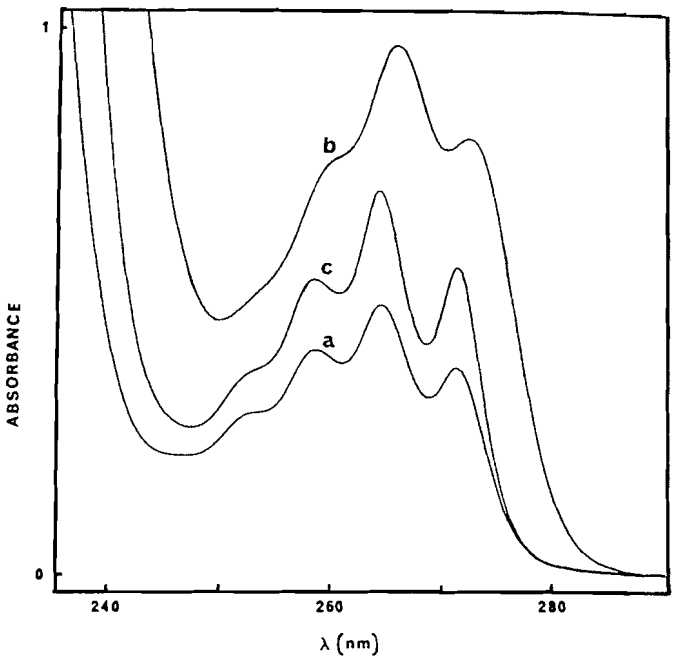

FIG. 1. UV spectra obtained with the phosphorane **1**. (a) 1 mM phosphorane in dioxane. (b) After the addition of one equivalent of CF_3SO_3H. (c) After the addition of water to the acidified solution.

Addition of the phosphorane to aqueous solution results in an absorbance *increase* at pH > 8, indicating direct conversion of the phosphorane to product, with an absorbance *decrease* at pH < 7, corresponding to the hydrolysis of a phosphonium ion. In both regions catalysis by added buffer is observed. At high pH the rate law is

$$[3] \quad k_B(obs) = k_B^H[H^+] + k_B^{OH}[OH^-] + k_B^0 + k_B^{HA}[HA]$$

where the first two terms represent H^+-catalyzed and OH^--catalyzed processes, the third a pH-independent reaction, and the fourth catalysis by added buffer acids. Rate constants are given in Table 1, and the rate–pH profile based upon extrapolation to zero buffer concentration is shown in Fig. 2. To ensure that the species undergoing reaction in these solutions was indeed the phosphorane, an ^1H NMR spectrum of a more concentrated solution of **1** was recorded as quickly as possible in 3:1 CD_3CN:D_2O containing 5 mM NaOD. In the initially recorded spectrum, the two doublets of the starting phosphorane were clearly visible. Later spectra showed the characteristic pattern of the products.

At pH < 7, where an absorbance decrease is observed, the rate law is

$$[4] \quad k_A(obs) = k_A^0 + k_A^B[A^-]$$

showing a pH-independent reaction (see Fig. 2) and a reaction catalyzed by the base component of the buffer. Rate constants obtained in this region are also given in Table 1.

Between pH 7 and pH 9, there is a transition between the two types of behavior that characterize the reactions at lower and higher pH. As illustrated in Fig. 3, a first-order absorbance change is observed in all solutions, but the absolute magnitude and direction change with pH, from the absorbance decrease observed at high pH to the decrease at low pH. Defining ΔAbs as

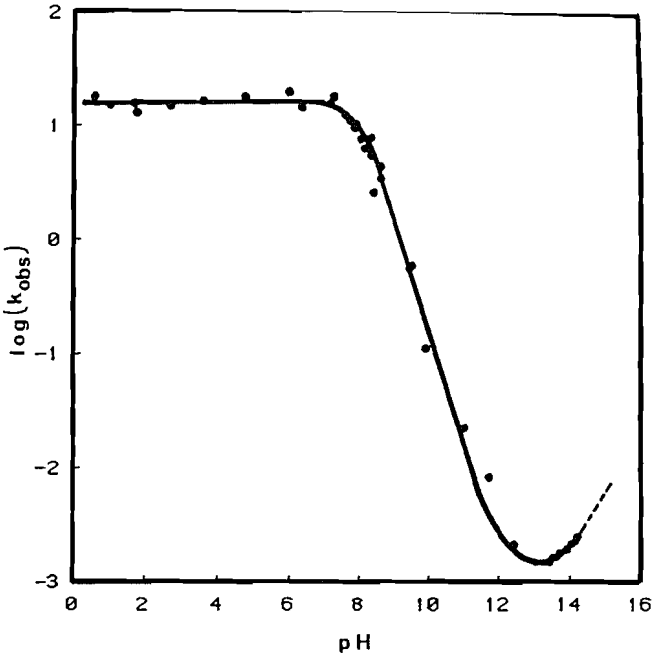

FIG. 2. Rate–pH profile for the hydrolysis of the phosphorane **1** in 1:3 acetonitrile:water at 25°C and ionic strength 1.0. See text for the significance of the various regions.

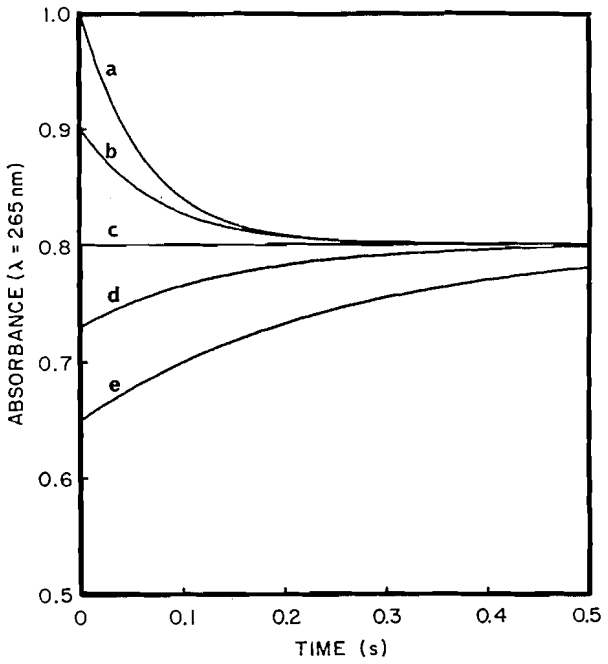

FIG. 3. Absorbance at 265 nm as a function of time for the hydrolysis of 1 mM phosphorane **1** at (a) pH 7.2; (b) pH 7.8; (c) pH 8.4; (d) pH 9.0; and (e) pH 9.6.

the initial absorbance minus the final absorbance, a plot of ΔAbs versus pH for a constant concentration of phosphorane is found to have the general form of an acid–base titration curve,

$$[5]\qquad \Delta Abs = \left(\frac{\Delta Abs(Acid)[H^+] + \Delta Abs(Base)K_a(Spect.)}{[H^+] + K_a(Spect.)}\right)$$

where ΔAbs(Acid) and ΔAbs(Base) are the absorbance changes that occur at low pH (<6) and high pH (>10.5) respectively. K_a(Spect.) is the apparent acidity constant; the value obtained from a fit of the experimental data is $(7 \pm 2)\times10^{-9}$.

The first-order rate constants obtained in this region connect the pH-independent region at low pH with the H^+-dependent region at high pH (see Fig. 2). These rate constants follow the rate law

$$[6]\qquad k_{Intermed.}(obs) = \left(\frac{k_A^0}{[H^+] + K_a(Kin.)}\right)$$

where $k_{Intermed.}$(obs) refers to rate constants obtained at zero buffer concentration, and K_a(Kin.) is a kinetic acidity constant. The constant k_A^0 is identical to the pH-independent rate constant observed in more acidic solutions (see eq. [4]), while the ratio k_A^0/K_a(Kin.) is the same as the constant k_B^H obtained at higher pH (see eq. [3]). Values of K_a(Kin.) were determined in two ways, from the ratio k_A^0/k_B^H as $(9 \pm 3)\times10^{-9}$, and from a fit to eq. [6] of the data in the intermediate range as $(10 \pm 2)\times10^{-9}$.

There must be an initial absorbance increase on adding the phosphorane to a solution with pH < ~9. This, however, could not be observed at any pH, even in experiments where the phosphorane in a basic solution (0.002 M NaOH) was mixed on a stopped-flow spectrophotometer. In these experiments a rapid increase in absorbance is expected, associated with the formation of the phosphonium ion, followed by the subsequent slower absorbance decrease that is illustrated in Fig. 3. All that was observed was the latter. We conclude that the rate of the initial process is beyond the limit of detectability of the stopped-flow apparatus, so that its rate constant must be greater than 500 s^{-1}.

Phosphonium ions

The ^1H NMR spectrum that results when **1** is reacted with an equivalent amount of CF_3SO_3H at −75°C in CD_2Cl_2 is shown in

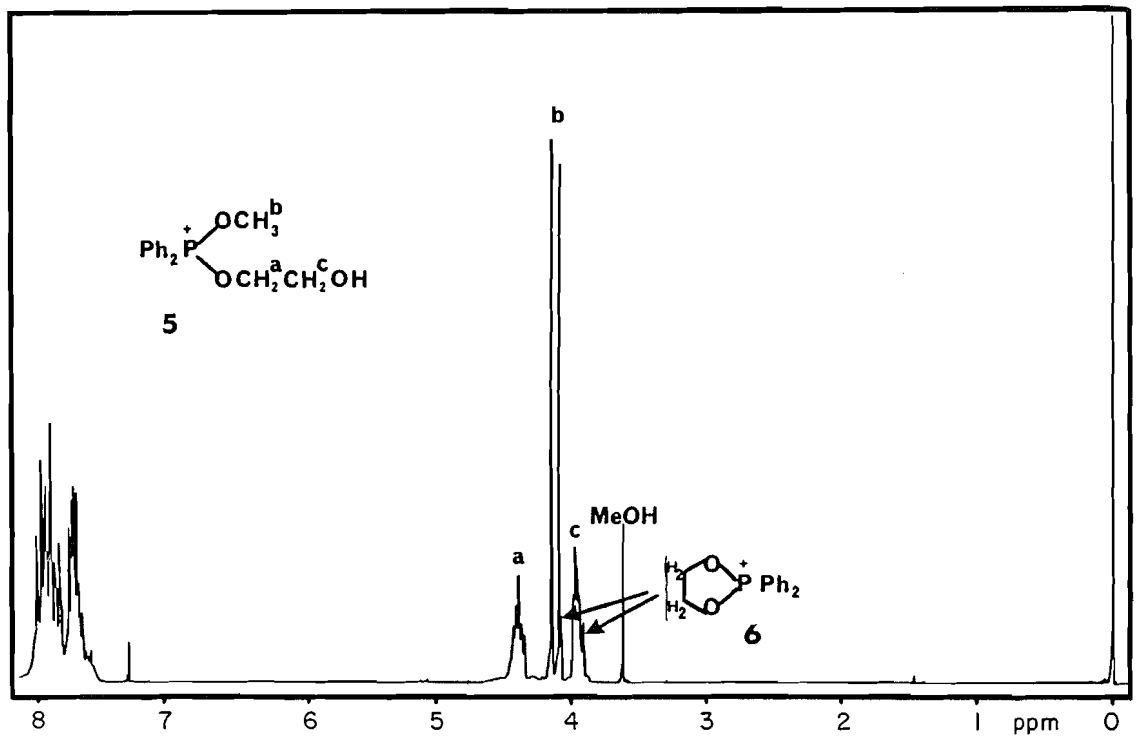

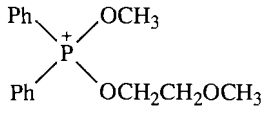

FIG. 4. ^1H NMR spectrum (200 MHz) of the phosphorane **1** (0.1 M) in CD_2Cl_2 after reaction at −70°C with one equivalent of trifluoromethanesulfonic acid.

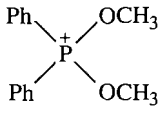

Fig. 4. For the most part, this spectrum is consistent with the formation of the ring-opened cation **5**. In particular, there is a doublet associated with the OCH_3 group still coupled with phosphorus, and complex multiplets due to the unsymmetrical $-CH_2CH_2-$ group. There is, however, a small amount of methanol also produced in this experiment, as verified by the addition of authentic alcohol. This suggests that some of the cyclic five-membered cation **6** is produced as well, and indeed two smaller peaks are visible in the ^1H NMR spectrum that are consistent with the doublet expected for the ethylene group of this cation. The situtation is more clearly revealed in the ^{31}P NMR spectrum, since here two resonances are clearly observed in a roughly 10:1 ratio, with the larger signal at +58.9 ppm and the smaller at +89.7 ppm. The 31 ppm difference strongly supports the assignment of the minor peak as the cyclic cation, since this is in line with the effect of the five-membered ring on the phosphorus chemical shift in a phosphonium ion (4).

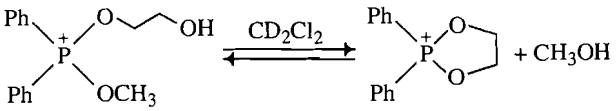
It is possible to demonstrate that the ring-opened **5** is indeed the species observed in the hydrolysis of **1** in aqueous acid. When a solution of this cation in anhydrous acetonitrile is mixed with dilute aqueous HCl on a stopped-flow apparatus, an absorbance decrease is observed, with a rate constant of 25 s^{-1}. The same result is obtained when an acetonitrile solution of the phosphorane is mixed with the aqueous acid. When a similar experiment is carried out with the cation **5** in acetonitrile being mixed with aqueous borate buffer of pH 10, an absorbance increase is observed, again with a rate constant identical to that obtained with the phosphorane. This indicates that the phosphonium ion recyclizes in the more basic solutions, regenerating the phosphorane. The absorbance change associated with the cyclization cannot, however, be observed, being complete within the mixing time on the stopped-flow apparatus.

The cation **7** as its $CF_3SO_3^-$ salt was prepared as a model for **5** by reacting 2-methoxyethyl diphenylphosphinate with $CF_3SO_3CH_3$. This cation hydrolyzes in 1:3 acetonitrile:water (μ = 1.0, 25°C) with a rate constant of 4×10^{-4} s^{-1}. The analogous cation **8** has been previously studied, with the rate constant reported in 100% water (μ = 0.1, 25°C) of 5.0×10^{-4} s^{-1} (8).

7

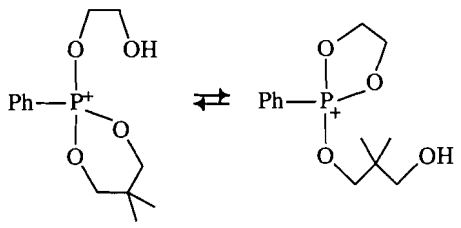


8

Discussion

Relative stability of cyclic five-membered and acyclic phosphonium ions

In the NMR experiment carried out in CD_2Cl_2 (Fig. 4), the two phosphonium ions would be present as a thermodynamic mixture of ion pairs, equilibrating by way of the phosphorane. This conclusion can be made since the rates should be very fast, the reaction in the forward direction involving a rapid cyclization (see later) and the reaction in the reverse direction the attack of a nucleophile on a very reactive cyclic five-membered cation (4). Based upon the ^{31}P NMR integration and the initial concentrations of the reagents, the equilibrium constant [**5**.CF_3SO_3-][CH_3OH]/[**6**·CF_3SO_3-] is approximately 10^{-3} M. This corresponds at −70°C to a difference in free energy of +2.7 kcal mol^{-1}.



[7]

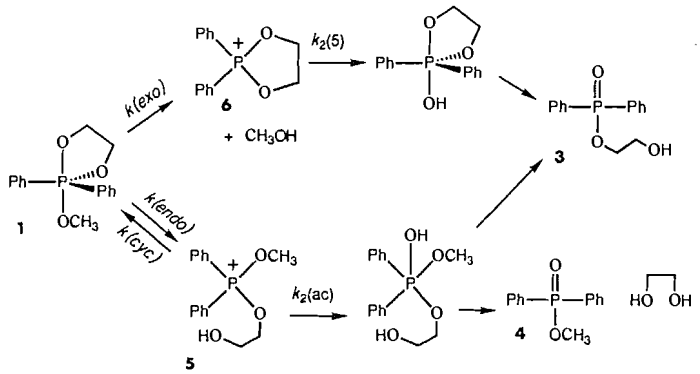
$CF_3SO_3^-$ $CF_3SO_3^-$

5 **6**

In the previous paper isomeric cyclic six-membered and five-membered phosphonium ions were compared. The conclusion was that for this equilibrium the free energy is +2.5 to +4.5 kcal/mol^{-1} at 25°C in water (4), with the higher number applying for the mechanistic model that we most favored.

[8] 

9 **10**



For this latter isomerization ΔG is probably fairly close to ΔH, since the rotational degrees of freedom in the reagent and product are similar, so that ΔS should be ~0. Thus ΔG is determined to a good approximation by the difference in potential energy between the six-membered and five-membered systems, associated with factors such as ring strain in the latter.

For the reaction in eq. [7], ΔS is not zero, but will contain a negative contribution associated with the loss of rotational degrees of freedom in the ethylene group as it forms the ring, offset by a positive contribution associated with the formation of two molecules from one. Estimates of these two effects are ~ −10 cal deg^{-1} mol^{-1} for the former and ~ +30 cal deg^{-1} mol^{-1} for the latter (9). Thus the overall ΔS should be ~ +20 cal deg^{-1} mol^{-1}, and ΔH is therefore about 7 kcal mol^{-1}. Considering the uncertainties in the analyses of the two equilibria of eqs. [7] and [8], it is perhaps risky to conclude that ΔH for the former is greater. What is clear is that in both cases there is an increase in potential energy associated with the formation of the cyclic five-membered phosphonium ion. However, this is not sufficient to entirely account for the enormously accelerated rate of hydrolysis of this type of cation. This was discussed in detail for a comparison of the two cyclic cations in the previous paper. Considering a comparison of a cyclic five-membered cation and an acyclic analog, the rate difference is around 10^8 (4), corresponding to $\Delta\Delta G^{\neq}$ of close to 11 kcal mol^{-1}. As the above calculation shows, this is greater than the difference in potential energy between the two cations.

Mechanism of acid hydrolysis of the monocyclic phosphorane 1

The mechanism for the acid-catalyzed hydrolysis of this phosphorane is shown in Scheme 1. Two different phosphonium ion intermediates can in principle be involved, as with the (5,6)-spirophosphorane discussed in the previous paper. In the latter case, both of the cations formed in ring-opening reactions that were in principle reversible. With the monocyclic derivative of the present study, the acyclic **5** also forms in a ring-opening reaction, and thus reversibility must be considered. However, the concentration of water is so much greater than that of methanol that **6**, if formed, would react with the former to go on to products. Thus for practical purposes the formation of this cation is irreversible.

As with the (5,6)-spiro derivatives the evidence points to the overall hydrolysis proceeding by way of the less thermodynamically stable cation. The first indicator of this is the products. As shown in Scheme 1, the reaction of the ring-opened **5** with water is expected to give rise to two phosphinate esters **3** and **4**, along with amounts of methanol and ethylene glycol equivalent to the former and latter respectively. In fact, neither **4** nor ethylene glycol were found (less than 1%), only **3**

SCHEME 1

and methanol, the products that would be expected of a hydrolysis proceeding by way of **6**. A further indication comes in the observation that the diphenylphosphonium ion **7** that models **5** actually undergoes hydrolysis orders of magnitude more slowly. Aside from a very small electronic effect associated with the 2-methoxy/2-hydroxy groups, the only difference between these two cations is the ability of **5** to cyclize and regenerate its phosphorane precursor. It is therefore concluded that no matter how far the ring-opening equilibrium lies toward **5**, the overall hydrolysis takes place via the strained cyclic cation, and not by a direct reaction of the former cation with water.

If the assumption is made that an equilibrium is maintained during the overall hydrolysis between the phosphorane and the ring-opened cation, then

$$[9] \quad k(\text{obs}) = (k_2(\text{ac}) + K^{\text{H}}(exo)K_a)\left(\frac{[\text{H}^+]}{[\text{H}^+] + K_a}\right)$$

where K_a is the equilibrium constant for the pseudo acid–base reaction involving **1** and **5** ([**1**][H$^+$]/[**5**]), k_2(ac) is the rate constant for the reaction of water with the cation **5**, and the exocyclic cleavage leading to **6** occurs with H$^+$-catalysis, so that $k(exo)$ of Scheme 1 is equal to $k^{\text{H}}(exo)$[H$^+$]. This equation is of the correct form to account for the observed rate–pH profile in solutions more acidic than pH 11 (see eq. [6] and Fig. 2). In acidic solutions where [H$^+$] > K_a, k(obs) is independent of pH, as is observed experimentally, and the pH-independent rate constant, $k_A{}^0$ of eq. [4], is equal to (k_2(ac) + $k^{\text{H}}(exo)K_a$). The direct reaction of **5** with water is modelled by the cation **7**, and thus k_2(ac) should be similar to the rate constant for the latter, i.e., around 4×10^{-4} s^{-1}. The actual observed $k_A{}^0$ is 15 s^{-1}, 40 000 times larger. Thus, as was concluded in the previous section, the contribution from k_2(ac) is negligible. Therefore, in acid solutions in the absence of buffer, k(obs) = $k_A{}^0 = k^{\text{H}}(exo)K_a$. The ring-opened **5** has formed essentially completely, but its hydrolysis proceeds by way of the phosphorane present in equilibrium in small amounts, with the rate-limiting step the H$^+$-catalyzed exocyclic cleavage. The rate is independent of pH since the phosphonium ion must first lose H$^+$ to form the neutral phosphorane. At higher pH where [H$^+$] < K_a and the phosphorane becomes the predominant species in the equilibrium, k(obs) becomes dependent on [H$^+$], with an observed second-order rate constant, $k_B{}^{\text{H}}$ of eq. [3], directly equal to $k^{\text{H}}(exo)$. The changeover from one behavior to the other occurs between pH 9 and pH 7; the K_a value is $(9 \pm 2) \times 10^{-9}$ (pK_a = 8.05), as determined both through an analysis of the kinetics and spectroscopically.

Reversibility of the ring-opening step

For the equilibrium assumption to be valid, two conditions must be met. The first is that $k_2(\text{ac}) < k(\text{cyc})$, that is, that hydration of the ring-opened cation is slower than its recyclization to the phosphorane. That this is true is demonstrated by the hydrolysis proceeding exclusively by way of the cyclic five-membered cation, even under acidic solutions where the ring-opened cation predominates. The ability of **5** to regenerate the phosphorane in basic solutions has also been demonstrated. Arguments will be presented shortly that $k(\text{cyc})$ is close to 10^6 times larger than $k_2(\text{ac})$, using for the latter the value expected from the comparison with the model **7**. The second requirement is that $k(endo) > k(exo)$; that is, starting with phosphorane the rate constant for ring-opening to form **5** is greater than the rate constant for exocyclic cleavage to **6**. That this condition is met is demonstrated by the fact that the observed rate constants do obey the rate law appropriate for the equilibrium situation. Moreover, the magnitude and direction of the absorbance changes exhibit the required dependency on H^+ concentration, and the spectroscopic K_a value so produced is in good agreement with the value determined in the kinetic analysis.

That the second condition is met can be further demonstrated for solutions around pH 8, on the basis that the actual equilibration process cannot be observed in these solutions while the exocyclic cleavage can still be seen. To illustrate the argument, we consider a pH 8.05 buffer containing 0.1 M $TrisH^+$. In this solution the measured rate of hydrolysis is 8.4 s^{-1}, with the buffer contributing about 10% (see later for a discussion of this buffer catalysis). Taking the model involving the equilibrium assumption, this solution contains a 50:50 mixture of phosphorane and **5**, and the actual value of $k(exo)$ is double that of $k(\text{obs})$, since half of the equilibrating mixture is unreactive. The approach to equilibrium occurs with a rate constant equal to the sum of the forward and reverse rate constants, $k(endo) + k(\text{cyc})$, and these are numerically equal at pH 8.05 because of the 50:50 equilibrium. The equilibration reaction is so fast that it cannot be observed even with the stopped-flow technique, leading to the conclusion that its rate constant is greater than 500 s^{-1}. Therefore the value of $k(endo)$ is greater than half this, which means that $k(endo)$ is greater than 15 times $k(exo)$.

The rate constant $k^{\text{H}}(exo)$ for H^+-catalyzed exocyclic cleavage is 1.7×10^9 M^{-1} s^{-1}, and the implication that $k(endo) > k(exo)$ means that $k^{\text{H}}(endo)$, the rate constant for H^+-catalyzed ring-opening, must be considerably larger. This is difficult to prove conclusively, but there is one important observation consistent with this interpretation, in that the kinetic and absorbance patterns consistent with reversible ring-opening are still observed in dilute HCl solutions where both endocyclic and exocyclic processes must occur with H^+-catalysis. In particular the magnitudes of the absorbance changes are consistent with those observed in buffer solutions, the absorbance change in dilute HCl being a decrease at the limit ($\Delta\text{Abs(Acid)}$) since phosphonium ion **5** fully forms. If $k^{\text{H}}(endo)$ were not significantly greater than $k^{\text{H}}(exo)$ some of the phosphorane would be immediately converted into products on addition to such a solution, less phosphonium ion **5** would therefore form, and the absorbance decrease associated with its reaction would be smaller.

Considering experimental uncertainties, $k^{\text{H}}(endo)$ must be greater than 10 times $k^{\text{H}}(exo)$, in other words, greater than 2×10^{10} M^{-1} s^{-1}. This number is in the range found for diffusion-controlled proton transfers involving H_3O^+, and is unlikely to exceed 5×10^{10} M^{-1} s^{-1}, the maximum observed for such processes (10). Thus we conclude that $k^{\text{H}}(endo)$ lies in the range $(2–5) \times 10^{10}$ M^{-1} s^{-1}. This also means that we can assign a value of 200–500 s^{-1} for the rate constant $k^0(\text{cyc})$ for the microscopic reverse process, the unassisted or water-catalyzed ring closure of **5** to reform the phosphorane. This conclusion arises since K_a is equal to the ratio $k^0(\text{cyc})/k^{\text{H}}(endo)$. The interesting feature of $k^0(\text{cyc})$ is that it is $\sim 10^6$ times $k_2(\text{ac})$, assuming that the latter will be the same as the rate constant obtained for the model **7** that cannot cyclize. This corresponds to a very large effective molarity of the internal hydroxy group in this cation, in the range $(2–5) \times 10^7$ M (converting $k_2(\text{ac})$ to bimolecular units). Effective molarities of 2-hydroxyethoxy groups in reactions at tetracoordinate phosphorus are generally large (11). The number obtained with the present system would appear at the upper end of ones previously measured.

These very large rate constants for $k^0(\text{cyc})$ and $k^{\text{H}}(endo)$ are also consistent with the failure to observe the kinetics of the pre-equilibrium stage at any pH. In the absence of catalysis by other species, the rate constant for the approach to equilibrium is given by $k^0(\text{cyc}) + k^{\text{H}}(endo)[\text{H}^+]$. With $k^{\text{H}}(endo)$ in the range $(2–5) \times 10^{10}$ M^{-1} s^{-1}, it can be easily seen that in acidic solutions the formation of the cation from the phosphorane is too fast to be observed by the stopped-flow technique, for example $k^{\text{H}}(endo)[\text{H}^+]$ being greater than 2×10^3 in a pH 7 solution. In more basic solutions, the rate of equilibration becomes dominated by $k^0(\text{cyc})$. At pH 8.5, for example, the approach to equilibrium will occur with a rate constant of greater than 260 s^{-1}, using the lower limits for these two rate constants. This corresponds to a half-life of 3 ms, which is just at the limit of detectability. Moreover, since at this pH there is about a 4:1 ratio of phosphorane and phosphonium in equilibrium, the actual absorbance "burst" associated with the approach to this equilibrium would be small, and thus very difficult to detect.

General acid catalysis

The buffer catalysis observed for the overall hydrolysis is explained by general acid catalysis of the exocyclic cleavage. This appears as true general acid catalysis at pH > 9, and general base catalysis at pH < 7, where the phosphonium ion **5** predominates in the initial equilibrium. In the latter case, a proton must be lost prior to the rate-limiting general acid step, and the observed rate constants for general base catalysis (k_A^B of eq. [4]) are related to the true rate constants for the general acid reaction $k^{\text{HA}}(exo)$ by the expression

$$[10] \qquad k^{\text{HA}}(exo) = \frac{k_A{}^B K_a(\text{HA})}{K_a}$$

where $k_a(\text{HA})$ is the acidity constant of the catalyzing acid, and K_a is the equilibrium constant previously defined relating the phosphorane and ring-opened phosphonium ion **5**. Figure 5 shows the Brønsted plot obtained for $k^{\text{HA}}(exo)$, combining the rate constants measured directly at high pH ($k^{\text{HA}}(exo) = k_B{}^{\text{HA}}$), along with ones calculated from eq. [10] for the data from low pH. This plot consists of a linear portion for acids with $pK_a(\text{HA}) > 3$, shared by oxygen acids and protonated amines alike, with a slope α of 1.00 ± 0.05. For acids with $pK_a(\text{HA}) < 3$ the plot curves, and it appears that α is approaching a limiting value of zero as $k^{\text{HA}}(exo)$ approaches the diffusion limit of $10^9–10^{10}$ M^{-1} s^{-1}. This break from linearity occurs with catalysts belonging to a single class, the carboxylic acids, so that it cannot be attributed to the presence of different structural types.

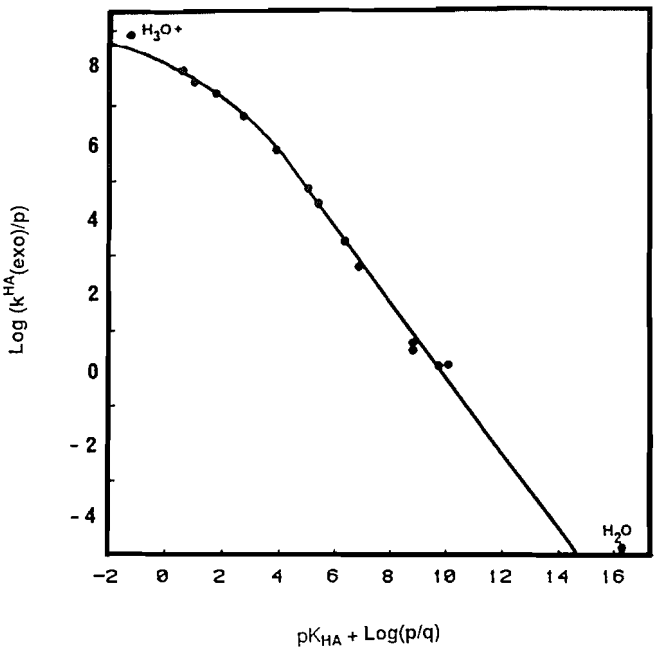

FIG. 5. Brønsted plot for general acid catalysis of exocyclic cleavage in the hydrolysis of the phosphorane **1**. The water rate constant has been converted to second-order units by dividing k_B^0 by the concentration of water in this solvent.

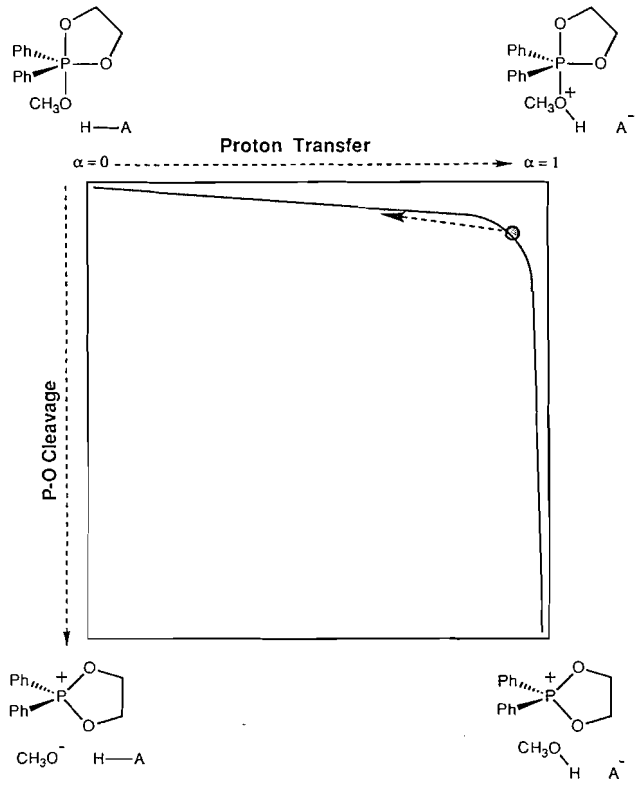

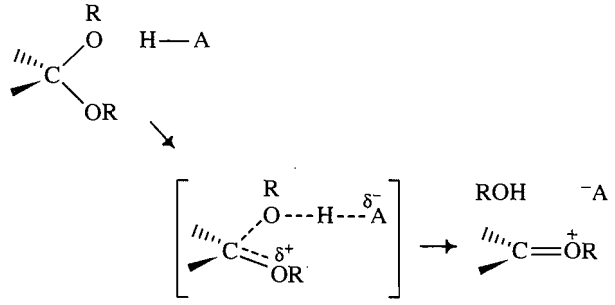

FIG. 6. Reaction coordinate diagram for the general acid-catalyzed exocyclic cleavage of the phosphorane **1**. The reaction is considered to be concerted, with almost complete proton transfer in the transition state, and only a small amount of phosphonium ion character. For strong acids, $pK_a < 3$, the transition state moves in the direction of the arrow toward the phosphorane corner, and the Brønsted value decreases.

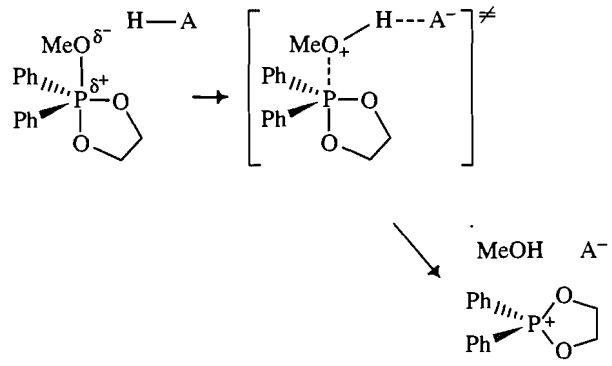
This process is in some ways analogous to the general acid-catalyzed hydrolyses of acetals and ortho esters (12, 13), the C=O analogs of phosphoranes. With the acetal/ortho ester class there is now considerable evidence in favor of a mechanism with proton transfer and C—O bond breaking concerted (eq. [11]), with partial proton transfer to the departing alkoxide and partial oxocarbocation character in the transition state (14–18).

[11]



The picture with the phosphorane must, however, be different. The first noteworthy feature is the k^H value for H^+-catalysis, which is several orders of magnitude larger than any that have been observed with acetals and ortho esters, even with derivatives such as tropone diethyl ketal where very stable and observable (19) oxocarbocation intermediates are formed. With the acetals and ortho esters there is a general trend that the larger the k^H value, the smaller the Brønsted α. This is explained by a model where the more reactive systems have earlier transition states with less proton transfer. By analogy to the acetal system, the large k^H observed for the phosphorane leads to the expectation of a relatively low α. Exactly the opposite is observed, with the α value implying almost complete proton transfer in the transition state.

The Brønsted plot for the phosphorane in fact bears some resemblance to an "Eigen curve" for a simple proton transfer (20). This suggests a rate-limiting proton transfer to the exocyclic oxygen to form a protonated phosphorane, followed by a fast P—O cleavage to yield the phosphonium ion. We, however, feel that the mechanism cannot be as simple as this. A close comparison of the Brønsted plot of Fig. 5 and an "Eigen" Brønsted plot for a simple proton transfer shows that the former does not have exactly the same characteristics, a sharper "break" being observed with the Eigen plot. Moreover, the break with the phosphorane occurs near pH 2, implying that if the reaction were simple proton transfer, the conjugate acid of the phosphorane has a pK_a value of about +2. This is unlikely. Protonated phosphoranes have been argued to be very strong acids with large negative pK_a values (21), associated with the presence of the electron-withdrawing groups attached to phosphorus.

A reaction coordinate diagram for a general acid-catalyzed P—O cleavage is shown in Fig. 6. This has axes of P—O bond cleavage (y axis) and proton transfer (x axis). The α value is determined by the amount of proton transfer and is measured along the x axis. A similar diagram is drawn for the general acid-catalyzed C—O cleavage of acetals and ortho esters, and with these there is evidence from structure–activity correlations that the transition state lies towards the center of the diagram, showing significant amounts of both proton transfer and C—O bond cleavage (14–18). What we propose for the phosphorane, however, is a situation such as that described by the pathway indicated in Fig. 6, where the cleavage is concerted, but the transition state lies close to the protonated phosphorane

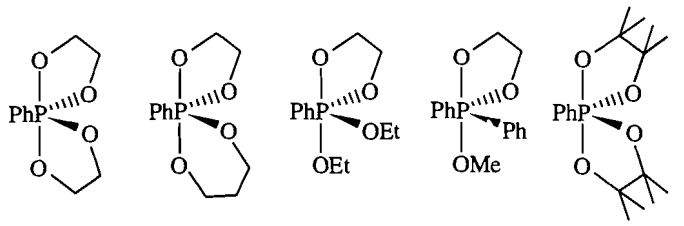
[12] 

corner. With weak acids, there is almost complete proton transfer in the transition state, so that the Brønsted α value is close to one. When the acids become sufficiently strong, around $pK_a(HA) < 3$, a Hammond effect results in movement of the transition state toward the phosphorane, and the α value decreases. It can be noted that the apical bonds in phosphoranes are highly polarized (22, 23). One can then imagine a model where, on encountering a weak acid, an almost complete proton transfer takes place before the P—O bond starts cleaving. We are currently conducting a detailed examination of this system, varying the aromatic substituent to provide a measure of phosphonium ion character in the transition state, and varying the basicity of the leaving alcohol to probe how this affects the amount of proton transfer.

pH-Independent hydrolysis



This section is concerned with the term k_B^0 of eq. [3], which becomes important around pH 12. At this pH the phosphorane is the dominant species present in the ring-opening equilibrium, and there are two possible mechanisms for a pH-independent hydrolysis, one involving a straightforward ionization of the exocyclic P—OCH_3 bond, and the second, a reaction in which water acts as a general acid catalyst to assist the cleavage, as in eq. [12] with HA = H_2O. As shown in Fig. 5, the pH-independent rate constant, after correcting to bimolecular units, lies above the Brønsted line for the other general acids. Similar findings are made with acetals and ortho esters that show pH-independent hydrolyses, and this has been argued as support for a non-assisted heterolysis (24). The deviation from the Brønsted line in the present case, however, is not great and, considering that water can be especially effective as a catalyst (25), the general acid mechanism probably cannot be eliminated.

[13] 

1 **6**

Hydroxide ion reaction

The catalysis by hydroxide ion observed at very high pH was not investigated in detail, but it is likely to involve an associative mechanism proceeding by way of a hexacoordinated anion, as has been suggested for the (5,5)-spirophosphoranes (1). A comparison of second-order rate constants for the hydroxide ion reaction is shown as follows:

0.062 (ref. 1) 0.44 (ref. 4) 0.38 (ref. 26) 0.001 $<10^{-4}$ (ref. 26)

The first three phenyltetraalkoxyphosphoranes react with hydroxide at similar rates. The relatively low reactivity of **1** is probably due to a steric effect exerted by the additional phenyl group. As shown by the last entry, an octamethyl derivative of the (5,5)-spirophosphorane undergoes an extremely slow OH^- hydrolysis, if at all, and this must be related to a steric effect.

Experimental section

Materials

2,2-Diphenyl-2-methoxy-1,3,2-dioxaphospholane (1) was prepared by the reaction of methyl diphenylphosphonite (27), ethylene glycol, and *N*-chlorodiisopropylamine (28) according to the method of Trippett and co-workers (29). The crude product was obtained as a viscous, colorless oil, which was further purified, albeit with substantial loss of material, by first dissolving in pentane, followed by washing with half of the volume of propylene carbonate at 0–5°C. This phosphorane had ^{31}P NMR ($CDCl_3$) δ: −26.4; ^1H NMR ($CDCl_3$) δ: 7.9–7.2 (10H, mult.), 3.8 (4H, d, J_{P-H} = 12 Hz), 3.1 (3H, d, J_{P-H} = 11 Hz).

2-Methoxyethyl diphenylphosphonate was prepared from diphenylphosphinyl chloride in dry ether through the addition of an ether solution of equivalent amounts of 2-methoxyethanol and triethylamine at 0°C under nitrogen. The triethylamine hydrochloride was removed by filtration, the ether was evaporated, and the ester recrystallized from benzene–hexane; mp 37.5–38.0°C; NMR ($CDCl_3$) δ: +32.4; ^1H NMR ($CDCl_3$) δ: 7.9–7.0 (10H, mult.), 4.2–3.8 (2H, mult.), 3.5 (2H, t, J_{H-H} = 5 Hz), 3.2 (3H, s).

The (2′-methoxyethoxy)diphenylmethoxyphosphonium ion (7) was prepared in methylene chloride solution (3 mL) by reacting 2-methoxyethyl diphenylphosphinate (1 mmol) with one equivalent of methyl trifluoromethanesulfonate. The reaction was monitored by ^{31}P NMR spectroscopy. The cation had ^{31}P NMR, δ: +58.7. Kinetic studies were performed directly on this solution.

Methyl diphenylphosphinate (4) (8) was prepared as previously described.

Products

The phosphoranes were dissolved in 1:1 D_2O:acetonitrile containing appropriate buffer or acid. After a short period of time, the solution was frozen, and the solvents removed by lyophilization. The products were dissolved in $CDCl_3$, and ^{31}P and ^1H NMR spectra recorded. A single product, 2-hydroxyethyl phenylphosphinate **3** was obtained at both neutral and acidic pH. This had ^{31}P NMR δ: +35.2; ^1H NMR δ: 8.0–7.2 (10H, mult.), 4.30–3.95 (2H, mult.), 3.90–3.60 (2H, mult.). A sample of **3** was obtained after hydrolysis as white crystals with mp 101–103°C (lit.(7) mp 103.5–104.5°C). Anal. calcd. for $C_{14}H_{14}O_3P$: C 64.12, H 5.72, P 11.82; found: C 64.32, H 6.06, P 11.95.

Kinetic methods

Rate constants were obtained in 1:3 CH_3CN:H_2O, with the ionic strength being maintained at 1.00 with NaCl. The procedures for the measurements have been described previously (1–4).

Spectroscopic acidity constants were obtained by adding a small quantity (5–10 μL) of a stock solution of the phosphorane in methylene chloride to 5 mL of 0.005 M NaOH, and then mixing this with an appropriate buffer on the stopped-flow spectrophotometer. The total absorbance change, $\Delta Abs = A_0 - A_\infty$, was measured. Special care was taken to insure that the concentration of phosphorane was the same

For personal use only.

each time this was done. In addition, since the phosphorane is undergoing hydrolysis in the NaOH solution, the time interval between the intial preparation of this solution and the final mixing was kept constant.

Kinetics of breakdown of aryl hemiacetals of α-bromoacetophenone. Effect of phenol leaving groups on the lifetimes of tetrahedral intermediates

ROBERT A. MCCLELLAND,[1] V. M. KANAGASABAPATHY, AND N. MATHIVANAN
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received May 3, 1991

ROBERT A. MCCLELLAND, V. M. KANAGASABAPATHY, and N. MATHIVANAN. Can. J. Chem. **69**, 2084 (1991).

