FIG. 1. ^{13}C spectral line (bottom spectrum) and its point-by-point standard deviation on the same horizontal scale (top spectrum). Data wre calculated using the program NMRSTAT.

which is a smaller effect. Small drifts in frequency or phase of the line will affect the wings of the line, but will leave the peak height relatively unaffected. This is illustrated in Fig. 1, where the lower spectrum is a ^{13}C spectral line and the upper spectrum is its standard deviation. In this case the phase drifted accidentally during the course of the experiment, as could be seen from inspection of the individual spectra. This small drift gives the wings of the line a relatively high variation, but the standard deviation of the peak height is similar to that of the baseline. Under ideal conditions, the standard deviation spectrum shows no features near where a spectral line appears in the normal spectrum, but in the presence of small drifts in frequency or in phase, the standard deviation spectrum in Fig. 1 is quite common. This demonstrates that the peak height is stable, even in the presence of small instabilities in the instrument.

In integration, a non-zero baseline will cause slope and curvature of the integral, which mean that the value of the integral will depend strongly on the choice of endpoints. With a peak height, the baseline simply adds or subtracts a constant from the intensity, provided only that the baseline be stable. By plotting the peak height of a sample versus the peak height of a reference of known concentration, as a function of the concentration, we should obtain a straight line. The slope of this line will be proportional to the intensity, and any baseline effects will appear as a non-zero intercept. The intercept can be ignored, since the slope gives us the information we need. This redundancy is built into the experiment. The error bars on the individual peak heights and the linearity of the plot versus

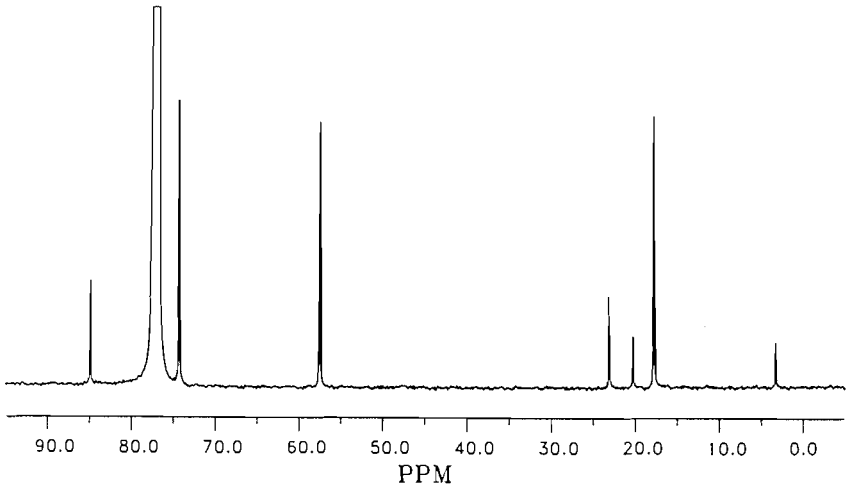

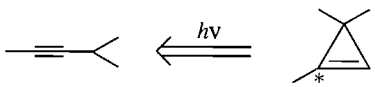

FIG. 2. ^{13}C NMR spectrum (10 000 scans) of compound **1** (labelled) plus the internal standard, ethanol.

reference concentration will then give a clear indication of the quality of the data.

This methodology obviously requires some more work than simply letting the spectrum accumulate for a long period of time, but with modern computer-controlled spectrometers, sample changers, and off-line data processing, much of this work can be automated and these techniques can become routine. We feel that the effort is worthwhile, since the internal consistency of the data will show its reliability.

Results

The compound studied in this paper is 4-methyl-2-pentyne (**1**), which is one of the products of the solution phase photolysis of 1,3,3-trimethylcyclopropene (**2**) (26). To elucidate the mechanism of this reaction,

1 **2**

compound **2** was synthesized with a ^{13}C label at position 1, and the postulated mechanisms lead to this label being at position 2 or position 3 of the alkyne **1** (26). It was therefore crucial to determine the enrichment at the various sites in **1** while working with a restricted amount of material (approximately 3.5 mg).

Compound **1** was dissolved in 0.7 mL of $CDCl_3$ and 4–5 mg of $Cr(acac)_3$ was added to speed up the spin relaxation. Inversion–recovery T_1 experiments indicated that all carbons under these conditions had T_1's of less than 1.1 s. For the quantitative work, a concentric insert (Wilmad WGS-5BL) with a precisely weighed amount of ethanol dissolved in $CDCl_3$ was inserted into the 5-mm NMR tube. Spectra were run on a Bruker AM500 spectrometer operating at 125.7 MHz for ^{13}C, with a $^{13}C/^{1}H$ 5-mm dual probehead. The experimental measurements consisted of 10 blocks of 1000 scans each, with a 7 s delay between scans. The 10 FIDs were processed under identical conditions with an exponential apodization function that added 40 Hz to the line broadening. These spectra were then combined together with a program NMRSTAT, written in Pascal for the ASPECT computer, to form an average spectrum and a standard deviation spectrum. In this way, the standard deviation of each point in the spectrum was calculated. One of the average spectra (i.e., a total of 10 000 scans) is shown in Fig. 2. For all of the present work, the standard deviation of each peak height was less than 4%.

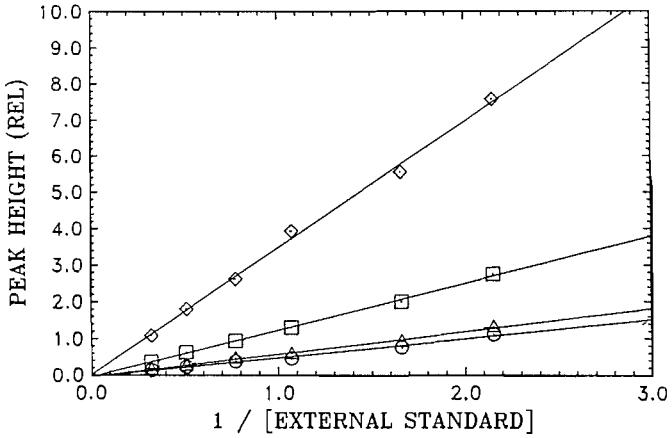

FIG. 3. Plot of normalized height of the peaks of compound **1** in the NMR spectrum versus the reciprocal of the standard concentration. Data are from Table 1. Diamonds represent carbon 2, squares represent carbon 3, circles represent carbon 1, and triangles represent carbon 4. Data from carbons 5 and 6 are not plotted.

The measurements were repeated for a series of ethanol concentrations, and the peak heights of the lines corresponding to compound **1** were divided by the height of the ethanol methylene peak at 57.5 ppm. Figure 3 shows a plot of the peak heights versus the reciprocal of the ethanol concentration for carbons 1, 2, 3, and 4 in compound **1**. Table 1 summarizes the data in Fig. 3, as well as the data for carbons 5 and 6, along with the linear regression slope and its error (two standard deviations) (27). The relative enrichment over natural abundance, defined by eq. [1], is also given in the table, along with its error.

$$[1] \quad \text{Enrichment} = \frac{\text{Slope of carbon}(n) - \text{Slope of carbon}(1)}{\text{Slope of carbon}(1)}$$

An authentic sample of **1** (Farchan Laboratories Inc., Gainesville, Florida) with no labelling was submitted to a similar analysis and the results are presented in the table. The slope of the graph obtained using peak heights corresponding to each peak is given, along with the error (two standard deviations of the slope from the linear regression). Because the signal-to-noise ratio was better for this sample, the integrals for each peak

were also calculated by fitting the spectra to Lorentzian curves using a simplex algorithm in the program NMR286 (Softpulse Software, Guelph, Ontario). As shown in the table, the slopes calculated from the integrals agree with those calculated from peak heights, but the integral slopes are considerably less precise.

Discussion

Figure 3 and Table 1 show unequivocally that positions 2 and 3 in compound **1** have been substantially enriched by the ^{13}C label in the starting material. The slopes indicate that these enrichments are about 1.5 times and 5.5 times over natural abundance. The regression and results from carbons 4, 5, and 6 suggest that the error in these measurements is about 15–20% (two standard deviations), assuming that there is no photochemical labelling at these other positions. The errors quoted are the error estimates from the regression, assuming that all the errors are random (27). The data on the natural abundance material indicate that when the signal-to-noise ratio is good, the results can be quite precise, and that the peak height measurement is better than an integration.

For this particular problem, these measurements cast considerable light on the mechanism of this reaction (26). However, these results have much broader application in all of NMR. They show that ^{13}C NMR quantitation on labelled material can be done near the level of natural abundance in a convincing and reliable fashion, and some estimates can be made of the errors. No particular experimental expertise or sophisticated equipment is required to perform these analyses. For careful quantitation, the measurements of peak heights are better, provided they are calibrated as in this work, because they are less susceptible to operator bias, and they give an honest estimate of the errors involved. The novel features of this work are the basic approach, and the computer program to calculate standard deviations of each point in a spectrum. NMR spectroscopists collect a tremendous amount of data in the accumulation of many FIDs for one spectrum. It now is possible to analyze and interpret these data much more fully than simply reporting their sum.

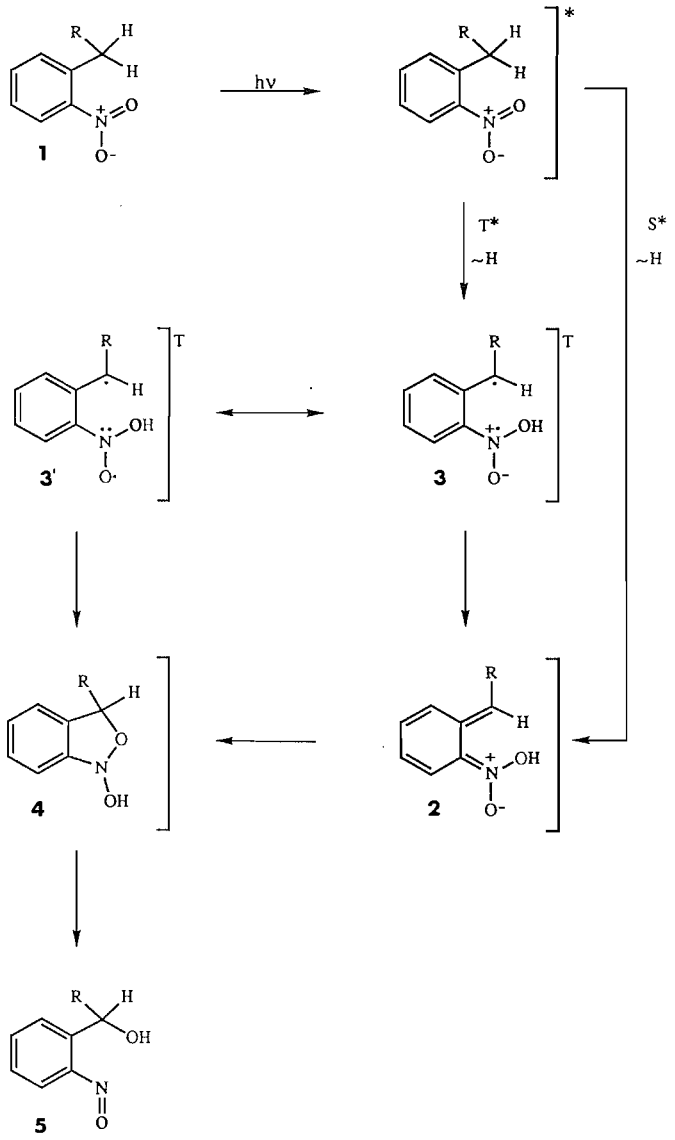
Two rigid nitrobenzene derivatives, 5-nitro-1,2,3,4-tetrahydro-1,4-methanonaphthalene (**6**), and 5-nitro-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**7**), have been synthesized and studied by picosecond flash absorption spectroscopy, steady-state irradiation, and MMX molecular mechanics calculations. Transients with lifetimes of 770 and 410 ps have been detected and assigned to the excited triplet states of **6** and **7**, respectively. Consistent with prediction, the *o*-quinonoid intermediate is not detected in the time domain between the laser excitation and the end of decay of the triplet state. Intramolecular abstraction of the bridgehead benzylic hydrogen by the cited triplet state proceeds with relative rates of 1:125 for **6** and **7**, respectively. Since structural constraints prohibit the formation of an orthoquinonoid intermediate in these systems, formation of the usual nitroso-alcohol **13** represents the first substantiation of the biradical route to product (**3′** → **4**, Scheme 1). Absorption of the intermediate triplet biradical resulting from hydrogen abstraction by the triplet excited state was not observed, and is therefore believed to be either very weak in the 400–700 nm region, or located outside the detection region. The kinetic results together with structural parameters determined by molecular mechanics show good correlation between structure and reactivity. Hydrogen atom transfer can proceed at up to 53° deviation from linearity of the C—H—O nuclei, with transfer rates decreasing sharply as the O···H distance increases from 1.3 to 1.6 Å. It is suggested that the conditions of the reaction from the excited triplet state meet those required for a hydrogen tunneling mechanism.

Key words: *o*-nitrotoluene photorearrangement, mechanism of; *o*-nitrobenzyl systems, mechanism of photorearrangement; O···H distance, influence of, in hydrogen abstraction mechanism; picosecond flash absorption spectroscopy study of *o*-nitrobenzyl photorearrangement; radical pathway to product in *o*-nitrotoluene photorearrangement.

D. GRAVEL, R. GIASSON, D. BLANCHET, R. W. YIP et D. K. SHARMA. Can. J. Chem. **69**, 1193 (1991).

On a synthétisé deux dérivés rigides du nitrobenzène, les 5-nitro-1,2,3,4-tétrahydro-1,4-méthanonaphtalène (**6**) et 5-nitro-1,2,3,4-tétrahydro-1,4-éthanonaphtalène (**7**) et on les a étudiés par spectroscopie d'absorption éclair (picoseconde), par irradiation à l'état stationnaire et par des calculs de mécanique moléculaire MMX. On a détecté des espèces transitoires de temps de vie de 770 et de 410 ps et on les a attribuées respectivement aux état triplets excités des produits **6** et **7**. En accord avec les prédictions, on n'a pas détecté l'intermédiaire *o*-quinonoïde dans l'espace de temps qui s'écoule entre l'excitation au laser et la fin de la désactivation de l'état triplet. Les vitesses relatives d'arrachement intramoléculaire de l'hydrogène benzylique en tête de pont par les états triplets mentionnés sont respectivement de 1:125 pour les composés **6** et **7**. Puisque des contraintes structurales empêchent la formation d'un intermédiaire *o*-quinonoïde dans ces systèmes, la formation du nitrosoalcool **13** habituel fournit la première preuve de l'existence d'une voie biradicalaire conduisant au produit (**3′** → **4**, schéma 1). On n'a pas observé d'absorption du biradical triplet intermédiaire résultant d'un enlèvement d'hydrogène par l'état triplet excité; on croit donc qu'elle est très faible dans la région de 400–700 nm ou qu'elle est située à l'extérieur de cette région de détection. Les données cinétiques combinées aux paramètres structuraux déterminés par la mécanique moléculaire présentent une bonne corrélation entre la structure et la réactivité. Le transfert de l'atome d'hydrogène peut se produire jusqu'à une déviation de 53° par rapport à la linéarité des noyaux C—H—O; les vitesses de transfert diminuent rapidement lorsque la distance O···H passe de 1,3 à 1,6 Å. On suggère que les conditions de la réaction à partir de l'état triplet excité correspondent à celles requises pour un mécanisme de transfert d'hydrogène par effet tunnel.



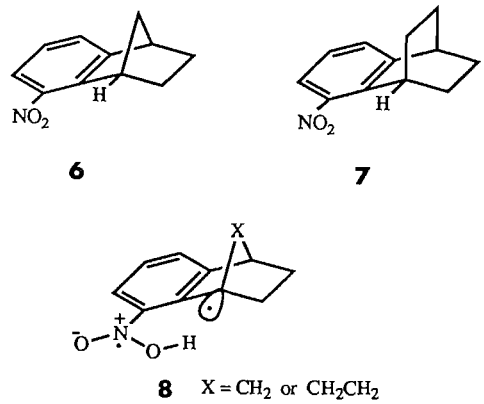
Mots clés: mécanisme de photoréarrangement de l'*o*-nitrotoluène; mécanisme du photoréarrangement de systèmes *o*-nitrobenzyliques; influence de la distance O···H sur le mécanisme d'enlèvement d'hydrogène; étude par spectroscopie d'absorption éclair (picoseconde) du photoréarrangement *o*-nitrobenzylique; voies radicalaires conduisant aux produits dans le photoréarrangement de l'*o*-nitrotoluène.

[Traduit par la rédaction]

Introduction

The well-established general photoreactivity of the *o*-nitrobenzyl system **1** to display intramolecular hydrogen abstraction has been widely exploited in the development of a number of photochromic compounds (1), photolabile protecting groups (2), and, more recently, photoresists (3). According to a general scheme elaborated over the years (4) the primary ground state "product" or intermediate in these reactions is the *o*-quinonoid species, **2**, resulting from intramolecular transfer of the benzylic hydrogen to the nitro group (5) (Scheme 1). The hydrogen atom transfer reaction can, *a priori*, proceed via either (i) an excited $n\pi^*$ triplet state associated with the nitro group to form the triplet biradical **3**, or (ii) an excited singlet state associated with the nitro group to form a short-lived singlet biradical that rapidly collapses to the quinonoid intermediate **2**. Since the geometries of the singlet biradical and the *o*-quinonoid intermediate **2** are

[1]Authors to whom correspondence may be addressed.



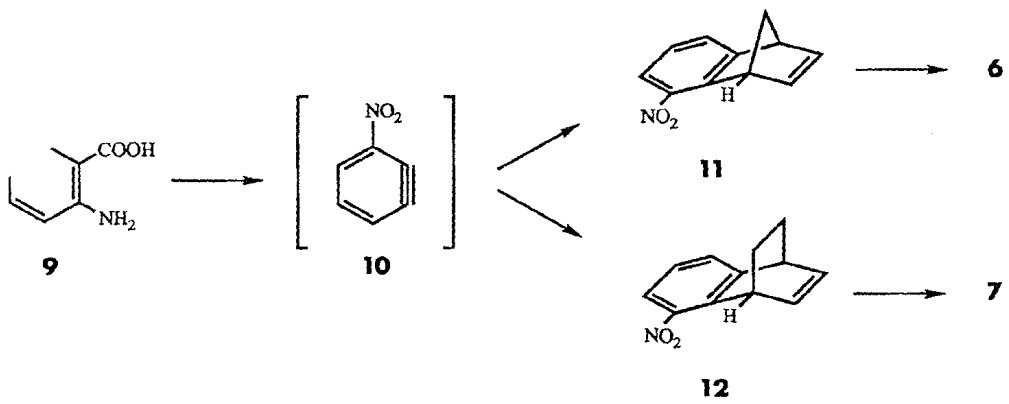
SCHEME 1

not likely to differ significantly, the potential curves of these two species are probably close together. Consequently, the energy barrier separating the singlet biradical and the *o*-quinonoid species **2** is likely to be small and may even be insignificant, so that it may be more appropriate to consider the reaction from the singlet excited state as a concerted [1,5]-sigmatropic shift (6). Our previous demonstration that the singlet state pathway is indeed involved in some of these systems, and that it proceeds extremely rapidly (7), is in accord with these views.

Following the hydrogen transfer step, the primary intermediate(s): *o*-quinonoid **2** and (or) triplet biradical **3**, proceed(s) respectively to the cyclized *N*-hydroxybenzisoxazolidine **4**, the former by a polar cyclization mechanism, and the latter by intersystem crossing to the *o*-quinonoid **2** or, alternatively, by radical cyclization to **4** via the mesomeric form **3′**, following intersystem crossing. (To our knowledge, path **3′** → **4** has never been substantiated in these systems.) Finally, ring chain tautomerism yields the familiar nitrosoalcohol **5**, an internal redox product.

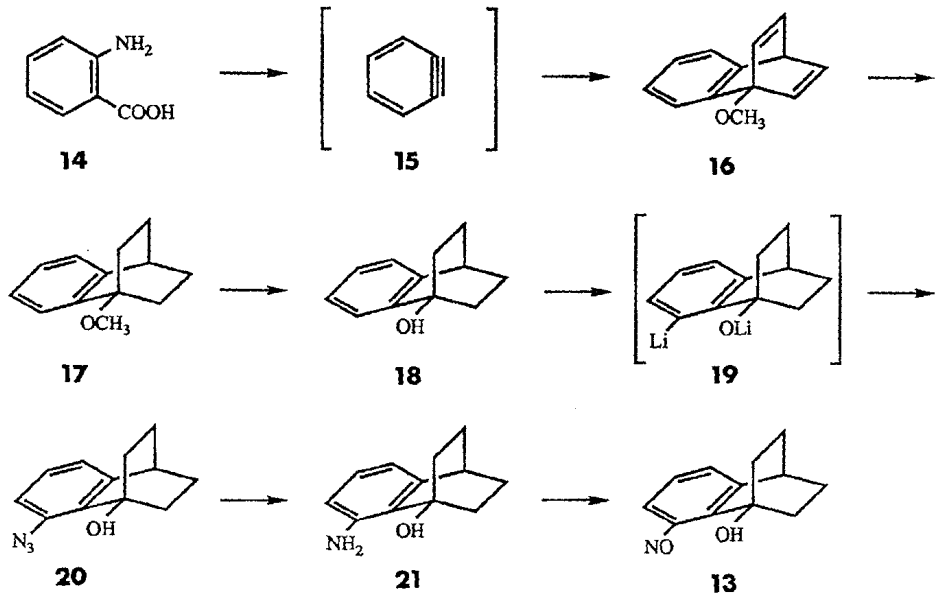
As part of our continuing effort in the study of the reaction mechanism of these systems, we conceived and synthesized two model *o*-nitrobenzyl compounds, **6** and **7**, the rigidity of which provides defined C—H···O—N geometry, distance, and structural constraints. These constraints were expected to simplify the reaction mechanism, and therefore to give us new insight into the H-atom transfer in the excited state. Indeed, fusion of the *o*-nitrobenzyl system to either a bicyclo[2.2.1]-heptane or bicyclo[2.2.2]octane system should, because of Bredt's rule (8), preclude the formation of the *o*-quinonoid intermediate directly from the singlet excited state (7), or following the collapse of a precursor biradical **8**. The choice of

these two rigid models should thus clear up an optical window in the 400–500 nm wavelength region where the *o*-quinonoid intermediate is known to absorb (7). This should facilitate the detection, by time-resolved spectroscopy, of the expected triplet state and corresponding biradical. The triplet excited state of **6** and **7** is not known, but should have similar spectral properties as the triplet excited state of other nitrobenzylic molecules (7, 9), which we have recently studied.



Models **6** and **7** were therefore studied by picosecond absorption spectroscopy and steady-state irradiation to correlate reactivity with the spectroscopic results. The kinetic results and quantum yields, together with the structural parameters of compounds **6** and **7** determined by molecular mechanics, enabled us to obtain *quantitative* data on the effect of geometry, distance, and structural constraints on the efficiency of H-atom transfer and, for the first time, probe the intervention of the radical cyclization path in these systems.

Results and discussion



Synthesis of the bicyclic models 6 and 7, and the expected primary photoproduct from 7

As outlined in Scheme 2, synthesis of the bicyclic models **6** and **7** was carried out in a straightforward manner following a procedure reported by Paquette and co-workers (10) for the preparation of bicyclic adduct **11**. Starting from 6-nitroanthranilic acid (**9**), diazotization using isoamyl nitrite leads to 3-nitrobenzyne (**10**), which is trapped *in situ* by [4+2] cycloaddition with either cyclopentadiene or cyclohexadiene, to form respectively the bicyclic adduct **11** or **12**. As reported by Paquette and co-workers (10), adduct **11** is formed in good yield (58–70%) and isolated by simple flash chromatography. The same is not true, however, for the preparation of adduct **12**, which was formed in very low yield and mixed with a number of secondary products resulting mainly from [2+2] and ene reaction (11). In the case of **11**, hydrogenation of the pure material using Wilkinson's catalyst (12), in order to preserve the nitro group, led to 93% of the desired dihydro adduct **6**. In the case of **12**, hydrogenation of the crude reaction product, after

For personal use only.

SCHEME 2

SCHEME 3

elimination of the polar impurities, led to a complex reaction mixture from which 14% of the desired dihydro adduct **7** could be isolated by semi-preparative HPLC.

Scheme 3, on the other hand, depicts a total and unambiguous synthesis of the primary photoproduct **13** expected from the photolysis of model **7**. Essentially, the strategy involves building the bicyclic skeleton with a bridgehead hydroxyl group by a [4+2] cycloaddition analogous to that described above, followed by a β-lithiation reaction of the type reported by Meyer and Seebach (13*a*) for benzyl alcohols to eventually introduce the nitroso group. In a first step, the bicyclic adduct **16** was prepared following a procedure of Tabushi *et al.* (14) that involves diazotization of anthranilic acid (**14**) to yield benzyne (**15**), which is trapped by anisole. The product, isolated with some difficulty in a 25% yield, was then subjected to hydrogenation (10% palladium on carbon) to yield 91% of the tetrahydro adduct **17**, which was demethylated by trimethylsilyliodide (15). The resulting alcohol **18**, which was obtained in 92% yield, was subjected to a β-lithiation reaction (13) and the dilithio compound **19** formed was treated *in situ* with triisopropylbenzenesulfonyl azide (16) to yield 80% of the desired azidoalcohol **20**. The latter was then reduced by sodium borohydride (17) to yield 84% of the corresponding aminoalcohol **21**. Finally, oxidation of **21** to the desired authentic nitrosoalcohol **13** took place in the presence of a sulfuric-acid-free solution of peracetic acid (18); the compound was isolated in the dimeric form (mp 168–170°C) in 72% yield.

Picosecond flash absorption spectroscopy and steady-state photolysis

The transient absorption spectra from picosecond excitation of the bicyclic compounds **6** and **7** at 355 nm (see Fig. 1), using the third harmonic from a YAG laser system, were assigned to the triplet excited state on the basis of the similarity of their spectra and lifetimes with those that we previously reported for other relatively unreactive simple nitrobenzene compounds (5, 9), and by the observed decrease in the transient lifetimes of **6** and **7** on addition of the triplet quencher, 1-hydroxymethyl-1-methyl-2,4-cyclohexadiene[2] ($k_q = (1.2 \pm 0.8) \times 10^9\ M^{-1}\ s^{-1}$ and $(2.6 \pm 0.5) \times 10^9\ M^{-1}\ s^{-1}$ for **6** and **7**, respectively). The two transient absorption bands at 425–450 nm and a weaker band in the 600–650 nm region are almost identical in terms of the peak position, width, and area with those due to the triplet state for the simple nitrobenzene compounds. The transient from the more strained benzobicyclo[2.2.1]heptane derivative **6** decayed with a lifetime, τ, of 710 ps, significantly slower

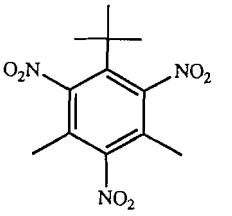
than its benzobicyclo[2.2.2]octane homologue **7** (410 ps). On the other hand, the intensities of the absorption of the triplet states of **6** and **7** are similar. Making the reasonable assumption that the extinction coefficients for triplet absorption are similar for the two homologous molecules, the results strongly suggest that the relative triplet yields are similar for **6** and **7**. These results are in sharp contrast with those of more reactive *o*-nitrobenzylic compounds such as the phenyl and *p*-cyanophenyl-*o*-nitrobenzyl ethers (**1**, R = PhO-; *p*-CNC_6H_4O-) that, even at times immediately after the laser pulse, are characterized by a major absorption band in the 425–450 nm region, comprising overlapping *o*-quinonoid and triplet excited states, and a weaker band in the 600–650 nm region due to the triplet excited state alone. We had previously shown that with the ethers **1**, a fast initial singlet excited state contribution to the formation of the *o*-quinonoid intermediate was followed by a slower, most probably triplet, contribution (7). (Schnabel and Wong have also recently shown this duality of contributions for the case of *o*-nitrobenzyl ester groups in polymer matrices (19).) The more reactive phenyl *o*-nitrobenzyl ether was shown to give weaker transient triplet–triplet absorption spectra as a result of more efficient reaction from the singlet.

In an effort to correlate the reactivity of models **6** and **7** with the spectroscopic results, the disappearance rate ratio (relative quantum yields) of both model compounds was measured. Photolysis of 10^{-2} M solutions of compounds **6** and **7** in dioxane at 350 nm using a Rayonet photochemical reactor gave rates of 0.15 and 10, respectively, relative to the disappearance of *o*-nitrotoluene taken as 1 (**1**, R = H). We believe that the enhanced rate of disappearance of **7** is not due to reaction from the singlet excited state. For efficient singlet reaction to occur from **7** and still obtain similar Φ_{IC} for **6** and **7** (*vide supra*), k_{IC} and τ_S would have to change in such a way as to completely compensate for the enhanced k_r from the singlet excited state, which appears highly improbable on the basis of the similarity of the two structures. Furthermore, recent work[3] on a variety of *o*-nitrobenzyl systems suggests that while both the singlet and triplet excited states can contribute to the formation of the *o*-quinonoid reactive intermediate, the singlet excited state seems to contribute significantly for only those more reactive *o*-nitrobenzylic molecules (generally speaking, those with an oxygen substituent at the benzylic carbon are most reactive). Comparing the relative quantum yields of disappearance (relative to *o*-nitrotoluene) of **6** and **7** (0.15 and 10, respectively) with those of methyl *o*-nitrobenzyl ether (**1**, R = CH_3O-) and *p*-cyanophenyl-*o*-nitrobenzyl ether (**1**, R = *p*-CNC_6H_4O-) (31 and 110, respectively), **6** and **7** are clearly in the less reactiv group (11). In the case of the *o*-nitrobenzyl compounds witho structural constraints, the geometries of the singlet biradical ar the *o*-quinonoid intermediate are not likely to differ signi cantly and the potential curves of these two species are probab close together. Consequently, for these compounds, the ener barrier separating the singlet biradical and the *o*-quinon species **2** is likely to be small and may even be insignificant, that it may be more appropriate to consider the reaction from t state as a concerted [1,5]-sigmatropic shift (6), which wc account for the extreme reactivity of the singlet as compare the triplet state. For the geometrically constrained compoun and **7**, however, the low-energy concerted pathway f short-lived excited singlet state to the *o*-quinonoid interme represents a prohibitively high-energy pathway.



At this point, it remained to be demonstrated that reacti indeed due to benzylic hydrogen abstraction and formatio nitrosoalcohol as primary photoproduct. HPLC analysis lished that four products (see, however, below) are fc during the steady-state photolysis of compound **7** at 350 acetonitrile. To show that one of these peaks corresponds

23

expected photoproduct **13**, small amounts of materials were isolated by semi-preparative HPLC. The small amounts of compounds available and the presence of impurities, however, prevented unambiguous characterization of the products by mass spectrometry and proton NMR. A total synthesis of authentic product **13** was therefore carried out as outlined in Scheme 2 (*vide supra*); the pure compound, isolated as the crystalline nitroso dimer, was characterized by mass spectrometry, proton NMR, and IR. This authentic sample was then used to identify the peak corresponding to the primary photoproduct **13** in the chromatogram of the photolyzed solution of **7**. Furthermore, a solution of synthetic **13** in acetonitrile was also photolyzed at 350 nm. HPLC analysis of the solution showed three peaks due to the formation of photoproducts. These three peaks have retention times identical to those of the three unknown peaks present in the chromatogram of photolyzed solution of **7**. This then demonstrates unambiguously that compound **13** is the only primary photoproduct in the photolysis of **7**, and that the three other photoproducts arise from subsequent photolysis of **13**.

From the set of experiments described above, it follows that intramolecular benzylic hydrogen abstraction does take place in the faster reacting model compound **7** and that it is the only photochemical pathway open to this compound. Indeed, if **7** was to react by intermolecular hydrogen abstraction, other primary photoproducts would be observed. Finally, the formation of **13** also substantiates, for the first time, the intervention of the radical cyclization path $\mathbf{3}' \rightarrow \mathbf{4}$ (Scheme 1) in an *o*-nitrobenzyl system as suggested earlier (2*b*).

From the relative quantum yields of disappearance and triplet lifetimes (τ_6, τ_7), one can calculate the relative rate constants for reaction from the triplet state, k_7/k_6, of **6** and **7**:

$$k_7/k_6 = \Phi_{rel7}/\Phi_{rel6} \times \tau_6/\tau_7 = 125$$

To obtain some explanation why intramolecular H transfer might be more favorable in **7** than in **6**, we carried out molecular mechanics calculations[4] on these two compounds to determine their geometries. The nitro group was rotated around the C—N bond to minimize the distance between the O atom of the nitro group and H atom of the benzylic carbon. The results are recorded in Table 1. Döpp and co-workers (21) have analyzed the geometric requirements for the intramolecular abstraction of the homobenzylic *tert*-butyl hydrogens by the *o*-nitro group of *tert*-butyl-2,6-dinitrobenzylic compounds **22** and **23**, in the solid state. Using X-ray crystallographic structures as models for the excited state, homobenzylic hydrogens in which $r_{H\cdots O} < 2.6$ Å; $136° < \angle$ C—H···O $\leq 180°$; and $90° < \angle$ H···O—N $< 120°$ were identified as those being mainly responsible for the reaction (see Table 1). In the present study, we found compound **7** capable of H-atom abstraction in spite of the fact that its C—H···O angle deviates 53° from linearity. Linearity of the C—H···O angle does not seem to be as critical as H transfer distance (r_{if}),[5] for abstraction to occur. Indeed, we observed that the rate of the reaction decreases by a factor of 125 (*vide supra*) as the transfer distance increases from 1.3 to 1.6 Å, in compounds **7** and **6** respectively. These H transfer distances are sufficiently short for the transfer to occur by hydrogen tunneling across the barrier. In terms of the Golden Rule treatment of Siebrand *et al.* (22), a nonlinear C—H—O reaction would require the inclusion of lower-frequency bending modes resulting in a decreased interaction between the initial and final states, which would be more pronounced for **6** than **7**. The treatment predicts a sensitive dependence on the *transfer distance* and this is most probably the *major factor responsible for the difference in the transfer rates* we have observed for the two model compounds.

Intramolecular hydrogen abstraction by the triplet excited state of compounds **6** and **7** is expected to lead to the corresponding triplet biradical **8**. However, at times of 1–3 ns, corresponding to three times the triplet lifetimes, no signal greater than ca. 0.03 OD units, considered as significant with respect to fluctuations due to noise, baseline reproducibility, and solvent blank signal, etc., was observed. Thus for a signal whose position, band shape, and width are not characterized, the biradical **8** eludes detection because its absorption in the 400–700 nm region is too weak relative to the detectability of the apparatus, or is simply located outside the window accessible by our system. Unlike biradicals whose radical centres are isolated by one (or more) -CH_2- group(s), the location of the absorption of **8** cannot be predicted with certainty. Although to the extent that the biradical spectrum resembles the additive spectrum from the two radical centres because of the minimal orbital overlap between the two centres (on the bridgehead carbon and on the nitrogen and π-system), we expect only a weak absorption band such as that associated with the Ar-NO_2 radical (23), which absorbs at 410–450 (ϵ_{max} = 500 mol^{-1} cm^{-1}).

In conclusion, we have characterized the excited triplet $n\pi^*$ state of the bicyclic compounds **6** and **7** and determined their relative rate constants for H-atom transfer. These results corre-

[4]Calculations using the programs MODEL and MMX. MMX is an enhanced version of Allinger's MMP2 calculations (20).

[5]The H transfer distance (r_{if}) is the distance between the equilibrium position of the hydrogen in the initial state (C—H···O) and the final state (C···H—O): $r_{if} = r_{H\cdots O} - r_{H-O}$. We assumed r_{H-O} to be equal to 0.96 Å, the sum of the covalent radii of the atoms. Probable lengthening and distortion of the N—O bond in the $n\pi^*$ excited state of the nitro group were neglected.

late well with the structural parameters, and in particular the H···O distance, determined by molecular mechanics. We have shown that the H-atom transfer reaction can proceed at up to 53° deviation from linearity of the C—H—O nuclei, with transfer rates decreasing sharply as the O···H distance increases from 1.3 to 1.6 Å. Further studies on rigid nitrobenzyl systems with different geometries could provide a detailed map of k_r as a function of C—H···O distances, of the angle of the C—H—O nuclei, and of the angle of H—O—N, thus providing an experimental basis for future theoretical calculations. Finally, the formation of nitrosoalcohol **13** in the irradiation of bicyclic model **7** provides unambiguous proof of the biradical pathway to product (**3′** → **4**, Scheme 1) in *o*-nitrobenzyl systems.

Experimental section

General

Melting points were taken on a Büchi apparatus and are uncorrected. ^{1}H NMR spectra were recorded in $CDCl_3$ on Varian VXR300 (300 MHZ), Bruker WH400 (400 MHz), and Bruker WH90 (90 MHz) instruments and chemical shifts are given in ppm relative to TMS. IR spectra were recorded on Perkin–Elmer 710B and Perkin–Elmer 783 spectrophotometers. High and low-resolution mass spectra were determined on AEI MS-902 and V.G. Micromass 12-12 spectrometers, respectively. Photolyses were carried out in Pyrex tubes in a Rayonet RPR-100 photochemical reactor equipped with 16 RPR 3500 Å lamps and a MGR-100 merry-go-round. The HPLC setup used consisted of two Waters 6000A pumps, a Waters 680 gradient controller, a Waters U6K injector, a Waters Lambda-Max 481 variable wavelength UV–visible detector, and a Spectra-Physics SP4270 electronic integrator. The HPLC grade acetonitrile used (BDH Omnisolv or Aldrich Gold Label) was degassed prior to use. Flash chromatographies (24) were carried out using Merck 230–400 mesh silica and glass-distilled solvents (hexanes and ethyl acetate).

1,3-Cyclohexadiene, anthranilic acid, palladium catalyst (10% on carbon), iodotrimethylsilane, sodium borohydride, tetrabutylammonium sulfate, and sodium acetate were purchased from Aldrich and used as received. Anisole (Aldrich) was distilled over sodium, and *N,N,N′,N′*-tetramethylethylenediamine (Aldrich) over calcium hydride. Cyclopentadiene (Aldrich) was distilled prior to use and collected at low temperature (−78°C) to prevent dimerization. Dichloromethane, chloroform, and *n*-heptane were dried by distillation over P_2O_5. Benzene and toluene were dried by distillation over sodium/benzophenone. Acetone was dried by distillation over calcium hydride, and ether by distillation over lithium aluminium hydride.

Flash photolysis experiments

The photophysical experiments used a Nd:YAG laser system consisting of a passively mode-locked (Kodak 9740 dye in chlorobenzene) 7.0 × 90 mm oscillator (ends at Brewster angle), a 7.0 × 115 mm preamplifier, and a 9.35 × 115 mm amplifier, which produced up to ca. 4 mJ frequency-tripled single pulses at 355 nm of ca. 35 ps FWHM pulse duration. Time-resolved spectra were recorded using the pump-probe technique. The 355-nm ultraviolet excitation beam was split off from the colinear second harmonic and fundamental beams by means of a 355-nm reflecting/1.06-μm transmitting beam splitter. The transmitted 1.06-μm pulse was optically delayed by ca. 10 ns and then focussed, by means of a 1-m focal length lens, into a 5-cm cell containing a solution of 30% H_3PO_4 in H_2O to generate the continuum probe pulse, which provided useful coverage from ca. 400 nm to <750 nm. Using a Hamamatsu C979 streak camera equipped with a C1000 type 18 head, the FWHM width of the polychromatic continuum pulse was found to be ca. 35 ps. Variable delays of up to 10 ns between the probe and excitation pulses were obtained by inserting a variable optical delay line in the path of the exciting UV pulse. As both the spectrum and intensity of the probe beam changed from shot to shot, it was necessary to split off a portion of the probe beam (using a prism beam splitter) for use as a "reference" beam. The spectra reference beams (which bypassed the 2-mm pathlength sample cell) were recorded simultaneously along with those of the main "sample" probe beam (which interrogated the excited portion of the sample cell) by focussing both beams at different heights along the slits of a monochromator/spectrograph (Instrument SA (JY) model HR-320) fitted with a SIT vidicon detector (EG&G PAR model 1254) with two-dimensional light-sensing capabilities. Spectroscopic grade acetonitrile was obtained from Caledon Laboratories. The time-resolved spectra were recorded using ca. 1 mJ 355-nm laser pulse energy and ca. 8×10^{-3} M of compounds **6** and **7** in acetonitrile solutions. This excitation energy represents a compromise between the need to minimize the possibility of nonlinear effects (zero laser intensity) and the need for adequate signal (high laser intensities). In flash photolysis studies of *o*-nitrobenzylic compounds with the present system arrangement, we observed that energies up to 3 mJ did not change the shape of the transient spectra nor could we observe any measurable change in the kinetics. We did observe small nonlinearity in the initial concentration of the transients and small baseline changes (ca. equal to or up to twice the noise) at ca. 10 ns due to laser-induced thermal effects above ca. 1.5 mJ; so, for this reason and to more closely approximate the ideal condition for zero nonlinearity at zero excitation intensity, we generally chose to live with slightly noisier signals than with a possible artifact, especially when the frequency of the signal is low (broad band as is the present case) and that of the noise high, and when we are looking for a weak unknown transient. The recoverable triplet excited state signal and the non-appearance of an equally strong *o*-quinonoid signal in terms of the band width, band position, and band area, while not the optimum, are nevertheless adequate for our qualitative interpretation. Typically, nine shots are averaged to obtain better signal-to-noise. With the OMA system used in our experiment there is only a marginal increase in signal-to-noise ratio of the spectrum with further averaging owing to drift within the system. Characterization of the triplet excited states of **6** and **7** is based on the similarity of their spectra and lifetimes to those that we previously reported for other relatively unreactive nitrobenzene compounds (5, 9), and on the observed decrease in the transient lifetimes of **6** and **7** on addition of ca. 1.5 M of the triplet quencher, 1-hydroxymethyl-1-methyl-2,4-cyclohexadiene.[2]

Synthesis of materials

1,4-Dihydro-5-nitro-1,4-methanonaphthalene (11)

Compound **11** was prepared from 6-nitroanthranilic acid (**9**) and cyclopentadiene according to the procedure described by Paquette and co-workers (10). Purification by flash chromatography (hexanes) gave **11** as a yellow solid with a 70% yield (lit. (10) 58%); mp 58.5–59°C (lit. (10) mp 59–60°C).

5-Nitro-1,2,3,4-tetrahydro-1,4-methanonaphthalene (6)

A solution of 1,4-dihydro-5-nitro-1,4-methanonaphthalene (**11**) (0.70 g; 3.7 mmol) and tris(triphenylphosphine)rhodium(I) chloride (12) (0.14 g; 0.15 mmol) in benzene (30 mL) was shaken under hydrogen pressure (50 psi; 1 psi = 6.89 kPa) in a Parr reactor for 17 h. The resulting reaction mixture was filtered over a pad of silica and the solvent evaporated. Distillation of the residue under reduced pressure afforded compound **6** as a yellow oil (0.66 g; 93%); IR ($CHCl_3$) ν:1527 (NO_2), 1360 (NO_2) cm^{-1}; ^{1}H NMR (90 MHz; $CDCl_3$) δ: 7.79 (dd, J = 1.2 and 8.1 Hz, 1H), 7.43 (dd, J = 1.2 and 7.2 Hz, 1H), 7.18 (dd, J = 7.2 and 8.1 Hz, 1H), 4.27 (br s, 1H), 3.45 (br s, 1H), 2.14–1.06 (m, 6H); HRMS m/z calcd.: 189.0790; found: 189.0780.

5-Nitro-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (7)

A solution of 6-nitroanthranilic acid (10) (2.0 g; 11 mmol) and 1,3-cyclohexadiene (13.3 mL; 140 mmol) in acetone (30 mL) was added to a refluxing solution of isoamyl nitrite (25) (1.8 mL; 14 mmol) in CH_2Cl_2 (20 mL). The resulting reaction mixture was stirred under argon for 2 h. After evaporation of the solvent, the residue was dissolved in a 95:5 mixture of hexanes/ethyl acetate and the resulting solution was filtered through a pad of silica in order to remove polar impurities. Evaporation of the solvent gave 1.2 g of a yellow oil containing a mixture of products. The residue was dissolved in benzene (60 mL) and tris(triphenylphosphine)rhodium(I) chloride (12) (0.30 g;

0.32 mmol) was added. The solution was shaken under hydrogen pressure (50 psi) for 20 h in a Parr reactor. The reaction mixture was filtered over a pad of silica and the solvent evaporated. The desired compound was isolated from the residue by semi-preparative HPLC (CH_3CN/H_2O 70:30; 9.4 × 250 mm CSC S50DS2 C_{18} column). 5-Nitro-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**7**) was obtained as a yellow oil (0.32 g; 14%); IR ($CHCl_3$) ν: 1525, 1350 (NO_2) cm^{-1}; ^1H NMR (400 MHz; $CDCl_3$) δ: 7.78 (dd, J = 1.2 and 8.2 Hz, 1H), 7.38 (dd, J = 1.2 and 7.3 Hz, 1H), 7.27 (dd, J = 7.3 and 8.2 Hz, 1H), 3.89 (br s, 1H), 3.11 (br s, 1H), 2.0–1.7 (m, 4H), 1.5–1.3 (m, 4H); HRMS m/z calcd.: 203.0947; found: 203.0912.

*1,4-Dihydro-1-methoxy-1,4-ethenonaphthalene (**16**)*

Compound **16** was prepared from anthranilic acid (**14**) and anisole according to a procedure described by Tabushi *et al.* (14). The desired product, isolated from the reaction mixture by flash chromatography (hexanes/ethyl acetate 95:5), was contaminated with phenyl benzoate. Hydrolysis of phenyl benzoate in refluxing aqueous NaOH (10%), followed by a second flash chromatography (hexanes/ethyl acetate 95:5), gave pure **16** in 25% yield (lit. (14) 25%) as a colorless oil.

*1-Methoxy-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**17**)*

A catalytic amount of palladium on carbon (10% Pd) was added to a solution of 1,4-dihydro-1-methoxy-1,4-ethenonaphthalene (**16**) (0.48 g; 2.6 mmol) in ethyl acetate (15 mL). The reaction mixture was stirred under hydrogen atmosphere for 3 h. Used catalyst was removed by filtration over a pad of Celite and the solvent was evaporated. Product **17** was purified by flash chromatography (hexanes/ethyl acetate 95:5) and was obtained as a colorless oil (0.45 g, 91%); ^1H NMR (300 MHz; $CDCl_3$) δ: 7.45 (dd, J = 1.4 and 7.2 Hz, 1H), 7.29 (td, J = 1.8 and 7.2 Hz, 1H), 7.23 (td, J = 1.4 and 7.2 Hz, 1H), 7.18 (dd, J = 1.8 and 7.2 Hz, 1H), 3.56 (s, 3H), 2.96 (quintet, J = 2.7 Hz, 1H), 2.05–1.86 (m, 4H), 1.65–1.43 (m, 4H); HRMS m/z calcd.: 188.1201; found: 188.1210.

*1-Hydroxy-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**18**)*

A solution of 1-methoxy-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**17**) (0.10 g; 0.53 mmol) and iodotrimethylsilane (0.1 mL; 0.69 mmol) in $CHCl_3$ was stirred for 72 h under argon and at room temperature. Methanol (0.1 mL) was added to the reaction mixture and the solvent was evaporated. The residue was dissolved in ether and the solution washed with saturated aqueous $NaHSO_3$, saturated aqueous $NaHCO_3$, and brine. The solution was dried over $MgSO_4$ and the solvent evaporated. Product **18** was purified by flash chromatography (hexanes/ethyl acetate 80:20) and was obtained as a white solid (85 mg, 92%); mp 131.5–133°C; IR (film) ν: 3500–3100 (OH) cm^{-1}; ^1H NMR (300 MHz; $CDCl_3$) δ: 7.47 (dd, J = 1.4 and 7.3 Hz, 1H), 7.29 (td, J = 1.4 and 7.3 Hz, 1H), 7.22 (td, J = 1.4 and 7.3 Hz, 1H), 7.16 (dd, J = 1.4 and 7.3 Hz, 1H), 2.98 (m, 1H), 1.97–1.83 (m, 4H), 1.62–1.43 (m, 5H); HRMS m/z calcd.: 174.1044; found: 174.1050.

*5-Azido-1-hydroxy-1,2,3,4-tetrahydro-14-ethanonaphthalene (**20**)*

A solution of *n*-BuLi (0.46 mL of a 2.5 M solution in hexane; 1.15 mmol) and *N,N,N',N'*-tetramethylethylenediamine (0.17 mL; 1.15 mmol) in *n*-heptane (0.2 mL) was added slowly to a warm (90°C) solution of 1-hydroxy-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**18**) (0.10 g; 0.57 mmol) in *n*-heptane (2 mL). The reaction mixture was stirred 2 h at 85°C under argon atmosphere, and then cooled to 0°C (13). A solution of triisopropylbenzenesulfonyl azide (16) (0.40 g; 1.15 mmol) in ether (1 mL) was added, and the resulting reaction mixture was brought to room temperature and stirred for 2 h. The reaction mixture was cooled again to 0°C and quenched by the addition of water (2 mL). The aqueous phase was neutralized with 10% aqueous HCl and extracted twice with ether. The organic extracts were combined, washed with brine, and dried over $MgSO_4$. The solvent was evaporated and the product was isolated by flash chromatography (hexane/ethyl acetate 85:15). Compound **20** was obtained as a yellow solid (0.10 g; 80%); mp 78.5–80.0°C; IR (film) ν: 3600–3200 (OH), 2115 (N_3) cm^{-1}; ^1H NMR (300 MHz; $CDCl_3$) δ: 7.24 (dd, J = 7.3 and 8.2 Hz, 1H), 7.06 (dd, J = 1.1 and 8.2 Hz, 1H), 6.98 (dd, J = 1.1 and 7.3 Hz, 1H), 4.70 (s, 1H), 2.93 (m, 1H), 1.95–1.80 (m, 4H), 1.65–1.40 (m, 4H); HRMS m/z calcd.: 215.1058; found: 215.1050.

*5-Amino-1-hydroxy-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**21**)*

A solution of $NaBH_4$ (50 mg; 1.32 mmol) in water (0.2 mL) was added to a warm solution (80°C) of 5-azido-1-hydroxy-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**20**) (95 mg; 0.44 mmol) and tetrabutylammoninum sulfate (15 mg; 0.44 mmol) in toluene (0.5 mL), and the resulting reaction mixture was stirred vigorously at 80°C for 3 h. The reaction mixture was cooled to room temperature and quenched by the addition of 10% HCl. The aqueous phase was made basic with 50% aqueous KOH and was extracted with chloroform. The chloroform extracts were combined, washed with brine, and dried over $MgSO_4$. Compound **21** was obtained as a white solid after recrystallization from $CDCl_3$/petroleum ether (1:2) (70 mg; 84%); mp 165–166°C; IR (film) ν: 3500–3050 (OH), 3435, 3385 (NH_2) cm^{-1}; ^1H NMR (300 MHz; $CDCl_3$) δ: 6.97 (dd, J = 7.3 and 8.0 Hz, 1H), 6.56 (dd, J = 1.1 and 7.3 Hz, 1H), 6.52 (dd, J = 1.1 and 8.0 Hz, 1H), 4.63 (br s, 2H), 3.63 (br s, 1H), 2.85 (m, 1H), 1.98–1.70 (m, 4H), 1.61–1.45 (m, 4H); HRMS m/z calcd.: 189.1153; found: 189.1150.

*1-Hydroxy-5-nitroso-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**13**)*

A sulfuric-acid-free solution of peracetic acid was prepared by saturating commercial 32% aqueous peracetic acid with sodium acetate, centrifuging the mixture, and collecting the supernatant (18*a*). The resulting solution (0.13 mL; 1.94 mmol) was added to a solution of 5-amino-1-hydroxy-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**21**) (30 mg; 0.16 mmol) in water (16 mL). The suspension was stirred 3 h at room temperature, followed by 2 h at 40°C. The reaction mixture was made slightly basic by addition of 10% aqueous NaOH and was extracted with CH_2Cl_2. The combined extracts were washed with 10% aqueous HCl and brine, dried over $MgSO_4$, and the solvent was evaporated. Recrystallization of the residue gave the dimeric form of compound **13** as a white solid (23 mg; 72%); mp 168–170°C; IR (film) ν: 3540–3040 (OH), 1262 (NO *trans* dimer) cm^{-1}; ^1H NMR (300 MHz; $CDCl_3$) δ: 7.58 (dd, J = 1.3 and 7.4 Hz, 1H), 7.18 (dd, J = 7.4 and 8.7 Hz, 1H), 7.15 (s, 1H), 6.29 (dd, J = 1.3 and 8.7 Hz, 1H), 3.17 (m, 1H), 2.33–2.21 (m, 2H), 2.14–2.03 (m, 2H), 2.02–1.90 (m, 2H), 1.74–1.61 (m, 2H); LRMS (chemical ionization) m/z: 204 (monomer + H^+), 391 (dimer + H^+ − O).

*Measurement of the relative rates of disappearance of compound **6** upon photolysis*

The relative rate of disappearance of compound **6** was measured using 2-nitrotoluene as reference compound (k_{rd} = 1). Two solutions, one containing 10^{-2} M of compound **6** and one containing 10^{-2} M of 1-nitrotoluene in 1,4-dioxane, were prepared. At this concentration, virtually all of the incident light is absorbed, assuring equal irradiation. The solutions were photolyzed in Pyrex tubes (15 mm × 150 mm) using 16 RPR-3500 Å lamps (emission centered at 350 nm). Samples (1 mL) were taken at regular intervals in both solutions. Samples were analyzed by HPLC using a CH_3CN/H_2O 50:50 mixture as mobile phase, a reversed phase column (3.9 mm × 30 cm; μBondapac C_{18} (5 μm)), and a detection wavelength of 254 nm. A 5% solution of mesitylene in 1,4-dioxane was used as internal standard (1 mL was added to every sample). The natural logarithm of residual concentration as a function of time of photolysis was plotted for both compounds. Rates of disappearance of 2.3×10^{-7} s^{-1} and 1.5×10^{-6} s^{-1} were obtained by least-squares analysis of the resulting plots for compound **6** and 2-nitrotoluene, respectively. Normalization gave a relative rate of disappearance (k_{rd}) of 0.15 for compound **6**.

*Measurement of the relative rate of disappearance of compound **7** upon photolysis*

The procedure used for the determination of the relative rate of disappearance (k_{rd}) of compound **7** is identical to that for compound **6**, with the exception that 1-ethyl-2-nitrobenzene (k_{rd} = 40) (11) was used as reference instead of 2-nitrotoluene (k_{rd} = 1). Rates of disappearance of 9.7×10^{-5} s^{-1} and 3.8×10^{-4} s^{-1} were obtained for compound **7** and 1-ethyl-2-nitrobenzene, respectively. Normalization gave a relative rate of disappearance (k_{rd}) of 10 for compound **7**.

Preparative photolysis of compound 7: Correlation between the expected photoproduct and an authentic synthetic sample of 13

A 10^{-2} M solution of 5-nitro-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**7**) (20 mg) in acetonitrile (10 mL) was photolyzed in Pyrex tubes for 2 h (70% conversion) at 350 nm. The photolyzed solution was analyzed by HPLC using CH_3CN/H_2O 50:50 (2 mL/min) as mobile phase, a reversed phase column (3.9 mm × 30 cm; μBondapac C_{18} (5 μm)), and a detection wavelength of 320 nm. Chromatograms showed four peaks corresponding to photoproducts at retention times of 2.50, 3.74, 4.44, and 5.08 min. The area under the peak at 4.44 min was increased by the addition of a few drops of a solution of an authentic synthetic sample of **13** in acetonitrile. A small amount of the photoproduct giving rise to the peak at 4.44 min was isolated by semi-preparative HPLC using CH_3CN/H_2O 50:50 (8 mL/min) as mobile phase, a semi-preparative reversed phase column (9.4 mm × 25 cm; CSC S5ODS2 C_{18} (5 μm)), and a detection wavelength of 280 nm. Because only a very small amount of photoproduct was isolated, many of the NMR signals of the photoproduct were obscured by signals generated by the solvent. However, the aromatic region was clear and the following signals were observed: (300 MHz; CH_3CN) δ: 7.67 (dd, J = 1.2 and 7.2 Hz), 7.23 (dd, J = 7.2 and 8.3 Hz), 6.23 (dd, J = 1.2 and 8.3 Hz). These signals are in perfect accord with those of the authentic sample: (300 MHz; CH_3CN) δ: 7.67 (dd, J = 1.3 and 7.5 Hz), 7.22 (dd, J = 7.5 and 8.4 Hz), 6.23 (dd, J = 1.3 and 8.4 Hz). The isolated photoproduct and the authentic synthetic sample were also analyzed by low resolution mass spectrometry using chemical ionization as ion source. Both samples showed peaks at m/z 204, corresponding to the protonated nitroso monomer, and at m/z 391, corresponding to the protonated nitroso dimer after loss of an atom of oxygen.

Photolysis of compound 7 and of its primary photoproduct 13

A solution of 5-nitro-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**7**) and one of 1-hydroxy-5-nitroso-1,2,3,4-tetrahydro-1,4-ethanonaphthalene (**13**) in acetonitrile were prepared and photolyzed in Pyrex tubes for 20 min at 350 nm. The photolyzed solutions were analyzed by HPLC using CH_3CN/H_2O 50:50 (2 mL/min) as mobile phase, a reversed phase column (3.9 mm × 30 cm; μ Bondapac C_{18} (5 μm)), and a detection wavelength of 254 nm. Chromatograms of the photolyzed solution of model compound **7** showed four peaks growing at retention times of 2.45, 3.85, 4.65, and 5.30 min while the peak corresponding to compound **7** at retention time 11.25 min was decreasing. Chromatograms of the photolyzed solution of synthetic **13**, which is the expected primary product of **7**, showed three peaks growing at retention times of 2.45, 3.85, and 5.30 min while the peak corresponding to compound **13** at a retention time of 4.65 min was decreasing. This experiment shows that **13** is the sole primary photoproduct resulting from photolysis of **7** and that the other products observed result from the subsequent photolysis of the primary product (**13**).

Boric acid: a new regiospecific decarboxylating agent. Syntheses of cyclic imines, β-enaminones, and β-enaminodiketones from β-enaminoesters

PHILIPPE DELBECQ, DANIEL BACOS, JEAN PIERRE CELERIER, AND GÉRARD LHOMMET[1]

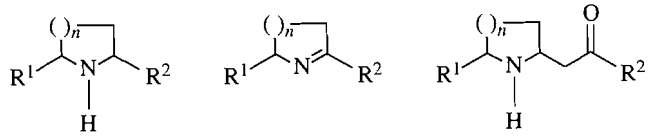
Laboratoire de chimie des hétérocycles, Unité de recherche associée n°455, Université Pierre et Marie Curie, 4 Place Jussieu, 75252 Paris CEDEX 05, France

Received September 26, 1990

PHILIPPE DELBECQ, DANIEL BACOS, JEAN PIERRE CELERIER, and GÉRARD LHOMMET. Can. J. Chem. **69**, 1201 (1991).

The synthesis of cyclic imines **2**, β-enaminones **6**, and β-enaminodiketones **7** is described. Regio- and stereospecific thermolysis of β-enaminoesters **4** with boric acid permit these preparations in generally good yields.

Key words: boric acid, cyclic β-enaminoesters, decarboxylation, cyclic imines, cyclic β-enaminones.



PHILIPPE DELBECQ, DANIEL BACOS, JEAN PIERRE CELERIER et GÉRARD LHOMMET. Can. J. Chem. **69**, 1201 (1991).

La synthèse d'imines **2**, de β-énaminones **6** et de β-énaminodicétones cycliques **7** est décrite. Cette nouvelle voie de synthèse met à profit l'action régio- et stéréo-spécifique de l'acide borique vis-à-vis des β-énaminoesters cycliques **4**.

Mots clés : acid borique, β-énaminoesters cycliques, décarboxylation, imines cycliques, β-énaminones cycliques.

Introduction

The significant bioacid activity of ant venoms has stimulated considerable interest and has led to the isolation of a large number of substances (1). Characteristic components present alkaloid structures with a monocyclic skeleton such as 2,5-dialkyl or dialkenyl pyrrolidines or pyrrolines **1** and **2** ($n = 1$) in the genus *Monomorium* (1) or 2,6-dialkyl piperidines or piperideines **1** and **2** ($n = 2$) in the genus *Solenopsis* (2). Ring substituent configurations are generally *trans* for five- and six-membered rings, but *cis* structures have been found in some species. Functionalized aza-heterocycles such as aminoketones have been isolated in the genus *Cryptolaemus montrouzieri* (3). Aminoketones such as **3** may also be precursors of numerous natural products (4).

1 **2** **3**

R^1, R^2 = alkyl or alkenyl

$( )_n = (CH_2)_n$

Monalkylated derivatives **1**, **2**, and **3** (R^1 = H) are also interesting for their insecticidal activities, and for their synthetic potential (5). Herein we wish to report our studies on the development of a general synthetic methodology for the preparation of monosubstituted cyclic imines and enamines. We describe the decarboxylation of cyclic β-enaminoesters and ketoesters in the presence of boric acid.

The general strategy for synthesis of cyclic imines, enamines, or amines is based on the availability of cyclic β-enaminoesters **4**, which are easily prepared in a few steps from lactams (6). A retrosynthetic study of compounds **1–3** in Scheme 1 shows that β-enaminoesters **4** can serve as key intermediates, which allow versatile preparation of amines or imines. Decarboxylation of **4** can directly lead to imines **2**.

Results and discussion

Compounds **4** are obtained by imidoylation of lactim ethers with Meldrum's acid, followed by monodecarboxylating transesterification (6) and then regiospecific C-alkylation with alkyl or alkenyl halides (*7a*). Results are summarized in Table 1.

TABLE 1. Alkylation of cyclic β-enaminoesters

Decarboxylation using boric acid was reported by Wehrli and Chu, who demonstrated that β-ketoesters were transformed into ketones when the initial ester was enolizable (8). Because of the structural analogy existing between β-ketoesters and β-enaminoesters, we find that thermolysis of compounds **4** with boric acid is a good route to cyclic imines **2**. After transesterification by boric acid, a thermal rearrangement takes place. The boric complexes shown in brackets in Scheme 2 are not isolated but are treated with hydrochloric acid to lead to **2**. The yields are generally good, regardless of ring size. Because boric acid catalyzes the interconversion of tautomers **4** and **4'**, our method permits the formation of iminoesters **4'** whose structures are suitable for thermal rearrangement.

This method is particularly useful in preparing not only cyclic

imines **2**, which possess an insecticidal activity comparable with ant venom components, but also other natural products such as *Coniceine* **2** ($n = 2$, R = $-C_3H_7$) (Table 2).

We extended these results by preparing cyclic enaminones **6** in the same way. Such structures are important building blocks for the synthesis of numerous natural products, but only a few enaminones have been isolated due to their unstability. We had previously shown that regiospecificity in the acylation of β-enaminoesters depends on heterocycle size (7), so a direct condensation between lactim ethers and β-ketoesters is the best way to prepare β-enaminoketoesters **5** (14). In any case, this condensation is stereospecific and only *E* compounds **5** are obtained (14) (Scheme 3).

Treatment of **5** with alkoxides has been reported to be regiospecific but leads only to β-enaminoesters **4** via a deacylation reaction (15), and decarboxylations in acidic media (16, 17)

7*f*	3	3	20	25

are not regiospecific. Under our reaction conditions, however, boric acid can be used to prepare cyclic β-enaminones **6** (18). Once more, the decarboxylation is regio- and stereospecific and *Z* derivatives **6** are obtained (Table 3).

If the R subsituent of the β-ketoester bears another ester function, new β-enaminoketodiesters **5** (R = $-(CH_2)_m-CO_2CH_3$) are prepared (Table 4). Again the thermolysis is regiospecific, only the conjugated ester being decarbalkoxylated with boric acid (Table 5). When R = $-(CH_2)_3-CO_2CH_3$ the five-membered ring compound **6** was isolated, which demonstrates the regiospecificity of the reaction (Scheme 4). However, the enaminone-diester intermediate is generally not isolated and a cyclization by intramolecular C-acylation occurs. Some of these bicyclic β-enaminodiketones **7** have been prepared by direct condensation between lactim ethers and cyclic β-diketones, but our method is more general and permits the syntheses of various compounds **7** regardless of the size of the heterocycle.

Conclusion

In conclusion, this investigation demonstrates that boric acid is a versatile reagent for organic synthesis, especially for the preparation of cyclic imines, β-enaminones, and β-enaminodiketones via stereospecific and regiospecific decarboxylation of substituted cyclic β-enaminoesters.

Experimental

Melting points were determined in open capillaries with a Büchi apparatus and are uncorrected. ^1H NMR spectra were recorded on Varian A60-A and Bruker 80, 200, and 500 MHz spectrometers. Chemical shifts are reported in δ values relative to Me_4Si as internal standard. Abbreviations used are m: multiplet, s: singlet, d: doublet, t: triplet, q: quartet, br s: broad singlet. Infrared spectra were taken on a Philips PU 9700 spectrometer.

Preparation of alkylated cyclic β-enaminoesters 4

General procedure for 5- or 6-membered rings

Cyclic β-enaminoesters (0.02 mol) prepared by imidoylation of lactim ethers as described by Celerier *et al.* (6) were added to a suspension of sodium hydride (0.022 mol) in anhydrous toluene (50 mL). After heating until dissolution of the sodium salt, the mixture was cooled, then halide (0.025 mol) in toluene (50 mL) was added dropwise. After heating 12 h at reflux, water was added and the aqueous phase separated, neutralized with 10% aqueous hydrochloric acid solution, and extracted with chloroform (3 × 30 mL). Organic phases were combined and dried over sodium sulfate. Crude products were purified by distillation or recrystallization.

General procedure for 7-membered rings

Cyclic β-enaminoesters (0.02 mol) (6) were refluxed in 50 mL of alkyl iodide for 12 h. Excess iodide was evaporated; the precipitate was washed three times with diethyl ether, and then poured into 50 mL of saturated aqueous potassium carbonate. The solution was extracted with chloroform (3 × 50 mL), and the organic layers were dried over sodium sulfate, evaporated, and the crude products purified by distillation or recrystallization.

Ethyl 5-phenyl-2-(α-tetrahydropyrrolylidene) pentanoate **4***e*. Yield: 61%; bp (0.01 Torr; 1 Torr = 133.3 Pa): 225°C; IR (neat) ν(cm^{-1}): 3360, 1620, 1570; ^1H NMR ($CDCl_3$) δ(ppm): 1.23 (3H, t, *J* = 7 Hz), 1.50–1.78 (10H, m), 3.20–3.42 (2H, m), 4.15 (2H, q, *J* = 7 Hz), 7.20 (5H, br s), 8.00–8.40 (1H, m). Ethyl 2-(α-hexahydropyridylidene)-dodecanoate **4***r*. Yield: 70%; bp (0.01 Torr): 155°C; IR (neat) $\nu(cm^{-1})$: 3220, 1630, 1590; ^1H NMR ($CDCl_3$) δ(ppm): 0.75–0.95 (3H, m), 1.20–2.25 (25H, m), 2.25–2.55 (2H, m), 3.10–3.45 (2H, m), 4.00–4.20 (2H, m), 9.00–9.25 (1H, m). Anal. calcd. for $C_{19}H_{35}NO_2$: C 73.73, H 11.40, N 4.53; found: C 73.48, H 11.26, N 4.31.

Ethyl 2-(α-hexahydropyridylidene)-dodecenoate **4***s*. Yield: 50%; bp (0.01 Torr): 165°C; IR (neat) $\nu(cm^{-1})$: 3200, 1630, 1580; ^1H NMR ($CDCl_3$) δ(ppm): 1.26 (3H, t, J = 7 Hz), 1.20–2.65 (22H, m), 3.10–3.35 (2H, m), 4.11 (2H, q, J = 7 Hz), 4.80–5.20 (2H, m), 5.50–6.15 (1H, m), 8.80–9.20 (1H, m). Anal. calcd. for $C_{19}H_{33}NO_2$: C 74.22, H 10.81, N 4.56; found: C 74.51, H 10.59, N 4.62.

Ethyl 3-phenyl-2-(α-hexahydroazepinylidene)-propanoate **4***w*. Yield: 42%; bp (0.05 Torr): 155°C; IR (neat) $\nu(cm^{-1})$: 3240, 1630, 1585; ^1H NMR ($CDCl_3$) δ(ppm): 1.16 (3H, t, J = 7 Hz), 1.25–1.75 (6H, m), 2.25–2.60 (2H, m), 3.15–3.30 (2H, m), 3.70 (2H, s), 4.20 (2H, q, J = 7 Hz), 7.10–7.20 (5H, m), 9.05–9.30 (1H, m). Anal. calcd. for $C_{17}H_{23}NO_2$: C 74.69, H 8.48, N 5.12; found: C 74.41, H 8.26, N 5.05.

Cyclic imines **2***: general procedure for preparation*

A mixture of β-enaminoester **4** (0.04 mol) and 2.78 g of solid boric acid (0.045 mol) was heated 1 h at 180°C in an Erlenmeyer equipped with a distillation column to collect water and alcohol. The reaction mixture was then cooled, and water (40 mL) and dichloromethane (10 mL) were added. After the precipitate was dissolved, the aqueous layer was extracted with CH_2Cl_2 (3 × 25 mL), the organic layers combined, dried over sodium sulfate, and solvent removed under reduced pressure. Crude products were then distilled.

2-(1-Phenylethyl)-3,4-dihydro-5H-pyrrole **2***d*. Yield: 80%; bp (0.01 Torr): 110°C; IR (neat) $\nu(cm^{-1})$: 1650, 1610, 1500; ^1H NMR ($CDCl_3$) δ(ppm): 1.70–2.30 (2H, m), 2.45–3.35 (6H, m), 3.85–4.20 (2H, m), 7.35–7.55 (5H, br s); ^{13}C NMR ($CDCl_3$) δ(ppm): 22.6, 32.6, 35.3, 60.9, 126.1, 128.2, 128.4, 141.6, 177.4. Anal. calcd. for $C_{12}H_{15}N$: C 83.19, H 8.73, N 8.09; found: C 83.01, H 8.98, N 7.82.

2-(4-phenylbutyl)-3,4-dihydro-5H-pyrrole **2***e*. Yield: 40%; bp (0.01 Torr): 118°C; IR (neat) $\nu(cm^{-1})$: 1640, 1605, 1495; ^1H NMR ($CDCl_3$) δ(ppm): 1.45–2.05 (6H, m), 2.10–2.75 (6H, m), 3.65–3.90 (2H, m), 7.05–7.25 (5H, br s); ^{13}C NMR ($CDCl_3$) δ(ppm): 22.0, 25.4, 30.7, 33.0, 35.1, 36.6, 125.1, 127.6, 141.7, 177.2. Anal. calcd. for $C_{14}H_{19}N$: C 83.53, H 9.51, N 6.96; found: C 83.16, H 9.73, N 7.15.

2-(1-Pentenyl)-3,4-dihydro-5H-pyrrole **2**f. Yield: 80%; bp (20 Torr): 60°C; IR (neat) $\nu(cm^{-1})$: 3080, 1650; ^1H NMR ($CDCl_3$) δ(ppm): 1.35–2.10 (6H, m), 215–2.50 (4H, m), 3.55–3.85 (2H, m), 4.65–5.00 (2H, m), 5.55–5.90 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 22.4, 25.4, 32.9, 37.1, 60.6, 114.7, 138.1, 177.9. Anal. calcd. for $C_9H_{15}N$: C 78.77, H 11.02, N 10.21; found: C 79.04, H 11.15, N 9.87.

2-(1-Hexenyl)-3,4-dihydro-5H-pyrrole **2***g*. Yield: 70%; bp (0.5 Torr): 52°C; IR (neat) $\nu(cm^{-1})$: 3080, 1640; ^1H NMR ($CDCl_3$) δ(ppm): 1.35–2.05 (8H, m), 2.10–2.65 (4H, m), 3.60–4.00 (2H, m), 4.80–5.25 (2H, m), 5.35–6.15 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 22.1, 25.4, 28.3, 33.1, 36.7, 114.0, 138.1, 177.4. Anal. calcd. for $C_{10}H_{17}N$: C 79.40, H 11.34, N 9.26; found: C 79.12, H 11.48, N 9.06.

2-(1-Heptenyl)-3,4-dihydro-5H-pyrrole **2***h*. Yield: 80%; bp (0.05 Torr): 60°C; IR (neat) $\nu(cm^{-1})$: 3080, 1650; ^1H NMR ($CDCl_3$) δ(ppm): 1.20–1.80 (10H, m), 1.85–2.45 (4H, m), 3.45–3.85 (2H, m), 4.75–5.15 (2H, m), 5.35–6.10 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 22.1, 25.7, 28.2, 28.5, 33.1, 33.3, 36.7, 60.3, 113.8, 138.3, 177.5. Anal. calcd. for $C_{11}H_{19}N$: C 79.94, H 11.59, N 8.48; found: 8.07, H 11.71, N 8.26.

2-(1-Nonenyl)-3,4-dihydro-5H-pyrrole **2***i*. Yield: 70%; bp (3 Torr): 100°C; IR (neat) $\nu(cm^{-1})$: 3080, 1640; ^1H NMR ($CDCl_3$) δ(ppm): 1.10–1.85 (14H, m), 1.90–2.50 (4H, m), 3.50–3.90 (2H, m), 4.75–5.15 (2H, m), 5.30–6.10 (1H, m). ^{13}C NMR ($CDCl_3$) δ(ppm): 22.3, 26.1, 28.6, 28.7, 28.9, 29.1, 33.5, 36.8, 60.5, 113.8, 138.7, 177.8. Anal. calcd. for $C_{13}H_{23}N$: C 80.76, H 11.99, N 7.25; found: C 80.45, H 12.28, N 7.03.

2-(1-Undecenyl)-3,4-dihydro-5H-pyrrole **2***j*. Yield: 80%; bp (0.01 Torr): 105°C; IR (neat) $\nu(cm^{-1})$: 3090, 1645, 1640; ^1H NMR ($CDCl_3$) δ(ppm): 1.10–1.75 (14H, m), 1.80–2.10 (4H, m), 2.15–2.55 (4H, m), 3.60–3.95 (2H, m), 4.75–5.20 (2H, m), 5.55–6.15 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 22.6, 26.4, 28.9, 29.1, 29.4, 33.8, 37.1, 60.8, 114.1, 139.1, 178.3, Anal. calcd. for $C_{15}H_{27}N$: C 81.38, H 12.29, N 6.33; found: C 81.02, H 12.51, N 6.04.

2-(1-Undecanyl)-3,4-dihydro-5H-pyrrole **2***k*. Yield: 90%; bp (0.01 Torr): 100°C; IR (neat) $\nu(cm^{-1})$: 1635; ^1H NMR ($CDCl_3$) δ(ppm): 0.65–1.00 (3H, m), 1.10–2.20 (20H, m), 2.20–2.60 (4H, m), 3.65–4.00 (2H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 14.1, 22.6, 26.4, 29.4, 29.5, 29.6, 31.9, 33.9, 37.1, 60.8, 178.3. Anal. calcd. for $C_{15}H_{29}N$: 80.64, H 13.09, N 6.27; found: C 80.37, H 12.83, N 6.52.

2-Methyl-3,4,5,6-tetrahydropyridine **2***m*. Yield: 65%; bp (60 Torr): 70°C; IR (neat) $\nu(cm^{-1})$: 2920, 1660; ^1H NMR ($CDCl_3$) δ(ppm): 1.08 (3H, t, J = 7 Hz), 1.45–1.85 (4H, m), 1.95–2.40 (4H, m), 3.40–3.78 (2H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 10.6, 19.7, 22.0, 28.8, 33.8, 49.2, 171.8. Anal. calcd. for $C_{17}H_{13}N$: C 75.61, H 11.79, N 12.60; found: C 75.42, H 11.93, N 12.65.

2-(1-Phenylethyl-3,4,5,6-tetrahydropyridine **2***p*. Yield: 70%; bp (0.01 Torr): 85°C; IR (neat) $\nu(cm^{-1})$: 1655, 1590, 1490; ^1H NMR ($CDCl_3$) δ(ppm): 1.30–1.65 (4H, m), 1.70–2.15 (2H, m), 2.20–2.55 (2H, m), 2.60–3.00 (2H, m), 3.35–3.70 (2H, m), 7.05–7.25 (5H, br s); ^{13}C NMR ($CDCl_3$) δ(ppm): 19.6, 21.9, 29.6, 32.6, 42.4, 49.2, 125.8, 128.3, 142.0, 170.1. Anal. calcd. for $C_{13}H_{17}N$: C 83.37, H 9.15, N 7.48; found: C 83.,64, H 9.08, N 7.20.

2-(4-Phenylbutyl)-3,4,5,6-tetrahydropyridine **2***q*. Yield: 30%; bp (0.1 Torr): 1.15°C; IR (neat) $\nu(cm^{-1})$: 1660, 1595, 1500; ^1H NMR ($CDCl_3$) δ(ppm): 1.35–1.80 (8H, m), 1.85–2.30 (4H, m), 2.40–2.75 (2H, m), 3.35–3.70 (2H, m), 7.10–7.30 (5H, br s); ^{13}C NMR ($CDCl_3$) δ(ppm): 19.4, 21.7, 25.8, 28.8, 31.0, 35.6, 40.7, 49.0, 125.4, 128.0, 128.1, 142.3, 170.5. Anal. calcd. for $C_{15}H_{21}N$: C 83.66, H 9.83, N 6.51; found: C 83.51, H 10.05, N 6.44

2-(1-Undecenyl)-3,4,5,6-tetrahydropyridine **2***s*. Yield: 70%; bp (0.01 Torr): 113°C; IR (neat) $\nu(cm^{-1})$: 3075, 1660, 1640, 1640, 1590; ^1H NMR ($CDCl_3$) δ(ppm): 1.15–1.45 (16H, m), 1.50–1.90 (4H, m), 1.95–2.35 (4H, m), 3.25–3.70 (2H, m), 4.80–5.20 (2H, m), 5.45–6.10 (1H, m). Anal. calcd. for $C_{16}H_{29}N$: C 81.63, H 12.42, N 5.95; found: C 81.82, H 12.21, N 5.69.

2-(1-Phenylethyl)-3,4,5,6-tetrahydro-5H-azepine **2***w*. Yield: 39%; bp (0.05 Torr): 105°C; IR (neat) $\nu(cm^{-1})$: 1660, 1580, 1495, 1440; ^1H NMR ($CDCl_3$) δ(ppm): 1.05–1.90 (8H, m), 2.05–3.00 (4H, m), 3.35–3.70 (2H, m), 7.05–7.20 (5H, br s). Anal. calcd. for $C_{14}H_{19}N$: C 84.37, H 8.60, N 7.03; found: 84.17, H 8.85, N 6.91.

β-Enaminones **6***: general procedure for preparation*

A mixture of β-enaminoketoester **5** (0.01 mol) and solid boric acid (0.1 mol for all compounds, except 0.02 mol for acetyl derivatives) was heated 1 h in an oil bath at 225°C. After cooling, the reaction mixture was poured into a beaker containing 30 mL of water, 20 mL of chloroform, and 10 g of potassium carbonate. After agitation (0.5 h) and concentration under reduced pressure to half the original volume, 20 mL of 20% hydrochloric acid and methanol (1:1) was added and the mixture stirred 0.5 h, neutralized with K_2CO_3, extracted with chloroform (3 × 30 mL), dried over sodium sulfate, and the solvents removed under reduced pressure. All crude products were purified by distillation or recrystallization. For thermally sensitive products, purification was achieved by column chromatography.

(α-Tetrahydropyrrolyidene)-propanone **6***a*. Yield: 50%; bp (0.1 Torr): 122°C (19), IR (neat) $\nu(cm^{-1})$: 3300, 2980, 2880, 1610, 1540, 1500, 1430; ^1H NMR ($CDCl_3$) δ(ppm): 1.75–2.20 (2H, m), 2.05 (3H, s), 2.30–2.80 (2H, m), 3.40–3.70 (2H, m), 5.10 (1H, s), 10.50–11.30 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 21.2, 28.4, 32.1, 47.3, 89.5, 167.2, 194.4.

1-(α-Tetrahydropyrrolylidene)-2-pentanone **6***b*. Yield: 46%; purified by chromatography (silica gel 60, Et_2O, R_f: 0.32); IR ($CHBr_3$) $\nu(cm^{-1})$: 3280, 3020, 2960, 2870, 1610, 1525, 1500, 1460, 1430; ^1H

NMR ($CDCl_3$) δ(ppm): 0.80–0.95 (3H, m), 1.50–1.70 (2H, m), 1.85–2.10 (2H, m), 2.15–2.30 (2H, m), 2.50–2.65 (2H, m), 3.50–3.60 (2H, m), 5.10 (1H, s), 9.60–10.05 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 14.1, 19.6, 21.3, 32.3, 43.9, 47.4, 89.3, 167.4, 198.2. Anal. calcd. for $C_9H_{15}NO$: C 70.55, H 9.87, N 9.14; found: C 70.28, H 9.70, N 9.16.

(α-Tetrahydropyrrolylidene)-acetophenone **6***c*. Yield: 60%; mp (ethanol): 109°C (20, 21); IR ($CHBr_3$) ν(cm^{-1}): 3280, 3020, 2880, 1605, 1575, 1510, 1480, 1425; ^1H NMR ($CDCl_3$) δ(ppm): 1.90–2.10 (2H, m), 2.65–2.80 (2H, m), 3.55–3.75 (2H, m), 5.80 (1H, s), 7.30–7.50 (3H, m), 7.80–7.95 (2H, m), 10.10–10.45 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 21.4, 32.9, 47.7, 86.5, 127.0, 128.1, 130.4, 140.3, 169.2, 188.0.

(α-Hexahydropyridylidene)-propanone **6***d*. Yield: 43%; bp (0.1 Torr): 98°C (7*b*); IR (neat) ν(cm^{-1}): 3400, 2940, 2860, 1605, 1560, 1520, 1445, 1420; ^1H NMR ($CDCl_3$) δ(ppm): 1.50–1.95 (4H, m), 1.85 (3H, s), 2.05–2.45 (2H, m), 3.10–3.50 (2H, m), 4.75 (1H, s), 10.70–11.50 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 19.2, 22.2, 28.3, 28.4, 40.8, 93.3, 164.1, 193.7.

1-(α-Hexahydropyridylidene)-2-pentanone **6***e*. Yield: 30%; purified by chromatography (silica gel 60, Et_2O, R_f: 0.44); IR ($CHBr_3$) ν(cm^{-1}): 3200, 3020, 2940, 2870, 1600, 1540, 1445, 1420; ^1H NMR ($CDCl_3$) δ(ppm): 0.80–0.95 (3H, m), 1.35–1.85 (6H, m), 2.05–2.20 (2H, m), 2.25–2.35 (2H, m), 3.20–3.35 (2H, m), 4.80 (1H, s), 10.95–11.25 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 14.0, 19.3, 19.7, 22.3, 28.4, 40.9, 43.9, 92.9, 164.0, 197.1. Anal. calcd. for $C_{10}H_{17}NO$: C 71.81, H 10.25, N 8.38; found: C 72.04, H 10.21, N 8.52.

(α-Hexahydropyridylidene)-acetophenone **6***f*. Yield: 50% (21); purified by chromatography (silica gel 60, Et_2O, R_f: 0.51); IR ($CHBr_3$) ν(cm^{-1}): 3350, 3020, 2940, 2860, 1595, 1580, 1530, 1480, 1440, 1420: ^1H NMR ($CDCl_3$) δ(ppm): 1.60–1.90 (6H, m), 2.40–2.55 (2H, m), 3.30–3.45 (2H, m), 5.00 (1H, s), 7.25–7.50 (3H, m), 7.70–7.90 (2H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 19.3, 22.2, 28.9. 41.1, 90.1, 126.7, 128.0, 130.2, 140.6, 165.9, 187.1.

(α-Hexahydroazepinylidene)-propanone **6***g*. Yield: 39%; bp (0.05 Torr): 110°C; IR (neat) ν(cm^{-1}): 3400, 2920, 2860, 1600, 1560, 1440; ^1H NMR ($CDCl_3$) δ(ppm): 1.30–1.85 (4H, m), 2.00 (3H, s), 2.10–2.50 (2H, m), 3.10–3.50 (2H, m), 4.75 (1H, s), 10.80–11.70 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 25.8, 28.7, 29.3, 30.4, 34.6, 44.0, 93.9, 169.4, 194.9. Anal. calcd. for $C_9H_{15}NO$: C 70.55, H 9.87, N 9.14; found: C 70.59, H 9.72, N 8.98.

1-(α-Hexahydroazepinylidene)-2-pentanone **6***h*. Yield: 40%; purified by chromatography (silica gel 60, Et_2O, R_f: 0.64); IR (neat) ν(cm^{-1}): 3350, 3020, 2930, 2870, 1690, 1590, 1460, 1430; ^1H NMR ($CDCl_3$) δ(ppm): 0.75–0.95 (3H, m), 1.40–1.75 (8H, m), 2.05–2.30 (4H, m), 3.15–3.35 (2H, m), 4.90 (1H, s), 10.70–11.20 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 13.9, 19.5, 25.8, 29.3, 30.4, 34.7, 43.9, 44.0, 93.5, 169.5, 198.3. Anal. calcd. for $C_{11}H_{19}NO$: C 72.88, H 10.57, N 7.73; found: C 72.99, H 10.55, N 7.79.

(α-Hexahydroazepinylidene)-acetophenone **6***i*. Yield: 27% (21, 22); purified by chromatography (silica gel 60, Et_2O, R_f: 0.70); mp: 76°C; IR ($CHBr_3$) ν(cm^{-1}): 3250, 3020, 2920, 2850, 1715, 1590, 1580, 1540, 1460, 1440; ^1H NMR ($CDCl_3$) δ(ppm): 1.50–2.10 (6H, m), 2.40–2.60 (2H, m), 3.40–3.55 (2H, m), 5.40–6.00 (1H, m), 7.10–7.60 (3H, m), 7.70–8.10 (2H, m), 11.50–11.85 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 25.6, 29.1, 30.6, 35.4, 44.5, 90.7, 126.9, 128.1, 130.4, 140.3, 171.8, 188.2.

Methyl 6-(α-tetrahydropyrrolylidene)-5-oxohexanoate **6** (n = 1, m = 3). Yield: 49% (23); bp (0.1 Torr): 170°C; IR (neat) ν(cm^{-1}): 3280, 3020, 2950, 2880, 1720, 1610, 1530, 1500, 1450, 1430; ^1H NMR ($CDCl_3$) δ(ppm): 1.60–1.95 (4H, m), 1.95–2.30 (4H, m), 2.30–2.55 (2H, m), 3.25–3.50 (2H, m), 3.47 (3H, s), 4.90 (1H, s), 9.50–9.75 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 21.2, 32.2, 33.4 40.4, 47.4, 51.2, 89.0, 167.5, 173.7, 196.2.

β-Enaminoketodiesters **5***: general procedure for preparation*

Ketodiester (0.05 mol) and 0.055 mol of lactim ether were heated 14 h at 120°C without solvent. Crude products were then purified.

Dimethyl-2-(α-tetrahydropyrrolylidene)-3-oxohexane-1,6-dioate **5***a* (n = 1, m = 2). Yield: 52%; mp (ethanol): 49°C; IR ($CHBr_3$) ν(cm^{-1}): 3200, 3020, 1720, 1670, 1590, 1540, 1470, 1435; ^1H NMR ($CDCl_3$) δ(ppm): 1.85–2.10 (2H, m), 2.45–2.85 (2H, m), 3.05–3.20 (4H, m), 3.50–3.85 (2H, m), 3.65 (3H, s), 3.70 (3H, s), 11.30–11.55 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 20.9, 29.2, 35.3, 36.7, 47.9, 50.5, 51,5, 98.1, 168.9, 174.3, 174.9, 197.4. Anal. calcd. for $C_{12}H_{17}NO_5$: C 56.46, H 6.71, N 5.49; found: C 56.44, H 6.75, N 5.44.

Dimethyl-2-(α-tetrahydropyrrolylidene)-3-oxoheptane-1,7-dioate **5***b* (n = 1, m = 3). Yield: 47%; mp (ethanol): 61°C; IR ($CHBr_3$) ν(cm^{-1}): 3200, 3020, 2940, 1720, 1670, 1580, 1540, 1435; ^1H NMR ($CDCl_3$) δ(ppm): 1.80–2.10 (4H, m), 2.25–2.40 (2H, m), 2.75–2.85 (2H, m), 3.05–3.15 (2H, m), 3.55–3.70 (2H, m), 3.60 (3H, s), 3.70 (3H, s), 11.25–11.70 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 21.0, 33.8, 35.2, 40.7, 48.0, 50.6, 51.4, 51.6, 98.4, 169.2, 174.1, 174.7, 199.1. Anal. calcd. for $C_{13}H_{19}NO_5$: C 57.98, H 7.11, N 5.20; found: C 57.86, H 7.05, N 5.10.

Dimethyl-2-(α-hexahydropyridylidene)-3-oxohexane-1,6-dioate **5***c* (n = 2, m = 2). Yield: 41%; purified by chromatography (silica gel 60, Et_2O, R_f: 0.49); IR ($CHBr_3$) ν(cm^{-1}): 3550, 2950, 2870, 1725, 1600, 1460, 1430; ^1H NMR ($CDCl_3$) δ(ppm): 1.55–1.75 (4H, m), 2.40–2.50 (2H, m), 2.55–2.65 (2H, m), 2.75–2.90 (2H, m), 3.20–3.35 (2H, m), 3.55 (3H, s), 3.60 (3H, s), 12.40–12.55 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 18.9, 21.0, 27.7, 29.3, 35.6, 41.5, 50.9, 51.5, 100.7, 168.9, 169.9, 174.1, 195.1. Anal. calcd. for $C_{13}H_{19}NO_5$; C 57.98, H 7.11, N 5.20; found: C 57.86, H 6.98, N 5.41.

Dimethy-2-(α-hexahydropyridylidene)-3-oxoheptane-1,7-dioate **5***d* (n = 2, m = 3). Yield: 34%; purified by chromatography (silica gel 60, Et_2O, R_f: 0.59); IR ($CHBr_3$) ν(cm^{-1}): 3400, 3020, 2940, 2860, 1720, 1680, 1590, 1470, 1460, 1445, 1430; ^1H NMR ($CDCl_3$) δ(ppm): 1.60–2.00 (6H, m), 2.25–2.35 (2H, m), 2.45–2.55 (2H, m), 2.55–2.65 (2H, m), 3.25–3.40 (2H, m), 3.60 (3H, s), 3.65 (3H, s), 12.65–12.80 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 19.0, 21.0, 21.1, 27.6, 33.0, 33.6, 39.7, 41.4, 51.0, 101.3, 168.4, 170.2, 173.9. Anal. calcd. for $C_{14}H_{21}NO_5$: C 59.35, H 7.47, N 4.94; found: C 59.47, H 7.57, N 4.89.

Dimethyl-2-(α-hexahydroazepinylidene)-3-oxohexane-1,6-dioate **5***e* (n = 3, m = 2). Yield: 21%; purified by chromatography (silica gel 60, Et_2O, R_f: 0.69); IR ($CHBr_3$) ν(cm^{-1}): 3600, 3000, 2940, 2860, 1730, 1695, 1590, 1575, 1460, 1430; ^1H NMR ($CDCl_3$) δ(ppm): 1.30–1.65 (6H, m), 2.25–2.45 (4H, m), 2.60–2.75 (2H, m), 3.15–3.30 (2H, m), 3.45 (3H, s), 3.55 (3H, s), 11.90–12.25 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 24.2, 28.2, 28.9, 29.9, 30.9, 35.2, 43.9, 51.0, 51.3, 101.5, 170.3, 173.0, 173.7, 194.7. Anal. calcd. for $C_{14}H_{21}NO_5$: C 59.35, H 7.47, N 4.94; found: C 59.28, H 7.62, N 4.92.

Dimethyl-2-(α-hexahydroazepinylidene)-3-oxoheptane-1,7-dioate **5***f* (n = 3, m = 3). Yield: 27%; purified by chromatography (silica gel 60, Et_2O, R_f: 0.59); IR ($CHBr_3$) ν(cm^{-1}): 3350, 3020, 2940, 2860, 1720, 1690, 1595, 1460, 1430; ^1H NMR ($CDCl_3$) δ(ppm): 1.50–1.80 (6H, m), 1.80–2.00 (2H, m), 2.20–2.40 (2H, m), 2.40–2.70 (4H, m), 3.30–3.50 (2H, m), 3.60 (3H, s), 3.70 (3H, s), 12.05–12.35 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 20.8, 24.4, 28.4, 30.1, 31.1, 33.6, 39.6, 44.1, 51.4, 102.3, 170.9, 172.8, 173.9, 196.4. Anal. calcd. for $C_{15}H_{23}NO_5$: C 60.59, H 7.80, N 4.71; found: C 60.78, H 7.93, N 4.76.

β-Enaminodiketones **7***: general procedure for preparation*

β-Enaminoketodiester **5** (R = $-(CH_2)_m-CO_2CH_3$) (0.01 mol) and 0.1 mol of solid boric acid were heated 1 h at 230°C. Work-up was similar to the preparation of enaminones.

2-(α-Tetrahydropyrrolylidene)-1,3-cyclopentanedione **7***a* (n = 1, m = 2). Yield: 12% (24); mp (acetone): 210°C; IR ($CHBr_3$) ν(cm^{-1}): 3250, 3020, 1670, 1605, 1570, 1485, 1420; ^1H NMR ($CDCl_3$) δ(ppm): 2.00–2.20 (2H, m), 2.47 (4H, s), 3.15–3.30 (2H, m), 3.65–3.80 (2H, m), 10.30–10.55 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 20.3, 31.9, 33.8, 48.1, 105.0, 172.8.

2-(α-Tetrahydropyrrolylidene)-1,3-cyclohexanedione **7***b* (n = 1, m = 3). Yield: 40%; mp (ethanol): 158°C; IR ($CHBr_3$) ν(cm^{-1}): 3150, 3020, 2950, 2880, 1630, 1580, 1540, 1470, 1440; ^1H NMR

($CDCl_3$) δ(ppm): 1.60–1.85 (2H, m), 1.85–2.05 (2H, m), 2.20–2.45 (4H, m), 3.15–3.35 (2H, m), 3.45–3.65 (2H, m), 11.70–11.95 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 19.6, 20.5, 35.5, 38.4, 47.8, 106.7, 176.7, 197.9. Anal. calcd. for $C_{10}H_{13}NO_2$; C 67.02, H 7.31, N 7.82; found: C 66.99, H 7.22, N 7.98.

2-(α-Hexahydropyridylidene)-1,3-cyclopentanedione **7***c* (n = 2, m = 2). Yield: 10% (24); purified by chromatography (silica gel 60, acetone/pentane, 7:3, R_f: 0.38); IR ($CHBr_3$) ν(cm^{-1}): 3300, 3020, 1660, 1600, 1500, 1465, 1400; ^1H NMR ($CDCl_3$) δ(ppm): 1.65–2.00 (4H, m), 2.25–2.60 (4H, m), 3.00–3.25 (2H, m), 3.35–3.55 (2H, m), 11.75–11.95 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 17.6, 20.9, 26.3, 32.9, 33.9, 41.8, 105.8, 171.1, 202.3, 206.

2-(α-Hexahydropyridylidene)-1,3 cyclohexanedione **7***d* (n = 2, m = 3). Yield: 36% (24); purified by chromatography (silica gel 60, acetone, R_f: 0.73); IR ($CHBr_3$) ν(cm^{-1}): 3400, 3020, 2950, 2870, 1620, 1590, 1560, 1455; ^1H NMR ($CDCl_3$) δ(ppm): 1.60–1.90 (6H, m), 2.30–2.45 (4H, m), 3.00–3.15 (2H, m), 3.30–3.50 (2H, m), 13.10–13.50 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 18.7, 19.5, 20.4, 29.5, 39.0, 41.9, 107.9, 174.6, 198.1.

2-(α-Hexahydroazepinylidene)-1,3-cyclopentanedione **7***e* (n = 3, m = 2). Yield: 15% (24); purified by chromatography (silica gel 60, acetone/pentane, 3:7, R_f: 0.23); IR ($CHBr_3$) ν(cm^{-1}): 3350, 3020, 2930, 2860, 1660, 1600, 1490, 1460, 1430; ^1H NMR ($CDCl_3$) δ(ppm): 1.45–1.65 (4H, m), 1.65–1.80 (2H, m), 2.35 (4H, br s), 3.20–3.35 (2H, m), 3.35–3.50 (2H, m), 11.95–12.20 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 23.4, 26.5, 27.5, 30.7, 33.4, 44.7, 105.4, 177.1, 206.6.

2-(α-Hexahydroazepinylidene)-1,3-cyclohexanedione **7***f* (n = 3, m = 3). Yield: 20% (25); purified by chromatography (silica gel 60, acetone, R_f: 0.77); mp: 93°C; IR ($CHBr_3$) ν(cm^{-1}): 3350, 3020, 2930, 2850, 1620, 1565, 1460, 1415; ^1H NMR ($CDCl_3$) δ(ppm): 1.50–1.90 (8H, m), 2.30–2.45 (4H, m), 3.10–3.25 (2H, m), 3.40–3.55 (2H, m), 13.05–13.40 (1H, m); ^{13}C NMR ($CDCl_3$) δ(ppm): 19.5, 23.3, 27.2, 29.6, 30.3, 39.0, 44.2, 108.6, 180.3.

Chemistry of chromotropic acid. ^1H and ^{13}C NMR spectroscopy of chromotropic acid and its derivatives

PARIS E. GEORGHIOU,[1] CHI KEUNG (JIMMY) HO, AND CHESTER R. JABLONSKI
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received November 9, 1990

This paper is dedicated to Dr. Hugh J. Anderson on the occasion of his 65th birthday

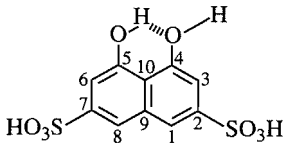
PARIS E. GEORGHIOU, CHI KEUNG (JIMMY) HO, and CHESTER R. JABLONSKI. Can. J. Chem. **69**, 1207 (1991).

The ^1H and ^{13}C NMR spectra of chromotropic acid (CTA) (4,5-dihydroxy-2,7-naphthalenedisulphonic acid) have been unambiguously assigned. Proton NOED spectra were used to show the proximity of both H-3 and H-6 and the hydroxyl groups. Two-dimensional ^1H–^{13}C NMR correlation spectra of CTA, of its corresponding diacetoxy derivative, and of 3-bromo- and 3,6-dibromo-CTA support the assignments. A regioselective deuterium exchange reaction of the C-3 and C-6 protons of CTA with deuterium oxide was observed during the NMR experiments. This latter finding is strongly indicative of the mode of formation, and of the nature of the chromogen formed in the reaction of CTA with formaldehyde in the well-known CTA–formaldehyde analytical reaction.

Key words: chromotropic acid, 3-bromochromotropic acid, 3,6-dibromochromotropic acid.

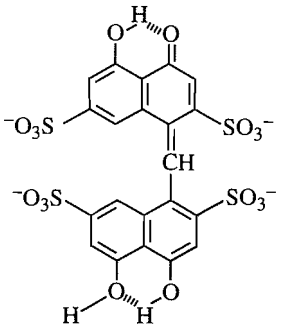
PARIS E. GEORGHIOU, CHI KEUNG (JIMMY) HO et CHESTER R. JABLONSKI. Can. J. Chem. **69**, 1207 (1991).

On a fait un attribution non-ambiguë des spectres RMN du ^1H et du ^{13}C de l'acide chromotropique (ACT) (acide 4,5-dihydroxy-naphtalène-2,7-disulfonique). On a utilisé les spectres d'EOND du proton pour démontrer que les H-3 et H-6 ainsi que les groupements hydroxyles sont à proximité les uns des autres. Les spectres RMN ^1H–^{13}C de corrélation bidimensionnelle de l'ACT, de son dérivé diacétoxylé et des acides 3-bromo- et 3,6-dibromo-chromotropiques sont en accord avec les attributions. Au cours des expériences de RMN en présence d'oxyde de deutérium, on a observé une réaction d'échange régiosélective du deutérium avec les protons en C-3 et en C-6 de l'ACT. Cette observation est un indice précieux du mode de formation et de la nature du chromogène formé lors de la réaction de l'ACT avec le formaldéhyde au cours de la réaction analytique bien connue de l'ACT–formaldéhyde.



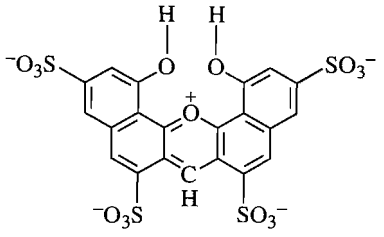
Mots clés : acide chromotropique, acide 3-bromochromotropique, acide 3,6-dibromochromotropique.

[Traduit par la rédaction]



Introduction

Chromotropic acid (CTA) **1** (4,5-dihydroxy-2,7-naphthalenedisulphonic acid) is employed as an analytical reagent and as an intermediate in the syntheses of numerous azo dyes, which are used extensively both in the dye industry and in analytical chemistry (1–3). In North America it has found widespread use as the chromogen-forming reagent in the analysis of formaldehyde using the method recommended by the National Institute for Occupational Safety and Health (NIOSH), Method P&CAM 125 (4, 5). The exact nature of the chromogen and its formation by the reaction of CTA with formaldehyde has, however, not been unambiguously proven. The most often quoted structure (4–8) for the chromogen formed between CTA and formaldehyde has been the *para,para*-quinoidal adduct **2**, but no direct proof of this structure has ever been presented. The structure is based on an analogy to the reaction of formaldehyde with aromatic compounds in the LeRosen test (8).



Kamel and Wizinger (9) proposed the mono-cationic dibenzoxanthylium structure **3** as an alternative. This structure is the one that is most consistent with the chemistry of the reaction (10). As part of our ongoing studies of methods for the analysis of formaldehyde we were interested in understanding the chemistry of the formaldehyde–CTA reaction through the use of NMR spectroscopy. Surprisingly, considering its widespread use, there does not appear to be an unambiguous assignment of either its ^1H or ^{13}C NMR spectrum in the literature. Lajunen *et al.* (11) reported a ^{13}C NMR study of CTA, but the ^{13}C NMR spectrum was not definitively assigned. More recently, Freeman *et al.* (12) described the 250-MHz ^1H NMR spectrum of CTA and other naphthalene-based dyestuff intermediates with assignments based on comparisons with mono-substituted naphthalenes. This paper describes our findings using through-bond and through-space NMR correlation techniques, which allowed the unambiguous assignment of the ^1H and ^{13}C NMR spectra of CTA and its mono and dibromo derivatives. These assignments enabled us to propose an hypothesis for the chemistry of the CTA–formaldehyde chromogen-forming reaction (10).

Experimental

^{1}H NMR spectra were recorded with the following instruments at the designated frequencies: Varian Anaspect EM 360 (60 MHz), Bruker WP-80 (80 MHz), or GE GN-300NB (300 MHz) spectrometers. ^{13}C NMR spectra were recorded with the Bruker WP-80 (20.1 MHz) and (or) the GE GN-300NB (75.47 MHz) instrument. The solvent used was either deuterium oxide or water as noted in the experimental details. Proton nuclear Overhauser effect difference (NOED) spectra were determined under steady state conditions (13) on a GE 300-NB instrument using a set of 16K interleaved experiments of 8 transients cycled 12 to 16 times through the list of decoupling frequencies. In each experiment the decoupler was on in continuous wave (CW) mode for 6 s with sufficient attenuation to give an approximate 70–90% reduction in intensity of the irradiated peak. A 24 s delay preceded each frequency change. A set of four "dummy" scans was employed to equilibrate the spins prior to data acquisition. No relaxation delay was applied between successive scans of a given frequency. Difference spectra were obtained on zero-filled 32K data tables that had been digitally filtered with a 1–2 Hz exponential line-broadening function.

Ultraviolet and visible spectra were determined on a Unicam SP.800 ultraviolet spectrophotometer. Infrared spectra were recorded on a Perkin–Elmer 1320 infrared spectrophotometer using KBr disks. Sephadex LH-20 purchased from Pharmacia Fine Chemicals was used in the gel permeation chromatography.

*Purification of 4,5-dihydroxy-2,7-naphthalenedisulphonic acid disodium salt (**1**)*

The material purchased from Sigma Chemical Co. was specified as being only 98% pure. Purified **1** was obtained by dissolving 20 g of the Sigma product in 100 mL of water in a 125-mL Erlenmeyer flask on a hot plate. A solution of 20 g of sodium chloride in 50 mL of hot water was added to the chromotropic acid solution until a precipitate formed. The flask was stoppered and the solution was allowed to first crystallize at room temperature and then at low temperature in a refrigerator. The crystals were filtered with suction and dried in air. The product was almost colourless: UV (H_2O) λ_{max} absorbances: 316, 332, 346 nm. IR (KBr) ν_{max}: 3500 (-SO_2O-H and ArO-H), 1200 (S=O) cm^{-1}. ^{1}H NMR (300 MHz; D_2O, TSP internal standard) δ ppm: 7.20 (d, J = 1.4 Hz, 1H, Ar-H), 7.92 (d, J = 1.4 Hz, 1H, Ar-H). ^{13}C NMR and APT (D_2O) δ ppm: 106.44 (C-3 and C-6), 116.18 (C-10), 118.12 (C-1 and C-8), 134.64 (C-9), 141.36 (C-2 and C-7), 153.76 (C-4 and C-5). 2-D ^{1}H–^{13}C correlation (D_2O): 7.20 ppm correlates with 106.44 (C-3 and C-6), 7.92 ppm correlates with 118.12 (C-1 and C-8).

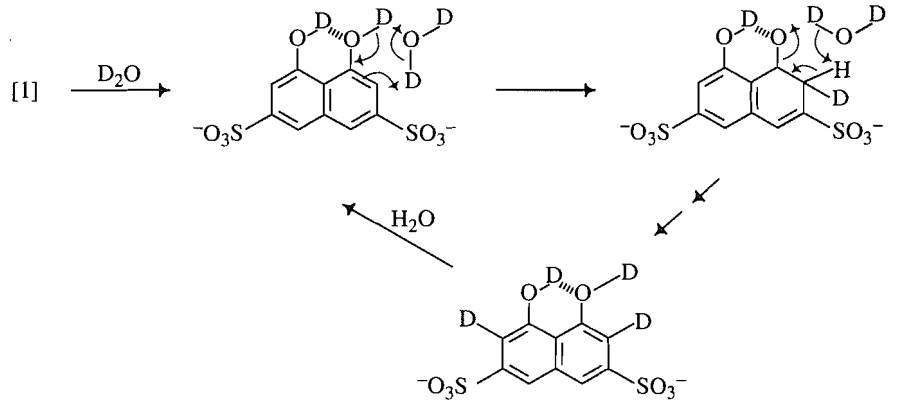
Deuterium exchange experiments with chromotropic acid

In a typical experiment, an NMR tube was charged with a solution containing 67 mg of purified **1** in 0.30 mL of deuterium oxide. A small amount of DSS as internal standard was added to the solution. The NMR tube was heated in a boiling water bath. ^{1}H NMR spectra were recorded at 10 min intervals until the signal at 7.20 ppm completely disappeared and the signal at 7.92 ppm collapsed to a sharp singlet. The deuterium exchange could be reversed by adding 0.1 mL of water to the NMR tube. The ^{13}C NMR spectra were recorded for a freshly prepared deuterium oxide solution of purified **1**, and following heating of the NMR tube in a boiling water bath for 15 min. Side-by-side comparison of the spectra indicate that the intensity of the 106.44 ppm signal (C-3 and C-6) was reduced by over 90%. All other signals were unchanged.

*4,5-Diacetoxy-2,7-naphthalenedisulphonic acid disodium salt (**4**)*

In a 25-mL Erlenmeyer flask, 1.0 g (2.68 mmol) of chromotropic acid disodium salt was dissolved in 3.0 mL of 3.0 M aqueous sodium hydroxide. To this solution was added approximately 2 g of crushed ice, followed by 0.6 mL of acetic anhydride. The mixture was stirred for 5–10 min with ice-bath cooling. The diacetate separated out as colourless, crystalline needles. It was filtered by suction, washed with portions of absolute ethanol, and dried in air. Recrystallization from water afforded 0.52 g (40%) of crystals having a decomposition point at 320°C. X-ray crystallographic analysis revealed that the compound was a dihydrate: UV (H_2O) λ_{max} absorbances: 315, 329, 339 nm. ^{1}H NMR (D_2O) δ ppm: 2.43 (s, 3H, CH_3-), 7.72 (d, J = 2 Hz, 1H, Ar-H), 8.52 (d, J = 2 Hz, 1H, Ar-H).

*3,6-Dibromo-4,5-dihydroxy-2,7-naphthalenedisulphonic acid disodium salt (**5**a)*



In a 25-mL Erlenmeyer flask, 1.9 g (5.1 mmol) of chromotropic acid disodium salt was mixed with 12 mL of concentrated sulphuric acid (96%, d = 1.84 g/mL). The mixture was heated and stirred at 80°C until all the solid dissolved. The solution was cooled to approximately 15°C and, with continuous cooling and stirring, a solution of 0.8 g (5.0 mmol) of bromine in 3.0 mL of glacial acetic acid was added dropwise over 1 h. After the addition of bromine, the solution was stirred and cooled for an additional 3 h. To this solution, approximately 15 g of ice was added. The white precipitate was filtered off with suction, using a sintered glass funnel. The residue was dissolved in a minimal amount of water at room temperature. To this aqueous solution one half of its volume of concentrated hydrochloric acid solution was added. The grey-white leaflets were suction filtered using a sintered glass funnel, and were press-dried. The residue was further dried under vacuum to afford 1.25 g (46%) of **5***a*, which decomposed above 40°C with liberation of bromine: UV (H_2O) λ_{max} absorbances: 340, 358, 375 nm. ^{1}H NMR (D_2O) δ ppm: 8.10 (s, Ar-H). ^{13}C NMR (D_2O) δ ppm: 102.44 (C-3 and C-6), 116.26 (C-10), 122.04 (C-1 and C-8), 130.74 (C-9), 140.11 (C-2 and C-7), 149.62 (C-4 and C-5). 2-D ^{1}H–^{13}C correlation (D_2O): 8.10 ppm correlates with 122.04 (C-1 and C-8); APT (D_2O): 122.04 ppm (C-1 and C-8, one attached proton).

*3-Bromo-4,5-dihydroxy-2,7-naphthalenedisulphonic acid disodium salt (**6**)*

In a 25-mL Erlenmeyer flask, 1.9 g (5.1 mmol) of chromotropic acid disodium salt was mixed with 12 mL of concentrated sulphuric acid (96%, d = 1.84 g/mL). The mixture was heated and stirred at 80°C until all the solid dissolved. The solution was cooled to approximately 15°C and, with continuous cooling and stirring, a solution of 0.4 g (2.5 mmol) of bromine in 3.0 mL of glacial acetic acid was added dropwise over 3 h. After the addition of bromine, the solution was stirred and cooled for an additional 1 h. To the solution approximately 15 g of ice was added. The white precipitate was suction-filtered using a sintered glass funnel. The residue was dissolved in a minimal amount of water at room temperature. To this aqueous solution one half of its volume of concentrated hydrochloric acid solution was added. The grey-white leaflets were once again filtered off using suction and a sintered glass funnel, and were press-dried. The residue was further dried under vacuum to afford 0.98 g (40%) of **6**, which decomposed at 40°C with liberation of bromine: UV (H_2O) λ_{max} absorbances: 316, 336, 348 nm. ^{1}H NMR (D_2O) δ ppm: 7.17 (d, J = 2 Hz, 1H, Ar-H), 7.80 (d, J = 2 Hz, 1H, Ar-H), 8.10 (s, 1H, Ar-H). ^{13}C NMR (D_2O) δ ppm: 100.51 (C-3), 107.06 (C-6), 115.96 (C-10), 118.62 (C-8), 121.33 (C-1), 132.63 (C-9), 140.17 (C-7), 141.28 (C-2), 151.35 (C-4), 152.23 (C-5).

Results and discussion

The 300-MHz ^{1}H NMR spectrum of CTA shows two AX-type doublets (7.92, 7.20 ppm, J = 1.4 Hz), which is consistent for structure **1** assuming negligible interannular coupling (14). An unambiguous assignment of this spectrum, however, cannot be made on the basis of neighbouring group effects alone. Of the two types of protons on the CTA molecule, one type (on C-3, or C-6) is *ortho* to the sulphonic acid group, and the other type (on C-1, or C-8) is *para* to the hydroxyl but *ortho* to the sulphonic acid group. Since these two types of protons are both *ortho* to the sulphonic acid group, the effect of the electron-withdrawing sulphonic acid group should be the same on both of them. The hydroxyl group on the other hand is *ortho* to the proton on C-3 (or C-6) and *para* to the proton on C-1 (or C-8). It has been shown that the *ortho* and *para* position protons in phenol are equally affected by the hydroxyl group and have similar chemical shifts (15). In naphthalene, however,

SCHEME 1

due to ring current effects (15), the α protons, which are closer to both rings, appear downfield (7.81 ppm) with respect to the β protons (7.46 ppm). By analogy with naphthalene therefore, the signals at 7.92 ppm could be tentatively assigned to the proton on C-1 (and C-8) and the signals at 7.20 ppm can be assigned to the proton on C-3 (and C-6). Nevertheless, the assignment of chemical shifts using only the arguments made above or those made by Freeman *et al.* (12) is clearly not sufficient for a multi-substituted naphthalene derivative such as CTA.

During the ^{1}H NMR experiments on CTA in deuterium oxide it was observed that the signals at 7.20 ppm gradually diminished in intensity. The signals ultimately disappeared completely and the doublet at 7.92 ppm was converted into a sharp singlet. This specific exchange could be reproduced within 0.5 h at 90°C. That a simple hydrogen–deuterium exchange occurred was established by regenerating the original spectrum by the addition of water to the solution contained in the NMR tube. These findings could be accounted for by the pathway shown in Scheme 1.

Even though Scheme 1 shows exchange of the C-3 and C-6 protons, the alternative exchange of the C-1 and C-8 protons could, in principle, be equally likely. This ambiguity is of importance in understanding the reactions of CTA, thus it was necessary to definitively assign the ^{1}H NMR spectrum of CTA.

The corresponding diacetate of CTA, **4**, was synthesized to provide additional evidence for the assignment of the ^{1}H NMR spectrum of CTA. The proximity of the methyl protons of the acetoxy group to the proton on C-3 (or C-6) suggested that a nuclear Overhauser effect (NOE) (16) in the ^{1}H NMR spectrum could be observed. The 300-MHz ^{1}H NMR spectrum of **4** consists of a single signal at 2.19 ppm due to the acetate methyl groups and a pair of sharp AX-type doublets at 8.27 and 7.48 ppm ($J \sim 1.6$ Hz). Assignment of the low-field signals to the C-1, C-8 protons and the C-3, C-6 protons respectively was established by NOED experiments conducted at 300 MHz. Irradiation of the signal at 7.48 ppm enhanced the acetate signals whereas irradiation of the 8.27 ppm signal did not. The assignment of the 7.48 ppm signal to the proton on C-1 (C-8) was confirmed by irradiating the acetate signal, which resulted in a clearly enhanced signal at 7.48 ppm relative to that at 8.27 ppm. Thus, the higher-field signal is due to the protons *ortho* to the acetoxy group. Two-dimensional ^{1}H–^{13}C NMR chemical shift correlation (16) spectra provided additional evidence for these assignments. These results suggest that the higher-field signal that undergoes deuterium exchange in CTA is due to the protons *ortho* to the hydroxyl group, C-3 and C-6.

Proton NOED spectra of CTA itself confirmed the above assignments by unambiguously showing that the higher-field resonance is proximal to the hydroxyl group. The experiments were conducted in DMSO-d_6 solution to slow exchange at the hydroxyl site. To confirm that the assignment of the peaks in DMSO-d_6 is the same as those in D_2O, a dilution study was conducted in DMSO-d_6/D_2O. No change in the relative positions of the two low-field signals was observed. Figure 1 shows a small positive enhancement of the hydroxyl resonance on partial saturation of the higher-field peak. The correlation was confirmed by observation of a selective enhancement of the high-field resonance when the hydroxyl peak was saturated.

Lajunen *et al.* (11) assigned the 25-MHz ^{13}C NMR spectrum of CTA in D_2O, which consisted of six signals (see Table 1), to their respective carbon atoms by analyzing the response of the ^{13}C chemical shifts to varying pH. The largest effect on the chemical shift was observed for the C-4, C-5, and C-10 signals when the pH was changed from 4.5 to 8.0. At basic pH one of the hydroxyl groups is dissociated into the corresponding oxyanion. Dissociation of the second hydroxyl group, however, is not possible in aqueous solution since it is very strongly hydrogen-bonded to the neighbouring oxyanion via an intramolecular six-membered ring. Nevertheless, none of their assignments can be considered to be unambiguous.

We wished to assign the ^{13}C NMR spectrum of CTA using more direct evidence based on through-bond scalar C–H coupling interactions. The 75-MHz broad band decoupled spectrum of CTA in DMSO-d_6 consists of six signals with approximately the same chemical shifts (Table 1) as noted by Lajunen in D_2O. Our experiments confirmed their original assignments. A 2-D HETCOR spectrum optimized for one-bond coupling revealed that the lower-field ^{1}H signal at 7.92 ppm assigned to the proton on C-1 (and C-8) was correlated with the signal at 117.50 ppm. The ^{1}H signal at 7.20 ppm assigned to the proton on C-3 (and C-6) was correlated with the ^{13}C signal at 108.22 ppm.

The proton-coupled ^{13}C NMR spectrum of CTA revealed that the signal due to C-3 (and C-6) was split into a doublet of doublets ($^1J = 162.4$ Hz; $^3J = 6.3$ Hz), the signal due to C-10 was split into an approximate quintet ($^3J = 5.9$ Hz), and that due to C-1 (and C-8) was split into a doublet of triplets ($^1J = 165.1$ Hz; $^3J = 5.0$ Hz). The C-9 signal appeared as an apparent triplet ($^2J = 2.5$ Hz), the signal due to C-2 (and C-7) was an

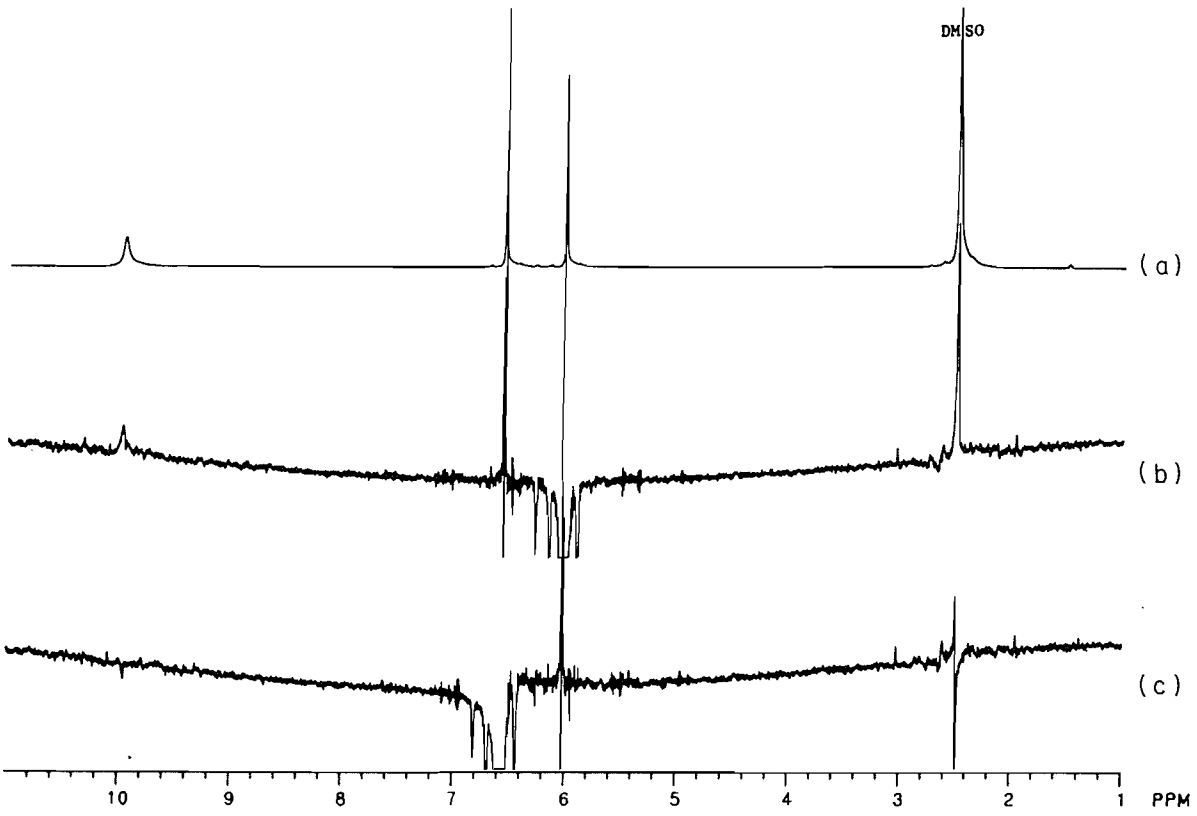

FIG. 1. Proton NOED spectra of chromotropic acid in DMSO-d_6: (a) reference spectrum; (b) saturation (×256) of 6.02 ppm signal showing positive enhancement of 9.98 ppm signal; (c) saturation (×256) of 6.60 ppm signal indicating no enhancement of 9.98 ppm signal.

TABLE 1. ^{13}C NMR chemical shifts for chromotropic acid (**1**) and derivatives (**5***a*, **6**)

Compound (solvent)	C-1	C-2	C-3	C-4	C-5	C-6	C-7	C-8	C-9	C-10	Reference
1 (D_2O)	118.12	141.36	106.44	153.76	153.76	106.44	141.36	118.12	134.64	116.18	This work
1 (DMSO-d_6)	117.50	147.22	108.22	154.98	154.98	108.22	147.22	117.50	135.97	115.65	This work
1 (H_2O)	119.4	142.7	107.8	154.8	154.8	107.8	142.7	119.4	135.9	117.8	11
5*a* (D_2O)	122.04	140.11	102.44	149.62	149.62	102.44	140.11	122.04	130.74	116.26	This work
6 (D_2O)	121.33	141.28	100.51	151.35	152.23	107.06	140.17	118.62	132.63	115.96	This work

unresolved multiplet, and the C-4 (and C-5) signal was split into an apparent doublet (^2J = 1.7 Hz).

Confirmation of the ^{13}C NMR assignments was obtained from two long-range HETCOR experiments (17) optimized for couplings of 10.0 and 7.7 Hz respectively. The ^1H signal of H-3 (and H-6) at 7.20 ppm was correlated ($^2J_{H,C}$) with the ^{13}C signals due to C-4 (and C-5), C-2 (and C-7), as well as ($^3J_{H,C}$) with C-1 (and C-8) and C-10. The ^1H signal of H-1 (and H-8) at 7.92 ppm was correlated ($^2J_{H,C}$) with the ^{13}C signals due to C-9, as well as ($^3J_{H,C}$) with C-1 (and C-8), C-10 and C-3 (and C-6).

The ^{13}C NMR of the deuterium-exchanged CTA in D_2O revealed that the intensity of the signal assigned to C-3 (and C-6) was diminished by over 90%. All other signals were unchanged. Thus it is the C-3 (and C-6) of CTA and not C-1 (and C-8) which are labile.

The 3,6-dibromo, 3,6-dichloro, and 3,6-diiodo derivatives **5***a*,*b*,*c* have been reported in the literature (18) and their NMR spectra were of interest for comparative purposes. Attempts to synthesize these dihalogenated derivatives using the method of Maslowska and Duda (18) were unsuccessful. The procedures reported by Kuznetsov and Basargin (19) for the synthesis of the monobrominated 3-bromo-CTA **6** afforded only the dibrominated product **5***a*. Modification of their procedure, however, afforded **6** in approximately 40% yields. The ^1H NMR spectrum of **5***a* consisted of a single line at 8.10 ppm; that of **6** showed three signals in the aromatic region: one singlet at 8.10 ppm corresponding to the proton on the brominated ring and an AX pattern (7.17 and 7.80 ppm, $J \sim 2$ Hz) for the non-brominated ring. The ^{13}C NMR spectra of **5***a* and **6** consisted of six and 10 signals respectively and their chemical shifts are summarized in Table 1.

The 2-D ^1H–^{13}C HETCOR spectrum of **6** revealed that the singlet at 8.10 ppm in the ^1H NMR spectrum is correlated ($^1J_{H,C}$) with the ^{13}C signal at 121.33 ppm, which is due to C-1 of **6**. The doublet at 7.80 ppm (J = 2 Hz) in the ^1H NMR spectrum is correlated ($^1J_{H,C}$) with the ^{13}C signal at 118.62 ppm, which can be assigned to C-8. The doublet in the proton

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

spectrum at 7.17 ppm (J = 2 Hz) is correlated ($^1J_{H,C}$) with the ^{13}C signal at 107.06 ppm, which is due to C-6.

It is interesting that the deuterium exchange reaction at C-3 and C-6 observed with CTA in deuterium oxide is regioselective. This could be due to intermolecular assistance by the proximal hydroxyl groups, or due to steric inaccessibility of the C-1 and C-8 positions. The NMR spectra of **5***a*, **6**, and CTA that follow from the evidence presented here provide essential information for interpreting the spectra observed when the reaction of CTA and formaldehyde was monitored directly by NMR (10). On the basis of these *in situ* experiments and calibration-line studies, it was concluded that the mono-cationic dibenzoxanthylium structure **3** for the chromogen is most consistent with the chemistry of the reaction (10).

Bond lengths (corrected and uncorrected) and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, bond lengths and angles involving hydrogen, torsion angles, and structure factors have been deposited.[4]

Results and discussion

As already suggested by the spectroscopic data and elemental composition, the crystallographic analysis confirms formula **4**, and thus shows the possibility of cyclocondensation of *N*-(2-hydroxyalkyl)hydroxamic acids in the presence of Lewis acid boron compounds even when chelate-forming reactions such as those observed for the salicylohydroxamate **6** (2) and the hydroxyacetohydroxamate **7** (3) are not involved. The resulting open-chain BF_3-adduct **4** (Fig. 1) is a stable compound and represents a new type of *N*-oxide boron complex with a boron,nitrogen-(1,3)betaine structure (7).

The O(2)BF_3 grouping in **4** has a distorted tetrahedral geometry with bond angles at boron ranging from 103.9(2)° for F(1)—B—O(2) to 113.3(2)° for F(1)—B—F(2). BF_3 itself has a trigonal planar structure both in the gas phase (8) and in the solid state (9, 10). Tetracoordination of the boron atom leads to lengthening of the B—F bonds in **4** (mean 1.382 Å (corr.) and 1.361 Å (uncorr.)) compared to those reported for

TABLE 4. Intra-annular torsion angles (deg) standard deviations in parentheses

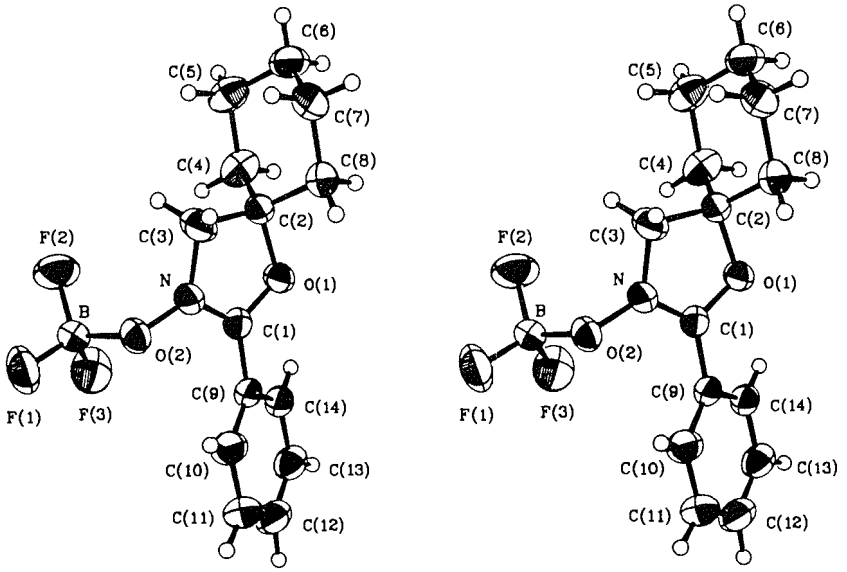

FIG. 1. Stereoview of **4**; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

crystalline BF_3: mean values of 1.278 Å (9) and 1.289 Å (10). This is consistent with a weakening of the $pp(\pi)$-interaction between boron and the fluorine ligands upon complex formation. The mean B—F distance in **4** is greater than the corresponding mean B—F bond length (1.345 Å (uncorr.)) reported for pyridine–BF_3 (11). This could result from stronger coordination in the *N*-oxide BF_3-adduct **4** than in pyridine–BF_3. To the best of our knowledge, there are no other structures of heterocyclic *N*-oxide BF_3 complexes in the literature. It is probably safe to assume that the O—B coordinative bond in zwitterionic N—O—B complexes like **4** is generally stronger than the N—B bonds of comparable, but more sterically hindered, N—B adducts.

The libration-corrected O—B bond length in **4** (1.530 Å) is in good agreement with the O—B distance of 1.533 Å derived from semiempirical MNDO calculations on the BF_3 complex of an acetaldehyde adduct of pyridine, **9** (12), which corresponds to an analogous *B,N*-(1,4)betaine structure. An O—B distance of 1.54 Å has been calculated for the BF_3 complex of dimethylsulfoxide (13). While there is a paucity of structural information reported for BF_3 complexes with basic oxides (14), the crystal structure of the related benzaldehyde–BF_3 adduct features an O—B bond length of 1.591 Å (15). The O—B distance in **4** is very similar to the (C)F—B distance of 1.528(8) Å recently reported for an isoelectronic F_3B–FC linkage in a binuclear ferracyclopentadiene derivative (16). The average terminal B—F distance of 1.37(1) Å for the F_3B—FC adduct is similar to that in **4** (see above).

The five-membered 2-oxazoline ring is nearly planar (maximum deviation from the mean plane is 0.070(2) Å for C(3)) and has a flattened C(3)-envelope conformation. The phenyl ring is not coplanar with the oxazoline ring (dihedral angle between normals to the mean planes = 28.8°) in spite of conjugation or possible π-interaction between the imidate moiety and the aromatic ring system. The C(1)—C(9) bond length of 1.468 Å is somewhat longer than the comparable $C(sp^2)$–C(ar) distance of 1.450 Å in compound **6** (2), in which the phenyl ring is held in an approximately coplanar orientation with respect to the oxazoline ring by chelate formation via the *ortho*-phenolic ligand. The cyclohexane ring in **4** has a relatively undistorted chair conformation (see Table 4), with the oxygen atom of the spiro-linked oxazoline ring occupying an equatorial position and the methylene substituent (C(3)) in an axial position.

As observed earlier for compounds **6** (2) and **7** (3), the C(1)—N bond in **4** has distinct double bond character. The bond length of 1.317 Å corresponds to a π-bond order between 0.7 and 0.8 on the basis of a bond length vs. bond order plot (17), and resembles the C=N^+ bond distance in **2** (1) and other boron chelates of hydroxamic acids such as **8** (18) and related hydroxamates (19–23). The double bond character of the iminium C=N^+ bond in the open-chain *B,N*-betaine **4** appears to be somewhat reduced relative to that in the cyclic *B,N*-betaines **6** (1.294 Å) and **7** (1.281 Å). The C(1)—O(1) bond in **4** (1.323 Å) is equal in length to the corresponding bond in the oxazoline moiety of **6** (1.323 Å) and similar to the same bond in the oxazoline ring of **7** (1.310 Å), indicative of greatly reduced double bond character of the imidate C—O bonds in all three compounds. The N—O bond distance in **4** (1.371 Å) is similar to those in **6** (1.369 Å) and **7** (1.367 Å), and can also be compared with that in the difluoroboron chelate **8** (1.374 Å).

In the solid state, the shortest intermolecular contacts may represent three weak C—H···F interactions (H···F = 2.47(3), 2.49(3), and 2.55(2) Å). All other intermolecular distances correspond to normal van der Waals interactions.

Received August 31, 1990

WOLFGANG KLIEGEL, UTE SCHUMACHER, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **69,** 1212 (1991).

The reaction of *N*-hydroxy-*N*-[(1-hydroxycyclohexyl)methyl]benzamide with dimethylether-boron trifluoride gives 5,5-penta-methylene-2-phenyl-4,5-dihydrooxazol-*N*-oxide(*N*—*O*—*B*)trifluoroborane [3-(2,2,2-trifluoro-1-oxa-2-borataethyl)-5,5-pentamethylene-2-phenyl-1-oxa-3-azonia-2-cyclopentene] in high yield. Crystals of the product are monoclinic, $a = 8.1147(4)$, $b = 15.448(1)$, $c = 11.4144(6)$ Å, $\beta = 95.133(5)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.043$ and $R_w = 0.058$ for 2178 reflections with $I \geq 3\sigma(I)$. The structure analysis confirms that the title compound has an open-chain boron-nitrogen betaine structure and, as such, is the first isolated and fully characterized open-chain non-chelate boron complex of a cycloimidate *N*-oxide (cyclohydroximate). Bond lengths (corrected for libration) involving the tetrahedrally coordinated boron atom are O—B = 1.530(3) and F—B = 1.370(2)–1.391(2) Å.

Key words: crystal structure, organoboron compound, boron compound.

WOLFGANG KLIEGEL, UTE SCHUMACHER, STEVEN J. RETTIG, et JAMES TROTTER. Can. J. Chem. **69,** 1212 (1991).

La réaction du *N*-hydroxy-*N*-[(1-hydroxycyclohexyl)méthyl]benzamide avec le complexe méthoxyméthane/trifluorure de bore conduit au 5,5-pentaméthylène-2-phényl-4,5-dihydrooxazol-*N*-oxyde(*N*—*O*—*B*)trifluoroborane [3-(2,2,2-trifluoro-1-oxa-2-borataéthyl)-5,5-pentaméthylène-2-phényl-1-oxa-3-azonia-cyclopent-2-ène], avec un rendement élevé. Les cristaux de ce produit sont monocliniques, groupe d'espace $P2_1/c$, avec $a = 8{,}1147(4)$, $b = 15{,}448(1)$ et $c = 11{,}4144(6)$ Å, $\beta = 95.133(5)°$, $Z = 4$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs de $R = 0{,}043$ et $R_w = 0.058$ pour 2178 réflexions avec $I \geq 3\sigma(I)$. L'analyse de la structure confirme que le composé mentionné dans le titre existe sous la forme d'une bétaïne bore/azote à chaîne ouverte et qu'il s'agit ainsi du premier complexe d'un cycloimidate *N*-oxyde (cyclohydroximate)/bore, non-chélaté, en chaîne ouverte à être isolé et complètement caractérisé. Les longueurs de liaison (corrigées pour la libration) impliquant l'atome de bore coordiné d'une façon tétraédrique sont O—B = 1,530(3) et F—B = 1.370(2)–1,391(2) Å.

Mots clés: structure cristalline, composé organoborique, composés du bore.

[Traduit par la rédaction]

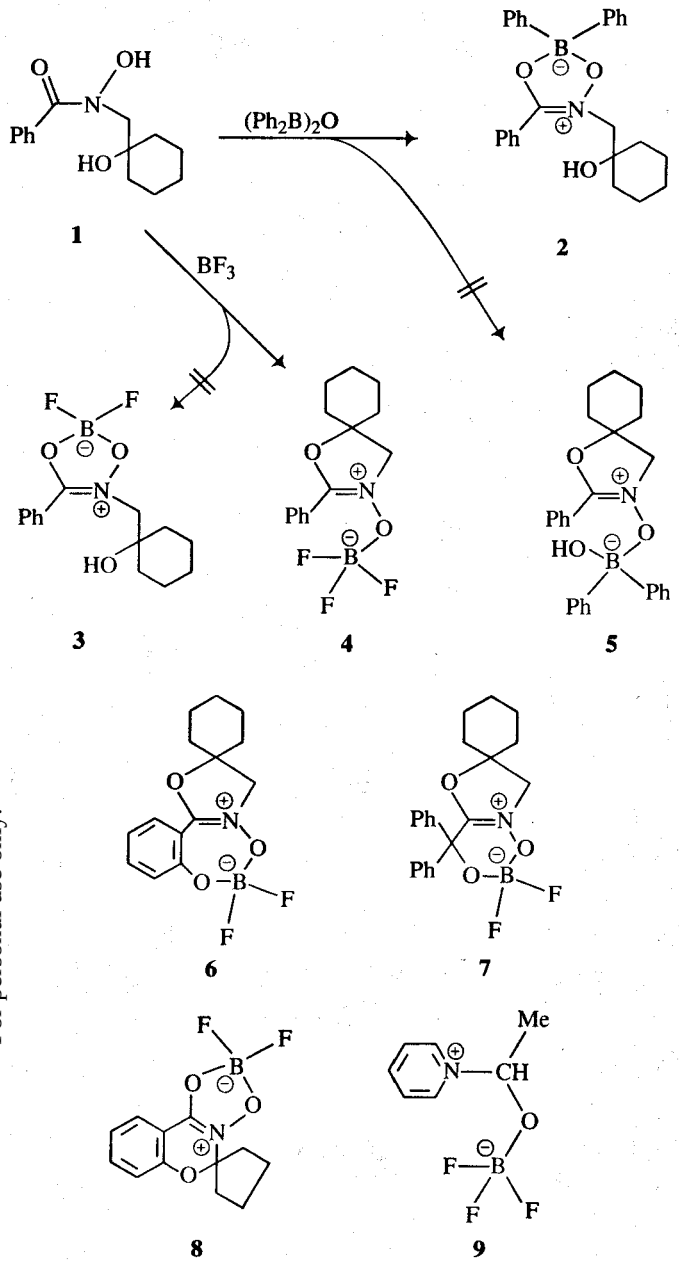
Introduction

The reaction of the *N*-(2-hydroxyalkyl)-benzohydroxamic acid **1** with oxybis(diphenylborane) yields the diphenylboryl hydroxamate **2** having a five-membered boron chelate structure. Alternative isomeric structures include an open-chain adduct **5** of diphenylborinic acid at a 2-oxazoline *N*-oxide moiety, formed by cyclocondensation during the reaction with the Lewis-acid boron compound. The postulated isomer **5**, however, was ruled out by an X-ray crystallographic analysis (1).

Justification for the inclusion of the cyclocondensate structure **5** in structural considerations is based on earlier observations of similar cyclizations during chelate forming reactions of salicylohydroxamic (2) and hydroxyacetohydroxamic acid derivatives (3), and now, in this work, arises from an experiment designed to result in the formation of the difluoroboron chelate **3** via reaction of **1** with boron trifluoride. The elemental analysis, infrared, and ^{1}H nmr data for the resulting crystalline compound are consistent with the loss of one mole of water and the addition of one mole of BF_3 during the course of the reaction, indicating a non-chelate BF_3 complex with the postulated boron – nitrogen betaine structure **4**. The 2-oxazoline *N*-oxide fragment of **4** resembles the identical moieties within the difluoroboron chelates **6** (2) and **7** (3). In addition, the C=N$^+$ stretching vibration in the infrared spectrum of **4** (at 1650 cm^{-1}) is in good agreement with the corresponding C=N$^+$ bands in the spectra of **6** (1660 cm^{-1}) and **7** (1670 cm^{-1}).

To the best of our knowledge, compound **4** is the first isolated open-chain non-chelate boron complex of a cycloimidate *N*-oxide (cyclohydroximate). Thus an X-ray crystallographic analysis of this compound has been undertaken for proof and structural elucidation.

Experimental



*5,5-Pentamethylene-2-phenyl-4,5-dihydrooxazol-*N*-oxide(*N*—*O*—*B*) trifluoroborane, **4***

N-Hydroxy-*N*-[(1-hydroxycyclohexyl)methyl]benzamide, **1** (2.49 g, 10 mmol),[2] is dissolved in 100–150 mL diethylether. Dimethyl ether-boron trifluoride (1.14 g, 10 mmol) is added and the mixture is left standing at room temperature for 12 h. The solvent is then removed *in vacuo*. Crystallization begins upon cooling and/or upon addition of petroleum ether, giving a colorless material. Yield: 2.74 g (92%). M.p. 146–147°C (from CH_2Cl_2/diethyl ether). *Anal.* calcd. for $C_{14}H_{17}BF_3NO_2$: C 56.22, H 5.73, B 3.61, N 4.68; found: C 56.39, H 5.82, B 3.51, N 4.65. Infrared (KBr): 1650 (shoulder at 1660) cm^{-1} (C=N$^+$). ^{1}H nmr (90 MHz, $CDCl_3$/TMS): δ(ppm) = 1.35–1.88 and 1.88–2.30 (m, 6H, and m, 4H, —$(CH_2)_5$—), 4.29 (s, N—CH_2), 7.35–7.77, and 8.18–8.43 (m, 3H, and m, 2H, C_6H_5). Crystals suitable for X-ray analysis were obtained by recrystallization from absolute ether/CH_2Cl_2.

X-ray crystallographic analysis of ***4***

A crystal ca. 0.38 × 0.50 × 0.50 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 39.8–43.3°) measured on a diffractometer with Mo-K_α radiation ($\lambda_{K\alpha1}$ = 0.70930, $\lambda_{K\alpha2}$ = 0.71359 Å). Crystal data at 21°C are as follows

$C_{14}H_{17}BF_3NO_2$ fw = 299.10

Monoclinic, a = 8.1147(4), b = 15.448(1), c = 11.4144(6) Å, β = 95.133(5)°, V = 1425.1(2) Å^3, Z = 4, ρ_c = 1.394 Mg m^{-3}, $F(000)$ = 624, μ(Mo-K_α) = 1.11 cm^{-1}. Absent reflections: $h0l$, l odd, and $0k0$, k odd, uniquely indicate the space group $P2_1/c$ (No. 14).

Intensities were measured with graphite-monochromated Mo-K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.3–10.0° min^{-1} over a range of (0.80 + 0.35 tan θ)° in ω (scan extended by 25% on each side for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every hour of X-ray exposure time throughout the data collection, showed only small random variations. The data were processed[3] and corrected for Lorentz and polarization effects. Of the 3265 independent reflections measured, 2178 (66.7%) had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = [C + 2B + (0.040(C-B))^2]$ with C = scan count, B = normalized total background count.

TABLE 1. Final positional (fractional × 10^5) and isotropic thermal parameters (U × 10^3 Å^2) with estimated standard deviations in parentheses*

*U_{eq} = (1/3) trace (diagonalized U).

The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were refined with isotropic thermal parameters. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 4. The weighting scheme $w = 1/\sigma^2(F)$ gave uniform average values of $w(|F_o|-|F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 258 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.043 and R_w = 0.058 for 2178 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o|-|F_c|)^2$, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o|-|F_c|)^2/\Sigma w|F_o|^2)^{1/2}$. On the final cycle of refinement the maximum parameter shift corresponded to 0.03σ. The mean error in an observation of unit weight was 2.08. The final difference map showed maximum fluctuations of −0.21 to +0.29 e Å^{-3}.

The thermal motion has been analyzed in terms of the TLS model (5). The rms error in the temperature factors U_{ij} (derived from the least-squares analysis) is 0.0010 Å^2. Four structural subunits were separately analyzed (rms ΔU_{ij} = 0.0009–0.0024 Å^2). The bond lengths have been corrected for libration (5, 6) using shape parameters q^2 of 0.08 for all atoms. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1.

[3]Computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN80, Multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

Bond lengths (corrected and uncorrected) and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, bond lengths and angles involving hydrogen, torsion angles, and structure factors have been deposited.[4]

Results and discussion

As already suggested by the spectroscopic data and elemental composition, the crystallographic analysis confirms formula **4**, and thus shows the possibility of cyclocondensation of *N*-(2-hydroxyalkyl)hydroxamic acids in the presence of Lewis acid boron compounds even when chelate-forming reactions such as those observed for the salicylohydroxamate **6** (2) and the hydroxyacetohydroxamate **7** (3) are not involved. The resulting open-chain BF_3-adduct **4** (Fig. 1) is a stable compound and represents a new type of *N*-oxide boron complex with a boron,nitrogen-(1,3)betaine structure (7).

The O(2)BF_3 grouping in **4** has a distorted tetrahedral geometry with bond angles at boron ranging from 103.9(2)° for F(1)—B—O(2) to 113.3(2)° for F(1)—B—F(2). BF_3 itself has a trigonal planar structure both in the gas phase (8) and in the solid state (9, 10). Tetracoordination of the boron atom leads to lengthening of the B—F bonds in **4** (mean 1.382 Å (corr.) and 1.361 Å (uncorr.)) compared to those reported for

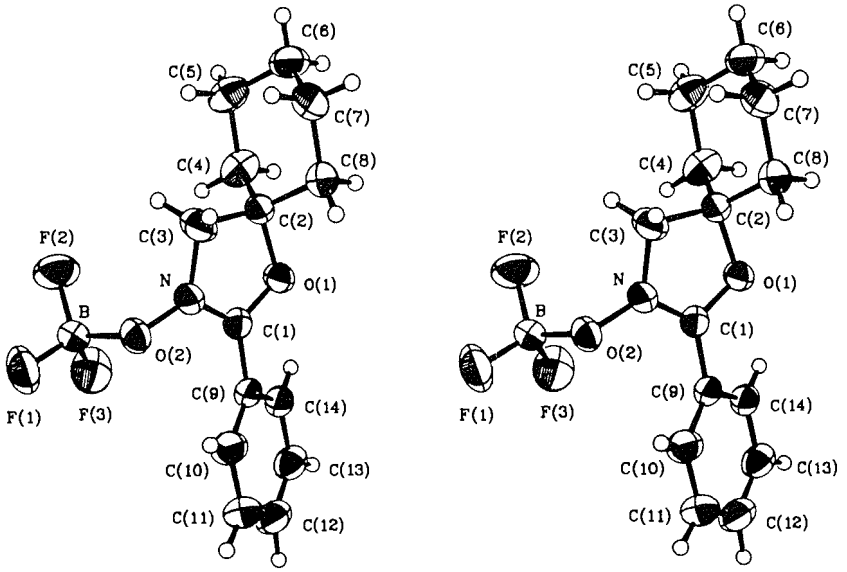

FIG. 1. Stereoview of **4**; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

crystalline BF_3: mean values of 1.278 Å (9) and 1.289 Å (10). This is consistent with a weakening of the $pp(\pi)$-interaction between boron and the fluorine ligands upon complex formation. The mean B—F distance in **4** is greater than the corresponding mean B—F bond length (1.345 Å (uncorr.)) reported for pyridine–BF_3 (11). This could result from stronger coordination in the *N*-oxide BF_3-adduct **4** than in pyridine–BF_3. To the best of our knowledge, there are no other structures of heterocyclic *N*-oxide BF_3 complexes in the literature. It is probably safe to assume that the O—B coordinative bond in zwitterionic N—O—B complexes like **4** is generally stronger than the N—B bonds of comparable, but more sterically hindered, N—B adducts.

The libration-corrected O—B bond length in **4** (1.530 Å) is in good agreement with the O—B distance of 1.533 Å derived from semiempirical MNDO calculations on the BF_3 complex of an acetaldehyde adduct of pyridine, **9** (12), which corresponds to an analogous *B,N*-(1,4)betaine structure. An O—B distance of 1.54 Å has been calculated for the BF_3 complex of dimethylsulfoxide (13). While there is a paucity of structural information reported for BF_3 complexes with basic oxides (14), the crystal structure of the related benzaldehyde–BF_3 adduct features an O—B bond length of 1.591 Å (15). The O—B distance in **4** is very similar to the (C)F—B distance of 1.528(8) Å recently reported for an isoelectronic F_3B–FC linkage in a binuclear ferracyclopentadiene derivative (16). The average terminal B—F distance of 1.37(1) Å for the F_3B—FC adduct is similar to that in **4** (see above).

The five-membered 2-oxazoline ring is nearly planar (maximum deviation from the mean plane is 0.070(2) Å for C(3)) and has a flattened C(3)-envelope conformation. The phenyl ring is not coplanar with the oxazoline ring (dihedral angle between normals to the mean planes = 28.8°) in spite of conjugation or possible π-interaction between the imidate moiety and the aromatic ring system. The C(1)—C(9) bond length of 1.468 Å is somewhat longer than the comparable $C(sp^2)$–C(ar) distance of 1.450 Å in compound **6** (2), in which the phenyl ring is held in an approximately coplanar orientation with respect to the oxazoline ring by chelate formation via the *ortho*-phenolic ligand. The cyclohexane ring in **4** has a relatively undistorted chair conformation (see Table 4), with the oxygen atom of the spiro-linked oxazoline ring occupying an equatorial position and the methylene substituent (C(3)) in an axial position.

As observed earlier for compounds **6** (2) and **7** (3), the C(1)—N bond in **4** has distinct double bond character. The bond length of 1.317 Å corresponds to a π-bond order between 0.7 and 0.8 on the basis of a bond length vs. bond order plot (17), and resembles the C=N^+ bond distance in **2** (1) and other boron chelates of hydroxamic acids such as **8** (18) and related hydroxamates (19–23). The double bond character of the iminium C=N^+ bond in the open-chain *B,N*-betaine **4** appears to be somewhat reduced relative to that in the cyclic *B,N*-betaines **6** (1.294 Å) and **7** (1.281 Å). The C(1)—O(1) bond in **4** (1.323 Å) is equal in length to the corresponding bond in the oxazoline moiety of **6** (1.323 Å) and similar to the same bond in the oxazoline ring of **7** (1.310 Å), indicative of greatly reduced double bond character of the imidate C—O bonds in all three compounds. The N—O bond distance in **4** (1.371 Å) is similar to those in **6** (1.369 Å) and **7** (1.367 Å), and can also be compared with that in the difluoroboron chelate **8** (1.374 Å).

In the solid state, the shortest intermolecular contacts may represent three weak C—H···F interactions (H···F = 2.47(3), 2.49(3), and 2.55(2) Å). All other intermolecular distances correspond to normal van der Waals interactions.

Received September 24, 1990

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **69**, 1217 (1991).

The reaction of *N,N'*-bis(1-cyano-1-methylethyl)-*N,N'*-dihydroxymethanediamine with phenylboronic acid gives 6,8-bis(1-cyano-1-methylethyl)-2,4-diphenyl-1,3,5-trioxa-6,8-diaza-2,4-diboracyclooctane in good yield. Crystals of the product are monoclinic, $a = 9.2681(9)$, $b = 15.946(1)$, $c = 15.491(1)$ Å, $\beta = 95.946(8)°$, $Z = 4$, space group $P2_1/n$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.047$ and $R_w = 0.064$ for 2936 reflections with $I \geq 3\sigma(I)$. The central eight-membered $O(BON)_2C$ ring has a boat–boat ("saddle") conformation and features cross-ring non-bonding N···B distances of 2.475 and 2.755 Å, which are significantly shorter than the sum of van der Waals radii (~3.15 Å). Features of the molecular geometry are consistent with weak dative N → B interactions, particularly in the case of the shorter transannular contact. The formally trigonal boron atom involved in the short interaction is displaced 0.098 Å from the plane of its three substituents towards the nitrogen atom while the corresponding displacement for the other boron atom is 0.017 Å. The C(phenyl)—B distances are equal within experimental error at the two B atoms (1.545(3) and 1.547(3) Å), but the (B)O—B and (to a lesser extent) the (N)O—B bonds to the boron atom involved in the shorter transannular interaction are longer than the others (1.371(3) and 1.392(3) vs. 1.354(3) and 1.388(3) Å). The structure may be thought of as an intermediate in the transition from an eight-membered monocylic system to a bridged ring system.

Key words: crystal structure, organoboron compound, boron compound.

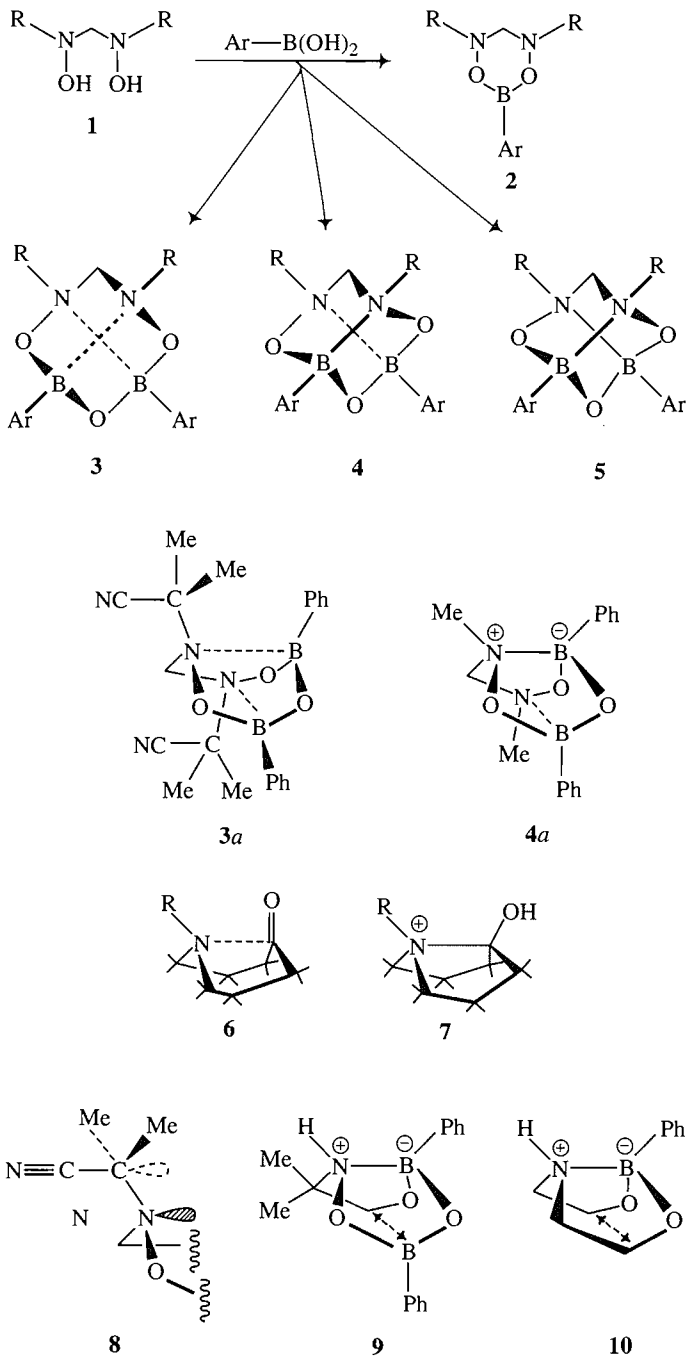
WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **69**, 1217 (1991).

La réaction de la *N,N'*-bis(1-cyano-1-méthyléthyl)-*N,N'*-dihydroxyméthanediamine avec l'acide phénylboronique conduit au 6,8-bis(1-cyano-1-méthyléthyl)-2,4-diphényl-1,3,5-trioxa-6,8-diaza-2,4-diboracyclooctane, avec un bon rendement. Les cristaux de ce produit sont monocliniques, groupe d'espace $P2_1/n$, avec $a = 9,2681(9)$, $b = 15,946(1)$ et $c = 15,491(1)$ Å, $\beta = 95,946(8)°$ et $Z = 4$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0,047$ et $R_w = 0,064$ pour 2936 réflexions avec $I \geq 3\sigma(I)$. Le cycle central à huit chaînons, $O(BON)_2C$ existe dans une conformation bateau–bateau («selle»); les interactions non-liantes N···B à travers le cycle sont caractérisées par des distances de 2,475 et 2,755 Å qui sont beaucoup plus courtes que la somme des rayons de van der Waals (~3,15 Å). Les caractéristiques de la géométrie moléculaire sont en accord avec des interactions datives faibles N → B, en particulier dans le cas du contact transannulaire le plus court. Par rapport au plan de ses trois substituants, l'atome de bore formellement plan trigonal impliqué dans l'interaction la plus courte est déplacé de 0,098 Å vers l'atome d'azote; par comparaison, le déplacement correspondant de l'autre atome de bore est de 0,017 Å. Aux erreurs expérimentales près, les distances C(phényl)—B (1,545(3) et 1,547(3)) sont les mêmes pour les deux atomes de bore; toutefois, les longueurs des liaisons (B)O—B et (à un degré moindre) (N)O—B des atomes de bores impliqués dans l'interaction transannulaire sont plus longues que les autres (1,371(3) et 1,392(3) vs. 1,354(3) et 1,388(3) Å). On peut imaginer que la structure est un intermédiaire dans la transition allant d'un système monocyclique à huit chaînons à un système cyclique ponté.

Mots clés : structure cristalline, composé organoboré, composé boré.

[Traduit par la rédaction]

Introduction



The *N,N'*-dihydroxy-*N,N'*-dialkylaminal **1** reacts with arylboronic acid to give the six-membered cyclocondensate, **2**, provided that the basicity of the aminal nitrogen atom is reduced (e.g. by α-cyanoalkyl substitution) and the boronic acid is sterically hindered (e.g. by *ortho*-substitution of the aryl residue). The structure of the cycloboronate **2***a*, substituted in such a manner (R = $C(CH_3)_2CN$, Ar = 2,4,6-$(CH_3)_3C_6H_2$), has been elucidated by an X-ray crystallographic study (1). In cases of simple *N*-alkyl substitution (R = alkyl) and an unsubstituted phenylboronic acid (Ar = phenyl) the products are bicyclic 1:2 condensates **4** with transannular N → B coordination (2). This was established by an X-ray crystallographic analysis of compound **4***a* (R = CH_3, Ar = C_6H_5) (3).

In this work we describe the reaction of the weakly basic *N,N'*-dihydroxyaminal **1** (R = $C(CH_3)_2CN$) with sterically unhindered phenylboronic acid. Surprisingly this condensation also results in a 1:2 reaction product between the "diol" **1** and the boronic acid, as shown by elemental analysis, nmr and mass spectral data. In the ^{13}C and ^{11}B nmr spectra the "magnetic equivalence" of the carbon nuclei directly attached to N and N' of the aminal function and also of the two boron nuclei suggest an essentially symmetric cyclooctane ring system **3** or, less likely, a highly strained tricyclooctane (dinoradamantane) skeleton **5**. The bicyclo[3.3.0]octane structure **4**, however, cannot be excluded because of possible fluxional behavior in solution leading to nmr signal coalescence during fast topomerization via alternating N→B coordination (2). The presence of an N—B bond, as realized in the bicyclic structure of type **4** in the solid state reported recently (3), would be somewhat contradictory to the assumption of reduced nitrogen donor

capacity as a result of the presence of α-cyano groups in the compound under consideration here. An X-ray crystallographic analysis was undertaken in order to provide detailed information on the structure in the solid state.

Experimental

6,8-Bis(1-cyano-1-methylethyl)-2,4-diphenyl-1,3,5-trioxa-6,8-diaza-2,4-diboracyclooctane, **3**a *(R = $C(CH_3)_2CN$, Ar = C_6H_5)*

N,N'-Bis(1-cyano-1-methylethyl)-*N,N'*-dihydroxymethanediamine **1** (R = $C(CH_3)_2CN$) (4) (1.06 g, 5 mmol) and phenylboronic acid (1.22 g, 10 mmol) are suspended in 20 mL of benzene and refluxed for 1 h with continuous removal of water using a Dean Stark trap. Nearly all of the solvent is distilled off *in vacuo*, and petroleum ether (bp 30–70°C) is added. Upon cooling, colorless crystals are formed. Yield: 1.71 g (85%). Mp 149–150°C (from toluene). *Anal.* calcd. for $C_{21}H_{24}B_2N_4O_3$: C 62.73, H 6.02, B 5.38, N 13.94; found: C 62.73, H 6.05, B 5.41, N 13.91. Infrared (KBr): 2240 (very weak, C≡N), 1600 cm^{-1} (aryl C=C). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.47 (s, 2 CH_3), 1.53 (s, 2 CH_3), 3.90 (s, N—CH_2—N), 7.27–7.60 (m, 6 aromatic H, *m*- and *p*-), 7.77–8.00 (m, 4 aromatic H, *o*-). ^{13}C nmr (100 MHz, $CDCl_3$/TMS): δ (ppm) = 24.57 (2 CH_3), 25.97 (2 CH_3), 57.48 (2 *C*—CN), 72.08 (N—CH_2—N), 119.17 (2 *C*N), 127.94, 131.77, and 134.81 (12 aromatic C). ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$): δ (ppm) = 28.7 (broad). Mass spectrum (70 eV, 60°C): *m/z* = 402 (40%, M^+), 290 (55%, M − H_2C=N(O)—C(CN)$(CH_3)_2$), 275 (100%, M − H_2C=N(O)—C(CN)$(CH_3)_2$—CH_3), 236 (8%), 181 (12%, $C_6H_5BOC_6H_5$), 105 (13%, C_6H_5BOH), 77 (12%, C_6H_5), 68 (6%, $(CH_3)_2C(CN)$). The main fragmentation scheme is shown in Fig. 1.

Crystals suitable for X-ray analysis were obtained by recrystallization from toluene.

X-ray crystallographic analysis of **3**a

A crystal ca. 0.30 × 0.32 × 0.45 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least squares on setting angles for 25 reflections (2θ = 82.2–102.3°) measured on a diffractometer with Cu-K_α radiation (λ = 1.54178 Å). Crystal data at 21°C are as follows

$C_{21}H_{24}B_2N_4O_3$ f.w. = 402.07

Monoclinic, *a* = 9.2681(9), *b* = 15.946(1), *c* = 15.491(1) Å, β = 95.946(8)°, *V* = 2277.0(3) $Å^3$, *Z* = 4, ρ_c = 1.173 Mg m^{-3}, *F*(000) = 848, μ(Cu-K_α) = 5.98 cm^{-1}. Absent reflections: 0*k*0, *k* odd, and *h*0*l*, *h* + *l* odd, uniquely indicate the space group $P2_1/n$ (No. 14).

Intensities were measured with graphite-monochromated Cu-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of (1.15 + 0.20 tan θ)° in ω (with up to eight rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 155°. The intensities of three check reflections, measured every 200 reflections throughout the data collection, showed only small random variations. After data reduction,[2] an empirical

*$B_{eq} = (8/3)\pi^2\Sigma\Sigma U_{ij}a_i^*a_j^*(\mathbf{a}_i\cdot\mathbf{a}_j)$.

absorption correction, based on azimuthal scans for three reflections, was applied. Transmission factors range from 0.86 to 1.00. Of the 4964 reflections measured, 4690 were unique (R_{int} = 0.016) and 2936 (62.6%) had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = [S^2(C + 4B) + 0.035F^2)^2]/Lp^2$ with S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å, $B_H = 1.2B_{bonded\ atom}$). A correction for secondary extinction was applied, the final value of the extinction coefficient being 4.95×10^{-6}. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 5. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix least-squares refinement of 272 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.047 and R_w = 0.064 for 2936 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.08σ. The mean error in an observation of unit weight was 2.24. The final difference map showed maximum fluctuations of ±0.16 e Å^{-3}. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, bond lengths and angles involving hydrogen, and structure factors have been deposited.[3]

Results and discussion

The X-ray analysis confirms an eight-membered cyclic pyroboronate structure of the type **3** for compound **3***a* (see Fig. 2). The eight-membered ring has a distorted boat–boat ("saddle") conformation (see Table 4) which is generally only adopted when attractive transannular interactions occur. Analogous conformations for other medium-size heterocyclic rings are also known to be stabilized by such interactions (6). Transannular interactions in **3***a* are possible between the suitably placed donor–acceptor pairs N(1)···B(2) and N(2)···B(1). The intramolecular non-bonded distances of 2.755(3) and 2.475(3) Å, respectively, are suggestive of possible weak dative interactions, particularly in the latter case. Both of these N···B contacts are considerably shorter than the sum of van der Waals radii (~3.15 Å), and they are also shorter than the non-bonding intramolecular N···B contact of 3.082 Å in **4***a* (3) which lies at the upper end of the range between the transannular N—B bond in **4***a* (1.742 Å) and a van der Waals contact. If both of the weak transannular N···B contacts in **3***a* are looked upon as weak dative bonds the ring skeleton of **3** corresponds roughly to a widened form of the tricyclic ("dinoradamantane") skeleton of **5**, which is "half-realized" in the bicyclooctane framework of **4**.

Further support for the significance of the transannular interactions in **3***a* comes from comparison with non-bonded distances in molecules having ring systems geometrically similar to that in **4***a*: C···B = 3.416 Å in **9** (7) and C···C = 3.812 Å in **10** (8). The C···B distance in **9** is expected to be longer than the corresponding N···B distance in **4***a* because of the methylene group in the place of the amine function. The corresponding C···C contact in **10** is strictly non-bonding. Steric strain, particularly that imposed by ring fusion resulting from the formation of the relatively short transannular N—B bond, is most likely responsible for the longer non-bonding

N···B distance in **4***a* compared with that in **3***a*. The better donor qualitifes of the aminal nitrogen atoms in **4***a*, which are responsible for the formation of the "normal" transannular N—B bond, should otherwise lead to shorter N···B distances than in **3***a* with its weakly basic aminal nitrogen atoms.

Considering the difference between the two N···B distances in **3***a* (the N(2)···B(1) contact is 0.28 Å shorter) and the even larger difference between the N—B bond and the N···B contact in **4***a*, along with the general geometry of both molecules, the structure of **3***a* may be thought of as an intermediate in the transition from an eight-membered monocyclic system to the bridged-ring system of **4***a*. Similar relationships have been discussed for cyclic aminoketones **6** (with incipient nucleophilic addition of the amino group to the carbonyl function) and their transannular reaction products **7** (9). X-ray structure analyses of several eight-membered aminoketones **6** revealed transannular N···C(O) non-bonding distances between 2.46 and 2.76 Å (10) while the reaction products **7** show an N^+—C bond length of 1.64 Å (ref. 6, p. 126). These distances are very similar to the analogous N···B/N—B distances in **3***a* and **4***a*. The displacements (towards the cross-ring nitrogen) of the two boron atoms in **3***a* from the planes defined by their substituent atoms are 0.098(2) Å for B(1) and 0.017(2) Å for B(2). The value for B(2), while statistically significant, is not really consistent with any appreciable pyramidalization; values similar to this might easily arise from inter- and/or intramolecular steric forces. The value for B(1) (involved in the shorter of the transannular N···B interactions), however, is substantially larger and since there are no unusually short inter- or intramolecular contacts involving the relevant phenyl and —CMe_2(CN) substituents, indicates partial pyramidalization. If the weak interaction with N(2) is considered, the overall geometry at B(1), an axially elongated trigonal pyramid, is consistent with a system not far along the pathway between trigonal planar and tetrahedral.

The detailed geometry about the boron and nitrogen atoms in **3***a* is also consistent with a weak but significant interaction between B(1) and N(2). The partial pyramidalization of B(1) can also be inferred from the sum of the bond angles at B(1) involving the O and C atoms, 358.6(3)°. The corresponding value for B(2) is 359.9(3)°. The B—C(aryl) distances (1.545(3) and 1.547(3) Å) are nearly the same as that involving the sp^2-boron atom in **4***a* (1.548 Å). The B—O(N) distances do not differ significantly, but that involving B(1) is marginally longer (1.392(3) vs. 1.388(3) Å). Within the anhydridic B(1)—O(2)—B(2) portion of the ring the B—O distance of 1.371(3) Å involving B(1) is significantly longer than that of 1.354(3) Å for B(2) indicative of reduced O—B $pp(\pi)$ interaction, and hence reduced double bond character of the O—B bonds at B(1) relative to B(2). The difference between the two transannular N···B contacts in **3***a* is also reflected by the C—N bonds of the aminal function: C(1)—N(2) (1.467(2) Å) is longer than C(1)—N(1) (1.454(3) Å) in accordance with the increased positive charge at N(2). In compound **4***a* this difference is more pronounced as a result of the greater charge

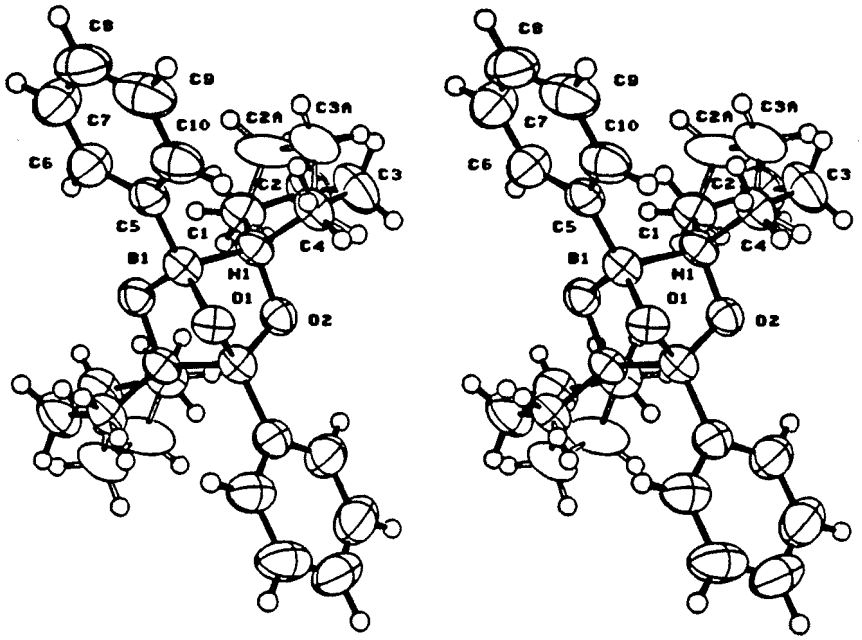

FIG. 2. Stereoview of **3***a*; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

difference between the two ring nitrogen atoms: N^+—CH_2 = 1.479, N—CH_2 = 1.452 Å (3). As in **4***a* (3) the N—O bonds of **3***a* show a similar small difference in length, that at the nitrogen atom having the higher positive charge (N(2)—O(3) = 1.446(2) Å) being shorter than that at the other nitrogen atom (N(1)—O(1) = 1.452(2) Å). Once again this difference is less pronounced than in **4***a* where N^+—O = 1.447 and N—O = 1.462 Å. In the six-membered monocyclic arylboronate **2***a* there are no such differences in aminal N—C and N—O bond lengths between the chemically equivalent nitrogen atoms (1).

Similar to **2***a* (1) the α-cyanoalkyl moieties of **3***a* show evidence of stereoelectronic (anomeric) effects. An antiperiplanar orientation of both nitrogen electron pairs with respect to the α-positioned cyano groups, **8**, enables some overlap between the nitrogen *n*-orbitals and the σ* orbitals of the adjacent C—C(cyano) bond, resulting in relatively short C—N(amine) and long C—C(cyano) bonds (the C(2)—N(1) = 1.472(3) and C(6)—N(2) = 1.480(3) Å bond lengths are not significantly different from the usual value of 1.472(5) Å for three-coordinate nitrogen N—C bonds, but the C(2)—C(3) = 1.474(4) and C(6)—C(7) = 1.479(4) Å bonds are significantly longer than the normal C—C(cyano) bond length of 1.44(1) Å). This effect is not as marked as that observed for **2***a*, probably a consequence of the competition for the nitrogen lone pair by the transannular interaction with the unoccupied boron p_z orbitals in **3***a*.

Unlike the monocyclic arylboronate **2***a* (1) which has opposite configurations (*R*,*S*) at the two amine centres, **3***a* has the same configuration at both nitrogen atoms. The molecule shown in Fig. 2 is the (6*R*,8*R*)-enantiomer, the centrosymmetric crystals containing equal numbers of the (6*R*,8*R*)- and (6*S*,8*S*)-enantiomers. If the boron atoms in **3***a* are also considered tetracoordinate the relative configuration is (2*SR*,4*SR*,6*RS*,8*RS*),[4] comparable to that observed for the bicyclic compound **4***a* (3).

As is typical for sterically unhindered arylboronate derivatives, the phenyl rings are approximately coplanar with the O_2BC mean planes. The dihedral angles between normals to the phenyl and O_2C planes are 7.8° for B(1) and 2.1° for B(2). The shortest intermolecular contact involving non-hydrogen atoms, N(4)···C(11) = 3.418(3) Å, corresponds to a normal van der Waals interaction.

The reaction of *N*-hydroxypyrrolidine with either oxybis(diphenylborane) or phenylboronic acid gives 1,4-diphenyl-3,3:6,6-bis(tetramethylene)-2,5,7-trioxa-3,6-diazonia-1,4-diboratabicyclo[2.2.1]heptane in moderate yield. Crystals of the product are orthorhombic, $a = 10.984(2)$, $b = 14.619(2)$, $c = 12.311(2)$ Å, $Z = 4$, space group *Pccn*. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.039$ and $R_w = 0.043$ for 908 reflections with $I \geq 3\sigma(I)$. This is the first heterocyclic [2.2.1]heptane system containing a six-membered BONBON ring and a B—O—B bridge to be structurally characterized. The molecule has exact C_2 symmetry with the twofold axis passing through the bridging oxygen atom. Bond lengths involving the tetrahedrally coordinated boron atom are B—O(B) = 1.423(3), B—O(N) = 1.497(3), B—N = 1.703(3), and B—C(phenyl) = 1.577(4) Å.

Key words: 2,5,7-trioxa-3,6-diazonia-1,4-diboratabicyclo[2.2.1]heptane ring system, crystal structure, organoboron compound.

WOLFGANG KLIEGEL, ULF RIEBE, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **69**, 1222 (1991).

La réaction de la *N*-hydroxypyrrolidine avec soit l'oxybis(diphénylborane) ou l'acide phénylboronique conduit au 1,4-diphényl-3,3:6,6-bis(tétraméthylène)-2,5,7-trioxa-3,6-diazonia-1,4-diboratabicyclo[2.2.1]hepatane, avec un rendement raisonnable. Les cristaux de ce produit sont orthorhombiques, groupe d'espace *Pccn*, avec $a = 10{,}984(2)$, $b = 14{,}619(2)$ et $c = 12{,}311(2)$ Å et $Z = 4$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de $R = 0{,}039$ et $R_w = 0{,}043$ pour 908 réflexions avec $I \geq 3\sigma(I)$. Il s'agit du premier système hétérobicyclo[2.2.1]heptane comportant un cycle à six chaînons BONBON et un pont B—O—B à être caractérisé d'un point de vue structural. La molécule possède une symétrie C_2 exacte, avec un axe binaire passant par l'atome d'oxygène qui crée le pont. Les longueurs des liaisons impliquant l'atome de bore coordiné d'une façon tétraédrique sont : B—O(B) = 1,423(3), B—O(N) = 1,497(3), B—N = 1,703(3) et B—C(phényl) = 1,577(4) Å.

Mots clés : système cyclique 2,5,7-trioxa-3,6-diazonia-1,4-diboratabicyclo[2.2.1]heptane, structure cristalline, composé organoboré.

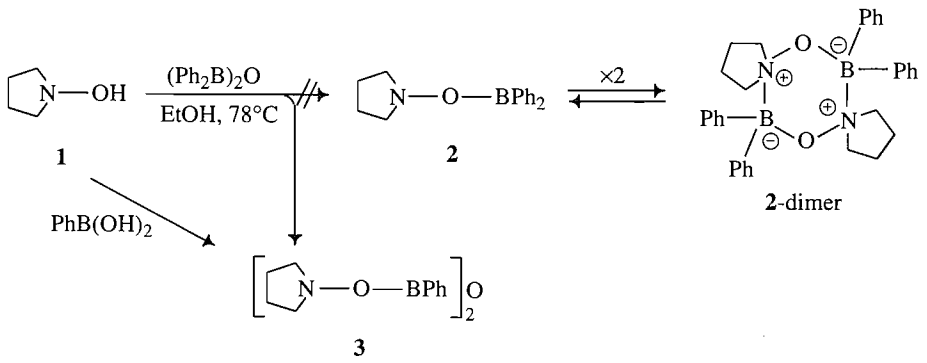
Introduction

The reaction of *N*-hydroxypyrrolidine, **1**, and oxybis(diphenylborane) in boiling ethanol did not lead to the diphenylboryloxyamine **2** or its dimer, but resulted instead in the formation of a crystalline product with analytical data consistent with an oxybis(B-pyrrolidinoxy-phenylborane) structure **3**. Compound **3** was identified by elemental analysis, ^{1}H nmr spectroscopy, reaction with diphenylcarbazone,[2] and also by synthesis via condensation of **1** with phenylboronic acid. Three possible structures for the product **3** were considered. The open-chain pyroboronate **3***A*, similar to the ethylboronate **4** proposed as an intermediate in the oxidation of O-(diethylboryl)-acetone oxime (2), can be ruled out on the basis of the ^{11}B nmr chemical shift for **3** ($\delta(Et_2OBF_3) = 9.0$ ppm) which is consistent with a tetrahedral boron species. A trigonal planar phenylboronate with ester and anhydride functions would be expected to display an ^{11}B δ value of approximately 30 ppm (3). Compound **4** has an ^{11}B resonance at 19 ppm (2), intermediate between the above-mentioned values.

The five-membered chelate structure **3***B*, derived from **3***A* by intramolecular N → B coordination, possesses the BOBON ring system present in diphenylboron chelate **5**, the structure of which has been determined by an X-ray crystallographic analysis (4). The ^{11}B nmr spectrum of **5**, however, displays two separate signals at δ = 10.5 and 30.3 ppm (5) as was expected from the presence of two different types of boron atoms (sp^2 and sp^3). Compound **3** displays only one signal in its ^{11}B nmr spectrum, suggesting either fluxional behavior of **3***B* with both boron and both nitrogen atoms involved, a symmetrical bicyclic structure **3***C* with a reasonably strained norbornane ring skeleton, or (less likely) intermolecular N → B adducts of **3***A*. Structure **3***C* represents, formally, an intramolecular N → B adduct of **3***B* or the twofold intramolecular adduct of **3***A*. A somewhat similar strained bicyclic ring system has recently been characterized for compound **6** (6). For unambiguous proof of the bicyclo[2.2.1]heptane structure **3***C* at least in the solid state, an X-ray crystallographic analysis of **3** was performed.

Experimental

1,4-Diphenyl-3,3:6,6-bis(tetramethylene)-2,5,7-trioxa-3,6-diazonia-1,4-diboratabicyclo[2.2.1]heptane, **3**C



Method (*a*): *N*-hydroxypyrrolidine (0.88 g, 5 mmol) and oxybis(diphenylborane) (0.87 g, 2.5 mmol) are dissolved in 20 mL of ethanol and the mixture is refluxed for 30 min. The solvent is distilled off *in*

The substance gives a red color reaction with diphenylcarbazone (1%) in methanolic soluton. Crystals of **3***C* suitable for X-ray analysis were obtained by method (*a*) without recrystallization.

X-ray crystallographic analysis of **3**C

A crystal ca. 0.35 × 0.43 × 0.50 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 20.1–34.0°) measured on a diffractometer with Mo-K_α radiation (λ = 0.71069 Å). Crystal data at 21°C are as follows

$C_{20}H_{26}B_2N_2O_3$ f.w. = 364.06

Orthorhombic, a = 10.984(2), b = 14.619(2), c = 12.311(2) Å, V = 1976.8(5) $Å^3$, Z = 4, ρ_c = 1.223 Mg m^{-3}, $F(000)$ = 776, μ(Mo-K_α) = 0.75 cm^{-1}. Absent reflections: 0*kl*, *l* odd, *h*0*l*, *l* odd, and *hk*0, *h* + *k* odd, uniquely indicate the space group *Pccn* (No. 56).

Intensities were measured with graphite-monochromated Mo-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 16° min^{-1} over a range of (1.20 + 0.35 tan θ)° in ω (with up to eight rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random variations. After data reduction,[3] an empirical absorption correction, based on azimuthal scans for three reflections, was applied. Transmission factors range from 0.95 to 1.00. Of the 2269 independent reflections measured, 908 (40.0%) had intensities greater than or equal to 3σ(F^2) above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.035F^2)^2]/Lp^2$ with S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor. The relatively small fraction of data having significant intensity is due to the inclusion of reflections with 2θ between 45 and 55°, of which only about 10% were "observed."

The structure was solved by direct methods. The molecule is situated on a crystallographic C_2 axis which passes through the bridging oxygen atom O(1). The pyrrolidine ring was found to be twofold conformationally disordered (78:22), the peripheral atoms C(2) and C(3) were refined using a split-atom twofold disordered model. The site occupancy factors were initially estimated from Fourier map peak heights and were subsequently adjusted (but not refined) to result in approximately equal equivalent isotropic thermal parameters for the two well-resolved components. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å, B_H = 1.2 $B_{bonded\ atom}$). A correction for secondary extinction was applied, the final value of the extinction coefficient being 1.23 × 10^{-6}. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 7. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 142 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.039 and R_w = 0.043 for 908 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.01σ. The mean error in an observation of unit weight was 1.89. The final difference map showed maximum fluctuations of ±0.12 e $Å^{-3}$. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, bond lengths and angles involving hydrogen, and structure factors have been deposited.[4]

Results and discussion

The X-ray analysis shows that compound **3** indeed forms the bicyclic twofold N—B adduct **3***C* in the solid state (see Fig. 1). The ^{11}B nmr spectrum, which is consistent with the presence of tetracoordinated boron, suggests that the structure **3***C* is stable in solution as well as in the solid state. To the best of our knowledge this is the first example of a full heterocyclic "norbornane" ring system of the BONBON type with a B—O—B

bridge. Similar B—O—B bridges have previously been found in the less strained bicyclo[3.3.1]nonane skeletons of various boron heterocycles such as **7** (8) and, similarly, in acyloxy- or acylamino-derivatives of boric or boronic acids of the type **8** (9–11).

The molecule **3***C* has exact C_2 symmetry in the solid state, the ring skeleton being similar to that of 7-oxabicyclo[2.2.1]heptane, **9**, which has been shown to possess C_{2v} symmetry in the gas phase by microwave spectroscopy (12). The angle at the B—O—B bridge in **3***C* (98.0(3)°) is somewhat larger than the corresponding angle of 95.3° in **9** (12) and similar to values of 97.4° and 96.6° reported for other derivatives of 7-oxabicyclo-[2.2.1]heptane (13) and 7-oxabicyclo[2.2.1]hept-2-ene (14), respectively. All of these oxygen-bridged species show angles at the bridging oxygen atom larger than the 93.1 angle at the bridging methylene group in norbornane itself (15). The bond angles at the bridging oxygen atoms of the less strained bicyclo[3.3.1]nonane derivatives **7** and **8** are substantially larger: 110.1–111.9° in **7** (16), 109.9° in **8***a* (R = CH_3, X = CH_3COO, Y = O) (9), 108.6° in **8***b* (R = CH_3, X = F, Y = O) (10), and 110.9° in **8***c* (R = CF_3, X = Cl, Y = 2,6-$(CH_3)_2C_6H_3N$) (11).

The N—B bond in **3***C* (1.703(3) Å) is shorter than that in the monocyclic compound **5** (1.728 Å) (4) which contains a similar BOBON ring system. The N—B bond in **5**, however, is subject to more steric hindrance and one of the boron atoms in **5** is sp^2 hybridized and involved in a pp(π) interaction with the hydroxylamine oxygen atom. This is reflected by the considerable difference between the (sp^3)B—O(N) distance of 1.497(3) Å in **3***C* and the (sp^2)B—O(N) distance of 1.422 Å in **5** (4). The (sp^3)B—C(phenyl) bond in **3***C* (1.577(4) Å) is about 0.02 Å longer than the (sp^2)B—C(phenyl) bond in **5** (1.553 Å) (4) and other phenylboronates containing similar BOBON rings (1.548–1.559, mean 1.554 Å) (17–21). The (sp^3)B—C(phenyl) bond in the present structure is the shortest yet observed for a "$PhBO_2N$" compound and is comparable to the recently reported (sp^3)B—C(phenyl) distance of 1.579 Å (21) in a bicyclic pyroboronate with relatively weak transannular N—B bonding. The steric constraints imposed by the formation of the bicyclo[2.2.1]heptane system are at least partly responsible for the shortness of the (sp^3)B—C(phenyl) bond in **3***C*. With the boron atoms in the bridgehead positions, ring constraints result in larger than tetrahedral bond angles about the boron atom involving the phenyl carbon atom (average C—B—O/N = 115.6°). This leads to increased *s*-character in the hybrid orbital at boron involved in the B—C bond and hence a shorter bond distance. As discussed in an earlier paper (22), the sum of all four bonds to boron in tetrahedral "$PhBO_2N$" compounds remains essentially constant. In the present case the short B—C bond is balanced by a relatively long N—B bond. The (sp^3)B—C(phenyl) bond length in the phenylboronate complex **6** (6) of 1.591 Å lies within the range of 1.582 to 1.633 Å reported for (sp^3)B—C(phenyl) distances in other phenylboronate complexes (17–19, 22–28).

The (sp^3)B—O—B(sp^3) bridge in **3***C* (sum of bond lengths 2.846 Å) is, as expected, longer than the (sp^3)B—O—B(sp^2) bridge in **5** (2.816 Å) which contains a characteristic very short anhydridic (sp^2)B—O bond (1.329 Å) and an (sp^3)B—O bond of 1.487 Å (4). The difference of about 0.07 Å between the two types of B—O bonds in **3***C* is roughly the same as the mean difference of 0.05 Å between the (sp^3)B—O(B) and (sp^3)-B—O(N) bonds in the tricyclic compound **10** (22) which incorporates a twisted BONBON boat with a B—OBO—B

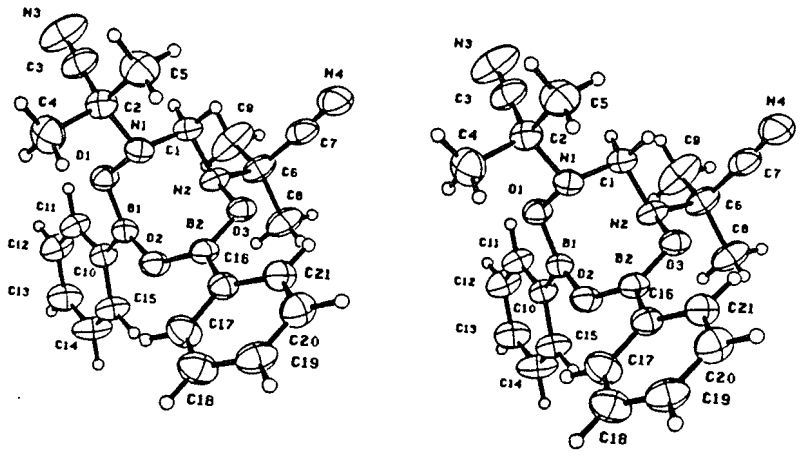

FIG. 1. Stereoview of **3***C*; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

bridge, the shorter bond always being the anhydridic "pyroboronate" B—O bond. The bond lengths within the B—O—N sequence in **3***C* (1.497(3) and 1.447(2) Å, respectively) are not significantly different from those in **10** (1.497 and 1.443, 1.492 and 1.452 Å). The main differences between the BONBON moieties in the two compounds are in the N—B bonds (**3***C*: 1.703(3) Å, **10**: 1.649 and 1.658 Å) and in the degree of distortion of the BONBON heterocycle.

Both possible conformations of the pyrrolidine ring (resulting from the disordering of atoms C(2) and C(3)) correspond to slightly distorted *N*-envelopes with the nitrogen atom displaced 0.512(2) Å from the C(1)C(2)C(3)C(4) mean plane and 0.338(2) Å from the C(1)C(2A)C(3A)C(4) mean plane. There are some very short intermolecular distances across the centre of symmetry at (1/2, 0, 1/2) involving the 22% occupied disordered sites (C(2A) ... C(3A) = 2.84(2), C(3A) ... C(3A) = 2.98(4), H(4A) ... H(6A) = 1.33 Å, and three C ... H contacts in the range 1.96–2.37 Å). Adjacent molecules can therefore not both have the minor sites occupied. These short intermolecular contacts are also most likely responsible for the unbalanced occupancies of these otherwise equivalent sites. The phenyl ring is planar within experimental error with the boron atom lying in the phenyl mean plane (displacement 0.001(3) Å).

Received November 2, 1990

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **69**, 1227 (1991).

The preparation of *N,N'*-bis(1-phenyl-2-nitroethyl)-*N,N'*-dihydroxymethanediamine and its subsequent reaction with 4-methoxyphenylboronic acid to yield 4,6-bis(1-phenyl-2-nitroethyl)-2-(4-methoxyphenyl)-1,3-dioxa-4,6-diaza-2-boracyclohexane are described. Crystals of the latter compound are monoclinic, a = 8.4790(8), b = 16.2100(9), c = 9.4367(6) Å, β = 109.342(5)°, Z = 2, space group $P2_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.032 and R_w = 0.039 for 1749 reflections with $I \geq 3\sigma(I)$. The molecule has a six-membered BONCNO cycloboronate structure. Bond lengths involving the trigonal planar boron atom are (N)O—B = 1.362(4) and 1.364(5), (aryl)C—B = 1.548(4) Å.

Key words: organoboron compound, crystal structure, cycloboronate, methanediamine.

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **69**, 1227 (1991).

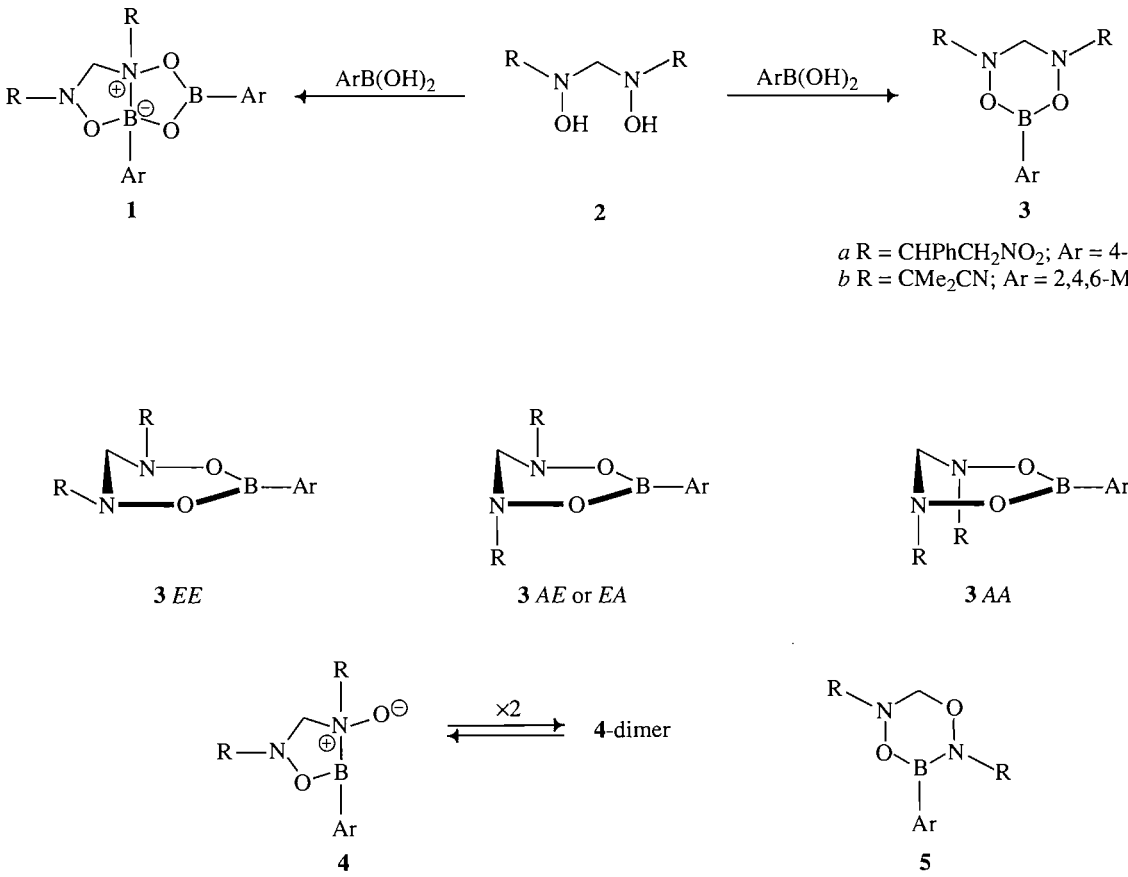
On décrit la préparation de la *N,N'*-bis(1-phényl-2-nitroéthyl)-*N,N'*-dihydroxyméthanediamine et sa réaction subséquente avec l'acide 4-méthoxyphénylboronique qui conduit au 4,6-bis(1-phényl-2-nitroethyl)-2-(4-méthoxyphényl)-1,3-dioxa-4,6-diaza-2-boracyclohexane. Les cristaux de ce dernier composé sont monocliniques, avec a = 8,4790(8), b = 16,2100(9) et c = 9,4367(6) Å, β = 109,342(5)°, Z = 2 et groupe d'espace $P2_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode directes et on l'affinée par la méthode des moindres carrés jusqu'à des valeurs respectives de R = 0,032 et R_w = 0,039 pour 1749 réflexions avec $I \geq 3\sigma(I)$. La molécule contient une structure cycloboronate BONCNO à six chaînons. Les longeurs des liaisons impliquant l'atome de bore plan trigonal sont (N)O—B = 1,362(4) et 1,364(5), (aryl)C—B = 1,548(4) Å.

Mots clés : composé organoboré, structure cristalline, cycloboronate, méthanediamine.

[Traduit par la rédaction]

Introduction

The condensation of a newly synthesized *N*-(β-nitroalkyl) substituted dihydroxyaminal **2***a* (R = $CHPhCH_2NO_2$) with *p*-methoxyphenylboronic acid (Ar = 4-$MeOC_6H_4$) did not lead to the 1:2 reaction product with the general structure **1** which is the usual product of the reaction of simple *N*-alkyl derivatives **2** with arylboronic acids (1, 2). The elemental analysis and spectral data for the isolated crystalline substance was consistent with a 1:1 condensation product of **2***a* and the boronic acid, having a probable structure **3**. As we have recently reported (3), a six-membered cyclic arylboronate **3***b* has been obtained by condensation of a weakly basic aminal **2***b* (R = CMe_2CN) with a sterically hindered arylboronic acid (Ar = 2,4,6-$Me_3C_6H_2$). On the basis of this result, the formation of a cyclic condensate **3***a* would be plausible on the grounds of an attenuation of the basicity at the aminal nitrogen centres by the electron-withdrawing β-nitroalkyl residues. The arylboronic acid moiety in **3***a*, however, is not hindered sterically, but its Lewis acidity may perhaps be reduced by the inductive and mesomeric effects of the *p*-methoxy group (4).



In compound **3***b* both of the bulky *N*-cyanoalkyl substituents were found to occupy equatorial positions of a semiplanar ring ("sofa" conformation) **3 EE**, most likely stabilized by the minimization of steric interactions (3). For compound **3***a*, having less bulky *N*-alkyl substituents, the axial-equatorial isomer (**3 AE or EA**) must be considered. Axial-equatorial isomers are known to be the predominant form present in solutions of 3,5-dimethyl-1-oxa-3,5-diazacyclohexane (5), the only form present in solutions of a related seven-membered cyclic aminal (6), and in equilibrium with other isomers in solutions of simple 1,3-diazacyclohexanes (7). The axial-axial conformer **3 AA** is thought to be highly unfavorable due to 1,3-*syn*-diaxial steric interaction, inducing the inversion at nitrogen leading to **3 AE/EA** or the ring inversion converting **3 AA** directly to **3 EE**. Other possible structures for the condensation product include the five-membered ring system **4** or its dimer, and the six-membered cycloboronate **5**, which could be considered as a rearrangement product of **4** resulting from an aminal-*N*-oxide rearrangement to an *N,O*-acetal (8).

Infrared and nmr spectroscopic data do not allow for an unambiguous assignment of one of the alternative structures **3–5**. In the ^1H nmr spectrum, two different signals were found for the CH_2 protons of the aminal methylene group, one predominant signal at 3.68 ppm (65–80% of the total peak area for CH_2) and another signal at 3.58 ppm (20–35%). It is not yet clear whether this phenomenon results from an equilibrium between two forms in solution, or from partial decomposition in the chosen solvent.[2] An X-ray crystallographic study has been

[1]Previous paper in this series: ref. 18.

[2]*N*-(β-Nitroalkyl)aminals of the type **2***a* seem to be quite unstable compounds (see Experimental section). Preliminary variable-temperature nmr studies of the cycloboronate **3***a* show broadening and splitting of the dominant methylene signal into an AB pattern at lower temperatures, the minor signal remaining unaffected.

undertaken in order to determine the structure and conformation of this material in the solid state.

Experimental

N,N′-Bis(1-phenyl-2-nitroethyl)-N,N′-dihydroxymethanediamine, 2a

N-(1-Phenyl-2-nitroethyl)-hydroxylamine (9) (5.46 g, 30 mmol) is dissolved, with slight heating, in 30 mL ethanol (96%). The solution is cooled down to room temperature and mixed with aqueous formaldehyde (15 mmol of a 40% solution). Stirring is continued until crystallization commences. The solution is then cooled down to −18°C and, after 6 h, filtered. The crystalline precipitate is washed with ethanol.[3] Yield: 3.27 g (58%). Melting point 116–117°C (from ethanol/petroleum ether). *Anal.* calcd. for $C_{17}H_{20}N_4O_6$: C 54.25, H 5.36, N 14.89; found: C 54.21, H 5.39, N 14.82. Infrared (KBr): 3180 (O—H), 1600 (C⋯C, weak), 1550 cm^{-1} (NO_2). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 3.50 (s, N—CH_2—N), 4.22–5.02 (ABX pattern, 2 CH_2CH), 7.08–7.52 (m, 2 C_6H_5), 9.35 (s, 2 OH, exchangeable). Mass spectrum (70 eV, 60°C): *m/z* = 150 (25%, $C_6H_5CHCH_2NO_2$), 104 (100%, $C_6H_5CHCH_2$), 91 (12%, C_7H_7), 77 (19%, C_6H_5).

4,6-Bis(1-phenyl-2-nitroethyl)-2-(4-methoxyphenyl)-1,3-dioxa-4,6-diaza-2-boracyclohexane, 3a

2*a* (0.75 g, 2 mmol) and 4-methoxyphenylboronic acid (0.30 g, 2 mmol) are suspended in 20 mL of benzene and refluxed for 1 h with continuous removal of water using a Dean Stark trap. After partial evaporation of the solvent *in vacuo*, petroleum ether (bp 30–75°C) is added. Colorless crystals form upon slow cooling. Yield: 0.85 g (86%). Melting point (decomp.) 148–149°C (from benzene). *Anal.* calcd. for $C_{24}H_{25}BN_4O_7$: C 58.56, H 5.12, B 2.20, N 11.38; found: C 58.53, H 5.17, B 2.48, N 11.38. Infrared (KBr): 1600 (C⋯C), 1555 cm^{-1} (NO_2). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 3.58 and 3.68 (s and s, 20–35% and 65–80%,[4] N—CH_2—N), 3.78 (s, OCH_3), 4.35–5.33 (overlapping ABX systems, 2 CH_2CH), 6.85 and 7.50 (dd, *J* = 9 Hz, B—C_6H_4), 7.00–7.35 (m, 2 C_2H_5). Mass spectrum (70 eV, 150°C): *m/z* = 492 (9%, M^+), 432 (4%, M − CH_2NO_2), 372 (6%, M − 2(CH_2NO_2)), 328 (11%, M − N = $CH(C_6H_5)CH_2NO_2$), 281 (6%), 268 (13%, $(CH_3OC_6H_4BO)_2$), 197 (6%), 150 (13%, $C_6H_5CHCH_2NO_2$), 134 (16%, $CH_3OC_6H_4BO$), 121 (20%), 104 (100%, $C_6H_5CHCH_2$), 91 (39%, C_7H_7), 77 (36%, C_6H_5), 65 (15%).

X-ray crystallographic analysis of 3a

A crystal ca. 0.10 × 0.20 × 0.25 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 69.6–94.0°) measured on a diffractometer with Cu-K_α radiation (λ = 1.54178 Å). Crystal data at 21°C are as follows

$C_{24}H_{25}BN_4O_7$ fw = 492.29

Monoclinic, *a* = 8.4790(8), *b* = 16.2100(9), *c* = 9.4367(6) Å, β = 109.342(5)°, *V* = 1223.8(1) $Å^3$, *Z* = 2, ρ_c = 1.336 Mg m^{-3}, *F*(000) = 516, μ(Cu-K_α) = 7.83 cm^{-1}. Absent reflections: 0*k*0, *k* odd, space group $P2_1$ (No. 4) from structure analysis.

Intensities were measured with graphite-monochromated Cu-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 16° min^{-1} over a range of (1.00 + 0.20 tan θ)° in ω (with up to eight rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 155°. The intensities of three check reflections, measured every 200 reflections throughout the data collection, showed

[3]The product thus obtained is analytically pure. During recrystallization from ethanol, decomposition to *N,N*-bis(1-phenyl-2-nitroethyl)-hydroxylamine, mp 103–105°C, occurs (10). The thermal instability of **2***a* can also be seen in the EI mass spectrum which does not display a molecular ion peak.

[4]Variable for successive experiments at room temperature over a period of several hours.

only small random variations. After data reduction,[5] an empirical absorption correction, based on azimuthal scans for three reflections, was applied. Transmission factors range from 0.89 to 1.00. Of the 2785 reflections measured, 2606 were unique (R_{int} = 0.021) and 1749 (67.1%) had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.025F^2)^2]/Lp^2$ with S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure analysis was initiated in the noncentrosymmetric space group on the basis of the E-statistics, this choice being confirmed by the subsequent successful solution and refinement of the structure. The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å, $B_H = 1.2B_{bonded\ atom}$). A correction for secondary extinction was applied, the final value of the extinction coefficient being 5.46×10^{-4}. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 11. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix least-squares refinement of 325 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.032 and R_w = 0.039 for 1749 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$. A parallel refinement of the mirror-image structure resulted in marginally higher residuals, the R and R_w factor ratios being 1.003 and 1.002, respectively.

On the final cycle of refinement the maximum parameter shift corresponded to 0.06σ. The mean error in an observation of unit weight was 1.45. The final difference map showed maximum fluctuations of ±0.12 e Å^{-3}. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal

parameters, torsion angles, intermolecular contacts, least-squares planes, bond lengths and angles involving hydrogen, and structure factors have been deposited.[6]

Results and discussion

The X-ray analysis establishes the cycloboronate structure **3***a* for the condensation product of **2***a* with *p*-methoxyphenylboronic acid (Ar = 4-$CH_3OC_6H_4$). This is the second reported example of the new BONCNO heterocycle **3**, the only other fully characterized member of this class being **3***b* (3). In striking contrast to the *N*-(α-cyanoalkyl) substituted **3***b*, which has both of the *N*-substituents in equatorial positions of the semiplanar C(1)-envelope ring (form **3 EE**), the *N*-(β-nitroalkyl) derivative **3***a* exists in the **3 AE** form in the solid state (Fig. 1). This difference could result from a less sterically hindered axial *N*-alkyl substituent in **3***a*, as well as from dipolar and stereoelectronic effects would could favor the axial position of one of the *N*-substituents. In such an arrangement the antiperiplanar orientation of the non-bonding electron pair at N(1) with respect to the C(1)—N(2) bond could contribute to the stabilization of the molecular geometry by a generalized anomeric effect via n–σ* overlap (12) and/or minimization of the destablilizaing, through space, n–n interaction between the two nitrogen lone pairs (13). The presence of an n–σ*(π) effect is suggested by the relatively short N(1)—C(1) bond (1.443(4) Å) compared to the adjacent C(1)—N(2) bond (1.465(4) Å). In addition, the axially positioned substituent at N(1) does not interfere with the substituent at B(1) because of the essentially planar arrangement at the sp^2 boron, the nearly coplanar orientation of the *B*-aryl ring (dihedral angle between normals to the mean planes is 17.3°), and the near planarity of the N—O—B—O—N moiety of **3***a* (planar to within 0.066(3) Å).

Although the nitro group of the axial N(1) substituent neighbors the boronate function, the O(4)···B(1) non-bonding distance (3.196 Å) approaching the normal van der Waals distance of 3.07 Å (14), it is unlikely to contribute to the stabilization of the conformation **3 AE**. Any significant O···B interaction should result in some degree of pyramidalization above the O(1)—O(2)—C(18) plane at the B(1) atom due to partial rehybridization of the sp^2 boron atom. The boron atom is actually displaced from the plane of its substituents by a considerable 0.109(4) Å, but in the opposite direction from O(4), probably a result of packing forces (see Fig. 2) in view of the otherwise normal geometry for a trigonal planar boron atom at B(1). An example of true partial pyramidalization, with a similar displacement of the boron atom, has recently been reported for an eight-membered heterocycle containing a weak transannular N···B interaction (15).

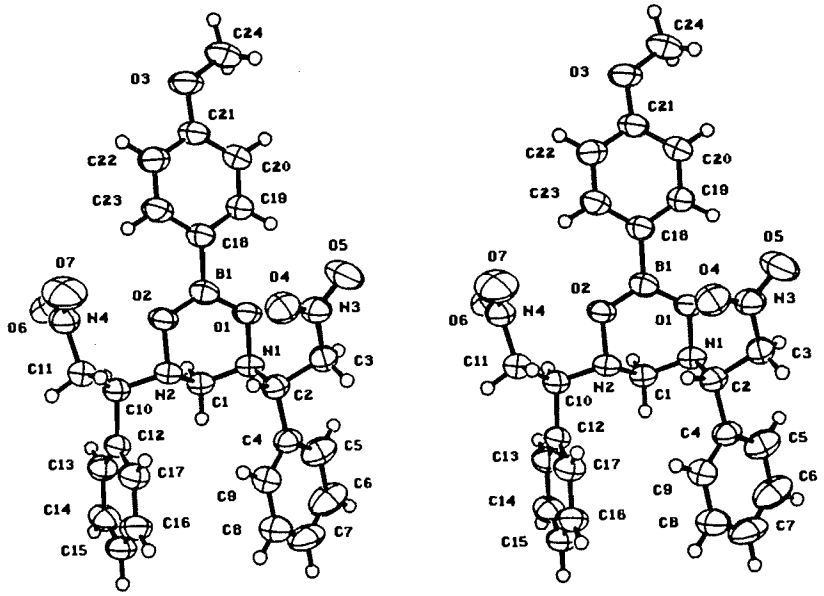

FIG. 1. Stereoview of the 4,6-bis(1-phenyl-2-nitroethyl)-2-(4-methoxyphenyl)-1,3-dioxa-4,6-diaza-2-boracyclohexane molecule; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

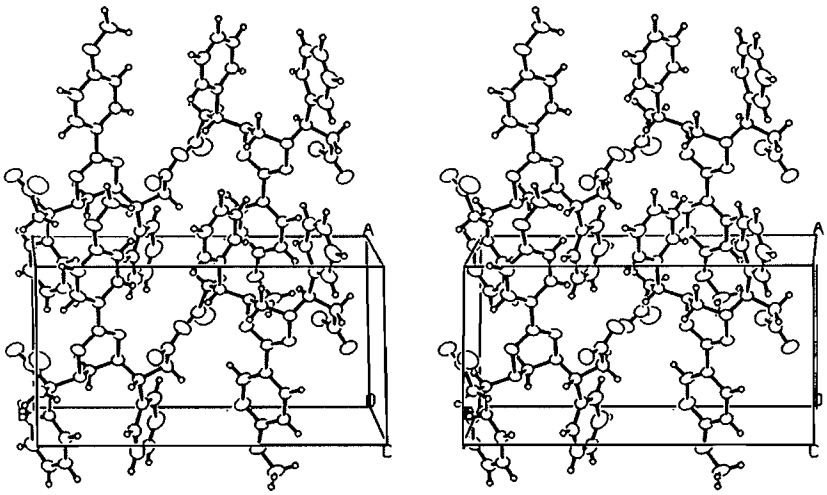

FIG. 2. Stereoview of the packing arrangement of 4,6-bis(1-phenyl-2-nitroethyl)-2-(4-methoxyphenyl)-1,3-dioxa-4,6-diaza-2-boracyclohexane; 32% probability thermal ellipsoids are shown for the non-hydrogen atoms.

The size of the *N*-(β-nitroalkyl) substituents might account for the fact that bisaxial conformer **3 AA** is not observed in the solid state. The **3 AA** conformer would undergo severe 1,3-*syn*-diaxial steric interactions, thus **3 AE** represents the preferred (and perhaps exclusive) form of compound **3***a*. Similar experimental findings for 3,5-dimethyl-1-oxa-3,5-diazacyclohexane in solution explained the most stable axial-equatorial form in terms of the anomeric effect and reduced 1,3-diaxial interactions (5). *Ab initio* studies of the basic 1-oxa-3,5-diazacyclohexane system, however, revealed the diaxial form as the most stable geometry of this cyclic aminal, interpreted as a consequence of anomeric interactions (16). Another indication of an anomeric effect involving one of the nitrogen lone pairs might be the widening of the N(1)—C(1)—N(2) angle in the **3 AE** form of **3***a* (111.5(2)°) relative to the corresponding angle of 106.4° in the **3 EE** form of **3***b* (3). Similar tendencies have been calculated for the **AE** and **EE** forms of *N,N'*-dimethyl-1-oxa-3,5-diazacyclohexane: 109.09 and 107.25°, respectively (16); the N—C—N angle for the **AA** form is larger still: 113.05° (16).

The N—O bond lengths in **3***a* (mean 1.462 Å) are very similar to those observed in **3***b* (mean 1.461 Å) (3) and in the simple aminal **2** (R = CH_3) (1.458 Å) (17). As in **3***b* (3), the partial double bond character (corresponding to a π-bond order of ~0.5) of the O—B bonds in the approximately planar N—O—B—O—N ring fragment is reflected by short O—B distances (mean 1.363 Å) resulting from *pp*(π) back donation. The B(1)—C(1) distance of 1.548(4) Å is slightly shorter than the corresponding B—C(aryl) bond of 1.560 Å in **3***b*, the latter value being typical for six-membered phenylboronates (ref. 3 and references therein). Inductive effects resulting from the presence of the *p*-methoxy group in **3***a* probably contribute to the slight shortening of the B—C(aryl) bond. The orientation of

For personal use only.

the *B*-aryl substituent with respect to the boron coordination plane (see above) is similar to that reported for most arylboronates except the mesityl derivative **3***b* which has a nearly perpendicular orientation of these groups.

Because of the axial and equatorial positioning of the *N*-alkyl groups in **3***a* (**AE** form) the compound displays the same configuration at both amine centres (S,S), in contrast to the opposite configurations (R,S) observed at the amine nitrogen atoms in the **EE** form of **3***b* (3). The chiral centres at C(2) and C(10) also both have S configurations, thus the stereoisomer shown in Fig. 1 is the S,S,S,S isomer. Since the material crystallizes in a chiral space group ($P2_1$), each crystal consists of only one stereoisomer. Presumably the bulk sample contains equal numbers of crystals composed of S,S,S,S and R,R,R,R isomers (assuming that the aminal **2***a*, synthesized from racemic starting materials, is a racemate as well). It has not yet been determined whether other stereoisomers such as that derived by inversion at both nitrogen atoms (R,R,S,S, diastereoisomer — results from ring inversion) are also formed.

Photoelectrochemical transduction between ionic and electronic conduction mediated by bis(maleonitriledithiolato)nickelate(II) in a polyviologen film

MARK C. LEFEBVRE, DAVID A. BIRO, AND COOPER H. LANGFORD[1]

Laboratories for Inorganic Materials, Department of Chemistry and Biochemistry, Concordia University, 1455 de Maisonneuve W., Montreal (Que.), Canada H3G 1M8

Received

MARK C. LEFEBVRE, DAVID A. BIRO, and COOPER H. LANGFORD. Can. J. Chem. **69**, 1233 (1991).

The photoelectrochemistry of a polymer coated electrode exploiting the chromophore bis(maleonitriledithiolato)nickelate(II) to link the redox self-exchange conductor poly(xylylviologen) to the solution couple $Fe(CN)_6^{3-/4-}$ is described. The diffusion coefficient for the $Fe(CN)_6^{3-/4-}$ redox couple in the film is 4.2×10^{-9} cm^2/s. The system was developed in an attempt to improve on a system where a quaternary ammonium substituted polystyrene/polyvinylpyridine blend films functioned as a good ionic conductor but poor electronic conductor in consequence of the trap states. The expected improvement in electronic conductivity is seen but at the expense of lower ionic mobility.

Key words: polyviologen, bis(maleonitriledithiolato)nickelate(II), polymer conduction, photoelectrode.

MARK C. LEFEBVRE, DAVID A. BIRO et COOPER H. LANGFORD. Can. J. Chem. **69**, 1233 (1991).

Nous avons etudié la photoélectrochimie du chromophore bis(maleonitriledithiolato)nickelate(II) dispersé dans le polymère redox poly(xylylviologène) qui est utilisé comme mediateur pour le transfert d'électron entre le polymère et le couple redox $Fe(CN)_6^{3-/4-}$. Le coefficient de diffusion pour le $Fe(CN)_6^{3-/4-}$ dans ces filmes est de $4{,}2 \times 10^{-9}$ cm^2/s. Le système a été developpé pour améliorer un autre système ou des films d'un mélange de polystyrène et polyvinylpyridine contenant des groupements ammonium quaternaires fonctionnait comme un bon conducteur ionique, mais un mauvais conducteur électronique. La conductivité électronique du nouveau polymère est augmenté tel qu'attendu, mais sa mobilité ionique est plus faible.

Mots clés : polyviologène, bis(maleonitriledithiolato)nickelate(II), conduction dans polymers, photoélectrode.

Introduction

In a series of publications (1–3) we have described ion-exchange polymer coatings based on quaternary ammonium derivatized polystyrene blended with polyvinylpyridine for use on transparent electrodes. The polymer mediates the transduction of ionic to electronic currents via the excited states of dyes located at the interface between hydrophobic domains (where ions migrate readily) and hydrophilic domains (where current is carried by electron hopping). The physics of these systems is now becoming well characterized. The principal limit on their performance is imposed by the characteristics of the hydrophobic domain. In the hydrophilic domain, ion mobilities are near those for aqueous solution.

As the slow response to switching first indicated (1–3), electronic conduction involves a broad distribution of deep and shallow trap sites in these complex amorphous materials. This report describes an attempt to overcome the main limitation by exploiting a polyviologen polymer known to have favourable redox hopping characteristics and acceptor states well matched to the low-lying excited state of the chromophore (4, 5). In this work the chromophore is bis(maleonitriledithiolato)nickelate(II).

The maleonitriledithiolate (mnt) ligand forms a square planar complex with nickel which is strongly coloured. Its spectral characteristics are retained with different counterions. The complex is also known to be electrochemically and photoelectrochemically active in solution and in polymer films (6). The solution electrochemistry of the complex displays a reversible one electron transfer between 2− and 1− ion charges. Reduction from 2− to 3− or oxidation from 1− to 0 is less reversible (6). The photoelectrochemical activity of the complex is not easily exploited in solution since the states excited with visible light have been shown to have a very short lifetime (7).

Poly(xylyl)viologen (PXV), a cationic redox polymer can be used as an electrode modifier. Viologens have been used as electron acceptors in previous photoelectrochemical schemes (4, 5). They have several useful characteristics: reversible one electron reduction to a monocation radical, ion exchange capacity, and a distinct change in colour between the two oxidation states. Facile redox processes are considered to be the primary mode of charge transport in this conducting polymer (8).

Any given system can have a combination of three channels of charge migration, metal-like electronic conduction, redox (self exchange) hopping, and ion diffusion. In wet junction cells one mode must be ion migration and this is usually coupled to a second. The channels may often be considered to correspond to *hydrophylic* domains where the solvent soluble ions readily move and *hydrophobic* domains where the spacing and orientation of molecules necessary for intermolecular electron jumping (electronic and redox self-exchange) is attained (2).

Polymers, which are amorphous or semicrystalline, may have very many localized energy states over a wide band of energies arising from chain ends, interphase regions between amorphous and crystalline zones, interphase regions between hydrophylic and hydrophobic zones, and the effects of local or bulk dipoles induced by the material's structure. This can give rise to broad distributions of acceptor and donor states for the polymer. All these localized states are capable of trapping (partially stabilizing) a charge carrier. Trap-controlled migration is charge diffusion which is highly dependent upon the depths of the intrinsic traps of the conducting medium.

The $Ni(mnt)_2^{2-}$ chromophore has been ion exchanged into polymeric films to extend the excited state lifetimes and to improve charge separation efficiency (3, 6). The support polymer showed the ability to segregate into hydrophobic and hydrophylic domains. The charge transport mechanism is believed to occur via the combination of localized trap states in the hydrophobic domains with ionic charge transport in the hydrophylic domains (similar behaviour was noted for films containing porphyrin and phthalocyanine complexes (2)). Ionic conduction appeared good, but overall response was poor due to trap-

[1]To whom correspondence should be addressed.

controlled migration. The system was probably limited by poor overlap of the complex's excited state with the accepting states of the polymer as well as the deep trap nature of the polymer. PXV-Ni(mnt)$_2$ is studied here in an effort to match the accepting levels of the polymer with the excited state of the mnt more closely, and to exploit a polymer with better carrier transport characteristics (4, 5).

Experimental

Materials

All materials were reagent grade unless otherwise specified. $[(C_2H_5)_4N]_2[Ni(S_4C_6N_4)_2)_2]$ (Ni(mnt)$_2$) was prepared according to the method outlined by Persaud and Langford (9).

Poly(xylyl)viologen bromide (PXV-Br$_2$) was prepared by reacting equimolar amounts of 4,4′-bipyridyl (Fluka) with α,α′-dibromo-(*p*)-xylene (Aldrich) in acetonitrile (Caledon HPLC grade) in a sealed vessel for 24 h (10). This condensation polymerization gave yields over 85%. The average polymer so produced is know to contain eight or nine repeat units giving an average molecular weight of roughly 3500 g/mol (10, 11). A polymer blend of PXV-Br$_2$ with polyethylene oxide (PEO) was prepared with 1% (w/v) aqueous PXV-Br$_2$ and 1% (w/v) aqueous PEO (Aldrich 100 000 g/mol).

Methods

Electrodes, roughly 1 × 5 cm, were cut from sheets of SnO_2-coated Pyrex glass (Swift Glass Co., Connecticut). They were cleaned in chromic acid, rinsed, and stored in ethanol. Aliquots of 0.2 mL of aqueous solutions of the preformed polymer were drop cast upon levelled dry electrodes and allowed to dry slowly for uniform film formation. The electrodes were bordered with a clear inert insulating lacquer (that gave no background electrochemical signal) leaving an area of 1 cm^2 exposed. Contact to the electrodes was established with nickel alligator clip contacts. Film thicknesses were measured with a micrometer. The Ni(mnt)$_2^{2-}$ ion was incorporated into the prepared films by ion exchange from acetonitrile solutions of the Ni(mnt)$_2^{2-}$ tetraethylammonium salt. The electrodes were left in the solutions for 15 h.

Solutions for electrochemical measurements were 0.10 M KCl and 2.00 mM of $K_3Fe(CN)_6 \cdot 3H_2O$ and $K_4Fe(CN)_6$ in 0.10 M KCl. Measurements were carried out in an electrochemical cell equipped with a platinum counter electrode and an Ag/AgCl (saturated KCl) reference electrode. The volume of solutions was typically 25 mL. Cyclic voltammetry was done using a Metrohm E506 potentiostat coupled with a Metrohm E612 scanner. Voltammetric experiments were done at scan rates from 10 to 100 mV/s. Potentials and peak separation data tabulated here are those evaluated at 100 mV/s scan rate. All solutions were deoxygenated with prepurified nitrogen for 10 min prior to experiments.

A tungsten halogen lamp (EKN 300W Sylvania) coupled with a locally made power supply was used as an adjustable light source to obtain short-circuit photocurrents. A 5 cm water filter was used in conjunction with an ultraviolet filter to remove IR and UV radiation. Dark currents for all experiments were allowed to stabilize (10–15 min). Short-circuit current measurements were taken using a multimeter (Kiethley model 177) coupled to a strip chart recorder. Irradiation intensities were evaluated using a Coherent 210 power meter and were adjusted to 100 mW/cm^2. All solutions were deoxygenated for 10 min with prepurified nitrogen while the systems attained a steady current. Solutions were also stirred at a constant rate.

Ultraviolet–visible spectra were obtained on an Hewlett Packard 8452A diode array spectrophotometer interfaced to an IBM/PC. Near infrared spectra were measured on a Shimadzu UV-160. Some spectra of solid films in SnO_2-coated electrodes, blanked accordingly when scatter from the opaque films was not too great, were recorded. In most cases, however, films were dissolved into known quantities of either water or dimethylformamide (Aldrich, Spec grade) and solution spectra obtained. Fluorescence of solid films was measured using a Perkin Elmer MPF-44. Fourier transform infrared spectra were obtained from films on an IRTRAN2 disc on a Bomem Michelson 102 FTIR.

Results

Physical characterization

Solutions of PXV-Br$_2$ (1% (w/v)) as well as the 1:1 blend with PEO were cast upon clean SnO_2 electrodes. These were light yellow coloured films. PXV-Br$_2$ is water soluble, but upon ion-exchange with Ni(mnt)$_2^{2-}$ the films become water insoluble, thus allowing aqueous electrochemistry. With Ni(mnt)$_2^{2-}$ present, the films were brown in colour. PXV-Ni(mnt)$_2$/PEO films appeared darker than the PXV-Ni(mnt)$_2$ films.

Spectroscopy

PXV-Br$_2$ exhibited strong absorbance at 260 nm in good agreement with a published spectrum (10). A broad peak at 540 nm due to the reduced viologen moiety was obtained by the addition of a small amount of sodium hydrogen sulfite to aqueous PXV-Br$_2$. Re-oxidation of the viologen by ambient oxygen was complete in about 10 min. Ni(mnt)$_2^{2-}$ was ion exchanged into the PXV-Br$_2$ film to investigate possible interactions between the polymer and the Ni(mnt)$_2^{2-}$ counterion. A spectrum is shown in Fig. 1*a*. Discernible peaks for the PXV-Ni(mnt)$_2$ film were observed at 478, 388 nm (intensities: 3800, 6600 M^{-1} cm^{-1}, respectively) which compare very closely in wavelength and intensity to reported spectra of Ni(mnt)$_2$ complexes (9, 12). Also noted was a small peak near 555 nm which may reflect absorption by the reduced form of viologen (11) indicating some ground state oxidation of the dye by PXV.

Figure 1*b* shows the spectrum from 400 nm to the near infrared for PXV-Ni(mnt)$_2$. The principle visible region absorption is observed at 478 nm. A broad low intensity peak is noted for PXV-Ni(nmt)$_2$ near 890 nm which is not observed in either the Ni(mnt)$_2^{2-}$ or the PXV^{2+} salts. This absorbance is assigned to PXV-Ni(mnt)$_2$ charge transfer.

The vibrational spectrum of the PXV-Br$_2$ (Fig. 2*a*) corres-

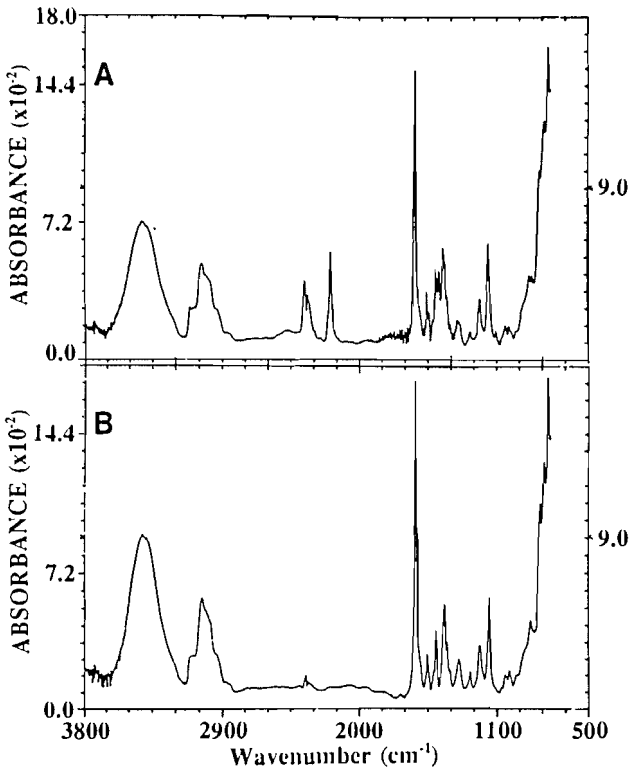

FIG. 2. (*a*) FTIR spectrum of PXV-Ni(mnt)$_2$ on AgCl and (*b*) PXV-Br$_2$ on AgCl.

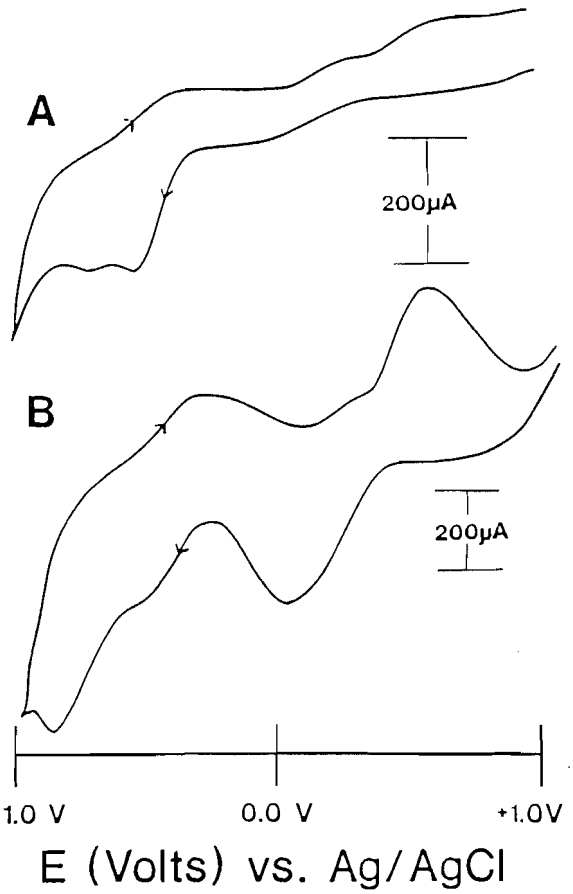

FIG. 3. Cyclic voltammograms of a SnO$_2$/PXV-Ni(mnt)$_2$ modified electrodes (*a*) in contact with 0.10 M KCl and (*b*) in contact with 2.00 mM Fe(CN)$_6^{3-/4-}$ and 0.10 M KCl. Scan rate was 100 mV/s for both starting at an initial potential of +0.8 V. Anodic currents are upwards and anodic potentials are to the right. Voltammograms were qualitatively similar at KCl = 1.00 M.

ponds very closely to a published spectrum for a similar polyviologen (13). Pronounced viologen peaks were at 1631 cm^{-1} (attributed to ν(C=N)), 1445 cm^{-1} (ν(C—N)) and 1155 cm^{-1} (ν(C—C)). Upon incorporation of Ni(mnt)$_2^{2-}$ new peaks observed in the PXV-Ni(mnt)$_2$ spectrum (Fig. 2*b*) corresponded closely to published IR data for Ni(mnt)$_2^{2-}$ salts (14). Prominent mnt peaks at 2191 cm^{-1} (ν(C≡N)), 1489 cm^{-1} (ν(C=C)), and weaker ones at 1105 cm^{-1} (π(C—CN) and 865 cm^{-1} (ν(C—S)) were observed. PXV peaks at 3400, 3000, 1630 cm^{-1} (the 1630 cm^{-1} peak being tentatively assigned to ν(C—N$^+$)) (13) exhibited a decrease in intensity. Distinct PXV peaks shifts were also noted at 1156 and 1216 cm^{-1}. Strong electrostatic interactions between the ion pair is a proposed explanation for the changes in the PXV related peaks.

Fluorescence emission was undetectable in steady-state room temperature measurements of Ni(mnt)$_2^{2-}$. Upon incorporation into the polymer film irradiation at 478 nm (the main visible absorption of the chromophore) results in emission at 555 nm.

Electrochemistry

In the absence of a redox couple cyclic voltammograms show small peaks for the Ni(mnt)$_2^{2-}$ one-electron oxidation (Fig. 3*a*). The waves were often very broad and appeared irreversible with ΔE_p = 0.30 V at 10 mV/s. The observed Ni(mnt)$_2^{2-}$ potentials are consistent with literature values (12). Upon continuous cycling these peaks decrease in intensity. This decrease is not due to leaching of the chromophore from the film since none was subsequently observed in the supporting electrolyte, but is attributed to crosslinking of the polymer and expulsion of counterions from the film. On the cathodic scan, films turn from their brown colour to a deep violet–blue at potentials less than −0.6 V (versus Ag/AgCl), indicating the presence of the viologen radical cation, but this colour develops only slowly. The films also return to their initial colour slowly at a potential more anodic than +0.4 V, thus reflecting the electrochromic nature of the viologen.

The viologen (4,4′-bipyridyl) peaks on the negative sweep of the voltammogram are weak and are not well defined since they occur near the cathodic limit of the solvent. In some cases the second reduction peak of the viologen was not observed. It has been suggested that the lack of the second reduction peak in viologens may be due to a conproportionation reaction [1] of the viologen (15, 16).

[1] $(PXV)^0 + (PXV)^{2+} = 2(PXV)^{1+}$

The viologen dication to radical monocation reduction potential, observed at −0.45 V agrees with the literature (10). The PXV-Ni(mnt)$_2$/PEO blend showed a slightly more negative value of −0.49 V. Cyclic voltammograms for the blend did not show any significant advantage over films of the neat viologen polymer.

The second reduction of viologen is known to be irreversible (16). When the system was cycled more cathodic than this second reduction potential a decrease in all voltammetric peaks was observed due to loss of electro-activity of the polymer. This loss of electro-activity is attributed to crosslinking and contraction of the polymer film (17). Also, when the viologen is reduced counterions are forced from the film into solution (18).

An equimolar solution of the ferri/ferrocyanide redox couple greatly improved the conduction of the films (Fig. 3*b*). The Fe(CN)$_6^{3-/4-}$ couple showed a voltammetric wave at 0.27 V

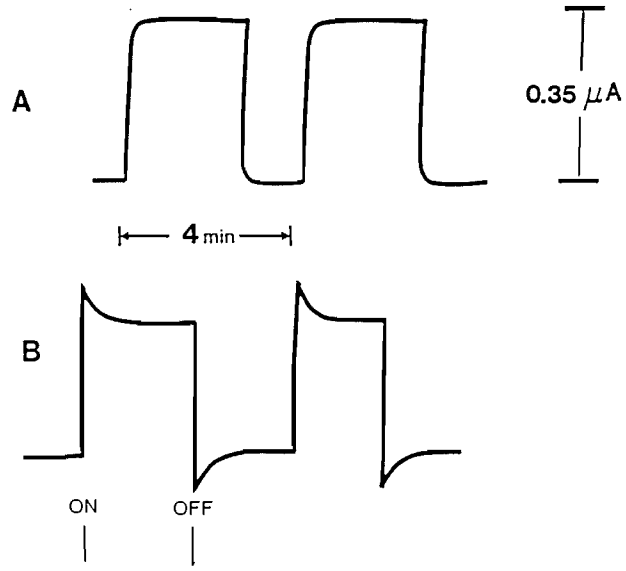

FIG. 4. Short-circuit photocurrents as a function of illumination time for PXV-Ni(mnt)$_2$ modified SnO_2 electrodes in contact with 2.00 mM $Fe(CN)_6^{3-/4-}$ and 0.10 M KCl. (*a*) A profile showing fast temporal response and (*b*) a profile showing capacitive response. Both were illuminated with light greater than 400 nm with an intensity of 100 mW/cm^2.

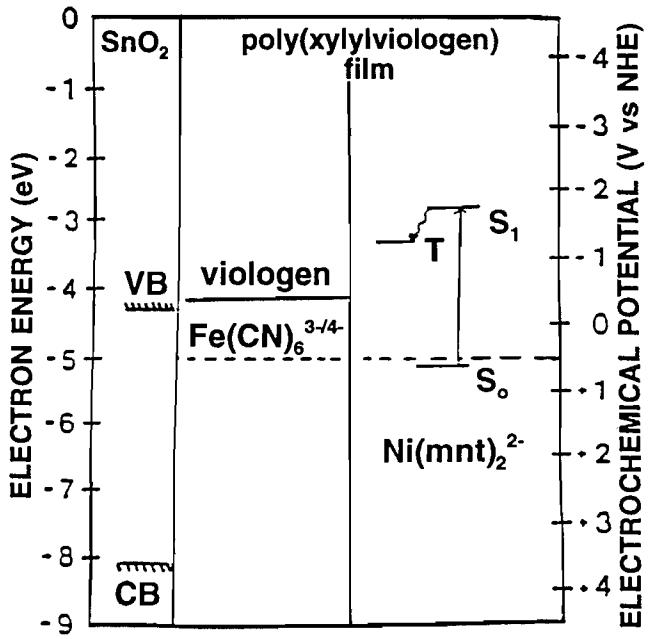

FIG. 5. Energy level diagram. The acceptor level of the polymer film is shown here relative to the energy levels of the SnO_2 electrode, the solution redox couple, and the Ni(mnt)$_2$ dye.

with ΔE_p = 200 to 400 mV for scan rates from 10 to 100 mV/s. The redox couple readily penetrates the film, but loaded films subsequently placed into supporting electrolyte alone showed leaching of 75% of the $Fe(CN)_6^{3-/4-}$ into solution within 30 min as evidenced by the decrease in $Fe(CN)_6^{3-/4-}$ currents. The $Fe(CN)_6^{3-/4-}$ signal largely masked the $Ni(mnt)_2^{2-}$ reduction signal as the redox couple penetrated the film. Solutions showed no evidence of leaching of the chromophore upon incorporation of the redox couple. The concentration of the redox couple in one film evaluated by integration of the area underneath the voltammetric waves was determined to be 1.2×10^{-4} mol/cm^3 while the concentration of $Ni(mnt)_2^{2-}$ was 2.8×10^{-5} mol/cm^3.

The rate of charge transport through a polymer film can be described by effective diffusion coefficients which include electron hopping, ion migration, and other aspects of carrier mobilities (19). The coefficient from three films containing the $Fe(CN)_6^{3-/4-}$ couple evaluated using a potential step from 0 to +1.0 V was $4.2 \pm 0.8 \times 10^{-9}$ cm^2/s, this being two orders of magnitude below that found for the redox couple in another ion-exchange polymer studied in this laboratory (3).

Photoelectrochemistry

The photoelectrochemical behaviour of polymer films was studied in background electrolyte in the presence and absence of $Fe(CN)_6^{3-/4-}$ redox couple. The background current for all electrodes studied was non-zero (−20 to +20 nA) and all photocurrents were anodic. Short-circuit photocurrents in only background electrolyte were all very small (≈30 nA) for intensities of 100 mW/cm^{-2} and the temporal response of the films was typical of a trap-controlled process (3). The magnitude of the photocurrents was 365 ± 25 nA/cm^2 for a series of three PXV-Ni(mnt)$_2$ electrodes at 100 mW/cm^2 in 2.00 mM $Fe(CN)_6^{3-/4-}$ in 0.10 M KCl. The PEO containing polymer blend fabricated in an effort to increase the hydrophilicity and hence the ionic conductivity of the films resulted in even smaller photocurrents. The photocurrents of PXV-Ni(mnt)$_2$/PEO films which had higher $Ni(mnt)_2^{2-}$ concentrations were 2/3 those of PXV-Ni(mnt)$_2$ films. These blends reflected an effort to create hydrophylic domains within the films to improve ionic diffusion. The perchlorate electro-inactive anion was incorporated into the PXV film to render the PXV film insoluble to allow examination of aqueous photoelectrochemistry of the polymer without the dye. Short-circuit photocurrents reached 50 ± 5 nA/cm^2 for electrodes not containing the dye most likely due to light absorption by the $Fe(CN)_6^{3-/4-}$ redox couple.

Photocurrent profiles for the polymer films studied are illustrated in Fig. 4. New PXV-Ni(mnt)$_2$ films demonstrated prompt response to light on/light off switching reaching a steady state current in about 10 seconds (Fig. 4*a*). After 1 h of use, however (shorter in some cases), the films would start to show slight capacitive response to switching (Fig. 4*b*). Cross-linking within the polymer and loss of ions from the film are probable causes.

Discussion

Exchange of $Ni(mnt)_2^{2-}$ anions into a catonic film has proven to be an effective method to exploit the short-lived metal to ligand charge transfer states excited by irradiation with visible light (3). In the earlier study photocurrent increased linearly with film thickness up to >6 μm, allowing construction of films harvesting a high fraction of the light. Overall conversion efficiency, however, remained low. Time dependence of the photocurrents revealed the probable limit. Charge migration across the film required trap-controlled electron migration via the acceptor states of an amorphous polymer film with many deep trap sites. The present study was designed to ameliorate this problem by exploiting a polymer known for facile electron exchange conduction. Unfortunately, the present study highlights the major *advantage* of the previously studied film, the ionic mobility across the film is similar to that in water.

A proposed energy level diagram for the photovoltaic system is illustrated in Fig. 5. The acceptor level of the PXV^{2+} would lie close to the potential for the viologen dication to radical

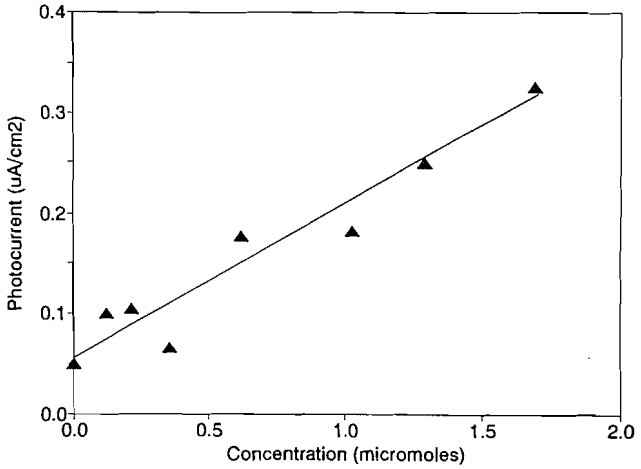

FIG. 6. Short-circuit photocurrent as a function of $Ni(mnt)_2^{2-}$ concentration within polymer film modified electrodes in contact with 2.00 mM $Fe(CN)_6^{3-/4-}$ and 0.10 M KCl. Electrodes were irradiated with light greater than 400 nm with an intensity of 100 mW/cm^2.

cation reduction. The excited states of the dye are assigned on the basis of absorption bands (9) of the mnt complexes.

A proposed reaction sequence for the system is as follows. The $Ni(mnt)_2^{2-}$ absorbs in the visible region populating its excited states. The proximity of the dye to the polymer cations leads to oxidation of the dye's excited state by the polymer's viologen moiety. Redox self-exchange of the viologen along with migration of compensating counterions shuttles the electron to the electrode surface and ultimately into the conduction band of the semiconductor giving an anodic photocurrent. $Fe(CN)_6^{4-}$ in the film reduces the oxidized $Ni(mnt)_2^{1-}$ species and excess $Fe(CN)_6^{3-}$ diffuses out to be reduced itself at the Pt cathode, thus completing the circuit.

It is known that if redox sites are bound to polymer chains electron-hopping can be significant (20), but there is the possibility that the redox carrier could be the $Ni(nmt)_2^{2-}$ dye itself. Figure 6 shows the $Ni(nmt)_2^{2-}$ concentration dependence of the observed short-circuit photocurrents. This result is roughly linear which, when extrapolated to zero concentration, corresponds to the observed short-circuit photocurrents in the absence of $Ni(nmt)_2^{2-}$. Should $Ni(mnt)_2^{2-}$ have been the primary redox carrier in this system Fig. 6 would have appeared parabolic (redox self-exchange being bimolecular). The observed increase in short-circuit photocurrents is simply due to the increase in light absorption, implying that primary redox exchange conduction is via the polymer backbone.

The temporal photocurrent profile for the PXV-$Ni(mnt)_2$ system illustrates improved conduction within the film over the trap-controlled migration observed for the ion-containing polymer blend studied previously (3). Fewer deep traps and more efficient charge separation are responsible for the fast response to light on/light off switchings.

Electro-activity of redox centres in most redox polymer films depends on ionic conductivity. The migration of charge compensating ions in the opposite direction to charge migration is necessary to preserve electroneutrality in local regions of the film. Ionic diffusion coefficients within the PXV^{2+} film were two orders of magnitude smaller than in the previously studied ion containing polymer blend (3), whereas photocurrents were one order of magnitude smaller. Thus spatial charge separation appears more efficient, but the loss of ionic mobility within the film gives an overall loss of performance. A maximally efficient device needs a combination of the electronic conductivity afforded by an efficient redox self-exchange polymer and the ionic mobility afforded the very hydrophylic films of Biro and Langford (3). In this case, improvement of one parameter was accomplished at the more than compensating expense of the other.

Study of the properties of pyridine-2-azo-*p*-phenyltetramethylguanidine as a metal ion complexing agent[1]

KENNETH T. LEFFEK AND ARNOLD JARCZEWSKI[2]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received January 2, 1991

KENNETH T. LEFFEK and ARNOLD JARCZEWSKI. Can. J. Chem. **69**, 1238 (1991).

Pyridine-2-azo-*p*-phenyltetramethylguanidine (PAPT) was synthesized and the properties of this compound examined. The dissociation constants of the conjugate acids in H_2O are pK'_a H_2O = 10.41 ± 0.06, and pK''_a H_2O = 2.62 ± 0.02 at 25°C at I = 0.1, and in acetonitrile are pK'_a = 18.0 ± 0.2 and pK''_a = 10.4 ± 0.2. The properties of metal–ligand chelates in acetonitrile have been examined and the stability constants for Ni^{2+}, Co^{2+}, and Zn^{2+} complexes measured. The rates of reaction of PAPT with Ni^{2+}, Co^{2+}, and Zn^{2+} in acetonitrile have been determined and the activation parameters measured for the complex formation of LNi^{2+}. The stability constants for both complexing centres of PAPT have been calculated. The ^{13}C NMR spectra for PAPT and LNi^{2+} are quoted. The expected enhancement of the metal ion complexing ability of PAPT due to the strongly electron-releasing nature of the tetramethylguanidinyl group was not found.

Key words: metal ion complexes, pyridine-2-azo-*p*-phenyltetramethylguanidine, stability constants, pK_a.

KENNETH T. LEFFEK et ARNOLD JARCZEWSKI. Can. J. Chem. **69**, 1238 (1991).

On a synthétisé la pyridine-2-azo-*p*-phényltétraméthylguanidine (PAPT) et on a examiné ses propriétés. Dans l'eau, les constantes de acides conjugués sont pK'_a H_2O = 10,41 ± 0,06 et pK''_a H_2O = 2,62 ± 0,02, à 25°C, avec I = 0,1 alors que, dans l'acétonitrile, pK'_a = 18,0 ± 0,2 et pK''_a = 10,4 ± 0,2. On a déterminé les propriétés des chélates métal–ligand dans l'acétonitrile et on a déterminé les constantes de stabilité des complexes avec Ni^{2+}, Co^{2+} et Zn^{2+}. On a déterminé les vitesses de réaction du PAPT avec Ni^{2+}, Co^{2+} et Zn^{2+} dans l'acétonitrile et on a mesuré les paramètres d'activation pour la formation du complexe LNi^{2+}. On a calculé les constantes de stabilité des deux centres de complexation du PAPT. On rapporte les spectres RMN du ^{13}C NMR PAPT et du LNi^{2+}. Bien que le groupe tétraméthylguanidinyle soit fortement électrodonneur, on n'a pas observé l'augmentation attendue de la capacité du PAPT à former des complexes avec les ions métalliques.

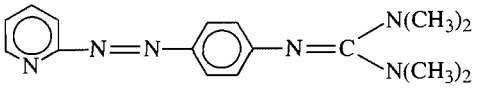
[Traduit par la rédaction]

Introduction

Pyridine-2-azo-*p*-dimethylaniline (PADA), originally synthesized by Faessinger and Brown (1), has been thoroughly examined with respect to its ability to chelate several metal ions with the *d*-orbitals (2–6). Of the bivalent metal ions, nickel(II) has received considerably more attention than the others (2, 3, 7, 8–12). The usefulness of PADA lies, in part, in the magnitude of the stability constants of the appropriate metal complexes in water (2, 7) as well as in various nonaqueous solvents (9, 11, 12). The kinetics of metal ion binding to PADA have been measured using a variety of methods (3, 6, 7, 8–11, 13–15), and the activation parameters and mechanism of reactions have been discussed (7–11, 13, 14, 16, 17). The Eigen–Wilkins formulation (18) of the mechanism for metal complex formation is valid for water (7, 9, 10), nonaqueous solvents (9, 11), and mixed solvents (8).

PADA–metal complex formation was used as a model system to examine and discuss the mechanism of biologically important reactions of enzymes containing either Co^{2+} or Zn^{2+} (16). Also, PADA appears to be a useful ligand for the study of the kinetics and mechanism of fast metal–ligand substitution processes taking place in aqueous and micellar solutions (10).

This work seeks to develop a new complexing agent with a stronger electron-releasing group than the dimethylamino group in PADA.



A series of 2-phenyl-1,1,3,3-tetramethylguanidine first synthesized by Kesler and Liebfritz (19), and extended by Pruszynski (20) and Leffek *et al.* (21), offers an opportunity to introduce such a group. The ^{35}Cl nuclear quadrupole resonance spectra for a series of five chloro-substituted 2-phenyltetramethylguanidines (22) indicated a very strong electron-releasing effect for the TMG group with a Hammett σ_p value of −0.88. This was confirmed (21) by a correlation of the pK of the conjugate acids and σ for 12 *meta*- and *para*-substituted 2-phenyl-1,1,3,3-tetramethylguanidines, from which it was calculated that σ_p for the TMG group was −0.80.

Taking into account the usefulness of PADA as a metal ion complexing agent and the strongly electron-releasing effect of the TMG group (21), we decided to synthesize the PADA analogue with the TMG group substituted for *p*-dimethylaniline, a weaker electron-releasing group, in the hope that the new compound would have a stronger ability to bond the metal ions than PADA itself. Therefore the purpose of the present work is to synthesize and study the properties of pyridine-2-azo-*p*-phenyltetramethylguanidine (PAPT) as a complexing ligand.

Results and discussion

The ^{13}C NMR spectra of pyridine-2-azo-*p*-phenyltetramethylguanidine (PAPT) synthesized according to a modified Faessinger–Brown method (1) were run in acetonitrile, dimethyl sulfoxide, and dimethyl sulfoxide/D_2O mixture (3:1). The ^{13}C NMR data for these spectra are collected in Table 1.

The spectra show no evidence of impurities. The peaks were assigned by analogy with those observed by Holloway and Hubbard (12) for pyridine-2-azo-*p*-dimethylaniline (PADA), which are also shown in Table 1. The spectra of these two compounds are very similar except for the signals arising from

PAPT

[a]From ref. 12.

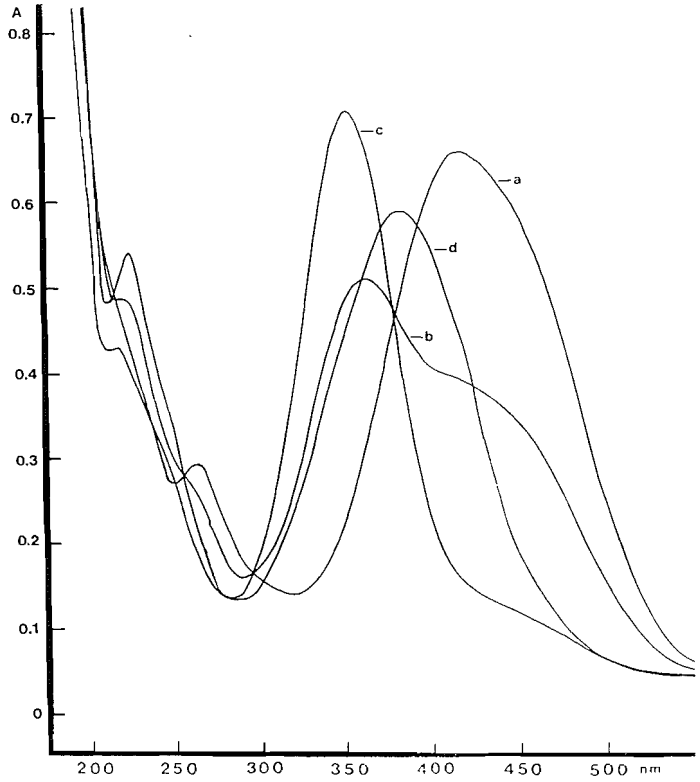

FIG. 1. Spectra of pyridine-2-azo-*p*-phenyltetramethylguanidine (PAPT) (5×10^{-5} M) in water: (a) pH 11.5; (b) pH 10.3; (c) pH 9.0; (d) pH 1.0.

