Figure 1 contains the structural formulae and numbering schemes. Bond lengths and angles are listed in Table 1, while torsional angles involving ring skeletal atoms are provided in Table 2. ORTEP diagrams are presented in Fig. 2 while Fig. 3 shows the ^{13}C solid phase NMR spectra. The ^{13}C chemical shifts are collected in Table 3 while the crystallographic data are in Table 4 and the atomic parameters in Table 5.

(i) Dibenzo-15-crown-5 ether (1)

In solution, the ^{13}C NMR of **1** shows nine resonances (down to 163 K) consistent with its symmetry properties and rapid conformational interchange in the central macrocyclic ring on the NMR timescale for this temperature range. The 200 MHz

1

2 ≡ **1**·NaNCS

FIG. 1. Structure and numbering scheme.

^{1}H spectrum shows a complex multiplet centered at δ 6.95 ppm (aromatics), a sharp singlet at δ 4.33 ppm (H-7,8), and multiplets centered at δ 4.16 and 3.89 ppm respectively. A ^{1}H–^{1}H NOESY experiment showed a correlation between the aromatics and the multiplet centered at 4.16 ppm, thereby indicating that these latter protons must be those on the C-15 and C-18 sites. As expected, there was also a NOESY correlation between the aromatics and the singlet at 4.33 ppm due to cross relaxation between protons on C-3 and C-14 with those on C-7 and C-8 respectively.

In the case of C-15, 16, 17, and 18 the geminal protons on each of these carbons are magnetically nonequivalent. Rapid conformational exchange in the 15-membered ring at room temperature results in each member of a geminal pair having the same chemical shift. From a spin coupling viewpoint, however, each member of a geminal pair is unique and hence the occurrence of magnetic nonequivalence (19, 20). As a result a complex multiplet is observed for the four protons on C-15 and C-16 (and by symmetry on C-17 and C-18), which must be analyzed as an AA′XX′ spin system. Such analysis was done using the LAME program (21). Tables 6 and 7 contain ^{1}H data.

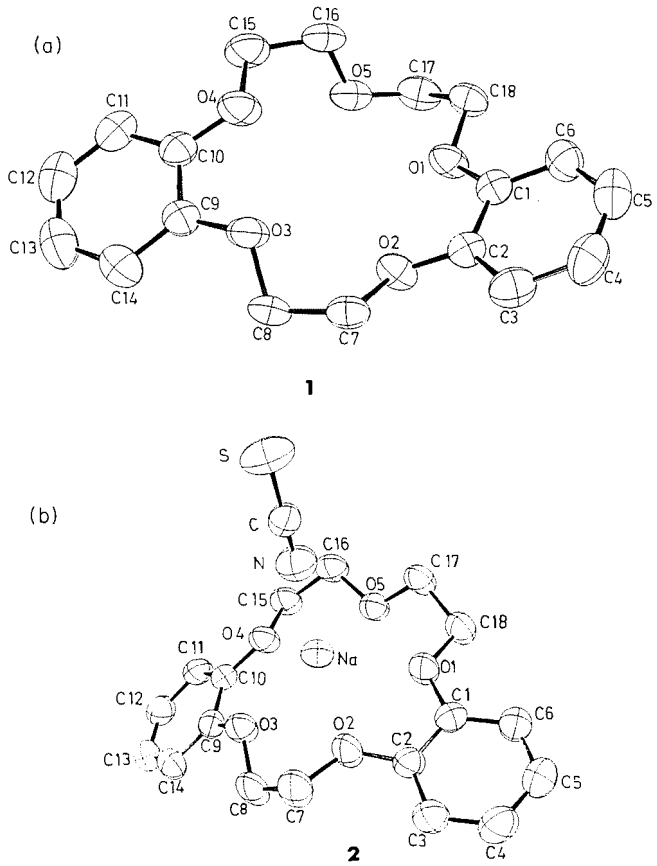

FIG. 2. ORTEP diagrams.

The nine ^{13}C signals observed for **1** at room temperature in solution can be assigned via a combination of methods with limitations as specified. The aromatic region consists of three closely spaced pairs of resonances near 149, 121, and 115 ppm. By analogy with results on related materials (16, 18), the carbons bearing oxygen will be the most deshielded and appear near 149 ppm. The *ortho* sites (C-3, 6, 11, and 14) will be the most shielded and appear near 115 ppm.

For the methylene carbons, unambiguous assignment of the C-7,8 pair to the resonance at 68.38 ppm was made via the one-bond ^{1}H–^{13}C heteronuclear correlation (HETCOR) experiment. Due to their almost identical chemical shifts (69.76 and 69.80 ppm), the C-15,18 vs. C-16,17 pairs could not be distinguished.

Notably, there are *six* clearly resolvable methylene carbon resonances for **1** in the solid state ^{13}C NMR spectrum. This is consistent with the absence of any molecular symmetry elements in the X-ray crystallographic structure. Furthermore, there is a remarkably large range of chemical shifts in the solid for these carbons (8.7 ppm) vs. 1.4 ppm in solution. In view of this, it is instructive to examine the torsional environments of the methylene carbons in the crystal structure as presented in Table 6. Ignoring hydrogens, the C-16 and C-17 sites are involved in four such networks, while the C-7,8 and C-15,18 sites are present in five.

In the attempt to assign resonances in the solid state spectrum to particular carbons, comparison will be made between the torsional environments for pairs of carbons, which are rendered equivalent in solution via conformational averaging. Such averaging is absent in the solid, and hence the steric influences may be more readily apparent in the observed chemical shifts. The basic tenets for the analysis have been presented earlier (16) and involve the known dihedral angle dependence of the γ-steric shift in ^{13}C NMR (22). Generally, carbons situated in a γ-*gauche* relation or bearing such substituents will be shielded by ca. 5 ppm relative to counterparts in γ-*trans* orientations. Also there is a tendency to maximum shielding for *cis* coplanar networks (23) with maximum deshielding for a dihedral angle of 120°.[2]

Comparison of the torsional networks for C-15 vs. C-18 reveals important differences, which would be expected to lead to increased shielding for the C-18 site. For the O—C*—C—O network, the angle for C-18 is 51.5°, whereas that for C-15 has expanded to 70.3°. Most important, however, is the difference in the C—O—C—C* network, where C-15 is involved in an essentially *trans* interaction with C-17 whereas C-18 bears a *gauche* type relation to C-16. Hence one can make a strong case for the attribution of the most shielded resonance at 61.88 ppm to C-18 and that for C-15 to the most deshielded line at 70.59 ppm.

Regarding the C-7 and C-8 sites, data in Table 8 show that their respective torsional environments are quite similar, with offsetting differences present in the dihedral angles in the C—O—C*—C and C—O—C—C* networks. Accordingly we expect these carbons to have nearly identical chemical shifts in the solid, and we assign the resonances at 66.90 and 67.36 ppm to these carbons.

For the remaining C-16 and C-17 methylene carbons, the most significant difference in their torsional environments appears to be the contraction of the O—C—C—O dihedral angle to 51.5° in the case of C-17 in contrast to the value of 70.3° for C-16. Such a contraction should lead to increased shielding at C-17 (23 and footnote 2) and hence we attribute the line at 65.25 ppm to C-17 and that at 68.75 ppm to C-16. Of course all these assignments await unambiguous confirmation, perhaps via ^{13}C–^{13}C INADEQUATE experiments as recently reported for the plastic crystal camphor (24). It may, however, be necessary to synthesize **1** with ^{13}C enrichment to enhance the connectivities in the two-dimensional solid phase experiment. The feasibility of such experiments using ^{29}Si enriched zeolites has been demonstrated recently (25) and the techniques applied to natural abundance samples (26).

In the aromatic region of the solid phase ^{13}C spectrum the effect of nonaveraged conformations is also evident in the increased multiplicity of resonances relative to the solution spectrum. Based on the torsional angle arguments presented above, C-6 is expected to be the most shielded *ortho* aromatic carbon (at 111.11 ppm), since it is nearly coplanar ($\theta = 6.5°$) to C-18.

The spatial disposition of the oxygen lone pairs will also affect the electron density and hence the chemical shift of the nonoxygenated aromatic carbons. The optimal geometry for conjugative electron release will be that in which the lone pairs occupy orbitals that are perpendicular to the plane of the aromatic ring. As a result, the lone pairs on O-1, for example, will influence the electronic environment at the *ortho* carbon (C-6) and the *para* carbon C-4. From the X-ray data, the lone pair orientations can be determined for each oxygen and the values of the angles between these orbitals and the plane of the aromatic ring obtained. Results are as follows, using θ_1 and θ_2 for the two lone pairs on each oxygen respectively. For O-1,

$\theta_1 = 66.5°$, $\theta_2 = 53.5°$; for O-2, $\theta_1 = 89.2°$, $\theta_2 = 31.8°$; for O-3, $\theta_1 = 82.3°$, $\theta_2 = 37.7°$; and for O-4, $\theta_1 = 75.1°$ and $\theta_2 = 44.9°$.

If one assumes that the effectiveness of overlap is related to the sine of the angle and that one can treat the two orbitals in an additive fashion, then an order of effectiveness of conjugative lone pair release can be established. Such an order is O-1 > O-4 > O-3 > O-2. In terms of the order of predicted shielding at carbons *ortho* to oxygen, this leads to the prediction that C-6 should be the most shielded, followed by C-11, C-14, and C-3. It is notable that this is the same order of shielding that one predicts based on the simple dihedral angle dependence of the γ-steric shift in butane (23).

Presumably in the case of the observed difference in shielding at the C-4,5,11,12 sites it is the aforementioned stereoelectronic influence of the oxygen lone pairs which dominates. Via the same arguments presented above, the O-1 site is most effective as a conjugative electron donor, and hence it is the carbon *para* to it, i.e., C-4, which is predicted to be the most shielded. Accordingly we attribute the resonance at 118.85 ppm to this carbon. The other three carbons appear as a broad singlet with a shoulder centered at 121.03 ppm.

(ii) Dibenzo-15-crown-5·NaNCS complex (2)

In solution the ^1H and ^{13}C NMR spectra are, with the exception of minor chemical shift differences, quite similar to those of the free ligand **1**. Analysis of the O-CH_2-CH_2-O proton spin coupling pattern as an AA′XX′ system leads to very similar values for all coupling constants, suggesting that there is little change in the average conformation of the 15-membered ring upon complexation *in solution*. The precise K, however, for free and complexed Na^+ is as yet unknown for this system.

Examination of the *solid phase* ^{13}C NMR spectra in Fig. 3, however, reveals substantial differences in chemical shifts between the free and complexed dibenzo-15-crown-5 species. For **1**, all six CH_2-O resonances are resolved with an overall shift difference of 8.71 ppm, whereas in **2**, only four resonances are resolved in this region with an overall shift difference of 4.26 ppm. By contrast, for **2** all eight non-oxygenated aromatic carbons are observed, with a substantially larger range

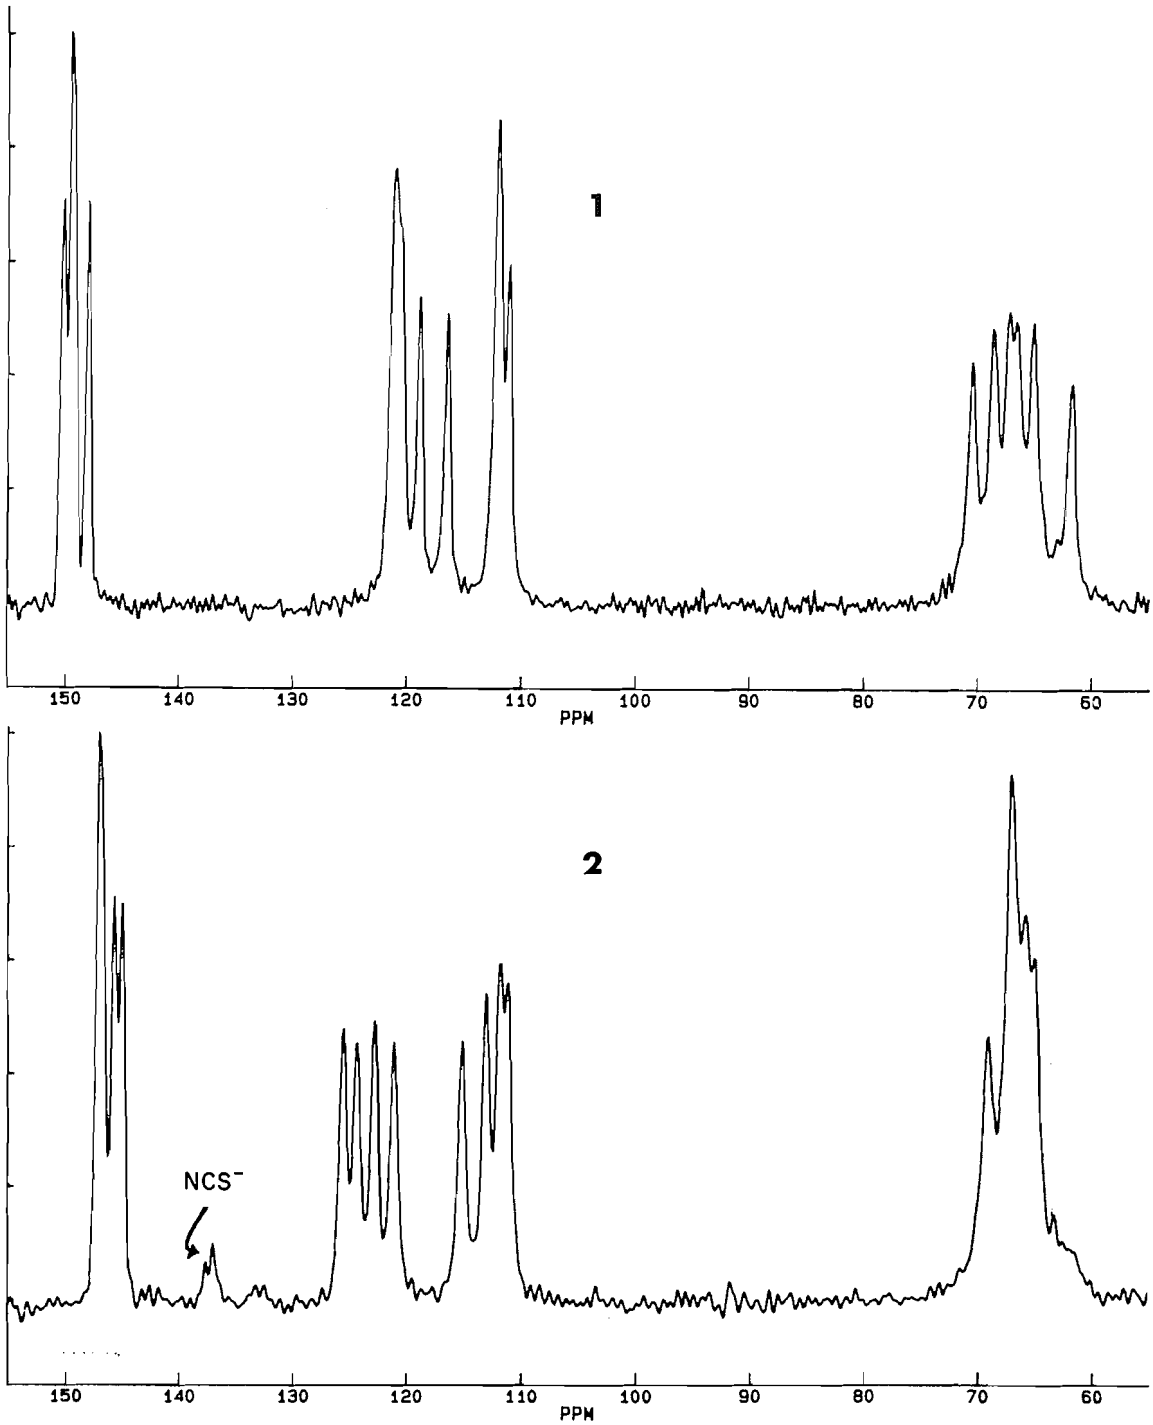

FIG. 3. ^{13}C CPMAS spectra (45.3 MHz).

of shifts than found for **1**. From the total number of ^{13}C lines observed, however, it is clear that neither **1** nor **2** possesses any symmetry elements, in agreement with the X-ray crystallographic structures.

Comparison of the X-ray data for **1** and **2** reveals that the major change in geometry has occurred in the C16—O5—C17—C18 fragment, where a dihedral angle of 66.5° in **1** has changed to 171.0° in **2**. There is also a substantial change in the C9—O3—C8—C7 unit, where the torsional angle of 179.3° in **1** has contracted to 147.6° in **2**. All other dihedral angle changes upon complexation are less than 15°.

Although one cannot rule out steric and electronic effects of the Na^+ and NCS^- species on ^{13}C chemical shifts, it is of interest to attempt an analysis of shielding differences in **2** based on torsional environments of the carbon atoms involved relative to results discussed previously for **1**.

The methylene carbon resonances for solid **2** cover the range 65.00–69.26 ppm. Based on our assignments for **1**, it is mandatory that C-18 (at 61.88 ppm in **1**) must be deshielded by at least 3.12 ppm in **2**. Examination of the torsional environment of C-18 (Table 9) reveals one major reason why this is the case, namely that the C16—O5—C17—C18 torsion angle has

[a]Throughout this work esd's are in parentheses and refer to the last digit printed.
[b]$R_f = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[c]$R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma(w|F_o|)^2]^{1/2}$ where $w = 1/\sigma^2 I$.
[d]Goodness of fit = $[\Sigma w(|F_o| - |F_c|)^2/(\text{No. of reflections} - \text{No. of parameters})]^{1/2}$.

increased from 66.5° in **1** to 171.0° in **2**. Resonances for C-16 and C-17 may also be affected, but other angle changes involving these carbons may tend to offset this perturbation.

Conversely, the C-15 resonance of **2** may be expected to be slightly shielded relative to **1**, since there is a contraction of the O4—C15—C16—O5 angle from 70.3° in **1** to 56.4° in **2**. Hence the shift in position of this resonance from 70.59 ppm in **1** to 69.26 ppm in **2** can be explained. Other assignments of methylene carbons of **2** must be regarded as tentative due to peak overlap and the small range of shifts observed.

Regarding assignments for the non-oxygenated aromatic carbons, arguments analogous to those used for **1** lead to a predicted order of shielding of C-14 > C-11 > C-6 > C-3 in **2**. Considering the stereoelectronic influence of the oxygen lone pairs, O-3 in **2** will be the most effective donor of electrons and hence the carbon *para* to it, C-12, will be the most shielded. For the remaining carbons, the predicted order of shielding is C-13 > C-4 > C-5.

Clearly, however, these assignments must be regarded with some caution until methods for unambiguous attribution of solid phase ^{13}C resonances become available or appropriately labelled materials are prepared. The experimental solid phase ^{13}C results for these materials do, however, hold some promise to be of substantial importance in helping to unravel stereochemical contributions to ^{13}C NMR chemical shifts.

(iii) Features of sodium complexation in 2

The geometry of coordination to Na^+ in **2** can best be described as pentagonal pyramidal. From the X-ray data, it is

evident that an approximate pentagonal plane is defined by the five oxygens of the crown ether. For this plane the $(\chi)^2$ value is 6713.492. The distances (in Å) from each oxygen to the mean plane are as follows: O-1, 0.0528 (18); O-2, −0.0031 (20); O-3, −0.0764 (21); O-4, 0.0977 (19); and O-5, −0.0850 (19). Coordination is completed by the N atom of the thiocyanate anion. The plane defined by C-19, N, and S bears an angle of 83.26° to the mean plane defined by the five oxygens. The Na—O distances and the O—Na—O angles are included in Table 1.

Experimental

(a) Spectra

The ^{13}C CPMAS solid phase spectra were recorded at 45.3 MHz on a Bruker CXP-180 spectrometer. Cross polarization (CP) times were typically 3 ms with the radio frequency field amplitude being 60 kHz. Satisfactory signal-to-noise ratios were obtained after a maximum of 400 accumulations. The sweep width was 20 kHz with a recycle time of 4–8 s. Normally 2K data points were collected with zero filling to 8K before Fourier transformation. Magic angle spinning (MAS) rates of ca. 3 kHz were obtained using Kel-F spinners of the Andrew–Beams type. Chemical shifts were measured relative to external solid hexamethylbenzene (HMB) and converted to the TMS scale via the factor of 16.9 ppm, which is the chemical shift for the CH_3 group of HMB.

Solution ^{13}C NMR spectra were recorded at 75.3 MHz on a Varian XL-300 spectrometer under conditions of complete ^1H noise decoupling. The NOESY spectra were obtained on the same instrument with mixing times of 0.3 s. For the ^1H–^{13}C HETCOR experiment, delays were set to correspond to an average $^1J_{CH}$ value of 140 Hz. Standard ^1H spectra were run on a Varian XL-200 system and simulations of spectra were done via the LAME (21) program.

(b) Crystallographic measurements and structure solutions

A summary of the crystal data is given in Table 4. Diffraction intensities were collected on a Picker diffractometer using Cu radiation and the $\theta/2\theta$ scan technique with profile analysis (27). Three standards were measured every 100 reflections. The space group was determined by systematic absences. Unit cell parameters were obtained by least-squares refinement of the setting angles for 24 reflections with a 2θ range between 90 and 110°. Lorentz and polarization factors were applied but no correction for absorption was made.

Structures were solved by direct methods plus Fourier maps and were refined by full matrix least-squares analysis with weights based on counting statistics. H atoms were found from difference maps and their positions were refined isotropically. Non-H atoms were refined anisotropically. All calculations were performed using the NRC VAX Crystal Structure programs (28). A full listing of bond lengths and angles is presented in Table 1, with torsional angles involving non-H atoms in Table 2, and the final atomic positional parameters in Table 5. Anisotropic thermal parameters and final structure factors are available as supplementary data.[3]

(c) Materials

Dibenzo-15-crown-5 (**1**) was prepared by reaction of 1,2-bis(2-chloroethyl)ether with 1,2-bis-(*o*-hydroxyphenoxy) ethane (18) in the presence of 2 molar equivalents of NaOH. A typical procedure follows.

The diol (4.92 g, 0.02 mol), butanol (4 mL), and NaOH (1.72 g, 0.043 mol, dissolved in 3 mL H_2O) were combined and brought to reflux. To this mixture was added dropwise with stirring 2.86 g (0.02 mol) of the 1,2-bis(2-chloroethyl)ether diluted with 4 mL butanol over a period of 20 min. Refluxing was continued for 20 h. The cooled reaction mixture was then acidified with concentrated HCl and the butanol and water were removed by rotary evaporation. The resulting crude product was dissolved in CH_2Cl_2 and washed with water. After the organic layer was dried over $MgSO_4$, the solvent was removed and the material subjected to flash column chromatography on silica gel using CH_2Cl_2 as eluent. Recrystallization from CH_2Cl_2/hexane gave **1**, mp 114–115°C, in 35% overall yield. Mass spectrum (CI), *m/z*: 317 (M + 1).

The NaNCS complex of **1** was prepared according to the following procedure. Equimolar quantities of **1** and NaNCS were dissolved in a minimum volume of dry methanol and allowed to stand for 2–3 h. The solvent was removed by rotoevaporation and the resulting solid recrystallized from 30:70 ethanol/CH_2Cl_2 to give the complex, mp 147–148°C.

Reactions of δ-valerolactone with lithio trithio-orthoformates

PETER YATES,[1] AZZA SEIF-EL-NASR, AND JENNIFER STANTON
Department of Chemistry, University of Toronto, Toronto, Ont., Canada M5S 1A1

JIRI J. KREPINSKY[1]
Department of Molecular and Medical Genetics, University of Toronto, Toronto, Ont., Canada M5S 1A8

Received, July 19, 1990

PETER YATES, AZZA SEIF-EL-NASR, JENNIFER STANTON, and JIRI J. KREPINSKY. Can. J. Chem. **69**, 415 (1991).

δ-Valerolactone (**3**), on treatment with tris(methylthio)methyllithium (**7**) followed by weakly acidic aqueous work-up, gave a tautomeric mixture of 1,1-bis(methylthio)-6-hydroxy-2-hexanone (**8***a*) and tetrahydro-2-bis(methylthio)methyl-2-pyranol (**8***b*). Under analogous conditions **3** reacted with tris(phenylthio)methyllithium (**10**) to form tetrahydro-3-(phenylthiocarbonyl)-2-pyranone (**11**). With 2-(methylthio)-1,3-dithian-2-yllithium (**16**) it gave a tautomeric mixture of 2-(5-hydroxy-1-oxopentyl)-2-(methylthio)-1,3-dithiane (**17***a*) and 2-(tetrahydro-2-hydroxy-2-pyranyl)-2-(methylthio)-1,3-dithiane (**17***b*). Treatment of **17** with methanol in the presence of acidic ion-exchange resin gave a mixture of 2-(5,6-dihydro-3-(methylthio)-2(4*H*)-pyranyl)-1,3-dithiane (**20**), 2-(tetrahydro-2-methoxy-2-pyranyl)-1,3-dithiane (**21**), and 2-(tetrahydro-2-methoxy-4-(methylthio)-2-pyranyl)-1,3-dithiane (**22**). Similar treatment of **20** gave a mixture of **20**, **21**, and **22**. Compound **21** was synthesized independently by similar treatment of 2-(tetrahydro-2-hydroxy-2-pyranyl)-1,3-dithiane (**23**). The origins of the anomalous products are discussed briefly. It is concluded that because of these anomalies the preparation of tetrahydro-2-hydroxypyran-2-carboxylic acid acetals and related glycosides via trithio-orthoformate derivatives can encounter difficulties, although dithioacetals may serve this purpose.

Key words: 1,3-dithianes, α-hydroxy acids, δ-lactones, trithio-orthoformates.

PETER YATES, AZZA SEIF-EL-NASR, JENNIFER STANTON et JIRI J. KREPINSKY. Can. J. Chem. **69**, 415 (1991).

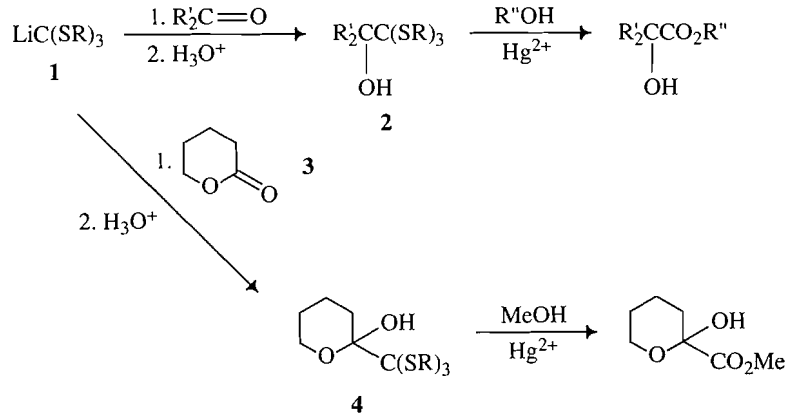
La δ-valérolactone (**3**), par une réaction avec le tris(méthylthio)méthyl-lithium suivie d'une récupération en milieu aqueux, légèrement acide, conduit à un mélange de 1,1-bis(méthylthio)-6-hydroxy-hexan-2-one (**8***a*) et tétrahydro-2-bis(méthylthio) méthyl-pyran-2-ol (**8***b*). Dans des conditions analogues, le composé **3** réagit avec le tris(phénylthio)méthyl-lithium (**10**) pour donner la tétrahydro-3-(phénylthiocarbonyl)-pyran-2-one (**11**). Et avec le 2-(méthylthio)-1,3-dithian-2-yl-lithium (**16**), il donne un mélange tautomère de 2-(5-hydroxy-1-oxopentyl)-2-(méthylthio)-1,3-dithiane (**17***a*) et de 2-(tétrahydro-2-hydroxy-pyran-2-yl)-2-(méthylthio)-1,3-dithiane (**17***b*). Le traitement du composé **17** par du méthanol, en présence d'une résine échangeuse d'ions acide, conduit à un mélange de 2-(5,6-dihydro-3-(méthylthio)-4*H*-pyran-2-yl)-1,3-dithiane (**20**), de 2-(tétrahydro-2-méthoxy-pyran-2-yl)-1,3-dithiane (**21**) et de 2-(tétrahydro-2-méthoxy-4-(méthylthio)-pyran-2-yl)-1,3-dithiane (**22**). Par un traitement similaire, le produit **20** fournit un mélange des composés **20**, **21** and **22**. On a synthétisé le composé **21** par une méthode indépendante en soumettant le 2-(tétrahydro-2-hydroxy-pyran-2-yl)-1,3-dithiane (**23**) à un traitement semblable. On discute brièvement des origines des produits anormaux. Sur la base de ces anomalies, on croit que la préparation des acétals de l'acide tétrahydro-2-hydroxy-pyran-2-carboxylique et des glycosides apparentés, via les dérivés trithio-orthoformiates, peut donner lieu à des difficultés, même si les dithioacétals peuvent être utilisés à leur place.

Mot clés : 1,3-dithianes, acides α-hydroxy, δ-lactones, trithio-orthoformates.

[Traduit par la rédaction]

The reaction of aldehydes or ketones with lithio trithio-orthoformates (**1**) is a well-known method for the preparation of masked α-hydroxy acids (**2**) (1). The corresponding reaction of δ-lactones, including **3** and aldonolactones, to give masked tetrahydro-2-hydroxy-pyran-2-carboxylic acids has also been reported (2) (Scheme 1).[2] The masked α-hydroxy acid derivatives of type **4** are of synthetic interest since acetalization followed by unmasking of the carboxylic acid provides a route to glycosides of type **5**, i.e., of the neuraminic or 3-deoxy-D-manno-2-octulopyranosonic (KDO) acid type, which might circumvent the competing elimination of water that bedevils the glycosylation with the α-hydroxy acids themselves and gives products of type **6** (Scheme 2). We describe here an investigation of the reactions of δ-valerolactone (**3**) with several lithio trithio-orthoformates, which reveals the interesting complications that may arise in the course of the reactions themselves or in subsequent acetalization reactions.[3]

The lithio derivative **7** (**1**, R = Me) was prepared from tris(methylthio)methane by reaction with one equivalent of *n*-butyllithium and was treated with **3** in tetrahydrofuran for 4 h. Under these conditions, attack at the carbonyl group was accompanied by loss of a methylthio group (eq. [1]). In deuteriochloroform the ^1H and ^{13}C nmr spectra of the product showed it to be a 2:1 mixture of the "open" and "closed" tautomers **8***a* and **8***b* (such tautomerism has been reported previously in related cases (3)). In hexadeuteriodimethyl sulfoxide only **8***a* could be detected in the nmr spectra (Tables 1 and 2). Crystallization of the product from ethyl acetate/hexanes gave **8***a* as a crystalline solid, mp 44–46°C, whose elemental composition confirmed the loss of a methylthio group and whose ir spectrum (ν_{max} 3392, 1701 cm^{-1}) confirmed the presence of hydroxyl and carbonyl groups. It is considered that compound **8***a* arises from the first-formed adduct **9** during the work-up under mildly acidic conditions (Scheme 3).



Treatment of δ-valerolactone with the lithio derivative **10** (**1**, R = Ph), prepared from tris(phenylthio)methyllithium and *n*-butyllithium under the same reaction and work-up conditions as those used with **7**, did not lead to the simple adduct. Instead it gave a crystalline product, $C_{12}H_{12}O_3S$, which is assigned structure **11** (eq. [2]). This assignment is based on its ^1H nmr

spectrum (δ 1.8–2.5 (m, 4H, H-4 and H-5), 3.95 (t, 1H, H-3), 4.45 (t, 2H, H-6), 7.45 (s, 5H, Ph)), and the presence of two strong bands with ν_{max} 1733 and 1695 cm^{-1} and the absence of a hydroxyl stretching band in its ir spectrum.

We propose that **11** arises as shown in Scheme 4. Tris(phenylthio)methyllithium is known to undergo decomposition in solution to give tetrakis(phenylthio)ethylene (**12**) and lithium thiophenoxide (**13**) (5, 6*a*) (eq. [3]). Reaction of δ-valerolactone (**3**) with the latter could give the anion **14**. Addition of this to **12** and elimination of thiophenoxide would give the intermediate

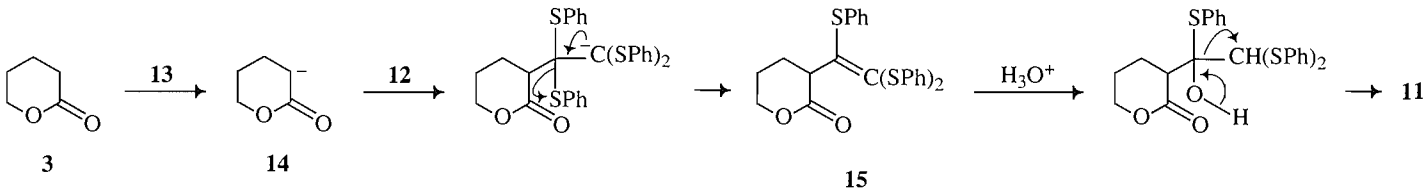
[2] 

15, which in turn could be converted to the observed product **11** as shown.

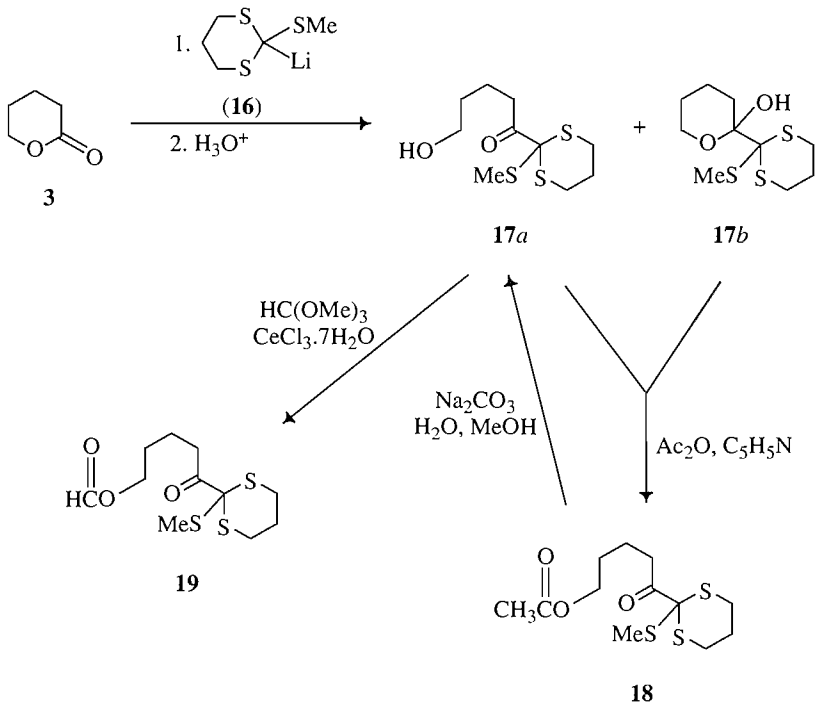
The third lithio trithio-orthoformate investigated was 2-lithio-2-(methylthio)-1,3-dithiane (**16**), prepared from *n*-butyllithium and 2-(methylthio)-1,3-dithiane, itself obtained by methylthioylation of 1,3-dithiane (6) and monodemethylthioylation of 2,2-bis(methylthio)-1,3-dithiane, a by-product in the methylthioylation. Reaction of **16** with δ-valerolactone under the usual conditions proceeded without complication and gave a tautomeric mixture of the simple adducts **17***a* and **17***b* (Scheme 5). The complexity of the spectra of this mixture made detailed interpretation difficult and the isolation of a single component was investigated. Acetylation of the mixture with acetic anhydride and pyridine at room temperature gave a single product, the open acetate **18**; the analogous open formate **19** was also obtained by treatment of the mixture with trimethyl orthoformate and cerous chloride heptahydrate (cf. ref. 7).



[3] $2(PhS)_3CLi \longrightarrow (PhS)_2C{=}C(SPh)_2 + 2PhSLi$
10 **12** **13**

Hydrolysis of the acetate in weakly basic aqueous methanol gave the single, open adduct **17***a*.[4] It was later found that **17***a* could be obtained by column chromatography of the mixture of **17***a* and **17***b*. The ir spectra of compounds **17***a*, **18**, and **19** show carbonyl stretching bands at ν_{max} 1702–1703 cm^{-1}, establishing the presence of the ketonic group; that of **17***a* also showed a hydroxyl stretching peak at 3389 cm^{-1} and those of **18** and **19** have additional carbonyl stretching peaks at 1735 and 1723 cm^{-1}, respectively, confirming the presence of the acetate and formate groups. The ^1H and ^{13}C nmr spectra of **17***a*, **18**, and **19** are given in Tables 1 and 2, and are in good accord with the structures assigned.

Ironically, although the reaction of δ-valerolactone with **16**, unlike its reactions with the other lithio trithio-orthoformates **7** and **10**, gave the simple adduct without complication, the same was not true of the second reaction of interest, the acetalization of this adduct. This latter problem is not attributable to the fact that **17** was in its open form, since under the reaction conditions used equilibration with closed structures can occur. The acetalization reactions studied all involved reaction with methanol. Initially methanolic hydrogen chloride was used, but it was found that the reactions were complex and capricious. It was later found that the conditions of choice were treatment with methanol in the presence of an acidic ion-exchange resin. Under



[4]The obtention of **17***a* under some conditions and of a mixture of **17***a* and **17***b* under others must result from failure to reach tautomeric equlibrium.

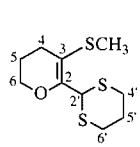
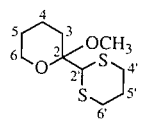
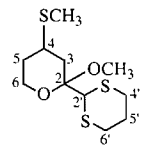
SCHEME 4

SCHEME 5

these conditions the reactions were reproducible, although three products were still formed.







One of these, obtained in 28% yield, was a crystalline compound, $C_{10}H_{16}OS_3$, which is assigned structure **20**. A second product, $C_{10}H_{18}O_2S_2$, isolated in low yield (7%), is considered to have structure **21**, while a third product, $C_{11}H_{20}O_2S_3$, obtained in 23% yield, is assigned structure **22**.

The structures of compounds **20** and **21** readily follow from their origin, composition, and spectra. Neither shows a carbonyl stretching band in its ir spectrum and the signals in their ^1H and ^{13}C nmr spectra can be assigned as in Tables 3 and 4. The structure of compound **21** was confirmed by its preparation as the major product (75%) by acetalization of **23**, the adduct from δ-valerolactone and 1,3-dithiane (3), with methanol and acidic ion-exchange resin (Scheme 6).

The assignment of structure **22** was more challenging. Its composition showed that it is isomeric with the simple acetalization product from **17**. Its ^1H and ^{13}C nmr spectra (Tables 3 and 4) clearly show that it is not the latter; particularly noteworthy are the one-proton signals at $^H\delta$ 3.00 and 4.50, assignable to -C*H*(S-)-S- and -C*H*(S-)-S-, respectively (*vide infra*). These spectra established that the OCH_3 and SCH_3 groups are retained, and the absence of a carbonyl stretching band in its ir spectrum showed that the compound is of the closed type. Its origin, composition, and spectra narrow the choice to one of the diastereomers of **22**, **24** or **25**. Detailed analysis of its ^1H nmr spectra as discussed below permitted the unambiguous choice of structure **22** and the assignment of the relative configuration shown in **26**.

values showed that of the six methylene groups, three form a $-CH_2-CH_2-CH_2-$ sequence with no H–H connectivity with the remainder of the molecule. The proton chemical shift values are in accord with their presence as the C-4′, C-5′, and C-6′ protons of a 1,3-dithiane ring. All but one of the remaining proton signals can be assigned to a $-CH_2CHCH_2CH_2O-$ sequence and the remaining proton signal, which showed no H–H coupling, is assignable on the basis of both its ^1H and ^{13}C nmr chemical shifts to the C-2′ proton of the 1,3-dithiane ring. These results lead to the choice of structure **22** for the product. Confirmatory

20 **21** **22**

evidence was provided by one-bond and multiple bond carbon–proton chemical shift correlation and 1D polarization transfer (INEPT) spectra (see Table 5).[5]

Consideration of the coupling constants shows that the SCH_3

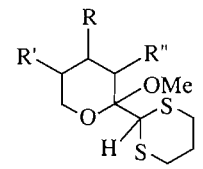
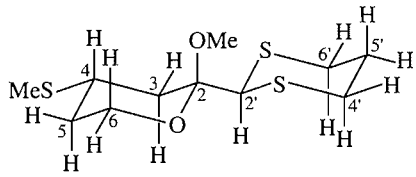
SCHEME 7



group is located equatorially. Since it would be expected that the 1,3-dithianyl ring would take up the equatorial orientation at C-2, this and the SCH_3 group must be *cis* with respect to the pyran ring, as in **26**. Such a relationship is expected if the introduction of the OCH_3 group is reversible, as is likely.

It is not difficult to postulate types of reaction pathway that would account for the formation of **20** and **21**. As in other cases the reaction sequences may include open or closed intermediates. We illustrate in Scheme 7 two of the latter type, which account for the formation of **20** and **21**.[6] Compound **21** is analogous to compound **8** obtained from **7**; we have previously given in Scheme 3 an open version of this type of reaction.



The origin of **22** is more difficult to discern. One possibility is that C-4 develops cationic character in the course of the reaction, for example via intermediates of type **27** and **28** (Scheme 8). The former is also postulated as an intermediate in

[6]The postulated acid-catalyzed nucleophilic attack on sulfur in **27** is closely related to that postulated in Scheme 3 and finds analogy in our observation of the conversion of 2,2-bis(methylthio)-1,3-dithiane to 2-(methylthio)-1,3-dithiane by base-catalyzed nucleophilic attack on sulfur.

26

the formation of **20** (Scheme 7). Then SCH_3 migration could occur as shown in **28**.[7]

In sum, although we have uncovered several reactions of interest, the reactions of none of the three lithio trithioorthoformates **7**, **10**, and **16** with δ-valerolactone has provided a viable route to acetals of type **5** under the conditions that we have used.[8] Indeed, our results with **16** indicate that under these conditions elimination can still compete with acetalization.

Since we have found that the C-2 acetal **21** can be prepared in acceptable yield from the C-2′ dithioacetal **23**, an alternative avenue worthy of exploration is the unmasking and oxidation of such acetals to give compounds of type **5**.

SCHEME 8

Experimental

Melting points (mp) were determined with a Thomas–Hoover capillary melting point apparatus, and are uncorrected.

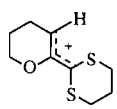
Infrared (ir) spectra of the neat compounds were recorded with a Nicolet FTIR 5DX; only strong (s) bands are reported. Proton magnetic resonance (^{1}H nmr) spectra were recorded in deuteriochloroform (unless otherwise specified) with a Varian T-60, Gemini 200, Varian XL-400, or Bruker AM500 spectrometer. Peak positions are reported on the delta (δ) scale in ppm. Signal multiplicities are reported as singlet (s), doublet (d), triplet (t), and multiplet (m). Carbon-13 magnetic resonance (^{13}C nmr) spectra were recorded in deuteriochloroform (unless otherwise specified) with a Varian XL-200 or Varian XL-400 spectrometer, operating in the pulsed Fourier transform mode. Peak positions are reported on the delta (δ) scale in ppm. Mass spectra were recorded with a Bell and Howell CEC 21-490, VG 70-250S, or VG ZAB SE[9] mass spectrometer. Peak positions are reported in mass-to-charge (m/z) units with the relative abundances in parentheses (rel. %). Ionization was effected by electron impact, unless otherwise indicated.

Silica gel (35–70 μm) was used for column chromatography. Analytical thin-layer chromatography was carried out on aluminum-backed plates that had been precoated with 0.20 mm of silica gel.

Reaction of tris(methylthio)methyllithium (7) with δ-valerolactone (3). Formation of 6-hydroxy-1,1-bis(methylthio)-2-hexanone (8a) and tetrahydro-2-bis(methylthio)methyl-2-pyranol (8b)

A solution of tris(methylthio)methane (23.6 g, 153 mmol) in anhydrous THF (130 mL) was cooled at −78°C under argon. One equivalent of *n*-butyllithium in hexane was added, and the mixture was stirred for 30 min. A solution of δ-valerolactone (5.00 g, 49.9 mmol) in anhydrous THF (40 mL) was then added. The mixture was stirred for 4 h, allowed to warm gradually to −20°C, and treated with saturated aqueous ammonium chloride. The mixture was extracted with chloroform and the extract was washed with water, dried over anhydrous magnesium sulfate, and concentrated. The residue was chromatographed on silica gel with hexane/ethyl acetate (7:3 v/v) as the eluent to yield **8***a* and **8***b* (7.05 g, 34.9 mmol; 70%) as a pale yellow oil. Crystals were formed upon storing at −4°C overnight. Recrystallization from hexane/ethyl acetate (9:1 v/v) yielded **8***a* as white crystals, mp 44–46°C; ir ν_{max} (KBr): 1701 (s), 3390 (s) cm^{-1}; ms m/z (rel. %): 208 (2, M^+), 109 (28), 108 (75), 107 (100), 101 (26), 83 (13), 61 (23), 55 (28). Anal. calcd. for $C_8H_{16}O_2S_2$: C 46.20, H 7.74, S 30.78; found: C 46.07, H 7.82, S 30.44.

Reaction of tris(phenylthio)methyllithium (10) with δ-valerolactone (3). Formation of tetrahydro-3-(phenylthiocarbonyl)-2-pyranone (11)



A solution of tris(phenylthio)methane (1.57 g, 4.6 mmol) in anhydrous THF (19.4 mL) was cooled at −78°C under argon. One equivalent of *n*-butyllithium in hexane (2.5 M; 1.84 mL) was added and the mixture was stirred for 15 min. A solution of δ-valerolactone (150 mg, 1.50 mmol) in anhydrous THF (6.75 mL) was added and the reaction mixture was stirred for 4 h. The work-up and purification of the crude product as for **8** yielded **11** (172 mg, 0.73 mmol, 48%) as a pale yellow oil, which crystallized upon being stored in the freezer (−4°C) overnight. Recrystallization from hexane/methanol (9:1 v/v) yielded **11** as white crystals, mp 63–65°C; ir ν_{max}: 1733 (s), 1692 (s) cm^{-1}; ^{1}H nmr (60 MHz) δ: 1.8–2.5 (m, 4H), 3.95 (t, 1H), 4.45 (t, 2H), 7.45 (s, 5H) ppm; ms m/z (rel. %): 236 (12, M^+), 149 (7), 127 (100), 110 (68), 109 (45), 99 (12), 83 (39), 65 (28). Exact Mass calcd. for $C_{12}H_{12}O_3S$: 236.0507; found: 236.0509.

Preparation of 2-(methylthio)-1,3-dithiane

(i) From 1,3-dithiane

Freshly sublimed 1,3-dithiane (2.66 g, 22.1 mmol) was dissolved in anhydrous THF (20 mL) and cooled at −78°C under argon. *n*-Butyllithium in hexane (1.6 M; 16.54 mL, 26.5 mmol) was added over 25 min, and the solution was stirred for 2 h. Dimethyl disulfide (3.61 mL, 40.1 mmol) was added over 10 min, and the reaction mixture was allowed to warm gradually to room temperature and then poured into 0.05 N hydrochloric acid (200 mL). The THF was removed by evaporation, and the aqueous layer was extracted several times with dichloromethane/pentane (1:1 v/v). The extracts were combined and washed with 10% aqueous sodium bicarbonate, water, and saturated aqueous sodium chloride, dried over anhydrous magnesium sulfate,

[7]A referee has suggested that **i** might be an intermediate in the formation of **22** and **20**. We have considered mechanisms such as this where methanethiol is eliminated and re-added. However, we find it difficult to accept that with methanol as solvent the formation of the methoxy analogs of these methylthio compounds is not observed.

i

[8]The differences between certain of our results and those reported earlier (2) may be attributable to differences in reaction conditions, but we have been unable to check this (see ref. 4, footnote §).

[9]We thank Dr. H. Pang, Carbohydrate Research Centre, University of Toronto, for recording and discussing the spectra taken on this spectrometer.

For personal use only.

and concentrated to give a yellow oil (1.0 g). The crude product was purified by sublimation (50°C, 0.25 Torr; 1 Torr = 133.3 Pa) of the excess 1,3-dithiane present, followed by distillation of the desired 2-(methylthio)-1,3-dithiane (120°C, 0.25 Torr) (lit. (*6b*) bp 50°C, 0.25 Torr), as a colorless oil (886 mg, 24%); ^{1}H nmr (200 MHz) δ: 1.95 (m, 2H), 2.15 (s, 3H), 2.60 (m, 2H), 3.15 (m, 2H), 4.75 (s, 1H) ppm; ^{13}C nmr (200 MHz) δ: 16.8, 25.2, 26.6, 48.1 ppm. The residue was distilled (140°C, 0.25 Torr) to afford 2,2-bis(methylthio)-1,3-dithiane as a colorless oil; ^{1}H nmr (200 MHz) δ: 1.95 (m, 2H), 2.16 (s, 6H), 2.92 (t, 4H) ppm; ^{13}C nmr (200 MHz) δ: 16.0, 24.0, 30.0, 66.4 ppm.

(ii) From 2,2-bis(methylthio)-1,3-dithiane

A solution of 2,2-bis(methylthio)-1,3-dithiane (3.24 g, 15.3 mmol) in anhydrous THF (63.3 mL) was cooled to −78°C under argon. One equivalent of *n*-butyllithium (1.6 M; 9.56 mL) was added, and the mixture was stirred for 1.5 h, allowed to warm to −40°C, added to water, and extracted with carbon tetrachloride. The extract was dried over anhydrous magnesium sulfate, and evaporated to afford a yellow oil. The crude product was identified as a mixture of the starting material and 2-(methylthio)-1,3-dithiane by nmr spectroscopy. Purification was effected by distillation as above to afford the latter compound (69%).

*Reaction of 2-lithio-2-(methylthio)-1,3-dithiane (**16**) with δ-valerolactone (**3**). Formation of 2-(5-hydroxy-1-oxopentyl)-2-(methylthio)-1,3-dithiane (**17**a) and 2-(tetrahydro-2-hydroxy-2-pyranyl)-2-(methylthio)-1,3-dithiane (**17**b)*

A solution of 2-(methylthio)-1,3-dithiane (2.09 g, 12.6 mmol) in anhydrous THF (5 mL) was cooled to −78°C under argon. One equivalent of *n*-butyllithium (1.6 M; 7.78 mL) was added, and the mixture was stirred for 15 min to give **16**. A solution of δ-valerolactone (411 mg, 4.10 mmol) in anhydrous THF (23 mL) was added, and the reaction mixture stirred for 4 h, allowed to warm gradually to −20°C, treated with saturated aqueous ammonium chloride, and extracted with chloroform. The extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to afford a mixture of **17***a* and **17***b* as a yellow oil (2.06 g).

*Acetylation of **17**a and **17**b. Formation of 2-(5-acetyloxy-1-oxopentyl)-2-(methylthio)-1,3-dithiane (**18**)*

The crude product from the above reaction (2.06 g) was dissolved in anhydrous pyridine (4.46 mL), acetic anhydride (71.4 mL) was added, and the mixture was stirred under argon for 4 h. The reaction mixture was poured into ice-water and extracted with chloroform. The extract was washed with water, dried over anhydrous sodium sulfate, and evaporated to afford a yellow oil (1.8 g). Chromatography of the crude product on a silica column with hexane/ethyl acetate (7:3 v/v) as eluent afforded **18** (40% overall yield); ir ν_{max}: 1736 (s), 1700 (s) cm^{-1}; ^{13}C nmr (200 MHz; C_6D_6) δ: 16.5, 20.9, 21.6, 25.2, 27.3, 27.5, 28.6, 35.5, 64.4, 113.2, 199.4 ppm; ms *m/z* (rel. %): 308 (2, M^+), 261 (17), 165 (100), 119 (30). Anal. calcd. for $C_{12}H_{20}O_3S_3$: C 46.72, H 6.54, S 31.18; found: C 46.86, H 6.54, S 30.89.

*Hydrolysis of **18**. Formation of **17**a*

A solution of compound **18** (104 mg, 0.33 mmol) in aqueous basic methanol (70 mg of sodium carbonate/26 mL of 4% aqueous methanol) was stirred for 2.5 h at room temperature. The reaction mixture was treated with water (50 mL), and extracted with chloroform. The extract was washed several times with water, dried over anhydrous sodium sulfate, and evaporated to afford a pale yellow oil (87 mg, 90%); ir ν_{max}: 3389 (s), 2915 (s), 1700 (s) cm^{-1}; ms *m/z* (rel. %): 219 (3.5, $(M - SCH_3)^+$) 165 (35), 119 (100), 91 (32.5).

*Reaction of **17**a with trimethyl orthoformate. Formation of 2-(5-formyloxy-1-oxopentyl)-2-(methylthio)-1,3-dithiane (**19**)*

A solution of compound **17***a* (0.272 g, 1.02 mmol) in trimethyl orthoformate (0.68 mL) with a catalytic amount of cerium(III) chloride heptahydrate (2.5 mg) was stirred at room temperature for 46 h. The excess trimethyl orthoformate was removed under water aspirator pressure to afford a pale yellow oil (199 mg). The crude product was purified by chromatography on a silica column with hexane/ethyl acetate (7:3 v/v) as eluent, giving **19** as the only product eluted (45 mg, 24%); ir ν_{max}: 1723 (s), 1703 (s) cm^{-1}; ms *m/z* (rel. %): 294 (2, M^+), 247 (17), 165 (100), 119 (18), 91 (9).

*Reaction of **17**a with methanol and acidic ion-exchange resin. Formation of 2-(5,6-dihydro-3-(methylthio)-2(4H)-pyranyl)-1,3-dithiane (**20**), 2-(tetrahydro-2-methoxy-2-pyranyl)-1,3-dithiane (**21**), and 2-(tetrahydro-2-methoxy-4-(methylthio)-2-pyranyl)-1,3-dithiane (**22**)*

Dowex 50X8-100 ion-exchange resin (Dowex-50W-hydrogen, strongly acidic cation. 8% cross-linking, 50–100 dry mesh) was treated with 1 N hydrochloric acid, filtered, washed with water, and dried by azeotropic distillation with benzene. It was rinsed several times with anhydrous methanol before use.

Compound **17***a* (208 mg, 0.75 mmol) in anhydrous methanol (45 mL) was added to a tenfold excess of the acidic ion-exchange resin, and the mixture was stirred at room temperature under argon for 44 h. The reaction mixture was filtered through Celite to remove the resin, diluted with water (60 mL), and extracted with chloroform (3 × 25 mL). The combined extracts were washed with water (4 × 20 mL), dried over anhydrous sodium sulfate, and evaporated. Chromatography of the residue on a silica column with hexane/ethyl acetate (6:4 v/v) as eluent gave two major products and one minor product.

Compound **20** (52 mg; 28%) was eluted first as a pale yellow oil that crystallized upon standing in the freezer (−4°C) overnight. Recrystallization from hexane/ethyl acetate (7:3 v/v) afforded white crystals, mp 65.5–66.5°C: ms *m/z* (rel. %): 248 (100, M^+), 201 (24), 159 (83), 119 (21), 73 (10). Anal. calcd. for $C_{10}H_{16}OS_3$: C 48.35, H 6.49, S 38.72; found: C 48.41, H 6.52, S 38.52.

Compound **21** was eluted second as a pale yellow oil (17 mg; 7%). Exact Mass calcd. for $C_{10}H_{18}O_2S_2$: 233.0670 (M − 1); found:[10] 233.0683.

Compound **22** was eluted third as a pale yellow oil (48 mg; 23%); ms *m/z* (rel. %): 279 (9, $(M - 1)^+$), 266 (3), 201 (15), 161 (100), 133 (8), 101 (26), 85 (15), 71 (19). Exact Mass calcd. for $C_{11}H_{20}O_2S_3$: 279.0457 (M − 1); found:[11] 279.0450.

*Reaction of 2-(5-hydroxy-2-oxopentyl)-1,3-dithiane (**23**) with methanol and acidic ion-exchange resin. Formation of **21***

Compound **23** (727 mg, 3.26 mmol) (3) in anhydrous methanol (80 mL) was added to Dowex 50-X8-100 acidic ion-exchange resin prepared as above (7.3 g). The reaction mixture was stirred at room temperature under argon and worked up as before to give a pale yellow oil. Column chromatography on silica with hexanes/ethyl acetate (6:4 v/v) gave **21** as the only major product (580 mg; 75%), as a colorless oil whose spectra were identical with those of **21** obtained from **17***a*.

*Reaction of **20** with methanol and acidic ion-exchange resin. Formation of **21** and **22***

Compound **20** (48.3 mg, 0.195 mmol) in anhydrous methanol was treated with Dowex-50-X8-100 acidic ion-exchange resin as above. Chromatography as before gave compounds **20** (8.7 mg; 18%), **21** (13.8 mg; 30%), and **22** (18.1 mg; 32%), whose spectra were identical with those of the corresponding products obtained from **17***a*.

The photoaddition of 1,3-diketonatoboron difluorides with benzene derivatives

YUAN L. CHOW AND XINXIN OUYANG
Department of Chemistry, Simon Fraser University, Burnaby, B.C., Canada V5A 1S6

Received July 11, 1990

YUAN L. CHOW and XINXIN OUYANG. Can. J. Chem. **69**, 423 (1991).

The boron difluoride complexes of 2-acetylcyclohexanone, 2-acetylcyclopentanone, and acetylacetone (abbreviated as $ACHBF_2$, $ACPBF_2$, and $AABF_2$) were irradiated in the presence of benzene to give the 1:1 adducts as the primary photoadducts; for certain BF_2 complexes, toluene, chlorobenzene, benzonitrile, and methyl benzoate were also used as substrates. The 1,5-diketone photoadducts were assumed to form by a [2+2] photocycloaddition followed by cyclobutane opening and hydrolysis to give 1,2 adducts. They undergo a variety of secondary thermal reactions, probably acid catalyzed, to give enol ethers, enol acetates, acetophenones, and ketonylacetophenones. The efficiency of these secondary reactions determines the final products. Photoaddition with a monosubstituted benzene preferentially occurs at the 3,4 bond without regioselectivity. Under oxygen, $ACHBF_2$ photolytically reacts with benzene to give a secondary oxidation product of a 10-membered cyclic alkylphenone, which is proven by X-ray crystallographic analysis to have the benzene ring and carbonyl group in orthogonal orientation. It is shown that the singlet excited state $ACHBF_2$ initiates the photoaddition, probably through the formation of the benzene exciplex, which could be detected by its emission. While the Stern–Volmer rates are small, the quantum yield of photoaddition products is as high as 0.12–0.19 under limiting conditions.

Key words: [2+2] photocycloaddition, non-planar alkanophenone, macrocyclic alkanophenone, boron difluoride complexes, photoaddition to benzenes.

YUAN L. CHOW et XINXIN OUYANG. Can. J. Chem. **69**, 423 (1991).

Opérant en présence de benzène, on a irradié les complexes difluorure de bore des 2-acétylcyclohexanone ($ACHBF_2$), 2-acétylcyclopentanone ($ACHBF_2$) et acétylacétone ($AABF_2$) et on a obtenu des photoadduits primaires 1 : 1; pour certains complexes du BF_2 on a aussi utilisé le toluène, le chlorobenzène, le benzonitrile et le benzoate de méthyle comme substrats. On a fait l'hypothèse que les photoadduits 1,5-dicétoniques se forment par une photocycloaddition [2+2] suivie d'une ouverture du cyclobutane et d'une hydrolyse qui conduit aux adduits 1,2. Ils subissent diverses réactions thermiques secondaires, probablement acido-catalysées, qui conduisent à des éthers énoliques, des acétates énoliques, des acétophénones et des cétonylacétophénones. L'efficacité de ces réactions détermine la nature des produits finaux. La photoaddition sur un benzène monosubstitué se produit d'une façon préférentielle, mais sans régiosélectivité, sur la liaison 3,4. En présence d'oxygène, l'$ACHBF_2$ réagit d'une façon photolytique avec le benzène pour donner un produit d'oxydation secondaire comportant une alkylphénone cyclique à dix chaînons dans laquelle on a démontré, par une analyse par diffraction des rayons-X, qu'il existe un cycle benzénique et un groupement carbonyle en position orthogonale. On a démontré que l'état excité singulet du $ACHBF_2$ initie la photoaddition, probablement par le biais de la formation de l'exciplexe du benzène que l'on a pu détecter par son émission. Même si les vitesses de Stern–Volmer sont faibles, le rendement quantique des produits de photoaddition atteint 0,12–0,19, dans des conditions limitantes.

Mots clés : photocycloaddition [2+2], alcanophénone non planaire, alcanophénone macrocyclique, complexes du difluorure de bore, photoaddition à des benzènes.

[Traduit par la rédaction]

We have demonstrated that the singlet excited state of 1,3-diketonatoboron difluorides undergoes photocycloaddition of the diketone moiety to simple olefins, and also sensitizes various electron rich olefins to undergo cation radical reactions (1–3). The primary reaction of the BF_2 complexes has been suggested to involve some degree of electron transfer from excited substrates, as indicated by a correlation of log k_q (where k_q is the quenching rate constant of a BF_2 complex fluorescence) and ionization potentials of substrates (1). Using dibenzoylmethanatoboron difluoride ($DBMBF_2$) as a model, we have described the photocycloaddition with some olefins; such a reaction is shown to be regiospecific and highly stereoselective. Further, its mechanism is shown to be highly unusual in involving the excimer of $DBMBF_2$ (3). While $DBMBF_2$ does not photolytically add to benzene derivatives, we have been surprised to observe that alkyl-type 1,3-diketonatoboron difluorides photolytically add to benzene derivatives. As photoaddition to benzene generally affords unusual products (4–9), we have carried out an investigation, which is the subject of this report.

Results

For this work, acetylacetonatoboron difluoride ($AABF_2$) (10, 11), 2-acetylcyclohexanonatoboron difluoride ($ACHBF_2$) (12), and 2-acetylcyclopentanonatoboron difluoride ($ACPBF_2$) (13) were prepared from the corresponding 1,3-diketones according to the reported procedures. These BF_2 complexes exhibited UV absorption peaks at nearly the same wavelength as the parent 1,3-diketones but with greater optical densities (Fig. 1). For comparison, the UV absorption maxima of the parent 1,3-diketones are as follows: acetylacetone, 271 nm (ϵ 6200); 2-acetylcyclopentanone, 283 nm (ϵ 4000, br); 2-acetylcyclohexanone, 283.5 nm (ϵ 7980).

Photolysis of $ACHBF_2$ in benzene or a mixture of benzene and acetonitrile under nitrogen efficiently consumed the BF_2 complex to yield acetophenone **1** and enol ether **2** in a 1:5 ratio as shown by GC analysis. A similar photolysis under oxygen afforded acetophenone and keto ester **5** in a 1:1 ratio, and a small amount of enol acetate **3**. The enol acetate **3** was known to be a photolabile compound (14, 15); its structure was readily identified from its typical enol acetate IR absorption at 1760, 1229, 1172, 770, and 712 cm^{-1} and the ^{13}C NMR signal for the ester CO at 169.31 ppm without the presence of a ketone CO signal.

While acetophenone was readily determined by coinjection with an authentic sample, the structure of **2** was deduced from its physical data: (i) the ^1H NMR signals of a CH_3 doublet at 1.61

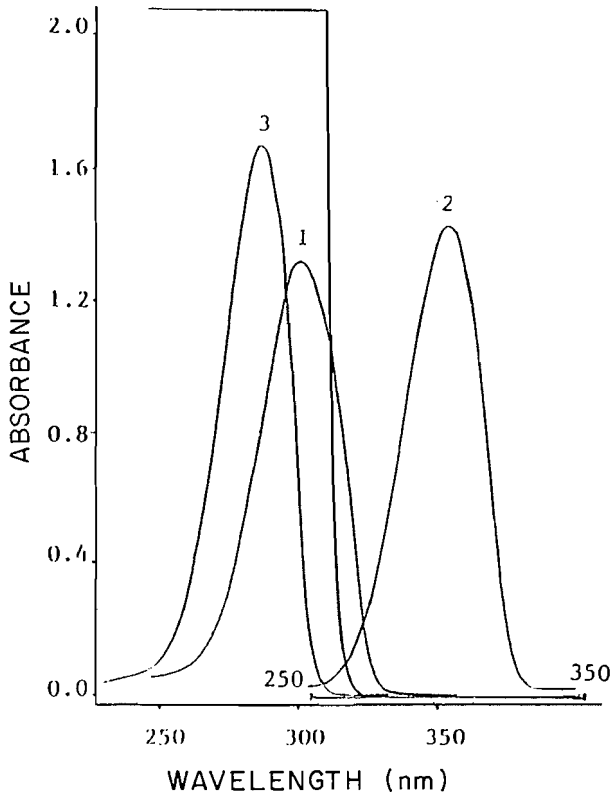

FIG. 1. The absorption spectra of $ACHBF_2$ (**1**, 1.0×10^{-4} M) and $ACPBF_2$ (**2**, 1.0×10^{-4} M) in CH_3CN, and $AABF_2$ (**3**, 1.0×10^{-4} M and 1.0×10^{-3} M) in ether.

ppm and methine quartet at 5.08 ppm (J = 6.4 Hz), and (ii) a tetra-substituted olefinic bond as shown by ^{13}C NMR data as well as the enol ether absorption at 1658 and 1196 cm^{-1}. The keto ester **5** was obtained in high yield by methylene blue sensitized oxygenation of **2** that obviously involved singlet oxygen. The structure of keto ester **5** could be deduced on the basis of an oxidative cleavage of **2** by the cycloaddition of singlet state oxygen to form dioxetane **4**, followed by a ring cleavage (16–18). However, the IR absorption at 1709 cm^{-1} and ^{13}C NMR spectrum for the ketone group at 207.48 ppm are typical for a non-conjugated carbonyl but not common to a conjugated carbonyl group (19), as shown in **5**. In addition, a distinct fluorescence peak at 330 nm is not typical for acetophenone-type compounds. Using X-ray crystallographic analysis, this compound was shown to have the structure shown in **5**. The X-ray computed structure showed that the C=O group was oriented nearly perpendicular to the plane of the benzene ring, therefore would not allow resonance interaction on account of the orthogonal orientation. The ORTEP view of the molecular structure is reproduced in Fig. 2 (20); the torsional angle defined by C(2)—C(1)—C(13)—O(1) is 101.0° and that by C(6)—C(1)—C(13)—O(1) is 80.5°. Inspection of the Dreiding model of structure **5** also showed that the benzyl $CHCH_3$ group strongly interacts with the C=O group at all conceivable conformations and forces the C=O group to orient out of coplanarity. This solved the spectroscopic anomaly shown above.

A similar photoaddition of $ACHBF_2$ to toluene under nitrogen was slower, and yielded product mixtures of positional isomers that defied attempts to separate them. It gave an equal mixture of 3- and 4-methylacetophenone (**6**) and that of enol ethers **7**. A 1:1 mixture of keto ester **8** was obtained either by photooxygenation of the mixture of enol ethers **7** or by a similar

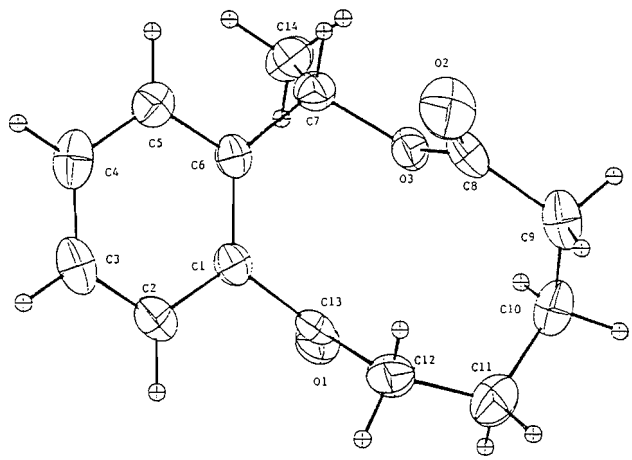

FIG. 2. ORTEP view of the molecular structure of **5**; important torsion angles (°) are: C(2)—C(1)—C(13)—O(1), 101.0 (3); C(6)—C(1)—C(13)—O(1), 80.5 (3); C(1)—C(6)—C(7)—C(14), 93.4 (3).

photoaddition of $ACHBF_2$ in toluene under oxygen. These mixtures gave poorly resolved peaks by GC analysis, could not be easily separated, and hence were analyzed as mixtures. The ^1H NMR spectrum of the mixture of **7** clearly gave two sets of signals similar to those of enol ether **2**. In particular, two sets of broad singlets (6.84 and 6.87 ppm) and double doublets (6.95 and 7.06 ppm, 6.91 and 6.96 ppm) defined two isomers, arising from the 1,2,4- and 1,2,5-substitution patterns on the benzene ring (19). Likewise, the mixture of keto esters **8** also showed two sets of ^1H NMR signals with the two aromatic singlets at 7.01 and 6.84 ppm and double doublets at 6.91 + 6.96 and 7.09 + 7.14 ppm. The ^{13}C NMR spectrum of this mixture showed two carbonyl signals, at 208.0 ppm for the ketone and 172.0 ppm for the ester. Although an X-ray structural analysis was not performed, the ^{13}C NMR signal at 208.0 ppm and the IR absorption at 1720 cm^{-1} for the ketone group unmistakably suggest that the neighboring carbonyl group is not coplanar with the benzene ring.

The photoaddition of $ACHBF_2$ with chlorobenzene, methyl benzoate, and benzonitrile in acetonitrile also occurred; the efficiency of the photoaddition was in the same order as given above. In all cases, mixtures of isomeric acetylated products were obtained as the major products, in addition to small amounts of dehydration products as shown by CI mode mass spectrometry. The minor products were assumed to be the corresponding enol ethers similar to **2** and **7**. For methyl benzoate, the acetylated products were isolated as a mixture and analyzed by ^1H NMR and GC spectra to contain a 3:1 ratio of 3- and 4-acetyl methyl benzoates **9**. However, under similar conditions $ACHBF_2$ failed to photolytically add to anisole, and the BF_2 complex was recovered nearly quantitatively.

The photoaddition of $ACPBF_2$ in benzene–ether (2:3 v/v ratio) gave a mixture of acetophenone, one minor, and one major product in a 5:1:5 ratio. From GC–MS inspection, the major product was shown to be a 1:1 addition product of ACP with benzene, such as 1,5-diketone **10**. The minor product was not isolated and was probably **12**, arising from dehydration in analogy to the formation of **2** and **7**. The yield of acetophenone increased if the photolysate was left untreated at room temperature; washing of the photolysate with water prevented the increase. When the photoaddition was carried out in the presence of either pyridine or tributylamine, the primary adduct **10**, enol ether **12**, and acetophenone were obtained in a 12:1:1 GC

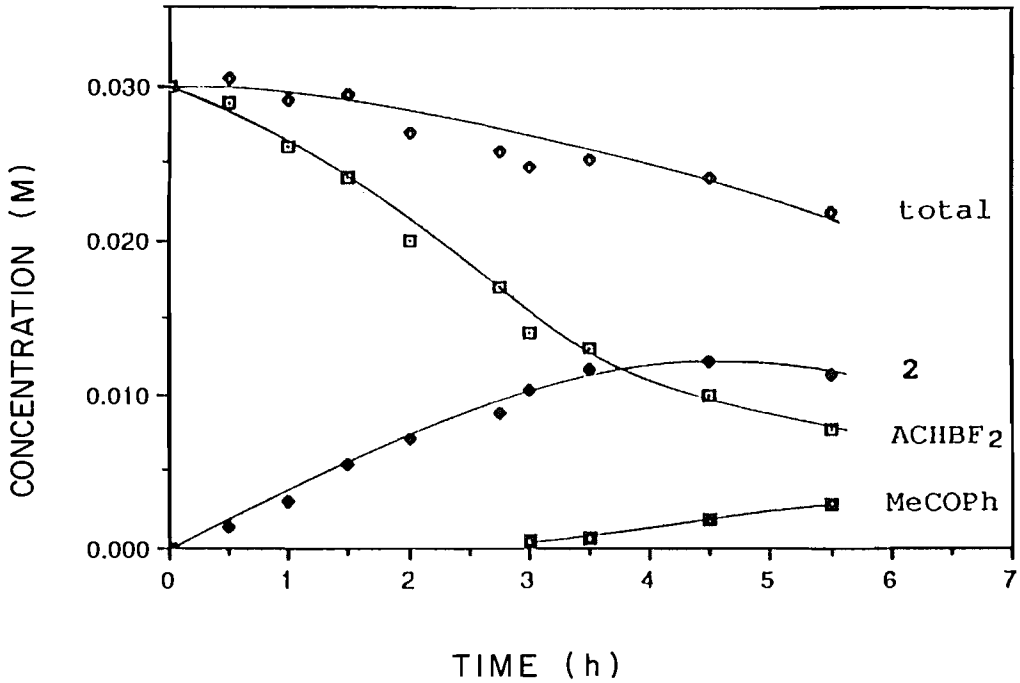

FIG. 3. The profile of the material balance in a photoaddition of $ACHBF_2$ (0.03 M) to benzene (2 M) in dioxane.

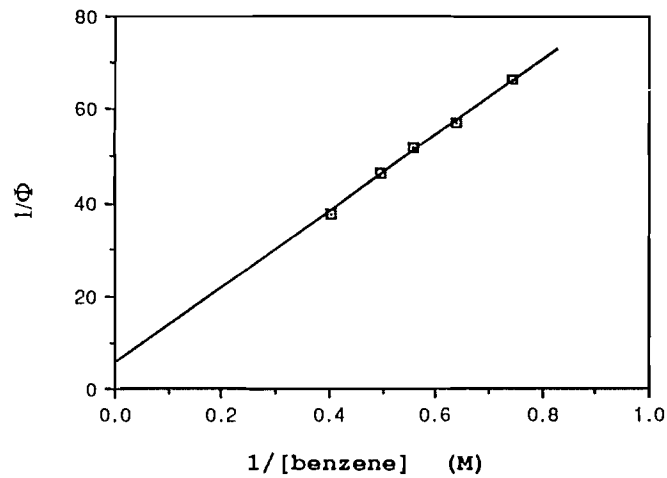
ratio. Such a crude product clearly showed allylic protons as a double doublet (3.49 ppm) and a double multiplet (3.05 ppm) with the coupling constant of 8.3 Hz for a *cis* orientation, and four olefinic protons at 5.95 ppm. Column chromatography of the photolysate gave no primary adduct **10** but 2-(2′-acetylphenyl)-cyclopentanone (**11**), which must arise from dehydrogenation of **10** during chromatography.

The photoaddition of $AABF_2$ with benzene was carried out under similar conditions as above and was monitored with GC analysis to show rapid formation of a peak corresponding to the 1:1 adduct **13** (M^+ 178 by CI mode) and a small amount of acetophenone **1**. The peak intensity of **13** started to decrease at about 50% $AABF_2$ conversion and the acetophenone peak started to appear; continuing irradiation of this photolysate afforded a complex mixture. When the photolysate was washed with a base, 1,5-diketone **13** was isolated as a stable compound with a small amount of 2-acetonylacetophenone **14** (21, 22). When the photolysate was not neutralized, **13** underwent facile secondary reactions to give a mixture that was chromatographed to afford a 1:1 mixture of 2-acetonylacetophenone (**14**) and 4-acetonylacetophenone (**15**). The ^1H NMR spectrum of the mixture showed a typical AA′BB′ system at 7.30 and 7.93 ppm (J = 8.3 Hz) for the *para* isomer **15** (21) in addition to other signals for the *ortho* isomer **14** (22). The diketone **15** was shown to be formed by acid-catalyzed thermal, but not by photochemical, reaction. The coupling constant of two allylic protons in **13** was determined to be 7.2 Hz, which confirmed the *cis* orientation of the two ketone side chains.

Mechanistic studies of this photoaddition were carried out using the photoaddition of $ACHBF_2$ to benzene as a model system. In Fig. 3, the profile of $ACHBF_2$ consumption and the formation of acetophenone and enol ether **2** were plotted versus the reaction time. It clearly demonstrated that acetophenone was a secondary photoproduct. $ACHBF_2$ did not show aggregate formation in the ground state, as demonstrated by UV spectroscopy. It showed weak fluorescence in acetonitrile with a peak at 355 nm; the lowest singlet excited state energy level was estimated to be E_s 91 kcal/mol (at 315 nm). The intensity of the fluorescence peak increased on the addition of benzene (0.5 M level), probably owing to emission from an exciplex of $ACHBF_2$ with benzene. The result from our group also showed that the $DBMBF_2$–benzene exciplex emits at about the fluorescence peak of $DBMBF_2$ itself.[1] In ether it showed phosphorescence emission at 77 K with a peak at 469 nm; the lowest triplet state energy is estimated to be 66–67 kcal/mol from the onset of the spectrum at 430 nm. The quantum yield (Φ) of the photocycloaddition was measured at various concentrations of benzene using a quantitative GC determination of enol ether **2**. The plot of the reciprocal of enol ether quantum yield (Φ) against that of benzene concentrations gave a good straight line as shown in Fig. 4. In dioxane, the $K_q\tau_0$ (= 5.4/81) was 0.067 and $\Phi_{limiting}$ (= 1/5.4) was 0.19; in acetonitrile, the $k_q\tau_0$



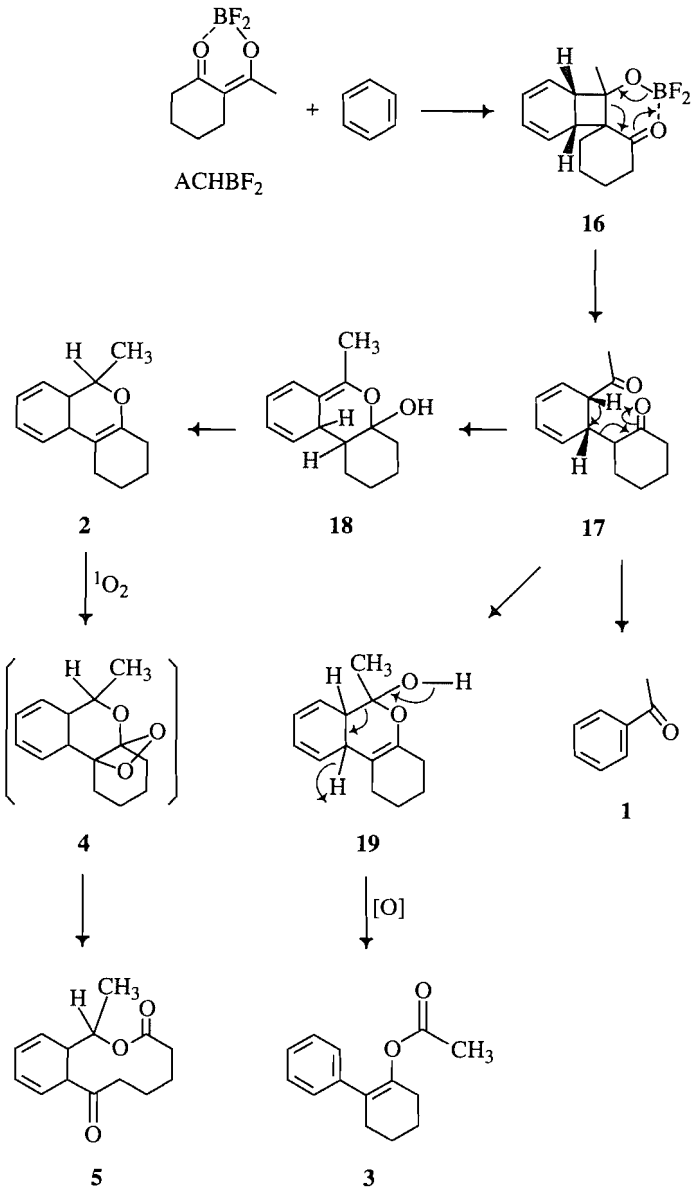


FIG. 4. A plot of the reciprocal of the quantum yields of **2** vs. the reciprocal of benzene concentration in the photoaddition of $ACHBF_2$ in dioxane.

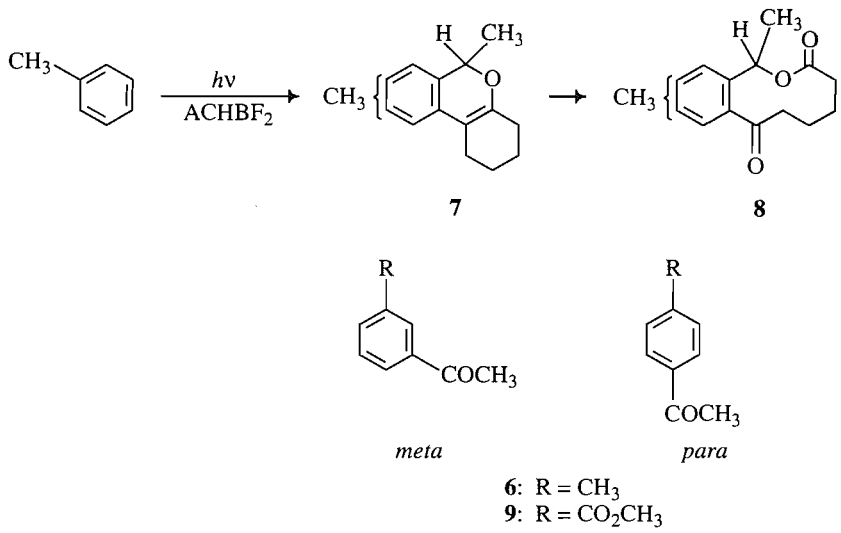
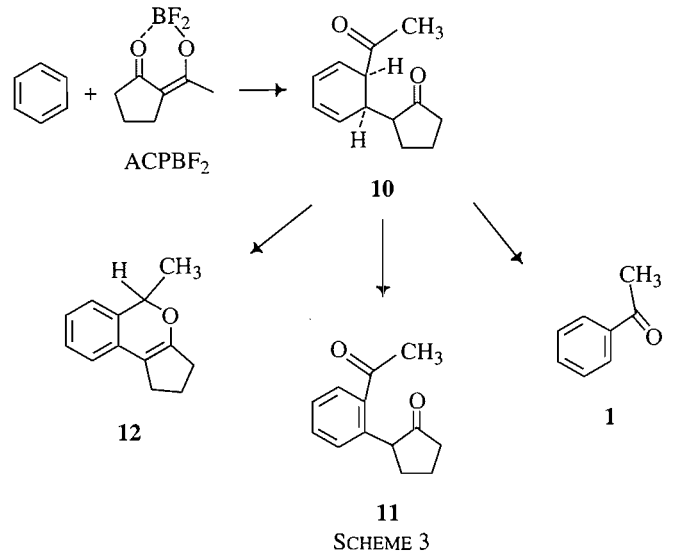
SCHEME 1

(= 8/247) was 0.032 and $\Phi_{limiting}$ (= 1/8) was 0.12. Owing to the long extrapolation, the error margin of intercepts was probably very large, and both $k_q\tau_0$ and $\Phi_{limiting}$ values must be regarded as an approximation. In contrast to the $DBMBF_2$ photoaddition to olefins (3), the quantum yield of **2** in this photoaddition was independent of [$ACHBF_2$] over the range of 0.02–0.04 M. The quantum yield was not affected in the presence of 1,3-pentadiene or 1,3-cyclohexadiene (up to 0.012 M) but was rapidly reduced in the presence of 1,2-dibromoethane in the 0.02–0.06 M range. The effect of this heavy atom containing compound was exponential above a concentration of 0.06 M and could not be analyzed quantitatively. Attempted sensitization of the photoaddition with benzophenone or xanthone as sensitizers failed to give any photoaddition product **2**.



Discussion

As shown in the photoaddition of $ACPBF_2$ and $AABF_2$ to benzene, the primary products are 1:1 adducts of ACP or AA with benzene, i.e., 1,5-diketones such as **10** and **13**. From the structures of subsequent products shown in Scheme 1, the unisolated 1:1 adduct is deduced to be **17**. Indeed **13** is semi-stable and can be isolated and analyzed by ^1H NMR. The primary product is assumed to be formed by a [2+2] photocycloaddition to a BF_2 complex to form a cyclobutane derivative **16** (see Scheme 1); the ring opening and hydrolysis should give 1,5-diketone **17** (or **10** or **13**). This mechanism is proposed in analogy to the photoaddition of dibenzoylmethanatoboron difluoride to olefins (3). The hydrolysis of the BF_2 moiety generates hydrofluoric acid, which promotes acid-catalyzed reactions to be described below. The other photoaddition products arising from the alternative enol isomer (endocyclic double bond) of $ACHBF_2$ and $ACPBF_2$ to benzenes have not formed to a detectable extent as shown by careful searches in GC analysis. Should such photoaddition occur, acetophenone derivatives could not be obtained. It appears that these unsymmetrical BF_2 complexes preferentially react as exocyclic olefin isomers, exclusively, by some unknown reason. It should be pointed out that the proposed mechanism would predict the *cis* orientation of the ketone substituents in 1,5-diketones **10**, **13**, and **17** if the reaction is concerted. While the stereochemistry is eventually lost in aromatization of the ring in the subsequent reactions, the *cis* orientation is proven in the case of **10** and **13**.



The observed substitution patterns of the photoaddition products in **6**–**9** (Scheme 2) and the lack of *ortho* substituted product could be explained by postulating that $ACHBF_2$ reacts with monosubstituted benzene at the 3,4 position exclusively but without regioselectivity. If photoaddition also occurs at the 2,3 position, the production of *ortho* substituted compound corresponding to **6**–**9** would be expected, since the orientation of $ACHBF_2$ approaching a monosubstituted benzene does not have much regioselective control. The absence of the $ACHBF_2$ attack at the 2,3 position, which may arise from the steric factor of the monosubstituted group, is a significant advantage. However, the complete lack of regioselectivity in the photoaddition of these BF_2 complexes is a major impediment to their synthetic applications.

Having decided the mechanism of primary photoaddition of BF_2 complexes to benzene derivatives, we are in a position to discuss the secondary reactions. The 1,5-diketones **10**, **13**, and **17** and the allied 1:1 adducts in this photoaddition exhibit a wide range of reactivities and patterns. The primary adducts **10** and **13** are obviously more stable than **17** and the allied adducts of $ACHBF_2$ with monosubstituted benzenes under the photolysis conditions. While the adducts of the latter group have undergone thermal reactions during photolysis, **10** and **13** do survive under the experimental conditions. One of the thermal reactions is the elimination of a ketone with aromatization (cyclohexanone in Scheme 1, cyclopentanone in Scheme 3, and acetone in Scheme 4), which is evidently acid catalyzed since pyridine or tributylamine added to neutralize HF formed during the photolysis does reduce the formation of acetophenone. It should be pointed out that acetophenone derivatives could be obtained by photoinitiated Norrish Type II photoreaction (23). A Type II photocleavage appears to contribute insignificantly to the formation of acetophenone since the yield of acetophenone in $ACHBF_2$ is not changed significantly by using a 350 nm irradiation source or a high concentration of $ACHBF_2$ complex. Other BF_2 complex photoadditions should follow the same pattern. This acid-catalyzed elimination drains the primary photoadduct 1,5-diketones to unwanted acetophenone derivatives, which is particularly serious for relatively stable 1,5-diketones such as **10** and **13**. Fortunately, such a process can be controlled with the addition of a tertiary amine.

SCHEME 2

SCHEME 3

SCHEME 4

1,5-Diketone **17** also efficiently undergoes other thermal reactions, most likely acid catalyzed; hence the concentrations of **17** as well as acetophenone are low during the photoaddition as shown by GC examinations. In Scheme 1, the most economical mechanisms are formulated for the formation of **2** and **3**. The enolization of **17** on either site followed by hemiketal formation may proceed readily to give **18** and **19**, probably arising from the particular structural feature (as opposed to **10** and **13**). It is speculated that 1,5-diketone **17** can easily assume conformations convenient for undergoing intramolecular enol ether formations. The process **17** → **18** should be faster than **17** → **19** because of achieving extended conjugation in the dehydration step. However, at this stage the oxidizing species or reduction products involved in the transformation **19** → **3** under nitrogen have not been identified.

The identification of 4-acetonylacetophenone (**15**) in the photoaddition of $AABF_2$ to benzene (Scheme 4) has led us to ascertain that the corresponding dihydro precursor is not formed as a primary photoproduct arising from a [2+4] cycloaddition. The photoaddition of an excited state olefin to benzene or such a photoaddition involving a cyano-substituted substrate generally gives 1,2 adducts (6, 7). The photoaddition involving excited state benzenes with an olefin can give all possible 1,2, 1,3, and 1,4 adducts with retention of stereochemistry, and has been shown to be derived from a common intermediate, which appears to be benzvalene (4, 5, 8). In the present photoaddition, singlet excited state $AABF_2$ is not expected to sensitize benzene from the energetic consideration nor to follow the [2+4] addition pattern. The photolysate has been carefully scrutinized by GC–MS and ^1H NMR analysis to show the absence of other primary photoadducts than **13**. For a heavily functionalized system such as **13**, it may undergo many types of phototransformation by itself. While the acid-catalyzed formation of *para*-isomer **15** from **13** obviously requires a dehydrogenation step, it is premature to suggest a mechanism because pertinent information is scarcely available at this stage.

Having defined the overall reaction pattern, we wish to discuss the primary photoreaction step of the BF_2 complex photoaddition with benzene derivatives. As indicated by the absorption curves of $ACHBF_2$ and other complexes (Fig. 1), undoubtedly the excitation of the BF_2 complexes is the primary step to initiate the photoreaction under the irradiation conditions using a Pyrex filter. $ACHBF_2$ shows only weak fluorescence emission, which overlaps with the exciplex emission with benzene at about 360 nm. This poses a severe limitation to conducting fluorescence quenching experiments. The lack of

For personal use only.

fluorescence of these BF_2 complexes suggests a fast intersystem crossing, therefore short singlet excited state lifetimes. The photoaddition with benzene most likely occurs from the corresponding exciplex. The quantum yields of the formation of enol ether **2** can be monitored readily by GC analysis. The lack of diene quenching of the quantum yield Φ and the failure to sensitize the photoreaction with a triplet sensitizer suggest that the singlet excited state BF_2 complex undergoes the photoaddition. This is confirmed by a heavy atom effect by 1,2-dibromoethane, which promotes the intersystem crossing of singlet excited state $ACHBF_2$ and reduces the quantum yield of **2**. Therefore, the $k_q\tau_0$ obtained in Fig. 4 must represent the product of the reaction rate constant and lifetime of the singlet excited $ACHBF_2$. The low values of 0.032 M^{-1} in CH_3CN and 0.067 M^{-1} in dioxane must mean that the reactive bimolecular encounter has low probability. This may be caused by the short lifetime of the singlet excited state of $ACHBF_2$ as suggested by weak fluorescence. However, reasonably good limiting quantum yields of 0.12 and 0.19 should suggest that a high proportion of exciplex is partitioned to give product **2**.