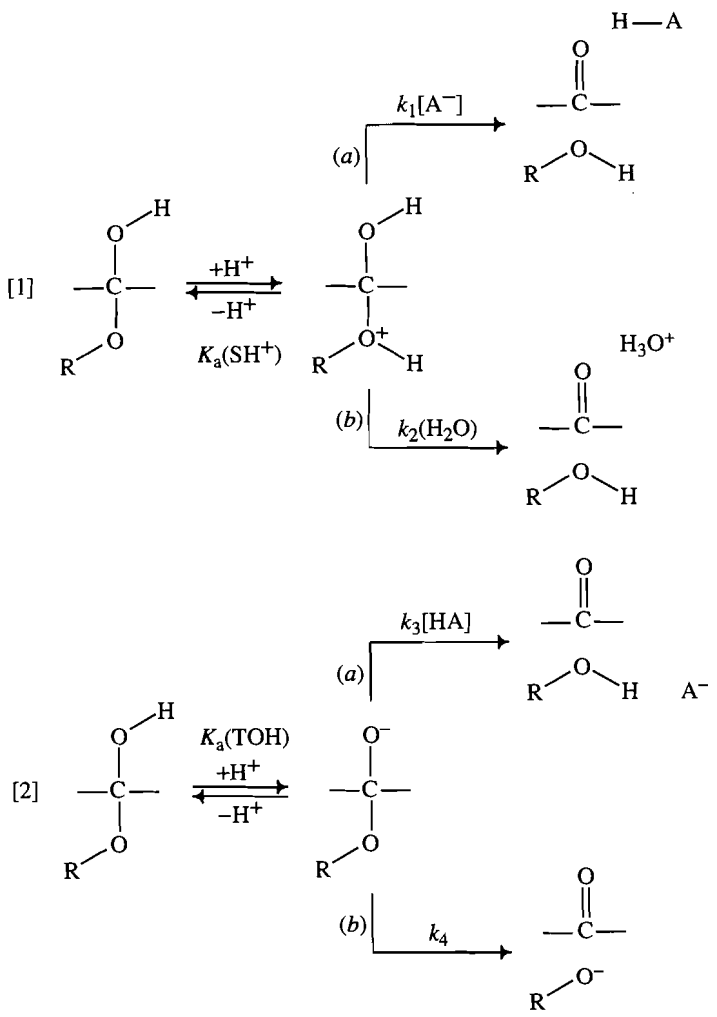
The kinetics of breakdown of seven aryl hemiacetals of α-bromoacetophenone (TOH) have been examined, with aryl substituents 4-MeO, 4-Me, 3-Me, H, 3-MeO, 4-Cl, 3-Cl. The hemiacetals were generated as intermediates in the aqueous bromination of α-aryloxystyrenes, where the breakdown of the hemiacetal is the rate-limiting stage in the overall reaction. Base catalysis of the breakdown shows large Brønsted β values (0.8–1.0) and similarly large β_{lg} values (−0.8 to −1.0). These are argued to arise because of a preassociation mechanism in which the hydrogen-bonded intermediate $TO^- \cdots HA$ loses aryloxide faster than diffusional separation of the acid–base pair. This mechanism is enforced by lifetimes of the deprotonated hemiacetals TO^- in the 10^{10}–10^{12} s^{-1} range. Such lifetimes were estimated in two independent ways, by extrapolation of data previously obtained for alkyl hemiacetals of α-bromoacetophenone, and through a calculation based upon the experimental catalytic coefficients, and estimates of the acidity constants for TOH and the equilibrium constants for formation of hydrogen-bonded complexes. The pH-independent breakdown has $\beta_{lg} = -1.03$, and the point lies near the Brønsted line for the carboxylate catalysts. This, therefore, also occurs by a preassociation mechanism with water as the catalyst forming the intermediate $TP^- \cdots H_3O^+$, which loses aryloxide faster than diffusional separation. Catalysis by hydroxide ion occurs with rate constants of 8×10^9 M^{-1} s^{-1} independent of aryl substituent. This represents rate-limiting diffusional encounter of the hemiacetal and hydroxide ion, the hydrogen-bonded intermediate $TOH \cdots OH^-$ rapidly proceeding on to products. Acid catalysis of the hemiacetal breakdown occurs by a class "n" mechanism in which the acid assists departure of the substitued phenol. Alkyl hemiacetals of α-bromoacetophenone break down by a class "e" mechanism where the leaving group is fully protonated before bond cleavage. The class "e" mechanism can be excluded for the aryl derivatives, since rate constants much greater then diffusion are required to explain the observed catalytic coefficients. The different mechanism is followed in order to avoid the fully protonated hemiacetal, which, being of an O-protonated anisole structure, is of very high energy.

Key words: hemiacetal kinetics, preassociation, intermediate lifetime.

ROBERT A. MCCLELLAND, V. M. KANAGASABAPATHY et N. MATHIVANAN. Can. J. Chem. **69**, 2084 (1991).

On a étudié la cinétique de la décomposition de sept hémi-acétals aromatiques, portant les substituants 4-OMe, 4-Me, 3-Me, H, 3-OMe, 4-Cl et 3-Cl, de l'α-bromoacétophénone (TOH). On a formé les hémi-acétals comme intermédiaires par bromation d'α-aryloxystyrènes en milieu aqueux; dans ces conditions, la décomposition des hémi-acétals est l'étape qui limite la vitesse globale de la réaction. Une décomposition catalysée par les bases présente des valeurs β de Brønsted élevées (0,8 à 1,0) et, de la même manière, des valeurs β_{lg} élevées (−0,8 à −1,0). On suggère que ces résultats sont causés par un mécanisme de pré-association dans lequel la perte d'un arylate, par l'intermédiaire impliqué dans la liaison hydrogène $TO^- \cdots HA$ est plus rapide que la séparation causée par la diffusion de la paire acide–base. Ce mécanisme est imposé par des temps de vie des hémi-acétals déprotonés, TO^-, qui sont de l'ordre de 10^{10} à 10^{12} s^{-1}. On a évalué ces temps de vie de deux façons indépendantes : par une extrapolation de données obtenues antérieurement pour des hémi-acétals aliphatiques de l'α-bromoacétophénone suivie d'un calcul basé sur les coefficients catalytiques expérimentaux et par des évaluations des constantes d'acidité du TOH et des constantes d'équilibre pour la formation de complexes impliquant des liaisons hydrogènes. Pour la décomposition qui ne dépend pas du pH, la valeur de $\beta_{lg} = -1{,}03$ et ce point se trouve prés de la ligne de Brønsted pour les catalyseurs carboxylates. Cette réaction se produit donc par un mécanisme de pré-association dans lequel l'eau agit comme catalyseur conduisant à la formation de $TO^- \cdots H_3O^+$ pour lequel la perte d'un arylate est plus rapide que la séparation due à la diffusion. Quel que soit le substituant du noyau aromatique, les constantes de vitesse pour les réactions catalysées par l'ion hydroxyde sont toutes égales à 8×10^9 M^{-1} s^{-1}. Cette valeur est égale à une rencontre de l'hémi-acétal et d'un ion hydroxyde dont la vitesse serait limitée par la diffusion et dont l'intermédiaire $TOH \cdots OH^-$ se transforme rapidement en produits. La décomposition acido-catalysée des hémi-acétals se produit par un mécanisme de classe « n » dans lequel l'acide aide au départ du phénol. La décomposition des hémi-acétals aliphatiques de l'α-bromoacétophénone se produit par un mécanisme de classe « e » dans lequel le groupe nucléofuge est complètement protoné avant le bris de la liaison. On peut exclure le mécanisme de classe « e » pour les dérivés aromatiques car des constantes de vitesse beaucoup plus grandes que la diffusion sont nécessaires pour expliquer les coefficients catalytiques observés. Le mécanisme différent est suivi afin d'éviter l'hémi-acétal complètement protoné qui, possédant une structure d'anisole O-protoné, possède une énergie très élevée.

Mots clés : la cinétique de hémi-acétals, pré-association, intermédiaire, temps de vie.



[Traduit par la rédaction]

Detailed kinetic studies of the general acid–base catalyzed breakdown of hydrates and hemiacetals have been carried out for a considerable period of time, and various kinetically equivalent mechanisms have been considered (1, 2). Based upon the analysis of structure–reactivity parameters, the general acid-catalyzed reaction has been suggested to proceed via the mechanism of eq. [1*a*], with base-catalyzed breakdown of the protonated hemiacetal as the rate-limiting step, while the general base reaction follows eq. [2*a*], with the rate-limiting step the acid-catalyzed breakdown of the hemiacetal conjugate base (3–5). These mechanisms are termed class "e" and class "n" respectively (2, 3), the catalyst acting on the electrophilic component, the carbonyl, in the acid reaction and the nucleophilic component, the alcohol, in the base reaction. Anal-

yses of energy contour diagrams (6), isotopic mapping (7), and vibrational calculations (8) have provided additional support for the general base mechanism, while the energy contour analysis suggests a slight modification in the acid mechanism (9). The hydroxide ion catalyzed reaction proceeds with pre-equilibrium deprotonation, as in the general base reaction, but RO^- likely departs with no assistance (eq. [2*b*]). The H_3O^+-catalyzed reaction likely follows the class e acid mechanism, with pre-equilibrium protonation and water acting as a general base (eq. [1*b*]]).

The above mechanisms were established through detailed studies of alkyl hemiacetals and hydrates of formaldehyde (3) and acetaldehyde (4), as well as hydrates of substituted benzaldehydes (5). We have been interested in the effect of structural changes that increase the free energy of the tetrahedral form relative to the breakdown products. Studies of the base-catalyzed breakdown of cyclic hemiacetals with phenol (10) and carboxylate (11) leaving groups have shown that the class n mechanism is no longer followed. With hemiorthoester tetrahedral intermediates derived from benzoic acid, the base-catalyzed reaction was found to still follow a class n type of mechanism, but with the proton transfer step rate-limiting (12, 13). This mechanism is enforced (2, 14) by the short lifetime of the anionic intermediate in respect to its breakdown by expulsion of RO^-, as in eq. [2*b*]. A situation similar to this was observed with the 2,2,2-trifluoroethyl hemiacetal of α- bromoacetophenone (15). With this system, a change in mechanistic behaviour from the normal type n reaction, with

X = 4-MeO, 4-Me, 3-Me, H, 3-MeO, 4-Cl, 3-Cl

the initial deprotonation rapid and reversible, to the mechanism with rate-limiting proton transfer occurred on changing the leaving alcohol from 2-chloroethyl to trifluoroethyl. This also was traced to the decreased lifetime of the anionic tetrahedral intermediate with trifluoroethoxide as the leaving group.

In this paper we report a further extension of the α-bromoacetophenone system to aryl hemiacetals. This structural change results in a further decrease in the lifetime of the deprotonated form of the hemiacetal, such that the general base-catalyzed breakdown nows occurs by a preassociation mechanism. It will also be argued that the acid reaction follows an alternative kinetically equivalent pathway, due to the high energy of the protonated tetrahedral intermediate of the class e mechanism.

Experimental section

α-Aryloxystyrenes were prepared by the reaction of aryl benzoates (16, 17) with Tebbe's reagent (18–20). In a typical procedure, titanocene dichloride (2.15 g, 8.6 mmol) and a toluene solution of trimethylaluminum (8.7 mL of 2 M solution, 17.2 mmol) were mixed and allowed to stand 3 days at room temperature under nitrogen. This solution was then transferred by syringe to a solution of the appropriate aryl benzoate (7.8 mmol) in 16 mL of rigorously dried toluene containing 80 μL of dry pyridine. The addition was carried out under nitrogen at −45°C; the reaction was maintained at this temperature for 45 min and then allowed to warm to room temperature. The reaction was quenched by the careful addition of 2.4 mL of 15% aqueous sodium hydroxide. The dark-red mixture was diluted with ether, dried over magnesium sulfate, and the solvent removed to furnish a dark oil. This oil was extracted three times with a small amount of hexane, the hexane fractions pooled, and the solvent removed. (Failure to perform this extraction resulted in difficulty in the chromatography, apparently due to the hexane-insoluble inorganic contaminants blocking the column.) The crude vinyl ether was purified on neutral alumina employing dry hexanes as eluant. The products were obtained as clear oils in yields ranging from 60 to 70%.

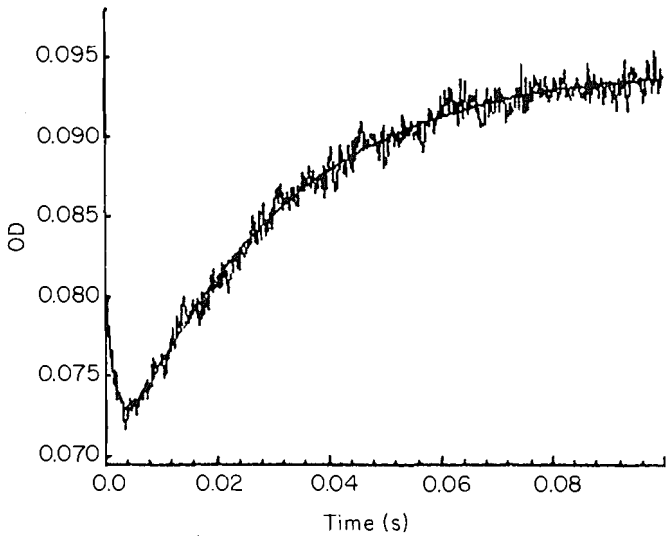
Kinetic experiments

A 2×10^{-5} M solution of the α-aryloxystyrene was dissolved in 0.002 M NaOH and mixed on a stopped-flow spectrophotometer with an equal volume of a solution containing 1.5×10^{-5} M bromine, 0.002 M HCl, and the appropriate buffer. The ionic strength was maintained at a concentration of 0.1 after mixing with NaCl, and the stopped-flow apparatus was thermostated at 25.0 ± 0.1°C. Since low concentrations of buffers were employed in many of the experiments, mixed samples were collected from the effluent of the stopped-flow apparatus and the pH recorded. Initial kinetic experiments were carried out with a Durrum–Gibson stopped-flow apparatus, as previously described (15). The later kinetic experiments were carried out with a High-Tech Scientific SF-51 stopped-flow apparatus interfaced with a Hewlett–Packard model 300 microcomputer. Increases in absorbance due to the formation of the product ketone α-bromoacetophenone were monitored at 250 nm. First-order rate constants were calculated from a least-squares fit to the general equation for an exponential process. Rate constants from replicate measurements agreed within ±3%.



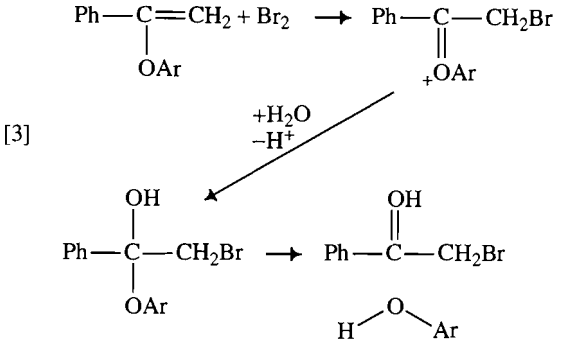


FIG. 1. Absorbance at 250 nm versus time on mixing a solution of 10 μM bromine, 0.002 M HCl, and a 1:1 HOAc:NaOAc buffer of total concentration 0.004 M with an equal amount of 20 μM α-(3-methoxyphenoxy)styrene in 0.002 M NaOH. The line drawn through the experimental data is the computer fit to a double exponential equation with exponents of 513 and 34.1 s^{-1} for the decreasing and increasing phases respectively.

Results

Generation of hemiacetals

The hemiacetals were generated by the aqueous bromination of α-aryloxystyrenes. This method of studying the kinetics of breakdown of hemiacetals was discussed previously in the context of α-alkoxystyrenes (22). The basis of the approach is that the two reaction stages preceding the decomposition of the hemiacetal are very fast. For α-alkoxystyrenes there was ample precedent. The bromination stage had been established to occur with a bimolecular rate constant approaching the diffusion limit (23), and the hydration of the oxocarbocations was also known to be very rapid (24–26). Thus, on mixing aqueous solutions of vinyl ether and bromine, the first two

[3]

stages occur very quickly, resulting in the buildup of the hemiacetal. The rate-limiting stage in the formation of the product α-bromoacetophenone is the breakdown of the hemiacetal, and rate constants measured by following the appearance of this ketone are the rate constants specifically for this stage.

With the α-aryloxystyrenes the bromination stage is possibly slower, since there is not as much stabilization of the incipient oxocarbocation. We were therefore initially concerned that the rate-limiting stage with these vinyl ethers may have shifted towards the first stage. However, the kinetic evidence suggested that this was not the case. In particular, the rate constants for the formation of the α-bromoacetophenone were independent of the initial concentrations of bromine, but did show general acid–base catalysis. Both these observations are consistent with rate-limiting hemiacetal breakdown and are not expected for rate-limiting bromination. It was in fact possible to observe with α-aryloxystyrenes with electron-withdrawing substituents a very rapid *decrease* in absorbance, which we presume represents the disappearance of vinyl ether in the bromination stage. A kinetic trace illustrating this is shown in Fig. 1. The absorbance decreases were extremely rapid, occurring with rates corresponding to half-lives of ~1 ms that are just at the limit of the stopped-flow apparatus. In fact a considerable portion of this decrease must have occurred in the 2-ms dead time, where it would have not have been observed. As shown in Fig. 1 the decrease was followed by a slower exponential *increase* in absorbance with the kinetic characteristics mentioned above consistent with hemiacetal breakdown. Thus, although the bromination stage may have been slowed somewhat, even with these compounds it is faster than hemiacetal breakdown.

One further note concerns the relative ratio of bromine and vinyl ether in the kinetic experiments. While with the α-alkoxystyrenes we had employed excess bromine, similar conditions with the α-aryloxystyrenes resulted in kinetic traces with drifting infinity absorbances. This was traced to a reaction of the excess bromine with the substituted phenol that is one of the products of the bromination of these vinyl ethers. This problem was not encountered when the kinetic experiments were carried out with α-aryloxystyrene in excess, such that the bromine was completely consumed in the first reaction stage.

Kinetics of the breakdown of hemiacetals

Kinetic experiments were carried out at 25.0°C and ionic strength 0.1 in solutions containing HCl, and chloroacetate,

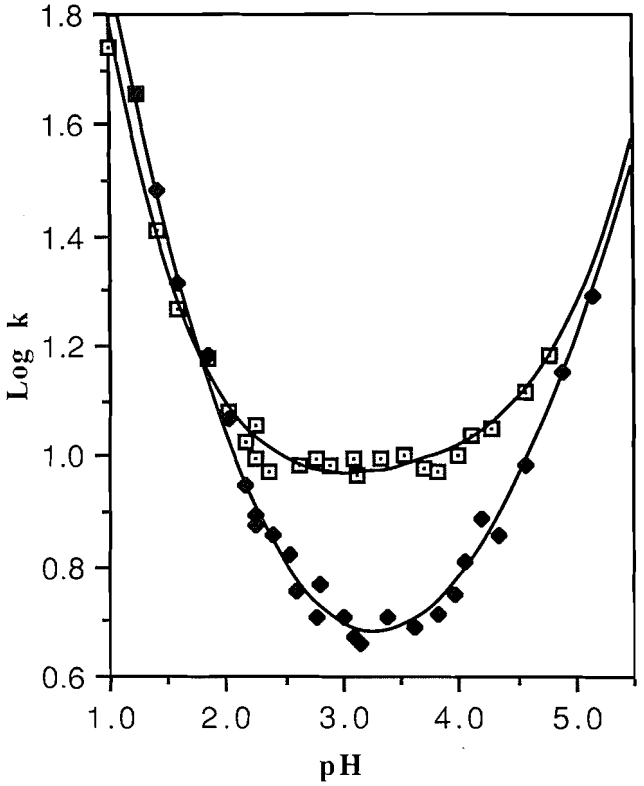

FIG. 2. Rate–pH profiles for the breakdown of α-bromoacetophenone hemiacetals: (⊡) phenyl; (◆) *p*-methoxyphenyl. Rate constants below pH 3 were measured in HCl solutions; above pH 3, they were determined by extrapolation to zero buffer concentration.

3-chloroproponiate, and acetate buffers. These buffers were chosen since they are unreactive towards bromine. More basic buffers could not be employed since rate constants associated with the catalysis by the base component became so large that, even at the minimal concentrations required to maintain buffering capacity, the observed rates were too fast for accurate measurement even by the stopped-flow technique. As noted in the previous section, an exponential increase in the absorbance of the α-bromoacetophenone was observed in each solution. First-order rate constants followed the rate law

$$[4] \quad k(\text{obs}) = k_{\text{H}}[\text{H}^+] + k_0 + k_{\text{OH}}[\text{OH}^-] + k_{\text{HA}}[\text{HA}] + k_{\text{A}}[\text{A}^-]$$

typical of hemiacetal breakdown. In all buffers the buffer dilution plots (k(obs) versus total buffer concentration) were excellently linear. This included chloroacetate and chloropropionate where quite high buffer concentrations could be employed. Rate–pH profiles based upon extrapolation to zero buffer concentration are shown for two of the systems in Fig. 2. Catalytic coefficients are listed in Table 1. There was pronounced catalysis by the base component of the buffer. This was particularly true for acetate buffers, a solution containing 0.001 M CH_3COO^-, for example, reacting with the phenyl hemiacetal with a contribution of 64 s^{-1} from the buffer alone. These accelerations made it difficult to obtain accurate intercepts in the buffer dilution plots in the more basic acetate buffers. These are the solutions where the term in hydroxide becomes important, and thus there were considerable errors in evaluating k_{OH}. In fact with the 3-MeO, 4-Cl, and 3-Cl systems this constant could not be evaluated with reliable precision.

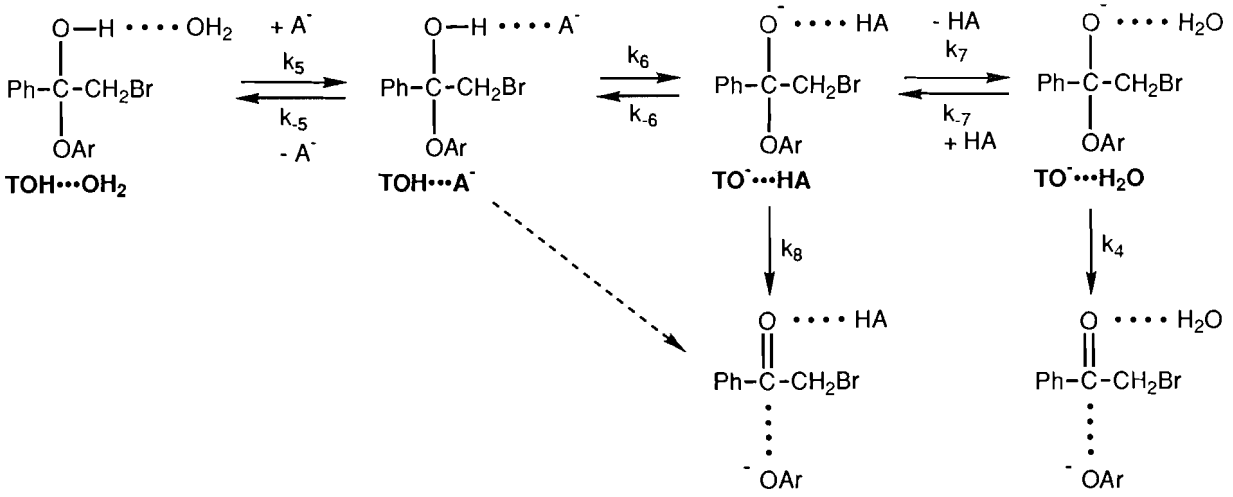
The lines are based upon linear regression including the water point.



Discussion

Mechanism of general base catalysis

The rate constants for base catalysis are strongly affected by both the substituent in the aryl ring and the nature of the catalyzing base. These features are illustrated in Figs. 3 and 4, which show respectively Brønsted-like plots of log k versus pK_a(ArOH), and Brønsted plots of log k versus the pK_a of the conjugate acid of the catalyzing base. Values of β_{lg} and β obtained from these correlations are given in Table 2. Both are large, having absolute magnitudes in the range 0.8–1.0. These are indicative of transition states in which there is almost complete proton transfer to the catalyzing base and, at the same time, substantial rupture of the C—OAr bond forming the aryloxide anion.

In the base catalysis of the breakdown of the alkyl hemiacetals of α-bromoacetophenone, the ethyl and chloroethyl derivatives proceed by the normal class n mechanism, but there is a change with the trifluoroethyl compound to a mechanism where the deprotonation step has become rate-limiting (15). The latter behaviour arises from a situation where the rate constant k_4 of eq. [2*b*] becomes very large with the good trifluoroethoxide leaving group, so that the hemiacetal anion, once it is formed, proceeds on to products faster than it can protonate and revert to the neutral hemiacetal. The occurrence of a rate-limiting proton transfer was indicated experimentally by a Brønsted β value near unity, with more compelling evidence being supplied by the observation of breaks in both the rate–

pH profile and buffer dilution plots. The latter are associated with a change in rate-limiting step at the higher concentrations of hydronium ion or the buffer acid, where protonation of the hemiacetal anion by the acid begins to compete with its breakdown. At very high acid concentrations deprotonation becomes reversible, and the rate-limiting step is the breakdown.

With the aryl hemiacetals the Brønsted β values are also large. However, there are no signs of breaks or curvature even with 0.5 M buffer acid. Moreover, the β_{lg} values imply that there is substantial aryloxide ion character in the transition state. A much smaller dependence on the nature of OAr is expected for a rate-limiting proton transfer, since the substituents are remote from the charged center in the hemiacetal anion. The implication is that yet another mechanistic behavior is being followed.

One clue comes in considering what the magnitude of the rate constant k_4, for breakdown of the hemiacetal anion, is likely to be with the aryloxide leaving groups. Values of this rate constant were obtained with the alkyl derivatives, and it was found that a plot of log k_4 versus the pK_a value of the leaving alcohol was linear, with a β_{lg} of −0.87 (15). The rate constants are provided in Table 3, where it can be seen that for the trifluoroethyl derivative k_4 is large, approaching 10^9 s^{-1}. With the assumption that the log k_4 – pK_a correlation extends to aryloxide leaving groups, values of k_4 can be estimated for the latter. These are also given in Table 3, where it can be seen that there is a further increase over the trifluoroethoxide k_4 by about two orders of magnitude to numbers in the 10^{11} s^{-1} range. With breakdown this fast, a further change in reaction mechanism is expected, to a preassociation mechanism (2).

In terms of acid–base catalysis a "preassociation mechanism" arises when the substrate molecule in a complex with the catalyst undergoes some reaction at a rate that is faster than the catalyst separates away by diffusion. The consequence is that the catalyst is associated with the substrate in the rate-limiting step of the overall reaction, although there is no proton transfer component to that step. Such a mechanism for hemiacetal breakdown is provided in Scheme 1. The species $TOH\cdots OH_2$ and $TO^-\cdots H_2O$ are the starting hemiacetal and conjugate base associated only with solvent water molecules, and the rate constant k_4 of eq. [2*b*] and Table 3 refers to the breakdown of the latter anion. Conversion of $TOH\cdots OH_2$ to $TO^-\cdots H_2O$ by reaction with a base such as carboxylate ion proceeds in three steps: step 5, diffusional encounter of the base and the hemiacetal to form the hydrogen-bonded complex $TOH\cdots A^-$; step 6, proton transfer within this complex to form a new hydrogen-bonded complex $TO^-\cdots HA$; and step 7, diffusional separation of TO^- and HA. When the proton transfer is in the thermodynamically unfavorable direction, as it is for a hemiacetal and $RCOO^-$, the rate-limiting step in this three-step sequence is the diffusional separation, step 7. This situation arises since the thermodynamically favorable proton transfer converting the complex $TO^-\cdots HA$ back to $TOH\cdots A^-$ is very fast, having virtually no barrier. Thus the rate constant k_{-6} is around 10^{13} s^{-1} and is greater than k_7, the rate constant for the diffusional separation. The consequence is that the species $TO^-\cdots HA$ forms reversibly from $TOH\cdots OH_2$ and A^-, most of the time reverting to $TOH\cdots A^-$. Net proton transfer only occurs on those occasions when the acid diffuses away. In a preassociation mechanism, breakdown of the complex $TO^-\cdots HA$ by expulsion of ArO^- (step 8 of Scheme 1) becomes faster than diffusional separation ($k_8 > k_7$). This provides a route to products that involves deprotonation by A^-, but does not require separation of the catalyst prior to the

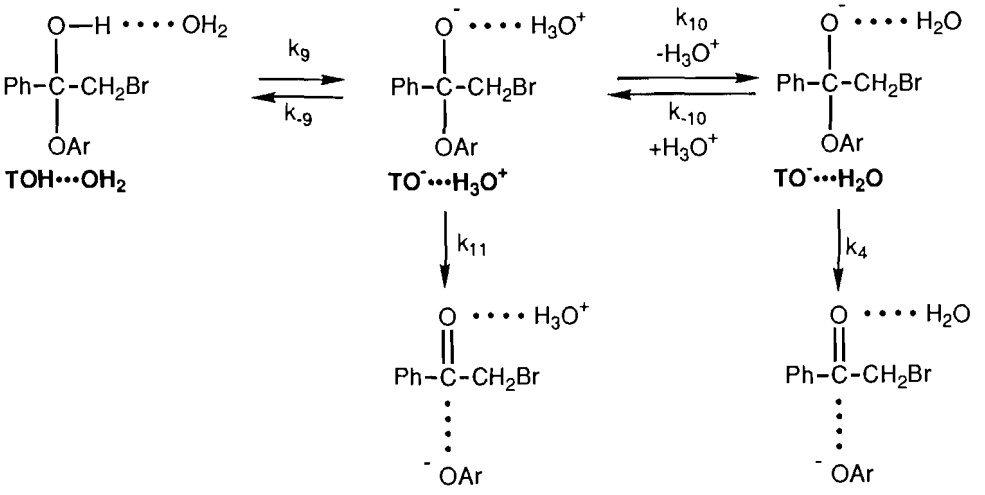
[g] Chloroacetic acid.
[h] Acetic acid.

C—O cleavage. There is still a barrier to the expulsion of ArO^-, so that $k_8 < k_{-6}$. Thus the rate-limiting step is the breakdown of the hydrogen-bonded complex $TO^-\cdots HA$, step 8, with the catalyst still associated with the substrate. If k_8 were to become greater than k_{-6}, the intermediate $TO^-\cdots HA$ would not exist and loss of ArO^- would be concerted with the proton transfer in $TOH\cdots A^-$ (see dashed arrow in Scheme 1).

Jencks has defined several criteria that point to a preassociation mechanism (2), and these are met with the aryl hemiacetals. Such mechanisms require that the Brønsted β values approach unity, since the proton is completely transferred in the transition state (although values exactly unity are not expected since the conjugate acid of the catalyzing base is present in the rate-limiting step and this can have a small effect (see below)). The rate-limiting step involves cleavage of the C—OAr bond, and thus there should be a substantial leaving-group effect, as is also observed. Finally, a preassociation mechanism is expected to have a larger rate constant than one calculated for an overall proton transfer to the catalyzing base. As argued above, the rate-limiting step for this proton transfer is the diffusional separation of $TO^-\cdots HA$. The preassociation mechanism short-circuits this and thus has a faster rate. This is also the case for the aryl hemiacetals. For example, for 3-chloropropionate removing a proton from the 4-chlorophenyl hemiacetal, a rate constant of $4 \times 10^2\ M^{-1}\ s^{-1}$ is calculated considering the relative acidities of the hemiacetal (see below for calculation) and 3-chloropropionic acid, and using $5 \times 10^9\ M^{-1}\ s^{-1}$ for the proton transfer in the reverse, thermodynamically favorable, direction $\{k(TOH\cdots OH_2 + A^- \rightarrow TO^-\cdots H_2O + HA) = 5 \times 10^9 \times K_a(TOH)/K_a(HA)\}$. The observed catalytic coefficient for the breakdown of this hemiacetal catalyzed by 3-chloropropionate is $5.5 \times 10^3\ M^{-1}\ s^{-1}$, over 10 times larger.

Preassociation mechanisms for base-catalyzed breakdown of a hemiacetal are expected in a rather narrow window of lifetimes of the hemiacetal anion. For such a mechanism to occur, the breakdown of this species must be faster than diffusional separation of $TO^-\cdots HA$, but slower than the reverse proton transfer. This requires that $k_8 > k_7$ and $k_8 < k_{-6}$. The value of k_7 should be around $10^{10}\ s^{-1}$ while k_{-6} should be around $10^{13}\ s^{-1}$. The estimates of $\sim 10^{11}\ s^{-1}$ arrived at by extrapolation of the data for the alkyl hemiacetal anions (Table 3) are obviously consistent with this idea. The following analysis provides additional support, and in fact shows that reasonable numbers for k_8 emerge by considering equilibrium constants expected for this system.



We first estimate the acidity constants of the hemiacetal ($K_a(TOH) = [TO^-][H^+]/[TOH]$, Table 3, using a previously described method. This involves the application of an equation of Hine and Koser (27) for carbonyl hydrates to provide the pK_a for the hydrate of α-bromoacetophenone, statistically correcting this number to obtain a value of the ethyl hemiacetal, and then assuming that a correlation of $pK_a(TOH)$ with $pK_a(ROH)$ has a slope of 0.2 (3, 4, 15). The constant $pK_a(ROH)$ refers to the acidity constant of the alcohol or phenol leaving group. The acid and base that are referred to in the acidity constant $K_a(TOH)$ are the species $TOH\cdots OH_2$ and $TO^-\cdots H_2O$ of Scheme 1, the hemiacetal and conjugate base solvated by water, and the following relationship with the equilibrium constants of the individual steps then applies

$$[5] \quad K_5K_6K_7 = K_a(TOH)/K_a(HA)$$

where $K_a(HA)$ is the acidity constant of the buffer acid HA. The constants K_5 and K_7 refer to equilibria involving the formation or breakdown of hydrogen-bonded complexes in water. To estimate these we have made use of a general equation suggested by Stahl and Jencks (28), as modified from an original proposal of Hine (29). This equation is based upon observations that the strengths of hydrogen-bonded complexes in water follow Brønsted relationships in the acidities and basicities of the two pairs of reagents. The third equilibrium constant K_6 refers to proton transfer within the hydrogen-bonded complexes. This can be calculated from K_5 and K_7 using eq. [5].

For the processes in Scheme 1 the inequality $k_{-6} > k_7 + k_8$ applies, as discussed previously. Moreover, with k_4 of the order of magnitude suggested by the extrapolation from the alkyl series, the intermediate $TO^-\cdots H_2O$, if it forms, must proceed on to products. This corresponds to a situation $k_4 > k_{-7}[HA]$, and it can be seen that even if [HA] were to approach 1 M, the inequality would hold. Thus, in terms of Scheme 1, proton transfer to a buffer base A^- can result in products in two ways, through breakdown of $TO^-\cdots HA$ by the pathway of step 8, or through diffusional separation to form $TO^-\cdots H_2O$

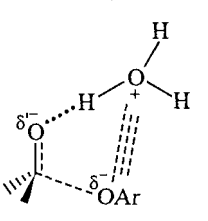
SCHEME 2

and HA···OH_2, followed by the rapid breakdown of the former by step 4. Since $TO^- \cdots HA$ forms reversibly,

[6] Rate = k_A(obs)[TOH][A^-] = $\{(k_7+k_8)K_5K_6\}$[TOH][A^-]

and the catalytic coefficient for general base catalysis is equal to $(k_7+k_8)K_5K_6$. As discussed in the previous paragraph, values of the two equilibrium constants can be calculated. The rate constant k_7 can also be estimated from the relationship $K_7 = k_7/k_{-7}$ using a value for k_{-7}, the rate constant for diffusional encounter of TO^- and HA, of 5×10^9 M^{-1} s^{-1} (30, 31). Thus only k_8 remains, and this can be calculated from the experimentally determined catalytic coefficients.

Results of these calculations are illustrated in Table 4, where it can be seen that the numbers so produced are consistent with the requirements of the preassociation mechanism. The values of k_8 are greater than k_7, and, moreover, lie in the range expected on the basis of the extrapolation from the alkyl hemiacetals (compare to k_4 values in Table 3). The values of k_8 also show a small effect due to the presence of HA, and this is expected. The hydrogen bond involving the oxygen and HA effectively disappears in the breakdown of $TO^- \cdots HA$, since the interaction of a carboxylic acid and a weakly basic C=O is very weak. Thus there should be a negative Brønsted α for the actual breakdown step. In fact the α values calculated using the rate constants k_8 given in Table 4 lie in the range from −0.10 to −0.15, typical of hydrogen-bonded complexes (28, 32).

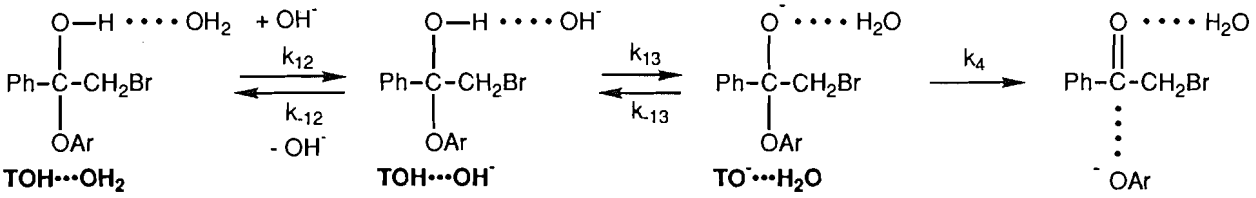


Water catalysis

The β_{lg} values for the pH-independent reaction is −1.03, similar to values for the carboxylates (Fig. 3). Moreover, the rate constant fits reasonably well along with the carboxylates on the Brønsted plot for base catalysis (Fig. 4). The conclusion therefore is that the pH-independent reaction is similar to that of the carboxylates, a preassociation with water acting as a general base. Such a mechanism is shown in Scheme 2. Proton transfer within the hydrated hemiacetal TOH···OH_2 produces the hydrogen-bonded ion pair $TO^- \cdots H_3O^+$, and breakdown of this species before diffusional separation of TO^- and H_3O^+ would correspond to a preassociation reaction exhibiting pH-independent kinetics. Using arguments similar to those discussed in the previous section, the rate law for this scheme is

[7] Rate = k_0[TOH] = $(k_{10} + k_{11})K_9$[TOH]

where the reversibly formed intermediate $TO^- \cdots H_3O^+$ proceeds on to products either by direct breakdown via step 11, or through diffusional separation of the two ions. As argued previously, if $TO^- \cdots H_2O$ forms, it will proceed to products faster than it will protonate. The back proton transfer in $TO^- \cdots H_3O^+$ is also extremely fast so that the formation of this species from TOH···OH_2 is reversible ($k_{-9} > k_{10} + k_{11}$).



Using procedures similar to above, values of the individual rate constants can be estimated. This is illustrated here for the phenyl hemiacetal. The equilibrium constant $1/K_{10}$ for formation of the hydrogen-bonded complex $TO^- \cdots H_3O^+$ is calculated as 6.7 M^{-1} using the equation of Stahl and Jencks. This in turn provides $K_9 = 4.4 \times 10^{-11}$ through the relationship K_a(TOH) = K_9K_{10}, and $k_{10} = 3.0 \times 10^9$ s^{-1} through the relationship $K_{10} = k_{10}/k_{-10}$ using $k_{-10} = 2 \times 10^{10}$ M^{-1} s^{-1} (30). The experimental $k_0 = 9$ $s^{-1} = (k_{10}+k_{11})K_9$ from eq. [7], from which k_{11} is calculated as 2.0×10^{11} s^{-1}. As with the carboxylates, this rate constant is indeed found to be significantly larger than the rate constant k_{10} for diffusional separation, consistent with a preassociation mechanism. Moreover, the value is within the range expected on the basis of the extrapolation from the alkyl compounds. Interestingly, k_{11} is calculated to be larger than k_8, the rate constant for breakdown within the complex $TO^- \cdots HA$. A number of assumptions have gone into these calculations, so that this difference may not be real. It can, however, be explained by a stabilizing electrostatic interaction (33) between the spectator H_3O^+ and the departing aryloxide in the transition state for breakdown of $TO^- \cdots H_3O^+$.

Hydroxide ion catalysis

The mechanism for this reaction, shown in Scheme 3, is analogous to those of the carboxylates and water, with hy-

For personal use only.

SCHEME 3

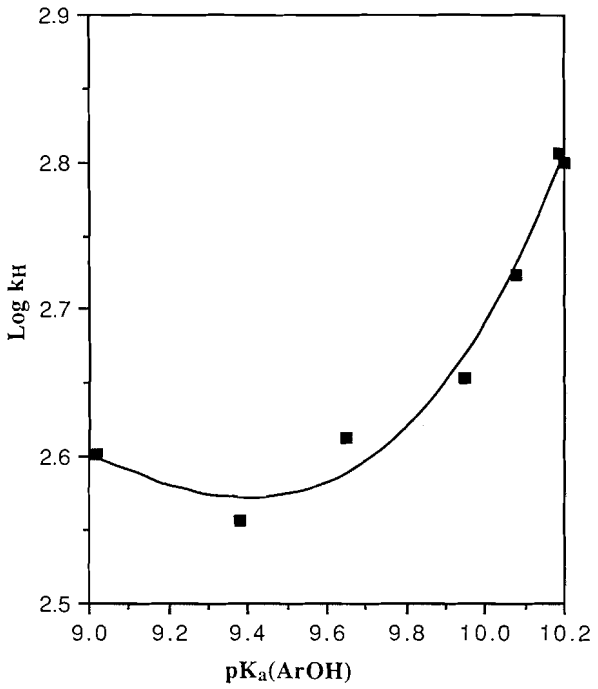
droxide ion functioning as the base catalyst. There is, however, an important difference, in that step 12, the formation of the initial hydrogen-bonded complex TOH···OH^- is now the rate-limiting step in the overall reaction. This situation arises since the proton transfer, TOH···OH^- → TO^-···H_2O, has become thermodynamically favored with the much stronger base. Thus k_{13} is greater than k_{-12} that is, proton transfer within TOH···OH^- occurs faster than the diffusional separation of TOH and OH^-. Furthermore, k_{-13} can be estimated to be around 10^9 s^{-1}, smaller than k_4, so that TO^-···H_2O, once it is formed, goes on to products. (To calculate k_{-13}, K_{12} was calculated using the Stahl and Jencks equation, K_{13} from the relation $K_{12}K_{13} = K_a(TOH)/K_w$, and k_{-13} from K_{13} using $k_{13} = 10^{13}$ s^{-1}.) Thus once TOH···OH^- forms, it will proceed on to products faster than the hydroxide can diffuse away. The consequence is that the catalytic coefficient for hydroxide ion is simply equal to k_{12}, the rate constant for diffusional encounter of OH^- and TOH. The experimental values are 8×10^9 M^{-1} s^{-1}, independent of the aryl substituent, consistent with this interpretation.

Lifetimes of hemiacetal anions

Within the series of α-bromoacetophenone hemiacetals we have now seen a progression from a normal class n mechanism to a mechanism with rate-limiting proton transfer, essentially the reverse of a "trapping" mechanism (2, 15), to a preassociation mechanism, as the lifetime of the conjugate base of the hemiacetal decreases with better leaving groups. Further decreases in lifetime are still possible. For example, the anion of the 4-nitrophenyl hemiacetal is estimated to have a rate constant of k_4 of 2×10^{13} s^{-1}, while with acetate as leaving group k_4 is estimated to be 10^{15} s^{-1}. Both of these numbers are greater than the rate constant for a vibration, and thus the anion in each case cannot exist. With these systems, therefore, proton transfer and C—OR bond cleavage will be concerted and TOH···A^- will proceed directly to the product without the intermediacy of TO^-···HA, as illustrated by the dashed arrow of Scheme 1. There is precedence for this from a study of the breakdown of a cyclic hemiacylal, where it was concluded that proton transfer to a base and loss of carboxylate were concerted (11).

Acid catalysis

Because of the very efficient base catalysis and the limitations on the buffers that can be employed with bromine, data were obtained for acid catalysis with only one buffer acid, chloroacetic acid, as well as H_3O^+. A plot of log k_H for the latter catalysis versus pK_a(ArOH) is curved, with rate acceleration for the hemiacetals with electron-donating substituents but, then, little change with the electron-withdrawing ones (Fig. 5). There are insufficient data to make a conclusive statement about such a plot for chloroacetic acid, although there again appears to be acceleration by electron donors. Based upon the two catalysts, the Brønsted α is 0.20–0.25. The catalysts are of different charge type, so that this must be regarded as an approximation. A reasonable conclusion is that α is low.



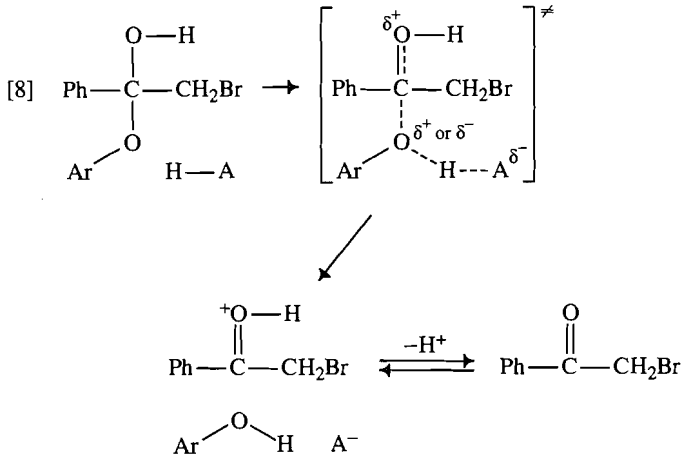


FIG. 5. Brønsted-type correlation of rate constants for H_3O^+ catalysis with the acidity constant of the leaving phenol for the breakdown of hemiacetals of α-bromoacetophenone.

One conclusion that can certainly be made is that these catalysts are *not* acting by the class e mechanisms of eq. [1]. This statement is made on considering the values expected for $K_a(SH^+)$, the acidity constant for the hemiacetal protonated on the phenolic oxygen. Acidity constants for protonated aromatic ethers are in fact not known, since anisole and its derivatives C-protonate in concentrated acids to form resonance-stabilized cyclohexadienyl cations (34, 35). If the simple assumption is made that the onium ions $CH_3CH_2OH_2^+$ and $PhOH_2^+$ have the same difference in pK_a as is observed for deprotonation of the neutral acids CH_3CH_2OH and C_6H_5OH, then pK_a for $PhOH_2^+$ is about −8, since the value for $CH_3CH_2OH_2^+$ is −2 (36). The protonated hemiacetal of this study has additional electron-withdrawing substituents; the OH group, for example, will have an effect of 2–2.5 pK_a units on its own (37). The consequence is that $pK_a(SH^+)$ for the phenyl hemiacetal can be estimated to be −11. To account for the experimental catalytic coefficients with such a number, the rate constant of k_1 of eq. [1] must be 2×10^{15} M^{-1} s^{-1} for chloroacetate, and k_2, 5×10^{13} s^{-1}. Both these rate constants are well above the diffusional limit, particularly k_1, which cannot be greater than $\sim 10^{10}$ M^{-1} s^{-1}. Thus, even if the acidity constant $K_a(SH^+)$ has been overstimated, the class e mechanism cannot apply.