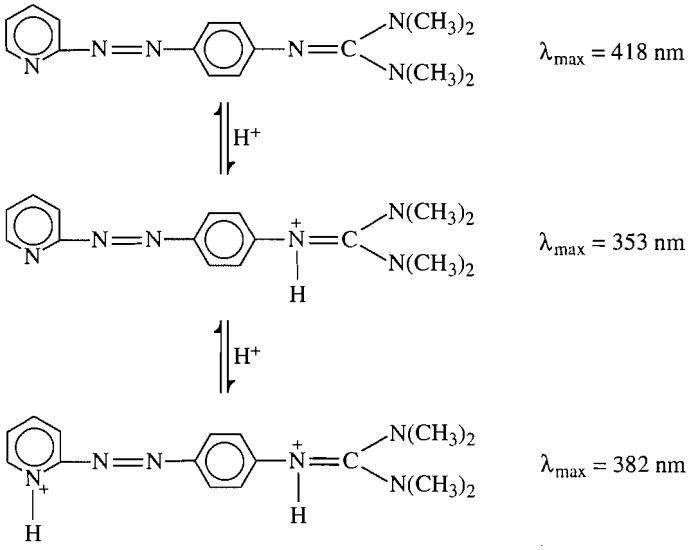
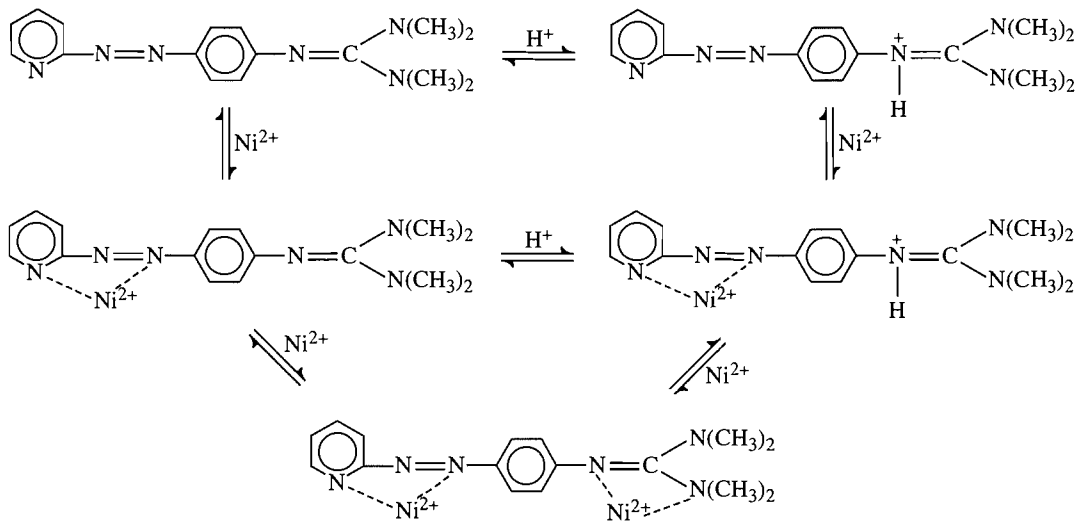


the 2 and 6 carbon atoms of the phenyl ring, where the PAPT molecule shows a marked downfield shift relative to PADA. The spectra of nine ring-substituted phenyltetramethylguanidines recently published (21) show similar peaks for the 2 and 6 carbon atoms, but phenyltetramethylguanidine itself does not (23). Its *ortho* carbon atoms appear at 114.4 ppm. The calculated values for the pyridine ring were obtained (24) using eq. [1] in which $\delta C_{(k)}$ is the chemical shift of carbon atom k in the pyridine ring and A_{ik} is the shift increment predicted for carbon k upon the introduction of a substituent R at carbon i. The A_{ik} values for the azo group were taken from Holloway and Hubbard (12). The calculated values for the phenyl ring were obtained (24) using eq. [2] in which $A_i(R_i)$ is the chemical shift for a substituent in the ith position. A_i values for the azo group were taken from the literature (25, 26) and A_i values for the TMG group were average values from the nine published spectra of ring-substituted phenyltetramethylguanidines (21), i.e., A_{Cl}, +23.6; A_{ortho}, −7.8; A_{meta}, −0.5; A_{para}, −9.7. The calculated values for the dimethylamino carbons and the guanidinyl carbon are averages from the nine published spectra (21).

$$[1] \quad \delta C_{(k)} = C_{(k)} + \sum_i A_{ik}(R)$$

$$[2] \quad \delta C_{(k)} = 128.5 + \sum_i A_i(R_i)$$

As was concluded for PADA (12), the ^{13}C NMR spectra are consistent with a single isomer of PAPT, with a *trans* arrangement across the azo double bond.



The UV–visible spectra of pyridine-azo-*p*-phenyltetramethylguanidine (PAPT) in water give three absorption maxima at λ 418, 353, and 382 nm, indicating the following equilibria:

An isosbestic point between PAPT and protonated PAPT is observed at 374 nm, as illustrated in Fig. 1.

It is noted that the unprotonated form exists only under

SCHEME 1

strongly alkaline conditions, and already at pH 10 two forms exist, the unprotonated form and the monoprotonated form (Fig. 1). At pH 9 almost all the compound exists in the monoprotonated form. Strongly acid conditions, from pH 2.5 to 1.0, shift the equilibrium to the diprotonated form.

The dissociation constant values pK'_a and pK''_a at 25°C, at constant ionic strength $I = 0.1$, maintained with KCl, were measured as: $pK'_a = 10.41 \pm 0.06$, $pK''_a = 2.62 \pm 0.02$.

In acetonitrile solvent the three forms L, LH^+, and LH_2^{2+} have λ_{max} at 411, 343, and 402 nm respectively, with an isosbestic point at 371 nm as shown in Fig. 2. The curves were obtained by gradual acidification with perchloric acid in acetonitrile, which is a strong acid in this solvent (27).

The appropriate values of pK_a in acetonitrile solvent were measured with dipicrate–monopicrate and monopicrate-free base buffers (28, 29) using a method already described (21). The pK'_a and pK''_a at 25°C were 18.0 ± 0.2 and 10.4 ± 0.2 respectively.

Since the nitrogen electrons of the guanidinyl substituent are delocalized in the direction of the pyridine-2-azo group, then, compared to PADA, we can expect three effects concerning the complexing abilities of PAPT towards metal cations with *d* electrons:

1. Only the free, unprotonated ligand can show a strong complexing ability.
2. The monoprotonated form will have a strongly reduced complexing power, since the protonated guanidinyl group will not be a powerful electron-donating group.
3. Both complexing centres can bond M^{2+} cations, giving LM^{2+} and $L(M^{2+})_2$ complexes.

In acetonitrile solvent we can distinguish the species shown in Scheme 1. These equilibria are demonstrated in Figs. 2–4.

It is obvious that protonation of PAPT will reduce its complexing power due to the decreased value of the pK''_a (2.62), which is even smaller than the corresponding value for 2-aminopyridine ($pK_a = 6.71$). When PAPT is protonated, the electron-releasing properties of the guanidinyl substituent will not only be suppressed but the positive charge of its NH group will cause a reverse effect, pulling the π electrons out of the phenyl ring and decreasing the equilibrium constant for the formation of LH^+M^{2+} complexes (Scheme 1).

The existence of the $LNi^{2+}H^+$ complex was deduced from the

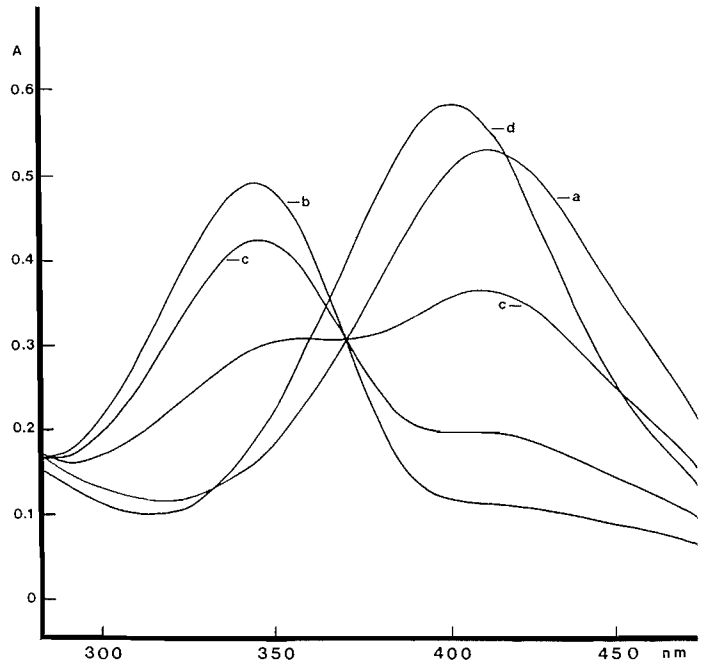

FIG. 2. Spectra of pyridine-2-azo-*p*-phenyltetramethylguanidine (PAPT) (4×10^{-5} M) in acetonitrile solvent: (a) unprotonated; (b) monoprotonated; (c) equilibrium between L and LH^+; (d) diprotonated.

^{13}C NMR spectra. The ^{13}C NMR spectrum of the free ligand in DMSO/D_2O (3:1) mixture is summarized in Table 1, together with the resonance peaks in DMSO and CD_3CN. The addition of the anhydrous $Ni(ClO_4)_2$ to the solutions of PAPT in these solvents caused a progressive relaxation of the resonance with increasing Ni^{2+} concentration by the paramagnetic nature of the system. The solution of the free ligand was systematically dosed with Ni^{2+} up to a 1:1 molar ratio of the metal to ligand. The spectrum showed a decrease in the intensity of the NMR peaks with each addition of Ni^{2+}, but no broadening of the peaks was observed.

The spectrum in the DMSO/D_2O mixture showed the same relaxed resonances in the presence of Ni^{2+} as observed in DMSO solvent, indicating that the presence of water, which strongly protonates the basic centre in the guanidinyl group

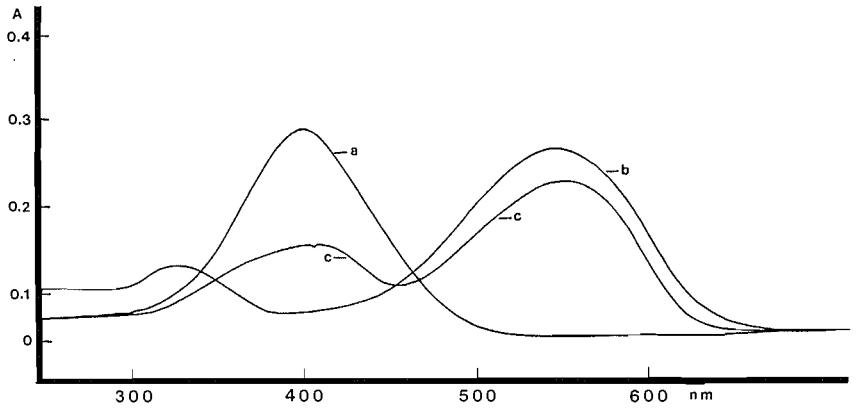

FIG. 3. Spectra of pyridine-2-azo-*p*-phenyltetramethylguanidine (2×10^{-5} M) with $Ni(ClO_4)_2$ (2×10^{-3} M) in acetonitrile solvent: (a) free ligand; (b) L:Ni^{2+}, 1:1; (c) large excess of Ni^{2+} over ligand, 1:400.

(Scheme 1), does not prevent the complexing by the pyridine azo group. The same conclusion can be reached from the relaxed spectrum of LNi^{2+} in CD_3CN. The addition of D_2O did not change the paramagnetic character of the system, indicating the presence of protonated LNi^{2+} complex (Scheme 1).

Reaction of PAPT with Ni(II) in acetonitrile solvent

PAPT in acetonitrile solvent, absorbing at $\lambda_{max} = 411$ nm, appears to be in the unprotonated form (Fig. 3(a)). The addition of anhydrous $Ni(ClO_4)_2$ (1:1) gives a blue-coloured species absorbing at $\lambda_{max} = 556$ nm (Fig. 3(b)). A large excess of Ni^{2+} over PAPT produces a shift from 556 nm to $\lambda_{max} = 565$ and 414.5 nm. These two maxima are assigned to LNi^{2+} (λ_{max} 556 nm) and $L(Ni^{+2})_2$ (λ_{max} 415 nm) (Fig. 3(c); Scheme 1).

The $LNi^{2+}H^+$ complex is not seen in the visible spectrum since its absorption is masked by the absorption peak of the LH^+ moiety. The protonation of LNi^{2+} shifts the absorption maximum from 556 to 345 nm, which is much closer to the LH^+ absorption than to that of LNi^{2+}, as shown by spectra (a) and (c) in Fig. 4.

The reaction of PAPT with Ni^{2+} to produce LNi^{2+} is much faster than the reaction with the second complexing centre (Fig. 5). In the first moment only the blue colour of the LNi^{2+} complex is observed at $\lambda_{max} = 565$ nm (Scheme 1), but in time an equilibrium with $L(Ni^{2+})_2$ (λ_{max} 415 nm) is reached. There was no indication of $L(Ni^{2+})_2$ when the ligand was in excess over Ni^{2+}.

Stability constants for LNi^{2+} and $L(Ni^{2+})_2$ formation have been measured spectrophotometrically using both stopped-flow and conventional spectrophotometry.

The following equilibria were considered:

$$L + Ni^{2+} \leftrightharpoons LN^{2+}$$

$$LNi^{2+} + Ni^{2+} \leftrightharpoons L(Ni^{2+})_2$$

Then

$$K_1 = \frac{[LNi^{2+}]}{[Ni^{2+}]\,[L]} \qquad \lambda_{max} = 565\ \text{nm}$$

$$K_2 = \frac{[L(Ni^{2+})_2]}{[LNi^{2+}]\,[Ni^{2+}]} \qquad \lambda_{max} = 415\ \text{nm}$$

$$\beta = K_1K_2 = \frac{[L(Ni^{2+})_2]}{[Ni^{2+}]^2\,[L]}$$

The stability constants were determined by standard methods

FIG. 4. [a]Initial concentration, 2×10^{-5} M.

(2, 16) using a constant initial concentration of the ligand and a varying excess of Ni^{2+}. Since the equilibrium constants are large, the optical density of the complexed solutions did not change very much with varying Ni^{2+} concentration. Reasonable agreement was obtained between the method of Klotz and Loh Ming (2) and that of Cayley and Hague (16), but the reported values cannot be considered to be precisely determined. Since the method of Cayley and Hague is the simpler of the two, it was used for all of these reported stability constant values. In this procedure d, the optical density of the complexed solution, is plotted against $d - d_0/[M]$ in which d_0 is the optical density of the ligand alone and [M] is the total metal ion concentration. The slope of this graph is $-1/K$. A least-squares fit to measurements carried out at 565 and 415 nm for the first and second equilibria at 25°C gave $K_1 = (6.1 \pm 0.9) \times 10^5\,L\,mol^{-1}$; $K_2 = (8.4 \pm 1.8) \times 10^3\,L\,mol^{-1}$, so that $\beta = (5.1 \pm 1.3) \times 10^9\,L^2\,mol^{-2}$.

The first equilibrium is fairly well separated from the second one (Scheme 1), allowing kinetic measurements for this reaction to be made.

The addition of water destroys the blue-coloured LN^{2+}, producing the complex $LNi^{2+}H^+$, absorbing at 345 nm (Fig. 4). Only the ^{13}C NMR study indicates that this is $LNi^{2+}\,H^+$, and not LH^+, which absorbs at 343 nm (Fig. 2). Therefore the kinetic measurements for the first, fast, reaction (Scheme 1) of PAPT with Ni^{2+} to yield the product LNi^{2+} can be performed in a dry system and in a limited range of excess of Ni^{2+} concentration.

The concentration of PAPT was 2×10^{-5} M and the concentration of Ni^{2+} was set in a moderate range, always in excess to fit the pseudo-first-order conditions, low enough to minimize the influence of the second step of reaction to produce the $L(Ni^{2+})_2$ complex (Scheme 1). The kinetic measurements were performed for five different concentrations of $Ni(ClO_4)_2$ in the range of 8×10^{-5} to 6×10^{-4} M, at five temperatures between 10° and 35°C.

Each k_{obs} value at a particular Ni^{2+} concentration was obtained from five separate kinetic runs, which were averaged electrically by a data collector coupled to a stopped-flow spectrophotometer.

The plots of k_{obs} against Ni^{2+} concentration are linear, yielding the second-order rate constant, k_f, from the slope. The intercept, k_b, would be the first-order rate constant for the dissociation of the LNi^{2+} complex to the starting materials, if the second complexation equilibrium had no interfering effect. The rate constants k_f and k_b, with their standard deviations, were computed from the plots of k_{obs} against the Ni^{2+} concentration using a least-squares fit. The results are presented in Table 2. The k_f^{25} value of $3.85 \times 10^3\,dm^3\,mol^{-1}\,s^{-1}$ is about four times smaller than the corresponding rate constant for the reaction of PADA in acetonitrile solvent ($1.7 \times 10^3\,cm^4\,mol^{-1}\,s^{-1}$ (9)). This result is surprising if the tetramethylguanidinyl group is more strongly electron releasing than the dimethylamino group in PADA.

In Table 2 the rate constants, k_b, have significant values. Bennetto and Imani (9) found for the reaction of PADA with Ni^{2+} in CH_3CN that the plots of the first-order rate constants against Ni^{2+} concentration passed through the origin, indicating $k_b \sim 0$ and a very large equilibrium constant for the metal ion – ligand reaction.

The equilibrium constant (K_1), measured as the ratio $k_f/k_b = 1 \times 10^4$ at 25°C, is very much smaller than that measured at equilibrium. This discrepancy is attributed to interferences of the second complexation reaction with another Ni^{2+} ion. Since the equilibrium constant of the first complexation is so large, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

second reaction would not introduce any error in the determination of k_f, but would give rise to a spurious k_b.

The values of the activation parameters for the reaction were calculated as $\Delta H^{\neq} = 4.6 \pm 0.1$ kcal mol^{-1} and $\Delta S^{\neq} = -26.6 \pm 0.4$ cal mol^{-1} deg^{-1}. The enthalpy of activation $\Delta H^{\neq}$ is smaller by 1.5 kcal mol^{-1} and the entropy of activation $\Delta S^{\neq}$ is more negative by 7.3 cal mol^{-1} deg^{-1} than the same reaction for PADA (9). The free energy value is smaller by 0.8 kcal mol^{-1} for the reaction of PADA in the same conditions (9).

The second complex $L(Ni^{2+})_2$ formed by the reaction of LNi^{2+} with Ni^{2+} at the guanidinyl centre, absorbing at $\lambda_{max} =$ 415 nm, has a smaller stability constant, $K_2 = (8.41 \pm 1.6) \times 10^3$, and this equilibrium was reached in a slower step, as is shown in Fig. 5.

To compare the complexing abilities of the pyridine azo centre and the guanidinyl centre, the equilibrium constant for the reaction of phenyltetramethylguanidine with $Ni(ClO_4)_2$ in acetonitrile was also measured, at 236 nm, the maximum of the absorption peak of an equimolar mixture of these two compounds. The value of K^{25} for a phenyltetramethylguanidine concentration equal to 2×10^{-5} M and a varying concentration of Ni^{2+}, at $\lambda_{max} = 236$ nm, was $(1.8 \pm 0.9) \times 10^4$ L mol^{-1}. This confirms that Ni^{2+} complexes with both the pyridine and TMG parts of the PAPT molecule and that the pyridine azo centre forms the more stable complex.

The second-order rate constant, k_f, was also determined for the reaction of Ni^{2+} with phenyltetramethylguanidine at 236 nm and was found to be 46.8 ± 0.7 dm^3 mol^{-1} s^{-1} at 25°C. This is about 80 times smaller than the corresponding value of PADA with Ni^{2+} (9), confirming the qualitative results shown in Fig. 5.

In conclusion, the new complexing agent pyridine-2-azo-*p*-phenyltetramethylguanidine (PAPT) reacts with Ni^{2+} ion in CH_3CN, giving two complexes, LNi^{2+} and $L(Ni^{2+})_2$. The first complex, LNi^{2+}, is formed in a faster reaction, which is, however, slower than the analogous reaction with PADA, and the second, $L(Ni^{2+})_2$, is formed in a slower reaction. The $\beta = (K_1K_2 = 5 \times 10^9)$ for both steps is very large. However, the TMG substituent group does not manifest itself as a more powerful electron-releasing group than the dimethylamino group.

Reaction of PAPT with Co(II) in acetonitrile solvent

A $Co(ClO_4)_2$ solution was used as the complexing agent. The reaction of an equimolar (2×10^{-5} M) concentration of PAPT and Co^{2+} gave two absorption peaks at 568 and 411 nm assigned to LCo^{2+} and $L(Co^{2+})_2$ respectively. The second step of the reaction to give the $L(Co^{2+})_2$ complex is relatively faster than the corresponding reaction of Ni^{2+}.

The estimated value of the stability constant $K_1^{25} = (1.2 \pm 0.4) \times 10^5$ L mol^{-1} for LCo^{2+} was in the same order of magnitude as that for LNi^{2+}. The estimated value of the rate constant of the reaction was $K_f^{25} = (4.2 \pm 0.6) \times 10^4$ dm^3 mol^{-1} s^{-1}. Both the stability and the rate constants were measured using a stopped-flow spectrophotometer. The LCo^{2+} complex was less stable than LNi^{2+}, making a precise kinetic study very difficult.

Reaction of PAPT with Zn(II) in acetonitrile solvent

Anhydrous $ZnCl_2$ was used to examine the reaction of PAPT with Zn^{2+}. The reaction shows two absorption peaks at 557 and 585 nm after the solutions of PAPT and $ZnCl_2$ were mixed. These were assigned to two different LZn^{2+} complexes, one in which the Zn^{2+} is complexed at the pyridine azo site and the other in which the Zn^{2+} is complexed at the guanidinyl site. In time, both peaks decreased while a third one at 409 nm, assigned to $L(Zn^{2+})_2$, grew. The addition of water causes a slow decomposition of the coloured species, giving λ_{max} at 340 nm, assigned to the protonated $LZn^{2+}H^+$ complex.

Using moisture-free conditions and the stopped-flow technique, the stability constant at 557 nm was determined as $K^{25} = (6.9 \pm 0.6) \times 10^4$ dm^3 mol^{-1}.

These values for the reaction of PAPT with Co^{2+} and Zn^{2+} are considered as preliminary results.

Experimental

Materials

The synthesis of pyridine-2-azo-*p*-phenyltetramethylguanidine (PAPT) was carried out starting with 2-(4-nitrophenyl)tetramethylguanidine (20). This compound (0.05 mol, 11.8 g) was dissolved in dry toluene (75 mL) and clean sodium (0.1 mol, 2.4 g) was added with stirring under a positive pressure of dry nitrogen. The mixture was carefully warmed until the reaction started, after which cooling was necessary to keep the reaction under control. After the vigorous reaction had stopped, the reaction mixture was refluxed until the sodium had disappeared. To this suspension of the disodium derivative, 2-aminopyridine (0.05 mol, 4.7 g) was added all at once and the reaction mixture was refluxed for another hour. When the reaction was complete, the solvent was removed under reduced pressure. After work-up (1), the crude oily product was extracted with benzene and the extract applied to a column filled with Kieselgel 100, 70–230 mesh, suspended in benzene. The subsequent elution with benzene and acetone gave the product, which after crystallization from heptane gave red crystals, mp 89°C; *m/z* (rel.int.%) 296(25.7), 268(12.6), 224(15.4), 197(12.9), 190(21.0), 146(20.3).

There were two other by-products, mp 175°C and 212°C. The product with mp 175°C is pyridine-2-azo-aniline; *m/z* (rel.int.%) 198(1.9), 170(27.5), 120(5.9), 92(39.8), 56(15.1). The product with mp 212°C gave a mass spectrum *m/z* (rel.int.%) 431(7.7), 413(23.0), 312(8.2), 397(6.2). This high molecular weight product, which must be formed by another coupling reaction, was not identified.

The anhydrous salts of $Ni(ClO_4)_2$ and $Co(ClO_4)_2$ were prepared from their hexahydrates by heating small samples of them over P_2O_5 in a vacuum oven at 120°C (9). Analysis of these anhydrous salts showed no evidence of decomposition. The samples were weighed in a dry-box and the solutions were prepared by dissolving the salt in dry (less than 0.01% water) acetonitrile.

Determination of dissociation constants

The determination of the dissociation constants pK_a of PAPT in water was accomplished spectrophotometrically using the method described by Albert and Serjeant (30), at 25°C at constant ionic strength $I = 0.1$ maintained by KCl, by means of a Cary 219 spectrophotometer and an Orion Research model 601 meter. To remove CO_2, doubly distilled water was boiled and during subsequent cooling saturated with nitrogen.

The dissociation constants of PAPT in acetonitrile solvent were measured using the Coetzee and Padmanabham method (28), according to the procedure already described (21).

Determination of stability constants

The stability constants of the complex of PAPT with Ni^{2+}, Co^{2+}, and Zn^{2+} in CH_3CN were measured spectrophotometrically at the λ_{max} characteristic of the appropriate complex, using a stopped-flow (Durrum–Gibson) or a UV–vis (Cary 219) spectrophotometer, depending on the type of reaction. The measurements for LNi^{2+}, LCo^{2+}, and LZn^{2+} were followed by the stopped-flow method and those for LNi^{2+} and $L(Ni^{2+})_2$ by conventional spectrophotometry using a Cary 219. The concentrations of the solutions for measurement of LNi^{2+}, LCo^{2+}, and LZn^{2+} were $[L] = 2 \times 10^{-5}$ M, with the concentration of M^{2+} reaching 200-fold excess.

The stability constants K were determined by measuring the optical

densities of the solutions of a fixed total ligand concentration with a varying excess of total metal ion concentration (2, 16). If d is the optical density of the solution of the complex and d_0 that of the ligand alone, a plot of d against $(d - d_0)/[M^{2+}]$ gives a straight line of slope $-1/K$. The measurements for LNi^{2+} were also performed according to the procedure described by Klotz and Loh Ming (2). There was no difference in the results obtained by these very similar methods.

Kinetic measurements

The kinetic measurements were performed using a stopped-flow Durrum–Gibson spectrophotometer with the metal ion concentration in an excess to assure pseudo-first order conditions. In both the equilibrium and kinetic measurements the reaction cells were thermostated to keep the temperature constant within ±0.1°C.

The solutions were always freshly prepared before the measurements and they were kept under a positive pressure of dry nitrogen to prevent atmospheric moisture.

Reçu le 4 mars 1991

GUY J. COLLIN, HÉLÈNE DESLAURIERS et GEORGE R. DE MARÉ. Can. J. Chem. **69**, 1245 (1991).

La photochimie du *cis*-penta-1,3-diène a été étudiée à 184,9 et à 147,0 nm en phase gazeuse. Les produits majeurs observés à 184,9 nm, outre le *trans*-penta-1,3-diène, sont le cyclopenta-1,3-diène, et divers radicaux révélés par l'addition d'iodure d'hydrogène. Le cyclopentadiène est formé très probablement via l'élimination successive de deux atomes d'hydrogène avec isomérisation concurrente du radical pentadiènyle vers la structure cyclopentènyle : Φ_0(cyclo-C_5H_6) ≈ 0,25. L'élimination du radical méthyle (Φ_0 = 0,50) est également importante. Il y a formation concomitante des radicaux CH_2=CHCH=$\dot{C}$H*, et dans une moindre mesure des radicaux CH_2=C=CH$\dot{C}H_2$*. On n'a cependant pas pu établir si ce dernier radical provient de l'isomérisation du précédent, ou s'il provient d'une molécule de penta-1,2-diène** résultant de l'isomérisation de la molécule photoexcitée. On a pu enfin observer une isomérisation conduisant vers la formation de penta-1,4-diène ($\Phi_0 \approx 0{,}03_5 \pm 0{,}01_5$). À 147,0 nm, on retrouve les mêmes caractéristiques, avec une fragmentation plus poussée des intermédiaires. L'énergie supérieure disponible à cette longueur d'onde explique cette observation. Globalement, la photofragmentation du *cis*-penta-1,3-diène s'apparente beaucoup plus à la photochimie des alcènes acycliques et assez peu à celle du buta-1,3-diène qui passe surtout pas l'isomérisation vers la structure buta-1,2-diène.

Mots clés : penta-1,3-diène, photolyse, UV lointain, réactions monomoléculaires, fragmentation, stabilisation.

GUY J. COLLIN, HÉLÈNE DESLAURIERS, and GEORGE R. DE MARÉ. Can. J. Chem. **69**, 1245 (1991).

We have studied the 184.9 and 147.0 nm photochemistry of gaseous *cis*-1,3-pentadiene: the main products observed at 184.9 nm are *trans*-1,3-pentadiene and 1,3-cyclopentadiene. The formation of radicals also occurs as shown through the use of DI as a radical scavenger. Cyclopentadiene is the likely product of successive eliminations of two hydrogen atoms from the photoexcited molecule after rearrangement of the pentadienyl radical to the cyclopentenyl structure: Φ_0(cyclo-C_5H_6) ≈ 0.25. Elimination of a methyl radical ($\Phi_0 \approx 0.50$) also occurs, with formation of CH_2=CHCH=$\dot{C}$H* and, in a lower yield, CH_2=C=CH$\dot{C}H_2$*. However, it is not possible to identify properly the mechanism of the formation of the latter radical. It may be the result of the isomerization of either the first photoexcited molecule or the excited 1,3-butadienyl radicals. A small amount of 1,4-pentadiene formation is also observed ($\Phi_0 \approx 0.03_5 \pm 0.01_5$). At 147.0 nm, the same characteristics are observed, together with higher fragmentation due to the higher energy content of the photoexcited molecules. It appears that the photofragmentation at both wavelengths is more in line with that of acyclic alkenes than with that of 1,3-butadiene, which tends to undergo isomerization of the photoexcited molecules to the 1,2-butadiene structure.

Key words: 1,3-pentadiene, far UV, vacuum UV, photolysis, monomolecular, fragmentation, stabilization.

Introduction

La photochimie des diène-1,3 a été relativement bien étudiée, tout particulièrement à 253,7 nm, donc par voie photosensibilisée. Elle a fait l'objet de rapport dans plusieurs manuels de référence (1, 2). Plus spécifiquement, la photoisomérisation *cis–trans* en solution, de même que la formation de cyclopropènes et de cyclobutènes substitués a été observée (3–5). À plus courtes longueurs d'onde, les travaux sont plus rares. Il est cependant pertinent de mentionner un travail réalisé à 228,8 nm. On y rapporte la mise en évidence d'un excimère (6). Aucun travail ne semble avoir spécifiquement porté sur la fragmentation de la molécule excitée et à plus courtes longueur d'onde.

La photofragmentation du buta-1,3-diène est mieux connue (7, 8). Nous avons, en particulier, montré que la molécule photoexcitée (buta-1,3-diène)** s'isomérise vers la forme (buta-1,2-diène)** avant rupture de la liaison C—CH_3.

[1] CH_2=CH—CH=CH_2 + $h\nu$ → (CH_2=CH—CH=CH_2)**

[2] (CH_2=CH—CH=CH_2)** → (CH_2=C=CH—CH_3)**

[3] (CH_2=C=CH—CH_3)** → CH_2=C=$\dot{C}$H + ·CH_3

1. Auteur à qui adresser toute correspondance.

Le présent travail se propose de vérifier la validité du mécanisme précédent dans le cas du *cis*-penta-1,3-diène (cPd13). Si ce mécanisme est acceptable, il se propose également d'étudier la chimie du radical CH_2=C=CH—$\dot{C}H_2$ qui pourrait être éventuellement formé par décomposition de la molécule (CH_2=C=CH—CH_2—CH_3)** excitée.

Partie expérimentale

Photoirradiation

Les techniques expérimentales sont bien connues. La lampe à mercure, basse pression (Philipps), émet principalement à 184,9 nm et surtout à 253,7 nm (9). La lampe de résonance à xénon émet presqu'exclusivement à 147,0 nm entre 120 et 250 nm (10). Ces émissions, ainsi que les coefficients d'absorption du penta-1,3-diène, sont vérifiées à l'aide d'un monochromateur McPherson d'un demi-mètre. La formation du butane normal dans la photolyse de l'éthylène sert d'actinomètre. Toutes les irradiations sont réalisées à la température de la pièce : $T = 20 \pm 2$°C.

Quelques irradiations ont été réalisées avec un filtre en Vycor. Ce filtre éliminait complètement la raie située à 184,9 nm et atténuait de quelque 30% la raie située à 253,7 nm.

Produits chimiques

Le *cis*-penta-1,3-diène est un produit A.P.I. (99,91 ± 0,02%). La principale impureté observée est le *trans*-penta-1,3-diène dont la

concentration variait entre 0,06 et 0,12% dépendamment de l'échantillon utilisé. Ces échantillons contenaient des traces de C_2H_4 + C_2H_6 (4–26 ppm), d'acétylène (3–15 ppm), de cyclopenta-1,3-diène (8 ppm). L'oxygène (99,99%) et l'hexafluorure de soufre (99,99%) proviennent de chez Matheson et l'iodure de deutérium de chez Merck Sharp and Dohme du Canada. Tous ces produits sont utilisés tels que reçus, après dégasage à la température de l'azote liquide lorsque leur pression de vapeur saturante le permet.

Analyses

Toutes les analyses sont effectuées par chromatographie en phase gazeuse avec détecteur à flammes ionisantes. On a utilisé de façon séparée, deux colonnes remplies en acier inoxydable. La première (6 m, ϕ : 6 mm) en est une de squalane (20%) déposée sur «firebrick» (11). La seconde en est de Ucon LB 550X (7,50 m, ϕ : 6 mm) maintenue à 50°C (12).

Résultats

(a) À 184,9 nm

La photolyse du cPd13, en l'absence d'additif montre la formation importante du *trans*-penta-1,3-diène (trPd13). Le rendement quantique de ce produit varie entre 0,4 et 1,7 avec une incertitude relative au moins égale à ±25% étant donné le niveau d'impuretés (tableau 1). Ce rendement quantique semble augmenter légèrement avec l'augmentation de pression. Le penta-1,4-diène est aussi formé avec un rendement beaucoup plus faible que ce soit en l'absence ou en présence d'intercepteurs (tableau 1) : $\Phi(\text{penta-1,4-diène}) \approx 0{,}03_5 \pm 0{,}01_5$ quelle que soit la pression au sein du réacteur. D'autres produits, tels que le méthane (Φ <0,01), l'éthylène, l'acétylène, le propylène, buta-1,3-diène sont aussi observables avec des rendements quantiques inférieurs à 0,05. En présence de 10% d'oxygène, la photolyse montre la formation des mêmes produits (tableau 2). Le produit majeur observable est le cyclopenta-1,3-diène dont le rendement décroît rapidement avec l'augmentation de la pression. L'ajout de SF_6 a un effet similaire sur la plupart des rendements (figure 1).

L'irradiation réalisée à travers le filtre en Vycor ne produit qu'une faible isomérisation *cis–trans* à peine discernable du niveau d'impureté.

En présence de DI ou de D_2S, le méthane est un produit majeur (Φ ≈ 0,5 sous une pression de 1 Torr), de même que les *cis*- et *trans*-pentène-2 et surtout le trPd13 (tableau 3). On retrouve également des quantités importantes d'éthylène, de propène, de buta-1,3-diène, et dans de moindres quantités, d'acétylène, de buta-1,2-diène et un peu de cyclopentène.

(b) À 147,0 nm

Les caractéristiques principales relevées à 184,9 nm se retrouvent à 147,0 nm. Les produits majeurs sont encore le *trans*-penta-1,3-diène, le cyclopentadiène, l'acétylène et le vinylacétylène. On ne retrouve cependant pas de penta-1,4-diène et la formation de produits légers semble quantitativement plus importante. Les rendements de ces produits diminuent avec l'augmentation de la pression (tableau 4, figure 2).

L'effet combiné de l'oxygène et de l'iodure de deutérium a

Effet du SF_6 sur l'inverse des rendements quantiques de l'acétylène : (□) $y = 4,68 + 0,017x$; $r^2 = 0,96$; du vinylacétylène : (◇) $y = 5,60 + 0,020x$; $r^2 = 0,97$; et de l'éthylène : (■) $y = 14,9 + 0,041x$; $r^2 = 0,90$.

été exploré. L'oxygène diminue la formation des *cis*- et *trans*-pentène-2 générés par le DI sans toutefois vraiment interférer avec l'isomérisation *cis–trans* du monomère (tableau 5).

Discussion

1. À 184,9 nm

(a) Isomérisation de la molécule photoexcitée

Le principal produit observé à 184,9 nm est le *trans*-penta-1,3-diène. L'isomérisation *cis–trans* du penta-1,3-diène a été maintes et maintes fois observée et discutée, que ce soit en photosensibilisation (2, 3, 6), en radiolyse (13), dans des systèmes catalysés (14) ou par voie thermique (15). La photoisomérisation à 366 nm catalysée par le Pyrex a aussi été observée (16), de même que la photochimie directe à 253,7 nm (17). Les possibilités sont donc nombreuses. La quantité d'informations recueillies ici est insuffisante pour permettre une discussion éclairée. Rappelons seulement que la formation d'une molécule éthylénique électroniquement excitée dans l'état V (π,π^*) permet un retour vers l'état fondamental soit vers la structure *cis*, soit vers la structure *trans* (réf. 2, p. 475). La présence de radicaux et d'atomes d'hydrogène ou d'iode permet aussi d'obtenir cette isomérisation *cis–trans* à travers leur addition réversible sur cette double liaison (14). Le rendement quantique voisin de l'unité, mesuré en présence ou en l'absence d'oxygène (tableau 1), compte tenu des réactions de fragmentations observées, laisse entrevoir la possibilité d'un mécanisme en chaîne.

Un autre isomère linéaire observé est le penta-1,4-diène. Son rendement est relativement peu affecté par la présence d'intercepteurs : $\Phi([5] = 0,03_5 \pm 0,01_5$. L'observation de ce produit a aussi été faite en photochimie directe à 253,7 nm et il a permis de calculer un temps de vie de la molécule excitée de 2×10^{-8} s (18). On peut donc suggérer une réaction d'isomérisation directe de la molécule photoexcitée à travers un déplacement sigmatropique [1,3] d'un atome d'hydrogène. Ce processus a été observé dans divers alcènes cycliques (19) et acycliques (20). Dans ce dernier cas, les rendements sont d'autant plus importants que la liaison éthylénique déplacée est d'autant plus substituée (21). Cette isomérisation semble impliquer la molécule photoexcitée après sont retour à l'état fondamental, donc à partir de la molécule vibrationnellement très chaude (22).[2]

[4] $cPd13 + h\nu \rightarrow (cPd13)^{**}$, I

[5] $(cPd13)^{**} \rightarrow CH_2{=}CHCH{=}CHCH_3{\ddagger}$

[6] $CH_2{=}CHCH{=}CHCH_3{\ddagger} \rightarrow CH_2{=}CHCH_2CH{=}CH_2$

2. Un arbitre a très justement remarqué que le rendement en penta-1,4-diène présente une tendance nette (bien que faible) à l'augmentation en présence de SF_6. Cette augmentation est tout à fait en accord avec la présence de molécules vibrationnellement chaudes.

(b) L'élimination d'un atome d'hydrogène

La décroissance observée du rendement en cyclopentadiène-1,3, que ce soit à 184,9 ou à 147,0 nm, est importante. Dans un premier temps, on peut supposer que un ou plusieurs intermédiaires sont impliqués dans le processus de formation, selon le mécanisme suivant :

[7] $(cPd13)^{**} \rightarrow \overline{CH_2CHCHCHCH_2}^* + H$

[8] $(cPd13)^{**} \rightarrow$ autres produits

[9] $(cPd13)^{**} + M \rightarrow cPd13 + M$

[10] $\overline{CH_2CHCHCHCH_2}^* \rightarrow$ cyclo-C_5H_7*

[11] $\overline{CH_2CHCHCHCH_2}^* + M \rightarrow \overline{CH_2CHCHCHCH_2} + M$

[12] cyclo-C_5H_7* → cyclo-C_5H_6 + H

[13] cyclo-C_5H_7* + M → cyclo-C_5H_7 + M

L'application du principe de quasi-stationarité des concentrations des espèces réactives à ce mécanisme conduit à l'expression suivante, où $[M]$ est la pression :

$$[14] \quad [\Phi(\text{cyclo-}C_5H_6)] = \frac{k_7 k_{10} k_{12}}{(k_{10} + k_{11}[M])(k_{12} + k_{13}[M])(k_5 + k_7 + k_8 + k_9[M])}$$

L'inverse du rendement quantique du cyclopenta-1,3-diène est donc une fonction cubique de la pression. La régression d'ordre 3, appliquée à la courbe :

$$[15] \quad [\Phi(\text{cyclo-}C_5H_6)]^{-1} = a + b[M] + c[M]^2 + d[M]^3$$

montre un coefficient de corrélation excellent ($r^2 = 0,971$) (figure 3). Un calcul similaire obtenu avec une régression d'ordre 2 conduit à un coefficient de corrélation au moins aussi bon, avec cependant une constante b, du produit $b[M]$, négatif. Ces résultats indiquent clairement l'effet de stabilisation dû à l'effet de pression sans pouvoir vraiment choisir entre un mécanisme faisant intervenir deux (23) ou trois étapes de stabilisation (trois intermédiaires susceptibles de stabilisation).

Afin d'améliorer la sensibilité du traitement statistique, les mêmes résultats ont été traités en traçant la fonction :

$$[16] \quad \frac{\left(\frac{1}{\Phi} - a\right)}{P} = b' + c'[M] + d'[M]^2$$

où a, b', c' et d' sont des constantes positives composées des coefficients k_7 à k_{13}. On obtient ainsi (figure 4) une courbe quadratique ayant trois coefficients positifs, avec un coefficient de corrélation convenable, légèrement meilleur que celui obtenu à partir d'une relation linéaire. On peut donc raisonnablement préférer un mécanisme impliquant trois intermédiaires susceptibles de stabilisation.

Nous avons, par ailleurs, montré récemment que les radicaux pentadiényles excités, formés dans la photochimie à 184,9 nm du méthyl-3 penta-1,4-diène, conduisent facilement à la formation de cyclopenta-1,3-diène (24). Cependant, la nature exacte de ce processus (cyclisation 1–5 du radical pentadiényle ou passage via un intermédiaire vinylcyclopropyle) n'a pu être précisée (25).

Il faut enfin relever que, par extrapolation à pression nulle, donc en l'absence de réaction de stabilisation, le rendement en cyclopenta-1,3-diène est voisin de 0,25, permettant d'afficher une valeur minimum du rendement de la réaction [7] : $\phi([7]) \geq 0,25$.

(c) L'élimination d'un radical méthyle

La mesure des radicaux méthyles s'effectue relativement bien en présence de DI ou de D_2S : réaction suivante (26, 29) :

[17] $\cdot CH_3 + DI \text{ ou } D_2S \rightarrow CH_3D + \cdot I \text{ ou } \cdot SD$

Sous une pression de 1 Torr, $\Phi_{DI}(\text{méthane}) \approx \Phi_{D_2S}(\text{méthane})$

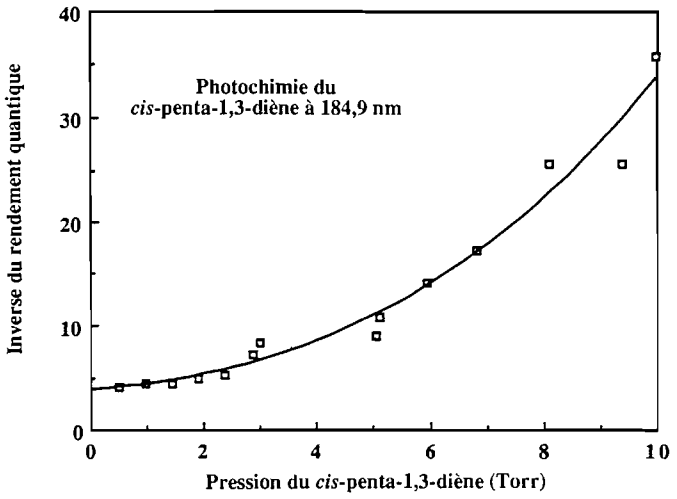

FIG. 3. Photochimie du mélange *cis*-penta-1,3-diène : oxygène (100 : 10) à 184,9 nm. Effet de la pression totale sur l'inverse du rendement quantique du cyclopenta-1,3-diène : $y_2 = 4{,}20 - 0{,}039x + 0{,}29x^2$; $r^2 = 0{,}973$; ou $y_3 = 3{,}82 + 0{,}42x + 0{,}14x^2 + 0{,}0115x^3$; $r^2 = 0{,}971$.

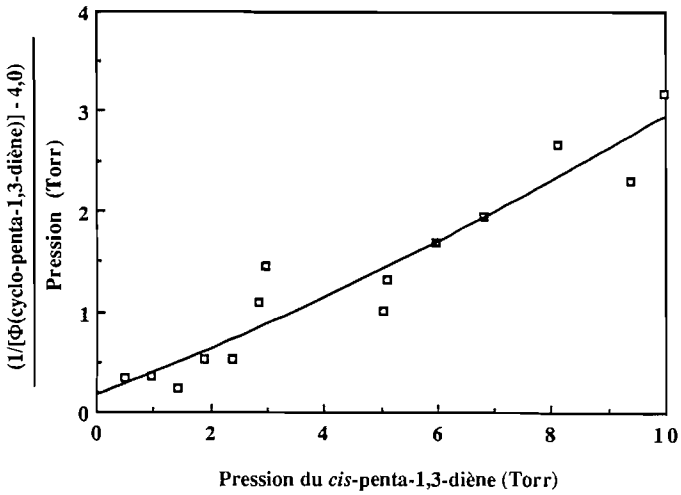

FIG. 4. Photochimie du mélange *cis*-penta-1,3-diène : oxygène (100 : 10) à 184,9 nm. Effet de la pression totale sur la fonction

$$\left(\frac{1}{\Phi(\text{cyclo-}C_5H_6)} - 4{,}0\right) \Big/ P = f([M]):$$

$y = 0{,}166 + 0{,}22M + 0{,}006M^2$; $r^2 = 0{,}97$.

$\approx 0{,}50 \pm 0{,}03$, alors qu'en l'absence d'interception ou en présence d'oxygène, le rendement en méthane ne dépasse pas 0,02. On peut donc estimer un rendement en radicaux méthyles voisin de $0{,}48 \pm 0{,}04$.

[18] $(cPd13)^{**} \rightarrow CH_2{=}CH{-}CH{=}CH^* + \cdot CH_3$

[19] $(cPd13)^{**} \rightarrow CH_2{=}C{=}CH{-}CH_2{-}CH_3{**}$

[20] $CH_2{=}C{=}CH{-}CH_2{-}CH_3{**} \rightarrow CH_2{=}C{=}CH{-}\dot{C}H_2{*} + \cdot CH_3$

La réaction [18] prévoit la rupture directe de la liaison C—CH_3 de la molécule *cis*-penta-1,3-diène photoexcitée. Les réactions [19] et [20], à l'exemple du buta-1,3-diène cité plus haut, proposent l'isomérisation de la molécule photoexcitée, via un transfert interne, 1,3, d'un atome d'hydrogène avant rupture d'une liaison C—CH_3 située en position β par rapport à une double liaison. Cette liaison est, en générale, la plus fragile dans les hydrocarbures insaturés acycliques. Elle entraîne une décomposition relativement facile des molécules vibrationnellement excitées (30).

La présence des radicaux C_4H_5 est confirmée à travers la formation observée en présence de DI des buta-1,3- et -1,2-diène (réactions d'interception similaire à la réaction [17]). Cela n'implique pas nécessairement la concurrence des deux mécanismes, puisque l'interconversion (isomérisation) des deux radicaux C_4H_5* excités ne peut pas être complètement éliminée (il s'agit aussi d'un transfert interne 1,3 d'un atome d'hydrogène) :

[21] $CH_2{=}CH{-}CH{=}\dot{C}H^* \Leftrightarrow CH_2{=}C{=}CH{-}\dot{C}H_2{*}$

(d) La rupture d'une liaison carbone–carbone (autre que C—CH_3)

La formation d'un certain nombre de produits légers en C_2 et C_3 réclame la rupture d'une liaison C—C située à l'intérieur de la molécule photoexcitée. C'est le cas de la formation de l'acétylène, de l'éthylène, du propène, ... Les rendements quantiques de ces produits suivent une loi de type Stern–Volmer (23) :

[22] $[\Phi(x)]^{-1} = [\Phi_0(x)]^{-1}(1 + k_s/k_d[M])$

où k_d est la constante de vitesse d'ordre 1 et k_s la constante de vitesse d'ordre 2, respectivement des réactions de décomposition et de stabilisation de l'intermédiaire excité.

[23] $(cPd13)^{**} \rightarrow CH_2{=}\dot{C}H^* + \cdot CH{=}CHCH_3$

[24] $CH_2{=}\dot{C}H^* \rightarrow CH{\equiv}CH + H$

[25] $CH_2{=}\dot{C}H^* + M \rightarrow CH_2{=}\dot{C}H + M$

L'équation [22] devient :

[26] $[\Phi(C_2H_2)]^{-1} = \Phi_0(C_2H_2)^{-1}(1 + k_{25}/k_{24}[M])$

où Φ_0 est le rendement mesuré par extrapolation à pression nulle. Au moins deux autres propositions de mécanismes sont disponibles :

[27] $(cPd13)^{**} \rightarrow CH_2{=}\dot{C}H + \cdot CH{=}CHCH_3{*}$

[28] $\cdot CH{=}CHCH_3{*} \rightarrow CH{\equiv}CH + \cdot CH_3$

[29] $(cPd13)^{**} \rightarrow \cdot CH_3 + CH_2{=}CHCH{=}CH^*$

[30] $CH_2{=}CHCH{=}CH^* \rightarrow CH_2{=}\dot{C}H + CH{\equiv}CH$

réactions auxquelles il faut ajouter les réactions de stabilisation des radicaux excités. Ces deux derniers mécanismes montrent que l'on ne peut pas indiquer l'ordre chronologique des fragmentations, réactions [23]–[24], [27]–[28] ou [29]–[30]. Ajoutons seulement que, compte tenu de l'énergie disponible à 184,9 nm, il est peu probable que deux radicaux excités issus de la même molécule puissent aussi se fragmenter. Les radicaux vinyles et propèn-1-yles apparaissant simultanément dans les réactions [23] et [27], ne sont pas susceptibles de fragmentation conjointe.

Si l'on ne peut connaître avec certitude l'identité du précurseur, la droite Stern–Volmer permet cependant d'obtenir une idée assez juste du temps de vie de l'intermédiaire. Ainsi, le rapport de sa pente divisée par son ordonnée à l'origine permet de connaître le rapport k_d/k_s mesuré, en terme d'unité de pression. En utilisant la pression comme horloge interne, ou plus scientifiquement, en identifiant k_s à la constante de vitesse

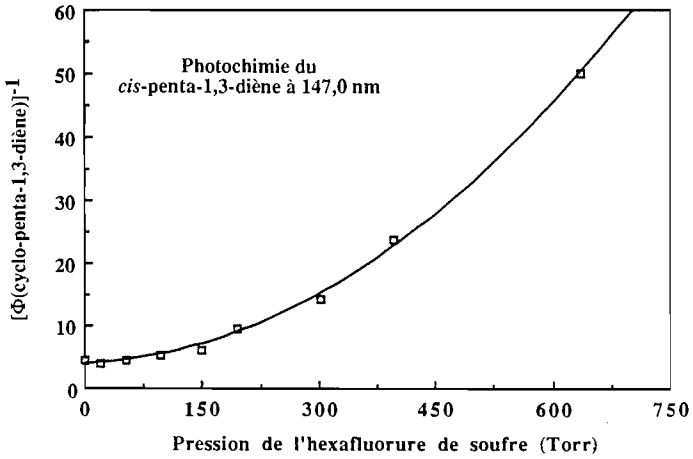

FIG. 5. Photochimie du mélange *cis*-penta-1,3-diène : oxygène (1,0 : 0,12 Torr) à 147 nm. Effet du SF_6 sur l'inverse du rendement quantique du cyclopenta-1,3-diène : $y_2 = 4{,}00 + 0{,}0043x + (1{,}07 \times 10^{-4})x^2$; $r^2 = 0{,}998$ ou $y_3 = 4{,}46 + 0{,}0097x + (1{,}71 \times 10^{-4})x^2 - (6{,}87 \times 10^{-8})x^3$; $r^2 = 0{,}999$.

de collision physique, on peut évaluer k_d et donc le temps de vie de l'intermédiaire.

Les rapports k_d/k_s ainsi calculé pour l'acétylène, l'éthylène et le propène sont, respectivement, égaux à 97,5, 76 et 86 Torr. Avec une fréquence de collision sous une pression de 1 Torr telle que $\omega = 1{,}45 \times 10^7\ s^{-1}$, le temps de vie de l'intermédiaire responsable de la formation du propène est de 0,80 ns. Ce temps de vie est relativement long comparativement au temps de vie calculé pour la molécule pentène-1 photoexcitée à 184,9 nm (31). On peut donc raisonnablement proposer que la stabilisation porte plutôt sur l'intermédiaire radicalaire que sur la molécule (cPd13)** elle-même.

2. À 147,0 nm

(a) La fragmentation par rupture de liaison

La photodécomposition de la molécule photoexcitée à 147,0 nm conduit à une variété importante de produits (tableau 4), donc de chemins réactionnels. L'énergie disponible (811 kJ E^{-1}) est énorme relativement aux énergies nécessaires à la rupture d'une liaison C—H ou C—CH_3. Compte tenu du mécanisme proposé à 184,9 nm et de ce que l'on connaît, par ailleurs, de la photochimie des alcènes acycliques à la même longueur d'onde (29), on peut proposer le mécanisme de type suivant :

[31] $(cPd13)^{**} \rightarrow \cdot R_1^* + \cdot R_2$

[32] $\cdot R_1^* \rightarrow \cdot R_3 + M$

où $\cdot R_1^*$ est un radical suffisamment excité pour donner lieu à une réaction de fragmentation subséquente, $\cdot R_2$ et $\cdot R_3$ sont, soit un atome d'hydrogène, soit un radical et M une molécule stable. En ne comptant pas le méthane, l'éthane, et le méthyl-4 pentène-2 qui sont probablement produits par réactions radicalaires, et le *trans*-penta-1,3-diène dont on ne sait pas très bien comment il est formé (voir plus haut), la somme des produits moléculaires légers apparaissant à 0,45 Torr (tableau 4) est de 0,94 ($\pm$0,15). Cette identité entre le nombre de molécules photoexcitées et le nombre de molécules qui se décomposent est peut-être fortuite. En effet, bien que les cas soient relativement rares et de peu d'importance quantitative, la photofragmentation pourrait produire en une seule étape deux molécules stables (32). Ce type de réaction commande une réorganisation (isomérisation) et une énergie relativement exigeante de la molécule photoexcitée pour atteindre une géométrie convenable :

[33] $CH_3CH{=}CHCH{=}CH_2^{**} \rightarrow (M)^{**} \rightarrow CH_3CH{:} + C_3H_4$

[34] $CH_3CH{:} \rightarrow C_2H_4$

En retournant au mécanisme type mentionné plus haut, la formation du cyclopenta-1,3-diène rapportée à 184,9 nm (réactions [7]–[13] sont de ce type) : $\Phi_0(\text{cyclo-}C_5H_6) \approx 0{,}25$ (figure 5). La courbure positive de la droite Stern–Volmer est ici, aussi, évidente. Malgré une coefficient de corrélation exemplaire ($r^2 = 0{,}999$), on doit remarquer que la régression du 3^e degré introduit des coefficients négatifs alors qu'ils devraient être tous positifs. Un traitement similaire à celui réalisé à 184,9 nm (figure 4) montre que les résultats ne peuvent définitivement pas être traités à l'aide d'une régression d'ordre trois, ne laissant que la possibilité d'un ordre deux, donc d'un mécanisme ne faisant intervenir que deux étapes de stabilisation.

Il en est de même de la formation de l'acétylène, réactions [23]–[30], du vinylacétylène, réaction [18] suivie de

[35] $CH_2{=}CH{-}CH{=}\dot{C}H^* \rightarrow CH_2{=}CHC{\equiv}CH + \cdot H$

Les formations de l'éthylène et du propène peuvent aussi se rattacher à ce type de mécanisme pourvu, cependant, qu'il soit précédé par un réarrangement de la molécule photoexcitée. L'efficacité du SF_6, pour stabiliser les intermédiaires, est ici plus faible que ce qui a été observé à 184,9 nm. L'énergie plus importante disponible à 147,0 nm est sans doute responsable d'une durée de vie plus courte des intermédiaires excités. Les temps de vie, calculés à travers les droites Stern–Volmer pour les intermédiaires présidant à la formation de l'acétylène et du vinylacétylène sont voisins : 0,25 ns.

L'identification et la mesure des rendements quantiques des radicaux ne sont pas nécessairement simples. Il faut tenir compte des réactions radical–radical, de l'addition des atomes d'hydrogène sur le penta-1,3-diène, ... Les formations de l'éthane et du méthyl-4 pentène-2, en l'absence d'intercepteurs radicalaires, sont à mettre au compte de ces réactions :

[36] $\cdot CH_3 + \cdot CH_3 \rightarrow C_2H_6$

[37] $\cdot H + cPd13 \rightarrow CH_3CH{=}CHCHCH_3$

[38] $CH_3CH{=}CHCHCH_3 + CH_3 \rightarrow CH_3CH{=}CHCH(CH_3)_2$

Ces réactions permettent d'établir une valeur minimum des rendements en radicaux méthyles et en atomes d'hydrogène : $\Phi(\cdot CH_3) > 2\Phi(C_2H_6) + \Phi(C_6H_{12}) \approx 0{,}23$ et $\Phi(\cdot H) > \Phi(C_6H_{12})$.

L'augmentation des rendements en méthane et en éthylène en présence d'iodure d'hydrogène confirme la présence des radicaux méthyles et vinyles. La quantification est cependant plus problématique. En effet, l'iodure de deutérium initie la formation d'une quantité importante de *cis*- et de *trans*-pentène-2. Il en ressort qu'en fin d'irradiation, la majeure partie de l'additif est consommé. Il n'agit donc plus avec toute l'efficacité requise. L'addition simultanée d'oxygène et d'iodure d'hydrogène augmente de façon importante le rendement en méthane, tout en réduisant la formation de ces deux pentène-2. Les rendements en méthane alors obtenus $\Phi_{DI+O_2}(\text{méthane}) \approx$ 0,24–0,27 sont probablement plus réalistes. Il ne faut pas oublier que l'oxygène est lui-même capable d'intercepter les radicaux méthyles. Les valeurs $\Phi(\cdot CH_3)$ doivent donc être supérieures aux valeurs $\Phi_{DI+O_2}(\text{méthane})$, mesurées.

Reactions of Muonium with simple biochemical solutes in water and micelles

MARY V. BARNABAS[1] AND DAVID C. WALKER
Department of Chemistry and TRIUMF, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6
Received February 15, 1991

MARY V. BARNABAS and DAVID C. WALKER. Can. J. Chem. **69**, 1252 (1991).

Rate constants are reported for the reaction of muonium atoms in water with some 36 organic compounds, many of interest in biology. These k_M values range from $<10^5$ to 7×10^{10} M^{-1} s^{-1}, according to the *type* of reaction involved, with the sugar–phosphate backbones of nucleic acids being at the low end and their bases at the high end. They are compared with corresponding published H-atom data (k_H), where possible, and show kinetic-isotope-effects ranging over five orders of magnitude. Since all k_H data were obtained at pH = 1, while k_M values refer to pH ~ 7 of the natural state, the pH-dependence of k_M was examined in representative cases. The changes found result from protonation of the solute rather than a changed reactivity of Mu on being converted to MuH^+. On localizing the solutes in the hydrophobic phase of dilute micelles, the reactivity of Mu was again measured ($k_{M(mic)}$). The resulting "enhancement" factor was considered in terms of: the reaction mechanism, its dependence on microenvironment (solvation), and the concentrating effect of mutual confinement to small sections of a biphasal system.

Key words: kinetic isotope effects, muonium, biochemicals, micelles.

MARY V. BARNABAS et DAVID C. WALKER. Can. J. Chem. **69**, 1252 (1991).

On a déterminé les constantes de vitesse, dans l'eau, d'atomes de muonium avec 36 composés organiques, dont plusieurs ont un intérêt biologique. Ces valeurs de k_M varient de $< 10^5$ à 7×10^{10} M^{-1} s^{-1} suivant le *type* de réaction impliqué; les composés comportant les phosphates de sucre des acides nucléiques réiques réagissent généralement les moins rapidement alors que leurs bases se trouvent à l'autre bout du spectre de réactivité. Lorsque c'est possible, on a comparé ces valeurs avec les données correspondantes publiées pour les atomes d'hydorgène (k_H); on a observé des effets isotopiques cinétiques s'étiques s'étalant sur cinq ordres de grandeur. Puisque toutes les données relatives aux k_H ont été déterminées à un pH = 1, alors que les valeurs de k_M se réfèrent au des pH = 7 de l'état naturel, on a examiné la relation entre le pH et les valeurs des k_M, pour des cas représentatifs. Les changements qui ont été observés sont plutôt dus à la protonation du soluté qu'à un changement de réactivité du Mu lorsqu'il se transforme en MuH^+. On a de nouveau mesuré la réactivité des Mu ($k_{M(mic)}$) aprés leur localisation dans les phases hydrophobes de micelles diluées. On a évalué le facteur d'« augmentation » de la réactivité en fonction: du mécanisme de la réaction, de sa dépendance sur le microenvironnement (solvatation) et sur l'effet d'augmentation de la concentration par un confinement mutuel dans des faibles sections d'un système à deux phases.

[Traduit par le rédaction]

Introduction

Simple organic compounds which are basic constituents of biological systems were selected for this study. The principal functional groups targeted were carbonyls, amides, thiocarbonyls, carboxylic acids, amino acids, as well as representative DNA and RNA bases, their sugars, nucleosides and nucleotides.

These compounds were subjected to reaction with free muonium atoms in aqueous solution as produced by muon bombardment of water. Muonium (Mu) is the hydrogen-like atom with a positive muon of 2.2 μs lifetime as its nucleus (1). Mu has one-ninth the mass of ^1H, and is produced at the end of ~38% of the high energy muon tracks in water. Given a suitable muon beam, one can directly observe rates of reaction of Mu and expect to see subtle kinetic isotope effects compared to ^1H because of the unusually large isotopic–mass ratio. Muonium reaction rates are observed by the nuclear physics counting technique of muon spin rotation (μSR) (1, 2). In this technique the species of interest (Mu) is both produced and detected, one atom at a time. A summation is then made over a large number of such events to determine the relaxation of the spin precession — from which the chemical rate constant is determined.

Experimental

In the μSR technique (1, 2) each muon is timed as it arrives at the sample and its decay-positron is timed when the muon decays. A lifetime histogram is then composed from the accumulation of ~10^7 such events. With the sample placed in an external transverse magnetic field the direction of emission of positrons fluctuates as the muon's spin precesses, because the positron is ejected predominantly along the muon's spin vector at the moment it decays. This means that a positron detector in the plane of precession sees a typical lifetime histogram with the Mu precession frequency superposed on it. The amplitude of this oscillation is proportional to the yield and the rate of damping is proportional to Mu's rate of reaction. In pure water the oscillation has a half-life of about 4 μs, but as Mu reacts with solutes this is reduced by a factor proportional to k_M.

An eight parameter MINUIT χ^2-minimization fitting procedure is applied to each histogram and gives the muonium relaxation, λ in eq. (1), as one of these parameters.

$$[1] \qquad N_t = N_0 \exp(-t/\tau)[1 + A_M \exp(-\lambda t)\cos(\omega_M t + \phi_M) + A_D \cos(\omega_D t + \phi_D)] + Bg$$

where N_t is the number of counts in the histogram corresponding to time t; N_0 a normalization factor; τ the mean muon lifetime; A_M and A_D, ω_M and ω_D, and ϕ_M and ϕ_D are the asymmetries, angular speed, and initial phases of the "muonium atoms" and "diamagnetic muon components", respectively; and Bg is the time-independent background signal. λ is the relaxation in the presence of solute, λ_0 the value with [solute] = 0, so that $\Delta\lambda = \lambda - \lambda_0 = k_M[S]$.

μSR equipment was used on beamlines M20 and M13 at the TRIUMF cyclotron in Vancouver. Aqueous solutions were made from triply distilled water and thoroughly deoxygenated by bubbling with pure N_2. The micelles used were cetyltrimethylammonium bromide (CTAB), sodium dodecylsulphate (SDDS), and sodium octylsulphate (SOS). A typical micelle consists of 50–80 surfactants so the inherent impurities of the surfactant molecules contribute to the "background" relaxation λ_0. The solutes were invariably Reagent Grade or better.

Impurities could be a problem for the weakly reacting solutes but not for efficient ones.

An experiment was usually repeated at a few solute concentrations, so that a plot of relaxation against solute concentration yielded a mean value of k_M. However, only a small range of concentrations can be used for an given solute due to a restriction imposed by μSR. This technique requires one to adjust the solute concentration until the muonium *chemical* lifetime falls into the narrow observational time-window around the 2 μs lifetime when its muon decays. For solutes with $k_M \sim 10^{10}$ this requires only $\sim 10^{-4}$ M, but for solutes with $k_M < 10^6$ one needs concentrations of 1 M or more. In the latter cases impurities could be responsible for the observed reaction and only upper limits on k_M are reliable. With the micelle experiments there were additional limitations: first the impurities in the surfactants pushed λ_0 up and restricted the highest usable concentrations, so that only lower limits of $k_{M(mic)}$ were measureable; and second, the lowest concentrations usable were at about two times the crictical-micelle-concentrations, which put an upper limit on rate measurements.

Results

Table 1 records values of k_M for 36 compounds and $k_{M(mic)}$ values (many just limits) for 26 of them. For 17 of these compounds k_M has been reported previously (3, 4) and only the $k_{M(mic)}$ values are new. They are grouped according to functionality. Included among them are simple aliphatic amides and diamides, ring amides, thio-amides, carboxylic acids, purine and pyrimidine bases, constituents of nucleic acids' sugar–phosphate backbones, and a few common compounds added for comparison purposes. The structures are given in Fig. 1. All these data refer to solutions at natural pH (usually close to 7). Table 2 presents k_M data at two different pH values for a range of reaction types, including three inorganic compounds.

These data are subject to a number of experimental errors. Each μSR measurement carries a statistical uncertainty, usually taken as one standard deviation. In any one run there

are three or four separate counters involved, each producing its own histogram, fit independently and yielding a separate value for λ. These counters have different efficiencies and intrinsic asymmetries and the spread of their separate results tend, surprisingly, not to be covered by the statistical error bars. Nevertheless one has obtained three or four independent values of Δλ and hence k for a given solution. These can be averaged, and another solution made up and run, thus reducing the probability of errors from impurities, weighings, dilutions, deoxygenations, etc. Overall, however, even when Δλ is in the accurate range around 1×10^6 s^{-1}, the rate constants probably have at least a ±25% error associated with them. In the k regions where [S] > 0.1 M there is also the considerable uncertainty stemming from the possibility of impurities.

Discussion

The major objectives of this research were (*i*) to measure k_M for molecules of biological significance in the hope of drawing general inferences about basic reaction mechanisms; (*ii*) to compare Mu with ^1H as a measure of general kinetic isotope effects; and (*iii*) to study these reactions in micelles to explore the role of membrane isolated processes, and to compare reactions in water with those in hydrophobic microenvironments. All three aspects can have implications for radiobiology (5).

(*i*) k_M *values – effect of structure on reactivity*

Figure 2 displays the k_M data of Table 1 in a form which groups the compounds into four categories. The ordinate is logarithmic so a considerable range of reactivities is involved. k_M depends on the type of reaction and its detailed mechanism and therefore on the nature of each functional group present. Muonium atoms are usually regarded as strong reducing agents like e^-_{aq}; but they also undergo a variety of completely different *types* of reactions, like H. For instance, Mu is seen to "add" across a double or triple bond, "abstract" an H or halogen, "substitute" in place of a bonded H or halogen, undergo an acid-base reaction by exchanging a proton (in this case a muon) to yield e^-_{aq}, or, when interacting with a paramagnetic chemical entity, Mu may either "combine" with it to form a diamagnetic molecule or merely change its multiplicity in an electron-exchange interaction (6). Of all these possible Mu reactions, the *products* can be detected or identified only in the case of addition — and then only because level-crossing-resonance spectroscopy (LCR) allows muonated free radicals to be seen (7). In general one must rely on chemical inferences to deduce mechanisms. In Mu's reactions with the organic compounds of this study addition and abstraction seem to dominate.

To exemplify the diversity of Mu reactivity, compare acetamide, acetone and thioacetamide, with k_M values of $<10^5$, 1.1×10^8 and 3×10^{10} $M^{-1}s^{-1}$ respectively. Changing the —NH_2 group to —CH_3 increases the rate by at least 2 orders of magnitude, and the change of carbonyl to thiocarbonyl increases the rate by >5 orders of magnitude. This tendency can be explained qualitatively in the following terms: The —$CONH_2$ linkage of acetamide is rigid and planar with maximum conjugation of πe^-s in the C=O bond with the non–bonding pair of N. This makes it less reactive to addition by Mu than a free carbonyl, so only abstraction occurs (from —CH_3 or —NH_2). In the case of acetone, the carbonyl π system is available for attack and Mu is known to add to the O (8). This directional preference in attaching to the O may be partly because Mu is weakly nucleophilic (9) and put off the C by its two electron–releasing methyls, and partly because the C-centered >Ċ—OMu radical formed is stabilized by hyperconjugation. In thioacetamide, however, the Mu–addition is known to be different and to occur at C, giving rise to a thiyl radical (RṠ) (10, 11). The dipole moments of thioamides are larger than those of corresponding amides, and the C=S group is inherently more polarizable than the C=O group on account of the larger kernal of electrons in the S atom, with the result that the double bond is weakened so that Mu adds rapidly at C.

Unfortunately, thioacetone was not available for comparison with the above, but thiourea was. It shows a reaction even less efficient than acetone, and shows by far the slowest reaction of all the C=S-containing molecules. Also, in an LCR study (11), thiourea showed no RṠ resonance where the other thiocompounds did. All these suggests Mu adds at the S rather than the C for the specific case of thiourea. In contrast to thiourea, tetramethylthiourea reacts with Mu at $k_M = 4 \times 10^{10}$, while thioacetamide and dimethylthioformamide are also highly reactive toward Mu and have been seen to give thiyl LCRs (11): so it looks as if the double keto–enol exchange stabilization of thiourea must play a unique role in eliminating reaction of Mu at the C of its C=S.

Almost every system has a different message and the following are worth drawing attention to: (*a*) Mu abstracts

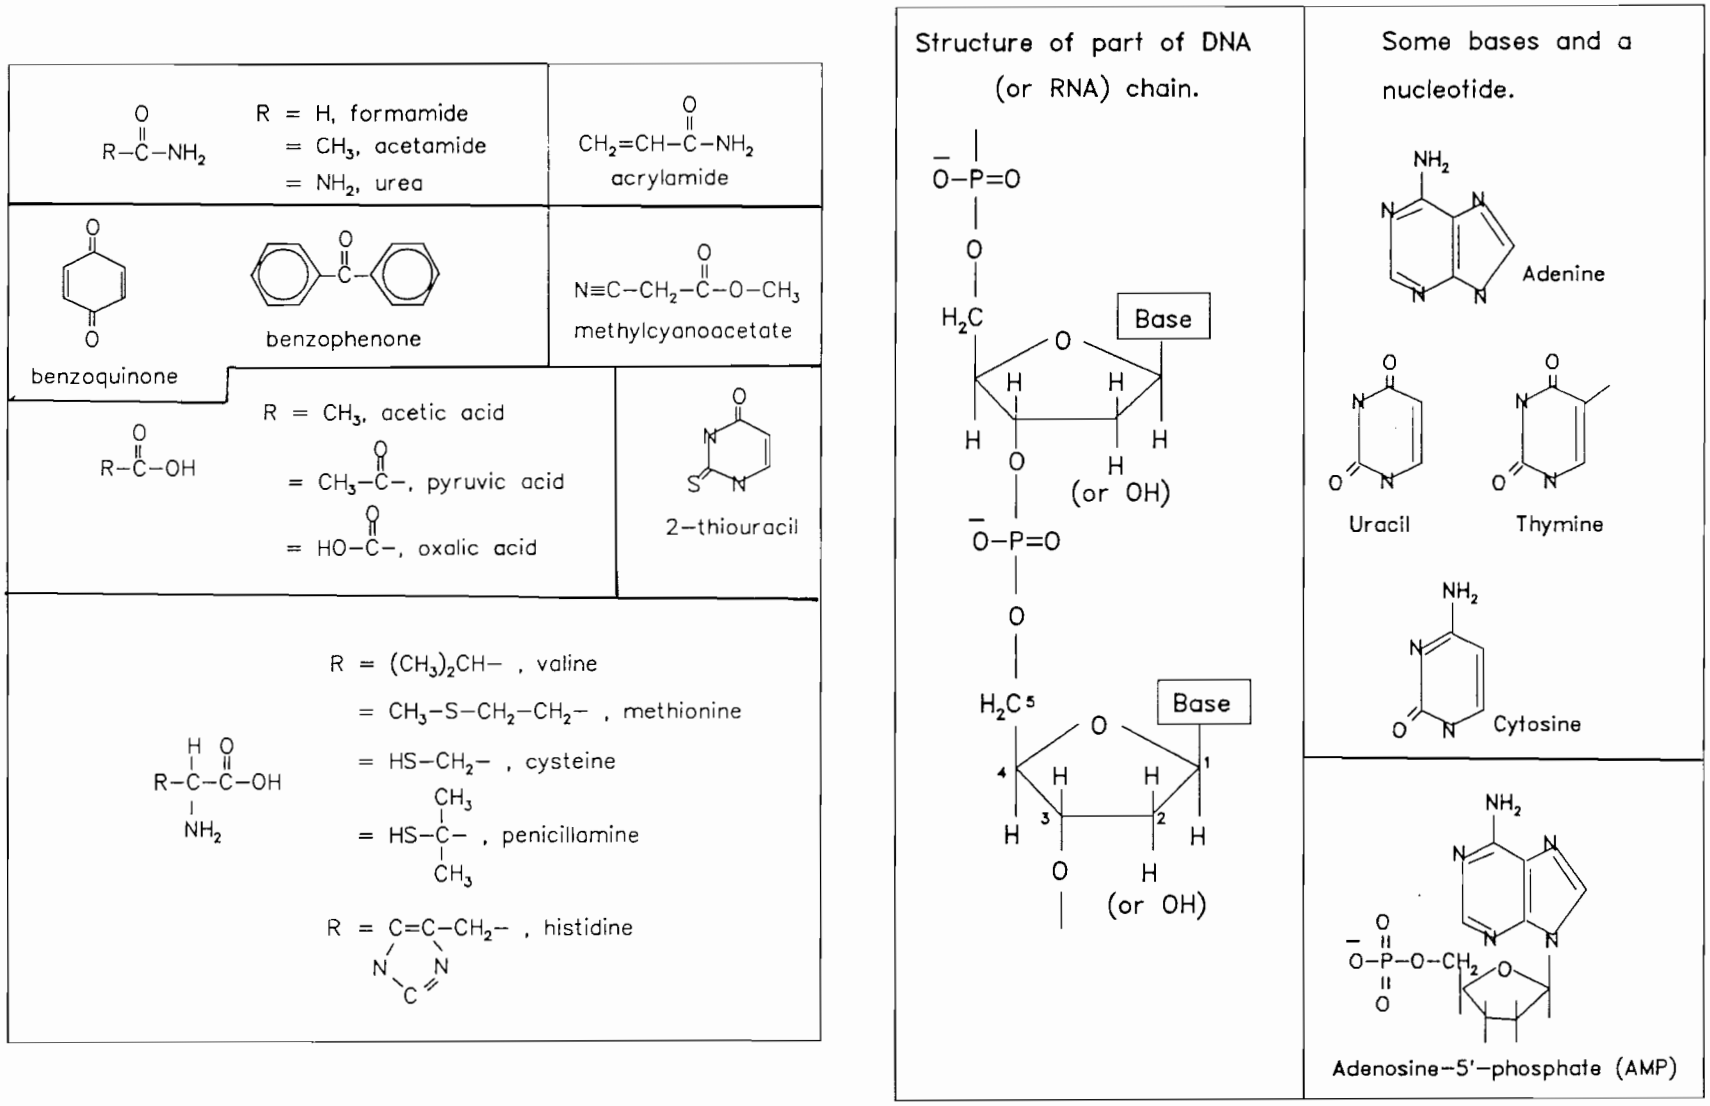

FIG 1. Structures of most of the chemicals used here.

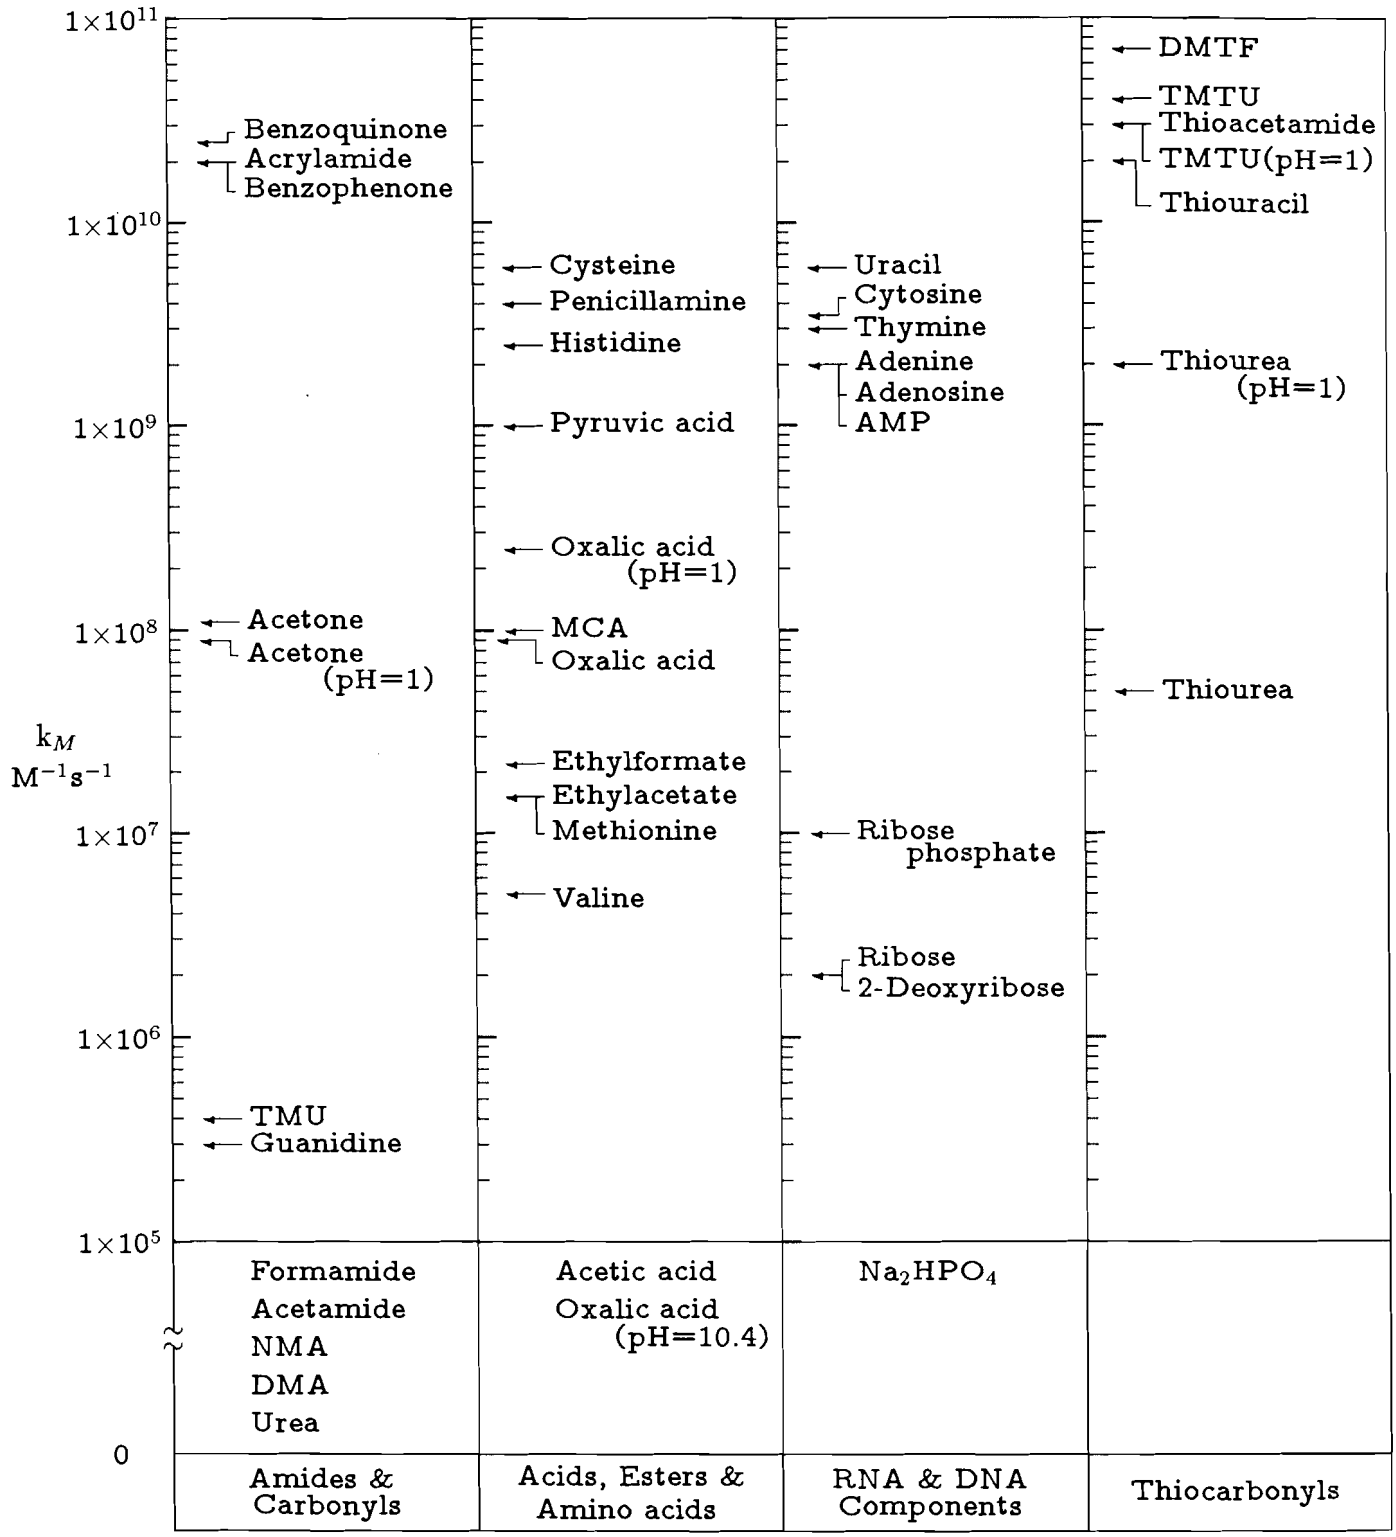

FIG 2. A sketch showing the variation of k_M, separated into compounds of different functional groups.

an H from the —SH of penicillamine with $k_M = 4 \times 10^9$, which is orders of magnitude faster than Mu abstractions from C—H, and faster than H-atoms abstract (12). (*b*) Mu adds to the —C≡N bond of methylcyanoacetate faster than to the >C=N of guanidine. (*c*) Mu adds across an unsubstituted cyclic C=C, as in uracil, faster than across a methyl- or methylene- substituted one, as in thymine or histidine — *i.e.* Mu is significantly sterically hindered by CH_3 in C=C addition. (*d*) Both benzoquinone and benzophenone react with Mu much faster than benzene or acetone. (*e*) Carboxylic groups are unreactive towards Mu, whether as esters, anions or undissociated —COOH, so the reaction with oxalic acid is probably an addition reaction, like H (13). (*f*) The DNA and RNA sugar–phosphate backbones, either as separate units or as ribose-5-phosphate, are essentially unreactive (not above the level where impurities dominate) whereas the purine or

For personal use only.

pyrimidine bases are quite reactive, whether as separate chemicals (*eg* adenine) or nucleosides (adenosine) or nucleotides (adenosine-5-phosphate, AMP). One can therefore expect the radiobiology of nucleic acids to arise by attack of radiolysis species at the inner bases rather than at the helical backbone.

(*ii*) *Kinetic isotope effects* – k_M/k_H

Use is made of muonium as an isotope of H primarily because Mu is easier to detect (given a source of muons!) due to its radioactive nature, spin characteristics and magnetic moment. In comparing k_M with the corresponding k_H, note must be taken of the fact that most H-atom data obtained by pulse radiolysis involve converting e^-_{aq} to H by having the water at pH $\sim$ 1; whereas the data of Fig. 2 were obtained for Mu reactions at pH $\sim$ 7, as in nature. For several solutes (Table 2 and others (14)) the analogous pH = 1 solutions were studied. For most solutes unaffected by acid, k_M didn't change, implying, as expected, that the reactivity of muonium atoms themselves are not altered significantly by protonation to MuH^+. Furthermore Mu's pK_a (to give e^-_{aq} by muon transfer to OH^-) is known to be about 10 (15). However, some solutes are protonated at pH 1 but not at pH 7, so their reactivity towards Mu could be altered for that reason. Oxalic acid seems to fall into that category, possibly aided towards an addition reaction when both carboxylic groups are protonated. Another change arises for thiourea (already seen to be at odds with general concepts) and tetramethylthiourea. The former increases at low pH while the latter decreases, and they happen to finish with almost the same k_M at pH 1. But for molecules like acetone there is no change with pH and even an alcohol such as 2-propanol shows only a two-fold change in k_M.

Bearing in mind these possible differences from protonation, the comparison of Mu with ^1H is shown in the central column of Table 1. This kinetic isotope effect is seen to range from 750 (oxalic acid) and 33 (acetone — known to be an addition reaction (8)) to $\sim$0.01 for abstraction reactions (2-deoxyribose or 2-propanol).

At least three factors have to be considered when analysing kinetic isotope effects. First is the pre-exponential encounter-frequency term given by the ratio of mean velocities or diffusion constants, where the ratio k_M/k_H should be $\sim$3; second is the activation barrier favouring H because of the higher vibrational energy of the Mu-transition state; and third is the quantum tunneling effect, where Mu should be favoured if the effect of reduced mass wins out over the larger barrier height and width (6). Fast addition reactions seem to comply with the first, slow abstractions with the second, and odd ones such as carbonyls with the third.

(iii) *Effect of added micelles*

Micelles are the simplest artificial systems to be used to mimic biological membranes. In fact they are far from uniformly spherical and show considerable water penetration (16). Organic solutes localize at micelles according to Poisson statistics, so, for three times as many solutes as micelles in solution — as in these experiments — there should be <6% unoccupied micelles and <8% with more than six solutes. The presence of micelles creates three microenvironments in which reaction may occur: an inner hydrocarbon core, an external aqueous medium containing lose ion atmospheres, and the boundary region (Stern layer). The latter may be the most important for all polar solutes forced by bulk water out of its interstices. It may be the region where Mu reacts and where large phenomenological reaction-rate enhancements occur (17).

A few general comments about muonium-micelle reactions are in order. Muonium is not itself significantly "localized" at micelles — that is, its mean residence time was found to be no longer than the time it would take to diffuse through that volume of an equally viscous liquid (18). This lack of *mutual* localization by Mu (in addition to the organic solute) means that the "concentration" to be used in evaluating k_M is **not** the local intra-micellar concentration, but merely the mean value based on total volume of solution (19). Therefore, there is no automatic concentrating-effect arising from the fact that the organic solute is confined to the small volume of a micelle. In fact, for a highly efficient reaction, the effective rate constant can be diminished by the bunching of solute molecules at micelles. $k_{M(mic)}$ values can be expected to depend on the type of reaction, its rate constant in water, the region of micelle in which the solute is localized, and on the number of solute molecules per micelle. Some solutes do not preferentially localize due to their much greater solubility in water than in hydrocarbons: one such example here, thiourea, supports the proposition that Mu is not strongly localized at micelles (18), in not showing $k_M \gg k_{M(mic)}$. Finally, H-atoms cannot be similarly studied in micelles (20) because H reacts $\sim 10^2$ times faster than Mu with the surfactants themselves.

Of the $k_{M(mic)}$ data which are not just showing an upper limit, there are enhancement factors up to 20 000 (2-propanol — a very slow abstraction), 290 (acetone — conversion from addition to abstraction (21)), values of 10–50 (for aminoacids and sugars), to no-change (for a range of rates from diffusion-limited additions, such as acrylamide, to moderately fast abstactions, as with methionine). It was hoped that the enhancement factor would be useful in deciding what reaction mechanism was involved, but there is not yet a simple enough pattern present to do that.

Conclusions

The rate constants of Mu reactions present a range of almost six orders of magnitude, while kinetic isotope effects (relative to H) differ for different types of reactions from 0.007 to 750. The change in apparent reactivity on adding micelles varies in a variety of ways for different functional groups. The reactions of Mu with the many components of DNA and RNA show that the addition reaction with the bases is much more favourable than the abstraction of a H from a sugar unit. There are no significant micelle–induced enhancement effects for the major components of nucleic acids.

Excess molar volumes of (a cycloalkane + an alkanol) at 298.15 K

T. M. LETCHER AND J. MERCER-CHALMERS
Department of Chemistry, Rhodes University, Grahamstown, South Africa

Received December 7, 1990

T. M. LETCHER and J. MERCER-CHALMERS. Can. J. Chem. **69**, 1259 (1991).

In this work we report the excess molar volumes, V_m^E for the miscible mixtures $\{xc\text{-}C_5H_{10} + (1 - x)CH_3OH\}$ and $\{xc\text{-}C_kH_{2k} + (1 - x)C_lH_{2l+1}OH\}$ where $k = 5, 6, 7, 8$, or 10 and $l = 2$ or 3. The V_m^E results are discussed in terms of the size of the cycloalkane ring and the type of alcohol.

Key words: Excess volumes, cycloalkane + alkanol.

T. M. LETCHER et J. MERCER-CHALMERS. Can. J. Chem. **69**, 1259 (1991).

On a déterminé les volumes molaires en excès, V_m^E, pour des mélanges miscibles de $\{xc\text{-}C_5H_{10} + (1 - x)CH_3OH\}$ et de $\{xc\text{-}C_kH_{2k} + (1 - x)C_lH_{2l+1}OH\}$ dans lesquels $k = 5, 6, 7, 8$ ou 10 et $l = 2$ ou 3. On discute des valeurs de V_m^E obtenues en fonction de la grandeur du cycloalcane et du type d'alcool.

Mots clés : volumes en excès; cycloalcane + alcool.

Introduction

The excess molar volume, V_m^E was measured as a function of mole fraction x at 298.15 K and one atmospheric pressure for the mixtures $\{xc\text{-}C_5H_{10} + (1 - x)CH_3OH\}$ and $\{xc\text{-}C_kH_{2k} + (1 - x)C_lH_{2l+1}OH\}$ where $k = 5, 6, 7, 8$, or 10 and $l = 2$ or 3. The mixtures defined by $k = 6, 7, 8$, or 10 with $l = 1$ are not included as they are not miscible over the whole composition range. Of the sixteen data sets presented in this work four have been reported (1–4).

Experimental

The cycloalkanes were purified as previously described (5). The alkanols were dried as before (6, 7) and in all cases the water impurity (by Karl Fischer titration) was found to be less than 2×10^{-3} mole fraction. The cycloalkanes and the alkanols were analysed by g.l.c. and in all cases the purity was found to be better than 99.8 mol%.

The V_m^E values were calculated from molar masses and densities of pure liquids and mixtures using an Anton-Paar DMA 601 vibrating-tube density meter, thermostated at 298.15 ± 0.002 K. The method has been described (8).

Results

The V_m^E results have been deposited with the National Research Council of Canada[1] and the Redlish Kister equation:

$$[1] \quad V_m^E = x(1 - x)\Sigma_{r=0}A_r(1 - 2x)^r$$

has been fitted to the results. The coefficients A_r are given in Table 1, together with the standard deviation σ calculated from

$$\sigma = \sqrt{\Sigma(V_{m,exp} - V_{m,calc})^2/(n - n_p)}$$

where n is the number of observations and n_p the number of parameters.

Discussion

Our V_m^E results for (cyclopentane + ethanol) and (cyclohexane + ethanol) are within 0.005 $cm^3\ mol^{-1}$ of the results

reported by Marsh and Burfitt (1). The V_m^E values reported here for (cyclohexane + ethanol) and those of ref. 1 compare well to those reported by Pardo and van Ness (2) but differ by as much as 0.03 $cm^3\ mol^{-1}$, in the worst case, when compared to the published results of Scatchard and Satkiewicz (3). Our results for (cyclohexane + 1-propanol) compare reasonably well with those published by Janssens and Ruel (4) and differ by only 0.012 $cm^3\ mol^{-1}$ from their smoothing curve.

The V_m^E values for all the mixtures, except for (cyclodecane + 2-propanol) at low cyclodecane concentrations, are positive over the whole composition range. This is most likely a result of the breakdown of the hydrogen bonding between the alcohol molecules on addition of the cycloalkane. The $V_{m,maximum}^E$ for all the systems presented here lie between +0.16 and +0.57 $cm^3\ mol^{-1}$.

The $V_m^E(x = 0.5)$ results for all sixteen systems has been plotted as a function of cycloalkane carbon number, k, in Fig. 1. The values for the cyclopentane systems are very much lower than the values predicted by the pattern generated by the other cycloalkanes. This is reminiscent of the $V_m^E(x = 0.5)$ values obtained for cycloalkane + n-alkane mixtures (9). For these mixtures the $V_m^E(x = 0.5)$ values for the cyclopentane systems are all less positive than the $V_m^E(x = 0.5)$ predicted by the pattern generated by the cyclohexane, cycloheptane, cyclooctane, and cyclodecane systems. It is possible that the small size of the cyclopentane molecule results in a compact packing structure within the hydrogen bonded network of alcohol molecules, resulting in a small overall volume of mixing.

The magnitude of $V_m^E(x = 0.5)$, for mixtures of a cycloalkane + a 1-alkanol is also dependant on the 1-alkanol chain length. From Fig. 1, for any given cycloalkane, $V_m^E(x = 0.5)$ decreases with increasing alkanol chain length. This could be a direct result of the fact that hydrogen bonding decreases in alcohols with increasing chain length. The breakdown of this hydrogen bonding on mixing results in methanol producing a more positive V_m^E than ethanol, and ethanol in turn producing a more positive effect than 1-propanol. The effect of the branched alkane chain in 2-propanol produces an effect which lies between that of ethanol and 1-propanol.

The photocycloaddition of naphthoates with acetylacetone; dramatic acid promotions of product quantum yields

YUAN L. CHOW[1] AND XIAO-YUN LIU

Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received December 20, 1990

YUAN L. CHOW and XIAO-YUN LIU. Can. J. Chem. **69**, 1261 (1991).

In acetonitrile and methanol, methyl 1- and methyl 2-naphthoate (1- and 2-$NpCO_2CH_3$) underwent [2+2] photocycloaddition with acetylacetone (acacH) from a reactive species derived from the lowest spectroscopic singlet excited state to give cyclobutane derivatives such as **9** that ring-opened to afford addition products of acetyl and acetonyl moieties at the 7,8-position for 1-$NpCO_2CH_3$ (**2** and **3**) and the 1,2-position for 2-$NpCO_2CH_3$ (**7**). Further irradiation of **3** and **7** caused a deep-seated rearrangement of **3** to give **4** and an intramolecular addition of **7** to give the caged product **8**. The photocycloaddition quantum yields were increased remarkably in the presence of a trace amount (<0.001 M) of protic acids. For example, the limiting quantum yield of **2** and **3** with $\Phi_{adducts} = 0.033$ (in the absence) increased to $\Phi_{adducts} > 0.5$ under comparable conditions in the presence of $[H_2SO_4] = 0.001$ M, approaching the maximum asymptotically at about this concentration; the increases of the quantum yield could not be correlated with H_2SO_4 concentrations. The acid promotion of the product formation elevated the photocycloaddition to a significantly useful preparative reaction. The photocycloaddition of 2-$NpCO_2CH_3$ was quenched by tributylamine, dimethylaniline, and methyl iodide, and could not be initiated by typical triplet sensitization. Strong fluorescence of 2-$NpCO_2CH_3$ at 358 nm in CH_3CN was quenched by acetylacetone, tributylamine, dimethylaniline, and methyl iodide, the last of which concurrently enhanced the phosphorescence intensity of 2-$NpCO_2CH_3$. In the presence of $[H_2SO_4] > 0.005$ M the fluorescence intensity at 358 nm was quenched and a new fluorescence at 470 nm corresponding to protonated ^{1}2-$NpCO_2CH_3$ appeared. However, in the $[H_2SO_4] < 0.002$ M region, the new fluorescence was not observed, indicating that the protonation scarcely occurred. The Stern–Volmer constant, obtained by the quantum yield monitor, of the 2-$NpCO_2CH_3$ photocycloaddition with acacH was more than an order of magnitude smaller than that obtained by the quenching of 2-$NpCO_2CH_3$ fluorescence by acacH. The discrepancies outlined above clearly demonstrate that the reactive intermediate of the photocycloaddition is not the exciplex of the spectroscopic singlet excited species of ^{1}2-$NpCO_2CH_3$ and acacH, but one that is derived from the exciplex. It is speculated that this unknown reactive intermediate interacts with a proton to promote the photocycloaddition.

Key words: photocycloaddition of naphthoates, photorearrangement of styryl ketones, acid catalysis of quantum yields, fluorescence of protonated naphthoates, acid enhancement of singlet quenching.

YUAN L. CHOW et XIAO-YUN LIU. Can. J. Chem. **69**, 1261 (1991).

Dans l'acétonitrile et le méthanol, les 1- (et 2-) naphtoates de méthyle (1- et 2-$NpCO_2CH_3$) subissent une photocycloaddition [2+2] avec l'acétylacétone (acacH), par le biais d'une espèce réactive obtenue à partir de l'état excité singulet spectroscopique le plus bas, conduisant à des dérivés du cyclobutane du type **9** qui donnent lieu à une ouverture de cycle et à la formation de produits d'addition des portions acétyle et acétonyle sur les positions 7 et 8 du 1-$NpCO_2CH_3$ (**2** et **3**) et sur les positions 1 et 2 du 2-$NpCO_2CH_3$ (**7**). Une irradiation prolongée des composés **3** et **7** provoque des transpositions profondes de **3** en **4** et une addition intramoléculaire de **7** en **8**, un composé en forme de cage. Les rendements quantiques de photocycloaddition augmentent d'une façon remarquable en présence d'une trace (<0,001 M) d'acide protique. Par exemple, le rendement quantique limite des produits **2** et **3** passe de $\Phi_{(produits)} = 0{,}033$ (absence d'acide) à plus de 0,5 (pour $[H_2SO_4] = 0{,}001$ M) avec une croissance asymptotique qui atteint son maximum autour de cette valeur; on n'a pas pu établir de corrélation entre le rendement quantique et la concentration en H_2SO_4. La catalyse acide de la formation des produits a transformé la photocycloaddition en une réaction préparative d'une grande utilité. La photocyloaddition du 2-$NpCO_2CH_3$ est désactivée par la tributylamine, la diméthylaniline et l'iodure de méthyle et elle ne peut pas être initiée par des sensibilisateurs typiques de triplets. La fluorescence importante du 2-$NpCO_2CH_3$ à 358 nm est désactivée par l'acétylacétone, la tributylamine, la diméthylaniline et l'iodure de méthyle; ce dernier produit provoque en même temps une augmentation de l'intensité de la phosphorescence du 2-$NpCO_2CH_3$. En présence d'une $[H_2SO_4] > 0{,}005$ M, l'intense fluorescence à 358 nm est désactivée et il y a apparition d'une nouvelle fluorescence à 470 nm, correspondant au ^{1}2-$NpCO_2CH_3$. Toutefois, lorsque la $[H_2SO_4] < 0{,}002$ M, on n'observe pas la nouvelle fluorescence ce qui indiquerait que la protonation se produit à peine. La constante de Stern–Volmer de la photocycloaddition du 2-$NpCO_2CH_3$ avec l'acacH, obtenue en observant le rendement quantique, est au moins 10 fois plus faible que celle obtenue par la désactivation de la fluorescence du 2-$NpCO_2CH_3$ par l'acacH. Les différences mentionnées plus haut démontrent clairement que l'intermédiaire réactif de la photocycloaddition n'est pas l'exciplexe des espèces excitées singulets spectroscopiques du ^{1}2-$NpCO_2CH_3$ et de l'acacH, mais plutôt un autre qui est dérivé de cet exciplexe. On suppose que cet intermédiaire réactif inconnu interagit avec un proton pour promouvoir la photocycloaddition.

Mots clés : photocycloaddition des naphtoates, photoéarrangement de styrylcétones, rendements quantiques acido-catalysés, fluorescence de naphtoates protonés, désactivation acido-catalysée de singulets.

Introduction

Whereas photocycloaddition of naphthalene derivatives with olefins has been well established (1), there is an obscure area in photochemistry where the reaction involves naphthalene derivatives and enones (2–7). As the excited state of both classes of compounds can initiate photochemical reactions (1–7), their mutual photoreactions appear to have escaped the attention of investigators. This was the reason that we undertook a mechanistic investigation after finding the photocycloaddtion of acetylacetone (acacH) and methyl naphthoates.

Cyano group substituted naphthalenes have been shown to undergo singlet excited state photocycloaddition with electron-

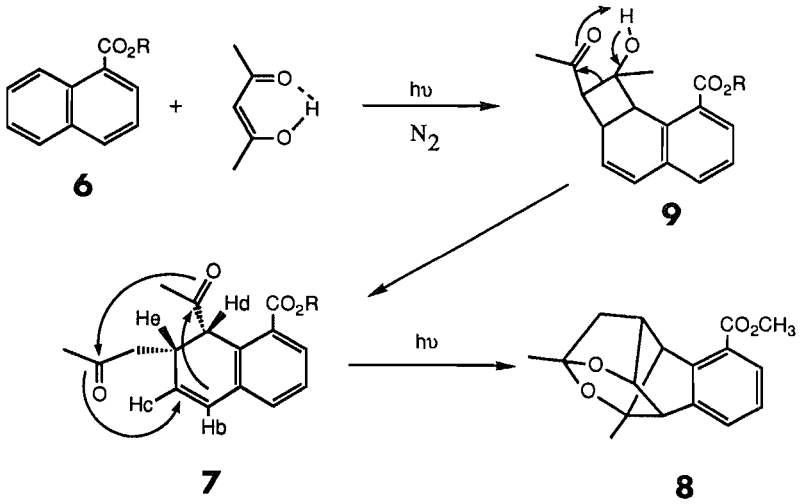
For personal use only.

rich olefins to give cyclobutane and azetine products (1, 8). The published investigations reveal important aspects of the mechanisms, in which the intermediacy of an exciplex has been implied (8–11). Other types of naphthalene derivatives have also been investigated but not as extensively as the photocycloaddition of naphthonitriles (1, 12). On the other hand, [2+] photocycloaddition of acacH to simple olefins is a well-established reaction, known as the de Mayo reaction (2–7, 13), in which the net result involves the addition of acetyl and acetonyl groups across a C=C double bond. This reaction has been claimed to occur from the triplet excited acacH (14); though its quantum yields are generally low, it has been used in many synthetic applications, providing excellent to satisfactory results (2, 3, 7). As far as we are aware, the photocycloaddition of acacH to aromatic compounds has not been reported except for our preliminary communications (15–17).

Results



Photocycloaddition

Photolysis of methyl 2-naphthoate (2-$NpCO_2CH_3$, **1**) and acetylacetone in acetonitrile for 15 h resulted in slow formation of the addition product **2** in 33% yield, in addition to a trace amount (<2%) of another isomer **3**: this isomer became the major product in the presence of a trace amount of H_2SO_4 (0.0005 M) in which **2** was also isolated as the minor product. Unreacted 2-$NpCO_2CH_3$ was recovered to fill the balance of the percentage yields. The formation of **2** and **3** was extraordinarily accelerated in the presence of H_2SO_4 up to 0.001 M concentration. The structure of **2** was readily decided on the basis of, firstly, ^{13}C NMR signals at 207.5, 205.8 (for two unconjugated CO), and 173.7 ppm (for a CO_2R carbonyl) and, secondly, a broad IR absorption at 1730 cm^{-1} and, finally, two AB quartets and a singlet at 4.47 ppm (18). One AB quartet at 5.81 and 6.51 ppm (J = 9.5 Hz) arises from the neighboring protons of the conjugated olefinic bond, and the other at 3.19 and 3.03 ppm (J = 18.5 Hz) from the diastereotopic geminal methylene protons. For **3** the ^{13}C NMR signals and IR absorptions were comparable; in addition the similar olefinic protons were present, showing an AB quartet at 6.41 and 6.50 ppm (J = 10 Hz). The ^1H NMR spectrum also showed an ABX pattern at 4.71, 2.28, and 2.56 ppm (J = 18, 7.5, and 5.5 Hz). The ^1H NMR coupling patterns and their chemical shifts clearly indicated that both **2** and **3** were the isomeric products in the addition of acetyl and acetonyl groups on the 1,2-position of **1**, with alternate regiochemistry. A 2+2 photocycloaddition followed by the cyclobutane ring opening was assumed, in analogy to the de Mayo reaction (2, 13); that led us to assign the stereochemistry as shown, which was also consistent with the subsequent reaction. The NOE results of **2** also supported the assignment by showing that the methine proton (4.47 ppm) and the methoxy methyl are close to each other (19). Similar photolysis of solutions of 2-$NpCO_2CH_3$ and acacH in various solvents in a merry-go-round gave **2** in 0% (in cyclohexane), 10% (in benzene), 9.3% (in THF), 19.5% (in acetonitrile), and 19% (in CH_3OH) yields. This trend was shown to be opposite to that observed in the de Mayo reaction (2).

Photolysis of **3** led to the formation of diketo-ester **4**, in 60% yield, which was also formed as a by-product in prolonged irradiation of the photocycloaddition of **1**. For **4**, the ^{13}C NMR and IR spectra showed the necessary signals for the carbonyl groups, and an ABX system at 4.63, 3.19, and 3.15 ppm (J = 18, 8, and 4.5 Hz) was still present in the ^1H NMR spectra. However, the two olefinic protons in **3** were converted to what appeared to be two cyclopropyl protons that were oriented *cis* to each other, as shown by an AB quartet of H_b (d, 3.17 ppm, J = 9 Hz) and H_e (d, 3.06 ppm, J = 9 Hz). The NOE experiments (19) demonstrated that irradiation of H_f (s, 2.28 ppm) or H_a (dd) caused the enhancement of H_c and H_d, and that irradiation of H_b and H_a (s, 1.99 ppm) caused the enhancement of H_e. An excited state of **3** should be able to undergo an oxa-di-π-methane rearrangement or a similar path by the formation of a strained oxetane intermediate **5** and a subsequent ring opening as shown (20, 21) to give **4**. This mechanistic consideration led to the assigned stereochemistry.

Similar photolysis of methyl-1-naphthoate **6** (1-$NpCO_2CH_3$) and acacH in CH_3CN under similar conditions for 8 h gave diketone **7**, in 30% yield, which was most likely formed by a similar pathway as described above via the intermediate **9**. In the presence of a trace amount of H_2SO_4 (0.0001–0.001 M), while no new product appeared, the formation of **7** was accelerated enormously. Prolonged photolysis of a neutral photolysate gave a caged product **8**, which was also obtained in a 40% yield by

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

irradiation of diketone **7** with a 200-W Hanovia lamp through a Pyrex filter. In the latter photolysis of **7**, a small amount of a product short of the CH_3CO − H moiety was also detected by GC–MS analysis. This compound was assumed to be methyl 7-acetonyl-1-naphthoate. The structure of **7** was easily decided from ^1H and ^{13}C NMR and IR spectra, which showed the expected carbonyl signals (see Experimental). Decoupling experiments showed that H_c (dd, 5.78 ppm, J = 9.5 and 25 Hz) was coupled with H_b (6.51 ppm) and H_e (m, 3.33 ppm), and that the latter (H_e) was coupled with H_d (d, 4.32 ppm, J = 7 Hz) and H_c. However, a combined effort of spectroscopic investigations could not solve the structure of **8** except to show that both ketone groups and the olefinic moiety had disappeared as the consequence of irradiation. Multiplicity sorting in ^{13}C NMR indicated the presence of six quaternary carbons, which require a caged structure. The presence of proton singlets at 3.13 and 3.72 ppm was useless in illuminating the structural features. Eventually the structure was determined to be **8**, as shown by single crystal X-ray crystallography (15). The formation of **8** from an excited state diketone **7** can be visualized as an intramolecular cycloaddition involving three π-bonds (two C=O groups and one C=C group) as shown. It is probably initiated from the lowest triplet state of the styrene moiety in **7** by a radical mechanism. Though we failed to find a precedent for such a photocyloaddition, cycloadditions involving three olefinic π-bonds are known (21, 22). From this reaction, it required that the H_d and H_e protons in **7** must be *cis*-oriented, which was also indicated by their coupling constant of 7 Hz.

Photocycloaddition of ethyl 2-naphthoate and ethyl 1-naphthoate with acacH also gave the corresponding ethyl analogues of 1,5-diketones **2** and **7**. These products were described in the thesis submitted by one of the authors (17).

Mechanistic studies

The photocycloaddition of 2-$NpCO_2CH_3$ with acacH in acetonitrile was used as a model to carry out mechanistic studies. Owing to the overlap of absorption in the 300–330 nm area (Fig. 1) and the closeness of excited state energies for 2-$NpCO_2CH_3$ (E_s = 84.5, E_T = 59 kcal/mol) and acacH ($E_s \leq$ 90, E_T = 69–74 kcal/mol), the first question concerning this photocycloaddition was the excited state responsible for the cycloaddition. The quantum yields of 2-$NpCO_2CH_3$ disappearance (Φ_{Np}) in the photocycloaddition with acacH were determined in acetonitrile using RPR 3000 A as the light source under two sets of conditions; first was constant [2-$NpCO_2Me$] =

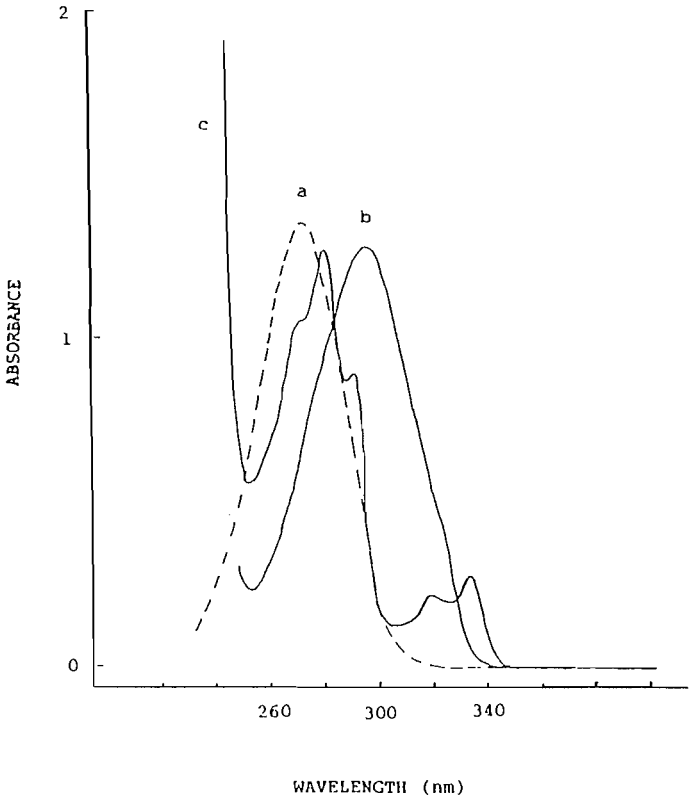


FIG. 1. The absorption spectra of (a) acacH (0.002 M), (b) 1-$NpCO_2CH_3$ (0.0002 M), and (c) 2-$NpCO_2CH_3$ (0.0002 M) in acetonitrile.

0.05 M with varying [acacH], 0.05–0.1 M, and the second was constant [acacH] = 0.05 M, with varying [2-$NpCO_2CH_3$], 0.05–0.1 M. The light intensity absorbed by 2-$NpCO_2CH_3$ (the first case) or by acacH (the second case) was estimated from the concentration and molar extinction coefficient at 300 nm as shown in the Experimental; the fraction of the intensity absorbed by 2-$NpCO_2CH_3$ or by acacH was used for the calculation of Φ_{Np} in two cases, respectively. While in the second case Φ_{Np} remained constant with increasing [2-$NpCO_2CH_3$], Φ_{Np} in the first case increased with increasing [acacH] (Fig. 2). For 1-$NpCO_2CH_3$, the results were similar within experimental errors (17). These clearly indicated that light absorption by naphthoates produced the primary excited species, initiating the train of events pertaining to the photocycloaddition. In our

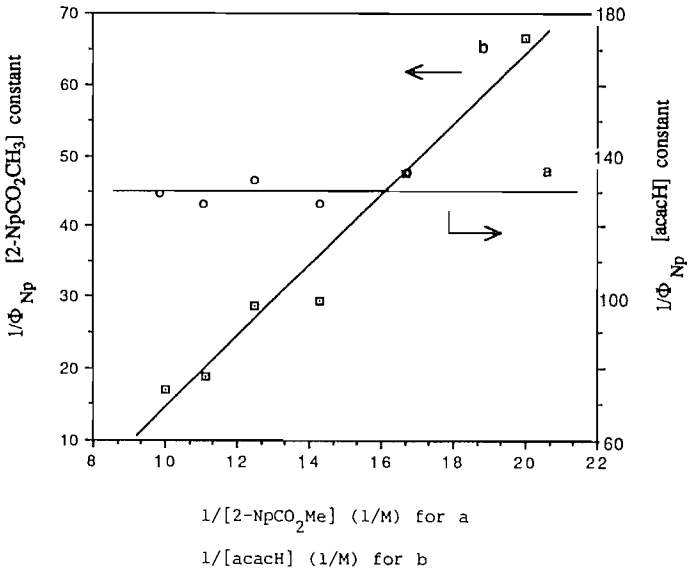

FIG. 2. The dependence of the quantum yields of the 2-$NpCO_2CH_3$ (Φ_{Np}) disappearance in the photocycloaddition (a) under the constant concentration of acacH (0.05 M), and (b) under the constant concentration of 2-$NpCO_2Me$ (0.05 M) in acetonitrile with 300 nm irradiation.

communication (15), we wrongly stated that the excitation of acacH caused the photocycloaddition; the erroneous experiment was caused by wrong absorbancy correction processes.

The quantum yield of **2** (Φ_p) for the photocycloaddition of 2-$NpCO_2CH_3$ in acetonitirile was determined as a function of [acacH] = [A], 0.08–0.3 M, in which appropriate corrections on light absorbed by 2-$NpCO_2CH_3$ were made. The plots of $1/\Phi_p$ vs. 1/[A] yielded a straight line with slope = 14.2 and intercept = 30; calculated $k_q\tau_0$ and the limiting Φ_p are 2.1 ± 0.3 M^{-1} and 0.033 ± 0.004, respectively, average values from repeated experiments. The plot was done according to eq. [1] assuming that an unspecified reactive state of 2-$NpCO_2CH_3$ reacted with a substrate at a rate ratio of $k_q\tau_0$ and the limiting quantum yield of β (21); in the present case the reaction rate constant with acetylacetone is k_{ca} (Table 1). It will be shown later, in the Discussion, that this reactive state is not the spectroscopic singlet excited state but an unknown species derived therefrom.

$$[1]\quad 1/\Phi_p = 1/\beta + 1/\beta k_q\tau_0[A])$$

The photocycloaddition of 2-$NpCO_2CH_3$ could not be sensitized by typical triplet sensitizers such as xanthone (E_T 74.1 kcal/mol) and benzophenone (E_T 69.2 kcal/mol) under conditions such that either the 2-$NpCO_2CH_3$ or acacH concentration was overwhelmingly higher than the other and the sensitizer absorbed the incident light. Also this photocycloaddition was efficiently quenched by tributylamine or dimethylaniline; at the 0.01 M level the quantum yield of **2** was reduced to about 1/6 and 1/3 respectively. This photocycloaddition in the presence of [acacH] = 0.08 M was quenched by tributylamine, giving $k_{TBA}\tau' = 233 \pm 30\,M^{-1}$ (Table 1) from two series of experiments and standard Stern–Volmer plots according to eq. [2],

$$[2]\quad \frac{\Phi^0}{\Phi} = 1 + k_{TBA}\tau'[TBA]$$

where $\tau' = 1/(1/\tau_0 + k_{CA}[acacH])$. Φ^0 and Φ are the quantum yields of **2** in the absence and presence of TBA, which is shown to interact with the spectroscopic singlet excited state 2-

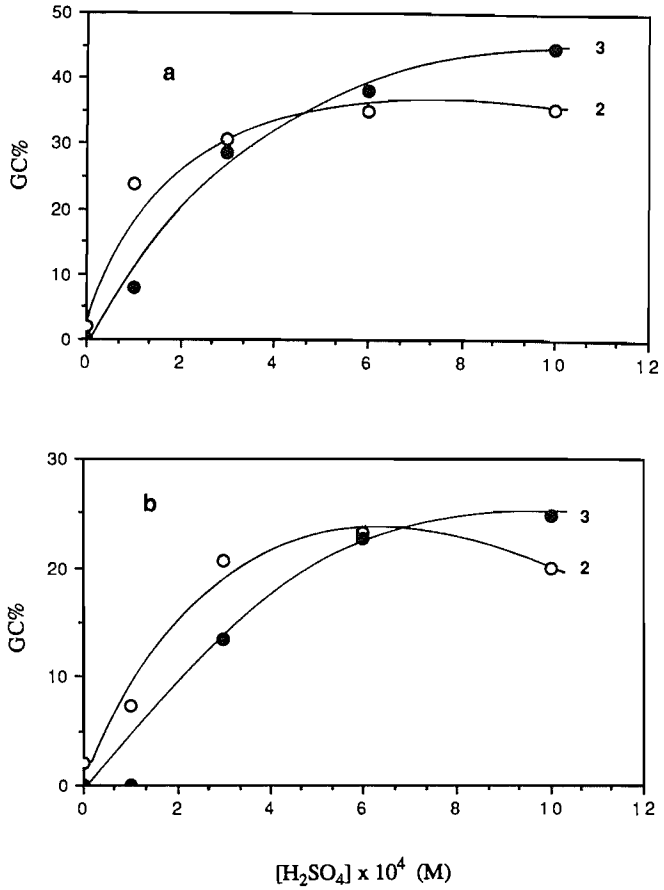

FIG. 3. The effects of sulfuric acid on percentage yields of photocycloaddition of 2-$NpCO_2CH_3$ (0.02 M) and acacH (0.05 M) in (a) acetonitrile and (b) methanol; nitrogen-purged samples were irradiated with 300-nm light in a merry-go-round under the same conditions.

$NpCO_2CH_3$ having a lifetime τ_0 = 8.5 ns measured by fluorescence quenching (*vide infra*). Likewise, oxygen (air-saturated solution) and biacetyl quenched the photocycloaddition efficiently. In contrast, the photocycloaddition of acacH with cyclohexene (a de Mayo reaction) was not quenched by tributylamine and dimethylaniline. This observation supported the conclusion that excited acacH is not the reactive species in the present photocycloaddition of naphthoates and acacH. In the presence of small amounts of iodomethane (<0.002 M), the quantum yield of **2** was drastically reduced, but in the [CH_3I] >0.005 M region, the yields of **3** increased significantly and that of **2** also started to increase. These photolysates were shown to contain an acid (probably HI), which was detectd by wet litmus paper. It was certain the photolytically generated HI in the higher [CH_3I] region acted as acid catalyst to promote the photocycloaddition.

Under a set of photolysis conditions, photocycloaddition of 2-$NpCO_2CH_3$ (0.02 M) with acacH (0.08 M) in acetonitrile was carried out in the presence of a trace amount of acid. As shown in Table 1, the formations of **2** and **3** were dramatically increased in the presence of less than 10^{-3} M acid. The acid catalysis was the largest with sulfuric acid, and the percent increases of **2** and **3** were shown to be asymptotically approaching maximum values at about 0.001 M H_2SO_4 (Fig. 3); the combined quantum yield of **2** and **3** was estimated to be 0.16 in the presence of [H_2SO_4] = 0.001 M as compared to 0.0045 in the absence of

TABLE 1. The quenching of 2-$NpCO_2CH_3$ fluorescence intensities and photocycloaddition in acetonitrile[a]

	$k_q\tau(m^{-1})$	τ(ns)	$k_q(m^{-1}\,s^{-1})$
Biacetyl (k_{BA})	95±2	3.5[d]	(k_{diff} = 2.7 × 10^{10})[c]
acacH (k_{AA})	28.7±1.5	8.5[e,f]	3.4 (±0.2) × 10^9
Tributylamine (k_{TBA})	127±2	3.5[d]	3.6 (±0.1) × 10^{10}
Iodomethane (k_{1M})	40±1	8.5[e]	4.7 (±0.1) × 10^9
H_2SO_4 (k_{H^+})	35.3±1.1	3.5[d]	1.01 (±0.03) × 10^{10}
H_2SO_4 (k_{H^+}) ([acacH] = 0.08 M)	13.2±0.4	1.8[d,g]	7.3 (±0.2) × 10^9
acacH (k_{AA}) ([H_2SO_4] = 0.001 M)	28.4±0.6	7.8[e,h]	3.6 (±0.1) × 10^9
acacH (k_{CA})[b]	2.1	(8.5)[e]	(2.5 × 10^8
Tributylamine (k_{TBA})[b] [acacH] = 0.08 M)	233±30	7.25[e,i]	3.2 (±0.4) × 10^{10}

[a]All experiments were run in acetonitrile either under nitrogen or under air, except the last two; relative intensities of 2-$NpCO_2CH_3$ fluorescence at 358 nm were monitored with the excitation at 330 nm.

[b]In these two experiments, the quantum yield of **2** in the photocycloaddition of 2-$NpCO_2CH_3$ with acacH was monitored: irradiation used Rayonet RPR 3000 lamps under nitrogen.

[c]The diffusion-controlled rate constant at 25°C in acetonitrile is assumed as the bimolecular quenching rate constant in order to calculate τ values in the presence of oxygen quenching from the air. In methanol, $k_q\tau$ = 71 and k_{diff} = 1.8 × 10^{10} M^{-1} s^{-1}, which gives τ = 3.9 ns.

[d]These reactions were run without N_2 purging, and τ = 3.5 ns was used for calculation.

[e]This reaction was run udner N_2 and τ_0 = 8.5 ns was used; τ_0 was obtained from biacetyl quenching under nitrogen assuming k_q = 2.7 × 10^{10} M^{-1} s^{-1}.

[f]In methanol $k_q\tau_0$ and k_q are 24.4 ± 0.9 M^{-1} and 2.6 (±0.1) × 10^9 M^{-1} s^{-1}.

[g]The lifetime was modified from the contribution of k_{AA} [acacH] to 1.8 ns.

[h]The lifetime was modified from the contribution of k_{H^+} [H_2SO_4] to 7.8 ns.

[i]The lifetime was modified from the contribution of k_{CA} [acacH] to 7.25 ns.

H_2SO_4. In the presence of [H_2SO_4] = 0.001 M and [acacH] = 0.9–1.2 M the combined quantum yields were ≥0.5. Similarly, the yields of **7** were increased in the same pattern as Fig. 3, by more than 10-fold at [H_2SO_4] = 0.001 M. Attempts to correlate the quantum yields with the concentrations of H_2SO_4 did not yield reproducible results and failed to give a recognizable plot.

Naphthoate fluorescence studies

Taking advantage of the strong fluorescence shown by naphthoates, we studied quenching patterns of singlet excited naphthoates with various substrates. The fluorescence intensity of 2-$NpCO_2CH_3$ was quenched rapidly in unpurged solution by biacetyl to give the Stern–Volmer rate of $k_{BA}\tau$ = 95 M^{-1} in acetonitrile and 71 M^{-1} in methanol. Adapting k_{BA} as being equal to the diffusion-controlled rate constant, 2.7 × 10^{10} M^{-1} s^{-1} in acetonitrile and 1.8 × 10^{10} M^{-1} s^{-1} in methanol (23), τ was calculated to be 3.5 and 3.9 ns in these solvents, respectively. Similar quenching experiments with a nitrogen-purged solution of 2-$NpCO_2CH_3$ and the same calculation procedure gave a lifetime τ_0 of 8.5 ns in acetonitrile and 9.4 ns in methanol; τ_0 was longer than τ since oxygen quenching was eliminated, and was regarded as the inherent lifetime of lowest singlet excited 2-$NpCO_2CH_3$ without bimolecular processes (24, 25).

The fluorescence intensities of 2-$NpCO_2CH_3$ (10^{-4}–10^{-3} M in acetonitrile) in the absence (I^0) and presence (I) of a substrate were measured to obtain a Stern–Volmer plot and to calculate the slope ($k_q\tau$ value); unless specified, experiments were carried out in acetonitrile (Table 1) (21). The rate constant of the interaction of singlet excited state 2-$NpCO_2CH_3$ with a substrate (k_q) can be calculated on the basis of lifetimes (τ or τ_0) estimated above and is shown in Table 1. Owing to the overlaps of absorption curves between acacH and 2-$NpCO_2CH_3$ in the 300-nm region, the fluorescence intensities have to be corrected for the amount absorbed by acacH. The plots were examined at three different excitation wavelengths to give very similar $k_q\tau$ values. Such interference did not exist with other substrates. While tributylamine most likely interacted with singlet excited 2-$NpCO_2CH_3$ by electron transfer (26), methyl iodide did so by promoting its intersystem crossing (27). The latter was confirmed by the observation of proportionately enhanced phosphorescence spectra at 77 K for a solution containing increasing concentrations of methyl iodide (see Fig. 5, later). The quenching of 2-$NpCO_2CH_3$ fluorescence intensities by acacH was examined at 7, 22, and 50°C; the Stern–Volmer plots gave slopes ($k_q\tau_0$ values) of 31 ± 1, 24 ± 1, and 8.5 ± 1.0 M^{-1} respectively, tending to decrease with increasing temperature. Assuming that the unimolecular reactions of singlet excited 2-$NpCO_2CH_3$ involving electron demotion were not affected significantly in this temperature range, τ_0 could be taken as approximately constant. Therefore the rate constant of the acacH interaction with singlet excited 2-$NpCO_2CH_3$ decreases with increasing temperature; such a negative temperature effect in fluorescence quenching suggests the presence of an exciplex (27, 28), i.e., *(2-$NpCO_2CH_3$ ... acacH).

The fluorescence pattern of 2-$NpCO_2CH_3$ was not affected in the presence of [H_2SO_4] 0.0002–0.002 M, but in the region of [H_2SO_4] > 0.005 M, the fluorescence intensity at 359 nm started to be reduced and a new fluorescence peak emerged at 470 nm with the isosbestic point at 414 nm (Fig. 4). A similar fluorescence change in the presence of sulfuric acid was published recently when this work was completed (29). In the presence of [acacH] = 0.08 M, the 2-$NpCO_2CH_3$ fluorescence spectra also varied on addition of H_2SO_4 with a pattern similar to that shown in Fig. 4. In both cases the Stern–Volmer plots monitored at 359 nm gave good straight-line correlations, and

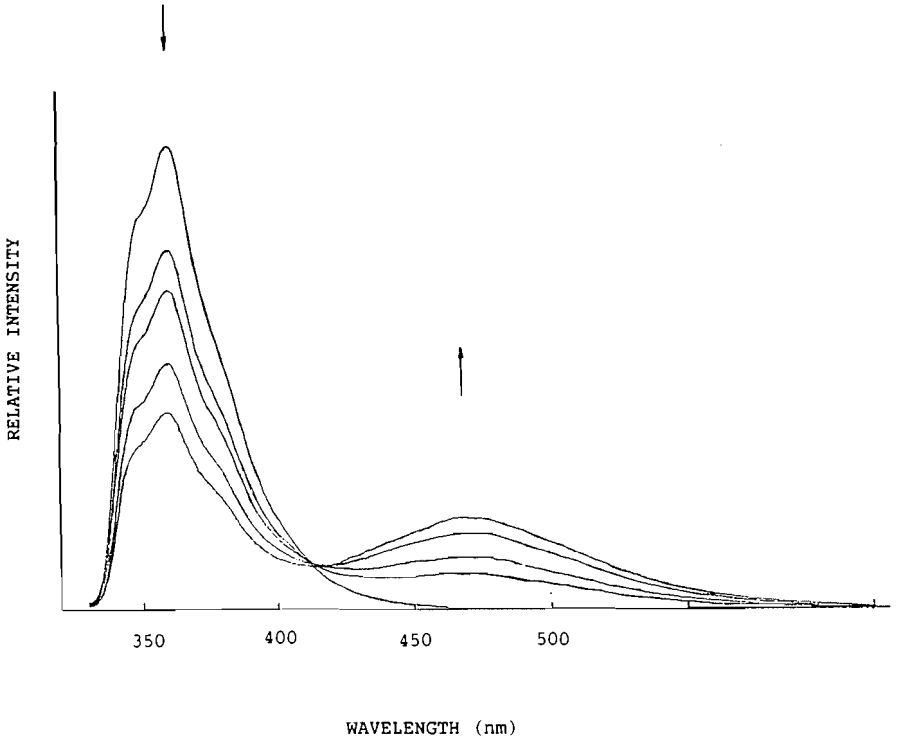

FIG. 4. The effects of H_2SO_4 (0, 0.0063, 0.0125, 0.0250, 0.375 M) on 2-$NpCO_2CH_3$ fluorescence in acetonitrile, under air at room temperature with the excitation wavelength at 300 nm; the fluorescence peak of ^{1}2-$NpCO_2CH_3$ at 359 nm and that of protonated ^{1}2-$NpCO_2CH_3$ at 470 nm.

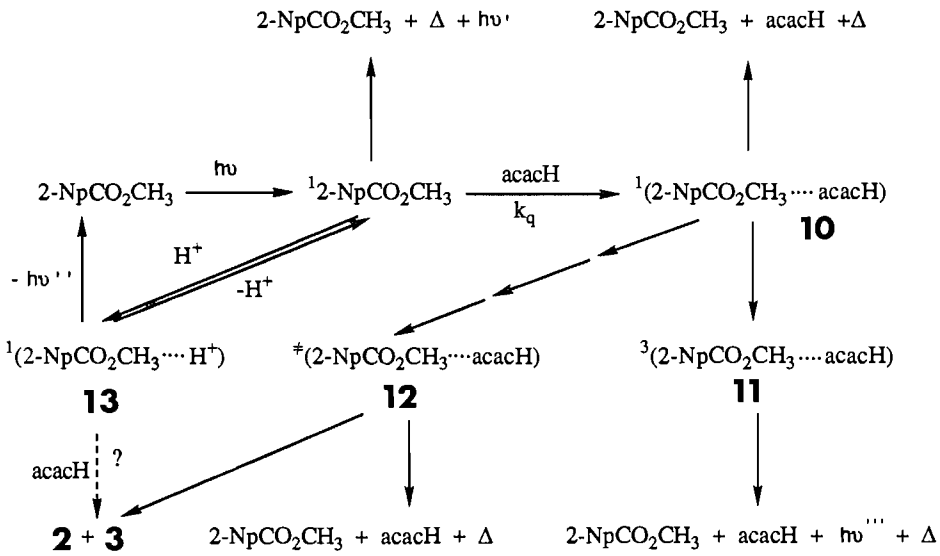
TABLE 2. Acid promotion on the photocycloaddition of methyl 2-naphthoate and acacH in acetonitrile[a]

Acids (M)	% Conversion **1**	% Formation **3**	% Formation **2**
None (control)	2.06	0	2.06
H_2SO_4 (0.0003)	66.6	20.8	24.4
H_3PO_4 (0.0003)	12.6	4.4	8.2
HCl (0.0003)	22.0	7.2	10.6
BF_3OEt_2 (0.0003)	37.4	9.2	20.2
CF_3COOH (0.0005)	13.7	2.9	10.5

[a]The solutions containing 2-$NpCO_2Me$ (0.02 M), acacH (0.05 M), and one of above acids were irradiated under nitrogen for 3 h (6 h for CF_3COOH) in a merry-go-round; the photolysates were analysed with GC with error margin ±5%.



calculated rate constants of the acid association of singlet excited 2-$NpCO_2CH_3$ are comparable whether in the presence or absence of acacH (Table 1). The quenching of 2-$NpCO_2CH_3$ fluorescence by acacH in the presence of a low concentration of H_2SO_4 (0.001 M) showed that the $k_q\tau$ value monitored at 359 nm was 28.4 (±0.6) M^{-1} and was indistinguishable from that in the absence of H_2SO_4. This lack of effect was a significant contrast to the acid effects on quantum yields displayed in Fig. 3 and Table 2. Thus we failed to find experimental confirmation of the dramatic acid effects with 2-$NpCO_2CH_3$ fluorescence. In acetonitrile, 1-$NpCO_2CH_3$ exhibited a fluorescence peak at 362 nm, which was quenched by the increasing concentrations of $[H_2SO_4]$ = 0.005–0.06 M (but not in the <0.005 M region), giving a relatively weak new fluorescence peak at 470 nm with the isosbestic point at 423 nm. The new peak was assumed to arise from the acid complex species of the lowest singlet excited 1-$NpCO_2CH_3$.

Finally, the absorption spectra of neither naphthoates nor acacH in acetonitrile and methanol were modified in the presence of the other in the concentration range of 0.01–0.5 M for either component. Likewise, these absorption spectra were not changed in the presence of sulfuric acid up to 0.01 M. These experiments indicated that there were no ground state complex formations under the photolysis conditions.

Discussion

The photocycloaddition of 2-$NpCO_2CH_3$ to acacH exhibits low quantum efficiency (e.g., a limiting Φ of 0.033) but gives acceptable yields of the final products in a prolonged photolysis. As the photoreaction simultaneously introduces acetyl and acetonyl groups across a naphthalene double bond, it is a synthetically effective reaction to construct carbon skeletons. While the product resembles the de Mayo reaction, the present photocycloaddition originates from a reactive state of naphthoates, as clearly indicated by the agreement in the rate constants, k_{TBA} (see Table 1), of tributylamine quenching of the product

SCHEME 1

quantum yields (see estimation below) and the fluorescence intensity. The fact that tributylamine does not quench the photocycloaddition of acacH with cyclohexene demonstrates fundamental mechanistic differences between the present photocycloaddition and the de Mayo reaction. However, the most significant observation in this photocycloaddition is the dramatic promotion of product quantum yields by trace amounts of various protic acids (Table 2 and Fig. 3), which elevates this photocycloaddition to a synthetically significant reaction.

Owing to the fact that the primary cyclobutane adducts are destroyed in the secondary reaction, the stereochemistry of the photocycloaddition is reduced to the orientation of the acetyl and acetonyl groups on the ring; their orientation is shown to be the *cis* mode, from ^{1}H NMR data and subsequent reactions. While the primary photoreaction can be explained by a common reaction pathway of the addition and ring opening, with a cyclobutane such as **9** as the intermediate, the secondary photoreactions of **7** to **8** and **3** to **4** are extraordinary and only possible because of the particular disposition of the participating functional groups. From a structural point of view, the photoreaction of **7** to **8** should involve a coordinated addition of three π-bonds (two carbonyl and one carbon–carbon double bond) to give the caged product by electron shifts as indicated by arrows. The photorearrangement of **7** should occur from the lowest excited state, which is most likely to be the triplet excited state localized at the styrene moiety (21, 23). Regardless of stepwise reaction or otherwise, the *cis* orientation of the two ketone groups can allow the coordinated cyclization by 1,5-bond formations as shown in **8**, owing to stereochemical constraints. The excitation of **3** causes a net 1,2-migration of the acetyl group with the concomitant bond shift to form a cyclopropane ring that can be visualized as an oxa-di-π-methane rearrangement (20, 21). In theory, the strained structure **5** can be formed from excited intramolecular oxetane formation from **3**; the strain energy in **5** may promote electron reorganization to give **4**. Whether the intermediate is **5** or the corresponding 1,4-diradical cannot be easily resolved; the intermediate **5** provides better visualization of the stereochemical consequence in **4**.

Extensive efforts to unravel the mechanism of the photocycloaddition using fluorescence quenching of 2-$NpCO_2CH_3$ as the model have not been fruitful at this stage. There are a number of indications that the reactive species originates from the lowest spectroscopic singlet excited state, which emits at about 359 nm (^{1}2-$NpCO_2CH_3$ in Scheme 1). Firstly, iodomethane imparts heavy atom effects by promoting intersystem crossing (21) of singlet excited 2-$NpCO_2CH_3$ as shown by k_{IM} in fluorescence quenching and phosphorescence enhancement; Fig. 5b demonstrates such enhancement through the interaction within "a quenching sphere" of ^{1}2-$NpCO_2CH_3$ with iodomethane in a solid solution to generate the triplet state. The quantum yield of product **2** is indeed reduced in the low concentration region of $[CH_3I] \sim 0.001$ M. Secondly, quenchers of 2-$NpCO_2CH_3$ fluorescence such as biacetyl and *tertiary* amines Table 1) also quench the quantum yield of product **2** in the photoaddition. Because the reactive state of the photocycloaddition is uncertain, a quantitative correlation is possible only if we assume that $k_{CA}\tau_0 = 2.1\,M^{-1}$ represents the portion of successful photocycloaddition in the total quenching of singlet excited 2-$NpCO_2CH_3$ (τ_0 = 8.5 ns, Table 1); k_{CA} is estimated to be $2.5 \times 10^8\,M^{-1}\,s^{-1}$. This allows us to estimate $\tau' = 7.25$ ns in eq. [2] and, therefore, $k_{TBA} = 3.2 \times 10^{10}\,M^{-1}\,s^{-1}$. The agreement with that obtained from fluorescence quenching of $k_{TBA} = 3.6 \times 10^{10}\,M^{-1}\,s^{-1}$, in spite of entirely different conditions and nature of monitors, indicates convincingly the involvement of singlet state 2-$NpCO_2CH_3$.

Thirdly, while 2-$NpCO_2CH_3$ fluorescence intensities are systematically quenched by acacH in a frozen state at a low range of <0.02 M, 2-$NpCO_2CH_3$ phosphorescence intensities are not reduced even by high concentrations of acacH except for small decreases at the peaks that may arise from low quantum yields of the photocycloaddition of 2-$NpCO_2CH_3$ to form **2** and **3** (Fig. 5a). Such fluorescence quenching in solid solution is controlled by the probability of quencher being present in the vicinity (i.e., within a quenching sphere) as formulated by Perrin (in ref. 21). In view of the fact that the generation of neither 2-$NpCO_2CH_3$ nor acacH triplet states by sensitization initiates the photocycloaddition, and that the excitation of 2-$NpCO_2CH_3$ is responsible for the photocycloaddition with acacH, the photocycloaddition must originate from a singlet state, and, most likely, from that of 2-$NpCO_2CH_3$. Singlet excited acacH is not likely the originator owing to a short lifetime; if it is, tributylamine should not be able to quench the photocycloaddition. The pattern of emission with a near total conservation of the original triplet population of 2-$NpCO_2CH_3$

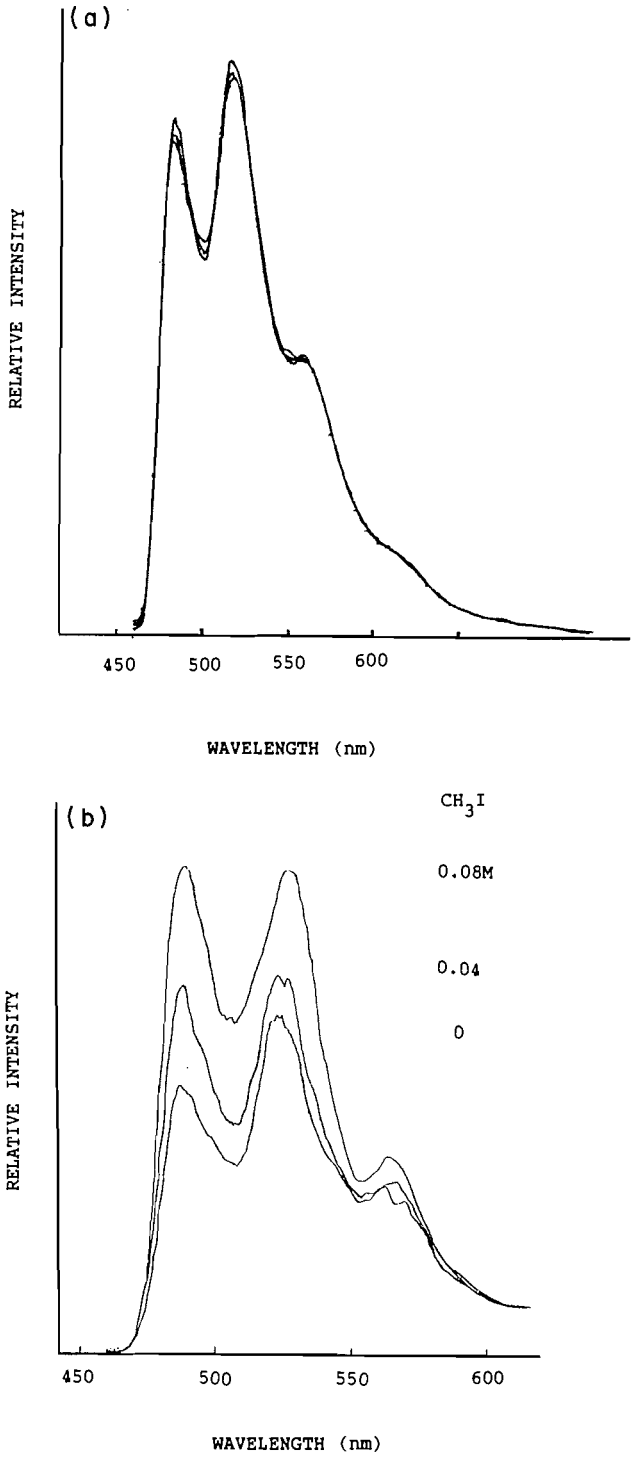

FIG. 5. (a) The phosphorescence spectra of 2-$NpCO_2CH_3$ (0.02 M) in a mixture of isopropanol and ether (1:3 ratio by volume) at 77 K under nitrogen in the presence of acacH (0.0–0.5 M); λ excitation 350 nm. (b) The enhancement of the 2-$NpCO_2CH_3$ phosphorescence spectrum in the presence of methyl iodide.

demonstrates interesting energy transfer, most likely occurring within excited state complexes such as those proposed as singlet and triplet exciplexes **10** and **11** in Scheme 1. Within these exciplexes one can envisage rapid migration along the energy ladder scheme without other energy wasting radiationless decays; ^{1}2-$NpCO_2CH_3$ + acacH → **10** → (2-$NpCO_2CH_3$... ^{1}acacH) → (2-$NpCO_2CH_3$...^{3}acacH) → (^{3}2-$NpCO_2CH_3$... acacH) (**11**) → 2-$NpCO_2CH_3$ + phosphorescence.

While evidence listed above supports the 2-$NpCO_2CH_3$ reaction arising from the singlet excited manifold, there is other critical evidence indicating that *the spectroscopic singlet state (Scheme 1, ^{1}2-$NpCO_2CH_3$) is not directly involved in the photocycloaddition*. The primary reason is the mismatch of the Stern–Volmer constant ($k_q\tau_0$) obtained from fluorescence quenching as compared to that from the quantum yield monitor of **2** (k_{AA} vs. k_{CA}, Table 1); the former is more than an order of magnitude larger than the latter. Secondly, whereas H_2SO_4 promotes the quantum yields of **2** and **3** very significantly in the [H_2SO_4] <0.001 M range, the protonation of spectroscopic singlet excited 2-$NpCO_2CH_3$ cannot be detected in this range by fluorescence emission either at 359 nm or 470 nm. We propose complex **12** derived from the singlet exciplex **10** as the immediate reactive state to give **2** and **3**, as shown in Scheme 1. While 2-$NpCO_2CH_3$ in **10** has the well-defined lowest spectroscopic singlet state, that in **12** possesses an unknown electronic state and its quantitative relation with respect to **10** has not been defined. Certain types of photochemical reactions originating from excited states of olefins and enones are susceptible to acid catalysis (30–32) for which the protonation of an intermediate, suggested to be a twisted state (32–35), has been proposed as the reactive intermediate. It is tempting to suggest a twisted state of 2-$NpCO_2CH_3$ to complex **12** without specifying the structures and electronic states. The kinetic relations among **10**, **11**, and **12** must be resolved to illuminate the reactive state.

The quenching by TBA and methyl iodide is definitely demonstrated to occur at the spectroscopic singlet excited state of 2-$NpCO_2CH_3$ according to fluorescence quenching studies; these quenching effects should be transmitted proportionally along the subsequent steps leading to complexes **11** and **12** to affect the quantum yields. The proportionality is supported by the agreement in k_{TBA} obtained by two types of quenching in the presence and absence of acacH as shown in Table 1. However, the crucial question is how a low concentration of H_2SO_4 manages to promote the photocycloaddition. The protonation of ^{1}2-$NpCO_2CH_3$ would be insignificant under the experimental conditions of Fig. 3 at [acacH] = 0.08 and [H_2SO_4] $<10^{-3}$ M, as can be judged from rate constants k_{AA} and k_{H^+} in Table 1. It is proposed that sulfuric acid at <0.001 M in acetonitrile can interact with complex **12** to render the observed promotional effects. While the exact pathway remains obscure at this stage, this proposal implies that the reactive complex **12**, †(2-$NpCO_2CH_3$...acacH), probably carries higher electron polarization than ^{1}2-$NpCO_2CH_3$, which would allow **12** to localize higher electron density in one site, where it would be protonated more easily. The possibility of an interaction of complex **10** with an acid is deemed less likely because the 2-$NpCO_2CH_3$ portion in **10** possesses a reasonably similar electronic configuration and chemical reactivity to that of the spectroscopic singlet state. Further, if this protonation occurs, the effects should be reflected in a Stern–Volmer analysis of the quantum yields of **2**. The failure to correlate the quantum yield of products **2** and **3** with [H_2SO_4] indicates the complexity of the reactions involving acid participation. It is clear that such reactions do not involve protonated ^{1}2-$NpCO_2CH_3$, **13**, which fluoresces with a broad band at 420 nm, as the reactive intermediate in acid promotion processes, as shown by previous calculations and in Figs. 3 and 4. In view of the indistinguishable $k_q\tau$ values for ^{1}2-$NpCO_2CH_3$ fluorescence quenching by acacH, either in the absence or presence of [H_2SO_4] = 0.001 (28.7 and 28.4 M^{-1}, see Table 1), it is the formation pathways beyond **10** that must be involved in acid promotions.

Inability to resolve kinetics of the photocycloaddition pre-

vents us from going beyond this point. Naphthalenes and other aromatic derivatives are known to be polarized on excitation, generating extraordinary excited state acidic or basic properties (36, 37), which last as long as their lifetimes. Napththoates (pK^0 = −8 to −9) and naphthoic acid (pK^0 = −7 to −8) obviously become much more basic with pK^* = 1–2 in their singlet excited state (38, 39), and can be protonated under ordinary reaction conditions, as shown in the literature and here. A pertinent question in this regard is whether complex **13** is also reacting with acacH to give products **2** and **3** in a high H_2SO_4 concentration region.

Interim conclusion

In acetonitrile and methanol, 1- and 2-$NpCO_2CH_3$ photolytically undergo photocycloaddition with acacH to give products **2**, **3**, and **7** with the addition of acetyl and acetonyl groups in low quantum yields. This useful synthetic method is significantly improved when run in the presence of H_2SO_4 at about 0.001 M, in which the quantum yield of the product is increased by more than an order of magnitude to ≥0.5. Mechanistic studies show that the photocycloaddition of 2-$NpCO_2CH_3$ occurs from an unknown species originating from its spectroscopic singlet excited state. Whereas this singlet-state 2-$NpCO_2CH_3$ exhibited an interesting fluorescence pattern in the reaction with H_2SO_4, the protonated singlet excited 2-$NpCO_2CH_3$ is not the key species in the acid-promoted reaction. Thus while the acid-promoted photocycloaddition is synthetically useful, its mechanism remains unknown.

Experimental

General conditions

Unless otherwise specified, the following experimental conditions were used. Melting points (mp) were determined on a Fisher–Johns apparatus, and were uncorrected. Infrared spectra (IR) were recorded with a Perkin–Elmer 559B spectrophotometer using neat liquid film, Nujol mull, or KBr pellet. Ultraviolet and visible spectra (UV) were taken with a Varian Cary 210 spectrophotometer. Mass spectra (MS) and gas chromatography – mass spectra (GC–MS) were obtained on a Hewlett–Packard 5985 GC–MS system either by electron ionization or by chemical ionization. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded with a Bruker WM-400 spectrometer in $CDCl_3$ solution using tetramethylsilane (TMS) as an internal standard. Chemical shifts are reported in δ values in ppm and coupling constants (J) in Hz. The coupling patterns are presented as s (singlet), d (doublet), t (triplet), q (quartet), and m (multiplet). The chemical shifts of ^{13}C NMR spectra are also reported in ppm relative to TMS. Elemental analyses were carried out by Mr. M. K. Yang using a Carlo Erba model 1106 elemental analyzer. Gas chromatography (GC) analyses were performed on a Hewlett–Packard 5790A chromatograph (FID), equipped with an OV-1 capillary column and a Hewlett–Packard 3390A chart integrator. Retention times (R_t) are reported in minutes (min). Phosphorescence and fluorescence spectra were taken with a Perkin–Elmer MPF 44B spectrophotometer and were uncorrected. Percentage yields in preparative experiments were calculated

based on the amount of the naphthalene derivatives present at the start of the reaction.

Chemicals and apparatus

For the preparative photochemical reactions, reagent grade solvents were distilled prior to use. Acetonitrile was distilled over P_2O_5. For spectroscopy, commercial spectroscopic grade solvents were used as supplied. Methyl 1-naphthoate (1-$NpCO_2Me$), and methyl 2-naphthoate (2-$NpCO_2Me$) were prepared from the corresponding naphthoic acids by H_2SO_4-catalyzed esterfication. The spectral data are listed in Tables 3–6. Acetylacetone (BDH) was distilled.

Photolysis apparatus and quantum yield determination

The first apparatus was a Hanovia-type reaction vessel (180 mL, Pyrex glass) fitted with a 200-W Hanovia medium-pressure mercury lamp (654A 36). The second apparatus consisted of eight quartz tubes (to accommodate 5 mL of solution) placed in a Rayonet photochemical reactor equipped with RPR 3000 Å lamps (16 × 21 W) or RPR 3500 Å lamps (16 × 24 W); a fan to circulate the air provided a constant temperature of 31 ± 1°C. Sometimes, a long cylindrical reaction vessel (3 × 20 cm, quartz) was inserted into a quartz water-cooled lamp housing; this set-up was used instead of test tubes.

The actinometer solution was prepared as follows. Benzophenone (456 mg, 2.50 mmol) and benzhydrol (921 mg, 5.0 mmol) were dissolved in benzene (25 mL). An aliquot (3 mL) from each of the above stock solutions was pipetted into a test tube. The actinometer solution (5 mL) containing 0.050 M benzophenone and 0.10 M benzhydrol was transferred into a quartz tube and purged with nitrogen for 10 min. The actinometer known to have the quantum yield of 0.74 (40) was irradiated, together with sample solutions, for 5 min. The absorbance (A) at 342 nm of benzophenone was measured with 0.10-cm optical path cells before and after irradiation, respectively. The light intensity was calculated by absorbance changes.

Quantum yields were determined using the second type of apparatus equipped with 350-nm or 300-nm light sources. Photolysates were analyzed by GC with octadecane ($C_{18}H_{38}$, added into the sample solution before irradiation) or xanthone (added after irradiation) as an internal standard (IS). The amount of a product formed or a starting material reacted was calculated from predetermined calibration curves

TABLE 5. IR data of the products

and the corresponding quantum yield Φ was calculated using the benzophenone–benzhydrol actinometry.

Since both naphthoates and acacH absorb light in the 300-nm region, the fraction of the incident light absorbed by naphthoates was determined according to the following equation:

$$A = A^0 [(\epsilon_{Np} C_{Np})/(\epsilon_{Np} C_{Np} + \epsilon_{acacH} C_{acacH})]$$

where A^0 is the light absorbed, ϵ_{Np} and ϵ_{acacH} are the extinction coefficients of NpR and acacH at 300 nm, respectively, and C_{Np} and C_{acacH} are the concentrations of NpR and acacH, respectively. Similarly, the fraction of the incident light absorbed by acacH could be calculated by replacing the numerator of $\epsilon_{Np}C_{Np}$ with $\epsilon_{acacH}C_{acacH}$.

The photocycloaddition of naphthoates with acetylacetone

An acetonitrile solution of acetylacetone and a naphthoate was placed in eight quartz tubes. After the solution was sealed and purged

with oxygen-free nitrogen for 10 min, the tubes were irradiated with a light source of 300 or 350 nm. Reactions were monitored by GC. A zero-hour sample was kept in the dark and analyzed by GC as a control. To avoid secondary photoreactions, the irradiation was stopped when the conversion of naphthalene derivative was around 50–60% as determined by GC. The residue was flash-chromatographed to give product. The spectral data are listed in Tables 3–6.

Methyl 2-naphthoate

A solution of 2-$NpCO_2Me$ (300 mg, 1.6 mmol) and acacH (1.6 g, 16 mmol) in acetonitrile (50 mL) was irradiated with 300-nm lamps. After irradiation for 15 h, the light yellow photolysate gave two GC (200°C) peaks at R_t 2.73 min for 2-$NpCO_2Me$ and at R_t 5.02 min for **2** in the ratio of 1:1. A trace amount of a second product (R_t 4.83 min) was also detected. The yellow residue was chromatographed using 30% ethyl acetate in hexanes as the eluant to give 2-$NpCO_2Me$ (112.8 mg) and a yellow oily compound (152 mg, 33%) of 1-acetyl-2-acetonyl-2-carbomethoxy-1,2-dihydronaphthalene (**2**), which was distilled bulb-to-bulb. Anal. calcd. for $C_{17}H_{18}O_4$: C 71.33, H 6.29; found: C 71.29, H 6.42%.

A solution of 2-$NpCO_2Me$ (300 mg, 1.6 mmol), acacH (500 mg, 5 mmol), and a trace amount of sulfuric acid (about 0.0005 M) in acetonitrile (50 mL) was irradiated with 300-nm lamps for 9 h. The light brown photolysate showed three GC peaks (200°C) at R_t 4.83 min (**3**, 45%), 5.02 min (**2**, 23%), and 2.73 min (2-$NpCO_2Me$, 15%). The residue was flash-chromatographed using 30% ethyl acetate in hexanes as the eluant to give a yellow oily compound of **2** (36 mg, 8%) and a light yellow powder (**3**, 72 mg, 16%) of 1-acetonyl-2-acetyl-2-carbomethoxy-1,2-dihydronaphthalene. The latter was further purified by recrystallization from cyclohexane to afford white crystals (70 mg, mp 81–82°C). Anal. calcd. for $C_{17}H_{18}O_4$: C 71.33, H 6.29; found: C 71.51, H 6.08%.

When a similar solution was over-irradiated for 24 h under similar conditions, the photolysate afforded two major product peaks at R_t 6.07 min (**4**, 31%) and 5.02 min (**2**, 15%). The crude product was chromatographed as above, followed by preparative TLC separation (using 50% ethyl acetate in hexanes) to give **4** (51 mg) as a yellow oil.

A solution of **3** (2.3 mg, 0.008 mmol) in acetonitrile (0.4 mL) in a quartz tube was irradiated similarily for 1 h. GC analysis of the photolysate showed 3.5% of **3** and 61% of **4**.

Methyl 1-naphthoate

A solution of 1-$NpCO_2Me$ (300 mg, 1.6 mmol) and acacH (1.6 g, 16 mmol) in acetonitrile (50 mL) was irradiated with 300-nm lamps. After irradiation for 8 h, the GC analysis (200°C) of the photolysate showed that 52% of 1-$NpCO_2Me$ survived (R_t 2.62 min) and 34% of **7** (R_t 6.91 min) was formed. The yellow oily residue was flash-chromatographed twice using 30% ethyl acetate in hexanes as eluant to give a pale yellow powder (139 mg, 30.4%) and 1-$NpCO_2Me$ (120 mg). The former was further recrystallized from acetonitrile to afford white crystals of 1-carbomethoxy-7-acetonyl-8-acetyl-7,8-dihydronaphthalene (**7**, mp 107–107.5°C).

A solution of 1-$NpCO_2Me$ (1 g, 5.6 mmol) and acacH (430 mg, 4.3 mmol) in methylene chloride (180 mL) was irradiated in the Hanovia apparatus. After irradiation for 187 h, GC analysis (column at 150–230°C at 10°C/min) of the photolysate showed that 62% of 1-$NpCO_2Me$ (R_t 3.57 min) survived and two products were formed with R_t 6.31 min (**8**, 30%) and 7.99 min (**7**, 7%). The residue was flash-chromatographed using 20% ethyl acetate in hexanes as eluant to give a crude product (66.5 mg, R_t 6.31 min), which was recrystallized from acetonitrile to give white crystals of 1,8-dimethyl-2,9-dioxa-5,6-(3′-carbomethoxybenzo)tetracyclo[5, 2, $0^{3,11}$ $0^{4,8}$]undecane (**8**, 31 mg): mp 117–117.5°C. Anal. calcd. for $C_{17}H_{18}O_4$: C 71.33%, H 6.29%; found: C 71.42% and 71.23%, H 6.47% and 6.34%. The structure of **8** was determined by X-ray crystallography (15).

A solution of **7** (4.2 mg, 0.015 mmol) in methylene chloride (1 mL) in a quartz tube was irradiated at 300 nm. A sample solution was withdrawn at 1-h intervals and analyzed by GC. After 6 h of irradiation, the GC analysis (150–230°C at 10°C/min) showed three peaks at R_t 7.99 min for **7** (24%), R_t 6.31 min for **8** (16%), and an unknown product (R_t 7.33 min, 39%). The unknown product showed GC–MS (CI) peaks at m/e 243 (M+1, 47%), 211 (100%). No further study of this unknown compound was done.

A solution of **7** (4.7 mg, 0.016 mmol) in methylene chloride (1 mL) was irradiated through a Pyrex filter with a 200-W Hanovia lamp. After 6 h of irradiation, GC (150–230°C at 10°C/min) analysis of the photolysate showed three peaks at R_t 7.99 for **7** (22%), R_t 6.31 min for **8** (46%), and R_t 7.33 min for the unknown compound (14%).

Triplet sensitization

A stock soslution of 2-$NpCO_2CH_3$ (0.02 M), acacH (0.08 M), and octadecane (IS) was prepared. Three sample solutions were prepared in quartz tubes in which No. 1 contained the stock solution (5 mL) without a sensitizer, No. 2 the solution (5 mL) and xanthone (0.05 M), and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

No. 3 the solution (5 mL) with benzophenone (0.05 M). The above three solutions were irradiated for 6 h at 350 nm. While **2** was obtained (22%) from No. 1 solution, this product could not be detected by GC for No. 2 and No. 3 solutions.

Quenching

Five acetonitrile solutions (1 mL) containing 2-$NpCO_2Me$ (0.02 M), acacH (0.08 M), octadecane (as IS, 0.005 M), and TBA (0, 0.0015, 0.003, 0.0045, and 0.006 M) were irradiated at 350 nm for 2 h. The quantum yields were determined and analysed by the Stern–Volmer relation (eq. [1]) to afford slopes ($k_q\tau$) of 237 ± 29 and 230 ± 31 in two series of experiments. Two solutions (5 mL) were prepared in quartz tubes, in which No. 1 contained no DMA, and No. 2 contained DMA (0.01 M). The solutions were irradiated for 4 h to afford quantum yields of **2** of 0.0043 for No. 1 and 0.0008 for No. 2.

Quenching of the de Mayo reaction

Three solutions (5 mL) in hexanes were prepared in quartz tubes, each of them containing acacH (0.05 M, 0.25 mmol), cyclohexene (0.5 M, 2.5 mmol), and decahydronaphthalene (as IS, 0.004 M, 0.02 mmol); No. 2 tube also contained *N*,*N*-dimethylaniline (0.01 M, 0.05 mmol) and No. 3 tube tributylamine (0.01 M, 0.05 mmol), while No. 1 tube was used as a control. The solutions were irradiated in the second apparatus at 300 nm for 4 h. The relative yields of the addition product (identified by coinjection with an authentic compound) were 11.8% for No. 1, 9.4% for No. 2, and 10.7% for No. 3 solution.

TODD L. ARSENAULT, DONALD W. HUGHES, DAVID B. MACLEAN, WALTER A. SZAREK, ANDREW M. B. KROPINSKI, and JOSEPH S. LAM. Can. J. Chem. **69**, 1273 (1991).

AK1401 is a mutant of *Pseudomonas aeruginosa* strain PAO1 (serotype O5) that does not express O-antigen, but does express "A-band" lipopolysaccharide (LPS). The polysaccharide portion of the A-band LPS (A-PS) from AK1401 was found to consist mainly of D-rhamnose, with smaller amounts of 3-*O*-methylrhamnose, ribose, mannose, glucose, and a 3-*O*-methylhexose. ^{1}H nuclear magnetic resonance spectra of the intact A-PS indicated that the main structural feature was a repeating trisaccharide of α-D-rhamnose having the following structure:

$$[\rightarrow 2\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow 3)\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow 3)\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow]_n$$

The ^{1}H NMR spectrum of the repeating unit was completely assigned through the use of 2D shift-correlated and relayed coherence transfer NMR spectroscopy. The linkage positions and sequence of residues were found by nuclear Overhauser enhancement difference spectroscopy.

Key words: *Pseudomonas aeruginosa*, lipopolysaccharide, ^{1}H NMR.

TODD L. ARSENAULT, DONALD W. HUGHES, DAVID B. MACLEAN, WALTER A. SZAREK, ANDREW M. B. KROPINSKI et JOSEPH S. LAM. Can. J. Chem. **69**, 1273 (1991).

Le AK1401 est une espèce mutante du *Pseudomonas aeruginosa* de la lignée PAO1 (sérotype O5) qui n'exprime pas de O-antigène, mais qui exprime un lipopolysaccharide (LPS) de «bande-A». On a trouvé que la portion polysaccharide du LPS de bande-A du AK1401 est principalement formée de D-rhamnose, avec des quantités plus faibles de 3-*O*-méthylrhamnose, de ribose, de mannose, de glucose et d'un 3-*O*-méthylhexose. Les spectres de résonance magnétique nucléaire du ^{1}H du PS-A indiquent que la caractéristique structurale principale est un motif trisaccharide de α-D-rhamnose, de structure :

$$[\rightarrow 2\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow 3)\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow 3)\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow]_n$$

Faisant appel à la RMN en 2D avec corrélation des déplacements et transfert de cohérence par relais, on a fait une attribution complète du spectre RMN du ^{1}H du motif. On a déterminé les positions de liaison et la séquence des résidus par l'effet Overhauser nucléaire différentiel.

Mots clés : *Pseudomonas aeruginosa*, lipopolysaccharide, RMN du ^{1}H.

[Traduit par la rédaction]

Introduction

Pseudomonas aeruginosa is an opportunistic pathogen that infects persons having compromised immune systems, such as burn victims, organ transplant recipients taking anti-rejection drugs, and cystic fibrosis (CF) patients. CF patients commonly suffer respiratory tract infections of *P. aeruginosa* that are potentially fatal (1). *Pseudomonas aeruginosa* infections in general are very difficult to eradicate because of resistance to a wide variety of antibiotics (1), but the mucoid colonies present in CF lungs are even more persistent because the cell-surface lipopolysaccharide (LPS) antigens change upon colony formation (1, 2). This latter phenomenon can make vaccination ineffective, since the bacteria no longer express the LPS antigens to which antibodies were raised.

Lipopolysaccharides are cell-surface molecules common to all Gram-negative bacteria. They consist of a carbohydrate/lipid portion ("Lipid A", which anchors the LPS in the outer membrane) and a carbohydrate portion, consisting of a short "core oligosaccharide" and a high molecular weight "side-chain polysaccharide" (3). The carbohydrate portion is linked to the Lipid A by a very acid-labile linkage involving 2-keto-3-deoxyoctulosonic acid (KDO), and thus may be liberated by mild acid-catalyzed hydrolysis, which results in precipitation of the insoluble Lipid A. Within a species, there is little variation in the structures of the core and lipid A, but the side-chain polysaccharides are highly variable; in the case of *P. aeruginosa*, they consist of repeating units composed of 2–5 monosaccharides, and commonly contain uronic acids, amino sugars, and some unusual sugars (see ref. 4). These side-chain structures are often called "O-antigens", and their variation is used in immunological typing schemes to define serotypes within a particular species. Vaccines currently used against pathogenic

Gram-negative bacteria commonly consist of a mixture of O-antigens from several serotypes of the same species.

Rivera *et al.* (5) have described a minor type of LPS, designated "A-band" LPS, from *P. aeruginosa* strain PAO1 (serotype O5), which differed from the classical LPS ("B-band" LPS) described above in its mobility on polyacrylamide gel electrophoresis. It was shown that this new type of LPS did not react with monoclonal antibodies to the O-antigen; also, the side-chain polysaccharide contained only neutral sugars, and was shorter than the O-antigen. Rivera and McGroarty (6) later postulated that the A-band LPS is present along with B-band LPS in cultures, but that the B-band expression stops under certain conditions (such as prolonged antibiotic therapy) leaving the A-band LPS as the principal cell-surface antigen.

Upon establishment of colonies in a CF lung, *P. aeruginosa* becomes non-typable, a result which implies that the O-antigens are no longer present. However, Lam *et al.* (2) have shown, through the use of monoclonal antibodies, that expression of A-band LPS is conserved in a high percentage of clinical isolates from CF patients. Furthermore, this antigen was found to be present in 11 of the 17 IATS[3,4] serotypes (2), thus indicating that it is a "common antigen". Since the A-band LPS is conserved upon infection, and since it is a common antigen, vaccines based on this type of LPS might be more successful in preventing pulmonary infections of *P. aeruginosa* than the current vaccines based on O-antigens.

AK1401 is a rough mutant of strain PAO1 (7) that, in spite of being defective in the synthesis of O-antigen, produces a high molecular weight LPS that reacts with A-band specific monoclonal antibodies (2). Thus, AK1401 is a potentially attractive source of A-band LPS because the LPS can be obtained free from contaminating O-antigen. Rough B-band LPS is still produced; however, this is easily removed by size-exclusion chromatography. Because of the lack of O-antigens, AK1401 can be used also to screen serum samples for the presence of antibodies to A-band LPS. Accordingly, we undertook a structural study of the A-band LPS from AK1401 with the intention of preparing synthetic vaccines based upon subunits of the structure that could be used for protection against *Pseudomonas* infections.

In the present work the structure of the polysaccharide portion of A-band LPS (A-PS) from AK1401 was examined by a combination of spectroscopic and degradative techniques. The monosaccharide composition was found by gas chromatography (GC) and gas chromatography – mass spectrometry (GC–MS) (8) of the alditol acetates derived from a hydrolysate of the A-PS. The absolute configuration of the rhamnose component was found by GC and GC–MS of (−)-2-octyl glycoside peracetates (9). The anomeric configurations were found by determination of the C-1–H-1 coupling constants (10). The ^{1}H NMR spectrum was assigned for the principal monosaccharides with the aid of ^{1}H–^{1}H shift-correlated (COSY) and relayed coherence transfer (RELAY) experiments, and this assignment was used to infer the linkage positions and sequence of residues in the polysaccharide by observation of inter-residue nuclear Overhauser enhancements (nOe's). The similarity of this structure with those of other neutral LPS's from *P. aeruginosa* (11–13) is discussed.

Experimental

Sample preparation

AK1401 cells were grown overnight at 37°C in 500 mL of tryptic soy broth (Difco) and then used to inoculate 4.5 L of tryptic soy broth in an SLS fermentor (Labline). The temperature was maintained at 37°C, the rotation rate was 200 rpm, and the aeration rate was 10 L min^{-1}. The cells were harvested, at late logarithmic or early stationary phase, by centrifugation. LPS was isolated by the method of Darveau and Hancock (14), and hydrolyzed in 1% acetic acid at 100°C for 90 min. The lipid A was removed by centrifugation, and the supernatant was lyophilized to dryness. The residue was dissolved in 0.05 M pyridinium acetate buffer (pH 5.3) and chromatographed on Bio-Gel P-4 (minus 400 mesh). The component of highest molecular weight was used in this study.

Prior to analysis, the A-PS sample was chromatographed on Sephadex G-50 in 0.05 M pyridinium acetate buffer. The void-volume fraction was collected and lyophilized. For ^{1}H and ^{13}C NMR analysis, an A-PS sample (7 mg) was exchanged three times with 99.9% D_2O (MSD Isotopes), the sample being lyophilized after each exchange. Finally, the sample was dissolved in 0.8 mL of 99.996% D_2O ("D_2O PLUS", MSD Isotopes).

Compositional analysis

A sample of A-PS (<1 mg) was dissolved in 1 mL of 2 M HCl in a thick-walled Teflon screw-cap vial (capacity ≈ 8 mL), and the solution was kept for 3 min in a Panasonic 700-W microwave oven at medium-high power;[5] the sample was cooled at least 15 min before opening the reaction vial. The sample was evaporated to near dryness under reduced pressure, and residual water and acid were removed by evaporating with 3 portions of 1-propanol. Alternatively, hydrolysis was performed at 120°C in 1 mL of 2 M trifluoroacetic acid in a sealed glass tube for 1.5 h; the water and acid then were removed under reduced pressure.

The dry residue was dissolved in 1 mL of water, and the solution was treated with 5 mg of sodium borohydride at ambient temperature for 4 h (or overnight). The reaction mixture was quenched by the addition of 5% acetic acid in methanol, and evaporated. Further portions of 5% acetic acid in methanol were added, and the solution was distilled until the presence of boron could no longer be detected (flame test). The residue was dried under vacuum and treated with 1 mL of acetic anhydride at 110°C for 2 h. The reaction mixture was cooled, poured into water, and extracted with chloroform. The combined chloroform extracts were washed extensively with 5% aqueous sodium hydrogen carbonate, dried over anhydrous sodium sulfate, and concentrated.

A series of alditol acetate standards (arabinitol, xylitol, 2-deoxyglucitol, 6-deoxygalactitol, and 3-*O*-methylrhamnitol peracetates) was prepared from the corresponding aldoses as described above. Rhamnitol, ribitol, glucitol, galactitol, and mannitol peracetates were prepared on a larger scale as follows. The sugar (0.5 g) was reduced with 0.5 g of sodium borohydride in 10 mL of water as described above. The alditols were acetylated using 10 mL of acetic anhydride; in the cases of glucitol, mannitol, and galactitol peracetates, the products were obtained by pouring the reaction mixture into methanol and collecting the crystalline materials. Overall yields were ≈50%. The identity of all products was confirmed by GC and CI-MS using ammonia as the reagent gas.

Gas chromatography was performed on a 30 m × 0.5 mm DB1701 wide-bore capillary column (J&W Scientific) using a Hewlett–Packard 5890 instrument equipped with an on-column injector and a HP3390A integrator. The oven temperature was 200°C, and the flame-ionization

[3]IATS refers to "International Antigenic Typing System"; for definition, see P. V. Liu, H. Matsumoto, H. Kusama, and T. Bergan. Int. J. System. Bacteriol. **33**, 256 (1983).

[4]It has been found recently that the antigen is present in 12 of the 17 serotypes (M. Y. C. Lam. Ph.D. Thesis, University of Guelph, Guelph, Ont. 1990).

[5]This experiment was similar to that described for the rapid total hydrolysis of proteins (S.-T. Chen, S.-H. Chiou, Y.-H. Chu, and K.-T. Wang. Int. J. Peptide Protein Res. **30**, 572 (1987)). The reaction vessel was fabricated from a 1 in. diameter Teflon rod; the minimum wall thickness was 6 mm, and the thread depth was 1 cm.

detector was kept at 280°C. The carrier gas was helium at a pressure of 8 psig (1 psi = 6.89 kPa).

GC–MS was performed on a VG Micromass 7070F mass spectrometer equipped with a Varian model 3700 GC having a J&W Scientific on-column injector. The column described above was used, except that the oven temperature was reduced to 180°C and the helium backing pressure was only 2 psig. The interface temperature was kept at 250°C, the ion source at 200°C, the electron energy at 70 eV, and the accelerating potential at 4 kV. The mass spectrometer was scanned from either 350 or 300 to 40 amu at 2 s per decade, with a 1-s interscan delay. The data were acquired and processed on a Digital Electronics Corporation PDP 11/24 computer using VG 11/250 software.

Absolute configuration

A sample of A-PS hydrolysate was treated with 0.5 mL of (−)-2-octanol and 1 drop of trifluoroacetic acid in a sealed tube at 140°C for 20 h. The mixture was evaporated under reduced pressure, and the residue was treated with 10 mg of fused sodium acetate and 1 mL of acetic anhydride at 110°C for 1 h. The reaction mixture was poured into water and extracted with chloroform. The extracts were washed extensively with 5% aqueous sodium hydrogen carbonate, dried, and concentrated. Standard samples for retention-time comparison were prepared similarly, using L-rhamnose with either (−)-2-octanol or (±)-2-octanol. GC analysis was performed as above.

Nuclear magnetic resonance spectroscopy

All of the NMR spectra were recorded on a Bruker AM-500 spectrometer. The ^1H spectra were acquired at 500.137 MHz using a 5-mm dual frequency $^1H/^{13}C$ probe. Spectra were acquired over 2.45 kHz in 8K data points (1.671 s acquisition time). Sample temperature was maintained at 30°C by a Bruker BVT-1000 variable temperature unit. The residual HDO signal was suppressed by saturation for 1.0 s prior to acquisition. The free induction decays (FID's) were processed using Gaussian multiplication for resolution enhancement, and before Fourier transformation were zero-filled to 16K.

Nuclear Overhauser enhancement (nOe) difference spectra were obtained by subtraction of the off-resonance control free induction decay (FID) from the on-resonance FID. The proton of interest was selectively irradiated for 0.2 s, and the decoupler was gated off during acquisition. A 2.0-s relaxation delay was used. For each irradiation 8 scans were acquired with the cycle of irradiations repeated 20 times. FID's were processed using exponential multiplication (line-broadening 4.0 Hz) and were zero-filled to 32K before Fourier transformation. The sample was not degassed, so the enhancements were not quantitated. All of the observed nOe's were negative.

COSY and RELAY 2D NMR spectra were acquired in the absolute-value mode using the standard pulse sequences $90°–t_1–90°–$ACQ and $90°–t_1–90°–\tau–180°–\tau–90°–$ACQ, respectively. Spectra in $F2$ were acquired over a 2.45-kHz spectral width in 1K data points. The COSY data were acquired in 96 scans for each of the 256 FID's, whereas the RELAY data were acquired in 128 scans. The 90° ^1H pulse width was 19.2 μs. A 1.0-s relaxation delay was used, during which the HDO signal was suppressed by presaturation. The RELAY experiments used the phase cycling scheme given in ref. 15, and used a fixed delay τ of 0.040 s. Zero-filling in $F1$ produced a 512 × 512 data matrix with a digital resolution of 4.787 Hz/point in both dimensions. During 2D Fourier transformation a sine-bell squared window function was applied to both dimensions. The transformed data were then symmetrized.

The ^{13}C spectra were recorded at 125.759 MHz using the 5-mm dual frequency probe. The spectra were acquired in 105 000 scans over 29.4-kHz spectral width in 32K data points. A 30° pulse width of 2.0 μs was used. The data were processed using exponential multiplication (line broadening 4.0 Hz). The values of the $^1H–^{13}C$ one-bond coupling constants were obtained using the gated decoupling technique. A 0.5-s relaxation delay was used. The FID was processed using exponential multiplication (line broadening 3.0 Hz) and was zero-filled to 64K before Fourier transformation.

Chemical shifts for the ^1H NMR spectra are reported in ppm relative to TMS using the HDO signal at 4.60 ppm as internal reference. The ^{13}C chemical shifts were referenced relative to 1,4-dioxane in D_2O at 67.4 ppm as an external reference.

Results and discussion

Examination of the ^1H and ^{13}C NMR spectra of the A-PS (see Fig. 1) shows that the main structural feature is a trisaccharide repeating unit of 6-deoxyhexoses. The H-1 signal for each monosaccharide appeared as a broad singlet (linewidth ≈ 3 Hz), indicating that the value of the H-1–H-2 coupling constant is of this magnitude; this result is consistent with all of the three monosaccharides having the *manno* configuration. Analysis of the alditol acetates showed rhamnose to be the principal monosaccharide (see Table 1). Thus, the bulk of the A-PS is a polymer of rhamnose (a "rhamnan") with three distinct rhamnose units.

Rhamnans have been previously reported to be present in lipopolysaccharide preparations from *Pseudomonas aeruginosa* (11, 12), as well as *P. syringae* (16, 17) and *P. cepacia* (18). Those from *P. aeruginosa* occur as minor components of the LPS, and their presence is seen only after the major O-antigens are selectively hydrolyzed with acid or base; the rhamnans found in the other species are in fact the side chains of the principal LPS's. The two known rhamnans from *P. aeruginosa* (and that from *P. syringae*) have the same repeating unit, comprised of two α-(1→3)-linked rhamnoses and one α-(1→2)-linked rhamnose. A polymer of this repeating unit was synthesized by Tsvetkov *et al.* (13), and its ^{13}C NMR spectrum was reported to be identical with that of the natural rhamnan identified in ref. 12. The reported values of the ^{13}C NMR chemical shifts are ≈0.1 ppm higher than those found for the A-PS (see Table 2), suggesting that the polysaccharide portion of A-band LPS from AK1401 has the same repeating unit. Since the differences in chemical-shift values are consistent, they may be attributable to slight differences in standardization of the two instruments. The similarity between the A-band LPS described by McGroarty and co-workers (5, 6) and the "common antigen" described by Yokota *et al.* (11) had been established by the use of a monoclonal antibody (MAb E87, see ref. 6). The present data confirm this observation, since they show that the repeating unit of the polysaccharide portion of A-band LPS from AK1401 is the same as the repeating unit of the common antigen.

Some differences do exist in the structure of the A-PS from AK1401 compared to the polysaccharides reported previously, notably in the types of monosaccharides that are present as minor components. The monosaccharide composition of A-PS from AK1401 was found by GC and GC–MS analysis of the alditol acetates, and the results obtained under two sets of hydrolytic conditions are shown in Table 1; the difference in the results obtained under the two sets of conditions is noteworthy. Identities were confirmed by coinjection of standard samples, except for the 3-*O*-methylhexose, which was identified from its mass spectrum alone, and which was distinguished from a 4-*O*-methylhexose by GC–MS analysis of the alditol-d_1 acetates.[6]

The minor monosaccharides found for the A-PS derived from AK1401 are slightly different from those found in other rhamnan-based polysaccharides of *Pseudomonas*. For example, Yokota *et al.* (11) found that the polysaccharide from *P. aeruginosa* ATCC 27584 contained rhamnose, a 6-deoxy-3-*O*-methylhex-

[6]The sample of alditol-d_1 acetates was prepared by Dr. A. Sen (Queen's University); the GC–MS data were acquired by J. Peltier (McMaster University).

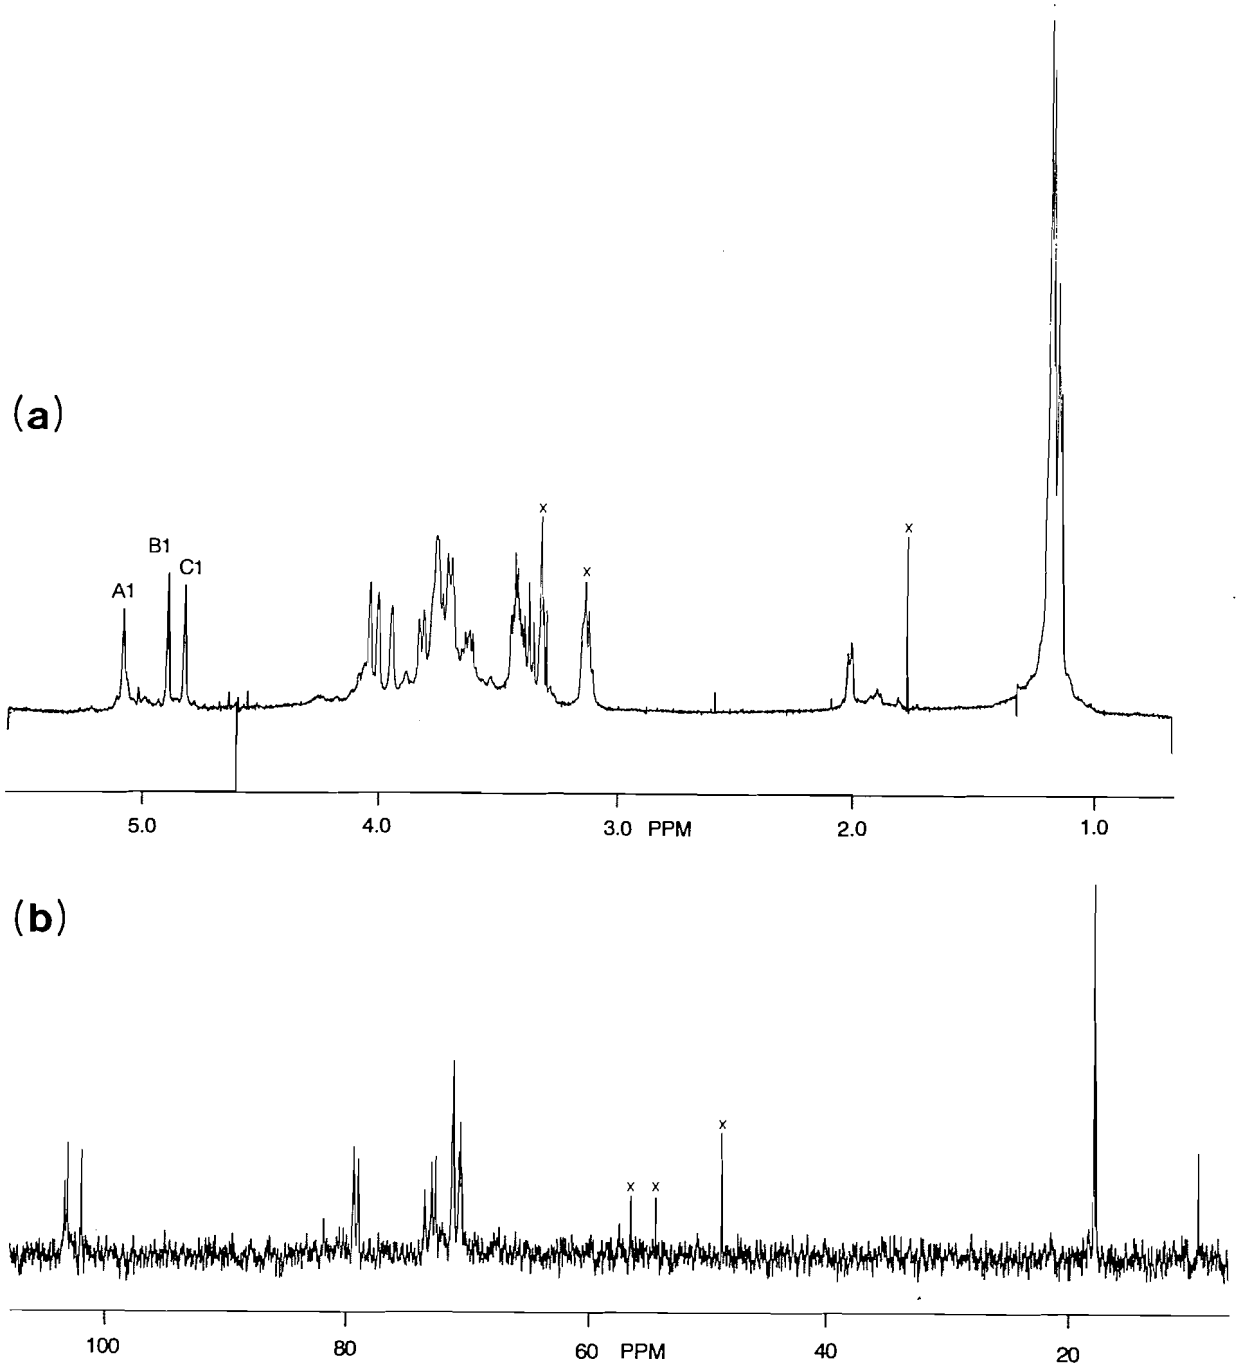

FIG. 1. (a) The 500-MHz ^{1}H NMR spectrum of A-PS from AK1401 in D_2O. The signals for the anomeric protons of residues A, B, and C are indicated. Peaks marked "X" are unassigned. (b) The 125-MHz ^{13}C NMR spectrum.

ose, xylose, glucose, and galactosamine. In the polysaccharide from *P. aeruginosa* serotype O7, Kocharova *et al.* (12) found rhamnose, mannose, glucose, and an unidentified sugar, which was first thought to be ribose; however, no ribitol pentaacetate was found by GC analysis of the alditol acetates derived from the polysaccharide. In contrast, our results clearly show the presence of ribitol pentaacetate in the same type of analysis performed on the A-PS from AK1401. Smith *et al.* (16, 17) studied a polysaccharide from the plant pathogenic species *P. syringae*, and found it to be composed almost entirely of rhamnose, with several minor sugars occurring in much lower amounts than those found in *P. aeruginosa*.

The rhamnose in the A-PS was found to be the unusual D-enantiomer. The same result was reported for the rhamnan from *P. aeruginosa* ATCC 27584 by Yokota *et al.* (11), based on the sign of the optical rotation of the methyl rhamnoside derived from a hydrolysate. Kocharova *et al.* (12) concluded that the rhamnan from *P. aeruginosa* serotype O7 also had only D-rhamnose, based on the sign of the optical rotation of the intact polysaccharide, and by analogy to the results of Smith *et al.* (17), who found only D-rhamnose in a rhamnan, having the same repeating unit, from *P. syringae*. The latter result was obtained using the same method as in the present work, which is better than methods based on optical rotations, since it shows directly that no L-rhamnose is present.

The anomeric configuration of each of the three principal

TABLE 1. Composition of the A-PS from *P. aeruginosa* AK1401

Retention time (min)	Component[a]	Relative intensity[b] A[c]	Relative intensity[b] B[d]
7.9	3-*O*-Methylrhamnitol tetraacetate	26 (1)	9 (0.5)
8.5	Rhamnitol pentaacetate	100	100
9.2	Ribitol pentaacetate	11 (0.5)	13 (0.8)
19.1	3-*O*-Methylhexitol pentaacetate	3	—
20.6	Mannitol hexaacetate	9 (0.5)	13 (3)
22.9	Glucitol hexaacetate	8 (0.6)	20 (4)

[a]Identities are based on electron-impact mass spectra and coelution on GC with authentic standards.
[b]Relative intensities were determined by normalizing the integrated areas from the chromatogram obtained by GC with a flame-ionization detector (referenced to rhamnitol pentaacetate = 100) and averaging several runs. The values in parentheses are the standard deviations for each average intensity.
[c]Values obtained using 2 M HCl in a Teflon vial. In this determination ethyl stearate and ethyl palmitate were detected also; ethyl palmitate coelutes with 3-*O*-methylrhamnitol tetraacetate under the GC conditions used, an aspect that accounts for the elevated relative intensity of this component.
[d]Values obtained using 2 M trifluoroacetic acid in a sealed glass tube.

rhamnose units seen in the NMR spectra was found to be α. The values of J_{C1-H1} were 176, 173, and 173 Hz, and the chemical shifts of the ^{13}C resonances (see Table 3) were 102.0, 103.2, and 103.4 ppm, respectively; Table 3 also shows the chemical shifts of the anomeric ^{13}C and ^1H resonances reported by others. This assignment is in agreement with those of Yokota *et al.* (11) and Kocharova *et al.* (12), which were based on comparisons of chemical shifts using reference compounds. It should be noted that the assignment of the anomeric configuration by determination of the J_{H1-H2} could not be made in this case, because the signals for the anomeric protons were not sufficiently resolved in the spectrum of the A-PS.[7] In contrast, the values of J_{C1-H1} are markedly different between α- and β-rhamnopyranosides (18, 19).

The assignment of the pyranoid ring to the rhamnose units was based on the similarity of the NMR spectral data to those reported by Tsvetkov *et al.* (13) and Smith *et al.* (17); the assignments by these groups were confirmed by synthesis and by methylation analysis, respectively.

The signals for each of the three principal monosaccharides in the 500-MHz ^1H NMR spectrum of the intact A-PS could be assigned, in spite of several overlapping signals, through the use of 2D shift-correlated (COSY) and relayed coherence transfer (RELAY) experiments. The signals of the three anomeric protons were labelled A1, B1, and C1 (where A1 refers to the signal of H-1 of residue A, and so on) starting with the resonance at lowest field (see Fig. 1). COSY spectra were interpreted by starting from the signal of the anomeric proton of each residue, and locating the signal of H-2 of that residue by finding the coupled resonance (by observation of an off-diagonal peak in the COSY spectrum). Thus, proton A1 at 5.079 ppm is coupled to the proton at 3.946 ppm, since there is an off-diagonal peak in the COSY spectrum that correlates them; therefore, the signal at 3.946 ppm is assigned to proton A2, and its neighbor (A3) may be found in a similar fashion. In this way, all of the resonances of a given monosaccharide may be found by analysis of the nearest-neighbor connectivities shown in the COSY spectrum.

In the case of residue B, there are two potential B3-B4 crosspeaks, one of which correlates B3 to the multiplet at 3.442 ppm, and the other correlates B3 with the resonance at 3.13 ppm. This feature may be the result of overlapping resonances at the position of the signal assigned to proton B3, or alternatively B3 has two neighbors in addition to B2. The use of the RELAY experiment in resolving the ambiguity caused by overlapping resonances is illustrated in Fig. 2. Since this experiment shows next-nearest-neighbor connectivities in addition to nearest-neighbor connectivities (the information

[7]It has been reported (A. de Bruyn, M. Anteunis, R. de Gussem, and G. G. S. Dutton. Carbohydr. Res. **47**, 158 (1976)) that J_{H1-H2} = 1.8 Hz for α-rhamnopyranose, 1.1 Hz for β-rhamnopyranose, and 1.7 Hz for methyl α-rhamnopyranoside.

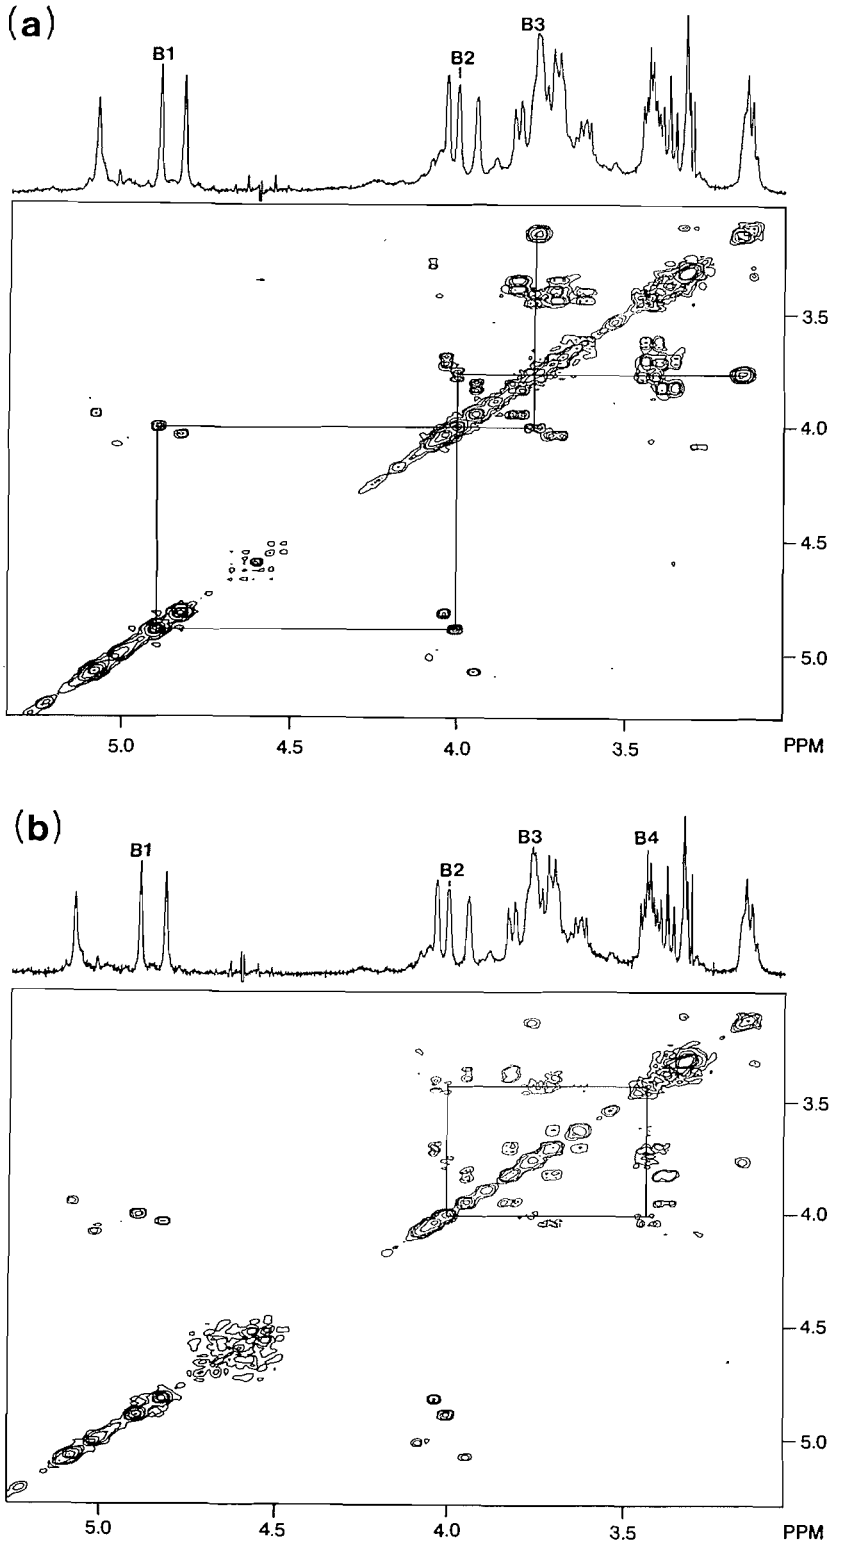

FIG. 2. Portions of the COSY and RELAY spectra of the A-PS from AK1401 in D_2O. In the COSY experiment (a), the signals for protons B1, B2, and B3 may be assigned, since crosspeaks are evident for B1–B2 and B2–B3; however, the assignment of B4 is ambiguous because there are two possible B3–B4 crosspeaks (due to overlapping signals on the diagonal). In the RELAY experiment (b), an additional crosspeak for B2-B4 was observed, thus allowing the assignment of B4; only the B2-B4 correlation is indicated for clarity.

contained in a COSY spectrum), the assignment of the signal for proton B4 is clarified by the presence of an additional crosspeak which correlates B2 to B4. Thus, the RELAY experiment shows a correlation between the known B2 resonance at 4.002 ppm and the B3 resonance at ≈3.77 ppm (as in COSY), and also a correlation between the B2 resonance and the resonance at 3.442 ppm. Therefore, the signal at 3.442 ppm is assigned to proton B4, and the additional crosspeak seen in the COSY spectrum that correlated the B3 resonance to the resonance at 3.13 ppm must be the result of another resonance overlapped

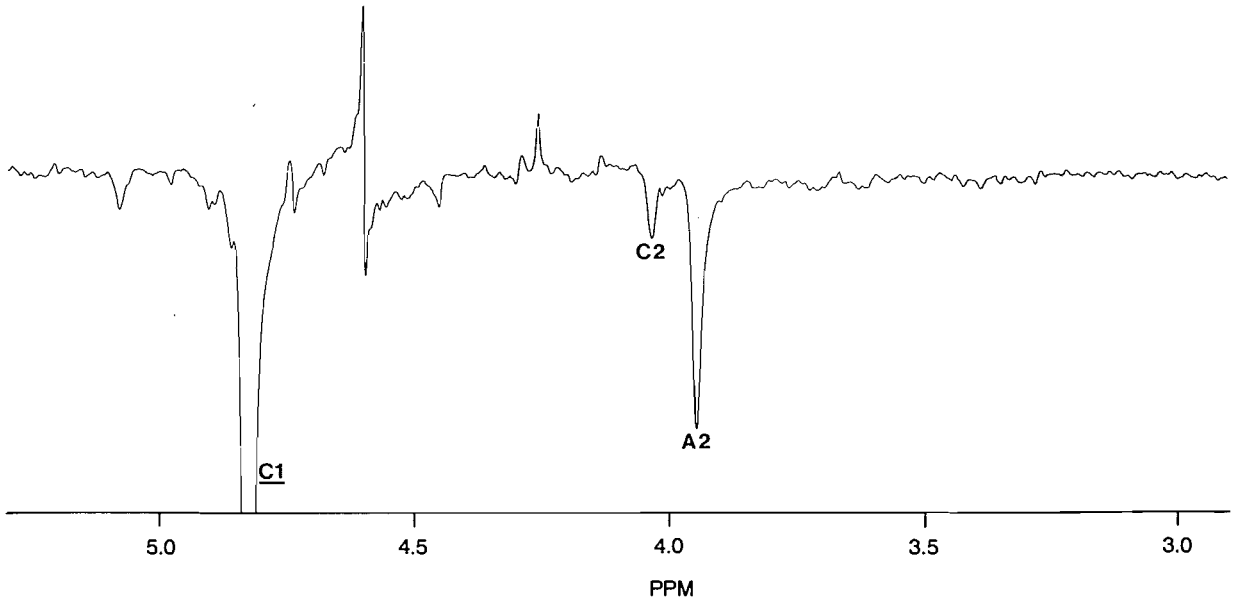

FIG. 3. A representative nOe difference experiment. Upon irradiation of proton C1, negative enhancements of A2 and C2 were observed. The inter-residue enhancement allowed the assignment of the sequence of residues (C → A) and the linkage position {C-(1→2)-A}.

TABLE 4. ^{1}H NMR data for A-PS from AK1401 in D_2O

Proton	Chemical shift	Multiplicity	Coupling constant(s)
Residue A			
H-1	5.079	br s	$J_{1,2}$ = 1.7 Hz[a]
H-2	3.946	br s	$J_{2,3}$ = 3.3 Hz[a]
H-3	3.825	dd	$J_{3,4} \approx 10$ Hz
H-4	3.374	apparent t	$J_{4,5} \approx 10$ Hz
H-5	3.71	m[b]	—
H-6,6′,6″	1.175	d	$J_{5,6}$ = 5.5 Hz
Residue B			
H-1	4.894	br s	$J_{1,2} < 2$ Hz
H-2	4.002	br s	$J_{2,3} \approx 3$ Hz
H-3	3.77	br m[c]	$J_{3,4} \approx 10$ Hz
H-4	3.442	sextet[d]	$J_{4,5} \approx 10$ Hz
H-5	3.76	br m[c]	—
H-6,6′,6″	1.175	d	$J_{5,6}$ = 5.5 Hz
Residue C			
H-1	4.823	br s	$J_{1,2} < 2$ Hz
H-2	4.037	br s	$J_{2,3} \approx 3$ Hz
H-3	3.71	m[b]	$J_{3,4} \approx 10$ Hz
H-4	3.432	sextet[d]	$J_{4,5} \approx 10$ Hz
H-5	3.62	dq	—
H-6,6′,6″	1.140	d	$J_{5,6} \approx 6$ Hz

[a] $J_{1,2}$ and $J_{2,3}$ for residue A were determined from the spectrum at 80°C.
[b] The signals of H-5 of residue A and H-3 of residue C were overlapped.
[c] H-3 and H-5 of residue B are part of the same multiplet, together with an unknown resonance.
[d] The H-4 signals of residues B and C were overlapped.

TABLE 5. Observed nuclear Overhauser enhancements

Irradiated proton	Enhanced signals[a]
A1	B3 (strong), C5, A2, H-6's
B1	B2, C3-A5 multiplet
C1	A2 (strong), C2
A2	C1 (strong), A3, A1
B2	B1, C3-A5 multiplet
C2	C1, B5, C3-A5 multiplet
A3	A2 (weak)
B3–B5	A1, C2, H-6's, B2
C3–A5	B1, H-6's, C2, B2, B4-C4 multiplet, A4
C5	H-6's, A1, B4-C4 multiplet
C6	C4-B4 (weak), C5
A6–B6	C3-A5, B5, A4, B4-C4 multiplet

[a] Enhanced signals are listed in order of decreasing intensity.

with that of B3. The nature of this additional resonance was not clarified by the RELAY spectrum, so that it and the resonance at 3.13 ppm remain unassigned. It is interesting to note that the signal at 3.13 ppm is absent when the A-band LPS from AK1401 was obtained by extraction using a different procedure (phenol–chloroform – petroleum ether). A summary of the signal assignments is given in Table 4. Some of the coupling constants were obtained by observation of the ^{1}H NMR spectrum at 80°C; however, the chemical shifts reported are those from the room-temperature spectrum.

The sequence of and linkage positions between residues A, B, and C were determined by observation of inter-residue nOe's. The result of a representative nOe experiment is shown in Fig. 3, and the data are in Table 5. If one considers the linkage α-D-Rha*p*-(1→2)-D-Rha*p*, it is apparent from a Dreiding model that the anomeric proton cannot approach within a distance of 3 Å to the H-3 of the next residue. Thus, an α-(1→2) linkage would not show a significant nOe of the signal of H-3 upon irradiation of the anomeric proton of the neighboring unit (see also ref. 18). Since irradiation of protons A1 and B1 resulted in nOe's of the signals of protons B3 and C3, respectively, neither of the linkages, A → B and B → C, can be α-(1→2). Since irradiation of C1 gave a strong nOe of the signal of A2, but not of any H-3 signal, only C → A can be a 1 → 2 linkage, whereas A → B and B → C are α-(1→3) linkages. Furthermore, the results of the nOe difference experiments involving intra-residue connectivities provide confirmatory evidence for the α configuration, as indicated, for example, by the absence of an nOe of H-3 or H-5 upon irradiation of H-1. Thus, the repeating-unit structure of the A-PS from AK1401 is as follows.

$$[\rightarrow 2\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow 3)\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow 3)\text{-}\alpha\text{-D-Rha}p\text{-}(1\rightarrow]_n$$

A **B** **C**

This complete assignment of the ^{1}H NMR spectrum complements the assignment of the ^{13}C NMR spectrum of this repeating unit reported by Tsvetkov *et al.* (13).

Although this repeating unit is the same as that found by other workers (11, 12, 16), our work represents the first complete assignment of the ^{1}H NMR spectrum of the polysaccharide. Work is in progress to determine the role of the minor sugar constituents in the structure of the A-PS.

Conclusions

The polysaccharide portion of A-band LPS from *Pseudomonas aeruginosa* mutant AK1401 (derived from strain PAO1, serotype O5) was found to have the same repeating-unit structure as other rhamnans from *P. aeruginosa* (11, 12), and from *P. syringae* (16, 17). The A-PS consists principally of rhamnose, but also has lesser amounts of 3-*O*-methylrhamnose, ribose, glucose, mannose, and a 3-*O*-methylhexose; these minor sugars differ from those found in other rhamnans from *Pseudomonas*. The rhamnose was shown to be the unusual D-enantiomer. The ^{1}H NMR spectrum of the intact A-PS was assigned for the three rhamnose units of the repeating structure, and this assignment allowed the determination of the linkage positions and sequence of residues by nOe difference spectroscopy.

Acknowledgements

This work was supported by grants from the Canadian Cystic Fibrosis Foundation (CCFF) and the Natural Sciences and Engineering Research Council of Canada. One of us (T.L.A.) gratefully acknowledges the receipt of Ontario Graduate Scholarships (1986–1987 and 1988–1989) and a CCFF Studentship (1989–1990). The authors would like to thank Dr. J. C. Richards (National Research Council, Ottawa) for helpful discussion regarding the nOe experiments, Dr. G. O. Aspinall (York University) for kindly providing a sample of 3-*O*-methylrhamnose, Dr. A. Sen (Queen's University) for preparing A-band LPS isolated by phenol–chloroform – petroleum ether extraction, and for preparing the sample of alditol-d_1 acetates, and J. Peltier for some of the GC–MS data.

Effets des sels de terres rares sur quelques phosphates dérivés des métabolites de la glycolyse

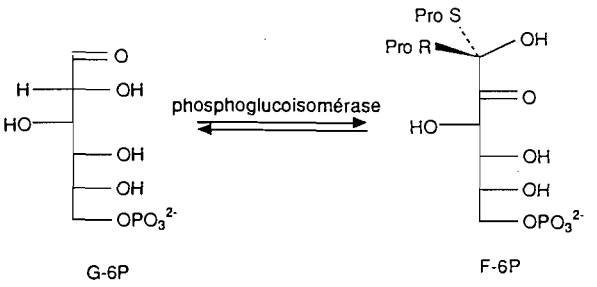
CLAUDE RABILLER,[1] PHILIPPE EYMARD ET MAHMOUD MESBAHI
Laboratoire de RMN et réactivité chimique, Unité associée 472 du Centre national de la recherche scientifique, Faculté des sciences et techniques, 2 rue de la Houssinière, 44072 Nantes CEDEX 03, France

Reçu le 13 décembre 1990

CLAUDE RABILLER, PHILIPPE EYMARD et MAHMOUD MESBAHI. Can. J. Chem. **69**, 1281 (1991).

Les dérivés phosphatés du glucose et du fructose sont des intermédiaires importants dans la fermentation des sucres. L'étude du devenir de leurs protons (ou deutérons) par spectroscopie RMN doit fournir des informations sur les transferts de protons (ou deuterons) susceptibles d'intervenir au cours de cette bio-transformation. Dans cette note, nous décrivons l'influence de la complexation de ces métabolites avec le chlorure de praséodyme ainsi que celle du pH sur leurs déplacements chimiques protoniques. On décrit par ailleurs les conditions dans lesquelles tous les protons des formes α et β de ces sucres cycliques sont individualisés. On a trouvé que le glucose-1-phosphate présente les meilleures aptitudes pour ce type d'étude. De plus, la comparaison du comportement de ces composés avec celui de l'acide 2-phosphoglycérique permet de préciser la conformation de ce dernier.

Mots clés : dérivés phosphatés des sucres, RMN, effets des terres rares.



CLAUDE RABILLER, PHILIPPE EYMARD, and MAHMOUD MESBAHI. Can. J. Chem. **69**, 1281 (1991).

Phosphate derivatives of glucose and fructose are well-known intermediates in sugar fermentation. Proton and deuterium NMR spectroscopy studies of the fermentation process provide information about proton (deuteron) transfers that are likely to occur in such biotransformations. In this paper we describe the influence of complexation of those metabolites with praseodymium trichloride and of pH on their proton NMR chemical shifts. We determine the conditions under which all the protons of both the α and β forms of these cyclic sugars are separated. Glucose-1 phosphate was found to be the most suitable derivative for this type of study. Furthermore, comparing the behaviour of these compounds with 2-phosphoglyceric acid allows us to specify the exact conformation of the latter.

Key words: phosphate sugar derivatives, NMR, LIS effects.

Introduction

La bioconversion du glucose en alcool, en glycérol ou en acide lactique fait intervenir un certain nombre de métabolites bien connus tels que les dérivés phosphatés du glucose, du fructose et des sucres à trois atomes de carbone. Les transferts de protons accompagnant les différentes étapes de cette bio-transformation suscitent encore de nombreux travaux (1–4). Il en est ainsi par exemple de l'isomérisation du glucose-6-phosphate (G-6P) en fructose-6-phosphate (F-6P) :

G-6P F-6P

Le proton introduit en position pro-*R* provient à la fois du milieu et d'un transfert intramoléculaire (3, 4). On ignore cependant avec certitude dans quelle proportion et quels sont les facteurs susceptibles de la modifier. Pour ce type d'étude, la RMN du proton ou du deutérium en abondance naturelle (5–8) est susceptible d'apporter des renseignements complémentaires dans la mesure où les différents sites « protons » ou « deutérons » d'une molécule donnée sont bien séparés.

Cependant, qu'il s'agisse du glucose, du fructose, de leurs dérivés monophosphatés, bis-phosphatés ou de l'acide gluconique, la quasi-isochronie des déplacements chimiques rend cette approche très délicate. Ainsi, par exemple, les sept protons du fructose-1,6 bis-phosphate résonnent sur une plage de 0,5 ppm !

Lorsque l'on veut étudier ces métabolites, on a en général recours à leurs dérivés dont certains présentent des spectres mieux résolus. Des renseignements intéressants, bien qu'incomplets, ont pu être obtenus sur le glucose (9) à partir de son pentaacétate par RMN du deutérium. Il faut cependant souligner que les techniques de dérivatisation utilisées dans la chimie des sucres sont souvent délicates à manier et nécessitent de plus la mise en oeuvre de laborieuses techniques de séparation.

Une autre approche consiste à utiliser les effets de sels de terres rares en milieu aqueux (Lanthanide Induced Shift : LIS). La littérature recèle de très nombreux travaux relatifs aux effets LIS en milieu organique. Assez curieusement, peu d'études ont été consacrées aux solutions aqueuses et moins encore aux sucres dans ce milieu. Le comportement des déplacements chimiques des acides glycérique, gluconique et lactobionique a cependant fait l'objet d'un travail détaillé (10). Une très grande dépendance des déplacements chimiques en fonction de la concentration en sel de terre rare et du pH y est observée. Les nitrates d'europium et de praséodyme déplacent les protons à champ faible alors qu'une augmentation du pH provoque l'effet inverse.

On imagine alors le parti que l'on peut tirer de ces deux effets contradictoires en vue d'individualiser les différents protons ou deutérons des métabolites que nous nous proposons d'étudier. L'objet de ce travail est donc de déterminer si les phosphates dérivés du glucose présentent le même type de comportement que les acides de l'étude précédente et, dans l'affirmative, d'optimiser les conditions de concentration et de pH pour obtenir la meilleure séparation des massifs. Seront ainsi étudiés les glucose-6- et -1-phosphates (G-6P et G-1P), le fructose-6-phosphate (F-6P), le fructose-1,6 bis-phosphate (F-1,6P), l'acide gluconique et à titre de comparaison, l'acide 2-phospho-

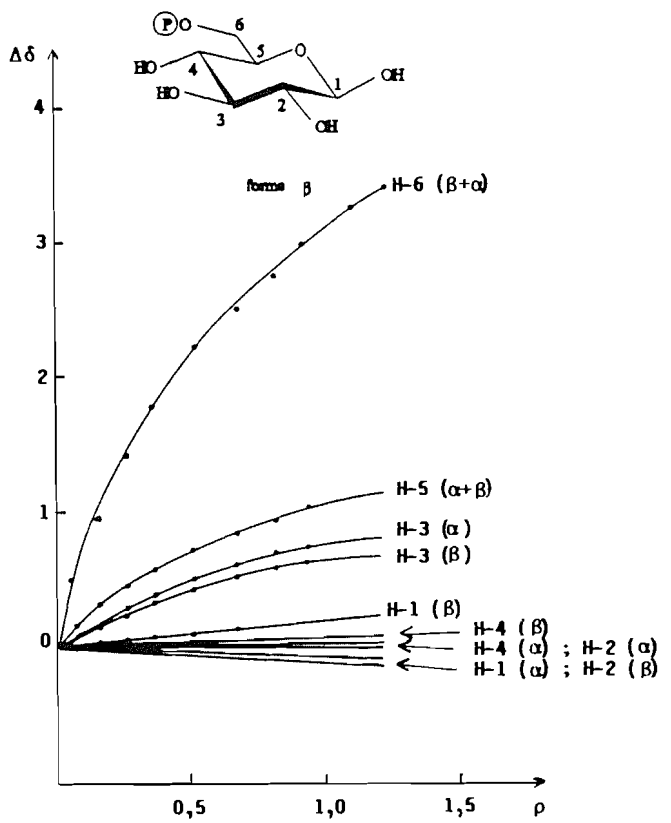

FIG. 1. Variation des déplacements chimiques des protons du glucose-6-phosphate **1** en fonction de la concentration en sel de praséodyme; $\Delta\delta$ (ppm) = δ_H (ρ = 0) − δ_H (ρ = x); ρ = [$PrCl_3 \cdot 6H_2O$] [Glucose-6-phosphate]; C = 0,1 mol/L dans D_2O.

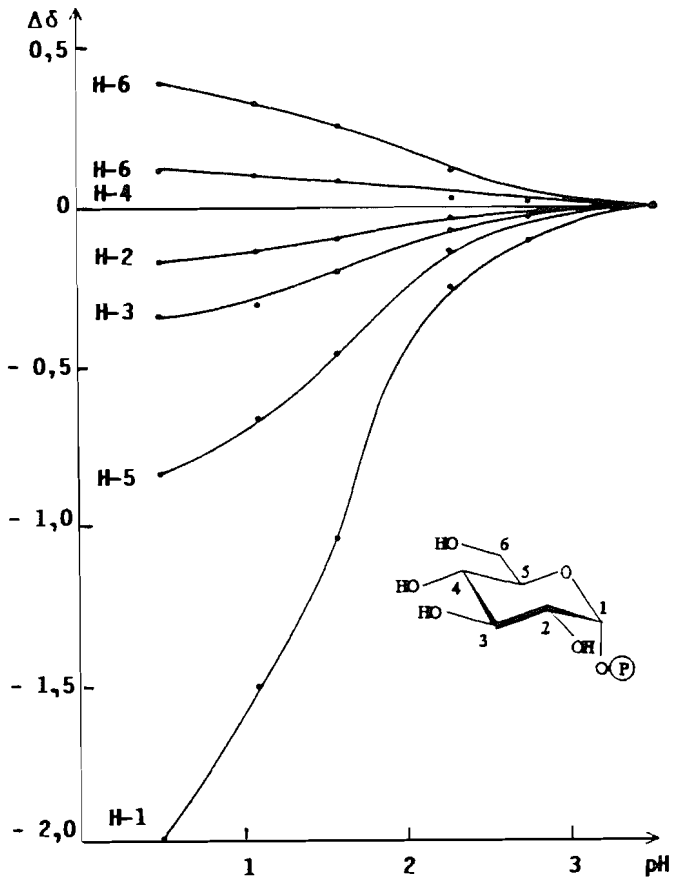

FIG. 2. Variation des déplacements chimiques des protons du glucose-1-phosphate **2** complexé à $PrCl_3 \cdot 6H_2O$ (ρ = 0,25), en fonction du pH; $\Delta\delta$ (ppm) = δ_H (pH = 3,5) − δ_H (pH = x); ρ = 0,25 = constante; C = 0,1 mol/L dans D_2O.

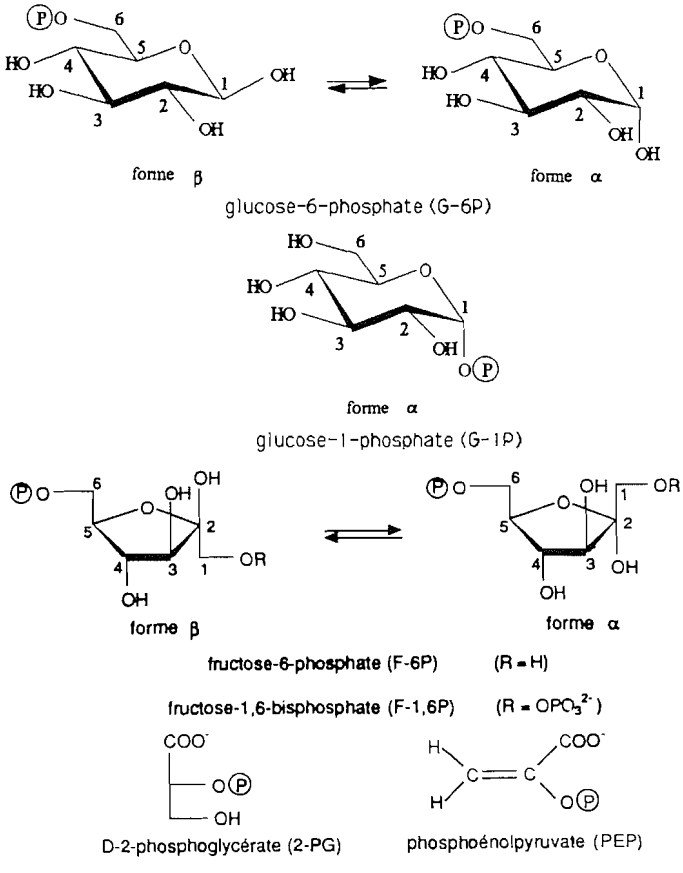
glycérique (2-PG) ainsi que l'acide phosphoénolpyruvique (PEP). Le sel de terre rare utilisé est le chlorure de praséodyme $PrCl_3 \cdot 6H_2O$.

Partie experimentale

Les différents composés phosphorés étudiés au cours de ce travail proviennent de chez Sigma. Ils ont été utilisés sans autre purification. Le chlorure de praséodyme $PrCl_3 \cdot 6H_2O$ a été fourni par Ventron (Karlsruhe). Nous l'avons transformé en $PrCl_3 \cdot 6D_2O$ par dissolution dans D_2O (fournie par le service des Molécules Marquées, CEA Saclay) suivie d'un séchage sous pression réduite.



Les spectres de RMN ont été enregistrés sur un appareil Bruker WM opérant à la fréquence de 250 MHz pour le proton. Les expériences COSY-HH ont été menées sur un spectromètre Bruker AM 500 MHz à l'aide d'un train de séquences multiimpulsionnelles pré-programmées sur l'appareil (programme COSY-H-H-DQC) avec l'élimination du pic de l'eau.

Les déplacements chimiques (en ppm) sont mesurés à partir du sel de sodium de l'acide 4,4-diméthyl-4-silapentanesulfonique (DSS) (Merck).

Les solutions sont préparées par introduction de 0,5 mmol de produit et d'une petite quantité de DSS dans 5 mL d'eau lourde. On introduit progressivement des quantités connues de sel de praséodyme $PrCl_3 \cdot 6D_2O$, détermine à chaque fois la valeur de ρ et mesure le pH correspondant. Si nécessaire, on acidifie le milieu à l'aide d'une solution 6,2 N DCl, pour solubiliser le complexe formé. Avant chacune des mesures de RMN, ces solutions sont filtrées.

Résultats et discussion

Les structures des différents hydrates de carbone phosphatés étudiés sont les suivantes :[2]

2. Dans la suite du texte, le groupement phosphate sera schématisé par O Ⓟ.

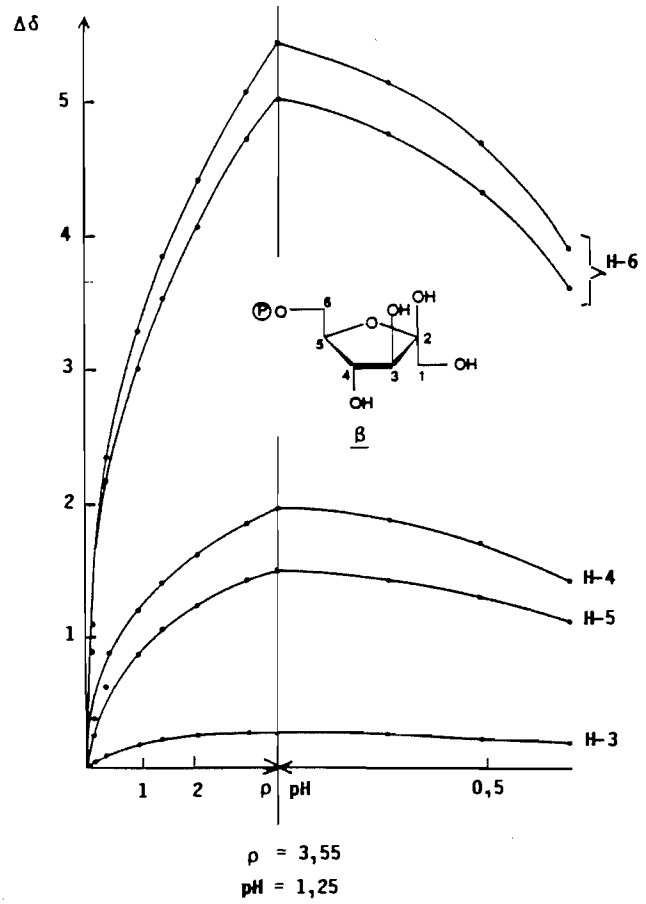

FIG. 3. Variation des déplacements chimiques des protons du fructose-6-phosphate **3** en fonction de la concentration en sel de praséodyme [$PrCl_3 \cdot 6H_2O$] et du pH (seuls les protons de la forme β sont représentés).

$$\Delta\delta\ (\text{ppm}) = \delta_H\ (\rho = 0) - \delta_H\ (\rho = x) \qquad 0 \leq \rho \leq 3{,}55$$
puis $$\Delta\delta\ (\text{ppm}) = \delta_H\ (\text{pH} = 1{,}25 - \delta_H\ (\text{pH} = x) \quad 1{,}25 \leq \text{pH} \leq 0{,}17$$

avec ρ = constante = 3,55; C = 0,1 mol/L dans D_2O.

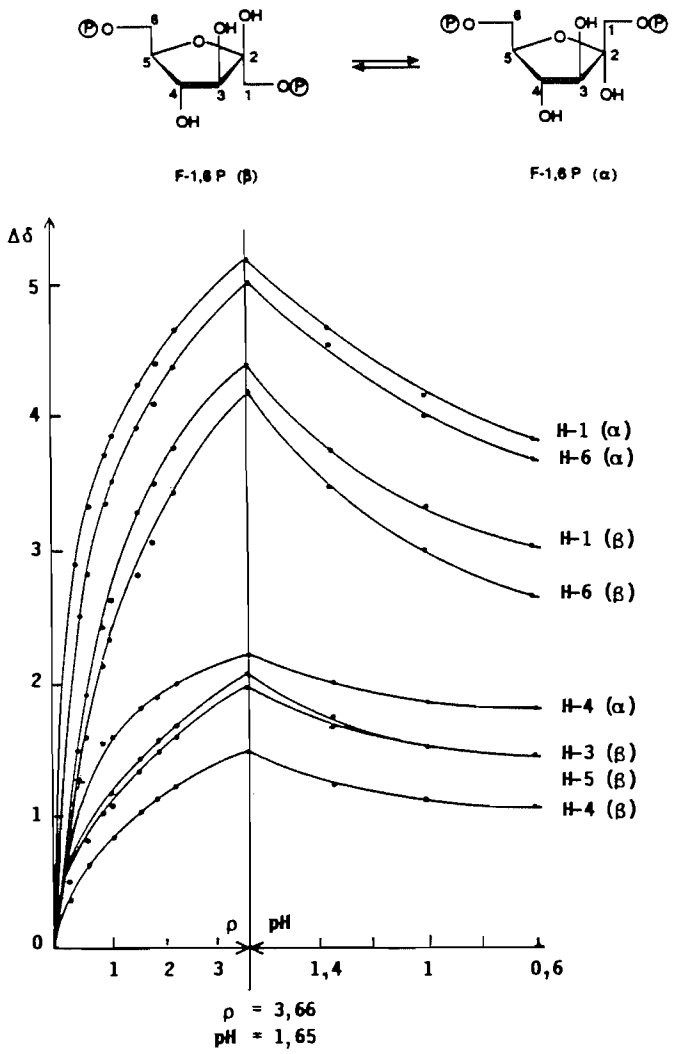

FIG. 4. Variation des déplacements chimiques des protons du fructose-1,6 bis phosphate **4** en fonction de la concentration en $PrCl_3 \cdot 6H_2O$ et du pH.

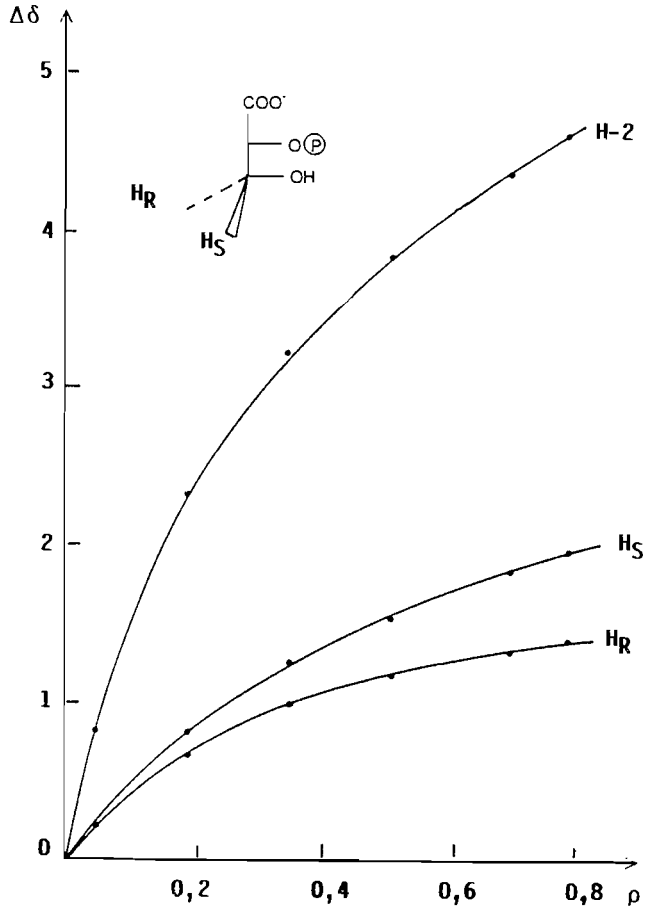
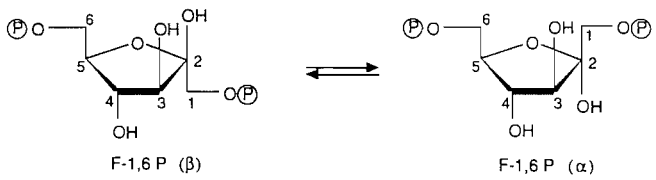
$$\Delta\delta\ (\text{ppm}) = \delta_H\ (\rho = 0) - \delta_H\ (\rho = x) \qquad 0 \leq \rho \leq 3{,}66$$
puis $$\Delta\delta\ (\text{ppm}) = \delta_H\ (\text{pH} = 1{,}65) - \delta_H\ (\text{pH} = x) \quad 1{,}65 \leq \text{pH} \leq 0{,}6$$

Les courbes de variation des déplacements chimiques protoniques avec la concentration en sel de praséodyme et en fonction du pH sont représentées sur les figures 1 (glucose-6-phosphate), 2 (glucose-1-phosphate), 3 (fructose-6-phosphate), 4 (fructose-1,6 bis-phosphate), 5 (acide D-phospho-2 glycérique) et 6 (acide phosphoénolpyruvique). Il faut noter que l'addition de $PrCl_3 \cdot 6H_2O$ aux solutions des sucres étudiés se traduit non seulement par de fortes variations de déplacement chimique mais également par un élargissement des raies d'autant plus important que la valeur de ρ est grande. Il peut être ainsi délicat d'attribuer les protons du fait de l'impossibilité d'analyser la multiplicité des massifs et de mesurer les constantes de couplage. L'attribution a alors été réalisée à l'aide de la séquence RMN bi-dimensionnelle COSY-HH. La figure 7 représente ainsi le spectre 2D COSY-HH du F-1,6P. Les variations de déplacement sont calculées à partir de la récente attribution du spectre ^1H de ce composé (11). L'analyse des raies du glucose-1-phosphate a été réalisée sur la base de travaux antérieurs (12). Par ailleurs, le complexe substrat–$PrCl_3 \cdot 6H_2O$ est totalement insoluble à pH = 6–7. Il est nécessaire d'acidifier le milieu dans tous les cas jusqu'à une valeur de pH ~ 2–3 pour obtenir une dissolution totale. L'examen des figures 1–6 indique que tous les protons sont déplacés à champs faibles sous l'influence du chlorure de praséodyme. Un effet inverse intervient pour les protons éloignés du phosphore : c'est le cas par exemple des protons H-4 et H-2 du G-6P ou H-6 du G-1P.

De plus, compte tenu des valeurs Δδ observées, il est clair que le centre de complexation se situe essentiellement sur la fonction phosphate. Les protons localisés à proximité du phosphore sont très fortement déplacés. C'est le cas des protons H-6, H-5 du G-6P, H-1, H-5 du G-1P, H-6, H-5, H-4 du F-6P ou H-1, H-6 du F-1,6P. La comparaison des formes structurales α et β de ce dernier illustre également ce propos. La forme α qui possède les deux groupes phosphates en *cis* présente des variations de déplacement $\Delta\delta_{H\text{-}1\alpha}$ et $\Delta\delta_{H\text{-}6\alpha}$ plus intenses que les correspondantes de la forme β. Le proton H-4 du F-1,6P (α) qui se trouve en *cis* des deux fonctions phosphate subit également des écarts de déplacement plus importants que ceux observés pour H-4β (voir figure 4).

Au contraire, pour une valeur de ρ donnée, une diminution du pH entraîne un abaissement des déplacements chimiques des protons proches du phosphore et une augmentation des déplacements protons éloignés (cas des H-6 du G-1P, voir figures 2 et 8). Ces tendances sont également confirmées en comparant le comportement des formes α et β du G-6P.





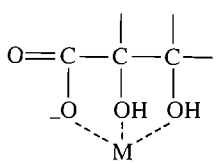


FIG. 5. Variation des déplacements chimiques des protons de l'acide D-2-phosphoglycérique **5** avec la concentration en $PrCl_3 \cdot 6H_2O$; $\Delta\delta$ (ppm) = δ_H (ρ = 0) − δ_H (ρ = x); C = 0,1 mol/L; pH = 1,8 (à ρ = 0).

Il faut noter de plus que l'allure des courbes $\Delta\delta$ en fonction de ρ est manifestement le résultat de deux phénomènes puisque l'addition du $PrCl_3 \cdot 6H_2O$ se traduit non seulement par la complexation du substrat, mais également par une modification non négligeable du pH. Nous donnons à titre indicatif cette variation dans le cas de l'étude $\Delta\delta = f(\rho)$ pour le F-1,6P (voir tableau 1). L'écart de 0,7 unité de pH, en passant de ρ = 0 à ρ = 3,66, est susceptible d'infléchir grandement la courbe de variation $\Delta\delta = f(\rho)$. En effet à ρ = constante (3,55), on note sur la figure 3 un abaissement des déplacements chimiques d'environ 1,5 ppm par unité de pH pour les protons H-6 du F-6P. Ces observations vont tout à fait dans le sens de celles effectuées antérieurement sur des composés analogues possédant une fonction acide carboxylique (10). De plus, les auteurs de ce travail postulent l'existence d'une complexation à trois centres du type :

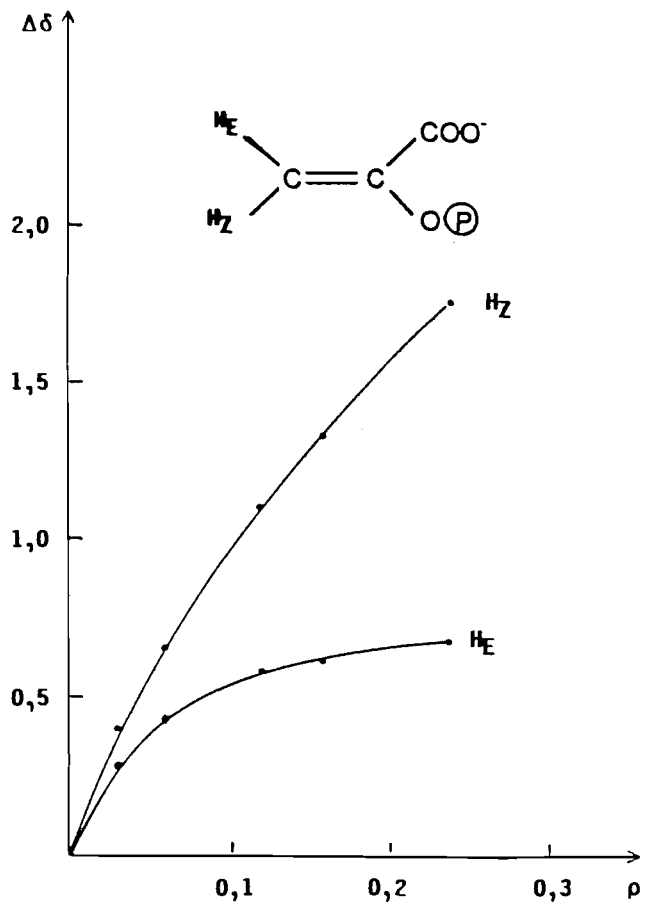

FIG. 6. Variation des déplacements chimiques des protons de l'acide phosphoénolpyruvique **6** en fonction de la concentration en $PrCl_3 \cdot 6H_2O$; $\Delta\delta$ (ppm) = δ_H (ρ = 0) − δ_H (ρ = x); C = 0,1 mol/L.

TABLEAU 1. Variation du pH avec la concentration en $PrCl_3 \cdot 6\ H_2O$ d'une solution de fructose-1,6 bis phosphate (0,1 mol/L dans D_2O; pH ajusté à 2,35 avec une solution 6,2 N de DCl)

ρ^a	0	0,29	0,48	0,61	1,09	1,88	2,33	3,6
pH	2,35	2,25	2,15	2,05	2,00	1,85	1,80	1,65

[a] ρ = [$PrCl_3 \cdot 6\ H_2O$] [Substrat]

Cela ne semble pas être le cas en ce qui concerne les formes α ou β du G-1P ou G-6P et du F-6P ou du F-1,6P, dont les structures se prêtent mal à l'établissement d'une telle association. On trouvera dans le tableau 2, les meilleures conditions de séparation pour les divers métabolites étudiés.

De plus, le PEP, qui ne possède que deux centres de complexation, voit cependant ses protons fortement déplacés (voir figure 6). La fonction phosphate apparaît donc comme un puissant agent de complexation pour le praséodyme. Cette tendance est également fortement confirmée par l'amplitude relative des variations de déplacements des protons éthyléniques H(Z) et H(E). L'attribution des protons du PEP a été réalisée sur la base d'expériences de deutération stéréosélective enzymatique (13) et chimiques (14). En solution aqueuse, on mesure $\delta_{H(Z)}$ = 5,51 ppm et $\delta_{H(E)}$ = 5,87 ppm (référence DSS). Lors des additions successives de $PrCl_3 \cdot 6H_2O$, on constate que H(Z) se déplace beaucoup plus rapidement que H(E) (H(Z) « double » H(E)). Pour une valeur de ρ = 0,24, on a $\Delta\delta_{H(Z)}$ = 1,75 ppm et $\Delta\delta_{H(E)}$ = 0,68 ppm. Ces mesures montrent sans ambiguité une nette préférence pour le groupe OPO_3H_2 par

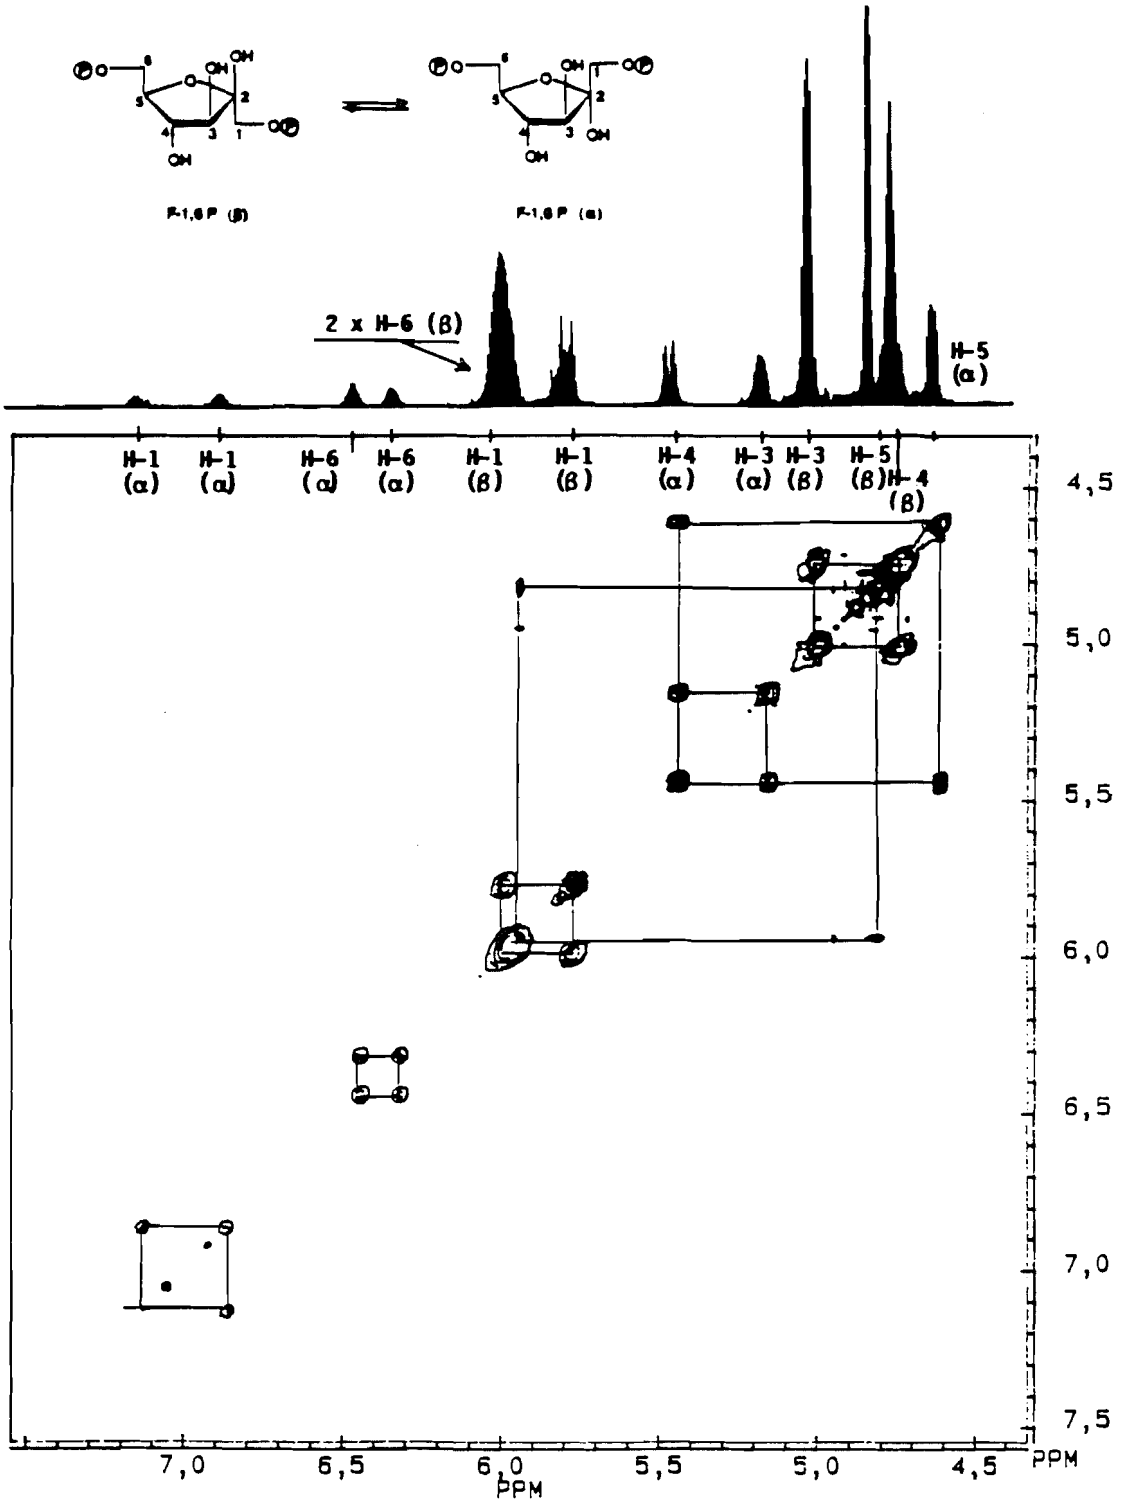

FIG. 7. Spectre COSY H–H du fructose-1,6 phosphate en présence de $PrCl_3 \cdot 6H_2O$ (ρ = 1,09, pH = pH = 1,2), C = 0,1 mol/L dans D_2O [SW = 1600 Hz, NE = 128, SI = 1K, NS = 400, D_1 = 2,0 s, D_4 = 2 × 10^{-3} s, P_1 = 14,5 μs, D_0 = 5 μs, P_2 = 7,3 μs). La transformation du signal est effectuée sur une matrice de 512K. La corrélation entre H-5 et H-6 n'est pas observée pour la forme α, ce qui n'est pas étonnant compte tenu de la faible intensité présentée par cette même corrélation pour la forme β largement majoritaire.

rapport au groupe COOH. On peut appliquer cette remarque à l'étude conformationnelle de l'acide 2-phosphoglycérique (2-PG). La figure 5 montre l'évolution des déplacements de chacun des trois protons de cette molécule. Le proton H-2 se déplace très rapidement à champ faible ($\Delta\delta_{H\text{-}2}$ = 4,3 ppm pour ρ = 0,79). Quant aux protons H-1*R* et H1-*S*, ils présentent une différence notable de comportement ($\Delta\Delta\delta_{H\text{-}1}$ = ($\Delta\delta_{H\text{-}1R}$ − $\Delta\delta_{H\text{-}1S}$) ≅ 0,5 ppm pour une valuer de ρ = 0,79). L'attribution de ces deux protons a été réalisée par la synthèse du 3 *S*-[3-^{2}H]-2-phosphoglycérate.[3] La méthode utilisée met en oeuvre la préparation du *Z*-[3-^{2}H]-PEP (14), suivie de l'action réversible de l'énolase (17). On peut écrire, pour cette molé-

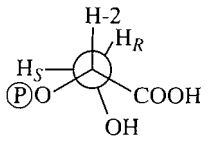
[b]Les protons de la forme α n'ont pas été assignés du fait de la faible abondance de cette structure.



cule, les trois conformères *gauches* autour de la liaison C2—C3 :

1 2 3

Peu de choses sont connues actuellement sur la conformation privilégiée de cette molécule en solution. L'analyse conformationnelle sur la base des constantes de couplage est en effet difficile à mener du fait de la décevante simplicité du spectre de RMN des protons H(*R*) et H(*S*) à pH acide (15). L'induction de grandes variations de déplacement en présence de chlorure de praséodyme permet une analyse au premier ordre du spectre des protons H-2, H(*R*) et H(*S*). H-2 présente ainsi deux couplages de valeurs respectives 2,5 et 5,0 Hz. Ces valeurs sont en accord

avec une structure *gauche* du type **2**, pour laquelle H(*S*) se trouve à proximité du phosphore avec un angle dièdre $\phi_{H\text{-}2,H(S)}$ proche de 90°. L'existence d'une telle conformation serait justifiée par l'établissement d'une liaison hydrogène entre les fonctions alcool et acide carboxylique, la fonction OPO_3H_2 étant déjà complexée au praséodyme :

Conclusion

Au cours de ce travail, nous avons montré que la fonction phosphate constituait un excellent agent de complexation pour le praséodyme. Les grandes variations de déplacement chimique observées en fonction de la concentration en sel de terre rare et du pH autorisent l'étude séparée de presque tous les protons des dérivés phosphatés des sucres (G-1P, G-6P, F-6P ou -F,6P). Il est même possible de séparer les formes α et β. Nous avons rassemblé, dans le tableau 2, les déplacements chimiques de chacune de ces substances dans les meilleures conditions expérimentales de séparation. Le G-1P existant uniquement sous forme α, est très certainement le composé qui se prêtera le mieux à des études mécanistiques par RMN du proton ou du deutérium. Les déplacements chimiques sont en effet bien individualisés pour des valeurs de ρ assez faibles (ρ ~ 0,25) et la résolution dans ces conditions est encore satisfaisante, ainsi que l'indiquent les deux spectres réalisés à pH = 2,3 et 2,6 représentés sur la figure 8. Une contribution concernant l'analyse conformationnelle de l'acide 2-phosphoglycérique a pu également être apportée.

Remerciements

Les auteurs remercient vivement Monsieur Michel Bonneau pour son assistance technique dans la réalisation des figures ainsi que la Société Eurofins (Nantes) pour la réalisation des spectres COSY à 500 MHz.

Inhibition of papain by peptide nitriles: conversion of the nitrile group into other functionalities via the papain:nitrile thioimidate ester adduct[1]

BARBARA J. GOUR-SALIN,[2] PAULE LACHANCE, AND ANDREW C. STORER
Biotechnology Research Institute, 6100 Royalmount Ave., Montreal, P.Q., Canada H4P 2R2

Received December 21, 1990

BARBARA J. GOUR-SALIN, PAULE LACHANCE, and ANDREW C. STORER. Can. J. Chem. **69**, 1288 (1991).

Peptide nitriles are reversible inhibitors of papain that form thioimidates with the cysteine thiol in the enzyme's active site. These thioimidates undergo reactions with thiols and amines to form acids and amidines, respectively. These reactions were also found to be stereospecific. Only a thioimidate derived from an L-amino acid nitrile will react with exogenous nucleophiles. These reactions were followed by ^{13}C and ^{15}N NMR techniques.

Key words: papain, nitrile, ^{13}C NMR, ^{15}N NMR, thioimidate.

BARBARA J. GOUR-SALIN, PAULE LACHANCE et ANDREW C. STORER. Can. J. Chem. **69**, 1288 (1991).

Les nitriles de peptides sont des inhibiteurs réversibles de la papaïne qui forment des thioimidates avec le thiol de la cystéine du site actif de l'enzyme. Ces thioimidates réagissent avec les thiols et les amines pour former respectivement des acides et des amidines. On a aussi observé que ces réactions sont stéréospécifiques. Seul un thioimidate obtenu à partir d'un nitrile d'un acide L-aminé pourra réagir avec des nucléophiles exogènes. On a observé ces réactions à l'aide de techniques RMN du ^{13}C et du ^{15}N.

Mots clés : papaïne, nitrile, RMN du ^{13}C, RMN du ^{15}N, thioimidate.

Enzymes are now widely recognized as practical catalysts for synthesis (1). Esterases and lipases are used for the cleavage of racemic esters to yield optically active acids and for the removal of acyl groups from racemic acylates to produce optically active alcohols. Alcohol dehydrogenases are increasingly used to catalyze the oxidation and reduction of hydroxyl and carbonyl compounds.

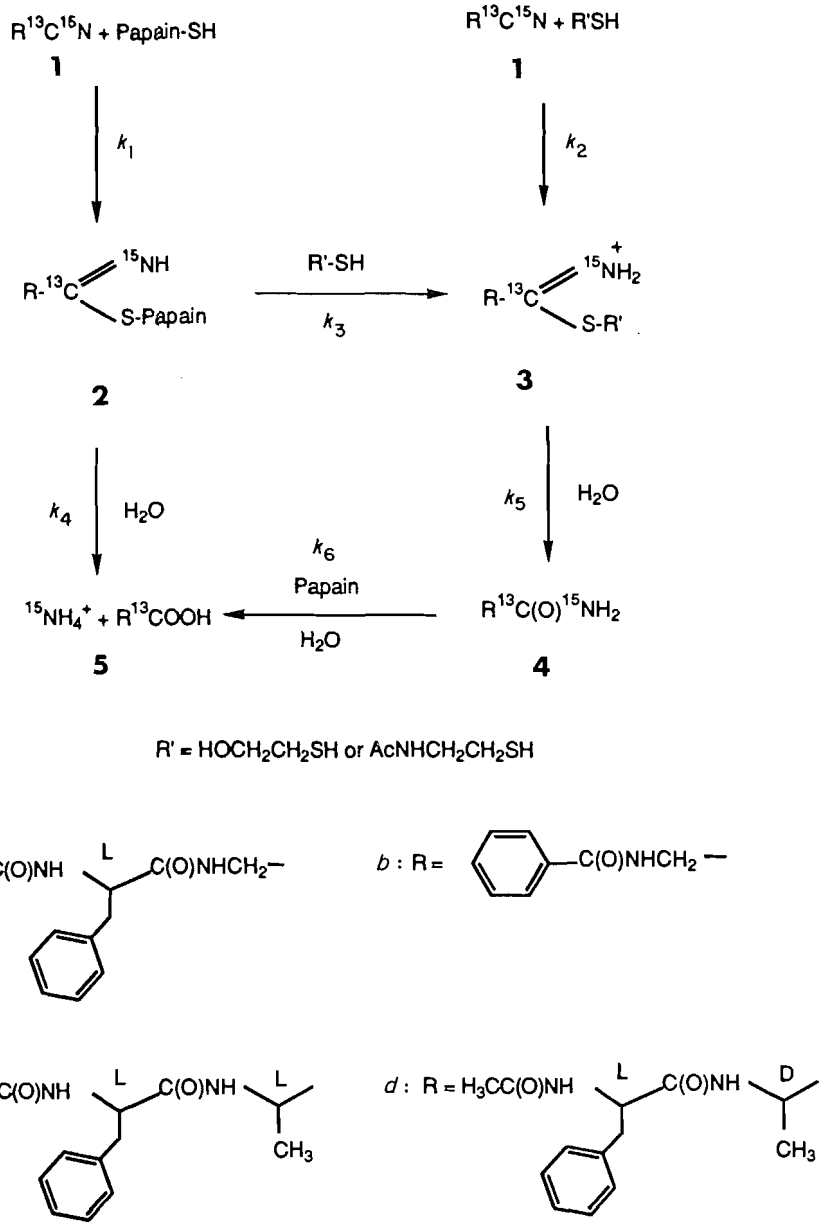
In 1937 Weiss (2) suggested that papain acts as a catalyst in the hydrolysis of peptide bonds by virtue of the sulfhydryl group, which can accept the acyl group of a substrate RCO-NHR′ to form an intermediate acyl-enzyme, which then can undergo hydrolysis or aminolysis. Although this hypothesis was long disregarded, the evidence for its validity is now substantial (3); the reactive sulfhydryl group of Cys-25 can readily donate its proton ot His-159 (4), thus making it a strong nucleophile in the thiolysis of amides.