Experimental section

Materials and general conditions

Commercially available benzenes were distilled before use. Unless specified otherwise the following conditions prevailed. The boron difluoride complex of β-diketones was prepared from the reactions with BF_2 etherate in methylene chloride according to the published procedures (12). $ACHBF_2$ was recrystallized from CH_2Cl_2/hexanes in 70% yield; mp 79–79.5°C; $ACPBF_2$ was recrystallized from ether/hexanes in 63% yield; mp 65.5–70°C; $AABF_2$ was recrystallized from ether in 45% yield; mp 42.5–43°C (lit. (11) mp 43°C).

Gas chromatographic (GC) analyses were performed on a Hewlett–Packard 5790 chromatograph equipped with an FID and an HP-1 (12 m × 0.20 mm) capillary column, and connected to a Hewlett–Packard 3390A chart integrator. Preparative GC was conducted on a Varian 1700 chromatograph equipped with an OV-1 packed column (4 ft × 0.25 in., 15%, Chromsorb A, 60–80 mesh). Melting points were determined on a Fisher–John apparatus (uncorrected). Infrared (IR) spectra were determined on a Perkin–Elmer 559B (neat film or KBr), and (or) a BOMEM Michelson 120 (FT–IR). Mass spectra (MS) and gas chromatography – mass spectra (GC–MS) were taken with a Hewlett–Packard 5985 GC–MS system in electron impact ionization (EI) and (or) chemical ionization (CI) mode. Nuclear magnetic resonance spectra were obtained on either a Bruker 100SY spectrometer equipped with Aspect 2000 software or a Bruker WH400 spectrometer. Chemical shifts (δ) for ^1H and ^{13}C spectra were reported in ppm with reference to tetramethylsilane. The coupling constants are reported in Hz. Ultraviolet and visible (UV/VIS) spectra were recorded on a Varian Cary 210 spectrophotometer. Emission spectra were obtained on a Perkin–Elmer MPF-44B spectrophotometer (uncorrected).

General procedure of photoaddition

A solution of BF_2 complex was irradiated in a Hanovia-type irradiator with a 200-watt medium pressure mercury lamp (645A 36) under constant purging of nitrogen. Alternatively, a solution of a BF_2 complex was distributed in an appropriate number of Pyrex or quartz tubes (1.2 × 10 cm) and was purged with nitrogen for 15 min. These tubes were irradiated with RPR 3000 Å (16 × 21 watt) or RPR 3500 Å (16 × 24 watt) lamps in a Rayonet photochemical reactor. At intervals, the photolysate was withdrawn for GC analysis. At the end of irradiation, the photolysate was washed twice with water and the solution was evaporated to afford a crude product, which was flash chromatographed. The spectroscopic data of the products are summarized in Tables 1–4.

$ACHBF_2$ to benzene

$ACHBF_2$ (760 mg, 4.0 mmol) in benzene (80 mL) was irradiated with a 200-watt Hanovia lamp for 2.5 h under nitrogen. The photolysate showed GC peaks (170°C) corresponding to acetophenone (R_t 0.91 min), $ACHBF_2$ (R_t 1.99 min), enol ether **2** (R_t 2.38 min), and a minor product in a peak area ratio of 15:1:69:2. The enol ether **2** was isolated as an oil; UV λ_{max} 285 nm (log ε, 4.11) in *n*-heptane; see Tables 1–4 for other data. Anal. calcd. for $C_{14}H_{16}O$: C 83.96, H 8.05; found: C 84.26, H 8.13.

[a]The sample is a mixture of two regioisomers.
[b]The sample contains a 1:1 mixture of 1,2- and 1,4-disubstituted isomers (**14** and **15**).

The photoreaction was repeated in solvent consisting of benzene and acetonitrile (1:2 by volume) under oxygen. The photolysate showed the GC peaks corresponding to acetophenone (37%, R_t 0.91 min), enol acetate **3** (10%, R_t 1.55 min), and keto lactone **5** (37%, R_t 3.43 min). The enol acetate **3**, a known compound (14, 15), was isolated by flash chromatography as an oil. The keto lactone **5** was also obtained in the chromatography operation and was recrystallized from ether/hexane to afford white crystals for X-ray analysis (Fig. 2): mp 116.5–117.5°C; UV absorption, λ_{max} 295 nm (sh) and 258 nm (ε 323) in CH_3OH, 295 nm (ε 73), 286 nm (ε 93), 264 nm (ε 288), and 258 nm (ε 323). Anal. calcd. for $C_{14}H_{16}O_3$: C 72.39, H 6.94; found: C 72.34, H 6.88.

A solution of enol ether **2** (298 mg) in CH_3CN/CH_3OH (3:1 by volume) containing methylene blue (10^{-5} M) was irradiated under oxygen for 75 min with a 200-watt Hanovia lamp through a GWV filter (cutoff at 350 nm). The crude product was filtered through a column of silicic acid to afford keto lactone **5** (238 mg).

$ACHBF_2$ to toluene

A solution of $ACHBF_2$ (932 mg, 5.0 mmol) in toluene (120 mL) was irradiated under nitrogen for 7 h with a 200-watt Hanovia lamp to give a photolysate that showed GC (180°C) peaks for 3- and 4-methylacetophenone (12%, R_t 1.01 min), $ACHBF_2$ (19%, R_t 1.79

11	217.6, 202.0, 137.7, 137.6, 131.7, 130.6, 129.4, 126.7, 54.5, 38.1, 31.4, 29.1, 20.9
13	208.69, 207.26, 130.28, 125.43, 128.92, 123.69, 51.28, 42.11, 30.44, 30.05, 28.92

[a]^{13}C NMR was measured with a mixture of two regioisomers.

min), and a mixture of enol ethers **7** (63%, R_t 2.63 min). The enol ethers **7** were isolated as a 1:1 mixture of 3- and 4-methyl-substituted isomers as shown by ^{1}H NMR spectra (see Table 2). **6** was isolated as a mixture containing 4-methylacetophenone and 3-methylacetophenone in a 1.1:1 ratio shown by GC analysis at 100°C.

A mixture of the isomers of **7** (248 mg) in CH_3CN/CH_3OH (3:1 by volume) was photooxygenated using methylene blue (10^{-5} M) as the sensitizer under oxygen for 1.5 h. The residue of the photolysate was chromatographed to afford a 1:1 mixture of keto ester **8** (171 mg, 59%).

$ACHBF_2$ with other monosubstituted benzenes

Methyl benzoate (5 mL) and $ACHBF_2$ (205 mg) in acetonitrile (35 mL) were photolyzed under nitrogen as shown above to give two GC peaks. The photolysate was worked up to afford a mixture of methyl 3-acetylbenzoate (72%) and methyl 4-acetylbenzoate (28%). The latter was reported to show ^{1}H NMR signals at 8.15 and 7.97 ppm (24).

Photolysis of $ACHBF_2$ with chlorobenzene or benzonitrile was carried out under conditions similar to the above to give acetylated products as the major products as shown by GC–MS analysis. The photoaddition to the former was faster than that to methyl benzoate, and that to benzonitrile was the slowest.

Photolysis of $ACHBF_2$ in the presence of anisole did not show consumption of $ACHBF_2$.

$ACPBF_2$ with benzene

A solution of $ACPBF_2$ (371 mg, 2.1 mmol) in benzene (16 mL) and anhydrous ether (24 mL) was irradiated with a Hanovia lamp for 45 min under nitrogen to give a photolysate that showed GC (160°C) peaks for acetophenone (R_t 0.92 min), 1,5-diketone **10** (R_t 2.39 min), and what appeared to be enol ether **12** (R_t 2.12 min; GC–MS m/e: 186(M^+, 27), 171(100), 128(13), and 115(11)) in a ratio of 5:5:1. On standing at room temperature for several hours, it showed an additional GC peak for **11** (R_t 2.98 min) at the expense of the peak for **10**. When the photolysis was run in the presence of tributylamine (500 mg) the ratio of these GC peaks was 1:12:1. The photolysate was quickly washed with water and dried–evaporated to give a crude product that showed ^{1}H NMR signals at 3.49 ppm (dd, J = 8.3 and 2.7 Hz, 1H), 3.05 (m, 1H), and 5.95 (m, 4H), and GC–MS (CI) m/e: 205 (M^+ + 1, 78),

[a]GC–MS spectrum was taken with a mixture of two regioisomers.

187(44 and 121(100); (EI) *m/e*: 204 (M^+, 0.2), 186(0.4), 161(9), 143(15), 126(47), 117(39), 105(39), 91(29), 84(100), and 77(20).

The crude product was chromatographed to afford acetophenone (75 mg, 29%) and diketone **11** (72 mg, 17%).

$AABF_2$ with benzene

$AABF_2$ (620 mg, 4.2 mmol) in a mixture of benzene (20 mL) and ether (60 mL) was irradiated under nitrogen and the photolysate was monitored by GC analysis (120°C). At the 120 min irradiation, the GC peaks for acetophenone (R_t 1.17 min), $AABF_2$ (R_t 1.46 min), and 1,5-diketone **13** (R_t 2.69 min; GC–MS *m/e*: 178 (M^+, 2), 135(52), 117(26), 77(23) and 43(100)) showed the ratio of 8:46:41; further irradiation resulted in a decrease of **13**. This photolysate was washed with water without the addition of tributylamine. The product was chromatographed to afford acetophenone and a fraction containing a 1:1 mixture of **14** and **15**. Physical data of **13**–**15** are summarized in Tables 1–4.

In a separate experiment, after a 2 h irradiation, tributylamine (0.6 mL) was added to the photolysate, which was worked up in the usual manner to afford a crude product. This was chromatographed to afford a fraction containing 1,5-diketone **13** contaminated with 12% 2-acetonylacetophenone (**14**).

In a separate experiment, a similar photoaddition was run in the presence (1 equivalent) and absence of pyridine; the yield of **13** started to decrease in the latter case but approached a maximum in the former case. Also, the yield of acetophenone built up rapidly in the latter case in contrast to consistently low yields in the former case.

Quantum yield determination

The quantum yields of the enol ether **2** (Φ) were determined in a Rayonet photochemical reactor equipped with a rotating platform and RPR 3000 Å lamps (16 × 21 watt). The solution contained tetradecane as the internal standard and was nitrogen purged. The benzophenone–benzhydrol system in benzene was used for the actinometry with a quantum yield of 0.74 (25). The solution was irradiated for 60–75 min resulting in 6–15% yields of **2**. The yields of enol ether **2** were calculated from the predetermined response plot. The quantum yield calculation details are provided in the M.S. thesis by X. X. Ouyang.[2]

Received August 2, 1990

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR, ROBERT C. THOMPSON, and JAMES TROTTER. Can. J. Chem. **69**, 432 (1991).

Novel and reliable methods for the synthesis of the polymers $[Cu(4\text{-}Xpz)_2]_x$ (where X = H, Cl, Br, and Me; pz = pyrazolate) are presented. The X = Cl compound was obtained as green and brown forms. Single crystals of the polymers with X = Me and X = Cl (green form) suitable for X-ray analysis have been obtained. $[Cu(4\text{-}Mepz)_2]_x$ and $[Cu(4\text{-}Clpz)_2]_x$ are isomorphous, crystallizing with four formula units per unit-cell in the orthorhombic space group *Ibam*, a = 9.7436(6), 9.155(4), b = 12.6106(8), 12.968(6), and c = 7.7482(6), 7.717(5) Å, respectively, for the 4-Me and 4-Cl derivatives. The structures were refined by full-matrix least-squares procedures to R = 0.027 and 0.041 for 430 and 246 reflections with $I \geq 3\sigma(I)$, respectively. Magnetic susceptibility studies over the temperature range 2 to 300 K have revealed that all the polymers exhibit very strong antiferromagnetic exchange between copper(II) centres in the extended linear chains. Discontinuities displayed in the susceptibility versus temperature plots suggest the presence of phase transitions at ~133 and ~108 K in the X = Cl (green form) and X = Br materials, respectively. The four compounds, X = H, Br, Me, and Cl (green form) also exhibit thermochromism over the 77 to 176 K region. The magnetic data have been analyzed employing an isotropic Heisenberg model for antiferromagnetic exchange in extended chain polymers. Values of the exchange coupling constant, J, for the room temperature forms of these materials are determined as −81, −105, −96, −104, and −88 cm^{-1} for 4-X = H, Br, Me, Cl (green form), and Cl (brown form), respectively. The magnitude of the exchange coupling is discussed in relation to structural parameters for the X = H, Me, and Cl (green form) compounds.

Key words: copper(II) 4-substituted pyrazolate polymers, crystal structures, magnetic exchange.

MARTIN K. EHLERT, STEVEN J. RETTIG, ALAN STORR, ROBERT C. THOMPSON et JAMES TROTTER. Can. J. Chem. **69**, 432 (1991).

On présente de nouvelles méthodes fiables de synthèse des polymères $[Cu(4\text{-}Xpz)_2]_x$ (où X = H, Cl, Br et Me; pz = pyrazolate). Le composé avec X = Cl a été obtenu sous des formes verte et brune. On a obtenu des cristaux uniques des polymères avec X = Me et X = Cl (forme verte), appropriés pour des analyses par diffraction des rayons-x. Les composés $[Cu(4\text{-}Mepz)_2]_x$ et $[Cu(4\text{-}Clpz)_2]_x$ sont isomorphes et ils crystallisent avec 4 unités de formules par maille, dans le groupe d'espace orthorhombique *Ibam*, avec a = 9,7436(9), 9,155(5), b = 12,6106(8), 12,968(6) et c = 7,7482(6), 7,717(5) Å, respectivement pour les dérivés 4-Me et 4-Cl. On a affiné les structures par la méthode des moindres carrés jusqu'à des valeurs respectives de R = 0,027 et 0,041 pour 430 et 246 réflexions avec $I \geq 3\sigma(I)$. Des études de susceptibilité magnétique effectuées de 2 à 300 K ont révélé que tous les polymères présentent un échange antiferromagnétique très fort entre les centres cuivre(II) des chaînes linéaires allongées. Les discontinuités observées dans la courbe de susceptibilité en fonction de la température suggèrent la présence de transitions de phase à respectivement ~133 K et ~108 K dans les composés avec X = Cl (forme verte) et X = Br. Les quarte composés, X = H, Br, Me et Cl (forme verte) présentent aussi de la thermochromie entre 77 K et 176 K. On a analysé les données magnétiques à l'aide du modèle isotrope de Heisenberg pour l'échange antiferromagnétique dans les chaînes étendues de polymères. On a déterminé que les valeurs de la constance de couplage, J, pour les formes de ces matériaux existant à la température ambiante, sont respectivement −81, −105, −96, −104 et −88 cm^{-1} pour les produits 4-X = H, Br, Me, Cl (forme verte) et Cl (forme brune). On discute de l'amplitude du couplage d'échange en relation avec les paramètres structuraux des composés X = H, Me et Cl (forme verte).

Mots clés : polymères des pyrazolates de cuivre(II) substitués en position 4, structures cristallines, échange magnétique.

[Traduit par la rédaction]

Introduction

Earlier we reported a novel synthesis of the $[Cu(pz)_2]_x$ polymer and obtained crystals suitable for X-ray analysis (1). Our interests were in metal pyrazolate complexes which would provide examples of extended linear-chain polymers with bridging pyrazolate ligands acting as pathways for strong magnetic exchange between metal centres. These expectations were met in the $[Cu(pz)_2]_x$ polymer which indeed exhibited an infinite chain structure and strong antiferromagnetic coupling. The present account describes the effects of varying the substituent at the 4-position of the pyrazolate bridging ligands on the structural and magnetic properties of these polymeric materials.

Experimental

Pyrazole (Aldrich Chemical Co.) and 4-methylpyrazole (Aldrich Chemical Co.) were used as supplied. $[Cu(pz)_2]_x$ was prepared as described previously (1).

Synthesis

4-Bromopyrazole

Pyrazole (13.6 g, 200 mmol) was dissolved in 50 mL of warm water. Bromine (32.0 g, 200 mmol) was added dropwise, with stirring, to this solution until the yellow color of Br_2 persisted. The resulting solution was refluxed for 30 min and cooled. Concentrated aqueous NaOH was added to the reaction solution until it was slightly basic, resulting in precipitation of an off-white solid. The mixture was suction filtered, the solid washed with cold water and air dried. The solid was then dissolved in a minimum amount of diethyl ether and suction filtered to remove any entrained NaBr. The diethyl ether was removed from the filtrate under vacuum leaving an off-white powder of 4-bromopyrazole. Melting point (recrystallized from petroleum ether) 90.5–92.5°C. *Anal.* calcd. for $C_3H_3BrN_2$: C 24.52, H 2.06, N 19.06; found: C 23.86, H 1.96, N 18.81.

4-Chloropyrazole

4-Chloropyrazole was prepared using a variation of a literature method (2). Pyrazole (13.6 g, 200 mmol) was dissolved in 100 mL of glacial acetic acid. To this solution was added NaOCl (aq) (256 mL of

0.780 M, 200 mmol) with stirring. The resulting solution was left for 18 h at room temperature and then neutralized with Na_2CO_3. The neutralized solution was extracted with 3 × 250 mL portions of CH_2Cl_2. The CH_2Cl_2 extracts were combined, condensed under vacuum, and washed with dilute NaOH (aq). The NaOH solution was extracted with 2 × 100 mL portions of CH_2Cl_2. The CH_2Cl_2 extracts were combined and dried *in vacuo* yielding 4-chloropyrazole as a white powder. Yield 85%; mp 72–75°C. *Anal.* calcd. for $C_3H_3ClN_2$: C 35.14, H 2.95, N 27.32; found: C 35.16, H 2.93, N 27.47.

$[Cu(4\text{-}Mepz)_2]_x$

Copper metal shot was cleaned by washing with 12 M HCl, then water, and finally acetone. About 3 g of the cleaned copper shot was combined with 4-methylpyrazole (3 g, 36 mmol) in a 5 mL round bottomed flask fitted with a condenser and gas-tee. The mixture was heated at 115°C (below reflux temperature) with stirring, for 8 h, under a dioxygen atmosphere. The reaction mixture was then allowed to cool, washed with CH_2Cl_2 to both extract the mixture from the flask and to dissolve soluble components. The resulting slurry was then suction filtered and washed with acetone yielding $[Cu(4\text{-}Mepz)_2]_x$ as a fine green powder. The product was dried in air at 110°C for 0.5 h. *Anal.* calcd. for $C_8H_{10}CuN_4$: Cu 28.15, C 42.57, H 4.47, N 24.82; found: Cu 28.20, C 42.57, H 4.42, N 24.82.

Single crystals suitable for X-ray diffraction studies were prepared by a method similar to that used for the preparation of bulk compound. The conditions differed in that the mixture was not stirred, the apparatus was flushed with dinitrogen gas and air was allowed to diffuse into the reaction vessel via a pinhole leak, and the reaction was allowed to proceed for 3 days. The reaction mixture was washed with acetone yielding dark green crystals of $[Cu(4\text{-}Mepz)_2]_x$.

$[Cu(4\text{-}Brpz)_2]_x$

Freshly prepared amorphous $Cu(OH)_2$ (0.487 g, 5.00 mmol) was combined with 4-bromopyrazole (4.41 g, 30.0 mmol) in a 10 mL round-bottomed flask fitted with a condenser and gas-tee. The mixture was heated to 145°C (below reflux temperature) with stirring, for 16 h under a dinitrogen atmosphere. After this time the reaction mixture was cooled and 5 mL of acetone added. The reaction mixture was then refluxed for 3 h causing the sublimed 4-bromopyrazole to be washed back into the flask. At the cessation of the reaction the mixture was allowed to cool and solidify. The solid was then treated with ethanol to remove it from the flask and dissolve soluble components. The slurry thus obtained was suction filtered and washed with water, ethanol, and CH_2Cl_2. The resulting green power was dried *in vacuo* for 2 h at room temperature. Yield 50%. *Anal.* calcd. for $C_6H_4Br_2CuN_4$: Cu 17.81, C 20.27, H 1.13, N 15.76; found: Cu 18.1, C 20.26, H 1.11, N 15.88.

Attempts to grow single crystals of this compound were made by repeating the reaction without stirring. Single crystals did form, however, they were too small for X-ray diffraction studies.

$[Cu(4\text{-}Clpz)_2]_x$

Cu_2O (0.358 g, 5.00 mmol), 4-chloropyrazole (4.39 g, 42.8 mmol), and 1.5 mL of xylene were combined in a 10 mL round-bottomed flask fitted with a condenser and gas-tee. The mixture was heated at 130°C (below reflux temperature) for 8.5 h with vigorous stirring under a dioxygen atmosphere. The mixture was extracted from the flask with CH_2Cl_2, suction filtered, washed with CH_2Cl_2, and finally acetone. The resulting fine green powder was dried in air at 110°C for 0.5 h. Yield 75%. *Anal.* calcd. for $C_6H_4Cl_2CuN_4$: Cu 23.84, C 27.03, H 1.51, N 21.02; found: Cu 23.87, C 27.25, H 1.60, N 21.25.

Single crystals of $[Cu(4\text{-}Clpz)_2]_x$ were grown by combining copper metal shot and 4-chloropyrazole in a test tube, then heating the mixture to 120°C, without stirring, for 3 days. The reaction mixture was washed with acetone, yielding dark green crystals of the desired product in addition to some brown and bluish-grey crystals.[1]

A brown form of $[Cu(4\text{-}Clpz)_2]_x$ was prepared as follows. $Cu(OH)_2$ (0.73 g, 7.5 mmol), 4-chloropyrazole (4.6 g, 45 mmol), and 2 mL of xylene were combined in a 10 mL round-bottomed flask fitted with a condenser and heated at 135°C for 6 days in air, with stirring. The mixture was extracted from the flask with acetone, suction filtered, washed with acetone, and air dried, yielding a fine powder which consisted mostly of a brown material together with a trace of green material. *Anal.* calcd. for $C_6H_4Cl_2CuN_4$: C 27.03, H 1.51, N 21.02; found: C 27.10, H 1.54, N 21.20.

Physical characterization

The $[Cu(4\text{-}Xpz)_2]_x$ materials were found to be insoluble in both polar and non-polar solvents. They are decomposed on dissolution in acid. Differential scanning calorimetry measurements, obtained with a Mettler DSC 20 Standard Cell and TC 10 TA Processor as described previously (3), showed the compounds to decompose, without melting, at the indicated temperatures: $[Cu(4\text{-}Mepz)_2]_x$ (270°C), $[Cu(4\text{-}Brpz)_2]_x$ (290°C), $[Cu(4\text{-}Clpz)_2]_x$ (green) (290°C), $[Cu(4\text{-}Clpz)_2]_x$ (brown) (285°C). All three of the new green copper pyrazolates exhibit thermochromism, as was observed in $[Cu(pz)_2]_x$ but with the new polymers the color at low temperature is more of a blue–green compared to the blue color observed for $[Cu(pz)_2]_x$.

Electronic spectra (350 to 900 nm) were recorded using Nujol mulls suspended on filter paper with a Shimadzu UV-2100 spectrometer.

Infrared spectra (4000–250 cm^{-1}) were obtained using a Perkin-Elmer Model 598 spectrophotometer. Tabulated band frequencies have been deposited.[2] Samples were prepared as mulls in Nujol and hexachlorobutadiene and pressed between KBr and KRS-5 (Harshaw Chemical Co.) plates, respectively.

Magnetic susceptibilities were measured over the temperature range 2–300 K using a Quantum Design (MPMS) SQUID magnetometer (field = 10 000 G). Because the materials studied here have very small magnetic moments, a specially designed sample holder was employed. The sample holder was made from Delron and possessed a constant cross-sectional area, thus minimizing its contribution to the SQUID signal. In addition, all samples were studied over the same temperature range using a combination of vibrating sample magnetometer and Gouy balance equipment as described previously (4). Although there was more scatter in the data points with the latter equipment the agreement with the SQUID data was good. Only the data obtained with the SQUID magnetometer are reported here. Temperature measurement with this instrument was achieved using a combination of Ge and Pt resistance thermometers. Susceptibility calibration was achieved using high purity nickel and bismuth standards. Magnetic susceptibilities were corrected for diamagnetism: copper, −11; $C_3H_3N_2$, −40; $C_4H_5N_2$, −52; $C_3H_2ClN_2$, −57; and $C_3H_2BrN_2$, −67 (values in 10^{-6} cm^3 mol^{-1}). A correction of 60 × 10^{-6} cm^3 mol^{-1} was applied for temperature independent paramagnetism of the copper(II) ion. Tabulated values of temperature, magnetic susceptibility, and magnetic moment have been deposited.[2]

The esr spectra were obtained using an X-band homodyne spectrometer with a Varian 12-inch magnet equipped with a MkII Fieldial control. An Ithaco Dynatrac 391A lock-in amplifier was used to obtain phase-sensitive detection at 100 kHz. Data acquisition was carried out using a Qua-Tech 12-bit data acquisition board (ADM·12-10) together with a Qua-Tech parallel expansion board (PXB-721) incorporated into an IBM XT computer. The relevant data processing software is as described previously (5, 6). The microwave frequency was measured with a HP5246L frequency counter equipped with a HP5255A plug-in. Field calibration was accomplished using a Varian Gaussmeter, the output of which is also collected by the IBM computer. The absolute field is corrected for the placement of the gaussmeter probe by calibrating against peroxylamine sulfate in aqueous solution and is in error by *ca.* 0.01 G. Sample temperature was controlled using a Varian E-257 temperature controller.

X-ray powder diffractograms were collected with a Rigaku Rotaflex rotating anode X-ray powder diffractometer (nickel-filtered Cu-K_α radiation).

[1]The bluish-grey crystals are soluble in polar solvents; however, the material is not stable in solution and was not characterized further.

Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

C, H, and N microanalyses were performed by P. Borda of this department. Cu analyses were performed using iodometric titrations.

X-ray crystallographic analyses of $[Cu(4\text{-}Mepz)_2]_x$ and $[Cu(4\text{-}Clpz)_2]_x$

Crystallographic data for both compounds appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 75.0–117.7° for $[Cu(4\text{-}Mepz)_2]_x$ and 9.4–17.4° for $[Cu(4\text{-}Clpz)_2]_x$. The intensities of three standard reflections, measured every 150 reflections throughout the data collections, were essentially constant for both compounds. The data were processed[3] and corrected for Lorentz and polarization effects and absorption (empirical, based on azimuthal scans for three reflections).

The structures are isomorphous with that of the parent compound $[Cu(pz)_2]_x$ (1). The structure analyses were initiated using the coordinates of the Cu and pyrazolyl ring atoms from the unsubstituted structure, the remaining non-hydrogen atom in both cases being positioned by direct methods for difference structures. The non-hydrogen atoms were refined with anisotropic thermal parameters and hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å,

$B_H = 1.2B_{\text{bonded atom}}$) except for the ring hydrogen atom in $[Cu(4\text{-}Mepz)_2]_x$ which was refined with an isotropic thermal parameter. The methyl hydrogen atoms in $[Cu(4\text{-}Mepz)_2]_x$ were observed to be disordered from a difference map, a (1:1) twofold disordered model was calculated based on the difference Fourier peaks. Neutral atom scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International tables for X-ray crystallography (7). Final atomic coordinates and equivalent isotropic thermal parameters are given in Table 2 and bond lengths and angles appear in Table 3. Anisotropic thermal parameters, bond lengths and angles involving hydrogen, general torsion angles, intermolecular distances, least-squares planes, and measured and calculated structure factor amplitudes for the both structures are included as supplementary material.[2]

Results and discussion

Encouraged by our success in preparing the pure polymeric $[Cu(pz)_2]_x$ material by reacting metallic copper with molten pyrazole ligand in the presence of oxygen (1) we have extended our investigations to include substituted pyrazole ligands with the idea of changing the structural parameters of the materials and thus their other physical properties. In the present account we restrict ourselves to 4-substituted pyrazole derivatives and describe the preparation and properties of the $[Cu(4\text{-}Xpz)_2]_x$ polymer species where X = Cl, Br, or Me. In addition to the copper/molten ligand method, syntheses starting with $Cu(OH)_2$ (4-Brpz) and Cu_2O(4-Clpz) are described. Two forms of the 4-Clpz derivative were obtained, one green and one brown. Analytically pure samples of all polymers were obtained and X-ray diffraction quality single crystals were grown for the compounds $[Cu(4\text{-}Mepz)_2]_x$ and $[Cu(4\text{-}Clpz)_2]_x$ (green). The polymers are air-stable, thermally quite robust and, consistent with their extended structures, insoluble in a wide range of solvents.

The crystal structures of the $[Cu(4\text{-}Mepz)_2]_x$ and $[Cu(4\text{-}Clpz)_2]_x$ (green) materials confirm their polymeric nature. The coordination geometry about the Cu atom in $[Cu(4\text{-}Clpz)_2]_x$ is shown in Fig. 1 and the crystal structure of the polymer in Fig. 2. The coordination geometry about the Cu atoms is distorted tetrahedral with Cu—N distances of 1.961(5) and 1.962(2) Å in the 4-Cl and 4-Me structures, respectively, values very similar to the value of 1.957(2) Å previously observed for the $[Cu(pz)_2]_x$ polymer (1). The three unique N—Cu—N angles correspond to N atoms related to one another by three mutually perpendicular twofold axes intersecting at the metal (D_2 symmetry): those within the planar six-membered $Cu(N—N)_2Cu$ rings are 100.5(3) (4-Cl) and 99.9(1)° (4-Me) and the others are 92.4(2) and 140.8(3)° (4-Cl) and 93.7(1) and 139.7(1)° (4-Me). The corresponding values for $[Cu(pz)_2]_x$ are 99.4(1), 94.3(1), and 139.5(1)° respectively.

The X-ray powder diffraction pattern for $[Cu(4\text{-}Brpz)_2]_x$ was indexed to an orthorhombic unit-cell. Fifteen unambiguously indexed diffraction peaks were employed in a least-squares refinement of the unit-cell parameters with the following results: $a = 9.44(1)$, $b = 13.32(2)$, $c = 7.70(1)$ Å. Systematically absent reflections in the diffraction pattern are consistent with the space group *Ibam*. Miller indices, observed d spacings and

their relative intensities and calculated d spacings based on the least-squares refinement of indexed reflections are listed in Table 4. Diffraction peaks not included in the analysis are those which could not be unambiguously indexed because they consist of several overlaping diffraction peaks.

Single crystals of the compound $[Cu(4\text{-}Brpz)_2]_x$ obtained were too small for a single crystal X-ray structure determination; nonetheless, visual observation under a microscope revealed they are of similar color to and possess the same morphology as those of the other 4-substituted pyrazolates. $[Cu(4\text{-}Brpz)_2]_x$ exhibits thermochromism as do the other green copper pyrazolates discussed here. These observations provide substantial evidence that $[Cu(4\text{-}Brpz)_2]_x$ is isomorphous and probably isostructural with $[Cu(pz)_2]_x$, $[Cu(4\text{-}Mepz)_2]_x$, and $[Cu(4\text{-}Clpz)_2]_x$ (green).

As described in the Experimental section, $[Cu(4\text{-}Clpz)_2]_x$ can be prepared in two forms, green and brown polymorphs. It is apparent from X-ray powder diffraction patterns[2] that the two forms are structurally distinct and, furthermore, that a trace of the green form is present in the sample of the brown form. While details of the structure of the brown form of $[Cu(4\text{-}Clpz)_2]_x$ remain unknown, comparison of its solubility and thermal properties with those of the structurally characterized pyrazolate complexes suggest a polymeric structure for this material also. Moreover its magnetic properties are consistent with an extended chain polymeric structure, strongly suggesting a very similar structure to that of the other pyrazolates under discussion here, with differences primarily involving the detailed stereochemistry of the CuN_4 chromophore (see below).

Electronic spectra

Electronic spectra are shown in Fig. 3. The $[Cu(4\text{-}Xpz)_2]_x$ polymers (with the exception of the brown form of $[Cu(4\text{-}Clpz)_2]_x$) all exhibit a single broad asymmetric band in the visible region centered at about 15 600 cm^{-1}. This band compares with the band at 15 400 cm^{-1} which we reported for $[Cu(pz)_2]_x$, and probably involves all four of the d–d transitions, unresolved, expected for a CuN_4 chromophore of distorted tetrahedral geometry (8). The higher energy band at ~25 000 cm^{-1} for the 4-Cl (green) and 4-Me derivatives and at ~27 000 cm^{-1} for the 4Br compound is likely of charge transfer origin as previously suggested (1). The brown form of the 4-Cl derivative shows a very broad absorption over the region studied (Fig. 3) with indications of band maxima at 25 600, 20 000, and 16 700 cm^{-1}. The maximum at 25 600 cm^{-1} is probably charge transfer in origin while the more complex nature of the spectrum in the visible region may indicate a lower symmetry for the CuN_4 chromophore in this material.

Magnetic properties

The strong antiferromagnetic exchange observed previously in $[Cu(pz)_2]_x$ is present also in the $[Cu(4\text{-}Xpz)_2]_x$ polymers. In all four compounds the magnetic moment decreases significantly with temperature; moreover, as in the 4-H compound, susceptibility maxima are seen in the χ_m vs. T plots for the 4-Me, 4-Br, 4-Cl (green), and 4-Cl (brown) compounds occurring at 180, 200, 195, and 160 K, respectively. Plots of susceptibility versus temperature are shown for the 4-Me and 4-Cl (green form) compounds in Fig. 4. All compounds show an increase in susceptibility as temperature decreases at the lowest temperatures studied reflecting the presence of small amounts of paramagnetic impurities in the samples, as discussed previously

for $[Cu(pz)_2]_x$. An interesting feature of the susceptibility data for the 4-Cl (green) and 4-Br derivatives is a discontinuity occurring at 133 and 108 K, respectively, suggesting the presence of a structural phase change in these materials. Repeated measurements revealed that these discontinuities are reversible and, although small, are reproducible. It is important to note that all four of the green compounds which we have studied show thermochromism in which they reversibly go from a room temperature green to a blue or blue–green color at low temperatures. Qualitative observations using a variety of slush baths indicate this occurs somewhere in the 176 to 77 K range for the 4-Me, 4-Br, and 4-Cl (green) compounds and that for the 4-H compound the color change from green begins at about 176 K and is complete by 133 K. It is possible that the thermochromism and the magnetic discontinuities are linked and that the absence of observable discontinuities in the χ_m vs. T plots for the 4-H and 4-Me compounds is due to the fact that the phase changes in these materials are either too small to affect the magnetic data noticeably or occur over a range of temperatures and hence do not result in a sharp χ_m vs. T discontinuity.

As previously described for $[Cu(pz)_2]_x$ (1), we have analyzed the magnetic data according to the isotropic Heisenberg model for exchange coupled linear chains employing the polynomial developed by Hall and others (9, 10). Computer fits to the model using experimental data over the 2 to 300 K range were made for all five compounds and the best fit values of J, g, and % paramagnetic impurity are given in Table 5. Because of the discontinuity in the data for the 4-Cl (green) and 4-Br derivatives we have also, for these compounds, obtained fits to the data in the high temperature region only and, for comparison, have done the same for the other compounds. In these cases the fits were obtained setting the % paramagnetic impurity arbitrarily to zero. Best fit values of the other parameters are given in Table 5 and these fits are compared graphically for two of the compounds in Fig. 4. For each compound, the parameters J and g differ relatively little whether all the data or only the high temperature data are used in the analysis. Attempts to fit the low temperature data only to the model were, on the other hand, not successful leading to significantly higher $|J|$ values and,

more importantly, unrealistic g values on the order of 3.0. That such high g values are unrealistic was confirmed by electron spin resonance studies which were made on these compounds at room temperature and at ~90 K. The g values obtained in this study are given in Table 6. At room temperature, all compounds exhibit a single broad esr band at $g_0 \sim 2.11$. At ~90 K the spectrum of the 4-Cl (brown) compound is unchanged while those of the other materials change to typical 2 g-value spectra with $g_\parallel$ values in the range 2.22–2.24 and $g_\perp$ values of ~2.08. An examination of the esr spectrum of $[Cu(pz)_2]_x$ at intermediate temperatures revealed only a gradual change from one type of spectrum to the other. The low temperature isotropic g_0 values calculated from the expression $g_0 = (1/3)(g_\parallel + 2g_\perp)$ agree to within 1% of the values obtained at room temperature (Table 6), indicating no significant change in g_0 with temperature. In addition there is generally good agreement between the esr g values and those obtained from fits to the magnetic data over the whole temperature range or using the high temperature data only. Additional attempts to fit the low temperature data to a Heisenberg two-dimensional model (11) and an Ising linear chain model (12) were also unsuccessful. It would appear then that our inability to fit the low temperature data satisfactorily to the model means either that the low temperature forms of these materials do not model well as Heisenberg chains or sheets, or Ising chains and/or the source of the paramagnetic tail is not being properly modeled here. Finally, it is important to note that the g and J values obtained here for $[Cu(pz)_2]_x$ from the SQUID magnetometer data agree, within experimental error, with those reported earlier from VSM and Gouy balance data (1).

We turn now to a consideration of how the nature of the pyrazolate bridge and structure affect the magnitude of exchange coupling in the compounds under investigation. It seems reasonable to assume that the values of J obtained from the high temperature data analyses properly reflect the magnitude of exchange in the room temperature forms of these compounds and these J values will be used in considerations which follow. Single crystal X-ray diffraction studies show that the 4-H, 4-Me, and 4-Cl (green) derivatives are isomorphous and are very similar structurally. Moreover, the analysis of the X-ray powder pattern of the 4-Br derivative shows it is isomorphous and very probably isostructural with the other three compounds. It is perhaps not too surprising then that these four compounds exhibit very similar magnetic properties: strong antiferromagnetic exchange with $|J|$ values in the range 81 to 105 cm^{-1}. The absolute values of J obtained for the 4-Cl and 4-Br derivatives are the same within experimental error and slightly larger than the value for the 4-Me derivative. The value of $|J|$ for the 4-H

derivative is significantly smaller than those obtained for the other three compounds. This variation does not correlate with simple ideas based on relative ligand basicity, since one would expect the halo-substituted pyrazolate ligands to be least basic (as a measure of this: pK_a's for the $H_2$4-Xpz$^+$ cations are 3.09, 2.53, 0.64, and 0.60 for X = Me, H, Br, and Cl, respectively (13–15)), to form the weakest bonds with copper, and therefore to provide the poorest rather than the most efficient pathways for exchange.

We suggested previously (1) that, as for the related neutral pyrazine ligand, it is perhaps the π system of the pyrazolate bridge which provides the pathway for superexchange between the metal ions. A HAM molecular orbital calculation (16) on the pyrazolate ion reveals the highest occupied molecular π orbital shown in Fig. 5a. The orientation of this orbital with respect to the magnetic orbital on copper in $[Cu(pz)_2]_x$ is shown in Figs. 5b and 5c. Defining the angle formed between the plane of the

pz ring and the Cu—N bond as α and the dihedral angle between adjacent Cu_2N_4 rings as β (Fig. 5*c*) it is clear that increased overlap between the HOMO and the magnetic orbital and therefore increased exchange would be expected as β increases or α decreases. The α and β angles for the three compounds for which the structures are known are given in Table 7. Comparing the 4-Me compound with the 4-H derivative we see that the former has a slightly greater β and a significantly smaller α and hence a higher value of $|J|$ would be expected, as is indeed observed. Unfortunately, there are no other unambiguous comparisons which can be made among these three compounds; for example, on going from the 4-Cl to the 4-H derivative both α and β decrease resulting in opposing effects on orbital overlap and therefore magnitude of exchange. Nonetheless, we feel that our results do indicate that an important factor in determining the magnitude of exchange in metal pyrazolate complexes is the overlap between the pyrazolate π-orbital system and the metal's magnetic orbital. Such a factor, for example, seems likely to account for the difference in $|J|$ between the green and brown forms of $[Cu(4\text{-}Clpz)_2]_x$.

A study of the electrolytic solution process using the scaled particle theory. 5. Heat capacity of aqueous ions at elevated temperatures

UTPAL SEN
Central Electrochemical Research Institute, Karaikudi 623 006, Tamilnadu, India

Received February 6, 1990[1]

UTPAL SEN. Can. J. Chem. **69**, 440 (1991).

A theory composite of the scaled particle theory and the Born model of solvent continuum has been used to theoretically calculate the standard heat capacity of hydration as well as the partial molal heat capacity of aqueous ions and electrolytes at elevated temperatures. The uncertainties in the second temperature derivatives of solvent dielectric constant at various temperatures present a barrier to an accurate heat capacity prediction by the theory. Nevertheless, the agreement between the predicted standard heat capacity of electrolytes in solution and the corresponding experimental data, particularly at higher temperatures, is encouraging. Moreover, the composite theory seems to provide the most accurate thermodynamic predictions to date for aqueous electrolytes at higher temperatures without involving any arbitrary adjustable parameter. We therefore use this theory to find the proper ionic scale of the partial molal heat capacities at elevated temperatures.

Key words: scaled particle theory, solvent continuum model of Born, standard heat capacity of aqueous ions, absolute scale for hydration thermodynamic quantities.

UTPAL SEN. Can. J. Chem. **69**, 440 (1991).

On a utilisé une théorie composite, basée sur la théorie des particules scalaires et sur le modèle de Born du continuum de solvant, pour calculer d'une façon théorique la capacité calorifique standard de l'hydratation ainsi que la capacité calorifique molale partielle des ions et des électrolytes aqueux, à températures élevées. On a démontré que les incertitudes liées aux secondes dérivées de la température de la constante diélectrique du solvant à diverses températures empêchent de prédire correctement la capacité calorifique sur une base théorique. Toutefois, on a trouvé encourageante la bonne corrélation qui existe entre les données expérimentales et les capacités calorifiques standard des électrolytes en solution, particulièrement aux températures plus élevées. De plus, il semble que la théorie composite puisse fournir les meilleures prédictions à date pour les électrolytes aqueux, à températures élevées, sans pour cela faire appel à des paramètres arbitraires ajustables. On l'a donc utilisée pour déterminer la bonne échelle ionique des capacités calorifiques molales partielles, à des températures élevées.

Mots clés : théorie des particules scalaires, modèle de Born du continuum du solvant, capacité calorifique standard d'ions aqueux, échelle absolue pour les quantités thermodynamiques d'hydratation.

1. Introduction

The need for the data related to the thermodynamic behaviour of electrolytes in solution at elevated temperature is obvious, particularly in understanding corrosion problem in electric power industries and the behaviour of minerals in geothermal systems. A few recent experimental efforts to determine high temperature thermodynamic data for aqueous electrolytes suggest that the trend of the thermodynamic behaviour of electrolytes at elevated temperatures is quite unusual and interesting (1–4). However, such data are few and often only partially cover the temperature range between the normal melting point and the critical temperature of water (1–10). There are, of course, a few attempts to theoretically generate high temperature data through empirical equations and through using simplified models (11–29). Horvath (30) compiled some of the advances made in the various attempts for theoretical calculation of entropy and heat capacity of aqueous at various temperatures. Recently, Tanger and Helgeson (31) revised their earlier empirical approach (29) of thermodynamic calculations by introducing additive correction terms to the effective electrostatic radii of aqueous ions to account for the pressure and temperature dependence of the solvent structure and presented the calculated values of various thermodynamic functions of aqueous ions at various temperatures and pressures (30). However, the arbitrariness of the correction terms could not be altogether done away with in spite of generous computer applications.

Very recently, Tanger and Pitzer (32) revised an earlier semi continuum approach (33) which they claim to provide a realistic identification of both inner-shell and outer-shell contributions to the ion-hydration process. Inner shell is assumed to involve six H_2O molecules of hydration whereas the outside of the inner shell region is represented by the Born continuum approach. The prediction has been extended to 1000°C and 5000 bar. An empirical parameter that represents the Born radius has to be used for alkali metal halides and hydroxides. The very complicated calculations are however essentially associated with some experimental data from gas phase mass spectrometric studies for obtaining the equilibrium constant for the successive hydrations for six water molecules per solute ions.

In our earlier communications (14–18), we have developed a simple composite theory which has been remarkably successful in predicting the hydration and partial molal entropies of electrolyte solutions at elevated temperatures. Partial molal heat capacity, however, is probably the most important thermodynamic function for electrolytes over extended temperatures since it can be used to generate enthalpy, free energy, and entropy as functions of temperature. Moreover, it is an extremely scientific probe to the hydration, hydrogen-bonding, and structures of electrolytic solutions.

In this paper we have used the theory and concept to theoretically predict the behaviour of the hydration and the partial molal heat capacities of electrolyte solutions at elevated temperatures. An attempt has also been made to obtain the ionic heat capacity scales at higher temperatures and to find the possible values of the standard partial molal entropy and heat capacity of the aqueous hydrogen ion at different elevated temperatures.

2. Nature of the problem

Standard free energy of solvation (or hydration) has been traditionally accepted as the equivalent of the total work needed for bringing 1 mole of a gaseous solute species at 1 atm pressure from vacuum to a solvent (or water) so that it would form a 1 mole of solution (34).

$$M^+(g, 1\ atm, T) + X^-(g, 1\ atm, T) = M^+(aq, 1\ m, T) + X^-(aq, 1\ m, T)$$

The equilibrium response of the solvent molecules to the incorporated solute species and the nature of the forces that uniquely determine the response are to be defined to gain insight into the solution process. When the solute species is an ion its introduction can bring about several changes in the solvent system. For instance, if sufficient space does not already exist solvent molecules must move apart to accommodate the solute ion. Furthermore, if the solvent is polar as in the case of water, the solvent molecules will align with the ionic field produced by the solute ion. Any theory purporting to accurately describe real ionic solution process must include these as well as other interactions such as hydrogen bonding, etc. The process, no doubt, is complicated. Nevertheless, there is a need to understand the dominant mechanisms that determine the equilibrium properties of solutions, and for this purpose a simplified model is preferred (35).

3. Review of theory

We have, however, found that the overall interaction phenomenon in an ion–solvent system can be conveniently split into two additive parts: (*i*) the interaction due to the presence of an ionic species of finite size in a uniform dielectric solvent system and (*ii*) the so-called specific interactions occurring at various distances apart from the incorporated ion which may result in the formation of the so-called multi layer solvation zones in the solution (16). The free energy involved in the first part of the interaction process as mentioned above may be conveniently estimated with the help of the Born charging equation (36). *A priori* fixation of the value of the interaction free energy for the second part (denoted as ΔG^*), on the other hand, seems difficult and may require various kinds of speculation (37). It has been, however, realized that ΔG^* which apparently has its major contribution from the strong interactions in the vicinity of a dissolved ion, would be relatively insensitive to temperature variations (14–16). An interesting analysis of the Born equation has been put forward by Honig and co-workers (38, 39).

3.1. Methods of calculation

According to the above theory proposed on the basis of the scaled particle approach (which has been extremely successful in thermodynamic predictions for solvation process with neutral gases as solutes (40)) the solvation process of ions can be seen as a simple combination of two steps: (*i*) the formation of a cavity of appropriate size in the solvent system for the accommodation of the solute species and (*ii*) the introduction of the solute ion into the cavity which interacts with the surrounding solvent. Consequently, when this interaction process is again subdivided as stated above into the Born-type electrostatic interaction and the sum of the other kinds of specific interactions occurring in the various regions around the incorporated solute ions, which the Born continuum model cannot recognise, the standard free energy of solvation, ΔG_s^0 for ions can be represented by

[1] $$\Delta G_h^0 = \Delta G_c^0 + \Delta G_i^0 + \Delta G_x$$

[2] $$\Delta G_h^0 = \Delta G_c^0 + (\Delta G_{Born}^0 + \Delta G^*) + \Delta G_x$$

where ΔG_h^0, ΔG_c^0, ΔG_i^0, ΔG_x, ΔG_{Born}^0, and ΔG^* are the free energy of hydration, cavity formation, interactions, standard state alteration, electrostatic free energy calculated from the Born equation (36), and the free energy of specific interactions which the simple Born equation can not recognise. It has been our experience that the term ΔG^* is relatively temperature insensitive. Perhaps the temperature insensitivity may be due to the opposing nature of the temperature variations of the free energy quantities associated with the number of solvent molecule immobilized due to the strong electrostatic field in the near vicinity of the incorporated solute ion on the one hand and the free energy of individual solvent molecules on the other hand. Whatever the solution process, if we consider $(\partial \Delta G^*/\partial T)_P$ $(= -\Delta s^*)$ to be negligible, the calculation of the thermodynamic quantities is simplified and does not as such involve any arbitrary parameters. We may therefore have the following expressions for the entropy and heat capacity of hydration:

[3] $$\Delta s_h^0 = \Delta s_c^0 + \Delta s_{Born}^0 + \Delta s_x$$

[4] $$\Delta c_{P(h)}^0 = \Delta c_{P(c)}^0 + \Delta c_{P(Born)}^0 + \Delta c_{P(x)}$$

Here we are mainly concerned with the calculation of heat capacity and the following are expressions for the various terms associated with the calculation.

[5] $$\Delta c_{P(h)}^0 = c_H \Delta H_c^0 - (c_0 + c_1 d_2 + c_2 d_2^2)$$

[6] $$c_H = (2/T) - \alpha_P + (\partial \ln \alpha_P/\partial T)_P$$

[7] $$\Delta H_c^0 = B_0 + B_1 d_2 + B_2 d_2^2 + B_3 d_2^3$$

[8] $$B_0 = (\alpha_P R T^2 y)/(1 - y)$$

[9] $$B_1 = [(3\alpha_P R T^2 y)/(1 - y)^2]/d_1$$

[10] $$B_2 = (3\alpha_P R T^2 y)[(1 - 2y)/(1 - y)^3]/d_1^2$$

[11] $$B_3 = \pi P N/6$$

[12] $$c_0 = R[(y\alpha_P T)/(1 - y)^2]^2(1 - y)^2$$

[13] $$c_1 = R[(y\alpha_P T)/(1 - y)^2]^2[6(1 - y)]/d_1$$

[14] $$c_2 = R[(y\alpha_P T)/(1 - y)^2]^2[3(4y + 5)]/d_1^2$$

[15] $$\Delta c_{P(Born)}^0 = \left[\frac{N(ze)^2}{d_2}\right]\left[\frac{T}{D^2}\right]\left[\left(\frac{\partial^2 D}{\partial T}\right) - \frac{2}{D}\left(\frac{\partial D}{\partial T}\right)^2\right]$$

[16] $$\Delta c_{P(x)} = 2\alpha_P R T - R + R T^2(\partial \alpha_P/\partial T)_P$$

where $\Delta c_{P(c)}^0$ and ΔH_c^0 are heat capacity and enthalpy respectively of cavity formations calculated using the scaled particle theory (40); y, d_1, d_2, and α_P are the compactness factor (or reduced density), solvent molecular diameter, solute diameter, and volume expansion coefficient at constant pressure, respectively. More details on the equations and the symbols used are available elsewhere (13–15). A comparison of the scale particle theory (SPT) and other hard sphere perturbation approaches in describing the temperature dependence of Δc_P^0 for non-electrolytes has been discussed by Fernandez-Prini and others (41–43). Barta and Hepler (44) recently applied the SPT for calculating thermodynamics of aqueous ions at 25°C with much success and reviewed some earlier applications of the theory for similar purposes.

In the calculation of thermodynamic functions the solute diameter (d_2) was taken to be twice the Pauling's ionic crystal radius (45) which is assumed not to change significantly throughout the temperature range. The solvent diameter (d_1) at

[a]Reference 16 and references therein.

different temperatures has been calculated from the respective isothermal compressibility data using Mayer's method (46).

The partial molal heat capacities ($\bar{c}^0_{P_2}$) can be obtained from the standard heat capacities of hydration using the following equation:

$$[17]\quad \Delta c^0_{P(h)} = \bar{c}^0_{P_2} - c^0_{P(GAS)}$$

If c^0_P of monatomic gaseous ions at all temperatures can be taken as 21 J mol^{-1} K^{-1} then eq. [17] can be written as

$$[18]\quad \Delta c^0_{P(h)} = \bar{c}^0_{P_2} - 21n$$

where n is the number of ions in the electrolyte (47).

At temperatures above 100°C, the vapour pressure of the solvent water begins to cause a difference between the standard state functions at 1 atm and those at ambient vapour pressure of the solvent. The effect may be given by

$$[19]\quad [\partial \bar{c}^0_{P_2}/\partial P] = -T[\partial^2 \bar{v}^0_2/\partial T^2]_P$$

If one can assume that $(\partial^2 \bar{v}^0_2/\partial T)$ does not change much over the pressure range involved (which may not be true at very high temperature), one may get

$$[20]\quad \bar{c}^0_{P_2(P)} - \bar{c}^0_{P_2(1)} = -T[\partial^2 \bar{v}^0_2/\partial T^2]_P(P-1)$$

where $\bar{c}^0_{P_2(1)}$ is the partial molal heat capacity at 1 atm, and $(\partial^2 \bar{v}^0_2/\partial T^2)_P$ is the second derivative of the partial molal volume of the electrolyte at infinite dilution. The partial molal volume data for electrolyte at different temperatures have been compiled by Millero (48). Those data for NaCl and $BaCl_2$ from 75 to 200°C (the limit up to which data are available) were fitted to smooth curves and differentiated to give the necessary derivatives. The second derivatives are not very accurately known but the magnitude of correction to the $\bar{c}^0_{P_2}$ data is not large up to 200°C (about 5 units for $BaCl_2$ at 200°C). The same may be higher at higher temperatures, particularly above 250°C or so from where the vapour pressure of water rises quite sharply with increase in temperature. There are other uncertainties in that higher temperature range, for example, uncertainties due to the solvent dielectric constant and its derivatives may be much higher. Therefore the pressure correction on $\bar{c}^0_{P_2}$ has not been included.

4. Results and discussion

Various physical parameters at different temperatures used in the theoretical calculations of the heat capacities are listed in Table 1.

4.1. Standard heat capacities of hydration

Equations [6] and [17] have been used to obtain the standard heat capacity of hydration ($\Delta c^0_{P(h)}$) and the corresponding standard partial molal heat capacity of the electrolytes. Figures

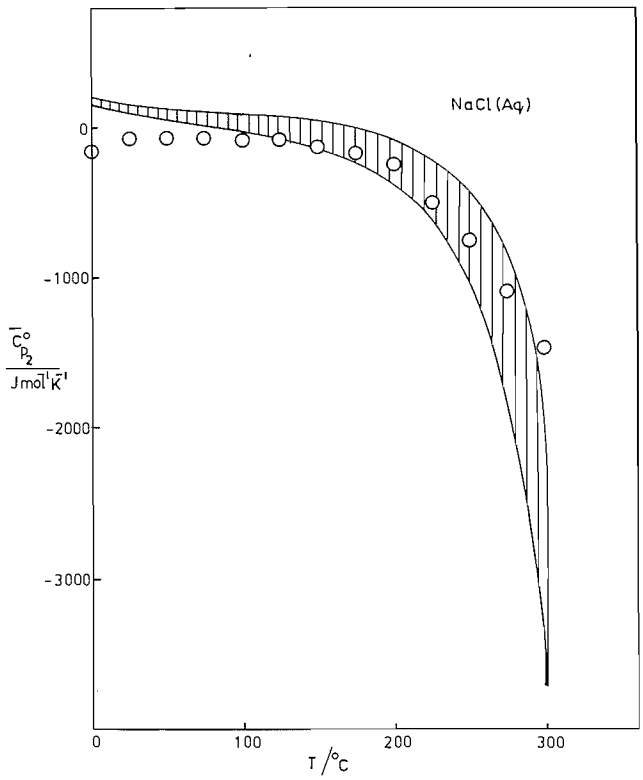

FIG. 1. Predicted (band) and observed (symbol) partial molal heat capacities ($\bar{c}^0_{P_2}$), J mol^{-1} K^{-1} for aqueous NaCl at different temperatures.

1–3, which provide a comparison of the calculated and experimental values of $\bar{c}^0_{P_2}$ for aqueous NaCl, $BaCl_2$, $GdCl_3$ at various temperatures, would give an estimate on the accuracy of the prediction. The agreement is fairly good particularly at the higher temperature ranges. We are, however, concerned about the limit of uncertainty at higher temperatures, which could be large. Yet another way to generate the heat capacity values is to get the derivatives of the corresponding entropy data and use the following equation

$$[21]\quad \Delta c^0_{P(h)} = T(\partial \Delta s^0_h/\partial T)_P$$

To obtain $(\partial \Delta s^0_h/\partial T)_P$ at different temperatures, we have fitted the predicted Δs^0_h values of NaCl and $BaCl_2$ reported in refs. 15, 16 in polynomials of various degrees. Figures 4 and 5 would show the comparison of such $\Delta c^0_{P(h)}$ values with the experimental heat capacity values. Table 2 contains the coefficients of the polynomial fit of third degree which gives the best fit.

As mentioned earlier the specific interaction term Δs^* and its temperature derivative $(\partial \Delta s^*/\partial T)$ and also $T(\partial \Delta s^*/\partial T)$

($= \Delta c^*_P$) has been asumed to be negligible in our calculations. Experimental works summarized by Helgeson and co-workers (28, 29, 31) has, however, shown that the contributions of specific interaction to $\Delta c^0_{P(h)}$ which may be close to Δc^*_P in our notation becomes significantly large as the temperature drops to

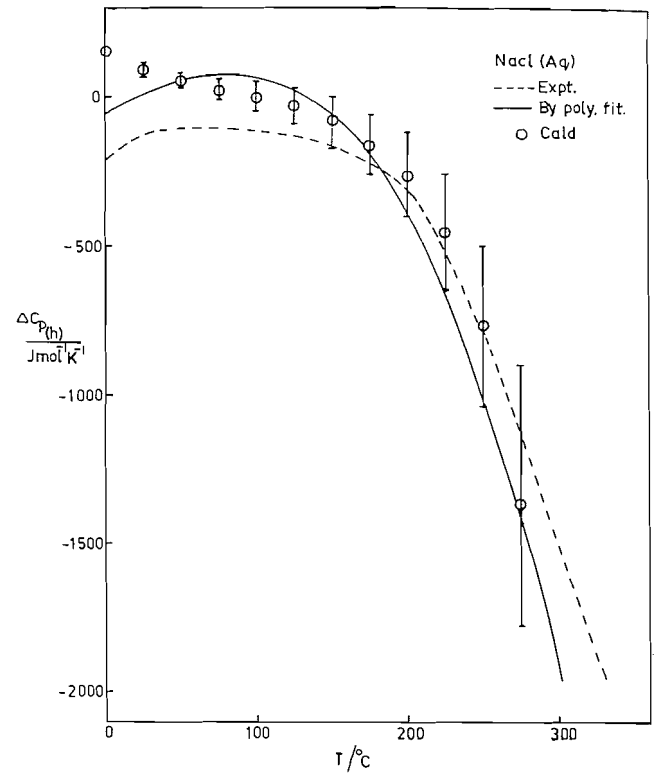

FIG. 4. Calculated and experimental values of standard heat capacity of hydration ($\Delta c^0_{P(h)}$), J mol^{-1} K^{-1} of aqueous NaCl at different temperatures.

room temperature and below. This may be one of the possible reasons of the rather wide disagreements between the predicted and the experimental values of heat capacity of hydration ($\Delta c^0_{P(h)}$) of electrolytes at lower temperatures. Since Helgeson and co-workers did not attempt to avoid arbitrary adjustments for the Born radius of the solute ion, an additional term had to be involved. However, Helgeson and co-workers (31) omitted the standard state correction terms on the plea that it is discontinuous at the critical point of water. The values of such standard state heat capacity terms for hypothetical ions of radii 1 and 2 Å are listed in Table 6.

4.2. Correspondence principle

Criss and Cobble (12) observed that not only the entropy of ions, $\bar{s}^0_T$ at temperature T will be in linear relationship with entropy $\bar{s}^0_{T_R}$ at the reference temperature T_R but there could be a similar linear relationship between the heat capacity $\bar{c}^0_{P(T)}$ at T and the corresponding entropy $\bar{s}^0_{T_R}$ at the reference temperature T_R. However, they use the average heat capacity $\bar{c}^0_{P_2}\Big]_{25}^{T}$ when 25°C is the reference temperature. They give the following relationships

$$[22] \quad \bar{c}^0_{P_2}\Big]_{25}^{T_2} = (\bar{s}^0_{T_2} - \bar{s}^0_{25})/\ln [(T + 273)/298]$$

and

$$[23] \quad \bar{s}^0_{T_2} = a_{T_2} + b_{T_2}\bar{s}^0_{25}$$

They used the average heat capacity data at smaller and smaller intervals to equate them with the actual heat capacity data. However we do not need to go through this exercise and can calculate heat capacities directly. The linear correspondence

D (J mol^{-1} K^{-4})	-2.358253×10^{-7}	-1.50241×10^{-5}

equation involving heat capacities and entropy at a reference temperature is

[24] $\bar{c}^0_{P(T)} = A_T + B_T \bar{s}^0_{100}$

Since our prediction of thermodynamics function is relatively more accurate at higher temperature ranges when the hydrogen bonding in solvent water is considerably weak the reference temperature preferred is 100°C. Table 3 list A_T and B_T in eq. [24] and Fig. 6 shows the typical correspondence plots at these temperatures. We may mention here that the correspondence curves with heat capacity and entropy need not be much different for cations and anions as suggested by Crisis and Cobble (12).

4.3. Single ion heat capacities

There is no direct experimental method which can provide individual ionic heat capacity values at different temperatures. There have been, however, a number of extrathermodynamic non-experimental methods proposed from time to time to generate individual ionic contributions of thermodynamic properties in aqueous systems (49, 50). Most of them were, however, confined to the values at 25°C. The method proposed by Crisis and Cobble (11, 12) is still very much in use to give entropies and heat capacities of aqueous ions, particularly at higher temperatures. However, we have doubts about the validity of the arbitrarily chosen individual ionic values they proposed, particularly those at elevated temperatures (16). Our theory as described above is capable of producing accurate predictions on

[a]For monovalent ions and to be added for cations and to be subtracted for anions.

both entropy and heat capacity values of aqueous electrolytes over a wide range of temperatures. The method does not involve any arbitrary adjustable parameter. It may be seen from Figs. 1–3 that the predictions of heat capacity values are accurate for mono-, di-, and trivalent metal chlorides. We therefore recommend the calculated values of the heat capacity of chloride ion, $\bar{c}^0_{P(Cl^-)}$ for setting up the ionic scale for partial molal heat capacity at different temperatures. Table 4 lists the values of the standard partial molal heat capacity of aqueous chloride ion at different temperatures, recommended for splitting the values of the standard heat capacity of aqueous electrolytes into the corresponding ionic contributions. The predicted standard heat capacity values for a few ions are presented in Table 5. Tanger and Helgeson (31) listed their calculated values of heat capacity of some ions on conventional scale but did not suggest any absolute scale for the ionic values.

4.4. Standard partial molal capacities of the hydrogen ion at different temperatures

One limitation of any prediction of properties of ions by theoretical calculations involving the actual diameter of the ion is that it cannot give a practical value on the property of hydrogen ion (unhydrated) which is generally accepted to have point dimension or zero diameter. In our earlier attempt to generate the value of partial molal entropy of hydrogen ion at different temperatures, we used some experimental emf data involving HCl solution. Recently, results of some calorimetric measurements with HCl solution at some higher temperatures have been reported (10). Those values would be apparently more accurate compared to the values generated using the high temperature emf readings through a number of temperature derivatives. From the experimental values of heat capacity of aqueous HCl at different temperatures obtained from ref. 10 and through some extrapolations our recommended values of standard partial molal heat capacity of aqueous chloride ion at the corresponding temperatures have been subtracted to generate the partial molal heat capacity of the aqueous hydrogen ion at that temperatures. Those values of heat capacity are then used to yield the corresponding partial molal entropy of hydrogen ion in solution. The entropy values were obtained graphically using the following equation

$$[25]\quad \bar{s}^0_T = \bar{s}^0_{T_R} + \int_{T_R}^{T} (\bar{c}^0_P \mathrm{d}T)/T$$

where T_R = 298 K and $\bar{s}^0_{T_R}$ = 22 J mol^{-1} K^{-1}.

It has been already pointed out earlier (16) that if the hydration of an ion is defined as the process where an ion (in the gaseous state) in field-free space is inserted into a large quantity of the solvent, which carries no net electrical charge, then the interaction of the ion in the process of transfer through electrical double layer at the free surface of the solution (51) may have to be considered. This involves the surface dipole potential (χ) (52) and also its temperature derivatives (53) at different temperatures. Such effects on the transfer of cations and anions across the solution surface would obviously be opposite and cancel one another when their neutral combination into the corresponding salt has been considered. It may also be mentioned that the value of the surface dipole potential as well as its temperature derivatives are believed to approach zero with increasing temperature and the potential term vanishes altogether at the critical temperature of the solvent (54). The reported values (53) of the first temperature derivatives of the gas water surface potential ($\partial\chi/\partial T$) at different temperatures have been used for the correction of the calculated values of $\bar{s}^0_{H^+}$ at different temperatures (16). The estimated values of such entropy correction forms at different temperatures have been plotted against temperature and from the slope at each temperature the ionic correction term for heat capacity, $\bar{c}^0_{P(corr)}$ for that temperature can be calculated using $\bar{c}^0_{P(corr)} = T(\partial \bar{s}^0_{corr}/\partial T)$. The estimated correction terms per monovalent ion for the transfer entropy and heat capacity functions have been included in Table 4.

The values of the absolute standard partial molal heat capacity and entropy of aqueous hydrogen ion at different temperatures obtained as described above are listed in Table 6. We believe that the present values of the absolute standard partial molal entropy of hydrogen ion, generated directly using calorimetric data, might be more accurate than those that were generated indirectly through emf data and listed in ref. 16.

Some years ago, Ackermann (55) proposed a model for the arrangement of solvent water molecules in the so-called hydration shell of the hydrogen ion and calculated the heat capacity of the ion at different temperatures. These values were used to yield the partial molar entropy of hydrogen ion using eq. [25]. These values are also included in the table for comparison. Later Criss and Cobble (11, 12) suggested values for partial molal entropy of hydrogen ion at different temperatures up to 200°C with the help of the correspondence principle. When plotted against temperature, these data produce a nearly linear curve at higher temperature ranges. The corresponding values of the heat capacity of aqueous hydrogen ion have been calculated using eq. [21]. All these values are included in Table 5. Figures 7 and 8 would give an idea about the trends of variations of $\bar{s}^0_{H^+}$ and $\bar{c}^0_{P(H^+)}$ with temperature proposed by different authors. It can be seen from these figures that both this work and the work of Ackermann (55) show that $\bar{s}^0_{H^+}$ and $\bar{c}^0_{P(H^+)}$ become more negative with increase in temperature. The values proposed by Criss and Cobble (11, 12) do, however, follow the opposite trend and become increasingly more positive with increase in temperature.

Abraham and Marcus (22) used the TATB assumption (49, 50) viz.,

$$\Delta c^0_{P(h)}{}^{(Ph_4P^+)} = 772 \text{ J mol}^{-1} \text{ K}^{-1} \approx 774 \text{ J mol}^{-1} \text{ K}^{-1} = \Delta c^0_{P(h)}{}^{(Ph_4B^-)}$$

at 25°C for fixing the absolute scale for heat capacity of hydration of aqueous ion. However, they did not suggest any absolute scale for higher temperatures.

4.5. *Temperature behaviour of cationic and anionic heat capacities*

Ackermann (55) plotted the values of $\bar{c}^0_{P_2}$ of a few cations and anions as a function of temperature. It was observed that for cations, which are comparatively smaller in size, the negative value increases with increase in temperature from the very beginning. However, for anions larger in size, some tendency to decrease the negative value at low temperatures, and then after passing through a rather ill-defined maximum, a trend of increasing the negative value of $\bar{c}^0_{P_2}$ with increase in temperature as in the case of smaller cations were observed. In Fig. 9 we have plotted the predicted values of $\bar{c}^0_{P_2}$ of two hypothetical ions having crystal radii 1 Å, representing the typical monovalent cation and 2 Å representing the typical anion. Our observation is similar to that by Ackermann (55). The sharp increase in the negative value of $\bar{c}^0_{P_2}$ does occur at a comparatively higher temperature if the size of the ion is comparatively large. Thus, as in the case of temperature effects on $\bar{s}^0_2$ (16), the size of the ion plays the most important role to define the temperature effect on the partial molal heat capacity of aqueous ions. Table 7

5. Conclusion

The theoretical prediction of partial molal heat capacities of aqueous electrolytes at elevated temperatures using the unified approach consisting of the scaled-particle theory and the Born charging equation (14, 15) may not be as accurate as the prediction of the corresponding entropy data using the same composite theory, but the large uncertainty in the temperature derivatives of the solvent dielectric constant specially at the higher temperatures used in the theoretical calculation seemed to be a major hurdle. Comparatively, contributions to the uncertainty due to some other approximations are of little or no significance to the predicted value. Nevertheless this might be the most accurate and wide ranging theoretical predictions to date without using any arbitrary adjustable parameters, as far as the heat capacity of aqueous electrolytes and ions are concerned. This work thus suggests that the primitive Born continuum dielectric model can be very useful provided some other simple considerations be duly introduced.

Other workers have also been successful in utilizing the Born equation for theoretical thermodynamic predictions for aqueous electrolytes at different temperatures (20, 29, 31, 32). Sometimes, particularly at the temperatures lower than the boiling point of water (100°C), some of these theoretical predictions may seem closer to the experimentally observed values than those in the present work. One example is the recent work of Tanger and Helgeson (31). But the fact that so many complicated assumptions involving several rather arbitrarily chosen adjustable parameters could be altogether avoided with only one simple and experimentally substantiated assumption (14–16)

that the free energy involved in the strong ion–solvent interaction in the near vicinity of the solute ion is relatively temperature insensitive, without significantly sacrificing the accuracy of the theoretical prediction, is certainly thought provoking.

The Born charging equation (30) does not distinguish a cation from an anion. It only concerns the size, or in other words, the surface charge density of the solute ionic species. The success of the Born approach, particularly at higher temperatures, perhaps indicates that at temperatures near or above the boiling point of water, hydrogen bonding is weak and therefore the energy involved in solvent orientations around a cation of a particular size may not be much different from that around an anion of the same size. Obviously, an accurate knowledge of the physical parameters of the solvent used, along with an accurate diameter of the solute ion is extremely important in accurate thermodynamic predictions.

Tetrahalogenomercury(II) complexes. A study of their electronic spectra, formation constants, ionic strength, and cation effects

TREVOR R. GRIFFITHS AND RICHARD A. ANDERSON
School of Chemistry, The University, Leeds LS2 9JT, United Kingdom

Received April 5, 1990[1]

TREVOR R. GRIFFITHS and RICHARD A. ANDERSON. Can. J. Chem. **69**, 451 (1991).

The unambiguous electronic absorption spectra of HgX_4^{2-} (X = Cl, Br, or I) in methanol have been determined for the first time. The spectra were resolved into their component Gaussian bands, and assigned using a correlation diagram for T_d symmetry. The effects of second-order spin–orbit coupling account satisfactorily for the observed band intensities and splittings. The formation constants, K_4, as a function of ionic strength were computed over the complete spectral range by multiple linear regression analysis and were, extrapolated to infinite dilution, 0.4 ± 0.1 for HgI_4^{2-} and $HgBr_4^{2-}$, and 5.7 ± 0.2 for $HgCl_4^{2-}$. Significant cation effects were observed upon the spectra of HgX_2 with added X^-, and may partially be explained in terms of the extended Debye–Hückel equation.

Key words: electronic absorption spectra, mercury(II) halide complexes, formation constants, ionic strength, Gaussian band analysis.

TREVOR R. GRIFFITHS et RICHARD A. ANDERSON. Can. J. Chem. **69**, 451 (1991).

On a déterminé pour la première fois le spectre d'absorption électronique non ambiguë du HgX_4^{2-} (X = Cl, Br ou I) dans le méthanol. On a résolu le spectre en ses bandes gaussiennes et on les assignées en se basant sur un diagramme de corrélation pour une symétrie T_d. Les effets de couplage spin-orbite du deuxième ordre expliquent bien les intensités et les couplages des bandes observées. Faisant appel à une analyse de régression linéaire multiple, on a calculé les constantes de formation, K_4, en fonction de la force ionique pour le domaine complet du spectre et on les a extrapolées à dilution infinie : 0,4 ± 0,1 pour le HgI_4^{2-} et le $HgBr_4^{2-}$ et 5,7 ± 0,2 pour le $HgCl_4^{2-}$. On a observé des effets de cation marqués sur les spectres des HgX_2 auxquels on avait ajouté du X^-; on peut les expliquer partiellement en fonction de l'équation de Debye–Hückel étendue.

Mots clés : spectre d'absorption atomique, complexes d'halogénures mercuriques(II), constantes de formation, force ionique, analyse gaussienne des bandes.

[Traduit par la rédaction]

The reaction of HgX_2 (X = Cl, Br, or I) with excess halide, X, to form the tetrahedral anion HgX_4^{2-} is well known in aqueous solution and in dipolar aprotic solvents (1–10). However, only a few studies have been made in protic solvents. Compounds of the type Q_2HgX_4 (where Q = *N*-cetyl-γ-picolium; X = Br, Cl) dissociated in ethanol to give HgX_3^-, HgX_4^{2-} not being detected (11). A similar feature was observed by Deacon and West (12) when investigating the spectra of Q_2HgI_4 (Q = Me_4P or PyH) in ethanol and methanol, but a large excess of added iodide gave the tetraiodo species. Raman studies of $HgCl_2$–LiCl mixtures in methanol indicated (13) the formation of $HgCl_3^-$ and $HgCl_4^{2-}$ but the electronic spectra of $HgBr_4^{2-}$ and $HgCl_4^{2-}$ in methanol have not been reported.

Stability constant measurements for HgX_4^{2-} in water are numerous, but only a few have been reported in dipolar aprotic solvents (5, 6), and none in protic solvents.

This paper describes the electronic spectra of HgX_4^{2-} in methanol, and the assignment of the transitions of their resolved bands, together with the (stepwise) formation constants of HgX_4^{2-} and the effect of cation variation on the equilibrium $HgX_3^- + X^- \rightleftharpoons HgX_4^{2-}$. The analysis of spectra to obtain component bands has previously only been applied for the Gaussian component bands of $HgBr_4^{2-}$ and HgI_4^{2-} in acetonitrile by Day and Seal (10). They obtained the spin–orbit coupling constants and discussed the energy levels and transitions concerned: we use a different theoretical approach, and obtain similar but more complete findings.

Experimental

All chemicals were of analytical or spectrograde quality where available and purified as necessary.

Spectra were recorded using an Applied Physics Cary 14 H spectrophotometer, modified to yield spectra in digital form on paper tape, in addition to the conventional chart output. The details have been published elsewhere (14).

For resolving a spectrum the conventional least-squares method of fitting a set of component bands requires an assumption concerning the type of band distribution involved. The usual distribution functions considered are Gaussian, Cauchy (Lorentzian), or the product or sum functions of both (15). Day and Seal (10) chose the Gaussian function for the resolution of their absorption spectra of HgX_4^{2-}. We tested these functions with our spectra, and found the Gaussian function best fitted our observed spectra. The thermostatted spectra were recorded five times, at 1 nm intervals, and averaged in the Leeds University computer (ICL 1906A) before curve fitting. This improved the convergence rate and the standard deviation.

If the minimised parameters gave a poor fit to the experimental data points it was for one of two reasons (and occasionally both). Reason one, the contribution of the absorption edge at higher energies was not included in the minimisation. This effectively weighted the data points on the high energy side of the band, causing the minimised band position to move to higher energies, the band width to increase, and the band height to increase. The procedure of "band peeling", fitting the low energy data to one band, removing it, fitting the remaining data, and so on was not used because it is less accurate: it demands no contribution to the absorption by the next band at the peak maximum of the first band, and assumes no hidden bands. Our procedure of removing successively the highest energy data point until the calculated band parameters became effectively constant eliminates these difficulties.

Reason two, poor resolutions will be obtained when attempts are made to minimise for too few bands, for example, when an observed single band displaying asymmetry contains hidden bands and a fit is attempted for one or two bands.

Calculation of formation constants

There are several ways of calculating formation constants from spectra, but after testing, the following method was found to be the most reliable and statistically accurate.

At any given wavelength, the absorbance of a solution will be given by $A = \Sigma M_i E_i$, where A is the observed absorbance, M_i and E_i are the molar concentration and molar absorbance at that wavelength of the ith species in solution. This equation holds true for all wavelengths. Thus if A is measured for "n" different wavelengths, then "n" linear equations of "i" unknowns may be derived. For $n \gg i$ these linear equations may be accurately solved for M_i by means of multiple linear regression analysis. A library computer program was amended to perform this analysis for up to six species in solution. In this study only two-species equilibria were used, $HgX_3^- + X^- \rightleftharpoons HgX_4^{2-}$, over the wavelength regions where only the two mercury-containing species absorbed.

The program output consisted of the required concentrations, with their standard error, and parameters indicating the accuracy of the main computation and the precision of the fitted data. These included the residual sum of squares, the regression sum of squares, F ratio, multiple correlation coefficient, degrees of freedom of the F ratio, plus a table of residuals and standardised residuals. Formation constants, with their standard error, were computed from the regression coefficients.

This method has the advantage that conditions of constant ionic strength were not necessary, and hence the variation of formation constant with ionic strength could be studied. Another advantage was the use of complete spectra in a calculation, since the equation is valid for any wavelength range. Thus the formation constants calculated from data covering different wavelength ranges should be the same. If they are significantly different it may be assumed that one of the spectra employed is inaccurate over part of the spectrum. A useful check was that total metal concentration may be computed, and this must tally with the known quantity in solution. In accordance with custom, K_3 and K_4 refer to the formation of HgI_3^- and HgI_4^{2-}, respectively.

Results

The complete conversion of all HgX_2 in solution to HgX_4^{2-} does not occur when the mole ratio of X/Hg (here termed R) is four or slightly greater. This is generally true for dipolar aprotic solvents (7) but is not so for protic solvents (12).

A. Spectra

(1) Spectrum of HgI_4^{2-}

Figure 1 shows that between R values of 100 and 1 000 the two main peaks of HgI_4^{2-} in methanol began to form. Thereafter the spectra rapidly changed as HgI_3^- was converted to HgI_4^{2-} and peaks arose at 268 and 326 nm. Above R = 20 000 little further change was observed but an R value of over 100 000 was required before the molar absorbance values at these peaks were maximised.

No attempt was made in this study to maintain a constant ionic strength for the solutions, particularly since the solubility of the system would be exceeded before complete conversion occurred. However, the effect of dilution at various R values was examined (Fig. 2). For R = 100 the spectra changed only slightly on dilution, but for R = 5 000 the spectral change was from a typical HgI_4^{2-} profile to a HgI_3^- one. This may help explain why somewhat different results and conclusions at times arise from X-ray, Raman, and other techniques employed on HgX_3^- and HgX_4^{2-} studies in solution if solutions of differing concentrations are employed (1–10).

(2) Spectrum of $HgBr_4^{2-}$

The spectral changes accompanying the reaction between $HgBr_2$ and Br^- in methanol at 20°C are shown in Fig. 3. Complete conversion to $HgBr_4^{2-}$, with a peak at 250 nm, occurred when R reached 60 000, after which the spectra did not change.

Potassium bromide was used for R values up to 1 000, but thereafter the more soluble NaBr was employed. The effect of equal mole ratios of KBr and NaBr on the spectra were not identical (Fig. 4), the potassium ion apparently effecting greater conversion to $HgBr_4^{2-}$.

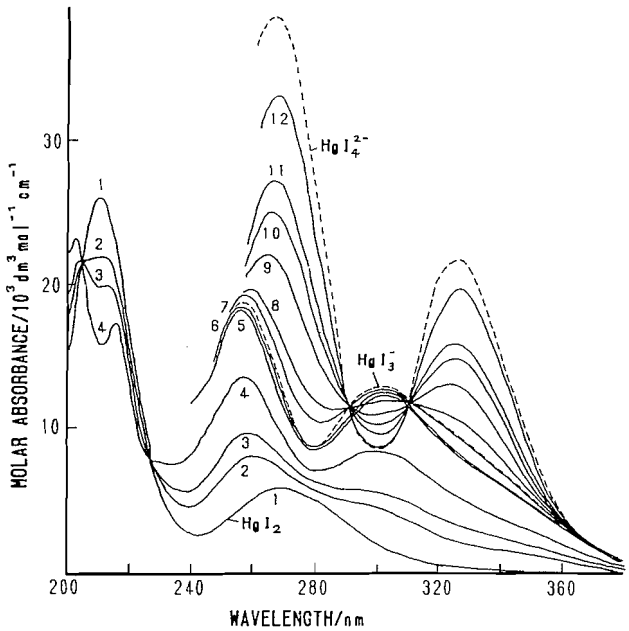

FIG. 1. Ultraviolet absorption spectra changes obtained upon addition of iodide to HgI_2 (6.7×10^{-5} mol dm^{-3}) in methanol at 20°C. Iodide/mercury mole ratios (R) are, progressively: (*1*), 2.0(HgI_2); (*2*), 2.2; (*3*), 2.3; (*4*), 2.4; (*5*), 2.8; (*6*), 8; (*7*), 80; (*8*), 1 000; (*9*), 2 000; (*10*), 3 000; (*11*), 4 000; (*12*), 60 000.

(3) Spectrum of $HgCl_4^{2-}$

The reaction between $HgCl_2$ and added Cl^- in methanol at 20°C is illustrated in Fig. 5. The peak for $HgCl_4^{2-}$ appeared at R = 15 000 but the true peak position at 230 nm could not be identified until higher R values were employed. The minimum R value for complete conversion was 800 000.

Potassium and ammonium chloride were both used, as chloride sources, and Fig. 6 shows their specific cation effect at the same R value. The maximum value with KCl was 1 000, NH_4Cl was usable up to R = 15 000, and further increases in R were made using LiCl.

B. Formation constants

(1) Formation constants for HgI_4^{2-}

Formation constants were computed over a wide range of added iodide concentrations. Data points at 1 nm intervals between 350 and 260 nm were used. At wavelengths below 260 nm the spectra were not considered reliable due to the possibility of uncomplexed iodide absorption contributing to the recorded absorbance.

The formation constants varied with ionic strength over the whole concentration range studied. A plot of log K_4, vs $I^{1/2}$ (I = ionic strength) gave a smooth curve, while that of K_4 vs $I^{1/2}$ yielded a straight line (Fig. 7), which extrapolated to 0.4 at infinite dilution.

(2) Formation constants for $HgBr_4^{2-}$

The formation constants for $HgBr_4^{2-}$ were computed from data points at 1 nm intervals in the range 240–300 nm. The variation of log K_4 and K_4 with $I^{1/2}$ is shown in Fig. 8. For those solutions where NaBr was the added halide, a straight line occurred in both plots. The line involving log K_4 extrapolated to 0.42 ± 0.04 (least-squares fit) at infinite dilution, while that for

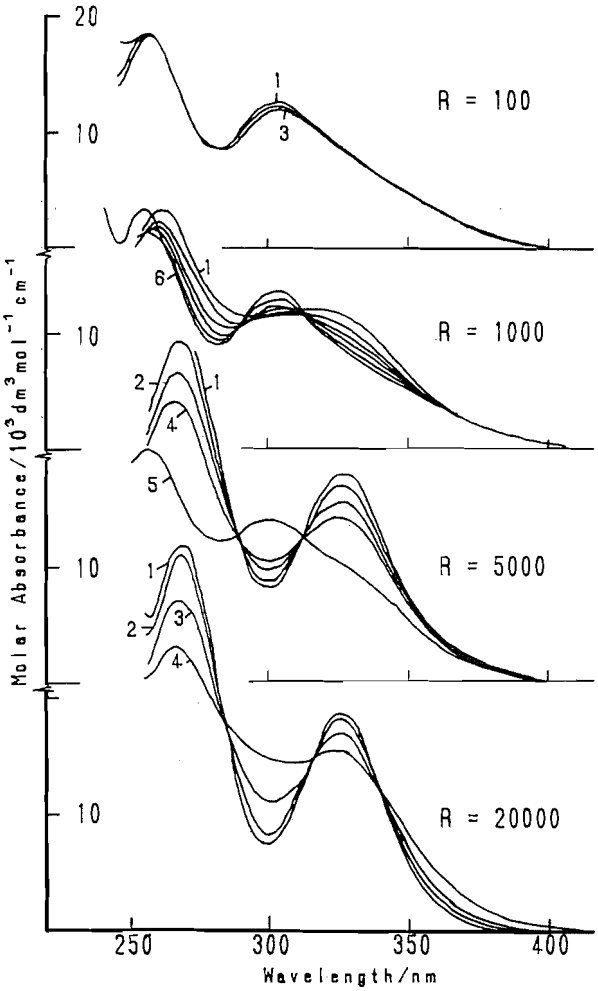

FIG. 2. Effect of ionic strength variation upon the ultraviolet absorption spectra of HgI_2 in methanol at 20°C. At selected iodide/mercury mole ratios (R) the solutions are diluted: note that with increasing dilution the equilibria, $HgI_2 \rightleftharpoons HgI_3^-$ or $HgI_3^- \rightleftharpoons HgI_4^-$, are shifted to the left. At R = 100, ionic strength (I) is (*1*), 0.014; (*2*), 0.005; (*3*), 0.003. At R = 1 000, I is (*1*), 0.072; (*2*), 0.057; (*3*), 0.040; (*4*), 0.028; (*5*), 0.011; (*6*), 0.006. At R = 5 000, I is (*1*), 0.36; (*2*), 0.29; (*3*), 0.20; (*4*), 0.14; (*5*), 0.06. At R = 20 000, I is (*1*), 0.58; (*2*), 0.46; (*3*), 0.23; (*4*) 0.12.

K_4 gave 0.4 ± 0.04 at $I^{1/2} = 0$. The values of K_4 for solutions containing KBr were greater than those for equivalent concentrations of NaBr.

With KBr the K_4 plot gave a straight line with the same intercept as the NaBr plot, but had a different slope. The log K_4 plot employing KBr consisted of two straight lines, that at high ionic strength intercepted at log $K_4 = 0.58 \pm 0.04$. At low ionic strength the slope was greater and the line extrapolated to $I^{1/2} = 0.06 \pm 0.04$.

(3) Formation constants for $HgCl_4^{2-}$

Here formation constants were computed over the range 205–260 nm. The plots of log K_4 and K_4 vs $I^{1/2}$ are shown in Fig. 9. Initially, a linear relationship holds with the line intersecting the abscissa at $I^{1/2} = 0.10$, but above $I^{1/2} = 0.30$, K_4 remained constant at 5.70 ± 0.20 (equivalent log K_4 = 0.75 ± 0.03, which compares well with log K_4 plot intercept of 0.76 ± 0.02). Detailed comparison of cation effects on K_4 values between KCl and NH_4Cl were not possible due to insufficient data points.

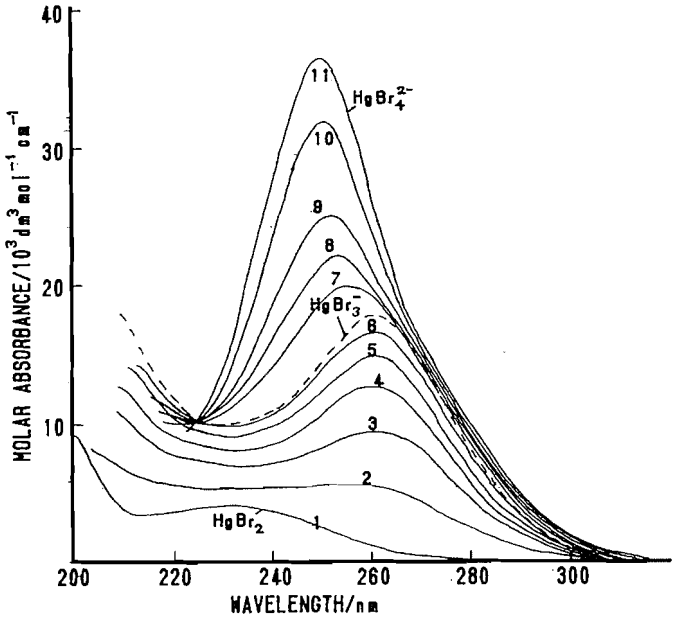

FIG. 3. Ultraviolet absorption spectra changes obtained upon addition of bromide to $HgBr_2$ (1.1×10^{-4} mol dm^{-3}) in methanol at 20°C. Bromide/mercury mole ratios (R) are, progressively: (*1*), 2.0 ($HgBr_2$); (*2*), 4; (*3*), 20; (*4*), 40; (*5*), 90; (*6*), 200; (*7*), 800; (*8*), 1 200; (*9*), 1 600; (*10*), 20 000; (*11*), 60 000 ($HgBr_4^{2-}$). Note that, compared with the iodide system, much greater R values are required initially to produce observable changes, even though essentially the same R values are needed for complete conversion to the tetrahalides. The dotted curve is the calculated spectrum of $HgBr_3^-$ in methanol. A single isosbestic point is seen at 226 nm, for the equilibrium $HgBr_3^- \rightleftharpoons HgBr_4^{2-}$.

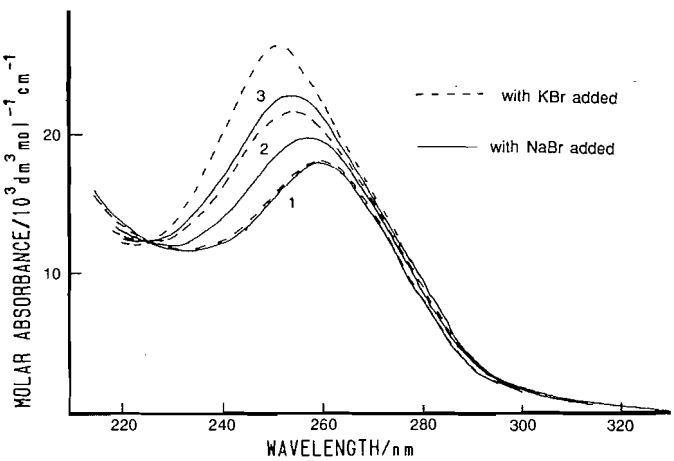

FIG. 4. Effect of cation, and cation size, on the ultraviolet absorption spectra on the reaction between $HgBr_2$ and Br^-. The effect is small below bromide/mercury mole ratios (R) of around 1 000, but more marked when R values refer to the equilibrium $HgBr_3^- \rightleftharpoons HgBr_4^{2-}$, the potassium ion shifting the equilibrium more towards $HgBr_4^{2-}$. Each spectral pair has equal mole ratios of NaBr and KBr. R values are (*1*), 1 000; (*2*), 5 000; (*3*), 10 000, with a fixed concentration of $HgBr_2$ at 8.9×10^{-5} mol dm^{-3}.