This leaves the alternative class n mechanism (1, 3), in which the acid catalyzes the departure of the substituted phenol. This mechanism is directly analogous to that of a general acid-catalyzed hydrolysis of a full acetal, for which proton

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

transfer is concerted with C—OR bond cleavage forming an intermediate oxocarbocation (38). Interestingly, for acetals such as benzaldehyde aryl methyl acetals with aryl leaving groups (39), plots of log k versus pK_a(ArOH) are curved in the same manner as observed in this study.

This class n mechanism for the hemiacetal can be considered to be forced on the system by the very high energy of the fully protonated species, coupled with the ease of cleavage of the C—OAr bond. As shown in eq. [8], the oxygen of the leaving group can bear a partial positive charge or a partial negative charge in the transition state depending on whether proton transfer or bond cleavage has progressed to the greater extent. The curved pK_a(ArOH) correlation observed for H_3O^+ catalysis (Fig. 5) indicates that the actual situation depends on substituent, proton transfer being more important for the electron donors but then, with better leaving groups, bond breaking catching up. The low α value indicates that not a great deal of proton transfer is in fact required to reach the transition state.

Conclusion

Phenols or phenolates as leaving groups in the breakdown of α-bromoacetophenone hemiacetals result in dramatically different mechanistic behavior from that observed with simple alkyl derivatives. The changes are a direct consequence of the effect of the phenyl ring on the energies and lifetimes of important reaction intermediates. General base catalysis and water catalysis occur by preassociation mechanisms, in which a hydrogen-bonded intermediate loses aryloxide faster than diffusional separation of acid–base pair. This mechanism is enforced by the short lifetime of the hemiacetal anion when it has an aryloxide leaving group. Acid catalysis occur by a class n mechanism in which the acid assists departure of the phenol. Alkyl hemiacetals break down by class e mechanisms where the leaving group is fully protonated before bond cleavage. The different mechanism with the aryl hemiacetals avoids this intermediate, which, being of an O-protonated anisole structure, is of very high energy.

PATRIZIO CECCHI, ADRIANO PIZZABIOCCA, GABRIELE RENZI, CINZIA SPARAPANI, and MAURIZIO SPERANZA. Can. J. Chem. **69**, 2094 (1991).

The gas-phase methylation of 2- and 3-methyl-pyrroles (**2P** and **3P**), -furans (**2F** and **3F**), and -thiophenes (**2T** and **3T**) by $(CH_3)_2F^+$ ions, from γ radiolysis of CH_3F, has been investigated at pressures ranging from 50 to 760 Torr, in the presence of a thermal radical scavenger (O_2) and variable concentrations of an added base (NMe_3: 0–10 Torr). The mechanism of the methylation process is discussed and the intrinsic positional selectivity of the $(CH_3)_2F^+$ ions evaluated in the framework of the Charge and Frontier Orbital Control concept. Owing to the very large energy gap between the LUMO of $(CH_3)_2F^+$ and the HOMOs of the selected heteroaromatic substrates, their gas-phase methylation is characterized by a distinct affinity of the ionic electrophile toward those substrate positions with the highest net negative charge, i.e., the C3 in **2P** (100%), the C4 in **3P** (100%), the heteroatom of **2F** and **3F** (>80%), the C5 of **2T** (32%), and the C2 of **3T** (47%). Analysis of the methylated product distribution from **2F** and **3F** as a function of the experimental conditions reveals that the interaction of the $(CH_3)_2F^+$ with the heteroatom of furans gives rise to the reversible formation of two sets of electrostatic adducts, i.e., a "chelate" adduct (**III**) and a single proton-bonded adduct (**IV**), the first rapidly evolving to the α-substituted heteroarenium intermediate by proximity effects and the latter slowly rearranging to the chelate structure **III**. Formation of these categories of electrostatic adducts from furans, which is much less extensive in the case of thiophenes and absent in pyrroles, accounts for the apparent pronounced affinity of gaseous alkylating electrophiles, irrespective of their LUMO energy, for the α carbons of furans.

Key words: gas-phase ion chemistry, electrophilic aromatic substitutions, radiolysis, dimethylfluoronium ions, methylated heteroarenes.

PATRIZIO CECCHI, ADRIANO PIZZABIOCCA, GABRIELE RENZI, CINZIA SPARAPANI et MAURIZIO SPERANZA. Can. J. Chem. **69**, 2094 (1991).

Opérant à des pressions allant de 50 à 760 Torr, en présence d'un piège thermique à radicaux (O_2) et à des concentrations variables de base ajoutée (NMe_3 : 0–10 Torr), on a étudié la méthylation en phase gazeuse des 2- et 3-méthyl-pyrroles (**2P** et **3P**), -furanes (**2F** et **3F**) et -thiophènes (**2T** et **3T**) par les ions $(CH_3)_2F^+$ obtenus par radiolyse γ du CH_3F. On discute du mécanisme du processus de méthylation et on a évalué la sélectivité positionnelle intrinsèque des ions $(CH_3)_2F^+$ à l'aide du concept du contrôle de la charge et des orbitales frontières. À cause de la grande différence d'énergie entre l'OM BV du $(CH_3)_2F^+$ et les OM HO des substrats hétéroaromatiques choisis, leur méthylation en phase gazeuse est caractérisée par une affinité distincte de l'électrophile ionique pour les positions du substrat qui portent les charges négatives nettes les plus élevées, soit les positions C3 du **2P** (100%), C4 du **3P** (100%), C5 du **2T** (32%), C2 du **3T** (47%) et l'hétéroatome de **2F** et **3F** (>80%). L'analyse de la distribution des produits de méthylation des produits **2F** et **3F** en fonction des conditions expérimentales révèle que l'interaction entre le $(CH_3)_2F^+$ et l'hétéroatome des furanes donne lieu à la formation réversible des deux ensembles d'adduits électrostatiques, soit un adduit de nature «chélatée» (**III**) et un adduit liant un seul proton (**IV**); sous l'influence d'effets de proximité, le premier évolue rapidement vers une intermédiaire hétéroarénium α-substitué alors que le second se transpose lentement vers la structure chélatée **III**. La formation de ces catégories d'adduits électrostatiques avec les furanes, qui est beaucoup moins importante dans le cas des thiophènes et qui est absente avec les pyrroles, permet d'expliquer l'affinité apparemment très prononcée des électrophiles alkylants gazeux, quelle que soit l'énergie de leur OM BV, pour les carbones α des furanes.

Mots clés : chimie ionique en phase gazeuse, substitutions aromatiques électrophiles, radiolyse, ions diméthylfluoronium, hétéroarènes substitués.

[Traduit par la rédaction]

Introduction

In the preceding papers of this series, the intrinsic reactivity features of unsubstituted five-membered heteroaromatic rings toward a variety of alkylating cations have been evaluated in the dilute gas state, i.e., in a reaction environment entirely free from those complicating factors, such as solvation, ion pairing, etc., which normally prevent meaningful kinetic measurements of the same processes in solution (2). The emerging reactivity picture is consistent with quantitative predictions based upon a simplified version of the Shaik and Pross Curve Crossing model (3), whose quantitative applicability till now appears restricted exclusively to gas-phase alkyl-cation additions to five-membered heteroaromatic rings (1).

In the gas-phase alkylation of heteroarenes by onium ions,

such as the dimethylfluoronium ion $(CH_3)_2F^+$ (4), the mode of attack of the electrophile cannot be regarded as a genuine addition process, such as for carbenium ions, but rather as a nucleophilic displacement. As a consequence, the simplified version of the Curve Crossing model used in the preceding paper of this series for rationalizing gas-phase addition of carbenium ions to heteroarenes (1) hardly applies in this case since the model neglects the contribution of the leaving CH_3F moiety to the activation barrier of the $(CH_3)_2F^+$ methylation of the heteroaromatic substrate.

To enlarge the experimental kinetic evidence on which to base any verification of the applicability of the Curve Crossing model (3) to $(CH_3)_2F^+$ ion attack on heteroarenes, the investigation has been now extended to estimating the reactivity features of the onium electrophile toward 2- (**2P**) and 3-methylpyrrole (**3P**), 2- (**2F**) and 3-methylfuran (**3F**), and 2- (**2T**) and 3-methylthiophene (**3T**). It is expected that this study will allow a first experimental assessment of the reactivity and orienting properties of the selected heteroaromatic substrates toward a typical Friedel–Crafts methylating reactant, the $(CH_3)_2F^+$ ion (5). In fact, any attempt to kinetically investigate the same process in the condensed phase under Friedel–Crafts conditions has met with no success to date.

Furthermore, additional interest is attached to $(CH_3)_2F^+$ regarding the nature and the stability of the primary adducts generated from the interaction of the gaseous electrophile with the heteroatom of furans and thiophenes (2). It was, indeed, generally observed, at variance with the behavior of pyrroles and with model predictions (1), that these substrates undergo predominant α substitution from alkylating electrophiles, either alkyl carbenium and alkyl onium ions, irrespective of their LUMO energy. A comparative analysis of the positional selectivity of $(CH_3)_2F^+$ toward isomeric methyl-furans and -thiophenes may help in elucidating the origin of the surplus of α substitution observed for this class of heteroaromatics in the gas phase.

The kinetic approach adopted in this study has been already presented (4). It is based upon the preparation of stationary concentrations of $(CH_3)_2F^+$ ions from γ-radiolysis of CH_3F gaseous mixtures, containing an effective thermal radical scavenger, i.e., O_2. Their attack on selected methylheteroarenes is investigated under conditions, i.e., 50–760 Torr (1 Torr = 133.3 Pa) and presence of a powerful cation trap (NMe_3: 0–10 Torr), ensuring efficient collisional thermalization and rapid deprotonation of the onium reactant and its daughter heteroarenium intermediates, whose isomeric distribution can therefore be determined from the relative abundance of the corresponding alkylated neutral derivatives.

Experimental section

Materials

Methyl fluoride (>99%), oxygen (>99.99%), and trimethylamine (>99%) (Matheson Co.) were used without further purification. 2-, 3-Methylthiophene, 2,5-dimethylthiophene, 2-methylfuran, 2,5-dimethylfuran, and 2,5-dimethylpyrrole were research grade chemicals from Aldrich Chemical Co. 2,3-, 2,4-, and 3,4-Dimethylthiophene (6), 3-methylfuran (7), 2,3- (8), 2,4- (9), 3,4-dimethylfuran (10), 2- (11), 3-methylpyrrole (12), 2,3- (13), 2,4- (14), 3,4- (15), 1,2- (16), an 1,3-dimethylpyrrole (17) were prepared according to established procedures. All these compounds were purified by preparative GLC on the same columns employed in the analysis of the reaction mixture and their identity checked by conventional mass spectrometric and NMR analyses.

Procedure

The procedure for the preparation of the radiolytic samples has previously been reported (4). Typical experimental conditions were as follows: CH_3F, 50–760 Torr; heteroaromatic substrate, 0.5–2.0 Torr; O_2, 5 Torr; NMe_3, 0–10 Torr. The irradiations were carried out at 37.5°C in a 220 Gammacell from Nuclear Canada Ltd. to a dose of 1.5×10^4 Gy at a rate of 5×10^5 Gy h^{-1}, as determined by a Fricke dosimeter. Control experiments, carried out at doses ranging from 1×10^4 to 1×10^5 Gy, showed that the relative yields of products are largely independent of the dose. The analysis of the irradiated mixtures was performed with a Perkin–Elmer Sigma 1B or a Hewlett–Packard 5730 gas chromatograph equipped with a flame ionization detector. The following columns were employed: (*i*) a 6 m long, 2 mm i.d. glass column, packed with SP 1200:Bentone 34 5%:1.75% on 80–100 mesh Supelcoport, operated at temperatures ranging from 80 to 90°C, 1°C min^{-1}; (*ii*) a 50 m long, 0.2 mm i.d. fused silica WCOT-UCON LB 550X capillary column, operated at 60°C; (*iii*) a 3.5 m long, 2 mm i.d. glass column, packed with 5% Carbowax 20M on 80–100 Carbopack, operated at temperatures ranging from 120 to 130°C, 1°C min^{-1}; (*iv*) a 30 m long, 0.32 mm i.d. stainless steel Carbowax 20M column, operated at 100°C.

The products were identified by comparison of their retention volumes with those of authentic standard compounds and their identity confirmed by GLC–MS (Hewlett–Packard 5988A). Their yields were measured from the area of the gas chromatographic elution peaks, using individual calibration factors.

Results

Gas-phase attack of radiolytic $(CH_3)_2F^+$ ions on 2- (**2P**) and 3-methylpyrrole (**3P**) yields the corresponding β-methylated derivatives, namely 2,3- (**23P**) and 3,4-dimethylpyrrole (**34P**), respectively, as the only detectable methylation products. Their absolute yield, expressed as the number of molecules M produced per 100 eV of energy absorbed by the gaseous mixture ($G_{(M)}$ values), was measured under various experimental conditions, at the constant temperature of 37.5°C and for the total dose of 1.5×10^4 Gy (dose rate: 5×10^5 Gy h^{-1}). For both substrates, the $G_{(M)}$ value of the corresponding β-methylated derivative, measured in the absence of added bases (NMe_3), is found to decrease at low pressure, ranging from ca. 0.3 at 760 Torr to ca. 0.1 at 50 Torr. At 760 Torr and in the presence of NMe_3, the absolute yields of **23P** from **2P** and of **34P** from **3P** decrease significantly, dropping by a factor ranging from 10 to 20 at the highest base concentration (10 Torr). Under these conditions, however, the sharp decrease of the β-methylated derivatives of **2P** and **3P** is in part counterbalanced by the formation of appreciable amounts of the corresponding β-*N*,*N*-dimethylaminomethyl derivatives, whose $G_{(M)}$ value is found to increase from ca. 0.02, at $P(NMe_3) = 1$ Torr, to ca. 0.12, at $P(NMe_3) = 10$ Torr.

Dimethylfluoronium ion attack on 2-methylfuran (**2F**) produces all the expected methylated derivatives, namely 2,3- (**23F**), 2,4- (**24F**), and 2,5-dimethylfuran (**25F**), but no detectable formation of the 3,4-dimethylated isomer (**34F**) is observed. Their overall $G_{(M)}$ value, measured in the absence of added NMe_3, increases from 1.2 at 760 Torr to 2.1 at 50 Torr. In the presence of variable concentrations of NMe_3, the overall $G_{(M)}$ value of the methylated products sharply decreases, levelling off to ca. 0.002 at $P(NMe_3) = 10$ Torr. No concomitant formation of *N*,*N*-dimethylaminomethyl derivatives of **2F** is observed, at variance with the behavior of pyrroles **2P** and **3P**. A similar picture arises from the $(CH_3)_2F^+$ ion attack on 3-methylfuran (**3F**), which leads to the exclusive formation of **23F**, **24F**, and **34F**.

Similarly, dimethylfluoronium ion methylation of 2- (**2T**) and 3-methylthiophene (**3T**) yields the corresponding methylated derivatives, namely 2,3- (**23T**), 2,4- (**24T**), and 2,5-dimethylthiophene (**25T**) (from **2T**) and 2,3- (**23T**), 2,4- (**24T**),

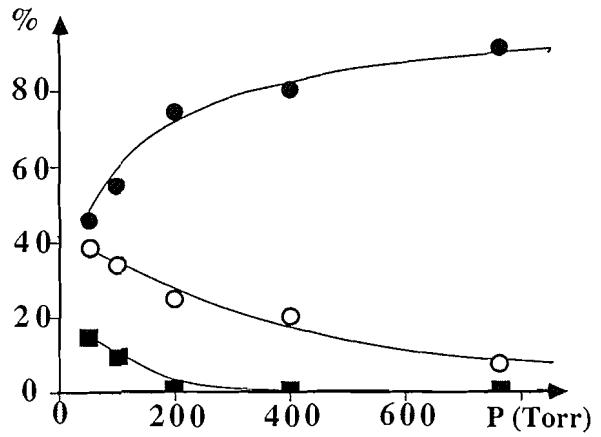

FIG. 1. Relative yields of isomeric dimethylfurans from $(CH_3)_2F^+$ attack on 2-methylfuran **2F** as a function of the total pressure (P) of the system in the absence of NMe_3: 2,5-dimethylfuran (**25F**, full circles); 2,3-dimethylfuran (**23F**, open circles); 2,4-dimethylfuran (**24F**, full squares).

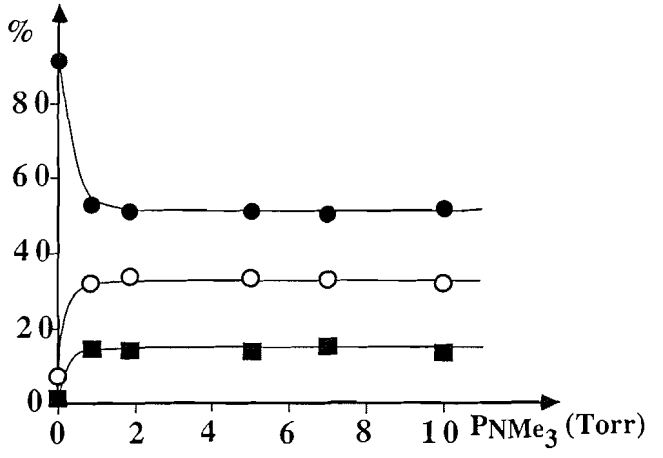

FIG. 2. Relative yields of isomeric dimethylfurans from $(CH_3)_2F^+$ attack on 2-methylfuran **2F** at 760 Torr as a function of the partial pressure of NMe_3 ($P(NMe_3)$): 2,5-dimethylfuran (**25F**, full circles); 2,3-dimethylfuran (**23F**, open circles); 2,4-dimethylfuran (**24F**, full squares).

and 3,4-dimethylthiophene (**34T**) (from **3T**). Their overall $G_{(M)}$ value, measured in the absence of NMe_3, increases from ca. 0.7 at 760 Torr to ca. 1.5 at 50 Torr. A dramatic lowering of the overall $G_{(M)}$ value of the methylated products is determined by addition of NMe_3 to the gaseous mixtures, a decrease by a factor of over 5 being observed at $P(NMe_3)$ = 10 Torr. In analogy with the results from isomeric methylfurans, no appreciable amounts of N,N-dimethylaminomethyl derivatives of **2T** and **3T** are formed in the irradiated mixtures with NMe_3.[4]

The isomeric distributions of the products from $(CH_3)_2F^+$ methylation of methylfurans and methylthiophenes were measured under largely different experimental conditions and are reported in Figs. 1–8. The relative yields of the methylated products from both isomeric methylfurans and methylthiophenes markedly depend upon the total pressure of the system (Figs. 1, 3, 5, and 7) and the presence of the added NMe_3 (Figs.

[4]The absolute and relative yields of products have an uncertainty level of ca. 10%.

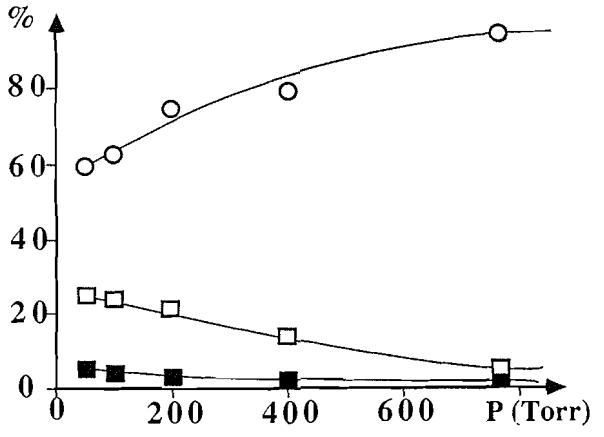

FIG. 3. Relative yields of isomeric dimethylfurans from $(CH_3)_2F^+$ attack on 3-methylfuran **3F** as a function of the total pressure (P) of the system in the absence of NMe_3: 2,3-dimethylfuran (**23F**, open circles); 3,4-dimethylfuran (**34F**, open squares); 2,4-dimethylfuran (**24F**, full squares).

FIG. 4. FIG. 8. Relative yields of isomeric dimethylthiophenes from $(CH_3)_2F^+$ attack on 3-methylthiophene **3T** at 760 Torr as a function of the partial pressure of NMe_3 ($P(NMe_3)$): 2,3-dimethylthiophene (**23T**, open circles); 3,4-dimethylthiophene (**34T**, open squares); 2,4-dimethylthiophene (**24T**, full squares).

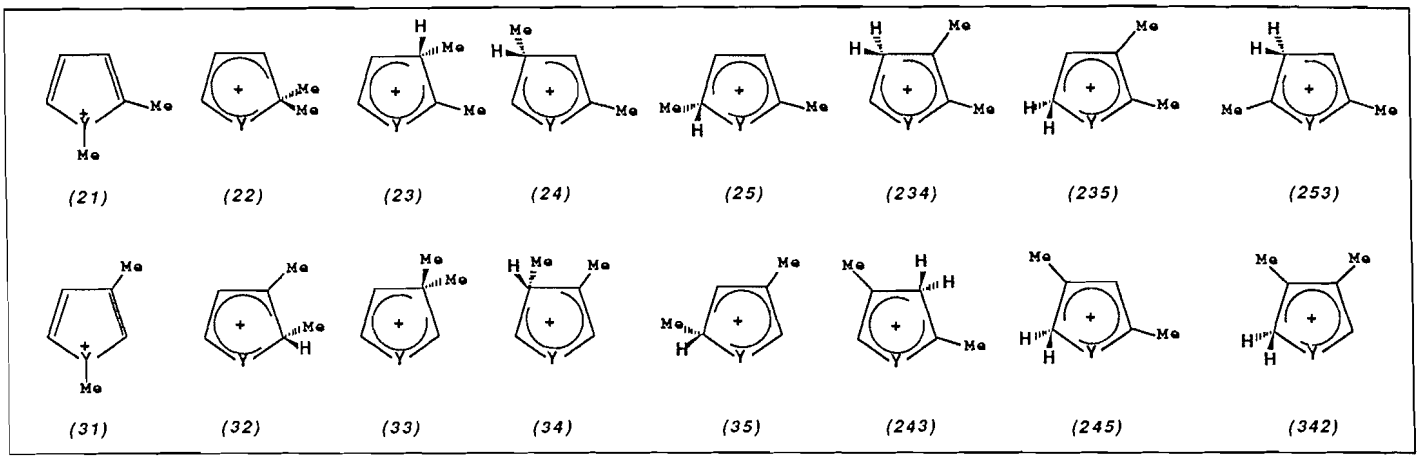
2, 4, 6, 8). In fact, a **25F**:**23F**:**24F** = 53%:33%:14% distribution is observed in the **2F** systems irradiated at 760 Torr in the presence of NMe_3 (Fig. 2). At the same pressure, but in the absence of added bases, the product composition changes dramatically to **25F**:**23F**:**24F** = 92%:7%:1% (Fig. 2). A decrease of the total pressure of the gaseous mixture leads again to an increase of the relative yield of **23F** and **24F** at the expense of **25F** until, at total pressure of 50 Torr, approximately the same distribution, measured in the presence of NMe_3, is restored (Fig. 1). The same qualitative behavior is observed for the methylated products from **3F** (Figs. 3 and 4), whose isomeric distribution, measured at atmospheric pressure, changes from **25F**:**34F**:**24F** = 61%:20%:19%, in the presence of NMe_3, to 95%:5%:1%, in the absence of added bases (Fig. 4).

Relative to the methylfuran systems, the effect of NMe_3 upon the isomeric distribution of the methylated products from **2T** (Figs. 5 and 6) and **3T** (Figs. 7 and 8) is less pronounced. In fact, the isomeric composition of the methylated derivatives of **2T** changes from **25T**:**23T**:**24T** = 40%:38%:22%, in the presence of NMe_3, to 51%:35%:14%, in the absence of the base (Fig. 6). Similarly, the product distribution from **3T** changes from **23T**:**24T**:**34T** = 53%:24%:23%, in the systems with NMe_3, to 57%:17%:26%, in the systems without added bases (Fig. 8). In all methylthiophene systems, however, approximately the same original product composition, measured in the presence of NMe_3, is restored as the total pressure of the samples is lowered to 50 Torr (Figs. 5 and 7).



Discussion

Nature of the substitution process

As outlined in previous papers (4), the conditions typical of the present experiments, in particular the low concentrations of the heteroaromatic substrate (0.2–1.0 mol%) diluted with a large excess of CH_3F, exclude direct radiolysis of the starting compound as a significant route to its methylated products. The presence of an efficient thermal radical scavenger, such as oxygen, in the gaseous samples strongly inhibits possible free-radical pathways in favor of the competing ionic reaction pattern, whose role is testified to by the marked effect of the ion trap NMe_3 on the methylated product yields.

The pure Lewis-acid nature of the stable $(CH_3)_2F^+$ ions (ΔH_f^0 = 146 kcal mol^{-1}) (18) from the γ-radiolysis of CH_3F has been amply demonstrated by mass spectrometric (19) as well as radiolytic studies (4, 20). Accordingly, the radiolytic $(CH_3)_2F^+$ ions, thermalized by many unreactive collisions with the parent CH_3F molecules, are able to attack the heteroaromatic substrate, present in trace amounts in the gaseous mixture, yielding eventually the corresponding isomeric methylated heteroarenium intermediates **I** (eq. [1]). Their formation is energetically allowed, as shown in Figs. 9 and 10, and represents the only significant reaction channel available to the $(CH_3)_2F^+$ reactant.

Several reaction channels are open to the heteroarenium intermediates, excited by the exothermicity of their formation process. A direct route to the methylated products is represented by the collisional stabilization of the excited intermediate, followed by loss of a proton to a suitable base B (NMe_3 or other gaseous bases formed from γ-radiolysis of the batch gas), as illustrated in eq. [1] (a). In competition with collisional quenching, the excited intermediate may undergo several secondary reactions, including isomerization or fragmentation with loss of a H_2 molecule to the benzyl-type ion **II** (eq. [1] (b)). Extensive occurrence of this latter pro-

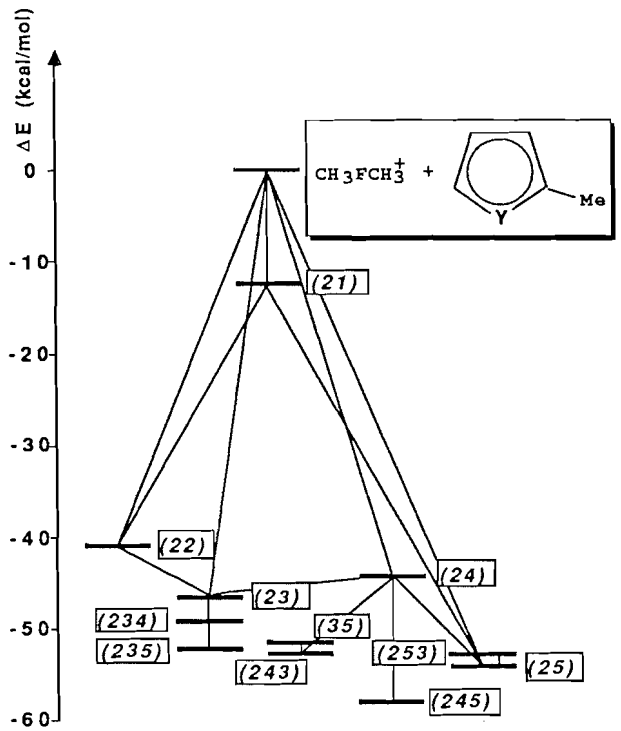


FIG. 9. Energetics of the gas-phase $(CH_3)_2F^+$ attack on 2-methylfuran **2F** to form its primary methylated intermediates (*21*, *22*, *23*, *24*, and *25*) and their isomerized forms (*234*, *235*, *243*, *35*, *253*, and *245*). The first and second figures of the italic numbers refer to the positions of the two methyl groups, whereas the last figure refers to the position of the sp^3-hybridized carbon. Thermochemical data taken from refs. 18 and 21. The formation enthalpies of the heteroarenium intermediates were obtained by lowering the overestimated MNDO calculated values (cf. refs. 18 and 21*b*) by 15 kcal mol^{-1}. Similar energetics are involved in the methylation of 2-methylthiophene, whereas the exothermicity of the methylation of 2-methylpyrrole is ca. 10 kcal mol^{-1} higher.

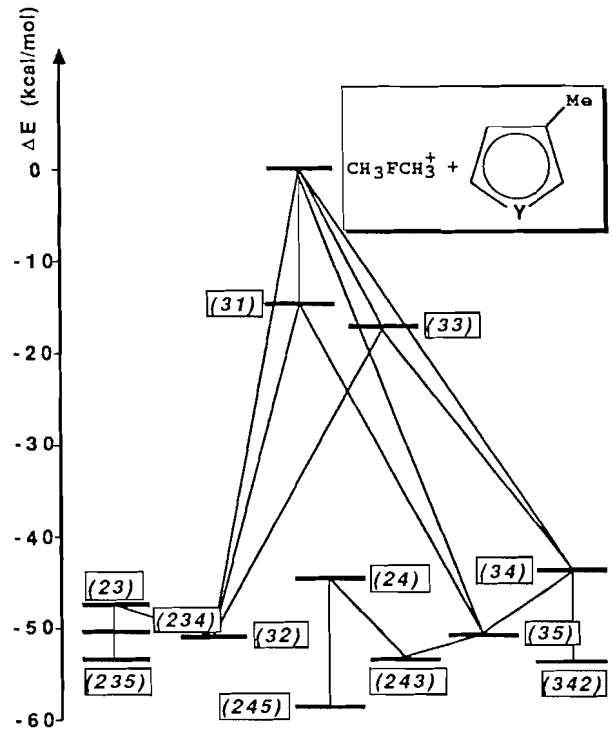

FIG. 10. Energetics of the gas-phase $(CH_3)_2F^+$ attack on 3-methylfuran **3F** to form its primary methylated intermediates (*31*, *32*, *33*, *34*, and *35*) and their isomerized forms (*23*, *234*, *235*, *243*, *24*, *245*, and *342*). The first and second figures of the italic numbers refer to the positions of the two methyl groups, whereas the last figure refers to the position of the sp^3-hybridized carbon. Thermochemical data taken from refs. 18 and 21. The formation enthalpies of the heteroarenium intermediates were obtained by lowering the overestimated MNDO calculated values (cf. refs. 18 and 21*b*) by 15 kcal mol^{-1}. cess under chemical-ionization mass spectrometric conditions (0.1–1.0 Torr) was observed in previous related studies (4).

The relative extent of the competing processes, shown in eq. [1], appears regulated by changes in the reaction environment. Isomerization and fragmentation processes of intermediates **I** are expected to be depressed in systems at atmospheric pressure and with the highest concentrations of NMe_3, where their efficient quenching and rapid neutralization can take place.

The relatively constant methylated product distribution measured in the systems with NMe_3 (see, for instance, Figs. 2, 4, 6, and 8) corroborates the above expectation with regard to the isomerization of the ionic intermediates **I** under such con-

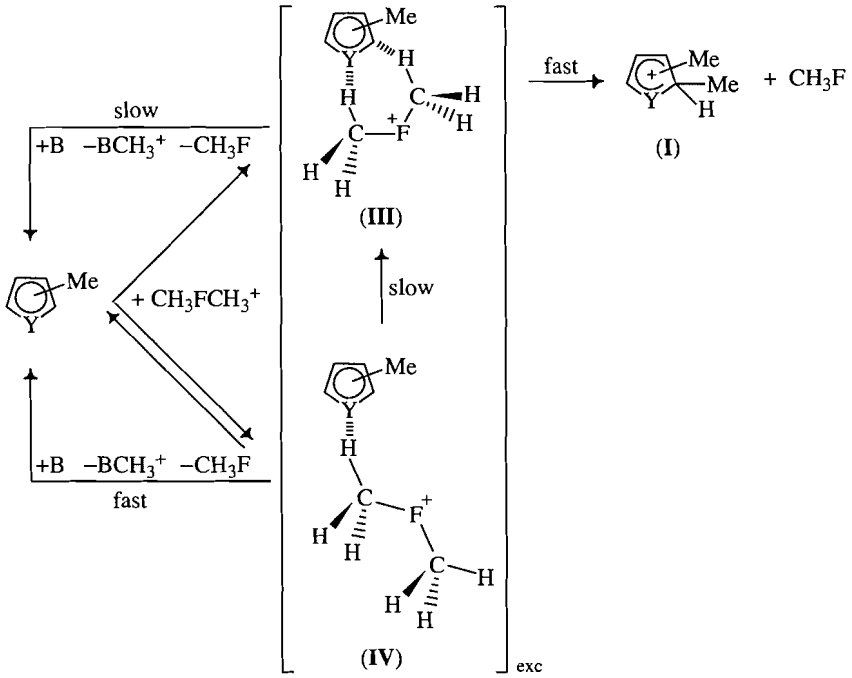
ditions. Concerning the fragmentation of the methylation intermediates **I** from methyl-furans and -thiophenes, the lack of any measurable amounts of their *N*,*N*-dimethylaminomethyl derivatives in the presence of NMe_3 and the relatively high yields of their methylated neutral products in the absence of added bases ($G_{(M)}$ = 1.2–2.1 (dimethylfurans); 0.7–1.5 (dimethylthiophenes)) indicate effective collisional quenching and neutralization of the corresponding primary methylation intermediates **I** prior to fragmentation to **II** and H_2. No similar conclusion can be reached regarding the extent of fragmentation of the methylated intermediates **I** from methylpyrroles under the same conditions. In fact, isolation of appreciable amounts of the β-*N*,*N*-dimethylaminomethyl derivatives of **2P** and **3P**, even at 760 Torr and in the presence of 10 Torr of NMe_3, points to extensive fragmentation of the corresponding methylated heteroarenium ions **I** to **II** and H_2 occurring in a time comparable with that of their effective collisional quenching and neutralization under such conditions (eq. [1]). As suggested by the comparatively low $G_{(M)}$ values of the methylated products from pyrroles (0.1–0.3), the extent of fragmentation of their β-methylated heteroarenium precursors **I** is likely increased in the absence of NMe_3 and at low pressures, yielding substantial amounts of their benzyl-type daughter species **II** whose occurrence cannot, however, be monitored by the formation of isolable products. Under such conditions, in fact, the benzyl-type fragments **II** cannot be trapped by NMe_3 to eventually yield their *N*,*N*-dimethylaminomethyl derivatives, but rather may further attack another molecule of pyrrole giving rise to an oligomerization process.



The residual fragmentation of the methylated heteroarenium intermediates from **2P** and **3P** at 760 Torr and in the presence of NMe_3, namely under conditions where the same process involving the corresponding intermediates from methyl-furans and -thiophenes is prevented, is probably due to the relatively high excess energy deposited in the methylation intermediates. In fact, thermochemical calculations show that $(CH_3)_2F^+$ ion methylation of methylpyrroles is over 10 kcal mol^{-1} more exothermic (ΔH^0 = −66 kcal mol^{-1}) relative to the same reactions with methyl-furans (ΔH^0 = −55 kcal mol^{-1}) and -thiophenes (21).

From the above considerations, it can be concluded that the isomeric composition of the methylated products (and the *N*,*N*-dimethylaminomethylated ones as well, in the case of methylpyrroles **2P** and **3P**) recovered from the systems at the highest total (760 Torr) and NMe_3 partial pressure (10 Torr) closely reflects the relative population of the primary *C*-methylated intermediates from attack of $(CH_3)_2F^+$ on the carbon centers of the selected substrates.

In the absence of NMe_3, namely under longer-lived ion conditions, while β-substituted products are still exclusively formed from methylpyrroles (100% **23P** from **2P**; 100% **34P** from **3P**), significant modifications in the relative distribution of the methylated products from methyl-furans and -thiophenes are observed (Figs. 2, 4, 6, and 8). Thus, the relative yield of **25F** from **2F** increases from 53 to 92% and that of **23F** from **3F** from 61 to 95% at the expense of the other relevant isomers. The variations in the relative yields of the corresponding methylated isomers from methylthiophenes are less pronounced, but still significant (from 40 to 51% for **25T** from **2T** and from 53 to 57% for **23T** from **3T**).

In analogy with the conclusions reached in previous related investigations (2, 4), such behavior is due to the presence of the

[2]

n-electrons of the heteroatom of furans and thiophenes, which can establish more or less effective electrostatic interactions with the proton centers of the ionic electrophile. Proximity factors may favor evolution of a properly oriented fraction of these electrostatic adducts, i.e., **III** of eq. [2], to the C_α-substituted σ-bonded heteroarenium intermediates **I** with a frequency that is high if compared to the collision frequency between the adduct and B = NMe_3. This accounts for the apparent discrepancy of a high-energy LUMO electrophile, such as $(CH_3)_2F^+$ (SCF STO-3G calculated $\varepsilon_{(LUMO)} = +1.77$ eV) (1), displaying a high affinity for the α positions of furans (53% at C5 of 2-methylfuran and 61% at C2 of 3-methylfuran). The remaining fraction of electrostatic adducts, i.e., **IV** of eq. [2], does not present an appropriate orientation for its rapid evolution to σ-bonded intermediates **I** before colliding with NMe_3 and, therefore, is readily destroyed by the base. In the absence of NMe_3, under longer-lived ion conditions, however, this latter fraction of electrostatic adducts, if stabilized by unreactive collision with the bath gas molecules, may also slowly acquire the appropriate configuration of structure **III** and thence evolve to the corresponding C_α-substituted σ-bonded heteroarenium intermediates **I**. This behavior accounts for the apparent increase of the relative yield of **25F** from **2F** and of **23F** from **3F**, in the gaseous samples containing no added bases irradiated at 760 Torr. In this perspective and in agreement with previous conclusions (2, 4), the much less pronounced increase of the relative yields of **25T** from **2T** and of **23T** from **3T**, observed under the same conditions, is consistent with the much lower tendency of the sulfur atom of thiophenes to establish electrostatic interactions with the proton centers of the ionic electrophile (22).

As the total pressure of the reaction mixtures decreases (Figs. 1, 3, 5, and 7), namely under long-lived *excited-ion* conditions, a methylated product distribution, which closely approaches that measured in the presence of NMe_3, is obtained from both methylfurans and methylthiophenes. Such a pressure effect is reminiscent of that observed in the $(CH_3)_2F^+$ methylation of unsubstituted furan and thiophene (4), which found a simple rationale in the extensive isomerization of the excited primary heteroarenium intermediates to the thermodynamically most stable structure via multiple intramolecular 1,2-methyl group shifts. However, such an isomerization route, although not excludable *a priori*, appears unlikely in the present case owing to the following considerations.

According to the thermochemical data reported in Figs. 9 and 10, isomer *245* is the thermodynamically most stable structure accessible in the isomerization via intramolecular 1,2-methyl group shifts of primary methylated heteroarenium intermediates of eq. [1], excited by the exothermicity of their formation process. By virtue of this isomerization pathway favoring formation of *245*, a distinct increase of its neutral 2,4-dimethylated product should be observed under long-lived excited-ion conditions, i.e., at low pressure in the absence of NMe_3, in contrast with experimental evidence. Contrariwise, the product distribution obtained under these conditions closely approaches that measured under kinetically controlled conditions, i.e., at 760 Torr and in the presence of 10 Torr of NMe_3 (cf. Figs. 1–8). Such a pressure effect on the product composition is better accounted for by the alternative hypothesis of a reversible formation of the electrostatic adducts **III** and **IV**, which, if not stabilized by collision with the bath gas molecules, may back-dissociate, although to a different extent, yielding again the heteroarene and the ionic electrophile (eq. [2]). Increase of the excitation level of the electrostatic adducts, i.e., by decreasing the system pressure, is reflected in their more extensive back-dissociation to reactants. The resulting onium ion has a high probability of attacking another molecule of substrate, by far the most abundant nucleophile present in the gaseous mixture. It may attack again the heteroatom of the substrate, yielding once more the readily dissociable electrostatic adducts **III** and **IV**. Alternatively, it may attack the ring carbons of the heteroarene, producing the methylated heteroarenium ions **I** with loss of a CH_3F moiety, an event which makes the attack irreversible.

The consequence of the reversible attack of the onium ion on the heteroatom of the substrate is that the ring carbons of

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12

the heteroarene represent the reaction sink for the $(CH_3)_2F^+$ ions, which therefore are able to produce the primary distribution of *C*-methylated heteroarenium intermediates in high yields. The observation that approximately the same distribution of their primary methylated intermediates **I** is obtained at 50 Torr implies relatively high energy barriers for any conceivable methyl group shifts in the primary excited heteroarenium intermediates (23), in contrast with our previous hypothesis (4).

As mentioned above, the initial population of the electrostatic adducts **IV** emerges directly from a comparative analysis of the isomeric distribution of the neutral *C*-methylated products, as measured under kinetically controlled conditions, i.e., at 760 Torr and in the presence of NMe_3, where conversion of adducts **IV** to the α-methylated heteroarenium intermediates **I** is minimized, and at the same pressure, but in the absence of NMe_3, where back-dissociation of the adducts **IV** (and **III**) is prevented and their conversion to the heteroarenium ions **I** is allowed. The increase of the relative yield of **25F** from **2F** (from 53 to 92%), as the NMe_3 partial pressure decreases from 10 Torr to zero, is consistent with the relative extent of direct interaction of the $(CH_3)_2F^+$ on the oxygen of **2F** to give the electrostatic adducts **III** and **IV** exceeding 80%. By the same procedure, the corresponding increase of the relative yield of **23F** from **3F** (from 61 to 95%) can be accounted for by the relative extent of attack of the ionic electrophile on the oxygen of **3F** as exceeding 80%. Furthermore, the fact that such an increase is reflected in the accompanying decrease of not only **34F** (from 20 to 4%) *but also* **24F** (from 19 to 1%) suggests that the methyl substituent in the ensuing electrostatic adducts **III** and **IV** directs their conversion predominantly to the σ-bonded heteroarenium intermediate *32*, rather than to its isomer *35* (Figs. 9 and 10). The relatively minor increase in the abundance of **25T** from **2T** (from 40 to 51%), as the NMe_3 partial pressure decreases from 10 Torr to zero, indicates that establishment of electrostatic interactions between $(CH_3)_2F^+$ and the sulfur atom of **2T** is comparatively much less effective (>20%), in conformity with expectations (22). Similarly, in **3T**, direct attack of the ionic electrophile on the heteroatom of the substrate does not exceed 10%, as indicated by the increase of the relative yield of **23T** from 53 to 57%. The observation that such an increase takes place at the expense of the **24T** isomer (from 24 to 17%) suggests, in analogy with the conclusion reached for **3F**, that the methyl substituent in the adducts formed (**III** and **IV**) induces their total conversion to the σ-bonded heteroarenium intermediate *32*. Concerning the *N*-center of methylpyrroles **2P** and **3P**, the lack of any detectable amounts of both the α- and *N*-substituted derivatives under all experimental conditions reflects the lack of *n*-electrons on the heteroatom of pyrroles and, therefore, its low propensity to electrostatically interact with the incoming electrophile.

In conformity with the above considerations, the intrinsic positional selectivity of the $(CH_3)_2F^+$ ion toward the selected heteroaromatic substrates can be evaluated as reported in Fig. 11.

Positional selectivity

The intrinsic regiospecificity of gaseous $(CH_3)_2F^+$ toward pyrroles **2P** and **3P** demonstrates the tendency of the heteroaromatic molecule to drive the ionic electrophile toward the ring carbons with the highest value of the net negative charge (the C3 in **2P** and the C4 in **3P**) (24). This tendency conforms

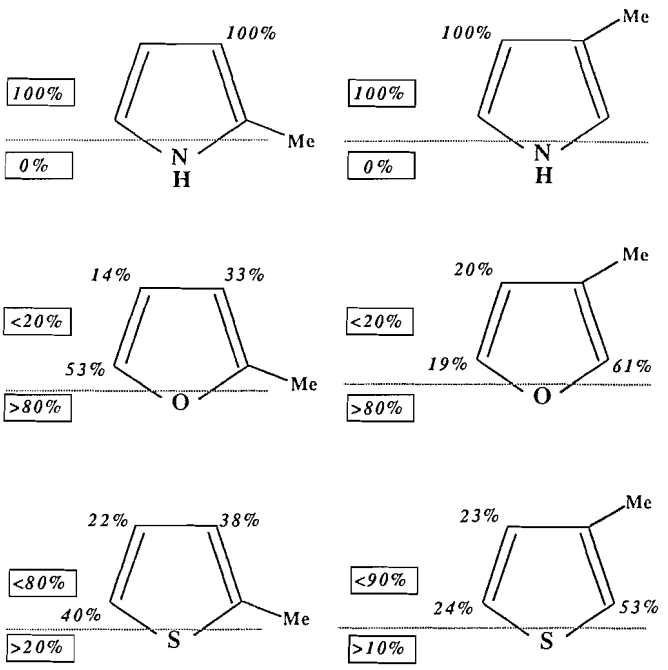

FIG. 11. Positional selectivity of gaseous $(CH_3)_2F^+$ ions toward isomeric methyl-pyrroles, -furans, and -thiophenes.

to that expected on the grounds of the Charge and Frontier Orbital Control Concept (25). Within this model, which is included in the more general Curve Crossing model (3), the reactivity properties of the ionic electrophile toward the selected methylpyrroles are essentially determined by the energy gap between the HOMO of the donor ($\varepsilon_H > -6.6$ eV)[5] and the LUMO of the ionic acceptor ($\varepsilon_L = +1.8$ eV) (1). Accordingly, the total perturbation energy in the orbital interaction between the methylpyrrole molecule and the $(CH_3)_2F^+$ electrophile is essentially determined by electrostatic interactions within the encounter pair, owing to the very large energy gap ($\varepsilon_H - (\varepsilon_L > -8.4$ eV) between the HOMO of the heteroarene and the LUMO of the electrophile, which is somewhat proportional to the difference between the vertical ionization potential of the donor and the vertical electron affinity of the acceptor (1). Hence, since $(CH_3)_2F^+$ methylation of isomeric methylpyrroles is a "charge-controlled" reaction, the $(CH_3)_2F^+$ electrophile is primarily oriented toward the reaction sites of pyrroles with the highest net negative charge (the C3 of **2P** and the C4 of **3P**).