More recently, papain has also been exploited in the field of preparative peptide synthesis where it is used for the formation rather than the cleavage of peptide bonds (5). This methodology has been used in the synthesis of such biologically important compounds as the enkephalins (5*a*) and dynorphin (5*e*). In these cases, the reaction mechanism is the microscopic reverse of that describing the pathway of proteolysis. This paper focuses on the exploration of the possibility of using papain for the catalysis of different reactions.

Peptide nitriles such as *N*-(*N*-acetyl-L-phenylalanyl)glycinenitrile (*N*-Ac-L-PheGlyCN) (**1***a*) and benzoylamidoacetonitrile (hippurylnitrile) (**1***b*) are strong competitive inhibitors of papain (6). The nitrile functionality forms a covalent adduct with the thiol group of cysteine 25 in the active site of papain yielding a thiomidate ester (**2**) linkage (Scheme 1) (7). Thioimidates are the precursors of a large number of heterocyclic compounds. For example, thioimidates readily undergo nucleophilic attack by a wide range of amino compounds. The most usual pathway involves loss of the thiol with formation of an amidine system (8) but the alternative, loss of ammonia and its replacement with the nucleophile, can also take place (9). Subsequent reaction of the amidine with β-keto-esters, β-diketones, or malonic acid derivatives results in the production of pyrimidines. Bifunctional amines such as the *o*-phenylenediamines condense with thioimidates to yield benzimidazoles (9) whereas condensation with *o*-aminophenols yields benzoxazoles (9) and with hydrazines gives 1,2,4-triazoles (9). Unlike non-enzyme bound thioimidates, which hydrolyze very quickly at neutral pH's (10), the papain:nitrile thioimidate complex is very slow to hydrolyze at pH 6.0 (11). The hydrolysis of the non-enzyme bound thioimidate proceeds via addition of H_2O to the protonated thioimidate, presumably to form a tetrahedral intermediate that then collapses to either the amide and thiol, or thiol acid and free amine. In this case the pK_a of the enzyme-bound thioimidate must be much lower than the unbound one and at pH 6.0 most of the thioimidate adduct is in its non-protonated state, a fact accounting for its slow hydrolysis. Because of this it seemed feasible that the enzyme-bound thioimidate might be able to undergo reactions with nucleophiles. This was shown to be the case in a preliminary communication (11) in which the thioimidate **2***a* formed from the reaction of papain and *N*-(*N*-acetyl-L-phenylalanyl)glycinenitrile (**1***a*) does indeed react with external thiols. We now report further examples of the addition of external nucleophiles to a variety of nitrile:papain thiomidate adducts.

Experimental

Papain was prepared by the method of Storer and Carey (12). Enzyme prepared in this manner was found to contain >0.8 mol of active cysteine per mol of protein.



All compounds were checked for purity either by HPLC or TLC and all new compounds were then subjected to high resolution Exact Mass analysis to confirm their identities.

NMR measurements

^{13}C and ^{15}N NMR samples were prepared in 10-mm NMR tubes in 25 mM phosphate buffer (0.5 mM EDTA), pH 6.0 containing 10% D_2O and 10% acetone. The pH of all samples was checked before and after data acquisition and did not change appreciably. All spectra were recorded at 298 K by using a Bruker AM 500 spectrometer operating at 125 MHz. The carbon-13 spectra were collected with 32K data points over a range of 30 kHz using a 30° pulse width of 8 μs and a relaxation delay of 1 s. The internal reference was the methyl carbon resonance of acetone assigned to 30.7 ppm, as had previously been determined from a blank sample containing TSP (sodium 3-trimethylsilylpropionate-

[1]NRCC No. 32423.

SCHEME 1

2,2,3,3-d_4) and acetone. The ^{15}N NMR spectra were collected at 298 K at 50 MHz. For these spectra, a neat sample of nitromethane was used as an external reference. The spectra were acquired using 32K data points over a range of 20 kHz with a 30° pulse width of 8 μs and no relaxation delay. The ^1H NMR spectra were collected at 298 K at 500 MHz. Tetramethylsilane was used as an internal reference.

Kinetic measurements

Papain was assayed with the substrate carbobenzoxy-L-phenylalanyl-L-arginine-4-methyl-coumarinyl-7-amide (Cbz-L-Phe-Arg-MCA). Hydrolysis of the substrate was monitored on a Perkin–Elmer LS-5B fluorimeter by excitation at 380 nm and measuring fluorescence emission at 440 nm upon release of the 7-amino-4-methylcoumarin (MCA) product. Assay solutions contained 2 nM papain, 12.5 mM phosphate, 0.2 mM EDTA, and 15% acetone. All kinetic experiments were carried out at pH 6.20 and 25.0°C. Inhibitor and substrate concentrations were kept in excess of the enzyme and the inhibitor concentration covered a range of at least $0.3–10\,K_i$ to optimize the precision of the K_i determination. The inhibition constant K_i was obtained from initial rate measurements by plotting the reciprocal of initial rate versus inhibitor concentration (Dixon plot) for various substrate concentrations. At least eight inhibitor concentrations were used for each substrate concentration. With the *N*-Ac-L-Phe-D-AlaCN derivative, the kinetic analysis showed evidence that a slow binding step occurs after formation of the initial enzyme-inhibitor complex.

Molecular modelling

A search of conformational space was carried out to locate low-energy structures for the *N*-Ac-L-Phe-D,L-Ala thioimidate intermediates. These calculations, which were done using SYBYL 5.32 (Tripos Assoc. Inc.) on a Silicon Graphics 4D/280 computer, indicate that the favored (ϕ,φ) angles for *N*-Ac-L-Phe-L-Ala thioimidate are in the (−90, 150) region of ϕ–φ space. This corresponds to the so-called "A-conformer" (13). For *N*-Ac-L-Phe-D-Ala thioimidate, the favored (ϕ,φ) angles are reversed, (150, −90). In these calculated structures the alanine methyl group hinders attack on the thioimidate carbon in the D-Ala but not in the L-Ala isomer.

Mass spectrometric measurements

All FAB and EI (70 eV) mass spectrometric measurements were conducted using a VG Analytical ZAB-EQ tandem hybrid mass spectrometer equipped with a VG 11-250J data system. Chemical

ionization (Cl) analyses using isobutane reagent gas were performed on a Finnigan 4500 quadrupole mass spectrometer equipped with an INCOS data system. Sample sizes in the range of 100–300 nmol were dissolved in 1–2 μL of glycerol or 2-hydroxyethyl sulfide (Sigma Chemicals) and deposited on a gold probe tip prior to their FAB analyses. An 8-keV Xe^0 beam (Ion Tech FAB gun 1 mA discharge current) was used. Conventional FAB mass spectra were obtained at a resolving power (10% valley definition) of 1000, scanning the range m/z 50–1000 Da with a cycle time of approximately 10 s. Mass assignments were reliable to within 0.1 Da. In Cl analyses approximately 0.1 mg of material was deposited in a glass capillary prior to its thermal desorption. The probe was heated for 25–300°C at a rate of 20°C/min and the quadrupole mass analysor was scanned from 50–700 with a cycle time of 3 s.

Accurate mass measurements of ions formed in FAB ionization were performed by peak matching using a matrix cluster (m/z: 185, 277, 369, 461) as reference ion. The resolving power was typically 8000 in all mass measurements.

N-*(N-Acetyl-L-phenylalanyl)-[1-^{13}C]glycinenitrile (^{13}C-**1**a)*

This compound was prepared by the procedure outlined by Liang and Abeles (7*a*). Doubly labelled K^{13}C^{15}N was used to obtain ^{13}C^{15}N-**1***a*: mp 188–189°C (lit. (7*a*) mp 189°C). ^{1}H NMR (acetone-d_6, **1***a*), δ: 1.85 (s, 3H, $CH_3C(O)$), 2.91 (d of d, J = 8.65, 13.9 Hz, 1H, ArCH), 3.16 (d of d, J = 5.61, 13.9 Hz, 1H, ArCH), 4.18 (d, 2H, J = 7 Hz, CH_2CN), 4.64 (d of d, J = 5.61, 8.65 Hz, 1H, α-CH), 7.2–7.27 (m, 5H, ArH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, ^{13}C-**1***a*, partial), δ: 117.1 (^{13}CN), 127.6, 129.2, 129.6, 136.5 (ArC), 174.1 (C(O)NH), 174.3 (C(O)NH). ^{15}N NMR (80% H_2O, 10% D_2O, 10% acetone, ^{13}C^{15}N-**1***a*), δ: −142.3 (d, J = 17.6 Hz, ^{13}C^{15}N), −257.8 (d, J = 20.4 Hz, C(O)NH), −278 (d, J = 33.1 Hz, C(O)NH). MS (El), calcd.: 245.1164; found: 245.1163.

N-*(N-Acetyl-L-phenylalanyl)-[1-^{13}C]glycinamide (^{13}C-**4**a)*

The amide was prepared by the method of Thompson, Andrews, and Hanzlik (14). The ^{13}C label was introduced by using ^{13}C-labelled glycine in the synthesis of methyl glycinate: mp 184°C (lit. (14) mp 184°C). ^{1}H NMR ($CDCl_3$, *N*-(*N*-acetyl-L-phenylalanyl)glycine-[1-^{13}C]methyl ester), δ: 1.98 (s, 3H, $CH_3C(O)$), 3.08 (m, 2H, CH_2), 3.7 (d, J = 3.9 Hz, 3H, $^{13}C(O)OCH_3$), 3.9 (m, 1H, CHAr), 4.0 (m, 1H, CHAr), 4.7 (m, 1H, α-CH), 7.2–7.3 (m, 5H, ArH). ^{1}H NMR (CD_3OD, *N*-(*N*-acetyl-L-phenylalalanyl)-[1-^{13}C]glycinamide), δ: 1.95 (s, 3H, CH_3), 2.92 (d of d, J = 8.67, 13.7 Hz, 1H, CHAr), 3.12 (d of d, J = 6.47, 13.7 Hz, 1H, CHAr), 3.65 (d of d, J = 5.2, 17.1 Hz, 1H, $CH^{13}C(O)$), 3.84 (d of d, J = 5.2, 17.1 Hz, 1H, $CH^{13}C(O)$), 4.49 (d of d, J = 6.5, 8.6 Hz, 1H, α-CH), 7.12–7.22 (m, 5H, ArH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, *N*-(*N*-acetyl-L-phenylalanyl)-[1^{13}C]glycinamide, partial), δ: 174.7 ($C(O)NH_2$) ppm. ^{15}N NMR (80% H_2O, 10% acetone, *N*-(*N*-acetyl-L-phenylalanyl)-[1-^{13}C]glycinamide), δ: −257.1 (d, J = 18.0 Hz, C(O)NH), −271 (d, J = 30.2 Hz, C(O)NH), −277 (d, J = 16.7 Hz, $C(O)NH_2$) ppm.

N-*(N-Acetyl-L-phenylalanyl)-[1-^{13}C]glycine (^{13}C-**5**a)*

The ^{13}C labelled *N*-(*N*-acetyl-L-phenylalanyl)glycine methyl ester was hydrolyzed by the method of Knowles *et al.* (15) to give the ^{13}C-carboxylic acid, but in very low yields. Consequently, the methyl ester was cleaved enzymatically using the methodology of Sabbioni and Jones (16). *N*-(*N*-Acetyl-L-phenylalanyl)glycine methyl ester (1.0 g, 3.59 mmol) was dissolved in an aqueous solution of KH_2PO_4 (20 mL) adjusted to pH 7.0 using 1 M NaOH at room temperature. Pig liver esterase (800 units) was added and the pH was maintained at 7.0 by pH-stat controlled addition of 1 M aqueous NaOH. The hydrolysis was continued until 1 equivalent of base had been taken up. The reaction mixture was washed with Et_2O (6 × 50 mL) and the emulsion that formed was broken by vacuum filtration. The aqueous phase was acidified to pH 2 using 2 M HCl and extracted with ethyl acetate (3 × 50 mL). The organic layer was dried and the solvent removed *in vacuo* to yield 480 mg (1.82 mmol, 51% yield) of the acid: mp 158.5–159°C (lit. (15) mp 164.5–165.5°C). ^{1}H NMR (DMSO-d_6), δ: 1.8 (s, 3H, $CH_3C(O)$), 2.71 (d of d, J = 10.6, 13.8 Hz, 1H, ArCH), 3.0 (d of d, J = 4.4, 10.6 Hz, 1H, ArCH), 3.76 (d, J = 5.7 Hz, 2H, CH_2), 4.53 (m, 1H, α-CH), 7.1–7.3 (m, 5H, ArH), 8.1 (d, J = 8.6 Hz, 1H, NH), 8.3 (t, J = 6.0 Hz, 1H, NH), 12.6 (br s, 1H, COOH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: 176.2 (COOH).

N-*(N-Acetyl-L-phenylalanyl)-[1-^{13}C^{15}N]glycine anilide (^{13}C^{15}N-**6**a)*

The synthesis of this compound was based on the method Lowe and Yuthavong (17) used for the preparation of *N*-(*N*-acetyl-L-phenylalanyl)glycine *p*-nitroanilide. To a suspension of *N*-(*N*-acetyl-L-phenylalanyl)-[1-^{13}C]glycine (**5***a*) (21.9 mg, 8.29 × 10^{-2} mmol) in CH_2Cl_2 (10 mL) was added triethylamine (0.006 mL, 8.29 × 10^{-5} mol). A clear solution formed, which was cooled to −10°C under N_2. A solution of ethyl chloroformate (0.008 mL, 8.29 × 10^{-2} mmol) in methylene chloride was added dropwise. After 15 min a solution of ^{15}N-aniline (0.007 mL, 8.29 × 10^{-2} mmol) in CH_2Cl_2 (2 mL) was added to the stirred solution. Stirring was continued for 1 h after which the white precipitate was filtered off, washed with saturated $NaHCO_3$, and recrystallized from EtOAc/hexane to give 9.7 mg (2.86 × 10^{-2} mmol, 34.5% yield) of the desired amide (**6***a*). ^{1}H NMR (acetone-d_6), δ: 1.93 (s, 3H, CH_3), 2.99 (d of d, J = 8.8, 13.6 Hz, 1H, CHAr), 3.19 (d of d, J = 5.8, 13.6 Hz, 1H, CHAr), 3.79 (d of t, J = 5.35, 16.9 Hz, 1H, $CH^{13}C(O)^{15}N$),4.02 (d of t, J = 5.8, 16.9 Hz, 1H, $CH^{13}C(O)^{15}N$), 4.53 (m, 1H, α-CH), 7.0–8.0 (m, ArH, NH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: 169.18 (d, J = 15.8 Hz, $^{13}C(O)^{15}NH$). ^{15}N NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: −253.3 (d, J = 15.8 Hz, ^{15}NHAr).

*[1-^{13}C^{15}N]Benzoylamidoacetonitrile (^{13}C^{15}N-**1**b)*

Benzoylamidoacetonitrile ($BzNHCH_2CN$) (**1***b*) was prepared by the method of Storer and co-workers (7*b*). Doubly labelled K^{13}C^{15}N was used to obtain ^{13}C^{15}N-**1***b* and K^{13}CN was used to obtain ^{13}C-**1***b*, mp 133–136°C (lit. (18) mp 144°C). ^{1}H NMR (DMSO-d_6, **1***b*), δ: 4.45 (d, J = 5.6 Hz, 2H, CH_2), 7.6–8.1 (m, 5H, ArH), 9.34 (br s, 1H, NH). ^{13}C NMR (DMSO-d_6, ^{13}CN-**1***b*), δ: 172.5 (C(O)NH), 137.8, 134.4, 133.2 (ArC), 123.5 (d, ^{13}C^{15}N), 33.6 (CH_2). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, ^{13}C^{15}N-**1***b*), δ: 170.8 (C(O)NH), 117.6 (d, J = 17.9 Hz, ^{13}C^{15}N). ^{15}N NMR (80% H_2O, 10% D_2O, 10% acetone, ^{13}C^{15}N-**1***b*), δ: −142.5 (d, J = 17.9 Hz, ^{13}C^{15}N). MS (El), calcd.: 160.0636; found:160.0641.

*[1-^{13}C]Benzoylamidoacetamide (^{13}C-**4**b)*

This compound was synthesized using the method of Thompson *et al.* (14). The sodium salt of hippuric acid (2 g, 10.0 mmol) was dissolved in MeOH (25 mL) and cooled to 0°C. Hydrogen chloride was bubbled through the stirred solution for 1 h. The reaction mixture was stirred overnight and the NaCl filtered off. The methanol was removed *in vacuo* to yield a yellow oil, which was recrystallized from ethyl acetate/hexane to give methyl hippurate (1.9 g, 9.8 mmol, 98% yield). ^{1}H NMR (D_2O, TSP), δ: 3.7 (s, 3H, OCH_3), 4.1 (s, 2H, CH_2), 7.45–7.77 (m, 5H, ArH). This was redissolved in methanol, cooled to 0°C, and NH_3 was bubbled through the solution for 8 h. The methanol was removed and the product recrystallized from MeOH to give 1.4 g (7.7 mmol, 78% yield, mp 167–170°C (dec.)) of [1-^{13}C]benzoylamidoacetamide (^{13}C-**4***b*). ^{1}H NMR (DMSO-d_6), δ: 3.8 (d, J = 5.85 Hz, 2H, CH_2), 7.47–7.9 (m, 5H, ArH), 8.7 (br s, 1H, NH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, partial NMR), δ: 170.5 (ArC(O)NH), 174.5 ($C(O)NH_2$). ^{15}N NMR (80% H_2O, 10% D_2O, 10% acetone), δ: −276.4 ($C(O)NH_2$). MS (El), calcd.: 178.0743; found: 178.0748.

N-*(N-Acetyl-L-phenylalanyl)-D,L-[^{13}C^{15}N]alaninenitrile (^{13}C^{15}N-**1**c,d)*

α-Aminopropionitrile was prepared by modifying the procedure for the synthesis of alanine (19). A solution of acetaldehyde (112 μL, 2.2 mmol) in diethyl ether (70 μL) was cooled to 0°C and NH_4Cl (117 mg, 2.2 mmol) in water (390 μL) was added. Potassium cyanide (K^{13}C^{15}N) (130 mg, 2.2 mmol) in water (300 μL) was added slowly and after stirring for 30 min the reaction was allowed to warm to room temperature and stirred for an additional 4 h to yield a solution of α-aminopropionitrile.

To a solution of *N*-acetyl-L-phenylalanine (310 mg, 1.5 mmol) in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

methylene chloride (5 mL) at −15°C was added *N*-methylmorpholine (164 μL, 1.5 mmol) and a solution of isobutylchloroformate (193 μL, 1.5 mmol) in CH_2Cl_2 (20). The solution was stirred for 15 min. At this time *N*-methylmorpholine (217 μL, 2.2 mmol) was added to the α-aminopropionitrile solution and the whole was slowly added to the solution containing the mixed anhydride of *N*-acetyl-L-phenylalanine. The reaction mixture was stirred at −15°C for 1.5 h and overnight at room temperature. Water (15 mL) was added and the aqueous layer was extracted with CH_2Cl_2 (2 × 15 mL), washed with saturated $NaHCO_3$, 2 N HCl, and saturated NaCl. The organic layer was dried and the solvent removed *in vacuo* to give the desired nitrile, which was recrystallized from ethyl acetate (30% yield). ^{1}H NMR (DMSO-d_6, both diastereomers), δ: 1.29 (d, J = 7.2 Hz, CH_3), 1.4 (d, J = 6.7 Hz, CH_3), 1.75 (s, $CH_3C(O)$), 1.78 (s, $CH_3C(O)$), 2.7–2.8 (m, CHAr), 2.89–2.97 (m, CHAr), 4.45 (m, α-CH), 4.72 (m, α-CH), 7.15–7.32 (m, ArH), 8.2 (m, NH), 8.75 (m, NH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, partial, both diastereomers), δ: 174.3, 174.3 (C(O)NH), 173.4, 173.3 (C(O)NH), 119.8 (d, J = 11.4, $^{13}C^{15}N$), 119.9 (d, J = 115 Hz, $^{13}C^{15}N$). ^{15}N NMR (80% H_2O, 10% D_2O, 10% acetone, partial, both diastereomers), δ: −144.5 (d, J = 11.4 Hz, $^{13}C^{15}N$), −144.7 (d. J = 11.5 Hz, $^{13}C^{15}N$). MS (El), calcd.: 259.1322; found; 259.1325.

N-(N-*Acetyl-L-phenylalanyl)-L-[1-^{13}C]alanine methyl ester (^{13}C-**8**)*

N-Acetyl-L-phenylalanine (5 g, 24.1 mmol) and the hydrochloride salt of L-alanine methyl ester (21) (3.37 g, 24.1 mmol) were suspended in methylene chloride (75 mL) and cooled to 0°C. Triethylamine (3.36 mL, 24.1 mmol) was added dropwise and the mixture stirred 20 min at which time HOBt (3.26 g, 24.1 mmol) was added. After a further 20 min stirring, DCC (4.98 g, 24.1 mmol) was added and the solution stirred at 0°C overnight. The solvent was removed *in vacuo* and the residue suspended in EtOAc. The DCU was removed by filtration and the organic layer washed with 5% citric acid, saturated $NaHCO_3$ solution, and brine. The organic layer was dried, the solvent removed, and the residue recrystallized from ethyl acetate to give 7.05 g (90% yield) of the desired product: mp 188–189°C. IR (KBr disk): 3280, 1750, 1635, 1540, 1380 cm^{-1}. ^{1}H NMR (DMSO-d_6), δ: 1.3 (d of d, J = 4.6, 7.2 Hz, 3H, CH_3), 1.73 (s, 3H, CH_3), 2.7 (d of d, J = 10.1, 13.8 Hz, 1H, CHAr), 3.0 (d of d, J = 4.3, 13.8 Hz, 1H, CHAr), 3.6 (s, 3H, OCH_3), 4.3 (m, 1H, α-CH), 4.55 (m, 1H, α-CH), 7.2–7.3 (m, 5H, ArH), 8.05 (d, J = 8.5 Hz, 1H, NH), 8.47 (d, J = 7.0 Hz, 1H, NH). MS (El), calcd.: 292.1423; found: 292.1416.

N-(N-*Acetyl-L-phenylalanyl)-L-[1-^{13}C]alaninamide (^{13}C-**4**c)*

The amide was prepared using the methodology of Thompson, Andrews, and Hanzlik (14). *N*-(*N*-Acetyl-L-phenylalanyl)-L-[1-^{13}C]-alanine methyl ester (**8**) (1.33 g, 4.81 mmol) was dissolved in methanol and cooled to 0°C in an ice bath. NH_3 was bubbled through the solution for 3 h. The solution was allowed to warm to room temperature and stirred for an additional 8 h. The solvent was removed *in vacuo* and the white precipitate was recrystallized from MeOH/ EtOAc/Et_2O to give 0.76 g (2.89 mmol, 60% yield) of the desired amide (mp > 230°C). IR (KBr disk): 3300, 1620, 1545 cm^{-1}. ^{1}H NMR (DMSO-d_6), δ: 1.2 (d of d, J = 4.1, 7.1 Hz, 3H, CH_3), 1.75 (s, 3H, CH_3), 2.72 (d of d, J = 9.9, 13.8 Hz, 1H, CHAr), 3.05 (d of d, J = 4.5, 13.8 Hz, 1H, CHAr), 4.2 (m, 1H, α-CH), 4.5 (m, 1H, α-C), 6.9 (s, 1H, NH), 7.13 (s, 1H, NH), 7.2–7.3 (m, 5H, ArH), 8.02 (d, J = 7.5 Hz, 1H, NH), 8.08 (d, J = 8.3 Hz, 1H, NH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: 177.6 ($C(O)NH_2$), 174.4 (C(O)NH), 173.4 (C(O)NH), 136.7, 129.6, 129.2, 127.7 (ArC). ^{15}N NMR (80% H_2O, 10% D_2O, 10% acetone), δ: −256.4 (C(O)(NH), −257.8 (C(O)NH), −277.8 ($C(O)NH_2$). MS(El), calcd.: 277.1426; found: 277.1433.

N-(N-*Acetyl-L-phenylalanyl)-L-[1-^{13}C]alaninenitrile (^{13}C-**1**c)*

The amide was dehydrated to the nitrile using the method of Stephens *et al.* (22). The amide (0.75 g, 2.71 mmol) was dissolved in 5 mL of pyridine and cooled to 0°C. A solution of *p*-toluenesulfonyl-chloride (0.71 g, 3.72 mmol) in anhydrous pyridine (5 mL) was added drop by drop over a period of 30 min. The solution was allowed to warm to room temperature and stirred overnight. Water (5 mL) was added and the solution stirred for an additional 1 h. The solvent was removed *in vacuo* and the residue dissolved in EtOAc, washed with saturated Na_2CO_3 solution, decolourized with carbon, filtered, and the solvent removed *in vacuo*. The solid was recrystallized from EtOAc to yield 21.0 mg (30% yield) of the desired product: mp 207–210°C. IR (KBr disk): 3220, 3030, 1630, 1540 cm^{-1}. ^{1}H NMR ($CDCl_3$), δ: 1.4 (d of d, J = 5.8, 7.3 Hz, 3H, CH_3), 2.0 (s, 3H, CH_3), 3.0 (d of d, J = 8.2, 13.8 Hz, 1H, CHAr), 3.1 (d of d, J = 6.5, 13.8 Hz, 1H, CHAr), 4.6 (m, 1H, α-CH), 4.7 (m, 1H, α-CH), 6.1 (br s, 1H, NH), 6.2 (br s, 1H, NH), 7.2–7.4 (m, 5H, ArH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: 174.3 (C(O)NH), 173.3 (C(O)NH), 136.4, 129.7, 129.2, 127.6 (ArC), 119.8 (^{13}CN). ^{15}N NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: −144.5 (d, J = 11.4 Hz, $^{13}C^{15}N$). MS (El),calcd.: 259.1321; found: 259.1327.

N-(N-*Acetyl-L-phenylalanyl)-D-[1-^{13}C]alaninenitrile (^{13}C-**1**d)*

This diastereomer was synthesized in the same manner as *N*-(*N*-acetyl-L-phenylalanyl)-L-[1-^{13}C]alaninenitrile except that in this case D-alanine-1-^{13}C was used as starting material; mp 194–195°C. ^{1}H NMR (DMSO-d_6, *N*-(*N*-acetyl-L-phenylalanyl)D-[1-^{13}C]alanine methyl ester), δ: 1.2 (d of d, J = 4.85, 7.1 Hz, 3H, CH_3), 1.76 (s, 3H, CH_3), 2.7 (d of d, J = 9.4, 13.6 Hz, 1H, CHAr), 2.9 (d of d, J = 5.25, 13.6 Hz, 1H, CHAr), 3.65 (s, 3H, OCH_3), 4.25 (m, 1H, α-CH), 4.55 (m, 1H, α-CH), 7.2–7.3 (m, 5H, ArH), 8.05 (d, J = 8.4 Hz, 1H, NH), 8.4 (d, J = 7.3 Hz, 1H, NH). ^{1}H NMR (DMSO-d_6, *N*-(*N*-acetyl-L-phenylalanyl)-D-[1-^{13}C]alaninamide) (^{13}C-**4***d*), δ: 1.1 (d of d, J =4.1, 7.1 Hz, 3H, CH_3), 1.77 (s, 3H, CH_3), 2.78 (d of d, J = 9.0, 13.6 Hz, 1H, CHAr), 2.92 (d of d, J = 6.0, 13.6 Hz, 1H, CHAr), 4.12 (m, 1H, α-CH), 4.42 (m, 1H, α-CH), 7.0 (br s, NH), 7.2–7.3 (m, 5H, ArH), 8.1 (d, J = 7.9 Hz, 1H, NH), 8.15 (d, J = 7.4 Hz, 1H, NH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: 178.1 ((CO)NH), 136.5, 129.6, 127.7 (ArC). ^{15}N NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: −277.6 ($C(O)NH_2$). ^{1}H NMR (DMSO-d_6, *N*-(*N*-acetyl-L-phenylalanyl)-D-[1-^{13}C]alaninenitrile) (^{13}C-**1***d*), δ: 1.28 (t, J = 6.0 Hz, 3H, CH_3), 2.0 (s, 3H, CH_3), 2.77 (d of d, J = 9.1, 13.6 Hz, 1H, CHAr), 2.9 (d of d, J = 5.7, 13.6 Hz, 1H, CHAr), 4.45 (m, 1H, α-CH), 4.70 (m, 1H, α-CH, 7.1–7.4 (m, 5H, AH), 8.2 (d, J = 8.2 Hz, 1H, NH), 8.77 (d, J = 7.3 Hz, 1H, NH). ^{13}C NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: 174.3 ((CO)NH), 173.3 ((CO)NH), 136.3, 129.6, 127.6 (ArC), 119.9 (CN). ^{15}N NMR (80% H_2O, 10% D_2O, 10% acetone, partial), δ: −144.8 (d, J = 11.5 Hz, CN). MS (El), calcd.: 259.1322; found: 259.1238.

Results and discussion

As reported (11), *N*-(*N*-acetyl-L-phenylalanyl)glycinenitrile (*N*-Ac-L-PheGlyCN) **1***a* reacts with mercaptans in the absence of enzyme to form *N*-(*N*-acetyl-L-phenylalanyl)glycinamide (*N*-Ac-L-PheGlyNH_2) **4***a*, probably via the thioimidate **3***a* (Scheme 1). In the presence of papain, in a parallel reaction, the formation of this amide is catalyzed. This additional parallel conversion to amide **4***a* probably results from the attack of the thiol on the enzyme-bound thioimidate **2***a* to yield a free non-enzymic thioimidate **3***a* that, relative to the enzyme-bound thioimidate adduct **2***a*, is known to hydrolyze rapidly to give **4***a* (10). The amide **4***a* is subsequently hydrolyzed via papain's well-characterized amidase activity to the carboxylic acid (23) (*N*-Ac-L-PheGlyCOOH) **5***a*. (Scheme 1). Here we wish to report the interaction of a variety of enzyme-bound thioimidates **2** with different nucleophiles.

First, the reaction of aniline with the thioimidate formed from papain and *N*-(*N*-acetyl-L-phenylalanine)glycinenitrile will be discussed. Control experiments were conducted. It has been already established (11) that, in the absence of any added nucleophile, the reaction of $^{13}C^{15}N$-**1***a* with papain slowly leads to the corresponding carboxylic acid ^{13}C-**5***a* and ammonium ion. A second control experiment involved reacting *N*-Ac-L-PheGlyCN with an excess of aniline. No enzyme was present.

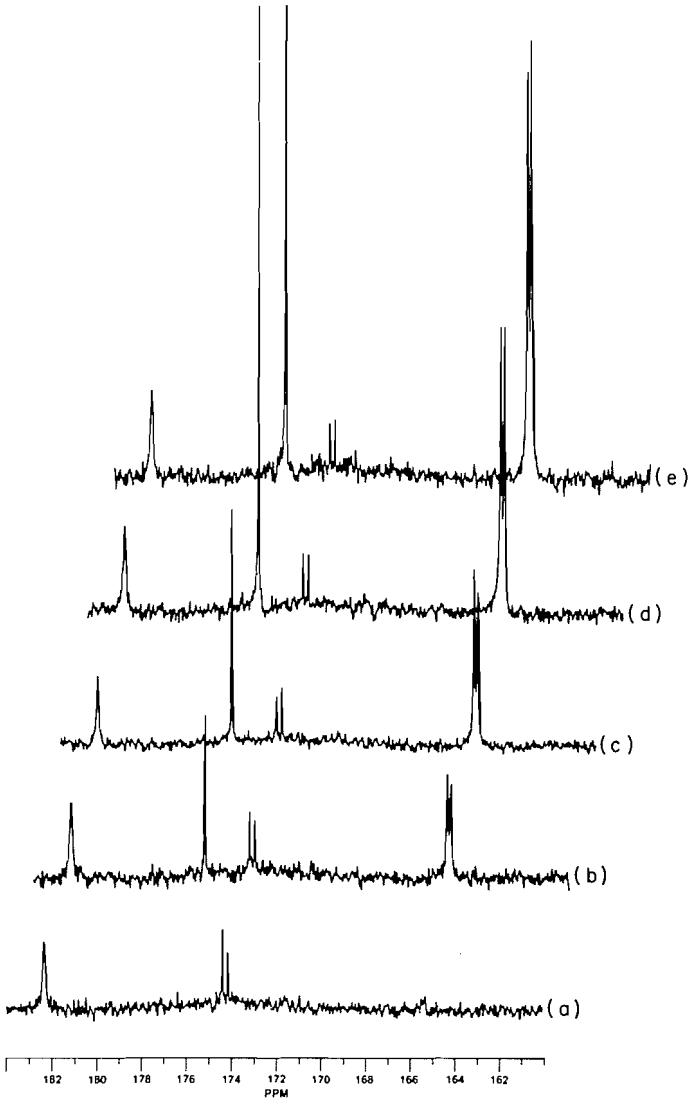

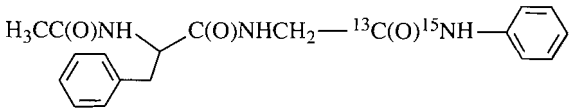

FIG. 1. Partial ^{13}C NMR spectra of 10 mM *N*-Ac-L-PheGly-$^{13}C^{15}N$ ($^{13}C^{15}N$-**1***a*) + 0.18 mM papain + 30 mM aniline (a) after 1 day; (b) after 8 days; (c) after 15 days; (d) after 22 days; (e) after 42 days.

After a period of 22 days there had been no reaction between aniline and *N*-Ac-L-PheGlyCN. Additionally, after a period of 26 days there was no reaction between aniline and the enzyme alone.

In Fig. 1 the partial ^{13}C NMR spectra of the reaction $^{13}C^{15}N$-**1***a* and papain in the presence of aniline are shown as a function of time. Spectrum (a) was taken one day after mixing and indicates only the presence of starting materials as indicated by the two resonances at 174.0 and 174.2 ppm, which represent the two carbonyl carbons of the amide functionalities in the starting material. The resonance at 182.4 ppm corresponds to the papain thioimidate adduct $^{13}C^{15}N$-**2***a*. After 7 days (spectrum (b)) the resonance at 176.8 ppm indicates that the acid ^{13}C-**5***a* is present. Ammonium ion can also be detected simultaneously in the ^{15}N NMR spectrum. A doublet at 165.4 ppm ($J_{^{13}C^{15}N}$ = 20.0 Hz) also appears. Concomitantly, a doublet centred at −277.9 ($J_{^{13}C^{15}N}$ = 20.0 Hz) appears in the ^{15}N NMR spectrum (Table 1). These peaks are not observed in the control experiments and result from the interaction of aniline with the papain:nitrile thioimidate adduct. When ^{13}C-**1***a* is used instead of $^{13}C^{15}N$-**1***a*, the resonance at 165.4 appears as a singlet. If ^{13}C-**1***a* is used in conjunction with aniline-^{15}N, the adduct appears as a doublet centred at 165.4 ($J_{^{13}C^{15}N}$ = 20.0 Hz) in the ^{13}C NMR spectrum and a new doublet at −255.8 ppm ($J_{^{13}C^{15}N}$ = 20.0 Hz) appears in the ^{15}N NMR spectrum. If $^{13}C^{15}N$-**1***a* is used in conjunction with aniline-^{15}N, the adduct appears as a triplet centred at 165.4 ($J_{^{13}C^{15}N}$ = 20.0 Hz). In the ^{15}N NMR spectrum, a doublet at −255.8 ($J_{^{13}C^{15}N}$ = 20.0 Hz) and a multiplet centred at −277.9 appear (Table 1).

The coupling indicates that neither of the amides, *N*-(*N*-acetyl-L-phenylalanyl)glycinamide **4***a* nor *N*-(*N*-acetyl-L-phenylalanyl)glycine anilide **6***a* can be the product in this case.

6*a*

This information was confirmed by synthesizing both amides (14, 17). The ^{13}C NMR spectrum for [1-^{13}C]*N*-Ac-L-PheGlyNH$_2$ indicates that the amide carbonyl of the terminal amide functionality absorbs at 174.7 ppm. The three amide resonances of this compound appear at −257.4, −271.2, and −276.7 ppm in the ^{15}N NMR spectrum. For [1-$^{13}C^{15}N$]*N*-(*N*-acetyl-L-phenylalanyl)glycine anilide $^{13}C^{15}N$-**6***a* the terminal carbonyl resonance appears as a doublet at 169.2 ppm ($J_{^{13}C^{15}N}$ = 15.8 Hz) and the anilide resonance in the ^{15}N NMR spectrum appears at −253.3 ppm ($J_{^{13}C^{15}N}$ = 15.5 Hz) (Table 1).

This would indicate that the product is an amidine. The amidine group is the nitrogen analog of carboxylic acids. It combines the properties of an azomethine-like C=N double bond (24) with an amide-like C—N single bond (25). The two nitrogens in an amidine group are nonequivalent. However, monosubstituted amidines may exhibit tautomerism. For example ^{15}N NMR data are reported for *N*-phenylbenzamidine and *N*-methylbenzamidine (25) in DMSO. For *N*-phenylbenzamidine there is a preference for the amino form over the imino form, δ ^{15}N (−151, −275 ppm). However, for *N*-methylbenzamidine there appears to be no clear preference for one form over the other, δ ^{15}N (−234, −238 ppm).

If the amidine is protonated to give the amidinium cation there is complete charge delocalization and the two nitrogens become equivalent. This is reflected in the ^{15}N NMR data for the amidinium cations of *N*-phenylbenzamidine (δ −270, −280 ppm) and *N*-methylbenzamidine (δ −269, −270 ppm). The difference in resonances is dependent only on the difference in the substitution of the nitrogens. Unsubstituted amidines are stronger bases than aliphatic amines. Benzamidine (26) has a pK_a of 11.2. In our pH 6.0 reaction mixture we would expect to have the benzamidinium cation and for it to exhibit one ^{15}N resonance as the two nitrogens become equivalent in the cationic form. And indeed for benzamidine we find only one ^{15}N resonance at −278.0 ppm. This evidence would suggest that in our case the amidinium cation **7***a* is being formed from the reaction of *N*-Ac-L-PheGlyCN and aniline via the intermediacy of the thioimidate:papain adduct (Scheme 2). Unlike the amide formed from the reaction of *N*-Ac-L-PheGlyCN with papain in the presence of thiols, the amidine is not hydrolyzed to *N*-Ac-L-PheGlyCOOH. The peak representing ^{13}C-**5***a* appears at the same rate with or without aniline in the reaction mixture.

To summarize, there is no reaction between aniline and the nitrile without papain. With papain an amidine that does not hydrolyze to a carboxylic acid is formed. This represents a

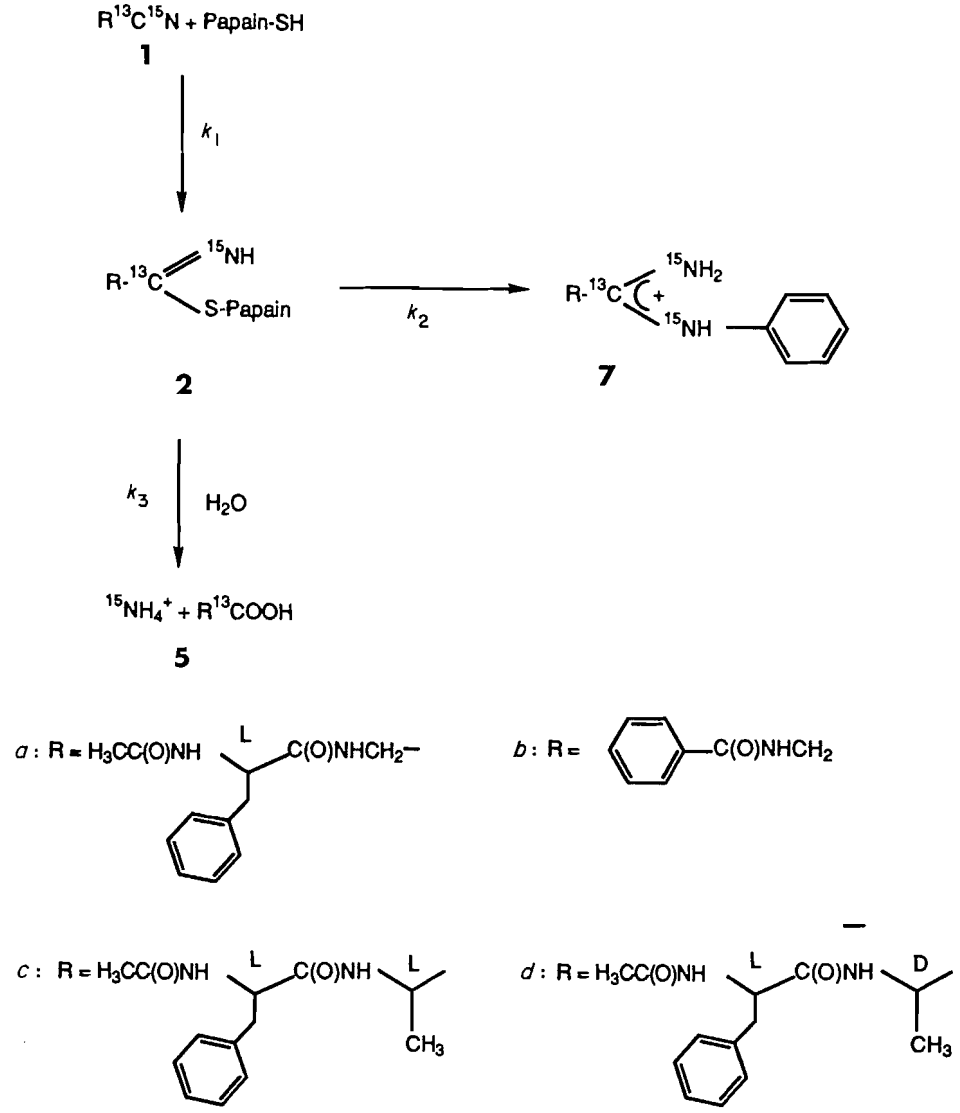
[a]Internal reference was the methyl carbon resonance of acetone assigned to 30.7 ppm.
[b]Nitromethane was used as an external reference.

reaction that is very difficult to do synthetically but can be accomplished, at least on small scale, at neutral pH's and ambient temperatures with papain. In fact all attempts to synthesize the authentic amidine **7***a* by the method of Bailey *et al.* (27) failed. Other amino nucleophiles were also used. The reaction of benzylamine with *N*-Ac-L-PheGly$^{13}C^{15}N$ also resulted in the formation of an amidine, as evidenced by a doublet at 164.0 ppm (J = 19.6 Hz). However, for aliphatic amines such as ethylamine and ethylenediamine no reaction took place.



Now that it has been established that the thioimidate adduct resulting from the reaction of *N*-(*N*-acetyl-L-phenylalanyl)-glycinenitrile and papain reacts with a variety of nucleophiles to yield a variety of products, it was decided that other nitrile inhibitors should be investigated. The same reactions were carried out using benzoylamidoacetonitrile (BzNHCH$_2$CN) **1***b*, another known inhibitor of papain. Incubation of ^{13}C-**1***b* with papain resulted in the immediate formation of the thioimidate represented by a peak at 182.9 ppm (Fig. 2c). The peak at 170.8 ppm represents the amide carbonyl of $^{13}C^{15}N$-**1***b*. After a period of 1 day we see a small peak from the hydrolysis of the thioimidate to the corresponding carboxylic acid **5***b* at 176.8 ppm. Concomitantly the NH_4^+ is released and appears in the ^{15}N NMR spectrum (Table 1). The identification of the acid was further verified by acquisition of the ^{13}C NMR spectrum of a known sample of benzoylamidoacetic acid (BzNHCH$_2$COOH) **5***b*. The carbon of the carboxylic acid functionality appears at the same position as that found in the reaction mixture.

When $^{13}C^{15}N$-**1***b* is treated with an excess of thiol (β-mercaptoethanol, *N*-acetylcysteamine), a doublet centred at 174.8 ppm ($J_{^{13}C^{15}N}$ = 17.0 Hz) appears in the ^{13}C NMR spectrum (Fig. 2a) and concomitantly a doublet appears in the ^{15}N NMR spectrum (−276.4 ppm, $J_{^{13}C^{15}N}$ = 17.0 Hz). A corresponding signal appears as a singlet when ^{13}C-**1***b* is used as starting material (Fig. 2b). The ^{13}C chemical shift is identical to the carbonyl absorption of authentic benzoylamidoacetamide-1-^{13}C (BzNHCH$_2$C(O)NH_2) ^{13}C-**4***b* synthesized by the method of Thompson *et al.* (14).

Two days after mixing β-mercaptoethanol and benzoylamidoacetonitrile in the presence of papain (Fig. 3a), a large doublet representing the amide $^{13}C^{15}N$-**4***b* appears in the ^{13}C NMR spectrum, as does a singlet indicating the presence of the corresponding acid ^{13}C-**5***b*. The amide **4***b* is being formed and converted to the acid **5***b* at approximately twice the rate (by

SCHEME 2

NMR integration) as amide is formed from the reaction of the nitrile **1***b* with β-mercaptoethanol alone. As the reaction proceeds, the carboxylic acid **5***b* resonance enlarges at the expense of the nitrile **1***b* and the amide **4***b* resonances. When cysteamine is used in place of β-mercaptoethanol, the reaction proceeds in a similar manner. As in the case with *N*-(*N*-acetyl-L-phenylalanyl)glycinenitrile, it seems clear that the conversion to amide **4***b* results from the attack of the thiol on the enzyme-bound thioimidate to yield a non-enzymic thioimidate that hydrolyzes rapidly (10) to yield the amide **4***b*, which in the presence of papain is further hydrolyzed to the carboxylic acid **5***b* (Scheme 1).

The reaction of benzoylamidoacetonitrile ($BzNHCH_2CN$) with aniline was also investigated. Control experiments indicated that there is no reaction between [1-$^{13}C^{15}N$]benzoylamidoacetonitrile $^{13}C^{15}N$-**1***b* and aniline (no papain) over a period of months. Similarly, there is no reaction between aniline and papain. As before, benzoylamidoacetonitrile and papain will react slowly to form the carboxylic acid **5***b*. As with the reaction of *N*-(*N*-acetyl-L-phenylalanyl)glycinenitrile and aniline in the presence of papain, benzoylamidoacetonitrile and aniline react to form the amidinium ion **7***b*, as evidenced by the growth of a doublet at 166.1 ppm in the ^{13}C NMR spectrum (Scheme 2).

Enzymes are recognized as practical catalysts for asymmetric syntheses, with their abilities to undergo stereospecific transformations (28). Therefore, the stereoselectivity of the reaction of exogenous nucleophiles with the thioimidate adduct resulting from the interaction of two diastereomers *N*-(*N*-acetyl-L-phenylalanyl)-L-alaninenitrile (*N*-Ac-L-Phe-L-AlaCN) **1***c* and *N*-(*N*-acetyl-L-phenylalanyl)-D-alaninenitrile (*N*-Ac-L-Phe-D-AlaCN) **1***d* was investigated. Firstly we had to ensure that *N*-AcPheAlaCN was also a covalent inhibitor of papain and underwent the same types of reactions as *N*-AcPheGlyCN. A diastereomeric mixture of *N*-Ac-L-Phe-L-Ala$^{13}C^{15}N$ and *N*-Ac-L-Phe-D-Ala$^{13}C^{15}N$ was synthesized based on the method of Storer and co-workers (29). When the diastereomeric mixture was incubated with papain, two thioimidate resonances appeared in the ^{13}C NMR spectrum (186.3, 186.8 ppm). It appeared that only one of these was hydrolyzed to form the *N*-(*N*-acetyl-L-phenylalanyl)alanine (*N*-Ac-L-PheAla^{13}COOH) (179.6 ppm) and $^{15}NH_4^+$. Both diastereomers yielded amides *N*-(*N*-acetyl-L-phenylalanyl)-[1-

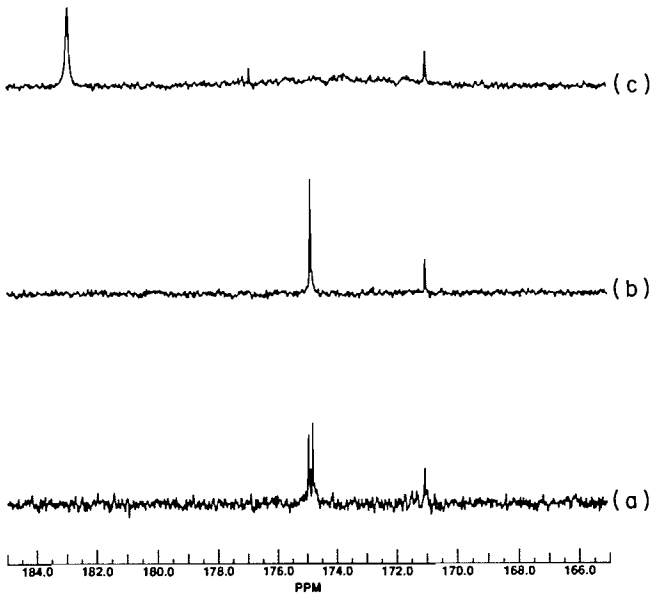

FIG. 2. Partial ^{13}C NMR spectra (a) 10 mM $BzNHCH_2{}^{13}C^{15}N$-**1***b*) + 30 mM β-mercaptoethanol (after 1 day); (b) 10 mM $BzNHCH_2{}^{13}CN$ (^{13}C-**1***b*) + 30 mM β-mercaptoethanol (after 1 day); (c) 10 mM $BzNHCH_2{}^{13}CN$ (^{13}C-**1***b*) + 0.19 mM papain (after 1 day).

^{13}C]alaninamide (*N*-AcPhe-[1-^{13}C]Ala$^{15}NH_2$) **4***c*, **4***d* when incubated with an excess of β-mercaptoethanol at pH 6 (178.8, 177.7 ppm) (Table 1).

To clarify the role of each diastereomer, they were synthesized separately. L-Alanine-[1-^{13}C]methyl ester was synthesized from [1-^{13}C]L-alanine by the method of Brenner and Huber (21). L-Alanine methyl ester was coupled to *N*-acetyl-L-phenylalanine. The resulting ester (^{13}C-**8**) was then converted to an amide (^{13}C-**4***c*), which in turn was dehydrated to yield the desired nitrile ^{13}C-**1***c*. The D analog was synthesized in a similar manner starting from [1-^{13}C]D-alanine. *N*-Ac-L-Phe-L-Ala^{13}CN reacts with papain (Fig. 4b) to form the thioimidate ^{13}C-**2***c* whose resonance is centred at 186.4 ppm. The thioimidate is slowly hydrolyzed to give *N*-Ac-L-Phe-L-Ala$^{13}COOH$ (^{13}C-**5***c*) (179.6 ppm) (Fig. 4b). *N*-Ac-L-Phe-L-Ala^{13}CN reacts with an excess of β-mercaptoethanol to give *N*-Ac-L-Phe-L-[1-^{13}C]-AlaNH_2 (^{13}C-**4***c*) (177.7 ppm) whose terminal amide carbonyl carbon resonance was verified by comparison with the resonance for authentic *N*-Ac-L-Phe-L-[1-^{13}C]AlaNH_2 (^{13}C-**4***c*). When the time course of the reaction of ^{13}C-**1***c* and papain in the presence of β-mercaptoethanol was undertaken, the results were similar to those found for the reaction of *N*-Ac-L-PheGly^{13}CN + β-mercaptoethanol. At the concentration of enzyme used in this reaction (0.324 mM), build-up of amide ^{13}C-**4***c* is not observed. Only the production of acid (^{13}C-**5***c*) at the expense of the nitrile (^{13}C-**1***c*) (119.8 ppm) is observed. Analysis of the peak integrations indicate that acid is formed at approximately 1.5 times the sum of the rate for amide formation in the blank and the rate of hydrolysis of the thioimidate to form acid. If a lower concentration of papain is employed (0.18 mM), an amide resonance is observed. When doubly labelled starting material is used one also sees an absorption at −277.8 ppm in the ^{15}N NMR spectrum, which is consistent with the authentic amide $^{13}C^{15}N$-**4***c*. Therefore, the mechanism appears to be the same as that outlined in Scheme 1 (Table 1).

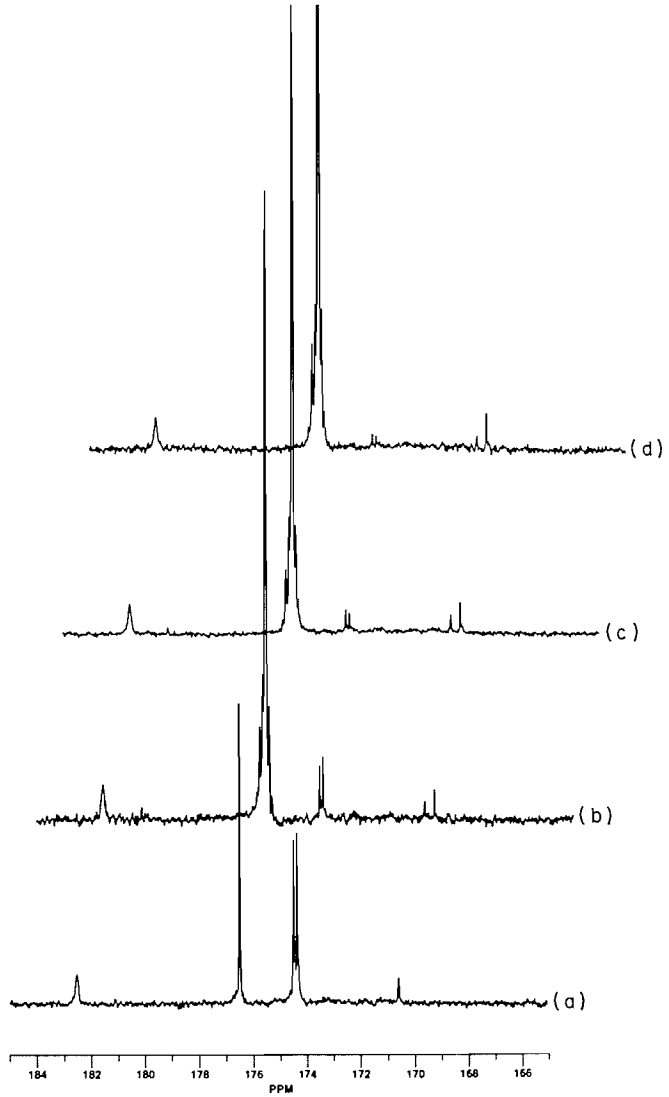

FIG. 3. Partial ^{13}C NMR specrtra of 10 mM $BzNHCH_2{}^{13}C^{15}N$ ($^{13}C^{15}N$-**1***b*) + 0.19 mM papain + 30 mM β-mercaptoethanol (a) after 2 days; (b) after 6 days; (c) after 10 days; (d) after 13 days.

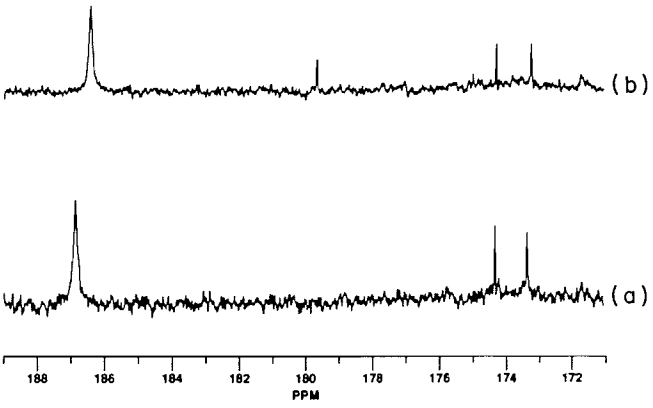

FIG. 4. Partial ^{13}C NMR spectra (a) 10 mM *N*-Ac-L-Phe-D-Ala^{13}CN (^{13}C-**1***c*) + 0.30 mM papain (after 21 days); (b) 10 mM *N*-Ac-L-Phe-L-Ala^{13}CN (^{13}C-**1***c*) + 0.29 mM papain (after 1 day).

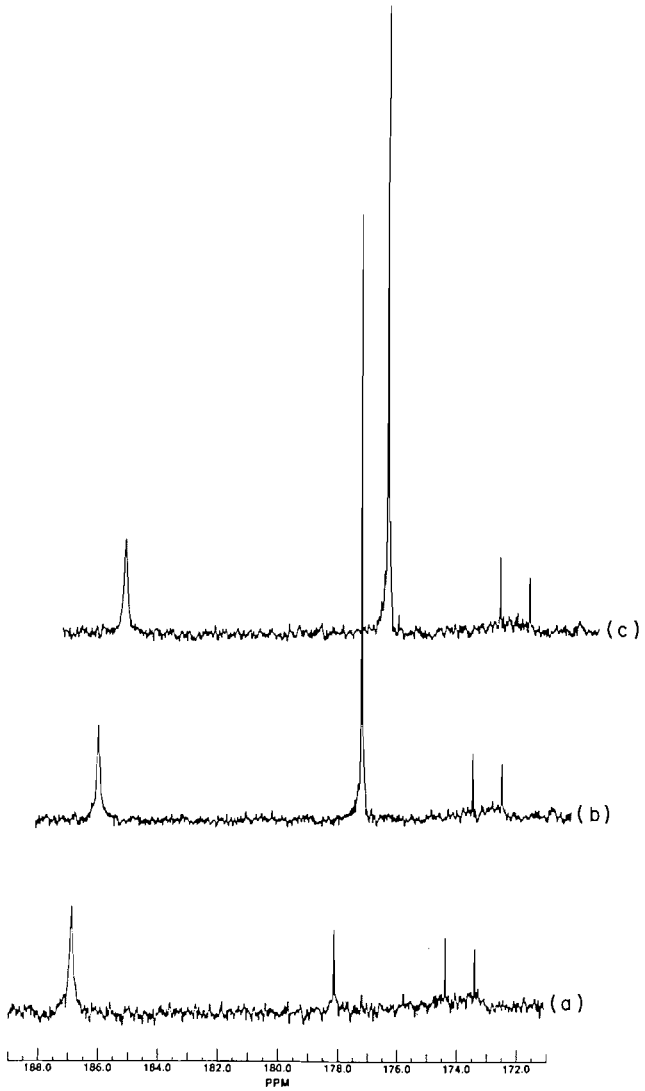

FIG. 5. Partial ^{13}C NMR spectra of 10 mM *N*-Ac-L-Phe-D-Ala^{13}CN (^{13}C-**1***d*) + 0.30 mM papain + 30 mM β-mercaptoethanol (a) after 1 day; (b) after 6 days; (c) after 27 days.

The same series of reactions was carried out with *N*-Ac-L-Phe-D-Ala^{13}CN. This diastereomer reacts with papain to form the thioimidate ^{13}C-**2***d*, which absorbs at 186.8 ppm. This thioimidate ^{13}C-**2***d* does not hydrolyze to the acid ^{13}C-**5***d* even after a period of 4 weeks (Fig. 4a). The nitrile reacts with β-mercaptoethanol to yield the corresponding amide ^{13}C-**4***d* (178.8 ppm) (Table 1). This reaction is not catalyzed in a parallel reaction by papain as is the L,L diastereomer. When the time course of the reaction of *N*-Ac-L-Phe-D-Ala^{13}CN (^{13}C-**1***d*), papain, and β-mercaptoethanol was run, there was no conversion of the amide (^{13}C-**4***d*) to the acid (^{13}C-**5***d*) (Fig. 5). One sees only build-up of the amide at the same rate as that formed from the reaction of nitrile and β-mercaptoethanol alone. In this case, in Scheme 1, k_3, k_4, and $k_6 = 0$.

With aniline as a nucleophile, the following results were obtained. Aniline and *N*-Ac-L-Phe-L,D-AlaCN in the absence of papain do not react even after a period of 6 weeks. A time course of the reaction of the L,L diastereomer, papain, and aniline indicates the formation of the amidine **7***c* (169.4 ppm). The thioimidate ^{13}C-**1***c* formed from the reaction of papain and *N*-Ac-L-Phe-L-Ala^{13}CN (^{13}C-**1***c*) is slowly hydrolyzed to the acid ^{13}C-**5***c*. However, with the L,D diastereomer there is formation of the thioimidate ^{13}C-**2***d* (186.8 ppm) but no hydrolysis to acid (^{13}C-**5***d*) nor reaction with aniline to form the amidine (Table 1). For *N*-Ac-L-Phe-D-AlaCN, $k_2 = k_3 = 0$ in the reactions depicted in Scheme 2.

The inhibition constants for the deactivation of papain with *N*-Ac-L-Phe-L-AlaCN and *N*-Ac-L-Phe-D-AlaCN were measured and the values of 6 and 18 μM, respectively, were obtained. This would indicate that while both diastereomers are good inhibitors, something must be blocking the attack of external nucleophiles in the case of the L,D diastereomer. Molecular modelling and energy minimization experiments indicate that the A-conformer thioimidate (13) is the lowest energy form for both diastereomers, but nucleophilic attack on this thioimidate intermediate is blocked in the case of the L,D diastereomer by the methyl side chain of the alanine residue, the backbone of Trp 26, and the backbone of Ser 24.

The viability of using papain as a nitrile hydrolyzing enzyme has been established, as well as its ability to do stereospecific transformations. Using the above reactions, papain can be used as an enantioselective nitrilase. This leads to the possibility of the production of optically pure amino acids, which can be produced by an enzymatic Strecker synthesis.

The crystal structure of 3′,3″,5′,5″-tetrabromophenolphthalein ethyl ester (TBPE) has been determined by X-ray diffraction at room temperature. This compound crystallizes in space group $P\bar{1}$, with a = 12.361(4), b = 12.533(4), c = 9.986(2) Å, α = 99.57(3), β = 112.76(2), γ = 100.73(3) °, and Z = 2. The structure was solved by direct methods and refined by full-matrix least-squares calculations to a residual of 0.034 for 1862 observed reflections. TBPE is propeller shaped about the central carbon and crstallizes with one molecule of benzene solvent per asymmetric unit. In 1:1 CD_2Cl_2:$CDCl_3$ solution complete ^1H and ^{13}C NMR signal assignments have been made via $^1H^1H$ COSY and $^1H^{13}C$ HETCOR experiments. The quinoidal and phenolic integrities are retained on the NMR timescale. By contrast for an acetone-d_6 solution only 14 ^{13}C resonances are found and the colour of the solution changed from green to dark blue. These changes in acetone solution are attributed to the presence of a trace of base which induces the loss of the phenolic proton of TBPE and the existence of resonance forms which render the phenolic and quinoidal rings equivalent.

Key words: crystal structure, NMR, 3′3″5′5″-tetrabromophenolphthalein ethyl ester.

ANTONY C. CHIVERTON, SUZANNE FORTIER, JOHN W. BOVENKAMP, D. THORAVAL, G. W. BUCHANAN et B. A. DAWSON. Can. J. Chem. **69**, 1298 (1991).

On a déterminé la structure cristalline de l'ester éthylique de la 3′,3″,5′,5″-tétrabromophénolphthaléïne (ETBP) par diffraction des rayons-X, à la température ambiante. Ce composé cristallise dans le groupe d'espace $P\bar{1}$, avec a = 12,361(4), b = 12,533(4), c = 9,986(2) Å, α = 99,57(3), β = 112,76(2), γ = 100,73(3)° et Z = 2. On a résolu la structure par des méthodes directes et on l'a affinée par des calculs de moindres carrés (matrice entière) jusqu'à une valeur de R = 0,034 pour 1862 réflexions observées. L'ETBP a la forme d'une hélice avec un atome de carbone au centre et il cristallise avec une molécule de benzène par unité asymétrique. En solution dans un mélange $CD_2Cl_2/CDCl_3$ 1:1, on a fait une attribution complète des raies des spectres rmn du ^1H et du ^{13}C en faisant appel à des expériences de $^1H^1H$ COSY et $^1H^{13}C$ HETCOR. À l'échelle de temps de la rmn, les intégrités quinonoïdales et phénoliques sont maintenues. Par ailleurs, avec les spectres détermines dans l'acétone-d_6, on n'observe que 14 résonances ^{13}C et la couleur de la solution change du vert à bleu foncé. On attribue les changements observés dans l'acétone à la présence d'une trace de base qui induit la perte du proton phénolique de l'ETBP et à l'existence de formes de résonance qui rendent les cycles phénoliques et quinonoïdales équivalentes.

Mots clés : structure cristalline, rmn, ester ethylique de la 3′,3″,5′,5″-tétrabromophénolphthaléïne.

[Traduit par la rédaction]

Introduction

Indicator dyes have been found useful for the detection of droplets of toxic liquids containing a basic nitrogen. Consequently they have been incorporated into adhesive backed detector papers. In 1981, the commonly used indicator dye ethyl-bis(2,4-dinitrophenyl) acetate was found to be mutagenic (1). TBPE has been suggested as a replacement (2) and it has been found to be non-mutagenic by the Ontario Research Foundation (3).

TBPE is an acid/base indicator dye which, unlike most phenolphthaleins, exists in an open ester form rather than the usual lactone form. The phenolic proton is removed in the pH range 3.6–4.2 (4). The resulting charge is delocalized between the phenol and quinoid rings producing a change in colour from yellow, at pH below the 3.6–4.2 range, to dark blue above this pH range. TBPE was first synthesized by Davis and Schuhmann (5), using a five-step procedure starting with phenolphthalein. Other synthetic studies were reported by Sun *et al.* (6). The synthetic route which was used to produce the samples for this work is described in ref. 2. Patents have been submitted for the use of TBPE for the detection of toxic liquids (7). The present paper reports single crystal X-ray diffraction and soluton NMR studies on TBPE.

Experimental

X-ray crystal structure determination

The title compound was synthesized by procedures presented previously (2, 5). Pertinent data about the crystal used and the measurement of diffraction intensities are summarized in Table 1. The crystal was mounted at the end of a glass fibre. The intensity data were collected on an Enraf-Nonius CAD-4 diffractometer using graphite

monochromated radiation, Mo Kα (λ = 0.71073 Å). The intensities were collected using the θ–2θ scanning procedure and three reflections were measured after every 7200 s of exposure time to check on the stability of the crystal. A 5.2% loss in intensity was observed and a linear decay correction was applied; the maximum and average corrections were 1.0270 and 1.0136, respectively. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods using the program MULTAN80 (8). All of the hydrogen positions, except for five, were found in different Fourier maps. The positions of H21A, H21B, H22B, H22C, and H24 were calculated. The structure was refined by full-matrix least-squares. The function minimized was $\Sigma w||F_0| - |F_c||^2$, where $w = 4F^2[\sigma^2(F^2) + (0.04F^2)^2]$. All reflections with $I \geq 3\sigma(I)$ were used. Anisotropic temperature factors were used for the non-hydrogen atoms. Isotropic temperature factors equal in magnitude to the equivalent isotropic values of their parent atoms were assigned to the hydrogens. The hydrogen atoms were included in the calculations, but neither their positions nor their temperature factors were refined. The scattering factors were taken from Cromer and Waber (9). Anomalous dispersion coefficients were taken from Cromer (10). All calculations were done on a PDP 11/23 computer using the Enraf-Nonius SDP program package (11). The program ORTEP (12) was used for the preparation of the illustration.[3]

Nuclear magnetic resonance studies

All spectra were recorded at 298 K on a Bruker AM-400 spectrometer equipped with an Aspect 3000 computer and process controller using DISNMR version 87. Standard microprograms from the Bruker Software Library were employed.

The $^1H^1H$ COSY experiment used N-type phase cycling with a 45° mixing pulse. Typically, the free induction decays were acquired over 1024 data points for each of the 256 values of the evolution time, with a digital resolution of *ca.* 5 Hz/point. The raw data were zero filled in F1 prior to Fourier transformation using the sine-bell window function for both F1 and F2. The matrix was symmetrized about the diagonal.

The $^1H^{13}C$ COSY spectra were obtained using a low decoupler power in the CW mode (composite phase decoupling) with polarization transfer from ^1H to ^{13}C. Typically, the FID's were acquired over 4096 data points for each of the 128 or 256 values of the evolution time, with digital resolution of 7 Hz/point F2 and 5–10 Hz/point in F1. The raw data were zero filled in F1 prior to Fourier transformation using the sine bell window function. Proton relaxation delays of 3–5 s were utilized. For the long range correlations, the delays were chosen normally to emphasize couplings of *ca.* 7.5 Hz.

Discussion

X-ray crystal structure determination of TBPE

The atomic parameters are given in Table 2 and an ORTEP (12) illustration of the molecule with the atomic numbering and ring labelling schemes used throughout is shown in Fig. 1. Hydrogen atoms are omitted to simplify the picture. The labelling of the hydrogen atoms refers to the number of their parent atom. Bond lengths and angles are listed in Table 3.

All bond lengths were found to be within the expected ranges given by Allen *et al.* (13). There is no evidence of any hydrogen bonding effects as there are no oxygen–oxygen distances less than 4.448(9) Å. The three rings of TBPE are planar. The maximum perpendicular distance between any atom in one of the rings, the phenolic (A), quinoid (B), or ethyl ester (C) and the calculated least-squares plane of that ring is 0.04(1), 0.02(1), and 0.02(1) Å, respectively. The three-ring structure of

TBPE exhibits a propeller geometry with A, B, and C rings making angles of 12.6(5), 39.9(5), and 69.9(5)° with the plane defined by the central carbon and the three connecting ring carbons (the central plane). In the so-defined central plane, the maximum perpendicular distance of any atom to the least-squares plane is 0.02(1) Å. The open ester form is observed in the title compound.

A search for molecules containing a central carbon with only three six-membered aromatic rings attached was performed using the Cambridge Structural Database (14). The search found 12 structures (15–22) that satisfied these criteria. As expected all of these structures exhibit a propeller shape. Indeed, Brooks and Stucky (15) state that due to steric requirements three phenyl rings attached to a single central carbon cannot be coplanar. The rings, therefore, are twisted out of the central plane and form a propeller shape. All of the structures found were charged species, either cations, anions, or radicals, in contrast to TBPE, which is a neutral molecule. Typical values for the twist angles of the rings out of the central plane cluster around 30° as shown in Pararosaniline (17). In this case the three aniline rings are twisted out of the central plane by 34.1, 34.1, and 27.4°. The structure of triphenylmethyllithium tetramethylethylenediamine (15) exhibits a larger range of twist angles, with values of 19.7, 30.6, and 44.8°. A set of five

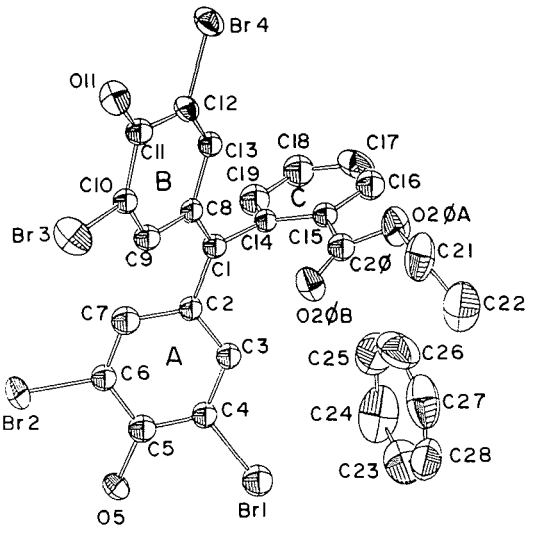

FIG. 1. Ortep illustration of TBPE.

triphenylmethyl radical structures with varying degrees of chlorine substitution at the *ortho*-position of the phenyl rings was determined by Veciano *et al.* (22). Depending on the extent of substitution, the rings were twisted out of the central plane by angles ranging from 37.7 to 65.3°. The average twist angle was 49.9°. TBPE can also be compared to structures in which one of the phenyl rings is replaced by a five-membered ring. For example, ferrocenyldiphenylcarbenium tetrafluoroborate (23) is also a propeller-shaped molecule. In this structure the three rings make angles of 18.3, 38.2, and 56.8° with the central plane. The ferrocenyl cyclopentadiene ring makes the smallest twist angle with the central plane.

TBPE is seen to have a considerably larger range of twist angles, from 12.6 to 69.90°, than all of the structures mentioned above. The quinoid ring (B) has a twist angle of 12.6(5)°. This relatively small angle is due to the presence of the double bond which, indeed, would suggest that this ring should be coplanar with the central plane. Steric requirements, however, force the quinoid ring to deviate from this ideal coplanarity and twist into a propeller shape. The phenolic ring (A) is twisted out of the plane by 39.9(3)°. This value is the closest to the magnitudes previously reported. The phenolic ring is also the ring which most closely resembles the rings present in the previous studies. The ethyl ester ring (C) exhibits the largest twist angle of 69.9(5)°. Veciana *et al.* (22) and McKechnie and Paul (18) have suggested that the magnitude of the twist angle is determined largely by the extent of substitution at the *ortho*-positions of the phenyl rings. If this hypothesis is extended to include the effects of the size of the substituent, then the structure of TBPE supports this suggestion. The large ethyl ester group at the *ortho*-position of ring C appears to force this ring to deviate from coplanarity with the central plane to a greater degree than the single atom substituents used in the previously cited studies. In addition, the larger range for twist angles found in TBPE can be explained by the fact that TBPE is a neutral molecule in contrast to all of the twelve structures in the comparison group.

Nuclear magnetic resonance studies

(i) ^1H NMR spectrum

The chemical shifts for the fourteen protons of TBPE are presented in Table 4. The numbering scheme is the same as in the X-ray study with the hydrogen atoms labelled according to their parent atom.

ment identified the OH proton at 6.40 ppm. The most deshielded proton resonance is the doublet of doublets at 8.05 ppm, which is due to H16. This assignment follows from the observation of a long range (^3J) correlation to the ester carbonyl carbon at 165.48 ppm and is consistent with the known deshielding influence of an ester function on *ortho* aromatic protons (25). With this assignment in hand the $^1H^1H$ COSY experiment leads to ready identification of resonances for H17, H18, and H19. From the spin coupling pattern, chemical shifts, and integrated intensities the CH_2 and CH_3 groups are readily identified.

The remaining resonances in the ^1H spectrum consist of a three-proton singlet at 7.40 ppm and a one-proton singlet at 7.90 ppm. Due to rapid rotation about the C1—C2 bond, the protons on C3 and C7 will have identical chemical shifts and thus two of the three protons at 7.40 can be assigned to H3 and H7. The remaining two singlets of one proton intensity must therefore arise from the non-equivalent H9 and H13 sites of the quinoid ring. The proton having the chemical shift of 7.90 ppm must lie in the deshielding "outer" region of one of the adjacent aromatic moieties.

From the X-ray data one can obtain information regarding the preferred conformation of TBPE in the solid. Assuming similar solution geometry, a distinction between H9 and H13 resonances can be made.

The X-ray data show that the interplanar angle between rings A and B is 45.8(4) while that between rings B and C is 102.1(4)

and between A and C is 92.2(4)°. From molecular models it is clear that H9 lies in the "outer" *i.e.* deshielding region of ring B while H13 is situated almost directly above the C14 site of ring C. On the basis of the known anisotropic effect of aromatic rings on ^{1}H resonances (26), one can assign H9 as giving rise to the deshielded resonance at 7.90 ppm.

(ii) ^{13}C NMR spectrum

The ^{1}H decoupled ^{13}C NMR spectrum of TBPE in 1:1 CD_2Cl_2:$CDCl_3$ solution at 298 K shows 20 resonances, whose chemical shifts are presented in Table 5.

Initially, the APT (27) experiment was used to distinguish between protonated and nonprotonated aromatic carbons. Secondly, the relative intensities of the resonances as determined from a suppressed nuclear Overhauser experiment furnished information regarding sites which are averaged by bond rotation, since only 20 lines are observed for TBPE which possesses 22 carbons.

Since the ^{1}H spectrum has been completely assigned, the ^{13}C chemical shifts for the ten carbons bearing hydrogen follow directly from the 1-bond ^{1}H–^{13}C correlation experiment (24). A typical spectrum illustrating these correlations is shown in Fig. 2. The double intensity ^{13}C resonance at 134.94 ppm for the C3,C7 pair, which are rendered equivalent by rapid rotation about the C1—C2 bond, is readily apparent.

TABLE 6. ^{13}C chemical shifts for TBPE in acetone-d_6 (δ_C from TMS ± 0.01)*

δ_C	Relative intensity	Assignment
14.28	1	CH_3(C22)
62.75	1	CH_2(C21)

140.24	2	C2,8
160.72	2	C5,11
166.62	1	C20

*0.05 M solution.

For assignment of the non-protonated (quaternary) aromatic carbon resonances, the long range (*i.e.* ^2J or ^3J) correlation experiments are valuable along with consideration of chemical shifts for related molecules. The brominated quinoid carbons C10 and C12 are distinguished by the fact that C12 exhibits a ^2J correlation to the proton at 7.40 ppm (H13) while C10 correlates to the proton resonance at 7.90 ppm (H9). The quinoid carbonyl (C11) at 172.69 ppm correlates to both H9 and H13 as expected, and its chemical shift is in close accord with data for related 1,3-dibromo-2 quinoid molecules (28).

In the phenolic ring, the well-documented effects of substituents on aromatic ^{13}C shifts (29) lead to the prediction that the brominated carbons C4,C6 should resonate near 110 ppm. The intensity of the quaternary resonance at 109.83 ppm shows the expected single long range (^2J) correlation to the H3,H7 protons. For C5 the expected chemical shift is near 160 ppm based on model phenolic compounds (29). Accordingly, the resonance at 158.98 can be assigned to C5 and it shows the expected correlation (^3J) to the H3,H7 protons. The remaining quaternary carbon which correlates to H3,H7 only, appears at 151.26 ppm and must, by elimination, be attributed to C2.

At this point, four resonances remain to be assigned which arise from the quaternay carbons C1, C8, C14, and C15. The resonance at 139.49 ppm shows "long range" correlation to H16 and H18, while the 131.53 resonance correlates with H17 and H19. Initially, the delays in the long range C—H correlation experiment were set to emphasize C—H couplings of 7.5 Hz so that the strongest correlations will be observed for couplings of this magnitude. It is known from early work (30) that $^3J_{CCCH}$ in benzene is 7.4 Hz, while the $^2J_{CCH}$ value is 1.0 Hz. Hence the correlations which are observed under these conditions will arise via ^3J networks. Accordingly, we assign the 139.49 resonance to C14 and the 131.53 line to C15. Finally, the ^{13}C resonance at 132.62 ppm shows a correlation with a proton resonance at 7.40 ppm while the carbon at 129.71 shows no correlations under these conditions. The remaining unassigned carbons are C1 and C8. In the case of C8, there are no vicinal hydrogens and hence the lack of observed correlations would not be surprising in view of the lower magnitudes for ^2J

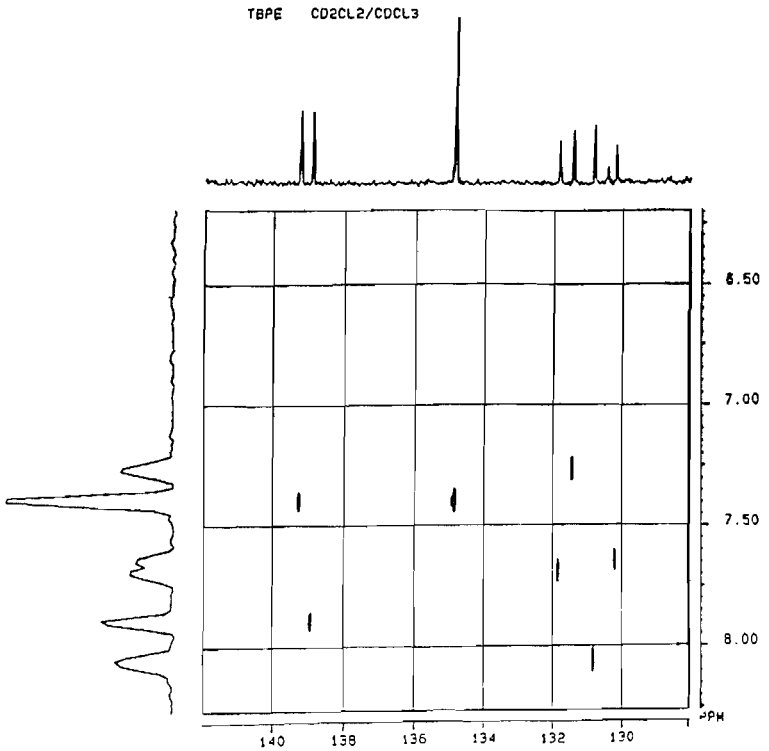

FIG. 2. ^{1}H ^{13}C correlation experiment spectrum for TBPE in CD_2Cl_2:$CDCl_3$.

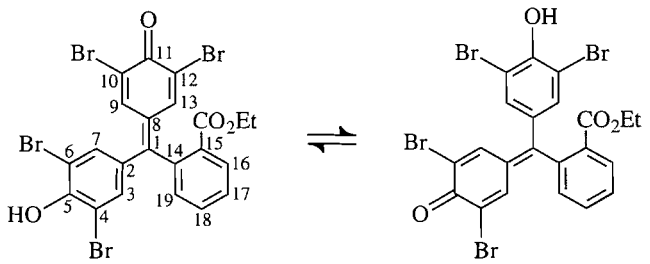


couplings mentioned above. For C1, however, there are five vicinal hydrogens. Failure to observe correlations to more than one site here must be due to dihedral angle effects arising from the non-planarity of the three aromatic rings with respect to the plane occupied by C1, C2, C8, and C14. From the X-ray data, the dihedral angle between C1 and H19 is 110.1°. Assuming a similar geometry in solution, the $^{3}J_{CCCH}$ value is expected to be less than 2 Hz (31). Again on the basis of the X-ray data, the expected dihedral angles between C1 and the H3,H7 pair will be *ca.* 40° different from the planar situations which lead to maximal coupling. In the solid state, however, the H9 and H13 sites are within 12.6° of being coplanar with C1. Thus it is reasonable to expect a correlation with one or both of these sites. Experimentally, the correlation to the 7.40 proton resonance indicates that this arises from the vicinal C1—H13 interaction.

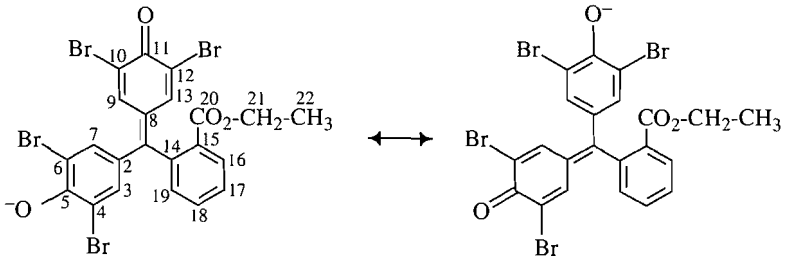
With the delays set to emphasize 3.75 Hz ^{13}C—^{1}H coupling, the ^{13}C resonance at 129.71 correlates to the ^{1}H line at 7.90 ppm. This confirms the identity of C8 and the correlation arises from a ^{2}J pathway to H9.

(iii) ^{13}C NMR spectrum in acetone-d_6

The initial point to note here is that the colour of the acetone-d_6 solution of TBPE is dark blue in contrast to the green solution in the 1:1 CD_2Cl_2–$CDCl_3$ solvent mixture. A further difference is that the ^{13}C NMR spectrum in acetone-d_6 shows a total of 14 resonances in contrast to the 20 observed in the CD_2Cl_2–$CDCl_3$ medium. Methods of resonance assignment were similar for the two solvent media and results are presented in Table 6 for the acetone-d_6 case. Clearly there is, in acetone-d_6, a situation in which the environments of C4,6,10,12 are averaged to one as are the environments of C3,7,9,13 as well as the C2,8 and C5,11 pairs, respectively.

We believe that the explanation for the colour change between the two media and the differing number of ^{13}C resonances lies with the normal trace of acid present in $CDCl_3$. This gives the solution in CD_2Cl_2–$CDCl_3$ a lower pH, consistent with its green colour. In this medium there is a keto–enol type tautomerism as shown below. These equilibria are usually slow on the NMR timescale and hence separate ^{13}C resonances are seen for the phenolic vs. the quinoidal ring carbons of TBPE.

As stated in the Introduction, TBPE loses its phenolic proton above pH 4.2 and changes colour to dark blue. The ^{13}C NMR behaviour of TBPE in acetone-d_6 is consistent with such an occurrence, since the groups of carbons C4,6,10,12; C3,7,9,13; C5,11 and C2,8 are rendered degenerate due to the existence of resonance between rings **A** and **B** as depicted below.



Assuming minimal influence of solvent on ^{13}C chemical shifts, one can check for the existence of averaging of the assigned ^{13}C shifts in the two media using additivity and weighted chemical shift averaging. Such data are presented in Table 7. It is evident that the agreement between predicted and observed shifts on the basis of averaging is excellent for the C4,6,10,12 positions as well as for the C3,7,9,13 and C2,8 sites.

There is poor agreement between predicted and observed ^{13}C data for the C5,11 pair, with the observed shift in acetone-d_6 being *ca.* 5 ppm more shielded than predicted. This is, however, entirely *consistent* with the suggested deprotonation of the phenolic site in acetone-d_6. Such a deprotonation will lead

TABLE 7. Comparison of observed ^{13}C shifts for TBPE in acetone-d_6 and values predicted on the basis of averaging of shifts in CD_2Cl_2–$CDCl_3$

Site	δ_C in CD_2Cl_2–$CDCl_3$	Average	δ_C in acetone-d_6
C4,6; C10; C12	109.83; 124.69; 124.02	117.09	117.96
C3,7; C9; C13	134.94; 139.36; 139.59	137.21	138.60
C2; C8	151.53; 129.71	140.62	140.28
C5; C11	158.98; 172.96	165.97	160.72

A B

to an increase in electron density at the C5,11 site and thus a more shielded ^{13}C resonance.

The question arises at this point as to why TBPE, with a pK_a of *ca.* 4 should behave as a strong acid in acetone, since the pK_a of protonated acetone is *ca.* −7 (32). A possible explanation for this observation is that the acetone-d_6 contains traces of base, since the commercial material (MSD isotopes) is prepared from the protio precurser via base-catalyzed exchange in D_2O. To check this possibility, the pH of a 50:50 (by volume) mixture of commercial acetone-d_6 and ultrapure water was compared to that of ultrapure water alone, using a Fisher Accumet 925 pH meter. The pH of the acetone-d_6 mixture was 0.7 units higher than that of ultrapure water, suggesting that there is indeed a trace of base present. In a 0.05 M solution of TBPE in acetone, the acetone is present at a concentration of *ca.* 15 M, so that the effect of any trace impurity on the solute properties will be greatly enhanced.

Additional support for the proposed existence of the monoanionic form of TBPE in acetone-d_6 comes from the ^{13}C NMR spectrum of the pure K^+ salt of TBPE (5) in acetone-d_6. Again the solution is dark blue in colour and 14 ^{13}C resonances are observed, whose chemical shifts are generally within 2 ppm of those for TBPE itself in the same solvent medium.

HONG WANG, RICHARD J. BARTON, BEVERLY E. ROBERTSON, JOHN A. WEIL, and KEITH C. BROWN. Can. J. Chem. **69**, 1306 (1991).

Two polymorphic crystal forms (yellow and orange) of 2,2-di(*p*-nitrophenyl)-1-picrylhydrazine were crystallized from the same dichloromethane solution, and their crystal structures determined. The yellow form is triclinic, $P\bar{1}$, a = 9.055(3), b = 10.396(4), c = 13.3187(3) Å, α = 89.83(2), β = 79.89(3), γ = 70.83(3)° at 228 K; R = 0.060, and R_w = 0.057 for 3511 reflections with $I > 2\sigma_I$. The orange form is monoclinic, $P2_1/c$, a = 8.999(3), b = 25.041(11), c = 12.207(5) Å, β = 121.66(2)° at 223 K; R = 0.053, and R_w = 0.058 for 3651 reflections with $I > 2\sigma_I$. The molecular structures in the two crystal forms are very similar. Both forms contain one solvent molecule per molecule of 2,2-di(*p*-nitrophenyl)-1-picrylhydrazine. In each, the two hydrazine nitrogen atoms have strong resonance interactions with the vicinal aromatic groups and both are sp^2 hybridized. The molecular structure around the N—N linkage shows a staggered conformation. Thus the resonance interaction between the picryl group and the other two *p*-nitrophenyl groups is negligible. The difference in color between the two crystal forms is attributed to a difference in molecular packing.

Key words: crystal structure, polymorphism, picrylhydrazine, conformation.

HONG WANG, RICHARD J. BARTON, BEVERLY E. ROBERTSON, JOHN A. WEIL et KEITH C. BROWN. Can. J. Chem. **69**, 1306 (1991).

À partir d'une même solution de dichlorométhane, les deux formes polymorphes (jaune et orange) de la 2,2-di(*p*-nitrophényl)-1-picrylhydrazine ont pu être obtenues à l'état cristallin et on a déterminé leur structure cristalline. La forme jaune est triclinique, $P\bar{1}$, a = 9,055(3), b = 10,396(4) et c = 13,3187(3) Å, α = 89,83(2), β = 79,89(3) et γ = 70,83(3)°, à 228 K; R = 0,060 et R_w = 0,057 pour 3511 réflexions avec $I > 2\sigma_I$. La forme orange est monoclinique, $P2_1/c$, a = 8,999(3), b = 25,041(11) et c = 12,207(5) Å, β = 121,66(2)°, à 223 K; R = 0,053 et R_w = 0,058 pour 3651 réflexions avec $I > 2\sigma_I$. Les structures moléculaires des deux formes cristallines sont très semblables. Les deux formes contiennent une molécule de solvant par molécule de 2,2-di(*p*-nitrophényl)-1-picrylhydrazine. Dans chacune, il existe de fortes interactions de résonance entre les deux atomes d'azote de l'hydrazine et les groupements aromatiques vicinaux et les deux ont une hybridation du type sp^2. Dans la structure moléculaire, la liaison N—N présente une conformation décalée. L'interaction de résonance entre le groupe picryle et les deux autres groupes *p*-nitrophényles est donc négligeable. On attribue les différences dans la couleur des deux formes cristallines à une différence dans l'empilement moléculaire.

Mots clés : structure cristalline, polymorphisme, picrylhydrazine, conformation.

[Traduit par la rédaction]

Introduction

The results presented here are part of ongoing structural studies of a series of diaryl picrylhydrazine derivatives. These show a variety of interesting structural effects. For example, the structure determination of 2,2-diphenyl-1-picrylhydrazine has shown that it forms a clathrate-type host–guest inclusion compound with some organic solvents (1). If the two phenyl rings are constrained to be approximately coplanar, as in 9-(2,4,6-trinitroanilino)-carbazole (2), the electron affinity of the picryl group and the electron-donation property of the planar carbazole moiety promote a π-molecular charge-transfer interaction between adjacent molecules. This leads to a structure based on infinite stacks, similar to those in many π-molecular donor–acceptor compounds, but here containing only one molecular species.

In 2,2-diphenyl-1-picrylhydrazine and in the carbazole, the conformation of each molecule, and other properties dependent on the conformation, are strongly influenced by the existence of an intramolecular hydrogen bond between one hydrazine nitrogen atom, N(1), and an oxygen atom of an *ortho*-nitro substituent on the picryl group (3, 4).

In nitroaromatic compounds, the electron-withdrawing property of the nitro groups tends to make such molecules strongly dipolar, at least locally. As a consequence, such molecules tend to co-crystallize with solvent molecules, and exhibit polymorphism. The clathration and π-molecular properties of the picrylhydrazines too are related to the tendency of these groups to form strong electric dipoles.

The related diphenylpicrylhydrazyl free radicals also exhibit polymorphism and a tendency to include solvent molecules in their crystal structures (5, 6). The crystal structure of the potassium salt of the 1-(*N,N*-diphenylhydrazono)-2,4,6-trinitrobenzenide anion has also been reported (7).

Because the 2,2-di(*p*-nitrophenyl)-1-picrylhydrazine molecule contains nitro substituents on the phenyl rings on both sides of the hydrazine linkage, it is less polar as a unit than any of the species discussed above. The 2,2-di(*p*-nitrophenyl)-1-picrylhydrazine molecule was first reported by Weil, Sane, and Kinkade (8), and its potassium salt was reported by Weil

and Janusonis (9).[3] When this compound is crystallized from dichloromethane, two distinctly different crystal forms are simultaneously obtained from the same solution: one is yellow, D2N(y), and the other orange, D2N(o).

Experimental

The compound 2,2-di(*p*-nitrophenyl)-1-picrylhydrazine was synthesized following the method described by Weil, Sane, and Kinkade (8), and was crystallized from dichloromethane.

The space groups and approximate unit-cell parameters for the yellow and orange forms were determined by X-ray diffraction, using precession photographs, at room temperature. The intensity data collection and the accurate unit-cell parameter determination for both forms was carried out on a modified four-cricle diffractometer using a θ–2θ scan mode, graphite-monochromated Mo$K\alpha$ radiation and reduced temperature. Reduced temperatures were maintained using an Enraf-Nonius low temperature nitrogen flow system modified to accommodate a computerized control mechanism (λ(Mo$K\alpha$) = 0.71069 Å for data collection; λ(Mo$K\alpha_1$) = 0.70926 Å for unit-cell parameter determination).

The crystal data and experimental parameters for both forms are listed in Table 1. Three reference reflections were measured after every 47 reflections. The intensities of the standard reflections fell by 0% and 5% for D2N(y) and D2N(o), respectively. The variances σ_I of intensities were estimated both from counting statistics and from machine instability.

The intensities were corrected for the Lorentz and polarization effects and reduced to structure amplitudes. No dispersion or absorption corrections were made. The structure amplitudes, and their variances, of reflections for which the intensities were less than $3\sigma_I$ were calculated from the intensities and σ_I by the Baysian statistical method (10).

The structures of both crystal forms were solved by direct methods and Fourier syntheses. After the positions of all the non-hydrogen atoms were located and refined, the positions of the hydrogen atoms were found by difference Fourier synthesis. For both forms, solvent molecules (in a 1:1 ratio) were included in the crystals. The final structures were refined by full-matrix least squares with anisotropic temperature factors for non-hydrogen atoms and isotropic temperature factors for hydrogen atoms. Only those reflections with $I > 2\sigma_I$ were used.

The least-squares weights w for the refinements were calculated from the expression $w = (\sigma_c{}^2 + \sigma_m{}^2)^{-1}$. The $\sigma_c{}^2$ are the aforementioned variances calculated from σ_I; the $\sigma_m{}^2$ were calculated in order to remove systematic trends with respect to F and sin θ/λ from the weighted deviates of the structure factors, $w(|F_o| - |F_c|)^2$ (11, 12). The refinement data for the crystal structures are also listed in Table 1. All the calculations were performed using the XTAL system

[3]In ref. 9, p. 1250, "with triethyl-*n*-butyl ammonium hydroxide" should read "with trichloroacetic acid".

of crystallographic programs (12) and the scattering factors used were those contained in the XTAL system. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$.

Results and discussion

Molecular structure

The coordinates and temperature factors of the non-hydrogen atoms of the D2N(y) and D2N(o) molecules are listed in Tables 2 and 3, respectively.[4] The bond lengths, bond angles, and selected dihedral angles are listed in Tables 4 and 5. Figure 1 is a stereoscopic view of the D2N(y) molecule. The atom-numbering scheme is given in Fig. 2.[5] Labels for the planes of the molecule are defined in Fig. 3. The estimated standard deviations of all functions of the atom parameters were calculated using both the variances and the covariances of the atom parameters (12).

Both crystal forms contain one solvent molecule (CH_2Cl_2) per asymmetric unit. The 2,2-di(*p*-nitro-phenyl)-1-picrylhydrazine molecules adopt similar conformations in the two polymorphic forms. However, significant differences exist, such as in the extent of rotation of the *p*-nitro groups (of the mono-nitrophenyl groups) out of the planes of their phenyl rings. The influence of the dihedral angles between each of the two mono-nitrophenyl planes and the picryl plane is also significant, as shown in Table 5.

[4] Lists of structure amplitudes, anisotropic temperature factors, H-atom coordinates, least-squares planes, and bond distances and angles and figures showing the correlations of the dihedral angles of the nitro groups with endocyclic angles and C—NO_2 bond lengths for picrylhydrazine derivatives, diphenylhydrazyl, diphenylpicryl hydrazinate and trinitroanaline, the correlation between the endocyclic angles and all C—NO_2 bond lengths for D2N(y) and D2N(o), and packing diagrams for D2N(y) and D2N(o), may be purchased from the Depository for Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Ont., Canada K1A 0S2.

[5] Note that the crystallographic numbering convention is such that the mono- and di-substituted hydrazine atoms are N(7) and N(8), respectively.

The hydrazine hydrogen atom forms an intramolecular bond with one oxygen atom, O(22), of one of the nitro groups on the picryl group *ortho* to the N—N linkage, as in the related picrylhydrazine derivatives (1, 2, 13) and nitroaniline derivatives (14, 15). Because of this, the hydrogen-bonded nitro group is forced to be nearly coplanar with the picryl plane. The interatomic distances and angles associated with the hydrogen bond, for several picrylhydrazine derivatives and for the trinitroaniline molecule, are given in Table 6. The distances N(7)···O(22) (Table 6) are considerably shorter than the normal value 2.90 Å (16) for N—H···O bonds, because the angle N—H···O is far from 180°.

The bond lengths and the torsional angles of the central fragment of the picrylhydrazine derivatives and of other related molecules are summarized in Tables 7 and 8. In the picrylhydrazine derivatives, all the C(1)—N(7) bonds have similar

Plane least-squares fitted to the position of atoms N(7), N(8), C(11), C(21).

lengths. All of them are significantly shorter than the average C—N single bond (1.456 Å) (17) and some of them are close in length to the C—N partial double bond in the related hydrazyl (6) (1.352 Å) and in trinitroaniline (18) (1.340 Å).

The sum of the three bond angles around the N(7) atom are 356.4(4) and 353.0(4)° for D2N(y) and D2N(o), respectively, suggesting that the N(7) atom is close to being sp^2 hybridized. The sums of the three bond angles around N(8) in D2N(y) and D2N(o) are 346.1 and 350.1°, respectively. The deviations of the nitrogen-atom position from the plane of the N(8) σ-bond system[6] are 0.226(2) and 0.249(1) Å. These parameters indicate that N(8) also is close to having sp^2 hybridization, but with a more appreciable amount of sp^3 character.

Table 7 lists the angles between the phenyl planes and the plane of the N(8) σ-bond system. In all cases except trinitroanilinocarbazole, the phenyl rings adopt the configuration of two propellers of a three-propeller system. In D2N and in diphenylpicrylhydrazine, the two propellers are turned by substantially different amounts from coplanarity with the N(8) σ-bond system, the difference being largest for D2N.

[6]The plane of the σ-bond system is the plane fitted (by least squares) to the central atom and the three atoms connected to it by bonds.

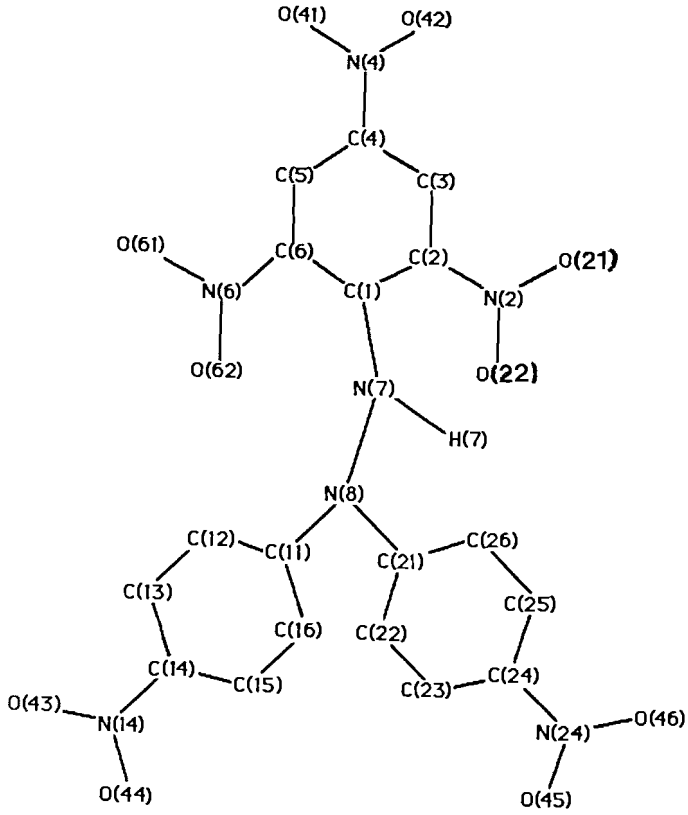

FIG. 2. Atom numbering scheme of 2,2-di(*p*-nitrophenyl)-1-picrylhydrazine.

The dihedral angles between the plane fitted to the phenyl ring of the picryl group and the plane formed by atoms C(1), N(7), and N(8) are 28.1(3) and 23.7(2)° in D2N(y) and D2N(o), respectively. The angles between the plane of the N(8) σ-bond system and the plane fitted to the phenyl ring formed by atoms C(11) to C(16) are 13.2(1) and 21.6(1)°, respectively. The nitrogen lone-pair *p* orbitals are able to interact with the π-electrons of the picryl group in the former case and those of the phenyl ring in the latter.

The angles between the plane of the N(8) σ-bond system and the plane fitted to the phenyl ring formed by atoms C(21) to C(26) are 77.5(1) and 66.5(1)° for D2N(y) and D2N(o), respectively. It follows that here less π-interaction occurs.

Consistent with this, the N(8)—C(11) bond lengths are significantly shorter than the N(8)—C(21) bond lengths. A similar correlation between the dihedral angles and the C—N bond length was observed in the 2,2-diphenyl-1-picrylhydrazyl free radical (5, 6, 19).

For 2,2-diphenyl-1-picrylhydrazine, the dihedral angles between the N(8) σ-bond system and one of the phenyl planes (formed by atoms C(11)—C(21)) are 14.8 and 18.1° for the crystals obtained from tetrahydrofuran and chloroform, respectively (1). The bond lengths equivalent to the N(8)—C(11) bond lengths are 1.437(6) and 1.428(6), respectively, for 2,2-diphenyl-1-picrylhydrazine, which are larger than the

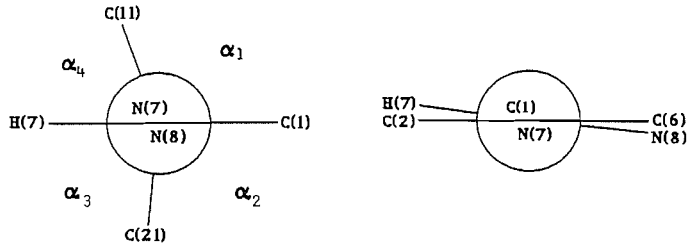

FIG. 4. Newman projections of the central fragment of picrylhydrazine derivatives (*a*) the N—N linkage, (*b*) the C(1)—N(7) bond. Values of α_1, α_2, α_3, and α_4 are given in Table 8.

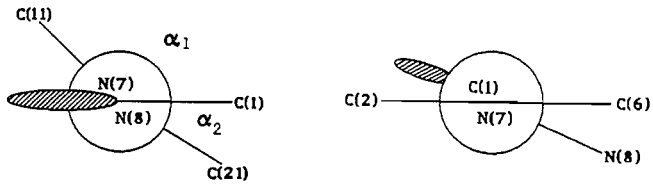

FIG. 5. Newman projections of the central fragment of the diphenylpicrylhydrazyl free radical (*a*) the N—N linkage, (*b*) the C(1)—N(7) bond. Values of α_1, α_2, are given in Table 8. The shaded area represents the assumed location of the lone-pair orbitals of N(7).

values found here (*i.e.*, 1.414(3) and 1.413(3) Å for D2N(y) and D2N(o), respectively). This illustrates the role of the *p*-nitro substitutes in enhancing resonance interaction with the hydrazine nitrogen atoms when the interplanar angles between the phenyl ring and nitrogen plane permit such interaction.

The *p*-nitro substituents may also be assumed to play a role in enhancing resonance interaction between the picryl group and the hydrazine atom N(7). However, the N(7)—C(1) distances are much shorter than the bonds to N(8), suggesting that the *o*-nitro groups of the picryl ring further enhance the resonance interaction.

The dihedral angles between the planes fitted to the picryl ring and to atoms C(1), N(7), and N(8) are larger than those (17.1(5)°) found for 2,2-diphenyl-1-picrylhydrazine (1) and those (14.8(3) and 12.8(2)°) for the two independent molecules in 2,4,6-trinitroanalinocarbazole (2). However, they are smaller than the values (31.6 and 34.5°) found for the related hydrazyl, where the conformational flexibility is not restricted by an intramolecular hydrogen bond (6).

Views of the Newman projections (20) along the N(7)—N(8) bond and along the C(1)—N(7) are given in Fig. 4 for the D2N molecule, and Fig. 5 for the picrylhydrazyl. The atom arrangement around the N—N linkage shows a staggered conformation, which minimizes the steric repulsions between the picryl group at one end of the N—N linkage and the aromatic groups at the other.

The large torsional angles (α_3 and α_4 in Table 8) between the N(7) σ-bond plane and the N(8) σ-bond plane indicate suppression of resonance interaction between the picryl group and the aromatic groups, through the N—N linkage, consistent with the observation that the influence of the *para*-substituents of the phenyl groups on the chemical shift of the hydrazine proton and carbon atoms of the picryl groups is insignificant (21).

The hydrazine nitrogen atoms in the picrylhydrazine molecules are sp^2 hybridized and the N—N bond lengths are essentially those of a single bond. However, they are shorter than the N—N bond lengths of 1.449(4) Å in the hydrazine (H_2N—NH_2) molecule (22) and 1.451(3) Å in dimethyldi(di-

[a]See ref. 25 for definitions.

phenylphosphino)hydrazine (23), but are much longer than the N—N double bond (1.24 Å) in the 2,2′,4,4′,6,6′-hexanitroazobenzene molecule (24).

The shortening of the N(8)—C(11) bond through resonance interaction with the *p*-nitro group on the phenyl group C(11)—C(16) leads to an increase in the N(7)—N(8) bond lengths to 1.414(3) and 1.413(3) Å, from the values of 1.381(5) and 1.400(5) Å found in the structures of crystals of 2,2-diphenyl-1-picrylhydrazine crystallized from tetrahydrofuran and chloroform (1), and 1.381(3) and 1.380(4) Å found for the two independent molecules in the structure of 2,4,6-trinitroaniline (2).

The *o*-nitro substituent on the picryl group not involved in the intramolecular hydrogen bond forms a large dihedral angle (angle between planes A and D in Table 5) with the plane of the picryl group, because of steric repulsion from the aromatic groups at the other end of the N—N linkage. The *p*-nitro substituent of the picryl group forms a non-zero rotation angle (angles between planes A and C in Table 5) with respect to the picryl plane, caused by the steric hindrance effect of neighboring molecules in the crystals. In 2,2-diphenyl-1-picrylhydrazyl (6) and in potassium 1-(*N*,*N*-diphenylhydrazono)-2,4,6-trinitrobenzenide (7) there is no intramolecular hydrogen bonding, and both *o*-nitro groups are rotated significantly from coplanarity with the picryl ring.

The deviations of the angles of the picryl ring from 120° are related to the properties of the substituents (25). The larger endocyclic angles at atoms C(2), C(4), and C(6) are induced by the electron-withdrawing properties of the nitro groups attached there. As a consequence of these enlarged angles, the endocyclic angles at C(1), C(3), and C(5) are decreased to maintain closure of the phenyl ring. The relatively larger decrease of the angle at C(1) arises from the electron-donating property of the hydrazine group attached there.

The endocyclic angles at atoms C(2), C(4), and C(6), the dihedral angles formed by the nitro groups with the phenyl plane, and the C—NO_2 bond lengths are all mutually correlated, as expected.

The puckering of the six-member ring of the trinitroanilino groups was analyzed using the method of Cremer and Pople (26–28). The configuration is described by the amplitude of the puckering with respect to the mean plane of the molecule and by phase angles which define the character of the puckering. The results indicate that the picryl rings have half-boat[7] conforma-

[7]The half-boat conformation of the six-membered ring is analogous to the envelope conformation which applies to five-membered rings, except that five (rather than four), atoms are near a common plane in the case of the six-membered ring.

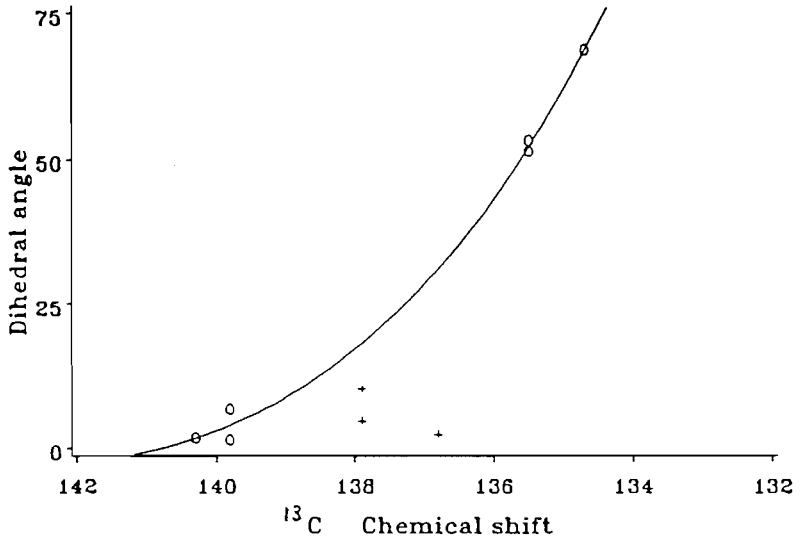

FIG. 6. Correlation of the out-of-plane rotation angles (deg) of the nitro groups and the ^{13}C chemical shifts (ppm) of the carbon atom on which the nitro group is substituted for the picryl rings in D2N(o) and D2N(y) and 2,2-diphenyl-1-picrylhydrazine. The values of the chemical shifts are given with respect to the internal TMS peaks. (○, *o*-nitro groups; +, *p*-nitro groups).

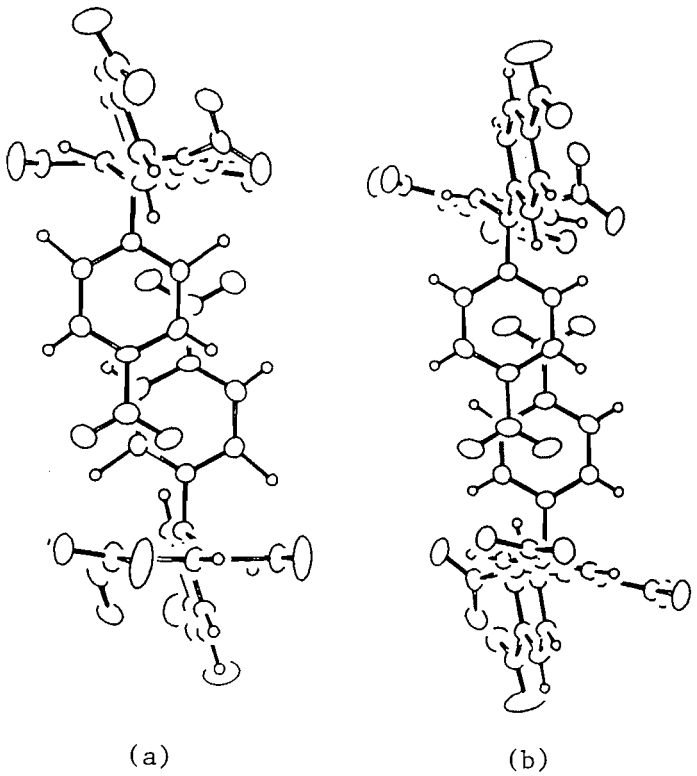

FIG. 7. Overlap of adjacent molecules of (*a*) D2N(y), (*b*) D2N(o).

tions. The puckering amplitudes Q of the picryl rings in the hydrazines (0.059 and 0.102 in D2N(y) and D2N(o)) are larger than that in the hydrazyl free radical (6) but smaller than that in the hydrazinate (0.23). The puckering coefficients of all three substituted phenyl rings in the hydrazines D2N(y) and D2N(o) are listed in Table 9.

Since the NMR chemical shift is directly related to the electron density at the nucleus, its magnitude for the carbon (^{13}C) atom on which a nitro group is substituted will be affected by the rotation angle of the nitro group with respect to the picryl plane. Unfortunately, the available chemical shifts were measured in liquid solution, whereas the rotation angles of the nitro groups were obtained in the crystal. The molecular structure in the crystal is not necessarily identical to that in solution. However, the steric hindrance between the diarylamino group and the picryl group, as well as the intramolecular hydrogen bond, restrict the *o*-nitro groups from rotating about their C—N bonds, and the rotation angles of the two *o*-nitro groups in the solid state are expected to be similar to those in solution.

A plot of the dihedral angle between the plane of the nitro groups on the picryl rings and the plane of the ring to which they are bonded (as determined from the X-ray diffraction results) versus the ^{13}C chemical shift of the nitro-bonded carbon atoms for D2N and 2,2-diphenyl-1-picrylhydrazine, is given in Fig. 6. The ^{13}C NMR spectra of D2N and 2,2-diphenyl-1-picrylhydrazine were obtained at 250 K in acetone-d_6 by Currie *et al.* (21). All *p*-nitro groups, including those on the picryl rings, have greater freedom to assume a variety of angular positions about their N—C bonds than do the *o*-nitro group, in response to the variations in their environments in the liquid. The rotational freedom of the *p*-nitro groups is manifested by their large temperature factors. Therefore, the curve through the points in Fig. 6 was fitted only to those points representing the *o*-nitro groups. The large deviations of those points representing the *p*-nitro groups from the curve indicates either that their N—C rotation angles in the solid state are substantially smaller than the time-averaged values in solution, or that carbon atoms with *para* substituents have considerably different chemical shifts than those with *ortho* substituents (24).

Molecular packing

In many cases, for a given molecule, crystal forms with different molecular packing may be obtained under different crystallization conditions, particularly from different solutions. In our case, however, the yellow form and the orange form of D2N were crystallized virtually simultaneously, from a common dichloromethane solution.

The two crystal forms were examined by EPR to investigate the possibility that one or the other might have been nucleated

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

by picrylhydrazyl free radicals, possibly present as an impurity in the original solution. However, the EPR spectral traces showed no evidence for the presence of free radicals in either crystal form.

The two forms of D2N have similar melting points, 124.8°C for the yellow form and 119.5°C for the orange form. They presumably have similar enthalpies of crystallization and similar probabilities of nucleating in dichloromethane solution. The difference in color between the two crystal forms must be a consequence of the difference in molecular packing. For example, a recent study of a series of perylene derivatives by Klebe *et al.* (29) showed such an effect. The absorption characteristics of these derivatives were assumed to be influenced by the electronic interaction between two adjacent perylene moieties which packed with their planes roughly coplanar, and which were separated by 3.34–3.65 Å. In both D2N(y) and D2N(o), the plane of the *p*-nitrophenyl group containing C(21) is coplanar with the plane of the same group of an adjacent molecule related by a center of symmetry. The overlapping area of the two planes for molecules in the D2N(y) crystal is only slightly different than that in the D2N(o) crystal, as illustrated in Fig. 7. Nevertheless, the small difference in overlap may account for the difference in color.

D2N crystals do not form chains, as is the case in 9-(2,4,6-trinitroanilino)carbazole (2). This may be related to the presence of the *p*-nitro substituents on the phenyl group, which decreases the overall polarity of the molecule, and to the absence of a bond forcing the two phenyl groups to be nearly coplanar.

An unexpected acyloin rearrangement and oxidation of a camphor derivative

JOHN M. MCINTOSH[1] AND KENNETH C. CASSIDY[2]

Department of Chemistry and Biochemistry, University of Windsor, Windsor, Ont. Canada N9B 3P4

Received February 15, 1991

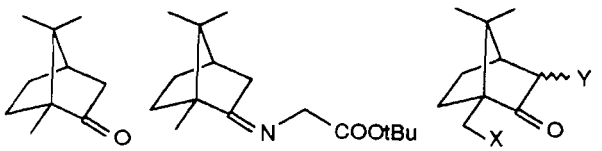
JOHN M. MCINTOSH and KENNETH C. CASSIDY. Can. J. Chem. **69**, 1315 (1991).

The trimethylsiyl ether **7** derived in two steps from camphor underwent ring expansion via an acylion rearrangement to afford two products (**8** and **9**) when desilylation was attempted. Compound **9** was stable but **8** was oxidized in air to homocamphoric acid anhydride **11**.

Key words: camphor, acyloin rearrangement.

JOHN M. MCINTOSH et KENNETH C. CASSIDY. Can. J. Chem. **69**, 1315 (1991).

Lorsqu'on essaie d'effecteur une désilylation de l'éther triméthylsilylé **7**, obtenu en deux étapes à partir du camphre, celui-ci subit une extension de cycle par le biais d'une transposition aux acyloïnes qui conduit à deux produits (**8** et **9**). Le composé **9** est stable, mais le produit **8** est oxydé par l'air en anhydride de l'acide homocamphorique **11**.

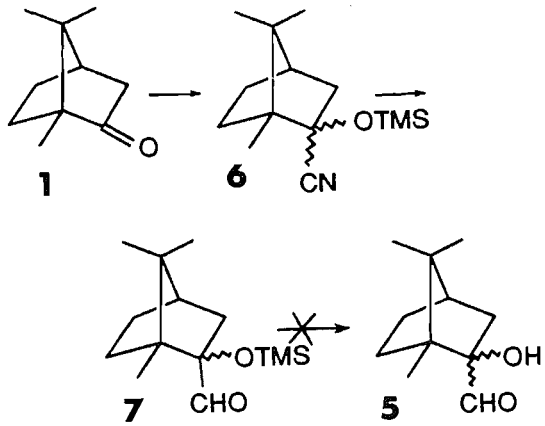


Mots clés : camphor, transposition aux acyloïnes.

[Traduit par la rédaction]

Introduction

The literature on the chemistry of camphor (**1**) is enormous. This extraordinarily compact structure has been exposed to almost every conceivable reaction condition and a great diversity of products has been isolated (1). Recently the chemistry of camphor has enjoyed a renaissance due to its use in asymmetric synthesis. It has served as both a direct source of chiral centres of known configuration (2) and as a chiral directing agent (3).[3] The factors that make camphor attractive in this area are its ready availability in both enantiomeric forms, its rigid structure, which limits the influence of conformational change on reaction pathways, and the number and diversity of known transformations that allow access to other chiral molecules of known configuration, which frequently are not obviously related to **1**.



For a number of years, we have been engaged in a study of the stereochemistry of the alkylation of chiral imines of glycinate esters. Much of the work has centred on the use of the camphor imine **2**. Our results in this area have been documented (4), as has our inability to perform aldol condensations on the enolate of **2**. A number of reports (5) suggested to us that the incorporation of a second centre, hydroxylic in nature, into the skeleton of **1** might facilitate such aldol condensations. We have already reported (6) the approaches we took to the preparation of **3** and **4**, and the unexpected product obtained when **4** was

1 **2** **3** X=H, Y=OH **4** X=OH, Y=H

condensed with *tert*-butyl glycinate. We now report the unexpected transformation found when the preparation of the camphor derivative **5** was attempted.

The proposed synthesis of **5** is shown in Scheme 1. The mixture of cyanohydrin ether stereoisomers **6** was prepared in 95% yield as previously described (7). Reduction of **6** with

1 **6** **7** **5**

SCHEME 1

DIBAL-H proceeded uneventfully to give the silyl ether (**7**) of the desired hydroxyaldehyde **5**. NMR analysis of both **6** and **7** indicated an approximately 6:1 ratio of stereoisomers. The accepted mechanism (7) for the formation of cyanohydrin TMS ethers with TMSiCN involves attack of cyanide ion on a ketone–trimethylsilyl complex. Assuming that this is a kinetically controlled process, it suggests that the isomer of **6** with an *endo*-oriented cyano group should be preferred.

The desilylation of **7** proved to be anything but routine. Exposure to either Bu_4NF or $BF_3 \cdot OEt_2$ in CH_2Cl_2 afforded two products (**8** and **9**) that were isomeric with both product **5** and each other. However, neither of these exhibited the expected aldehyde proton in the ^1H NMR. The ratio of these was found to be approximately the same as the ratio of the stereoisomers **6** and **7**.

Both **8** and **9** had the molecular weight (mass spectra) of 182 ($C_{11}H_{18}O_2$). The ^1H and ^{13}C NMR spectra for **8** and **9** are given in Tables 1 and 2. The infrared of both compounds indicated the presence of both a carbonyl and an alcohol group. The ^{13}C NMR (both proton decoupled and DEPT-135 edited) of the major product showed three quaternary methyl groups, a ketonic carbon, a secondary carbinol carbon, three methylene groups, and one other methine carbon. The ^1H NMR confirmed the presence of three methyl groups (singlets) and a one-proton triplet. Decoupling experiments revealed that the signal at δ = 4.21 was coupled with protons resonating at δ = 2.32 and 2.15

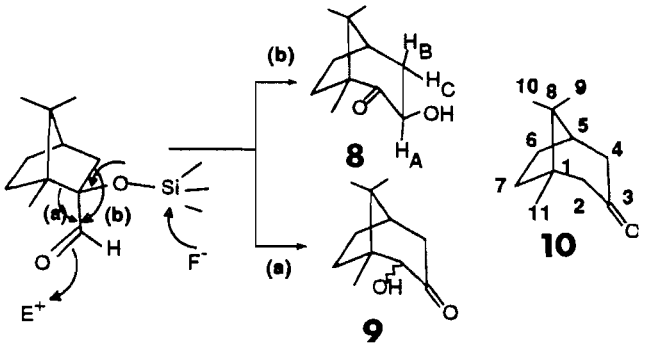
[a]See ref. 9.

On the basis of these data, the assignments given in Table 1 were made and the structure **8** assigned to this compound. The stereochemistry is inferred from the coupling constants calculated for the energy-minimized conformation of **8**. The dihedral angles bewteen protons A and B (151°) and A and C (35°) respectively predict (8) coupling constants of similar magnitude (ca. 8 Hz) and this agrees with the observed triplet. The lack of extraneous signals in the ^{13}C NMR of **8** and in the ^{1}H and ^{19}F NMR of its Mosher ester indicates that only one of the possible diastereomers was present. The dihedral angles calculated for the epimer (30° and 85°) lead to coupling constants that vary widely in magnitude and do not agree well with those observed.



The minor isomer had many of the same characteristics but the Mosher ester could not be formed. The NMR data ensure that only one steroisomer is present and the most obvious differences with **8** were the presence of an AB quartet with signals at δ = 2.75 and 2.3 and that the secondary carbinol proton appeared as a slightly broadened *singlet* (δ = 4.00). Decoupling experiments showed that this signal was coupled only to the OH proton. Further, the signals at 2.75 and 2.3 were coupled to each other and the latter was also coupled to a signal at 2.0. These data and other decoupling experiments led to the assignments shown in Table 2. On the basis of the NMR evidence and a proposed mechanism, the structure **9** was suggested for this compound. The proton and carbon NMR data for the related compound **10** have been reported by Lightner and co-workers (9). The resonance assignments were made without comment and the values we obtained for **9** were consistent with those reported. In an effort to assign the stereochemistry of **9**, the NOE difference spectrum was obtained. The secondary carbinol proton showed a strong positive correlation with the methyl group at 1.25 ppm and a much weaker interaction with the methyl group resonating at 0.95 ppm in the ^{1}H spectrum. The 1.25 ppm methyl singlet also showed close proximity to the proton resonating at 2.75 ppm. These data appear to require the *endo* configuration of the C-2 hydroxy group in **9**. If structure **9** is correct, the methyl resonance at 1.25 would necessarily be due to C(9) and that at 0.95 would be C(11), assignments that do not correspond to those reported for compound **10**. That our assignments for **9** are correct was shown by the proton–carbon correlated 2-D spectra, which indicated the positive correlations shown in Table 3.

It is possible that **8** and **9** are formed independently as shown in Scheme 2 or that they represent a mixture that can be formed from, and equilibrate via, a common ene-diol intermediate. Such an equilibrium was observed in reactions of **3** (6). The latter case seems unlikely since the same ratio of **8** and **9** was

obtained using Bu_4NF and $BF_3 \cdot OEt_2$ and the former would be unlikely to cause enolization of either **8** or **9**. In the former case, the stereoisomer of **8** and **9** that is produced will, of course, depend on which of the two diastereotopic faces of the aldehyde carbonyl group is attacked by the migrating bond.

At this point, the 2-D spectra of **8** were desired to compare with those of **9**. In preparation for these experiments, the normal spectra were re-recorded and it was clear that the original material had been essentially completely converted into another product **11**. This process had occurred while crystals of **8** had been allowed to stand in air at ambient temperature. This material showed a doubling of the carbonyl band in a region suggestive of a six-membered ring anhydride, but *no* hydroxyl absorptions in the infrared spectrum. Both the mass spectrum (molecular weight = 198, $C_{11}H_{16}O_3$) and the DEPT-135 edited ^{13}C NMR indicated the presence of only 16 protons, suggesting an oxidation had occurred. In addition, the ^{13}C NMR (Table 4) showed two carbonyl carbons at 173 and 170 ppm and no sp^3 carbon attached to oxygen. These data seemed best accommodated by homocamphoric anhydride **11** (Fig. 1).

Hydrolysis of **11** provided the known (10) diacid **12** (homocamphoric acid). The NMR spectra of homocamphoric acid have apparently not been described. However, the similarity of the ^1H and ^{13}C spectra with those of the well-known camphoric acid (11*a,c*) and camphoric anhydride (11*b*; ^1H NMR) and the coincidence of the melting point of **12** obtained in this work to that reported (10) in the literature ensure the structural assignment.

The facile rearrangement of **5** to **8** and **9** is an example of an acyloin rearrangement (12). The stereospecific acid-catalyzed reaction has been most thoroughly studied in the context of the expansion of the D-ring of steroids, but alkaloid and terpene

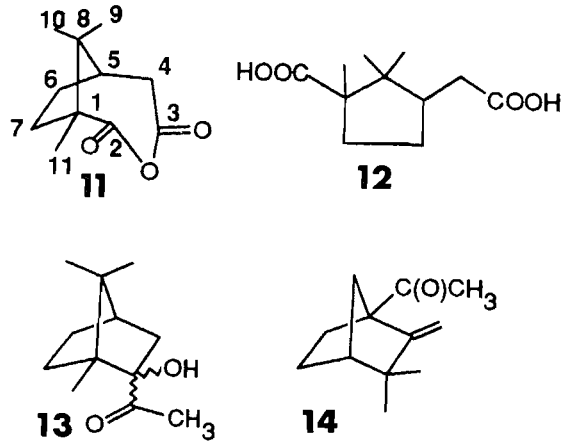

FIG. 1.

examples are also well known (see, for example, ref. 13). However, to our knowledge, it does not seem to have been reported in the literature on camphor. Relief of ring strain would seem to be the likely driving force for the rearrangement, but the corresponding methyl ketone **13** ("2-acetylborneol") has been prepared (14) and rearranged under vigorously acidic conditions ($KHSO_4$, 180°C) to give **14** ("2-acetylcamphene"). A variety of other ring-opened and rearranged bicyclo[2.2.1]heptyl products, but no ring-expanded products, were described. The rearrangement outlined here must be considered to be yet another chapter in the story of the molecular gymnastics of camphor derivatives.

It is not clear why **8** should be so sensitive to aerial oxidation. The isomer **9** does not exhibit this reactivity, nor do more highly strained molecules such as 3-hydroxycamphor (6). The failure of **9** to undergo the same oxidation also argues against the interconversion of **8** and **9** as noted previously. At this time we cannot comment meaningfully on this reaction.

Experimental

Infrared spectra were run as neat liquids or KBr mulls; NMR spectra were run at 300 MHz for ^1H and 75 MHz for ^{13}C in $CDCl_3$ solution. Assignments shown in brackets ([ ]) may be interchanged. DEPT editing refers to the DEPT-135 pulse sequence. Where this was performed, the multiplicities that would have been seen in the proton-coupled spectra are indicated. Column chromatography utilized silica gel 60 (Merck), solvents were removed under reduced pressure, and the drying agent used was anhydrous magnesium sulfate. Mosher esters were prepared from commercially available (*R*)-(+)-α-(trifluoromethyl)phenylacetic acid using the literature procedure (15). Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn.

Preparation of 2-hydroxy-1,7,7-trimethylbicyclo[2.2.1]heptane-2-carboxaldehyde TMS ether (7)

To a cooled solution of 62 g (0.25 mol) of crude **6** (7) in 100 mL of dry toluene was added 190 mL of a solution of DIBAL (1.5 M in toluene) dropwise with stirring. After the addition was complete, the solution was allowed to warm to ambient temperature. TLC (4% pet. ether/ether) analysis showed starting material was still present so the solution was refluxed gently for 3 h. The cooled solution was poured slowly over a mixture of 75 mL of H_2SO_4 and stirred overnight. The solution was filtered, the organic layer separated, and the aqueous layer extracted with toluene. The combined organic layers were dried and evaporated to afford an oil (60 g), which was distilled to give **7** as a 6:1 mixture of epimers (48 g, 75%), bp 75–80°C (0.1 Torr; 1 Torr = 133.3 Pa); IR (neat): 2957, 1731, 1252, 1124 cm^{-1}; ^1H NMR: 9.52 [9.41] (s, 1H), 2.15 (m, 1H), 1.82–1.5 (m, 3H), 1.45–1.00 (m, 3H), 0.95 [0.97] (s, 3H), 0.91 [0.90] (s, 3H), 0.82 (s, 3H), 0.09 (s, 9H).

				20.50	q	[C10]

Anal. calcd. for $C_{14}H_{26}O_2$: C 65.88, H 10.27; found: C 65.74, H 10.32.

Chromatography failed to separate the epimers.

Attempted preparation of 2-hydroxy-1,7,7-trimethylbicyclo[2.2.1]-heptane-2-carboxaldehyde (5)

To 10 mL of CH_2Cl_2 was added 3.5 g (0.014 mol) of **7**. The solution was cooled to 0°C in ice and 1.8 mL (0.015 mol) of $BF_3O \cdot OEt_2$ was added slowly. After 15 min, GC (column A) showed no starting material. The solution was allowed to warm to room temperature and then quenched by the slow addition of saturated aqueous $NaHCO_3$. The organic layer was separated, the aqueous layer was extracted with ether, and the combined organic layers dried and evaporated to afford a white solid that showed two components on TLC analysis (R_f 0.37 and 0.52, 2:1 pet. ether:ether). The mixture was chromatographed to afford 0.4 g of **9** (MS: m/z = 182; mp 154–156°C; IR: 3481, 2922, 1716, 1059 cm^{-1}) and 1.04 g of **8** (MS: m/z = 182; mp 175–184°C (dec); IR: 3475 (br), 2966, 1707, 1024 cm^{-1}). The ^1H and ^{13}C NMR data for **8** and **9** can be found in Tables 1 and 2. Anal. calcd. for **9** ($C_{11}H_{18}O_2$): C 72.49, H 9.95; found: C 72.05, H 9.94.

The same result was obtained when **7** was treated with $Bu_4N^+F^-$ in THF.

Only unsatisfactory analytical data could be obtained for **8**, presumably due to oxidation to **11**.

The Mosher ester of **8** was prepared as follows. To 1 mL of dry pyridine was added 100 mg of **8**. The solution was cooled to 0°C and 0.15 g of MPTA-Cl (14) was added. A precipitate formed instantly. The mixture was stirred overnight while warming to ambient temperature, then poured into 5 mL of 10% HCl and extracted with ether. The ether was dried and evaporated to give 0.27 g of a yellow oil, which was purified by column chromatography. The yield of purified ester was 71%; IR: 2972, 1750, 1721, 1258, 1169 cm^{-1}; ^1H NMR: 7.72 (m, 2H), 7.45 (m, 3H), 5.62 (t, 1H, J = 9.6 Hz), 3.71 (s, 3H), 2.30–1.05 (m, 7H), 1.02 (s, 3H), 0.95 (s, 3H), 0.82 (s, 3H); ^{13}C NMR: 207.11, 166.03, 132.41, 129.52, 128.31, 127.50, 73.83, 57.78, 55.78, 47.40, 44.29, 34.19, 33.66, 27.15, 23.15, 19.81, 13.61; ^{19}F NMR: 5.55 (TFA = 0).

After standing at room temperature in air for several days, compound **8** had been transformed into **11**. This was separated from residual **8** by chromatography and obtained as a white solid, mp 138–140°C; IR: 2972, 1782, 1745, 1118, 1041 cm^{-1}. The ^1H and ^{13}C NMR data are given in Table 4.

Homocamphoric acid (12)

Anhydride **11** (50 mg, 0.25 mmol) was added to 1 mL of H_2O containing 50 mg of NaOH. The mixture was refluxed 1 h, cooled, and stirred at room temperature overnight. Acidification with concentrated HCl gave a white precipitate, which was dissolved in ether, washed with brine, dried, and evaporated to afford **12** (81%) as a white powder, mp 237–238°C (dec.) (lit. (10) mp 238°C); IR: 3266–2800, 2945, 1696, 1313, 1303 cm^{-1}; ^1H NMR: 11.05 (s, 2H), 2.4–2.04 (m, 3H), 2.02–1.75 (m, 2H), 1.40–1.15 (m, 2H), 1.10 (s, 3HO, 0.98 (s, 3H), 0.65 (s, 3H); ^{13}C NMR: 177.36 (s), 174.40 (s), 54.87 (s), 44.29 (s), 43.20 (d), 35.26 (t), 31.92 (t), 26.61 (t), 21.81 (q), 21.39 (q), 19.32 (q).

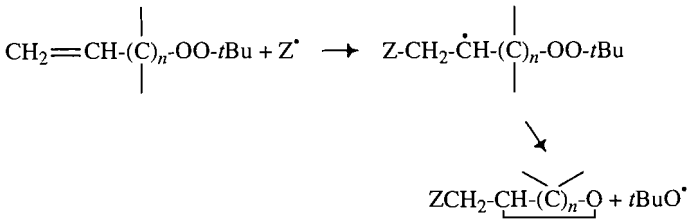
Reçu le 6 décembre 1990

X. LUBEIGT, F. FLIES, M. J. BOURGEOIS, E. MONTAUDON et B. MAILLARD. Can. J. Chem. **69**, 1320 (1991).

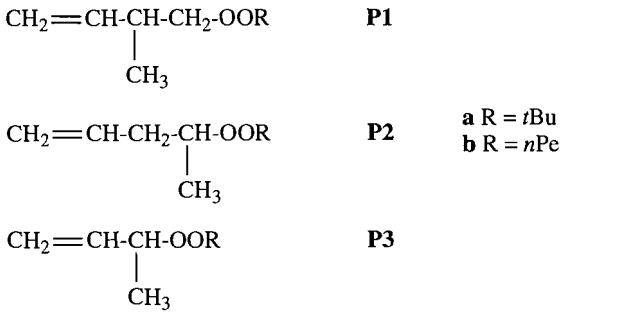
La décomposition induite dans le chlorure de méthylène de peroxydes β- et γ-insaturés comportant un substituant sur la chaîne liant la fonction peroxydique et la double liaison est étudiée. La stéréochimie des oxiranes et oxétanes disubstitués obtenus est déterminée par RMN ^{13}C. La stéréosélectivité de la réaction est discutée.



Mots clés : peroxydes insaturés, substitution homolytique intramoléculaire, addition radicalaire, hétérocycles oxygénés.

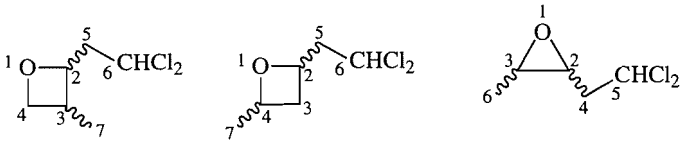
X. LUBEIGT, F. FLIES, M. J. BOURGEOIS, E. MONTAUDON, and B. MAILLARD. Can. J. Chem. **69**, 1320 (1991).

Homolytic decomposition induced by addition of dichloromethyl radicals to β- and γ-unsaturated peroxides having a substituent on the chain linking the unsaturation and the peroxide function was studied. The stereochemistry of the heterocycles produced was determined by ^{13}C NMR and the stereoselectivity of intramolecular homolytic substitution on the peroxidic bond discussed.



Key words: unsaturated peroxides, homolytic intramolecular substitutions, radical additions, oxygenated heterocycles.

Depuis plusieurs années nous avons abordé l'étude de la décomposition induite de composés peroxydiques insaturés et montré l'intérêt synthétique de cette réaction pour l'obtention d'hétérocycles oxygénés :



Nous avons, au cours de travaux précédents (1), déterminé les limites d'application de cette réaction. Nous venons d'aborder l'étude de la stéréochimie des substitutions homolytiques intramoléculaires de radicaux alkyle sur des liaisons peroxydiques. Cette analyse a été réalisée à partir des additions radicalaires du chlorure de méthylène à des composés peroxydiques insaturés comportant un substituant sur la chaîne liant les deux fonctions réactives que sont la double liaison et la liaison O—O. Nous avons ainsi mis en évidence l'existence d'une certaine stéréosélectivité dans la formation d'hétérocycles à cinq chaînons (2). La prédominance de l'isomère *cis* ou *trans* dépend tout d'abord de la position relative des substituants et est influencée notamment par leur taille et celle du radical oxyle partant; par contre le volume du radical Z attaquant la double liaison et la température à laquelle est effectuée la réaction n'ont que peu d'influence sur la stéréosélectivité.

Ayant vu précédemment (3, 4) que les peroxydes β- et γ-insaturés subissent une décomposition homolytique induite pour conduire à des oxiranes et des oxétanes, nous avons voulu compléter le travail précédent par l'étude de la stéréochimie des hétérocycles susceptibles de se former par addition radicalaire du chlorure de méthylène aux peroxydes modèles suivants :

Identification des éthers cycliques

Les hétérocycles attendus sont les suivants :

1 **2** **3**

La technique généralement utilisée pour identifier les hétérocycles diastéréoisomères X et Y repose sur l'analyse des spectres RMN ^{13}C des mélanges : (1) les signaux correspondant à X et à Y sont repérés : ceci ne présente de difficultés que si X et Y sont en proportions relatives peu différentes; (2) la corrélation signal–carbone basée sur des déplacements chimiques est facilitée par la technique du DEPT et, éventuellement, par analogie avec les spectres de composés voisins décrits dans la littérature; (3) l'attribution *cis–trans* est réalisée par comparaison des différences de déplacements chimiques ($\Delta\delta$) de chaque carbone des deux isomères avec les valeurs correspondantes des modèles de la littérature, lorsque ceux-ci sont connus. Dans les cas où cette analyse n'est pas possible ou ne permet pas de tirer des conclusions, d'autres méthodes d'identification sont utilisées.

TABLEAU 1. RMN $^{13}C^a$ des oxétanes disubstitués en 2,3

Oxétane		Carbone 2	3	4	5	6	7	Attribution
	trans	85,0	37,4	73,5	22,8		17,5	
R1	*cis*	79,6	31,8	74,5	16,9		13,0	
	$\Delta\delta^b$	+5,4	+5,6	−1	+5,9		+4,5	
	X	86,5	36,4	78,0	51,3	70,2	18,4	*trans*
1	Y	81,8	32,5	79,4	46,7	70,8	14,6	*cis*
	$\Delta\delta^b$	+4,7	+3,9	−1,4	+4,6		+3,8	

[a] δ en ppm par rapport au TMS.
[b] Pour la référence, $\Delta\delta = \delta(trans) - \delta(cis)$; pour **1**, $\Delta\delta = \delta(X) - \delta(Y)$.

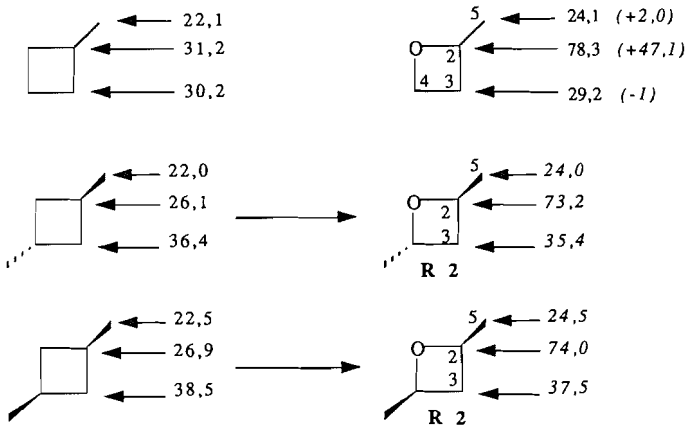
2-(2,2-Dichloroéthyl)-3-méthyloxétane, 1

Le composé modèle le plus proche est le 2,3-diméthyloxétane, **R1** (5). Le repérage des signaux correspondant à X et à Y d'une part, la corrélation signal–carbone d'autre part, ne présentent pas de difficultés. Les variations de déplacement chimique des différents carbones montrent que les composés X et Y ont respectivement les configurations *trans* et *cis* (tableau 1).

2-(2,2-Dichloroéthyl)-4-méthyloxétane, 2

Cette étude s'avérait difficile en raison de la faible différence de proportions des diastéréoisomères d'une part, et de l'absence de données de la littérature d'autre part. L'obtention d'une fraction enrichie en l'un des isomères, par HPLC, a permis d'éliminer la première difficulté. Afin de pallier la seconde, nous avons calculé, par une technique d'incrémentation, les déplacements chimiques des carbones du 2,4-diméthyloxétane, **R2**, à partir de ceux du 1,3-diméthylcyclobutane, du 2-méthyloxétane et du méthylcyclobutane (5, 6).

La comparaison des déplacements chimiques des carbones des méthylcyclobutane et 2-méthyloxétane permet de déterminer l'influence de l'oxygène sur les carbones vicinaux (figure 1). Les déplacements chimiques des carbones des isomères *trans* et *cis* de **R2** peuvent alors être estimés empiriquement, à partir des spectres des 1,3-diméthylcyclobutanes *trans* et *cis* et des incréments calculés. Les valeurs théoriques ainsi estimées sont rapportées dans le tableau 2.



Les quantités relatives voisines des composés X et Y dans le mélange rendent difficiles le repérage des isomères et la corrélation signal–carbone : il reste d'ailleurs une indétermination au niveau des carbones 2 et 4. La comparaison des spectres des oxétanes chlorés avec ceux calculés pour les 2,4-diméthyloxétanes suggère l'attribution indiquée dans le tableau 2.

1,1-Dichloro-3,4-époxypentane

Les modèles de la littérature (7, 8) apportent peu d'éléments de comparaison; le 2,3-époxypentane, **R3**, est décrit dans le tableau 3 à titre d'exemple. L'attribution *cis–trans* ne peut donc se faire comme précédemment.

Les diastéréoisomères X et Y constituant l'époxyde **3** ont pu être séparés par HPLC, ce qui a facilité l'analyse. Si le repérage des carbones 4, 5 et 6 est aisé, grâce aux techniques habituelles (tableau 3), il n'en est pas de même pour les carbones 2 et 3 qui ne peuvent être différenciés a priori; une proposition sera formulée.

L'identification de X et Y (respectivement *trans* et *cis*) est rendue possible grâce aux carbones 4 et 6 (tableau 4). Il est en effet connu, et cela peut être observé dans les dérivés des oxétanes et des tétrahydrofuranes (2), que dans les composés

expérimental ; *calculé*

FIG. 1.

comportant deux substituants vicinaux (ici CH_3 et CH_2CHCl_2), les carbones correspondants sont plus blindés par effet γ dans l'isomère *cis* que dans l'isomère *trans*.

Proposition d'attribution des carbones 2 et 3

Une proposition peut être faite pour lever l'indétermination relative au repérage des carbones 2 et 3 de chacun des diastéréoisomères X et Y de l'époxyde **3**. Il s'agit d'un calcul empirique, basé sur des observations effectuées sur le 2-éthyl-3-méthyltétrahydrofurane et son homologue dichloré (figure 2) : on remarque en effet que la présence de deux chlores sur le substituant éthyle entraîne un fort blindage du carbone γ (carbone 2) et un déblindage du carbone δ (carbone 3).

Si cette remarque est également valable dans le cas des époxydes, on peut alors essayer de différencier les carbones 2 et 3 pour chaque isomère, à partir des données de la littérature (7) et de ces incréments. Les valeurs indiquées dans la figure 2 ne constituent qu'une proposition et non une affirmation, compte tenu du mode de détermination des incréments (issus d'un hétérocycle différent) d'une part, et des faibles différences des déplacements chimiques observés d'autre part.

Résultats

L'addition radicalaire du dichlorométhane aux différents peroxydes insaturés a été réalisée en présence de peracétate de *tert*-butyle, à 110°C, durant 12 h (rapport molaire 50 : 1 : 0,5). L'influence de la température sur la stéréosélectivité de la substitution homolytique intramoléculaire a été étudiée en

opérant à 80°C et à 40°C en présence de peroxyde de benzoyle et de perdicarbonate de diéthyle respectivement. Les résultats sont rassemblés dans le tableau 5.

Discussion

Comme dans le cas de la formation des hétérocycles oxygénés à cinq chaînons, nous voyons que la position relative des substituants est un facteur important sur la distribution des oxiranes et oxétanes diastéréoisomères. Par contre, que les substituants se trouvent portés par des carbones en α (essais 1, 2, 5 et 6) ou en β (essais 3 et 4) dans l'éther obtenu, c'est le composé *trans* qui est majoritaire.

L'explication de la formation préférentielle du dérivé *trans* dans le cas des dérivés α-disubstitués est la même que celle avancée pour la création des cycles à cinq chaînons : le radical attaquant adopte préférentiellement la conformation B (figure 3) dans laquelle les substituants vicinaux sont les plus éloignés. Il importe à ce niveau de remarquer que la distribution des isomères varie peu avec la taille du cycle (essais 1 et 5, et 2 et 6), la nature du radical partant, *tert*-butoxyle ou *n*-pentyloxyle (essais 1 et 2, et 5 et 6), ou la température de réaction (essais 7, 8, 1 et 11, 12, 5).

Dans le cas des cycles β-disubstitués, on observe que la taille du cycle a une influence non négligeable sur la répartition des diastéréoisomères puisque l'oxétane *trans* prédomine légère-

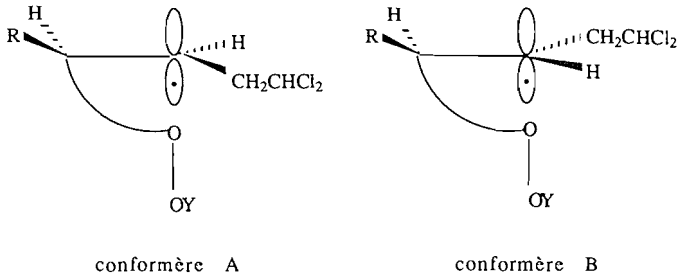

FIG. 3.

ment, alors que c'est l'inverse en série tétrahydrofurane (*cis*/*trans* : 53 : 47) (2). Ceci peut s'expliquer si l'on admet que la structure de l'éther est préétablie par la conformation qu'adopte le radical adduit dans l'état de transition. En effet, dans le tétrahydrofurane, la forme C (précurseur du composé *cis*) a une énergie plus basse que la forme D (précurseur du *trans*); dans l'oxétane, la situation est inversée (figure 4). En ce qui concerne la nature du groupe partant (essais 3 et 4) et la température de la réaction (essais 9, 10 et 3), elles n'ont pratiquement pas d'influence sur le cours de la réaction.

Une remarque importante est relative aux rendements d'obtention des oxétanes : ils sont modestes (24 et 10%, essais 1 et 3) comparativement à ceux des hétérocycles à trois (58%, essai 5) et cinq chaînons (43–58%) (2) formés à partir des peroxydes de *tert*-butyle par exemple. À côté de ces oxétanes, des peroxydes adduits **PA1** et **PA2** sont obtenus respectivement à partir des peroxydes **P1** (rendement 21%) et **P2** (rendement 20%) (figure 5) : ceci confirme que la vitesse de la substitution homolytique intramoléculaire est dans ce cas-là plus faible que celle du transfert d'hydrogène du solvant (4).

Conclusion

Les substitutions homolytiques intramoléculaires de radicaux alkyle sur les liaisons peroxydiques conduisant à la formation d'éthers cycliques à trois et quatre chaînons donnent préférentiellement l'isomère *trans*. Toutefois, on n'observe une certaine stéréosélectivité de la réaction que pour l'obtention des dérivés 2,3-disubstitués.

Partie expérimentale

Techniques analytiques

L'analyse des produits de réaction par chromatographie en phase gazeuse a été effectuée sur les appareils suivants : Intersmat IGC 112 F (ionisation de flamme, gaz vecteur : azote), équipé de colonnes en acier inox de 2 mm de diamètre intérieur : OV 17 (10% sur Chromosorb W HP, 80–100 mesh, longueur 1,5 m), FFAP (10% sur Chromosorb W AW, 80–100 mesh, longueur 2 m) et Carbowax 20 M (5% sur Chromosorb W DMCS, 80–10 mesh, longueur 3 m); et Delsi DI 200 (ionisation de flamme, gaz vecteur : azote), équipé de colonnes capillaires en silice fondue : CP Sil 5 CB (longueur 25 m, diamètre intérieur 0,32 mm) et BP 20 (longueur 25 m, diamètre intérieur 0,22 mm). Ces appareils sont associés à un intégrateur Intersmat ICR-1B donnant les temps de rétention et les surfaces des pics. Les dosages ont été effectués par la méthode de l'étalon interne.

Les spectres RMN ^1H ont été enregistrés sur des appareils Perkin–Elmer R 24B fonctionnant à 60 MHz et Bruker AC 250 fonctionnant à 250 MHz. Tous les composés étudiés sont en solution dans le tétrachlorure de carbone, en présence de TMS ou de benzène comme référence interne. Les spectres RMN ^{13}C ont été enregistrés dans des solutions de chloroforme deutéré sur des appareils Bruker WP 90 fonctionnant à 23,6 MHz et AC 250 fonctionnant à 62,9 MHz.

Les spectres de masse ont été réalisés sur un spectromètre à simple focalisation VG Micromass 16F, couplé avec un chromatographe en phase gazeuse Intersmat IGC 121M.

Techniques réactionnelles

Les réactions sont effectuées sur des mélanges constitués par le chlorure de méthylène, le peroxyde et l'amorceur dans les rapports molaires 50 : 1 : 0,5.

La durée et la température des réactions dépendent de la nature de l'amorceur : perdicarbonate de diéthyle (PDCE) : 40°C; 8 jours; peroxyde de benzoyle (PB) : 80°C; 24 h; peracétate de *tert*-butyle (PA) : 110°C; 12 h. Les conditions propres à chaque expérience sont rappelées dans les tableaux de la partie théorique.

(i) Études analytiques

La solution (2 cm^3) est introduite dans une ampoule de 10 cm^3. Celle-ci, fermée hermétiquement, est placée dans un bain d'huile thermostaté.

Les rendements sont déterminés par CPG directement sur le mélange réactionnel selon la méthode de l'étalon interne. Les proportions relatives des différents diastéréoisomères sont déduites des surfaces relatives des pics correspondants, ceux-ci étant supposés avoir le même coefficient de réponse.

(ii) Études préparatives

La solution (90 cm^3) est introduite dans un autoclave en acier de 125 cm^3 que l'on place dans une étuve préalablement chauffée à 110, 80 ou 40°C.

Après élimination du solvant, l'hétérocycle est isolé par distillation. La structure de chaque isomère est déterminée à l'aide de la RMN ^1H et ^{13}C, par comparaison avec des molécules modèles voisines de la littérature. Les pourcentages relatifs *cis*/*trans* sont obtenus par CPG.

Matières premières

(i) Amorceurs

Le *peroxyde de benzoyle*, produit commercial, est purifié par extraction au chloroforme. Le *peracétate de* tert-*butyle et le perdicarbonate de diéthyle* sont respectivement synthétisés selon les références 9 et 10.

(ii) Précurseurs des peroxydes

À l'exception de l'*hydroperoxyde de* tert-*butyle* (produit commercial séparé du peroxyde de di-*tert*-butyle, avec lequel il est en mélange, par distillation de ce dernier), du *but-3-ène-2-ol* et du *1-bromopentane*, tous les précurseurs doivent être préparés.

L'*hydroperoxyde de pentyle* est préparé selon la référence 11 par

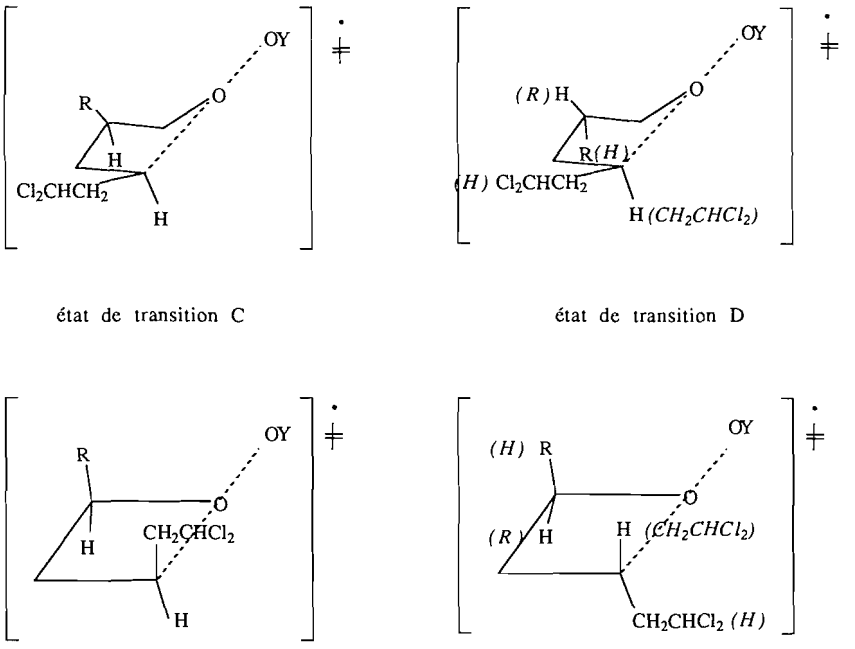

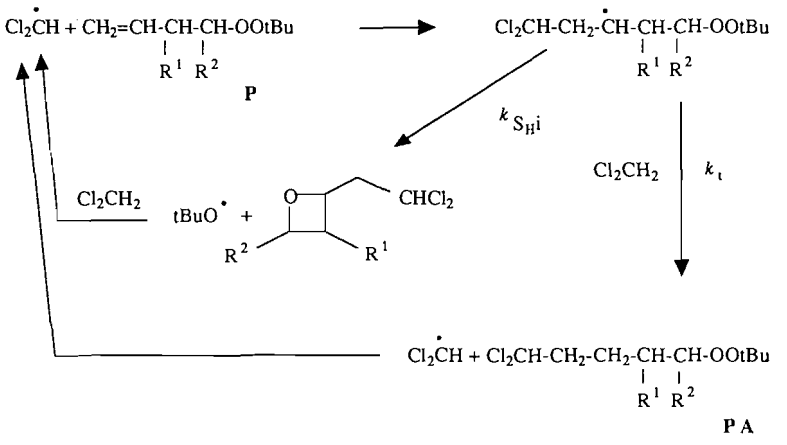

FIG. 4.

P1, PA1 : $R^1 = CH_3$, $R^2 = H$
P2, PA2 : $R^1 = H$, $R^2 = CH_3$

FIG. 5.

action de l'eau oxygénée en milieu basique sur le mésylate de 1-pentyle; Rdt 56%; n_D^{20} 1,4127; Eb_{10} 54°C (litt. (11) : Eb_4 41–42°C).

L'*hydroperoxyde de 1-méthylprop-2-ényle* est synthétisé par photo-oxygénation du but-2-ène, selon un protocole dérivé de la référence 12. Dans 100 cm^3 de CCl_4 refroidi à −20°C, on introduit lentement 40 g de but-2-ène et des traces de tétraphénylporphyrine. Un courant d'oxygène traverse la solution irradiée par une lampe de sodium de 400 W et maintenue à −20°C. Au bout de 5 h, l'hydroperoxyde est transformé en son sel de sodium à l'aide de 200 cm^3 d'une solution de NaOH 1 N. La phase aqueuse séparée est acidifiée. L'hydroperoxyde ainsi régénéré est alors extrait à l'éther. Cette solution éthérée est lavée à l'eau, puis séchée sur sulfate de sodium anhydre. Après évaporation du solvant, la pureté de l'hydroperoxyde est vérifiée par dosage; Rdt 22%.

Le *2-méthylbut-3-ène-1-ol* provient de la réduction de l'acide 2-méthylbut-3-énoïque lui-même issu de la carbonatation du bromure de but-3-ène-2-ylemagnésium.

Le *pent-4-ène-2-ol* est obtenu par condensation organomagnésienne du bromure d'allylemagnésium sur l'éthanal.

(iii) Peroxydes

Ils sont synthétisés par action de l'hydroperoxyde correspondant, en milieu basique, sur le mésylate de l'alcool convenable (préparé selon la référence 13) ou sur le 1-bromopentane (pour **P3b**), selon des méthodes mises au point au laboratoire (14–16). Leurs caractéristiques physiques et spectroscopiques sont rassemblées dans le tableau 6.

BRIAN A. KEAY and JEAN-LOUIS J. BONTRONT. Can. J. Chem. **69**, 1326 (1991).

A series of aryl bromides undergo a palladium-catalyzed coupling reaction with 3-[(*tert*-butyldimethylsilyl)oxymethyl]-4-(tri-*n*-butylstannyl)furan to provide 4-aryl-3-[(*tert*-butyldimethylsilyl)oxymethyl]furans in moderate to good yields.

Key words: palladium, cross-couplings, stannanes, 3,4-disubstituted furans.

BRIAN A. KEAY et JEAN-LOUIS J. BONTRONT. Can. J. Chem. **69**, 1326 (1991).

Des réactions de couplage, catalysées par le palladium, entre divers bromures d'aryle et le [(*tert*-butyldiméthylsilyl)oxyméthyl]-3-(triméthylstannyl)-4-furanne conduisent avec des rendements relativement faibles aux aryl-4-[(*tert*-butyldiméthylsilyl)oxyméthyl]-3-furannes.

Mots clés : palladium, couplage croisé, stannanes, furannes disubstitués en positions 3 et 4.

[Traduit par la rédaction]

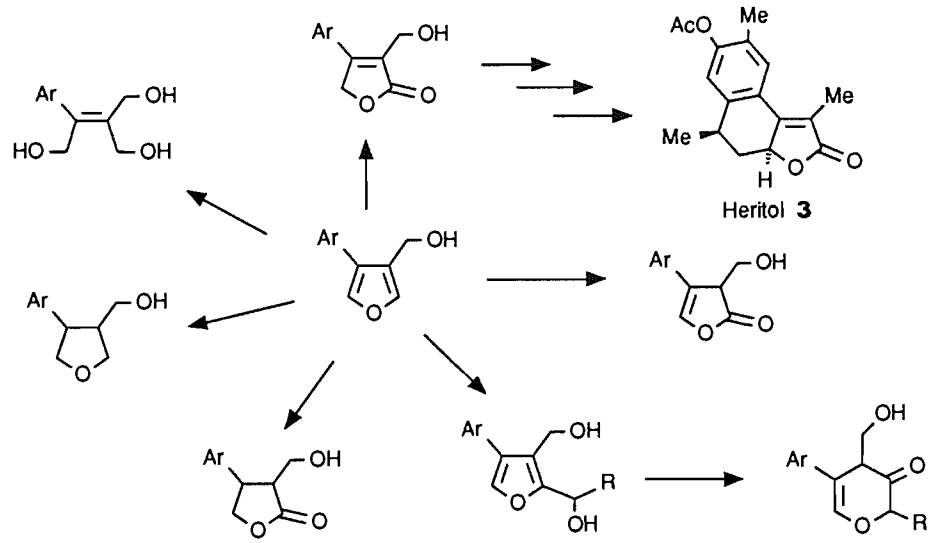
The preparation of 3,4-disubstituted furans is a formidable task since furan derivatives tend to lithiate (1) and add electrophiles (2) in the C-2 and C-5 positions. Elaborate methods for the preparation of 3,4-disubstituted furans have therefore been developed to overcome these tendencies. Some of these include inter- (3) and intra-molecular (4) Diels–Alder–retro-Diels–Alder sequences, synthesis of the furan ring from acyclic (5) and cyclic (6) precursors, and chemical modifications of commercially available 3,4-furandicarboxylic acid (7). We have recently described a simple preparation of 3,4-disubstituted furans **1** (8) via a regiospecific C-4 lithiation of 2-(*tert*-butyldimethylsilyl)-3-(hydroxymethyl)furan **2** (Scheme 1). Quenching the dianion with electrophiles followed by a carbon to oxygen silyl migration afforded 3,4-disubstituted furans **1** in good yields.

The scope of these procedures does not include the preparation of 4-aryl-3-substituted furans. Since furan rings can be converted to a variety of other ring systems (Scheme 2), we sought a general method for the preparation of 4-aryl-3-substituted furans for further elaboration into natural products such as Heritol **3**, the ichthyotoxic constituent of the mangrove plant *Heritiera littoralis* (9).

A suitable method for the introduction of aryl groups at the C-4 position of furan rings could involve the palladium-catalyzed coupling reaction between aryl halides and organostannanes developed by Stille and co-workers (10). Recent reports of successful arylhalide–arylstannyl couplings (11) and the lack of examples reported utilizing stannylfurans (12)[3] led us to study the palladium-catalyzed coupling reaction between various arylbromides and stannylfurans **4**–**7** (Scheme 1). We herein report our findings.

Stannylfurans **4**–**8** were prepared as outlined in Scheme 1. Thus, 3-(hydroxymethyl)furan **9** was silylated to provide the silyl alcohol **10** (95%) (15). Treatment of **10** with 1.7 equivalents

SCHEME 1



of *n*-butyllithium (THF, HMPA) provided furan **2** (87%) via a 1,4 O→C silyl migration (8*a*). Regiospecific lithiation of furan **2** at C-4 with 2.2 equivalents of *n*-butyllithium (DME, 0°C), followed by trapping of the dianion with either tri-*n*-butyl- or trimethyl-stannyl chloride (1.1 equivalents), provided stannylfurans **4** (89%) and **5** respectively (8*b*). A 1,4 C→O silyl migration of compounds **4** and **5** (NaH, DMF) provided stannylfurans **6** and **8** respectively (>95%) (8*c*). Desilylation of furan **6** with tetra-*n*-butylammonium fluoride (THF, room temperature) afforded alcohol **7** (88%).

Stannylfuran **4** was initially employed in the coupling reaction with bromobenzene (1.1 equiv.) and tetrakis(triphenylphosphine)palladium(0) (TTPP, 2 mol%) in refluxing toluene. Analysis of the reaction mixture after 5 h indicated that only 50% of the bromobenzene had reacted. The addition of another 2 mol% of palladium catalyst and refluxing for another 6 h were required to provide coupled furan **11** (51%) and 10% of destannylated furan **2** (Scheme 3). The long reaction time, poor yield of furan **11**, and the presence of destannylated furan **2** are in contrast to results reported from typical coupling reactions using bromobenzene (10, 11*g*). No improvement in the yield

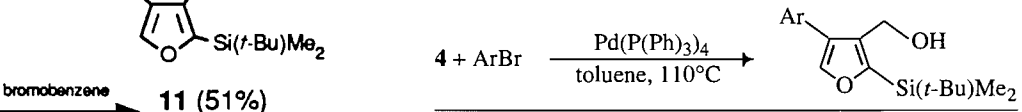
[3]Furylzinc and furylboronic acids have been used in palladium-catalyzed coupling reactions, see refs. 13 and 14 respectively.

SCHEME 2

SCHEME 3



of furan **11** was observed when the trimethylstannylfuran **5** was employed with bromobenzene under identical conditions; destannylated furan **2** was also isolated (11%). These observations were not limited to bromobenzene, as both 3-bromotoluene and 2-bromonaphthalene coupled with furan **4** to provide furans **12** and **13** respectively in poor yields (Table 1).

The disappointing results obtained for the coupling reactions of furans **4** and **5** were overcome by the use of furan **6** as the starting material. Compound **6** coupled smoothly with bromobenzene to provide coupled furan **14** in 90% yield within 1 h (Table 2). Destannylated furan **10** (Scheme 1) was neither detected (by ^{1}H NMR) nor isolated.

The coupling reaction was extended to a number of aromatic bromides (Table 2). In general, yields were high, and reaction times were short (1–6 h, entries 1, 2, 5, and 7). Exceptions were noted when sterically hindered aryl bromides were employed (entries 3, 4, and 6). Longer reaction times and, in the case of bromomesitylene, additional palladium catalyst were required for the reaction to proceed to completion. The absence of any coupled product from the reaction with 2-bromopyridine was surprising since it has been used successfully in other palladium-catalyzed couplings (16). The reaction also failed for 1-bromo-2-methoxybenzene despite the addition of more catalyst after 6 and 12 h.[4] This result may be due to both steric interactions and electronic factors (6).

[4]It is well documented that couplings with methoxy-substituted aryl bromides proceed slowly, and usually require additional catalyst, see ref. 10.

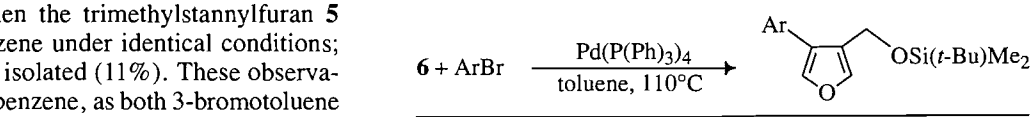


TABLE 1. Palladium-catalyzed coupling reactions of furan **4**

	ArBr	Time (h)	Yield (%)
1.	Bromobenzene	18	**11** (51)[a]
2.	3-Bromotoluene	18	**12** (55)[a]
3.	2-Bromonaphthalene	18	**13** (46)[a]

[a](10–12%) Destannylated furan **2** was also isolated.

TABLE 2. Palladium-catalyzed coupling reactions of furan **6**

	ArBr	Time (h)	Yield (%)

[a]Added more catalyst after 3 h.
[b]Added more catalyst after 6 and 12 h.
[c]Recovered 80% of furan **6**.
[d]Recovered 20% of furan **6**.

The poor results observed for stannyl furans **4** and **5** are in contrast to results reported from typical coupling reactions with bromobenzene. These observations could be due to the presence of the unprotected hydroxymethyl group at C-3 and (or) the bulky *tert*-butyldimethylsilyl moiety at C-2 of furans **4** and **5** (Scheme 1). Further experiments were performed to elucidate the reason for our observation.

To determine if the free hydroxyl group in our systems was responsible, we coupled stannyl furan **7** with bromobenzene

SCHEME 4

(Scheme 4) under the same conditions used for furans **4** and **5**. Coupled product **21** was obtained in 82% yield after 3 h (110°C); no destannylated furan **9** (Scheme 1) was observed (by ^{1}H NMR). This result clearly indicates that the hydroxyl group was not interfering with the reaction. Echavarren and Stille reported similar results with palladium-catalyzed cross-couplings between aryl triflates and vinyl stannanes containing free hydroxyl groups (17).

The presence of the *tert*-butyldimethyl silyl group at C-2 of furans **4** and **5** was shown to be responsible for the destannylation of furans **4** and **5**. Refluxing either furan **4** or **5** in toluene for 12 h in the absence of both the palladium catalyst and bromobenzene provided destannylated furan **2** in 13% yield. Stannylated furans **6** and **7**, and **8** (with no C-2 silyl group), did not provide destannylated furans **10** and **9** respectively under identical conditions. Furans **4** and **5** were also found to undergo facile protiodestannylation (18) when treated with 0.1% aqueous HCl (THF, 10 min) while furans **6–8** showed no signs of protiodestannylation after 1 h under identical conditions.

Examination of molecular models indicated that the trisubstituted compound **4** is sterically congested. These unfavourable steric interactions are not observed in stannyl furans **6–8** since the furan rings are only disubstituted (at C-3 and C-4). In the absence of a substituent at C-2, the C-3 moiety can rotate away from the stannyl group, thereby reducing the steric interactions in furans **6–8** when compared to furans **4** and **5**. Thus protiodestannylation occurs to relieve the strong steric interaction among the substituents in furans **4** and **5**. In addition, the hindered nature of furan **4** may be the reason for the longer reaction times (18 h vs. 1 h for furan **6**) required for the cross-coupling with bromobenzene (Table 1).

We have therefore shown that 4-aryl-3-substituted furans can be prepared via a palladium-catalyzed coupling reaction. The reactions are simple to perform and the products are easily purified. In addition, the silyl-protected hydroxymethyl group on the furan ring can be modified to convert the products from the coupling reaction into other 3,4-disubstituted furans. Synthetic applications of this methodology towards Hertiol **3** are currently in progress.

Experimental

Nuclear magnetic resonance spectra were obtained with a Bruker AC300 spectrometer using deuterochloroform as solvent (and internal standard). All ^{1}H NMR and ^{13}C NMR spectra were obtained at 300 and 75 MHz respectively. Infrared spectra were obtained with a Nicolet 5DK-FTIR spectrometer. Low and high resolution mass spectra were obtained with either a Varian CH5 or VG 7070F and a Kratos MS80RFA spectrometer respectively. Elemental analyses were performed by either Guelph Chemical Laboratories, Guelph, Ontario, or at the University of Calgary.

Flash column chromatography was performed using E. Merck silica gel (230–400 mesh A.S.T.M.) by the method developed by Still *et al.* (19). All solvents were dried and distilled prior to use.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]furan (**10**)*

To a solution of *tert*-butyldimethylsilyl chloride (6.1 g, 40 mmol) in DMF (20 mL) at 0°C under an atmosphere of argon was added imidazole (5.7 g, 84 mmol) and 3-hydroxymethylfuran **9** (3.6 g, 37 mmol). After 12 h at 25°C, diethyl ether and aqueous sodium chloride were added. The organic layer was washed six times with saturated aqueous sodium chloride, dried (Na_2SO_4), and the solvent removed *in vacuo* to afford, after distillation, a clear colourless oil **10** (95%), bp 106–109°C/20 Torr (1 Torr = 133.3 Pa); IR (neat): 1063 cm^{-1}; ^{1}H NMR δ: −0.04 (s, 6H), 0.81 (s, 9H), 4.54 (s, 2H), 6.42 (m, 1H), 7.51 (m, 2H); ^{13}C NMR δ: −2.85, 18.21, 25.80, 57.52, 109.66, 125.85, 139.38, 143.14; mass spectrum, *m/e*: 212 ($M^{\cdot+}$). Anal. calcd. for $C_{11}H_{20}O_2Si$: C 62.21, H 9.49; found: C 62.34, H 9.43.

*2-(*tert*-Butyldimethylsilyl)-3-(hydroxymethyl)furan (**2**)*

To a mixture of furan **10** (0.69 g, 3.3 mmol) and HMPA (0.62 mL, 3.6 mmol) dissolved in THF (10 mL) under an atmosphere of argon at −78°C was added *n*-butyllithium (1.43 mL, 2.5 M in hexane, 3.6 mmol). The solution was allowed to come to room temperature over 6 h and stirred at room temperature overnight. Saturated ammonium chloride was added and the solution extracted with diethyl ether. The organic layer was washed three times with saturated copper sulfate, dried (Na_2SO_4), and the solvent removed *in vacuo* to afford, after distillation, a white crystalline solid **2** (87%), bp 75–78°C/0.02 Torr; IR (KBr): 3319, 1070 cm^{-1}; ^{1}H NMR δ: 0.01 (s, 6H), 0.89 (s, 9H), 1.5 (bs, 1H), 4.57 (s, 2H), 6.46 (d, 1H, J = 1.8 Hz), 7.57 (d, 1H, J = 1.8 Hz); ^{13}C NMR δ: −5.73, 18.12, 25.69, 57.10, 110.52, 135.87, 146.69, 154.96; mass spectrum, *m/e*: 212 ($M^{\cdot+}$). Anal. calcd. for $C_{11}H_{20}O_2Si$: C 62.21, H 9.49; found: C 62.27, H 9.47.

*2-(*tert*-Butyldimethylsilyl)-3-(hydroxymethyl)-4-(tri-*n*-butylstannyl)furan (**4**)*

To a solution of furan **2** (1.5 g, 6.9 mmol) in dry DME (20 mL) at −78°C under an atmosphere of argon was added *n*-butyllithium (7.6 mL, 2.0 M in hexane, 15.2 mmol). After 15 min at 0°C, tri-*n*-butylstannyl chloride (1.9 mL, 6.9 mmol) was added and the solution stirred for 1 h. Saturated ammonium chloride was added, the solution extracted with ethyl acetate, and the solvent removed *in vacuo* to afford, after silica gel column (petroleum ether/ethyl acetate 20:1) and distillation, stannylated furan **4** (89%) as a clear colourless oil, bp 148–150°C/0.12 Torr; IR (neat): 3425, 1464, 1251 cm^{-1}; ^{1}H NMR δ: 0.28 (s, 6H), 0.87 (t, 9H, J = 4.1 Hz), 0.88 (s, 9H), 0.94 (t, 6H, J = 3.7 Hz), 1.2–1.4 (m, 6H), 1.44–1.55 (m, 6H), 2.05 (s, 1H), 4.50 (s, 2H), 7.35 (s, 1H); ^{13}C NMR δ: −5.52, 9.95, 13.65, 17.33, 26.37, 27.29, 29.18, 58.30, 115.75, 141.02, 151.53, 154.78(s); mass spectrum, *m/e*: 444 ($M^{\cdot+}$ − *t*-Bu); HRMS (EI) calcd. for $C_{19}H_{37}O_2Si^{120}Sn$ ($M^{\cdot+}$ − *t*-Bu): 445.1585; found ($M^{\cdot+}$ − *t*-Bu): 445.1578.

*2-(*tert*-Butyldimethylsilyl)-3-(hydroxymethyl)-4-(trimethylstannyl)furan (**5**)*

The above procedure was used, followed by quenching the dianion with trimethylstannyl chloride. Work-up provided furan **5** (88%) as a clear colourless oil, bp 88–92°C/0.04 Torr; IR (neat): 3450, 1471, 972 cm^{-1}; ^{1}H NMR δ: 0.30 (s, 9H, $J_{H,Sn}$ = 54.6 and 57.1 Hz), 0.30 (s, 6H), 0.92 (s, 9H), 4.57 (s, 2H), 7.40 (s, 1H); ^{13}C NMR δ: −8.77, −5.48, 17.32, 26.40, 58.12, 116.50, 140.89, 151.59, 154.54; mass spectrum, *m/e*: 361 ($M^{\cdot+}$ − Me); HRMS (EI) calcd. for $C_{13}H_{25}O_2Si^{120}Sn$ ($M^{\cdot+}$ − Me): 361.0653; found: 361.0625.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]-4-(tri-*n*-butylstannyl)furan (**6**)*

To a solution of stannylfuran **4** (0.32 g, 0.63 mmol) in dry DMF (1 mL) was added sodium hydride (0.8 mg, 0.04 mmol) under an atmosphere of argon. After 5 min at 25°C, diethyl ether and saturated sodium chloride were added. The diethyl ether was washed six times with saturated sodium chloride, dried (Na_2SO_4), and the solvent removed *in vacuo* to afford, after distillation, compound **6** (98%) as a clear colourless oil, bp 138°C/0.21 Torr; IR (neat): 1464, 1254, 1106, 1073, 1040, 842 cm^{-1}; ^{1}H NMR δ: 0.08 (s, 6H), 0.89 (t, 9H, J = 7.0 Hz), 0.92 (s, 9H), 1.05 (t, 6H, J = 5.1 Hz), 1.43 (m, 6H), 1.51 (m, 6H), 4.55 (s, 2H), 7.14 (s, 1H), 7.44 (s, 1H); ^{13}C NMR δ: −5.25, 9.71, 13.65, 18.48, 25.98, 27.32, 29.14, 59.11, 114.14, 130.77,

139.63, 147.82; mass spectrum, *m/e*: 444 ($M^{\cdot+}$ − *t*-Bu); HRMS (EI) calcd. for $C_{19}H_{37}O_2Si^{120}Sn$ ($M^{\cdot+}$ − *t*-Bu): 445.1585; found ($M^{\cdot+}$ − *t*-Bu): 445.1594.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]-4-(trimethylstannyl)furan (**8**)*

The above procedure was followed using furan **5** to afford furan **8** (88%) after work-up and distillation, bp 78–82°C/0.04 Torr; IR (neat): 1257, 1074, 839 cm^{-1}; ^1H NMR δ: 0.08 (s, 6H), 0.28 (s, 9H, $J_{H,Sn}$ = 55.0 and 57.3 Hz), 4.56 (s, 2H), 7.17 (s, 1H), 7.44 (s, 1H); ^{13}C NMR δ: −9.03, −5.15, 18.51, 26.03, 58.53, 115.59, 130.50, 139.67, 147.92; mass spectrum, *m/e*: 361 ($M^{\cdot+}$ − Me); HRMS (EI) calcd. for $C_{13}H_{25}O_2Si^{120}Sn$ ($M^{\cdot+}$ − Me): 361.0653; found: 361.0638.

*3-(Hydroxymethyl)-4-(tri-*n*-butylstannyl)furan (**7**)*

To a solution of furan **6** (100 mg) in THF (5 mL) at 0°C was added 1.1 equivalents of tetra-*n*-butylammonium fluoride. After 5 h at 0°C, diethyl ether and saturated ammonium chloride were added. The organic layer was separated, dried, and removed *in vacuo* to leave an oil. Flash chromatography (silica gel, EtOAc/pet. ether 1:5) followed by distillation provided furan **7** (92%) as a colourless oil, bp 80–84°C/0.04 Torr; IR (neat): 3423, 1496, 1040 cm^{-1}; ^1H NMR δ: 1.92 (t, 9H), 1.08 (m, 6H), 1.38 (m, 6H), 1.51 (m, 6H), 4.51 (s, 2H), 7.18 (s, 1H), 7.52 (s, 1H); ^{13}C NMR δ: 9.58, 13.59, 27.24, 29.11, 58.05, 114.97, 130.31, 140.02, 148.17; mass spectrum, *m/e*: 331 ($M^{\cdot+}$ − *n*-Bu); HRMS (EI) calcd. for $C_{13}H_{23}O_2{}^{120}Sn$ ($M^{\cdot+}$ − *n*-Bu): 331.0724; found: 331.0755.

General tin coupling procedure

To a solution of a stannylated furan (82 mg, 0.16 mmol) in dry toluene (2 mL) were added an aryl bromide (0.18 mmol) and tetrakis(triphenylphosphine)palladium(0) (2 mol%). The mixture was refluxed. After the appropriate time (Table 1 or 2) either the solution was worked up or more catalyst was added. The work-up was as follows: the solution was cooled to room temperature, water (1 mL) added, and the mixture filtered through Celite. The mixture was extracted with diethyl ether, dried (Na_2SO_4), and the solvent removed *in vacuo*. Silica gel chromatography (petroleum ether/ethyl acetate 50:1), followed by either a distillation or recrystallization, afforded coupled products.

*2-(*tert*-Butyldimethylsilyl)-3-(hydroxymethyl)-4-phenyl furan (**11**)*

Yield 51%; bp 105°C/0.3 Torr; IR (neat): 3450, 1488, 1254, 1099, 999, 829, 782 cm^{-1}; ^1H NMR δ: 0.35 (s, 6H), 0.94 (s, 9H), 1.6 (bs, 1H), 4.60 (s, 2H), 7.27–7.31 (m, 1H), 7.36–7.41 (m, 2H), 7.52–7.55 (m, 2H), 7.70 (s, 1H); ^{13}C NMR δ: −5.55, 17.51, 26.41, 55.13, 127.11, 127.25, 128.27, 128.72, 132.29, 133.93, 144.00, 158.09; mass spectrum, *m/e*: 231 ($M^{\cdot+}$ − *t*-Bu): HRMS (EI) calcd. for $C_{13}H_{15}O_2Si$ ($M^{\cdot+}$ − *t*-Bu): 231.0842; found ($M^{\cdot+}$ − *t*-Bu): 231.0836.

*2-(*tert*-Butyldimethylsilyl)-3-(hydroxymethyl)-4-(3-methylphenyl)-furan (**12**)*

Yield 55%; bp 120–125°C/0.05 Torr; IR (neat): 3431, 1608, 1471, 1251 cm^{-1}; ^1H NMR δ: 0.38 (s, 6H), 0.97 (s, 9H), 2.40 (s, 3H), 4.63 (s, 2H), 7.27 (m, 1H), 7.3–7.5 (m, 2H), 7.35 (s, 1H), 7.71 (m, 1H); ^{13}C NMR δ: −5.53, 17.27, 21.45, 26.44, 55.20, 125.37, 127.16, 127.69, 128.81, 129.03, 132.21, 134.06, 136.25, 143.96, 157.92; mass spectrum, *m/e*: 245 ($M^{\cdot+}$ − *t*-Bu). Anal. calcd. for $C_{18}H_{26}O_2Si$: C 71.47, H 8.67; found: C 71.37, H 8.79.

*2-(*tert*-Butyldimethylsilyl)-3-(hydroxymethyl)-4-(2-naphthyl)furan (**13**)*

Yield 46%; bp 155–160°C/0.05 Torr; IR (neat): 3456, 1601, 1392 cm^{-1}; ^1H NMR δ: 0.41 (s, 6H), 1.01 (s, 9H), 4.42 (s, 1H), 7.40–7.55 (m, 4H), 7.71 (s, 1H), 7.8–8.0 (m, 3H); ^{13}C NMR δ: −5.55, 17.37, 26.54, 55.51, 124.52, 125.36, 125.73, 125.94, 126.26, 128.07, 128.11, 128.35, 129.63, 132.70, 133.60, 136.10, 145.09, 157.10; mass spectrum, *m/e*: 281 ($M^{\cdot+}$ − *t*-Bu); HRMS (EI) calcd. for $C_{17}H_{17}O_2Si$ ($M^{\cdot+}$ − *t*-Bu): 281.0998; found: 281.0980.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]-4-phenylfuran (**14**)*

Yield 90%; bp 89°C/0.03 Torr; IR (neat): 1468, 1255, 1095, 1074, 857, 776 cm^{-1}; ^1H NMR δ: 0.08 (s, 6H), 0.93 (s, 9H), 4.68 (s, 2H), 7.27–7.31 (m, 1H), 7.35–7.41 (m, 2H), 7.45–7.55 (m, 4H); ^{13}C NMR δ: −5.29, 19.23, 25.86, 56.53, 124.42, 126.23, 127.01, 127.89, 128.59, 132.38, 139.95, 141.73; mass spectrum, *m/e*: 288 ($M^{\cdot+}$), 231 ($M^{\cdot+}$ − *t*-Bu); HRMS (EI) calcd. for $C_{13}H_{15}O_2Si$ ($M^{\cdot+}$ − *t*-Bu): 231.0842; found ($M^{\cdot+}$ − *t*-Bu): 231.0859.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]-4-(2-formylphenyl)furan (**15**)*

Yield 85%; bp 82–85°C/0.02 Torr; IR (neat): 1694, 1468, 1256, 1075, 839, 774 cm^{-1}; ^1H NMR δ: −0.05 (s, 6H), 0.82 (s, 9H), 0.47 (s, 2H), 7.40–7.71 (m, 5H), 8.01 (dd, 1H, *J* = 8.1 and 2.3 Hz), 10.05 (s, 1H); ^{13}C NMR δ: −5.58, 16.21, 25.77, 58.09, 121.66, 125.79, 127.43, 128.1, 131.8, 133.51, 134.86, 135.7, 141.23, 141.98, 192.12; mass spectrum, *m/e*: 259 ($M^{\cdot+}$ − *t*-Bu); HRMS (EI) calcd. for $C_{14}H_{15}O_3Si$ ($M^{\cdot+}$ − *t*-Bu): 259.0791; found ($M^{\cdot+}$ − *t*-Bu): 259.0795.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]-4-(2,4,6-trimethylphenyl)-furan (**16**)*

Yield 55%; bp 90°C/0.07 Torr; IR (neat): 1471, 1256, 1078, 849 cm^{-1}; ^1H NMR δ: −0.1 (s, 6H), 0.83 (s, 9H), 2.05 (s, 6H), 2.29 (s, 3H), 4.29 (s, 2H), 6.89 (s, 2H), 7.17 (d, *J* = 1.6 Hz, 1H), 7.48 (d, *J* = 1.6 Hz, 1H); ^{13}C NMR δ: −5.74, 19.4, 20.58, 21.01, 25.84, 56.94, 123.00, 125.64, 127.85, 128.08, 137.07, 137.76, 139.79, 140.66; mass spectrum, *m/e*: 330 ($M^{\cdot+}$), 273 ($M^{\cdot+}$ − *t*-Bu); HRMS (EI) calcd. for $C_{16}H_{21}O_2Si$ ($M^{\cdot+}$ − *t*-Bu): 273.1311; found ($M^{\cdot+}$ − *t*-Bu): 273.1324.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]-4-(2-methylphenyl)furan (**17**)*

Yield 80%; bp 85°C/0.1 Torr; IR (neat): 1550, 1082, 841, 780 cm^{-1}; ^1H NMR δ: −0.06 (s, 6H), 0.84 (s, 9H), 2.23 (s, 3H), 4.42 (s, 2H), 7.12–7.25 (m, 4H), 7.30 (d, 1H, *J* = 1.3 Hz), 7.45 (d, 1H, *J* = 1.3 Hz); ^{13}C NMR δ: −5.59, 18.28, 20.33, 25.83, 56.65, 124.59, 125.46, 125.69, 127.56, 129.98, 130.60, 131.60, 137.01, 140.38, 140.57; mass spectrum, *m/e*: 245 ($M^{\cdot+}$ − *t*-Bu); HRMS (EI) calcd. for $C_{14}H_{17}O_2Si$ ($M^{\cdot+}$ − *t*-Bu): 245.0998; found ($M^{\cdot+}$ − *t*-Bu): 245.0991.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]-4-[4-(phenyl)phenyl]furan (**18**)*

Yield 70%; bp 95°C/0.13 Torr; IR (neat): 1470, 1256, 1075, 838, 765 cm^{-1}; ^1H NMR δ: 0.11 (s, 6H), 0.92 (s, 9H), 4.71 (s, 2H), 7.31–7.63 (m, 11H); ^{13}C NMR δ: −5.30, 18.25, 25.83, 56.49, 124.40, 125.91, 126.99, 127.27, 128.21, 128.55, 128.76, 139.83. 140.02, 140.76, 141.18, 141.83; mass spectrum, *m/e*: 364 ($M^{\cdot+}$), 307 ($M^{\cdot+}$ − *t*-Bu); HRMS (EI) calcd. for $C_{19}H_{19}O_2Si$ ($M^{\cdot+}$ − *t*-Bu): 307.1155; found ($M^{\cdot+}$ − *t*-Bu): 307.1152.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]-4-(2-methylnaphthyl)furan (**19**)*

Yield 82%; bp 103°C/0.09 Torr; IR (neat): 1470, 1256, 1084, 838, 793, 743 cm^{-1}; ^1H NMR δ: −0.28 (s, 3H), −0.25 (s, 3H), 0.74 (s, 9H), 2.32 (s, 3H), 4.25 (s, 2H), 7.35–7.45 (m, 5H), 7.60 (s, 1H), 7.75–7.82 (m, 2H); ^{13}C NMR δ: −5.90, 18.22, 20.78, 25.76, 56.87, 121.87, 124.81, 125.79, 126.00, 126.59, 127.71, 128.40, 131.89, 133.65, 135.20, 140.74, 140.99; mass spectrum, *m/e*: 352 ($M^{\cdot+}$), 295 ($M^{\cdot+}$ − *t*-Bu); HRMS (EI) calcd. for $C_{18}H_{19}O_2Si$ ($M^{\cdot+}$ − *t*-Bu): 295.1155; found ($M^{\cdot+}$ − *t*-Bu): 295.1164.

*3-[(*tert*-Butyldimethylsilyl)oxymethyl]-4-(4-chlorophenyl)furan (**20**)*

Yield 88%; bp 95°C/0.1 Torr; IR (neat): 1515, 1092, 837 cm^{-1}; ^1H NMR δ: 0.07 (s, 6H), 0.89 (s, 9H), 4.60 (s, 2H), 7.33 (d, 2H, *J* = 4.8 Hz), 7.43 (d, 2H, *J* = 1.3 Hz), 7.48 d, 2H, *J* = 4.8 Hz), 7.53 (d, 1H, *J* = 1.3 Hz); ^{13}C NMR δ: −5.30, 18.25, 25.82, 56.16, 124.14, 125.43, 128.73, 129.16, 130.83, 132.90, 140.06, 141.98; mass spectrum, *m/e*: 265 ($M^{\cdot+}$ − *t*-Bu), 230 ($M^{\cdot+}$ − *t*-Bu − Cl); HRMS (EI) calcd. for $C_{13}H_{14}O_2SiCl$ ($M^{\cdot+}$ − *t*-Bu): 265.5293; found ($M^{\cdot+}$ − *t*-Bu): 265.5281.

*3-(Hydroxymethyl)-4-(phenyl)furan (**21**)*

Yield 82%; bp 70–72°C/0.04 Torr; IR (KBr): 3338, 1601, 1051 cm^{-1}; ^1H NMR δ: 4.65 (s, 2H), 7.3–7.6 (m, 7H); ^{13}C NMR δ: 55.20, 123.68, 126.81, 127.4, 128.34, 129.15, 131.61, 139.85, 141.62; mass spectrum, *m/e*: 174 ($M^{\cdot+}$); HRMS (EI) calcd. for $C_{11}H_{10}O_2$: 174.0680; found: 174.0672.

1,3-Diketonatoboron difluoride sensitized cation radical reactions

Y. L. CHOW[1] AND XIANEN CHENG
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received October 6, 1990[2]

Y. L. CHOW and XIANEN CHENG. Can. J. Chem. **69**, 1331 (1991).

Dibenzoylmethanatoboron difluoride ($DBMBF_2$) and allied BF_2 complexes interact from their singlet excited state with *trans*-anethole (*t*-A), quadricyclene (QC), and norbornadiene (NBD) by electron transfer to generate the corresponding cation radicals, which undergo the reported reactions. By sensitization, *t*-A undergoes dimerization to form the *anti* head-to-head and *syn* head-to-head dimers with retention of stereochemistry. The formation is reversible under sensitization conditions, leading to accumulation of the more stable *anti* isomer. However, irradiation of the absorption band of the $DBMBF_2$ – *t*-A ground state complex did not lead to dimerization of *t*-A. By $DBMBF_2$ sensitization, QC is cleanly converted to NBD while NBD is not affected. The calculation shows $QC^{+\cdot}$ possesses higher energy than $NBD^{+\cdot}$ by 7.5 kcal/mol, hence an irreversible rearrangement. Other sensitizers (e.g., cyanoaromatics and tetrachlorobenzoquinone) also promote these cation radical reactions but not as cleanly as $DBMBF_2$.

Key words: photosensitization by boron complexes, cation radical rearrangement, cation radical cycloaddition, electron transfer sensitization, photoreaction of ground state complexes.

Y. L. CHOW et XIANEN CHENG. Can. J. Chem. **69**, 1331 (1991).

Le difluorure de dibenzoylméthanatobore ($DBMBF_2$) et ses complexes apparentés réagissent dans leur état excité singulet avec l'anéthole-*trans* (*t*-A), le quadricyclène (QC) et le norbornadiène (NBD) par transfert d'électron pour générer les cations radicalaires correspondants qui subissent les réactions mentionnées. Le *t*-A sensibilisé donne les dimères tête–tête *anti* et tête–tête *syn* avec rétention de la stéréochimie. Cette réaction sensibilisée est réversible et conduit majoritairement à l'isomère *anti* le plus stable. Cependant l'irradiation de la bande d'absorption du complexe $DBMBF_2$–*t*-A dans l'état fondamental ne conduit pas à une dimérisation du *t*-A. Le QC sensibilisé par le $DBMBF_2$ se transforme proprement en NBD tandis que le NBD n'est pas affecté dans les mêmes conditions. Les calculs montrent que l'énergie du cation radicalaire $QC^{+\cdot}$ est de 7,5 kcal/mol supérieure à celle du cation radicalaire $NB^{+\cdot}$ et que le réarrangement est par conséquent irréversible. D'autres sensibilisateurs (par exemple les cyanoaromatiques et la tétrachlorobenzoquinone) favorisant également ces réactions mais pas aussi proprement que le $DBMBF_2$.

Mots clés : photosensibilisation par des complexes de bore, réarrangement des cations radicalaires, cycloaddition des cations radicalaires, sensibilisation par transfert d'électrons, réaction photochimique des complexes à l'état fondamental.

[Traduit par la rédaction]

Introduction

We have reported that dibenzoylmethanatoboron difluoride ($DBMBF_2$) reacts from its singlet excited state with simple olefins to form cycloaddition products (1, 2), and that 2-acetylcyclohexanonatoboron difluoride ($ACHBF_2$) and acetylacetonatoboron difluoride ($AABF_2$) similarly undergo photocycloaddition with a number of benzene derivatives (3). These primary photocycloadducts generally undergo hydrolysis at a certain stage to eliminate the BF_2 moiety and rearrange by acid catalysis to give final products under the photolysis conditions. In $DBMBF_2$ photocycloadditions to cyclic olefins, it has been established that the excimer reacts with cyclic olefins while the monomer of excited state $DBMBF_2$ contributes very little in the addition (2, 4). Strangely, a similar photocycloaddition to acyclic olefins exhibits the opposite pattern.

In a preliminary publication, evidence showed that the singlet excited $DBMBF_2$ interacts with many types of olefins to form exciplexes that are assumed to be the precursors of the subsequent chemical events, such as cycloadditions, cation radical reactions, and reverse electron transfer (1). The correlation of the $DBMBF_2$ fluorescence quenching rate constants (log k_q) by olefins against the ionization potential of donor olefins shows a departure from the Rehm–Weller full electron transfer model (1) involving an excited state electron acceptor (*A), such as $*DBMBF_2$, and a donor (D), as shown in eq. [1]. The near flat correlation region (Fig. 1 of ref. 1) involving electron-rich olefins coincides with specific types of chemical reactions that can be characterized as cation radical initiated reactions. We wish to describe such cation radical reactions promoted by singlet excited $DBMBF_2$ and to provide evidence for electron transfer processes.

Two model reactions chosen here are well established to involve cation radicals as the reactive intermediate. Bauld and co-workers (5, 6) demonstrated that the aminium radical initiated dimerization of *trans*-anethole (**1**) in CH_2Cl_2 ($E_{\frac{1}{2}}^{ox}$ = 1.11 V) follows formally concerted [$\pi^2 s + \pi^1 s$] cycloadditions with retention of configuration to give the head-to-head *trans*, *anti*,*trans*-cyclobutane **2** and the head-to-head *trans*,*syn*,*trans*-cyclobutane **3** in about 1:1 ratio at −35°C; at room temperature only the *anti* isomer **2**, the more stable of the two, is obtained (eqs. [2] and [3]). The reaction is nicely demonstrated to be a reversible cation radical chain reaction of $\mathbf{1}^{+\cdot}$ arising from thermal electron transfer to tris(*p*-bromophenyl)aminium hexachloroantimonate, and its activation parameters are determined through kinetic studies (6). Recently Lewis and Kojima (7, 8) used photoinitiated electron transfer sensitization (9,10-dicyanoanthracene and other cyano aromatics) of *trans*-anethole to induce its dimerization, leading to qualitatively similar results to those obtained by Bauld's group (5, 6). The less stable *syn* isomer **3** is the only product in direct photolysis of *tert*-anethole (7, 9). Applications of the addition of $\mathbf{1}^{+\cdot}$ to other olefins have also been reported (10).

The sensitized interconversion of quadricyclene (QC or **4**) and norbornadiene (NBD or **5**) is well characterized, as shown in eq. [4] (11–14). Triplet sensitization by aromatic ketones exclusively converts **5** to **4** (13, 14). This remarkable photoisomerization was beautifully demonstrated to involve different

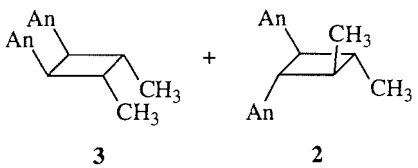
[a]The oxidation potentials of QC (0.91 V) and NBD (1.54 V) are cited from refs. 16 and 17.
[b]The thermodynamic free energy was approximately calculated according to $\Delta G = E_{(D/D^+)} - E_{(A^-/A)} - E_{00} - E_{coulombic}$ (20).



energy surfaces and a schematic representation of preferential transitions has been given (12). However, Solomon, Steel, and Weller pointed out earlier that the singlet state sensitized **4** → **5** isomerization is most likely to involve electron transfer (15), i.e., the isomerization occurs through cation radicals $\mathbf{4}^{+\cdot} \rightarrow \mathbf{5}^{+\cdot}$ in a radical ion pair. The involvement of these two distinct cation radicals is elegantly demonstrated by CIDNP results in electron transfer (e.g., 1-cyanonaphthalene and chloranil) sensitized reactions (16–18); the potential energy of $\mathbf{4}^{+\cdot}$ is estimated to be higher by 9–14 kcal/mol than that of $\mathbf{5}^{+\cdot}$, which drives the one-way isomerization. Extensive studies on similar sensitized interconversions have been published (19).

Results

The valence isomerization of quadricyclene (**4**) and norbornadiene (**5**) could be sensitized with acetylacetone or $AABF_2$ using a 300-nm light source or with $DBMBF_2$ using a 350-nm light source at about 30°C under concentrations in which the sensitizers absorbed all incident light. The photolysis was carried out either in CD_2Cl_2 or in CD_3CN solution using NMR spectroscopy to monitor progress. Taking advantage of the fact that NBD showed distinct low-field signals 3.6 and 6.8 ppm for the allylic and olefinic protons, and that these protons would shift to higher fields at ca. 1.4 ppm on isomerization to QC, the conversions either way could be monitored readily and unambiguously. In CD_2Cl_2, acetylacetone sensitized the conversion of NBD to QC smoothly, but did not affect the reverse isomerization, QC → NBD, in 12 h of irradiation. In contrast, $AABF_2$ and $DBMBF_2$ sensitized the conversion of QC to NBD but not that of NBD to QC in CD_2Cl_2 solution. The quantum yields of the conversion were determined and are listed in Table 1 together with reported sensitization data. Table 1 also contains the singlet and triplet energy levels, and redox potentials of compounds participating in the photoinduced electron transfer reaction, the free energy of which (ΔG) is calculated according to Weller's equation (20).

In CH_3CN, both $AABF_2$ and $DBMBF_2$ showed a similar sensitization pattern but with a lower quantum efficiency than that observed in CD_2Cl_2. Both sensitizers showed a quantum yield of 0.02 for conversion of QC to NBD. Taking advantage of the strong fluorescence of monomeric $DBMBF_2$ at 397 and 416 nm (4), the quenching of fluorescence intensities was studied in acetonitrile at $[DBMBF_2] = 5 \times 10^{-6}$ M using a Stern–Volmer type analysis to correlate the efficiency. Interestingly, both valence isomers quenched the fluorescence strongly with slopes ($k_q\tau_0$) of 14.1 M^{-1} for QC (**4**) and 6.8 M^{-1} for NBD (**5**). Using τ_0 of $DBMBF_2$ as 2.7 ns (4), the quenching rate constants (k_q) were 5.2×10^9 and $2.5 \times 10^9\ M^{-1}\ s^{-1}$, respectively (Table 2). $AABF_2$ showed fluorescence only at a concentration of 0.05 M (21); as its origin was uncertain, quenching experiments were not carried out. In all these irradiations the BF_2 complexes were not consumed and no other product(s) was detected by GC analysis.

Irradiation of an acetonitrile solution of **1** (0.5 M) containing a sensitizer gave a mixture of *syn* isomer **3** and *anti* isomer **2**, the ratio of which favored the latter increasingly with the duration of irradiation. With $DBMBF_2$ as the sensitizer, 4 h of irradiation yielded *anti*-**2** and *syn*-**3** in a 6:1 ratio. This ratio was very close

to that sensitized by 9,10-dicyanoanthracene in CH_3CN, reported recently (8). The GC analysis of the photolysate did not show a peak corresponding to *cis*-anethole, but no effort was made to confirm its absence. When this investigation was nearly complete, detailed investigations of the dimerization and isomerization of **1** by sensitization and direct excitation were published (7, 8). We will report the aspects not covered by these two most recent publications.

In view of the proven efficiency as electron acceptors in their excited state (16, 17), 9-cyanoanthracene (CA) and tetrachloro-1,4-benzoquinone (TCB) were also used as sensitizers in addition to the BF_2 complexes. The formations of *syn* isomer **3** and *anti* isomer **2** were plotted against irradiation times elapsed in the presence of $DBMBF_2$ as shown in Fig. 1. The formation profiles showed that both **2** and **3** were formed at about the same rate in the beginning, but the production of the less stable *syn* isomer **3** rapidly leveled off at about 30–60 min irradiation time while that of more stable *anti* isomer **2** increased steadily. TCB sensitized dimerization of *trans*-anethole (**1**) was also included for comparison (Fig. 2B). It exhibited a different profile from that of $DBMBF_2$ sensitization (Fig. 2A); both **2** and **3** were formed at about the same rate, though the *syn* isomer **3** started to increase more rapidly beyond 4 h of irradiation. The difference arises from the fact that TCB sensitizes the dimerization from its lowest triplet state with a lower energy (E_T 62 kcal/mol) participating electron transfer. CA and benzoylacetonatoboron difluoride ($BABF_2$) sensitized cases showed reaction profiles similar to that shown by $DBMBF_2$; these plots are described in the Ph.D. thesis presented by one of us (21).

$DBMBF_2$ also sensitized the cycloreversion of dimers **2** and **3** under comparable photolysis conditions to those used above to give *trans*-anethole **1** without the formation of *cis*-anethole. As shown in the profile of cycloreversions in Fig. 2, under comparable conditions the *syn* isomer **3** was sensitized to give **1** faster and in better yields than the *anti* isomer **2**. The poor yields of the monomer **1** in these cycloreversions (i.e., 18% from **2** and 71% from **3** based on reacted dimers) appeared to arise from polymerization as found in the aminium radical initiated cycloreversion reaction (5). No effort was made to identify polymers of **1**. The rapid cycloreversion of **3** was followed by the much slower formation of **2** as shown in Fig. 2A. It should be mentioned that in these sensitized reactions, whether dimerizations or cycloreversions, $DBMBF_2$ and $BABF_2$ remained unreacted during photolysis. During the reaction CA decreased slightly, showing some side reactions.

A colourless solution of $DBMBF_2$ turned bright yellow on addition of one of these and other electron-rich donors (20). Inspection of the UV spectra of these mixture solutions showed that the end absorption was red-shifted to various extents,

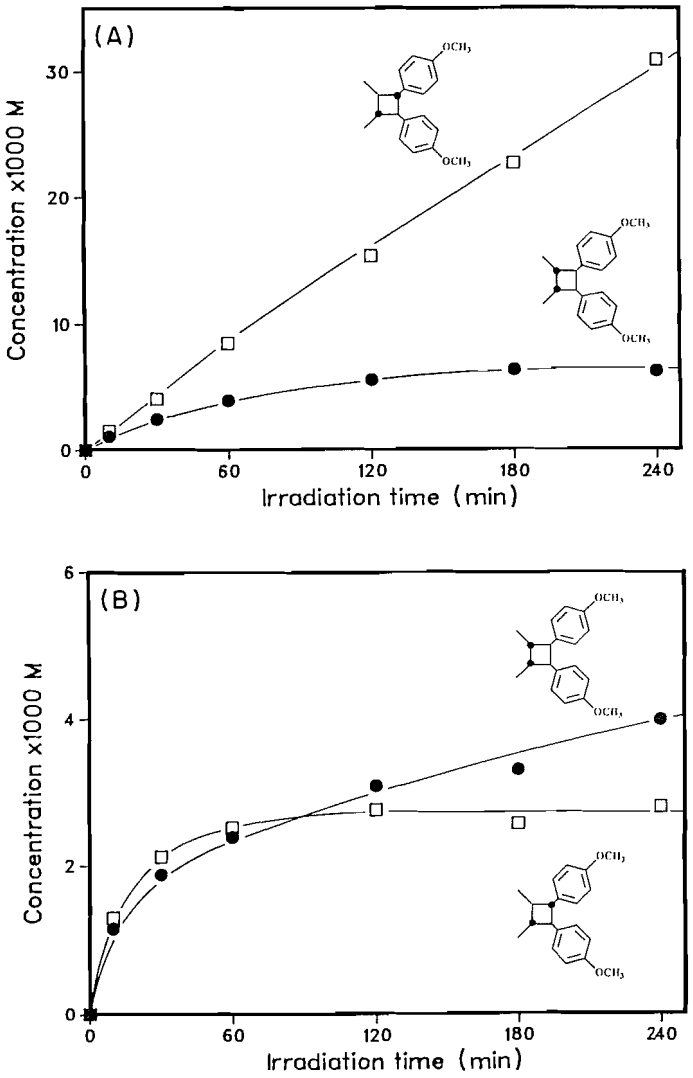

FIG. 1. The formation profile of the *syn*-**3** and *anti*-**2** dimers in the $DBMBF_2$ (A, 0.02 M) and tetrachlorobenzoquinone (B, 0.02 M) sensitized photolysis of **1** (0.5 M) in CH_3CN.

indicating the formation of charge transfer (CT) complexes. Among these, the red shift induced by **1** was most extensive (up to 500 nm) and the association constant was determined to be 0.44 M^{-1} by the Benesi–Hildebrand relation (4). The shifts induced by **4** and **5** were smaller. A solution containing $DBMBF_2$ (0.02 M) and *trans*-anethole **1** in CH_3CN was irradiated with monochromatic light at 312.8 nm for $DBMBF_2$ and at 437.0 nm for the $DBMBF_2$–**1** ground state complex, and

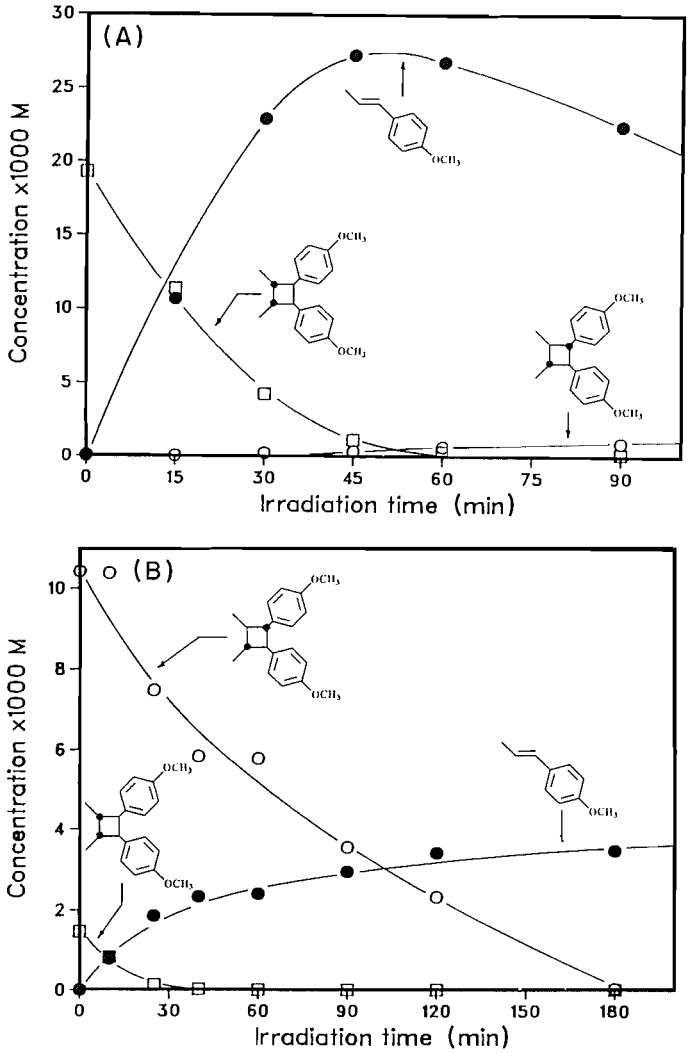

FIG. 2. $DBMBF_2$ (0.02 M) sensitized cycloreversion of the *anti*-**2** dimer (B, 0.02 M) and the *syn*-**3** dimer (A, 0.0192 M) in CH_3CN solution. In the upper figure A, the starting sample contains *syn*-**3** (12%).

the photolysates were analysed by GC. By taking into account the light intensities at these slit openings and the absorbancy, we could estimate the relative quantum yields of *anti*-**2** at 437 nm irradiation to be, at the maximum, 1% of that at 312.8 nm irradiation (see Experimental). It should be noted that at λ_{ex} = 312.8 nm, the incident light was absorbed by $DBMBF_2$ and **1** as well as by the CT complex of $DBMBF_2$–**1**. The fraction of light absorbed by the complex is relatively small owing to the small formation constant. As $DBMBF_2$ singlet excited state energy (E_s 73 kcal/mol) (4) is much lower than that of *trans*-anethole (81 kcal/mol estimated from the longest wavelength of the absorption curve at 355 nm), the excitation at 312.8 nm should be mainly localized in $DBMBF_2$. The results led to the surprising conclusion that excitation of the $DBMBF_2$–**1** ground state complex did not afford the dimerization initiated by $\mathbf{1}^{+\cdot}$. It must be mentioned that the excitation of the $DBMBF^2$–**1** absorption band did not show emission at all. Also $DBMBF_2$ fluoresence was quenched by **1** without showing new emission. The quenching efficiency was determined in the usual manner and the result from a Stern–Volmer analysis is listed in Table 2.

Discussion

Without detailed estimations of thermodynamic parameters (energetics), the results clearly indicated that the BF_2 complex

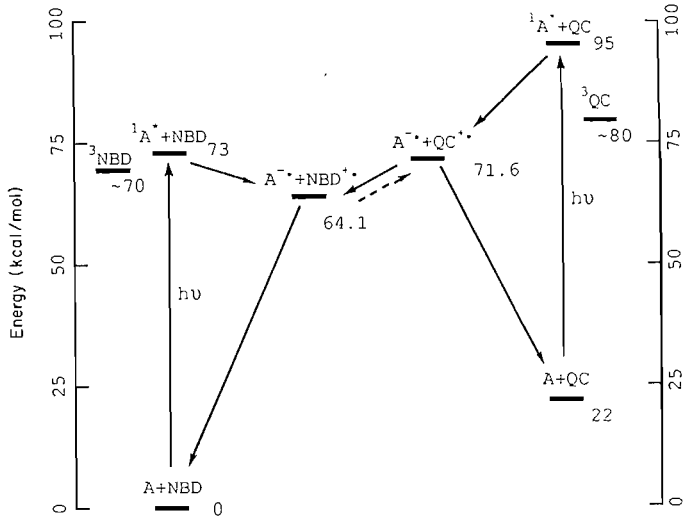

FIG. 3. Energy levels of relevant species in $DBMBF_2$ sensitized isomerization of QC and NDB.

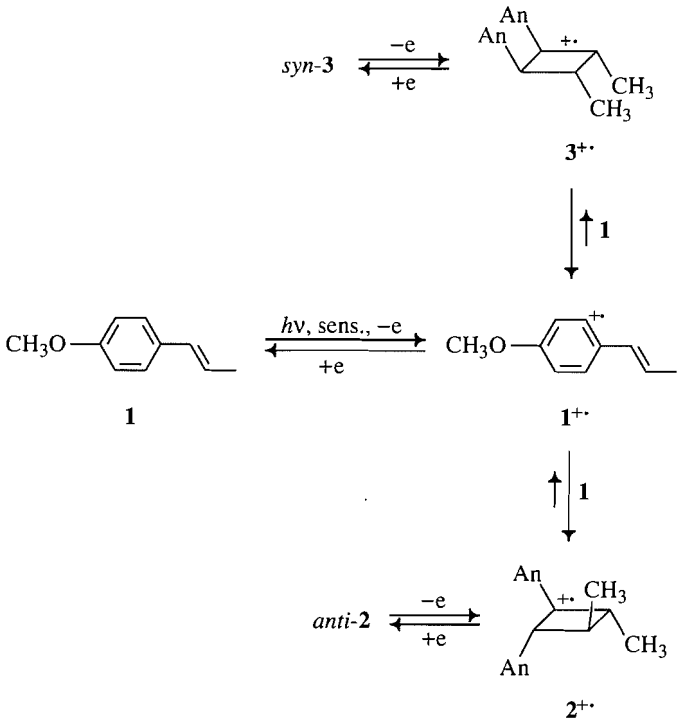

sensitized isomerization of QC to NBD (**4**→**5**) and those of the dimerization of *trans*-anethole (**1**) are initiated by the primary intermediates, the corresponding cation radicals. This means that the primary photoreaction in these cases is a *bona fide* electron transfer process, in which the singlet excited states of BF_2 complexes are the electron acceptors, to give the anion radicals (e.g., $DBMBF_2^{-\cdot}$ and $AABF_2^{-\cdot}$) to counterbalance the cation radicals. As the correlation of the k_q values of these processes with ionization potential indicates (1), the solvent-separated ion pair could have been formed either in the encounter stage or from the solvent penetration of an exciplex radical ion pair (22, 23). With the help of reported data we wish to discuss the thermodynamics and mechanism of the overall reactions.

The acetylacetone (E_T = 69–74 kcal/mol) sensitized conversion of NBD to QC is analogous to acetophenone sensitization (13, 14), namely, by triplet energy transfer to NBD but not to QC, to induce one-way conversion (see Fig. 3 for the E_T levels). While both TCB (16, 17) and BF_2 complexes sensitize a clear conversion of QC to NBD, the former reacts from its triplet excited state as opposed to the singlet state of the latter. The interaction of singlet excited state $DBMBF_2$ with QC and NBD has been demonstrated by the fluorescence quenching to be nearly diffusion controlled (Table 2). Though no exciplex emission is observed, the energy level of the excitation is estimated as shown in Fig. 3 (where $DBMBF_2$ = A) by adapting the ground state of QC lying 22 kcal/mol above that of NBD (16, 17), which is arbitrarily taken as the base line. The potential energy of ion radical pairs (E_{IRP}) can be calculated from the reduction potential of the acceptor ($E_{A^-/A}$) and the oxidation potential of donor E_{D/D^+} according to eq. [1], where the Coulombic factor E_C is about −0.06 eV in CH_3CN (20).

$$E_{IRP} = E_{D/D^+} - E_{A^-/A} + E_C$$

The calculated energy levels of the ion radical pairs (Fig. 3) indicate that $QC^{+\cdot}$ must be at least 7.5 kcal/mol higher than $NBD^{+\cdot}$ in these pairs. This energy difference deters the $NBD^{+\cdot} \rightarrow QC^{+\cdot}$ conversion and accounts for the one-way valence isomerization QC → NBD. However, the ion radical pair generated from $AABF_2$ ($E_{A^-/A}$ = 1.78 V) with NBD should have the energy level high enough (by >5.2 kcal/mol) to cause triplet recombination, and is possible to generate triplet state NBD (E_T 68–70 kcal/mol). This is an analogous argument to

SCHEME 1

the case of 1-cyanonaphthalene sensitization (16, 17), though such a process is inefficient as shown by the low quantum yield of 0.01 (Table 1). The failure of $AABF_2$ sensitization to convert NBD to QC may arise from the slow intersystem crossing of $^1(AABF_2^-–NBD^+) \rightarrow {}^3(AABF_2^-–NBD^+)$, which can effectively retard the generation of triplet state NBD.

The formation of *syn*-**3** and *anti*-**2** in the sensitized dimerization of *trans*-anethole exhibits a pattern similar to those recently published by Lewis and Kojima (8) and to the early observations by Bauld's group (5, 6). The GC traces in Fig. 1 clearly show that in the early stage of the sensitized dimerization, *syn*-**3** and *anti*-**2** are formed in nearly equal probability. Owing to the more facile cycloreversion of *syn*-**3** than that of *anti*-**2**, the former reaches a stationary state rapidly while the latter increases nearly linearly. This suggests that the stereochemical approach of $\mathbf{1}^{+\cdot}$ and **1** is regiospecific in the head-to-head mode but in either *syn* or *anti* orientation. Subsequent cyclization has been proposed to be a stereospecific $[\pi^2 s + \pi^1 s]$ cycloaddition with retention of *trans* configuration (5). The lack of *cis* isomerization and the formation of other stereoisomeric dimers clearly indicate that the intermediacy of acyclic 1,4-cation radicals is not compatible in $\mathbf{1}^{+\cdot}$ initiated reactions and the cycloreversions. Such 1,4-cation radicals have been proposed to be viable intermediates in certain dimerizations (24, 25). Our conclusion agrees with those obtained in the thermally initiated and 9,10-dicyanoanthracene sensitized dimerization of **1** (5, 8).

We propose Scheme 1 to account for the sensitized reversible photodimerization of **1** (E_{D/D^+} = 1.11 V in CH_2Cl_2) to give **2** and **3**; the key step is the fast reversion of $\mathbf{3}^{+\cdot}$ in comparison to that of $\mathbf{2}^{+\cdot}$, probably owing to steric compressions. We believe that this step is responsible for accumulating *anti*-**2** and causing fast cycloreversion of *syn*-**3**. The step of electron transfer and reversal (i.e., **2** or **3** $\rightarrow \mathbf{2}^{+\cdot}$) is not responsible because of the fact that the oxidation potentials for *syn*-**2** (E_{D/D^+} 1.75 V) and *anti*-**3** (E_{D/D^+} 1.85 V) are very close to each other (8); such electron transfer reactions to either dimer should occur with comparable rates.

During the excitation of the charge transfer band of the $DBMBF_2$–**1** complex the failure to give dimerization of **1** is very surprising in view of the fact that the contact radical ion pair CIP must have been formed. It is assumed that the $DBMBF_2$–**1** complex in its excited state may possess a geometry prone to reverse electron transfer, which destroys cation radical $\mathbf{1}^{+\cdot}$ rapidly within the ion CIP so that $\mathbf{1}^{+\cdot}$ has no chance to diffuse away for reactions even in polar solvent. The significance of this negative result and proposal resides in the fact that the dynamic interaction of singlet excited $DBMBF_2$ with **1** can even initiate dimerization. The extension of the assumption made above leads us to propose that a solvent separated radical ion pair (SSIP) is derived from dynamic processes and undergoes slower reverse electron transfer because of geometrical factors. Therefore $\mathbf{1}^{+\cdot}$ can diffuse away to initiate dimerization. Such a SSIP may be formed from an encounter complex or generated by solvent penetration of exciplex ion pairs in polar solvent (22, 23). We have observed a similar example where excitation of a ground state complex failed to undergo a reaction, contrary to expectations (26). Such phenomena must be related to the exciplex reactivity and geometry, which increasingly attract the attention of photochemists.

Experimental

Materials and conditions

The instrumentation and conditions were the same as those described in refs. 2 and 4. NBD, 9-cyanoanthracene, *trans*-anethole (**1**), and tetrachlorobenzoquinone were recrystallized or redistilled from commercial products. QC was prepared by acetophenone sensitized isomerization of NBD (13). $DBMBF_2$ and $AABF_2$ were prepared in the previous work (2, 3). The authentic sample of the *syn*-**3** dimer was prepared by direct photolysis of **1** through a Pyrex filter (9), that of the *anti*-**2** by TCB sensitized dimerization in which *syn*-**3** was also formed. The latter was chromatographed to give a sample of *anti*-**2** contaminated with 12% of *syn*-**3**.

Sensitized dimerization of 1

A CH_3CN solution containing **1** (5.0×10^{-1} M), a sensitizer (2×10^{-2} M), and octadecane (9.0×10^{-3} M) as the internal standard was irradiated with a 350-nm light source. When TCB was used as the sensitizer, the solution was purged with nitrogen. At intervals, samples were withdrawn for GC analysis. The calibration curves of dimers **2** and **3** with respect to the internal standard were used to read percentage yields directly. At the end of a 4-h irradiation, $DBMBF_2$ and $BABF_2$ remained unchanged in concentration. When 9-cyanoanthracene was used as the sensitizer, its amount decreased by about 40% in 4 h of irradiation. TCB in CH_3CN developed a dark purple colour on addition of **1**; this colour disappeared on irradiation. But the amount of TCB could not be accurately analyzed by GC with a FID detector.

Sensitized cycloreversion of dimers

A CH_3CN solution containing $DBMBF_2$ (2.0×10^{-2} M), a dimer ($\sim 1 \times 10^{-2}$ M), and octadecane (2.0×10^{-3} M) was irradiated and analysed as above.

The monochromatic photolysis

A CH_3CN solution (2 mL) of $DBMBF_2$ (2.0×10^{-2} M), *trans*-anethole **1** (5.0×10^{-1} M), and octadecane (as the internal standard, 2.0×10^{-3} M) was placed in a 1-cm UV cell and was irradiated for 120 min at 312.8 nm. Separately, the same solution and conditions were used to irradiate at 437 nm. The light source used was a Kratos GM252 grating monochrometer, LH150 lamp housing, and LPS251HR power supply mounted on a light bench. The UV cell holder was placed 15 cm before the tip of the GM252. The settings for operating conditions were as follows: the current of the power supply at 8.20 A, the band width at 5 nm, and slit width at entry and exit at 15 nm. The

For personal use only.

200-W Xenon–mercury lamp (Oriel) had an output of 43 $\mu W/cm^2$ at 312.8 nm, and 27 $\mu W/cm^2$ at 437 nm. The relative yields of dimers **2** and **3** were calculated from the GC peaks with respect to the internal standard; these were 0.025 at 437 nm and 0.34 at 312.8 nm.

At 312.8 nm, the molal absorbance of **1** (ϵ_1) was 1833, and that of $DBMBF_2$ (ϵ_A) was 4100; taking the concentrations into consideration, only 8.2% of incident light was absorbed by $DBMBF_2$. The quantum yields at 437 nm (Φ(437 nm)) are estimated by the following equation to be 0.01 × Φ(312.7 nm).

$$\Phi(437\text{ nm}) = (\text{yield of dimers at 437 nm})/(\text{yield of dimers at 312.8 nm}) \times (\text{output ratio of the lamp}) \times (\text{fraction of light absorbed by } DBMBF_2 \text{ at 312.8 nm}) \times 1/(\text{fraction of light absorbed by the complex at 437 nm}) \times \Phi(312.7\text{ nm}) = 0.01\,\Phi(312.7\text{ nm})$$

Sensitized valence isomerization of QC and NBD

A solution containing a sensitizer and QC (or NBD) in CD_2Cl_2 (or CH_3CN) was placed in an NMR tube (5 mm i.d.), which was irradiated with a Rayonet reactor equipped either with RPR-3000 Å or RPR-3500 Å lamps. The progress of the reaction was followed with ^1H NMR spectroscopy with a Bruker 100SY equipped with Aspect 2000 software. The solvent peak $CHDCl_2$ (or CHD_2CN) was used as the internal standard. The peak ratios of NBD (4 olefinic protons) and QC (6 tertiary protons) at various concentrations with respect to the solvent peak were established before these experiments. The concentrations of QC or NBD were calculated on the basis of the integral ratios to the standard and the quantum yields were calculated based on benzophenone–benzhydrol actinometry. The error by this method is estimated to be ±10%, mainly arising from uncertainties in integrations. The details of the method are given in ref. 21.

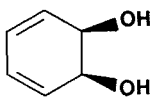
The Diels–Alder reactions of *N*-phenylmaleimide and dimethyl acetylenedicarboxylate with benzene oxide (1,3,5-cyclohexatriene 1,2-oxide, **3**) and its more substituted derivatives 1,2-dimethyl-1,3,5-cyclohexatriene 1,2-oxide (**7**) and 10-oxatricyclo[4.3.1.0]deca-2,4-diene (**11**) in a kinetic manner gave exclusively products of addition *anti* to the plane-nonsymmetrical oxygen. The structures of the adducts were determined unequivocally by nuclear Overhauser enhancements in their ^{1}H nuclear magnetic resonance spectra and by X-ray crystallographic methods. The π-facial stereoselectivity was rationalized in terms of unfavorable orbital interactions, steric hindrance between the dienophile and the *syn* face of benzene oxide, and σ-donation by the oxygen.

Key words: cycloaddition, Diels–Alder, *syn–anti*, π-facial stereoselectivity, benzene oxide.

JAMES R. GILLARD, MICHAEL J. NEWLANDS, JOHN N. BRIDSON et D. JEAN BURNELL. Can. J. Chem. **69**, 1337 (1991).

Les réactions de Diels–Alder de la *N*-phénylmaléimide et de l'acétylène dicarboxylate de méthyle avec l'oxyde de benzène (cyclohexatriène-1,3,5-oxyde-1,2, **3**) et avec ses dérivés plus substitués : le diméthyl-1,2-cyclohéxatriène-1,3,5-oxyde-1,2 (**7**) et le oxa-10-tricyclo[4.3.1.0]décadiène-2,4 (**11**) donnent uniquement et de façon cinétique les produits d'addition en position *anti* par rapport à l'oxygène plan-non symétrique. On a déterminé sans ambiguïté la structure des adduits en faisant appel à l'exaltation Overhauser nucléaire de leurs spectres de résonance magnétique nucléaire du ^{1}H et à la cristallographie de rayons X. On interprète la stéréosélectivité π-faciale en fonction des interactions défavorables des orbitales, de l'encombrement stérique entre le diénophile et la face *syn* de l'oxyde de benzène, et du comportement de l'oxygène comme donneur σ.



Mots clés : cycloaddition, Diels–Alder, *syn–anti*, stéréosélectivité π-faciale, oxyde de benzène.

[Traduit par la rédaction]

Introduction

Diels–Alder reactions involving some 5-heterosubstituted cyclopentadienes lead predominantly to products that arise by addition to the face of the diene *syn* to the heteroatom, i.e., to the more substituted face (1, 2). Other heteroatoms in a similar position force the cycloaddition to take place mainly *anti* to the heteroatom (2, 3), as do simple hydrocarbon substituents (4).[2] Other cyclic and acyclic systems with allylic heteroatom substituents have been examined: some add *syn* while others add *anti* (6).

There has been much less work on the π-facial (*syn–anti*) stereoselectivity of 1,3-cyclohexadiene derivatives with allylic heteroatom substitution (7). *cis*-Cyclohexa-3,5-diene-1,2-diol (**1**) and many of its derivatives add to ethylenic dienophiles

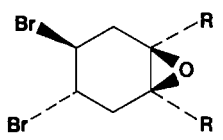
1

mainly *syn* to the oxygens (8).[3] On the other hand, *anti* addition is predominant with a 1,2,4-triazoline-3,5-dione dienophile (10), and singlet oxygen also adds mainly *anti* to the oxygen of **1** (11). The stereochemistry of the products of each of these processes has been determined in an unequivocal manner.

The benzene oxides are obvious structural relatives of the diols of type **1**, but the stereochemistry of their cycloaddition reactions has not, in most instances, been rigorously proven (12). Excellent pioneering work from the laboratory of Vogel focused on the valence tautomerism that exists between benzene oxides and oxepins (13). The oxide forms were trapped with dienophiles such as maleic anhydride, but the stereochemistry of the adducts was not determined. Reports of more recent work in which benzene oxides have been trapped with carbon dienophiles show each adduct as the result of addition to the face of the benzene oxide that is *anti* to the oxygen, but no evidence was provided for this stereochemical assignment (14). Similarly, adducts derived from 1,2,4-triazoline-3,5-dione dienophiles have been reported as the products of *anti* addition (15), but this assignment of stereochemistry was based on one structure that was determined by X-ray crystallography (16). In contrast, on acetone-sensitized excitation, diazomethane added to the face of a benzene oxide *syn* to the oxygen (17).

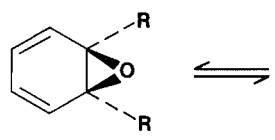
We report here the Diels–Alder cycloadditions of three benzene oxides with carbon dienophiles, and the first irrefutable proof for the stereochemistry of the products.

Results



Benzene oxide was prepared by a procedure very similar to that of Vogel *et al.* (18). Briefly, 1,4-cyclohexadiene was monobrominated in the cold, and epoxidation with *meta*-chloroperoxybenzoic acid gave **2**. Double dehydrobromination was effected with DBU. The ^{1}H nmr of the product displayed a single set of signals, but Vogel and Günther (13) demonstrated that this is really an average of the signals of benzene oxide (**3**) and its valence tautomer, oxepin (**4**). The addition of *N*-phenylmaleimide to an ether solution of the tautomeric mixture resulted in smooth conversion to a *single* adduct. The nmr data indicated a symmetrical molecule, i.e., the adduct was not formed from **4**. Nuclear Overhauser enhancement (nOe) measurements led to the structure **5** for the adduct, which was the result of an *endo* addition, *anti* to the oxygen. This *anti* addition was in marked contrast to the many known examples of an allylic oxygen atom directing addition *syn* to itself (1, 2, 8), so it

[1]Author to whom correspondence may be addressed.



[2]One example with 5-methyl-1,3-cyclopentadiene was reported to have no selectivity (5).

[3]Some older studies (9) incorrectly assumed these added *anti*.

seemed prudent to corroborate the structure by X-ray crystallography (Fig. 1).

The reactions of two more substituted, and seemingly more sterically hindered, benzene oxides were also examined. The order of the reactions in their preparation was different. The Birch reduction product of *ortho*-xylene was first epoxidized and then brominated to afford **6**. Double dehydrobromination with potassium *tert*-butoxide gave the dimethyl benzene oxide **7** along with its valence tautomer **8** (19). Reaction with *N*-phenylmaleimide was very much slower than with the unsubstituted diene. This observation was consistent with Vogel's work, which showed that the **7** ⇄ **8** equilibrium is very much in favor of the oxepin **8** form, due to eclipsing of the two methyls in the benzene oxide tautomer **7** (13). Nevertheless, the Diels–Alder reaction did take place and, as before, only one adduct was formed. The nmr data led to an unequivocal assignment of structure. The adduct was symmetrical, i.e., it was derived from **7** and not from **8**.[4] Irradiation of the methyl singlet in the ^1H nmr resulted in a significant nOe of the signal due to the protons α to the carbonyls, and vice versa. Thus, the structure of the adduct could only have been **9**, the product of *endo* addition, *anti* to the oxygen. Therefore, in spite of the much larger size of two methyl groups compared to two hydrogens, the cycloaddition still demonstrated complete π-facial stereoselectivity.

The same sequence of reactions as above, but starting with indan, led via **10** to the valence tautomers **11** and **12**. In this case Vogel (13) had reported that the equilibrium lies very much in favor of the benzene oxide form because in **12** there would be a very considerable amount of angle strain. The cycloaddition with *N*-phenylmaleimide was rapid. A single symmetrical adduct was obtained, and nOe measurements showed conclusively that the adduct possessed structure **13**.

The benzene oxide **11** reacted with *N*-methylmaleimide to give **14** in a manner very similar to the reaction of the *N*-phenyl dienophile. Then **13** was heated in $CHCl_3$ with *N*-methylmaleimide, and **14** was heated with *N*-phenylmaleimide. In neither

9 R = CH_3, R' = Ph
13 R = $-CH_2CH_2CH_2-$, R' = Ph
14 R = $-CH_2CH_2CH_2-$, R' = CH_3

case was any exchange detected. These experiments demonstrated that the adducts of **11** and, presumably, the adducts of the other two benzene oxides were formed under kinetic rather that thermodynamic control.

The Diels–Alder reaction of **11** with dimethyl acetylenedicarboxylate, a sterically less demanding dienophile, still gave only one adduct. Attempts to determine its stereochemistry unequivocally by means of nOe measurements failed. Therefore, the structure was determined by X-ray crystallography, and, as is evident from Fig. 2, the adduct was once again the result of addition to the face of **11** *anti* to the oxygen. In the crystal the molecule appears somewhat twisted, with the two carbomethoxy groups in slightly different conformations.

Discussion

These benzene oxides added exclusively *anti*, while similar cyclopentadienyl and cyclohexadienyl dienes with allylic oxygen functions all add *syn*. While there have been many theories forwarded to explain these *syn* additions, the *anti* additions that have been observed with other substituents have usually been rationalized by invoking steric hindrance. It is instructive to examine why the factors that might otherwise direct addition *syn* to an oxygen function fail completely to do so with **3**, **7**, and **11**.

Fukui and co-workers (21) postulated that in cyclopentadienyl systems mixing of diene π-orbitals with lone-pair orbitals associated with a plane-nonsymmetrical heteroatom leads to a perturbation of the π-system such that the electron density of the HOMO is significantly larger on the *syn* face. More recently, Inagaki *et al.* (22) used orbital mixing (π-system with *s*-orbitals on the sp^2 carbons of the diene) to explain differences in selectivity between different heteroatoms. An idea forwarded by Kahn and Hehre (23) was that for electrostatic reasons dienophiles should add to the more nucleophilic (i.e., *syn*) face. Anh (24) suggested a direct, favorable interaction between the heteroatom lone pair and the LUMO of the incoming dienophile.

Ab initio calculations[5] show that in the HOMO of benzene oxide (**3**) (Fig. 3) the *s*-orbital coefficients on the diene carbons are tiny, so the π-system could be only very slightly biased on the side of the oxygen due to "orbital mixing" of the type described by Fukui and Inagaki. Therefore, it is unlikely that the complete facial stereospecificity observed in this study can arise by this phenomenon. Also, it is obvious from Fig. 3 that a node must exist between the component of the HOMO residing on the oxygen and the LUMO of the incoming dienophile. The four next-highest occupied molecular orbitals are either symmetrical or have very small coefficients on oxygen. Therefore, the oxygen of the benzene oxides cannot be directly facilitating *syn* addition by any of the mechanisms mentioned above.

The geometry of the benzene oxides is such that the oxygen is almost perpendicular to the plane of the diene moiety whereas

[4]In contrast, adducts derived from this type of disubstituted benzene oxide ⇄ oxepin react with nitrogen dienophiles via the oxepin forms to give unsymmetrical adducts (15, 20).

[5]A communication that summarizes our parallel computational work with plane-nonsymmetrical diene systems is in preparation.

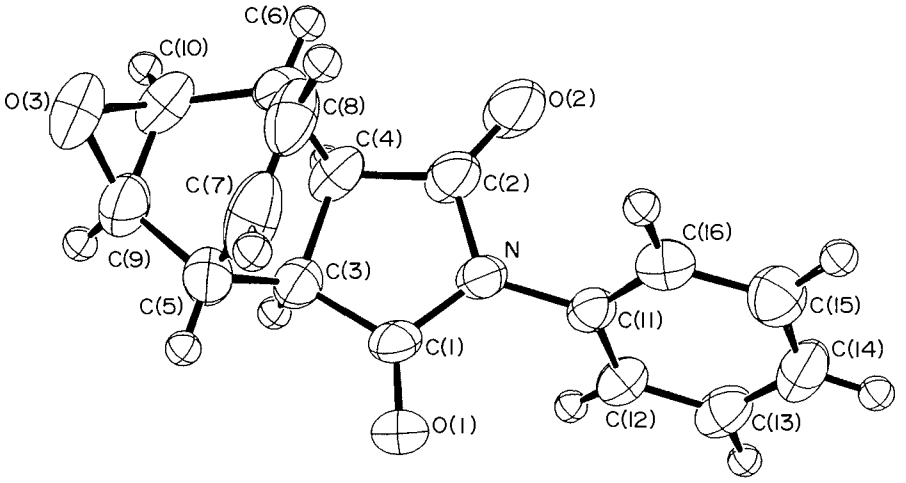

FIG. 1. Perspective view of **5** with ellipsoids scaled to 50% probability. Hydrogen atoms have been added to clarify the relative stereochemistry. (Numbering of the atoms conforms with the data in Table 2.)

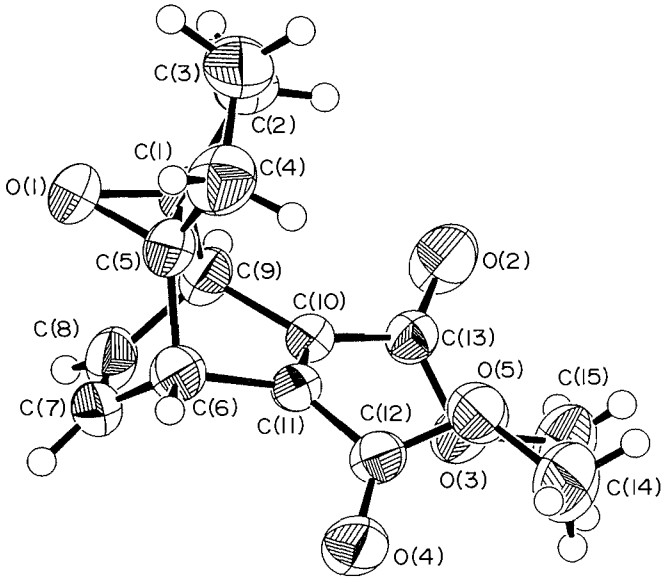

FIG. 2. Perspective view of **15** with ellipsoids scaled to 50% probability. (Numbering of the atoms conforms with the data in Table 4.)

the "oxirane substituents" (two hydrogens for **3**, two methyls for **7**, and $CH_2CH_2CH_2$ for **11**) are roughly coplanar with the diene moiety. There must be a significant steric interaction between the oxygen and an incoming dienophile on the *syn* face. Therefore, in marked contrast to other oxygen-bearing dienes (e.g., **1**), the unfavorable steric interactions in a *syn* transition state of a benzene oxide are not overwhelmed by an opposing attractive force. In fact, the molecular geometry leaves addition to the *anti* face unencumbered, and *anti* addition eventuates with both ethylenic and acetylinic dienophiles.

A model, based on work by Cieplak (25), that considers the σ-donor ability of an *anti* substituent has been espoused recently by le Noble and co-workers and by Macaulay and Fallis (2). Hydrogen and carbon have much greater σ-donor abilities than has oxygen (26). However, the Cieplak model specifies that facial selectivity can be modulated only by a σ bond *antiperiplanar* to the face of attack. The relative positions of the oxygen

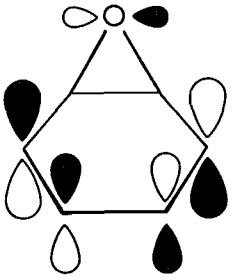

FIG. 3. Representation of the atomic orbital components of the highest occupied molecular orbital (HOMO) of **3**.

and the oxirane substituents vis-à-vis the plane of the diene moiety suggest that only σ-donation by the weaker σ-donor, the oxygen, can be considered to be operative. Thus, the facially specific addition of dienophiles *anti* to the oxygen of a benzene oxide is not inconsistent with the proposals of le Noble and Fallis (2).

Experimental

Melting points (mp) were determined on a Fisher–Johns apparatus and are uncorrected. Infrared spectra were recorded on a Mattson FT instrument. Mass spectral data were from a V.G. Micromass 7070HS instrument. Nuclear magnetic resonance (nmr) spectra were obtained on a General Electric GE 300-NB instrument or a Varian 360 instrument: ^1H shifts are relative to internal tetramethylsilane in $CDCl_3$; ^{13}C shifts are relative to the solvent resonance ($CDCl_3$ = δ 77.0). Nuclear Overhauser enhancement (nOe) data were obtained from sets of interleaved ^1H experiments (16K) of 8 transients cycled 12–16 times through the list of irradiated frequencies. The decoupler was gated on in CW mode for 6 s with sufficient attenuation to give a 70–90% reduction in intensity of the irradiated peak. Frequency changes were preceded by a 60-s delay. Four scans were used to equilibrate spins before data acquisition, but a relaxation delay was not applied between scans at the same frequency. The nOe difference spectra were obtained from zero-filled 32K data tables to which a 1–2 Hz exponential line-broadening function had been applied. Reactions were run under an atmosphere of dry nitrogen. Solvents were distilled, and aqueous solutions are implied for saturated NaCl, etc.

filtered, and the solid was discarded. The solution was washed with 20% $NaHSO_3$ (100 mL), saturated $NaHCO_3$ (2 × 100 mL), and saturated NaCl (200 mL), then dried ($MgSO_4$) and concentrated *in vacuo* to provide a yellow oil. Crystallization from cold hexane gave colorless **2** (6.97 g, 65%): mp 68–69°C; ir (KBr pellet) ν_{max}: 1415, 1009, 889 cm^{-1}; ^{1}H nmr δ: 4.30 (1H, ddd, J = 4.6, 6.7, 7.7 Hz), 4.20 (1H, ddd, J = 6.3, 6.3, 7.7 Hz), 3.24 (2H, m), 2.99 (1H, br dd, J = 4.5, 16.0 Hz), 2.90 (1H, ddd, J = 3.5, 6.3, 16.5 Hz), 2.65 (1H, dd, J = 6.3, 16.5 Hz), and 2.46 (1H, ddd, J = 3.2, 6.7, 16.0 Hz); ^{13}C nmr δ: 50.7 and 50.2 (oxirane carbons), 48.7 and 47.3 (2 × CHBr), 33.3 and 32.3 (2 × CH_2); ms m/z (%): 256 (M^+, 0.1), 177 (3), 176 (2), 175 (3), 174 (2), 95 (21), and 67 (100). Exact mass calcd. for $C_6H_8{}^{81}BrO$ (M^+ − Br): 176.9738; found: 176.9742; calcd. for $C_6H_8{}^{79}BrO$ (M^+ − Br): 174.9759; found: 174.9752.

*1,3,5-Cyclohexatriene 1,2-oxide/oxepin (**3** ⇄ **4**)*

A solution of **2** (1.07 g, 4.17 mmol) and DBU (2.50 g, 16.4 mmol) in anhydrous ether (20 mL) was stirred at room temperature for 24 h (19*a*), then poured into saturated $NaHCO_3$. Approximately 50 mL of ether was added, and the organic layer was washed with saturated $NaHCO_3$ (2 × 100 mL) and saturated NaCl (100 mL), and dried over anhydrous K_2CO_3. Evaporation of the solvent yielded **3** ⇄ **4** as a yellow liquid (0.270 g, 67%): ir (film) ν_{max}: 3028, 1609, 1431, and 1072 cm^{-1}; ^{1}H nmr δ: 6.26 (2H, complex m), 5.88 (2H, m), and 5.12 (2H, d, J = 4.5 Hz); ^{13}C nmr δ: 130.7, 128.6, 122.3, 120.2, 110.0, and 107.5; ms *ms*/*z* (%): 94 (M^+, 61), 78 (7), 68 (35), 66 (100), and 65 (68). Exact mass calcd. for C_6H_6O: 94.0418; found: 94.0420.

*Diels–Alder reaction of **3** with N-phenylmaleimide*

To the ether solution obtained after work-up of a reaction of 0.837 g (3.27 mmol) of **2** and 2.00 g of DBU was added 0.584 g (3.37 mmol) of *N*-phenylmaleimide in $CHCl_3$ (25 mL). After stirring at room temperature for 16 h, the solvents were evaporated. The ^{1}H nmr of the residue showed signals for only one adduct, which was rigorously purified by flash chromatography, then recrystallized from $CHCl_3$–C_6H_6 to yield 0.274 g (31% from **2**) of very pure **5**: mp 218–219°C; ir (KBr pellet) ν_{max}: 1709, 1388, 1195, and 726 cm^{-1}; ^{1}H nmr δ: 7.46–7.13 (5H), 5.91 (2H, apparent dd, J = 3.6, 4.6 Hz, vinyl H's), 3.65 (2H, m, bridgehead H's), 3.37 (2H, m, oxirane H's), and 3.05 (2H, apparent t, J = 1.8 Hz, H's α to C=O's); nOe data: irradiate 5.91: nOe at 3.65 (6%); irradiate 3.65: nOe's at 5.91 (6%), 3.37 (6%), and 3.05 (5%); irradiate 3.37: nOe's at 3.65 (7%) and 3.05 (5%); irradiate 3.05: nOe's at 3.65 (6%) and 3.37 (6%); ^{13}C nmr δ: 176.0, 131.4, 128.9, 128.6, 126.5, 126.2, 47.1 (oxirane carbons), 41.9 (α to C=O's), and 35.6 (bridgeheads); ms m/z (%): 267 (M^+, 35), 173 (22), 119 (32), and 91 (100). Exact mass calcd. for $C_{16}H_{13}NO_3$: 267.0895; found: 267.0892.

*X-ray structure determination of **5***

Data collection was on an Enraf–Nonius CAD-4 diffractometer with a graphite-crystal monochromator with MoKα_1 radiation (λ = 0.70930 Å). Crystallographic data are summarized in Table 1. Cell dimensions were determined by least squares from 25 reflections ($35.0 < 2\theta < 38.0°$). Integrated intensities were obtained by the $\theta/2\theta$ scan mode. Reference reflections measured during data collection showed no decrease in intensity. Corrections were applied for Lorentz and polarization effects, but not for absorption. The structure was solved by direct and Fourier methods. Least-squares refinements on F with anisotropic factors given to non-H atoms converged to R = 0.037, R_w = 0.035, S = 0.31. Weights were based on counting statistics, $w = 1/\sigma^2$ (F_o); Δ/s (max.) = 1.482. The largest peaks in the final difference map were +0.153 and −0.160 e/Å^3. All calculations were made with the NRC VAX Crystal Structure System (28), and atomic scattering factors were from International tables for X-ray crystallography (20). Figure 1 was prepared from the output of ORTEPII (30). Bond lengths and angles are given in Table 2, and positional and thermal parameters for refined atoms appear in Table 3.[6]

trans*-4,5-Dibromo-1,2-dimethylcyclohexene oxide (**6**)*

1,2-Dimethyl-1,4-cyclohexadiene (11.09 g, 102.7 mmol) was added to a solution of 31.8 g of the magnesium salt of monoperoxyphthalic acid (80%) hexahydrate (MMPP) (31) in 95% ethanol (500 mL). After stirring at room temperature for 3 h, H_2O (1 L) was added, and this was extracted with CH_2Cl_2 (300 mL). The organic extract was washed with H_2O (200 mL) and saturated NaCl (200 mL), dried ($MgSO_4$), and concentrated. Flash chromatography (4% acetone in pentane) of the residue yielded 5.4 g (42%) of the mono-epoxide: ^{1}H

[a]B_{iso} is the mean of the principal axes of the thermal ellipsoid.

nmr (60 MHz) δ: 5.3 (2H, apparent s), 2.3 (4H, apparent s), and 1.3 (6H, s). This was dissolved in $CHCl_3$ (100 mL) and cooled to −50°C. Bromine (5.64 g, 35.2 mmol = 0.81 mol-equiv.) (19*b*) was added dropwise at a rate that ensured that the solution not become orange. After warming to room temperature the solvent was evaporated in *in vacuo*. Recrystallization of the residue from hexane gave 7.59 g (76%) of **6** as colorless needles: mp 82–83°C; ir (KBr pellet) ν_{max}: 1466, 1384, 1322, 1167, 842, and 670 cm^{-1}, ^1H nmr δ: 4.26 (1H, ddd, J = 4.5, 8.3, 9.1 Hz), 4.15 (1H, ddd, J = 6.8, 7.7, 9.1 Hz), 2.90 (1H, dd, J = 4.5, 15.4 Hz), 2.69 (1H, dd, J = 6.8, 16.1 Hz), 2.61 (1H, dd, J = 7.7, 16.1 Hz), 2.29 (1H, dd, J = 8.3, 15.4 Hz), 1.34 (3H, s), and 1.32 (3H, s); ^{13}C nmr δ: 61.9 and 61.0 (oxirane carbons), 50.5 and 49.6 (2 × CHBr), 40.8 and 39.9 (2 × CH_2), 19.9 and 19.5 (2 × CH_3); ms m/z (%): 205 (11), 203 (12), 165 (1), 163 (1), 123 (20), 95 (7), 81 (17), 79 (11), and 43 (100).

*1,2-Dimethyl-1,3,5-cyclohexatriene 1,2-oxide/2,7-dimethyloxepin (**7** ⇄ **8**)*

Following the procedure of Paquette and Barrett (19*b*): **6** (2.1355 g, 7.52 mmol) in dry ether (50 mL) was cooled to 0°C before addition of 2.00 g of potassium *tert*-butoxide in four portions over 1 h. After stirring for 1 h the reaction was poured into H_2O (75 mL). After addition of more ether, the organic solution was washed with H_2O (75 mL), saturated $NaHCO_3$ (75 mL), and saturated NaCl (75 mL), then dried ($MgSO_4$) and concentrated to provide 0.7535 g (82%) of dimethylbenzene oxide/oxepin as a yellow liquid: ir (film) ν_{max}: 1658, 1160, and 743 cm^{-1}; ^1H nmr δ: 5.99 (2H, distorted t, $J \approx 3$ Hz), 5.44 (2H, complex m), and 1.91 (6H, s); ^{13}C nmr δ: 149.9, 127.5, 112.2, and 21.1; ms m/z (%): 122 (M^+, 43), 107 (8), 91 (14), 79 (90), 77 (56), and 43 (100). Exact mass calcd. for $C_8H_{10}O$: 122.0731; found: 122.0725.