C. Gaussian analysis of absorption spectra

The spectra of the tetrahalogenomercurates in methanol were subjected to derivative analysis (16) to determine the number and position of component bands, and then to Gaussian band analysis to determine the band parameters. An example of the ability of derivative analysis to locate the peak position of a band appearing as a shoulder in $HgBr_4^{2-}$ is shown in Fig. 10.

For personal use only.

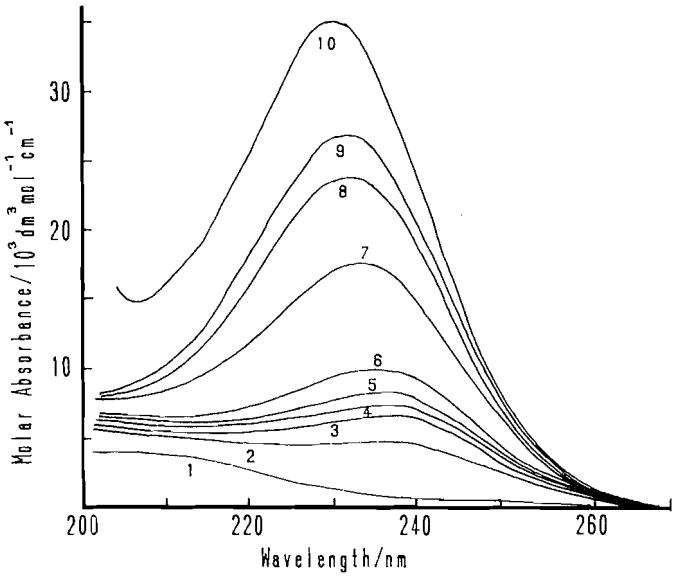

FIG. 5. Ultraviolet absorption spectra changes obtained upon addition of chloride to $HgCl_2$ (3.8×10^{-4} mol dm^{-3}) in methanol at 20°C. Chloride/mercury mole ratios (R) are, progressively: (*1*), 2.0 ($HgCl_2$); (*2*), 50; (*3*), 100; (*4*), 400; (*5*), 3 000; (*6*), 4 000; (*7*), 15 000; (*8*), 800 000 ($HgCl_4^{2-}$). R values are initially required to be higher than those in the iodo or bromo systems to produce observable changes and a much higher R value is necessary for complete conversion to $HgCl_4^{2-}$. No isosbestic points are observed for this system.

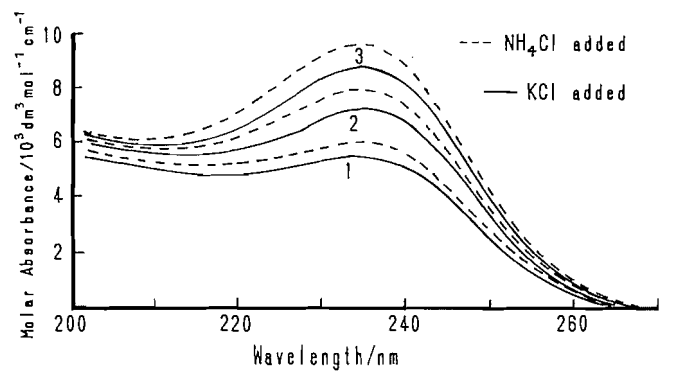

FIG. 6. Effect of cation, and cation size, on the ultraviolet absorption spectra of the reaction between $HgCl_2$ and Cl^-. Compared with the bromide case (Fig. 4), the effect is pronounced at much smaller chloride/mercury mole ratios (R), and the first equilibrium $HgCl_2 \rightleftharpoons HgCl_3^-$, is now affected. Each spectral pair has equal mole ratios of KCl and NH_4Cl. R values are (*1*), 200; (*2*), 300; (*3*), 400. Assuming crystallographic radii apply in methanol for K^+ and NH_4^+, 133 and 143 pm, respectively, the trend is the same as for the bromo system, but more pronounced at lower R values and for smaller differences in cation size.

Day and Seal (10) merely reported the results of their Gaussian analysis: we have found that such analyses are not always straighforward. The spectrum of HgI_4^{2-} was readily resolved into two bands corresponding closely to the observed peaks, but that of $HgBr_4^{2-}$, with its weak shoulder, was more difficult. Using our approach described above, resolution into two bands by Gaussian analysis, using the full spectrum, gave a poor fit to the data, though progressive removal of the high energy data improved the fit. However, over the whole spectral range, resolution into three bands, with one outside the range of

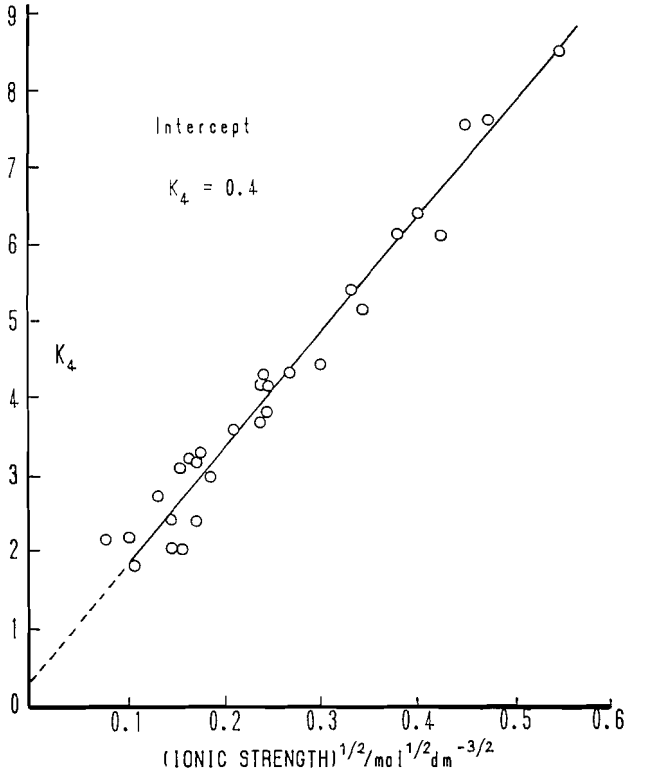

FIG. 7. Variation of K_4 for the formation of HgI_4^{2-} in methanol at 20°C with the square root of the ionic strength (I) of the solutions for which K_4 was determined from spectroscopic data. NaI and KI were both used as added iodide and there is no cationic effect.

the derivative spectra, fitted the data well (Fig. 11). The precision of this fit was confirmed since the band parameters for the two bands in the 'two band improved fit' were identical within experimental error with those of the same bands in the three band fit (Table 1). Day and Seal (10) did not report this third band for $HgBr_4^{2-}$.

The band at around 230 nm for $HgCl_4^{2-}$ could only be resolved into a single Gaussian band upon removal of a considerable proportion of the high energy side of the band profile (Fig. 12*a*). A better fit over the whole spectrum was obtained for three component bands (Fig. 12*b*). Second and fourth derivative spectra, using large convolution arrays, appeared to support the presence of one band, but with small convoluting arrays indicated the possibility of three bands, though the spectra were noisy. It is considered that three bands instead of one (10) should be used to explain the spectrum of $HgCl_4^{2-}$.

Discussion

A. Theory and interpretation

Figure 13 shows a correlation diagram for the molecular orbitals of HgX_4^{2-} species having T_d symmetry with the order of orbital energies as given by Day and Seal (10). Excluding the *d* electrons of the mercury atom there are 32 valency electrons, which fill the available orbitals up to and including the $^1T_1$ orbital. This electron configuration, $(1t_1)^6$, gives a $^1A_1$ ground state term.

Excitation of electrons in the $1t_1$ or $1e$ orbitals to the $3a_1$ orbital is symmetry forbidden, but excitation to it from $3t_2$ is allowed, giving a $(3t_2)^5(3a_1)^1$ configuration and a $^1T_2$ state. The

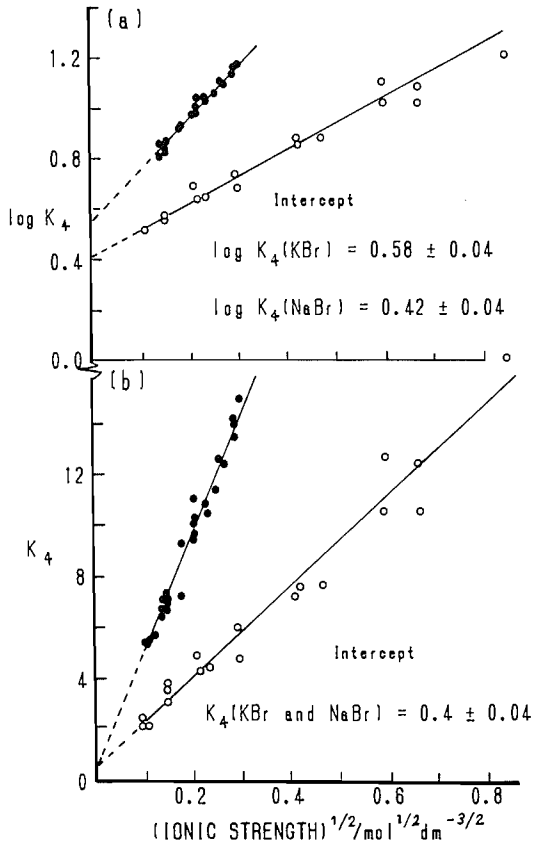

FIG. 8. Variation of log K_4 and K_4 for the formation of $HgBr_4^{2-}$ in methanol at 20°C with the square root of the ionic strength (I) of the solutions for which K_4 was determined from spectroscopic data. Open circles represent data using NaBr as added bromide, full circles, KBr.

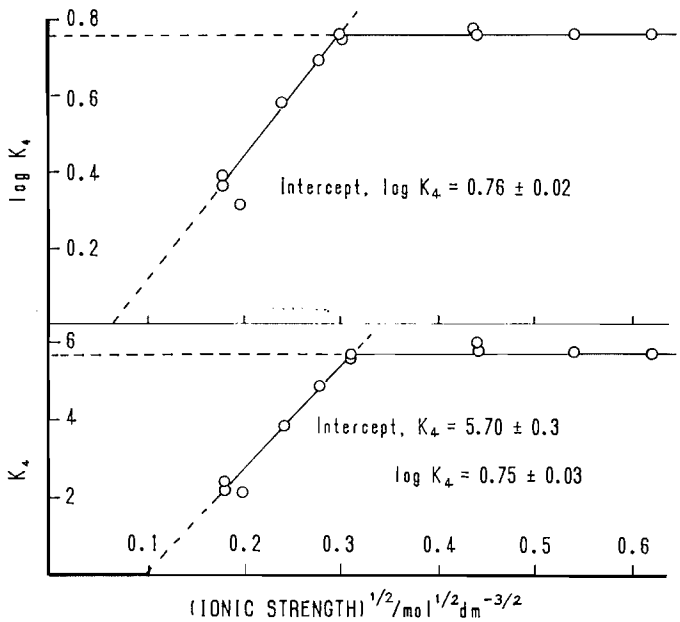

FIG. 9. Variation of log K_4 and K_4 for the formation of $HgCl_4^{2-}$ in methanol at 20°C with the square root of the ionic strength (I) of the solutions for which K_4 was determined from spectroscopic data. KCl and NH_4Cl were both used as added chloride, but the data points were insufficient to determine possible cationic effects.

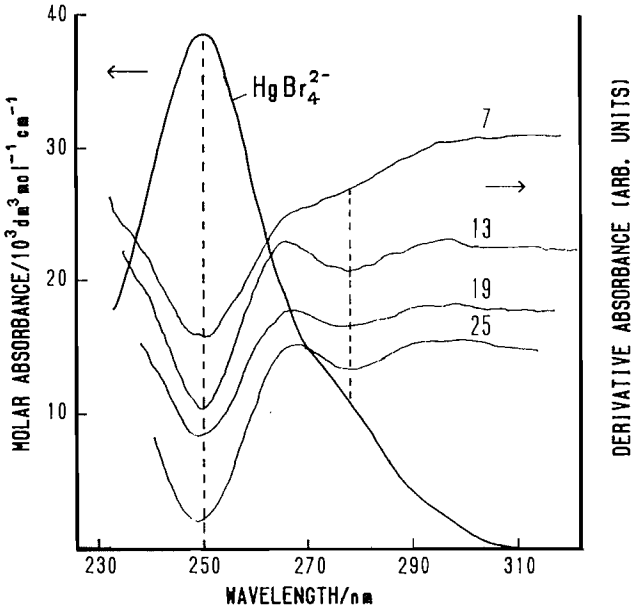

FIG. 10. Second and inverted fourth derivative curves superimposed on the ultraviolet absorption spectrum of $HgBr_4^{2-}$ in methanol at 20°C. The numbers indicate the number of data points used in calculating the derivatives. The curves show that the maxima of the main band and the lower-energy hidden band are clearly resolved only when convolutes > *ca.* 19 are employed.

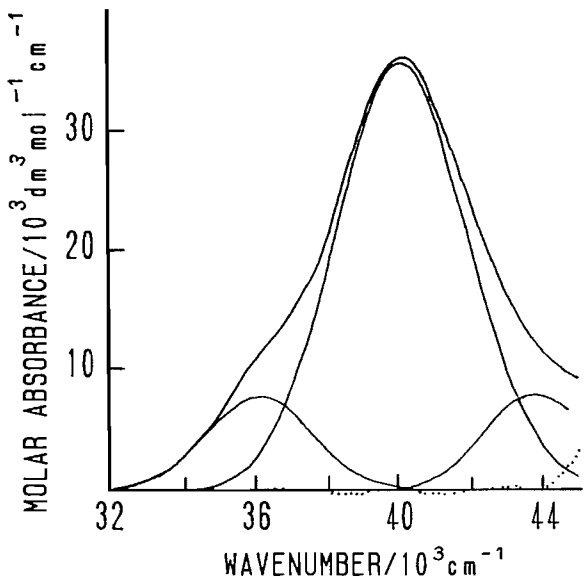

FIG. 11. Gaussian analysis of the ultraviolet absorption spectrum of $HgBr_4^{2-}$ in methanol at 20°C for three bands, fitting all available data points. Dotted line is the difference between the sum of the best fit of the Gaussian curves and the spectrum of $HgBr_4^{2-}$.

$^1A_1 \rightarrow {}^1T_2$ transition should therefore give an intense band in the spectrum of HgX_4^{2-}, which is observed. The allowed transition from the $2t_2$ and $1t_2$ orbitals would occur at much higher energies, outside the range of the recorded spectra.

Spin–orbit coupling may cause forbidden transitions to $^3T_2$, ^3E, and $^3T_1$ states, corresponding to $(3t_2)^5(3a_1)^1$, $(1e)^3(3a_1)^1$ and $(1t_1)^5(3a_1)^1$, respectively, and would be expected at lower energy than the allowed $^1T_2$ transition. The band analysis of the tetrahalide spectra showed a low energy band in HgI_4^{2-} and

*E_{max} = peak maximum (10^3 cm^{-1}); ϵ_m = molar absorbance (dm^3 mol^{-1} cm^{-1}); w = band width at half-height (10^3 cm^{-1}); A = band area (dm^3 mol^{-1} cm^{-1} × 10); o.s. = oscillator strength; Δ = band separation (10^3 cm^{-1}) of two lowest energy transitions; ζx spin–orbit coupling constants (10^3 cm^{-1}) for halides; *a* = this work; *b* = peak observed but E_{max} not reported by Day and Seal (10).

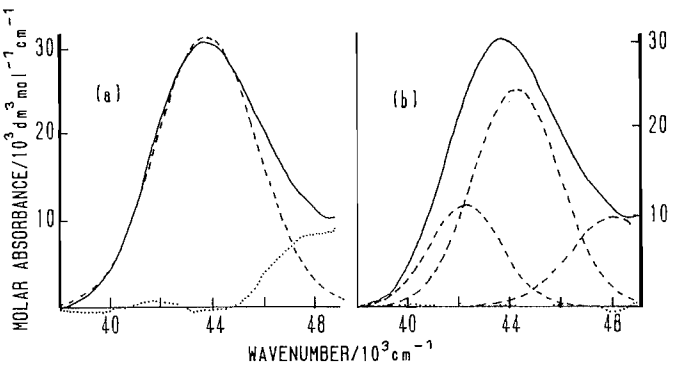

FIG. 12. Comparison of the Gaussian analysis of the ultraviolet absorption spectrum of $HgCl_4^{2-}$ in methanol at 20°C for (*a*) one band, and (*b*) for three bands (see text). Dotted line is the difference between the spectrum of $HgCl_4^{2-}$ and the Gaussian curve, (*a*), or the sum of Gaussian curves, (*b*).

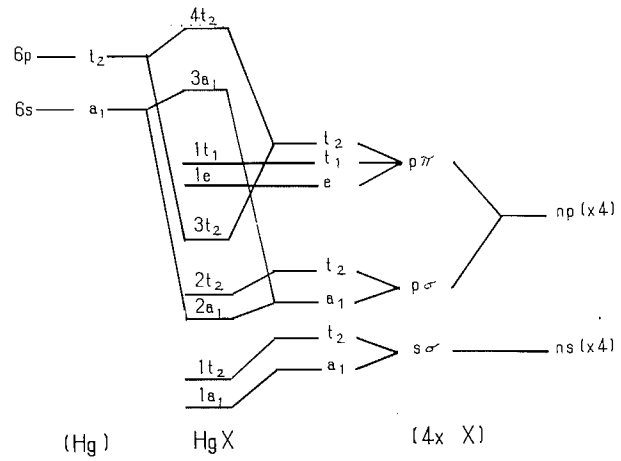

FIG. 13. Correlation diagram for the orbitals of HgX_4^{2-} species with T_d symmetry.

$HgBr_4^{2-}$, and probably one for $HgCl_4^{2-}$. The energy separation between the main band and the forbidden band increases from chloride to iodide, as expected from the spin–orbit coupling constants given by Jorgensen (17). The increased intensity of the second band (from the reliable results of HgI_4^{2-} and $HgBr_4^{2-}$) indicates its origin to be $^1A_1 \rightarrow {}^3T_2$, the $^3T_2$ state mixing with the $^1T_2$ state *via* spin–orbit coupling, thereby becoming partially allowed. Transitions to ^3E and $^3T_1$ states are both spin- and orbital-forbidden on symmetry considerations and are not found for HgX_4^{2-}. The various band parameters for HgX_4^{2-} in methanol are given in Table 1.

Table 1 shows that the band separation is greater than that expected for spin–orbit coupling in the halogen alone, because the transition involves electron transfer between the $3t_2$ and $3a_1$ molecular orbitals, both of which are made up of halogen and mercury atomic orbitals. To a first approximation the $3t_2$ orbital could be considered ligand localised while the $3a_1$ orbital is metal localised.

The trend towards higher energy from HgI_4^{2-} to $HgCl_4^{2-}$ for the main band is simply interpreted in terms of the molecular orbital scheme (Fig. 13): on going from X = I to X = Cl the energy difference between the 6*s* and 6*p* orbitals in mercury and the *np* and *ns* orbitals in the ligand increases. The difference between the bonding and antibonding orbitals, $3t_2$ and $3a_1$, respectively, thus increases from I to Cl.

Essentially the same conclusions are reached by Day and Seal (10), arguing slightly differently, from their analysis of HgX_4^{2-} spectra in acetonitrile, and their results are included in Table 1 for comparison. However, they reported that R values of around 15 were all that were necessary to obtain "essentially complete formation" of $HgBr_4^{2-}$ and $HgCl_4^{2-}$, and around R = 25 for HgI_4^{2-}.

This is much less than our minimum requirements, where the tetrachloro complex required the largest R value. They also reported "satisfactory Beer's law plots under these conditions", which we did not always find in methanol (see Fig. 2). How-

ever, their molar absorbance values were consistently higher than ours, suggesting that molar absorbance values may be solvent dependent, and that further halide addition may possibly lead to still higher values in acetonitrile for HgX_4^{2-}.

B. Formation constants and ionic strength

We have noted earlier (18) how that plots of K_4 (for the formation of HgX_4^{2-}) *vs.* I gave two intersecting straight lines for reactions in water. This was interpreted as a low ionic strength line corresponding to the formation of HgX_4^{2-} in a *three*-species equilibrium with HgX_2 and HgX_3^-. Also, no HgX_4^{2-} could form until HgX_3^- has been formed, and hence the intercept of this line is at $I > 0$, since HgX_3^- will only form in the presence of excess halide (and not by disproportionation of HgX_2 into HgX^+ and HgX_3^-). The intercept gives the minimum ionic strength at which HgX_4^{2-} will occur, and the intersection of the two lines indicates the ionic stength at which the change from a three- to a two-species equilibrium occurs in water. This pattern was followed by only $HgCl_4^{2-}$ in methanol, indicating that $HgCl_4^{2-}$ was not formed in solution until the ionic strength reached around 7×10^{-3} mol dm^{-3}, and that the two species equilibrium obtained above 0.1 mol dm^{-3}.

However, the K_4 plots for the iodo- and bromomercurates in methanol here gave single straight lines which did not cross the abscissa. This shows an absence of a measurable three-species equilibrium for these species in methanol, and almost complete conversion of HgI_2 to HgI_3^- before HgI_4^{2-} forms, which is borne out upon examining the spectra (Fig. 1).

C. Effect of ionic medium and added cation

The difference between the spectra of a solution containing, say KX, and that of one containing an equal molarity of NaX is due to the effect of the cation upon the equilibrium between mercuric halides and X^-, and not to an effect on the spectra of the individual species. We observed that $HgBr_4^{2-}$ has the same profile in KBr and NaBr solutions, although solutions containing $HgBr_3^-$ and $HgBr_4^{2-}$ in equilibrium gave different spectra for equal molarities of these two alkali bromides. Similarly, the effect of dilution or change in ionic strength on solution spectra is also interpreted as a change in equilibrium, and not the individual species changing spectra.

The effect of NaBr and KBr on the formation of $HgBr_4^{2-}$ was significant, and the K_4 values diverged with increasing ionic strength (Fig. 8*b*), but had the same value at infinite dilution.

The effect of cationic size on the activity coefficients of the $HgBr_3^-$ and $HgBr_4^{2-}$ may account for this effect. In the extended Debye–Hückel equation, $-\log \gamma = Az_1z_2I/(1 + aBI^{1/2})$, the mean ionic diameter, a, becomes more important as the ionic strength increases. The thermodynamic formation constant, K_T, is related to the activity coefficients by the equation $\log K_4 = \log K_T - \log \gamma(HgX_4^{2-}) + \log \gamma(HgX_3^-) + \log \gamma(X^-)$. The higher slope of the K_4(KBr) line compared to that of K_4(NaBr) is due to the ionic diameter of K^+ being greater than that of Na^+, and hence having greater effect on the $aBI^{1/2}$ term. Further, the B term also contains the inverse square root of the dielectric constant of the medium, *viz.*, $B = \text{constant}/(DT)^{1/2}$. A change from solvent water to methanol increases B by a factor of around three.

The effect of cationic size on the formation of HgI_4^{2-} using NaI and KI was negligible within experimental error (Fig. 7), whereas the effect of NH_4Cl compared with KCl, on $HgCl_4^{2-}$ formation, was large (Fig. 6).

This simple explanation of the cation effect in terms of the Debye–Hückel $aBI^{1/2}$ term, and dielectric constant change, is probably not complete: the effect of cation upon the entropy and enthalpy changes of the reactions may be significant. Khophar and Naraynankutty (19) have suggested this to explain the effect of different cationic media on the stability of Am(III) and Eu(III) complexes. They found that K values increased with decreasing hydration of medium cations (Li^+, H^+, K^+, and NH_4^+), and concluded that the effect was too large to be related to activity changes alone.

Thermodynamic investigation of the ternary K–Pb–Sn and Rb–Pb–Sn alloys

PETER J. TUMIDAJSKI

Department of Materials Engineering, The University of Western Ontario, London, Ont., Canada N6A 5B9

Received October 20, 1989[1]

PETER J. TUMIDAJSKI. Can. J. Chem. **69**, 458 (1991).

Activity coefficients for alkali metals in the K–Pb–Sn and Rb–Pb–Sn alloys were measured at 606°C (879 K) for compositions generally less than about 10 at.% alkali metal. An alkali metal concentration cell with a potassium or rubidium substituted β-Al_2O_3 solid electrolyte was used to perform the experiments. A coulometric titration technique was used to electrochemically generate the alkali metal in the Pb–Sn alloys. The results indicated that, for both potassium and rubidium alloys, as solvent composition is varied from pure tin to pure lead the liquid becomes more associated, suggesting the formation of complex species.

Key words: thermodynamics, alkali metals, liquid alloys.

PETER J. TUMIDAJSKI. Can. J. Chem. **69**, 458 (1991).

Opérant à 606°C (879 K) et généralement à des compositions atomiques en métal alcalin inférieures à 10%, on a mesuré les coefficients d'activité des métaux alcalins dans les alliages K–Pb–Sn et Rb–Pb–Sn. On a réalisé les expériences dans une cellule de concentration de métal alcalin dans laquelle on a remplacé l'électrolyte solide β-Al_2O_3 par un potassium ou un rubidium. On a utilisé une technique de titration coulométrique pour générer d'une façon électrochimique le métal alcalin dans les alliages de Pb–Sn. Les résultats indiquent que, pour les alliages de potassium ainsi que de rubidium, le liquide devient plus associé lorsqu'on fait varier la composition du solvant d'étain pur à plomb pur; ce résultat suggère qu'il y a formation d'espèces complexes.

Mots clés : thermodynamique, métaux alcalins, alliages liquides.

Introduction

An explanation of the thermodynamic behaviour of liquid alkali metal – lead alloys has proved challenging. Recent experimental results have shown that the thermodynamic properties of K–Pb (1) and Rb–Pb (2) alloys change abruptly at the equiatomic composition, in agreement with electrical resistivity measurements (3, 4). Furthermore, the heat capacities (5, 6), show this abrupt change occurs at equiatomic composition. Neutron diffraction patterns for the structure of equiatomic K–Pb and Rb–Pb display a sharp diffraction peak at low wave vector, indicating intermediate range ordering (7, 8) and a possible existence of the polyvalent anion, Pb_4^{4-}, similar to the Zintl ion which exists in the solid state.

To date, the thermodynamic properties for the binary K–Sn system has been reported only over a limited composition range (9). The thermodynamic properties for the Rb–Sn alloy and the ternary K–Pb–Sn and Rb–Pb–Sn alloys have not been reported. In this paper, we report potassium and rubidium activities in the Pb–Sn alloys. The results can be used to provide an understanding of the thermodynamic behaviour of the ternary systems and how they compare with the constituent binaries. In addition, there is an increased understanding of the influence of multicomponent solvents on the atomic interactions involving the alkali metals.

Experimental

The experimental procedure and technique has been described in detail elsewhere (1, 2, 10). Briefly, the electrochemical cell consisted of two half-cells, a secondary reference half-cell (RE), and a working half-cell (WE), represented schematically as,

$$\underset{\text{(RE)}}{\text{Bi–A}} \;\|\; \beta\text{-}Al_2O_3 \;\|\; \underset{\text{(CE)}}{\text{Bi–A}} \;\|\; \beta\text{-}Al_2O_3 \;\|\; \underset{\text{(WE)}}{\text{Pb–Sn–A}}$$

where A represents the alkali metal potassium or rubidium, respectively. RE contained 5 at.% alkali metal to reduce the alkali metal activity and its vapour pressure. Reference electrodes were calibrated against pure liquid alkali metal using similar concentration cells. The composition of WE was accurately varied by coulometric titration with the counter electrode (CE). Temperatures were measured with a calibrated (Pt–Pt 10 at.% Rh) thermocouple directly immersed in CE.

Results and discussion

The cell reaction for the alkali metal concentration cell is

$$[1] \quad A_{(\text{pure, l})} \rightleftharpoons \underline{A}$$

where $\underline{A}$ represents alkali metal in Pb–Sn alloys. The cell voltage can be expressed as

$$[2] \quad E = -\frac{RT}{F} \ln \gamma_A - \frac{RT}{F} \ln X_A$$

where F, R, and T have their usual meaning and γ_A and X_A are the activity coefficient and atom fraction of alkali metal, respectively. For dilute solutions eq. [2] can be simplified to

$$[3] \quad E = E_A^0 - \frac{RT}{F} \ln X_A$$

where E_A^0 represents the limiting standard potential of alkali metal in molten Pb–Sn alloys. The limiting standard potential defines a hypothetical standard state where the fraction of alkali metal in the Pb–Sn alloy approaches unity, but the alkali metal behaves thermodynamically as if it were infinitely diluted. Nernst plots for $X_A < 0.01$ at 606°C (879 K), as expressed by eq. [3], are given in Figs. 1 and 2 for the potassium and rubidium systems, respectively. Cell voltage is plotted against $\log_{10} X_A$. Also included in Fig. 1 are the results for the K–Sn binary reported earlier by Petric (9). The experimental data are well represented by the indicated least-squares lines. Linear regression analysis for the Nernst plots gave correlation coefficients of almost unity for all cases. Thus the solutions are Henrian. Calculated slopes for the Nernst plots are summarized in Table 1. The results are in excellent agreement with the theoretical values (RT/F) and indicate a one-electron transfer

System	Expt.	Slope	E_A^0 (mV)	$\mu_E^0[A]$ (kJ mol^{-1})
K–Sn	Ref. 9	74.11	278.5	−26.87
K–Pb–Sn	11, 13	76.21	335.9	−32.41
K–Pb	Ref. 1	131.87	394.5	−38.07*
			397.8	−38.38†
Rb–Sn	7	75.56	215.7	−20.81
Rb–Pb–Sn	1, 3, 4, 6	73.44	299.47	−28.89
Rb–Pb	Ref. 2	73.50	330.57	−31.90

*T = 640 K.
†Estimated value for T = 879 K.

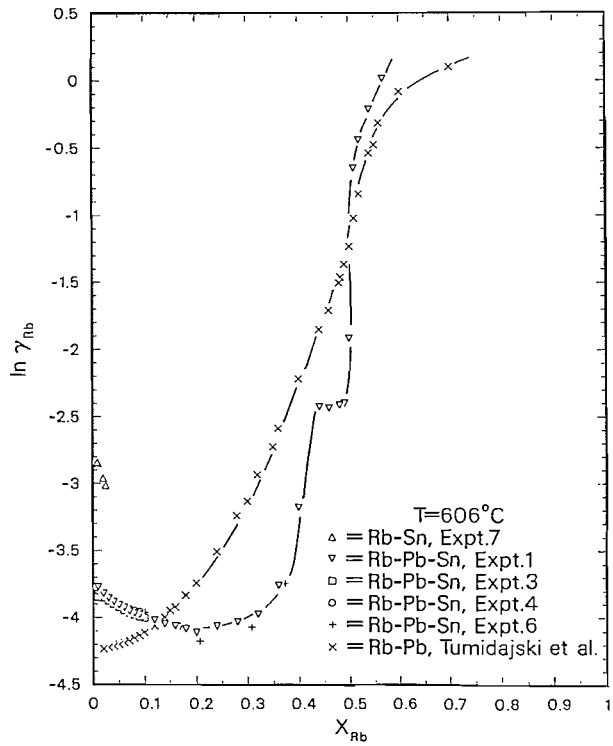

FIG. 3. Variation of ln γ_{Rb} versus composition at 606°C (879 K) for the entire composition range. The data for the Rb–Pb binary system were reported previously (2).

as expected. Values for the limiting standard potential, E_A^0, are included in Table 1, as well as a related thermodynamic property, the limiting excess chemical potential, defined by the expression,

$$[4] \quad \mu_0^E[\underline{A}] = -FE_A^0$$

It can be seen that the magnitudes of the limiting standard potentials and the limiting excess chemical potentials increase in the order Sn → Pb–Sn → Pb for both potassium- and rubidium-based alloys. The result indicates that Pb-based alloys are thermodynamically more stable than Sn-based alloys.

In Table 1 values for the limiting potential and excess chemical potential of the binary K–Pb alloy at 606°C (879 K) have been estimated using a previously proposed relationship (11),

$$[5] \quad E^0_{K-Pb-Sn} = (1 - t)E^0_{K-Pb} + tE^0_{K-Sn}$$

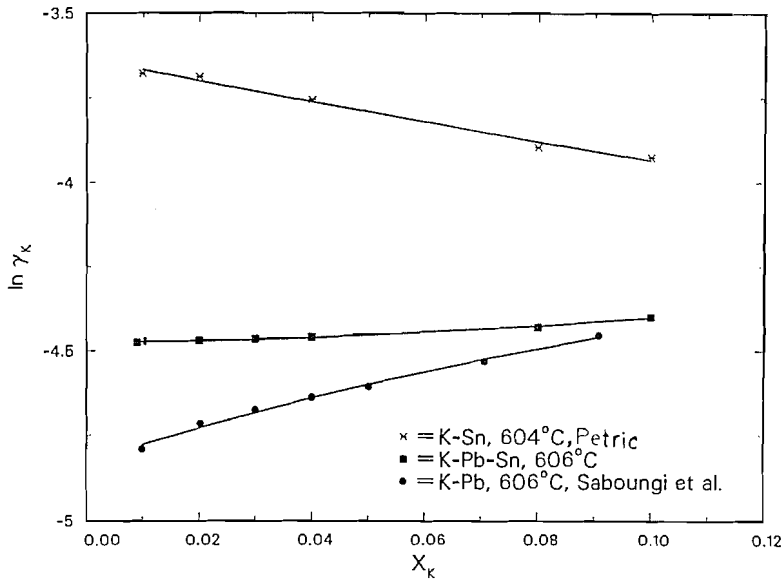

FIG. 4. Variation of ln γ_K versus composition for the limiting slope composition range. The data for the K–Sn binary system were reported previously (9).

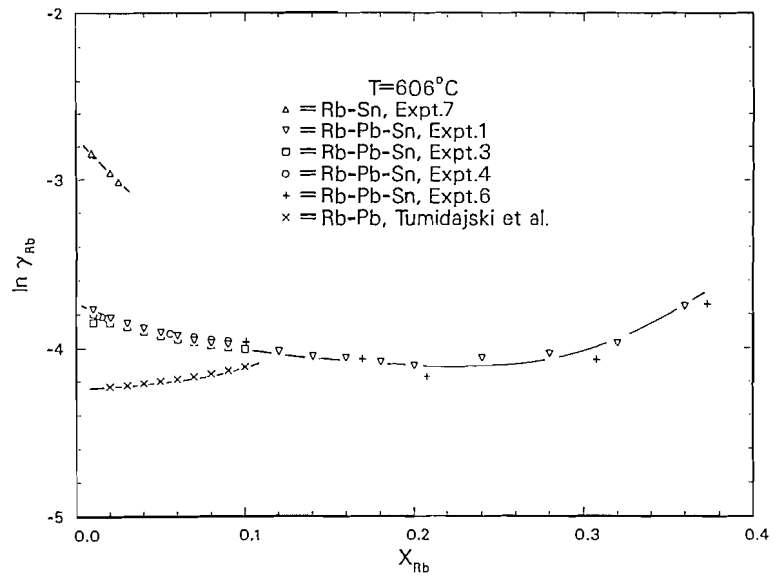

FIG. 5. Variation of ln γ_{Rb} versus composition at 606°C (879 K) for the limiting slope composition range. The data for the Rb–Pb binary system were reported previously (2).

or

[6] $\mu_0^E[K\text{–}Pb\text{–}Sn] = (1 - t)\mu_0^E[K\text{–}Pb] + t\mu_0^E[K\text{–}Sn]$

The t parameter is a solvent composition variable defined as

[7] $$t = \frac{X_{Pb}}{X_{Pb} + X_{Sn}}$$

The estimated values agree very well with previous experimental results (1) at 367°C (640 K). There is a slight increase in magnitude of the limiting potential and limiting excess chemical potential with temperature. The Nernst line for K–Pb in Fig. 1 was constructed using the value for E^0_{K-Pb} calculated with eq. [5] and the ideal Nernst slope.

As the alkali metal content increases beyond the Henrian regime, deviations from the Nernst law become significant. For each alloy composition, γ_A can be calculated from eq. [2] rearranged to,

[8] $$\ln \gamma_A = \frac{FE}{RT} - \ln X_A$$

Figure 3 shows the compositional dependence of ln γ_{Rb} at 606°C (879 K) for the Rb–Pb–Sn alloys. Included in Fig. 3 are results for the Rb–Pb system reported earlier (2). There are several interesting features. The solubility limit of Rb in Rb–Sn alloys was found to be approximately 3 at.% at 606°C (879 K). Beyond 3 at.% there exists a two-phase region as evidenced by a constant cell voltage. For the Rb–Pb–Sn ternary alloy there is a two-phase liquid–solid region in the interval $0.42 < X_{Rb} < 0.49$, and a compound forms at $X_{Rb} = 0.50$.

The limiting slope, ϵ, is defined as

TABLE 2. Limiting slope values for the A–Pb–Sn systems at 879 K

		$\ln \gamma_A = A + BX_A + CX_A^2$			
System	Expt.	A	B	C	$(\epsilon)_{X_A \to 0}$
K–Sn	Ref. 9	−3.63	−3.51	4.69	−3.5
K–Pb–Sn	11, 13	−4.47	0.82	6.43	0.8
K–Pb	Ref. 1	−4.82	5.20	−12.46	5.2
Rb–Sn	7*	−2.74	−10.79	—	−10.8
Rb–Pb–Sn	1, 3, 4, 6	−3.75	−3.46	9.07	−3.5
Rb–Pb	Ref. 2	−4.26	1.00	2.23	1.0

*T = 877 K over limited composition range.

$$[9] \quad \epsilon = \left(\frac{\partial \ln \gamma_A}{\partial X_A}\right)_{X_A \to 0}$$

The limiting slope is related to the nature and extent of ordering within solutions (12–14). A positive value for ϵ indicates attraction between alkali atoms and solvent atoms and a subsequent high probability of preferred co-ordination (*i.e.* complex formation) in the liquid state. A negative value for ϵ indicates attractive forces between the alkali atoms. A zero value for ϵ represents a random distribution of the neighboring atoms. Limiting slope plots (*i.e.* $\ln \gamma_A$ versus X_A) are presented in Figs. 4 and 5 for potassium and rubidium alloys, respectively. The experimental data points have been fitted to quadratic polynomial equations and are recorded in Table 2. The limiting slopes for K–Sn, Rb–Sn, and Rb–Pb–Sn systems are negative. These results could indicate a pairing between the alkali atoms in dilute solutions. However, the limited number of data points and the presence of phase boundaries precludes a full interpretation and understanding of the limiting slopes for the K–Sn, Rb–Sn, and Rb–Pb–Sn systems. For both the K–Pb and Rb–Pb binary alloys, the limiting slopes suggest an attraction between unlike atoms and a relative repulsion between like atoms. It is surprising that, albeit Pb and Sn are in the same group of the periodic table, they apparently behave differently when alloyed with alkali metal.

The thermodynamic behaviour of $ThCl_4$ – alkali chloride solutions was investigated using galvanic and formation cells of the type

$$(-)Th/ThCl_4\text{–}ACl//\text{asbestos diaphragm}//AgCl\text{–}ACl/Ag(+)$$

and

$$(-)Th/ThCl_4\text{–}CsCl/C,Cl_{2(g,\ 1\ atm)}(+)$$

where ACl represents NaCl, KCl, CsCl, or equimolar mixtures of NaCl–KCl, NaCl–CsCl, and KCl–CsCl. In addition, the thermodynamic behaviour of thorium in mixed alkali chloride – alkali fluoride melts was studied using an electrometric titration technique. It was found that these melts are highly nonideal due to the formation of octahedrally coordinated complexes.

Key words: $ThCl_4$ solutions, potentials, thermodynamic properties, titration.

[Traduit par la rédaction]

Introduction

Thorium is important for its potential application in the thermonuclear production of electricity. It is used to impart creep resistance in magnesium based alloys, and its low electron work function and high emission current are utilized in electronic devices. $ThCl_4$ – alkali halide solutions are of interest because they can be used for the production or refining of thorium or its alloys by electrolysis.

In a previous publication from this laboratory (1), the standard electrode potentials and the associated thermodynamic properties of dilute solutions of metal chlorides in binary and ternary fused salt solutions were reported. In this work the method is extended to $ThCl_4$ – alkali chloride solutions in the concentration range where $ThCl_4$ conforms to Henrian behaviour.

The electrode potentials in the $ThCl_4$–CsCl system with a higher concentration of $ThCl_4$ were determined using a chloride formation cell. The results are important to confirm the dilute solution behaviour and to provide an insight into the fundamental properties of these mixtures.

Finally, the course of the chemical reaction and the ionic equilibria involved when alkali fluoride is added to the $ThCl_4$–CsCl solutions was determined using an electrometric titration technique. The results indicate that it is possible to control the thermodynamic state of a solute species by using mixed chloride and fluoride ions.

[1]Revision received October 17, 1990.

Experimental

The preparation and purification of the materials used in this investigation have been described previously (1). $ThCl_4$ salts were obtained from Cerac in anhydrous condition in sealed ampoules packed under argon gas. The alkali fluorides were reagent grade; and were dried by vacuum heating at 400°C for several days. Thorium metal electrodes were obtained from Morton Thiokol (Alfa Products Division).

Electrochemical cells

Dilute solutions

The design of the electrochemical cell employed in the present investigation for the dilute solutions has been described in detail elsewhere (1). Briefly, the cell consisted of a thorium metal electrode dipping into a $ThCl_4$ – alkali chloride solution and a Ag–AgCl secondary reference electrode. The half-cell compartments were separated by an asbestos diaphragm.

The spontaneous cell reaction for the Th–Ag galvanic cell is,

$$[1] \quad Th_{(s)} + 4AgCl = ThCl_4 + 4Ag_{(s)}$$

where species in italics denotes species in solution. The corresponding Nernst equation is

[2] $$E_{cell} = (E^0_{ThCl_4} - E^0_{AgCl}) - \frac{2.303RT}{4F} \log (X_{ThCl_4}/X^4_{AgCl}) - \frac{2.303RT}{4F} \log (\gamma_{ThCl_4}/\gamma^4_{AgCl})$$

where F is the Faraday's constant of 96 487 J V^{-1} mol^{-1}, and R is the universal gas constant of 8.3144 J K^{-1} mol^{-1}. The standard state in all cases is the pure liquid metal chloride at the temperature of the experiments. $E^0_{ThCl_4}$ and E^0_{AgCl} are the standard cell potentials for the formation of pure liquid $ThCl_4$ and AgCl, respectively. Values for E^0_{AgCl} were obtained from the work of Pelton and Flengas (2). Values for $E^0_{ThCl_4}$ incorporate considerable error. However, the most recent compilation by Pankratz (3) has been used to approximate enthalpies and activity coefficients for the dilute solutions.

Following the development given previously (1) for dilute solutions, where activity coefficients are expected to be constant, eq. [2] can be simplified to,

[3] $$E_{cell} = E^0_{f(ThCl_4)} - E^0_{f(AgCl)} - \frac{2.303RT}{4F} \log \left(\frac{X_{ThCl_4}}{X^4_{AgCl}} \right)$$

$E^0_{f(ThCl_4)}$ and $E^0_{f(AgCl)}$ are the formal formation potentials representing the free energy of formation of unit mole fraction of the salt but behaving as if it were infinitely diluted in a given solvent. For $ThCl_4$ the formal formation potential and its corresponding reaction are given by

[4] $$Th_{(s)} + 2Cl_{2(g,\ 1\ atm)} \rightarrow \mathit{ThCl_4} \qquad \text{at } X = 1, \text{ and at its thermodynamic state of infinite dilution}$$

and

[5] $$E^0_{f(ThCl_4)} = E^0_{ThCl_4} - \frac{2.303RT}{4F} \log (\gamma_{ThCl_4})$$

Because values for $E^0_{f(AgCl)}$ have been determined previously (1), $E^0_{f(ThCl_4)}$ can be calculated from eq. [3].

Concentrated solutions

The cell design was similar to the chloride formation cells described elsewhere (4). The cell consisted of a thorium metal indicator electrode immersed in molten $ThCl_4$–CsCl solution of known composition, and a graphite chlorine electrode, which also dipped into a molten solution of the same composition. The two cell compartments were separated by an asbestos fiber diaphragm fused into silica glass. The spontaneous cell reaction is

[6] $$Th_{(s)} + 2Cl_{2(g,\ 1\ atm)} = \mathit{ThCl_4}$$

The Nernst equation is

[7] $$E_{cell} = E^0_{ThCl_4} - \frac{2.303RT}{4F} \log (\gamma_{ThCl_4} X_{ThCl_4})$$

Chloride-fluoride solutions

The applicability of the electrometric titration technique in fused salt solutions has been demonstrated previously (5–8). The electrochemical cell for the electrometric titration is essentially a chloride formation cell with a port to allow for the addition of alkali fluoride pellets. The cell consisted of a thorium indicator electrode immersed in a $ThCl_4$ – CsCl – alkali fluoride molten solution, and the graphite chlorine gas reference electrode, dipping into a $ThCl_4$–CsCl solution. The half-cell compartments were separated by a diaphragm consisting of an asbestos fiber fused in quartz. The cell can be described schematically as

$$(-)Th/ThCl_4\text{–}CsCl\text{–}AF//\text{asbestos diaphragm}//ThCl_4\text{–}CsCl/C, Cl_{2(g,\ 1\ atm)}(+)$$

where AF represents NaF, KF, or CsF. The concentration of $ThCl_4$ in the reference electrode compartment was fixed at 6.98×10^{-3} mole fraction. At the beginning of an experiment, prior to the addition of alkali fluoride, the composition in both half-cell compartments was equal. Junction potentials caused by compositional differences across the diaphragm due to the addition of alkali fluoride, were minimized by the presence of an excess of CsCl on both sides of the asbestos diaphragm.

Results and discussion

The procedure for a typical experimental run for the dilute and concentrated solutions has been described previously (1). Electrometric titration was performed by adding weighed amounts of NaF, KF, or CsF to the indicator electrode compartment. The emf between the reference and indicator electrode compartments was measured.

Table 1 summarizes the measured cell emf's for dilute $ThCl_4$ solutions. They have been expressed as least-squares lines of the form $E = A + BT$, where E is the cell potential in volts, and T is the temperature in Kelvin. Melt compositions have been expressed in terms of mole fraction of $ThCl_4$. The correlation coefficients in Table 1 indicate that there is a linear relationship between the cell emf and temperature. An estimate for the standard deviations of cell emf for the regression of cell emf on temperature is less than ±2 mV in all cases. Further, the measured emf values were stable and reproducible to within ±1 mV.

As expected for Henrian solutions, there is a linear relationship between the cell emf and the Nernstian concentration term, as expressed by eq. [3]. A linear regression analysis for the concentration term against the cell potential yielded a correlation coefficient of approximately 0.99 for every solvent. Also, the slopes of the lines correspond, within a 99% confidence level, to the theoretical slope for a four-electron electrode reaction. Several $ThCl_4$ – alkali chloride systems have been investigated previously. Yang, Hudson, and Chien (9), Inman, Hills, Young, and Bockris (10), and Martinot (11), investigated the $ThCl_4$–LiCl–KCl melts. Srinivasan and Flengas (12) and Smirnov *et al.* (13–15) performed experiments on the $ThCl_4$–NaCl–KCl system. More recently, Smirnov and Kudyakov (16) re-investigated $ThCl_4$ in alkali chlorides. With the exception of the Soviet work, all investigators found that the single-step reduction

$$Th^{4+} + 4e^- \rightarrow Th$$

is the predominant potential-determining reaction under equilibrium conditions. Smirnov and co-workers (13–15) proposed that the average valency of thorium in alkali chloride melts is less than four, suggesting the existence of thorium subhalides. The experimentally determined potentials in this work did not vary with time, and the absence of thorium metal electrode corrosion suggests that subhalide forming reactions are not significant.

Values for the formal potentials for $ThCl_4$, as calculated with eq. [3], are summarized in Table 2. The formal potentials are expressed in the form

$$E^0_f = A + BT$$

where E^0_f is in volts, and T is the temperature in Kelvin. All potentials represent spontaneous cell reactions and are given with positive signs to conform with the thermodynamic requirement of a decrease in reaction free energy. However, if it is desired to tabulate the emf values in the format of a series against common reference electrode, such as chlorine or silver chloride electrodes, it will be necessary to conform to IUPAC (17) sign convention and assign negative values to the more reactive electrode systems. The uncertainties in the formal potentials listed in Table 2 were obtained as described in a

*Equimolar.

previous publication (1). A comparison of the magnitude of the formal potentials indicates the pronounced effect of CsCl in creating thermodynamically stable solutions. The large magnitudes of the formal potentials for $ThCl_4$ suggest an extremely strong tendency of $ThCl_4$ to form complex species in these melts. The magnitude of the formal potentials decreases with increasing temperature, indicative of complex dissociation at the higher temperatures. The agreement of the present results with those of Srinivasan and Flengas (12) for NaCl–KCl–$ThCl_4$ is good and within experimental error.

The calculation of valid partial molar properties for the $ThCl_4$ – alkali chloride systems is complicated by the lack of reliable data for the free energy of formation of pure molten thorium tetrachloride. The linear approximation for the standard formation potential of $ThCl_4$ (3) is

$$[8] \quad E^0_{ThCl_4} = A^0 + B^0T = 2.8076 - 5.001 \times 10^{-4}T$$

Typical errors expected for standard formation potentials are well over ±200 mV. When the formal formation potential is expressed as

$$[9] \quad E^0_{f(ThCl_4)} = A + BT$$

It follows that

$$[10] \quad \overline{\Delta H}_{ThCl_4} = -4F(A - A^0)$$

and

$$[11] \quad \log \gamma_{ThCl_4} = (E^0_{ThCl_4} - E^0_{f(ThCl_4)}) \frac{4F}{2.303RT}$$

Thermodynamic properties for the $ThCl_4$ systems are summarized in Table 3. The results are informative in a qualitative manner for indicating and confirming general trends. The very small activity coefficients in combination with the exothermic enthalpies of mixing suggest strong interactions usually associated with the formation of complex species. Furthermore, in the presence of larger solvent cations there is an increase in interaction between thorium cation and its surrounding anions.

TABLE 2. Formal potentials in the $ThCl_4$ systems

System	$E_f^0 = A + BT^*$ (V) A	$B \times 10^4$	E_f^0 (V) 1073 K	1173 K	±E
$ThCl_4$–KCl	2.8934	−3.650	2.502	2.465	0.002

$ThCl_4$–NaCl–CsCl	2.8440	−2.970	2.576	2.534	0.001
$ThCl_4$–KCl–CsCl	3.1873	−5.895	2.555	2.496	0.001

*Temperature range 973–1173 K.

For more concentrated $ThCl_4$–CsCl solutions, it was found that initial saturation of the molten solution with chlorine took about 2 h during which the cell potential rose slowly. Once the melt was saturated with chlorine gas, the cell potential was stable and responded immediately to temperature or chlorine pressure changes. The emf values obtained during heating over a period of 24 h could be retraced on cooling, indicating that the changes are reproducible. The reversibility of the measured emf's was also verified by polarization tests whereby a small current from an external dry cell was passed through the cell. On disconnecting the applied potential, the cell emf returned to its equilibrium value to within ±1 mV. Krasnov and co-workers (18) and Smirnov and co-workers (19, 20) have postulated that for concentrated $ThCl_4$ – alkali chloride solutions, in the presence of thorium the solution process is significant and that the valency of thorium is intermediate between two and four.

0.2696	3.435	−7.198	−0.999	886–1034
0.3413	3.370	−6.892	−0.998	908–1025
0.4408	3.307	−6.782	−0.999	898–1029

The stability with time of the measured cell potentials of the thorium electrode, even in the more concentrated solutions, indicates that tetravalent ions are the predominant species in these melts. The results of the emf measurements are summarized in Table 4 expressed as least-squares lines of the form

$$E = A + BT \text{ (V)}$$

An estimate of the standard deviation for the linear regression of Table 4 is 0.5 mV in all cases. Below 0.3413 mole fraction of $ThCl_4$ the volatilities of the salts were low and the loss of $ThCl_4$ did not significantly alter the results. The thermodynamic properties of $ThCl_4$ were not calculated because of the large uncertainty in the free energy of formation of pure liquid $ThCl_4$. However, Fig. 1 is a plot of the Nernst concentration term versus cell potential for the $ThCl_4$–CsCl system at 1073 and 1173 K. The plots include results for the dilute galvanic and concentrated formation cells. It can be seen that the results for the former are consistent with the latter. Figure 1 also includes the standard potential for pure liquid $ThCl_4$ as calculated by Pankratz (3).

For titration experiments, the thorium electrode potential rose slowly for approximately 10 min after each addition of fluoride as dissolution of the pellet continued and mixing occurred; potentials were stable thereafter. For extended reaction times and for the higher alkali fluoride compositions, there was slight corrosion of the silica crucible and some dissolution of the thorium indicator electrode. Therefore, reaction times for these conditions were kept to a minimum. The titration curves obtained for 973 and 1023 K are given in Fig. 2 in which the cell potentials were plotted against the composition variable R, defined as,

[12] R = (total moles of alkali fluoride added/initial moles of $ThCl_4$)

The shapes of the curves indicate that reaction has taken place

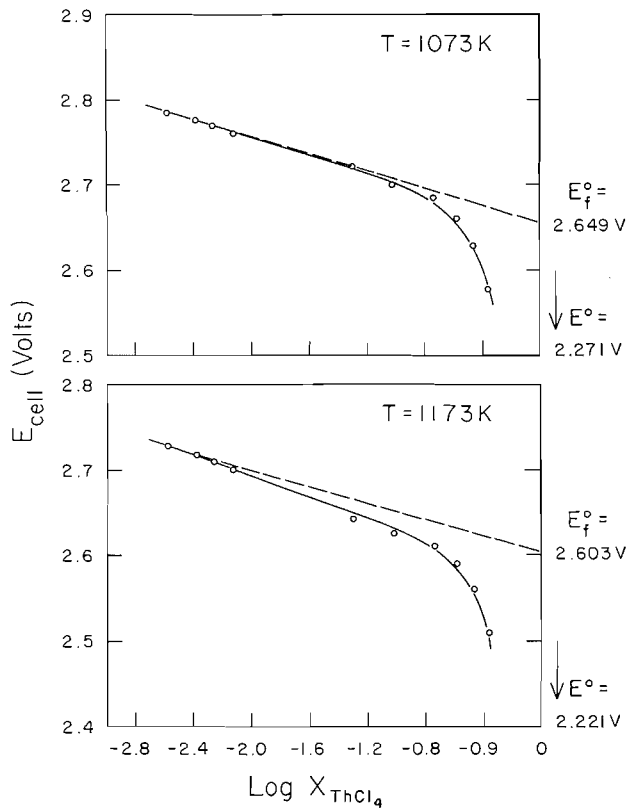

FIG. 1. Nernst plots for the $ThCl_4$–CsCl systems. E^0 represents the standard formation potentials of pure molten $ThCl_4$ at the indicated temperatures. Dotted lines represent a four-electron slope for E_{cell} versus log X_{ThCl_4} for the dilute solutions.

between the initial $ThCl_4$ in the $ThCl_4$–CsCl melt and the added alkali fluoride. A marked change in measured cell potential is expected to occur at the stoichiometric composition corresponding to the predominant species-forming reaction. Figure 2 also includes differential plots of the same titration curves. For both temperatures, and for all titrants, peaks are observed where the parameter R is approximately six. Hence, the addition of fluoride ions sets up an exchange reaction between octahedral complexes according to

[13] $ThCl_6^{2-} + 6F^- = ThF_6^{2-} + 6Cl^-$

For R greater than six, there is a slight but discernible change in cell potential for the addition of different alkali fluorides. The emf's decrease in the order CsF > KF > NaF.

The mass balance for the addition of CsF to a $ThCl_4$–CsCl mixture is given below. Reactions are assumed to occur in two steps. Initially, when $ThCl_4$ is added to CsCl, a chloro complex

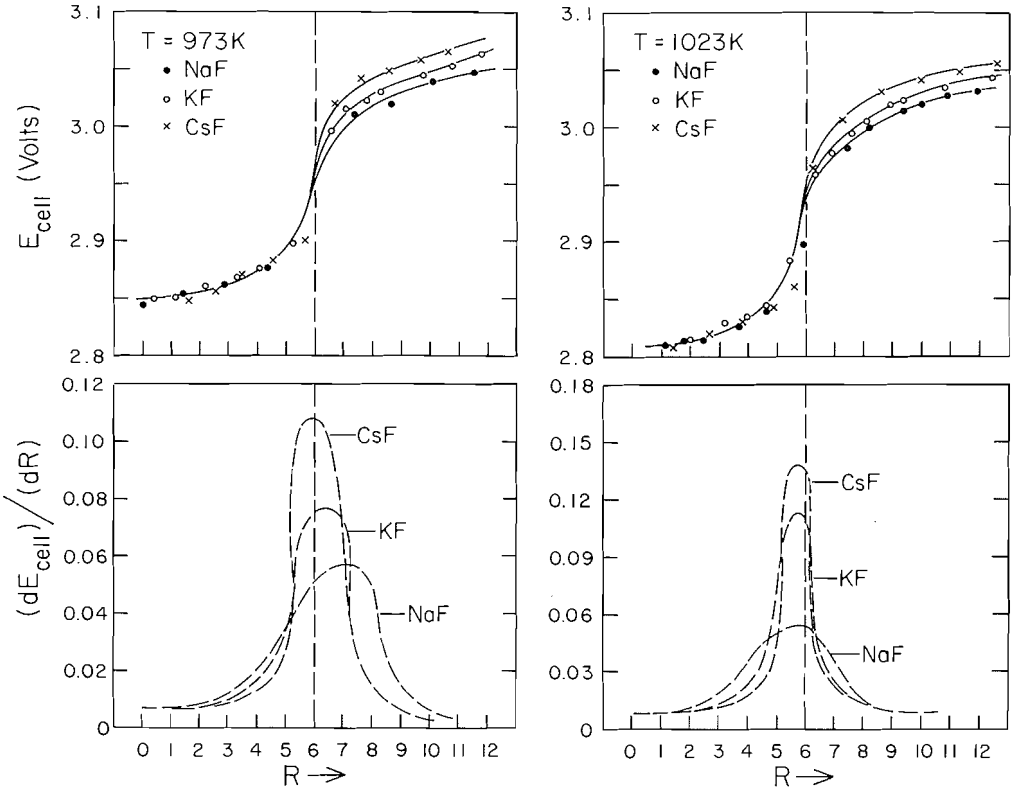

FIG. 2. Potentiometric titration curves during the addition of fluoride ions to $ThCl_4$–CsCl melts. $R = n_{AF}/n_{ThCl_4}$ = (mole ratio). dE/dR is also shown.

is formed, and the reaction is assumed to be complete. Therefore, the initial solution consists of a dilute solution of Cs_2ThCl_6 in CsCl. As CsF is added, the exchange reaction [13] between chloro and fluoro complex develops. The composition of the $ThCl_4$–CsCl–CsF melt is as follows:

	Complex-forming reaction:				
	$ThCl_4$	+	2CsCl	⟶	Cs_2ThCl_6
Initial	y		z		0
Equilibrium	0		$z - 2y$		y

	Exchange reaction:			
	Cs_2ThCl_6 +	6CsF	= Cs_2ThF_6	6CsCl
Initial	y	x	0	$z - 2y$
Equilibrium	$y(1 - \alpha)$	$x - 6\alpha y$	αy	$z - 2y + 6\alpha y$

$\Sigma = x + z - y$
$X_{Cs_2ThCl_6} = y(1 - \alpha)/\Sigma$
$X_{Cs_2ThF_6} = \alpha y/\Sigma$
$X_{CsF} = (x - 6\alpha y)/\Sigma$
$X_{CsCl} = (z - 2y + 6\alpha y)/\Sigma$
Note: α represents the degree of reaction per mole of the complex Cs_2ThCl_6.

The equilibrium constant for reaction [13] is

$$[14] \quad K = \frac{X_{Cs_2ThF_6} X^6_{CsCl}}{X_{Cs_2ThCl_6} X^6_{CsF}} = \frac{\alpha}{1 - \alpha} \frac{z - yz + 6\alpha y}{z - 6\alpha y}$$

The degree of reaction of Cs_2ThCl_6, α, is calculated from the expression for the formal formation potential of the Cs_2ThCl_6–CsCl system as

$$[15] \quad E_{cell} = E^0_{f(Cs_2ThCl_6)} - 2.303RT \log (X_{Cs_2ThCl_6})$$

For dilute solutions of Cs_2ThCl_6 in CsCl, the values for $E^0_{f(Cs_2ThCl_6)}$ are approximated by $E^0_{f(ThCl_4)}$ given in Table 2. At 973 K, with the appropriate substitutions, eq. [15] becomes,

$$[16] \quad E_{cell} = 2.741 - 0.0483 \log (y(1 - \alpha)/\Sigma)$$

For this system, the equilibrium constant is found to be infinitely large. Thus we assumed the exchange reaction to be virtually complete, and only negligible amounts of the chloro complex to be present.

Conclusions

Reversible emf measurements have been used to establish the thermodynamic behaviour of $ThCl_4$ in a number of binary and ternary fused alkali chloride solvents. In dilute solutions, Henrian behaviour is observed, and the calculated formal potentials, activities, and partial molar enthalpies of mixing indicate negative deviations from ideality, which become more negative as the size of the alkali metal cation in the solvent increases from sodium to cesium. Furthermore, thorium is present predominantly as a tetravalent cation.

Results for the more concentrated $ThCl_4$–CsCl solutions are in consonance with the dilute solution behaviour.

The addition of fluoride ions to the $ThCl_4$–CsCl solutions sets up an exchange reaction with the subsequent formation of octahedrally co-ordinated fluoro complexes of the type Cs_2ThF_6. The fluoro complexes represent an activity state for the thorium ions which is much lower than that in the all-chloride melt. Thus, it is possible to control the thermodynamic state of thorium ions by controlling the solvent composition and by using mixed chloride–fluoride melts.

Received July 12, 1990

ARNOLD JARCZEWSKI, GRZEGORZ SCHROEDER, and KENNETH T. LEFFEK. Can. J. Chem. **69**, 468 (1991).

Rate constants have been measured for the proton and deuteron transfer reactions of bis(2,4-dinitrophenyl)methane (**1**) with 1,1,3,3-tetramethylguanidine (TMG) and 1,5-diazabicyclo[5.4.0]undec-7-ene (DBU) in dimethyl sulfoxide (DMSO) and toluene solvents. Equilibrium constants, primary deuterium kinetic isotope effects, and activation parameters are reported. The reaction of **1** with DBU is faster than that with TMG by factors of 5 and 50 in toluene and DMSO respectively. The primary deuterium kinetic isotope effects, k_H/k_D = 7–9, which are independent of the polarity of the solvent, indicate an uncoupled mechanism of proton transfer and are in the "classical" region with little or no indication of a tunnelling contribution to the enthalpy of activation for these reactions.

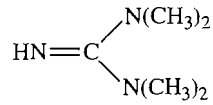
Key words: proton transfer, bis(2,4-dinitrophenyl)methane, deuterium isotope effects.

ARNOLD JARCZEWSKI, GRZEGORZ SCHROEDER et KENNETH T. LEFFEK. Can. J. Chem. **69**, 468 (1991).

On a mesuré les constantes de vitesse des réactions de transfert de proton et de deutéron entre le bis(2,4-dinitrophényl)méthane (**1**) et la 1,1,3,3-tétraméthylguanidine (TMG) ou le 1,5-diazabicyclo[5.4.0]undéc-7-ène (DBU), dans le diméthylsulfoxyde (DMSO) ou le toluène comme solvants. On rapporte les constantes d'équilibre, les effets isotopiques cinétiques primaires du deutérium et les paramètres d'activation. La réaction de **1** avec le DBU est plus rapide que celle avec la TMG par des facteurs de 5 et de 50 respectivement dans le toluène et le DMSO. Les effets isotopiques cinétiques primaires du deutérium, k_H/k_D = 7–9, qui sont indépendants de la polarité du solvant, indiquent que le mécanisme de transfert de proton n'est pas couplé; leur amplitude se trouve dans la région «classique» et ils ne suggèrent que peu ou pas d'existence de contribution d'un effet tunnel à l'enthalpie d'activation de ces réactions.

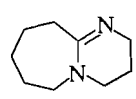
Mots clés : transfert de proton, bis(2,4-dinitrophényl)méthane, effets isotopiques du deutérium.

[Traduit par la rédaction]



Introduction

The mechanism of proton transfer reactions from carbon acids has been a subject of interest for many years (1–4), and the study of this mechanism has used primary deuterium kinetic isotope effects extensively (5–8), even though the parameters influencing these effects are still not well understood (8–10). From studies of the kinetics of the proton transfer reactions between 4-nitrophenylnitromethane and bases of different structure and strength, Caldin and Mateo (2) deduced that the large difference between the isotope effects in nonpolar and polar solvents could be attributed to the coupling of the proton transfer with the motion of solvent molecules in the polar solvents. This coupling effect was not appreciable in solvents of low polarity, such as toluene. The coupled mechanism causes an increase in the effective mass of the transferred proton, reducing the contribution of tunnelling to the overall process (14), and yielding a small or moderate isotopic rate ratio (4, 11–13). However, this simple picture was first questioned by Rogne and co-workers (15–17) and later by Kresge and Powell (18, 19), who showed that the large isotope effects for the reaction with tetramethylguanidine (TMG) could be artefacts caused by the exchange of hydrogen present on the nitrogen atom of the TMG molecule.



Our results obtained for different proton transfer reactions showed a rather weak dependence of the isotope effect on the polarity of the solvents used (4, 8, 10–12). The isotope effects found for these and other reactions (20, 21) are lower than 8, suggesting that an uncoupled mechanism of proton transfer takes place in polar solvent (4, 8, 10) in which the proton transfer precedes the solvent relaxation (10).

The other important factors governing the isotope effect are the structures of the carbon acid and the base. Steric hindrance was believed to enhance the isotope effect, based on the work of Lewis and Funderburk (22) on the reaction of 2-nitropropane with substituted pyridines in mixed *t*-BuOH/H_2O solvent and this was partly confirmed by our earlier results for other reaction systems (4, 5, 13). Bulky substituents in the reactant molecules could change the height of the potential energy barrier either because of increased repulsive forces or because of crowding of the reaction site, which leads to the exclusion of solvent molecules and so prevents the lowering of the energy barrier by solvent reorganization (23).

The marked dependence of the isotope effect on the presence of substituents close to the reaction site in either the carbon acid or the base was somewhat weakened by several studies (4, 8–10) in which the isotope effect was found to be not very sensitive to the crowding of the reaction site on the carbon acid. For the reaction of 2-methyl-4-nitrophenyl-1-nitropropane with 1,5-diazabicyclo[5.4.0]undec-7-ene (DBU) base, the effect was even reversed, with a larger isotope effect for 4-nitrilophenyl-1-nitroethane, which has much less crowding at the reaction site (10). Therefore, further study of the isotope

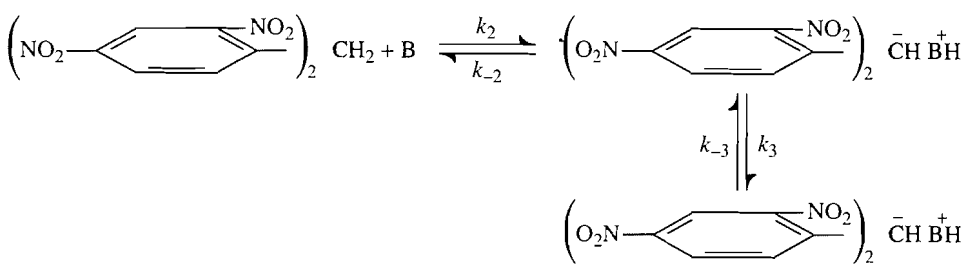
[a] K_i and K_{ip} are the equilibrium constants assuming free-ion or ion-pair products, given by eqs. [2] and [3] respectively.

effect as a function of steric crowding and solvent change is required to resolve these inconsistencies.

In this paper we present a study of the reaction between bis(2,4-dinitrophenyl)methane (**1**) and 1,1,3,3-tetramethylguanidine (TMG) (**2**) and 1,5-diazabicylo[5.4.0]undec-7-ene (DBU) (**3**) in dimethyl sulfoxide (DMSO) and toluene solvents. Both of these bases are very strong, and while TMG has the disadvantage of containing an exchangeable hydrogen and is very hygroscopic, DBU has neither of these problems.

Results and discussion



It was recently shown (8, 10) that the products of the proton transfer from 1-nitro-1-(4-nitrophenyl)-alkanes to DBU in acetonitrile exist extensively in the form of free ions rather than ion pairs. It is expected, therefore, that the products of the reaction between **1** and TMG and DBU in dimethyl sulfoxide solvent are probably free ions as shown in eq. [1]. In toluene solvent the product is probably the ion pair in eq. [1].

The reaction shows a strong absorption peak at 715 nm, which is believed to be characteristic of both the ion pair and the free carbanion ion. The absorbances at equilibrium, for a constant acid concentration and varying base concentration, were fitted by the least-squares method to the Hildebrand–Benesi equation for both free ions and ion-paired products, eqs. [2] and [3] respectively, where a and b are the initial concentrations of the carbon acid and base, A is the absorbance at equilibrium, and ε is the molar absorptivity.

$$[2] \quad \frac{a}{A} = \frac{A}{K_i b \varepsilon^2} + \frac{1}{\varepsilon}$$

$$[3] \quad \frac{a}{A} = \frac{1}{K_{ip} b \varepsilon} + \frac{1}{\varepsilon}$$

For the reactions in DMSO the results fitted eqs. [2] and [3] equally well, giving correlation coefficients for a linear least-squares fit of 0.979–0.999 for eq. [2] and 0.984–0.999 for eq.

[3]. It seems likely, therefore, that there is a partial, but probably extensive, dissociation of the ion pairs to free ions. Since the two species are indistinguishable by the visible absorption spectrum and it is assumed that the dissociation process, k_3, is much faster than the proton transfer, the kinetic equation [4] for the proton transfer may be applied to the reaction to a good approximation.

For the reactions in toluene a good fit is obtained with eq. [3] but not with eq. [2], confirming that the product is an ion pair. The equilibrium constants, with their standard deviations, for the reactions in DMSO and in toluene are shown in Table 1 for three temperatures, together with the molar absorptivities. The uncertainties in the molar absorptivities are quite large and the values recorded in Table 1 are not considered to be significantly different from each other.

The ion-pair equilibrium constants for the TMG and DBU reactions in toluene reflect the stronger basicity of the DBU base. However, in DMSO solvent, where the ion pairs are probably extensively dissociated into free ions and therefore only the K_i values should be interpreted, these equilibrium constants are almost the same for the two bases. In this case, the overall equilibrium constant, K_i, is the product of the equilibrium constant for the proton transfer to give the ion pair (K_{ip}), multiplied by the ion-pair dissociation constant, k_3/k_{-3}. K_{ip} must be greater for DBU than for TMG since it is the stronger base; therefore the ion-pair dissociation constant for the $TMGH^+$ ion pair has to be greater than that for DBU to yield the experimental result. Given the high degree of resonance delocalization of the positive charge in the $TMGH^+$ ion, this is a possible explanation.

The postulate that each of these strong bases abstracts a proton from DMSO yielding a DMSO anion as the active base would account for the equality of the K_i values, but predicts equal rate constants for the proton transfer reactions, which are not observed.

The pseudo-first-order constants, k_{obs}, were determined from kinetic runs carried out with excess base using a stopped-flow spectrophotometer, and were fitted to eq. [4] where b is the

$$[4] \quad k_{obs} = k_2 b + k_b$$

initial concentration of the base in each run and k_2 is the rate constant for the forward proton transfer reaction. Equation [4] gave a good fit for both proton and deuteron transfers. The results are collated in Table 2 for five different temperatures. In DMSO solvent k_b, the observed intercept of the plot of k_{obs} vs. base concentration, is $k_{-2}k_{-3}[BH^+]/k_3$, assuming that the dissociation of the ion pair and the association of the free ions in DMSO are much faster processes than the proton transfer to and from the carbon acid. Therefore, the figures shown for k_b in Table 2 cannot be readily interpreted for the reactions in DMSO.

Both TMG and DBU are very strong bases; the pK_a values of their conjugate acids in acetonitrile are 23.3 and 23.9 respectively (24). However, the difference in basicity must be larger in DMSO and toluene, since there is a rate factor of about 50 in favour of DBU in DMSO and about 7 in toluene. Such rate differences indicate a Bronsted β value well in excess of unity if the basicity difference is only 0.6 units. DBU is reacting as if it is a much stronger base than TMG in both of these solvents. Such an effect was also observed previously in acetonitrile itself (9), where a rate factor of 66 was observed and is not readily explained. It is possible that these observations could be related to the residual water that is always present in TMG no matter how thoroughly it is dried. However, earlier experiments (25) showed that replacing any ^-OH ion that may be present in the reaction mixture by ^-OD gave no kinetic isotope effect. An isotope effect of 50–80% would be expected if the reacting base was ^-OH (^-OD) rather than TMG.

It is also known that exchange between the deuterated substrate and the TMG hydrogen introduces no error in the determination of k_2 (26, 27). However, it does give spurious values for k_b. The lower values of k_b in Table 2 for the reactions in toluene indicate that some, but not complete, exchange is taking place.

Change of solvent polarity between DMSO and toluene has almost no effect on the second-order rate constant for the reaction with DBU base, whereas the same decrease in solvent polarity increases the rate constant for the TMG reaction by a factor of about 7 at 25°C. This change, which is the reverse of what would be expected for a reaction in which the transition state has more charge separation than the initial state, has been found previously for other proton transfer reactions (17, 28). Since Caldin has concluded that a major part of the energy barrier in proton transfer reactions is the breakdown of the initial state solvation shell (29), the origin of this rate change probably lies in the differences in the specific solvation of the two bases in DMSO and toluene. The observed rate changes require the postulate that the solvation of DBU is roughly the same in DMSO and toluene but the solvation of TMG is significantly greater in DMSO than it is in toluene.

The activation parameters for the reactions are shown in Table 3 and these allow the above free energy differences, measured by the rate constants, to be analyzed in terms of enthalpy and entropy contributions. Table 3 shows that the difference between the two bases for a given solvent lies predominantly in the enthalpy of activation, as would be expected. However, for the TMG base, changing the solvent from DMSO to toluene has a larger effect on the entropy of activation than it does on the enthalpy of activation, i.e., the larger rate constant in toluene is due to an entropy of activation effect, not an enthalpy of activation effect. The same may be true for the DBU reaction but the results are not precise enough to draw this conclusion.

In general, besides electrostatic and specific solvent interactions, the solvent environment in the vicinity of the reaction site

TABLE 3. Activation parameters for the proton and deuteron transfer reaction from bis(2,4-dinitrophenyl)methane bases in DMSO and toluene solvents

	TMG		DBU	
Parameter	DMSO	Toluene	DMSO	Toluene
ΔH_H^*(kcal mol^{-1})	5.37 ± 0.12	5.66 ± 0.17	3.11 ± 0.6	4.8 ± 1.0
ΔH_D^*(kcal mol^{-1})	5.81 ± 0.22	6.96 ± 0.33	4.42 ± 0.36	6.0 ± 1.0
ΔS_H^*(cal mol^{-1} deg^{-1})	−32.3 ± 0.5	−27 ± 1	−32 ± 2	−26 ± 4
ΔS_D^*(cal mol^{-1} deg^{-1})	−35 ± 1	−27 ± 1	−32 ± 1	−26 ± 4

can affect the proton transfer reactions in two different ways. One is by steric hindrance, which will operate to separate the acid and base, increasing the distance that the proton moves from the carbon acid to the base. The other is to form a solvent cage in which the reaction takes place under much smaller electrostatic effects of the solvent. The first case is common for the coupled mechanism of proton transfer (2, 14) and the second is described as the uncoupled mechanism (8, 10, 14) for which the values of the enthalpy of activation and primary deuterium kinetic isotopic effect are not very sensitive to the polarity of the solvent. The present results generally support the uncoupled mechanism, since the isotopic rate ratios, k_H/k_D at 25°C, lie in the range 9.3–7.2 and are smaller in toluene.

The isotope effects on the enthalpies of activation are substantial, large enough to account for the complete loss of the C–H or C–D stretching vibration, but not large enough to unequivocally indicate a contribution to the rate of the reaction from proton tunnelling.

Overall, these results show that there is no major change in the mechanism of proton transfer between the polar DMSO solvent and the nonpolar toluene solvent, supporting the operation of an uncoupled mechanism under both conditions.

Experimental

Materials

Bis(2,4-dinitrophenyl)methane was prepared using the nitration procedure of Fittig *et al.* (30). Bis(4-nitrophenyl)methane (5 g), prepared as previously described (28), was nitrated with a mixture of 90% HNO_3 (20 mL) and concentrated H_2SO_4 (100 mL) by heating the reaction mixture for 3 h at 120–140°C. The reaction mixture was then cooled and poured onto crushed ice. The solid was separated and recrystallized several times from acetonitrile. Yield 60%, mp 167–168°C; ^{1}H nmr, δ(ppm): 4.77 (s, 2H); 7.44, 7.54 (d, 1H); 8.33, 8.36, 8.43, 8.46 (d, d, 1H); 8.82, 8.80 (d, 1H); MS: 347 (M) (100%), 301 (47.6%), 257 (25.3%), 255 (17.9%), 195 (51.5%), 174 (30.9%), 119 (54.6%), 75 (75.3%).

The deuterated analogue was obtained by exchanging bis(2,4-dinitrophenyl)methane (0.6 g) with a solution of 0.1 M sodium ethoxide in ethanol-*d* (2 mL) in DMSO solvent. After 5 min the reaction mixture was neutralized by addition of 10% DCl in D_2O. This procedure was repeated twice, after which the reaction mixture was poured into excess D_2O. The crystals were filtered and the deuteration was confirmed by the disappearance of the proton nmr signal at δ 4.77 ppm. The mass spectrum indicated 99% deuteration, molecular peak 349.

1,1′,3,3′-Tetramethylguanidine (Aldrich) was dried over KOH pellets and distilled under reduced pressure. Only the middle fraction was collected and used.

1,8-Diazabicyclo[5.4.0]undec-7-ene (Aldrich) was similarly dried with KOH and the middle fraction of a reduced pressure distillation was used. All operations were carried out under nitrogen to exclude atmospheric moisture and CO_2.

Reagent grade DMSO (Reachim) was dried over CaH_2 and distilled over 3 Å molecular sieves at reduced pressure with a small amount of butyl hydrogen phthalate. The middle fraction boiling between 108 and 110°C was collected.

Reagent grade toluene (POCH) was kept for several days over clean sodium wire, then fractionally distilled over sodium. The fraction boiling between 110.5 and 111°C was collected.

Equilibrium measurements

The absorbance at equilibrium for reaction [1] was measured at 715 nm using a Specord M-40 spectrophotometer for a series of reactions with constant carbon acid concentration at either 5×10^{-5} or 2.5×10^{-4} M, and different base concentrations, always in large excess over the acid by a factor of 40–200 in DMSO and 10–400 in toluene.

Kinetic measurements

The kinetic runs were carried out using a stopped-flow spectrophotometer equipped with a thermostating device to keep the cell temperature constant within 0.1°C. An acid concentration of 2.5×10^{-5} M was used with base concentrations shown in Table 2.

The conformational behaviour of 2-aryloxytetrahydropyrans and 2-acetoxytetrahydropyran, and barrier to ring inversion[1]

ADAMA OUEDRAOGO AND JEAN LESSARD[2]

Département de chimie, Université de Sherbrooke, Sherbrooke (Québec), Canada J1K 2R1

Received July 27, 1990

ADAMA OUEDRAOGO and JEAN LESSARD. Can. J. Chem. **69**, 474 (1991).

The ^{13}C nuclear magnetic resonance data of a series of 2-(4-substituted-phenoxy)tetrahydropyrans at 156 K and in CF_2Br_2 and $CHFCl_2$ solvents show that the axial preference increases with electron withdrawal in the aryloxy group: from 79% ($\Delta G°_{E\rightarrow A} = -0.4$ kcal mol^{-1}) (4-OCH_3) to 90% ($\Delta G°_{E\rightarrow A} = -0.7$ kcal mol^{-1}) (4-NO_2) in CF_2Br_2. The axial preference (anomeric effect) is smaller in the more polar $CHFCl_2$ solvent, as expected, and the substituent effect is smaller also: change in $\Delta G°_{E\rightarrow A}$ from -0.3 (4-OCH_3) to -0.5 (4-NO_2) kcal mol^{-1}. However, the axial preference of 2-acetoxytetrahydropyran is shown to be smaller than that of 2-phenoxytetrahydropyran in CF_2Br_2 solvent although the acetoxy group is expected to be more electronegative than the phenoxy group. Furthermore, the polarity of the solvent has no effect on the conformational equilibrium of 2-acetoxytetrahydropyran. The results are interpreted in terms of both orbital and electrostatic interactions. The ring-inversion barrier of 2-alkoxy and 2-aryloxytetrahydropyrans, determined by the temperature-coalescence method, is lower than that of tetrahydropyran by about 1.5 kcal mol^{-1}.

Key words: 2-substituted tetrahydropyrans, conformational analysis, anomeric effect, ring inversion.

ADAMA OUEDRAOGO et JEAN LESSARD. Can. J. Chem. **69**, 474 (1991).

Les données de la résonance magnétique nucléaire du ^{13}C à 156 K, dans les solvants CF_2Br_2 et $CHFCl_2$, montrent que la préférence axiale d'une série de tetrahydropyranes portant, en position 2, un groupement phénoxy substitué à la position *para* croît avec le pouvoir électroattracteur du substituant : de 79% ($\Delta G°_{E\rightarrow A} = -0.4$ kcal mol^{-1}) pour un groupement OCH_3 à 90% ($\Delta G°_{E\rightarrow A} = -0.7$ kcal mol^{-1}) pour un groupement nitro dans CF_2Br_2. La préférence axiale (l'effet anomère) est moindre dans $CHFCl_2$, solvant plus polaire, tel qu'attendu, et l'effet de substituant est également plus faible : variation de $\Delta G°_{E\rightarrow A}$ de -0.3 (OCH_3) à -0.5 (NO_2) kcal mol^{-1}. Toutefois, dans CF_2Br_2, la proportion de conformère axial est moins élevée pour le 2-acétoxytétrahydropyrane que pour le 2-phénoxytétrahydropyrane même si le groupement acétoxy est plus électronégatif que le groupement phénoxy. De plus, la polarité du solvant n'a pas d'influence sur l'équilibre conformationnel du 2-acétoxytétrahydropyrane. Les résultats sont interprétés en termes d'intéractions orbitalaires et électrostatiques. La détermination de la barrière d'inversion de cycle d'alcoxy- et d'aryloxytétrahydropyranes par la méthode de coalescence de température montre que la barrière est plus faible que celle du tétrahydropyrane d'environ 1,5 kcal par mole.

Mots clés : tétrahydropyranes substitués en position 2, analyse conformationnelle, effet anomère, inversion de cycle.

Introduction

The preference for the axial orientation of the alkoxy group in 2-alkoxy tetrahydropyrans (*gauche* arrangement about the O(1)—C(2) bond) is known as the anomeric effect (1).[3] The *exo*-anomeric effect refers to the preferred orientation of the O—R bond of the alkoxy group, the R group being *gauche* to the ring oxygen (9–11). The anomeric effect has been explained both by electrostatic interactions destabilizing the antiperiplanar arrangement of a C—O—C—O fragment about the central O—C bond (dipole–dipole repulsions (12, 13) or lone pair – lone pair interactions (14)) and by orbital interactions stabilizing the *gauche* form, mainly the overlap between a nonbonding n orbital on the oxygens and the vacant σ^*_{C-O} orbitals (15–20) (double bond – no bond resonance in the valence bond representation). Evidence for the hyperconjugative stabilizing interactions has been provided by X-ray crystallographic studies (21–23). Theoretical studies support the involvement of n–σ^* stabilizing interactions (17–20, 23–26). Most probably, both electrostatic interactions (mainly dipole–dipole interactions) and orbital interactions (predominantly n–σ^* stabilization) play a role in the preferred conformation of a C—O—C—O—C system (17, 20, 24, 25).

The axial preference of a phenoxy group in 2-substituted tetrahydropyrans has been shown to be larger than that of an alkoxy group, e.g., 81% of conformer A for 2-phenoxytetrahydropyran (R = C_6H_5) as compared to 68% for 2-ethoxytetrahydropyran (R = C_2H_5) at 38°C (neat liquid) (27). This can be readily explained by considering the fact that a phenoxy group is more electron withdrawing than an alkoxy group because of n–π^*_{ring} overlap in the former and because a phenyl ring is more electronegative (sp^2 hybridized carbons) than an alkyl group. Thus a C—O-phenyl bond is a better σ-acceptor (lower energy σ^*_{C-O} orbital) than a C—O-alkyl bond, and the n_{endo} –$\sigma^*_{C(2)-OR}$ stabilization of the conformer with the OR group axial (conformer A) is larger for R = phenyl than for R = alkyl. The n_{exo}–$\sigma^*_{C(2)-O(9)}$ stabilization (*exo*-anomeric effect) for a 2-alkoxy group in a 2-substituted oxane appears to be stronger in the equatorial orientation (conformer E) (11) and so does have some influence on the axial preference. However, because the more electronegative oxygen of a phenoxy group is a poorer n-donor than that of an alkoxy group, the n_{exo}–$\sigma^*_{C(2)-O(1)}$ interaction should be smaller (less stabilizing) in 2-phenoxytetrahydropyran (**1**, R = C_6H_5) and thus have little influence on the axial preference. This might contribute to a small extent to the larger axial preference of the phenoxy group as compared to that of an alkoxy group.

Electrostatic interactions could also be involved in the larger axial preference of the phenoxy group. Since a C—O-phenyl bond might be more polar than a C—O-alkyl bond, dipole–dipole repulsion destabilizing the equatorial form (E) could be stronger in 2-phenoxytetrahydropyran (R = phenyl) than in 2-alkoxytetrahydropyrans (R = alkyl).

In this paper, we report the results of a study of the conforma-

tional equilibrium of a series of 2-(4-substituted-phenoxy)tetrahydropyrans **4***a–j*. The purpose of this study was to determine the effect of the substituent on the phenyl ring on the magnitude of the anomeric effect. In such a series, changes in the electron-donating and electron-withdrawing power of the substituent should bring about changes in both electronic and electrostatic interactions but should not have any significant influence on the steric bulk of the aryloxy group. An acetoxy group should be more electron withdrawing than a phenoxy group, and 2-acetoxytetrahydropyran (**3**) was included in the study. We also studied the conformational behaviour of 2-methoxytetrahydropyran (**1**) and 2-isopropoxytetrahydropyran (**2**) in order to evaluate the influence of the size of the R group. Aryloxy and acetoxy groups are bulkier than a methoxy group but probably smaller than an isopropoxy group. Finally, we determined the barrier to inversions of **2**, **4***a*, and **4***c* to see whether or not the anomeric effect has an influence on the inversion barrier of a tetrahydropyran ring.

Results and discussion

The synthesis of the 2-substituted tetrahydropyrans studied is described in the Experimental. All compounds were characterized by infrared, ^{1}H nmr, ^{13}C nmr, and mass spectrometry.

The conformational equilibria were determined from the ^{13}C nmr spectra at 156 K in CF_2Br^2/CD_2Cl_2 (92:8) and in $CHFCl_2/CD_2Cl_2$ (92:8). At 156 K, the conformational equilibrium was frozen and the carbon signals of each conformer were easily distinguished. The proportion of each conformer was determined by integrating the C-3 and C-4 resonances and either one or both of the C-5 and C-6 resonances, then taking the mean value. The spin-lattice relaxation time (T_1) and the nuclear Overhauser effects were assumed to be the same for carbons bearing axial and equatorial substituents. The chemical shifts are given in the Experimental.

2-Aryloxytetrahydropyrans 4

The equilibrium data for the 2-(4-substituted-phenoxy)tetrahydropyrans **4***a–j* are presented in Table 1 (CF_2Br_2) and Table 2 ($CHFCl_2$). In CF_2Br_2 solvent (Table 1), the data show that introducing an electron-donating group such as a methoxy (**4***a*) or a methyl (**4***b*) group at the *para* position of the phenoxy group causes a decrease in the magnitude of the anomeric effect, whereas a strong electron-withdrawing substituent such as a cyano (**4***i*) or a nitro (**4***j*) group leads to a larger anomeric effect. Bromine (**4***d*) and acetoxy (**4***e*), carbomethoxy (**4***j*), formyl (**4***g*), and trifluoromethyl (**4***h*) groups have practically no effect on $K_{E\rightarrow A}$. The overall change in $\Delta G^\circ_{E\rightarrow A}$ is relatively small: from −0.4 (4-OCH_3) to −0.7 (4-NO_2) kcal mol^{-1} ($\Delta\Delta G^\circ_{E\rightarrow A}$ = 0.3 kcal mol^{-1}). In the more polar $CHFCl_2$ solvent (Table 2), the overall change in $\Delta G^\circ_{E\rightarrow A}$ is still smaller: $\Delta\Delta G^\circ_{E\rightarrow A}$ = 0.2 kcal mol^{-1}. Electron-donating substituents have no effect on the magnitude of the anomeric effect (compare **4***a*, **4***b*, and **4***c*), a bromine (**4***d*) has again no effect, but all the remaining substituents that are electron withdrawing according to their substituent σ constants (28–31) bring about some increase of the anomeric effect, the largest influence being observed again with the nitro group (**4***j*), which has the largest σ value. The best Hammett correlation in CF_2Br_2 (r = 0.956; intercept = 0.076) was obtained using σ_p constants, which take into account both resonance and polar effects (28, 29, 31) and gave a ρ value of 0.32. In $CHFCl_2$, σ_p^- constants related to the resonance electron-withdrawing power of the substituent (28, 29) gave the best correlation (r = 0.890, intercept = 0.010) with a ρ value of 0.18.