The same model may also account for the apparent predominant formation of the α-methylated products **25F** from **2F** and **23F** from **3F**, once the preferential interaction between the ionic electrophile and the most negatively charged site of methylfurans, i.e., their oxygen atom, to yield the electrostatic adducts **III** and **IV** of eq. [2], is considered. In fact, rapid evolution of the "chelate" adducts **III** to the corresponding σ-bonded α-methylated intermediates **I** is favored by proximity of the CH_3 moiety of the electrophile to the C_α's of furans. The observation that, in spite of such an electrostatic coordination of the electrophile by the oxygen of **3F**, the **24F** derivative is formed with a yield (19%) slightly lower than that of **34F** (20%) points to some preference for a direct attack of the

[5]The HOMO energy of methylpyrroles is estimated as slightly higher than the STO-3G SCF calculated HOMO eigenvalue of pyrrole ($\varepsilon_H = -6.64$ eV) (1).

$(CH_3)_2F^+$ electrophile on the ring carbon of methylfurans with the highest net negative charge, e.g., the C4 of **3F** (26). The same factor determines as well the predominant pathway for evolution of the chelate adducts **III** from **3F** to the σ-bonded intermediate *32*, instead of to its isomer *35*.

Preliminary electrostatic interactions between the sulfur atom of methylthiophenes **2T** and **3T** and an ionic electrophile, such as $(CH_3)_2F^+$, are much less significant relative to furans (Fig. 11). This observation agrees well with others concerning unsubstituted thiophene and is attributable to the predominant localization of the net negative charge at the ring carbons of thiophenes, rather than at the heteroatom (27). As a result, the methylating electrophile is essentially directed to the ring carbons of methylthiophenes, wherein the combined effect of the electron-releasing methyl substituent and sulfur atom is maximized, i.e., at the C5 of **2T** and at the C2 of **3T** (28).

Conclusions

The intrinsic reactivity properties of gaseous $(CH_3)_2F^+$ ion toward methylated pyrroles, furans, and thiophenes qualitatively correspond to the expected behavior of a typical high-energy LUMO electrophile, which is electrostatically oriented toward the ring positions of the heteroaromatic substrate with the highest net negative charge. In methylpyrroles, the electron-releasing character of the methyl substituent adjacent to a β carbon significantly enhances the already distinct affinity of the $(CH_3)_2F^+$ ion for these positions of the pyrrolic ring. A similar activating effect of the methyl group is observed toward the most negatively charged unsubstituted α positions of methylthiophenes. Intense attractive interactions between the methylating electrophile and the heteroatom of methylfurans favor reversible formation of two different sets of electrostatic adducts with either a chelate structure **III** or a single proton-bonded form **IV** (eq. [2]). While rapid evolution of the first structure to the α-substituted heteroarenium intermediate is favored by proximity effects, relatively slow rearrangement of the open form **IV** to **III** takes place in competition with its back-dissociation or reaction with an external base. Reversible formation of electrostatic adducts **III** and **IV** in furans better accounts for the pronounced sensitivity of the relative composition of the substituted products to the experimental conditions adopted, ruling out a previously advanced alternative hypothesis of extensive intramolecular 1,2-methyl group shifts in their excited heteroarenium precursors.

It should be finally mentioned that the present gas-phase results represent the only meaningful kinetic measurement of the intramolecular selectivity of ionic alkylating reactants toward methyl-substituted five-membered heteroarenes, since the corresponding measurements under Friedel–Crafts conditions are complicated by the high sensitivity of the substrates to highly acidic media and to their tendency to undergo extensive polymerization (29).

Nucleic acid related compounds. 67. Synthesis of 5′-amino and 5′-methylthio chain-extended nucleosides from uridine[1]

STANISLAW F. WNUK, N. KENT DALLEY, AND MORRIS J. ROBINS[2]

Departments of Chemistry, Brigham Young University, Provo, UT 84602, U.S.A., Academy of Agriculture, 60625 Poznan, Wojska Polskiego 75, Poland, and University of Alberta, Edmonton, Alta., Canada T6G 2G2

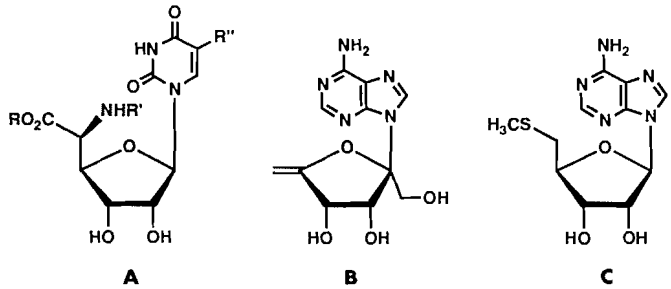
Received April 23, 1991

STANISLAW F. WNUK, N. KENT DALLEY, and MORRIS J. ROBINS. Can. J. Chem. **69**, 2104 (1991).

Treatment of 2′,3′-*O*-isopropylideneuridine-5′-aldehyde with the stabilized Wittig reagent, (*p*-toluenesulfonylmethylene)triphenylphosphorane, gave high yields of 1-[5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-*ribo*-hex-5(*E*)-enofuranosyl]uracil (**2**). This vinylsulfone (**2**) underwent isomerization readily in base to give the allylic sulfone, 1-[5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-*erythro*-hex-4(*Z*)-enofuranosyl]uracil (**3**). Treatment of **2** or **3** with aqueous trifluoroacetic acid gave the corresponding deprotected vinyl (**5**) or allylic (**6**) sulfones, and **5** was converted to **6** readily in basic solutions. Treatment of **2** with sodium borohydride, sodium thiomethoxide, or ammonia resulted in conjugate addition (at C5′ of the vinyl sulfone) to give the 5′-hydro, 5′-methylthio, or 5′-amino-5′,6′-dideoxy-6′-(*p*-toluenesulfonyl) nucleosides. The 5′-substituted diastereomers were deprotected, separated, and the configuration of a 5′-amino derivative was established by X-ray crystallography.

Key words: allylic sulfones, amino-nucleosides, 5′,6′-dideoxynucleosides, nucleosides, uridine, vinyl sulfones.

STANISLAW F. WNUK, N. KENT DALLEY et MORRIS J. ROBINS. Can. J. Chem. **69**, 2104 (1991).



Le traitement du 2′,3′-*O*-isopropylidène-uridine-5′-aldéhyde avec le réactif de Wittig stabilisé, (*p*-toluènesulfonylméthylène)triphénylphosphorane, fournit des rendements élevés du 1-[5,6-didésoxy-2,3-*O*-isopropylidène-6-(*p*-toluènesulfonyl)-β-D-*ribo*-hex-5(*E*)-énofuranosyl]uracil (**2**). En présence de base, cette vinylcétone (**2**) subit une isomérisation conduisant à la sulfone allylique, 1-[5,6-didésoxy-2,3-*O*-isopropylidène-6-(*p*-toluènesulfonyl)-β-D-*érythro*-hex-4(*Z*)-énofuranosyl]uracil (**3**). Le traitement des composés **2** ou **3** avec de l'acide trifluoroacétique aqueux fournit les sulfones correspondantes déprotégées vinylique **5** et allylique **6**; le composé **5** est facilement transformé en produit **6** en solutions basiques. Le traitement du composés **2** par le borohydrure de sodium, du thiométhylate de sodium ou de l'ammoniac conduit à une addition conjuguée (en C5′ de la vinylcétone) et à la formation des 5′-hydro-, 5′-méthylthio- ou 5′-amino-5′,6′-didésoxy-6′-(*p*-toluènesulfonyl)-nucléosides. Les diastéréoisomères substitués en 5′ ont été déprotégés, séparés et la configuration d'un dérivé 5′-amino a été déterminé par diffraction des rayons-X.

Mots clés : sulfones allyliques, amino-nucléosides, 5′,6′-didésoxynucléosides, nucléosides, uridine, vinylsulfones.

[Traduit par la rédaction]

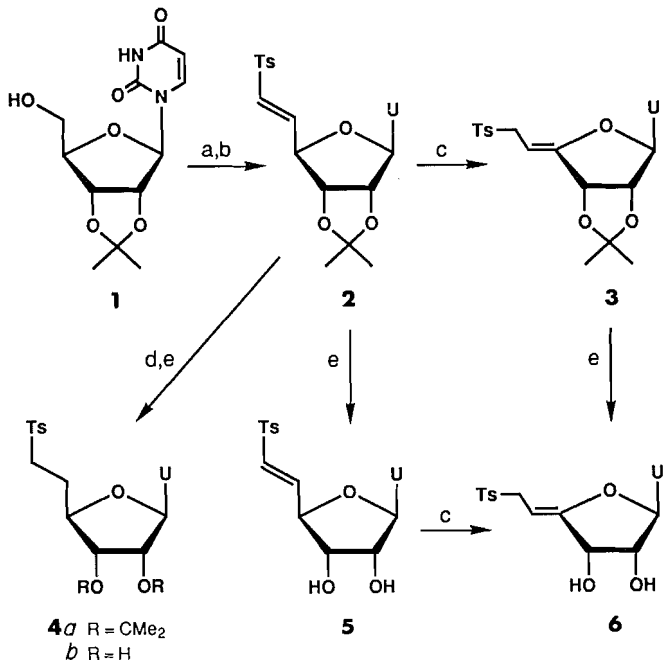
Introduction

Among the varied structural features present in nucleoside antibiotics (1*a*, 2*a*), the polyoxin and nikkomycin complexes (**A**) have a substituted 5′-amino-5′-deoxyhexofuranosyl uronic acid sugar backbone with a uracil or 5-substituted-uracil base (1*b*, 2*b*). Other nucleoside antibiotics (e.g., decoyinine (**B**)) have unsaturated sugar moieties and (or) further modifications at C5′ (1*c*, 2*c*). Methylthioadenosine phosphorylase catalyzes the glycosyl cleavage of 5′-*S*-methyl-5′-thioadenosine (**C**), and

A **B** **C**

the resulting 5-*S*-methyl-5-thioribose 1-phosphate is converted to methionine by salvage pathway enzymes (3). Pyrimidine nucleoside phosphorylases effect analogous cleavage of uridine nucleosides (4). Thus, the synthesis and biological evaluation of uridine nucleoside analogues modified at C5′ with amino or methylthio substituents is of current interest.

Chain extensions and other carbon–carbon bond forming reactions at C5′ of nucleosides have generally involved oxidation to 5′-aldehyde derivatives and treatment with Wittig-type reagents, or nucleophilic conversions with 5′-deoxy-5′-halonucleosides (5, 6). Wittig reactions of nucleoside 5′-aldehydes with stabilized ylides have provided 6′-substituted-5′,6′-unsaturated hexofuranosyl nucleosides (7–12). However, direct introduction of the methylene group at C5′ has met with limited success, and only recently has the direct synthesis of 5′-deoxy-5′-methyleneadenosine been reported (13). Seebach's silyl nitronate (nitro-aldol) methodology was used for chain extension of aldehyde sugars including a uridine 5′-aldehyde derivative (14). Barton *et al.* developed radical-mediated chemistry for the stereocontrolled synthesis of chain-lengthened nucleoside phosphonates (15*a*), vinyl sulfones (15*b*), and a phosphonate analogue of 3′-azido-3′-deoxythymidine 5′-monophosphate (AZTMP) (15*c*). A multistep synthesis of 5′-homo-AZT from 1,2;5,6-di-*O*-isopropylidene-3-*O*-mesyl-α-D-allofuranose (4% overall yield) was reported recently (16).



Chattopadhyaya and co-workers prepared 1-(2,3-dideoxy-3-*p*-toluenesulfonyl-β-D-*glycero*-pent-2-enofuranosyl)uracil and its adenine analogue (17) and the uracil 3′-phenylselenone analogue (18). These powerful Michael acceptors (vinyl 3′-sulfone or selenone) were utilized to functionalize the carbohydrate moiety of nucleosides. The chemistry of vinyl sulfones was reviewed recently (19). We now describe the efficient synthesis of a uridine vinylsulfone derivative (**2**), its use as a synthetic intermediate for Michael addition products, and its base-catalyzed rearrangement to the 4′,5′-unsaturated allylic sulfone (**3**).

SCHEME 1

Results and discussion

Moffatt oxidation of 2′,3′-*O*-isopropylideneuridine (**1**, Scheme 1) (7, 20), followed by treatment of the resulting 5′-aldehyde with the stabilized ylid, (*p*-toluenesulfonylmethylene)triphenylphosphorane (21, 22), gave the vinyl sulfone, 1-[5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-*ribo*-hex-5(*E*)-enofuranosyl]uracil (**2**, 85%). The ^1H NMR spectrum of **2** in Me_2SO-d_6 had a "collapsed" broad singlet for H5′ and H6′ whereas its spectrum in $CDCl_3$ had two doublets of doublets. The large vinyl coupling constant ($^3J_{5'-6'}$ = 15.0 Hz) was in harmony with the *E* configuration. Deprotection of **2** with aqueous trifluoroacetic acid gave 1-[5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-*ribo*-hex-5(*E*)-enofuranosyl]uracil (**5**, 89%).

Attempted application of methods for the reductive cleavage of carbon–sulfur bonds in saturated (23–25) and α,β-unsaturated (26–29) sulfones to **2** failed to give 5′-deoxy-2′,3′-*O*-isopropylidene-5′-methyleneuridine. The Corey sulfone cleavage conditions (23) with sodium (24) or aluminum (26) amalgam resulted in rearrangement of the vinyl to allylic sulfones (**2** → **3**) and (or) recovery of starting material. Formation of more complex mixtures was observed under more vigorous conditions. Attempted desulfonylation of **2** via conjugate addition of tributylstannyllithium (29) also failed, possibly resulting from interactions between the reagent and the uracil ring, in contrast to results with the adenosine analogue (13). The sodium dithionite procedure of Julia and co-workers (27, 28) caused loss of UV absorption, presumably resulting from nucleophilic addition of the reagent to C6 of uracil as anticipated from sodium bisulfite addition studies of Shapiro *et al.* (30).

Base-catalyzed isomerization of the vinyl sulfone **2** to a single allylic sulfone (**3**, 91%, exocyclic double bond tentatively assigned the less hindered *Z* configuration) occurred by stirring **2** in aqueous sodium hydroxide in acetonitrile or in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in THF. The bathochromic shift (λ_{max} 237 to 258 nm) and hypochromic effect (ε 22 200 to 10 300) accompanying conversion of the conjugated vinyl sulfone (**2**) into the allylic sulfone (**3**) was monitored by UV spectroscopy.

Attempted deprotection of 1-[5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-*erythro*-hex-4(*Z*)-enofuranosyl]uracil (**3**) at ambient temperature resulted in the expected acid-catalyzed decomposition of the exocyclic vinyl ether (31, 32). However, treatment of **3** with aqueous trifluoroacetic acid at 0°C for 25 min afforded **3**, uracil, and 1-[5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-*erythro*-hex-4(*Z*)-enofuranosyl]uracil (**6**, 22%) after silica column purification. Longer reaction times resulted in formation of greater quantities of uracil. The deprotected vinyl sulfone (**5**) underwent clean isomerization to **6** (81%) in aqueous sodium hydroxide. This provides an efficient route to **6** (61% from **1**), which differs from the usual methodologies for preparation of 4′,5′-unsaturated nucleosides that involve elimination of hydrogen and an activated O5′ function or halide from C4′ and C5′ (5, 6, 31, 32).

Conjugate reduction of **2** occurred with sodium borohydride in aqueous methanol to give **4***a* (83%). Deprotection with aqueous trifluoroacetic acid gave 1-[5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-*ribo*-hexofuranosyl]uracil (**4***b*, 71%). Treatment of **2** with sodium thiomethoxide in THF gave the 5′-methylthio-5′,6′-dideoxy diastereomers **7** (~1:1, >70%, Scheme 2). One diastereomer crystallized preferentially (19:1) during "diffusion crystallization" (33) from hexane/ethyl acetate. The mother liquor was purified by silica column chromatography and the second diastereomer then crystallized predominantly (1:4). Deprotection of the two mixtures with aqueous trifluoroacetic acid and crystallization afforded **8** (5′*R*, mp 219–220°C) and **9** (5′*S*, mp 125–128°C), respectively. The 5′-stereochemistry is tentatively assigned by parallel ^{13}C NMR shifts of C5′ relative to spectra of the 5′-amino analogues whose configurations were defined by X-ray crystallography of **12***b*(5′*R*). The ^{13}C NMR peak for C5′ of **8**(5′*R*) was at 1.2 ppm higher field than that of **9**(5′*S*). Shifts for C5′ of **10***b* (0.8 ppm) and **12***b* (0.6 ppm) (5′*R*) also were at higher fields than those of their *S* isomers.

Treatment of **2** with methanolic ammonia or aqueous ammonia in ethanol gave the 5′-amino-5′,6′-dideoxy diastereomers **10***a*(5′*R*) and **11***a*(5′*S*) (~1:1, 77%) plus the isomerization product **3** (19%). Purification by silica column chromatography resulted in partial separation of **10***a* and **11***a*. Treatment of a mixture of these diastereomers with 4-dimethylaminopyridine/acetic anhydride (34) gave the 5′-*N*-acetylamino derivatives **12***a*(5′*R*) and **13***a*(5′*S*), which were separated readily by chromatography. Deprotection of separated **10***a* and **11***a*, and **12***a* and **13***a* with aqueous trifluoroacetic acid gave **10***b* and **11***b*, and **12***b* and **13***b*, respectively. X-ray crystallography established the *R* configuration at C5′ of **12***b*. Removal of the *N*-acetyl group from **13***b*(5′*S*) was effected by heating with 1 M hydrochloric acid at ~90°C for 30 h to give **11***b*(5′*S*).

Attempted removal of the *p*-toluenesulfonyl group from a mixture of **10***a*/**11***a* by heating at reflux with magnesium turnings in MeOH as described recently (25) gave low yields (~14%) of slightly less polar (TLC) products. Although this mixture could be shown (^1H NMR and MS) (13) to contain 5′-deoxy-2′,3′-*O*-isopropylidene-5′-methyleneuridine, it was contaminated (10–15%) with by-products and was not investigated further.

In summary, Moffatt oxidation of 2′,3′-*O*-isopropylideneuridine and Wittig treatment of the resulting 5′-aldehyde with (*p*-toluenesulfonylmethylene)triphenylphosphorane gave efficient conversion to the chain-extended (*E*)vinyl sulfone. This in-

termediate underwent Michael addition of hydrogen (sodium borohydride), thiomethanol, and ammonia to give the corresponding 5′-substituted-5′,6′-dideoxy derivatives. Removal of the isopropylidene group was effected with aqueous trifluoroacetic acid. Base-catalyzed isomerization of the vinyl sulfone to give a single geometric isomer of the 4′,5′-unsaturated allylic sulfone occurred readily. Attempted desulfonylation by various methods failed. New 5′-substituted-6′-*p*-toluenesulfonyl-5′,6′-dideoxy nucleoside analogues have been prepared and characterized, including determination of C5′ stereochemistry by X-ray crystallography. Biological testing results will be reported separately.

Single crystal X-ray structure determination

The single crystal structural study was performed with a Siemens R3m/V automated diffractometer that utilized graphite monochromated Mo Kα radiation (λ = 0.71073 Å). The compound (**12***b*) crystallized in the orthorhombic space group $P2_12_12_1$ with $a = 7.302(2)$, $b = 11.352(4)$, and $c = 25.813(9)$ Å with $Z = 4$. A total of 2359 unique data points were taken of which 1443 were considered observed, $F > 3\sigma(F)$.

The structure was solved using direct methods and refined using a full-matrix least-squares procedure. All non-hydrogen atoms were refined anisotropically. Positional parameters for hydrogen atoms of the nucleoside were calculated using known stereochemical geometry or obtained from difference maps, and these parameters were not refined. The isotropic thermal parameter of each hydrogen atom was set equal to 1.2 times the equivalent isotropic thermal parameter of the atom to which it was bonded, and these parameters were not refined. The phenyl ring was refined as a rigid body with C—C bond lengths fixed at 1.395 Å and C—C—C angles fixed at 120°. A partial water of hydration was located in the difference map. Its oxygen atom was refined anisotropically with an occupancy factor of

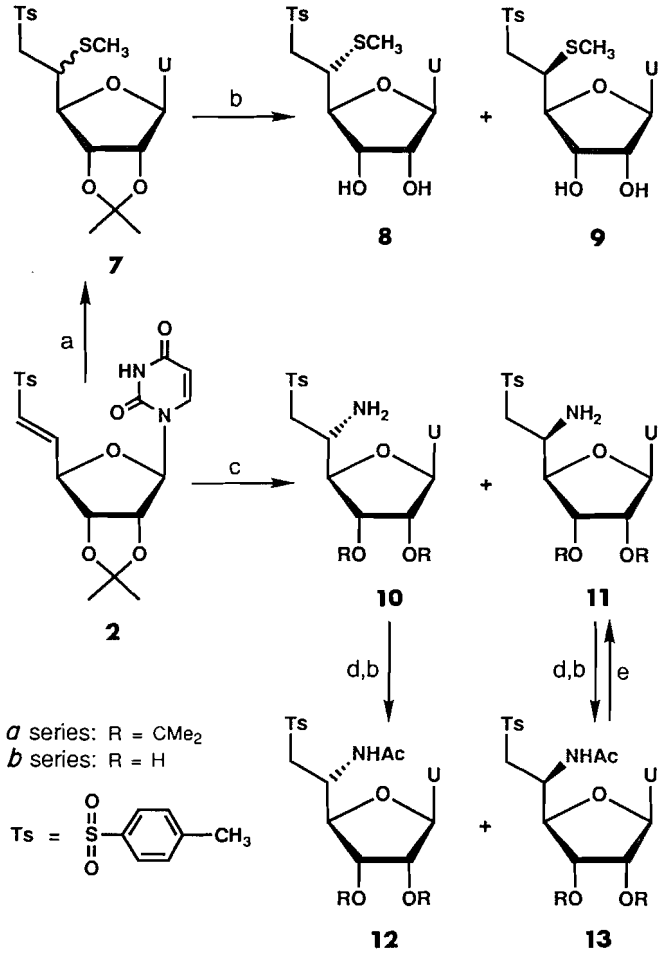
0.5. The water hydrogen atoms could not be located in difference maps and were not included in the refinement. The final R values were R = 0.0641 and R_w = 0.0574. All computer programs used in the structure solution, refinement, and display are included in the "SHELXTL PLUS" (35) program package. Standard atomic scattering factors (36) were used.

The drawing of the structure of **12***b* in Fig. 1 clearly established the *R* configuration at C5′. The pseudorotation angle of the furanose ring is 47.2°, indicating a $_4T^3$ conformation very close to $_4E$. The C6—N1–C1′—O4′ glycosyl torsion angle is 67.0(8)° and the C3′—C4′–C5′—N5′ torsion angle is 60.0(8)°. There are no intramolecular hydrogen bonds in the structure, but HO2′ and HN3 are involved in intermolecular hydrogen bonds. Also, HO3′ is hydrogen-bonded to the water of hydration. Details of the experimental procedure, structure solution, and refinement along with atomic positional and thermal parameters, bond lengths and angles, important torsion angles, and hydrogen bond data are included in the supplementary material.[3]

Experimental section

Uncorrected melting points were determined on a microstage block. UV spectra were recorded on a Hewlett Packard 8951A spectrophotometer. ^1H (200 MHz) and ^{13}C (50 MHz) NMR spectra were recorded on a Varian Gemini-200 spectrometer. ^1H spectra at 500 MHz were determined on a Varian VXR-500S spectrometer.

[3]Supplementary X-ray crystallography material may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.



Tables of atomic coordinates, bond lengths and angles, and details of the structure determination have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW, U.K.

SCHEME 2

Mass spectra (MS) were obtained with an AEI MS-12 instrument. Elemental analyses were determined by the microanalytical laboratories of the University of Alberta, Adam Mickiewicz University, Poznan, or M-H-W Laboratories. Reagents and solvents were of reagent quality, and solvents were purified and dried before use. Diffusion crystallization was performed with the solvent combinations noted as described previously (33) except the diffusion solvent is listed first, and the dissolving solvent or mixture second, in the present paper. (*p*-Toluenesulfonylmethylene)triphenylphosphorane (73%, crystallized from CH_2Cl_2/hexane, mp 182–183°C (lit. (21) mp 186–187°C, (22) 182–184°C)) was prepared (21) from triphenylphosphine and bromomethyl *p*-toluylsulfone (22). Thin-layer chromatography (TLC) was performed on Merck Kieselgel 60 F_{254} sheets with the following systems: S1 (MeOH/$CHCl_3$, 1:16), S2 ($Me_2CO/CHCl_3$, 1:3), S3 (EtOAc/*i*-PrOH/H_2O, 4:1:2, upper layer), S4 (MeOH/$CHCl_3$, 1:8), with sample observation under 254-nm light. Column chromatography was performed with Merck Kieselgel 60 (230–400 mesh).

*1-[5,6-Dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-*β*-D-ribo-hex-5*(E)*-enofuranosyl]uracil* **2**

Method A

A solution of **1** (2.84 g, 10 mmol), dicyclohexylcarbodiimide (DCC, 8.25 g, 40 mmol), and pyridinium trifluoroacetate (PTFA, 0.96 g, 5 mmol) in anhydrous Me_2SO (40 mL) was stirred at ambient temperature overnight. (*p*-Toluenesulfonylmethylene)triphenylphosphorane (21, 22) (5.17 g, 12 mmol) was added and stirring continued at ~35°C for 5 h. Me_2SO was evaporated *in vacuo* and the residue partitioned (EtOAc/H_2O). The organic phase was

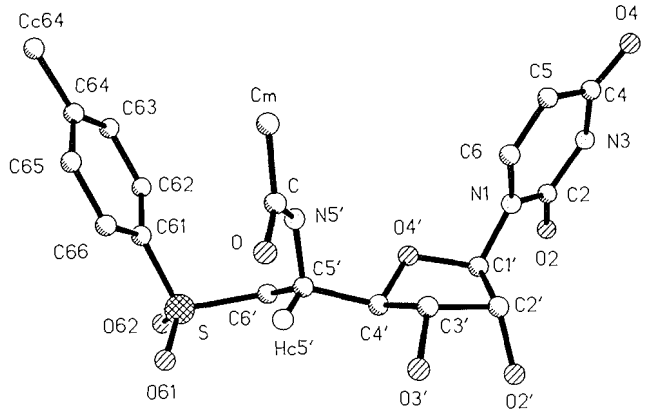

FIG. 1. Computer drawing of compound **12***b*. All hydrogen atoms except Hc5′ have been deleted for clarity and to emphasize the configuration at C5′.

washed (NaCl/H_2O), filtered (*N*,*N*′-dicyclohexylurea, DCU), dried ($MgSO_4$), evaporated, and the residue chromatographed (MeOH/$CHCl_3$, 1.5:98.5). Evaporation of appropriate fractions gave a white solid that was dissolved in $CH_2Cl_2/CHCl_3$ (20 mL, 1:1), filtered (traces of DCU), and the product precipitated with hexane. Recrystallization (MeOH) gave **2** (3.69 g, 85%) as white needles; mp 195–196°C; UV (MeOH) max: 237 nm (ε 22 200), min: 219 nm (ε 12 500); MS *m/z*: 434.1155 (1.6, M^+ = 434.1148). Anal. calcd. for $C_{20}H_{22}N_2O_7S$ (434.5): C 55.29, H 5.10, N 6.45, S 7.38; found: C 55.05, H 4.94, N 6.58, S 7.31.

Method B

A solution of **1** (4.26 g, 15 mmol) and DCC (12.36 g, 60 mmol) in anhydrous Me_2SO (60 mL) was stirred with cooling (ice-bath) while Cl_2CHCO_2H (0.62 mL, 0.97 g, 7.5 mmol) was added, and stirring was continued at ambient temperature for 2 h. (*p*-Toluenesulfonylmethylene)triphenylphosphorane (21, 22) (6.88 g, 16 mmol) was added and, after stirring overnight, TLC (S1) indicated complete conversion to a more rapidly migrating product. Oxalic acid dihydrate (5.67 g, 45 mmol) in MeOH (50 mL) was added and, after 30 min, DCU was filtered and the filtrate evaporated *in vacuo*. The residue was partitioned (EtOAc/H_2O) and the organic layer washed with H_2O (2 × 50 mL), $NaHCO_3/H_2O$, and NaCl/H_2O, dried ($MgSO_4$), and evaporated to give a yellow solid foam. Column chromatography (MeOH/$CHCl_3$, 1.5:98.5) and crystallization (MeOH) gave **2** (5.47 g, 84%) with identical data.

*1-[5,6-Dideoxy-6-(*p*-toluenesulfonyl)-β-D-*ribo*-hex-5(*E*)-enofuranosyl]uracil* **5**

A solution of **2** (217 mg, 0.5 mmol) in CF_3CO_2H/H_2O (9:1, 5 mL) was stirred at ~0°C for 25 min, evaporated, and coevaporated with EtOH. Crystallization of the residue (MeOH) gave **5** (175 mg, 89%) as white needles; mp 212–213°C; UV (MeOH) max: 238 nm (ε 21 000), shoulder: 260 nm (ε 9900), min: 221 nm (ε 12 600); MS *m/z*: 394 (1, M^+), 239 (25), 221 (100), 155 (43), 112 (56). Anal. calcd. for $C_{17}H_{18}N_2O_7S$ (394.4): C 51.77, H 4.60, N 7.10; found: C 51.79, H 4.65, N 7.03.

*1-[5,6-Dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-*erythro*-hex-4(Z)-enofuranosyl]uracil* **3**

To a stirred solution of **2** (217 mg, 0.5 mmol) in CH_3CN/H_2O (1:1, 15 mL) was added 1 M NaOH/H_2O (1 mL) (alternatively, DBU (0.075 mL, 76 mg, 0.5 mmol) in THF (10 mL) was used) and stirring was continued at ambient temperature for 4 h. TLC (S2) indicated complete conversion to one slightly slower migrating product. The solution was concentrated to half volume and EtOAc (30 mL) and 0.1 M HCl/H_2O (10 mL) were added. The organic layer was separated and the aqueous layer washed with EtOAc (2 × 10 mL). The combined organic phase was washed with $NaHCO_3/H_2O$, NaCl/H_2O, dried ($MgSO_4$), and evaporated to a white foam that was diffusion crystallized (hexane/EtOH) to give **3** (198 mg, 91%) as a white solid; mp 119–121°C; UV (MeOH) max: 258 nm (ε 10 300), min: 241 nm (ε 8000); MS *m/z*: 419.0897 (3, M − CH_3 [$C_{19}H_{19}N_2O_7S$] = 419.0913), 279.0979 (100, M − Ts [$C_{13}H_{15}N_2O_5$] = 279.0981). Anal. calcd. for $C_{20}H_{22}N_2O_7S$ (434.5): C 55.29, H 5.10, N 6.45, S 7.38; found: C 55.41, H 5.12, N 6.51, S 7.49.

*1-[5,6-Dideoxy-6-(*p*-toluenesulfonyl)-β-D-*erythro*-hex-4(Z)-enofuranosyl]uracil* **6**

Method A

A solution of **5** (100 mg, 0.25 mmol) in MeOH/H_2O (1:1, 30 mL) was treated with 1 M NaOH/H_2O (1 mL) and stirred at ambient temperature for 8 h (TLC (S3) showed a single slightly more polar product). Dried Dowex 50W-X8 (H^+) resin (0.3 g, 200–400 mesh) was added, stirred for 1 h, filtered, and washed with MeOH (2 × 10 mL). The combined filtrates were evaporated and the residue crystallized (MeOH) to give **6** (71 mg, 71%). Evaporation of the mother liquor and diffusion crystallization (hexane/MeOH) of the residue gave a second crop of **6** (10 mg, 10%); mp 196–197°C (dec.); UV (MeOH) max: 260 nm (ε 10 200), min: 243 nm (ε 8100); MS *m/z* 239 (38, M − Ts), 221 (100), 156 (60), 112 (84), 92 (82). Anal. calcd. for $C_{17}H_{18}N_2O_7S$ (394.4): C 51.77, H 4.60, N 7.10; found: C 51.95, H 4.66, N 7.18.

Method B

A solution of **3** (100 mg, 0.23 mmol) in CF_3CO_2H/H_2O (22:3, 5 mL) was stirred at ~0°C for 25 min, evaporated (<10°C), and coevaporated with EtOH. TLC (S4) of the residue showed three components with R_f 0.8 (**3**, ~40%), 0.48 (**6**, ~35%), and 0.39 (uracil, ~25%), which were separated by column chromatography (MeOH/$CHCl_3$, 1:24). Evaporation of appropriately pooled fractions gave **6** (20 mg, 22%) with identical data.

Extension of the deprotection time to 45 min resulted in formation of additional uracil without complete consumption of **3**.

*1-[5,6-Dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil* **4**a

To a magnetically stirred solution of **2** (260 mg, 0.6 mmol) in MeOH/H_2O (1:1, 60 mL) was added sodium borohydride (45 mg, 1.2 mmol). TLC (S2, two developments) after 18 h at ambient temperature indicated ~95% conversion to a slightly more polar product. The solution was concentrated to half volume and the residue was partitioned ($CHCl_3/H_2O$). The organic layer was washed with NaCl/H_2O, H_2O, dried ($MgSO_4$), and evaporated to give a foam that was purified by column chromatography ($Me_2CO/CHCl_3$, 1:9). Evaporation of appropriately pooled fractions and diffusion crystallization (hexane/EtOH) gave **4***a* (218 mg, 83%) as an amorphous powder; mp 108–110°C; UV (MeOH) max: 258, 223 nm (ε 10 200, 14 700), min: 238, 212 nm (ε 5900, 12 900); MS *m/z*: 436.1309 (1.2, M^+ = 436.1304), 421.1063 (19, M − CH_3), 325.1106 (89, M − B). Anal. calcd. for $C_{20}H_{24}N_2O_7S$ (436.5): C 55.04, H 5.54, N 6.42, S 7.35; found: C 54.79, H 5.68, N 6.55, S 7.58.

*1-[5,6-Dideoxy-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil* **4**b

A solution of **4***a* (174 mg, 0.4 mmol) in CF_3CO_2H/H_2O (9:1, 8 mL) was stirred at ~0°C for 40 min, evaporated, and coevaporated with EtOH to give an amorphous glass. Column chromatography (MeOH/$CHCl_3$, 1:24) and diffusion crystallization (hexane//EtOAc/MeOH) gave **4***b* (112 mg, 71%); mp 177–179°C; UV (MeOH) max: 260, 224 nm (ε 9300, 14 600), min: 239 nm (ε 6100); MS *m/z*: 284 (5, M − BH), 246 (20), 156 (24), 112 (100). Anal. calcd. for $C_{17}H_{20}N_2O_7S$ (396.4): C 51.51, H 5.09, N 7.07; found: C 51.40, H 5.29, N 7.05.

*1-[5,6-Dideoxy-2,3-*O*-isopropylidene-6,5-methylthio-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil 7(5′R/S)*

A solution of **2** (660 mg, 1.52 mmol) in anhydrous THF (20 mL) was added to a solution of sodium thiomethoxide (128 mg, 1.83 mmol) in anhydrous THF (10 mL) under N_2 and stirring was continued at ambient temperature for 7 h. Acetic acid (0.105 mL, 110 mg,

1.83 mmol) was added, the solution evaporated, and the residue partitioned ($CHCl_3$//$NaHCO_3$/H_2O). The organic layer was washed with NaCl/H_2O, dried ($MgSO_4$), evaporated, and the residue diffusion crystallized (hexane/EtOAc) to give **7** (210 mg, 29%, 5′(*R*/*S*) ~19:1) with mp 201–203°C; MS *m/z*: 467 (12, M − CH_3), 327 (100), 279 (82), 157 (91). Purification of the mother liquor by column chromatography (Me_2CO/$CHCl_3$, 1:9) and diffusion crystallization of the residue (hexane/EtOAc), gave **7** (325 mg, 44% 5′(*R*/*S*) ~1:4).

*1-[5,6-Dideoxy-5(*R*)-methylthio-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil {1-[6-deoxy-5-*S*-methyl-5-thio-6-(*p*-toluenesulfonyl)-α-L-talofuranosyl]uracil} **8**(5′R)*

A solution of **7** (150 mg, 0.31 mmol, 5′(*R*/*S*) ~19:1) in CF_3CO_2H/H_2O (9:1, 5 mL) was stirred at ~0°C for 30 min, evaporated, coevaporated with EtOH, and crystallized (EtOH, two crops) to give **8**(5′*R*) (116 mg, 85%) as fine white needles; mp 219–220°C; UV (MeOH) max: 260, 222 nm (ε 10 200, 15 400), min: 240 nm (ε 6100); MS *m/z*: 442 (1, M^+), 358 (24), 287 (93), 239 (72), 271 (58), 221 (100), 155 (52), 113 (66). Anal. calcd. for $C_{18}H_{22}N_2O_7S_2$ (442.5): C 48.86, H 5.01, N 6.33; found: C 48.84, H 5.07, N 6.36.

*1-[5,6-Dideoxy-5(*S*)-methylthio-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil {1-[6-deoxy-5-*S*-methyl-5-thio-6-(*p*-toluenesulfonyl)-β-D-allofuranosyl]uracil} **9**(5′S)*

A solution of **7** (200 mg, 0.41 mmol, 5′(*R*/*S*) ~1:4) in CF_3CO_2H/H_2O (9:1, 5 mL) was stirred at ~0°C for 30 min, evaporated, coevaporated with EtOH, and the resulting brown glass purified on a short silica column (MeOH/$CHCl_3$, 1:24). The residue was crystallized (hexane/EtOH) and recrystallized (MeOH, two crops) to give **9**(5′*S*) (114 mg, 63%) as cream-colored crystals; mp 125–128°C; UV (MeOH) max: 260, 224 nm (ε 9800, 14 500), min: 240 nm (ε 5900); MS *m/z*: 287 (28, M − Ts), 221 (45), 155 (100), 91 (82), 113 (52). Anal. calcd. for $C_{18}H_{22}N_2O_7S_2$ (442.5): C 48.86, H 5.01, N 6.33; found: C 48.71, H 5.19, N 6.42.

*1-[5-Amino-5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil **10**a(5′R)/**11**a(5′S)*

A solution of **2** (326 mg, 0.75 mmol) in anhydrous MeOH (30 mL) was treated with saturated NH_3/MeOH (30 mL) (or concentrated NH_3/H_2O (2 mL) in EtOH (20 mL)) and stirring was continued at ambient temperature for 4 h. TLC (S2) indicated complete consumption of **2** (R_f 0.53) with formation of more polar components (R_f 0.48 (**3**, minor), R_f 0.16/0.14 (**11***a*/**10***a*, ~1:1)). The reaction mixture was evaporated and subjected to column (80 g, 3.5 × 30 cm) chromatography. Slow elution (Me_2CO/$CHCl_3$, 3:22, 700 mL; followed by MeOH/$CHCl_3$, 1.5:98.5, 1200 mL) and evaporation of appropriately pooled fractions gave **3** (62 mg, 19%), **11***a* (115 mg, 34%), overlapping fractions of **11***a*/**10***a* (37 mg, 11%), and **10***a* (108 mg, 32%). The more rapidly eluted diastereomer was crystallized (MeOH) to give 1-[5-amino-5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-allofuranosyl]uracil (**11***a*(5′*S*)) (96 mg, 28%); mp 230–231°C; UV (MeOH) max: 224, 258 nm (ε 16 600, 10 800), min: 239, 212 nm (ε 6100, 13 600); MS *m/z*: 436.1175 (2, M − CH_3 [$C_{19}H_{22}N_3O_7S$] = 436.1178), 296.1244 (15, M − Ts), 198.0590 (100, $TsCH_2CHNH_2$); MS (ci, NH_3) *m/z*: 452 (100, M + 1). Anal. calcd. for $C_{20}H_{25}N_3O_7S$ (451.5): C 53.21, H 5.58, N 9.31, S 7.10; found: C 53.26, H 5.58, N 9.26, S 7.14. The more slowly eluted 1-[5-amino-5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-α-L-talofuranosyl]uracil (**10***a*(5′*R*)) failed to crystallize; UV (MeOH) max: 224, 258 nm (ε 16 000, 10 400), min: 239, 213 nm (ε 6100, 14 000); MS *m/z*: 436.1181 (1.8, M − CH_3 [$C_{19}H_{22}N_3O_7S$] = 436.1178), 296.1247 (13, M − Ts), 198.0592 (100, $TsCH_2CHNH_2$); MS (ci, NH_3) *m/z*: 452 (100, M + 1).

*1-[5(*R*)-Acetamido-5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil **12**a(5′R) and 1-[5(*S*)-acetamido-5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil **13**a(5′S)*

A mixture of **10***a*/**11***a* (~1:1, 157 mg, 0.35 mmol) in Ac_2O (1.5 mL) was treated with 4-dimethylaminopyridine (DMAP, 4 mg, 0.032 mmol) and stirred at ambient temperature for 5 h. TLC (S4) indicated complete consumption of **10***a*/**11***a* (R_f ~0.53) with formation of two well-resolved products (R_f 0.57 and 0.49). MeOH (3 mL) was added, the solution stirred for 1 h, evaporated *in vacuo*, and the residue partitioned ($CHCl_3$/(AcOH/H_2O, 1:99)). The organic phase was washed with $NaHCO_3$/H_2O, NaCl/H_2O, dried (Na_2SO_4), evaporated, and the residue subjected to column chromatography (MeOH/$CHCl_3$, 1.5:98.5). Evaporation of sequentially pooled fractions and diffusion crystallization (hexane/EtOAc) gave 1-[5-*N*-acetyl-5-amino-5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-α-L-talofuranosyl]uracil **12***a*(5′*R*) (81 mg, 47%); mp 110–115 (transition), 164–167°C; UV (MeOH) max: 258, 226 nm (ε 9800, 14 200), min: 240 nm (ε 5800); MS *m/z*: 478.1281 (7.7, M − CH_3 [$C_{21}H_{24}N_3O_8S$] = 478.1284), 338.1353 (11, M − Ts), 198.0589 (100, $TsCH_2CHNH_2$); MS (ci, NH_3) *m/z*: 494 (100, M + 1). Anal. calcd. for $C_{22}H_{27}N_3O_8S$ (493.5): C 53.54, H 5.51, N 8.51; found: C 53.61, H 5.58, N 8.49.

Further elution gave 1-[5-*N*-acetyl-5-amino-5,6-dideoxy-2,3-*O*-isopropylidene-6-(*p*-toluenesulfonyl)-β-D-allofuranosyl]uracil **13***a*-(5′*S*) (79 mg, 46%); MS *m/z*: 493.1505 (0.3, M^+ [$C_{22}H_{27}N_3O_8S$] = 493.1518), 478.1279 (8, M − CH_3), 338.1351 (7, M − Ts), 198.0586 (100, $TsCH_2CHNH_2$). It was confirmed that acetylation of a purified sample of **11***a*(5′*S*) gave **13***a*(5′*S*).

*1-[5(*R*)-Amino-5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil **10**b(5′R) and 1-[5(*S*)-amino-5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil **11**b(5′S)*

Solutions of **10***a*(5′*R*) (55 mg, 0.12 mmol) and **11***a*(5′*S*) (60 mg, 0.13 mmol) in CF_3CO_2H/H_2O (9:1, 5 mL) were stirred at ~0°C for 7 h and 8 h, respectively. Evaporation and coevaporation (EtOH) gave amorphous products that were purified on dry-packed silica columns (S3) to give 1-[5-amino-5,6-dideoxy-6-(*p*-toluenesulfonyl)-α-L-talofuranosyl]uracil **10***b*(5′*R*) (41 mg, 83%) (MeOH/EtOAc); mp 196–198°C; UV (MeOH) max: 260, 224 nm (ε 10 200, 15 200), min: 240 nm (ε 5000); MS *m/z*: 394 (1, M − NH_3), 264 (2), 170 (36), 156 (18), 155 (20), 112 (52), 92 (100). Anal. calcd. for $C_{17}H_{21}N_3O_7S$ (411.4): C 49.63, H 5.14, N 10.21; found: C 49.53, H 5.14, N 10.11. The diffusion crystallized (hexane/MeOH/EtOAc) 1-[5-amino-5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-allofuranosyl]uracil **11***b*(5′*S*) (39 mg, 73%) had mp 203–206°C (dec.); UV (MeOH) max: 260, 224 nm (ε 9900, 15 100) min: 240 nm (ε 4900); MS *m/z*: 394 (1, M − NH_3), 264 (5), 239 (6), 198 (56), 156 (55), 112 (82), 92 (100). Anal. calcd. for $C_{17}H_{21}N_3O_7S$ (411.4): C 49.63, H 5.14, N 10.21; found: C 49.86, H 5.29, N 10.04.