*Diels–Alder reaction of **7** with N-phenylmaleimide*

A solution of 0.1286 g (1.05 mmol) of dimethylbenzene oxide/oxepin (**7**/**8**) and *N*-phenylmaleimide (0.1660 g, 0.958 mmol) in $CHCl_3$ (50 mL) was heated at reflux for 10 h. The ^1H nmr of the crude mixture showed signals for only one adduct (**9**), which was isolated by flash chromatography as colorless crystals: mp 261–262°C; ir (KBr pellet) ν_{max}: 1709, 1388, 1195, and 726 cm^{-1}; ^1H nmr δ: 7.47–7.13 (5H), 5.97 (2H, dd, J = 3.6, 4.5 Hz), 3.38 (2H, m), 3.13 (2H, apparent t, J = 1.6 Hz), and 1.44 (6H, s); nOe data: irradiate 5.97: nOe at 3.38 (7.5%); irradiate 3.38: nOe's at 5.97 (8.5%), 3.13 (5%), and 1.44 (1%); irradiate 3.13: nOe's at 3.38 (9.5%) and 1.44 (2.5%); irradiate 1.44: nOe's at 3.38 (12%) and 3.13 (10.5%); ^{13}C nmr δ: 176.5, 131.5, 129.0, 128.7, 127.5, 126.3, 57.6 (oxirane carbons), 42.2 (α to C=O's), 41.7 (bridgeheads), and 13.8 (2 × CH_3); ms m/z (%): 295 (M^+, 7), 253 (29), 175 (10), 161 (9), 148 (8), 133 (8), 119 (11), 106 (77), 105 (76), 93 (19), 91 (23), 77 (28), and 43 (100). Exact mass calcd. for $C_{18}H_{17}NO_3$: 295.1207; found: 295.1209.

trans-*3,4-Dibromo-10-oxatricyclo[4.3.1.0^{1,6}]decane (**10**)*

To a stirred, room temperature solution of 5,8-dihydroindan (28.47 g, 0.237 mol) in $CHCl_3$ (350 mL) was added 1.0 g of Aliquat 336 (Aldrich) and, over a period of 2 h, a solution of 88 g of 80% MMPP in H_2O (450 mL). This was stirred vigorously for a further 2 h. A white solid that formed at the interface was dissolved by addition of 1 M NaOH (100 mL). The organic layer was washed with H_2O (200 mL), saturated $NaHCO_3$, and saturated NaCl (400 mL), then dried ($MgSO_4$) and concentrated. Flash chromatography (4% acetone in hexane) gave 23.89 g (74%) of the mono-epoxide: ^1H nmr (60 MHz) δ: 5.3 (2H, br s) and 2.8–1.3 (10H as complex m) including a large narrow m at δ 2.4 (approx. 4H). This was brominated as for **6**, to provide **10** as a crystalline solid (87%): mp 87–88°C; ir (KBr pellet) ν_{max}: 1415, 1069, and 933 cm^{-1}; ^1H nmr δ: 4.41 (1H, ddd, J = 4.3, 5.4, 6.6 Hz), 4.30 (1H, ddd, J = 4.9, 6.2, 6.6 Hz), 3.01 (1H, dd, J = 4.3, 15.8 Hz), 2.82 (1H, dd, J = 6.2, 16.4 Hz), 2.67 (1H, dd, J = 4.9, 16.4 Hz), 2.42 (1H, dd, J = 5.4, 15.8 Hz), 2.04 (2H, distorted quintet), 1.59 (3H, distorted septet), and 1.42 (1H, m); ^{13}C nmr δ: 65.5 and 64.6 (oxirane carbons), 49.9 and 47.0 (2 × CHBr), 34.6, 33.5, 31.8, 31.2, and 19.6; ms m/z (%): 298 (0.3), 296 (0.7) and 294 (0.4) all M^+, 217 (0.7), 215 (0.7), 135 (100), 117 (13), 107 (24), 93 (44), 91 (25), 79 (62), 77 (24), and 55 (32).

*10-Oxatricyclo[4.3.1.0]deca-2,4-diene (**11**)*

The dibromide **10** (1.1975 g, 4.05 mmol) was dehydrobrominated in the same manner as **6** to give **11** (0.4940 g, 91%) as a pale yellow liquid: ir (film) ν_{max}: 1437, 1271, 1187, 1055, 911, 868, and 773 cm^{-1}; ^1H nmr (60 MHz) δ: 6.3 (4H, symmetrical m) and 2.9–1.1 (6H as a complex m); ^{13}C nmr δ: 128.3, 126.9, 70.7, 29.4, and 18.1; ms m/z

(%): 134 (M^+, 67), 133 (21), 117 (17), 115 (18), 106 (21), 105 (38), 91 (86), 79 (43), 78 (100), 77 (39), and 51 (48). Exact mass calcd. for $C_9H_{10}O$: 134.0731; found: 134.0737.

Diels–Alder reaction of ***11*** *with* N*-phenylmaleimide*

A solution of **11** (95.3 mg, 0.710 mmol) and *N*-phenylmaleimide (120.3 mg) in $CDCl_3$ (1.0 mL) was stirred at room temperature for 16 h. The ^1H nmr of the crude mixture showed signals for only one adduct (**13**), which was isolated as colorless crystals (0.1565 g, 72%) following flash chromatography (30% ethyl acetate in hexane): mp 261–262°C; ir (KBr pellet) ν_{max}: 1713, 1597, 1385, and1185 cm^{-1}; ^1H nmr δ: 7.48–7.14 (5H), 6.03 (2H, dd, J = 3.3, 4.7 Hz), 3.65 (2H, m), 3.26 (2H, apparent t, J = 1.7 Hz), 2.03 (2H, m), and 1.89–1.74 (4H, multiplets); nOe data: irradiate 6.03: nOe at 3.65 (10.5%); irradiate 3.65: nOe's at 6.03 (11%) and 3.26 (5.5%); irradiate 3.26: nOe's at 3.65 (12%) and a multiplet at approx. 1.75 (4%); irradiate 2.03: nOe's at 3.65 (3%) and 1.75 (10.5%); irradiate 1.75: nOe's at 3.26 (13.5%) and 2.03 (30%); ^{13}C nmr δ: 176.4, 131.4, 129.0, 128.6, 127.9, 126.3, 64.2 (oxirane carbons), 42.2 (α to C=O's), 37.4 (bridgeheads), 25.3 (2 × CH_2), and 25.0 (CH_2); ms m/z (%): 307 (M^+, 74), 173 (33), 160 (17), 159 (14), 134 (100), 133 (30), 132 (29), 131 (32), 117 (31), 104 (42), 93 (34), 91 (47), 78 (42), and 77 (32). Exact mass calcd. for $C_{19}H_{17}NO_3$: 307.1207; found: 307.1193.

Diels–Alder reaction of ***11*** *with* N*-methylmaleimide*

A solution of **11** (0.231 g, 1.72 mmol) and *N*-methylmaleimide (0.192 g, 1.72 mmol) in $CDCl_3$ (2 mL) was stirred at room temperature for 16 h, after which time ^1H nmr indicated that most of the diene had been consumed, and signals for only one adduct were evident. The adduct was purified by flash chromatography (50% ethyl acetate in hexane) to give colorless crystals of **14** (0.327 g, 77%): mp 151–153°C; ir (KBr pellet) ν_{max}: 1772 (w) and 1702 cm^{-1}; ^1H nmr δ: 5.88 (2H, dd, J = 3.3, 4.6 Hz), 3.52 (2H, m, bridgeheads), 3.06 (2H, narrow m, α to C=O's), 2.89 (3H, s, *N*-CH_3), and 2.05–1.62 (6H, multiplets); nOe data: irradiate 3.06: nOe's at 3.52 (8%) and ca. 2.75 (3%); irradiate ca. 2.75: nOe's at 3.52 (3%), 3.06 (15%), and ca. 2.00 (35%); ^{13}C nmr δ: 177.2, 127.6, 64.0, 42.0, 36.9, 25.2, 24.8, and 24.4 (CH_3); ms m/z (%): 245 (M^+, 16), 244 (6), 217 (29), 186 (32), 160 (21), 159 (18), 134 (100), 133 (44), 132 (47), 131 (57), 104 (86), 91 (66), 78 (88), and 77 (45). Exact mass calcd. for $C_{14}H_{15}NO_3$: 245.1051; found: 245.1056.

Diels–Alder reaction of ***11*** *with dimethyl acetylenedicarboxylate*

A solution of **11** (0.166 g, 1.24 mmol) and dimethyl acetylenedicarboxylate (150 μL, 1.24 mmol) in $CHCl_3$ (5 mL) was stirred at room temperature for 16 h, after which time ^1H nmr indicated the presence of only one adduct. Flash chromatography (20% acetone in hexane) yielded **15** as a pale yellow oil (0.344 g, 84%) that crystallized slowly on standing: mp 72–75°C; ir (film) ν_{max}: 2954, 1717, 1635, and 1270 cm^{-1}; ^1H nmr δ: 6.32 (2H, dd, J = 3.5, 4.2 Hz), 4.16 (2H, apparent br t, J = 3.7 Hz), 3.80 (6H, s), and 1.60–1.98 (6H, m); irradiation of the signal at δ 3.80 resulted in no significant nOe's; ^{13}C nmr δ: 166.2, 147.2, 131.3, 70.9, 52.3 (2 × OCH_3), 44.9 (bridgeheads), 27.2 (2 × CH_2), and 25.9 (CH_2); ms m/z (%): 276 (M^+,15), 244 (93), 220 (34), 217 (50), 205 (53), 189 (77), 188 (60), 185 (76), 157 (50), and 129 (100).

X-ray structure determination of ***15***

Data collection was on a Rigaku AFC6S diffractometer with a graphite monochromator with MoKα radiation (λ = 0.71069 Å). Crystallographic data are summarized in Table 1. Cell constants and an orientation matrix for data collection were obtained by least squares using the setting angles of 25 reflections ($38.3 < 2\theta < 43.4°$). Data collection used the ω–2θ scan technique. Omega (ω) scans of several intense reflections, made before data collection, had an average width at half-height of 0.03° with a take-off angle of 6.0°. Scans of (1.05 + 0.30 tan θ)° were made at a speed of 32.0°/min (in ω). The weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of 2 rescans), and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. Three reference reflections, measured every 150 reflections, remained constant. Intensities were corrected for Lorentz and polarization effects; a correction for secondary extinction was applied. The structure was solved by direct methods. Full-matrix least-squares refinement with anisotropic factors given to all non-H atoms converged

[a]B_{iso} is the mean of the principal axes of the thermal ellipsoid.

15

to $R = 0.045$, $R_w = 0.040$, $S = 1.83$. The weighting scheme was based on counting statistics. The maximum shift/error in the final cycle was 0.12. The largest peaks in the final difference map were +0.22 and −0.15 e/Å^3. Atomic scattering factors were from International tables for X-ray crystallography (29); anomalous dispersion effects were included in F (32). All calculations were made with the TEXSAN crystallographic software package (33). Figure 2 was prepared from the output of ORTEPII (30). Bond lengths and angles are given in Table 4, and positional and thermal parameters for refined atoms appear in Table 5.[6]

ABDALLAH ALBOURINE, MICHELLE PETIT-RAMEL, GERMAINE THOMAS-DAVID et JEAN JACQUES VALLON. Can. J. Chem. **69**, 1344 (1991).

Les constantes de stabilité des complexes binaires de la 1-canavanine (Can) et la 1-arginine (Arg) avec Ni^{2+} et Zn^{2+} ont été déterminées à 25°C et à force ionique $\mu = 0{,}1$ ($NaNO_3$). Cette technique est complétée par des mesures spectrophotométriques et de dichroïsme circulaire dans les domaines ultraviolet et visible. Ainsi nous avons calculé les absorbances molaires et les dichroïsmes circulaires molaires de la 1-canavanine et la 1-arginine ligands et de leurs complexes avec Ni^{2+} et Zn^{2+}. Pour le nickel(II), ces différentes mesures mettent en évidence trois complexes, NiL, NiL_2 et NiL_3. La 1-canavanine, ligand tridenté, prend un caractère bidenté lors de la formation du complexe $Ni(Can)_3$. En ce qui concerne le zinc(II), cette étude conduit à deux espèces complexées : ZnL et ZnL_2.

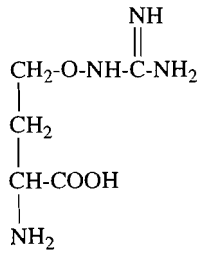
Mots clés : 1-arganine, 1-canavanine, coordination binaire du nickel, coordination binaire du zinc, dichroïsme circulaire.

ABDALLAH ALBOURINE, MICHELLE PETIT-RAMEL, GERMAINE THOMAS-DAVID, and JEAN JACQUES VALLON. Can. J. Chem. **69**, 1344 (1991).

The stability constants of binary complexes of 1-canavanine (Can) and 1-arginine (Arg) with Ni^{2+} and Zn^{2+} have been calculated at 25°C and at ionic strength $\mu = 0.1$ ($NaNO_3$). This technique is completed with spectrophotometry and circular dichroïsm measurements in the ultraviolet and visible ranges. Thus we determined the molar absorbances and the molar circular dichroïsm of ligands and complexes with Ni^{2+} and Zn^{2+}. Concerning the nickel(II), these measurements display three complexes, NiL, NiL_2, and NiL_3. 1-Canavanine, which generally has a tridentate ligand behaviour, becomes a bidentate ligand in the $Ni(Can)_3$ complex. With regard to zinc(II), this study only displays the ZnL and ZnL_2 species.

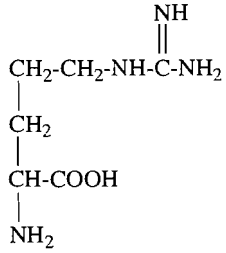
Key words: 1-arginine, 1-canavanine, circular dichroïsm, nickel binary coordination, zinc binary coordination.

Introduction



Ce mémoire se situe dans le prolongement d'un examen comparé des propriétés complexantes de la 1-canavanine et de la 1-arginine avec le cuivre(II) (1).

La 1-canavanine ou acide amino-2 (guanidinoxy)-4 butyrique, analogue structural de la 1-arganine, entre dans la composition des germes de certaines légumineuses (2). Fischer et Belitz l'utilisent comme indicateur de protéines de soja dans les produits alimentaires carnés (3). En outre, elle se révèle très utile pour l'étude des mécanismes bactériens de la dégradation des protéines anormales et le contrôle génétique des réactions métaboliques (2).



Nous avions signalé que la 1-canavanine possède, cependant, des propriétés antimétaboliques car elle provoque des altérations structurales et fonctionnelles fatales pour la protéine (2). Cette toxicité provient de sa ressemblance structurale avec la 1-arginine qui lui permet de réagir avec les enzymes spécifiques de celle-ci (4).

Bien que les composés minéraux ne constituent qu'une fraction très faible des tissus cellulaires, ils restent cependant essentiels au maintien de la vie. Parmi ces éléments, les métaux alcalins et alcalino-terreux ont toujours eu une place prépondérante vis-à-vis des protéines et acides aminés.

En ce qui concerne les métaux de transition, nous retiendrons le caractère essentiel du nickel chez les animaux supérieurs (5–8) dont la carence entraîne certains syndromes chez plusieurs animaux tel que le rat (9). Le nickel est également essentiel pour les plantes : l'uréase du Jack bean (canavalia ensiformis) et du soja (glycine max) contenant de la 1-canavanine, sont en effet des métalloenzymes à nickel (10–13). De même, il induit l'hydrolyse de l'arginine par l'uréase du soja.

1-Canavanine

1-Arginine

Quant au zinc, élément indispensable au métabolisme humain, il entre de même dans la composition de nombreuses enzymes. Il faut noter que la dose quotidienne de zinc nécessaire à l'homme adulte (0,3 mg/kg) est facilement obtenue par des conditions normales d'alimentation (14). Le zinc(II), notamment considéré comme un catalyseur acide, favorise la coupure des chaînes péptidiques dans la mesure où il est susceptible de former des complexes stables avec les acides aminés constituant l'enchaînement (15).

La démarche suivie pour la mise en évidence des espèces complexées $M_pH_qL_rL'_s$ ainsi que le calcul de leurs constantes de stabilité β_{pqrs} et de leurs facteurs intensifs émane directement du protocole développé dans le précédent mémoire (1).

$Zn(Arg)_2$	1020	7,95	3,95	pH 6,75–11	3,91	3,96

Résultats

Rappelons que la déprotonation du groupement guanidyle (log $K = 11,58$) de la 1-arganine n'intervient pas dans le domaine de pH correspondant à la complexation des métaux de transition (pH <10). Seuls le groupement aminé (log $K = 8,98$) d'une part et le groupement carboxylate (log $K = 2,22$) d'autre part sont concernés (1).

Dans le cas de la 1-canavanine, au contraire, les trois groupements : aminé (log $K = 9,16$), guanidyle (log $K = 6,98$) et carboxylate (log $K = 2,15$) participent à la chélation (1).

Il faut noter que, si les travaux concernant la 1-arginine complexée ou non sont nombreux (16, 19), nous ne disposons d'aucune donnée bibliographique concernant la complexation du nickel et du zinc par la 1-canavanine.

1. Ni(II)–1-canavanine et Ni(II)–1-arginine

1. A. Mesures potentiométiques

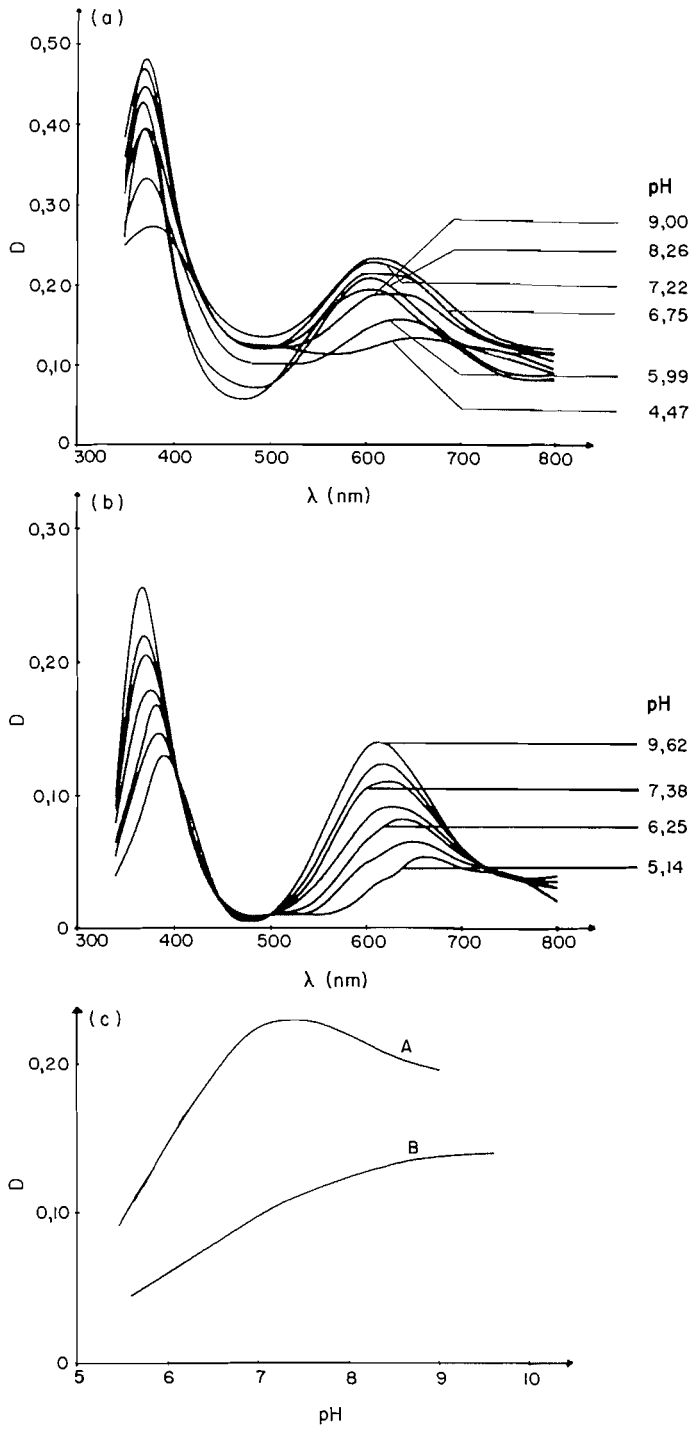
Les rapports métal : ligand (1 : 3 et 1 : 5) étudiés conduisent aux classiques courbes de formation $\bar{n} = f(pL)$ (fig. 1a). Pour les deux systèmes, elles tendent vers $\bar{n} = 3$, ce qui implique la formation des espèces successives ML, ML_2 et ML_3 dont on peut apprécier graphiquement les constantes de stabilité. Les valeurs définitives des constantes affinées par la méthode de pit-mapping, ainsi que les données bibliographiques, sont rassemblées dans le tableau 1. Les courbes de répartition sont représentées sur les figures 1b et 1c. Quel que soit le ligand, 1-canavanine ou 1-arginine, le complexe ML_2 reste toujours majoritaire.

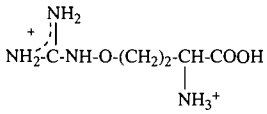
1. b. Mesures spectroscopiques

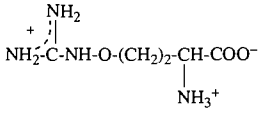
Les solutions utilisées pour les mesures spectrophotométriques sont 0,010 M en Ni^{2+} et 0,025 M en 1-canavanine d'une part; 0,020 M en Ni^{2+} et 0,050 M en 1-arginine d'autre part. Le domaine de longueur d'onde envisagé est compris entre 300 et 800 nm.

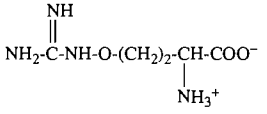
Pour des pH inférieurs à 5, comme le montrent les deux faisceaux de spectres (fig. 2a et fig. 2b), nous sommes en présence de deux bandes attendues, correspondant au nitrate de nickel(II) : l'une étroite dont le maximum très aigu est à 370 nm, l'autre beaucorp plus large possède deux maxima (640 et 650 nm). Ces observations ont conformes aux travaux de Nicholls (18).

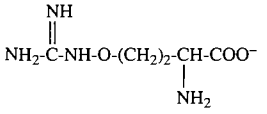
Pour les pH supérieurs à 5, ces transitions de très faible absorbance se trouvent amplifiées et décalées vers les plus faibles longueurs d'onde grâce à l'effet hypsochrome normal du

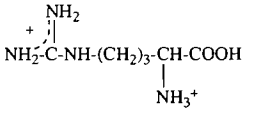


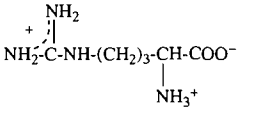


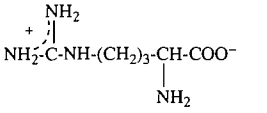












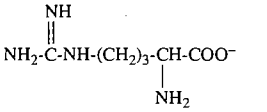


FIG. 2. (a) Faisceau des spectres d'absorption du système 1-canavanine (0,025 M)–nickel(II) (0,01 M). (b) Faisceau des spectres d'absorption du système 1-arginine (0,05 M)–nickel(II) (0,02 M). (c) Variation du maximum d'absorption (610 nm) en fonction du pH pour les systèmes 1-canavanine–nickel(II) (A) et 1-arginine–nickel(II) (B).

champ de ligand de chaque coordinat. En outre, les deux maxima de la bande située vers 640 nm tendent à s'aplatir et à se confondre en un seul vers 610 nm.

L'absorbance molaire du système Ni(II)–1'arginine (fig. 2c) augmente progressivement au delà de pH 5 de manière analogue à celle du système Cu(II)–l'arginine (1). Ceci se justifie par la formation graduelle des complexes NiArg, $Ni(Arg)_2$ et $Ni(Arg)_3$ de plus en plus stables. L'absorbance molaire de chaque

TABLEAU 2. Facteurs intensifs spectrophotométriques et dichroïques de la l-canavanine et de la l-arginine

	Spectrophotométrie		Dichroïsme circulaire	
	λ(nm)	ε	λ(nm)	Δε
l-Canavanine				
	213	324	213	+1,06
	213	375	213	+0,62
	213	3717	213	+0,66
	213	3392	213	+1,67
l-Arginine				
	200	2000	210	+1,59
	200	2000	210	+0,94
	200	2000	210	+0,07
	200	2000	210	+4,64

complexe est calculée puis affinée à 610 nm (tableau 2). Elle croit normalement avec l'augmentation du nombre de cycles de chélation.

Dans le cas du système Ni(II)–l-canavanine, il faut distinguer deux étapes (fig. 2c): (*i*) $5 < pH < 7.5$: l'absorbance augmente avec le pH, les courbes de répartition indiquant la formation successive des complexes NiCan et $Ni(Can)_2$. (*ii*) $7.5 < pH < 9$: l'absorbance diminue lorsqu'apparait le complexe $Ni(Can)_3$.

Cette dernière observation, après calcul des absorbances molaires à 610 nm (tableau 3), tend à montrer que le nombre de cycles de chélation est plus faible pour l'espèce $Ni(Can)_3$ que pour l'espèce $Ni(Can)_2$.

Les mêmes solutions sont ensuite examinées par dichroïsme circulaire entre 300 et 750 nm (fig. 3a et fig. 3b). L'examen des spectres dichroïques montre que pour chacun des deux ligands, les complexes obtenus présentent un comportement dichroïque différent : Le système nickel–l-canavanine fait apparaître cinq bandes bien différenciées (357, 410, 553, 620 et 695 nm) alors que le système nickel–l-arginine ne comporte que trois bandes (355, 568 et 667 nm). Les amplitudes dichroïques des complexes évoluent de la même manière que leur densité optique.

TABLEAU 3. Facteurs intensifs spectrophotométriques et dichroïques des complexes de la l-canavanine et de la l-arginine avec Ni^{2+} et Zn^{2+}

	Spectrophotométrie		Dichroïsme circulaire	
	λ (nm)	ε	λ (nm)	Δε
NiCan	610	9,67	620	−0,0019
$Ni(Can)_2$	610	12,31	620	−0,0203
$Ni(Can)_3$	610	6,10	620	−0,0126
NiArg	610	4,67	568	−0,0009
$Ni(Arg)_2$	610	5,74	568	−0,0080
$Ni(Arg)_3$	610	9,59	568	−0,0091
ZnCan	—	—	213	+0,22
$Zn(Can)_2$	—	—	213	−9,00
ZnArg	—	—	210	−1,75
$Zn(Arg)_2$	—	—	210	−0,02

Les figures 3a et 3b permettent de calculer le dichroïsme circulaire molaire en fonction du pH à 620 nm pour la l-canavanine et à 586 nm pour la l-arginine et d'estimer, pour ces longueurs d'onde, les facteurs intensifs dichroïques respec-

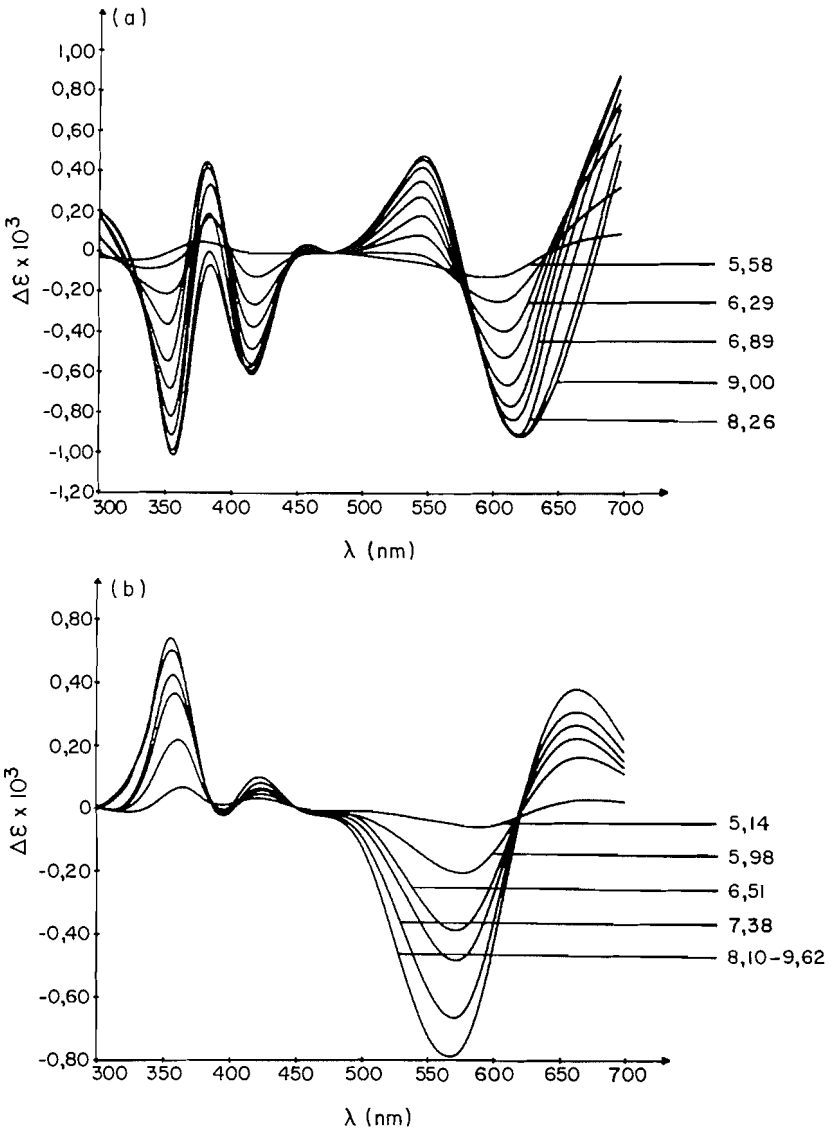

FIG. 3. (a) Faisceau des spectres d'absorption dichroïque du système 1-canavanine (0,025 M)–nickel(II) (0,01 M). (b) Faisceau des spectres d'absorption dichroïque du système 1-arginine (0,05 M)–nickel(II) (0,02 M).

tifs de chaque complexe. Ces paramètres sont ensuite affinés et consignés dans le tableau 3.

2. Zn(II)–1-canavanine et Zn(II)–1-arginine

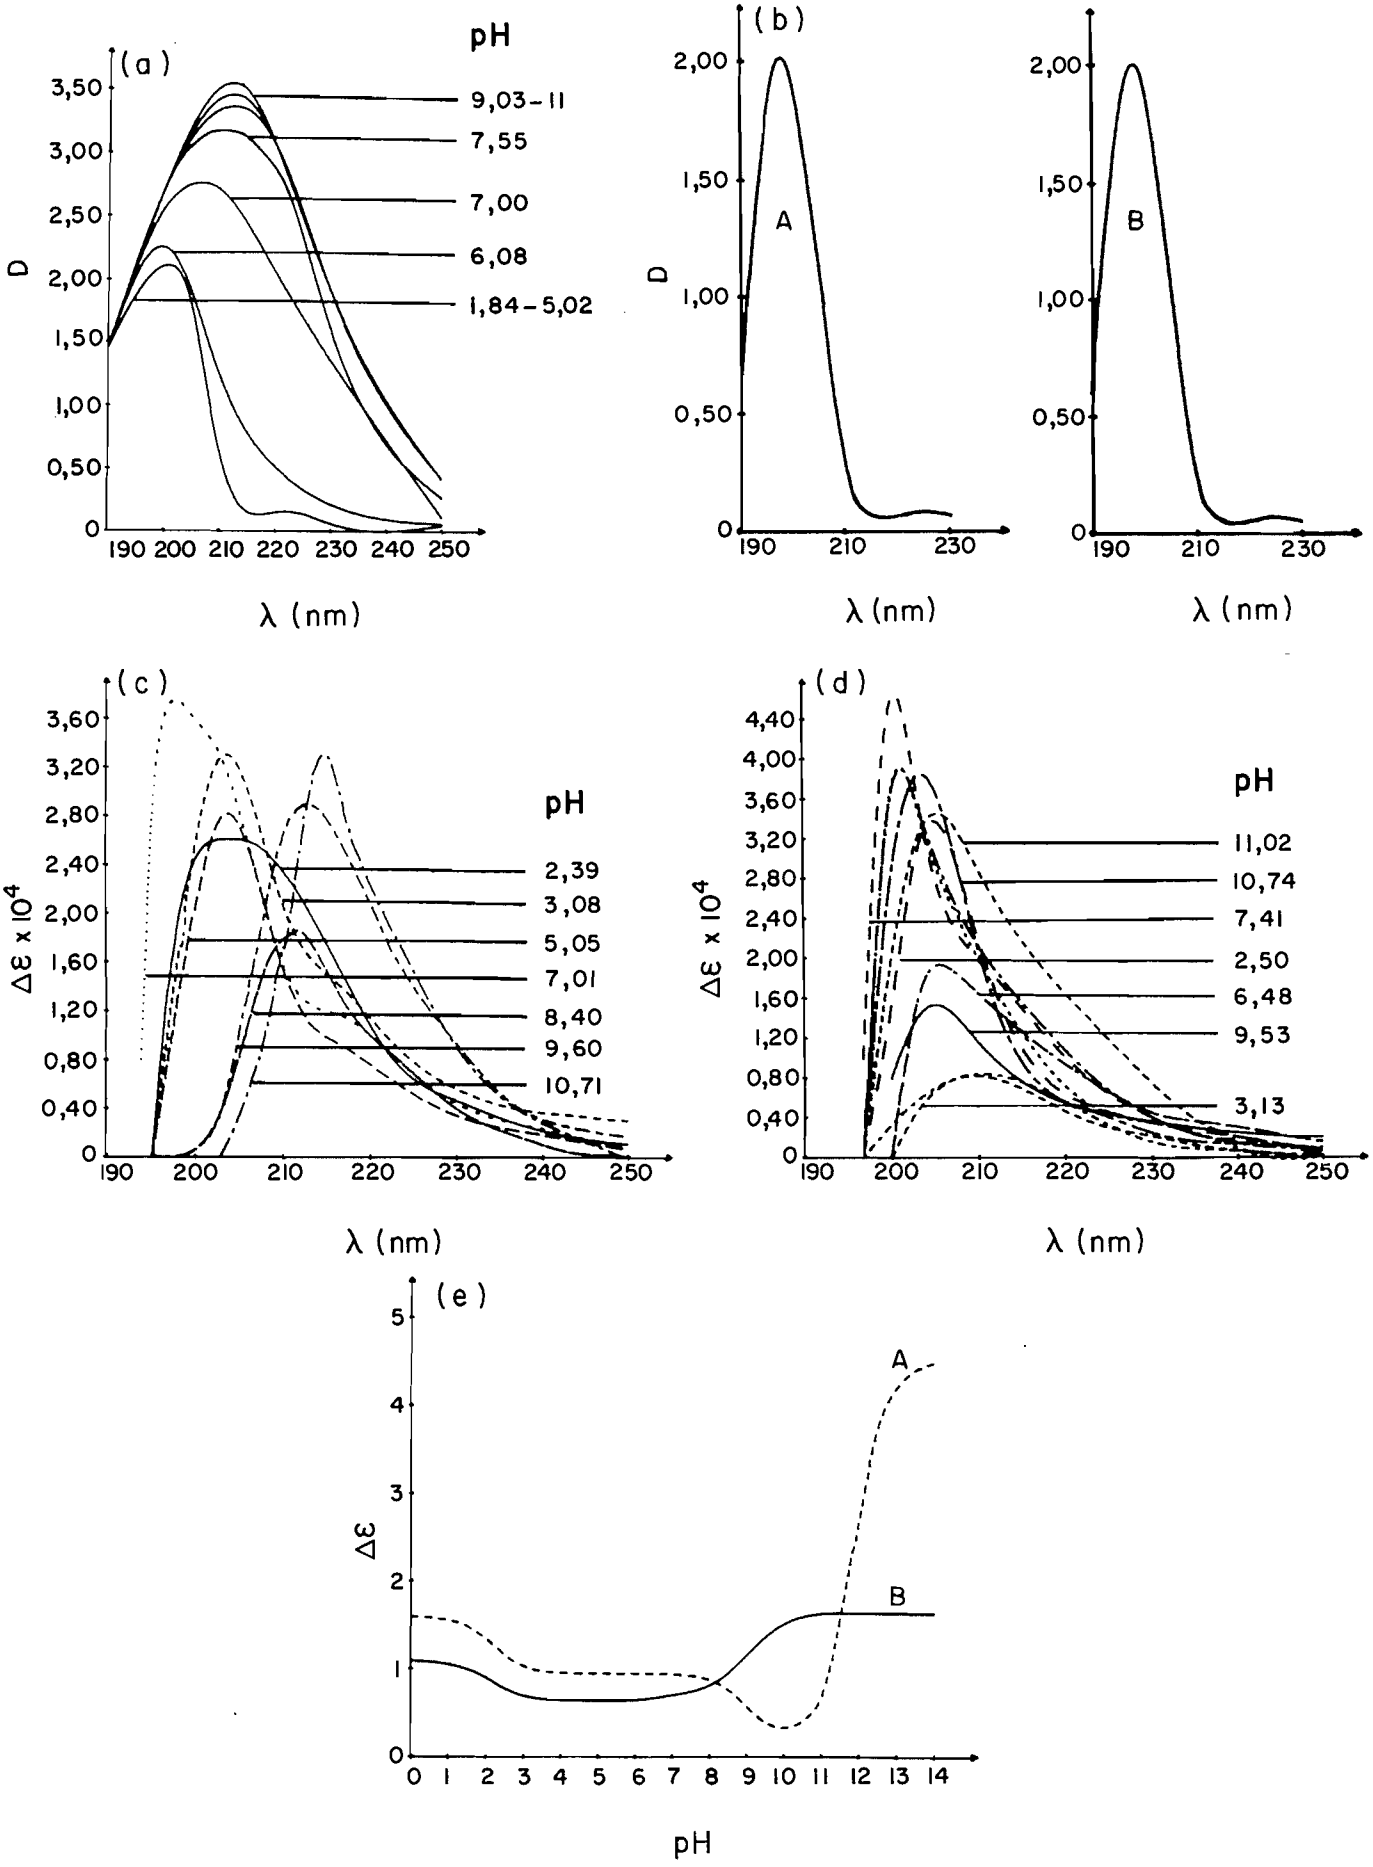
2. A. Mesures potentiométriques

Les deux rapports métal : ligand (1 : 3 et 1 : 5) conduisent aux courbes de formation $\bar{n} = f(\mathrm{pL})$ de la figure 1d.

Dans ce cas, seuls se forment les complexes ML et ML_2. Leurs constantes de stabilité sont réunies dans le tableau 1 et les courbes de répartition représentées sur les figures 1e et 1f.

2. B. Mesures spectroscopiques

Les mesures spectrophotometriques et dichroïques sont réalisées dans le domaine de l'ultraviolet (190–250 nm) où absorbent également chacun des ligands. Outre les espèces complexées, nous devons, alors, tenir compte de la contribution de leurs formes protonées.



(a) Ligands: Nous avons contrôlé les variations d'absorbance et de dichroïsme circulaire avec le pH de manière à mettre en évidence les facteurs intensifs de chaque forme protonée.

Les solutions de 1-canavanine et de 1-arginine étudiées sont 0,01 M en acide aminé. Les spectres d'absorption lumineuse et de dichroïsme circulaire ont été enregistrés entre 190 et 250 nm.

En ce qui concerne les mesures spectrophotométriques, dans le cas de la 1-canavanine (fig. 4a), nous observons une évolution de la longueur d'onde du maximum d'absorption ainsi que de l'amplitude d'absorption au fur et à mesure que le pH augmente. Les valeurs des facteurs intensifs des formes protonées sont estimées et affinées à 213 nm (tableau 2).

Pour la 1-arginine (fig. 4b), quel que soit le pH, la position et l'amplitude de la bande d'absorption restent invariables. Le maximum d'absorption est situé à 200 nm pour toutes les formes protonées; leur absorbance molaire est la même (tableau 2).

FIG. 4. (a) Faisceau des spectres d'absorption de la 1-canavanine (0,01 M). (b) Spectres d'absorption de la 1-arginine (0,01 M); A : pH = 5; B : pH = 10. (c) Spectres d'absorption dichroïque de la 1-canavanine (0,01 M). (d) Spectres d'absorption dichroïque de la 1-arginine (0,01 M). (e) Dichroïsme circulaire molaire de la 1-canavanine (213 nm) (B) et de la 1-arginine (210 nm) (A) en fonction du pH.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

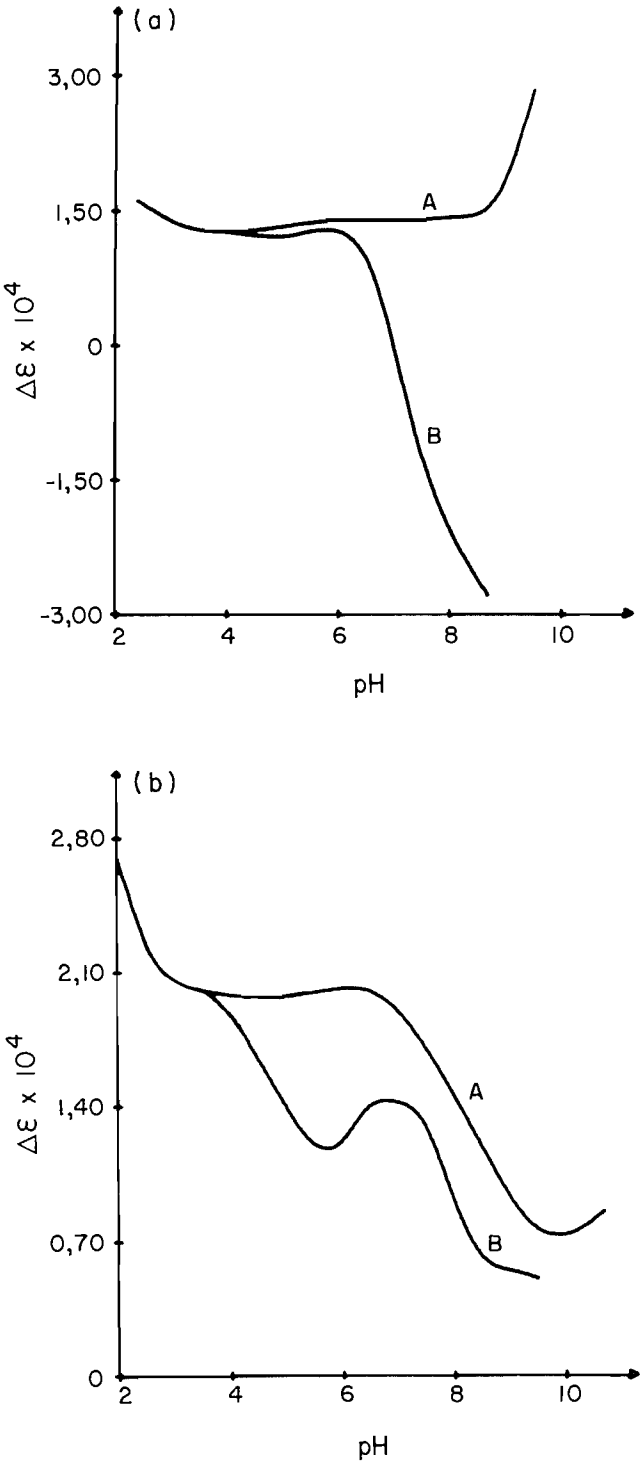


FIG. 5. (a) Absorption dichroïque de la 1-canavanine seule (0,01 M) (A) et du système 1-canavanine (0,01 M)–zinc(II) (0,002 M) (B) en fonction du pH à 213 nm. (b) Absorption dichroïque de la 1-arginine seule (0,01 M) (A) et du système 1-arginine (0,01 M)–zinc(II) (0,002 M) (B) en fonction du pH à 210 nm.

Quant au dichroïsme circulaire, que ce soit pour la 1-canavanine (fig. 4c) ou la 1-arginine (fig. 4d), la dépronation des molécules se traduit par un déplacement bathochrome des maxima d'absorption dichroïque.

Nous calculons de façon approchée les facteurs intensifs relatifs à chaque forme protonée pour une longueur d'onde donnée (213 nm pour la 1-canavanine et 210 nm pour la 1-arginine) qui sont ensuite affinés (tableau 2).

La figure 4e représente les dichroïsmes circulaires molaires en fonction du pH recalculés à l'aide des facteurs intensifs dichroïques pour les deux ligands. Ces deux courbes mettent parfaitement en évidence les différentes formes protonées.

(b) Zn(II)–1-canavanine : Les concentrations utilisées, pour les mesures spectrophotométriques et dichroïques, sont 0,01 M en ligand et 0,002 M en métal; soit un rapport ligand : métal égal à 5 de manière à éviter la formation d'espèces hydroxylées.

Nous n'avons pas observé de variation appréciable de longueur d'onde ou de densité optique par spectrophotométrie. Cette méthode ne permet donc pas de mettre en évidence les complexes formés entre la 1-canavanine et le zinc(II).

Par contre, les spectres dichroïques permettent de tracer la variation du dichroïsme circulaire du système en fonction du pH à 213 nm (fig. 5a, courbe B).

$2 < pH < 5$: les courbes A et B sont confondues, la réponse dichroïque correspond au ligand libre non complexé.

$pH > 5,5$: le dichroïsme circulaire de la 1-canavanine subit une profonde modification : formation des complexes ZnCan et surtout $Zn(Can)_2$ en bon accord avec les mesures potentiométriques (fig. 1e). Les dichroïsmes circulaires molaires des complexes ZnCan et $Zn(Can)_2$ sont notés dans le tableau 3.

(c) Zn(II)-1-arginine : Les concentrations de travail restent les mêmes et, comme précédemment, la spectrophotométrie ne permet pas d'identifier les différents complexes.

La figure 5b montre au contraire une variation appréciable de l'amplitude dichroïque avec le pH lors de la formation des complexes, notamment de l'espèce ZnArg. Les valeurs des dichroïsmes molaires des deux complexes affinées à 210 nm sont données dans le tableau 3.

Discussion

1. Complexation avec le nickel(II)

La 1-canavanine et la 1-arginine génèrent trois espèces successives complexes NiL, NiL_2 et NiL_3 mises en évidence par potentiométrie, spectrophotométrie et dichroïsme circulaire.

Les courbes de répartitions (fig. 1b et fig. 1c) montrent dans chaque cas un complexe ML_2 majoritaire.

Les mesures spectrophotométriques et surtout dichroïques du système nickel(II)–1-arginine confirment ces résultats dans la mesure où les absorbances molaires comme les dichroïsmes circulaires molaires des complexes NiArg, $Ni(Arg)_2$ et $Ni(Arg)_3$ augmentent avec le degré de coordination, donc avec le nombre de cycles de chélation (19, 20).

Ceci nous conduit à souligner un point intéressant concernant le nombre de positions chélatantes de la 1-canavanine. Nous avons montré, en effet, que la 1-canavanine, contrairement à la 1-arginine, présente un caractère tridenté vis-à-vis du cuivre(II) dans un état de coordinence 6 (1). Or, le nickel(II) favorise la formation d'une espèce $Ni(Can)_3$ dans laquelle la 1-canavanine ne peut être qu'un coordinat bidenté.

Les mesures spectrophotométriques présentent une augmentation de l'absorbance molaire du complexe $Ni(Can)_2$ par rapport à NiCan ensuite une diminution de l'absorbance du complexe $Ni(Can)_3$. Les complexes NiArg, $Ni(Arg)_2$ et $Ni(Arg)_3$ présentent au contraire une absorbance molaire régulièrement croissante.

Les mesures dichroïques dépendant étroitement du nombre de cycles de chélation (20) recoupent aisément cette hypothèse dans la mesure où le dichroïsme circulaire molaire de NiCan (deux cycles de chélation, ligand tridenté) est inférieur à celui

du complexe $Ni(Can)_3$ (trois cycles de chélation, ligand bidenté) lui-même inférieur à celui du complexe $Ni(Can)_2$ (quatre cycles de chélation, ligand tridenté).

Si l'examen comparé des spectres dichroïques des complexes du cuivre (1) ne permet pas une différenciation nette entre la 1-arginine et la 1-canavanine, les spectres de chaque complexe du nickel(II), très différents (fig. 3a et fig. 3b), devraient pouvoir être considérés comme des facteurs intéressants de contrôle de qualité.

2. Complexation avec le zinc(II)

Les complexes de zinc(II) formés avec la 1-canavanine et la 1-arginine identifiés par potentiométrie sont au nombre de deux : ZnL et ZnL_2.

L'étude spectroscopique de ces complexes nécessite un examen préalable des propriétés optiques des deux coordinats.

La spectrophotométrie ultraviolet montre que la 1-canavanine et la 1-arginine, comme la plupart des acides aminés (17), absorbent dans le domaine de longueurs d'onde 200–220 nm. Cette technique confirme la différence existant entre la 1-canavanine et la 1-arginine (fig. 4a et fig. 4b) malgré leur ressemblance structurale : les spectres d'absorption de la 1-arginine ne subissent aucune modification en fonction du pH; les spectres d'absorption de la 1-canavanine présentent en fonction du pH un effet bathochrome appréciable.

En outre, les mesures de dichroïsme circulaire à 213 nm pour la 1-canavanine et 210 nm pour la 1-arginine permettent de tracer les courbes de dichroïsme circulaire en fonction du pH. Ces courbes mettent parfaitement en évidence les différentes formes protonées ainsi que leur domaine d'existence. Ces résultats sont conformes à l'étude potentiométrique de ces deux ligands (1).

Si la spectrophotométrie ultraviolet ne permet pas l'identification des chélates de la 1-canavanine et la 1-arginine, les spectres dichroïques des espèces compléxées traduisent beaucoup mieux l'influence de la coordination sur la variation du dichroïsme circulaire des formes protonés des ligands. Nous avons, en outre, mis en évidence la différence nette de comportement dichroïque des formes $Zn(Arg)_2$ et $Zn(Can)_2$.

Nous avons signalé dans l'introduction une certaine toxicité de la 1-canavanine ainsi que le rôle du nickel et du zinc dans les enzymes. Cette toxicité peut être liée à la stabilité des complexes métalliques formés avec ces oligo-éléments enzymatiques plus importante pour la 1-canavanine que pour la 1-arginine. Il existe en effet une corrélation entre la stabilité et l'effet chélate important dû au caractère tridenté de la 1-canavanine.

Partie expérimentale

Matériel

Nous disposons d'une chaîne de mesures étalonnée avec précision : électrode de verre|solution thermostatée|KCl saturé|électrode calomel.

Le jeu d'électrodes est relié à un potentiomètre Isis 2000 Tacussel et les mesures sont effectuées sur des solutions aqueuses thermostatées à 25°C ± 0,1°C et sous atmosphère d'azote. La force ionique de chaque solution est maintenue constante à l'aide d'une solution de $NaNO_3$ 0,1 M.

Les spectres d'absorption sont tracés à l'aide d'un spectrophotomètre Varian 634 et les spectres dichroïques à l'aide d'un dichrographe Jobin–Yvon Mark IV. Les cuves Hellma sont en quartz et ont des trajets optiques différents : 1 cm pous les mesures d'absorption dans le visible; 1 mm pour les mesures d'absorption dans l'ultraviolet; 5 cm pour les mesures dichroïques dans le visible; 0,2 mm pour les mesures dichroïques dans l'ultraviolet.

Réactifs

La 1-canavanine est sous forme sulfate de canavanine ou sous forme « free base » (Sigma) et la 1-arginine sous forme free base (Sigma). Ces acides aminés sont conservés à basse température.

Les sels métalliques sont introduits d'une part sous forme de nitrate de nickel(II) : $Ni(NO_3)_2 \cdot 6H_2O$ (Prolabo) et d'autre part sous forme de sulfate de zinc(II) : $ZnSO_4 \cdot 7H_2O$ (Prolabo). Ils sont dissous dans l'eau distillée et leurs titres sont déterminés par un dosage complexométrique à l'EDTA.

Triterpenoid glycosides from the Northeastern Pacific marine sponge *Xestospongia vanilla*

SANDRA A. MORRIS, PETER T. NORTHCOTE, AND RAYMOND J. ANDERSEN[1]

Departments of Chemistry and Oceanography, University of British Columbia, Vancouver, B.C., Canada V6T 1Z4

Received March 18, 1991

SANDRA A. MORRIS, PETER T. NORTHCOTE, and RAYMOND J. ANDERSEN. Can. J. Chem. **69**, 1352 (1991).

Isoxestovanin A (**6**), xestovanin B (**7**), xestovanin C (**8**), dehydroxestovanin A (**9**), epidehydroxestovanin A (**10**), dehydroxestovanin C (**11**), and secodehydroxestovanin A (**12**), seven new triterpenoid glycosides, have been isolated from the Northeastern Pacific sponge *Xestospongia vanilla*. The structures of the metabolites were determined by a combination of spectroscopic analysis and chemical degradation. The aglycone of **6** has the new isoxestovanane triterpenoid carbon skeleton. Compounds **7**, **8**, and **11** are the first *X. vanilla* triterpenoid glycosides known to contain three monosaccharide subunits.

Key words: triterpenoid, glycoside, sponge, Xestospongia.

SANDRA A. MORRIS, PETER T. NORTHCOTE et RAYMOND J. ANDERSEN. Can. J. Chem. **69**, 1352 (1991).

On a isolé des extraits de sept nouveaux glycosides triterpéniques : la isoxestovanine A (**6**), la xestovanine B (**7**), la xestovanine C (**8**), la déhydroxestovanine A (**9**), la épidéhydroxestovanine A (**10**), la déhydroxestovanine C (**11**) et la secodéhydroxestovanine A (**12**), á partir de la *Xestospongia vanilla*, l'éponge du Pacifique Nord-est. On a déterminé la structure des métabolites par analyse spectrale et par dégradation chimique. L'aglycone du composé **6** a le sequelette carboné du nouveau triterpène isoxestovanane. Les composés **7**, **8** et **11** sont les premiers glycosides triterpéniques *X. vanilla* connus qui contiennent trois sous-unités monosaccharides.

Mots clés : triterpène, glycoside, éponge, Xestopongia.

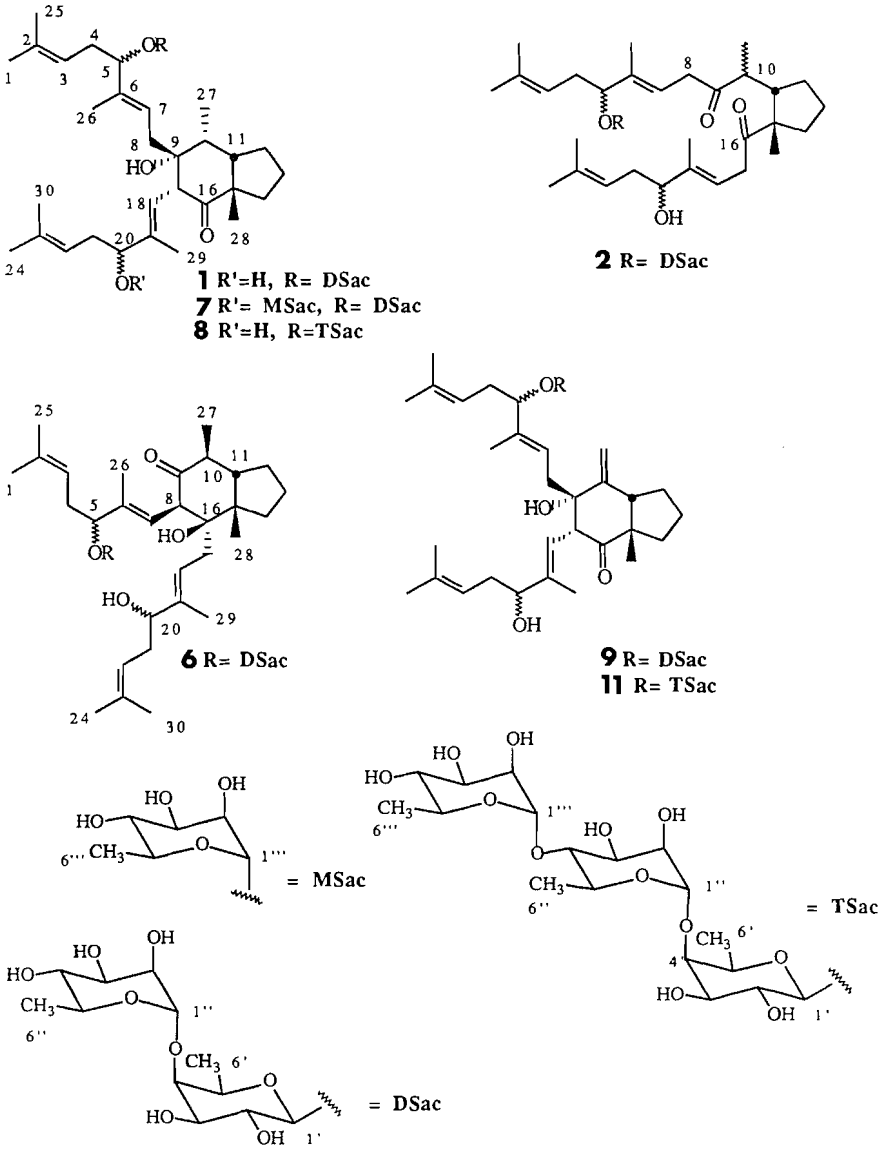
The Northeastern Pacific sponge *Xestospongia vanilla* is an extremely rich source of terpenoid metabolites. We have previously reported the isolation of xestodiol (1), xestovanin A (**1**) (2), secoxestovanin A (**2**) (2), xestenone (**3**) (3), secoxestenone (**4**) (4), and xestolide (**5**) (4) from *X. vanilla*. Xestodiol is an 18-carbon apocarotenoid, xestovanin A (**1**) and secoxestovanin A (**2**) are triterpenoid glycosides with the new xestovanane and secoxestovanane carbon skeletons, and xestenone (**3**), secoxestenone (**4**), and xestolide (**5**) are degraded triterpenoids (4) that represent three additional unprecedented terpenoid skeletons. The discovery of triterpenoid glycosides in *X. vanilla* is of particular interest because only one other marine sponge, *Asteropus sarsinosum*, has been found to contain this type of metabolite (5). Prior to their discovery in the sponges *X. vanilla* and *A. sarsinosum*, the only known marine sources of triterpenoid glycosides were echinoderms (6).

A continuing investigation of the terpenoid metabolism of *X. vanilla* has led to the isolation of seven new metabolites, isoxestovanin A (**6**), xestovanin B (**7**), xestovanin C (**8**), dehydroxestovanin A (**9**), epidehydroxestovanin A (**10**), dehydroxestovanin C (**11**), and secodehydroxestovanin A (**12**), whose structures are reported herein. One of the metabolites, isoxetovanin A (**6**), has the new isoxestovanane triterpenoid carbon skeleton, five (compounds **7**, **8**, **9**, **10**, and **11**) have the xestovanane carbon skeleton, and one (compound **12**) has the secoxestovanane skeleton. As part of this investigation, an interesting geographic variation in the metabolite content of *X. vanilla* has been observed.



Specimens of *X. vanilla* were collected by hand using SCUBA in exposed surge channels along the shoreline of the Deer group of islands in Barkley Sound and along the northern tip of Anthony Island in the Queen Charlotte Islands group, British Columbia. The Bamfield specimens of *X. vanilla* (1000 g, dry weight) yielded the previously described metabolites xestovanin A (**1**) (50 mg) and secoxestovanin A (**2**) (5 mg) along with the new metabolites isoxestovanin A (**6**) (11 mg), xestovanin B (**7**) (12 mg), xestovanin C (**8**) (10 mg), dehydroxestovanin A (**9**) (12 mg), and secodehydroxestovanin A (**12**) (20 mg), whereas the Anthony Island specimens yielded dehydroxestovanin A (**9**) (15 mg), epidehydroxestovanin A (**10**) (14 mg), dehydroxestovanin C (**11**) (10 mg), and secodehydroxestovanin A (**12**) (20 mg).

New metabolites from the Bamfield specimens

Isoxestovanin A (**6**) was isolated as an optically active ($[\alpha]_D$ −4.4 (*c* 0.16, MeOH)) colorless glass that gave an intense pseudomolecular ion at m/z 787 Da ($C_{42}H_{68}O_{12}$ + Na) in the FABMS. A comparison of the ^1H and ^{13}C NMR data obtained for isoxestovanin A (**6**) (Tables 1 and 2) with the NMR data previously obtained for xestovanin A (**1**) showed that the two molecules were closely related triterpenoid glycosides. Therefore, the highest mass ion observed in the EIHRMS of **6** at m/z 436.3336 Da ($C_{30}H_{44}O_2$, ΔM −0.5 mmu) could be attributed to the loss of a disaccharide substituent and one molecule of water from the parent ion to give a fragment containing the carbon skeleton of the triterpenoid aglycone. The presence of an intense peak at m/z 311 Da in the FABMS of isoxestovanin A (**6**), which could be assigned to a disaccharide fragment ($C_{12}H_{22}O_9$ + H), provided further evidence for a general structure consisting of a triterpenoid aglycone attached to a disaccharide.

A total of 42 resonances were observed in the ^{13}C NMR spectrum of isoxestovanin A (**6**) (Table 2), an APT experiment (7) identified 61 protons attached to carbon atoms (10 × CH_3, 6 × CH_2, 19 × CH), and the ^1H NMR spectrum (Table 1) contained resonances that could be assigned to six secondary hydroxyl protons and one tertiary alcohol proton. The combined NMR data provided carbon and hydrogen counts that were in agreement with the molecular formula ($C_{42}H_{68}O_{12}$) inferred for **6** from the FABMS and EIHRMS data. A detailed analysis of the ^{13}C NMR, ^1H NMR, NOE, and COSY data

[1]Author to whom correspondence may be addressed.

for **6** (Tables 1, 2, and 4[2]) led to the identification of two acyclic aglycone fragments (Fragment A: C1–C8 plus Me25 and Me26; Fragment B: C17–C24 plus Me29 and Me30) and the attached disaccharide and alcohol substituents that were nearly identical to the corresponding fragments of xestovanin A (**1**). Additional support for the nature of the C5 disaccharide substituent came from a standard GC analysis (8) (see Experimental) of the monosaccharides present in **6**. Only L-rhamnose and D-fucose were detected as expected from the NMR data. The magnitudes of the $^1J_{C,H}$ for the anomeric carbons and their attached protons in **6** were determined from a gated decoupled ^{13}C NMR experiment (fucose $^1J_{C,H}$ 156.8 Hz; rhamnose $^1J_{C,H}$ 171.0 Hz). They were consistent with a fucose β glycosidic linkage and a rhamnose α glycosidic linkage (9), as in xestovanin A (**1**).

The remaining portion of the aglycone in **6** had to contain 10 carbon atoms, it had to incorporate ketone (IR, 1710 cm^{-1}; ^{13}C NMR, acetone-d_6, δ 210.5), tertiary alcohol (^{13}C NMR, δ 83.6,s; ^1H NMR, Me_2SO-d_6, δ 4.42,s), secondary methyl (^1H NMR, δ 0.88,d), and tertiary methyl (^1H NMR, δ 0.96,s) functionalities, and it had to be bicyclic. Consideration of all of the spectral data for isoxestovanin A (**6**), in conjunction with the assumption that the aglycone had an unrearranged triterpenoid carbon skeleton, led to the conclusion that the 10-carbon bicyclic portion of its aglycone had a constitution corresponding to the expected product of intramolecular aldol condensation between the C8 methylene carbon and the C16 ketone functionality in secoxestovanin A (**2**). The resulting bicyclic fragment (see Fig. 1) contained a cyclohexanone functionality as required by the IR and ^{13}C NMR data for **6** (IR, 1710 cm^{-1}; ^{13}C NMR, acetone-d_6, δ 210.5). Correlations observed between the Me28 (δ 1.09) protons and C16 (δ 83.6) and between the Me27 protons (δ 0.95) and C9 (δ 210.5) in the HMBC spectrum (10) (acetone-d_6) of **6** provided strong support for the proposed structure. Additional HMBC correlations between both the Me27 (δ 0.95) and Me28 (δ 1.09) protons and the C11 resonance (δ 55.5) provided direct evidence for the C11—C15 bond. Further support for the proposed structure

[2]Supplemental material (24 pages): Table 4 (NOE results); selected ^1H and ^{13}C NMR spectra for compounds **6–12**; ^1H NMR data (acetone-d_6) for compounds **6**, **8**, **9**, **10**, and **11**; and spectral data for the peracetates of **6** and **9** has been deposited. A complete set of data may be purchased from The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

came from the COSY data for **6**, which contained correlations that could be assigned to the continuous spin system extending from the Me27 protons, through the H11 methine, and around the cyclopentane ring to H14 and H14′ (Table 1).

A series of NOE difference experiments helped establish the relative stereochemistry around the bicyclic ring system in isoxestovanin A (**6**) and also supported the proposed constitution. Irradiation of Me28 (δ 1.09: acetone-d_6) induced NOEs in H11 (δ 1.81), H14 (δ 1.65), and in the C16 hydroxyl proton (δ 3.49), and irradiation of H11 (δ 1.81) induced NOEs in Me27 (δ 0.95) and Me28 (δ 1.09). This series of NOEs were consistent with a *cis* ring fusion. Congestion in the ^{1}H NMR

Fragment B

spectrum of isoxestovanin A (**6**) recorded in Me_2SO-d_6 (Table 1) or acetone-d_6[2] precluded the use of NOE experiments to establish the relative stereochemistries at C8 and C10. However, in the ^{1}H NMR spectrum of isoxestovanin A (**6**), recorded in 10:1 acetone-d_6/benzene-d_6, the H8 and H10 resonances were well resolved and irradiation of H10 (δ 2.17) induced an NOE (8%) in H8 (δ 3.95), demonstrating that the two protons were 1,3 diaxial to each other as shown in Fig. 1. The 1,3-diaxial NOE between H8 and H10 also supported the proposed placement of the 10-carbon side chain containing the disaccharide substituent (Fragment A), which terminates in C8, adjacent to the C9 ketone functionality (i.e., 1,3 to C10). A COSY correlation (Table 1) between H8 (δ 3.79) and the 16OH proton (δ 4.42) was assigned to W coupling, indicating that H8 and the 16OH group were attached to adjacent carbons and that the 16OH was axial. Additional information about the conformation and relative stereochemistry of the bicyclic ring system came from a measurement of the H10/H11 vicinal coupling

[a–j]May be interchanged within a column. Hydrogen attachments were determined via APT. Assignments are partially based on HETCOR data. The di- and trisaccharide assignments are tentative.

constant in **6** (10:1 acetone-d_6/benzene-d_6). Irradiation of the Me27 resonance (δ 1.05) caused the H10 resonance (δ 2.17) to collapse to a doublet with $J = 11.1$ Hz, indicative of a *trans* diaxial coupling. The H10/H11 coupling constant in xestovanin A (**1**), where H10 is axial and H11 is equatorial, was found to be 5.9 Hz. Taken together, the above results completely defined the relative stereochemistry and conformation of the bicyclic portion of **6** to be that shown in Fig. 1.

Isoxestovanin A (**6**) has the new isoxestovanane triterpenoid carbon skeleton. As with the previously reported xestovanins (2), the absolute configurations of the sugar carbons are correct as shown in the structure for **6**, the relative stereochemistries at C8, C10, C11, C15, and C16 are correct as drawn but their configurations relative to the sugars is arbitrary, and no information is available about the configurations at C5 and C20. Repeated attempts to determine the complete stereochemistry of the xestovanins, either by X-ray of a suitable crystalline derivative or by chemical degradation, have been unsuccessful. It is interesting to note that isoxestovanin A (**6**) and xestovanin A (**1**) have the opposite relative configurations at C10. The relative stereochemistry at C10 of secoxestovanin A (**2**) had originally been assigned to be the same as that of xesto-

vanin A (**1**), assuming a biogenetic relationship between them (2). It is now clear that the original assumption about the C10 configuration in **2** is unjustified and it must be considered undetermined as shown.

Xestovanin B (**7**) was isolated as an optically active ($[\alpha]_D$ −45.5 (*c* 0.3, MeOH)) colorless oil that gave a pseudomolecular ion at *m/z* 933 Da (M^+ + Na) in the FABMS consistent with a molecular formula of $C_{48}H_{78}O_{16}$. The ^{13}C NMR (48 resolved resonances: Table 2), APT (69 hydrogen atoms attached to carbon: 11 × CH_3, 6 × CH_2, 24 × CH), and ^1H NMR data (eight secondary and one tertiary alcohol protons: Table 1) substantiated the carbon and hydrogen counts in the molecular formula of **7**.

The ^1H NMR spectra of xestovanin B (**7**) recorded in either acetone-d_6 or Me_2SO-d_6 showed a strong resemblance to the ^1H NMR spectra of xestovanin A (**1**) recorded in the same solvents[2] (Table 1), and COSY and NOE experiments conducted on **7** established a series of connectivities and stereochemical relationships that demonstrated the presence of the same aglycone found in xestovanin A (**1**). The chemical shifts of the resonances assigned to H18, H20, H21, and H21′ in **7** showed slight downfield shifts relative to the corresponding resonances in xestovanin A (**1**) (Table 1). In the COSY spectrum of xestovanin B(**7**) (Table 1), the resonances assigned to the H5 and H20 methine protons (δ 4.05 and 3.95) failed to show correlations into hydroxyl protons, indicating that in **7** there were ether linkages at both C5 and C20.

Acetal resonances at δ 95.8(s), 98.7(s), and 101.2(s) and 12 deshielded methine resonances in the region δ 71.2–78.0 in the ^{13}C NMR spectrum (Table 2), and three methyl doublet resonances in the ^1H NMR spectrum (δ 1.11, 1.13, and 1.15) of xestovanin B (**7**) that could not be accounted for by the aglycone were assigned to three 6-deoxyhexose residues. A standard GC analysis (8) (see Experimental) of the monosaccharides liberated from **7** identified only L-rhamnose and D-fucose. Correlations in the COSY spectrum of **7** (Table 1) identified two independent spin systems with chemical shifts that were virtually identical to the chemical shifts observed for the protons in the fucose and rhamnose components of the C5 disaccharide substituent in xestovanin A (**1**) (Table 1). In addition, scalar couplings were observed in the COSY spectrum of **7** between alcohol protons and the methine protons at H2′ and H3′ of the fucose and at H2″, H3″, and H4″ of the rhamnose, and an NOE was observed between the anomeric proton (H1″) of the rhamnose and H4′ of the fucose (Table 4[2]). Two of the acetal resonances in the ^{13}C NMR spectrum of **7** (δ 98.7 and 101.2) had chemical shifts identical to the resonances assigned to the rhamnose and fucose anomeric carbons (δ 98.6 and 101.2) in xestovanin A (**1**) and a gated decoupled ^{13}C NMR spectrum revealed that the one-bond C–H coupling constants for these two anomeric carbons in **7** were in agreement with the α and β anomeric configurations at rhamnose and fucose, respectively (9). Therefore, it was apparent that xestovanin B (**7**) had a disaccharide substructure that was identical to the disaccharide substituent at C5 of xestovanin A (**1**) and it had to be attached at either C5 or C20 of the aglycone. Congestion in the ^1H NMR spectrum of **7** made it impossible to locate the position of attachment of the disaccharide substituent by NOE experiments.

A methyl resonance at δ 1.13(d) and a deshielded methine resonance at δ 4.61 in the ^1H NMR spectrum of xestovanin B (**7**) were assigned to the protons on C6 and C1 of the remaining monosaccharide. Starting with these two resonances, it was possible to assign resonances to the remainder of the protons in the monosaccharide on the basis of correlations observed in the COSY spectrum (Table 1). The resonances assigned to H2, H3, and H4 in this 6-deoxyhexose unit each showed further COSY correlations to alcohol protons, indicating that the monosaccharide was linked to the rest of the molecule only through the anomeric carbon. Irradiation of the anomeric proton (δ 4.61) induced a strong NOE in the H20 resonance (δ 3.95) of the aglycone, consistent with the connection of the sugar through a glycosidic linkage to C20. Attachment of a monosaccharide substituent to C20 implied that by default the disaccharide substituent had to be attached to the aglycone at C5 in xestovanin B (**7**), just as it is in xestovanin A (**1**).

The results of the sugar analysis carried out on xestovanin B (**7**) required that the 6-deoxyhexose attached to C20 had to be either D-fucose or L-rhamnose. The resonance assigned to H4 (δ 3.38: acetone-d_6) of this monosaccharide appeared as a triplet with a coupling constant of 8.5 Hz, indicating that the proton was axial and that the sugar was L-rhamnose. The C–H coupling constant between the remaining anomeric carbon (δ 95.8) resonance and its attached proton was found to be 171.9 Hz, indicating that the L-rhamnose was attached to C20 through an α-glycosidic linkage (9) as shown in the representation **7** of the complete structure of xestovanin B.

Xestovanin C (**8**) was isolated as an optically active ($[\alpha]_D$ −25 (*c* 0.2, MeOH)) colorless glass that also gave a pseudomolecular ion in the FABMS at *m/z* 933 Da (M^+ + Na) appropriate for a molecular formula of $C_{48}H_{78}O_{16}$, suggesting that it was an isomer of xestovanin B (**6**). The electron impact mass spectrum of xestovanin C (**8**) failed to show a parent ion. A fragment ion observed at *m/z* 436.3342 Da ($C_{30}H_{44}O_2$) was the highest mass observed in the HREIMS and it was attributed to the loss of a trisaccharide substituent plus one molecule of water from the parent molecule to give a fragment containing the carbon skeleton of a triterpenoid aglycone. The presence of an intense fragment ion at *m/z* 455 Da in the FABMS of **8**, which could be assigned to a trisaccharide fragment ($C_{18}H_{32}O_{13}$), supported this analysis. The ^{13}C NMR (48 resolved resonances: Table 2), APT (69 protons attached to carbon: 11 × CH_3, 6 × CH_2, 24 × CH), and ^1H NMR data (nine OH protons: Table 1) for **8** confirmed the carbon and hydrogen counts in the molecular formula.

A careful comparison of the ^1H NMR, ^{13}C NMR, COSY, and NOE data (Tables 1, 2, and 4[2]) recorded for xestovanin C (**8**) with the data recorded for xestovanin A (**1**) indicated that the two molecules contained identical triterpenoid aglycones. Further analysis of the ^1H and ^{13}C NMR data recorded for xestovanin C (**8**) suggested that there were three 6-deoxyhexose moieties in the molecule. Resonances at δ 99.8(d), 102.2(d), and 102.5(d) in the ^{13}C NMR spectrum were assigned to the anomeric carbons and resonances at δ 1.11(d), 1.13(d), and 1.14(d) in the ^1H NMR spectrum were assigned to the C6 protons of the three monosaccharides. A standard GC analysis (8) (see Experimental) of the sugars liberated from xestovanin C (**8**) identified only L-rhamnose and D-fucose. Comparison of the chemical shifts of the anomeric proton and carbon resonances (acetone-d_6) assigned to the monosaccharides in xestovanin C (**8**) (δ, ^1H: 4.19, 5.25, and 5.29; ^{13}C: 99.8, 102.2, and 102.5) with the chemical shifts of the anomeric protons and carbons in the fucose (δ, ^1H: 4.17; ^{13}C: 99.7) and rhamnose (δ, ^1H: 5.27; ^{13}C: 102.5) units in xestovanin A (**1**) showed that one fucose and two rhamnose units were present in **8**. The H20 methine resonance in **8**

showed coupling into an alcohol proton and it also underwent an acetylation shift upon conversion of **8** to the octaacetate **13**, whereas the H5 methine proton did not couple to an alcohol proton and it did not undergo an acetylation shift. Therefore, it was apparent that xestovanin C (**8**) had a trisaccharide substituent at C5 of the aglycone.

Irradiation of the fucose anomeric proton (H1′) in xestovanin C octaacetate (**13**) (δ 4.30) induced NOEs in H5 of the aglycone (δ 4.10) and in H3′ (δ 4.93) and H5′ (δ 3.55) of the fucose itself, demonstrating that the fucose was attached to C5 of the aglycone through a β glycosidic linkage. The magnitude of the scalar couplings observed between H1′ and H2′ (J = 7.2 Hz) and between C1′ and H1′ (J = 156.3 Hz) (9) of the fucose residue in **8** confirmed the β-anomeric configuration. Analysis of the sugar methine to alcohol proton correlations observed in the COSY data obtained for xestovanin C (**8**) revealed that H2′ and H3′ of the fucose, H2″ and H3″ of one rhamnose, and H2‴, H3‴, and H4‴ of the second rhamnose were vicinal to alcohol protons (Table 1). All of the resonances assigned to these same protons underwent acetylation shifts as a result of the conversion of xestovanin C (**8**) to its octaacetate **13** (see Experimental). The COSY and acetylation shift data showed that the fucose was linked to the anomeric carbon of one rhamnose through C4′ and that the two rhamnose units were also joined through a 1,4 linkage. One-bond scalar couplings of 170.0 and 171.0 Hz were observed between the anomeric protons (δ H1″ and H1‴) and the anomeric carbons (δ C1″ and C1‴) of the two rhamnose residues, indicating that both had α glycosidic linkages in xestovanin C (**8**) as shown (9).

Dehydroxestovanin A (**9**) was isolated as an optically active ($[\alpha]_D$ −45 (c 0.8, MeOH)) pale yellow glass. ^{1}H and ^{13}C NMR spectra recorded on **9** (Tables 2 and 3) showed strong similarities to those of xestovanin A (**1**) (Tables 1 and 2), suggesting that **9** was a triterpenoid glycoside closely related to **1**. The molecular formula of dehydroxestovanin A (**9**) was determined by considering a number of pieces of MS and NMR evidence. An intense pseudomolecular ion (M^+ + Na), appropriate for a molecular formula of $C_{42}H_{66}O_{12}$, was observed at m/z 785 Da in the FABMS spectrum of **9**. Clearly resolved resonances for 42 carbon atoms were observed in the ^{13}C NMR spectrum, an APT experiment showed that there were 59 hydrogen atoms bonded to carbon (9 × CH_3, 7 × CH_2, 18 × CH) (Table 2), and the ^{1}H NMR and COSY spectra revealed that the seven remaining hydrogen atoms were associated with one tertiary and six secondary alcohol functionalities (Table 3). The highest mass peak that was observed in the EIHRMS of **9** appeared at m/z 434.3191 Da ($C_{30}H_{42}O_2$, ΔM +0.6 mmu) and it was attributed to the loss of a disaccharide substituent and one equivalent of water from the parent molecule to give a fragment containing the carbon skeleton of the triterpenoid aglycone. Both the pseudomolecular ion in the FABMS and the aglycone fragment ion in the HREIMS of **9** were found at two mass units less than the corresponding ions in the mass spectra of xestovanin A (**1**), indicating that the aglycone of **9** was a dehydro derivative of the aglycone of **1**.

The characteristic resonances assigned to the Me27 and H10 protons in the ^{1}H NMR spectra of xestovanin A (**1**) (Table 1) were missing in the ^{1}H NMR spectrum of dehydroxestovanin A (**9**) (Table 3) and the ^{13}C NMR spectrum of **9** contained one less aliphatic methine resonance, one less aliphatic methyl resonance, and two more olefinic resonances than the ^{13}C NMR spectrum of xestovanin A (**1**) (Table 2). Analysis of the COSY spectrum (Table 3) showed that a pair of olefinic resonances at δ 5.04 and 5.17 were coupled to each other and that they were both coupled to a methine resonance assigned to H11 (δ 2.67), indicating that dehydroxestovanin A (**9**) possessed an olefinic bond between C10 and C27. Irradiation of H27*E* (δ 5.17) induced an NOE in H11 (δ 2.67) in agreement with the presence of a $\Delta^{10,27}$ olefinic functionality (Table 4[2]). Resonances at δ 150.4 and 111.0 in the ^{13}C NMR spectrum of **9** were assigned to C10 and C27, respectively.

Comparison of the ^{1}H NMR, COSY, NOE, and ^{13}C NMR data obtained for dehydroxestovanin A (**9**) (Tables 2 and 3) with the same data obtained for xestovanin A (**1**) (Tables 1 and 2) showed that, except for the oxidation level of the C10/C27 bond, the remaining portions of the aglycones in the two molecules were identical. Standard sugar analysis (8) (see Experimental) identified D-fucose and L-rhamnose residues and inspection of the NMR data (Tables 2 and 3) assigned to the sugars showed that dehydroxestovanin A (**9**) contained the same disaccharide substituent found in xestovanin A (**1**). COSY (Table 3) evidence demonstrated that the disaccharide was attached to C5 in dehydroxestovanin A (**9**) just as in xestovanin A (**1**).

Secodehydroxestovanin A (**12**) was isolated as a colorless oil that gave a pseudomolecular peak (M^+ + Na) in the FABMS consistent with a molecular formula of $C_{42}H_{66}O_{12}$. The ^{13}C NMR, APT, and ^{1}H NMR data agreed with the assigned molecular formula. A detailed analysis of the ^{13}C NMR (Experimental), ^{1}H NMR (Table 3), and COSY data (Table 3) showed that **12** was the $\Delta^{10,27}$ analogue of secoxestovanin A (**2**). Thus, COSY and NOE experiments (Tables 3 and 4[2]) identified two 10-carbon aglycone fragments (C1–C8 plus Me25 and Me26: C17–C24 plus Me29 and Me30) and their attached alcohol and disaccharide substituents, which were identical to the corresponding fragments in secoxestovanin A (**2**). The chemical shifts of two carbonyl resonances in the ^{13}C NMR spectrum of **12** indicated the presence of one saturated (δ 211.5: C16) and one unsaturated (δ 199.6: C9) ketone, and two deshielded singlets in the ^{1}H NMR spectrum (δ 5.68 and 6.15: acetone-d_6) were assigned to the methylene protons on the $\Delta^{10,27}$ olefin that was conjugated to the unsaturated ketone. A COSY experiment optimized for long-range couplings showed a correlation between H27*Z* (δ 5.68) and a methine assigned to H11 (δ 3.17: acetone-d_6), and in the normal COSY spectrum it was possible to find correlations starting with the H11 methine and continuing around the cyclopentane ring to the C14 methylene protons (Table 3). An NOE between the H11 methine resonance (δ 3.17) and a methyl singlet resonance at δ 1.33, which was assigned to Me28, confirmed their *cis* relationship on the cyclopentane ring. Irradiation of the H27*Z* resonance at δ 6.15 induced an NOE in a resonance at δ 3.40 that was assigned to one of the H8 methylene protons on the basis of COSY correlations. The observation of an NOE between H27*Z* and H8 demonstrated that the 10-carbon fragment (C1–C8 plus Me25 and Me26) containing the disaccharide substituent was attached to the enone system at C9 as shown in **12**.

New metabolites from the Anthony Island specimens

Epidehydroxestovanin A (**10**) was isolated as an optically active ($[\alpha]_D$ −3.8 (c 3.8, MeOH)) pale yellow glass. An intense pseudomolecular ion at m/z 785 Da ($C_{42}H_{66}O_{12}$ + Na) was observed in the FABMS of **10** even though the highest mass ion observed in the EIHRMS was at m/z 434.3189 Da,

corresponding to an elemental composition of $C_{30}H_{42}O_2$ (ΔM +0.5 mmu). The pseudomolecular ion in the FABMS of **10** had the same mass as the pseudomolecular ion in the FABMS of dehydroxestovanin A(**9**), and the highest mass ion observed in the EIHRMS of **10**, attributed to the aglycone portion of the molecule, had the same mass and elemental composition as the highest mass ion in the EIHRMS of **9**. Furthermore, a comparison of the ^{13}C and ^{1}H NMR data for epidehydroxestovanin A (**10**) with the NMR data for dehydroxestovanin A (**9**) (Tables 2 and 3) revealed that the two molecules had nearly identical triterpenoid glycoside structures.

A detailed analysis of the COSY data for epidehydroxestovanin A (**10**) showed that the triterpenoid aglycone portion of the molecule possessed the same scalar coupled spin systems as the aglycone in dehydroxestovanin A (**9**) (Table 3). The only notable differences in the ^{1}H NMR data for the two molecules were slight changes in the chemical shifts of several resonances assigned to protons in the region of the bicyclic ring system. In particular, the resonances assigned to H11, H17, H18, and Me28 were slightly more shielded in epidehydroxestovanin A (**10**) (acetone-d_6: δ 2.54(H11), 3.58(H17), 5.52(H18), 1.13(Me28)) than the resonances assigned to the same protons in dehydroxestovanin A (**9**) (acetone-d_6: δ 2.67(H11), 3.67(H17), 5.60(H18), 1.21(Me28)). Since all of the MS and NMR data indicated that compounds **9** and **10** had identical constitutions, it was apparent that they were stereoisomers. Inspection of the ^{1}H and ^{13}C NMR data for **10**, along with the results of a standard GC analysis of the monosaccharides released upon hydrolysis (D-fucose and L-rhamnose), confirmed that the acyclic fragments C1–C8 and C18–C24, including the C5 disaccharide substituent, had identical stereochemical configurations in dehydroxestovanin A (**9**) and epidehydroxestovanin A (**10**) (Tables 2 and 3). Therefore, the stereochemical difference had to be in the bicyclic region of the aglycone.

The nearly identical ^{13}C NMR chemical shifts of the resonances assigned to C8, C9, C10, and C11 in epidehydroxestovanin A (**10**) (δ 38.7(C8), 79.4(C9), 150.3(C10), 52.8(C11)) and in dehydroxestovanin A (**9**) (δ 38.8(C8), 79.4(C9), 150.4(C10), 52.5(C11)) indicated that the relative configurations at C9 and C11 were identical in the two molecules. However, a series of NOE experiments carried out on **10** showed that the one point of stereochemical difference between **9** and **10** was the configuration at C17. Thus, irradiation of H11 (δ 2.54) induced NOEs in H27*E* (δ 5.15), H12 (δ 1.99), and Me28 (δ 1.13) confirming the usual *cis* relationship between H11 and Me28. Irradiation of Me28 (δ 1.13) induced NOEs in H11 (δ 2.54), H14 (δ 1.42), and H18 (δ 5.52). The observation of an NOE between Me28 and H18 in **10** was in contrast to the NOE results observed for dehydroxestovanin A (**9**), where irradiation of Me28 induced an NOE in H17, and this Me28/H18 NOE in **10** required that the side chain containing C18 be *cis* to Me28 as shown in Fig. 2.

Dehydroxestovanin C (**11**) was isolated as an optically active ($[\alpha]_D$ −24.6 (*c* 0.08, MeOH)) colorless glass that gave an intense pseudomolecular ion in the FABMS at *m/z* 931 Da ($C_{48}H_{76}O_{16}$ + Na) and a highest mass peak in the EIHRMS at *m/z* 434.3191 Da ($C_{30}H_{42}O_2$: ΔM +0.6 mmu). The structure of dehydroxestovanin C (**11**) was readily assigned by comparing its ^{1}H and ^{13}C NMR data (Tables 2 and 3) with the corresponding NMR data for xestovanin C (**8**) and dehydroxestovanin A (**9**) (Tables 1–3). This comparison showed that **11** contained an aglycone portion that was identical to the aglycone of dehydroxestovanin A (**9**) and a trisaccharide portion that was identical to the trisaccharide portion of xestovanin C (**7**). COSY, NOE, and HETCOR data obtained for **11** supported the assigned structure, and GC analysis (8) (see Experimental) of the sugars released from **11** identified only L-rhamnose and D-fucose as expected.

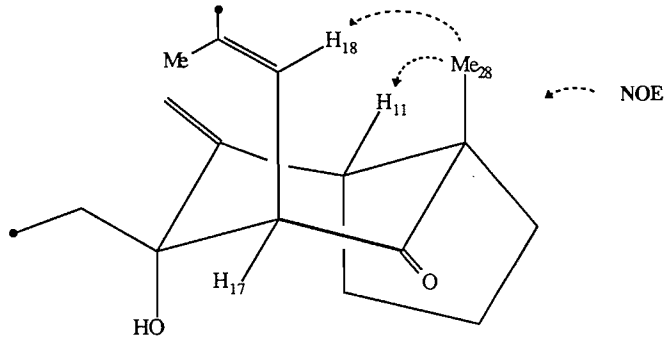

FIG. 2.

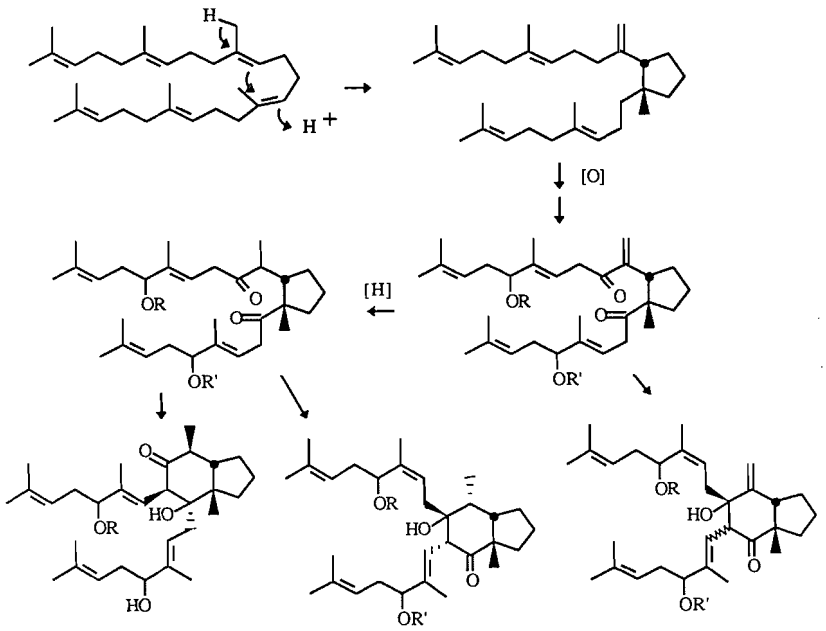
Discussion

The new *X. vanilla* triterpenoid glycosides reported here include the first example of the isoxestovanane carbon skeleton (i.e., **6**) and the first example of a xestovanin containing a trisaccharide substituent (i.e., **8**). Scheme 1 shows a proposed biogenetic pathway to the *X. vanilla* triterpenoid aglycones starting from squalene. The secoxestovanane skeleton can readily arise from a single proton initiated cyclization and the xestovanane and isoxestovanane skeletons represent alternate intramolecular aldol cylization pathways on a 9,16-diketosecoxestovanane precursor. It is interesting to note that all of the triterpenoids from the Anthony Island specimens (i.e., **9**, **10**, **11**, and **12**) have a $\Delta^{10,27}$ olefinic functionality, while the major triterpenoids from the Bamfield specimens (i.e., **1**, **2**, **6**, **7**, and **8**) have the $\Delta^{10,27}$ olefin reduced. Detailed examination of repeated collections of *X. vanilla* from Bamfield failed to show any major seasonal variation in metabolite content. Therefore, one possible explanation for the observed geographic variation would be an absence in the Anthony Island population of *X. vanilla* of the enzyme that reduces the $\Delta^{10,27}$ olefin. Some members of the *X. vanilla* family of triterpenoid glycosides exhibit moderate antifungal and antibacterial activities (see Experimental).



Experimental

Freshly collected sponge (1000 g) was homogenized with methanol in a Waring blender. Concentration of the methanol extract *in vacuo* gave an aqueous suspension that was exhaustively extracted first with hexane and then with dichloromethane. Purification of the dichloromethane soluble material by Sephadex LH20 chromatography (9:1 MeOH/CH_2Cl_2) gave a series of early eluting fractions containing crude mixtures of triterpenoid glycosides. The mixtures of glycosides were further purified by sequential application of open column reversed-phase chromatography (multi-step gradient: 2:3 acetone/H_2O to 7:3 acetone/H_2O) and reversed-phase HPLC (eluents: either 55:45 acetone/H_2O (compounds **1**, **2**, **6**, **7**, **8**, **11**, **12**) or 3:1 MeOH/H_2O (compounds **9**, **10**)) to give pure metabolites.

Determination of the absolute configurations of the sugars

A small sample (5–10 mg) of triterpenoid glycoside was hydrolyzed with 3 M aqueous trifluoroacetic acid at 60°C for 4 h. (Note: The C5 disaccharide could also be obtained by treating the xestovanins with 1 mL of MeOH and 1 mL of 0.5 M $KOH_{(aq)}$ followed by heating to 90°C for 2 h.) Removal of the water and trifluoroacetic acid under reduced pressure gave a clear gum that was reacted with

SCHEME 1

250 μL of (+)-2-octanol and 1 drop of trifluoroacetic acid in a sealed vial at 130°C for 12 h (8). Removal of the reagents *in vacuo* gave a mixture of 2-octylglycosides that were reacted with acetic anhydride and pyridine (0.5 mL of each) at 100°C for 30 min. Excess reagents were removed *in vacuo* to yield a mixture of peracetylated (+)-2-octylglycosides. Standards were prepared in an identical fashion from D- and L-fucose and L-rhamnose. A sample of D-rhamnose was not available; therefore, L-rhamnose was derivatized with (−)-2-octanol to provide the enantiomer of (+)-2-octyl-D-rhamnoside. The product mixture and standards were analysed by capillary GC (HP SE54 column; temperature programme: 120°C for 2 min followed by an increase in temperature of 20°C/min to a final temperature of 250°C). The observed retention times for the standards were as follows: peracetylated (+)-2-octyl-D-fucoside (5.24, 5.33, 5.40 min); peracetylated (+)-2-octyl-L-fucoside (5.31, 5.45, 5.63 min); peracetylated (+)-2-octyl-L-rhamnoside (5.00, 5.07, 5.21, 5.36 min); peracetylated (−)-2-octyl-L-rhamnoside (5.14, 5.28, 5.52 min). The observed retention times (in minutes) for the peracetylated (+)-2-octylglycosides obtained from the isoxestovan A (**6**) hydrolysate were 5.02, 5.08, 5.23, 5.34, and 5.40. These retention times corresponded to the expected values for a mixture of D-fucose and L-rhamnose. Similar values were obtained for all of the other new *X. vanilla* triterpenoid glycosides.

Xestovanin A (***1***): The data obtained for this compound were the same as those found previously. Additional data are the following: $[\alpha]_D$ −42.0 (*c* 0.30, MeOH); ^{13}C NMR (acetone-d_6, 75 MHz), see Table 2.

Isoxestovanin A (***6***): Colorless glass; $[\alpha]_D$ −4.4 (*c* 0.16, MeOH); IR (film), ν_{max}: 3406, 1710, 1512, 1448, 1070, 1030 cm^{-1}; ^{1}H NMR (acetone-d_6, 400 MHz), see supplemental material; ^{1}H NMR (DMSO-d_6, 400 MHz), see Table 1; ^{13}C NMR (acetone-d_6, 75 MHz), see Table 2; LRFABMS, pseudomolecular ion, *m/z*: 787 ($M^+(C_{42}H_{68}O_{12})$ + 23 (Na)), 437 ($C_{30}H_{45}O_2$), 418 ($C_{30}H_{42}O$), 367 ($C_{25}H_{35}O_2$), 311 ($C_{12}H_{23}O_9$); LREIMS, *m/z* (formula, relative intensity): 436 ($C_{30}H_{44}O_2$, 29), 418 ($C_{30}H_{42}O$, 4), 367 ($C_{25}H_{35}O_2$, 88), 349 ($C_{25}H_{33}O$, 10), 163 ($C_{11}H_{15}O$, 40); HREIMS *m/z*: 436.3336 ($C_{30}H_{44}O_2$, Δ*M* −0.5 mmu: $M^+ - C_{12}H_{22}O_9 - H_2O$).

Xestovanin B (***7***): Colorless oil; $[\alpha]_D$ −45.5 (*c* 0.29, MeOH); ^{1}H NMR (Me_2SO-d_6), see Table 1; ^{13}C NMR (acetone-d_6, 75 MHz), see Table 2; LRFABMS, pseudomolecular ion, *m/z*: 933 ($C_{48}H_{78}O_{16}$ + Na).

Xestovanin C (***8***): Colorless glass; $[\alpha]_D$ −25.0 (*c* 0.12, MeOH); IR (film), ν_{max}: 3423, 2933, 1708, 1366, 1225, 1045, 838, 801, 766 cm^{-1}; ^{1}H NMR (acetone-d_6, 400 MHz), see supplemental material; ^{1}H NMR (DMSO-d_6, 400 MHz), see Table 1; ^{13}C NMR (acetone-d_6, 75 MHz), see Table 2; LRFABMS, pseudomolecular ion, *m/z*: 933 (M^+ ($C_{48}H_{78}O_{16}$) + 23 (Na)), 455 ($C_{18}H_{31}O_{13}$), 436 ($C_{30}H_{44}O_2$); LREIMS, *m/z* (formula, relative intensity): 436 ($C_{30}H_{44}O_2$, 34), 418 ($C_{30}H_{42}O$, 7), 385 ($C_{25}H_{37}O_3$, 9), 367 ($C_{25}H_{35}O_2$, 33), 349 ($C_{25}H_{33}O$, 18), 301 ($C_{20}H_{29}O_2$, 14), 229 ($C_{16}H_{21}O$, 14), 203 ($C_{14}H_{19}O$, 26), 163 ($C_{11}H_{15}O$, 15), 147 ($C_{11}H_{15}$, 14), 139 ($C_9H_{15}O$, 10); HREIMS, *m/z*: 436.3342 ($C_{30}H_{44}O_2$, Δ*M* 0.0 mmu: $M^+ - C_{18}H_{32}O_{13} - H_2O$).

Xestovanin C octaacetate (***13***): A 5-mg sample of xestovanin C was acetylated at room temperature with acetic anhydride and pyridine. The pure compound was isolated as a pale yellow glass; IR (film), ν_{max}: 3385, 3000, 2929, 1751, 1716, 1371, 1242, 1227, 1072, 1041 cm^{-1}, ^{1}H NMR ($CDCl_3$, 400 MHz), δ: 1.08 (d, *J* = 7.0 Hz, 3H, H27), 1.20 (m, 1H, H14), 1.21 (d, *J* = 6.3 Hz, 3H, H6‴), 1.33 (d, *J* = 6.4 Hz, 3H, H6″), 1.34 (d, *J* = 6.4 Hz, 3H, H6′), 1.35 (s, 3H, H28), 1.42 (m, 1H, H13), 1.50 (m, 1H, H13), 1.50 (br s, 3H, H26), 1.52 (br s, 3H, H29), 1.60 (br s, 3H, H25), 1.61 (br s, 3H, H30), 1.64 (br s, 3H, H1), 1.67 (br s, 3H, H24), 1.70 (m, 1H, H12), 1.81 (m, 1H, H12), 1.99 (m, 1H, H11), 1.99 (s, 3H, −OCO*CH*$_3$), 2.01 (s, 3H, −OCO*CH*$_3$), 2.03 (s, 3H, −OCO*CH*$_3$), 2.05 (s, 3H, −OCO*CH*$_3$), 2.06 (s, 3H, −OCO*CH*$_3$), 2.10 (s, 3H, −OCO*CH*$_3$), 2.14 (s, 3H, OCO*CH*$_3$), 2.15 (m, 1H, H8), 2.17 (s, 3H, −OCO*CH*$_3$), 2.22 (m, 1H, H4), 2.27 (dq, *J* = 7.0, 5.9 Hz, 1H, H10), 2.28 (m, 1H, H8), 2.30 (m, 1H, H21), 2.42 (m, 1H, H21), 2.43 (m, 1H, H4), 3.55 (dq, *J* = 6.4, <1 Hz, 1H, H5′), 3.60 (d, *J* = 9.6 Hz, 1H, H17), 3.70 (t, *J* = 9.4 Hz, 1H, H4″), 3.81 (dd, *J* = 3.0, <1 Hz, 1H, H4′), 3.98 (dq, *J* = 9.8, 6.3 Hz, 1H, H5‴), 4.00 (dq, *J* = 9.5, 6.4 Hz, 1H, H5″), 4.20 (dd, *J* = 9.3, 5.6 Hz, 1H, H5), 4.30 (d, *J* = 7.9 Hz, 1H, H1′), 4.82 (d, *J* = 2.0 Hz, 1H, H1″), 4.90 (br t, *J* = 7.9 Hz, 1H, H3), 4.93 (dd, *J* = 10.4, 3.1 Hz, 1H, H3′), 5.00 (d, *J* = 1.8 Hz, 1H, H1‴), 5.01 (br t, *J* = 7.3 Hz, 1H, H22), 5.07 (t, *J* = 9.8 Hz, 1H, H4‴), 5.16 (dd, *J* = 3.3, 2.0 Hz, 1H, H2‴), 5.17 (br t, *J* = 6.9 Hz, 1H, H20), 5.20 (dd, *J* = 10.4, 7.9 Hz, 1H, H2′), 5.26 (br d, *J* = 9.4 Hz, 1H, H7), 5.26 (dd, *J* = 9.8, 3.3 Hz, 1H, H3‴), 5.30 (dd, *J* = 9.4, 3.2 Hz, 1H, H3″), 5.42 (dd, *J* = 3.2, 2.0 Hz, 1H, H2″), 5.65 (br d, *J* = 9.8 Hz, 1H, H18) ppm; LRFABMS, pseudomolecular ion, *m/z*: 1269 ($M^+(C_{64}H_{94}O_{24})$ + 23 (Na)).

Dehydroxestovanin A (***9***): Pale yellow glass; $[\alpha]_D$ −45.0 (*c* 0.78, MeOH); IR (film), ν_{max}: 3406, 2979, 2938, 2896 (sh), 1701, 1660 (sh), 1464, 1381, 1253, 1129, 1072, 1046, 1031, 981 cm^{-1}; ^{1}H NMR (acetone-d_6, 400 MHz), see supplemental material; ^{1}H NMR (DMSO-d_6, 400 MHz), see Table 3; ^{13}C NMR (acetone-d_6, 75 MHz), see Table 2; LRFABMS, pseudomolecular ion, *m/z*: 785 ($M^+(C_{42}H_{66}O_{12})$ + 23(Na)), 435 ($M^+ - C_{12}H_{21}O_9 - H_2O$), 309 ($C_{12}H_{21}O_9$); LREIMS,

Antifungal and antibacterial activities

Inhibition of test microorganisms was measured in a standard disc assay. Xestovanin A (**1**), dehydroxestovanin A (**9**), and epidehydroxestovanin A (**10**) inhibited the fungus *Pythium ultimum* (200 μg/disc). Dehydroestovanin C (**11**) inhibited *Staphylococcus aureus*, *Bacillus subtilis*, and *Candida albicans* (150 μg/disc).

Cleavage of the radical cations of alkenes; 1-butene and 4,4-dimethyl-1-pentene. *Ab initio* calculations on the interaction between the allyl and alkyl radical and carbocation moieties[1]

XINYAO DU, DONALD R. ARNOLD,[2] RUSSELL J. BOYD, AND ZHENG SHI
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3
Received March 15, 1991

XINYAO DU, DONALD R. ARNOLD, RUSSELL J. BOYD, and ZHENG SHI. Can. J. Chem. **69**, 1365 (1991).

Carbon–carbon bond cleavage of the radical cations of 1-butene ($C_4H_8^{\dagger}$) and 4,4-dimethyl-1-pentene ($C_7H_{14}^{\dagger}$) will generate the allyl and alkyl radical and carbocation fragments. Alternative bonding arrangements between the allyl and methyl moieties in $C_4H_8^{\dagger}$ and between the allyl and *tert*-butyl moieties in $C_7H_{14}^{\dagger}$, possible metastable intermediates or transition states preceding complete separation of the fragments, have been investigated by *ab initio* molecular orbital calculations. Structures were fully optimized at the UHF/6-31G* or UHF/STO-3G levels, and some of the calculations on $C_4H_8^{\dagger}$ were expanded with single point MP2/6-31G*//UHF/6-31G* computations. The $C_4H_8^{\dagger}$ radical cation, having a structure similar to that of 1-butene, is more stable than the separated fragments: 183 kJ mol^{-1} lower in energy than the sum of the energies of the allyl cation and the methyl radical, and 385 kJ mol^{-1} lower than the sum of the energies of an allyl radical and a methyl cation, at the MP2/6-31G* level. The corresponding values at the UHF/STO-3G level are 276 and 415 kJ mol^{-1}, respectively. There is less bonding interaction between the allyl and *tert*-butyl moieties in $C_7H_{14}^{\dagger}$. The summation of the energies of the allyl radical and *tert*-butyl cation is 123 kJ mol^{-1} lower than the summation of the energies of the allyl cation and *tert*-butyl radical, and 115 kJ mol^{-1} higher in energy than the bonded radical cation $C_7H_{14}^{\dagger}$, at the UHF/STO-3G level. These calculated values are compared with thermochemical data and with experimental results on the cleavage of these, and related, radical cations.

Key words: radical cation, cleavage, *ab initio* calculations, electron transfer, photochemistry.

XINYAO DU, DONALD R. ARNOLD, RUSSELL J. BOYD et ZHENG SHI. Can. J. Chem. **69**, 1365 (1991).

La rupture de la liaison carbone–carbone des cations radicalaires du butène-1 ($C_4H_8^{\dagger}$) et du diméthyl-4,4-pentène ($C_7H_{14}^{\dagger}$) génèrent des fragments de radicaux alkyles et de carbocations. Faisant appel aux calculs *ab initio* d'orbitales moléculaires, on a étudié des dispositions alternatives de la liaison entre les unités alkyle et méthyle du $C_4H_8^{\dagger}$ et entre les unités allyle et *tert*-butyle du $C_7H_{14}^{\dagger}$ qui sont des intermédiaires métastables possibles ou des états de transition précédants la séparation complète des fragments. On a optimisé ces structures aux niveaux UHF/6-31G* ou UHF/STO-3G et on a développé certains calculs relatifs au cation radicalaire $C_4H_8^{\dagger}$ avec des calculs du point unique MP2/6-31G*//UHF/6-31G. Le cation radicalaire $C_4H_8^{\dagger}$, ayant une structure similaire à celle du butène-1, est plus stable que les fragments séparés : l'énergie est de 183 kJ mol^{-1} inférieure à la somme des énergies du cation allyle et du radical méthyle et de 385 kJ mol^{-1} inférieure à la somme des énergies du radical allyle et du cation méthyle au niveau MP2/6-31G*. Les valeurs correspondantes au niveau UHF/STO-3G sont respectivement de 276 et de 415 kJ mol^{-1}. Il y a moins d'interaction de liaison entre les unités allyle et *tert*-butyle du $C_7H_{14}^{\dagger}$. La sommation des énergies du radical allyle et du cation *tert*-butyle est de 123 kJ mol^{-1} inférieure à la sommation des énergies du cation allyle et du radical *tert*-butyle, et de 115 kJ mol^{-1} supérieure à l'énergie du cation radicalaire lié $C_7H_{14}^{\dagger}$, au niveau UHF/STO-3G. On a comparé ces valeurs calculées aux données thermochimiques et aux résultats expérimentaux obtenus lors de la rupture de ces cations radicalaires et des cations radicalaires apparentés.

Mots clés : cation radicalaire, rupture, calculs *ab initio*, transfert d'électrons, photochimie.

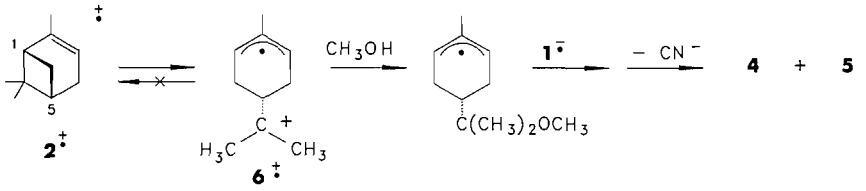
Introduction

When a solution of 1,4-dicyanobenzene (**1**), (−) α-pinene (**2**), and biphenyl (**3**) in acetonitrile–methanol (3:1) was irradiated, the 1:1:1 adducts (±) **4** and (±) **5** were obtained in good yield (reaction [1]) (2). The key step in the mechanism proposed to explain this result, following the photoinduced single electron transfer, involves cleavage of the initially formed α-pinene radical cation $\mathbf{2}^{\dagger}$ to the distonic radical cation $\mathbf{6}^{\dagger}$ (Scheme 1). Reaction of the resulting tertiary cationic centre with methanol and coupling of the ambident allylic radical, at either end (symmetric) and from both sides, with the radical anion $\mathbf{1}^{\cdot-}$, followed by rearomatization by loss of cyanide ion, completes the sequence. There was no evidence for any reaction of the initially formed alkene radical cation ($\mathbf{2}^{\dagger}$) other than cleavage to $\mathbf{6}^{\dagger}$. Unreacted α-pinene recovered from the reaction mixture was not racemized; formation of $\mathbf{6}^{\dagger}$ was not reversible. Furthermore, **4** and **5** are formed in almost equal amounts; there was no evidence for an interaction between the allylic radical and the cationic centre of the distonic radical cation $\mathbf{6}^{\dagger}$ that might sterically hinder formation of the *cis* product (**4**).

A strong bonding interaction between the cationic centre and the central carbon of the allylic radical in $\mathbf{6}^{\dagger}$ would lead to the same radical cation as that which would be formed initially from tricyclene (1,7,7-trimethyltricyclo[2.2.1.$0^{2,6}$]heptane) (**7**).



Reaction [1]

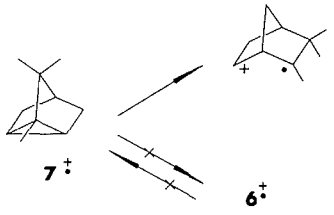

SCHEME 1

However, when **7** was subjected to these reaction conditions (reaction [2]), different products (**8–11**) were obtained.[3] These products were not detected in the reaction mixture starting with α-pinene (**2**) (reaction [1]); thus there is good evidence that the radical cations **2**·+, **6**·+, and **7**·+ do not interconvert under these conditions (Scheme 2). Cleavage of the radical cation of **7** occurs at the more heavily substituted C1—C2 bond. However, the stereochemistry and the regiochemistry of the products (**8–11**), and the fact that the nitrile **9** is a major product, are all indicative of nucleophilic assistance during the cleavage of **7**·+.[4]

Reaction [2]

Similar reactions, carbon–carbon bond cleavages (3) and rearrangements (4), of radical cations are known; however, little is known about the detailed course of these reactions. As in the examples just described, direct observation of these processes is made difficult by the fact that radical cations of this type are generally unstable transient species. Furthermore, when the radical cation is generated by photoinduced single electron transfer, deactivation by back electron transfer is usually rapid. Back electron transfer from the radical anion to the radical cation within the radical ion pair has a rate constant of ca. 10^8 s^{-1} (5), so that cleavage and rearrangement must be even more rapid in order to compete.

SCHEME 2

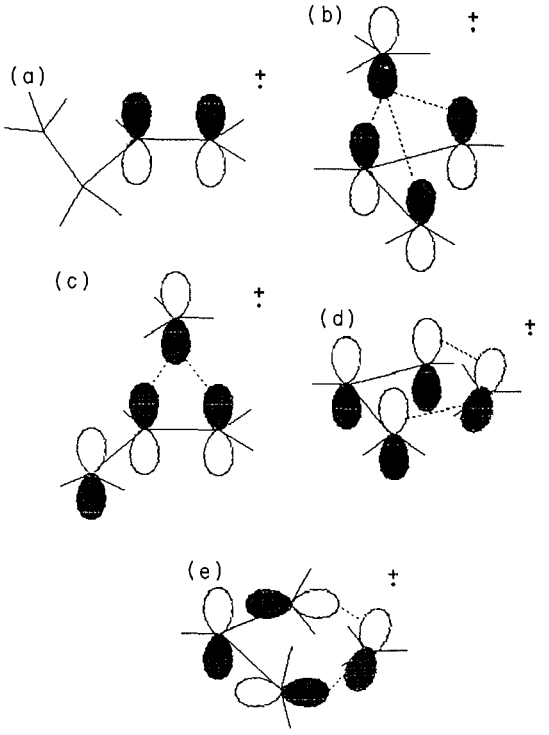

FIG. 1. Possible metastable intermediates/transition states preceding the complete separation of the allyl and alkyl fragments from the radical cation of alkenes.

One of the main objectives of this programme is to gain insight into the detailed nature of these cleavage and rearrangement processes. We have applied *ab initio* molecular orbital calculations to the problem. α-Pinene (**2**) and tricyclene (**7**) are relatively large molecules, currently beyond the scope of all but the simplest *ab initio* molecular orbital calculation methods. Therefore we began our study by choosing the radical cations of 1-butene (**12**) and 4,4-dimethyl-1-pentene (**13**) as archetypical examples of alkene radical cations that are small enough to treat by reliable methods (MP2/6-31G*, UHF/6-31G*, and UHF/STO-3G).

There is experimental evidence that illustrates the complexity of the problem even with these relatively simple alkenes. The normal electron impact ionization mass spectra of the C_4H_8 isomers, 1-butene (**12**), *cis*- and *trans*-2-butene (**14**), and the cyclic isomers methylcyclopropane (**15**) and cyclobutane (**16**), are all very similar (6). The molecular ions equilibrate to a common structure(s) before or during fragmentation. The behaviour of the initially formed radical cations has been studied by neutralization–reionization mass spectrometry.

[3]D. R. Arnold and X. Du. Unpublished results.

[4]The solvent acetonitrile–methanol (3:1) is ca. 6 M methanol. The cyanide ion is present in relatively low concentration, generated upon rearomatization of the intermediate 4-cyanocyclohexadienyl anion (Scheme 1). Nucleophilic assistance during the cleavage of cyclopropane radical cations has been reported (3*a*).

Using this technique it was possible to show that even though the initially formed radical cations readily undergo carbon–carbon bond cleavage, carbon–hydrogen bond cleavage, and rearrangement, five distinct radical cations ($C_4H_8^{+\cdot}$) could still be characterized (6*a*).

Additional evidence for the structure and reactivity of the C_4H_8 radical cations comes from electron spin resonance (ESR) studies carried out in Freon matrices at low temperatures under conditions where the radical cations are relatively stable (7). Butene-1 (**12**), *cis*- and *trans*-2-butene (**14**), and 2-methylpropene (**17**) all give distinct ESR spectra attributed to their respective radical cations (7*a*). Analysis of the ESR proton hyperfine splitting of the radical cations of **12** and *cis*- and *trans*-**14** indicates that these radical cations maintain a structure similar to that of the original alkene; they are essentially planar (7, 8).

Computational

Molecular orbital calculations are particularly valuable for revealing the structure and relative energy of local minima, possible metastable intermediate(s), preceding the complete separation of the allyl and alkyl fragments from the radical cation formed initially.

In addition to the structure closely resembling the alkene (Fig. 1a), a possible bridged structure for the radical cation would have the alkyl moiety interact with the allyl moiety, approaching in two nearly parallel planes (Fig. 1b). This is a structure that might also result from cleavage of the radical cation of an alkylcyclopropane or as an intermediate/transition state in the suprafacial 1,3-sigmatropic rearrangement of an alkene radical cation (9).[5] In the case of $C_4H_8^{+\cdot}$ this structure has C_s symmetry.

Another possible structure would have the alkyl moiety interact with adjacent carbons of the allyl moiety (Fig. 1c). A similar "nonclassical" structure has been proposed to explain the ESR spectrum of the radical cation of methylenecyclobutane (**17**$^{+\cdot}$) (10).

Other possible structures for the radical cation were not given detailed consideration because of obvious unfavourable energetics or symmetry. Alternative arrangements having the allyl and alkyl moieties approach along two perpendicular planes (Figs. 1d and 1e) are unlikely; either the orbital overlap is unsymmetric (Fig. 1d) or overlap throughout the allyl system is lost (Fig. 1e).

The *ab initio* molecular orbital calculations were carried out with the GAUSSIAN 86 series of programs (11). The charge and spin distributions were calculated by Mulliken population analysis (12). Structures were fully optimized at the UHF/6-31G* and UHF/STO-3G levels. The energies for some optimized structures were corrected for electron correlation using single point MP2/6-31G*//UHF/6-31G* computations. Limitations of these methods have been discussed (13). The calculated energies for the neutral alkenes, for several alternative structures of the alkene radical cations, and for the fragment alkyl and allyl radicals and cations are listed in Table 1.

Calculations on the 1-butene (12) system

The geometry optimization of the radical cation of 1-butene (**12**$^{+\cdot}$), having a structure similar to that of the alkene (Fig. 1a), was carried out at both the UHF/STO-3G and UHF/6-31G* levels. Minima were found for three of the four possible conformers around the C2—C3 carbon–carbon single bond.[6] The conformer with the methyl group *skew* and a hydrogen on C3 *eclipsed* with the vinyl group is the global minimum (**12**$^{+\cdot}$**a**, Fig. 2). The related conformation, that having the methyl group *gauche* and a hydrogen on C3 *anti* to the vinyl group, is not a minimum; calculations starting with this initial structure collapsed to the global minimum. The conformer next in energy above the minimum has C1, C2, C3, and C4 all in a plane, with the methyl group *eclipsed* with the vinyl group. The least stable conformer has the alternative planar structure with the methyl group *anti* to the vinyl group. Calculations on the neutral molecule 1-butene (**12**) find the same relative order of stability for the conformers (14).

The bridged structure analogous to Fig. 1b was also fully optimized at both the UHF/STO-3G and at the UHF/6-31G* levels. The initial search for a minimum imposed a C_s symmetry constraint and confined the allyl moiety to a plane. Having identified a stationary point, a similar structure (**12**$^{+\cdot}$**b**, Fig. 3)

[5]An *ab initio* (UHF/6-31G*) study of the 1,3-hydrogen migration of the radical cation of 1-propene has identified a similar structure as a transition state (9*a*). An earlier calculation using semi-empirical methods (MINDO/3) indicated the same structure was an intermediate; however, no energy minimum was found for the 1,3-methyl migration of the radical cation of 1-butene (**12**$^{+\cdot}$) (9*b*).

[6]The four possible conformers of 1-butene resulting from rotation around the C2—C3 carbon–carbon single bond are as follows: with the methyl group and the vinyl group at an angle of ca. 0° (*eclipsed*), 60° (*gauche*), 120° (*skew*), and 180° (*anti*).

was obtained without imposing these constraints. Further characterization of the stationary point showed one imaginary frequency on diagonalization of the force constant matrix; therefore, while the UHF/6-31G* calculations identify **12**‡**b** as a stationary point, more stable than the separated fragments, it is a transition state, not an intermediate (15).

Calculations on the structure analogous to Fig. 1c were attempted only at the UHF/STO-3G level and were initially subject to constraint; the C4 carbon of the methyl moiety was confined to a plane perpendicular to the C1—C2 bond lying between the C1 and C2 atoms. Even with this constraint the calculation did not converge. When the constraints were removed the calculation converged to the global minimum structure **12**‡**a** shown in Fig. 2. Therefore, calculations at the UHF/STO-3G level do not find a stable structure analogous to Fig. 1c for $C_4H_8^{\ddagger}$ and this structure was not considered further.

Single point calculations (MP2/6-31G*//UHF/6-31G*) were carried out on the neutral molecule (**12**) and on the radical cation in structures **12**‡**a** and **12**‡**b**; the results are summarized in Table 1.

Calculations on the 4,4-dimethyl-1-pentene (13) system

The geometry optimization of the radical cation of 4,4-dimethyl-1-pentene (**13**‡), in a structure similar to that of the alkene, was carried out only at the UHF/STO-3G level. All four possible conformers were considered and three minima were identified. As in the case of the 1-butene radical cation (**12**‡), the global minimum for **13**‡ has the *tert*-butyl group *skew* (ca. 120°) to the plane of the vinyl group (**13**‡**a**, Fig. 4). The conformers having the *tert*-butyl group *eclipsed* and *anti* to the vinyl group were energy minima but were considerably higher in energy. Calculations initiated with the radical cation in the conformation having the *tert*-butyl group *gauche* (ca. 60°) with the plane of the vinyl group converged to the global minimum. This order of stability for the conformers of the radical cation of **13** is the same as that observed for the parent molecule (16).

Calculations on the bridged structure analogous to Fig. 1b were also performed at the UHF/STO-3G level. Initially the structure was confined to C_s symmetry with the central carbon of the *tert*-butyl moiety in a plane perpendicular to the allyl moiety and through C2. The resulting stationary point was then fully optimized without these constraints; C_s symmetry was maintained (**13**‡**b**, Fig. 5). This structure is less stable than the separated *tert*-butyl cation and allyl radical fragments, one imaginary frequency was found on diagonalization of the force constant matrix; therefore, **13**‡**b** is not an intermediate.

Results and discussion

The most stable of the structures considered for the radical of 1-butene (**12**‡) is very similar to that of the alkene (**12**‡**a**, Fig. 2). The hydrogen on C3 and the three carbons, C1, C2, and C3, are all in the same plane. The allyl moiety is nearly planar, the terminal methylene group is only slightly (<1°) twisted out of the C1—C2—C3 plane. The methyl group is *skew* (119.8°) to the plane of the vinyl group and the C3—C4 bond length (1.554 Å) is normal. The singly occupied molecular orbital (SOMO) is largely associated with the π bond between C1 and C2. There is little positive change (0.161)

or spin (0.033) density on the methyl moiety. This conformer is only 1.3 kJ mol^{-1} more stable than the conformer having C1, C2, C3, and C4 all essentially in the same plane, with the methyl group *eclipsed* with the vinyl group. The alternative planar arrangement, that with the methyl group *anti* to the vinyl group, is 3.5 kJ mol^{-1} above the global minimum.

Analysis of the ESR spectrum of the radical cation of 1-butene (**12‡**) in a Freon matrix at low temperature shows

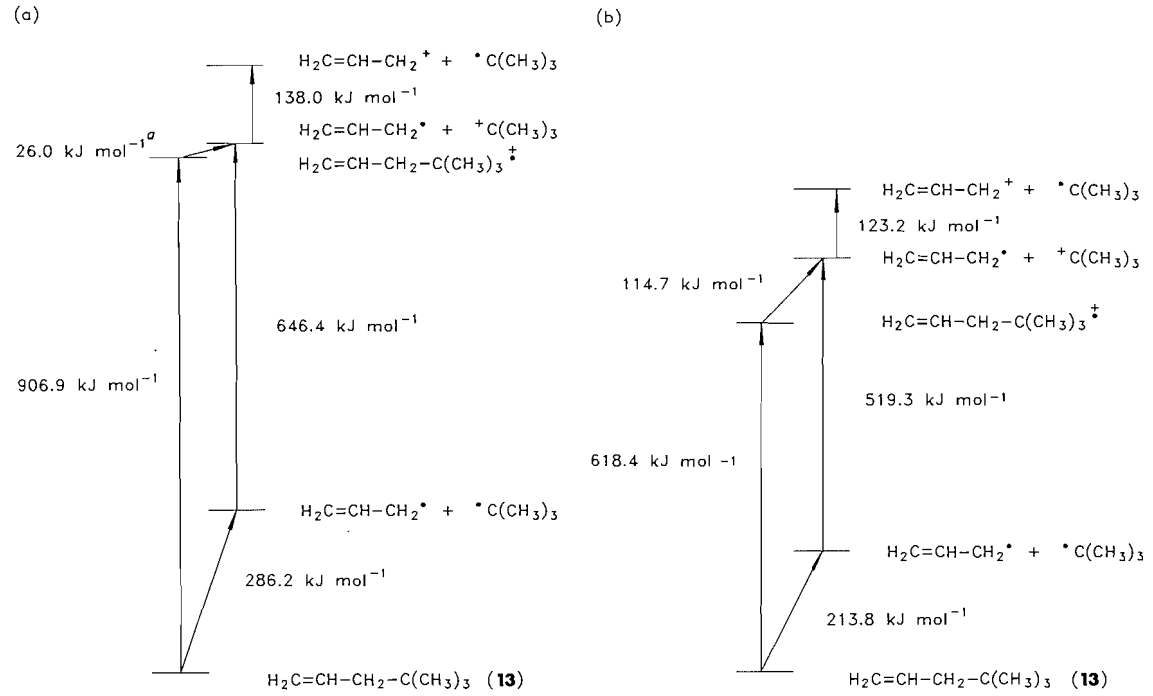

FIG. 9. Thermochemical cycles for the cleavage of the radical cation **13‡a**. (a) Experimental results (17). (b) Differences in calculated (UHF/STO-3G) total energies.
[a]Value calculated by completing the cycle.

equivalent hyperfine coupling due to the hydrogens on C3. This has led to the assignment of the planar structure, that having the methyl group *eclipsed* with the vinyl group, for the radical cation (*7b*). The results of these calculations lead us to suggest that the *skew* conformer is in fact favoured; however, the two hydrogens on C3 appear equivalent in the ESR spectrum because the rotational barrier, which equilibrates the two hydrogens, through the planar conformer is small.

The bridged structure **12‡b** (Fig. 3) is an energy maximum, a possible transition state in the suprafacial 1,3-sigmatropic methyl migration of **12‡**. This structure is 148.5 kJ mol^{-1} less stable than the global minimum **12‡a** (Fig. 2) and is only 34.4 kJ mol^{-1} more stable than the sum of the energy of the allyl cation and the methyl radical (MP2/6-31G*). The structure is similar to that found for the transition state for the 1,3-hydrogen migration in the propene homolog (*9a,b*). The allyl moiety is almost planar, H3 is only 21° out of the plane of C1, C2, and C3, and the C2—C4 bond length is relatively long (1.909 Å). The angle between H3—C2—C4 is 97.6°. Significant positive charge (0.439) and spin (−0.292) density are on the methyl moiety. This structure is related to the radical cation that could form upon cleavage of methylcyclopropane. However, when the radical cation of methylcyclopropane cleaves, fragmentation to give the alternative radical cation, that having the more heavily substituted (i.e., the more stable secondary) cationic centre, would be preferred.

An accurate description of the bonding involved in **12‡b** is provided by an analysis of the individual molecular orbitals (Fig. 6). In the highest filled molecular orbital (Fig. 6a) the orbital coefficients for the p_x orbitals on C1 and C3 are small; bonding involves both σ and π bonds. The major contributors to the singly occupied molecular orbital (SOMO) are the p_y atomic orbitals on C1 and C3 (Fig. 6b). This species (**12‡b**) is best described as having the methyl moiety partially bonded to all of the carbons of the allyl moiety. The positive charge density is largely associated with the methyl moiety while the unpaired electron is largely distributed between the terminal carbons of the allyl moiety. These bonding orbitals correlate with the orbitals of the methyl cation and the allylic radical. Correlation with the methyl radical and allylic cation is symmetry forbidden (Fig. 7).

Calculations on the radical cation of 4,4-dimethyl-1-pentene (**13‡**) were carried out only at the UHF/STO-3G level. Comparison of the results from the two basis sets calculations on **12‡** indicates that the minimum structures for the radical cation are relatively more stable, compared to the energy of the separated fragments, with the lower level basis set (UHF/STO-3G). In the case of **13‡** the minimum having the structure close to that of the alkene (**13‡a**, Fig. 4) is closer in energy (114.7 kJ mol^{-1}) to the separated fragments and, while the calculation of the radical cation having the bridged structure **13‡b** (Fig. 5) does converge, the calculated energy at the stationary point is higher (25 kJ mol^{-1}) than the sum of the energy of the separated fragments. The C2—C4 bond length (2.00 Å), in this transition state, is relatively long. Bonding between the *tert*-butyl and allyl moieties in **13‡** is weaker than bonding between the methyl and allyl moieties in **12‡**. The calculated stability of these bonded radical cation structures (**13‡a** and **13‡b**) would be even less if the larger basis set (UHF/6-31G*) was used.

The cleavage process

These radical cations can undergo carbon–carbon bond cleavage in two modes: formation of the allyl radical and alkyl cation, or formation of the allyl cation and alkyl radical. The energy requirements for these alternatives can be estimated both from experimental thermochemical data (Figs. 8a and 9a (17)) and from the calculated values listed in Table 1 (Figs. 8b,

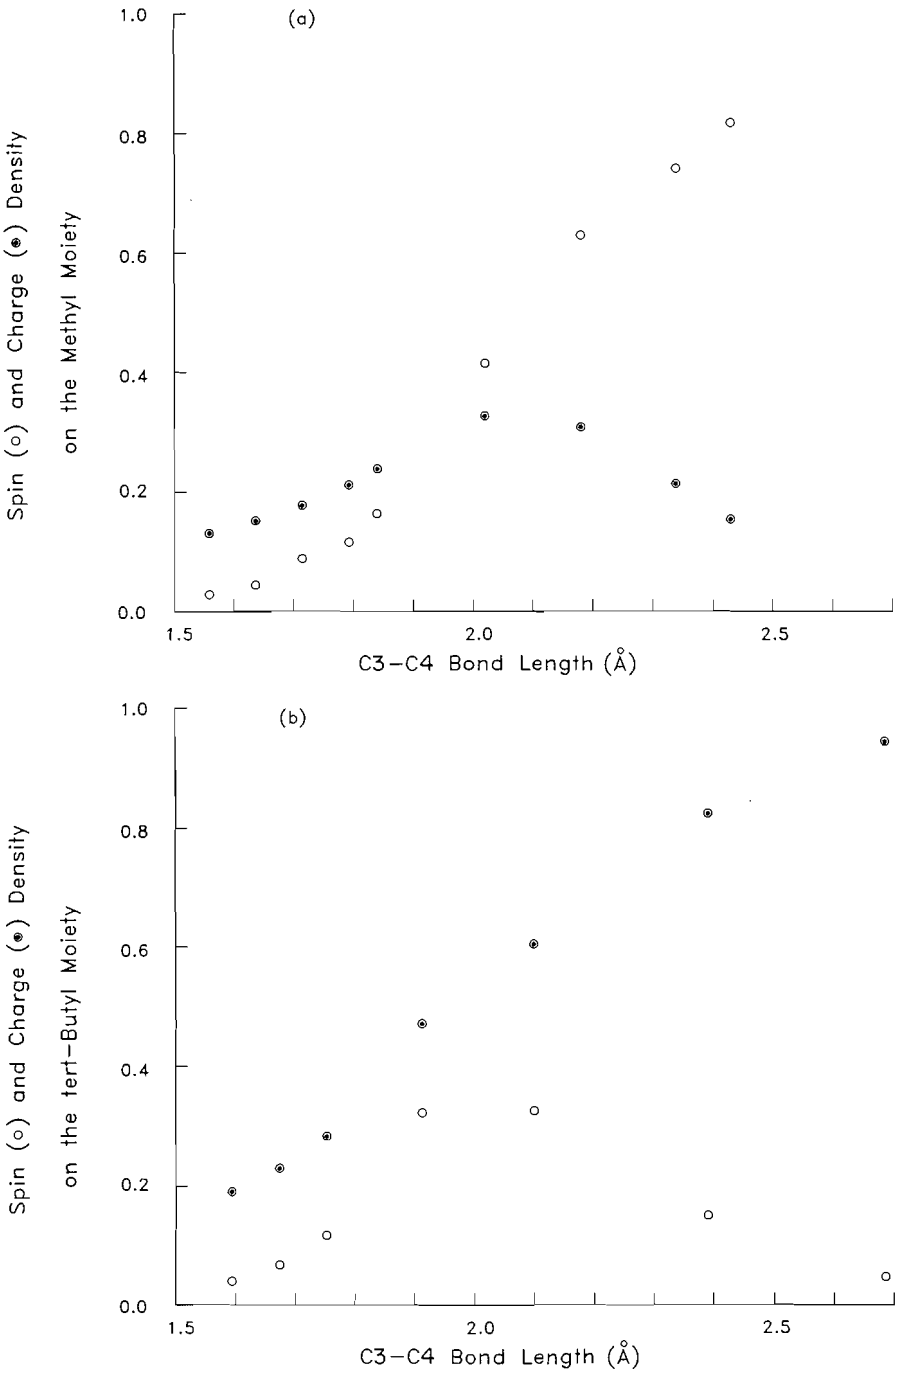

FIG. 10. The calculated (UHF/STO-3G) spin and charge densities on the alkyl fragment of the radical cation (a) **12**‡**a** and (b) **13**‡**a** as a function of allylic bond length.

8c, and 9b). For the cleavage of the radical cation of 1-butene (**12**‡), there is good agreement between the experimental results and the calculated energy values when the larger basis set is used and when electron correlation is considered (MP2/6-31G*) (Fig. 8b). The largest discrepancy caused by neglect of electron correlation involves the calculated homolytic C3—C4 bond dissociation energy. Bond dissociation energies calculated using Hartree–Fock theory are generally low (13). While formation of the alkyl radical and allylic cation is favoured in the case of **12**‡, cleavage to the alkyl cation and allyl radical is favoured in the case of **13**‡.

When the radical cations **12**‡**a** and **13**‡**a** cleave, there is no intrinsic barrier that favours cleavage in either mode. The singly occupied orbital of the product, alkyl or allyl radical, is determined on the basis of energetics. Figures 10a and b show the calculated (UHF/STO-3G) spin and charge densities on the methyl and *tert*-butyl fragments as the allylic C3—C4 bond is progressively lengthened; the rest of the structure was optimized. The initial stages of bond lengthening increase both charge and spin densities on both the methyl moiety and the *tert*-butyl moiety. However, as the bond lengthening increases beyond ca. 2 Å, spin density increases on the methyl moiety while charge density increases on the *tert*-butyl group.

There is experimental evidence indicative of these alterna-

tive modes of cleavage of 12^+ and 13^+. The mass spectrum of 1-butene (**12**) shows the base peak at $m/z = 41$, the allyl cation, and the peak at $m/z = 15$ for the methyl cation has a relative abundance of only 6%; there is a significant (40%) peak due to the molecular ion ($m/z = 56$). The base peak in the mass spectrum of 4,4-dimethyl-1-pentene (**13**) is due to the *tert*-butyl cation ($m/z = 57$) and the peaks due to the allylic cation ($m/z = 41, 53\%$) and the molecular ion ($C_7H_{14}^+$, $m/z = 98$, <1%) are both relatively minor (18).

The interaction of an alkenyl radical cation with an alkene results in formation of an excited complex that fragments to yield new cations, radicals, and alkenes. This process has been studied by triple quadrupole mass spectrometry and the principal reaction between the ethenyl radical cation and ethylene yields a $C_4H_8^+$ complex that fragments exclusively to the allyl cation and the methyl radical. In marked contrast, reaction of the radical cation of 2-methylpropene with 2-methylpropene gives a $C_7H_{14}^+$ complex that yields the 2-methylallyl radical and the *tert*-butyl cation as the only products (19).

Conclusions

Removal of a single electron from 1-butene yields a relatively stable radical cation 12^+**a** with a structure closely resembling the original alkene. This intact radical cation is significantly more stable than the separated allyl and alkyl fragments. Fragmentation to the allyl cation and the methyl radical is energetically favoured over formation of the allyl cation and methyl radical. The alternative bridged structure for the radical cation, 12^+**b**, formed by interaction of allyl and methyl fragments in which the unpaired electron resides mainly on the terminal carbons of the allyl moiety and nearly half the positive charge is distributed on the methyl moiety, is not an energy minimum.

Substitution of a *tert*-butyl group in place of the methyl group has a profound effect on the nature of the radical cation. Removal of a single electron from 4,4-dimethyl-1-pentene yields a radical cation, 13^+**a**, which is only slightly more stable than the separated fragments. Cleavage of the $C_7H_{14}^+$ radical cation to the allyl radical and *tert*-butyl cation is favoured over the alternative formation of the allyl cation and *tert*-butyl radical. These differences between 12^+ and 13^+ can be attributed to variation in the difference in the ionization potential of the two alternative fragments and to the variation in the stability of the alkyl cation: (1) Fragmentation of the radical cation occurs in the direction that gives the carbocation of that fragment having the lower ionization potential. (2) If the carbocation is stable, cleavage of the radical cation is favoured and bonding interaction between the fragments is minimized. These correlations have been recognized previously for cleavage of radical cations in solutions of polar solvents (3*b*, 20). Cleavage of radical cations in acetonitrile–methanol (3:1) solution occurs in the direction that gives the carbocation of that fragment having the lower oxidation potential.

The results of these calculations are in good agreement with the observed behaviour of the radical cations of α-pinene (reaction [1]) and tricyclene (reaction [2]). The initial single electron transfer step in reaction [1] should give a weakly bonded radical cation (2^+). Cleavage of 2^+ to 6^+ will be assisted by relief of strain associated with the four-membered ring (9*c*). Formation of the allylic radical and *tert*-carbocation is consistent with these calculations. Furthermore, the absence of a minimum for structure 13^+**b** makes it unlikely that there is significant bonding interaction between the allyl radical and carbocation centres in 6^+. This is consistent with the observed stereochemistry; there is little preference for formation of the *trans* products **5**, and no rearrangement to the radical cation obtained from **7**. Nucleophilic assistance in the cleavage of the radical cation of tricyclene (**7**) is also consistent with theory. The radical cation of cyclopropane maintains the three-membered ring; cleavage to the trimethylene radical cation is endothermic (21).

A theoretical approach to the acid-catalyzed hydration of the carbonyl group: the case of formaldehyde

DANIEL PEETERS AND GEORGES LEROY

Laboratoire de chimie quantique, Université Catholique de Louvain, Pl. Louis Pasteur n° 1, B 1348, Louvain-la-Neuve, Belgium

Received November 13, 1990[1]

DANIEL PEETERS and GEORGES LEROY. Can. J. Chem. **69**, 1376 (1991).

The analysis of the hydration of formaldehyde in the presence of a hydrated proton was performed. Molecular quantum chemistry methods were used to explore the potential energy hypersurface. Calculations were performed at RHF-4-31G level. The structures were obtained through the use of first and second derivatives of the potential energy hypersurface thereby guaranteeing the nature of the extremum. The incidence of one or two water molecules on the reaction is discussed. It has been found that a low energy reaction path exists when the hydration process is catalyzed by a proton and two water molecules. The reaction mechanism rests on successive addition/elimination processes and reveals the respective roles of the oxygen lone pairs and of the C=O double bond upon the mechanism.

Key words: ab initio calculations, carbonyl reactivity, acid catalysis, hydration, reaction mechanism.

DANIEL PEETERS et GEORGES LEROY. Can. J. Chem. **69**, 1376 (1991).

L'hydration du formaldéhyde en présence d'un proton hydraté a été analysée. Les méthodes de la chimie quantique moléculaire sont utilisées dans l'analyse de l'hypersurface d'énergie potentielle. Les structures d'équilibre ont été obtenues à partir de méthodes utilisant les dérivées première et seconde de l'énergie potentielle, garantissant par là la nature de l'extrémum local. L'influence d'une et deux molécules d'eau supplémentaires est discutée. Cette étude montre l'existence d'un chemin de réaction à basse énergie dans l'hydratation catalysée par un proton en présence de deux molécules d'eau. Le méchanisme repose sur une succession d'étapes d'addition/elimination et montre les rôles respectifs des paires libres de l'atome d'oxygène et de la double liaison C=O dans ce mécanisme.

Mots clés : calcul ab initio, reactivité du carbonyl, catalyse acide, hydratation, mécanisme de réaction.

I. Introduction

The reactivity of the carbonyl group within a given molecule is known to be an important feature in both organic chemistry and biochemistry. Among many other reactions of this functional group reversible hydration is also important. Some of the hydrates are known to be stable solids, others which do not give solid hydrates can nevertheless be observed in an aqueous solution reaction:

$$R_1R_2CO + H_2O \rightleftarrows R_1R_2C(OH)_2$$

Even when this process is not clearly identified in a reaction mechanism, it is often suggested that it takes place with a small equilibrium constant. The hydrate may be difficult to detect, but it will be subsequently introduced as an intermediate in a sequence of elementary processes leading to an overall mechanism. In the gas phase, this reaction usually does not take place, although in some cases a small, but meaningful, equilibrium constant exists in the vapor mixture. These reactions are further subject to acid and base catalysis. Some reaction mechanisms involving several water molecules have been proposed. A review of the experimental approach to these considerations may be found in the comprehensive review of Bell (1) and the mechanism of general acid and base catalysis of the reactions of water and alcohols with formaldehyde has been described by Jencks and co-workers (2). These authors have arrived at the conclusion that the general acid catalysis of the addition of water to the carbonyl group occurs through a class "e" mechanism.

In the case of formaldehyde, various experimental approaches attest to the ease of such a reaction with an equilibrium constant close to 2×10^3. The reaction itself takes place in two steps, the first step leads to a molecular complex with a release of the heat of solution (1.63 to 1.96 kcal mol^{-1} for acetaldehyde (3)) followed by a hydration process corresponding to a reaction enthalpy ranging from 5.7 to 14.6 kcal mol^{-1}, with a suggested value of 8.0 kcal mol^{-1} (to be compared to a value of circa 5.0 kcal mol^{-1} for acetaldehyde (1)). It is further well established that the solution polymerizes to paraformaldehyde upon evaporation. If the formaldehyde is subjected to sulfuric acid catalysis, it forms a trimer (trioxane), if it is distilled it forms a linear polymer (Delrin).

This reaction is of particular theoretical interest. It is the simplest reaction of the carbonyl group and can be taken as a model for more complex situations. It also constitutes a challenge for theoreticians due to the fact that it does not take place in the gas phase, but requires the introduction of water into the computation in order to be followed realistically by quantum mechanics. The interaction between a single water molecule and formaldehyde has been analyzed by various authors. Quite recently, an extensive analysis of the many complexes appearing on the energy hypersurface has been performed by Kumpf and Danewood (4). The properties of these complexes, namely the behavior of the electronic spectrum of formaldehyde perturbed by the presence of water, has been studied by Blair and co-workers (5). The hydration process itself has been studied for neutral species by Williams *et al.* in several papers (6). Since an extensive analysis of the literature has been performed by these authors, we shall refer our readers to these reviews. These authors studied in a first approach the catalyzed addition mechanism (6*a*) and completed the examination by studying the influence of solvation on this mechanism (6*b*).

In this work we intend to study, from a theoretical point of view, the behavior of the carbonyl group of formaldehyde in the presence of water molecules, one of these bearing a proton. This will be accomplished by the analysis of various extrema appearing on the potential energy hypersurface. In the "supermolecule" approach, some well-defined situations of $H_2CO \cdot H^+ \cdot (H_2O)_n$ and $H_2C(OH)_2 \cdot H^+ \cdot (H_2O)_{n-1}$ clusters (where n equals

$H_2CO \cdot H^+ \cdot H_2O$	C	−189.95292	0.00	42.10	3.54	72.17

1, 2, and 3) are examined. This paper may be considered a continuation of our previous work (7) on the behavior of water molecules sharing a proton. Some $H^+ \cdot (H_2O)_n$ clusters were studied with a special interest on the proton exchange between the various acceptor sites. In this case, a formaldehyde molecule will replace a water molecule. The clusters obtained will be allowed to rearrange on that part of the reaction hypersurface which describes diol formation. This analysis may also be considered a prerequisite to other reactions involving the carbonyl group.

II. Method

Our approach consists of first, the determination of the fully optimized geometry of the various structures. These structures are further solvated to small clusters and are treated as supermolecular systems. Any symmetry constraint has *a priori* been removed. As the most important entities concerned in this work are composed of three water molecules, we limited our choice of the basis set to the valence split 4-31G basis of Pople and coworkers using the GAUSSIAN series of programs (8, 9). Nevertheless this allows an analytical computation of the first and second derivatives of the energy hypersurface of any system studied, guaranteeing the nature of the local extremum.

The current reproaches to such a supermolecule approach invoke the basis set limitations leading to a well-known basis set superposition error and the lack of electron correlation. It is known that currently all these requirements can not be satisfied for the systems under consideration. As the second derivatives are the only guarantee of the nature of the extremum, we have chosen a methodological approach allowing this constraint to be fulfilled. Indeed, on our own experience, algorithms resting solely on first derivatives very often lead to improper points on the hypersurface giving one or even more negative eigenvalues when treated properly. Along the same lines, the natural tendency to start the optimization with symmetrical structures also presents many drawbacks. Thus the strategy we have employed throughout this paper starts from broken symmetry, followed by a full optimization of the structure guaranteed by the local analysis of the hypersurface up to the second order. To avoid basis set superposition error, which exists but is crudely corrected for by counterpoise calculations, we have decided to rest our discussion on structures belonging to the same hypersurface as fas as possible (i.e. presenting the same number of variables and parameters). In this case, the error is minimized for an error of the same magnitude should be observed for all partners. In addition, the intermolecular correlation energy of these systems remains almost constant on the hypersurface. This conclusion rests on arguments deduced from a preceding paper (6).

The results obtained in this way may be used in the computation of some thermodynamical properties. Indeed, as soon as the geometry of the system is known, one may calculate its moment of inertia and obtain the related rotational data. Furthermore, the knowledge of the normal modes of vibrations and their frequencies allows the introduction of zero point energy (ZPE) corrections. Consideration of the translational, rotational, and vibrational motions allows the computation of the internal energy under standard conditions. In addition, the entropy may be estimated from the use of statistical thermodynamics. Some care must be taken in using this datum, as it is only meaningful under the assumption of "perfect" behavior of the system. This means that we admit that the counter ion plays no explicit role for ionized system; that the neighborhood does not interact further with the structure under consideration and that the internal motions remain conventional vibrational modes at the temperature considered.

III. Results

The results are grouped by the number of water molecules added to formaldehyde. Thus Table 1 presents the data obtained following the procedure described in the preceding paragraph for $H_2CO \cdot 1H_2O$ and its rearranged counter parts such as $CH_2(OH)_2$. Figure 1 presents the corresponding structures accompanied by the most relevant bond lengths. To clarify the presentation, the position index of the structure in the figure is added as the second entry in the table, the first being the most appropriate chemical formula. In this case neutral, as well as protonated species, are shown explicitly. The tables report the fully optimized total energy and the energy increase relative to the most stable structure on the surface. The zero point energies, thermal corrections from 0 to 298.15 K and the entropies obtained within the harmonic approximation are also given. These data are not corrected for the possible free internal rotations. In this context, Tables 2 and 3, complemented by Figs. 2 and 3, present the data and structures obtained by adding one or two additional water molecules to the previous systems. This addition is made in the presence of an extra proton to simulate an acidified medium. Finally, for the purpose of completing our discussion, Table 4 and Fig. 4 present some structures obtained by replacing a water molecule with methanol.

One must keep in mind that such systems contain many degrees of freedom (36 for those with 14 atoms) and present a number of stable structures which may be important. In addition, the presence of labile parameters in clusters and complexes makes the determination of a true extremum quite difficult. Thus we do not pretend the list of structures reported here is exhaustive. However, all of these structures are true extrema presenting no negative eigenvalue for the second

derivatives matrix, or at most one for transition states. In the case of transition states, the eigenvector corresponding to this negative curvature has been analyzed to ensure its correct behavior along the reaction path, avoiding undesirable transition states such as those related to rotations or flip-flop motions. In conclusion, other stable structures which could be determined are believed to bring no further insight to the problem.

IV. Discussion

(a) Methyleneglycol

A crude examination of the equilibrium structures obtained for the complex "water–formaldehyde" and the methanediol molecule provides information for the reaction

$$H_2CO \cdot H_2O \rightleftarrows H_2C(OH)_2$$

The reaction energy found at 0 K equals -9.68 kcal mol^{-1}, which is slightly decreased by ZPE and thermal corrections to a value of -7.24 kcal mol^{-1}. This difference is essentially due to the ZPE corrections as low frequency modes are present in the complex but not in the reactant molecules. The same kind of considerations lead to an overall entropy change of some -15.41 eu bringing the Gibbs free energy to -2.64 kcal mol^{-1} for the described process. This results compares favorably to the experimental values of -4.0 to -4.5 kcal mol^{-1} for the global reaction in solution.[2] The transition state shown in Fig. 1 corresponds to the rotation of the formaldehyde molecule in the complex and may not, in any case, be considered an addition transition state. Indeed, the corresponding reaction coordinate contains no contribution from the bonds in formation. Such a transition state presents a high energy and, as shown by Williams, the introduction of more water molecules is required to maintain the reaction in an acceptable energy range.

It should be mentioned that a second conformer is obtained for methyleneglycol. In this conformer, an OH bond bisects the CH_2 group, while in the most stable conformer a hydrogen bridge is established with the opposite oxygen center. The anomeric effect (10) predicts that this species is slightly less stable (45 kcal mol^{-1}) than the first. However, since it presents nearly the same vibrators and entropy, the Gibbs free energy between this species and the complex falls to a small value (-0.13 kcal mol^{-1}) which justifies a nearly one-to-one equilibrium for this species even though globally the overall constant is much smaller.

Finally the association step described by the reaction:

$$H_2CO + H_2O \rightleftarrows H_2CO \cdot H_2O$$

is highly exothermic from a theoretical point of view (-7.04 kcal mol^{-1}) but may not be considered so exothermic when compared to the experimental value (-1.6, -2.0 kcal mol^{-1}) as it does not describe the global solvation process (i.e. the reorganization of all the associated solvent molecules).

Since it is well known that the reactions of carbonyls respond to acid catalysis (2), we examined the various species obtained by protonation of the preceding systems. The addition of a bare proton either on the complex or on the diol leads in both cases to a molecule–ion complex. In the former the proton is captured by the water molecule yielding a $H_2CO \cdot H_3O^+$ complex (Fig. 1*C*). In the latter, the proton is trapped by an hydroxyl group giving

[2]These values are obtained from the association constants given in Table 1 of ref. 1. The K_2 values range from 10^{-3} to 4.5×10^{-4}, giving Gibb's free energies between 4.09 and 4.56 kcal mol^{-1}.

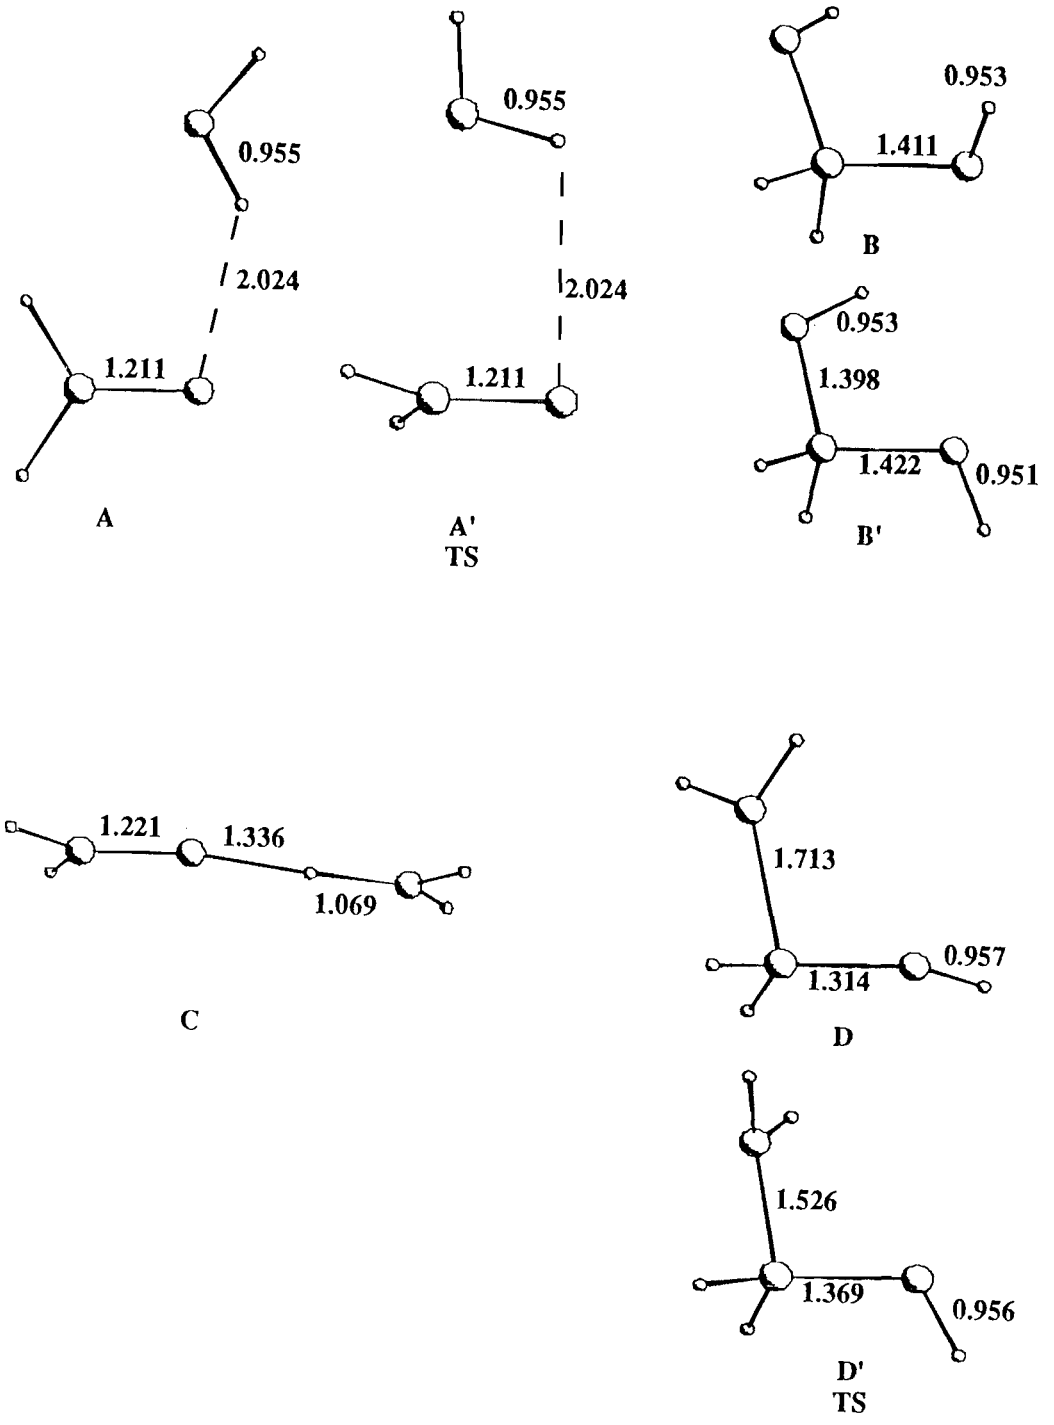

FIG. 1. Structures of neutral and protonated methanediol and the complexes between water and formaldehyde (distances in Å).

another complex symbolized by $H_2COH^+ \cdot H_2O$ (Fig. 1*D*) which is some 7.49 kcal mol^{-1} less stable. Entropy as well as thermal corrections increase this tendency towards instability. All the other conformations obtained by rotating the OH bonds about the CO bond have led to rotational transition states rather than stable conformers. It may be surprising to find a transition structure (Fig. 1*D'*) resembling a protonated diol with no corresponding minimum, but we have explored the hypersurface and followed carefully the corresponding eigenvector in both directions. No minimum could be found and the structure smoothly rearranges upon rotation to the stable complex (Fig. 1*D*). During this rotation, the CO bond shortens while the water molecule moves off. Finally, a direct proton transfer transition structure can be obtained; however, it passes through an impressive activation barrier of some 29.6 kcal mol^{-1}. Summarizing these first observations, we may conclude that an anlaysis of the protonated energy hypersurface corresponding to the protonated diol molecule does not lead to such minimum, as only molecular cationic complexes are found.

(b) Systems with a second water molecule

Further hydration of the previously protonated systems will

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12

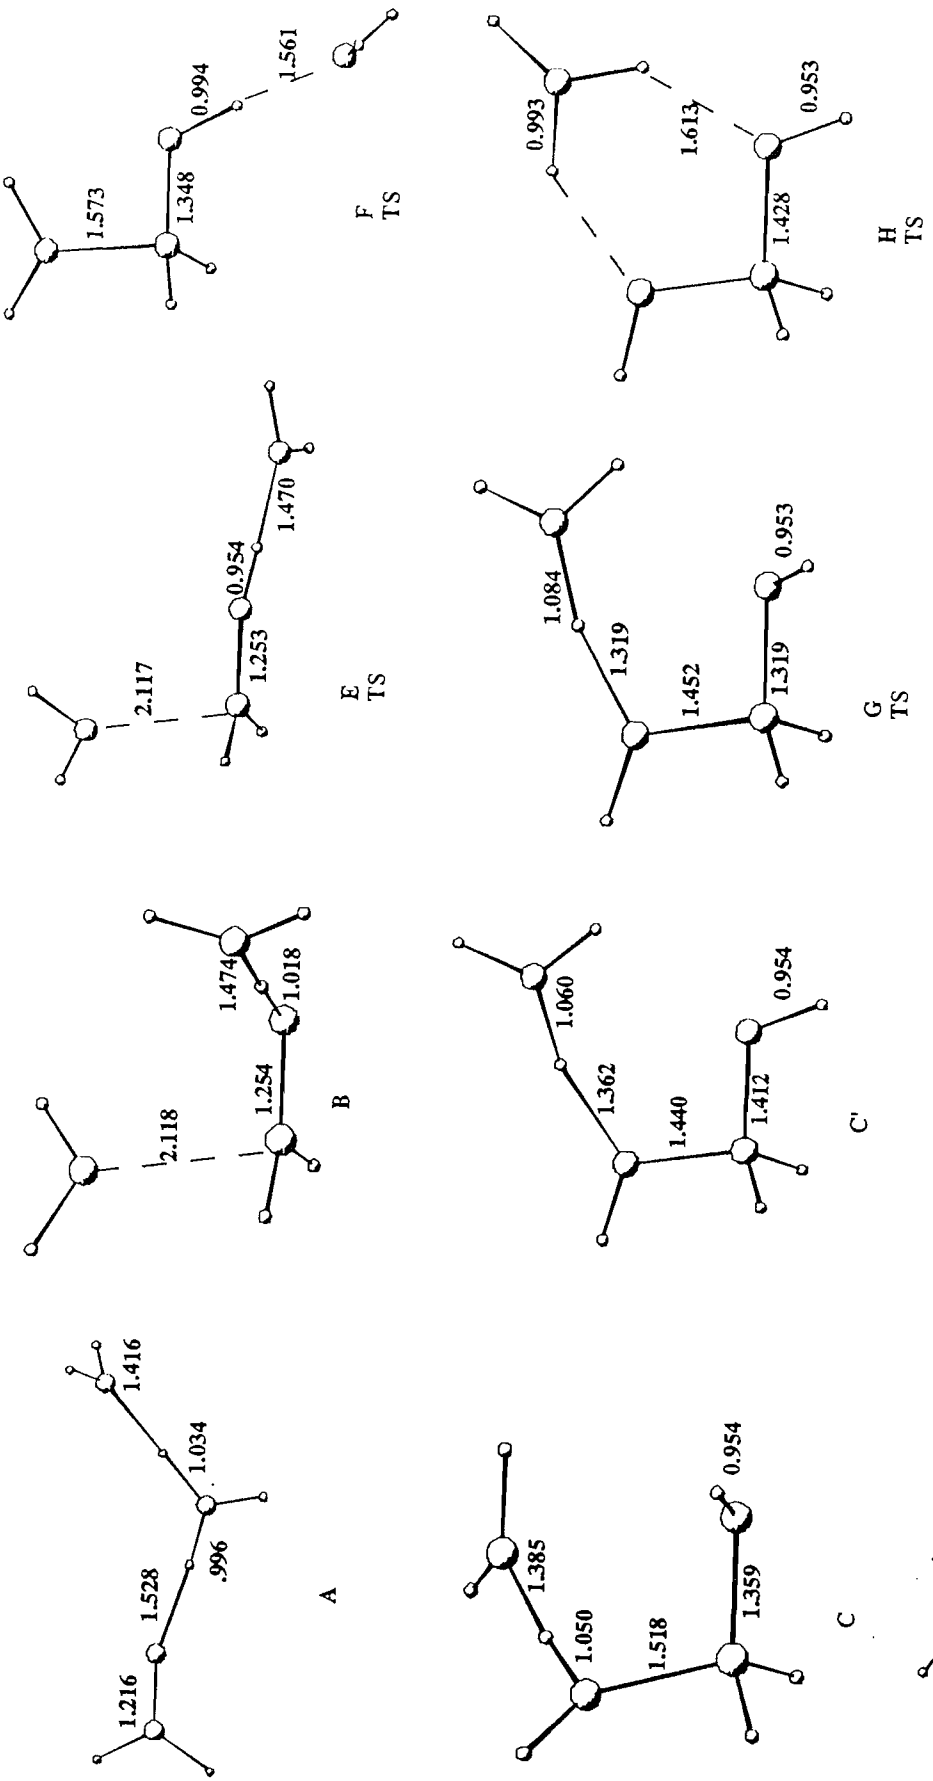

FIG. 2. Structures of solvated methanediol and the related complexes of formaldehyde in the presence of a proton (distances in Å).

produce many chemically distinct species as shown in Fig. 2. Starting from the $H_2CO \cdot H_3O^+$ complex (Fig. 1*C*), one may add an extra water molecule either on the hydronium part, or on the carbon center (Fig. 2*A*, *B*). Both lead to stable minima, even though the former is energetically more stable. Starting from the $H_2COH^+ \cdot H_2O$ complex (Fig. 1*D*), a molecule may be added on the water site or undeneath the complex on the carbon center (Fig. 2*C*, *D*). Both situations lead to stable structures. Looking at the former situation, a second stable minimum is obtained by a 90° rotation of the OH bond about the CO bond (Fig. 2*C'*).

The most stable system obtained from an energetic point of view, corresponds to the $H_2CO \cdot H_5O_2^+$ complex (Fig. 2*A*) while the less stable structure corresponds to the double hydration of the H_2COH^+ ion (Fig. 2*D*). On examination of their geometry, one notices that in the latter structure the addition of a second water molecule appreciably repels both molecules from the carbon centre. In the first complex, the identification of the formula relies on the OH distances reported from the structure. It has been established previously that in the $H_7O_3^+$ species the OH bonds shared by two oxygen atoms are equivalent and close to the standard bond length of H_3O^+. In this case, the bond pointing toward the carbonyl group is close to the conventional bond length of a water molecule while the other bond is much longer, even though the proton is not symmetrically located between the two water molecules.

The three remaining structures appear between these two extremes and are those related to our problem. The system described by Fig. 2*B* reveals that the two water molecules also exert an important mutual interaction in this case. The presence of a molecule near the protonated carbonyl group repels the other molecule connected to the carbon center. However, the proton initially attached to the water molecule (Fig. 1*C*) moves to the carbonyl center no matter what the orientation taken by the water molecule. In some sense, the presence of these two water molecules extensively reorganizes the structure of the carbonyl group. Nevertheless, this molecule–ion complex does not evolve to a diol-like system.

Finally, two more stable structures can be proposed (Fig. 2*C*, *C'*). The first one corresponds to a sensibly stabilized complex between the protonated formaldehyde and a water dimer. The distance between the carbon center and the water molecule decreases significantly (0.2 Å) if one compares this situation to the one water molecule complex (Fig. 1*B*) and prepares the formation of the CO bond. This bond formation is completed in the other conformer which lies 1 kcal mol^{-1} higher in terms of total energy and 1.23 kcal mol^{-1} higher in Gibbs free energy. Such a difference allows for a good thermodynamical equilibrium between these structures.

Some transition states connecting the previously described systems can be found. For example, rotation transition states can be observed. When the water molecule located close to the carbonyl oxygen rotates (Fig. 2*E* one finds a transition state lying some 0.56 kcal mol^{-1} higher in energy. This difference is totally resorbed by the ZPE, thermal corrections and, at the free energy level, by the entropy. This allows globally for a free rotation of the system.

Since the conformer described by Fig. 2*C'* is a stable one, one may ask what happens when the second water molecule is added on the second hydroxyl group (Fig. 2*F*). In this case the structure becomes a rotation transition state leading to Fig. 2*B*. Its internal coordinates are quite close to the latter, and after a careful analysis of the hyperstructure, no stable structure could be found in this region of the potential hypersurface. Upon rotation of the OH function, the CO bond shortens and the water molecule moves off as described before (Fig. 1*D* and *D'*).

Finally, two more transition structures merit our attention. The first one (Fig. 2*G*) connects the two stable structures of diol type (Fig. 2*C*, *C'*) at less than 1 kcal mol^{-1} of free activation energy, ensuring by the way a good transformation rate. This corresponds to a rotation of the $(H_2O)_2$ moiety coupled to a synchronous rotation of the OH group. The second transition structure (Fig. 2*H*) describes the proton exchange between the two hydroxyl groups through a H_3O^+ relay in energetic conditions close to the preceding example.

At this stage, one may thus conclude that even though the most stable situation does not correspond to a diol structure, as soon as this level is attained on the potential hypersurface, an important reorganization of the structures is made possible at low energy constrain and at high rate due to the presence of a second water molecule in the system,

(c) Systems with a third water molecule

Having noticed the influence of a second water molecule on the reorganization of the system, we thought it would be appropriate to investigate the behavior of a third water molecule. We find that the structures corresponding to the complex $H_2CO \cdot H_7O_3^+$ are the most stable (Fig. 3*A*, *A'*), with an energetic preference of some 3.37 kcal mol^{-1} in favour of the complexation of the hydrated H_3O^+ part rather than the H_2O terminal group. Similarly, the situation corresponding to the addition of a water molecule onto the carbon center of $H_2CO \cdot H_5O_2^+$ (Fig. 3*B*) is again unfavorable when compared to $H_2CO \cdot H_3O^+$. The distance between the incoming oxygen atom and the carbon center is the largest described so far (2.495 Å). This intermediate may be taken as the limiting structure describing the reaction between water and the $H_2CO \cdot H_5O_2^+$ structure, even though the corresponding reaction energy equals 11.98 kcal mol^{-1}.

The addition of the water molecule either on the carbonyl proton (Fig. 2*C*) or on the water site (Fig. 2*B*) leads to a new structure (Fig. 3*C*) which is a compromise between the two intermediates previously reported. Indeed the CO distance of the entering water molecule approaches a bond length close to a diol-like system as it increases slightly when we compare it to the diol-like situation (Fig. 2*C*). This is due to the repulsion of the water molecule close to the protonated carbonyl. On the other hand, the OH distance between the carbonyl group and the proton shortens when compared to the carbonyl-like situation (Fig. 2*B*). The situation corresponding to a hydration of the diol (Fig. 3*C'*) is again a rotation transition state related to the preceding complex. No definite diol-like compounds appear with this arrangement.

The addition of the extra water molecule may also lead to a complex between a water trimer and the protonated formaldehyde molecule. In this case two stable conformers may be found (Fig. 3*D*, *D'*) whose structures resemble more closely the diol molecule as the number of water molecules increases. Indeed, in this case both CO distances are modified towards the diol CO equilibrium distance. Upon successive hydration the carbonyl elongates (Figs. 1*D*, 2*C*, 3*D*) by some 0.004 Å, while the other conformer, initially a transition state (Fig. 1*D'*) is stabilized to a diol resembling complex (Figs. 2*C'*, 3*D'*). This situation has an energy of about 5 kcal mol^{-1} higher than the most stable structure and may plausibly lie along the reaction path.

Finally, another very stable diol structure exists. It corresponds to a complex between $CH_2(OH)_2$ and $H_5O_2^+$ shown in

Fig. 3*B'*. This structure is the second structure examined with respect to the energy of the various species. It lies only 2.80 kcal mol^{-1} higher than the most stable structure. In this case, therefore, we have two energetically low-lying species which belong explicitly to either the protonated formaldehyde class, or to the diol system.

(d) A brief summary

At this stage it is worthwhile summarizing the most important points from this discussion. (*i*) The protonated form of methanediol rearranges to either a complex between a water molecule and a protonated formol; or a complex between formaldehyde and a hydronium ion. No diol-like structure has been found for such a system. (*ii*) The additon of a single water molecule leads to a stable $H_2CO \cdot H_5O_2^+$ complex. A complex between methanediol and a hydronium ion is found some 8.14 kcal mol^{-1} higher. This complex is itself 1 kcal mol^{-1} higher than a diol-like structure obtained by the complexation of a water dimer and protonated formaldehyde. (*iii*) The addition of a second water molecule confirms the stability of the $H_2CO \cdot H^+(H_2O)_n$ complexes, but in this case a $H_2C(OH)_2 \cdot H_5O_2^+$ appears at only 2.80 kcal mol^{-1} from the most stable previous complex. This hypersurface is thus the only one containing a diol molecule.

From this point of view, one may propose a global reaction correspondong to

$$R_1R_2CO \cdot H_5O_2^+ + H_2O \rightleftarrows R_1R_2C(OH)_2 \cdot H_5O_2^+$$

Before considering the reaction mechanism itself, it is worthwhile to have a look at the effect of the substitution of a water molecule by some other solvating species such as methanol.

(e) Incidence of the co-reactant

In the presence of a methanol molecule, the product will be a hemiacetal. To achieve this analysis, we have optimized the most important structures lying along the reaction pathway, substituting a hydrogen atom by a methyl group. The corresponding results are reported in Fig. 4 and Table 4 and will be discussed below. If one considers a neutral methanol molecule added to a protonated formaldehyde, two almost isoenergetic structures appear (ΔE = 0.61 kcal mol^{-1}). Only the most pertinent to our discussion is shown. This structure resembles a protonated hemiacetal more than a complex between methanol and formaldehyde. Indeed the bond lengths are not far from the conventional valence bond length (1.40 and 1.42 Å for C—O in the neutral hemiacetal). The other structure is obtained by rotation of the methanol moiety by some 140° about the C-O axis. Rotation of the proton about the CO bond generates a rotation transition structure lying at 2.19 kcal mol^{-1}. This is the same for both conformers. Starting from this first structure, a water molecule has been added to the various sites of interest yielding the structures presented in the figure. These structures can be compared to the two water molecule case.

Some tendencies previously presented remain: (*i*) The addition of a water molecule on the methanol site produces a significant shortening of the C—O bond in formation and a lengthening of the other CO bond. (*ii*) The addition of a water molecule on the protonated carbonyl site repels the methanol and shortens the CO bond.

These results confirm that, qualitatively, methanol acts comparable to water, in which case this second water molecule may be considered as a model for a second methanol molecule.

On the other hand, the main differences are: (*i*) The complexes or molecules in the methanol case show much shorter bond lengths than in the water case. It is surprising to notice that these bond lengths are close to the isoelectronic system with two or three water molecules (Fig. 4*A*, *A'* and Fig. 2*C*, *C'*; Fig. 4*B*, *B'* and Fig. 3*D*, *D'*). This suggests that the structure is determined by the number of electrons rather than by the number and nature of the molecules involved in the complex. (*ii*) A rotation transition state rather than a stable structure is obtained upon rotation of the OH bond (Fig. 4*B'*). (*iii*) Even though the structures seem to be more like molecules than complexes, the interconversion energies are about twice those obtained between water and formaldehyde.

Finally, the exchange of a proton from the methoxy to the alcohol site through a hydronium ion relay is very easy, requiring only 2.19 kcal mol^{-1}. The corresponding transition state is close to the product, in structure as well as in energy.

These observations allow us to conclude that the deductions stated for the hydration process of formaldehyde can be generalized to the hemiacetal formation process.

V. A possible reaction mechanism

At this stage, it is interesting to look at a reaction mechanism relating the formol reactant to the diol product in the presence of an acid catalyst such as a hydrated proton. Taking into account the global reaction proposed in the previous section:

$$R_1R_2CO \cdot H_5O_2^+ + H_2O \rightleftarrows R_1R_2C(OH)_2 \cdot H_5O_2^+$$

this reaction mechanism must be viewed from three complementary viewpoints: the energy of the system, the geometry of the various intermediates, and the electronic structure of the various partners.

(a) From an energy viewpoint

The reactant can be described by Fig. 2*A* which leads upon

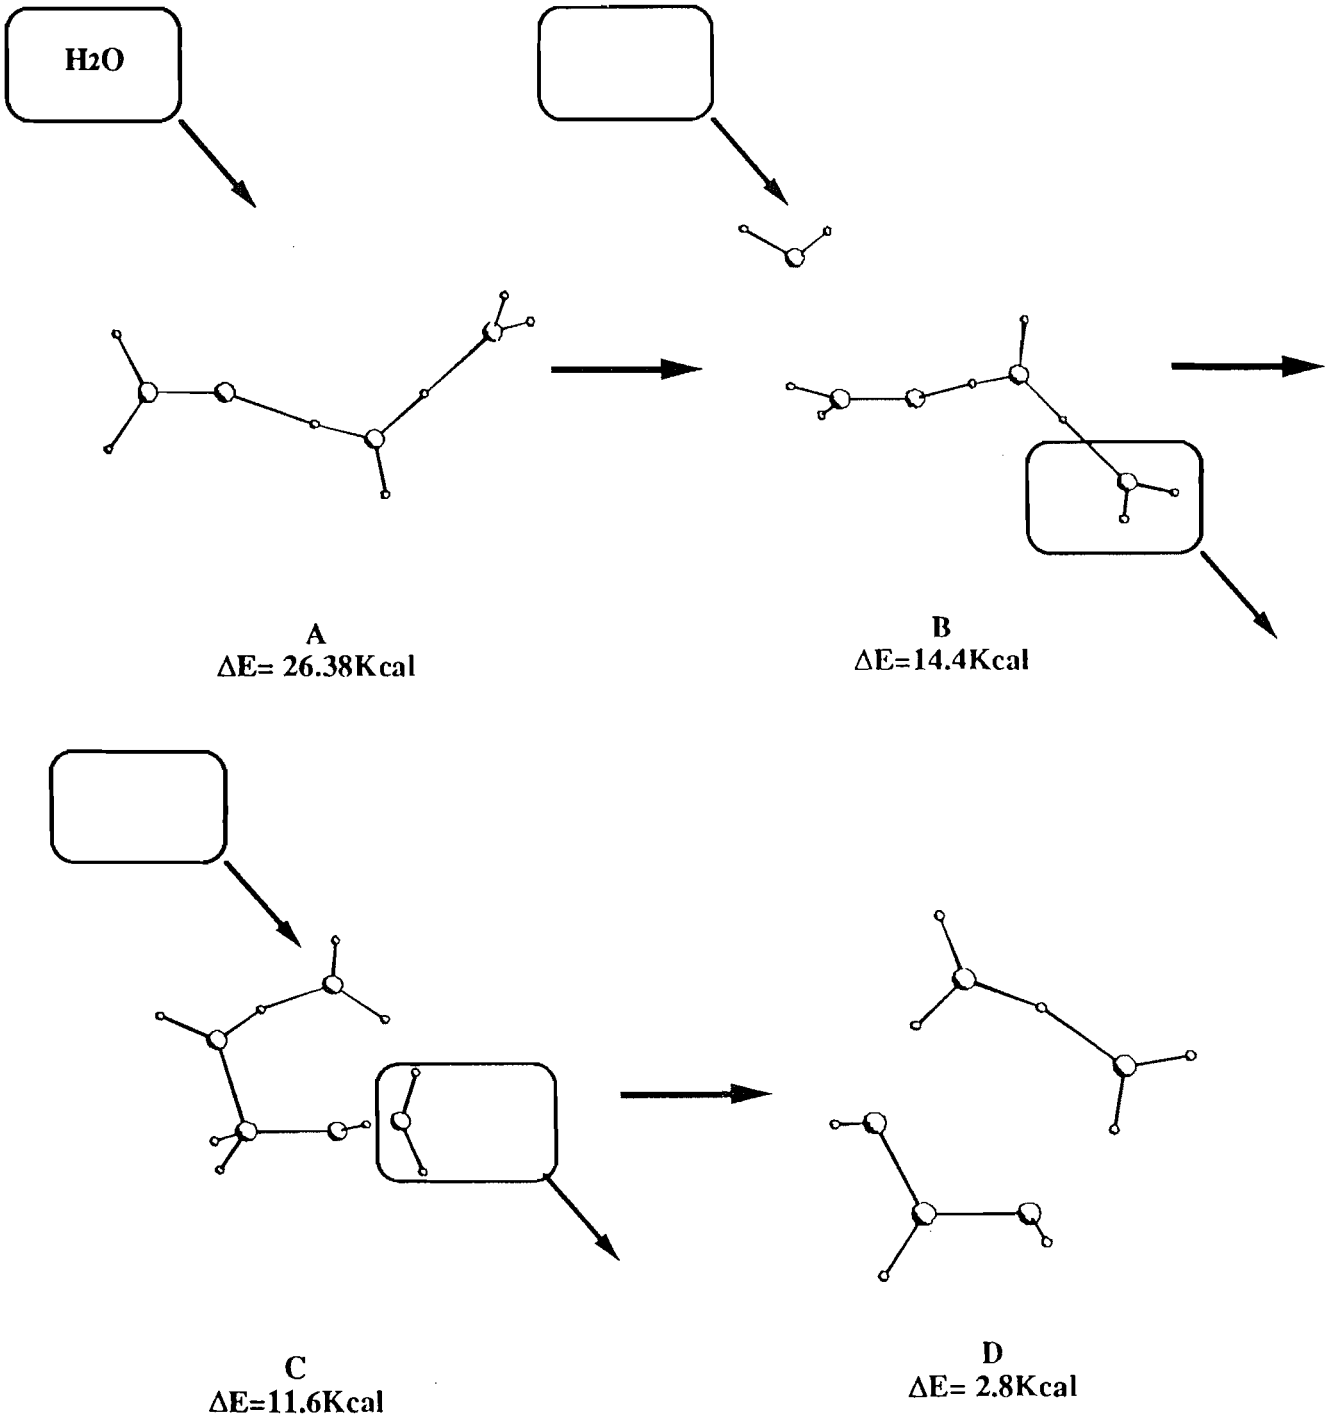

FIG. 5. Reaction energies of the hydration of formaldehyde in the presence of a proton and water molecules (the energies are given relative to the most stable structure of the potential energy hypersurface $H_2CO \cdot H^+ \cdot (H_2O)_3$).

addition of a water molecule to the reactant complex (Fig. 3*B*). The successive rearrangements of water molecules, one leaving one site while presumably another adding to another site, produce a logical sequence of low energy lying elimination/addition situations presented in Fig. 5. The relative energies are given with reference to the most stable structure belonging to the surface (Fig. 3*A*). The complete sequence refers to the acid catalysts in presence of two water molecules, i.e., $H_5O_2^+$ with a low reaction energy of 2.8 kcal. Considering the structural complementarity of $H_5O_2^+$ and methanediol, one may admit that the addition of any supplementary water molecule will not change the reaction energy nor the mechanism. It will probably change the relative energies of the intermediate species by stabilizing structures such as B through a complementary solvation process, and reduce the overall "activation" energy.

(b) From a structural viewpoint

As the water molecule enters the system, a complex is formed

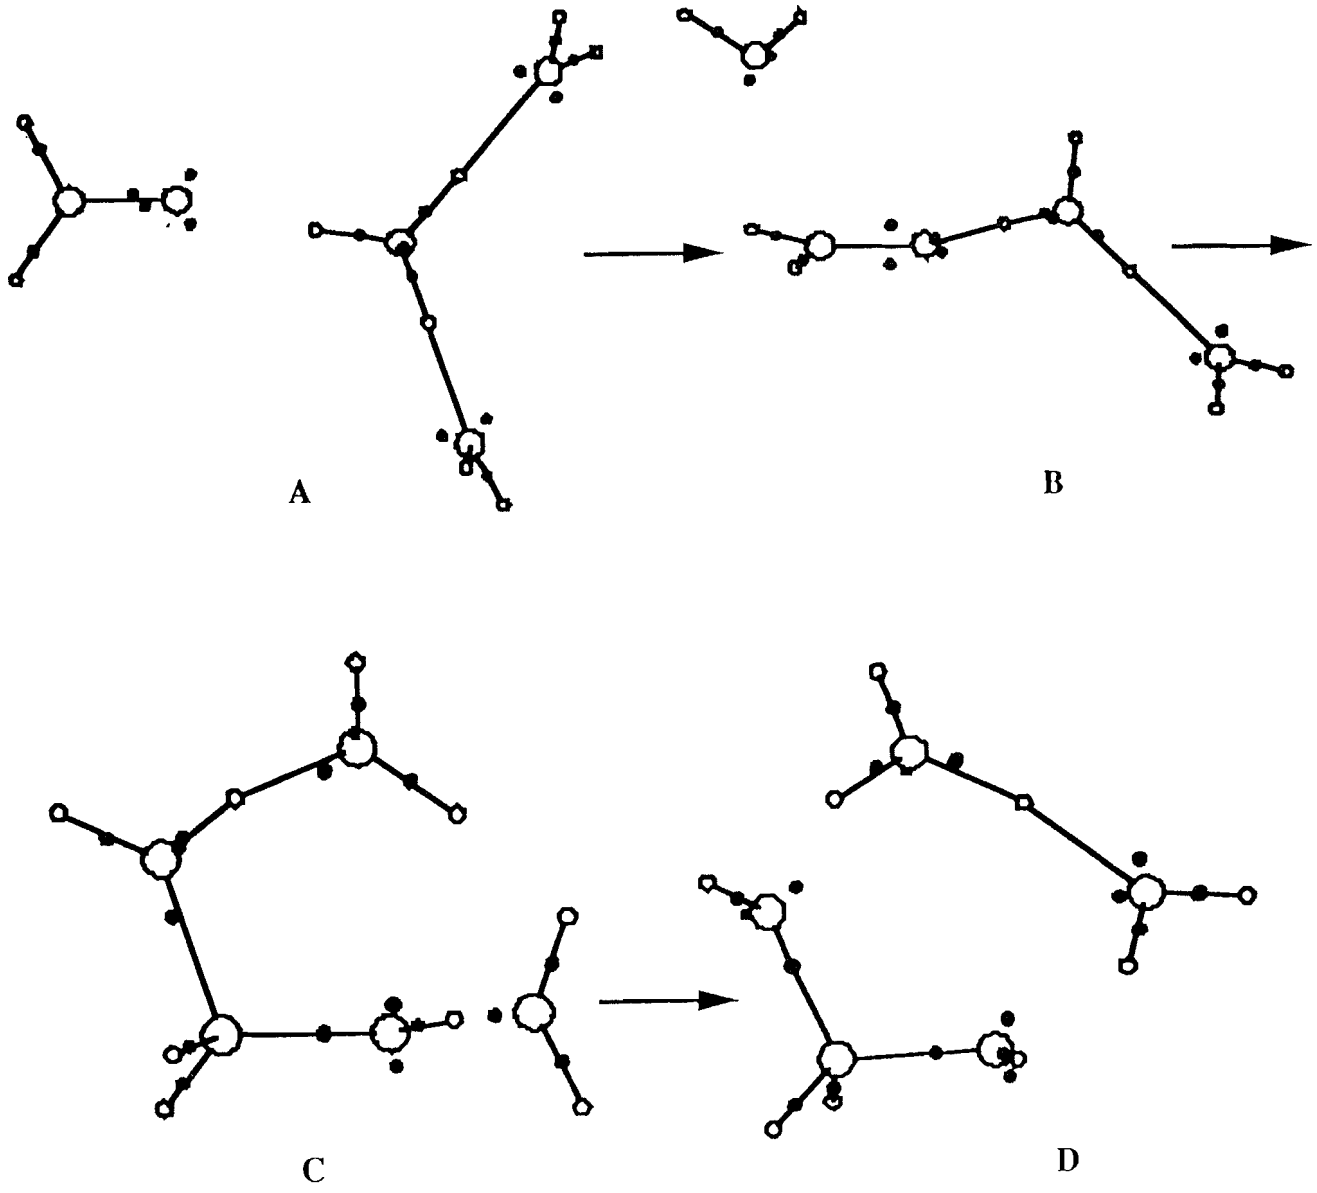
For personal use only.



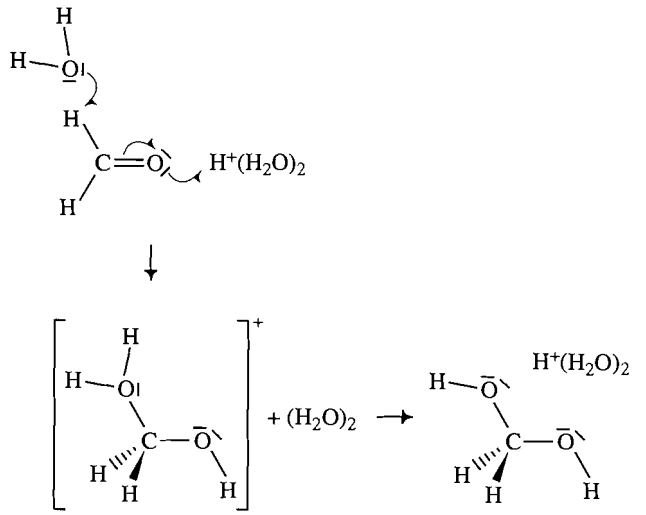


FIG. 6. Centroids of localized orbitals associated with the various structures along the reaction path of the hydration of formaldehyde in the presence of a proton.

with the initial $H_2CO \cdot H_5O_2^+$ species (Fig. 5*B*). Three steps have been determined to induce this reaction. First, the proton shifts from the $H_5O_2^+$ water entity to the carbonyl group. Meanwhile, one water molecule leaves $H_5O_2^+$ and another enters, forming a water dimer (Fig. $5B \rightarrow D$). This reaction mechanism is totally compatible with the suggestions of Eigen (11) and Bell (1, 12) who stated that the transition state for the addition of water to formaldehyde would contain one or two water molecules. In the proposed mechanism, these water molecules appear in intermediate complexes, related to the reactants and products by energetically low lying transition states.

(c) From an electronic viewpoint

The chemist is generally interested in the electronic description of a reaction mechanism. To this end, we have localized the molecular orbitals (13) obtained for the most pertinent structures lying on the hypersurface. The results of this procedure are presented in Fig. 6. The dots represent the centroids of charges giving the mean position of the electron pair associated with a localized orbital. The formation of the diol appears to follow a clear and simple electronic mechanism. Indeed, the exchanged proton coming from the water complex, lies in the formaldehyde molecular plane (Fig. 6*A*, *B*). It is captured by a lone pair of formaldehyde during the approach of a water molecule perpendicular to this molecular plane. Meanwhile, a σ C—O bond is formed and the C=O double bond rearranges. In the latter case, the π electron pair moves to the lone pair domain of the oxygen atom. Finally, a proton from the added water molecule moves into the lone pair domain of an ancillary water molecule, which then rearranges its electronic structure to a $H_5O_2^+$ complex. This mechanism may be shown schematically in the following way:

Let us point out here that this theoretical description of the mechanism is in full agreement with the conclusions obtained by Jencks and co-workers (2) from their experimental approach. Nevertheless, our method provides a better insight of the molecular elementary processes successively taking place during the reaction.

VI. Conclusions

In this paper we have analyzed the addition of water molecules to formaldehyde. This reaction mechanism was studied under the influence of a proton to model the effect of an acid catalyst. The main conclusions of this work are that: (*i*) In the presence of a single proton, no methanediol molecule is obtained. The molecule evolves to a molecule-ion complex. (*ii*) The same reaction, in the presence of a water molecule, leads to various situations, among which the complex $H_2CO \cdot H_5O_2^+$ is the most stable. Nevertheless, stable structures corresponding to the chemical formula of methanediol appear on the potential energy hypersurface. They are situated at some 8 kcal mol^{-1} higher than the most stable structure but they define a region on the hyperstructure where their interconversion can be fulfilled easily and at a fairly good rate. (*iii*) A second water molecule acts on the system in a similar way, i.e. the $H_2CO \cdot H_7O_3^+$ complex is the most stable structure but the number of diol-like situations increases. These compounds are more stable than those obtained previously, as they lie at only 2.8 kcal mol^{-1} higher than the most stable structure and inside the range of accessible conformers of $H_2CO \cdot H_7O_3^+$. In this sense, reactants and products coexist in chemical equilibrium on the hypersurface. (*iv*) This analysis leads us to propose a reaction mechanism for the acid catalyzed hydration of formaldehyde. In the first step of this mechanism, the hydrated proton aligns with a lone pair of formaldehyde. This proton is captured by the lone pair forming a covalent C—O bond, while the π electron pair shifts to become a lone pair. This rearrangement allows the concomitant addition of a water molecule on the carbon site by the formation of a second C—O covalent bond. Finally, the proton located on this oxygen moves back to the surrounding water molecules. (*v*) The preceding conclusions can be generalized to other reactions, namely those in which an alcohol molecule replaces a water molecule, leading to the formation of a hemiacetal.

Acknowledgments

This work has been made possible thanks to continuous support to our laboratory by the National Fund for Scientific Research (Belgium). The authors would like to thank Dr. Steven J. Berthel for reading and improving the English of their manuscript.

Thermodynamical detection of hydrophobic hydration of tris(2,4-pentanedionato)-cobalt(III) and tris(3,5-heptanedionato)cobalt(III) in water

YASUKI YOSHIMURA

Laboratory of Chemistry, College of Humanities and Social Sciences, Iwate University, Ueda, Morioka, 020 Japan

Received December 20, 1990

YASUKI YOSHIMURA. Can. J. Chem. **69**, 1388 (1991).

The solubilities of tris(2,4-pentanedionato)cobalt(III) and tris(3,5-heptanedionato)cobalt(III) in water, heptane, and 1,2-ethanediol were determined over the temperature range 5–50°C and from these data the thermodynamic quantities of solution at 25°C were estimated. The free energy (ΔG_t^0), enthalpy (ΔH_t^0), and entropy (ΔS_t^0) of transfer of these chelates from heptane to some solvents were calculated from the corresponding thermodynamic quantities of solution. When ΔH_t^0 and ΔS_t^0 were separately plotted against ΔG_t^0, the data of transfer from heptane to water deviated markedly from a correlation obtained for the data of transfer to the solvents other than water. This finding indicates that these chelates are subject to hydrophobic hydration in their aqueous solutions. The solubility of tris(glycinato)cobalt(III) in water was also determined over the temperature range 5–60°C and its temperature dependence of the solubility is compared with that for the cobalt(III) chelates of the β-diketones.

Key words: tris cobalt(III) chelates of β-diketones and glycine, temperature dependence of solubility, thermodynamic parameters of solution, thermodynamic parameters of transfer, hydrophobic hydration.

YASUKI YOSHIMURA. Can. J. Chem. **69**, 1388 (1991).

On a déterminé les solubilités du tris-(pentadionato-2,4)cobalt(III) et du tris(heptadionato-3,5)cobalt(III) dans l'eau, dans l'heptane et dans l'éthanediol dans un intervalle de température allant de 5 à 50°C. À partir de ces données on a évalué les paramètres thermodynamiques de solution à 25°C. On a calculé, l'énergie libre (ΔG_t^0), l'enthalpie (ΔH_t^0) et l'entropie (ΔS_t^0) de transfert de ces chélates à partir de l'heptane vers d'autres solvants, en se basant sur les paramètres thermodynamiques de solution. Les courbes de ΔH_t^0 et de ΔS_t^0 en fonction de ΔG_t^0 dévient beaucoup d'une corrélation obtenue pour les données de transfert vers des solvants autres que l'eau. Ces observations indiquent que ces chélates sont sujets à une hydratation hydrophobe dans leurs solutions aqueuses. On a également déterminé la solubilité du tris(glycinato)cobalt(III) dans l'eau dans l'intervalle de température allant de 5 à 60°C et on a comparé l'influence de la température sur la solubilité avec celle des chélates de cobalt(III) de β-dicétones.

Mots clés : chélates de tris cobalt(III) de β-dicétones, influence de la température sur la solubilité, paramètres thermodynamiques de solution, paramètres thermodynamiques de transfert, hydratation hydrophobe.

[Traduit par la rédaction]

The author has investigated through solubility measurements a dissolution behavior of tris(2,4-pentanedionato)cobalt(III) ($Co(acac)_3$) in the aqueous mixed solvents of dimethyl sulfoxide (DMSO) (1), 1,4-dioxane (D) (2), 2-methyl-2-propanol (TBA) (2), 2-butoxyethanol (BE) (3), and 2-ethoxyethanol (EE) (3). The enthalpy (ΔH_s^0) and entropy of solution (ΔS_s^0) for $Co(acac)_3$ in water estimated from temperature dependence of the solubility are negative (1) and its heat capacity of solution ($\Delta C_{p,s}^0$) is positive (2).

It has been extensively found that nonpolar nonelectrolytes dissolve in water with negative ΔH_s^0 and ΔS_s^0, and with positive $\Delta C_{p,s}^0$ (see, for example, ref. 4). This finding is explained in terms of hydrophobic hydration. Thus $Co(acac)_3$ seems to behave as a hydrophobic solute in water. For alkanes which are typically hydrophobic nonelectrolytes their hydrophobic properties increase with an increase in number of carbon atoms (5). From an analogy, the substitution of alkyl groups for two terminal methyl groups of 2,4-pentanedione (acac) in $Co(acac)_3$ is expected to increase the hydrophobic property.

The hydrophobic hydration is brought about by an effect of hydrophobic solutes on the hydrogen-bonded network structure of water and is phenomenon characteristic of aqueous solution (6–8). To make sure that metal chelates such as $Co(acac)_3$ are subject to the hydrophobic hydration, their thermodynamic quantities of solution in water need to be compared with those in some solvents other than water. This confirmation seems to provide useful information in a field such as solvent ex trac tion of metal chelates.

In this study, some alkyl-substituted β-diketones and their cobalt(III) chelates are synthesized and the solubilities of these chelates in water (W), heptane (Ht), and 1,2-ethanediol (ethylene glycol, EG) are determined over the temperature range 5–50°C. From these data the thermodynamic quantities of solution at 25°C are estimated and these quantities in W are compared with those in Ht and EG. Furthermore, in order to establish an unique feature for temperature dependence of the solubilities of these chelates in W, the solubility of tris(glycinato)cobalt(III) ($Co(gly)_3$) in W is also determined over the temperature range 5–60°C.

Experimental

Preparation of cobalt(III) chelates

3,5-Heptanedione (dipropionylmethane, DPrM), 2,6-dimethyl-3,5-heptanedione (diisopropionylmethane, DIPrM), and 2,2,6,6-tetramethyl-3,5-heptanedione (dipivaloylmethane, DPM) were synthesized according to the procedure of Adams and Hanser (9). Cobalt(III) chelates of these β-diketones were synthesized by the same method as $Co(acac)_3$ (10). The crude chelates were recrystallized from acetone solutions. *Anal.* calcd. for $Co(DPrM)_3$ ($Co(C_7H_{11}O_2)_3$): C 57.27, H 7.55; found: C 56.96, H 7.59. *Anal.* calcd. for $Co(DPM)_3$ ($Co(C_{11}H_{19}O_2)_3$): C 65.11, H 9.44; found: C 64.89, H 9.61. The melting point of the purified $Co(DPrM)_3$ was 55.7–56.1°C. As crystalline $Co(DIPrM)_3$ decomposed on standing in a silica gel desiccator, the solubility measurement of this chelate was not carried out. The purification of commercial $Co(acac)_3$ was described previously (1).

fac-Isomer of $Co(gly)_3$ was synthesized by methods reported in literatures (11, 12), recrystallized from aqueous sulphuric acid solution

(about 50% by volume), and then dried for 3 h at 160°C. *Anal.* calcd. for $Co(gly)_3$ ($Co(C_2H_4O_2N)_3$): C 25.64, H 4.30, N 14.95; found: C 25.28, H 4.45, N 15.01.

Solvent

Commercial Ht (reagent grade, Wako Chemical Industries Ltd.) was stirred with concentrated sulphuric acid for 24 h with a magnetic stirrer, washed with dilute sodium hydroxide solution and water, refluxed over calcium hydride for 2 h, and then finally distilled. EG (reagent grade, Wako Chemical Industries Ltd.) was dried over molecular sieves (type 4A) for a week and distilled three times under reduced pressure. Commercial 99.5% ethanol (E) (Wako Chemical Industries Ltd.) was dried over molecular sieves (type 4A) for a week and distilled. The water contents in the purified Ht, EG, and E, measured by Karl Fischer titration, were less than 0.01, 0.05, and 0.02% by weight, respectively.

Solubility measurement

The solubility measurement was carried out by using the same apparatus and procedure as described previously (1–3). In the procedure, an aliquot of solution saturated with each chelate was withdrawn in 5 or 10 cm^3 volumetric flask by weight and diluted to the mark with water (for the systems other than Ht) or Ht (for Ht system). The concentration (in mol dm^{-3}) of the chelate in this solution was analyzed spectrophotometrically and the solubility in mol kg^{-1} (S_m) was obtained by calculating the mole numbers of the chelate in the aliquot of the saturated solution from the concentration. In the spectrophotometric determination, the absorbance was measured at the following wavelengths in the respective systems: for $Co(acac)_3$, 323 nm (W, EG, and E systems), 322 nm (Ht system); for $Co(DPrM)_3$, 323.5 nm (W and EG systems), 594 nm (Ht system); for $Co(DPM)_3$, 588 nm (Ht system); for *fac*-$Co(gly)_3$, 217 nm (W system). For all chelates, calibration curves in both aqueous and Ht solutions were straight in the concentration regions tested and the Beer's law equations were obtained by using the least-squares method. Since the absorbance in aqueous solutions was not affected by adding small amount of EG or E, the calibration curves in aqueous solutions were used for the solubility measurement in the EG and E systems.

In the preparation of the calibration curve for *fac*-$Co(gly)_3$, stock solution of the chelate was prepared by dissolving weighed crystal in 1 cm^3 of about 20% solution (by volume) of perchloric acid because of low solubility in W. Since the resulting calibration curve referred to the solutions containing 0.5 cm^3 of 20% perchloric acid per 5 cm^3, in the procedure of solubility measurement also the working solution to determine spectrophotometrically the concentration of the chelate was made up by adding 0.5 cm^3 of 20% perchloric acid solution to the aliquot of the saturated solution withdrawn in 5 cm^3 volumetric flask.

Determination of partition coefficient

The partition coefficient (P) of $Co(DPrM)_3$ between W and Ht was determined by the same procedure as used for the determination of P for $Co(acac)_3$ between W and dodecane (3). The equilibrium concentrations of $Co(DPrM)_3$ in both the phases were determined spectrophotometrically. The value of P was calculated as the ratio of the equilibrium concentration in aqueous phase to that in Ht phase.

Results

Solubilities of cobalt(III) chelates

The S_m values of $Co(acac)_3$ in Ht, EG, and E, of $Co(DPrM)_3$ in W, Ht, and EG, and of $Co(DPM)_3$ in Ht are tabulated in Tables 1, 2, and 3, respectively. The solubility measurement was repeated at least three times at each temperature. The errors given in these tables denote deviations at a 95% confidence level and are less than 2% in most cases.

In the previous work (1), it has been found that the solubility values of $Co(acac)_3$ in W obtained from absorbances at two different wavelengths agree with each other, and that $Co(acac)_3$ is not decomposed in W under the condition adopted in the solubility measurement. In the present systems also, the solubility data at 25°C were reproducible within the experimental errors when the solutions at the end of experiment at the highest temperature were allowed to attain equilibrium at 25°C. This result shows that these chelates are not decomposed in the course of the equilibration as well.

The solubility of $Co(DPM)_3$ in W was examined by extracting the chelate in saturated aqueous solution with dodecane. But the reproducibility of this method was poor because of its extremely low solubility (S_m was roughly $\sim 10^{-7}$ mol kg^{-1} at 25°C). When EG was stirred with $Co(DPM)_3$ for 72 h at 50°C, no absorption due to $Co(DPM)_3$ was detected in the EG phase. Accordingly, the solubility of $Co(DPM)_3$ in EG seems to be lower than that in W.

The solubilities of $Co(acac)_3$ and $Co(DPrM)_3$ in W decreased with an increase in temperature. This temperature dependence of solubility markedly differs from that in solvents such as Ht, EG, E, DMSO, D, TBA, BE, and EE. It is interesting to examine whether the above temperature dependence

§Solubility value obtained by reequilibrating at 25°C the solution saturated at 60°C.

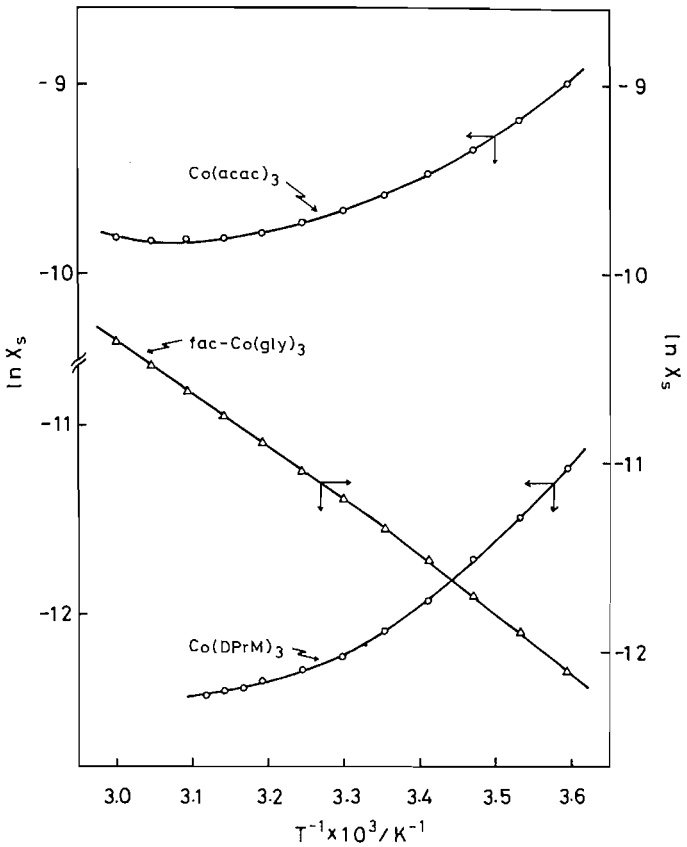

FIG. 1. Solubility curves of $Co(acac)_3$, $Co(DPrM)_3$, and *fac*-$Co(gly)_3$ in W depicted by plotting ln X_s against $1/T$.

of solubility observed in W is characteristic of $Co(acac)_3$ and $Co(DPrM)_3$ or not. Thus, the solubility of *fac*-$Co(gly)_3$ in W was also determined.[1]

The solubility of *fac*-$Co(gly)_3$ in W is listed in Table 4. At the temperatures above 40°C, the solubility values were obtained from absorbances not only at 217 nm but at 520 nm. These solubility values agreed with each other within the experimental errors. Furthermore, when the solution saturated at 60°C was re-equilibrated at 25°C, the solubility data at 25°C was reproducible (see Table 4). These results confirm that *fac*-$Co(gly)_3$ is not decomposed under the experimental condition.

The S_m values were converted to solubility in mole fraction (X_s) and ln X_s was plotted against $1/T$. These solubility curves for $Co(acac)_3$, $Co(DPrM)_3$, and *fac*-$Co(gly)_3$ in W are shown in Fig. 1. Figure 1 suggests that the temperature dependence of solubility found for $Co(acac)_3$ and $Co(DPrM)_3$ in W results from a peculiar interaction of these chelates with water.

Activity coefficient of cobalt(III) chelates in saturated solutions

Since infinite dilution is selected as the standard state for solute, it is required to examine whether the saturated solutions examined in this work may be regarded as ideal dilute solutions or not. In the previous work (3), it has been demonstrated that the P values of $Co(acac)_3$ between W or

[1]The solubility of *mer*-$Co(gly)_3$ in W was also determined and it was found that when the values for ln S_m were plotted against $1/T$, the solubility curve broke suddenly at around 35–45°C. An explanation of this anomalous behavior is investigated and will be reported elsewhere.

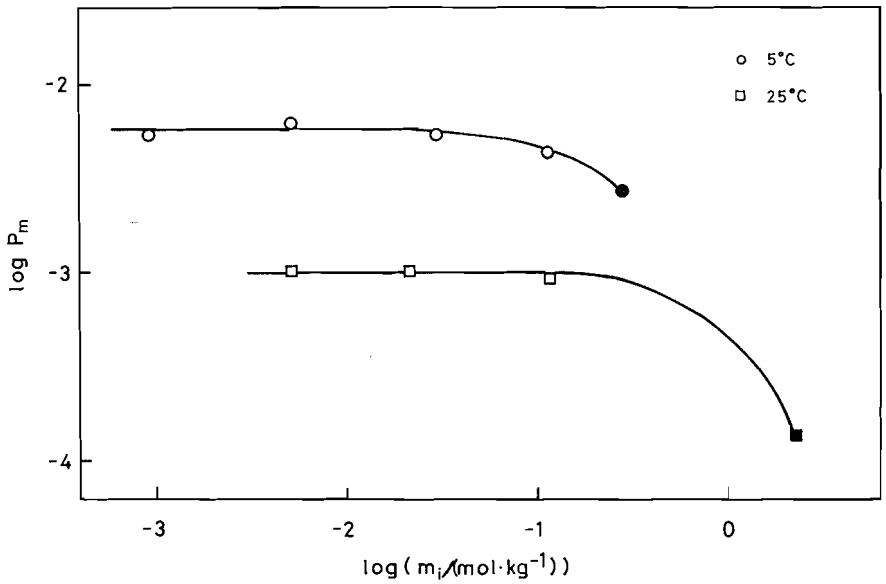

FIG. 2. Dependence of the partition coefficient based on molality (P_m) of $Co(DPrM)_3$ between W and Ht on the initial concentration of $Co(DPrM)_3$ in Ht phase (m_i). Full symbols denote the ratio of the solubility in molality of $Co(DPrM)_3$ in W to that in Ht.

DMSO and dodecane are in accord with the ratios of solubilities in the respective solvents and that the activity coefficients of $Co(acac)_3$ in these saturated solutions may be regarded as unity. The solubilities of $Co(acac)_3$ in EG or Ht, of $Co(DPrM)_3$ in W, and of *fac*-$Co(gly)_3$ in W are similar in magnitude to the solubility of $Co(acac)_3$ in W (1). The solubilities of $Co(acac)_3$ in E and of $Co(DPrM)_3$ in EG are similar in magnitude to the solubility of $Co(acac)_3$ in DMSO (1). Since it has been demonstrated that the activity coefficient of $Co(acac)_3$ in its saturated aqueous or DMSO solution is unity, it seems to be reasonable that the activity coefficients of $Co(acac)_3$ in EG, Ht, or E, of $Co(DPrM)_3$ in W or EG, and of *fac*-$Co(gly)_3$ in W may be regarded as unity.

Figure 2 shows a dependence of the partition coefficient based on mol kg^{-1} (P_m) for $Co(DPrM)_3$ between W and Ht on its initial concentration in Ht phase (m_i). The P_m values were nearly independent of m_i over the values of 9.2×10^{-4} to 0.115 mol kg^{-1} at both 5 and 25°C. But the ratio of the solubility in W to that in Ht was lower than P_m at both temperatures. This result indicates that the activity coefficient must be taken into account for the saturated solution of $Co(DPrM)_3$ in Ht because the activity coefficient of $Co(DPrM)_3$ in the saturated aqueous solution is regarded as unity.

In order to estimate the activity coefficient of $Co(DPrM)_3$ in Ht (γ(Ht)), P_m was determined four times at each temperature where the solubility in Ht was measured (m_i was 9.0×10^{-3} mol kg^{-1}) and converted to the partition coefficient based on mole fraction (P_x). The γ(Ht) value was calculated by

$$[1] \quad \gamma(\mathrm{Ht}) = X_s(\mathrm{W})/(P_x X_s(\mathrm{Ht}))$$

where X_s(W) and X_s(Ht) denote the solubility in W and Ht, respectively. In Table 5, the values for P_x, $X_s(W)/X_s(Ht)$, and γ(Ht) of $Co(DPrM)_3$ are listed.

The solubility of $Co(DPM)_3$ in Ht is also fairly high and from an analogy to the result shown in Fig. 2 it may be inferred that in this case also the activity correction is required. Unfortunately, the above procedure to estimate γ(Ht) could not be applied because of extremely low solubility of $Co(DPM)_3$ in W.

TABLE 5. Partition coefficient (P_x) of $Co(DPrM)_3$ between W and Ht and activity coefficient (γ(Ht)) of $Co(DPrM)_3$ in saturated Ht solution

T/°C	$P_x \times 10^4$*	$(X_s(W)/X_s(Ht)) \times 10^4$†	γ(Ht)‡

*P_x is defined as the ratio of equilibrium concentration of $Co(DPrM)_3$ (on mole fraction scale) in aqueous phase to one in Ht phase and mean of the values measured four times at the $Co(DPrM)_3$ concentration of 9.0×10^{-3} mol kg^{-1} is listed. Errors denote 95% confidence levels.

†Ratio of solubility in mole fraction in W to that in Ht of $Co(DPrM)_3$.

‡Calculated from [1].

Thermodynamic quantities of solution for cobalt(III) chelates

The values for ΔH_s^0, ΔS_s^0, $\Delta C_{p,s}^0$, and the free energy of solution (ΔG_s^0) were estimated by using Clarke and Glew procedure (13, 14). In the estimation, the values of $R \ln X_s$ (R = 8.3144 J K^{-1} mol^{-1}) were fitted, except for the dissolution of $Co(DPrM)_3$ in Ht where the $R \ln (\gamma X_s)$ values were fitted. Other details of the estimation have been reported elsewhere (3). The thermodynamic parameters thus estimated are listed in Table 6, where the values for the same process of $Co(acac)_3$ estimated from the solubility data in W, DMSO, D, BE, EE, and TBA reported previously (1–3) are also contained.

Discussion

The solubilities of the β-diketone cobalt(III) chelates studied in this work increase in the following sequence: $Co(DPM)_3 \ll Co(DPrM)_3 < Co(acac)_3$ in W; $Co(acac)_3 < Co(DPM)_3 < Co(DPrM)_3$ in Ht; $Co(DPM)_3 \ll Co(acac)_3 < Co(DPrM)_3$ in

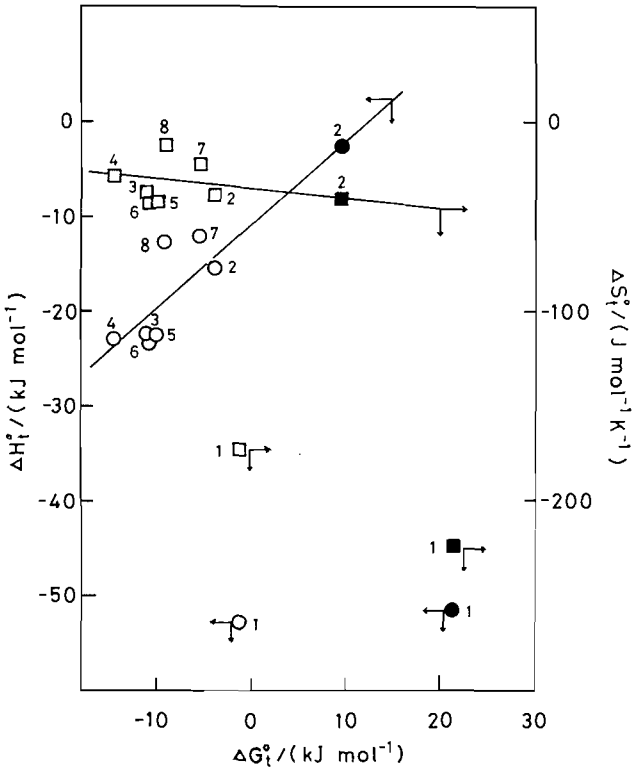

FIG. 3. Correlation between the enthalpy (ΔH_t^0) or entropy of transfer (ΔS_t^0) and the free energy of transfer (ΔG_t^0) for the transfer process of $Co(acac)_3$ and $Co(DPrM)_3$ from Ht to the following solvents: 1, W; 2, EG; 3, DMSO; 4, D; 5, BE; 6, EE; 7, TBA; 8, E. Circles are the plot of ΔH_t^0 vs. ΔG_t^0 and squares are the plot of ΔS_t^0 vs. ΔG_t^0. Full symbols denote the data for $Co(DPrM)_3$ and open symbols denote the data for $Co(acac)_3$.

EG. The solubilities of the corresponding copper(II) chelates in W also increase in the same order as the cobalt(III) chelates, whereas the solubilities in Ht increase in order $Cu(acac)_2 < Cu(DPrM)_2 < Cu(DPM)_2$ (15). On the basis of the theoretical prediction that in a homologous series, a solid having higher melting point is less soluble in nonpolar solvent such as Ht than one having lower melting point at a given temperature (16), the solubility sequence for $Co(DPM)_3$ and $Co(DPrM)_3$ in Ht can be explained by the low melting point of $Co(DPrM)_3$. The solubility sequence of the copper(II) chelates in Ht is also consistent with the above prediction (15).

The thermodynamic parameters of solution for $Co(acac)_3$ and $Co(DPrM)_3$ in W are peculiar compared to those in the other solvents in the following aspects: (*i*) ΔH_s^0 and ΔS_s^0 in W are negative, while those in the other solvents are positive; (*ii*) $\Delta C_{p,s}^0$ in W is large positive value, while that in the other solvents is near to 0. In order to make clear a difference in solvation of these chelates, a comparison of the thermodynamic parameters of transfer of the chelates from a solvent to the other solvents is more favorable.

Thus, the free energy (ΔG_t^0), enthalpy (ΔH_t^0), and entropy of transfer (ΔS_t^0) of $Co(acac)_3$ and $Co(DPrM)_3$ from Ht to the other solvents at 25°C were calculated by substracting the corresponding parameters of solution in Ht from those in the other solvents. For the transfer of $Co(DPrM)_3$ from Ht to W, the values thus obtained (ΔG_t^0; ΔH_t^0, 21.2; −51.6 kJ mol^{-1}; ΔS_t^0, −244 J K^{-1} mol^{-1}) agreed nearly with the values obtained from the plot of ln P_x vs. $1/T$ (ΔG_t^0; ΔH_t^0, 21.2; −55.7 kJ mol^{-1}; ΔS_t^0, −258 J K^{-1} mol^{-1}).

In Fig. 3, the values for both ΔH_t^0 and ΔS_t^0 are plotted against ΔG_t^0. Both ΔH_t^0 and ΔS_t^0 are negative in all cases. This result implies that the solvation of $Co(acac)_3$ or $Co(DPrM)_3$ in W, EG, DMSO, D, BE, EE, TBA, and E is stronger than the solvation in Ht. This conclusion is reasonable. For the transfer process to the solvents other than W, a rough linear correlation was found between ΔH_t^0 or ΔS_t^0 and ΔG_t^0. While ΔG_t^0 decreases with a decrease in ΔH_t^0 and with an increase in ΔS_t^0, the decrease in ΔG_t^0 is governed by decreasing ΔH_t^0 rather than by increasing ΔS_t^0 except for TBA and E. The data for the transfer to W deviate markedly from the correlation lines. This result shows definitely that some solvation characteristic of W, that is, hydrophobic hydration occurs.

If the above deviation for the transfer process from Ht to W may be attributed to the hydrophobic hydration, larger devia-

For personal use only.

tion for $Co(DPrM)_3$ indicates that the hydrophobic hydration of $Co(DPrM)_3$ is stronger than that of $Co(acac)_3$. This conclusion is reasonable because hydrophobic parts of $Co(DPrM)_3$ are larger than those of $Co(acac)_3$.

$Co(acac)_3$ in W gives the solubility curve with a minimum at 50–55°C (see Fig. 1). $Cr(acac)_3$ also yields similar solubility curve in W (17). The solubility curve of $Co(DPrM)_3$ in W is also essentially identical. On the other hand, the solubility curve of *fac*-$Co(gly)_3$ in W is practically straight.

fac-$Co(gly)_3$ seems to be essentially hydrophilic. It has been found that the crystal of *fac*-$Cr(gly)_3 \cdot H_2O$ has a three-dimensional network of intermolecular hydrogen bonds between the chelate molecules, and that the water molecule in the crystal also serves to link two molecules of the chelate (18). These facts suggest that the dissolution of *fac*-$Co(gly)_3$ in W results from hydrophilic hydration composed of the hydrogen bond between the carboxylic and/or amino groups of the chelate and water molecules. Yamamoto and Nishi have also investigated a behavior of the hydration for a series of alkyl carboxylic acids in aqueous solutions and suggested that formic acid, which has no methyl group, undergoes the hydrophilic hydration through the hydrogen bond between the carboxylic group and water molecules (19).

The thermodynamic parameters of solution in W for *fac*-$Co(gly)_3$ listed in Table 6 also do not show the pronounced trend for the hydrophobic hydration, that is, large negative ΔH_s^0 and ΔS_s^0, and large positive $\Delta C_{p,s}^0$. The negative ΔS_s^0 found for *fac*-$Co(gly)_3$ is interesting in connection with the three-dimensional network of crystalline *fac*-$Cr(gly)_3 \cdot H_2O$. But an interpretation of this finding requires further examination.

The hydrophobic hydration has been interpreted as the phenomenon that a hydrophobic solute brings about a lowering of both enthalpy and entropy by increasing order of the network structure of water around the solute (4). Since the order of the water structure decreases with an increase in temperature (see, for example, ref. 20), the effect of the hydrophobic hydration may also be expected to diminish with increasing temperature (21). Thus, the hydrophobic effect seems to disappear at sufficiently high temperatures. Shinoda has pointed out that the disappearance of the hydrophobic hydration brings about a straightening of solubility curve at sufficiently high temperatures (22). The substitution of alkyl group for a hydrogen atom of the methylene group in glycine is expected to increase the hydrophobic property. In view of the finding that *fac*-$Co(gly)_3$ in W gives the straight solubility curve, an examination of the solubility in W for cobalt(III) chelates of the alkyl substituted α-amino acids is of interest in connection with the above Shinoda's viewpoint. Such examination is carried out and will be reported elsewhere.

The thermodynamics of the vaporization of liquid indium(I) bromide by modified entrainment

PETER J. GARDNER AND STEVE R. PRESTON

Department of Chemistry, Royal Holloway and Bedford New College, University of London, Egham Hill, Egham, Surrey, TW20 0EX United Kingdom

Received January 28, 1991

PETER J. GARDNER and STEVE R. PRESTON. Can. J. Chem. **69**, 1394 (1991).

The transport of gaseous In(I)Br in an argon carrier gas was studied in the temperature range 680 to 935 K by the modified entrainment method. Combination of the entrainment results with a literature equation for the total vapour pressure above the liquid gave the following expressions for the temperature dependence of the vapour pressures of the monomer (InBr) and dimer (In_2Br_2) respectively: $\ln (p_1^0/p^0) = -(13457 \pm 59)/T + (24.240 \pm 0.077) - (1.306 \pm 0.014) \ln T - (0.001164 \pm 0.000021)T$, (680–950 K) and $\ln (p_2^0/p^0) = -(6490 \pm 1650)/T + (2.9 \pm 2.2)$, (680–810 K); $p^0 = 10^5$ Pa. The dimer concentration is *ca.* 14% at 680 K and decreases to *ca.* 4% at 810 K.

Key words: high temperature thermodynamics, indium(I) bromide, vaporization thermodynamics.

PETER J. GARDNER et STEVE R. PRESTON. Can. J. Chem. **69**, 1394 (1991).

On a étudié le transport du bromure d'indium gazeux In(I) Br par l'argon, à des températures allant de 680 à 935 K en utilisant la méthode d'entrainement modifié. En combinant les résultats obtenus par entrainement avec une équation relative à la pression de vapeur totale au-dessus du liquide répertoriée dans la littérature, on peut représenter l'effet de la température sur les pressions de vapeur du monomère (InBr) et du dimère (In_2Br_2) respectivement par les expressions suivantes : $\ln (p^0/p^0) = -(13457 \pm 59)/T + (24{,}240 \pm 0{,}077) - (1{,}306 \pm 0{,}014) \ln T - (0{,}001164 \pm 0{,}000021)T$, (680–950 K) et $\ln (p_2^0/p^0) = -(6490 \pm 1650)/T + (2{,}9 \pm 2{,}2)$, (680–810 K); $p^0 = 10^5$ Pa. La concentration du dimère est approximativement de 14% à 680 K et elle diminue à 4% environ à 810 K.

Mots clés : thermodynamique des hautes températures, bromure d'indium(I), thermodynamique des vaporisations.

Introduction

Metal halides, for example, indium(I) bromide, have been used since the early 1960s in the development of the current generation of "metal halide" mercury discharge lamps (1). The effect of the inclusion of the metal halide within the lamp envelope is to improve significantly the spectral distribution and the colour rendition of the lamp. To simulate the spectral distribution it is necessary to know the thermodynamic and transport properties of the included halides over a wide range of temperature. A recent examination (2) of the vaporization of indium(I) bromide gave an equation for the total vapour pressure above the liquid between 570 and 950 K.

This paper describes a study of indium(I) bromide vaporization by a complementary technique, the modified entrainment method, and in combination with the results above, yields separate vapour pressure equations for the monomer and dimer species.

Experimental

Materials

Indium(I) bromide, a bright orange crystalline material, was prepared by reaction of high purity samples of indium metal and bromine; it was part of the same batch used in the quasi-static vapour pressure manometry study (2) and its synthesis has been described (2) in detail. Indium analyses by EDTA titration were 58.98 and 58.52 mass% and bromine analysis by potentiometric titration of the hydrolysate using a reversible silver: silver bromide electrode gave 41.0 mass percent (for InBr, In = 58.96%; Br = 41.04%).

Argon was purified by passage through a commercial rare gas purifer (model RGP-4, B.O.C. Ltd.) which removes O_2 and N_2 (titanium getter at 700°C), H_2, hydrocarbons, and CO (CuO at 450°C), CO_2 and H_2O (molecular sieves).

Apparatus

The modified entrainment apparatus and recent improvements to it have been described elsewhere (3–6). Briefly, the sample is contained in a spherical silica capsule suspended from one arm of a recording microbalance (Cahn R100). The opening of the capsule is in the form of a vertical capillary (*ca.* 20 mm long × 1 mm i.d.) that is inset into the capsule by approximately 5 mm. Argon gas flows downwards (90 cm^3 (stp) min^{-1}) over the end of the capillary, flushing away emergent gasses; the argon flow rate was controlled by a mass flow controller. The capsule was suspended in a silica furnace tube at the centre of a temperature plateau of a vertically mounted tube furnace (Trans Temp Inc.). Temperature measurement (±1 K) was via a calibrated chromel: alumel thermocouple mounted axially just below the capsule. The experimental parameter is the rate of mass loss ($\dot{w}$) at a preset temperature and which varied in this work from $\approx 5.1 \times 10^{-11}$ kg s^{-1} (680 K) to $\approx 1.1 \times 10^{-8}$ kg s^{-1} (935 K). The capillary length was determined by a travelling microscope and the mean capillary radius was obtained by filling the capillary with mercury and weighing; length (l) = 1.8815 ± 0.0019 cm, radius (r) = 0.05301 ± 0.00062 cm giving a diffusive resistance ($l/\pi r^2$) of 213.1 ± 2.5 cm^{-1}.

Results and discussion

A mass spectrometric study (2, 7) of the vapour above liquid In(I)Br at 500 K indicates the presence of both monomer and dimer species with the monomer predominant. No higher states of aggregation were detected. Consequently, our results were interpreted assuming the following equilibria

[1] $\mathrm{InBr(l)} \rightleftharpoons \mathrm{InBr(g)} \qquad \Delta H_1, \Delta S_1$

[2] $\mathrm{2InBr(g)} \rightleftharpoons \mathrm{In_2Br_2(g)} \qquad \Delta H_2, \Delta S_2$

If the ratio of the dimer to monomer flux in the capillary is β, then the partial pressures of the monomer (p_1^0) and the dimer (p_2^0) may be written as

$$[3] \quad p_1^0 = \frac{P}{(1+\beta)}\left(1 - \exp\left(\frac{-\dot{w}RTl(1+\beta)}{D_1AM_1P(1+2\beta)}\right)\right)$$

$$[4] \quad p_2^0 = \frac{P\beta}{(1+\beta)}\left(1 - \exp\left(\frac{-\dot{w}RTl(1+\beta)}{D_2AM_1P(1+2\beta)}\right)\right)$$

In these equations, P is the operating pressure (≈9 mm Hg

TABLE 1. Some typical values from the simultaneous soluton of eqs. [3] to [5]

T/K	p_1^0/Pa	p_2^0/Pa	β
703	1400	175	0.091
769	5730	557	0.073
790	8980	426	0.036

above atmospheric pressure), $\dot{w}$ is the rate of mass loss at temperature (T), l/A is the diffusive resistance, and M_1 is the monomer molecular mass. Transport occurs in a three component system (InBr, In_2Br_2, Ar) so D_i are multicomponent diffusion coefficients of i into the mixture. An outline of the derivation of eqs. [3] and [4] and the estimation of D_i are described in an Appendix. Using results from the quasi-static vapour pressure manometry study (2), an equation for the total pressure (p_T) of dimer and monomer may be written

$$[5] \quad p_T = p_1^0 + p_2^0$$

Given reliable estimates of D_i (see Appendix), eqs. [3]–[5] contain three unknowns, β, p_1^0, and p_2^0; an analytic solution is not feasible so the expressions were solved numerically with an initial guess of $0 < \beta < 10$. The analytical form of the minimized function was explored at different temperatures to establish that only one root existed in this range. Some typical values are collected in Table 1.

The algorithm failed for input data above ≈830 K in that negative roots for β (and hence p_2^0) were obtained. If the diffusion coefficients were exact and the experimental input was free from random error then β should tend asymptotically to zero at high temperatures. Given small errors in D_i and scatter in $\dot{w}$, catstrophic failure occurs for $T > 830$ K. To extract some information from the high temperature data points we note that eqs. [3]–[5] reduce to [6] as $\beta \rightarrow 0$ and $p_1^0 \rightarrow p_T$.

$$[6] \quad p_T = P\left(1 - \exp\left(\frac{-\dot{w}RTl}{\mathfrak{D}_1 A M_1 P}\right)\right)$$

Transport now occurs in a two component system (Ar, InBr) and $\mathfrak{D}_1$ is the binary diffusion coefficient of InBr in Ar. This diffusion coefficient was extracted by inversion of eq. [6] and checked against the estimated values given in the Appendix; agreement to within ≈5% was noted.

Of the 70 data points ($\dot{w}$, T) recorded only 30 gave a positive root for β and realistic values for p_1^0 and p_2^0. The results for p_2^0 were linearly regressed to the form ln (p_2^0/p^0) vs. $1/T$ to yield the following vapour pressure equation ($p^0 = 10^5$ Pa)

$$[7] \quad \ln\left(\frac{p_2^0}{p^0}\right) = \frac{-(6490 \pm 1650)}{T} + (2.9 \pm 2.2)$$

The equilibrium to which this equation applies is

$$[8] \quad 2InBr(l) \rightleftharpoons In_2Br_2(g) \qquad \Delta H_8, \Delta S_8$$

and the valid temperature range for eq. [7] is 680–810 K. The uncertainty intervals (± standard deviation) are large because p_2^0 is obtained as a difference between two large pressures of similar magnitude, p_T and p_1^0.

The treatment of the results for p_1^0 was different in that an expression for $\Delta C_p(l \rightarrow g)$ was included in the regression. The heat capacity for lnBr(l) has been reported (8) in the form $C_p = a + bT$ over the range 580–700 K. It was assumed valid over our experimental temperature range and combined with a corresponding expression for C_p(g) obtained by the usual statistical thermodynamic procedures using molecular parameters from Huber and Herzberg (9). From 650 to 950 K,

TABLE 2. Enthalpy and entropy changes at 815 K for reactions [1], [2], and [8]

Reaction	ΔH kJ mol^{-1}	ΔS J K^{-1} mol^{-1}
[1] InBr(l) ⇌ In Br(g)	96.8±0.2	102.2±0.3
[2] 2InBr(g) ⇌ In_2Br_2(g)	−140±14	−180±18
[8] 2InBr(l) ⇌ In_2Br_2(g)	54±14	24±18

$$[9] \quad C_p\,(InBr,l)/J\,K^{-1}\,mol^{-1} = (47.93 \pm 0.12) + (0.01964 \pm 0.00018)T$$

$$[10] \quad C_p\,(InBr,g)/J\,K^{-1}\,mol^{-1} = (37.07 \pm 0.02) + (0.00028 \pm 0.00002)T$$

$$[11] \quad \Delta C_p/\,J\,K^{-1}\,mol^{-1} = (-10.86 \pm 0.12) - (0.01936 \pm 0.00018)T$$

With ΔC_p in the form $A + BT$ (as in eq. [11]), regression of $[R \ln (p_1^0/p^0) + A \ln T + 0.5BT]$ vs. $1/T$ gave

$$[12] \quad \ln\left(\frac{p_1^0}{p^0}\right) = \frac{-(13457 \pm 59)}{T} - (1.306 \pm 0.014)\ln T - (0.001164 \pm 0.000021)T + (24.240 \pm 0.077)$$

Included in this regression are 11 high temperature points from ref. 2 from 839 to 950; this is the temperature range where the dimer concentration is vanishingly small so $p_1 \approx p_T$. The valid temperature range for eq. [12] is now 680–950 K. A simpler two-parameter equivalent of equation [12] is

$$[13] \quad \ln\left(\frac{p_1^0}{p^0}\right) = \frac{-(11641 \pm 31)}{T} + (12.29 \pm 0.04)$$

Uncertainty intervals are ±one standard deviation of the regression coefficients for eqs. [7] to [13]. The principal uncertainty in p_2^0 arises from the random error given by the standard deviations of the regression coefficients in eq. [7]. Other contributing errors, from the uncertainty in diffusive resistance (2%) and from the estimation of diffusion coefficients (5%) are trivial. For p_1^0, however, these minor uncertainties contribute significantly to the overall error. The error in the partial pressures arising from random error in the regression coefficients A and B in an equation of the form $\ln p = A - BT$ was evaluated from eq. [14] (10).

$$[14] \quad \sigma_p = [(p'_B)^2\sigma^2_B + (p'_A)^2\sigma^2_A + 2p'_Bp'_A\sigma_A\sigma_B\rho(A,B)]^{1/2}$$

In eq. [14], p'_x are first derivatives of p with respect to X, σ_x are standard deviations of the regression coefficients and $\rho(A,B)$ is the cross correlation coefficient for A and B, which is effectively $\rho(\Delta S_v, \Delta H_v)$. This was estimated as 0.88 from the correlation between ΔS_v and ΔH_v of the twelve group I halides (MX; M = Na, K, Rb, Cs; X = Cl, Br, I) obtained from Topor's results (11). The variation of p_1^0 and p_2^0 with temperature and with appropriate uncertainty intervals is shown in Fig. 1.

The thermodynamic constants for eqs. [1], [2], and [8] are connected via $\Delta H_2 = \Delta H_8 - 2\Delta H_1$ and values are collected in Table 2. The value for the dimerization enthalpy (ΔH_2) fits satisfactorily with the trend in ΔH_2 vs. molecular mass for other (12, 13) monovalent bromide dimers, M_2Br_2 (−228 (M = Li),

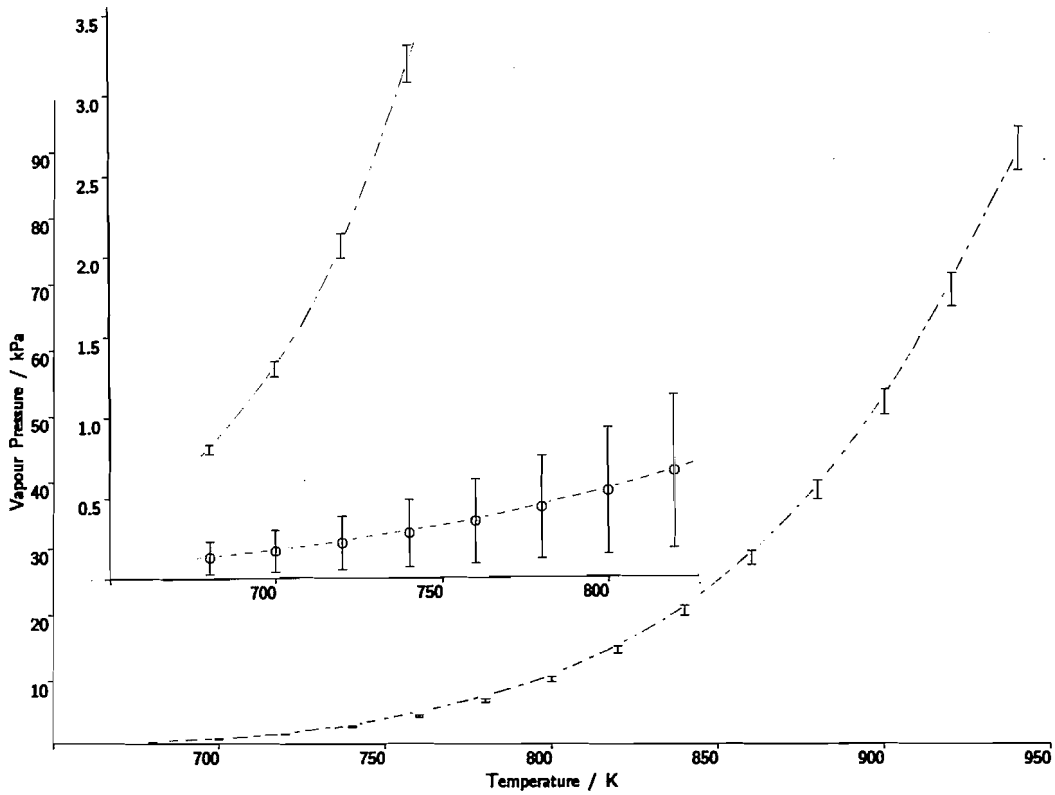

FIG. 1. The variation of the partial pressure of the indium bromide monomer (----) and dimer (○, – – – –) with temperature. Uncertainty bars indicate the probable error (50% c.i., from eq. [14]).

−200 (M = Na), −182 (M = K), and −127 (M = Cs) kJ mol^{-1}).

Appendix

Flux equations and partial pressures

The partial pressure of the ith species at the bottom of the capillary (p_i^0) is related to the pressure at the open end of the capillary (p_i^l), the total pressure (P), the flux of the ith species (j_i) and the total flux (J) by eqs. [A1] and [A2] (14)

$$[A1] \quad \frac{p_i^0}{P} = \frac{j_i}{J} - \left[\frac{j_i}{J} - \frac{p_i^l}{P}\right] e^{-\xi_i}$$

$$[A2] \quad \xi_i = \frac{JRTl}{D_i P}$$

Quantities in eq. [A2] have been defined in the main text under eqs. [3] and [4]. The downward flow of carrier gas flushes away emergent gas from the top of the capillary so $p_i^l = 0$. If a coupling parameter (β), defined as $j(In_2Br_2)/j(InBr)$, is used to

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

connect the two contributing equilibria [1] and [2], then

$$[A3] \quad \frac{j_1}{J} = \frac{1}{(1+\beta)}, \quad \frac{j_2}{J} = \frac{\beta}{(1+\beta)}$$

where 1 = InBr and 2 = In_2Br_2. Substitution of [A3] into [A1] with $p_i^l = 0$ gives the partial pressure eqs. [3] and [4] directly. The central assumption of modified entrainment is that the *equilibrium* partial pressure obtains in the capsule and this assumption has been discussed (15).

An expression for p_T, the total pressure, is used in eq. [5] and was obtained by a weighted 3-parameter regresson of the raw results for p_T (2)

$$[A4] \quad \ln(p_T/\text{Pa}) = 41.550 - 2.368 \ln T - \frac{13120.7}{T}$$

This is not identical to the corresponding equation from ref. 2 as these workers regressed their data with an estimated constant value of $\Delta C_p(l \rightarrow g, 650\text{–}950\ K) = -33.5\ J\ K^{-1}\ mol^{-1}$. From eq. [11] it is clear that this estimate is in error; at the mid-temperature, eq. [11] gives $\Delta C_p(l \rightarrow g, 800\ K) = -26.3\ J\ K^{-1}\ mol^{-1}$. Secondly, Mucklejohn *et al.* (2) did not weight their results during regression; the importance of appropriate weighting in the regression of logarithmic functions has been stressed (16). Equation [A4] includes the weighting factor, $w_i = p_T^2$.

Diffusion coefficients

There are no literature data for diffusion coefficients for the indium bromide/argon system. However, reliable estimation procedures are well-established; Reid *et al.* (17) tabulate estimated diffusion coefficients for over 100 binary systems with an overall absolute deviation of 7%. In this work we estimate the Lennard–Jones collision diameter (σ) from an empirical correlation between σ and moment of inertia (6).

$$[A5] \quad \sigma/\text{Å} = (3.411 \pm 0.087) + (0.549 \pm 0.047) \times 10^{19} \, (I/\text{g cm}^2)^{1/2}$$

With molecular dimensions for InBr from Huber *et al.* (9) and estimated (see below) constants for In_2Br_2, σ(InBr) = 4.65 Å and $\sigma(In_2Br_2)$ = 5.54 Å. The symmetry for In_2Br_2 was assumed D_{2h} and structural constants were estimated by analogy with the alkali metal bromide dimers which have been studied by electron diffraction (18). For those bromides, plots of θ_{dimer}(Br—M—Br) vs. $r_{monomer}$(M—Br) and r_{dimer}(M—Br) vs. $r_{monomer}$(M—Br) are approximately linear and interpolation at r(In—Br) = 2.54 Å gave estimated constants for In_2Br_2; r(In—Br) = 2.78 Å, θ(In—Br—In) = 78°, θ(Br—In—Br) = 102° and $I_xI_yI_z = 3.48 \times 10^{-111}$ g^3 cm^6. Diffusion coefficients are relatively insensitive to choice of well-depth (ϵ_i) and these were estimated using Svehla's (19) linear correlation between ϵ_i and T_B, the normal boiling temperature. Hence (ϵ/k_B)InBr = 1109 K and $(\epsilon/k_B)In_2Br_2$ = 1723 K. With the Lorentz–Berthelot combining rules (20) for σ_{12} and ϵ_{12}/k_B and Neufeld's formula (21) for the diffusion collision integral, diffusion coefficients were calculated from the standard kinetic theory of gases equation (22) and regressed to a power law in T over the experimental temperature range (680–940 K).

TABLE A1. Representative ternary diffusion coefficient correction factors (γ_i in eq. [A8])

T/K	γ_i	γ_2
680	0.996	0.992
747	0.980	0.963
790	0.954	0.915
810	0.933	0.878

$$[A6] \quad \mathfrak{D}(\text{InBr, Ar})/\text{m}^2\,\text{s}^{-1} = 6.26 \times 10^{-6}\left(\frac{T}{273}\right)^{1.802}$$

$$[A7] \quad \mathfrak{D}(In_2Br_2, \text{Ar})/\text{m}^2\,\text{s}^{-1} = 4.32 \times 10^{-6}\left(\frac{T}{273}\right)^{1.848}$$

In these equations $\mathfrak{D}_i$ are the binary gaseous diffusion coefficients. A second order treatment (23) was used to quantify ternary (Ar, InBr, In_2Br_2) diffusion coefficients. This treatment permits the ternary diffusion coefficient ($D_{i,\text{mixture}}$) to be written in terms of $\mathfrak{D}_{ij}$, where j is the majority component (Ar).

$$[A8] \quad D_{i,\text{mixture}} = \frac{\mathfrak{D}_{i,\text{Ar}}}{\gamma_i}$$

$$[A9] \quad \gamma_i = 1 + B_i\,\bar{\xi}_i$$

$$[A10] \quad B_1 = 0.5\left(\frac{D(3,2)D(1,2)\beta}{(1+\beta)} - 1\right)$$

$$[A11] \quad B_2 = 0.5\left(\frac{D(3,1)D(2,1)}{(1+\beta)} - 1\right)$$

$$[A12] \quad \bar{\xi}_i = \frac{\dot{w}RTl(1+\beta)}{D_{i,\text{mix}}AM_1P(1+2\beta)}$$

$$[A13] \quad D(k,l) = \left(\frac{M_l}{M_k}\right)^{1/2} - 1$$

Notice in this sequence of equations that γ_i in [A9] is itself a function [A12] of the ternary coefficient [A8] that is being estimated; hence a reiterative procedure is employed initially setting $\gamma_i = 1$ and terminating when successive estimates of γ_i are within 1 in 10^4. Less than six iterations were sufficient in all cases. Some typical values of γ_i are collected in Table A1.

LUKOSE MATHEW, EMMANUEL Y. OSEI-TWUM, and JOHN WARKENTIN. Can. J. Chem. **69**, 1398 (1991).

α-Hydroperoxyalkyl diazenes ($Me_2C(OOH)N{=}NR$, **1**, R = CH_2CF_3, CH_2CH_2OMe, $CH(Me)_2$, CMe_3, CH_2Ph, Ph, CH_2CH_2OPh, and *c*-$C_3H_5CD_2$) decompose in benzene, at 50°C or less, by a mechanism involving free radical (R•) intermediates. The radicals were trapped with 1-methyl-4-nitroso-3,5-diphenylpyrazole, **2**, to afford spin adducts (nitroxyls) that were observed by ESR spectroscopy. When the solvent was ethyl vinyl ether, radicals from **1** (R = CH_2CH_2OPh) were trapped by the solvent and the adduct radicals so formed were spin trapped by **2**. These observations support free radical mechanisms for thermolysis of **1** and for the hydroxyalkylations that occur when **1** are decomposed in solutions containing enol ethers or other unsaturated substrates. The ring-opening of cyclopropylmethyl radicals (cpm) to 3-butenyl radicals was used to estimate the rate constant for radical trapping by **2**. For cpm the rate constant is given by $\log k_{cpm} = (10.7 \pm 0.4) - (3.9 \pm 0.5)/\theta$ where $\theta = 2.3\,RT$ kcal mol^{-1}. At 25°C, the spin trapping rate constant has the value 6.9×10^7 M^{-1} s^{-1}.

Key words: hydroperoxyalkyl diazenes; radicals, spin trapping; spin trapping, rate constant.

LUKOSE MATHEW, EMMANUEL Y. OSEI-TWUM et JOHN WARKENTIN. Can. J. Chem. **69**, 1398 (1991).

Les α-hydropéroxyalkyldiazènes ($Me_2C(OOH)N{=}NR$, **1**, R = CH_2CF_3, CH_2CH_2OMe, $CH(Me)_2$, CMe_3, CH_2Ph, Ph, CH_2CH_2OPh et *c*-$C_3H_5CD_2$) se décomposent dans le benzène à une température égale ou inférieure á 50°C selon un mécanisme impliquant des radicaux libres (R•) intermédiaires. On a piégé les radicaux libres avec le méthyl-1-nitroso-4-diphényl-3,5-pyrazole, **2**, pour obtenir des adduits de spin (nitroxyles) que l'on a observés par spectroscopie de ESR. L'éther ethylvinylique utilisé comme solvant piège les radicaux provenant du composé **1** (R = CH_2CH_2OPh) et les adduits radicalaires ainsi formés sont captés par le composé **2**. Ces observations tendent à prouver que la thermolyse du composé **1** et l'hydroxyalkylation, qui se produit lorsque le composé **1** se décompose dans des solutions contenant des éthers énoliques ou d'autres substrats insaturés, impliquent un mécanisme radicalaire. On s'est basé sur l'ouverture du cycle des radicaux cyclopropylméthyles (cpm) qui conduit aux radicaux buténynl-3 pour évaluer la constante de vitesse de la capture des radicaux par le composé **2**. Pour le cpm, la constante de vitesse est donnée par la rélation : $\log k_{cpm} = (10{,}7 \pm 0{,}4) - (3{,}9 \pm 0{,}5)/\theta$ où $\theta = 2{,}3\,RT$ kcal mol^{-1}. On évalue la constante de capture de spin à $6{,}9 \times 10^7$ M^{-1} s^{-1} à 25°C.

Mots clés : hydropéroxyalkyldiazènes; radicaux, capture de spin; capture de spin, constante de vitesse.

[Traduit par la rédaction]

Introduction

Spin trapping is a well-known technique (1–4) for the indirect detection of a short-lived free radical (R•). The method involves an addition reaction of such a radical to an efficient scavenger (spin trap) to afford a long-lived radical (spin adduct). The latter is easily detected and its ESR spectrum contains information about the radical of interest (R•).

Nitroso compounds are important spin traps because they are readily available and because they react rapidly and irreversibly with many radicals, eq. [1]. Moreover, hyperfine in-

[1] $$R'NO + R^{\bullet} \longrightarrow R'RNO^{\bullet}$$

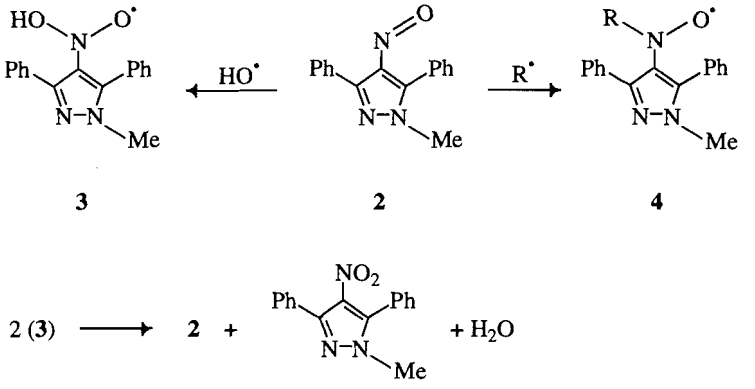
teractions between the unpaired electron and magnetic nuclei in R of the adduct can be large because R is attached directly to N, which carries much of the spin density of a nitroxyl radical. Disadvantages of nitroso compounds as spin traps include the tendency of some (e.g., Me_3CNO) toward photolysis and subsequent self-generated ESR spectra and the tendency of others to form nitroso dimers that are in equilibrium with the monomers (4). Although the monomer/dimer equilibrium does not present a problem in studies where identification of radicals is the objective, there are difficulties with kinetic studies. First, the highest concentration of monomeric nitroso compound is severely limited by dimer formation. Second, the actual concentration of nitroso spin trap is subject to greater uncertainty if dimerization is important.

In 1982, Kaur and Perkins (5) reported the use of 1-methyl-4-nitroso-3,5-diphenylpyrazole (**2**) for spin trapping of alkyl and aryl radicals. The advantages of **2** over some other nitroso spin traps are that it is monomeric in solution to at least 0.03 M (5), and that it is stable to visible light and is, therefore, not by itself a source of nitroxyl radicals.

α-Hydroperoxyalkyl diazenes ($R^1R^2C(OOH)N{=}NR^3$) and some cyclic analogues have been known for some time as sources of free radicals (6–8) including the hydroxyl radical (9). However, some of them afford diazonium ion intermediates instead (10) and others cause oxygen atom transfers that convert olefins to epoxides (11) and thioethers to sulfoxides (12) by non-radical mechanisms under neutral conditions.

In this paper we report spin trapping, with **2**, to demonstrate the formation of free radicals during thermal decomposition of a family of hydroperoxyalkyl diazenes ($Me_2C(OOH)N{=}NR$, **1**). The Arrhenius equation for spin trapping of cyclopropylmethyl with **2** is reported also.

Methods, results, and discussion



α-Hydroperoxyalkyl diazenes (**1**) decompose slowly at ambient temperature in solution (eq. [2]):

[2] $$Me_2C(OOH){=}NR \longrightarrow HO^{\bullet} + Me_2CO + N_2 + R^{\bullet}$$

a: R = CH_2CF_3; *b*: R = CH_2CH_2OMe; *c*: R = $CHMe_2$; *d*: R = CMe_3; *e*: R = CH_2Ph; *f*: R = Ph; *g*: R = $CD_2C_3H_5$ (C_3H_5 = cyclopropyl); *h*: R = CH_2CH_2OPh

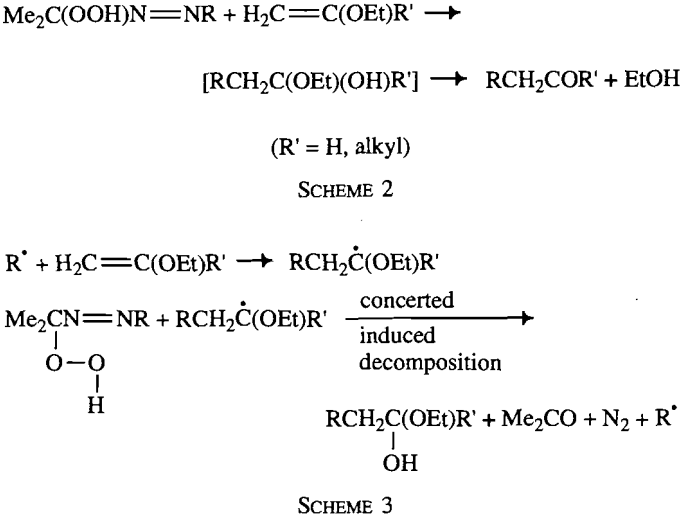
SCHEME 1

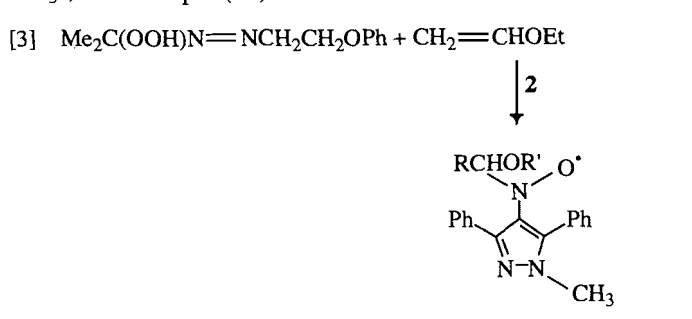


Consequently ESR spectra of spin adducts between R·(from **1**) and spin trap **2** could be recorded within minutes of warming a cold benzene solution of the reactants to room temperature in the ESR cavity. The initial ESR spectrum was complicated, however, probably because of the presence of hydroxyl radical spin adduct **3** together with spin adduct **4**, Scheme 1. Spin adducts of hydroxyl radicals and nitroso compounds are unstable (13), affording nitro compound, nitroso precursor, and water as illustrated in Scheme 1. That process could explain why the ESR spectra became clean and simple as time progressed, the concentration of **4** increasing steadily until its spectrum dominated after about 10 min.

The ESR spectra of **4***c*–**4***f* were reported by Kaur and Perkins (5). Our ESR spectra for those adducts are in good to fair agreement with published (5) spectra (lit. values in parentheses); **4***c*: g = 2.0061, a_N = 13.1 (13.2) G, a_H (1H) = 5.8(5.9) G; **4***d*: a_N = 14.4(13.4) G; **4***e*: g = 2.0068, a_N = 13.0(13.0) G, a_H (2H) = 7.5(7.7) G; **4***f*: g = 2.0056, a_N = 9.8(9.8) G, a_H (3H) = 2.63(2.65) G, a_H (2H) = 0.85 (0.8) G.