The larger axial preference with electron withdrawal in the Ar group and the somewhat smaller preference with electron donation could result from changes in n_{endo}–$\sigma^*_{C(1)—OAr}$ orbital interactions in the axial conformer[4] but could result also from changes in dipole–dipole interactions. Both orbital and electrostatic interactions can likewise explain the solvent effects observed, that is, the lower axial preference[5] as well as the smaller influence of the substituent on the phenyl ring on $\Delta G^\circ_{E\rightarrow A}$ in the more polar $CHFCl_2$ solvent, also capable of forming hydrogen bonds. Indeed, the n_{endo}–$\sigma^*_{C(1)—OAr}$ orbital stabilization could be decreased by hydrogen bonding of the ring oxygen to $CHFCl_2$, and dipole–dipole repulsions in the more polar equatorial conformer should be weaker in $CHFCl_2$.

Studies on the influence of a methoxy group and of a nitro group in the *para* position of the phenyl ring on the conformational equilibrium of *trans*-2,3-diaryloxy-1,4-dioxanes (37) were reported before but no significant effect was observed. The

[4] Evidence for an increase in n_{endo}–$\sigma^*_{C(1)—OAr}$ orbital interaction upon increasing the electron withdrawal in the Ar group of 2-aryloxytetrahydropyrans, that is, upon decreasing the energy of the $\sigma^*_{C(1)—OAr}$ orbital, has been provided by bond length changes in a series of axial 2-aryloxytetrahydropyrans (32): the exocyclic C(2)—OAr bond lengthens while the endocyclic C(2)—O(1) bond shortens.

[5] It is well known that the anomeric effect decreases with increasing polarity of the solvent (27, 33–36).

conformational equilibria studied by ^{1}H nmr were highly biased (axial preference of 98–99%) and were estimated by an approximate method of analysis so that the small influence of the substituent on the phenyl ring could not be detected.

In their investigation of the conformation equilibria of 2-[(4-substituted-phenyl)selenol]-1,3-dithianes, Pinto *et al.* (38) observed a more pronounced substituent effect than in the case of 2-aryloxytetrahydropyrans. With the 2-arylselenodithianes, the $\Delta G^\circ_{E\rightarrow A}$ (180 K) ranges from −0.61 (4-OCH_3) to −1.10 (4-NO_2) kcal mol^{-1} in CH_2Cl_2 for a $\Delta\Delta G^\circ_{E\rightarrow A}$ value of 0.49 kcal mol^{-1} (180 K) as compared to a $\Delta\Delta G^\circ_{E\rightarrow A}$ value of 0.2 kcal mol^{-1} (156 K) in $CHFCl_2$ for 2-aryloxytetrahydropyrans. The positive ρ values and the variations of ^{13}C and ^{77}Se chemical shifts led the authors to the conclusion that the orbital interaction component predominates over the electrostatic component (38).

It is noteworthy that in the case of 2-(4-substituted-phenoxy)-cyclohexanones studied by Cantacuzene and Tordeux (39), electron-withdrawing substituents have a sizeable effect on the conformational equilibrium, this time leading to a decrease of axial population from 52% (4-H) to 17% (4-NO_2) in CCl_4 solvent at 298 K whereas electron-donating substituents have little effect, the axial population being 54% for a methoxy substituent. The overall substituent effect is thus much larger than in 2-aryloxytetrahydropyrans and 2-(arylseleno)-1,3-dithians, $\Delta G^\circ_{E\rightarrow A}$ (298 K) values ranging from −0.10 (4-OCH_3) to 0.93 (4-NO_2) kcal mol^{-1}. On the other hand, for the analogous 2-(4-substituted-phenoxy)methylenecyclohexanes where the equatorial conformer predominates (75% in $CHFCl_2$ solvent at 220 K), the 4-substituent has no significant effect on the conformational equilibrium (40). The 4-substituent also has no significant effect on the conformational equilibrium of 3-(4-substituted-phenoxy)benzocycloheptenes, where the equatorial orientation (C_e conformation) also predominates over the axial orientation (C_a conformation) in THF-d_8 solvent at 156 K (41).

*2-Acetoxytetrahydropyran (**3**)*

The equilibrium data for the 2-isopropoxy (**2**), 2-methoxy (**1**), 2-phenoxy (**4***c*), and 2-acetoxy (**3**) tetrahydropyrans in CF_2Br_2 and $CHFCl_2$ solvents at 156 K are recorded in Table 3. The lower axial preference of the isopropoxy group (entries 1 and 5) as compared to the methoxy group (entries 2 and 6) has been reported before (^{1}H nmr studies in various solvents (36) and in the neat liquid (27)) and was attributed to the larger steric interactions with the bulkier isopropoxy group in the axial orientation. The larger anomeric effect of the phenoxy group (entries 3 and 7) as compared to the methoxy group has also been observed previously (27) and was discussed in the Introduction. An acetoxy group is also more electronegative than a methoxy group and thus has a larger axial preference than a methoxy group, as shown by a comparison of entries 4 and 8 with entries 2 and 6 respectively and by equilibration of 2-oxy-4-methyltetrahydropyrans and 2-oxy-6-methyltetrahydropyrans (33).

An acetoxy group should be more electronegative than a phenoxy group and the energy of the $\sigma^*_{(C-OR)}$ orbitals should decrease in the following order: $\sigma^*_{C-OCH_3} > \sigma^*_{C-OPh} > \sigma^*_{C-OAc}$ (42). And the $n_{endo}-\sigma^*_{C(1)-OR}$ orbital stabilizing interaction in 2-oxytetrahydropyrans should increase in the order $OCH_3 <$ OPh < OAc. The fact that the axial preference of the acetoxy group is not larger than that of the phenoxy group in the less polar CF_2Br_2 solvent (compare entries 3 and 4 of Table 3) suggests that specific electrostatic interactions might be involved in the case of the acetoxy group, which would more than counteract the larger $n_{endo}-\sigma^*_{C(2)-OAc}$ overlap in the axial conformer. In addition, the acetoxy group is the sole oxygenated substituent among those investigated in this work that does not show a decrease of axial population in going from the less polar (CF_2Br_2) to the more polar ($CHFCl_2$) solvent (compare entries 4 and 8 of Table 3). Again, specific electrostatic interactions associated with the acetoxy group could result in similar polarities for both conformers. In 2-oxymethylenecyclohexanes (43) and benzocycloheptenes (41) bearing an oxygenated substituent (OR, OAr, OCOR) at position 2, the acetoxy group also shows an unexpected conformational behaviour in having a much smaller axial preference than the methoxy group in a nonpolar solvent. Furthermore, the solvent effect is smaller with the acetoxy group than with the methoxy group and is even reversed in the case of 3-acetoxybenzocycloheptene (increase of axial population in the more polar solvent) (41). The peculiar conformational behaviour of the acetoxy group in the latter two series was also tentatively attributed to specific electrostatic interactions by Aubin and St-Jacques (41).

Barrier to ring inversion

The barriers to ring inversion of 2-isopropoxytetrahydropyran (**2**), 2-acetoxytetrahydropyran (**3**), 2-(4-methoxyphenoxy)tetrahydropyran (**4***a*), 2-phenoxytetrahydropyran (**4***c*), and 2-(4-nitrophenoxy)tetrahydropyran (**4***j*) were studied in order to see if the barrier is influenced by the anomeric effect. The activation energies, $\Delta G^{\neq}_{A\rightarrow E}$ and $\Delta G^{\neq}_{E\rightarrow A}$, were calculated from the coalescence temperature (T_c) for the carbon 6 signal using two different methods developed for unequal proportions of conformers (44, 45). Both methods gave practically the same values of activation energies, the largest difference observed being 0.2 kcal mol^{-1}. The mean values are reported in Table 4 for the 2-isopropoxy (**2**), 2-phenoxy (**4***c*), and 2-(4-methoxyphenoxy) (**4***a*) derivatives. In the case of 2-acetoxytetrahydropyran (**3**) and 2-(4-nitro-phenoxy)tetrahydropyran (**4***j*), the coalescence occurred somewhere between 196 and 186 K but it was not possible to determine the coalescence temperature with satisfactory accuracy because of smaller proportions of equatorial conformer and smaller chemical shift differences. However, the temperature range where coalescence was observed indicates that the energies of activation for the ring inversion of **3** and **4***j* must be similar to those reported in Table 4 for **2**, **4***c*, and **4***a*.

The barrier to ring inversion of tetrahydropyran is 10.2 kcal

mol^{-1} in the nonpolar CS_2 solvent (46) and 10.3 kcal mol^{-1} in the polar $CHFCl_2$–CD_3OD solvent (47). As shown by the $\Delta G^{\neq}_{A\rightarrow E}$ values of Table 4, the polarity of the solvent also has little influence on the barrier of 2-oxytetrahydropyrans. However, the introduction of an oxygenated substituent at position 2 of the tetrahydropyran ring lowers the barrier by 1.4–1.8 kcal mol^{-1}. In contrast, the introduction of an oxygenated group on the cyclohexane ring has virtually no effect on the ring-inversion barrier: $\Delta G^{\neq}_{E\rightarrow A}$ value of 10.4 kcal mol^{-1} for phenoxycyclohexane ($\Delta G^{\neq}_{A\rightarrow E}$ = 9.9 kcal mol^{-1}) (48) compared to a $\Delta G^{\neq}$ value of 10.3 kcal mol^{-1} for cyclohexane (49).[6] Thus, the anomeric effect does lower the barrier to ring inversion of a tetrahydropyran ring. This could be due to the fact that the n_{exo}–$\sigma^*_{C(2)—O(1)}$ orbital overlap (*exo*-anomeric effect) can be maintained throughout the inversion process and thus impart some sp^2 character to carbon 2. Methylenecyclohexane, which has one sp^2-hybridized carbon atom, has a lower inversion barrier ($\Delta G^{\neq}$ = 8.4 kcal mol^{-1} (50)) than cyclohexane. The *endo*-anomeric effect is most probably not the cause of the lower inversion barrier of 2-oxytetrahydropyrans. Indeed, dipole–dipole repulsions as pictured by Edward (12) and by Kabayama and Patterson (13) would be expected to cause an increase of $\Delta G^{\neq}_{A\rightarrow E}$ with respect to the ring-inversion barrier of tetrahydropyran since they would increase during the A→E inversion process. Similarly, the loss of the n_{endo}–$\sigma^*_{C(2)—OR}$ orbital stabilization during the A→E conformational change should also lead to an increase of $\Delta G^{\neq}_{A\rightarrow E}$ with respect to $\Delta G^{\neq}$ for the ring inversion of tetrahydropyran.

Interestingly, 2-methylmethylenecyclohexane (**5***a*) and 2-methoxymethylenecyclohexane (**5***b*) have similar barriers to ring inversion (48): $\Delta G^{\neq}_{E\rightarrow A}$ = 9.9 kcal mol^{-1} and $\Delta G^{\neq}_{A\rightarrow E}$ = 8.9 kcal mol^{-1} for **5***a*, which exists preferentially as the equatorial conformer (95% at 170 K in CF_2Br_2 (51)); $\Delta G^{\neq}_{E\rightarrow A}$ = 9.0 kcal mol^{-1} and $\Delta G^{\neq}_{A\rightarrow E}$ = 9.4 kcal mol^{-1} for **5***b*, in which the axial conformer is more stable (78% at 163 K in CF_2Br_2 (51)). The axial conformer of the latter is stabilized by a π–$\sigma^*_{C—OR}$ orbital interaction (51) (generalized *endo*-anomeric effect (52)) but there should be no significant n_{exo}–$\sigma^*_{C(1)—C(2)}$ overlap, that is, no stabilization akin to the *exo*-anomeric effect, because of the high energy of a $\sigma^*_{C—C}$ orbital.

In 2-oxytetrahydropyrans, the n_{exo}–$\sigma^*_{C(2)—O(1)}$ orbital overlap would be expected to be weaker for a phenoxy group than for an alkoxy group because of the electron-withdrawing effect of the phenyl ring (due to both resonance (n–π^* overlap) and inductive effects). As seen from Table 4 (entries 1–4),

[6] It is noteworthy that tetrahydropyran and cyclohexane have very similar barriers to ring inversion so the replacement of one CH_2 group of cyclohexane by an oxygen atom has virtually no effect on the activation energy for the inversion process.

E A

5*a* R = CH_3
5*b* R = OCH_3

2-phenoxytetrahydropyran (**4***c*) has a lower $\Delta G^{\neq}_{E\rightarrow A}$ value than 2-isopropoxytetrahydropyran (**2**) but both compounds have similar $\Delta G^{\neq}_{A\rightarrow E}$ values.

Conclusions

In 2-(4-substituted-phenoxy)tetrahydropyrans **4***a–j*, the axial preference, hence the anomeric effect, increases slightly with electron withdrawal in the aromatic ring. The effect is smaller in $CHFCl_2$ than in the less polar CF_2Br_2 solvent. Both orbital and dipole–dipole interactions can account for the substituent and solvent effects.

The axial preference of the acetoxy group is somewhat smaller in CF_2Br_2 than that of the less polar and less electronegative phenoxy group. Electrostatic interactions specific to the acetoxy group might counterbalance the effect of a stronger n_{endo}–$\sigma^*_{C(1)—OAc}$ orbital overlap in the axial orientation. These specific interactions would also be responsible for the absence of a solvent effect on the axial preference of 2-acetoxytetrahydropyran (**3**).

The barrier to ring inversion of 2-alkoxy and 2-aryloxytetrahydropyrans is lower than that of tetrahydropyran by about 1.5 kcal mol^{-1}. This could be due to some sp^2 character of carbon 2, which would be maintained throughout the inversion process through the n_{exo}–$\sigma^*_{C(2)—O(1)}$ overlap (*exo*-anomeric effect).

Experimental[7]

The general information is the same as that given in ref. 43. Variable and low temperature ^{13}C nmr data were obtained with a Bruker WH-400 (±1 K, control unit BVT 1000 calibrated with methanol) Fourier transform spectrometer at the "Laboratoire Régional de RMN de l'Université de Montréal".[8]

Preparation of 2-oxytetrahydropyrans

The 2-oxytetrahydropyrans **1**, **2**, **3**, **4***a*, **4***c*, **4***d*, **4***e*, and **4***h* were prepared from 2,3-dihydropyran and the corresponding alcohol, or acetic acid (freshly distilled over phosphorous pentoxyde),[9] or the corresponding phenol according to the method described by Woods and Kramer (53). For the other 2-oxytetrahydropyrans, the corresponding phenol was not soluble enough in 2,3-dihydropyran and the phenol was dissolved in tetrahydrofuran (preparation of **4***f*), benzene (preparation of **4***g* and **4***j* with the use of *p*-toluene sulfonic acid as catalyst), or dichloromethane (preparation of **4***i*). The physical constants and spectral characteristics of each 2-oxytetrahydropyran are given below. For those already reported in the literature, only the ^{13}Cmr data at room temperature are given (tetramethylsilane as reference).

2-Methoxytetrahydropyran (**1**) (refs. 36, 53): ^{13}Cmr ($CDCl_3$) δ: 19.4 (C-2), 25.5 (C-5), 30.6 (C-3), 55.0 (OCH_3), 61.9 (C-6), 99.9 (C-2) ppm.

2-Isopropoxytetrahydropyran (**2**) (ref. 27): ^{13}Cmr ($CDCl_3$) δ: 20.0 (C-2), 21.6 and 23.6 (2 × CH_3, isopropyl group), 25.7 (C-5), 31.4 (C-3), 62.6 (C-6), 68.3 (O—CH<), 96.8 (C-2) ppm.

2-Acetoxytetrahydropyran (**3**)

The product was isolated as a liquid (83% yield after distillation): bp 55–59°C (3.5 Torr; 1 Torr = 133.3 Pa). It was purified further by distillation: bp 56°C (3.5 Torr); ir ($CHCl_3$) ν_{max}: 1730, 1365, 1220, 1190 cm^{-1}; ^1Hmr ($CDCl_3$) δ: 1.5–1.9 (3 × CH_2), 2.1 (s, CH_3CO), 3.7–4.2 (m, 2H, CH_2O), 6.0 (t, J = 3.2 Hz, H-2) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.7 (C-4), 21.2 (CH_3CO), 25.0 (C-5), 29.2 (C-3), 63.4 (C-6), 92.7 (C-2), 169.8 (C=O) ppm; m/e: 84 ($M^+ - 44$).

2-(4-Methoxyphenoxy)tetrahydropyran (**4**a)

The product was purified by distillation, followed by chromatography on basic alumina (benzene as eluent), and was homogeneous by tlc (74% yield): bp 128°C (4.8 Torr); ir ($CHCl_3$) ν_{max}: 1510, 1210, 1035 cm^{-1}; ^1Hmr ($CDCl_3$) δ: 1.3–2.2 (3 × CH_2), 3.8 (s, CH_3O), 3.4–4.3 (m, CH_2O), 5.4 (t, J = 3 Hz, H-2), 6.8–7.3 (m, 4H) ppm; ^{13}Cmr ($CDCl_3$) δ: 19.0 (C-4), 25.3 (C-5), 30.5 (C-3), 55.6 (CH_3O), 62.1 (C-6), 97.4 (C-2), 114.6 (C-3′), 117.9 (C-2′), 151.2 (C-4′), 154.6 (C-1′) ppm; m/e: 208 (M^+).

2-(4-Methylphenoxy)tetrahydropyran (**4**b)

The product was purified by distillation (80% yield): bp 103°C (2 Torr); ir ($CHCl_3$) ν_{max}: 1610, 1580, 1505, 1220 cm^{-1}; ^1Hmr ($CDCl_3$) δ: 1.3–1.9 (3 × CH_2), 2.1 (s, CH_3), 3.1–3.8 (m, CH_2O), 5.0 (t, J = 3 Hz, H-2), 6.3–6.8 (m, 4H) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.9 (C-4), 20.5 (CH_3), 25.3 (C-5), 30.5 (C-3), 62.0 (C-6), 96.7 (C-2), 116.6 (C-2′), 129.8 (C-3′), 130.9 (C-4′), 155.0 (C-1′) ppm; m/e: 192 (M^+).

2-Phenoxytetrahydropyran (**4**c) (refs. 27, 53): ^{13}Cmr ($CDCl_3$) δ: 18.9 (C-4), 25.3 (C-5), 30.5 (C-3), 62.1 (C-6), 96.5 (C-2), 116.6 (C-2′), 121.6 (C-4′), 129.4 (C-3′), 157.1 (C-1′) ppm.

2-(4-Bromophenoxy)tetrahydropyran (**4**d)

The product was purified by chromatography on basic alumina (benzene as eluent) (72% yield) and was recrystallized from benzene–pentane: mp 55.5–56°C; ir ($CHCl_3$) ν_{max}: 1590, 1580, 1470, 1210 cm^{-1}; ^1Hmr ($CDCl_3$) δ: 1.2–1.9 (3 × CH_2), 3.2–3.8 (m, CH_2O), 5.0 (bs, H-2), 6.3–6.6 (m, 2H), 6.7–7.0 (m, 2H) ppm; ^{13}Cmr ($CDCl_3$) δ; 18.7 (C-4), 25.2 (C-5), 30.3 (C-3), 61.9 (C-6), 96.6 (C-2), 113.8 (C-4′), 118.4 (C-2′), 132.2 (C-3′), 156.3 (C-1′) ppm; m/e: 256, 258 (M^+).

2-(4-Acetoxyphenoxy)tetrahydropyran (**4**e)

The product was purified by chromatography on silica gel (hexane – ethyl acetate 10:90 as eluent) (91% yield) and recrystallized from ether–hexane: mp 55.5–56.5°C; ir ($CHCl_3$) ν_{max}: 1745, 1600, 1500, 1370, 1230, 1180 cm^{-1}; ^1Hmr ($CDCl_3$) δ: 1.6–2.0 (3 × CH_2), 2.3 (s, CH_3CO), 3.3–4.2 (m, CH_2O), 5.4 (br s, H-2), 7.0 (s, 4H) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.8 (C-4), 21.0 (CH_3CO), 25.2 (C-5), 30.4 (C-3), 61.9 (C-6), 96.8 (C-2), 117.2 (C-2′), 122.2 (C-3′), 145.0 (C-4′), 154.9 (C-1′), 169.6 (C=O) ppm; m/e: 236 (M^+). Exact Mass calcd. for $C_{13}H_{16}O_4$: 236.1047; found: 236.1049.

2-(4-Formylphenoxy)tetrahydropyran (**4**f)

The product was isolated as an oil (48% yield) after chromatographic separation on silica gel (ethyl acetate – hexane as eluent): ir ($CHCl_3$) ν_{max}: 2850, 2750, 1700, 1600, 1580, 1505, 1250, 1160 cm^{-1}; ^1Hmr ($CDCl_3$) δ: 1.6–1.9 (3 × CH_2), 3.6–3.9 (m, CH_2O), 5.5 (br s, H-2), 7.1 (m, 2H), 7.8 (m, 2H), 7.9 (s, CHO) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.5 (C-4), 25.1 (C-5), 30.1 (C-3), 62.1 (C-6), 96.2 (C-2), 116.6 (C-2′), 130.5 (C-4′), 131.8 (C-3′), 162.3 (C-1′), 190.9 (CHO) ppm; m/e: 206 (M^+). Exact Mass calcd. for $C_{12}H_{14}O_3$: 206.0942; found: 206.0930.

2-(4-Carbomethoxyphenoxy)tetrahydropyran (**4**g)

The crude product, mp 55–61°C (70% yield), was purified by chromatography on alumina (benzene–ether 1:9) and recrystallization from methylene chloride – petroleum ether 30–60°C: mp 63–64°C; ir ($CHCl_3$) ν_{max}: 1710, 1605, 1580, 1505, 1275, 1240, 1200, 1110 cm^{-1};

[7]The following data may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6: ^{13}C chemical shifts at 156 K for each conformer of 2-methoxytetrahydropyran (**1**), 2-isopropoxytetrahydropyran (**2**), 2-acetoxytetrahydropyran (**3**), and 2-(4-substituted-phenoxy)tetrahydropyrans (**4***a–j*); variations of C-2 (or C-4) and C-6 chemical shifts with temperature in CF_2Br_2 and $CHFCl_2$ for **2**, **3**, **4***c*, and **4***j*; data used for the Hammett correlations.

[8]We thank Dr. Minh Tan Phan Viet for his help and availability.

[9]The addition of a catalytic amount of *p*-toluenesulfonic acid did accelerate the reaction.

^{1}Hmr ($CDCl_3$) δ: 1.2–1.9 (3 × CH_2), 3.3–3.6 (m, CH_2O), 3.7 (s, CH_3O), 5.2 (t, J = 3 Hz, H-2), 6.7 (m, 2H), 7.5 (m, 2H) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.3 (C-4), 24.8 (C-5), 29.8 (C-3), 51.2 (CH_3O), 61.3 (C-6), 94.9 (C-2), 114.5 (C-2′), 121.8 (C-4′), 129.9 (C-3′), 158.9 (C-1′), 169.6 (C=O) ppm; m/e: 236 (M^+). Exact Mass calcd. for $C_{13}H_{16}O_4$: 236.1049; found: 236.1054.

*2-(4-Trifluoromethylphenoxy)tetrahydropyran (***4h***)*

The product was purified by chromatography on silica gel (ethyl acetate – hexane 10:90) (85% yield), then recrystallized from benzene–pentane: mp 38.5–39.5°C; ir ($CHCl_3$) ν_{max}: 1610, 1580, 1510, 1325, 1245, 1200 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.6–2.1 (3 × CH_2), 3.6–3.9 (m, CH_2O), 5.5 (m, H-2), 7.1–7.2 (m, 2H), 7.5–7.7 (m, 2H) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.6 (C-4), 25.2 (C-5), 30.3 (C-3), 62.1 (C-6), 96.4 (C-2), 116.5 (C-2′), 126.8 (q, J = 3.8 Hz, C-3′), 159.7 (C-1′) ppm (the absorption of C-4′ was not detected); m/e: 246 (M^+). Exact Mass calcd. for $C_{12}H_{13}F_3O_2$: 246.0867; found: 246.0861.

*2-(4-Cyanophenoxy)tetrahydropyran (***4i***)*

The product was purified by recrystallization from ether – petroleum ether 30–60°C (95% yield): mp 69.5–70°C; ir ($CHCl_3$) ν_{max}: 2240, 1605, 1580, 1505, 1245, 1195 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.3–2.0 (3 × CH_2), 3.3–3.7 (m, CH_2O), 5.2 (m, H-2), 6.7 (m, 2H), 7.1 (m, 2H) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.4 (C-4), 25.0 (C-5), 30.0 (C-3), 62.1 (C-6), 96.3 (C-2), 104.7 (C-4′), 117.0 (C-2′), 119.2 (C-1′), 133.8 (C-3′), 160.5 (C≡N) ppm; m/e: 203 (M^+). Exact Mass calcd. for $C_{12}H_{13}NO_2$: 203.0946; found: 203.0950.

*2-(4-Nitrophenoxy)tetrahydropyran (***4j***)*

The product was purified by recrystallization from ether—hexane (31% yield): mp 59.5–60.5°C; ir ($CHCl_3$) ν_{max}: 1615, 1600, 1515, 1350, 1205 cm^{-1}; ^{1}Hmr ($CDCl_3$) δ: 1.5–2.2 (3 × CH_2), 3.7–4.1 (m, CH_2O), 5.7 (m, H-2), 7.3 (m, 2H), 8.3 (m, 2H) ppm; ^{13}Cmr ($CDCl_3$) δ: 18.3 (C-4), 24.9 (C-5), 29.9 (C-3), 62.1 (C-6), 96.4 (C-2), 116.2 (C-2′), 125.7 (C-3′), 141.9 (C-4′), 162.2 (C-1′) ppm; m/e: 233 (M^+).

Étude thermodynamique des trois isomères du dihydroxybenzène

R. SABBAH[1] ET E. N. L. E. BULUKU

Centre de thermodynamique et de microcalorimétrie du Centre national de la recherche scientifique, 26, rue du 141è RIA, 13003-Marseille, France

Reçu le 2 octobre 1990

R. SABBAH et E. N. L. E. BULUKU. Can. J. Chem. **69**, 481 (1991).

Le présent travail porte sur l'étude thermodynamique des trois isomères du dihydroxybenzène. Cette étude a permis la détermination des enthalpies de combustion, de sublimation, de fusion et de transition des 1,2-, 1,3- et 1,4-dihydroxybenzènes. Les techniques utilisées ont été la calorimétrie de combustion de faibles quantités de substances, la calorimétrie de changement d'état (sublimation), l'analyse thermique différentielle et la mesure des capacités calorifiques. L'ensemble des résultats expérimentaux a permis de : mettre en évidence l'existence d'une liaison hydrogène intramoléculaire dans l'isomère *ortho*; préciser la stabilité relative des trois molécules de dihydrobenzènes; et déterminer : à partir de l'enthalpie de sublimation, une valeur énergétique pour les liaisons intermoléculaires; l'énergie de conjugaison expérimentale et de la comparer à la valeur théorique; l'enthalpie d'atomisation à partir de laquelle a été calculée l'enthalpie de la liaison intramoléculaire C_b—OH.

Mots clés : thermodynamique, calorimétrie, analyse thermique différentielle, 1,2-dihydroxybenzène ou catéchol; 1,3-dihydroxybenzène ou résorcinol; 1,4-dihydroxybenzène ou hydroquinone ou quinol; enthalpies de combustion, de sublimation, de fusion, de transition; énergie de conjugaison; enthalpies d'atomisation, de liaisons inter- et intra-moléculaires; température du point triple et de transition.

R. SABBAH and E. N. L. E. BULUKU. Can. J. Chem. **69**, 481 (1991).

The present work is concerned with a thermodynamic study of the three isomers of dihydroxybenzene. By combustion calorimetry of small amounts of substance, sublimation calorimetry, differential thermal analysis, and heat capacity measurements, it was possible to determine the enthalpies of formation of 1,2-, 1,3-, and 1,4-dihydroxybenzene in the condensed and gaseous phases, their enthalpies of fusion and transition, and the temperature of their triple point and transition. The experimental results are used to discuss the relative stability and determine the conjugation energy of the three compounds. The values are in good agreement with the theoretical values obtained from a quantum chemical calculation. The enthalpies of atomization enabled us to determine an energy value for the intramolecular C_b—OH bond in dihydroxybenzenes and to correlate it with previous results obtained from a study of alkane-diols. The enthalpies of sublimation were discussed. An intramolecular hydrogen bond was displayed in the *ortho* isomer. Intermolecular hydrogen bonds associated with van der Waals interactions exist in dihydroxybenzenes. Their energy contributions were determined.

Key words: thermodynamics, calorimetry, differential thermal analysis, 1,2-benzenediol or 1,2-dihydroxybenzene or catechol; 1,3-benzenediol or 1,3-dihydroxybenzene or resorcinol; 1,4-benzenediol or 1,4-dihydroxybenzene or hydroquinone or quinol; enthalpies of combustion, of sublimation, of fusion, of transition, energy of conjugation, enthalpies of atomization, of inter- and intramolecular bonds; triple point and transition temperatures.

I. Introduction

Les travaux réalisés jusqu'ici sur l'étude des propriétés thermodynamiques des dihydroxybenzènes (en abrégé DHB) tant en phase condensée que gazeuse sont peu nombreux (1–6). La comparaison précise et rationnelle du comportement des isomères de position, caractérisés par la similitude de leurs propriétés, nécessite une étude globale et homogène.

Soucieux de mettre en évidence et d'interpréter le lien qui existe entre les grandeurs énergétiques et la structure des DHB et de mieux cerner l'importance relative des forces de cohésion cristalline dans ces composés, nous avons été amenés à étudier les trois isomères du DHB. Ces trois diols aromatiques sont présents dans le règne végétal et les produits issus de la pyrolyse du charbon. Compte tenu de leurs propriétés et de leurs applications directes et indirectes (7, 8), la détermination de leurs grandeurs thermodynamiques est souhaitable afin d'élucider certains problèmes liés à leur structure et à leur utilisation courante.

II. Partie expérimentale

II.1. Produits

Les trois molécules de DHB utilisées dans ce mémoire sont des produits Aldrich, de degré de pureté supérieur ou égal à 99%. La pureté du DHB-1,2 (99,92 mol%) et du DHB-1,3 (99,98 mol%), déterminée par ATD, a été jugée satisfaisante. Seul le DHB-1,4, dont l'échantillon commercial a pour degré de pureté 99,79 mol%, a été recristallisé dans l'eau déminéralisée puis sublimé sous une pression résiduelle de 10^{-2} Torr (1 Torr = 133,322 Pa) à 363 K. La pureté du produit ainsi traité est de 99,96 mol%.

La plupart des substances étant sensibles à la lumière, nous avons pris la précaution de les manipuler à l'abri de celle-ci.

II.2. Appareillage, technique et mode opératoire

Pour réaliser l'étude consignée dans ce mémoire, nous avons utilisé comme techniques : la calorimétrie de combustion de faibles quantités de substances, la calorimétrie de sublimation, l'analyse thermique différentielle et la mesure de capacités calorifiques.

II.2.1. Calorimétrie de combustion

Les expériences réalisées par calorimétrie de combustion, l'ont été en utilisant l'appareillage décrit dans la référence 9. Précisons ici que : la microbombe est en acier inoxydable (Superimphy 625, ATGE2); son volume interne est de 42,9 mL à température ambiante; la sensibilité de la pile du calorimètre CRMT est de 62,33 $\mu V\ mW^{-1}$; celle de l'amplificateur est de 30 mV pleine échelle; l'oxygène N45, utilisé dans nos expériences, provient de l'Air Liquide; son degré de pureté est supérieur à 99,995%.

II.2.2. Calorimétrie de sublimation

Pour mesurer directement la quantité de chaleur mise en jeu par la sublimation de nos substances, nous avons utilisé un calorimètre Tian–Calvet associé à une cellule d'effusion de Knudsen. L'appareillage et le mode opératoire ont été décrits dans la référence 10. Toutefois, il y a lieu de préciser ici que le signal issu du calorimètre est amplifié par un nanovoltmètre Keithley modèle 147 (sensibilité utilisée : 30 μV pleine

TABLEAU 1. Degré de pureté, température des points triple et de transition, enthalpies de fusion et de transition des DHB

Paramètre	DHB-1,2	DHB-1,3	DHB-1,4
Pureté (mol%)	99,929±0,002	99,985±0,002	99,965±0,007
$T_{\text{point triple}}$(K)[a]	377,80±0,03	383,54±0,02	445,98±0,03
$\Delta_{\text{fus}}H_{\text{m}}$(kJ mol^{-1})	15,00±0,34	15,25±0,21	21,09±0,40
$T_{\text{trs}}(\alpha \rightarrow \beta)$(K)[a]		366,8±1,4	
$\Delta_{\text{trs}}H_{\text{m}}(\alpha \rightarrow \beta)$(kJ mol^{-1})		0,72±0,06	

[a]Définies par rapport à l'EIPT-68.

TABLEAU 2. Grandeurs physiques à 298,15 K des substances étudiées

Substance	Formule brute	M[a] (g mol^{-1})	ρ (g cm^{-3})	$-(\partial U/\partial P)_T$ (J g^{-1} atm^{-1})[b]
Acide benzoïque	$C_7H_6O_2$	122,1234	1,320 (12)	0,01163 (12)
Coton	$CH_{1.833}O_{0.828}$	27,1061	1,5 (12)	0,029 (12)
DHB-1,2	$C_6H_6O_2$	110,1124	1,149 (13)	(0,013)
DHB-1,3	$C_6H_6O_2$	110,1124	1,272 (13)	(0,013)
DHB-1,4	$C_6H_6O_2$	110,1124	1,328 (13)	(0,013)

[a]Les masses molaires ont été calculées à partir du tableau des masses atomiques de 1987 (14).
[b]1 atm = 101,325 kPa.
Les valeurs placées entre parenthèses ont été estimées.

échelle) puis digitalisé à l'aide d'un voltmètre numérique AOIP modèle MN 5121 ou Keithley modèle 175. L'acquisition et le traitement des données ont été réalisés à l'aide d'un ordinateur Zénith modèle 159 ou Commodore modèle 4032.

Si, pour la molécule de DHB-1,2, nous n'avons eu aucune difficulté à la sublimer à 298,15 K en utilisant un calorimètre dont la sensibilité des piles est de 24,62 μV mW^{-1} et un trou d'effusion de diamètre égal à 1,5 mm, il n'en a pas été de même pour les deux autres molécules.

La faible pression de vapeur saturante du DHB-1,3 et du DHB-1,4 nous a obligés à travailler à 334,6 K. À cette température, la sensibilité des piles du calorimètre est de 17,04 μV mW^{-1} et le diamètre du trou d'effusion utilisé est de 1,5 mm.

II.2.3. Analyse thermique différentielle

Cette technique nous a permis de déterminer le degré de pureté de nos substances, la température de leurs points triple et de transition et de mesurer leur enthalpie de fusion (tableau 1). L'appareillage et le mode opératoire ont été décrits dans la référence 11.

III. Résultats

Nous avons consigné dans le tableau 2 les grandeurs physiques à 298,15 K des substances utilisées qui interviennent dans les calculs menant aux résultats expérimentaux.

III.1. Calorimétrie de combustion

En calorimétrie de combustion, l'équivalent énergétique du calorimètre (U_{cal}) a été obtenu à partir de huit combustions d'acide benzoïque, échantillon 39i du N.B.S., pour lequel $\Delta_c u^0$(s, 298,15 K) = (−26414 ± 3) J g^{-1}. Dans ces expériences, nous avons utilisé environ 5 mg d'acide et 0,2 mg de coton (dont l'énergie de combustion, préalablement déterminée au laboratoire, a pour valeur : $\Delta_c u^0$(s, 298,15 K) = (−16399 ± 23) J g^{-1} (15). Nous trouvons pour U_{cal}(298,15 K) la valeur (16,040 ± 0,006) J V^{-1} s^{-1}.

Les résultats expérimentaux obtenus par calorimétrie de combustion sont consignés dans les tableaux 3–5.

III.2. Calorimétrie de sublimation

En calorimétrie de sublimation, l'étalonnage de notre système calorimétrique a été réalisé par effet Joule avant et après les expériences.

À cause de la faible pression de vapeur saturante des substances étudiées, nous avons admis l'identité $\Delta_{\text{sub}}H_{\text{m}}(T\text{K}) = \Delta_{\text{sub}}H^0_{\text{m}}(T\text{K})$. Par ailleurs, dans le cas du DHB-1,3 et du DHB-1,4, pour calculer $\Delta_{\text{sub}}H^0_{\text{m}}$(298,15 K) à partir de $\Delta_{\text{sub}}H^0_{\text{m}}$(334,6 K), nous avons utilisé la relation suivante :

$$\Delta_{\text{sub}}H^0_{\text{m}}(298{,}15\text{ K}) = \Delta_{\text{sub}}H^0_{\text{m}}(334{,}6\text{ K}) + \int_{334{,}6\text{ K}}^{298{,}15\text{ K}} (C^0_{\text{p,m}}(\text{g}) - C^0_{\text{p,m}}(\text{s}))\,\text{d}T$$

après nous être assurés par ATD que la substance ne présente aucun changement de phase entre 298,15 et 334,6 K. La valeur de $\int_{298{,}15\text{ K}}^{334{,}6\text{ K}} C^0_{\text{p,m}}(\text{s})\text{d}T$ a été obtenue par la méthode de chute en utilisant un calorimètre Tian–Calvet et un four maintenus respectivement à 298,15 et 334,6 K. Quant à l'intégrale $\int_{298{,}15\text{ K}}^{334{,}6\text{ K}} C^0_{\text{p,m}}(\text{g})\text{d}T$, elle a été déterminée à partir d'une méthode incrémentale en utilisant les données des capacités calorifiques à l'état gazeux de la littérature pour les molécules de benzène et d'hydroxybenzène (16).

Nous avons consigné dans le tableau 6 les résultats expérimentaux obtenus par calorimétrie de sublimation.

Signalons qu'aucune valeur aussi bien pour $\Delta_c H^0_{\text{m}}$(s, 298,15 K) que pour $\Delta_{\text{sub}}H^0_{\text{m}}$(298,15 K) pour le DHB-1,2 n'a été trouvée dans la littérature. Nos valeurs expérimentales ne peuvent donc faire l'objet d'aucune comparaison.

En ce qui concerne le DHB-1,3, nous enregistrons un écart respectivement de 0,2% et 9,4% entre nos valeurs de $\Delta_c H^0_{\text{m}}$(s, 298,15 K) et $\Delta_{\text{sub}}H^0_{\text{m}}$(298,15 K) et celles de Desai *et al.* (17). Pour ce qui est de la sublimation, ces auteurs ne précisent pas dans leur publication la technique de mesure utilisée.

En ce qui concerne le DHB-1,4, Pedley *et al.* (1) proposent 99,2 ± 1,7 kJ mol^{-1} comme valeur de $\Delta_{\text{sub}}H^0_{\text{m}}$(298,15 K). Celle-ci a été obtenue par Magnus en 1956 (18) par mesures de pression de vapeur en fonction de la température. Elle diffère de la nôtre de 5,4%. D'autres chercheurs comme de Kruif *et al.* (4) ont déterminé l'enthalpie de sublimation de ce même composé et ont trouvé la valeur de 103,9 ± 1 kJ mol^{-1} toujours à partir de mesures de pression de vapeur en fonction de la

DHB-1,4	2847,5±1,2	371,1±1,3	94,13±0,53	277,0±1,4

température dans l'intervalle $337 \leq T/K \leq 351$. Les différentes valeurs de l'enthalpie de combustion du DHB-1,4 proposées par Pedley *et al.* (1) sont comprises entre 2825 et 2856 kJ mol^{-1}. À ces valeurs, il faut ajouter celles qui sont consignées par Pilcher et Sutton dans leur mémoire (19) et qui s'échelonnent de 2804–2870 kJ mol^{-1}. Notre valeur (2847,5 ± 1,2 kJ mol^{-1}) est située dans cet intervalle.

Rappelons que les méthodes indirectes de détermination de l'enthalpie de sublimation (ou vaporisation) d'une substance, qui consistent à mesurer des pressions de vapeur en fonction de la température en vue d'appliquer l'équation de Clausius–Clapeyron à l'équilibre solide (ou liquide)–vapeur, sont toujours moins précises que les méthodes calorimétriques directes et ce d'autant plus que la pression de vapeur saturante des composés étudiés est faible.

III.3. Enthalpie de formation des DHB à l'état gazeux

La comparaison des valeurs de $\Delta_fH^0_m$(g, 298,15 K) (tableau 7) permet de constater que la stabilité des trois isomères décroît du *méta*, au *para* et à l'*ortho*. Pareille observation a été faite au laboratoire lors de l'étude des acides aminobenzoïques (20). Le traité de chimie organique (8) nous dit que, du point de vue de la réactivité, l'isomère *méta* serait assez stable car les deux OH s'influencent peu.

III.4. Pression de vapeur saturante des DHB

Comme nous l'avons indiqué dans les références 21 et 22, il nous est possible, à partir de nos essais, d'évaluer la pression de vapeur saturante des substances étudiées en utilisant la relation:

$$P \approx \Delta P = (dm/dt)(1/aF)\,(2\pi RT/M)^{1/2}$$

dans laquelle $\Delta P(T)$ est la différence de pression de vapeur de part et d'autre du trou d'effusion; $P(T)$, la pression mesurée par effusion à la température T; dm/dt, la masse de substance effusée par unité de temps; R, la constance des gaz parfaits; M, la masse molaire de la substance; F, le facteur de Clausing et a, l'aire de l'orifice d'effusion. Les pressions de vapeur saturante à 298,15 K pour le DHB-1,2 et à 334,6 K pour les deux autres isomères sont consignées dans le tableau 6. Le seul résultat qui peut être comparé aux données de la littérature, concerne la pression de vapeur saturante du DHB-1,4. La valeur que nous trouvons à 334,6 K (6×10^{-4} Torr) est compatible avec celle de de Kruif *et al.* (4) ($7{,}5 \times 10^{-4}$ Torr à 330 K).

III.5. Analyse thermique différentielle des DHB

Les principaux résultats obtenus sont consignés dans le tableau 1. Des trois molécules qui nous intéressent, seul le DHB-1,3 présente une transition irréversible entre 298,15 K et la température de fusion. Si l'on se réfère aux tableaux 8 et 9, nous remarquons une parfaite cohérence entre nos valeurs et celles de la littérature pour les températures des points triple et de transition. Il n'en est pas de même en ce qui concerne l'enthalpie de fusion et de transition.

TABLEAU 8. Comparaison de nos résultats (T_{pt} et T_{trs}) avec ceux de la littérature

Substance	Nos valeurs	Littérature
	T_{pt}(K)	
DHB-1,2	377,80±0,03	376,85–378,15 (2, 3, 23–26)
DHB-1,3	383,54±0,02	382,55–384,15 (2, 3, 5, 24, 26)
DHB-1,4	445,98±0,03	444,95–447,15 (4, 26)
	T_{trs}(K)	
DHB-1,3	366,8±1,4	366,75–369,15 (3, 5)

TABLEAU 9. Comparaison de nos résultats ($\Delta_{fus}H_m$ et $\Delta_{trs}H_m$) avec ceux de la littérature

Substance	Nos valeurs	Littérature
	$\Delta_{fus}H_m$(kJ mol^{-1})	
DHB-1,2	15,00±0,34	20,50–22,76 (2, 3, 24–27)
DHB-1,3	15,25±0,21	18,90–22,07 (2, 3, 24, 26)
DHB-1,4	21,09±0,40	26,50–27,32 (2, 3, 26)
	$\Delta_{trs}H_m$(kJ mol^{-1})	
DHB-1,3	0,72±0,06	0,92–1,37 (3, 5, 6)

Nous avons essayé d'expliquer la raison pour laquelle nos valeurs de $\Delta_{fus}H_m$ et de $\Delta_{trs}H_m$ sont inférieures à celles de la littérature. Parmi les facteurs éventuellement responsables de la différence observée, nous pouvons citer :

1. La vitesse de chauffage utilisée par nos prédécesseurs; elle est généralement plus élevée que la nôtre (3, 5, 25).
2. La façon d'étalonner l'analyseur thermique. Certains auteurs (3) utilisent l'effet Joule qui n'est pas, à notre avis, le meilleur moyen pour réaliser ce travail. En effet, afin de minimiser les erreurs, il est conseillé de réaliser l'étalonnage de l'appareil dans les mêmes conditions que les mesures en utilisant des substances d'intercomparaison (28).
3. Certains résultats sont fort anciens (26).

III.6. Incertitude expérimentale

L'incertitude qui accompagne les résultats expérimentaux représente l'écart moyen σ_m et tient compte des erreurs sur les termes et facteurs de l'expression conduisant au calcul de la grandeur thermodynamique.

IV. Discussion

L'ensemble des résultats expérimentaux consignés dans le tableau 7 permet la détermination de certaines grandeurs énergétiques liées à la structure des molécules étudiées et à leur réseau cristallin.

IV.1. Energie de conjugaison

Les trois molécules de DHB étudiées dans ce mémoire sont conjuguées. En conséquence, nous avons essayé de déterminer d'abord leur énergie de conjugaison expérimentale puis avons comparé celle-ci à la valeur théorique obtenue en utilisant la méthode de calcul décrite dans la référence 29.

L'énergie de conjugaison est, par définition, égale à la différence entre l'énergie réelle de la molécule et l'énergie qu'elle aurait si les divers systèmes insaturés qu'elle comporte étaient indépendants. Sur le plan pratique, pour la déterminer, nous utilisons les enthalpies standard de combustion à l'état gazeux

TABLEAU 10. Energie de conjugaison des DHB

Substance	$E_{conj,exp}$(kJ mol^{-1})	$E_{conj,théor}$(kJ mol^{-1})
DHB-1,2	177,5	175,0
DHB-1,3	184,4	174,3
DHB-1,4	176,7	174,9

de la molécule réelle et de la molécule fictive, non conjuguée. La première de ces grandeurs s'obtient expérimentalement tandis que la seconde nécessite le recours aux systématiques. En ce qui nous concerne, nous avons utilisé celle de Klages, consignée dans la référence 30. Quant au calcul de l'énergie de conjugaison théorique, nous avons utilisé la méthode décrite dans la référence 29 en utilisant le jeu de paramètres suivant :

$$\alpha_0 = \alpha + 2{,}500\ \beta_0 \qquad \alpha_{c\text{-}(0)} = \alpha$$

$$\beta_{c-0} = 0{,}750\ \beta_0$$

β_0 est l'intégrale de recouvrement dans la molécule de benzène et a, pour valeur absolue, 131,7 kJ mol^{-1}. Les calculs effectués nous ont permis d'obtenir les résultats consignés dans le tableau 10.

Comme nous pouvons le constater, il existe un accord satisfaisant entre les différentes valeurs expérimentales et théoriques de l'énergie de conjugaison. De ce fait, les molécules de DHB seraient planes à l'état gazeux. Signalons, au passage, que les molécules de DHB-1,2 (31), de DHB-1,3 (forme α qui nous intéresse) (32) et de DHB-1,4 (33) sont pratiquement planes à l'état solide. Notons qu'avec le même jeu de paramètres et en utilisant le même procédé de calcul, nous avons obtenu un parfait accord entre les valeurs expérimentale et théorique de l'énergie de conjugaison de l'hydroxybenzène. $E_{conj,exp}$ = 163,1 kJ mol^{-1} et $E_{conj,théor}$ = 162 kJ mol^{-1}. La molécule d'hydroxybenzène serait plane à l'état gazeux; elle l'est pratiquement déjà à l'état condensé (34). Les données numériques nécessaires au calcul de $E_{conj,exp}$ de ce composé ont été empruntées à la référence 1.

IV.2. Enthalpie d'atomisation

Pour déterminer la somme des enthalpies des liaisons intramoléculaires d'une molécule, il est indispensable de connaître son enthalpie d'atomisation. Celle-ci, à l'état standard et à la température T, est liée à la transformation suivante : molécule (considérée comme gaz idéal, état fondamental, T) → atomes (chacun d'eux considéré comme gaz idéal, état fondamental, T).

Sur le plan expérimental, si l'on considère une molécule de formule générale : $C_aH_bO_c$, la réaction d'atomisation s'écrit :

$$C_aH_bO_c(g) \rightarrow aC(g) + bH(g) + cO(g)$$

L'enthalpie liée à cette réaction s'appelle « enthalpie d'atomisation expérimentale » et est égale à :

$$\Delta_{a,exp}H^0_m = a\Delta_fH^0_mC(g) + b\Delta_fH^0_mH(g) + c\Delta_fH^0_mO(g) - \Delta_fH^0_mC_aH_bO_c(g)$$

Aussi, à partir de l'enthalpie de formation d'une molécule à l'état gazeux et de celle des différents constituants C, H et O que l'on emprunte aux tables (35) et qui, à 298,15 K, valent respectivement : 716,67 ± 0,44, 217,997 ± 0,006 et 249,17 ± 0,10 kJ mol^{-1}, est-il possible de calculer son enthalpie d'atomisation expérimentale. Nous trouvons pour nos trois molécules de DHB les valeurs consignées dans le tableau 11.

Pour déterminer l'enthalpie de liaison $H(C_b\text{—}OH)$ dans les molécules de DHB, nous sommes partis de $\Delta_{a,exp}H^0_m$ (298,15 K). En effet, on sait que l'enthalpie d'atomisation est

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

TABLEAU 11. Enthalpie d'atomisation expérimentale des DHB

Substance	$\Delta_{a,exp}H^0_m$ (298,15 K)(kJ mol^{-1})
DHB-1,2	6381,1±1,8
DHB-1,3	6391,0±1,8
DHB-1,4	6383,3±1,9

égale à la somme des enthalpies des liaisons intramoléculaires, compte tenu des facteurs de stabilisation et de déstabilisation.

Pour ce qui est des liaisons C_b—C_b, nous avons utilisé le procédé de calcul consigné dans la référence 9. Celui-ci fait intervenir un paramètre lié à la géométrie de la molécule (l'indice de liaison l_{rs} entre deux atomes directement liés r et s) obtenu à partir du calcul théorique de l'énergie de conjugaison (fig. 1). La relation reliant H_{rs} à l_{rs} (9) s'écrit : H_{rs} (kJ mol^{-1}) = 246,0 l_{rs} + 342,6.

Quant à H(C_b—H) nous avons utilisé la valeur 415,88 kJ mol^{-1} (36). Ainsi, dans le cas présent, pour calculer H(C_b—OH), cela revient à retrancher de $\Delta_{a,exp}H^0_m$(298,15 K) la part énergétique des différentes liaisons C_b—C_b et C_b—H. Le calcul effectué nous a permis d'obtenir les valeurs consignées dans le tableau 12. Nous avons adopté la valeur moyenne de 848 kJ mol^{-1} pour H(C_b—OH) dans les DHB. Le même calcul, réalisé avec la molécule d'hydroxybenzène, nous a fourni les résultats suivants : $\Delta_{a,exp}H^0_m$(298,15 K) = 5953,6 ± 1,4 kJ mol^{-1} et H(C_b—OH) = 841 kJ mol^{-1}.

Ces valeurs de H(C_b—OH) nous paraissent cohérentes avec celles qui ont été précédemment trouvées au laboratoire à la suite de l'étude des alcanediols-1,2 et ω-alcanediols (37,38). En effet, dans les alcanediols la distance interatomique C—O est de 1,43 Å et H(C—OH) est comprise entre 819,5 et 827 kJ mol^{-1}. Dans l'hydroxybenzène, cette distance est de 1,39 Å (34); elle est de 1,36 Å dans le DHB-1,3 (32) et de 1,372 Å (31) dans le DHB-1,2. Les distances C_b—O sont ici plus courtes que dans les alcanediols, ce qui explique les valeurs légèrement plus fortes obtenues pour H(C_b—O).

IV.3. Existence de liaisons intermoléculaires dans les DHB

Comme on le sait, l'enthalpie de sublimation d'une substance organique est liée aux interactions intermoléculaires.

Dans le cas des DHB, ces interactions sont du type van der Waals et concernent les forces de dispersion et d'interactions dipolaires. À côté de ces interactions, il existe aussi des liaisons hydrogène intermoléculaires. Il nous a donc paru intéressant de déterminer la part énergétique des forces de van der Waals et des liaisons hydrogène intermoléculaires. Pour ce faire, nous avons appliqué un procédé de calcul qui a déjà été utilisé au laboratoire dans l'étude des acides ω-aminés (39) des alcanediols (37, 38, 40) et des chlorobenzènes (41). Il consiste, dans notre cas, à déterminer la contribution énergétique des forces de dispersion (London) en considérant qu'elle est égale à l'enthalpie de sublimation des diméthylbenzènes, composés isoélectroniques des DHB.

À une température donnée (ici 298,15 K), la différence Δ_1 des enthalpies de sublimation des DHB et des diméthylbenzènes correspondants représente la somme des énergies d'interaction dipolaire et des liaisons hydrogène intermoléculaires, tableau 13. Afin de séparer la contribution énergétique des liaisons hydrogène intermoléculaires, nous avons comparé les enthalpies de sublimation des dichlorobenzènes, qui présentent un moment dipolaire mais ne forment pas de liaisons hydrogène intermoléculaires, à celles des diméthylbenzènes correspondants.

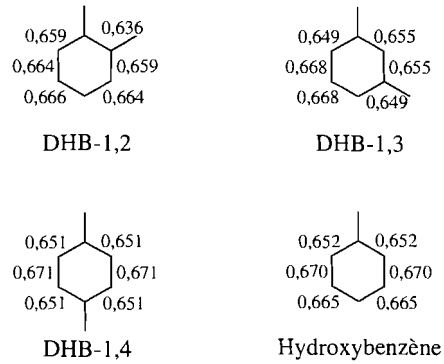

FIG. 1. Indices de liaison dans les trois isomères du DHB et dans l'hydroxybenzène.

TABLEAU 12. Enthalpie de la liaison C_b–OH dans les DHB

Substance	H(C_b–OH)(kJ mol^{-1})
DHB-1,2	845,4
DHB-1,3	850,9
DHB-1,4	846,8

TABLEAU 13. Comparaison des enthalpies de sublimation des DHB, des diméthylbenzènes et des dichlorobenzènes isoélectroniques

	$\Delta_{sub}H^0_m$ (298,15 K) (kJ mol^{-1})		
	−1,2	−1,3	−1,4
di–OH A :	87,50	86,00	94,13
di–Cl B :	64,35	62,78	65,15
di–CH_3 C :	59,82	58,26	60,18
Δ_1 = A − C :	27,68	27,74	33,95
Δ_2 = B − C :	4,53	4,52	4,97
$\Delta_1 - \Delta_2$:	23,15	23,22	28,98

La différence des enthalpies de sublimation des dichlorobenzènes et des diméthylbenzènes Δ_2 représente la contribution énergétique due aux forces d'interaction dipolaire. Comme on peut le constater, celle-ci est faible. La différence $\Delta_1 - \Delta_2$ représente la part énergétique pouvant être attribuée aux liaisons hydrogène intermoléculaires. Comme il ne peut se former que deux ponts hydrogène par molécule de DHB, en prenant la molécule de DHB-1,4, comme référence, il s'en suit que l'enthalpie d'une liaison hydrogène intermoléculaire peut être estimée à 14,5 kJ mol^{-1}.

Les données numériques utiles aux différents calculs précédents ont été empruntées aux références 13,16 et 42–45. Pour calculer $\Delta_{sub}H^0_m$(298,15 K) lorsque celle-ci n'est pas accessible expérimentalement, nous avons utilisé la relation $\Delta_{sub}H^0_m$(298,15 K) = $\Delta_{vap}H^0_m$(298,15 K) + $\Delta_{fus}H_m$(298,15 K). Pour calculer $\Delta_{fus}H_m$(298,15 K) à partir de $\Delta_{fus}H_m$(T_{fus} K), nous avons utilisé la règle de Sidgwick qui consiste à écrire que $\Delta_{fus}H_m(T\text{K}) = \Delta_{fus}H_m$(298,15 K) + $k(T - 298{,}15)$ avec k = 0,055 kJ mol^{-1} K^{-1}.

IV.4. Existence d'une liaison hydrogène intramoléculaire dans l'isomère ortho

Si nous comparons entre elles les valeurs de l'enthalpie de sublimation des isomères *ortho* et *para* de DHB, nous consta-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

tons que celle de l'isomère *para* (ou DHB-1,4) est plus élevée de 6,63 kJ mol^{-1}. Cette différence doit être attribuée au fait que la molécule de DHB-1,2 présente moins de liaisons hydrogène intermoléculaires que les deux autres isomères. En effet, elle est la seule à pouvoir former une liaison hydrogène intramoléculaire. Cependant, cette chélation est moins forte que celle qui existe, par exemple, dans l'acide hydroxy-2 benzoïque. En effet, la différence que l'on note entre les valeurs de l'enthalpie de sublimation des isomères *ortho* et *para* de cet acide est égale à 20,9 kJ mol^{-1} (46). Pour connaître la raison de cette différence, il suffit de comparer entre elles les distances O—H---O dans les molécules de DHB-1,2 et d'acide hydroxy-2 benzoïque. Dans le premier cas, cette distance vaut 2,80 Å (31), dans le second 2,59 Å (47).

D'autres observations faites sur les propriétés physico-chimiques des DHB tendent à prouver l'existence de cette liaison hydrogène intramoléculaire dans la molécule de DHB-1,2.

1. A partir de nos expériences de sublimation, il s'avère que la pression de vapeur saturante du DHB-1,2 est, quelle que soit la température, toujours plus forte que celle du DHB-1,4.

2. L'isomère *para* présente, à l'état liquide, des associations intermoléculaires par liaisons hydrogène plus nombreuses que l'isomère *ortho*. En conséquence, il est insoluble dans un liquide non associé comme le benzène alors que l'isomère *ortho* l'est.

3. La température du point triple (ou de fusion), qui renseigne sur la force des liaisons intermoléculaires, est plus élevée dans le cas du DHB-1,4 que dans celui du DHB-1,2. Il en est de même pour l'enthalpie de fusion (tableau 1).

IV.5. Calcul de l'enthalpie de sublimation du DHB-1,4 par voie incrémentale

Nous avons essayé de retrouver par le calcul à partir des contributions énergétiques apportées par le noyau benzénique et les deux fonctions OH, l'enthalpie de sublimation du DHB-1,4. Dans le réseau cristallin, celui-ci se trouve à l'état moléculaire et ne présente pas de liaison hydrogène intramoléculaire. Afin de tenir au mieux compte des interactions que peuvent avoir le noyau benzénique et les deux fonctions OH au sein du cristal de DHB-1,4, nous avons cherché à calculer ces contributions à partir des grandeurs énergétiques de molécules ayant une nature chimique voisine de celle qui nous intéresse.

Nous avons déterminé la contribution du chaînon OH à partir de deux composés : benzène et hydroxybenzène, en recherchant dans la littérature les principales données qui nous permettaient d'obtenir leur enthalpie de sublimation à 298,15 K. Pour le benzène, il nous fallait calculer cette grandeur à partir de $\Delta_{vap}H^0_m(298{,}15\,K)$ et de $\Delta_{fus}H_m(298{,}15\,K)$. La première de ces deux grandeurs est empruntée à la littérature (45). Quant à la seconde, nous l'avons calculée à partir de $\Delta_{fus}H_m(278{,}68\,K)$ = 9,84 kJ mol^{-1} (16) et en utilisant la règle de Sidgwick signalée ci-dessus. Nous trouvons $\Delta_{sub}H^0_m(298{,}15\,K)$ = 44,83 kJ mol^{-1}. Quant à l'hydroxybenzène, substance solide à 298,15 K, nous avons emprunté à la référence 1 la valeur de $\Delta_{sub}H^0_m(298{,}15\,K)$. Celle-ci est égale à 68,66 kJ mol^{-1}. En conséquence, la part du chaînon OH est égale à 23, 83 kJ mol^{-1}; celle de deux OH à 47,66 kJ mol^{-1}. Il s'en suit que l'enthalpie de sublimation du DHB-1,4, calculée à partir des différentes contributions, est égale à 92,49 kJ mol^{-1}; elle diffère seulement d'environ 1,7% de la valeur expérimentale.

Remerciements

Monohalogénocyclopropanation des esters et des acides α-éthyléniques diversement alkylés. Activation et stéréosélection antithermodynamique

ROGER BARLET,[1] BAHMAN BAHARMAST ET MICHEL VIDAL

Laboratoire d'études dynamiques et structurales de la sélectivité (LEDSS), Université Joseph Fourier, Bâtiment chimie recherche, BP53X, 38041 Grenoble CEDEX, France

Reçu le 28 février 1990

ROGER BARLET, BAHMAN BAHARMAST et MICHEL VIDAL. Can. J. Chem. **69**, 489 (1991).

L'halogénocyclopropanation des acides et des esters α-éthyléniques par le dichlorométhane en présence de MeLi/LiBr est obtenue avec d'excellents rendements. Dans le cas des esters les adduits halogénocyclopropaniques obtenus sont uniquement hydroxylés alors que dans le cas des acides on obtient en sus les adduits carbonylés qui sont majoritaires, même dans le cas d'un excès de MeLi. Dans le cas des acides α-éthyléniques, la cyclopropanation intervient très majoritairement au niveau d'un intermédiaire type hydrate de cétone lithié qui active considérablement le pontage. Le produit primaire de cycloaddition est suffisamment stable pour ne pas être massivement attaqué par le méthyllithium et permettre l'obtention prédominante des cétones halogénocyclopropaniques, obtenues à l'hydrolyse. Dans le cas des esters la réaction est également activée par la formation primaire d'un hémiacétal mais la cycloaddition intervient de façon plus équilibrée, à la fois sur cet intermédiaire et sur l'alcoolate qui en résulte par action ultérieure de MeLi. Dans les deux cas on observe le maintien, comme dans le cas des alcools α-éthyléniques, d'une nette stéréosélection *syn*, malgré les effets stériques et électroniques antagonistes, lorsque le groupement alkyle et le groupement fonctionnel sont en position *cis* par rapport à la double liaison.

Mots clés : halogénocyclopropanation, activation, stéréosélection *syn*.

ROGER BARLET, BAHMAN BAHARMAST, and MICHEL VIDAL. Can. J. Chem. **69**, 489 (1991).

The halogenocyclopropanation of α,β-unsaturated acids and their esters through a reaction with dichloromethane and MeLi/LiBr proceeds with excellent yields. With the esters, the only halogenocyclopropanic adducts obtained are the hydroxylated ones while the acids lead to carbonylated adducts as major products, even when there is an excess of MeLi. With the acids, the cyclopropanation takes place selectively with a lithiated hydrate of ketone type intermediate favouring the formation of the ring. The stability of the primary product of the cycloaddition is such that it does not react massively with the methyllithium and that the halogenocyclopropane ketones can be isolated after hydrolysis. With the esters, the reaction is also activated by the primary formation of an hemiacetal; however, the cycloaddition is more equilibrated between this intermediate and the alkoxide which results from the later action of the MeLi. In both cases, a net *syn* stereoselectivity is observed in the unsaturated alcohols in spite of the opposite steric and stereoelectronic effects operating when the alkyl and functional groups are in a *cis* relation around the double bond.

Key words: halogenocyclopropanation, activation, *syn* stereoselectivity.

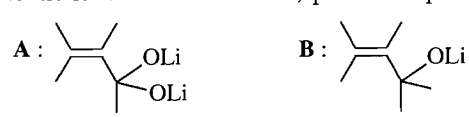
Introduction



Nous avons pu montrer antérieurement que la réaction de monohalogénocyclopropanation sur les oléfines fonctionnalisées s'avère très générale et fournit d'excellents rendements (1–4). Cette réaction de transfert peut être commodément mise en oeuvre par action du méthyllithium, associé au bromure de lithium, sur divers générateurs de monochlorocarbènes tels que le chlorure de méthylène ou le dichloro-1,1 éthane en présence de substrats variés. Nous avons récemment obtenu des résultats surprenants avec des alcools α-éthyléniques, en mettant en évidence un effet synergique alkyle–alcoolate dans la stéréosélection *syn* majoritaire des alcools α-éthyléniques *cis*-méthylés (5).

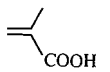
Poursuivant ce travail sur les acides et les esters α-éthyléniques nous sommes en mesure, compte tenu de nous derniers résultats, de mettre en évidence un net effet d'activation des fonctions acide et ester par rapport aux fonctions cétone, dioxolanne ou alcool. En même temps on observe, dans le cas où alkyle et groupement fonctionnel sont *cis*, le maintien d'une stéréosélection *syn* (halogène se plaçant du côté du groupement fonctionnel) allant à l'encontre des interactions stériques et électrostatiques attendues. On obtient, en effet, les produits d'addition les plus encombrés (alkyle, halogène et groupement fonctionnel du même côté du cycle) et les plus polaires (halogène et oxygène électronégatifs em position *cis*).

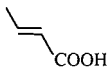
Halogénocyclopropanation des acides α-éthyléniques

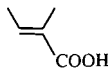
Résultats expérimentaux (tableau 1)

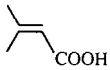
Les acides **1**–**5**, diversement méthylés, sont soumis à l'action du générateur de carbénoïde CH_2Cl_2/MeLi/LiBr, à reflux d'éther, selon la méthode que nous avons antérieurement développée (5). Un équivalent de bromure de lithium se trouve en effet associé, sous forme soluble et stable, à une équivalent de méthyllithium formé, de façon commode, à partir du bromure de méthyle et du lithium. La préparation du méthyllithium à partir du chlorure de méthyle entraîne, au contraire, la précipitation du chlorure de lithium et la passivation du lithium par l'halogénure insoluble. De plus, le méthyllithium est alors très réactif et s'enflamme à l'air. En règle générale 4 équivalents de méthyllithium sont utilisés pour 1 équivalent d'acide. Dans ces conditions opératoires deux entités successives, l'hydrate de cétone potentielle **A** et l'alcoolate **B**, peuvent à priori subir la

Structure **A** Structure **B**









cycloaddition et conduire respectivement, après hydrolyse, aux cétones et aux alcools α-halogénocyclopropaniques comme produits primaires de pontage.

Les acides donnent effectivement, de façon très générale, les adduits carbonylés et les adduits hydroxylés en proportion très variable selon le substrat envisagé et avec d'excellents rende-

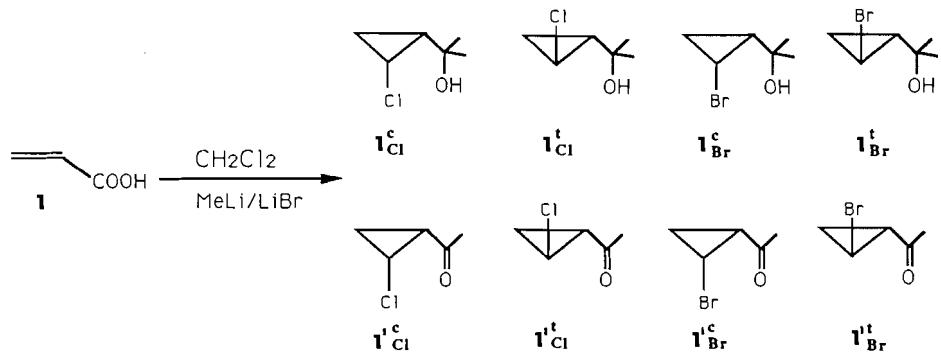

FIG. 1.

ments. Dans chacun des cas on obtient un couple d'adduits chlorés, majoritaire, et un couple d'adduits bromés, obtenu par échange d'halogènes au niveau du carbénoïde ou du complexe carbène–sel. Par contre, on peut limiter ou même inhiber totalement cet échange d'halogène en travaillant à −30°C et ne conserver alors que les adduits chlorés (2). Dans chaque couple les termes *cis* (composé **c** 1′*R**2′*R**) et *trans* (composé **t** 1′*R**2′*S**) précisent la position relative du groupement fonctionnel porté par le carbone 1′ du cycle et de l'halogène porté par le carbone 2′ du cycle. À titre d'exemple figurent ci-dessous les adduits de l'acide acrylique **1** (voir figure 1).

L'obtention d'adduits bromés, à côté des adduits chlorés, malgré l'utilisation du chlorure de méthylène comme générateur de carbène, peut être considérée comme une limitation au plan synthétique qui disparait si on travaille à basse température. L'accés aux adduits bromés, difficile à partir du bromure de méthylène, peut ainsi constituer un avantage dans l'étude de la réactivité comparée des adduits lorsqu'est mis en oeuvre le pouvoir nucléofuge des halogènes. Par exemple, nous menons actuellement des études d'élimination sur de tels composés dont les premiers résultats viennent d'être publiés (12).

Détermination des configurations

De façon générale en CPG les alcools *cis* sont moins retenus que les alcools *trans*, à l'inverse des cétones.

La détermination des diverses configurations prend essentiellement appui sur la spectrographie de RMN.

Les configurations des adduits de cycloaddtion des produits **1** et **2** sont déterminées en RMN ^{1}H par effet LIS après complexation avec les chélates de l'Europium Eu(dpm)$_3$. Cette complexation déplace plus fortement les protons situés en *cis* du groupement fonctionnel que ceux situés en *trans* conformément

TABLEAU 3. RMN ^{13}C : déplacements chimiques caracteristiques des couples d'alcools α-chlorocyclopropaniques ($CDCl_3$, $\delta \times 10^6$)

	Carbone porteur de halogène		Carbone cyclopropanique porteur du carbone hydroxylé	
Composés	*cis*	*trans*	*cis*	*trans*
1 *c,t*	33,9	31,2	23,6	28,2
2 *c,t*	41	37,1	27,9	29,8
3 *c,t*	40,1	38,2	35,5	39
5 *c,t*	43,7	39,2	35,7	39,5

à nos résultats antérieurs (2, 6). Les configurations des adduits du produit **3** sont déterminées par l'examen du multiplet présenté par le proton, fortement blindé, lié au carbone porteur du groupement fonctionnel : quadruplet pour les composés *cis* ($^3J_{cis} \simeq 7$–8 Hz, $^3J_{trans} \simeq 4$–5 Hz), triplet grossier pour les composés *trans* (deux $^3J_{trans}$ voisins de 4 Hz). Dans les composés de cycloaddition des acides **4** et **5** le proton lié au carbone porteur de l'halogène présente un couplage $^3J_{trans}$ dans les composés *cis*, inférieur à $^3J_{cis}$ dans les composés *trans*, conformément à ce que nous avons observé antérieurement (5). De façon générale, par effet de dilution, les protons hydroxyliques des composés *cis* sont moins déplacés vers les champs forts que ceux des composés *trans* à cause de la persistance d'une liaison hydrogène intramoléculaire entre ces protons et l'halogène.

Il apparaît cependant, au vu des spectres de RMN ^1H, que l'hydrogène géminé avec l'halogène, systématiquement plus déblindé dans le cas des cétones *trans*, ce qui constituait un critère d'identification stéréochimique (2), ne montre pas ici, dans le cas des alcools nouvellement décrits, un déplacement chimique établissant une corrélation claire avec la nature du stéréoisomère. Le tableau 2 montre en effet que c'est tantôt l'alcool *cis* tantôt l'alcool *trans* qui conduit au blindage le plus élevé pour ce proton. Le carbonyle orienté vers le cycle (conformation *cisoïde* prouvée en particulier par la valeur élevée de ν_{CO} pour les cétones *cis*) déblinde les protons CHX quel que soit l'effet des méthyles substitués sur le cycle. Par contre, l'hydroxyle entraîne un effet d'anisotropie beaucoup moins net et la substitution méthylée joue alors un grand rôle.

Les spectres de RMN ^{13}C montrent que le carbone cyclopropanique porteur de l'halogène est davantage déblindé dans le cas des stéréoisomères *cis* que dans le cas des *trans*. À l'inverse, le carbone cyclopropanique portant le carbone hydroxylé est davantage blindé dans le cas des stéréoisomères *cis* (tableau 3).

La conformation des cétones **1′**–**5′** est de type *cisoïde* comme nous l'avons montré antérieurement lorsque ces adduits étaient issus du pontage des dioxolannes correspondants (2).

Discussion

L'ensemble de nos résultats nous amènent aux conclusions suivantes :

Dans le cas des acides **2**, **3** et **5** la cyclopropanation n'intervient qu'au niveau de l'intermédiaire **A**, même avec un excès de MeLi (figure 2). On obtient en effet sensiblement la même répartition de produits, fortement en faveur des adduits cétoniques, que l'on utilise 3, 4 ou 5 équivalents de MeLi. Dans le cas des acides **1** et surtout **4**, un défaut de MeLi entraîne une augmentation de la proportion de cétones (alcool/cétone = 70 : 30 pour l'acide **1** et 45 : 55 pour l'acide **4** dans le cas de l'utilisation de 3 équivalents de MeLi).

Dans tous les cas de figure nous pensons disposer d'arguments en faveur de la cyclopropanation de l'hydrate de cétone lithié **A** plutôt que de l'alcoolate **B**. Cet hydrate, porteur de 2 atomes d'oxygène, renforcerait l'assistance lithium du carbénoïde-oxygène du substrat, que nous avons invoquée dans le cas des oléfines α-fonctionnalisées faiblement nucléophiles (2, 5), et rendrait compte des rendements de pontage particulièrement élevés dans le cas présent des acides. Cette assistance entraînerait une accélération de la cyclopropanation telle qu'après l'addition de deux équivalents de MeLi on observe déjà, sauf dans le cas de l'acide **1**, la formation de 15–30% de produits de cycloaddition ce qui signifie que la vitesse de l'attaque nucléophile du carboxylate de lithium pour conduire à l'hydrate **A** n'est guère supérieure à la vitesse de cyclopropanation de cet hydrate. Même dans le cas de l'acide **1** le rendement de cyclopropanation, très supérieur à celui de la cétone méthylée correspondante **11** (cf. tableau 4) et conduisant aux mêmes couples d'alcools (90% contre 55%), semble clairement indiquer que l'intermédiaire ponté n'est pas l'alcoolate tertiaire **B** mais bien l'hydrate **A** (voie ② prépondérante par rapport aux voies ① et ②′ dans le schéma réactionnel de la figure 2 mais avec transformation ③ importante).

Ces résultats confirment que, dans les conditions ordinaires de température, lors de l'attaque d'un alkyllithium sur un acide, le complexe intermédiaire **A** a une stabilité suffisante pour ne se transformer majoritairement en cétone qu'à l'hydrolyse (7). On peut ajouter que nos conditions d'hydrolyse, addition lente d'eau au milieu réactionnel ou mélange réactionnel ajouté à un grand excès d'eau, ne modifient pas de façon sensible la répartition entre adduits hydroxylés et adduits carbonylés. L'excès d'eau à l'hydrolyse ne joue donc pas, dans notre cas, de rôle majeur contrairement aux indications de la littérature (7*c*, 8).

Sauf dans le cas de l'acide **1** on peut dire que le méthyllithium en excès s'hydrolyse plus rapidement que l'adduit de l'intermédiaire **A** qui évolue peu en cours de manipulation (transformation ③ faible).

De façon générale, la stéréochimie est indépendante du nombre d'équivalents de MeLi utilisés. La stéréosélection, par cyclopropanation de l'hydrate de cétone, observée ici, s'avère très voisine de celle observée dans le pontage des alcools α-éthyléniques (5), c'est à dire le cas où les substrats primaires de réaction sont des alcoolates. On retrouve l'effet directeur *syn* des substituants alkyles sur la double liaison et l'effet directeur *anti* des groupements hydrate ou alcoolate de lithium lorsque

For personal use only.

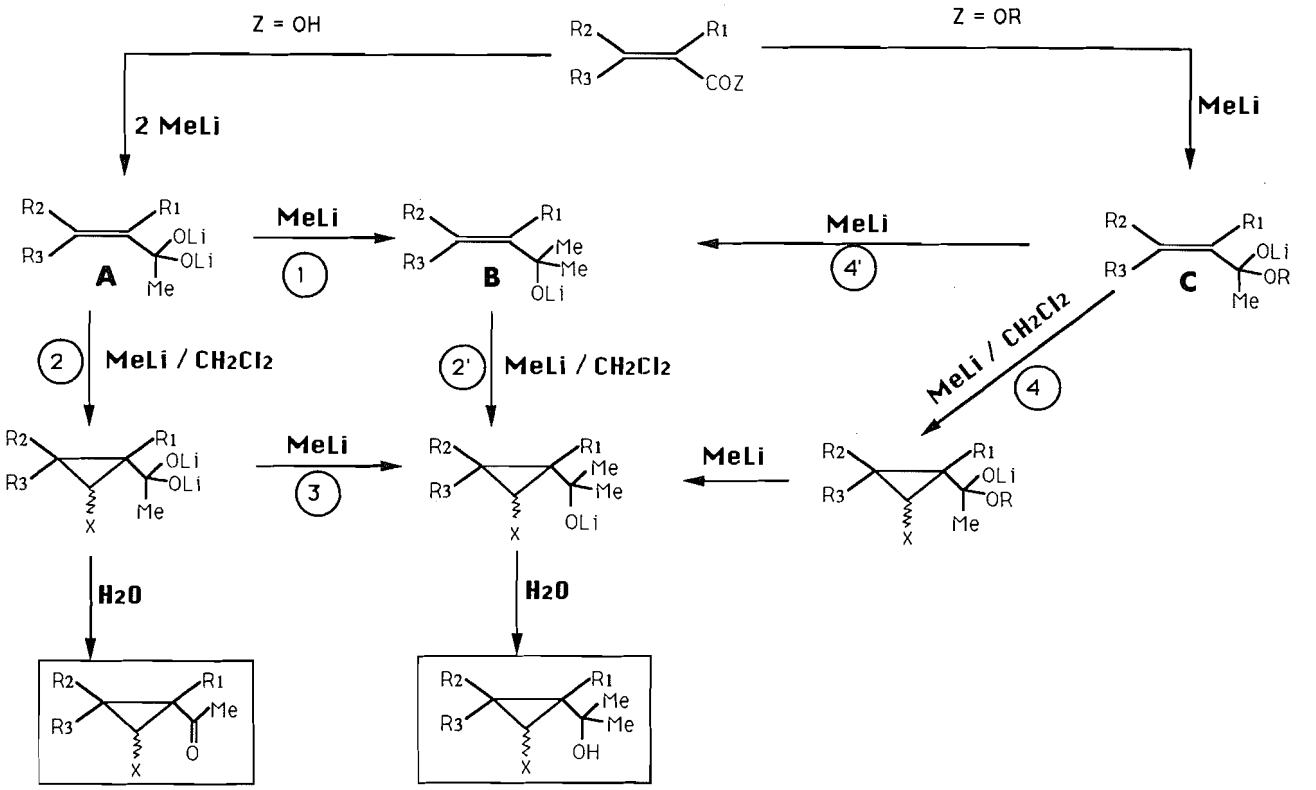

FIG. 2. Halogénocyclopropanation des acides et esters α-éthyléniques. Schéma réactionnel.

ces groupements sont en position *trans*. De même, lorsqu'ils sont *cis* (cas du composé **5**) on retrouve une synergie alkyle – hydrate de lithium encore plus surprenante que la synergie alkyle–alcoolate (5) dans la mesure où l'interaction répulsive stérique et surtout électronique, mise en oeuvre dans l'adduit *cis* majoritaire, devrait être encore accrue par la présence de deux groupements OLi dans l'hydrate de lithium au lieu d'un seul dans l'alcoolate. Cette synergie se manifeste, là encore, par une grande réactivité de l'intermédiaire **A**, traduite par un fort rendement de pontage et une augmentation de la stéréosélection liée à l'accroissement de la pression stérique (cas des adduits bromés).

Nous pensons que cette synergie prend appui sur plusieurs facteurs cumulatifs intervenant tous au niveau de l'état de transition et favorisant un contrôle cinétique en faveur du produit de cycloaddition le plus contraint. Ainsi la diffusion des charges et l'interaction entre l'halogène négatif et la charge partielle positive acquise par le méthyle, en cours de transfert carbénique, explique l'effet directeur *syn* des alkyles (9). Les interactions orbitalaires secondaires, invoquées par Hofmann *et al.* et dues aux hydrogènes de l'alkyle en *cis*, peuvent intervenir dans une telle réaction menée dans des conditions relativement exothermiques où substrat et réactif restent assez éloignés (10). Une assistance, au niveau des intermédiaires **A** et **B**, par les ions Li positif et les halogènes du carbénoïde expliquerait l'effet directeur *syn* du groupement fonctionnel. Nous avons en effet vérifié que cet effet directeur *syn* est sensiblement atténué si le lithium est crypté sélectivement. Cette intervention de Li positif, insuffisante pour orienter de façon *syn*, en l'absence d'alkyle en *cis*, devient au contraire déterminante lorsqu'un alkyle en *cis* permet une synergie des effets. Tout se passe comme si un effet d'accrochage alkyle–halogène rendait alors possible l'assistance Li positif – halogène négatif.

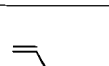
Halogénocyclopropanation des esters α-éthyléniques

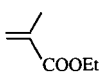
Résultats expérimentaux (tableau 4)

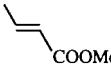
Les esters **6–10**, homologues des acides **1–5**, donnent, avec d'excellents rendements, les couples d'adduits hydroxylés, à l'exclusion d'adduits carbonylés. Les alcools obtenus peuvent également résulter de la cyclopropanation des cétones correspondantes **11–15** dont les résultats figurent également dans le tableau 4.

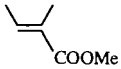
Discussion

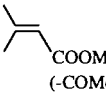
Sauf dans le cas du composé **10**, les esters donnent de meilleurs rendements de cycloaddition que les cétones correspondantes. Ceci accrédite à nouveau l'hypothèse d'une cyclopropanation au niveau d'un intermédiaire activé, hémiacétalique **C** tel que mentionné dans le schéma de la figure 2.











Le fait qu'en général, sauf pour l'ester **10**, le pontage soit déjà de l'ordre de 20–30% après addition de 2 équivalents de MeLi va dans le même sens. Par contre, après addition de 1 équivalent de MeLi, les adduits ne sont formés qu'à l'état de traces. Il semble donc que la vitesse de cyclopropanation et la vitesse de formation de l'alcoolate soient voisines, et que la vitesse de formation de **C** à partir de l'ester soit sensiblement supérieure. La cyclopropanation interviendrait de façon partielle au niveau de l'intermédiaire **C**, apparemment moins activé et moins stable que les intermédiaires de type **A** formés à partir des acides (voie ④ simultanée à la voie ④' dans la figure 2).

Par contre pour l'ester **10**, la cyclopropanation interviendrait surtout au niveau de l'alcoolate comme semblent l'indiquer, tout à la fois, l'absence de tout pontage après l'addition de deux équivalents de MeLi et l'absence d'amélioration, dans ce cas là, du rendement du pontage de l'acide par rapport au pontage de la cétone.

Il est remarquable de constater que le pontage des esters n'a

*La cycloaddition faite sur l'ester éthylique correspondant donne rigoureusement les mêmes résultats.

jamais, dans nos conditions, conduit aux cétones correspondantes. L'intermédiaire hémiacétalique **C** est suffisamment peu stable pour évoluer vers l'alcoolate soit avant soit, de façon plus limitée, après cyclopropanation. À l'inverse de l'hydrate de cétone **A**, issu des acides, l'hemiacétal **C** serait déstabilisé par cyclopropanation. Aussi bien l'hemiacétal **C** que son produit de cycloaddition évolueraient ainsi plus rapidement vers un alcoolate qu'un ester ordinaire capable de fournir des cétones par action des organolithiens (11).

Structure **A**

Dans le cas de l'ester **10**, où le méthyle et le groupement ester sont *cis*, on observe, à nouveau, une nette stéréosélection en faveur du produit de cycloaddition *cis* malgré les effets stérique et électronique déstabilisants, que ces effets interviennent au niveau de l'alcoolate ou de l'hemiacétal. L'accroissement de cette stéréosélection *syn* dans la cycloaddition de l'ester **10**, comparée à celle de l'ester **15**, semble bien indiquer que l'intermédiaire hémiacétalique **C** subit en partie la cyclopropanation.

Conclusion

La mise en oeuvre d'une telle réaction d'halogénocyclopropanation sur les acides et les esters α-éthyléniques montre que la durée de vie des intermédiaires **A** et **C**, respectivement formés par addition nucléophile initiale sur le carboxylate ou l'ester, est importante. Nous avons pu donner ainsi une nouvelle extension à cette réaction qui autorise l'accès direct à des cétones halogénocyclopropaniques sans passer par la protection du carbonyle sous forme de dioxolanne (2).

La diversité des composés halogénocyclopropaniques fonctionnalisés ainsi accessibles nous permet d'étudier actuellement les réactions d'élimination sur ces substrats, en direction des composés cyclopropéniques ou cyclopropylidéniques correspondants. Nous premiers résultats dans ce domaine laissent présager un cours réactionnel très variable en fonction de la nature des substrats avec accès possible à des composés alléniques ou diéniques (12).

Partie expérimentale

Les spectres de RMN ^{1}H et ^{13}C ont été enregistrés dans la grande majorité des cas, dans $CDCl_3$ sur WP Brücker 80 SY. Les spectres infrarouges ont été réalisés sur un appareil Perkin–Elmer 397 (ou 521 pour les études en solution).

La CPG analytique a été effectuée sur Aérograph 600 D à ionisation de flamme, le plus souvent avec colonnes Carbowax, et la CPG préparative sur Autoprep A 700 et A 705 avec des colonnes Carbowax sauf dans le cas des adduits hydroxyles de l'acide **5** où la séparation a été obtenue sur colonne Ucon Oil. Selon les cas la longueur des colonnes utilisées était de 1 à 3 mètres (3 ou 9 mm de section).

Les analyses élémentaires ont été réalisées par le Service Central de microanalyse du CNRS, échangeur de Solaize, BP 22, 69390 Vernaison, France.

Cyclopropanation des acides et des esters α-éthyléniques

Le méthylithium associé au bromure de lithium est obtenu par barbotage du bromure de méthyle dans un mélange éther diéthylique – lithium martelé en fines lamelles. Avant utilisation l'éther est distillé sur $LiAlH_4$.

La cyclopropanation s'opère selon un mode opératoire conforme à celui décrit antérieurement (2, 3, 5). Le méthyllithium, environ N, est additionné, sous azote, à un mélange de 0,1 mol d'acide ou d'ester et 0.3–0,4 mol de CH_2Cl_2 jouant à la fois le rôle de générateur de carbène et de solvant. L'addition s'opère en 1 h environ, à un rythme tel que le reflux d'éther soit entretenu. Des prélèvements intermédiaires, en cours de réaction (après addition de 2, 3 et 4 équivalents pour les acides, après addition de 1, 2 et 3 équivalents pour les esters), sont immédiatement hydrolysés, par un excès d'eau saturée en chlorure d'ammonium, afin de vérifier l'état d'avancement de la réaction par CPG analytique. Les réactions sont arrêtées après addition de 5 équivalents de MeLi sur les acides et de 3,5 équivalents sur les esters, c'est à dire après addition d'un excès théorique de MeLi de l'ordre de 20–25%, excès tenant compte à la fois de la cyclopropanation et de l'évolution du groupement fonctionnel vers un alcoolate tertiaire. L'hydrolyse, très exothermique, est menée le plus souvent par addition progressive du produit de réaction à un grand excès d'eau glacée. L'addition lente d'eau au milieu réactionnel refroidi est également mise en oeuvre, sur le produit de pontage des acides, afin de vérifier si les conditions d'hydrolyse jouent un rôle dans la répartition entre adduits hydroxylés et carbonylés. Après neutralisation par le chlorure d'ammonium, séparation des phases et extraction de la phase aqueuse à l'éther, on obtient un mélange brut dont les divers constituants ne peuvent pas être séparés par distillation fractionnée mais sont aisément séparables par CPG préparative.

Séparation et détermination des pourcentages d'adduits obtenus

La séparation des mélanges complexes d'adduits obtenus est faite par CPG. Le couple de dérivés chlorés précède normalement le couple de dérivés bromés dans l'ordre de sortie de colonne. Cependant le premier dérivé bromé est parfois moins retenu que le deuxième dérivé chloré.

La détermination des pourcentages est faite, après agrandissement des diagrammes par diminution de l'atténuation, par détermination des surfaces x des pics et étalonnage interne. Une moyenne est effectuée entre plusieurs évaluations qui sont relativement homogènes ($\Delta x/x <$ 0,03).

Identification stéréochimique des adduits

Les adduits hydroxlyés et carbonylés de l'acide 2-méthyl-but-2-

ènoïque **4** et de l'acide 3-méthyl-but-2-ènoïque **5** ne sont pas des produits nouveaux. Nous avons décrit antérieurement ces composés (2) de même que les adduits carbonylés issus de l'acide 2-méthyl-prop-2-énoïque **2** (2). Ces derniers adduits carbonylés ont également été, pour certains d'entre eux, décrits par d'autres équipes (13, 14).

Les adduits carbonylés de l'acide acrylique **1** et les adduits hydroxylés de **1**, **2** et **3** n'ont, à notre connaissance, pas été décrits. La caractérisation de ces adduits prend appui sur le faisceau homogène suivant d'observations expérimentales : ordre de sortie en CPG; distinction générale en IR entre les deux stéréoisomères carbonylés *cis* et *trans* (ν_{CO} supérieur d'environ 10 cm^{-1} pour les cétones *cis*, 1705 cm^{-1} contre 1695 cm^{-1} à l'état pur); distinction possible en IR entre les deux stéréoisomères hydroxylés *cis* et *trans* par effet de solvant (l'alcool *cis* en solution à 5×10^{-3} mol L^{-1} donne, le plus souvent, persistance d'une bande ν_{OH} liée vers 3480–3500 cm^{-1} due à une chélation entre l'hydroxyle et l'halogène); distinction en RMN entre les deux stéréoisomères hydroxylés (dans le cas des composés *cis* moindre déplacement du signal dû à OH vers les champs forts par dilution. Ainsi $\mathbf{1}^c_{Cl}$, $\mathbf{2}^c_{Cl}$, $\mathbf{3}^c_{Cl}$, $\mathbf{5}^c_{Cl}$ sont respectivement blindés de 0,45 ppm, 0,40 ppm, 0,48 ppm et 0,38 ppm en passant de $c = 0{,}6$ mol L^{-1} à $c = 0{,}3$ mol L^{-1}. Les isomères chlorés *trans* correspondants sont blindés de 0,70 ppm dans les mêmes conditions), complexation avec les chélates de l'Europium conduisant au fort déblindage d'un seul proton dans le cas de $\mathbf{1}'^c_{Cl}$, $\mathbf{2}^c_{Cl}$, $\mathbf{3}^c_{Cl}$ alors que deux protons sont fortement déblindés dans le cas des homologues $\mathbf{1}'^t_{Cl}$, $\mathbf{2}^t_{Cl}$, $\mathbf{3}^t_{Cl}$ (de même pour $\mathbf{1}'^c_{Br}$, $\mathbf{2}^c_{Br}$, $\mathbf{3}^c_{Br}$ vis-à-vis de $\mathbf{1}'^t_{Br}$, $\mathbf{2}^t_{Br}$, $\mathbf{3}^t_{Br}$).