*1-[5(*R*)-Acetamido-5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil **12**b(5′R) and 1-[5(*S*)-acetamido-5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-ribo-hexofuranosyl]uracil **13**b(5′S)*

Solutions of **12***a*(5′*R*) (65 mg, 0.13 mmol) and **13***a*(5′*S*) (60 mg, 0.12 mmol) in CF_3CO_2H/H_2O (9:1, 5 mL) were stirred at ~0°C for 3 h and 2 h, respectively. Evaporation and coevaporation (EtOH) gave amorphous products that were diffusion crystallized to give 1-[5-*N*-acetyl-5-amino-5,6-dideoxy-6-(*p*-toluenesulfonyl)-α-L-talofuranosyl]uracil **12***b*(5′*R*) (48 mg, 88%, hexane/MeOH/EtOAc); mp 259–260°C (dec.); UV (MeOH) max: 260, 226 nm (ε 9700, 14 100), min: 241 nm (ε 5100); MS *m/z*: 453 (2, M^+), 342 (11), 240 (31), 198 (94), 156 (38), 112 (100). Anal. calcd. for $C_{19}H_{23}N_3O_8S$ (453.5): C 50.33, H 5.11, N 9.27; found: C 50.13, H 5.05, N 9.05. For the X-ray study, this product was recrystallized (MeOH) to give near cubic crystals with mp 261–262°C. The 1-[5-*N*-acetyl-5-amino-5,6-dideoxy-6-(*p*-toluenesulfonyl)-β-D-allofuranosyl]uracil (**13***b*(5′*S*)) (37 mg, 68%, MeOH two crops) had mp 166–169°C; UV (MeOH) max: 260, 224 nm (ε 9800, 14 500), min: 240 nm (ε 5100); MS *m/z*: 342 (15, M − B), 240 (22), 198 (42), 155 (32), 112 (100), 92 (78). Anal. calcd. for $C_{19}H_{23}N_3O_8S{\cdot}0.5H_2O$ (462.5): C 49.34, H 5.23, N 9.09; found: C 49.25, H 5.49, N 8.96.

*Deacetylation of **13**b(5′S) to **11**b(5′S)*

A solution of **13***b*(5′*S*) (45 mg, 0.1 mmol) in MeOH (0.5 mL) was treated with 1 M HCl/H_2O (4 mL) and heated at ~90°C for 30 h. The reaction mixture was cooled, neutralized to pH ~7 with solid

$NaHCO_3$, and evaporated. The residue was extracted (hot MeOH) and purified by column chromatography (S3) to give **11***b*(5′*S*) (25 mg, 61%) with data identical to those of the product of the reaction of **11***a*(5′*S*) → **11***b*(5′*S*) described above.

A voltammetric study of the kinetics of the hexacyanomanganate(III) disproportionation in acidic medium

GUILLERMO LÓPEZ-CUETO[1] AND CARLOS UBIDE[2]

División de Química Analítica, Facultad de Ciencias, Universidad de Alicante, Apdo. 99, 03080-Alicante, Spain

Received March 11, 1991

GUILLERMO LÓPEZ-CUETO and CARLOS UBIDE. Can. J. Chem. **69**, 2112 (1991).

The fast disproportionation of hexacyanomanganate(III) in acidic medium yields $Mn(CN)_6^{2-}$ and $Mn(H_2O)_6^{2+}$. The reaction has been studied by amperometry, with a rotating platinum-disk electrode, at a 1.0 V (vs. SCE) constant potential, in the acidity range 0.01–2.0 M and at temperatures between −5 and 15°C. A reversible one-electron process takes place with a 0.85 V (vs. SCE) half-wave potential that is not dependent on acidity. The reaction kinetics is pseudo-first order in $[Mn(CN)_6^{3-}]$ and the rate constant depends on acidity according to the equation: $k_{obs} = k_a + k_b[H_3O^+] + k_c[H_3O^+]^2$. At 5°C and ionic strength 2.0, the determined values of k_a, k_b, and k_c were $(2.20 \pm 0.08) \times 10^{-3}$ s^{-1}, $(4.9 \pm 0.2) \times 10^{-3}$ s^{-1} M^{-1}, and $(1.40 \pm 0.10) \times 10^{-3}$ s^{-1} M^{-2}, respectively. A mechanism is proposed where the three terms of k_{obs} are assigned to pathways involving hexacyanomanganate(III) in three different states of protonation. From the effect of temperature the activation parameters, $\Delta H^{\neq}$ and $\Delta S^{\neq}$, for each pathway are also reported.

Key words: hexacyanomanganate(IV), disproportionation, kinetics, amperometry, rotating platinum-disk electrode.

GUILLERMO LÓPEZ-CUETO et CARLOS UBIDE. Can. J. Chem. **69**, 2112 (1991).

La dismutation rapide de l'ion hexacyanomanganate(III), en milieu acide, fournit du $Mn(CN)_6^{2-}$ et du $Mn(H_2O)_6^{2+}$. On a étudié la réaction par ampérométrie, à l'aide d'une électrode de platine à disque tournant, à un potentiel constant de 1,0 V (vs. SCE), à des acidités allant de 0,01 à 2,0 M et à des températures allant de −5 à 15°C. Il se produit un processus réversible à un électron avec un potentiel de demi-vague de 0,85 V (vs. SCE) qui ne dépend pas de l'acidité. La cinétique de la réaction est du pseudo-premier ordre en $[Mn(CN)_6^{3-}]$ et la constante de vitesse est liée à l'acidité par l'équation : $k_{obs} = k_a + k_b[H_3O^+] + k_c[H_3O^+]^2$. À 5°C et à une force ionique de 2,0, les valeurs déterminées pour k_a, k_b et k_c sont respectivement $(2{,}20 \pm 0{,}08) \times 10^{-3}$ s^{-1}, $(4{,}9 \pm 0{,}2) \times 10^{-3}$ s^{-1} M^{-1} et $(1{,}40 \pm 0{,}10) \times 10^{-3}$ s^{-1} M^{-2}. On propose un mécanisme dans lequel les trois termes de k_{obs} sont attribués à des voies réactionnelles impliquant de l'hexacyanomanganate(III) dans trois états différents de protonation. En se basant sur l'effet de la température, on a aussi déterminé les paramètres d'activation, $\Delta H^{\neq}$ et $\Delta S^{\neq}$, pour chacune des voies réactionnelles.

Mots clés : hexacyanomanganate(IV), dismutation, cinétique, ampérométrie, électrode de platine à disque tournant.

[Traduit par la rédaction]

Introduction

The oxidation state 3+ of manganese is known to be very unstable because it is a strong oxidant, and thus it has been widely used as a one-electron oxidizing agent (1, 2). Mn(III) can often be made less oxidizing by complex formation (3), but in some cases these complexes show a thermodynamic tendency to disproportionate to Mn(IV) and Mn(II) (4–6), and therefore the disproportionation processes of Mn(III) compounds have special relevance. Nevertheless, the number of kinetic studies on Mn(III) disproportionation reactions is rather scarce in the literature (5, 6).

Cyanide ion strongly stabilizes Mn(III) as $Mn(CN)_6^{3-}$ in alkaline-cyanide medium (7–9). However, when $K_3Mn(CN)_6$ is dissolved in acidic solution it rapidly disproportionates to yield $Mn(H_2O)_6^{2+}$ and $Mn(CN)_6^{2-}$ (10, 11) and this explains why a change in the uv–visible spectra of the fresh acidic solutions of $Mn(CN)_6^{3-}$ is observed. The manganese(IV) cyano complex formed decomposes to $Mn(H_2O)_6^{2+}$ and $(CN)_2$, but the reaction is quite slow at room temperature (11) and thus the $Mn(CN)_6^{2-}$ solution can be used for oxidizing purposes for a period of time (12). The kinetics of the decomposition reaction of $Mn(CN)_6^{2-}$ has already been studied and a mechanism has been proposed (11). Trageser and Eysel (10) proposed a reaction scheme for the $Mn(CN)_6^{3-}$ disproportionation in which some part of $Mn(CN)_6^{3-}$ undergoes acid hydrolysis to yield $Mn(H_2O)_6^{3+}$ and this species oxidizes $Mn(CN)_6^{3-}$ to $Mn(CN)_6^{2-}$. This scheme is chiefly based on some thermodynamic considerations, but no kinetic evidence was reported on this reaction. In a previous paper (11) we reported that the kinetics of this reaction appeared to be close to a pseudo-first-order dependence, which seems to agree with the Trageser and Eysel scheme rather than with a bimolecular direct disproportionation. In the present paper the kinetics of the $Mn(CN)_6^{3-}$ disproportionation reaction in acidic medium is studied and a reaction mechanism is proposed. The reaction is quite fast at room temperature (at 25°C, half-life ~ 13 s) and thus the measurements have been taken well under room temperature using amperometric monitoring (spectrophotometric monitoring needs some extra care to avoid condensation of water on the outside of the cell). The amperometric measurements allowed some extra information about the redox properties of the involved species. Moreover, the voltammetric behavior of both the $Mn(CN)_6^{3-}$ and the $Mn(CN)_6^{2-}$ complexes at a rotating platinum-disk electrode in the same medium is described.

Experimental section

Apparatus

A 506 E Metrohm polarograph with a Metrohm 628-10 rotating platinum-disk electrode as working electrode, a platinum wire as auxiliary electrode, and a homemade saturated calomel electrode as reference electrode were used. The electrode rotation speed was 500 r.p.s. A 50 mL EA 880 Metrohm vessel was used as the reaction cell. The temperature in the vessel was continuously monitored by means of a Pt 100 temperature probe and kept constant (±0.1°C) by circulating an ethanol–water mixture from a thermostatic bath controlled by the probe.

Reagents

Potassium hexacyanomanganate(III) was prepared according to the method of Lower and Fernelius (13) and characterized as described previously (14). Nitric acid, sodium nitrate, and manganese(II) sulfate of analytical reagent grade and distilled, deionized water were used throughout.

Procedure

The reaction mixtures were prepared by adding the proper amount of solid $K_3Mn(CN)_6$ to 50 mL of a stirred solution having the required concentrations of Mn(II), nitric acid, and sodium nitrate (to adjust the ionic strength), and thermostated to the desired temperature (whenever $K_3Mn(CN)_6$ is taken into acidic solution HCN is produced, so *care* should be taken). After the solid was completely dissolved (between 5 and 60 s depending on the temperature) the magnetic stirrer was stopped. Then alternatively either current–voltage curves at different times or the current–time curve (the kinetic curve) were taken. The current–time curve was recorded, at least for three half-lives, at a 1.0 V (vs. SCE) constant potential. The pseudo-first-order rate constant, k_{obs}, was determined by plotting ln i_l vs. time (where i_l is the value of the limiting current) and linear regression analysis was applied (the value of i_∞ can be considered negligible). The temperature was varied between −5 and 15°C, the ionic strength between 0.1 and 2.0, the acidity between 0.01 and 2.0 M, the initial Mn(II) concentration between 0 and 0.01 M, and the initial $K_3Mn(CN)_6$ concentration between 3×10^{-4} and 3×10^{-3} M. Each kinetic run was usually repeated once, with the replicate measurement agreeing to within ±4% for 95% of the cases, and the value of k_{obs} was taken as the mean of the two runs.

Results and discussion[3]

Current–potential curves

The voltammogram obtained at a rotating platinum-disk electrode from a fresh acidic solution of $K_3Mn(CN)_6$ shows a one-electron anodic wave with a half-wave potential of about 0.85 V (vs. SCE) (Fig. 1, where anodic currents are considered positive and cathodic currents negative). Then a rapid change is spontaneously produced in the described voltammogram; the anodic current decreases while, at the same time, a cathodic current is produced, so that a composite anodic–cathodic current–potential curve is formed (Fig. 1). When the described transformation goes to completion only a cathodic current–voltage curve remains with a half-wave potential of about 0.85 V (vs. SCE). These electrochemical reactions involve the reversible couple $Mn(IV) + e^- \rightleftharpoons Mn(III)$, where Mn(IV) and Mn(III) represent the corresponding cyano complexes.

The variation of the limiting currents (i_l), of both the anodic and the cathodic processes, with time is shown in Fig. 2. As can be seen, the cathodic current tends towards a final value of about half the initial anodic current value. That is consistent with the following stoichiometry

$$[1] \qquad 2Mn(III) = Mn(IV) + Mn(II)$$

The manganese(IV) produced will remain in the form of cyano complex (Fig. 1), while manganese(II) will form the aquo complex (10, 11). Though the remaining acidic solution of the Mn(IV) cyano complex decomposes, this reaction proceeds very slowly at low temperature (11) and therefore only quite slow changes are observed in the voltammogram after the disproportionation reaction has gone to completion.

[3]Values of k_{obs}, k_{calc}, k_{calc}/k_{obs} for the disproportionation reaction may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Ont., K1A 0S2.

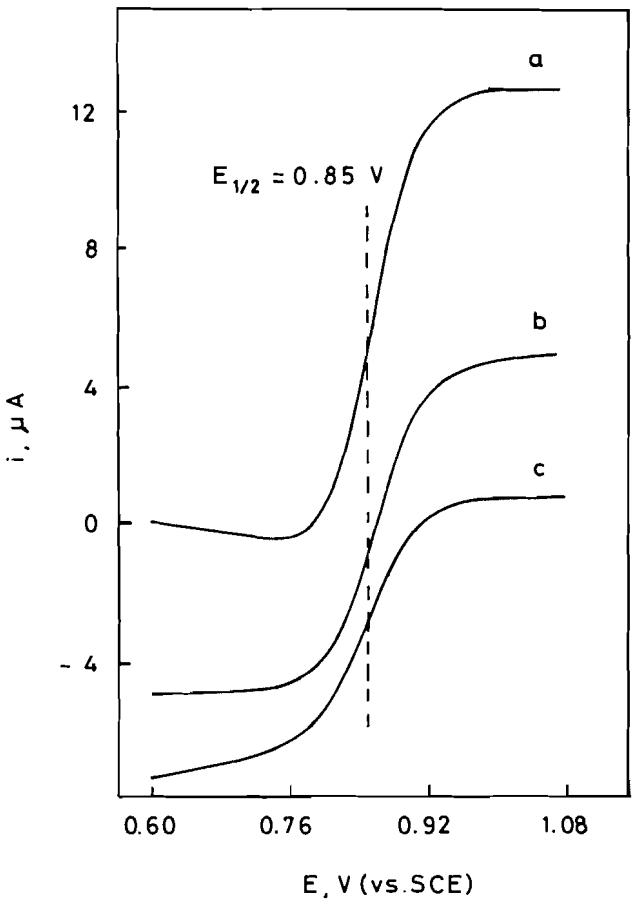

FIG. 1. Evolution of the current–potential curves of a fresh acidic solution of the Mn(III) cyano complex. Scan starting time: (*a*), 0; (*b*) 4; (*c*) 15 min. HNO_3, 0.1 M; *T*, 5°C. (Along the recording of the curve (*a*) the effect of the disproportionation reaction on the cathodic currents can clearly be observed. This effect is compensated for in curves (*b*) and (*c*) by the background current).

The half-wave potential remains essentially constant (0.85 ± 0.01 V, $n = 4$) when the H_3O^+ concentration varies in the range from 0.1 to 2.0 M (theoretically a one-proton reversible dependence in the mentioned acidity range would produce a change of about 0.077 V on the half-wave potential). This seems to indicate that protons are not involved in the electrode reaction.

Kinetics of disproportionation

Plots of ln i_l vs. time were linear for at least three half-lives. A first-order dependence on [Mn(III)] can therefore be inferred

$$[2] \qquad -\frac{d[Mn(III)]}{dt} = k_{obs}[Mn(III)]$$

The value of k_{obs} decreased about 30% when ionic strength increased from 0.1 to 1.0 and tended to level off for higher values (up to 2.0). On the other hand, k_{obs} was found to be independent of the $Mn(CN)_6^{3-}$ and Mn(II) initial concentrations (at least within the range studied) and thus the reaction does not seem to follow kinetics similar to that of the Mn(III) disproportionation in weakly complexing acidic medium, in which an equilibrium is involved (3):

$$[3] \qquad Mn(III) + Mn(III) \rightleftharpoons Mn(IV) + Mn(II)$$

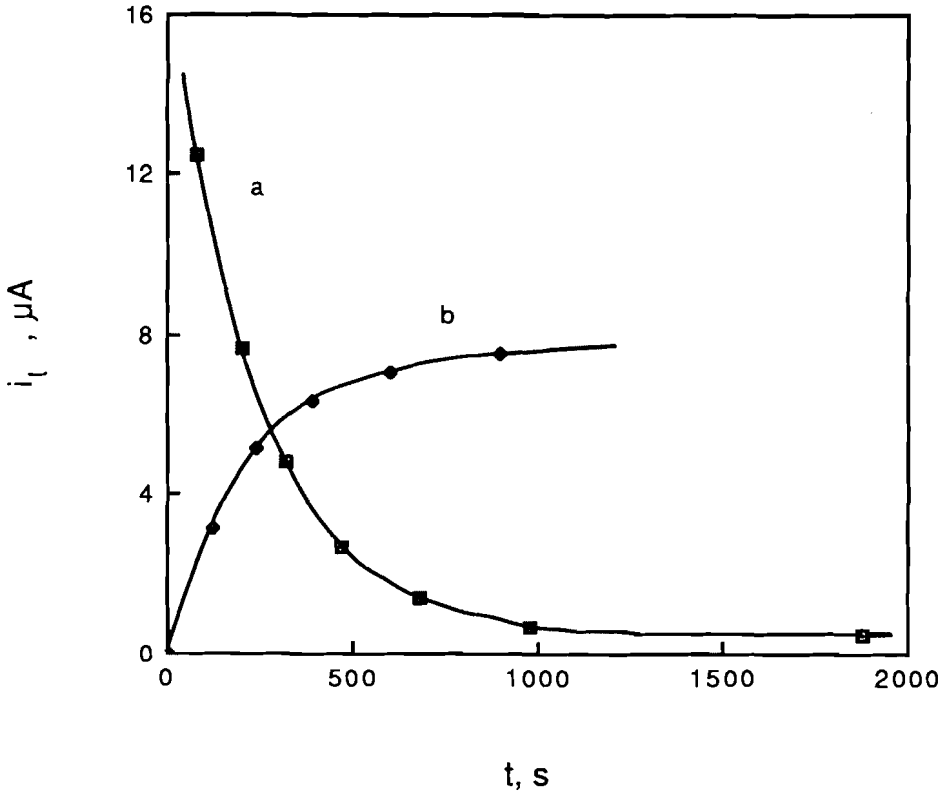

FIG. 2. Variation of the (*a*) anodic and (*b*) cathodic limiting current (i_l) with time during the disproportionation of the Mn(III) cyano complex. HNO_3 = 0.1 M; T = 5°C.

On the contrary, the $Mn(CN)_6^{3-}$ disproportionation seems to follow a scheme such as

$$[4] \qquad Mn(III) \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Mn(III)^* \quad \text{(intermediate)}$$

$$[5] \qquad Mn(III)^* + Mn(III) \xrightarrow{k_2} Mn(IV) + Mn(II)$$

and then, according to reactions [4] and [5]

$$[6] \qquad v = -\frac{d[Mn(III)]}{dt} = \frac{2k_1k_2[Mn(III)]^2}{k_{-1} + k_2[Mn(III)]}$$

But if reaction [5] is fast enough, $k_2[Mn(III)] \gg k_{-1}$. Therefore

$$[7] \qquad v = k_{obs}[Mn(III)]$$

k_{obs} being $2k_1$.

The value of k_{obs} depends on acidity. This dependence was found to lie between first and second order. Thus the following tentative equation was tested:

$$[8] \qquad k_{obs} = k_a + k_b[H_3O^+] + k_c[H_3O^+]^2$$

Following this equation a plot of $(k_{obs} - k_a)/[H_3O^+]$ vs. $[H_3O^+]$ should be straight. Figure 3 shows such a plot for temperatures ranging between −5 and 15°C. The values of k_a, k_b, and k_c at each temperature were obtained by non-linear regression analysis applied to the experimental points according to eq. [8]. Values of $k_a = (2.20 \pm 0.08)\ 10^{-3}\ s^{-1}$, $k_b = (4.9 \pm 0.2)\ 10^{-3}\ s^{-1}\ M^{-1}$, and $k_c = (1.40 \pm 0.10)\ 10^{-3}\ s^{-1}\ M^{-2}$ were obtained at 5°C and ionic strength 2.0. On the other hand, plots of $\ln (k/T)$ vs. $1/T$ for each rate constant allowed us to calculate the activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$ of the three reaction paths (Table 1).

If eq. [8] applies and the activation parameters are known, the value of the overall rate constant can be calculated theoretically (k_{calc}):

$$[9] \qquad k_{calc} = \frac{RT}{Nh}\left\{\exp\left(\frac{\Delta S_a^{\neq}}{R} - \frac{\Delta H_a^{\neq}}{RT}\right) + \exp\left(\frac{\Delta S_b^{\neq}}{R} - \frac{\Delta H_b^{\neq}}{RT}\right)[H_3O^+] + \exp\left(\frac{\Delta S_c^{\neq}}{R} - \frac{\Delta H_c^{\neq}}{RT}\right)[H_3O^+]^2\right\}$$

where R is the gas constant, T the absolute temperature, N is Avogadro's number, h is Planck's constant, and a, b, and c refer to the three paths given by eq. [8].

The values of k_{calc} obtained from eq. [9] were compared with the experimental ones (k_{obs}) by obtaining the k_{calc}/k_{obs} relation for different reaction conditions (the k_{obs} values ranged between 4.37×10^{-4} and 9.23×10^{-2}). The average value obtained for the k_{calc}/k_{obs} ratio was 0.995 with a standard deviation of 0.005 (assuming a gaussian distribution of the quotients). These results prove that both eq. [8] and the obtained values for the activation parameters hold throughout the ranges studied.

Reaction mechanism

According to eqs. [2] and [8] a mechanism with three par-

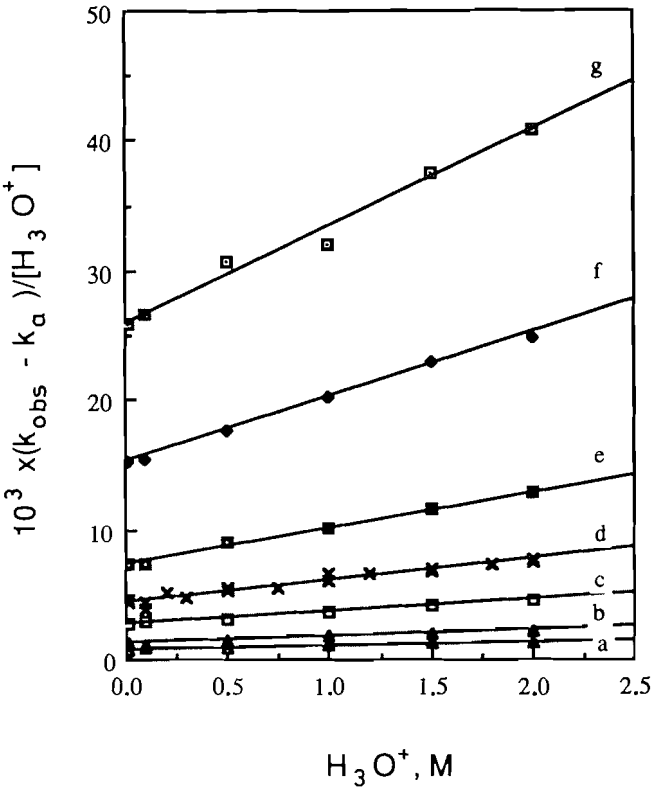

FIG. 3. Plots of $(k_{obs} - k_a)/[H_3O^+]$ vs. $[H_3O^+]$ for the disproportionation reaction of hexacyanomanganate(III) in acidic solution at ionic strength 2.0. Temperatures, °C: (*a*), −5; (*b*), −2; (*c*), 2; (*d*), 5; (*e*), 8; (*f*), 12; (*g*), 15.

allel pathways involving zero, one, and two protons, respectively, may be considered. The predominant species of the Mn(III) and Mn(IV) cyano complexes should have the same number of protons because it has already been shown above that the reversible electrode reaction $Mn(III) \rightleftarrows Mn(IV) + e^-$ involves zero protons. According to previous work (15), the predominant species of the Mn(IV) cyano complex in acidic solution should be at least monoprotonated, and so the Mn(III) and Mn(IV) predominant species will be $Mn(CN)_5(CNH)^{2-}$ and $Mn(CN)_5(CNH)^-$, respectively, both of them being species partially protonated on the nitrogen of some of the coordinated cyano groups as previously reported (11) and stated for some other cyano complexes (16).

The following equilibria should be considered before the rate-determining step

[10] $Mn(CN)_5(CNH)^{2-} + H_3O^+ \overset{\beta_1}{\rightleftharpoons} Mn(CN)_4(CNH)_2 + H_2O$

[11] $Mn(CN)_5(CNH)^{2-} + 2H_3O^+ \overset{\beta_2}{\rightleftharpoons} Mn(CN)_3(CNH)_3 + H_2O$

Each one of the three manganese(III) species will participate in a mechanism like the one schematized by reactions [4] and [5]. According to the scheme three parallel pathways will have to be considered, and the determining steps will be:

[12] $Mn(CN)_5(CNH)^{2-} \underset{k_{-a}'}{\overset{k_a'}{\rightleftharpoons}}$ intermediate (a)

[13] $Mn(CN)_4(CNH)_2^- \underset{k_{-b}'}{\overset{k_b'}{\rightleftharpoons}}$ intermediate (b)

TABLE 1. Activation parameters for the disproportionation reaction of hexacyanomanganate(III) in acidic solution at ionic strength 2.0 (each value is accompanied by its standard error)

Rate constant	$\Delta H^{\ddagger}$/kJ mol^{-1}	$\Delta S^{\ddagger}$/J mol^{-1} K^{-1}
k_a/s^{-1}	99.6 ± 1.0	63 ± 4
k_b/s^{-1} M^{-1}	109.4 ± 1.2*	105 ± 4*
k_c/s^{-1} M^{-2}	104 ± 2*	74 ± 7*

*These values are apparent since the rate constant includes a protonation equilibrium constant.

[14] $Mn(CN)_3(CNH)_3 \underset{k_{-c}'}{\overset{k_c'}{\rightleftharpoons}}$ intermediate (c)

Finally, each of the intermediate species will react quickly with the predominant Mn(III) cyano complex:

[15] $Mn(CN)_5(CNH)^{2-}$ + intermediate (a), (b), (c) $\overset{\text{fast}}{\rightleftharpoons}$ Mn(II) + Mn(IV)

The resulting Mn(II) species should be labile cyano-aquo complexes that rapidly lose the coordinated cyanides to give $Mn(H_2O)_6^{2+}$. As far as the Mn(IV) species is concerned, all of them will be transformed into $Mn(CN)_5(CNH)^-$, as this appears to be the predominant species in an acidic medium (15).

We have been looking for some experimental proof of the existence of the postulated intermediates (steps [12]–[14]), but neither spectral (uv–visible) nor electrochemical (cyclic voltammetry) evidence has been found, probably because the steady-state concentrations lie under their detection limits. Nonetheless, the existence of the intermediates has been postulated to explain the pseudo-first-order kinetics found. Unidentified steady-state intermediates of rearranged structure have sometimes been proposed to justify the experimental results (15, 17). The intermediates proposed here should have an oxidizing power high enough to oxidize the manganese(III) cyano complex to manganese(IV). These intermediates would probably be Mn(III) species at least partially dissociated (cyano-aquo complexes) in such a way that their oxidation potentials would approach that of the $Mn(H_2O)_6^{3+}/Mn(H_2O)_6^{2+}$ couple so that reaction [15] would be thermodynamically favorable. On the other hand, and according to thermodynamic considerations, Trageser and Eysel (10) proposed that the $Mn(CN)_6^{3-}$ disproportionation may take place through its oxidation to $Mn(CN)_6^{2-}$ via the $Mn(H_2O)_6^{3+}$ species formed in the previous hydrolytic decomposition of some part of the manganese(III) cyano complex. Our results seem to agree with these proposals.

From the proposed mechanism a pseudo-first-order rate law can be deduced, where the observed rate constant will have the form

$$[16] \quad k_{obs} = 2\,\frac{k_a' + k_b'\beta_1[H_3O^+] + k_c'\beta_2[H_3O^+]^2}{1 + \beta[H_3O^+] + \beta_2[H_3O^+]^2}$$

The monoprotonated species of the Mn(III) cyano complex, $Mn(CN)_5(CNH)^{2-}$, has been proposed above as predominant,

and from here: $1 \gg \beta_1[H_3O^+] \gg \beta_2[H_3O^+]^2$, and eq. [16] reduces to

$$[17] \quad k_{obs} = 2k_a' + 2k_b' + 2k_b'\beta_1[H_3O^+] + 2k_c'\beta_2[H_3O^+]^2$$

which may be written as

$$[8] \quad k_{obs} = k_a + k_b[H_3O^+] + k_c[H_3O^+]^2$$

where $k_a = 2k_a'$, $k_b = 2k_b'\beta_1$, and $k_c = 2k_c'\beta_2$.

The constants k_b and k_c include protonation equilibrium constants. Therefore the activation enthalpies and entropies for paths *b* and *c* are actually apparent and not much can be said on their numerical values (Table 1). On the other hand, k_a is a true rate constant and at low acidities it is the main part of k_{obs}. The activation enthalpy value of k_a appears to be rather high for a reaction in solution; from this a low rate constant could be expected. Nevertheless, relatively high values for k_a at not too high temperatures have been found ($k_a = 1.07 \pm 0.07) \times 10^{-2}$ s^{-1} at 15°C). This must be attributed to the high positive value of $\Delta S_a^{\neq}$, which suggests a strong dissociation in the activated complex formation. This result supports the hypothesis of a partially aquated cyano complex.

A number of disproportionation reactions have been reported to follow second-order kinetics (including uranium(V) (18), plutonium(V) (19), and americium(V) (20)) and it has been interpreted in terms of a bimolecular determining step, but some other disproportionation reactions have been reported to follow pseudo-first-order dependences. This appears to happen especially when the metal ion is in a complexed form, as Mo(V) complexes with EDTA, cysteine, histidine, and citric acid (21), neptunium(V) bonded in an inert cation–cation complex (22), and americium(V) in phosphoric acid (23) and in phosphotungstate solutions (24). On the other hand, the complexes of manganese(III) with $H_2P_2O_7^{2-}$ (6) and CyDTA in methanolic base (5) media also disproportionate following pseudo-first-order kinetics. In our case and according to reaction [4] only one Mn(III) is involved in the rate-determining step. It can be argued that [4] does not really correspond to a disproportionation. Nevertheless, considering the whole process (reactions [4] and [5]), two Mn(III) are involved and so it can be considered a disproportionation, in the same way as some precedences (5, 6, 10, 21–24).

Received December 21, 1989[3]

T. S. BANIPAL, B. S. LARK, and S. SINGH. Can. J. Chem. **69**, 2117 (1991).

Total vapour pressures for binary mixtures containing acetic acid, propionic acid, isobutyric acid, and trimethylacetic acid with acetonitrile have been measured for the entire composition range at 298.15 and 318.15 K using a static manometric method. All systems show positive deviations from Raoult's law, enhanced by both an increase in temperature and an increase in the methylation of acetic acid. Activity coefficients have been calculated by taking into consideration the dimerization of these carboxylic acids in the vapour phase. TS^E values obtained from G^E and earlier reported H^E values are found to be negative for acetic acid, about zero for propionic and isobutyric acids, and positive for trimethylacetic acid for the whole composition range. The results have been interpreted in terms of various contributions such as depolymerization, heteromolecular dipole–dipole interactions, and the increasing dimerization constant and steric hindrance with increase of complexity of the acid.

Key words: excess Gibbs energy, carboxylic acids, acetonitrile, activity coefficients.

T. S. BANIPAL, B. S. LARK et S. SINGH. Can. J. Chem. **69**, 2117 (1991).

Utilisant une méthode manométrique statique et opérant à 298,15 et 318,15 K, on a mesuré les pressions de vapeur totales de mélanges binaires d'acétonitrile avec les acides acétique, propanoïque, isobutyrique et triméthylacétique sur l'ensemble des compositions. Tous les systèmes présentent des déviations positives par rapport à la loi de Raoult et elles sont majorées tant par une augmentation de la température que par le degré de méthylation de l'acide acétique. On a calculé les coefficients d'activité en tenant compte de la dimérisation de ces acides en phase vapeur. On a trouvé que, pour l'ensemble des compositions, les valeurs de TS^E obtenues à partir des valeurs de G^E et des valeurs de H^E rapportées antérieurement sont négative pour l'acide acétique, approximativement égales à zéro pour les acides propanoïque et isobutyrique et positive pour l'acide triméthylacétique. On a interprété les résultats en fonction de diverses contributions comme : la dépolymérisation, les interactions hétéromoléculaires dipôle–dipôle et l'augmentation de la constante de dimérisation ainsi que de l'empêchement stérique avec une augmentation de la complexité de l'acide.

Mots clés : énergie de Gibbs dans l'excès, acides carboxyliques, acétonitrile, coefficients d'activité.

[Traduit par la rédaction]

Introduction

Carboxylic acids are strongly associated liquids showing peculiar mixing properties with various solvents (1–15). The mixing behaviour of these acids with non-polar solvents is characterised by double or even higher magnitude of positive G^E values as compared to corresponding H^E values, resulting in negative TS^E values. This behaviour has been explained by the breaking up of acid trimers to dimers and monomers, and the formation of dimers from the monomers thus set free on the addition of an increasing proportion of non-polar solvents (1–3, 9). In the case of protic solvents like CH_3OH, in spite of the evidence that AB and AB_2 (A = acid monomer, B = CH_3OH) types of species are formed (16, 17), entropy changes are large and positive (10, 11). Predominant depolymerization of both acid and CH_3OH molecules explains this trend. As a continuation of our work in which we have reported V^E and H^E values of acetic acid, propionic acid, isobutyric acid, and trimethylacetic acid with acetonitrile (4), in this paper we report total vapour pressures and free energy results for such mixtures. Acetonitrile is an aprotic and purely polar solvent with high dielectric constant ($\epsilon = 36.01$) and dipole moment ($\mu = 3.37$ D) at 298.15 K and, unlike CH_3OH, is non-hydrogen bonding in nature (18). Thus the results may help us to sort out the various contributions and explain the magnitude of excess thermodynamic functions of carboxylic acid mixtures.

Experimental

Acetic acid (AR, BDH), propionic acid (AR, BDH), isobutyric acid (LR, SRL), trimethylacetic acid (GR, Tokyo Kasei Kogyo Co., Ltd., Japan), and acetonitrile (LR, E. Merck) were further purified by the methods reported earlier (1–5).

Details of the static manometric method used for the measurement of total vapour pressures appear elsewhere (1, 2, 19). The temperature of the water thermostat, in which the mixing cell was kept, was controlled to ±0.005 K with the help of a 0.001 K Beckmann thermometer. The Beckmann thermometer was calibrated by determining the transition temperature of Glauber's salt (32.384°C). The manometer was housed in the air thermostat kept at 50 ± 0.1°C and the necessary correction was applied to convert the pressures to 0°C. The pressures were read with a 0.001 cm cathetometer.

Results and discussion

Measured total vapour pressures for all the systems as a function of mole fraction of acid at 298.15 and 318.15 K are presented in Table 1 and illustrated in Figs. 1–4 along with the partial pressures (at 298.15 K). All the systems show positive deviations from Raoult's law with maximum lying in the acid-rich region, and shifting to higher mole fraction with increasing complexity of the acid and magnitude have the following order:

acetic acid < propionic acid < isobutyric acid < trimethylacetic acid

This order is just opposite to that for non-polar solvents (cyclohexane and *n*-heptane) as reported earlier (1–3). Furthermore, these deviations increase with the rise in temperature. It may also be seen that the positive deviations in the acetonitrile-rich

$l_1 = x_2^2$
$m_1 = -x_2^2(1 - 4x_1)$
$n_1 = x_2^2(1 - 8x_1 + 12x_1^2)$
$o_1 = -x_2^2(1 - 12x_1 + 36x_1^2 - 32x_1^3)$
$p_1 = x_2^2(1 - 16x_1 + 72x_1^2 - 128x_1^3 + 80x_1^4)$

$l_2 = x_1^2$
$m_2 = x_1^2(1 - 4x_2)$
$n_2 = x_1^2(1 - 8x_2 + 12x_2^2)$
$o_2 = x_1^2(1 - 12x_2 + 36x_2^2 - 32x_2^3)$
$p_2 = x_1^2(1 - 16x_2 + 72x_2^2 - 128x_2^3 + 80x_2^4)$

region are much smaller than those in the acid-rich region and the mixtures approach ideality as $x \rightarrow 0$.

The activity coefficients of the components in the mixtures were calculated from the total vapour pressures and the composition in the liquid phase, taking into consideration the dimerization constants (3, 11, 12) of the carboxylic acids in the vapour phase, by the method reported earlier (1–3). Estimated activity coefficients fitted to the following equations

$$[1] \quad \ln \gamma_A = Al_1 + Bm_1 + Cn_1 + Do_1 + Ep_1$$

$$[2] \quad \ln \gamma_B = Al_2 + Bm_2 + Cn_2 + Do_2 + Ep_2$$

by the method of least squares are included in Table 1. Equations [1] and [2] satisfy the Gibbs–Duhem equation and the values of constants A, B, C, etc., are given in Table 2. l_1, m_1, n_1, $\cdots$ and l_2, m_2, n_2, $\cdots$ are functions of mole fractions

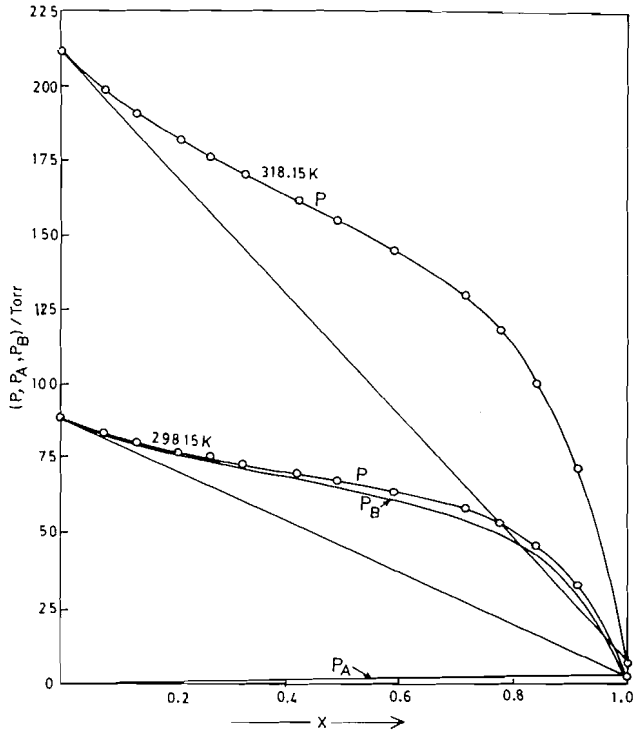

FIG. 3. Plot of total pressure (P) and partial pressures (P_A, P_B) vs. x for isobutyric acid + acetonitrile.

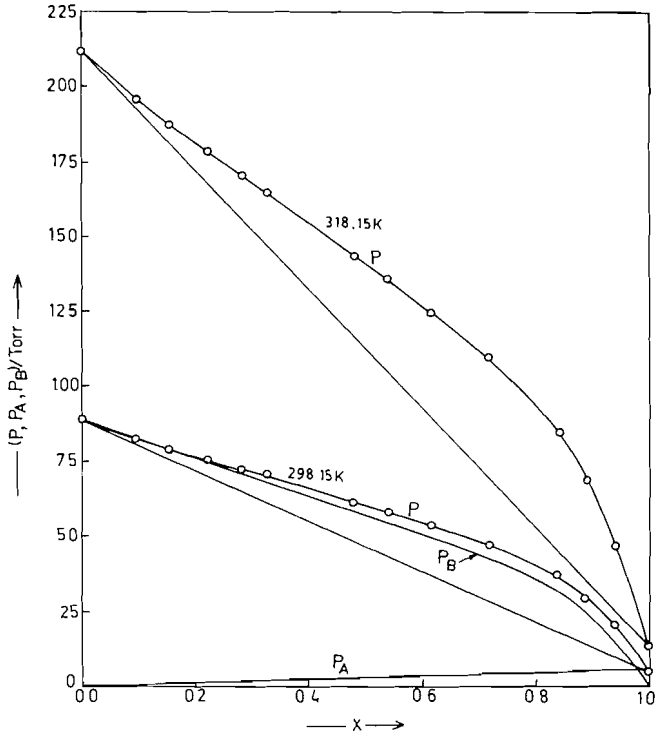

FIG. 2. Plot of total pressure (P) and partial pressures (P_A, P_B) vs. x for propionic acid + acetonitrile.

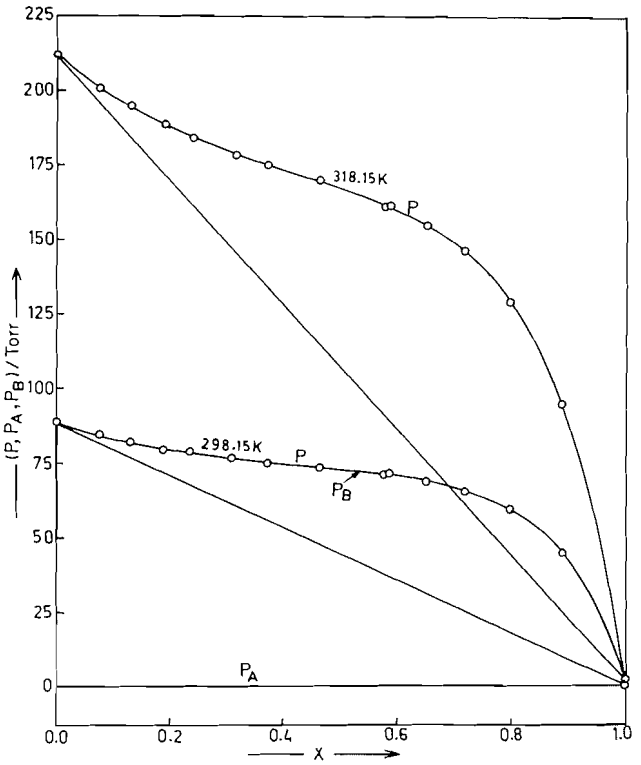

FIG. 4. Plot of total pressure (P) and partial pressures (P_A, P_B) vs. x for trimethylacetic acid + acetonitrile.

only and are given at the bottom of Table 2. Mole fractions of the acid in the vapour phase, residual pressures (the difference between the observed and calculated pressures), and standard deviations are also included in Table 1. Consistency of the activity data was checked from the plots of ln (γ_A/γ_B) vs. x, where negligible area was found under the curves for each system.

The excess Gibbs free energies derived from activity coef-

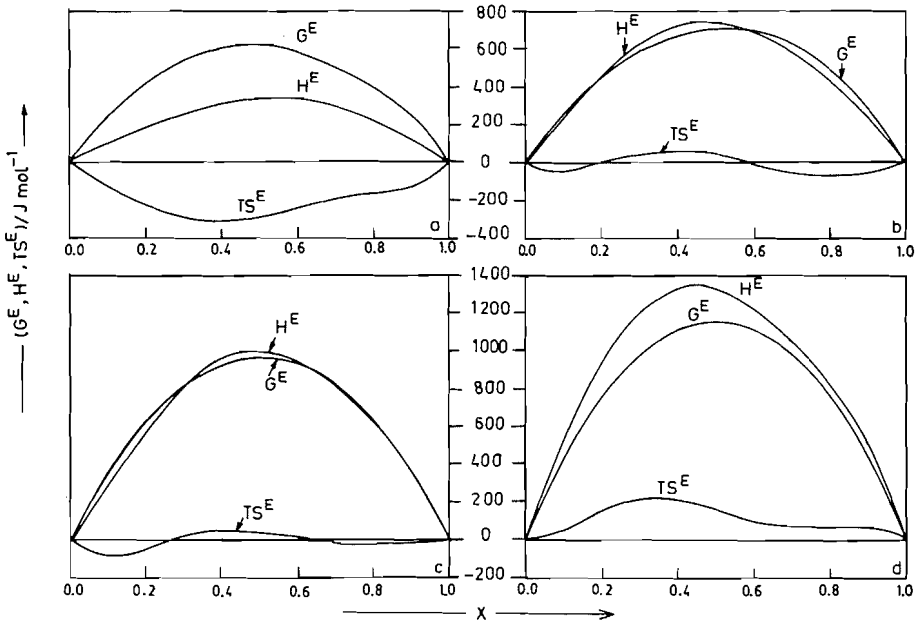

FIG. 5. Plot of G^E, H^E, and TS^E vs. x: (*a*) acetic acid + acetonitrile; (*b*) propionic acid + acetonitrile; (*c*) isobutyric acid + acetonitrile; (*d*) trimethylacetic acid + acetonitrile.

ficients at rounded mole fractions at 298.15 and 318.15 K and experimental excess enthalpies taken from our earlier report (4) at 308.15 K for all the systems are summarized in Table 3. A slight decrease in G^E values with the increase of temperature for all the systems, which may be due to the increased dipole–dipole interactions, is in line with the previously reported excess volume results (4) where the negative magnitude of V^E becomes more negative with the rise in temperature. H^E values calculated from the temperature dependence of G^E are included in Table 3 and the agreement with experimental values is good, considering the inherent large uncertainties associated with this method. TS^E values, estimated by utilizing the mean G^E, at 308.15 K (obtained as average of the corresponding values at 298.15 and 318.15 K), are summarized in Table 3 and illustrated along with the plots of G^E and H^E values in Fig. 5.