The ESR spectra of the new members of the family **4** appear to be normal; **4***a*: a_N = 11.5 G, a_H (2H) = 6.3 G, a_F (3F) = 1.13 G (Fig. 1); **4***b*: a_N = 12.6 G, a_H (2H) = 8.8 G, splitting to the more remote CH_2 group not resolved: **4***g*: g = 2.0057, a_N = 12.8 G, a_D (2D) = 1.5 G; **4***h*: a_N = 12.6 G, a_H (2H) = 8.6 G. Observation of all of the ESR spectra, **4***a*–**4***h*, from prescursors **1***a*–**1***h*, serves to support a free radical mechanism for thermolysis of α-hydroperoxyalkyldiazenes (**1**) as a class.

In a previous report (8) the use of compounds of type **1** for hydroxyalkylation of olefinic substrates was described. Best yields were obtained in the hydroxyalkylation of enol ethers (Scheme 2) to afford aldehydes or ketones (8). Those products, and the fact that rapid decomposition of hydroperoxy diazenes of type **1** is strongly inhibitied by 2,2,6,6-tetramethylpiperidine-*N*-oxyl radical (TMPO) led to the suggestion of a radical chain mechanism for hydroxyalkylation, with chain-carrying steps illustrated in Scheme 3 (8).



It was possible to provide support for that mechanism by intercepting the α-ethoxyalkyl radical intermediate of Scheme 3. A solution of **1***h* in ethyl vinyl ether containing **2** (1.0×10^{-3} M) gave rise, at ambient temperature, to the ESR spectrum of a radical to which structure **5***a* could be assigned, eq. [3]. The ESR spectrum, with g = 2.0063, a_N = 12.0 G, a_H (1H) = 4.25 G resembles that of **5***b* (3), with a_N = 13.5 G, a_H = 4.6 G (in ethanol), and that of $PhCH(OCHMe_2)N(O^{\cdot})CMe_3$, with g = 2.0063, a_N = 13.7 G, a_H = 1.17 G (14).

SCHEME 2

SCHEME 3

Although additional weak signals were superimposed on the spectrum of **5***a*, it is clear that addition of $PhOCH_2CH_2^{\cdot}$ to ethyl vinyl ether (ca. 10 M) competes effectively with spin trapping of $PhOCH_2CH_2^{\cdot}$ by **2** (1.0×10^{-3} M). If the latter trapping has a rate constant near 1.1×10^8 M^{-1} s^{-1} at 50°C (see below) then the rate constant for addition to ethyl vinyl ether must have a value greater than 4.5×10^4 M^{-1} s^{-1}. This calculation includes the estimate that at least 80% of the radicals detected were **5***a* and that the other 20% were spin adducts from $PhOCH_2CH_2^{\cdot}$ and **2**. We were unable to find rate constants in the literature for addition of any radicals to any enol ethers. However, the rate constants for addition of alkyl radicals to vinyl acetate (a reasonable model) are about one order of magnitude smaller; 2×10^3 M^{-1} s^{-1} at 50°C for $CCl_3^{\cdot}$, for example (15).

5*a* R = $PhO(CH_2)_3$, R' = Et
5*b* R = Me, R' = H

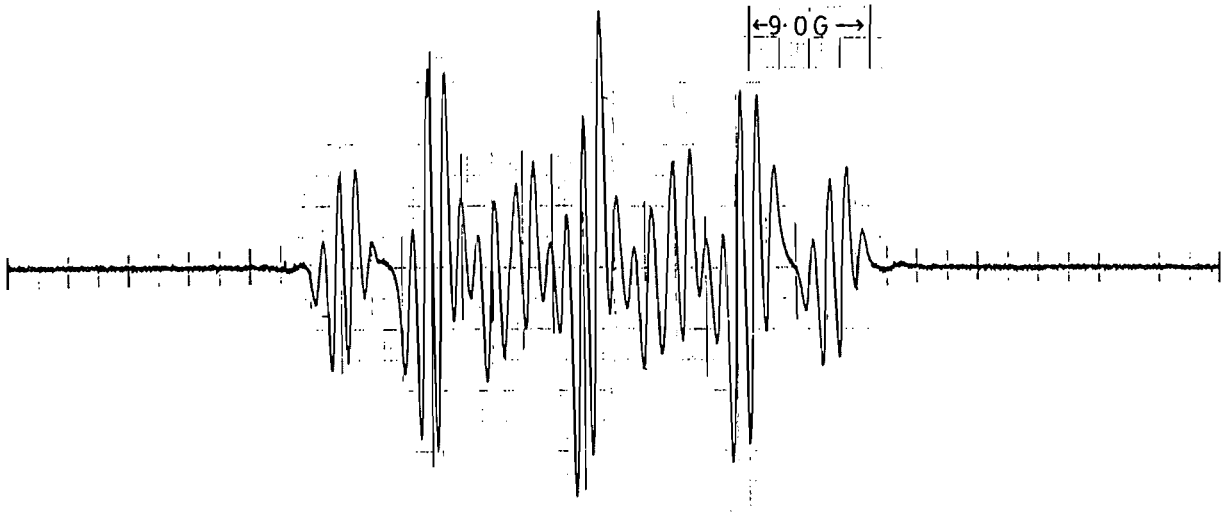

FIG. 1. ESR spectrum of nitroxyl radical from addition of $CF_3CH_2^{\cdot}$ to **2** in benzene.

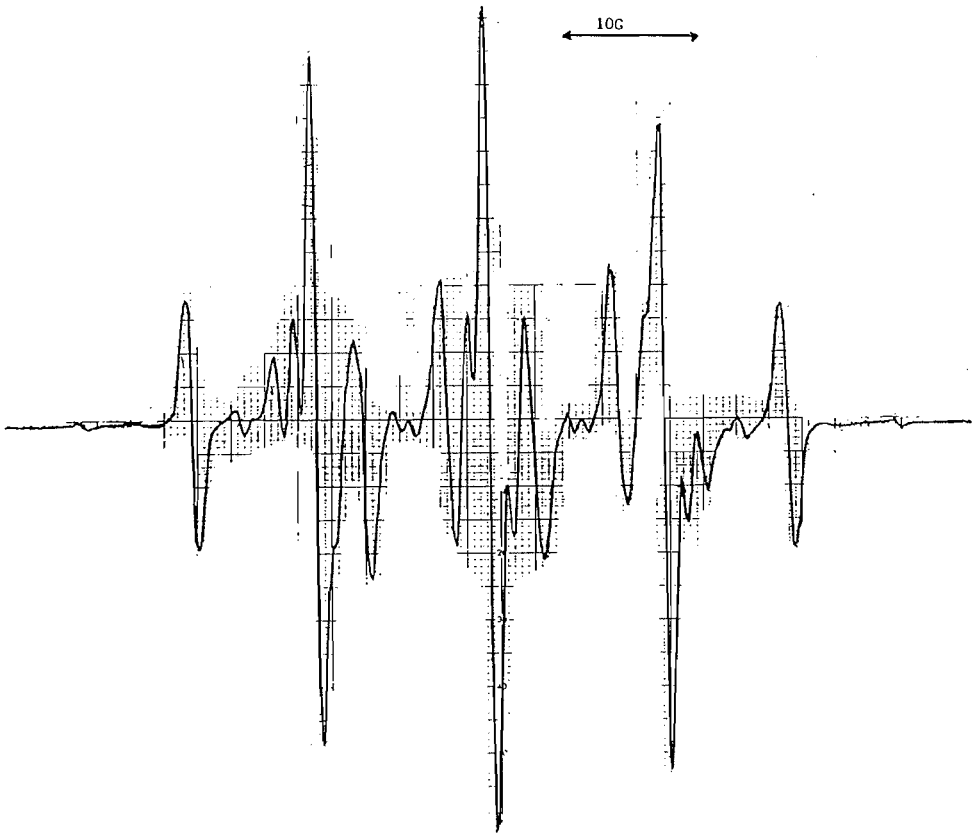

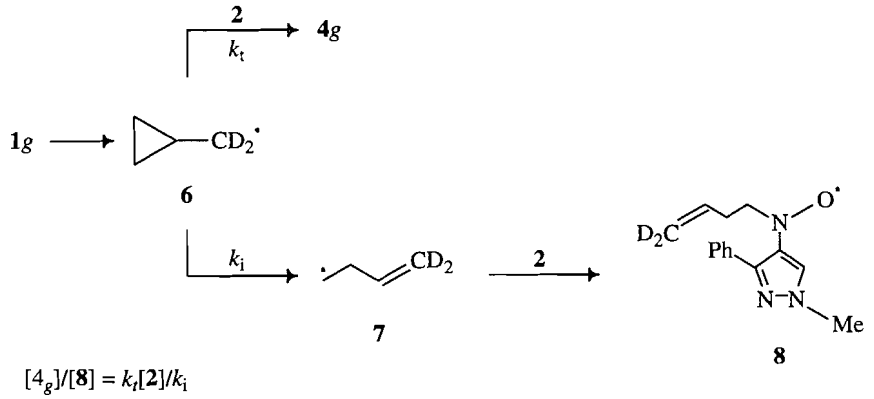

FIG. 2. Superimposed ESR spectra of **4***g* and **8**. See text and Scheme 4.

In addition to the spectra of radical adducts of **2**, Kaur and Perkins (5) estimated the rate constant, at 40°C, for spin trapping of undecyl radical (U$^{\cdot}$) with **2**. That rate constant was obtained from an experiment in which phenyl-*N*-*tert*-butylnitrone (PBN) was allowed to compete with **2** for U$^{\cdot}$ and the rate constant for reaction of U$^{\cdot}$ with PBN was taken to be 1.3×10^5 M^{-1} s^{-1}, the value reported for trapping of 5-hexenyl radicals (16) by PBN. It is very important, because of the interdependence of rate constants for free radical reactions, to obtain derived numbers from as many sources as possible, to provide for a consistent set of data (17). For that reason, we decided to estimate the rate constant for spin trapping of a primary radical by **2** against a different clock, the well-calibrated (18–22) and frequently used cyclopropylmethyl (cpm) free radical clock.

To distinguish between the spin adducts from cpm and 3-buten-1-yl radicals by ESR spectroscopy, the deuterated precursor **1***g* was prepared. Thermolysis of **1***g* afforded **6**, which in the presence of **2** underwent competitive spin trapping and ring-opening to afford **4***g* and **7** (Scheme 4). The latter was spin trapped also to form **8** and the ratio **4***g*/**8** was determined by double integration of the ESR spectra (Fig. 2), which are significantly different because of the different splitting constants to protium and deuterium; for **8**, $g = 2.0039$, $a_N = 12.8$ G, a_H (2H) = 9.27 G. That ratio was related to the rate

[a]Ratio of spin adducts (Scheme 4), from the ESR spectra.
[b]Corrected for temperature effects on volume, through use of the coefficient of cubical expansion of the solvent benzene.
[c]Calculated (19) from $\log(k_i/s^{-1}) = 13.31 - 7.26/\theta$.
[d]Calculated from the relationship in Scheme 4.

constants for spin trapping of cpm and for rearrangement of cpm in the usual (23) way, Scheme 4, and the spin trapping rate constant (k_t) was calculated by substituting for k_i its numerical value from the Arrhenius equation (19), $\log (k_i/s^{-1}) = 13.31 - 7.26/\theta$. The hydrogen/deuterium kinetic isotope effect on k_i was assumed to be negligible and trapping by **2** was treated as pseudo first order.

To attain ratios (**4g/8**) near the ideal value of unity, relatively large concentrations of **2** were required and it was necessary to establish that **2** remains monomeric in solution at high concentrations. Measurements of the extinction coefficient of **2** at λ = 738 nm in benzene were made at both 23 and 40°C over the concentration range (2.0–196) × 10^{-3} M (Table 1). Within experimental error, the extinction coefficient was independent of concentration and temperature (ϵ = 95 ± 2 at 40°C; 92 ± 3 at 23°C) in complete agreement with the findings of Kaur and Perkins (5) for concentrations up to 0.03 M. The reasonable assumption was then made that **2** remains monomeric at concentrations (0.91–0.96 M) nearly fivefold higher than the maximum concentration at which ϵ could be measured (0.20 M).

Data for competitive spin trapping and isomerization of **6**, for the temperature range 283–333 K are in Table 2. A least-squares treatment of the data gives eq. [4] as the Arrhenius expression for the spin trapping rate constant, k_t, with correlation coefficient 0.97. At 40°C, eq. [4] gives $k_t = 9.4 \times 10^7$ M^{-1} s^{-1}, which is in satisfactory agreement (roughly three-fold larger) with the value reported (5) for spin trapping of undecyl radicals with **2**.[3] At 25°C, $k_t = 6.9 \times 10^7$ M^{-1} s^{-1}. These numbers are minimum values, presumably, that would rise if **2** actually is partly dimeric at concentrations near 0.96 M (Table 2).[3]

[4] $\log (k_t/M^{-1}\,s^{-1}) = (10.7 \pm 0.4) - (3.9 \pm 0.5)/\theta$

where $\theta = 2.3\,RT$ kcal mol^{-1}

Both the pre-exponential factor and the activation energy are larger than those for trapping of 5-hexenyl radicals with 2-methyl-2-nitrosopropane, for which $\log A = 8.4$ and $E_a = 2$ kcal mol^{-1} were reported (25).[4] Qualitatively, the difference can be rationalized. In 2-methyl-2-nitrosopropane the nitroso nitrogen is very hindered (neopentylic) but not conjugated, whereas in **2** the nitroso group presumably has less steric protection but some conjugative interaction with the pyrazole ring. The larger frequency factor and activation barrier for **2** are therefore in accord with expectation. The 25°C rate constant (6.9×10^7 M^{-1} s^{-1}) is, within experimental error, the same as that (3.9×10^7 M^{-1} s^{-1}) for trapping a primary alkyl radical with nitrosodurene (16).

Experimental

Electron spin resonance (ESR) spectra were recorded at ambient temperature with a Bruker ER 100 D spectrometer operating at 9.6 GHz and equipped with a Te-102 rectangular cavity. Proton NMR

[3]The new data imply that rate constants based on spin trapping with **2**, and referred to the Kaur and Perkins number, can probably be increased by a factor of two (24).

[4]These numbers become $\log A = 8.6$ and $E_a = 1.8$ kcal mol^{-1} if the most recent value (26) of the rate constant for cyclization of 5-hexenyl to cyclopentylmethyl is used.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12

spectra were obtained with a Varian EM-390, a Bruker WP-80, or a Bruker WM-250 spectrometer, while ^{13}C and ^{19}F spectra were run on Bruker WP-80 and WM-250 spectrometers, respectively. Tetramethylsilane and $CDCl_3$ were used as internal references for ^1H and ^{13}C spectra, respectively. External trichlorofluoromethane was used to calibrate ^{19}F spectra. Solvents from Caledon Chemical Co. Ltd., Georgetown, were distilled in glass and stored over molecular sieves.

Synthesis of 1-methyl-4-nitroso-3,5-diphenylpyrazole, 2

The nitrosopyrazole was prepared[5] by the procedure of Boyd and Norris (27). Recrystallized material melted at 92–94°C. ^1H NMR (200 MHz, $CDCl_3$) δ: 3.83 (s, 3H), 7.46–7.56 (m, 8H), 7.99–8.10 (m, 2H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 37.3 (CH_3), 127.1 (C-4, tent.), 129.7 (C-4 of Ph); 128.5, 128.8, 129.1, 130.1 (4 × C-2, C-3 of Ph), 130.4 (C-4 of Ph), 131.0 (C-1 of Ph), 158.0 (C-3, tent.), two quaternary carbon signals are apparently coincident with ArH signals.

Synthesis of α-hydroperoxyalkyldiazenes, 1

Caution: 1 are probably explosive! The procedure for preparation of **1** by autoxidation of substituted hydrazones of acetone has been described and some NMR spectra (^1H and ^{13}C) and mass spectra of the precursors and products have been reported (8). Those NMR spectra are included here, together with additional spectra (^{13}C NMR, IR, and UV) to provide all the spectroscopic data in one place. The UV extinction coefficients for all except **1***g* are ca. 20.

$Me_2C(OOH)N{=}NCH_2CF_3$, **1***a*: IR (CCl_4) cm^{-1}: 3520 (br, OH), UV(λ_{max}, hexane) nm: 372. ^1H NMR (90 MHz, $CDCl_3$) δ: 1.40 (s, 6H), 4.27 (q, J_{HF} = 9 Hz, 2H), 8.80 (s, br, 1H). ^{19}F NMR (235.4 MHz), δ: −66.8 (t, J_{HF} = 9 Hz). ^{13}C NMR (22.6 MHz) δ: 21.30 (Me), 68.58 (q, J_{CF} = 29.1 Hz, CH_2), 104.22 (Me_2C), 123.69 (q, J_{CF} = 251.0 Hz, CF_3).

Kadsulignan C and D, two novel lignans from *Kadsura longipedunculata*

JIA-SEN LIU,[1] MEI-FEN HUANG, AND HONG-XING ZHOU
Shanghai Institute of Materia Medica, Academia Sinica, 319 Yueyang Rd., Shanghai 200031, China

Received February 7, 1991

JIA-SEN LIU, MEI-FEN HUANG, and HONG-XING ZHOU. Can. J. Chem. **69**, 1403 (1991).

Two novel lignans, kadsulignan C (**4**) and D (**5**), were isolated from the root bark of *Kadsura longipedunculata*. Their structures, including absolute configurations, were elucidated by 2D $^1H-^{13}C$ long-range COSY experiments and chemical transformation to the known compound **10**.

Key words: isolation and structure, absolute configuration, kadsulignan C, kadsulignan D, lignans, *Kadsura longipedunculata*.

JIA-SEN LIU, MEI-FEN HUANG et HONG-XING ZHOU. Can. J. Chem. **69**, 1403 (1991).

On a isolé de l'écorce de la racine du *Kadsura longipedunculata* deux nouveaux lignanes, les kadsuligane C (**4**) et D (**5**). On a élucidé leur structure et établi leur configuration absolue à l'aide d'expériences COSY à longue distance en résonance magnetique nucléaire du ^1H et du ^{13}C, et en les transformant chimiquement pour aboutir au composé **10** connu.

Mots clés : isolation et structure, configuration absolue, kadsulignane C, kadsulignane D, lignanes, *Kadsura longipedunculata*.

Introduction

The bark of the root *Kadsura longipedunculata* Finet. et Gapnep. is used as a traditional Chinese drug (1) to improve circulation of the blood, invigorate vital energy, and to treat rheumatoid arthritis as well as gastric or duodenal ulcer. In our previous papers we reported the isolation and structure elucidation of three new compounds, (+)-anwulignan (**1**) (2), schisanlactone E (**2**), and changnanic acid (**3**) (3) from plant material collected in the Zhejiang province of China. The pharmacological screening of compounds **1–3** indicated that each exhibits activity against leukemia P388 cell *in vitro* (IC_{50}, 1.5, 1.0, and 10 μg/mL respectively for **1**, **2**, and **3**). In addition, compound **1** shows an inhibitory effect to HBsAg of human serum of chronic hepatitis B carriers *in vitro* (2). A recent bioassay indicated that **2** and **3** show antagonistic activity to leukotriene D_4 *in vitro*.[2] Each of these findings support traditional medical usage of the root bark.

In our continuing studies on the chemistry of *K. longipedunculata* two new lignan compounds, which we have named kadsulignan C (**4**) and D (**5**), were isolated from the root bark extract. Both compounds **4** and **5** show moderate cytotoxicity against leukemia P388 cell *in vitro* (IC_{50} 50 and 10 μg/mL, respectively).[2] In the present paper we report the isolation, structure elucidation, and absolute configuration of kadsulignan C (**4**) and D (**5**). A discussion of the absolute configuration of benzoyl oxokadsurane (**12**), an analogous compound recently reported in the literature (8), is also presented.

Results and discussion

Kadsulignan C (**4**), $C_{31}H_{30}O_{11}$, is a pale yellow crystalline compound, the spectra of which display partial features similar to the dibenzocyclooctadiene lignans commonly found in this family of plants. Its infrared (ir), ^1H and ^{13}C nmr, and high resolution mass spectra (hrms) indicate the presence of the cyclooctadiene ring substituted with hydroxyl, acetoxyl, benzoxyl, and two methyl groups. However, its ultraviolet (uv) spectrum (λ_{max} 220, 276, 335 nm) shows that kadsulignan C (**4**) possesses a spiroenone ring different from the spirodienone

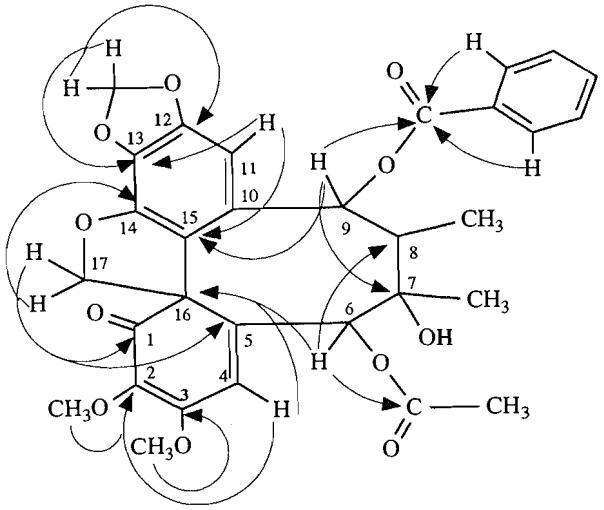

FIG. 1. 2D $^1H-^{13}C$ long-range shift correlation via $^3J_{CH}$ in kadsulignan C (**4**).

lignans kadsulignan A (**6**) and B (**7**) recently reported in our previous paper (4). A comparison of the ^{13}C nmr data of **4** with those of the spirodienone lignan **6** (4) reveals that the spiro carbon (C-16, δ 62.8, s) in compound **4** shifts upfield about 25 ppm while the carbonyl carbon (C-1, δ 194.9, s) of the enone ring shifts downfield over 10 ppm relative to the same carbons in compound **6**. These facts show that the spiro carbon (C-16) is not connected to oxygen and that the enone ring **4** is not an α,β,α′,β′-dienone. Furthermore, the ^1H nmr (δ 4.68, 4.04, d each, J = 9.1, H-17) and ^{13}C nmr spectra (δ 79.3, t, C-17) suggest the presence of a methylene group adjacent to an oxygen atom in the molecule of **4**. Analysis of 2D $^1H-^{13}C$ COSY and 2D $^1H-^{13}C$ long-range COSY spectra allowed us to establish the connectivity between carbon–hydrogen nuclei via $^1J_{CH}$ and between carbon–carbon nuclei via $^3J_{CH}$. In the 2D long-range COSY spectrum, the oxymethylene protons (H-17) correlate to the carbonyl carbon (C-1), C-5, and C-14 while H-4 and H-6 correlate to the spiro carbon (C-16) via $^3J_{CH}$. Thus, a spiro ring skeleton is established for kadsulignan C as shown in Fig. 1. A further analysis of the 2D $^1H-^{13}C$ long-range COSY spectrum illustrated each substituent position, benzoxyl at C-9, acetoxyl at C-6, methylenedioxyl at C-12 and C-13, and two methoxyls at C-2 and C-3 (Fig. 1). Nuclear Overhauser experiments (nOe,

[a]δ, ppm, in $CDCl_3$ (400 MHz); *J*, Hz, in parentheses; the assignments are based on selective decoupling and nOe experiments.

Table 3) provided further evidence for the structure and elucidated the relative stereochemistry of kadsulignan C as shown in structure **4**.

Kadsulignan D (**5**), $C_{32}H_{36}O_{11}$, is also a pale yellow crystalline compound with a similar uv to that of **4**. Comparison of the ^1H and ^{13}C nmr spectra of **4** and **5** (Tables 1 and 2) indicates that the structural difference between **4** and **5** is in the acid moiety: two angeloyl groups in compound **5** replace the benzoyl and acetyl groups in compound **4**. Further support of the presence of two angeloxyls is provided by the hrms fragmentation pattern, which displays fragment peaks of $[M - C_5H_8O_2]^+$ and $[M - C_{10}H_{16}O_4]^+$. The 2D ^1H–^{13}C COSY and 2D ^1H–^{13}C long-range COSY spectra of kadsulignan D (**5**) show similar correlations to those shown in Fig. 1 except that H-6 and H-9 correlate respectively to a carbonyl carbon of each angeloxyl group. Furthermore, nOe enhancements are observed between the olefinic hydrogen (H-3′) and both methyls (H-5′ and H-4′) of the acid moiety (Table 3). This experiment distinguishes the angeloxyl from tigloxyl, a geometric isomer of angeloxyl, since in the case of tigloxyl, only the nOe enhancement between the olefinic hydrogen H-3′ and the methyl H-4′ would be observed. In addition, these nOe experiments also indicate that kadsulignan D (**5**) has the same relative stereochemistry as compound **4**.

An attempt to apply the exciton chirality method of circular dichroic spectroscopy (cd) (5) to assign the absolute configurations of **4** and **5** was unsuccessful because multiple chromophores complicated the Cotton curves. However, chemical conversion of **4** and **5** into a known dibenzocyclooctadiene lignan enabled us to assign their absolute configurations. Thus, treatment of **4** with chlorotrimethylsilane/sodium iodide in anhydrous acetonitrile (6) cleaved the spirooxy ring with concomitant aromatization and demethylenation to afford compound **8**. Compound **8** was methylated and hydrolyzed, affording deacetyl deangeloyl kadsurarin (**10**) (7). Since the absolute configuration of **10** is known, the absolute configuration of **4** may be unambiguously assigned as 6*S*,7*S*,8*S*,9*R*,16*S*. Similarly kadsulignan D (**5**) also gave compound **10** upon chemical conversion. Therefore, its configurations are the same as those of **4**. It is interesting to note that the cd spectra of **4** and **5** are considerably different (see Table 4) and this fact is attributed to differences in perturbance of multiple chromophores.

Recently, the isolation and structure of an analogous lignan, benzoyl oxokadsurane (**12**), from *K. coccinea* was reported (8). Comparison of the cd data of compounds **4** and **12** (see Table 4) reveals that the cd curves of **12** are similar to those of compound **4**, indicating the same absolute configurations of C-16 and C-9 in both compounds **4** and **12**. Based on the absolute configuration assignment of **4**, benzoyl oxokadsurane (**12**) may have a 7*R*,8*R*,9*R*,16*S* configuration. This conclusion is the same as that in the literature (8). However, the absolute configuration reported was assigned by the cd exciton chirality method (5) using a negative Cotton effect at 230–270 nm to predict an *R* configuration for the benzoate (C-9). Since there are three negative Cotton effects and no positive diagnostic Cotton effect in the region 230–270 nm (Table 4), the cd spectrum of compound **12** has no feature of exciton coupling in that region (5). Therefore, the cd exciton chirality method is not applicable to the prediction of absolute configuration of the benzoate in compound **12**.

Experimental

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. The following instruments were used to record spectra: uv, Shimadzu uv-3000; ir, Perkin Elmer 599B; ^1H nmr and *n*Oe experiments, Bruker AM400 (400 MHz); ^{13}C nmr, 2D ^1H–^{13}C COSY, and 2D ^1H–^{13}C long-range COSY experiments, Bruker AC100 (25.19 MHz for ^{13}C nmr, 100 MHz for ^1H nmr); hrms, Varian MAT-711; cd, Jasco J500A; optical rotations, Jasco DIP181. Silica gel for column chromatography was manufactured at the Quingdao Haiyang Chemical Factory. The hptlc plates were manufactured at the Yantai Institute of Chemical Technology.

*Isolation of kadsulignan C (**4**) and D (**5**)*

The crude alcoholic extract of the root bark (3.5 kg) of *K. longipedunculata* collected in the Lin-An district of Zhejiang province, China, was suspended in water and extracted with ether. The ether was chromatographed on a silica gel eluting, in turn, with petroleum ether, benzene, benzene – ethyl acetate (10:1 and 4:1). The mid-fractions eluted with benzene – ethyl acetate (4:1) gave a crystalline mixture containing mainly two compounds. The crystalline mixture was rechromatographed over silica gel using benzene – ethyl acetate (6:1) as eluent. Concentration of the early fractions led to the isolation of kadsulignan C (**4**), 310 mg, which was crystallized from chloroform – petroleum ether. The mother liquor of the crystalline mixture was chromatographed repeatedly over silica gel eluting with petroleum ether – diethyl ether (1:1). Collection of the later fractions from the separations led to the isolation of kadsulignan D (**5**), 250 mg, which was crystallized from diethyl ether – petroleum ether.

collected and purified by hptlc using chloroform–methanol (100:2) to give compound **8**, 5.0 mg; uv (CH_3OH) λ_{max} (log ε): 224 (4.46), 250 (sh), 284 (3.35) nm; ^{1}H nmr ($CDCl_3$) δ: 1.32 (3H, d, J = 7.1 Hz, Me-8), 1.38 (3H, s, Me-7), 2.29 (1H, s, D_2O exchangeable, OH-7), 2.29 (1H, q, J = 7.1 Hz, H-8), 3.38, 3.94 (3H each, s, OCH_3 ×2), 5.09, 5.71 (1H each, brs, D_2O exchangeable, OH-1, OH-14), 5.64, 5.88 (1H each, s, H-9, H-6), 5.98, 5.99 (1H each, d, J = 1.4 Hz, OCH_2O), 6.53, 6.74 (1H each, s, H-11, H-4), 1.62 (3H, s, CH_3CO), 7.28 (2H, td, J = 1.5, 6.6 Hz, H-2′, H-6′), 7.45 (1H, td, J = 1.5, 6.2 Hz, H-4′), 7.25 (2H, overlapping solvent peak, H-3′, H-5′); hrms m/z: 566.1818 (M^+, 11% calcd. for $C_{30}H_{30}O_{11}$, 566.1788), 444.1481 (M^+ − PhCOOH, 73%), 384.1247 (M^+ − PhCOOH − CH_3COOH, 48%), 341.1045 (M^+ − $C_{11}H_{13}O_5$, 100%); cd (CH_3OH) Δε (nm): +8.8 (221), 0 (229), −20.2 (240), −3.7 (280).

Methyl ether (9) of compound 8

Compound **8** (5.0 mg) was methylated with an ethereal solution of CH_2N_2 for 7 days. The reaction mixture was worked up in the usual way, then purified by hptlc using petroleum ether – diethyl ether (1:1) to provide compound **9**, 4.2 mg, ^{1}H nmr ($CDCl_3$) δ: 1.28 (3H, d, J = 7.1 Hz, Me-8), 1.34 (3H, s, Me-7), 2.22 (1H, q, J = 7.1 Hz, H-8), 2.27 (1H, brs, D_2O exchangeable, OH-7), 3.13, 3.45, 3.82, 3.97 (3H each, s, OCH_3 ×4), 5.74, 6.03 (1H each, s, H-9, H-6), 5.94, 5.95 (1H each, d, J = 1.4 Hz, OCH_2O), 6.55, 6.86 (1H each, s, H-11, H-4), 7.46 (1H, brt, J = 7.0 Hz, H-4′), 7.19–7.30 (4H, m, overlapping solvent peak, Ph-H ×4); ms m/z: 594 (M^+), 472 (M^+ − PhCOOH), 412 (M^+ − PhCOOH − CH_3COOH), 369, 359, 122, 105.

Deacetyl deangeloyl kadsurarin (10)

Compound **9** (4.2 mg) dissolved in 10% methanolic potassium hydroxide (3 mL) was refluxed for 7.5 h. The reaction mixture was treated with a)ter (2 mL) and extracted with ether. The ether extract was purified by hptlc using petroleum ether – ethyl acetate (1:1) to give **10**, 2.4 mg. The ^{1}H nmr, ms, ir, and cd of the reaction product are identical with an authentic sample of compound **10** derived from kadsurarin (7).

Compound **11** treated with CH_2N_2 for 12 days and worked up in the usual way; it was hydrolyzed with 10% methanolic potassium hydrox-

ide as described above. The product obtained from this reaction is identical with compound **10**.

Compound 11

Kadsulignan D (**5**) (100 mg) was treated for 20 min with chlorotrimethylsilane (0.3 mL) and sodium iodide (300 mg) in anhydrous acetonitrile (9 mL) in the manner described for the preparation of compound **8**. Compound **11**, 20.4 mg, was isolated from the reaction mixture; ^{1}H nmr ($CDCl_3$) δ: 1.29 (3H, s, Me-7), 1.30 (3H, d, J = 7.1 Hz, Me-8), 1.39, 1.42 (3H each, s, Me-2′ ×2), 1.82, 1.86 (3H each, dd, J = 7.9, 1.4 Hz, Me-3′ ×2), 2.22 (1H, q, J = 7.1 Hz, H-8), 2.29 (1H, brs, D_2O exchangeable, OH-7), 3.88, 3.92 (3H each, s, OCH_3 ×2), 4.94, 5.81 (1H each, brs, D_2O exchangeable, OH-1, OH-14), 5.52, 5.60 (1H each, s, H-9, H-6), 5.93, 5.95 (1H each, brs, OCH_2O), 5.91–6.00 (2H, m, covered, H-3′, ×2), 6.43, 6.69 (1H each, s, H-11, H-4); ms m/z: 584 (M^+), 484 ($M^+ - CH_3CH{=}C(CH_3)COOH$), 412 ($M^+ - CH_3CH{=}C(CH_3)COOH - C_4H_8O$), 384 ($M^+ - CH_3CH{=}C(CH_3)COOH$ ×2).

Received July 23, 1990[3]

SAUL WOLFE and CHAN-KYUNG KIM. Can. J. Chem. **69**, 1408 (1991).

In the conformations that correspond to the C6-X1-C2-X3-C4 moieties of 1,3-dioxane, 1,3-dithiane, and cyclohexane in their chair conformations, the model systems $CH_2(OH)_2$, $CH_2(SH)_2$, and *gauche*-butane contain "axial" and "equatorial" hydrogens. The vibrational frequencies of the diastereomeric monodeuterated CHD derivatives of these model compounds have been computed *ab initio* at the 6-31G*//6-31G* level of theory, scaled by 0.9, and used to calculate the conformational deuterium isotope effects in these systems, as well as the stretching and bending components of these isotope effects. The results are in very good agreement with the experimental observations and with some of the interpretations given by Anet for the six-membered rings. Using an equation suggested by McKean, the scaled isolated stretching frequencies have been used to predict the bond dissociation energies of the diastereotopic hydrogens of these molecules. The results suggest that the preference for radical abstraction of the axial C2 hydrogen in a 1,3-dioxane will be diminished in cyclohexane, and reversed in a 1,3-dithiane.

Key words: stereochemistry, isotope effects, bond dissociation energies.

SAUL WOLFE et CHAN-KYUNG KIM. Can. J. Chem. **69**, 1408 (1991).

Les systèmes modèles, $CH_2(OH)_2$, $CH_2(SH)_2$ et le butane *gauche* contiennent des hydrogènes « axial » et « équatorial», dans les conformations qui correspondent aux unités C6-X1-C2-X3-C4 du 1,3-dioxane, du 1,3-dithiane et du cyclohexane dans leur conformation chaise. On a calculé les fréquences de vibration des dérivés diastéréoisomères monodeutériés CHD de ces composés modèles à l'aide de calculs *ab initio* au niveau théorique 6-31G*//6-31G* gradué à 0,9 et on les a utilisés pour calculer l'effet isotopique du deutérium dans ces systèmes, aussi bien que les composantes de la déformation et de l'élongation de ces effets isotopiques. Les résultats s'accordent parfaitement avec les résultats expérimentaux et avec certaines interprétations de Anet relatives aux cycles à six chaînons. On a utilisé les fréquences isolées d'élongation graduées pour prédire les énergies de dissociation des liaisons des hydrogènes diastéréoisomères de ces molécules en utilisant une équation suggérée par McKean. Les résultats suggèrent que la préférence pour une abstraction radicalaire de l'hydrogène axial en C9 dans le 1,3-dioxane sera moins marquée dans le cyclohexane et sera inversée dans le 1,3-dithiane.

Mots clés : stéréochimie, effets isotopiques du deutérium, énergies de dissociation des liaisons.

Introduction

Linear correlations exist between C—H bond lengths and isolated C–H stretching frequencies (1), between isolated C–H stretching frequencies and C—H bond dissociation energies (1, 2), and between one-bond C–H coupling constants and the inverse of C—H bond lengths (3). Since diastereotopic hydrogens in organic compounds have different bond lengths (3), their different stretching frequencies, bond dissociation energies, and C–H coupling constants lead to a multiplicity of stereoelectronic "effects", including the Bohlmann bands (infrared), Perlin effect (nmr) (3), relative rates of radical abstraction (4), and conformational deuterium isotope effects (5).

In the course of a recent study of the Perlin effect (3), we calculated the 6-31G* (6) optimized geometries of a number of molecules $CH_2(XH)_2$ in conformations that simulate the chair conformations of six-membered rings containing the X-C-X moiety. In every case the trends in C—H bond lengths of the model structures were found to reproduce those observed for the cyclic structures. Three of the molecules of the earlier study, namely, X = S (**1**), X = O (**2**), and *gauche*-butane (**3**) are shown in Fig. 1; in each case the diastereotopic "axial" and "equatorial" hydrogens are readily identified. Using a modification of LINK 716 of GAUSSIAN 86 (7, 8*a*),[4] we have now calculated the vibrational frequencies of the diastereomeric monodeuterated analogs of **1**–**3** and, by use of the computer programme provided as Supplementary Data,[5] have employed these frequencies to obtain the "equatorial" ⇄ "axial" equilibrium constants.

Conformational deuterium isotope effects

In the cases of **1** and **2**, analysis of individual frequencies allowed the total equilibrium constant to be partitioned into its stretching and bending components. It is generally observed that frequencies computed at the 6-31G* level are systematically too high by 10% (2, 9); a uniform scaling factor of 0.9 was, therefore, employed throughout. It has recently been shown (10) that this practice amounts to an empirical simulation of the effect of electron correlation.

The results are summarized in Table 1, together with the experimental results of Anet and Kopelevich for cyclohexane and the 5,5-dimethyl-1,3-dioxanes and 1,3-dithianes (5*a*–*c*),

Aydin and Günther for cyclohexane (5*d*), and the theoretical calculations of Williams on cyclohexane (5*e*).

In **2** and **3**, the "axial" hydrogen (deuterium) has the longer bond, and the lower stretching frequency. This trend is reversed in **1**. Considing only the zero-point energy differences that might be expected to result from the differences in the C–H (C–D) stretching frequencies, the "axial" deuterated isomer should be preferred in the case of **1**, and the "equatorial" deuterated isomer shoud be preferred in the cases of **2** and **3** (5*a*–*c*).

As can be seen, the sign of ΔG is in each case consistent with an analysis based only on the presumed zero-point energy differences. Moreover, the ΔG calculated for the model systems seem to agree with experiment, especially in the comparison of **2** with a 1,3-dioxane, and the comparison of *gauche*-butane with cyclohexane. However, when the primary and secondary

isotope effects associated with all of the other stretching and bending vibrations are examined, a more subtle discussion of **1** becomes necessary. The stretching contribution to ΔG has the *same* sign in **1** and **2**, but the stretching and bending contributions to the free energy difference in **1** have *opposite* signs, and the *bending* contributions dominate. Thus an analysis of **1** that emphasizes C–H (C–D) stretching would not account for the sign of ΔG.

Table 2 examines all of the stretching frequencies of the diastereomeric monodeuterated derivatives of **1** and **2**. In **2**, ν_1 and ν_2 refer to O–C–O stretching, ν_5 and ν_6 refer to O–H stretching, and ν_3 and ν_4 are the C–H (C–D) stretching frequencies. The O–C–O and O–H effects cancel so that, as expected, differences in C–H (C–D) vibrations are the dominant factor that determines the stretching contribution to the conformational preference. Examination of ν_3 and ν_4 reveals that the C–D (2220 → 2115 cm^{-1}) and C–H (3012 → 2879 cm^{-1}) stretching frequencies are lower when the D (H) are "axial". Since the decrease in the C–H frequency is larger, the final result is that the isomer in which hydrogen is "axial" (and deuterium is "equatorial") has the lower zero-point energy. The result of this analysis is consistent with the idea (3) that in the oxygen compound **2** the (n_p,σ^*_{CH}) orbital interaction controls the geometry of the CH_2 moiety.

In **1**, ν_1 and ν_2 are the symmetric and antisymmetric S–C–S stretching frequencies, ν_4 and ν_5 are the symmetric and antisymmetric S–H stretching frequencies, and ν_3 and ν_6 are the

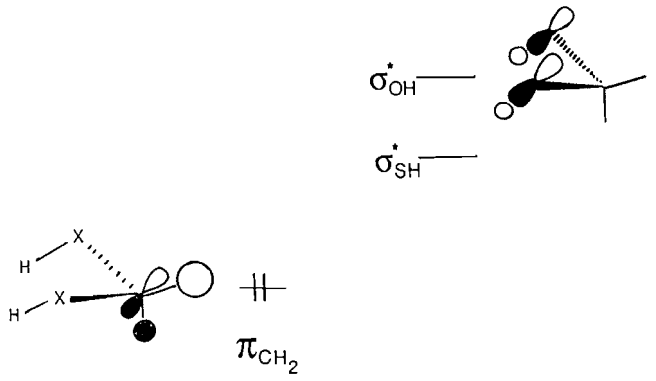

FIG. 2. Orbital interaction diagram for $CH_2(XH)_2$, showing charge transfer from π_{CH_2} to $\sigma^*_{(XH)_2}$.

C–H (C–D) stretching frequencies. Here we observe that the C–H (C–D) and S–H differences between the isomers cancel, but both of the S–C–S stretching freqencies are lower in the isomer having "equatorial" deuterium. This means that in **1** the "equatorial" preference of the stretching contribution to the equilibrium isotope effect is not caused by C–D (C–H) directly, but through an effect transmitted from C–D (C–H) to the C—S bonds. The picture suggested by this finding can be conveyed in two ways: (i) in terms of hyperconjugation, the description (H—S—C— $H_{eq} \Leftrightarrow H^+$ S=C H^-_{eq}) predicts concomitant C–H_{eq} weakening and S–C strengthening; (ii) in terms of

TABLE 4. Calculated bond dissociation energies of diastereotopic hydrogens

Molecule	C—H hydrogen	$\nu^{is}_{C—H}$[a]	C—H bond dissociation energy[b]
Methanol	Antiperiplanar[c]	2968 (2979)[d]	101.5
	gauche[c]	2893 (2921)[d]	94.8 (95.5)[d]

[d]Experimental value (1*b*).

orbital interactions (11), the low-lying σ^*_{SH} acceptor orbitals control the geometry of the CH_2 moiety via charge transfer from π_{CH_2} (see Fig. 2). This charge transfer is strengthened by a strengthening of the S–C bond, accompanied by a preferential weakening of the C—H_{eq} bond, because H_{eq} has the larger coefficient in π_{CH_2} (3).

The charge transfer argument leads to the prediction that the H—C—H angle in **1** will be smaller than tetrahedral (12). Because the coefficients of the two hydrogen atomic orbitals are out-of-phase in the donor orbital, π_{CH_2}, depopulation of this orbital will be facilitated by a decrease in the H—C—H angle (11). Indeed, the H—C—H angles of **1** and **2** are 108.0° and 110.2°, respectively.

Table 3 summarizes the bending frequencies of the undeuterated and the "equatorial" and "axial" deuterated derivatives of **1** and **2**. For the undeuterated compounds, all C–H bending frequencies are lower in **1**. The largest effect of monodeuteration of this compound is seen in ν_4 and ν_7. In each case the frequency of the bending vibration is lower when deuterium is "axial"; this is the origin of the large negative ΔG_{bend} seen in Table 1. Interestingly, in **2**, the conformational effect of isotopic substitution on ν_4 is negligible, so that when all bending vibrations are taken into account, deuterium prefers the "equatorial" site (positive ΔG_{bend}).

Bond dissociation energies

McKean (1) has advocated the use of eq. [1] to estimate C—H bond dissociation energies from "isolated" C–H stretching frequencies. Since the appropriate degree of deuteration of **1**–**3** allows the isolated C–H stretching frequencies of these compounds to be computed, and the equilibrium isotope effects described above seem to be reasonable, we have used eq. [1] to calculate the "axial" and "equatorial" C—H bond dissociation energies (D.E.). Table 4, which includes the diastereotopic deuterium isolated (2) methyl hydrogens of methanol as a benchmark, summarizes the results.

$$[1] \quad \text{D.E. (kcal/mol)} = 0.08963\nu(\text{C–H})_{is} - 164.5$$

The value for the weaker *gauche* hydrogen of methanol is in excellent agreement with experiment, and both calculated frequencies are within 1% of the experimental values (13). Since the *gauche* hydrogen of methanol is topologically equivalent to the "axial" C2 hydrogen in a pyranose ring, it follows that this hydrogen will react preferentially in radical abstraction (4). The same trend is seen in **2**: the "axial" C2 hydrogen will be more reactive in radical abstraction (4). The difference in bond dissociation energies favoring "axial" abstraction is greatly diminished in **3**, and reversed in **1**. We expect that radical attack upon C—H bonds of a cyclohexane ring will exhibit little axial–equatorial selectivity, but radical abstraction from C2 of a 1,3-dithiane should exhibit a preference opposite to that of a 1,3-dioxane.

Origin of the dual-band laser emission from 7-diethylamino-4-methylcoumarin (C1) in solution: effect of hydrogen-bonding interaction by hydroxylic molecules[1,2]

R. W. YIP[3] AND Y. X. WEN

Département de chimie, Université du Québec à Montréal, C.P. 8888, Succ. A, Montréal, Qué, Canada H3C 3P8

Received August 20, 1990[4]

R. W. YIP and Y. X. WEN. Can. J. Chem. **69**, 1413 (1991).

Ultraviolet absorption measurements on 7-diethylamino-4-methylcoumarin (C1) and its rigid analogue C102 in which the 7-amino group is structurally prevented from twisting in *n*-butyl acetate (*n*BuOAc) solutions containing submolar concentrations of *n*-butyl alcohol showed weak 2:1 alcohol:dye complexation. These results contrast with those from fluorescence measurements which revealed a 1:1 alcohol:dye excited state complex for the C1 dye. These results together with N_2 laser excited amplified spontaneous emission (ASE), and laser gain measurements on C1 and C102 in *n*BuOAc with alcohol or acetonitrile co-solvent show that dual ASE from C1 originates from a quasi-equilibrium concentration of hydrogen-bonded or acetonitrile-solvated excited state complex. The results are inconsistent with a TICT–*n*BuOAc exciplex for C1 in *n*BuOAc. The laser gain of the twin ASE peaks at 420 nm and 455 nm from C1 can be tuned by adding a small quantity of hydroxylic co-solvent to dried *n*BuOAc. ASE was found to be a selective probe for a H-bonded C1 complex whose fluorescence is normally obscured by that from the "free" dye.

Key words: aminocoumarins, dual amplified spontaneous emission, excited state hydrogen-bonding complex, laser gain.

R. W. YIP et Y. X. WEN. Can. J. Chem. **69**, 1413 (1991).

Les spectres d'absorption UV de la 7-diéthylamino-4-méthylcoumarine (C1) et de son analogue rigide C102, dans lequel on bloque la rotation du groups 7-amino, on été déterminé en solution dans l'acétate de *n*-butyle contenant des concentrations submolaires d'alcool *n*-butylique; ils montrent une faible complexation alcool–colorant dans un rapport de 2:1. Ces résultats contrastent avec ceux obtenus à partir des mesures de fluorescence qui révèlent la présence d'un complexe de l'état excité alcool–colorant 1:1 pour le colorant C1. Ces résultats combinés à une émission spontanée amplifiée provoquée par un laser au N_2 (ASE) et à des mesures d'amplification par un laser sur les composés C1 et C102 dans le *n*-BuOAc avec l'alcool ou l'acétonitrile comme co-solvant montrent que l'émission spontanée double obtenue à partir du composé C1 provient d'une concentration à l'état de quasi-équilibre de liaisons hydrogènes ou de complexes à l'état excité solvatés par l'acétonitrile. Les résultats sont imcompatibles avec l'existence d'un exciplexe TICT–*n*BuoAc dans le nBuOAc. On peut synthoniser l'amplification par un laser des deux pics à 420 et à 455 nm du composé C1, en ajoutant des petites quantités de co-solvant hydroxylé au nBuOAc sec. On a trouvé que l'émission spontanée induite par un laser au N_2 (ASE) est une sonde sélective pour les complexes liés par des liaisons hydrogènes dont la fluorescence est normalement cachée par celle du colorant "libre".

Mots clés: Aminocoumarines, émission spontanée doublement amplifiée, complexe lié par des liaisons hydrogènes dans l'état excité, amplification au laser.

[Traduit par la rédaction]

Introduction

Unlike the model *p*-*N*,*N*-dimethylaminobenzonitrile system, which exhibits *dual* internal charge transfer (ICT) emissions from the planar and the perpendicularly twisted ICT (TICT) R_2N—Ph conformations (1, 2), the important bichromophoric fluorescent 7-diethylamino-4-methylcoumarin (C1) laser dye exhibits only a *single* fluorescence band with near-TICT solvatochromic properties (3, 4). Since the cross section $\sigma_E(\lambda)$ for amplified spontaneous emission (ASE) is related to the fluorescence profile $F(\lambda)$ (5), a *single* ASE band is expected. Surprisingly, *dual* ASE ascribed to a planar and a TICT form has been reported for C1 in moderately polar solvents such as *n*-butyl acetate (*n*BuOAc), ethers, and chloroalkanes (6). The TICT form is believed to exist as a TICT–solvent exciplex (stabilized by specific interaction with the solvent O or Cl heteroatom) at laser-excited transitory concentrations that relaxes back to the planar form (6). However, recent excited state absorption (ESA) studies on C1 and the rigidized analogue, C102 (2,3,5,6-1*H*, 4*H*-tetrahydro-8-methylquinolazino[9,9*a*,1-*gh*]coumarin) failed to reveal a unique ESA absorption due to the TICT form (7). In view of the fundamental importance of the TICT state in the photophysics of bichromofluorophores (1, 2), the unexpected implication of a large σ_E for the TICT exciplex, and the possible modification of the laser gain profile of the aminocoumarins, we now report uv absorption, fluorescence, and ASE results on C1 and C102 as part of our study of conformationally sensitive excited states.

Experimental section

ASE studies used a 50 μJ PRA LN100 N_2 laser for transverse excitation (7*d*, 8) (2″ focal length quartz cylindrical lens) of a dye solution contained in an upright 1 cm rectangular 4-window fluorescence quartz cell, and a JY HR 320 monochromator and a silicon diode array/OMA (EG&G 1412F/1461) system for detection of the emission. The transverse excitation geometry has been previously described (8). Briefly it consisted of a laser excitation beam which is at right angle to the axis passing through the cell and the centre of the monochromator slits. The line image formed by focussing the N_2 laser excitation beam with a cyclindrical lens defines the ASE gain region which is coaxial with the axis passing through the cell and the centre of the monochromator slits. The length of the line image was controlled by a pair of slits placed near the cell in the excitation beam. The cell

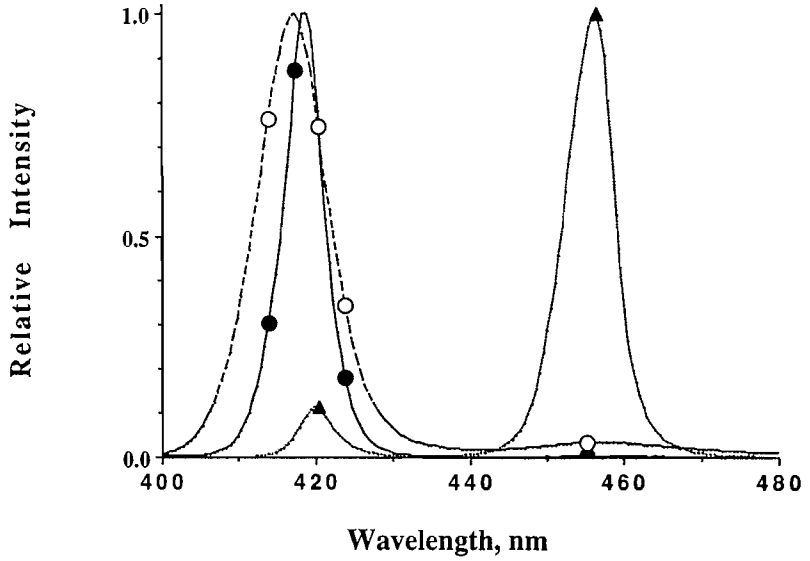

FIG. 1. ASE of C1 O, unpurified *n*BuOAc; OO, dried *n*BuOAc; V, water-saturated *n*BuOAc.

was canted several degrees to avoid feedback from reflection at the parallel cell walls. Digital data from the 1461 detector interface was collected and analyzed using an IBM AT clone connected to the 1461 interface unit via serial interfacing. Typically, the emission from 10 excitation pulses were integrated over 3 min. Appropriate glass neutral density filters were used to keep the signal counts below the maximum limit of ca. 15 000 counts. At a detector temperature of −15°C, the background over this period was < 10 counts and was subtracted from the signal. The wavelength of the monochromator-OMA system was calibrated with an Ultra-Violet Products Inc. Hg and Kr Pen-Ray lamp. Solvents (Caledon distilled in glass) and nBuOAc (Fisher reagent) were refluxed over CaH_2 for 1 h and distilled. The C1 and C102 (Exciton Corp.) were recrystallized from methanol–water and sublimed. Absorption and fluorescence spectra were measured with a Cary-2200 uv/vis spectrophotometer and a Perkin-Elmer MPF-44 spectrofluorimeter, respectively.

Results and discussion

The ASE spectrum of C1 but not the rigidized C102 in unpurified *n*BuOAc showed two bands at 420 and 455 nm, consistent with previous observations (6). However, further investigations of C1 in dried *n*BuOAc (or THF) revealed a single ASE band at 420 nm, with only a trace of the 455 nm band; and conversely in water-saturated *n*BuOAc solution. These results (Fig. 1) show conclusively that the dual ASE 455 nm band from C1 in *n*BuOAc originates from traces of water probably *H*-bonded (6*d*, 9) to the excited C1 dye and not from a TICT–solvent exciplex (6*a-c*).

The role of hydrogen bonding in the dual ASE of C1 in *n*BuOAc was investigated by adding submolar concentrations of methanol or *n*-butyl alcohol (*n*BuOH). Figure 2*a* shows that the *proportion* of the long to short wavelength bands was altered by the addition of methanol. In contrast, the ASE spectra from C102 showed the normally observed continuous shift in the wavelength *position* of the single peak with increasing alcohol concentration. Though less dramatic, dual ASE was also observed for C1 in *n*BuOAc + dried acetonitrile (AN) as co-solvent (Fig. 2*b*). This unanticipated result seem to suggest that high dielectric constant solvents like AN can also participate in complexing with the highly dipolar excited state of C1. At high or neat concentrations of methanol (or *n*BuOH), structure, due possibly to specific alcohol self-associated complexes

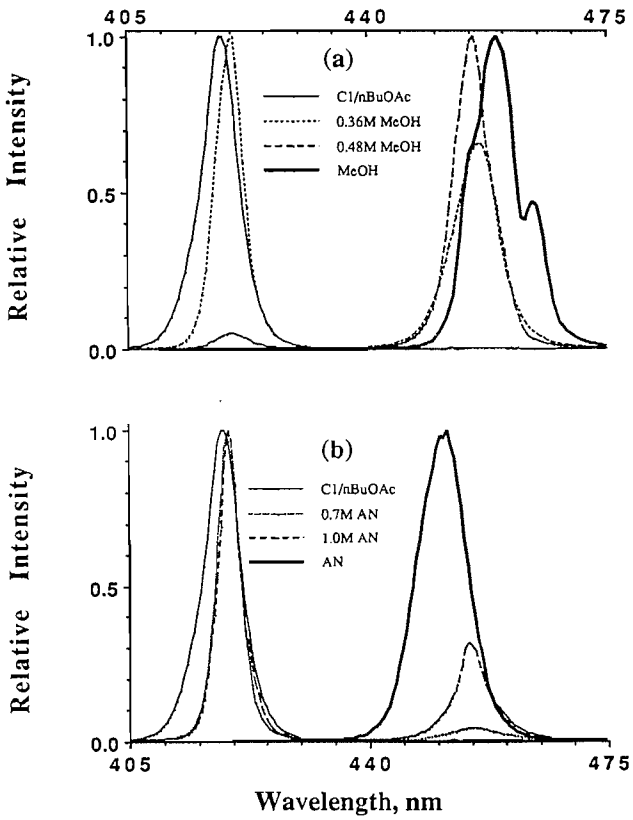

FIG. 2. ASE of C1 in (*a*) *n*BuOAc + methanol; (*b*) *n*BuOAc + acetonitrile.

with C1, can be observed reproducibly in the long-wavelength C1 ASE band. Should this suggestion be substantiated by future experiments, ASE would then be a powerful technique to study alcohol self-association (10) in solution, since, as far as we are aware, there is no method of direct measurement in solution at ambient temperature of specific signals due to particular associated species of alcohol, although important indirect information can be gained from thermodynamic (10*a*, *b*) and other methods (10*c*, *d*).

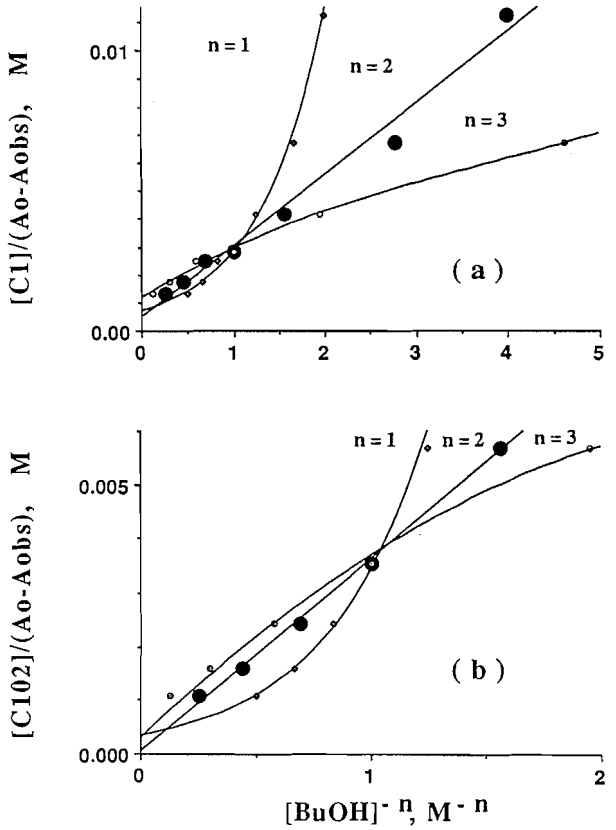

FIG. 3. Plot of $[dye]/(A_0 - A_{obs})$ vs. $[BuOH]^{-n}$ for (*a*) C1 and (*b*) C102 coumarin dyes. Solid points represent the experimental data for $n = 2$. $[Dye] = 3.98 \times 10^{-5}$ M; $[BuOH] \approx 0 - 2$ M.

The uv absorption of C1 (and C102) in *n*BuOAc + *n*BuOH was studied to determine whether, as was in the case of 1-methylindole and *n*BuOH (11), ground state complexation was solely responsible for the fluorescence properties. The uv absorption spectra of C1 and C102 in *n*BuOAc with different concentrations of *n*BuOH showed isosbestic wavelengths λ_{iso}^{ab} at 369 and 378 nm, respectively, which show that the dyes form complexes with alcohol. For the equilibrium:

$$D + n\text{ROH} = D..n\text{ROH}$$

the corresponding absorbance A_{obs}, from both the free and complexed dye as a function of [ROH], is

$$[1] \quad [D]_0/(A_0 - A_{obs}) = [(\epsilon - \epsilon_{cx})L]^{-1}(1 + K_{gs}^{-1}[ROH]^{-n})$$

where ϵ and ϵ_{cx} are the extinction coefficients of the "free" and complexed dye D, and A_0 is the absorbance and $[D]_0$ is the dye concentration at [ROH] = 0. This equation follows from the definition of the equilibrium for formation of a dye–alcohol complex, in which the free dye concentration is expressed as a difference in concentration between the initial dye concentration and the concentration of complexed dye, *i.e.*., $[D]_0 - [D_{cx}]$; and replacing the free and complexed dye concentrations by their optical absorbances. Figure 3*a* shows the fit to the data for C1 and Fig. 3*b* for C102 to eq. [1] for different values of *n*, the number of alcohol molecules complexed with each dye molecule. The data clearly show a best fit for $n = 2$ (D..2(*n*BuOH), D = C1 or C102) for both coumarin dyes. From the above plot we obtained $K_{gs} = 0.19 \pm 0.03$ (C1) and 0.016 ± 0.003 M^{-2} (C102), which shows that C102 is only weakly complexed to alcohol in the ground state. C1 shows small non-negligible extent of complexation with alcohol in the ground state.

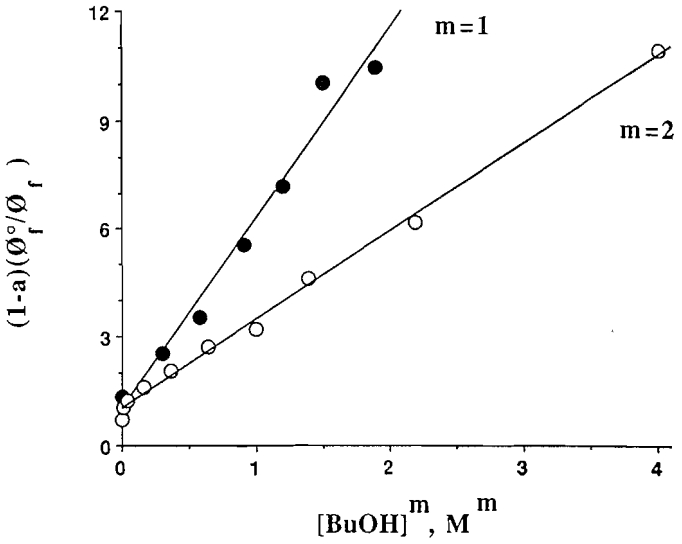

FIG. 4. Plot of $(1 - a)(\Phi_f^0/\Phi_f)$ vs. $[BuOH]^m$. Solid circles are data for C1 with $m = 1$ and open circles are data for C102 with $m = 2$. $[Dye] = 3.98 \times 10^{-5}$ M; [BuOH] = 0–2 M.

The fluorescence spectra of C1 and C102 in *n*BuOAc with different amounts of added *n*BuOH showed a distinct isosbestic wavelength for C1 (λ_{iso}^{fl} at 425 nm) but not for C102. The results suggest that with C1 but not C102, an equilibrium exists between the excited state dye and its alcohol complex. This would explain the presence of only one ASE band for C102. To assess the relative contribution of ground and excited state dye interaction in the alcohol to the fluorescence quenching by alcohol, the Stern–Volmer constant for fluorescence quenching of the "free" excited state dye by alcohol was determined by calculating the fraction of the total *absorbed light* and *fluorescence intensity* due to the free dye. The analysis was facilitated by exciting the dyes at their *absorption* λ_{iso}^{ab} and keeping the dye concentration constant. Under these conditions, the intensity of light absorbed by the system is independent of the alcohol concentration and remains constant. Knowing the ground state equilibrium constant, the fraction of the total light absorbed by the free dye can be calculated from the equation

$$[2] \quad a = (K_{gs}[ROH]^n)/(1 + K_{gs}[ROH]^n)$$

The fluorescence quantum yield ratio for the *uncomplexed* excited state dye, Φ_f/Φ_f^0, where $\Phi_f = \Phi_f^0$ at [ROH] = 0, can be obtained from the measured total fluorescence intensity ratios I/I^0, where I and I^0 are the intensities in the presence and absence of [ROH]:

$$[3] \quad I/I^0 = \Phi_f/\Phi_f^0 + \beta(\lambda)\Phi_{cx}/\Phi_{cx}^0$$

where $\beta(\lambda) = I_{cx}^{\infty}/I_f^0$ and I_{cx}^{∞} = intensity when the solvent has been completely replaced by the ROH, and I_f^0 = intensity for [ROH] = 0. From Φ_f/Φ_f^0 as a function of [ROH], K_{sv} can be obtained from

$$[4] \quad \Phi_f/\Phi_f^0 = (1 - a)/(1 + K_{sv}[ROH]^m)$$

The data from C1 and *n*BuOH (Fig. 4) displayed a good fit

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

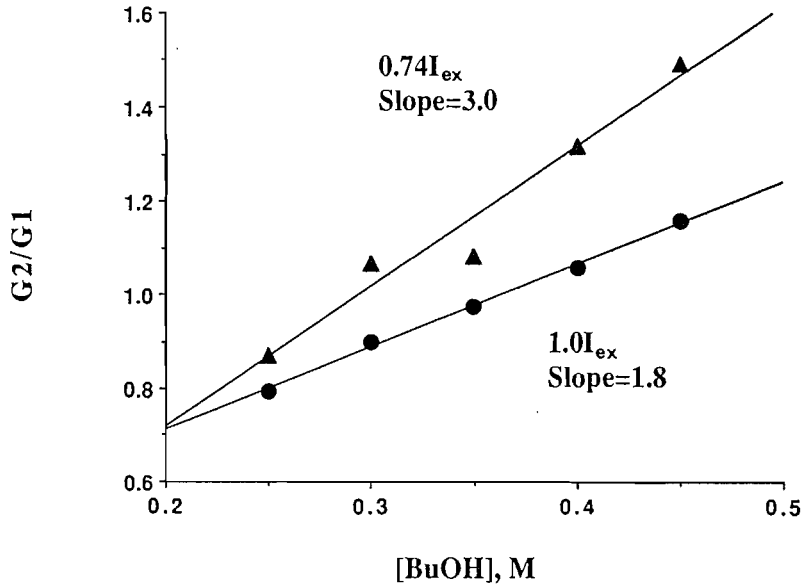

FIG. 5. Ratio of gains at 455 and 420 nm, G(455 nm)/G(420 nm) vs. [BuOH] for C1 in *n*BuOAc at two relative intensities.

to equation [4] with $m = 1$ and $K_{sv} = 5.3 \pm 0.8$ M^{-1}, which implies detachment of one alcohol molecules upon excitation of the complex, consistent with a large dipole change (*i.e.*, a highly dipolar C1*) and rupture of a H...N bond in C1*. The fluorescence results taken together with those from absorption show that *the principal quenching process by alcohol is dynamic quenching of the excited state dye* and not that due to ground state complexation.

The data presented thus far suggest that in the presence of a hydroxylic component such as alcohol, excited C1 and its hydrogen-bonded complex are in equilibrium:

$$C1^* + HOR = [C1..HOR]^*$$

and that the two ASE bands (at 420 and 455 nm) are due to free and complexed dye molecules. If this is correct, then the ratio of the gain factors for the two ASE bands, G(455 nm)/G(420 nm) should be linearly dependent on the alcohol concentration, and an excited equilibrium constant extracted from the data should be considerably larger than that associated with the ground state equilibrium. Neglecting absorption losses (7), the laser gain G is given by

$$[5] \quad G(\lambda) = \sigma_E(\lambda)N(\lambda)$$

where σ_E is the stimulated emission cross section (6), and N is the population of the fluorescing state. Thus the quantity σ(455 nm)N(455 nm)/σ(420 nm)N(420 nm) for the two ASE bands can be determined by measuring their laser gains (8).

The ASE gain of the C1 dye was determined by changing the gain length of a transversely excited of dye solution cell according to a method previously described (8). Using the same experimental arrangement as that used in determining the ASE spectra, the focussed line excitation image on the cell was masked so that the excitation length (the gain region) can be altered between L and $2L/3$ to give ASE intensities I_L and $I_{2L/3}$. The gain $G(\lambda)$ in this case is given by:

$$[6] \quad G(\lambda) = (3/L \ln \{\tfrac{1}{2}((R-1) + [(R-1)^2 + 4(R-1)]^{1/2})\}$$

where $R = I_L(\lambda)/I_{2L/3}(\lambda)$. By measuring R, and knowing L, the gain G can be calculated. A concentration of 7.4 mM of C1 dye in *n*BuOAc was used in the measurements.

The results (Fig. 5) for the two threshold- and maximum-limited relative excitation intensities (I_{ex}) show linear G(455 nm)/G(420 nm) — (*n*BuOH] plots and a smaller slope at the *higher laser intensity, i.e.*, a *lower* gain for the 455 nm ASE band. These results are in harmony with our model in which we expect (*a*) a linear dependance of G(455 nm)/G(420 nm) on [*n*BuOH]; and (*b*) a decreased population of the complexed species at the higher intensity, since it is well known that at high laser intensities incomplete equilibration occurs because of a decrease in lifetime of the initially formed species (12). The previous explanation for the long-wavelength ASE band (455 nm in *n*BuOAC) — that due to an enhanced transitory TICT-exciplex populations (6*a*) — implies a higher population at high I_{ex}, contrary to our results. We can also crudely estimate[5] the extrapolated zero-excitation intensity slope and hence K_{es} from

$$[7] \quad G(455 \text{ nm})/G(420 \text{ nm}) \approx N(455 \text{ nm})/N(420 \text{ nm}) = K_{es}[ROH]$$

The value of K_{es} (6.4 M^{-1}) from eq. [7] is considerably greater than that corresponding to the ground state equilibrium.

In conclusion, dual ASE from C1 in a polar environment originates from a quasi-excited state equilibrium concentration of H-bonded or acetonitrile-solvated complex. The results are inconsistent with a planar ICT and an evanescent laser-excited population of TICT–*n*BuOAc exciplex as an explanation for the previously reported dual ASE from C1 in *n*BuOAc. The present results and those from parallel ESA studies (7) of C1 in *n*BuOAc indicate a single non-90° conformational (with respect to the ring C—N bond) excited state species which is significantly more polar than that of C102. Of significance in the use of coumarin dyes in laser applications is the sensitive dependence of the ASE profile from C1 in dried *n*BuOAc on

[5]Assuming similar σ_E for the 422 and 455 nm bands. Difference in the σ_E (ref. 5) due to the factors λ^4, τ_f, and Φ_f is estimated to be <10%.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

the concentration of hydroxylic co-solvent. This suggests that the lasing profile can be tuned by adding a small quantity of alcohol. In addition, this sensitive ASE dependence on hydroxylic co-solvents can be used to selectively probe for H-bonded excited-state dye molecules whose normal fluorescence is usually obscured by that from the free C1 dye. The results for the coumarin C1 dye illustrate that the strongly overlapping normal fluorescence bands can be experimentally "deconvolved" into two characteristic ASE bands due to distinct species of a fluorophore. The origin of the structures observed in the ASE of C1 in *n*BOAc at high to neat alcohol concentrations are not known but may be due to solvent structure.

Voltammetric determination of Al(III) with adsorptive preconcentration of the pyrocatechol violet complex

DRAGIC V. VUKOMANOVIC, JOHN A. PAGE,[1] AND GARY W. VANLOON
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6
Received January 11, 1991

DRAGIC V. VUKOMANOVIC, JOHN A. PAGE, and GARY W. VANLOON. Can. J. Chem. **69**, 1418 (1991).

A method is described for the determination of aluminium in aqueous samples by linear scan voltammetry after adsorptive accumulation of the pyrocatechol violet (PCV) complex. A pH 6.5 triethanolamine/perchloric acid electrolyte is used for the determination with adsorption onto a mercury drop electrode at −0.50 V (vs a Ag/AgCl/satd KCl reference). Scanning cathodically after adsorption gave a current peak at −0.70 V for reduction of adsorbed PCV and a peak at −0.90 V for reduction of the adsorbed Al–PCV complex. The peaks were well resolved. Using 1.0 μM PCV and a 60 s adsorption period gave linear calibration curves for Al in the range 1 to 25 ng mL^{-1} Al. The detection limit was 0.1 ng mL^{-1} Al. For analysis, calibration by the method of standard additions is required. Most other metal species do not interfere, but vanadium (V(IV) and V(V)) forms a complex with PCV that is adsorbed and reduced at the same potential as Al–PCV. The interference may be eliminated by complexation of the V with citrate. Al and V present together may be determined by analysis in the absence of citrate (total: Al + V) and in the presence of citrate (Al); V is determined as the difference in the two values.

The analysis of a range of samples with Al concentrations from 6 ng mL^{-1} to 3 μg mL^{-1} gave results which were in good agreement with those obtained by other methods.

Key words: aluminium, pyrocatechol violet, adsorption, voltammetry, environmental.

DRAGIC V. VUKOMANOVIC, JOHN A. PAGE et GARY W. VANLOON. Can. J. Chem. **69**, 1418 (1991).

On décrit une méthod de détermination de l'aluminium en solutions aqueuses par voltamétrie à balayage linéaire après une accumulation de l'adsorption du complexe violet de pyrocathécol (PCV). On utilise un électrolyte de type triéthanolamine/acide perchlorique à un pH de 6,5 pour effectuer cette détermination avec adsorption sur une électrode à goutte de mercure à −0,50 V (par rapport à une électrode de réference de type Ag/AgCl/KCl saturé). Le balayage de la cathode après l'adsorption donne un pio de courant à −0,70 V pour la réduction du PCV adsorbé et un pio à −0,90 V pour la réduction du complexe Al–PCV adsorbé. Les pice sont bien résolus En utilisant 1,0 μM de PCV avec une période d'adsotion de 60 s on obtient des courbes d'étalonnage linéaires pour le Al avec des concentrations de Al allant de 1 à 25 ng mL^{-1}. La limite de détection est de 0,1 ng mL^{-1}. Il faut utiliser la méthode des additions standards pour l'étalonnage en vue de l'analyse. Cette détermination ne subit pas l'influence de la plupart des autres métaux mais le vanadium V(IV) et le vanadium V(V) forment un complexe avec le PCV qui est adsorbé et réduit au même potentiel qui le complexe Al–PCV. On peut éliminer cette interférence en complexant le vanadium avec le citrate. On peut déterminer par analyse en l'absence de citrate l'aluminium et le vanadium présents (Al + V total) et en présence du citrate on déterminer l'aluminium uniquement. La différence entre ces deux valeurs donne alors le vanadium seul. L'analyse d'un certain nombre d'échantillons contenant des concentrations en aluminium allant de 6 ng mL^{-1} à 3 μg mL^{-1} donne des résultats qui s'accordent très bien avec ceux obtenus par d'autres méthodes.

Mots clés : aluminium, pyrocathécol violet, adsorption, voltamétrie, environmental.

[Traduit par la rédaction]

Introduction

Aluminium analysis at the trace level is of importance because of the possible human and environmental toxic properties of the element. However, direct voltammetric methods for the element are limited by the difficulty of reduction of the Al(III) species and a concurrent reduction of hydrogen ion from aqueous acid solution at a Hg electrode.

While there are no anodic stripping methods (ASV) for Al, adsorptive accumulation followed by a voltammetric measurement of the adsorbed species (AdV) can be used in cases where the metal species itself is not readily determined by ASV. In the usual form of AdV, an excess of a ligand is used to convert the analyte species to a complex that can be adsorbed on the surface of a microelectrode. The adsorption is carried out in such a way that the rate of accumulation on the electrode is proportional to the concentration of the analyte species in the solution. The adsorbed species is then measured, usually by linear scan voltammetry (LSV), with a current peak for oxidation or reduction of the coordinate ligand. Some of the excess free ligand may also be adsorbed and undergo reaction in the LSV step and this must not interfere with the analyte measurement. The method must be calibrated under conditions of use, usually by standard additions of the analyte species. The method was first used for the determination of Ni(II) as the dimethylglyoxime complex (1) and AdV procedures have now been published for some 20 elements with detection limits in the range 0.001 to 1 ng mL^{-1} of the element (2). The method has also been used for the determination of adsorbable organic species (3).

Two AdV methods have been described for Al(III). In one (4), Solochrome Violet RS (SVRS), a di-*o*-hydroxy phenyl azo reagent is used to complex the Al(III). Adsorption on a Hg drop electrode at −0.45 V (vs. Ag/AgCl/satd. KCl) and subsequent LSV gives a current peak at −0.61 V for reduction of the metal complex. Using a pH 4.5 acetate electrolyte and 120 s adsorption from stirred solution, analysis was carried out in the range 0.27 to 11 ng mL^{-1} Al. The estimated detection limit, based on 10 min adsorption, was 0.15 ng mL^{-1}. It was necessary to heat the sample solution to 90°C to ensure quantitative formation of the metal complex. If significant concentrations of Cu(II) and Fe(III) were present in the sample, these interfered in the analysis.

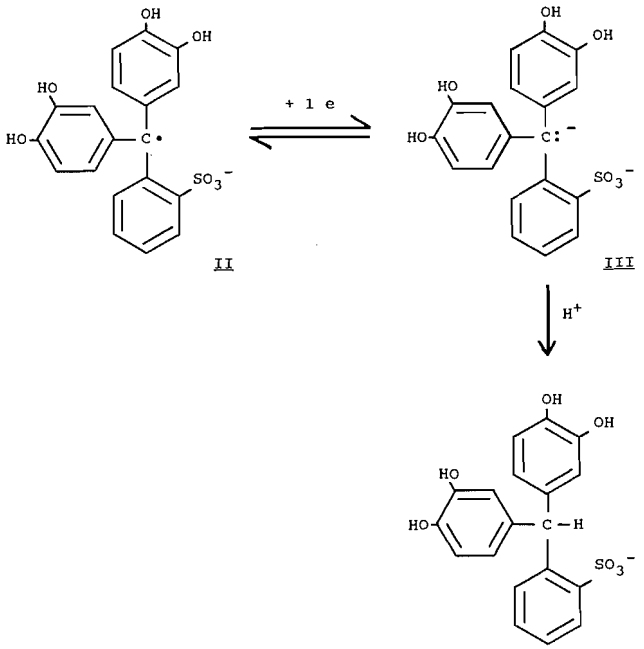

FIG. 1. Structure and ionization of pyrocatechol violet (PCV) — H_4L and H_3L^- forms only.

In the second method (5), 1,2-dihydroxy anthraquinone-3-sulfonic acid (DASA) is used as the ligand. The metal complex adsorbs on a Hg drop electrode at −0.90 V (vs. Ag/AgCl/satd. KCl) and gives a current peak for reduction of the complex near −1.1 V, depending on the electrolyte. The measurement was carried out at pH 7.1 in a buffered electrolyte. The detection limit, based on 45 s adsorption from stirred solution, was 0.03 ng mL^{-1} Al, while the sensitivity was 7 na (ng $mL^{-1})^{-1}$. A serious interference was identified in Zn(II) but this element could be masked by the addition of ethylenediaminetetracetate (EDTA). The method was employed for the analysis of aquatic samples, but surface active organic species were found to interfere.

This paper reports on the use of pyrocatechol violet (PCV: 3,3′,4′-trihydroxyfuchsone-2″-sulfonic acid, H_4L) for the determination of Al(III). The reagent is a member of a class of sulfonephthalein compounds and the structure can be written either as a quinone or as a zwitterion (6, 7) as shown in Fig. 1. The PCV is a strong acid with respect to the ionization of the H_4L, but a weak acid with respect to further ionization. The pK_a values for ionization of the —OH protons in aqueous solution at 25°C are $H_3L^- = 7.8$, $H_2L^{2-} = 9.8$, and $HL^{3-} = 11.7$, respectively (8). The reagent forms complexes with metal ions by coordination through the —OH groups. Complexes with metal ions coordinated to both catechol rings of the PCV have been reported as well as complexes with a single metal ion coordinated to one, two, and three PCV groups. Reported values (8) for the stepwise coordination of Al(III) to the L^{4-} form of PCV are log $K_1 = 25.1$, log $K_2 = 22.3$, log $K_3 = 20.7$ and an Al_2L_1 complex with log $K_{21} = 24.1$ has also been reported. PCV has been used for the spectrophotometric determination of a number of metal ions (9) and is recommended for the spectrophotometric determination of Al(III) (10–12). A pH of 6.1 to 6.2 is optimal for the determination. The complex is readily formed at room temperature and is stable in neutral solutions. Voltammetric studies of PCV and its metal complexes do not appear to have been reported.

Experimental

A Princeton Applied Research Corporation Model 174A Polarographic Analyzer was employed with a Model 303 Static Mercury Drop Electrode. The voltammograms were recorded using a Hewlett–Packard Model 7004A X–Y recorder. The three electrode system consisted of a 15 mL quartz glass cell with a static Hg electrode, a Pt auxiliary electrode and a Ag/AgCl/satd. aq KCl reference electrode separated from the analytical solution by a Vycor frit bridge. For polarography, a 2 s drop life was employed. The electrolyte was stirred as required using a 0.9 cm Teflon "Spin Fin" driven at a rotation rate of 500 Hz. All potentials reported are relative to the Ag/AgCl reference electrode. The usual AdV experiment involved adsorption for 60 s from stirred solution on a Hg drop (size "M", $A = 0.018$ cm^2) at −0.50 V. The stirring was turned off and after a 10 s pause, the voltammetric measurement was made by scanning the electrode potential from −0.50 to −1.00 V at 0.05 V s^{-1}.

The electrolytes were deaerated with N_2 gas and blanketed with the gas throughout the experiment. The N_2 gas was CANOX "oxygen free" grade purified by passage over hot BASF catalyst (30% by wt. Cu on support material). The sample and cell manipulations were carried out in a laminar flow clean hood with a high efficiency air filter. The glassware was cleaned by soaking in 3 M aq. HNO_3, rinsed with good quality distilled water and conditioned with pure electrolyte before use. Losses of Al(III) were found to be significant with freshly cleaned "active" vessels.

The PCV was a reagent grade chemical supplied by BDH Chemicals. The ^1H NMR spectrum indicated a pure material. For AdV, a stock 0.10 mM PCV solution was prepared by dissolving a weighed amount of the reagent (pure material assumed) in distilled water. The solution was stable for periods exceeding 6 weeks.

The stock Al(III) solution was prepared by dissolution of 2.006 g of Al turnings (99.8%) in 50 mL of 12 M hydrochloric acid and dilution to exactly 2 L with distilled water. A 1.003 μg mL^{-1} Al standard for analytical work was prepared by dilution of the stock solution with a pH 2.0 HCl electrolyte.

The supporting electrolyte solutions were prepared from reagent grade chemicals. The triethanolamine (TEA) was a 97% by wt. reagent. The stock 0.5 M triethanolamine perchlorate electrolyte ((TEAH)(ClO_4) = THX) was made up by addition of 1.0 M aq. TEA to 1.0 M aq. $HClO_4$ to give a pH of 6.5 (near equal volumes). The stock 0.5 M HOAc/0.5 M NaOAc buffer solution was prepared by addition of aq. NaOH to aq. HOAc to give a pH of 4.7. Other buffer systems including BES (*N*,*N*-bis(2-hydroxyethl)-2-aminoethane sulfonic acid), $NH_2OH.HCl$ and HEPES, MES, PIPES, TRIS and BIS-TRIS (13) were also investigated. These systems were prepared from reagent grade chemicals as needed.

Results and discussion

I. Pyrocatechol violet (PCV)

Polarography of a 0.10 mM PCV solution in a 0.020 M THX electrolyte at pH 6.5 gave two reduction steps with $E_{1/2}$ values of −0.70 V and −1.05 V. The limiting current of the first (principal) wave was about 6/7 that of the total limiting current of the two waves. Polarography of Cd(II) in a 0.10 M KCl electrolyte gave a limiting current value ~5% greater than the total limiting current observed for the same molar concentration of PCV, indicating that the overall reduction of the PCV was a two-electron process.

The behaviour is consistent with that observed in an electrochemical study of some closely related species (7, 14). The reduction mechanism proposed in these definitive studies is shown in Fig. 2. In neutral or slightly acidic solutions the PCV will be largely present as a H_3L^- species. This species undergoes protonation to species I which then undergoes a one-electron reduction to a radical species II. The radical can undergo a further one-electron reduction to species III or it

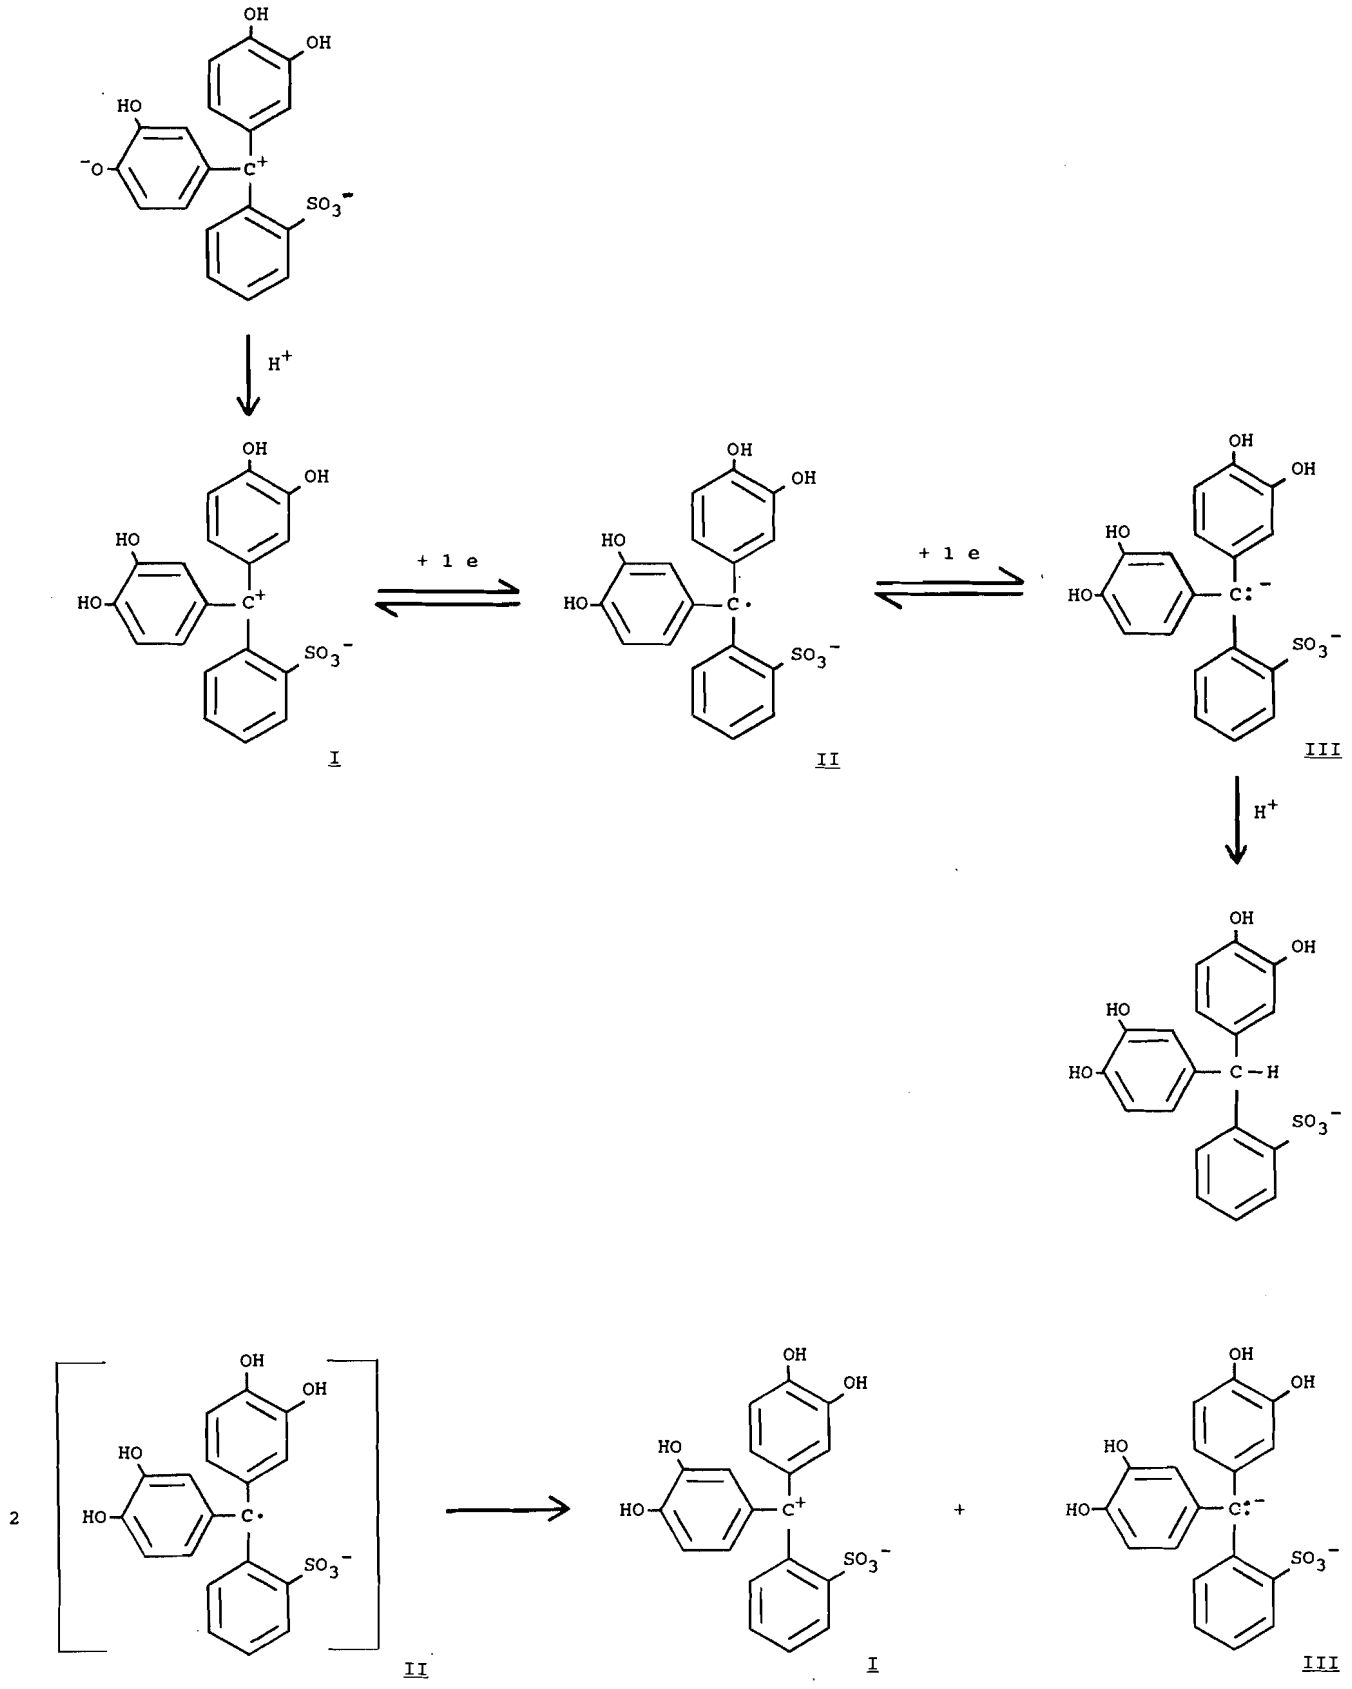

FIG. 2. Reduction mechanism for pyrocatechol violet (PCV) — adapted from that for phenol red (7, 14).

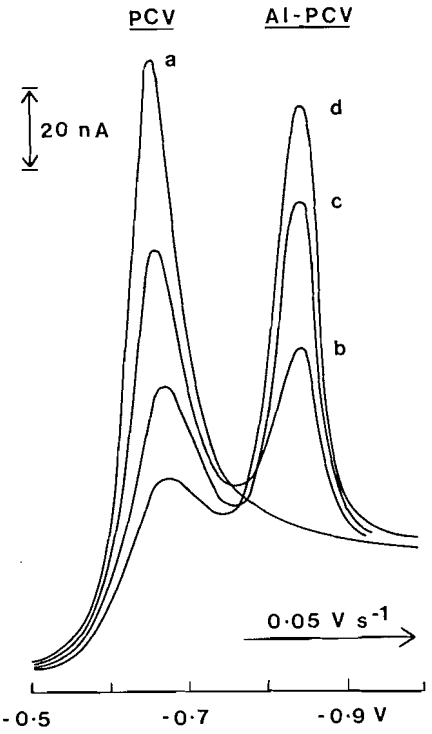

FIG. 3. Reduction of adsorbed PCV and Al–PCV: I vs E; 0.020 M THX electrolyte, pH 6.5, 60 s ads 0.5 μM PCV; *a*: 0, *b*: 5, *c*: 10, *d*: 15 ng mL^{-1} Al(III).

can disproportionate to give III and regenerate I. The stability with respect to disproportionation is dependent upon the substituents present and differs from member to member in a series of sulfonephthaleins. In the final step, species III is protonated to give a stable reduced H_5L^- species. The first polarographic wave observed with PCV represents the formation of III via a one-electron reduction and disproportionation of the intermediate while the second wave represents the formation of III by direct reduction of the intermediate formed in the first step. Controlled potential reduction at potentials on the plateau of either step leads to a two-electron reduction of the PCV.

The behaviour of adsorbed PCV is shown in Fig. 3*a*. The sharply defined cathodic peak is expected for the reduction of a surface layer of adsorbed PCV (15). At pH 6.5, the peak was independent of the adsorption potential over the range 0.00 to −0.50 V and independent of the ionic strength of the THX electrolyte over the range 0.010 to 0.10 M. With increasing electrolyte pH, the peak potential shifted to more negative values as shown in Fig. 4*a* indicating consumption of hydrogen ion in the reduction process. There was a slight increase in the peak current and little change in peak shape with increasing pH. The peak width at half-maximum was ~0.08 V.

The AdV behaviour was dependent on adsorption time as shown in Fig. 5. Initially, the current peak increased as expected for adsorption at a rate dependent upon the PCV concentration, but the peak grew only to a maximum then decreased with time. The maximum was dependent upon the concentration of PCV in the solution. There was no change in peak potential or shape over the range of adsorption times. In other experiments, the PCV was adsorbed from stirred solution for various times, then the electrode was held at the adsorption potential for up to 300 s in an unstirred electrolyte before reduction of the adsorbed material. A negligible additional adsorption of PCV would be expected in the waiting period. The additional residence time of the PCV on the electrode did not affect the PCV peak, indicating that the adsorbed PCV was stable. Extrapolation of the response at low adsorption times indicates that at the higher surface concentrations some of the adsorbed PCV becomes electroinactive. Given the quinoid nature of the PCV, the deactivation may result from a polymerization of the adsorbed species initiated by a radical intermediate in the reduction process.

II. Aluminium(III)/pyrocatechol violet (Al–PCV)

The combining ratio of Al with PCV in the THX electrolyte at pH 6.5 was determined spectrophotometrically. The total PCV concentration was maintained at 0.05 mM and Al(III) was added to excess. The PCV absorption (λ_{max} 444 nm) decreased while that of the Al–PCV (λ_{max} 596 nm) grew with a well-defined isosbestic point at 515 nm. Under these conditions, the mole ratio of Al and PCV in the complex was 1:1 as determined from the changes in the peak absorbance of either the PCV or the Al–PCV.

Direct current polarography of 0.10 mM PCV/0.056 mM Al(III) in a 0.050 M THX electrolyte at pH 6.5 gave two reduction waves with $E_{1/2}$ values of −0.64 and −1.02 V. The steps were near equal while the total limiting current was equal to that for the same concentration of free PCV. Increasing the Al(III) concentration resulted in a decrease in the first step and a growth in the second step, with the total limiting current constant. The first wave results from the reduction of free PCV, while the second represents the reduction of complexed PCV, both presumably by an overall two-electron process.

The AdV behaviour of Al–PCV is shown in Fig. 3*b*, *c*, *d*. The adsorbed Al–PCV was more difficult to reduce than adsorbed PCV but both current peaks were well defined. Addition of Al(III) to the PCV solution resulted in a decrease in the AdV peak for PCV and an increase in the Al–PCV peak. The reaction between the PCV and Al(III) was rapid. The peak height data shown in Fig. 6 indicates a 1:1 mole combining ratio and similar adsorption and reduction processes for free and complexed PCV.

The AdV peak current for Al–PCV increased linearly with scan rate over the range 0.02 to 0.5 V s^{-1}. Triangular wave voltammetry gave no evidence of anodic processes corresponding to oxidation of the products of reduction. The peak potential for reduction of the absorbed complex shifted to more negative values with increasing pH as shown in Fig. 4*b*. The separation of the peak potentials for PCV and Al–PCV was a maximum near pH 6.5 The Al–PCV peak from a given concentration of added Al(III) was a maximum at pH 6.5 as shown in Fig. 7. The decrease at high pH may result from partial hydrolysis of the added Al(III) while that at low pH may be due to an incomplete reaction of the Al(III) with PCV. At pH 6.5, increasing the concentration of the THX electrolyte resulted in a slight decrease in the Al–PCV peak current.

The AdV peaks for PCV and Al–PCV were dependent upon the adsorption time as shown in Fig. 8. With a fixed PCV concentration, the Al–PCV peak grew with time to a limiting value dependent upon the Al(III) concentration. At short times there was a peak for reduction of adsorbed PCV but this peak grew to a maximum and then decreased with adsorption time.

The AdV peak corresponding to surface saturation with Al–

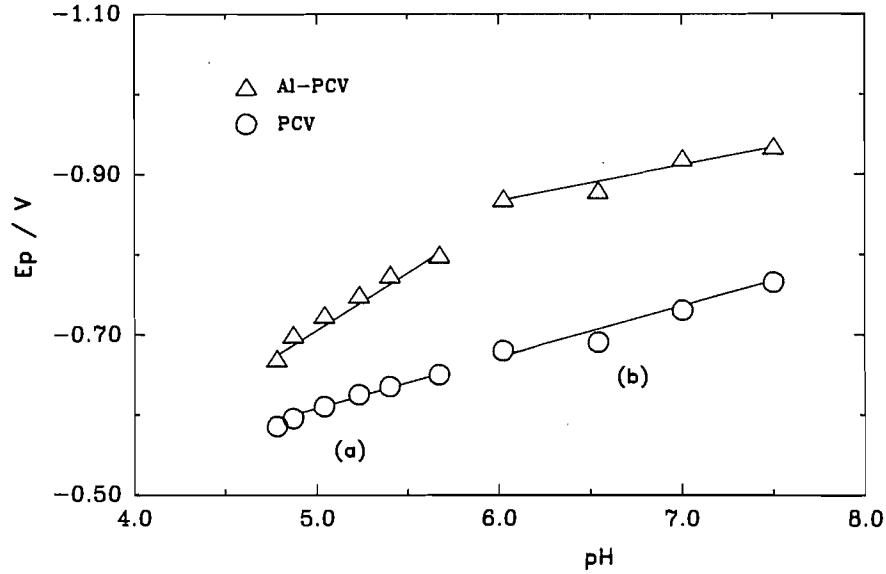

FIG. 4. Reduction of adsorbed PCV and Al–PCV: E_p vs pH; (*a*) acetate and (*b*) THX electrolytes, 60 s ads, v = 0.05 V s^{-1} 0.5 μM PCV/10 ng mL^{-1} Al(III).

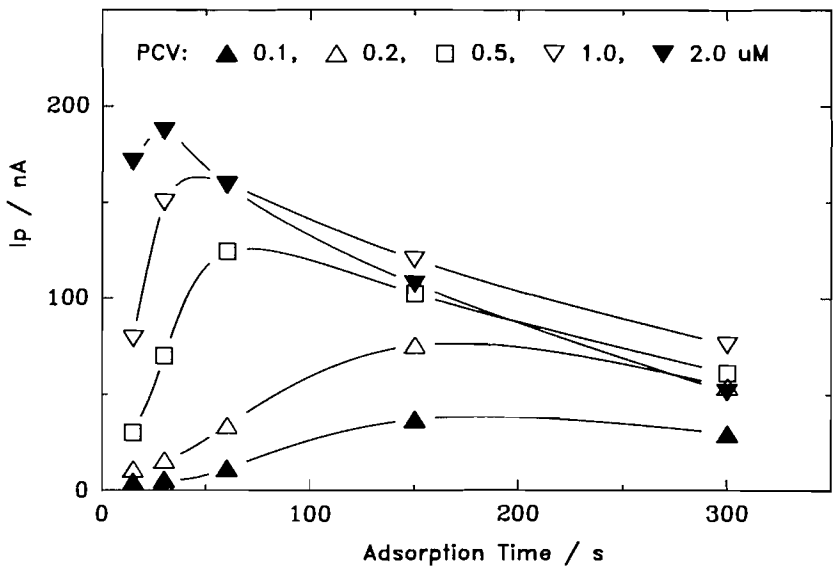

FIG. 5. Reduction of adsorbed PCV: I_p vs adsorption time; 0.020 M THX electrolyte, pH 6.5, 60 s ads, v = 0.05 V s^{-1}.

PCV was a function of the electrolyte composition. In the case of a 4.0 μM PCV/3.0 μM Al(III) solution, the peak for the Al–PCV reduction limited at 295 nA and 0.56 μC with a scan rate of 0.05 V s^{-1}. Assuming a two-electron reduction, this gives 1.8×10^{12} molecules of Al–PCV on the 0.018 cm^2 Hg drop (1.04 nm^2 per Al–PCV). The area is near that calculated for surface saturation with other metal complexes in AdV (1).

III. pH

While pH 6.5 is optimal with good resolution of the PCV and Al–PCV peaks and good sensitivity with respect to added Al(III), the buffer capacity of the THX is minimal at this pH (pK_a $TEAH^+$ = 7.8). Experiments using other buffered electrolytes were carried out to investigate the effect of buffer capacity. At pH 6.5, PIPES (pK_a = 6.8), MES (pK_a = 6.2), TRIS (pK_a = 8.1), and $NH_2OH.HCl$ (pK_a = 6.0) electrolytes gave peak resolution and sensitivity approaching that of the THX, while BES (pK_a = 7.2), BIS-TRIS (pK_a = 6.8), and HEPES (pK_a = 7.6) electrolytes gave poor resolution of the PCV and Al–PCV reduction peaks. In no case did the increased buffer capacity of the solution produce better defined or separated peaks for the reduction of the adsorbed species.

Aluminium analysis

For analysis of aqueous samples in the range 3 to 10 ng mL^{-1} Al, a pH 6.5 electrolyte, 0.020 M in THX with 1.0 μM added PCV is recommended. The pH adjustment should be made by dropwise addition of 0.05 and 0.01 M aq. $HClO_4$ or TEA solutions to the sample as required. Samples with high Al(III) concentrations should be diluted before pH adjustment to bring them within the recommended concentration range. Care should be taken to avoid local excesses of base that might produce irreversible hydrolysis of the Al(III). The pH adjustment is followed by the addition of 400 μL of 0.5

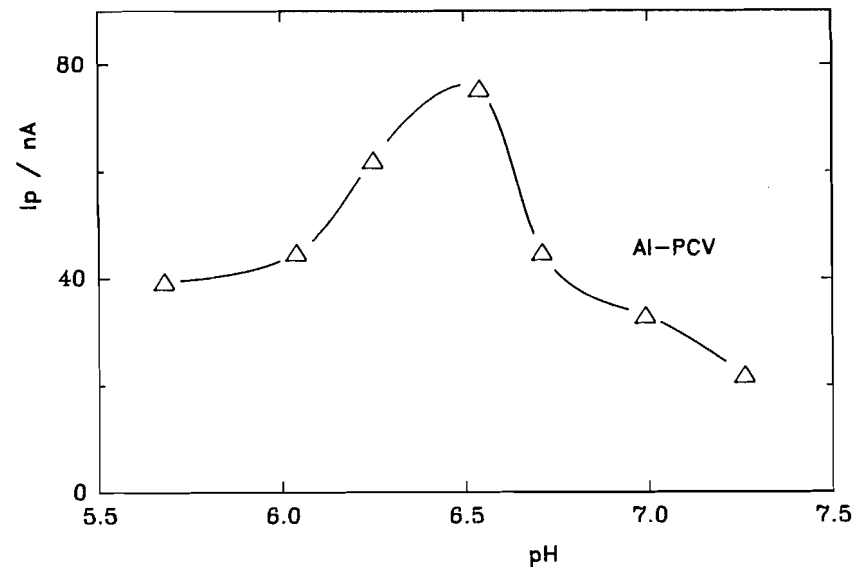

FIG. 7. Reduction of adsorbed Al–PCV: I_p vs. pH; 0.020 M THX electrolyte, 60 s ads, $\nu = 0.05$ V s^{-1}, 0.5 μM PCV/10 ng mL^{-1} Al(III).

M THX (pH = 6.5) and 100 μL of 100 μM PCV solution per 10 mL of electrolyte. The final pH should be in the range 6.0–7.0.

The AdV should be carried out as described in the Experimental section with the Al–PCV peak measured from an estimated baseline. Calibration of the method should be by standard additions of Al(III). Three standard additions with a single AdV measurement after each addition are recommended. The total concentration of Al(III) after the additions should not exceed 20 ng mL^{-1}.

In the absence of interferences, the conditions give an amount of PCV in the sample in excess of the Al(III). If species such as Cu(II) and Pb(II) that coordinate with the ligand are present, the amount of added PCV must be increased. A peak for PCV must persist through the analysis and standard additions of Al(III). The 60 s adsorption gives a low fractional surface coverage of the electrode with adsorbed species. The recommended pH gives a good separation of the peaks for PCV and Al–PCV.

Using standards prepared from the standard Al(III) solution, the method gave a linear calibration curve over the range 1 to 20 ng mL^{-1} Al. The slope of the calibration line (sensitivity) was 10 nA (ng mL^{-1})$^{-1}$. The detection limit (DL) was estimated by analyses of a 3 ng mL^{-1} Al standard. The standard deviation of the signal for 10 replicate analyses was ±0.30 nA, giving a detection limit of 0.10 ng mL^{-1} based on a protection factor of 3 (16). For samples with low Al(III) concentrations (<1 ng mL^{-1}), the PCV concentration may be reduced and the adsorption time increased to enhance the Al–PCV signal.

Interferences

A number of metal ions were tested for interference in the

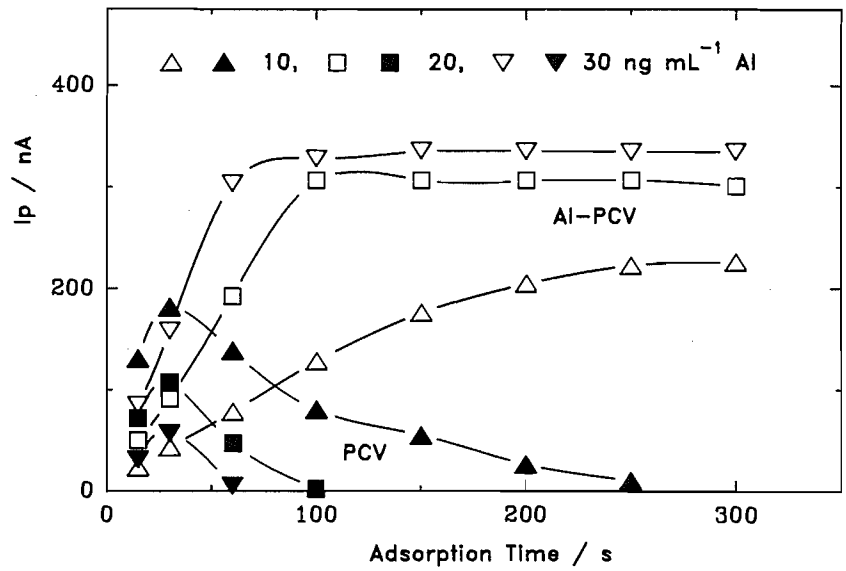

FIG. 8. Reduction of adsorbed PCV and Al–PCV: I_p vs. adsorption time; 0.020 M THX electrolyte, pH 6.5, 60 s ads, v = 0.05 V s^{-1}, 4.0 μM PCV with added Al(III).

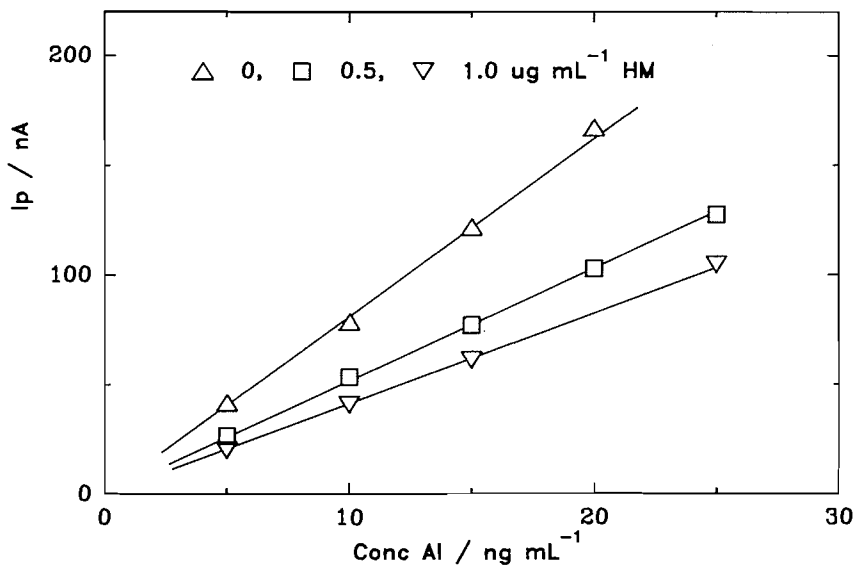

FIG. 9. Adsorption and reduction of Al–PCV: I_p vs. conc. Al(III), 0.020 M THX electrolyte, pH 6.5, 60 s ads, v = 0.05 V s^{-1}, 1.0 μM PCV with added humic material.

determination using a 1.0 μM PCV electrolyte with 10 ng mL^{-1} added Al(III), with addition of various metal ions.

Of the species tested, Ag(I), Cd(II), Co(II), Fe(III), Hg(II), Mn(II), Mo(VI), Ni(II), Pb(II), Sn(II), and Zn(II) did not interfere at concentrations up to 0.2 μg mL^{-1}. The addition of Cr(III), Th(IV), and Ti(III) produced small shifts in the baseline but did not otherwise interfere at concentrations up to 0.2 μg mL^{-1}. The addition of Ga(III), In(III), Sn(II), and U(VI) gave peaks overlapping those for PCV and Al–PCV but the sensitivity was low and interference significant only when their concentrations were greater than 0.01, 0.13, 0.2, and 0.02 μg mL^{-1}, respectively, representing unusually high levels for aqueous environmental samples. The addition of Cr(VI) produced an interfering peak at −0.90 V, but Cr(III) did not interfere at concentrations up to 0.2 μg mL^{-1}. Reduction of the Cr(VI) by the addition of $NH_2OH.HCl$ (200 μg mL^{-1} sample) removed the interference.

Added Cu(II) and Pb(II) were found to form metal complexes that could be adsorbed and reduced. Adsorption at −0.05 V gave peaks for reduction of adsorbed Cu–PCV at −0.21 V, Pb–PCV at −0.47 V, PCV at −0.70 V and Al–PCV at −0.90 V, suggesting simultaneous analysis. The Cu–PCV and Pb–PCV were more readily reduced than PCV itself indicating reduction of the metal centre of the absorbed complex. With 60 s adsorption, the sensitivity for Cu, Pb, and Al was 10, 3, and 10 nA (ng mL^{-1})$^{-1}$, respectively. In the determination of Al(III) with adsorption at −0.50 V, Cu–PCV and Pb–PCV species would be adsorbed and simultaneously reduced and would not interfere in the determination, provided the PCV was sufficient for complexation of all species.

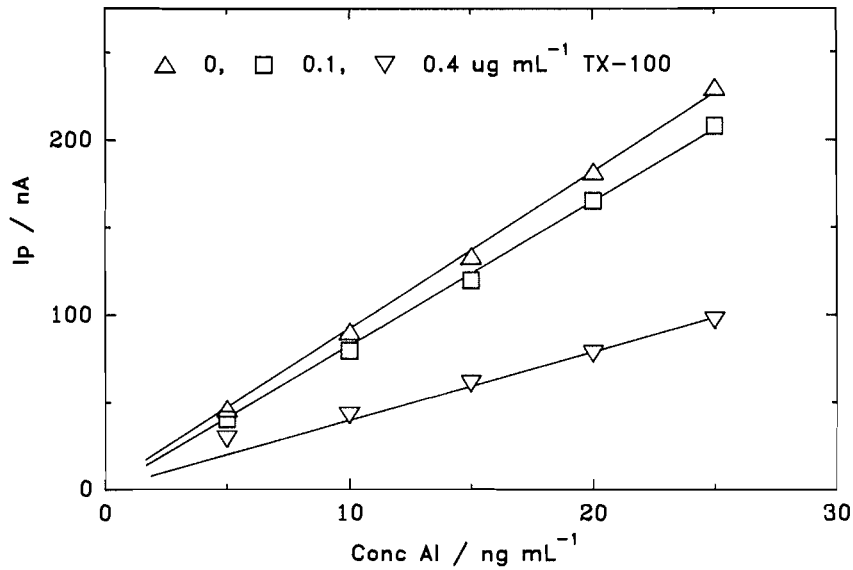

FIG. 10. Adsorption and reduction of Al–PCV: I_p vs. conc. Al(III), 0.020 M THX electrolyte, pH 6.5, 60 s ads, v = 0.05 V s^{-1} 1.0 μM PCV with added Triton X-100.

Both V(IV) and V(V) were found to give a well-defined peak with PCV at the same peak potential as that for reduction of adsorbed Al–PCV. In the absence of Al(III), the peak was suitable for V analysis. Using a 60 s adsorption, the sensitivity for V was 4 nA (ng mL^{-1})$^{-1}$.

The method was also tested for interference from various anionic species. The testing was performed using a 1.0 μM PCV solution with 10 ng mL^{-1} added Al(III), with the anions added as solutions of their Na salts.

The addition of Cl^-, SO_4^{2-}, and PO_4^{3-} at concentrations up to 2 μg mL^{-1} did not alter the response with respect to Al. The addition of F^-, oxalate, and tartrate decreased the sensitivity without shifting the potential of the PCV and Al–PCV reduction peaks. Additions of Al(III) in the presence of up to 2 μg mL^{-1} of each of these (six) species gave linear calibration curves indicating analysis was possible by the method of standard additions. With citrate, there was no peak for Al–PCV in the presence of 1 μg mL^{-1} of the anion and it appeared that complexation of the Al(III) prevented the formation of the PCV complex. The AdV peak for V–PCV was not affected by citrate. It is possible to determine V(IV) and V(V) without interference from Al(III) in the presence of citrate and stepwise analysis for both elements is also possible. The combined Al–PCV and V–PCV peak is first recorded and standard additions of Al(III) are made. Sodium citrate is then added to the sample (1 mg L^{-1}) to complex the Al(III) and the V-PCV peak recorded. The V-PCV peak is then used to provide the reference value for extrapolation of the standard addition data to give the Al(III) concentration. The concentration of the V species can then be determined using standard additions of a V species in the presence of citrate.

Surface active materials present in the electrolyte are also a potential interference. Figures 9 and 10 show that while a linear calibration can be obtained for Al in the presence of surface active materials, the sensitivity is reduced. On a weight scale the suppressive effect of Triton X-100, a nonionic alkylphenylethoxylate surfactant was greater than that of a natural humic material. Analysis by standard addition calibration would appear to be valid in the presence of the surface active agents.

Analysis

Using the standard procedure, a number of water samples representing a range of electrolytes were analyzed for Al(III) with the results tabulated in Table 1. The tap waters were drawn from the local water supplies while the pore waters were obtained in a soil chemistry study (17). One sample was a St. Lawrence River Water Sample (SLRS-1) certified by the Marine Analytical Chemistry Standards Program of the National Research Council of Canada. The samples were diluted with distilled water before analysis to bring them within the recommended concentration range for analysis.

In each case the analyses were carried out at pH 6.5 with measurements on the sample and on the sample after each of three standard additions. Each measurement was repeated 4 times (4 × 4 = 16 data points per analysis). The confidence interval reported represents the uncertainty in the result derived from extrapolation of the calibration data. Compara-

tive ICP-MS data obtained on the samples was generally in good agreement with the AdV results. In the case of Sample #4, a soil pore water of neutral pH, analysis at pH 6.5 after a 200-fold dilution of the sample gave a result which was significantly less than that obtained by the ICP-MS method. When the sample was acidified to pH 2 with HNO_3 before dilution and then analyzed at pH 6.5, the Al(III) concentration value was comparable to that found by ICP-MS. It is known (17) that a substantial portion of the Al(III) in a neutral soil pore water is present in the form of organic complexes and it is possible that the method does not measure Al(III) in these forms. Acidification appears to release the bound Al(III) and it is not taken up on readjustment of the sample pH to 6.5. Advantage could be taken of this irreversible release of Al(III) to measure bound Al(III) in solution. The other pore water samples analyzed were acidic in nature and the results after adjustment to pH 6.5 compared well with the total Al(III) value obtained by ICP-MS.

DOMINIQUE COSTA, BICE FUBINI, ELIO GIAMELLO, and MARCO VOLANTE. Can. J. Chem. **69**, 1427 (1991).

A new type of surface site, different from those previously described, which gives rise to a paramagnetic oxygen species upon adsorption of O_2 at low temperature, has been found at the surface of crystalline quartz. This site is abundant on freshly cleaved surfaces or on chemically etched ones but absent on crystal growth faces or on samples annealed at high temperature. The abundance of this site is not related to the other surface radicals characteristic of the quartz surface originated by mechanical grinding in air. The EPR spectral features of the signal suggest an ozonide type radical O_3^-. The adsorption of oxygen onto quartz dusts variously treated in order to modulate their fibrogenic potential *in vivo* indicates that a relationship may exist between the presence of this site and quartz pathogenicity.

Key words: quartz, oxygen radical species, ozonide, silicosis, EPR.

DOMINIQUE COSTA, BICE FUBINI, ELIO GIAMELLO et MARCO VOLANTE. Can. J. Chem. **69**, 1427 (1991).

On a trouvé à la surface du quartz cristallin un nouveau site de surface, différent de ceux décrits antérieurement, qui conduit à une espèce d'oxygène paramagnétique lors de l'adsorption de l'oxygène à basse température. Ce site se trouve en abondance sur les surfaces fraichement coupées ou sur celles qui sont décapées alors qu'il est absent sur les faces des cristaux en croissance ou sur des échantillons condensés à haute température. L'abondance de ce site n'est pas relié aux radicaux de surface caractéristiques de la surface du quartz travaillée par broyage mécanique dans l'air. Les caractéristiques spectrales du signal en RPE suggèrent un radical du type ozonide O_3^-. L'adsorption de l'oxygène sur de la poussière de quartz, traitée de différentes façons dans le but de moduler leur potentiel fibrogénique *in vivo*, indique qu'il peut exister une relation entre la présence de ce site et la pathonégicité du quartz.

Mots clés : quartz, espèce d'oxygène radicalaire, ozonide, silicose, RPE.

[Traduit par la rédaction]

Introduction

Most crystalline silica polymorphs are toxic to humans when inhaled in particulate forms, as they cause silicosis, the well-known pulmonary fibrosis, that afflicts people exposed to silica dusts for long periods of time (1, 2). In recent years the possible carcinogenicity of quartz has also been under debate (3, 4). The mechanism of action of the silica particle at the molecular level is still unknown, particularly as far as the specific role of the quartz surface is concerned. While the surface chemistry of amorphous silica (non-toxic) has been widely investigated because of its industrial use as high surface area material, few papers (5, 6) have been devoted to the characterisation of the surface of quartz dusts. Among the various surface functionalities which may be regarded as possible initiators of the chain of events ending up in formation of the pneumonoconiotic lesions typical of silicosis, surface radicals should be taken into account. Indeed, such a hypothesis has been recently put forward by some of us and other authors (7–15). Various radical centres are in fact present at the surface of freshly ground and of aged dusts, originated by rupture of the silicon–oxygen bond and subsequent reaction of dangling bonds with atmospheric components. Active oxygen forms, such as silylperoxide, $SiO_2\cdot$ and superoxide O_2^- anions, whose potential toxicity is widely accepted, have been suggested to exist on samples ground in air (8–12). The assignments have been made on the basis of literature data both on bulk (16, 17) and on powdered samples (18–22). It must, however, be pointed out that these paramagnetic species are rather stable with time and mild thermal treatments (9). Moreover, the modifications detected in the EPR spectrum after long standing in aqueous solutions mimicking the biological environment do not seem to indicate that these particular radical species are the only initiators of the pathogenic process (10, 11). It is in fact unlikely that one of these forms alone would trigger the biochemical reactions originating macrophage activation and release of fibroblast stimulating factors. Most probably the action of the quartz surface is due to a complex interplay, during phagocytosis, between different kinds of surface functionalities. Animal experiments have shown (23, 24) that freshly ground dusts are more fibrogenic, or at least provoke lesions in much shorter time, than aged dusts (13). The latter, however, are still fibrogenic even years after standing in air, *e.g.*, DQ 12 or Min-U-Sil, largely used in medical research (F. Pott, private communication, 1990). The primary cause of the overall toxicity, if due to radical species, has thus to be sought in a complex interplay between biological entities (cell membranes, macrophage metabolites) and the various active sites at the dust surface or others originated in a biological medium.

The present paper reports new data on an additional site which is EPR silent but can be evidenced by the formation of a paramagnetic form upon adsorption of molecular oxygen at 77 K. This radical, already reported in a previous paper by some of us (25), occurs similarly to the one reported years ago and assigned to $SiO_3\cdot$ by Radtsig and co-workers on vacuum-ground fused silica (19), but its origin appears unrelated to the formation of the other known radical sites. Several quartz samples, known to exhibit distinct fibrogenic effects, have been examined in the present paper: freshly ground and aged dusts, samples heated *in vacuo*, chemically etched dusts, and micro-

crystals grown in hydrothermal conditions. The effect on the active site of substances capable of inhibiting silicosis (*e.g.*, Al salts, polyvinylpyridine-*N*-oxide ≡ PVPNO) has also been investigated.

Experimental

Materials

(1) Freshly ground pure crystals were obtained from extremely pure *a*-quartz chips (purified by subsequent melting and recrystallization, 99.999%, Atomergic) (9) and from natural Madagascar quartz crystals (a relatively pure natural *a*-quartz). Grinding was performed in an agate ball mill either in a water-free atmosphere or in presence of a substantial water vapour pressure (20 Torr). A dry atmosphere favors the formation of surface radicals, whereas a moist one depresses it (10, 12, 14). The product is not uniform in size, being made up of submicron particles in contact with larger ones (25).

(2) Microcrystals grown in hydrothermal conditions have been prepared at CRSOCI-CNRS Orleans, with the help of Dr. Erre, following a procedure previously described (26).

(3) The typical *SiO_2 aged dust, i.e.* kept standing in air long periods of time (years), was Min-U-Sil 5 *a*-quartz (Pennsylvania Glass Sand Co) with particle size below 5 μm and BET surface area of about 2 m^2 g^{-1}.

Thermal and chemical treatments

(1) Thermally heated samples were prepared either by heating pure quartz dusts in vacuum at 1073 K for 12 h or by heating this material in nitrogen atmosphere at 1573 K for the same period of time. This procedure provides samples with virtually no surface radicals left. The former still bears a substantial amount of silanols and is thus hydrophilic, whereas the latter one is hydrophobic (results to be published).

(2) HF-etched and NaOH-etched quartz samples were obtained by keeping samples ground in moist atmosphere respectively in aqueous solutions of HF (0.1 and 1 M) (from a commercial 40% solution in water, Merck) or of NaOH (0.1 M) for 2 h at 313 K. The samples were then washed several times and dried *in vacuo* at room temperature. In the case of the HF 1 M etching, 35% in weight was lost because of solubilization of SiO_2.

(3) Catechol (1,2-dihydroxybenzene)-etched quartz was obtained by contacting some 80 mg of Madagascar quartz ground in moist atmosphere with 10 mL of a 5×10^{-2} M aqueous solution of catechol (Janssen Chimica) at 313 K then washing it and vacuum-drying at room temperature.

(4) The *PVPNO* treatment was realized by contacting some 80 mg of the quartz powder with a PVPNO solution (50 mg PVPNO in 10 mL water) for 1/2 h and subsequently drying without washing.

(5) The *aluminum* treatment was carried out contacting some 80 mg of Madagascar quartz ground in moist atmosphere with 10 mL of a saturated solution of $NaAlO_2$ in water. The sample was then washed several times in water and dried *in vacuo* at room temperature.

To evaluate separately the effect of modifications due to the basicity of the solution from those induced by the AlO_2^- ion itself, a treatment was also made in a pure NaOH aqueous solution having the same pH (11.4) as the $NaAlO_2$ one.

Electron spin resonance

Electron spin resonance spectra were taken on a Varian E 109 spectrometer operating at X band. The spectra were recorded *in vacuo* at 77 K. These are appropriate conditions for detection of most of the surface paramagnetic species (9).

For the oxygen adsorption experiments, an appropriate EPR cell was employed which allowed the sample to be kept *in vacuo* for long periods of time and also to submit it to treatments with gases. Oxygen adsorption was performed by admitting oxygen onto the sample and then cooling the sample to 77 K. Spectra were recorded either in the presence of the gas or after evacuation at 77 K, in order to leave only the layer irreversibly adsorbed at this temperature.

To enable comparison between spectra arising from different samples, the same sample weight was always employed (some 60 mg); because of different particle size, quantitative comparisons between different kind of samples have to be made on the basis of the respective surface areas. Varian pitch ($g = 2.0029$) was used as reference standard for g value calibration.

Results

Evidence for a weakly bound oxygen paramagnetic form on quartz dusts

Upon contact of quartz dusts with oxygen at 77 K, a paramagnetic adsorbed species is formed, which is detectable by EPR. Figure 1 reports the typical spectrum of a pure quartz dust ground in dry air (*a*), after contact with oxygen and subsequent evacuation at 77 K (*b*), under 25 Torr of oxygen (*c*) and of the standard aged dust (Min-U-Sil), both in vacuum (*d*), and under 25 Torr of oxygen (*e*). The spectra under vacuum have been largely discussed in previous papers (7, 9); they are produced by the cleavage of Si—O—Si bonds during grinding and subsequent reaction with atmospheric components. The final product is mainly $SiO_2\cdot$ (silylperoxide $g_{zz} = 2.064$, $g_{yy} = 2.007$, $g_{xx} = 2.002$) and O_2^- (superoxide anion, $g_{zz} = 2.044$, $g_{yy} = 2.010$, $g_{xx} = 2.002$). A few unreacted Si· radicals (usually called E′ centres) are detectable having the $g_\perp$ component at $g = 2.000$. On Min-U-Sil at 77 K, there are also some sets of lines superimposed onto the major spectrum which are very likely sextets of hyperfine components due to isolated aluminum atoms as impurities in the quartz matrix (27).

Upon contact with O_2 at 77 K, on both solids (spectra *b*, *c*, *e* in Fig. 1) a new sharp line appears at $g = 2.0000 \pm 0.0005$ (indicated hereafter as O_2(ads)) superimposed on the spectrum of Si· in the original spectrum. The intensity of this line is greater on the freshly ground sample than on the aged dust. In spite of the coincidence of the g values, this line arises from a paramagnetic form different from the E′ center. Inspection of the saturation curves (intensity vs. microwave power) of the E′ signal and of the one obtained for O_2(ads) in Fig. 2 in fact reveals two different behaviors. Upon evacuation of the sample at room temperature, the initial spectra (Fig. 1, *a* and *d*) are restored. If the evacuation is carried out at 77 K, a part of the paramagnetic adsorbed species remains at the surface as the signal does not disappear even after prolonged outgassing at 77 K. This is clearly visible with the freshly ground sample, Fig. 1*b*. At 77 K this form is thus stable, even in the absence of oxygen in the gas phase. Figure 3 reports the spectra obtained by subsequently contacting a freshly ground dust with oxygen at increasing pressure. The intensity I of the $g = 2.000$ signal, measured by the peak-to-peak height of the line, increases with the oxygen pressure; the linewidth is unaffected by the presence of oxygen in the gas phase. In the inset a sort of adsorption isotherm is reported, where the relative intensity of the O_2(ads) signal in arbitrary units is reported as a function of the equilibrium pressure. This has been obtained by subtraction, from the overall signal at $g = 2.000$, of the contribution of the E′ center measured before contact with oxygen. Such a behavior of the isotherm (Langmuirian type) is typical of a reversible adsorption process.

It is noteworthy that, upon regrinding of Min-U-Sil and of other aged dusts, the intensity of the adsorbed oxygen signal increases. The centers capable of forming O_2(ads), which hereafter we will call O_2(ads) "precursor sites", are thus mainly located at the freshly created surfaces.

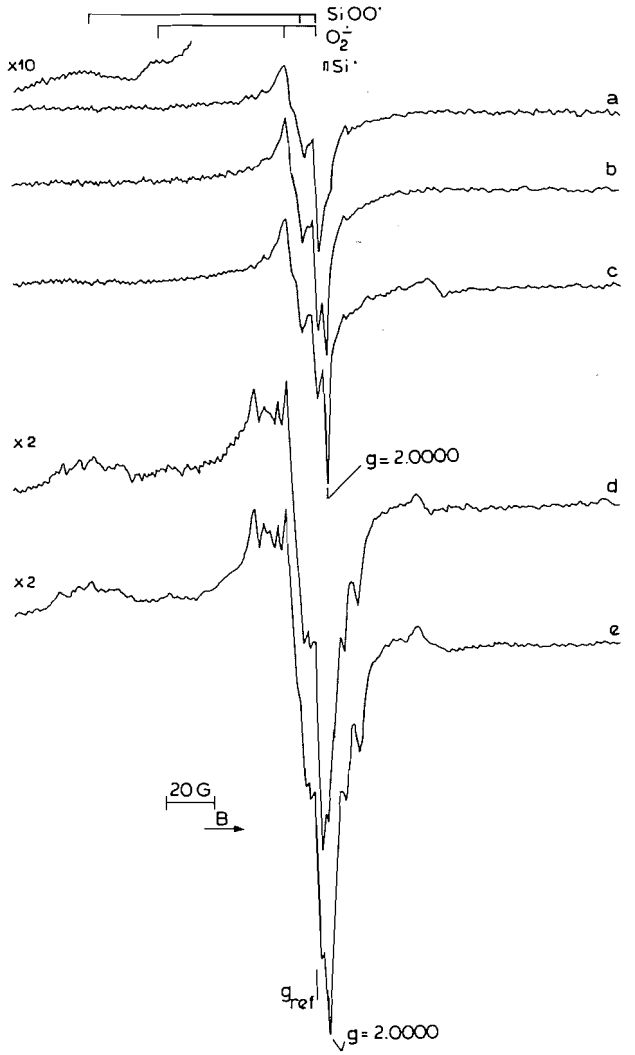

FIG. 1. Electron paramagnetic resonance spectra of freshly ground pure quartz dust: (*a*) in vacuum, (*b*) after contact with oxygen followed by evacuation of oxygen at 77 K, (*c*) and under 25 torr O_2; Min-U-Sil 5 dust (*d*) in vacuum and (*e*) under 25 Torr O_2. Spectra recorded at 77 K.

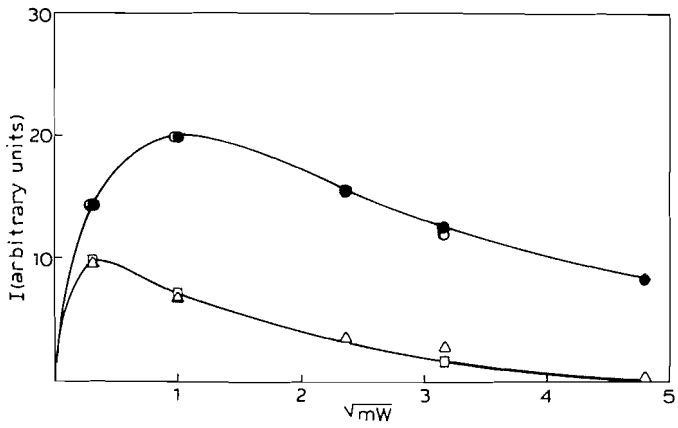

FIG. 2. Freshly ground pure quartz dusts: saturation curves (intensity of the line, measured as peak-to-peak height of the $g = 2.000$ component, versus the square root of microwave power) of (*a*) the E′ signal before contact with oxygen and (*b*) after evacuation at room temperature (Fig. 1*a*) (□, △) and of the O_2(ads) signal under 20 Torr oxygen (○) and 30 Torr oxygen (●).

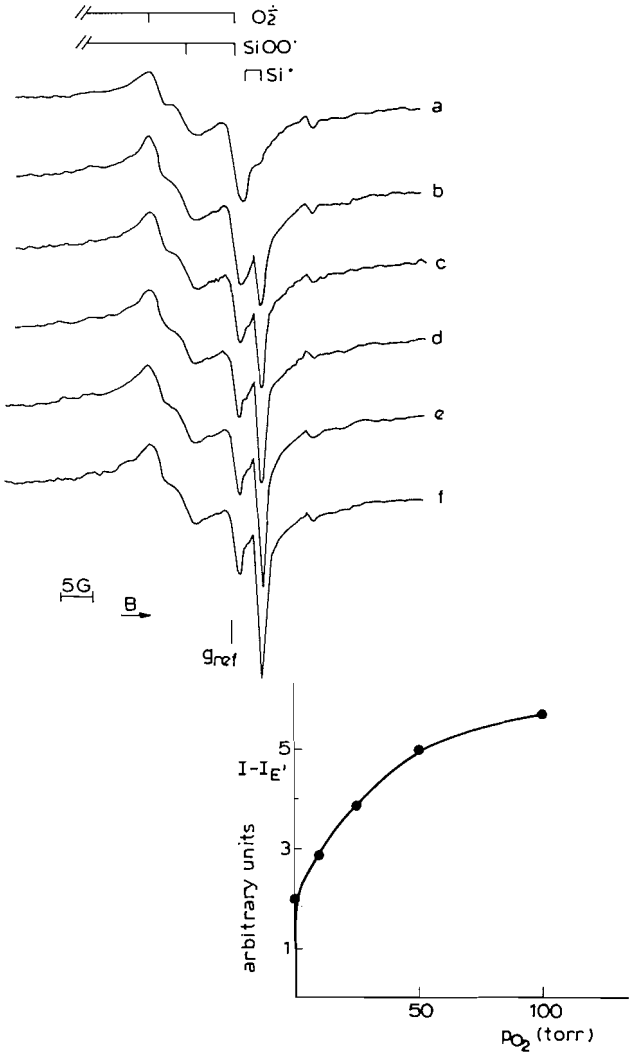

FIG. 3. Electron paramagnetic resonance spectra (at 77 K) of freshly ground pure quartz dust, (*a*) before and (*b*) after adsorption of O_2 followed by evacuation at 77 K and under increasing oxygen pressure: (*c*) 10, (*d*) 25, (*e*) 50, and (*f*) 100 Torr. Inset: intensity of the O_2(ads) signal (arbitrary units) obtained by subtraction from total intensity of the signal at $g = 2.0000$ (superimposition of O_2(ads) and E′ signals) of the intensity of the E′ signal alone, observed when recording under vacuum (spectrum *a*).

Relationship between the center for O_2 adsorption and the other paramagnetic forms: effect of chemical treatments

To investigate if the O_2(ads) precursor site is related to the presence of the other paramagnetic forms, the same experiment was carried out on samples where the other radicals were progressively eliminated. This can be done either *chemically*, *e.g.*, by immersion in solutions reacting with the SiO_2 framework itself (such as HF, NaOH, catechol) or *thermally*, *e.g.*, by heating the dusts *in vacuo* or nitrogen atmosphere. Details on this procedure will be reported in a future paper. Figure 4*a* reports the spectrum obtained before (upper trace) and after (lower trace) contact with O_2 ($p = 25$ Torr) of a sample previously left standing 2 h in an 0.1 M HF solution. The chemical treatment affects the radical population by destroying the outermost layers of the particle. In contrast, the O_2(ads) precursor site is still present and in this case the O_2(ads) signal dominates the spectrum. The same thing happens on treatment of

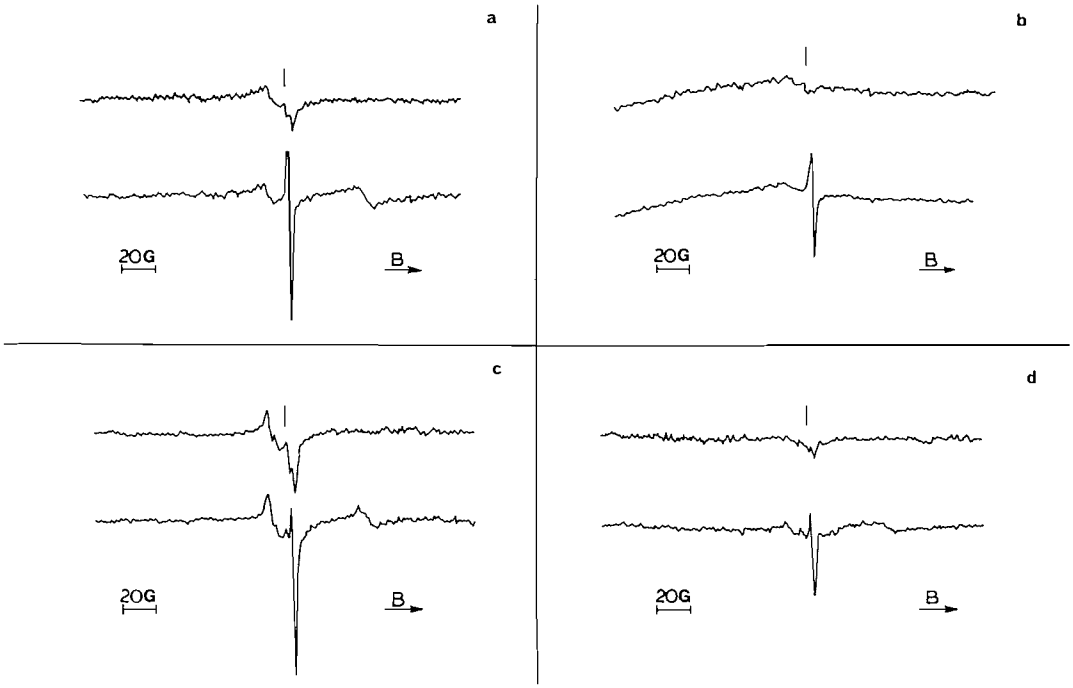

FIG. 4. Influence of etching on the O_2(ads) signal. Electron paramagnetic resonance spectra (at 77 K), recorded before (upper trace) and after (lower trace) adsorption of oxygen (25 Torr) on: (*a*) freshly ground pure quartz crystals after HF etching, 0.1 M, 2 h; (*b*) Madagascar quartz ground in moist air after HF etching, 1 M, 2 h; (*c*) freshly ground pure quartz crystals after NaOH etching, 0.1 M, 2 h; (*d*) Madagascar quartz ground in moist air after catechol etching, 5×10^{-2} M, 30 min.

the same sample with aqueous NaOH (Fig. 4*c*). The chemical treatment erodes some of the paramagnetic sites, modifying the EPR spectrum (by a different mechanism and to a different extent than HF) but either leaves unaffected or recreates the sites capable of interaction with O_2. A more severe treatment (HF 1 M, 2 h, elimination of 35% of weight of the material) on a sample with initially few radicals (Madagascar quartz ground in moist air) completely erodes the radical signals (Fig. 4*b*, upper trace). Even in such a case the paramagnetic adsorbed oxygen is formed (Fig. 4*b*, lower trace). The spectrum consists only of the O_2(ads) signal, which is apparently axial (expanded spectrum in Fig. 5) with $g_\perp = 2.0000 \pm 0.0005$ and $g_\parallel \sim 2.0015 \pm 0.0005$.

Figure 5 reports a spectrum obtained by subtraction of the two spectra in Fig. 4*a* for the evaluation of the modifications produced by the contact with oxygen; it is noteworthy that the spectrum obtained in this way is very similar to the one obtained on a radical-free surface. This clearly indicates that the reaction with oxygen occurs independently of other radical species. To check whether some modifications in the signal features might be observed at increasing oxygen pressure, the saturation of the signal was tested in two well-defined conditions: (*1*) after contact with oxygen and evacuation at 77 K (spectra *b* in Figs. 1 and 3) thus leaving at the surface only the fraction of adsorbate irreversibly held at 77 K, and (*2*) under an equilibrium pressure of 200 Torr. The curves are reported in Fig. 5. Despite the different position of the maximum, likely due to the influence of the large amount of O_2 present in the cell on the relaxation of the centres, the two curves behave similarly to the upper curve in Fig. 2, suggesting that the same species O_2(ads) is present on the two kinds of samples (freshly ground and chemically etched samples). It is also noteworthy that the lower curve in Fig. 5 (O_2(ads) in the absence of any residual oxygen pressure) is definitely different from the lower curve in Fig. 2 (E' centres) being both recorded in the absence of residual oxygen in the gas phase.

Figure 4 also presents the spectra obtained on Madagascar quartz ground in moist air treated with catechol and subsequently contacted with oxygen (Fig. 4*d*, upper trace and lower trace, respectively). Catechol is known to be one of the most powerful organic chemicals able to react with the silica framework (28). In fact, most of the radicals present in the original sample are eroded after the chemical treatment. Upon contact with oxygen, however, the same EPR signal appears.

All data in Fig. 4 thus confirm two main facts: *(i) Most of the original radicals are located at the surface or in the subsurface layer*, microcracks, etc..., as already hypothesized in previous papers (7, 9). Chemical treatments with HF, NaOH, and catechol, all capable of reacting with the silica framework, erode the original radicals. The loss in weight, which is around 10% for 0.1 M treatments, indicates how the reaction has not proceeded in depth. Details on the differences in reactivity of the three reagents will be reported elsewhere. In the present paper, we only stress that all these treatments modify the state of the surface. *(ii) The chemical treatments leave mainly unaffected or else recreate the site responsible for oxygen adsorption* and formation of the labile oxygen radical.

Effect of thermal treatments

Upon thermal treatment the original surface radicals on quartz dusts are modified and progressively eliminated (9). In some cases, mainly on samples with complex spectra, such as Min-U-Sil (9), even after treatment *in vacuo* at 1073 K a broad signal remains. Conversely, on pure quartz or cristobalite (unpublished results) all radicals are annealed between 873 and 1073 K, and thus no EPR signals are detected. Under

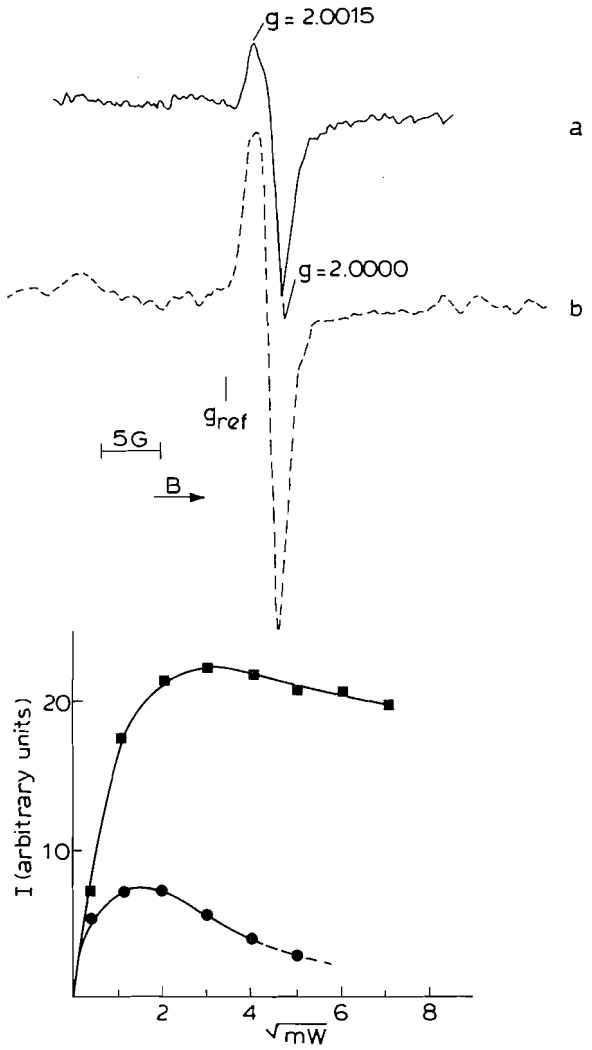

FIG. 5. O_2(ads) adsorbed oxygen signal on HF-etched samples: (*a*) as in Fig. 4*b*, recorded on an expanded scale; (*b*) EPR spectrum of the O_2(ads) signal, obtained by computer subtraction of the first of the two spectra in figure 4a from the second one. Inset: saturation curves of the O_2(ads) signal (Signal intensity, arbitrary units, versus square root of microwave power), for the fraction of O_2(ads) left at the surface after outgassing at 77 K (●) and O_2(ads) in equilibrium with pO_2 = 200 Torr (■).

these conditions the quartz samples, in contrast to amorphous silicas, are still largely hydrophilic (29), whereas after treatment at 1573 K they are mainly hydrophobic (unpublished results).

The interaction with O_2 at 77 K was tested on two samples of Madagascar quartz treated respectively at 873 and 1573 K, in order to have two samples deprived of their radicals, one largely hydrophilic, *i.e.*, bearing patches of vicinal silanols, and the other one, hydrophobic, thus exhibiting at the surface only siloxane bridges and isolated silanols (29). In both cases no signals were observed upon contact with oxygen even at high pressure. These results indicate that thermal treatments, unlike chemical treatments, destroy the sites reacting with oxygen at 77 K.

Origin of the samples

All the samples examined so far were either fresh or aged crystalline quartz dusts obtained by mechanical grinding. To investigate the role of crystallinity and of the grinding process, two other samples have been considered: Aerosil 50, a pyrogenic amorphous silica with a relatively low surface area (already employed by some of us in adsorption work (30) and as standard in studies on the toxicity of mineral dusts (31)), and a powder made up of microcrystals obtained by hydrothermal growth, *i.e.*, only exposing growth faces (26). In both cases, no signal was observed upon contact with O_2. It can therefore be concluded that the formation of the paramagnetic form upon adsorption of oxygen at 77 K only occurs when the exposed surface is *created by grinding* and is not inhibited by chemical etching of the ground surface.

Stability of the sites reacting with O_2

The sites responsible for the formation of the paramagnetic oxygen species at 77 K are more abundant on freshly ground than on aged dusts (Fig. 1). It has already been mentioned that grinding aged dusts enhances the formation of this species, by creating new sites. As to the stability of these sites, it has been seen (by contacting the sample periodically with O_2 and then running EPR spectra) that their number slowly decays with time, particularly if the sample is kept in moist atmosphere.

Effect of treatments with substances used to prevent quartz pathogenicity: Al^{3+} ions and PVPNO

Polyvinylpyridine-*N*-oxide (PVPNO) is a polymer used to prevent silicosis (32). Its mechanism of action is not known; it may simply cover the surface by hydrogen bonding to silanols (33), or it may react via its —N═O group with active sites (34). Figure 6 reports the spectra of Madagascar quartz ground in moist air before and after contact with O_2 (Fig. 6*a*) and the same treated with PVPNO and subsequently contacted with O_2 (Fig. 6*b*). The treatment with PVPNO clearly inhibits the formation of O_2(ads). This inhibition may be caused by simple adsorption of the polymer on the quartz surface, thus screening the active sites. Alternatively a reaction may occur between the polymer and the surface involving modification or elimination of the site itself.

Administration of aluminum salts is another method used to prevent silicosis. The effect of Al^{3+} in blunting SiO_2 toxicity has been largely confirmed by *in vivo* experiments by Le Bouffant *et al.* (35). One quartz sample (the same batch of Madagascar quartz ground in moist air used for the PVPNO experiment) was contacted with a $NaAlO_2$ solution for 1 h. The final spectrum (in Fig. 6*c*, upper trace) shows that the original paramagnetic signals are decreased, indicating that $NaAlO_2$ also affects the active sites population. This effect, which differs from what happens after a treatment with NaOH solution with the same pH of the $NaAlO_2$ solution, will be extensively discussed in a future paper. Only a very small signal appears after contact with O_2 (Fig. 6*c*, lower trace), indicating that treatment with the aluminum ions interferes with the relevant sites and inhibits the formation of the oxygen radical form. In conclusion, via different chemical of physico-chemical paths, both of the above substances inhibit the formation of the oxygenic paramagnetic form.

Discussion

There is clear evidence that in some cases a particular site is present at the quartz surface, which reacts with dioxygen at 77 K to give a weakly bound paramagnetic adduct. To understand the chemical nature of the site and of the paramagnetic form to which it gives rise, both the physico-chemical condi-

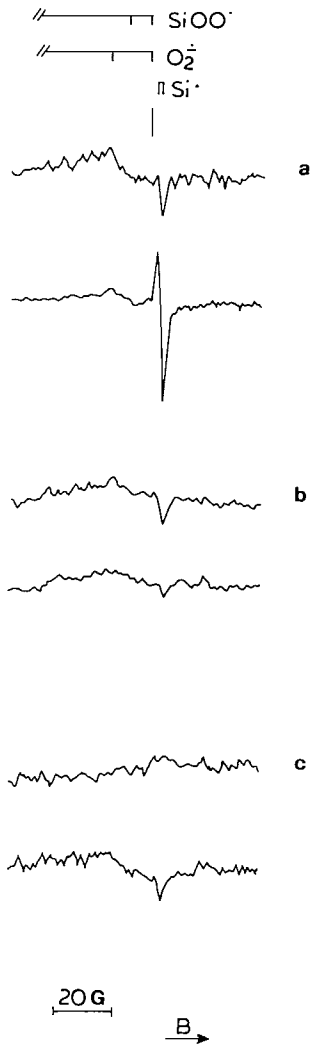

FIG. 6. Electron paramagnetic resonance spectra (77 K) of Madagascar quartz ground in moist air, under vacuum (upper trace) and under 25 Torr of oxygen (lower trace), after different chemical treatments: (*a*) before any treatment; (*b*) after treatment with aqueous PVPNO; (*c*) after treatment with aqueous $NaAlO_2$.

tions in which the site appears and the EPR spectral features must be considered.

(1) State of the ground surface and origin of the site

The site appears to be present only on surfaces of crystalline material which are powdered by mechanical grinding. The maximum abundance is found on freshly ground samples and the number of sites decays with time, particularly in moist atmosphere. Regrinding again increases the number of the sites.

It is known since the work of Antonini and Hochstrasser on quartz (18) that mechanical treatments such as grinding originate homolytic rupture of the Si—O bond, as demonstrated by the appearance of an EPR spectrum due to Si· dangling bonds (also called E′ centres). The same conclusions were derived by Radtsig and co-workers who extensively investigated the grinding of vitreous silica under vacuum and the reactivity of the ground materials with several molecules (19, 20). These authors claim that SiO· centres, formed in parallel with Si· during grinding, are also present on the solid, even though (having a degenerate ground level) they are not visible by EPR (16, 19).

The effect of mechanical treatments on various crystalline polymorphs of SiO_2 in air and in controlled atmospheres has been reported by some of us (7, 9, 12). It has been shown that radical centres are formed by the simultaneous action of grinding and reaction of oxygen with the newly created surface. The most abundant centres so formed are the silylperoxide radical (SiOO·) and the superoxide ($O_2^{\cdot-}$) radical ion. The former is created by reaction between Si· and molecular oxygen. The superoxide species are very likely formed during grinding by electron transfer from the solid to molecular oxygen. The electrons released by the solid are probably those of defects, generated upon mechanical treatment, analogous to those observed on several oxides submitted to other kind of activation such as γ- or neutron irradiation.

In conclusion, the surface of quartz ground in air exhibits, beside the typical silica functionalities (silanols and siloxanes), radical centres such as SiOO·, $O_2^{\cdot-}$, and unreacted residual Si· (all observed by EPR) and SiO· which is EPR silent. The above-mentioned species are fairly stable with time, but a decrease with time in the intensity of the spectra was found both by Vallyathan *et al.* (13) and by some of us (8), the decrease being more pronounced in moist than in dry atmosphere. The newly discovered site too seems to be affected by moist atmosphere, confirming its relationship with the other radicals. However, its abundance seems unrelated to the others, particularly when chemical treatments have caused the original radical population to be partially or completely eroded (Fig. 5). On the basis of these findings we can assume that the site is produced, like the others, by mechanical grinding. In contrast to the others, this site either is located in a surface region which is not affected by chemical treatments (e.g. microcracks) or is progressively eliminated and restored by the chemical treatment. In contrast, thermal treatments, whereby most surface radicals are annealed, also eliminate this site. In such a case, even after prolonged exposure to various substances which does in fact create some radicals (unpublished results), this form is still absent.

(2) Assignments

The perpendicular component of the EPR signal of O_2(ads) falls at $g = 2.0000$, corresponding exactly to that of the well known E′ center (Si·) in polycrystalline SiO_2. The presence of two superimposed signals is proved by the fact that the two lines have a different saturation curve (Figs. 2 and 5). The dependence on the oxygen pressure indicates that the spectrum arises from reaction of O_2 with a suitable surface site, so as to produce a paramagnetic form.

Several lines arising from the O_2 spectrum, if large doses of O_2 are admitted on the sample at 77 K ($p_{O_2} > 10$ Torr), can be seen in various parts of the spectrum. These lines, however, are distinguishable from the signal under discussion because, unlike the $g = 2.0000$ component, they are broadened with increasing O_2 pressure, and they disappear by simple evacuation at 77 K.

The new signal is therefore produced by reaction of an EPR-silent surface species with dioxygen.

The assignment of a detailed structure to the observed species is not straightforward. Some observations reported in the literature were particularly interesting due to the clear analogies with our case. The first one is reported by Radtsig and co-workers (19, 20) on the surface chemistry of ground

For personal use only.

fused SiO_2. A surface species is formed upon oxygen adsorption which has the same adsorptive behavior (appearance–disappearance as a function of the oxygen pressure) found in the present work. In that case too the observation of the whole spectrum of the oxygen adduct was seriously limited by overlap with other signals. The authors only report a component at $g = 2.008$, *i.e.*, a value quite different from that observed for O_2(ads). The species was assigned by Radtsig to $SiO_3\cdot$ arising from the reaction of O_2 with the EPR-silent $SiO\cdot$ site. No discussion about the chemical bonding in the species (ionicity–covalency) or about its geometry is done in Radtsig's papers, where the $SiO_3\cdot$ representation is merely indicative of the chemical composition of the species.

The second case is that of the ionic triatomic oxygen species observed on several oxides (36, 37). These are two species: the ozonide O_3^- ion which shows stability and g values very different from those of O_2(ads) and the T-shaped "so-called" ozonide. The latter species on V_2O_5 (38) exhibits $g_\perp = 2.0001$ (very close to the O_2(ads) component observed in the present case), $g_\parallel = 2.0017$ and is destroyed by evacuation at 150 K. The structure of the species (an oxygen molecule coordinated "side on" onto an O^- site) has been demonstrated by employing ^{17}O-enriched oxygen (39). The same experimental approach is, unfortunately, impossible in our case due to the low intensity of the observed signal. It is therefore not possible to assign a detailed structure to O_2(ads) even though the two above-mentioned species, $SiO_3\cdot$ (19, 20) and the T-shaped side-on O_3^-, show a behavior very close to that observed for O_2(ads). It is clear, however, that a weakly bound polynuclear oxygen radical is formed upon selective reaction of dioxygen with an EPR-silent site on the surface of quartz.

(3) Possible relationship with quartz pathogenicity

The site reacting with oxygen may be related somehow to the molecular event occurring during macrophage activation, ending up with the formation of fibroblast-stimulating growth factors (1, 40). In contrast to the other oxygen paramagnetic species which are strongly bound at the surface, oxygen is bound very weakly to the O_2(ads) site. Such a site could thus interact in a biological medium with various molecules, and perhaps act as a catalytic site where the biochemical cascade reactions are triggered.

Some facts would be in agreement with such a hypothesis: (*i*) It is well known that freshly ground dusts are more pathogenic and yield the fibrotic response in a shorter time than aged dusts (23, 26). The O_2(ads) precursor site is by far more abundant on freshly cleaved surfaces than on aged ones. (*ii*) The well-known inhibitors of quartz toxicity, the polymer PVPNO and aluminum ions, also blunt the specific O_2(ads) sites. In the case of PVPNO the action may be just a screening of the site by the polymer. As to the effect of $NaAlO_2$, it is noteworthy that a sample kept at the same pH as the $NaAlO_2$ solution but in NaOH does not lose its capability of reacting with O_2. In such a case there is thus a direct chemical action of the aluminum ion on the active site. (*iii*) Etching in HF increases fibrogenicity (41, 42) and on HF-etched quartz, unlike other radicals, the ozonide is still present. (*iv*) Thermal treatments which decrease fibrogenicity (43) also decrease or eliminate the active site.

One datum, namely the absence of the ozonide on the hydrothermally grown microcrystals, does not fit this correlation. In fact a similar specimen was found to be relatively fibrogenic (24, 26) although the fibrogenic response was delayed by comparison with ground material of the same size. In such a case it is possible that the active sites are created after prolonged immersion in a biological environment where several molecules may slowly react with the SiO_2 framework. The biochemical process of macrophage activation during quartz phagocytosis is somehow complex as many growth factors are released in the medium. It is therefore not easy to identify which are the surface-active sites responsible for the pathogenic biological response. It is likely, moreover, that several chemical functionalities will play some role in the overall toxicity, acting at different stages of particle inhalation and retention (25). This renders even more difficult the possibility of drawing clear-cut conclusions from the comparison of surface states and fibrogenicity *in vivo*. Nevertheless, the above-mentioned facts indicate that this site, reacting with O_2, should be considered as one of the possible agents of quartz pathogenicity.

Conclusions

A polynuclear paramagnetic species, probably of the ozonide type, is formed, when O_2 is contacted with crystalline silica dusts at 77 K, on a specific site at the surface which is EPR silent. The purity of the quartz employed samples ensures that the site arises from the silica framework and cannot be originated by any sort of impurity. Possible candidates are the $SiO\cdot$ or O^- species originated during grinding. This active form is also detectable in the absence of the other well-known surface radicals, if the latter ones have been eliminated by chemical treatments, whereas thermal treatments also eliminate the sites capable of O_2(ads) formation. A correspondence has been found between the presence of the site, giving rise to the ozonide form on variously treated quartz dusts and their fibrogenicity, which suggest a relationship between this site and silica pathogenicity.

MARK S. WORKENTIN, BRIAN J. FAHIE, and WILLIAM J. LEIGH. Can. J. Chem. **69**, 1435 (1991).

The photochemistry of β-phenyl-4-methoxypropiophenone (**1**) in the isotropic and liquid crystalline (nematic and smectic B) phases of *trans,trans*-4′-alkyl-(1,1′-bicyclohexyl)-4-carbonitrile (CCH-*n*) and *trans*-4-alkylcyclohexyl-*trans*-4′-alkylcyclohexylcarboxylate (OS-*nm*) mesogens has been investigated using nanosecond laser flash photolysis techniques. Solubility limits of **1** as a function of temperature in the smectic phases have been rigorously determined by ^{2}H NMR spectroscopy, using α-, methoxy-, and β-phenyl-deuterated analogs of the ketone. Triplet decay of **1** in the smectic (Crystal B) phase of CCH-4 is multiexponential, suggesting that the ketone is solubilized in a distribution of conformations in the highly-ordered liquid crystalline lattice. The average triplet lifetime of **1** at various temperatures throughout the smectic phase is about a factor of three longer than that in homologous nematic and isotropic phases at the same temperature. The differences in the Arrhenius parameters for triplet decay in the smectic and nematic/isotropic phases are very small, however. The present results for **1** in the smectic phase of the CCH-*n* mesogens correct the interpretation of previously reported data obtained with higher concentration mixtures, and afford an accurate indication of the true effects of smectic B liquid crystalline order on the conformation-dependent triplet state behavior of this molecule. In OS-*nm* liquid crystals, triplet decay follows clean first order kinetics in all phases, but the variations in Arrhenius dependence with solvent phase are similar to those observed in the CCH-*n* liquid crystals.

Key words: smectic, liquid crystals, ^{2}H NMR, nanosecond laser flash photolysis, intramolecular triplet quenching, photochemistry.

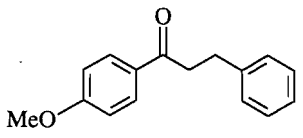
MARK S. WORKENTIN, BRIAN J. FAHIE et WILLIAM J. LEIGH. Can. J. Chem. **69**, 1435 (1991).

On a étudié la photochimie de la β-phényl-4-méthoxypropiophénone (**1**) dans les phases isotropes et cristalline liquide (nématique et smectique) des mésogènes *trans,trans*-4′-alkyl-(1,1-bicyclohexyl)-4-carbonitrile (CCH-*n*) et *trans*-4-alkylcyclohexyl-*trans*-4′-alkyl-cyclohexanecarboxylate (OS-*nm*) en utilisant la technique de photolyse éclair avec un laser à nanoseconde. On a déterminé rigoureusement par la rmn du ^{2}H, la limite de solubilité du composé **1** en fonction de la température dans la phase smectique, en utilisant les analogues α-méthoxy et β-phényl deutériés de la cétone. La décroissance du triplet du composé **1** dans la phase smectique (cristal B) du CCH-4 est multiexponentielle, suggérant ainsi que la cétone est solubilisée avec une distribution de conformations dans le réseau cristallin liquide fortement ordonné. La durée de vie moyenne du triplet du composé **1** à différentes températures à travers la phase smectique est environ trois fois plus longue que celle du triplet dans les phases homologues nématique et isotrope à la même température. Cependant la différence dans les paramètres d'Arrhénius pour la décroissance du triplet dans les phases smectique et nématique/isotrope, est très faible. Les résultats actuels relatifs au composé **1** dans la phase smectique du mésogène CCH-*n* corrigent l'interprétation des résultats obtenus antérieurement avec des mélanges dont la concentration était plus élevée, et fournissent une indication précise sur les effets réels de l'ordre cristallin du liquide smectique B sur la conformation de cette molécule qui dépend du comportement du triplet. Dans les cristaux liquides du OS-*nm*, la décroissance du triplet suit parfaitement une cinétique d'ordre un dans toutes les phases mais les variations d'Arrhénius en fonction du solvant sont semblables à celles observées dans les cristaux liquides du CCH-*n*.

Mots clés : smectique, cristaux liquides, rmn du ^{2}H, photolyse éclair au laser à nanoseconde, blocage du triplet intramoléculaire, photochimie.

[Traduit par la rédaction]

Introduction



There is considerable interest in the potential effects of liquid crystalline order on the molecular and conformational mobility of dissolved solutes, as well as on various aspects of chemical reactivity that depend on these factors (1). Photochemical and photophysical techniques have been most useful in providing information on the effects of liquid crystals on the rates of conformational and diffusive motions of solutes. These techniques have included static and time-resolved spectroscopic techniques, as well as more qualitative product analysis methods.

We have reported the results of nanosecond laser flash photolysis studies on the triplet state behavior of β-phenyl-4-methoxypropiophenone (**1**) and several derivatives in the smectic (crystal-B) and nematic liquid crystalline phases of *trans,trans*-4′-butylbicyclohexyl-4-carbonitrile (CCH-4) and the 4′-ethyl homolog (CCH-2) (2, 3). β-Phenyl ketones such as **1** possess characteristically short triplet lifetimes in fluid isotropic solvents owing to efficient intramolecular quenching of the carbonyl triplet state by through-space interactions with the β-phenyl ring (4, 5). These interactions involve the n,π* state (6) (which must be either the lowest state or within 2–3 kcal/mol of the lowest state) and require prior formation of a gauche conformation of the molecule (5–8); see eq. [1]. Re-

CCH-4: $n = 4$
CCH-2: $n = 2$
CCH-3: $n = 3$

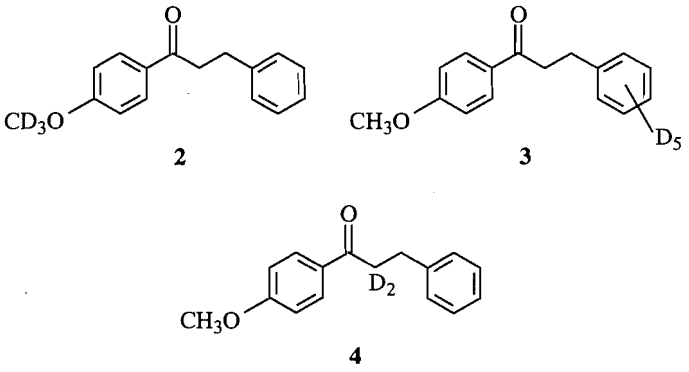
stricting the conformational mobility of the molecule results in an increase in the triplet lifetime. This has been demonstrated for **1** and its parent molecule (β-phenylpropiophenone) using various organized media such as zeolites (7), polymers (6), and cyclodextrin inclusion complexes (8), as well as thermotropic liquid crystals (2, 3). Under these conditions, the triplet lifetime may provide a direct measure of the rates of those conformational motions that allow the molecule to assume the gauche quenching geometry.

[1] 

Our original studies of **1** in the isotropic and liquid crystalline phases of CCH-4 and CCH-2 employed 1.0 mol% samples, a composition that was chosen because it provided adequate optical densities for laser flash photolysis experiments with a nitrogen laser (337 nm) and using 0.7 mm thick cells (2). Under these conditions, triplet decay appears to follow reasonably clean first order kinetics. For the mixtures of **1** with CCH-4, Arrhenius plots of the triplet decay rate showed a distinct change in slope at a temperature close to the smectic–nematic (S–N) transition temperature of the pure mesogen. They indicated increases of ca. 12 kcal/mol and ca. 35 eu in the energy and entropy of activation for triplet decay of **1** in the bulk smectic phase relative to the corresponding values for the nematic and isotropic phases (2). These results were touted as being among the largest reported effects on the conformational mobility and chemical reactivity of solutes dissolved in liquid crystalline media. On the other hand, phase-independent triplet Arrhenius behavior was observed for similar (1.0 mol%) mixtures of **1** in CCH-2 (2). This result is surprising since the smectic phase of this mesogen is known to be more highly ordered than that of CCH-4 (9).

Recently, we have published ^{2}H NMR evidence which indicates that the physical nature of the 1.0 mol% mixture of **1** and CCH-4 that was studied previously is in fact much more complicated than we originally supposed (10). It was shown that the solubility limit of **1** in the smectic phase is temperature dependent and much lower than 1 mol%. It was further shown that the portion of solute in excess of the solubility limit is localized in a solute-enriched nematic phase throughout the 35–53°C temperature range (10), and in a highly concentrated isotropic liquid below 35°C (10–12). We suggested that the triplet lifetimes reported for **1** over the 28–53°C temperature range are actually average values of those due to the ketone in the coexisting smectic and nematic (above 35°C) or isotropic (below 35°C) solutions. Since the proportions of the two co-existing phases — and the concentration of solute in them — varies with temperature, the reported Arrhenius behavior affords an inaccurate indication of the true effects of the smectic phase on the conformational mobility of **1**. We have subsequently suggested (11, 12) that similar problems are likely to have plagued many of the reported studies of solute reactivity or spectroscopy in highly-ordered smectic phases, particularly those using CCH-*n* mesogens (2, 3, 13–16).

OS-53: $n = 5$; $m = 3$
OS-35: $n = 3$; $m = 5$



We now report the results of laser flash photolysis and further ^{2}H NMR studies of **1** in the liquid crystalline and isotropic phases of several CCH-*n* mesogens. This work features a careful determination of the solubility limits of the probe in the smectic phases and triplet lifetime data obtained from homogeneous samples of composition well below the solubility limit. By employing various selectively deuterated analogs of **1**, we have now successfully observed distinct ^{2}H NMR spectra of the solute as homogeneous solutions in both the smectic and nematic phases of CCH-4. These allow a more accurate determination of the solubility limits of **1** in the smectic phase than was possible with the α-deuterated analog, which does not exhibit an observable ^{2}H NMR spectrum in this liquid crystalline phase (10). For comparison, we have also carried out similar experiments with mixtures of **1** in the isotropic and liquid crystalline phases of two *trans*-4-alkylcyclohexyl-*trans*-4′-alkylcyclohexylcarboxylate (OS-*nm*) liquid crystals. The smectic phases of these materials have been previously characterized by X-ray diffraction methods (17). The present results afford a true, generalizable indication of the effects of highly ordered smectic liquid crystals on the conformation-dependent triplet state behavior of this molecule.

Results

The selectively deuterated derivatives of **1** that have been employed in this work for ^{2}H NMR experiments (**2–4**) were synthesized using modifications of the reported procedure for the synthesis of **1** (*6a*) (see Experimental section).

Deuterium NMR spectra of **2–4** as 0.1–0.6 mol% mixtures with CCH-4, CCH-2, and the two OS-*nm* liquid crystals were recorded on a 500 MHz spectrometer (operating at 76.8 MHz) at various temperatures throughout the 0–84°C temperature range using the quadrupolar echo pulse sequence (18). Spectra were recorded at 3–5°C intervals starting at the upper end of the temperature range, to ensure that those recorded in the bulk smectic phases are those of uniformly aligned samples. The solvents are all aligned spontaneously by the spectrometer magnetic field when in the nematic phase, and the alignment persists as the temperature is lowered into the corresponding smectic phase (10–12). Sample concentrations were adjusted by trial and error to establish the solubility limits of **1** at representative temperatures throughout the smectic phase ranges

of CCH-4 (K-28°-S-53°-N-80°-I) (9), OS-53 (K-25°-S-39°-N-53°-I) (17), and OS-35 (K-24°-S-52°-N-54°-I) (17), following the procedure reported previously (10–12). Figure 1 shows representative 76.8 MHz ^2H NMR spectra of 0.21–0.25 mol% samples of **2** and **3** in the nematic and smectic phases of CCH-4 and OS-35. The 0.25 mol% sample of **2**/CCH-4 is homogeneous from 12–45°C, as revealed by the presence of only a single quadrupolar doublet in the NMR spectrum (*e.g.* Fig. 1*a*; 38°C). Similarly, 0.1 mol% samples of **4** in OS-53 and **2** in OS-35 were found to be homogeneous from 4–34°C and 10–46°C, respectively (the smectic–solid transitions (K–S) of all three materials supercool substantially). Compound **4** shows no detectable spectral features in homogeneous smectic solutions of OS-35 or CCH-4, but does so in OS–53. Depending on the temperature, spectra of biphasic mixtures (*i.e.*, of composition above the smectic phase solubility limit) showed smectic + nematic or smectic + isotropic phase components in all cases. A few examples of spectra of this type are included in Fig. 1.

We are unable to observe spectra of **2** and **4** in the smectic phase of CCH-2. Even with 0.1 mol% samples, spectra in the 20–44°C range exhibit only an isotropic singlet, indicating that the solubility of **1** in this smectic phase is substantially lower than 0.1 mol%.

Table 1 lists quadrupolar splittings obtained from the spectra of **2–4** in each of the nematic and smectic phases studied. Those listed for nematic phases were recorded within 1–2°C of the smectic–nematic (S–N) transition temperature, while those listed for the smectic phases were generally recorded at 30 ± 2°C.

Spectra of **2** and **3** as 0.25 mol% solutions in CCH-4 were also recorded at 37°C with a 400 MHz solid state spectrometer (at 61.4 MHz) employing a home-built deuterium probe. The sample was oriented in the spectrometer magnet by cooling from the nematic phase, with the sample tube arranged so that its long axis was parallel to the field direction. Spectra recorded for **2** under these conditions were similar to those recorded with the 500 MHz spectrometer (*e.g.*, Fig. 1*a,b*). Those for **3** were somewhat better resolved, because of a shorter 90° pulse and higher accumulated S/N on the 400 MHz spectrometer. The spectrum of **3** on this spectrometer shows two doublets: a strong inner doublet of splitting 10.5 kHz and a weaker outer doublet of splitting 84.0 kHz (at 37°C). Spectra were then recorded with the sample tube oriented perpendicular to the field direction. In both cases, the appearance of the spectrum changes dramatically with sample orientation, indicating the solute to be well oriented in the liquid crystal (19).

Nanosecond laser flash photolysis experiments employed the pulses from an excimer laser filled with N_2/He (337 nm;

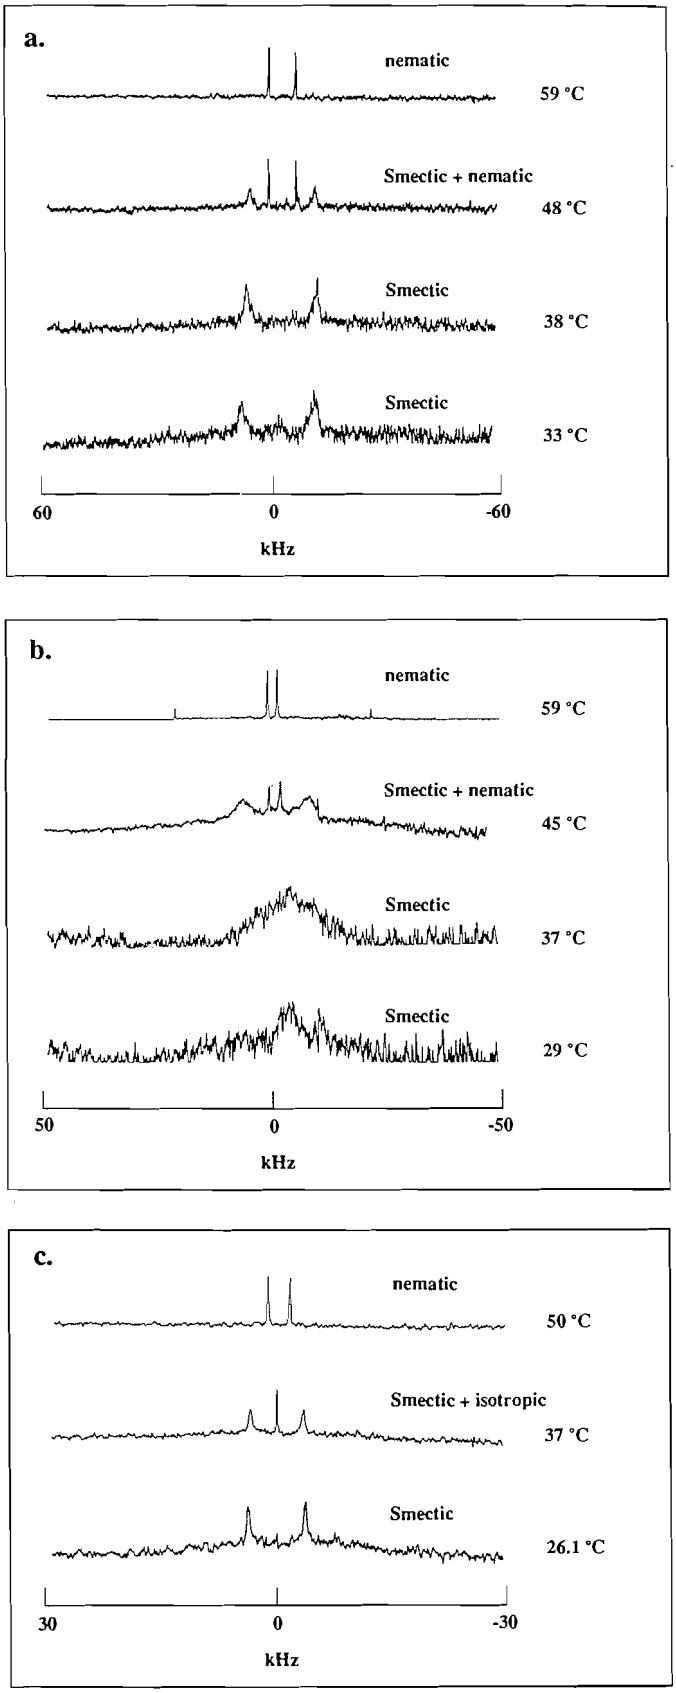

FIG. 1. ^2H NMR spectra of mixtures of (*a*) **2** (0.25 mol%) and (*b*) **3** (0.21 mol%) with CCH-4 and (*c*) **2** (0.25 mol%) with OS-35, recorded at various temperatures between 24 and 84°C using the quadrupolar echo pulse sequence.

TABLE 1. Quadrupolar splittings from ^2H NMR spectra of **2**–**4** in the nematic and smectic B phases of CCH-*n* and OS-*nm* liquid crystals[a]

Liquid crystal	Phase	**2**	**3**		**4**
			ortho/meta	*para*	
CCH-4	N[b]	7.7	2.1	43.5	25.2
	S[c]	19.4	10.5[d]	84.0[d]	[e]
CCH-2	N[b]	5.1	[f]	[f]	18.8
OS-53	N[b]	4.4	0.2	28.7	22.2
	S[c]	6.5	1.6	[e]	33.0
OS-35	N[b]	2.9	0.4	19.1	14.3
	S[c]	7.3	3.9	[e]	[e]

[a]Recorded at 76.8 MHz, using the quadrupolar echo pulse sequence. Errors in splittings are ca. ±0.1 kHz.
[b]N = nematic; spectra were recorded 1–2° above the S–N transition temperature.
[c]S = smectic; spectra were recorded at 30°C.
[d]Recorded at 61.4 MHz, 37°C.
[e]No signals observable.
[f]Not recorded.

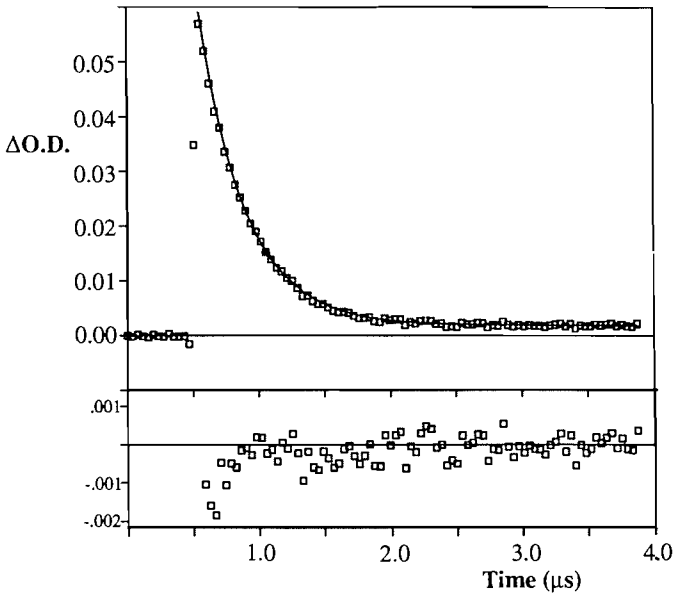

FIG. 2. Representative decay trace from nanosecond laser flash photolysis of a degassed 0.1 mol% solution of **1** in OS-53 at 9.5°C. A plot of the residuals from single-exponential least squares analysis of the data is included.

<6 ns) or Xe/HCl/H_2/He (308 nm; ≤12 ns) mixtures and a microcomputer-controlled detection system (20). Low concentration samples of **1** in CCH-4 and the OS-*nm* liquid crystals were sealed in 3 × 7 mm Suprasil quartz cells after degassing with several freeze–pump–thaw cycles. Sample compositions were 0.25 mol% for CCH-4 and 0.1 mol% for the OS-*nm* liquid crystals. In general, the samples were allowed to anneal for several days at a temperature roughly midway through the smectic phase range, and then slowly cooled to the lower temperature limit. Handling the samples in this way insures that they are homeotropically aligned (*i.e.* glassy). Samples that were cooled quickly from the nematic phase or allowed to sit at room temperature for extended periods of time crystallized and were unsuitable for laser flash photolysis experiments. Static UV absorption spectra of **1** in the various phases of each of the liquid crystals studied showed no discernible differences as a function of solvent phase.

Experiments were also carried out with 1.0 mol% mixtures of **1** with CCH-2 (K-29°-S-44°-N-48°-I) (9), a 2:1 mixture of CCH-2 and CCH-4 (CCH-2/4; K-10°-S-25°-N-57°-I) (9), and CCH-3 (S_2-39°-S_1-53°-N-80°-I) (9). Flash photolysis experiments with solutions of **1** in the nematic phases were carried out using 1.0 mol% samples in 0.7 × 7 mm Pyrex cells, because the turbidity of the unoriented nematic phases rendered the 3 × 7 mm nematic samples opaque, resulting in low light transmission and poor quality results. Experiments were also carried out with deoxygenated 1×10^{-3} M solutions of **1** in acetonitrile over the 5–60°C range.

Laser flash photolysis of all these samples yields intense transient absorptions (λ_{max} = 385 nm) assignable to the triplet state of **1** (2, 3, 6–8). Triplet decays for the nematic and isotropic phase samples followed clean first order kinetics in every case. Decays also followed clean first order kinetics for the smectic solutions of **1** in OS-53 and OS-35; a representative example is shown in Fig. 2. In the case of the 0.25 mol% **1**/CCH-4 sample however, triplet decay is multiexponential at all temperatures throughout the 30–50°C range. Figure 3 shows representative decay traces for this sample at 30.4 and 45.8°C. With each trace is included a plot of the residuals obtained from curve-fitting of the data to two exponential decays. In general, the fit of the data to two exponentials improves at higher temperatures in the smectic phase range. However, the relative contributions of the two components and their lifetimes vary erratically, probably owing to the quality of the data. For this reason, least squares fitting of the data to a single exponential decay was employed to extract average triplet lifetimes for **1** in the smectic phase of CCH-4, using a minimum of 100 data points in each case. These analyses gave linear correlation coefficients of 0.99 or better in every case. Small amounts of residual absorption were frequently evident in the decay traces for the smectic phase samples, but these were not reproducible and never amounted to more than 5–10% of the maximum transient O.D. The fit to two exponentials does not improve at lower laser power, ruling out possible contributions to transient decay from bimolecular triplet processes.

The Arrhenius plot for the 0.25 mol% **1**/CCH-4 mixture is shown in Fig. 4*a*. The (upper) nematic phase line was constructed by combining data from the 1.0 mol% samples with the less extensive data from the 0.25 mol% samples in this range. Also included in this plot are the data obtained from the 1.0 mol% sample of **1** in CCH-2/4, which is nematic over the 25–54°C range (9). Figure 4*b* shows the Arrhenius plot obtained from the lifetime data obtained in OS-53; that obtained with OS-35 is similar to the OS-53 plot and is not shown. Nematic and isotropic phase data for these solvents were obtained from samples of two concentrations (0.1 and 0.6 mol%). Sample opaqueness is a particular problem at temperatures within the S–N transition, making it difficult to obtain data over these ranges. Activation parameters obtained from least-squares analysis of the data according to the Arrhenius and Eyring equations are summarised in Table 2. Table 2 also includes triplet lifetimes for **1** at 30°C in each of the

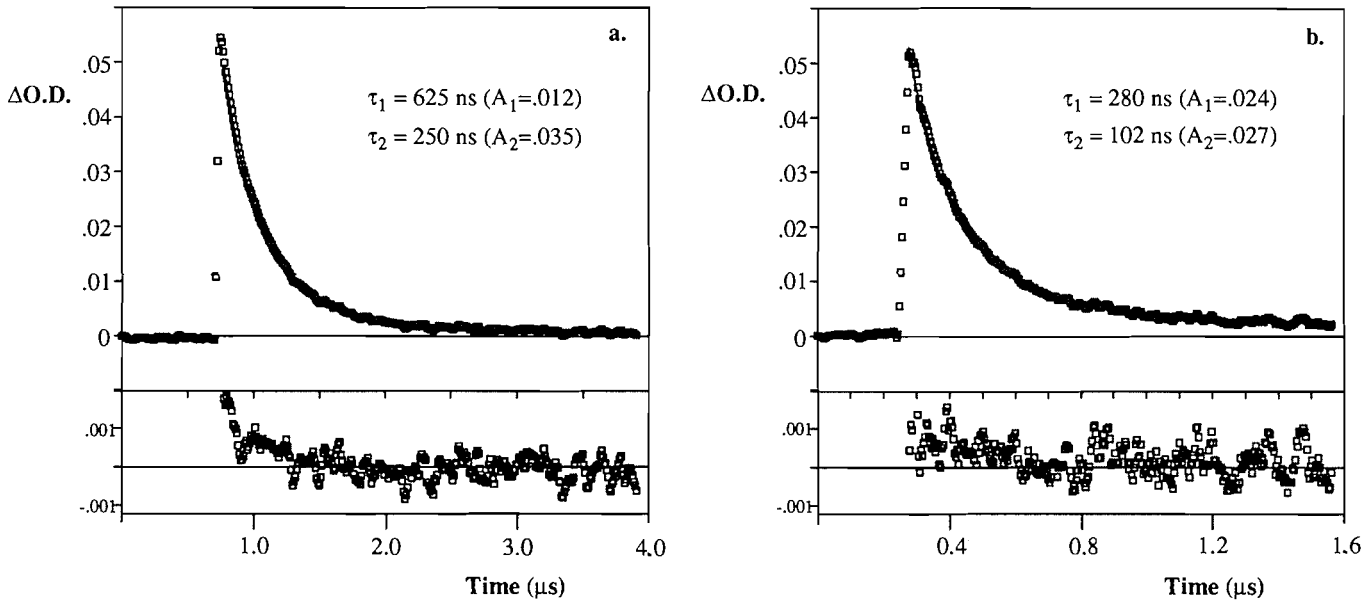

FIG. 3. Representative decay traces from nanosecond laser flash photolysis of a degassed 0.25 mol% smectic solution of **1** in CCH-4 at (*a*) 30.4°C and (*b*) 45.8°C. A plot of the residuals from two-exponential curve-fitting of the data is included for each trace.

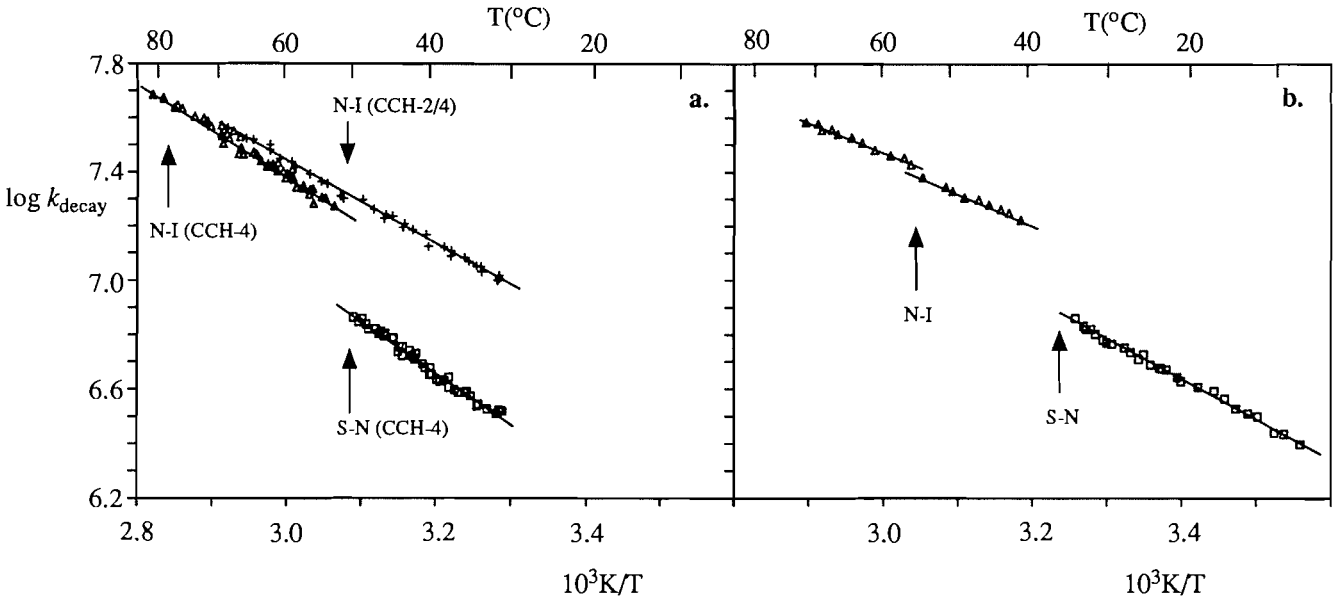

FIG. 4. Arrhenius plots for triplet decay of **1** in (*a*) CCH-*n* and (*b*) OS-53 liquid crystals. (*a*) □, 0.25 mol% **1** in CCH-4; △, 1.0 mol% **1** in CCH-4; +, 1.0 mol% **1** in CCH-2/4; (*b*) 0.1 mol% **1** in OS-53; □, smectic phase data; △, nematic and isotropic phase data.

phases studied; in some cases, these were estimated by extrapolation of the Arrhenius plots defined by data determined at higher temperatures.

Laser flash photolysis experiments were also carried out for 0.01 and 0.1 mol% samples of **1** in purified CCH-2 from 30–70°C (3 × 7 mm cells; 308 nm laser). Decay traces from the 0.1 mol% sample analysed for clean first order kinetics and the lifetimes were superimposable on the Arrhenius plot reported previously for a 1.0 mol% sample (2). The 0.01 mol% sample afforded poor quality traces that appear to be at least two-component in nature. The poor quality of these traces is due to light scattering, which is more pronounced with samples of this mesogen than with those of CCH-4, combined with weak transient signals. The long-lived component of these traces analysed for a lifetime in excess of 1 μs, with a fairly large (±60%) associated error.

Discussion

The morphologies of the smectic phases of the materials employed in the present work have all been established by X-ray diffraction methods (17, 21). That of CCH-4 is classified as a bilayer crystal-B phase (21–23); the constituent molecules are arranged in correlated bilayers of thickness just slightly less than twice the molecular length. Within the

bilayers, the molecules are hexagonally close-packed and oriented parallel to one another and perpendicular to the layer plane (21–23). Crystal-B phases possess some degree of three-dimensional positional order (22). The 4′-butyl derivative (CCH-4) forms an enantiotropic smectic phase, and is hence more useful as a reaction solvent than the 4′-propyl derivative (CCH-3), which forms monotropic smectic phases (24*a*). The enantiotropic smectic phase of CCH-2 is characterized by rhombohedral packing and threefold symmetry (21). Miscibility studies have shown that it is a more highly-ordered smectic phase than those of CCH-4 and CCH-3 (9). As a photochemical reaction solvent, it has found considerably less extensive use than CCH-4 (2, 3, 14).

On the basis of X-ray diffraction data, De Maria and coworkers have assigned the smectic phases of OS-53 and OS-35 as smectic B (hexagonal packing of molecules in single layers, with the long axes perpendicular to the layer planes). To the extent that these phases show long-range positional order (17), they should probably also be classified as crystal B. On a qualitative level, they can thus be viewed as similar in order and rigidity to the crystal B phase of CCH-4. However, on a more quantitative level, their relationship to each other and to CCH-4 and CCH-2 are unknown.

The ^2H NMR spectra of the 0.21–0.25 mol% samples of **2**–**4** in CCH-4 which are shown in Fig. 1*a*,*b* define the distinctive spectral patterns characteristic of homogeneous solubilization of these probes in the nematic (53–78°C) and smectic (<48°C) phases of this mesogen. Solubilization in the isotropic phase (>80°C) is characterized by a narrow-line singlet. The nematic phase spectra are characterized by one or more quadrupolar doublets depending on the number of non-equivalent deuteria in the solute. The magnitude of the quadrupolar splitting is a function of the time-averaged angle subtended by the applied magnetic field and the individual C—D bond direction, which is dictated by the overall time-averaged orientation of the solute (25). The maximum splittings observed for each derivative thus vary according to the deuteration site. In the nematic phase, these are 7.7 kHz for **2** and 25.2 kHz for **4** and occur at the lower end of the nematic phase temperature range (*i.e.*, at the *bulk* S–N transition temperature, where ordering in the nematic phase is at a maximum). The nematic phase spectra for **3** are similar to those reported previously for ring-deuterated alkylphenones in CCH-4 (12). They exhibit two sets of doublets: a relatively strong inner doublet with a maximum splitting of 2.1 kHz due to the *ortho*- and *meta*-deuterons, and a weak outer doublet of 43.5 kHz maximum splitting due to the *para*-deuteron. The large difference between the quadrupolar splittings of the *para*- and *ortho*-/*meta*-deuterons is due to differences in their time-averaged orientation with respect to the applied field. The larger value observed for the former indicates that the solute is preferentially oriented with the *para*-C—D bond axis of the β-phenyl ring near perpendicular to the applied magnetic field, parallel to the preferred orientation of the host matrix (because CCH-4 has negative diamagnetic anisotropy (26)). The quadrupolar splitting is at a maximum for deuteria in this orientation.

The smectic phase spectra of **2** and **3** consist of considerably broader absorptions and much larger quadrupolar splittings compared to the nematic phase spectra. In the case of **2**, the doublet splitting is *ca.* 2.5 times larger than in the nematic phase and does not vary appreciably with temperature throughout the 25–50°C range. In the case of **3**, the spectrum consists of broad absorptions flanked by a weaker doublet. The weak outer doublet, which is presumably due to the *para*-deuterons, is unobservable with the spectrometer used to record the spectra shown in Fig. 1*b*. The appearance of the broad inner absorptions changes dramatically as the temperature is lowered below 40°C. Using the 400 MHz solid state NMR spectrometer, both components of the spectrum of **3** can be resolved; at 37°C, the inner doublet splitting is ca. five times larger than in the nematic phase, while the splitting of the weaker outer doublet is *ca.* two times larger. No spectral features are observable at any temperature for homogeneous solutions of **4** in the smectic phase of CCH-4, as noted previously (10). This

may indicate that the reorientation rate of the α-CD bonds in the solute is similar in magnitude to the quadrupolar coupling constant, *ca.* 185 kHz (12, 27). The consistently larger splittings observed for **2** and **3** in the smectic compared to the nematic phase indicates that as expected, the solute experiences a greater degree of order (at both ends of the molecule) in the former type of phase. The fact that the appearance of the spectrum changes with sample orientation indicates that the solute is also well-aligned in the smectic phase (19).

The ^{2}H NMR spectra of **2–4** in the liquid crystalline phases of OS-53 and OS-35 are qualitatively similar to those in CCH-4, as expected since OS-*nm* liquid crystals also possess negative diamagnetic anisotropy (24*b*). The splittings are comparatively smaller, however. This presumably indicates that the solute is somewhat less ordered in the nematic and smectic phases of the OS-*nm* liquid crystals than it is in the corresponding phases of CCH-4. As well, a discernible doublet is observed for smectic solutions of **4** in OS-53, in contrast to the behavior of this analogue in smectic solutions of CCH-4 and OS-35.

Spectra recorded at temperatures within phase transitions show signals due to the solute in both the upper- and lower-temperature phases. As we have noted previously, these characteristics can be employed to determine the solubility limits of a solute in the smectic phase as a function of temperature, as well as the type of phases that are present in biphasic liquid crystalline samples. The spectra shown in Fig. 1*a*,*c* demonstrate that the solubility limit of **1** in the crystal B phase of CCH-4 is 0.21 mol% at some temperature higher than 38°C but lower than 48°C (43–44°C, in fact). The solubility limit increases with decreasing temperature throughout the smectic phase range (for example, in a 0.34 mol% **2**/CCH-4 mixture, the nematic phase signals persist to 38°C). At temperatures corresponding to *ca.* 5°C below the S–N transition temperatures of the pure mesogens, the solubility limit of **1** in the OS-*nm* smectic phases is roughly half that in the crystal B phase of CCH-4.

Spectra of a 1.0 mol% mixture of **2** and CCH-4 verify our previous conclusion (10) that a 1.0 mol% **1**/CCH-4 mixture is biphasic throughout the complete 30–52°C range: smectic + nematic between 35 and 52°C, and smectic + isotropic below 35°C.

The Arrhenius plots in Fig. 4 show that the average triplet decay rate of **1** undergoes a significant decrease (by a factor of 2–3) as the samples transform from nematic to smectic solutions. The difference can be ascribed to a sudden change in the conformational mobility of the solute at the S–N transition, consistent with the considerable difference in the degree of order present in the two phases. Sudden "jumps" of this type are observed in many of the properties associated with liquid crystals at transitions between weakly-ordered and highly-ordered phases (28). For a single liquid crystal, the effect is not due to changes in the local polarity experienced by the solute in the two phase types, since there is no change in the static UV absorption spectra of the samples at the phase transitions. The similarities in the Arrhenius plots for homogeneous solutions of **1** in CCH-4, OS-53, and OS-35 indicate that the effect is quite general.

The Arrhenius behavior observed for **1** in CCH-4 in the present work represents the true effects of this liquid crystal on the conformational mobility of the molecule. It confirms our suggestion (10) that the reported behavior of **1** in this liquid crystal (2), which was obtained using a 1 mol% sample, is distorted due to the biphasic nature of a sample of that concentration. The reported triplet lifetimes obtained with that sample represent average values of the lifetime of the ketone in the mobile (nematic or isotropic) phase and the smectic phase, weighted according to the distribution of ketone in the two phases. Since this distribution varies with temperature (mostly nematic at 50°C and mostly smectic at 30°C) (10), the resulting Arrhenius line would be expected to span from the nematic phase line at its low temperature extreme to the true smectic phase line at its low temperature extreme, as was observed (2).

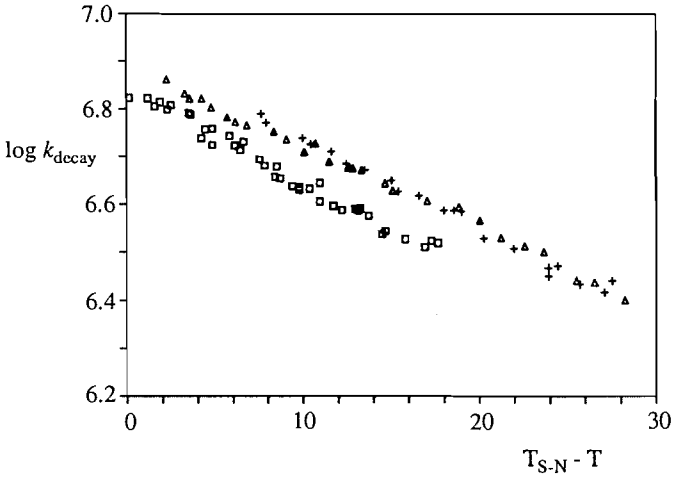

FIG. 5. Plot of log k_{decay} vs. reduced temperature ($T_{S-N} - T$) for triplet decay of **1** in the smectic B phases of CCH-4 and OS-*nm* liquid crystals: □, 0.25 mol% **1** in CCH-4; △, 0.1 mol% **1** in OS-53; +, 0.1 mol% **1** in OS-35. T_{S-N} is the lower temperature onset of the bulk smectic–nematic transition, taken to be 48.5°C for CCH-4, 36°C for OS-53, and 48°C for OS-35.

Figure 5 shows a plot of log k_{decay} versus reduced temperature ($T_{S-N} - T$), constructed by combining the data for *all three* of the smectic phases studied. The T_{S-N} values used to calculate the reduced temperatures were defined as 1°C below the midpoint of the S–N transition range for the mixtures as determined by ^{2}H NMR. The data for the two OS-*nm* smectic phases fall on the same line and appear to be displaced (by 4–5°C) from that defined by the CCH-4 data. We interpret the coincidence of the data for the OS-*nm* liquid crystals as indicating that the factors responsible for determining the triplet lifetime of **1** — local solvent polarity (8b) and rigidity — are similar in the two liquid crystals. The observed displacement of the data for smectic CCH-4 from the line defined by the OS-*nm* data could result from the solute experiencing higher local polarity (6) or greater rigidity in CCH-4. The fact that the nematic/isotropic phase data for the **1**/OS-*nm* mixtures are similarly displaced from those of the **1**/CCH-4 mixtures suggests that the difference in the behavior of **1** in the two classes of smectic phases is largely due to differences in local solvent polarity.

Triplet decay of **1** in CCH-2 was previously reported to be phase-independent, and this was taken to indicate that the solute experiences very little restraint to its conformational mobility in the smectic phase of this mesogen (2). In fact, the present NMR studies of **2** and **4** in CCH-2 indicate that the solubility limit of **1** in smectic CCH-2 is well below 0.1 mol% throughout its complete temperature range, and the bulk of the solute is solubilized in an isotropic liquid phase that coexists with a smectic phase of composition >99.9 mol%

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

CCH-2. Thus, the phase-independent triplet state behavior of **1** in CCH-2 is due to the fact that the solute resides largely in an isotropic (and briefly, a nematic) phase throughout the complete temperature range investigated. Below the bulk S–N transition, it is solubilized in a highly concentrated isotropic liquid, but experiences similar effects on mobility as at lower concentrations in the bulk isotropic phase. The much longer lifetimes observed for **1** in a 0.01 mol% sample of smectic CCH-2 suggest that this phase does indeed reduce the mobility of the ketone compared to the isotropic phase.

Triplet decay of **1** in the crystal B phase of CCH-4, even for homogeneous solutions, follows multi-exponential kinetics. This indicates that the ketone is solubilized in a distribution of sites in the liquid crystalline lattice (with varying effects on the conformational mobility of the probe), or in a distribution of conformations. Since triplet decay in these cases can be fairly successfully modelled with a simple first order treatment, the distribution of lifetimes spans only a factor of two or three. The lifetime distribution is comparatively narrower in the OS-*nm* smectic phases, since triplet decay is more accurately represented by simple first order kinetics.

Interestingly, the noticeable changes that occur in the triplet decay rate of **1** in CCH-4 and OS-*nm* at the S–N transitions are the result of barely perceptible alterations in the Arrhenius parameters for triplet decay in the two phase types. For CCH-4, the activation energy and entropy for triplet decay in the crystal-B phase are less than 1.0 kcal/mol and 2 eu higher, respectively, than the corresponding values for the nematic phase. Similar small differences are observed for the OS-*nm* liquid crystals. These barely perceptible changes in the energetics associated with intramolecular quenching at the S–N phase transition may indicate that the solute is in fact rather poorly restrained in the smectic B phases, in spite of the high degree of liquid crystalline order that is known to be associated with this type of phase (21, 22). An alternate possibility is that the solute is well-restrained in the smectic phase, but need undergo only small-amplitude conformational motions to achieve the quenching geometry. This could be the case if the preferred conformation (or distribution of similar conformations) is one in which the β-phenyl ring is already close to that required for intramolecular triplet quenching to occur, or if the spatial requirements for β-phenyl quenching are not as stringent as is implied in eq. [1]. While β-phenyl quenching is known to require overlap of the β-phenyl π-system with the carbonyl *n*-orbital (and hence a *gauche* or eclipsed conformation), the precise geometry or range of geometries required for quenching is unknown.

It is well-known that solutes are incorporated in liquid crystals in a manner dictated by best-packing considerations (28). In liquid crystals of rod-like molecules, rod-like solutes tend to assume the same average orientation as that defined by the solvent matrix (29). However, it does not follow that flexible solutes will necessarily adopt all-*trans* conformations; rather, they will prefer whatever conformations are stabilized the most by the liquid crystalline matrix. Semi-empirical dihedral driver calculations (AM1(30)) for **1** indicate that there exists a *gauche* conformation which is only 2 kcal/mol less stable than the lowest energy all-*trans* conformation; space-filling models indicate that the overall shape of this rod-like conformer is only slightly bulkier than that of the *trans* conformer. Even with reasonably tight packing of the solute in the crystal-B phase, intramolecular quenching in these conformers could occur with relatively slight changes in the overall shape of the

[2] 

excited solute (see reaction [2]), and thus with only slight restriction due to the ordered solvent matrix.

The two solubilization models that are consistent with the flash photolysis data — loose packing with little restriction on large-amplitude conformational motions versus tight packing with little restriction on small-amplitude conformational motions — could presumably be distinguished by further ^{2}H NMR studies that afford quantitative information on the motional rates of the β-phenyl ring deuteria. The first model requires that the β-phenyl ring reorient at rates similar to or faster than the triplet decay rate of **1**, while the second allows for reorientation rates much slower than the triplet decay rate. Studies of this type are in progress.

The Arrhenius parameters for triplet decay of **1** in the various nematic and isotropic phases vary slightly throughout the series (see Table 2). While this may be due to variations in solvent microviscosity, it is difficult to rule out the possibility that minor quenching impurities account for the slight variations in lifetime throughout the series of mesogenic solvents. For CCH-2/4 and the OS-*nm* liquid crystals, for which data have been collected throughout substantial temperature ranges in both the nematic and isotropic phases, there is little or no detectable change in triplet Arrhenius behavior at the N–I transition temperatures. This generalizes our previous conclusion that intramolecular quenching in **1** is unaffected by nematic solvent order in CCH-*n* liquid crystals (2, 3).

Summary and conclusions

The triplet decay rate of β-phenyl-4-methoxypropiophenone (**1**) is a factor of *ca.* 2.5 slower in the smectic B liquid crystalline phases of CCH-*n* and OS-*nm* mesogens than in the corresponding nematic and isotropic phases. Triplet decay is multiexponential in the smectic phase of CCH-4, indicating that the ketone is solubilized in a distribution of conformations or in a distribution of sites in the liquid crystal lattice. The substantial difference in the triplet lifetimes of **1** in the smectic and nematic/isotropic phases is the result of barely perceptible differences in Arrhenius parameters for decay in the highly-ordered and mobile phases, however. The results indicate that, in spite of the high degree of order associated with this type of liquid crystal, the solute experiences fairly small restrictions to the conformational motions required for β-phenyl quenching. This could be the case if the solute's preferred conformation (or distribution of similar conformations) in the liquid crystal is one in which the β-phenyl ring is already close to that required for intramolecular triplet quenching to occur, or if the spatial requirements for β-phenyl quenching are not as stringent as is commonly thought.

Experimental

^{1}H NMR spectra were recorded on Varian EM390 (90 MHz) or Bruker AC200 (200 MHz) spectrometers in deuteriochloroform solution, and are reported in parts per million downfield from tetramethylsilane. Ultraviolet absorption spectra were recorded on a Hewlett-Packard HP8451 UV spectrometer. Mass spectra and exact masses were recorded on a VGH ZABE mass spectrometer; the latter employed a mass of 12.000000 for carbon. Melting points were determined on a hot stage microscope with a Cole-Parmer Model 8110-10 Type K thermocouple.

Acetonitrile (Caledon HPLC) was refluxed over calcium hydride and distilled under nitrogen. Acetone (BDH Reagent) used in the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

preparation of **1** was refluxed over anhydrous potassium carbonate and distilled.

β-Phenyl-4-methoxypropiophenone (**1**) (3), β-phenyl-4-methoxypropiophenone-α,α-d_2 (**4**) (10), and β-phenyl-4-hydroxypropiophenone (4) were prepared in earlier studies. Bromobenzene-d_5, 4-methoxyacetophenone, 4-hydroxyacetophenone, iodomethane-d_3 (all from Aldrich Chemical Co.), dichloromethane (Baker, HPLC grade), CCH-4, CCH-3, CCH-2, OS-35, and OS-53 (E. Merck) were used as received from the suppliers. For some of the flash photolysis experiments, CCH-2 was recrystallised three times from pentane (Baker Photrex).

β-Phenyl-4-(methoxy-d_3)propiophenone (**2**) was prepared from β-phenyl-4-hydroxypropiophenone, iodomethane-d_3, and potassium carbonate in refluxing acetone (4), and was recrystallized twice from aqueous ethanol (mp = 94–95°C). It exhibited the following ^{1}H NMR spectrum: δ(ppm) = 3.1 (m, 2H), 3.2 (m, 2H), 6.9 (d, 2H), 7.2 (s, 5H), 7.9 (d, 2H). Exact mass: calcd. for $C_{16}H_{13}O_2D_3$: 243.1350; found: 243.1346.

β-(Phenyl-d_5)-4-methoxypropiophenone (**3**) was prepared by condensing 4-methoxyacetophenone with benzaldehyde-d_5 (prepared from phenyl-d_5 magnesium bromide and *N*-formylmorpholine (31)) and hydrogenation of the resulting chalcone derivative over Raney nickel in deoxygenated ethyl acetate (4). Compound **3** was recrystallised twice from 95% ethanol (mp 95–97°C) and exhibited the following ^{1}H NMR spectrum: δ(ppm) = 3.04 (m, 2H), 3.24 (m, 2H), 3.85 (s, 3H), 6.90 (d, 2H), 7.92 (d, 2H). Exact mass: calcd. for $C_{16}H_{11}O_2D_5$: 245.1464; found: 245.1465.

Deuterium NMR spectroscopy

^{2}H NMR experiments were carried out at 76.78 MHz on a Bruker AM500 NMR spectrometer equipped with an Aspect 3000 computer, a Bruker BVT-100 Variable Temperature Unit, and a 10 mm VSP broadband probe. Temperatures were controlled to within 0.2°C and were calibrated with a copper–constantan thermocouple. Samples were prepared by combining the appropriate amounts of solute and liquid crystal and heating to the isotropic phase to ensure complete sample mixing. They were then placed in 5 mm NMR tubes. The sample and probe were allowed to equilibrate at each temperature for 10–20 min prior to recording the spectrum. Spectra were recorded on stationary samples using the quadrupolar echo pulse sequence (18), collecting 16K data points per scan over a 40–170 kHz sweep width. Depending on the bulk concentration and temperature, 96–12000 scans were collected with a 0.2–0.4 s delay between scans, and averaged. A few experiments were carried out at 61.4 MHz on a Bruker MSL400 NMR spectrometer equipped with an Aspect 3000 computer, Bruker BVT-100 Variable Temperature Unit, and a home-built deuterium probe. The π/2 pulse width was determined to be 14–16 μs for the AM500 and 4 μs for the MSL400 spectrometers by trial and error using $CDCl_3$(10%)/$CHCl_3$ solutions. The data were processed using exponential multiplication and 80–100 Hz line-broadening prior to obtaining the Fourier transform.

Laser flash photolysis

Nanosecond laser flash photolysis experiments employed the pulses from a Lumonics TE-861M excimer laser filled with Xe/HCl/H_2/He (308 nm, 15 ns, *ca.* 40 mJ) or N_2/He (337 nm, 6 ns, *ca.* 4 mJ) mixtures and the microcomputer-controlled detection system which has been described elsewhere (20). The sample compartment was surrounded by an insulated quartz sleeve, through which heated nitrogen was passed in order to heat the sample. Sample temperatures were measured using a copper-constantan thermocouple or a Cole-Parmer Type K digital thermocouple thermometer and are accurate to ±0.1°C. The samples were allowed to equilibrate at each temperature for at least 20 min prior to recording the decay trace.

Samples were contained in 3 × 7 mm or 0.7 × 7 mm cells constructed from rectangular Suprasil quartz or Pyrex tubing, respectively (Vitro Dynamics). Except for the low concentration samples in CCH-2, they were prepared by weighing out the appropriate amount of solute and liquid crystal and heating to the isotropic phase to ensure complete sample mixing. Samples of composition <0.1 mol% were prepared by adding an aliquot of a standard solution of **1** in dichloromethane to the appropriate amount of liquid crystal. The mixture was dissolved completely in dichloromethane and the solvent was removed on a rotary evaporator and then pumped under high vacuum (*ca.* 10^{-4} Torr) for several hours. Samples of 1 mol% or greater **1** were contained in the 0.7 mm cells, while all others were contained in the 3 mm cells. They were degassed with five freeze–pump–thaw cycles and sealed on a vacuum line. Except where noted, samples were annealed for several days at 38°C, which produced homeotropically aligned samples.

Acknowledgments

We wish to thank E. Merck (Darmstadt) for generous gifts of the CCH-*n* and OS-*nm* liquid crystals, and Dr. C. Fyfe (University of British Columbia) for the use of his solid state NMR spectrometer. The financial support of the Natural Sciences and Engineering Research Council of Canada is gratefully acknowledged.

Stereochemistry and kinetics of amines addition to acetylenic esters

SABER M. SHARAF, SAMIR K. EL-SADANY, EZZAT A. HAMED, AND ABDEL-HAMID A. YOUSSEF[1]
Department of Chemistry, Faculty of Science, Alexandria University, Alexandria, Egypt

Received October 19, 1990

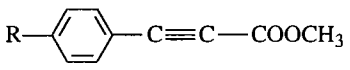
SABER M. SHARAF, SAMIR K. EL-SADANY, EZZAT A. HAMED, and ABDEL-HAMID A. YOUSSEF. Can. J. Chem. **69**, 1445 (1991).

The reactions of a series of methyl *para*-substituted phenylpropiolates **1***a–e* with piperidine, morpholine, and diethylamine in methanol and dimethylformamide (DMF) have been studied and their rates measured. The products were methyl β-(*N*,*N*-dialkylamino)-*p*-substituted cinnamates **2–4***a–e*. ^{1}H NMR spectra were used to determine the configuration of the products. The ρ values in methanol ranged between 0.34 and 1.24 whereas in DMF they were between 0.85 and 1.88. The values of $\Delta S^{\neq}$ favor a bimolecular rate-limiting step mechanism.

Key words: nucleophilic addition to acetylenic esters.

SABER M. SHARAF, SAMIR K. EL-SADANY, EZZAT A. HAMED et ABDEL-HAMID A. YOUSSEF. Can. J. Chem. **69**, 1445 (1991).

On a étudié les réactions d'une série de phenylpropiolates de méthyle substitués en position *para*, **1***a–e* avec la pipéridine, la morpholine et la diéthylamine dans le méthanol et dans le diméthylformamide (DMF) et on a également mesuré les vitesses de réaction. On a obtenu des β-(*N*,*N*-dialkylamino)cinnamates de méthyle substitués en position *para* **2–4***a–e* et on a déterminé leur configuration à partir des spectres RMN du ^{1}H. La valeur de ρ se situent entre 0,34 et 1,24 dans le méthanol et entre 0,85 et 1,88 dans le DMF. Les valeurs de $\Delta S^{\neq}$ suggèrent qu'une réaction bimoléculaire constitue l'étape déterminante.



Mots clés : addition nucléophile aux esters acétyléniques.

[Traduit par la rédaction]

Introduction

Nucleophilic additions to activated alkynes have been studied from synthetic and stereochemical points of view (1, 2). Previously, it was suggested (3, 4) that the reaction of amines with acetylenic compounds may involve *cisoid* additions, whereas others (2, 5) have found *transoid* products. Both types of additions depend upon many factors. These include the basicity, steric requirements of the amines, substituents in the aromatic ring conjugated with the acetylenic bond, and the nature of the solvent as well as the temperature (5–10).

In continuation of our studies on the reactions of acetylenic compounds (9), this work involves the study of the stereochemistry and kinetics of the addition of piperidine, morpholine, and diethylamine to methyl *p*-substituted phenylpropiolates **1***a–e* in methanol and dimethylformamide (DMF).

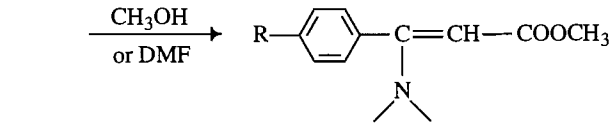
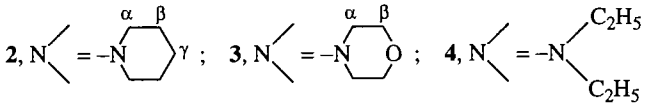
Results and discussion



The products obtained from the reaction of amines and the acetylenic esters **1***a–e* in methanol and DMF have been isolated and identified as methyl β-(*N*,*N*-dialkylamino) *p*-substituted cinnamates, eq. [1]. ^{1}H NMR data indicate the presence of only one piperidino, morpholino, or *N*,*N*-diethylamino group. The IR bands at 1495–1560 cm^{-1} indicate a double bond stretching, which is a typical conjugated β-enamino-ester structure (11). The strong band at 1690–1700 cm^{-1} was assigned to the >C=O of the conjugated ester group (12).

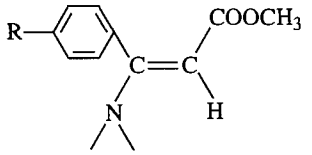
Configuration of the products



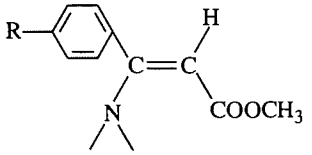
The elucidation of the configuration of the products was, however, difficult due to the fact that only one geometrical isomer (except **2–4***e* in DMF) is accessible. The ^{1}H NMR data of the products obtained from the reaction of **1***a–e* with piperidine, morpholine, and diethylamine in methanol showed a

[1] 

1 *a–e*



2–4*a–e*



singlet for a vinylic proton at δ 4.72–5.00. The *E* configuration of these products was established by comparing the chemical shifts of the vinylic protons in their ^{1}H NMR spectra to the related derivatives (9, 13, 14). Furthermore, the calculated chemical shift values of the vinylic protons, obtained by applying the NMR rules of additivity (15, 16), for *E*- and *Z*-β-(*N*,*N*-dialkylamino) cinnamate esters ($\delta_{calc.}$ = 4.72 and 5.20 ppm, respectively) indicated the *E* configuration for the isolated products **2–4***a–e* (δ_{obs} = 4.72–5.00 ppm).

The products obtained from these reactions in DMF also gave a singlet vinylic proton for *E* adducts **2***a–d*, **3***a–d*, and **4***a–d*, whereas **2***e*, **3***e*, and **4***e* showed two vinylic protons at δ 4.72–5.00 and 5.23–5.63 ppm indicating the presence of a mixture of *E* and *Z* isomers, respectively. Similarly, two singlets at δ 3.47–3.50 and 3.62–3.65 ppm were observed for the OCH_3 group of the *p*-nitro esters with a ratio *E*:*Z* of 73:27%; 67:33%; 63:37%, respectively, depending on the amine used.

[a]Methanol.
[b]DMF.

Kinetics of the reactions

The kinetics of the formation of methyl β-(*N*,*N*-dialkylamino) *p*-substituted cinnamates in methanol and DMF were studied by following the gradual decrease of amine concentration as a function of time. The reactions in methanol showed second-order kinetics, those in DMF followed third-order kinetics, first order in the substrate and second order in the amine (Table 1).

The rates of amine addition to **1***a–e* in both solvents depend on the type of amine and the *p*-substituent. The order of reactivity of amines is piperidine > morpholine > diethylamine, suggesting that these reactions are controlled not only by the basicity of the amines but also by their steric requirements (17).

Hammett plots gave good straight lines for these reactions with a slight deviation from linearity for the reactions of **1***e* in DMF. The ρ values ranged between +0.34:1.24 and +0.85:1.88 in methanol and DMF respectively, depending on the temperature and the amine used. These values of ρ, as shown before (9), point to the formation of a transition state with some anionic character developed at the carbon atom adjacent to the carbomethoxy group.

The thermodynamic parameters $\Delta S^{\neq}$ and $\Delta H^{\neq}$ were calculated using the least-squares method, Table 1. The observed negative entropies of activation $\Delta S^{\neq}$ are expected for adduct formation from neutral species, and the magnitudes of $\Delta S^{\neq}$ values point to the formation of highly ordered transition states. This suggests that the mechanism of these addition reactions is a bimolecular one (17, 18).

Mechanism of the reaction

The reaction in methanol involves an initial rate-limiting addition step of the amine to the appropriate acetylenic ester **1***a–e*. The function of the methanol molecule can be regarded as a proton donor through a six-membered transition state **6** leading to the formation of the *E* isomer, predominantly independent of the substrate/amine molar ratio.

The reaction in DMF, however, showed a second-order dependence of the amine used, since the amine molecule exists as a hydrogen-bonded dimer (17). The participation of the amine dimer can be interpreted as a synchronous proton transfer in which one molecule of the acetylenic ester shares with it to form a cyclic transition state **6**, Scheme 1. A similar mechanism was suggested earlier for the reaction of 1,3-diphenyl-2-propyn-1-one with morpholine in dioxane (18) and *trans*-chalcone with pyrrolidine in heptane (19).

The reactions of **1***e* with amines in DMF yielded a mixture of *E* and *Z* isomers (Scheme 1). This could occur by either a two-step process in which addition of the amine led to **5**, which underwent protonation to the *E*/*Z* mixture, or by the competing formation of **5** and **6**.

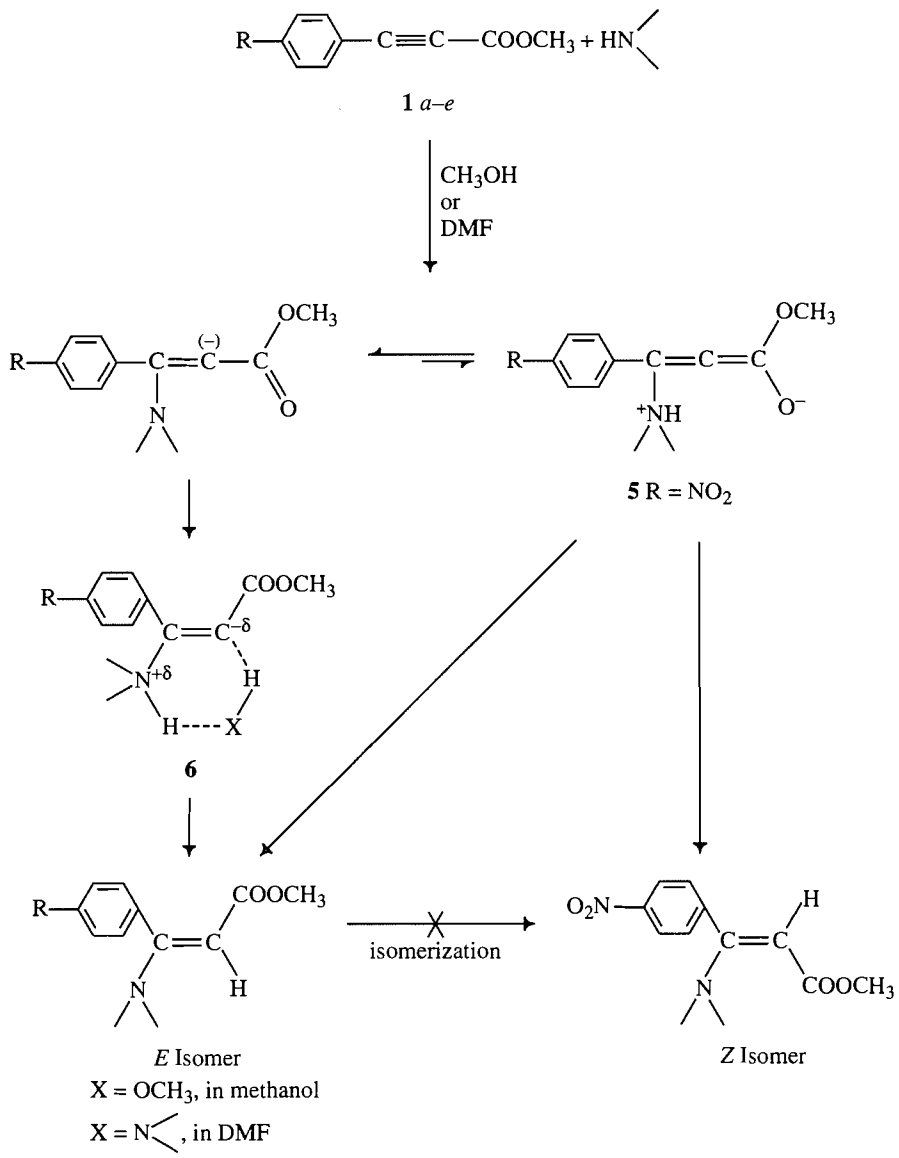
The reaction of **1***e* with morpholine in methanol and DMF was followed by ^{1}H NMR spectroscopy. In methanol only the *E* product was identified throughout the whole reaction. However, in DMF two vinylic protons were observed and their ratio did not change with time. This indicates that the mechanism proceeds via *syn*-addition with absence of isomerization of the product under the reaction conditions.

In conclusion, *syn*-additon via **6** is favored for the reaction of **1***a–e* with different amines in methanol and **1***a–d* in DMF, since it leads to the formation of only the *E* isomer, as observed. In the case of the reaction of **1***e* with amines in DMF there is a competing *anti*-protonation, giving a mixture of *E* and *Z* isomers.

Experimental

Infrared and ultraviolet spectra were measured on Pye Unicam SP 1025 and SP 800 spectrometers, respectively.

The ^{1}H NMR spectra were measured on a Varian EM 390 90-MHz spectrometer. Microanalyses were done at the microanalytical laboratories, Alexandria University; melting points and boiling points are uncorrected.



Preparation of starting materials

para-Substituted phenylpropiolic acids were prepared by heating methyl 2,3-dibromo-3-(*p*-substituted phenyl)-propanoates (20) with 25% methanolic potassium hydroxide on a steam bath. The methyl esters **1***a–e* were, however, obtained by treatment of the acids with dry hydrogen chloride gas in methanol.

Reaction products

The desired acetylenic ester (0.001 mol) was dissolved in the appropriate solvent (10 mL) and threefold molarity of the amine was added. The mixture was thermostated at 40°C for 10 half-lives. The reaction mixture was poured into ice-cold water and the solid formed was filtered and recrystallized from methanol–water. The samples used for ^{1}H NMR studies were those isolated from the reaction before recrystallization.

Reaction in methanol

E-*Methyl* β-*piperidino-cinnamate* **2**a

Colurless needles, yield 91%; mp 56°C; IR(KBr): 1720 and 2840 cm^{-1}; UV (methanol): λ = 294 nm (ε = 19 200); ^{1}H NMR ($CDCl_3$) δ: 7.60–7.00 (m, 5H, Ph), 4.85 (s, 1H, *E*-olefinic), 3.40 (s, 3H, -OCH_3), 3.20–2.80 (m, 4H, α-$2CH_2$), and 1.80–1.10 (m, 6H, β- and γ-$3CH_2$) ppm. Anal. calcd. for $C_{15}H_{19}O_2$: C 73.43, H 7.81, N 5.71; found: C 72.99, H 7.70, N 5.78.

E-*Methyl* β-*piperidino*-p-*methylcinnamate* **2**b

Colourless needles, yield 88%; mp 54°C; IR(KBr): 1685, 2860, and 2940 cm^{-1}; UV (methanol): λ = 274 nm (ε = 18 600); ^{1}H NMR ($CDCl_3$) δ: 7.50–7.00 (m, 4H, aryl), 4.93 (s, 1H, *E*-olefinic), 3.37 (s, 3H, -OCH_3), 3.32–2.70 (m, 4H, α-$2CH_2$), 2.37 (s, 3H, *p*-CH_3), and 1.73–1.10 (m, 6H, β- and γ-$3CH_2$) ppm. Anal. calcd. for $C_{16}H_{21}NO_2$: C 74.09, H 8.16, N 5.40; found: C 74.23, H 8.03, N 5.14.

E-*Methyl* β-*piperidino*-p-*bromocinnamate* **2**c

Colourless plates, yield 95%, mp 105°C; IR(KBr): 1700, 2860, and 3000 cm^{-1}; UV (methanol): λ = 294 nm (ε = 15 200); ^1H NMR ($CDCl_3$) δ: 7.45–7.00 (m, 4H, aryl), 4.93 (s, 1H, *E*-olefinic), 3.50 (s, 3H, $-OCH_3$), 3.25–2.90 (m, 4H, α-$2CH_2$), and 1.86–1.24 (m, 6H, β- and γ-$3CH_2$) ppm. Anal. calcd. for $C_{15}H_{18}BrNO_2$: C 55.58, H 5.59, N 4.32; found: C 55.33, H 5.39, N 4.40.

E-*Methyl* β-*piperidino*-p-*chlorocinnamate* **2**d

Colourless plates, yield 91%; mp 102°C; IR(KBr): 1690, 2800, and 3000 cm^{-1}; UV (methanol): λ = 295 nm (ε = 29 000); ^1H NMR ($CDCl_3$) δ: 7.50–6.95 (m, 4H, aryl), 4.90 (s, 1H, *E*-olefinic), 3.47 (s, 3H, $-OCH_3$), 3.25–2.85 (m, 4H, α-$2CH_2$), and 1.90–1.22 (m, 6H, β- and γ-$3CH_2$) ppm. Anal. calcd. for $C_{15}H_{18}ClNO_2$: C 64.39, H 6.48, N 5.00; found: C 64.55, H 6.57, N 5.19.

E-*Methyl* β-*piperidino*-p-*nitrocinnamate* **2**e

Yellow plates, yield 93%; mp 125°C; IR(KBr): 1690, 2860, and 2980 cm^{-1}; UV (methanol): λ = 278 nm (ε = 22 600); ^1H NMR ($CDCl_3$) δ: 8.20, 7.37 (dd, 4H, aryl); 4.94 (s, 1H, *E*-olefinic), 3.47 (s, 3H, $-OCH_3$), 3.25–2.90 (m, 4H, α-$2CH_2$), and 1.85–1.26 (m, 6H, β- and γ-$3CH_2$) ppm. Anal. calcd. for $C_{15}H_{18}N_2O_2$: C 62.06, H 6.25, N 9.65; found: C 62.44, H 6.21, N 9.83.

E-*Methyl* β-*morpholino-cinnamate* **3**a

Colourless needles, yield 90%; mp 74°C; IR(KBr): 1710, 2860, and 2960 cm^{-1}; UV (methanol): λ = 288 nm (ε = 17 000); ^1H NMR ($CDCl_3$) δ: 7.64–7.10 (m, 5H, Ph), 5.00 (s, 1H, *E*-olefinic), 3.85–3.55 (m, 4H, β-$2CH_2$), 3.50 (s, 3H, $-OCH_3$), and 3.28–2.92 (m, 4H, α-$2CH_2$) ppm. Anal. calcd. for $C_{14}H_{17}NO_3$: C 67.99, H 6.93, N 5.66; found: C 67.80, H 7.00, N 5.66.

E-*Methyl* β-*morpholino*-p-*methylcinnamate* **3**b

Colourless plates, yield 93%; mp 54°C; IR(KBr): 1710 and 2980 cm^{-1}; UV (methanol): λ = 288 (ε = 19 000); ^1H NMR ($CDCl_3$) δ: 7.34–6.85 (m, 4H, aryl), 4.93 (s, 1H, *E*-olefinic), 3.80–3.55 (m, 4H, β-$2CH_2$), 3.50 (s, 3H, $-OCH_3$), 3.28–2.85 (m, 4H, α-$2CH_2$), and 2.40 (s, 3H, *p*-CH_3) ppm. Anal. calcd. for $C_{15}H_{19}NO_3$: C 74.09, H 8.16, N 5.40; found: C 74.23, H 8.03, N 5.14.

E-*Methyl* β-*morpholino*-p-*bromocinnamate* **3**c

Colourless needles, yield 95%; mp 98°C; IR(KBr): 1710, 2800, and 3000 cm^{-1}; UV (methanol): λ = 288 nm (ε = 14 400); ^1H NMR ($CDCl_3$) δ: 7.47, 7.15 (dd, 4H, aryl), 4.93 (s, 1H, *E*-olefinic), 3.76–3.54 (m, 4H, β-$2CH_2$), 3.47 (s, 3H, $-OCH_3$), and 3.18–2.85 (m, 4H, α-$2CH_2$) ppm. Anal. calcd. for $C_{14}H_{16}BrNO_3$: C 51.55, H 4.94, N 4.29; found: C 51.43, H 5.00, N 4.19.

E-*Methyl* β-*morpholino*-p-*chlorocinnamate* **3**d

Colourless needles, yield 96%; mp 85°C; IR(KBr): 1700, 2840, and 2980 cm^{-1}; UV (methanol): λ = 288 nm (ε = 14 000); ^1H NMR ($CDCl_3$) δ: 7.44, 7.00 (m, 4H, aryl), 4.93 (s, 1H, *E*-olefinic), 3.78–3.56 (m, 4H, β-$2CH_2$), 3.47 (s, 3H, $-OCH_3$), and 3.20–2.90 (m, 4H, α-$2CH_2$) ppm. Anal. calcd. for $C_{14}H_{16}ClNO_3$: C 59.68, H 5.72, N 4.97; found: 59.94, H 5.67, N 5.05.

E-*Methyl* β-*morpholino*-p-*nitrocinnamate* **3**e

Yellow crystals, yield 98%; mp 123°C; IR(KBr): 1690 and 2900 cm^{-1}; UV (methanol): λ = 274 nm (ε = 30 000); ^1H NMR ($CDCl_3$) δ: 8.30, 7.50 (dd, 4H, aryl), 5.00 (s, 1H, *E*-olefinic), 3.73–3.60 (m, 4H, β-$2CH_2$), 3.46 (s, 3H, $-OCH_3$), and 3.13–2.96 (m, 4H, α-$2CH_2$) ppm. Anal. calcd. for $C_{14}H_{16}N_2O_5$: C 57.43, H 5.52, N 9.58; found: C 57.43, H 5.53, N 9.40.

E-*Methyl* β-*(*N,N-*diethylamino)-cinnamate* **4**a

Colourless crystals, yield 96%; mp 35°C; IR(KBr): 1700 and 2990 cm^{-1}; UV (methanol): λ = 290 nm (ε = 21 160); ^1H NMR ($CDCl_3$) δ: 7.85–7.25 (m, 5H, Ph), 4.83 (s, 1H, *E*-olefinic), 3.60 (s, 3H, $-OCH_3$), 3.50–3.10 (q, 4H, $2CH_2$), and 1.40–1.05 (t, 6H, $2CH_3$) ppm. Anal. calcd. for $C_{14}H_{19}NO_2$: C 72.05, H 8.21, N 6.00; found: C 71.90, H 8.16, N 5.90.

E-*Methyl* β-*(*N,N-*diethylamino)*-p-*methylcinnamate* **4**b

Colourless crystals, yield 96%; mp 47°C; IR(KBr): 1690 and 2990 cm^{-1}; UV (methanol): λ = 288 nm (ε = 21 120); ^1H NMR ($CDCl_3$) δ: 7.32–6.96 (m, 4H, aryl), 4.77 (s, 1H, *E*-olefinic), 3.43 (s, 3H, $-OCH_3$), 3.33–2.88 (q, 4H, $2CH_2$), 2.67 (s, 3H, *p*-OCH_3), and 1.24–0.92 (t, 6H, $2CH_3$) ppm. Anal. calcd. for $C_{15}H_{21}NO_2$: C 72.84, H 8.53, N 5.66; found: C 72.81, H 8.70, N 5.68.

E-*Methyl* β-*(*N,N-*diethylamino)*-p-*bromocinnamate* **4**c

Colourless needles, yield 95%; mp 96°C; IR(KBr): 1690, 2980, and 3000 cm^{-1}; UV (methanol): λ = 296 nm (ε = 21 600); ^1H NMR ($CDCl_3$) δ: 7.50–7.15 (dd, 4H, aryl), 4.80 (s, 1H, *E*-olefinic), 3.47 (s, 3H, $-OCH_3$), 3.28–2.98 (q, 4H, $2CH_2$), and 1.28–1.00 (t, 6H, $2CH_3$) ppm. Anal. calcd. for $C_{14}H_{18}BrNO_2$: C 53.87, H 5.81, N 4.48; found: C 53.76, H 5.65, N 4.30.

E-*Methyl* β-*(*N,N-*diethylamino)*-p-*chlorocinnamate* **4**d

Colourless needles, yield 96%; mp 85°C; IR(KBr): 1690 and 2990 cm^{-1}; UV (methanol): λ = 290 nm (ε = 25 000); ^1H NMR ($CDCl_3$) δ: 7.35–7.20 (dd, 4H, aryl), 4.83 (s, 1H, *E*-olefinic), 3.50 (s, 3H, $-OCH_3$), 3.28–2.92 (q, 4H, $2CH_2$), and 1.28–0.95 (t, 6H, $2CH_3$) ppm. Anal. calcd. for $C_{14}H_{18}ClNO_2$: C 62.29, H 6.78, N 5.89; found: C 62.59, H 6.86, N 5.60.

E-*Methyl* β-*(*N,N-*diethylamino)*-p-*nitrocinnamate* **4**e

Yellow crystals, yield 96%; mp 123°C; IR(KBr): 1700 and 3000 cm^{-1}; UV (methanol): λ = 280 nm (ε = 54 666); ^1H NMR ($CDCl_3$) δ: 8.18, 7.40 (dd, 4H, aryl), 4.72 (s, 1H, *E*-olefinic), 3.50 (s, 3H, $-OCH_3$), 3.28–2.94 (q, 4H, $2CH_2$), and 1.18–0.95 (t, 6H, $2CH_3$) ppm. Anal. calcd. for $C_{14}H_{18}N_2O_4$: C 60.43, H 6.47, N 10.07; found: C 59.99, H 6.34, N 10.04.

Reaction in DMF

The same products were isolated as in methanol with all amines, except that **1***e* gave two isomers.

E- *and* Z-*Methyl* β-*piperidino*-p-*nitrocinnamate*

This compound showed the same IR, UV, and elemental analyses as the *Z* isomer **2***e*. ^1H NMR ($CDCl_3$) δ: 8.40–7.94, 7.44–7.00 (2m, 4H, aryl), 5.23 (s, 1H, *Z*-olefinic, 27%), 4.97 (s, 1H, *E*-olefinic, 73%), 3.65 (s, 3H, *Z*-OCH_3, 27%), 3.47 (s, 3H, *E*-OCH_3, 73%), 3.20–2.85 (m, 4H, α-$2CH_2$), and 1.85–1.10 (m, 6H, β- and γ-$2CH_2$) ppm.

E- *and* Z-*Methyl* β-*morpholino*-p-*nitrocinnamate*

This compound showed the same IR, UV, and elemental analyses as that isolated from the reaction in methanol. ^1H NMR ($CDCl_3$) δ: 8.34–7.86, 7.50–6.98 (2m, 4H, aryl), 5.63 (s, 1H, *Z*-olefinic, 33%), 5.00 (s, 1H, *E*-olefinic, 67%), 3.85–3.63 (m, 4H, β-$2CH_2$), 3.62 (s, 3H, *Z*-OCH_3, 33%), 3.47 (s, 3H, *E*-OCH_3, 67%); and 3.18–2.80 (m, 4H, α-$2CH_2$) ppm.

E- *and* Z-*Methyl* β-*(*N,N-*diethylamino)*-p-*nitrocinnamate*

This compound showed the same IR, UV, and elemental analyses as the product isolated from methanol. ^1H NMR ($CDCl_3$) δ: 8.40–7.86, 7.60–6.85 (2m, 4H, aryl), 5.37 (s, 1H, *Z*-olefinic, 37%), 4.72 (s, 1H, *E*-olefinic, 63%), 3.65 (s, 3H, *Z*-OCH_3, 37%), 3.50 (s, 3H, *E*-OCH_3), 3.34–2.90 (q, 4H, $2CH_2$), and 1.40–0.85 (t, 6H, $2CH_3$) ppm.

Kinetic measurements

The rate of reaction was determined by following the decrease in amine concentration by titration against hydrochloric acid using methyl red as indicator (21).

The reactions of **1***a–e* (0.1–0.025 M) with amines (0.1–0.025) in methanol were measured under second-order kinetics (1:1). Plots of log $-dc/dt$ vs. log C_{mean} showed that these reactions are second order. The observed rate constants k_2 were calculated from the special second-order rate constant equation:

$$k_2 = 1/t \cdot 1/a \cdot x/a-x$$

where t, a, and x are time, initial concentration of the amine, and concentration of amine consumed in the reaction, respectively.

The reactions of **1***a–e* (0.025 M) with amines (0.05 M) in DMF were carried out using a 1:2 molar ratio respectively. Mathematical calculation indicates that the reaction is third order. The third-order rate constants k_3 were calculated from the equation:

$$k_3 = 1/t\,(1/C_t^2 - 1/C_0^2)$$

where t, C_0, and C_t are time, initial concentration of the amine, and concentration of the amine consumed during the reaction.

Cadmium chloride mediated regiocontrol of dienolates and ketene thioacetals: γ condensation with aldehydes

BO LEI AND ALEX G. FALLIS

The Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received February 7, 1991

BO LEI and ALEX G. FALLIS. Can. J. Chem. **69**, 1450 (1991).

The use of cadmium chloride to control the regioselectivity of vinylogous anions upon condensation with aldehydes is described. Addition occurred preferentially at the γ position with substituted crotonates and 2-ethylidene-1,3-dithiane (**6**). Experiments demonstrated that this selectivity arose as a consequence of isomerization of the initially formed kinetic α product to the thermodynamic γ product (e.g., **2** to **4**). The optimum results were achieved with 2 equivalents of cadmium chloride and quenching at 0°C.

Key words: vinylogous anions, cadmium, condensation, dithiane.

BO LEI et ALEX G. FALLIS. Can. J. Chem. **69**, 1450 (1991).

On décrit l'utilisation du chlorure de cadmium pour contrôler la régiosélectivité de la réaction de condensation entre les anions vinylogues et les aldéhydes. Les crotonates substitués et l'éthylidène-2-dithiane-1,3 (**6**) conduisent à une addition préférentielle en position γ. Les expériences démontrent que cette sélectivité résulte de l'isomérisation du produit cinétique α formé initialement en produit thermodynamique γ (e.g., **2** à **4**). On obtient les meilleurs résultats lorsqu'on utilise deux équivalents de chlorure de cadmium avec refroidissement à 0°C.

Mots clés : anions vinylogues, cadmium, condensation, dithiane.

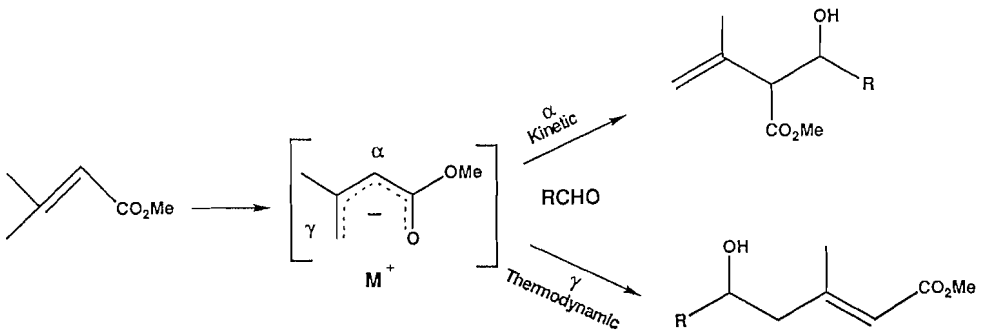
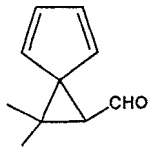
Introduction



Synthetic applications of allylic carbanions, such as those employed in allyl transfer (1–3), the vinylogous Reformatsky reaction (4–7), and related species derived from ketene dithioacetals (8-10) are of widespread current interest. In spite of considerable study, the effective control of the new carbon–carbon bond at either the α or the γ position is still a significant challenge. The regioselective condensation of heteroatom-stabilized allylic anions and resonance-stabilized enolates depends upon the complex interplay of several different factors. These include the nature of the heteroatom(s), the extent of charge delocalization, steric effects, solvation, the type of electrophile, and the characteristics of the counterion. Synthetic difficulties are compounded by the observation that halides and carbonyl systems often exhibit the opposite regiochemistry (9). In addition, as illustrated in Scheme 1, the kinetic and thermodynamic products frequently differ. Nevertheless, this circumstance can be utilized to facilitate the desired control.

Selective carbon–carbon bond formation at the γ position is important for the synthesis of terpenoid natural products and consequently a variety of methods have been developed to control the reactive site (11–15). A number of different metals and counterions have been examined, including lithium, magnesium, zinc, tin, silicon, palladium, etc. We wish to report that organocadmium reagents generated *in situ* from the corresponding alkyl lithium derivatives condense preferentially, under thermodynamic conditions, with aldehydes at the γ position of the allylic anion (preliminary communication: ref. 16). This is in contrast to the reported behaviour of the "crotylcadmium" reagent prepared from crotyl magnesium bromide, which afforded exclusively the methallyl adducts (17, 18).



Results and discussion

We required a reliable procedure for the direct introduction of a conjugated allyl unit for our total synthesis of (+)-longifolene (19). In spite of the previous studies in this area (referenced above) this transformation is often not as straightforward as it appears. The spiro-cyclopropyl aldehyde **1** was prepared in 84% yield by oxidation (active MnO_2) of the corresponding alcohol, itself available in two steps from cyclopentadiene (20). Treatment of methyl 3-methylcrotonate (methyl 3,3-dimethylacrylate) with lithium diisopropylamide (LDA) at −78°C in tetrahydrofuran (THF), to generate the anion, followed by condensation with aldehyde **1** afforded the α product **2** exclusively (Table 1, Entry 1). This is in accord with the normal regiochemical behaviour encountered with lithium enolates. Dugger and Heathcock (11) established that upon condensation with benzaldehyde the product mixture was influenced by the length of the reaction time and the quenching temperature. For example, after a reaction time of 10 s followed by quenching at −70°C the hydroxy-ester **5** was formed, while if the initial reaction mixture was allowed to warm to 10–15°C before quenching the γ isomer **3** and the corresponding lactone were isolated. Similar results were reported by Johnson and White (12) who examined the behaviour of the lithium dianion from the corresponding acid. They noted that the kinetic α products were formed at −78°C while at higher temperatures (22 and 65°C) the reaction was reversible and the more stable γ products dominated. Hudlicky and co-workers (4) found that the regioselectivity in the Reformatsky reaction of ethyl 4-bromocrotonate with carbonyl substrates was dependent on the polarity of the solvent and the hardness of the metal. Under their modified conditions (dry Zn, THF) we found that methyl 3-bromomethyl-2-butenoate (Table 1, Entry 2) reacted with benzaldehyde to give only **3**. In contrast, when the spiro-cyclopropyl aldehyde **1** was used we obtained a 40:60 α/γ mixture of **2** and **4**; this ratio became 60:40 when methyl 4-bromocrotonate was employed (Table 1, Entry 4). This change in regiochemistry may partly be a consequence of the hindered carbonyl group in **1**, since the dianion studies (12) indicated that steric effects could exert a prominent influence. Modification of the conditions using an ultrasonic bath and (or) dimethoxyethane (DME) as the solvent provided no significant improvement in the α/γ ratio.

In a parallel series of experiments various lithium anion–

salt combinations derived from 2-ethylidene-1,3-dithiane (**6**) were examined (Table 2). Previously Ziegler and Tam (8) had established that alkylation of the lithium anion derived from **6** afforded the α product preferentially. A similar result was encountered with **1**, in which **7** was the dominant product (Table 2, Entry 1). The corresponding copper derivative, derived from **6**, gave the γ allylation product exclusively when they employed a variety of allylic halides as the electrophiles. However, with the spiro-cyclopropyl aldehyde **1**, even the copper derivative afforded a significant quantity of the undesired α product **7** in addition to the γ isomer **8** (Table 2, Entry 3), and **7** became the dominant product in the presence of zinc chloride (Table 2, Entry 2).

Except for the reaction of organocadmium reagents with acyl halides, organocadmium species have received relatively little attention (21). Pure, salt-free alkyl cadmiums do not react with carbonyl compounds but this reactivity may be altered significantly by the addition of magnesium or lithium salts (22). Thus, various combinations of cadmium salts and organometallics would be expected to alter the reactivity and possibly also the selectivity in our systems. This was found to be the case.

The addition of anhydrous cadmium chloride powder to the preformed lithium anion at −78°C, followed by warming and quenching at 0°C with saturated aqueous ammonium chloride, markedly increased the quantity of the γ product **8**. The α/γ ratio was changed to 10:90 for both benzaldehyde and the spiro-aldehyde **1** (Table 2, Entries 4 and 5). This effect appears to be general and added cadmium salts also worked well with

TABLE 2. Dithioketene acetal condensations[a]

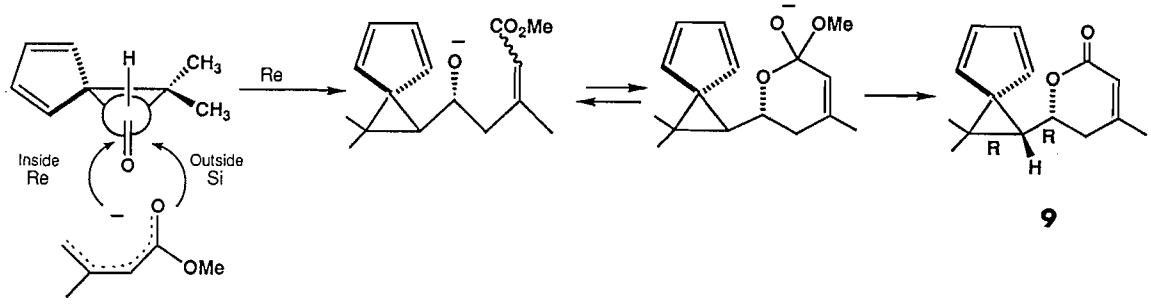
5.	PhCHO	LDA/$CdCl_2$	10:90	95

[a]Substrate: 



substituted crotonates so that the γ product **4** predominated as summarized in Table 1 (Entries 6–9). Thus cadmium halides reverse the normal regiochemical behaviour encountered with simple lithium enolates and do not require heating the reaction mixture above 0°C. Lithium dialkylamides undergo 1,4-addition to methyl crotonate unless hexamethylphosphoramide (HMPA) is added, in which case deprotonation occurs (23). To encourage deprotonation the bulkier base lithium dicyclohexylamide was employed with added HMPA. Unfortunately the presence of the polar solvent HMPA reduced the influence of the cadmium chloride (Table 1, Entry 5).

Relatively few investigations into the composition and structure of organocadmium reagents have been conducted. "Purified" organocadmiums, isolated by distillation, such as di-*n*-butylcadmium (24) have a dialkyl structure. It is assumed that the *in situ* reagents were similar, although clearly they must be part of a complex equilibrium, since yields were less if the ratio of the lithium to cadmium species was not 2:1. Solvation effects are also important, as the γ selectivity diminished in the presence of polar additives such as HMPA while more soluble salts such as cadmium iodide only altered the ratio slightly and the yields tended to be lower.

Quenching studies established that the γ condensation product **4** arose from isomerization of the alkoxide of the initial kinetic product **2**. The standard reaction with lithium diisopropylamide and cadmium chloride was quenched at −78°C with acetic acid in THF. Work-up established that only the α product **2** was present. This material was redissolved in THF and treated separately with lithium diisopropylamide and cadmium chloride, initially at −78°C and then at 0°C for 1 h. The products consisted of **2** and **4** in a similar α/γ ratio (15:85) to the one observed previously. In addition a small quantity of the unsaturated lactone **9** was formed. This lactone **9** was the only γ product (Table 1, Entry 9) when the (+)-*R*-spiro-aldehyde **1** was employed. The reaction was conducted in the standard manner with the cadmium chloride mediated anion and quenched at 0°C after stirring for 2 h. This result is similar to earlier studies (11) in which dihydro-α-pyrones were the major products upon quenching at 15°C in related reactions with LDA as the base. Spectral data established the lactone structure **9**. These included the vinyl methyl singlet at δ 1.87, the cyclopropyl hydrogen as a doublet (δ 2.31, J = 4.4 Hz), and the methine proton on the carbon bearing oxygen as doublet of doublet of doublets at δ 4.48 (J = 4.4, 10.1, 11.1 Hz) in the ^{1}H nmr spectrum. A COSY spectrum confirmed that the cyclopropyl hydrogen was adjacent to this methine hydrogen, which was itself adjacent to the ring methylene protons.