Caractéristiques des nouveaux produits

Les analyses élémentaires sont satisfaisantes (C, H et O ±0,1%, Cl ±0,15%, Br ±0,25%), à condition qu'elles soient effectuées rapidement après la séparation chromatographique, sinon les écarts sur la composition en halogène deviennent importants bien que les spectres RMN demeurent pratiquement inchangés.

Les spectres IR des alcools sont voisins et montrent à l'état de film pur une vibration $\nu_{C\text{-}H}$ vers 3040–3055 cm^{-1}, une vibration ν_{OH} vers 3400 cm^{-1}, un vibration $\nu_{C\text{-}O}$ vers 1125 cm^{-1} et une vibration persistante à 680 cm^{-1}. Les cétones présentent une bande $\nu_{C\text{-}H}$ vers 3050 cm^{-1}, $\nu_{C=O}$ intense vers 1705 cm^{-1} pour les *cis* et 1695 cm^{-1} pour les *trans*, et des bandes présentes pour tous les stéréoisomères vers 1360 cm^{-1} (COMe), 1325, 1170 et 690 cm^{-1}.

Dans la caractérisation des produits nouveaux ci-après nous rapportons les fréquences en cm^{-1} des maxima d'absorption des spectres IR effectués à l'état de films purs, les données des spectres de RMN ^1H, enregistrés dans $CDCl_3$, selon la nomenclature habituelle ($\delta \times 10^6$, J en Hz, s = singulet, m = multiplet, dd = doublet de doublets, dt = doublet de triplets) et enfin les analyses centésimales :

Theoretical and experimental approaches to the barrier to rotation about the Csp^2—Csp^3 bond in benzyl silane. Hyperconjugative stabilization of the perpendicular conformation

TED SCHAEFER,[1] RUDY SEBASTIAN, AND GLENN H. PENNER[2]
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

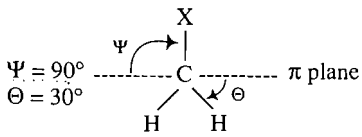
Received August 20, 1990

TED SCHAEFER, RUDY SEBASTIAN, and GLENN H. PENNER. Can. J. Chem. **69**, 496 (1991).

The ^{1}H nuclear magnetic resonance spectra of benzyl silane and benzyl trichlorosilane, obtained in CS_2 and benzene-d_6 solutions, are analyzed. The long-range coupling constants between the methylene and *para* ring protons are used to derive apparent twofold barriers about the Csp^2—Csp^3 bonds of 7.4 ± 1.6 and 8.1 ± 1.1 kJ/mol for the silane and the trichlorosilane, respectively. These are higher than that for ethylbenzene and are attributed mainly to the stabilization of the perpendicular conformer, that with the C—Si bond in a plane perpendicular to the phenyl plane, by $\sigma-\pi$ conjugation (hyperconjugation) of the C—Si bond and the π electron system. Molecular orbital computations confirm the predominantly twofold nature of the internal barrier in benzyl silane and also for benzyl germane and stannane. The calculated barriers for the silane derivatives are rather higher than the experimental values. The computed barriers have magnitudes that appear to change with X in much the same order as do the hyperconjugative interactions deduced in other ways for $CH_2X(CH_3)_3$ groups (X = Sn, Ge, Si, C). The angles CCX in benzyl-X (X = CH_3, SiH_3, $SiCl_3$, GeH_3, SnH_3) are all computed to decrease smoothly as $\sin^2\psi$, where ψ is the angle by which the C—X bond twists out of the phenyl plane.

Key words: conformations, benzyl silane and trichlorosilane; NMR, benzyl silane and trichlorosilane; MO calculations, benzyl silane and trichlorosilane.

TED SCHAEFER, RUDY SEBASTIAN et GLENN H. PENNER. Can. J. Chem. **69**, 496 (1991).



On a analysé les spectres RMN du ^{1}H du benzyl silane et du benzyl trichlorosilane, déterminés en solutions dans le CS_2 ou dans le benzène-d_6. On a utilisé les constantes de couplage à longue distance entre les protons méthyléniques et les protons en *para* du cycle pour évaluer que les barrières binaires apparentes autour des liaisons Csp^2—Csp^3 sont respectivement 7,4 ± 1,6 et 8,1 ± 1,1 kJ/mol pour les dérivés silane et trichlorosilane. Ces valeurs sont plus élevées que celle obtenue avec l'éthylbenzène et on attribue principalement ces différences à la stabilisation de l'isomère perpendiculaire, celui dans lequel la liaison C—Si est maintenue dans un plan perpendiculaire au plan du noyau phényle par une conjugaison $\sigma-\pi$ (hyperconjugaison) de la liaison C—Si et du système électronique π. Des calculs d'orbitales moléculaires confirment la nature principalement binaire de la barrière interne dans le benzyl silane ainsi que dans les benzyl germane et stannane. Les barrières calculés pour les dérivés silanes sont sensiblement plus hautes que les valeurs expérimentales. La variation des amplitudes des barrières calculées pour les dérivés silanes avec X semble suivre l'ordre des interactions d'hyperconjugaison déduites sur d'autres bases pour les groupements $CH_2X(CH_3)_3$ (X = Sn, Ge, Si, C). Les calculs indiquent que les angles CCX, des benzyl-X (X = CH_3, SiH_3, $SiCl_3$, GeH_3 et SnH_3), doivent diminuer doucement comme le $\sin^2\psi$, où ψ est l'angle que fait la liaison C—X avec le plan du noyau phényle.

Mots clés: conformations, benzyl-silane et -trichlorosilane; RMN, benzyl-silane et -trichlorosilane; calculs MO, benzyl-silane et -trichlorosilane.

[Traduit par la rédaction]

Introduction

The stable conformer of ethylbenzene is **1** (X = CH_3) in which the exocyclic C—C bond lies in a plane perpendicular to the benzene plane (1). In solution (2–4), **1** is more stable than

1

the in-plane conformer (ψ = 0°) by 5–6 kJ/mol, with an outlier at 9.6 kJ/mol (5), attributable to $\sigma-\pi$ conjugation (hyperconjugation) of the C—C bond with the π electron system and also, more simply, partially to steric repulsion between the methyl group and the *ortho* C—H bond when ψ = 0° (6). In terms of perturbational molecular orbital theory, the relative stability of **1** arises from a two-orbital four-electron destabilizing interaction when ψ = 0° (7).

When X = $C(CH_3)_3$, the relative stability of **1** rises to more than 20 kJ/mol (8, 9), but drops (10) to about 10 kJ/mol when X is $Si(CH_3)_3$, $Ge(CH_3)_3$, or $Sn(CH_3)_3$, interpretable as a hyperconjugative stabilization (11, 12) of **1** because substitution by chlorine at the *ortho* positions changes the internal barrier by only a small amount. By way of contrast, such substitution in ethylbenzene leads to a very large increase in the stability of **1** (13).

As a further test of the hyperconjugative model we now report ^{1}H nmr data for benzyl silane and benzyl trichlorosilane. The former compound, lacking methyl substituents at silicon, should display even lower residual steric repulsions than in benzyl trimethylsilane for a ψ of 0°. Hence the barrier should be a good estimate of the hyperconjugative stabilization energy of **1** (X = SiH_3). The latter compound may provide a test of the influence of electronegative substituents on the hyperconjugative interaction of the C—Si bond. A derived barrier can then be compared with the type of evidence (12) provided by measurements of ^{13}C chemical shifts, for example. Furthermore, compounds of the type benzyl-XH_3 (S = C, Si, Ge, Sn) lend themselves to reasonably tractable molecular orbital computations. The ensuing conformational predictions can be compared to the available barrier measurements and may provide support for the hyperconjugative model. Such calculations are reported here for X = Si, Ge, Sn and turn out to be useful even though

[g] Including many degeneracies involving the silyl protons. The magnitudes of $^5J(H, SiH_3)$, $^6J(H, SiH_3)$, and $^7J(H, SiH_3)$ are estimated as 0.05(2), 0.02(2), and 0.03(2) Hz, respectively.
[h] Ring protons only.

the benzyl germane and stannane were not available to us for measurements of their ^{1}H nmr parameters.

Experimental

Benzyl trichlorosilane (Fluka) was reduced to the silane with $LiAlH_4$ in the normal way. Solutions of these compounds in CS_2/C_6D_{12}/TMS and C_6D_6/TMS solvent mixtures (Table 1) were filtered into 5 mm o.d. nmr sample tubes. These tubes were degassed by five cycles of the freeze–pump–thaw procedure and were then flame-sealed.

The ^{1}H nmr spectra were accumulated at a probe temperature of 300 K on a Bruker AM300 nmr spectrometer in a manner previously described in detail (14). The spectra of benzyl silane in the CS_2/C_6D_{12}/TMS mixture were rather tightly coupled, the chemical shifts of the ring protons extending over only 37.5 Hz and that between the *ortho* and *para* protons being 2.7 Hz. Small long-range coupling constants between the silyl and ring protons introduced further complications. In the event, the analyses of the spectra were not as precise as could be wished (Table 1). The trichloro derivative gave spectra more amenable to precise analysis.

Ab initio molecular orbital computations utilized an Amdahl 5870 system and the program GAUSSIAN 86 (15). Geometry-optimization procedures allowed all bond angles and lengths to vary, with the constraint, however, that the phenyl moiety remain planar.

Results and discussion

Spectral analyses

The ^{1}H nmr spectra were analyzed with the computer program NUMARIT (16), as extensively modified by R. Sebastian in this laboratory. The spectral parameters obtained in this way appear in Table 1.

The apparent twofold barriers to rotation about the Csp^2—Csp^3 bond

The apparent twofold barriers, V_2, to rotation about the Csp^2—Csp^3 bond are obtainable via the relationship (17, 18) $^6J(H,CH_2) = {}^6J_{90} < \sin^2\theta >$. Here $^6J_{90}$ is the value of the coupling constant for $\theta = 90°$ in **1**, while $<\sin^2\theta>$ is the expectation value determined by the magnitude of V_2, as found from a hindered rotor model or by a classical averaging procedure. In toluene, $^6J_{90}$ is −1.20 Hz (14) and arises from a σ–π coupling mechanism. An α substituent more electronegative than hydrogen reduces σ–π overlap between the α C—H bonds and the π system, causing a reduction in the magnitude of $^6J_{90}$. Thus, in ethylbenzene, $^6J_{90}$ is very likely −1.16 Hz (2) and is −1.02 Hz when X is a methoxy group (19, 20). If the substituent is less electronegative than hydrogen, the magnitude of $^6J_{90}$ is expected to be greater than in toluene and is supported by our INDO MO FPT (21, 22) computations on benzyl silane. These have the maximum magnitude[3] of $^6J_{90}$ as −1.34 Hz, as compared to −1.22 Hz for toluene (17). Another estimate of $^6J_{90}$ for benzyl silane may be had from the general recent agreement that the $Si(CH_3)_3$ and SiH_3 groups are less electronegative than hydrogen (23–25). A lower limit to the magnitude of $^6J_{90}$ is then the −1.20 Hz for toluene. A previous estimate of $^6J_{90}$ for benzyl trimethylsilane is −1.26 Hz (10).

[3] The minimum magnitude lies within 0.01 Hz of that computed for toluene (17); an experimental investigation of the magnitude of ^6J at $\theta = 0$ is available (47).

[a]In kJ/mol.
[b]The 6-31 G computations done only for $\psi = 0°$, 45°, and 90°. At $\psi = 0°$, the C—X bond lies in the benzene plane.
[c]For $\psi = 0$, 30, 60, 90°, only.
[d]In au.

$^6J_{90}$ for benzyl silane is probably taken safely as -1.27 ± 0.07 Hz, spanning the value for toluene and the INDO value above. Because $^6J(H,CH_2)$ for the CS_2/C_6D_{12} solution of benzyl silane is −0.448(1) Hz, $<\sin^2\theta>$ follows as 0.353 ± 0.020 and V_2 as $7.4^{+1.7}_{-1.4}$ kJ/mol.

Turning to benzyl trichlorosilane, one recent estimate (26) has the $SiCl_3$ group as 0.1 of a Pauling unit less electronegative than hydrogen, whereas another finds the $SiCl_3$ group as 0.5 units more electronegative than the methyl group (27), for which $^6J_{90}$ appears to be −1.16 Hz (2). It seems safe to take $^6J_{90}$ as -1.16 ± 0.04 Hz for benzyl trichlorosilane, as spanning the range of values indicated by the disparate electronegativity values. Because $^6J(H,CH_2)$ is −0.40 1 (1) Hz (Table 1), $<\sin^2\theta>$ follows as 0.346 ± 0.012 at 300 K. The apparent V_2 is then 8.1 ± 1.1 kJ/mol.

To within experimental error, these apparent twofold barriers are the same as those deduced for benzyl trimethysilane (10). It has been suggested that, for analogous tin compounds, methyl substituents should increase, and chlorine substituents decrease, the extent of hyperconjugation (12). The accuracy of our V_2 estimates is insufficient to confirm such trends for the silicon compounds. Furthermore, small steric contributions to the internal barriers for the methyl and chloro derivatives cannot be excluded (10).

However, the purely hyperconjugative contribution to the barrier should be twofold, the $\sigma-\pi$ conjugation varying as $\sin^2\psi$ (see **1**). Accordingly, molecular orbital computations become of interest and are reported here for benzyl-XH_3 (X = Si, Ge, Sn). These can be compared with the available computations for X = C (2).

Theoretical barriers

The theoretical barriers are reported in Table 2, the relative energies computed at various ψ values being fit to internal potentials as displayed. The striking results are two. First, the twofold barrier is much larger for benzyl silane, germane, and stannane than for ethylbenzene. Second, the fourfold is a much smaller fraction of the twofold component for the former compounds. In ethylbenzene the fourfold component has been attributed to specific steric interactions involving the C—H bonds of the methyl group and those *ortho* to the substituent (2). As the Csp^2—Csp^3 bond is artificially lengthened (2), the fourfold becomes smaller relative to the twofold component. In this interpretation, the decreased importance of the fourfold component of the internal rotational barrier for the silane, germane, and stannane is a consequence of lower short-range repulsive interactions when ψ is 0° in **1**. The large twofold component for these compounds is then evidence for $\sigma-\pi$ conjugation of the C—X bond with the π orbitals of the ring, being a maximum at $\psi = 90°$ and behaving as $\sin^2\psi$, that is, in a twofold manner; this conjugation is also appreciably larger for Si, Ge, Sn than for X = C. The computed twofold components of the internal barrier, using the minimal basis set, decrease in magnitude in the order Sn > Si > Ge > C (Table 2) for benzyl-XH_3, noting also that those for Si and Ge differ by only 0.6 kJ/mol. This order is very similar to that (11) deduced for σ or $\sigma-\pi$ resonance interactions of $CH_2X(CH_3)_3$ groups, which is Sn > Ge ~ Si > C.

The theoretical, mainly twofold, barriers for X = SiH_3 and $SiCl_3$ are rather larger than those deduced from $^6J(H,CH_2)$. Whether this arises from an inadequacy in the size of the employed basis sets, which is possible, or from a solvent effect on the barrier cannot be decided at present. For the similarly nonpolar ethylbenzene the internal barrier is solvent independent in the sense that it is the same in CCl_4, CS_2, acetone-d_6, and in perfluoromethylcyclohexane (2), and very little different from the mean of various magnitudes deduced from experiments on the vapor (28–30). Because benzene, in its influence on the conformational stabilities of solute molecules, behaves as a much more polar solvent than indicated by its dielectric constant (31), the data in Table 1 imply a small or negligible solvent dependence of the internal barriers in benzyl silane and benzyl trichlorosilane. At present, the experimental and theoretical data are qualitatively consistent with a predominantly twofold barrier in benzyl silane arising from a hyperconjugative stabilization of the perpendicular conformer.

Remarks on benzyl trichlorosilane

According to the ^{13}C nmr chemical shifts of the aromatic carbon atoms in benzyl stannane derivatives (12), the extent of $\sigma-\pi$ conjugation decreases as methyl groups are replaced by chlorine atoms at tin. A similar course of events might be expected for benzyl silane and benzyl trichlorosilane. Yet the internal barriers are effectively equal for the two compounds.

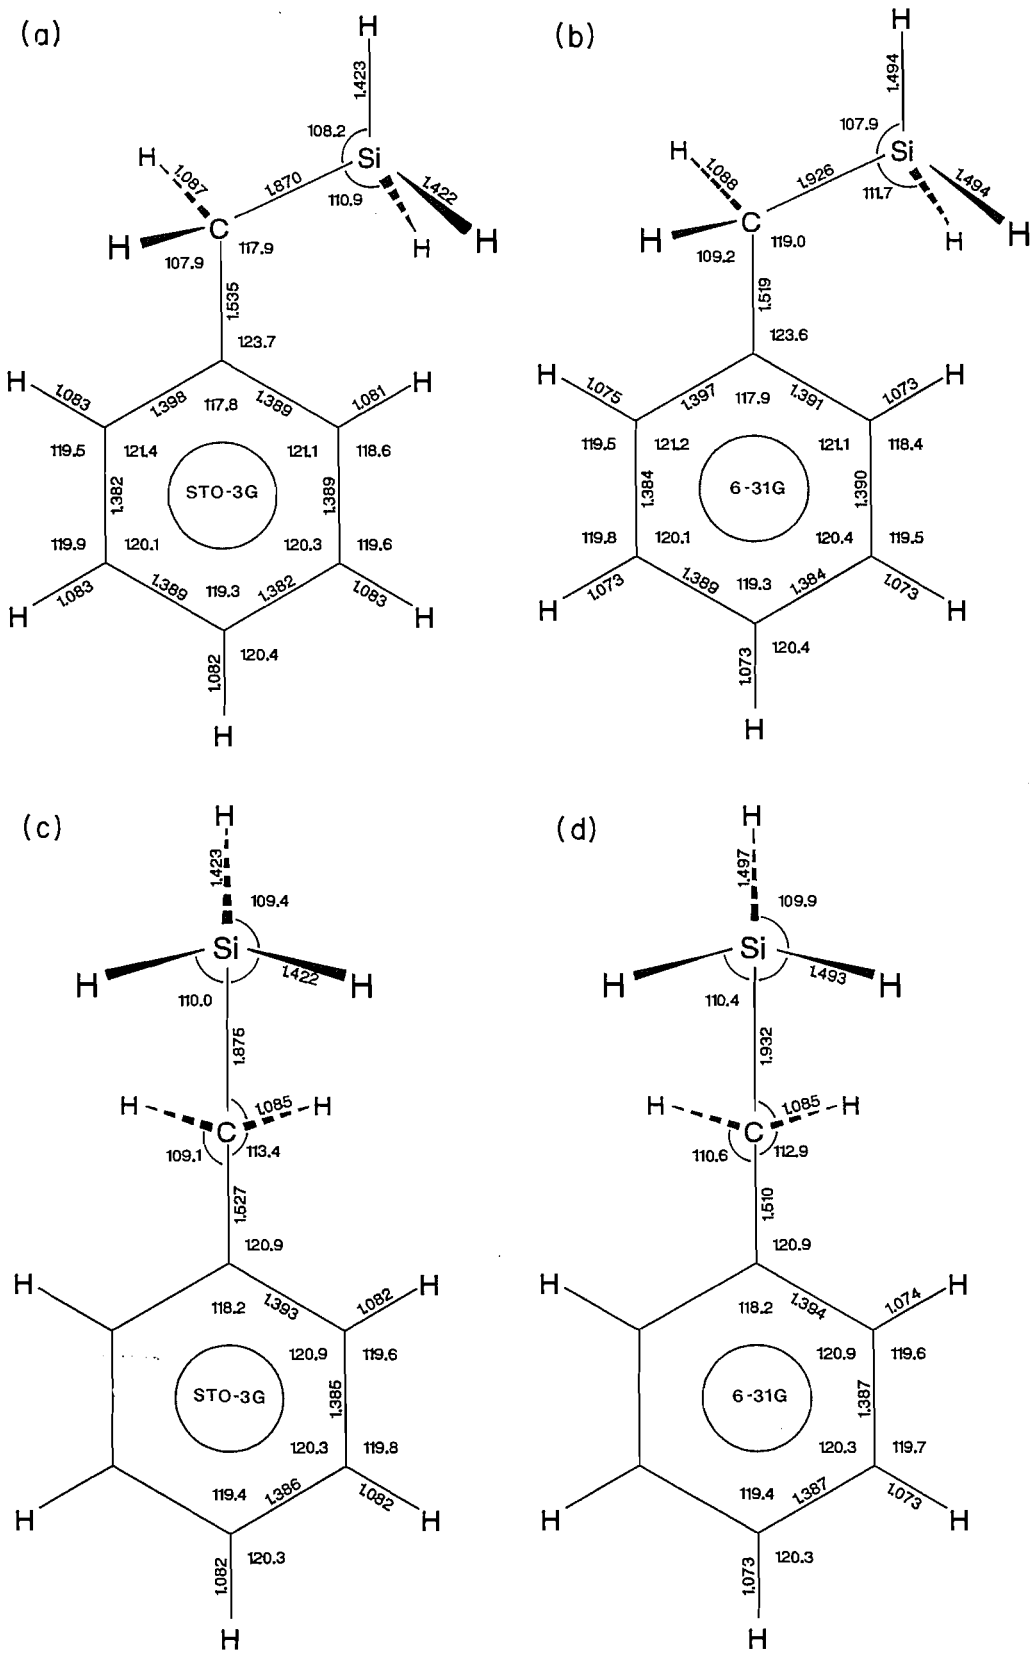

FIG. 1. The structures of the conformations of lowest and highest energies for benzyl silane are shown as computed with the minimal, and with the split-valence, 6-31G basis sets. The computed bond angles within the phenyl group are very close to those predicted (38, 39) from substituent parameters as given for a methyl substituent and determined mainly from X-ray diffraction. The C—Si bond length at the STO-3G level of theory is very close to that of 1.867 Å in methylsilane (40–42), as is the CSiH angle. However, the Si—H bond length in methylsilane is 1.484 Å, so that the STO-3G basis underestimates this length rather badly, whereas it is better reproduced by the split-valence basis set. General comparisons of the performances of the various basis sets can be found in ref. 43, particularly Tables 6.6 and 6.10. The Csp^2—Csp^3 bond length is better found with the larger basis.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

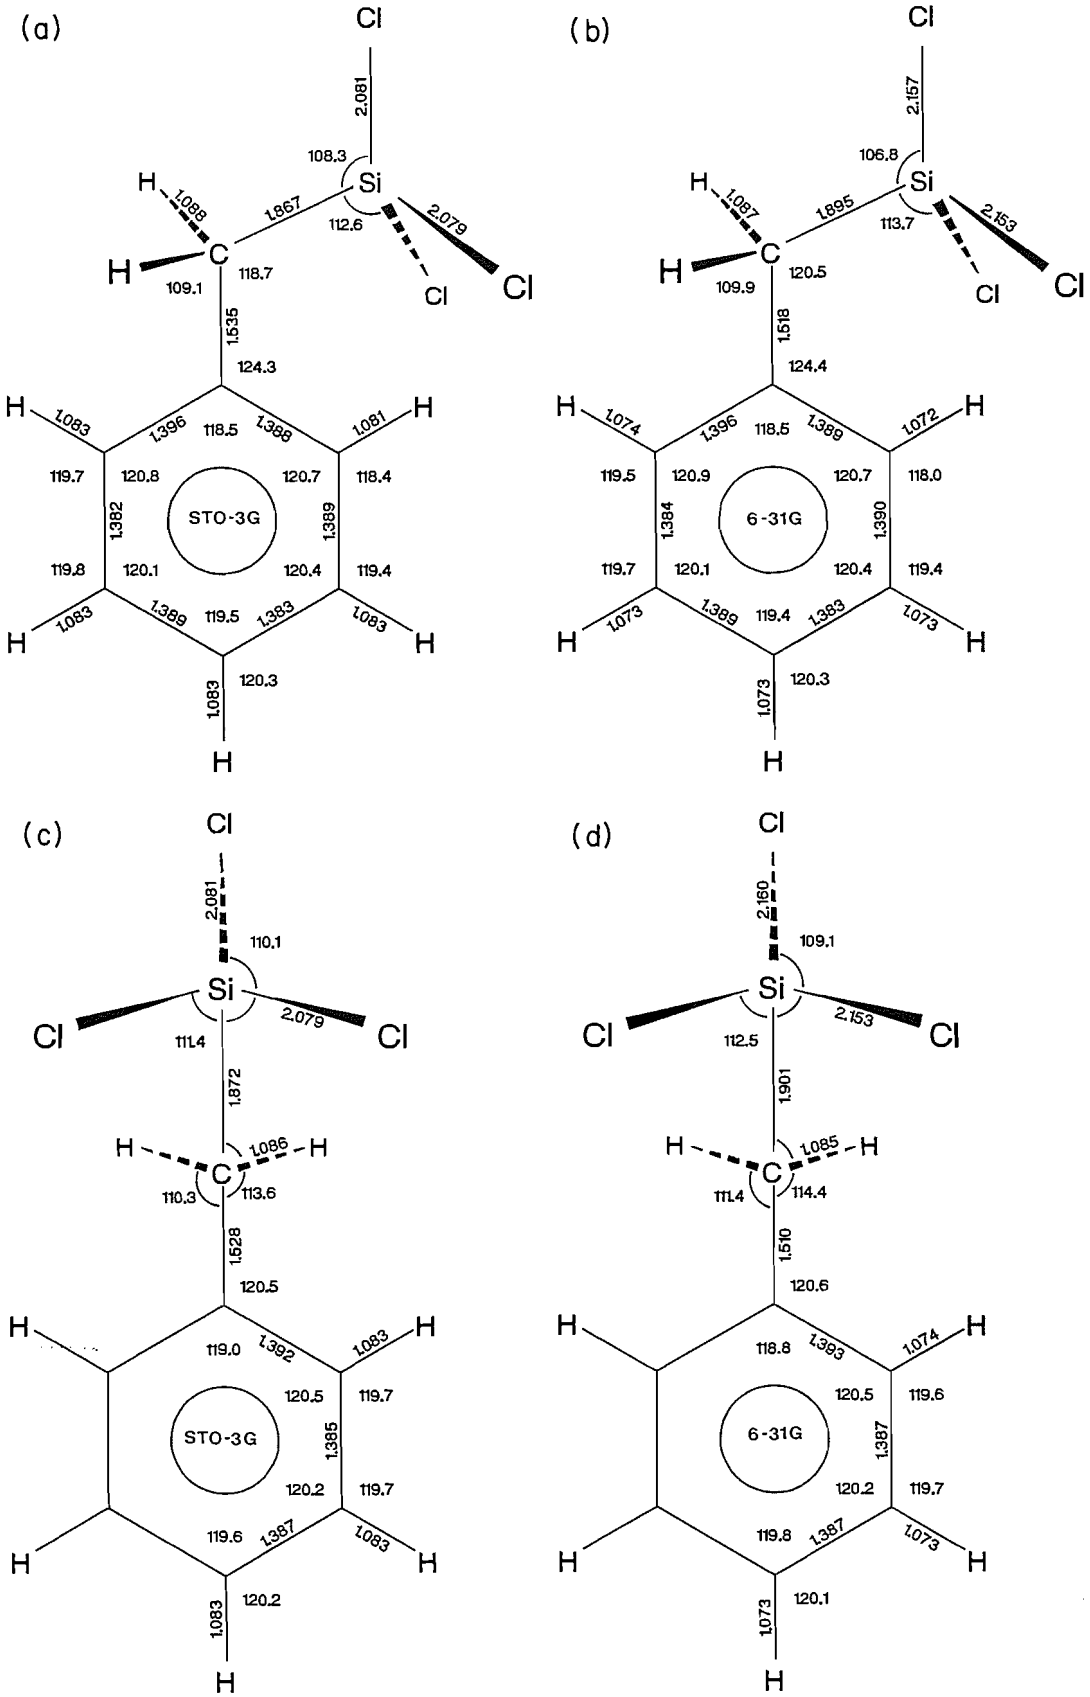

FIG. 2. The structures of the low and high energy conformations of benzyl trichlorosilane are given. Judging by CH_3SiCl_3 (44) and ref. 45, both basis sets overestimate the Si—Cl bond length, the minimal by as much as 0.05 Å. The Si—C bond length in the methyl compound is 1.876(30) Å. From data in ref. 45, the 6-31G basis appears to overestimate this length considerably. These structures can serve as a starting point for computation with larger basis. It does not follow (46) that the larger basis sets will yield more reliable internal barriers.

Two possibilities present themselves. First, chlorine atoms being larger than hydrogen atoms, a decrease in the hyperconjugative barrier is being compensated by a steric destabilization of the in-plane conformation. However, the internal barriers in benzyl silane and benzyl trimethylsilane (10) are also equal to within experimental error. There are conflicting estimates in the literature concerning the steric sizes of chlorine atoms and methyl groups (32, 33), so that this possibility is moot. Second, it is not at all clear that electron transfer to, or, at least, polarization of, the π electron system of the phenyl group by $\sigma-\pi$ conjugation should be a measure of the size of the internal barrier[4] to rotation about the Csp^2—Csp^3 bond. Thus, for benzyl-X in CS_2 solution, the chemical shift or δ value of the *para* proton is 7.006 (H), 7.019 (CH_3), 6.980 (SiH_3), 7.131 ($SiCl_3$), 7.201 (Cl), and 7.231 (F), while benzene has a δ value of 7.218 (12, 14, 34, 35). These δ values are not simply related to the barriers in these compounds; rather, they more likely are roughly proportional to the electronegativity of X.

The molecular orbital computations (Table 2) with both the minimal and the 6-31G bases imply a larger twofold barrier in the trichlorosilane than in the silane, the former by about 1 kJ/mol, the latter by 2.6 kJ/mol. These *increases* are compatible with the experimental data in solution, perhaps because of the relatively large errors in the latter. At these levels of molecular orbital theory, therefore, the hyperconjugative barriers are not proportional to electron donation to, or rearrangement of the electron densities of, the aromatic ring by the substituents.

Additional considerations

A recent measurement (36) of the free energy of activation for the rotation about the Csp^2—Csp^3 bond in a derivative of $C_6H_5CH(Si(CH_3)_3)_2$ gives a value some 30 kJ/mol lower than that (37) for $C_6H_5CH(C(CH_3)_3)_2$; the lower value is attributed to smaller steric interactions as a consequence of the difference in the C—Si and C—C bond lengths. These results are indirect evidence for the hyperconjugative model of the internal barrier in the title compounds. They are consistent with the measured increase in the barrier to internal rotation in benzyl silane relative to ethyl benzene in the sense that purely steric forces should cause a lower barrier in the silane derivative.

It is interesting, therefore, to compare the theoretical equilibrium structures of the low and high energy conformations of benzyl silane and also of benzyl trichlorosilane. Figure 1 gives the STO-3G and 6-31G structures for benzyl trichlorosilane. The figure captions discuss the reliability of the computed bond lengths involving the silicon atom. Here certain bond angles in the side chain are to be discussed.

The striking bond angles in the conformation of high energy (the silicon atom lies in the benzene plane) are C(2)C(1)C(α) and CCSi, the former being near 124° and the latter as large as 119° in benzyl silane for the larger basis set. In the perpendicular, most stable, conformation the former angle approaches 120°, as expected given the local geometry at C(1), and the latter contracts markedly. These changes are intuitively those expected on the basis of steric repulsions in the planar conformer. In the trichlorosilane, however, the corresponding angles, although somewhat larger, have not increased as much as might be anticipated on the basis of the large chlorine atoms (compare Figs. 1 and 2 for a given basis). Comparison of the CCX angles (X = CH_3, SiH_3, $SiCl_3$, GeH_3, SnH_3), for the seven different ψ values, in the STO-3G computations, reveals that their changes are proportional to $\sin^2\psi$. The CCX angle is given by $A + B\sin^2\psi$, as shown, numbers in parentheses being the standard errors in the fit to seven values of ψ. Note (Table 2) that this dependence on $\sin^2\psi$ holds whatever the relative importance of the various terms in the internal rotational potential. The stabilization of the perpendicular conformer by $\sigma-\pi$ interactions (hyperconjugation) is proportional to $\sin^2\psi$, so that the present relationship is indirect evidence for this phenomenon. Furthermore, for ethylbenzene, the perturbational molecular orbital analysis of Wolfe and co-workers (7), attributing the barrier to a repulsive four-electron, two-orbital interaction for the planar conformer, may be accommodated by the assumption that this interaction decreases as $\sin^2\psi$. The larger deformations in the planar conformers for X = Si, Ge, Sn are not necessarily indicative of larger steric repulsions; their values will depend on the force constants in question, which are not known.

X	A/deg	B/deg
CH_3	116.07(8)	−3.78(12)
$SiCH_3$	118.26(8)	−4.67(12)
$SiCl_3$	118.62(6)	−4.97(10)
$GeCl_3$	118.50(7)	−4.62(12)
SnH_3	119.25(1)	−4.84(2)

In summary, the present experimental and theoretical data, together with the experiments on benzyl trimethyl-X (X = Si, Ge, Sn, Pb) and their 2,6-dichloro derivatives (10), are consistent with a hyperconjugative model for the internal rotational barriers, at least when X = Si, Ge, Sn.

2-Phenyladamantane as a model for axial phenylcyclohexane. ^{1}H NMR and molecular orbital studies of motion about the Csp^2—Csp^3 bond

TED SCHAEFER,[1] CHRISTIAN BEAULIEU,[2] AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2
Received September 4, 1990

The ^{1}H NMR spectra of the aromatic groups of 2-phenylcyclohexane and 2-phenyladamantane, in CS_2/C_6D_{12} solution at 300 K, are analyzed to yield the long-range coupling constants between the α and ring protons. The coupling over six bonds is related to the internal rotational potential about the Csp^2—Csp^3 bond in these molecules. It is confirmed that the equatorial isomer of phenylcyclohexane has the parallel conformer, that in which the aromatic plane lies in the symmetry plane bisecting the cyclohexane moiety, as the most stable. The apparent twofold barrier to rotation about the exocyclic carbon–carbon bond follows as 7.1 kJ/mol from the six-bond coupling constant. For 2-phenyladamantane, the six-bond coupling constant strongly implies that the perpendicular conformer, perhaps slightly skewed, is that of lowest energy and that the apparent twofold barrier to rotation about the Csp^2—Csp^3 bond is about 7.5 kJ/mol. Insofar as 2-phenyladamantane mimics axial phenylcyclohexane, these results confirm recent conclusions about the conformation of the latter and provide evidence for its internal mobility. Geometry-optimized AM1 and STO-3G MO computations are reported for the internal motion in both isomers of phenylcyclohexane. The former agree best with experiment for the equatorial isomer, but both imply a significant fourfold, of opposite sign to the twofold, component of the internal rotational potential. For the axial isomer, the two sets of computations find a skewed perpendicular conformer as most stable, in rough agreement with force-field results. However, the barrier to rotation about the Csp^2—Csp^3 bond is computed as small and AM1 has the parallel conformer as more stable than the perpendicular.

Key words: 2-phenyladamantane, ^{1}H NMR and internal rotation; phenylcyclohexane, ^{1}H NMR and internal rotation; MO computations, 2-phenyladamantane and phenylcyclohexane.

TED SCHAEFER, CHRISTIAN BEAULIEU et RUDY SEBASTIAN. Can. J. Chem. **69**, 503 (1991).

Afin d'obtenir les constantes de couplage à longue distance entre les protons α et ceux du cycle, on a analysé les spectres RMN du ^{1}H des groupements aromatiques du 2-phénylcyclohexane et du 2-phényladamantane, en solution dans du CS_2/C_6D_{12}, à 300 K. Le couplage à travers six liaisons est lié au potentiel de la rotation interne autour de la liaison Csp^2—Csp^3 de ces molécules. On confirme que l'isomère équatorial le plus stable du phénylcyclohexane est le conformère parallèle, celui dans lequel le plan du noyau aromatique se trouve dans le plan de symétrie bissecteur de la portion cyclohexanique. Sur la base de la constante de couplage à travers six liaisons, il ressort que la barrière binaire apparente à la rotation autour de la liaison carbone–carbone exocyclique est de 7,1 kJ/mol. Pour le 2-phényladamantane, la constante de couplage à travers six liaisons suggère fortement que le conformère perpendiculaire, possiblement un peu décalé, est le plus stable et que la barrière binaire apparente à la rotation autour de la liaison Csp^2—Csp^3 est d'environ 7,3 kJ/mol. En autant que le 2-phényladamantane imite bien le phénylcyclohexane axial, ces résultats confirment les conclusions récentes concernant la conformation de ce dernier et ils fournissent de nouvelles données concernant sa mobilité interne. On rapporte des calculs d'OM AM1 et STO-3G, réalisées sur des molécules dont la géométrie a été optimisée, relatifs au mouvement interne dans les deux isomères du phénylcyclohexane. Les premiers donnent le meilleur accord avec les données expérimentales concernant l'isomère équatorial; toutefois, les deux suggèrent une composante quaternaire importante, de signe opposé à celui de la composante binaire du potentiel de rotation interne. Dans le cas de l'isomère axial, les deux ensembles de calculs suggèrent que le conformère perpendiculaire décalé est le plus stable; ces conclusions se rapprochent des résultats obtenus avec les champs de force. Toutefois, ces calculs indiquent que la barrière à la rotation autour de la liaison Csp^2—Csp^3 est faible; de plus, les calculs AM1 donnent le conformère parallèle comme plus stable que le conformère perpendiculaire.

Mots clés : 2-phényladamantane, RMN du ^{1}H et rotation interne; phénylcyclohexane, RMN du ^{1}H et rotation interne; calculs d'OM, 2-phényladamantane et 2-phénylcyclohexane.

[Traduit par la rédaction]

Introduction

The free energy difference between equatorial, **1** and **2**, and axial, **3** and **4**, phenylcyclohexane is an old and famous problem (1). Recently (1), Squillacote and Neth used a cryogenic trapping technique to show that the equatorial conformer is favored by 11.3 ± 1.1 kJ in free energy in propane-d_8 solution, thereby narrowing considerably the uncertainty in this quantity. Furthermore, the entropy difference between the axial and equatorial forms must be small because the free energy difference changes very little over a range of 800 K.

Squillacote and Neth also use the nuclear Overhauser effect (incoherent transfer of magnetization) in a demonstration that **4**, the perpendicular conformer of axial phenylcyclohexane, is more stable than the parallel conformer, **3**, in solution. In equatorial phenylcyclohexane it is the parallel conformer, with a (bisected) low energy structure analogous to that of isopropylbenzene (2), which is most stable. For 3,5-dichlorophenylcyclohexane the *apparent* twofold barrier to rotation about the Csp^2—Csp^3 bond in benzene-d_6 solution was assessed (3) at 8.4 ± 1.3 kJ/mol on the basis of the conformational dependence of ^6J(H, CH), the σ–π spin–spin coupling constant over six bonds between the α proton in the methine C—H bond and the *para* ring proton. Long-range coupling constants of this kind are generally about 1 Hz in magnitude and would be difficult, perhaps impossible, to extract for axial phenylcyclohexane at −160°C, the temperature at which the trapped molecule is not converting rapidly to the equatorial form, simply because the effective T_2 is too small to allow the requisite narrow ^{1}H NMR peaks. However, it was suggested to us by Craig Takeuchi that

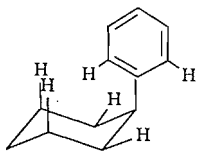
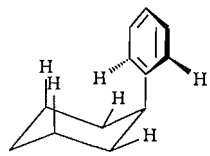
2-phenyladamantane, **5** and **6**, may well serve as a model of axial phenylcyclohexane at ambient temperatures, where high resolution ^{1}H NMR spectra should be reasonably accessible.[3]

Such spectra are reported here for a CS_2 solution. Their analysis yields long-range coupling constants which confirm that the parallel conformation, **5**, is not favored, and which yield an approximate barrier to rotation about the Csp^2—Csp^3 bond. A similar treatment is accorded the ^{1}H NMR spectrum of (equatorial) phenylcyclohexane.



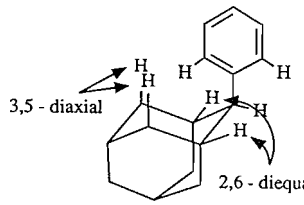
equatorial - parallel

1



equatorial - perpendicular

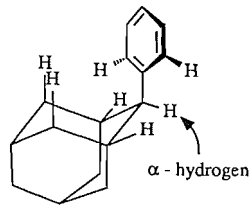
2



axial - parallel

3

axial - perpendicular



4

3,5 - diaxial

2,6 - diequatorial

5

α - hydrogen

6

In addition, semiempirical AM1 and *ab initio* STO-3G MO computations are reported for the two forms of phenylcyclohexane. The results may be compared with molecular mechanics calculations of conformer stabilities in the literature.

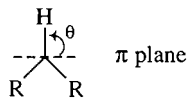
Experimental

The 2-phenyladamantane was prepared by treatment of 2-phenyladamantanone (Aldrich) with C_6H_5MgBr to yield 2-hydroxy-2-phenyladamantane. The latter was reduced to the hydrocarbon with H_2/Pd (charcoal) followed by purification on a silica gel column with hexane as eluent. The yield was poor and this synthesis is not recommended. A later synthesis involved the reduction of the alcohol using the $NaBH_4/CF_3SO_3H$ procedure (4) and gave much better yields.[4] The 2-phenyladamantane gave satisfactory mass, ^{1}H NMR, and ^{13}C NMR (5, 6) spectra.

Solutions of 2-phenyladamantane and phenylcyclohexane (Aldrich), in a CS_2/C_6D_{12}/TMS solvent mixture (see Table 1 for details), were transferred to 5-mm o.d. NMR tubes, were degassed by five freeze–pump–thaw cycles, and the tubes were then flame-sealed under vacuum.

^{1}H NMR spectra were accumulated on a Bruker AM300 spectrometer in a manner described previously (7) and had a digital resolution of 0.12 Hz/point with an acquisition time of 42 s. Those ring protons not coupled appreciably to β-protons give peak widths of about 0.07 Hz. As can be seen in Fig. 1, the *ortho* protons couple by about 0.18 Hz to the β-protons (equatorial 2,6-protons in **5**) in 2-phenyladamantane. The latter resonate at 2.42 ppm (see ref. 1 for their assignment in axial phenylcyclohexane) and were decoupled from the ring protons in the spectrum subjected to spectral analysis. In phenylcyclohexane the corresponding coupling constant is much smaller, rather as in isopropylbenzene (2).

The AM1 (8) and STO-3G (9) molecular orbital computations used the program GAUSSIAN 86 (10). All bond angles and lengths were optimized at each angle of rotation about the Csp^2—Csp^3 bond in axial and equatorial phenylcyclohexane; the nuclei of the phenyl group, however, were constrained to a plane.



Results and discussion

Spectral analyses

The ^{1}H NMR spectra of the aromatic protons were analyzed with the computer program NUMARIT (11), extensively altered and improved by R. Sebastian. The spectral parameters appear in Table 1. In Fig. 1 the *ortho* region yields broad peaks, some with triplet structure, attributable to coupling constants involving the β-alkyl protons with δ = 2.42. Decoupling procedures caused considerably sharper *ortho* proton peaks, which, however, displayed a greater width than those from *meta* or *para* proton peaks. This residual width, if not due to short spin-lattice relaxation times, may well arise from unresolved coupling constants with the 3,5-axial protons in **5** or **6** because motion about the Csp^2—Csp^3 bond entails occasional short distances between the hydrogen atoms carrying the protons in question. However, the 3,5-proton peaks could not be assigned, leaving the matter uncertain.

Internal motion in equatorial phenylcyclohexane

The coupling constant over six formal bonds, ^6J_p(H, CH) ≡ ^6J, is proportional to $\sin^2\theta$, where the torsion angle, θ, is illustrated in **7** (2, 7, 12); the available evidence (13) is that ^6J

1

effectively vanishes when θ is zero. Furthermore, $^6J_{90}$ is somewhat dependent on the electronegativity of the α-substituents, experimental assessments (14, 15) of this dependence being available. For isopropylbenzene, $^6J_{90}$ is −1.12 Hz (2). Therefore a measurement of ^6J yields an expectations value of $\sin^2\theta$, which can be related to the barrier to rotation about the Csp^2—Csp^3 bond by a hindered rotor model (12) or by a classical averaging procedure; at ambient temperatures for the barrier magnitudes and reduced moments of inertia of many benzene derivatives these two procedures yield essentially the same barrier magnitudes. The measured ^6J is usually an immediate marker of the conformation of lowest energy.

Thus, for phenylcyclohexane (Table 1), ^6J is −0.243 (4) Hz and, with $^6J_{90}$ as −1.12 Hz, $\langle\sin^2\theta\rangle$ follows as 0.217 (4). Were the barrier very high and were the perpendicular form, **2** with θ = 90°, of low energy, $\langle\sin^2\theta\rangle$ would be near unity. Were the barrier high but with the parallel form of low energy, **1** with θ = 0°, $\langle\sin^2\theta\rangle$ would approach zero. For a vanishing barrier, with **1** and **2** then being two of an infinite number of isoenergetic conformations, $\langle\sin^2\theta\rangle$ would be 0.5. Clearly, the value of 0.217 (4) implies a finite barrier with **1** as the conformation of low energy, just as for isopropylbenzene (2). An apparent

[3]In **5**, the numbering of the alkyl protons conforms to that in phenylcyclohexane, facilitating an unambiguous later discussion; of course, the phenyl group is attached at position 2 in adamantane.

[4]We thank George A. Doss (Ashraf Abdel-Sayed) for advice concerning a third method of synthesis, a Friedel–Crafts reaction of 2-bromoadamantane with benzene.

TABLE 1. The ^{1}H NMR spectral parameters of the aromatic protons of phenylcyclohexane, **1**, and 2-phenyladamantane, **6**, in CS_2/C_6D_{12} solution at 300 K

Parameter	**1**[a]	**6**[b,f]	Parameter	**1**[a]	**6**[b,f]

[a]For a 4.0 mol% solution in CS_2, containing also 10 mol% of C_6D_{12} and 0.5 mol of TMS.
[b]For a ca. 1 mol% solution in the CS_2/C_6D_{12}/TMS mixture.
[c]These shifts of the α C—H proton are not optimized, the resonance consisting of a myriad of overlapping peaks.
[d]In Hz at 300.135$_2$ MHz to low frequency of internal TMS.
[e]Numbers in parentheses are the standard deviations of the last significant figure.
[f]The analysis for **6** pertains to a spectrum obtained while decoupling the equatorial 2,6 protons (see **5** in the text); these couple to the *ortho* protons of the phenyl group by ±0.18 Hz (see also the caption to Fig. 1).

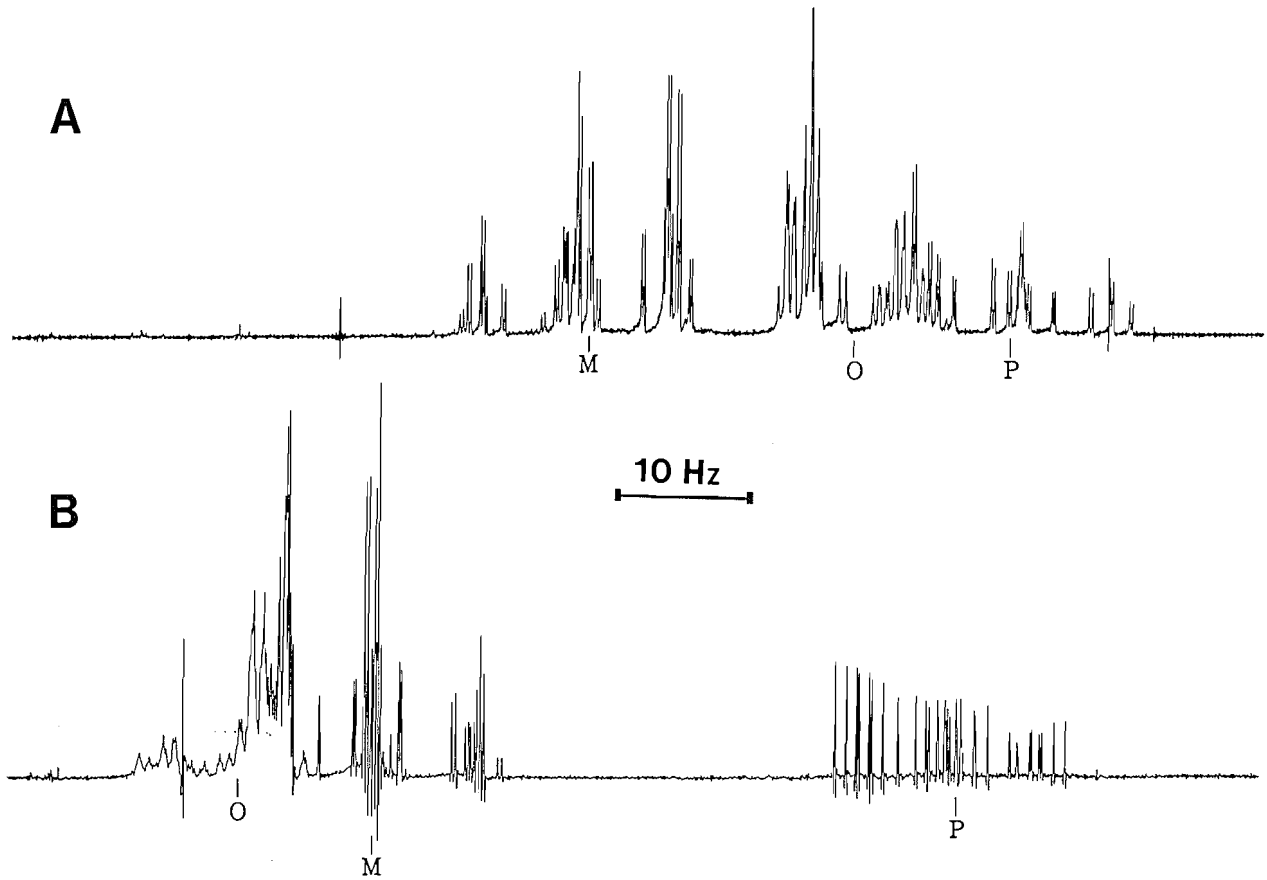

FIG. 1. In A, the ^{1}H NMR spectrum of the phenyl group of a 4 mol% solution of phenylcyclohexane is displayed at 300 Mz and 300 K. The chemical shift positions, obtained from the spectral analysis detailed in Table 1, are indicated. The analogous ^{1}H NMR spectrum for a very dilute solution of 2-phenyladamantane is shown in B. The large relative descreening of the *ortho* protons is similar to that found for axial phenylcyclohexane at 113 K (1). These protons are coupled to the neighbouring β alkyl protons by 0.18 Hz, as deduced from decoupling experiments described in the text. The analysis of the ^{1}H NMR spectrum to yield the parameters in Table 1 used the one in which the β-alkyl protons were decoupled.

twofold barrier, V_2, follows as 7.1 kJ/mol. Were $^6J_{90}$ equal to −1.20 Hz, as in toluene (7), then the apparent V_2 would rise to 7.6 kJ.

The presence of a significant fourfold component will alter the barrier magnitude. This possibility is discussed below in connection with molecular orbital computations of the barrier profile.

Internal motion in 2-phenyladamantane

^6J is −0.889 (5) Hz in 2-phenyladamantane. The discussion

in the previous section allows the immediate conclusion that the parallel conformer, **5**, cannot be that of low energy because a rigid **5** would have a vanishing ^6J. If perpendicular **6** has the lowest energy, then the apparent V_2 is 7.5 (1) kJ/mol because $\langle\sin^2\theta\rangle$ is 0.794 (4) at 300 K. This indication, that the internal barriers in equatorial phenylcyclohexane and 2-phenyladamantane are equal, recalls the fact (1) that the entropies of the axial and equatorial forms of phenylcyclohexane are also the same.

An alternative interpretation of ^6J takes a skewed **6** as the conformation of lowest energy. Suppose, as suggested by the computations described below, that a θ near 60° defines the low energy form, the one in which the C(1)—C(2) bond eclipses the C(α)—C(β) bond of the alicyclic group. If this conformer is rigid, then $\langle\sin^2\theta\rangle$ is 0.75 and ^6J follows, in principle, as (−1.12) (0.75) or −0.84 Hz. If motion towards **6** costs less energy than that towards **5**, as would be expected, then $\langle\sin^2\theta\rangle$ would increase somewhat from 0.75, causing a larger magnitude of ^6J, perhaps as large as the measured 0.89 Hz. This interpretation is compatible only with a relatively large barrier to rotation about the Csp^2—Csp^3 bond in 2-phenyladamantane, perhaps in the vicinity of 25 kJ/mol, and, intuitively, appears unlikely but not impossible. To reach **5** does entail a rather close approach of the *ortho* and 3,5-protons.

Of course, 2-phenyladamantane and axial phenylcyclohexane are different molecules. Yet, insofar as the phenyl group in the latter appears (1) to induce geometric distortion of the cyclohexane ring only at the site of attachment, 2-phenyladamantane may provide a reasonable model of the motion of the phenyl group in the cyclohexane derivative. Note also that the order of the chemical shifts (Fig. 1) of the aromatic protons in 2-phenyladamantane is the same as that of axial phenylcyclohexane (1). Furthermore, Squillacote and Neth (1) report that the *ortho* protons in the latter are deshielded by 0.2 ppm relative to their shielding in the equatorial isomer. Table 1 reports a deshielding of 0.160 ppm for the *ortho* protons of the adamantane relative to the cyclohexane derivative. The shift to high frequency is attributed (1) to steric hindrance of the *ortho* by the 2,6 hydrogen atoms, so that **6** and **4** are probably very similar in their internal motional behaviour.[5] Consistent with this statement is the observation that the 2,6-protons of **6** and **4** are both shifted to higher frequencies, in such a way as to isolate their peaks from those of the other alkyl protons, presumably due to steric interactions with *ortho* aromatic hydrogen atoms. In axial cyclohexane at 113 K in propane-d_8, the α-protons are screened less by ca. 0.7 ppm than they are in the equatorial isomer (1). At 184 K, in a 50 vol% solution of $C_6D_{11}H$, the corresponding number is 0.478 (2) ppm (16), whereas at 300 K, for dilute solutions in CS_2/D_6D_{12}, the α-proton of 2-phenyladamantane is deshielded by 0.530 ppm relative to that in equatorial phenylcyclohexane. Given that torsional excursions of the phenyl group about the Csp^2—Csp^3 bond will be of significantly larger amplitude at 300 K than at 113 K, thereby averaging a number of shift values for the α-proton, and that the β-sites are different, this shift is consistent with similar ground state phenyl conformations in the axial adamantane and cyclohexane derivatives.

The existence of a ^5J(H,H) of ±0.18 Hz between the *ortho* and 2,6-protons in 2-phenyladamantane is again evidence for a close approach of the C—H bonds carrying the coupled nuclei in **6**. There is little doubt that this is a proximate (17–21) coupling constant, mediated by overlap of the orbitals on the hydrogen atoms of the β and *ortho* C—H bonds. In a standard model of 2-phenyladamantane, the coupled nuclei are separated by a little less than 2.2 Å in the perpendicular conformer, just as required for a proximate coupling mechanism. The residual extra width of the *ortho* proton peaks in **6** after the decoupling of the 2,6-protons (see experimental) may well be due to a small coupling interaction with the 3,5-protons. In the standard parallel conformation, the internuclear distance would be ca. 1.6 Å, implying a large coupling constant and also, of course, a large repulsion between the hydrogen atoms. The population of this conformer is therefore indicated as small, in line with the nOe studies (1) on axial phenylcyclohexane at 113 K.

The axial isomers are unstable because of steric repulsions even in the perpendicular conformation of the phenyl group. The indication, from ^6J, that the freedom of motion about the exocyclic C—C bond is much the same as in the equatorial isomer implies that the strongly repulsive *ortho*–3,5 interactions in the parallel conformers, **3** and **5**, raise the energy of the axial isomers by roughly the same amount as the repulsive 2,6–*ortho* interactions in the perpendicular, equatorial, **2**, raise its energy relative to **1**. In other words, $E_3 - E_4 \sim E_2 - E_1$, with the caveat, of course, that **6** and **4** are different molecules.

It is of interest whether (practically applicable) molecular orbital calculations on axial and equatorial phenylcyclohexanes bear out the experimental results, previous computations having concentrated on force-field approaches (1).

AM1 and STO-3G MO computations

The computed relative energies of axial and equatorial phenylcyclohexane, as a function of the torsion angle, θ, about the Csp^2—Csp^3 bond are found in Table 2. These energies can be fit to the internal rotational potentials in eqs. [1]–[4]; the angle θ is zero in the parallel conformers, **1** and **3**. The standard

TABLE 2. AM1 and STO-3G geometry-optimized computations of the internal barriers to rotation in axial and equatorial cyclohexane

	Relative energy, kJ mol^{-1}			
	Equatorial		Axial	
θ, deg[a]	AM1[f]	STO-3G[g]	AM1[b]	STO-3G[c]
0	0.000	0.000[d]	0.000	0.000[e]
15	1.039	1.091	0.557	0.090
30	2.479	3.130	0.886	−0.262
45	2.686	4.997	−0.674	−0.966
60	3.941	8.345	−1.189	−2.533
75	7.303	13.633	1.003	−1.380
90	9.271	16.062	2.502	−0.538

[a]For the equatorial isomer, θ = 0° refers to the parallel conformer, **1**, of the text, in which the α C—H bond lies in the aromatic plane. For the axial isomer, θ = 0° again identifies the parallel conformer, **3**, with the α C—H bond in the aromatic plane.

[b]The minimum energy occurs at θ = 55.3°, corresponding to a relative energy of −1.364 kJ mol^{-1}.

[c]The minimum energy is −2.676 kJ mol^{-1}, corresponding to a θ = 57.0°.

[d]The total energy of this conformer is −458.231 326 au.

[e]The total energy of this conformer is −458.223 366 au.

[f]AM1 has the equatorial isomer at θ = 0° as 13.578 kJ mol^{-1} more stable than the axial isomer with θ = 55.3°.

[g]The total energy of the equatorial isomer at θ = 0° is computed as 18.220 kJ mol^{-1} lower in energy than the axial isomer at θ = 57.0° (STO-3G).

[5]The chemical shifts of the *para* protons in **1** and **6** in Table 1 differ by only 0.015 ppm, confirming that redistribution of electron density in the phenyl group is small in going from equatorial to axial conformers.

errors in the fits to the twofold term, in $\sin^2\theta$, and so forth, are given in parentheses.

[1] $V(\theta)/\text{kJ mol}^{-1}$ (equatorial, AM1) = 7.18 (1) $\sin^2\theta$ −1.95 (1) $\sin^2 2\theta$ + 2.11 (1) $\sin^2 3\theta$ + 0.03 (1) $\sin^2 4\theta$

[2] $V(\theta)/\text{kJ mol}^{-1}$ (axial, AM1) = 0.36 (3) $\sin^2\theta$ −1.95 (3) $\sin^2 2\theta$ + 2.21 (3) $\sin^2 3\theta$

[3] $V(\theta)/\text{kJ mol}^{-1}$ (equatorial, STO-3G) = 14.33 (5) $\sin^2\theta$ −3.11 (5) $\sin^2 2\theta$ + 1.87 (5) $\sin^2 3\theta$

[4] $V(\theta)/\text{kJ mol}^{-1}$ (axial, STO-3G) = −1.80 (2) $\sin^2\theta$ −0.98 (2) $\sin^2 2\theta$ + 1.32 (2) $\sin^2 3\theta$ + 0.22 (9) $\sin^2 4\theta$ + 0.26 (2) $\sin^2 6\theta$ − 0.77 (9) $\sin^2 8\theta$

Considering first the AM1 results, and noting that the sixfold term, in $\sin^2 3\theta$, contributes to the barrier height, the latter is 9.3 kJ for the equatorial isomer and corresponds to the perpendicular conformer, **2**, as expected intuitively. The *apparent* V_2 is 7.3–7.6 kJ/mol for a CS_2/C_6D_{12} solution, deduced from ^6J. Note, now, that the potential in eq. [1] corresponds to a $\langle\sin^2\theta\rangle$ of 0.245 at 300 K, somewhat higher than the 0.21 based on ^6J. Were the theoretical fourfold term to vanish, or were it positive, the $\langle\sin^2\theta\rangle$ value would be lower than 0.245. The negative fourfold component in eq. [1] means that out-of-plane motion of the α C—H bond in the low-energy conformer, **1**, is facilitated by its presence. A *pure* V_2 of 9.3 kJ/mol, corresponding to the theoretical barrier *height*, would entail a $\langle\sin^2\theta\rangle$ of 0.167. The experimental value of 0.21 is an upper limit, but cannot distinguish between a pure twofold barrier and a multifold potential. A modest agreement between theory and experiment appears to exist, judging by $\langle\sin^2\theta\rangle$ values; this is not true for the axial isomer, judging by 2-phenyladamantane as a model.

The AM1 data for the axial isomer in Table 2, together with the potential function in eq. [2], imply a very low barrier to rotation about the Csp^2—Csp^3 bond. The $\langle\sin^2\theta\rangle$ value at 300 K is 0.50, quite different from the experimental value of 0.79 for 2-phenyladamantane. It is conceivable that the low theoretical barrier is correct and that the cyclohexane moiety distorts during the rotation so as to lower the torsional barrier, a possibility presumably not available to the rigid adamantyl fragment (but note that any distortion in axial phenylcyclohexane appears (1) to be confined to the attachment site and that the entropy difference (1) between axial and equatorial isomers is apparently zero). An indication that the AM1 results are erroneous comes from its prediction of the perpendicular conformer, **4**, as the least stable, contrary to experiment (1) and to force-field calculations (1, 22, 23). Yet AM1 has the conformation of lowest energy at θ = 55.3°, with a C(1)—C(2) bond of the aromatic ring nearly eclipsing the C(α)—C(β) bond of the alicycle. The MMII computation (1), in the present notation, finds θ as 64° in the minimum-energy, (skewed) perpendicular, conformer. For 2-phenyladamantane, ^6J very clearly indicates that, for the conformer of lowest energy, a θ value nearer 90° than 60° is that of lowest energy. Note that a *rigid* conformer, defined by a θ of 64°, has $\langle\sin^2\theta\rangle$ as 0.81, corresponding to a ^6J of −0.90 Hz, very near the experimental value. Of course, the motion about the Csp^2—Csp^3 bond is not restrained by an infinite potential. Hence the proper interpretation of ^6J likely is that the conformation of lowest energy has a θ *nearer 90° than 60°* and that the potential is such that $\langle\sin^2\theta\rangle$ becomes 0.79 in CS_2/C_6D_{12} at 300 K.

AM1 predicts the axial as 13.6 kJ/mol less stable than the equatorial isomer (footnotes to Table 2). MMII simulations (1) yield 14.3 kJ/mol for this comparison, while the free energy difference at 113 K in propane-d_8 is 11.3 ± 1.1 kJ/mol. Given (1) that the entropies of the two isomers are much the same, small corrections (24) to the computed energies for zero-point energy differences and enthalpy differences between 0 and 113 K are also necessary, as well as for differences in solvation energies at 113 K.

Turning to the STO-3G optimizations, the potential function for internal rotation in eq. [3] for the equatorial isomer has $\langle\sin^2\theta\rangle$ as 0.133. The low value ensues from the large computed barrier height of 16.1 kJ/mol. While qualitatively similar to the AM1 potential in eq. [1], it is likely that it is quantitatively inferior to the latter, as judged by the experimental value of 0.21 for $\langle\sin^2\theta\rangle$ in CS_2/C_6D_{12}. The minimal basis set also overestimates the corresponding internal barrier in isopropylbenzene (2), as measured in solution. It is unlikely that polarity differences between **1** and **2**, causing solvent stabilization of either, are significant. The computed dipole moments at all θ values vary by 0.03 D at most, the largest value being 0.39 D. It may be noted that the corresponding barrier in ethylbenzene does not alter in solvents of widely different polarity (25). The $\langle\sin^2\theta\rangle$ value for isopropylbenzene in CS_2/C_6D_{12} is (2) slightly larger than for phenylcyclohexane, possibly because of easier relaxation of the side chain in the former during the rotational motion. A recent force-field computation (26) has a barrier height of 10.2 kJ/mol for equatorial phenylcyclohexane but the symmetry of the internal potential is not stated. Hence an estimate of $\langle\sin^2\theta\rangle$ cannot be made; if this force field were to predict a predominantly twofold symmetry, then it would be clear that the geometry-optimized AM1 computations agreed best with experimental data in CS_2/C_6D_{12}.

For axial phenylcyclohexane, the STO-3G potential in eq. [4] has $\langle\sin^2\theta\rangle$ as 0.584 at 300 K. In contrast to the AM1 predictions, the perpendicular **4** is correctly found as more stable than **3**, but only by 0.54 kJ/mol. The most stable conformer of this isomer is calculated as that with θ = 57.8, not very different from the θ values of 55.3° from AM1 and 64° from a force field (1). The rather small barrier to rotation about the Csp^2—Csp^3 bond is indicated by the value of 0.584 for $\langle\sin^2\theta\rangle$ (free rotation corresponds to 0.5) and, rather like AM1 above, the STO-3G result contrasts sharply with the experimental value of 0.79 for 2-phenyladamantane (the *rigid* **6**, analogous to *rigid* **4**, has $\langle\sin^2\theta\rangle$ as unity).

In view of the present molecular orbital results for axial phenylcyclohexane and in view of the indications (1) that the slightly skewed perpendicular conformer **4** is rather stable, together with a similar conclusion for 2-phenyladamantane, it would be of great interest to have a molecular mechanics treatment of the internal rotational barrier in **4** and **6**. The barriers are probably predominantly steric in nature, so that the force-field computations may well decide whether the barrier in **4** really is much lower than in **6**, the latter having a rather rigid alicyclic skeleton.

There exists one early CNDO/2 MO computation on axial phenylcyclohexane (30), which, however, does not allow for relaxation of bond lengths and angles during rotation about the Csp^2—Csp^3 bond. The barrier to rotation is calculated as 28.9 kJ/mol; this number appears untenable considering the appearance (1) of the ^{1}H NMR spectrum at 113 K.

The coupling constants, $^4J(H,CH)$ and $^5J(H,CH)$

The coupling constant between the *ortho* and α protons,

For personal use only.

^4J(H,CH)$\equiv^4J$, is dominated by a $\sigma-\pi$ contribution, proportional to $\sin^2\theta$, but also contains a small σ component, going as $\cos^2\theta$ (27, 28). Its actual values for $60° \leq \theta \leq 90°$ for a particular molecule are somewhat uncertain (27). It is -0.994 (6) Hz for fluorene (29) where θ is very near 60° and, for example, has a mean of -0.98 Hz for a molecule (no. 41 in ref. 27) in which the mean $\sin^2\theta$ is 0.72; in another molecule (no. 40 of ref. 27) it has a value of -1.16 Hz for a θ near 90°. For 2-phenyladamantane, ^4J is -1.038 (7) Hz, clearly compatible with a large average θ, characterizing a nonrigid conformer, **6**, with a $\langle\sin^2\theta\rangle$ of 0.79 derived from ^6J. More precisely, the σ component of ^4J has been assessed at -0.32 Hz (27) and, because $\langle\cos^2\theta\rangle$ is 0.21, the $\sigma-\pi$ component of ^4J in **6** becomes -0.97 Hz. Hence this component is implied as $-0.97/0.79$ or about -1.22 Hz at $\theta = 90°$. The latter falls between the limits of the magnitudes implied by the examples cited above. For phenylcyclohexane, ^4J is -0.577 (4), reflecting the small value of $\langle\sin^2\theta\rangle$ for **1** with an appreciable internal barrier; it is also close to the ^4J of -0.559 (1) Hz for isopropylbenzene in the same solvent (2).

^5J(H,CH) consists (7) of a $\sigma-\pi$ term, in $\langle\sin^2\theta\rangle$, and a σ term, in $\langle\sin^2(\theta/2)\rangle$. The latter term is 0.5 for an internal rotational potential containing only evenfold components, as implied by the molecular orbital results in eqs. [1]–[4]. It follows that ^5J should be larger in 2-phenyladamantane than in phenylcyclohexane, as it is, but only by 0.07 (1) Hz instead of the ca 0.17 Hz one might have expected on the basis of about 0.3 Hz for the $\sigma-\pi$ component in toluene. Similar discrepancies are known for ^5J in fluorene (29), for example.

Three empirical equations are proposed to fit the experimental values of the dissociation constant for picric acid, chosen as guide-solute working in the *N*, *N*-dimethylformamide/2-methoxyethanol solvent system. The work was performed operating at 19 temperatures ranging from −10 to +80°C in the pure solvents and in their nine mixtures, identified by the mole fraction (X) of one component. This empirical treatment, which describes the dependence of the dissociation constant on temperature and composition of the solvent mixture, is represented by functions of the type $K = K(T)$, $K = K(X)$, and $K = K(T, X)$. The $K = K(T, X)$ equation in its complete form is composed of 20 terms, some of which can be eliminated because of small statistical weight; the number and type of these terms vary on passing from one solvent system to another and the best-fitting form is suggested. A comparison among various $K = K(T, X)$ equations proposed in the present and in previous works has been made.

Key words: dissociation equilibria, binary nonaqueous solvent mixtures, picric acid, *N,N*-dimethylformamide, 2-methoxyethanol.

ANDREA MARCHETTI, CARLO PRETI, MARA TAGLIAZUCCHI, LORENZO TASSI et GIUSEPPE TOSI. Can. J. Chem. **69**, 509 (1991).

On propose trois équations pour ajuster les valeurs expérimentales des constantes de dissociation de l'acide picrique comme soluté, guide de travail, dans le système de solvant formé de *N*, *N*-diméthylformamide/2-méthoxyéthanol. On a réalisé le travail en opérant à 19 températures allant de −10 à +80°C, dans les solvants purs et dans neuf de leurs mélanges identifiés par la fraction molaire (X) de l'un des composants. Ce traitement empirique, qui décrit la relation entre la constante de dissociation et la température et la composition des mélanges de solvants, est représenté par des fonctions du type $K = K(T)$, $K = K(X)$ et $K = K(T, X)$. La forme complète de l'équation $K = K(T, X)$ est composée de 20 termes dont quelques-uns peuvent être éliminés parce que leur poids statistique est faible; la quantité et le type de ces termes varie lorsqu'on passe d'un système de solvant à un autre et on suggère la meilleure forme d'ajustement. On présente une comparaison entre les diverses équations $K = K(T, X)$ proposées dans ce travail et antérieurement.

Mots clés: équilibre de dissociation, mélanges de solvants binaires non-aqueux, acide picrique, *N,N*-diméthylformamide, 2-méthoxyéthanol.

[Traduit par la rédaction]

Introduction

The acid–base equilibria of weak electrolytes in solution are, in general, not independent of the solvent; in particular, the role of the medium in ionization and dissociation reactions, in spite of the remarkable work of many authors, has still not been completely elucidated (1). In fact, each solution of any weak solute represents a system quite complex to describe, owing to the multitude of physical-chemical processes that take place therein, sometimes involving species, such as solvated ions or molecules, of unknown stoichiometric composition.

In any case, the ionization and dissociation reactions are related to transport phenomena in solution and are strongly influenced by such thermomechanical properties of the solvent as density, viscosity, and dielectric constant.

The usefulness of employing mixed solvent systems (binary or higher) lies in the possibility of making continuous variations of the properties of the medium. Our interest centres in a more detailed interpretation of the changes observed in the shape of the acid–base conductometric titration curves obtained in nonaqueous solvents (2–4). The trends vary by modifing either the morphological properties (type and molecular size of titrant, titrand, and solvent) of the system, and (or) the structural properties (by temperature variations or by mixing the solvent with a cosolvent); in fact, changes in the nature of the mutual orientation may constrain the medium to assume a significant liquid structure (SLS) (5–7). All these considerations have led to a systematic investigation of the conductometric behavior of a guide-solute in a series of organic solvents, their binary mixtures, and mixtures with water.

For these purposes, the knowledge of the dissociation constants of the weak electrolytes utilized and of the association constants of the adducts formed is necessary and fundamental. In our previous papers, we reported the dissociation constants, evaluated by the conductometric method in the −10 to +80°C temperature range, of picric acid in 1,2-ethanediol (Gliet), 2-methoxyethanol (Gliem) (8), and their binary mixtures (9, 10), in the Gliet/water (11) and Gliem/water (12) solvent systems.

The present work, therefore, represents a further extension of previous studies; it concerns the conductometric determination of the dissociation constants of picric acid in *N,N*-dimethylformamide (DMF) and in a series of binary DMF/Gliem mixtures covering the whole composition range, working at 19 temperatures from −10 to 80°C. Because our purpose was the investigation of the properties of mixed solvent systems, a guide-solute needed to be chosen; picric acid was utilized because it is stable in our experimental conditions, it is a medium-strength electrolyte in water, and it is completely soluble in Gliem, in DMF, in their binary mixtures, and in all the other previously investigated solvent systems.

2-Methoxyethanol (Gliem) is a widely used alcoholic solvent for scientific studies and for industrial applications because of solvating properties associated with its almost-aprotic character (13). In fact, owing to its low autoprotolysis constant ($pK_{autoprot}$ = 20.5) (14) and other physical-chemical properties, it is possible to classify Gliem as a solvent midway between protic

and dipolar almost-aprotic. DMF, on the contrary, is a quite dipolar aprotic solvent with a high dielectric constant (37.51 at 25°C) and a large dipole moment (μ = 3.82 D at 25°C) (15), which probably enables it to stabilize ions, molecules, and other dissolved species through dipole and induced dipole interactions.

Ionization and dissociation constants in DMF have been determined for a fairly large number of substances (16–19). A few studies, however, have been made on the thermodynamics of ionization of acids in this pure solvent and in binary mixtures with a cosolvent, also operating over a reasonably large temperature range. In view of the importance of DMF as a solvent or cosolvent, it would be desirable to have more data on ionization and dissociation of weak electrolytes in order to achieve a better understanding of these processes in DMF solutions.

In addition, we have chosen this binary system to verify some peculiarities in its behavior and to compare with those results observed in the analogous Gliet/Gliem solvent system (10). In fact, Gliem being the common solvent for these investigations, the most significant differences in the observed behavior of the ionization and dissociation of picric acid are certainly ascribable to the chemical differences between Gliet and DMF.

Experimental section

Materials

2,4,6-Trinitrophenol (picric acid), supplied by BDH (purum ca. 95%), was twice purified by recrystallization from hot ethanol and diethyl ether (mp 122°C (lit. (15) mp 122–123°C)).

The solvents, *N*,*N*-dimethylformamide and 2-methoxyethanol (containing <0.10% and <0.05% water, respectively, by Karl-Fischer titration) were Carlo Erba high purity grade and they were used after purification by passage on a neutral alumina column.

Apparatus

The conductances of the solutions were measured with an Amel model 123 conductivity bridge operating in the 0.1×10^{-6} to 0.3 S (scale-end) range, with a sensitivity of ±1.0%, and using platinized platinum electrodes (cell constant 9.12 cm). Temperature control was provided by a Lauda K2R thermostatic bath maintained to within ±0.02°C. Viscosity measurements were performed using a Schott-Geräte AVS 400 viscosity-measuring system, equipped with a series of Ubbelhode viscometers. The densities at various temperatures were determined with a digital density meter, Anton Paar model DMA 60, equipped with a density measuring cell model DMA 602, with a sensitivity up to 0.000 001 g cm^{-3}. The dielectric constants were measured using a WTW-DM01 dipole meter equipped with two stainless-steel cylindrical cells: MFL2 ($7 < \epsilon < 21$) was calibrated with dichloromethane (ϵ = 9.08 at 20°C), pyridine (ϵ = 12.30 at 25°C), butan-1-ol (ϵ = 17.80 at 20°C), and acetone (ϵ = 20.70 at 25°C) (15); MFL3 ($21 < \epsilon < 90$) was calibrated with ethanol (ϵ = 24.30 at 25°C), methanol (ϵ = 32.63 at 25°C), glycerol (ϵ = 42.50 at 25°C), and water (ϵ = 80.37 at 20°C) (15). A frequency of 2.0 MHz was used. Karl Fischer titrations were performed with an automatic titration system (Crison model KF431) equipped with a digital burette (Crison model 738).

Procedure

The solvent mixtures were prepared by weight. The solutions of picric acid at different concentrations were obtained by successive dilution of stock solutions, freshly prepared by weight; concentrations in volume were then calculated from weight concentrations and densities. Conductance readings were recorded when they became invariant with time; this took about 30 min for each measurement. Solvent conductance corrections were applied to all data at different temperatures.

Results and discussion

To evaluate the experimental dissociation constant of picric acid in this binary solvent system using conductometric measurements performed at 19 temperatures ranging from −10 to +80°C, the equivalent conductances were determined for at least six concentrations for each solution in the two pure solvents and in their nine binary mixtures, which have been identified by the letters A, B, C, ... M; the compositions of the solvent systems appear in Table 2. The conductance data are reported in the Supplementary Tables 1–11 available from the Depository of Unpublished Data[3] and all the conductometric data were corrected for the specific conductances of the relative solvents at each investigated temperature. The corrected values were analyzed and processed by means of the Fuoss–Hsia equation (20), using a computing program kindly supplied by Prof. M. Goffredi and modified by us to take into account the effect of the variation of solution concentrations with density of the solvents at various temperatures.

The equation

$$[1] \qquad \Lambda = \Lambda_0 - S(C\gamma)^{1/2} + EC\gamma \log(C\gamma) + J_1 C\gamma - J_2(C\gamma)^{3/2} - K_A C\gamma f_{\pm}^2 \Lambda$$

was used, where the symbols have their usual meaning (21). The above equation provides the limiting ionic conductivity Λ_0, the association constant K_A (dissociation constant $K = K_A^{-1}$) (21, 22), and the interionic distance parameter $\mathring{a}$.

The calculating procedure starts from an initial value of Λ_0, estimated from a Λ vs. $C^{1/2}$ plot, and a first chosen $\mathring{a}$ value, generally 5 Å; afterwards only a few iterations are necessary to obtain the parameters cited. Table 1 summarizes the dissociation constants K for picric acid in the DMF/Gliem solvent system at each investigated temperature, while the Λ_0 and $\mathring{a}$ values are presented in the Supplementary Tables 12 and 13 respectively, available from the Depository of Unpublished Data.

An immediate comparison between data from the DMF/Gliem solvent system and those from the Gliet/Gliem system appears evident from the analysis of K values of picric acid in the pure Gliet (K_{Gliet}) (10) and those in pure DMF (K_{DMF}) of this work.

In fact, K_{DMF} is always greater than K_{Gliet} (by one or two orders of magnitude) in the temperature range investigated. In addition, this behavior is observed in all the corresponding mixtures from B to L. These differences could probably be explained on the basis of a simple qualitative discussion of the properties of the two pure solvents and their mixtures. DMF is an aprotic solvent having a potentially basic character because of the presence of the amino group in its molecule, while Gliet is a protic, potentially acidic, solvent ($K_{autoprot}$ = 15.8) (23).

It is noteworthy that these characteristics are probably predominant, so that K_{DMF} is always $> K_{Gliet}$, the dielectric constants of the two pure solvents being quite similar (ϵ ranges from 44.08 to 29.12 for DMF and 49.11 to 31.31 for Gliet (8) in the $-10 \leq t(°C) \leq 80$ range, μ_{Gliet} = 2.28 at 25°C) (15). Now, the trend among all the binary mixtures DMF/Gliem and Gliet/Gliem being the same, one may think that preferential or selective solvation of solute takes place and occurs in the DMF/Gliem solvent system through the molecules of DMF, which are more solvating than the Gliem molecules ($20.03 \leq \epsilon_{Gliem} \leq 13.02$ for $-10 \leq t(°C) \leq 80$) (8).

Considering now the values of the experimental dissociation constant relative to the DMF/Gliem solvent system, each set of K data was fitted by an equation of the type

[2] $\ln K = a_0 + a_1T + a_2/T + a_3 \ln T$

which certainly represents the most commonly used and the most accurate equation for K vs. T data fit. In fact, eq. [2] reproduces well the experimental K values with an average difference of 1.9% between calculated (Supplementary Table 14 available from the Depository of Unpublished Data) and experimental (Table 1) values. Figure 1 reports the experimental K values and the best-fitting curves, corresponding to the integrated Van't Hoff eq. [2], for our investigated solute in the DMF/Gliem solvent system.

The same trend vs. temperature is observed for the $\mathring{a}$ parameter, as shown by the data of Supplementary Table 13, available from the Depository of Unpublished Data. If we assume, according to Hsia and Fuoss (20), that this adjustment parameter may represent the distance of closest approach of the ions, examination of the $\mathring{a}$ values obtained as a function of the composition X of the mixture may suggest some considerations in terms of solute/solvent properties. Figure 2 shows the plot of $\mathring{a}$ values vs. X and it appears quite interesting; we may observe the presence of maximum values corresponding to X_{DMF} values of ca. 0.2, 0.5, and 0.8 and minimum values for the pure solvents and for ca. 0.33 and 0.70. Relatively high values of $\mathring{a}$ may indicate the presence of "loose" ion pairs, i.e., a greater separation of the ions due to the solvent molecules; on the contrary, when $\mathring{a}$ decreases tight ion pairs are probably formed. In conclusion, in the present case a minimum value of $\mathring{a}$ is observed for the pure Gliem, according also with its low dissociating ability; relatively low $\mathring{a}$ values are evident, corresponding to Gliem/DMF 1:2 and 2:1 ratios, while the highest $\mathring{a}$ values correspond to 1:3, 1:1, and 3:1 Gliem/DMF ratios. This behaviour could suggest that the formation of certain stoichiometrical solvent/cosolvent adducts (1:3, 1:1, and 3:1) may promote dissociation of ion pairs more than the other adduct ratios (1:2 and 2:1).

Turning now to the dissociation constant values, brief examination of Fig. 1 demonstrates the following details: (i) the curves K vs. T change progressively on passing from convex (system A) to concave shape (system M); (ii) the curves A, B, C present a relative maximum in K values in the temperature range investigated, which shifts towards lower temperatures as the X_{DMF} decreases, while all the other curves from D to M show a continuously decreasing trend with temperature. On the basis of these considerations it is possible to evaluate, for the three mixtures cited, values of K_{max} and corresponding T_{max} using the Van't Hoff equation in the following form:

[3] $$\left(\frac{\partial \ln K}{\partial T}\right)_P = 0$$

and employing the proper a_i coefficients for each binary mixture (Table 2). Equation [3] provides the following values of K_{max} and t_{max}(°C): 6.26×10^{-2} and 13.2, 5.92×10^{-2} and 10.1, and 5.30×10^{-2} and 7.9 for systems A, B, and C respectively. For the curve M, the decreasing trend is not very evident by examining the figure because all the curves have been reported in an unique compressed scale that makes the curve M flattened with respect to the others; however, the decreasing trend appears evident if one considers the K values of Table 1. (iii) Taking into account the progressive and regular variation of the shape of the curves in the plane $\pi\{K, T\}$ on passing from A to M and considering that the composition of binary mixtures varies continuously in the range $0 \leq X_{DMF} \leq 1$, one may reasonably think that the property K also varies continuously between the

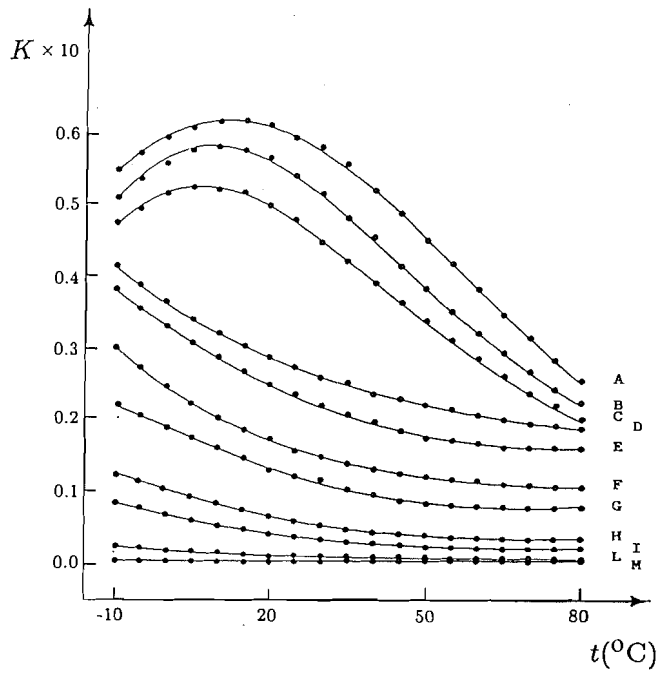

FIG. 1. Experimental dissociation constants of picric acid in the DMF/Gliem solvent system at different temperatures, and best fitting curves calculated by eq. [2].

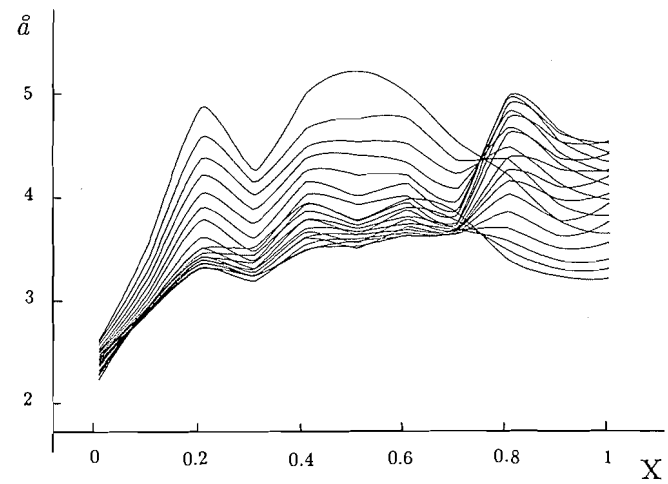

FIG. 2. The graphs of $\mathring{a}$ values plotted vs. X, at different temperatures varying from −10°C (top) to 80°C (bottom).

values obtained in DMF and in Gliem at each temperature investigated.

Now, on the basis of these considerations, we may assume that the dissociation constant of the solute should be described as a function of the two independent variables, temperature and composition, of the binary solvent system. In a general form, we can write:

[4] $K = K(T, X_{DMF})$

where, to simplify the notation, the subscript DMF will hereafter be omitted.

By considering the curves of Fig. 1 and the best-fit eq. [2], we may assume that the dependence of the dissociation constant on the composition of the binary mixture should be implicitly contained in the coefficients of eq. [2] for each solvent system, being defined by the proper X_r ($r = 1, 2, \ldots 11$ for A, B, ... M

[a]From ref. 12.

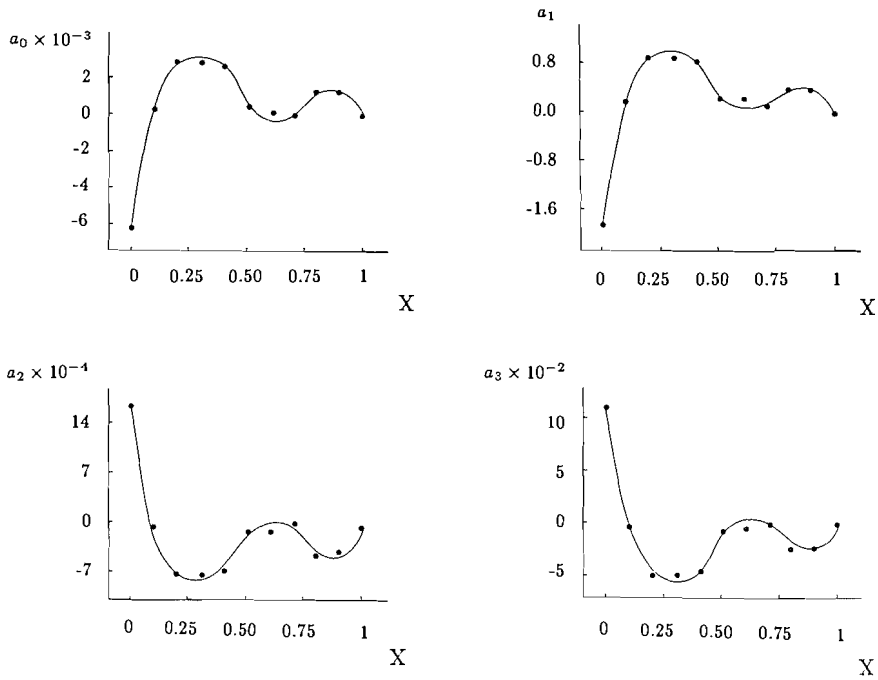

FIG. 3. The graphs of a_i coefficients of eq. [5] vs. X.

respectively). Therefore, we may write:

[5] $a_i = a_i(X)$ for $i = 0, 1, 2, 3$

and consequently, eq. [2] in the form

[2.1] $\ln K = a_0(X) + a_1(X)T + a_2(X)/T + a_3(X) \ln T$

The coefficients a_i, which were determined by analyzing the experimental K values with the multilinear regression package TSP (24), are reported in Table 2, while Fig. 3 reproduces the same table in graphic form. As is clear by examining this last figure, these coefficients show characteristics of "self similarity (25, 26) or *omotetia interna*" (27); in fact, by assuming

$$a_i(X_r) = a_i(X_r) \qquad \text{for } i = 0, 1; \quad r = 1, 2, \ldots 11$$

and

$$a_i(X_r) = -a_i(X_r) \qquad \text{for } i = 2, 3; \quad r = 1, 2, \ldots 11$$

the trend of the four curves is unique and perfectly superimposible. This homotetic (self-similar) behavior was also observed in our previous studies involving similar investigations (9–12).

It is noteworthy that although many studies of other authors (28–31) are present in the literature, no model equation making explicit the function [5] is available. Therefore, to correlate the experimental dissociation constant K with the composition of the binary solvent system, in our previous papers (10–12) we proposed an empirical equation of the type:

$$[6] \qquad \ln K = b_0 + b_1X + b_2\frac{(1 - X)}{(1 + X)} + b_3X^2 + b_4\frac{(1 - X^2)}{(1 + X^2)}$$

Also, the b_j coefficients (Table 3) were determined in the same manner as a_i (24) and they refer to all the $K = K(X)$ isothermal curves, some of which are shown in Fig. 4. By using eq. [6] for each temperature investigated, the calculated K values were obtained (Supplementary Table 15 available from the Depository of Unpublished Data) and they reproduce well the experimental values (average difference of ca. 6.4%).