It may be seen that for acetic acid + acetonitrile: $G^E > H^E$ and $TS^E < 0$; for propionic acid + acetonitrile and isobutyric acid + acetonitrile: $G^E \approx H^E$ and $TS^E \approx 0$; and for trimethylacetic acid + acetonitrile: $G^E < H^E$ and $TS^E > 0$.

Further observation is that G^E and H^E increase with the complexity of the acid and H^E is increasing at a much faster rate to reverse the negative sign of TS^E for acetic acid to positive for trimethylacetic acid. This trend is quite in line with the increasing dimerization constants of the acids with their complexity (dimerization constants for acetic acid, propionic acid, isobutyric acid, and trimethylacetic acid are 1.982, 2.301, 7.755, and 842.9 Torr^{-1}, respectively, at 298.15 K). Negative TS^E in the case of acetic acid may be because of strong hetero dipole–dipole interactions. However, being impeded through increasing steric hindrance by the successive methylation of acetic acid results in almost zero TS^E values for propionic acid and isobutyric acid, and positive for trimethylacetic acid.

Received November 26, 1990[3]

DAVID C. ADAMS, THOMAS BIRCHALL, ROMOLO FAGGIANI, RONALD J. GILLESPIE, and JOHN E. VEKRIS. Can. J. Chem. **69**, 2122 (1991).

The reaction of tin(II) fluoride with fluorosulfuric acid has been shown to produce tin(II) bisfluorosulfate. Crystals of $Sn(OSO_2F)_2$ are monoclinic, space group $P2_1/c$ with a = 5.195(1), b = 9.709(1), c = 13.861(1) Å, β = 110.12(1)°, Z = 4, R = 0.029, and R_w = 0.030 for 1461 unique reflections. The structure consists of a three-dimensional framework of fluorosulfate groups linked by O—Sn—O bridges with the two crystallographically independent fluorosulfates acting as tridentate bridging ligands between tin atoms. There are four short bonds (Sn—O = 2.338(3), 2.350(3), 2.398(4), and 2.427(3) Å) and two longer ones (Sn—O = 2.695(3) and 2.702(3) Å) around tin. The four short bonds have a disphenoidal, AX_4E, primary geometry with the lone pair occupying an equatorial site. If the two longer interactions are also considered the geometry is distorted octahedral, AX_4Y_2E. Two more non-bonding contacts of 3.420(4) and 3.319(4) Å complete an approximately dodecahedral arrangement of oxygen atoms around the tin. The fluorosulfate groups deviate significantly from C_{3v} symmetry and have the mean dimensions, S(1)—O = 1.419(4), S(1)—F = 1.541(4), S(2)—O = 1.435(3), S(2)—F = 1.539(3) Å, O—S(1)—O = 114.3(2)°, F—S(1)—O = 104.1(3)°, O—S(2)—O = 114.2(2)°, and F—S(2)—O = 104.1(2)°, respectively. The solid-state ^{119}Sn nmr spectrum shows only one single resonance with a shift of −1534 ppm which is substantially different from that of a solution in HSO_3F. The ^{119}Sn Mössbauer spectrum shows an unresolved quadrupole splitting as a result of a distorted environment around tin, produced by the stereochemically active non-bonding electron pair.

Key words: tin(II) bisfluorosulfate, ^{119}Sn Mössbauer, solid-state nmr, X-ray crystallography.

DAVID C. ADAMS, THOMAS BIRCHALL, ROMOLO FAGGIANI, RONALD J. GILLESPIE et JOHN E. VEKRIS. Can. J. Chem. **69**, 2122 (1991).

On démontre que la réaction du fluorure d'étain(II) avec l'acide fluorosulfurique conduit au bisfluorosulfate d'étain(II). Les cristaux du $Sn(OSO_2F)_2$ sont monocliniques, groupe d'espace P_1/c, avec a = 5,195(1), b = 9,709(1) et c = 13,861(1) Å, β = 110,12(1)°, Z = 4, R = 0,029 et R_w = 0,030 pour 1461 réflexions uniques. La structure comporte un squelette à trois dimensions de groupes fluorosulfates liés par des ponts O—Sn—O avec deux fluorosulfates cristallographiquement indépendants qui agissent comme ponts coordinants tricoordinés entre les atomes d'étain. Autour de l'étain, il existe quatre liaisons courtes (Sn—O = 2,338(3), 2,350(3), 2,398(4) et 2,427(3) Å) et deux liaisons plus longues (Sn—O = 2,695(3) et 2,702(3) Å). Les quatre liaisons plus courtes possèdent une géométrie primaire disphénoïdale, AX_4E, dans laquelle la paire d'électron libre occupe un site équatorial. Si les deux interactions plus longues sont aussi considérées, la géométrie est alors celle d'un octaèdre déformé, AX_4Y_2E. Deux autres contacts non-liants de 3,420(4) et 3,319(4) Å complètent un arrangement approximativement dodécaédrique des atomes d'oxygène autour de l'étain. La symétrie des groupes fluorosulfates s'éloigne beaucoup de C_{3v}; les dimensions moyennes sont les suivantes : (S(1)—O = 1,419(4) Å, S(1)—F = 1,541(4) Å, S(2)—O = 1,435(3) Å, S(2)—F = 1,539(3) Å, O—S(1)—O = 114,3(2)°, F—S(1)—O = 104,1(3)°, O—S(2)—O = 114,2(2)° et F—S(2)—O = 104,1(2)°. Le spectre rmn du ^{119}Sn à l'état solide ne présente qu'une résonance, avec un déplacement de −1534 ppm, qui est assez différente de celle d'une solution de HSO_3F. Le spectre de Mössbauer du ^{119}Sn présente un couplage quadripolaire non-résolu d'un environnement déformé autour de l'étain et qui est produit par la paire d'électron non-liée qui est stéréochimiquement active.

Mots clés : bisfluorosulfate d'étain(II), Mössbauer du ^{119}Sn, rmn de l'état solide; diffraction des rayons-X.

[Traduit par la rédaction]

Introduction

In an earlier paper we reported some spectroscopic studies of compounds prepared by the reaction of tin(II) fluoride with strong Lewis acids (1). $Sn(OSO_2F)_2$ was among the compounds studied at that time. Its vibrational and ^{119}Sn Mössbauer spectra indicated an appreciable covalent cation–anion interaction and, in addition, a detectable distortion of the environment about the central tin(II) nucleus was observed from the latter spectrum. However, no information regarding the structure of $Sn(OSO_2F)_2$ was obtained. In view of the improvements in spectrometers since the early seventies and of the superior counting statistics and better fitting procedures that are now available we have remeasured the Mössbauer spectrum of $Sn(OSO_2F)_2$ and we report this together with its X-ray crystal structure and the ^{119}Sn nmr spectra of the solid and its solution in HSO_3F.

Experimental

Materials and general procedures

Tin(II) fluoride (Ultrapure, Ventron, Alfa Products) was dried by heating to 60°C under vacuum overnight. Fluorosulfuric acid (Technical grade, J. T. Baker Chemical Co. N.J.) was purified by double distillation in an all-glass apparatus (2). A saturated solution of tin(II) bisfluorosulfate (1) in fluorosulfuric acid was allowed to stand overnight at room temperature. Well-formed colourless crystals obtained from this solution were filtered and dried by pumping on a vacuum line. A portion of this sample was pulverised to a fine powder in a nitrogen dry box and appropriate quantities of this portion were used for Mössbauer, solid-state, and solution nmr studies.

Crystallography

Colourless crystals of $Sn(OSO_2F)_2$ were sealed in Lindemann capillaries in a dry box equipped with a microscope. Precession photographs gave preliminary cell and symmetry information and accu-

[a] $U_{eq} = (1/3)(U_{11} + U_{22} + U_{33} + 2U_{13} \cos \beta)$.

rate cell parameters were obtained on a Nicolet P3 diffractometer from a least-squares refinement of x, ϕ, and 2θ for 15 well-centered high angle, $19° \leq 2\theta \leq 38°$, reflections.

Crystal data are as follows:

$Sn(OSO_2F)_2$, $M = 316.8$

Monoclinic, space group $P2_1/c$, $a = 5.195(1)$, $b = 9.709(1)$, $c = 13.861(1)$ Å, $\beta = 110.12°(1)$, $U = 656.4(2)$ $Å^3$, $Z = 4$, $D_c = 3.206$ g cm^{-3}, $F(000) = 592$, graphite-monochromated MoKα($\lambda = 0.71069$ Å), $\mu = 45.5$ cm^{-1}, $T = 296$ K.

Collection of the X-ray data and solution of the structure

An almost spherical crystal of 0.2 mm diameter was used for analysis. Intensities were measured on the Nicolet diffractometer using a θ(crystal)–2θ counter scan method, for the total of 1785 reflections with $3° \leq 2\theta \leq 55°$, (*hkl* range: $0 \leq h \leq 6$, $0 \leq k \leq 12$, $-18 \leq l \leq 16$). Two standard reflections were measured every 49 reflections and showed no variation with time (−2,0,6 (esd 1%) and 2,−3,−3 (1.2%)). The methods of selection of scan rates and initial data treatment have been described before (3). Lorentz, polarization (4), and ψ-scan absorption correction, PSI (5), were applied to all reflections. A total of 167 reflections of the 1785 collected were systematically absent and were removed from the data set. Equivalent reflections were averaged for a total of 1461 independent unique reflections ($R_{Int} = 0.017$). A three-dimensional Patterson map located the position of the tin atom and the remaining atoms were identified from a series of difference Fourier syntheses and least-squares refinements, using the program SHELX (6). Anisotropic thermal parameters were then assigned to all atoms and further refinement with full-matrix least-squares routines minimizing $\Sigma w(|F_o| - |F_c|)^2$, with the weight $w = 1/[\sigma^2(F) + 0.0005F_o^2]$, was terminated when the maximum shift/error fell to 0.005. Final R and R_w values were 0.029 and 0.030, respectively, for all measured unique reflections and 101 variables ($R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$ and $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma_w|F_o|^2]^{1/2}$). Residual electron density in the final difference map was <1 e $Å^{-3}$. Corrections were made for secondary extinction by the SHELX method (6), and scattering factors were those stored in this program. Density was not determined because of the instability of the compound in air. Fractional atomic coordinates are given in Table 1 and selected bond distances and angles in Table 2 (7).[4,5]

[4]A complete list of observed and calculated structure factors, anisotropic thermal parameters, and details of least-squares planes may be purchased from the Depository of Unpublished Data, CISTI, Document Delivery, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[5]All computations were carried out on a Cyber 170/815 and VAX 8600 computer. Programs used for initial data treatment are XRAY 76 (7*a*) and XTAL system of crystallographic programs (7*b*), University of Maryland, College Park, MD. 1983. Planes were calculated with the program LSQPL (7*c*). Diagrams were prepared from the program ORTEP-II (7*d*).

Mössbauer spectroscopy

A powdered absorber sample of $Sn(OSO_2F)_2$ containing approximately 10 mg cm^{-2} of ^{119}Sn was pressed into a 20 mm i.d. threaded Kel-F Mössbauer cell under an atmosphere of dried nitrogen. The ^{119}Sn spectrum was recorded with the absorber sample at 77 K in a Technology Systems cryostat. Cooling of the sample was maintained by 30 mbar of He exchange gas between the sample and the liquid N_2 reservoir. The source, $Ca^{119m}SnO_3$ (10 mCi, Amersham), was maintained at ambient temperature. An Elscint MFG-N-5 Mössbauer function generator, an Elscint MDF-N-5 driver/generator, and an Elscint MVT-4 velocity transducer operating in the constant-acceleration triangular-waveform mode were used. The transmitted radiation was detected by a NaI(Tl) (6.35 mm), scintillation counter (Harshaw), and the pulses fed through a Tennelec TC 211A linear amplifier to a CMTE Multichannel Data Processor (operating in the multiscaling mode), controlled by an IBM PC/AT microcomputer. The velocity scale was calibrated using a standard iron foil and a $^{57}Co/Rh$ source mounted on the reverse end of the transducer, calibration spectra are thus recorded without interruption of the drive sequence. The calibration spectra were computer fitted to give a linear velocity scale and folding point. Folded ^{119}Sn spectra were fitted using the program GMFP (8), using a Lorentzian line-shape approximation. All isomer shifts were referenced to $Ca^{119}SnO_3$ at ambient temperature.

^{119}Sn solid state and solution nmr measurements

The solid state ^{119}Sn nmr spectrum was obtained on a Varian VXR-300 spectrometer equipped with a Doty Scientific 7 mm standard probe. The spectrometer operated at a field of 7 T and at ^{119}Sn frequency of 111.702 MHz. The sample was packed in a sapphire rotor equipped with Kel-F endcaps. The magic angle spinning technique was used along with the following acquisition parameters: 90° ^{119}Sn pulse, 4 μs; recycle delay, 2 s; spinning speed, 3545 Hz. The reference was external $Sn(CH_3)_4$. A solution of $Sn(OSO_2F)_2$ in fluorosulfuric acid was prepared in a 10 mm precision nmr tube, and the ^{119}Sn nmr spectrum was run on a Bruker WM 250 spectrometer operating at a field of 5.872 T and at ^{119}Sn frequency of 93.276 MHz. The reference was external $Sn(CH_3)_4$.

Results and discussion

Description of the structure

The coordination around the Sn(II) atom is shown in Fig. 1 and a stereoscopic view of the unit cell is illustrated in Fig. 2. There are one tin atom and two crystallographically independent fluorosulfate groups in the asymmetric unit. It has previously been suggested that the ir spectrum of $Sn(OSO_2F)_2$ may be interpreted in terms of two non-equivalent SO_3F^- groups (1, 9). The structure consists of a three-dimensional network wherein each fluorosulfate group is bonded through its oxygens to three different tin(II) atoms. The Sn atom forms two short bonds to the oxygens O(22) and O(23)′ of lengths 2.338(3) and 2.350(3) Å and two longer ones to O(11) and O(12)′ of lengths 2.398(4) and 2.427(3) Å, respectively. The primary geometry about Sn can be described as AX_4E, disphenoidal, with the longer bonds in the axial positions and the lone pair presumably occupying one of the equatorial sites of a trigonal bipyramidal arrangement of five electron pairs in accordance with the VSEPR model (10). Because the lone pair occupies more space in the valence shell of the tin atom than the bond pairs, the O(11)—Sn—O(12)′ angle (146.9°) is less than 180° and the O(22)—Sn—O(23)′ angle (80.7°) is less than 120°. In $Sn(OSO_2F)$, the tin atom also forms two long bonds to the oxygens O(21)′ and O(13)′ of lengths 2.702(3) and 2.695(3) Å, respectively. Atom O(21)′ lies below and atom O(13)′ lies above the plane which is defined by atoms O(23)′, O(22), and Sn and at distances of 0.603(5) and 1.055(6) Å, respectively. These long Sn...O bonds complete a distorted octahedral, AX_4Y_2E (11), arrangement of oxygen atoms around tin. Two more long contacts, Sn...O(23)″ = 3.420(4) and Sn...F(11)′ = 3.319(4) Å, complete the environment of the Sn(II) ion. A least-squares plane defined by atoms O(11), Sn, O(12)′, O(23)″, and F(11)′ shows that the maximum displacement of any of these atoms from the mean plane is 0.182 Å. This is also shown by the sum of the angles O(11)—Sn—F(11)′ = 71.3°(1), F(11)′—Sn—O(23)″ = 71.7(1)°, O(23)″—Sn—O(12)′ = 69.8(1)° and O(11)—Sn—O(12)′ = 146.9(1)° which is 359.7(1)°. This geometry suggests that the Sn...O(23)″ and Sn...F(11)′ contacts bisect two of the XE edges of the disphenoid so that there is an approximately dodecahedral arrangement of oxygen atoms around the tin.

The AX_4E primary geometry found in $Sn(OSO_2F)_2$ has also been observed for a number of other compounds of Sn(II) coordinated by oxygen (Table 3). This well-defined geometry is consistent with the Sn—O bonds having substantial covalent character as was previously concluded from the vibrational spectrum (1). However, the Sn—O primary bonds in the present compound are longer than in the other compounds in Table 3 presumably because these bonds are more ionic. The two secondary bonds (average 2.70 Å) are considerably shorter than the sum of the van der Waals radii, which is 3.62 Å (16).

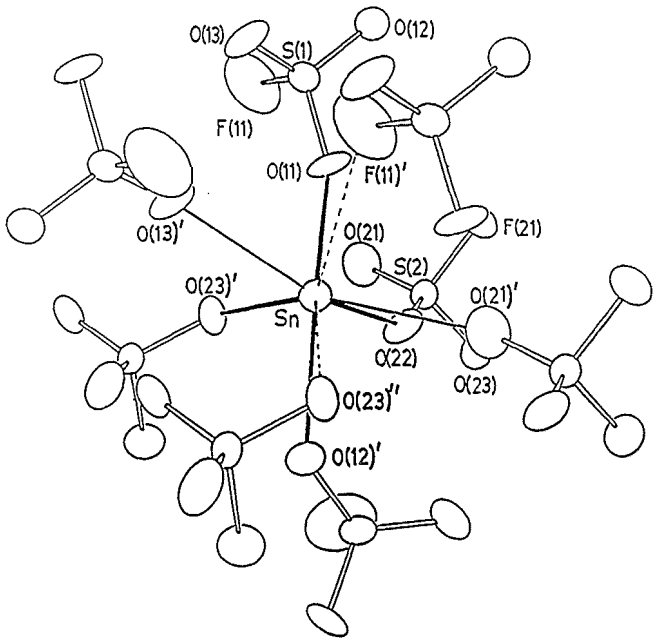

FIG. 1. The environment of the tin atom in $Sn(OSO_2F)_2$.

The fluorine atoms in the fluorosulfate groups were distinguished initially in the refinement on the basis of their significantly greater distances from the sulphur atoms and the final results indicate that these groups are ordered in the crystal. Potassium and ammonium fluorosulfates have ionic structures in which the SO_3F^- ions are disordered (17, 18) but in the more covalent structures of $Me_2Sn(OSO_2F)_2$ (19) and $I(OSO_2F)_2I$ (20) the fluorosulfate groups are ordered. The three S—O bond lengths are not equal and have the mean dimensions S(1)—O = 1.419(4) and S(2)—O = 1.435(3) Å. The S(1)—F(11) and S(2)—F(21) distances are 1.541(4) and 1.539(3) Å, respectively. The fluorosulfate groups deviate significantly from C_{3v} symmetry and this reduction in symmetry has been predicted earlier from spectroscopic results (1, 9). The angles O—S(1)—O, F—S(1)—O, O—S(2)—O, and F—S(2)—O have the mean values of 114.3(2)°, 104.1(3)°, 114.2(2)°, and 104.1(2)°, respectively, with the larger angles between the partially doubly bonded oxygens.

Mössbauer spectroscopy

The ^{119}Sn Mössbauer spectrum of $Sn(OSO_2F)_2$ was measured at 77 K. It consists of a single resonance in the tin(II) region, which has been successfully fitted to a small unresolved quadrupole splitting: $\delta = 4.19(1)$, $\Delta = 0.65(1)$, and $\Gamma = 0.97(2)$ mm s^{-1}. The present spectrum has a much narrower line width and is of considerably higher quality than our previously reported spectrum. This is a reflection of the improvements in instrumentation since 1971 and of the use of better counting statistics and fitting procedures. The unresolved quadrupole splitting may be attributed to a distortion of the environment of the tin nucleus from ideal cubic symmetry. The magnitude of the isomer shift ($\delta = 4.19$ mm s^{-1}) is high, showing that tin has considerable cationic character. However, the shift is smaller than that predicted for a "bare" tin(II) ion (21–23) or that observed for $Sn(SbF_6)_2$ ($\delta = 4.63$ mm s^{-1}) (24), $Sn(SbF_6)_2.2AsF_3$ ($\delta = 4.66$ mm s^{-1}) (25), or $Sn(II)[Sn(SO_3CF_3)_6]$ ($\delta = 4.69$ mm s^{-1}) (26), which appear

TABLE 3. Comparison of Sn—O distances and angles in $Sn(OSO_2F)_2$ with other compounds having a similar primary geometry

	O_{eq}—Sn—O_{eq}		O_{ax}—Sn—O_{ax}		
Compound	Bond (Å)	Angle (deg)	Bond (Å)	Angle (deg)	Reference
$Sn(O_2CH)_2$	2.17(av.)	79.7(av.)	2.36(av.)	158.2(av.)	12
Sn_2OSO_4	2.19(av.)	78.6(av.)	2.44(av.)	150.6(av.)	13
$[Sn(PhCOCHCOMe)_2]$	2.13	94.7	2.29	150.4	14
$SnO_5C_4H_4$	2.19(av.)	80.7	2.38(av.)	152.9	15
$Sn(OSO_2F)_2$	2.34(av.)	80.7	2.41(av.)	146.9	This work

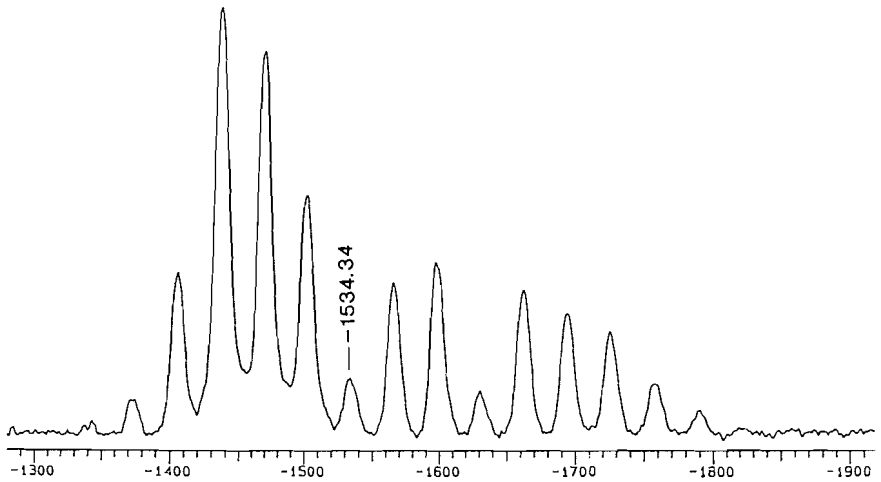

FIG. 3. ^{119}Sn SP-MAS spectrum of $Sn(OSO_2F)_2$; 90° ^{119}Sn pulse, 4 μs; recycle delay, 2 s; number of transients, 7620; spinning speed, 3545 Hz. The centre band is indicated.

to be highly ionic. Thus we conclude that the SnO bonds in $Sn(OSO_2F)_2$, while predominately ionic, have somewhat more covalent character than the SnF bonds in $SN(SbF_6)_2$.

Solid and solution-state nuclear magnetic resonance

The solid-state ^{119}Sn nmr spectrum of $Sn(OSO_2F)_2$ is shown in Fig. 3 with the centre band indicated. A comparison of the chemical shifts in the solid and in solution in HSO_3F is given in Table 4. No splitting of the ^{119}Sn resonance due to coupling with fluorine is observed in either the solid state or solution. It has been concluded from conductivity measurements that $Sn(OSO_2F)_2$ is partially ionized in solution in HSO_3F (27):

$$Sn(SO_3F)_2 \rightleftharpoons Sn(SO_3F)^+ + SO_3F^-$$

$$Sn(SO_3F)^+ \rightleftharpoons Sn^{2+} + SO_3F^-$$

The difference in the chemical shift between the solid state and the solution and its concentration dependence are consistent with this proposed ionization. The lack of any Sn—F coupling in solution as well as the observation of a single resonance in the ^{19}F nmr spectrum of a solution of $Sn(OSO_2F)_2$ in fluorosulfuric acid are also consistent with this ionization.

TABLE 4. ^{119}Sn nmr data for $Sn(OSO_2F)_2$

	Conc. M L^{-1}	δ, ppm[a]	$\Delta W_{1/2}$, Hz
Solid	—	−1534	ca. 1000
Solution in HSO_3F	0.34	−1628	125
	Saturated	−1636	85

[a]Relative to $Sn(CH_3)_4$.

The observation that there is only one tin signal in the ^{119}Sn solid-state nmr spectrum indicates that there is only one unique tin atom in the unit cell, and this is in accordance with the present X-ray structural analysis. The lack of an observable three-bond Sn—F coupling in the solid state is not surprising

in view of the ca. 1000 Hz line width of the Sn signal. Although not many examples are known, Harris *et al.* (28) list several Sn—F couplings in solution as being less than 30 Hz. A coupling of this magnitude would be unresolvable with the line width found for $Sn(OSO_2F)_2$ in the solid state.

Received February 21, 1991

JAMES CLAYTON BAUM, KATHLEEN ANNE DURKIN, LAURA PRECEDO, STACY BRIAN O'BLENES, JOHN EDWARD GOEHL, RICHARD FRANCIS LANGLER, GERALD KENDALL MACCORMACK, and LANA LOUISE SMITH. Can. J. Chem. **69**, 2127 (1991).

Sodium hydride reductions of aryl methanesulfonates afford dimeric sulfone-sulfonate esters as well as products arising from SO bond rupture. SO bond rupture becomes more competitive as the LUMO energy of the sulfonate ester declines. Exploration of the chemistry of a sulfone-sulfonate ester revealed a complex novel reaction that resulted in the formation of, *inter alia*, a dichloromethanesulfonate ester and a trichloromethanesulfonate ester. The first successful approaches to the synthesis of the heretofore unknown trichloromethanesulfonates and dichloromethanesulfonates are reported.

Key words: sodium hydride reductions, sulfenes, sulfone-sulfonate esters.

JAMES CLAYTON BAUM, KATHLEEN ANNE DURKIN, LAURA PRECEDO, STACY BRIAN O'BLENES, JOHN EDWARD GOEHL, RICHARD FRANCIS LANGLER, GERALD KENDALL MACCORMACK et LANA LOUISE SMITH. Can. J. Chem. **69**, 2127 (1991).

Les réductions des méthanesulfonates d'aryles par l'hydrure de sodium fournissent les esters sulfone-sulfonates dimères ainsi que des produits provenant de la rupture de la liaison SO. La rupture de la liaison SO devient plus importante lorsque l'énergie des OM BV des sulfonates diminue. Une exploration de la chimie d'un ester sulfone-sulfonate a révélé l'existence d'une nouvelle réaction complexe qui conduit à la formation, entre autres choses, d'esters dichloro- et trichloro-méthanesulfonates. On rapporte les premières approches réussies à la synthèse de ces dichloro- et trichloro-méthanesulfonates qui étaient inconnus jusqu'à maintenant.

Mots clés : réductions par l'hydrure de sodium, sulfènes, esters sulfone-sulfonate.

[Traduit par la rédaction]

Introduction

Phenyl methanesulfonate induces the condensation of *p*-toluenethiol and primary alcohols to afford sulfides (1). In pursuit of a variation of that approach to sulfide synthesis, phenyl benzenethiosulfonate was allowed to react with alkoxide ions. The expected sequence involved transformation of the thiosulfonate into a sulfonate ester and a thiolate anion with sequential thiolate anion alkylation by the newly formed sulfonate ester. Equation [1] depicts the outcome of such an experiment.

$$[1] \quad CH_3OH + PhSO_2SPh \xrightarrow[HMPA]{NaH} PhSCH_3 + (PhS)_2$$

The formation of disulfide led us to explore the possibility that direct hydride reduction of the thiosulfonate was responsible for formation of some disulfide. Although sodium hydride is best known as a base, there is some precedent indicating that it may act as a reducing agent (2).

A brief investigation of phenyl benzenethiosulfonate reductions established that better reducing hydrides dramatically increase the yield of disulfide (see Table 1). In consonance with our previous experience (3), yields of benzenesulfinate anions (trapped with methyl iodide and isolated as methyl phenyl sulfone) tended to be low.

Reaction of phenyl benzenethiosulfonate with potassium metal afforded diphenyl disulfide in 23% yield, reminiscent of the sodium hydride result included in Table 1. This experiment suggests that sodium hydride may well react by the single electron transfer mechanism one would presume for potassium metal. Although it seemed reasonable to expect that sodium hydride should be able to reduce related sulfur functionalities, phenyl benzenesulfonate would not react with sodium hydride under our reaction conditions.

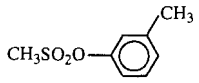
On the basis of this preliminary experience, we have undertaken a study of reactions between substituted aryl methanesulfonates and sodium hydride under the conditions of eq. [1].

TABLE 1. Yields of diphenyl disulfide and benzenesulfinate anions[a] isolated from reaction of phenyl benzenethiosulfonate with various hydrides in HMPA

Yield%)		
Diphenyl disulfide	Benzenesulfinate anions[a]	Hydride
32	36	NaH
58	21	$NaBH_4$
87	38	$LiAlH_4$

[a]Benzenesulfinate anions were isolated as phenyl methyl sulfone after trapping with methyl iodide.

Results and discussion



A series of aryl methanesulfonates **1***a*–**1***g* were prepared and allowed to react with sodium hydride in HMPA. Equation [2] depicts our results and Table 2 provides the product yields.

TABLE 2. Reaction of various methanesulfonates with sodium hydride in HMPA (eq. [2])

Methanesulfonate (**1**)		LUMO[a] eigenvalue (eV)	Yield[b] (%) Sulfone-sulfonate ester	Yield[b] (%) Corresponding phenol[c]
	(**1***a*)	+0.4030	**2***a* (54)	—
CH_3SO_2OPh	(**1***b*)	+0.3516	**2***b* (68)	43
	(**1***c*)	−0.0201	**2***c* (60)	47
	(**1***d*)	−0.5714	**2***d* (25)	76
	(**1***e*)	−0.6193	**2***e* (30)	64
	(**1***f*)	−1.0468	(0)	11
	(**1***g*)	−1.9839	(0)	55

[a]LUMO eigenvalues were calculated using the ZINDO program (*5b*).
[b]Starting methanesulfonates were completely consumed in these reactions.
[c]Yields calculated on the basis that 100% yield represents one mole of phenol obtained from 1 mole of starting methanesulfonate.

[2] 

1

2

Phenols cannot be formed exclusively by the processes that lead to the sulfone-sulfonate esters **2** because the phenolic yields are too high. An alternative pathway for phenol formation may involve single electron transfer (SET). SET from sodium hydride to the sulfonate esters **1** leading to products explicable through methylsulfonyl radicals and phenoxide anions would be consistent with our results on phenyl benzenethiosulfonate and previously reported results (3, 4, *5a*). In accord with this view, calculated sulfonate ester LUMO eigenvalues (Table 2) decline as observed yields of sulfone-sulfonate esters **2** decline. Thus, expected increases in facility for electron transfer correlate with increasing yields of sulfonate ester reduction products.

In contrast, the formation of a sulfone-sulfonate ester **2** seemed likely to begin with an acid–base step in which sodium hydride abstracts a proton from the methyl group of the starting methanesulfonate **1**. Skeletal assembly of the sulfone-sulfonate esters **2** may, thereafter, be imagined to proceed in three ways as shown in Scheme 1. Pathways *a* and *b* invoke sulfene intermediacy whereas pathway *c* envisions simple S_N2 attack of the carbanion at sulfonyl sulfur. Truce and Christensen (6) previously considered this dichotomy without adducing evidence for either possibility. When the reaction shown in eq. [2] was conducted on the methanesulfonate of phenol **1***b*, starting sulfonate ester was always completely consumed. Repetition of the reaction in the presence of an equivalent of sodium phenoxide gave the results shown in eq. [3].

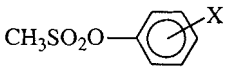
[3] $CH_3SO_2OPh + NaOPh + NaH \xrightarrow{HMPA}$

1*b*

$CH_3SO_2CH_2SO_2OPh + CH_3SO_2OPh$

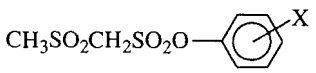
2*b* (3%) **1***b* (38%)

It seems unlikely that added phenoxide ion would impair the pathway *c* reaction (Scheme 1) whereas it would substantially reduce the amount of sulfene available for product formation by either pathway *a* or *b*. Furthermore, when the reaction shown in eq. [2] was repeated in the presence of an equivalent of phenyl benzenesulfonate, only **2***b* was isolated:



[4] $CH_3SO_2OPh + PhSO_2OPh + NaH \xrightarrow{HMPA}$

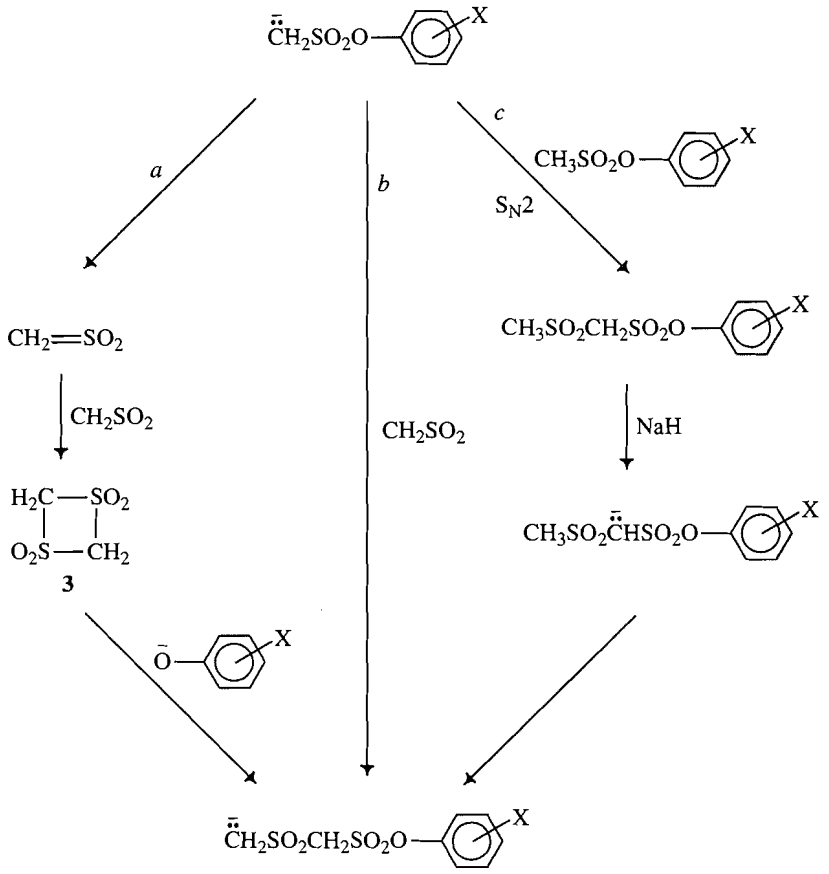
1*b*



$PhSO_2CH_2SO_2OPh$

The failure of phenyl methanesulfonate carbanions to attack at sulfonyl sulfur in phenyl benzenesulfonate while the usual formation of **2***b* proceeded normally is inconsistent with the S_N2 process in pathway *c*. On this basis, we have dismissed pathway *c* from further consideration.

A brief computational study of sulfene[2] showed that both the



1*a* X = *m*CH_3
1*b* X = H
1*c* X = *p*Cl
1*d* X = *p*CN
1*e* X = *p*CH_3SO_2
1*f* X = *p*CHO
1*g* X = *p*NO_2

2*a* X = *m*CH_3
2*b* X = H
2*c* X = *p*Cl
2*d* X = *p*CN
2*e* X = *p*CH_3SO_2

[2]R. F. Langler and L. Precedo, unpublished results. Procedural details for MNDO computations were provided earlier, see ref. 7.

SCHEME 1

planar and the nonplanar energy-minimized structures assign the largest LUMO coefficient to carbon. This result suggests that carbon is the preferred soft base site in sulfene. It would seem unlikely that an α-sulfonate carbanion (soft base) would attack sulfene at sulfur (hard acid) as required by pathway *b*. Possible soft base attack at carbon in sulfenes has some precedent (8). The sulfene dimer might be $CH_3SO_2CHSO_2$ (9) or the dithiacyclobutane tetraoxide structure **3** (10*a*, *b*). Although Scheme 1 depicts the cyclic sulfene dimer structure, both **3** and $CH_3SO_2CHSO_2$ provide the necessary hard acid sites at sulfur to permit completion of the sulfone-sulfonate ester skeletal assembly by reaction with phenoxide ion (hard base). The importance of phenoxide ion exophilicity for efficient sulfene formation is demonstrated by results in eq. [5].

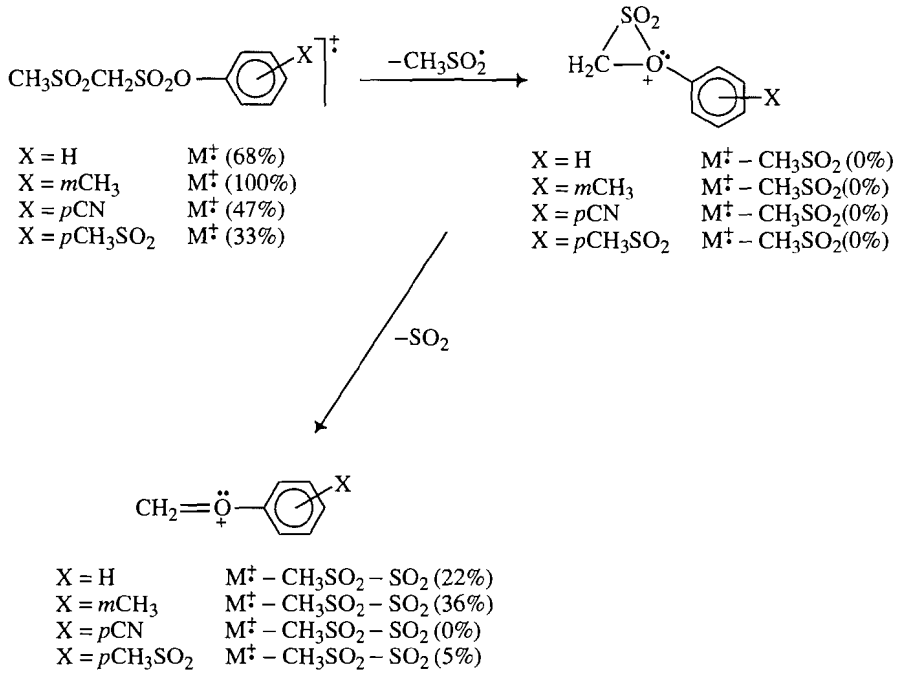
[5] $CH_3SO_2OCH_2CH(CH_3)_2 \xrightarrow[\text{HMPA}]{\text{NaH}}$ no reaction

This result[3] is consistent with the very large difference in pK_a's for a primary alcohol, CH_3OH (pK_a 29.0), and phenol (18.0) in DMSO, a solvent similar in nature to HMPA (10*c*). We conclude that (i) pathway *a* (Scheme 1) is the most reasonable rationale for sulfone-sulfonate ester **2** formation and (ii) sodium hydride can reduce selected sulfonate esters, probably by a SET mechanism.

[3]At the suggestion of a referee, isobutyl methanesulfonate was also treated with sodium hydride in the presence of sodium phenoxide. Again, no sulfone-sulfonate ester was formed. The product was a 5:3 mixture of isobutyl phenyl ether and unchanged methanesulfonate, respectively.

Subsequent efforts focused on the structure and reactivity of the sulfone-sulfonate esters **2**. Although sulfone-sulfonate esters have been known for some time (6, 9*d*, 11), this report includes details of the first mass spectrometric results for such compounds. The earlier studies (6, 9*d*, 11) dealt almost exclusively with the preparation of differently substituted systems: $ArCH_2SO_2CHXSO_3ArY$. Those systems which *do not* bear a π-acceptor on the ring show fragmentation, depicted in Scheme 2, strongly reminiscent of the Rämberg–Bäcklund process (12). Those systems which bear a π-acceptor appended to the ring do not undergo Rämberg–Bäcklund-like fragmentation but instead give $CH_3SO_2CH_2SO_2^+$ as the base peak of the spectrum. These divergent fragmentations are consistent with the requirement that the migrating phenoxy group be able to support substantial charge during the Rämberg–Bäcklund-like process.

The central methylene protons of sulfone-sulfonate esters **2** are so acidic that **2***b*, for example, can be quantitatively extracted into 2.5% aqueous sodium hydroxide solution (from chloroform solution) with a single extraction.[4] Consequently, before attempting nucleophilic substitution at sulfonyl sulfur, we have replaced the central protons with chlorine atoms:



[6] $CH_3SO_2CH_2SO_2OPh \longrightarrow CH_3SO_2CCl_2SO_2OPh$

2*b* **3***b*

Reaction of **3***b* with two equivalents of sodium methoxide gave the following surprising results:

[4]Compare this result with the requirement that the analogous benzylic β-disulfone have four such extractions to remove the bulk of it from chloroform solution (13).

SCHEME 2

[7] $CH_3SO_2CCl_2SO_2OPh + 2CH_3ONa \longrightarrow$

3*b*

$CH_3SO_2CHClSO_2OPh + CH_3SO_2C(CH_3)ClSO_2OPh$

4 **5**

$+ CH_3SO_3Na + CHCl_2SO_2OPh + Cl_2CSO_2OPh$

6 **7**

The sodium salt of methanesulfonic acid was identified by comparison with authentic material obtained by reaction of ethyl methanesulfonate with sodium methoxide. The structures of the oily chlorosulfone-sulfonate esters **4** and **5** were assigned on the basis of spectroscopic data and independent synthesis. A brief exploration of structural dependence for this reaction involved subjecting the dichlorodisulfone **8** (14) to the same

[8] $CH_3SO_2CCl_2SO_2Ph + 2CH_3ONa \longrightarrow$

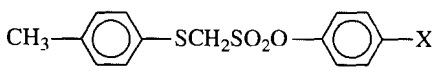
8

$CH_3SO_2C(CH_3)ClSO_2Ph$

9

reaction conditions. The crystalline chlorodisulfone **9** was fully characterized and independently synthesized. At this point, we were satisfied with the structural assignments for **4**, **5**, and **9**.

Apparently neither the dichloromethanesulfonate **6** nor the trichloromethanesulfonate **7** are previously known compounds. Attempts to prepare authentic samples by (i) reaction of phenol with the appropriate sulfonyl chloride in pyridine/triethylamine or (ii) reaction of sodium phenoxide with the appropriate sulfonyl chloride in acetone were unsuccessful. Both methods have been used to prepare other sulfonate esters (3).

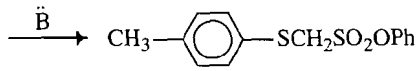


In an earlier study (14), we showed that sulfone-sulfides will furnish trichloromethyl sulfones upon exhaustive aqueous chlorinolysis (e.g., see eq. [9]).

[9] $pCH_3PhSCH_2SO_2Ph \xrightarrow[HOAc]{Cl_2/H_2O}$

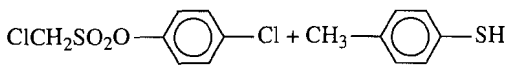
$Cl_3CSO_2Ph + pCH_3PhSO_2Cl$

90%

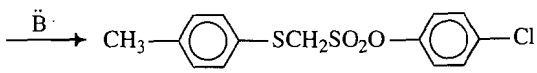


From this result, it seemed likely that a good yield of the trichloromethanesulfonate **7** might be obtained by chlorinolysis of an appropriate sulfide-sulfonate ester such as **10***a*. Since these

10*a* X = H
10*b* X = Cl



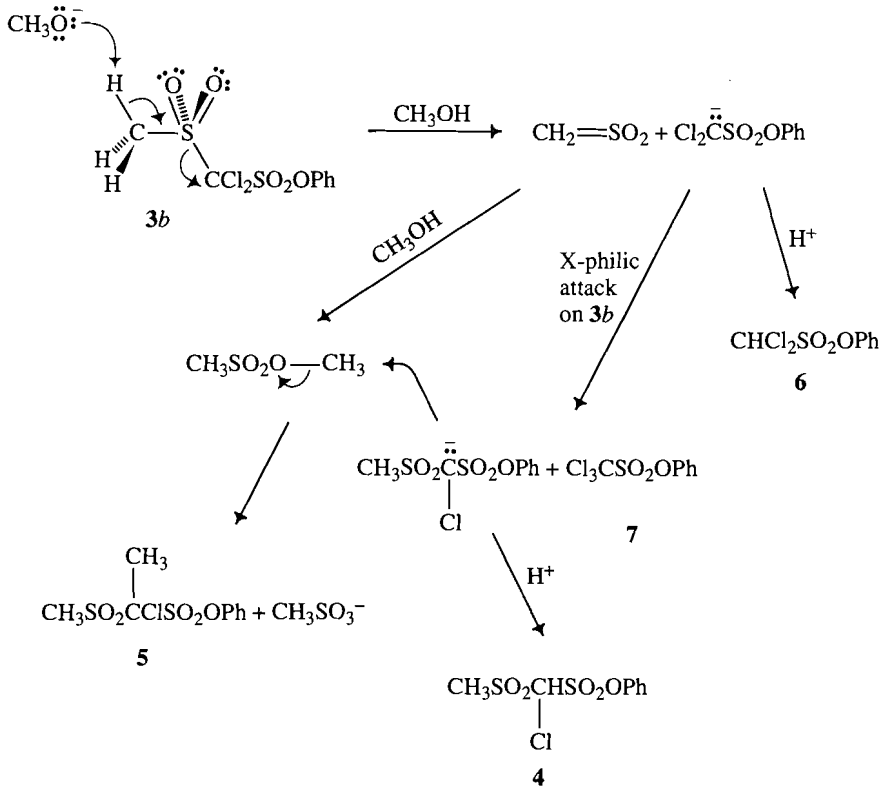
sulfide-sulfonate esters appear to be unknown compounds, we have selected **10***a* and **10***b* as targets.