In principle this condensation with methyl 3,3-dimethylacrylate anion in the presence of cadmium chloride could generate two diastereomers, depending upon the approach of the

SCHEME 2

reagent from either the "inside" Re face or the "outside" Si direction. A combination of beneficial electronic and steric interactions contributes to the selectivity of this reaction. Inside attack is favoured sterically as nonbonded interactions with the adjacent methyl groups are avoided, particularly when the carbonyl lies in approximately the same plane as the cyclopentadiene. In addition, this may allow the delocalized π system of the organocadmium reagent to interact favourably with the π system of the diene. The net result would be predominant attack from the inside Re face to generate the C5-(*R*)-lactone **9** (73%). The stereochemical assignment of the major lactone was confirmed by additional chemical transformations (19). A small amount (12%) of the C5-(*S*) diastereomer was also isolated. Only the *Z*-olefin can form the six-membered ring lactone and the *E*-olefin hydroxy-ester was not detected amoung the products. Thus, as illustrated in Scheme 2, the alkoxide that resulted from the initial condensation must have added to the ester carbonyl, when the geometry was favourable, to generate **9** after loss of methoxide. Isomerization to the observed product continued until the reaction was complete, and was consistent with the thermodynamic features of this reaction elucidated above.

In conclusion, cadmium chloride exerts a beneficial influence on vinylogous anions to alter their normal regiochemical behaviour. This process involves an equilibrium that facilitates the preparation of the γ condensation product and may be conducted at 0°C. This feature makes it useful for sensitive substrates where higher temperatures are deleterious. These procedures to influence the regioselectivity of carbonyl condensations will also be useful in other synthetic applications.

Experimental

Melting points were determined in capillary tubes with a Thomas–Hoover Uni-Melt apparatus, or with a Fisher–Johns melting point apparatus, and are uncorrected. Infrared (ir) spectra were recorded on a Perkin–Elmer 783 or 983G infrared spectrophotometer, and were calibrated with the 1601 cm^{-1} band of polystyrene film. Proton magnetic resonance spectra (^1H nmr) were measured at 80 MHz with a Bruker WP80 spectrometer or at 200 MHz with a Varian Gemini spectrometer or at 300 MHz with a General Electric GN 300 or a Varian XL-300 spectrometer in deuterochloroform. Carbon magnetic resonance spectra (^{13}C nmr) were measured at 50 MHz with a Varian Gemini spectrometer or at 75 MHz with a General Electric GN 300 spectrometer or a Varian XL-300 spectrometer. The residual solvent signal ($CDCl_3$) was used as an internal lock; $CDCl_3/^1H$: δ 7.262, ^{13}C: δ 77.00; and chemical shifts are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard. The number of protons, multiplicity, coupling constants, and proton assignments are indicated in parentheses. Mass spectra were determined on a V.G. Micromass 7070 HS instrument using an ionization energy of 70 eV, or on a Hewlett–Packard 5890A gas chromatograph – 5970B mass selective detector equipped with a 12.5 m capillary column (0.2 mm i.d.) coated with cross-linked dimethyl silicone (0.33 μm). Optical rotations were measured using a Perkin–Elmer 241 polarimeter (sodium light, cell length = 10 cm, c = g/100 mL).

Gas–liquid chromatographic analyses were conducted on a Hewlett–Packard 402B gas chromatograph equipped with a column (3 m × 6 mm i.d.) containing 1.5% OV-17 supported on Gas Chrome Q using helium as the carrier gas. Analytical thin-layer chromatography (tlc) employed commercial aluminum sheets precoated (0.2 mm layer) with silica gel 60 F_{254} (E. Merck). Flash column chromatography using E. Merck silica gel 60 (230–400 mesh) was employed for all column chromatography. The purity of all title compounds was judged to be ≥95% as determined by a combination of gc–ms, ^1H nmr, and ^{13}C nmr analysis.

Petroleum ether refers to a fraction with boiling range 30–60°C. Anhydrous diethyl ether (ether), tetrahydrofuran (THF), dimethoxyethane (DME), and dioxane were obtained by distillation from $LiAlH_4$ or potassium/benzophenone. Methanol and absolute ethanol were dried by distillation from magnesium. Dry hexamethylphosphoramide (HMPA), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and diisopropylamine were prepared by distillation from calcium hydride. Solutions in organic solvents were dried over anhydrous magnesium sulfate and stripped of solvent with a Büchi rotary evaporator connected to a water aspirator. Unless otherwise indicated, all reactions were conducted under an atmosphere of dry nitrogen.

2,2-Dimethylspiro[2,4]hepta-4,6-diene-1-ylcarboxaldehyde (1)

2,2-Dimethyl-1-hydroxymethylspiro[2,4]hepta-4,6-diene (3.0 g, 0.02 mmol) (20) in dichloromethane (25 mL) was added dropwise to a stirred, refluxing suspension of active MnO_2 (20) (30 g, 40 g if mixed with charcoal) in dichloromethane (250 mL). The mixture was stirred under reflux for 12 h, cooled to room temperature, and filtered through Celite and anhydrous $MgSO_4$. The solid residue was washed thoroughly with dichloromethane (200 mL) and the combined filtrates concentrated. The crude product was purified by flash chromatography (5% ethyl acetate/petroleum ether) to afford the spiro-aldehyde **1** (2.5 g, 84%) as a pale yellow liquid; ir (film): 2825 (H-CO), 2720 (H-CO), 1704 (C=O) cm^{-1}; ^1H nmr (300 MHz) δ: 1.42 (s, 3H, CH_3), 1.56 (s, 3H, CH_3), 2.78 (d, 1H, J = 6 Hz, cyclopropyl H), 6.17 (m, 1H, cyclopentadienyl H), 6.53 (m, 2H, cyclopentadienyl H), 6.60 (m, 1H, cyclopentadienyl H), 9.56 (d, 1H, J = 6 Hz, H-C=O); ^{13}C nmr δ: 198.0, 135.5, 132.4, 131.6, 131.4, 56.8, 49.4, 37.1, 26.8, 20.7. Exact Mass calcd. for $C_{10}H_{12}O$: 148.0888; found: 148. 0888.

Methyl 4-bromo-3-methyl-2-butenonate (lit. (25))

Methyl 3,3-dimethylacrylate (5.4 g, 47 mmol) was dissolved in carbon tetrachloride (50 mL) containing *N*-bromosuccinimide (NBS) (8.7 g, 49 mmol, Aldrich) and azobisisobutryonitrile (AIBN) (0.078 g). The mixture was stirred under reflux for 8 h, cooled, and filtered to remove the precipitate. The filtrate was concentrated and purified by distillation under reduced pressure (bp 45–70°C/0.6 Torr; 1 Torr = 133.3 Pa) (lit. (25) bp 112–130°C/35 Torr) to afford the bromoester (6.9 g, 68%) as a 1:1 *Z*,*E* mixture: ^1H nmr (80 MHz) *Z*, δ: 1.99 (d, 2H, J = 2 Hz, CH_3-C=C), 3.65 (s, 3H, OCH_3), 4.47 (m, 2H, CH_2Br), 5.68 (d, 1H, J = 2 Hz, H-C=C); *E*, δ: 2.21 (d, 3H, J = 2 Hz, CH_3-C=C), 3.65 (s, 3H, OCH_3), 3.86 (d, 2H, J = 1 Hz, CH_2Br), 5,87 (m, 1H, H-C=C).

General procedure for Reformatsky reaction

Active zinc powder (5 molar equivalents, zinc dust (Aldrich) was quickly washed with 50% acetic acid, filtered, rinsed thoroughly with water and DME, and dried under vacuum at 110°C for 12 h) suspended in anhydrous THF (2 mL) was placed in a three-necked flask equipped with a condenser and a dropping funnel (4). The aldehyde (benzaldehyde or **1**, ca. 2 mmol) and the bromoester in anhydrous THF (10 mL) were placed in the dropping funnel. A few drops of the THF solution containing the starting materials were added to the stirred suspension, followed by a small crystal of iodine, and the reaction heated. Once reflux commenced and the iodine color discharged, the remainder of the THF solution was added dropwise to the reaction while stirring under reflux. After the addition was complete, reflux was continued for another hour, the reaction cooled to room temperature, quenched with saturated aqueous ammonium chloride, and filtered. The filtrate was extracted with ether (2 × 10 mL) and the combined extracts washed with brine, dried, filtered, and concentrated. The product was purified by chromatography (20% ethyl acetate/petroleum ether) (see Table 1 for α : γ ratios and yields).

Methyl 2-isopropylidenyl-3-hydroxy-3-(2',2'-dimethylspiro[2.4]-hepta-4',6'-dien-1'-yl)propanoate (**2**): ir ($CHCl_3$): 3660 (OH), 1730 (C═O), 1650 (C═C) cm^{-1}; ^1H nmr (300 MHz) δ: 1.41 (s, 3H, CH_3), 1.48 (s, 3H, CH_3), 1.68 (s, 3H, CH_3-C═C), 2.28 (d, 1H, J = 10.5 Hz, cyclopropyl H), 2.82 (br s, 1H, OH), 3.47 (d, 1H, J = 7.5 Hz, CH-CO_2Me), 3.69 (s, 3H, OCH_3), 4.02 (m, 1H, CH-O), 4.76 (s, 1H, H-C═C),4.83 (s, 1H, H-C═C), 6.18 (m, 2H, cyclopentadienyl H), 6.41 (m, 1H, cyclopentadienyl H), 6.50 (m, 1H, cyclopentadienyl H); ^{13}C nmr δ: 172.9, 139.1, 137.9, 132.5, 132.2, 129.0, 115.6, 71.0, 59.8, 51.9, 51.5, 46.8, 35.7, 26.4, 22.0, 21.0, ms m/z: 262 (M^+), 244 ($M^+ - H_2O$).

Methyl 5-hydroxy-3-methyl-5-(2',2'-dimethylspiro[2.4]hepta-4',6'-dien-1'-yl)-2-pentenoate (**4**): ir (film): 3480 (OH), 3060 (H-C═C), 1720 (C═O), 1635 (C═C) cm^{-1}; ^1H nmr (300 MHz) δ: 1.38 (s, 3H, CH_3), 1.43 (s, 3H, CH_3), 1.71 (s, 3H, CH_3), 1.95 (d, 2H, J = 6.5 Hz, CH_2-C═C), 2.15 (d, 1H, J = 10.6 Hz, cyclopropyl H), 3.35 (br s, 1H, OH), 3.62 (s, 3H, OCH_3), 4.22 (m, 1H, CH-O), 5.15 (s, 1H, H-C═C), 6.15 (m, 2H, cyclopentadienyl H), 6.38 (m, 2H, cyclopentadienyl H), 6.50 (m, 2H, cyclopentadienyl H); ^{13}C nmr ($CDCl_3$) δ: 164.4, 138.7, 137.8, 132.5, 131.3, 128.9, 127.7, 70.5, 56.3, 52.1, 51.2, 42.9, 34.5, 27.1, 22.5, 19.9; ms m/z: 262 (M^+), 244 ($M^+ - H_2O$).

Methyl 5-hydroxy-3-methyl-5-phenyl-2-pentenoate (**3**) (lit. (11)): ir (film): 3450 (OH), 1725 (C═O), 1640, 1600 (C═C) cm^{-1}; ^1H nmr (80 MHz) δ: 1.57 (s, 3H, CH_3), 3.02 (d, 1H, J = 4.4 Hz, CH_2), 3.40 (d, 1H, J = 8.8 Hz, CH_2), 3.74 (s, 3H, OCH_3), 4.83 (s, 1H, H-C═C), 4.85 (s, 1H, OH), 5.05 (dd, 1H, J = 4.4, 8.8 Hz, *H*-C-OH), 7.33 (s, 5H, phenyl H); ms m/z: 220 (M^+).

Methyl 5-hydroxy-5-(2',2'-dimethylspiro[2.4]hepta-4',6'-dien-1'-yl)-2-pentenoate: ir (film): 3450 (OH), 1720 (C═O), 1650 (C═C) cm^{-1}; ^1H nmr (80 MHz) δ: 2.05 (d, 1H, J = 3.5 Hz, cyclopropyl H), 2.25 (br s, 1H, OH), 2.30–2.60 (m, 2H, CH_2), 3.72 (s, 3H, OCH_3), 4.55 (m, 1H, *H*-C-OH), 5.76 (d, 1H, J = 6 Hz, C═C*H*-CO_2Me), 6.18 (m, 2H, cyclopentadienyl H), 6.43 (m, 2H, cyclopentadienyl H), 6.88 (m, 1H, H-C═C-CO_2Me); ms m/z: 248 (M^+).

Methyl 2-vinyl-3-hydroxy-3-(2',2'-dimethylspiro[2.4]hepta-4',6'-dien-1'-yl)propanoate: ir (film): 3490 (OH), 1730 (C═O), 1640 (C═C) cm^{-1}; ^1H nmr (80 MHz) δ: 2.80 (d, 1H, J = 3 Hz, OH), 3.25 (dd, 1H, J = 6, 12 Hz H-C-CO_2Me), 3.65 (s, 3H, OCH_3), 4.52 (m, 1H, *H*-C-OH), 5.25 (m, 2H, CH_2═C), 5.60–5.90 (m, 1H, *H*C═CH_2), 6.22 (m, 1H, cyclopentadienyl H), 6.45 (m, 1H, cyclopentadienyl H); ms m/z: 248 (M^+).

Condensations of aldehydes with 2-ethylidene-1,3-dithiane (**6**)

The 2-ethylidene-1,3-dithiane was prepared by Grignard addition to carbon disulfide and alkylation (8, 26, 27) and distilled to yield 3.81 g (52%) of dithiane **6** as a foul smelling, pale yellow, liquid: bp 61–62°C/0.3 Torr (lit. (8) bp 43–44°C/0.1 Torr); ^1H nmr (80 MHz) δ: 1.76 (d, 3H, J = 7 Hz, CH_3), 2.18 (m, 2H, CH_2), 2.87 (m, 4H, SCH_2), 6.00 (q, 1H, J = 7 Hz, H-C═C); ms m/z: 146 (M^+).

A: LDA only

An LDA solution was prepared from diisopropylamine (0.232 g, 2.3 mmol, Aldrich) and *n*-butyllithium (2.5 M in hexane, 0.9 mL, 2.2 mmol, Aldrich) in anhydrous THF (5 mL) at −25°C. Dithiane **6** (0.321 g, 2.2 mmol) in anhydrous THF (2 mL) was added, forming a yellow solution. After stirring at −25°C for 30 min, the solution was cooled to −78°C, and a THF solution (10 mL) of the spiro-aldehyde **1** (0.220 g, 1.5 mmol) added dropwise. The resulting solution was stirred at −78°C for a further 30 min, warmed to 0°C, and quenched with saturated aqueous ammonium chloride. The mixture was extracted with ether (2 × 20 mL) and the combined ether extracts were washed with brine, dried, filtered, and concentrated. The product was purified by chromatography (20% ethyl acetate/petroleum ether) to give 0.349 g (86%) of the α dithiane **7** and 0.051 g (10%) of γ dithiane **8**; α : γ = 90:10, total yield 96%.

2-Vinyl-2-[1-hydroxy-1-(2',2'-dimethylspirol[2.4]hepta-4',6'-dien-1'-yl)]-1,3-dithiane (**7**): ^1H nmr (80 MHz) δ: 1.39 (s, 3H, CH_3), 1.45 (s, 3H, CH_3), 1.89 (m, 2H, -SCH_2-C*H*$_2$-SCH_2-), 2.35 (d, 1H, J = 9.9 Hz, OH), 2.53 (d, 1H, J = 4.5 Hz, cyclopropyl H), 2.83 (m, 4H, SH_2), 3.89 (dd, 1H, J = 4.5, 9.9 Hz, *H*-C-OH), 5.11–5.59 (m, 3H, H-C═C), 6.15–6.50 (m, 4H, cyclopentadienyl H). Exact Mass calcd. for $C_{16}H_{22}OS_2$: 294.1111; found: 294.1115.

2-[3-Hydroxy-3-(2',2'-dimethylspiro[2.4]hepta-4',6'-dien-1'-yl)propylidene]-1,3-dithiane (**8**): ir (film): 3410 (OH), 1600 (C═C) cm^{-1}; ^1H nmr (300 MHz) δ: 1.39 (s, 3H, CH_3), 1.41 (s, 3H, CH_3), 2.03 (d, 1H, J = 9.6 Hz, cyclopropyl H), 2.18 (m, 2H, -SCH_2-C*H*$_2$-SCH_2-), 2.58 (dd, 2H, J = 5.7, 7.5 Hz, CH_2-C═C), 2.88 (t, 4H, J = 6.0 Hz, SCH_2), 2.97 (s, 1H, OH), 3.41 (m, 1H, *H*-C-OH), 6.07 (t, 1H, J = 7.5 Hz, H-C═C), 6.37 (m, 1H, cyclopentadienyl H), 6.44 (m, 1H, cyclopentadienyl H), 6.49 (m, 2H, cyclopentadienyl H). Exact Mass calcd. for $C_{16}H_{22}OS_2$: 294.1111; found: 294.1119.

B: LDA/$ZnCl_2$

2-Ethylidene-1,3-dithiane (**6**) (0.204 g, 1.4 mmol) in anhydrous THF (2 mL) was added dropwise to an LDA solution prepared from diisopropylamine (0.152 g, 1.5 mmol) and *n*-butyllithium (2.5 M in hexane, 0.6 mL, 1.5 mmol, Aldrich) in anhydrous THF (5 mL) at −40°C. The yellow solution was stirred at −40°C for 40 min and zinc chloride (0.2031 g, 1.5 mmol, Aldrich) added. After stirring at −40°C for an additional 30 min, the reaction was cooled to −78°C, and the spiro-aldehyde **1** (0.192 g, 1.3 mmol) in anhydrous THF (10 mL) was added dropwise. The reaction was continued for a further hour at −78°C, warmed to 0°C, and quenched with saturated aqueous NH_4Cl. The mixture was extracted with ether (2 × 20 mL) and the combined ether extracts were washed with brine, dried, filtered, concentrated, and purified by chromatography (15% ethyl acetate/petroleum ether) to give 0.163 g (43%) of triene **7** (α product) and 0.104 g (27%) of triene **8** (γ product); α : γ = 60:40, total yield 70%.

C: LDA/CuI·P(MeO)$_3$

An LDA solution was prepared from diisopropylamine (0.36 mL, 2.6 mmol) and *n*-butyllithium (2.7 M in hexane, 0.96 mL, 2.6 mmol, Aldrich) in anhydrous THF at −25°C. Dithiane **6** (0.365 g, 2.5 mmol) in anhydrous THF (1 mL) was added to the solution. The reaction solution was stirred at −25°C for 30 min, and cooled to −78°C, followed by addition of trimethylphosphite cuprous iodide complex (0.906 g, 2.8 mmol) in anhydrous THF (2 mL) (based on ref. (8). A yellow precipitate gradually formed during 1 h of stirring. The spiro-aldehyde **1** (0.370 g, 2.5 mmol) in anhydrous THF (10 mL) was added dropwise to the yellow suspension over a period of 30 min, resulting in a greenish solution. The solution was stirred at −78°C for 1 h, warmed to 0°C, stirred at 0°C for 30 min, and quenched with saturated aqueous NH_4Cl. A minimum amount of water was added to just dissolve the white precipitate and the mixture was stirred at 0°C for 10 min and extracted with ether (3 × 15 mL). The combined ether extracts were washed with brine, dried, filtered, and concentrated. Chromatography (20% ethyl acetate/petroleum ether) gave 0.159 g (22%) of **8** (α product) and 0.289 g (39%) of **7** (γ product); α : γ = 35:65, total yield 61%.

D: LDA/$CdCl_2$

The dithiane **6** (2.2 mmol) in anhydrous THF (5 mL) was added dropwise to an LDA solution prepared from diisopropylamine (2.3 mmol) and *n*-butyllithium (2.5 M in hexane, 2.3 mmol) in anhydrous THF (10 mL) at −40°. After stirring at −40°C for 30 min, the reaction was cooled to −78°C and cadmium chloride powder (1.5 mmol, Aldrich, Gold label, previously ground in a mortar and dried in vacuum at 110°C) was added in one portion. The resulting white suspension was stirred at −78°C for 30 min and an anhydrous THF solution (10 mL) containing aldehyde (benzaldehyde or spiro-aldehyde **1**, 1.0 mmol) was added over a period of 30 min. After the addition was complete, the reaction was conducted at −78°C for a further hour, warmed to 0°C, stirred at 0°C for 0.5 h, and quenched with saturated aqueous NH_4Cl. The mixture was filtered through Celite and the filtrate extracted with ether (2 × 15 mL). The combined ether extracts were washed with brine, dried, filtered, and concentrated. The oily residue was purified by chromatography (15% ethyl acetate/petroleum ether) to give the α product and the γ product in total yield of 90–95%; 10:90 ratio (Table 2).

2-[3-Hydroxy-3-phenylpropylidene)-1,3-dithiane: ir (film): 3410 (br, OH), 1605, 1585 (C=C), 705 (s, C-S) cm^{-1}; ^1H nmr (80 MHz) δ: 2.01–2.27 (m, 3H), 2.60–2.93 (m, 6H), 4.74 (t, 1H, J = 6.4 Hz, HC-O), 5.97 (t, 1H, J = 7.4 Hz, H-C=C), 7.37 (m, 5H, phenyl H). Exact Mass calcd. for $C_{13}H_{16}OS_2$: 252.0642; found: 252.0647.

2-Vinyl-2-(1-hydroxy-1-phenyl)-1,3-dithiane: ir (film): 3450 (br, O-H), 3080, 3060, 3025 (phenyl H), 1625 (C=C) cm^{-1}; ^1H nmr (80 MHz) δ: 1.94 (m, 2H, CH_2), 2.80 (m, 4H, SCH_2), 2.94 (d, 1H, J = 3.2 Hz, OH), 4.90 (d, 1H, J = 3.2 Hz, H-C-O), 5.35–6.00 (m, 3H, H-C=C), 7.26–7.48 (m, 5H, phenyl H). Exact Mass calcd. for $C_{13}H_{16}OS_2$: 252.0642; found: 252.0657.

E: LDA/$CdCl_2$ reaction with methyl 3,3-dimethylacrylate

An LDA solution (2.1 equiv.) was prepared from diisopropylamine and *n*-butyllithium in anhydrous THF at −78°C. A THF solution of the methyl acrylate (2.0 equiv.) was added dropwise to the solution, to form a pale yellow solution. After stirring for 30 min at −78°C, cadmium chloride powder (1 equiv., Aldrich, Gold label, ground in a mortar and dried under vacuum at 110°C overnight) was added in one portion and the resulting suspension stirred for 30 min further, followed by addition of aldehyde (benzaldehyde or spiro-aldehyde **1**) in THF with a syringe pump (0.1 mL/min). After the addition was complete, the reaction was continued for an additional hour, then allowed to warm to 0°C, stirred for 30 min at 0°C, and quenched with saturated aqueous NH_4Cl. The mixture was filtered through Celite and the filtrate extracted with ether (2 × 20 mL). The combined ether extracts were washed with brine, dried, filtered, and concentrated. Chromatography (20% ethyl acetate/petroleum ether) afforded the hydroxy-ester **4** or **3** (γ product) and the hydroxy-ester **2** or **5** (α product); (see Table 1 for α : γ ratios and yields).

F: Thermodynamic study of LDA/$CdCl_2$ reaction

Methyl 3,3-dimethylacrylate (0.114 g, 1.0 mmol, THF, 5 mL) was treated with LDA, as described above, at −78°C and, after stirring for 30 min, cadmium chloride powder (0.0916 g, 0.5 mmol, Aldrich, Gold label, previously ground in a mortar and dried under vacuum at 110°C overnight) was added in one portion. The suspension was stirred for 30 min at −78°C and an anhydrous THF solution (10 mL) containing the spiro-aldehyde **1** (0.074 g, 0.5 mmol) was added dropwise over a period of 45 min. The reaction was stirred for 1 h at −78°C and then quenched by slowly adding acetic acid (1 mL) in anhydrous THF (2 mL). The mixture was filtered through Celite and the filtrate extracted with ether (2 × 20 mL). The combined ether layers were washed with brine, dried, filtered, and concentrated. Chromatography (20% ethyl acetate/petroleum ether) yielded hydroxy-ester **2** (0.103 g, 79%).

An LDA solution (0.8 mmol) in THF (5 mL) was treated with cadmium chloride powder (0.046 g, 0.4 mmol) at −78°C as described above. A solution of the hydroxy-ester **2** (0.103 g, 0.39 mmol) in anhydrous THF (10 mL) was added and the resulting suspension stirred for 1 h at −78°C. The reaction was warmed to 0°C, stirred for 1 h, and then quenched with saturated aqueous NH_4Cl. Ether extraction and work-up as above followed by chromatography (15% ethyl acetate/petroleum ether) gave hydroxy-ester **4** (0.076 g, 73%) and recovered starting material **2** (0.014 g, 13%), α : γ = 15:85.

G: LDA/CdI_2 reaction of benzaldehyde with methyl 3,3-dimethylacrylate

The lithium anion of methyl 3,3-dimethylacrylate (1.03 g, 9 mmol, THF, 5 mL) was generated at −78°C with LDA as described above. The solutions was stirred for an additional 30 min, followed by addition of cadmium iodide (1.65 g, 4.5 mmol, Aldrich, Gold label, dried under vacuum for 2 h at 110°C) in one portion. The cadmium iodide slowly dissolved and formed a light yellow solution. Benzaldehyde (0.424 g, 4 mmol, Aldrich, redistilled) in anyhdrous THF (5 mL) was added dropwise. The resulting solution was stirred for 1 h at −78°C, for 30 min at 0°C, and quenched with saturated aqueous NH_4Cl. The mixture was worked up as above by extraction with ether (2 × 20 mL) and flash chromatography (20% ethyl acetate/petroleum ether) to give hydroxy-ester **3** (γ product, 0.519 g, 59%) and hydroxy-ester **5** (α product, 0.051 g, 6%), α : γ = 10:90, 65% total yield.

H: $LiNCy_2$/$CdCl_2$ reaction of benzaldehyde with methyl crotonate

A THF solution (2 mL) containing hexamethylphosphoramide (HMPA) (1.79 g, 10 mmol, Aldrich) was added to a lithium dicyclohexylamide ($LiNCy_2$) solution prepared from dicyclohexylamine (1.63 g, 9 mmol) and *n*-butyllithium (2.6 M in hexane, 3.5 mL, 9 mmol) in anhydrous THF (20 mL) at 0°C. The solution was stirred for 30 min at 0°C, then cooled to −78°C, followed by the addition of methyl crotonate (0.905 g, 9 mmol, Aldrich) in anhydrous THF (5 mL). After stirring for 30 min at −78°C, cadmium chloride powder (0.825 g, 4.5 mmol, Aldrich, Gold label, previously ground in a mortar and dried under vacuum at 110°C overnight) was added in one portion. The resulting suspension was stirred for 30 min at −78°C and a solution of benzaldehyde (0.424 g, 4 mmol, Aldrich, redistilled) in anhydrous THF (5 mL) was added dropwise to the suspension. The reaction was continued at −78°C for 1 h, at 0°C for 30 min, and quenched with saturated aqueous NH_4Cl. The mixture was filtered through Celite, and the filtrate was extracted with ether (2 × 20 mL). The combined organic extracts were washed with brine, dried, filtered, concentrated, and purified by chromatography (20% ethyl acetate/petroleum ether) to give methyl 5-hydroxy-5-phenyl-2-pentenoate (γ product, 0.338 g, 41%) and methyl 2-vinyl-3-hydroxy-3-phenylpropanoate (α product, 0.328 g, 40%), α : γ = 50:50, 81% total yield.

Methyl 5-hydroxy-5-phenyl-2-pentenoate (lit. (12)): ir (film): 3490 (OH), 3080, 3060, 3030 (phenyl C-H), 1715 (C=O), 1600 (C=C) cm^{-1}; ^1H nmr (80 MHz) δ: 2.13 (m, 2H, CH_2), 2.80–3.15 (m, 2H, H-C-O, OH), 3.69 (s, 1H, OCH_3), 5.81 (m, 1H, C=CH-CO_2Me), 6.85 (m, 1H, H-C=C-CO_2Me), 7.25 (m, 5H, phenyl H).

Methyl 2-vinyl-3-hydroxy-3-phenylpropanoate (lit. (12)): ir (film): 3490 (OH), 1725 (C=O), 1460 (C=C) cm^{-1}; ^1H nmr (80 MHz) δ: 2.89 (d, 1H, J = 2.6 Hz, OH), 3.35 (dd, 1H, J = 2.6, 5.8 Hz, H-C-CO_2Me), 3.61 (s, 3H, OCH_3), 5.05 (m, 1H, *H*-C-OH), 5.32 (m, 2H, C=CH_2), 5.96 (m, 1H, -C=CH_2), 7.32 (m, 5H, phenyl H). Exact Mass calcd. for $C_{12}H_{14}O_3$: 206.0942; found: 206.0968.

*(+)-(5R,1′R)-3-Methyl-5-(2′,2′-dimethylspiro[2.4]hepta-4′,6′-dien-1′-yl)-6-oxa-2-cyclohexenone (**9**)*

An LDA solution was prepared from diisopropylamine (0.32 mL, 2.3 mmol) and *n*-butyllithium (2.5 M, 0.9 mL, 2.3 mmol, Aldrich) in anhydrous THF (5 mL) at −40°C, and a solution of methyl 3,3-dimethylacrylate (0.2510 g, 2.2 mmol) in anhydrous THF (2 mL) was added dropwise. After stirring for 20 min, cadmium chloride powder (0.366 g, 2.0 mmol, Aldrich, Gold label, previously ground in a mortar and dried overnight under vacuum at 110°C) was added in one portion. The suspension was stirred for 30 min at −40°C, and a solution of (+)-spiro-aldehyde **1** (0.159 g, 1.1 mmol) (15) in anhydrous THF (5 mL) was added by syringe pump (0.1 mL/min). After the addition was complete, stirring was continued for a further 30 min at −40°C. The reaction was allowed to warm to 0°C, stirred for 2 h at

0°C, and then quenched with saturated aqueous NH_4Cl. The mixture was filtered through Celite and the filtrate was extracted with ether (2 × 15 mL). The combined organic layers were dried, filtered, and concentrated. Chromatography (15% ethyl acetate/petroleum ether) afforded (+)-triene lactone **9** (0.185 g, 73%), as a colourless liquid, and α product **4** (0.038 g, 15%). (+)-Triene-lactone **9**; $[\alpha]^{22}$ +17.7° (*c* 3.4, $CHCl_3$); ir (film): 1710 (C=O), 1650 (C=C) cm^{-1}; ^1H nmr (200 MHz) δ: 1.39 (s, 3H, CH_3), 1.43 (s, 3H, CH_3), 1.87 (s, 3H, CH_3-C=C), 1.93 (m, 1H, axial HC-C=C), 2.09 (m, 1H, eq. CH-C=C), 2.31 (d, 1H, J = 4.4 Hz, cyclopropyl H), 4.48 (ddd, 1H, J = 4.4, 10.1, 11.1 Hz, H-C-O), 5.76 (s, 1H, H-C=C), 6.17 (m, 1H, cyclopentadienyl H), 6.28 (m, 1H, cyclopentadienyl H), 6.49 (m, 1H, cyclopentadienyl H), 6.58 (m, 1H, cyclopentadienyl H); ^{13}C nmr and DEPT δ: 164.6 (C=O), 156.0 (C=C), 136.4 (C=CH), 132.3 (C=CH), 131.6 (C=CH), 129.7 (C=CH), 116.8 (C=CH), 76.6 (CH), 51.1 (quaternary C), 42.1 (CH), 35.6 (CH_2), 31.9 (quaternary C), 27.2 (CH_3), 23.0 (CH_3), 20.4 (CH_3). Exact Mass calcd. for $C_{15}H_{18}O_2$: 230.1302; found: 230.1303. Anal. calcd. for $C_{15}H_{18}O_2$: C 78.21, H 7.88; found: C 78.02, H 7.69.

Semihydrogenation of 1,2-bis(3,4-dicyanophenyl)ethyne gave *cis*-1,2-bis(3,4-dicyanophenyl)ethene. From these precursors, binuclear phthalocyanines were produced containing linear binuclear phthalocyanines having an ethyne bridge and a mixture of *cis* and *trans* isomers of binuclear phthalocyanines linked by an ethene bridge. The *cis* and *trans* isomers could be separated and differentiated by gel permeation chromatography as the very extended *trans* isomer elutes faster than the cofacial globular *cis* isomer. Strong coupling between the conjugated binuclear phthalocyanine was not observed when examined by cyclic voltammetry.

Key words: phthalocyanines, cofacial, binuclear, cyclic voltammetry.

STEVEN VIGH, HERMAN LAM, PAVEL JANDA, A. B. P. LEVER, CLIFFORD C. LEZNOFF et RONALD L. CERNY. Can. J. Chem. **69**, 1457 (1991).

La semi-hydrogénation du 1,2-bis(3,4-dicyanophényl)éthyne conduit au *cis*-1,2-bis(3,4-dicyanophényl)éthène. À l'aide de ces précurseurs, on a préparé des phthalocyanines binucléaires contenant des phthalocyanines binucléaires linéaires possédant un pont éthyne et un mélange des isomères *cis* et *trans* des phtalocyanines binculéaires liées par un pont éthène. On a pu séparé et différencié les isomères *cis* et *trans* grâce à la chromatographie à perméation de gel; en effet l'isomère *trans*, plus étendu, s'élue plus rapidement que l'isomère *cis* globulaire cofacial. Lorsqu'on les a soumis à de la voltampérométrie cyclique, on n'a pas observé de couplage important entre la phtalocyanine binucléaire conjuguée.

Mots clés : phtalocyanines, cofacial, binucléaire, voltampérométrie cyclique.

[Traduit par la rédaction]

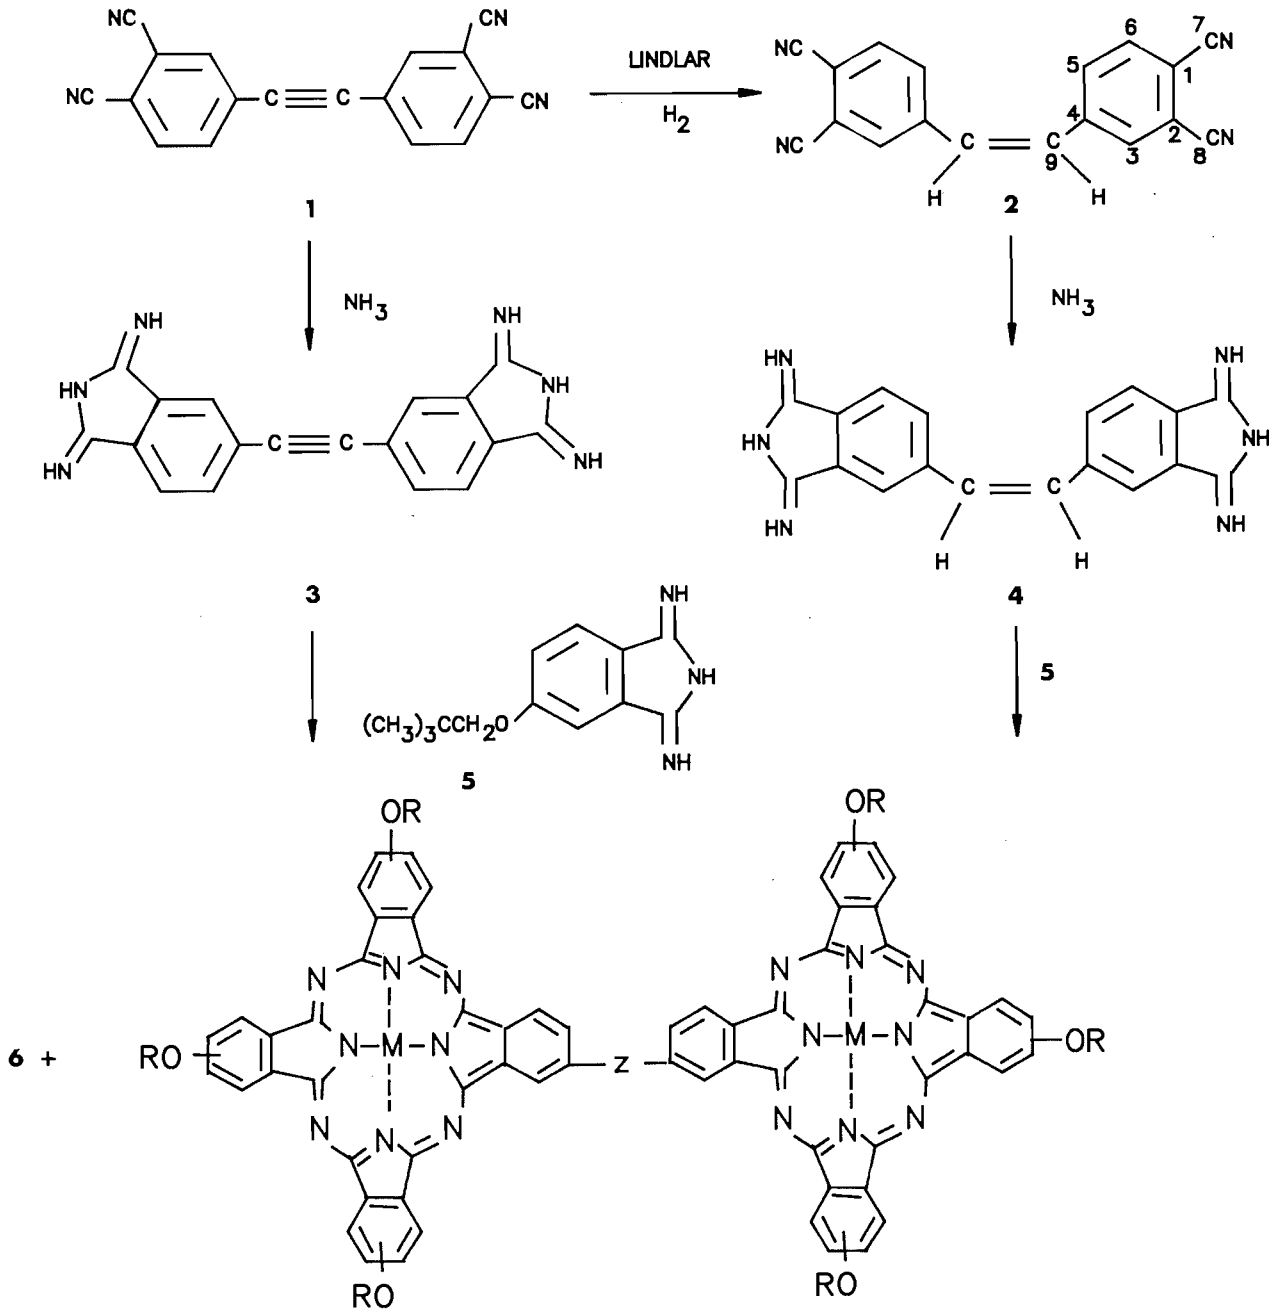
Introduction

It has been shown (1–4) that binuclear porphyrins, constrained to lie in cofacial configurations, are effective in catalyzing the 4e reduction of O_2 to H_2O. The long-term instability of these porphyrin catalysts, however, has led us to prepare the more stable cofacial binuclear and multinuclear (5–7) phthalocyanines (8–10), having bridges of five (5, 8), four (6), three (7), two (6), one (9), zero (7), and even "(−1)" bridges (10). The electrochemistry of some of these cofacial (7, 11) and conjugated planar (10) metallophthalocyanines exhibted interesting mixed valence species, but only the 2e reduction of O_2 was observed, albeit with greater efficiency than mononuclear species. We had never attempted to prepare a binuclear phthalocyanine that is both conjugated and cofacial but we have now succeeded in this quest and report its synthesis, and its spectroscopic and electrochemical properties.

Results and discussion

Synthetic aspects

Semihydrogenation of 1,2-bis(3,4-dicyanophenyl)ethyne (**1**) (6) in acetonitrile with Lindar's catalyst (12) gave *cis*-1,2-bis(3,4-dicyanophenyl)ethene (**2**) in 94% yield. Treatment of **1** and **2** with gaseous ammonia in a solution of sodium methoxide in methanol (5, 13) gave their respective diiminoisoindolines **3** and **4**. Mixed condensation (5, 13) of **3** with the diiminoisoindoline (**5**) (5) derived from 4-neopentoxyphthalonitrile (5, 14) gave, upon chromatographic purification using flash (15) and gel permeation chromatography (8, 16), 2,9,16,23-tetraneopentoxyphthalocyanine (**6**) in 49% yield and the desired binuclear phthalocyanine (**7**), linked by an ethyne group in 7.4% yield (Scheme 1). Binuclear phthalocyanine **7** was readily converted into its diCo(II) derivative (**8**) by treatment with anhydrous $CoCl_2$ in 77% yield. Similarly, condensation of **4** and **5** gave mononuclear **6** in 53% yield and a mixture of the *cis* and *trans* binuclear phthalocyanines **9** and **10**, linked by ethene groups (Scheme 1). Gel permeation chromatography, using tetrahydrofuran as eluant, succeeded in separating the linear fast-moving *trans*-binuclear bisphthalocyaninylethene (**10**) from the slower cofacial *cis*-binuclear bisphthalocyaninylethene (**9**). The infrared spectra of **9** and **10** were not characteristically different for these *cis* and *trans* isomers and their mass spectral data were identical. Unfortunately, the NMR spectra of **8–10** were uninformative due to their insolubility in appropriate solvents and the fact that these compounds consist of a mixture of 36 regioisomers, with the result that most NMR signals are broad and featureless. Both isomers gave good elemental analysis. These isomers exhibted similar spectral and analytical data but did show mobility differences on gel permeation chromatography. In addition, the major product is the *cis*-**9**, the predicted product, while the formation of *trans*-**10** by known facile *cis–trans* isomerization is understandable. Metallation of **9** with $CoCl_2$ or $Zn(OAc)_2$ gave the diCo(II) and diZn(II) derivatives **11** and **12** respectively.



Electronic spectra

The *trans* metal-free species **10** has an electronic spectrum typical of a largely uncoupled mononuclear metal-free phthalocyanine (5, 18) while the *cis* isomer **9** has a blue-shifted *Q*-band spectrum consistent with extensive intramolecular coupling

SCHEME 1

(18–20). Similar extensive intramolecular coupling is observed in the spectra of the *cis* dimetallated species **11** and **12**, which exhibit typical broad, blue-shifted *Q*-band absorption (8, 11, 18, 19, 21, 22) (Fig. 1). They likely therefore adopt a basically cofacial conformation required by the *cis*-ethene linkage.

Electrochemistry

Differential pulse voltammetry (DPV) data for the cobalt complexes **8** and **11** are reported in Table 1. These complexes are not nearly so well behaved electrochemically as most previously described cobalt phthalocyanine derivatives (8, 11,18). Although DPV peaks were obtained as listed, the cyclic voltammograms were generally broad and ill-defined, showing a series of overlapping and apparently irreversible waves.

Comparison with the control, CoTNPc (18) species leads to fairly obvious assignments. The ethyne derivative, **8**, has redox processes, as assigned, at potentials almost identical with those of the corresponding mononuclear CoTNPc. No splitting of these waves is noted. The first oxidation is then assigned to the simultaneous oxidation of both rings to the *bis*-$Co^{II}Pc(-1)$

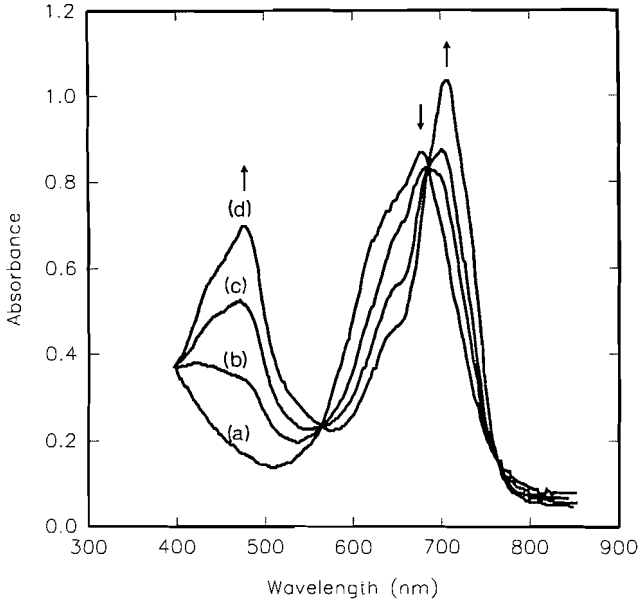

FIG. 1. Spectroelectrochemistry of CoPc=PcCo in DCB solution with 0.1 M TBAP, deoxygenated by Ar. Bulk electrolysis at −1 V vs. SCE reference electrode. Spectra taken using the Guided Wave fiber optic probe: (a) starting oxidized form $Co^{II}Pc = PcCo^{II}$; (d) final reduced form $Co^{I}Pc{=}PcCo^{I}$. Spectra changed during the bulk electrolysis from (a) to (d) according to arrows.

TABLE 1. Electrochemical data[a]

	Process			
Complex	I	II	?	III
CoTNPc[b]	0.03	−0.91	−2.07	
Ethyne **8**	0.14	−0.87	−2.09	
cis-Ethene **11**	0.13	−0.91	−1.52	−1.80

[a]Differential pulse voltammetry data, $E_{\frac{1}{2}}$ values approximated as the means of the forward and reverse peak positions, in DCB, in volts vs. ferricenium/ferrocene. This couple is observed in these studies at 0.495 V vs. AgCl/Ag on a platinum electrode surface.

[b]Data from ref. 18.

radical phthalocyanine species, and reduction involves the simultaneous reduction to the *bis*-$Co^{I}Pc(-2)$ species, and then subsequently, at −2.09 V (vs. ferrocene), reduction to the *bis*-$Co^{I}Pc(-3)$ species.

The *cis* cobalt ethene complex **11** also shows potentials at roughly those exhibited by CoTNPc but the apparent $[Co^{I}Pc(-2)]_2^{2-}/[Co^{I}Pc(-3)]_2^{4-}$ process is about 0.2 V more positive than expected. This last observation is reminiscent of the behaviour of recently described napthalene (11, 21) and anthracene (11) bridged cobalt phthalocyanines, which show splitting of their Co^{II}/Co^{I} couples and the formation of mixed valence $Co^{II}Pc \cdot Co^{I}Pc$ species. Spectroelectrochemical studies (Fig. 1) polarized just negative of this wave (at −1.0/ V vs. ferrocene) give a spectrum λ_{max} 475 nm (MLCT), 708 nm (*Q* band) typical of a fully reduced cobalt(I) phthalocyanine species (5, 8, 10, 11, 18, 21, 22), and unlike a mixed valence $Co^{II}Pc \cdot Co^{I}Pc$ binuclear species. The reduction is fully reversible (Fig. 2) since spectroelectrochemical reoxidation regenerated the original spectrum. There is no spectroscopic evidence for a mixed valence intermediate.

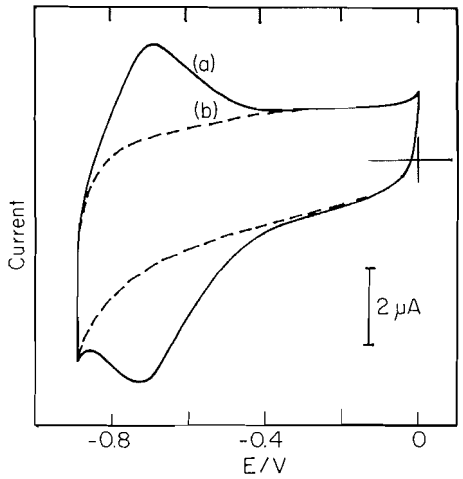

FIG. 2. Cyclic voltammetry of HOPG/CoPc=PcCo electrode in aqueous solution of 0.1 M phosphate buffer, pH = 7, Ar, scan rate v = 100 V/s, potential vs. SCE. (a) HOPG/CoPc=PcCo; (b) HOPG (residual current).

We conclude therefore that the interaction between the rings in the ethene derivative **11** is too small to stablize the mixed valence $Co^{II}Pc \cdot Co^{I}Pc$ species. Moreover, there appears to be an additional redox process at −1.52 V (vs. ferrocene). The origin of the −1.52 V couple is obscure; it may indeed be due to an impurity process.

Oxygen reduction

Complexes **8** and **11** were also deposited as monolayer films on highly pyrolytic graphite rotating disk electrodes following methods described earlier (23). These modified electrodes electrocatalyse the reduction of molecular oxygen in a two-electron process to hydrogen peroxide. No four-electron reduction to oxygen was observed. Since we have extensively discussed the two-electron reduction of oxygen by cobalt phthalocyanines in the past (11, 23) no further discussion is presented here.

Experimental

Matheson high purity argon was used to maintain inert atmosphere conditions. Infrared (ir) spectra were recorded on a Pye Unicam SP1000 infrared spectrophotometer using KBr discs. Nuclear magnetic resonance (nmr) spectra for protons and carbons were recorded on a Bruker AM300 nmr spectrometer. The position of signals is reported in δ units. (The splitting of the signals is described as singlets (s), doublets (d), triplets (t), quartets (q), doublets of doublets (dd), or multiplets (m)). The ^1H nmr spectra of 10^{-4} M solutions of the phthalocyanines were obtained by averaging 500–3000 scans over the absorption range. The ultraviolet–visible spectra (uv) were recorded on a Hewlett Packard HP8451A diode array spectrophotometer. Mass spectra (ms) were recorded at 70 eV on a VG Micromass 16F mass spectrometer in the EI mode. The FAB spectra were obtained with a Kratos MS-50 triple analyzer mass spectrometer equipped with a FAB ion source of standard Kratos design and Ion Tech atom gun. The sample was dissolved in chloroform and a microlitre of the resulting solution added to a microlitre of *m*-nitrobenzyl alcohol on the probe tip. The spectra of the molecular ions of the binuclear phthalocyanines were obtained by signal averaging up to 256 scans over the approximate mass range. The number in parentheses after the indaicated ion shows the percentage of the base peak represented by that ion. Melting points (mp) were determined using a Kofler hot stage melting point apparatus and are uncorrected. Flash chromatography was performed using silica gel of particle size 20–45 μm. All reactions were stirred with a magnetic stirrer. All solvents were freshly distilled before use. Thin-layer

chromatography (tlc) was performed using silica gel G as the absorbant. Microanalyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario.

Electrochemical data were obtained with a Princeton Applied Research (PARC) model 173 potentiostat, or a PARC model 174A polarographic analyzer coupled to a PARC model 175 universal programmer. Cyclic voltammetry and differential pulse voltammetry (DPV) were carried out under an atmosphere of argon, or nitrogen, using a conventional three-electrode cell. The working electrode was described by the cross-sectional area of a 27-gauge platinum wire (area 10^{-3} cm^2), and sealed in glass. A platinum wire also served as the counter electrode. The reference electrode was a silver wire quasireference electrode, referenced internally to the ferricenium/ferrocene (Fc^+/Fc) couple.

Spectroelectrochemical measurements were made with a 0.45-mm path-length optically transparent thin-layer electrode (OTTLE) cell, utilizing a gold minigrid (500 lines/in., 60% transmittance) (17), in conjunction with the Hitachi Perkin–Elmer model 340 spectrometer.

Preparation of 1,2-bis(3,4-dicyanophenyl)ethylene (1)

Compound **1** was prepared as reported by Marcuccio *et al.* (6); yield 85%, mp 285–287°C (lit. (6) mp 286–288°C); ^{1}H nmr (DMSO-d_6, 300 MHz) δ: 8.42 (d, J = 1.6 Hz, 2H, Ar*H*-3), 8.22 (d, J = 8 Hz, 2H, Ar*H*-6), 8.11 (d, J = 8 Hz, 2H, Ar*H*-5).

Preparation of 1,2-bis(3,4-dicyanophentl)ethene (2)

A solution of 1.0 g (3.6 mmol) of pure **1** in 300 mL of acetonitrile was stirred under hydrogen (1 atm (101.3 kPa), 25°C) in the presence of Lindlar's catalyst (12) (250 mg) until absorption of hydrogen (88 mL) had ceased. The catalyst was filtered and the filtrate was evaporated to give 0.950 g (94% yield) of a yellow powder **2**. Recrystallization in methanol yielded white, needle-like crystals, mp 196–197°C; ir (cm^{-1}): 3090–2920, 2210 (CN), 1590, 1550, 1490, 1380, 1230, 920, 870, 850, 810, 770, 720; uv (CH_3CN) λ_{max} (log ε): 308 (4.09), 276 (4.07), 224 (4.38); ^{1}H nmr (DMSO-d_6, 300 MHz) δ: 8.00 (s, 2H, Ar*H*-3), 7.98 (d, J = 8 Hz, 4H, Ar*H*-6), 7.61 (d, J = 8 Hz, 2H, Ar*H*-5), 6.95 (s, 2H, C*H*=CH); ^{13}C nmr δ: 141.2 (C-4), 134.1 + 134.0 (C-5 + C-9), 133.6 (C-3), 131.0 (C-6), 115.8 + 115.6 (C-7 + C-8), 115.1 (C-2), 113.3 (C-1); ms m/z: 280(M^+), 254. Anal. calcd. for $C_{18}H_8N_4$: C 77.13, H 2.87, N 19.98; found: C 77.10, H 3.21, N 20.17.

Preparation of the bis-1,3-diiminoisoindoline of 1,2-bis(3,4-dicyanophenyl)ethyne (3)

The bisphthalonitrile **1**, 0.30 g (1.08 mmol), was added to a solution of 30 mg of sodium in 30 mL of dry methanol. Since the bisphthalonitrile **1** did not dissolve, the mixture was heated to 60°C. The mixture was stirred at 60°C for 0.75 h under reflux conditions, while ammonia gas was bubbed into the solution. The reaction mixture gradually turned green during which time a green precipitate was observed. The reaction was cooled to room temperature and the addition of ammonia gas was discontinued. Evaporation of the solvent gave crude **3**, which was used directly in condensation reactions without further purification. Compound **3** did not exhibit a nitrile absorption in its ir spectrum.

Preparation of the bis-1,3-diiminoisoindole of 1,2-bis(3,4-dicyanophenyl)ethene (4)

The bisphthalonitrile **2**, 0.300 g (1.07 mmol), was added to a solution of 30 mg of sodium in 30 mL of dry methanol. The mixture was stirred at room temperature for 0.75 h while ammonia gas was bubbled into the solution. The reaction mixture gradually became green, during which time a green precipitate was observed. The addition of ammonia gas was discontinued. Evaporation of the solvent gave crude **4**, which was used directly in condensation reactions without further purification. Compound **4** did not exhibit a nitrile absorption in its ir spectrum.

Preparation of the 1,2-bis-2'-(9',16',23'-trineopentoxyphthalocyaninyl)ethyne (7)

The two crude diiminoisoindolines **5** and **3**, obtained from 6.0 g (28 mmol) of 4-neopentoxyphthalonitrile (5) (**5**), and 300 mg (1.08 mmol) of **1**, were heated to 150°C (oil bath) in 30 mL of 2-*N*,*N*-dimethylaminoethanol for 72 h under an argon atmosphere. The mixture was cooled to room temperature, diluted with water, filtered, and washed thoroughly with water followed by methanol until the filtrate was almost clear. The crude product was extracted with methanol in a Soxhlet apparatus until the extract was clear of brown and yellow impurities. The crude product was purified by flash chromatography using a 5 cm diameter column packed with flash silica gel 12 cm high. The crude product was preabsorbed on a small amount of flash silica gel and eluted with toluene to give 300 g of the monomeric 2,9,16,23-tetraneopentoxyphthalocyanine (**6**) in 49% yield. Further elution with 2-methoxyethanol/toluene (2:98) gave a fraction consisting largely of dimer **7**, containing traces of monomer and some green material. Finally, elution with 2-methoxyethanol/toluene (1:4) gave a green fraction consisting largely of trimer and impurities. The dimer fraction was further purified by gel permeation chromatography (8, 16). Elution wih tetrahydrofuran removed all traces of monomer and green material from the major dimer band. Evaporation of the solvent gave a dark blue product. This product was washed with acetonitrile/acetone to remove traces of fluorescent impurities, detectable by tlc using toluene/2-methoxyethanol (98:2) as eluant to give, in 7.4% yield, 125 mg of **7** as a dark blue, shiny solid; ir (cm^{-1}): 3300 (N-H), 1610, 1480, 1400, 1240, 1100, 1020 (N-H), 750; uv (*o*-dichlorobenzene (DCB)) λ_{max} (log ε): 678 (4.36), 660 (4.39), 648 (4.45); ms m/z: 1569.8 (23), 1568.8 (58), 1567.8 (M^+ + 1, 100), 1566.8 (M^+, 86). Anal. calcd. for $C_{96}H_{94}N_{16}O_6$: C 73.54, H 6.04, N 14.29; found: C 73.30, H 5.95, N 13.94.

Preparation of 1,2-bis-2'-(9',16',23'-trineopentoxyphthalocyaninyl)-ethyne dicobalt(II) (8)

A mixture of 50 mg (0.032 mmol) of metal-free dimer **7** and 100 mg (0.77 mmol) of anhydrous cobalt(II) dichloride in 10 mL of a 1:1 mixture of 2-methoxyethanol/dichlorobenzene was heated at 16°C for 20 h under an argon atmosphere. The crude reaction mixture, after cooling, was evaporated under high vacuum to remove the 2-methoxyethanol/dichlorobenzene. The remaining residue was precipitated with a water/methanol (1:1) mixture. After filtering, the dark blue, shiny solid obtained was extracted with methanol in a Soxhlet apparatus until the extract was clear. The dark blue solid was dried to give 41 mg (76% yield) of **8**; ir (cm^{-1}): 1620, 1530, 1480, 1410, 1380, 1240, 1100, 760; uv (DCB) λ_{max} (log ε): 686 (4.21), 658 (4.23), 650 (4.19), 638 (4.18), 630 (4.19), 302 (4.33), 262 (4.04); ms m/z: 1683.6 (23), 1682.6 (58), 1681.6 (M^+ + 1, 100), 1680.6 (M^+, 86). Anal. calcd. for $C_{96}H_{90}N_{16}O_6Co_2$: C 68.56, H 5.39, N 13.39, Co 7.01; found: C 67.82, H 5.68, N 12.99, Co 6.80.

Preparation of cis *and* trans *1,2-bis-2'-(9',16',23'-trineopentoxyphthalocyaninyl)ethene (9 and 10)*

The two crude diiminoisoindolines, **5** and **4**, obtained from 6.0 g (28 mmol) of 4-neopentoxyphthalonitrile (5) and 300 mg (1.07 mmol) of **2**, were heated to 150°C (oil bath) in 30 mL of 2-*N*,*N*-dimethylaminoethanol for 72 h under an argon atmosphere. The mixture was cooled to room temperature, diluted with water, filtered, and washed thoroughly with water followed by methanol until the filtrate was almost clear. The crude product was extracted with methanol in a Soxhlet apparatus until the extract was clear of brown and yellow impurities. The crude product was purified by flash chromatography using a 5 cm diameter column packed with flash silica gel 12 cm high. The crude product was preabsorbed on a small amount of flash silica gel and eluted with toluene/hexane (1:1) to give 3.2 g of the monomeric **6** in 53% yield. Further elution with toluene gave a fraction consisting largely of dimer and monomer. Finally, elution with 2-methoxyethanol/toluene (2:98) gave a green fraction consisting largely of trimer and impurities. The dimer fraction was further purified by flash chromatography (3 cm diameter column). Elution with toluene/hexane (25:75) up to 100% toluene gave an even purer fraction of dimer with a small trace of monomer. This dimer fraction was further purified by gel permeation chromatography (8, 16) applying no more than 50 mg of dimer per chromatographic run. Elution with tetrahydrofuran removed all traces of monomer. The main dimer band of **9** was observed but a front-running blue band consisting of **10** was also noticed. These two

fractions were collected separately. Evaporation of the solvent gave 470.3 mg of **9** and **10** (28% yield, 378 mg of **9** and 92.3 mg of **10**) as dark blue solids, having identical ir and ms spectroscopic properties; ir (cm^{-1}): 3300 (N-H), 1620, 1480, 1400, 1240, 1100, 10.20 (N-H), 750; uv for **9** (DCB) λ_{max} (log ε): 704 (5.06), 650 (5.00), 344 (5.08); uv for **10** λ_{max} (log ε): 704 (4.76), 678 (4.77), 658 (4.78), 650 (4.77), 340 (4.86); ms *m/z*: 1571.7 (23), 1570.7 (58), 1569.7 (M^+ + 1, 100), 1568.7 (M^+, 86). Anal. calcd. for $C_{96}H_{90}N_{16}O_6Co_6$ for **9**: C 73.44, H 6.16, N 14.27; found: C 73.51, H 6.52, N 14.24. Anal. calcd. $C_{96}H_{96}N_{16}O_6$ for **10**: C 73.44, H 6.16, N 14.27; found: C 73.85, H 6.39, N 14.55.

*Preparation of the 1,2-bis-2'-(9',16',23'-trineopentoxyphthalocyaninyl)ethyne dicobalt(II) (**11**)*

A mixture of 50 mg (0.032 mmol) of metal-free dimer (**9**) and 100 mg (0.77 mmol) of anhydrous cobalt(II) dichloride in 13 mL of a 5:3:5 mixture of 2-methoxyethanol/dichlorobenzene/toluene was heated at 160°C for 20 h under an argon atmosphere. Flash chromatography of the crude reaction mixture on a 3 cm diameter column of flash silica gel and elution with dimethylformamide (DMF) gave, in 78.5% yield, 42.2 mg of **11** as a dark blue solid; ir (cm^{-1}): 1615, 1480, 1400, 1240, 1100, 1015, 755; uv (DCB) λ_{max} (log ε): 682 (4.82), 650 (4.76), 300 (4.91); ms *m/z*: 1685.6 (23), 1684.6 (58), 1683.6 (M^+ + 1, 100), 1682.6 (M^+, 86). Anal. calcd. for $C_{96}H_{92}N_{16}O_6Co_2$: C 68.48, H 5.50, N 13.31, Co 7.00; found: C 68.71, H 5.85, N 13.54, Co 6.50.

*Preparation of 1,2-bis-2'-(9',16',23'-trineopentoxyphthalocyaninyl)-ethene dizinc(II) (**12**)*

A mixture of 60 mg (0.038 mmol) of metal-free dimer **9** and 100 mg (0.54 mmol) of anhydrous zinc acetate in 13 mL of a 5:3:5 mixture of 2-methoxyethanol/dichlorobenzene/toluene was heated at 160°C for 20 h under an argon atmosphere. Flash chromatography of the crude reaction mixture on a 3 cm diameter column of flash silica gel and elution with 2-methoxyethanol/toluene (1:3) gave, in 89% yield, 57.7 mg of **12** as a dark blue solid; ir (cm^{-1}): 1610, 1490, 1395, 1340, 1235, 1100, 1060, 1015, 750; uv (DCB) λ_{max} (log ε): 688 (4.99), 658 (4.91), 650 (4.88), 342 (4.99), 300 (4.85); ms *m/z*: 1701.6 (18), 1700.6 (31), 1699.6 (46), 1698.6 (68), 1697.6 (84), 1696.6 (100), 1695.6 (82), 1694.6 (85), 1693.6 (M^+ + 1, 54), 1692.6 (M^+, 47). Anal. calcd. for $C_{96}H_{92}N_{16}O_6Zn_2$: C 67.96, H 5.46, N 13.20, Zn 7.70; found: C 67.53, H 5.40, N 13.03, Zn 7.22.

Syntheses of glycosyl phosphates by phase transfer catalysis

RENÉ ROY,[1] FRANÇOIS D. TROPPER, AND CHANTAL GRAND-MAÎTRE
Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received February 13, 1991

RENÉ ROY, FRANÇOIS D. TROPPER, and CHANTAL GRAND-MAÎTRE. Can. J. Chem. **69**, 1462 (1991).

The peracetylated glycosyl bromides of D-glucose (**1**), D-galactose (**2**), and D-lactose (**5**) were treated with dibenzyl phosphate in a catalytic two-phase system using tetrabutylammonium hydrogen sulfate as catalyst. The reactions proceeded by complete inversion at the anomeric centers and afforded a new stereospecific entry into 1,2-*trans*-β-D-glycosyl phosphates of peracetylated D-glucose (**3**), D-galactose (**4**), and the disaccharide D-lactose (**6**) in 83, 73, and 83% yields respectively. Interestingly, the glycosyl chloride **7** furnished the oxazoline **9** rather than the expected glycosyl phosphate **8**.

Key words: phase transfer catalysis, glycosyl phosphates, phosphotriesters.

RENÉ ROY, FRANÇOIS D. TROPPER et CHANTAL GRAND-MAÎTRE. Can. J. Chem. **69**, 1462 (1991).

Les bromures de glycosyles peracétylés du D-glucose (**1**), du D-galactose (**2**) et du D-lactose (**5**) ont été traités en présence de phosphate de dibenzyle dans des conditions de catalyse par transfert de phase utilisant le bisulfate de tétrabutylammonium comme catalyseur. Les réactions ont conduit à une inversion complète des centres anomériques et fournissent une nouvelle entrée stéréospécifique aux phosphates peracétylés des 1,2-*trans*-β-D-glycosyles du D-glucose (**3**), du D-galactose (**4**) et du disaccharide D-lactose (**6**) avec des rendements de 83, 73, and 83% respectivement. Il est intéressant de noter que le chlorure de glycosyle **7** a conduit à la formation de l'oxazoline **9** au lieu du phosphate de glycosyle attendu **8**.

Mots clés: catalyse par transfert de phase, phosphate de glycosyles, phosphotriesters.

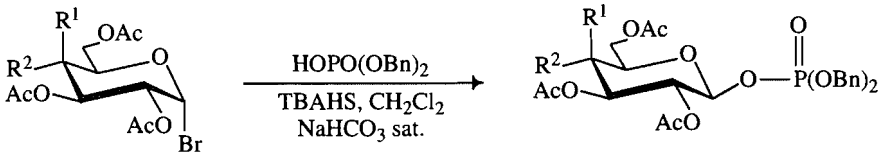
Introduction

Carbohydrate phosphates are important intermediates in a wide variety of biosynthetic processes (1). They constitute integral components of the core and lipid A region of lipopolysaccharides, sugar nucleotides, teichoic acids, bacterial polysaccharides, glycophospholipids, and phosphoinositides.

Previous methods for the synthesis of glycosyl 1-phosphates are essentially based on two fundamental concepts. In the first one, phosphoric acid, their salts, or dialkyl phosphates were used as nucleophiles on glycose peracetates (2), 1,2-orthoesters (3), halogenoses (4), 1,2-oxazolines (5), Brigl anhydrides (6), or on trichloroacetimidates (7). In the second approach, the anomeric hydroxyl groups were activated as lithium (8) or thallium (9) salts and reacted with electrophilic dialkyl phosphorochloridates. More recently, the phosphoramidite and H-phosphonate methods have also attracted interest (10). These methods and the occurrence of carbohydrate phosphates have been reviewed (11).

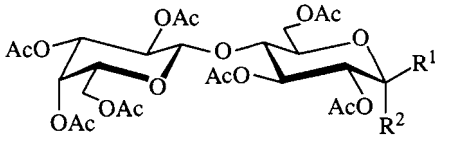
The widespread utilization of phase transfer catalysis (PTC) in carbohydrate chemistry (12) coupled with our own interests (13, 14) stimulated the application of this methodology to the synthesis of anomeric glycosyl phosphates from halogenoses. It was anticipated that dibenzylphosphate would be a potent nucleophile under a catalytic two-phase system. This procedure would give access to carbohydrate phosphotriesters from readily available reagents. We describe herein the successful practical syntheses of 1,2-*trans*-β-D-anomeric phosphates of peractylated D-glucose (**3**), D-galactose (**4**), and D-lactose (**6**). The reactions proceded by inversion at the anomeric centers and occurred with complete stereocontrol.



Results and discussion

Although there have been a number of recent applications of phase transfer catalysis (PTC) in carbohydrate chemistry (12–14), none of these dealt with the preparation of anomeric glycosyl phosphates. Because of the widespread occurrence of these important derivatives, it was decided to utilize PTC as a simple, practical entry into this class of carbohydrates. Our previous experience in PTC with a number of nucleophiles (phenoxides, thiophenoxides, azides, and carboxylates) (13, 14) prompted us to test the validity of using dibenzyl phosphate as nucleophile under the previously described conditions (13, 14). Thus, treatment of the α-bromides **1**, **2**, and **5** in methylene chloride and saturated sodium hydrogen carbonate with dibenzyl phosphate (2 equiv.) and tetrabutylammonium hydrogen sulfate (1 equiv.) at room temperature (1.5–3 days) afforded the corresponding β-D-glycosyl phosphates **3**, **4**, and **6** in 73–83% yields. Obviously, the reactions were much slower than those using phenoxides and thiophenoxides as nucleophiles (<45 min). The reactions occurred with complete inversion at the anomeric centers. Only traces of hydrolysis and dehydrobromination by-products were formed as side reactions. Changing the solvent, the catalyst, or the base (14) resulted in slower reactions and in lower yields.

The case of the 2-acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-α-D-glucopyranosyl chloride (**7**) is worthy of comment. We previously determined the usefulness of **7** as electrophile under PTC conditions with a wide variety of nucleophiles (13, 14). In these studies, it was also shown that the 2-methyl-(3,4,6-tri-*O*-acetyl-1,2-dideoxy-α-D-glucopyrano)-[2,1-*d*]-oxazoline (**9**) was the major product isolated under PTC conditions in the absence of extraneous nucleophiles (>6 h). This was attributed to the slow formation of the β-chloride analogue of **7** with concomitant anchimeric participation of the 2-acetamido group, thus providing the oxazoline **9**. In the actual case, however, even with added dibenzyl phosphate, the oxazoline **9** was the major product formed (TLC; ^{1}H NMR) within the first hour of reaction instead of the expected glycosyl phosphate **8**. Therefore, it is believed that the nucleophilic displacement of the α-chloride by dibenzyl phosphate might have occurred, followed by rapid intramolecular displacement of the phosphate by the amide function to provide the oxazoline **9**. This could be rationalized by a favored anchimeric participation from the acetamido group over the acetyl groups in **3**, **4**, and **6**.



The anomeric configurations of the above glycosyl phosphates were unambiguously established by ^{1}H and ^{13}C NMR spectroscopy (Tables 1 and 2). The complete assignments of all the protons and carbons were confirmed by COSY and

HETCOR experiments. The anomeric carbons of **3**, **4**, and **6** appeared at 96.2 ($^2J_{C,P}$ 4.7 Hz), 96.7 ($^2J_{C,P}$ 4.8 Hz), and 96.1 ($^2J_{C,P}$ 4.9 Hz) ppm respectively (Table 1). The anomeric proton of the glucosyl phosphate **3** appeared as a doublet of doublets centered at 5.33 ppm with $J_{1,2}$ and $^3J_{1,P}$ couplings of 7.5 Hz. The same coupling constants were obtained for the anomeric proton (5.30 ppm) of the glucosyl residue of the lactosyl phosphate **6** (Fig. 1). The case of the galactosyl phosphate **4** was, however, somewhat ambiguous (in $CDCl_3$) since the H-1 and H-2 protons appeared as an ABX system (300 MHz). Although the C-1 chemical shift and the $^2J_{C,P}$ coupling constant were similar to those observed for the β-phosphates **3** and **6** and thus indicative of the β-D configuration, it was decided to further confirm this assumption. A one-bond $^{13}C-^1H$ coupling constant, which showed a $^1J_{H1,C1}$ of 167 ± <1 Hz for **4**, was obtained by a heteronuclear gated decoupling experiment (300 MHz). This value indicated that the H-1 proton should have been equatorially disposed (α-anomer) since 160 Hz is assumed to be typical of β-anomers while 170 Hz is typical of the α-anomers (15). Since the literature cited (15) has not been applied or demonstrated on anomeric glycosyl phosphates, the ambiguity still remained. The anomeric region of the ^{1}H NMR spectra of **4** was then simulated (Fig. 2) based on the estimated chemical shifts of H-1, H-2, and H-3 obtained from the $^1H-^1H$ homonuclear shift correlated experiment. The data obtained (Table 2) showed a $J_{1,2}$ coupling constant of 8.1 Hz ($CDCl_3$),

typical of β-D-glycosides (axial proton). The apparent ambiguity was finally completely eliminated by running the ^1H NMR spectra of **4** in C_6D_6. The chemical shifts and coupling constants are included in Table 2. The H-1–H-3 system no longer appeared as an ABX pattern and was completely resolved.

In conclusion, treatment of halogenoses with dibenzyl phosphate under a catalytic two-phase system afforded 1,2-*trans*-β-D-glycosyl phophotriesters in good yields with complete stereocontrol. The method presents clear advantages over the previous ones because all the reagents are stable, nontoxic, and readily available. Moreover, β-glycosyl phosphates can give access to α-glycosyl phosphates by Lewis acid catalyzed anomerization (7) and were shown to act as useful glycosyl donors (16–18).

Experimental

General methods

The description of the general methods used is essentially the same as that recently published (14). The ^1H and ^{13}C NMR spectra at 300 and 75.4 MHz respectively were recorded on a Varian XL-300 spectrometer. The ^1H NMR spectra of **6** were recorded on a Bruker AM-500 MHz spectrometer. We acknowledge the assistance of NRC (Ottawa) for providing this instrument. The analyses were done as a first-order approximation. The carbon and proton chemical shifts are given relative to internal (deutero)chloroform at 77.0 and 7.24 ppm respectively. The homonuclear ^1H–^1H 45° COSY experiments on **6** were obtained on the Bruker instrument operating at 500.132 MHz. The spectra were collected as 512 × 256 blocks of data, which were processed using sinusoidal multiplication in each dimension before zero-filling to 1024 words in both dimensions followed by double Fourier transformation. The final data matrix was symmetrized. ^1H NMR simulations were performed using the standard NMR simulation package of the Varian XL-300 software (version 6.2, revision E). An initial spectrum was obtained using estimates of the chemical shifts (2D-COSY) and typical values for $J_{1,2}$ (7.5 Hz), $J_{2,3}$ (9 Hz), $J_{2,P}$, and $J_{3,P}$ (0 Hz) and a set value of $J_{1,P}$ (6.8 Hz) as measured from the ^{31}P NMR spectrum. This allowed initial assignment of the appropriate transitions. The measured experimental transition frequencies with their appropriate assignments were fixed in the simulation. Iteration on this data set gave the simulation shown in Fig. 2 and the final data are shown in Table 2. The peracetylated glycosyl bromides **1**, **2**, and **5** were prepared by the usual HBr/HOAc treatment of the peracetates (19).

*Dibenzyl(2,3,4,6-tetra-*O*-acetyl-β-*D*-glucopyranosyl) phosphate 3*

A solution of dibenzyl phosphate (135 mg, 0.49 mmol) and tetrabutylammonium hydrogen sulfate (82.5 mg, 0.24 mmol) in saturated sodium hydrogen carbonate (2 mL) was added to acetobromoglucose **1** (100 mg, 0.24 mmol) in methylene chloride (2 mL). The two-phase reaction mixture was stirred at room temperature for 72 h. Care was taken to maintain the pH of the aqueous phase at pH 8–9 by addition of a few drops of the saturated $NaHCO_3$ solution as required. Ethyl acetate was added (20 mL) and the resulting organic phase was successively washed with saturated $NaHCO_3$, water, and saturated NaCl. The organic phase was then dried with magnesium sulfate, filtered, and evaporated under reduced pressure. The residue was purified by radial silica gel chromatography using 2% *tert*-butanol in methylene chloride as eluant (with a few drops of triethylamine) to afford the pure glycosyl phosphate **3** (123 mg, 83%). Crystallization from diisopropyl ether gave needles of analytically pure **3**; mp 74.6–75.6°C; $[\alpha]_D$ −7.6 (*c* 1.0, $CHCl_3$) (lit. (7*b*) mp 76°C; $[\alpha]_D$ −6.5 (*c* 1.0, $CHCl_3$); lit. (3*a*) mp 76.5–78°C, $[\alpha]_D$ −8.4 (*c* 3, $CHCl_3$)). ^1H NMR (300 MHz) ($CDCl_3$) δ: 7.28 (m, 10H, Ph), 5.33 (dd, 1H, $J_{1,2}$ = 7.5, $^3J_{1,P}$ = 7.5 Hz, H1), 5.20 (dd, 1H, $J_{2,3}$ = 9.2, $J_{3,4}$ = 9.2 Hz, H3), 5.11 (dd, 1H, H2), 5.09 (dd, 1H, $J_{4,5}$ = 9.9 Hz, H4), 5.07 (d, 2H, $^3J_{H,P}$ = 7.4 Hz, CH_2Ph), 5.00 (d, 2H, $^3J_{H,P}$ = 7.1 Hz, CH_2Ph), 4.22 (dd, 1H, $J_{5,6'}$ = 4.8, $J_{6,6'}$ = 12.3 Hz, H6′), 4.09 (dd, 1H, $J_{5,6}$ = 2.2, H6), 3.79 (ddd, 1H, H5), 2.02, 1.99, 1.88 (4s, 12H, OAc). ^{13}C NMR ($CDCl_3$) δ: 170.4, 169.9, 169.3, 169.2 (OAc), 135.4, 135.2, 128.6, 128.5, 127.8, 127.7 (Ph), 96.2 (d, $^2J_{C,P}$ = 4.7 Hz, Cl), 72.6 (C5), 72.3 (d, $^4J_{C,P}$ = 1.5 Hz, C3), 71.1 (d, $^3J_{C,P}$ = 9.2 Hz, C2), 69.62 (d, $^2J_{C,P}$ = 5.8 Hz, CH_2Ph), 69.57 (d, $^2J_{C,P}$ = 5.5 Hz, CH_2Ph), 67.8 (C4), 61.4 (C6), 20.5, 20.45 (2×), 20.36 (OAc). *Dibenzyl (2,3,4,6-tetra-*O*-acetyl-β-*D*-galactopyranosyl) phosphate 4*

When the above procedure was applied on acetobromogalactose **2**, the title galactosyl phosphate **4** was obtained as an oil in 73% yield; $[\alpha]_D$ +3.3 (*c* 1.0, $CHCl_3$). ^1H NMR (300 MHz) ($CDCl_3$) δ: 7.33 (m, 10H, Ph), 5.40 (dd, 1H, $J_{3,4}$ = 3.5, $J_{4,5}$ = 1.2 Hz, H4), 5.31 (dd, 1H, $J_{1,2}$ = 8.1, $J_{2,3}$ = 9.8 Hz, H2), 5.30 (dd, 1H, $^3J_{1,P}$ = 7.4 Hz, H1), 5.07 (d, 2H, $^3J_{H,P}$ = 7.3 Hz, CH_2Ph), 5.03 (dd, 1H, $J_{3,4}$ = 3.5 Hz, H3), 5.00 (dd, 2H, $^3J_{H,P}$ = 7.0 Hz, CH_2Ph), 4.14 (dd, 1H, $J_{5,6'}$ = 6.8, $J_{6,6'}$ = 11.0 Hz, H6′), 4.08 (dd, 1H, $J_{5,6}$ = 6.0, H6), 4.00 (ddd, 1H, H5), 2.15, 1.97, 1.95, 1.90 (4s, 12H, OAc). ^1H NMR (300 MHz) (C_6D_6) δ: 7.12 (m, 10H, Ph), 5.79 (dd, 1H, $J_{1,2}$ = 8.0, $J_{2,3}$ = 10.5 Hz, H2), 5.51 (dd, 1H, $^3J_{1,P}$ = 7.8 Hz, H1), 5.40 (dd, 1H, $J_{3,4}$ = 3.5, $J_{4,5}$ = 1.1 Hz, H4), 4.97 (d, 2H, $^3J_{H,P}$ = 7.1 Hz, CH_2Ph), 5.14 (dd, 1H, H3), 4.99–5.09 (2H, ABX, H6,6′), 3.90 (d, 2H, $^3J_{H,P}$ = 7.1 Hz, CH_2Ph), 3.27 (ddd, 1H, $J_{5,6}$ = $J_{5,6'}$ = 6.5 Hz, H5), 1.71, 1.70, 1.56, 1.55 (4s, OAc). ^{13}C NMR ($CDCl_3$) δ: 170.2, 170.0, 169.8, 169.4 (OAc), 135.3, 135.2, 128.6, 128.55, 128.52, 127.8, 127.7 (Ph), 96.7 (d, $^2J_{C,P}$ = 4.8 Hz, C1), 71.7 (C5), 70.4 (C3), 69.6 (d, $^2J_{C,P}$ = 5.9 Hz, CH_2Ph), 69.55 (d, $^2J_{C,P}$ = 6.1 Hz, CH_2Ph), 68.6 (d, $^3J_{C,P}$ = 8.8 Hz, C2), 66.6 (C4), 61.0 (C6), 20.6, 20.5 (4 × OAc). CI (ether) *m/z*: 609 (1.1%, M + H^+). Anal. calcd. for $C_{28}H_{33}O_{13}P$: C 55.25, H 5.47, P 5.09; found: C 55.44, H 5.57, P 4.88.

*Dibenzyl (hepta-*O*-acetyl-β-*D*-lactosyl) phosphate 6*

Acetobromolactose **5** (250 mg, 0.36 mmol), dibenzyl phosphate (149 mg, 0.54 mmol, 1.5 equiv.), and tetrabutylammonium hydrogen sulfate (120 mg, 0.35 mmol, 1 equiv.) were dissolved in methylene chloride (2 mL). Saturated sodium hydrogen carbonate (2 mL) containing sodium carbonate (70 mg, pH 9.0) was then added to the organic solution. The two-phase reaction mixture was vigorously stirred at room temperature for 34 h until TLC (0.1% Et_3N in hexane:ethyl acetate, 1:1 v/w) indicated complete conversion of **5** (R_f 0.38) into the glycosyl phosphate **6** (R_f 0.27). Addition of ethyl acetate (20 mL) and washings of the organic phase as above, followed by drying (Na_2SO_4), filtration, and evaporation of the organic phase, furnished a glassy solid. Purification on silica gel column chromatography using chloroform:isopropanol as eluant (40:1, v/v) afforded 12 mg of the 2-acetoxylactal resulting from a dehydrobromination side-reaction, followed by **6** (266 mg, 83%) as a glassy solid; $[\alpha]_D$ −7.5 (*c* 0.97, $CHCl_3$). ^1H NMR (500 MHz) ($CDCl_3$) δ: 7.20–7.36 (m, 10H, Ph), 5.33 (dd, 1H, $J_{3,4}$ = 3.5, $J_{4,5}$ < 1 Hz, H4′), 5.30 (dd, 1H, $J_{1,2}$ = 7.5, $^3J_{1,P}$ = 7.5 Hz, H1), 5.19 (dd, 1H, $J_{3,4}$ = 9.2, $J_{2,3}$ = 9.3 Hz, H3), 5.09 (dd, 1H, $J_{1,2}$ = 7.8, $J_{2,3}$ = 10.4 Hz, H2′), 5.01 (dd, 1H, H2), 4.99 (app. d, 2H, $^2J_{C,P}$ = 7.3 Hz, J_{gem} < 1 Hz, CH_2Ph), 4.94 (dd, 1H, H3′), 5.03 (dd, 2H, $^2J_{C,P}$ = 7.3, J_{gem} = 2.8 Hz, CH_2Ph), 4.48 (dd, 1H, $J_{5,6}$ = 2.1, $J_{6,6'}$ = 12.2 Hz, H6 Glc), 4.47 (d, 1H, $J_{1,2}$ = 7.8 Hz, H1′), 4.11 (dd, 1H, $J_{5,6}$ = 6.9, $J_{6,6'}$ = 11.2 Hz, H6 Gal), 4.06 (dd, 1H, H6′ Gal), 4.02 (dd, 1H, $J_{5,6'}$ = 5.1 Hz, H6′ Glc), 3.85 (app. dd, 1H, $J_{5,6'}$ = 6.3 Hz, H5′), 3.84 (dd, 1H, $J_{4,5}$ = 10.0 Hz, H4), 3.71 (ddd, 1H, H5), 2.13, 2.04, 2.02 (2×), 2.00, 1.94, 1.88 (7s, 21H, OAc). ^{13}C NMR (300 MHz) ($CDCl_3$) δ: 170.3, 170.1 (2×), 170.0, 169.5, 169.0 (OAc), 135.3 (d, $^3J_{C,P}$ = 23.3 Hz, C-*ipso* Ph), 128.6 (C-*para*), 128.58, 128.54 (C-*meta*), 127.8, 127.7 (C-*ortho*), 101.0 (Cl′), 96.1 (d, $^2J_{C,P}$ = 4.9 Hz, Cl), 75.6 (C4), 73.4 (C5), 72.3 (C3), 71.5 (d, $^3J_{C,P}$ = 9.0 Hz, C2), 70.9 (C3′), 70.7 (C5′), 69.6 (d, $^2J_{C,P}$ = 6.2 Hz, CH_2Ph), 69.5 (d, $^2J_{C,P}$ = 6.3 Hz, CH_2Ph), 69.0 (C2′), 66.5 (C4′), 61.5 (C6), 60.8 (C6′), 20.7 (2×), 20.6 (3×), 20.5, 20.4 (OAc). Received March 27, 1991

MORRIS J. ROBINS, FRITZ HANSSKE, STANISLAW F. WNUK, and TADASHI KANAI. Can. J. Chem. **69**, 1468 (1991).

Treatment of ribonucleosides with thionyl chloride/pyridine/acetonitrile (0°C to ambient temperature) resulted in essentially quantitative formation of 5′-chloro-5′-deoxy-2′,3′-*O*-sulfinylnucleoside derivatives. These diastereomeric sulfite esters underwent deprotection readily with aqueous methanolic ammonia. This gave 5′-chloro-5′-deoxynucleosides without use of the suspected carcinogen, hexamethylphosphoramide (HMPA). Nucleophilic displacement with sodium thiolates in dimethylformamide (−30°C to ambient temperature) gave 5′-*S*-aryl(or alkyl)-5′-thionucleosides in high yields. Treatment of ribonucleosides with thionyl chloride/acetonitrile without pyridine followed by aqueous work-up gave diastereomeric 2′,3′-*O*-sulfinylnucleosides with an unmodified 5′-hydroxyl group. Diagnostic NMR shifts for cyclic sulfite ester stereochemistry are noted.

Key words: adenosine, 5′-*S*-aryl(or alkyl)-5′-thionucleosides, 5′-chloro-5′-deoxynucleosides, uridine, nucleosides.

MORRIS J. ROBINS, FRITZ HANSSKE, STANISLAW F. WNUK et TADASHI KANAI. Can. J. Chem. **69**, 1468 (1991).

Les ribonucléosides traités par un mélange de chlorure de thionyle/pyridine/acétonitrile donnent essentiellement et quantitativement des dérivés du chloro-5′-déoxy-5′-*O*-sulfinyl-2′,3′-nucléoside. Ces sulfites d'esters diastéréoisomères sont déprotégés facilement par l'ammoniac dans du méthanol aqueux pour donner les chloro-5′-déoxy-5′-nucléosides sans l'utilisation de l'hexaméthylphosphoramide (HMPA) soupçonné d'être cancérigène. Le déplacement nucléophile avec les thiolates de sodium dans le diméthylformamide (−30°C jusqu'à la température ambiante) donne les *S*-aryl(ou alkyl)-5′-thio-5′-nucléosides avec des rendements élevés. Le traitement des nucléosides par le mélange de chlorure de thionyle/acétonitrile sans la pyridine et le traitement aqueux subséquent donnent les *O*-sulfinyl-2′,3′-nucléosides avec le groupe hydroxyl-5′ non modifié. On a enregistré les déplacements chimiques en RMN relatifs à la stéréochimie de ces sulfites d'esters cycliques.

Mots clés : adénosine, *S*-aryl(ou alkyl)-5′-thio-5′-nucléosides, chloro-5′-déoxy-5′-nucléosides, uridine, nucléosides.

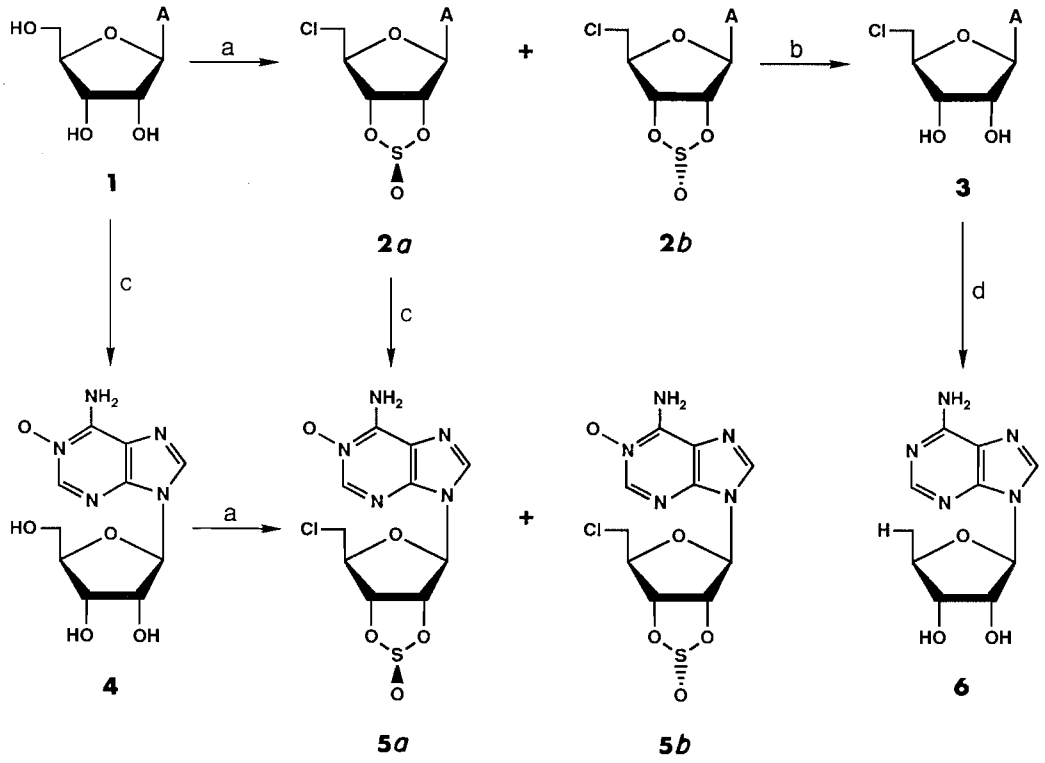
[Traduit par la rédaction]

Introduction

Procedures for modification at C5′ of ribonucleosides classically used 2′,3′-*O*-isopropylidene protection and activation of the 5′-hydroxyl group by *p*-toluenesulfonylation (1). Direct conversions of 2′,3′-*O*-isopropylidene nucleosides to 5′-chloro derivatives were reported with neat thionyl chloride (2) or thionyl chloride/dimethylformamide (DMF) (Vilsmeier–Haack reagent) (3). Dods and Roth also noted that treatment of unprotected uridine with thionyl chloride/DMF gave 5′-chloro-5′-deoxyuridine (3). Kikugawa and Ichino (4) reported that treatment of cytidine with thionyl chloride/DMF gave the 2,2′-anhydroarabinonucleoside (4*a*), but treatment of cytidine or adenosine with thionyl chloride/hexamethylphosphoramide (HMPA) followed by aqueous work-up gave the unprotected 5′-chloro-5′-deoxynucleosides (4*b*). Hogenkamp invoked HMPA-mediated oxyphosphonium activation at C5′ and pentavalent cyclic phosphorus bonding at O2′ and O3′ to rationalize this selective C5′ chlorination (5). However, Normant and Deshayes had reported the *absence* of Vilsmeier–Haack type phosphonium activation in conversions of alcohols to alkyl chlorides by thionyl chloride/HMPA and had noted acid–base complexation of hydrogen chloride by HMPA (6). Successful substitution of trimethyl phosphate for HMPA in this reaction was reported by Gibbs and Verkade (7), and Hřebabecký and Beránek (8) identified the formation of 2′,3′-cyclic sulfite ester intermediates in HMPA as well as other solvents. Thus, the formation of 2′,3′-*O*-sulfinyl intermediates (8, 9) that undergo displacement of the 5′-halosulfite group by halide in the polar solvating HMPA medium (6) is indicated, whereas the formerly considered chemical participation (1*c*, 5) of HMPA is unlikely. A number of 5′-chloro-5′-deoxynucleosides have been prepared by this thionyl chloride/HMPA procedure (4*b*), and earlier studies have been summarized (1, 10–12).

Sowa and Tsunoda reported that treatment of pyrimidine (13) or purine (14) nucleosides with thionyl chloride/acetonitrile followed by water resulted in formation of 2′,3′-*O*-sulfinyl esters with an unmodified 5′-hydroxyl group. We have confirmed these results and found that the addition of 2 equivalents of pyridine to suspensions of ribonucleosides and excess thionyl chloride in acetonitrile resulted in essentially quantitative conversions to the 5′-chloro-5′-deoxy-2′,3′-*O*-sulfinylnucleoside intermediates. Pyridine was not required for the conversion of 5′-substituted nucleosides to their 2′,3′-cyclic sulfite esters, and adenosine-1-oxide was converted to its 5′-chloro-5′-deoxy-2′,3′-*O*-sulfinyl derivatives without modification of the *N*-oxide function. The diastereomeric cyclic sulfite esters underwent hydrolysis readily in aqueous methanolic ammonia to provide an economical overall route to the synthetically useful 5′-chloro-5′-deoxynucleosides without use of the suspected carcinogen, and sometimes difficultly removable, HMPA.

Results and discussion



Treatment of a stirred suspension of adenosine (**1**, Scheme 1) with 3 equivalents of thionyl chloride and 2 equivalents of pyridine in acetonitrile at ~0°C followed by warming to ambient temperature resulted in quantitative (TLC, NMR) formation of a mixture of 5′-chloro-5′-deoxy-2′,3′-*O*-sulfinyladenosines (**2***a*/**2***b*). Fractional crystallization of the cyclic sulfite ester diastereomers occurred to give highly enriched *exo* isomer (**2***a*)

(a) $SOCl_2/C_6H_5N/MeCN$. (b) $NH_3/H_2O/MeOH$. (c) $3\text{-}ClC_6H_4CO_3H$/solvent. (d) $LiEt_3BH/THF/Me_2SO$

SCHEME 1

and an enriched sample of the *endo* isomer (**2***b*). It has been established that the ^1H NMR frequencies of geminal protons on 5-membered cyclic sulfite ester rings (1,3,2-dioxathiolan-2-oxides) are shifted downfield when proximal to the exocyclic oxygen atom and upfield when distal (9, 15–17). Known correlations for cyclic sulfite ^{13}C NMR shifts (9, 16) also were in harmony with our observed ^1H and ^{13}C NMR spectra (Tables 1 and 2). The isolation of several forms of these cyclic sulfite esters is noted in the experimental section. Treatment of **2***a*/**2***b* with aqueous methanolic ammonia at ambient temperature resulted in smooth deprotection to give 5′-chloro-5′-deoxyadenosine (**3**, 94%). Direct processing of crude **2***a*/**2***b* gave **3** with overall yields of >90%.

Treatment of **3** with lithium triethylborohydride/THF/DMSO at ambient temperature resulted in reductive dechlorination (18) to give 5′-deoxyadenosine (**6**, 93%) (19). This chlorination/deprotection/reduction sequence provides a concise and efficient route to **6** that offers an ambient temperature alternative to the radical-mediated dechlorination with tributylstannane (8, 11).

A modified oxidation of **1** to adenosine-1-oxide (**4**, 96%) (20) is noted in the experimental section. Treatment of **4** with $SOCl_2$/pyridine/acetonitrile gave the diastereomeric 5′-chloro-5′-deoxy-2′,3′-*O*-sulfinyladenosine-1-oxides (**5***a*/**5***b*, 94%) with no effect on the purine *N*-oxide functionality. Alternatively, oxidation of **2***a* with 3-chloroperoxybenzoic acid gave the *exo* isomer **5***a* (90%) without observed oxidation of the sulfite ester (21).

Treatment of 5′-azido-5′-deoxyadenosine (**7***a*, Scheme 2) or 5′-*O*-benzoyladenosine (**7***b*) with $SOCl_2$/acetonitrile resulted in formation of the respective 2′,3′-*O*-sulfinyl derivatives (**8***a*/**9***a* (96%) or **8***b*/**9***b* (95%)). Cytidine (**7***c*) and uridine (**7***d*) were converted to their 2′,3′-*O*-sulfinyl derivatives (**8***c*/**9***c* (84%) and **8***d*/**9***d* (82%)) analogously, as described (13). Inclusion of 2 equivalents of pyridine in the mixture with uridine resulted in formation of the 5′-chloro-5′-deoxy-2′,3′-*O*-sulfinyluridine diastereomers (**8***e*/**9***e*), which were deprotected to give 5′-chloro-5′-deoxyuridine (**10**, 82%).

Several methods have been employed for the nucleophilic displacement of leaving groups with thiols at C5′ of nucleoside derivatives (1, 22–26). However, the procedure of Borchardt *et al.* requires the condensation of liquid ammonia (25) and variable yields have been noted. The disulfide/phosphine procedure of Hata and co-workers (26) is conceptually elegant and gives high yields, but the use of tributylphosphine and purification from phosphine oxide by-products is required.

Treatment of the readily accessible adenine and uracil 5′-chloro-5′-deoxynucleosides (**3** and **10**, Scheme 3) with sodium thiolates (derived by treatment of thiols in dimethylformamide with sodium hydride at low temperature) resulted in rapid and quantitative conversion to the corresponding 5′-*S*-aryl(or alkyl)-5′-thionucleoside derivatives (**11***a–e*, 86–94% analytically pure). Other 5′-thioether derivatives have been prepared with equivalently high yields (unpublished results).

In summary, treatment of adequately soluble ribonucleosides and their 5′-substituted derivatives with thionyl chloride in acetonitrile resulted in essentially quantitative formation of the diastereomeric 2′,3′-*O*-sulfinyl derivatives. Presumably, the 5′-*O*-chlorosulfinyl group was hydrolyzed from unsubstituted nucleosides during work-up. Inclusion of 2 equivalents of pyridine in the reaction mixture with ribonucleosides resulted in near quantitative conversion to 5′-chloro-5′-deoxy-2′,3′-*O*-

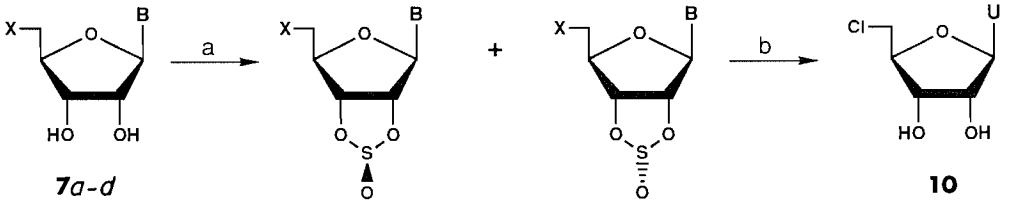
sulfinylnucleoside diastereomers. Treatment of these mixtures with aqueous methanolic ammonia effected deprotection to give the 5′-chloro-5′-deoxynucleosides in high yields. Nucleophilic displacement with sodium thiolates in DMF gave quantitative conversion to the 5′-*S*-aryl(or alkyl)-5′-thionucleoside derivatives, which were isolated in high yields. All of these conversions were effected at or below ambient temperature with readily available and inexpensive reagents under common bench-top conditions.

Experimental

Uncorrected melting points were determined with a microstage block. UV spectra were recorded with a Hewlett Packard 8451A diode array spectrophotometer. ^{1}H and ^{13}C NMR spectra were recorded with Bruker WH-200, WH-400, or Varian Gemini-200 spectrometers. Electron impact (MS) and chemical ionization (CI, NH_3) mass spectra were determined with AEI MS-50 and MS-12 instruments, respectively. Reagents and solvents were of commercial reagent quality. Thionyl chloride and all solvents were distilled before use. Pyridine was dried by reflux over, and distillation from, calcium hydride.

*5′-Chloro-5′-deoxy-2′,3′-*O*-sulfinyladenosines* **2a/2b**

Method A



A stirred suspension of adenosine (**1**, 13.35 g, 50 mmol) in CH_3CN (50 mL) was cooled in an ice/H_2O bath for 5 min. Addition of $SOCl_2$ (11 mL, 17.9 g, 150 mmol) was followed by cooling to 0°C. Pyridine (8.1 mL, 7.9 g, 100 mmol) was added and the resulting light yellow solution was stirred for 3–4 h at 0°C and allowed to warm to ambient temperature overnight. The mixture was cooled in ice/H_2O and H_2O (150 mL) was added to dissolve the colorless precipitate. The solution was carefully neutralized to pH 5–6 (solid $NaHCO_3$) and a colorless precipitate separated. The mixture was extracted with EtOAc (400 mL followed by 2 × 200 mL) and the combined organic phase was washed with saturated $NaHCO_3$/H_2O (200 mL) and H_2O, dried (Na_2SO_4), and filtered. Toluene (100 mL) was added and the solution concentrated (<30°C) *in vacuo* to ~300 mL. Toluene (100 mL) was added and evaporation was continued to ~100 mL. This mixture was cooled (4°C) for 4 h and filtered to give 12.6 g (67%) of the major *exo* diastereomer (**2***a*) as a colorless crystalline hemisolvate (verified by ^{1}H NMR): mp 178–181°C (softening transition), 232–233°C (dark brown "crystals" melting to dark fluid). Anal. calcd. for $C_{10}H_{10}ClN_5O_4S{\cdot}0.5C_4H_8O_2$ (375.8): C 38.35, H 3.76, N 18.64; found: C 38.44, H 3.77, N 18.40.

[d]Doublet of doublets (unless otherwise noted).
[e]Doublet of doublets of doublets (unless otherwise noted).
[f]Upfield resonance assigned to 5″(pro-*R*)-H.
[g]Singlet.
[h]Broad singlet.
[i]$^3J_{HO-CH}$.
[j]Triplet.
[k]$^3J_{HO-CH_2}$.
[l]Multiplet.
[m]"Collapsed" signals for H5′,5″.
[n]After heating a solution of **4** in D_2O at 100°C for 5.5 h in a sealed ampoule, its spectrum lacked the "exchangeable" proton peaks and the signal at δ 8.55.
[o]$J_{5''-4'}$.
[p]Hydrochloride salt.
[q]Signals were assigned from a spectrum of the diastereomeric mixture (correlated with integrated intensities).
[r]$^3J_{CH_3-4'}$.
[s]No signal was observed for OH5′.
[t]Determined at 200 MHz.
[u]Coupling constant obtained from a D_2O-exchanged spectrum.

Series	B	X
a	adenin-9-yl	N_3
b	adenin-9-yl	OBz
c	cytosin-1-yl	OH
d	uracil-1-yl	OH
e	uracil-1-yl	Cl

(a) $SOCl_2$/MeCN for *a*-*d*, $SOCl_2$/C_6H_5N/MeCN for *e*. (b) NH_3/H_2O/MeOH

[a]Chemical shifts (δ) at 75.5 MHz.
[b]All proton-decoupled peaks appeared as singlets.
[c]Hydrochloride salt.
[d]Assignments were made from a spectrum of the diastereomeric mixture.
[e]Peaks were not resolved.
[f]Peaks also at δ 128.63, 129.05, 129.25, 133.47 (Ar); 165.29 (CO).
[g]A peak also at δ 15.52 (SCH_3).
[h]Data parallel literature values (29).
[i]Peaks also at δ 127.14, 129.35, 130.11, 136.32 (Ar).
[j]Assignments might be reversed.
[k]Peaks also at δ 55.71 (OCH_3); 114.71, 125.50, 132.99, 158.46 (Ar).
[l]Peaks also at δ 55.48 (OCH_3); 115.06, 125.79, 132.55, 158.76 (Ar).
[m]Peaks also at δ 116.40, 123.17, 132.94, 156.83 (Ar).

3, B = adenin-9-yl
10, B = uracil-1-yl

11*a*, B = adenin-9-yl, R = CH_3
11*b*, B = adenin-9-yl, R = C_6H_5
11*c*, B = adenin-9-yl, R = 4-$CH_3OC_6H_4$
11*d*, B = uracil-1-yl, R = 4-$CH_3OC_6H_4$
11*e*, B = uracil-1-yl, R = 4-HOC_6H_4

SCHEME 3

This product was dried at 60°C *in vacuo* for 2 days to give **2***a*: mp 176–178°C (transition), 236–237°C (dec.); MS (CI, NH_3) *m/z*: 332 (100, M + 1, ^{35}Cl), 334 (40, M + 1, ^{37}Cl (and ^{35}Cl, ^{34}S)). Anal. calcd. for $C_{10}H_{10}ClN_5O_4S$ (331.7): C 36.21, H 3.04, Cl 10.69, N 21.11, S 9.67; found: C 36.20, H 3.05, Cl 10.55, N 21.03, S 9.88. Beautifully crystalline **2***a* was obtained by rapid crystallization from dry CH_3CN.

Three successive additions of toluene and concentrations of the mother liquor resulted in deposition of 5.4 g (29%) of an ~1:1 mixture of **2***a*/**2***b* hemisolvate. Slow concentration of this filtrate resulted in separation of 1.4 g (7%) of an ~1:4 mixture of this material. A portion of the latter solid was purified by preparative TLC (EtOAc/hexane, 20:1) to give colorless material with MS (CI, NH_3) *m/z*: 332 (100, M + 1, ^{35}Cl), 334 (40, M + 1, ^{37}Cl (and ^{35}Cl, ^{34}S)); and NMR spectral data (see Tables 1 and 2) for **2***b*.

Method B

Filtration and washing of the colorless precipitate obtained after neutralization to pH 5–6 in Method A and drying *in vacuo* gave 8.7 g (52%) of analytically pure **2***a* (found: C 36.10, H 3.11, Cl 10.63, N 21.02).

Method C (hydrochloride)

To a stirred suspension of **1** (1.34 g, 5 mmol) in pyridine (0.81 mL, 0.79 g, 10 mmol) and CH_3CN (15 mL) cooled in an ice/H_2O bath was slowly added $SOCl_2$ (1.84 mL, 3.0 g, 25 mmol). Stirring was continued at ~5°C for 3–4 h with warming to ambient temperature overnight. The resulting precipitate was filtered under a stream of dry N_2 and dried *in vacuo* over KOH and P_4O_{10} to give 1.69 g (92%) of colorless hygroscopic crystals of (**2***a*/**2***b*)·HCl: mp 165–175°C (transition), ~228°C (dec.); MS (CI, NH_3) *m/z*: 332 (26, M + 1, ^{35}Cl), 136 (100, B + 2). Anal. calcd. for $C_{10}H_{10}ClN_5O_4S$·HCl (368.2): C 32.62, H 3.01, Cl 19.26, N 19.02; found: C 32.64, H 2.93, Cl 19.11, N 18.98.

5′-Chloro-5′-deoxyadenosine **3**

To a stirred suspension of (**2***a*/**2***b*)·HCl (3.5 g, 9.5 mmol) MeOH (50 mL) was added H_2O (10 mL) and concentrated NH_3/H_2O

(5 mL). Stirring was continued for 30 min at ambient temperature and the clear, TLC-homogeneous solution was evaporated. The resulting colorless solid was crystallized from H_2O and dried *in vacuo* over P_4O_{10} to give 2.55 g (94%) of **3**: mp ~108–110°C (softening), ~188–190°C (dec.) (lit. (4*b*) mp 190°C (dec.), (7) mp 185–187°C (dec.)); MS *m/z*: 285.0627 (5.4, M^+(285.0629, ^{35}Cl)), 287.0599 (1.5, M^+(287.0599, ^{37}Cl)), 136.0616 (100, B + 2). Anal. calcd. for $C_{10}H_{12}ClN_5O_3$ (285.7): C 42.04, H 4.23, Cl 12.41, N 24.51; found: C 41.84, H 4.20, Cl 12.08, N 24.24.

5′-Deoxyadenosine ***6***

To a solution of **3** (286 mg, 1 mmol) in Me_2SO (15 mL) was added 1 M $LiEt_3BH$/THF (15 mL) and the solution stirred overnight at ambient temperature. **Cautious** addition of 5% HOAc/H_2O (40 mL) was followed by purging the **pyrophoric** Et_3B from the solution with N_2. The slightly yellow mixture was evaporated *in vacuo* at 50°C (bath temperature) and the residual syrup was dissolved in H_2O (30 mL) and applied to a column of Dowex 1 × 2 (OH^-) resin (2 × 20 cm). The column was washed with H_2O and the product eluted with MeOH/H_2O (3:2). Evaporation of the eluate and recrystallization of the product from H_2O gave 234 mg (93%) of **6**: mp ~134°C, with resolidification and remelting at 210–212°C (lit. (19*b*) mp 212–213°C (softens 135–140°C)); MS *m/z*: 251.1016 (M^+: 251.1018). Anal. calcd. for $C_{10}H_{13}N_5O_3$ (251.2): C 47.81, H 5.22, N 27.88; found: C 47.67, H 5.32, N 27.69.

Adenosine-1-oxide ***4***

A mixture of **1** (2.67 g, 10 mmol) and 3-chloroperoxybenzoic acid (6.09 g, 30 mmol as 85% reagent) in HOAc (40 mL) was stirred for 18 h at ambient temperature. To the white suspension was added Et_2O (50 mL). The crystalline product was filtered, washed thoroughly with Et_2O, and dried over KOH and P_4O_{10} to give 3.88 g (96%) of **4**·2HOAc (verified by ^1H NMR). Recrystallization of this material (95% EtOH) and drying gave **4**: mp 223–224°C (lit. (20) mp 155°C; 160°C (dec.)). Anal. calcd. for $C_{10}H_{13}N_5O_5$ (283.2): C 42.41, H 4.63, N 24.73; found: C 42.02, H 4.73, N 24.42.

*5′-Chloro-5′-deoxy-2′,3′-O-sulfinyladenosine-1-oxide hydrochlorides (***5***a/***5***b)·HCl*

A stirred suspension of **4** (1.42 g, 5 mmol) in CH_3CN (20 mL) was cooled in an ice/H_2O bath and $SOCl_2$ (1.1 mL, 1.8 g, 15 mmol) was added. The mixture was cooled to 0°C and pyridine (0.81 mL, 0.79 g, 10 mmol) was added. Stirring was continued and the mixture allowed to warm to ambient temperature overnight. The colorless precipitate was filtered (under dry N_2), washed with dry CH_3CN, and dried *in vacuo* over KOH and P_4O_{10} to yield 1.80 g (94%) of (**5***a*/**5***b*)·HCl (~6:1 by ^1H NMR). Anal. calcd. for $C_{10}H_{10}ClN_5O_5S$·HCl (384.2): C 31.26, H 2.89, N 18.23; found: C 31.84, H 2.90, N 18.20.

5′-Chloro-5′-deoxy-2′,3′-O-exo-sulfinyladenosine-1-oxide **5**a

A suspension of 3-chloroperoxybenzoic acid (3.05 g, 15 mmol as 85% reagent) and **2***a*·0.5EtOAc (1.88 g, 5 mmol) in 1,4-dioxane (15 mL) and EtOAc (50 mL) was stirred at ambient temperature overnight. The mixture was evaporated *in vacuo* to ~15 mL, stirred with Et_2O (100 mL), filtered, and the crystals washed thoroughly with Et_2O. This material was recrystallized (EtOAc/MeOH) and dried to yield 1.57 g (90%) of **5***a*: mp >195°C (dec.). Anal. calcd. for $C_{10}H_{10}ClN_5O_5S$ (347.7): C 34.54, H 2.90, Cl 10.20, N 20.14; found: C 34.34, H 2.88, Cl 10.23, N 20.22.

5′-Azido-5′-deoxy-2′,3′-O-sulfinyladenosines **8**a/**9**a

A stirred suspension of 5′-azido-5′-deoxyadenosine (27) (**7***a*, 1.17 g, 4 mmol) in CH_3CN (12 mL) was cooled in an ice/H_2O bath and $SOCl_2$ (0.88 mL, 1.43 g, 12 mmol) was added. Stirring at ambient temperature was continued for 6 h, H_2O (20 mL) added, and the resulting solution carefully neutralized to pH 5–6 (solid $NaHCO_3$) and extracted with EtOAc (3 × 30 mL). The combined organic phase was washed with saturated $NaHCO_3$/H_2O (20 mL) and H_2O (20 mL), dried (Na_2SO_4), and evaporated to give 1.3 g (96%) of **8***a*/**9***a* (~1.7:1 by ^1H NMR). Recrystallizations (EtOAc) gave the major *exo* isomer (**8***a*): mp 172–173°C; MS (CI, NH_3) *m/z*: 339 (100, M + 1). Anal. calcd. for $C_{10}H_{10}N_8O_4S$ (338.3): C 35.50, H 2.98, N 33.12, S 9.48; found: C 35.61, H 2.86, N 33.06, S 9.40.

5′-O-Benzoyl-2′,3′-O-sulfinyladenosines **8**b/**9**b

A cooled suspension of 5′-*O*-benzoyladenosine (28) (**7***b*, 1.48 g, 4 mmol) in CH_3CN (20 mL) was treated with $SOCl_2$ (1.28 mL, 2.1 g, 17.6 mmol) and worked up as described for the conversion of **7***a* → **8***a*/**9***a* to give 1.58 g (95%) of **8***b*/**9***b* (~1.5:1 by ^1H NMR). Recrystallizations (EtOAc) gave **8***b*: mp 186–187°C; MS (CI, NH_3) *m/z*: 418 (68, M + 1), 136 (100, B + 2). Anal. calcd. for $C_{17}H_{15}N_5O_6S$ (417.4): C 48.92, H 3.62, N 16.78, S 7.68; found: C 49.09, H 3.40, N 16.56, S 7.61.

*2′,3′-O-Sulfinylcytidine hydrochlorides (***8***c/***9***c)·HCl*

This mixture was prepared as described (13) (84% yield after drying *in vacuo* at 60°C over P_4O_{10}). **8***c*/**9***c*·HCl (~1.2:1 by ^1H NMR) had mp ~155–170°C (transition), 252–253°C (dec.) (lit. (13) mp 253–254°C). Anal. calcd. for $C_9H_{11}N_3O_6S$·HCl (325.7): C 33.19, H 3.71, Cl 10.88, N 12.90, S 9.84; found: C 33.18, H 3.60, Cl 10.90, N 12.95, S 9.84.

2′,3′-O-Sulfinyluridines **8**d/**9**d

This mixture was prepared as described (13) except the precipitated product was washed with MeOH/Et_2O (1:2). Drying *in vacuo* at ambient temperature over P_4O_{10} gave 82% of **8***d*/**9***d* (~2.3:1 by ^1H NMR) with mp 104–107°C (lit. (13) mp 104–105°C). Anal. calcd. for $C_9H_{10}N_2O_7S$ (290.3): C 37.24, H 3.47, N 9.65, S 11.05; found: C 36.94, H 3.39, N 9.64, S 10.78.

5′-Chloro-5′-deoxyuridine ***10***

A stirred suspension of uridine (**7***d*, 12.2 g, 50 mmol) in pyridine (8.1 mL, 7.9 g, 100 mmol) and CH_3CN (100 mL) was cooled in an ice/H_2O bath and $SOCl_2$ (18.2 mL, 29.7 g, 250 mmol) was slowly added. Stirring was continued at ambient temperature overnight and the mixture was evaporated *in vacuo* to give a slightly yellow solid foam. (When EtOAc and $NaHCO_3$/H_2O were added, the organic phase worked up, and the product mixture chromatographed on a silica column (C_6H_6/EtOAc, 1:1) as described (8), diastereomers **8***e* and **9***e* were obtained. See Tables 1 and 2 for NMR data.) The crude solid foam was dissolved in H_2O/MeOH (50:215 mL), concentrated NH_3/H_2O (30 mL) added, and the mixture stirred at ambient temperature for 1 h. The precipitated solids were filtered, and the filtrate concentrated to a small volume and then applied to a column of Dowex 1 × 2 (OH^-) resin. The column was washed with H_2O, the product eluted with 0.2 M $Et_3NH_2CO_3$/H_2O, and the eluate evaporated followed by additions and evaporations of H_2O *in vacuo*. The residue was recrystallized (MeOH/H_2O, 1:9) and dried over P_4O_{10} to give 10.7 g (82%) of colorless needles of **10**: mp 176–177°C (lit. (8) mp 176–178°C); MS *m/z*: 262.0354 (6.1, M^+(262.0357, ^{35}Cl)), 264.0326 (2.1, M^+(264.0327, ^{37}Cl)). Anal. calcd. for $C_9H_{11}ClN_2O_5$ (262.6): C 41.16, H 4.22, Cl 13.50, N 10.67; found: C 41.17, H 4.23, Cl 13.40, N 11.03.

General procedure for 5′-S-aryl(or alkyl)-5′-thionucleosides (details with ***11***a*)*

5′-S-Methyl-5′-thioadenosine ***11***a

Sodium hydride (0.29 g of 50% NaH/mineral oil, 6 mmol) was washed with Et_2O (2 × 10 mL) and suspended in anhydrous DMF (30 mL) at −30°C. Methanethiol (0.31 mL, 0.27 g, 5.5 mmol) was added slowly with magnetic stirring. When evolution of H_2 had ceased, a solution of **3** (1.43 g, 5 mmol) in anhydrous DMF (40 mL) was added dropwise. The mixture was allowed to warm to ambient temperature, stirred overnight, and evaporated *in vacuo*. The residue was treated with H_2O (50 mL), neutralized to pH 7 with dilute HCl/H_2O, and cooled. The crude product that separated was recrystallized from MeOH/H_2O (1:1, 150 mL) to give 1.28 g (86%) of colorless needles of **11***a*: mp 212°C (lit. (22) mp 207°C, (23) mp 213–214°C); UV (MeOH) max: 259 nm (ε 15 400); min: 226 nm (ε 2900); MS *m/z*: 297.0896 (8.5, M^+(297.0896)). Anal. calcd. for $C_{11}H_{15}N_5O_3S$ (297.3): C 44.43, H 5.09, N 23.55, S 10.78; found: C 44.25, H 5.07, N 23.52, S 10.99.

5′-S-Phenyl-5′-thioadenosine ***11****b*

Treatment of **3** with benzenethiol by the *general procedure* gave **11***b* (92%): mp 136–137°C (lit. (23) mp 136–138°C, (24) 139°C); UV (MeOH) max: 254 nm (ε 21 300); min 228 nm (ε 6000); MS *m/z*: 359.1055 (5.2, M^+(359.1052)), 136.0624 (100, B + 2H). Received July 4, 1990[3]

DANIEL DUCHARME, OSAMU SHIBATA, GAÉTAN MUNGER, and ROGER M. LEBLANC. Can. J. Chem. **69**, 1475 (1991).

Surface pressure, surface potential, and ellipsometric–area isotherms have been measured to investigate the properties of chlorophyll *a* – digalactosyldiacylglycerol monolayers at the nitrogen – water interface. The surface pressure – area isotherms of the mixed film show a pronounced negative deviation with respect to ideality, whereas the surface potential isotherms follow the additivity law for mixed films. As the mole fraction of Chl *a* increases from 0.1 to 0.5, each of the corresponding ellipsometric isotherm is shifted towards more negative values in the liquid expanded region. As the mole fraction is increased above 0.5, the ellipsometric $\delta\Delta$ values become more positive, with this trend continuing throughout the 0.5 to 0.9 mole fraction range. The combined effects of anisotropy in both the refractive indices and the absorption coefficient can explain the turnover observed in the ellipsometric $\delta\Delta$ isotherms as the mole fraction of Chl *a* becomes larger than 0.5.

Hydrophilic interactions have been ruled out on the basis of the agreement with the additivity law, which is observed for surface potentials of the mixed monolayers. The observed deviation exhibited in the π–*A* isotherms is interpreted in terms of the intermolecular cavity effect.

Key words: chlorophyll *a*, digalactosyldiacylglycerol, mixed monolayer, ellipsometry.

DANIEL DUCHARME, OSAMU SHIBATA, GAÉTAN MUNGER et ROGER M. LEBLANC. Can. J. Chem. **69**, 1475 (1991).

On a mesuré les isothermes de pression superficielle, de potentiel de surface et ellipsométrique pour étudier les propriétés des monocouches pures et en milange de la chlorophylle *a* et du digalactosyldiacylglycérol à l'interface azote-eau. Les isothermes de surface pression superficielle des films mixtes montrent une déviation négative prononcée par rapport au cas idéal, tandis que les isothermes de potentiel de surface suivent la loi d'additivité des films mixtes. Lorsque la fraction molaire de la chlorophylle *a* augmente à partir de 0,1 jusqu'à 0,5 chacun des isothermes ellipsométriques correspondants se déplace vers des valeurs plus négatives dans la région expansée de liquide. Lorsque la fraction molaire dépasse 0,5 jusqu'a atteindre 0.9 la valeur ellipsométrique $\delta\Delta$ devient plus positive. Les effets combinés de l'anisotopie à la fois dans les indices de réfraction et dans le coefficient d'adsorption peuvent expliquer le changement observé dans les isothermes $\delta\Delta$ ellipsométriques lorsque la fraction molaire de la chl *a* devient supérieure à 0,5.

On a écarté les interactions hydrophiles en raison de l'accord existant avec les lois d'additivité que l'on observe pour les potentiels de surface des monocouches mixtes. On attribue à l'effet de cavité intermoléculaire la déviation observée dans les isothermes π–*A*.

Mots clès : chlorophylle *a*, digalactosyldiacylglycérol, monocouche mixte, ellipométrie.

[Traduit par la rédaction]

1. Introduction[4]

The thylakoid membrane system of chloroplasts, the site of light-harvesting reactions of photosynthesis, contains, in addition to chlorophylls, a large proportion of glycolipids. The major lipid components are the uncharged MGDG and DGDG, which combined amount to about 60 to 70 mol% of the total lipids present in the membrane (1). Charged SQDG and PG are also present as minor glycolipid components. Considering the importance of Chl *a* in photosynthesis, it is necessary to have a good knowledge of the way this pigment interacts with its environment.

The results reported here, with monolayers as a model system, differ from those reported elsewhere using different models. With the introduction of Chl *a* into phospholipid bilayer membranes, evidence has been obtained for compound formation between Chl *a* and lipids involving interaction of the lipid phosphate with the magnesium ion in chlorophyll (2). Interactions of Chl *a* with the lipids of the thylakoid membrane have also been reported (3). From lifetime measurements of Chl *a* in lipid liposomes, as well as in vesicles of MGDG, DGDG, and SQDG, reports have also suggested that association of Chl *a* occurs with these lipids (4, 5).

However, information about Chl *a* – galactolipid interactions in monolayers at the gas–water interface is scarce (6). The results reported in the present work for Chl *a* – DGDG show a larger negative deviation from the additivity law than those reported for the Chl *a* – MGDG system (6).

This negative deviation, typically indicating condensation of mixed monolayers (7), has been interpreted in several ways. Explanations have included van der Waals interactions, configuration entropy effects, alterations of water molecules near the monolayer, and an intermolecular cavity effect (8, 9). Ellipsometric and surface potential isotherms of the system under study in this work reveal features which help in the understanding of the condensing effect observed in surface pressure isotherms.

Applying the additivity law to surface potential values of the mixture, it is shown that agreement between calculated and experimental values suggests the absence of any particular interactions between the monolayer components.

The ellipsometric angle $\delta\Delta$ is sensitive to changes of

refractive indices, to changes in the sign of the difference between refractive indices of an anisotropic film (birefringence), to the extent of absorption of the film, to the anisotropic character of the absorption coefficient, and to film thickness. Thus, ellipsometric isotherms can provide valuable information on interactions between mixed film components.

Analysis of the results based on both the surface potential, which is in agreement with the additivity law for mixed films, and ellipsometric behavior of the mixed films, does not provide evidence of any specific interactions between monolayer components within the 5 to 25 mN/m surface pressure range. The negative deviation observed in the π–A isotherms in this surface pressure range may be explained by the intermolecular cavity effect in the monolayer.

2. Methodology

(A) Pure components

Chl *a* was extracted from barley leaves and purified according to the method described in ref 10. TLC (G plate, Mandel Sci. Co., ON, Canada) was used to test the purity of the pigment, which resulted in a single spot of a R_f value of 0.40, using as the elution solvent a mixture of *n*-hexane/acetone (7:3, v/v). DGDG was extracted from barley leaves and purified by HPLC, using as the elution solvent a mixture of hexane/isopropanol/water (70:30:3, v/v/v). Fatty acid composition of the galactolipid, shown in Table 1, was determined by GC and found to be in good agreement with published values (11). The molar weights of Chl *a* and DGDG are 894 and 936 g mol^{-1}, respectively. These compounds were stored under argon at −134°C. Prior to use, they were dissolved in a mixture of *n*-hexane/ethanol (9:1, v/v). All solvents were distilled before use. Chl *a* was studied with two different spreading solvents: benzene and *n*-hexane/ethanol (9:1, v/v). Measurements were carried out on a phosphate buffer subphase (10^{-3} mol L^{-1}, pH = 8.0). The phosphate salts (Na_2HPO_4 and NaH_2PO_4, 99.5 mol%, J. T. Baker Chemical Co., Phillipsburg, NJ) employed for the buffer were used as received.

Deionized and prepurified water (Nanopure filter system, Barnsted, Boston, MA) was twice distilled in a quartz still (Model Bi-18, Amerisil Inc., Sayreville, NJ). Specific resistivity of water was 18 MΩ cm, with a surface tension ≥71 mN/m. Surface potential was measured by using an ^{241}Am electrode (Nuclear Radiation Development, Grand Island, NY) placed 1–2 mm above the subphase and located at approximately 12 cm from the float. The reference electrode was dipped in the subphase behind the float; reference surface potential was −350 mV with a standard deviation of ±30 mV. These variations in the reference potential are attributed to the variations, from run to run, of the water content in the gas phase surrounding the electrodes (7). These changes in the water content could have been related to fluctuations in the nitrogen flow close to the nitrogen–water interface.

The buffer subphase was allowed to stand 15 min in the trough and then compressed. The movable barrier was brought to approximately 1 cm from the float, and impurities were removed by vacuum aspiration with a pipette. Impurities were removed from the buffer by repeated compression and decompression cycles and vacuum aspirations, until no surface pressure could be detected. After zeroing the surface pressure transducer, the subphase was allowed to rest an additional 15 min and compressed again to check for the presence of any remaining impurities. Only after this procedure was carried out was the solution spread over the subphase. Experiments have shown that the baseline of the surface pressure does not drift by more than 1 mN/m within a 2-hour period for a clean subphase.

Surface pressure, surface potential, and ellipsometric isotherms were obtained according to the methods and instrumentation described previously (12). The film was compressed at a speed of 5 $Å^2$ $molecule^{-1}$ min^{-1}. Each of the three types of isotherms were measured at least 10 times for each of the compounds and averaged. The area per molecule was measured to ±3 and ±1.5 $Å^2$ $molecule^{-1}$ for Chl *a* and DGDG, respectively; the surface potential to an accuracy of ±15 mV; the ellipsometric $\delta\Delta$ to ±0.05° for Chl *a* as compared to ±0.02° for DGDG, and the ellipsometric $\delta\psi$ to ± 0.02°.

All measurements were carried out under dim green light and in a nitrogen environment. To ensure that Chl *a* does not bleach under illumination of the laser beam used for ellipsometric measurements, surface pressure was recorded during a 2-h irradiation of a compressed monolayer of Chl *a*. The observed decrease in surface pressure was comparable to that obtained with the laser turned off. Relative humidity within the Plexiglass enclosure was measured with a needle-type hygrometer (Cole Parmer, ON, Canada) and remained approximately constant at 50 ± 5% during the experiments. The temperature of the aqueous subphase was controlled at 20 ± 1°C.

(B) Mixed component films

Measurements of surface pressure, surface potential, and ellipsometric isotherms for mixed films were each repeated at least three times. Maximum deviations between extremes for each type of isotherm were in the same range as those reported above for the pure galactolipid. The uncertainties in the ellipsometric angles become higher the higher the mole fraction of Chl *a*.

3. Results

Surface pressure, surface potential, and ellipsometric isotherms

(A) Pure component films

Figure 1 shows the surface pressure (π), surface potential (ΔV), and ellipsometric ($\delta\Delta$ and $\delta\psi$) – area (A) isotherms of pure Chl *a*, DGDG and mixed component monolayers. For sake of clarity, some of the isotherms of the mixtures are not included.

The surface pressure – area isotherms have been measured by both a continuous and a step-wise compression method. The "step-wise" compression technique is necessary since, in obtaining experimental ellipsometer readings, approximately 5 to 10 min are required to measure the angles at one specific molecular area. The collapse pressure of Chl *a* was observed to be dependent on the method used. As shown in Fig. 1, from the liftoff at 138 $Å^2$ $molecule^{-1}$ to approximately 85 $Å^2$ $molecule^{-1}$ (π = 25 mN/m), no difference is observed between the two methods. However, from a molecular area of 85 $Å^2$ $molecule^{-1}$, the surface pressure isotherm measured by the step-wise method (solid line) deviates from that obtained by continuous compression (dashed line). The collapse pressure obtained by continuous compression is in close agreement with published values (6, 13).

For pure DGDG monolayer films, the liftoff was observed at approximately 145 $Å^2$ $molecule^{-1}$, with the collapse pressure measured at 42 mN/m. At a surface pressure of 10 mN/m, the

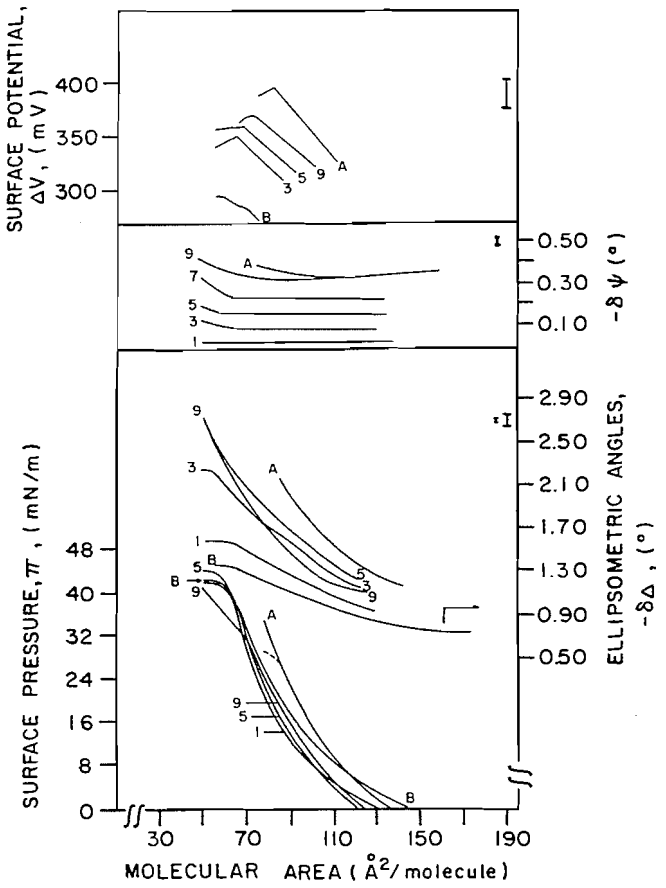

FIG. 1 Surface pressure (π), surface potential (ΔV) and ellipsometric ($\delta\Delta$ and $\delta\psi$) — area (A) isotherms of pure and mixed Chl *a* — DGDG at the nitrogen–water interface. The subphase was buffered at pH 8.0 using phosphate, 10^{-3} mol L^{-1}. Temperature was maintained at 20 ± 1°C for all experiments. Isotherms A and B are for pure Chl *a* and DGDG, respectively. Isotherm A measured by continuous (···) and, step-wise (—) compression, respectively. Values (1, 3, 5, 7, 9) represent mole fractions (0.1, 0.3, 0.5, 0.7, 0.9) of Chl *a* in the mixed film, measured by step-wise compression. Ellipsometric parameters: ϕ = 60.00 ± 0.05°; λ = 6328 Å. Bars at the upper right of each frame represent the maximum experimental error on each type of measurement. The two bars in the lowest frame are experimental errors on mixed films (shorter bar) and Chl *a*.

π–*A* isotherm of the galactolipid is more expanded than galactolipid extracted from Beta vulgaris (ref. 11) by approximately 10 to 15 Å^2 molecule^{-1}. The discrepancy in molecular area decreases as surface pressure increases. This could be due in part to the different subphase and spreading solvent which were used in the work with Beta vulgaris, in which case pure water and chloroform were employed. In this work, a phosphate buffer was used as a subphase and hexane: ethanol (9:1, v/v) as spreading solvent. Collapse pressures cannot be compared since the authors did not report this value.

As shown in Fig. 1, DGDG exhibits an ellipsometric "jump angle" of −0.72° at a molecular area of approximately 170 Å^2 molecule^{-1}. This jump angle corresponds to the onset of a photometric signal which allows reliable azimuth readings to be taken. From that molecular area and onward with further compression, $\delta\Delta$ decreases slowly as a function of the reduction of molecular area, and plateaus at approximately −1.34°. The onset of this plateau occurs at approximately 65 Å^2 molecule^{-1}. The shape and values of this ellipsometric isotherm resemble those of previously published isotherms for unsaturated phospholipids (14).

The ellipsometric behavior of Chl *a* is substantially different from that of the galactolipid. From the observed jump angle of −1.10° for Chl *a* and onward, $\delta\Delta$ decreases almost exponentially as a function of the reduction of the molecular area, reaching a value of approximately −2.1° in the collapse pressure region, as observed in the π–*A* isotherm (Fig. 1). Moreover, in contrast to DGDG, the change in the relative amplitude for the reflected to the incident light beam components, which is a measure of absorption, shows, as expected, a non-null $\delta\psi$ value for Chl *a*. The ellipsometric values obtained in this work differ from published data (15), in which these researchers report both $\delta\Delta$ and $\delta\psi$ first becoming positive, and then changing signs at about 150 Å^2 molecule^{-1}. From this area to approximately 80 Å^2 molecule^{-1}, the reported $\delta\Delta$ value changes from −1.30 to −1.90°, as compared to −1.10 to −2.1° in the present work. Concurrently, $\delta\psi$ is reported to vary from −0.14 to −0.19°, as compared to an essentially constant value of −0.35° in the present study.

Due to large photometric signal fluctuations at high molecular area, reliable measurements could not be taken prior to a molecular area of approximately 150 Å^2 molecule^{-1}. Therefore it is impossible to compare changes in sign of the ellipsometric angles in this work to those reported previously (15). In addition, it was necessary to reduce the sensitivity of the lock-in amplifier to the 25 mV scale, as compared to a 10 mV scale used with the galactolipid and the mixed films. Large fluctuations in the photometric signal have been reported for pentadecanoic acid in the G–LE (gaseous–liquid expanded) phase (16). These fluctuations have been attributed to the condensation of a liquid from the gas phase, characterized by the appearance of high density phase domains coexisting with the low density phase. As a function of the average density, the domains grow at the expense of the low density phase until a full condensation has taken place. As these domains are being moved in and out of the probe area by the convective motion of the water, fluctuations in the photometric signal arise. However, another explanation can be given for this phenomenon. For DPPC dye-labeled monolayers in the G–LE region, Lösche and Möhwald (17) have noted the appearance of holes. These holes are surrounded by molecules. At large molecular area, their instability, *i.e.* variation in size due to a low molecular density environment, can also give rise to the observed fluctuations in the photometric signal as the holes are moved in and out of the light beam by the convective motion of the water. A similar phenomenon could be responsible for the fluctuations observed in this study.

Benzene and *n*-hexane:ethanol (9:1, v/v) were used as spreading solvents for Chl *a*. Ellipsometric $\delta\Delta$ isotherms of Chl *a* measured with *n*-hexane:ethanol as the spreading solvent exhibit much better reproducibility (±0.05°) than those measured with benzene (±0.1°). From these observations, it has been decided that in further experiments, *n*-hexane:ethanol is the solvent of choice. With this solvent system, the π–*A* and the ΔV–*A* isotherms do not show significant spreading solvent-related differences.

The ΔV–*A* isotherms of both pure components exhibit the following features: (*i*) the onset of stable surface potential occurs at a slightly larger molecular area than the onset of surface pressure; (*ii*) a steady increase in surface potential is observed as molecular area decreases; (*iii*) in the collapse region, DGDG exhibits a plateau at 300 ± 15 mV, whereas

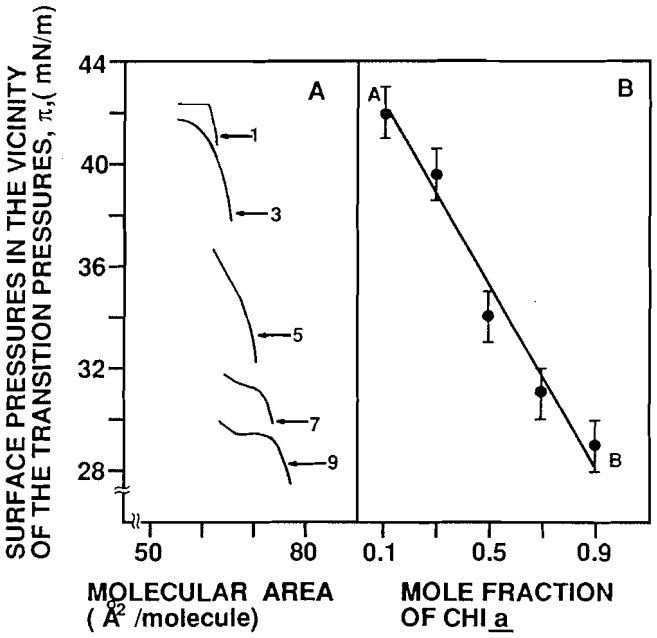

FIG. 2. (*A*) Surface pressures in the vicinity of the transition pressures as a function of molecular area measured by continuous compression. Labels and experimental conditions are identical to those of Fig. 1. (*B*) Surface pressures at the transition pressures as a function of mole fraction of Chl *a*. Area below line AB is the one phase region.

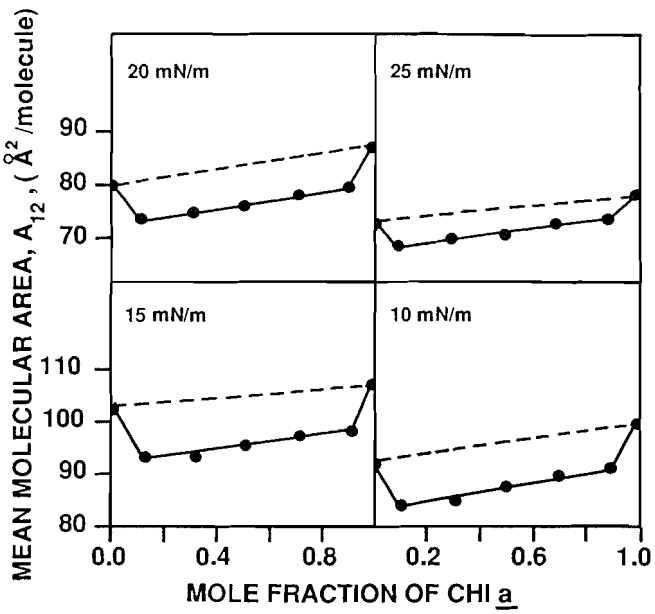

FIG. 3. Mean molecular areas (A_{12}) of mixed Chl *a* – DGDG monolayers as a function of mole fraction of Chl *a* at four different surface pressures (10, 15, 20, and 25 mN/m). Dashed curves are calculated results assuming the additivity rule. Solid circles are the experimental values.

Chl *a* shows a sudden decrease in surface potential at a molecular area that corresponds closely to the onset of collapse surface pressure observed in the π–*A* isotherm. Because of the scale of Fig. 1, it may not be apparent that the surface potential of DGDG has plateaued. The maximum value for surface potential values of Chl *a* is approximately 400 mV, which is in close agreement with published values (6).

(B) Mixed component films

Monolayer films of five mixtures of Chl *a* – DGDG have been measured, shown in Fig. 1 as mole fraction of Chl *a* (0.1, 0.3, 0.5, 0.7, 0.9). For π–*A* isotherms measured either by step-wise or continuous compression, none of the isotherms of the mixed films fall between those of the pure components as expected by the additivity rule for ideal mixtures. Step-wise compression of the 0.5, 0.7, and 0.9 mixtures did not show transition points in pressure (the transition points correspond to the surface pressure where a sudden change in slope in the π–*A* isotherms takes place) as well defined as those obtained by continuous compression. For mixtures with a higher content in Chl *a* (0.5, 0.7, and 0.9), the transition points measured by continuous compression were lower than those obtained by the step-wise technique. However, up to the transition points, no differences could be observed between the two methods. The mixed films, with the exception of the 0.9 mole fraction Chl *a*, measured by both techniques showed nearly a constant collapse pressure, with a transition point varying according to the mixture composition. Results obtained for continuous compression are presented in Fig. 2*A*. Application of the surface phase rule to this system shows that below the line AB (Fig. 2B), the two-components would be completely miscible.

The deviation from ideality is illustrated in Fig. 3, where mean molecular area (A_{12}) is plotted as a function of mole fraction of Chl *a*, for surface pressures of 10, 15, 20, and 25 mN/m. It is seen that the deviation from the additivity law tends to increase as the mole fraction of Chl *a* decreases, with the average gap between experimental and calculated values becoming smaller the higher the surface pressure. It is to be noted that an increased instability in the surface pressure arises after the onset of transition point pressures.

In contrast to the behavior of the π–*A* isotherms, those of the ellipsometric $\delta\Delta$–A isotherms for the mixtures fall between those of the pure components. In the 5 to 25 mN/m range, from approximately 125 to 80 Å^2 molecule^{-1}, with an increasing mole fraction of Chl *a* (0.1 to 0.5), each of the corresponding ellipsometric isotherms is shifted towards more negative $\delta\Delta$ values. The higher the mole fraction of Chl *a*, the lower the $\delta\Delta$ values (Fig. 1). However, a significant change in this trend is observed as the mole fraction of Chl *a* is increased above 0.5. The corresponding ellipsometric isotherms for the 0.7 (not shown) and 0.9 mole fractions are more positive than those of 0.5 and 0.3 mole fraction, with the 0.9 fraction of Chl *a* being the most positive. Although small, these observed differences in ellipsometric angles are larger than the uncertainties of the measurements. Furthermore, only the 0.1 and 0.3 mixtures show the same ellipsometric behavior as the pure galactolipid, with an ellipsometric plateau occurring at lower molecular areas (65 Å^2 molecule^{-1} for the 0.1 as compared to approximately 55 Å^2 molecule^{-1} for the 0.3 mole fraction). Concurrently, regardless of surface pressure, measured from 5 to 25 mN/m, the $\delta\psi$ angle decreases almost linearly as a function of increasing mole fraction of Chl *a* (see Fig. 4). At low molecular areas, below approximately 65 Å^2/molecule, in contrast to what is mentioned above, no differences in the $\delta\Delta$–A isotherms could be observed for the mixtures of the 0.5, 0.7, and 0.9 mole fraction of Chl *a*. Furthermore, in this molecular area region, with the exception of the 0.1 mole fraction, a significant decrease in $\delta\psi$ sets-in for all mixtures (see Fig. 1).

From the π–*A* isotherms (Fig. 1), the ellipsometric $\delta\Delta$ angle has been plotted as a function of the mole fraction of Chl *a* in Fig. 5 A, at five different surface pressures (5, 10, 15, 20, and 25 mN/m). This has been accomplished by selecting the molecular area, at the appropriate surface pressure of interest,

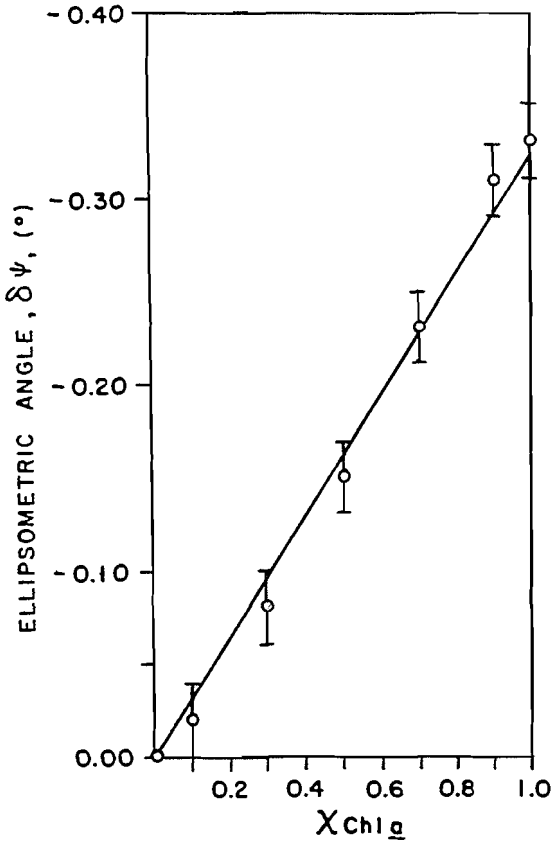

FIG. 4. Ellipsometric angle δψ as a function of mole fraction (χ) of Chl *a* for the Chl *a* – DGDG system for surface pressures between 5 and 25 mN/m. The ellipsometric parameters are identical to those of Fig. 1.

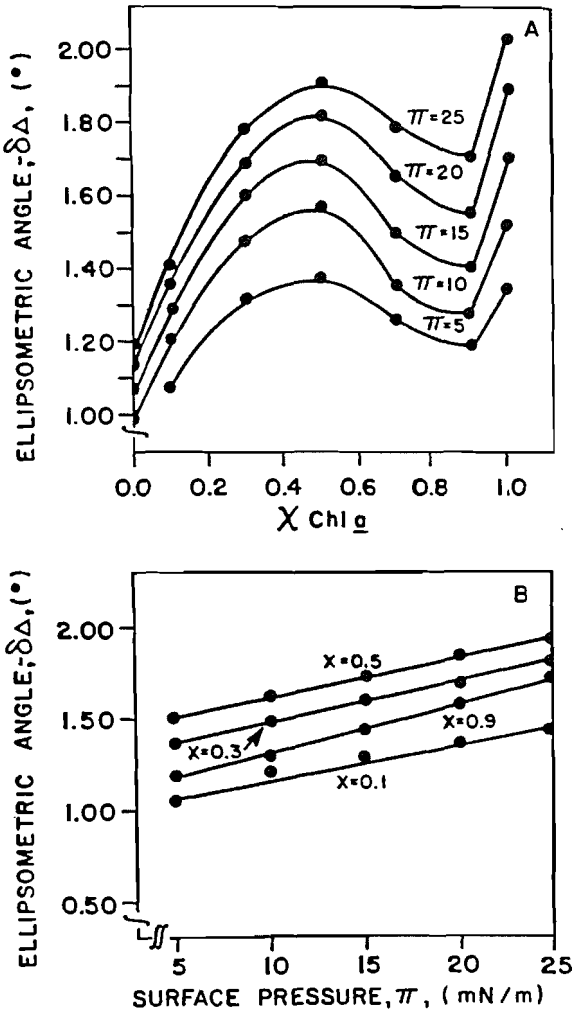

FIG. 5. (*A*) Ellipsometric angle δΔ as a function of mole fraction (χ) of Chl *a* for the Chl *a* – DGDG system at different surface pressures (5, 10, 15, 20, and 25 mN/m). (*B*) Ellipsometric angle δΔ as a function of surface pressure for the Chl *a* – DGDG system at different mole fractions of Chl *a*.

for pure compounds and each mole fraction of Chl *a*. The five curves in Fig. 5A exhibit a salient feature: each of them shows a minimum at $X_{\text{Chl }a}$ of 0.5. Furthermore, if the variation of δΔ is plotted as a function of the increasing surface pressure, a linear relationship, at constant mole fraction, is obtained for each of the mole fractions. These results are presented in Fig. 5*B*.

The Δ*V*–*A* isotherms, presented in Fig. 1, for the Chl *a* – DGDG mixtures have essentially the same features as the pure Chl *a*. We may point out the following significant features: (*i*) the Δ*V* isotherms are shifted towards higher values as the mole fraction of Chl *a* increases; (*ii*) each mixture shows a sudden decrease in surface potential at a molecular area which varies with the composition of the mixture; (*iii*) the change of slope in the Δ*V*–*A* isotherms corresponds approximately to the onset of the transition point, as shown in the π–*A* isotherms.

From surface potential values for the mixtures, the surface dipole moment has been calculated at several surface pressures (10, 15, 20, and 25 mN/m). The results for surface potential and surface dipole moment are plotted in Fig. 6 as a function of mole fraction of Chl *a*, from which it can be seen that the additivity rule is closely followed. The difference between these results and those shown in ref. 18 is due to a transcription error in the latter reference.

4. Discussion

This work was undertaken to determine the nature of interactions in mixed monolayers of Chl *a* – DGDG. The surface pressure – area isotherms for the mixed monolayers have shown a pronounced negative deviation from ideality for mixed films.

Figure 5*A* illustrates that over the surface pressure of interest, from 5 to 25 mN/m, and independent of surface pressure, the δΔ values show a minimum at a $X_{\text{Chl }a}$ value of 0.5. The ellipsometric values were observed to become more positive as the mole fraction of Chl *a* increases from 0.5 to 0.9, after which point, as seen in Fig. 5*A*, δΔ decreases again. At first glance, this is rather surprising since the ellipsometric δΔ is known to be more sensitive to refractive index than to film thickness (19). Since the length of the hydrophobic moieties of both components Chl *a* and DGDG are comparable, it can be assumed that the film thickness is constant at a given surface pressure, and independent of the species in excess. The refractive index of Chl *a* has been reported to be approximately 1.58 (15), a value that is likely to be higher than that of the galactolipid. The shape and values of the ellipsometric isotherm of the galactolipid resemble those of unsaturated phospholipids, for which the refractive index has been evaluated at approximately 1.46 (14, 20, 21). As a consequence, one would expect that, as the mole fraction of Chl *a* increases, the δΔ values would continuously decrease. The work in this report has shown that this ellipsometric

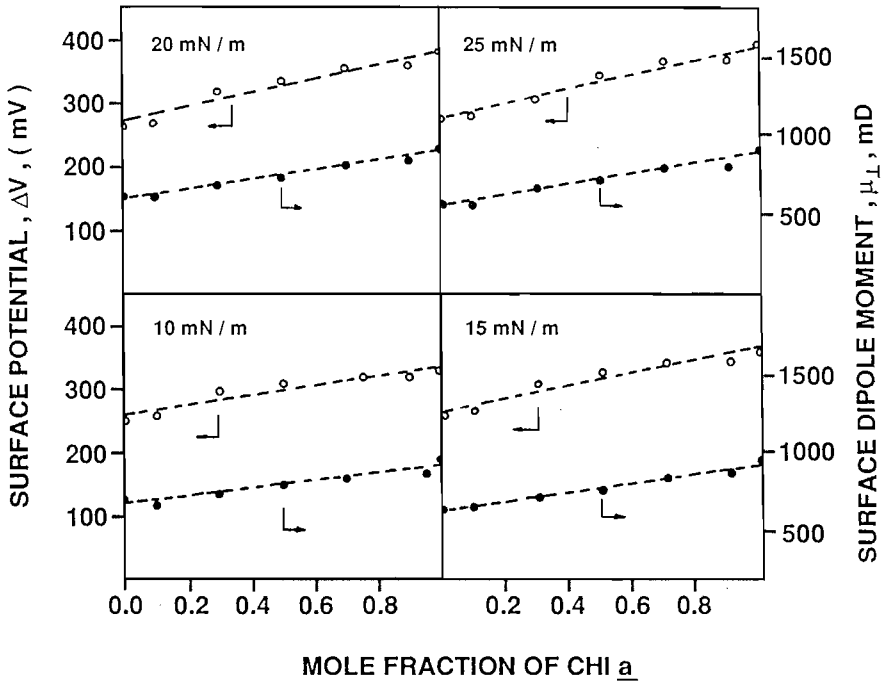

FIG. 6. Surface potential (● ←) and calculated surface dipole moment (● →) of Chl *a* – DGDG as a function of mole fraction of Chl *a* at different surface pressures (10, 15, 20, and 25 mN/m).

behavior is not a characteristic of the Chl *a* – DGDG mixed monolayers (see Fig. 5*A*). The reader is referred to ref. 15 for the pertinent ellipsometric equations.

Some investigators (22, 23) have argued that the Chl *a* molecule anchors to the aqueous substrate by the carbonyl group and neighbouring carboxymethyl group in ring V of the porphyrin ring. Based on this assumption, and from the onset of the ellipsometric jump angle, the experimental results imply that Chl *a* is oriented, becoming more vertically oriented upon monolayer compression. Since polarizability parallel to the porphyrin ring is higher than polarizability perpendicular to the ring (15), then as *d* increases, n_z increases at the expense of n_x. As compression proceeds, $\delta\Delta$ becomes more and more negative. Concurrently, as the porphyrin ring becomes more vertically oriented, k_z, associated with the optical *Z*-axis perpendicular to the water surface, is expected to increase at the expense of k_x. However, our results suggest that the *k* values are mainly a function of the concentration of Chl *a* (see Fig. 1, $\delta\psi$–*A* isotherms), and not as sensitive to orientation as reported elsewhere (15).

The lower or more negative $\delta\Delta$ values obtained for the Chl *a* isotherm, as compared to those for DGDG, can be attributed mainly to the higher refractive indices of the pigment. However, for a given film thickness (*d*), the permutation of the refractive indices makes $\delta\Delta$ more negative, for n_x larger than n_z. Similarly, for n_z greater than n_x and with the same film thickness, the $\delta\Delta$ values become more positive. The birefringence corresponds to this difference between refractive indices of the film. In addition to this effect, the extent of absorption, as indicated by the magnitude of the *k* values with $k_z > k_x$, contributes to making $\delta\Delta$ more positive.

The ellipsometric behavior of the mixed film may be explained applying the following assumptions: (*i*) the mixed film is governed by the same ellipsometric equations as the pure anisotropic homogeneous monolayer; (*ii*) refractive indices are additive; (*iii*) in the liquid expanded state, the polyunsaturated galactolipid aliphatic chains result in kinks which contribute to negative anisotropy (n_x larger than n_z) (24); (*iv*) at constant surface pressure, film thickness remains constant, independent of the species in excess; (*v*) the *k* values increase as the mole fraction of Chl *a* increases. Moreover, because of the high degree of hydration of the polar head groups, it is assumed that only the hydrophobic moiety is detected by ellipsometry. In consideration of these assumptions, the results presented in Fig. 5*A* may be explained on the basis of the difference in sign of the birefringence and the increase in absorption as Chl *a* increases in the mixed film. For $X_{\text{Chl } a}$ values of 0.1 to 0.5, where the galactolipid is in excess, the overall ellipsometric effect in the film is as if n_x were greater than n_z. This results in more negative $\delta\Delta$ values.

As the mole fraction of Chl *a* becomes larger than 0.5, the pigment is in excess. Since the rigid porphyrin ring in the Chl *a* molecule is more or less vertically oriented, as evidenced by the occurrence of the ellipsometric jump angle, and since the main contribution to refractive indices of the pigment is mainly from the extended π-electron system of the ring, it is expected that a change of sign ($n_z > n_x$) in birefringence combined with higher *k* values ($k_z > k_x$) would lead to more positive $\delta\Delta$ values. This change in birefringence, coupled with increased absorption (see Fig. 4), can explain, in the 5 to 25 mN/m range, why $\delta\Delta$ values of the 0.9 Chl *a* mole fraction are more positive than those for the 0.3 mole fraction (Fig. 5*A*), despite the fact that the refractive index of Chl *a* is greater than that of the galactolipid.

As seen in Fig. 5*B*, for each of the given mole fraction mixtures, $\delta\Delta$ decreases linearly as π increases up to 25 mN/m. At these surface pressures, the films are in the liquid expanded state. Since at a given mole fraction absorption does not vary (see Fig. 1 $\delta\psi$–*A* isotherms) and refractive indices remain nearly constant (24), $\delta\Delta$ decreases linearly as film thickness (*d*) increases as predicted by the ellipsometric equation.

For the pure galactolipid, an ellipsometric plateau ($\delta\Delta$–*A*) is observed in the final stage of compression. It is shown in Fig. 1 that for the mixed monolayers with the lower content in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

Chl *a*, the 0.1 and 0.3 Chl *a* – DGDG mixtures, this plateau in the ellipsometric isotherm is also observed. These plateaus occur in the same molecular area range as for the pure carbohydrate-containing lipid monolayer. This is not the case for mixed monolayers with a higher concentration of Chl *a*. When Chl *a* is in excess with respect to the lipid, the ellipsometric plateau is no longer observed, even if the film is compressed to lower molecular areas. These observations suggest that the optical properties of the mixed film are controlled by the species in excess in the film.

As observed in Fig. 4, $\delta\psi$ decreases linearly as a function of the increasing mole fraction of Chl *a*. This relationship, analogous to Beer's law for dilute solutions, does not provide evidence of interactions between monolayer components in Chl *a* – DGDG monolayers.

Under the experimental subphase conditions used in this work, *i.e.*, constant pH and ionic concentration, the negative deviations with respect to the ideality law in the π–*A* isotherm, cannot be attributed to the interactions of the polar head group components. This is shown from surface potential isotherms of the Chl *a* – DGDG monolayer mixtures. In any case, if interactions of this type occur, they are not evidenced in the surface potential isotherms. As shown in Fig. 6, the additivity rule is closely followed, strongly suggesting that for mixed monolayers the negative deviation in the π–*A* isotherms cannot be attributed to any specific interactions between the monolayer components. The surface dipole moment, which is proportional to the average surface potential per molecule, has been calculated and plotted as a function of the mole fraction of Chl *a* (Fig. 6). The conclusion concerning interactions of the polar head groups is the same as for surface potentials.

In the 0.1 to 0.5 mole fraction range of Chl *a*, DGDG is in excess with respect to the pigment. In the liquid-expanded state, the kinked aliphatic chains of DGDG may produce cavities which can be partially occupied by the hydrophobic moiety of the Chl *a*, leading to a reduction in the average area per molecule. The porphyrin ring is bulky and has about the same dimensions as the galactolipid chains (based on a CPK atomic model). Since the deviation from the additivity law seen in the π–*A* isotherms is negative, the porphyrin ring would occupy the cavity produced by the aliphatic DGDG chains in a plane perpendicular to this cavity. As the mole fraction of Chl *a* exceeds 0.5, the negative deviation observed may be explained by intermolecular cavities in the following manner. In L-B films of Chl *a*, for films deposited at 20 mN/m, the distance between the two adjacent porphyrin planes has been determined by infrared spectroscopy to be 7.1 Å (23). This distance would be sufficient to allow the aliphatic chains of DGDG to find room between adjacent porphyrin rings, thus reducing the molecular area of the mixed film.

A significant and interesting characteristic in the $\delta\psi$ and ΔV isotherms is the upturn in $\delta\psi$ and the downturn in ΔV at lower molecular areas (see Fig. 1). These features both vary with composition, and occur at approximately the same molecular area as that of the onset of the transition point pressure. The rapid decrease in $\delta\psi$ in this range is not attributed to an increase in optical absorption, but rather to increasing film thickness (25), and is in agreement with the model for partial or total rejection of the more easily collapsible component, Chl *a*, out of the monolayer (26, 27). A change in slope in the $\delta\Delta$–*A* isotherms is also observed in this molecular area range. However, the onset of the change in slope, in the surface potential and ellipsometric $\delta\psi$ isotherms, is close, but does not exactly coincide in molecular area values with the corresponding change in slope observed for the ellipsometric $\delta\Delta$ isotherms. It is tempting to correlate these observed changes to the phenomenon occurring at the onset of transition point pressures. These pressures are associated with the rejection of Chl *a* from the film.

The synthesis of some novel *N*-chloro-Δ^1-4-azasteroids by efficient *N*-chlorination of azasteroid lactams with trichloroisocyanuric acid

THOMAS G. BACK,[1] JOSEPH H.-L. CHAU, BRIAN P. DYCK, AND PATRICIA L. GLADSTONE
Department of Chemistry, University of Calgary, Calgary, Alta., Canada T2N 1N4

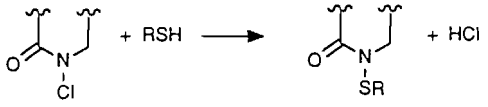
Received March 4, 1991

THOMAS G. BACK, JOSEPH H.-L. CHAU, BRIAN P. DYCK, and PATRICIA L. GLADSTONE. Can. J. Chem. **69**, 1482 (1991).

The preparation of *N*-chloro-Δ^1-4-azasteroids **2***a*–**2***c* from lactams **1***a*–**1***c* was achieved conveniently and in high yield with trichloroisocyanuric acid. The treatment of 20β-hydroxy-4-aza-5α-pregn-1-en-3-one (**1***d*) with this reagent produced the less stable *N*-chloro compound **2***d*, which reacted further to afford 4-aza-5α-pregn-1-en-3,20-dione (**4**) as the principal product. The similar chlorination of 4-azacholest-5-en-3-one (**5**) occurred at C-6, giving 6-chloro-4-azacholest-5-en-3-one (**6**). Photolysis of *N*-chloro-4-aza-5α-cholest-1-en-3-one (**2***a*) in methanol produced the transient *N*-acyl imine **7**, which was trapped by the solvent to afford 5-methoxy-4-azacholest-1-en-3-one (**8**), along with 4-azacholesta-1,5-dien-3-one (**9**) and its 6-chloro derivative **10**.

Key words: *N*-chloroazasteroid, Δ^1-4-azasteroid, *N*-chloro-Δ^1-4-azasteroid, trichloroisocyanuric acid, *N*-chlorination.

THOMAS G. BACK, JOSEPH H.-L. CHAU, BRIAN P. DYCK et PATRICIA L. GLADSTONE. Can. J. Chem. **69**, 1482 (1991).



Utilisant les lactames **1***a*–**1***c* et l'acide trichloroisocyanurique, on a préparé les *N*-chloro-Δ^1-4-azastéroïdes (**2***a*–**2***c*) avec aisance et d'excellents rendements. Lorsqu'on traite la 20β-hydroxy-4-aza-5α-pregn-1-èn-3-one (**1***d*) avec ce réactif, on obtient le composé *N*-chloro **2***d* qui est plus réactif et qui, par réaction subséquente, fournit la 4-aza-5α-pregn-1-èn-3,20-dione (**4**) comme produit principal. La chloration semblable de la 4-azacholest-5-èn-3-one (**5**) se produit en C-6 et fournit la 6-chloro-4-azacholest-5-èn-3-one (**6**). La photolyse de la *N*-chloro-4-aza-5α-cholest-1-èn-3-one (**2***a*) dans le méthanol fournit la *N*-acyl imine (**7**) transitoire qui est piégée par le solvant pour conduire à la 5-méthoxy-4-azacholest-1-èn-3-one (**8**) aux côtés de la 4-azacholesta-1,5-dièn-3-one (**9**) et de son dérivé 6-chloro (**10**).

Mots clés : *N*-chloroazastéroïde; Δ^1-4-azastéroïde; *N*-chloro-Δ^1-4-azastéroïde; acide trichloroisocyanurique; *N*-chloration.

[Traduit par la rédaction]

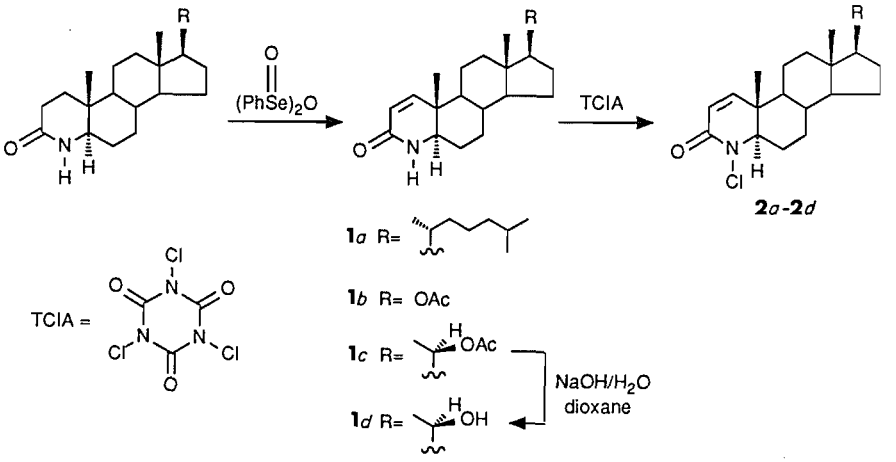
Many types of azasteroids are known (1) and some display interesting biological activity (for example, see ref. 2). The Δ^1-4-azasteroids **1** are of special current interest because certain such derivatives function as potent inhibitors of the enzyme 5α-reductase, as recently demonstrated by Rasmusson and co-workers (3). This enzyme is responsible for the conversion of testosterone to dihydrotestosterone, which has been implicated as the principal trophic hormone of the prostate gland (4). Thus, 5α-reductase inhibitors offer a possible nonsurgical alternative for the treatment of benign prostatic hypertrophy, a common affliction of elderly men. The Δ^1-4-azasteroids and related compounds are believed to function as competitive transition state inhibitors of this enzyme. However, new compounds that could bind to its active site through covalent bond formation are also of interest as potential affinity labels and irreversible inhibitors (5).

We recently reported (6) that certain *N*-chloroazasteroids react with model thiols to produce sulfenamides through the formation of new S—N bonds (eq. [1]). These *N*-chloro

[1] 

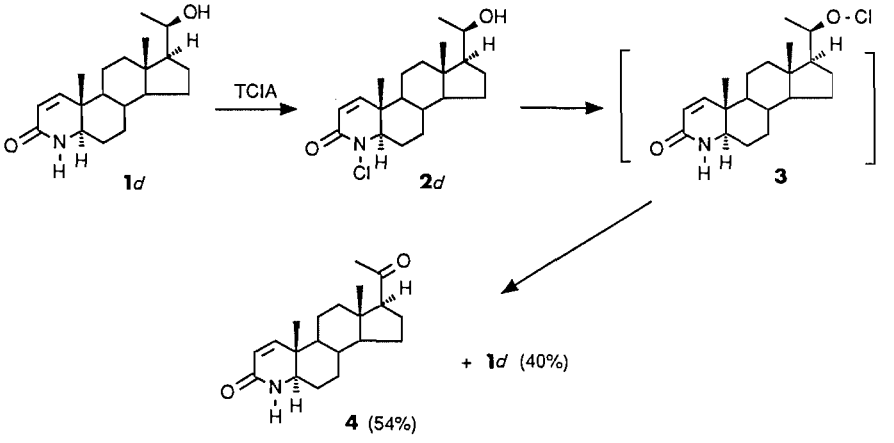
compounds are therefore envisaged to behave as chemoselective affinity labels for thiol (sulfhydryl) groups within active sites (7). We now report the preparation of a series of novel *N*-chloro-Δ^1-4-azasteroids **2** by chlorination of the corresponding lactams **1**. These compounds may be of value in future labelling and inhibition studies of 5α-reductase.

To date, our syntheses of other *N*-chloroazasteroids employed *N*-chlorosuccinimide (NCS) as the chlorinating agent (6). Other reagents such as sodium or *tert*-butyl hypochlorite were also investigated, but proved inferior. Although NCS gives generally satisfactory results, it suffers from several disadvantages. It can be used in stoichiometric amounts at room temperature in the presence of 1 equivalent of potassium *tert*-butoxide, or in excess amounts in refluxing chloroform without the added base. The former method can result in competing chlorination of the α-position of the lactam carbonyl group, as well as its epimerization if it is a chiral center. The latter method requires prolonged reaction times and the occasionally troublesome chromatographic removal of excess unreacted NCS. We now report that trichloroisocyanuric acid (TCIA) is an exceptionally efficient and convenient reagent for this purpose that avoids these problems.



Results and discussion

The required Δ^1-4-azasteroids **1***a*–**1**c were prepared by the dehydrogenation of the corresponding saturated lactams with benzeneseleninic anhydride (Scheme 1) by a procedure reported earlier (8). An alternative method employing 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) has also been reported for this purpose (9). Compound **1***d* was obtained by saponification of the acetate moiety of **1***c*.



The *N*-chlorination of azasteroids **1***a*–**1***c* with TCIA in chloroform solution afforded the *N*-chloro derivatives **2***a*–**2***c* in excellent isolated yields. The reaction is illustrated in Scheme 1 and the results are summarized in Table 1. Results obtained with NCS as the chlorinating reagent are also included in Table 1 for comparison. TCIA is an inexpensive, commercially available reagent that has previously been employed in other chlorination processes (10). It decomposes rapidly in basic aqueous media to form water-soluble products. This permits the use of excess reagent to ensure completion of the reaction and requires only a simple work-up with aqueous sodium bicarbonate to obtain essentially quantitative yields of the desired *N*-chloro compounds in high states of purity. The reactions in Table 1 were performed with 0.50–0.74 molar equivalents (i.e., 1.5–2.2 equivalents of chlorine) of TCIA and the mixtures were briefly

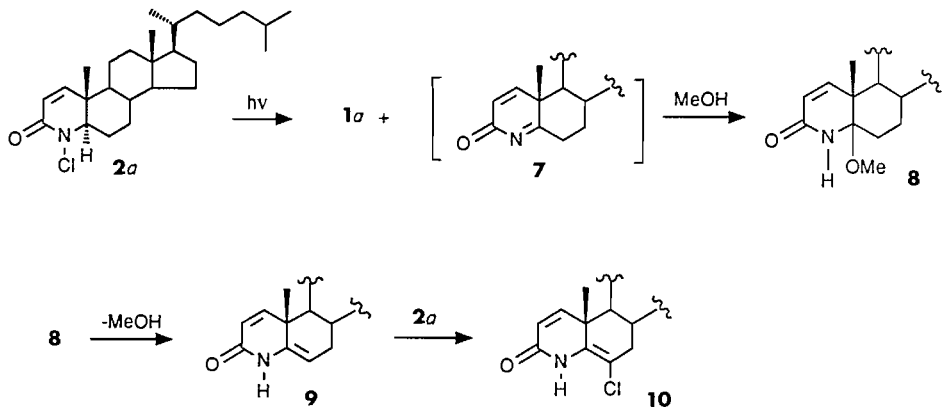
[a]All reactions were performed in refluxing chloroform.

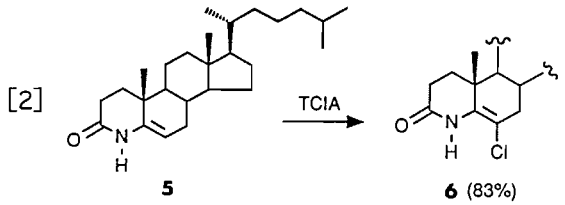
[b]Isolated yields are reported on products that were homogeneous on TLC with ^{1}H NMR and IR spectra identical to those of analytical samples.



[c]Products in entries 1, 3, 5, and 6 were isolated by preparative TLC; those in entries 2 and 4 did not require chromatographic purification.

refluxed to ensure the complete consumption of the starting materials. However, these reactions proceed rapidly even at room temperature, as evidenced by TLC analysis. Their rapid progress in the absence of pyrolytic initiation suggests that electrophilic, rather than free-radical mechanisms, are involved. Furthermore, adventitious photoinitiation was ruled out in a control experiment in which **1***a* and TCIA reacted rapidly (1 h) at room temperature in the dark. No significant side reactions were noted in any of the examples employing TCIA. The products are stable, crystalline solids that can be subjected to routine manipulation such as chromatography and stored for extended periods in the dark at or below 0°C. It is clear from these experiments that TCIA is superior to NCS for this purpose, both from the point of view of efficiency and convenience.

The *N*-chloro-20β-hydroxy derivative **2***d* proved to be less stable than **2***a*–**2***c*. Lactam **1***d* was chlorinated with TCIA in deuteriochloroform solution at room temperature, and the reaction was monitored by TLC and NMR. The formation of **2***d* was complete after 2 h, as evident from the appearance of a less polar product, along with the disappearance of the ^{1}H NMR signal at δ 5.68 (NH of **1***d*), and the shift to lower field of signals from δ 3.33 (C-5) and δ 0.98 (C-19) to δ 3.59 and δ 1.07, respectively. However, longer reaction times under these conditions, or attempts to isolate the product by the usual work-up, resulted in the decomposition of **2***d* to afford the 20-ketone **4** and the original lactam **1***d*, isolated in yields of 54 and 40%, respectively. This is consistent with the rearrangement of **2***d* to the isomeric hypochlorite **3**, followed by elimination of HCl, or hydrolysis to the free alcohol, as shown in Scheme 2. Related oxidations of secondary alcohols to ketones with various other *N*-halo reagents have been previously reported (11).



We also investigated the chlorination of azasteroid **5**, the Δ^5-isomer of **1***a*, with TCIA under similar conditions. Enamide **5** is an ambident nucleophile, where both the nitrogen atom and

SCHEME 3

C-6 are potential sites for electrophilic attack. In this case, none of the *N*-chloro compound was observed, and the 6-chloro derivative **6** (eq. [2]) was produced in 83% yield. Thus, *C*-chlorination is favoured over *N*-chlorination in this example, although we cannot rule out the possibility of initial kinetically controlled *N*-chlorination, followed by rapid isomerization to **6**.

We previously reported (6) that some *N*-chloroazasteroids undergo photochemical dehydrochlorination to generate reactive *N*-acyl imines (12). Some of these intermediates were trapped by solvent addition when the photolyses were performed in methanol. These results suggested that *N*-chloroazasteroids could function as photoaffinity labels (13), and we therefore attempted to determine whether the Δ^1-analogues would behave similarly. Thus, photolysis of **2***a* in methanol produced the enamide **9** and its 6-chloro derivative **10**, along with the parent lactam **1***a*, as shown in Scheme 3. These products are analogous to the ones previously obtained from the corresponding 1,2-saturated *N*-chloroazasteroid, and are presumably formed by a similar pathway, described earlier (6). However, in contrast to the saturated analogue, careful chromatography of the reaction mixture in the present example permitted the isolation of a small amount of the relatively unstable carbinolamide methyl ether **8**, which was characterized by IR and ^{1}H NMR spectroscopy. This confirms the generation of the *N*-acyl imine intermediate **7** under these conditions.

In conclusion, we have demonstrated that TCIA is a remarkably effective *N*-chlorinating reagent that permitted the facile preparation of several novel *N*-chloro-Δ^1-4-azasteroids with potentially interesting biological properties.

Experimental

Azasteriods **1***a*–**1***c* were prepared as described previously (8). Compound **1***c* was assumed to have the 20β configuration (14) as it was obtained by the sodium borohydride reduction of the 20-keto group of 4-aza-5α-pregnan-3,20-dione, prior to acetylation and dehydrogenation with benzeneseleninic anhydride. Enamide **5** was prepared according to a literature procedure (15). NCS and TCIA were obtained from the Aldrich Co. and were used without further purification. Melting points were determined on an A. H. Thomas hot-stage apparatus and are uncorrected. The IR spectra were recorded on a Nicolet 5DX spectrometer and NMR spectra were obtained on a Bruker ACE 200 instrument at 200 MHz in deuteriochloroform solvent with either chloroform or tetramethylsilane as the internal standard. Mass spectra were recorded on a Kratos MS 80 or a VG 7070 spectrometer by Drs. R. Yamdagni and Q. Wu. Elemental analyses were performed on an SCP Science model 440 elemental analyzer by Ms. D. Fox. Preparative TLC was carried out with Analtech 20 × 20 cm glass plates coated with 1 mm of silica gel GF.

Preparation of N*-chloro-4-aza-5α-cholest-1-en-3-one (***2***a) with NCS; typical procedure*

4-Azacholest-1-en-3-one (**1***a*) (98 mg, 0.255 mmol) and NCS (176 mg, 1.32 mmol) were refluxed for 12 h in 15 mL of chloroform. The solvent was then removed *in vacuo* and the residue was separated by preparative TLC (30% ethyl acetate – hexanes) to afford 91 mg (85%) of **2***a*, with R_f 0.62; mp 109–110°C (from hexanes); IR (Nujol); 1694, 1278, 805 cm^{-1}; ^{1}H NMR δ: 6.83 (d, J = 9.8 Hz, 1H), 5.94 (d, J = 9.8 Hz, 1H), 3.58 (dd, J = 12.5, 3.9 Hz, 1H), 2.32 (m, 1H), 2.06 (m, 1H), 1.06 (s, 3H), 0.92 (d, J = 6.4 Hz, 3H), 0.874 (d, J = 6.6 Hz, 3H), 0.871 (d, J = 6.6 Hz, 3H), and 0.69 (s, 3H); mass spectrum, *m/z* (relative intensity, %): 419 (M^+, 2), 385 (M^+ of **1***a*, presumably formed by thermal decomposition of **2***a* in the sample inlet, 75), 384 (36), 370 (23), 110 (100). Anal. calcd. for $C_{26}H_{42}ClNO$: C 74.34, H 10.08, N 3.33; found: C 74.43, H 10.29, N 3.47.

Preparation of N*-chloro-4-aza-5α-cholest-1-en-3-one (***2***a) with TCIA; typical procedure*

4-Azacholest-1-en-3-one (**1***a*) (109 mg, 0.283 mmol) and TCIA (33 mg, 0.14 mmol) were refluxed for 2 h in 5 mL of chloroform. The reaction mixture was extracted three times with aqueous $NaHCO_3$ solution, the combined aqueous layers were extracted once with chloroform, and the combined chloroform layers were dried ($MgSO_4$) and evaporated to constant weight *in vacuo* to afford 118 mg (99%) of **2***a*, which solidified upon standing, mp 103–108°C. It was homogeneous on TLC and gave IR and ^{1}H NMR spectra identical to those of the analytical sample produced in the preceding procedure.

The following compounds were prepared similarly (See Table 1 for yields and conditions).

*N-Chloro-17β-acetoxy-4-aza-5α-androst-1-en-3-one (***2***b)*: mp 136–137°C (from dichloromethane–hexanes); IR (film): 1733, 1690, 1248, 1038 cm^{-1}; ^{1}H NMR δ: 6.82 (d, J = 9.8 Hz, 1H), 5.94 (d, J = 9.8 Hz, 1H), 4.62 (dd, J = 9.0, 7.5 Hz, 1H), 3.59 (dd, J = 12.5, 3.9 Hz, 1H), 2.05 (s, 3H), 1.07 (s, 3H), 0.82 (s, 3H); mass spectrum, *m/z* (relative intensity, %): 365 (M^+, 5), 330 (96), 313 (26), 288 (22), 110 (75), 43 (100). Anal. calcd. for $C_{20}H_{28}ClNO_3$: C 65.64, H 7.71, N 3.82; found: C 65.67, H 7.98, N 3.72.

*N-Chloro-20β-acetoxy-4-aza-5α-pregn-1-en-3-one (***2***c)*: mp 112–113°C (from dichloromethane–hexanes); IR (Nujol): 1723, 1683, 1244, 1122, 810 cm^{-1}; ^{1}H NMR δ: 6.82 (d, J = 9.8 Hz, 1H), 5.94 (d, J = 9.8 Hz, 1H), 4.85 (dq, J = 10.2, 6.1 Hz, 1H), 3.59 (dd, J = 12.6,

3.9 Hz, 1H), 2.31 (m, 1H), 2.03 (s, 3H), 1.16 (d, J = 6.1 Hz, 3H), 1.06 (s, 3H), 0.67 (s, 3H); mass spectrum, m/z (relative intensity, %): 393 (M^+, 2), 391 (8), 359 (32, M^+ of **1***c*, presumably formed by thermal decomposition of **2***c* in the sample inlet), 284 (32), 110 (69), 43 (100). Anal. calcd. for $C_{22}H_{32}ClNO_3$: C 67.07, H 8.19, N 3.56; found: C 67.01, H 8.31, N 3.58.

*20β-Hydroxy-4-aza-5α-pregn-1-en-3-one (1*d)

20β-Acetoxy-4-aza-5α-pregn-1-en-3-one (**1***c*) (183 mg, 0.510 mmol) was stirred for 20 h in 8 mL of 1,4-dioxane and 5 mL of 1 M aqueous NaOH solution at 60°C. The solvent was evaporated *in vacuo*, the residue was taken up in water, acidified with 10% HCl solution, and extracted three times with chloroform. The chloroform layers were washed three times with aqueous $NaHCO_3$ solution, once with aqueous NaCl, dried ($MgSO_4$), and evaporated *in vacuo*. The residue crystallized from methanol–water to afford 122.5 mg (76%) of the title compound, mp 287–290°C; IR (Nujol): 3451, 3204, 1669, 1597, 1292, 1117, 816 cm^{-1}; ^1H NMR δ: 6.82 (d, J = 9.9 Hz, 1H), 5.81 (d, J = 9.9 Hz, 1H), 5.68 (br s, 1H), 3.74 (m, 1H), 3.33 (m, 1H), 2.15 (m, 1H), 1.15 (d, J = 6.1 Hz, 3H), 0.98 (s, 3H), 0.78 (s, 3H); mass spectrum, m/z (relative intensity, %): 317 (M^+, 73), 316 (11), 299 (16), 283 (18), 232 (19), 110 (100). Exact Mass calcd. for $C_{20}H_{31}NO_2$: 317.2355; found: 317.2344.

*Chlorination of 20β-hydroxy-4-aza-5α-pregn-1-en-3-one (1*d*) with TCIA*

The lactam (**1***d*) (18.6 mg, 0.059 mmol) and TCIA (4.6 mg, 0.020 mmol) were stirred in 2 mL of deuteriochloroform at room temperature for 90 min. TLC analysis (10% methanol–benzene) revealed the presence of a new component at R_f 0.37, as well as a trace of unreacted **1***d*. Additional TCIA (2.2 mg, 0.010 mmol) was added and stirring continued for 30 min to effect the complete disappearance of the starting material. An NMR spectrum then indicated the nearly quantitative formation of the *N*-chloro derivative **2***d* with signals at δ 6.84 (d, J = 9.8 Hz, 1H), 5.94 (d, J = 9.8 Hz, 1H), 3.74 (dq, J = 10.2, 6.2 Hz, 1H), 3.59 (dd, J = 12.6, 3.9 Hz, 1H), 2.30 (m, 1H), 2.16 (m, 1H), 1.15 (d, J = 6.1 Hz, 3H), 1.07 (s, 3H), 0.78 (s, 3H). New signals attributed to the ketone **4** (*vide infra*) were apparent after an additional 5 h.

The reaction was repeated with lactam **1***d* (43 mg, 0.13 mmol) and TCIA (16 mg, 0.068 mmol) in 3 mL of chloroform. After 75 min, the reaction mixture was washed three times with aqueous $NaHCO_3$ solution and the $NaHCO_3$ washings were extracted twice with chloroform. The combined chloroform layers were dried ($MgSO_4$) and evaporated *in vacuo*. The residue was separated by preparative TLC in 10% methanol–benzene to afford 17 mg (40%) of lactam **1***d*, R_f 0.21, identical to an authentic sample (TLC, IR, NMR), and 23 mg (54%) of 4-aza-5α-pregn-1-ene-3,20-dione (**4**), R_f 0.33; mp: sublimes from 300°C (recrystallized from dichloromethane–hexanes); IR (film): 3194, 1697, 1680, 1605, 829 cm^{-1}; ^1H NMR δ: 6.81 (d, J = 9.9 Hz, 1H), 5.82 (dd, J = 9.9, 1.5 Hz, 1H), 5.34 (br s, 1H), 3.34 (m, 1H), 2.55 (crude t, 1H), 2.14 (s, 3H), 0.98 (s, 3H), 0.65 (s, 3H), 0.65 (s, 3H); mass spectrum, m/z (relative intensity, %): 315 (M^+, 33), 300 (7), 272 (8), 244 (11), 110 (95), 43 (100). Exact Mass calcd. for $C_{20}H_{31}NO_2$: 315.2198; found: 315.2235. Further verification of the structure of **4** was obtained by its reduction with sodium borohydride in ethanol to produce **1***d* in 73% yield, identical to an authentic sample (TLC, IR, ^1H NMR).

When lactam **1***d* (53 mg, 0.17 mmol) was refluxed with NCS (63 mg, 0.47 mmol) in 10 mL of chloroform for 18 h, TLC and NMR analyses revealed the presence of starting material, ketone **4**, and several unidentified components.

Chlorination of 4-azacholest-5-en-3-one (5) with TCIA

The enamide **5** (121 mg, 0.314 mmol) and TCIA (24 mg, 0.103 mmol) were stirred for 1 h at room temperature in 5 mL of chloroform. The solution was then concentrated *in vacuo* and separated by preparative TLC (ethyl acetate) to afford 110 mg (83%) of 6-chloro-4-azacholest-5-en-3-one (**6**), R_f 0.75, identified by comparison of its IR and ^1H NMR spectra with those of an authentic sample (6).

Photolysis of N*-chloro-4-aza-5α-cholest-1-en-3-one (2*a*)*

A solution of compound **2***a* (132 mg, 0.314 mmol) in 15 mL of methanol was irradiated for 20 min in a Pyrex vessel with a Rayonet UV apparatus equipped with four 300-nm lamps. The reaction mixture was concentrated *in vacuo* and separated by preparative TLC (70% ethyl acetate – hexanes) to afford 17 mg (13%) of 6-chloro-4-azacholesta-1,5-dien-3-one (**10**) as an amorphous solid, R_f 0.79; IR (film): 3393, 1690, 1618, 1300, 1119, 1109 cm^{-1}; ^1H NMR δ: 7.27 (br s, 1H), 6.73 (d, J = 10.0 Hz, 1H), 5.87 (dd, J = 10.0, 1.9 Hz, 1H), 2.37 (dd, J = 17.1, 6.2 Hz, 1H), 1.26 (s, 3H), 0.92 (d, J = 6.4 Hz, 3H), 0.87 (d, J = 6.5 Hz, 6H), 0.71 (s, 3H); mass spectrum, m/z (relative intenstiy, %): 417 (M^+, 41), 402 (13), 41 (100). Exact Mass calcd. for $C_{26}H_{40}ClNO$: 417.2798; found: 417.2858. A more polar band afforded 29 mg (24%) of 4-azacholesta-1,5-dien-3-one (**9**), R_f 0.55; mp 214–216°C (from chloroform – ethyl acetate); IR (Nujol): 3190, 1693, 1618, 1223, 1178 cm^{-1}; ^1H NMR δ: 7.61 (br s, 1H), 6.73 (d, J = 10.0 Hz, 1H), 5.82 (dd, J = 10.0, 1.8 Hz, 1H), 5.00 (m, 1H), 2.08 (m, 2H), 1.23 (s, 3H), 0.92 (d, J = 6.4 Hz, 3H), 0.87 (d, J = 6.5 Hz, 6H), 0.71 (s, 3H): mass spectrum, m/z (relative intensity, %): 383 (M^+, 90), 369 (19), 135 (53), 40 (100). Anal. calcd. for $C_{26}H_{41}NO$: C 81.40, H 10.77, N 3.65; found: C 81.31, H 10.46, N 3.50. A polar component near the baseline afforded 46 mg (38%) of lactam **1***a*, identical to an authentic sample (TLC, ^1H NMR). Several overlapping bands between R_f 0.6 and 0.7 contained the carbinolamide methyl ether **8** (NMR), *vide infra*, which decomposed upon further attempts at purification.

In a separate experiment, **2***a* (65 mg, 0.16 mmol) was similarly irradiated and separated as quickly as possible by preparative TLC in a less polar solvent (30% ethyl acetate – hexanes). The band with R_f 0.44 afforded 8 mg (12%) of **8**; IR (film): 3250, 1686, 1623, 1068, 756 cm^{-1}; ^1H NMR δ: 6.46 (d, J = 10.0 Hz, 1H), 6.25 (br s, 1H), 5.84 (dd, J = 10.0, 2.0 Hz, 1H), 3.24 (s, 3H), 1.45 (s, 3H), 0.90 (d, J = 6.0 Hz) overlapping with 0.87 (d, J = 6.5 Hz, total 9H), 0.74 (s, 3H); ^{13}C NMR δ: 166.3 (C=O, C-3), 156.3 (CH, C-1), 119.7 (CH, C-2), 88.0 (quaternary C, C-5), 47.8 (MeO).

Acknowledgement

We gratefully acknowledge the financial support of the Natural Sciences and Engineering Research Council of Canada and Merck Frosst Canada Inc. P.L.G. and B.P.D. were summer research assistants sponsored by a Studentship from the Natural Sciences and Engineering Research Council of Canada and a University of Calgary Faculty of Science Special Award, respectively. We thank Dr. Leo Milward of Agriculture Canada for providing several high resolution mass spectra.

Diels–Alder reactions of activated 2*H*-thiopyrans

DALE E. WARD,[1] YUANZHU GAI, AND WAJDI M. ZOGHAIB
Department of Chemistry, University of Saskatchewan, Saskatoon, Sask., Canada S7N 0W0
Received March 19, 1991

DALE E. WARD, YUANZHU GAI, and WAJDI M. ZOGHAIB. Can. J. Chem. **69**, 1487 (1991).

The Diels–Alder reactivity of various 2*H*-thiopyrans bearing electron-donating substituents has been investigated. The approximate order of reactivity among the 2*H*-thiopyrans studied was 4,6-disubstituted >> 5-substituted > 4-substituted, 3,5-disubstituted >> 3-substituted. Good yields of predominantly *endo* adducts are obtained with reactive dienophiles. With less reactive dienophiles, reactions are much slower and yields are attenuated due to the competing thermal decomposition of the dienes under the reaction conditions. The adducts obtained are equivalent (via desulfurization) to those from unreactive *cis*-substituted dienes.

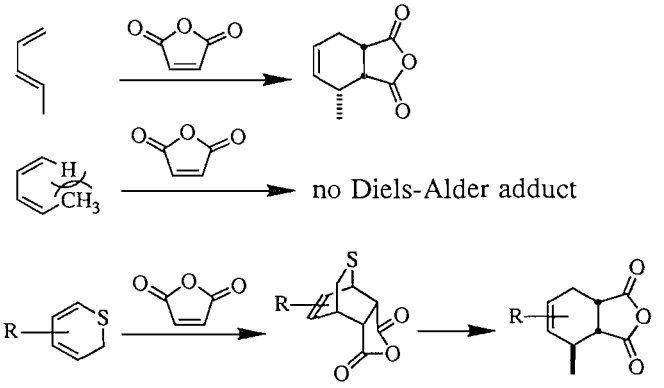
Key words: Diels–Alder, 2*H*-thiopyran.

DALE E. WARD, YUANZHU GAI et WAJDI M. ZOGHAIB. Can. J. Chem. **69**, 1487 (1991).

On a examiné la réactivité dans les réactions de Diels–Alder de divers 2*H*-thiopyranes portant divers groupes électrodonneurs. L'ordre approximatif de réactivité des divers 2*H*-thiopyranes étudiés est disubstitués en 4,6 >> substitués en 5 > substitués en 4, disubstitués en 3,5 >> substitués en 3. Avec des diénophiles réactifs, on a obtenu de bons rendements des adduits principalement *endo*. Avec des diénophiles moins réactifs, les réactions sont beaucoup plus lentes et les rendements sont atténués à cause de la réaction compétitive de décomposition thermique des dienes dans ces conditions réactionnelles. Les adduits obtenus sont équivalents (via la désulfurisation) à ceux obtenus à partir des dienes non-réactifs *cis*-substitués.

Mots clés : Diels–Alder, 2*H*-thiopyrane.

[Traduit par la rédaction]



Introduction

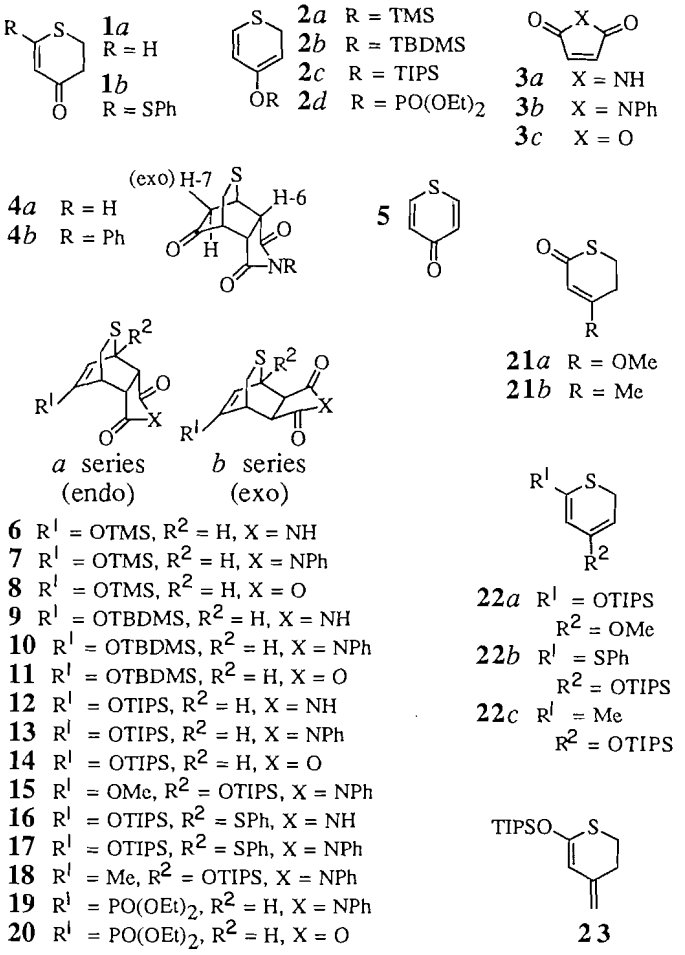
The Diels–Alder reaction is of fundamental importance to both the theory and the practice of organic chemistry (1). The formation of two carbon–carbon bonds and up to four stereogenic centers with predictable stereoselectivity and wide applicability are among the more notable attributes of this reaction. Recent advances include intramolecular applications (2), applications in asymmetric synthesis (i.e., the preparation of chiral scalemic adducts) (3), and the use of hetero dienes and dienophiles (4). The scope of the Diels–Alder reaction has broadened significantly with the use of Lewis acids (3, 5) or high pressure (6) or both (7) to enhance reactivity and (or) selectivity.

A major limitation of the Diels–Alder reaction is the lack of reactivity associated with *cis*-substituted dienes (8). For example, the reaction of *cis*-1,3-pentadiene with maleic anhydride (9) or with tetracyanoethylene (10) does not give an adduct under conditions where the *trans* isomer reacts quantitatively. Similarly, *trans*-1,3-pentadiene is 10^3 times more reactive than 4-methyl-1,3-pentadiene towards tetracyanoethylene (10). The low reactivity of *cis*-dienes towards [4+2] cycloaddition is attributed to the steric destabilization that occurs in the necessary *s-cis* conformation.

A potential strategy to overcome the low reactivity of *cis*-dienes involves the use of 2*H*-thiopyrans. Diels–Alder reactions of 2*H*-thiopyrans with dienophiles should provide adducts that, after desulfurization, would be synthetically equivalent to an adduct derived from a *cis*-diene (see Scheme 1). If 2*H*-thiopyrans could act as functional equivalents to the unreactive *cis*-dienes the scope of the Diels–Alder reaction might be significantly expanded.

The Diels–Alder reactions of 2*H*-thiopyrans have not been extensively investigated. Flemming and Murray studied (11) the reaction of the parent compound with three dienophiles and found that predominantly *endo* adducts were produced

SCHEME 1



in low yield. Harayama and Otsuyama reported (12) that reaction of the 4-trimethylsilyloxy derivative with dienophiles produced both Diels–Alder and Michael adducts in low yield. In an effort to find suitably reactive analogues, we investigated (13) Diels–Alder reactions of 2*H*-thiopyrans that were activated by electron-donating substituents. In contrast to Harayama and Otsuyama, we found that 4-trialkylsilyloxy-2*H*-thiopyrans react with typical dienophiles to give fair to excellent yields of Diels–Alder adducts with *endo* stereoselectivity. Desulfurization of these adducts provided compounds equivalent to an *endo* Diels–Alder adduct from the unreactive (*E*)-3-trimethylsilyloxy-1,3-pentadiene in good overall yield. To further define the scope of this use of 2*H*-thiopyrans as functional equivalents of *cis*-dienes we have examined the Diels–Alder reactivity of a variety of substituted derivatives and herein report the full results of this study.

Results and discussion

Our initial efforts focussed on the preparation of 2*H*-thiopyrans bearing an oxygen substituent at C-4. Treatment of the readily available 2*H*-thiopyran-4(3*H*)-one (**1***a*) (14) with chlorotrimethylsilane (TMSCl) under Danishefsky's con-

ditions (15) provided the diene **2***a*. Reaction with maleimide (**3***a*, 1 equiv.) in refluxing xylene for 16 h gave the adduct **4***a* (35%) along with **1***a* (20%) and 4*H*-thiopyranone (14*b*) (**5**, 25%).

The ^{1}H NMR spectrum of the crude reaction mixture indicated the presence of a 10:1 mixture of the stereoisomeric adducts **6***a*,*b* along with **1***a* and **5**. After chromatography over silica gel, only a single isomer of the hydrolyzed adduct (**4***a*) was isolated, which was assigned the *endo* stereochemistry on the basis of ^{1}H NMR. Specifically, in the spectrum of **4***a*, H-7$_{exo}$ exhibited a long-range W-coupling to H-6 with ^4J = 2 Hz; by contrast H-3$_{anti}$ was not spin coupled to H-5 (cf. Fig. 1). Although not isolated, we believe[2] that the *exo* isomer **6***b* is the minor component in the crude adduct **6***a*,*b*.

Monitoring the reaction of **2***a* with **3***a* by ^{1}H NMR revealed that both **1***a* and **5** were formed during reaction. The addition of a small amount of 2,6-di-*tert*-butyl-4-methylphenol (BHT) was effective in reducing the formation of **5**. However, despite pretreating the glassware with base and (or) with TMSCl and using carefully dried solvent, we were unable to completely suppress the formation of **1***a*. Under optimal conditions (**3***a*,

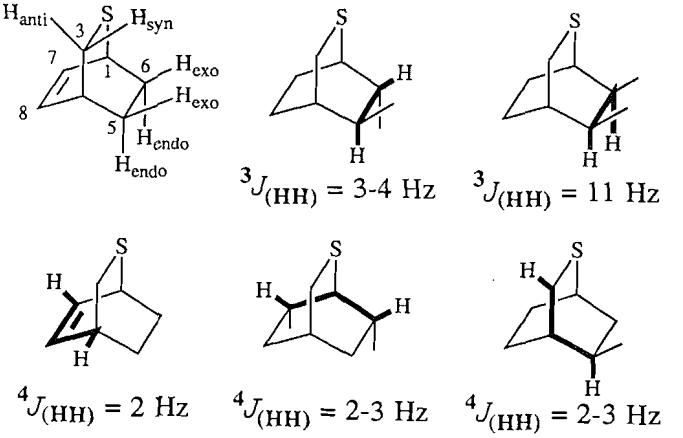

FIG. 1. Numbering system, labelling system, and typical H–H coupling constants for 2-thiabicyclo[2.2.2]oct-7-enes and 2-thiabicyclo[2.2.2]octanes.

2 equiv.; BHT, 0.2 equiv.; xylene, 110°C, 16 h) we obtained the adduct **4***a* (62%) along with **1***a* (28%) and **5** (9%).

Analogous results were obtained using *N*-phenylmaleimide (**3***b*) as the dienophile (Table 1). Attempted reaction of **2***a* with maleic anhydride (**3***c*) resulted in the rapid formation of **1***a*; in some experiments various amounts of the Diels–Alder adduct **5** (as a 3:1 mixture of *endo* and *exo* isomers[2]) could be detected but not isolated.

In an effort to obtain dienes that would be more stable, we prepared **2***b* and **2***c* by treatment of **1***a* with *tert*-butyldimethylsilyl trifluoromethanesulfonate (TBDMSOTf) and triisopropylsilyl trifluoromethanesulfonate (TIPSOTf), respectively, in the presence of Et_3N. Reaction of **2***b* with **3***a* (2 equiv.; BHT, 0.1 equiv.; xylene, 110°C, 16 h) gave the adduct **9***a* (53%) along with **1***a* (30%) and **5** (10%). Although the ^{1}H NMR spectrum of the crude reaction mixture indicated[2] the presence of a 10:1 mixture[3] of the stereoisomeric adducts **9***a*,*b*, only a single isomer was isolated. The *endo* stereochemistry was assigned to **9***a* based on the absence of W-coupling between H-3$_{anti}$ and H-5 in the ^{1}H NMR spectrum (cf. Fig. 1). The stereochemistry was confirmed by conversion of **9***a* into **4***a* ($HF_{(aq)}$, CH_3CN). Similar results were obtained in the reaction of **2***b* with **3***b* (Table 1). The reaction of **2***b* with **3***c* produced a 3:1 mixture of *endo*:*exo*[2] adducts **11** (54%) along with **1***a* (38%) and **5** (8%) as determined by ^{1}H NMR of the crude reaction mixture using an internal standard. The adducts could not be purified without extensive decomposition.

In contrast with **2***a* and **2***b*, reaction of **2***c* with dienophiles proceeded without significant production of **1***a* or **5** and addition of BHT to the reaction mixture was not necessary. Good yields of predominantly *endo* adducts were obtained in reactions of **2***c* with **3**. The *endo* stereochemistry was readily assigned to the major adduct on the basis of the lack of coupling between H-3$_{anti}$ and H-5 in the ^{1}H NMR spectrum[4] (cf. Fig. 1).

Reactions of **2***c* with **24** were much slower than those with

[2]The spectral characteristics (^{1}H and (or) ^{13}C NMR) of the major and minor adducts in the spectrum of the crude adduct closely resemble those of the homogeneous *endo* (e.g., **13***a*, **14***a*, **36***a*, and **39***a*) and *exo* (e.g., **19***b*, **36***b*, and **39***b*) adducts, respectively. Stereochemistry was readily assigned based on the consistent presence of coupling between H-3$_{anti}$ and H-5 only in the *exo* isomer (^4J = 2–3 Hz, cf. Fig. 1).

[3]This is presumably a kinetic mixture since control experiments show that individual solutions (toluene-d_8 or $CDCl_3$) of **13***a*, **19***a*, **19***b*, **26***a*, **26***b*, **36***a*, and **36***b* are unchanged after heating at 120°C for at least 48 h.

[4]The minor isomer shows coupling between H-3$_{anti}$ and H-5, J = 2–3 Hz.

3, and both the yields obtained and the stereoselectivity were attenuated (Table 1). The stereochemistry of the adducts (**25**–**27**) was determined by analysis of the coupling constants observed in the ^{1}H NMR spectra. The resonance for H-5$_{endo}$ was readily assigned on the basis of its W-coupling to H-3$_{anti}$ (ca. 2–3 Hz, cf. Fig. 1). The magnitude of the coupling constant between H-5$_{endo}$ and H-6 provides the basis for the assignment of stereochemistry at C-6 (see Fig. 1). The lower yields obtained in these cases are attributable to the thermal instability of the diene. A toluene-d_8 solution of **2***c* at 120°C decomposes to unidentified products (polymerization?) with $t_{1/2}$ = 6 days (^{1}H NMR). At higher temperatures the lifetime of the diene is substantially shortened.

The reaction of **2***c* with dimethyl fumarate or dimethyl maleate was also slow at 120°C and gave, in each case, a mixture of only the *trans* adducts **28** and **29**.[5] The stereochemistry of the adducts was assigned based on the coupling constants observed in the ^{1}H NMR spectra. The *trans* relationship between the carbomethoxy groups in both **28** and **29** was evident from the coupling constants between H-5 and H-6 (5.5 and 5 Hz, respectively) while the stereochemistry at C-5 was assigned based on the presence (1.5 Hz for **28**) or absence (0 Hz for **27**) of coupling between H-3$_{anti}$ and H-5 (cf. Fig. 1).

Thus far, we have been unable to isolate Diels–Alder adducts in reactions of **2***c* with acetylenic dienophiles. For example, reaction of **2***c* with dimethyl acetylenedicarboxylate (C_6D_6, 80°C) gave a complex mixture of products from which dimethyl 4-triisopropylsilyloxy-1,2-benzenedicarboxylate could be isolated in low yield. Similarly, reaction of **2***c* with methyl propiolate gave methyl 4-triisopropylsilyloxybenzoate along with several unidentified products.[6] The production of these aromatic esters is presumably the result of a facile retro Diels–Alder elimination of thioformaldehyde from the initially formed adduct (16). Attempted Diels–Alder reaction of **2***c* with benzoquinone resulted in the formation of **5**.

To further enhance Diels–Alder reactivity, we sought to prepare 2*H*-thiopyrans with two activating substituents. The *in situ* trapping of photochemically generated thioformaldehyde with Brassard's diene (17) according to the procedure of Vedejs *et al.* (14*a*) provided the thiopyranone **21***a* (50%). Treatment of the lithium diisopropylamide (LDA) derived enolate of **21***a* with TIPSOTf gave the unstable diene **22***a*. The reaction of **22***a* with **3***b* proceeded at 80°C within 4 h to give a 4:1 mixture[2] of **15***a*,*b* (20%) together with **21***a* (49%). The

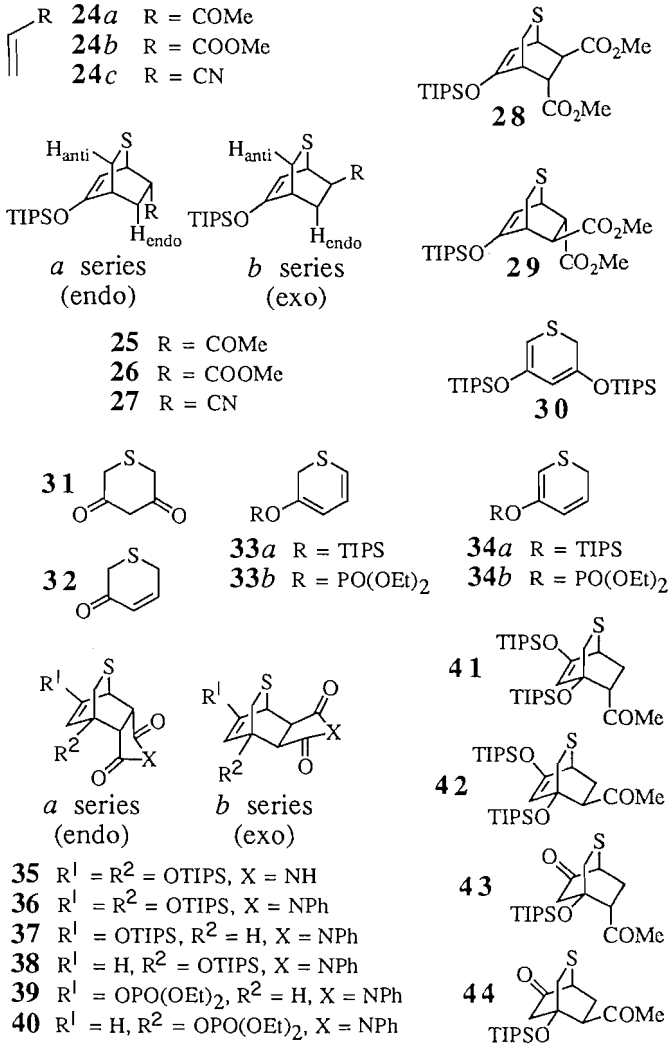
[5]Dimethyl maleate is isomerized into dimethyl fumarate (^{1}H NMR) under the reaction conditions.

[6]Some products were tentatively identified by ^{1}H NMR (13).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

more stable diene **22***b* was available by treating thiopyranone **1***b* with TIPSOTf in the usual way. Diels–Alder reaction of **22***b* with **3***a* at 110°C for 17 h provided the adducts **16***a,b* as a 1.2:1 mixture[3] of *endo*:*exo* diastereomers.[2] The reaction of **22***b* with **3***b* gave similar results (Table 1).

As expected, the dienes **22***a* and **22***b* are more reactive than **2***c*. Comparing reactions with similar dienophiles, the reactions of **22***a* and **22***b* proceed faster and at lower temperature than those of **2***c* (Table 1). However, the increased reactivity of **22***a* and **22***b* is offset by increased thermal instability and Diels–Alder adducts could not be obtained with the less reactive dienophiles **24**.



Alternatively, the 3,5-disubstituted 2*H*-thiopyran **30** was prepared from readily available **31** (18) by treatment with TIPSOTf (2.2 equiv.). The diene **30** reacted sluggishly with **3***a* and **3***b* to give adducts in fair yield with modest *endo*[2] selectivity (Table 1). Reactions with **24**[7] were much slower and resulted in low yields of adducts with poor stereoselectivity. The 3,5-disubstituted 2*H*-thiopyran **30** is similar to **2***c* in terms of stability and reactivity. However, **30** is considerably more stable and less reactive than the 4,6-disubstituted 2*H*-thiopyrans **22***a* and **22***b*.

Treatment of **21***b* (14*a*) with TIPSOTf gave an inseparable 3.6:1 mixture of **23** and the 6-substituted 2*H*-thiopyran **22***c*, respectively. Diels–Alder reaction of this mixture of dienes with **3***b* in $CDCl_3$ at 100°C gave a low yield of the *endo* adduct **18***a*. However, heating the 3.6:1 mixture of dienes **23** and **22***c* at 100°C in $CDCl_3$ in the presence of a catalytic amount of dichloromaleic anhydride (19) resulted in a 1:3 mixture of **23** and **22***c* (ca. 60%) together with **21***b* (ca. 40%) after 24 h (^{1}H NMR). Reaction of the 3.6:1 mixture of **23** and **22***c* with **3***b* in the presence of dichloromaleic anhydride ($CDCl_3$, 100°C, 24 h) gave the adduct **18***a* (30%) along with **21***b* (36%). These results imply that **22***c* is more reactive than **2***c*.

The 3- and 5-substituted 2*H*-thiopyrans **33***a* and **34***a* were available from **32** (20). Treatment of **32** with TIPSOTf and Et_3N gave a 1:4 mixture of **34***a* and **33***a* while treatment of the LDA derived enolate of **32** with TIPSOTf gave up to a 4:1 mixture of **34***a* and **33***a*. Heating a 4:1 mixture of **34***a* and **33***a* in toluene-d_8 at 100°C for 48 h resulted in a 1:4 mixture of **34***a* and **33***a* (^{1}H NMR). Conversely, after heating a toluene-d_8 solution of **33***a* at 100°C for 48 h, **34***a* could not be detected in the mixture. Prolonged heating (8 days) led to decomposition into unidentified products. The reaction of a 2:3 mixture of **34***a* and **33***a* with **3***b* (toluene-d_8, 100°C) for 24 h resulted in the complete disappearance of **34***a*, and the adduct **37***a* along with **33***a* were obtained after chromatography. Heating a toluene-d_8 solution of **33***a* and **3***b* at 100°C for 5 days gave the adduct **38***a* in 14% yield. The much lower reactivity of **33***a* compared to **34***a* is presumably the result of increased steric hindrance by the TIPS group at the bonding carbon (21).[8]

The use of dienol phosphates as stable analogues of dienol silyl ethers in Diels–Alder reactions has recently been reported (22). We examined the reactivity of the diethylphosphoryloxy-2*H*-thiopyrans **2***d*, **33***b*, and **34***b* and the results are presented in Table 1. In general, the phosphate dienes were more stable and less reactive than their silyl ether counterparts and little if any improvement in yields of Diels–Alder adducts was obtained.

Attempted reaction of **2***d* with **24***a* or **24***b* gave no adduct (^{1}H NMR) after 100 h at 140°C in toluene-d_8; increasing the reaction temperature to 160°C resulted in the decomposition of the diene to unidentified products within 24 h. In analogy with **34***a*, the diene **34***b* isomerizes to **33***b*. Heating a toluene-d_8 solution of **34***b* at 140°C for 72 h results in a 1:3 mixture of **34***b* and **33***b* (^{1}H NMR). By contrast, we did not detect evidence for the formation of **34***b* after prolonged heating of a solution of **33***b*. As with the silyl ether analogues, **33***b* is considerably less reactive than **34***b*.

Conclusion

2*H*-Thiopyrans bearing electron-donating substituents show enhanced Diels–Alder reactivity. By comparing the time and temperature of reactions of various dienes with similar dienophiles, the approximate order of reactivity among the 2*H*-thiopyrans is 4,6-disubstituted >> 5-substituted > 4-substituted, 3,5-disubstituted >> 3-substituted. Good yields of predominantly *endo* adducts are obtained with reactive dienophiles. With less reactive dienophiles, reactions are much slower and yields are attenuated due to the competing thermal decomposition of the dienes under the reaction conditions. The thermal

[7]Although adducts were detected in reactions of **30** with **24***a*, **24***b*, and **24***c*, only those from **24***a* were isolated and fully characterized.

[8]*trans*-Pentadiene is 1.5 times more reactive than 2-methylbutadiene towards maleic anhydride. Similarly, *trans*-1-methoxybutadiene is 3 times more reactive than 2-methoxybutadiene. By contrast, 2-*tert*-butylbutadiene is greater than 500 times more reactive than 1-*tert*-butylbutadiene (21).

instability of the silyloxydienes precludes the use of reaction temperatures above 120°C. This limitation is likely to be surmountable by the use of high pressure (6).

Desulfurization of the adducts derived from 2*H*-thiopyrans can provide products that are synthetically equivalent to Diels–Alder adducts of unreactive *cis*-substituted dienes (13). The coupling of an efficient Diels–Alder reaction of a 2*H*-thiopyran with desulfurization should provide a viable strategy to prepare compounds previously unavailable by Diels–Alder methods. Studies on the application of this strategy will be reported in due course.

Experimental

All solvents were distilled prior to use. Pyridine, *i*-Pr_2NH, and Et_3N were distilled from CaH_2 and stored over KOH pellets. Diethyl ether and THF were distilled from benzophenone potassium ketyl. Benzene, toluene, xylene, and CH_2Cl_2 were distilled from P_2O_5 under argon and stored over 3 Å molecular sieves. Toluene-d_8 was passed through neutral alumina immediately before use. $ZnCl_2$ was dried by melting several times under vacuum. Maleic anhydride was recrystallized from CCl_4. Unless otherwise noted, other commercially available reagents were used as received. Unless otherwise noted, reactions were carried out under an atmosphere of argon and reaction temperatures refer to the bath. Unless otherwise noted, all reported compounds were homogeneous by thin-layer chromatography (TLC) and by NMR.

Preparative thin-layer chromatography (PTLC) was carried out on glass plates (20 × 20 cm) precoated (0.25 mm) with silica gel 60 F_{254}. Materials were detected by visualization under an ultraviolet lamp (254 nm) and (or) by treating a 1-cm vertical strip removed from the plate with a solution of phosphomolybdic acid (5%) containing a trace of ceric sulfate in aqueous sulfuric acid (5% v/v), followed by charring on a hot plate. Flash column chromatography (FCC) was performed according to Still *et al.* (23) with Merck Silica Gel 60 (40–63 μm).

Mass spectra (MS) were recorded on a VG analytical retrofit of a single-sectored, magnetic scanning MS-12 linked to a Zenith computer. Electron impact (EI) ionization was accomplished at 70 eV and chemical ionization (CI) at 50 eV with ammonia as the carrier gas. Only partial data are reported. Infrared (IR) spectra were recorded on a Biorad FTS-40 Fourier transform interferometer using a diffuse reflectance cell. Only diagnostic peaks are reported. ^1H nuclear magnetic resonance (^1H NMR) spectra and ^{13}C nuclear magnetic resonance (^{13}C NMR) spectra were measured at 300 MHz and 75 MHz, respectively, on a Bruker AM-300 spectrometer. Unless otherwise noted, NMR spectra were obtained in $CDCl_3$ solution. For ^1H NMR, residual $CHCl_3$ in $CDCl_3$ was employed as the internal standard and assigned as 7.26 ppm downfield (δ) from tetramethylsilane (TMS). For ^{13}C NMR, $CDCl_3$ was employed as the internal standard and assigned as 77.0 δ relative to TMS. The ^1H NMR assignments are made on the basis of chemical shift, multiplicity, and, where necessary, confirmed by homonuclear decoupling and (or) NOE experiments. Chemical shifts and coupling constants were determined assuming first-order behavior. Multiplicity is indicated by one or more of: s (singlet), d (doublet), t (triplet), q (quartet), m (multiplet), br (broad); the list of coupling constants (*J*) corresponds to the order of the multiplicity assignment. ^1H NMR spectra were obtained with a digital resolution of 0.244 Hz/pt (sweep width = 4000 Hz, FID = 32 K data points) and coupling constants are reported to the nearest 0.5 Hz. The ^{13}C NMR assignments are made on the basis of chemical shift, multiplicity, and consistency within a series of similar structures. The multiplicity of ^{13}C NMR signals refers to the number of attached H's (i.e., s = C, d = CH, t = CH_2, q = CH_3) and was determined by *J*-modulation (24). Melting points were determined on a Gallenkamp melting point apparatus and are uncorrected.

6-Phenylthio-2H-thiopyran-4(3H)-one (1b)

NCS (71 mg, 0.52 mmol) was added portionwise to a solution of 2-phenylthiotetrahydro-4*H*-thiopyran-4-one (25) (112 mg, 0.5 mmol) in CCl_4 (6 mL) at 0°C. After stirring for 4 h at 0°C, the reaction mixture was filtered, and the combined filtrate and washings were concentrated and fractionated by PTLC (70% ether in hexane) to give **1***b* as an oil (45 mg, 41%); IR: 3276, 1661, 1647, 1519 cm^{-1}; ^1H NMR δ: 7.46 (5H, m, SC_6H_5), 5.92 (1H, s, H-5), 3.15 (2H, m, H-2), 2.65 (2H, m, H-3); ^{13}C NMR δ: 191.9 (s, C-4), 165.0 (s, C-6), [137.1 (s), 135.5 (d ×2), 130.5 (d), 129.8 (d ×2), SC_6H_5], 119.1 (d, C-5), 37.4 (t, C-3), 28.7 (t, C-2); MS (EI), *m/z* (relative intensity): 222 (M^+, 100), 189 (73).

4-Trimethylsilyloxy-2H-thiopyran (2a)

A solution of $ZnCl_2$ (1 mL, 1.5 M in ether) was added to a solution of **1***a* (114 mg, 1 mmol) in CH_2Cl_2 (10 mL), and Et_3N (0.85 mL, 6 mmol) and TMSCl (0.38 mL, 3 mmol) were added with stirring at room temperature. After 5 min the reaction mixture was concentrated and triturated with hexane. The combined hexane washings were concentrated and distilled to give **2***a* as a clear liquid (138 mg, 74%); bp 64–66°C, 2 Torr (1 Torr = 133.3 Pa); IR: 3045, 1627 cm^{-1}; ^1H NMR δ: 6.32 (1H, dd, *J* = 0.5, 10 Hz, H-6), 5.86 (1H, dd, *J* = 1.5, 10 Hz, H-5), 4.68 (1H, ddt, *J* = 0.5, 1.5, 5.5 Hz, H-3), 3.37 (2H, d, *J* = 5.5 Hz, H-2), 0.22 (9H, s, $Si(CH_3)_3$); ^{13}C NMR δ: 149.7 (s, C-4), 125.8 (d, C-6), 122.7 (d, C-5), 93.3 (d, C-3), 25.6 (t, C-2), 0.2 (q, $Si(CH_3)_3$); MS (CI), *m/z* (relative intensity): 187 ($[M + 1]^+$, 100), 186 (M^+, 23), 90 (26), 73 (15).

General procedure for preparation of silyloxy-2H-thiopyrans

To a solution of thiopyranone and Et_3N (3 equiv.) in CH_2Cl_2 (ca. 10 mL/mmol of thiopyranone) was added TBDMSOTf or TIPSOTf (1.05–1.2 equiv.) with stirring at room temperature. After 5 min the reaction mixture was concentrated and fractionated by FCC (hexane or pentane) using a column prepared from a slurry of silica gel in 3% v/v Et_3N in hexane or pentane. The yields obtained are essentially quantitative. The 2*H*-thiopyrans could not be distilled without extensive decomposition.

4-tert-Butyldimethylsilyloxy-2H-thiopyran (2b): IR: 3056, 1622 cm^{-1}; ^1H NMR δ: 6.32 (1H, dd, *J* = 0.5, 10 Hz, H-6), 5.88 (1H, dd, *J* = 1.5, 10 Hz, H-5), 4.67 (1H, ddt, *J* = 0.5, 1.5, 5.5 Hz, H-3), 3.37 (2H, d, *J* = 5.5 Hz, H-2), 0.22 (9H, s, $SiC(CH_3)_3$), 0.14 (6H, s, $Si(CH_3)_2$); ^{13}C NMR δ: 150.0 (s, C-4), 125.8 (d, C-6), 122.8 (d, C-5), 93.3 (d, C-3), 25.6 (t and q, C-2 and $SiC(CH_3)_3$), 18.1 (s, $SiC(CH_3)_3$), −4.5 (q, $Si(CH_3)_2$); MS (EI), *m/z* (relative intensity): 228 (M^+, 40), 187 (68), 75 (100).

4-Triisopropylsilyloxy-2H-thiopyran (2c): IR: 3043, 1614 cm^{-1}; ^1H NMR δ: 6.32 (1H, dd, *J* = 0.5, 10 Hz, H-6), 5.93 (1H, dd, *J* = 1.5, 10 Hz, H-5), 4.70 (1H, ddt, *J* = 0.5, 1.5, 5.5 Hz, H-3), 3.35 (2H, d, *J* = 5.5 Hz, H-2), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 150.3 (s, C-4), 125.8 (d, C-6), 122.9 (d, C-5), 92.6 (d, C-3), 25.8 (t, C-2), 17.9 (q, $Si(CH(CH_3)_2)_3$), 12.6 (d, $Si(CH(CH_3)_2)_3$); MS (EI), *m/z* (relative intensity): 270 (M^+, 45), 227 (65), 97 (100), 59 (61).

4-Diethylphosphoryloxy-2H-thiopyran (2d)

Methyllithium (0.17 mL, 1.27 M in hexanes, 0.22 mmol) was added dropwise to a solution of diisopropylamine (0.031 mL, 0.22 mmol) in THF (2 mL) at −78°C. After stirring for 10 min, a solution of **1***a* (20 mg, 0.18 mmol) in THF (1 mL) was added dropwise via syringe. After stirring for 1 h, diethyl chlorophosphate (0.064 mL, 0.44 mmol) was added and the reaction mixture was allowed to warm to room temperature and stirred for an additional 2.5 h. The reaction mixture was diluted with ether, washed with saturated NH_4Cl, saturated $NaHCO_3$, brine, dried over $MgSO_4$, concentrated, and fractionated by FCC (50% EtOAc in hexanes) to give **2***d* as an oil (23 mg, 54%); IR: 3052, 1640, 1552, 1274, 1029 cm^{-1}; ^1H NMR δ: 6.39 (1H, dt, *J* = 10, 1 Hz, H-6), 6.01 (1H, ddd, *J* = 0.5, 1.5, 10 Hz, H-5), 5.25 (1H, m, H-3), 4.15 (4H, dq, *J* = 8, 7 Hz, OCH_2), 3.44 (2H, ddd, *J* = 0.5, 2, 5.5 Hz, H-2), 1.32 (6H, dt, *J* = 1, 7 Hz, CH_3); ^{13}C NMR δ: 146.6 (s, C-4), 127.6 (d, C-6), 119.4 (d, C-5), 98.0 (d, C-3), 64.6 (t, OCH_2), 25.0 (t, C-2), 16.1 (q, CH_3), [C-3, 4, 5, and OCH_2CH_3

show coupling to ^{31}P, J = 4–8 Hz]; MS (CI), *m/z* (relative intensity): 268 ([M + 18]$^+$, 36), 251 ([M + 1]$^+$, 100).

(1R,4R*,5R*,6S*)-2-Thiabicyclo[2.2.2]octan-8-one-5,6-dicarboxylic acid imide (**4**a)*

A solution of **2***a* (240 mg, 1.3 mmol), **3***a* (252 mg, 2.6 mmol), and BHT (57 mg, 0.26 mmol) in xylene (3 mL) was heated at 110°C for 16 h. The ^1H NMR spectrum of the crude product indicated[2] the presence of a 10:1 mixture[3] of the adducts **6**. Fractionation by FCC (gradient elution: 25–50% EtOAc in hexane) gave **1***a* (41 mg, 28%) and **4***a* (170 mg, 62%); mp 215–217°C (MeOH); IR: 3381, 3176, 1778, 1720, 1708 cm^{-1}; ^1H NMR δ: 3.67 (1H, ddd, J = 2, 3.5, 9.5 Hz, H-6), 3.61 (1H, dt, J = 3.5, 3 Hz, H-1), 3.33 (1H, dd, J = 3, 9.5 Hz, H-5), 3.27 (1H, q, J = 3 Hz, H-4), 3.21 (1H, dd, J = 3, 11.5 Hz, H-3$_{syn}$), 3.13 (1H, dd, J = 3, 11.5 Hz, H-3$_{anti}$), 2.88 (1H, ddd, J = 2, 3, 20 Hz, H-7$_{exo}$), 2.63 (1H, dd, J = 3, 20 Hz, H-7$_{endo}$); ^{13}C NMR δ: ($(CD_3)_2CO$) δ: 208.0 (s, C-8), 178.1 and 177.5 (s, imide C=O), 48.7 (d, C-6), 45.8 (t, C-7), 44.6 and 44.0 (d, C-4, 5), 35.5 (d, C-1), 27.1 (t, C-3); MS (EI), *m/z* (relative intensity): 211 (M$^+$, 100), 183 (68), 112 (42), 97 (65).

Eluting the column with 20% MeOH in CH_2Cl_2 gave the polar **5** (13 mg, 9%).

(1R,4R*,5R*,6S*)-N-Phenyl-2-thiabicyclo[2.2.2]octan-8-one-5,6-dicarboxylic acid imide (**4**b)*

A solution of **2***a* (95 mg, 0.51 mmol), **3***b* (88 mg, 0.51 mmol), and BHT (22 mg, 0.1 mmol) in xylene (1 mL) was heated at 110°C for 16 h. The ^1H NMR spectrum of the crude product indicated[2] the presence of a 10:1 mixture[3] of the adducts **7**. Fractionation by FCC (gradient elution: 25–50% EtOAc in hexane) gave **1***a* (19 mg, 33%) and **4***b* (82 mg, 56%); mp 223–225°C (EtOAc); IR: 3064, 1772, 1708 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, C_6H_5), 3.78 (1H, ddd, J = 2, 3.5, 9.5 Hz, H-6), 3.72 (1H, dt, J = 3.5, 3 Hz, H-1), 3.47 (1H, dd, J = 3, 9.5 Hz, H-5), 3.37 (1H, q, J = 3 Hz, H-4), 3.22 (2H, m, H-3$_{syn}$ and H-3$_{anti}$), and 2.92 (1H, ddd, J = 2, 3, 20 Hz, H-7$_{exo}$), 2.65 (1H, dd, J = 3, 20 Hz, H-7$_{endo}$); ^{13}C NMR δ: 206.7 (s, C-8), 175.2 and 174.8 (s, imide C=O), [131.0 (s), 129.4 (d ×2), 129.2 (d), 126.2 (d ×2), N-C_6H_5], 46.6 (d, C-6), 45.2 (t, C-7), 43.9 and 42.3 (d, C-4, 5), 34.9 (d, C-1), 26.6 (t, C-3); MS (EI), *m/z* (relative intensity): 287 (M$^+$, 60), 86 (52), 84 (75), 57 (100).

Eluting the column with 20% MeOH in CH_2Cl_2 gave the polar **5** (5 mg, 9%).

(1R,4R*,5R*,6S*)-8-*tert*-Butyldimethylsilyloxy-2-thiabicyclo[2.2.2]-oct-7-ene-5,6-dicarboxylic acid imide (**9**a) and (1R*,4R*,5S*,6R*)-8-*tert*-butyldimethylsilyloxy-2-thiabicyclo-[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**9**b)*

A solution of **2***b* (20 mg, 0.088 mmol) and **3***a* (25 mg, 0.26 mmol) in xylene (1 mL) was heated at 110°C for 24 h. The ^1H NMR spectrum of the crude product indicated[2] the presence of a 10:1 mixture[3] of the adducts **9**. Fractionation by FCC (40% EtOAc in hexane) gave **1***a* (3 mg, 30%) and **9***a,b* (10:1, 15 mg, 53%) as an oil; IR: 3144, 3042, 1774, 1717, 1633 cm^{-1}; ^1H NMR δ for **9***a*: 8.70 (1H, brs, NH), 5.26 (1H, dd, J = 2, 7.5 Hz, H-7), 3.97 (1H, dd, J = 3.5, 7.5 Hz, H-1), 3.39 (1H, dd, J = 3.5, 8.5 Hz, H-6), 3.39 (1H, m, H-4), 3.04 (1H, dd, J = 3, 10.5 Hz, H-3$_{syn}$), 2.98 (1H, dd, J = 2.5, 8.5 Hz, H-5), 2.84 (1H, dd, J = 3, 10.5 Hz, H-3$_{anti}$), 0.87 (9H, s, $SiC(CH_3)_3$), 0.13 (3H, s, $SiCH_3$), 0.08 (3H, s, $SiCH_3$); partial data for **9***b*: 8.90 (1H, brs, NH), 5.46 (1H, dd, J = 2, 7.5 Hz, H-7), 3.89 (1H, dd, J = 3.5, 7.5 Hz, H-1), 2.64 (1H, ddd, J = 1.5, 2.5, 11 Hz, H-3$_{anti}$); ^{13}C NMR δ for **9***a*: 176.6 and 175.5 (s, imide C=O), 153.7 (s, C-8), 103.3 (d, C-7), 49.6 (d, C-6), 43.3 (d, C-5), 39.1 (d, C-4), 36.3 (d, C-1), 31.8 (d, C-3), 25.5 (q, $SiC(CH_3)_3$), 17.9 (s, $SiC(CH_3)_3$), −4.3 (q, $SiCH_3$), −5.0 (q, $SiCH_3$); MS (CI), *m/z* (relative intensity): 326 ([M + 1]$^+$, 100), 268 (30), 132 (29).

Eluting the column with 20% MeOH in CH_2Cl_2 gave the polar **5** (1 mg, 10%).

(1R,4R*,5R*,6S*)-N-Phenyl-8-*tert*-butyldimethylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**10**a)*

A solution of **2***b* (15 mg, 0.066 mmol) and **3***b* (30 mg, 0.17 mmol) in xylene (1 mL) was heated at 110°C for 16 h. The ^1H NMR spectrum of the crude product indicated[2] the presence of a 10:1 mixture[3] of *endo* and *exo* adducts **10**. Fractionation by FCC (25% EtOAc in hexane) gave **1***a* (2 mg, 26%) and **10***a* (16 mg, 60%) as an oil; IR: 3056, 1776, 1702, 1634 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, C_6H_5), 5.32 (1H, dd, J = 1.5, 7.5 Hz, H-7), 4.11 (1H, dd, J = 3.5, 7.5 Hz, H-1), 3.54 (1H, dd, J = 3.5, 8.5 Hz, H-6), 3.52 (1H, m, H-4), 3.14 (1H, dd, J = 3, 10.5 Hz, H-3$_{syn}$), 3.13 (1H, dd, J = 3, 8.5 Hz, H-5), 2.89 (1H, dd, J = 3, 10.5 Hz, H-3$_{anti}$), 0.89 (9H, s, $SiC(CH_3)_3$), 0.15 (3H, s, $SiCH_3$), 0.10 (3H, s, $SiCH_3$); ^{13}C NMR δ: 176.6 and 175.5 (s, imide C=O), 153.7 (s, C-8), [131.7 (s), 129.1 (d ×2), 128.6 (d), 126.2 (d ×2), N-C_6H_5], 103.3 (d, C-7), 49.6 (d, C-6), 43.3 (d, C-5), 39.1 (d, C-4), 36.3 (d, C-1), 31.8 (d, C-3), 25.5 (q, $SiC(CH_3)_3$), 17.9 (s, $SiC(CH_3)_3$), −4.6 (q, $SiCH_3$); MS (CI), *m/z* (relative intensity): 402 ([M + 1]$^+$, 72), 344 (100), 171 (20).

Eluting the column with 20% MeOH in CH_2Cl_2 gave the polar **5** (0.9 mg, 12%).

(1R,4R*,5R*,6S*)-8-Triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**12**a) and (1R*,4R*,5S*,6R*)-8-triisopropylsilyloxy-2-thiabicyclo[2.2.2]-oct-7-ene-5,6-dicarboxylic acid imide (**12**b)*

A solution of **2***c* (185 mg, 0.69 mmol) and **3***a* (100 mg, 1 mmol) in xylene (2.5 mL) was heated at 120°C for 72 h. The ^1H NMR spectrum of the crude product indicated[2] the presence of a 10:1 mixture[3] of the adducts **12**. Fractionation by FCC (25% EtOAc in hexane) gave **12***a,b* (10:1, 184 mg, 72%) as an oil; IR: 3154, 3059, 1780, 1718, 1630 cm^{-1}; ^1H NMR δ for **12***a*: 5.24 (1H, dd, J = 2, 7.5 Hz, H-7), 3.96 (1H, dd, J = 3.5, 7.5 Hz, H-1), 3.43 (1H, m, H-4), 3.39 (1H, dd, J = 3.5, 8.5 Hz, H-6), 3.06 (1H, dd, J = 3, 10.5 Hz, H-3$_{syn}$), 2.98 (1H, dd, J = 2.5, 8.5 Hz, H-5), 2.83 (1H, dd, J = 3, 10.5 Hz, H-3$_{anti}$), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); partial data for **12***b*: 5.45 (1H, dd, J = 2, 8 Hz, H-7), 3.88 (1H, dd, J = 4, 8 Hz, H-4), 2.66 (1H, m, H-3$_{anti}$); ^{13}C NMR δ for **12***a*: 177.5 and 176.5 (s, imide C=O), 153.6 (s, C-8), 102.4 (d, C-7), 50.6 (d, C-6), 44.6 (d, C-5), 38.9 (d, C-4), 35.9 (d, C-1), 31.7 (d, C-3), 17.8 (q, $Si(CH(CH_3)_2)_3$), 12.4 (d, $Si(CH(CH_3)_2)_3$); MS (CI), *m/z* (relative intensity): 368 ([M + 1]$^+$, 100), 324 (62).

(1R,4R*,5R*,6S*)-N-Phenyl-8-triisopropylsilyloxy-2-thiabicyclo-[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**13**a)*

A solution of **2***c* (95 mg, 0.35 mmol) and **3***b* (100 mg, 0.57 mmol) in xylene (2 mL) was heated at 120°C for 48 h. The ^1H NMR spectrum of the crude product indicated[2] the presence of a 10:1 mixture[3] of *endo* and *exo* adducts **13**. Fractionation by FCC (20% EtOAc in hexane) gave **13***a* (120 mg, 77%) as an oil; IR: 3066, 1778, 1713, 1633 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, C_6H_5), 5.33 (1H, dd, J = 2, 7.5 Hz, H-7), 4.11 (1H, dd, J = 3.5, 7.5 Hz, H-1), 3.58 (1H, m, H-4), 3.55 (1H, dd, J = 3.5, 8.5 Hz, H-6), 3.17 (1H, dd, J = 3, 10.5 Hz, H-3$_{syn}$), 3.13 (1H, dd, J = 2.5, 8.5 Hz, H-5), 2.89 (1H, dd, J = 3, 10.5 Hz, H-3$_{anti}$), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 176.6 and 175.5 (s, imide C=O), 153.7 (s, C-8), [131.7 (s), 129.0 (d ×2), 128.5 (d), 126.2 (d ×2), N-C_6H_5], 102.3 (d, C-7), 49.6 (d, C-6), 46.3 (d, C-5), 39.3 (d, C-4), 36.5 (d, C-1), 31.9 (d, C-3), 17.9 (q, $Si(CH(CH_3)_2)_3$), 12.5 (d, $Si(CH(CH_3)_2)_3$); MS (CI), *m/z* (relative intensity): 444 ([M + 1]$^+$, 100), 400 (53), 227 (17).

Reactions of 2b *and* 2c *with* 3c

Solutions of **3***c* (20 mg, 0.2 mmol) in toluene-d_8 (0.5 mL) containing **2***b* (23 mg, 0.1 mmol) and **2***c* (27 mg, 0.1 mmol), respectively, were sealed in NMR tubes and heated at 110°C for 16 h and 36 h, respectively. Using the residual protons in toluene-d_8 as an internal standard, ^1H NMR spectra of the solutions revealed the presence of **11***a* (41%), **11***b* (13%), **1***a* (38%), and **5** (8%) from **2***b*, and **14***a* (71%) and **14***b* (18%) from **2***c*. We were unable to purify the adducts without extensive decomposition. In one case, a reaction from **2***c* (42 mg, 1.5 mmol) gave, after FCC (75% ether in hexane), a small sample of pure **14***a* (6 mg, 11%).

(1R,4R*,5R*,6S*)-8-Triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid anhydride (**14**a)*: IR: 3056, 1866, 1779, 1723, 1633 cm^{-1}; ^1H NMR δ: 5.32 (1H, dd, J = 2, 7.5 Hz, H-7), 4.06 (1H, dd, J = 3.5, 7.5 Hz, H-1), 3.66 (1H, dd, J = 3.5, 9 Hz, H-6),

3.53 (1H, m, H-4), 3.25 (1H, dd, J = 2.5, 9 Hz, H-5), 3.09 (1H, dd, J = 3, 10.5 Hz, H-3$_{syn}$), 2.87 (1H, dd, J = 3, 10.5 Hz, H-3$_{anti}$), 1.10 (21H, m, Si(CH(CH$_3$)$_2$)$_3$); ^{13}C NMR δ: 171.4 and 170.0 (s, anhydride C=O), 154.0 (s, C-8), 102.8 (d, C-7), 50.1 (d, C-6), 43.9 (d, C-5), 39.0 (d, C-4), 35.8 (d, C-1), 31.1 (d, C-3), 17.8 (q, Si(CH(*C*H$_3$)$_2$)$_3$), 12.4 (d, Si(*C*H(CH$_3$)$_2$)$_3$); MS (CI), *m/z* (relative intensity): 369 ([M + 1]$^+$, 100), 325 (22), 148 (25).

(1R,4R*,5R*,6S*)-8-Methoxy-*N*-phenyl-1-triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**15**a) and (1R*,4R*,5S*,6R*)-8-methoxy-*N*-phenyl-1-triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**15**b)*

A solution of **22***a* (40 mg, ca. 80% pure by ^{1}H NMR, prepared from 14.4 mg of **21***a*) and **3***b* (17.3 mg, 0.1 mmol) in toluene-d_8 (0.4 mL) was sealed in an NMR tube under vacuum and heated at 80°C. After 4 h, ^{1}H NMR revealed the absence of **22***a*. The solution was concentrated and fractionated by PTLC (75% ether in hexane) to give **21***a* (7 mg, 49% from **21***a*) and a 4:1 mixture[2] of the adducts **15** (9.5 mg, 20% from **21***a*); IR: 3066, 1778, 1716, 1637 cm^{-1}; ^{1}H NMR δ for **15***a*: 7.15–7.50 (5H, m, NC$_6$H$_5$), 5.25 (1H, d, J = 1.5 Hz, H-7), 3.73 (1H, d, J = 8 Hz, H-6), 3.56 (1H, m, H-4), 3.54 (3H, s, OCH$_3$), 3.26 (1H, dd, J = 2.5, 10.5 Hz, H-3$_{syn}$), 3.20 (1H, dd, J = 2.5, 8.5 Hz, H-5), 3.04 (1H, dd, J = 2.5, 10.5 Hz, H-3$_{anti}$), 1.15 (21H, m, Si(CH(CH$_3$)$_2$)$_3$); partial data for **15***b*: 5.37 (1H, d, H-7), 3.60 (3H, s, OCH$_3$), 2.79 (1H, ddd, J = 2, 2, 10 Hz, H-3$_{anti}$); ^{13}C NMR δ for **15***a*: 176.2 and 172.2 (s, imide C=O), 156.4 (s, C-8), [131.4 (s), 129.2 (d ×2), 128.6 (d), 126.6 (d ×2), NC$_6$H$_5$], 103.2 (d, C-7), 83.7 (s, C-1), 56.6 (q, OCH$_3$), 55.3 (d, C-6), 43.7 (d, C-5), 37.4 (d, C-4), 35.0 (t, C-3), 18.4 (q, Si(CH(*C*H$_3$)$_2$)$_3$), 13.5 (d, Si(*C*H(CH$_3$)$_2$)$_3$); partial data for **15***b*: 159.1 (s, C-8), 105.6 (d, C-7), 31.8 (t, C-3); MS (EI), *m/z* (relative intensity): 473 (M$^+$, 4), 440 (100).

(1S,4R*,5R*,6S*)-1-Phenylthio-8-triisopropylsilyloxy-2-thiabicyclo-[2.2.2]oct-4-ene-5,6-dicarboxylic acid imide (**16**a) and (1S*,4R*,5S*,6R*)-1-phenylthio-8-triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-4-ene-5,6-dicarboxylic acid imide (**16**b)*

A solution of **22***b* (100 mg, 0.26 mmol), **3***a* (38 mg, 0.38 mmol), and BHT (4 mg, 0.02 mmol) in CDCl$_3$ (0.5 mL) was sealed in an NMR tube and heated at 110°C. After 17 h, ^{1}H NMR revealed the absence of **22***b* and the presence of a 1.2:1 mixture[2] of *endo*:*exo* adducts **16**. The solution was concentrated and fractionated by PTLC (75% ether in hexane) to give **1***b* (15 mg, 26%) and a 2:1 mixture of **16***a*,*b* (65 mg, 53%); IR: 3217, 3066, 1777, 1715, 1625 cm^{-1}; ^{1}H NMR δ for **16***a*: 8.45 (1H, brs, NH), [7.89 (2H, m), 7.36 (3H, m), SC$_6$H$_5$], 5.20 (1H, d, J = 2 Hz, H-7), 3.47 (1H, d, J = 8.5 Hz, H-6), 3.45 (1H, m, H-4), 3.14 (1H, dd, J = 3, 10 Hz, H-3$_{syn}$), 3.05 (1H, dd, J = 2, 8.5 Hz, H-5), 2.99 (1H, dd, J = 2.5, 10 Hz, H-3$_{anti}$), 1.10 (21H, m, Si(CH(CH$_3$)$_2$)$_3$); for **16***b*: 8.68 (1H, brs, NH), [7.67 (2H, m), 7.36 (3H, m), SC$_6$H$_5$], 5.19 (1H, d, J = 2 Hz, H-7), 3.28 (4H, m, H-3$_{syn}$, 4, 5, 6), 2.78 (1H, ddd, J = 2, 2, 10 Hz, H-3$_{anti}$), 1.10 (21H, m, Si(CH(CH$_3$)$_2$)$_3$); ^{13}C NMR δ for **16***a*: 176.7 and 173.8 (s, imide C=O), 154.0 (s, C-8), [137.3 (d ×2), 129.6 (s and d), 128.7 (d ×2), SC$_6$H$_5$], 105.6 (d, C-7), 56.4 (s, C-1), 54.2 (d, C-6), 46.2 (d, C-5), 40.0 (d, C-4), 36.8 (t, C-3), 17.8 (q, Si(CH(*C*H$_3$)$_2$)$_3$), 12.4 (d, Si(*C*H(CH$_3$)$_2$)$_3$); for **16***b*: 177.0 and 174.6 (s, imide C=O), 155.5 (s, C-8), [136.4 (d ×2), 131.0, 129.1 (d), 128.9 (d ×2), SC$_6$H$_5$], 108.3 (d, C-7), 56.3 (s, C-1), 55.7 (d, C-6), 47.3 (d, C-5), 37.6 (d, C-4), 33.5 (t, C-3), 17.7 (q, Si(CH(*C*H$_3$)$_2$)$_3$), 12.2 (d, Si(*C*H(CH$_3$)$_2$)$_3$); MS (CI), *m/z* (relative intensity): 475 ([M + 1]$^+$, 12), 442 (100), 367 (43), 324 (88), 97 (89).

(1S,4R*,5R*,6S*)-*N*-Phenyl-1-phenylthio-8- triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**17**a)*

A solution of **22***b* (45 mg, 0.12 mmol), **3***b* (27 mg, 0.16 mmol), and BHT (2 mg, 0.01 mmol) in CDCl$_3$ (0.5 mL) was sealed in an NMR tube and heated at 110°C. After 17 h, ^{1}H NMR revealed the absence of **22***b* and the presence of a 2:1 mixture[2] of *endo*:*exo* adducts **17**. The solution was concentrated and fractionated by PTLC (75% ether in hexane) to give **1***b* (2 mg, 7.5%) and **17***a* (38 mg, 57%; contaminated by a small amount (ca. 5%) of a structurally related, inseparable impurity); IR: 3059, 1777, 1717, 1623 cm^{-1}; ^{1}H NMR δ: [7.89 (2H, m), 7.15–7.50 (8H, m), SC$_6$H$_5$ and NC$_6$H$_5$], 5.26 (1H, d, J = 2 Hz, H-7), 3.57 (1H, m, H-4), 3.56 (1H, d, J = 8.5 Hz, H-6), 3.22 (1H, dd, J = 3.5, 10 Hz, H-3$_{syn}$), 3.15 (1H, dd, J = 2, 8.5 Hz, H-5), 3.04 (1H, dd, J = 3, 10 Hz, H-3$_{anti}$), 1.10 (21H, m, Si(CH(CH$_3$)$_2$)$_3$); ^{13}C NMR δ: 175.8 and 172.5 (s, imide C=O), 154.0 (s, C-8), [137.4 (d ×2), 129.7 (s), 129.6 (d), 128.6 (d ×2), SC$_6$H$_5$], [131.5 (s), 128.9 (d ×2), 128.6 (d), 126.2 (d ×2), N-C$_6$H$_5$], 106.0 (d, C-7), 57.0 (s, C-1), 52.9 (d, C-6), 45.0 (d, C-5), 40.3 (d, C-4), 36.9 (t, C-3), 17.8 (q, Si(CH(*C*H$_3$)$_2$)$_3$), 12.5 (d, Si(*C*H(CH$_3$)$_2$)$_3$); MS (CI), *m/z* (relative intensity): 552 ([M + 1]$^+$, 4), 444 (32), 400 (10), 121 (100).

(1R,4R*,5R*,6S*)-8-Methyl-*N*-phenyl-1-triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**18**a)*

A solution of **23** and **22***c* (3.6:1, 28 mg, 0.098 mmol), **3***b* (17.3 mg, 0.1 mmol), and dichloromaleic anhydride (2 mg) in CDCl$_3$ (0.4 mL) was sealed in an NMR tube and heated at 100°C for 22 h. The reaction mixture was concentrated and fractionated by PTLC (75% ether in hexane) to give **21***b* (4.5 mg, 36%) and **18***a* (13.7 mg, 30% from the diene mixture); IR: 1777, 1715 cm^{-1}; ^{1}H NMR δ: [7.40 (3H, m) and 7.13 (2H, m), NC$_6$H$_5$], 6.17 (1H, brs, H-7), 3.69 (1H, d, J = 8.5 Hz, H-6), 3.46 (1H, m, H-4), 3.28 (1H, dd, J = 3.5, 10.5 Hz, H-3$_{syn}$), 3.21 (1H, dd, J = 2.5, 8.5 Hz, H-5), 2.90 (1H, dd, J = 2.5, 10.5 Hz, H-3$_{anti}$), 1.90 (3H, d, J = 1.5 Hz, CH$_3$), 1.15 (21H, m, Si(CH(CH$_3$)$_2$)$_3$); ^{13}C NMR δ: 176.8 and 172.4 (s, imide C=O), 137.7 (s, C-8), 131.8 (d, C-7), [131.8 (s), 129.2 (d ×2), 128.6 (d), 126.6 (d ×2), NC$_6$H$_5$], 81.8 (s, C-1), 55.7 (d, C-6), 44.3 (d, C-5), 38.2 (d, C-4), 35.0 (t, C-3), 20.9 (q, CH$_3$), 18.3 (q, Si(CH(*C*H$_3$)$_2$)$_3$), 13.5 (d, Si(*C*H(CH$_3$)$_2$)$_3$); MS (CI), *m/z* (relative intensity): 458 ([M + 1]$^+$, 100), 414 (86), 366 (30).