The same considerations made for a_i may also be applied to b_j, suggesting a homotetic behavior and an implicit dependence on the temperature

[7] $b_j = b_j(T)$ for $j = 0, 1, 2, 3, 4$

The need to have an available $K = K(T, X)$ function has been resolved, as already done in some previous papers (10–12), by suggesting an empirical approach which leads to:

[8] $f(T, X) = \sqrt{f(T) \cdot f(X)}$

where $f(T)$ and $f(X)$ are eqs. [2] and [6] respectively. The above equation, which in its complete form contains 20 terms, has been simplified by omitting successively the terms having statistical weight ca. <1 (24). The best-fitting equation so obtained is

$$[9] \quad (\ln K)^2 = c_0 + c_1 T + c_4 X + c_5 XT + c_7 X \ln T + c_8 \frac{(1-X)}{(1+X)} + c_9 T \frac{(1-X)}{(1+X)} + c_{12} X^2 + c_{13} X^2 T + c_{15} X^2 \ln T + c_{16} \frac{(1-X^2)}{(1+X^2)} + c_{17} T \frac{(1-X^2)}{(1+X^2)}$$

where $c_0 = 10\,368.2$; $c_1 = -57.7703$; $c_4 = -21\,490.5$; $c_5 = 73.7774$; $c_7 = 1565.21$; $c_8 = -7620.24$; $c_9 = 42.8684$; $c_{12} = 14\,220.9$; $c_{13} = -13.7957$; $c_{15} = -2224.44$; $c_{16} = -2868.50$; $c_{17} = 15.6738$. This equation reproduces the experimental K values with an acceptable approximation, being 9.2% of the average difference between the experimental data of Table 1 and the calculated data of Supplementary Table 16, available from the Depository of Unpublished Data.

Figure 5 is provided by plotting eq. [9] and represents the $K = K(T, X)$ function; obviously the curves of the Figs. 1 and 4 correspond to the intersections of the surface with the $\pi\{K, T\}$ and $\pi\{K, X\}$ planes respectively.

The choice of eq. [9] was made taking into account the criterion of the lowest difference between calculated and experimental values, but at least two other criteria may be considered: (i) the simplicity of the equation and (ii) the possibility of extending the equation to the largest number of

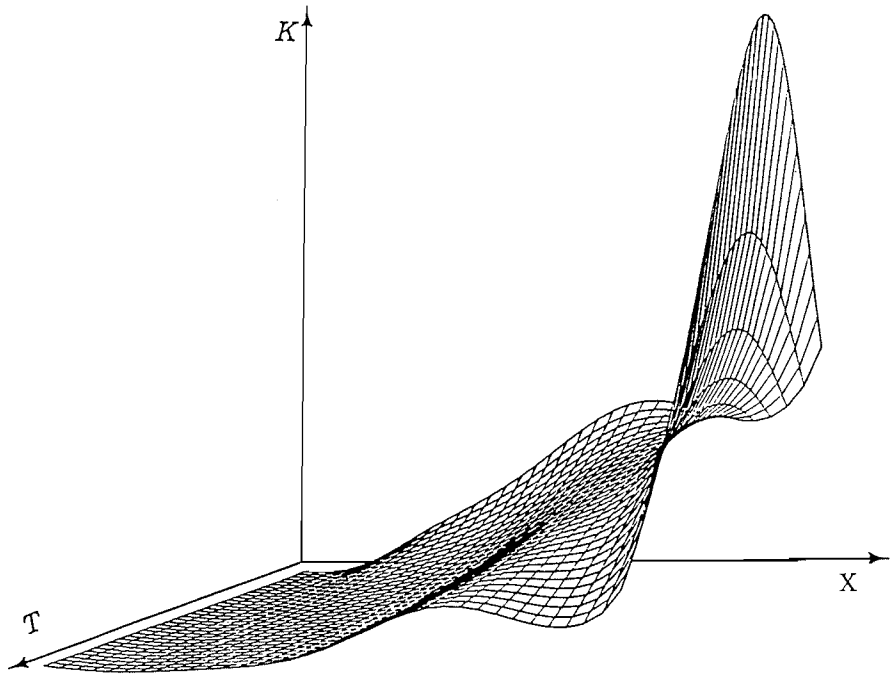

FIG. 5. Plot of $K = K(T, X)$ for picric acid in the DMF/Gliem solvent system.

solvent systems, with the agreement between calculated and experimental values obviously remaining acceptable.

If we apply criterion (i), it is possible to rule out the c_7 and c_{15} terms; in this way a simple and symmetrical equation, without ln T and $1/T$ terms, was obtained:

$$[10]\quad (\ln K)^2 = c_0 + c_1T + c_4X + c_5XT + c_8\frac{(1-X)}{(1+X)} + c_9T\frac{(1-X)}{(1+X)} + c_{12}X^2 + c_{13}X^2T + c_{16}\frac{(1-X^2)}{(1+X^2)} + c_{17}T\frac{(1-X^2)}{(1+X^2)}$$

where $c_0 = 8990.70$; $c_1 = -53.7602$; $c_4 = -12\,197.4$; $c_5 = 73.2864$; $c_8 = -6573.97$; $c_9 = 39.7636$; $c_{12} = 3194.08$; $c_{13} = -19.4608$; $c_{16} = -2523.09$; $c_{17} = 14.7213$; which leads to acceptable calculated K values (average difference of 10.6%).

Criterion (ii) has led us to apply to the present set of 209 K values the best-fit equations suggested in our previous papers (10–12) for three other solvent systems. In general, acceptable differences are observed (about 10%); the best agreement is achieved for the 13-term equation proposed for the Gliet/Gliem solvent system (10) with an average difference of 9.5%:

$$[11]\quad (\ln K)^2 = c_0 + c_1T + c_2\frac{1}{T} + c_4X + c_5XT + c_6\frac{X}{T} + c_8\frac{(1-X)}{(1+X)} + c_9T\frac{(1-X)}{(1+X)} + c_{12}X^2 + c_{13}X^2T + c_{16}\frac{(1-X^2)}{(1+X^2)} + c_{17}T\frac{(1-X^2)}{(1+X^2)} + c_{18}\frac{1}{T}\frac{(1-X^2)}{(1+X^2)}$$

where $c_0 = 4512.90$; $c_1 = -53.9021$; $c_2 = 1\,269\,630$; $c_4 = -9408.45$; $c_5 = 78.7915$; $c_6 = -1\,216\,533$; $c_8 = -9346.79$; $c_9 = 49.6370$; $c_{12} = 4519.54$; $c_{13} = -24.2143$; $c_{16} = 4003.31$; $c_{17} = 6.21057$; $c_{18} = -1\,162\,661$.

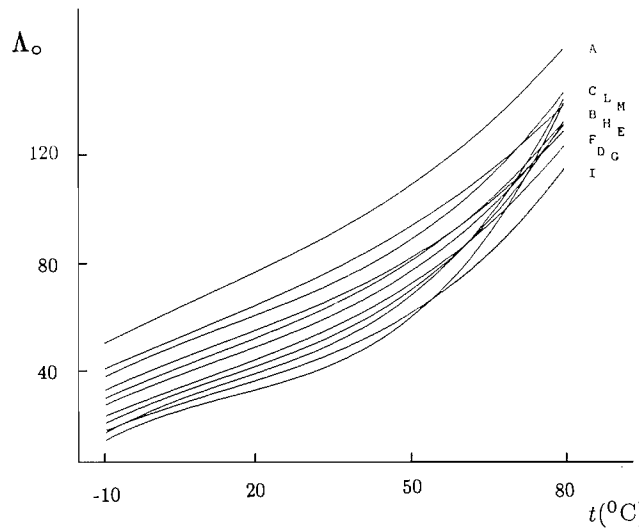

FIG. 6. Λ_0 vs. t (°C) plot for picric acid in the DMF/Gliem solvent system.

Starting from this last equation, if one eliminates the c_4 and c_{17} terms the following equation is obtained:

$$[12]\quad (\ln K)^2 = c_0 + c_1T + c_2\frac{1}{T} + c_5XT + c_6\frac{X}{T} + c_8\frac{(1-X)}{(1+X)} + c_9T\frac{(1-X)}{(1+X)} + c_{12}X^2 + c_{13}X^2T + c_{16}\frac{(1-X^2)}{(1+X^2)} + c_{18}\frac{1}{T}\frac{(1-X^2)}{(1+X^2)}$$

TABLE 5. λ_i^0 coefficients of eq. [13] for the *N*,*N*-dimethylformamide/2-methoxyethanol solvent system

System	λ_0^0 ($cm^2\,\Omega^{-1}\,mol^{-1}$)	λ_1^0 ($cm^2\,\Omega^{-1}\,mol^{-1}\,t^{-1}$)	$\lambda_2^0 \times 10^{-3}$ ($cm^2\,\Omega^{-1}\,mol^{-1}\,t^{-2}$)	$\lambda_3^0 \times 10^{-5}$ ($cm^2\,\Omega^{-1}\,mol^{-1}\,t^{-3}$)	$\sigma\Lambda_0$ ($cm^2\,\Omega^{-1}\,mol^{-1}$)
A	56.92	0.9154	−3.252	9.404	±0.45
B	46.86	0.7992	−1.829	7.356	±0.57
C	44.33	0.8382	−7.611	15.37	±1.78
D	39.16	0.7913	−5.260	11.45	±1.16
E	36.11	0.7862	−4.822	12.26	±1.21
F	33.62	0.7651	−5.885	14.14	±1.30
G	29.23	0.7242	−3.932	11.71	±1.13
H	27.13	0.7802	−8.906	19.19	±2.17
I	23.72	0.6736	−6.999	15.80	±1.75
L	24.30	0.8662	−13.85	26.20	±2.78
M	21.13	0.7681	−16.27	31.08	±3.25

where $c_0 = -2157.51$; $c_1 = -29.9573$; $c_2 = 1\,071\,488$; $c_5 = 46.1034$; $c_6 = -1\,041\,036$; $c_8 = -3863.85$; $c_9 = 31.6793$; $c_{12} = 1966.16$; $c_{13} = -15.8262$; $c_{16} = 5316.42$; $c_{18} = -982\,071.2$. This last equation (average difference 10.3%) takes into account all the above mentioned criteria and its terms all have high statistical weight. These considerations appear clearly if one examines Table 4, which summarizes all the equations cited.

Some qualitative considerations may be made regarding the trend and the changes of Λ_0 (Supplementary Table 12, available from the Depository of Unpublished Data). These values were fitted vs. temperature by a polynomial equation (32):

$$[13] \qquad \Lambda_0 = \sum_{i=0}^{3} \lambda_i^0 t^i$$

which reproduces well the experimental data (average difference between calculated and experimental values of ±2.2%. Table 5 contains the λ_i coefficients of eq. [13] and the relative standard deviations. Figure 6 shows the Λ_0 vs. temperature (°C) plot derived from eq. [13], which is characterized by a continuous and regular increase with increasing temperature; only in the case of the highest temperatures and for few mixtures are small deviations from the trend observed, probably arising from experimental errors.

Conclusions

The applicability of the empirical equations representing the functions $K = K(T)$ (eq. [2]), $K = K(X)$ (eq. [6]), and $K = K(T, X)$ (eq. [9]) to the dissociation constant of picric acid in the DMF/Gliem solvent system has been verified, giving quite acceptable average differences between experimental and calculated values (1.9% for eq. [2], 6.4% for eq. [6], and 9.2% for eq. [9]).

A comparison among the various $K = K(T, X)$ equations proposed in the present work and in previous studies (10–12) for similar solvent systems has been made by considering the criteria of the smallest difference between calculated and experimental values, of the simplest equation, and of the applicability to the largest number of solvent systems. This comparison has suggested that, in general, quite acceptable agreement between calculated and experimental values is achieved, even if the same equation may be employed with better results for the present system and for the previously studied Gliet/Gliem one.

Some simpler equations may be also utilized because the fitted K values are always in quite good agreement with the experimental results. In conclusion, the availability of $K = K(T, X)$ model equations allows us to calculate K values for any independent variable quantity T and X, if one supposes that the observed differences between experimental and calculated values (ca. 10%) should not be exceeded over all the points of the surface $K = K(T, X)$.

New halogenated sesquiterpenes from the red alga *Laurencia caespitosa*

MANUEL NORTE,[1] RAFAEL GONZÁLEZ, AGUSTÍN PADILLA, JOSÉ J. FERNÁNDEZ, AND JESÚS T. VÁZQUEZ

Centro de Productos Naturales Orgánicos "Antonio González", Instituto Universitario de Bio-Orgánica, Universidad de La Laguna, Carretera de La Esperanza, 2, 38206 La Laguna, Tenerife, Spain

Received August 22, 1990

MANUEL NORTE, RAFAEL GONZÁLEZ, AGUSTÍN PADILLA, JOSÉ J. FERNÁNDEZ, and JESÚS T. VÁZQUEZ. Can. J. Chem. **69**, 518 (1991).

Three new brominated sesquiterpenes have been isolated from the red alga *Laurencia caespitosa*. The structures of these metabolites have been elucidated by spectral analysis and chemical correlations. Their absolute configurations were established by CD methods.

Key words: red alga, Rhodomelaceae, halogenated sesquiterpenes, snyderane.

MANUEL NORTE, RAFAEL GONZÁLEZ, AGUSTÍN PADILLA, JOSÉ J. FERNÁNDEZ et JESÚS T. VÁZQUEZ. Can. J. Chem. **69**, 518 (1991).

On a isolé trois nouveaux sesquiterpènes bromés à partir de l'algue rouge *Laurencia caespitosa*. On a élucidé les structures de ces métabolites en se basant sur des analyses spectrales et sur des corrélations chimiques. On a établi leurs configurations absolues à l'aide de méthodes de DC.

Mots clés : algue rouge, Rhodomelaceae, sesquiterpènes halogénés, snyderane.

For personal use only.

The red alga *Laurencia caespitosa* collected at La Graciosa (Canary Islands) was found to be a rich source of regular and irregular halogenated sesquiterpenes (1). We recently published the isolation of three new irregular rearranged sesquiterpenoids, the laucapyranoids A, **1**; B, **2**, and C, **3** (2), which are related to caespitol **4** and isocaespitol **5**, metabolites previously isolated from the same alga (3).

We report here the isolation and structure elucidation of the monocyclofarnesane derivatives **6–8**, one of them with an unprecedented γ-snyderol system. In contrast with other kinds of sesquiterpenoid skeletons, the number of halogenated sesquiterpenes with a snyderane skeleton isolated from *Laurencia* is small (4).

These compounds were isolated by chromatography on silica gel followed by gel filtration chromatography on Sephadex LH-20, the final purification being carried out by HPLC.

The major metabolite of this series, compound **6**, was isolated as an oil, $[\alpha]_D$ +8.7 (*c* 0.172, $CHCl_3$). Its molecular formula was established as $C_{15}H_{25}O_2Br$ on the basis of its HRMS. The ^1H NMR spectrum showed the presence of two methines α to heteroatoms (δ 4.28 and 4.50), an exocyclic double bond (δ 4.77 and 5.10), and the characteristic chemical shifts due to the double bond of the last isoprene unit for the monocyclofarnesane derivatives (δ 5.07, 5.21, and 5.91). This was confirmed by the ^{13}C NMR spectrum as well as by the loss of the fragment (C_5H_9O) observed in the mass spectrum. The cyclic proton assignments begin with the direct coupling of H-8 (δ 4.28) to H-9 (δ 2.35 and 2.17) and, further, H-9 to H-10 (δ 4.50), and the direct coupling of protons finishes with the presence of quaternary centers at C-7 and C-11. The relative positions were confirmed by the long range coupling of H-8 to H-14 (δ 5.10). The nature of the heteroatoms at C-8 and C-10 was easily established as oxygen and bromine, respectively, by the correlation of the assigned proton signals to carbons in the ^1H–^{13}C COSY(HETCOR) spectrum: H-8 (δ 74.5) and H-10 (δ 63.5). The relative configurations of the chiral centers at C-6, C-8, and C-10 were established as follows. The coupling constant values observed for H-8 and H-10 (Table 1) showed that the hydroxyl group must be axial and the bromine atom

equatorial, which implies that they possess opposite orientations. On the other hand, the NOEDIFF experiment showed nOe enhancement for the H-10 signal when the H-6 signal at δ 2.3 was irradiated. These spectroscopic data agree with the structure of 8-hydroxy-β-snyderol for compound **6**.

Compound **7**, oil, $[\alpha]_D$ +16.8 (*c* 0.136, $CHCl_3$). Its HRMS

[a]Assignments made by ^{1}H–^{13}C heteronuclear COSY.
[b]Assignments made by comparison with **6**.
[c]Assignments made by homonuclear COSY.

showed it to be an isomer of **6** and the comparison of their NMR spectra showed that they are structurally related. Thus, the main differences observed, with respect to **6**, in the ^{1}H NMR spectrum of compound **7** were the absence of signals for the protons H-6 and H-14 together with the presence of a vinylic methyl group at δ 1.73. This was confirmed in the ^{13}C NMR spectrum by the presence of a Z tetrasubstituted double bond (δ 128.28, 140.92, and 22.56). On the basis of these data we assigned the structure of **7** as 8-hydroxy-γ-snyderol, which is the first example of a γ-snyderol derivative isolated from marine sources.

Compound **8**, oil, $[\alpha]_D$ +13.6 (*c* 0.77, $CHCl_3$), has a molecular formula of $C_{15}H_{22}O_2$. The presence in the molecule of an α,β-unsaturated carbonyl group was evidenced by the strong absorption at 1660 cm^{-1} in the IR spectrum and by a band in the UV spectrum at 274 nm. It was confirmed by the NMR spectral data, which allowed us to place the carbonyl group at the carbon C-8 and the double bond between the carbons C-9 and C-10.

Moreover, comparison of these data with those observed for **6** and **7** showed that this compound possesses the common side chain and that it belongs to the β-snyderol series. The final confirmation of the structure was obtained through the chemical correlation between **6** and **8**. Treatment of **6** with MnO_2 at room temperature for 2 h gave a compound that showed physical and spectroscopical data identical with those observed for compound **8**.

The circular dichroic exciton chirality method has proved to be an excellent tool for the determination of absolute configurations (5). We have applied the CD allylic benzoate method (6–8) to compounds **6** and **7**, which possess allylic alcohols. Their bromobenzoylation with 4-bromobenzoyl chloride in pyridine with DMAP as catalyst yielded the allylic benzoates **9** and **10** (CH_3CN, 243 nm, ε = 21 300), respectively. Their CD spectra exhibited a negative Cotton effect at 241.5 nm (Δε = −1.5) for **9** and a positive Cotton effect at 241.0 nm (Δε = +13.9) for **10**. Since the sign of the CD Cotton effect represents the chirality of the double bond – benzoate system, the observed negative exciton chirality for **9** and the positive one for **10** led to the absolute configuration shown for these compounds.

Experimental part

NMR spectra were recorded on a Bruker model WP 200 SY spectrometer (200 MHz), chemical shifts are reported relative to Me_4Si (δ, 0), and coupling constants are given in hertz. The 2D-NMR spectra were obtained using Bruker microprograms. Samples for nOe experiments were degassed by bubbling Ar through the solution. IR and UV spectra were recorded on Perkin–Elmer model 257 and Perkin–Elmer model 550D spectrophotometers. CD spectra were recorded on a Jasco J-600 spectropolarimeter. Optical rotations were determined for solution in $CHCl_3$ with a Perkin–Elmer model 241 polarimeter. Low and high resolution mass spectra were obtained from a VG Micromass ZAB-2F spectrometer. HPLC was carried out on a semipreparative silica gel μ-Porasil column attached to a Waters pump model 6000 and monitored with a differential diffractometer detector model R-401. Sephadex LH-20 obtained from Pharmacia was used for gel filtration chromatographies. Silica gel column chromatography, TLC, and PLC were performed on silica gel 60 G. The TLC plates were developed by spraying with 6 N sulphuric acid and heating. All solvents were purified by standard techniques. Anhydrous magnesium sulphate was used for drying solutions.

Collection, extraction, and chromatographic separation

Laurencia caespitosa was collected in shallow water at low tide at the island of La Graciosa in September 1986. The air-dried alga (5 kg) was extracted with acetone and diethyl ether. The solvents were evaporated *in vacuo* to afford 62 g of crude extract. This was chromatographed on a silica gel column eluted with a mixture of *n*-hexane/ethyl acetate of increasing polarity, and 50 fractions of 1 L each were collected. The fractions eluted with *n*-hexane/ethyl acetate 60:40 afforded after solvent evaporation the products **6**, **7**, and **8**.

These were chromatographed on Sephadex LH-20 (using as eluent $CHCl_3$/methanol/*n*-hexane 1:1:2) and, after silica gel column chromatography, gave pure **8** (25 mg) and a mixture of **6** and **7** (168 mg). This mixture was chromatographed on HPLC using *n*-hexane/ethyl acetate 70:30, affording the pure products **6** (136 mg) and **7** (30 mg).

Compound 6 (8-hydroxy-β-snyderol)

Oil, $[\alpha]_D$ +8.7 (*c* 0.172, $CHCl_3$). IR ($CHCl_3$) ν_{max}: 3590, 3000, 2970, 1640, and 1370 cm^{-1}. ^1H and ^{13}C NMR (200 MHz, $CDCl_3$), see Table 1. HRMS *m/z*: $C_{14}H_{20}O^{81}Br$ 285.0069 (calcd. 285.0677). MS (EI), *m/z* (relative intensity): 318, 316 (M^+, not obs.), 285, 283 (1, 1); 233, 231 (7, 7); 219 (19); 201 (10); 173 (6); 149 (14); and 133 (29).

Compound 7 (8-hydroxy-γ-snyderol)

Oil, $[\alpha]_D$ +16.2 (*c* 0.136, $CHCl_3$). IR ($CHCl_3$) ν_{max}: 3590, 3000, 2970, 1600, 1410, and 1360 cm^{-1}. ^1H and ^{13}C NMR (200 MHz, $CDCl_3$), see Table 1. HRMS *m/z*: $C_{14}H_{20}O^{81}Br$ 285.0658 (calcd. 285.0677). MS (EI), *m/z* (relative intensity): 318, 316 (M^+, not obs.); 285, 283 (1, 1); 233, 231 (41, 41); 219 (46); 201 (16); 161 (59); and 123 (41).

Compound 8 (8-keto-10-dehydrobrominated-β-snyderol)

Oil, $[\alpha]_D$ +13.6 (*c* 0.77, $CHCl_3$). IR ($CHCl_3$) ν_{max}: 3570, 3010, 3000, 2940, 1660, 1590, and 1420 cm^{-1}. UV (EtOH) λ_{max}: 274 nm (ε 8900). ^1H and ^{13}C NMR (200 MHz, $CDCl_3$), see Table 1. HRMS *m/z*: $C_{15}H_{22}O_2$ 234.1599 (calcd. 234.1620). MS (EI), *m/z* (relative intensity): 234 (M^+, 2), 219 (4), 201 (9), 175 (7), 161 (10), 149 (56), 135 (31), and 121 (40).

Compound 9 (8-(p-bromobenzoyl)-β-snyderol)

To compound **6** (16 mg, 0.05 mmol) dissolved in dry pyridine (2 mL) was added *p*-bromobenzoyl chloride (23 mg, 0.1 mmol) and the mixture was stirred for 5 h at room temperature under Ar. The usual work-up gave an oily residue, which was chromatographed on HPLC to furnish 14 mg of **9**; oil, $[\alpha]_D$ +0.9 (*c* 0.22, $CHCl_3$). ^1H NMR ($CDCl_3$) δ: 7.86 (2H, d, *J* = 8.6 Hz), 7.60 (2H, d, *J* = 8.6 Hz), 5.87 (1H, dd, *J* = 10.6 and 17.1 Hz), 5.53 (1H, t, *J* = 2.8 Hz), 5.34 (1H, s), 5.19 (1H, dd, *J* = 1.2 and 17.1 Hz), 5.04 (1H, dd, *J* = 1.2 and 10.6 Hz), 4.40 (1H, dd, *J* = 4.5 and 12.5 Hz), 2.59 (1H, ddd, *J* = 3.9, 4 and 14.4 Hz), 1.26 (3H, s), 1.23 (3H, s), and 0.85 (3H, s). MS (EI), *m/z* (relative intensity): 416, 414, 412 (8, 16, 8); 334, 332 (2, 2); 267, 265 (5, 6); 254, 252 (8, 7); and 185, 183 (100, 99).

Compound 10 (8-(p-bromobenzoyl)-γ-snyderol)

Compound **7** (16 mg, 0.05 mmol) was converted into **10** under the same conditions employed to transform **6** into **9**. Purification afforded 13 mg of **10**: oil $[\alpha]_D$ +89.5 (*c* 0.19, $CHCl_3$). ^1H NMR ($CDCl_3$) δ: 7.89 (2H, d, *J* = 8.6 Hz), 7.60 (2H, d, *J* = 8.6 Hz), 5.95 (1H, dd, *J* = 10.7 and 17.2 Hz), 5.35 (1H, dd, *J* = 2.5 and 2.8 Hz), 5.26 (1H, dd, *J* = 1.2 and 17.2 Hz), 5.15 (1H, dd, *J* = 1.2 and 10.7 Hz), 4.39 (1H, dd, *J* = 4.4 and 11.9 Hz), 1.65 (3H, s), 1.33 (3H, s), 1.26 (3H, s), and 1.13 (3H, s). MS (EI), *m/z* (relative intensity): 416, 414, 412 (3, 6, 3); 334, 332 (20, 19) and 235, 233 (96, 100); and 219 (10).

Transformation of 6 into 8

To a solution of **6** (16 mg, 0.05 mmol) in CH_2Cl_2 (3 mL) was added MnO_2 (10 mg, 0.12 mmol) and the mixture was stirred for 2 h at room temperature, filtered off, the solvent evaporated, and the residue chromatographed by HPLC. The physical and spectral properties of the ketone obtained were identical with those observed for compound **8**.

Synthèse, structure et études spectroscopiques RMN ^1H et ^{13}C de dérivés perhydrocyclododéca[*b*]furaniques

MICHEL ALBRAND, RENÉ DOLMAZON[1] ET PATRICK POLLET

Laboratoire de chimie organique, Département de biochimie, Institut national des sciences appliquées, 20 Avenue Albert Einstein, 69621 Villeurbanne CEDEX, France

Reçu le 25 juillet 1990

MICHEL ALBRAND, RENÉ DOLMAZON et PATRICK POLLET. Can. J. Chem. **69**, 521 (1991).

Une voie d'accès à une série de perhydrocyclododéca[*b*]furan-3-ols, perhydrocyclododéca[*b*]furan-3-ones et perhydrocyclododéca[*b*]furanes est décrite. Leurs configurations, en particulier celles de la jonction de cycles, sont précisées. Pour le couple de perhydrocyclododéca[*b*]furan-3-ones ou de perhydrocyclododéca[*b*]furanes, l'isomère *cis* est beaucoup moins stable que son épimère *trans*, en accord avec les résultats de l'analyse conformationnelle conduite par mécanique moléculaire. Leurs caractéristiques spectrales RMN ^1H et ^{13}C sont précisées.

Mots clés : perhydrocyclododéca[*b*]furanes, conformations, mécanique moléculaire, RMN ^1H et ^{13}C.

MICHEL ALBRAND, RENÉ DOLMAZON, and PATRICK POLLET. Can. J. Chem. **69**, 521 (1991).

A synthetic route to perhydrocyclododeca[*b*]furan-3-ols, perhydrocyclododeca[*b*]furan-3-ones, and perhydrocyclododeca[*b*]furan derivatives is described. Their configurations were determined. For the perhydrocyclododeca[*b*]furan-3-one and perhydrocyclododeca[*b*]furan pairs, the *cis* isomer was much less stable than the *trans* isomer. This agrees well with results from a conformational analysis, carried out by molecular mechanics. The ^1H and ^{13}C NMR spectra are reported.

Key words: perhydrocyclododeca[*b*]furans, conformations, force field calculations, ^1H and ^{13}C NMR.

La configuration *cis* ou *trans* de fusion de cycles à 12 et 5 atomes n'est pas clairement définie. Les tentatives d'assignation de structure effectuées sur les bicyclo[10,3,0]pentadécanones-13 (1–3) ont conduit à des analyses contradictoires, ce qui est dû essentiellement à l'impossibilité de distinguer et d'identifier chaque isomère du couple de jonction *cis* ou *trans*. Dans le cas du couple d'oxa-13 bicyclo[10,3,0]pentadécanes (4–6), les deux isomères ont été observés, mais aucune assignation de structure n'a été effectuée.

En raison de l'intérêt industriel (propriétés olfactives, parfums à odeur musquée) que suscitent ces deux types des composés précités, nous nous sommes intéressés à l'étude d'une série de dérivés oxa-13 bicyclo[10,3,0]pentadécaniques (perhydrocyclododéca[*b*]furanes), l'anisotropie introduite par l'hétéroatome oxygéné devant permettre de différencier spectroscopiquement (RMN ^1H et ^{13}C) le couple d'isomères de jonction. Nous décrivons la synthèse, la structure et les caractéristiques spectrales RMN ^1H (et pour certains ^{13}C) de perhydrocyclododéca[*b*]furanols-3 **4**–**7**, perhydrocyclododéca[*b*]furanones-3 **8**, **9** et perhydrocyclododéca[*b*]furanes **10**, **11**.

Synthèses

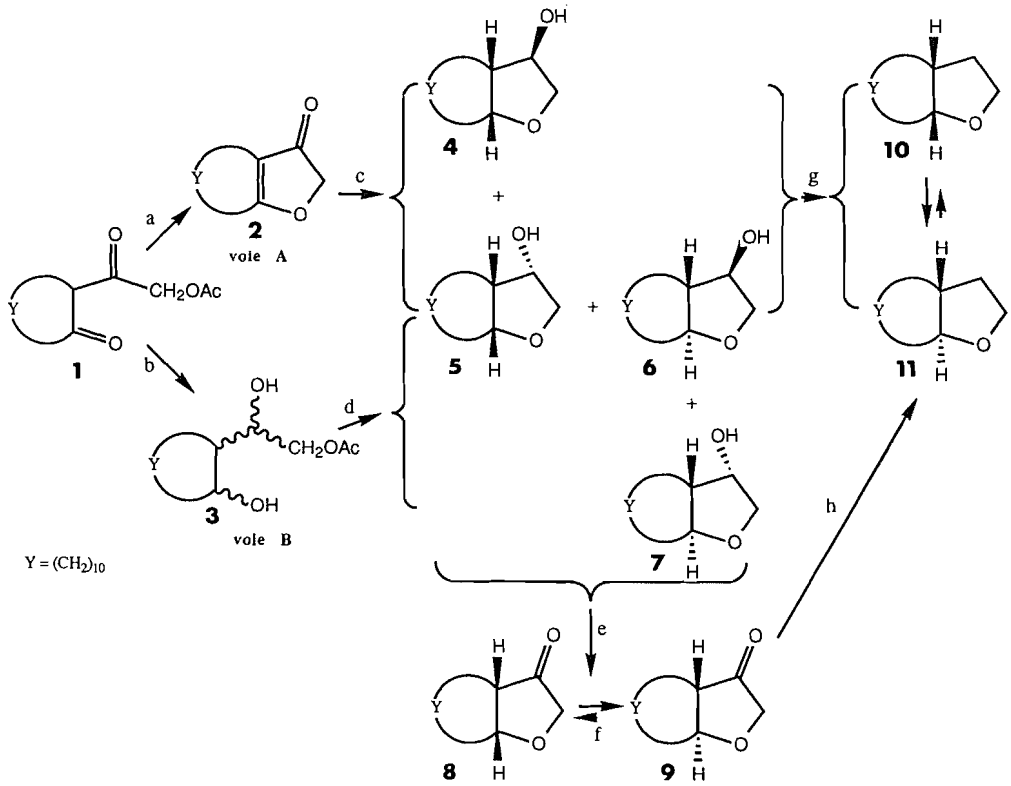
Les perhydrocyclododéca[*b*]furanols-3 **4**–**7** ont été obtenus selon deux voies A ou B à partir de l'acétoxyacétyl-2 cyclododécanone (**1**), préparée par acylation du morpholino-1 cyclododécène au moyen du chlorure de l'acide acétoxyacétique (figure 1). Nous avons déjà utilisé ces méthodes lors de la synthèse de perhydrocyclopenta[*b*]furanols-3 (8) et perhydrocyclohepta[*b*]furanols-3 (9).

Voie A : la β-dicétone acétoxylée **1** est préalablement cyclisée, dans l'acide sulfurique concentré, en cétone éthylènique **2**, hydrogénée ensuite, en catalyse hétérogène (Ni de Raney W_4), en alcools **4**, **5** et **6**, séparés et identifiés sous forme d'acétates correspondants **4***a*, **5***a* et **6***a*. La composition du mélange est respectivement la suivante : 53, 35 et 12%.

Voie B : la β-dicétone acétoxylée **1** est réduite par l'hydrogène, en présence de nickel de Raney W_4, en un mélange de dihydroxy acétates **3**, cyclisés ensuite en milieu acide en alcools **5**, **6** et **7**, séparés et identifiés sous forme d'acétates correspondants **5***a*, **6***a* et **7***a*. La composition du mélange est respectivement la suivante : 46, 34 et 20%.

L'oxydation de ces alcools (voies A ou B) dans des conditions décrites comme non épimérisantes (réactif de Jones (10) ou chlorochromate de pyridinium (11)) conduit à des mélanges des perhydrocyclododéca[*b*]furanones-3 **8** et **9** dont la composition varie en fonction de l'origine des alcools (voie A ou B) et aussi des traitements de purification. La cétone **8** a été dosée approximativement (par spectroscopie RMN ^1H) à 80%, dans le meilleur des cas, sur le mélange brut des deux cétones obtenues par oxydation des alcools issus de la voie A au moyen du réactif de Jones. Cette cétone **8** s'est avérée très instable; les tentatives de purification (distillation ou passage sur colonne de silice) n'ont fait que diminuer sa teneur dans les mélanges **8** + **9**. Divers mélanges de ces deux cétones, placés dans des conditions épimérisantes, en présence de triéthylamine (12), ont conduit à un mélange **8** + **9** de composition à l'équilibre 5 : 95.

Les perhydrocyclododéca[*b*]furanes **10** et **11**, composés connus (4–6), ont été obtenus à partir soit du mélange d'alcools saturés **4**–**6** par réduction de leurs tosylates au moyen de $LiAlH_4$ (13, 14), soit du mélange à l'équilibre des cétones saturées **8** + **9** par réduction de Wolff–Kishner dans la modification de Huang–Minlon (15). La stéréochimie de chacune de ces réductions, bien qu'elle soit imprévisible dans le cas d'une réduction de Wolff–Kishner (16), n'a pas fait l'objet d'études de notre part. Dans les deux cas, l'examen en chromatographie préparative en phase vapeur du mélange réactionnel a révélé la présence de deux isomères **10** et **11**, mal séparés, le premier élué (**11**) étant très fortement majoritaire 70–85%. Nos conditions d'analyse chromatographique se sont avérées épimérisantes. Un nouveau passage dans les mêmes conditions d'un échantillon préalablement enrichi en isomère **10** (teneur voisine de 40%, déterminée par RMN ^{13}C) a conduit à un nouveau mélange où la teneur en composé **10** n'était plus que de 15% environ.



Structures

1. Calculs des structures des bicycles perhydrocyclododéca[b]-furanes 8, 9, 10 et 11

La conformation L = [3333], du cyclododécane possède

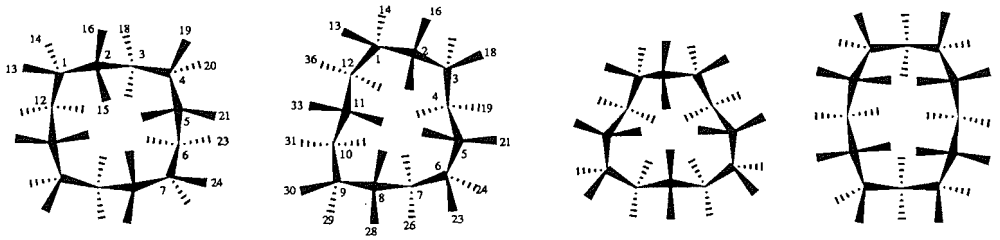
FIG. 1

approximativement la symétrie D_4 (figure 2). Cette conformation «carrée», trouvée dans la structure cristalline (17), est en accord avec les données RMN (18, 19) et est celle de plus basse enthalpie calculée (20). En accord avec la littérature (20), nos calculs effectués à l'aide du champ empirique de forces MMX (21) confirment l'existence de quatre conformations compétitives (figure 2) et montrent en particulier que l'enthalpie de la conformation M = [2334] n'est que de 1,02 kcal/mol supérieure à celle de la conformation carrée L. En raison de la moindre symétrie de la conformation M, cette dernière possède une entropie supérieure à celle de L, ce qui entraine une différence d'énergie libre inférieure à la différence d'enthalpie entre les conformères L et M, ce qui montre que les populations de L et M sont du même ordre de grandeur. Pour la suite de notre travail nous avons considéré que seules les conformations L, M et N possèdent une population significative à température ambiante.

Les dérivés tétrahydrofuraniques, comme les dérivés cyclopentaniques (22), sont connus pour leur extrême mobilité conformationnelle (22–25), la conformation évoluant entre deux formes extrêmes d'énergies voisines (1 kcal/mol), demi-chaise C_2 (26) et enveloppe C_s (27).



La fusion du cycle tétrahydrofuranique avec le cycle cyclododécane est très restrictive dans la mesure où le cycle à cinq membres ne tolère pas d'angle dièdre endocyclique supérieur à 50° (22) sans introduire rapidement de fortes contraintes stériques.

Les énergies des différentes conformations des bicycles **8**, **9**, **10** et **11** ont été calculées par minimisation des différentes conformations bâties à partir des conformations L, M et N du cyclododécane. Les conformations initiales mettant en jeu une ou deux liaisons de cycle endocyclique par rapport au cyclododécane, ainsi que celles impliquant un angle diédre endocyclique de fusion par rapport au cycle tétrahydrofuranne supérieur à 60° ont été négligées. Une étude systématique, conduite sur les conformations bâties sur L, a confirmé ces restrictions. Trois exemples de conformations optimisées des hétérobicycles sont représentées sur la figure 3. La géométrie et les énergies des cinq conformations privilégiées des composés **8**, **9**, **10** et **11** sont données respectivement dans les tableaux 1 et 2. L'analyse des résultats montre que pour chaque composé les faibles écarts énergétiques calculés entre les différentes conformations n'en privilégient aucune et que l'isomère *trans* est plus stable que l'isomère *cis* (écart énergétique significatif d'environ 2,5 kcal/mol entre les conformations les plus stables).

2. Détermination de structures

La nature de la jonction de cycles des dérivés perhydrocyclododéca[*b*]furaniques est déduite des résultats qui suivent. L'addition, à caractère *syn* stéréospécifique, d'hydrogène par catalyse hétérogène sur la cétone éthylènique **2** devrait conduire à deux alcools de jonction de cycles *cis*. L'obtention de trois alcools **4**, **5** et **6** (voie A) (figure 1) montre que les conditions dures, épimérisantes, nécessaires à la réduction de la double liaison tétrasubstituée, ont entrainé une épimérisation partielle de la cétone intermédiaire énolisable *cis*, comme nous l'avons déjà observé sur des systèmes voisins (28). L'oxydation, non épimérisante, de ce mélange d'alcools conduit à un mélange des cétones **8** et **9** où la cétone **8**, fortement majoritaire (80% au moins), s'avère très instable et s'épimérise très facilement en

FIG. 2. Conformations préférentielles du cyclododécane.

$LO_{21}C_{23}$[a] $MO_{13}C_{36}$ $MO_{18}C_{16}$

[a]L signifie que le conformère est bâti à partir de la conformation L du cyclododécane par substitution des atomes d'hydrogène 21 et 23 par l'atome d'oxygène et un atome de carbone du cycle tétrahydrofurannique.

FIG. 3. Types de conformations préférentielles des composés **8**, **9**, **10** et **11**.

cétone **9** plus stable. L'ensemble de ces données associé aux résultats des calculs précédents conduisent à attribuer une jonction de cycles *cis* à la cétone **8** et *trans* à la cétone **9**, nettement plus stable. Cette plus grande stabilité de l'isomère *trans* par rapport à l'isomère *cis* a été également constatée dans le cas du couple de bicyclo[10,3,0]pentadécène-14-ones-13 *cis* et *trans* (29). La comparaison des compositions des mélanges des alcools **4**, **5** et **6** (53, 35 et 12%) et des cétones *cis* et *trans* **8** et **9** (80 et 20%) obtenus selon la même voie A permet de déduire que les deux alcools fortement majoritaires **4** et **5** possèdent une jonction de cycles *cis*. L'autre couple d'alcools **6** et **7** de jonction de cycles *trans* est obtenu selon la voie B moins stéréosélective. L'assignation de structure au niveau du carbone C-3 pour chaque couple d'alcools de jonction *cis* ou *trans* a été établie à l'examen des données spectroscopiques RMN ^1H de leurs acétates. Pour un couple d'acétates, de jonction donnée, le déplacement chimique du proton carbinolique H-3 est plus important lorsqu'il est en *cis* du proton H-3a que lorsqu'il est en *trans* (8, 9, 30). L'épimérisation du perhydrocyclododéca[*b*]furane (**10**) en son épimère **11**, observé lors de l'analyse chromatographique (colonne DEGS, Chromosorb W NAW), permet d'attribuer la configuration *trans* à l'épimère le plus stable **11**. Cette épimérisation peut s'expliquer par formation d'un ion oxocarbonium (31, 32) (figure 4) obtenu par abstraction d'un ion hydrure (H-13a) (33). Cette dernière est engendrée par le caractère acide du Chromosorb et favorisée par l'assistance des orbitales libres de l'atome d'oxygène voisin.

3. Étude spectroscopique RMN ^1H et ^{13}C des perhydrocyclododéca[b]furanones-3 et perhydrocyclododéca[b]furanes

(a) RMN ^1H (300 MHz)

Les deux cétones isomères *cis* **8** et *trans* **9** sont différenciées par l'examen des signaux des protons en α de l'hétéroatome oxygéné. Le déplacement du proton de jonction H-13a est plus important dans l'isomère *cis* (4,31 ppm) que dans l'isomère *trans* (4,15 ppm), comme pour le couple de bicyclo[10,3,0]-pentadécène-14 ones-13 *cis* et *trans* (29). Un couplage longue distance de 0,7 Hz est observé entre l'un des protons H-2 et le proton H-3a pour la seule cétone *trans* comme dans le cas de la perhydrocyclohepta[*b*]furanone-3 *trans* (9). L'accès aux constantes de couplage vicinal du proton H-3a (8,0; 6,7 et 4,3 Hz) de la cétone *trans* **9**, par irradiation sélective des protons de jonction de cycles, comparées à celles calculées (tableau 2) pour les conformations les plus probables, confirme l'extrême mobilité de cette molécule à température ambiante. Les spectres des deux perhydrocyclododéca[*b*]furanes *cis* (**10**) et *trans* (**11**) ne présentent que de très faibles différences, indiquées dans la partie expérimentale.

(b) RMN ^{13}C

Les spectres des deux diastéréoisomères de chaque couple de cétones **8**, **9** et d'hétérocycles saturés **10**, **11** sont nettement différenciés, principalement au niveau des déplacements chimiques des atomes de carbone de l'hétérocycle oxygéné. Dans les deux cas, en passant de l'isomère *cis* à l'isomère *trans*, les déplacements chimiques des atomes de carbone de jonction sont légèrement plus importants (0,83–2,07 ppm) tandis que ceux des atomes de carbone C-2 sont légèrement plus faibles (1,26–1,35 ppm). Ces faibles variations peuvent être interprétées, dans le cas des deux atomes de jonction, en termes d'effets de substituants aliphatiques (34) introduits par le cycle cyclododécane sur l'hétérocycle. Ces effets seraient dépendants de la conformation du cyclododécane. Les études (19, 20) conduites à basses températures sur le cyclododécane en conformation carrée bloquée, révèlent un blindage de 4,3–4,8 ppm, selon les auteurs, des atomes de carbone «non coin» par rapport à ceux de «coin». Ce blindage est interprété (35, 36) en terme de combinaison d'effets γ-*gauche* pour les atomes de carbones non coin et d'effet «vicinal *gauche*» pour les carbones coin. Cette interprétation permet d'expliquer dans notre cas le faible blindage (0,83–2,07 ppm) des atomes des carbones de jonction, en passant de l'isomère *cis* à l'isomère *trans*. En effet l'examen

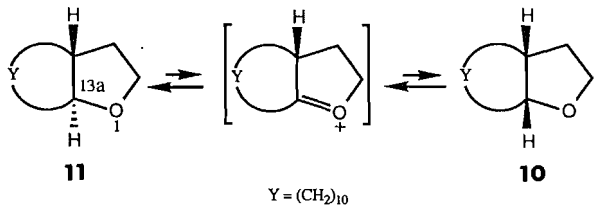

FIG. 4

des conformations calculées révèle que toutes celles de jonction *cis* mettent en jeu un atome de carbone coin du cyclododécane (cette notion de coin à été étendue à la conformation M), tandis que certaines de type $LO_{21}C_{23}$ de jonction *trans* ne mettent en jeu que des atomes de carbones non coin. Ce modeste blindage observé reflète donc simplement une participation des conformations de type $LO_{21}C_{23}$ dans les composés *trans*.

Partie expérimentale

Les points de fusion ont été déterminés au banc chauffant Kofler. Les distillations boule à boule ont été effectuées sur appareil Büchi. Les températures d'ébullition ne sont pas corrigées. Les spectres IR ont été enregistrés sur spectromètre Beckman Acculab 2. Les spectres de RMN ont été réalisés dans le deutériochloroforme sur spectromètres Bruker WP-80 ou AM-300 pour le proton (^{1}H) et Bruker AM-300 à 75,47 MHz pour le carbone 13 (^{13}C). Les déplacements chimiques sont exprimés en ppm par rapport au tétraméthylsilane. Les séparations par chromatographie en phase vapeur ont été réalisées aux températures de 155–190°C, sur un appareil Varian Aerograph 90 P équipé avec la colonne suivante : longeur 6 m; diamètre 1/4 de pouce; phase DEGS (20%) sur Chromosorb W NAW 60/80. Les analyses élémentaires ont été faites au laboratoire de Microanalyses, Centre national de la recherche scientifique, 69390 Vernaison, France.

Synthèse de l'acétoxyacétyl-2 cyclododécanone (1)

Une solution de 0,1 mol de chlorure de l'acide acétoxyacétique dans 50 mL de toluène anhydre est ajoutée lentement à une solution de 0,1 mol de morpholino-1 cyclododécène (2, 37) et 0,1 mol de triéthylamine dans 150 mL de toluène anhydre, placée à température ambiante sous bonne agitation. L'addition terminée, le mélange réactionnel est maintenu sous agitation pendant 48 h puis hydrolysé à température ambiante pendant 5 h avec 70 mL d'acide chlorhydrique environ 2 M. La phase organique est extraite avec du chlorure de méthylène, neutralisée, lavée à l'eau, séchée, concentrée et distillée sous pression réduite, Eb 150–180°C/1 Torr (1 Torr = 133,3 Pa); Rdt 57%; IR (film) : 1750, 1705 et 1625 cm^{-1}. La β-dicétone cristallise lentement. Une recristallisation dans l'éthanol permet d'éliminer la cyclododécanone résiduelle et d'obtenir la β-dicétone pure. Rdt 62%; *F* (éthanol) 72–74°C, RMN ^{1}H (80 MHz) : 1,00–3,00 (m, 20H), 2,14 (s, 3H, OAc), 3,80 (dd, *J* = 10,7 et 3,1 Hz, 1H cétonique), 4,66 (s, 2H, CH_2-O). Anal. calc. pour $C_{16}H_{26}O_4$: C 68,05, H 9,28; tr. : C 68,21, H 9,56. Les formes énoliques de cette β-dicétone ne sont pas détectées dans ces conditions, contrairement à ce que nous avons observé avec des β-dicétones comparables (8, 9). La très faible coloration avec le chlorure ferrique en solution éthanolique confirme le très faible taux d'énolisation de cette β-dicétone.

Synthèse de la décahydro-4,5,6,7,8,9,10,11,12,13(2 H)cyclododéca-[b]furanone-3 (2)

À 40 mL d'acide sulfurique concentré et froid sont ajoutées progressivement, sous bonne agitation, de façon que la température reste inférieure à −5°C, à 20 mmol de β-dicétone **1** recristallisée. Dès que la dissolution est totale, le mélange réactionnel est laissé à température ambiante pendant 0,5 h puis versé sur de la glace et extrait au chloroforme. La phase organique est neutralisée, lavée à l'eau, séchée et concentrée. Le résidu est purifié par passage sur colonne de silice avec l'éther éthylique comme éluant. Rdt 64%; *F* (éthanol) 68–69°C; IR ($CHCl_3$) : 1700, 1620 cm^{-1}, RMN ^{1}H (80 MHz) : 1,00–2,00 (m, 16H), 2,10–2,30 (m, 2H), 2,40–2,60 (m, 2H), 4,35

(s, 2H, CH_2-O). Anal. calc. pour $C_{14}H_{22}O_2$: C 75,63, H 9,97; tr. : C 75,82, H 9,90.

Synthèse des (acétoxy-2 hydroxy-1 éthyl)-2 cyclododécanols (3)

Une solution de 30 mmol de dicétone **1** dans 50 mL d'éthanol est hydrogénée en présence de nickel de Raney W_4 sous une pression initiale de 150 atm (1 atm = 101,3 kPa) pendant 24 h à 60°C. Après élimination du catalyseur et du solvant, le résidu est distillé sous pression réduite. L'huile visqueuse obtenue contient les dihydroxy acétates attendus, identifiés par spectroscopie IR. Rdt en composé brut 90%; IR (film) : 3500–3300, 1750–1725 cm^{-1}. Ces composés sont ensuite utilisés sans autre purification.

*Synthèse des perhydrocyclododéca[*b*]furanols-3* **4**–**7** *et de leurs acétates correspondants* **4**a–**7**a

(a) À partir de la cétone éthylènique **2**

Une solution de 50 mmol de cétone **2** dans 60 mL d'éthanol est hydrogénée en présence de nickel de Raney W_4 à 60°C sous une pression initiale de 140 atm pendant 24 h. Après élimination du catalyseur puis du solvant, le résidu est distillé sous pression réduite et conduit à un mélange d'alcools **4**–**6**; Eb 120–130°C/0,1 Torr; Rdt 85%; IR (film) : 3550–3200 cm^{-1}. Le mélange de ces alcools est transformé par l'anhydride acétique dans la pyridine anhydre, en acétates correspondants **4***a*–**6***a*. Ces trois acétates sont difficilement séparés et dosés par chromatographie en phase vapeur sur colonne DEGS à 190°C. L'ordre d'élution est le suivant : **6***a* (12%), **5***a* (35%) et **4***a* (53%). **4***a*–**6***a*, Eb 110–120°C/0,5 Torr; Rdt 80%; IR (film) : 1745 cm^{-1}. Anal. calc. pour $C_{16}H_{28}O_3$: C 71,60, H 10,52; tr. : C 71,35, H 10,39.

(b) À partir des dihydroxy acétates **3**

Une quantité de 10 mmol de dihydroxy acétates **3** est ajoutée à une solution de 2 mL de chlorure d'acétyle dans 60 mL d'éthanol absolu. Le mélange réactionnel est placé à reflux pendant 3 h puis concentré et distillé sous pression réduite pour conduire au mélange d'alcools **5**–**7**; Eb 120–130°C/0,1 Torr; Rdt 50%; IR (film) : 3550–3200 cm^{-1}. Le mélange de ces alcools est transformé en acétates correspondants **5***a*–**7***a* comme précédemment. Les trois acétates sont partiellement séparés par chromatographie en phase vapeur. L'ordre d'élution est le suivant : **6***a* puis **5***a* + **7***a*. Le dosage par chromatographie associé au dosage RMN ^1H (pour **5***a* et **7***a*) permet d'apprécier la composition du mélange : **6***a* (34%); **5***a* (46%) et **7***a* (20%); RMN ^1H (300 MHz) : **4***a*, 1,33–1,50 (m, 19H), 1,70 (m, 1H), 2,08 (s, 3H, OAc), 2,21 (m, ΣJ = 30 Hz, 1H, H-3a), 3,71–3,75 (dd, J = 10,4 et 2,9 Hz, 1H, H-2), 4,06–4,12 (m, 2H, H-2′ et H-13a), 5,24–5,28 (td, J = 5,8 et 2,9 Hz, 1H, H-3); **5***a*, 1,34–1,54 (m, 19H), 1,78 (m, 1H), 2,09 (s, 3H, OAc), 2,13–2,18 (m, 1H, H-3a), 3,73–3,77 (dd, J = 10,5 et 1,6 Hz, 1H, H-2), 3,86–3,91 (ddd, J = 7,7, 5,1 et 1,6 Hz, 1H, H-13a), 4,06–4,11 (dd, J = 10,5 et 4,5 Hz, 1H, H-2), 5,30–5,33 (td, J = 5,2 et 1,6 Hz, 1H, H-3); **6***a*, 1,33–1,50 (m, 19H), 1,75 (m, 1H), 2,06 (s, 3H, OAc), 2,19 (m, ΣJ = 20 Hz, 1H, H-3a), 3,83–3,91 (m, 2H, H-2 et H-13a), 3,92–3,97 (dd, J = 10,7 et 4,7 Hz, 1H, H-2′), 4,89–4,91 (m, ΣJ = 8,6 Hz, 1H, H-3); **7***a*, 1,33–1,50 (m, 19H), 1,76 (m, 1H), 2,07 (s, 3H, OAc), 2,20 (m, 1H, H-3a), 3,65–3,69 (dd, J = 10,8 et 1,6 Hz, 1H, H-2), 3,89–3,95 (m, 1H, H-13a), 4,16–4,21 (dd, J = 10,8 et 5,2 Hz, 1H, H-2′), 4,99–5,01 (m, 1H, H-3).

*Synthèse des perhydrocyclododéca[*b*]furanones-3* cis *(8) et* trans *(9)*

Les cétones **8** et **9** sont obtenues par oxydation non épimérisante des mélanges d'alcools **4**–**6** ou **5**–**7** au moyen du réactif de Jones (10) ou du chlorochromate de pyridinium (11). L'extrême instabilité de la cétone *cis* **8** a nécessité une analyse par RMN ^1H des mélanges bruts de cétones **8** et **9**. Les méthodes de purification utilisées (distillation, séparation sur colonne de silice ou chromatographie en phase vapeur) ont modifié la composition des mélanges (enrichissement en composé *trans*). Le mélange de cétones est obtenu avec un rendement (après distillation) de 85% quel que soit le mode d'oxydation; **8** + **9**, IR (film) : 1755 cm^{-1}. Anal. calc. pour $C_{14}H_{24}O_2$: C 74,95, H 10,78; tr. : C 74,95, H 11,07. La cétone *trans* en équilibre avec environ 5% de cétone *cis* cristallise (F 65–67°C). Les analyses spectrales RMN ^1H et ^{13}C de l'isomère *cis* ont été effectuées sur des mélanges ayant subi une purification rapide et partielle sur colonne de silice avec l'éther éthylique comme éluant; RMN ^1H (300 MHz) : **8**, (seuls les protons en α de l'atome d'oxygène ont été différenciés sans ambiguïté de ceux de l'isomère *trans*) 3,88–3,93 (d, J = 17,2 Hz, 1H, H-2), 3,98–4,04 (d, J = 17,2 Hz, 1H, H-2′), 4,28–4,35 (td, J = 5,8 et 7,5 Hz, 1H, H-13a); **9**, 1,33–1,84 (m, 18H), 2,31–2,38 (m, 1H, H-3a), 3,83–3,88 (d, J = 17,3 Hz, 1H, H-2), 4,06–4,11 (dd, J = 17,3 et 0,7 Hz, 1H, H-2′), 4,11–4,18 (m, J = 8,0, 6,7 et 4,3 Hz, 1H, H-13a); RMN ^{13}C : **8**, 21,46, 23,05, 23,31, 23,76, 24,32, 24,94, 25,00, 25,30, 26,17 (C-4 à C-13), 50,43 (C-3a), 69,48 (C-2), 81,90 (C-13a), 216,91 (C-3); **9**, 20,34, 22,71, 23,32, 23,45, 23,58, 23,92, 24,16, 24,58, 30,18 (C-4 à C-13), 48,36 (C-3a), 70,83 (C-2), 81,07 (C-13a), 218,26 (C-3).

*Synthèse des perhydrocyclododéca[*b*]furanes* cis *(10) et* trans *(11)*

(a) À partir des alcools **4**–**6**

À une solution à 0°C de 2 mmol du mélange d'alcools **4**–**6** provenant de la réduction catalytique de **2**, dans 1,5 mL de pyridine anhydre, sont ajoutées 2,2 mmol de chlorure de l'acide *para*-toluènesulfonique. Le mélange est laissé à 0°C pendant 5 h puis versé sur une solution d'acide chlorhydrique 2 M froid. L'extraction à l'éther conduit après séchage et élimination du solvant à 0,65 g de tosylates partiellement cristallisés. Ce résidu, dilué dans 10 mL de THF anhydre, est additionné à 0°C à une suspension de 0,5 g de $LiAlH_4$ dans 4 mL de THF anhydre. L'addition terminée, le mélange est placé à reflux pendant 2 h puis laissé 1 nuit à température ambiante. Le milieu réactionnel est hydrolysé à l'aide d'une solution aqueuse d'acide chlorhydrique 2 M, puis extrait à l'éther. La phase éthérée lavée à l'eau, séchée et concentrée, conduit à 0,3 g d'une huile contenant les perhydrocyclododéca[*b*]furanes attendus. Le produit brut, examiné en chromatographie en phase vapeur sur colonne DEGS à 155°C, révèle la présence du couple d'isomères *cis* et *trans* mal séparés. Le premier pic (majeur) correspond à l'isomère *trans* qui cristallise (F 30°C).

(b) À partir des cétones 8 et 9

À une solution de 2 mmol d'un mélange à l'équilibre de cétones **8** et **9** dans 2,5 mL de diéthylèneglycol sont ajoutés 0,25 mL d'hydrate d'hydrazine puis 0,3 g de potasse en pastilles. Le mélange est placé à reflux 0,5 h. L'élimination d'eau permet de porter la température du milieu à 200–220°C pendant 0,5 h. Le mélange préalablement refroidi est extrait à l'éther. La phase éthérée est lavée à l'eau, séchée puis concentrée. Le résidu 0,42 g contient le mélange des perhydrocyclododéca[*b*]furanes **10** et **11**, analysé comme précédemment. L'isomère *trans* est très majoritaire. Les deux composés sont identifiés par spectroscopie RMN ^{13}C. Leurs spectres RMN ^1H ne montrent que de très faibles différences. Les spectres de l'isomère *cis* sont tirés des spectres d'un mélange *cis* + *trans*; RMN ^1H (300 MHz) : **10**, 1,00–1,15 (m, 1H), 1,20–1,60 (m, 20H), 1,60–1,75 (m, 1H), 1,93–2,05 (m, 1H), 3,72–3,90 (m, 3H, H-2, H-2′ et H-13a); **11**, 1,20–1,70 (m, 21H), 2,01–2,14 (m, 2H), 3,75–3,88 (m, 3H, H-2, H-2′ et H-13a); RMN ^{13}C : **10**, 23,37, 23,44, 24,18, 24,64, 25,01, 25,72, 25,92, 26,70, 32,36 (C-3 à C-13), 40,62 (C-3a), 65,53 (C-2), 82,39 (C-13a); **11**, 21,75, 22,78, 23,46, 23,47, 23,91, 24,34, 24,83, 30,26, 31,29, 32,52 (C-3 à C-13), 38,83 (C-3a), 66,79 (C-2), 81,33 (C-13a).

The photochemistry of the rhodizonate dianion in aqueous solution

B. ZHAO AND M. H. BACK

Department of Chemistry, Ottawa-Carleton Chemistry Institute, University of Ottawa, Ottawa, Ont., Canada KIN 6N5

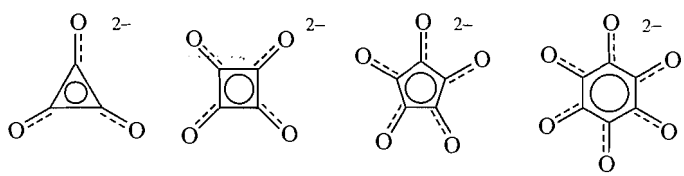
Received July 10, 1990

B. ZHAO and M. H. BACK. Can. J. Chem. **69**, 528 (1991).

The thermal and photochemical reactions of rhodizonate dianion have been studied in aqueous solution in the presence of various oxidizing agents. Both reactions are initiated by electron transfer to an acceptor which is a sufficiently strong oxidizing agent. With hydrogen peroxide and ferricyanide a square root dependence of the rate on the concentration of additive was observed whereas with tetracyanoethylene the rate was first order with respect to additive. This difference in behaviour is explained on the basis of the rate of separation of ions from the initial charge transfer complex. In most cases the main product was croconic acid. NMR analysis of other products indicated some formation of C—H bonds and possibly incorporation of an oxygen atom into the ring. A maximum quantum yield of 0.04 for disappearance of rhodizonate was observed in the presence of tetracyanoethylene.

Key words: photochemistry, rhodizonic acid, dianion, electron transfer.

B. ZHAO et M. H. BACK. Can. J. Chem. **69**, 528 (1991).



Opérant en solutions aqueuses, en présence de divers agents d'oxydation, on a étudié les réactions thermiques et photochimiques du dianion rhodizonate. Les deux réactions sont initiées par un transfert d'électron vers un accepteur qui est un agent oxydant suffisamment fort. Avec le peroxyde d'hydrogène et le ferricyanure, on a observé que la vitesse dépend du carré de la concentration d'additif; par ailleurs, avec le tétracyanoéthylène, la vitesse est du premier ordre par rapport à l'additif. On explique cette différence de comportement sur la base de la vitesse de séparation des ions à partir du complexe initial de transfert de charge. Dans la plupart des cas, le produit principal est l'acide croconique. Des analyses rmn des autres produits indiquent qu'il y a formation de quelques liaisons C—H et qu'il y a possiblement incorporation d'un atome d'oxygène dans le cycle. On a observé que le rendement quantique maximal est égal à 0,04 pour la disparition du rhodizonate en présence de tétracyanoéthylène.

Mots clés : photochimie, acide rhodizonique, dianion, transfert d'électron.

[Traduit par le rédaction]

Introduction

The dianions of the cyclic oxocarbons, ranging from deltate, $C_3O_3^{2-}$, to rhodizonate, $C_6O_6^{2-}$, were first recognized by West and Niu (1, 2) as members of a new type of aromatic series involving only carbon and oxygen atoms. The high degree of symmetry with the delocalized π bonding around the ring leads to strong absorption in the $\pi-\pi^*$ electronic transition. For the rhodizonic dianion the maximum absorption occurs at 483 nm ($\epsilon = 3.2 \times 10^4$ L mol^{-1} cm^{-1}) and the maximum shifts to lower wavelengths as the ring size decreases. Such strong absorptions usually spark the interest of photochemists for fundamental as well as practical reasons, but it appears that no systematic study of the photochemistry of this series of dianions has been reported.

Rhodizonic acid is a weak diprotic acid whose ionization constants are unusually close ($pK_1 = 4.3$; $pK_2 = 4.7$) (3, 4). The ionization processes are complicated by the strong hydration of both the undissociated acid and the monoanion. The abnormal enthalpy and entropy changes accompanying the second ionization are explained by the concurrent loss of two molecules of water in the formation of the dianion. Aerated, aqueous solutions of rhodizonic acid are unstable and in basic solution (pH > 10) quantitative conversion to croconic acid occurs. Exposure to light accelerates the disappearance of the acid but no mechanism for the photolysis reaction has been proposed.

Rhodizonic acid has been used extensively as an analytical reagent for metal ions, particularly iron, lead, and barium (5–7), and several patents for these procedures have been reported (8). Because of the importance of hydroxyquinones in biological processes (9), and in particular in the degradation of DNA (10), the electrochemical oxidation–reduction cycle of rhodizonic acid – tetrahydroxybenzoquinone – hexahydroxybenzene has been extensively studied (11). Inhibiting action has been observed with some enzymes (12). In another direction, the oxoanions have been fertile ground for theoretical studies of electronic structure (13).

The present study was undertaken to examine the photochemical behaviour of the oxocarbon dianions, starting with rhodizonate. A preliminary report appeared earlier in which it was suggested that electron transfer might occur in the photochemical reaction (14). We have now further explored this possibility using several electron acceptors and investigating the kinetics of the reaction. It will be seen that electron transfer does occur but because of rapid reversal is not efficient.

Experimental

Solutions of rhodizonic dianion were prepared daily from distilled and deionized water and deaerated by thorough flushing with Research Grade nitrogen (99.9995%). Oxygen was also removed by degassing under vacuum, using a cell designed so that the degassed solutions of rhodizonic acid and additive could be mixed directly in the spectrophotometer cell while under vacuum. The two procedures gave results identical within the experimental error. Reactions were studied in the range of pH 6–8, using appropriate buffer solutions, where the acid is fully ionized but the base-catalyzed reaction is negligible.

Solutions were irradiated directly in the spectrophotometer cell (1 cm × 1 cm) using a tungsten filament lamp in conjunction with a Schoeffel monochromator, with a band width of ~20 nm. All photolyses were performed at a wavelength of 483 nm, the maximum

of the visible absorption of rhodizonic dianion. To keep the absorbance of the solutions below about 0.9 the concentration of the dianion was kept below 2.5×10^{-5} M. The absorption spectra were recorded using a Unicam SP-1800 Spectrophotometer equipped with a thermostattated cell holder. The incident light intensity was measured using the potassium ferrioxalate actinometer, following procedures outlined by Rabek (15). For measurement of the NMR spectra of the products, the solution was concentrated, following photolysis, by removal of water under vacuum. Spectra were recorded on Varian XL-300.

All chemicals were reagent grade. Except for potassium ferricyanide which was recrystallized from warm water–ethanol solution, the chemicals were used without further purification.

Results

Rhodizonic acid is rapidly oxidized in air-saturated solutions in the dark, the rate increasing with increasing pH. Removal of oxygen stabilizes the system, but in the pH range 6–8 of the present experiments a small residual rate of disappearance of rhodizonate dianion remains in all solutions regardless of the procedures used for degassing. The origin is probably a trace of oxidizing impurity, perhaps residual oxygen.

The thermal and photochemical rates of disappearance of rhodizonic dianion were measured at 20°C in deaerated solutions in the presence and absence of several additives. Only the additives cupric ion, $Fe(CN)_6^{3-}$, H_2O_2, and tetracyanoethylene (TCNE) caused a thermal reaction substantially faster than the residual rate and only with the latter three was the rate increased on irradiation. The measurements of the photochemical rates were reproducible within about 5% as were the higher thermal rates. The slow residual dark reaction had more uncertainty, but was generally consistent. The results are summarized in Table 1. In all cases initial rates were measured.

The thermal dark reaction

Rhodizonate dianion is oxidized rapidly by oxygen or hydrogen peroxide in basic solution to give croconic acid. The first step in the reaction is believed to be attack by the hydroxide ion. The present results show that conversion to croconic acid and other products occurs in neutral or slightly acidic solutions and can be initiated by several oxidizing agents as well as oxygen and hydrogen peroxide.

The fact that reagents such as Cu^{2+}, $Fe(CN)_6^{3-}$, and TCNE are effective suggests that the first step is electron transfer and the first stages of the reaction may be written as

[1] $Rh^{2-} + A \rightleftarrows (Rh^{-\bullet} \ldots A^-)$

[2] $(Rh^{-\bullet} \ldots A^-) \rightleftarrows Rh^{-\bullet} + A^-$

[P] $Rh^{-\bullet} \rightarrow$ products

where $(Rh^{-\bullet} \ldots A^-)$ represents the caged complex before separation of the ions.

Two limiting cases may be considered for the kinetics of the reaction. (*a*) Only a small fraction of ions escape the cage before the reverse electron transfer regenerates the reactants but all those that escape react to form products. This corresponds to the condition $k_2 \ll k_{-1}$ and $k_{-2}[Rh^{-\bullet}]^2 \ll k_p[Rh^{-\bullet}]$. The rate of disappearance of rhodizonate is therefore,

$$\frac{-d}{dt}[Rh^{2-}] = k_2 k_1 [Rh^{2-}][A]$$

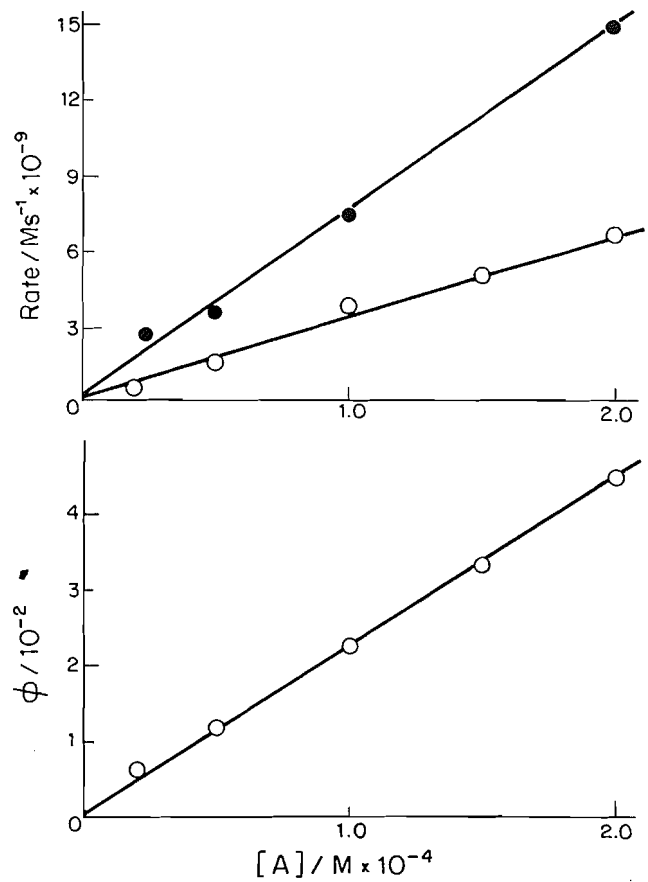

FIG. 2. (*a*) The rate of the thermal dark reaction of rhodizonate dianion with TCNE at pH 7 as a function of the concentration of TCNE. ○: 20°C; ●: 30°C. (*b*) The quantum yield of the photochemical reaction of rhodizonate dianion with TCNE at pH 7 as a function of the concentration of TCNE.

and is first order in concentration of acceptor. (*b*) If the ions escape the cage but still a major fraction undergo the reverse electron transfer and only a small fraction form products, corresponding to the condition $k_p[Rh^{-\bullet}] \ll k_{-2}[Rh^{-\bullet}]^2$, then the concentration of the monoanion radical will be controlled by the equilibrium constants for reactions [1] and [2]. The rate of disappearance of rhodizonate will then be given by

$$\frac{-d}{dt}[Rh^{2-}] = k_p\{K_1K_2[Rh^{2-}][A]\}^{1/2}$$

For this case it is not necessary that the intermediate step [1] attain equilibrium. Only an overall equilibrium involving the electron transfer is indicated and the intermediate step may not be kinetically important.

In the present experiments case (*b*) was observed with the oxidizing agents hydrogen peroxide and potassium ferricyanide. The results are shown in Fig. 1*a* where the rate of the reaction at a fixed concentration of rhodizonate is plotted as a function of $[A]^{1/2}$. Measurements of the rate at 30°C with $Fe(CN)_6^{3-}$ are also included. The rate of the reaction with TCNE, on the other hand, was a linear function of [A] and for this reagent therefore the mechanism corresponds to case (*a*). The results at both 20°C and 30°C are shown in Fig. 2*a*.

Table 1 also includes some experiments with constant concentration of TCNE and $Fe(CN)_6^{3-}$ and variable concentration of Rh^{2-}. Because the rate is measured by the change in absorbance of the rhodizonic acid, its concentration was not varied over a wide range but the results show that with TCNE the rate is proportional to the concentration of rhodizonate and with ferricyanide the rate is proportional to the square root of the concentration of rhodizonate.

At first sight it appears improbable that different limiting cases would be observed for similar reactants, particularly when k_p is the same, and k_{-2} is similar, for each reaction. The difference in rates between $k_{-2}[Rh^{-\bullet}]^2$ and $k_p[Rh^{-\bullet}]$, which governs the order of the rate, arises through the difference in the concentration of the rhodizonate monoanion in the two systems. The change-over in the order occurs when $[Rh^{-\bullet}] = k_p/k_{-2}$. The concentration of the monoanion is largely determined by the rate of separation of the caged complex, which is a function of the structure and properties of the oxidizing agent, including the charge distribution in the complex. It is interesting that similar rates are observed for TCNE and the other two reactants and indicates the compensating effects of k_2, k_{-2}, and k_p. For TCNE the measurements at 30°C, given in Table 2, together with a few measurements at 40°C, suggest an overall activation energy of approximately 40 kJ mol^{-1}.

The equilibrium constant for the over-all one-electron transfer process

[T] $Rh^{2-} + A \rightleftarrows Rh^{-\bullet} + A^-$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

may be expressed as

$$RT \ln K_T = nFE^0$$

where E^0 is the standard cell potential for the cell represented by reaction [T] and

$$E^0 = E^0(A/A^-) - E^0(Rh^{-\bullet}/Rh^{2-})$$

where $E^0(A/A^-)$ and $E^0(Rh^{-\bullet}/Rh^{2-})$ represent the standard reduction potentials for the reactions indicated. Although the experiments were not performed under standard conditions, the concentrations of rhodizonic acid and additive were in the same range, and $[Rh^{-\bullet}] = [A^-]$; hence $E(A/A^-) - E(Rh^{-\bullet}/Rh^{2-})$ will be similar to the cell potential under standard conditions, $E^0(A/A^-) - E^0(Rh^{-\bullet}/Rh^{2-})$. For a particular concentration of rhodizonic acid, K_1 and hence $[Rh^{-\bullet}]$ will therefore be proportional to $E^0(A/A^-)$. From the table it appears that the rate of the thermal reaction correlates roughly with the strength of the oxidizing agents. No oxidation was observed with the following reactants: $S_4O_6^{2-}$ ($E^0 = +0.08$ V); MV^{2+} ($E^0 = -0.42$ V); p-$NO_2C_6H_4CHO$ ($E^0 = -0.86$ V); m-$NO_2C_6H_4CHO$ ($E^0 = -1.02$ v). It may be concluded that oxidizing agents with standard reduction potential below approximately zero volts have not sufficient strength to oxidize rhodizonic acid. This correlation of the rate with potential supports the mechanism of electron transfer.

The photochemical reaction

An increase in rate on irradiation was observed with the reactants hydrogen peroxide, ferricyanide, and tetracyanoethylene. The quantum yields in all cases were low (maximum 4×10^{-2}) as expected when the reverse of reaction [2] is fast. A simple extension of the mechanism for the thermal reaction may be written as follows:

[I_{abs}]	$Rh^{2-} + h\nu$	$\rightarrow Rh^{2-}*$
[D]	$Rh^{2-}*$	$\rightarrow Rh^{2-}$
[1*]	$Rh^{2-}* + A$	$\rightarrow (Rh^{-\bullet} \ldots A^-)$
[−1]	$(Rh^{-\bullet} \ldots A^-)$	$\rightarrow Rh^{2-} + A$
[2]	$(Rh^{-\bullet} \ldots A^-)$	$\rightleftarrows Rh^{-\bullet} + A^-$
[P]	$Rh^{-\bullet}$	$\rightarrow$ products

For the reactants hydrogen peroxide and potassium ferricyanide, corresponding to case (*b*) where $k_p[Rh^{-\bullet}]^2 \ll k_{-2}[Rh^{-\bullet}]^2$, the total rate of disappearance of rhodizonate may be expressed as

$$-\frac{d}{dt}[Rh^{2-}] = k_p\{K_1K_2[Rh^{2-}][A]\}^{1/2} + k_p\left\{\frac{I_{abs}K_2k_1*[A]}{k_{-1}(k_D + k_1*[A])}\right\}^{1/2}$$

Since the rate of disappearance is not independent of [A], $k_D \gg k_1*[A]$, and the quantum yield, obtained by subtraction of the thermal rate from the total rate, may be expressed as

$$\phi = \frac{k_p}{I_{abs}^{1/2}}\left\{\frac{K_2k_1*[A]}{k_{-1}k_D}\right\}^{1/2}$$

The quantum yield for the photochemical reaction with hydrogen peroxide and potassium ferricyanide is shown as a function of $[A]^{1/2}$ for constant concentration of rhodizonate in Fig. 1*b*. The square root dependence on the concentration of additive was observed as predicted for both reactants.

For the reactant TCNE, corresponding to case (*a*), where $k_2 \ll k_{-1}$ and $k_{-2}[Rh^{2-}]^2 \ll k_p[Rh^{-\bullet}]$, the total rate is given as

TABLE 2. Thermal reaction of rhodizonate dianion at 30°C: $[Rh^{2-}] = 2.5 \times 10^{-5}$ M, pH = 7

Additive	Concentration of additive/M	Rate/M s^{-1}
TCNE	2.5×10^{-5}	2.8×10^{-9}
	5.0×10^{-5}	3.6×10^{-9}
	1.0×10^{-4}	7.4×10^{-9}
	2.0×10^{-4}	1.47×10^{-8}
$Fe(CN)_6^{3-}$	1.25×10^{-5}	1.2×10^{-9}
	2.5×10^{-5}	1.7×10^{-9}
	5.0×10^{-5}	2.5×10^{-9}
	2.0×10^{-4}	4.6×10^{-9}

$$-\frac{d}{dt}[Rh^{2-}] = k_2K_1[Rh^{2-}][A] + \frac{k_2I_{abs}k_1*[A]}{k_{-1}(k_D + k_1*[A])}$$

Following the previous reasoning, the quantum yield is given as

$$\phi = \frac{k_2k_1*[A]}{k_{-1}k_D}$$

The linear dependence of the quantum yield for the photochemical reaction with TCNE on the concentration of TCNE is shown in Fig. 2*b*, where the measurements were made with constant concentration of rhodizonic acid.

To test the dependence of the rate on the concentration of rhodizonate dianion, experiments were done with constant concentration of TCNE and ferricyanide with concentrations of rhodizonate of 1.25×10^{-5} M ($I_{abs} = 0.60\ I_0$), 2.5×10^{-5} ($I_{abs} = 0.84\ I_0$) and 5.0×10^{-5} M ($I_{abs} = 0.975 I_0$) and the results are included in Table 1. With TCNE the rate is proportional to I_{abs} while with ferricyanide the rate is proportional to $(I_{abs})^{1/2}$. Thus the mechanism of the oxidation of rhodizonate dianion with the oxidizing agents listed in Table 1 is the same for the thermal and the photochemical reaction. Irradiation of the dianion simply increases the rate of the initial electron transfer.

Products of the reaction

Detection and analysis of products in the dilute solutions used in the present experiments presented some difficulty. In an aqueous solution of ions absorption in the visible or ultraviolet often provides a basis for identification. The only product detected and quantitatively measured by its absorption spectrum was croconic acid. The fraction of rhodizonic acid converted to croconic acid, listed in Table 1, was different with each oxidizing agent. In basic solution rhodizonic acid is quantitatively converted to croconic acid with the oxidizing agents hydrogen peroxide or oxygen. In neutral solution the fraction converted is much less and with oxygen is only about 10%. The most efficient conversion occurred with Cu^{2+}. The fact that each oxidizing agent produced a different rate of conversion to croconic acid indicates that further steps are required for this conversion and these steps, or competing steps, may involve the oxidizing agent. It should be noted that secondary photolysis of croconic acid is not important because the wavelength of maximum absorption of the croconate dianion (363 nm) is far outside the narrow band width of the incident radiation. In basic solution the ring contraction is believed to occur by an α-oxo alcohol rearrangement following attack by hydroxyl ion. The present results show that the ring contraction giving croconic acid may be initiated in neutral solution with several oxidizing agents. No evidence for absorption in the visible and near

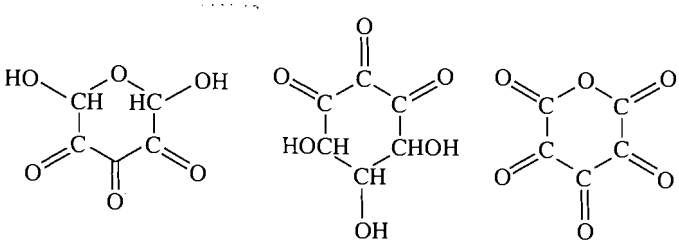

TABLE 3. ^{13}C NMR spectra of the products of the photochemical reaction of rhodizonate dianion

	^{13}C chemical shift for additives =		
Rh^{2-}	$Fe(CN)_6^{3-}$	H_2O_2	O_2

ultraviolet due to other products was obtained with any of the additives; weak absorbers would, of course, escape detection.

The ^{13}C NMR spectra of the reaction products from the reaction with ferricyanide, hydrogen peroxide and oxygen are summarized in Table 3, which includes the single resonance at 177 ppm observed in the neutral solution of rhodizonic acid before reaction. With all the reactants rhodizonic acid was completely consumed. The resonance at 188 ppm shows the presence of croconic acid dianion, formed in all three reactions. Other carbonyl resonances are present in the products from all reactants. Carbonyl resonances due to oxalic or formic acid are, however, absent. No evidence for products contining C—H bonds was obtained with the additives ferricyanide and hydrogen peroxide and except for the resonance at 76 ppm, the products appear similar from both reactants.

With oxygen the products are more diverse and may include secondary oxidations. The broad band proton decoupled spectra showed that the pairs of resonances with chemical shift 92.6 and 90.4 ppm and 77.1 and 75.1 ppm represent carbon atoms bonded to a single hydrogen atom. The resonance at 93.7 ppm which did not involve a C—H bond may indicate a geminol diol carbon, as suggested by Gelb, Schwargz, and Laufer (4) in their interpretation of the NMR spectra of aqueous solutions of rhodizonic acid. It seems clear that in the oxygen system reduction at a carbon atom has occurred and there is strong indication, particularly from the resonance at 91.5 ppm that an oxygen atom has been incorporated into the ring in an ether linkage. Possible products are ring compounds of the type:

Conclusions

The most important conclusion obtained from the present study is that both the thermal and photochemical conversion of rhodizonic acid to croconic acid and other products in aqueous solution are initiated by electron transfer to an acceptor which is a sufficiently strong oxidizing agent. This conclusion is based on several observations: (*a*) The rate of the thermal reaction in the absence of oxygen is increased in the presence of oxidizing agents with positive standard reduction potentials; (*b*) photolysis of the rhodizonic dianion in the presence of additives increased its rate of disappearance only with those additives which noticeably increased its thermal rate of reaction; (*c*) for any one oxidizing agent, the rates of the thermal and photochemical reactions have the same order with respect to the concentration of additive (either square root or linear).

Details of the subsequent reactions of the monoanion radical following the initial electron transfer step cannot be established at this stage. Because the fraction of the product appearing as croconic acid is not the same with each additive, several competing reactions must occur, which will be dependent on the pH of the solution as well as the reduction potential of the additive. The other products suggest that hydration of the monoanion is important and that oxygen may be incorporated into the ring through a ring-contraction mechanism. This type of mechanism does not invalidate the mechanism involving an α-oxo alcohol rearrangement following attack by hydroxide ion suggested for the conversion of rhodizonic acid to croconic acid in an oxygenated alkaline solution. The present results simply show that this conversion is a more general reaction and can occur in neutral solutions and with other oxidizing agents.

One of the aims of the present study was the exploration of the use of rhodizonic acid as a primary absorber of solar energy with subsequent conversion into a useful chemical system. The low quantum yields of the photochemical reaction observed in the present experiments do not provide much encouragement in the pursuit of this goal. It is nevertheless possible that a more efficient electron acceptor, combined with a suitable reactant for the subsequent conversion of the monoanion radical, might prove useful.

STEPHEN P. MEZYK and DAVID A. ARMSTRONG. Can. J. Chem. **69**, 533 (1991).

In basic solution Cu(II) ions form planar complexes of stoichiometry Cu(II).L_2 with penicillamine molecules, where both the nitrogen and sulphur atoms of the thiol [$(\ddot{N}H_2)CH(CO_2^-)C(CH_3)_2S^-$] are involved in the coordination. The rates of reduction of this complex by the formate radical and the thiyl radical of penicillamine have been measured by pulse radiolysis.

The rate constant for reaction [14] has been found to be $1.2 \pm 0.2 \times 10^8\ M^{-1}\ s^{-1}$

[14] $\cdot CO_2^- + Cu^{II}(PenS^-)_2 \rightarrow CO_2 + Cu^{I}(PenS^-)_2$

For the thiyl radical, which is not inherently reducing, reduction must involve the PenS.∴SPen$^-$ anion complex.

[2] PenS.∴SPen$^-$ + $Cu^{II}(PenS^-)_2 \rightarrow (PenS)_2 + Cu^{I}(PenS^-)_2$

Under the conditions of this study, ([PenS$^-$] ~ 10^{-2} M, pH = 10.0), this anion exists in free solution equilibrium with PenS·

[1] PenS· + PenS$^- \underset{}{\overset{K_1}{\rightleftharpoons}}$ PenS.∴SPen$^-$ $\quad K_1 = 60.0$

A systematic study of the dependence of the overall reduction rate on [PenS$^-$] showed that the reaction proceeded rapidly even when the PenS.∴SPen$^-$ concentration was negligibly small. This finding can be explained by the formation of an internal PenS.∴SPen$^-$ anion from the reaction of free PenS· with one of the PenS$^-$ ligands of the Cu(II) complex:

[3] PenS· + Cu(II)$(PenS^-)_2 \rightarrow$ (PenS$^-$)Cu(II)(PenS.∴SPen$^-$)

and the subsequent rapid transfer of an electron to Cu(II):

[4] (PenS$^-$)Cu(II)(PenS.∴SPen$^-$) → (PenS$^-$)Cu(I)(PenSSPen)

Analysis of the results gave $k_2 = 2.9 \pm 0.3 \times 10^8\ M^{-1}\ s^{-1}$ and $k_3 = 3.4 \pm 0.4 \times 10^8\ M^{-1}\ s^{-1}$.

Key words: penicillamine, thiyl, reduction, copper(II), radical, disulphide ion.

STEPHEN P. MEZYK et DAVID A. ARMSTRONG. Can. J. Chem. **69**, 533 (1991).

En solution basique, la pénicillamine et les ions Cu(II) forment des complexes plans de stoechiométrie Cu(II).L_2 dans lesquels les atomes d'azote et de soufre du thiol [$(:NH_2)CH(CO_2^-)C(CH_3)_2S^-$] sont impliqués dans la coordination. Utilisant la radiolyse pulsée, on a mesuré les vitesses de réduction de ce complexe par le radical formiate ainsi que par le radical thiyle de la pénicillamine.

On a trouvé que la constante de vitesse pour la réaction [14] est égale à $1{,}2 \pm 0{,}2 \times 10^8\ M^{-1}\ s^{-1}$.

[14] $\cdot CO_2^- + Cu^{II}(PenS^-)_2 \rightarrow CO_2 + Cu^{I}(PenS^-)_2$

Pour le radical thiyle, qui inhéremment n'est pas un réducteur, la réduction doit impliquer le complexe anionique PenS.∴SPen$^-$.

[2] PenS.∴SPen$^-$ + $Cu^{II}(PenS^-)_2 \rightarrow (PenS)_2 + Cu^{I}(PenS^-)_2$

Dans les conditions utilisées au cours de ce travail, ([PenS$^-$] ~ 10^{-2} M, pH = 10,0), cet anion existe en solution, en équilibre libre avec le PenS.

[1] PenS· + PenS$^- \underset{}{\overset{K_1}{\rightleftharpoons}}$ PenS.∴SPen$^-$ $\quad K_1 = 60.0$

Une étude systématique sur la relation entre la vitesse globale de réduction et la [PenS$^-$] montre que la réaction se produit rapidement, même lorsque la concentration de PenS.∴SPen$^-$ est très faible. Cette observation pourrait être expliquée par la formation d'un anion PenS.∴SPen$^-$ interne par la réaction du PenS· libre avec un des ligands PenS$^-$ du complexe du Cu(II):

[3] PenS· + Cu(II)$(PenS^-)_2 \rightarrow$ (PenS$^-$)Cu(II)(PenS.∴SPen$^-$)

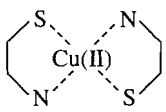
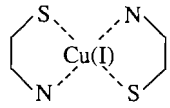
Introduction

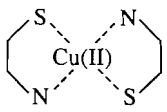
The importance of nitrogen- and sulphur-centered ligands in copper-containing enzymes and metallothionenes (1–3) has stimulated fundamental research on the structures of these systems. Because of the catalytic roles of several of the metalloproteins, oxidation–reduction reactions between sulphur species and copper systems are also of interest (4, 5). The bidentate 1,2-aminothiol ligands, cysteine and penicillamine, are among the simplest that can be used for model studies. Recently a report on the kinetics of oxidation of $Cu(I)_nL_{n+1}$ systems ($n = 1$ or 2) by thiyl radicals was made (6) for these two ligands. The thiyl (CysS·, PenS·) radicals are moderately strong one-electron oxidizing agents, with $E^0(RS\cdot/RS^-) = 0.77$ V (7). For typical alkaline conditions with thiol concentrations of 10^{-2} M, however, they are in equilibrium with the $\sigma\sigma^*$ bonded $RS.^{\cdot}.SR^-$ anion radicals (7), for example:

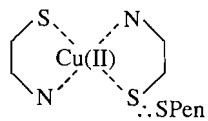




[1]/[−1] $PenS\cdot + PenS^- \rightleftharpoons PenS.^{\cdot}.SPen^-$

These are less strong oxidants ($E^0(RS.^{\cdot}.SR^-/2RS^-) = 0.57$ V (7)), and predictably were found to react less rapidly than the RS· species.