[10] $CH_3SO_2OPh + (CH_3C_6H_4S)_2$

10*a*

[11]



10*b*

Exhaustive chlorinolysis of **10***a* or **10***b* did indeed furnish the corresponding trichloromethanesulfonates in reasonable yields.

SCHEME 3

[12] $CH_3-C_6H_4-SCH_2SO_2O-C_6H_4-X \xrightarrow[HOAc]{Cl_2/H_2O}$

10*a* X = H
10*b* X = Cl

$Cl_3CSO_2O-C_6H_4-X + CH_3-C_6H_4-SO_2Cl$

The dichloromethanesulfonate **6** was obtained by thiolate anion induced dechlorination[5] of **7** as shown below:

[13] $Cl_3CSO_2OPh + 2PhSNa \longrightarrow CHCl_2SO_2OPh + (PhS)_2$

7 **6**

Since the dichloromethanesulfonate **6** is a new compound, we have converted it into the known phenyl chloromethanesulfonate by thiolate anion induced dechlorination.

Scheme 3 presents a proposed mechanism for the series of reactions leading to the product array in eq. [7]. Analogous processes would readily rationalize the formation of the chlorodisulfone **9** in eq. [8].

Conclusions

1. Aryl methanesulfonates react with sodium hydride to form sulfone-sulfonate esters and products arising from SO bond rupture.

2. SO bond rupture becomes more competitive as the sulfonate ester LUMO becomes lower in energy, thereby implicating SET as the most likely mechanism.

3. Reaction of a dichlorosulfone-sulfonate ester with methoxide ions has produced a dichloromethanesulfonate ester and a trichloromethanesulfonate ester. Neither functionality was previously known.

4. Rational synthesis of trichloromethanesulfonates through sulfide-sulfonate esters has been shown to be effective. Synthesis of the sulfide-sulfonate esters themselves requires further attention.

5. Thiolate anion induced dechlorination of trichloromethanesulfonates appears to be a satisfactory approach to the preparation of dichloromethanesulfonates.

Experimental

General

The ir spectra were recorded on a Perkin–Elmer 710B grating spectrophotometer. The ^1H nmr spectra were obtained on a Varian EM360L instrument using TMS as the internal standard. The ^{13}C nmr spectra were recorded on a Nicolet 360 N.B. highfield nmr spectrometer and are decoupled. Mass spectra were obtained on a Kratos MS 80 GC/MS. Melting points were determined on a Gallenkamp MFB-595 capillary melting point apparatus and are uncorrected.

Standard work-up

The crude reaction mixture was poured into water (100 mL) and concentrated hydrochloric acid (10 mL). The resultant mixture was washed with diethyl ether (three 100-mL aliquots). The combined wet ether layers were concentrated. The residue was poured into water (100 mL) and washed with diethyl ether (three 100-mL aliquots). The combined ether layers were dried ($MgSO_4$) and concentrated.

Hydride reductions of phenyl benzenethiosulfonate

The results presented in Table 1 were obtained in a similar manner. The reaction with sodium hydride will serve as the example.

A solution of phenyl benzenethiosulfonate (2.039 g, 8.15 mmol) in HMPA[6] (20 mL) was added dropwise to a suspension of sodium

[5]X-philic reactions have ample precedent in the chemistry of chlorosulfones (15*a*). For a review, see ref. 15*b*.

[6]HMPA (hexamethylphosphoramide) is toxic and carcinogenic (16).

hydride (0.388 g, 16.1 mmol) in HMPA (20 mL). Upon completion of the addition, the reaction mixture was stirred at ambient temperature for 1.5 h. A solution of methyl iodide (1.174 g, 8.27 mmol) in HMPA[6] (10 mL) was added dropwise to the reaction mixture. The reaction mixture was stirred at ambient temperature for 3 days.

Standard work-up afforded crude product, which was chromatographed on silica gel (200 g) employing a 3:2 mixture of carbon tetrachloride/methylene chloride (47 50-mL fractions). Thereafter the column was eluted with chloroform (50-mL fractions). Fractions 10–14 were combined and concentrated, yielding diphenyl disulfide (0.286 g, 1.31 mmol, 32%). Fractions 53–81 were combined and concentrated, furnishing phenyl methyl sulfone (0.459 g, 2.94 mmol, 36%).

Preparation of p-*methylsulfonylphenyl methanesulfonate* **1***e*

4-(Methylmercapto)phenol (5.005 g, 35.6 mmol) was converted to 4-(methylmercapto)phenyl methanesulfonate in standard fashion (3). Recrystallization from methanol afforded clean sulfide-sulfonate (6.115 g, 28.0 mmol, 79%, mp 75–77°C). The sulfide-sulfonate ester had ir ($CHCl_3$): 1380 and 1160 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.26 (4H, s), 3.13 (3H, s), and 2.47 (3H, s).

A solution of 4-(methylmercapto)phenyl methanesulfonate (5.008 g, 22.9 mmol) in chloroform (100 mL) was cooled with an ice/water bath. *m*-Chloroperoxybenzoic acid (85%, 12.46 g) was added in small portions over 1 h. The reaction mixture was stirred at ambient temperature for 5 days. Chloroform (100 mL) was added and the resultant mixture washed with 2.5% NaOH (100-mL aliquots) until the aqueous pH remained basic. The organic layer was dried ($MgSO_4$) and concentrated. The residue was recrystallized from methanol yielding clean sulfone-sulfonate ester **1***e* (4.181 g, 16.7 mmol, 73%, mp 117.5–118.5°C). The sulfone-sulfonate ester **1***e* had ir ($CHCl_3$): 1380, 1360, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.03 (2H, d, J = 9 Hz), 7.50 (2H, d, J = 9 Hz), 3.23 (3H, s), and 3.06 (3H, s). Anal. calcd. for $C_8H_{10}O_5S_2$: C 38.39, H 4.02; found: C 38.42, H 4.03.

The reaction of methanesulfonates **1**a–**1**g *with sodium hydride*

The appropriate methanesulfonate was reacted with sodium hydride in HMPA as outlined below for the cyanomesylate **1***d*. Final purification of products from reaction of **1***b* and **1***c* employed column chromatography. Results for these experiments are detailed in Table 2.

p-Cyanophenyl methanesulfonate **1***d* (1.005 g) in HMPA[6] (5 mL) was added dropwise to a suspension of sodium hydride (0.213 g) in HMPA (10 mL). Upon completion of the addition, the reaction mixture was stirred at ambient temperature for 1 h.

Standard work-up yielded a crude concentrate, which was dissolved in 2.5% sodium hydroxide solution (50 mL). The solution was acidified with concentrated hydrochloric acid (3 mL) and cooled with an ice/water bath. Crude *p*-cyanophenyl methylsulfonylmethanesulfonate **2***d* (0.173 g) was filtered off and the aqueous solution set aside. Recrystallization of crude sulfone-sulfonate ester from methanol afforded clean **2***d*.

The aqueous layer was concentrated to a final volume of 10 mL using hot benzene and a Dean–Stark trap. The aqueous concentrate was acidified with concentrated HCl (0.5 mL) and washed with diethyl ether (three 50-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated, yielding *p*-cyanophenol (0.458 g).

Recrystallized *m*-$CH_3PhOSO_2CH_2SO_2CH_3$ **2***a* (mp 63.9–64.3°C) had ir ($CHCl_3$): 1390, 1340, 1190, 1150, and 1120 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.26 (4H, s), 4.70 (2H, s), 3.30 (3H, s), and 2.40 (3H, s); ^{13}C nmr ($CDCl_3$) δ: 149.01, 140.85, 129.93, 128.88, 122.50, 118.95, 67.11, 42.40, and 21.28; ms *m*/*e*: M^+ 264 (100%), 157 (12%), 121 (37%), and 108 (79%). Anal. calcd. for $C_9H_{12}O_5S_2$: C 40.89, H 4.57; found: C 40.95, H 4.58.

Recrystallized $PhOSO_2CH_2SO_2CH_3$ **2***b* (mp 73.9–74.8°C) had ir ($CHCl_3$): 1390, 1340, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.43 (5H, s), 4.60 (2H, s), and 3.26 (3H, s); ^{13}C nmr ($CDCl_3$) δ: 148.98, 130.25, 128.11, 122.07, 66.84, and 42.31; ms *m*/*e*: M^+ 250 (68%), 157 (26%), 107 (22%), and 94 (100%). Anal. calcd. for $C_8H_{10}O_5S_2$: C 38.39, H 4.02; found: C 38.40, H 4.02.

Recrystallized *p*-$ClPhOSO_2CH_2SO_2CH_3$ **2***c* (mp 106.5–108°C) had ir ($CHCl_3$): 1395, 1345, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.40 (4H, s), 4.70 (2H, s), and 3.33 (3H, s); ^{13}C nmr ($CDCl_3$) δ: 147.15, 133.94, 130.33, 123.49, 67.09, and 42.35; ms *m*/*e*: M^+ + 2 286 (59%), 284 (75%), 157 (37%), 143 (31%), 141 (48%), 130 (62%), and 128 (100%). Preparation of $CH_3SO_2CCl_2SO_2OPh$ **3**b

The sulfone-sulfonate ester **2***b* (1.002 g, 4.01 mmol) was dissolved in glacial acetic acid (25 mL). Chlorine (ca. 200 mL/min) was bubbled into the solution for 30 min.

Chloroform (100 mL) was added and the resultant solution washed with 2.5% NaOH (three 100-mL portions). The organic layer was dried ($MgSO_4$) and concentrated. The product was recrystallized from methanol, giving clean dichlorosulfone-sulfonate ester **3***b* (0.899 g, 2.82 mmol, 71%, mp 67.1–69°C). **3***b* had ir ($CHCl_3$): 1420, 1370, 1220, 1180, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.50 (5H, s) and 3.53 (3H, s); ms *m*/*e*: M^+ + 4 322 (9%), 320 (38%), 318 (51%), 179 (9%), 177 (36%), and 175 (52%). Anal. calcd. for $C_8H_8Cl_2O_5S_2$: C 30.10, H 2.52; found: C 30.14, H 2.57.

Reaction of $CH_3SO_2CCl_2SO_2OPh$ **3**b *with methoxide ions*

Sodium metal (0.080 g, 3.47 mmol) was dissolved in methanol (50 mL). The dichlorosulfone-sulfonate ester **3***b* (0.505 g, 1.58 mmol) was added and the reaction mixture stirred at ambient temperature for 24 h.

Water (50 mL) and 10% HCl (6 mL) were added and the resultant mixture washed with chloroform (three 100-mL aliquots). The combined chloroform layers were dried ($MgSO_4$) and concentrated, affording crude product (0.432 g).

The crude was chromatographed on silica gel (43 g), and 45-mL fractions were collected. Initially products were eluted with carbon tetrachloride (25 fractions).

Fractions 4–6 were concentrated and combined, yielding the trichloromethanesulfonate **7** (0.143 g, 0.52 mmol, 33%). The trichloromethanesulfonate **7** (bp 160°C/55 Torr; 1 Torr = 133.3 Pa) had ir ($CHCl_3$): 1400, 1120 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.46 (s); ^{13}C nmr (CD_3COCD_3) δ: 151.81, 131.15, 129.02, 122.26, 100.92; ms *m*/*e*: M^+ + 4 278 (5%), 276 (12%), 274 (11%), 179 (7%),[8] 177 (37%),[8] 175 (56%),[8] 121 (32%), 119 (95%), and 117 (100%). Anal. calcd. for $C_7H_5Cl_3O_3S$: C 30.51, H 1.82; found: C 30.51, H 1.81.

Fractions 11–16 were concentrated and combined, yielding the dichloromethanesulfonate **6** (0.055 g, 0.23 mmol, 15%). The dichloromethanesulfonate **6** (bp 159°C/15 Torr) had ir ($CHCl_3$): 1400, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.46 (5H, s) and 6.40 (1H, s); ^{13}C nmr (CD_3COCD_3) δ: 150.65, 131.14, 128.86, and 77.07; ms *m*/*e*: M^+ +6 244 (3%), 242 (16%), 240 (22%), 143 (31%),[8] and 141 (100%).[8] Anal. calcd. for $C_7H_6Cl_2O_3S$: C 34.87, H 2.50; found: C 34.89, H 2.60.

---

[7]The methylene signal for **2***b* (δ 4.60 in $CDCl_3$) shifts to δ 5.43 in CD_3COCD_3. The shift is accompanied by significant broadening of the signal.

[8]These ions may be rationalized by the Rämberg–Bäcklund-like process discussed in the text of this article (see Scheme 2).

Another 15 fractions (chloroform) were collected. Fractions 28–30 were combined and concentrated, affording the methylated chlorosulfone-sulfonate ester **5** (0.110 g, 0.36 mmol, 23%). The methylated sulfonate ester **5** had R_f 0.81 on analytical tlc plates developed with chloroform; ir ($CHCl_3$): 1380, 1345, 1160, and 1140 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.53 (5H, s), 3.43 (3H, s), and 2.38 (3H, s). Fractions 32–37 were combined and concentrated, affording the chlorosulfone-sulfonate ester **4** (0.055 g, 0.19 mmol, 12%). The chlorosulfone-sulfonate ester had R_f 0,46 on analytical tlc plates developed with chloroform; ir ($CHCl_3$): 1400, 1350, 1140 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.43 (5H, s), 5.63 (1H, s), and 3.33 (3H, s).

Preparation of authentic $CH_3SO_2CHClSO_2OPh$ 4

Sodium metal (0.036 g, 1.56 mmol) was dissolved in methanol (50 mL) and benzenethiol (0.176 g, 1.60 mmol) was added. The dichlorosulfone-sulfonate ester **3***b* (0.504 g, 1.58 mmol) was added and the mixture stirred at ambient temperature for 1 h.

Acidification with 10% HCl (3 mL) and routine extraction with chloroform gave a mixture of **3***b* and **4**. The crude product mixture was dissolved in chloroform solution (three 50-mL aliquots). The aqueous layer was acidified with concentrated hydrochloric acid (9 mL) and backwashed with chloroform (three 100-mL aliquots). The combined backwash layers were concentrated, affording the monochlorosulfone-sulfonate ester **4** (0.223 g, 0.78 mmol, 49%); **4** was chromatographed on silica gel, furnishing homogeneous product that was identical with **4** described under "Reaction of $CH_3SO_2CCl_2SO_2OPh$ **3***b* with methoxide ions" by double spotted tlc, ir, and nmr.

Preparation of $CH_3SO_2CH(CH_3)SO_2OPh$

Sodium metal (0.093 g, 4.04 mmol) was dissolved in methanol (50 mL) and the sulfone-sulfonate ester **2***b* (0.999 g, 3.99 mmol) added. Methyl iodide (1.716 g, 12.1 mmol) in methanol (10 mL) was added dropwise. The reaction mixture was stirred overnight at ambient temperature.

Water (60 mL) was added and the resultant mixture washed with chloroform (five 50-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated, affording a mixture of starting **2***b*, monomethylated sulfone-sulfonate ester, and dimethylated sulfone-sulfonate ester.

The crude was dissolved in chloroform (50 mL) and the resultant solution washed with 2.5% NaOH (one 50-mL aliquot), which completely removed **2***b* (0.194 g).

The organic layer was washed with an additional set of 2.5% NaOH extractions (15 50-mL aliquots). The combined aqueous layers were acidified with concentrated hdyrochloric acid (55 mL). The aqueous solution was concentrated with benzene and a Dean–Stark trap. The organic solution was dried ($MgSO_4$) and concentrated, affording monomethylated sulfone-sulfonate ester (0.356 g). The partially purified product was chromatographed on silica gel (40 g) employing chloroform elution. Homogeneous, chromatographed $CH_3SO_2CH(CH_3)SO_2OPh$ (0.267 g, 1.01 mmol, 25%) had ir ($CHCl_3$): 1380, 1335, 1145 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.50 (5H, s), 4.73 (1H, q, J = 8 Hz), 3.26 (3H, s), and 1.96 (3H, d, J = 8 Hz); ms m/e: M^+ 264 (64%), 171 (23%), 121 (51%),[8] and 94 (100%).

Preparation of authentic $CH_3SO_2CCl(CH_3)SO_2OPh$ 5

$CH_3SO_2CH(CH_3)SO_2OPh$ (0.124 g, 0.47 mmol) was subjected to chlorinolysis and work-up as described under "Preparation of $CH_3SO_2CCl_2SO_2OPh$ **3***b*". Homogeneous **5** (0.128 g) had R_f 0.55 on analytical tlc developed with 3:1 chloroform/carbon tetrachloride. Spectra were identical with those described for **5** under "Reaction of $CH_3SO_2CCl_2SO_2OPh$ **3***b* with methoxide ions."

Reaction of $CH_3SO_2CCl_2SO_2Ph$ 8 with methoxide ions

The dichlorodisulfone **8** (0.500 g, 1.65 mmol) (14) was allowed to react as described for **3***b* under "Reaction of $CH_3SO_2CCl_2SO_2OPh$ **3***b* with methoxide ions".

Crude product was chromatographed on silica gel (50 g) employing carbon tetrachloride elution (50 mL fractions). Fractions 18–24 were concentrated and combined, affording trichloromethyl phenyl sulfone (0.016 g, 0.065 mmol, 4%). Fractions 35–38 were combined and concentrated, giving dichloromethyl methyl sulfone (0.009 g, 0.055 mmol, 3%). Fractions 39–44 provided a mixture of dichloromethyl methyl sulfone (0.022 g, 0.135 mmol, 8%) and the monochlorodisulfone **9** (0.079 g, 0.280 mmol, 17%). Fractions 45, 46 gave clean **9** (0.056 g, 0.198 mmol, 12%). A full description of **9** is provided under "Preparation of authentic $CH_3SO_2CCl(CH_3)SO_2Ph$ **9**".

Preparation of $CH_3SO_2CH_2SO_2Ph$

CrO_3 (13.500 g, 135 mmol) in glacial acetic acid (50 mL) was vigorously stirred at ambient temperature. $CH_3SO_2CH_2SPh$ (11.017 g, 54.5 mmol) (14) in glacial acetic acid (50 mL) was added dropwise. Upon completion of the addition, the reaction mixture was maintained at 90–100°C for 1 h.

Water (200 mL) was added and the resultant mixture washed with chloroform (three 100-mL portions). The combined organic layers were washed with 2.5% NaOH (100-mL aliquots) until the aqueous layer remained basic. The organic layer was dried ($MgSO_4$) and concentrated. Crude disulfone was recrystallized from methanol, furnishing clean product (7.477 g, 31.9 mmol, 59%, mp 150.1–152.1°C). The disulfone had ir ($CHCl_3$): 1340, 1140 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.81 (2H), 7.55 (3H), 4.45 (2H, s), and 3.20 (3H, s). Anal. calcd. for $C_8H_{10}O_4S_2$: C 41.01, H 4.30; found: C 41.13, H 4.37.

Preparation of authentic $CH_3SO_2CCl(CH_3)SO_2Ph$ 9

$CH_3SO_2CH_2SO_2Ph$ (3.019 g, 12.9 mmol) was methylated as described for **2***b* under "Preparation of $CH_3SO_2CH(CH_3)$ SO_2OPh". Crude product, which contained a mixture of starting disulfone and monomethylated product, was dissolved in chloroform (200 mL) and washed with 2.5% NaOH (eight 200-mL aliquots). The organic layer was dried (Na_2SO_4) and concentrated. The monomethylated disulfone was recrystallized from methanol, affording $CH_3SO_2CH(CH_3)SO_2Ph$ (1.886 g, 7.6 mmol, 59%, mp 103.7–105°C). The monomethylated disulfone had ir ($CHCl_3$): 1340, 1140 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 8.15 (2H), 7.85 (3H), 4.46 (1H, q), 3.36 (3H, s), and 1.73 (3H, d).

$CH_3SO_2CH(CH_3)SO_2Ph$ (1.087 g, 4.38 mmol) was chlorinated as described under "Preparation of $CH_3SO_2CCl_2SO_2OPh$ **3***b*". Crude **9** was recrystallized from methanol (2×), affording impure **9** (0.986 g). Impure **9** (0.3 g) was spotted on three preparative tlc plates. Each plate was developed (2×) with chloroform). The large band centered at R_f 0.61 was scraped from each plate. The combined bands were covered with 10% methanol in chloroform (100 mL). The mixture was stirred at ambient temperature for 1 h and filtered (0.240 g, 64%). Clean disulfone **9** was recrystallized from methanol (0.101 g, mp 105.8–106.1°C). **9** had ir ($CHCl_3$): 1330, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.96 (2H), 7.60 (3H), 3.40 (3H, s), and 2.20 (3H, s). Anal. calcd. for $C_9H_{11}ClO_4S_2$: C 38.22, H 3.92; found: C 38.45, H 3.90. The chlorodisulfone **9** obtained in this way was identical to **9** obtained from eq. [8] by ir, nmr, mp, and double spotted tlc.

*Preparation of p-CH_3-$PhSCH_2SO_2OPh$ 10*a

p-Tolyl disulfide (2.804 g, 11.4 mmol) in HMPA[6] (10 mL) was added to a suspension of sodium hydride (0.688 g, 28.6 mmol) in HMPA[6] (80 mL). Phenyl methanesulfonate **1***b* (2.342 g, 13.6 mmol) was added and the reaction mixture stirred at ambient temperature for 1 h 10 min.[9].

Standard work-up was augmented with a single washing of the organic layer with 2.5% NaOH (100 mL). The crude, so obtained, was chromatographed on silica gel (300 g) employing carbon tetrachloride (100-mL fractions) for elution. Fractions 85–113 were combined and concentrated, furnishing clean sulfide-sulfonate ester **10***a* (0.133 g, 0.452 mmol, 4%, mp 69.0–70.7°C). The sulfide-sulfonate ester had ir ($CHCl_3$): 1380, 1365, 1145 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.30 (9H, m), 4.40 (2H, s), and 2.33 (3H, s); ms m/e: M^+ 294 (11%) and 137 (100%). Anal. calcd. for $C_{14}H_{14}O_3S_2$: C 57.11, H 4.79; found: C57.32, H 4.80.

[9]Reaction times are critical for preparations of sulfide-sulfonate esters.

Preparation of p-*chlorophenyl chloromethanesulfonate*

A solution of *p*-chlorophenol (17.278 g, 135 mmol) and triethylamine (13.75 g, 136 mmol) in dry pyridine (150 mL) was cooled with an ice/water bath. Chloromethanesulfonyl chloride (19.936 g, 135 mmol) (17) was added dropwise. The reaction mixture was stirred at ambient temperature for 7 days.

Chloroform (300 mL) was added and the resultant mixture washed with 5% HCl (100-mL aliquots) until the aqueous pH remained acidic. The organic layer was washed with 2.5% NaOH solution (150 mL), dried ($MgSO_4$), and concentrated. The residue was rectified at reduced pressure, yielding a dark brown liquid (19.70 g).

A sample of the brown liquid (3 g) was chromatographed on silica gel (50 g) employing carbon tetrachloride elution (100-mL aliquots). Fractions 4–14 were combined and concentrated and the residue distilled, furnishing colorless *p*-chlorophenyl chloromethanesulfonate (1.809 g, bp 140°C/1.4 Torr). The chloromethanesulfonate had ir ($CHCl_3$): 1395, 1180, and 1160 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.36 (4H), 4.70 (2H, s); ms *m/e*: $M^{\cdot+}$ + 4 244 (5%), 242 (26%), 240 (37%), 143[8] (17%), 141[8] (51%), 129 (33%), and 127 (100%). Anal. calcd. for $C_7H_6Cl_3O_3S$: C 34.87, H 2.50; found: C 34.94, H 2.49.

Preparation of p-$CH_3PhSCH_2SO_2OPh$-*Cl*-p ***10****b*

p-Toluenethiol (0.413 g, 3.33 mmol) in HMPA[6] (5 mL) was added dropwise to a suspension of sodium hydride (0.077 g, 3.20 mmol) in HMPA[6] (5 mL). *p*-Chlorophenyl chloromethanesulfonate (0.685 g, 2.85 mmol) in HMPA (15 mL) was added dropwise and the reaction mixture stirred overnight.

Standard work-up provided crude product, which was chromatographed on silica gel (100 g) employing 1:1 carbon tetrachloride/methylene chloride for elution (100-mL fractions). Fractions 4–6 were combined and concentrated, giving impure **10***b* (0.359 g).

Impure **10***b* was rechromatographed on silica gel (50 g) employing carbon tetrachloride elution (50-mL fractions). Fractions 25–28 were combined and concentrated, affording sulfide-sulfonate ester **10***b* (0.244 g, 0.743 mmol, 26%). Recrystallized sulfide-sulfonate ester **10***b* had mp 74.6–75.2°C; ir ($CHCl_3$): 1380, 1360, 1170, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.33 (8H, m), 4.40 (2H, s), and 2.33 (3H, s); ms *m/e*: $M^{\cdot+}$ + 2 330 (0.4%), 328 (1.2%), and 137 (100%). Anal. calcd. for $C_{14}H_{13}ClO_3S_2$: C 51.13, H 3.98; found: C 51.03, H. 4.00.

Preparation of phenyl trichloromethanesulfonate and p-*chlorophenyl trichloromethanesulfonate*

The appropriate sulfide-sulfonate ester **10***a* or **10***b* provided the corresponding trichloromethanesulfonate (see eq. [12]). The procedure is exemplified by the details provided below for the chlorinolysis of **10***b*.

The sulfide *p*-chlorophenyl sulfonate ester **10***b* (1.020 g, 3.10 mmol) was suspended in glacial acetic acid (25 mL) and water (5 mL). Chlorine (ca. 200 mL/min) was bubbled into the solution for 8 h. Ice/water cooling was deployed as necessary to keep the reaction temperature between 20 and 30°C.

Water (50 mL) and chloroform (100 mL) were added to the reaction mixture and the layers separated. The organic layer was washed with 2.5% w/v sodium hydroxide solution (two 50-mL aliquots), dried ($MgSO_4$), and concentrated. The crude was chromatographed on silica gel (100 g) employing carbon tetrachloride elution (100-mL aliquots).

Fractions 4–10 were combined and concentrated, affording clean *p*-chlorophenyl trichloromethanesulfonate (0.536 g, 1.74 mmol, 56%, bp 166–170°C/35 Torr). The trichloromethanesulfonate had ir ($CHCl_3$): 1410, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.40 (s); ms *m/e*: $M^{\cdot+}$ + 8 316 (1%), 314 (3%), 312 (16%), 310 (26%), 308 (23%), 213 (5%),[8] 211 (16%),[8] 209 (17%),[8] 123 (6%), 121 (36%), 119 (80%), and 117 (100%). Anal. calcd. for $C_7H_4Cl_4O_3S$: C 27.12, H 1.30; found: C 27.16, H 1.20.

Fractions 17–24 were combined and concentrated, yielding *p*-toluenesulfonyl chloride (0.133 g, 0.700 mmol, 23%).

Chlorinolysis of **10***a* (0.961 g, 3.27 mmol) provided phenyl trichloromethanesulfonate **7** (0.580 g, 2.11 mmol, 65%), which was identical to **7** as described under "Reaction of $CH_3SO_2CCl_2SO_2OPh$ **3***b* with methoxide ions."

Preparation of phenyl dichlormethanesulfonate ***6***

Sodium metal (0.175 g, 7.61 mmol) was dissolved in methanol (100 mL). Benzenethiol (0.800 g, 7.27 mmol) was added to the reaction mixture. Phenyl trichloromethanesulfonate **7** (0.954 g, 3.48 mmol) was added and the reaction mixture stirred at ambient temperature for 1 h.

Water (100 mL) and 10% HCl (1 mL) were added and the resultant mixture washed with chloroform (three 50-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated. The residue was chromatographed on silica gel (200 g) employing 2:1 carbon tetrachloride/cyclohexane for elution (100-mL fractions). Fractions 18–50 were combined and concentrated, yielding clean phenyl dichloromethanesulfonate **6** (0.709 g, 2.95 mmol, 85%). The dichloromethanesulfonate **6** had bp 158–160°C/15 Torr; ir ($CHCl_3$): 1403, 1150 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.46 (5H, s) and 6.50 (1H, s); ^{13}C nmr (CD_3COCD_3) δ: 150.65, 131.14, 128.86, 122.61, and 77.07; ms *m/e*: $M^{\cdot+}$ +4 244 (3%), 242 (15%), 240 (22%), 143 (31%),[8] 141 (100%).[8] Anal. calcd. for $C_7H_6Cl_2O_3S$: C 34.87, H 2.50; found: C 34.89, H 2.60.

Conversion of ***6*** *into phenyl chloromethanesulfonate*

Sodium metal (0.186 g, 8.08 mmol) was dissolved in methanol (100 mL) and benzenethiol (0.929 g, 8.44 mmol) added. The dichloromethanesulfonate **6** (1.010 g, 4.20 mmol) was added and the reaction mixture stirred at ambient temperature for 7 days.

Water (100 mL) and 10% HCl (1 mL) were added and the reaction mixture washed with chloroform (three 50-mL aliquots). The combined organic layers were dried ($MgSO_4$) and concentrated. The residue was chromatographed on silica gel (100 g) employing carbon tetrachloride elution (100-mL fractions). Fractions 2–8 were concentrated and combined, affording diphenyl disulfide (0.611 g, 2.80 mmol, 66%). Fractions 13–22 were combined and concentrated, yielding unchanged dichloromethanesulfonate **6** (0.297 g, 1.23 mmol, 29%). Fractions 35–53 were combined and concentrated, providing phenyl chloromethanesulfonate, which was rectified at reduced pressure (0.116 g, 0.56 mmol, 13%, bp 122°C/1.7 Torr). This material was identical to that described under "Preparation of phenyl chloromethanesulfonate".

Preparation of phenyl chloromethanesulfonate

Phenyl chloromethanesulfonate was prepared following the procedure outlined for "Preparation of *p*-chlorophenyl chloromethanesulfonate". Phenyl chloromethanesulfonate had bp 122°C/1.7 Torr; ir ($CHCl_3$): 1390, 1190, 1170, 1140 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 7.33 (5H, s) and 4.66 (2H, s).

Preparation of $Cr_2(CO)_8(NO)_2$ and X-ray crystal structures of $Cr_2(CO)_8(NO)_2$ and $Cr_2(CO)_9NO^-$. Stereochemical comparisons to $Cr_2(CO)_{10}^{2-}$

A. P. MASTERS, M. PARVEZ, AND T. S. SORENSEN[1]

The Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

Received May 31, 1991

A. P. MASTERS, M. PARVEZ, and T. S. SORENSEN. Can. J. Chem. **69**, 2136 (1991).

$Cr_2(CO)_8(NO)_2$ (**1**) has been prepared and characterized, and the crystal structure determined, along with that of the related salt $Cr_2(CO)_9NO^-$ monoanion (**2**) as the CH_2Cl_2-solvated PPN^+ salt (where PPN^+ denotes the $(PPh_3)_2N^+$ monocation). Both **1** and **2** possess a metal–metal bonded structure analogous to that of $Mn_2(CO)_{10}$ and the electronically equivalent $Cr_2(CO)_{10}^{2-}$ dianion. Although $Cr_2(CO)_8(NO)_2$ (**1**) is slowly formed in poor yield from $Cr(CO)_4NO^-$ and $Cr(CO)_4NOBr$, it can be prepared in an almost quantitative yield by the one-electron oxidation of the monoanion with trityl hexafluorophosphate. The slowness of the former reaction makes $Cr(CO)_4NO^-$ useful as a two-electron reductant of organohalide bonds. Triclinic crystals of **1** incorporate two distinct molecules in the $P\bar{1}$ space group, although the geometries of each are almost identical. Triclinic crystals of monoanion (**2**) also belong to the $P\bar{1}$ space group. The Cr—Cr bond length is 3.00–3.02 Å in **1** and 2.995 Å in **2**, compared to 2.904 Å for the central Mn—Mn bond in $Mn_2(CO)_{10}$.

Key words: chromium nitrosyl, chromium carbonyl, X-ray crystal structure, metalate anion, metal–metal dimer.

A. P. MASTERS, M. PARVEZ et T. S. SORENSEN. Can. J. Chem. **69**, 2136 (1991).

On a préparé le $Cr_2(CO)_8(NO)_2$ (**1**), on l'a caractérisé et on a déterminé sa structure cristalline ainsi que celle du monoanion $Cr_2(CO)_9NO^-$ (**2**), sous la forme de sel du PPN^+ (où PPN^+ = monocation $(PPh_3)_2N^+$), solvaté par le CH_2Cl_2. Les composés **1** et **2** possèdent tous les deux une structure comportant une liaison métal–métal analogue à celle que l'on rencontre dans le $Mn_2(CO)_{10}$ et ils sont électroniquement équivalents au dianion $Cr_2(CO)_{10}^{2-}$. Même si le composé $Cr_2(CO)_8(NO)_2$ ne se forme que lentement et avec un faible rendement à partir du $Cr(CO)_4NO^-$ et du $Cr(CO)_4NOBr$, on peut le préparer avec un rendement pratiquement quantitatif par le biais d'une oxydation du monoanion par un électron avec l'hexafluorophosphate de trityle. La lenteur de la réaction précédente fait que le $Cr(CO)_4NO^-$ est utile comme réducteur à deux électrons des liaisons des halogénures organiques. Les cristaux tricliniques du composé **1** incorporent deux molécules distinctes dans le groupe d'espace $P\bar{1}$, même si les géométries de chacune de ces molécules sont pratiquement identiques. Les cristaux tricliniques du monoanion **2** appartiennent aussi au groupe d'espace $P\bar{1}$. La longueur de la liaison Cr—Cr est égale à 3,00–3,02 Å dans le composé **1** et à 2,995 Å dans le composé **2**; ces valeurs se comparent à la valeur de 2,904 Å que l'on observe pour la liaison centrale Mn—Mn du $Mn_2(CO)_{10}$.

Mots clés : nitrosyle de chrome, carbonyle de chrome, structure cristalline par rayons-X, anion métalate, dimère métal–métal.

[Traduit par la rédaction]

Introduction

In the reaction of $Mn(CO)_5^-$ with hindered α-bromo carbonyl compounds, one can get a facile two-electron reduction of the C—Br bond, resulting in $Mn(CO)_5Br$ and an enolate (1). However, a side product of this reaction is $Mn_2(CO)_{10}$, which appears to be formed from $Mn(CO)_5Br$ and $Mn(CO)_5^-$ in a reaction which can be competitive with the enolate-forming reaction.

In reactions of the isoelectronic anion $Cr(CO)_4NO^-$ (2) with α-bromo carbonyl compounds, similar complications have not been observed; however, we have occasionally seen traces of a very mobile light yellow TLC spot when analyzing crude reaction mixtures. Since $Mn_2(CO)_{10}$ behaves very similarly on TLC elution, there was a possibility that traces of the isoelectronic compound $Cr_2(CO)_8(NO)_2$ (**1**) were being observed in the former case. We were therefore interested in preparing and characterizing an authentic sample of $Cr_2(CO)_8(NO)_2$.

Several mixed monomeric chromium carbonyl nitrosyl complexes have been prepared under low-temperature photolysis conditions, including a possible $Cr(CO)_4NO$ species (3). Dimeric cyclopentadienylchromium carbonyl nitrosyl complexes are also known (4).

Results and discussion

Initial attempts to prepare **1** from $Cr(CO)_4NO^-$ and $Cr(CO)_4NOBr$ (reaction [1]) were beset by poor and variable yields along with slow reaction rates. Nevertheless, sufficient

[1] $PPN^+Cr(CO)_4NO^- + Cr(CO)_4NOBr \rightarrow Cr_2(CO)_8(NO)_2$ (generated *in situ*) $+ PPN^+Br^-$

information via mass spectral analysis was obtained to verify that **1** was indeed being formed and did in fact correspond to the unknown TLC spot referred to earlier. The fact that $Cr(CO)_4NOBr$ is unstable at room temperature and had to be generated *in situ* may partially account for the poor results. In the corresponding $W(CO)_4NOI$, the halide ligand has been successfully replaced (5) to generate W—M compounds, where M is a group IVA metal. However, $W(CO)_4NOI$ is a much more robust compound.

By analogy with manganese chemistry (6), the one-electron oxidation of $PPN^+Cr(CO)_4NO^-$ by carbocation salts was next projected as a route to $Cr_2(CO)_8(NO)_2$. Initial attempts to oxidize the monoanion with tropylium fluoroborate in THF solution did in fact produce $Cr_2(CO)_8(NO)_2$ (**1**) in some cases (together with bitropyl), but the reaction was unpredictable. Since tropylium fluoroborate is not very soluble in THF solution, reaction of the partly heterogeneous mixture was carried out at −80°C with slow warming to −20°C and then eventually to room temperature. Besides **1**, a second yellow metal-containing compound was also produced in quite variable yield; this compound was subsequently identified as $PPN^+Cr_2(CO)_9NO^-$ (denoted as PPN^+**2**) which was previously

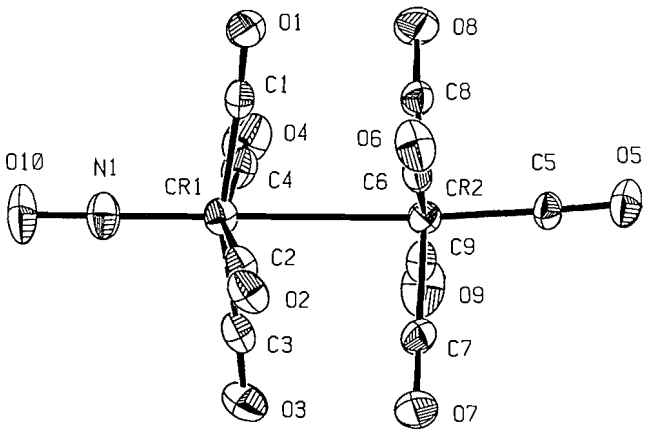

FIG. 2. ORTEP drawing (50% probability level) of the $Cr_2(CO)_9(NO)^-$ monoanion (**2**).

prepared in a rational route by Mantell and Gladfelter (2). Since this salt corresponds to a disproportionation-type process, which may in turn be associated with the heterogeneous nature of the reaction, we decided to use trityl hexafluorophosphate, which is more soluble in THF. In this case, the yield of $Cr_2(CO)_8(NO)_2$ (**1**) was good, the reaction was rapid, and none of the anionic dimer (**2**) was produced. Other reaction products are the well-known trityl radical dimer and (or) the peroxidation products of this, depending on how anaerobic the work-up is (7).

Relatively air-stable orange crystals of pure $Cr_2(CO)_8(NO)_2$ (**1**) were obtained from the crude reaction mixture by flash chromatography on silica gel. An infrared spectrum in *n*-hexane shows two main C—O stretches, at 1987 and 2023 cm^{-1}, along with a weak shoulder at 2032 cm^{-1}. The N—O stretch occurs at 1739 cm^{-1}. This simple infrared spectral pattern indicates a symmetrical structure, most probably with four equa-

torial carbonyls on each chromium together with an apical nitrosyl on each chromium. Crystals of the dimer **1** suitable for X-ray diffraction were obtained by recrystallization from pentane.

Since the crystal structure of the PPN^+ salt of the isoelectronic $Cr_2(CO)_{10}^{2-}$ dianion has been reported (8), and since the isoelectronic $Cr_2(CO)_9(NO)^-$ monoanion (**2**) was also available, we obtained the X-ray structures of both **1** and **2** in order to compare the structural features of all three compounds.

An unsuccessful attempt was made to prepare $Fe_2(CO)_6(NO)_2$, isoelectronic with $Fe_2(CO)_8^{2-}$ and $Co_2(CO)_8$, from the reaction of $Fe(CO)_3NO^-$ and tropylium fluoroborate. Also, an attempted reaction between $Cr(CO)_4NO^-$ and $Mn(CO)_5Br$ did not yield the unknown mixed Cr—Mn dimer $ON(CO)_4Cr—Mn(CO)_5$.

$Cr_2(CO)_8(NO)_2$ (**1**) forms triclinic crystals with four molecules in a centrosymmetric unit cell. The two crystallographically independent molecules (Fig. 1) have a very similar D_{4d}-type $Mn_2(CO)_{10}$ geometry. A summary of the low temperature data collection is given in Table 1. The $Cr_2(CO)_9(NO)^-$ monoanion (**2**) as the PPN^+ salt also forms triclinic crystals with two formula species and two solvated methylene chloride molecules of one-quarter occupancy in the unit cell. An ORTEP drawing of the crystallographically independent $Cr_2(CO)_9(NO)^-$ monoanion (**2**), which is of approximate C_{4v} symmetry, is shown in Fig. 2. A summary of the data collection parameters is given in Table 2. Summaries of selected bond lengths and angles for **1** and **2** are given in Tables 3 and 4.

Both structures are similar to the prototype $Mn_2(CO)_{10}$ structure, containing an electron pair metal–metal bond and a staggered arrangement of the equatorial carbonyls. As expected, each nitrosyl ligand in **1** and **2** occupies an apical position. This same overall geometry is also found in the $Cr_2(CO)_{10}^{2-}$ dianion (8). As with $Mn_2(CO)_{10}$ and $Cr_2(CO)_{10}^{2-}$, each of the two sets of four equatorial carbonyls points slightly inward. In **1**, this inward bending from the perpendicular averages 5.85 and 6.2° for the two independent molecules in the unit cell, while for **2**, the values are 8.3 and 2.7° for the one independent monoanion, with the largest distortion on the nitrosyl side. In $Mn_2(CO)_{10}$, the corresponding angle is about 3.5° while in $Cr_2(CO)_{10}^{2-}$ it is about 3°. The larger distortion in the apical NO ligand relative to the apical CO ligand is expected because of the greater metal electron back-donation associated with the nitrosyl ligand.

In the case of the $M(CO)_5$ fragment in the monoanion (**2**), or in the $Cr_2(CO)_{10}^{2-}$ dianion, this equatorial-belt CO distortion is accompanied by a significantly shorter apical M—CO bond length: of 1.81 Å vs. an average of 1.88 Å for the four M—$C_{eq}O$ bond distances in **2**, as compared to 1.84 vs. 1.87 Å in the dianion (8). In the dinitrosyl complex (**1**), the equatorial M—C bond lengths average to 1.93 and 1.94 Å in the two independent molecules (it is noteworthy that these distances are for 165 K vs. 295 K for the former structures). The M—NO bond lengths are virtually identical in **1** and **2**, as are the N—O bond lengths. The C—O bond lengths (apical vs. equatorial) in **2** are also the same within experimental error.

Finally, the Cr—Cr bond length is similar in all three cases, viz., 2.97 Å in the dianion, 2.995 Å in **2**, and 3.001 and 3.020 in the two crystallographically independent molecules of **1**. A comparison of the isoelectronic neutral complexes $Cr_2(CO)_8(NO)_2$, **1**, and $Mn_2(CO)_{10}$ (Mn—Mn = 2.9038(6) Å) (9, 10) shows a much larger difference.

A tentative identification of $Cr(CO)_4NO$ was made in a low-temperature matrix photochemical study (3). Cyclic voltammetric studies of $Cr(CO)_4NO^-$ and $Cr_2(CO)_8(NO)_2$ (**1**) are planned to test the lifetime of this species at room temperature.

Experimental

Preparation of $Cr_2(CO)_8(NO)_2$ (1)

The salt, $PPN^+Cr(CO)_4NO^-$, was prepared essentially as described by Mantell and Gladfelter (2). Under a nitrogen atmosphere in a Schlenk tube was added 0.250 g (0.34 mmol) of this salt and 2 mL of THF (purified over sodium-benzophenone ketyl). The solution was cooled to 0°C, and 0.133 g (0.34 mmol) of solid trityl hexafluorophosphate (Aldrich) was added. Upon being stirred for 10 min, the solution–suspension gradually changed color from red to brown and also formed a precipitate. Hexane (10 mL) was added, and the solution allowed to warm to room temperature. The resulting suspension

was filtered, the solid washed with a further 5 mL of hexane, and the combined yellow filtrate evaporated to yield a pale yellow solid. This mixture was flash chromatographed (CH_2Cl_2/silica, 1 cm × 25 cm column) to give 0.0676 g (0.17 mmol, 100%) of the title compound as the first eluted material, followed by several compounds derived from the trityl portion of the reaction. Trial reactions were initially conducted at −78°C, but the reaction is quite slow at this temperature.