(1R,4R*,5R*,6S*)-8-Diethylphosphoryloxy-*N*-phenyl-2-thiabicyclo-[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**19**a) and (1R*,4R*,5S*,6R*)-8-diethylphosphoryloxy-*N*-phenyl-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**19**b)*

A solution of **2***d* (15 mg, 0.06 mmol), **3***b* (14 mg, 0.08 mmol), and BHT (2 mg, 0.01 mmol) in CDCl$_3$ (0.4 mL) was sealed in an NMR tube and heated at 110°C. After 70 h, ^{1}H NMR revealed the absence of **2***d* and the presence[2] of a 10:1 mixture[3] of *endo*:*exo* adducts **19**. The solution was concentrated and fractionated by PTLC (75% EtOAc in hexane) to give **19***a* (15 mg, 59%); IR: 3066, 1777, 1710, 1643, 1279, 1027 cm^{-1}; ^{1}H NMR δ: 7.15–7.50 (5H, m, NC$_6$H$_5$), 6.08 (1H, brd, J = 7.5 Hz, H-7), 4.18 (1H, dd, J = 3.5, 7.5 Hz, H-1), 4.09 (4H, m, OCH$_2$), 3.75 (1H, m, H-4), 3.58 (1H, dd, J = 3.5, 8.5 Hz, H-6), 3.16 (1H, dd, J = 2.5, 8.5 Hz, H-5), 3.15 (1H, dd, J = 3, 10.5 Hz, H-3$_{syn}$), 3.01 (1H, dd, J = 3, 10.5 Hz, H- 3$_{anti}$), 1.29 (3H, t, J = 7 Hz, CH$_3$), 1.27 (3H, t, J = 7 Hz, CH$_3$); ^{13}C NMR δ: 176.0 and 175.0 (s, imide C=O), 148.4 (s, C-8), [131.6 (s), 129.1 (d ×2), 128.6 (d), 126.6 (d ×2), NC$_6$H$_5$], 111.8 (d, C-7), 64.9 (t, OCH$_2$), 48.9 (d, C-6), 43.4 (d, C-5), 37.2 (d, C-4), 35.6 (d, C-1), 32.0 (t, C-3), 16.0 (q, CH$_3$), [C-4, 7, 8, and OCH$_2$CH$_3$ show coupling to ^{31}P, J = 4–8 Hz]; MS (CI), *m/z* (relative intensity): 441 ([M + 18]$^+$, 55), 424 ([M + 1]$^+$, 100), 249 (70), 172 (32), 155 (48); and **19***b* (ca. 2 mg, 8%); IR: 3066, 1778, 1712, 1648, 1272, 1029 cm^{-1}; ^{1}H NMR δ: 7.15–7.50 (5H, m, NC$_6$H$_5$), 6.24 (1H, brd, J = 7.5 Hz, H-7), 4.23 (4H, m, OCH$_2$), 4.12 (1H, m, H-1), 3.64 (1H, m, H-4), 3.30 (2H, m, H-5, 6), 3.20 (1H, dd, J = 3, 11 Hz, H-3$_{syn}$), 2.80 (1H, brd, J = 11 Hz, H-3$_{anti}$), 1.39 (6H, brt, J = 7 Hz, CH$_3$); MS (EI), *m/z* (relative intensity): 423 (M$^+$, 10), 249 (100), 155 (67), 127 (58).

(1R,4R*,5R*,6S*)-8-Diethylphosphoryloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid anhydride (**20**a)*

A solution of **2***d* (25 mg, 0.1 mmol), **3***c* (15 mg, 0.15 mmol), and BHT (3 mg, 0.015 mmol) in CDCl$_3$ (0.4 mL) was sealed in an NMR tube and heated at 110°C. After 56 h, ^{1}H NMR revealed the absence of **2***d* and the presence[2] of **1***a* (ca. 10%) and a 6:1 mixture[3] of *endo*:*exo* adducts **20** (ca. 80%). The solution was concentrated and fractionated by PTLC (75% EtOAc in hexane) to give **20***a* (4.4 mg, 12%); IR: 3066, 1866, 1778, 1642, 1278, 1030 cm^{-1}; ^{1}H NMR δ: 6.10 (1H, ddd, J = 1.5, 1.5, 7.5 Hz, H-7), 4.16 (5H, m, OCH$_2$, and

H-1), 3.75 (1H, m, H-4), 3.71 (1H, dd, J = 3.5, 9 Hz, H-6), 3.27 (1H, dd, J = 2.5, 9 Hz, H-5), 3.10 (1H, dd, J = 3, 10.5 Hz, H-3_{syn}), 3.00 (1H, dd, J = 3, 10.5 Hz, H-3_{anti}), 1.36 (3H, dt, J = 1, 7 Hz, CH_3), 1.35 (3H, dt, J = 1, 7 Hz, CH_3); ^{13}C NMR δ: 170.8 and 169.5 (s, anhydride C=O), 148.5 (s, C-8), 112.4 (d, C-7), 65.1 (t, OCH_2), 49.4 (d, C-6), 44.0 (d, C-5), 36.9 (d, C-4), 34.9 (d, C-1), 31.3 (t, C-3), 16.0 (q, CH_3), [C-4, 7, 8, and OCH_2CH_3 show coupling to ^{31}P, J = 4–8 Hz]; MS (CI), *m/z* (relative intensity): 366 ([M + 18]$^+$, 100), 349 ([M + 1]$^+$, 56), 249 (24), 172 (16), 155 (45).

*4-Methoxy-*2H*-thiopyran-6(*3H,6H*)-one (**21***a*)*

A solution of methyl phenacyl sulfide (26) (166 mg, 1 mmol) in benzene (14 mL) was deaerated by bubbling argon through for 10 min. 1,3-Dimethoxy-1-trimethylsilyloxy-1,3-butadiene (17) (505 mg, 2.5 mmol) was added and the solution was irradiated in a Rayonette reactor (305 nm) through a 5% $CuSO_4$ filter at ca. 10–15°C for 4 h (14*a*). Concentration and fractionation by FCC (75% ether in hexane) gave **21***a* as an oil (72 mg, 50%); IR: 3032, 1737, 1627, 1611 cm^{-1}; ^{1}H NMR δ: 5.42 (1H, s, H-5), 3.68 (3H, s, OCH_3), 3.12 (2H, m, H-2), 2.66 (2H, m, H-3); ^{13}C NMR δ: 190.4 (s, C-6), 175.6 (s, C-4), 101.6 (d, C-5), 55.7 (q, OCH_3), 29.1 (t, C-3), 26.3 (t, C-2); MS (EI), *m/z* (relative intensity): 144 (M$^+$, 10), 86 (60), 84 (100).

*4-Methoxy-6-triisopropylsilyloxy-*2H*-thiopyran (**22**a)*

Butyllithium (0.092 mL, 2.18 M in hexanes, 0.2 mmol) was added dropwise to a solution of diisopropylamine (0.034 mL, 0.25 mmol) in THF (1 mL) at 0°C. After stirring at 0°C for 10 min, the solution was cooled to −78°C and a solution of **21***a* (14.4 mg, 0.1 mmol) in THF (1 mL) was added dropwise via syringe. After stirring for 1 h, TIPSOTf (0.06 mL, 0.22 mmol) was added and the reaction mixture was stirred for 0.5 h at −78°C and for an additional 4 h with the cooling bath removed. The reaction mixture was diluted with ether, washed with 5% Na_2CO_3, dried over $MgSO_4$, and concentrated to give the unstable **22***a* as an oil (40 mg, ca. 80% pure by ^{1}H NMR, main contaminant is **21***a*); ^{1}H NMR δ: 5.36 (1H, d, J = 1.5 Hz, H-5), 4.33 (1H, dt, J = 1.5, 5.5 Hz, H-3), 3.54 (3H, s, OCH_3), 3.49 (2H, d, J = 5.5 Hz, H-2), 1.15 (21H, m, $Si(CH(CH_3)_2)_3$).

*6-Phenylthio-4-triisopropylsilyloxy-*2H*-thiopyran (**22**b)*

Prepared from **1***b* according to the general procedure for the preparation of silyloxy dienes outlined above. The neat diene decomposes rapidly and is thus used immediately in the next step. ^{1}H NMR δ: 7.41 (5H, m, SC_6H_5), 6.09 (1H, d, J = 1.5 Hz, H-5), 4.78 (1H, dt, J = 1.5, 5.5 Hz, H-3), 3.36 (2H, d, J = 5.5 Hz, H-2), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$).

*4-Methyl-6-triisopropylsilyloxy-*2H*-thiopyran (**22**c) and 3,4-dihydro-4-methylene-6-triisopropylsilyloxy-*2H*-thiopyran (**23**)*

Treatment of **21***b* (prepared in 65% yield by the method of Vedejs *et al.* (14*a*)) according to the general procedure for the preparation of silyloxy dienes outlined above gave a 3.6:1 mixture of **23** and **22***c*; ^{1}H NMR δ for **23**: 5.75 (1H, s, H-5), [4.63 (1H, m) and 4.57 (1H, m), C=CH_2], 2.92 (2H, m, H-2), 2.58 (2H, m, H-3), 1.15 (21H, m, $Si(CH(CH_3)_2)_3$); for **22***c*: 5.42 (1H, s, H-5), 5.03 (1H, tq, J = 4, 1.5 Hz, H-3), 3.36 (2H, dq, J = 4, 1.5 Hz, H-2), 1.75 (3H, dt, J = 1.5, 1.5 Hz, CH_3), 1.15 (21H, m, $Si(CH(CH_3)_2)_3$).

General procedure for reactions of 2c *with* **24**

The distilled dienophile (0.67 mmol) was added to a solution of **2***c* (68 mg, 0.25 mmol) in toluene-d_8 (0.5 mL, filtered through neutral alumina) in a 5-mm NMR tube. The tube was evacuated, sealed, and heated at 120°C. Reaction was monitored by ^{1}H NMR and when the diene was consumed the tube was opened and the reaction mixture fractionated by FCC (25% EtOAc in hexane). The ratio of *endo*:*exo* adducts[2] did not change significantly over the course of the reaction.

Reaction with **24**a

A mixture[3] of **25***a,b* (2.3:1, 35 mg, 41%) was obtained after 168 h. Pure samples of **25***a* and **25***b* were obtained by PTLC (30% CH_2Cl_2 in hexane, five elutions).

*(1*R*,4R*,6S*)-6-Acetyl-8-triisopropylsilyloxy-2-thiabicyclo[2.2.2]-oct-7-ene (**25**a)*: IR: 3054, 1712, 1636 cm^{-1}; ^{1}H NMR δ: 5.24 (1H, dd, J = 2, 7.5 Hz, H-7), 3.89 (1H, dd, J = 2.5, 7.5 Hz, H-1), 3.15 (1H, ddd, J = 2.5, 4, 10 Hz, H-6), 3.01 (1H, dd, J = 3, 9.5 Hz, H-3_{syn}), 2.97 (1H, m, H-4), 2.78 (1H, dt, J = 9.5, 2 Hz, H-3_{anti}), 2.14 (1H, m, H-5_{endo}) [coupled with H-3_{anti}, J = 2 Hz], 2.13 (3H, s, $COCH_3$), 1.79 (1H, ddd, J = 1.5, 10, 13.5 Hz, H-5_{exo}), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 206.4 (s, $COCH_3$), 156.1 (s, C-8), 103.1 (d, C-7), 56.7 (d, C-6), 36.9 and 36.8 (d, C-1, 4), 33.3 (t, C-3), 27.8 (q, $COCH_3$), 26.7 (t, C-5), 17.9 (q, $Si(CH(CH_3)_2)_3$), 12.5 (d, $Si(CH(CH_3)_2)_3$); MS (EI), *m/z* (relative intensity): 340 (M$^+$, 35), 293 (79), 227 (26), 157 (30), 115 (54), 59 (100).

(1S,4R*,6R*)-8-Triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-6-carbonitrile (27b)*: IR: 3060, 2238, 1638 cm^{-1}; ^1H NMR δ: 5.37 (1H, dd, J = 2, 8 Hz, H-7), 3.70 (1H, dd, J = 2.5, 8 Hz, H-1), 3.12 (1H, dd, J = 3.5, 10 Hz, H-3_{syn}), 2.93 (1H, m, H-4), 2.89 (1H, ddd, J = 2.5, 6, 11.5 Hz, H-6), 2.81 (1H, dt, J = 10, 2.5 Hz, H-3_{anti}), 2.08 (1H, dddd, J = 2.5, 4.5, 11.5, 13.5 Hz, H-5_{endo}), 1.89 (1H, ddd, J = 1.5, 6, 13.5 Hz, H-5_{exo}), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 155.8 (s, C-8), 121.8 (s, CN), 104.3 (d, C-7), 37.9 and 35.8 (d, C-1, 4), 34.0 (t, C-3), 33.9 (d, C-6), 28.7 (t, C-5), 17.9 (q, $Si(CH(CH_3)_2)_3$), 12.5 (d, $Si(CH(CH_3)_2)_3$); MS (EI), *m/z* (relative intensity): 323 (M^+, 67), 323 (31), 227 (43), 147 (71), 59 (100).

(1R,4R*,5R*,6R*)-8-Triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid, dimethyl esther (28) and (1R*,4R*,5S*,6S*)-8-triisopropylsilyloxy-2-thiabicyclo[2.2.2]-oct-7-ene-5,6-dicarboxylic acid, dimethyl ester (29)*

A solution of **2***c* (68 mg, 0.25 mmol) and dimethyl fumarate (144 mg, 1 mmol) in toluene-d_8 (0.5 mL) was sealed in an NMR tube and heated at 120°C for 168 h. Fractionation by FCC (25% EtOAc in hexane) gave a 2.5:1 mixture of the adducts **28** and **29** (13 mg, 12%) as an oil; IR: 3060, 1738, 1639 cm^{-1}; ^1H NMR (C_6D_6) δ for **28**: 5.28 (1H, dd, J = 2, 7.5 Hz, H-7), 3.98 (1H, dd, J = 3, 8 Hz, H-1), 3.62 (1H, dd, J = 3, 5.5 Hz, H-6), 3.58 (1H, dd, J = 1.5, 5.5 Hz, H-5), 3.42 (3H, s, OCH_3), 3.36 (3H, s, OCH_3), 3.31 (1H, m, H-4), 2.79 (1H, dd, J = 3, 10.5 Hz, H-3_{syn}), 2.61 (1H, dd, J = 3, 10.5 Hz, H-3_{anti}), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); for **29**: 5.27 (1H, dd, J = 2, 7.5 Hz, H-7), 4.08 (1H, dd, J = 2.5, 5 Hz, H-6), 4.00 (1H, dd, J = 2.5, 7.5 Hz, H-1), 3.67 (1H, ddd, J = 1.5, 4.5, 5 Hz, H-5), 3.52 (1H, m, H-4), 3.30 (3H, s, OCH_3), 3.28 (3H, s, OCH_3), 3.08 (1H, dd, J = 3, 11 Hz, H-3_{syn}), 2.64 (1H, ddd, J = 1.5, 2.5, 11 Hz, H-3_{anti}), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ for **28**: 173.5 and 172.1 (s, $COOCH_3$), 154.4 (s, C-8), 104.6 (d, C-7), 52.3 (q ×2, OCH_3), 51.0 (d, C-6), 43.9 (d, C-5), 39.4 and 38.0 (d, C-1, 4), 33.1 (t, C-3), 17.9 (q, $Si(CH(CH_3)_2)_3$), 12.5 (d, $Si(CH(CH_3)_2)_3$); for **29**: 172.6 and 173.3 (s, $COOCH_3$), 156.0 (s, C-8), 103.5 (d, C-7), 52.2 (q ×2, OCH_3), 50.7 (d, C-6), 44.1 (d, C-5), 39.2 and 37.1 (d, C-1, 4), 28.3 (t, C-3), 17.9 (q, $Si(CH(CH_3)_2)_3$), 12.5 (d, $Si(CH(CH_3)_2)_3$); MS (EI), *m/z* (relative intensity): 414 (M^+, 58), 371 (58), 309 (41), 227 (64), 59 (100).

An identical experiment carried out with dimethyl maleate for 226 h gave a 1.2:1 mixture of the *trans* adducts **28** and **29** (30 mg, 29%). Dimethyl maleate isomerizes to dimethyl fumarate under the reaction conditions (^1H NMR).

3,5-Bis(triisopropylsilyloxy)-2H-thiopyran (30)

Prepared from 2*H*-thiopyran-3,5(4*H*,6*H*)-dione (**31**) (18) according to the general procedure for the preparation of silyloxy dienes outlined above using twice the amount of reagents; IR: 3061, 1631 cm^{-1}; ^1H NMR δ: 5.13 (1H, d, J = 0.5 Hz, H-4), 4.97 (1H, d, J = 0.5 Hz, H-6), 3.21 (2H, s, H-2), 1.10 (42H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 149.5 and 148.2 (s, C-3, 5), 104.5 (d, C-4), 88.7 (d, C-6), 29.2 (t, C-2), 17.8 (q, $Si(CH(CH_3)_2)_3$), 12.5 (d, $Si(CH(CH_3)_2)_3$); MS (EI), *m/z* (relative intensity): 442 (M^+, 100), 399 (16), 286 (20), 243 (24), 115 (37), 87 (38), 73 (53), 59 (95).

3-Triisopropylsilyloxy-2H-thiopyran (33a) and 5-triisopropylsilyloxy-2H-thiopyran (34a)

Butyllithium (0.082 mL, 2.18 M in hexanes, 0.18 mmol) was added dropwise to a solution of diisopropylamine (0.030 mL, 0.22 mmol) in THF (18 mL) at 0°C. After stirring at 0°C for 10 min, the solution was cooled to −78°C and a solution of **32** (20) (15.2 mg, 0.13 mmol) in THF (1 mL) was added dropwise via syringe. After stirring for 1 h, TIPSOTf (0.038 mL, 0.14 mmol) was added and the reaction mixture was stirred for 0.5 h at −78°C and saturated $NaHCO_3$ (ca. 1 mL) was added. The reaction mixture was diluted with CH_2Cl_2, washed with saturated $NaHCO_3$, dried over Na_2SO_4, concentrated, and fractionated by FCC (hexane, SiO_2 was pretreated with Et_3N) to give a 2:1–4:1 mixture of **34***a* and **33***a* as an oil (31 mg, 85%). Alternatively, treatment of **32** with TIPSOTf according to the general procedure for the preparation of silyloxy dienes outlined above gave a 1:4 mixture of **34***a* and **33***a*. The above mixtures were used in Diels–Alder reactions without further purification. Pure samples of the individual dienes were obtained by PTLC (hexane, two elutions).

For **33***a*: IR: 3059, 3026, 1631, 1555 cm^{-1}; ^1H NMR δ: 5.99 (1H, dd, J = 6.5, 9 Hz, H-5), 5.78 (1H, d, J = 9 Hz, H-6), 5.26 (1H, d, J = 6.5 Hz, H-4), 3.32 (2H, s, H-2), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 144.7 (s, C-3), 122.4 (d, C-5), 111.5 (d, C-6), 103.1 (d, C-4), 28.7 (t, C-2), 17.9 (q, $Si(CH(CH_3)_2)_3$), 12.6 (d, $Si(CH(CH_3)_2)_3$); MS (EI), *m/z* (relative intensity): 270 (M^+, 84), 227 (83), 115 (71), 87 (61), 59 (100).

For **34***a*: IR: 3036, 1626, 1547 cm^{-1}; ^1H NMR δ: 5.84 (1H, dm, H-4), 5.73 (1H, ddt, J = 0.5, 10, 5 Hz, H-3), 5.36 (1H, brs, H-6), 3.13 (2H, dm, J = 5 Hz, H-2), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 147.4 (s, C-5), 127.3 (d, C-4), 119.0 (d, C-3), 98.3 (d, C-6), 23.9 (t, C-2), 17.9 (q, $Si(CH(CH_3)_2)_3$), 12.5 (d, $Si(CH(CH_3)_2)_3$); MS (EI), *m/z* (relative intensity): 270 (M^+, 93), 227 (100), 97 (72), 59 (53).

3-Diethylphosphoryloxy-2H-thiopyran (33b) and 5-diethylphosphoryloxy-2H-thiopyran (34b)

Using the procedure described for the preparation of **2***d*, **32** (75 mg, 0.65 mmol) gave after fractionation by FCC (17% EtOAc in ether) **33***b* (14.2 mg, 9%); IR: 3052, 1647, 1278, 1029 cm^{-1}; ^1H NMR δ: 6.02 (2H, m, H-5, 6), 5.86 (1H, m, H-4), 4.21 (4H, dq, J = 8, 7 Hz, OCH_2), 3.49 (2H, brs, H-2), 1.38 (6H, dt, J = 1, 7 Hz, CH_3); MS (CI), *m/z* (relative intensity): 268 ($[M + 18]^+$, 52), 251 ($[M + 1]^+$, 100), 96 (64); and **34***b* (66.8 mg, 40%); IR: 3049, 1626, 1273, 1030 cm^{-1}; ^1H NMR δ: 5.98 (1H, brs, H-6), 5.91 (1H, d, J = 10 Hz, H-4), 5.68 (1H, dt, J = 10, 5.5 Hz, H-3), 4.12 (4H, dq, J = 8, 7 Hz, OCH_2), 3.20 (2H, dd, J = 1, 5.5 Hz, H-2), 1.35 (6H, t, J = 7 Hz, CH_3); ^{13}C NMR δ: 142.3 (s, C-5), 124.2 (d, C-4), 118.6 (d, C-3), 107.0 (d, C-6), 64.5 (t, OCH_2), 23.8 (t, C-2), 16.1 (q, CH_3), [C-4, 5, 6, and OCH_2CH_3 show coupling to ^{31}P, J = 4–8 Hz]; MS (CI), *m/z* (relative intensity): 268 ($[M + 18]^+$, 66), 251 ($[M + 1]^+$, 100), 155 (22), 96 (25).

(1S,4R*,5S*,6S*)-4,7-Bis(triisopropylsilyloxy)-2-thiabicyclo[2.2.2]-oct-7-ene-5,6-dicarboxylic acid imide (35a) and (1S*,4R*,5R*,6R*)-4,7-bis(triisopropylsilyloxy)-2-thiabicyclo-[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (35b)*

A solution of **30** (446 mg, 1 mmol) and **3***a* (97 mg, 1.3 mmol) in toluene (6 mL) was heated under reflux under Ar for 127 h. The reaction mixture was concentrated and fractionated by FCC (20% EtOAc in hexane) to give a mixture[3] of **35***a,b* (3:1, 270 mg, 50%); IR: 3209, 3078, 1782, 1718, 1631 cm^{-1}; ^1H NMR δ for **35***a*: 8.02 (1H, brs, NH), 4.93 (1H, d, J = 2 Hz, H-8), 3.68 (1H, dd, J = 2, 3.5 Hz, H-1), 3.46 (1H, dd, J = 3.5, 8.5 Hz, H-6), 2.96 (1H, d, J = 9.5 Hz, H-3_{syn}), 2.92 (1H, d, J = 8.5 Hz, H-5), 2.77 (1H, d, J = 9.5 Hz, H-3_{anti}), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); for **35***b*: 8.18 (1H, brs, NH), 5.12 (1H, d, J = 2 Hz, H-8), 3.58 (1H, dd, J = 2, 4 Hz, H-1), 3.39 (1H, dd, J = 4, 10 Hz, H-6), 3.16 (1H, d, J = 10 Hz, H-3_{syn}), 2.97 (1H, dd, J = 2, 10 Hz, H-5), 2.65 (1H, dd, J = 2, 10 Hz, H-3_{anti}), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ for **35***a*: 175.5 and 174.5 (s, imide C=O), 152.5 (s, C-7), 104.5 (d, C-8), 77.1 (s, C-4), 51.0 and 50.8 (d, C-5, 6), 39.5 (t, C-3), 37.8 (d, C-1), 18.3 and 17.8 (q, $Si(CH(CH_3)_2)_3$), 13.4 and 12.5 (d, $Si(CH(CH_3)_2)_3$); for **35***b*: 176.2 and 175.4 (s, imide C=O), 153.8 (s, C-7), 108.3 (d, C-8), 76.2 (s, C-4), 52.2 and 50.7 (d, C-5, 6), 38.4 (d, C-1), 36.4 (t, C-3), 18.2 and 17.8 (q, $Si(CH(CH_3)_2)_3$), 13.4 and 12.5 (d, $Si(CH(CH_3)_2)_3$); MS (CI), *m/z* (relative intensity): 540 ($[M + 1]^+$, 100), 496 (61), 384 (22), 340 (43), 148 (49).

(1S,4R*,5S*,6S*)-N-Phenyl-4,7-bis(triisopropylsilyloxy)-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (36a) and (1S*,4R*,5R*,6R*)-N-phenyl-4,7-bis(triisopropylsilyloxy)-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (36b)*

A solution of **30** (380 mg, 0.86 mmol) and **3***b* (175 mg, 1 mmol) in toluene (6 mL) was heated under reflux under Ar for 78 h. The reaction mixture was concentrated and fractionated by FCC (10% EtOAc in hexane) to give a mixture[3] of **36***a,b* (2:1, 365 mg, 69%). Pure samples of **36***a* and **36***b* were obtained by PTLC (10% ether in hexane, three elutions).

For personal use only.

For **36***a*: IR: 3045, 1779, 1719, 1631 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, C_6H_5), 4.99 (1H, d, J = 2 Hz, H-8), 3.81 (1H, dd, J = 2, 3.5 Hz, H-1), 3.58 (1H, dd, J = 3.5, 8.5 Hz, H-6), 3.05 (1H, d, J = 8.5 Hz, H-5), 3.05 (1H, d, J = 9 Hz, H-3_{syn}), 2.82 (1H, d, J = 9 Hz, H-3_{anti}), 1.10 (42H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 174.4 and 173.4 (s, imide C═O), 152.7 (s, C-7), [131.9 (s), 129.0 (d ×2), 128.4 (d), 126.4 (d ×2), N-C_6H_5], 104.6 (d, C-8), 77.4 (s, C-4), 49.8 and 49.7 (d, C-5, 6), 39.9 (t, C-3), 38.1 (d, C-1), 18.3 and 17.9 (q, $Si(CH(CH_3)_2)_3$), 13.5 and 12.5 (d, $Si(CH(CH_3)_2)_3$); MS (CI), *m/z* (relative intensity): 616 ($[M + 1]^+$, 100), 572 (93), 442 (31), 148 (87).

For **36***b*: IR: 3062, 1780, 1719, 1633 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, C_6H_5), 5.18 (1H, d, J = 2 Hz, H-8), 3.73 (1H, dd, J = 2, 3.5 Hz, H-1), 3.49 (1H, dd, J = 3.5, 10 Hz, H-6), 3.19 (1H, d, J = 10 Hz, H-3_{syn}), 3.12 (1H, dd, J = 2, 10 Hz, H-5), 2.68 (1H, dd, J = 2, 10 Hz, H-3_{anti}), 1.10 (42H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 175.3 and 174.4 (s, imide C═O), 154.0 (s, C-7), [131.7 (s), 129.2 (d ×2), 128.7 (d), 126.7 (d ×2), N-C_6H_5], 108.6 (d, C-8), 76.5 (s, C-4), 51.1 and 49.4 (d, C-5, 6), 39.3 (d, C-1), 36.6 (t, C-3), 18.3 and 17.7 (q, $Si(CH(CH_3)_2)_3$), 13.4 and 12.6 (d, $Si(CH(CH_3)_2)_3$); MS (CI), *m/z* (relative intensity): 616 ($[M + 1]^+$, 100), 572 (61), 442 (26), 148 (33).

(1S,4S*,5R*,6S*)-*N*-Phenyl-7-triisopropylsilyloxy-2-thiabicyclo-[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**37**a) and (1R*,4R*,5S*,6S*)-*N*-phenyl-4-triisopropylsilyloxy-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**38**a)*

A solution of **34***a* and **33***a* (2:3, 49 mg, 0.18 mmol) and **3***b* (29 mg, 0.17 mmol) in toluene-d_8 (0.5 mL) was sealed in an NMR tube and heated at 110°C. After 24 h the ^1H NMR spectrum of the reaction mixture revealed the absence of **34***a*. The reaction mixture was concentrated and fractionated by FCC (20% EtOAc in hexane) to give **33***a* (21 mg, 42%), **32** (2 mg, 4%), and **37***a* (19 mg, 57% from **34***a*); IR: 3060, 3030, 1780, 1710, 1637 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, C_6H_5), 4.98 (1H, dd, J = 2, 7.5 Hz, H-8), 3.87 (1H, dd, J = 2, 3.5 Hz, H-1), 3.67 (1H, dq, J = 7.5, 2.5 Hz, H-4), 3.55 (1H, dd, J = 3.5, 8.5 Hz, H-6), 3.11 (1H, dd, J = 2.5, 10 Hz, H-3_{syn}), 3.01 (1H, dd, J = 2.5, 8.5 Hz, H-5), 2.70 (1H, dd, J = 3, 10 Hz, H-3_{anti}), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 177.4 and 175.0 (s, imide C═O), 154.5 (s, C-7), [131.7 (s), 129.0 (d ×2), 128.6 (d), 126.3 (d ×2), N-C_6H_5], 98.9 (d, C-8), 48.9 (d, C-6), 43.6 (d, C-5), 38.7 (d, C-1), 34.1 (d, C-4), 33.8 (t, C-3), 17.9 (q, $Si(CH(CH_3)_2)_3$), 12.5 (d, $Si(CH(CH_3)_2)_3$); MS (EI), *m/z* (relative intensity): 443 (M^+, 6), 400 (100), 227 (42).

A solution of **33***a* (21 mg, 0.078 mmol) and **3***b* (14 mg, 0.08 mmol) in toluene-d_8 (0.5 mL) was sealed in an NMR tube and heated at 110°C. After 120 h the ^1H NMR spectrum revealed the absence of **33***a*. The reaction mixture was concentrated and fractionated by FCC (20% EtOAc in hexane) to give **38***a* (5 mg, 14%, contaminated (ca. 5%) with a structurally related inseparable impurity); IR: 3055, 1779, 1716 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, C_6H_5), 6.47 (1H, dd, J = 6.5, 9 Hz, H-7), 6.25 (1H, dd, J = 9 Hz, H-8), 3.99 (1H, dd, J = 3, 6.5 Hz, H-1), 3.66 (1H, dd, J = 3, 8.5 Hz, H-6), 3.12 (1H, d, J = 8.5 Hz, H-5), 3.08 (1H, d, J = 9.5 Hz, H-3_{syn}), 2.77 (1H, d, J = 9.5 Hz, H-3_{anti}), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 175.1 and 173.1 (s, imide C═O), 135.4 and 130.6 (d, C-7, 8), [131.8 (s), 129.2 (d ×2), 128.7 (d), 126.5 (d ×2), N-C_6H_5], 75.7 (s, C-4), 50.3 and 48.8 (d, C-5, 6), 38.5 (t, C-3), 32.7 (d, C-1), 18.3 (q, $Si(CH(CH_3)_2)_3$), 13.5 (d, $Si(CH(CH_3)_2)_3$); MS (CI), *m/z* (relative intensity): 444 ($[M + 1]^+$, 100), 400 (59).

(1S,4S*,5R*,6S*)-7-Diethylphosphoryloxy-*N*-phenyl-2-thiabicyclo-[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**39**a) and (1S*,4S*,5S*,6R*)-7-diethylphosphoryloxy-*N*-phenyl-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**39**b)*

A solution of **34***b* (19 mg, 0.076 mmol) and **3***b* (26 mg, 0.15 mmol) in $CDCl_3$ (0.4 mL) was sealed in an NMR tube and heated at 110°C. After 51 h, ^1H NMR revealed the absence of **34***b* and the presence[2] of a 10:1 mixture[3] of *endo*:*exo* adducts **39**. The solution was concentrated and fractionated by PTLC (75% EtOAc in ether) to give **39***a* (25 mg, 77%); IR: 3066, 1777, 1710, 1642, 1282, 1027 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, NC_6H_5), 5.78 (1H, brd, J = 7.5 Hz, H-8), 4.13 (4H, m, OCH_2), 4.02 (1H, m, H-1), 3.80 (1H, dddd, J = 2.5, 3, 3, 7.5 Hz, H-4), 3.58 (1H, dd, J = 3.5, 8.5 Hz, H-6), 3.13 (1H, dd, J = 3, 10.5 Hz, H-3_{syn}), 3.05 (1H, dd, J = 3, 8.5 Hz, H-5), 2.77 (1H, dd, J = 3, 10.5 Hz, H-3_{anti}), 1.31 (3H, t, J = 7 Hz, CH_3), 1.21 (3H, t, J = 7 Hz, CH_3); ^{13}C NMR δ: 176.6 and 174.6 (s, imide C═O), 149.2 (s, C-7), [131.6 (s), 129.2 (d ×2), 128.9 (d), 126.6 (d ×2), NC_6H_5], 107.1 (d, C-8), 64.8 (t, OCH_2), 49.0 (d, C-6), 43.1 (d, C-5), 36.7 (d, C-1), 34.0 (d, C-4), 32.8 (t, C-3), 16.0 (q, CH_3), [C-1, 7, 8 and OCH_2CH_3 show coupling to ^{31}P, J = 4–8 Hz]; MS (EI), *m/z* (relative intensity): 423 (M^+, 35), 377 (20), 250 (91), 230 (83), 104 (100); and **39***b* (ca. 2 mg, 6%); IR: 1778, 1712, 1648, 1278, 1029 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, NC_6H_5), 6.00 (1H, ddd, J = 1.5, 2, 8 Hz, H-8), 4.23 (4H, m, OCH_2), 4.00 (1H, dd, J = 2, 4 Hz, H-1), 3.71 (1H, dddd, J = 2.5, 3, 5, 8 Hz, H-4), 3.49 (1H, dd, J = 4, 10 Hz, H-6), 3.18 (1H, dd, J = 3, 11 Hz, H-3_{syn}), 3.06 (1H, ddd, J = 1.5, 5, 10 Hz, H-5), 2.77 (1H, ddd, J = 1.5, 2.5, 11 Hz, H-3_{anti}), 1.40 (3H, t, J = 7 Hz, CH_3), 1.39 (3H, t, J = 7 Hz, CH_3); MS (EI), *m/z* (relative intensity): 423 (M^+, 14), 377 (6), 250 (36), 249 (39), 29 (100).

(1R,4S*,5S*,6S*)-4-Diethylphosphoryloxy-*N*-phenyl-2-thiabicyclo-[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**40**a) and (1R*,4S*,5R*,6R*)-4-diethylphosphoryloxy-*N*-phenyl-2-thiabicyclo[2.2.2]oct-7-ene-5,6-dicarboxylic acid imide (**40**b)*

A solution of **33***b* (18 mg, 0.072 mmol) and **3***b* (20.8 mg, 0.12 mmol) in $CDCl_3$ (0.4 mL) was sealed in an NMR tube and heated at 110°C. After 270 h, ^1H NMR revealed the presence[2] of a >10:1 mixture of *endo*:*exo* adducts **40**. The solution was concentrated and fractionated by PTLC (33% EtOAc in ether) to give **33***b* (4 mg, 22%), the *endo* adduct **40***a* (15 mg, 50%); IR: 3065, 1778, 1714, 1597, 1279, 1033 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, NC_6H_5), 6.52 (1H, dd, J = 7, 9 Hz, H-7), 6.41 (1H, d, J = 9 Hz, H-8), 4.10–4.40 (4H, m, OCH_2), 4.01 (1H, dd, J = 3, 7 Hz, H-1), 3.87 (1H, d, J = 8 Hz, H-5), 3.68 (1H, dd, J = 3, 8 Hz, H-6), 3.60 (1H, d, J = 10 Hz, H-3_{syn}), 3.00 (1H, d, J = 10 Hz, H-3_{anti}), 1.36 (3H, t, J = 7 Hz, CH_3), 1.35 (3H, t, J = 7 Hz, CH_3); ^{13}C NMR δ: 174.5 and 173.0 (s, imide C═O), 132.0 (s, C-8), [131.6 (s), 129.2 (d ×2), 128.9 (d), 126.5 (d ×2), NC_6H_5], 131.1 (d, C-7), 80.7 (s, C-4), 64.7 and 64.2 (t, OCH_2), 49.6 (d, C-6), 45.8 (d, C-5), 34.0 (t, C-3), 33.1 (d, C-1), 16.1 (q, CH_3), [C-4, 5, 8 and OCH_2CH_3 show coupling to ^{31}P, J = 4–8 Hz]; MS (CI), *m/z* (relative intensity): 424 ($[M + 1]^+$, 100), 250 (29), 155 (30); and **40***b* (ca. 1.5 mg, 5%); IR: 1778, 1713, 1499, 1272, 1030 cm^{-1}; ^1H NMR δ: 7.15–7.50 (5H, m, NC_6H_5), 6.74 (1H, d, J = 9 Hz, H-8), 6.64 (1H, dd, J = 7, 9 Hz, H-7), 4.05–4.40 (4H, m, OCH_2), 4.00 (1H, dd, J = 3.5, 7 Hz, H-1), 3.89 (1H, dd, J = 2, 10 Hz, H-5), 3.39 (1H, dd, J = 3.5, 10 Hz, H-6), 3.35 (1H, d, J = 10 Hz, H-3_{syn}), 2.81 (1H, dd, J = 2, 10 Hz, H-3_{anti}), 1.37 (6H, m, CH_3); MS (EI), *m/z* (relative intensity): 424 ($[M + 1]^+$, 100), 250 (52), 155 (89).

(1S,4R*,5S*)-5-Acetyl-4-triisopropylsilyloxy-2-thiabicyclo[2.2.2]-octan-7-one (**43**) and (1S*,4R*,5R*)-5-acetyl-4-triisopropylsilyloxy-2-thiabicyclo[2.2.2]octan-7-one (**44**)*

A solution of **30** (110 mg, 0.25 mmol) and **24***a* (70 mg, 1 mmol) in toluene-d_8 (0.5 mL) was sealed in an NMR tube and heated at 110°C for 240 h. The reaction mixture was concentrated and fractionated by FCC (20% EtOAc in hexane) to give a mixture[2] of **41** and **42** (8:1, 18 mg, 14%) and **44** (5 mg, 5.6%). Attempted separation of **41** and **42** (PTLC, 10% EtOAc in hexane, three elutions) resulted in the isolation of **43**.

For **41** and **42** (8:1); ^1H NMR δ for **41**: 4.96 (1H, d, J = 1 Hz, H-8), 3.23 (1H, m, H-1), 3.05 (1H, dd, J = 6, 10 Hz, H-5), 2.96 (1H, d, J = 9 Hz, H-3_{syn}), 2.74 (1H, d, J = 9 Hz, H-3_{anti}), 2.26 (1H, ddd, J = 3, 10, 13 Hz, H-6_{exo}), 2.18 (3H, s, $COCH_3$), 2.01 (1H, ddd, J = 3, 6, 13 Hz, H-6_{endo}), 1.15 (42H, m, $Si(CH(CH_3)_2)_3$); partial data for **42**: 5.19 (1H, br, H-8), 2.31 (3H, s, $COCH_3$).

For **43**; IR: 1729, 1716 cm^{-1}; ^1H NMR δ: 3.30 (1H, ddd, J = 2, 6.5, 10.5 Hz, H-5), 3.14 (1H, dd, J = 2, 18 Hz, H-8_{endo}), 3.00 (1H, dd, J = 3, 3.5 Hz, H-1), 2.93 (1H, d, J = 9.5 Hz, H-3_{anti}), 2.88 (1H, dd, J = 2, 9.5 Hz, H-3_{syn}), 2.57 (1H, dd, J = 2, 18 Hz, H-8_{exo}), 2.46

(1H, ddd, J = 3, 6.5, 14 Hz, H-6$_{endo}$), 2.39 (1H, ddd, J = 3.5, 10.5, 14 Hz, H-6$_{exo}$), 2.30 (3H, s, $COCH_3$), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 210.8 (s, C-7), 201.2 (s, $COCH_3$), 75.6 (s, C-4), 52.1 (d, C-5), 46.5 (t, C-8), 40.5 (d, C-1), 36.0 (t, C-3), 34.3 (q, $COCH_3$), 30.4 (t, C-5), 18.2 (q, $Si(CH(CH_3)_2)_3$), 13.4 (d, $Si(CH(CH_3)_2)_3$); MS (CI), *m/z* (relative intensity): 374 ($[M + 18]^+$, 100), 357 ($[M + 1]^+$, 46), 313 (63).

For **44**; IR: 1719 cm^{-1}; ^1H NMR δ: 3.39 (1H, dd, J = 2, 10 Hz, H-3$_{syn}$), 3.10 (1H, ddd, J = 2, 7.5, 11 Hz, H-5), 3.01 (1H, d, J = 18 Hz, H-8$_{exo}$), 2.98 (1H, dd, J = 2, 4.5 Hz, H-1), 2.67 (1H, dd, J = 2, 10 Hz, H-3$_{anti}$), 2.60 (1H, ddd, J = 2, 7.5, 14.5 Hz, H-6$_{exo}$), 2.54 (1H, dd, J = 2, 18 Hz, H-8$_{endo}$), 2.31 (3H, s, $COCH_3$), 2.30 (1H, ddd, J = 4.5, 11, 14.5 Hz, H-6$_{endo}$), 1.10 (21H, m, $Si(CH(CH_3)_2)_3$); ^{13}C NMR δ: 210.8 (s, C-7), 201.5 (s, $COCH_3$), 74.8 (s, C-4), 53.2 (d, C-5), 52.0 (t, C-8), 40.4 (d, C-1), 34.1 (q, $COCH_3$), 28.8 and 28.4 (t, C-3, 5), 18.3 (q, $Si(CH(CH_3)_2)_3$), 13.4 (d, $Si(CH(CH_3)_2)_3$); MS (CI), *m/z* (relative intensity): 357 ($[M + 1]^+$, 100), 313 (61).

Reçu le 18 avril 1991

ROLAND CONTANT et RENÉ THOUVENOT. Can. J. Chem. **69**, 1498 (1991).

Les tungstoarsénates lacunaires di-, tri- et hexavacants α-$[HAs_2W_{16}O_{59}]^{11-}$, α-$[As_2W_{15}O_{56}]^{12-}$ et α-$[H_2As_2W_{12}O_{48}]^{12-}$ ont été préparés par dégradation alcaline ménagée de l'anion de type Dawson α-$[As_2W_{18}O_{62}]^{6-}$. Les relations entre tous ces anions et les deux isomères α-$[As_2W_{17}O_{61}]^{10-}$ ont été établies. Les dérivés mixtes saturés α-$[As_2V_xW_{18-x}O_{62}]^{(6+x)-}$ (x = 1,2,3) et α-$[As_2Mo_xW_{18-x}O_{62}]^{6-}$ (x = 1,3) ont été obtenus en comblant les lacunes avec le vanadium et le molybdène respectivement. L'anion mixte monovacant α_2-$[As_2Mo_2W_{15}O_{61}]^{10-}$ a aussi été obtenu et a été utilisé concurremment avec α-$[HAs_2W_{16}O_{59}]^{11-}$ pour synthétiser α-$[As_2Mo_2W_{16}O_{62}]^{6-}$; dans les deux cas il se forme simultanément les anions α-$[As_2Mo_xW_{18-x}O_{62}]^{6-}$ (x = 1 et 3). Toutes les espèces ont été caractérisées par polarographie et par spectrométrie IR. En s'appuyant sur la ressemblance des propriétés oxydo-réductrices et des processus de synthèse avec ceux des tungstophosphates lacunaires et mixtes correspondants, des structures ont été proposées pour toutes ces espèces. Dans le cas des tungstovanado- et molybdotungstoarsénates saturés les structures postulées ont été confirmées par RMN du tungstène-183 en solution. En outre, les spectres RMN de ces mêmes espèces ont été discutés en relation avec ceux des dérivés phosphoriques analogues. Finalement, les principales différences avec les anions tungstophosphoriques résident (i) dans l'existence d'un anion $[HAs_2W_{16}O_{59}]^{11-}$, dont la protonation permet de satisfaire la règle de Lipscomb, (ii) dans l'absence d'un oligomère analogue à $[P_8W_{48}0_{184}]^{40-}$, et (iii) dans la plus faible stablité des octadéca(molybdotungsto)diarsénates.

Mots clés : hétéropolyanions, tungstoarsénate, molybdotungstoarsénate, tungstovanadoarsénate, RMN ^{183}W.

ROLAND CONTANT and RENÉ THOUVENOT. Can. J. Chem. **69**, 1498 (1991).

The di-, tri-, and hexavacant lacunary tungstoarsenates α-$[HAs_2W_{16}O_{59}]^{11-}$, α-$[As_2W_{15}O_{56}]^{12-}$, and α-$[H_2As_2W_{12}O_{48}]^{12-}$ were prepared by controlled alkaline degradation of the Dawson-type anion α-$[As_2W_{18}O_{62}]^{6-}$. The relationships between all these anions and the two α-$[As_2W_{17}O_{61}]^{10-}$ isomers were established. The mixed saturated derivatives α-$[As_2V_xW_{18-x}O_{62}]^{(6+x)-}$ (x = 1,2,3) and α-$[As_2Mo_xW_{18-x}O_{62}]^{6-}$ (x = 1, 3) were obtained by refilling the lacunas with vanadium and molybdenum respectively. The new mixed anion α_2-$[As_2Mo_2W_{15}O_{61}]^{10-}$ was used concurrently with α-$[HAs_2W_{16}O_{59}]^{11-}$ to obtain α-$[As_2Mo_2W_{16}O_{62}]^{6-}$; in both cases minor parts of α-$[As_2Mo_xW_{18-x}O_{62}]^{6-}$ (x = 1 and 3) were obtained simultaneously. All species have been characterized by polarography and by IR spectrometry. Proposed structures, based on the similarity of the redox properties and syntheses processes to those of the corresponding Dawson-type lacunary and mixed tungstophosphates, were given for all these species. The structures of the "saturated" tungstovanado- and molybdotungstoarsenates were confirmed by ^{183}W solution NMR. In addition the ^{183}W solution NMR spectra of all these latter species are discussed in relation to those of the analogous phosphoric derivatives. Finally, the main differences with the corresponding tungstophosphoric anions lie in (i) the existence of $[HAs_2W_{16}O_{59}]^{11-}$, whose protonation satisfies Lipscomb's rule, (ii) the lack of a stable oligomer like $[P_8W_{48}O_{184}]^{40-}$, and (iii) the lower stability of the octadeca(molybdotungsto)diarsenates.

Key words : heteropolyanions, tungstoarsenate, molybdotungstoarsenate, tungstovanadoarsenate, ^{183}W NMR.

Introduction

Alors que les tungstophosphates ont fait l'objet ces dernières années de nombreuses publications (1–3), les tungstoarsénates(V) ont été très peu étudiés. Nous nous sommes intéressés ici à l'hydrolyse alcaline de l'anion α-octadécatungstodiarsénate α-$[As_2W_{18}O_{62}]^{6-}$ à structure de Dawson (4)[3] (en abrégé α-As_2W_{18}) (figure 1) dans le but d'isoler de nouveaux composés lacunaires (6) permettant la synthèse d'hétéropolyanions mixtes. En effet, en remplaçant dans ce type de complexe le phosphore(V) par l'arsenic(V), on peut espérer obtenir des espèces analogues mais avec des stabilités modifiées. Ces modifications, même de faible ampleur, peuvent être intéressantes pour la compréhension des mécanismes de formation ou pour les applications notamment catalytiques (7). L'étude, de l'hydrolyse alcaline entraînant le départ progressif d'atomes de tungstène, et de la réaction inverse d'acidification des espèces lacunaires d'une part, la comparaison des propriétés des tungstoarsénates ainsi obtenus avec celles des tungstophosphates correspondants d'autre part, permettent de déterminer la position probable de la lacune. Cette étude a été complétée par des mesures de RMN du tungstène-183 sur les composés mixtes saturés contenant du molybdène ou du vanadium.

Partie expérimentale

Préparations

α-$K_6As_2W_{18}O_{62} \cdot 14H_2O$

Un échantillon de 220 g de $Na_2WO_4 \cdot 2H_2O$ (0,67 mol) est dissous dans 300 mL d'eau, puis acidifié peu à peu par 100 mL d'acide HCl 4 M (0,4 mol). Dès que la solution est limpide, 150 mL d'acide arsénique concentré (1,65 mol) sont ajoutés rapidement et la solution est portée 4 h à reflux. À la solution refroidie sont ajoutés 140 g de NH_4Cl. Le précipité jaune est filtré et essoré puis redissous dans 250 mL d'eau. La solution est alors abandonnée 24 h vers 7°C. Les cristaux qui apparaissent en très faible quantité sont ceux d'un isomère récemment identifié (8–10). Le filtrat est alors traité par 40 g de KCl. Le précipité est filtré, essoré et recristallisé dans environ 150 mL d'eau. Anal. calc.

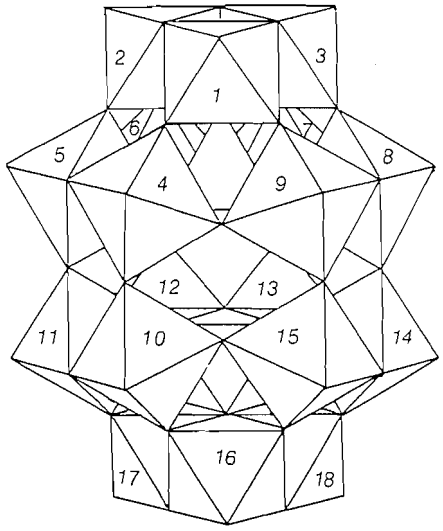

FIG. 1. Représentation en polyèdre de coordination de l'anion α-$[As_2W_{18}O_{62}]^{6-}$ et de ses dérivés de substitution (4, 5).

pour $K_6As_2W_{18}O_{62} \cdot 14H_2O$: K 4,75; W 67,01; As 3,04; H_2O 5,10; trouvé : K 4,71; W 66,67; As 3,07; H_2O 5,07.

α_2-$K_{10}As_2W_{17}O_{61} \cdot 21H_2O$

Un échantillon de 118,5 g (24 mmol) de $K_6As_2W_{18}O_{62} \cdot 14H_2O$ est dissous dans 360 mL d'eau puis traité par 360 mL (0,36 mol) d'une solution molaire de $KHCO_3$. Au bout de 40 min, le précipité est filtré, essoré puis redissous dans 500 mL d'eau chaude. Il apparaît au refroidissement un précipité blanc qui est filtré, essoré et séché à l'air. Anal. calc. pour $K_{10}As_2W_{17}O_{61} \cdot 21H_2O$: K 7,79; W 62,25; As 2,99; H_2O 7,53; trouvé : K 7,62; W 62,19; As 3,00; H_2O 7,52.

α-$K_{11}HAs_2W_{16}O_{59} \cdot xH_2O$

À une solution de 39,5 g (8 mmol) de $K_6As_2W_{18}O_{62} \cdot 14H_2O$ dans 150 mL d'eau sont ajoutés rapidement 100 mL (0,2 mol) d'une solution de tris(hydroxyméthyl)aminométhane 2 M puis au bout de 5 min 150 mL d'une solution de chlorure de potassium demi-saturée. Le précipité est filtré, essoré, lavé deux fois avec 50 mL d'éthanol puis séché à l'air. Anal. calc. pour $K_{11}HAs_2W_{16}O_{59} \cdot 28H_2O$: K 8,65; W 59,2; As 3,02; (H_2O + As_2O_5) 14,96; trouvé : K 8,43; W 59,0; As 3,05; (H_2O + As_2O_5) 15,01. Cette espèce est thermiquement peu stable. Sur le diagramme d'analyse thermique, il n'apparaît aucun palier avant la sublimation totale de As_2O_3.

α-$Na_{12}As_2W_{15}O_{56} \cdot 21H_2O$

À une solution de 99 g (20 mmol) de $K_6As_2W_{18}O_{62} \cdot 14H_2O$ dans 350 mL d'eau est ajouté 89 g (0,57 mol) de $NaClO_4 \cdot H_2O$. Le mélange est agité énergiquement, refroidi vers 10°C et le $KClO_4$ solide est filtré. On ajoute au filtrat 270 mL (0,27 mol) d'une solution molaire de carbonate de sodium. Le précipité est décanté puis filtré, essoré, lavé à l'éthanol et séché à l'air. Anal. calc. pour $Na_{12}As_2W_{15}O_{56} \cdot 21H_2O$: Na 6,19; W 61,9; As 3,36; H_2O 8,48; trouvé : Na 6,23; W 62,1; As 3,35; H_2O 8,54.

α-$K_{12}H_2As_2W_{12}O_{48} \cdot 23H_2O$

À une solution de 74 g (15 mmol) de $K_6As_2W_{18}O_{62} \cdot 14H_2O$ dans 250 mL d'eau sont ajoutés 250 mL (0,5 mol) d'une solution de tris(hydroxyméthyl)aminométhane 2 M. Au bout de 2,5 h d'évolution à température ambiante, on ajoute 75 g de KCl solide. S'il apparaît un précipité, il est filtré et au filtrat est ajouté 200 mL d'une solution de carbonate de potassium 2 M. Le précipité qui apparaît immédiatement est filtré, essoré et lavé deux fois à l'éthanol puis séché à l'air. Anal. calc. pour $K_{12}H_2As_2W_{12}O_{48} \cdot 23H_2O$: K 11,70; W 55,0; As 3,74; H_2O 10,77; trouvé : K 11,90; W 55,05; As 3,88; H_2O 10,87.

α-$(K_8LiH_3As_2W_{12}O_{47} \cdot 16,5H_2O)_n$

Un échantillon de 8 g (2 mmol) de α-$K_{12}H_2As_2W_{12}O_{48} \cdot 23H_2O$ est dissous dans une solution de 250 mL de chlorure de lithium molaire acidifiée par 6 mL d'acide chlorhydrique molaire. Après 3 h d'évolution à la température ambiante, 50 mL de chlorure de potassium saturé sont ajoutés. Le précipité est filtré, essoré, lavé à l'éthanol et séché à l'air. Anal. calc. pour $K_8LiH_3As_2W_{12}O_{47} \cdot 16,5H_2O$: K 8,39; Li 0,17; W 59,2; As 4,02; H_2O 8,69; trouvé : K 8,40; Li 0,22; W 58,7; As 4,20; H_2O 8,62.

1,2-$K_{10}As_2Mo_2W_{15}O_{61} \cdot 21H_2O$

À une solution de 150 mL de chlorure de lithium molaire acidifiée par 3 mL d'acide chlorhydrique molaire sont ajoutés 13,5 g (3 mmol) de $Na_{12}As_2W_{15}O_{56} \cdot 21H_2O$ puis 6 mL (6 mmol) d'une solution molaire de molybdate et peu à peu 15 mL d'acide chlorhydrique molaire. Le pH doit alors se fixer vers 4,5. On ajoute 60 mL d'une solution de chlorure de potassium saturée. Le précipité est filtré, essoré, lavé à l'alcool et séché à l'air. Anal. calc. pour $K_{10}As_2Mo_2W_{15}O_{61} \cdot 21H_2O$: K 8,07; W 56,92; Mo 3,96; As 3,10; H_2O 7,80; trouvé : K 8,21; W 57,12; Mo 3,97; As 3,06; H_2O 7,96.

1,2,3-$K_6As_2Mo_3W_{15}O_{62} \cdot 14H_2O$

À un mélange de 125 mL d'acide chlorhydrique molaire et 15 mL (15 mmol) de molybdate de sodium molaire on ajoute en agitant 20 g (4,4 mmol) de $Na_{12}As_2W_{15}O_{56} \cdot 21H_2O$. Après dissolution, on ajoute 25 g de chlorure de potassium. Le précipité est filtré, essoré puis recristallisé dans le minimum d'eau acidulée (pH = 2). Anal. calc. pour $K_{10}As_2Mo_3W_{15}O_{62} \cdot 14H_2O$: K 5,02, W 59,0; Mo 6,16; As 3,21; H_2O 5,39; trouvé : K 4,84; W 58,7; Mo 6,14; As 3,20; H_2O 5,21.

1,2-$K_6As_2Mo_2W_{16}O_{62}$

Cette espéce n'a pas été isolée à l'état pur mais a été identifiée comme la composante principale d'un mélange obtenu comme suit. À un mélange de 50 mL d'acide chlorhydrique molaire et de 4 mL (4 mmol) de molybdate de sodium molaire sont ajoutés 10 g (2 mmol) de $K_{11}HAs_2W_{16}O_{59}$,aq. Après agitation énergique, la solution, éventuellement filtrée, est additionnée de 8 g de chlorure de potassium. Le précipité jaune est filtré puis recristallisé dans le minimum d'eau acidulée (pH = 2). Anal. calc. pour $K_6As_2Mo_2W_{16}O_{62} \cdot 15H_2O$: K 4,91; W 61,5; Mo 4,02; As 3,14; H_2O 5,65; trouvé : K 4,62; W 61,9; Mo 3,98; As 3,09; H_2O 5,71.

Les mesures polarographiques et de RMN du tungstène-183 montrent que ce produit contient toujours une certaine proportion de $As_2Mo_3W_{15}$, de 1-As_2MoW_{17} et même de As_2W_{18}. Le résultat est analogue si la synthèse est effectuée en ajoutant du tungstate à $As_2Mo_2W_{15}$.

1-$K_6As_2MoW_{17}O_{62} \cdot 14H_2O(\alpha_2)$

À un mélange de 100 mL d'acide chlorhydrique molaire et 5 mL (5 mmol) de molybdate de sodium 1 M sont ajoutés 25 g (5 mmol) de α_2-$K_{10}As_2W_{17}O_{61} \cdot 21H_2O$. Après dissolution, 20 g de chlorure de potassium sont ajoutés. Le précipité jaune est filtré et recristallisé dans le minimum d'eau acidulée (pH = 2). Anal. calc. pour $K_6As_2MoW_{17}O_{62} \cdot 14H_2O$: K 4,84; W 64,4; Mo 1,98; As 3,09; H_2O 5,20; trouvé : K 4,72; W 65,2; Mo 1,91; As 3,09; H_2O 5,07.

4-$K_6As_2MoW_{17}O_{62} \cdot 15H_2O(\alpha_1)$

À un mélange de 40 mL d'acide chlorhydrique molaire et de 2 mL (2 mmol) de molybdate de lithium sont ajoutés 10 g (2 mmol) de α_1-$K_9LiAsw_{17}O_{61} \cdot 20H_2O$ (11). Quand la dissolution est totale, le sel de potassium est précipité par 10 g de KCl solide. Le précipité est filtré et essoré puis recristallisé dans 20 mL d'eau acidulée (pH = 2). Anal. calc. pour $K_6As_2MoW_{17}O_{62} \cdot 15H_2O$: K 4,82; W 64,2; Mo 1,97; As 3,08; H_2O 5,55; trouvé : K 4,97; W 63,7; Mo 1,97; As 3,07; H_2O 5,53.

1,2,3-$K_9As_2V_3W_{15}O_{62} \cdot 21H_2O$

À un mélange de 75 mL d'acide chlorhydrique molaire et de 19 mL (9,5 mmol) de $NaVO_3$ 0,5 M sont ajoutés 13,5 g de $Na_{12}As_2W_{15}O_{56} \cdot 21H_2O$ (3 mmol). Après dissolution, on ajoute 12 g de chlorure de potassium. Le précipité est filtré, essoré et recristallisé dans le minimum d'eau. Anal. calc. pour $K_9As_2V_3W_{15}O_{62} \cdot 21H_2O$: K 7,35; W 57,6; V 3,19; H_2O 7,90; trouvé : K 7,17; W 57,6; V 3,05; H_2O 7,77.

1,2-$K_8As_2V_2W_{16}O_{62} \cdot 19H_2O$

À une solution de 22 mL (11 mmol) de $NaVO_3$ 0,5 M additionnée de 45 mL de HCl molaire et 35 mL d'eau sont ajoutés 28 g de $K_{11}HAs_2W_{16}O_{59} \cdot 28H_2O$ (5,6 mmol). Après 15 min d'agitation énergique, la partie insoluble est filtrée. Au filtrat sont ajoutés 25 g de KCl solide. Le précipité jaune orangé est filtré, essoré et redissous dans 65 mL d'eau. Le louche qui apparaît est filtré sur papier et on laisse

cristalliser. Anal. calc. pour $K_8As_2V_2W_{16}O_{62} \cdot 19H_2O$: K 6,46; W 60,8; V 2,11; H_2O 7,06; trouvé : K 6,67; W 60,1; V 2,05; H_2O 7,15.

1-$K_7As_7VW_{17}O_{62} \cdot 16\ H_2O(\alpha_2)$

À une solution de 6 mL (3 mmol) de $NaVO_3$ 0,5 M additionée de 18 mL de HCl molaire et 75 mL d'eau sont ajoutés 15 g de α_2-$K_{10}As_2W_{17}O_{61} \cdot 21H_2O$ (3 mmol). Après dissolution, on ajoute 20 g de KCl solide. Le précipité jaune est filtré, essoré puis recristallisé dans le minimum d'eau. Anal. calc. pour $K_7As_2VW_{17}O_{62} \cdot 16\ H_2O$: K 5,61; W 64,04; V 1,04; H_2O 5,90; trouvé : K 6,04; W 62,9; V 1,03; H_2O 5,96.

Analyses

Les méthodes d'analyse du tungstène, du molybdène et du vanadium ont été décrites dans un article précédent (1). L'arsenic a été dosé par colorimètrie du complexe α-$[AsMo_{12}O_{40}]^{3-}$ en milieu eau–dioxanne (12), après séparation sous forme de Li_3AsO_4. Cette méthode n'est pas utilisable en présence de vanadium. Les métaux alcalins ont été dosés par spectrophotométrie de flamme et dans certains cas le potassium a été dosé par gravimétrie du tétraphénylborate (13). L'état d'hydratation, qui a été déterminé par analyse thermogravimétrique, est donné à titre indicatif, car il dépend des conditions de stockage.

Mesures physiques

Les spectres RMN du tungstène-183 ont été enregistrés sur des appareils à transformée de Fourier Bruker WM 250 ou AM 500 à 10,4 MHz et 20,8 MHz respectivement. Les déplacements chimiques du tungstène-183 ont été mesurés par rapport à une référence externe de Na_2WO_4 2 M dans D_2O alcalinisé, en utilisant comme référence secondaire une solution aqueuse saturée d'acide dodécatungstosilicique α-$[SiW_{12}O_{40}]^{4-}$ ($\delta = -103,8$ ppm). Les déplacements chimiques, sans correction de susceptibilité magnétique, sont donnés conformément aux recommandations de l'Union internationale de Chimie pure et appliquée, à savoir δ négatif correspond à une fréquence de résonance inférieure à celle de la référence (écran nucléaire plus élevé). Les solutions concentrées ont été obtenues en dissolvant environ 6 g du sel de potassium de l'hétéropolyanion dans 2 mL de $LiClO_4$ saturé; aprés la filtration, opérée directement dans le tube de RMN (Wilmad diamètre externe 10 mm), on ajoute 0,22 mL de D_2O.

Résultats

Polarographie

Toutes les espèces décrites sont suffisamment stables en solutions diluées pour pouvoir être caractérisées par polarographie (tableau 1). Il est bien connu (2) que pour les hétéropolyanions les processus de réduction dépendent de la structure plutôt que de la nature de l'hétéroatome. Il est donc possible de comparer les tungstoarsénates dérivant de As_2W_{18} aux tungstophosphates de type Dawson dont les structures peuvent être considérées comme établies (13). Ainsi ont pu être identifiés α_1- et α_2-As_2W_{17} dont les polarogrammes comme ceux des tungstophosphates correspondants se différencient essentiellement par le $E_{1/2}$ de la troisème vague (tableau 1). De même, les polarogrammes de As_2W_{15}, As_2W_{12} et des dérivés mixtes saturés molybdiques et vanadiques sont pratiquement identiques à ceux des tungstophosphates lacunaires et mixtes analogues. Par contre, P_2W_{16} n'a pas été isolé et le polarogramme de As_2W_{16} n'est pas suffisamment différent de ceux de α_2-As_2W_{17} et α-As_2W_{15} pour permettre de le caractériser sans ambiguïté.

Spectroscopies

Le spectre UV de α-$[As_2W_{18}O_{62}]^{6-}$ présente deux épaulements vers 240 et 300 nm respectivement sur une bande très intense dont le maximum est inférieur à 200 nm. Avec les espèces lacunaires, le pied de cette bande d'absorption se déplace vers l'ultraviolet au fur et à mesure de l'agrandissement de la lacune (6). Par contre, pour les composés mixtes saturés, dans lesquels un ou plusieurs atomes de vanadium ou de molybdène sont substitués aux atomes de tungstène, l'extrémité de la bande située dans le proche UV est déplacée vers le visible et les solutions sont rouges ou jaunes, mais il n'apparaît jamais de maximum permettant d'indentifier ces composés.

[c]Electrode de platine tournante : pH 1,0; HCl 0,1 M/NaCl 0,9 M.

Les bandes d'absorption IR dans la région 700–1000 cm^{-1} sont indiquées dans le tableau 2. Comme toujours dans le cas des polyanions fortement hydratés, les bandes sont larges et plus ou moins bien différenciées. Par rapport à l'anion As_2W_{18} (D_{3h}), les modes d'élongation ν(M—O—M) des ponts μ_{oxo} (14) apparaissent à des fréquences inférieures et généralement sous la form de bandes à plusieurs maxima et épaulements.

Le premier effet, déplacement de fréquences vers les faibles nombres d'ondes, est plus important pour les espèces polyvacantes et les espèces polysubstituées, ce qui est en accord avec une diminution de la stabilité de l'édifice polyanionique (diminution des constantes de force) (15).

Le second effet, éclatement des bandes de vibration, est relié à l'abaissement de la symétrie du polyanion dans les composés lacunaires et substitués : du fait de cet abaissement de symétrie, les tétraèdres AsO_4, non équivalents, devraient donner plusieurs bandes d'élongation. Cependant, contrairement à ceux du tétraèdre PO_4 ($\bar{\nu} > 1000\ cm^{-1}$) (16), les modes du tétraèdre AsO_4 apparaissent dans le domaine de vibration des liaisons M—O ($\bar{\nu} \approx 900\ cm^{-1}$) (14) et l'on n'observe au mieux, qu'une seule bande faible ou un épaulement; pour les autres espèces, les bandes du tétraèdre AsO_4 sont vraisemblablement masquées sous les bandes larges et intenses ν_{as}(M—O).

La technique spectroscopique la plus performante pour caractériser les différentes espèces est la RMN du tungstène-183. Elle a été utilisée pour les composés « saturés » contenant du molybdène et (ou) du vanadium. Les résultats qui apportent aussi des informations structurales sont discutés plus loin.

Hydrolyse partielle de l'anion α-$[As_2W_{18}O_{62}]^{6-}$: formation de composés lacunaires

La première étape de l'hydrolyse conduit toujours à α_2-As_2W_{17}. La réaction, qui est catalysée par les bases, est du premier ordre par rapport au polyanion (13). La vitesse dépend également de la nature du contre-ion : avec les alcalins par

exemple, elle varie dans l'ordre $K^+ > Na^+ > Li^+$. L'influence de la nature du contre-ion ou de la base devient plus importante au cours des étapes suivantes. Cette propriété est utilisée pour orienter l'hydrolyse vers la formation ou la séparation d'une espèce déterminée. Ainsi l'addition, à une solution de α_2-As_2W_{17}, de carbonate ou d'hydroxyde de sodium ou de potassium conduit à la formation simultanée de As_2W_{16} et As_2W_{15}. Les sels de ce dernier étant beaucoup moins solubles, ils précipitent même en solution diluée, permettant ainsi la séparation. L'utilisation d'une base aminée comme le tris(hydroxyméthyl)-aminométhane entraîne des modifications importantes: il se forme rapidement As_2W_{16}, puis, lentement, As_2W_{12}. Ce processus peut encore être perturbé par la présence, même en faible proportion, de Li^+, qui stabilise As_2W_{16}, ou de Na^+ qui favorise la formation et la stabilisation de As_2W_{15}.

Equilibre As_2W_{17}/As_2W_{16}

Ainsi, en présence des ions Li^+ ($c > 0,1$ M), la vitesse de formation de As_2W_{12} devient pratiquement nulle et il est alors possible d'étudier entre pH 7,5 et pH 8 l'équilibre qui s'établit entre les espèces As_2W_{17} et As_2W_{16}. Après addition du tampon tris(hydroxyméthyl)aminométhane dans la cellule polarographique (20°C), il faut environ 20 min pour que l'équilibre s'établisse, par conséquent les mesures sont effectuées au bout de 30 et 45 min.

La proportion de As_2W_{17} a été déterminée à partir de la hauteur de la première vague polarographique qui est nettement moins négative que la vague correspondante de As_2W_{16} (−0,66 et −0,77 volts/ECS respectivement à pH 7,85). En faisant varier la concentration en tungstate et en traçant log ($[As_2W_{17}]/[As_2W_{16}]$) en fonction de log $[WO_4^{2-}]$ à différents pH on obtient une série de droites de pente 1 (figure 2). À partir des valeurs de pK_{app} (tableau 3) obtenues à différents pH, il est facile de montrer que $\Delta pK_{app}/\Delta pH$ est voisin de moins 3 et que par conséquent les résultats sont en accord avec l'équilibre

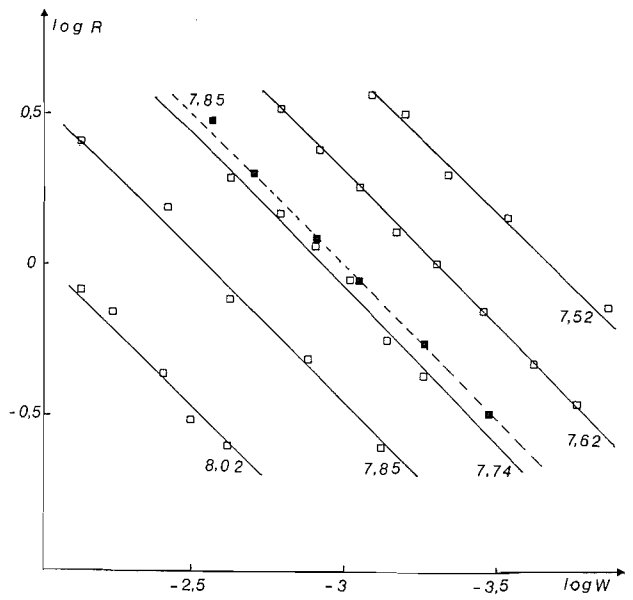

FIG. 2. Droites log $R = f(log\ W)$ ($R = [As_2W_{17}]/[As_2W_{16}]$; $W = [WO_4^{2-}]$) à différents pH : les conditions de force ionique ($I = 1,0$ M) et de concentration en Li^+ ($c = 0,80$ M) restent inchangées sauf pour la droite en pointillé ($I = 0,6$ M; $c = 0,40$ M).

suivant :

[1] $[As_2W_{17}O_{61}]^{10-} + 3H_2O \rightleftharpoons [HAs_2W_{16}O_{59}]^{11-} + WO_4^{2-} + 3H_3O^+$ (constante K)

Cette constante est fonction de la concentration de Li^+, celui-ci favorisant la formation de As_2W_{16} aux dépens de α_2-As_2W_{17}. Comme ce dernier donne un complexe 1–1 avec l'ion Li^+ (11), As_2W_{16} doit donner un complexe plus riche en Li^+. Compte tenu de la différence de force ionique, les résultats

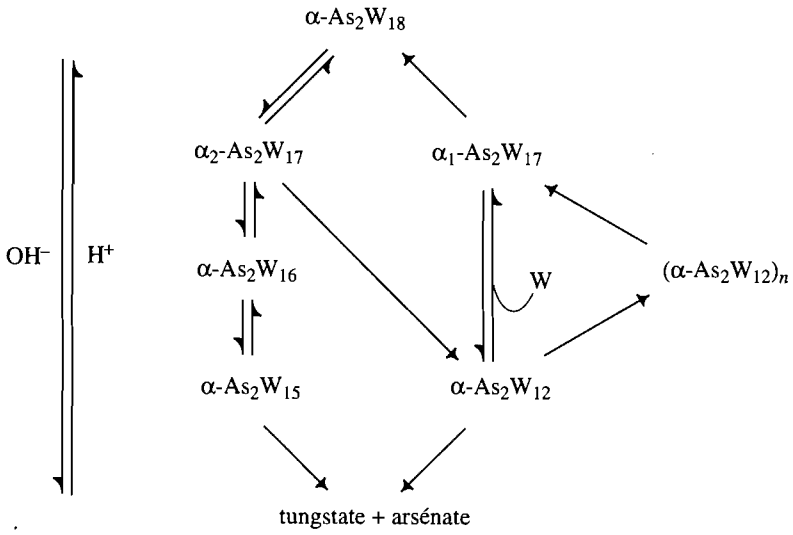

SCHÉMA 1

TABLEAU 3. Constantes de l'équilibre $[HAs_2W_{16}O_{59}]^{11-}/[As_2W_{17}O_{61}]^{10-}$ dans différentes conditions

$[Li^+]$ (M)	$[Cl^-]$ (M)	pH[a]	pK_{app}[b]	K_{app}	pK^b
0,80	1,00	7,52	3,66	$2,19\cdot10^{-4}$	26,22
0,80	1,00	7,62	3,30	$5,01\cdot10^{-4}$	26,16
0,80	1,00	7,74	2,94	$1,15\cdot10^{-3}$	26,16
0,80	1,00	7,85	2,56	$2,75\cdot10^{-3}$	26,11
0,80	1,00	8,02	2,04	$9,12\cdot10^{-3}$	26,10
0,40	0,60	7,85	2,99	$1,02\cdot10^{-3}$	26,54

[a]Le pH est fixé par le tampon tris(hydroxyméthyl)aminométhane, la concentration de $[(CH_2OH)_3\cdot CNH_3]^+$ étant maintenue égale à 0,2 M.
[b]Voir texte.

du tableau 3 ne sont pas en désaccord avec un complexe 2–1, ce qui correspondrait à l'équilibre :

$$[2] \quad [LiAs_2W_{17}O_{61}]^{9-} + Li^+ + 3H_2O \rightleftharpoons [Li_2HAs_2W_{16}O_{59}]^{9-} + WO_4^{2-} + 3H_3O^+$$

Ceci explique que les ions Li^+ stabilisent à la fois As_2W_{17} et As_2W_{16} et que le passage à As_2W_{12} et l'hydrolyse totale se trouvent fortement ralentis.

Stabilité des espèces lacunaires

L'ensemble des relations existant entre les différentes espèces dérivant de α-As_2W_{18} est représenté sur le schéma 1.

Parmi les espèces lacunaires décrites, α_2-As_2W_{17} est la seule qui soit stable en solution aqueuse; sa zone de stabilité est comprise entre pH 1 et pH 7. As_2W_{15} est plus stable que le composé phosphorique analogue, mais se transforme cependant en α_2-As_2W_{17}. Cette évolution est accélérée en milieu acide, mais ralentie par la présence de Li^+. As_2W_{16} est l'espèce qui, acidifiée, se transforme le plus rapidement même en présence de Li^+, le terme final étant aussi α_2-As_2W_{17}.

En solution aqueuse, As_2W_{12} n'est pas stable et, en milieu non tamponné, le stade ultime de l'évolution est un mélange contenant α_2-As_2W_{17} et les espèces provenant de l'hydrolyse basique (voir Schéma 1). En milieu acide, il se forme en outre As_2W_{18}. La présence de Li^+ ne modifie certainement pas le processus, mais elle modifie les vitesses, ce qui permet la séparation des composés intermédiaires. L'addition de tungstate à As_2W_{12} en présence de Li^+ et d'une quantité convenable d'acide, conduit quantitativement à α_1-As_2W_{17}. Dans les mêmes conditions, sans ajout de tungstate, il se forme un mélange d'espèces plus condensées $(As_2W_{12})_n$. Ces espèces se transforment en α_1-As_2W_{17} d'autant plus rapidement que la solution est plus diluée. Il ne se forme donc vraisemblablement pas d'oligomère cyclique analogue à P_8W_{48} (3*a*). Par contre, le comportement de α_1-As_2W_{17} est analogue à celui de α_1-P_2W_{17} : le solide doit être isolé en présence de Li^+ qui ralentit l'isomérisation $\alpha_1 \rightarrow \alpha_2$. Cette dernière est aussi ralentie par la protonation. Dans les mêmes conditions, l'isomérisation de α_1-As_2W_{17} est environ cinq fois plus rapide que celle de α_1-P_2W_{17}.

Action des ions métalliques sur les espèces lacunaires

Les hétéropolytungstates lacunaires monovacants sont connus pour donner des complexes 1–1 avec presque tous les métaux. Les complexes des deux isomères α_1- et α_2-As_2W_{17} avec les ions métalliques divalents et alcalins ont déjà été étudiés (11).

As_2W_{15} a un comportement analogue à celui de P_2W_{15} (17, 18): avec la plupart des ions divalents, il se forme les complexes $M_2(As_2W_{15})_2$ et $M_4(As_2W_{15})_2$; avec les métaux à haut degré d'oxydation comme Mo(VI) et V(V), il se forme $As_2M_3W_{15}$; avec les métaux de degré d'oxydation III ou IV, le comportement est intermédiaire et il peut se former soit l'un, soit l'autre type de complexes, soit éventuellement les deux.

As_2W_{16}, qui est un polyanion divacant, réagit avec de nombreux métaux en jouant probablement le rôle d'un ligand polydenté, mais seul $As_2V_2W_{16}$ a pu être isolé à l'état pur.

À partir de As_2W_{12}, il ne nous a pas été possible d'obtenir des composés mixtes purs : par exemple, contrairement à ce qui est observé avec P_2W_{12}, qui permet de préparer $P_2Mo_6W_{12}$ (6), l'action sur As_2W_{12} du molybdate en milieu acide ne conduit pas à $As_2Mo_6W_{12}$, mais à un mélange d'espèces saturées moins riches en molybdène.

Discussion

Considérations structurales

α-$[As_2W_{18}O_{62}]^{6-}$ possède la structure de Dawson établie sur

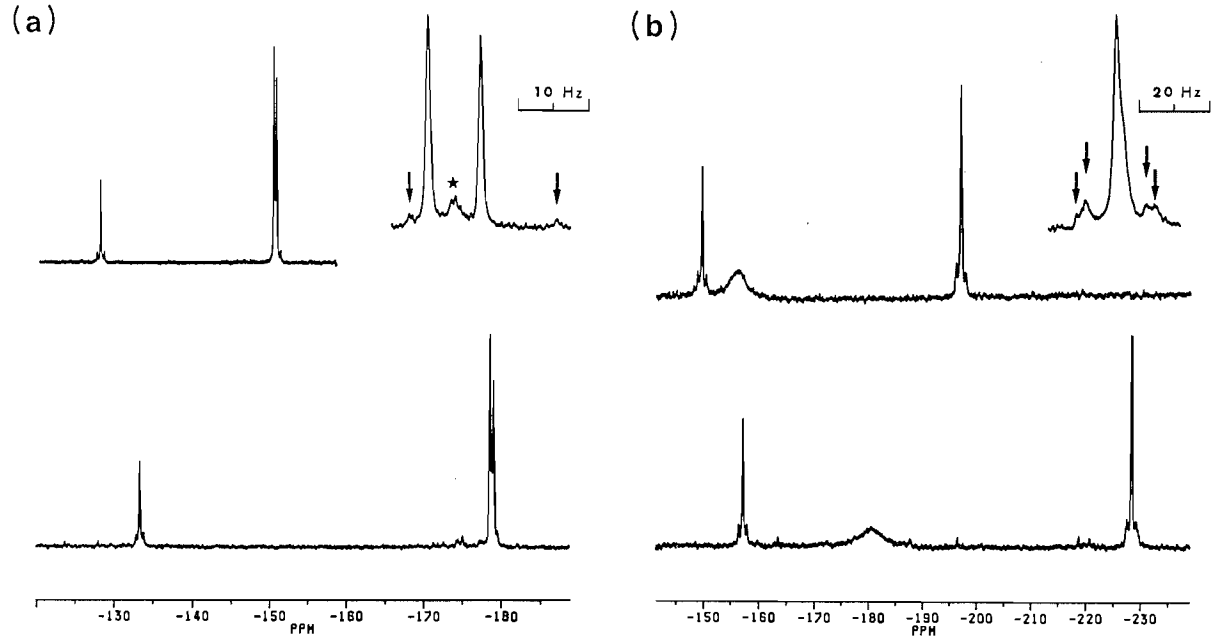

FIG. 3. Comparaison des spectres RMN du tungstène-183 (a) des ions $[As_2Mo_3W_{15}O_{62}]^{6-}$ (haut) et $[P_2Mo_3W_{15}O_{62}]^{6-}$ (bas) et (b) des ions $[As_2V_3W_{15}O_{62}]^{9-}$ (haut) et $[P_2V_3W_{15}O_{62}]^{9-}$ (bas). Conditions expérimentales : solutions aqueuses saturées des sels de lithium; concentration environ 0,5 M.

$[As_2Mo_3W_{15}O_{62}]^{6-}$: 20,8 MHz; 1546 acquisitions; facteur d'élargissement 1 Hz; la partie expansée, obtenue avec un facteur de rétrécissement de 0,4 Hz représente les deux signaux de résonance des tungstène équatoriaux; l'étoile indique les deux composantes internes (confondues) du système AB résultant de leur couplage mutuel ($\Delta\nu$ = 7,5 Hz, $^2J_{W-W} \approx 30$ Hz); les deux flèches localisent la paire de satellites autour du pic basse fréquence ($^2J_{W-W}$ = 20,5 Hz) correspondant au couplage polaire–équatorial dans la sous-unité AsW_9O_{34}. $[P_2Mo_3W_{15}O_{62}]^{6-}$: 20,8 MHz; 1802 acquisitions; facteur d'élargissement 1 Hz.

$[As_2V_3W_{15}O_{62}]^{9-}$: 10,4 MHz; 12 183 acquisitions; facteur d'élargissement 1 Hz; la partie expansée, obtenue avec un facteur d'élargissement de 0,3 Hz représente le signal de résonance du tungstène équatorial de la sous-unité AsW_9O_{34}; les flèches localisent les deux paires de satellites correspondant aux couplages équatorial–équatorial ($^2J_{W-W}$ = 21,5 Hz) et polaire–équatorial ($^2J_{W-W}$ = 17,4 Hz) respectivement. $[P_2V_3W_{15}O_{62}]^{9-}$: 10,4 MHz; 24 208 acquisitions; facteur d'élargissement 1 Hz.

le composé phosphorique (4) (figure 1). Pour les dérivés lacunaires dont les homologues phosphoriques existent, on peut considérer que, dans la mesure où les processus de synthèse et les propriétés oxydo-réductrices sont voisins, les structures sont identiques. Ainsi les lacunes se situent vraisemblablement (figure 1) (i) en position équatoriale (octaèdre 4) pour α_1-As_2W_{17}, (ii) en position polaire (octaèdre 1) pour $\alpha_2As_2W_{17}$, (iii) à la place d'un groupe W_3O_{13} polaire (octaèdres 1, 2 et 3) pour As_2W_{15}, (iv) à la place des six tungstènes qui forment le tiers longitudinal du polyanion saturé (octaèdres 1, 4, 9, 10, 15 et 16) pour As_2W_{12}. De la même manière, $As_2Mo_2W_{15}$ qui résulte du remplissage partiel de la lacune de As_2W_{15} conserve une lacune dans le même groupe polaire que les deux atomes de molybdène.

As_2W_{16} est la seule espèce pour laquelle in n'existe pas d'équivalent phosphorique stable. Étant donné que ce composé se met en équilibre avec α_2-As_2W_{17} et α-As_2W_{15}, il est probable que sa structure soit intermédiaire, c'est-à-dire que la lacune divacante serait située dans un groupement polaire (octaèdres 1 et 2). Cette hypothèse est parfaitement en accord avec le fait que l'addition d'un atome de tungstène sur $As_2Mo_2W_{15}$ et l'addition de deux atomes de molybdène sur As_2W_{16} conduisent instantanément au même $As_2Mo_2W_{16}$, caractérisé par polarographie et par RMN du tungstène-183.

If faut noter que la structure attribuée à As_2W_{16} entraînerait l'existence sur l'anion déprotoné « $[As_2W_{16}O_{59}]^{12-}$ » d'un octaèdre WO_6 possédant trois atomes d'oxygène non partagés et par conséquent violant la règle de Lipscomb (19) qui affirme

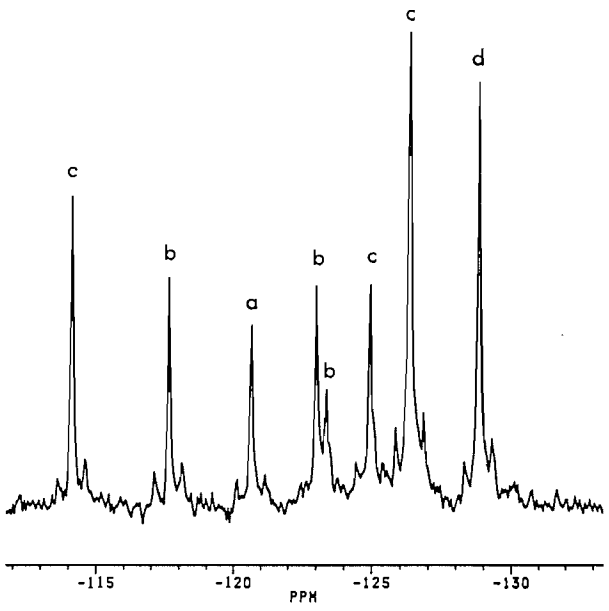

FIG. 4. Partie haute fréquence (résonance des tungstènes polaires) du spectre RMN du tungstène-183 d'une solution contenant $[As_2W_{18}O_{62}]^{6-}$ (pic a; 5%), $[As_2MoW_{17}O_{62}]^{6-}$ (pics b; 20%), $[As_2Mo_2W_{16}O_{62}]^{6-}$ (pics c; 50%) et $[As_2Mo_3W_{15}O_{62}]^{6-}$ (pic d; 25%). Conditions expérimentales : solution aqueuse saturée du sel de lithium; concentration globale environ 0,5 M; 20,8 MHz; 8762 acquisitions; facteur d'élargissement 1,2 Hz.

qu'une telle structure est instable. C'est sans doute pourquoi l'espèce obtenue, aussi bien à l'état solide qu'en solution, est l'espèce protonée $[HAs_2W_{16}O_{59}]^{11-}$, dans laquelle le proton doit se situer sur l'un des trois atomes d'oxygène externes de l'octaèdre WO_6. Ainsi la règle de Lipscomb est respectée, mais ceci explique la faible stabilitié, notamment thermique, de cette espèce.

RMN du tungstène-183 sur les espèces saturées

Les spectres sont comparables à ceux des composés phosphoriques analogues (1) (figure 3); cependant, contrairement à ^{31}P, ^{75}As (I = 3/2; 100%) ne donne lieu à aucun couplage observable et toutes les raies du tungstène-183 sont des singulets. Le spectre de α-As_2W_{18} a déjà été décrit (8, 9). Il présente deux pics d'intensité 2 (−144,1 ppm) et 1 (−120,8 ppm) correspondant respectivement aux 12 atomes de tungstène équatoriaux et aux 6 atomes polaires. On peut remarquer que le faible écart entre les deux signaux (23,4 ppm soit 243 Hz à 10,4 MHz) permet d'observer un léger effet de second ordre (système AB) pour les satellites tungstène–tungstène autour de chacun de ces pics ($^2J_{W—O—W}$ = 21,4 Hz). Pour les composés $As_2M_3W_{15}$, la symétrie est abaissée de D_{3h} à C_{3v} et si les trois atomes de tungstène polaires restent équivalents, il existe deux types de tungstènes équatoriaux et on doit s'attendre à trois pics d'intensité 2 : 2 : 1. Pour les composés $As_2M_2W_{16}$ et As_2MW_{17}, la symétrie est C_s puisqu'il ne reste qu'un plan miroir et les atomes de tungstènes équatoriaux se répartissent en six groupes de deux, tandis que les tungstènes polaires doivent donner trois pics dans les rapports 2 : 1 : 1 pour $As_2M_2W_{16}$ et 2 : 2 : 1 pour As_2MW_{17}.

Dérivés molybdotungstiques

Pour les composés molybdotungstiques, le nombre et les intensités relatives des raies correspondent effectivement à ces prévisions. Cependant, comme $P_2Mo_2W_{16}$, l'espèce $As_2Mo_2W_{16}$ n'a pas pu être obtenue pure et dans le spectre de ^{183}W de sa solution sont aisément identifiés As_2W_{18} (5%), As_2MoW_{17} (20%) et $As_2Mo_3W_{15}$ (25%) (figure 4). Par ailleurs, l'anion $As_2Mo_3W_{15}$, dont la solution ne présente initialement que les trois raies attendues, évolue progressivement vers un mélange de ces différentes espèces. Il semble donc que chacun de ces espèces conduise à un mélange dont la composition dépend, entre autres, du rapport molybdène tungstène initial.

Les régions de résonance des tungstènes polaires (amplitude maximale 12 ppm) et équatoriaux (amplitude maximale 10 ppm) sont toujours nettement séparées, cependant l'intervalle entre ces deux zones est notablement plus faible que dans les composés phosphoriques, de l'ordre de 20–25 ppm et 40–

[b]Système AB léger à 10,4 MHz.

45 ppm respectivement (tableau 4). À cette remarque près, le spectre ^{183}W de chacun des molybdotungstoarsénates est très semblable à celui du molybdotungstophosphate analogue (1) : en particulier, chaque région de résonance (tungstènes polaires d'une part, tungstènes équatoriaux d'autre part) de la solution de $As_2Mo_2W_{16}$ est pratiquement superposable à la région de résonance correspondante de la solution de $P_2Mo_2W_{16}$. Ainsi les atomes de tungstène subissent des incréments structuraux identiques dans les deux familles, à savoir un déblindage d'environ 3 ppm par atome de molybdène pour les atomes W dans le même groupement polaire que Mo, et un blindage de, en moyenne, 2,5 ppm par atome de molybdène pour les atomes de W du groupement polaire opposé confondus en projection avec le (ou les) atome(s) de molybdène.

Dérivés tungstovanadiques

Dans le cas des tungstovanadoarsénates, l'amplitude importante des déplacements chimiques pour chaque région de résonance entraîne un chevauchement de ces zones pour As_2VW_{17} et $As_2V_2W_{16}$. Les attributions respectives sont faites par comparaison avec les composés phosphoriques analogues (1) (tableau 5).

La proximité d'un atome de vanadium se traduit par une raie large (octuplet plus ou moins coalescé) pour les atomes W polaires et très large pour les atomes W équatoriaux (20). Le nombre de raies fines attendues est donc 2 pour $As_2V_3W_{15}(C_{3v})$, 6 pour $As_2V_2W_{16}(C_s)$ et 7 pour $As_2VW_{17}(C_s)$, ce qui est effectivement observé (figure 5). Relativement à As_2W_{18}, les variations de déplacements chimiques sont beaucoup plus importantes qu'en présence du molybdène, mais ces variations sont comparables à celles observées avec les composés phosphoriques : par exemple, pour As_2VW_{17} et $As_2V_2W_{16}$, les deux raies de résonance des tungstènes dans le groupement polaire ne contenant pas de vanadium sont séparées par plus de 40 ppm, le signal blindé correspondant au(x) tungstène(s) se confondant en projection avec le(s) atome(s) de vanadium. La raie de plus haute fréquence est attribuée aux atomes W adjacents au vanadium dans le groupement polaire, son déplacement chimique augmente d'environ 20 ppm par atome de vanadium. De même, les atomes de W équatoriaux adjacents au vanadium sont

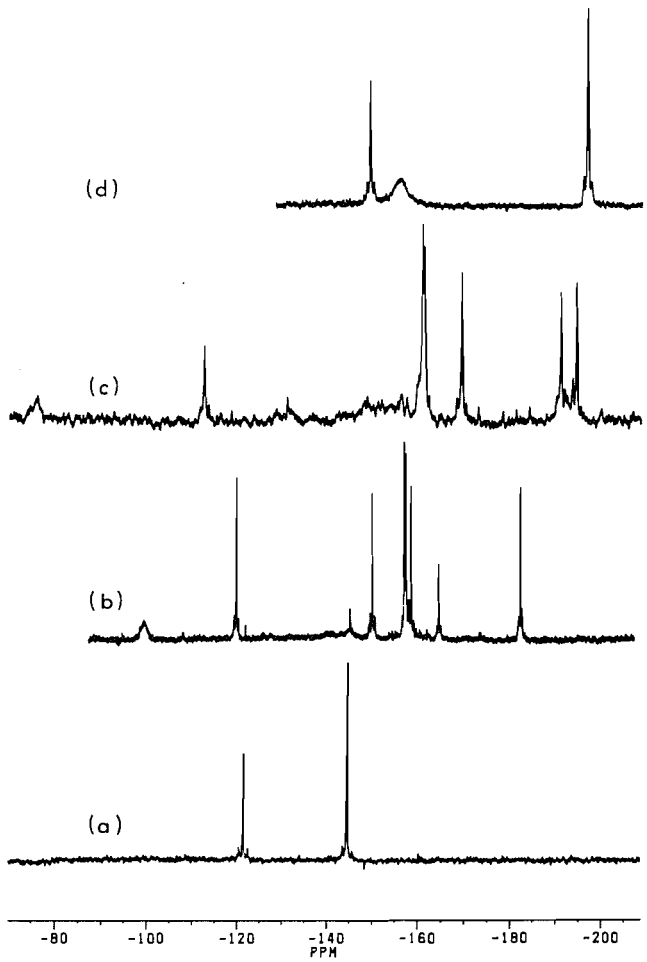

FIG. 5. Spectres RMN du tungstène-183 des anions $[As_2W_{18}O_{62}]^{6-}$ (a), $[As_2VW_{17}O_{62}]^{7-}$ (b), $[As_2V_2W_{16}O_{62}]^{8-}$ (c) et $[As_2V_3W_{15}O_{62}]^{9-}$ (d). Conditions expérimentales : solutions aqueuses saturées des sels de lithium; concentration environ 0,5 M. (a) $[As_2W_{18}O_{62}]^{6-}$: 10,4 MHz; 1000 acquisitions; facteur d'élargissement 1Hz; (b) $[As_2VW_{17}O_{62}]^{7-}$: 20,8 MHz; 17 221 acquisitions; facteur d'élargissement 1 Hz; (c) $[As_2V_2W_{16}O_{62}]^{8-}$: 10,4 MHz; 105 432 acquisitions; facteur d'élargissement 2 Hz; (d) $[As_2V_3W_{15}O_{62}]^{9-}$: 10,4 MHz; 12 183 acquisitions; facteur d'élargissement 1 Hz.

responsables des signaux larges vers -140 à -150 ppm, résonances de plus haute fréquence des raies équatoriales. Il est à remarquer que, pour l'espèce $As_2V_3W_{15}$, le signal est relativement fin (30 Hz au lieu de 150 à 200 Hz) (figures 3 et 5) du fait de la relaxation très rapide du noyau vanadium.

Tous ces résultats sont analogues à ceux observés sur les composés phosphoriques (1).

Les constantes de couplage de $As_2V_3W_{15}$ méritent quelques commentaires : les deux valeurs observées, soit, d'une part, entre tungstène polaire et tungstène équatorial d'un demi-anion AsW_9, environ 17 Hz et, d'autre part, entre tungstènes équatoriaux des demi-anions AsW_9 et AsV_3W_6, 21,5 Hz, sont nettement inférieures aux constantes de couplage analogues dans les anions tungstiques et molybdotungstiques qui sont de l'ordre de 20–21 Hz pour la première dans α-As_2W_{18} et $As_2Mo_3W_{15}$ (tableau 4) et 30,3 Hz pour la seconde dans le polytungstate dissymétrique β-As_2W_{18} (8). Cet affaiblissement des constantes de couplage homonucléaire tungstène–tungstène, attribué à un effet *trans* induit par les atomes de vanadium, est discuté en détail dans un autre article traitant de molybdotungstovanadosilicates à structure de Keggin.[4]

Reaction of carbonyl ylides with chloroform

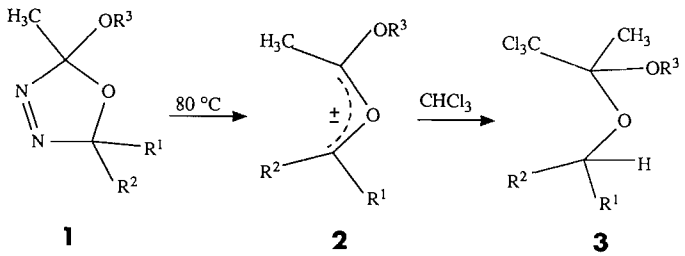
MICHEL BÉKHAZI, WITOLD LAWRYNOWICZ, AND JOHN WARKENTIN[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1
Received April 17, 1991

MICHEL BÉKHAZI, WITOLD LAWRYNOWICZ, and JOHN WARKENTIN. Can. J. Chem. **69**, 1507 (1991).

Carbonyl ylides **2**, generated by thermolysis of alkoxyoxadiazolines **1** in chloroform, react with chloroform to form ketals (**3**) of 1,1,1-trichloropropanone. The isotope effect at 80°C, determined by analysis of products from thermolysis of **1** in mixed solvent ($CHCl_3/CDCl_3$, both in large excess) was estimated to be $k_H/k_D = 5$. A mechanism involving concerted C—Cl and C—H bond formation between the ylide C atoms and the Cl and H atoms of chloroform is proposed. The ketals of 1,1,1-trichloropropanone are the first to be reported.

Key words: carbonyl ylide, reaction with chloroform; chloroform, reaction with carbonyl ylides; ketals, of 1,1,1-trichloropropanone; 1,1,1-trichloropropanone, ketals of.

MICHEL BÉKHAZI, WITOLD LAWRYNOWICZ et JOHN WARKENTIN. Can. J. Chem. **69**, 1507 (1991).



Les ylures de carbonyle **2**, obtenus par thermolyse d'alkoxyoxadiazolines **1** dans le chloroforme, réagissent avec le chloroforme pour former des cétals (**3**) de la 1,1,1-trichloropropanone. En se basant sur une analyse des produits de la thermolyse du composé **1** dans un mélange de solvants ($CHCl_3/CDCl_3$, les deux en très grand excès), on a évalué que, à 80°C, l'effet isotopique (k_H/k_D) est égal à 5. On propose un mécanisme impliquant une formation concertée de liaisons C—Cl et C—H à partir des atomes de C de l'ylure et les atomes de Cl et de H du chloroforme. Les cétals de la 1,1,1-trichloropropanone sont les premiers à être préparés.

Mots clés : ylure de carbonyle, réaction avec le chloroforme; chloroforme, réaction avec les ylures de carbonyle; cétals de la 1,1,1-trichloropropanone; 1,1,1-trichloropropanone, cétals de.

[Traduit par la rédaction]

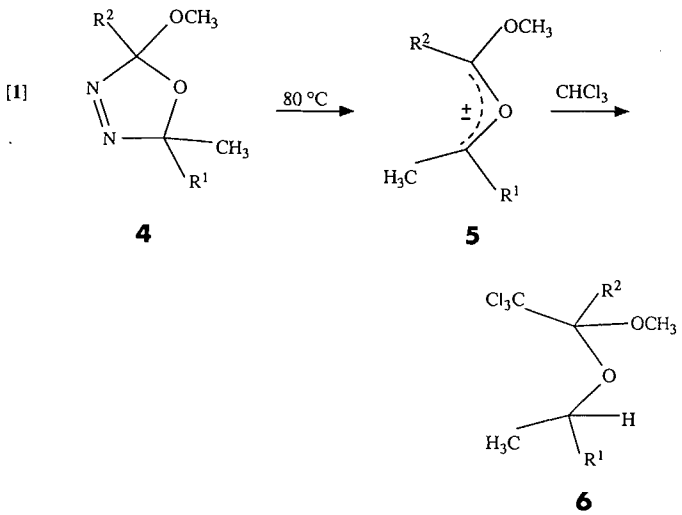
Introduction

Well-known thermal reactions of carbonyl ylides[2] include electrocyclic ring closures to oxiranes (1, 2), cycloadditions to dipolarophiles (3–6), 1,4-sigmatropic hydrogen shifts to form enol ethers (7–9), fragmentations to carbonyl compounds and carbenes (9–11), and reactions with alcohols to form ketals (10, 12, 13).[3] The latter reactions involve (formally) the protonation of one ylide carbon and alkoxylation of the other. To the best of our knowledge analogous reactions of carbonyl ylides with acids weaker than alcohols or water have not been reported nor are there any examples of such reactions of ylides with carbon acids of any pK_a. We now report the first examples of the trapping of carbonyl ylides by chloroform, a carbon acid of pK_a 24.1 (14).

1 **2** **3**

(*a*: $R^1 = R^2 = R^3 = CH_3$; *b*: $R^1 = R^2 = CH_3$, $R^3 = CH_2CH_3$; *c*: $R^1 = R^2 = CH_3$, $R^3 = CH(CH_3)_2$; *d*: $R^1 = R^2 = CH_3$, $R^3 = C(CH_3)_3$; *e*: $R^1 = R^2 = CH_3$, $R^3 = CH_2CH_2OCH_3$; *f*: $R^1 = R^2 = (CH_2)_4$, $R^3 = CH_3$; *g*: $R^1 = R^2 = (CH_2)_5$, $R^3 = CH_3$)

SCHEME 1



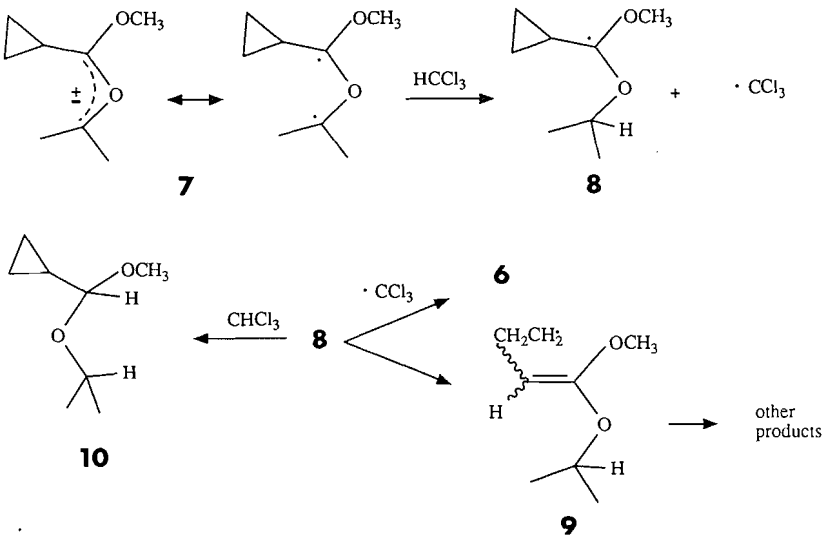
[1]Author to whom correspondence may be addressed.

[2]The literature concerning reactions of carbonyl ylides is extensive and only a few references to each type are given.

[3]In general, rate constants for the reactions listed are strongly substituent dependent and it is not possible to observe them all for a given ylide by judicious choice of the reaction conditions.

Methods, results, and discussion

Oxadiazolines, **1**, prepared by oxidation of *N*-acetylhydrazones of ketones with $Pb(OAc)_4$ (15), were thermolyzed at 80°C in degassed chloroform solutions (0.6–0.9 M) in sealed tubes (Scheme 1). Ketals (**3***a*–**3***g*) of 1,1,1-trichloropropanone (yields ranging from 18 to 55%) were separated by preparative gc and identified by ^1H nmr spectroscopy and by mass spectrometry. Oxadiazolines **4**, prepared by analogous approaches, afforded ketals **6** on thermolysis at 80°C in chloroform (eq. [1]).



4 **5** **6**

(*a*: $R^1 = CH_3$, $R^2 = CH_2CH_3$; *b*: $R^1 = CH_3$, $R^2 = c\text{-}C_3H_5$)

Major by-products ($(CH_3)_2CO$, $CH_3CO_2CH_3$, $CH_3CH{=}CH_2$, and $CH_3CH(OCH_3)OC(CH_3){=}CH_2$, from **1***a*) were those expected from carbonyl ylide and carbene intermediates (16). Thermolysis of **1***a* in neat $HSnBu_3$ afforded those same products without any materials containing isopropoxy groups. Formation of **3** from a free-radical intermediate, which abstracts H from $CHCl_3$, is therefore unlikely. Support for that

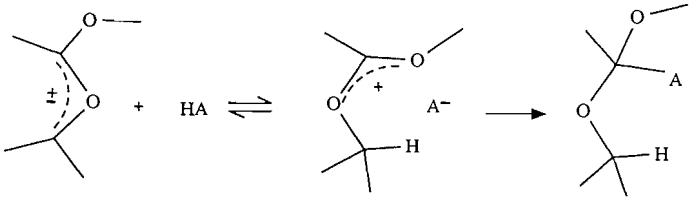


SCHEME 2

conclusion came from the finding that the 2-cyclopropyl analogue (**4***b*), prepared by oxidation of $(CH_3)_2C{=}NNHCO{-}\triangleleft$ with $Pb(OAc)_4$ in methanol (15) afforded **6***b* in a yield (25%) comparable to the yields from **1***a*–**1***c* (reaction [1]). If the process occurred by a free-radical pathway (e.g., Scheme 2) then significant ring opening to radical **9**, in competition with coupling to form **6***b*, could be expected because the rate constant for ring opening of cyclopropylmethyl to the 3-buten-1-yl radical is very large.[4] Moreover, radical **8** (and particularly its analogues from the other oxadiazolines) should be capable of H abstraction from $CHCl_3$ to form the appropriate acetal (**10**). Compounds of that type, which are very easily recognized by ^1H nmr spectroscopy ($\delta \simeq 5.1$) (11) were not obtained.

Finally, there is no precedent for radical chemistry of carbonyl ylides, nor is there any reason to expect ylides **2**, if they have singlet diradical character as expressed with **7** (Scheme 2), to be much more reactive towards $CHCl_3$ than toward $HSnBu_3$. In fact, data from the literature indicate that the reverse is probably true. Alkyl radicals (1°, 2°, and 3°) abstract from $HSnBu_3$ with rate constants in the range (1–2) $\times$ 10^6 M^{-1} s^{-1} at 300 K (18) whereas *n*-hexyl and *tert*-butyl radicals abstract H from $CHCl_3$ with rate constants 4.8 $\times$ 10^3 M^{-1} s^{-1} at 263 K (18) and 2.5 $\times$ 10^2 M^{-1} s^{-1} at 310 K (19), respectively. Thus $HSnBu_3$ is more reactive than $CHCl_3$, toward alkyl radicals, by a factor between about 10^2 and 10^4. Although the effects of oxy substituents on those rate constants are not known, it would be surprising if such substituents reversed the reactivity order.

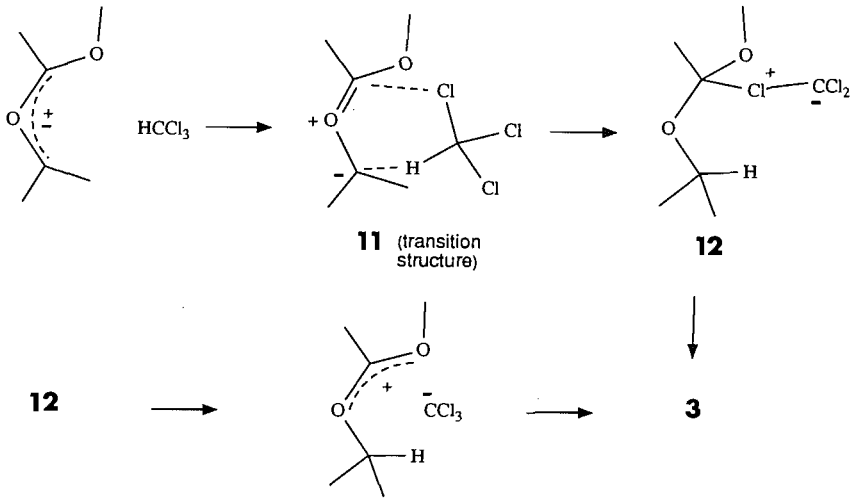
A polar mechanism (Scheme 3) can be ruled out on the basis of the finding that carbon acids comparable to or stronger than $CHCl_3$ (pK_a = 24.1) (14), such as diethyl malonate (pK_a = 13) (20), nitromethane (pK_a = 11) (20, 21), and acetonitrile (pK_a = 25) (20) failed to form isopropoxy groups[5] from **2***a*.

SCHEME 3

It is therefore unlikely that the initial process in chloroform is the proton transfer depicted in general form in Scheme 3. Dichloromethane likewise failed to intercept ylides **2** to form a product or products containing isopropoxy groups.

In light of the evidence against radical and simple acid–base chemistry in the first step, and in view of the fact that the regioisomers of **3** were not formed,[6] we propose the novel polar mechanism of Scheme 4 for the reaction of **2** and **5** with $CHCl_3$.

The mechanism of Scheme 4, involving concerted formation of ylide **12** and its subsequent conversion, either by a concerted 1,2-rearrangement or to **3** by way of ion pair **13**, can account for all of the observations. First, by involving both electrophilic attack at Cl and nucleophilic attack at H of $CHCl_3$, with a six-membered transition state, that mechanism differentiates $CHCl_3$ from carbon acids such as carbonyl and nitro compounds. For them, the analogous transition state would be 7-membered. The alternative mechanism, proton transfer as in Scheme 3, would involve separation of charges. That is largely avoided in the first step of Scheme 4 by having one ylide give way to another. For CH_2Cl_2, the analogous step would require the breaking of a stronger C—H bond or, from the point of view of product stability, the formation of an ylide less stabilized than **12**. Moreover, attack on $CHCl_3$ with the regiochemistry opposite to that depicted would involve a transition state analogue of **11** with partial charges less favourably disposed. Ion pair **13**, derived from **12** by a heterolytic dissociation, would be expected to collapse to **3** without much of a barrier.



The proposed mechanism (Scheme 4) is novel and there are relatively few obvious ways of testing it. One consequence of

[4]About 6.2 $\times$ 10^8 s^{-1} at 80°C (17). The two alkoxy substituents of **7** would be expected to retard its ring opening relative to that of the parent radical, but the rate constant is unlikely to be smaller than 10^6 s^{-1}.

[5]Some of the products formed in those solvents were not identified. Major products from **1***a* were acetone, methyl acetate, and $CH_3CH(OCH_3)OC(CH_3){=}CH_2$, which arise from fragmentations and from a 1,4-sigmatropic hydrogen shift in the carbonyl ylide intermediate. The minor products, although unidentified, did not have the easily recognized isopropoxy multiplets of **3** ($R^1 = R^2 = CH_3$).

[6]We estimate that we would have detected less than 5% of such products.

SCHEME 4

that mechanism is that there should be a hydrogen/deuterium kinetic isotope effect for reaction in a solvent consisting of $CHCl_3$ and $CDCl_3$, because C—H bond rupture is part of the rate-determining step. Such an isotope effect has been demonstrated, with oxadiazoline **1***b* as starting material and with a 1:1 solution of $CDCl_3$ in $CHCl_3$. Separation of the ketal **3***b* together with its labelled analogue, and integration of the ^1H nmr spectrum ($((CH_3)_2C(H)O$ vs. CH_3CH_2O) gave $k_H/k_D = 5$. That is a substantial kinetic isotope effect, in keeping with expectation for the concerted mechanism.

The products, like the mechanism by which they are formed, are of interest. A search of the literature revealed that the most congested ketals of acetone that have been prepared are the diisopropyl and the dicyclohexyl ketals (22), formed by treatment of the ketone with the alcohol and *p*-toluenesulfonic acid in the presence of molecular sieves. Ketals of 1,1,1-trichloro-2-propanone, including the most simple ones (the dimethyl and ethylene ketals) appear to be unknown, neither are its hemiketals nor the hydrate described. Apparently there is not a single method for the preparation of ketals of 1,1,1-trichloro-2-propanone, probably because of the steric hindrance caused by the trichloromethyl group. Models of the diisopropyl ketal (**3***c*) indicate that nonbonded interactions are substantial and that there are four distinct methyl group environments. Only two were evident from the ^1H nmr spectrum, which has the characteristics of compounds of the type $XYC[CH(CH_3)_2]$ with a molecular plane of symmetry but without such a plane through the isopropyl groups.

Experimental

The ^1H nmr spectra were recorded with an EM 390 spectrometer, on solutions made with $CDCl_3$ and reference TMS. Mass spectra were obtained with a VG 70-70F double focusing spectrometer or with a ZAB-E triple focusing instrument. Samples were introduced with the direct insertion probe and ionization was achieved by electron impact (70 eV) or by chemical means, with NH_3.

Ketals **3** were purified, in general, by centrifugal chromatography with a Chromatotron no. 7924 instrument fitted with a glass plate coated with silica (Merck Kieselgel 60 PF 254). The coating was 2 mm thick and 12 cm wide. Solvents for elution were distilled in glass before use. In most instances preparative glpc was required to remove remaining impurities from a ketal isolated by centrifugal chromatography. Preparative glpc was carried out with a steel column (0.25 in. × 8 ft) packed with OV-17 (10%) in a Varian Aerograph A90-P3 machine.

Chloroform from Caledon Laboratories, Ltd., and chloroform-*d* from Merck, Sharpe, and Dohme were used as received. Shaking the chloroform with aqueous bicarbonate, drying, and distillation did not affect the results (tested with **1***a* only), and most of the reactions were therefore done with ordinary chloroform.

The acetyl hydrazine and the ketones required to synthesize acetyl hydrazone precursors of **1** were from Aldrich Chemical Co., Inc.

Ketone acetylhydrazones

The general procedure involved stirring of 0.07 mol of acetylhydrazine with excess ketone and 0.02 mole of anhydrous sodium sulfate at room temperature for 4 h. Absolute ethanol was added, a little at a time, to dissolve the solid organic product and the solution was filtered to remove sodium sulfate hydrates. Evaporation of the ethanol and excess ketone under vacuum afforded crude acetyl hydrazone in quantitative yield. The hydrazones were recrystallized from absolute ethanol/petroleum ether.

2-Alkoxy-2,5,5-trialkyl-Δ^3-1,3,4-oxadiazolines, 1

Compounds **1** were prepared by oxidative cyclization of acyl hydrazones of ketones with lead tetraacetate in alcohol R^3OH or in a solution of that alcohol in methylene chloride (9, 10). They were purified, first by methanolysis (MeO^-, MeOH) of the 2-acetoxy oxadiazoline that is formed as a by-product, and then by bulb-to-bulb distillation at ca. 0.05 Torr (1 Torr = 133.3 Pa) (9, 10).

The ^1H nmr spectra of new oxadiazolines are listed below. All were run at 90 MHz in solvent $CDCl_3$ containing TMS.

Oxadiazoline **1***b*, δ: 1.20 (t, J = 7 Hz, 3H), 1.47 (s, 3H), 1.58 (s, 3H), 1.63 (s, 3H), 3.30 (m, diastereotopic, 2H). **1***c*, δ: 1.17 (d, J = 7 Hz, 6H), 1.45 (s, 3H), 1.58 (s, 3H), 1.62 (s, 3H), 3.53 (sept, J = 7 Hz, 1H). **1***d*, δ: 1.35 (s, 9H), 1.50 (s, 3H), 1.58 (s, 3H), 1.75 (s, 3H). **1***e*, δ: 1.43 (s, 3H), 1.57 (s, 3H), 1.63 (s, 3H), 3.37 (s) superimposed upon 3.16–3.66 (m), total 7H. **1***f*, δ: 1.60 (s, 3H), 1.65–2.40 (m, 8H), 3.07 (s, 3H). **1***g*, δ: 1.17–2.10 (m) with 1.55 (s) superimposed (13H), 3.06 (s, 3H); **4***a*, δ: 1.02 (t, J = 7.5 Hz, 3H), 1.48 (s, 3H), 1.60 (s, 3H), 1.87 (q, J = 7.5 Hz, 2H), 3.13 (s, 3H); **4***b*, δ: 0.10–0.37 (m, 4H), 0.97–1.37 (m, 1H), 1.33 (s, 3H), 1.40 (s, 3H), 3.09 (s, 3H).

Thermolysis of oxadiazolines

The general procedure involved sealing a solution of the oxadiazoline (0.8–1.0 M) in chloroform into an nmr tube after several cycles of freeze–pump–thaw degassing. The ^1H nmr spectrum was recorded and the tube was immersed in an oil bath and heated at 80°C for 5 days. An ^1H nmr spectrum, taken with the tube still sealed, was used for estimates of the yields. The sample was then analyzed by

For personal use only.

gc and gc/ms and the product of greatest interest (**3**) was separated and purified by preparative gc, on OV-17 packing at 180°C. Yields reported above in the text are averages of at least two runs except for the case of **1***b*, which was a single experiment. Yields from duplicate or triplicate runs were reproducible. For example, the yields of **3***c* from **1***c* were 32, 33, and 29% in three separate experiments.

Spectroscopic data for ketals 3 and 6

All ^{1}H nmr spectra of ketal products are 90 MHz spectra unless otherwise indicated. The solvent and reference were $CDCl_3$ and TMS throughout. Diastereotopism was observed in all cases where it was expected. The mass spectra confirmed the presence of three chlorine atoms, with M, M + 2, and M + 4 signals in the intensity ratio 1:1:0.3, where M is the signal corresponding to 3 × ^{35}Cl for the parent less OR, where OR is the smallest alkoxy group. M + 6 signals, expected at relative intensity 0.03, were not above noise in most cases.

Data for **3**a: ^{1}H nmr, δ: 1.26 (d, J = 6.1 Hz, 3H), 1.29 (d, J = 6.1 Hz, 3H), 1.78 (s, 3H), 3.53 (s, 3H), 4.26 (sept, J = 6.1 Hz, 1H), ms (EI), m/z (%): 203 (25), 205 (26), 207 (9), P − OCH_3; 175 (100), 177 (98), 179 (32), P − $OCH(CH_3)_2$. **3***b*, ^{1}H nmr δ: 1.23 (d, J = 6.0 Hz, 3H), 1.24 (t, J = 7.0 Hz, 3H), 1.28 (d, J = 6.0 Hz, 3H), 1.77 (s, 3H), 3.83 (q, J = 7.0 Hz, 2H), 4.26 (sept, J = 6.0 Hz, 1H); ms (m/z, %): 203 (6), 205 (6), 207 (2), P − OCH_2CH_3; 189 (19), 191 (19), 193 (7), P − $OCH(CH_3)_2$; ms (CI, NH_3), m/z: 266, 268, 270, M + NH_4^+. **3***c*, ^{1}H nmr, δ: 1.24 (d, J = 6.1 Hz, 6H), 1.28 (d, J = 6.1 Hz, 6H), 1.81 (s, 3H), 4.33 (sept, J = 6.1 Hz, 2H); ms (EI), m/z (%): 203 (28), 205 (30), 207 (12), P − $OCH(CH_3)_2$; 161 (100), 163 (96), 165 (33), $C_3H_4Cl_3O$; 103 (93), $C_5H_{11}O_2$. **3***d*, ^{1}H nmr, δ: 1.20 (d, J = 6.4 Hz, 3H), 1.23 (d, J = 6.4 Hz, 3H), 1.35 (s, 9H), 1.84 (s, 3H), 4.38 (sept, J = 6.4 Hz, 1H); ms (EI), m/z (%): 203 (11), 205 (11), 207 (3), P − $OC(CH_3)_3$; 161 (25), 163 (25), 165 (7), $C_3H_4Cl_3O$; 103 (100), $C_5H_{11}O_2$. **3***e*, ^{1}H nmr, δ: 1.25 (d, J = 6.2 Hz, 3H), 1.29 (d, J = 6.2 Hz, 3H), 1.80 (s, 3H), 3.41 (s, 3H), 3.58 (t, J = 5.4 Hz, 2H), 3.93 (t, J = 5.4 Hz, 2H), 4.28 (sept, J = 6.2 Hz, 1H); ms (EI), m/z (%): 219 (8), 221 (9), 223 (3), P − $OCH(CH_3)_2$; 203 (8), 205 (8), 207 (3), P − OCH_2CH_2OMe; 61 (100), $C_2H_5O_2$. **3***f*, ^{1}H nmr, δ: 1.4–1.9 (m, 8H), 1.66 (s, 3H), 3.40 (s, 3H), 4.40 (m, 1H); ms (EI), m/z (%): 229 (0.7), 231 (0.7), P − OCH_3; 175 (100), 177 (99), 179 (31), 181 (3.4), P − $OCH(CH_2)_4$; 161 (2.5), 163 (2.3), 165 (1.0), $C_3H_4Cl_3O$; 97 (26), 99 (17), 101 (3), $C_2H_3Cl_2$. **3***g*, ^{1}H nmr, δ: 1.1–1.4 (m) with 1.81 (s) superimposed, total 13H, 3.56 (s, 3H), 3.93 (m, 1H); ms (EI), m/z (%): 243 (2), 245 (2), P − OCH_3; 175 (100), 177 (100), 179 (32), 181 (3), P − $OCH(CH_2)_5$; 161 (4), 163 (4), 165 (1). **3***b*, (D-analogue, from $CDCl_3$), ^{1}H nmr, δ: 1.20 (t, J = 7.0 Hz), with D-coupled multiplets, ca. δ 1.2 superimposed, total 9H, 1.78 (s, 3H), 3.87 (q, J = 7.0 Hz, 2H); ms (EI), m/z (%): 204 (4), 206 (4), 208 (1), P − OCH_2CH_3; 189 (14), 191 (15), 193 (6), P − $OCD(CH_3)_2$; 161 (32), 163 (32), 165 (13), $C_2Cl_3O_2$; 125 (24), 127 (17), 129 (8), $C_2H_3Cl_2O$; 89 (96), $C_4H_9O_2$; 61 (100), $C_2H_5O_2$. **6***a*, ^{1}H nmr, δ: 0.23–1.00 (m, 5H), 1.08 (d, J = 6.2 Hz, 3H), 1.10 (d, J = 6.2 Hz, 3H), 3.47 (s, 3H), 4.47 (sept, J = 6.2 Hz, 1H).

Isotope effect

The H/D kinetic isotope effect was determined by the method of competition and product analysis. To **1***b* (0.155 g, 0.89 mmol) was added chloroform (0.72 g, 6.0 mmol) and deuteriochloroform (0.71 g, 5.9 mmol). The resulting solution, in an nmr tube, was degassed by means of three freeze–pump–thaw cycles. The tube was sealed and placed in a constant temperature bath at 80 ± 1°C for 5 days. The tube was cut, the volatiles were evaporated, and the residue was analyzed by nmr spectroscopy (500 MHz) using a 10-s delay time between pulses. The ratio of protio to deuterio adducts (**6***f*) was determined by integrating the methine septet against the methylene quartet several times and averaging. An isotope effect of 5 ± 1 was estimated from the average of two runs.

Structural and surface aspects of thermally treated copper aluminium mixed hydroxides

AWAD I. AHMED, S. E. SAMRA, AND S. A. EL-HAKAM
Chemistry Department, Faculty of Science, Mansoura University, Mansoura, A.R. Egypt
Received February 16, 1990[1]

AWAD I. AHMED, S. E. SAMRA, and S. A. EL-HAKAM. Can. J. Chem. **69**, 1511 (1991).

$CuO–Al_2O_3$ catalysts containing various amounts of copper oxide have been prepared by precipitation. The phase changes were studied by X-ray diffraction. The results obtained revealed that the thermal treatment of solid $CuO–Al_2O_3$ at 700°C produced only crystalline CuO. Heating to 900°C led to the formation of copper alumina spinel together with unreacted CuO and γ-Al_2O_3. The spinel content was found to increase with increasing copper content. Nitrogen adsorption–desorption isotherms on the calcined samples have been measured. Surface areas have been calculated and the pore structure analysed. The textural properties of the system were found to depend on both the copper content and the calcination temperature.

Key words: CuO, Al_2O_3 catalysts, structure, surface area, pore structure.

AWAD I. AHMED, S. E. SAMRA et S. A. EL-HAKAM. Can. J. Chem. **69**, 1511 (1991).

On a préparé, par précipitation, des catalyseurs de type $CuO–Al_2O_3$ contenant différentes quantités d'oxyde de cuivre. On a étudié les changements de phase par diffraction de rayons X. Les résultats obtenus révèlent que le traitement thermique du $CuO–Al_2O_3$ solide à 700°C produit uniquement du CuO cristallin. Le chauffage jusqu'à 900°C conduit à la formation de spinelle de cuivre alumine avec du CuO et du γ-Al_2O_3 qui n'ont pas réagi. On a trouvé que la spinelle augmente avec la teneur en cuivre. On a mesuré les isothermes d'adsorption–désorption de l'azote des échantillons calcinés. On a calculé les aires de surface et on a analysé la structure des pores. On a trouvé que les propriétés texturales du système dépendent à la fois de la teneur en cuivre et de la température de calcination.

Mots clés : CuO, Al_2O_3, catalyseurs, structure, aires de surface, structure des pores.

[Traduit par la rédaction]

1. Introduction

Metal oxides have long attracted attention since they are widely used and find many applications in several fields of investigation related to catalysis. It is found that better catalysts (1–6), refractories, and adsorbents are frequently produced by mixing two or more metal oxides. It is well known that for a better understanding of the function of catalysts their physical structure must be elucidated since structure may be greatly affected by their method of preparation and treatment (7). Attention is also currently directed towards certain aspects of the physical structure of active solids which characterize their "texture". These include surface area, pore geometry, and pore size distribution.

The catalytic activity and selectivity of catalysts may be greatly influenced by the geometrical characteristics of their surface. According to Schwab and Block (8) the dehydrogenation reaction takes place on flat surfaces whereas dehydration occurs in narrow pores.

The $CuO–Al_2O_3$ system may be considered as one of the most interesting binary system. The co-existence of CuO and Al_2O_3 in a binary system increases the range application of the mixed oxide solid.

In recent years copper oxide alumina systems have attracted considerable interest because of their selective properties in reactions involving hydrogen (9–13), selective hydrogenation of carbonyl groups in unsaturated aldehydes and ketones (14) and hydrogen transfer to ketones over hydroxyapatites (15). However, some aspects of the textural and catalytic behaviour of copper-containing catalysts are not completely understood.

The present investigation reports a study on the effect of thermal treatment on the structural and textural properties of copper aluminium mixed hydroxides.

2. Experimental

2.1 Materials

Different copper aluminium mixed hydroxide samples of various compositions were prepared from solutions of copper and aluminium chloride using 1 M NH_4OH at 70°C (BDH grade). Depending on the desired composition of mixed hydroxide, appropriate, calculated volumes of chloride solution were taken, and the NH_4OH solution was added dropwise with continuous stirring to give a pH of about 7.5. The precipitate was washed several times with distilled water till free from chloride and ammonium ions and dried at 100°C for 48 h.

The mixed oxide samples were obtained by heating the corresponding mixed hydroxide in air to temperatures between 300 and 900°C for 24 h. The compositions of the prepared mixed oxides were 0.10 CuO 1 Al_2O_3, (AC10), 0.25 CuO 1 Al_2O_3 (AC25), 0.50 Cu 1 Al_2O_3 (AC50), and 1 CuO 1 Al_2O_3 (AC1:1). The thermal products of the mixed oxides are designated AC10-*T*, AC25-*T*, AC50-*T*, and AC1:1-*T*, where *T* is the calcination temperature.

2.2 Techniques

The adsorption by nitrogen was measured at −196°C on the calcination products of the mixed oxides using a conventional volumetric apparatus. The adsorption was followed until near saturation and then the desorption was followed down to relative pressures at which the desorption branches of the isotherm join the adsorption ones. The samples were outgassed at 4 h under a reduced pressure of 10^{-5} Torr prior to any adsorption measurement.

An X-ray investigation of the thermal products of mixed hydroxide samples was carried out using a Geiger Flex D/MAX-IA X-ray diffractometer system. The patterns were obtained using nickel-filtered copper radiation (λ = 1.5405 Å) at 36 kV and 16 mA; the diffraction angle 2° was scanned at a rate of 2° min^{-1}.

3. Results and discussion

The X-ray investigation of the products of thermal treatment of AC50 at temperatures between 300 and 500°C (Fig. 1*a* and *b*) revealed the amorphous nature of the solids. On increasing the calcination temperature to 700°C (Fig. 1*c*) only

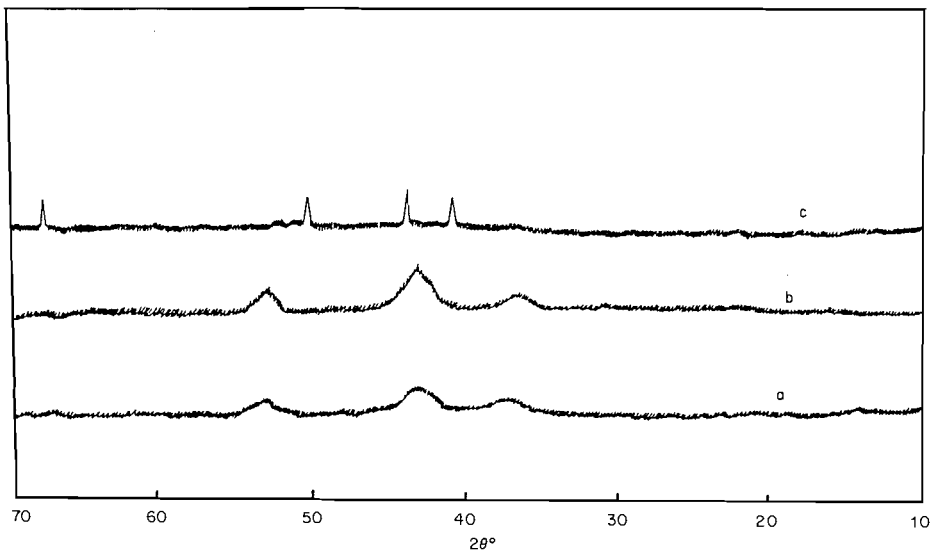

FIG. 1. X-ray diffraction patterns of (*a*) AC50-300, (*b*) AC50-500, and (*c*) AC50-700.

the crystalline CuO phase was obtained at *d* values of 1.174, 1.084, 0.918, and 0.832 Å. At temperatures lower than 500°C a mutual interaction between the two oxyhydroxides and the substitution of the cationic sites are common in the transition metal hydroxide gels as well as oxides, e.g. the $Co(OH)_2$–$Mg(OH)_2$ systems observed by Matyshak *et al.* (16). These observations were also observed by Mani and Rao (17) for the $Fe(OH)_3$–$Al(OH)_3$ system. They found that the samples calcined at 420°C were amorphous to X-rays, they also found from electron microscopic and diffraction studies the presence of clusters in these samples.

Figure 2 represents the X-ray diffraction patterns of the different mixed oxides calcined at 900°C. All the characteristic lines of both CuO and γ-Al_2O_3 and copper(II) aluminate ($CuAl_2O_4$) spinel were detected. The peaks, at 1.522 and 0.874 Å, are characteristic of γ-alumina, while the bands at *d* = 1.288, 1.130, and 0.996 Å are characteristic of $CuAl_2O_4$. The intensity of the diffraction lines of the $CuAl_2O_4$ spinel formed increases with increased copper content. A maximum intensity for the $CuAl_2O_4$ lines was attained at solid composition AC1:1-900. It is also seen from Fig. 2 that the increase in copper content was accompanied by the appearance of some copper(I) metal aluminate ($CuAlO_2$) phase besides $CuAl_2O_4$. This process may be represented as follows:

$$CuO + Al_2O_3 \rightarrow CuAl_2O_4$$

$$2CuAl_2O_4 \rightarrow 2CuAlO_2 + Al_2O_3 + \tfrac{1}{2}O_2$$

The presence of unreacted CuO and γ-Al_2O_3, together with the spinel phases, in all specimens heated to 900°C revealed that the solid-state reaction between copper and aluminium oxides yielding $CuAl_2O_4$ is a slow diffusion reaction (18). According to this mechanism CuO reacts with Al_2O_3 by diffusion of CuO to the $CuAl_2O_4$ interface. Since the O—Cu bond in CuO and O—Al bonds in Al_2O_3 are respectively ionic and covalent, the mobility of Cu^{2+} ions may be considerably higher than that of Al^{3+}.

Adsorption–desorption isotherms of nitrogen at −196°C were measured on the calcination products of AC10, AC25, AC50, and AC1:1 thermally treated at 300–900°C. Figure 3 shows a set of representative adsorption–desorption isotherms of nitrogen on the calcination products of AC10. The adsorption of nitrogen on all the thermal products of CuO–Al_2O_3 samples exhibits hysteresis. It is also shown that the area and shape of the hysteresis loops change with calcination temperature. The isotherms of all samples investigated are situated between types II and IV of the EDDT classification (19).

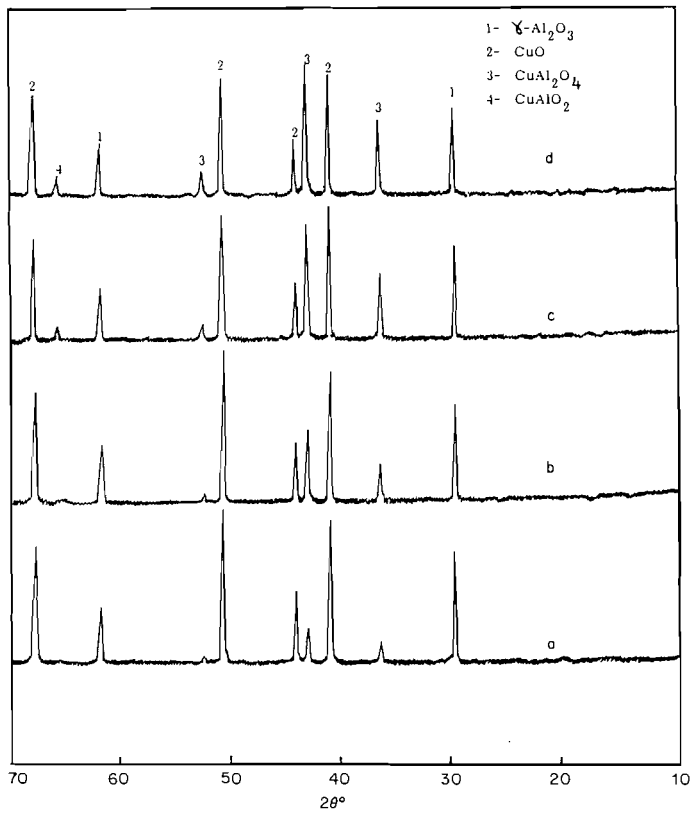

FIG. 2. X-ray diffraction patterns of (*a*) AC10-900, (*b*) AC25-900, (*c*) AC50-900, and (*d*) AC1:1-900.

From an analysis of the adsorption isotherms by the BET equation (20), the specific surface area values S_{BET} ($m^2\ g^{-1}$) were calculated, adopting a cross-sectional area for the nitrogen molecule of 16.2 Å (21). The specific surface areas and BET-*C* constants of the above samples are given in Table 1.

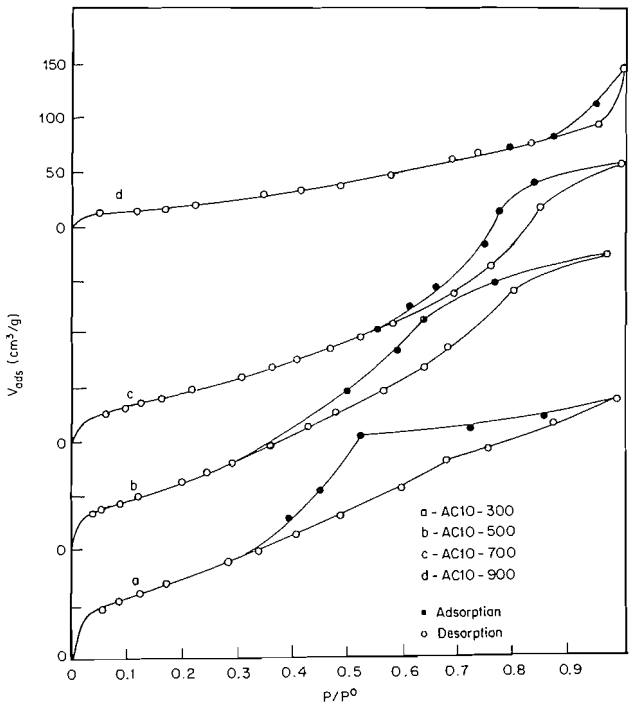

FIG. 3. Adsorption–desorption isotherms of nitrogen at −196°C on the calcination products of AC10.

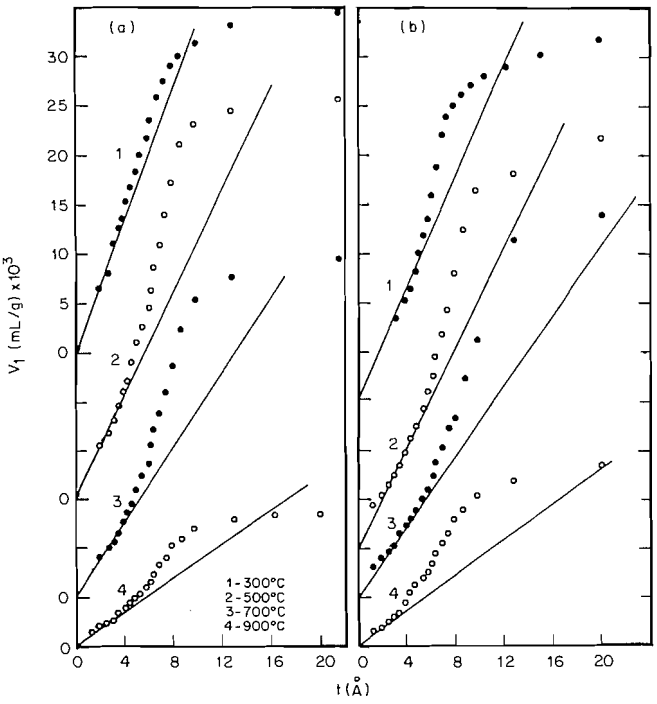

FIG. 4. V_1–t plots of nitrogen adsorbed on the calcination products of (*a*) AC10 and (*b*) AC25.

The surface areas of $CuO-Al_2O_3$ calcined in the temperature range 300–900°C reveal clearly that the increase of copper content in the precipitated alumina is associated with a marked decrease in the surface area. The effects were more pronounced at higher calcination temperatures. This may be interpreted by the diffusion of divalent copper ions in the matrix of alumina which appears to be associated with a more effective elimination of a good fraction of smaller pore, leading to a marked decrease in surface area. Within the temperature range investigated, the BET C constant changes with temperature and metal content.

The t plot of De Boer and co-workers (22, 23) has attracted a good deal of attention as a simple and direct means of interpreting nitrogen adsorption isotherms and characterising the porosity of solid adsorbents. The method consists of plotting the volume of nitrogen adsorbed on the solid under investigation against the corresponding statistical thickness, t, of the adsorbed layer of nitrogen on a nonporous reference solid. Lippens *et al.* (22) calculated the mean monolayer thickness as 3.541 Å and used this to calculate t ($t = 0.354V/V_m$) at the corresponding P/P^0 (where V is the volume of nitrogen adsorbed and V_m is the monolayer capacity). The slope of the linear t plot provides a measure of the surface area S_t ($m^2\ g^{-1}$) of the solid, according to the relation

$$S_t = \frac{V_1}{t} \times 10^4$$

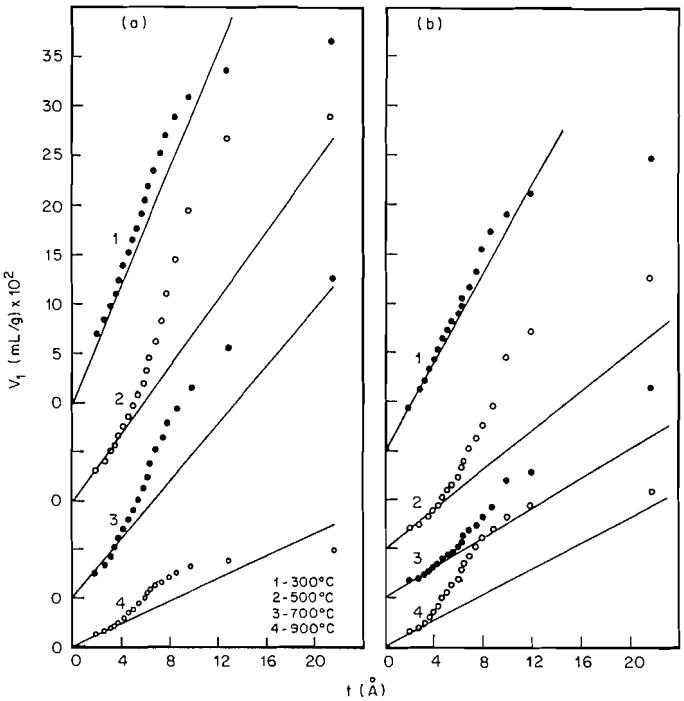

FIG. 5. V_l–t plots of nitrogen adsorbed on the calcination products of (*a*) AC50 and (*b*) AC1:1.

De Boer and co-workers have demonstrated that a deviation from the straight line is associated with the existence of pores in the solid. A downward deviation from the straight line (negative deviation) indicates the presence of micropores; their filling by the adsorbate molecules cuts down their surface from further adsorption, while an upward deviation from the straight line (positive deviation) indicates the presence of mesopores in which capillary condensation can take place, causing the amount adsorbed to increase beyond the straight line in the V_l–t plot. In these plots, the t curves of De Boer and co-workers (22, 23) and Mikhail *et al.* (24) were used.

Surface-area values calculated by the V_l–t method (S_t) are given in Table 1. Satisfactory agreement is observed between the corresponding S_{BET} and S_t values, indicating the correctness in the choice of the t curve used in the analysis. The V_l–t plots constructed for samples AC10, AC25, AC50, and AC1:1 heated at different temperatures are shown in Figs. 4 and 5. From these plots, an upward deviation is found to commence at lower t value for samples heated to 300°C. This positive deviation does not continue and reverts back at relatively higher t value ($\simeq$10 Å) indicating that the samples form a mixed pore system. When the temperature is raised above 300°C, most of the micropores are changed to mesopores. These changes are also reflected in the total pore volume (V_T), determined by the volume adsorbed at $P/P^0 = 0.95$ and the average pore radii.

Thermal treatment of CuO–Al_2O_3 samples up to 900°C is accompanied by a continuous decrease in surface area. The average pore radius indicates some widening up to 500°C for AC50 and AC1:1 and continuous to 700°C for AC10 and AC25. At this temperature it may be postulated (25) that, during calcination, the cryptocrystalline material moves from the surface of wider pores to fill the smaller capillaries or pores, so that the average pore radius increases. The increase in the total pore volume (V_T) observed at 500°C may be attributed to the removal of water molecules held in the intercrystalline pores, leading to an increase of the accessibility to the nitrogen molecules. Increasing the calcination temperature is accompanied by a decrease in pore radius and the appearance of microporosity as clearly shown in V_l–t plots (Figs. 4 and 5), indicating the commencement of a process of shrinkage.

There is another way to evaluate the total surface area, which might be used under favourable conditions as a substitute for the BET method. This comes from pore size analysis and the surface associated with the different groups of pores present. The pore size analysis carried out using nitrogen adsorption was made by using the corrected model-free method (26) for mesopore analysis, and the micropore method (27) for micropore analysis. Computation was carried out starting from $P/P^0 = 0.95$ down to $P/P^0 = 0.3$, so as to completely cover the hysteresis region of adsorption. It was decided that the parallel plate model can reasonably describe the shape of the pores. The results shown in Table 1 fulfill all criteria for correct pore structure analysis, namely agreement between the cumulative surface area (S_{cum}) and S_{BET}, as well as agreement between cumulative pore volume (V_{cum}) and total pore volume (V_T).

Pore volume distribution curves could be constructed and they are shown in Figs. 6 and 7, for the samples calcined at 500°C and AC25 calcined in the temperature range (300–

900°C). The pore volume distribution curves reveal several interesting points: (*1*) The number of pores, as shown by the height of the distribution curve, is substantially reduced on increasing both the copper content and the calcination temperature. This decrease parallels the decrease in surface area. (*2*) Solids with high copper oxide content have a noticeable effect on both the meso- and micropores in both number and size. A more significant effect was noticed for AC50 and AC1:1 where microporous (X-ray) amorphous solids are formed. (*3*) The effect of calcination temperature on the pore volume curves is mainly reflected in a decrease of their number. Small shifts to higher pore radii were observed specially at 500°C. On increasing the calcination temperature to 700°C a group of narrow pores was formed, owing to the formation of small crystallites of CuO. The presence of both micropores and mesopores in the samples points to inhomogeneity of the samples. At 900°C copper alumina spinels were formed which were characterised by a low degree of heterogeneity due to their crystallinity, and this is indicated by the drastic decrease in surface area and the disappearance of the sample mesoporosity. This is in accordance with the X-ray findings.

A tensammetric study of the adsorption of cationic polymers and copolymers

TRUIS SMITH-PALMER[1] AND CHERYL ROBERTS
Chemistry Department, Saint Francis Xavier University, Antigonish, Nova Scotia B2G 1C0

Received December 10, 1990[2]

TRUIS SMITH-PALMER and CHERYL ROBERTS. Can. J. Chem. **69**, 1516 (1991).

The tensammograms of several sets of cationic polyacrylamide copolymers are discussed and compared. Tensammograms are not affected by molecular weight, but plots of capacitive current at a chosen potential versus charge density give regular curves.

Key words: tensammetry, cationic, polyacrylamide, charge density.

TRUIS SMITH-PALMER and CHERYL ROBERTS. Can. J. Chem. **69**, 1516 (1991).

On a comparé et on discute des tensammogrammes de plusieurs ensembles de copolymères cationiques du polyacrylamide. Les tensammogrammes ne sont pas affectés par la masse moléculaire, mais des courbes du courant capacitif à un potentiel donné en fonction de la densité de charge fournissent des droites régulières.

Mots clés : tensammétrie, cationique, polyacrylamide, densité de charge.

Introduction

Cationic polyacrylamide copolymers come with a wide variety of functional groups and in a wide variety of molecular weights, although for the most part their weights tend to be smaller than those of their anionic counterparts, which are often 1–20 million. These cationic polymers are used in a variety of industries, often to help flocculate systems of negatively charged particles. There has been much discussion in the literature on their mechanism of action — whether it is due to charge neutralization (1), bridging, or a combination thereof (2) which depends on molecular weight and charge density. Whichever the mechanism, adsorption of the polymers must be considered as a first step. Many colloids of industrial interest such as clays, coal, and silica have negatively charged surfaces. However, the surfaces can become positively charged in the presence of certain modifiers, and there are other particles, e.g. goethite, which have positively charged surfaces. The nature of the surface charge would naturally be expected to affect the adsorption process.

Tensammograms are effectively plots of capacitive current versus applied potential (3). As the potential is scanned from 0 to −2 V, the surface of a static mercury drop is at first positively charged, with the charge gradually decreasing to zero then becoming increasingly negative. The capacitive current depends on the nature of the ions and/or molecules which are adsorbed onto the surface of the mercury drop at the potential in question. For surface-active molecules and some small polymers such as polyethylene glycol, there is usually a distinct potential range where surface adsorption occurs, and at the limits of this range, adsorption/desorption peaks are often seen (e.g. refs. 4, 5). Polyelectrolytes are also surface active, but are very much larger than detergents and are made up of alternating hydrophyllic and hydrophobic regions rather than the distinct "heads" and "tails" of detergents. The tensammograms of large polyelectrolytes do not always exhibit absorption or desorption peaks, as their size makes them absorb so strongly that such peaks would be outside the useful 0–2 V potential range. However, their tensammograms are distinctly different from the tensammogram for KCl alone and the general shape of the tensammograms of anionic and nonionic polyelectrolytes are distinctly different from those of cationic polyelectrolytes (6). Ions such as chloride which can adsorb onto the Hg surface can be replaced by the much larger polyelectrolytes, which can then undergo various rearrangements on the surface (7), or undergo partial desorption where just some of the segments desorb. Although the adsorption of different kinds of species effects the capacitive current differently (3), for a series of related compounds the effects on the current should be of the same sign but of varying magnitude. The surface of the mercury is featureless (structurally homogeneous), and should not itself influence the binding of the polymer. Thus by measuring the capacitive current at various potentials, one can gain insight into how the adsorption changes with surface charge.

We have previously shown that we can determine the concentration of polyacrylamides and cationic and anionic acrylamide copolymers using both polarographic maximum suppression (8) and tensammetry (6), and that we can use tensammetry to determine the mol% anionicity of anionic acrylamide/acrylate copolymers after complexation with tetraethylammonium chloride (9). In this paper we compare the tensammetric behaviour of various cationic polymers and copolymers in order to study parameters which affect their adsorption at various potentials. We have also examined the use of tensammetry in determining the charge densities (mol%) of the cationic acrylamide copolymers themselves. Various titrations (conductimetric, colorimetric) are currently used by most labs to determine the charge densities of cationic copolymers. These titrations rely on knowledge of the exact amount of polymer present, and for some the change of colour of the indicator is not sharp.

Experimental

Tensammograms were recorded, as described previously (6, 9), using a Princeton Applied Research (PAR) Model 174A Polarographic Analyzer and a Model 303 static mercury drop electrode (SMDE) in conjunction with a PAR Model 174A/50 AC Polarographic Analyzer Interface and a PAR Model 122 Lock-in Amplifier. The analog output of the polarograph was digitized using an Apple IIe microcomputer with Interactive Microware software (Lab Data Manager, Scientific Plotter) and hardware (ADALAB Interface card, ADA-AMP Instrumentation Amplifier). A modulation amplitude of 10 mV (p-p) at 200 Hz was used. The phase was adjusted to be 135 degrees away from the phase of the reference modulation to minimize faradaic currents. The hanging mercury drop electrode (small) and a scan rate of 5 mV/s were used. All potentials reported are relative to a silver-silver chloride reference electrode containing KCl (saturated).

The Magnifloc polymers were obtained from the American Cyanamid Corp. The Praestol polymers were obtained from Energy, Mines

and Resources (Edmonton) and Stockhausen, Germany. Standard deviations were determined using 12 measurements.

Results and discussion

At low concentration, capacitive current is a function of the concentration of surface active material in solution, as well as a function of the structure of that material. However, at concentrations upward of ~20 ppm, depending on the polymer in question, the adsorbed monolayer is saturated and tensammograms are not affected by concentration. Solutions of KCl give a tensammogram which has a characteristic hump at ~−300 mV where specific adsorption of Cl^- occurs (6), and another hump at ~−1800 mV which we attribute to the potassium ions (10). The tensammograms of a non-ionic polyacrylamide, Magnifloc 905N, and a set of standard cationic polyacrylamide copolymers, Magnifloc 491, 492, 494, and 496 (50 ppm) are shown in Fig. 1. These so-called "cationic polyacrylamides" are co-polymers of acrylamide and the methyl chloride quaternary of dimethyl aminoethyl acrylate [CH_2=$CHCO_2CH_2CH_2N(CH_3)_3Cl$]. The tensammograms of the cationic copolymers cross each other, and that of the non-ionic polyacrylamide, just before −600 mV.

At this potential only non-specific attraction of polymers to the electrode surface must occur, i.e., there will be no electrostatic attraction or repulsion between the surface and the polymers at this potential. However, as the water molecules near the surface will be oriented at random in the absence of a charge on the surface, polymers are able to readily approach the surface and are then held there by dispersion forces. The curve for the non-ionic polymer shows no Cl^- hump in the ~−300 mV region and the capacitive current there is depressed with respect to that of KCl alone (6). At this potential the surface of the mercury drop is positively charged and the cationics would be expected to adsorb to a lesser extent than does the polyacrylamide. The capacitive currents of the cationic copolymers become progressively higher as their charge densities increase, indicating that their effectiveness in replacing chloride ions from the surface decreases. Adsorption of positively charged polymers onto a positively charged surface has been reported previously (1). There the adsorption is not electrostsatic, but is the non-specific (dispersion forces) kind of bonding shown by non-ionic polymers. However, this attraction would be expected to be increasingly countered by electrostatic repulsion as the positive charge increased, thence the increase in capacitive current with % charge. At potentials more negative than the

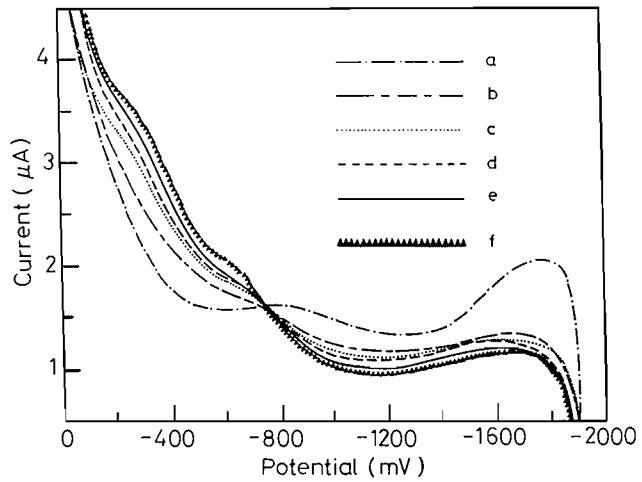

FIG. 3. Tensammograms of 50 ppm solutions of Magnifloc 905N (*a*), Praestol 611BC (*b*), Praestol 650BC (*c*), Praestol 644BC (*d*), Praestol 655BC (*e*), and Praestol 666 BC (*f*) in 0.25 M KCl.

crossover point, the cationic polymers would be expected to be increasingly attracted to the mecury surface as compared to the non-ionic polymer, as their % charge increases. This is manifested in the tensammograms by a decrease in the capacitive current. At potentials around −1600 mV the capacitive currents of all these polymers and of KCl show a similar rise. At this point the adsorption of potassium ions presumably predominates (10). The tensammograms of another series of copolymers where the cationic monomer is the methacrylate, [$CH_2C(Me)CO_2$-$CH_2N(CH_3)_3Cl$] are shown in Fig. 2. The presence of the extra methyl group is seen to have little effect on the overall shape of the tensammograms, or the crossover point. The most significant difference is that the tensammograms of the two copolymers of highest charge do not show a hump in the −1800 mV region, showing that they can effectively compete with the potassium ions. The tensammograms of a further series where the copolymer is the methyl chloride quaternary of dimethylaminopropylacrylamide (Fig. 3) are all fairly flat in the −1800 mV region and we must assume that the change in the copolymer makes it much better able to compete with K^+, even at low charge densities. The crossover point on these tensam-

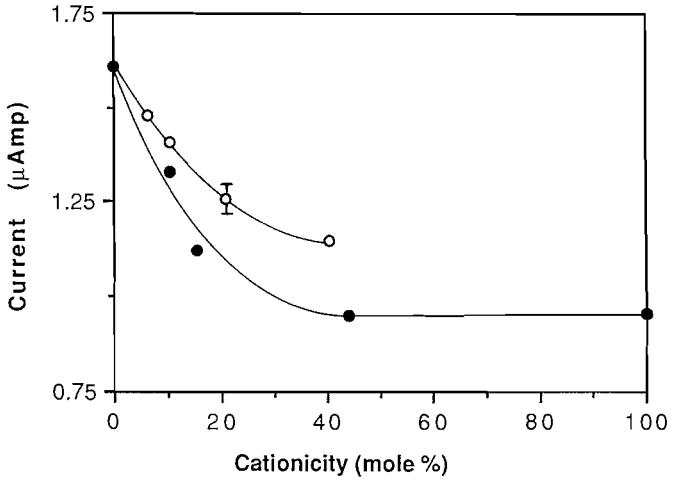

FIG. 5. Plot of current at −800 mV versus cationicity for 50 ppm solutions of dimethylaminoethylacrylate (○), and acrylamide and the methyl chloride quaternary of dimethylaminoethylmethacrylate (●) in 0.25 M KCL.

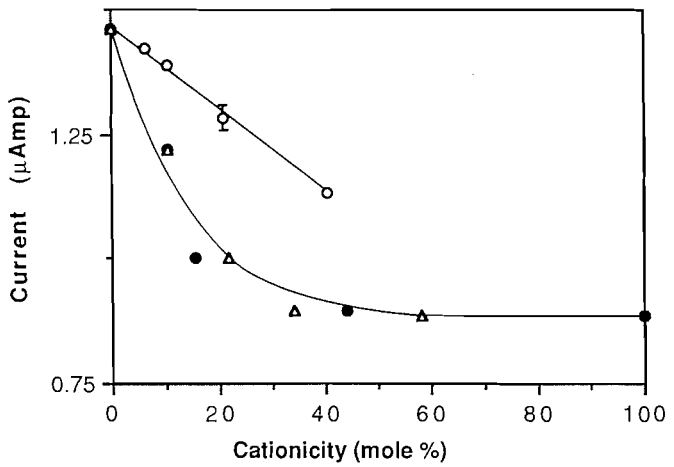

FIG. 6. Plot of current at −1100 mV versus cationicity for 50 ppm solutions of: copolymers of acrylamide and the methyl chloride quaternary of dimethyl aminoethylacrylate (○), acrylamide and the methyl chloride quaternary of dimethylaminoethylmethacrylate (●), and dimethylaminopropylacrylamide (△) in 0.25 M KCl.

mograms is at −760 mV, significantly more negative than for the acrylate copolymers.

By inspection of the tensammograms, potentials of −220 mV, −800 mV, and −1000 mV, were identified as points where the biggest changes in current occurred as a function of the copolymers' charge densities. Plots of capacitive current versus mol% cationicity are shown in Figs. 4, 5, and 6 for each of the potentials respectively. The plots show that the changes with charge density are fairly regular for each set, but that changing the cationic polymer does affect the capacitive current.

If the identity of the cationic monomer was known, the appropriate standard curves could be used to determine the mol% cationicity of a polymer. This method has the advantage of not being concentration dependent once a critical concentration is present, which is useful for polymers whose purity is questionable. The graphs at −800 mV and −1000 mV are the most useful because the tensammetric curves tend to be much more reproducible in this region. The actual currents measured in the tensammograms depend on the particular capillary being used. The electrodes were cleaned in HF and siliconized before use, but these cationic copolymers strongly adsorb onto glass and capillaries have to be changed fairly frequently. The tensammograms shown comparing the different cationic copolymers were all run on the same day using the same electrode, and using polymer solutions which were all prepared together 5 days prior to use. We have found that solutions of cationic polymers show aging effects — when freshly prepared they produce very fast settling rates of kaolin slurries, whereas much older solutions bring about drastically slower settling rates which depend more on the charge density (unpublished result). This may be due to the hydrolysis of the polymers, although aging effects have previously been reported for solutions of polyacrylamides (12).

When using tensammetry to determine the charge density of anionic acrylamide/acrylic acid copolymers, we found that the complexes formed with tetraethylammonium chloride gave distinct desorption peaks which were related to the charge density. For the cationic polymers above, the presence of ethanesulphonic, or pentanesulphonic acid changed the shapes of the tensammograms somewhat, but lead to no new distinct peaks, nor to improved 'standard' curves.

We next examined the tensammograms of a series of cationic polyelectrolytes (Magnifloc 567, 572, 573, 577 and 581) based on the reaction of dimethylamine and epichlorohydrin, giving [CH_2—$CH(OH)CH_2$—$N(CH_3)_2Cl$], with a range of average molecular weights varying from 5 000 to 250 000 respectively. Their tensammograms are almost identical to each other, with some slight differences occurring at their beginning. These polymers have high charge densities, and this is particularly shown by the lack of any hump at −1800 mV, similar to the tensammograms for the most highly charged Praestols. The tensammograms of three polydiallylydimethyl ammonium chlorides of different molecular weights, Magnifloc 585, 587, and 591, were also found to be independent of molecular weight, and to show a greatly decreased capacitive current with respect to KCl at −1800 mV.

Thus in general the molecular weight of a cationic polymer has little effect on its tensammogram. A similar result has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

reported previously for polyacrylamide (9). Thus we can say that the adsorption of these polymers onto a neutral or a negatively or positively charged mercury surface is independent of molecular weight. If this result can be extrapolated to smaller particles of various other identities where molecular weight is known to be an important parameter in controlling settling rates, it suggests that it is only the flocculation step and not the initial adsorption step that is molecular weight dependent. Adsorption isotherms determined on a system which is undergoing flocculation do not reveal this. If flocculation is occurring very fast with polymers of high molecular weight, particles are quickly bound together and removed from solution before the adsorption process is completed.

Conclusions

Positively charged polymers can adsorb onto a positively charged surface, but the extent of adsorption decreases with charge density. The adsorption onto the negatively charged mercury surface increases with charge density. However, as the surface becomes very negatively charged there is greater competition with cations and only the polyectrolytes of highest potential and charge effectively compete with K^+. The dependence of adsorption (as manifested by the capacitive current) on charge density can be used to estimate the charge density of unknown polymers to within ±5%.

Infrared spectra are reported for binary complexes between perfluoro-*tert*-butanol as proton donor and nitromethane and acetone as bases. The complexes have been investigated in low temperature solutions and in cryogenic matrices. The spectra have been evaluated in terms of frequency shifts ($\Delta\nu_{OH}$), half widths (FWHH) and anharmonicities (κ) caused by the hydrogen bonding of these complexes. The influence of the environment (solvents and solid matrices) as well as temperature on the spectra of the complexes has also been studied and is discussed in detail.

Key words: hydrogen bonding, temperature effects, solutions, matrix.

LOUISE SCHRIVER, ANDRÉ SCHRIVER, STEFAN PEIL et OTTO SCHREMS. Can. J. Chem. **69**, 1520 (1991).

On rapporte les spectres infrarouges des complexes binaires entre le perfluoro-*tert*-butanol, en tant que donneur de protons et le nitrométhane et l'acétone en tant que bases. On a étudié les complexes en solutions à basse température et dans des matrices cryogéniques. On a évalué les spectres en fonction des déplacements des fréquences ($\Delta\nu_{OH}$), des largeurs à mi-hauteur (FWHH) et des harmonicités (κ) provoquées par les liaisons hydrogènes dans ces complexes. On a également étudié l'influence de l'environnement (solvants et matrices solides) aussi bien que de la température sur les spectres des complexes, et on en discute largement.

Mots clés : liaisons, hydrogènes, effet de temperature, solutions, matrix.

[Traduit par la rédaction]

Introduction

Because of its strong acidic properties (pK_a = 5.4 at 298 K) (1) and weak tendency for self-association, perfluoro-*tert*-butanol (PFTB) is an excellent candidate as proton donor in the experimental studies of hydrogen bonded systems (2, 3). Schrems *et al.* (4) examined the PFTB – dimethyl ether complex in the gas phase, CCl_4 solution and solid argon as part of their studies on proton donor abilities of fluoroalcohols. Iskanderov *et al.* (5, 6) investigated hydrogen-bonded complexes between PFTB and various bases in cryosolvents like Kr, Xe, and Freons by means of IR spectroscopy. They also studied the low frequency spectra of some of these complexes (7). Recently, Luck *et al.* (8) examined in detail the IR spectra of the complexes between PFTB and acetonitrile-D_3 (AN-d_3) in dilute solutions of a large variety of solvents and isolated in solid Ne, Ar, Kr, Xe, and N_2 matrices. The near-infrared studies performed by Burneau (9) of the same system provided complementary information. The present report consequently extends the last two studies with two further proton acceptor molecules. In detail, we have investigated the IR and NIR spectra of two complexes involving PFTB as proton donor interacting with nitromethane (NM) and acetone (AC) for which only scarce information has been available so far (3). NM with a proton donor affinity (PA) of 180 kcal/mol is a weaker base than AN (PA = 187 kcal/mol) while AC (PA = 195 kcal/mol) is somewhat stronger. The aim of these studies is to manifest the correlation between base strength and spectral properties (frequency shifts $\Delta\nu_{OH}$, $\Delta 2\nu_{OH}$, band profiles, intensities and multiplicities, isotope shifts) obtained from the different phases and temperatures.

Experimental

The experiments were performed under similar conditions as previously described (8). PFTB was obtained from SCM Chemicals (Gainesville, FL, USA) and the rare gases were supplied by Messer Griesheim (Düsseldorf, FRG). Deuterated PFTB was prepared by successive exchanges with D_2O and vacuum distillation to an isotopic enrichment of 95%. Acetone, acetone-d_6, and nitromethane-d_3 (NM-d_3) were UVASOL® grade and obtained from Merck (Darmstadt, FRG). The Freons (from Dupont Nemours, France) were distilled and kept over P_2O_5 at 273 K. The spectra were resolved with an accuracy of 1 cm^{-1}. Careful attention was paid to the spectral backgrounds. The solvent absorptions have been subtracted. In matrix studies the experimental details have been found to be identical to those described in ref. 8.

Results

1. Complexes between PFTB and NM-d_3

Measurements in solution

Typical spectra of the fundamental and overtone OH stretching region of dilute solutions of PFTB and NM-d_3 in cryosolvent solutions (1:1 volume mixture of Freon 11 and Freon 114B2) at various temperatures (range 295–113 K) are pre-

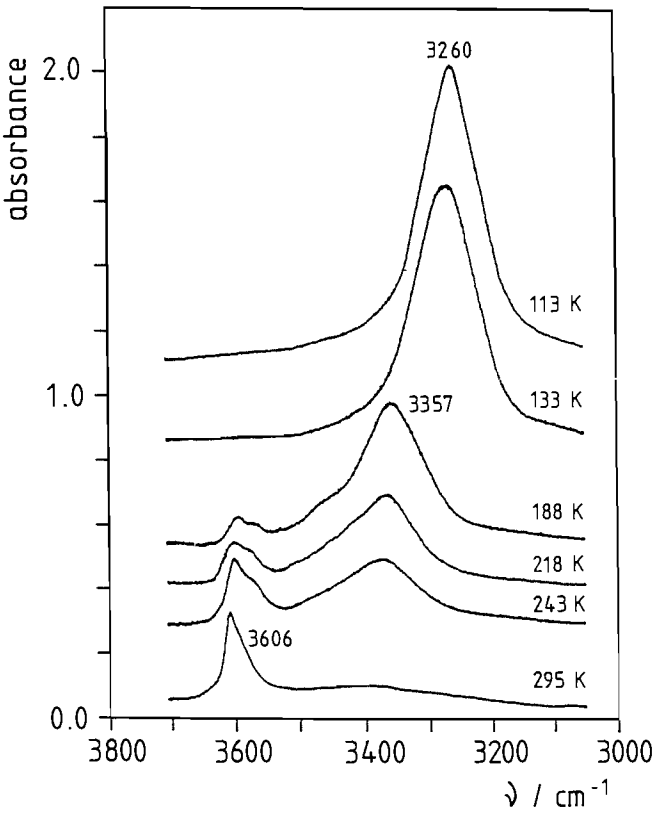

FIG. 1. Temperature effect on the fundamental ν_{OH} absorption of the PFTB···NM-d_3 complex diluted in a mixture of Freon 11 and Freon 114B2 (volume ratio 1:1). Concentrations (c) at room temperature were c[PFTB] = 0.015 mol, c(NM-d_3] = 0.03 mol. Pathlength (d) = 2 mm.

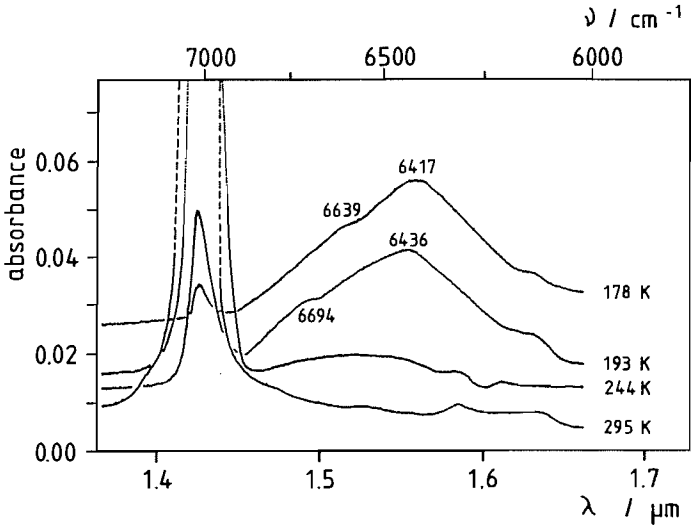

FIG. 2. Temperature effect on the first overtone of the OH stretching vibration of the PFTB···NM-d_3 complex diluted in Freon 11 and Freon 114B2 (volume ratio 1:1). Concentrations (c) at room temperature were c[PFTB] = 0.03 mol, c(NM-d_3] = 0.04 mol. Pathlength (d) = 44 mm.

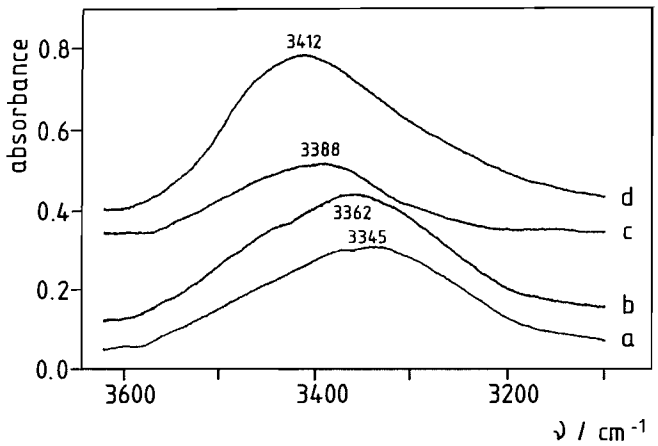

FIG. 3. Absorption spectra of PFTB/NM-d_3 mixtures at two molar fractions in the 3600–2900 cm^{-1} region:

(a) 0.5 mol PFTB in NM-d_3, pathlength (d) = 54 μm;
(b) Solution (a) diluted (1:2) in Freon mixture, d = 103 μm;
(c) Solution (a) diluted (1:10) in Freon mixture, d = 383 μm;
(d) 0.5 mol NM-d_3 in PFTB, pathlength (d) = 54 μm.

sented in Figs. 1 and 2. This 1:1 mixture of the Freons remains a liquid down to 130 K and becomes vitreous on passing to even lower temperatures (10). At room temperature we observe mainly the free OH absorption band ($\nu_{OH,f}$) at 3606 cm^{-1} in the ν_{OH} fundamental region. However, there is also a weak and broad OH absorption band ($\nu_{OH,b}$) with a maximum at about 3395 cm^{-1}.

The tendency for hydrogen bond formation increases with decreasing temperature. This can be illustrated by the decrease of the free OH band at 3606 cm^{-1} and the increase of the absorption band associated with bonded OH groups ($\nu_{OH,b}$). At 133 K, $\nu_{OH,f}$ has even disappeared completely, whereas $\nu_{OH,b}$ shows an intense symmetric band which is finally shifted to 3260 cm^{-1} at 113 K. Simultaneously, the half width of the band (FWHH) has been strongly reduced on passing from 295 to 243 K. At 133 K, the lowest temperature measured, FWHH reaches about 100 cm^{-1}. The shift of $\nu_{OH,b}$ from 3395 to 3260 cm^{-1} at 113 K clearly indicates that the hydrogen bond strength increases with decreasing temperature. From Fig. 1 it can be demonstrated that low temperatures do not only strengthen the hydrogen bond but also reduce the half width of $\nu_{OH,b}$.

In the 6000 to 7100 cm^{-1} region (see Fig. 2), a broad but weak band at about 6500 cm^{-1} appears with decreasing temperature while the $2\nu_{OH,f}$ of monomeric PFTB at 7033 cm^{-1} decreases simultaneously. The first overtone of the stretching mode of OH interacting with NM-d_3 increases in intensity with decreasing temperature as the associated $\nu_{OH,b}$ fundamental mode does. The maximum of the band is shifting from about 6490 cm^{-1} at 244 K to 6417 cm^{-1} at 178 K. It should be noted that at 193 K a submaximum is observed at about 6700 cm^{-1} which could be a combination tone of $2\nu_{OH,b}$ with a low frequency mode. At the same temperature, two further bands occur at 4303 and 3968 cm^{-1}. The first one is assigned to the combination mode of $\nu_{OH,b} + \nu_{6(CF_3)}$. By comparison with the PFTB–AN complex (9, 11) the second band is most likely a combination of $\nu_{OH,b}$ with the *out-of-plane bending mode* (τ_{OH}) assuming that τ_{OH} has its maximum absorption at 611 cm^{-1}.

For comparison spectra of two different binary mixtures recorded at room temperature are shown in Fig. 3. The spectra demonstrate the effect of changes in concentration as well as the influence of the nature of the solvent. Increasing concentration of either acceptor or proton donor favours complex formation. In solutions of PFTB in NM-d_3 the band maximum

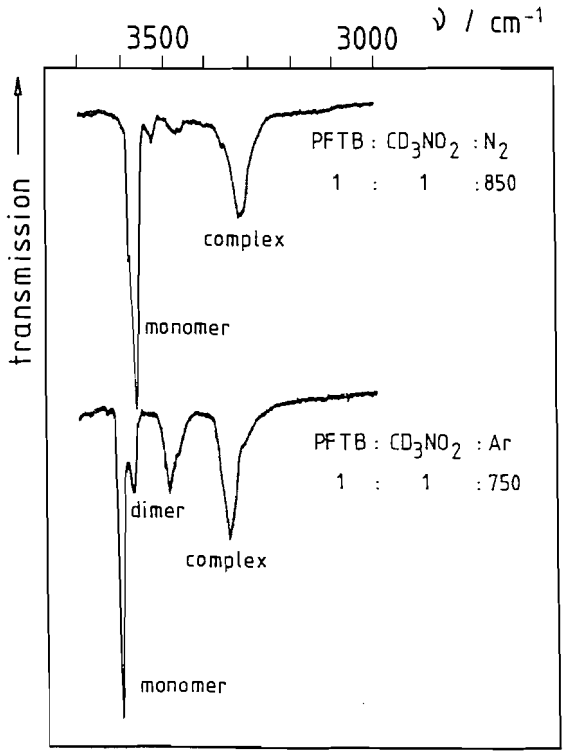

FIG. 4. OH stretching absorptions of PFTB/NM-d_3 in argon and nitrogen matrices at 10 K.

shifts to 3345 cm^{-1} with a half width (FWHH) of about 270 cm^{-1}. On the other hand, NM-d_3 dissolved in PFTB provides spectra with band maxima at higher frequencies than in dilute Freon solutions as demonstrated in Fig. 3. The interaction of the complexes with NM-d_3 as solvent is obviously stronger than with Freons. PFTB as solvent provides an environment which seems to be slightly more inert than the Freons.

Formation of 2:1 complexes has also to be kept in mind. However, we found no indication for the existence of a $(PFTB)_2\cdots$NM-d_3 complex in the binary solution of 0.5 mol NM-d_3 in PFTB while such a 2:1 complex was detected in a binary solution with AN-d_3 (8). The weaker hydrogen bonding with NM-d_3 obviously does not enhance a cooperative effect by increasing the oxygen basicity when the hydrogen bond is formed in the 1:1 complex.

Measurements in matrices

PFTB$\cdots$NM-d_3 complexes have also been studied in low temperature matrices. Typical spectra of PFTB$\cdots$NM-d_3 1:1 mixtures in Ar (PFTB:NM-d_3: Ar = 1:1:750) and N_2 (PFTB:NM-d_3:N_2 = 1:1:850) matrices are shown in Fig. 4. Infrared matrix spectra have been reported in the literature for PFTB (12–14) as well as for NM (15). In the matrices with PFTB:AN-d_3 1:1 mixtures the strongest new bands appear at 3358 cm^{-1} in Ar and at 3324 cm^{-1} in N_2. They can clearly be assigned to $\nu_{OH,b}$ of the 1:1 complex. In comparison with spectra obtained from solutions a substantial narrowing of the $\nu_{OH,b}$ absorption is observed. However, the bands are asymmetric on the low frequency side even at very high dilution.

Annealing of the matrices caused the appearance of a second component at about 3342 cm^{-1} in Ar and 3315 cm^{-1} in N_2. This shoulder could have several origins: (*i*) the existence of two conformations, (*ii*) contributions from 1:2 complexes of the type PFTB$\cdots$(AN-d_3)$_2$, (*iii*) other types of intermolecular interactions (16).

In both Ar and N_2 matrices the OH *bending mode* was observed at 1418 cm^{-1} with a blue shift of 36 cm^{-1} compared to the absorption of non-hydrogen bonded OH groups.

Deuterated PFTB was also investigated in Ar matrices. The ν_{OD} band is observed at 2498 cm^{-1}, providing an isotopic ratio $\nu_{OH}/\nu_{OD} = 1.34$. The halfwidth (FWHH) of the stretching band decreased by a factor of $\sqrt{2}$ on deuteration.

2. Complexes between PFTB and AC-d_6

Measurements in mixed Freon solutions

The experiments with PFTB/AC-d_6 mixtures have been performed in analogy to those with NM-d_3. From Fig. 5 it can be seen that remarkable changes occur in the band contours of $\nu_{OH,b}$ of PFTB (0.1 mol) complexed with AC-d_6 (0.15 mol) when the temperature is lowered from 295 to 98 K. At room temperature the band centered at about 3240 cm^{-1} is very broad (FWHH $\approx$ 340 cm^{-1}) with ill-defined submaxima. With decreasing temperature the intensity of this band increases gradually, showing considerably narrowing and frequency shifts. At 98 K this band becomes fairly symmetric and shows a well-defined maximum at 3030 cm^{-1}. Simultaneously, however, other bands appear at about 2830, 2715, and 2610 cm^{-1}. The absorption at 2827 cm^{-1} grows strongly with decreasing temperature. These band structures are similar to those observed for the PFTB$\cdots$AN-d_3 complex (8). They have been interpreted in terms of resonances between the ν_{OH} and either $2\nu_2$ (2827 cm^{-1} absorption) or combinations involving ν_2 to ν_6 modes (2708, 2610 cm^{-1} bands). The shift of the ν_{OH} absorption towards lower frequencies permits Fermi resonance with decreasing temperature and providing an enhancement of its intensity.

In the region of the first overtone a broad and weak absorption is observed at 298 K (Fig. 6). Its center is located at about 5640 cm^{-1} and shifts to lower frequencies with decreasing temperature. At 129 K its maximum is at 5258 cm^{-1} and a shoulder at 6037 cm^{-1}. Submaxima could be indications of contributions of resonances between the $2\nu_{OH}$ and various combination levels. Assignments of overtone and combination modes beyond all doubt are difficult to make, as for example for the two further absorptions in the spectra at about 4600 and 3930 cm^{-1}. With decreasing temperature their intensity diminishes slightly showing that they cannot belong to associated species. At 298 K the first one consists of two overlapped bands with maxima at 4722 and 4621.5 cm^{-1}. The 4722 cm^{-1} component disappears at low temperatures while the other one shifts its maximum to 4594 cm^{-1}. This could be due to a combination involving the ν_{OH} mode. The band at 3930 cm^{-1} is tentatively assigned to a combination of ν_{OH} with the *out-of-plane bending mode* τ_{OH}.

Measurements in matrices

Argon matrices

A typical spectrum of a mixture of PFTB and AC-d_6 isolated in solid argon at 6 K (PFTB:AC-d_6:Ar = 1:1:150) is shown in Fig. 7. The spectrum is characterized by absorption structures involving Fermi resonance similar to those observed in solutions at 88 K. Band maxima are located at 3071, 2837, 2708, and 2625 cm^{-1}. Annealing of the matrices generally leads to additional complex formation within the matrix but also to narrowing of the complex bands. As previously reported (17) a more favourable orientation of the complex and/or

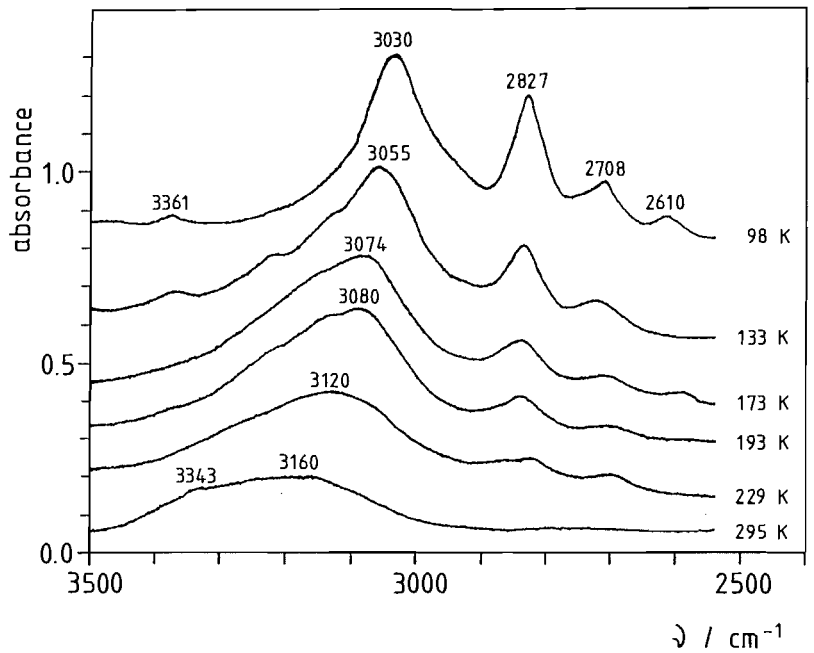

FIG. 5. Temperature effect on the ν_{OH} absorption of the PFTB···AC-d_6 complex diluted in a mixture of Freon 11 and Freon 114B2 (volume ratio 1:1). Concentrations (c) at room temperature were c[PFTB] = 0.1 mol, c(AC-d_6] = 0.15 mol. Pathlength (d) = 200 μm.

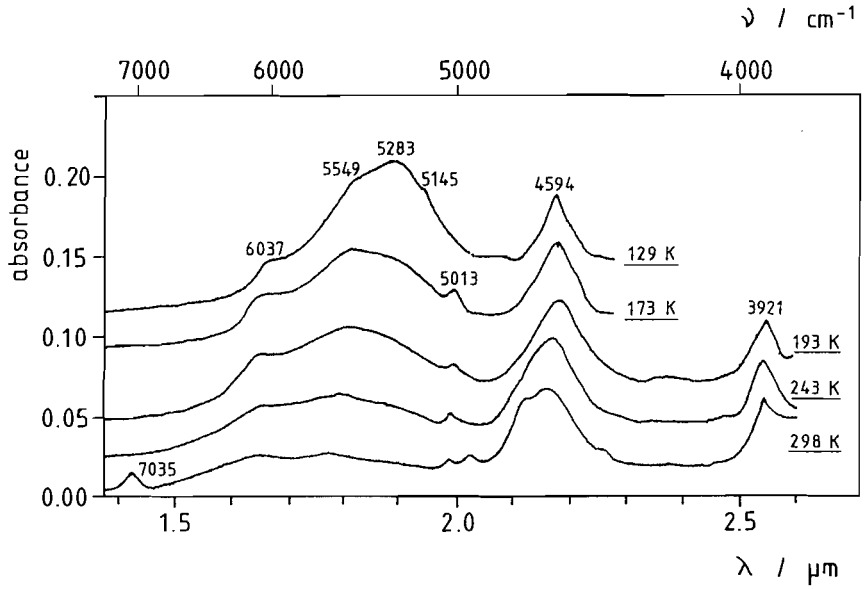

FIG. 6. Temperature effect on the first overtone of the OH stretching vibration in the PFTB···AC-d_6 complex diluted in a mixture of Freon 11 and Freon 114B2 (volume ratio 1:1). Concentrations (c) at room temperature were c[PFTB] = 0.1 mol, c(AC-d_6] = 0.15 mol. Pathlength (d) = 10 μm.

closer packing in the matrix after the annealing process might be responsible for this observation.

After deposition at 6 K the strong absorption at 3071 cm^{-1} also shows a shoulder at ≈3150 cm^{-1}. This shoulder disappears when AC-d_6 is replaced by AC. Consequently, it could be assigned to the combination $\nu_{s(CD_3)} + \delta_{s(CD_3)}$ previously observed in the IR spectra of AC-d_6 in solution (18). The OH bending mode of the complex appears at 1437.5 cm^{-1} with a blue shift of 55.5 cm^{-1} (Fig. 7). With increasing concentration of PFTB and after annealing to 35 K a shoulder on the low frequency side of the 3085 cm^{-1} band is observed at 3023 cm^{-1}. This is probably caused by 2:1 complexes of the type ROH···ROH···AC-d_6 (Fig. 8).

We have also performed some experiments with deuterated PFTB. The main absorption of the complex $\nu_{OD,b}$ was identified at 2298 cm^{-1}.

Nitrogen matrices

In nitrogen matrices the ν_{OH} absorption has maxima at 3054 cm^{-1} (FWHH ≈ 100 cm^{-1}) for the strongest band, and at 2840 cm^{-1} ($2\nu_2$ in resonance) and 2705 cm^{-1}. The OH *bending mode* has its maximum at 1436 cm^{-1}. The ν_{CO} absorption at

1696 cm^{-1} shows a red shift comparable to the one observed for AC:HI (19).

Discussion

The influence of the strength of the hydrogen bond on OH stretching frequencies, frequency shifts, bandwidths, and anhrmonicities is discussed on the basis of the experimental results described above.

(i) Frequency shifts

In Table 1 the maxima of the fundamental ν_{OH} absorptions are given for the two systems studied in solutions and matrices. For comparison, the results for the PFTB···AN-d_3 complex obtained from previous studies (8) are also included. As expected, $\Delta\nu_{OH}$ ($\Delta\nu_{OH} = \nu_{OH,gas} - \nu_{OH,b}$) increases with the strength of the base. However, in solutions at room temperature this observation is not so evident because of the broad $\nu_{OH,b}$ absorption. At low temperatures the band maxima are much better defined. Figure 9 shows the correlation between the observed frequency ν_{OH} and the temperature. A linear relation is obtained for the PFTB···AC-d_6 complex for the whole temperature range measured with the coefficient $d\nu/dT = 0.40$ cm^{-1} K^{-1}. In the case of the PFTB···NM-d_3 complex the relation is linear only at temperatures above 150 K with $d\nu/dT = 0.70$ cm^{-1} K^{-1}. For comparison $d\nu/dT = 0.55$ cm^{-1} K^{-1} for the PFTB···AN-d_3 complex (8). Obviously, there is a correlation of $d\nu/dT$ with the strength of the proton acceptor: the higher the $d\nu/dT$ value the stronger is the proton affinity of the acceptor. The fracture in the curve of the PFTB···NM-d_6 system at about 150 K indicates the phase transition from the liquid to the viterous phase.

The $\Delta\nu$ values observed at 185 K in solution are lower than those in matrices at 6 K, demonstrating the importance of the solvent effect.

Recently, a linear dependence between the observed frequencies ν_{OH} of alcohols on $T_c^{1/2}$ (T_c = critical temperature) of the solvent and matrix materials has been found (20). Differences in band shifts ($\Delta\nu_{OH}$) between different solvents can

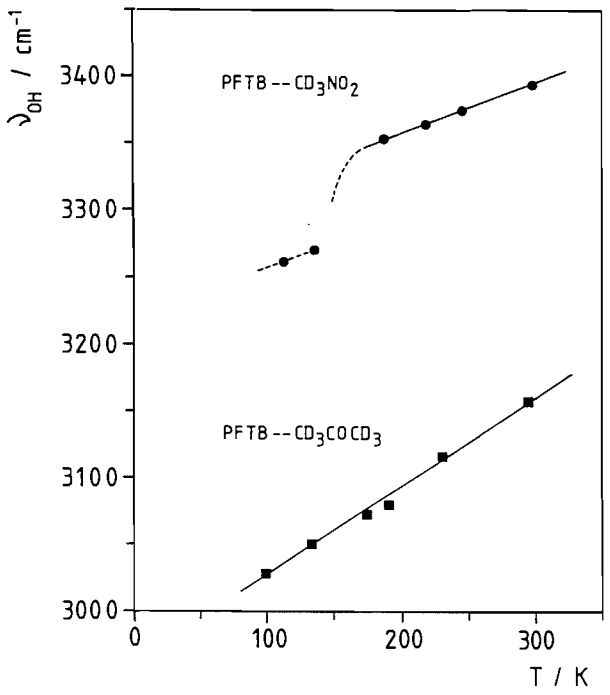

FIG. 9. OH stretching frequencies $\nu_{OH,b}$ for PFTB···AC-d_6 and PFTB···NM-d_3 complexes plotted as a function of temperature.

in a first approximation be considered as a measure of the intermolecular potential. Taking into account that the Lennard–Jones parameter ϵ_0 can be estimated at the critical temperature T_c as

$$\epsilon_0 = 0.74\, kT_c$$

and the pair potential U_{12} of dispersion forces between two different molecules 1 and 2 is given by

$$U_{12} = (U_{11} \cdot U_{22})^{1/2} \approx (T_{c1} \cdot T_{c2})^{1/2}$$

linear relationships between ν_{OH} of alcohols and $T_c^{1/2}$ of the solvent or matrix material have been obtained (20).

For ν_{OH} (Freon), extrapolated to temperatures where the matrix spectra are recorded (≈10 K) and the following proportionality holds:

$$\frac{\Delta\nu_{OH(Freon)}}{\Delta\nu_{OH(matrix)}} \sim \frac{T_{c(Freon)}^{1/2}}{T_{c(matrix)}^{1/2}}$$

with $\Delta\nu_{OH(Freon)} = \nu_{OH(gas)} - \nu_{OH,b(Freon)}$.

We have applied this relation for the two systems investigated. $\nu_{OH,b}$ in Freons, extrapolated to 10 K, are at 3282 ($\Delta\nu_{OH}$ = 348 cm^{-1}) and 2963 cm^{-1} ($\Delta\nu_{OH}$ = 667 cm^{-1}) for NM-d_3 and AC-d_6, respectively. $\nu_{OH,b}$ values for argon matrices are given in Table 2, $T_{c(Argon)}$ is 170.7 K. The good agreement between the two calculated Freon values for T_c (≈260 K) supports the approach described above.

In Fig. 10 we have plotted the ratio $(\nu_{gas} - \nu_{OH,b})/\nu_{gas}$ ($\nu_{OH,b}$ are values from argon matrices) against the proton affinity (PA). Results obtained with other bases like dimethyl ether (DME) (4), NH_3 (20), C_5D_5N (21) have also been included, as well as the results obtained with the proton donors HCl and HI (23, 24).

For weak and medium strong hydrogen-bonded complexes between hydrogen halides and various bases (15–25), the electrostatic interaction is the dominant term in the intermolecular potential. The observed $\Delta\nu/\nu_0$ ratio decreases from HF towards HI (22), correlating with the dipole moment of the HX bond. Figure 10 shows that for PFTB $\Delta\nu/\nu_0$ values are lower than for HCl but higher than for HI in cases of weak and medium strong hydrogen bonds. With very strong bases (PA > 200 kcal/mol) proton transfer has to be considered. How ever, proton sharing and proton transfer are only observed with HX molecules whose valence electrons are easily polarizable. Despite the strong acidity of PFTB no proton transfer reactions or proton sharing are observed, probably due to the weak polarizability of the OH oscillator.

(ii) Halfwidths (FWHH) of the complex bands

In the case of the PFTB···NM-d_3 complex the $\nu_{OH,b}$ absorption is much broader than that observed for the PFTB···AN-d_3 complex, thus indicating the existence of different conformations of the complex. For the PFTB···AC-d_6 complex, the ν_{OH} absorption obviously overlaps with combination tones. With decreasing temperature, strong narrowing is observed. The

PFTB/$(CD_3)_2CO$	Ar	3071	2298	162.0	(200 K)			

[a]The formula for the calculations of κ_{11}* and κ_{11}** are given in text.

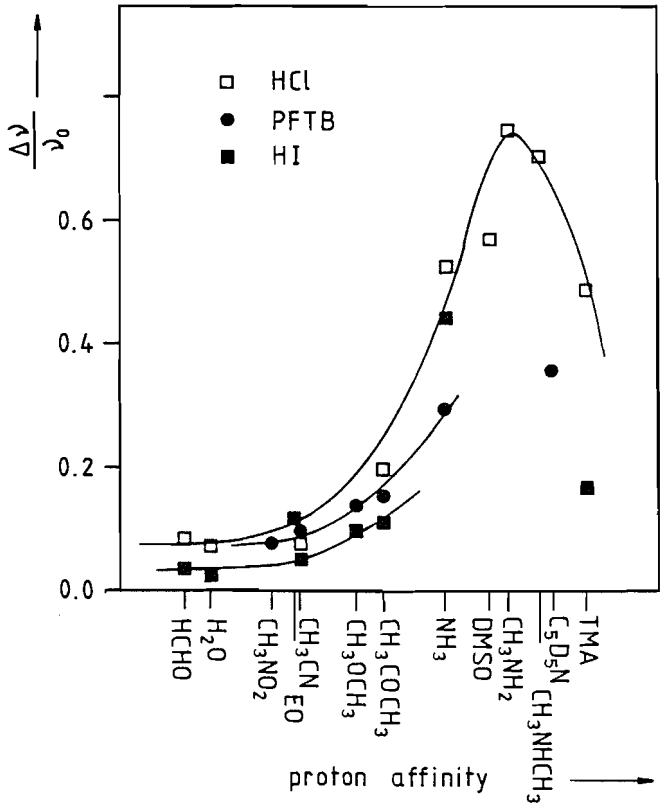

FIG. 10. Frequency ratio $\Delta\nu/\nu_0$ of the OH stretching band of PFTB complexes with different acceptors as function of the proton affinity PA of the base. For comparison, values for HCl and HI are also included.

slope d(FWHH)/dT is about 1.1 cm^{-1} K^{-1} for the first band of the AC-d_6 complex and 0.49 cm^{-1} K^{-1} for the NM-d_3 complex in the temperature interval 193 to 250 K. These values are considerably higher than those reported for the PFTB···AN-d_3 complex (0.15 cm^{-1} K^{-1} to 0.2 cm^{-1} K^{-1} depending on the nature of the solvent) (8). At the lowest temperature reached in solution (83 K) the observed bandwidth of $\nu_{OH,b}$ for the different complexes within the same solvent shows only weak dependence on base strength:

FWHH	Complex
109cm^{-1}	PFTB···NM-d_3
122cm^{-1}	PFTB···AN-d_3
131cm^{-1}	PFTB···AC-d_6

In the theories of hydrogen bonding, it is generally assumed that main band shaping factors are the mechanical and electrical coupling of the internal and external modes of the hydrogen bonds (26, 27). Broadening of the ν_s bands have been explained by stochastic effects in liquids (28–30) and rovibrational structure in the gas phase (31). However, in matrices usually a substantial narrowing of the absorption bands is observed due to the extreme low temperatures. This has been found for weak hydrogen bonding ($\Delta\nu/\nu_0 < 0.1$), where the ν_s band is very narrow (FWHH < 10 cm^{-1}). In the case of medium strong hydrogen bonding ($\Delta\nu/\nu_0$ between 0.1 and 0.2) two situations were encountered: (*i*) either narrow bands as for HF···NH_3 (32) and HCl···$S(CH_3)_2$ (33) systems, or (*ii*) broad bands with a strong narrowing on deuterium substitution as for HCl···DME (34) and HCl···ethylene oxide (35) complexes. The PFTB···NM-d_3 complex is weakly hydrogen bonded; the observed ν_{OH} bandwidth (25 cm^{-1}) is broader than expected. The band shows an asymmetrical profile with a shoulder after annealing.

The PFTB···AC-d_6 complex (medium strong hydrogen bonding) shows an OH band as broad as in solutions at 113 K. As suggested for HCl···DME or HCl···ethylene oxide complexes by Bernadet and Limonzi (36), the bandwidth could be an intrinsic property of the hydrogen bond.

(iii) Anharmonicity

From the IR and NIR absorptions the anharmonicity coefficient κ_{11} of the $\nu_{0\to1}$ OH vibration can be calculated according to the following relation (in Table 2 this coefficient ist marked as κ_{11}^{**}):

$$\kappa_{11} = \nu_{0\to1} - (\nu_{0\to2})/2$$

However, as previously demonstrated (37) the $2\nu_{OH}$ profiles are unlike and very broad at room temperature.

Another method described in references 9, 38 is to evaluate κ_{11} from ν_{OH} and ν_{OD} frequencies. The following relation is used with the assumption that the OH oscillator is isolated and the potential energy limited to the quartic term (in Table 2 this coefficient is market as κ_{11}^{*}):

$$\kappa_{11}^{*} = \frac{\varphi(\varphi\nu_{OD} - \nu_{OH})}{2(\varphi - 1)} \varphi = \left(\frac{\mu_{OD}}{\mu_{OH}}\right)^{1/2}$$

where μ = reduced mass.

Table 2 summarizes the results obtained for κ_{11} calculated by both methods for the PFTB···NM-d_3 complex. Only the second method was used for the PFTB···AC-d_6 complex. We observe that the anharmonicity coefficients are similar for the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

three systems reported here, indicating that the role played by the base strength is of minor importance. For the PFTB$\cdots$NM-d_3 complex κ_{11} values have been obtained at different temperatures. The results suggest that the anharmonicity coefficient is temperature independent as previously reported by Perchard and Perchard (38) for some associated alcohols.

Finally, from the spectra of the PFTB$\cdots$AC-d_6 complexes in matrices the anharmonicity coefficient of the deformation mode (κ_{22}) can be calculated according to the relation:

$$\kappa_{22} = \delta_{0\to1} - (\delta_{0\to2})/2$$

The obtained value $\kappa_{22} = 18.7\ cm^{-1}$ indicates a considerable increase of the anharmonicity due to hydrogen bonding as previously reported by Asselin and Sandorfy (39).

Acknowledgements

We thank the Ministere des Affaires Etrangeres, Paris, and the Deutsche Akademische Austauschdienst, Bonn, for financial assistance in the frame of the French–German Procope cooperation (project No. 1988/118, 1989/086) and the Deutsche Forschungsgemeinschaft, Bonn, for funds.

Hydroxyproline adsorption on a mercury electrode in neutral solution

M. M. GÓMEZ

Departamento de Química Física Aplicada, Facultad de Ciencias, Universidad Autónoma, 28049-Madrid, Spain

Received December 24, 1990

M. M. GÓMEZ. Can. J. Chem. **69**, 1528 (1991).

The adsorption of hydroxyproline (HPRO) on mercury in aqueous solutions of 10^{-2} M $KClO_4$ has been determined from electrocapillary and capacity measurements. Comparison of the results obtained for HPRO with those reported for proline (PRO) shows that the presence of a hydroxyl group in the molecule has a small effect on the adsorption process. The respective values for adsorption parameters are -7 and -5 μC cm^{-2} for the charges of maximum adsorption, -13.0 and -10.4 kJ mol^{-1} for the standard Gibbs energies of adsorption at zero charge, and -1.28 and $+0.6$ for the α parameter in the Frumkin isotherms. According to the analysis carried out for the normal component of the dipole moment of HPRO, -0.8 D, the more probable orientation of this aminoacid adsorbed on mercury is with the pyrrolidine ring parallel to the electrode surface resting the OH group away from the surface.

Key words: adsorption, double layer, aminoacids, hydroxyproline.

M. M. GÓMEZ. Can. J. Chem. **69**, 1528 (1991).

On a mesuré l'adsorption de l'hydroxyproline (HPRO) sur le mercure dans des solutions aqueuses de 10^{-2} M $KClO_4$ en utilisant les mesures de capacité et d'électrocapillarité. Les résultats obtenus, comparés à ceux répertoriés dans la littérature pour la proline (PRO), révèlent que la présence du groupe hydroxyle dans la molécule a très peu d'influence sur le processus d'adsorption. Les paramètres d'adsorption sont respectivement sont de -7 et de -5 μC cm^{-2} pour les charges d'adsorption maximum et $-13,0$ et $-10,4$ kJ mol^{-1} pour les énergies d'adsorption standard de Gibbs pour une charge nulle. La valeur de α est de $-1,28$ et 0,6 dans les isothermes de Frumkin. L'analyse de la composante normale du moment dipolaire de la HPRO, $-0,8$ D révèle que l'orientation la plus probable de cet acide aminé adsorbé sur le mercure est celle où le cycle de la pyrrolidine est parallèle à la surface de l'électrode avec le groupe hydroxyle éloigné de la surface.

Mots clés : adsorption, couche double, acides aminés, hydroxyproline.

Introduction

The elucidation of properties of biological molecules in solution is an essential step in the understanding of their physiological functions. The several studies carried out about the surface activity of primary aminoacids allowed one to establish relationships between molecular properties and the adsorption behaviour of these compounds. However, information about the surface properties of secondary aminoacids is not very extensive.

The secondary protein aminoacids comprise those whose structures are stable to acid hydrolysis. Of this group *N*-methyl and *C*-hydroxy derivatives are the most numerous. Hydroxyproline is the most abundant hydroxylated aminoacid, occurring in considerable amounts in hydrolysates of collagen and elastin (the principal proteins of connective tissue). Most of the hydroxyproline is hydroxylated in the γ-position (Fig. 1), but some forms of connective tissue also contain amounts of β-hydroxyproline (1).

Proline and hydroxyproline are very different from the other aminoacids in that they contain the pyrrolidine five-membered ring. In a previous paper, the adsorption of proline on a mercury electrode has been studied (2). The aim of the present study was to determine the structure of the mercury/solution interface for γ-hydroxyproline and to analyze how the presence of a hydroxyl group affects the adsorption process by comparing the results with those obtained for proline. Consequently, the same methods and procedures used for proline (PRO) have been applied to hydroxyproline (HPRO) and they will not be described in detail further. Potassium perchlorate was used as support electrolyte and the pH of the solution was kept equal to 5.8 in order to study the zwitterion form of HPRO.

Molecular structure of hydroxyproline

In addition to the normal conformational descriptors the conformation of PRO and derivatives is described by the mode of puckering of the pyrrolidine ring. The conformational analysis of five-membered rings is greatly facilitated by the concept of pseudorotation. The endocyclic torsion angles τ_j (Fig. 1*a*) are interrelated via the well-known pseudorotation equation. The puckering of the ring may be specified by the pseudorotational parameters P (phase angle of pseudorotation) and τ_m (puckering amplitude) computed from the τ_j angles (2).

It was stated that the atoms C_δ—N—C_α—C_β are nearly

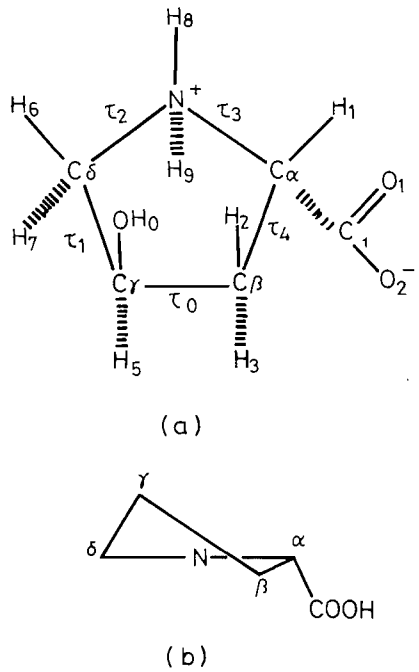

FIG. 1. (*a*) Labeling of the carbon atoms and protons of hydroxyproline in zwitterion form and τ notation of endocyclic angles; (*b*) perspective views of the N-type hydroxyproline ring conformation (3).

O—H_0	0.972				

coplanar and C_γ displaced from this plane. All conformations that are characterized by a positive value of torsion angle τ_0 (Fig. 1*a*) are denoted by N-type forms (Fig. 1*b*) and all conformations having a negative angle τ_0 by S-type forms.

The HPRO ring system in neutral or acidic medium displays a pure N-type state (3). The pseudorotational parameters calculated from the coupling constants of HPRO measured at pD = 6.5 are $P_N = 12.8°$ and $\tau_N = 43.6°C$ (Table IX in ref. 3).

From a neutron diffraction study (4) a value of −3.2° was estimated for the torsion angle O_1—C_1—C_α—N. The existence of an intramolecular hydrogen bond is not clear. The H_9....O_1 distance, 2.082 Å, is more than 0.3 Å smaller than 2.4 Å, the appropriate sum of van der Waals radii. Therefore, Donohue and Trueblood (5) have preferred not call to this short intramolecular contact a hydrogen bond.

In order to discuss the results of the present work, optimized geometries of HPRO have been estimated for the more favored conformation in neutral solution. First, the geometry of HPRO in molecular form was optimized by using the MM2 force field (6, 7). Then, the geometry in zwitterion form was built up from the MM2 geometry for the ring and from the neutron diffraction geometry for the $^+NH_2$—CH—COO^- fragment (4), see Table 1.

There are a lot of possible orientations of the HPRO molecule resting onto three different atoms over the electrode surface (XY plane). Those orientations with one oxygen atom resting onto the surface were rejected because the value of the perpendicular component μ_i of the dipole moment is positive, contrary to the results of the present work (see below). For all the remaining orientations, three different hydrogen atoms were placed in the XY plane and the corresponding molecular areas projected onto the electrode surface and the molecular heights were calculated from the optimized geometry given in Table 1. The molecular heights were calculated by adding the corresponding van der Waals radii to the higher and lower atoms. Likewise, the components μ_i of the dipole moment were obtained using the INDO method (8). The obtained results for the individual orientation, defined by the three hydrogen atoms contacting the electrode surface, are given in Table 2. Values of A_i correspond to the average molecular area obtained for orientations of the OH group of 30, 180, and 300°. The orientations of HPRO are grouped in two types. For the A-type the molecule is adsorbed with the ring perpendicular to the electrode surface. For the B-type orientation, the HPRO ring is adsorbed flat with the COO^- group away from the electrode surface. The total dipolar moment, calculated using the INDO method, was 12.6 D.

TABLE 2. Area, A_i, height, X_i, and perpendicular dipole moments, μ_i, for the individual orientations of N-type conformations of the zwitterion of hydroxyproline; three different hydrogen atoms contact the electrode surface for each individual orientation (see text)

Type of orientation	Contacting atoms	A_i/nm²	X_i/nm	μ_i/D

	H_3—H_5—H_7	0.53	0.60	−1.2
	H_8—H_6—O_0	0.48	0.64	−7.4
	H_1—H_8—O_0	0.44	0.60	−2.6
	Average	0.48	0.62	

Results and analysis

Electrocapillary and capacity measurements were carried out in aqueous solutions of 10^{-2} M $KClO_4$ at seven concentrations of HPRO in the same range used for PRO (2). The double-layer capacity was determined with an impedance bridge using a SCE as reference electrode and the cell which was described in a previous paper (9). The pzc was measured by means of a streaming electrode. The maximum interfacial tension was obtained by using a classical electrometer (10).

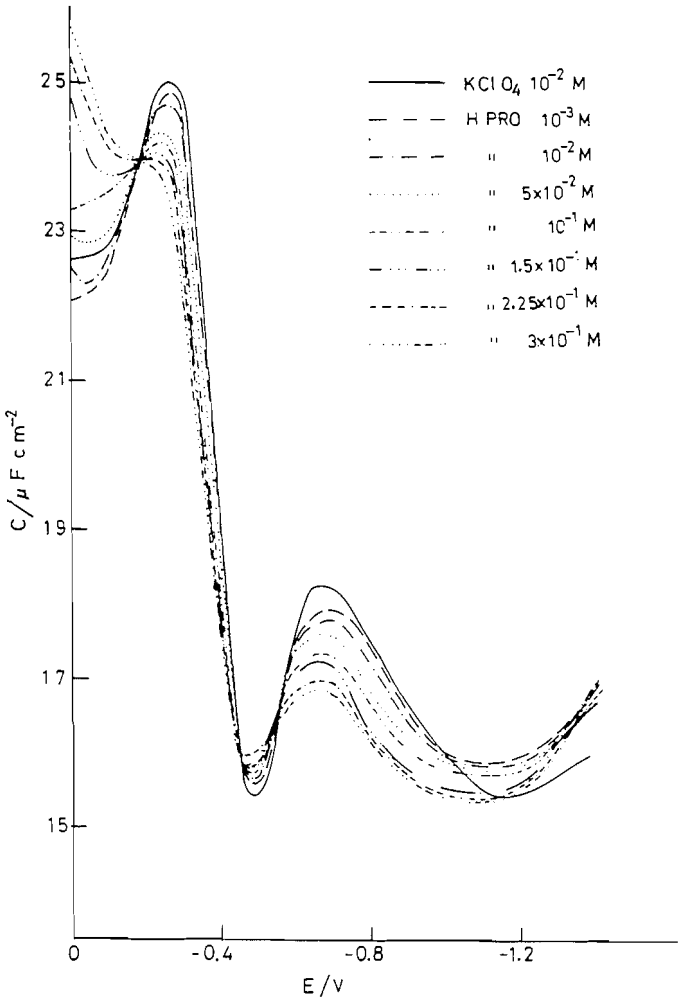

FIG. 2. (*a*) Capacity–potential (against saturated calomel electrode) curves for aqueous 10^{-2} M $KClO_4$ solutions containing different concentrations of hydroxyproline.

electrode on potential is close to that found for PRO (Fig. 2). Integration of the capacity curves provides the corresponding curves for electrode charge, σ^M, against the potential. The electrocapillary curves were obtained by integration of these curves. Results at zero charge for the potential, E, the capacity, C, and the interfacial tension, γ, given in Table 3, show small differences from the corresponding values found for PRO.

The relative surface excess, Γ, was determined at constant charge by numerical differentiation of the Parsons function, $\xi = \gamma + \sigma^M E$, with respect to the logarithm of the HPRO concentration, log c_{org}. The liquid junction potential in all solutions was assumed to remain constant. Activity coefficients for HPRO in water have been measured (11). These are very close to unity, being 1.001 at 0.3 mol dm^{-3}. However, there is no information about the activity coefficients in the present system which would allow the correct analysis to be done. The calculations were therefore carried out assuming a constant activity coefficient equal to unity. The error involved in this approximation would be small, probably comparable with experimental error. The variation of Γ with σ^M is shown in Fig. 3, where a maximum is observed for a charge about -5 μC cm^{-2}.

The saturation values of Γ, Γ_s, determined by extrapolation of $1/\Gamma$ vs. $1/c_{org}$ curves at different charges to $1/c_{org} = 0$ (12) do not seem to be reliable because no saturation is approached. The calculated values for the individual orientations of HPRO (Table 2) are spread between 0.42 and 0.53 nm^2, corresponding to 4.0 and 3.1×10^{-10} mol cm^{-2}, respectively. An average value of 0.46 nm^2 was taken as the actual value of the molecular area ($\Gamma_s = 3.6 \times 10^{-10}$ mol cm^{-2}).

The maximum coverage reached experimentally does not exceed 0.4. Therefore, the following analysis could not be entirely reliable.

The adsorption isotherm was analysed from the surface excess values. The coverage, θ, was calculated from $\theta = \Gamma/\Gamma_s$ with $\Gamma_s = 3.6 \times 10^{-10}$ cm^{-2}. A linear dependence of $\log \theta/(1-\theta)c$ upon θ was obtained in the range of studied charges. The fact that these straight lines show the same positive slope indicates that the adsorption follows a Frumkin isotherm (eq. [1]) which is apparently congruent to charge. The obtained value of +0.6 for the interaction parameter, α, indicates that an attractive force acts among the adsorbed molecules,

$$[1] \quad \beta c = \theta(1-\theta)^{-1} \exp(-2\alpha\theta)$$

where β is the adsorption coefficient.

The adsorption isotherm was also analysed by plotting the surface pressure as a function of the logarithm of HPRO concentration at constant charge within the range +3 to −9 μC cm^{-2}.

The surface pressure at constant charge (Φ) was determined from the expression $\Phi = \xi^b - \xi$, where ξ^b is the value for 10^{-2} M $KClO_4$ solution in the absence of HPRO at a given value of σ^M.

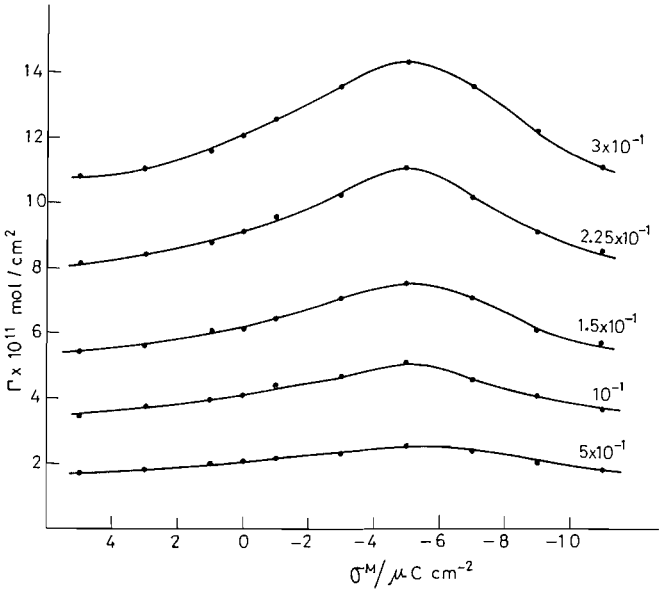

FIG. 3. Surface excess of hydroxyproline as a function of the surface charge density on a mercury electrode at 25°C. The hydroxyproline concentration, in mol L^{-1}, is indicated for each curve.

According to the Frumkin isotherm, the pressure-coverage relation is represented by eq. [2]:

$$[2] \quad \Phi = \Gamma_s RT[\ln(1-\theta) + \alpha\theta^2]$$

where R is the gas constant and T is the temperature in K.

The surface pressure vs. log HPRO concentration was plotted for eight values of σ^M. When the resulting curves are shifted along the x axis, it is observed that there is good superimposition and the curves coincide, within the experimental error, with the solid line corresponding to a Frumkin isotherm with $\alpha = 0.6$ and $\Gamma_s = 3.6 \times 10^{-10}$ mol cm^{-2} (Fig. 4). On the contrary, the composite surface pressure curve at constant potential shows points more scattered.

The standard Gibbs energy of adsorption, ΔG^0, of HPRO on the mercury electrode was calculated by the Parsons' method (13) and by the test of the Frumkin isotherm (eq. [1]). The results in both cases was very close. The value of ΔG^0 obtained at the charge of maximum adsorption, $\sigma^M_{max} = -5$ μC cm^{-2}, was −10.8 kJ mol^{-1}, the standard states being "ideally" pure substance both in solution and the interface (14). It was found that the standard Gibbs energy displays a parabolic variation with a maximum at charges around −5 μC cm^{-2}. Figure 5 shows a quadratic dependence of $(\Delta G^0 - \Delta G^0_{max})$ on $(\sigma^M - \sigma^M_{max})$ within the charge range of +5 to −11 μC cm^{-2}. The adsorption of the support electrolyte could be detectable by a breakdown of the quadratic dependence of the standard Gibbs energy with charge at positives charges (15, 16). Such a deviation has not been observed in the present system. Therefore, it is reasonable to assume that the adsorption of ClO_4^- in presence of HPRO was weak.

The change in the rational potential drop across the inner layer, $\Delta\phi^{M-2}$, at constant charge, shows a linear dependence on the relative surface excess, Γ (Fig. 6). Values of $\Delta\phi^{M-2}$ were calculated from:

$$[3] \quad \Delta\phi^{M-2} = E^N_\sigma - E^{base}_{\sigma=0} - \phi^{2-s}_\sigma$$

where E^N_σ is the measured potential in the presence of HPRO, $E^{base}_{\sigma=0}$ is the pzc of the base electrolyte and ϕ^{2-s}_σ is the diffuse-layer potential drop given by the Gouy–Chapman theory. The zero gradient at $\sigma^M \simeq -5$ μC cm^{-2} corresponds to the charge of maximum adsorption.

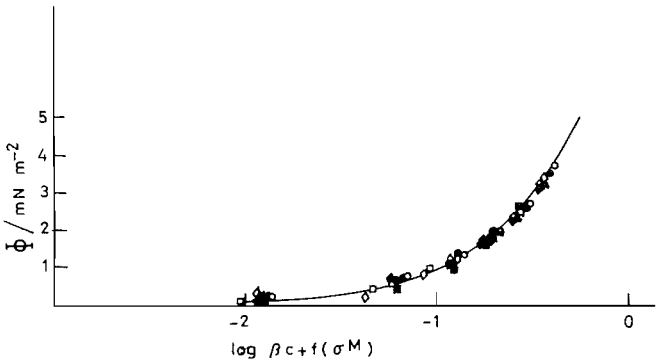

FIG. 4. Composite pressure curve for hydroxyproline adsorption on mercury electrode. The line was calculated from the Frumkin isotherm with $\alpha = 0.6$ and $\Gamma_s = 3.6 \times 10^{-10}$ mol cm^{-2}. Charges on mercury (μC cm^{-2}): (◇) +3; (◆) +1; (▲) 0; (△) −1; (●) −3; (○) −5; (■) −7; (□) −9.

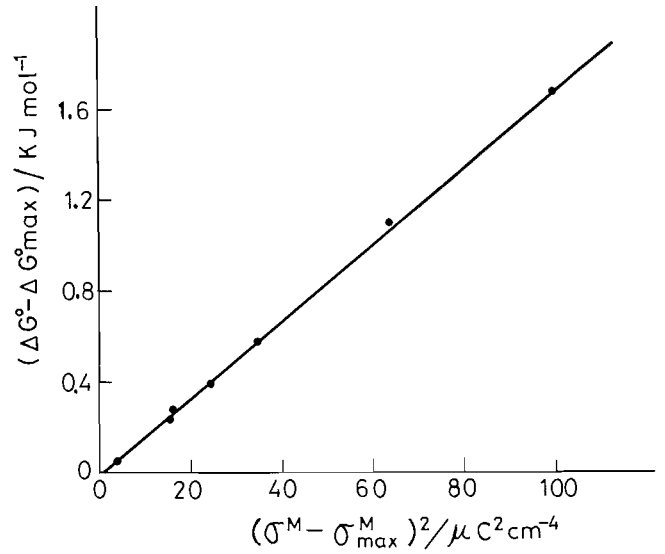

FIG. 5. Variation of the standard Gibbs energy of adsorption of hydroxyproline with the electrode charge. Charges ranging between +5 to −11 μC cm^{-2}.

The linear dependence of the gradient $(\partial\Delta\phi^{M-2}/\partial\theta)_{\sigma^M}$ on the electrode charge σ^M, which corresponds to a quadratic dependence for the standard Gibbs energy (17), is observed in all the charge range studied (Fig. 7).

The inner layer capacity at constant amount adsorbed, C_i, which is defined by eq. [4], was calculated from Fig. 6 by plotting potential-charge curves at selected coverage values and differentiating at constant charge.

$$[4] \quad C_i = (\partial\sigma^M/\partial\phi^{M-2})_\Gamma$$

Figure 8 shows that $1/C_i$ is a linear function of coverage, which is in accord with the model of two series capacitors:

$$[5] \quad \frac{1}{C_i} = \frac{1-\theta}{C_0} + \frac{\theta}{C_1}$$

where C_1 and C_0 are the inner layer capacities at saturation in the presence and in the absence of adsorbate, respectively (12). The C_0 capacity was calculated by using the Gouy–Chapman

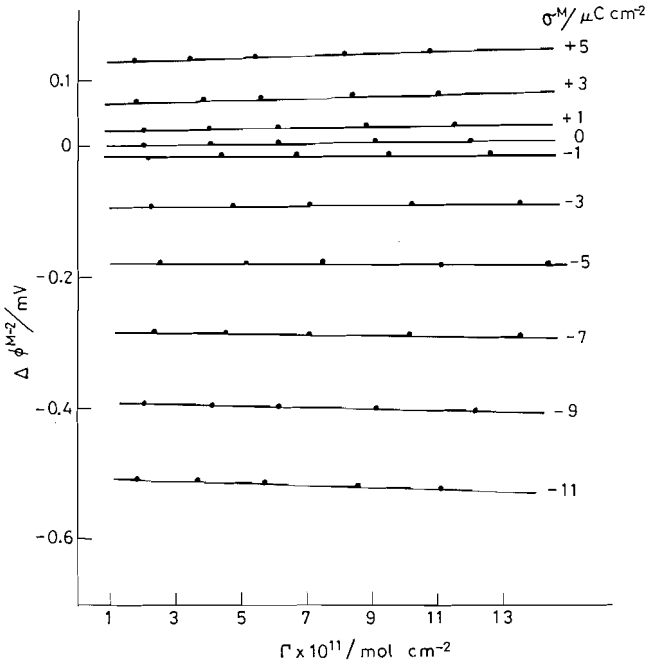

FIG. 6. Change in the potential drop across the inner layer upon adsorption of hydroxyproline at constant charge. The charge values are indicated for each curve.

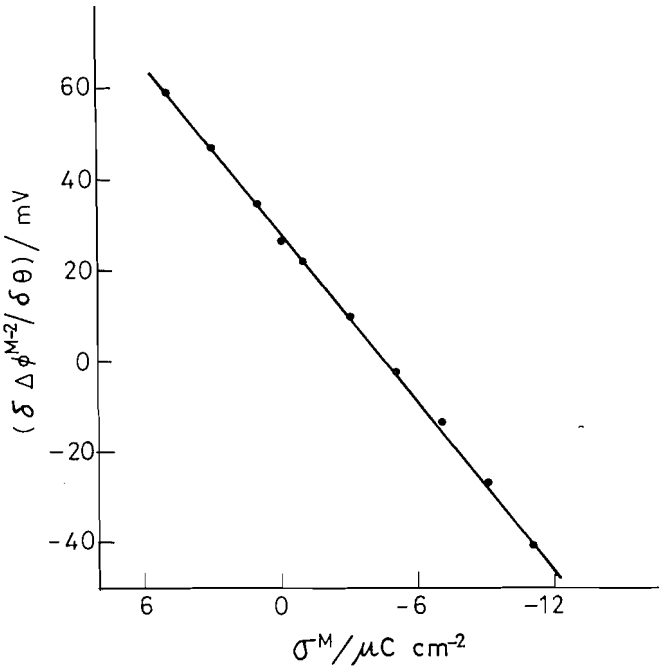

FIG. 7. Plot of the function $(\partial\Delta\phi^{M-2}/\partial\Gamma)_{\sigma^M}$ vs. the electrode charge for adsorption of hydroxyproline.

theory for the supporting electrolyte with values for $\partial\sigma^i/\partial\sigma^M$ estimated from the data of Payne (18). The C_1 capacity at different charges was obtained extrapolating values of $1/C_i$ in Fig. 8 to $\theta = 1$. The inner layer capacities are dependent on the electrode charge. The C_1 values increase as the charge is made less negative.

The capacity of the inner layer, regarded as a parallel plate condenser, is

$$[6] \quad C_i = \frac{\epsilon_i}{4\pi X_i}$$

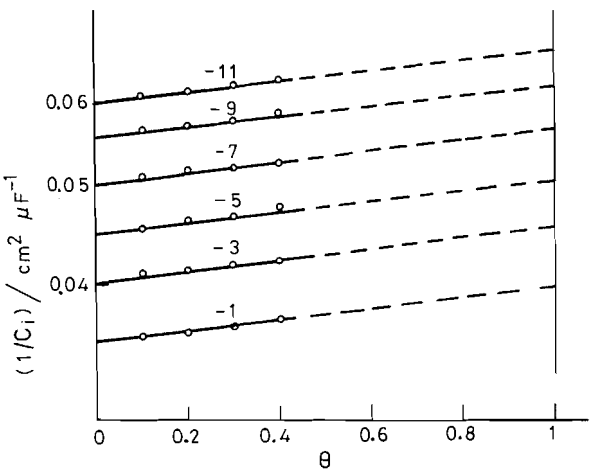

FIG. 8. Reciprocal of the inner layer capacity at constant amount adsorbed as a function of the coverage of hydroxyproline at constant charge as indicated by figures in the lines (in $\mu C\ cm^{-2}$).

where ϵ_i is the dielectric constant and X_i is the separation between the plates which can be considered equal to the height of the adsorbed molecules (12, 19). The dielectric constants of the inner layer at saturation (ϵ_a) and in the absence of HPRO (ϵ_ω) and the C_0 and C_1 values are given in Table 4 as a function of the surface charge. The ϵ_a and ϵ_ω values were calculated from eq. [6] assuming $X_a = 0.67$ nm and $X_\omega = 0.31$ nm for HPRO and water, respectively.

Discussion

The adsorption of HPRO on mercury shows small differences with the adsorption of PRO, as can be deduced by comparing the values of the corresponding parameters given in Table 5. Both compounds are weakly adsorbed obeying a Frumkin isotherm. However, there are some definite differences in the values determined for the shift of the potential of zero charge from $\theta = 0$ to $\theta = 1$, $\Delta E_{\sigma=0}$, the charge of the maximum adsorption, σ^M, the interaction parameter, α, and the standard Gibbs energy ΔG^0_σ.

The shift of the zero-charge potential upon a transition from $\theta = 0$ to $\theta = 1$ can be considered to be the difference between the potential drops due to the oriented adsorption of the organic substance dipoles and water, respectively, at $\sigma^M = 0$. The shift of pzc of HPRO was estimated by extrapolating the plot at $\sigma^M = 0$ in Fig. 6 to $\Gamma = \Gamma_s$. A value of 29 mV was obtained for $\Delta E_{\sigma=0}$ by assuming a linear relationship of ϕ^{M-2} with θ. The more negative value of σ^M_{max} and larger $\Delta E_{\sigma=0}$ for PRO suggest a larger normal component of the dipole moment (20).

At a given charge, σ^M = constant $\neq 0$, the potential shift, ΔE_σ, could be due to three factors: the replacement of the water dipoles already oriented at the electrode, the orientation of the adsorbate molecule, and a change in the inner layer thickness due to the adsorption of the adsorbate molecules. In general, ΔE_σ can be represented by (12, 21):

$$[7] \quad \Delta E_\sigma/\theta = \Gamma_s N \left(\frac{\mu_a}{\epsilon_a} - \frac{n\mu_\omega}{\epsilon_\omega}\right) - \sigma\left(\frac{X_a}{\epsilon_a} - \frac{X_\omega}{\epsilon_\omega}\right)$$

where n is the number of water molecules displaced by adsorption of one adsorbate molecule, N is the Avogadro's number and μ_a and μ_ω are the effective dipole moments of the adsorbate and water on the electrode, respectively. Although all the terms on the right-side in eq. [7] have the possibility to change with charge, Γ_s and X_a can be assumed constant for the adsorption of HPRO whose orientation on the mercury electrode does not change. It should be noted that the dipole moment and dielectric constant are influenced not only by the orientation of permanent dipoles, but also by induced dipoles formed in the electric field. Therefore, μ_a cannot be constant when the adsorbate shows a high polarizability although the orientation is constant (12).

The component of the dipole moment of HPRO perpendicular to the mercury surface was calculated at maximum adsorption, where there is no potential change (Fig. 6). The replacement of possible ClO_4^- ions present in the interface has not been considered. The term $n\mu_\omega$ was calculated from the potential drop due to the water dipoles adsorbed on the electrode, Δg^ω_{dipole}. Using the data of Bockris and Habib (22), Δg^ω_{dipole} was estimated to be -0.012 V at a charge of -5 μC cm^{-2}. By substituting values in eq. [7], a value of -0.8 D (1 D $\equiv 3.336 \times 10^{-30}$ Cm) was obtained for μ_a with the positive pole towards the electrode.

In the case of the adsorption of PRO (2), the component of the dipole moment and the dielectric constant at maximum charge was calculated by taking average values for the molecular height ($X_a = 0.65$ nm) and for the saturation surface concentration ($\Gamma_s = 3.7 \times 10^{-10}$ mol cm^{-2}) (see ref. 2). The obtained values were $\mu_a = -1.9$ D and $\epsilon_a = 10.6$. However, these values must be taken as rough estimates because the zwitterion of PRO could be adsorbed in a conformational equilibrium between N- and S-type forms.

The interaction parameter in the Frumkin isotherm is negative for PRO ($\alpha = -1.28$ at σ^M_{max}) and positive for HPRO ($\alpha = +0.6$). The difference between these values can be expressed in terms of adsorbate–adsorbate and adsorbate–solvent interaction differences (23):

$$[8] \quad RT(\alpha_P - \alpha_H) = (\Delta G^0_{s-P} - \Delta G^0_{s-H}) - (1/2)(\Delta G^0_{P-P} - \Delta G^0_{H-H})$$

where P, H, and s stand for PRO, HPRO, and solvent respectively. The empirical difference of -4.6 kJ mol^{-1} for $RT(\alpha_P - \alpha_H)$ could then be due to greater interfacial solubility and/or adsorbate-adsorbate repulsion for PRO than for HPRO. A more favourable interaction adsorbate/solvent at the interface for PRO is according with a greater bulk solubility (24). The estimation of the last term in eq. [8], due to the difference between the normal component of the dipole moment is only 0.34 kJ mol^{-1}. This figure was calculated by using the expression:

$$[9] \quad (\Delta G^0_{AA}) = 9.24\theta\mu_a^2/\epsilon_a R^3$$

which gives the free energy for dipole–dipole interaction by assuming localized adsorption for parallel hexagonal arrays (25). Taking values of $R = 0.79$ nm and $R = 0.81$ nm for the distance at full coverage and $\epsilon_a = 10.6$ and $\epsilon_a = 14.5$ for the dielectric constants of PRO and HPRO respectively, the calculated values of (ΔG^0_{AA}) for PRO and HPRO are 0.38 and 0.04 kJ mol^{-1}, respectively. On the other hand, differences in the α parameter could also be due to different specific interactions between pairs of adsorbed molecules of aminoacid i.e. hydrogen bonds. It was found that a short intermolecular hydrogen bond may contribute to the stability of the crystal structure of HPRO (4).

The standard Gibbs energy of adsorption is determined by two factors: the free transfer energy of the organic compound from the bulk solution to the surface, and the free energy of interaction between the electrode and the substance.

The surface activity of PRO and HPRO in aqueous solutions of 10^{-2} $KClO_4$ has been determined from surface tension measurements (26). The difference between the transfer free energies of HPRO and PRO at the air/solution interface was found to be 1.2 kJ mol^{-1}. This value is appreciably smaller than 3.4 kJ mol^{-1} estimated by Nozaki and Tanford (27) as a contribution of a hydroxyl group to the transfer energy. At the interface, the OH group of HPRO is probably only partially dehydrated because a part of the adsorbed molecule should be exposed to the aqueous phase, whereas on transfer of the molecule from water to nonaqueous solvent the hydroxyl group must completely be dehydrated and surrounded by nonaqueous medium.

At the mercury/solution interface, the standard Gibbs energy at $\sigma^M = 0$ for HPRO is 2.6 kJ mol^{-1} smaller than that obtained for PRO (see Table 5). By assuming that the transfer energy of an organic compound from the bulk to the uncharged mercury/solution interface is close to that for air/solution interface, the difference in the interaction energies of PRO and HPRO with the electrode would be *ca.* 1.4 kJ mol^{-1}. Therefore, it seems that the OH group addition to PRO affects very slightly the specific interaction electrode/adsorbate. Such a small contribution must be expected if one takes into account the fact that both molecules interact almost flat on the electrode surface and the OH group rest away from the surface.

The comparison of the empirical value of -0.8 D for the effective dipole moment derived from interfacial parameters with the calculated ones is not very reliable because the interfacial data provide macroscopic parameters. However, some information about the orientation of HPRO can be obtained from the results given in Table 2. The smaller values of μ_i are calculated for B-type orientations. When the molecule rests onto the H_3—H_5—H_7 atoms a value of -1.2 D was calculated for μ_i. Therefore, the zwitterion of HPRO could be adsorbed with the ring parallel to the electrode and the carboxyl and hydroxyl groups towards the bulk solution.

The photochemistry of RDX in solid argon at 10 K

JEFF ALIX AND SUSAN COLLINS
Department of Chemistry, California State University, Northridge, CA 91330, U.S.A.

Received September 4, 1990[1]

JEFF ALIX and SUSAN COLLINS. Can. J. Chem. **69**, 1535 (1991).

The photochemistry of RDX was studied in argon matrices at 10 K and examined by FTIR spectroscopy. The spectra and kinetics of product growth indicate that there are two decomposition pathways:

[I] $RDX \rightarrow 4NO + 2CH_2O + N_2 + CH_2 \rightarrow 4NO + 2CO + N_2 + CH_4 + H_2$

[II] $RDX \rightarrow N_2O + [O_3 + N_2]$ or $[N_2O_3] + CO_2 + C_2H_2 + N_2 + 2H_2$

The mechanism II nitrogen products can easily be rationalized for the chair configuration of RDX with axial NO_2 groups adjacent (C_s symmetry). When considering the carbon products of II, it may be necessary to postulate intermolecular reactions. Our studies gave no evidence for the symmetric triple fission path, which leads to N_2O and CH_2O, nor for the NO_2 stripping mechanism reported for the gas-phase thermal reactions, which leads to the formation of NO_2 and HCN. Rather, our findings were more consistent with the known condensed phase products. The production of CH_4, C_2H_2, N_2O_3, and O_3 are unique to the matrix study.

Key words: RDX, photochemistry, argon matrices.

JEFF ALIX et SUSAN COLLINS. Can. J. Chem. **69**, 1535 (1991).

Opérant à 10 K, dans des matrices d'argon et utilisant la spectroscopie FTIR, on a étudié la photochimie du RDX. Les spectres et la cinétique de la croissance des produits indiquent qu'il existe deux voies de décomposition :

[I] $RDX \rightarrow 4NO + 2CH_2O + N_2 + CH_2 \rightarrow 4NO + 2C0 + N_2 + CH_4 + H_2$

[II] $RDX \rightarrow N_2O + [O_3 + N_2]$ ou $[N_2O_3] + CO_2 + C_2H_2 + N_2 + 2H_2$

La formation des produits azotés par le méchanisme II peut facilement être rationalisée à partir de la configuration chaise du RDX et du NO_2 adjacent axial (syméthrie C_s). Lorsqu'on considère les produits carbonés obtenus par le mécanisme II, il peut être nécessaire de postuler des réactions intramoléculaires. Nos études n'ont pas permis de déceler des données permettant de suggérer l'existence du mécanisme impliquant une voie de fission triple syméthrique qui conduirait à du N_2O et à du CH_2O ou du mécanisme d'élimination de NO_2 rapporté pour les réaction thermiques en phase gazeuse et qui conduit à la formation de NO_2 et de HCN. Les résultats obtenus sont plutôt en accord avec les produits connus de la phase condensée. La formation de CH_4, de C_2H_2, de N_2O_2 et de O_3 ne se produit que dans les matrices.

Mots clés : RDX, photochimie, matrices d'argon.

Introduction

The technique of matrix isolation has proven to be extremely valuable for isolation of intermediates which are crucial in establishing chemical and photochemical mechanisms. 1,3,5-Trinitrohexahydro-*s*-triazine, RDX, is known to decompose by several pathways. The products obtained depend on the phase and temperature of the starting material. The condensed-phase decomposition occurs just above the melting point giving NO, N_2O, H_2, CO, CH_2O, and CO_2 (3). Another study showed that a primary deuterium kinetic isotope effect ($k_H/k_D = 1.5$) is associated with C—H breakage during the rate determining step under these conditions (4). When decomposition is studied at higher temperatures producing gas phase molecules, two other mechanisms predominate (3, 5). The first involves the NO_2 stripping mechanism in which all three NO_2 groups are removed before the triazine fragment decomposes to form HCN and presumably H_2. The second pathway, which clearly has been seen in molecular beam studies, is the symmetric triple fission to form CH_2NNO_2 fragments which then further decompose to form CH_2O and N_2O (6). Our study was motivated by the possibility of trapping the CH_2NNO_2 fragment and obtaining its infrared spectrum, and to determine whether the mechanisms in the matrix is similar to the gas or to the condensed phase mechanisms. We report here the matrix FTIR spectra of RDX and its photoproducts and their kinetic behavior at 10 K.

Experimental

The apparatus used for these experiments has been described recently (1). FTIR spectra were recorded on a Nicolet 20 DXB instrument with 1.0 cm^{-1} resolution. The RDX was deposited by heating it to approximately 200°C in a stainless steel vacuum line positioned in front of the CsI substrate window. Argon was passed over it at 1–2 mmol per h for 1 h. The argon stream entrained the RDX vapors and mixing occurred before deposition. The photolysis light source was an Oriel medium pressure xenon lamp. Broad band irradiation was used for all experiments.

An independent study involving the photolysis of a 1/1/200 matrix of $N_2O/CH_2O/Ar$ was necessary to elucidate some mechanistic features. The N_2O and CH_2O were deposited by separate jets and combined at the CsI substrate window. A lower limit of approximately five percent reactive pairs is expected at this concentration.

RDX was kindly supplied to us by Dr. Steve Rodgers at the Edwards Air Force Base. Argon (Matheson, 99.995%) and occasionally nitrogen (Airco, 99.995%) were used as matrix gases, and they were used without further purification. No significant experimental differences were found when the reaction was carried out in argon or nitrogen matrices. N_2O (Aldrich, 95%) was used without further purification. Formaldehyde was prepared from paraformaldehyde according to ref. 2.

Results

The present section will describe the infrared absorptions of the photochemical products and intermediates in Ar at 10 K.

The infrared spectra of RDX in argon at 10 K are shown in Fig. 1*A*. Photolysis of RDX is 80% complete in 40 min resulting

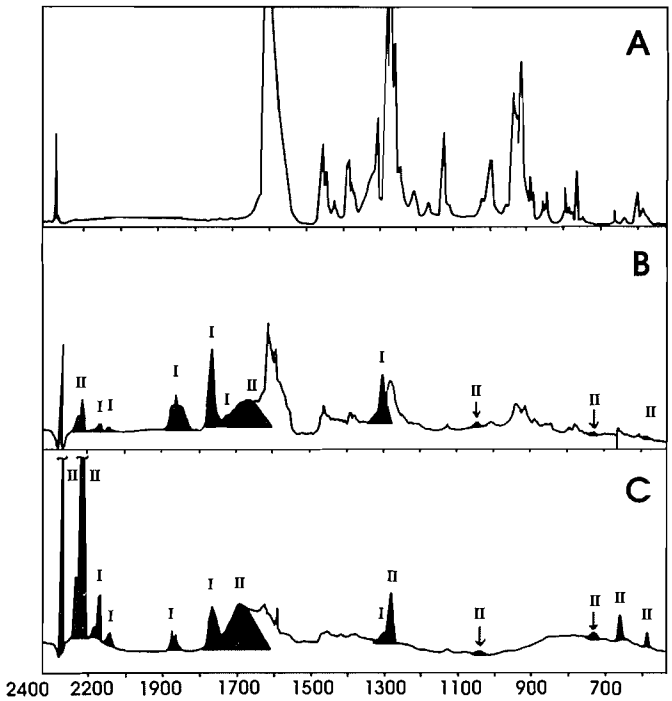

FIG. 1. FTIR absorption bands (*A*) of RDX is Ar at 10 K, (*B*) after 40 min photolysis, and (*C*) after 11 h photolysis. Bands with dark shading are product bands. Bands marked I and II are associated with mechanisms I and II, respectively.

in the product spectrum shown in Fig. 1*B*. After continued irradiation for 11 h, there is complete disappearance of the RDX bands and evidence of secondary photochemical reactions. Figure 1*C* shows the photolysis bands after eleven hours. Of the three spectra, only the 40 min spectrum contains RDX and products together as positive bands. The product bands in 1*B* and 1*C* are indicated by dark shading. Table 1 gives the frequencies and relative intensities of the product bands, normalized to the most intense band of its kind, at three different photolysis times. The molecule assignments associated with the listed bands will be discussed in the next section.

Figure 2 illustrates the kinetics of the product bands. Three distinct behavior patterns, types *A*, *B*, and *C*, are illustrated in 2*A*, 2*B*, and 2*C*. Type A behavior is characterized by simple first-order kinetics and by a fast rise at early photolysis times. Type B behavior also is first order, but these bands rise more slowly. At long photolysis times, some bands from types A and B disappear with a concomitant rise of type C bands. Thus at least two examples of consecutive reaction kinetics are seen.

In a separate argon matrix experiment, N_2O and CH_2O were deposited together and photolysed. After 1 h photolysis there was evidence of CH_2O decomposition to form CO, and annealing of the N_2O was evidenced by the sharpening of the N_2O FTIR bands. There was no evidence of any photoreaction between N_2O and CH_2O.

Discussion

We will discuss the assignment of the product bands and develop a mechanism for the reactions in terms of the kinetic behavior. All of the product molecules are known molecules, and in all cases, literature matrix spectra are available.

Mechanism I

NO. The bands at 1851.0 and 1777.5 cm^{-1} are assigned as NO and the $(NO)_2$ dimer. They follow type A kinetics. These bands appear in a unique portion of the IR spectrum and they compare very well with the literature argon matrix spectra of NO and $(NO)_2$ (7). After 11 h of photolysis, there appears to be some degradation of both the monomer and dimer.

CO. The band at 2140.0 cm^{-1} follows type C kinetics and is assigned to CO. This band also is very well known and appears in many photochemical studies (e.g., ref. 2).

CH_2O, CH_4, HCO, CH_2. The bands at 1740.0 and 1498.1 cm^{-1} appear at early photolysis times with type A kinetics. Consistent with these band frequencies is the molecule formaldehyde (8). The kinetics support the assignment since formaldehyde is known to photolyse in the matrix (9). CO is expected to be a photoproduct, and indeed, the band at 2140.0 cm^{-1} assigned to CO exhibits type C kinetics. Other

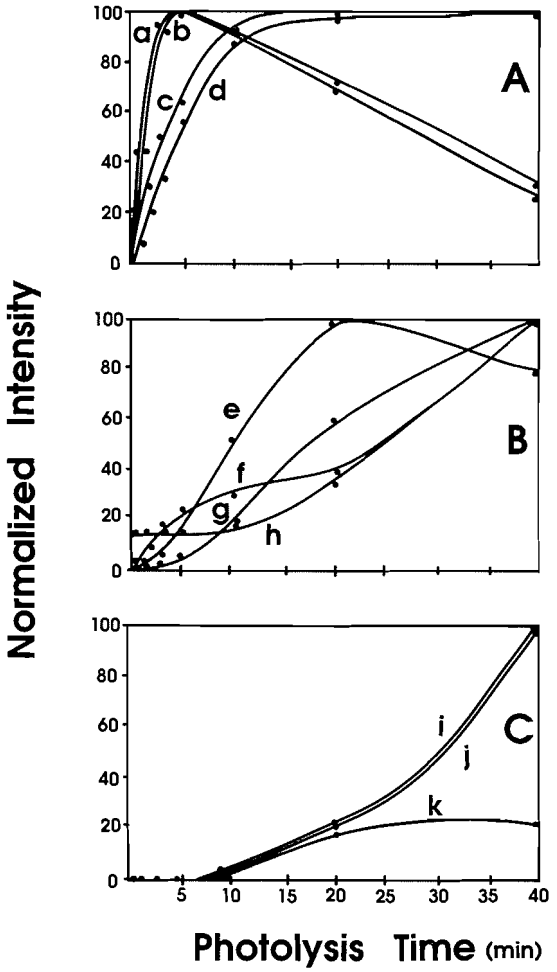

FIG. 2. Normalized FTIR product band intensities versus time. Curves marked *a*–*k* are from bands with the following frequencies; *a*, 1740.0; *b*, 1498.1; *c*, 1851.0; *d*, 1777.5; *e*, 1045.3; *f*, 2218.9; *g*, 733.3; *h*, 1693.2; *i*, 2140.0; *j*, 1300.0; *k*, 2085.0

bands appearing with type C kinetics due to the decomposition of formaldehyde appear at 1300.0 and 2085.0 cm^{-1}. We assign these bands as CH_4 and HCO (10, 11). The methane would account for the uptake of hydrogen from the formaldehyde photolysis, conceivably by the reaction of CH_2 with excited CH_2O. For this, the formation of methylene also must be postulated as a product. To date, there are no literature reports of a matrix spectrum of CH_2. All attempts to stablize methylene under matrix conditions have failed due to its extreme reactivity (12). The band at 2085.0 cm^{-1} is assigned to formyl. This is tentative at best and at least consistent with the photochemical breakdown of formladehyde. Another possibility is HCN, but this is ruled out since the known band for the CH bend at 717 cm^{-1} is not seen in our experiments. Thus we postulate that one of the decomposition mechanisms of RDX results in NO, CH_2O, and CH_2 which later react to form NO, CO, and CH_4. In order to balance the reaction, the production of N_2 and H_2 must be postulated to give the overall balanced reaction as:

$$[I] \quad RDX \rightarrow 4NO + 2CH_2O + N_2 + CH_2 \rightarrow 4NO + 2CO + N_2 + CH_4 + H_2$$

The CH_4 band at 1300.0 cm^{-1} is intense relative to the CO band at 2140.0 cm^{-1} in Fig. 1*B*, possibly due to some absorption of the parent RDX overlapping in that region. Alternatively, it may be necessary to postulate extra hydrogen from other sources, i.e., impurities, to react with methylene to give excess methane. Also one should note that a weak absorbance at 1740.0 cm^{-1} due to formaldehyde still remains in Fig. 1*B*.

Mechanism II

N_2O. The second decomposition reaction is characterized by type B, slower rise, kinetics. The bands at 2227.5, 2218.9, 1283.0, and 586.3 cm^{-1} are due to N_2O (13). These bands all follow type B kinetics. As an independent check, an authentic matrix sample of N_2O in argon (M/R = 1/100) was prepared and it gave an identical spectrum.

N_2O_3. The very broad band at 1693.2 cm^{-1} has type B growth behavior. This band is assigned as symmetric N_2O_3 which has an absorption band at 1690.6 cm^{-1} in the literature (14). It is known to be a product of the reaction of NO + O_2 or NO + O_3 in argon matrices. It is not necessary to postulate these reactions, however, since it can form directly from RDX. One could easily envision its formation from RDX in the chair conformation with the axial NO_2 groups adjacent to each other (C_s symmetry).

O_3. A type B band which exhibits consecutive reaction kinetics is at 1045.3 cm^{-1}. The assignment of O_3 is consistent with the IR spectrum (15). Such an intermediate certainly would be trapped at 10 K. Further support for this assignment comes from the similarity between the type B kinetics and the known tendency for decomposition under matrix photolysis conditions (16). Again, considering the C_s-symmetry chair configuration known for solid phase RDX, the two NO_2 groups are adjacent and they easily could react to form N_2O, O_3, and N_2 (17).

C_2H_2. The next set of type B bands are at 733.3 and 3291.2 cm^{-1}. These bands also are well known and are easily assigned to acetylene (18). The reaction of two adjacent methylene groups produced from the chair configuration of RDX would give acetylene. The reaction of two methylene groups in the matrix is known to produce highly vibrationally excited ethylene which immediately decomposes to form acetylene and hydrogen (19). As in mechanism I, the presence of another methylene group could conceivably result in the rapid formation of methane.

CO_2, H_2O. Comparison of the band at 2340.8 cm^{-1} in Figs. 1*A*, 1*B*, and 1*C* shows that CO_2 is present in the deposition spectrum as a consequence of our deposition method. There is only a slight increase during the initial 40 min of irradiation, but there is a dramatic increase during the 11 h photolysis. This is much more than we normally see in this period of time when the background pressure is 10^{-6} Torr. Thus, CO_2 certainly is a product associated with mechanism II. Matrix water at 1625.0 and 1597.6 cm^{-1} are seen in our experiments and are very well known to other researchers (e.g., ref. 14). We see normal amounts in the eleven hour spectrum compared to CO_2 absorbances in the 40 min spectrum, therefore we conclude that water is not a photoproduct of RDX.

If we consider one RDX molecule leading to products, then N_2 and H_2 must be postulated to balance the reaction:

$$[II] \quad RDX \rightarrow N_2O + [N_2O_3] \text{ or } [N_2 + O_3] + C_2H_2 + CO_2 + 2H_2 + N_2$$

This reaction would involve considerable movement of the atoms in forming the carbon products from one RDX molecule.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

Alternatively, more than one RDX molecule may participate in the formation of the carbon products.

While mechanisms I and II are consistent with the observed products and kinetic behavior, it might be considered that the two decomposition pathways are not necessarily primary processes, i.e., that the initial fragmentation involves the triple fission or NO_2 stripping mechanisms, and that these intermediates are not stabilized at 10 K. This can be ruled out in any event, since neither NO_2 nor HCN are observed products in our studies. The NO_2 photoproduct NO is seen in mechanism I, but it is not accompanied by HCN. The symmetric triple fission products, N_2O and CH_2O, also can be ruled out since our matrix deposition and photolysis of N_2O and CH_2O do not give our final mechanisms I or II products. Rather, no reaction occurs between them.

Conclusions

Reactions [I] and [II] are consistent with the condensed phase thermal chemistry and inconsistent with the gas phase thermal chemistry. The formation of methylene, ethylene, methane, N_2O_3, and ozone in our studies seems at first to be different from the known condensed phase chemistry. These differences may be unique to the matrix environment, the cryogenic temperature, the absence of true isolation, and possibly the photochemical process. In the limit that internal conversion is faster than chemical decomposition where thermal and photochemical studies are comparable, the matrix study shows that there must be two pathways leading to the higher temperature condensed phase results. The NO_2 stripping mechanism and the symmetric triple fission mechanism are results of high temperature gas phase studies only.

The conformation of the RDX in the solid phase is known to be the chair configuration with C_s symmetry. A consequence of the C_s symmetry is that the NO_2 groups are axial and adjacent. This structure could easily explain mechanisms I and II since no geometric rearrangement of RDX is necessary for product formation except perhaps the carbon products in mechanism II. Furthermore the C_{3v} averaged configuration, expected at higher temperatures, has the nitro groups pointing away from each other in the equatorial positions. This structure could more easily explain the stripping NO_2 mechanism and the symmetric triple fission processes seen in the gas-phase studies. Thus perhaps the barrier to the formation of the C_{3v} averaged configuration provides the cutoff, above which the NO_2 stripping and symmetric triple fission mechanisms occur and below which our mechanisms I and II give rise to the condensed phase products. The barrier may be thermal or viscous in nature.

Acknowledgements

The authors would like to thank Dr. Steve Rodgers from Edward Air Force Base for suggesting this project and supplying us with the RDX. We would like to thank Mary McMannamon for the formaldehyde and N_2O experiments. We also would like to acknowledge partial support from the Universal Energy Systems (grant # 210-S-9MG-115) and partial support from the Petroleum Research Foundation (grant # 19114-GB4) for this project.

Electronic absorption and fluorescence spectra of 2-phenyl-substituted benzothiazoles: study of excited-state proton transfer reactions

JOYKRISHNA DEY AND SNEH K. DOGRA[1]

Department of Chemistry, Indian Institute of Technology, Kanpur – 208016, India

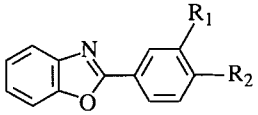
Received January 7, 1991

JOYKRISHNA DEY and SNEH K. DOGRA. Can. J. Chem. **69**, 1539 (1991).