During the course of the study described in ref. 6 it was also confirmed (cf: refs. 8, 9) that the $Cu(II)(PenS^-)_2$ species was stable for several hours at pH values above 10. Earlier work (10) had shown that this species, which was itself the product of the oxidation of $Cu(I)_nL_{n+1}$, could also be reduced by the same sulphur radicals. The purpose of the present investigation was to examine this interesting phenomenon in greater detail.

In principle $R_2CHS\cdot$ radicals with α hydrogens can undergo rearrangement to form the reducing species $R_2C\cdot—S^-$ or $R_2\dot{C}—SH$. However, PenS· has no α hydrogens. Thus the only way for it to be a reducing agent is through the formation of $PenS.^{\cdot}.SPen^-$, which although a mild oxidant is also a strong reductant ($E^0(RSSR/RS.^{\cdot}.SR^-) = -1.6$ V (7)). The rates of reactions [1] and [−1] are sufficiently fast (11) that for typical $PenS^-$ concentrations ($\sim 10^{-2}$ M) the relaxation time $\tau = k_{-1} + k_1[PenS^-]$ is about 0.4 μs. Thus equilibrium [1] would be maintained during the reactions of PenS· and $PenS.^{\cdot}.SPen^-$ with copper species, for which τ is typically 15 μs (data of ref. 6 and below).

Two modes of reduction are possible. The $PenS.^{\cdot}.SPen^-$ present in the bulk solution could directly reduce the Cu(II) species, reaction [2]:

[2] $PensS.^{\cdot}.SPen^- +$  → 

or the free PenS· could react with a $PenS^-$ ligand:

[3] $PensS\cdot +$  → 

I

Due to the strong negative value of $E^0(RSSR/RS.^{\cdot}.SR^-)$, the "internal disulphide anion" would be capable of rapidly transfering an electron to the Cu(II) center, viz.:

[4] $\mathbf{I} \rightarrow Cu(I)(PenS^-)(PenSSPen)$

II

The intermediate **I** should therefore have an extremely short lifetime, and it is reasonable to assume that the reaction rate would be controlled by k_3. The disulphide ligand in **II** should subsequently be replaced by $PenS^-$:

[5] $\mathbf{II} \xrightarrow{(+\ PenS^-)} Cu(I)(PenS^-)_2 + PenSSPen$

The primary object of this investigation was to assess the relative importance of reaction [2] and reactions [3] + [4], and, if possible, to determine their rate constants. At the same time the conditions affecting the photostationary state, reached when the rates of oxidation and reduction were equal (10), were also examined.

The PenS· radicals were produced by the radiolysis of nitrous oxide-saturated aqueous solutions of PenSH, buffered at the desired pHs. The relevant reactions are as follows (12, 13):

[6] $0.43H_2O \rightsquigarrow 0.28e_{aq}^- + 0.28H_3O^+ + 0.29\cdot OH + 0.05H\cdot + 0.05H_2 + 0.07H_2O_2$

(coefficients are in μmoles per J of radiation energy absorbed)

[7] $e_{aq}^- + N_2O + H_2O \rightarrow \cdot OH + N_2 + OH^-$

[8] $\cdot OH\ (\text{or } \cdot H) + PenSH \rightarrow H_2O\ (\text{or } H_2) + PenS\cdot$

[9] $\cdot OH + N_3^- \rightarrow OH^- + \cdot N_3$

[10] $\cdot N_3 + PenS^- \rightarrow N_3^- + PenS\cdot$

Reactions [6] through [8] were used at pH 10 and reactions [6], [7], [9], and [10] at pH 12. Formate radicals ($\cdot CO_2^-$) were formed by reactions [11] and [12]:

[11] $\cdot OH\ (\text{or } \cdot H) + HCO_2^- \rightarrow H_2O\ (\text{or } H_2) + \cdot CO_2^-$

[12*a*] $\cdot OH + OH^- \rightleftharpoons \cdot O^- + H_2O$

[12*b*] $\cdot O^- + HCO_2^- \rightarrow HO^- + \cdot CO_2^-$

Rate constants were determined both from analysis of the photostationary states and by the pulse radiolysis method.

Experimental

Materials

Triply distilled or deionised/chromatographed water was used in the preparation of all solutions. These were buffered with sodium tetraborate (20 mM, Fischer) and carefully deareated by bubbling with N_2O before the weighed amount of PenSH (Aldrich) was added. The desired quantity of CuCl or $CuCl_2$ (Aldrich) was normally added last, and then the final pH adjustment made, care being taken to prevent contact with air. All chemicals were of the highest purity research grade available.

Equipment

Continuous radiolyses were carried out by standard methods (12, 13) in "Gamma Cell" type irradiators, either at the University of Calgary or

Inset: dependence of peak intensity on ratio of total [PenSH]:[Cu(II)] for 10^{-4} M Cu(II) at pH 10.

the Radiation Laboratory at the University of Notre Dame. Dosimetry was carried out with the Fricke dosimeter solution (12). Pulse Radiolysis experiments were performed using the 1.5 MeV Van de Graaff in the Chemistry Department at the University of Calgary (14) or with the 8 MeV linear accelerator at Notre Dame (15). Experiments were performed at 23 ± 2°C.

Analytical procedures

Concentrations of sulphydryl were determined from the absorbance of PenS$^-$ at 250 nm at pH 10 or above, after quantitative dilution of the concentrations to give intensities in a measurable range. Concentrations of Cu(II)(PenS$^-$)$_2$ were determined from the characteristic absorbance maximum at 335 nm (see Fig. 1). The shape of the spectrum did not change significantly over the concentration range 0.25 to 2.0×10^{-4} M. However, the binding constant of the second PenS$^-$ ligand appears to be only about 1500 M and plots of absorbance versus concentration showed a variation of about 10% in the absorbance coefficient over the range 0.5 to 1×10^{-4} M. Thus, to avoid using an approximate Beer's law relation, concentrations of Cu(II) were read directly from absorbance plots.

For the pulse radiolysis experiments, as in ref. 6, the absorbances at 340 nm were corrected for the contributions of the sulphur radicals. These were calculated from their known absorbance coefficients at 340 nm and from their concentrations, which were determined as a function of time from the absorbances at 470 nm where the Cu(II) and Cu(I) species do not significantly absorb. In some experiments the corrected Cu(II)(PenS$^-$)$_2$ absorbances were plotted as a function of time, and initial rates of Cu(II) loss were found from the slopes. These rates were then divided by the total sulphur radical concentrations produced per pulse to yield k_I, the product of the second order rate constant for reaction with the Cu(II) complex and the concentration of the complex. This procedure has the advantage of eliminating any minor contributions to the rate from second order sulphur radical–radical reactions. It was also used with the $\cdot CO_2^-$ radical studies, but in this case no correction for PenS·/PenS.∴SPen$^-$ absorbance was needed. In other pulse radiolysis experiments the values of k_I were calculated from the decays of the absorbances of the PenS.∴SPen$^-$ radicals at 470 nm.

Results

Spectrum and stability of Cu(II)(PenS$^-$)$_2$

The solid line in Fig. 1 is the spectrum of Cu(II)(PenS$^-$)$_2$ in 10 mM PenSH at pH 10. A similar spectrum was observed at pH 12, and both were in good agreement with the earlier data obtained by Wilson and Martin (8). At pH 10 and above the decay of the absorption spectrum exhibited a first order half life of about 5 h. Experiments with Cu(II)(PenS$^-$)$_2$ were therefore completed within as short a time as possible after the solutions were prepared, in general <45 min. This decay is due to the thermal reaction [13] (8, 9), which occurs much faster with

[13] $$2Cu(II)(PenS^-)_2 + 2PenS^- \rightarrow 2Cu(I)(PenS^-)_2 + PenSSPen$$

amino thiols that do not possess shielding β-methyl groups. The inhibition of this reaction in the case of PenSH is strongest at high pH, where both the amino and sulphydryl groups are deprotonated and available to bind the Cu(II). Thus the intensity and the stability of the 335 nm peak fell off with pH, 10 being the minimum practical pH for the techniques used here. The dependence of intensity on the ratio of PenSH to Cu(II) is shown in the inset of Fig. 1. Experiments were conducted with ratios of 20 to 100 to ensure two ligands were bound to each Cu(II).

^{60}Co γ-radiolysis

The production of PenS· radicals in 0.5 to 2×10^{-4} M Cu(II) solutions caused bleaching of the Cu(II)(PenS$^-$)$_2$ absorption, but eventually a stationary intensity was always reached. At that time the fraction of Cu(II)(PenS$^-$)$_2$ remaining was, within experimental error, independent of total copper concentration over the range studied. At pH 10 the photostationary state was found to be independent of dose rate and of total PenSH concentration over the range 4×10^{-3} to 5×10^{-2} M. Some

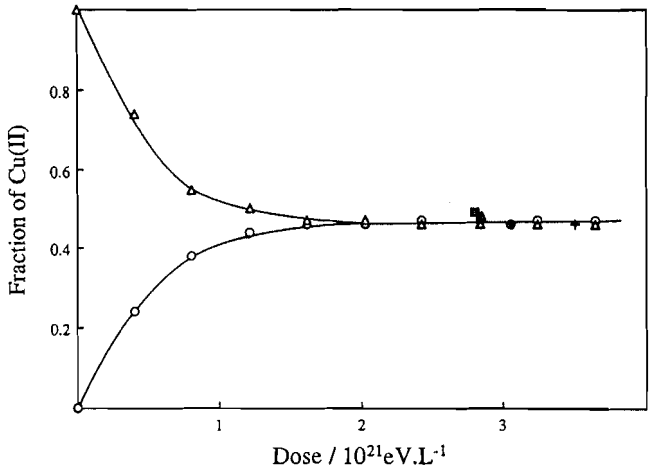

FIG. 2. The approach to stationary state in γ radiolysis at pH 10. Conditions as follows: dose rate = 1.50×10^{21} eV L^{-1} min^{-1} (240 G per min), total [PenSH] = 10^{-2} M, $[Cu(II)]_{initial}$: (●) 5×10^{-5}, (△) 1×10^{-4}, (■) 2×10^{-4} M, respectively; (○) $[Cu(II)]_{initial} = 0.0$, but $[Cu(I)]_{initial} = 1 \times 10^{-4}$ M; [PenSH] = 5×10^{-2} M; $[Cu(II)]_{initial} = 1 \times 10^{-4}$ M, (▲) dose rate = as above, (+) dose rate = 1.13×10^{20} eV L^{-1} min (18.1 G per min).

of these results have been plotted in Fig. 2. This figure also demonstrates that the same fraction of total copper was converted to $Cu(II)(PenS^-)_2$ when the starting reagent was entirely in the form of $Cu(I)_n(PenS^-)_{n+1}$. The initial slopes of the upper and lower curves show that the yields of $Cu(II)(PenS^-)_2$ removal and formation were both 5.7 ± 0.2 molecules per 100 eV or 0.57 ± 0.02 μmoles per J of radiation energy adsorbed. These values agree with the yields of PenS· radicals expected from reactions [6] through [8] (12, 13). This and the identical photostationary fractions of Cu(II) complex obtained from reduction and oxidation lead to the conclusion that the only significant primary products of the reaction of PenS· radicals with $Cu(II)(PenS^-)_2$ are Cu(I)–penicillamine complexes.

In contrast to the above results with PenS· radicals, the production of $\cdot CO_2^-$ radicals via reactions [6], [7], [11], and [12] at pH 12 in 10^{-4} M $Cu(II)(PenS^-)_2$ solutions produced 96+% reduction. That observation is in accord with reaction [14]. This reaction is expected to give a quantitative yield of Cu(I),

$$[14] \qquad \cdot CO_2^- + Cu(II)(PenS^-)_2 \rightarrow CO_2 + Cu(I)(PenS^-)_2$$

since there are no PenS· radicals present and $E^0(CO_2/\cdot CO_2^-)$ is −1.85 to −1.90 V (16, 17). At pH values nearer to the sulphydryl pK (~8.50, where fractions of the various ionic forms were taken from ref. 18), the concentration of PenSH rises and some PenS· are produced via reaction [15] (17).

$$[15] \qquad \cdot CO_2^- + PenSH \rightarrow HCO_2^- + PenS\cdot$$

The level of Cu(II) complex at the photostationary state then rises. However, reaction [15] was negligible at pH 10 with 4×10^{-3} M total PenSH. Pulse radiolysis experiments to determine the rate constant of reaction [14] were therefore done under those conditions — see below.

Because a small amount of H_2O_2 is formed in reaction [6], it was necessary to determine whether this influenced the photostationary concentrations. Hence, reactions of H_2O_2 with PenSH were studied in the presence and absence of Cu(I) and Cu(II) complexes. Millimolar concentrations of H_2O_2 reacted with 10^{-2} M PenSH at pH 10 on the time scale of a minute. This is similar to the observations of Barton *et al.* (19) for other amino thiols. When Cu(I) was present at ~10^{-4} M it was oxidized to about the same extent as seen in the γ radiolysis, suggesting that PenS· radicals were formed as a result of ·OH radical production in a reaction between Cu(I) and H_2O_2. This finding is in accord with observations of Goldstein and Czapski (20). Addition of H_2O_2 to solutions already at the photostationary $Cu(II)(PenS^-)_2$ concentration had no effect on the Cu(I):Cu(II) ratios, but $PenS^-$ was still oxidized, as in the absence of copper.

These observations show that H_2O_2 has no significant effect on the photostationary concentrations of Cu(I) and Cu(II). However, at pH 10 small (~0.003) absorbance increases with a half life of ~70 min occurred after radiolysis to steady state. When the increase in absorbance had ceased, the system reverted to the overall slow ($t_{1/2}$ ~5 h) decay due to reaction [13]. The small post irradiation effect is probably due to rearrangements of liganded copper species, which enhance the $PenS^-$–Cu(II) C.T. transition intensities without causing significant changes in the overall spectrum shape. One rearrangement of this type, involving a Cu(I)–Cu(II) mixed valence species, was observed in ref. 6, but on a shorter time scale.

One important characteristic of the formation of mixed Cu valence species is the presence of absorption bands in the region of 500 nm and above (21, 22). While there was no evidence of significant absorption in that region at the irradiation times required to reach the photostationary state, in radiolyses of very long duration such absorptions were seen. Here it should be stressed that these long term observations were seen on time scales of hours, and do not effect conclusions drawn from the stationary state, measured after 4 min for the higher dose rate and 20 min for the lower, shown in Fig. 2.

Analysis of the photostationary states

The existence of stationary concentrations of Cu(I) and Cu(II) during radiolysis requires that the rate of reduction equal the rate of oxidation. Thus, writing the formulae for the rates of reduction and oxidation on the left and right respectively, one has

$$[16] \qquad \{k_2\theta + k_3\}[Cu(II)(PenS^-)_2][R\cdot]/(1+\theta) = \{(k_{17}\theta + k_{18})[Cu(I)(PenS^-)_2] + k_{19}[Cu(I)_2(PenS^-)_3]\}[R\cdot]/(1+\theta)$$

$$[17] \qquad PenS.\therefore SPen^- + Cu(I)(PenS^-)_2 \rightarrow 2PenS^- + Cu(II)(PenS^-)_2$$

$$[18] \qquad PenS\cdot + Cu(I)(PenS^-)_2 \rightarrow PenS^- + Cu(II)(PenS^-)_2$$

$$[19] \qquad PenS\cdot + Cu(I)_2(PenS^-)_3 \rightarrow Cu(I)(PenS^-)_2 + Cu(II)(PenS^-)_2$$

Here k_{17}, k_{18}, and k_{19} refer to the oxidation reactions [17], [18], and [19], the rate constants of which were reported in ref. 6. The symbol $\theta = K_1(PenS^-)$. The quantity $[R\cdot]$ is the total concentration of sulphur radicals, while $\theta/(1+\theta)$ and $(1+\theta)^{-1}$ are, respectively, the fractions of $PenS.\therefore SPen^-$ and PenS·. Cancelling the $[R\cdot]/(1+\theta)$ terms and rearranging give

$$[20] \qquad \{k_2\theta + k_3\} = \{(k_{17}\theta + k_{18})[Cu(I)(PenS^-)_2]_{ss} + k_{19}[Cu(I)_2(PenS^-)_3]_{ss}\}[Cu(II)(PenS^-)_2]_{ss}^{-1}$$

where the subscripts on the concentration terms signify stationary state concentrations.

Calculation of the quantity on the right hand side of expression [20] requires a knowledge of k_{17}, k_{18}, k_{19}, K_1, and

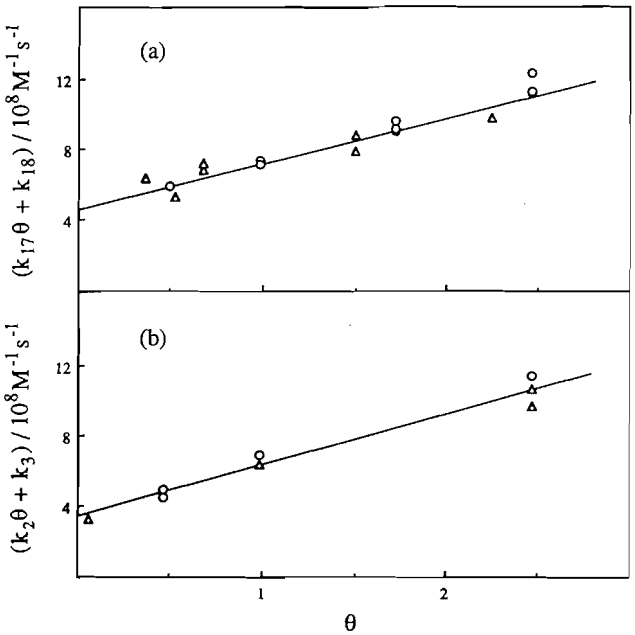

FIG. 3. (*a*) Values of $(k_{17}\theta + k_{18})$ plotted against θ. Circles and triangles are data from this study and ref. 6, respectively. (*b*) Values of $(k_2\theta + k_3)$ plotted against θ. Circles and triangles are data from analyses of the stationary state and pulse radiolysis respectively.

K_{21}, the equilibrium constant for the reaction

[21] $$2Cu(I)(PenS^-)_2 \rightleftharpoons Cu(I)_2(PenS^-)_3 + PenS^-$$

The values of k_{17}, k_{18}, k_{19}, and K_1 as reported in ref. 6 were $<2 \times 10^8$, $(4.5 \pm 0.5) \times 10^8$, and $(5.5 \pm 0.3) \times 10^8$ in $M^{-1}\,s^{-1}$ and 113 ± 14, respectively. The magnitude of K_1 is dependent on pH because of the changes which occur in the charge of the $PenS^-$ species as the amino groups deprotonate. Further work since ref. 6 was published has shown that the value of 16 used for pH 10 was too low.[4] The correct value is 60 ± 3, which is in better agreement with an earlier result of Purdie and co-workers (18). Since K_1 determines the magnitude of θ and the fractions of the two forms of radicals, this finding necessitated a re-evaluation of k_{17} and k_{18}. New pulse radiolysis results on the oxidation at low Cu(I) concentration are presented in the next section, along with the data of ref. 6 recalculated with the correct K_1. These combined data gave $k_{17} = (2.7 \pm 0.3) \times 10^8\ M^{-1}\ s^{-1}$, which is ~40% larger than the upper limit assigned in ref. 6. The magnitude of k_{18} found here was $(4.6 \pm 0.5) \times 10^8\ M^{-1}\,s^{-1}$, essentially unchanged.

The quantity of the right hand side of expression [20] was calculated from the parameters above (with the corrected k_{17} and K_1) for the values of θ and the photostationary state concentrations of the copper species from Fig. 2. These data have been plotted in Fig. 3*b*. Reference to expression [20] shows that the intercept is k_3 and the slope k_2. Further comment is deferred until the pulse radiolysis results have been presented.

Pulse radiolysis experiments

The points in Fig. 1 show the "bleaching spectrum" observed on reacting PenS· and $\cdot CO_2^-$ radicals with $Cu(II)(PenS^-)_2$. The agreement with the spectrum of the starting material demonstrates that no new species absorbing in the 300 to 500 nm region were created. The main process, therefore, is the

[4]S. P. Mezyk. To be published.

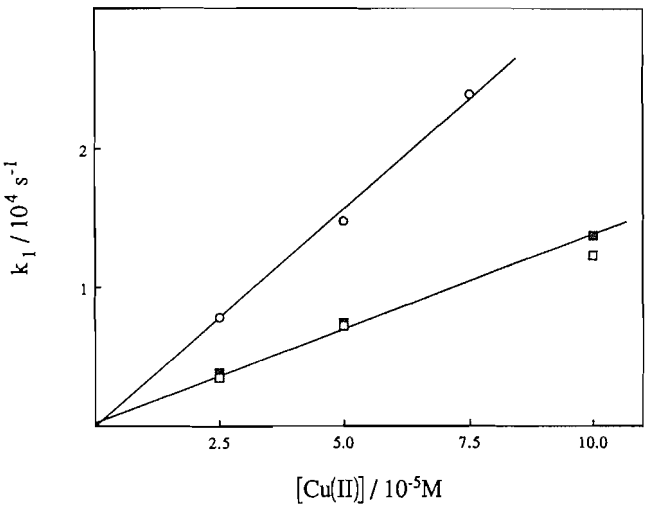

FIG. 4. Dependence of pseudo-first order rate constant obtained in pulse radiolysis experiments on concentration of Cu(II) for reduction by: $\cdot CO_2^-$ radical at pH 10 (■) and 12 (□) respectively, PenS· radical formed via reaction [10] at pH 12 (○).

conversion of $Cu(II)(PenS^-)_2$ to $Cu(I)_nL_{n+1}$ species, which do not have significant absorbance above 300 nm.

The square symbols in Fig. 4 are values of k_1 for the reaction of $\cdot CO_2^-$ radicals with $Cu(II)(PenS^-)_2$ in formate-containing solutions, determined as described in the Experimental section and plotted against the $Cu(II)(PenS^-)_2$ concentration. The results are seen to be independent of pH, and the slope yields $k_{14} = (1.2 \pm 0.2) \times 10^8\ M^{-1}\,s^{-1}$.

Values of k_1 for the reaction between the sulphur radicals of penicillamine and $Cu(II)(PenS^-)_2$ at different concentrations were determined with total PenSH concentrations of 50 and 20 mM at pH 10, and 4 mM at pH 12. The corresponding θ values are 2.47, 0.99, and 0.06, respectively. The conditions for the two solutions at pH 10 were similar to those for the γ radiolyses. Based on the data of ref. 18, the concentration of non-ionized PenSH would have been $>4 \times 10^{-3}$ M and this should be sufficient to convert any C-centered radicals formed by ·OH (23) to PenS· in reactions similar to reaction [15] (24). The pH 12 experiment was done for the purpose of minimizing θ, so that the fraction of PenS· radicals would approach unity. At this pH the non-ionized PenSH concentration is very low and C-centered radicals, would not be converted quantitatively to PenS·. Therefore, 0.1 M N_3^- was incorporated in the solution and PenS· was produced exclusively via reaction [10]. The dependence of k_1 on the Cu(II) concentration has been illustrated for the pH 12 solution in Fig. 4.

Analysis of the data for the PenS· and PenS∴SPen$^-$ reactions requires reference to expression [16]. From the left hand side the rate of the reduction reaction can be written as

$$-d[R\cdot]/dt = (k_2\theta + k_3)[R\cdot](1 + \theta)^{-1}[Cu(II)(PenS^-)_2]$$

The pseudo-first order rate constant determined from pulse radiolysis, k_1, is given by

$$k_1 = -(d[R\cdot]/dt)/[R\cdot]$$

or

[22] $$k_1 = (k_2\theta + k_3)(1 + \theta)^{-1}[Cu(II)(PenS^-)_2]$$

It follows that the slopes of plots of k_1 against $[Cu(II)(PenS^-)_2]$,

TABLE 1. Summary of rate constants for oxidation of Cu(I) and reduction of Cu(II) species liganded by penicillamine (units: $10^8\ M^{-1}\ s^{-1}$)

Radical species	Copper species		
	$Cu(I)(PenS^-)_2$	$Cu(I)_2(PenS^-)_3$	$Cu(II)(PenS^-)_2$
$PenS.\therefore SPen^-$	2.7 ± 0.3 [17][a]	—	2.9 ± 0.3 [2]
$PenS\cdot$	4.6 ± 0.5 [18]	5.5 ± 0.3 [19]	3.4 ± 0.4 [3]
$CO_2\cdot^-$	—	—	1.2 ± 0.2 [14]

[a]Reaction numbers used in the text are given in parentheses.

like the one in Fig. 4, correspond to values of $(k_2\theta + k_3)/(1 + \theta)$. The magnitudes found for this quantity in units of $10^8\ M^{-1}\ s^{-1}$ were 2.8 and 3.1 from two experiments for $\theta = 2.47$, 3.2 for $\theta = 0.99$, and 3.1 for $\theta = 0.06$. These have been multiplied by the values of $(1 + \theta)$ to yield $(k_2\theta + k_3)$, and the latter plotted against θ in Fig. 3*b*. They agree with the data from the photostationary state within the experimental uncertainties of $\pm 10\%$. From a linear least-mean-squares analysis of all the data k_3 was found from the intercept to be $(3.4 \pm 0.4) \times 10^8\ M^{-1}\ s^{-1}$ and the value of k_2 given by the slope was $(2.9 \pm 0.3) \times 10^8\ M^{-1}\ s^{-1}$.

As pointed out above, pulse radiolysis experiments on the θ dependence of the rate of oxidation of Cu(I) were done to correct the value of k_{17}. As in ref. 6, the Cu(I) concentration used (20 μM) was sufficiently low that $Cu(I)(PenS^-)_2$ would have been the only species present. The expression for the pseudo-first order rate constant from the pulse radiolysis experiments is analogous to [22] above, namely:

$$[23] \qquad k_1' = (k_{17}\theta + k_{18})(1 + \theta)^{-1}[Cu(I)(PenS^-)_2]$$

Values of $(k_{17}\theta + k_{18})(1 + \theta)^{-1}$ were obtained from the slopes of plots of k_1' versus $[Cu(I)(PenS^-)_2]$. These have been multiplied by the appropriate values of $(1 + \theta)$ and plotted against θ in Fig. 3*a*. The results from ref. 6, recalculated with $K_1 = 60$, have also been included. A least-mean-squares linear fit to the combined data gave the values of k_{17} and k_{18} reported in the preceding section. A summary of these and other rate constants appears in Table 1.

Discussion

Earlier studies of the reduction of Cu(II) complexes by $\cdot CO_2^-$ have involved a variety of complexing ligands, including the amino compounds glycine and histidine (25). The second order rate constants typically fall into the range $1–7 \times 10^8\ M^{-1}\ s^{-1}$. The rate constant of $1.2 \times 10^8\ M^{-1}\ s^{-1}$ found here for $Cu(II)(PenS^-)_2$ in reaction [14] is, in particular, very similar to $1.0 \times 10^8\ M^{-1}\ s^{-1}$ for oxidized glutathione (26) in which the copper is also bound by S- and N-centered ligands. Thus the present rate for $\cdot CO_2^-$ seems to fall in line with those for other systems with similar types of ligand.

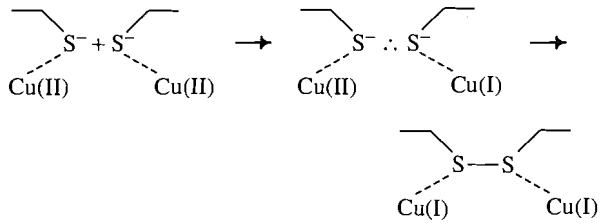
In contrast to the situation with $\cdot CO_2^-$, the rates of reduction of Cu(II) complexes by thiyl radicals and disulphide anions are relatively unknown. The present results confirm the observation in ref. 10 that these reductions are reasonably efficient processes. Actually the rate constants k_2 and k_3 determined here are a factor of ~ 2 smaller than the value of $6.5 \times 10^8\ M^{-1}\ s^{-1}$ estimated in the earlier study (10) for the reduction by $PenS\cdot$ and $PenS.\therefore SPen^-$ combined (the relative contributions were not resolved). However, in that study relatively high concentrations of NH_3 and Cl^- were present due to the NH_4Cl/NH_4OH buffer used, and the copper ion complexes probably contained the smaller NH_3 and Cl^- ligands (6). In the present investigation of the reduction it has been assumed that $Cu(II)(PenS^-)_2$ is the only Cu(II) species of any significance, which is in accord with the results of the ESR study of Davis and co-workers (9).

This work appears to be the first study in which rates of reduction have been resolved in terms of the contributions of the RS and $RS.\therefore SR^-$ species.

It should be stressed that the occurrence of a direct reaction between $RS\cdot$ and $Cu(II)(PenS^-)_2$ was confirmed by the experiments performed at pH 12, where the contribution of the $RS.\therefore SR^-$ species was negligible. The reaction rate was first order in $RS\cdot$ and $Cu(II)(PenS^-)_2$ (see Fig. 4). These findings are consistent with reaction [3] as the rate controlling step and no significant role for [−3]. That conclusion

$$[-3] \qquad \mathbf{I} \rightarrow Cu(II)(PenS^-)_2 + PenS\cdot$$

can be rationalised by the large rate expected for the intra-complex electron transfer reaction [4]. Based on $E^0(Cu(II)L_2/(Cu(I)L_2) \sim 0.2$ V (27) and $E^0(RSSR/RS.\therefore SR^-) = -1.6$ V (7), the driving force of ~ 1.4 V ensures a rate in the region of $10^8\ s^{-1}$ over the short distance involved (28). Reaction [5] would then occur after the oxidation and could not effect the rate. However, it may be noted that ligand substitution reactions with Cu(I) species are normally very rapid (29).



It may be noted that one of the *p* orbital lone pairs of the bound $PenS^-$ ligand would be tied up in coordination with the Cu(II), leaving only one pair available for the $PenS\cdot$ radical attacking in reaction [3]. Since $\sigma\sigma^*$ bonds are readily formed with sulphur species having only one lone pair (30), this should not prevent the formation of the "internal" $PenS.\therefore SPen^-$ complex. However, it may be expected to alter the rate of complexation, and this feature is reflected in the fact that k_3 $(= 3.4 \times 10^8\ M^{-1}\ s^{-1})$ is about 10 times smaller than k_1 $(= 3 \times 10^9\ M^{-1}\ s^{-1})$, the rate of complexation of $PenS\cdot$ radicals by free $PenS^-$ (11).

Quantitative analysis of the photostationary state has provided a second source of rate constant data and a means of ensuring that the rate constants for oxidation and reduction fit into a self-consistent framework. That this is the case is established by the agreement between the values of $(k_2\theta + k_3)$ from pulse radiolysis and analysis of the photostationary concentrations plotted in Fig. 3*b*. The corrected value of k_{17} $(= 2.7 \times 10^8\ M^{-1}\ s^{-1})$ is, as pointed out in the Results section, about 40% larger than the previously estimated upper limit (6). It is now more consistent with the value of the corresponding rate constant for the cysteine species.

The observations reported here provide further information relating to reaction pathways which may occur in the removal of thiyl radicals created in biological systems. They also have relevance to thermal chemical reactions in thiylate species. For example, the rate-controlling step in reaction [13] has been

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

shown to be a second order reaction between two $Cu(II)(RS^-)_x$ complex ions (9, 21). It has generally been assumed that they interact to produce two Cu(I) species and a disulphide (RSSR), which is a complex two-electron transfer process. We would suggest that $RS\therefore SR^-$ intermediates also be considered as possible transients in these systems, viz:

[24] 

The shared disulphide ligand would then be replaced by RS^-, as in reaction [5]. Reactions of this kind are also of possible interest in proteins with multiple copper–thiylate ligand sites.

Redox reactions with ferrocene/ferricenium species of radicals derived by H atom abstraction from alcohols and diols

S. R. LOGAN

Department of Applied Physical Sciences, University of Ulster, Coleraine, N. Ireland, BT52 1SA

Received August 30, 1990

S. R. LOGAN. Can. J. Chem. **69**, 540 (1991).

The effect of various alcohols and diols in diminishing the extent of the photo-oxidation of 4-ferrocenylbutanoate ion in the presence of N_2O has been investigated. Where the hydroxyl radical generated in the photo-initiated electron transfer reacts with an alcohol by H atom abstraction at the α-position, the resulting radical is capable of reducing the ferricenium zwitterion to the ferrocenyl anion. Abstraction at other positions produces radicals that are essentially inert in this system and rate constants are derived for the reaction of OH with some such compounds. Non-vicinal diols behave similarly to the corresponding alcohols. With vicinal diols, a dehydration process, which occurs the more slowly the more highly substituted the diol, converts the radical -CR(OH)$\dot{C}$(OH)- into -$\dot{C}$RCO-, which is an oxidizing species. The behaviour of pinacol was found to be anomalous.

Key words: radical reactions, redox behaviour, alcohols.

S. R. LOGAN. Can. J. Chem. **69**, 540 (1991).

On a étudié l'habilité de divers alcools et diols à diminuer le taux de photo-oxydation de l'ion 4-ferrocénylbutanoate en présence de N_2O. Lorsque le radical hydroxyle généré lors du transfert de charge photo-initié réagit avec un alcool par l'enlèvement d'un atome de H en position α, le radical qui en résulte est capable de réduire le zwitterion ferricénium en anion ferrocényle. Des ablations à d'autres positions fournissent des radicaux qui sont essentiellement inertes dans ce système; on a aussi évalué les constantes de vitesse des réactions du OH avec quelques composés de ce type. Les diols qui ne sont pas vicinaux se comportent comme les alcools correspondants. Avec les diols vicinaux, il se produit une déshydratation d'autant plus lente que le diol est plus substitué; elle transforme le radical -CR(OH)$\dot{C}$(OH)- en -$\dot{C}$RCO- qui est une espèce oxydante. On a trouvé que le comportement du pinacol est anormal.

Mots clés : réactions radicalaires, comportement rédox, alcools.

[Traduit par la rédaction]

Introduction

Previously, the use of a photochemical technique was demonstrated (1) for measuring the rate of attack of the hydroxyl radical on an organic solute and the redox behaviour of the resulting radical towards the ferrocene/ferricenium system. The technique is appropriate to any group of water-soluble compounds provided that they are transparent in the relevant range of UV wavelengths.

Since the early work using the Fenton system (2, 3), several studies of the reaction of the hydroxyl radical with alcohols have been carried out. Some (4–6) have used flow systems and ESR spectroscopy to identify the radicals or mixture of radicals formed. Others have been primarily concerned (7–11) with the rate constant for OH attack and these mostly used a pulse radiolysis technique, employing the effect of an added alcohol in reducing the fraction of OH radicals reacting with another solute, where such reaction led to an easily measured intermediate. Since in most cases the observed intermediate is not the original product of the reaction of OH with this solute, but may be formed from the original product in a subsequent reaction, it is desirable that these rate constants be checked by a different method, as it has been shown (12) that such methods are occasionally liable to error.

There have been various other radiation chemical studies focussing on the identity and behaviour of the radicals formed (13–18) by hydroxyl radical attack on alcohols and diols. The present study, using a photochemical technique, is intended to complement these.

The initial photochemical events were established in earlier work (19, 20). The photo-excitation of the ferrocenyl moiety leading to electron transfer to N_2O may be summarized in eq. [1].

[1] $$Fc(CH_2)_3CO_2^- + N_2O \xrightarrow{h\nu} \overset{+}{F}\dot{c}(CH_2)_3CO_2^- + N_2 + O^- (\xrightarrow{H^+} OH)$$

In the presence of a solute RH, the hydroxyl radical formed in reaction [1] may react by either of the following reactions:

[2] $$OH + Fc(CH_2)_3CO_2^- \rightarrow OH^- + \overset{+}{F}\dot{c}(CH_2)_3CO_2^-$$

[3] $$OH + RH \rightarrow H_2O + R$$

Where the solute is an alcohol, the radical formed by OH radical attack at the α-position is usually a reducing species (20), for example:

[4] $$OH + CH_3CH_2OH \rightarrow H_2O + CH_3\dot{C}HOH \text{ (predominantly)}$$

[5] $$CH_3\dot{C}HOH + \overset{+}{F}\dot{c}(CH_2)_3CO_2^- \rightarrow CH_3CHO + H^+ + Fc(CH_2)_3CO_2^-$$

If OH attack on the alcohol were exclusively at the α-position and reaction [5] were fully efficient, then all the ferricenium zwitterions formed in reaction [1] could be reduced back to the ferrocenyl anion at high concentrations of the alcohol.

If, on the other hand, hydroxyl attack on the alcohol were to produce inert radicals (for example, from a tertiary alcohol), then there would be no process corresponding to reaction [5], so the quantum yield of the ferricenium species, denoted by Φ (Fc^+) would be equal to Φ_p, the quantum yield of step [1].

Experimental

4-Ferrocenylbutanoic acid was prepared as previously described (19). The alcohols and diols were BDH Analar or Aldrich 99% or Gold Label grades and were used as supplied. Doubly distilled water was used in the preparation of solutions and in rinsing the apparatus. Solutions were made up in 10^{-2} mol dm^{-3} borax to maintain pH 9.

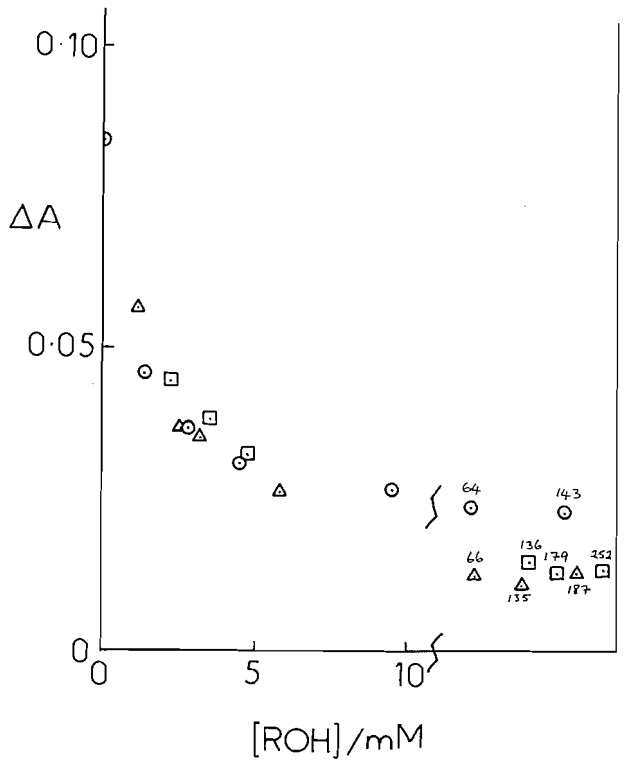

FIG. 1. Absorbance change at 625 nm caused by a flash of 442 J energy as a function of the concentration of added alcohols. The solution contained 2.5×10^{-4} M 4-ferrocenylbutanoate in 0.01 M borax with 0.023 M nitrous oxide: ⊙ 1-propanol; △ 2-propanol; ⊡ 2-propanol-d_1. For the points to the right of the barrier, the number indicates the value of the abscissa.

Since the ferrocenyl anion undergoes slow oxidation from dissolved oxygen, solutions were freshly made up every two days.

After a sample had been degassed by four cycles of freeze–pump–thaw, it was equilibrated with N_2O at a pressure of 85 kPa to give a concentration (21) of 0.023 mol dm^{-3}. The cells and the flash photolysis apparatus have been previously described (22). With the filter compartment filled with distilled water, the cell was mounted in position and the absorbance change at 625 nm (the position of maximum absorbance of the ferricenium zwitterion) caused by the discharge of 442 J through the flash tubes was monitored.

Results and discussion

When 1-propanol was added to the samples of 4-ferrocenylbutanoic acid in borax buffer at pH 9, saturated with N_2O, the absorbance change at 625 nm produced by a 442 J flash was found to decrease, as shown in Fig. 1. However, the plateau achieved at high concentrations corresponds to 0.27 of the original absorbance, in the absence of any added solute that might compete with 4-ferrocenylbutanoate ion for the hydroxyl radical produced (19) concomitantly with photoinduced electron transfer from the anion to N_2O. Thus not all the radicals formed by attack of OH on this alcohol cause reduction of the ferricenium species, Fc^+, that is generated in the photoinduced electron transfer, step [1].

It was initially attempted to treat these results on the basis that the reaction of OH with 1-propanol produces two types of radicals, where the first reduces the ferricenium zwitterion and the second does not. The species concerned are presumably $CH_3CH_2\dot{C}HOH$ and, secondly, a combination of $CH_3\dot{C}HCH_2OH$ and $\dot{C}H_2CH_2CH_2OH$, mainly the former. If one were to assume the formation of these two types to the relative extents of f and $(1 - f)$, then the quantum yield of the ferricenium species can be expressed as follows:

$$[6]\quad \Phi(Fc^+) = \Phi_p\left\{1 + \frac{k_2[Fc]}{k_2[Fc] + k_3[RH]} - \frac{fk_3[RH]}{k_2[Fc] + k_3[RH]}\right\} = \Phi_p\left\{(1 - f) + \frac{(1 + f)k_2[Fc]}{k_2[Fc] + k_3[RH]}\right\}$$

This implies that the addition of RH will cause Φ (Fc^+) to fall as [RH] is increased, levelling out at $(1 - f)\Phi_p$.

However, using the data from the studies of 1-propanol, it would appear as if the fraction f has the value 0.46, whereas earlier work (7, 15, 16) put the yield of the radical $CH_3CH_2\dot{C}HOH$ at around 0.6 of the total. Furthermore, the correspondence between eq. [6] and these 1-propanol data was tested using the relevant reciprocal plot, pertaining to eq. [7].

$$[7]\quad \frac{1}{\Phi(Fc^+) - (1 - f)\Phi_p} = \frac{1}{(1 + f)\Phi_p}\left\{1 + \frac{k_3[RH]}{k_2[Fc]}\right\}$$

The plot did not deviate from linearity but the ratio of slope to intercept gave a value for k_3 well in excess of the literature value of 2.8×10^9 dm^3 mol^{-1} s^{-1} (23).

The resolution of these anomalies was found from the following hypothesis. If only one radical species were produced and it were capable of reducing Fc^+ but with a sufficiently low rate constant for the reaction equivalent to step [5] that other processes such as combination or disproportionation could compete, eq. [6] would still be applicable with f representing the fraction of all radicals that actually do react in this manner. However, it is not to be expected that f would be independent of RH concentration, in that a much greater efficiency of the redox reaction is to be expected at low RH concentrations, where far fewer radicals R· are produced than ferricenium zwitterions, than at high RH concentrations, where the two species are generated in comparable amounts. So if fortuitously the reciprocal plot gives a straight line, deductions from the ratio of slope to intercept using eq. [7] could be quite erroneous since the factor $(1 - f)$ would not be a constant over the range of RH concentrations.

Previous work (1) on this system supports this hypothesis. While the strongly reducing radical $CO_2^{\cdot-}$ reduces Fc^+ with 100% efficiency, even though the rate constant for its dimerization is quite high (24), other reducing radicals such as $CH_3\dot{C}(OH)CO_2^-$ and $\dot{C}H(OH)CO_2^-$ reacted more slowly (1) with Fc^+. Clearly in this system high efficiency in reducing Fc^+ requires that the redox reaction is virtually diffusion controlled. Where the rate constant for this reduction process is substantially less, inter-radical reactions of R· can compete against reaction [5] and the proportion so doing increases with the size of the pool of radicals R·, which increases with RH concentration. Thus with 1-propanol the proposal is that, at high concentrations, of the major radical formed, $CH_3CH_2\dot{C}HOH$, only about three-quarters engage in reducing the ferricenium zwitterion. As the other radicals are inert, the fraction reacting in this way constitute 0.46 of all those formed.

In Fig. 1 there is also shown the effect on ΔA of the addition of 2-propanol. This causes a decrease, eventually to 0.16 of the initial value. Previous studies (4, 5, 13, 14, 16, 18) have

TABLE 1. Summary of the plateau values of the absorbance change, ΔA_∞, and of the limiting fractions, f, of the radicals produced by OH attack which actually cause reduction of Fc^+ to Fc, for various alcohols and non-vicinal diols

Alcohol/diol	$\frac{\Delta A_\infty}{\Delta A_0} = \frac{1-f}{2}$	f
1-Propanol	0.27 (±0.02)	0.46 (±0.04)
2-Propanol	0.15	0.70
2-Propanol-d_1	0.16	0.68
2-Butanol	0.26	0.48
2-Methylpropan-1-ol	0.24	0.52
2,2-Dimethylpropan-1-ol	0.28	0.44
2-Methylbutan-3-ol	0.28	0.44
Propane-1,3-diol	0.12	0.76
Hexane-2,5-diol	0.15	0.70
Pentaerythritol	0.02	0.96

shown that hydroxyl radical attack produces mainly the radical $CH_3\dot{C}(OH)CH_3$. Obviously this radical, which is readily oxidized to acetone, does not reduce Fc^+ with a sufficiently high rate constant to avert inter-radical reactions. Studies with the partially deuterated alcohol, $CH_3CD(OH)CH_3$, show that this compound causes a more gradual decrease in ΔA to the same limiting value. These support the earlier conclusions regarding the point of attack and imply that the kinetic isotope effect $k_H/k_D = 1.27 \pm 0.1$. Thus on the basis of the recommended value (23) of 1.9×10^9 dm^3 mol^{-1} s^{-1} for the reaction of OH with 2-propanol, the rate constant for OH + $CH_3CD(OH)CH_3$ is 1.5×10^9 dm^3 mol^{-1} s^{-1}.

The effect of the addition of other alcohols to this system was found to follow the general pattern shown in Fig. 1. However, the position of the final plateau value varied from one compound to another as shown in Table 1, in which in the last column is shown the value of f, the fraction of the radicals (produced by OH attack on the alcohol) that actually cause reduction of Fc^+ to Fc. These values for f pertain to the experimental conditions of the present work.

In the case of 2-butanol, there is evidence (15) that OH attack produces the radicals $CH_3CH_2\dot{C}(OH)CH_3$ and $CH_3\dot{C}HCH(OH)CH_3$, with the former much the more abundant. The f value of 0.52 is consistent with fairly efficient reduction of Fc^+ by this radical. From previous ESR (5) and other (13–15) studies of 2-methylpropan-1-ol, the predominant product radical from OH abstraction is $(CH_3)_2CH\dot{C}HOH$. From the low f value of 0.52, it is apparent that this is a rather inefficient reducing agent. From 2,2-dimethylpropan-1-ol, the expected radical is $(CH_3)_3C\dot{C}HOH$, exclusively. Since f is only 0.44, this also must be an inefficient reducing agent. From 2-methylbutan-3-ol, the product radicals expected are $(CH_3)_2CH\dot{C}(OH)CH_3$ and $(CH_3)_2\dot{C}CH(OH)CH_3$, with the former the more abundant. Since the second radical would be inert in this system, the f value of 0.44 suggests that not all the radicals of the former type are effective in causing reduction.

In Fig. 2 are shown the effects on ΔA of the addition of three tertiary alcohols. With abstraction at the α-position ruled out, it might be anticipated that all will give rise to inert radicals. Addition of *tert*-butanol caused a decrease to 0.54 of the initial ΔA. This slight deviation from one-half may reflect the formation, in addition to the radical $\dot{C}H_2C(CH_3)_2OH$, of a small

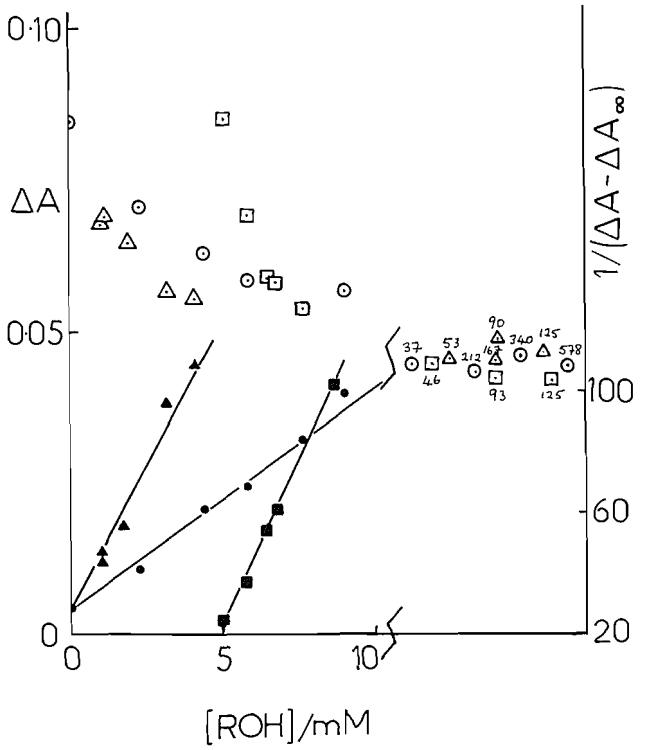

FIG. 2. Absorbance change at 625 nm caused by a flash of 442 J energy as a function of the concentration of added alcohols: ⊙ *tert*-butanol; △ *tert*-amyl alcohol; ⊡ 2,3-dimethylbutan-2-ol. Also (r.h. scale and filled symbols), plots of $(\Delta A - \Delta A_\infty)^{-1}$ against ROH concentration as a test of eq. [7], with $f = 0$.

amount of the radical (16) $(CH_3)_3CO^\bullet$, which is an oxidizing agent. The finding that 2-methylbutan-2-ol lowers ΔA only to 0.54 of its initial value is surprising, since one may anticipate less rather than more abstraction from the hydroxy group, with the radical $CH_3\dot{C}HC(CH_3)_2OH$ predominating.

On addition of 2,3-dimethylbutan-2-ol, it was found that after the flash, the absorbance change decreased over the following ca. 2 ms. The value recorded at the end of the flash was found, at high concentrations, to fall to 0.49 of its original value, consistent with the reaction of the OH radical producing predominantly the radical $(CH_3)_2\dot{C}C(CH_3)_2OH$. The subsequent decrease may then be attributed to a further reaction of some proportion of these radicals.

For these tertiary alcohols, which lead to radicals that do not contain the feature -$\dot{C}$(OH)-, it is possible to apply eqs. [6] and [7] to the value of ΔA found at the end of the flash. On this basis, the relative rate constant k_3/k_2 was determined for each alcohol, and using, as previously (1), the value (12) of 1.09×10^{10} dm^3 mol^{-1} s^{-1} for k_2, the rate constant for the reaction of the hydroxyl radical with the ferrocenyl anion, the rate constants for the reaction of OH with these alcohols were found to be, for *tert*-butanol, 7.6×10^8; 2-methylbutan-2-ol, 1.8×10^9 and 2,3-dimethylbutan-2-ol, 2.4×10^9 dm^3 mol^{-1} s^{-1}. The first two lie within the range of previous determinations (23); for the third, no value is listed in this compilation.

In Fig. 3 are shown the effects on ΔA of the addition of some diols. Ethane-1,2-diol causes a decrease to only 0.82 of the initial value, indicating that the radical resulting from OH attack behaves as an oxidizing agent. This reaction has been intensively studied (4, 15, 16, 18) and it is known that the

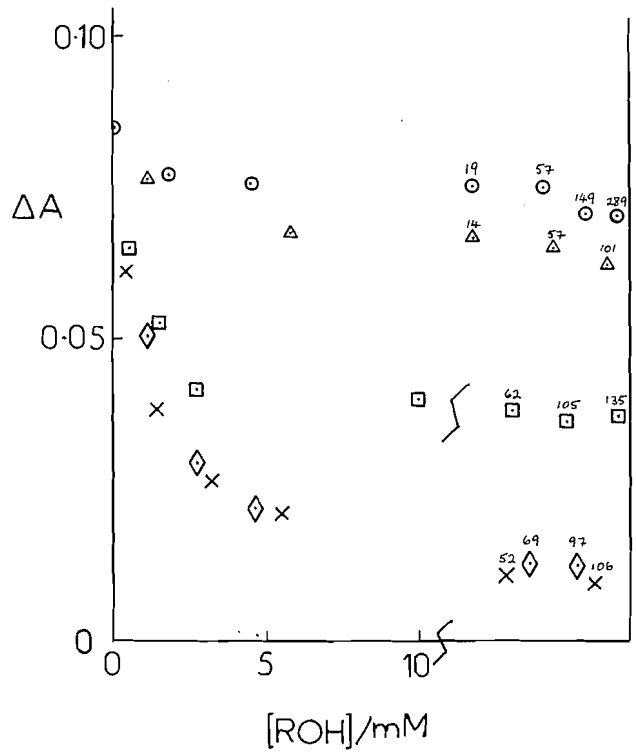

FIG. 3. Absorbance change at 625 nm caused by a flash of 442 J energy as a function of the concentration of added diols: ⊙ ethane-1,2-diol; △ propane-1,2-diol; ⊡ butane-2,3-diol; × propane-1,3-diol; ◇ hexane-2,5-diol.

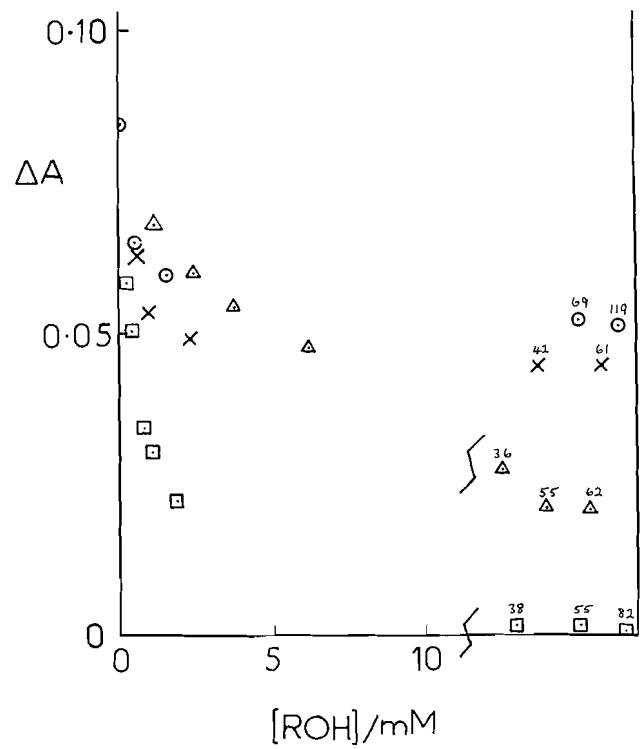

FIG. 4. Absorbance change at 625 nm caused by a flash of 442 J energy as a function of the concentration of added hydroxy compounds: ⊙ glycerol; ⊡ pentaerythritol; × erythritol; △ pinacol.

radical $\dot{C}H(OH)CH_2OH$ initially formed readily dehydrates to $\dot{C}H_2CHO$. In the present system this latter radical oxidizes Fc to Fc^+ at pH 9 with appreciable efficiency.

When propane-1,2-diol, a growth in absorbance was found over a period of ca. 0.5 ms after the flash, with the final figure, at high concentrations, being 0.75 of that found initially. From ESR studies (6), it is known that the hydroxyl radical abstracts chiefly from the middle carbon to give the radical $CH_3\dot{C}(OH)CH_2OH$, with a lesser amount of $\dot{C}H(OH)CH(OH)CH_3$ and a very small yield of $\dot{C}H_2CH(OH)CH_2OH$, which will be inert in this system. Dehydration of the first two radicals yields oxidizing species. The rise in absorbance on the millisecond time scale reflects the slowness of the dehydration of these radicals.

With butane-2,3-diol, a similar increase in absorbance was found over a period of 1–2 ms. At high concentrations, the final absorbance change corresponded to 0.43 of the initial value, which means that the radicals formed are causing net reduction rather than oxidation, but the rise on the ms time scale shows that oxidation is occurring in these later stages. There is ESR evidence (6) that the reaction of OH produces $CH_3\dot{C}(OH)CH(OH)CH_3$ and $CH_3\dot{C}HCOCH_3$, where the latter radical results from the dehydration of the former. But this dehydration process must be sufficiently slow to allow some radicals $CH_3\dot{C}(OH)CH(OH)CH_3$ to engage in reduction of Fc^+. Slow dehydration of the first radical produces the second, which is an oxidizing species whose reaction with Fc is apparent on the millisecond time scale.

On the basis of the reactions of the resulting radicals with tetranitromethane, it has been estimated (16) that OH attack at the methyl group may account for 29% of the total reaction with this diol. The radical $\dot{C}H_2CH(OH)CH(OH)CH_3$, which should be quite inert in the present system, was, however, not detected (6) by ESR, and it might seem surprising that it could be such a significant product. However, the rate constant for OH attack on the six methyl hydrogens of this diol may be estimated from its known rates of reaction (23) with *tert*-butanol and pinacol. On this basis and the quoted overall rate constant (23) of 1.3×10^9 dm^3 mol^{-1} s^{-1}, the figure of 29% would seem quite probable. Moreover, the quoted rate constant (23) for the reaction of OH with this diol is less than that (23) with 2-butanol, which supports the view (1) that H atom abstraction from the grouping $-CH(OH)CH_2-$ is actually impeded by the insertion of another hydroxy group to give $-CH(OH)CH(OH)-$.

Addition of propane-1,3-diol and hexane-2,5-diol causes ΔA to be diminished respectively to 0.12 and 0.15 of the original value. The predominant radicals are expected to be $\dot{C}H(OH)CH_2CH_2OH$ and $CH_3\dot{C}(OH)CH_2CH_2CH(OH)CH_3$, which should behave, respectively, like those from a primary alcohol and from 2-butanol. These non-vicinal diols clearly resemble comparable alcohols.

The effect of other hydroxy compounds on ΔA is shown in Fig. 4. The behaviour of glycerol is similar to that of ethane-1,2-diol, except that less oxidation is caused by the radicals resulting from OH attack. This is consistent with the slower (25) acid-catalysed dehydration of the radicals $CH_2(OH)\dot{C}(OH)CH_2OH$ and $\dot{C}H(OH)CH(OH)CH_2OH$ as compared to $\dot{C}H(OH)CH_2OH$, but not with the reports (26) of faster hydroxide-catalysed dehydration. Erythritol shows similar behaviour.

The addition of pentaerythritol causes ΔA to decrease to 0.02 of its original value. On this molecule, OH attack will produce the radical $(HOCH_2)_3C\dot{C}HOH$, which is apparently

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 195.138.81.100 on 09/07/12
For personal use only.

more efficient in reducing Fc^+ than is $(CH_3)_3C\dot{C}HOH$, the radical formed from neopentyl alcohol. From the manner in which ΔA is decreased, the rate constant for OH reaction is estimated as $4.4 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$, which is slightly higher than the previous value (23).

Pinacol causes a decrease in ΔA, eventually to 0.23 of the original value. This may seem surprising since the ESR evidence is consistent with the radical formed by OH attack being mostly $\dot{C}H_2C(CH_3)(OH)C(OH)(CH_3)_2$, which should be inert. However, recognizing that the presence of alkyl hydrogens only in methyl groups renders the hydroxyl hydrogen more liable to attack, one product of OH attack should be the radical $(CH_3)_2C(OH)C(CH_3)_2O\cdot$. While alkoxy radicals generally are oxidizing agents, this one is unusual since it readily fragments to give acetone and the reducing radical, $CH_3\dot{C}(OH)CH_3$. However, while such a reaction could account for the decrease in ΔA to less than half its original value, it is difficult to see how it can lead to the final ratio being as small as 0.23. Assuming that the relative rates of reaction of OH with individual methyl and hydroxyl hydrogens are the same in *tert*-butanol and pinacol, and accepting the figure (16) for the former of 4.3% reaction at the hydroxyl, one estimates only a 6.3% yield of this reducing radical from pinacol. This cannot suffice to account for the results obtained.

For all compounds studied, in at least one experiment, after the solution had been flashed as described above, air was allowed into the vessel and the solution was equilibrated with it to give an oxygen concentration of the order of $3 \times 10^{-5}\ mol\ dm^{-3}$. Since this procedure made no difference when no alcohol or diol was present it would seem that any effect in their presence must be due to reactions of O_2 with the radicals formed by OH attack. With all these compounds, except one, the addition of O_2 caused a perceptible growth in absorbance over the few milliseconds after a further flash, consistent with the reaction of the radical with O_2, followed by slow oxidation of the ferrocenyl anion by this peroxy radical. The exception was ethan-1,2-diol, where an oxidizing radical is already formed in the absence of O_2. With propan-1,2-diol a slight rise was observed, of about the same size as was found in the absence of O_2.

Conclusion

These studies show that the radicals formed by H atom abstraction at the α-position from primary or secondary alcohols are not as efficient reducing agents of the ferricenium zwitterion as the corresponding radicals from α-hydroxyacids (1). Thus while the radical $CH_3\dot{C}(OH)CO_2^-$ manages to reduce an equal amount of Fc^+ within 0.5 ms (1), $CH_3\dot{C}(OH)CH_3$ is not correspondingly effective. The behaviour of the tertiary alcohols resembles that of the alkanoates and alkandioates (1) and the data permit the derivation of the rate constant for OH attack.

The reaction of *N'*-hydroxy-*N*-[(1-hydroxycyclohexyl)methyl]benzamide and diphenylborinic anhydride gives 4-[(1-hydroxycyclohexyl)methyl]-2,2,5-triphenyl-1,3-dioxa-4-azonia-2-borata-4-cyclopentene in nearly quantitative yield. Crystals of the product are monoclinic, $a = 9.9117(6)$, $b = 13.308(1)$, $c = 17.339(2)$ Å, $\beta = 99.420(7)°$, $Z = 4$, space group $P2_1/c$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.040$ and $R_w = 0.047$ for 2423 reflections with $I \geq 3\sigma(I)$. The molecule has a normal five-membered hydroxamic acid chelate structure, the BONCO ring having a *B*-envelope conformation. Bond lengths (corrected for libration) (N)O—B = 1.535(3), (C)O—B = 1.569(3), C—B = 1.603(3) and 1.601(3) Å are normal for this type of complex.

Key words: organoboron compound, boron compound, crystal structure.

WOLFGANG KLIEGEL, UTE SCHUMACHER, MAHMOOD TAJERBASHI, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **69**, 545 (1991).

La réaction du *N'*-hydroxy-*N*-[(1-hydroxycyclohexyl)méthyl]benzamide et de l'anhydride de l'acide diphénylborinique conduit au 4-[(1-hydroxycyclohexyl)méthyl]-2,2,5-triphényl-1,3-dioxa-4-azonia-2-boratacyclopent-4-ène; le rendement est pratiquement quantitatif. Les cristaux de ce produit sont monocliniques, groupe d'espace $P2_1/c$, avec $a = 9,9117(6)$, $b = 13,308(1)$ et $c = 17,339(2)$Å, $\beta = 99,420(7)°$ et $Z = 4$. On a déterminé la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs respectives de $R = 0,040$ et $R_w = 0,047$; 2423 réflexions avec $I \geq 3\sigma(I)$. La molécule existe dans une structure normale, avec un acide hydroxamique chelate à cinq chainons; le cycle BONCO existe dans la conformation *B*-enveloppe. Les longueurs des liaisons (corrigées pour la libration): (N)O—B = 1,535(3), (C)O—B = 1,569(3), C—B = 1,603(3) et 1,601(3)Å, sont normales pour ce type de complexe.

Mots clés : composé organoborique, composé du bore, structure cristalline.

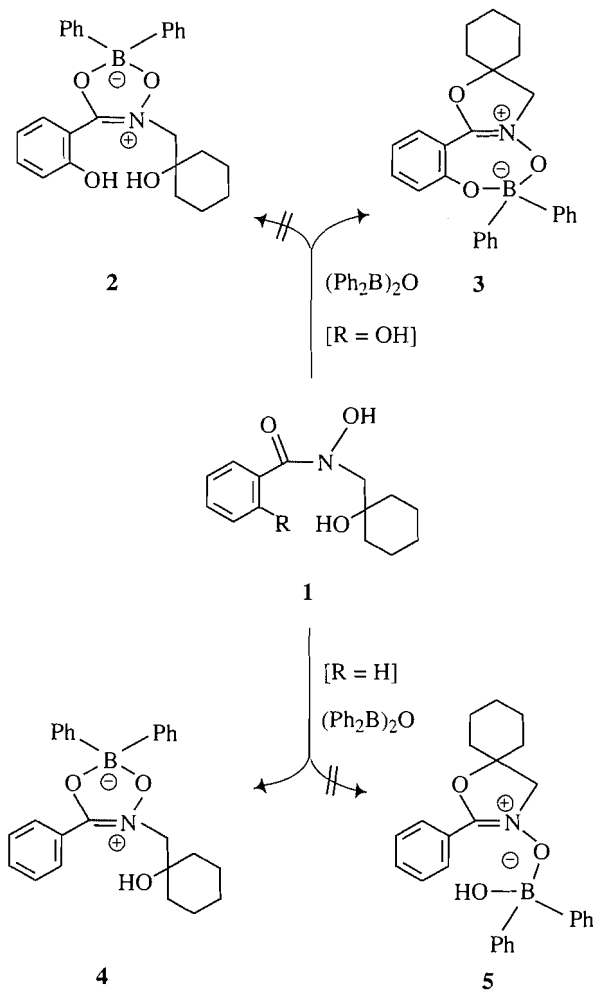
[Traduit par la rédaction]

Introduction

In a previous attempt to synthesize the five-membered diphenylboron chelate **2** by reaction of the *N*-(2-hydroxyalkyl)salicylohydroxamic acid **1** (R = OH) with the anhydride of diphenylborinic acid we obtained the seven-membered chelate **3**, the structure of which has been determined by X-ray crystallography (1). One of the donor moieties of the bidentate ligand in **3** is a 2-oxazoline *N*-oxide group resulting from an intramolecular condensation reaction that converts the *N*-(2-hydroxyalkyl)hydroxamic acid function into the heterocyclic *N*-oxide. The second donor group in **3** is the phenolate residue.

In order to obtain more information about the reactivity and chelating properties of polyfunctional hydroxamic acids of the type **1**, we synthesized the benzohydroxamic acid **1** (R = H), omitting the phenolic hydroxyl group. The remaining functional groups of **1** (R = H) would still allow cyclocondensation under the influence of the Lewis acid diphenylborinic anhydride leading to the 2-oxazoline *N*-oxide derivative **5**. This parallels the formation of **3**, the difference being that chelate formation involving the phenolic oxygen atom of **3** is not possible with compound **1** (R = H). The reaction of **1** (R = H) with the anhydride $(Ph_2B)_2O$ gave a nearly quantitative yield of a crystalline product with an elemental analysis consistent with the isomers **4**–**7**. Rechelatization of the product with diphenylcarbazone showed an intact diphenylboron moiety in the typical blue color reaction (2). By ^{1}H nmr spectroscopy three phenyl groups could be identified, as well as a single methylene group, a pentamethylene group, and one exchangeable OH proton. Neither the nmr spectrum nor the infrared spectrum (the latter with a distinct C=O/C=N band at 1595 cm^{-1}) allowed a definite assignment of the diphenylboron hydroxamate structure **4**, although the chemical shift of the OH proton signal at δ = 2.68 ppm (in $CDCl_3$) or 4.87 ppm (in d_6-dmso) is suggestive of an alcoholic hydroxyl function. Nevertheless, the isomeric structure **5**, an open-chain complex of diphenylborinic acid with the 2-oxazoline *N*-oxide corresponding to the cyclic derivative **3**, has to be considered. The structure **5** would represent another example of the type of *N*-oxide boron complex recently characterized for the analogous BF_3 adduct (3). Less probable, but not ruled out on the basis of spectroscopic data, are both the six-membered and seven-membered diphenylboron chelates **6** and **7**, respectively. Structure **6** would involve the *N*-hydroxy and the alkanol groups as chelating ligands, and in structure **7** the carbonyl and alkanol oxygen atoms would be available as donors. An X-ray crystallographic analysis has been undertaken in order to make a definitive structural assignment.

Experimental



N-Hydroxy-N-[(1-hydroxycyclohexyl)methyl]benzamide, 1 (R = H)

Benzoylchloride (2.81 g, 20 mmol) is diluted in 30 mL dry tetrahy-

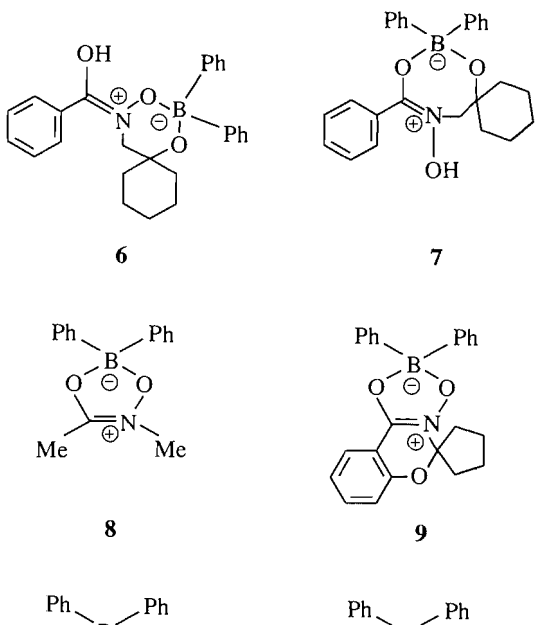
drofuran and added dropwise to a solution of 1-(hydroxylamino)cyclohexanol (4) (2.90 g, 20 mmol) and triethylamine (20 mmol in 100 mL dry tetrahydrofuran) at −15°C, with continuous stirring. After stirring for 12 h at room temperature, the solvent is removed *in vacuo*, and the residue is dissolved in 100 mL of 2N NaOH. The alkaline aqueous solution is extracted twice with 100 mL diethylether and is acidified with HCl. The acid solution is extracted with 5 × 100 mL diethylether, and the combined extracts (from the acid solution) are dried over Na_2SO_4. Evaporation of the ether yields 3.51 g (70%) of colorless crystals, mp 124–125°C (from diethylether). *Anal.* calcd for $C_{14}H_{19}NO_3$: C 67.45, H 7.68, N 5.62; found: C 67.35, H 7.69, N 5.56. Infrared (KBr): 3385 and 3140 (broad, O—H), 1630 cm^{-1} (C=O). ^1H nmr (90 MHz): (*a*) ($CDCl_3$/TMS): δ (ppm) = 0.90–1.87 (m, —$(CH_2)_5$—), 3.70 (s, N—CH_2), 7.13–7.67 (m, C_6H_5); (*b*) (d_6-dmso/TMS): δ (ppm) = 0.95–1.85 (m, —$(CH_2)_5$—), 3.67 (s, N—CH_2), 4.27 (s, broad, exchangeable, C—OH), 7.25–7.73 (m, C_6H_5), 9.65 (s, broad, exchangeable, N—OH).

4-[(1-Hydroxycyclohexyl)methyl]-2,2,5-triphenyl-1,3-dioxa-4-azonia-2-borata-4-cyclopentene, 4

1 (R = H; 0.50 g, 2 mmol) and oxybis(diphenylborane) (0.35 g, 1 mmol) are dissolved in a small quantity of ethanol with slight heating. The solution is cooled down until crystallization starts. Yield: 0.63 g (76%), mp 124–126°C (from ethanol). *Anal.* calcd. for $C_{26}H_{28}BNO_3$: C 75.55, H 6.83, B 2.62, N 3.39; found: C 75.35, H 6.88, B 2.61, N 3.39. Infrared (KBr): 3590 (sharp) and 3540 (broad, O—H), 1595 cm^{-1} (C=O/C=N). ^1H nmr (90 MHz): (*a*) ($CDCl_3$/TMS): δ (ppm) = 1.00–1.80 (m, —$(CH_2)_5$—), 2.68 (s, exchangeable, OH), 3.80 (s, N—CH_2), 7.0–7.8 (m, 3 C_6H_5); (*b*) (d_6-dmso/TMS): δ (ppm) = 1.10–1.80 (m, —$(CH_2)_5$—), 3.87 (s, N—CH_2), 4.87 (s, exchangeable, OH), 7.0–8.1 (m, 3 C_6H_5). The substance gives a blue color reaction with diphenylcarbazone in methanolic solution, indicating the presence of a Ph_2B moiety (2). Crystals suitable for X-ray crystallography were obtained by recrystallization from benzene/petroleum ether, mp 128°C.

X-ray crystallographic analysis of 4



A crystal ca. 0.32 × 0.32 × 0.35 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least squares on setting angles for 25 reflections (2θ = 30.0–39.4°) measured on a diffractometer with Mo-K_α radiation ($\lambda_{K\alpha 1}$ = 0.70930, $\lambda_{K\alpha 2}$ = 0.71359 Å). Crystal data at 21°C are as follows:

$C_{26}H_{28}BNO_3$ fw = 413.32

Monoclinic, a = 9.9117(6), b = 13.308(1), c = 17.339(2) Å, β = 99.420(7)°, Z = 4, ρ_c = 1.217 Mg m^{-3}, $F(000)$ = 880, μ(Mo-K_α) = 0.73 cm^{-1}. Absent reflections: $0k0$, k odd, and $h0l$, l odd, uniquely indicate the space group $P2_1/c$ (No. 14).

Intensities were measured with graphite-monochromated Mo-K_α radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.1–10.0° min^{-1} over a range of (0.70 + 0.35 tan θ)° in ω (scan extended by 25% on each side for background measurement) was employed. Data were measured to 2θ = 60°. The intensities of three check reflections, measured every hour of X-ray exposure time throughout the data collection, showed only small random variations. The data were processed[2] and corrected for Lorentz and polarization effects. Of the 6551 independent reflections measured, 2423(37.0%) had intensities greater than or equal to 3σ(I) above background where $\sigma^2(I) = [C + 2B + (0.040(C - B))^2]$ with C = scan count, B = normalized total background count.

The structure was solved by direct methods, the coordinates of all

[2]Computer programs used include locally written programs for data processing and locally modified versions of the following: MULTAN80, multisolution program by P. Main, S. J. Fiske, S. E. Hull, L. Lessinger, G. Germain, J. P. Declercq, and M. M. Woolfson; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; FORDAP, Patterson and Fourier syntheses, by A. Zalkin; ORTEP II, illustrations, by C. K. Johnson.

non-hydrogen atoms being determined from an *E*-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (C(sp^2)—H = 0.97, C(sp^3)—H = 0.98 Å, $U_H = 1.2U_{bonded\ atom}$) except for the OH hydrogen atom which was refined with an isotropic thermal parameter. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 5. The weighting scheme $w = 1/\sigma^2(F)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 284 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.040$ and $R_w = 0.047$ for 2423 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$. On the final cycle of refinement the maximum parameter shift corresponded to 0.17σ. The mean error in an observation of unit weight was 1.45. The final difference map showed maximum fluctuations of ± 0.16 e Å^{-3}.

The thermal motion has been analyzed in terms of the TLS model (6). The rms error in the temperature factors U_{ij} (derived from the least-squares analysis) is 0.0014 Å^2. The five rings in the structure (plus substituent non-hydrogen atoms) were separately analyzed (rms ΔU_{ij} = 0.0018–0.0026 Å^2). The bond lengths have been corrected for libration (6, 7) using shape parameters q^2 of 0.08 for all atoms. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths (corrected and uncorrected) and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, and structure factors have been deposited.[3]

Results and discussion

As already assumed on the basis of the chemical shift value for the OH proton signal in the ^{1}H nmr spectra, the structure is that of the diphenylboron chelate **4** with a free hydroxyalkyl group. In contrast to the intramolecular condensation of the phenolic derivative **1** (R = OH) during the reaction with oxybis-(diphenylborane) leading to **3**, the benzohydroxamic acid without the phenol function, **1** (R = H), does not give a similar cyclocondensate, **5**, stabilization via a seven-membered chelate arrangement like that in **3** no longer being possible. The diphenylboron hydroxamate **4** represents another example of a stable "normal" hydroxamic acid chelate of the diphenylborenium cation (Ph_2B^+), like **8** (8), **9** (9), **10** (10), and others (11).

The short C=N distance[4] of 1.312(2) Å in **4** is similar to the corresponding values of 1.306, 1.300, and 1.309 Å reported for **3** (1), **8** (8), and **9** (9), respectively. From plots of π-bond order vs. bond length for C⋯N bonds (12, 13), these distances have π-bond orders between 0.70 and 0.85. The π-bond order of the C=O bond (1.293(2) Å), estimated to be about 0.5 from a plot of C—O distance vs. MO-π-bond order (13), is considerably less than that expected for a C=O double bond. Comparison of the C=O distance in **4** with those in **8** (8) (1.337 Å) and **9** (9) (1.288 Å) shows the influence of the adjacent (conjugated) aryl substituent on the C=O bond: there is obviously more double bond character in the C—O groups of **4** and **9** than there is in the aliphatic substituted hydroxamate **8**. Nevertheless, the π-interaction between the phenyl group and the hydroxamate system in **4** is somewhat reduced relative to compound **9**. This is manifested not only by the slightly longer C=O bond of **4**, but also by the longer C(1)—C(9, phenyl) bond (1.476(3) Å) in **4**, indicating lesser π contribution than in **9** where the corresponding C(O)—C(aryl) distance is 1.438 Å. Further support for this difference in π interaction is provided by the fact that the approximate coplanarity of the phenyl ring and the hydroxamate chelate ring noted for **9** is not observed for **4**.

The N—O bond in **4** (1.396(2) Å) is the longest yet observed in five-membered boron hydroxamate chelates of the types **8–10**. Only compound **10** ($R^1 = C_6H_{11}$, $R^2 = CH_3$) shows a similar long N—O bond of 1.389 Å. Like compound **4**, **10** possesses a cyclohexyl substituent, separated by one carbon atom from the nitrogen. In both cases the hydroxamate nitrogen atom could gain more basicity by this substitution pattern and thus enhance the single bond character of the N—O bond. In the boron chelates **11** (R = H (14) and R = CH_3 (15)) with a basic hydroxylamine nitrogen each, the N—O bond lengths are 1.409 (uncorr.) and 1.410 Å, respectively.

The two O—B bond lengths in **4** are significantly different (1.535(3) and 1.569(3) Å), which is normal for boron chelates of unsymmetrical ligands like **3**, **9**, or **10**. The mean C—B /mean O—B bond length ratio of 1.031 for **4** is indicative of intermediate overall binding strength of the *O,O*-chelating ligand with respect to the "Ph_2B^+" moiety. These ratios range from 1.017 to 1.066 (mean 1.035) for other "Ph_2BO_2" com-

pounds having five-membered chelate rings (refs. 9, 16 and references therein).

The orientation of the two *B*-phenyl rings (angle between normals to the mean planes = 82.9°) is quite different from the symmetrical disposition of the two phenyl rings observed for the symmetrically substituted hydroxamate **8** (8). The hydroxyl group of the cyclohexane ring (which has a chair conformation) is in an axial position and the chelate ring is connected via a methylene link at an equatorial position, a normal orientation for such differently space filling substituents. The five-membered chelate ring has a *B*-envelope conformation with the boron atom displaced 0.415(3) Å from the O(1)O(2)NC(1) mean plane.

The most significant intermolecular contacts correspond to van der Waals interactions across a centre of symmetry between hydroxyl groups (O(3)···H(O3)($1 - x$, $1 - y$, $1 - z$) = 2.55(4) and H(O3)···H(O3) = 1.99(8) Å), the geometry of this interaction being inconsistent with hydrogen bonding. The OH group is, however, involved in a weak intramolecular C—H···O in-

On the ground and excited state dipole moments of planar vs. twisted nitroaniline analogues

HEMANT K. SINHA AND KEITH YATES

Department of Chemistry, Lash Miller Chemical Laboratories, University of Toronto, Toronto, Ont., Canada M5S 1A1

Received September 5, 1990

HEMANT K. SINHA and KEITH YATES. Can. J. Chem. **69**, 550 (1991).

Planar and conformationally twisted *p*-nitroaniline (PNA) and *N*,*N*-dimethyl-*p*-nitroaniline (DMPNA) systems have been subjected to electric field study (electrochromism) to understand their charge transfer characteristics in the ground and excited states. The observed values of ground and excited state dipole moments suggest that twisting of either the donor (D) with respect to the acceptor (A) or vice versa can have a large impact on the resultant charge distribution, particularly on the excited state charge distribution. These observations remarkably support the TICT hypothesis and minimum overlap rule, as proposed by Grabowski *et al.* Simple molecular orbital calculations provide adequate explanation for the observed changes in the dipole moment and reasonable agreement has been found in each case studied.

Key words: electrochromism, dipole moments, charge transfer.

HEMANT K. SINHA et KEITH YATES. Can. J. Chem. **69**, 550 (1991).

Afin de mieux comprendre les caractéristiques de transfert de charge dans leurs états fondamentaux et excités, on a étudié des systèmes de *p*-nitroaniline (PNA) et de *N*,*N*-diméthyl-*p*-nitroaniline (DMPNA) plans et conformationnellement déformés en les soumettant à des champs électriques (électrochromisme). Les valeurs observées pour les moments dipolaires des états fondamentaux et excités suggèrent que la déformation soit du donneur (D) par rapport à l'accepteur (A) ou vice versa peut avoir une influence marquée sur la distribution des charges, particulièrement sur la distribution de la charge dans l'état excité. Ces observations apportent un support remarquable à l'hypothèse TICT et à la règle du recouvrement minimal proposée par Grabowski et ses collaborateurs. Des calculs simples d'orbitales moléculaires fournissent une explication raisonnable des changements observés dans le moment dipolaire et l'accord acceptable qui a été trouvé dans chacun des cas étudiés.

Mots clés : électrochromisme, moments dipolaires, transfert de charge.

[Traduit par la rédaction]

Introduction

Numerous examples are available in the literature concerning steric effects on conjugation in the ground state (1). According to the generally accepted maximum overlap rule, the coplanarity of the donor (D) and acceptor (A) orbitals is the first condition for maximum resonance interaction, i.e., maximum charge transfer from the D to A orbitals. Therefore, for conjugated systems significant contribution to the molecular wavefunctions is expected from the intramolecular charge transfer (ICT) structures. The percentage of contribution of ICT structures to molecular wavefunctions is directly reflected in the permanent dipole moment of the molecule. Hence, any deviation from coplanarity between D and A orbitals, which directly hinders their charge transfer interactions, results in a decrease in the molecular dipole moment in the ground state and achieves a minimum value for the perfectly orthogonal conformation, where there will be minimum resonance interactions. Analogously, coplanarity has been found to be equally important for excited state charge transfer processes. Structurally, more pronounced changes in the dipole moment upon electronic excitation have been observed for conjugated planar π-electronic systems of polar organic compounds (2). Experimentally, this has been verified from the direct measurement of the excited state dipole moment, either via solvatochromic shift methods or by more reliable electro-optical methods (2).

However, the maximum overlap rule has been challenged recently for the electronically excited state, on the basis of extensive charge transfer that has been found to occur in systems having completely orthogonal D and A orbitals, for certain kinds of organic molecules (3). The term twisted intramolecular charge transfer (TICT), as coined by Grabowski *et al.*, is characterized by the mutually perpendicular conformation of D and A moieties and a large contribution from ICT structures to molecular wavefunctions (4). Thus it is proposed that, in those molecules that show TICT behaviour, the ICT in the excited state is governed by a *minimum overlap rule*. Several types of experimental and theoretical evidence for the TICT mechanism, and the continuing search for molecules having TICT nature, have given the proposed TICT hypothesis a strong footing. Recent excited state dipole moment determinations by electro-optical fluorescence measurements on the locally excited (LE) state and TICT state (5) provide direct experimental evidence for the more polar character of the TICT state in comparison to that of the LE state, supporting the hypothesis.

It has been observed that excitation of an initially twisted molecule (twisted in the ground state due to steric effects) results in complete population of the TICT state (6). This is manifested by the fact that these molecules show only TICT fluorescence, but no emission from the LE state. Therefore, a study of the excited states of the twisted molecules (twisted across the D–A bond in the ground state) should provide more insight into the TICT phenomena. Until now there has been no effort to probe directly the charge transfer characteristics of twisted molecules in the Franck–Condon excited states. Since the electro-optical absorption method is the most suitable way to determine the dipolar character of a molecule in its vertical excited state, this method has been employed here (2). Furthermore, since we are looking at vertical excited states, solvent-assisted conformational changes during the excited state lifetime will not contribute to our experimental observations and hence will provide a true picture of the excited state charge distribution free of solvent interactions. In our continuing effort to understand the charge transfer characteristics of twisted molecules, we report in this paper a systematic study of ground and excited state dipole moments of some model compounds. Recent study has shown that not only is the nature of the D and A groups important concerning charge transfer in the excited state, but relative localization of HOMO and LUMO is also equally

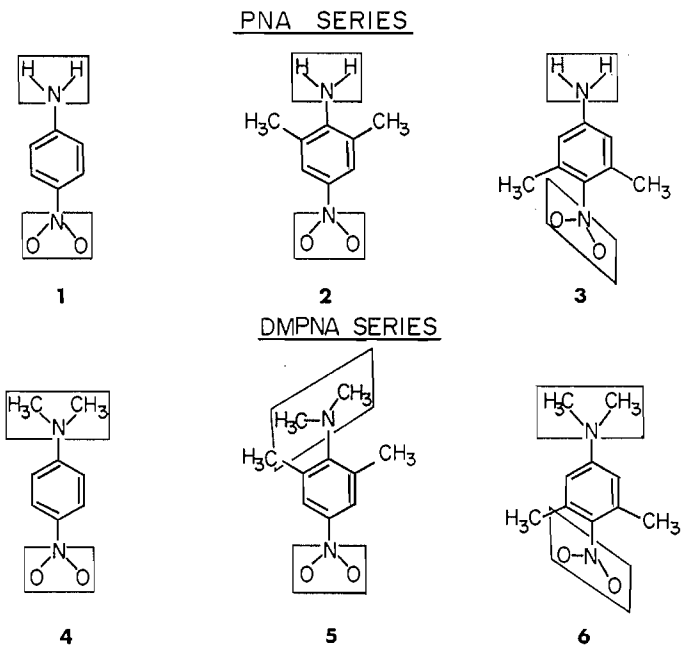

FIG. 1. Planar and conformationally twisted *p*-nitroaniline (PNA) and *N,N*-dimethyl-*p*-nitroaniline (DMPNA) systems.

important (7*a*). In this paper we have carried out an electro-optical absorption study on some carefully selected planar and selectively twisted nitroaniline analogues (see Fig. 1) to look into the factors that determine the charge transfer characteristics in twisted molecular systems. Furthermore, as these molecules are either nonfluorescent or weakly fluorescent, this method is the only suitable way to determine directly the charge distribution in their excited states. Simple molecular orbital calculations have been carried out to emphasize the importance of relative localization of HOMO and LUMO on the ICT in the excited state. These studies will be particularly important in terms of understanding photophysics, photochemistry, and nonlinear optical behaviour of nitroanilines.

Theory of electric field perturbation

The complete experimental and physical description of electro-optical absorption measurements on macroscopic systems has been presented fully in previous papers (7). This will not be repeated, except the basic principles, which are briefly summarized.

The effect of a uniform external electric field, E_{ext}, on the molar absorption coefficient of a molecule in solution phase can be given as

$$[1]\quad \Delta\epsilon = F_{int}^2 \epsilon \left[A_\chi + B_\chi/15h \frac{\partial/\partial\nu(\epsilon/\nu)}{(\epsilon/\nu)} + C_\chi/30h^2 \frac{\partial^2/\partial\nu^2(\epsilon/\nu)}{(\epsilon/\nu)} \right]$$

where F_{int} is the corrected electric field at the location of the molecule in solution, h is Planck's constant, and χ is the angle between the polarization direction of incident light and the direction of the electric field vector. For a molecule possessing a large permanent dipole moment, since the contribution from molecular polarizability terms to field signal can be considered negligible in comparison to that of the dipole moment terms, the A_χ, B_χ, and C_χ terms are related to various dipole moment parameters by the following equations:

$$[2]\quad A_\chi = 1/30(3\cos^2\chi - 1)\beta^2[3(\hat{p}\cdot\mu_g)^2 - \mu_g^2]$$

$$[3]\quad B_\chi = 5\beta(\mu_g\cdot\Delta\mu) + (3\cos^2\chi - 1)\beta[3(\hat{p}\cdot\mu_g)(\hat{p}\cdot\Delta\mu) - (\mu_g\cdot\Delta\mu)]$$

$$[4]\quad C_\chi = 5\Delta\mu^2 + (3\cos^2\chi - 1)[3(\hat{p}\cdot\Delta\mu)^2 - \Delta\mu^2]$$

In these equations, $\hat{p}$ is a unit vector in the direction of the transition moment, μ_g and $\Delta\mu$ are, respectively, the ground state dipole moment and the change in dipole moment on electronic excitation, and $\beta = (\kappa T)^{-1}$, where κ is the Boltzmann constant and T is the temperature.

Methods

The apparatus used for electro-optical absorption measurements is described in detail in ref. 7*a*. For each molecule the electric field signals were collected at three different values of χ and for several wavelengths λ within the absorption band of interest. The derivative terms in eq. [1] were computed numerically from a digitized absorption spectrum. The contribution from the second-derivative term (see eq. [1]) to the electric field signal was found to be very small, as observed in several other polar molecules (7). Therefore, this term has been neglected in the regression analysis. The coefficients A_χ, B_χ, and their standard deviations are obtained by multiple linear regression (see eq. [1]). Finally, the molecular parameters were calculated from the slopes and intercepts of least-squares plots of A_χ and B_χ versus $(3\cos^2\chi - 1)$.

We have used the spherical cavity approximation for correcting the externally applied field to an internal field at the location of the molecule in solution (8). No correction has been made for the effect of dipole reaction field or for the contribution of molecular polarizability to the electric field signal. Since these will be approximately of the same order of magnitude for each molecule studied here, direct comparison of their dipolar character will not be subject to serious error due to lack of the above corrections. Furthermore, recent electric field measurements comparing the gas phase and solution phase results on similar polar molecules, such as *p*-nitroanisole and *p*-cyanoaniline, show that the combined error due to the spherical cavity approximation and lack of a reaction field correction is less than 10% (9).

Materials

p-Nitroaniline (**1**) and *N,N*-dimethyl-*p*-nitroaniline (**4**) were obtained from Aldrich Chemicals. 2,6-Dimethyl-4-nitroaniline (**2**) was obtained by nitration of 1-(*p*-toluenesulphonylamino)-2,6-dimethylbenzene followed by hydrolysis as described in the literature (10). 3,5-Dimethyl-4-nitroaniline (**3**) was synthesized by simple nitration of 3,5-dimethylaniline by nitric acid (11). The above nitration gave both 2-nitro and 4-nitro derivatives, which were separated by thin-layer chromatography. *N,N*,2,6-Tetramethyl-4-nitroaniline (**5**) and *N,N*,3,5-tetramethyl-4-nitroaniline (**6**) were obtained by *N*-methylation of compounds **2** and **3** by freshly distilled dimethyl sulphate (12). All the compounds were recrystallized from appropriate solvents and the purity was checked by various spectroscopic analyses. Spectro-grade dioxane, from Aldrich Chemicals, was used as solvent without further purification. The solution was continuously circulated by a micro pump into the electric field cell from a reservoir to avoid any significant photochemical decomposition.