Crystals of **1** suitable for X-ray analysis were obtained by recrystallization from pentane at low temperatures. Crystals of **1** decomposed at about 88°C in a melting point tube. Mass spectral analysis showed a molecular ion (M^+) at m/z = 388, with prominent fragment ions at 360 ($M - CO^+$), 332 ($M - 2CO^+$), 304 ($M - 3CO^+$), 220 ($Cr_2(CO)_2(NO)_2^+$), 192 ($Cr_2(CO)(NO)_2^+$), 162 ($Cr_2(CO)(NO)^+$), 160 ($Cr_2(CO)_2^+$), 134 (Cr_2NO^+), 132 (Cr_2CO^+), 104 (Cr_2^+), 80 ($CrCO^+$), 57, 56 ($Cr(NO)_2^{2+}$), 55 ($Cr(NO)(CO)^{2+}$). Compound **1** was also produced in 18% isolated yield (reaction [1]) in a reaction of 2,4-dibromo-3-pentanone, trimethylsilyl chloride, and two molar equivalents of $PPN^+Cr(CO)_4NO^-$ in methylene chloride solvent (carried out on a 0.14 mmol scale in a Schlenk tube with 2 mL of solvent), starting at −78°C and stirring for 1 h, allowing to warm to −15°C over 1 h, and then stirring a further 1 h.

Preparation of $Cr_2(CO)_9(NO)^-$ (2) as the PPN^+ salt

A suspension of 0.52 g (0.71 mmol) of $PPN^+Cr(CO)_4NO^-$, 0.12 g (0.68 mmol) of tropylium fluoroborate (Aldrich), and 4 mL of purified THF was stirred overnight at room temperature under a N_2 atmosphere and then left in a refrigerator for 4 days. Hexane (2 mL) was added, and the heterogeneous mixture was filtered to yield, after evaporation, a yellow oil. Most of this oil, which was hexane insoluble, was taken up in methylene chloride and flash chromatographed on silica gel; elution with methylene chloride gave 0.0443 g (0.048 mmol, 21%, based on the most favorable disproportionation stoichiometry) of an orange crystalline product. Crystals suitable for X-ray diffraction were obtained by recrystallization from 3:2 hexane – methylene chloride. A mass spectrum and ^1H NMR spectrum indicated that PPN^+ was present. An IR spectrum in methylene chloride showed C—O stretches at 1980 (sh), 1961, 1891, and 1863 cm^{-1}, with a possibly very weak band at 2059 cm^{-1}; an N—O stretching frequency was observed at 1670 cm^{-1}. When the X-ray crystal structure was solved, it became apparent that the anion was

2, a compound previously prepared by Mantell and Gladfelter (2). Stirring **1** in purified THF solution, overnight at 20°C under N_2, with $PPN^+BF_4^-$ did not produce any reaction, suggesting that **2** is not formed directly from **1**.

Crystal structure determination of ***1***

Accurate cell dimensions and a crystal orientation matrix were determined on an Enraf-Nonius CAD-4 diffractometer by a least-squares refinement of the setting angles of 25 reflections with θ in the range 10–15°. Intensity data were collected by the $\omega/2\theta$ scan method using variable scan speed (1.54–6.67° min^{-1}), scan width (1.00 + 0.35 tan θ)°, and monochromatized Mo Kα radiation in the range $2° < \theta < 25°$ with h 0 to 9, k −16 to 16, and l −16 to 16. Three reflections monitored every 2 h of exposure time decreased by 8.2%; data were corrected for decay by appropriate scaling. The intensities of 5403 reflections were measured, of which 3118 had $I > 3\sigma(I)$, where $\sigma^2 I = S + 2B + [0.04(S - B)]^2$ with S = scan count and B = time-averaged background count extended 25% on each side. Data were corrected for Lorentz-polarization effects and absorption

effects (DIFABS (11)), with absorption coefficients ranging from 0.683 to 1.383.

The structure was solved by direct methods. Refinement of the structure was by full-matrix least-squares calculations, initially with isotropic and finally with anisotropic temperature factors. Refinement converged with $R = 0.061$ and $wR = 0.067$. In the refinement cycles, weights were derived from the counting statistics. Scattering factors were those of Cromer and Mann (12), and allowance was made for anomalous dispersion (Cromer and Liberman (13)). A difference map calculated at the conclusion of the refinement had no chemically significant features. All computer programs used in this study were part of XTAL2.6 (Hall and Stewart (14)), and Fig. 1 was plotted with ORTEP II (15). A list of the final fractional coordinates of **1** is given in Table 5.[2]

Crystal structure determination of **2**

Accurate cell dimensions and a crystal orientation matrix were determined on an Enraf-Nonius CAD-4 diffractometer by a least-squares refinement of the setting angles of 25 reflections with θ in the range 10–15°. Intensity data were collected by the $\omega/2\theta$ scan method using variable scan speed (1.25–4.00° min^{-1}), scan width (0.80 + 0.35 tan θ)°, and monochromatized Mo Kα radiation in the range $2° < \theta < 24°$ with h 0 to 12, k −15 to 15, and l −18 to 18. Three reflections monitored every 2 h of exposure time showed insignificant variations. The intensities of 7991 reflections were measured, of which 4992 had $I > 3\sigma(I)$, where $\sigma^2 I = S + 2B + [0.04(S - B)]^2$ with S = scan count and B = time-averaged background count extended 25% on each side. Data were corrected for Lorentz polarization; an absorption correction was deemed unnecessary.

The structure was solved by direct methods. Refinement of the structure was by full-matrix least-squares calculations, initially with isotropic and finally with anisotropic temperature factors for the non-hydrogen atoms except for the solvent atoms, which had only partial occupancy and which were refined with isotropic temperature factors. At an intermediate stage in the refinement, a difference map revealed most of the H atoms which were included in the subsequent cycles at geometrically idealized positions (C—H 0.95 Å) with a fixed overall isotropic temperature factor; H atoms of the solvent molecule were ignored. Refinement converged with $R = 0.0777$ and $wR = 0.0804$. In the refinement cycles, weights were derived from the counting statistics. Scattering factors were those of Cromer and Mann (12) and Stewart, Davidson, and Simpson (16) with corrections for anomalous dispersion (Cromer and Liberman (13)). A difference map calculated at the conclusion of the refinement had no chemically significant features. The computer programs used in this study were SHELX'76 (17), and ORTEP II (15). A list of the final fractional coordinates of **2** is given in Table 6.[2]

[2]A complete set of structure factor listings, anisotropic thermal parameters, and hydrogen atom parameters is available for **1** and **2** and may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Ont., Canada K1A 0S2.

High-resolution amplified spontaneous emission (ASE) gain spectroscopy to study excited state complexation

R. W. YIP[1] AND Y-X. WEN

Département de chimie, Université du Québec à Montréal, C.P. 8888, Succ. A, Montréal (Québec), Canada H3C 3P8

Received June 3, 1991

This paper is dedicated to Dr. Richard Norman Jones

R. W. YIP and Y-X. WEN. Can. J. Chem. **69**, 2142 (1991).

Weakly bound excited state complexes involving 7-diethylamino-4-methylcoumarin have been studied by ASE gain spectroscopy to explore the applicability of the method for studying excited state complexation. Comparative steady state spectrofluorometric and ASE gain measurements showed that ASE gain measurements are capable of giving information on excited state complexation of the laser dye but with greater ease and frequency resolution.

Key words: excited state complex, amplified spontaneous emission, laser gain, ASE gain spectroscopy.

R. W. YIP et Y-X. WEN. Can. J. Chem. **69**, 2142 (1991).

Dans le but d'explorer la champ d'application de la méthode pour l'étude de la complexation d'états excités, on a examiné des complexes d'états excités faiblement liés, impliquant la 7-diéthylamino-4-méthylcoumarine par spectroscopie du gain d'émissions spontanées amplifiées. Une comparaison des états stationnaires tels que mesurés par spectrofluorométrie et par le gain d'émissions spontanées amplifiées montre que ces dernières mesures peuvent donner de l'information sur la complexation de l'état excité de lasers á colorant; la mesure est plus facile et la résolution des fréquences est meilleure.

Mots clés : complexe d'état excité, émission spontanée amplifiée, gain de laser, spectroscopie du gain d'émission spontanée amplifiée.

Introduction

Since the 1960's, spectrofluorimetry has been widely applied to study excited state molecular complexation (1). The systems studied include the biologically important indoles in polar solvents (2, 3), coumarin dyes in solvent mixtures (4), and *trans-n*-styrylphenanthrene isomers in *n*-hexane/amines (5). Highly sensitive, conventional spectrofluorimetric measurements on solution molecular complexes often lack spectral resolution; thus, in order to resolve the overlapping fluorescence bands into their components, extremely precise measurements and assumptions regarding the shapes of the component bands are necessary.

By contrast, the bands from amplified spontaneous emission (ASE) gain spectroscopy introduced by Silfvast and coworkers (6*a*, *b*), are intrinsically narrower than those of the corresponding fluorescence emission. Although almost exclusively used since the 1970's to study the fundamental characteristics of lasers (6*b*, *c*–10), ASE spectroscopy may be a useful spectroscopic technique to resolve normally heavily overlapping bands due to "free" and complexed dyes or dyes in heterogeneous environments. In a recent study of the dual ASE bands of 7-aminocoumarin dyes in different solvents, distinctly resolved bands (9) due to uncomplexed species and hydrogen-bonded complexes (10) were observed.

The objective of the present work is to explore the applicability of ASE gain spectroscopy to the study of excited state complexation. Towards this objective we have (i) established a relationship between a constant derived from ASE gain measurements and the Stern–Volmer constant for fluorescence quenching or the ground state complexation constant from uv/vis absorption study, and (ii) carried out ASE gain measurements on weakly bound complexes comprising excited state 7-diethylamino-4-methylcoumarin (coumarin-1) in solvent systems containing either dichloromethane or *n*-butyl acetate as cosolvents. In these solvent systems, the steady state fluorescence spectra show no or extremely small frequency shifts with concentrations of dichloromethane. The clearly resolved bands observed in the ASE gain spectra in the same systems demonstrate the superior frequency resolution of the method.

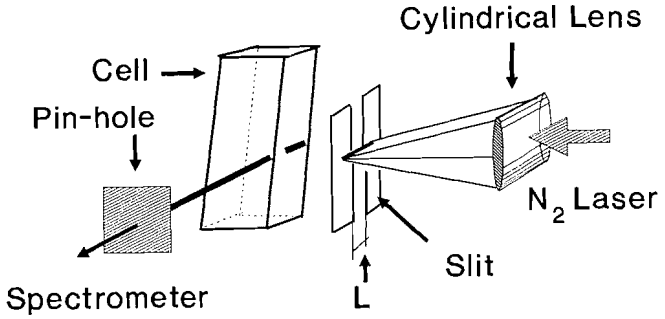

FIG. 1. ASE gain spectrometric system.

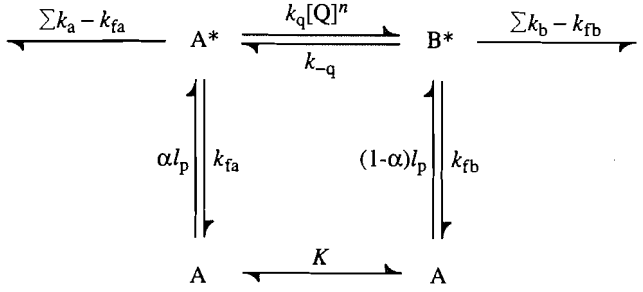

Experimental section

ASE gain studies used a PRA LN100 N_2 laser (60 μJ, pulse width ≈0.3 ns) for transverse excitation (2 in. focal length cylindrical quartz lens) of a dye solution contained in an upright 1-cm rectangular 4-window quartz fluorescence cell, and a JY HR 320 monochromator and a silicon diode array/OMA (EG&G 1412F/1461) system for detection of the emission. The transverse excitation geometry illustrated in Fig. 1 is as previously described (6, 10). For increased signal/noise ratio, at least 15 spectra measured under the same conditions were used to get the average spectrum. A pumping intensity of 100 kW was chosen for most of the studies by using a specific filter; this is slightly higher than the threshold pumping intensity for the laser dye. The ratio (R) of the average spectra with full cell width L and partial cell width (2/3)L ($R = I_L(\mathrm{WL})/I_{(2/3)L}(\mathrm{WL})$), has been used to transfer to its ASE gain spectrum by eq. [1] (8, 10):

$$[1] \qquad G(\mathrm{WL}) = (3/L)\ln\{1/2((R-1)+[(R-1)^2+4(R-1)]^{1/2})\}$$

SCHEME 1

n-Butyl acetate (*n*BuOAc) (Fisher reagent) was refluxed over CaH_2 for 1 h and distilled. 1-Butanol (Fisher Certified A.C.S.), dichloromethane (CH_2Cl_2) (Anachemia spectro), and 2,2,4-trimethyl pentane (isooctane) (Matheson Coleman & Bell spectro) were used without further treatment. Preliminary studies of the ASE of coumarin-1 in untreated and CaH_2-treated dichloromethane gave, in contrast with *n*BuOAC, identical results. The 7-diethylamino-4-methylcoumarin (coumarin-1) (Exciton Corp.) was recrystallized from methanol–water and sublimed. Absorption and fluorescence spectra were measured with a Cary-2000 uv/vis spectrophotometer and a Perkin–Elmer-44 spectrofluorimeter, respectively.

Steady state fluorescence and ASE gain kinetics

A. Fluorescence quenching

For a normal two-component system, the ratio of fluorescence intensity at wavelength WL with and without quencher (I(WL) and I^0(WL) respectively), can be considered as the sum of two contributions by the free and complexed species (refer to Scheme 1) (10):

$$[2] \qquad I(\mathrm{WL})/I^0(\mathrm{WL}) = \Phi_a/\Phi_a^0 + \beta(\mathrm{WL})(\Phi_b/\Phi_b^0)$$

where Φ_i and Φ_i^0 (i = a or b) are the quantum yields with and without quencher (of free or complexed species respectively), and β(WL) is the ratio of the intensity in neat quencher and in neat solvent.

In the far blue region shown in Fig. 2, the contribution of the complex can be eliminated ($\beta(\mathrm{WL} \rightarrow 0)$. Thus, the intensity ratio in eq. [2] can be simply replaced by the quantum yield ratio of the free species, which should satisfy eq. [3] (10, 11):

$$[3] \qquad I(\mathrm{WL})/I^0(\mathrm{WL} = \Phi_a/\Phi_a^0 = (1-\alpha)/(1+K_{SV}[Q]^n)$$

where α is the fraction of light absorbed by ground state complex **B** and satisfies (10, 11)

$$[4] \qquad \alpha = K[Q]^m/(\sigma_{pa}/\sigma_{pb} + K[Q]^m)$$

where $\sigma_{pi}(WL_p)$ (i = a, b) are absorption cross sections of species **A** and **B**, WL_p is the pumping (excitation) wavelength, and K_{SV} is the Stern–Volmer constant defined by

$$[5] \qquad K_{SV} = k_q\tau_a/(1+k_{-q}\tau_b)$$

where τ_a, τ_b are the lifetimes of excited state free and complexed species defined as the reciprocal of $\sum k_a$ and $\sum k_b$, respectively, and K, k_q, and k_{-q} are the equilibrium and kinetic constants illustrated in Scheme 1; m and n are the stoichiometric constants of ground and excited state complexes, respectively.

B. Gain coefficient

The small-signal ASE gain is proportional to the population of the excited state as described in eq. [6] (6*c*, 8):

$$[6] \qquad g(\mathrm{WL}, t) = \sigma_e(\mathrm{WL})N(t) - g_{ai}(\mathrm{WL}, t)$$

where σ_e(WL) is the stimulated emission cross section, N is the population of the fluorescing state, and g_{ai} is the sum of possible losses due to the internal transitions between excited singlet–singlet and triplet–triplet states. In view of the location of the singlet–singlet absorption band (12) and the near-unity quantum yields of coumarin-1 in aprotic and moderately polar protic solvents (13), the gain of coumarin-1 in aprotic (isooctane, *n*BuOAc, and CH_2Cl_2) or moderately polar protic (*n*BuOH) solvents can be approximated by eq. [7]:

$$[7] \qquad g(\mathrm{WL}, t) = \sigma_e(\mathrm{WL})N(t)$$

The experimentally observable ASE gain in eq. [1] is the integral of eq. [7] with respect to the exposure time of the detector as expressed below:

$$[8] \qquad G(\mathrm{WL}) = \int_0^\infty g(\mathrm{WL}, t)\mathrm{d}t = \sigma_e(\mathrm{WL}) \int_0^\infty N(t)\mathrm{d}t$$

The ASE gain ratio of excited state species $\mathbf{B}^*$ and $\mathbf{A}^*$ can be represented by

$$[9] \qquad R_g = G_b(WL_b)/G_a(WL_a)$$
$$= (\sigma_{eb}/\sigma_{ea})\left(\int_0^\infty [\mathbf{B}^*(t)]\mathrm{d}t \Big/ \int_0^\infty [\mathbf{A}^*(t)]\mathrm{d}t\right)$$
$$= (\sigma_{eb}/\sigma_{ea}) \cdot R_p$$

where σ_{ei} (i = a, b) are stimulated emission cross sections of species $\mathbf{A}^*$ and $\mathbf{B}^*$, respectively, and R_p is the ratio of the integral populations of species $\mathbf{B}^*$ and $\mathbf{A}^*$.

C. Relationship between the gain ratio R_g *and* K_{SV} *or* K

The gain ratio (R_g) determined from ASE gain experiments is proportional to the ratio (R_p) of integral populations as described in eq. [9]. Based on the kinetics illustrated in Scheme 1, the differential populations of $\mathbf{A}^*$ and $\mathbf{B}^*$ with respect to time can be expressed by the following equations:

$$[10a] \qquad \mathrm{d}[\mathbf{A}^*]/\mathrm{d}t = (1-\alpha)I_p + k_{-q}[\mathbf{B}^*] - (\sum k_a + k_q[Q^n + \sigma_{ea}I_{ea})[\mathbf{A}^*]$$

$$[10b] \qquad \mathrm{d}[\mathbf{B}^*]/\mathrm{d}t = \alpha I_p + k_q[Q]^n[\mathbf{A}^*] - (\sum k_b + k_{-q} + \sigma_{eb}I_{eb})[\mathbf{B}^*]$$

where $[\mathbf{A}^*]$, $[\mathbf{B}^*]$ are the populations of excited states; σ_{ei} (i = a, b) are the stimulated cross sections of species $\mathbf{A}^*$ and $\mathbf{B}^*$; I_p is the pumping photon rate, and I_{ei} (I_p dependent) are the stimulated emission photon rates per area of species $\mathbf{A}^*$ and $\mathbf{B}^*$; and the remaining terms are defined in Scheme 1.

1. Pumping at threshold ($I_{ei} \rightarrow 0$, i = a, b)

Under transient conditions corresponding to excitation at t = 0 by a δ-function laser pumping of negligible duration (14), which is valid for the short duration N_2 laser pulse ($t_p \approx 300$ ps) in comparison to the lifetimes of fluorescent species ($t_i \approx 3$ ns), a zero pumping rate per area ($I_p = 0$) in the equation set [10] can be assigned for $t > 0$. Therefore, the equation set [10]

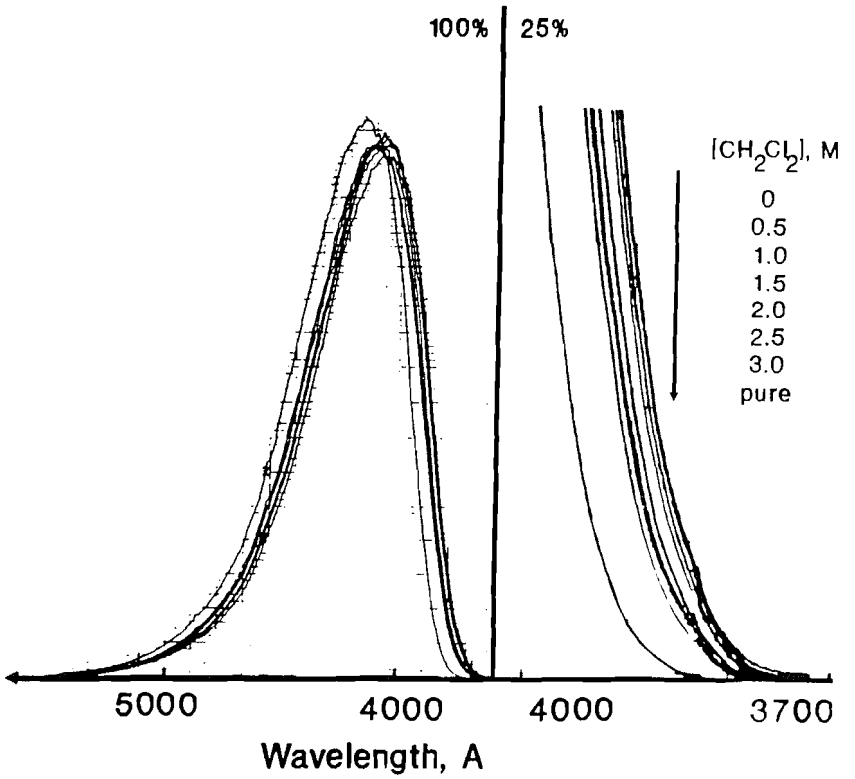

FIG. 2. Fluorescence spectra (excited at 361.2 nm) of coumarin-1 (0.035 mM) in *n*BuOAc containing different amounts of CH_2Cl_2 (0–3.0 M), and in pure CH_2Cl_2 at room temperature; right part is the amplified spectra from 3700 Å to 4000 Å.

can be simplified by eliminating the first terms and stimulated emissions (I_{ei}, i = a, b) as follows:

$$[11a] \quad d[\mathbf{A}^*]/dt = k_{-q}[\mathbf{B}^*] - k_1[\mathbf{A}^*]$$

$$[11b] \quad d[\mathbf{B}^*]/dt = k_q[Q]^n[\mathbf{A}^*] - k_2[\mathbf{B}^*]$$

where the coefficients are

$$[11c] \quad k_1 = \sum k_a + k_q[Q]^n$$

$$[11d] \quad k_2 = \sum k_b + k_{-q}$$

From eq. [11*a*], the population of species $\mathbf{B}^*$ can be represented by the population of species $\mathbf{A}^*$ as follows:

$$[12] \quad [\mathbf{B}^*] = (d\mathbf{A}^*]/dt + k_1[\mathbf{A}^*])/k_{-q}$$

Introducing the first-order derivative of eq. [12] with respect to time into eq. [11*b*], and replacing $[\mathbf{B}^*]$ in eq. [11] by [12], the simple second-order differential equation of $[\mathbf{A}^*]$ with respect to time is given by the following equation:

$$[13] \quad \frac{d^2[\mathbf{A}^*]}{dt^2} + B\frac{d[\mathbf{A}^*]}{dt} + C[\mathbf{A}^*] = 0$$

where $B = k_1 + k_2$, and $C = k_1k_2 - k_{-q}k_q[Q]^n$.

Since $B^2 - 4C = (k_1 - k_2)^2 + 4k_{-q}k_q[Q]^2 > 0$, the population of species $\mathbf{A}^*$ can be solved from eq. [13] (15):

$$[14a] \quad [\mathbf{A}^*] = C_1 \exp(S_1t) + C_2 \exp(S_2t)$$

where $C_{1,2}$ are the constants that can be found by considering the initial conditions, the parameters $S_{1,2}$ are

$$[14b] \quad S_1 = [-B^2 + (B^2 - 4C)^{1/2}]/2$$

$$[14c] \quad S_2 = [-B^2 - (B^2 - 4C)^{1/2}]/2$$

and B and C are as defined in eq. [13].

With eqs. [12] and [14], the population of species $\mathbf{B}^*$ can be expressed in the form of

$$[15] \quad [\mathbf{B}^*] = [(S_1 + k_1)C_1 \exp(S_1t) + (S_2 + k_1)C_2 \exp(S_2t)]/k_{-q}$$

Under the transient conditions, the initial populations of species $[\mathbf{A}^*(0)]$ and $[\mathbf{B}^*(0)]$ excited by a δ-function laser pulse at $t = 0$ can be presented by

$$[16a] \quad [\mathbf{A}^*(0)] = (1 - \alpha)I_0$$

$$[16b] \quad [\mathbf{B}^*(0)] = \alpha I_0$$

where I_0 is the total number of incident photons absorbed by both species.

By introducing the initial conditions (eqs. [16]) into eqs. [14] and [15], we get

$$[17a] \quad [\mathbf{A}^*(0)] = C_1 + C_2 = (1 - \alpha)I_0$$

$$[17b] \quad [\mathbf{B}^*(0)] = [(S_1 + k_1)C_1 + (S_2 = k_1)C_2]/k_{-q} = \alpha I_0$$

Replacing C_2 in eq. [17*b*] by eq. [17*a*], and dividing the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 123.30.183.119 on 09/08/12
For personal use only.

non-zero common factors of C_1 in both sides, the constant C_1 can be obtained:

$$[18a] \quad C_1 = [k_{-q}\alpha - (S_2 + k_1)(1 - \alpha)]I_0/(S_1 - S_2)$$

and the constant C_2 is given by

$$[18b] \quad C_2 = [(S_1 + k_1)(1 - \alpha) - k_{-q}\alpha]I_0/(S_1 - S_2)$$

Since the experimentally observable ASE gain ratio R_g is proportional to the ratio of the integral populations of species $\mathbf{B}^*$ and $\mathbf{A}^*$ as described in eq. [9], the integral populations of both species, which can be solved from eqs. [14], [15], and [18], are as follows:

$$[19a] \quad \int_0^\infty [\mathbf{A}^*]dt = \int_0^\infty \{C_1 \exp(S_1 t) + C_2 \exp(S_2 t)\}dt = (I_0/C)[\alpha k_{-q} + (1 - \alpha)k_2]$$

$$[19b] \quad \int_0^\infty [\mathbf{B}^*]dt = \int_0^\infty \{[(S_1 + k_1)C_1 \exp(S_1 t) + (S_2 + k_1)C_2 \exp(S_2 t)]/k_{-q}\}dt = (I_0/C)[(1 - \alpha)k_q[Q]^n + \alpha k_1]$$

Therefore, the gain ratio can be derived from eqs. [9] and [19] as

$$[20] \quad R_g = (\sigma_{eb}/\sigma_{ea})\frac{\alpha k_1 + (1 - \alpha)k_q[Q]^n}{(1 - \alpha)k_2 + \alpha k_{-q}}$$

where $k_{1,2}$ are defined in eq. [11*c*, *d*].

(i) Excited state complexation at $\alpha \rightarrow 0$ *(or* $K \rightarrow 0$*).* For the dynamic quenching process, the ASE gain ratio R_g in eq. [20] can be simply expressed by

$$[21a] \quad R_g = (\sigma_{eb}/\sigma_{ea})\frac{k_q[Q]^n}{\sum k_b + k_{-q}} = (\sigma_{eb}/\sigma_{ea})(\tau_b/\tau_a)K_{SV}[Q]^n = K_{ASE}[Q]^n$$

where $k_{1,2}$ have been replaced by the terms $\sum k_a + k_q[Q]^n$ and $\sum k_b + k_{-q}$, respectively. Hence the K_{ASE} obtained from ASE gain measurement is related to the Stern–Volmer constant K_{SV} (defined in eq. [5]) by

$$[21b] \quad K_{ASE} = (\sigma_{eb}/\sigma_{ea})(\tau_b/\tau_a)K_{SV}$$

where $\tau_i(\tau_i = 1/\sum k_i$, i = a, b) are lifetimes of species $\mathbf{A}^*$ and $\mathbf{B}^*$.

(ii) Ground state complexation only. By ignoring the excited state complexation ($k_q[Q]^n \ll \alpha \sum k_a$, $k_{-q} \ll (1 - \alpha)\sum k_b$), the ASE gain ratio can be obtained from eq. [20] by eliminating the terms with $k_q[Q]^n$ and k_{-q}, as expressed by the following equation:

$$[22a] \quad R_g = (\sigma_{eb}/\sigma_{ea}) \cdot \frac{\alpha \sum k_a}{(1 - \alpha)\sum k_b} = (\sigma_{eb}/\sigma_{ea})(\sigma_{pb}/\sigma_{pa})(\tau_b/\tau_a) \cdot K \cdot [Q]^m = K_{ASE}[Q]^m$$

where $\alpha/(1 - \alpha)$ has been replaced by the term of $(\sigma_{pb}/\sigma_{pa})K[Q]^m$ from eq. [4]. Therefore, the K_{ASE} constant obtained from ASE gain measurement can derive the information about the ground state complexation by

$$[22b] \quad K_{ASE} = (\sigma_{eb}/\sigma_{ea})(\sigma_{pb}/\sigma_{pa})(\tau_b/\tau_a) \cdot K$$

Hence K is the ground state complexation constant with stoichiometric constant m.

2. Effect of pumping intensity

In the above discussion, the pumping intensity effect (16–20) represented by the stimulated emission rates (I_{ea} and I_{eb}) in equation set [10] was not considered. Since the stimulated emission rate (I_{ea} or I_{eb}) is a function of the excited state population as well, the solution of the equation set [10], which could only be solved numerically, is very complicated. However, for moderate pumping intensities over the threshold, the stimulated emission rate (I_{ea} or I_{eb}) can be considered as a function of the pumping intensity with a small perturbation of the excited state population, which can be assumed constant for a specific pumping intensity. Therefore, the solution to the moderate pumping case can be found by derivations similar to those used for the threshold pumping case, except that the coefficients $k_{1,2}$ in eqs. [11]–[20] are now given by

$$[23a] \quad k_1 = \sum k_a + k_q[Q]^n + \sigma_{ea}I_{ea}$$

$$[23b] \quad k_2 = \sum k_b + k_{-q} + \sigma_{eb}I_{eb}$$

instead of eqs. [11*c*, *d*].

As the pumping intensity is increased above the threshold value (W_{th}), stimulated emission will compete with spontaneous emission and radiationless deactivation of species $\mathbf{A}^*$ and $\mathbf{B}^*$, which leads not only to a shortening of the decay time but also to strong non-exponential decay (18). For the purpose of extrapolation to K_{ASE} at the pumping intensity threshold value, $K_{ASE}(W_{th})$, eq. [20] can be simplified for the dynamic quenching process ($\alpha \rightarrow 0$):

$$[24a] \quad R_g = (\sigma_{eb}/\sigma_{ea})(k_q/k_2)[Q]^n = K_{ASE}[Q]^n$$

Here the K_{ASE} constant obtained from ASE gain measurement can be described by

$$[24b] \quad K_{ASE} = (\sigma_{eb}/\sigma_{ea})(k_q/k_2) = (\sigma_{eb}/\sigma_{ea})[k_q/(\sum k_b + k_{-q} + \sigma_{ea}I_{ea})] = (\sigma_{eb}/\sigma_{ea})(\tau_b/\tau_a)\frac{1 + k_{-q}\tau_b}{1 + k_{-q}\tau_b + \tau_b\sigma_{ea}I_{ea}}K_{SV}$$

Since the stimulated emission $\sigma_{eb}I_{eb}$ is pumping intensity dependent, eq. [24*b*] can be expressed in the simple form of

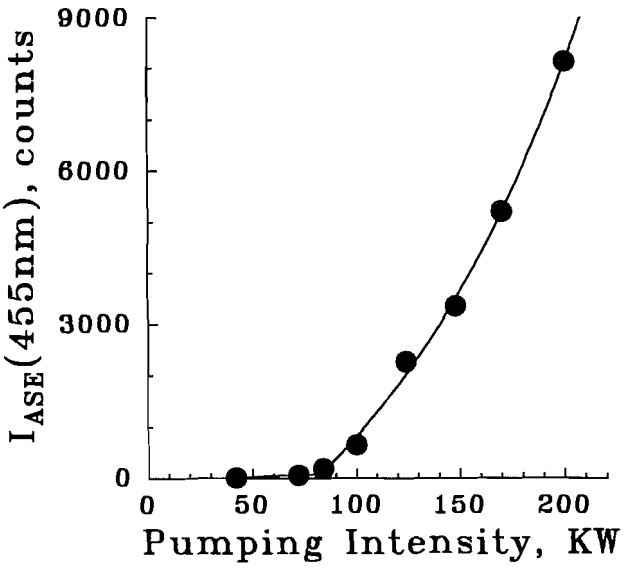

FIG. 3. ASE intensity (I_{ASE}) of coumarin-1 (8.0 mM) in pure *n*BuOH vs. pumping intensity (W) (dark circles) fitted by solid line as expressed by eq. [26].

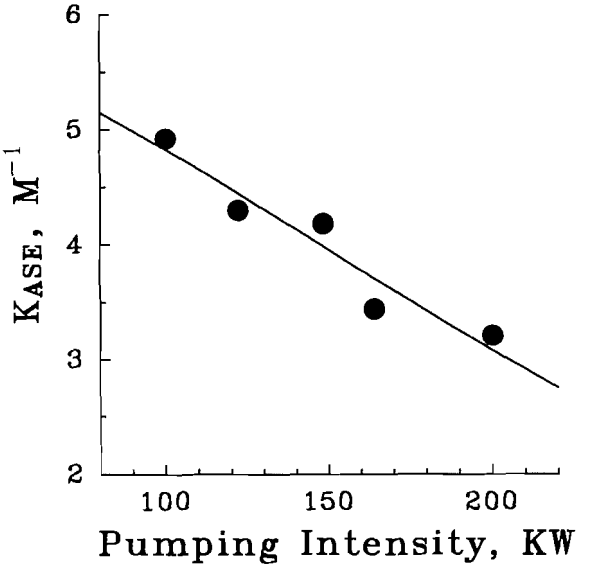

FIG. 4. Pumping intensity effects on K_{ASE} of coumarin-1 (8.0 mM) in *n*BuOAc containing different amounts of *n*BuOH (dark circles) fitted by solid line as described by eq. [25*b*].

$$[25a] \quad K_{ASE} = K_{ASE}(W_{th})/\{1 + \Gamma \cdot I_{eb}(W)\}$$

where Γ is a constant and $K_{ASE}(W_{th})$ is as defined in eq. [21*b*].

At intensities above the pumping threshold ($W \geq W_{th}$), we expect and observe an exponential function with respect to the pumping intensity for relatively small ASE signals (20). The dependence of the total ASE (I_{ASE}) of coumarin-1 in pure *n*BuOH at peak position (WL_b = 455 nm) on the pumping intensity (W) is shown in Fig. 3. The circles are the experimental points and the solid line is the best fit computed from the equation

$$[25b] \quad I_{ASE} = 4103 \cdot \{\exp(0.00909 \cdot (W - W_{th})) - 1\}$$

with $W_{th} = 80 \pm 5$ kW.

TABLE 1. Kinetic constants of coumarin-1 in different solvent mixtures

Solvent	Quencher	E_T^N of quencher[a]	Quenching constants (M^{-1}) K_{SV}[b]	K_{ASE}[c]	K[d]
*n*BuOAc	*n*BuOH	0.602	5.3	4.9	0.2[e]
*n*BuOAc	CH_2Cl_2	0.309	0.36	0.33	0.09

[c]Under 100-kW pumping intensity, if not specified.
[d]From uv/vis absorption study.
[e]In units of M^{-2}; ref. 10.
[f]No dynamic contribution; K = 0.26 M^{-1} was obtained from fluorescence spectra using eq. [27*b*].

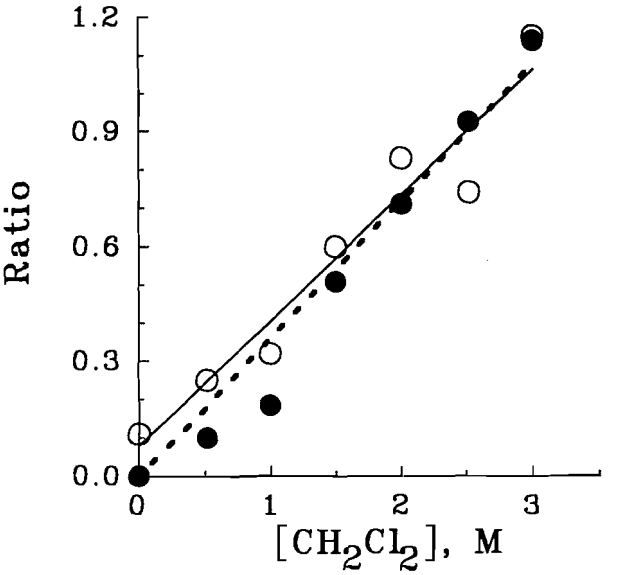

FIG. 5. Plot of Φ_a^0/Φ_a^{-1} and R_g versus $[CH_2Cl_2]$. Dark circles: Φ_a^0/Φ_a^{-1} ([coumarin-1]:0.035 mM) from conventional spectrofluorimetry fitted by dark dots line (K_{SV} = 0.36 M^{-1}); blank circles: R_g ([coumarin-1]:8.0 mM) from ASE gain spectroscopy fitted by solid line (K_{ASE} = 0.33 M^{-1}).

Since the spontaneous emission (I_{sb}) contribution is negligible ($I_{sb} \ll I_{eb}$) for pumping intensities $W > W_{th}$, the stimulated emission (I_{eb}) can be considered as the total ASE ($I_{eb} = I_{ASE}$). Applying eq. [25*a*] to simulate the experimental values of K_{ASE} by considering eq. [26] as the pumping intensity dependence of the stimulated emission (I_{eb}) in eq. [25*a*] for pumping intensities $W \geq W_{th}$, we obtained

$$[26] \quad K_{ASE} = K_{ASE}(W_{th})/\{1 + 0.341 \times [\exp(0.00909 \cdot (W - W_{th})) - 1]\}$$

where $K_{ASE}(W_{th}) = 5.2 \pm 0.3$ M^{-1}. The results are shown in Fig. 4 where the filled circles are the experimental values from the slopes of gain ratio (R_g) vs. concentration of *n*BuOH using eq. [21*a*], and the solid curve is calculated from eq. [25*b*].

Discussion

The fluorescence spectra of coumarin-1 in *n*BuOAc containing different amounts of CH_2Cl_2 (refer to Fig. 2) show

slight shifts in the peak position with changing concentration of CH_2Cl_2, which is mainly due to the excited state complexation between dye and quencher (CH_2Cl_2). The Stern–Volmer constant K_{SV} determined from eq. [3] is much larger than the ground state constant K from uv/vis absorption study (as listed in Table 1), which implies a higher capability of complexation in the excited state than in the ground state. In a system containing *n*BuOH, significant changes in the fluorescence spectra have been observed due to its strong H-bonding effect between alcohol and dye in the excited state (10).

In the isooctane/*n*BuOAc system, where there is no H-bonding effect in the excited state, there is only a slight shift in the fluorescence spectra of coumarin-1 with increasing concentration of *n*BuOAc. The value of the Stern–Volmer constant for dynamic quenching in the excited state determined from eq. [3] was found to be zero. With $K_{SV} = 0$, eq. [3] for the fluorescence quenching becomes:

$$[27a] \quad \Phi_a/\Phi_a^0 = 1 - \alpha$$

Since the sample is excited at the isosbestic wavelength ($WL_p = WL_{iso}$), the ratio of $\sigma_{pa}/\sigma_{pb} = 1$ in eq. [4] defining α, and eq. [27*a*] for the ground state equilibrium becomes:

$$[27b] \quad \Phi_a/\Phi_a^0 = 1/(1 + K[Q]^m)$$

The value of $K = 0.26\ M^{-1}$ obtained from the fluorescence quenching using eq. [27*b*] is similar to that obtained from the absorption measurement (Table 1).

Similarly, the weak binding effect of coumarin-1 in isooctane mixed with *n*BuOAc is also observed from their ASE gain spectra. To increase the signals, 200-kW pumping intensity was applied to get a gain ratio that satisfies eq. [22*a*] ($m = 1$). A value of K_{ASE} obtained by using eq. [22*a*] in Table 1 is comparable to the ground state complexation constant K from uv/vis absorption studies as presented by eq. [22*b*].

Table 1 also shows that the Stern–Volmer constants increase in the order:

$$[28] \quad K_{SV}\ (n\text{BuOAc}) < K_{SV}\ (CH_2Cl_2) < K_{SV}\ (n\text{BuOH})$$

which parallels quencher polarity (E_T^N (21)). The most significant factor, however, appears to be H-bonding between dye and quencher, consistent with our earlier conclusion (10).

As discussed in the previous section, the gain ratio of complexed and free species should satisfy eq. [21*a*]. A linear relation between R_g and concentration of CH_2Cl_2 is observed in Fig. 5 as expected. The ASE quenching constants K_{ASE} obtained experimentally in *n*BuOAc with CH_2Cl_2 and *n*BuOH (Table 1) are comparable to the K_{SV} from conventional spectrofluorimetry. Since the increase of the gain ratio R_g with CH_2Cl_2 or *n*BuOH is mainly due to excited state complexation between dye and CH_2Cl_2 or *n*BuOH (dynamic quenching), the K_{ASE} constant should satisfy eq. [21*b*] with unit stoichiometric constant ($n = 1$) as observed experimentally. Similarly, the K_{ASE} constant of coumarin-1 in the cosolvents isooctane and *n*BuOAc should be directly related to its ground state constant K (refer to eq. [22*b*]), because of the dominance of the static quenching over ground state complexation constant. When only the dynamic contribution is considered, the values of K_{ASE} for the different quenchers parallel those of the Stern–Volmer constant (eq. [28]).

When the dominant process is dynamic quenching, as in the case of coumarin-1 in *n*BuOAc mixed with *n*BuOH (10), the value of K_{ASE} at threshold, $5.2 \pm 0.3\ M^{-1}$, should be consistent with that determined from the Stern–Volmer quenching as discussed below.

TABLE 2. Comparison of K_{ASE} of coumarin-1 in *n*BuOAc[a] containing different amount of *n*BuOH[b] from ASE gain spectroscopy to that from conventional spectrofluorimetry

[d]Obtained from the best fit (eq. [25*b*]).
[e]Estimated from the Stern–Volmer constant using eq. [21*b*].

By estimating the ratios of $\sigma_{eb}(455\text{ nm})/\sigma_{ea}(420\text{ nm})$, τ_b/τ_a of coumarin-1 in pure *n*BuOH and *n*BuOAc as listed in Table 2, an ideal value of the K_{ASE} constant ($K_{ASE} = 5.8 \pm 1.7$ M^{-1}) can be estimated from the K_{SV} determined from conventional spectrofluorimetry by means of eq. [21*b*]. This value is similar to the K_{ASE} constant determined by extrapolation to the threshold intensity (W_{th}) using eq. [25*b*] ($K_{ASE}(W_{th}) = 5.2 \pm 0.3$ M^{-1}). The agreement between these two K_{ASE} constants also confirms the anticipated equivalence of these two techniques for the study of excited state complexation.

In Fig. 6, the separated two-component ASE gain spectra of coumarin-1 in *n*BuOAc with different amounts of CH_2Cl_2 were obtained directly from eq. [1]. By comparison with their fluorescence spectra in Fig. 2, a significantly higher resolution is observed for the gain spectra, which is very useful to identify multicomponent spectra with close peak positions.

During the sample preparation, the gain ratio (R_g) was found to be relatively insensitive to the variation of the coumarin-1 concentration ($\pm 10^{-4}$ M). By comparison, the quantum yield ratio measurements from conventional spectrofluorimetry were carried out with coumarin-1 concentrations of 0.035 mM and the difference between each sample and reference had to be less than 0.5% or $\approx \pm 10^{-7}$ M.

In conclusion, excited and ground state complexation of coumarin-1 in different solvents with or without quenchers has been investigated and a correlation between ASE gain spectroscopy and conventional spectrofluorimetry has been established, which has been confirmed in both experiment and theory. Although obviously limited to fluorophores capable of undergoing stimulated emission, the advantage of ASE gain spectroscopy over conventional spectrofluorimetry was found to be (a) higher frequency resolution to permit identification of multicomponents with close band positions; (b) easier sample preparation (no precise requirement about the dye concentration); (c) fast data treatment.

By comparing the excited state quenching constants with the empirical parameters for quencher polarity E_T^N (21), the reduction of the ASE gain of free species or enhancement of the ASE gain of complexes with respect to the quencher polarity E_T^N can be explained in terms of H-bonding formation between dye and quencher.

[2]The stimulated emission cross section $\sigma_{ei}(WL_i)$ (i = a, b) is given by the relationship (17):

$$\sigma_{ei}WL_i\ {}^4E_i(WL_i)/(8\pi\tau_i c n_i^2)$$

where $E_i(WL_i)$ is the fluorescence line shape function, n_i the refractive index of the solution at WL_i, τ_i is the lifetime of the fluorescing state without stimulated emission, and c the velocity of light *in vacuo*. Therefore, the ratio of the stimulated emission cross section of coumarin-1 in *n*BuOH to that in *n*BuOAc can be estimated by

$$\sigma_{eb}/\sigma_{ea} = (WL_b/WL_a)^4(\tau_a/\tau_b)(n_a/n_b)^2(E_b(WL_b)/E_a(WL_a))$$
$$\approx (WL_b/WL_a)^4(\Phi_a/\Phi_b)(n_a/n_b)^2(\Phi_b/\Phi_a)$$
$$= (WL_b/WL_a)^4(n_a/n_b)^2$$
$$= (455/420)^4 \cdot 1 = 1.4$$

Here the fluorescence line shape ratio of peaks $WL_b = 455$ nm and $WL_a = 420$ nm is approximated by its quantum yield ratio under assumption of equal band width, and the index ratio can be assumed to be unity.