The absorption and fluorescence spectral properties of 2-(3′-hydroxyphenyl)-, 2-(4′-hydroxyphenyl)-, and 2-(3′,4′-dihydroxyphenyl)-, and 2-(4′-hydroxy-3′-methoxyphenyl), 2-(3′-hydroxy-4′-methoxyphenyl)-, and 2-(3′-methoxyphenyl)benzothiazoles have been studied in a number of solvents of varying polarity. The ionization constants (pK_a) for various prototropic reactions of these molecules in both S_0 and S_1 states are determined. The effect of substitution on the spectral properties and on the pK_a values are discussed. The molecules have been found to undergo biprotonic phototautomerism in dilute acid solutions. On the basis of the fluorimetric titration behaviour of the molecules (except 2-(3′-methoxyphenyl)benzothiazole), the existence of monocation–zwitterion equilibrium in the S_1 state is proposed. PPP-SCF-MO-CI method has been used to calculate charge densities on the heteroatoms.

Key words: spectra, proton transfer.

JOYKRISHNA DEY et SNEH K. DOGRA. Can. J. Chem. **69**, 1539 (1991).



On a étudié, dans un certain nombre de solvants de polarité différente, les propriétés spectrales d'absorption et de fluo rescence des composés suivants : 2-(hydroxy-3′-phényl), 2-(hydroxy-4′-phényl), 2-(3′,4′-dihydroxyphényl)-, 2-(4′-hydroxy-3′-méthoxyphényl), 2-(3′-hydroxy-4′-méthoxyphényl)-, et 2-(3′-méthoxyphényl)benzothiazole. On a déterminé les constantes d'ionisation (pK_a) de plusieurs réactions prototropiques de ces molécules dans les états S_0 et S_1. On discute de l'effet des substitutions sur les propriétés spectrales et sur les valeurs du pK_a. On a trouvé que les molécules subissent un phototautomérisme biprotonique en solution diluée acide. On propose l'existence d'un équilibre monocation-zwittérion dans l'état S_1 en se basant sur le comportement du titrage fluorométrique des molécules (à l'exception du 2-(3′-méthoxyphényl)-benzothiazole). On a utilisé la méthode PPP-SCF-MO-CI pour calculer la densité de charge des hétéroatomes.

Mots clés : spectres, transfert de proton.

1. Introduction

The excited state proton-transfer (ESPT) reactions in organic molecules capable of emitting fluorescence has been a subject of great interest among researchers. It has been observed that the basicity or acidity of aromatic amines and alcohols changes by several orders of magnitude upon electronic excitation. The proton dissociation constants (pK_a^*) in the lowest excited singlet state (S_1) of a large number of organic acids and bases have been reported (1–5). The ESPT reactions of naphthols (6, 7) in aqueous and micellar media are well studied. Recently, the excited-state intramolecular proton-transfer reaction of 2-(2′-hydroxyphenyl)benzothiazole (8) and similar molecules (9, 10), because of their uses as potential proton-transfer lasers (11), have been studied extensively. However, no attention has been paid for such studies to 2-(3′-hydroxyphenyl)- and 2-(4′-hydroxyphenyl)benzothiazoles. In a continuation of our studies on the proton-transfer reactions of 2-[phenyl-substituted]benzazoles (benzimidazoles (10, 12), benzoxazoles (9*a*, 13), and benzothiazoles (14)) we have undertaken this investigation to study the absorption and fluorescence spectral properties of **I** and **II** in organic solvents of different polarity and in aqueous solutions of various acid/base concentrations. To study the effect of substituent on the spectral properties and proton-transfer reactions of **I** and **II** we have also included **III**, **IV**, **V**, and **IM**.

I: $R_1 = OH$, $R_2 = H$ — **IV**: $R_1 = OCH_3$, $R_2 = OH$
II: $R_1 = H$, $R_2 = OH$ — **V**: $R_1 = OH$, $R_2 = OCH_3$
III: R_1, $R_2 = OH$ — **IM**: $R_1 = OCH_3$, $R_2 = H$

To support our experimental results semiempirical PPP-SCF-MO-CI calculations have been performed to calculate charge densities on the basic centers of **I**, **II**, and **III**.

2. Experimental

Materials

All compounds were prepared as described in the literature (15) and purified by repeated recrystallization from aqueous ethanol. The purity of the compounds was established by TLC, melting points, and fluorescence excitation spectra in methanol. H_2SO_4 (98%), KOH (B.D.H.), and ortho-H_3PO_4 (B.D.H.) were all reagent grade. Analytical grade cyclohexane (SRL), 1,4-dioxane (E. Merck), acetonitrile (E. Merck), and methanol (B.D.H.) were purified by usual methods (16). Spectrograde ethylacetate (B.D.H.) and analytical grade ethanediol and glycerol (SRL) were used directly. Triply distilled water was used for studies in aqueous solution. The solvents thus obtained showed no detectable fluorescence in the region 250 to 500 nm. pH values of the solutions made by mixing appropriate amount of dilute KOH and H_3PO_4 solutions were measured in a Toshniwal digital 46 CL pH-meter fitted with a combined glass electrode. Aqueous solutions of higher acidity/basicity were prepared following the Hammett's acidity (H_0) (17*a*) and Yagil's basicity (H_-) (17*b*) scales. The fluorescence quantum yields were measured in solutions having absorbances less than 0.1, by comparison with a quinine bisulfate (0.1 N H_2SO_4) solution ($\phi_f = 0.55$) (18). The fluorophore concentration of the solutions (containing not more than 1% (v/v) methanol) was $\sim 5 \times 10^{-5}$ M. All solutions were prepared just before measurements. No attempt was made to remove oxygen from the solutions for fluorescence measurements. All experiments were carried out at ~298 K.

Absorption and fluorescence spectra

The absorption spectra were measured on Shimadzu UV-190 spectrophotometer. All fluorescence measurements were performed in the spectrofluorimeter fabricated in our laboratory which has been described earlier (19). Fluorescence spectra reported here are all corrected.

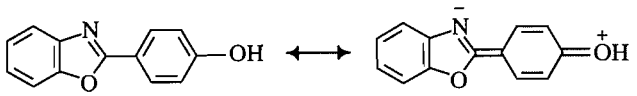
Method of calculation



The molecular orbital calculations have been performed by using the semi-empirical PPP-SCF-MO method combined with a singly excited CI calculation (20–22). The one center repulsion integrals ($\gamma_{\mu\mu}$) were calculated from the corresponding valence-state ionization potentials (I_μ) and electron affinities (A_μ) by using the Pariser–Parr approximation. The two-centre repulsion integrals ($\gamma_{\mu\nu}$) were determined by using the Nishimoto–Mataga (22*b*) approximation. The two-centre core resonance integrals ($\beta_{\mu\nu}$) were calculated by the Nishimato–Forster (22*c*) approximation. The empirical parameters used for the calculations were the same as given in ref. 13. The C—C and C—O bond lengths were assumed to be 1.395 and 1.35 Å, respectively. The bond angles were taken to be equal to those of regular hexagon (120°) and pentagon (108°).

The calculations have been carried out on our institute's Dec-1090 computer. The program (23) for the calculations was obtained from QCPE, Indiana University, Bloomington, USA.

3. Results and discussion

3.1. Solvent dependence of absorption and fluorescence spectra

The absorption and fluorescence spectral data of the molecules studied in different solvents are compiled in Tables 1 and 2, respectively. The absorption spectra of the molecules in methanol agree with those reported in the literature (24). The long wavelength absorption band of **II** is red-shifted relative to that of **I** and can be explained by the resonance effect of the —OH group. This increases the magnitude of transition moment vector, which is reflected by the high intensity (log ϵ, Table 1) of the lowest energy absorption band and by the higher fluorescence quantum yield. The absorption spectrum

II **II'**

of **I** closely resembles that of 2-phenylbenzothiazole (PBT) (24) and is consistent with the fact that the charge migration from the —OH group at 3′ position will be localized on the phenyl ring rather than delocalized over the whole molecule and therefore, it has very little effect on the absorption spectrum of (PBT).

The absorption spectra of **III**, **IV**, and **V** are structured and are not very different from each other. The longest wavelength absorption bands of these molecules are red-shifted compared to that of **II**. This can be explained by the resonance effect as described earlier for **II**. The structured absorption spectra may be caused by the formation of hydrogen bond between the hydroxyl proton and the oxygen atom of adjacent —OH or —OCH_3 group. This intramolecular hydrogen bond (IHB), which makes the molecule more rigid, may also be one of the reasons for the red shift of the longest wavelength absorption band of the molecules.

The absorption spectra of the molecules almost remain unaffected by the solvents employed, except for the loss of the vibrational structure and a small blue shift in water. This is consistent with the fact that the resonance effect of hydroxyl group is smaller than that of amino group and thereby the absorption spectra will not be affected much by the solvents. Water, being a very strong hydrogen-bonding solvent, will

break the IHB in **III**, **IV**, and **V**, resulting in a blue-shifted broad absorption band. Like absorption spectra, the fluorescence spectra of **III**, **IV**, and **V** in cyclohexane are also structured and the emission maxima are red-shifted relative to that of **I** or **II**. This can be explained on the same lines as described above for the absorption spectra. In contrast to the absorption spectra, the fluorescence spectra of the molecules are red-shifted in hydrogen-bonding solvents. It is well known that —OH group becomes more acidic in the S_1 state. As a result the hydrogen bond between the positively polarized hydrogen of the —OH group and the acceptor atom of the proton acceptor solvent becomes stronger in S_1 state and thus the fluorescence maximum shifts to longer wavelength.

The results in Table 2 indicate that the fluorescence quantum yields of the molecules increase with the increase of polarity and hydrogen-bonding capacity of solvents. The higher quantum yield of **II** in polar solvents can be attributed to the stabilization of the rigid structure **II′**. The same is also true for **III**, **IV**, and **V**. Moreover, it is now firmly established that the presence of IHB enhances the rates of radiationless transitions in a molecule (25). This explains the low fluorescence quantum yields for **III**, **IV**, and **V** in cyclohexane. In polar and protic solvents, IHB is partially broken in competition with the intermolecular hydrogen bond resulting in an increase of quantum yield. The very low fluorescence quantum yield of all the neutral molecules in dichloromethane is due to fluorescence quenching by the solvent molecules, as it is well established (26) that dichloromethane quenches the fluorescence of the fluorophores although not too efficiently. Similar behaviour in water is explained below.

I exhibits a dual fluorescence (λ_f = 390 nm, 510 nm) in methanol and water. The longest wavelength emission band is relatively weak and is only observed at higher solute concentration ($\sim 10^{-4}$ M). When water is added to methanol the intensity of 510 nm band increases and reaches a maximum in solution containing 35% (v/v) water, whereas the intensity of 390 nm band decreases and reaches a minimum at this composition of methanol–water. With further increase in the percentage of water, intensity of the long wavelength band decreases. Similar behaviour has also been observed in acetonitrile–water and dioxane–water mixtures, indicating that the dual fluorescence in methanol, acetonitrile, and dioxane is due to the presence of a trace amount of water. We attribute the appearance of the 510 nm band to the formation of anion, a result of deprotonation from the —OH group. The very low ϕ_f value of the neutral molecule in water is thus due to monoanion formation, whereas similar behaviour is not observed in **II** and thus its fluorescence quantum yield increases as compared to other solvents. This assignment is based on the following facts.

(*i*) The fluorescence excitation spectra (pH ~ 7) recorded for both emission bands are similar and resemble the absorption spectra of neutral species. This indicates that both species have the same ground state precursor, *i.e.* neutral molecule.

(*ii*) The addition of KOH to the solution in 35% water – methanol mixture increases the intenstiy of the 510 nm band and decreases that of the other fluorescence band (390 nm). Furthermore, on acidification (3 < pH < 7) the opposite behaviour is observed. This proves that the species in the S_1 state are in reversible equilibrium.

(*iii*) Under similar conditions the methoxy derivative (**IM**) of the molecule **I** exhibits only the normal Stokes-shifted band characteristic of the neutral molecule. Therefore, the excited state process in **I** must involve deprotonation from the —OH group.

(*iv*) The fluorescence excitation spectrum (in the basified water–methanol mixture) recorded at the 510 nm emission band is similar to the absorption spectrum of anion in the same solution.

Assignment of 510 nm fluorescence band to the formation of excimer or exciplex is neglected on the ground that the ratio of fluorescence intensities at the band maxima (I_{510}/I_{390}) does not change with the increase of solute concentration.

Thus water molecules in methanol, acetonitrile, or dioxane act as proton acceptors leading to the following reaction.

$$[1] \quad ROH^* + H_2O \rightleftharpoons RO^- + H_3O^+$$

The decrease of fluorescence intensities of neutral and monoanion species with the increase of percentage of water (>35%) may be due to quenching by water molecules.

Effect of acid concentrations

The absorption and fluorescence spectra of all the molecules have been studied in the H_-/pH/H_0 range of 16 to −10.4. The spectral properties of the prototropic species of all molecules, compiled in Table 3, are discussed under the following headings.

*2-(3′-Methoxyphenyl)benzothiazole (**IM**)*

IM is present as a neutral in the H_-/pH range of 16 to 3.0. In solutions of pH less than 3.0 both absorption and fluorescence spectra shift to longer wavelengths. Based on earlier results (14) (*i.e.* protonation at tertiary nitrogen atom leads to

a red shift in the absorption and fluorescence spectra if $\pi \rightarrow \pi$ is the lowest energy transition) the red-shifted absorption and fluorescence bands can be assigned to the monocation formed by protonation of the ring nitrogen atom. The value of the acidity constant for the monocation–neutral equilibrium (Table 4) as well as the similarity of the spectral characteristics of monocation of **IM** with those of PBT (27) (λ_f = 390 nm) also confirm this assignment. The fluorescence intensity of the neutral band (λ_a = 380 nm) decreases with the concomitant rise of the monocation band (λ_f = 445 nm) as the pH is lowered. No further change in the spectral properties is observed when acid concentration is increased below H_0 = 0.0. The spectral characteristics of neutral and monocation forms of **IM** are depicted in Fig. 1 and the relative intensity change of the monocation and neutral molecule are plotted as a function of pH/H_0 in Fig. 2.

Compounds II, III, IV, and V

The absorption of fluorescence spectra of these molecules are red-shifted in solutions of pH > 7.0. This can be ascribed to the formation of the monoanion. The absorption spectra of **III** exhibit a further red shift in solutions of pH > 10.0. Since **III** has two dissociable —OH groups, the latter shift is due to the dianion formation. The red shifts in the absorption and fluorescence maxima of the monoanions relative to those of the corresponding neutral molecules (**II**, **III**, and **IV**) are almost similar, indicating thereby that monoanions are formed by the deprotonation of the 4′-OH groups. Consequently the dianion of **III** is formed from dissociation of 3′-OH group. This is further manifested by the fact that pK_a for neutral–monoanion equilibrium is nearly similar for **II**, **III**, and **IV** (Table 4). The fluorescence spectrum (λ_f = 510 nm) of the monoanion of **V** is very significantly red-shifted, as compared to those of **II**, **III**, and **IV**, although there is not much difference in the absorption band maxima of this species in these molecules. This is due to the large solvent relaxation in the excited state as observed in **I** as discussed below. In all cases, as the pH is raised, the fluorescence intensity of the monoanion increases simultaneously with the decrease of the neutral band. Since **III** decomposes at higher pH, it was not possible to record fluorescence spectra in solutions of pH above 11.0.

In the pH region of 7 to 3, the molecules are neutral in both the S_0 and S_1 states. Like **IM**, the absorption and fluorescence spectra shift to longer wavelengths (except for **II**) at $H_0 < 0$ and red-shifted bands can be assigned to monocation formed by protonating tertiary nitrogen atom. The fluorescence intensity of the monocation species of the compounds, especially for **III** and **IV**, increases slowly up to H_0 −3 and then sharply with further increase of acidity. Although nice isosbestic points are observed in the absorption spectra of these conjugate acid–base pair in the pH/H_0 range of 3 to −1.0, no correspondence is noticed between the decrease in the fluorescence intensity of the neutral species and increase in the fluorescence intensity of monocation (see Fig. 3). This indicates that either the fluorescence intensity of the neutral molecule is quenched by the protons (because the fluorescence intensity of neutral species is not quenched by the equivalent amount of SO_4^{2-} ions, obtained by the addition of K_2SO_4) or

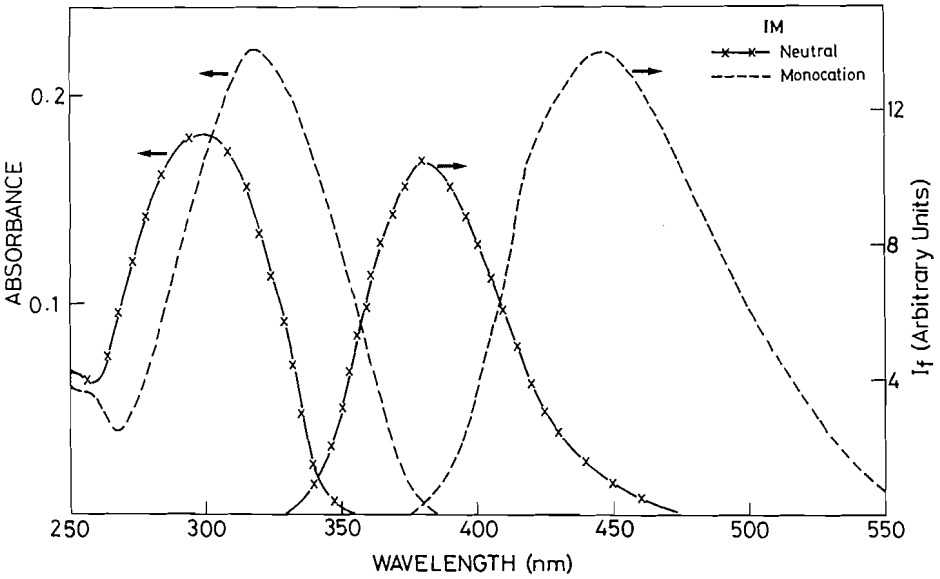

FIG. 1. Absorption (left) and fluorescence (right) spectra of the prototropic species of 2-(3′-methoxyphenyl)benzothiazole (**IM**).

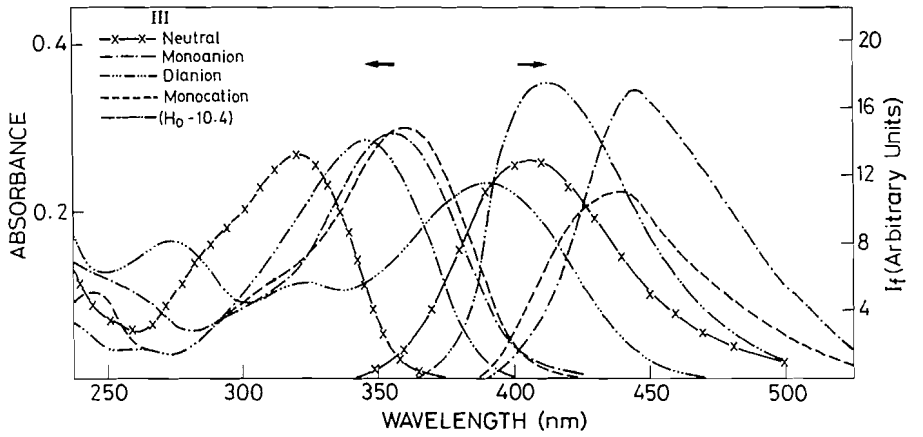

FIG. 2. Absorption (left) and fluorescence (right) spectra of the prototropic species of 2-(3′,4′-dihydroxyphenyl)benzothiazole (**III**).

there exists a non-fluorescent species in between neutral and monocation. The existence as well as nature of this species will be established in the subsequent section. In concentrated H_2SO_4 acid (H_0 −10.4), the absorption and fluorescence spectra of the monocations of all these molecules shift to shorter wavelengths which can be ascribed to the protonation on the —OH or —OCH_3 group at the 4′ position (since the protonation of —OH or —OCH_3 group at the 3′ position in **I** or **IM** does not bring about any spectral change) forming dications. The spectral profiles of the various prototropic species of **III** are depicted in Fig. 3.

2-(3′-Hydroxyphenyl)benzothiazole (I)

The absorption properties of I in aqueous solutions of pH/H_0 ranging from 13 to −10.4 are similar to those of the **II**, **III**, **IV**, and **V**. Thus the red-shifted absorption spectra of **I** (Fig. 4) at pH 13.0 and H_0 −1.0 can be assigned to the monoanion and monocation, respectively. The fluorescence characteristics of I in solutions pH/H_0 <2 are also similar to those observed for molecules discussed in the last section.

The fluorescence spectral characteristics in the pH range 0.0 to 13 are different from the ground state reactions and also different from those of the other molecules. The molecule exhibits dual fluorescence (λ_f = 390, 510 nm) in this pH region. As already mentioned the short and long wavelength bands are due to the neutral molecule and monoanion, respectively. The intensities of the bands remain unchanged in the pH range 3.0 to 8.0. When the pH increases to above 8.0 the intensity of the 510 nm band increases and that of 390 nm band decreases. On the other hand, when the pH is decreased to below 3.0, the intensities of both bands decrease. The relative intensity change of the 510 nm band as a function of pH/H_0 is shown in Fig. 3. The plot thus obtained is a stretched sigmoid curve with two inflection points, one corresponds to the ground state pK_a value (9.8) and the other to the excited state pK_a value (1.8). The intensity change of the 390 nm band could not be plotted because of its very low intensity in aqueous solutions. Similar features have also been observed in 1-, 2-naphthols (6) and 9-phenanthrol (28). This indicates that the rate of proton transfer in the S_1 state of **I** is comparable to the rate of its fluorescence decay.

The appearance of the monoanion fluorescence band in the region of pH 3 to 8 must be due to the excited state prototropic reaction because anionic species is completely absent in solu-

[a,f]Calculated using absorption and fluorescence maxima of the species, respectively.

tions of pH < 7 in the ground state. Therefore, the fluorescence properties in the region corresponding to the complete titration curve can be explained by the kinetics of the excited state reaction. The pathways of decay available to the excited-state prototropic species can be represented by the scheme

SCHEME 1

where k_3 and k_3' are the pseudo first order rate constants for the deprotonation and second order protonation reactions, k_f and k_r are the radiative and non-radiative decay constants for ROH* and k_f' and k_r' are the corresponding quantities for RO^{-}*. If the equations derived by Weller (2), using the steady-state principle, are applied, then the relative fluorescence intensities of the neutral and monoanion species can be given by the equations

$$[5] \quad I/I_0 = \frac{1 + k_3'\tau_0'[H_3O^+]}{1 + k_3\tau_0 + k_3'\tau_0'[H_3O^+]}$$

$$[6] \quad I'/I_0' = \frac{k_3\tau_0}{1 + k_3\tau_0 + k_3'\tau_0'[H_3O^+]}$$

where I_0 or I_0' is the fluorescence intensity of only one species, and I or I' is the same for the species at any pH in which both the conjugate acid and base are present; τ_0 and τ_0' are the radiative life times of the neutral and monoanion species, respectively. Since in the pH region 8.0 to 3.0, the concentration of H_3O^+ is very small, the rate (k_3') of the backward reaction will be very small compared to the radiative decay rate ($1/\tau_0'$) of the monoanion. Under such condition the eqs. [5] and [6] reduce to equations

$$[7] \quad I/I_0 = \frac{1}{1 + k_3\tau_0}$$

and

$$[8] \quad I'/I_0' = \frac{k_3\tau_0}{1 + k_3\tau_0}$$

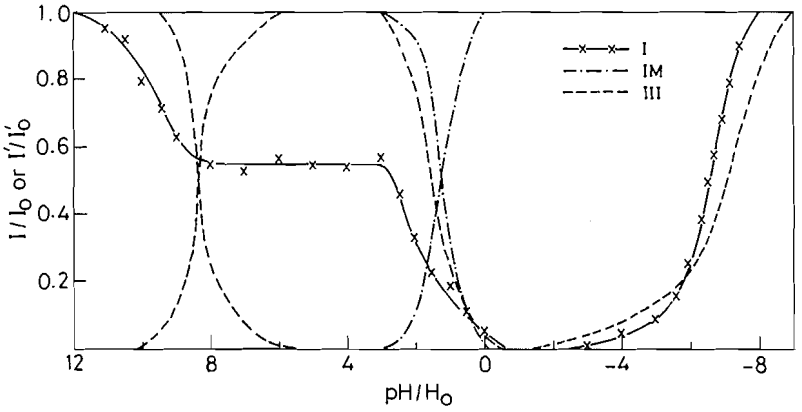

FIG. 3. Fluorimetric titration curves for compounds **I**, **IM**, and **III**.

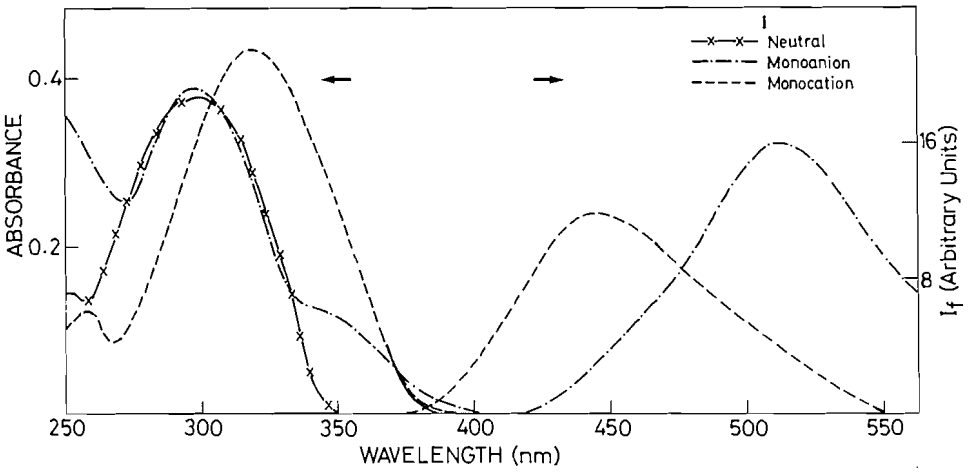

FIG. 4. Absorption (left) and fluorescence (right) spectra of the prototropic species of 2-(3′-hydroxyphenyl)benzothiazole (**I**).

respectively, which clearly show that the relative intensities of the neutral and anion forms are independent of $[H_3O^+]$ in the above pH region. Substituting the value of $I'/I_0' = 0.55$ in eq. [8] we get $k_3\tau_0 = 1.22$. Thus knowing τ_0 one can calculate k_3.

Acidity constants

The acidity constants of the various prototropic reactions, as mentioned below, in the S_0 state are determined using absorption spectral data and the pK_a values so obtained are tabulated in Table 4.

[1] Dication $\rightleftharpoons$ monocation + H^+

[2] Monocation $\rightleftharpoons$ neutral + H^+

[3] Neutral $\rightleftharpoons$ monoanion + H^+

[4] Monoanion $\rightleftharpoons$ dianion + H^+

Equilibrium [4] is possible only for **III**. The pK_a value for equilibrium [1] could not be determined as the formation of dication was not complete even at H_0 −10.4. From the data of Table 4, it is clear that for **II**, the pK_a[3] value of reaction [3] is much smaller and that of reaction [2] is higher than that for **I**. This is consistent with the fact, as discussed earlier, that **II** is resonance-stabilized, as a result of which the hydroxyl proton becomes more acidic and the pyridinic nitrogen atom becomes more basic. MO calculations show that the π-electron density (Table 5) at the oxygen atom of —OH group in **II** is smaller than that in **I**. This is more pronounced in the S_1 state thus providing that —OH group becomes more acidic upon excitation. On the other hand, charge density at the tertiary nitrogen atom of **II** is more than that in **I** and thus making it more basic. Based on this discussion, pK_a[3] value for **III** indicates that the first deprotonation will occur from the hydroxyl group at position 4′, followed by from position 3′. Little higher values of pK_a[3] for **IV** and **V** could be because of the presence of electron donating methoxy group at the ortho-position to the hydroxyl group. Similarity of pK_a[2] values for compounds **I** and **IM** and higher value for **II** can be explained on the same lines as has been done before for pK_a[3].

The pK_a* values for the various prototropic reactions have been determined using fluorimetric titrations and Forster cycle method employing absorption and fluorescence data wherever applicable and are compiled in Table 4. The Forster cycle method cannot be used to calculate (*a*) pK_a*[1], because ground state pK_a value is not known, (*b*) pK_a*[2], because the prototropic reaction involved in the ground state is different from that occurring in the S_1 state (see below), (*c*) pK_a*[4] cannot be determined using fluorescence data as the dianion of **III** is non-fluorescent. As expected, pK_a*[3] values indicate that hydroxyl group become stronger acid on excitation. On the other hand, ground state pK_a[3] values have been obtained

from the fluorimetric titrations curves (Fig. 3) for **II**, **III**, **IV**, and **V**, indicating that prototropic equilibrium [3] is not established in the S_1 state during the lifetimes of these molecules. Stretched sigmoid fluorimetric titration curves have been noticed for **I** in the pH range to 11, giving two pK_a[3] values, one agreeing with the ground state pK_a[3] value and the other the excited state pK_a[3] value. This indicates that the lifetimes of the respective conjugate acid–base pair of **I** are comparable with the reciprocal rate constants of these prototropic reactions.

As mentioned earlier, no correspondence is observed between the decrease in the fluorescence intensity of neutral species and the increase in the fluorescence intensity of monocation. On the basis of the following discussion, we conclude that the decrease in the fluorescence intensity of neutral species is due to the formation of non-fluorescent zwitterion rather than due to proton-induced fluorescence quenching. (*i*) Prototropic equilibrium for the monocation–neutral reaction of **IM** has clearly established that formation of non-fluorescent species is because of the presence of —OH group, which is absent in **IM**. Further the structures of **I** and **IM** are not very different from each other. If **I** undergoes proton-induced fluorescence quenching it should also be observed for **IM**. On the other hand, the proton-induced fluorescence quenching has been observed for both 2-naphthol and 2-methoxy naphthalene (29). (*ii*) pK_a* values are generally determined from the formation curve of that species. The pK_a*[2] values thus obtained for the monocations of these molecules indicate that the tertiary nitrogen atom become weaker base upon excitation, which is contrary to the established results. (*iii*) Our PPP calculations have also indicated that charge density increases at the basic nitrogen atom, suggesting that the tertiary nitrogen atom becomes a stronger base in the S_1 state. (*iv*) Since the formation of zwitterion in the S_1 state involves biprotonic mechanism, its formation will depend on the environments. That is why it is only formed in the pH/H_0 range 3 to −2. (*v*) When similar titration is performed in cyclohexane with trifluoroacetic acid the formation of monocation is complete at much lower acid concentration and the increase in the intensity of monocation is comparable with the decrease of the neutral species. This is because the formation of zwitterion will be less favourable in non-polar than in polar media.

It has also been noticed that the shape of the fluorimetric titration (Fig. 3) curves for the formation of monocation do not conform to the trend observed in the titration curves for neutral molecules, *i.e.* it rises very slowly in the beginning and then sharply, as if there are two breaks. Since no changes have been noticed in the absorption spectra at $H_0 < -2$, we attribute this to an excited state phenomenon. In our opinion, the first break is due to the formation of monocation from non-fluorescent zwitterion and the increase of intensity in the second step is due to the decrease in the rates of radiationless processes in monocation. This could be due either to an increase in viscosity of the medium or a decrease in the number of free water molecules to solvate the monocations with the increase of acid concentration. Because of this, only the approximate values of pK_a* for the monocation–zwitterion equilibria are reported.

Conclusions

The higher values of molar extinction coefficient of the lowest energy transition and fluorescent quantum yield and low value of pK_a[3] of **II** compared to the corresponding values of **I** indicate the resonance effect of the —OH group leading to structure **II′**. The structured absorption and fluorescence spectra exhibited by **III**, **IV**, and **V** are indicative of the presence of intramolecular hydrogen bond between the —OH proton and the oxygen atom of the adjacent —OH or —OCH_3 group. The rate of deprotonation reaction in molecules **II**, **III**, **IV**, and **V** is slower than the rates of radiative decays whereas in **I** the proton-transfer rate is comparable to the rate of radiative decay. The prototropic reactions of the molecules, except for **IM**, in the acidity region of $H_0 = 0.0$ to $H_0 = -9.0$ in the S_1 state are different from those in the S_0 state. The fluorimetric titration curves in this region of acidity have led to a prediction of the monocation–zwitterion equilibrium. The zwitterions are formed from neutral molecules as a result of biprotonic photoautomerism.

Received December 5, 1990[2]

ZHIPENG DENG and DEREK G. LEAIST. Can. J. Chem. **69**, 1548 (1991).

The Taylor dispersion (peak-broadening) technique is used to measure the ternary mutual diffusion coefficients of the mixed salt solutions $MgCl_2$ + $MgSO_4$ + H_2O and Na_2SO_4 + $MgSO_4$ + H_2O at 25°C. The dispersion of the solutes is followed by differential refractometry. A simple least-squares procedure is developed to calculate the ternary diffusion coefficients from the refractive index profiles. The coefficients are measured at 0.04, 0.20, or 0.40 mol dm^{-3} total salt for the molar salt ratios 1:3, 1:1, or 3:1. The measured diffusion coefficients are compared with the limiting values for the completely dissociated salts.

Key words: mixed salt solutions, multicomponent diffusion, Taylor dispersion, ternary diffusion coefficients.

ZHIPENG DENG et DEREK G. LEAIST. Can. J. Chem. **69**, 1548 (1991).

On a utilisé la technique de dispersion de Taylor (élargissement des bandes) pour mesurer les coefficients de diffusion mutuels ternaires de solutions mixtes de sels $MgCl_2$ + $MgSO_4$ + H_2O et Na_2SO_4 + $MgSO_4$ + H_2O, à 25°C. On a suivi la dispersion des solutés par réfractométrie différentielle. On a développé une méthode simple des moindres carrés pour calculer les coefficients de diffusions ternaires à partir des profils des indices de réfraction. On a mesuré les coefficients à des concentrations totales de sel de 0,04, 0,20 et 0,40 mol dm^{-3}, pour des rapports molaires de sel de 1:3, 1:1 et 3:1. On a comparé les coefficients de diffusion mesurés avec les valeurs limites obtenues pour les sels complètement dissociés.

Mots clés : solutions de sels mixtes, diffusion à plusieurs composantes, dispersion de Taylor, coefficients de diffusion ternaire.

[Traduit par la rédaction]

1. Introduction

Relatively few diffusion studies have dealt with mixed salt solutions despite the practical importance of these systems and their interesting properties. Most of the reported data (1–8) have been obtained for 1–1, 1–2, or 2–1 salts. The present study was undertaken to measure the ternary mutual diffusion coefficients of the higher-valent systems $MgCl_2$ + $MgSO_4$ + H_2O and N_2SO_4 + $MgSO_4$ + H_2O. The information available for mixtures of 1–2 or 2–1 salts might not be a reliable guide to the behavior of 1–2 + 2–2 or 2–1 + 2–2 systems owing to the strong association of 2–2 salts (9–12).

Diffusion data for mixtures of 1–1 + 2–2 salts (such as NaCl + $MgSO_4$ + H_2O) would also be useful. Unfortunately, the diffusion of two salts lacking a common ion (13) is a more complicated quaternary process (three independent solute fluxes) which is beyond the scope of the present study.

Multicomponent diffusion is usually studied by optical (3–6), conductimetric (14, 15) or diaphragm-cell (13) techniques. These techniques are reliable, but they have not gained wide popularity, largely because the experimental procedures are so laborious. Recently, the more convenient Taylor dispersion (peak-broadening) technique (1, 16–19) for measuring binary diffusion was extended to three- and four-component systems (20–23). In a Taylor experiment, a narrow band of solution is injected into a laminar carrier stream of different composition which flows in a long capillary tube. The injected solutes spread out as they flow along the tube. A liquid-chromatography detector (usually a differential refractometer) monitors the broadened distribution of dispersed solutes as they flow out of the tube. Ternary diffusion coefficients can be calculated by moments analysis (21) or, more accurately, by fitting the dispersion equations to the eluted solute peaks (22, 23).

The dispersion technique has significant advantages over other diffusion experiments. Most important of all, it is immune to errors from convection, even if the injected solution is less dense than the carrier stream. A wide range of dilute or concentrated solutions can be studied if differential refractometry is used to detect the eluted solutes. By connecting the detector to a microcomputer, the collection of the data is easily automated. The run times are conveniently short, and calibration of the dispersion tube is not required.

In this paper an improved least-squares procedure is developed to calculate ternary diffusion coefficients from dispersion profiles.

2. Experimental

Reagent grade $MgSO_4$ (Baker), $MgCl_2 \cdot 6H_2O$ (BDH) and Na_2SO_4 (BDH) were used as received. The water content of each salt was checked by drying samples to constant weight in a vacuum oven at 350°C. Solutions were prepared with distilled deionized water in calibrated volumetric flasks. Solutions of $MgCl_2$, Na_2SO_4, and $MgSO_4$ (0.10 mol dm^{-3}) had the respective pH values 5.7, 5.9, and 7.3.

The dispersion equipment consisted of a metering pump, an injection valve fitted with a 20×10^{-6} dm^{-3} sample loop, a Teflon capillary tube (length 25.90 m, inner radius 4.339×10^{-4} m), and a differential refractometer detector (Waters Model 401, 10^{-5} dm^{-3} flow cells) at the tube outlet. The refractometer output voltage was measured at accurately-timed 20–30 s intervals with a digital voltmeter (Hewlett-Packard Model 3478A). The dispersion tube was coiled in a 0.7 m-diameter helix and held at 25.00 ± 0.03°C during the experiments. Sample retention times were typically 5000–6000 s.

3. Theory

Diffusion in a three-component solution composed of solute 1 + solute 2 + solvent 0 obeys the ternary Fick equations (1)

[1] $j_1 = -D_{11}\nabla c_1 - D_{12}\nabla c_2$

[2] $j_2 = -D_{21}\nabla c_1 - D_{22}\nabla c_2$

where j_1 and j_2 are the molar flux densities of the solutes in the volume-fixed frame; c_1 and c_2 are the solute concentrations in moles per unit volume. The ternary diffusion coefficient D_{ik} gives the flux of solute i produced by the gradient ∇c_k in the concentration of solute k. The cross-terms $-D_{12}\nabla c_2$ and $-D_{21}\nabla c_1$ allow for coupled diffusion: the transport of each solute produced by gradient in the other solute. Fluxes of dissolved salts, for example, tend to be strongly coupled by electrostatic forces. Association reactions can also lead to large cross-terms.

The flux of solvent (component 0), which does not appear explicitly in the diffusion equations, can be evaluated by solving eqs. [1] and [2] together with the condition of zero volume flow: $j_1V_{1m} + j_2V_{2m} + j_0V_{0m} = 0$. V_{im} is the partial molar volume of component i.

Consider a ternary dispersion experiment in which a laminar carrier stream of composition $\bar{c}_1$, $\bar{c}_2$ flows at mean speed U in a long capillary tube of inner radius r. Diffusion is initiated at time $t = 0$ by injecting a small volume of ΔV of solution of composition $\bar{c}_1 + \Delta c_1$, $\bar{c}_2 + \Delta c_2$ into the carrier stream. The solution near the center of the tube flows more rapidly than the solution near the tube wall. Consequently, the injected solutes spread out as they flow along the tube. The broadened distribution of the solutes is monitored at the tube outlet, a distance L downstream from the point of injection.

Price (20) has shown that the radially-averaged concentrations of the eluted solutes are given by

[3] $$c_i(t) = \bar{c}_i + (2/r^3U)(3/\pi^3t)^{1/2} \times \sum_{k=1}^{2} A_{ik}D_k^{1/2} \exp\left[-12D_k(t - t_R)^2/r^2t\right] \qquad (i = 1,2)$$

t_R is the mean retention time, L/U. D_1 and D_2 are the eigenvalues of the 2 by 2 matrix $\mathbf{D}$ of the ternary diffusion coefficients.

[4] $$D_1 = \{D_{11} + D_{22} + (D_{11} - D_{22})[1 + 4D_{12}D_{21}/(D_{11} - D_{22})^2]^{1/2}\}/2$$

[5] $$D_2 = \{D_{11} + D_{22} - (D_{11} - D_{22})[1 + 4D_{12}D_{21}/(D_{11} - D_{22})^2]^{1/2}\}/2$$

The A_{ik} coefficients are abbreviations for

[6] $A_{11} = \Delta V[(D_{22} - D_1)\Delta c_1 - D_{12}\Delta c_2]/(D_2 - D_1)$

[7] $A_{12} = \Delta V[(D_{22} - D_2)\Delta c_1 - D_{12}\Delta c_2]/(D_1 - D_2)$

[8] $A_{21} = \Delta V[(D_{11} - D_1)\Delta c_2 - D_{21}\Delta c_1]/(D_2 - D_1)$

[9] $A_{22} = \Delta V[(D_{11} - D_2)\Delta c_2 - D_{21}\Delta c_1]/(D_1 - D_2)$

Equations [3] are valid provided the flow is laminar and (17, 24) $0.8r^2/D_i < t_R < Lr/50D_i$.

It is difficult in practice to measure the concentration of each eluted solute. Instead, the broadened distribution of the solutes is followed indirectly by measuring the refractive index profile $n(t)$ across the eluted sample.

[10] $n(t) = \bar{n} + R_1[c_1(t) - \bar{c}_1] + R_2[c_2(t) - \bar{c}_2]$

where $\bar{n}$ is the baseline refractive index of the bulk of the carrier solution; $R_1 = dn/dc_1$ and $R_2 = dn/dc_2$ are the molar refractivities of the solutes, evaluated at the carrier stream composition, $\bar{c}_1$, $\bar{c}_2$.

Highly sensitive flow-through differential refractometers are available commercially. These instruments give a linear response — the voltage $v(t)$ — to the changes in the refractive index $n(t)$ of the eluted solution relative to the background refractive index $\bar{n}$ of the carrier stream. The detector signal is represented by the expression

[11] $v(t) = k[n(t) - \bar{n}] + B_0 + B_1t$

where k is the detector sensitivity, dv/dn, and B_0 is the baseline detector voltage. The term B_1t is often included to allow for small linear drifts in the baseline signal.

Equations [3] and [6]–[11] may be combined to give the working equations

[12a] $$v(t) = v_{max}\left(\frac{t_R}{t}\right)^{1/2}\left[W_1 \exp\left(-\frac{12D_1(t - t_R)^2}{r^2t}\right) + (1 - W_1)\exp\left(-\frac{12D_2(t - t_R)^2}{r^2t}\right)\right] + B_0 + B_1t$$

[12b] $$W_1 = (a + b\alpha_1)D_1^{1/2}/[(a + b\alpha_1)D_1^{1/2} + (1 - a - b\alpha_1)D_2^{1/2}]$$

for the detector signal. v_{max} represents the height of the eluted solute peak relative to the baseline. α_1 stands for the fraction of the initial refractive index contributed by solute 1:

[13] $\alpha_1 = R_1\Delta c_1/(R_1\Delta c_1 + R_2\Delta c_2)$

W_1 and $1 - W_1$ give the normalized weights of the exponential terms. The parameters a and b are constants for a given system and carrier stream composition.

D_1, D_2, v_{max}, B_0, and B_1 are most easily evaluated by using least squares to fit eq. [12] to the measured detector voltages. a and b can also be evaluated provided the data set includes two or more peaks with different values of α_1. (For better accuracy the values of α_1 should be widely separated, such as 0.0 and 1.0 rather than 0.4 and 0.6.) The retention time t_R can also be treated as a least-squares parameter, in which case flow-rate calibrations are unnecessary. Conveniently, detector calibration is not required because the refractometer sensitivity k is not used in the calculations.

The solute peaks obtained for ternary diffusion closely resemble two overlapping Gaussians, centered on time t_R, with variances $r^2L/24D_1U$ and $r^2L/24D_2U$. Notice, however, that for the special initial conditions satisfying $a + b\alpha_1^{(1)} = 1$, the exponential term in D_2 vanishes, leaving the eigenfunction in D_1. The concentration vector

[14] $$\begin{pmatrix} \alpha_1^{(1)}/R_1 \\ (1-\alpha_1^{(1)})/R_2 \end{pmatrix} = b^{-1}\begin{pmatrix} (1-a)/R_1 \\ (a+b-1)/R_2 \end{pmatrix}$$

is therefore an eigenvector of **D**, with eigenvalue D_1. Similarly, the exponential term in D_1 vanishes for initial conditions satifying $a + b\alpha_1^{(2)} = 0$. The vector

[15] $$\begin{pmatrix} \alpha_1^{(2)}/R_1 \\ (1-\alpha_1^{(2)})/R_2 \end{pmatrix} = b^{-1}\begin{pmatrix} -a/R_1 \\ (a+b)/R_2 \end{pmatrix}$$

is therefore an eigenvector of **D**, with eigenvalue D_2.

Once the eigenvalues and the eigenvectors of **D** have been evaluated, **D** itself can be recovered by the similarity transform (21, 25)

[16] $$\mathbf{D} = \begin{pmatrix} (1-a)R_1 & -a/R_1 \\ (a+b-1)/R_2 & (a+b)/R_2 \end{pmatrix}\begin{pmatrix} D_1 & 0 \\ 0 & D_2 \end{pmatrix}\begin{pmatrix} (1-a)R_1 & -a/R_1 \\ (a+b-1)/R_2 & (a+b)/R_2 \end{pmatrix}^{-1}$$

and hence

[17] $$D_{11} = D_1 + [a(1-a-b)/b](D_1 - D_2)$$

[18] $$D_{12} = (R_2/R_1)(a/b)(1-a)(D_1 - D_2)$$

[19] $$D_{21} = (R_1/R_2)[(a+b)(1-a-b)/b](D_2 - D_1)$$

[20] $$D_{22} = D_2 + [a(1-a-b)/b](D_2 - D_1)$$

The initial concentration differences Δc_1, Δc_2 should be small enough to ensure that the diffusion coefficients do not vary appreciably across the eluted solute peaks. If this condition is met, the calculated D_{ik} coefficients represent differential values at the composition $\bar{c}_1$, $\bar{c}_2$ of the carrier stream.

4. Results

The ternary diffusion coefficients of $MgCl_2(1) + MgSO_4(2) + H_2O$ and $Na_2SO_4(1) + MgSO_4(2) + H_2O$ were measured at total salt concentrations of 0.04, 0.20, or 0.40 mol dm^{-3} and molar salt ratios of 1:3, 1:1, or 3:1.

Solute peaks for the system $MgCl_2(1) + MgSO_4(2) + H_2O$ are illustrated in Fig. 1. Peak number 1 was generated by injecting excess $MgCl_2$ ($\Delta c_1 = 0.05$, $\Delta c_2 = 0.00$ mol dm^{-3}; $\alpha_1 = 1.00$) into the carrier stream. Peak number 2 was generated by injecting excess $MgSO_4$ ($\Delta c_1 = 0.00$, $\Delta c_2 = 0.050$ mol dm^{-3}; $\alpha_1 = 0.00$). The composition of the carrier stream in this example is: $\bar{c}_1 = 0.10$, $\bar{c}_2 = 0.10$ mol dm^{-3}.

A least-squares procedure (22, 25, 26) based on Newton's method was used to fit eq. [12] to the measured solute peaks. The object was to minimize the sum S of the squared deviations between the measured detector voltages and those calculated from eq. [12].

[21] $$S = \sum_i [v(t_i)_{meas} - v(t_i)_{calc}]^2$$

The minimization was accomplished by adjusting the values of the fitting parameters a, b, D_1, D_2 and, for each peak, v_{max}, t_R, B_0, and B_1.

Given initial estimates of the various fitting parameters, represented by p_1^0, p_2^0, ..., the calculated detector voltages can be approximated by the first-order Taylor series (a different Taylor!) in the parameters

[22] $$v(t_i)_{calc} = v^0(t_i)_{calc} + \sum_m [\partial v^0(t_i)_{calc}/\partial p_m]\Delta p_m$$

The least-squares conditions $\partial S/\partial \Delta p_m = 0$ provide the set of linear equations

[23] $$\sum_m \sum_i \frac{\partial v^0(t_i)_{calc}}{\partial \Delta p_l}\frac{\partial v^0(t_i)_{calc}}{\partial \Delta p_m}\Delta p_m = \sum_i \frac{\partial v^0(t_i)_{calc}}{\partial \Delta p_l}[v(t_i)_{meas} - v^0(t_i)_{calc}]$$

which are easily solved (with a microcomputer) for the parameter increments Δp_m which reduce S. The calculations are repeated using the improved parameter estimates $p_1^0 + \Delta p_1$, $p_2^0 + \Delta p_2$, ..., and so on, until the minimum in S is located, as indicated by negligible parameter changes.

Two to four peaks with different values of α_1 were fitted simultaneously. In most cases convergence was achieved after 3–5 iterations. The standard deviations between the measured and the calculated voltages was typically 0.3% of the peak voltage. The values of α_1 were in the range 0.0–1.0.

Once a, b, D_1, and D_2 had been evaluated, eqs. [17]–[20] were used to calculate the D_{ik} coefficients. The standard deviation of the D_{ik} values, $\pm 0.01 \times 10^{-9}$ m^2 s^{-1}, was estimated by repeating the fitting procedure for 3–4 sets of replicate peaks. The average values of the D_{ik} coefficients obtained at each composition are given in Tables 1 and 2. The ratio R_2/R_1 of the salt refractivities required to calculate the cross-coefficients D_{12} and D_{21} was calculated by taking the ratio of the peak areas generated per mole of excess injected salt (22, 23).

The initial concentration differences (Δc_1, Δc_2) were typically 0.05 mol dm^{-3}. A few runs were made with concentration differences one-half as large. Since the results did not differ significantly, the measured diffusion coefficients can be interpreted as differential values at the composition of the carrier stream ($\bar{c}_1$, $\bar{c}_2$).

As the solute fraction of salt 1

[24] $$f_1 = \bar{c}_1/(\bar{c}_1 + \bar{c}_2)$$

drops to zero, D_{12} vanishes by definition because the gradient in salt 2 cannot produce a coupled flow of salt 1 if the solution is free of salt 1. In this limit D_{22} approaches the value of the binary diffusion coefficient for salt 2. Similarly, as $f_1 \rightarrow 1$, D_{21} vanishes and D_{11} approaches the binary value for salt 1.

These ideas are illustrated in Fig. 2 where the diffusion coefficients of $MgCl_2(1) + MgSO_4(2) + H_2O$ for 0.40 mol dm^{-3} total salt are plotted against the solute fraction of $MgCl_2$. Figure 3 shows the diffusion coefficients of the $Na_2SO_4(1) + MgSO_4(2) + H_2O$ system plotted against the solute fraction of Na_2SO_4. The values of D_{12} and D_{21} appear to extrapolate

correctly to zero for both systems. (A precise extrapolation is not possible because the functional form of D_{ik} versus f_1 is not known.) In addition, the extrapolated values of D_{11} and D_{22} appear to be consistent with the previously reported (27, 28) binary diffusion coefficients of $MgCl_2$, Na_2SO_4, and $MgSO_4$ at 0.40 mol dm^{-3}. Similar agreement is obtained at 0.04 and 0.20 mol dm^{-3} total salt.

[a]Units: $\bar{c}_i$ in mol dm^{-3}; D_{ik} in 10^{-9} m^2 s^{-1}.
[b]Reference 27.

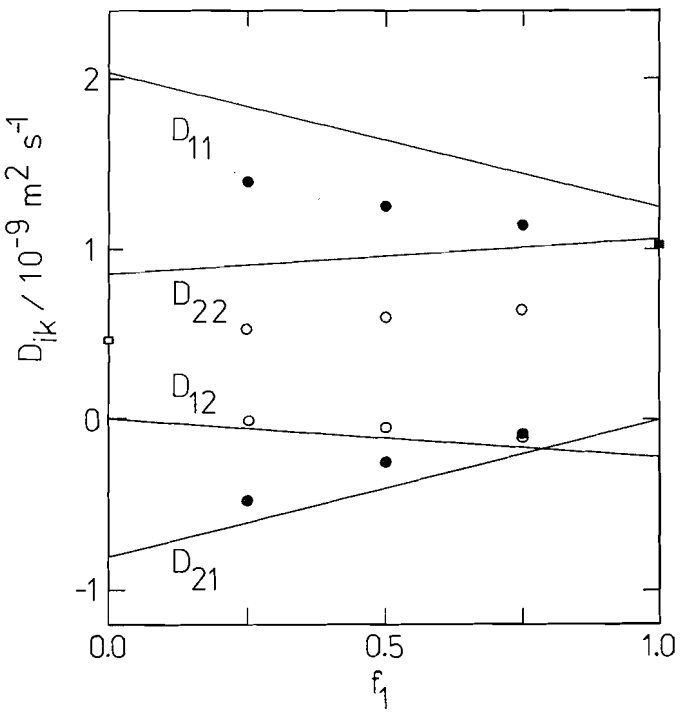

FIG. 2. Measured diffusion coefficients of $MgCl_2$(1) + $MgSO_4$(2) + H_2O at 0.40 mol dm^{-3} total salt: ●,○, ternary values (this work); ■,□, binary values (27, 28). The solid lines give limiting ternary diffusion coefficients calculated from eqs. [25]–[28].

5. Discussion

In an earlier least-squares analysis of Taylor profiles (22), D_{11}, D_{12}, D_{21}, and D_{22} were treated as fitting parameters, rather than the a, b, D_1, and D_2 parameters used here. However, the expressions for the derivatives $\partial v^0/\partial D_{ik}$ are so complicated that it was necessary to resort to numerical differentiation. By contrast, the derivatives with respect to a, b, D_1, and D_2 are easy to evaluate analytically, which simplifies the equations and speeds up the convergence. For these reasons the present least-squares procedure represents an improvement. Check cal-

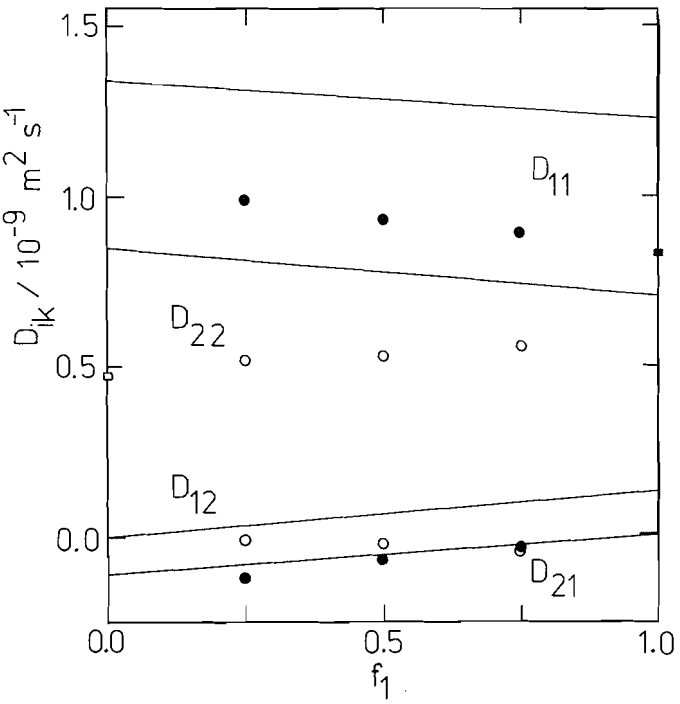

FIG. 3. Measured diffusion coefficients of $Na_2Cl_4(1)$ + $MgSO_4(2)$ + H_2O at 0.40 mol dm^{-3} total salt; ●,○, ternary values (this work); ■,□, binary values (27, 28). The solid lines give limiting ternary diffusion coefficients calculated from eqs. [25]–[28].

culations showed that the two procedures gave identical D_{ik} values within the experimental precision.

The accuracy of the ternary dispersion technique was checked by measuring the diffusion coefficients of sucrose + KCl + H_2O and $MgCl_2$ + NaCl + H_2O at 25°C. The measured diffusion coefficients agreed closely (standard deviation 0.03 × 10^{-9} m^2 s^{-1}) with accurate values obtained previously by optical interferometry (29, 30). Details of the comparison are given in ref. 22.

The D_{ik} coefficients can also be calculated from the temporal moments of the eluted solute peaks (21). Unfortunately, small drifts in the baseline detector signal magnify the errors in the higher moments. Consequently, least-squares procedures are more reliable (22).

Accurate limiting ternary diffusion coefficients of infinitely dilute, completely dissociated salts can be calculated from the limiting ionic conductivities by using the extended Nernst equations:

$$[25]\quad D^0_{11} = \hat{D}_1 + t_1(\hat{D}_3 - \hat{D}_2)$$

$$[26]\quad D^0_{12} = t_1(\hat{D}_3 - \hat{D}_1)$$

$$[27]\quad D^0_{21} = t_2(\hat{D}_3 - \hat{D}_2)$$

$$[28]\quad D^0_{22} = \hat{D}_2 + t_2(\hat{D}_3 - \hat{D}_1)$$

$$[29]\quad \hat{D}_i = RT\Lambda_i/(z_iF)^2$$

$$[30]\quad t_i = \hat{c}_i z_i^2 \hat{D}_i \Big/ \sum_k \hat{c}_k z_k^2 \hat{D}_k$$

where $\hat{c}_i$, z_i, Λ_i, $\hat{D}_i$, and t_i are, respectively, the concentration, charge, limiting molar conductivity, diffusion coefficient and transference number of ion 1.

For the $MgCl_2$ + $MgSO_4$ + H_2O system, the ions are numbered as follows: $Cl^-(1)$, $SO_4^{2-}(2)$, $Mg^{2+}(3)$. For the Na_2SO_4 + $MgSO_4$ + H_2O system they are numbered: $Na^+(1)$, $Mg^{2+}(2)$, $SO_4^{2-}(3)$. In both cases ion 3 is the common ion. At 25°C, the limiting conductivities of aqueous Na^+, Cl^-, Mg^{2+}, and SO_4^{2-} ions are respectively (12) 0.005010, 0.007635, 0.01060, and 0.01600 S m^2 mol^{-1}. The corresponding limiting ionic diffusion coefficients are 1.334 × 10^{-9}, 2.033 × 10^{-9}, 0.706 × 10^{-9}, and 1.065 × 10^{-9} m^2 s^{-1}.

In Fig. 2 the limiting ternary diffusion coefficients of $MgCl_2(1)$ + $MgSO_4(2)$ + H_2O (solid lines) are plotted against the solute fraction of $MgCl_2$. The diffusion coefficient of the weakly-hydrated Cl^- ions is almost three times larger than the diffusion coefficient of the Mg^{2+} ions. Consequently, a relatively large electric field is generated by the gradient in $MgCl_2$. The field slows down the Cl^- ions and speeds up the Mg^{2+} ions to maintain electroneutrality. If dissolved $MgSO_4$ is present, the electric field will also drive a substantial coupled flow of SO_4^{2-} ions, countercurrent to the flow of $MgCl_2$, which explains why the cross-coefficient D^0_{21} takes larger, negative values.

In the limit $f_1 \rightarrow 0$, the diffusion coefficient D^0_{11} for the $MgCl_2(1)$ salt corresponds to the tracer diffusion coefficient of Cl^- ions in supporting $MgSO_4$ solutions. D^0_{11} therefore rises as f_1 decreases. The composition-dependence of D^0_{12} and D^0_{22} is much weaker because the Mg^{2+} and SO_4^{2-} ions have similar diffusivities.

Similar considerations apply to the limiting ternary diffusion coefficients of $Na_2SO_4(1)$ + $MgSO_4(2)$ + H_2O plotted in Fig. 3. The composition-dependence of D^0_{11} and D^0_{21} is less pronounced for this system because Na^+ is less mobile than Cl^-.

The ternary diffusion coefficients calculated from limiting ionic conductivities are of course accurate only at infinite dilution. Nevertheless, experience has shown that D^0_{ik} values can provide a qualitative guide to the diffusion behavior of dilute or even moderately-concentrated univalent mixed-salt solutions.

Figures 2 and 3 show that the diffusion coefficients at 0.40 mol dm^{-3} total salt, after allowance is made for the 20–30% higher viscosity of the solutions relative to pure water, agree qualitatively with the limiting D^0_{ik} values calculated for the completely dissociated salts. Similar agreement is found at 0.20 and 0.40 mol dm^{-3} total salt. This result is surprising. Except in very dilute solutions, an appreciable fraction of the dissolved $MgSO_4$ diffuses as neutral ion pairs, unaffected by the electric field induced by gradients in $MgCl_2$ or Na_2SO_4. One might therefore expect only weak interactions between the diffusing salts. Yet Fig. 2 shows that the magnitude of D_{21} can exceed D_{22} (at high $MgSO_4$ salt fractions), which indicates that the concentration gradient in $MgCl_2$ can produce a larger flow of $MgSO_4$ than the gradient in $MgSO_4$. The reasonable agreement between the measured diffusion coefficients and the limiting values must be fortuitous.

With use of one- and two-dimensional NMR spectroscopy and deuterium labelling, the photochemistry of 9-*endo*-hydroxy-9-*exo*-vinyl-bicyclo[4.2.1]nonadiene (**1**) and the 9-*exo*-(11-dimethylvinyl)- (**2**) and 9-*exo*-ethyl- (**3**) analogues has been studied. Irradiation of **1–3** gave novel 8-membered ring systems **4–6** by a light-induced rearrangement process, in which the hydroxyl proton is transferred on one side of the molecule toward one of the termini of the endocyclic diene. This rearrangement process thus involves a formal hydrogen transfer, during which either H^+ or $H^\bullet$ may be transferred to a reactive diene intermediate. Replacement of the hydroxyl proton by deuterium in **1–3**, and ^2H NMR of the corresponding photoproducts, confirmed that the hydrogen translocation occurs intramolecularly. Prolonged irradiation of **4** and **5** results in the formation of pyran products **10** and **11** by an intramolecular photocycloaddition of the triplet excited state of the α,β-unsaturated ketone to 1,3-*cis,cis*-cyclooctadiene, via a stabilized bisallylic biradical intermediate. Conformational studies of the structurally more rigid system **10**, which is derived from **4**, revealed that the hydroxyl proton was transferred on the *endo* side of the molecule.

Key words: intramolecular hydrogen transfer, photochemistry of hydroxy-alkyl-bicyclononadienes, intramolecular photocycloaddition, conformational studies.

FRANCISCUS W. A. M. MIESEN, HANS C. M. BAETEN, HARM A. LANGERMANS, LEO H. KOOLE et HENK A. CLAESSENS. Can. J. Chem. **69**, 1554 (1991).

Faisant appel à la spectroscopie RMN en une ou en deux dimensions et au marquage par le deutérium, on a étudié la photochimie du 9-*endo*-hydroxy-9-*exo*-vinyl-bicyclo[4.2.1]nonadiène (**1**) et de ses analogues 9-*exo*-(11-diméthylvinyl)- (**2**) et 9-*exo*-éthyl- (**3**). L'irradiation des composés **1–3** conduit à de nouveaux systèmes cycliques à 8 chaînons (**4–6**) par un processus de transposition induit par la lumière dans lequel le proton hydroxylique est transféré d'un côte de la molécule vers l'une des extrémités du diène endocyclique. Ce réarrangement implique donc un transfert formel d'hydrogène au cours duquel soit un H^+ ou un $H^\bullet$ est transféré vers un intermédiaire diénique réactif. Le remplacement du proton hydroxylique des composés **1–3** par du deutérium et la RMN du ^2H des photoproduits correspondants a permis de confirmer que la translocation de l'hydrogène se produit d'une façon intramoléculaire. Une irradiation prolongée des composés **4** et **5** conduit à la formation des pyranes **10** et **11** qui résultent d'une photocycloaddition intramoléculaire de l'état triplet de la cétone α,β-insaturée sur le 1,3-*cis,cis*-cyclooctadiène, par le biais d'un intermédiaire biradicalaire bisallylique stabilisé. Des études conformationnelles du système plus rigide du composé **10** dérivé du produit **4** révèlent que le proton hydroxylique est transféré vers la face *endo* de la molécule.

Mots clés: transfert d'hydrogène intramoléculaire, photochimie d'hydroxy-alkyl-bicyclononadiènes, photocycloaddition intramoléculaire, études conformationnelles.

Introduction

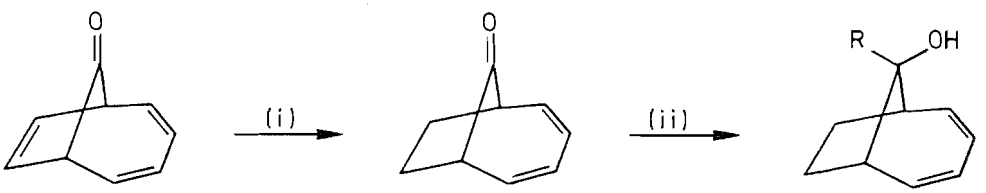

Photo-excitation of cycloalkenes may result in a substantial apparent increase of molecular basicity, leading in protic media to light-induced protonation of the olefin. On direct and sensitized irradiation in methanol, cyclohexenes, cycloheptenes, and cyclooctenes show initial *cis/trans* isomerization followed by protonation of the resulting highly strained isomers (1–5). This process is facilitated by the concomitant relief of strain in this intermediate (6). In striking constrast, cyclopentenes do not undergo photoprotonation on direct irradiation in methanol (7), but afford a mixture of products as a result of trapping a radical-cation intermediate. Such a radical cation may be the result of an electron ejection from a Rydberg excited state, rather than a ($\pi\pi^*$) state (8–10). On sensitized irradiation, cyclopentenes and other highly constrained cyclic olefins exhibit reactions involving radical intermediates, which probably originate from intermolecular reactions by the ($\pi\pi^*$) excited state itself (5, 11). This behaviour is thought to be associated with the inability of these olefins to undergo *cis/trans* isomerization. Although photoprotonation of cycloalkenes in protic media is thus well documented, the photochemistry of compounds combining such chromophores and suitably positioned hydroxyl groups enjoyed only limited study (12, 13). Under UV irradiation alcohols add to olefins in two modes: (a) the addition takes place at the hydroxyl group or (b) the addition takes place at the carbon atom to which the hydroxyl group is attached.

In the present paper we describe a photochemical study of 9-*endo*-hydroxy-9-*exo*-vinyl-bicylo[4.2.1]nona-2,4-diene (**1**), and the 9-*exo*-(2′-methylpropenyl)- (**2**) and 9-*exo*-ethyl- (**3**) analogues. We have studied the photochemistry of these compounds partly on the basis of deuterium labelling experiments. The structural and conformational properties of the isolated photoproducts were investigated with one- and two-dimensional NMR techniques, low temperature ^{13}C NMR, and semi-empirical AM1 quantum-chemical calculations.

Results and discussion

Synthesis, purification, and identification

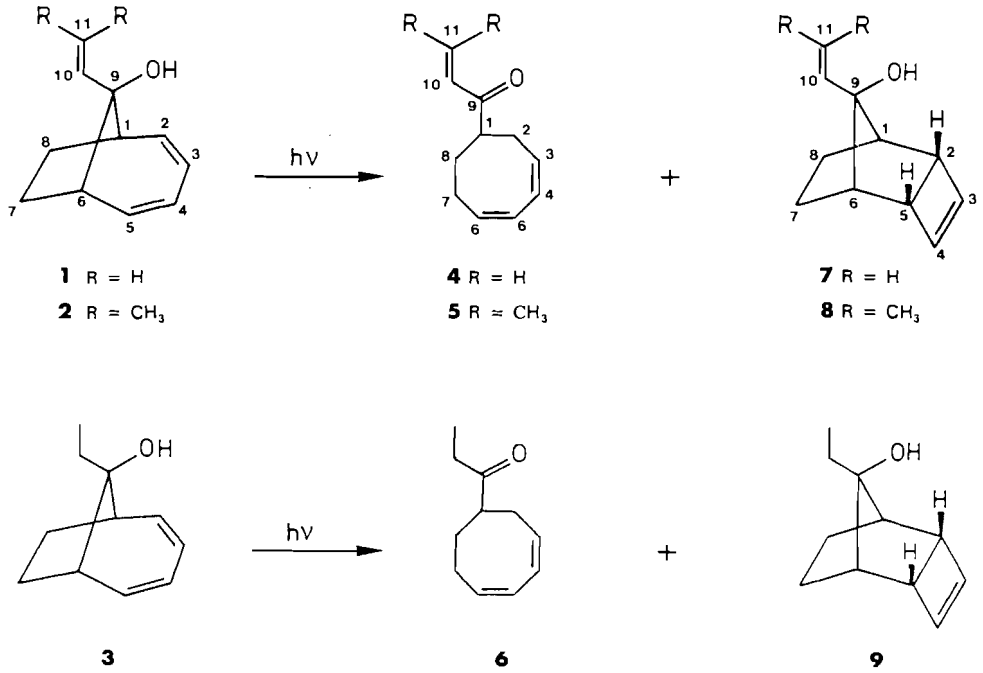
Compounds **1–3** were prepared in two steps from bicyclo-[4.2.1]nona-2,4,7-triene-9-one (Scheme 1) (14). The first step involves selective hydrogenation of the C(7)—C(8) bond, using Ni_2B as a catalyst (15–17). The product, bicyclo[4.2.1]nona-2,4-diene-9-one, was obtained in pure form after silica gel column chromatography. The second step in the synthesis of **1–3** is a Grignard reaction with vinyl-, 2,2-dimethylvinyl-, or ethylmagnesium bromide, respectively. It should be noted that this reaction affords the 9-*endo*-hydroxy epimers exclusively (18, 19). Compounds **1–3** were purified by silica gel column chromatography; their identity and purity were assessed by one- and two-dimensional ^1H NMR (COSY), ^{13}C NMR (including INEPTP), and two-dimensional $^1H/^{13}C$ correlation (for a survey of these techniques see ref. 20), and mass spectrometry. All photoproducts were isolated via preparative HPLC separation of the crude reaction mixtures. Molecular structures could be unequivocally established by the above-mentioned methods.

Photochemistry

UV irradiation of compounds **1–3** in *n*-hexane led to the formation of the novel 8-membered ring systems **4–6**, resulting from a new intramolecular formal hydrogen-transfer reaction (Scheme 2). Simultaneously, the expected products of a disrotatory electrocyclic ring closure reaction **7–9** were formed. Prolonged irradiation of photoproducts **4** and **5** led to the strained pyran structures **10** and **11** (Scheme 3).

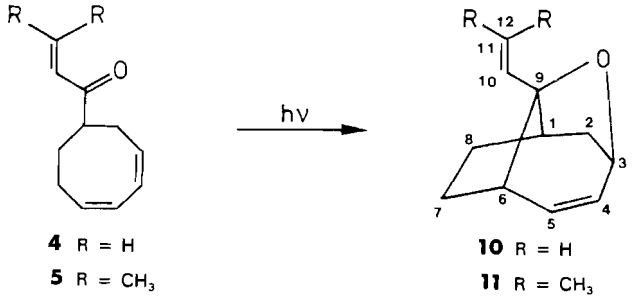
In studying the photochemistry of **1–3**, we monitored the kinetics of formation and disappearance of materials at different photolysis time intervals (GC analysis). The results for the irradiation of **1** are presented in Fig. 1. Our data clearly show that **1** is initially converted to **4** and **7**; compound **10** is formed from **4** in a secondary photoreaction.

Analogously, irradiation of compound **2** initially produces **5** and **8**, and compound **5** is converted to **11** upon prolonged irradiation. The experiments with compound **3** merely showed formation of **6** and **9**, i.e., compound **6** does not show the secondary photoreaction.



Verification of the stereochemistry of these reactions could be obtained with compound **1***a* (Scheme 4). Transfer of deuterium toward C(2) was evident from the ^1H and ^{13}C NMR spectra of **4***a*. The ^2H NMR spectrum of **4***a*, recorded at 77 MHz, showed a singlet signal at δ 2.3 ppm, exactly at the position of one of the H(2) protons in compound **4** (compare Figs. 2a and 2b). This demonstrates that the transfer of deuterium occurs at one face of the molecule exclusively.

The light-induced conversions **1** → **4**, **2** → **5**, and **3** → **6** may be formulated as proceeding via an initial photoprotonation process followed by a collapse of the resulting carbocation intermediate (cf. the photofragmentation of homoallylic alcohols (7, 21, 22)). Such a photoprotonation process, concomitant with the breaking of one of the bridgehead bonds, would be in line with the involvement of an olefinic intermediate exhibiting enhanced reactivity (6, 7). However, at present the exact nature of this intermediate cannot be defined and transfer of the hydroxylic hydrogen in the form of $H^\bullet$ or even H^- cannot be excluded. Even the cyclic reorganization of electrons (as shown in Fig. 3) involved in the overall reaction may be formulated as an 8-electron analogue of an oxy-retro-ene reaction (23).[2]



Concerning the stereochemistry, we could not establish *exo* or *endo* orientation of deuterium in **4***a*, since the conformational flexibility of the 8-membered ring precludes the application of Karplus-type equations to translate the vicinal proton–proton *J*-coupling constants into proton–proton dihedral angles (24). However, for the structurally more rigid system **10***a*, which is derived from **4***a* (Scheme 4), it could be unequivocally established that deuterium is located on the *endo* face of **10***a* and hence also on the *endo* face of **4***a* (see section of conformational studies). Additional evidence for the presence of deuterium on C(2) was obtained from a comparison of the ^{13}C NMR spectra of **4** and **4***a*. In **4***a*, the C(2) signal is split into three lines of equal intensity and $J = 19.4$ Hz due to one-band *J*-coupling with deuterium ($I = 1$). Interestingly, a small signal is also visible at δ 1.6 ppm in the ^2H NMR spectrum of **4***a*. The small peak is found exactly at the position of one of the H(8) protons in compound **4** (compare Figs. 3a and 3b). The explanation for the appearance of the small peak in Fig. 3b may lie in the occurrence of a thermal suprafacial [1,5]-H sigmatropic shift, occurring during the thermal isomerization of *cis,trans*-cyclooctadiene (COD) to *cis,cis*-COD, according to Scheme 5 (25, 26). Evidently this [1,5]-H shift would place deuterium in an isochronous position in the ^2H NMR spectrum, when compared with the *endo*-located H(8) in compound **4**.

Of course, the occurrence of this [1,5]-H shift is not detectable from the ^1H and ^{13}C NMR spectra of compound **4**. It may be noted that the UV irradiation of **1** and **2** does not induce a sigmatropic [1,3]-OH shift in the head group. In fact, we anticipated that this reaction could occur, in analogy with the previous work of our group on the photochemistry of 8-hydroxygermacrene B (12) and 4-methyl, 4-ethyl disubstituted 3-alkylidene 2-naphthalenol compounds (13, 27). For these

[2]We wish to thank one of the reviewers for suggesting this possible explanation.

SCHEME 2

SCHEME 3

systems, the occurrence of a planar photochemical [1,3]-OH shift was firmly established on the basis of experimental and theoretical data (27–29).

The 8-membered ring systems **4** and **5** are converted into the strained pyrans **10** and **11** in a secondary photoreaction (in ≈16 and 6% yields respectively). To the best of our knowledge, this reaction represents a novel photocycloaddition, which is reminiscent of the Paterno–Buchi reaction of ketones with alkenes, leading to the formation of oxetanes (30, 31). These reactions generally proceed from an attack of an (n,π^*) state of the carbonyl compound on an unsaturated substrate. In general, photocycloadditions of (n,π^*) states are expected to proceed via diradical intermediates (32, 33). These intermediates are produced either directly or indirectly from $S_1(n,\pi^*)$ or $T_1(n,\pi^*)$ states in the oxetane formation.

In our system the α,β-unsaturated ketone would have a singlet (n,π^*) state of lower energy than the singlet state of the conjugated *cis,cis*-COD system, while the triplet (n,π^*) state is almost equal to the triplet of the *cis,cis*-COD system. For the saturated ketone, however, the photocycloaddition is absent, and its triplet state is considerably higher than the triplet of the *cis,cis*-COD system. Consequently the triplet of the saturated ketone would be quenched by energy transfer many times faster than the α,β-unsaturated ketones, because of the large exothermicity of the process. For approximate energy levels see Table 1.

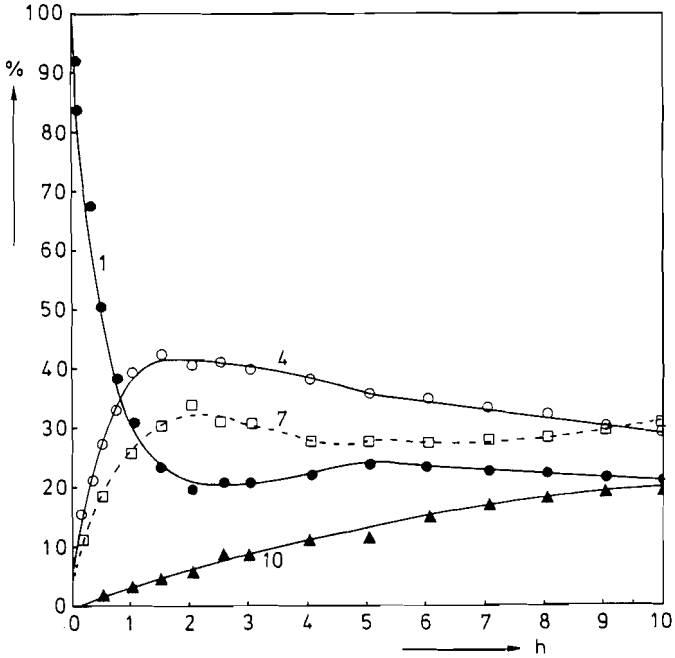


FIG. 1. Plot for conversion (%) of compound **1** to photoproducts **4**, **7**, and **10** as function of time (h).

Energy transfer to the *cis,cis*- or *cis,trans*-COD system results in a photostationary state composition of *cis,cis*- and *cis,trans*-cyclooctadienes (35, 36). It should be noted that the *cis,trans* isomer may isomerize to *cis,cis* either by a *cis/trans* isomerization about the *trans* double bond or by a [1,5]-H shift for the thermal isomerization (25, 26).

Since intersystem crossing (ISC) is very fast in α,β-unsaturated ketones, and singlet processes are normally too slow to compete, a mechanism involving a triplet excited state is

SCHEME 4

preferred over a singlet excited process. A mechanism involving the formation of a charge-transfer, stabilized exciplex, leading to a biradical that can collapse to the strained pyrans or undergo radiationless decay to the ground-state molecules, is rather remote for the *cis,cis*-COD system (37, 38). In the oxetane formation of acetone and COD (ISC is slower in this case) the total rate of fluorescence quenching of the ketone is significantly slower than the rate of ISC (38). Therefore we consider the pyran formation to occur predominantly from the triplet state of the α,β-unsaturated ketone, and a chemical reaction can indeed compete with the triplet energy transfer to the COD, because of the decrease in diene character of the 8-membered ring. Based on an alkoxy model (39), the intramolecular pyran formation, like intramolecular cycloaddition, is

TABLE 1. Approximate singlet and triplet energy levels

Compound	S_1 (kcal/mol)	T_1 (kcal/mol)
α,β-Unsaturated ketone[a]	74	70
Saturated ketone[a]	84	78
cis,cis-Cyclooctadiene[b]	>80	70–73
cis,trans-Cyclooctadiene[b]	—	<70

[a]Data obtained from N. J. Turro (34).
[b]Data obtained from R. S. H. Liu (in ref. 36).

expected to obey a "rule of five" (40), involving the stabilized diradicaloid intermediate:

The formation of photoproducts **7–9** involves a ring closure of the endocylic dienes in **1–3**. As can be seen in Fig. 1, the photoprotonation reaction and the ring closure occur with approximately equal probability during the irradiation of **1**. Similar results were obtained for **2** and **3**. The photochemical ring closure of **1–3** follows a disrotatory route, as predicted by the Woodward and Hoffmann rules (41). The *endo* orientation of the protons H(2) and H(5) was established on the basis of the NMR spin–spin coupling constant $J_{H(1)-H(2)}$, and comparison with literature data (42).

Conformational studies

The ^{1}H NMR spectrum of the compounds **1–3** in the ground state showed a long-range spin–spin coupling between H(10) and the hydroxyl proton ($^4J_{HCCOH} \approx 1.5$ Hz). This reveals that the coupling path is in all-*trans* ("W") conformation, i.e., the OH group resides in the plane of C(9), C(10), and C(11). The C(10)—C(11) double bond in **1** and **2** is therefore approximately orthogonal with respect to the endocyclic diene system. The conformational properties of **1–3** were investigated further on the basis of semi-empirical MO calculations. Dreiding models of **1–3** provided initial starting conformations. The geometries of **1–3** were optimized using the AM1 Hamiltonian of the AMPAC program (43, 44). The optimized conformations of **1–3** showed *trans* conformation of the coupling path H-O-C(9)-C(10)-H(10) in the head group (Fig. 4a).

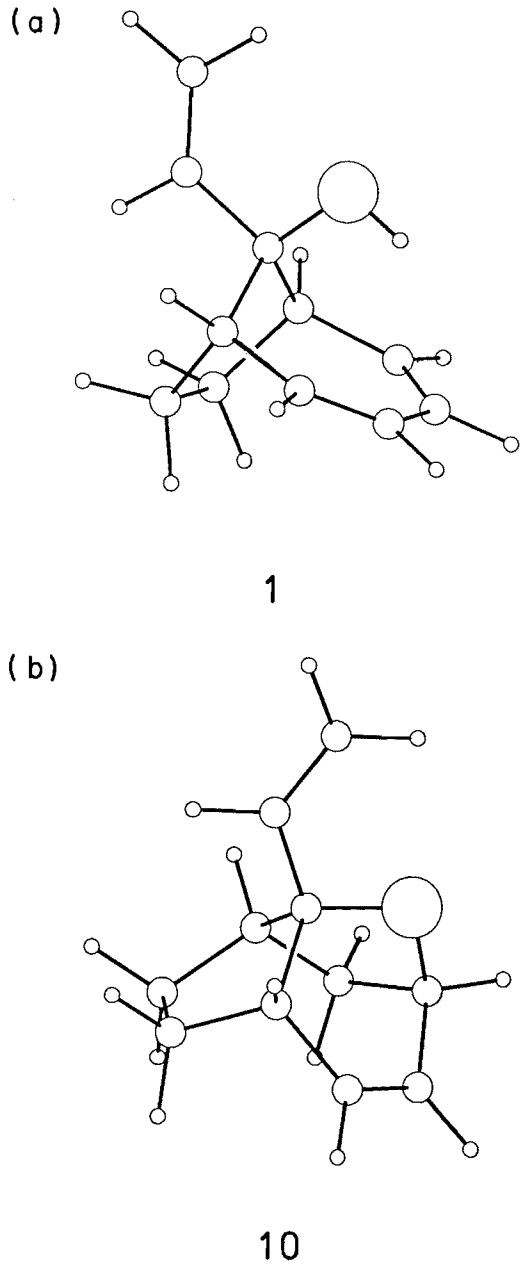

FIG. 4(a). Optimized conformation of **1** studied with AM1 calculation method showing *trans* conformation of the coupling path in the head group ($\Delta H_f = -2.78$ kcal/mol). (b) Optimized conformation of **10** from which proton–proton torsion angles for the Karplus relations have been extracted ($\Delta H_f = -8.03$ kcal/mol).

Inspection of the AM1-optimized conformation of **1** confirms that the hydroxyl proton is proximate to C(2) ($r_{OH-proton-C(2)} = 2.52$ Å). Essentially the same conformation was found in the AM1 calculation on structures **2** and **3**. (The AM1 calculations on **1–3**, **10**, and **11** resulted in the following enthalpies of formation (ΔH_f): ΔH_f(**1**) = −2.78 kcal/mol, ΔH_f(**2**) = −17.80 kcal/mol, ΔH_f(**3**) = −34.67 kcal/mol, ΔH_f(**10**) = −8.03 kcal/mol, ΔH_f(**11**) = −23.47 kcal/mol.)

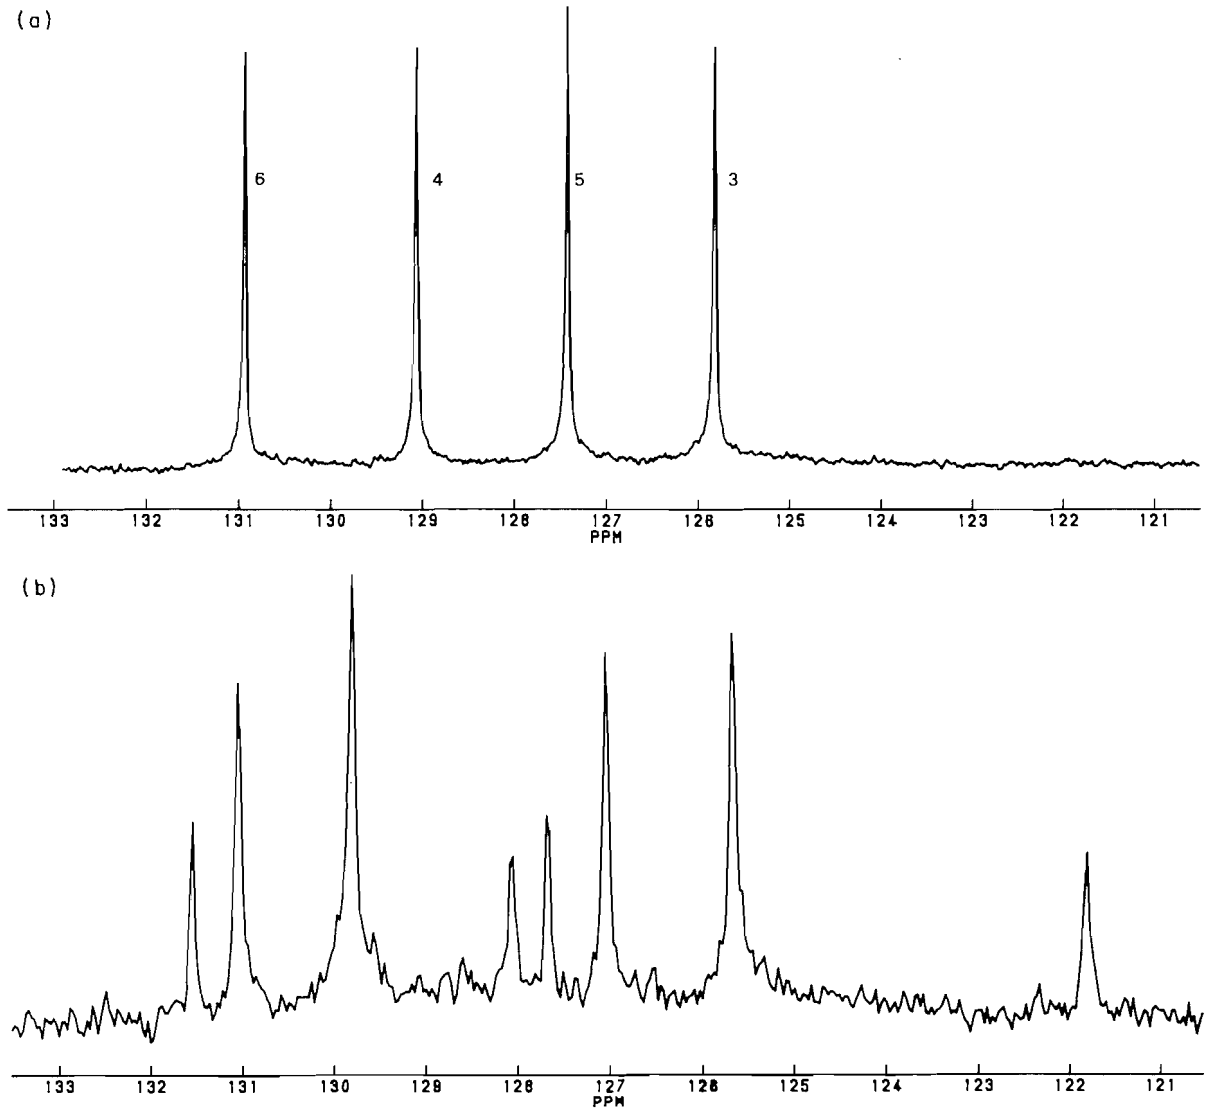

FIG. 5.(a). Olefinic region of the ^{13}C NMR spectrum in of **6** at 20°C (100 MHz, solvent CD_2Cl_2). The assignments are based on a ^{13}C–^{1}H correlation experiment. (b) Decoalescence in the olefinic region of ^{13}C NMR spectrum of **6** at −90°C (100 MHz, solvent CD_2Cl_2). Clearly, two distinct molecular conformations are present in a ratio of approximately 1:2 at this temperature. These observations closely resemble the data of Anet *et al.* on *cis,cis*-cyclooctadiene, and *cis,cis*-cyclooctadiene mono-epoxide (refs. 45–47).

The conformational properties of the 8-membered ring compounds **4**–**6** are more difficult to characterize, since there is no obvious starting geometry for the AM1 calculations. Rather it must be expected from the work of Anet and Yavari on *cis,cis*-1,3-cyclooctadiene and *cis,cis*-cyclooctadiene mono-epoxide (45–47) that compounds **4**–**6** are involved in a complex conformational equilibrium. We obtained convincing evidence for the flexible nature of compounds **4**–**6** from variable-temperature ^{13}C NMR measurements. Upon lowering the sample temperature from 20 to −90°C in CD_2Cl_2 we observed decoalescence phenomena for **4**–**6**. As a typical example, Figs. 5a and 5b show the olefinic regions in the ^{13}C NMR spectra of compound **6**, as measured at 20°C and −90°C.

The observation of two sets of ^{13}C NMR peaks at −90°C clearly shows that at least two distinct conformations coexist at this temperature. It should be noted that our ^{13}C NMR spectral data on compounds **4**–**6** closely resemble the data of Anet and Yavari on *cis,cis*-1,3-cyclooctadiene and *cis,cis*-cyclooctadiene mono-epoxide (45–47). The conformational properties of the strained pyrans **10** and **11** were again studied with the AM1 calculation method. Starting geometries were obtained from Dreiding molecular models. In the optimized conformation of **10** (Fig. 4b) we especially focused on the proton–proton torsion angles Φ_1 (H(1)-C(1)—C(2)-H(2)) = −2.2°; Φ_2 (H(1)-C(1)—C(2)-H(2′)) = 119.2°; Φ_3 (H(3)-C(3)—C(2)-H(2)) = −23.6°; Φ_4 (H(3)-C(3)—C(2)-H(2′)) = 96.4°. Thus, from a simple Karplus dependency of $^{3}J_{HH}$ on the proton–proton torsion angle (24), one expects that $^{3}J_{H(1)-H(2,endo)}$ and $^{3}J_{H(3)-H(2,endo)}$ are substantially larger than $^{3}J_{H(1)-H(2',exo)}$ and $^{3}J_{H(3)-H(2',exo)}$. Interestingly, these tentative conclusions are in line with the experimental ^{1}H NMR data on compound **10**, which show that the downfield H(2) proton (δ 2.24 ppm) has relatively large coupling constants with its vicinal neighbours H(1) and H(3) (i.e., 10.1 and 6.2 Hz, respectively, see experimental section), while the upfield H(2) proton (δ 1.63 ppm) shows much smaller $^{3}J_{HH}$ couplings with H(1) and H(3) (i.e., <1 Hz in both cases). Therefore, we tentatively assign the downfield H(2) proton as H(2,*endo*), and the upfield H(2′) proton as H(2′,*exo*). Having

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

this assignment, it is worthwhile to reexamine the ^{1}H NMR spectrum of the C(2)-deuterated compound **10***a*. Now it seems likely that it is H(2,*endo*) and not H(2′,*exo*) that is replaced by deuterium in **10***a*. Thus the photochemical formal proton transfer reaction **1** → **4** proceeded *exclusively* on the *endo* face of the molecule. We anticipate that this holds also for the analogous photochemical reactions **2** → **5** and **3** → **6**.

Concluding remarks

UV irradiation of compounds **1**–**3** leads to a new photochemical rearrangement process, in which the hydroxyl hydrogen is transferred on the *endo* side of the molecule toward one of the terminals of the endocyclic diene. This reaction is probably driven by the enhanced reactivity of the diene moiety after photo-excitation, leading to a protonation of the olefin. However, the reaction can also be considered as an oxy-retro-ene type reaction. The 8-membered ring structures **4** and **5** are converted relatively slowly to the strained pyrans **10** and **11** in a secondary photoreaction. This reaction is not observed for the ethyl counterpart **6**. Most likely, the reaction of **4** and **5** is a photo-cycloaddition, resembling the Paterno–Buchi reaction. We believe that the reaction develops from the T_1 excited state of the α,β-unsaturated ketone, leading to the strained pyran products, which may arise from a bisallylic radical intermediate.

Experimental

General procedures

All solvents and commercial reagents were reagent grade and dried with the appropriate drying agents. Argon was dried over Drierite pellets. Column chromatography was performed using Silica-60 as the stationary phase. Proton, deuterium, and carbon-13 NMR spectra were recorded on a Bruker AM400[3] or a Bruker AM600[4] spectrometer in $CDCl_3$ solution. Chemical shifts are reported in ppm (δ), relative to tetramethylsilane as an internal standard. Coupling constants (*J*) are given in Hz. GC analyses were performed on a Kipp Analytica 8200 instrument with FID detection (25 m × 0.22 mm i.d.; column type: WCOT fused silica; stationary phase CP WAX 51). All HPLC separations were run on a system that consists of a Waters 6000A pump, a 4 × 100 mm Lichrosorb 60 (5 μm) column, and a Philips Unicam PU4020 UV detector (254 nm). Mass spectral data were obtained on a Hewlett Packard 5970A system by electron ionization at 70 eV.

Synthesis

Bicyclo[4.2.1]nona-2,4-diene-9-one

This compound was prepared via selective hydrogenation of the C(7)—C(8) bond in bicyclo[4.2.1]nona-2,4,7-triene-9-one (14) (Scheme 3). This reaction is not straightforward, as is evident from the work of Brown (15), Gilissen *et al.* (16,17), and Schuster and Kim (18). We used Ni_2B as hydrogenation catalyst, which was prepared as follows: $Ni(Ac)_2 \cdot 4\,H_2O$ (230 mg, 0.92 mmol) was dissolved under an argon atmosphere with magnetic stirring in 20 mL of ethanol in a 500-mL Erlenmeyer flask. A solution of 33 mg $NaBH_4$ in 20 mL of ethanol was transferred dropwise into the reaction vessel, yielding a black suspension of Ni_2B. Subsequently, bicylo[4.2.1]nona-2,4,7-triene-9-one (1 g, 7.4 mmol) was added, and hydrogen gas was allowed into the flask (atmospheric pressure). Stirring was continued until 170 mL (6.9 mmol) hydrogen gas was absorbed. Ethanol was evaporated, and the residue was dissolved in 100 mL of dry ether. Standard work-up (addition of 50 mL saturated aqueous $NaHCO_3$, filtration, and repeated washing of the aqueous phase with ether) yielded a mixture of the desired diene, and the starting compound (ratio ≈ 5:1), which was chromatographed on a silica gel column using CH_2Cl_2 as eluent (R_f diene = 0.43; R_f triene = 0.49). This afforded 460 mg of the desired product (yield 45%). ^{1}H NMR ($CDCl_3$) δ: 5.58–5.96 (4H, m, H(2–5)), 2.69–2.87 (2H, m, H(1,6)), 2.10–2.46 (4H, m, H(7,8)). ^{13}C NMR ($CDCl_3$) δ: 216.44 (s, C(9)), 129.55 (d, C(2,5)), 126.12 (d, C(3,4)), 50.35 (d, C(1,6)). 34.55 (t, C(7,8)). EI-MS; 134 (m^+), 106, 91, 78 (base peak), 51, 39, 27.

9-endo-Hydroxy-9-exo-vinyl-bicyclo[4.2.1]nona-2,4-diene (1)

Magnesium turnings (1.27 g, 52.7 mmol) and 15 mL of dry THF were transferred into a 250-mL reaction flask equipped with a reflux cooler (connected with a methanol cryostat (−60°C)), a dropping funnel, and a mechanical stirrer. During the experiment, dry argon was slowly passed through the reaction vessel. Vinyl bromide (0.5 g, 4.7 mmol) and a small iodine crystal were added. After start-up of the reaction, 15 mL of dry THF was added immediately, followed by the main portion of vinyl bromide (6.25 g, 58.3 mmol) in 10 mL of dry THF, over a period of 1 h. After completion of the addition, the mixture was stirred for 1 h, and cooled to 0°C with an ice bath. Bicyclo[4.2.1]-nona-2,4-diene-9-one (1.68 g, 12.5 mmol), dissolved in 15 mL of dry THF, was added dropwise over a period of 1 h. The reaction was allowed to proceed for 6 h at 0°C, and for 14 h at ambient temperature. Then, the reaction was finished through addition of 35 mL of 3 N HCl at 0°C. THF was removed and the residue was mixed with 100 mL of diethyl ether. The organic layer was washed with $NaHCO_3$, dried over $MgSO_4$, and concentrated. Column chromatography using CH_2Cl_2 as eluent afforded 5.19 g of pure **1** (R_f 0.35, yield 91%). ^{1}H NMR ($CDCl_3$) δ: 6.18–6.34 (1H, dd, H(10)), 5.75–6.01 (4H, m, H(2–5)), 5.38–5.49 (1H, dd, H(11, *trans*)), 5.12–5.22 (1H, dd, H(11, *cis*)), 3.07 (1H, d, OH), 2.48–2.58 (2H, m, H(1,6)), 2.02–2.08 (4H, m, H(7,8)). ^{13}C NMR ($CDCl_3$) δ: 142.81 (d, C(10)), 136.13 (d, C(2,5)), 126,14 (d, C(3,4)), 113.88 (t, C(11)), 77.49 (s, C(9)), 49.44 (t, C(1,6)), 38.17 (t, C(7,8)). EI-MS: 147, 115, 107, 95, 91, 79 (base peak), 65, 55, 39, 27.

9-endo-Hydroxy-9-exo-(2′-methylpropenyl)-bicyclo[4.2.1]nona-2,4-diene (2)

The Grignard reagent was prepared from 1-bromo-2-methylpropene (2.35 g, 17.4 mmol) and magnesium turnings (0.37 g, 15.2 mmol) in 30 mL of dry THF. The reaction was allowed to proceed for 6 h at 40°C. Bicyclo[4.2.1]nona-2,4-diene-9-one (1 g, 7.45 mmol) in 10 mL of dry THF was slowly added in 30 min. The reaction mixture was stirred for 48 h, poured onto crushed ice, and 100 mL 1 N NH_4Cl solution was added. Subsequently, the pH of the solution was lowered to 5, via addition of 1 N HCl solution. Usual work-up procedure and repeated column chromatography, using hexane–dichloromethane (30:70) as eluent, afforded pure **3** (R_f 0.20, yield 0.44 g, 31%). ^{1}H NMR ($CDCl_3$) δ: 5.70–6.11 (4H, m, H(2–5)), 5.45–5.55 (1H, m, H(10)), 2.87–2.88 (1H, d, OH), 2.55–2.72 (2H, m, H(1,6)), 1.95–2.04 (4H, m, H(7,8)), 1.91–1.92 (3H, d, CH_3), 1.77–1.78 (3H, d, CH_3). ^{13}C NMR ($CDCl_3$) δ: 138.21 (s, C(11)), 136.37 (d, C(2,5)), 130.59 (d, C(10)), 125.76 (d, C(3,4)), 76.57 (s, C(9)), 48.58 (d, C(1,6)), 37.92 (t, C(7,8)), 27.83 and 20.60 (q, CH_3). EI-MS: 190 (m^+), 175, 147, 105, 83 (base peak), 55, 41, 39, 29, 27.

9-endo-Hydroxy-9-exo-ethyl-bicyclo[4.2.1]nona-2,4-diene (3)

The Grignard reagent was prepared from ethyl bromide (1.21 g, 11.1 mmol) and magnesium turnings (0.27 g, 11.1 mmol) in 30 mL of dry diethyl ether. Bicyclo[4.2.1]nona-2,4-diene-9-one (1.36 g, 10.1 mmol), dissolved in 15 mL of dry diethyl ether, was added dropwise in 30 min at 0°C. After completion of the reaction (30 min at 0°C and 90 min at ambient temperature), the suspension was poured onto 30 g of crushed ice. Hydrochloric acid (25 mL of a 1 N solution) was slowly added. Standard work-up and column chromatography with CH_2Cl_2 as eluent yielded 0.92 g (54%) of pure **2** (R_f 0.33). ^{1}H NMR ($CDCl_3$) δ: 5.80–6.05 (4H, m, H(2–5)), 2.84 (1H, s, OH), 2.40–2.55 (2H, m, H(1,6)), 1.95–2.05 (4H, m, H(7,8)), 1.69–1.86 (2H, q, H(10)), 0.92–1.11 (3H, t, H(11)). ^{13}C NMR ($CDCl_3$) δ: 136.45 (d, C(2,5)), 125.71 (d, C(3,4)), 77.44 (s, C(9)), 48.17 (d, C(1,6)), 37.83 (t, C(10)), 32.05 (t, C(7,8)), 9.34 (q, C(11)). EI-MS: 164 (m^+), 135, 117, 107, 91, 79, 65, 57 (base peak), 41, 39, 29.

[3]NMR facility of the Eindhoven University of Technology.

[4]The 600-MHz ^{1}H NMR spectra were recorded on the Bruker AM600 NMR spectrometer of the Dutch National hf NMR facility at Nijmegen, The Netherlands.

TABLE 2. Irradiation of bicyclononadienes[a]

Olefin	Amount (mg)	Time (h)	Yield (%)[b] 1–3	4–6	7–9	10,11
1	460	1.5	22	41	30	4
		10	21	30	30	16
2	440	1.5	23	18	56	—
		8	1	15	73	6
3	460	1.5	16	34	50	0
		10	1	34	65	0

[a]Irradiations were conducted as described in this section using ≈500 mL of *n*-hexane containing ≈3 mmol of olefin.

[b]Yields were determined by gas-chromatographic analysis of aliquots removed periodically from the irradiation mixture.

Irradiation procedure

All photochemical experiments (as shown in Table 2) on **1–3** were performed in ≈500 mL of *n*-hexane (concentration ≈6 mM), which was dried over sodium prior to use.

Irradiations were performed using a 500-W medium Hg lamp (Hanau TQ78) through quartz. Cooling of the lamp and the reaction mixture was accomplished by means of a closed circuit filled with methanol. In this way, the temperature in the reaction vessel was maintained around 0°C. Before and during irradiation, the reaction mixture was purged by a stream of dry argon, to remove all traces of oxygen. All photoreactions were monitored by means of gas chromatography. After irradiation, the solvent was removed on a rotatory evaporator. The reaction mixture was separated by HPLC using CH_2Cl_2/hexane (10:90 or 15:85) as eluent. Isolation of products was continued until sufficient material was obtained for NMR characterization.

Spectral and analytical data of photoproducts

The nomenclature of compounds is according to the IUPAC convention. However, to obtain as much consistency as possible, the numbers in the NMR data were assigned as in Schemes 2 and 3, and may differ from IUPAC convention.

6-(1'-Oxo-propenyl)-1,3-cis,cis-*cyclooctadiene (**4**)*

^{1}H NMR ($CDCl_3$) δ: 6.46 (1H, dd, H(10)), 6.26 (1H, dd, H(11, *trans*)), 5.95–5.84 (2H, m, H(4,5), $^3J_{H(4)-H(3)}$ = 11.3 Hz, $^3J_{H(4)-H(5)}$ = 4.28 Hz, $^3J_{H(5)-H(6)}$ = 11.3 Hz), 5.76 (1H, dd, H(11, *cis*)), 5.65 (2H, m, H(3,6), $^3J_{H(3)-H(2)}$ = 7.12 Hz, $^3J_{H(3)-H(2')}$ = 2.5 Hz, $^3J_{H(6)-H(7)}$ = 7.04 Hz, $^3J_{H(6)-H(7')}$ = 2.50 Hz), 2.93 (1H, m, H(1), $^3J_{H(1)-H(2)}$ = 9.13 Hz, $^3J_{H(1)-H(2')}$ = 2.27 Hz, $^3J_{H(1)-H(8)}$ = 4.36 Hz, $^3J_{H(1)-H(8')}$ = 8.86 Hz), 2.48 (1H, m, H(2')), 2.48 (1H, m, H(7) or H(7')), 2.30 (1H, m, H(2), $^2J_{H(2)-H(2')}$ = 15.29 Hz), 2.12 (1H, m, H(7') or H(7)), 1.85 (1H, m, H(8) or H(8')), 1.63 (1H, m, H(8') or H(8)). ^{13}C NMR ($CDCl_3$) δ: 204.50 (s, C(9)), 136.11 (d, C(10)), 132.06 (d, C(3) or C(6)), 130.17 (d, C(6) or C(3)), 129.03 (t, C(11)), 128.64 (d, C(4) or C(5)), 127.15 (d, C(5) or C(4)), 45.48 (d, C(1)), 30.60 (t, C(2)), 27.67 (t, C(7)), 26.75 (t, C(8)). Enantiospecific syntheses of (+)-hyosamine and (−)-hyosamine

HANS H. BAER,[1] TONG CHEN, AND JERZY B. GIZIEWICZ

The Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received April 15, 1991

HANS H. BAER, TONG CHEN, and JERZY B. GIZIEWICZ. Can. J. Chem. **69**, 1563 (1991).

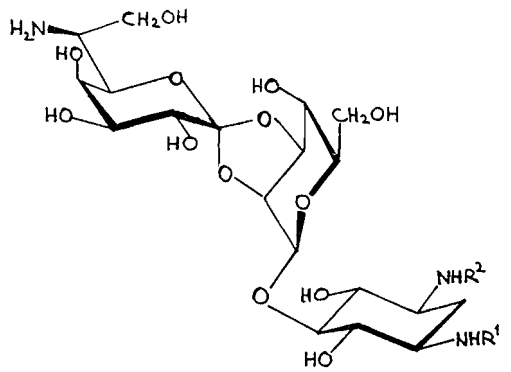
Two constituent components of the stereoisomeric aminocyclitol antibiotics hygromycin B and destomycin A, namely, (+)-hyosamine and (−)-hyosamine (1L- and 1D-(1,3/2,4,6)-4-amino-6-methylamino-1,2,3-cyclohexanetriol **1** and **2**, respectively) were synthesized independently in enantiospecific fashion from the common preparative precursor **3**, 1L-(1,3/2,4,6)-6-azido-1,2-*O*-isopropylidene-4-nitro-1,2,3-cyclohexanetriol, which is conveniently accessible from D-mannose. The key strategy involved selective and sequential reduction of the nitrogenous functions in **3** to the amino stage and installation of an *N*-methyl group in appropriately blocked derivatives. Several variations based on this principle were examined, and one approach to **1** as well as two approaches to **2** were successfully completed. The target amines were characterized as their crystalline penta-*N*,*O*-acetyl derivatives **12** and **22**.

Key words: aminocyclitol antibiotics, enantiospecific syntheses of hyosamines, nitrogen-substituted 1,2,3-cyclohexanetriols.

HANS H. BAER, TONG CHEN et JERZY B. GIZIEWICZ. Can. J. Chem. **69**, 1563 (1991).

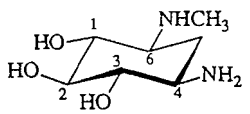
Le 1L-(1,3/2,4,6)-6-azido-1,2-*O*-isopropylidène-4-nitro-cyclohexane-1,2,3-triol (**3**), facilement accessible à partir du D-mannose, a été utilisé comme produit de départ commun pour la synthèse énantiospécifique indépendante de deux aminocyclitols stéréo-isomères présents dans les antibiotiques hygromycine B et destomycine A, soit les (+)-hyosamine et (−)-hyosamine (1L- et 1D-(1,3/2,4,6)-4-amino-6-méthylamino-cyclohexane-1,2,3-triols, respectivement **1** et **2**). La stratégie clé implique la réduction sélective et séquentielle des fonctions azotées du composé **3** en fonctions aminées et l'incorporation d'un groupe *N*-méthyle dans les dérivés adéquatement bloqués. On a examiné plusieurs variations basées sur ce principe; une approche conduisant au composé **1** et deux approches conduisant au produit **2** ont été complétées avec succès. Les amines recherchées ont été caractérisées par leurs dérivés cristallins penta-*N*,*O*-acétylés, **12** et **22**.

Mots clés: antibiotiques dérivés de l'aminocyclitol, synthèses énantiospécifiques d'hyosamines, cyclohexane-1,2,3-triols substitués par de l'azote.



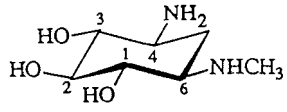
[Traduit par la rédaction]

Introduction

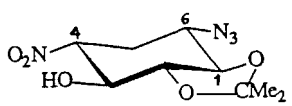


The aminocyclitol antibiotics hygromycin B and destomycin A produced by *Streptomyces hygroscopicus* and *Streptomyces rimofaciens*, respectively, are diastereomers. Each consists of an amino-methylamino-cyclohexanetriol unit (an *N*-methyl-2-deoxystreptamine) to which is glycosidically linked the rare sugar D-talose, which, in turn, bears on its O-2,O-3 positions a 6-amino-6-deoxyheptono-1,5-lactone, attached in orthoester fashion. The sole structural difference between the two antibiotics is the enantiotopic position of the *N*-methyl substituent in the diaminocyclitol (1). Thus, hygromycin B yields on hydrolysis the dextrorotatory fragment **1**, termed (+)-hysamine (1L-(1,3/2,4,6)-4-amino-6-methylamino-1,2,3-cyclohexanetriol), whereas destomycin A gives the 1D enantiomer, levorotatory (−)-hyosamine (**2**).

Although racemic hyosamine was synthesized in the laboratories of Nakajima (2) and Suami (3), no enantiospecific synthesis of **1** appears to have been recorded. Two chiral syntheses of **2** have been described by the same groups of workers. The first synthesis (4) started from achiral 1,2,4,5/3-cyclohexanepentol and used an enantiospecific biochemical oxidation as the key step of generating chirality, and after numerous further steps the optically active target compound was obtained in low overall yield. The second approach (5) was carbohydrate based, commencing with *N*-acetyl-D-glucosamine and employing nitroalkane cyclization strategy. Again, the overall yield over many steps was very poor.



The present paper presents new, enantiospecific approaches to **1** and **2** that start from a common chiral precursor. We recently developed (6) a new synthesis of 2-deoxystreptamine (i.e., **1** or **2** without the *N*-methyl group) that starts from



hygromycin B: $R^1 = H$, $R^2 = CH_3$
destomycin A: $R^1 = CH_3$, $R^2 = H$

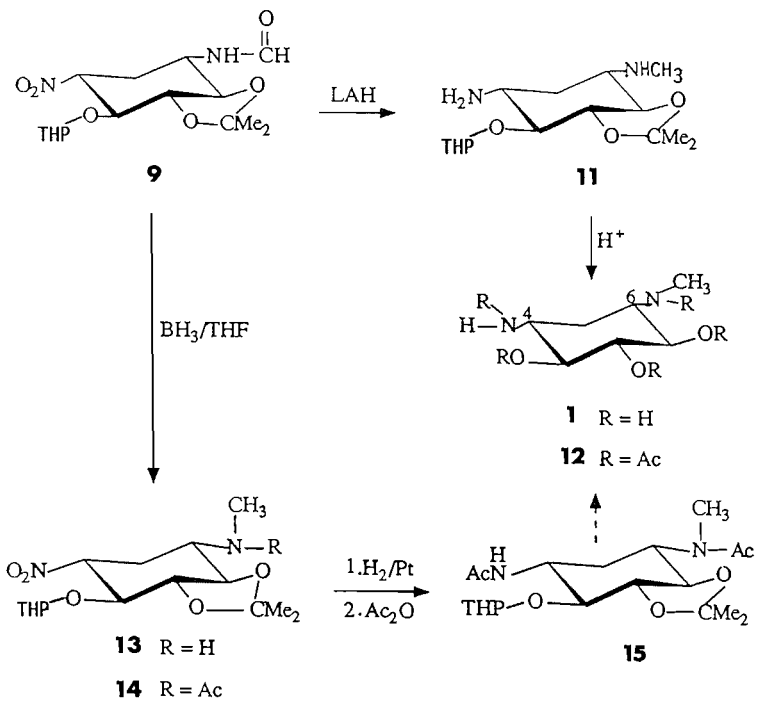
SCHEME 1

economical D-mannose and proceeds to the (achiral) target via several chiral precursors and derivatives. The purpose of the enterprise was to obtain such chiral derivatives in a stereospecific manner, for potential use in syntheses of unsymmetrically substituted, and hence optically active, 2-deoxystreptamines (such as **1** and **2**, and others) without the need for racemate resolution at some stage. One key intermediate in that work (6) was 1L-(1,3/2,4,6)-6-azido-1,2-*O*-isopropylidene-4-nitro-1,2,3-cyclohexanetriol (**3**), the point of departure for the present study.

Results and discussion



Compound **3** is available from D-mannose in eight facile preparative operations involving nitro sugar chemistry, with yields in the 80–90% range for each step except the last one, a Fischer-type cyclization (7), which gave a 67% yield of pure **3** (6). Compound **3** possesses two nitrogen and three oxygen functions in the same disposition and relative configurational relationship as the hyosamines, and it was reasoned that the two nitrogenous groups, being of different oxidation states, should be able to undergo sequential reduction to the amino stage so that appropriate manipulations should make possible an individual *N*-methylation of either, leading enantiospecifically to **1** and **2**. Several approaches to the realization of this concept are described.

Preparation of starting compounds

For the various designs of routes to **1** and **2** that follow, the cyclitol derivatives **5**–**10** were required as initial stepping stones. Their preparation from the azidonitro cyclitol **3** is illustrated in Scheme 1. Catalytic transfer hydrogenation of **3** over palladium on charcoal in the presence of 1,4-cyclohexadiene selectively reduced the azido group, to produce the aminonitro cyclitol **4**. Although the strained, *trans*-fused dioxolane ring in **3** is very prone to acid hydrolysis, it fortunately tolerates exposure to acetic acid in low concentration (and even to *p*-toluenesulfonic acid in catalytic amounts) for short periods of time, and acetic acid was therefore provided in the transfer hydrogenation medium in a quantity sufficient to neutralize the engendered amine **4** and thus prevent the medium from becoming basic. This precaution was deemed advisable because **3** (and **4**) can undergo base-catalyzed epimerization at C-3 through a retro nitroaldol reaction (6), and although **3** is thermodynamically preferred over its 3-epimer, epimerization occurring to even a minor extent would be most undesirable.[2] For the same reason of presumptive sensitivity, the nitroamine **4**

[2]Epimerization at C-4 is also theoretically possible but in practice poses no risk because of the well-established, great preference of nitro groups on six-membered sugar or cyclitol rings for adopting, or remaining in, an equatorial orientation (8).

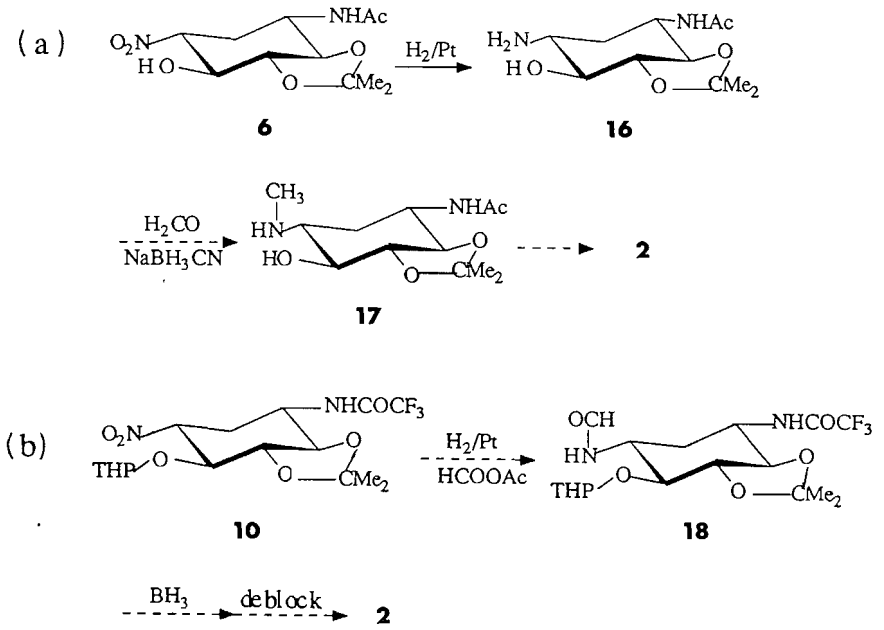
SCHEME 2

was not isolated for characterization but was treated *in situ* with formyl acetate and so converted into the stable formamide **5**, isolated crystalline in 90% yield. Performance of the transfer hydrogenation of **3** in the presence of acetic acid and acetic anhydride furnished the crystalline acetamide **6** in 97% yield.

Crude nitroamine **4**, generated as for the preparation of **5**, was treated in aqueous solution with ethyl chloroformate in the presence of either pyridine or sodium hydrogen carbonate, to produce the carbamate **7**. Although high yields of crude **7** were obtained in several experiments, the product tended to be contaminated by more-polar by-products and required chromatographic purification, after which pure crystalline **7** was isolated in yields of 40–57%. One of the by-products, isolated in one instance in 10% yield, was found by microanalysis and spectroscopy to be the corresponding triol **7***a*, resulting from hydrolytic loss of the isopropylidene group. A second by-product (14%), separated chromatographically in the same experiment, had a polarity (tlc) intermediate beteen **7** and **7***a* and somewhat surprisingly turned out to be the bis-carbamate **7***b*, previously described as the racemic form (9); its deacetonation with 50% acetic acid gave known (9) *N,N'*-diethoxycarbonyl-2-deoxystreptamine (**7***c*). As far as **7***a* is concerned, it has not been clarified whether hydrolysis occurred during the reaction or during processing or chromatography, or whether an impure sample of **3** that had partially become deacetonated during storage was inadvertently used. More intriguing was the encounter with a fairly significant amount of **7***b* in at least one experiment. Although nitroarenes are readily reduced to aminoarenes in phase transfer hydrogenation under a variety of conditions, the same does not normally seem to be the case for nitroalkanes. A comprehensive review (10) of the method makes no mention of nitroalkane reduction, which is why we chose it for selective azide reduction, with obvious success. However, NO_2 *can* evidently undergo slow reduction to NH_2. No attempts were made to pinpoint the cause in the observed instance; this might be difficult because, for such a heterogeneous reaction, precise reproducibility of conditions is hard to achieve and the quality of the batch of catalyst used or the efficacy of agitation (by ultrasound) may have played a role. At any rate, the observations suggest that reactions with **3** need to be performed with circumspection.



A further intermediate required for one of the planned syntheses was an O-3 protected derivative of **5**. The tetrahydropyranyl ether **9** was obtained in 93% yield by treatment of **5** with 2,3-dihydropyran. Alternatively, **3** was first tetrahydropyranylated to give its 3-THP ether **8**, which was subsequently hydrogenated and *N*-formylated, as for the preparation of **5**, to furnish an 86% yield of crystalline **9**. Finally, the trifluoroacetamide **10** was prepared from **8** by transfer hydrogenation followed by *N*-acylation of the resulting amine with trifluoroacetic anhydride. As was to be expected, the THP ethers **8**, **9**, and **10** (and products derived from them in later sections) arose as mixtures of epimers due to asymmetry at the acetalic C-2′ position. This was reflected in the nmr spectra of these compounds. Partial separation of epimers was observed in some cases after chromatography or fractional crystallization (see Experimental), but separation was not necessary for the conduct of further operations.

Synthesis of (+)-hyosamine

The synthesis of (+)-hyosamine was accomplished as shown in Scheme 2. The blocked formamidonitro compound **9** was treated with lithium aluminum hydride in refluxing 1,4-dioxane to effect concurrent reduction of the nitro and formamido groups.[3] The resulting, *O*-protected cyclitol **11** was not characterized other than by giving an immobile. ninhydrin-positive spot in tlc. It was deprotected by hydrolysis with trifluoroacetic acid to furnish the target compound **1**, m/z 177 for $[M + 1]^+$ as required (chemical ionization mass spectrum). For definitive characterization the product was peracetylated to give its crystalline penta-*N,O*-acetyl derivative **12**, m/z 387 ([M +

[3]This reduction was originally tried with the unprotected alcohol **5** but failed because of solubility problems. Upon addition of the hydride the starting material precipitated from the solution (ether or dioxane) as an insoluble alkoxide, and no reduction in heterogeneous phase was observed.

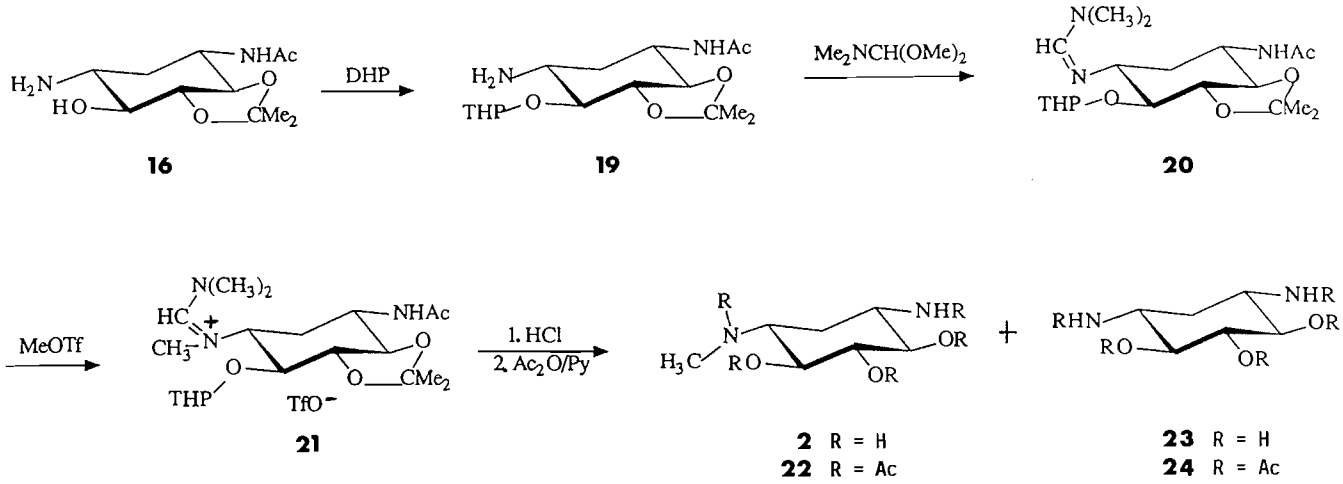
SCHEME 3

1]$^+$), in 23% yield based on **9**. Its melting point and specific rotation (but with opposite sign) agreed with the data recorded for the known enantiomer **22** (4, 5), and its ^{1}H nmr spectrum with data reported (2) for the synthetic racemate.



A second aproach to **1** was pursued in an exploratory way (Scheme 2). Treatment of **9** with borane–tetrahydrofuran complex effected reduction of the formamido group alone, leaving the nitro group intact. The crude methylamino derivative **13** so obtained was crystalline but gave a poor ^{1}H nmr spectrum, probably because of contamination by some boron complex; nevertheless, the spectrum confirmed a complete transformation of NHCHO into $NHCH_3$, which was also indicated by the mass spectrum showing a strong [M + 1]$^+$ peak for **13** at m/z 331. Upon *N*-acetylation of **13**, crystalline and well-characterized *N*-methylacetamide **14** was obtained, and platinum-catalyzed hydrogenation of the latter, followed by *N*-acetylation, afforded the amorphous, unsymmetrically blocked (+)-hyosamine derivatives **15**, charcaterized by ^{1}H nmr and mass spectra. It should no doubt be possible to remove all the blocking groups by standard procedures and thus arrive at **1**; more importantly, intermediates useful for generating regiospecifically substituted derivatives of **1** should be obtainable from **15** by applying selective deprotection procedures.

Syntheses of (−)-hyosamine

In first attempts to synthesize **2**, the strategies illustrated in Scheme 3 were pursued. It was considered that the acetamidonitro cyclitol **6** could be converted into the amine **16**, which after *N*-methylation to **17** and deprotection would furnish **2** (Scheme 3(a)). Hydrogenation of **6** over Adams catalyst proceeded very well, with consumption of the theoretical amount of hydrogen overnight at ordinary temperature and pressure. The amorphous amine **16** was characterized by its mass spectrum only, but was authenticated by its successful use in crude form in a subsequent experiment (see Scheme 4). Unfortunately, attempted monomethylation of **16** failed to provide **17** in a practical way. The method of reductive alkylation (11) with formaldehyde and sodium cyanoborohydride gave a complex pattern of products (tlc) that discouraged further efforts. In similar work, Suami *et al.* (5) had methylated an aminocyclitol by hydrogenation in formalin solution with a palladium catalyst, but the desired *N*-methyl derivative was obtained in only 28% yield, accompanied by 18% of *N,N*-dimethyl derivative and 37% of unmethylated product. This did not augur well for our project and we therefore turned to another approach (Scheme 3(b)). It was hoped that the formamido-trifluoroacetamido cyclitol **18**, to be produced from the nitro precursor **10** by catalytic hydrogenation followed by *N*-formylation, might be reducible by borane in the formamido group (compare the successful reduction of **9**) without undue reduction of the trifluoroacetamido group. Being a strong Lewis acid, borane is expected to attack preferentially at centers of high electron density; ordinary amides are readily reduced to alkylamines, but trichloroacetaldehyde is not attacked to any great extent, nor are acyl chlorides (12), and it appeared worthwhile to examine whether selective reduction is possible in **18**. The fact that trifluoroethylamines have been prepared by reduction of trifluoroacetamides by use of mixtures of sodium borohydride and aluminum trichloride (or boron trifluoride), in which borane is believed to be the active reductant (13), militated against the proposition, but, on the other hand, we were encouraged by a series of model experiments that we performed. 1-Formamido- and 1-trifluoroacetamido-1-deoxy-D-xylitol tetraacetates were treated with borane under identical conditions, and the results were evaluated by tlc and mass spectrometry. It was found that both amides were in fact reduced, but the former reacted about 10 times faster than the latter. This finding held promise for an acceptably selective reduction in **18** and prompted us to prepare its precursor **10**. However, the plan was brought to naught when **10** rather unexpectedly proved to be extraordinarily resistant to catalytic hydrogenation (with a 34% recovery of unchanged **10** after many days, and after multiple additions of fresh charges of platinum catalyst), and no pure **18** could be elaborated. This experience contrasted starkly with the facile hydrogenations of the nitro compounds **6** and **14** (and **7**; see below).

The first successful route to **2** is depicted in Scheme 4. Crude **16**, obtained from **6** as mentioned before, was tetrahydropyranylated to yield 83% (based on **6**) of its 3-THP ether **19**,

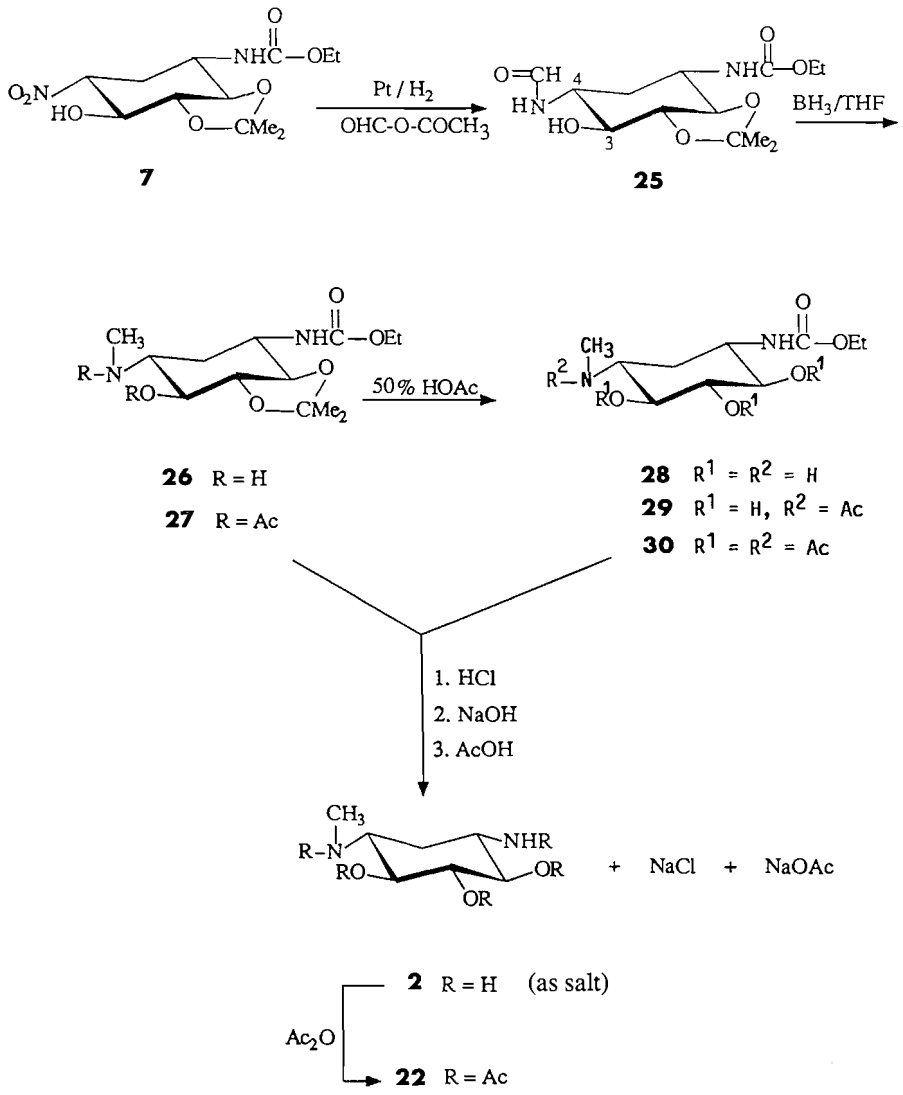
SCHEME 4

which without purification was subjected to *N*-methylation by the method of O'Donnell *et al.* (14). This one-pot procedure involves generation of a formamidine (**20**) by action of *N,N*-dimethylformamide dimethyl acetal, followed by reaction with methyl triflate (→**21**) and hydrolysis with boiling hydrochloric acid. The hydrolysis converts the amidinium function in **21** into a methylamino group and, of course, removes all blocking groups from the molecule, which emerges as **2**·dihydrochloride. The product obtained was not homogeneous in tlc, however. It showed two closely spaced, ninhydrin-positive spots, one identical with that of enantiomer **1** (hence attributable to **2**), and the other migrating like an authentic sample of 2-deoxystreptamine (**23**). Conventional peracetylation of the reaction mixture and column chromatography furnished the crystalline penta-*N,O*-acetyl derivative **22** of (+)-hyosamine in 20% yield from **19**, agreeing in its physical constants and ^{1}H nmr spectrum with literature data (2, 4, 5) and with the enantiomer **12**, and crystalline penta-*N,O*-acetyl-2-deoxystreptamine (**24**) (15) in 14% yield. Identification of the latter revealed that *N*-methylation of **19** by this procedure was incomplete, a circumstance that prompted us to seek yet another approach.

To that end, we returned to the concept of selective amide reduction by borane. The reagent has been shown to be capable of reducing amides without affecting carbamate functions present in the same molecule (12*c*, 16). Therefore, the reaction sequence depicted in Scheme 5 was devised. Like **6** and **14**, the nitrocarbamate **7** could be smoothly hydrogenated over Adams catalyst, and the amine engendered was *N*-formylated *in situ*, to give the crystalline formamido carbamate **25** in 76% yield. Treatment with borane in refluxing tetrahydrofuran for 5 h then reduced the formamido to a methylamino group, leaving the ethyl carbamate function intact. At the end of such a reduction it is necessary to decompose amine–boron complexes formed, which is normally done by acidification of the reaction mixture with hydrochloric acid (12*c*, 16). Adopting that work-up procedure in first experiments (and recognizing that this would also cleave off the isopropylidene protecting group[4]), we obtained what according to ^{1}H nmr and mass spectra of the crude product was the desired hyosamine ethyl carbamate (as hydrochloride). However, the product proved difficult to isolate and purify. When, instead, the processing was performed with water and a stream of carbon dioxide, the acetonide group was largely retained and the product was easier to handle. It required chromatographic purification, though, and pure **26** was obtained in 35% yield only. A substantial proportion of **26** (43%) emerged from the column as a syrup contaminated by a minor amount of deacetonated material that, we suspect, may have risen at least in part on the column under the influence of the silica gel. Acetylation of this fraction failed to give crystalline material but yielded a syrupy mixture of the *N,O*-diacetyl derivative **27** (major component) and the *N,O,O,O*-tetraacetyl derivative **30** as evaluated by ^{1}H nmr, ^{13}C nmr, and mass spectra.



The acetonide **26** exhibited an nmr-spectral peculiarity (see below) which was felt to be possibly attributable to its strained bicyclic structure, and we were therefore interested in obtaining for comparison a pure sample of its product of deacetonation (**28**). Overnight treatment of pure **26** with 50% acetic acid at room temperature cleanly hydrolyzed the ketal, but the compound underwent *N*-acetylation in the process,[5] giving the methylacetamido triol **29**.

For completion of the synthesis, the mixture of blocked derivatives **27** and **30** was to be hydrolyzed. Whereas boiling with dilute hydrochloric acid (1–2 M) could be expected to effect *O*- and *N*-deacetylation (and of course deacetonation in **27**), cleavage of the carbamate was anticipated to require more-forcing conditions and the mixture was therefore heated at 100°C in 6 M HCl. The more-labile groups were split off rapidly, but the carbamate resisted completely under these drastic conditions for at least 2 h, according to the ^{13}C nmr spectrum of the hydrolyzate. Evidently, after an early cleavage of the *N*-acetyl group the compound exists as a methylammonium ion whose charge electrostatically impedes further protonation for carbamate hydrolysis. (For the same reason, glyco-

[4]At this stage of the synthesis the group had become dispensable. In the analogous borane reduction of **9** (Scheme 2), retention of the acetonide was desired and acid treatment was therefore omitted. Processing was performed with methanol instead, and some boron apparently remained in the product.

[5]Partial acetylation even of hydroxyl groups in carbohydrates with *hot* 50% acetic acid has been reported (17), and minor proportions of *O*-acetylated products were occasionally observed to arise under conditions of deacetalation with hot 80% acetic acid (18). The occurrence of (more facile) *N*-acetylation in the present instance should therefore not be surprising; possibly it took place during processing by evaporation of the acid at moderately elevated temperature.

SCHEME 5

sides of amino sugar hydrochlorides are extremely resistant to acid hydrolysis.) However, subsequent saponification with 2 M sodium hydroxide removed the ethoxycarbonyl substituent and produced **2**, extracted from the resulting salt mixture, after peracetylation, as crystalline pentaacetyl derivative **22** in 60% yield. The product was identical in every respect with **22** from the previous synthesis. Although not all operations have been optimized, the overall yield in the four steps from **3** was 20%.

Nuclear magnetic resonance spectra

Some of the nmr parameters for the compounds prepared (see the experimental section) deserve special comment. Thus, the ^1H spectra of the pentaacetylhyosamines **12** and **22** exhibited the phenomenon of signal multiplication already observed in the synthetic racemate (2). There were *two* *N*-methyl signals, namely, a broadened and a sharp singlet at δ 2.81 and 2.72, respectively, in an intensity ratio of ~3:2, integrating jointly to 3 protons,[6] and instead of the expected five 3-proton singlets for the acetyl groups around δ 2.0 there was a cluster of numerous singlets (13–14) with varying intensities but correctly integrating to five times the combined *N*-CH_3 signal intensity. Furthermore, *two* low-field doublets (δ 5.70 and 5.63, J = 8 Hz) integrating together to 1 proton were seen for the amidic NH. The phenomenon has been attributed "probably (to) the space requirement of the methylacetamido group" (2). It seems possible that free rotation of that group about the bond connecting it to the ring is sufficiently impeded by the neighboring acetoxyl for individual rotamers to become spectroscopically recognizable; however, it may also be a rotational-barrier effect in one or both of the amidic CO—N bonds, as is well known to occur in *N,N*-dimethylformamide. Conceivably both factors may contribute. The 4-acetamido-6-(*N*-methyl)-acetamido derivative **15** displayed the same phenomenon, showing two major *N*-CH_3 singlets in 2:1 intensity ratio (each being accompanied by a minor satellite at slightly lower field, presumably due to tetrahydropyranyl epimerism), and a cluster of several $COCH_3$ singlets integrating to 6 protons. Steric hindrance of the methylacetamido group would appear less plausible in this case, and the 4-nitro analog **14** gave only one sharp, 3-proton singlet each for the *N*-CH_3 and $COCH_3$ groups, thus revealing no rotamers. The same was true for the 4-(*N*-methyl)acetamido 6-carbamate **29**, for which homogeneity was moreover confirmed by a ^{13}C nmr spectrum.

[6]In one of the spectra taken, the broadened singlet was resolved into two sharp singlets at δ 2.84 and 2.81 whilst the singlet at δ 2.72 was unchanged. This was probably a temperature or concentration effect.

Surprisingly in light of the above observations, the nonacetylated *N*-methylamino compounds **13** and **27** displayed duplicate NH-CH_3 signals. These were doublets (J = 6.1 and 5.9 Hz) at δ 2.53 and 2.69 (ratio ~1:2), and δ 2.60 and 2.44 (ratio 1:1.2), respectively. While we refrain from further comment regarding **13** because this compound had not been isolated in entirely pure state, **27** was analytically pure and we conclude that it exists in solution as a mixture of stable, magnetically nonequivalent species. This was borne out by the ^{13}C nmr spectrum in which the peaks for *N*-CH_3 and all the ring carbon atoms (but not those for the ethyl carbamate and the isopropylidene methyl groups) were accompanied by satellites showing 75–90% intensities relative to the main peaks. Perhaps the phenomenon is due to the possibility of hydrogen bonding between the vicinal methylamino and hydroxyl groups, in $CDCl_3$ solution. It is to be noted that the ^{13}C nmr spectrum of hyosamine **1** in water contains only the seven resonances expected for the structure (1).

Finally, it is interesting to compare the ^1H spectra of the formamides **5**, **9**, and **25**. Whereas the nitroformamide **5** and (both 2′-epimers of) its 3-THP ether **9** in $CDCl_3$ solution showed one singlet (δ 8.18) for the formyl proton, in the formamido carbamate **25** in acetone-d_6 two rotameric forms apparently interconverted slowly enough to become manifest. The spectrum contained a slightly broadened singlet (δ 8.13, $J_{CHO,NH} < 1$ Hz) and a doublet (δ 8.03, $J_{CHO,NH}$ = 12 Hz) in a ratio of ~4:1, integrating to 1 proton of the formyl group, and the corresponding amidic NH signals (also ~4:1) appeared as a doublet (δ 7.3, $J_{NH,4}$ = 7 Hz, with slightly broadened lines) and a triplet (δ 6.7, $J_{NH,4} = J_{NH,CHO}$ = 12 Hz). Upon deuterium exchange the NH signals disappeared and the two formyl signals became sharp singlets. The ^{13}C spectrum likewise showed a major and a minor set of signals for the formyl and cyclitol ring carbon atoms, attributed to rotamers. Again, hydrogen bonding with the vicinal hydroxyl group could be responsible for the effect.

Experimental

Thin-layer chromatography (tlc) was performed on precoated silica gel plates, and spots were made visible by spraying the plates with 5% H_2SO_4 in EtOH or, for amines, with 2% ninhydrin in EtOH, and heating them on a hot plate. Column chromatography was performed with silica gel Merck 9385 (particle size 20–45 μm) or equivalent material. The following solvent combinations (v/v) were used for chromatography, unless otherwise specified: MeOH/$CHCl_3$ 1:1 (*A*), 1:5 (*B*), 1:9 (*C*), 1:19 (*D*), and 1:49 (*E*); EtOAc/hexane 3:1 (*F*), 3:2 (*G*), 1:1 (*H*), 1:3 (*I*), and 1:9 (*J*); Et_2O/hexane 1:1 (*K*) and 1:4 (*L*); MeOH/EtOAc 1:6 (*M*); MeCN/conc. aq. NH_3/water 3:2:1 (*N*) and 4:1:2 (*O*); MeOH/CH_2Cl_2 1:9 (*P*) and 1:49 (*Q*).

Melting points were determined in capillaries with a Gallenkamp electrothermal apparatus. Optical rotations were measured at room temperature in a Perkin Elmer 241 polarimeter. Infrared data (ν_{max}) refer to spectra obtained from Nujol mulls for solids, or from thin films for syrups, unless otherwise indicated; only bands of particular structural significance are listed. Mass spectral data (m/z) were obtained by the chemical ionization mode using ether as the ionizing gas. Nuclear magnetic resonance (nmr) data given without special notation refer to spectra taken from $CDCl_3$ solutions at 300 MHz (for ^1H) or 75.43 MHz (for ^{13}C) with a Varian XL-300 instrument. Data denoted by 200 MHz (for ^1H) or 50.3 MHz (for ^{13}C) were obtained with a Varian Gemini 200 instrument. Solvents other than $CDCl_3$ are stated.

*1L-(1,3/2,4,6)-6-Azido-1,2-*O*-isopropylidene-4-nitro-1,2,3-cyclohexanetriol (3)*

Compound **3** was prepared as described (6), and verified by its well-resolved ^1H nmr spectrum to be free from 3-epimer (6); ^{13}C nmr (50.3 MHz), not previously recorded, δ: 113.3 (O_2CMe_2), 86.4 (C-4), 79.0, 78.4 (C-1, 2), 71.5 (C-3), 57.0 (C-6), 32.9 (C-5), 26.4 (CMe_2).

*1L-(1,3/2,4,6)-6-Formamido-1,2-*O*-isopropylidene-4-nitro-1,2,3-cyclohexanetriol (5)*

To a solution of **3** (516 mg, 2 mmol) in MeOH (20 mL) containing AcOH (0.18 mL) was added 10% Pd-C (400 mg, suspended in a small amount of MeOH), followed by 1,4-cyclohexadiene (1.6 mL). An N_2 atmosphere was provided and the flask immersed in an ultrasonic bath at 45°C. After sonication until **3** (R_f 0.9, acid spray) was completely replaced by the amine **4** (R_f 0.2, ninhydrin spray; tlc with EtOAc), which normally took 30 but occassionally up to 120 min, the catalyst was filtered off and washed with MeOH, and to the filtrate was added 1 mL of formyl acetate (19). *N*-Formylation was complete after 30 min at 25°C when tlc (EtOAc) showed **5** as a single spot, R_f 0.65. The solvent was evaporated and several portions of added EtOH were evaporated from the syrupy residue to remove acid. The slightly turbid solution of the residue in EtOAc was clarified with Celite, and **5** was then obtained crystalline (470 mg, 90%) from EtOAc/$CHCl_3$/Et_2O; mp 167–168°C (unchanged after recrystallization from 2-propanol); $[\alpha]_D$ +31.3 (*c* 0.6, MeOH); ν_{max}: 3350 (br, OH and NH), 1675 (amide CO), 1550 (NO_2) cm^{-1}; ^1H nmr, δ: 8.18 (s, slightly broadened, CHO), 4.73 (br s, NH), 4.51 (m, H-4), 4.41 (t, $J_{2,3} = J_{3,4}$ = 9.2 Hz, H-3), 4.18 (m, H-6), 3.56 (t, $J_{1,2} = J_{1,6}$ = 9.2 Hz, H-1), 3.48 (t, $J_{1,2} = J_{2,3}$ = 9.2 Hz, H-2), 2.91 (dt, $J_{4,5eq} \approx J_{5eq,6} \approx$ 4.8 Hz, $J_{5ax,5eq}$ = 13.3 Hz, H-5eq), 2.78 (br s, OH), 1.87 (dt, $J_{4,5ax} = J_{5ax,6}$ = 12.2 Hz, $J_{5ax,5eq}$ = 13.3 Hz, H-5ax), 1.46 (s, 6H, CMe_2); m/z: 261 ($M^+ + 1$, base peak), 245 ($M^+ + 1 - O$), 243 ($M^+ + 1 - H_2O$), 203 ($M^+ + 1 - Me_2CO$), 185 ($M^+ + 1 - H_2O - Me_2CO$). Anal. calcd. for $C_{10}H_{16}N_2O_6$ (260.2): C 46.15, H 6.20, N 10.77; found: C 46.27, H 6.29, N 11.04.

*1L-(1,3/2,4,6)-6-Acetamido-1,2-*O*-isopropylidene-4-nitro-1,2,3-cyclohexanetriol (6)*

Compound **3** (516 mg) was subjected to transfer hydrogenation as described for the preparation of **5**, except that acetic anhydride (0.4 mL) was added to the medium, along with the AcOH (0.18 mL). The reaction was monitored by tlc (solvent *C*), which indicated that the conversion of **3** (R_f 0.7) into **6** (R_f 0.3) was virtually complete after sonication at 45°C for 20 min. Hydrogenation was stopped after 30 min, the catalyst was removed and washed exhaustively with MeOH, and the filtrate was concentrated with consecutive additions of three portions of fresh MeOH and then brought to dryness. Added EtOH and toluene were evaporated from the residue until a smell of acetic acid was no longer noticeable. The cloudy solution of the residue in EtOAc was clarified by passage through a plug of Celite/activated carbon, and concentrated, and **6** then crystallized upon addition of some $CHCl_3$ and, eventually, some hexane. Isolated and washed with a mixture of the same solvents, **6** (532 mg, 97%) had mp 175–177°C, raised to 185–186°C by recrystallization from 2-propanol; $[\alpha]_D$ +40.3 (*c* 0.5, MeOH); ν_{max}: 3390 (sharp , NH), 3260 (br, OH), 1650 (amide CO), 1545 (NO_2) cm^{-1}; ^1H nmr, δ: 5.58 (br d, $J_{6,NH}$ = 6.3 Hz, NH), 4.50 (m, H-4), 4.39 (t, $J_{2,3} = J_{3,4}$ = 9.0 Hz, H-3), 4.10 (m, H-6), 3.49 (AB-m, 2H, $J_{1,2} = J_{1,6} = J_{2,3}$ = 9 Hz, H-1,2), 2.92 (dt, $J_{4,5eq} = J_{5eq,6}$ = 5.1 Hz, $J_{5ax,5eq}$ = 13.3 Hz, H-5eq), 2.75 (br s, OH), 1.99 (s, 3H, Ac), 1.77 (dt, $J_{4,5ax} = J_{5ax,6}$ = 12.3 Hz, $J_{5ax,5eq}$ = 13.3 Hz, H-5ax), 1.44 and 1.45 (2s, 6H, CMe_2); m/z: 275 ($M^+ + 1$, base peak), 217 ($M^+ + 1 - Me_2CO$), 199 ($M^+ + 1 - H_2O - Me_2CO$). Anal. calcd. for $C_{11}H_{18}N_2O_6$ (274.3): C 48.17, H 6.62, N 10.21; found: C 48.28, H 6.65, N 10.26.

*1L-(1,3/2,4,6)-6-Ethoxycarbonylamido-1,2-*O*-isopropylidene-4-nitro-1,2,3-cyclohexanetriol (7) and derivatives 7a–7c*

Compound **3** (516 mg) was converted by catalytic transfer hydrogenation into the amine **4**, as described for the preparation of **5**. The catalyst was filtered off and washed well with MeOH, and the filtrate was evaporated to a syrup that was taken up in water (20 mL). Pyridine (0.23 mL, 1.44 mol. equiv.) was added and then, dropwise, ethyl chloroformate (0.23 mL, 1.2 mol. equiv.). The mixture was stirred at room temperature for 1 h, after which the conversion of **4** (R_f 0.2) into **7** (R_f 0.6) was complete (tlc, solvent *C*). The mixture was diluted with an equal volume of water and extracted with EtOAc (3 × 20 mL), with addition of brine to destabilize the emulsion that tended to form. The dried (Na_2SO_4) and concentrated extract gave a syrup that was passed through an SiO_2 column (2.3 × 20 cm) by means of solvent *I*, to give

For personal use only.

crystalline **7**, (242 mg, 40%). A 57% yield was achieved in a similar experiment in which the ethoxycarbonylation was performed at 0°C in the presence of $NaHCO_3$ (1.2 mol. equiv.) instead of pyridine. Usually the crude product contained small amounts of by-products that migrated more slowly in tlc. Crystalline **7** had mp 76–78°C; $[\alpha]_D$ +24.1 (*c* 1.1, $CHCl_3$); ν_{max}: 3350 (br, NH and OH), 1700–1680 (urethane CO), 1545–1530 (NO_2 and urethane NH) cm^{-1}; ^1H nmr, (DMSO-d_6 at 55°C; assignments confirmed by COSY), δ: 7.14 (d, $J_{6,NH}$ = 8.8 Hz, NH), 5.95 (d, $J_{3,OH}$ = 5.8 Hz, OH-3), 4.71 (ddd, $J_{3,4}$ = 9.4, $J_{4,5eq}$ = 5.0, $J_{4,5ax}$ = 12.6 Hz, H-4), 4.08–3.96 (m, 3H, H-3 and OCH_2Me), 3.88 (crude octet with broadened center peaks, W = 35 Hz, H-6), 3.47 (sym. septet, 2H, W = 34.3 Hz with line separations of 9.15, 6.25, and 1.75 Hz, H-1,2), 2.34 (dt, $J_{4,5eq}$ = $J_{5eq,6}$ = 4.8 Hz, $J_{5ax,5eq}$ = 12.7 Hz, H-5eq), 1.86 (apparent q, W = 36.6 Hz, with splittings of 12.6, 11.4, and 12.6 Hz, consistent with $J_{4,5ax} \approx J_{5ax,5eq} \approx 12.6$ and $J_{5ax,6} \approx 11.4$ Hz, H-5ax), 1.38 and 1.37 (2s, 3H each, CMe_2), 1.17 (t, 3H, J = 7.1 Hz, ethyl CH_3 *m/z*: 305 ($M^+ + 1$), 260 ($M^+ + 1 - OEt$), 247 ($M^+ + 1 - Me_2CO$). Anal. calcd. for $C_{12}H_{20}N_2O_7$ (304.3): C 47.62, H 6.63, N 9.21; found: C 47.43, H 6.70, N 8.98.

In one experiment, performed on a 2-mmol scale in the presence of $NaHCO_3$ during *N*-acylation at 0°C, the slow-moving by-products seen in tlc of the crude **7** appeared especially prominent, and they were isolated for examination. Column chromatography was performed using 2:3 EtOAc/hexane, and after collection of pure **7** (350 mg, 57.5%) the elution was continued and sequentially gave crystalline **7***b* (95 mg, 13.7%) and crystalline **7***a* (55 mg, 10.4%), R_f 0.35 and 0.1 (tlc with solvent *C*).

1D(1,3/2,4,6)-4-Ethoxycarbonylamido-6-nitro-1,2,3-cyclohexanetriol[7] (7a) had mp 202–204°C; $[\alpha]_D$ +22.9 (*c* 0.6, MeOH); ν_{max} ($CHCl_3$): 3300 (br, OH and NH), 1675 (urethane CO), 1560–1540 (amide II and NO_2) cm^{-1}; ^1H nmr (DMSO-d_6), δ: 6.99 (d, $J_{4,NH}$ = 8.5 Hz, NH), 5.62, 5.23, 4.93 (3d, exchangeable, J = 5.6, 4.6, and 4.4 Hz, OH-1,2,3), 4.60 (ddd, $J_{5eq,6}$ = 4, $J_{1,6}$ = 10, $J_{5ax,6}$ = 12 Hz, H-6), 3.94 (q, 2H, J = 7 Hz, O-CH_2Me), 3.50–3.35 and 3.10 (2m, 4H total, H-1,2,3,4), 2.14 (dt, $J_{4,5eq} \approx J_{5eq,6} \approx 4$ Hz, $J_{5ax,5eq}$ = 12 Hz, H-5eq), 1.75 (~q, $J_{4,5ax} \approx J_{5ax,6} \approx J_{5ax,5eq} \approx 12$ Hz, H-5ax), 1.13 (t, 3H, J = 7 Hz, ethyl CH_3); ^{13}C nmr (50.3 MHz, DMSO-d_6), δ: 156.4 (CO), 86.7 (C-6), 75.3, 74.1, 74.0 (C-1,2,3), 59.9 (OCH_2), 50.7 (C-4), 32.7 (C-5), 14.8 (ethyl CH_3); *m/z*: 265 ($M^+ + 1$, weak), and no species of greater mass. Anal. calcd. for $C_9H_{16}N_2O_7$ (264.2): C 40.91, H 6.10, N 10.60; found: C 41.07, H 6.08, N 10.74.

1L-(1,3/2,4,6)-4,6-Di-(ethoxycarbonylamido)-1,2-O-isopropylidene-1,2,3-cyclohexanetriol (7b) had mp 188–190°C (lit. (9) for racemate, mp 199–200°C); $[\alpha]_D$ +10.8, $[\alpha]_{546}$ +13.3, $[\alpha]_{436}$ +21.6, $[\alpha]_{365}$ +28.4 (*c* 1.2, $CHCl_3$), and $[\alpha]_D$ +1.1, $[\alpha]_{365}$ −0.43 (*c* 1.2, MeOH); ν_{max} ($CHCl_3$): 3300 (br, OH and NH), 1670 (urethane CO), 1545 (amide II) cm^{-1}; ^1H nmr (200 MHz, DMSO-d_6), δ: 7.26 and 7.05 (2d, exchangeable, J = 8.6 and 7.7 Hz, 2NH), 5.12 (d, exchangeable, J = 4.8 Hz, OH-3), 3.97 (q, 4 H, J = 7 Hz, $2OCH_2$Me), 3.7–3.2 (complex m, unresolved, H-1,2,3,4,6), 1.85 (dt, $J_{5eq,5eq}$ = 12 Hz, H-5eq), 1.33 (s, 6H, CMe_2), 1.27 (m, overlapped by adjacent signals, H-5ax), 1.15 (t, 6H, J = 7 Hz, 2 ethyl CH_3); in $CDCl_3$ solution, the dt for H-5eq was at δ 2.24, CMe_2 gave two separate signals (δ 1.42, 1.40), and also the OEt groups gave separate (but overlapping) quartets at δ 4.08 and triplets at δ 1.20; ^{13}C nmr (50.3 MHz, DMSO-d_6), δ: 156.5 156.0 (2CO), 110.2 (O_2CMe_2), 81.2, 78.5, 71.6 (C-1,2,3), 60.0, 59.9 ($2OCH_2$), 53.3, 49.0 (C-4,6), 36.6 (C-5), 27.1, 27.0 (CMe_2), 14.8 (double intensity, 2 ethyl CH_3). Anal. calcd. for $C_{15}H_{26}N_2O_7$ (346.4): C 52.01, H 7.57, N 8.08; found: C 51.82, H 7.46, N 7.98.

[7]For **7** the rules of nomenclature (20) require that the triol system is numbered so as to give any *substituted* (by isopropylidene in this case) OH groups the lowest possible locant numbers. For **7***a*, however, with unsubstituted OH groups only, the sense of numbering is dictated by alphabetic precedence of other substituents present and must here be reversed because EtOCONH comes before NO_2. As a result, the configurational prefix 1D applies.

(1,3/2,4,6)-Di-(ethoxycarbonylamido),1,2,3-cyclohexanetriol (7c) was obtained by overnight treatment of **7***b* (95 mg) with 50% aqueous AcOH (10 mL) at room temperature, after which **7***b* (R_f 0.35) was seen replaced by immobile **7***c* (tlc with solvent *C*). The acid was evaporated with additions of EtOH, and the white residue was passed through an SiO_2 column (1.5 × 10 cm) by elution with solvent *P*, a solvent that was also used for monitoring the effluent by tlc. There was obtained 63 mg (75%) of crystalline **7***c*, mp 235–237°C (lit. (9) mp 321–232°C); ^1H nmr (DMSO-d_6) δ: 6.90 (d, 2H, J = 7.6 Hz, 2NH), 4.85 (d, J = 3.7 Hz, OH-2), 4.65 (d, 2H, J = 3.9 Hz, OH-1,3), 3.95 (q, 4H, J = 7.1 Hz, $2OCH_2$), 3.20 (m, 2H, H-4,6), 3.00 (m, 3H,H-1,2,3), 1.75 (dt, $J_{5ax,5eq}$ = 13 Hz, H-5eq), 1.15 (t, 6H, J = 7.1 Hz, ethyl CH_3; superimposed on m, 1H, for H-5ax); ^{13}C nmr (50.3 MHz, DMSO-d_6), δ: 156.3 (2CO), 77.1 (C-2), 74.2 (C-1,3), 59.6 ($2OCH_2$), 51.5 (C-4,6), 35.2 (C-5), 14.8 (2 ethyl CH_3); *m/z*: 307 ($M^+ + 1$, base peak), 261 ($M^+ + 1 - EtOH$), 215 ($M^+ + 1 - 2EtOH$). Anal. calcd. for $C_{12}H_{22}N_2O_7$ (306.3): C 47.05, H 7.24, N 9.20; found: C 47.29, H 6.82, N 9.11.

1L-(1,3/2,4,6)-6 Azido-1,2-O-isopropylidene-4-nitro-3-O-(tetrahydropyran-2-yl)-1,2,3-cyclohexanetriol (8)

A solution of **3** (747 mg, 3 mmol), 2,3-dihydropyran (1.4 mL, 15 mmol), and *p*-toluenesulfonic acid monohydrate (57 mg) in 1,4-dioxane (25 mL) was kept at 25°C for 1 h; tlc (solvent *I*) had revealed that conversion of **3** (R_f 0.3) into **8** (two epimers, R_f 0.7 and 0.65) was nearly complete after 30 min. Saturated aqueous $NaHCO_3$ (3 mL) was added and the mixture was evaporated. The residue was distributed between water and $CHCl_3$, and the organic phase washed with water, dried, and concentrated to a syrup of crude **8** (1.00 g, 97%) that could be used directly for preparing **9** or **10**. For analytical characterization, the crude **8** was chromatographed on an SiO_2 column (3.8 × 12 cm) by elution with hexane followed by solvent *J*. Early fractions contained pure, faster-moving epimer, which crystallized in fine needles upon concentration of the eluate and addition of hexane; yield, 522 mg; double mp at 97–99 and 112–113°C; $[\alpha]_D$ −118.6 (*c* 1, $CHCl_3$); ^1H nmr, δ: 5.11 (t, J = 2.4 Hz, H-2′), 4.57 (ddd, $J_{4,5eq}$ = 5.0, $J_{3,4}$ = 9.35, $J_{4,5ax}$ = 12.3 Hz, H-4), 4.48 (t, $J_{2,3}$ = $J_{3,4}$ = 9.35 Hz, H-3), 3.67 (ddd, $J_{5eq,6}$ = 4.7, $J_{5ax,6}$ = 11.4, $J_{1,6}$ = 9.9 Hz, H-6), 3.5 (m, 3H, containing H-6′,6″ signals and a t, J = 9.5 Hz, for H-1), 3.38 (t, $J_{1,2}$ = $J_{2,3}$ = 9.4 Hz, H-2), 2.56 (dt, $J_{4,5eq} \approx J_{5eq,6} \approx 4.7$ Hz, $J_{5ax,5eq}$ = 13.2 Hz, H-5eq), 2.05 (octet, $J_{4,5ax}$ = 12.5, $J_{5ax,6}$ = 11.5, $J_{5ax,5eq}$ = 13.2 Hz, H-5ax), 1.7–1.5 (m, 6H, H-3′,3″,4′,4″,5′,5″), 1.45 and 1.43 (2s, 3H each, CMe_2); *m/z*: 343 ($M^+ + 1$, base peak), 327 ($M^+ + 1 - O$), 315 ($M^+ + 1 - N_2$), 285 ($M^+ + 1 - Me_2CO$), 268 ($M^+ - O - Me_2CO$), 242 ($M^+ + 1 - C_5H_9O_2$ (tetrahydropyranyloxy)). Anal. calcd. for $C_{14}H_{22}N_4O_6$ (342.3): C 49.12, H 6.48, N 16.36; found: C 49.01, H 6.47, N 16.47.

Further elution of the column produced mixed fractions containing both epimers as well as slower-moving impurities. These latter were separated off by repeated chromatography but the second epimer could not be obtained free from the first one, even though the product crystallized from hexane; yield, 130 mg; mp 95–96°C; $[\alpha]_D$ −65.4 (*c* 1, $CHCl_3$). The ^1H nmr spectrum showed all the signals listed above for the first epimer (which in fact preponderated ~2:1), and most of the signals of the second epimer coincided with these, except for H-2′ (δ 4.67, t, J = 3.7 Hz), H-3 (δ 4.40, t, J ~ 9 Hz), H-6′ or H-6″ (δ 4.00, septet, J = 3.5, 9, and 11 Hz), CMe_2 (δ 1.47 and 1.45, 2s). The mass spectrum showed the same peaks, in almost the same intensity ratios, as that of the pure first epimer. The microanalytical data found were C 49.02, H 6.43, N 16.46.

1L-(1,3/2,4,6)-6-Formamido-1,2-O-isopropylidene-4-nitro-3-O-(tetrahydropyran-2-yl)-1,2,3-cyclohexanetriol (9)

From alcohol **5**

Compound **5** (260 mg, 1 mmol) in dry 1,4-dioxane (20 mL) was treated at 25°C with 2,3-dihydropyran (0.9 mL) in the presence of *p*-toluenesulfonic acid monohydrate (38 mg). The reaction was complete after 2 h as revealed by tlc (solvent *C*), which showed **9** (R_f 0.5) and no more **5** (R_f 0.3). The acid catalyst was neutralized with Et_3N,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

the mixture concentrated, and a chloroform solution of the residue was washed with water, dried ($MgSO_4$), and evaporated. The crude crystalline material was chromatographed on SiO_2 (2.2 × 15 cm) with solvent *C*. The combined fractions containing **9** were evaporated, and EtOH was evaporated from the residue, whereupon **9** crystallized. The crystals were triturated with EtOAc and hexane, stored at 0°C, collected, and washed with hexane; yield, 165 mg (48%); mp 208–209°C; $[\alpha]_D$ −47.7 (*c* 0.9, $CHCl_3$); ^1H nmr, δ: 8.18 (s, CHO), 5.70 (d, $J_{6,NH}$ = 6 Hz, NH), 5.12 (t, *J* = 2 Hz, H-2′), 4.62 (m, H-4), 4.50 (t, $J_{2,3} = J_{3,4}$ = 9.5 Hz, H-3), 4.16 (m, H-6), 3.6–3.4 (m, 4H, containing 2 triplets with *J* = 9–10 Hz, H-1,2,6′,6″), 2.83 (dt, $J_{4,5eq}$ = $J_{5eq,6}$ = 4.7 Hz, $J_{5ax,5eq}$ = 13.1 Hz, H-5eq), 1.93 (~sextet, $J_{4,5ax} \approx J_{5ax,6} \approx$ 11.5 Hz, $J_{5ax,5eq}$ = 13 Hz, H-5ax), 1.65–1.45 (m, 6H, H-3′,3″,4′,4″,5′,5″), 1.42 and 1.41 (2s, 6H, CMe_2); *m/z*: 345 ($M^+ + 1$, base peak), 287 ($M^+ + 1 - Me_2CO$), 261 ($M^+ + 1 - C_5H_8O$ (dihydropyran)). Anal. calcd. for $C_{15}H_{24}N_2O_7$ (344.4): C 52.32, H 7.03, N 8.13; found: C 52.40, H 7.06, N 7.96.

The mother liquor of the crystalline **9** was concentrated and passed once more through a column as just described, to give a second crop of **9** (156 mg, 45%) that failed to crystallize. It gave the same mass spectrum as crystalline **9**, but the ^1H nmr spectrum indicated a mixture of epimers: All signals listed above were present, and there was a second set of similar or identical signals that partly coincided or overlapped with the first set, except for H-2′ (δ 4.68, narrow t), H-3 (δ 4.42, t, *J* ≈ 9 Hz), H-6′ or H-6″ (δ 4.00, m), and CMe_2 (δ 1.44 and 1.43, 2s). Epimer proportions varied somewhat in different preparations.

From tetrahydropyranyl ether ***8***

Compound **8** (342 mg, 1 mmol; epimer mixture) was dissolved in MeOH (15 mL) containing AcOH (0.06 mL, 1 mmol), 1,4-cyclohexadiene (0.5 mL), and 10% Pd-C (300 mg), and was sonicated under N_2 at 45°C for 30–60 min. The formation of ninhydrin-positive amine was indicated by tlc (R_f 0.0 with solvent *K*, 0.45 with solvent *C*). Formyl acetate (0.5 mL) was then added, and the conversion of the amine into ninhydrin-negative **9** (R_f 0.5, solvent *C*) was complete after 30 min. The catalyst was filtered off and washed with MeOH, the filtrate neutralized with Et_3N, and the solvent evaporated to give crude crystalline **9**. This was taken up in a little $CHCl_3$ and applied to an SiO_2 column (2.3 × 10 cm). Elution with hexane followed by solvent *I* (100 mL) produced fast-moving impurities, and subsequent elution with solvent *G* (200 mL) gave **9** (295 mg, 86%) as a crystalline mixture of epimers (2:1 according to ^1H nmr). The mass spectral data were identical with those given in the preceding section. A partial separation of epimers was observed when a sample was rechromatographed by use of solvent *E*. A nearly homogeneous epimer crystallized on concentration of some eluate fractions and, after trituration with ether–hexane and drying, melted at 196–197°C and showed $[\alpha]_D$ −64.7 (*c* 1, $CHCl_3$). Its ^1H nmr data were identical with those given above for crystalline **9**. Both crystalline preparations contained traces of the second epimer, as indicated by very minor signals in the spectra, with the product made from **5** appearing to contain slightly more of it. This may also explain the discrepancy in the $[\alpha]_D$ values; a chromatographic fraction consisting of approximately equal proportions of the epimers (^1H nmr evidence) had $[\alpha]_D$ −5, which indicated that the second epimer must be dextrorotatory.

*1L-(1,3/2,4,6)-1,2-*O*-Isopropylidene-4-nitro-3-*O*-(tetrahydropyran-2-yl)-6-trifluoroacetamido-1,2,3-cyclohexanetriol (**10**)*

Compound **3** (774 mg, 3 mmol) was tetrahydropyranylated, and the crude epimer mixture **8** obtained was subjected to transfer hydrogenation (see the preparation of **9**), but not subsequently treated with formyl acetate. Instead, the amine-containing hydrogenolysis solution was filtered, the catalyst washed well with MeOH, and the filtrate evaporated. To a solution of the residue in CH_2Cl_2 (25 mL) was added dry pyridine (1 mL) followed by trifluoroacetic anhydride (1 mL), at 0°C. The dark olive-colored mixture was concentrated, and several portions of added EtOH were evaporated from the crystalline residue, which showed two strong spots for epimers of **10**, R_f 0.43 and 0.35, accompanied by trace spots for **8** (R_f 0.65 and 0.55) that had resisted hydrogenolysis (tlc with solvent *I*). A solution of the material in $CHCl_3$ was washed with water, dried ($MgSO_4$), and evaporated, and the product purified by chromatography on a short column of SiO_2 by use of solvent *L*. The eluted product having R_f 0.43–0.35 (solvent *I*) was recrystallized from $CHCl_3$–hexane to give **10** (508 mg, 41%), mp 199–200°C. The ^1H nmr spectrum was practically identical with that of **9**, except for the absence of the low-field formyl proton singlet, a substantial downfield shift (to δ 6.42) of the NH signal, and a minor upfield shift (to δ 4.08) of the H-6 multiplet. Mass spectrum: *m/z*: 413 ($M^+ + 1$, base peak), 397 ($M^+ + 1 - O$), 355 ($M^+ + 1 - Me_2CO$), 329 ($M^+ + 1 - C_5H_8O$ (dihydropyran)), 313 ($M^+ + 1 - O - C_5H_8O$), 271 ($M^+ + 1 - Me_2CO - C_5H_8O$). Anal. calcd. for $C_{16}H_{23}F_3N_2O_7$ (412.3): C 46.60, H 5.62, N 6.79; found: C 46.71, H 5.34, N 6.46.

*1L-(1,3/2,4,6)-4-Acetamido-1,2,3-tri-*O*-acetyl-6-(*N*-methyl)acetamido-1,2,3-cyclohexanetriol (**12**)*

A solution of **9** (170 mg, 0.5 mmol) and $LiAlH_4$ (75 mg) in dry 1,4-dioxane (10 mL) was gently boiled inder reflux for 1.5 h. Celite was added to the cooled and vigorously stirred mixture, and the excess of hydride was decomposed by slow addition of MeOH followed by some water. The solids were filtered off and washed with MeOH. The filtrate showed a strong, immobile, ninhydrin-positive spot in tlc (solvent *C*), attributed to the *O*-protected diamine **11**; starting compound **9** (R_f 0.5) was absent. After solvent evaporation the product was treated overnight at room temperature with 90% trifluoroacetic acid (2 mL) in MeOH (10 mL). The mixture was concentrated at reduced pressure, and residual acid was removed by coevaporation with benzene. The brown, amorphous product dissolved in a little water was applied to a column (1 × 10 cm) of Dowex-50W(H^+) cation exchange resin, which was exhaustively washed with water and then eluted with aqueous, 3.5 M NH_3. Evaporation of the ammoniacal eluate gave crude (+)-hyosamine (**1**) as a light-brown, amorphous material, R_f 0.25 (ninhydrin-positive, with the brown impurities travelling with the solvent front; tlc with solvent *N*). An authentic sample of 2-deoxystreptamine (**23**) spotted for comparison had R_f 0.35. A small sample of **1** was purified on a small column of SiO_2 with solvent *O*, which readily eliminated the fast-moving impurities and gave **1** as a white solid; *m/z*: 177 ($M^+ + 1$) and 161 ($M^+ - CH_3$) in agreement with the composition $C_7H_{16}N_2O_3$. The bulk of the crude **1** was treated with 1:1 Ac_2O/pyridine (2 mL) for 16 h at 25°C. Processing by addition of excess MeOH, coevaporation of the solvent with toluene, and chromatography on SiO_2 (1.2 × 25 cm, solvent *C*) gave **12** (45 mg, 23.5%), mp 156–157°C (from EtOH–Et_2O–hexane) (lit. (5) mp 156.5–157°C for the enantiomer); $[\alpha]_D$ −4.4 (*c* 1, MeOH) (lit. (4) $[\alpha]_D$ −7.5 (MeOH)). It is noteworthy that the pentaacetyl derivative of (+)-hyosamine is levorotatory, and that of (−)-hyosamine is dextrorotatory (4); ^1H nmr, δ: 5.74 and 5.66 (2d, 1H total, $J_{NH,4} \approx$ 8 Hz, NH), 5.1–4.7 (m, 3H, ill-resolved, H-1,2,3), 4.2–3.8 (m, 2H, H-4,6), 2.81 and 2.72 (broadened s and s, ratio ~3:2, total 3H, *N*-CH_3), 2.05–1.89 (multiple s, 15H, 5 Ac); *m/z*: 387 ($M^+ + 1$), 343 ($M^+ - Ac$), 327 ($M^+ + 1 - AcOH$).

*Crude 1L-(1,3/2,4,6)-1,2-*O*-isopropylidene-6-methylamino-4-nitro-3-*O*-(tetrahydropyran-2-yl)-1,2,3-cyclohexanetriol (**13**)*

A solution of **9** (295 mg, 0.85 mmol, epimer mixture) in dry THF (12 mL) containing 2.2 mol. equiv. of BH_3 (added as 1.4 mL of 1.34 M BH_3–THF complex) was boiled gently under reflux, with exclusion of atmospheric moisture. After 30 min a complete replacement of **9** (R_f 0.5) by two new products, R_f 0.8 and 0.45, was indicated by tlc (solvent *C*). (A separate pilot experiment had shown that continued boiling with additional BH_3 did not change the pattern.) Excess MeOH was carefully added to the cooled mixture, which was then evaporated, and several portions of added MeOH were evaporated from the colorless, crystalline residue of crude **13**. After thorough drying it weighed 303 mg (i.e., 20 mg in excess of the theoretical yield, presumably due to incomplete removal of boron). The ^1H nmr spectrum was poorly resolved but clearly demonstrated that the formyl group of **9** (s at δ 8.18) had been replaced by an *N*-methyl group which gave 2 doublets (*J* 5.9 and 6.1 Hz) at δ 2.69 and 2.53, in an ~2:1 intensity ratio and integrating to 3 protons. Mass spectrum, *m/z*: 331 ($M^+ + 1$, strong), 273 ($M^+ + 1 - Me_2CO$), 247 ($M^+ + 1 - C_5H_8O$ (dihydropyran)).

For personal use only.

*1L-(1,3/2,4,6)-1,2-O-Isopropylidene-6-(N-methyl)acetamido-4-nitro-3-O-(tetrahydropyran-2-yl)-1,2,3-cyclohexanetriol (**14**)*

Crude **13** (410 mg) was *N*-acetylated by treatment with Ac_2O in methanolic solution (2 h, 25°C). The solvent was evaporated, and a solution of the residue in $CHCl_3$ was washed with aqueous $NaHCO_3$ and water, dried ($MgSO_4$), and concentrated to give a crystalline mass that was inhomogeneous in tlc (solvent *H*), showing strong spots at R_f 0.75 and 0.2, and several intermediate trace spots. Column chromatography on SiO_2 (2.3 × 10 cm) yielded the less-polar (unidentified) product (120 mg) by elution with solvent *I* (200 mL), and crystalline **14** (R_f 0.2; 275 mg, 55%) by subsequent elution with solvent *G* (300 mL). End fractions containing some even more-polar material (R_f 0.1; 49 mg) were discarded. Compound **14** had mp 189–192°C (not recrystallized); ^{1}H nmr, δ: 5.13 (narrow t, H-2′), 4.68 (m, 2H, H-4,6), 4.48 (t, with small satellite t at 4.40 for epimer, $J_{2,3} = J_{3,4} = 9.7$ Hz, H-3), 3.64 (dd, $J_{1,2} = 8.8$, $J_{1,6} = 11$ Hz, H-1), 3.50 (m, 3H, H-2,6′,6″), 2.94 (s, with small satellite at 2.86, 3H, *N*-CH_3), 2.38 (m, H-5eq), 2.11 (s, 3H, Ac), 2.01 (~q, splittings 12–13 Hz, H-5ax), 1.65–1.45 (m, 6H, H-3′,3″,4′,4″,5′5″), 1.42 and 1.39 (2s, 3H each, CMe_2); *m/z*: 373 ($M^+ + 1$, base peak), 315 ($M^+ + 1 - Me_2CO$), 289 ($M^+ + 1 - C_5H_8O$), 231 ($M^+ + 1 - Me_2CO - C_5H_8O$); in accord with mol. wt. 372 for $C_{17}H_{28}N_2O_7$.

*1L-(1,3/2,4,6)-4-Acetamido-1,2-O-isopropylidene-6-(N-methyl)-acetamido-3-O-(tetrahydropyran-2-yl)-1,2,3-cyclohexanetriol (**15**)*

A solution of nitro compound **14** (268 mg, 0.72 mmol) in 99% EtOH (25 mL) was shaken with PtO_2 (227 mg, 1 mmol) under H_2 at ordinary pressure and room temperature. The required volume of H_2 (94 mL; calcd., 93 mL) was consumed overnight, and the solution showed a positive ninhydrin reaction. Acetic anhydride (1.5 mL) was added, and after 15 min the ninhydrin test was negative. The catalyst was filtered off and washed exhaustively with EtOH, and the evaporated filtrate gave a gel-like residue that showed **15** as a slow-moving (solvent *C*) or immobile (EtOAc) spot in tlc, and a contaminant migrating with the solvent front, but **14** (R_f 0.7 and 0.6, respectively) was absent. Chromatography on SiO_2 (2.3 × 10 cm) by elution with EtOAc (100 mL, to remove the nonpolar impurity) followed by solvent *M* furnished **15** as a colorless syrup that failed to crystallize and was dried on the oil pump to a hard glass (280 mg, quantitative); ^{1}H nmr, δ: 2.88 and 2.80 (2s, intensity ratio 2:1, total 3H, *N*-CH_3), 2.15–1.90 (multiple s, total 6H, 2Ac); each of the *N*-CH_3 signals was accompanied by a minor satellite at slightly lower field, probably due to 2′-epimerism. Mass spectrum, *m/z*: 385 ($M^+ + 1$), 327 ($M^+ + 1 - Me_2CO$), 301 ($M^+ + 1 - C_5H_8O$, base peak), 243 ($M^+ + 1 - Me_2CO - C_5H_8O$).

*1L-(1,3/2,4,6)-6-Acetamido-4-amino-1,2-O-isopropylidene-1,2,3-cyclohexanetriol (**16**)*

Nitro compound **6** (274 mg, 1 mmol) was dissolved in 99% EtOH (20 mL) containing AcOH (0.06 mL) and hydrogenated over Adams catalyst (114 mg of PtO_2, 0.5 mmol) at ambient temperature and pressure. After 18 h, the calculated volume (90 mL) of H_2 was consumed, and tlc showed a strong ninhydrin-positive spot (R_f 0.3) for **16**, while **6** (R_f 1.0) was absent (solvent *A*, double irrigation). The catalyst was washed exhaustively with EtOH, and evaporation of the filtrate gave syrupy **16** that was dried *in vacuo* to a colorless, hard glass (240 mg, 98%), homogeneous in tlc; *m/z*: 245 ($M^+ + 1$, base peak), 187 ($M^+ + 1 - Me_2CO$). It was used without further characterization for the preparation of **22**.

*Attempted preparation of the formamidotrifluoroacetamido derivative **18***

The nitrotrifluoroacetamido **10** (0.50 g) was hydrogenated over PtO_2 (0.1 g) as just described for the hydrogenation of **6**. Hydrogen uptake was very slow, and only a trace of ninhydrin-positive product was seen after 16 h (tlc with solvents *I* and *C*). Hydrogenation was continued for 6 days, with additions of fresh catalyst (3 × 0.1 g), after which reduction was still far from complete. Catalyst and solvent were removed, and the procedure was repeated with fresh catalyst for another 4 days, without satisfactory progress. Work-up then gave a crystalline but inhomogeneous material (tlc) containing some amine (ninhydrin test), which was *N*-formylated in MeOH solution (15 mL) with formyl acetate (1 mL) during 3 h. The processed mixture was chromatographed on SiO_2. Elution with solvent *I* produced unchanged **10** (173 mg, 34% recovery, mp 199–200°C), and subsequent elution with solvents *G*, *F*, and EtOAc gave three fractions of products having R_f 0.6 (31 mg), 0.3 (176 mg), and 0.2 (double spot; 116 mg) in tlc with solvent *H*. One of them may have been **18** but the matter was not pursued.

*1D-(1,3/2,4,6)-4-Acetamido-1,2,3-tri-O-acetyl-6-(N-methyl)acetamido-1,2,3-cyclohexanetriol (**22**) from **16***

Amine **16**, obtained as a glassy foam (~290 mg) by hydrogenation of **6** (330 mg, 1.2 mmol), was pulverized and suspended in 1,4-dioxane (25 mL) to which 2,3-dihydropyran (500 mg, 6 mmol) and *p*-TsOH · H_2O (250 mg, 1.3 mmol) were added. The mixture was stirred at room temperature, and DMF (2 mL) was added after 0.5 h to aid in dissolving the starting material; after 2 h the clear solution appeared free from **16** (R_f 0.2) and showed a strong spot for its 3-THP ether **19** (R_f 0.8, plus a weak spot at R_f 0.7 attributed to the 2′-epimer; tlc with solvent *A* and ninhydrin indication). The mixture was made slightly basic with Et_3N, and evaporated, with residual DMF being eliminated by coevaporation with toluene. The dry residue was purified on a column of SiO_2 (2.2 × 13 cm), which was irrigated first with $CHCl_3$ (to remove a yellow, fast-moving impurity) and then with solvents *D* (100 mL) and *A* (200 mL), to furnish ninhydrin-positive fractions that gave **19** (329 mg, 83.6% based on **6**) as a glassy foam; *m/z*: 329 ($M^+ + 1$) and 245 ($M^+ + ″\tau + + - C_5H_8O$ (dihydropyran)) in harmony with the composition $C_{16}H_{28}N_2O_5$.

The crude **19** (328 mg, 1 mmol) in CH_2Cl_2 (10 mL) was treated overnight at 25°C with *N,N*-dimethylformamide dimethyl acetal (0.2 mL). Solvent evaporation gave a pale yellow syrup presumed to contain the *N,N*-dimethylformamidine **20**; *m/z*: 384 ($M^+ + 1$, base peak). The syrup was redissolved in CH_2Cl_2 (10 mL) and treated overnight at 25°C with methyl trifluoromethanesulfonate (0.17 mL, 1.5 mmol) to generate the *N,N,N′*-trimethylformamidinium salt **21**. The mixture was evaporated to a syrup that was immediately boiled under reflux for 1.5 h with 6 M HCl (10 mL). The dark-colored hydrolyzate containing some tarry decomposition products was diluted with water and extracted with $CHCl_3$, which took out much of the color. The clear yellow aqueous phase was evaporated to give a brownish, crystalline residue of aminocyclitol hydrochlorides, R_f 0.3–0.4 (double spot; tlc with solvent *N*). The faster spot migrated like authentic 2-deoxystreptamine (**23**) spotted for comparison, and the slower one was attributed to (−)-hyosamine (**2**). Dissolved in a little aqueous MeOH, the material was applied to a small column of Dowex-50W(H^+) resin (~10 mL). Rinsing with MeOH and water eluted the brown impurities, and subsequent elution with 5% aqueous NH_3 produced the amines, without separation. The residue obtained by evaporation of the ammoniacal eluate was dried in a desiccator and then treated with Ac_2O and pyridine (16 h, 25°C). Processing by coevaporation of the reagents with added toluene gave a syrupy mixture of peracetyl derivatives **22** (R_f 0.4, like **12**) and **24** (R_f 0.3, migrating like an authentic sample; tlc with solvent *C*). Note that the relative mobilities were reversed in comparison to unprotected **2** and **23**. Column chromatography (SiO_2, 2.3 × 15 cm; solvent *D*) of the mixture yielded **22** (77 mg, 20% based on **19**) and **24** (52 mg, 14%), both as fine colorless needles from EtOH–Et_2O–hexane.

Compound **22** had mp 156–157°C as reported (5); $[\alpha]_D$ +4.6 (*c* 1, MeOH) (lit. $[\alpha]_D$ +5.4 (4) and +7.5 (5)); *m/z*: 387 ($M^+ + 1$, base peak), 373 ($M^+ + 2 - Me$), 345 ($M^+ + 2 - Ac$), 327 ($M^+ + 1 - AcOH$), 254 ($M^+ + 1 - AcNH_2 - AcNHMe$). The ^{1}H nmr spectrum was indistinguishable from that of **12**.

Compound **24** had mp 318–321°C (lit. (15) mp 322–323°C); $[\alpha]_D$ 0 (*c* 2, MeOH); ^{1}H nmr (2-deoxystreptamine numbering), δ: 5.68 (br d,

2H, NH-1,3), 5.23 (t, $J_{4,5} = J_{5,6} = 9.8$ Hz, H-5), 4.88 (t, 2H, splitting ~ 10 Hz, H-4,6), 4.17 (m, 2H, H-1,3), 2.42 (m, H-2eq), 2.03 (s, 6H, AcO-4,6), 1.99 (s, 3H, AcO-5), 1.90 (s, 6H, AcNH-1,3), 1.38 (m, H-2ax); *m/z*: 373 ($M^+ + 1$, base peak), 359 ($M^+ + 2 -$ Me), 331 ($M^+ + 2 -$ Ac), 313 ($M^+ + 1 -$ AcOH), 254 ($M^+ + 1 - 2AcNH_2$).

1L-(1,3/2,4,6)-6-Ethoxycarbonylamido-4-formamido-1,2-O-isopropylidene-1,2,3-cyclohexanetriol (25)

Platinum dioxide (550 mg) suspended in 99% EtOH (20 mL) containing AcOH (0.17 mL) was prehydrogenated, nitrocarbamate **7** (600 mg, 2 mmol) in EtOH (10 mL) was added, and the mixture vigorously shaken under H_2 at ambient temperature and pressure. After 30 h, **7** (R_f 0.5) was completely replaced by the corresponding amine, which gave an immobile, ninhydrin-positive spot (tlc with solvent *C*). The H_2 supply was disconnected, the mixture cooled (0°C), and formyl acetate (3 mL) was introduced, after which the mixture was stirred for 2 h at room temperature. Thin-layer chromatography then showed almost complete replacement of the amine spot by a single spot for **25**, R_f 0.15. Filtration and evaporation of the solution, with several additions of fresh EtOH, gave **25** as colorless crystals (460 mg, 76%). An analytical sample was freed from a trace of impurity (immobile) by passage through an SiO_2 column with $CHCl_3$ containing 3% of MeOH. Pure **25** had R_f 0.45 (solvent *B*), mp 127–129°C; $[\alpha]_D$ +6.1 (*c* 0.9, $CHCl_3$); ν_{max} ($CHCl_3$): 3300 (br, OH and NH), 1678 and 1543 (amide I and II) cm^{-1}; ^1H nmr (acetone-d_6) δ: 8.13 and 8.03 (slightly broadened s, and d with J = 12 Hz, intensity ratio ~4:1, 1H total, formyl), 7.3 and 6.7 (d with J = 7 and t with J = 11 Hz, both broadened, ratio 4:1, 1H total, formamido NH), 6.4 (br t, carbamate NH), 4.7 and 4.5 (2d with J = 4.7 Hz, ratio 1:4, total 1H, OH-3), 4.01 (q, 2H, OCH_2), 3.9–3.8, 3.7, 3.5–3.4 (3m, ill-resolved, 2, 1, and 2H, H-1,2,3,4,6), 2.24 (dt, $J_{4,5eq} = J_{5eq,6} = 4.5$ Hz, $J_{5ax,5eq} = 13.2$ Hz, H-5eq), 1.47 (~q, splittings 11–13 Hz, H-5ax), 1.36 and 1.33 (2s, 3H each, CMe_2), 1.16 (t, 3H, J = 7.1 Hz, ethyl CH_3). Upon D_2O exchange the NH and OH signals disappeared and the small doublet at δ 8.03 collapsed to a singlet while the broadened singlet at δ 8.13 became sharp; ^{13}C nmr (50.3 Mz, acetone-d_6), for the major rotamer, δ: 161.8 (formamido CO), 156.3 (carbamate CO), 110.7 (O_2CMe_2), 81.7, 79.0, 73.2, (C-1,2,3) 60.2 (OCH_2), 51.4, 49.4 (C-4,6), 36.2 (C-5), 26.6 and 26.5 (CMe_2), 14.3 (ethyl CH_3); small signals for the minor rotamer, δ: 164.8 (formamido CO), 110.9 (O_2CMe_2), satellites to above C-1,2,3 and C-5 signals, and 55.0 (presumably C-4). Mass spectrum, *m/z*: 303 ($M^+ + 1$, base peak), 258 ($M^+ + 1 -$ OEt), 285 ($M^+ + 1 - H_2O$), 245 ($M^+ + 1 - Me_2CO$), 227 ($M^+ + 1 - H_2O - Me_2CO$). Anal. calcd. for $C_{13}H_{22}N_2O_6$ (302.3): C 51.65, H 7.34, N 9.27; found: C 51.48, H 7.54, N 9.14.

1L-(1,3/2,4,6)-6-Ethoxycarbonylamido-1,2-O-isopropylidene-4-methylamino-1,2,3-cyclohexanetriol (26), and acetylated derivatives **27**, **29**, and **30**

A solution of **25** (653 mg, 2.15 mmol) in THF (10 mL, dried over Na) was added dropwise during 5 min to 1 M borane in THF (5 mL), maintained at 0°C under N_2 in a flask equipped with dropping funnel, reflux condenser, and gas inlet. The colorless solution was then heated at reflux for 5 h, under N_2. Replacement of **25** (R_f 0.2) by a ninhydrin-positive product (R_f 0.55) was seen in tlc (solvent *P*). The mixture was cooled to 25°C, a few drops of water were added, and a stream of CO_2 was passed through for 20 min. Evaporation of the solvent followed by evaporation of six portions of MeOH sequentially added to the syrupy residue gave crude **26**. Chromatographic purification (SiO_2, 2 × 20 cm) using solvent *Q* furnished pure **26** as a colorless, brittle glass (218 mg, 35%); ^1H nmr, δ: 4.09 and 1.22 (q, 2H, and t, 3H, respectively, J = 7.1 Hz, OCH_2CH_3), 2.60 and 2.44 (2d, J = 6.1 and 5.9 Hz, intensity ratio 1:1.2, 3H total, N-CH_3), 1.42 (s, 6H, CMe_2). The ^{13}C nmr spectrum showed, near most resonances, a second resonance (given in brackets) of 70–95% intensity; δ: 156.0 (CO), 112.2 [112.3] (O_2CMe_2), 80.5 [80.6], 78.5 [78.3], 69.7 [69.1] (C-1,2,3), 63.1 [63.9] (C-4), 61.2 (OCH_2), 49.2 [49.1] (C-6), 42.5 [42.6] (N-CH_3), 27.7 [27.55] (C-5), 26.7 (CMe_2), 1.44 (ethyl CH_3). Mass spectrum, *m/z*: 298 ($M^+ + 1$). Anal. calcd. for $C_{13}H_{24}N_2O_5 \cdot 0.5H_2O$ (297.4): C 52.51, H 8.47, N 9.42; found: C 52.40, H 8.63, N 9.19.

Further elution of the chromatographic column gave a fraction (268 mg, 43%) consisting apparently of **26** (major component) and its product of deacetonation (**28**). This mixture was acetylated by overnight treatment with 1:1 Ac_2O/pyridine (8 mL) at room temperature. After processing by dilution with CH_2Cl_2, washing of the solution with water, aqueous $NaHCO_3$, and water, drying (Na_2SO_4), and evaporation with added portions of toluene, a colorless syrup that failed to crystallize was obtained. It showed two spots, R_f 0.8 (major) and 0.95 (minor) in tlc (solvent *P*), and spectroscopic examination suggested that the material consisted mainly of the *N,O*-diacetyl derivative (**27**) of **26**, accompanied by a small proportion of the *N,O,O,O*-tetraacetyl derivative (**30**) of **28**. Thus, the ^1H nmr spectrum exhibited substituent resonances for carbamate OCH_2CH_3 (m at δ 4.09 and 1.22, intensity ratio 2:3), the N-CH_3 group (s at δ 2.89, 2.83, and 2.74, ratio 1:2:1, 3H total), the *N*- and *O*-acetyl groups (multiple singlets at δ 2.12–1.96), and the acetonide CH_3 groups (s at δ 1.43 and 1.41). Integration for the total of acetyl signals was somewhat greater than 6H, whereas it was somewhat less than 6H for the acetonide CH_3 groups. The ^{13}C nmr spectrum (ADEPT plot) showed CH_3 resonances (δ) for CH_3CH_2O (14.5), $OCOCH_3$ (20.9–20.4), $NCOCH_3$ (22.15–22.1), $O_2C(CH_3)_2$ (26.7–26.4), and N-CH_3 (32.0). The mass spectrum showed prominent peaks for **27** at *m/z* 373 (54%, $M^+ + 1$), 315 (100%, $M^+ + 1 - Me_2CO$), and 269 (12%, $M^+ + 1 - Me_2CO -$ EtOH) in accord with the composition $C_{17}H_{28}N_2O_7$, and small peaks for **30** at *m/z* 417 (9%, $M^+ + 1$) and 357 (2%, $M^+ + 1 -$ AcOH) in agreement with $C_{18}H_{28}N_2O_9$. Column chromatography with solvent *F* failed to separate the products.

1D-(1,3/2,4,6)-4-Ethoxycarbonylamido-6-(N-methyl)acetamido-1,2,3-cyclohexanetriol (**29**) was obtained when a sample of pure **26** was treated overnight at room temperature with 50% aqueous AcOH, whereby **26** (R_f 0.55) was converted into a product having R_f 0.1 (tlc, solvent *P*). The acid was evaporated with several additions of toluene and the syrupy **29** dried in a oil-pump vacuum over KOH; ^1H nmr (DMSO-d_6), δ: 6.19 (d, J = 8.5 Hz, carbamate NH), 3.96 (q, 2H, J = 7.1 Hz, OCH_2), 3.20 (m, $W \approx 35$ Hz, H-4), 3.1–2.9 (m, 3H, narrowed on D_2O exchange, H-1,2,3), 2.29 (s, 3H, NCH_3; superposed on m for H-6), 1.92 (dt, $J_{4,5eq} \approx J_{5eq,6} \approx 12.7$ Hz, H-5eq), 1.87 (s, 3H, *N*Ac), 1.15 (t, 3H, J = 7.1 Hz, ethyl CH_3), 0.99 (~q, splittings ≈ 12.3 Hz, H-5ax); ^{13}C nmr (DMSO-d_6, ADEPT plot), δ: 173.1 (amide CO), 156.2 (carbamate CO), 76.5 (C-2), 74.4 (double line seen on expansion, C-1,3), 59.8 (OCH_2), 58.9 (C-6), 51.5 (C-4), 32.6 (NCH_3), 31.9 (C-5), 22.3 (*N*Ac), 14.9 (ethyl CH_3).

1D-(1,3/2,4,6)-4-Acetamido-1,2,3-tri-O-acetyl-6-(N-methyl)acetamido-1,2,3-cyclohexanetriol (22) from **26**

A 30-mg sample of the mixture of acetylated compounds **27** (major componnt) and **30** obtained from **26** as described was heated for 2 h on a steam bath in 6 M HCl (2 mL). After dilution with water, the acid was evaporated *in vacuo* and the residue dried in a desiccator over KOH. The ^{13}C nmr spectrum (D_2O) indicated that the acetonide and all acetyl groups were cleaved off but the carbamate group was retained; δ: 158.1 (CO), 74.9, 73.5, 71.5 (C-1,2,3), 61.7 (OCH_2), 57.2, 50.6 (C-4,6), 29.6 (NCH_3), 27.5 (C-5), 13.6 (ethyl CH_3). To the aqueous solution of the product was added an equal volume of 4 M NaOH, the mixture was heated for 3 h on a steam bath, cooled, neutralized with AcOH, and evaporated to dryness. The white mass of NaCl, NaOAc, and **2** (in salt form) was dried in a desiccator, then covered with Ac_2O (3 mL), and agitated overnight at room temperature. Removal of the anhydride by repeated coevaporation with toluene, extraction of the desiccator-dried salt mass with $CHCl_3$, and evaporation of the colorless extract gave **22**, which crystallized from a small amount of EtOH upon careful addition of Et_2O and hexane, and storage at −18°C; yield, 18 mg (60%); mp 157–158°C (lit. (5) mp 156.5–157°C); $[\alpha]_D$ +6.8 (*c* 1.8, MeOH) (lit. $[\alpha]_D$ +7.5 (5) and +5.4 (4)); *m/z*: 387 ($M^+ + 1$, base peak), 373 ($M^+ + 2 -$ Me), 345 ($M^+ + 2 -$ Ac), 327 ($M^+ + 1 -$ AcOH). For personal use only.

^{1}H nmr data (200 MHz) were the same as for **12** and for **22** prepared from **16**, except that the stronger of the two *N*-CH_3 signals (previously seen as a broadened singlet at δ 2.81) appeared as separate singlets at δ 2.84 and 2.81.

The dual pathway in photocycloaddition of 1,3-diketonatoboron difluorides: excimer reactions

YUAN L. CHOW AND XIANEN CHENG
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6
Received December 20, 1990

YUAN L. CHOW and XIANEN CHENG. Can. J. Chem. **69**, 1575 (1991).

The lowest singlet excited state of dibenzoylmethanatoboron difluoride $DBMBF_2$, a model compound of the BF_2 complexes of 1,3-diketones, reacted with various simple olefins to give regiospecific and stereospecific photocycloadducts of 1,5-diketones similar to those from the de Mayo type reaction. $DBMBF_2$ in acetonitrile exhibited two discrete fluorescences at 398 and 416 nm for the monomer and at 522 nm for the excimer; they were both quenched, but in different proportions, by a simple olefin. An "oxygen test" showed that the excimer of $DBMBF_2$ is formed irreversibly in acetonitrile. The quantum yields of the photocycloaddition were shown to be proportional not only to olefin concentrations but also to $DBMBF_2$ concentrations. Kinetic analysis has established that the total quantum yield is the sum of those arising from the interactions of the singlet excited $DBMBF_2$ and its excimer, respectively, with an olefin, i.e., the sum of the quantum yields of exciplex and triplex pathways. The contributions from the two pathways are determined by the type of olefins and the range of $DBMBF_2$ concentrations. For endocyclic olefins, the triplex pathway is more important and the corresponding photocycloaddition becomes very efficient as soon as the excimer starts to form in $[DBMBF_2] > 0.001$ M. For the monosubstituted olefins, on the contrary, the exciplex pathway is always more important than the triplex pathway; they react primarily from the singlet excited state of $DBMBF_2$.

Key words: singlet state photocycloaddition, irreversible excimer formation, excimer cycloaddition, triplex and exciplex reactions.

YUAN L. CHOW et XIANEN CHENG. Can. J. Chem. **69**, 1575 (1991).

L'état excité singulet le plus bas du difluorure de dibenzoylméthanatobore ($DBMBF_2$, un composé modèle des complexes du BF_2 avec les 1,3-dicétones) réagit avec diverses oléfines simples pour donner des photocycloproduits régiospécifiques et stéréospécifiques de 1,5-dicétones semblables à ceux obtenus lors des réactions observées par de Mayo. Dans l'acétonitrile, le $DBMBF_2$ présente deux bandes discrètes de fluorescence à 398 et à 416 nm pour le monomère et à 522 nm pour l'excimère; elles sont toutes les deux désactivées, mais à des degrés différents, par une oléfine simple. Un «test à l'oxygène» démontre que l'excimère du $DBMBF_2$ se forme d'une façon irréversible dans l'acétonitrile. On a démontré que les rendements quantiques de photocycloaddition ne sont pas seulement proportionnels aux concentrations d'oléfine mais aussi aux concentrations de $DBMBF_2$. Une analyse cinétique a permis d'établir que le rendement quantique total est égal à la somme de ceux résultant des interactions respectives de l'état excité singulet du $DBMBF_2$ et de son excimère avec une oléfine, soit la somme des rendements quantiques des voies impliquant l'exciplexe et l'état triplet. On a déterminé les contributions de ces deux voies par types d'oléfines et par plages de concentrations de $DBMBF_2$. Pour les oléfines endocycliques, la voie impliquant l'état triplet est plus importante et la photocycloaddition correspondante devient très efficace aussitôt que l'excimère commence à se former lorsque $[DBMBF_2] > 0{,}001$ M. Au contraire, pour les oléfines monosubstituées, la voie impliquant l'exciplexe est toujours plus importante que celle impliquant l'état triplet; elles réagissent principalement à partir de l'état excité singulet du $DBMBF_2$.

Mots clés : photocycloaddition par l'état singulet, formation irréversible d'un excimère, cycloaddition par un excimère, réactions des excimères et des états triplets.

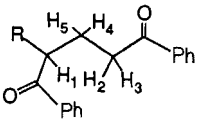
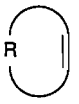
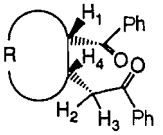
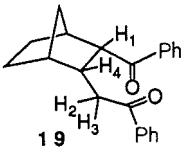
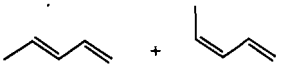
Introduction

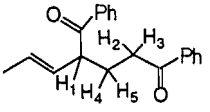












In a preliminary communication (1) we summarized various types of photoreactions displayed by dibenzoylmethanatoboron difluoride ($DBMBF_2$), a representative of the BF_2 complexes of 1,3-diketones; they involve photocycloaddition with olefins, sensitization of electron-rich olefins by electron transfer to form cation radicals, exciplex–excimer formations, and subsequent reactions therefrom. It was proposed that these photoreactions could be related to some degree of single electron transfer in the interaction of the singlet excited $DBMBF_2$ with substrates in which the former acted as an electron acceptor. We wish to describe the synthetic and mechanistic details of the [2 + 2] photocycloaddition of $DBMBF_2$ with simple olefins and the subsequent formation of 1,5-diketones, in which the role played by the $DBMBF_2$ excimer (2) is demonstrated by kinetic studies.

The [2 + 2] photocycloaddition (3–8) of β-diketones (from their enol form) with simple olefins is generally known as the de Mayo reaction (3) and has been suggested to take place from the triplet state of β-diketones (7). While this reaction is a very efficient methodology to construct carbon skeletons, it suffers from low quantum efficiencies. However, published results show that chemical yields are reasonable with long irradiation. The photocycloaddition described here, while it displays similar product patterns to the de Mayo reaction, involves the singlet excited state of $DBMBF_2$ and gives much higher quantum efficiency.

In the enol form, β-diketones are excellent ligands to form chelate complexes with all types of metal ions. While these metal β-diketonates show relatively few irreversible photochemical reactions, they do undergo efficient electron transfer reactions with excited state ketones (9). In aprotic solvent, β-diketones react rapidly with boron trifluoride to form tetracoordinated chelate complexes of boron difluorides that have been known for almost 65 years (10–19). Recently such BF_2 complexes have been patented as latent catalysts for epoxy resin polymerization (20, 21) and photoconducting sensitizers in polymeric films (22, 23). However, the extent of actual commercial applications is obscure. It has been suggested that the BF_2 complexes of β-diketones are good electron accep-

[e]By GC–MS, three minor isomers (11%, <3%, and <3%) were recorded.

tors and can find their applications in photoimaging processes (22). Indeed such BF_2 complexes were shown to have lower reduction potentials (11) and more efficient fluorescence (2, 15–19) than the parent β-diketones.

Results

Photocycloadditions

The photocycloaddition of $DBMBF_2$ to acyclic olefins **1–3** was regiospecific, giving a single product **11–13** in each case (Table 1). Their structures were readily determined from their GC–MS, IR, and ^{13}C and ^1H NMR spectroscopic data as 1,5-diketones (see Tables 7–10, supplementary material).[1]

[1]Tables 7–10, which contain IR, GC–MS, and ^1H and ^{13}C NMR data of the products, may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

The alternative regio-isomers could not be detected by GC–MS of the photolysates; if formed, they could be detected by GC in yields as low as 3% and would be readily recognized from their NMR spectra owing to their symmetry element. The photocycloaddition to cyclic olefins **4–8** also occurred just as efficiently to yield a single product in each case except that of cyclopentene, in which case 10% of the minor product was obtained in addition to the major product **14**. As **14** was shown to have the *cis* configuration, both from the vicinal coupling constant of the neighbouring methine protons (6.8 Hz) (23) as well as the consequence of a 5–4 ring fusion in the intermediate stage **21** (see Discussion), we assume the unisolated isomer to be the *trans* isomer derived from an acid-catalyzed isomerization of **14** during isolation. Indeed the GC peak of this minor *trans* isomer increased if a longer time elapsed in the isolation processes. While the stereochemistry of *vic*-disubstituted

TABLE 2. Experimental and computed vicinal coupling constants of the methine protons in 1,5-diketones **14–18**

Cycloadducts	Ring size	*J* values (Hz)		
		trans (calcd.)	*cis* (calcd.)	Found
14	5	11.9	7.2	6.8
15	6	12.2	3.7	6.8
16	7	10.5	6.3	3.8
17	8	11.8	5.5	4.2
18	8	11.7	2.8	4.0

diketones **14** and **15** could be judged to be *cis* orientation from the relevant ^1H coupling constant (23) of 6.8 Hz, that of higher member cycloalkanes **16–18** could not readily be decided. Therefore, the stereochemistry of diketone substituted cycloalkanes **14–18** was examined by calculating the vicinal coupling constants for *cis* and *trans* orientation using MM-2 minimized structures (24, 25). In the calculations, the effects of the dihedral angle of the substituted vicinal protons as well as the polar interactions of the substituents were taken into consideration to arrive at the calculated values shown in Table 2. As the observed values are much closer to the calculated values of the *cis* orientation than those of the *trans* orientation, we concluded that our products **14–18** possessed the *cis* configuration.

The major product from the photocycloaddition to norbornene was assigned to the *cis,endo* configuration as in **19** because of two observations, namely, (i) irradiation of H1 caused >20% enhancement of H4 and the *syn* bridge proton (26) and (ii) the *anti* bridge proton was not coupled to H1 and H4, as shown by decoupling experiments. The minor isomer (10%) was not obtained by an acid treatment of **19**, as shown by the GC monitor. This led us to suggest the unisolated minor product as the *cis,exo* isomer corresponding to **19**. The *cis,exo* isomer showed a very strong *m/e* 251 fragment arising from the McLafferty rearrangement followed by the loss of a cyclopentenyl moiety. In contrast, the *cis,endo* isomer **19** could not easily lose a cyclopentenyl moiety, but showed the alternative *m/e* 213 fragment arising from the facile loss of a C_6H_5CO moiety; the detailed mechanism is described in the Ph.D. thesis (27) submitted by one of us.

The photocycloaddition of $DBMBF_2$ to 1,3-pentadiene was an exception since similar irradiation processes in the presence of other electron-rich dienes (cyclohexadiene and 2,4-dimethyl-1,3-pentadiene) caused sensitization without cycloaddition (1). In this reaction, four 1:1 photoaddition products were obtained, as shown by GC–MS; two of them were in trace amounts (<3%, by GC) and probably regioisomeric to the other two. The two major products, **20** (*trans* isomer) and its *cis* isomer, were obtained in 32 and 11% yield, respectively, but could not be obtained in a pure state. The former showed that the CH_3 protons had allylic coupling of 1.8 Hz, much bigger than that of 1.0 Hz for the latter; this provided the rationale (23) for the assignment of the *trans* orientation to **20**.

Under the photolysis conditions used above, $DBMBF_2$ failed to react with 1-methylcyclohexene; careful GC examinations during photolysis showed that the starting materials were not consumed.

TABLE 3. The quantum yields of the photocycloaddition of $DBMBF_2$ (0.01 M) to olefins (1.0 M) in CH_3CN[a]

Olefin	IP (eV)	Quantum yields[b]
3,3-Dimethyl-1-butene (**3**)	9.45	0.18 (0.12)[c]
1-Hexene (**1**)	9.36	0.28
1,5-Hexadiene (**2**)	9.29	0.38
Cyclohexene (**5**)	8.94	0.03
Cycloheptene (**6**)	8.87	0.12 (0.20)[c]

[a]CH_3CN solutions (5 mL) containing each olefin were irradiated in a merry-go-round.
[b]Standard deviations of 6%.
[c]These two figures are obtained at $[DBMBF_2] = 0.07$ M.

Quantum yields

The quantum yields of the product formations (Φ) of $DBMBF_2$ photocycloaddition to several olefins (1.0 M) were measured in a carousel under identical conditions for comparison. The quantum yields were essentially the same for nitrogen-purged or unpurged solutions, but were reduced drastically by the addition of quadricyclene. In agreement with this observation, it is noted that $DBMBF_2$ fluorescence was not reduced in the presence of oxygen (air). As shown in Table 3, for two separate series of monosubstituted acyclic and disubstituted cyclic olefins, Φ was higher for olefins with lower ionization potentials. Subsequently, the quantum yields of the product formations for 3,3-dimethyl-1-butene (**3**) and cycloheptene (**6**) were determined over the range of olefin concentrations [O] $\approx$ 0.05–1.00 M at $[DBMBF_2] = 1.0 \times 10^{-2}$ M; the usual Stern–Volmer plots of $1/\Phi$ vs. reciprocals of olefin concentrations (Fig. 1) gave the experimental quenching rates ($= k_q\tau_0$ = intercept/slope) of 0.38 M^{-1} for **3** and 5.13 M^{-1} for **6**, respectively (Table 4).

The quantum yields of the product formations for the photocycloaddition at increasing concentrations of $DBMBF_2$ over the range 0.01–0.07 M were determined in the presence of a fixed initial concentration of an olefin (1.0 M). Taking the Φ value at $[DBMBF_2] = 0.01$ M as the reference point, Φ/Φ_0 at various $[DBMBF_2]$ were plotted as shown in Fig. 2. For cyclic olefins **5**, **6**, and **7** the ratio characteristically increased with increasing $[DBMBF_2]$ as opposed to the decreasing trend exhibited by acyclic olefin **3**.

Fluorescence quenching

In the concentration range of $[DBMBF_2]$ 10^{-6}–10^{-2} M in CH_3CN, $DBMBF_2$ fluoresces (2) with two peaks at 398 and 416 nm from its monomeric excited state; the former becomes progressively weaker at higher concentration, registering only the latter emission peak at $[DBMBF_2]$ 10^{-3}–10^{-2} M. To eliminate internal filter effects, the fluorescence spectra were taken with a "front-face" configuration for those solutions with $[DBMBF_2] > 10^{-4}$ M. The emission intensities of these two peaks at a fixed $DBMBF_2$ concentration were reduced successively in the presence of increasing amounts of an olefin. The quenching of $DBMBF_2$ fluorescence by **3** was expressed by Stern–Volmer plots (I_0/I vs. concentrations of olefins) in Fig. 3. It was noted that the I_0/I points monitored at either 398 or 416 nm were correlated by a single straight line, and that the slopes ($=$ experimental $k_x\tau_0'$) decreased when quenching experiments were carried out at higher $DBMBF_2$ concentrations (Table 4). Similar patterns were observed for $DBMBF_2$ fluo-

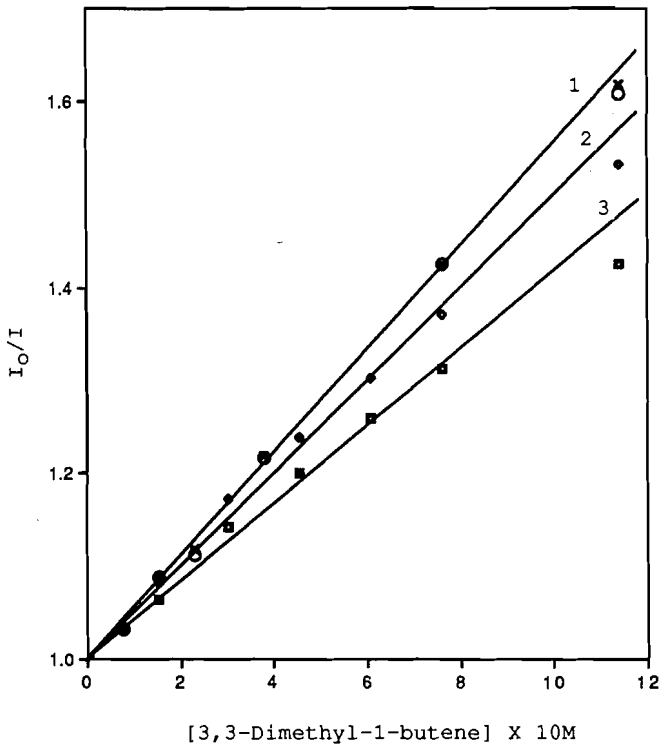
[c]The $k_q\tau_0$ was obtained from the monitor of cycloaddition quantum yields.

rescence quenching at 398 and 416 nm by cycloheptene, **6**. The decreases of slopes (= $k_x\tau_0'$) (in Table 4) were small, about 10% with 5000-fold decrease in $DBMBF_2$ concentration, but reproducible.

Taking advantage of the fact that in the region of [$DBMBF_2$] $> 5 \times 10^{-2}$ M a well-separated broad excimer fluorescence band could be observed (2), the possibility of the interaction of the excimer with olefins was investigated. From time-resolved fluorimetry,[2] the lifetime of the excimer was shown to be 50 ns in acetonitrile, more than an order of magnitude higher than the monomer lifetime. This suggested that the excimer was formed by an irreversible process, which was also supported by an "oxygen test" (28, 29); excimer fluorescence intensities were significantly reduced by oxygen in the presence of air while $DBMBF_2$ fluorescence remained unaffected. There are many cases of interactions of exciplexes or excimers with a substrate leading to termolecular photochemical and photophysical phenomena (30–39). Steady-state exciplex (excimer) fluorescence quenching has been analysed by Medinger and Wilkinson (30) as well as by Caldwell and coworkers (31–33) to follow a simple Stern–Volmer relation if the corrected intensity ratios of exciplex (excimer) fluorescence, $I_0(ex)/I(ex) \div I_0(mono)/I(mono)$, are plotted against quencher concentrations, where $I_0(ex)$ and $I_0(mono)$ are the exciplex (excimer) and monomer intensities in the absence of the quencher, i.e., [Q] = 0. The excimer intensities at 522 nm in the presence (I) and absence (I_0) of an olefin at the same $DBMBF_2$ concentration were used to calculate the quenching by the olefin (Fig. 4). Owing to the fact that the fluorescence intensity (i.e., concentration) of the excimer varies drastically in this $DBMBF_2$ concentration range, the latter reading (I') was obtained by normalizing with respect to the peak height at the 437-nm fluorescence peak (dashed curves); this peak corresponds to the monomer fluorescence at 416 nm observed in dilute solutions, which was red-shifted with the appearance of the excimer peak. This experimental manoeuvre essentially normalized excimer intensities to constant monomer intensity,

[2]J. Korppi-Tommola. University of Jyväskylä, Finland. Unpublished results.



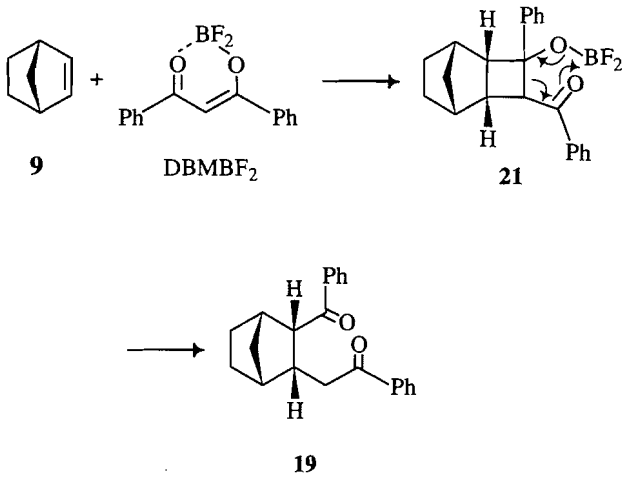


FIG. 3. Stern–Volmer plots of the quenching of $DBMBF_2$ fluorescence by 3,3-dimethyl-1-butene (**3**) in CH_3CN: plot 1, $[DBMBF_2] = 5 \times 10^{-6}$ M, and monitored at 398 and 416 nm; plots 2 and 3, $[DBMBF_2] = 10^{-3}$ and 10^{-2} M, and monitored at 416 nm.

i.e., I' is equivalent to the term of $I_0(\text{ex}) \div I_0(\text{mono})/I(\text{mono})$ (31). The plot of I'/I for cycloheptene revealed that the quenching efficiency of the excimer as represented by the slope was $k_t\tau_m = 6.77\ M^{-1}$ if the point of [**6**] = 0.329 M was ignored; at this high concentration, extensive quenching caused a large margin of error due to weak excimer emission. Under the same procedure, it was shown that the excimer intensities were feebly quenched by **3**; the slope was about 0.4 M^{-1}.

Discussion

The quenching of monomer fluorescence of $DBMBF_2$ at 398 and 416 nm by an olefin concurrent with the photoaddition of the olefin with $DBMBF_2$ can be regarded as a qualitative indication that $DBMBF_2$ reacts from its lowest singlet excited state with the olefins to yield 1,5-diketones **11–20** with excellent regiospecificity. The 1,5-diketones from the photoreaction are conveniently interpreted with a [2 + 2] photocycloaddition pattern shown below in analogy to the de Mayo reaction (3–8). However, the present photoaddition of $DBMBF_2$ with olefins is distinctly different from the de Mayo reaction in that the former is a singlet state reaction with much higher quantum efficiency than the latter. In fact, we showed that DBM does not add photolytically to these simple olefins by prolonged irradiation. Furthermore, we have shown that acetylacetone slowly adds photolytically to norbornene to give only the *cis,exo* adduct (27), in contrast to the major product of the *cis,endo* adduct **19** in the $DBMBF_2$ photocycloaddition. As the photocycloaddition probably involves a complex pattern, as suggested by the results of Figs. 2–4, it is premature to discuss its limitation, scope, and stereochemistry in detail as the reactive steps are being investigated.

However, the available data show that the overall consequence of the addition is stereospecific with the *cis*-addition mode and, probably, sensitive to steric hindrance. In the communication (1) it was concluded that an exciplex between the singlet excited state $DBMBF_2$ and an olefin is involved through partial electron transfer interactions, as suggested by the correlation of log k_q with the energy required to transfer a single electron to singlet excited state $DBMBF_2$ from a substrate. Subsequently we discovered that the kinetics of the interaction of the singlet state $DBMBF_2$ with an olefin are more complex, arising from the concurrent interaction of the $DBMBF_2$ excimer, particularly in a high $[DBMBF_2]$ region, as shown in the results.

The participation of the excimer in photocycloaddition is indicated by two observations. First of all, the measured quenching rates of monomer fluorescence intensities exhibit small but finite decreases with increases of $DBMBF_2$ concentrations (Table 4, Fig. 3); this trend hints at the presence of a competing reaction step that involves $DBMBF_2$. Secondly, the variations of the quantum yield of the photocycloaddition with $DBMBF_2$ concentrations (Fig. 2) suggest that the excimer is involved in the photocycloaddition. Scheme 1 is therefore proposed as a basis for kinetic analysis of chemical and physical events upon excitation of $DBMBF_2$ (A) in the presence of olefin (O), where $^*(A,O)$ is an exciplex and $^*(A,A,O)$ is a triple complex, analogies of which have been proposed in other photoreactions and have been referred to as triplexes (31–33). In this scheme, the excimer $^*(A,A)$ is formed from $^*A$ irreversibly as shown above. The quenching of exciplexes is a well-known phenomenon (31–39) and the involvement of a stilbene excimer in cycloaddition (40) has been suggested. The present case is the first well-established example of photoreactions originated by quenching of an excimer.

On the basis of Scheme 1, the quenching of $DBMBF_2$ fluorescence by an olefin can be expressed by the Stern–Volmer relation as shown in eq. [1]. This predicts the slope ($= k_x\tau_0'$) of the plots must be affected by the $k_m[A]$ term because the excimer $^*(A,A)$ is formed irreversibly, i.e., the slope is reduced at higher $DBMBF_2$ concentrations; this is what is found (Table 4). In a low concentration range of $[DBMBF_2] < 10^{-3}$ M where the excimer formation is insignificant (i.e., $k_m[A] \ll k_d$), the lifetime τ_0 ($= 1/k_d$) of singlet excited $DBMBF_2$ was previously estimated, by a biacetyl quenching experiment (2), to be 2.7 ns. Using this τ_0 value, the fluorescence quenching rate constants at $[DBMBF_2] = 5 \times 10^{-6}$ M (Fig. 3 and Table 4) are calculated to be $k_x = 2.1 \times 10^8\ M^{-1}\ s^{-1}$ for **3** and $k_x = 1.78 \times 10^9\ M^{-1}\ s^{-1}$ for **6**

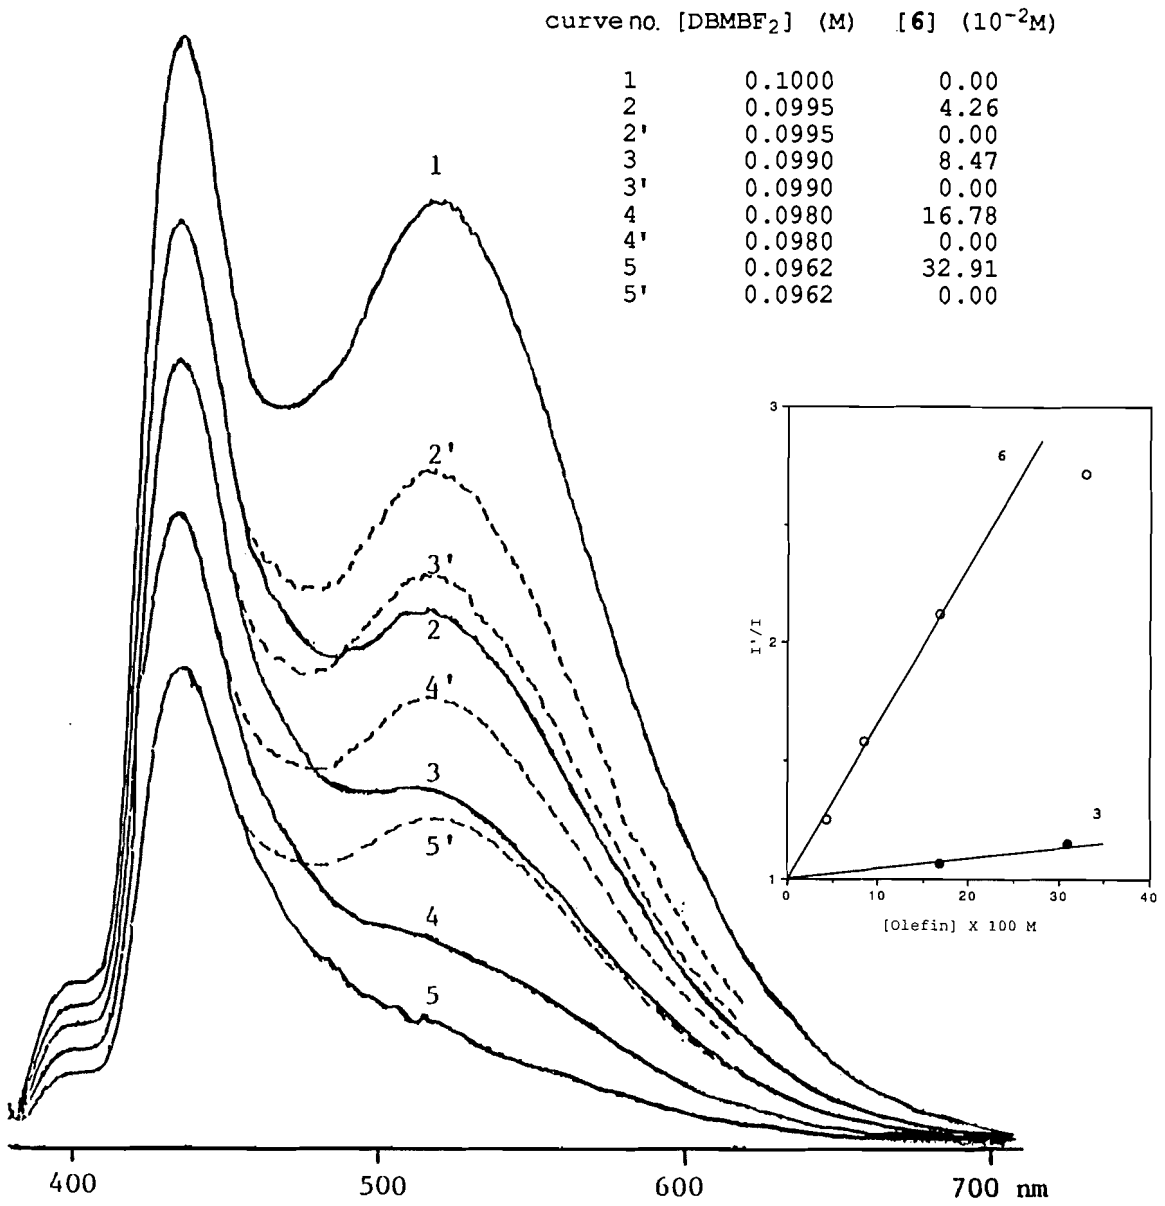

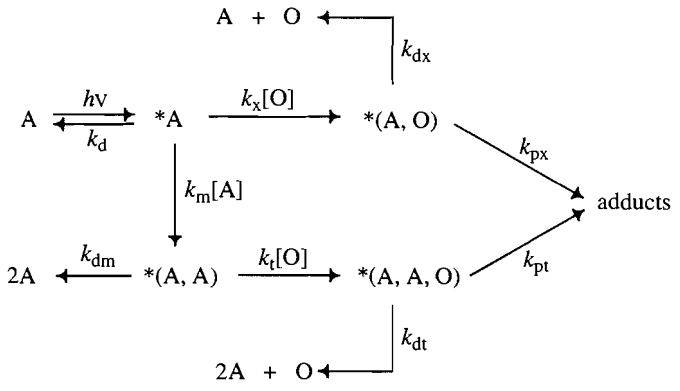

FIG. 4. The quenching of fluorescence intensities of $DBMBF_2$ (0.100–0.0962 M) excimer fluorescence intensities by cycloheptene **6** in CH_3CN, λ_{ex} 365 nm; the dashed curves were taken with the same [$DBMBF_2$] as these solid curves without **6** and were normalized with respect to the corresponding solid curves at 437 nm. Inset: The Stern–Volmer plots monitored at 522 nm.

SCHEME 1

(Table 5). These values can be regarded as the real quenching rate constants of monomeric singlet excited $DBMBF_2$ by the olefins, because we have established that $DBMBF_2$ does not form ground state aggregates (2) and that the excimer formation is feeble at [$DBMBF_2$] = 5×10^{-6} M. The fluorescence quenching pattern in the [$DBMBF_2$] 10^{-4}–10^{-1} M range can be expressed by eq. [1].

$$[1] \quad I_0/I = 1 + k_x[O]/(k_d + k_m[A]) = 1 + k_x\tau_0'[O]$$

The rate constant of the excimer formation k_m was estimated from the decrease of the 416-nm peak to 6×10^9 M^{-1} s^{-1}, assuming that at [$DBMBF_2$] = 0.06 M the peak intensity is halved. This value is in agreement with the fact that the photo-

TABLE 5. The reaction parameters of singlet excited state $DBMBF_2$ with olefins **3** and **6** at 1 M concentration

	3	**6**
k_x (M^{-1} s^{-1})[a]	0.21×10^9	1.78×10^9
M (eq. [3])	0.53	0.13
	$k_{px} = 1.13k_{dx}$	$k_{px} = 0.15k_{dx}$
M (1/intercept)[b]	0.5	0.14
N (eq. [4])	0.04	0.69
$k_t\tau_m$[c]	0.4	6.8
	$k_{pt} = 0.14k_{dt}$	$k_{pt} = 3.8k_{dt}$

[a]These values are obtained from the quenching of $DBMBF_2$ fluorescence in Table 4.
[b]The intercept of the plots in Fig. 1.
[c]Obtained from the plots in Fig. 4.

cycloaddition quantum yield began to be affected in the region of $[DBMBF_2] > 10^{-2}$ M as shown in Fig. 2.

On the basis of Scheme 1, the quantum yield of cycloadduct (Φ) can be represented by the sum of that from the exciplex (Φ_x) and that from the triplex (Φ_t) as in eq. [2]: Φ is the function of the concentrations of both olefin and $DBMBF_2$. A direct solution of eq. [2] is difficult unless some rate constants are known from other experiments, such as time-resolved fluorimetry.

$$[2] \quad \Phi = \Phi_x + \Phi_t = (Mk_x[O] + Nk_m[A])/(k_d + k_x[O] + k_m[A])$$

where

$$[3] \quad M = k_{px}/(k_{dx} + k_{px})$$

$$[4] \quad N = \{k_{pt}/(k_{dt} + k_{pt})\} \times \{k_t[O]/(k_{dm} + k_t[O]\}$$

However, under the limiting conditions of constant concentration of olefin [O] = 1 M, such as used in Fig. 2 and Table 3, it is possible to estimate the relative importance of the two pathways. From the first derivative ($d\Phi/d[A]$) of eq. [2], it can be shown that a plot of eq. [2] will have a positive slope when $N > (Mk_x[O])/(k_d + k_x[O])$, and vice versa. While the complex relation cannot easily be simplified, it essentially means that if the triplex pathway (k_t and k_{pt}) is faster than the exciplex pathway (k_x and k_{px}), a positive slope is obtained; the cases of **5**, **6**, and **7** in Fig. 2 are examples. In the opposite case, as for **3**, a negative slope is obtained.

A more quantitative analysis of the proposed mechanism with respect to eq. [2] can be made if k_m and k_x estimated for **3** and **6** above are substituted into eq. [2] at [O] = 1 M to give eqs. [5] and [6], respectively.

$$[5] \quad \Phi \text{ (for } \mathbf{3}) = (0.21M + 6N[A])/(0.58 + 6[A])$$

$$[6] \quad \Phi \text{ (for } \mathbf{6}) = (1.78M + 6N[A])/(2.15 + 6[A])$$

The values of M and N can be obtained by using the Φ values determined for **3** and **6** at $[DBMBF_2] = 0.01$ and 0.07 M given in Table 3, from which $M = 0.53$, $N = 0.04$ for **3**, and $M = 0.13$, $N = 0.69$ for **6** are obtained (see Table 5). Using these values, the calculated quantum yield ratios Φ/Φ_0 for **3** and **6** at $[DBMBF_2]$ 0.01–0.07 M are shown as the dashed lines in Fig. 2. The good coincidence with the experimental points for both olefins clearly supports dual photocycloaddition pathways for singlet excited state $DBMBF_2$ with olefins. The acceptability of these M and N values is tested by varying the values for drawing the curves by ±10%; as these test drawings deviate drastically from the experimental points, the calculated M and N values appear to be reasonable. Furthermore, from the definitions in eq. [3], M represents the limiting quantum yields and could be obtained from the reciprocals of the intercept in plots of $1/\Phi$ vs. $1/[O]$ in Fig. 1; 1/(intercept) for **3** is 1/2 = 0.5 and for **6** is 1/7 = 0.14. These values are very close to those M values calculated above.

TABLE 6. Calculated % contributions of the exciplex pathway (Φ_x) and the triplex pathway (Φ_t) to the quantum yield of photocycloaddition as a function of $DBMBF_2$ concentration[a]

Olefin	$[DBMBF_2]$ (M)					
	0.001	0.005	0.010	0.050	0.100	0.220
3 Φ_x(%)	99.8	98.9	97.9	90.3	82.3	67.8
Φ_t(%)	0.2	1.1	2.1	9.7	177	32.2
6 Φ_x(%)	98.2	91.8	84.8	52.8	35.9	20.3
Φ_t(%)	1.8	8.2	15.2	47.2	64.1	79.7

[a]The data are calculated from eq. [5] for **3** and from eq. [6] for **6** at the olefin concentration of 1.0 M.

The slopes of the plots (dashed lines) for **3** and **6** in Fig. 2 indicate the relative contribution of the exciplex pathway (Φ_x) versus the triplex pathway (Φ_t). The relative contributions of these two quantum yields can be calculated from the first and second terms, respectively, in eqs. [5] and [6] for these two olefins. As shown in Table 6, the photocycloaddition pattern for acyclic olefin **3** is clearly different from that for cyclic olefin **6**. For acyclic olefin **3**, the exciplex pathway remains the major pathway up to very high concentrations of $DBMBF_2$. In contrast, for cyclic olefin **6** the triplex pathway has started to show as early as $[DBMBF_2] = 5 \times 10^{-3}$ M (i.e., at the $[DBMBF_2]$ where the excimer barely started to show its presence (2)) and becomes dominant at about $[DBMBF_2] = 0.05$ M and above; other cyclic olefins should show a similar trend in view of the positive slopes of the Φ/Φ_0 vs. $[DBMBF_2]$ plots in Fig. 2. This reaction pattern is nicely confirmed by the strong quenching of the excimer fluorescence at 522 nm by **6** with the quenching rate ($k_t\tau_m$ where $\tau_m = 1/k_{dm}$ is the lifetime of the excimer) of 6.8 M^{-1} as opposed to the feeble quenching (0.04 M^{-1}) shown by **3**.

These data can be used to evaluate the relative importance of two decay modes of exciplex *(A,O) and triplex *(A,A,O) from the known numerical values of M and N at [O] = 1 M. According to eq. [3], direct substitution of M values gives $k_{px} = 1.13k_{dx}$ for **3** and $k_{px} = 0.15k_{dx}$ for **6**. Acyclic olefin **3** shows better efficiency than cyclic olefin **6** for the collapse of *(A,O) to the cycloadducts. In eq. [4], the second term is converted to $k_t\tau_m/(1 + k_t\tau_m)$ at [O] = 1 M. The substitution of N values gives $k_{pt} = 0.16k_{dt}$ for **3** and $k_{pt} = 3.8k_{dt}$ for **6**. These relations indicate that cyclic olefin **6** is more efficient than acyclic olefin **3** to convert triplex *(A,A,O) to the product. The kinetic parameters are summarized in Table 5 for comparison.

The foregoing discussion clearly indicates that the photocycloaddition of $DBMBF_2$ to simple olefins follows complex mechanisms that are dependent on the type of olefins (either cyclic disubstituted **6** or acyclic monosubstituted **3**) and the $DBMBF_2$ concentration. Table 5 shows that the exciplex path-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 84.41.108.74 on 09/07/12
For personal use only.

way is more important for the monosubstituted acyclic olefin **3**, for which the triplex pathway from the excimer is secondary under all conditions. Endocyclic olefins, such as **6**, primarily react with the $DBMBF_2$ excimer with high efficiency; as shown in Table 6 this reaction pathway becomes noticeable as soon as the excimer is being formed, at [$DBMBF_2$] as low as 0.005 M. Finally, it is useful to examine the slopes obtained in Fig. 1. The mechanism outlined in Scheme 1 dictates that $k_q\tau_0$ values obtained from the double reciprocal plots of $1/\Phi$ vs. 1/[olefin] (Fig. 1 and Table 4) must be a composite of two reaction pathways arising from the consequence that quantum yields determined are those of total Φ ($= \Phi_x + \Phi_t$). Qualitatively, depending on the extent of triplex pathway contributions to Φ, the calculated $k_q\tau_0$ is either smaller (as for **3**) or larger (as for **6**) than those determined from monomer fluorescence quenching as shown in Table 4 (top three rows).

Other factors influencing the importance of the dual reaction pathway are of course possible; e.g., the polarity of solvent and the temperature are two common factors that may be examined. However, such investigations should use the time-dependent fluorescence decay technique, a more efficient method for clear demonstration.

Experimental section

Materials and general conditions

Commercially available olefins were distilled before use. Unless specified otherwise the following conditions prevailed. The boron difluoride complex of dibenzoylmethane was prepared from the reaction of the ligand with BF_3 etherate in acetonitrile according to the published procedure; $DBMBF_2$ mp 192–194°C (lit. (11) mp 193–194°C). The IR and NMR spectra of $DBMBF_2$ have been reported (10).

Gas chromatographic (GC) analyses were performed on a Hewlett–Packard 5790 chromatograph equipped with a FID and an OV-1 (12 m × 0.20 mm) or HP-1 (25 m × 0.20 mm) capillary column, and connected to a Hewlett–Packard 3390A chart integrator. Preparative GC was conducted on a Varian 1700 chromatograph equipped with an OV-1 packed column (4 ft × 0.25 in., 15%, Chromsorb A, 60–80 mesh). Melting points were determined on a Fisher–Johns apparatus (uncorrected). Infrared (IR) spectra were recorded on a Perkin–Elmer 559B (neat film or KBr), and (or) a BOMEM Michelson 120 (FT-IR). Mass spectra (MS) and gas chromatography – mass spectra (GC–MS) were taken with a Hewlett–Packard 5985 GC–MS system by the electron-impact ionization (EI) and (or) chemical ionization (CI) mode. Nuclear magnetic resonance spectra were acquired on either a Bruker 100SY spectrometer equipped with Aspect 2000 software or a Bruker WH400 spectrometer. Two-dimensional (2D) NMR spectra were recorded on the latter. Chemical shifts (δ) for ^1H and ^{13}C spectra are reported in ppm with reference to tetramethylsilane. The coupling constants are reported in Hz. Ultraviolet and visible (UV/VIS) spectra were recorded on a Varian Cary 210 or a Philips PV8720 spectrophotometer. Emission spectra were obtained on a Perkin–Elmer MPF 44B spectrophotometer (uncorrected). The fluorescence spectra of $DBMBF_2$ in acetonitrile without degassing were taken with excitation at 365 nm in a right-angle arrangement for [$DBMBF_2$] $< 1 \times 10^{-4}$ M or in a front-face cell for [$DBMBF_2$] $> 10^{-4}$ M.

The photocycloaddition of $DBMBF_2$ and olefins

A solution of $DBMBF_2$ (1.5 mmol) and an olefin (15 mmol) in acetonitrile (30 mL) was distributed equally in six Pyrex test tubes (13 × 100 mm) that were placed in a "merry-go-round" mounted in a Rayonet photoreactor equipped with 3500 Å lamps. Without degassing, these samples were irradiated at about 31°C. Samples were taken at intervals for GC analysis, in which the appearance of products and (or) disappearance of $DBMBF_2$ were examined. If the reaction was slow, irradiation was stopped at about 80% consumption of $DBMBF_2$.

The photolysates were evaporated, and the residues were taken for flash chromatography using hexane – ethyl acetate as eluent. For photolysates with 80% completion of photoreaction, the residue was treated with hexane. Insoluble $DBMBF_2$ was filtered and the hexane solution was chromatographed. Olefins, products, and % yields based on consumed $DBMBF_2$ are given in Table 1. The IR, NMR, and GC data are given in Tables 7–10.[1] Compounds **11** and **19** were distilled and analysed. For **11**: Anal. calcd. for $C_{21}H_{24}O_2$: C 81.78, H 7.84; found: C 81.58, H 7.96. For **19**: Anal. calcd. for $C_{22}H_{22}O_2$: C 82.99, H 6.96; found: C 83.29, H 6.75.

Quantum yield measurement

The same air-cooled Rayonet photoreactor was used for the quantum yield determinations. Five millilitres each of sample and actinometry solutions were loaded into Pyrex test tubes (100 mm × 13 mm) that were evenly distributed on a rotary merry-go-round for irradiation at 31°C. Degassed benzene solutions of benzophenone (5×10^{-2} M) and benzhydrol (1×10^{-1} M) were used for actinometry, assuming a quantum yield of 0.74. The consumption of benzophenone was measured by the absorption at 340 nm. Octadecane (2.0×10^{-3} M) was added to the sample solution before photolysis to act as an internal standard for GC analysis. The conversion of $DBMBF_2$ was controlled to about 20% except for a few cases of 20–30% conversion.

Computation of vicinal proton coupling constant

The vicinal proton spin–spin coupling constants of the methine protons in **14–18** were computed using the MM-2 program, VAX/VMS Version 4.5, in which not only the dihedral angle of the vicinal protons but also the polar interactions of the substituents were considered. The conformers assumed were the "envelope" for cyclopentane, a chair for cyclohexane, a twisted chair for cycloheptane, and the "crown" for cyclooctane. Only the equatorial conformer was considered for *trans*-substituted compounds.

The quenching of $DBMBF_2$ excimer fluorescence

A 0.1 M $DBMBF_2$ solution in acetonitrile was prepared. Sample solutions were prepared by injecting the necessary amounts of cycloheptene **6** with a microsyringe. The corresponding reference solutions were prepared by injecting the same volumes of acetonitrile instead of **6**. First, a sample solution fluorescence was recorded as shown by the solid lines (Fig. 4). The corresponding reference solution fluorescence was taken by adjusting the pen to the height at 437 nm of the sample spectrum (shown as dashed lines). The fluorescence intensities at 522 nm for the samples corresponding to those for the reference (I/I') were plotted against the olefin concentrations (Fig. 4, insert). Front-face illumination was used in this experiment.

Thermal diffusion with hydrolysis in aqueous solutions of sodium carbonate

HUI LÜ AND DEREK G. LEAIST[1]

Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received February 5, 1991

HUI LÜ and DEREK G. LEAIST. Can. J. Chem. **69**, 1584 (1991).

A conductimetric technique is used to measure thermal diffusion in aqueous solutions of sodium carbonate. In dilute solutions hydrolysis produces significant amounts of sodium bicarbonate and sodium hydroxide: $Na_2CO_3 + H_2O = NaHCO_3 + NaOH$. The applied temperature gradient causes the various solutes to migrate to the cooler parts of the solution. NaOH is found to diffuse more rapidly than $NaHCO_3$, leading to the accumulation of excess NaOH (relative to $NaHCO_3$) at the cold plate. Binary $Na_2CO_3(m) + H_2O$ mixtures therefore separate into ternary $Na_2CO_3(m_1) + NaOH(m_2) + H_2O$ mixtures under nonisothermal conditions. The steady-state molality gradients dm_1/dT and dm_2/dT and the ternary heats of transport of aqueous Na_2CO_3 and NaOH are reported.

Key words: aqueous sodium carbonate, hydrolysis, mixed electrolytes, Soret coefficient, thermal diffusion.

HUI LÜ et DEREK G. LEAIST. Can. J. Chem. **69**, 1584 (1991).

On a utilisé un technique conductimétrique pour mesurer la diffusion thermique dans des solutions aqueuses de carbonate de sodium. En solutions diluées, l'hydrolyse conduit à la formation de quantités importantes de bicarbonate de sodium et d'hydroxyde de sodium : $Na_2CO_3 + H_2O = NaHCO_3 + NaOH$. Lorsqu'on applique un gradient de température, il y a migration des divers solutés vers les parties les plus froides de la solution. On a trouvé que le NaOH diffuse plus rapidement que le $NaHCO_3$; il en résulte une accumulation de l'excès du NaOH (relatif au $NaHCO_3$) au niveau de la plaque froide. Dans des conditions qui ne sont pas isothermes, les mélanges binaires de $Na_2CO_3(m) + H_2O$ se séparent donc en mélanges ternaires de $Na_2CO_3(m_1) + NaOH(m_2) + H_2O$. On a aussi déterminé les gradients de molalité de l'état stationnaire dm_1/dT et dm_2/dT ainsi que les chaleurs de transport ternaire des solutions aqueuses de Na_2CO_3 et de NaOH.

Mots clés : carbonate de sodium aqueux, hydrolyse; électrolytes mixtes; coefficient de Soret, diffusion thermique.

[Traduit par la rédaction]

1. Introduction

A concentration gradient develops when a temperature gradient is applied to a convection-free solution (1–4). Aqueous salts, for example, usually migrate to the cooler parts of a nonisothermal solution. The separation that is achieved is expressed by the Soret coefficient

$$[1] \quad \sigma = -m^{-1}(dm/dT)_{\infty \text{ or steady state}}$$

which gives the fractional change in solute molality per degree at steady state. Measured Soret coefficients can be used to calculate enthalpies of transport — the heat that must be absorbed to maintain constant temperature when solute diffuses out of an element of solution. Heats of transport can in turn provide fundamental information about solute–solvent and solute–solute interactions, including hydration.

The work reported here concerns the diffusion behavior of aqueous sodium carbonate, a hydrolyzing salt. The work was motivated by the practical importance of carbonates and other hydrolyzing salts (such as phosphate, sulfide, cyanide, iron, aluminum, and uranium salts). In addition, aqueous hydrogen and hydroxide ions, which are hydrolysis products, have unusually large heats of transport (5, 6), so the consequences for thermal diffusion might be significant, especially in dilute solutions where hydrolysis is extensive.

Equations are developed here for calculating the Soret coefficients of hydrolyzing salts from nonisothermal conductivity measurements. Soret coefficients and heats of transport are then reported for aqueous Na_2CO_3 at 25°C and salt molalities down to 0.001 mol kg^{-1}. This salt was chosen because isothermal diffusion data (7, 8) are available, which simplifies the analysis enormously. In the most dilute solutions that were studied, about 35% of the total carbonate ions were hydrolyzed.

2. Theory

2.1 Isothermal diffusion

Before the thermal diffusion of aqueous sodium carbonate is discussed, it is helpful to summarize briefly its unusual isothermal diffusion behavior (7, 8).

Only minor amounts of carbonate are hydrolyzed at Na_2CO_3 concentrations above *ca.* 0.05 mol dm^{-3}. There are two major solute species, Na^+ and CO_3^{2-}, but only one solute flux is independent because the electroneutrality condition guarantees that the two ions diffuse at the same speed. In this case the diffusion of the salt is a binary process described by Fick's equation

$$[2] \quad J_1 = -D\nabla C_1$$

with binary diffusion coefficient D. C_1 is the concentration of dissolved Na_2CO_3, in moles per unit volume, and J_1 is the molar flux density of the salt.

Dilute solutions

Dilute sodium carbonate solutions contain four major solute species: Na^+ and CO_3^{2-} ions together with HCO_3^- and OH^- ions produced by the hydrolysis reaction (7, 8)

$$[3] \quad CO_3^{2-}(aq) + H_2O = HCO_3^-(aq) + OH^-(aq)$$

$$K(25°C) = 2.15 \times 10^{-4}$$

Electroneutrality and local reaction equilibrium place two constraints on the ionic concentrations. At thermodynamic equilibrium, there is a third constraint: the concentrations of HCO_3^- and OH^- are identical. Only one solute concentration is therefore independent, which is consistent with the well-known result that aqueous Na_2CO_3 can be treated as a binary solution under equilibrium conditions.

However, once a gradient in the concentration of Na_2CO_3 is formed, the various ions will begin to diffuse, at different speeds. In particular, the relatively mobile OH^- ions will diffuse more rapidly than the HCO_3^- ions, making the OH^- ions more abundant than HCO_3^- ahead of the diffusion boundary. Although electroneutrality and local reaction equilibrium still hold, the restriction of equal concentrations of HCO_3^- and OH^- no longer applies.

With two constraints on the four solute species, two nonequilibrium solute concentrations remain independent. Diffusion of dilute aqueous sodium carbonate is therefore a ternary process described by the extended Fick equations (7, 8)

$$[4] \quad J_1 = -D_{11}\nabla C_1 - D_{12}\nabla C_2$$

$$[5] \quad J_2 = -D_{21}\nabla C_1 - D_{22}\nabla C_2$$

C_1 represents the concentration of the total sodium carbonate component (hydrolyzed plus unhydrolyzed forms): $C_1 = [HCO_3^-] + [CO_3^{2-}]$. C_2 represents the concentration of "added" NaOH, *i.e.* the NaOH in excess of that produced by the carbonate hydrolysis: $C_2 = [OH^-] - [HCO_3^-]$ ([Y] denotes the concentration of species Y.)

Ternary diffusion coefficient D_{ik} gives the flux density J_i of component i produced by the gradient in the concentration of component k. The cross-coefficient D_{21} takes large positive values for dilute solutions owing to the relatively large coupled flow of the NaOH(2) component produced by the extensively hydrolyzed Na_2CO_3(1) component (7, 8).

Further details of the diffusion of aqueous $NaCO_3$, and other hydrolyzing solutes, can be found elsewhere (7–12).

2.2 Nonisothermal diffusion

What happens when a temperature gradient is applied to an aqueous solution of sodium carbonate? Following accepted practice (1, 3, 13), the description below employs salt molalities (m_i) (rather than molarities (C_i)) to avoid complications arising from differential thermal expansion of the solutions.

Consider a column of height a of uniform binary aqueous sodium carbonate solution at molality $\bar{m}_1$. The temperature gradient $\Delta T/a$ is established at time $t = 0$ by holding the base of the column ($x = 0$) at temperature T and the top of the column ($x = a$) at $T + \Delta T$. Warm-up corrections and convection are assumed to be negligible.

If hydrolysis is unimportant ($m_1 > 0.05$ mol kg^{-1}), the sodium carbonate molality along the column is given by the expression (13)

$$[6] \quad m_1(x,t) = \bar{m}_1 + \left(\frac{x}{a} - \frac{1}{2}\right)\Delta m_{1\infty} + \frac{4\Delta m_{1\infty}}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{(2n-1)^2}\cos(b_n x)\exp(-b_n^2 Dt)$$

for the binary thermal diffusion of a single solute component. b_n is an abbreviation for $(2n - 1)\pi/a$.

The steady-state molality difference

$$[7] \quad \Delta m_{1\infty} = m_1(a,\infty) - m_1(0,\infty)$$

between the top and the bottom of the column is attained as $t \rightarrow \infty$.

From measured values of $\Delta m_{1\infty}$, the Soret coefficient

$$[8] \quad \sigma = -(\Delta m_{1\infty}/\bar{m}_1)\Delta T$$

and the molar heat of transport (1–4)

$$[9] \quad H_1^* = \nu RT^2(1 + \mathrm{d}\ln\gamma_\pm/\mathrm{d}\ln m_1)_T\sigma$$

can be derived. $\gamma_\pm$ is the stoichiometric mean molal ionic activity coefficient and ν is the number of moles of ions per mole of dissolved salt (3 for Na_2CO_3).

Dilute solutions

A temperature gradient applied to a dilute solution of sodium carbonate will generate gradients in the concentrations of each of the Na^+, CO_3^{2-}, HCO_3^-, and OH^- ions. Owing to the relatively large heat of transport of the OH^- ion (5), the thermally-induced gradient in the concentration of OH^- ions will exceed that of HCO_3^-, generating a ternary nonequilibrium system with gradients in both the Na_2CO_3(1) and the NaOH(2) components (14):

$$[10] \quad m_i(x,t) = \bar{m}_i + \left(\frac{x}{a} - \frac{1}{2}\right)\Delta m_{i\infty} + \frac{4}{\pi^2}\sum_{n=1}^{\infty}\sum_{k=1}^{2}\frac{A_{ik}\cos(b_n x)}{(2n-1)^2}\exp(-b_n^2 D_k t)$$

D_1 and D_2 are the eigenvalues of the diffusion coefficient matrix (evaluated at the mean cell temperature):

$$[11] \quad D_1 = [D_{11} + D_{22} + (D_{11} - D_{22})[1 + 4D_{12}D_{21}/(D_{11} - D_{22})^2]^{1/2}]/2$$

$$[12] \quad D_2 = [D_{11} + D_{22} - (D_{11} - D_{22})[1 + 4D_{12}D_{21}/(D_{11} - D_{22})^2]^{1/2}]/2$$

The A_{ik} parameters are abbreviations for

$$[13] \quad A_{11} = [(D_{11} - D_2)\Delta m_{1\infty} + D_{12}\Delta m_{2\infty}]/(D_1 - D_2)$$

$$[14] \quad A_{12} = [(D_1 - D_{11})\Delta m_{1\infty} - D_{12}\Delta m_{2\infty}]/(D_1 - D_2)$$

$$[15] \quad A_{21} = [-D_{21}\Delta m_{1\infty} + (D_2 - D_{22})\Delta m_{2\infty}]/(D_2 - D_1)$$