Theoretical calculations

The basic Hückel molecular orbital method was modified empirically as follows. The Coulomb Integrals H_{ii} for the heteroatoms of the aromatic side chain were scaled to the molecular ionization potentials of the simplest compounds (13), such as nitromethane, methylamine, *N,N*-dimethylamine, etc., using the approximate linear relationship between the E_{HOMO} and I_p reported by Streitwieser for a series of aromatic hydrocarbons (14). This gave heteroatom parameters $h_N(NO_2) = 1.5$, $h_O(NO_2) = 1.66$, $h_N(NMe_2) = 0.95$, and $h_N(NH_2) = 1.3$. The

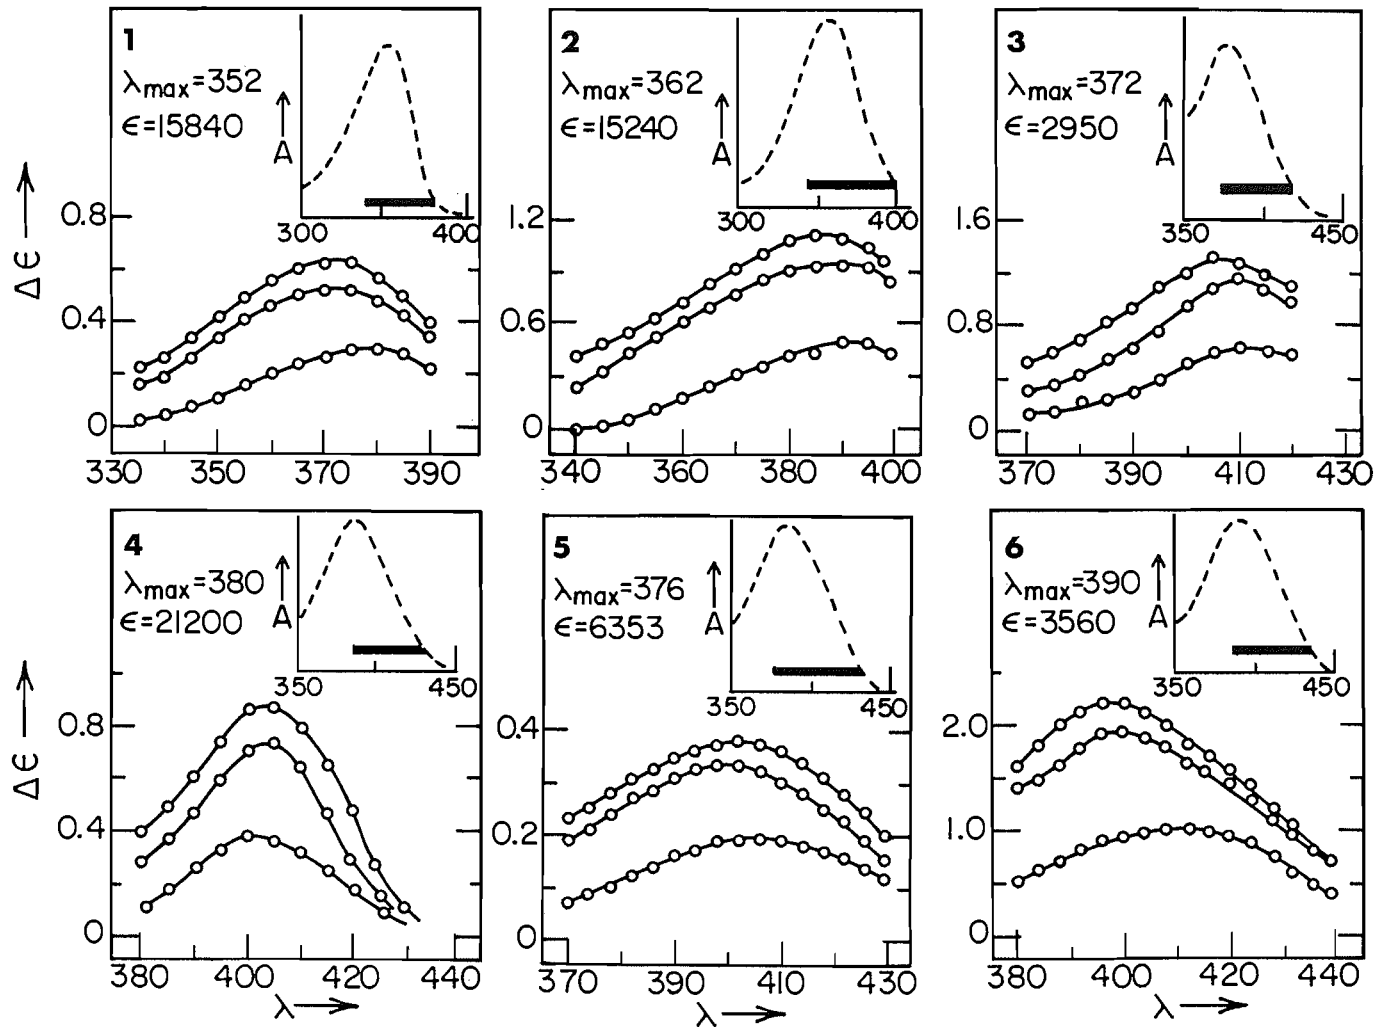

FIG. 2. Electric field spectra of the PNA and DMPNA systems at χ = 0, 25, and 50°. F_{ext} (external field) = 3.77 × 10^4 V/cm (rms). The inserted figures are the absorption spectra and the solid lines indicate the wavelength range on which electric field signals have been collected.

bond integrals H_{ij} for the $C_{aromatic}$—N bond and the N—O bonds were scaled to the curved relationship between k_{XY} and experimental XY bond length (13), also reported by Streitwieser (14). This gave k_{CN} = 0.8 and k_{NO} = 1.65. For the aromatic ring, standard values of H_{ii} and H_{ij} were used unmodified. Overall, the combination of these empirically derived H_{ii} and H_{ij} terms led to calculated values of energy of the HOMOs for compounds **1** and **4**, which gave values of I_p interpolated from the above linear relationship that are close to the reported experimental values. Furthermore, the calculated electron denisty distributions led to values of dipole moments for **1** (6.0 D) and **4** (6.8 D) that were in very good agreement with the experimental values obtained by dielectric methods (6.2 D for **1** and 6.8 D for **4**) (15). The dipole moments for orthogonal forms, i.e., compound **3**, **5**, and **6**, calculated by setting h_{C-N} = 0, were also in good agreement with the experimental values (see Table 1). Excited state dipole moments were calculated by promoting one electron from the HOMO to the LUMO and recalculating the q_i terms. These gave values of μ_e that were consistently higher than the observed values. However, the calculated and observed changes in dipole moments reflect the same trend. μ_e values based on INDO/S calculations on compounds **4**, **5**, and **6**, where σ-electrons are included in the calculation, also result in similar higher μ_e values (16). In addition, the symmetries of the calculated HOMO and LUMO could be be used to predict the directions of the transition moments.

TABLE 1. Ground and excited state dipole moments of the PNA and DMPNA systems obtained from electrochromic measurements in dioxane solution at 298 K

Compound	μ_g	$\Delta\mu\cdot\mu_g$	$\Delta\mu$	μ_e

Experimental results

The electric field signals at three settings of polariztion angle χ are shown in Fig. 2. The continuous lines in these figures were computed from the least-squares values of A_χ and B_χ using eq. [1]. The excellent agreement between the observed and calculated electric field spectrum suggests that eq. [1] adequately describes the field-induced changes in the absorption spectrum.

The molecular parameters obtained from the experiments are compiled in Table 1.

In the *p*-nitroaniline (PNA) series (compounds **1**, **2**, and **3**), substitution of methyl groups *ortho* to the amino group does not affect the planarity of the molecule, i.e., the D (-NH_2) and A (-NO_2) are still nearly in the same plane. This is evident from the fact that the absorption spectrum of **2** shows a small red shift with respect to that of **1**, as expected, and the extinction coefficients of **1** and **2** are very similar. On the other hand, considerable twisting of the -NO_2 group was observed in the case of **3** due to the steric effect of the *ortho* methyl groups. The twisting of the -NO_2 group was accompanied by a large decrease in the intensity and a small bathochromic shift of the long wavelength charge transfer (CT) transition with respect to that of **1**. Based on the approximate $\cos^2\theta = \epsilon/\epsilon_0$ relationship (ref. 1*a*, p. 414, and ref. 17), the angle between the aniline moiety and the -NO_2 group was calculated to be nearly 60° for compound **3**. The ground state dipole moment calculated from the electric field experiment also leads to a similar conclusion. For example, the μ_g's of **1** (5.5 D) and **2** (5.8 D) are very similar, reflecting the complete conjugation in both and little contribution from the steric factor due to the presence of *ortho* substituents in the latter. On the other hand, a dipole moment of 3.1 D, as observed in case of **3**, is nearly the same as that of nitromethane (3.0 D) (15), which indicates almost complete removal of charge transfer coupling between the -NO_2 group and the aromatic moiety due to deconjugation in the ground state. The μ_e's observed for **1** (13.7 D) and **2** (13.8 D) are also very similar, again suggesting very little difference in the planarity along the whole molecular skeleton. The large change in the dipole moment (μ_e = 22.6 D) observed in the case of **3**, which is nearly twice as large as that of its planar analogues, i.e., molecules **1** and **2**, makes it clear that conjugation between the D and A, in this case, is of little importance in deciding upon the magnitude of charge transfer character in the excited state. Recently, excited state dipole moments of similar magnitude have been reported for twisted nitrobenzene systems (7*b*). In all three cases, the transition moment direction has been found to be approximately in the same direction as μ_g.

The results obtained for the *N,N*-dimethyl-*p*-nitroaniline (DMPNA) series (compounds **4**, **5**, and **6**) are very different when compared with those of the PNA series described above. Similar to compound **3**, the intensity of the first charge transfer transition in the case of **6** was markedly decreased, with a small bathochromic shift in the absorption maximum due to the presence of *ortho* methyl substituents with respect to that of compound **4**. The absorption spectrum of compound **6** resembles as a whole the spectrum of *N,N*-dimethylaniline. When the *ortho* positions of the *N,N*-dimethylamino group in compound **4** are substituted, as in compound **5**, the dimethylamino group will be twisted out of the plane of the aromatic ring. This is accompanied by a marked hypochromic effect and a moderate hypsochromic effect on the first charge transfer band of compound **4**. This results in a spectrum that is closely similar to the spectrum of the correspondingly alkylated nitrobenzene. The smaller μ_g values of compounds **5** and **6** in comparison to that of their planar analogue, i.e., compound **4**, indicate that lack of coplanarity leads to a small degree of overlap between the D (-NMe_2) and A (-NO_2) orbitals, which ultimately leads to a weak charge transfer character in the ground state. The change in the magnitude of μ_g upon twisting either the D or the A group in the DMPNA series is not as pronounced as in the PNA series, indicating that a significant amount of conjugation exists even if the D or A groups are twisted by more than 60° from the plane of the benzene ring. This may be due to the very strong electron-donating ability of the -NMe_2 group in comparison to that of the -NH_2 group, and an equally strong electron-accepting nature of the -NO_2 group. Therefore a small degree of interaction between them could lead to significant charge transfer character in the ground state. The observed μ_e's are substantially different from what was observed in the PNA series. For example, twisting of the nitro group, as in compound **6**, results in a very small change in the dipole moment, whereas twisting of the *N,N*-dimethylamino group, as in compound **5**, brings the largest change in the dipole moment upon electronic excitation in comparison to the change in dipole moment observed in their planar analogue, i.e., compound **4**. The anomalous behaviour observed for these two series of compounds can be given a satisfactory explanation on the basis of simple theoretical calculations (see discussion below).

TABLE 2. Ground and excited state dipole moments of the PNA and DMPNA systems obtained from theoretical calculations

System	θ^a	ϕ^b	μ_g	μ_e	$\Delta\mu$
1	0	0	6.0	19.1	13.1
2	90	0	4.1	13.7	9.6
3	0	90	4.3	22.8	18.4

[a]Angle between the amino or *N,N*-dimethylamino group and the benzene ring.

[b]Angle between the nitro group and the benzene ring.

Theoretical results

Modified HMO calculations were carried out to obtain a theoretical explanation for the observed changes in dipole moments. Several other semiempirical SCF methods, such as MINDO/3 (18), MNDO (19), and AM1 (20), were also attempted, but none of them was successful in explaining the experimental results. All the above methods predict the -NO_2 group to be a mere spectator when it is out of the plane of the aromatic system. Such discrepancies in reproducing the experimental results, particularly for nitro-substituted aromatics, have been reported in the literature for these semiempirical methods (21).[1] Furthermore, due to the variational approach used in these SCF methods, which can only give the lowest energy state of a given symmetry, the excited state calculations are not valid for molecules having S_1 states belonging to totally symmetric representation, since the S_0 state is always totally symmetric for any closed shell system (22, 23). This has been found to be the case for the PNA and DMPNA systems, where the S_1 states in both cases belong to totally symmetric representation (A_1). All the above three methods show a slight *decrease* in dipole moment upon electronic excitation for both compounds **1** and **4**, and the first two methods suggest that an orthogonal conformation, where the nitro group and the aniline moiety are perpendicular to each other, is the most stable conformation in the ground state. These predictions are found not to be true experimentally (24). However, simple HMO type calculations, which are not subject to the above limitations, show a trend that

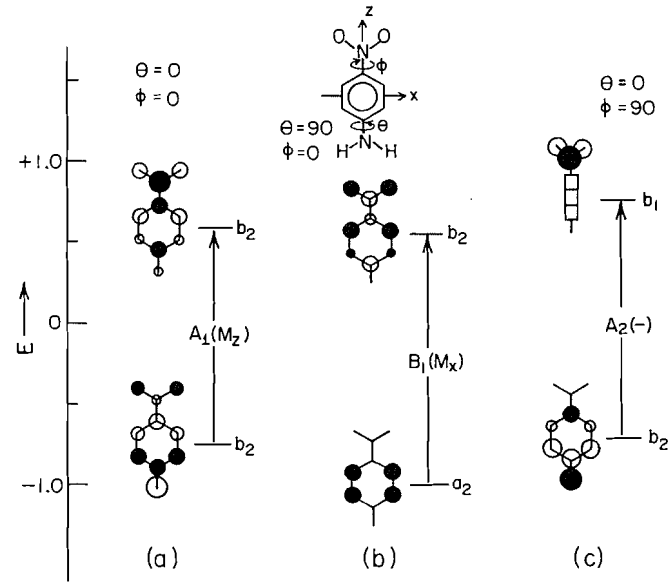

FIG. 3. Molecular orbital diagram of the PNA series; (a) all planar, (b) amino twisted, (c) nitro twisted.

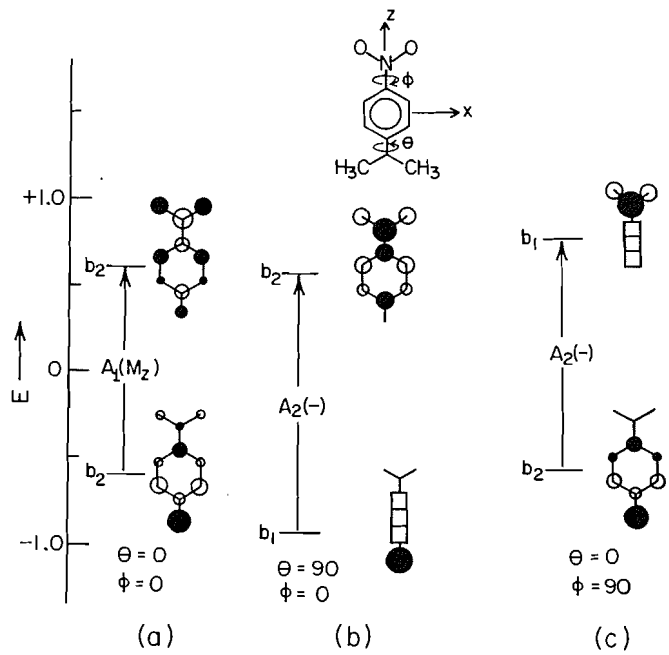

FIG. 4. Molecular orbital diagram of the DMPNA series; (a) all planar, (b) *N,N*-dimethylamino twisted, (c) nitro twisted.

is in fairly good agreement with the experimental results. Table 2 summarizes the theoretical results obtained from the HMO calculations.

Figures 3a and 3c show the MO diagram of planar and twisted PNA systems respectively. It is apparent that the difference in the charge transfer characteristics of the planar and twisted conformations arises mainly because of the specific localization of HOMO and LUMO upon twisting the nitro group. For example, the LUMO changes from a nitrobenzene type orbital in the planar form to a purely antibonding nitro group orbital in the perpendicular form. Therefore electronic excitation of twisted PNA, as in compound **3**, results in a complete electron transfer from the aniline group to the nitro group, producing a highly dipolar structure (μ_e calcd. = 22.8 D). On the other hand, on twisting the amino group out of plane, which cannot easily be achieved experimentally, produces merely a nitrobenzene type transition (Fig. 3b), with a μ_e (μ_e calcd. = 13.7 D) value similar to that observed in nitrobenzene (7*b*). In planar PNA, since the transition is an A_1 type transition (HOMO(b_2) → LUMO(b_2)), the transition should be M_z polarized, i.e., parallel to μ_g, which is along the *Z*-direction (see Fig. 3 for molecular coordinate axes). However, on twisting the nitro group out of plane, the HOMO(b_2) to LUMO(b_1) transition intensity falls to zero for the perfectly perpendicular form (in this π-electronic approximation), the transition being formally equivalent to a forbidden transition.

The theoretical results obtained for the DMPNA series are very different from those of the PNA series, discussed above. Because of the large difference in the ionization potentials of $-NH_2$ and $-N(CH_3)_2$, which is near 1.2 eV, in the planar form the HOMO becomes more localized on the *N,N*-dimethylamino group, whereas LUMO is a delocalized nitrobenzene type orbital (see Fig. 4a). The charge localization and the charge transfer on electronic excitation become more dramatic upon deconjugating the *N,N*-dimethylamino group from the rest of the aromatic system, as shown in Fig. 4b. However, when the *N,N*-dimethylamino group is perfectly orthogonal to the aromatic ring, the HOMO(b_1) to LUMO(b_2) transition is a forbidden transition. The $\Delta\mu$ calculated for this perpendicular form (23.5 D) is significantly higher than that for the planar configuration (15.9 D). This matches the results obtained from electric field measurements. The theoretical results obtained for the *N,N*-dimethylaminobenzonitrile system (in both planar and perpendicular form) by several π-electronic calculations are very similar to those observed for the DMPNA system, i.e., the excited state dipole moment of the perpendicular form is higher than the corresponding value for the planar form and the HOMO to LUMO transition becomes forbidden for the perfectly perpendicular configuration, where the *N,N*-dimethylamino group is perpendicular to the benzonitrile π-system (5, 25). In an analogous way, by twisting the nitro group by 90° and keeping the *N,N*-dimethylamino group in the plane of the benzene ring (Fig. 4c), as in compound **6**, HMO calculations indicate a change in dipole moment ($\Delta\mu$ = 21.7 D) that is nearly of the same magnitude as observed for compound **5**. In this case also, the HOMO(b_2) to LUMO(b_1) transition become forbidden for the perfectly perpendicular configuration. The calculated large dipole moment is again caused by the relative localization of the HOMO, which is a *N,N*-dimethylaniline type, and the LUMO, which is an antibonding nitro group orbital (see Fig. 4c). The calculated dipole moments for the DMPNA series are consistently higher than those observed experimentally.

Discussion

Recently we reported that in twisted nitrobenzene systems, where the nitro group is perpendicular to the aromatic benzene ring, the magnitude of charge transfer upon electronic excitation corresponds to nearly a full unit electron transfer from the benzene ring to the nitro group (7*b*). This creates a highly dipolar structure in the electronically excited state, as observed in nitromesitylene (μ_e = 21.6 D). The relative localization of the HOMO and LUMO, which is responsible for such a high degree of charge transfer, was evident from the theoretical and experimental results obtained for the model compounds. In this

paper we have extended the above work to various comformations of nitroaniline analogues to provide further support for the earlier results.

Compounds **1**, **4**, and the derivatives are some of the best known examples that show extensive charge transfer both in the ground and excited states (26, 27). This is partly due to the strong electron-withdrawing power of the $-NO_2$ group and also the strong electron-donating ability of the $-NH_2$ and $-NMe_2$ groups. In fact, $-NMe_2$ is by far a better electron donor than the $-NH_2$ group, which is evident from the large difference in their ionization potentials (1.2 eV). This has been directly verified experimentally by several spectroscopic methods, for example, from the direct determination of ground and excited state dipole moments by electro-optical methods, which reflect their charge transfer nature (27). Furthermore, these molecules are important in terms of their TICT behaviour, which cannot be investigated by the usual fluorescence techniques due to the reasons mentioned earlier. The electro-optical technique provides a unique method of establishing TICT character in such molecules. Since this method deals with the vertical excited states, the conformation of the molecule has to be modified prior to excitation, as done in these model molecules by substituting methyl groups at the *ortho* positions to either D or A.

The results obtained for compound **1** (μ_g = 5.5 D and μ_e = 13.7 D) show excellent agreement with those reported by Liptay (2*b*). Since compound **2** is identical to compound **1** as far as the planarity of the π-electron system is concerned, which is evident from its spectral behaviour as discussed earlier, the observed μ_g (5.8 D) and μ_e (13.8 D) values are similar to those of compound **1**. This indicates that they exhibit similar charge transfer characteristics both in the ground and excited states. However, in compound **3**, where the nitro group is nearly orthogonal to the aniline moiety, the excited state is extremely dipolar in nature. The observed μ_e of compound **3** is nearly twice as large as that of its planar analogue and corresponds to almost a full unit charge transfer from the D to A orbitals. These observations are similar to those reported for twisted nitrobenzene systems (7*b*), such as nitromesitylene. Even though the charge transfer interaction is diminished considerably in the ground state upon deconjugation of the π-system due to twisting of the C—NO_2 bond, it is enhanced dramatically in the excited state. This emphasizes the fact that *minimum overlap* of the D and A orbitals favours the maximum charge transfer interaction in the excited state for such systems.

The reason for such extensive charge transfer in the excited state of the twisted system, as in compound **3**, can be satisfactorily explained on the basis of MO diagrams, shown in Fig. 3. It is clear that for the planar system (compounds **1** and **2**), both HOMO and LUMO have mixed character. Therefore, because of delocalized charge distribution both in the ground and excited states, a moderate change in the dipole moments was observed upon electronic excitation. On the other hand, in the twisted system, as in compound **3**, the electronic excitation takes place from an orbital that is predominantly aniline type to an exclusively antibonding nitro orbital (see Fig. 3c), which results in complete charge separation with a large excited state dipole moment (22.6 D). This raises the possibility of the existence of a distinct TICT state for compound **3** and other similar compounds, particularly in polar solvents. Unfortunately, this prediction cannot be tested by other techniques because of the nonfluorescent nature of compound **3**, as pointed out earlier. The totally nonemissive nature of compound **3**, both at room temperature and low temperature, could be due to fast nonradiative processes from a low-lying, well-characterized TICT state. In all three cases, the transition polarization direction of the absorption band is along the direction of charge transfer, i.e., parallel to both μ_g and μ_e, which agrees with the predicted transition moment direction based on the symmetry properties of HOMO and LUMO except for compound **3**, where the transition is forbidden in the π-electron approximation.

The results obtained for compound **4**, which were also reported by Liptay (2*b*) from similar measurements, show excellent agreement (see Table 1). It is very clear from Table 1 that the DMPNA series behaves differently from the PNA series. Recently, in an attempt to analyze the TICT nature of compound **4**, Dobkowski *et al.* pointed out that TICT state formation is possible from the thermodynamic point of view (16). This was predicted on the basis of a linear correlation of the TICT fluorescence maxima with the difference of the oxidation potential of the donor and the reduction potential of the acceptor group, which has been found for several molecules showing TICT fluorescence. On the basis of the temperature dependence of the fluorescence spectra, they concluded that compound **4** does not relax to a TICT state. However, the fluorescence method adopted by them is not very conclusive because these compounds (**4**–**6**) are nonfluorescent at room temperature and very weakly fluorescent at low temperature (compound **6** is nonfluorescent even at low temperature), unlike other TICT emitting molecules such as the *N*,*N*-dimethylaminobenzonitrile system (5). However, the observation that has gone largely unnoticed in their experiments is the tremendously large Stokes shift observed for compound **5** in comparison to that for compound **4** at 100 K. For example, the Stokes shift observed for compound **4** is nearly 50 nm, whereas for compound **5** it is more than 125 nm. This large Stokes shift for **5** is in accord with our experimental observation that the excited state of **5** has considerably larger dipolar character than that of **4**. These observations clearly suggest that a distinct TICT state in the case of **4** is feasible, at least in polar solvents. However, the lack of TICT fluorescence in **4** may be caused by efficient nonradiative processes from the TICT state, such as intersystem crossing to T_1, which are very probable for such nitro compounds.

In compound **6**, where the $-NO_2$ group is twisted out of the plane of the benzene ring, the change in dipole moment on electronic excitation is not as large as that of compound **5**. In fact, for **6** the $\Delta\mu$ is at a minimum when compared with the other two conformations of the DMPNA series (see Table 1). This behaviour would be expected if the $-NO_2$ group orbitals are considered to be essentially not involved in the electronic transition process. In such a case the molecule will more or less resemble the parent *N*,*N*-dimethylaniline (DMA) in terms of its electronic transitions. In fact, the absorption spectral features of compound **6**, as described earlier, resemble as a whole those of DMA, supporting the above description. However, the calculated $\Delta\mu$ for **6** does not agree with the trend observed experimentally. This is primarily due to the fact that theoretically there is still significant interaction of the $-NO_2$ antibonding orbital in the LUMO of **6**, even if the $-NO_2$ group is out of the plane of the π-system, as shown in the MO diagram (Fig. 4c). Therefore, the HOMO to LUMO transition results in extensive charge transfer from the D to A orbitals, creating a large $\Delta\mu$. It should also be noted that the lowest energy transition in **6** becomes forbidden in the perfectly orthogonal configuration, as

TABLE 3. Expected dipole moment changes based on simple HOMO and LUMO descriptions

Compound	θ^a	ϕ^b	HOMO	LUMO	CT ($\Delta\mu$)
1, 2	0	0	Mainly anilino type	Mainly nitrobenzene type	Moderate (8.2 D)
3	0	90	Purely anilino type	Purely nitro type	Extensive (19.5 D)
4	0	0	Mainly *N,N*-dimethylamino type	Mainly nitrobenzene type	Moderate (6.2 D)
5	90	0	Purely *N,N*-dimethylamino type	Mainly nitrobenzene type	Extensive (10.7 D)
6	0	90	Mainly *N,N*-dimethylamino type	Mainly benzene type	Small (5.4 D)

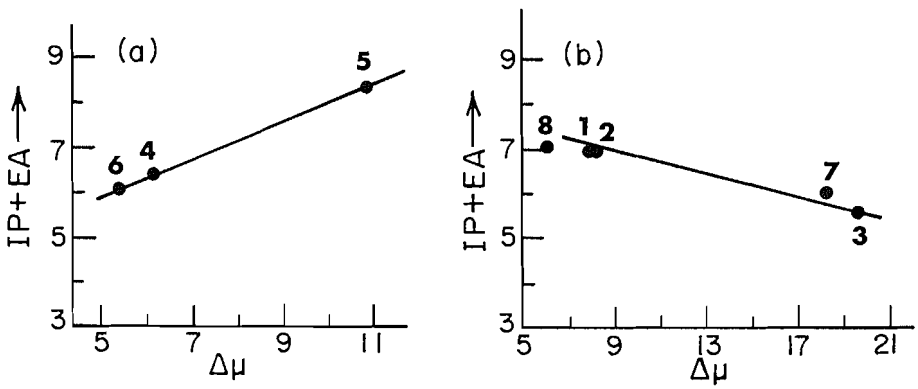

FIG. 5. Plot of IP + EA vs. $\Delta\mu$; (a) DMPNA series, (b) PNA series. The points corresponding to numbers **7** and **8** are, respectively, the values of nitromesitylene and nitrobenzene obtained from ref. 7*b*.

found in the case of compound **5**. On the other hand, the second transition, i.e., from HOMO to the second LUMO, exactly resembles the HOMO to LUMO transition expected for planar DMA. In fact, the calculated change in dipole moment ($\Delta\mu$ = 6.3 D) for planar DMA obtained from HMO calculations is very similar in magnitude to that of compound **6** (5.4 D) found experimentally. These observations strongly suggest that in **6**, the $-NO_2$ group acts merely as a spectator, and therefore is involved to a very small extent in the lowest energy electronic transition. Since compound **6** is also nonfluorescent even at low temperature, no conclusive explanation can be given regarding its TICT character. However, this experimental observation supports the fact that a twist of the acceptor ($-NO_2$) group in the DMPNA series does not introduce any TICT character in the parent molecule.

A very qualitative description based on the nature of the HOMO and LUMO, as shown in Table 3, can be used in explaining the observed changes in the dipole moments. In Fig. 5 the experimental values of the ionization potentials and electron affinities,[2] based on the description of HOMO and LUMO in Table 3, have been plotted against the observed change in the dipole moments. The good correlation observed for both the PNA and DMPNA series indicates that the above simple description is quite reasonable in explaining the charge transfer processes in the excited states of such systems. The two separate straight lines observed for the PNA and DMPNA series could be due to the large difference in the ionization potentials of the $-NH_2$ and $-NMe_2$ groups, which drastically changes the nature of the HOMO. These observations indicate that since ICT in the excited state is dependent on the nature of orbitals involved in the electronic transition, and since the ionization potential of the donor and the electron affinity of the acceptor decide specifically the localization of HOMO and LUMO in a typical $\pi\pi^*$ transition of such systems, a large change of ionization potential or electron affinity by twisting either the donor or acceptor group significantly changes the charge transfer character of the excited state. Therefore, the primary condition of planarity of the conjugated system, for maximum ICT, as observed generally for the ground state, is not a necessary condition for the excited state charge transfer process, supporting the minimum overlap rule for such systems.

Stereoselectivity of C(3) methylation and aldol condensation of camphor and derivatives

J. H. HUTCHINSON, D. L. F. LI, T. MONEY,[1] AND M. PALME
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Y6

AND

M. R. AGHARAHIMI AND K. F. ALBIZATI
Department of Chemistry, Wayne State University, Detroit, MI 48202, U.S.A.

Received August 14, 1990

J. H. HUTCHINSON, D. L. F. LI, T. MONEY, M. PALME, M. R. AGHARAHIMI, and K. F. ALBIZATI. Can. J. Chem. **69**, 558 (1991).

The stereoselectivity of methylation and aldol condensation of camphor and derivatives is determined by the presence or absence of a C(7) *syn*-methyl group and (or) C(5) and C(6) *endo*-hydrogen atoms.

Key words: camphor, C(3) methylation, C(3) aldol.

J. H. HUTCHINSON, D. L. F. LI, T. MONEY, M. PALME, M. R. AGHARAHIMI et K. F. ALBIZATI. Can. J. Chem. **69**, 558 (1991).

En se basant sur la présence ou sur l'absence d'un groupement C(7) *syn*-méthyle et (ou) d'atomes d'hydrogène C(5) et C(6) *endo*, on a déterminé la stéréosélectivité des réactions de méthylation et aldoliques du camphre et de ses dérivés.

Mots clés : camphre, C(3) méthylation, C(3) aldol.

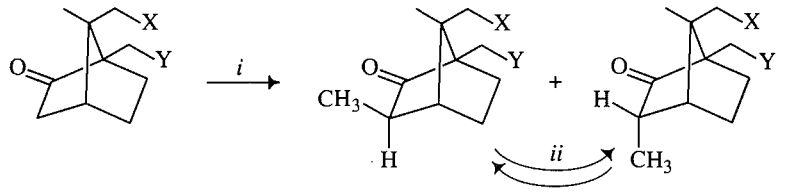
[Traduit par la rédaction]

C(3) methylation

The early literature (1–7) indicates that C(3) monomethylation of camphor (**1**) is readily accomplished, but the stereoselectivity of this process was not clearly established. Recent investigations (8, 9), however, have shown that sequential treatment of (+)-camphor (**1**) in THF with lithium diisopropylamide (1 mole equivalent) and methyl iodide (excess) at 0°C provides a product (~75% yield) that was shown by nmr (400 MHz) and capillary glc to be a mixture (~4:1) of 3-*exo*-methylcamphor (**2***a*) and 3-*endo*-methylcamphor (**2***b*) (Scheme 1). Subsequent treatment of this mixture with NaOMe in MeOH or with HCl and HOAc provides a mixture (~9:1) in which the major component is 3-*endo*-methylcamphor (**2***b*). The C(3) methylation of (+)-9-bromocamphor (**3**) (8, 9), (+)-9,10-dibromocamphor (**5**) (8), or (−)-4-methylcamphor (**7**) can be accomplished similarly and, in each case, nmr (400 MHz) evidence established that the ratio of *exo*-methyl to *endo*-methyl epimers was ~2:1 (Scheme 1). Subsequent equilibration with acid (HCl and HOAc) provided the corresponding 3-*endo*-methyl derivatives in 90–95% yield. Related to these observations is the fact that 6-methoxyepicamphor (**9**) can be converted exclusively to the *exo*-2-allyl derivative (**10**) (10). It has also been shown that camphor enol *tert*-butyldimethylsilyl ether (**11**) undergoes a Mukaiyama reaction to provide the *exo* product (**12**) (11) and that the related silyl ether (**13**) reacts with Eschenmoser's salt to yield a mixture (~6:1) of *exo* and *endo* products, **14***a* and **14***b* (12).

It has been suggested (8) that the unexpected preference of camphor and derivatives to undergo *exo* protonation, *exo* alkylation, or *exo* aldol condensation (see below) with carbonyl compounds could be due, *at least in part*, to the steric effect of the 5-*endo* hydrogen atom on the approach of electrophiles to the corresponding enolate ion. Support for this proposal has been provided by the fact that kinetic methylation of 5,6-dehydrocamphor (**15**) and 9-bromo-5,6-dehydrocamphor (**17**) provides mixtures (~12:1) in which the major products **16***a* and **18***a* are produced by *endo* methylation. It has also been shown that methylation of dehydro-10-norcamphor (**19**) and derivatives (**20–22**) (13*a–c*, 14) results in the almost exclusive formation of C(3)-*endo* methylated derivatives. Thus, in camphor and norcamphor compounds having a C(7) *syn*-methyl group and C(5) *endo*-hydrogen or substituents, kinetic *exo* methylation seems to be preferred, while in those compounds having a C(7) *syn*-methyl group and lacking a C(5) *endo* substituent (i.e., 5,6-dehydro derivatives) *endo* methylation is preferred. In compounds lacking a C(7) *syn*-methyl group (e.g., **23–25**), *exo* methylation occurs (15, 16) and the presence or absence of C(5) *endo*-hydrogen does not significantly affect the stereoselectivity of the reaction.

In contrast to the results described above, C(3) methylation of 3-methylcamphor (**2***a*,*b*) displays *endo* stereoselectivity (8). For example, addition of excess CD_3I to 3-methylcamphor enolate yields a product whose ^1H and ^2H nmr spectra indicate that it is a mixture (3.4:1) of 3-*exo*-methyl-3-*endo*-trideuteriomethylcamphor (**26***a*) and its C(3) epimer (**26***b*) (Scheme 2).



The striking difference in stereoselectivity between camphor enolate (**28**) (80% *exo* attack) and 3-methylcamphor enolate (**29**) (80% *endo* attack) can be explained by using the mechanism advanced by House and Umen (17) to explain preferential axial alkylation in substituted cyclohexanones. Thus, the enolate of 3-methylcamphor could be skewed (cf. **29**) to avoid eclipsing of the C(3) methyl group and the oxygen anion. The direction of this distortion would favour movement of the oxygen atom away from the C(10) methyl group and the C(3) methyl substituent to move up towards the C(3) hydrogen. The net result of this distortion would be to favour *endo* attack at the C(3) position.

Indirect support for the reasons advanced above to explain the stereoselective *exo* methylation of camphor (**1**) and *endo* methylation of 3-methylcamphor (**2***a*,*b*) was obtained by examining the stereoselectivity of methylation of 3,4-dimethylcamphor (**8***a*,*b*). In the enolate (**30**) derived from this compound, the downward movement of the C—O^- bond to avoid eclipsing with the C(3)—CH_3 bond would result in the corresponding upward movement of the C(3)—CH_3 bond. This would lead to increased torsional strain between the C(3)—CH_3

and C(4)—CH_3 bonds and increased steric interaction between the C(3) and C(4) methyl groups. Therefore it is reasonable to expect that the balance of effects would result in less distortion of the enolate (**30**) of 3,4-dimethylcamphor (**8***a*,*b*) in the direction proposed for the enolate (**29**) derived from 3-methylcamphor (**2***a*,*b*). In the event, alkylation of 3,4-dimethylcamphor (**8***a*,*b*) with trideuteriomethyl iodide provided a mixture (~2:1) in which the major product (**27***a*) (Scheme 2) resulted from *endo* methylation of enolate **30**. Thus, in keeping with the prediction given above, 3,4-dimethylcamphor (**8***a*,*b*) undergoes *endo* methylation to a lesser extent than 3-methylcamphor (**2***a*,*b*). The initial assignment of structure to **27***a* and **27***b* was made by assuming that the nmr signals for the *exo* and *endo* methyl

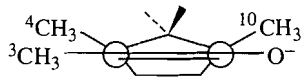
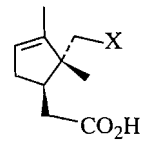
groups in **27***a* and **27***b* have the same relative relationship as those recorded for other C(3) epimeric pairs (cf. Scheme 1). These assignments were supported by nOe experiments; for example, irradiation at the C(8) methyl resonance (δ 0.76) led to enhancement of the signal at δ 1.05 (*exo*-3-methyl) and irradiation at the C(3) *endo*-methyl resonance (δ 0.97) resulted in enhancement of the signal at δ 1.69 (C(5) *endo*-hydrogen).

C(3) aldol condensation



Aldol reactions of the enolates of camphor, 5,6-dehydrocamphor, and norcamphor exhibit the same selectivities as observed in the alkylations and are general phenomena.[2] Several aldehydes were allowed to react with the camphor



28

enolate under standard aldol reaction conditions. The results are shown in Table 1. In every case, only two products were observed spectroscopically and confirmed by isolation using hplc on silica. The two products were the *exo-threo* adduct **33***a* (major) and the *endo-threo* adduct **33***b* (minor). No other

33*b*

adducts were observed under these conditions. This is consistent with the normally observed trend in which an *E*-enolate gives rise to predominantly *threo* adducts. This may indicate the occurrence of a closed (cyclic) transition state in these cases. Interestingly, when the reactions were run in THF containing 20–30% HMPA, no change in the product ratios was observed. A steric effect is noted in that the aldehydes with the two largest steric requirements (R = phenyl and *tert*-butyl) gave the highest *exo*/*endo* ratios. However, there is very little difference in *exo*/*endo* selectivity through the series where R = Me, Et, or *i*-Pr. Phenylacetaldehyde is exceptional since it shows the lowest *exo*/*endo* ratio (1.6:1) but is considerably larger than acetaldehyde or propionaldehyde. The stereochemistry of the adducts was assigned by analysis of ^1H nmr coupling constants

[2]Stereoselective aldol reactions were first observed with (+)-9-bromocamphor, cf. ref. 24.

SCHEME 3

involving the C3, C4, and carbinol hydrogens (25).[3] The identity of the cation had a negligible effect on stereoselectivity. When the camphor enolate was generated with either potassium or sodium hexamethyldisilazide at low temperature and treated with benzaldehyde, the same two adducts were formed in nearly the same ratio as was observed in the case of LDA deprotonation.

Aldol reaction of 5,6-dehydrocamphor (**15**) with PhCHO or *t*-BuCHO produces the *endo* adducts **34***a* and **34***b* (Scheme 3) in 84 and 78% yield respectively, along with <5% of *exo* adducts. In contrast, norcamphor provided only *exo* adducts **36***a* and **36***b* in 82 and 68% yield, respectively. No other aldol isomers were observed by ^{1}H nmr spectroscopy in the crude reaction products. We attempted the aldol reaction of bicyclo-[2.2.1]hept-5-en-2-one (**37**), but the reaction was complicated by a fast dimerization of **37**, providing two aldol dimers (**38**) as the major products and only a minor amount (no more than 35%) of a mixture of the two *exo* adducts (**39**) in approximately a 2:1 ratio (measured by ^{1}H nmr). This dimerization was observed previously by Minter.[4] We have shown in an unrelated project that the intermediate β-oxido ketone in aldol reactions can be deprotonated to give an aldolate dianion.[5] Since dimerization is a major factor in this system, it is likely that excess LDA will be present and can deprotonate **40** to **41**,

[3]For the use of nmr in assigning the configurations of aldol adducts, see ref. 25*a*; for the use of nmr in assigning the stereochemistry of bicyclo[2.2.1]heptanes, see ref. 25*b*.

equilibrating the α position. We are, therefore, reluctant to draw conclusions from this result.

To confirm that we were dealing with kinetically generated product mixtures, we treated the *exo-threo* adduct **33***a* (R = Ph) with 0.5 equiv. of LDA in THF at −78°C and allowed the reaction to warm to 0°C and to be held at this temperature for 3–4 h. Significant isomerization to the *endo* adduct **33***b* (R = Ph) was observed along with camphor and benzaldehyde resulting from retroaldol reaction (Scheme 3). Since *exo* → *endo* isomerization was observed under what appear to be equilibrating conditions, we conclude that the product mixtures under the standard conditions were determined kinetically. We did not, however, observe isomerization of adducts of **34***a* or **36***a* under these conditions.

In general, the stereoselectivity of C(3) alkylation and aldol condensation of bicyclo[2.2.1]heptan-2-one derivatives is associated with at least three factors, viz., (1) C(5) *endo*-hydrogen (or other substituents), which directs *exo*; (2) the C(7) *syn*-methyl group, which directs *endo*; and (3) enolate geometry in C(3) substituted compounds. The relative importance of these factors is presumably dependent on structural factors in the ketone substrate.

Experimental

Unless otherwise stated, the following are implied. Melting points (mp) were determined on a Kofler micro heating stage and are uncorrected. The capillary glc analysis was carried out on a Hewlett–Packard 5880A gas chromatograph employing a flame ionization detector and using a W.C.O.T. narrow bore (0.21 mm × 12 m) Carbowax 20 M column. Helium was used as the carrier gas. The 400 MHz ^1H nmr spectra were recorded on a Bruker WM-400 instrument. The 270 MHz ^1H nmr spectra were recorded on a 270 MHz instrument constructed from a Bruker console, a Nicolet computer model 293A with a Diablo disk, and a 270 MHz superconducting magnet supplied by Oxford Instruments. Signal positions are given in delta (δ) with tetramethylsilane (TMS) as an internal reference. Signal multiplicity and integrated areas are indicated in parentheses. The solvent used was deuteriochloroform. Infrared spectra were recorded on a Perkin–Elmer 137 spectrophotometer and optical rotations were measured using a Perkin–Elmer 141 polarimeter. Low resolution mass spectra were obtained using a Varian/MAT model CH_4B mass spectrometer and high resolution mass spectra using a Kratos MS50 instrument. Microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia, Vancouver.

*(+)-5,6-Dehydrocamphor (**15**)*

(−)-6-*endo*-Bromocamphor (18, 19) (6.5 g, 0.028 mol), potassium hydroxide (7.89 g, 0.14 mol), dimethyl sulfoxide (280 mL), and water (40 mL) were stirred together at 120°C for 2 h. The solution was diluted with water, extracted with ether (3 × 300 mL), and the combined ether extracts washed with brine (3 × 100 mL), dried over anhydrous magnesium sulfate, and the solvent evaporated to give a yellow oil (2.2 g). Purification by column chromatography (silica gel; petroleum ether (30–60°C)/ether, 9:1) afforded a volatile white solid, (+)-5,6-dehydrocamphor (**15**) (2.0 g, 47%); $[\alpha]_D$ +756 (*c* 0.50, CH_2Cl_2) (lit. (20, 21) $[\alpha]_D$ −735 (*c* 1.0, EtOH)) for the enantiomer; ν_{max}: 1735 cm^{-1}; δ ($CDCl_3$, 400 MHz) (22): 0.91 (3H, s), 1.01 (3H, s), 1.07 (3H, s), 1.93 (1H, d, *J* = 16.5 Hz), 2.2 (1H, ddd, *J* = 16.5 Hz, 3.5 Hz, and 1.0 Hz), 2.68 (1H, br s), 5.58 (1H, br d, *J* = 5.5 Hz), 6.71 (1H, dd, *J* = 5.5 Hz and 3.0 Hz); *m/e* (relative intensity): 150 (M^+, 12), 93 (58), 85 (59), 71 (92), 69 (100). Exact Mass calcd. for $C_{10}H_{14}O$: 150.1045; found: 150.1049.

The aqueous phases were combined and acidified with 1 N hydrochloric acid, extracted with ether (3 × 300 mL), and the combined ether extracts washed with brine (3 × 100 mL) and dried over anhydrous magnesium sulfate. Removal of the solvent gave (−)-α-campholenic acid (**31**) (1.88 g, 40%); $[\alpha]_D$ −8.2 (*c* 2.25, CH_2Cl_2) (lit. (22) $[\alpha]_D$ −9.0 (*c* 1.1, $CHCl_3$); ν_{max} (film): 2950, 1710 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.80 (3H, s), 1.02 (3H, s), 1.62 (3H, br s), 1.94 (1H, m), 2.20–2.35 (2H, m), 2.40–2.52 (2H, m), 5.24 (1H, br s); *m/e* (relative intensity): 168 (M^+, 28), 153 (64), 135 (28), 108 (100), 107 (82), 93 (80), 91 (42).

*(−)-3-*endo*-Methyl-5,6-dehydrocamphor (**16**a)*

(+)-5,6-Dehydrocamphor (**15**) (2.0 g, 13.3 mmol) was added to a freshly prepared solution of lithium diisopropylamide (1.87 mL, 12.9 mmol) in dry THF (25 mL) at 0°C under argon and the enolate allowed to form over 0.5 h. Methyl iodide (4.0 mL, 65 mmol) was then added and the reaction stirred for a further 0.5 h before being quenched with 1 N hydrochloric acid. The mixture was extracted with ether (3 × 50 mL) and the combined ether extracts washed with brine (3 × 25 mL) and dried over anhydrous magnesium sulfate. Removal of the solvent yielded a pale yellow oil (2.0 g). Capillary glc analysis of the crude product indicated the ratio of 3-*endo*- (**16***a*) to 3-*exo*-methyl-5,6-dehydrocamphor (**16***b*) to be approximately 12:1.

Purification by column chromatography (silica gel; petroleum ether (30–60°C)/ether, 9:1) afforded starting material (0.21 g) and a mixture of 3-*endo*- and 3-*exo*-methyl-5,6-dehydrocamphor (1.68 g, 86% yield based on recovered starting material). The ^1H nmr (400 MHz) spectrum and capillary glc analysis showed the ratio of 3-*endo*- to 3-*exo*-methyl-5,6-dehydrocamphor to be approximately 12:1.

A mixture of 3-*endo*- and 3-*exo*-methyl-5,6-dehydrocamphor (**16***a*,*b*) (50 mg) was treated with a freshly prepared solution of potassium *tert*-butoxide (1.0 mL, 1.0 M) at 50°C for 12 h. The solution was diluted with water, extracted with ether (3 × 20 mL), and the combined ether extracts washed with brine (3 × 10 mL) and dried over anhydrous magnesium sulfate. Removal of the solvent yielded a pale yellow oil (48 mg, 96%). Capillary glc and the 400 MHz ^1H nmr spectrum indicated the presence of one epimer, 3-*endo*-methyl-5,6-dehydrocamphor (**16***a*). Low temperature crystallization (CO_2/acetone) from pentane provided pure (−)-3-*endo*-methyl-5,6-dehydrocamphor (**16***a*) as a colourless oil; $[\alpha]_D$ +676.0 (*c* 1.5, CH_2Cl_2); ν_{max} ($CHCl_3$): 1740 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.93 (3H, s), 1.01 (3H, s), 1.05 (3H, d, *J* = 7.3 Hz), 1.06 (3H, s), 2.41 (1H, dd, *J* = 7.0 Hz and 3.5 Hz), 2.54 (1H, t, *J* = 3.4 Hz), 5.53 (1H, d, *J* = 5.0 Hz), 6.51 (1H, dd, *J* = 5.0 Hz and 3.4 Hz); *m/e* (relative intensity): 164 (M^+, 8.3), 121 (28), 108 (64), 105 (19), 93 (100), 77 (28). Exact Mass calcd. for $C_{11}H_{16}O$: 164.1207; found: 164.1200. Anal. calcd. for $C_{11}H_{16}O$: C 80.44, H 9.82; found: C 80.60, H 9.75.

*(−)-9-Bromo-5,6-dehydrocamphor (**17**)*

(−)-6-*endo*-9-Dibromocamphor (3, 18) (423 mg, 1.36 mmol), potassium hydroxide (382 mg, 6.8 mmol), dimethyl sulfoxide (13 mL), and water (2 mL) were stirred at 70°C for 48 h. The solution was diluted with water, extracted with ether (3 × 100 mL), and the combined ether extracts washed with brine (3 × 50 mL), dried over anhydrous magnesium sulfate, and the solvent evaporated to give a yellow oil (136 mg). Purification by column chromatography (silica gel; petroleum ether (30–60°C)/ether, 25:1) gave (−)-9-bromo-5,6-dehydro-

camphor (**17**) (68.2 mg, 22%) as a white crystalline solid, mp 46.5–48.5° (sealed tube); $[\alpha]_D$ +377 (*c* 0.5, CH_2Cl_2); ν_{max} ($CHCl_3$): 1740 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.05 (3H, s), 1.08 (3H, d, *J* = 1 Hz), 2.01 (1H, d, *J* = 17 Hz), 2.22 (1H, ddd, *J* = 17 Hz, 3.5 Hz, and 1 Hz), 3.0 (1H, br s), 3.22 (1H, br d, *J* = 6 Hz), 6.49 (1H, dd, *J* = 6 Hz and 3 Hz); *m/e* (relative intensity): 230/228 (M^+, 2/2), 188/186 (19/19), 107 (100), 91 (29), 79 (21). Exact Mass calcd. for $C_{10}H_{13}OBr$: 230.0129/228.0150; found: 230.0135/228.0149. Anal. calcd. for $C_{10}H_{13}OBr$: C 52.42, H 4.72, Br 34.87; found: C 52.40, H 5.60, Br 34.77.

The aqueous phases were combined, acidified with 1 N hydrochloric acid, extracted with ether (3 × 100 mL), and the combined ether extracts washed with brine (3 × 50 mL). Removal of the dried solvent afforded a crude solid (130 mg), which was purified by column chromatography (silica gel: petroleum ether (30–60°C)/ether/acetic acid, 150:50:1) to give hydroxy-α-campholenic acid (**32**) as a white crystalline solid, mp 102–103.5°C; $[\alpha]_D$ −19.52 (*c* 0.21, CH_2Cl_2); ν_{max} ($CHCl_3$): 3000 (br), 1705 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.82 (3H, s), 1.65 (3H, br s), 1.97 (1H, m), 2.34 (1H, dd, *J* = 16 Hz and 9 Hz), 2.64 (1H, dd, *J* = 16 Hz and 5.5 Hz), 2.70 (1H, m), 3.42 (1H, d, *J* = 11 Hz), 3.54 (1H, d, *J* = 11 Hz), 5.41 (1H, br s); *m/e* (relative intensity): 184 (M^+, 0.01), 166 (17), 151 (32), 107 (59), 94 (100), 93 (80), 91 (63), 79 (95). Exact Mass calcd. for $C_{10}H_{16}O_3$: 184.1100; found: 184.1102. Anal. calcd. for $C_{10}H_{16}O_3$: C 65.19, H 8.75; found: C 65.01, H 8.70.

*(−)-9-Bromo-3-*endo*-methyl-5,6-dehydrocamphor (**18***a*)*

(−)-9-Bromo-5,6-dehydrocamphor (**17**) (380 mg, 1.66 mmol) was added to a freshly prepared solution of lithium diisopropylamide (1.58 mmol) in dry THF (5 mL) at 0°C under argon and the enolate allowed to form over 0.5 h. Methyl iodide (0.44 mL, 6.9 mmol) was then added and the reaction stirred for a further 0.5 h before being quenched with 1 N hydrochloric acid. The mixture was extracted with ether (3 × 50 mL) and the combined ether extracts washed with brine (3 × 25 mL) and dried over anhydrous magnesium sulfate. Removal of the solvent yielded a yellow oil (370 mg).

Purification by column chromatography (silica gel; petroleum ether (30–60°C)/ether, 8:1) afforded starting material (50 mg) and (−)-9-bromo-3-methyl-5,6-dehydrocamphor (290 mg, 82%) as a mixture of epimers. The 400 MHz ^1H nmr spectrum of this mixture indicated the ratio of 3-*endo*- to 3-*exo*-methyl epimers (**18***a* and **18***b*) to be ~14:1.

The mixture of (−)-9-bromo-3-*endo*- and (−)-9-bromo-3-*exo*-methyl-5,6-dehydrocamphor (30 mg) was treated with freshly prepared potassium *tert*-butoxide in *tert*-butanol (1.0 mL, 1.0 M) at 50°C for 12 h. The solution was diluted with water, extracted with ether (3 × 25 mL), and the combined ether extracts washed with brine (2 × 10 mL) and dried over anhydrous magnesium sulfate. Removal of the solvent afforded a pale yellow oil (28 mg). The 400 MHz ^1H nmr spectrum of the crude product indicated the presence of one epimer, (−)-9-bromo-3-*endo*-methyl-5,6-dehydrocamphor (**18***a*).

Low temperature crystallization (CO_2/acetone) from pentane provided pure (−)-9-bromo-3-*endo*-methyl-5,6-dehydrocamphor (**18***a*) as a white crystalline solid, mp 44–45°C; $[\alpha]_D$ +337 (*c* 1.23, CH_2Cl_2); ν_{max} ($CHCl_3$): 2980, 1740 cm^{-1}; δ ($CDCl_3$, 400 MHz): 1.04 (3H, s), 1.07 (3H, d, *J* = 7 Hz), 1.08 (3H, d, *J* = 2 Hz), 2.39 (1H, dq, *J* = 7 Hz and 3.5 Hz), 2.95 (1H, br s), 3.21 (1H, d, *J* = 10 Hz), 4.03 (1H, d, *J* = 10 Hz), 5.61 (1H, d, 6 Hz), 6.43 (1H, dd, *J* = 6 Hz and 3.2 Hz); *m/e* (relative intensity): 244/242 (M^+, 1.0/1.0), 188/186 (16/17), 135 (6.9), 121 (4.6), 107 (100), 91 (23), 79 (14). Exact Mass calcd. for $C_{11}H_{15}OBr$: 244.0286/242.0306; found: 244.0298/242.0308. Anal. calcd. for $C_{11}H_{17}OBr$: C 54.34, H 6.22, Br 32.86; found: C 54.54, H 6.28, Br 33.00.

*Alkylation of (−)-4-methylcamphor (**7**)*[6]

(−)-4-Methylcamphor (**7**) (23)[7] (4.32 g, 26.0 mmol) in dry THF (20 mL) was added to a freshly prepared solution of LDA in THF (30 mL) (derived from *n*-butyllithium (15.6 mL, 1.6 M in hexane) and diisopropylamine (3.5 mL, 25 mmol)) at 0°C under argon. After 30 min, methyl iodide (6.5 mL, 105 mmol) was added and the reaction mixture stirred for a further 30 min before being quenched with 1 M HCl solution. The reaction mixture was extracted with ether (3×) and the ether extracts were combined and washed with water (3×) and dried over anhydrous magnesium sulfate. Removal of the solvent yielded a light yellow solid (4.86 g). Capillary glc analysis (OV-101, 80°C) of the crude product indicated the ratio of *exo*- to *endo*-3,4-dimethylcamphor (**8***a* and **8***b*) was ~2:1.

Purification of the crude mixture by column chromatography (silica gel 230–400 mesh, elution with petroleum ether/ether, 98:2) afforded the starting material (**7**) (0.94 g) and a mixture of **8***a* and **8***b* (3.15 g, ~67%; 78% yield based on recovered starting material); ^1H nmr (400 MHz) and capillary glc analysis showed the ratio of **8***a* to **8***b* to be 2.0–2.5:1.

A sample of pure *exo*-3,4-dimethylcamphor (**8***a*) was obtained by chromatographing the above mixture using the same conditions. This provided **8***a* as a white crystalline solid, mp 140–141°C (sealed tube); ν_{max} ($CHCl_3$): 1720 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.70 (3H, s, C(9) methyl), 0.81 (3H, s, C(8) methyl), 0.92 (3H, s, C(10) methyl), 1.00 (3H, s, C(4) methyl), 1.08 (3H, d, *J* = 8 Hz, C(3) methyl), 1.33–1.49 (2H, m, C(5) and C(6) *endo* protons), 1.59 (1H, ddd, *J* = 12 Hz, 12 Hz, and 4 Hz, C(6) *exo* proton), 1.80 (1H, ddd, *J* = 12 Hz, 12 Hz, and 5 Hz, C(5) *exo* proton), 1.92 (1H, q, *J* = 7.5 Hz, C(8) proton); *m/e* (relative intensity): 180 (M^+, 10.3), 152 (4.3), 137 (26.6), 109 (26.9), 96 (31.7), 83 (100.0), 55 (56.4), 41 (78.8). Exact Mass calcd. for $C_{12}H_{20}O$: 180.1514; found: 180.1513. Anal. calcd. for $C_{12}H_{20}O$: C 79.94, H 11.18; found: C 79.68, H 11.21.

*endo-3,4-Dimethylcamphor (**8**b)*

A mixture of *exo*- and *endo*-3,4-dimethylcamphor (**8***a*,*b*) (0.25 g, 1.40 mmol) in glacial acetic acid/concentrated hydrochloric acid (2.0 mL, 9:1) was heated at 80°C for 6 h. The solution was cooled, diluted with water, extracted with ether (3×), and the ether extracts washed with saturated sodium bicarbonate solution (3×) and water (3×), and dried over anhydrous magnesium sulfate. Removal of the solvent yielded a white crystalline product (0.25 g, 100% yield); 400 MHz ^1H nmr and capillary glc analysis showed the ratio of *exo*- (**8***a*) to *endo*-3,4-dimethylcamphor (**8***b*) to be 1:19. Column chromatography (silica gel 230–400 mesh, elution with petroleum ether/ether, 99:1) yielded fractions containing pure **8***b* (monitored by capillary glc), which were combined and solvent evaporated to provide **8***b* as a white crystalline solid, mp 106–108°C (sealed tube); ν_{max} ($CHCl_3$): 1720 cm^{-1}; δ ($CDCl_3$, 400 MHz): 0.73 (3H, s, C(9) methyl), 0.88 (3H, s, C(8) methyl), 0.92 (3H, s, C(10) methyl), 0.97 (3H, s, C(4) methyl), 1.10 (3H, d, *J* = 8 Hz, C(3) methyl), 1.24 (1H, m, C(5) *endo* proton), 1.47 (1H, m, C(6) *endo* proton), 1.54–1.63 (2H, m, C(6) *exo* and C(5) *exo* protons), 2.08 (1H, dq, *J* = 7.5 Hz and 2 Hz, C(3) proton); *m/e* (relative intensity): 180 (M^+, 13.1), 152 (5.9), 137 (34.0), 109 (68.0), 96 (44.0), 83 (100.0), 55 (54.6), 41 (71.0). Exact Mass calcd. for $C_{12}H_{20}O$: 180.1514; found: 180.1520. Anal. calcd. for $C_{12}H_{20}O$: C 79.94, H 11.18; found: C 79.73, H 11.20.

*Methylation of 3,4-dimethylcamphor (**8**a,b)*

To a solution of lithium diisopropylamide in dry THF (prepared from diisopropylamine (0.31 mL, 2.2 mmol) and *n*-butyl lithium (1.5 M in THF, 1.5 mL) in dry THF (5 mL) at 0°C for 15 min) was added 3,4-dimethylcamphor (**8***a*,*b*) (0.4 g, 2.2 mmol) in dry THF (5 mL) and the mixture was stirred at 0°C for 20 min. Trideuteriomethyl iodide (0.56 mL, 8.8 mmol) (purified by passing through basic alumina) was added to this solution and after 30 min the reaction mixture was acidified with HCl (1 N). Extraction with ether and work-up in the usual way provided crude 3-trideuteriomethyl-3,4-dimethylcamphor (**26***a*,*b*) as a mixture of epimers. Column chromatography (SiO_2; elution with petroleum ether:ether, 98:2) provided the epimeric mixture **26***a*,*b* as a white crystalline solid; δ ($CDCl_3$, 400 MHz): 0.76 (3H, s, $C(8)H_3$), 0.88 (3H, s, $C(9)H_3$), 0.90 (3H, s, $C(10)H_3$), 0.93 (3H, s, $C(11)H_3$), 0.97 (1H, s, *endo*-3-methyl), 1.05 (2H, s, *exo*-3-methyl). The *exo*:*endo* ratio was ~2:1.

[6]The optical purity of (−)-4-methylcamphor was ~80% (cf. ref. 23*b*).

General procedure for the aldol reaction of camphor, norcamphor, and 5,6-dehydrocamphor with aldehydes

Lithium diisopropylamide (LDA) was prepared by reaction of diisopropylamine (1.00 mL, 7.0 mmol) with *n*-butyllithium (2.50 mL of a 2.5 M solution in hexane, 6.25 mmol) in 4 mL of dry THF at −78°C. The solution was stirred for 15 min and then a solution of camphor (0.91 g, 6.0 mmol) in dry THF (4 mL) was added dropwise (15 min). After the addition, the solution was stirred for 1.5 h (in the case of **15** and **37**, 2.5 h), treated with freshly distilled aldehyde (6.0 mmol), and stirred for an additional 15 min. The reaction was quenched at −78°C with a saturated aqueous solution of $NaHCO_3$ (50 mL). The cold bath was then removed and the mixture extracted with ether (3 × 50 mL). The combined organic layers were washed with saturated NaCl, dried over Na_2SO_4, and concentrated *in vacuo* to afford the adduct mixture.

Acetylation of an exo/endo *aldol adduct mixture*

A solution of triethylamine (13.9 mL, 100 mmol), acetic anhydride (4.7 mL, 50 mmol), and DMAP (0.122 g, 1.0 mmol) was cooled to −5°C. To this was added dropwise a solution (10 mL) of the *exo*:*endo* adduct mixture in CH_2Cl_2 (15 mL). The mixture was allowed to stir for 15 min and cold water (40 mL) was added. The aqueous layer was extracted with Et_2O (3 × 20 mL). The combined organic layers were washed with 5% HCl (2 × 20 mL), saturated aqueous $NaHCO_3$ (2 × 20 mL), water (3 × 30 mL), saturated aqueous NaCl, and then dried over anhydrous Na_2SO_4. Removal of the solvent *in vacuo* afforded a mixture of the *exo*:*endo* acetates.

General procedure for the isomerization of aldol adducts

Lithium diisopropylamide (LDA) was prepared by reaction of diisopropylamine (0.168 mL, 1.2 mmol) with *n*-butyllithium (0.419 mL of a 2.5 M solution in hexane, 1.05 mmol) in 4 mL of dry THF at −78°C. The solution was stirred for 15 min and a solution of a camphor aldol adduct (2.0 mmol in 4 mL of dry THF) was added. After the addition, the cold bath was removed and the solution was stirred for 3–4 h at room temperature. The reaction was then quenched with a saturated aqueous solution of $NaHCO_3$ (10 mL). The mixture was extracted with ether (3 × 10 mL) and the combined organic layers were washed with saturated aqueous NaCl, dried over Na_2SO_4, and concentrated *in vacuo* to afford the adduct mixture.

The isomeric aldol adducts or the derived acetates in all cases were separated cleanly by semi-preparative hplc on silica using hexane/ethyl acetate mixtures that varied from 90:10 to 65:35 depending on the mixture.

exo-threo *Adduct of camphor with pivalaldehyde (**33**a, R = t-Bu)*: ir (neat): 3487, 2956, 1720, 1478, 1393, 1362, 1104, 1084, 1055, 1015 cm^{-1}; ^1H nmr (300 MHz, $CDCl_3$), δ: 3.85 (t, *J* = 13.7 Hz, 1H), 3.36 (t, *J* = 6.5 Hz, 1H), 1.96 (m, 2H), 1.81 (d, *J* = 6 Hz, 1H), 1.66 (m, 1H), 1.48 (m, 1H), 1.36 (m, 1H), 0.94 (s, 3H), 0.92 (s, 3H), 0.89 (s, 3H), 0.87 (s, 9H); ^{13}C nmr (300 MHz, $CDCl_3$), δ: 223.6, 81.1, 57.4, 53.9, 49.6, 47.4, 26.6, 29.9, 27.9, 25.3, 20.2, 20.1, 9.0; ms *m/e* calcd. for $C_{15}H_{26}O_2$ + H: 239.2010; found: 239.2007.

Application of ^{59}Co NMR to the investigation of interactions between cobalt sepulchrate and various counterions

JOÃO SOTOMAYOR, HELENA SANTOS, AND FERNANDO PINA[1]

Faculdade de Ciências e Tecnologia, Universidade Nova de Lisboa, Quinta da Torre, 2825 Monte de Caparica, Portugal and Centro de Tecnologia Química e Biológica, Apartado 127, 2780 Oeiras, Portugal

Received July 6, 1990

JOÃO SOTOMAYOR, HELENA SANTOS, and FERNANDO PINA. Can. J. Chem. **69**, 567 (1991).

Association constants for the ion pairs formed between $[Co(Sep)]^{3+}$ and the anions fluoride, chloride, bromide, iodide, perchlorate, and oxalate were obtained from the chemical shifts of the ^{59}Co resonance that occur upon addition of such anions to solutions of the cobalt complex. The usefulness of ^{59}Co NMR to obtain formation constants, in order to calculate the "true" quantum yields for the ion pairs, is discussed.

Key words: association constant, cobalt sepulchrate, ion pair, ^{59}Co NMR, quantum yield.

JOÃO SOTOMAYOR, HELENA SANTOS et FERNANDO PINA. Can. J. Chem. **69**, 567 (1991).

Faisant appel aux déplacements chimiques observés dans les spectres RMN du ^{59}Co lors de l'addition de tels anions à des solutions du complexe de cobalt, on a déterminé les constantes d'association des paires d'ions qui se forment entre le $[Co(Sep)]^{3+}$ et les anions fluorure, chlorure, bromure, iodure, perchlorate et oxalate. On discute de l'utilité de la RMN du ^{59}Co pour la détermination des constantes de formation nécessaires pour calculer les «vrais» rendements quantiques des paires d'ions.

Mots clés : constante d'association, sépulchrate de cobalt, paire d'ions, RMN du ^{59}Co, rendement quantique.

[Traduit par la rédaction]

Introduction

Solutions of Co(III) complexes (for instance $Co(NH_3)_6^{3+}$ and $Co(en)_3^{3+}$ (en = ethylenodiamine)) and several reductive anions, such as I^-, exhibit deviations from additivity of their electronic absorption spectra due to the appearance of a new band, which has been ascribed to an ion pair charge transfer (IPCT) from the anion to the metal (1). We have reported a similar behaviour for the $Co(Sep)^{3+}$ complex (Sep = sepulchrate = 1,3,6,8,10,13,16,19-octaazabicyclo[6.6.6]eicosane) and the anions I^- (2), oxalate (3), and citrate (4). Irradiation in this "new band" causes the formation of photoproducts, a result that has been interpreted as due to the thermal evolution of the primary species, $Co(Sep)^{2+}$, and the oxidized anion, and that supports the previous identification of the IPCT band. It was also shown that the association constants for this kind of ion pair are not very high and, therefore, the assumption that all the complex is involved in the ion pair is not valid. As a consequence, to calculate the quantum yields for the irradiation in the IPCT band, based on the light absorbed by the ion pair, the so called "true" quantum yield, it is essential to evaluate their association constants.

Two important factors must be taken into account, regardless of the physical method that is selected to obtain the association constants of the ion pairs: (i) the influence of the "innocent" anions (i.e., anions that in principle do not cause any effect on the physical variable that is measured) that are used to keep the ionic strength constant; (ii) the presence of higher order ion pairs, such as $[Co(Sep)^{3+}(X^-)_2]^-$ and $[Co(Sep)^{3+}(X^-)_3]$ (X = anion).

Previously we used a spectrophotometric technique to determine the association constants of ion pairs (5). However, the results do not provide definite information about either the effect of the innocent anion or the formation of higher order ion pairs.

Laszlo and co-workers (6) have shown that ^{59}Co NMR is a sensitive probe for investigating ion pairing. In the present article, ion association is monitored by ^{59}Co NMR and the dependence of the ^{59}Co chemical shift upon addition of the counterion is investigated.

Experimental

$Co(Sep)Cl_3 \cdot H_2O$ was synthesized following the method of Sargeson and co-workers (7) as modified by Indelli.[2] All chemicals used in this preparation and in subsequent operations were of reagent grade.

NMR spectra were recorded using a Bruker CXP-300 spectrometer operating at 71.2 MHz for ^{59}Co. The spectral width was 20 000 Hz and 8192 points were used for data acquisition. The probe temperature was kept at 298 K using the standard VT unit of the Bruker spectrometer and at least 15 min were allowed for thermal equilibration of each sample. The spectra were run without spinning the NMR tube. A coaxial capillary containing D_2O was inserted into the 10 mm NMR tube, to provide a lock signal.

Aqueous solutions of several electrolytes (KF, KCl, KBr, KI, $NaClO_4$, $K_2C_2O_4$) with different concentrations and 5 mM cobalt sepulchrate were prepared. Spectra were recorded and shifts of the cobalt resonance were measured, relative to the $Co(Sep)^{3+}$ chloride salt solution spectrum.

All the electrolytes had potassium as the counterion, except perchlorate, for solubility reasons.

Results and discussion

Although addition of perchlorate, used to maintain a constant ionic strength, does not change the electronic absorption spectra of cobalt amino complexes, being regarded as the innocent anion, it gives rise to a chemical shift of the ^{59}Co NMR absorption band. For this reason all the experiments were performed at uncontrolled ionic strength.

Figure 1 shows the observed chemical shift of the ^{59}Co resonance of aqueous solutions containing 5×10^{-3} M $Co(Sep)^{3+}$ in the presence of the anions F^-, Cl^-, Br^-, I^-, ClO_4^-, and $C_2O_4^{2-}$. Sodium salts of the added anions show the same chemical shifts in the ^{59}Co resonance as the potassium analogues.

The simplest model to account for the observed resonance shift on the cobalt(III) complex, M, upon addition of anion, A,

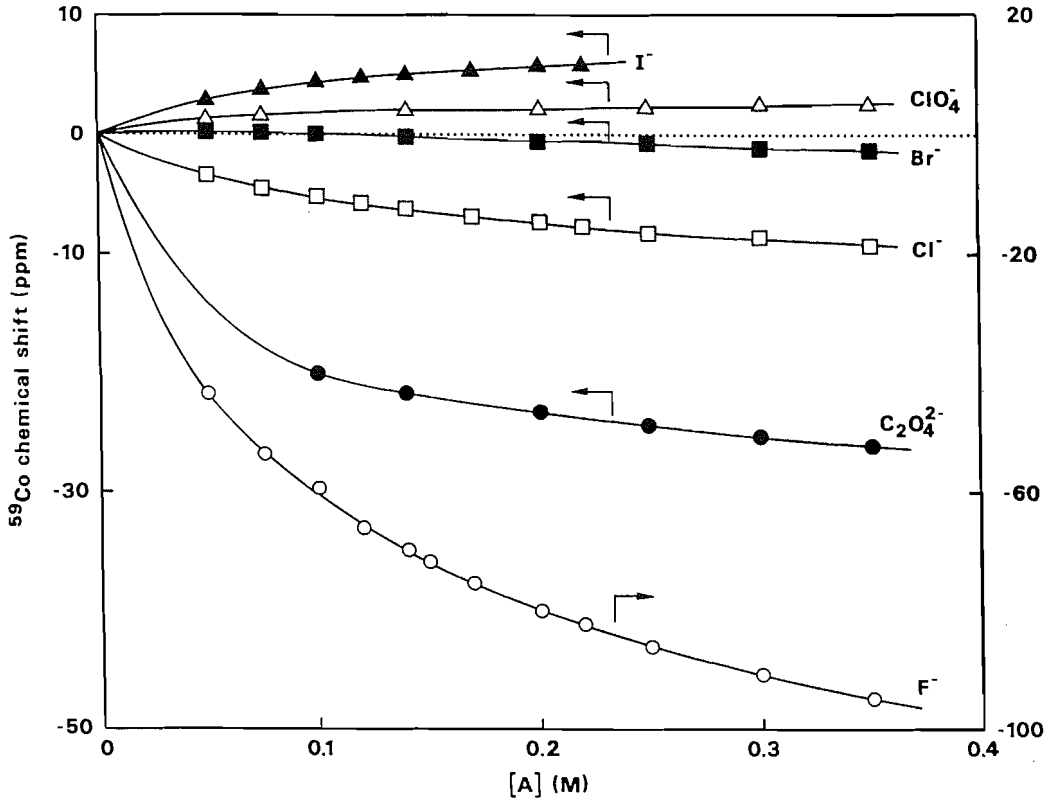

FIG. 1. ^{59}Co chemical shift of aqueous solutions containing 5×10^{-3} M $Co(Sep)^{3+}$ and various anions.

TABLE 1. Thermodynamic association constants calculated from ^{59}Co chemical shifts for the $Co(Sep)^{3+}$ ion paired with various anions, assuming 1:1 equilibrium

Anion	K_1^0	Δw_1(ppm)
F^-	35 ± 1	−123 ± 1
Cl^-	23 ± 1	−13.4 ± 0.2
Br^-	—	−0.5[a]
I^-	31 ± 1	9.1 ± 0.2
ClO_4^-	41 ± 2	3.10 ± 0.05
$C_2O_4^{2-}$	277 ± 68	−26.5 ± 0.2

[a]Innocent anion. Estimated value.

is demonstrated by considering equilibrium [1] and eq. [2]

[1] $M + A \rightleftharpoons MA$

$$[2] \quad K_1^0 = \frac{[MA]}{[M][A]} \frac{f_{MA}}{f_M f_A} = K_1 f_1$$

in which K_1^0 is the thermodynamic formation constant at infinite dilution, and f_i are the activity factors, calculated by the Davies type expression, valid up to 1 M (8).

$$[3] \quad \log f_i = -AZ_i^2\left(\frac{\sqrt{I}}{1 + Ba\sqrt{I}} - CI\right)$$

where $C = 0.3$ and the other parameters have the usual meaning.

Working on a large excess of A, eq. [4] is obtained:

$$[4] \quad W_{obs} - W_{obs(0)} = \frac{\Delta w_1 K_1^0 [A]_0}{f_1 + K_1^0 [A]_0}$$

where W_{obs} is the ^{59}Co NMR frequency upon addition of the anion $[A]_0$, to an initial concentration of metal complex $[M]_0$, $W_{obs(0)}$ is the resonance of the free complex, and $\Delta w_2 = w_1 - w_0$ is the difference between the adduct and the complex frequencies, respectively. This equation is formally equivalent to the one obtained for the spectrophotometric method, with the difference that the ^{59}Co NMR frequencies replace the molar absorptivities at the wavelength used. For this reason the known Benesi–Hildebrand approach (9) developed for the spectrophotometric method, slightly modified to account for the ionic strength changes, can also be used.

$$[5] \quad \frac{[A]_0}{W_{obs} - W_{obs(0)}} \times \frac{1}{f_1} = \frac{1}{K_1^0 \Delta w_1} + \frac{1}{\Delta w_1} \frac{[A]_0}{f_1}$$

A plot of $\dfrac{[A]_0}{W_{obs} - W_{obs(0)}} \times \dfrac{1}{f_1}$ versus $\dfrac{[A]_0}{f_1}$ will give a linear relation from which it is possible to obtain the thermodynamic formation constant, and the frequency of the resonance of the adduct. The results are summarized in Table 1. The values of the a parameter are 6 Å for the $Co(Sep)^{3+}$ and $[Co(Sep)^{3+}.X^{n-}]^{(3-n)+}$ ion pairs by comparing with similar cases (10), 3 Å for F^-, Cl^-, Br^-, and I^- (10*b*), 3.5 Å for ClO_4^-, and 4.5 Å for oxalate ion (10*a*). The errors presented for $(K_1^0, \Delta w_1)$ and $(K_1^0, \Delta \varepsilon_1)$ were obtained from the construction of the joint confidence region, for the plots of eq. [5] (11, 12).

If we consider a more complex model, adding one or two more equilibria in order to account for higher order adducts, a generalized Benesi–Hildebrand equation is obtained (5), eq. [8]:

[6] $MA + A \overset{K_2}{\rightleftharpoons} MA_2$

[7] $MA_2 + A \overset{K_3}{\rightleftharpoons} MA_3$

TABLE 2. Thermodynamic association constants by NMR and spectrophotometric methods, assuming 1:1 equilibrium

	Method			
	Spectrophotometric		NMR	
Anion	K_1^0	$\Delta\varepsilon_1^{max}$ (M^{-1} cm^{-1})	K_1^0	Δw_1 (ppm)
F^-	[a]	[a]	35 ± 1	−123 ± 1
Cl^-	21 ± 5	1054 ± 46	23 ± 1	−13.4 ± 0.2
Br^-	23 ± 1	1393 ± 7	[b]	[b]
I^-	22 ± 1	829 ± 28	31 ± 1	9.1 ± 0.2
ClO_4^-	[b]	[b]	41 ± 2	3.10 ± 0.05
$C_2O_4^{2-}$	597 ± 112	1005 ± 93	277 ± 68	−26.5 ± 0.2

[a]Not measurable.
[b]Innocent anion.

$$[8] \quad \frac{[A]_0}{W_{obs} - W_{obs(0)}} \times \frac{1}{f_1} = \frac{1}{K_1^0 \beta_1} + \frac{\beta_2}{\beta_1} \frac{[A]_0}{f_1}$$

where

$$[9] \quad \beta_1 = \Delta w_1 + \frac{K_2^0}{f_2} \Delta w_2 [A]_0 + \frac{K_2^0}{f_2} \frac{K_3^0}{f_3} \Delta w_3 [A]_0^2$$

$$[10] \quad \beta_2 = 1 + \frac{K_2^0}{f_2} [A]_0 + \frac{K_2^0}{f_2} \frac{K_3^0}{f_3} [A]_0^2$$

and $\Delta w_2 = w_2 - w_0$ and $\Delta w_3 = w_3 - w_0$ where w_2 and w_3 are the frequencies of the resonance of MA_2 and MA_3 adducts, respectively.

The ^{59}Co NMR chemical shifts reported in Fig. 1 become more markedly high field as the hydrogen bond ability of the various anions increases. This ability depends on the electronegativity of the anion placed near the cobalt ion, which will increase the shielding on the ^{59}Co nucleus. In fact, we observed a high field chemical shift in the order $F^- > Cl^- > Br^- > I^-$.

Similar results were described by Masuda *et al.* (13) for $Co(en)_3^{3+}$ and different anions, and were attributed in part to the deformation of the coordination sphere of the Co(III) ion.

As all NMR spectra are referred to the $Co(Sep)^{3+}$ chloride salt solution spectrum, what we define as the zero chemical shift includes the small interaction between the cobalt ion and the Cl^- (negligible because of the small concentration of the chloride) and the shielding of the water molecules in the solvation sphere. Therefore, Fig. 1 shows the competition for hydrogen bonding between the water molecules and the various anions. In the case of Br^-, this anion has an effect equivalent to the water and we observe almost zero chemical shift.

Fitting of eq. [8] for the simultaneous 1:1 and 1:2 equilibria gives a large uncertainty for the second constant, which indicates that the ^{59}Co NMR does not give any experimental evidence for the formation of higher order adducts.

The fact that equilibrium [1] gives good results in the NMR chemical shift method does not indicate that this equilibrium is the only one present in solution. The method is not sensitive enough to reveal the small deviations in the linearity of eq. [5] that would result from higher order ionic interactions.

Different values of the association constant for a given ion pair are usually obtained by independent physical methods, such as NMR and UV/VIS absorption (Table 2). For instance, ClO_4^- is either an innocent or an active anion depending on the method used to probe its behaviour.

The UV/VIS absorption technique is based on the observation of the IPCT, which results from the combination of the molecular orbitals (HOMO–LUMO) of the anion and the metal complex. This interaction is clearly at the shorter distance range, when compared with ^{59}Co NMR, where several longer distance interactions are expected to affect the chemical shift (6, 14).

In conclusion, the application of physical methods other than UV/VIS absorption, to calculate the association constants required for evaluation of the fraction of the light absorbed by the ion pair, is not useful. In fact, the ion pair is "defined" by the detection method, since different physical methods measure different association constants.

The synthesis of nor- and bisnorlupanes[1,2]

AMAL WAHHAB,[3] MARGARET OTTOSEN, AND FRANK W. BACHELOR
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received July 6, 1990

AMAL WAHHAB, MARGARET OTTOSEN, and FRANK W. BACHELOR. Can. J. Chem. **69**, 570 (1991).

In the course of our studies on geochemical biomarkers we required a series of lupane standards. We report here an efficient synthesis of lupane (**1**) in three steps from betulin (**3**) in an overall yield of 47.2%. 17β(H)-28-Norlupane (**2**) was obtained in 90% purity employing Barton's method for the decarboxylation of 3-oxolupan-28-oic acid (**10**). 24,28-Bisnorlupane (**4**) and 24-norlupane (**5**) were obtained by a series of reactions involving formation of the oxime, the seconitrile, the epoxynitrile, ring closure, and finally a Wolff–Kishner reduction of the C3 carbonyl to the methylene. Also, to aid in the quantitative determination of these lupanes from oil shales and geological samples, 3-deuterolupane (**6**) and 2,3-dideuterolupane (**7**) were needed, and a method for their preparation is reported.

Key words: lupane, 24-norlupane, 28-norlupane, 24,28-bisnorlupane, 3-deuterolupane, 2,3-dideuterolupane.

AMAL WAHHAB, MARGARET OTTOSEN et FRANK W. BACHELOR. Can. J. Chem. **69**, 570 (1991).

Dans le cadre de nos études sur les biomarqueurs géochimiques, on a eu besoin d'une série de lupanes de référence. On rapporte ici une synthèse efficace du lupane (**1**) en trois étapes, à partir de la bétuline (**3**) et avec un rendement global de 47,2%. On a obtenu le 17β(H)-28-norlupane (**2**) à un état de pureté de 90% en appliquant la méthode de Barton à la décarboxylation de l'acide 3-oxolupan-28-oïque (**10**). On a obtenu les 24,28-bisnor- (**4**) et 24-nor- (**5**) lupanes par une série de réactions impliquant la formation de l'oxime, du séconitrile et de l'époxynitrile, une fermeture de cycle et finalement une réduction de Wolff–Kishner du carbonyle en C3 en un méthylène. De plus, afin d'aider à la détermination quantitative de ces lupanes dans les huiles de schistes et d'échantillons géologiques, on a aussi développé une méthode de préparation des 3-deutéro- (**6**) et 2,3-dideutéro- (**7**) lupanes.

Mots clés : lupane, 24-norlupane, 28-norlupane, 24,28-bisnorlupane, 3-deutérolupane, 2,3-dideutérolupane.

[Traduit par la rédaction]

Introduction

Pentacyclic triterpanes of the hopane series are known to be present as ubiquitous biological markers in nearly all sediments and crude oils (1–3). However, since the report of the identification of two isomeric C28-triterpanes of the lupane series in Tertiary sediments from West Greenland and the Gulf of Suez (4), interest in the lupanes has been growing. More recently, some isomeric C28-lupanes were found in the offshore Beaufort–MacKenzie Delta oils (5). Furthermore, a C29-triterpane, tentatively identified as 24-norlupane, was the almost exclusive constituent of the saturated cyclic hydrocarbons in Tertiary coal from the Beaufort–MacKenzie Delta.[4] This prompted a need for authentic samples of 28-nor-, 24-nor-, and 24,28-bisnorlupanes to compare with materials found in oil shales and other geological samples.

Lehn and Ourisson (7) have prepared lupane (**1**) starting from lupeol, by catalytic hydrogenation, oxidation with CrO_3, and finally Wolff–Kishner reduction in unreported yields. Rullkötter *et al.* (4) prepared 28-norlupane (**2**) starting from betulin (**3**) by acetylation followed by catalytic hydrogenation, saponification to dihydrobetulin, oxidation with *N*-bromosuccinimide, and Wolff–Kishner reduction to yield lupan-28-ol, which after photo-oxidation resulted in a mixture of 28-norlupenes. Column chromatographic separation and catalytic hydrogenation yielded a mixture of 17(αH) and 17(βH)-28-norlupanes.

To our knowledge, the syntheses of 24,28-bisnorlupane (**4**), 24-norlupane (**5**), 3-deuterolupane (**6**), and 2,3-dideuterolupane (**7**) have not been reported, but reports of either the isolation or identification of **4** and **5** in oil samples have been published (2–4).[5]

Betulin (**3**), commercially available, was the most logical choice for a starting material to prepare our target molecules. Schemes 1–4 depict our strategy for preparing compounds **1**, **2**, **4**, and **5**, and Schemes 5 and 6 outline that of compounds **6** and **7**.

Results and discussion

As outlined in Scheme 1, lupane **1** was prepared in three steps in an overall yield of 47.2% from **3**. Catalytic hydrogenation of **3** over 10% Pd/C in ethyl acetate gave dihydrobetulin **8** in 96% yield, mp 275–277°C (lit. (7) mp 278–280°C). Pyridinium chlorochromate oxidation of **8** in CH_2Cl_2 furnished the keto aldehyde **9** in 87.8% yield, mp 190–195°C (lit. (8) mp 196–198°C). The ^{13}C nmr of **9** showed the keto carbon at 217.7 ppm and the aldehydic carbon at 206.9 ppm. The Huang–Minlon modified Wolff–Kishner reduction (9) of **9** gave lupane in 56% yield, mp 186.5–188°C (lit. (7) mp 184–188°C). The ^1H and ^{13}C nmr spectra of **1** agreed well with reported data (10). The mass spectrum of **1** shows a molecular ion peak at m/z 412 and a base peak at m/z 191, which is a prominent and most characteristic fragment ion of lupanes and other triterpanes (11, 12).

An approach different from that of Rullkötter *et al.* (4) was taken to prepare 28-norlupane (**2**). Scheme 2 shows our strategy. Starting from **9**, a number of different oxidation procedures were tried, to oxidize the keto aldehyde **9** to the keto acid **10**. No reaction was observed with silver oxide (13) or calcium hypochlorite (14) and only moderate yields of **10** (46%) were obtained by prolonged reaction with CrO_3/pyridine (15).

[5]According to the numbering in lupane, see ref. 6, the methyl group removed is C24, hence it should be named 24,28-bisnorlupane instead of 23,28-bisnorlupane, as named by Rullkötter *et al.* (4).

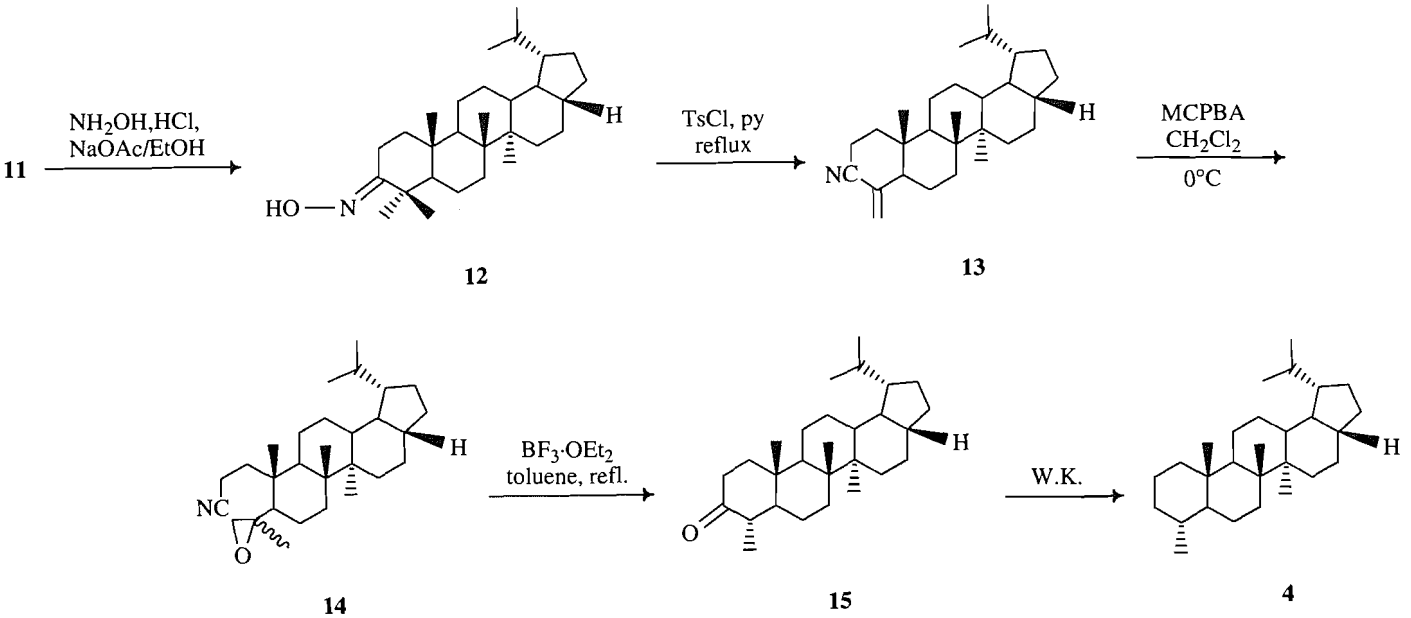
SCHEME 1

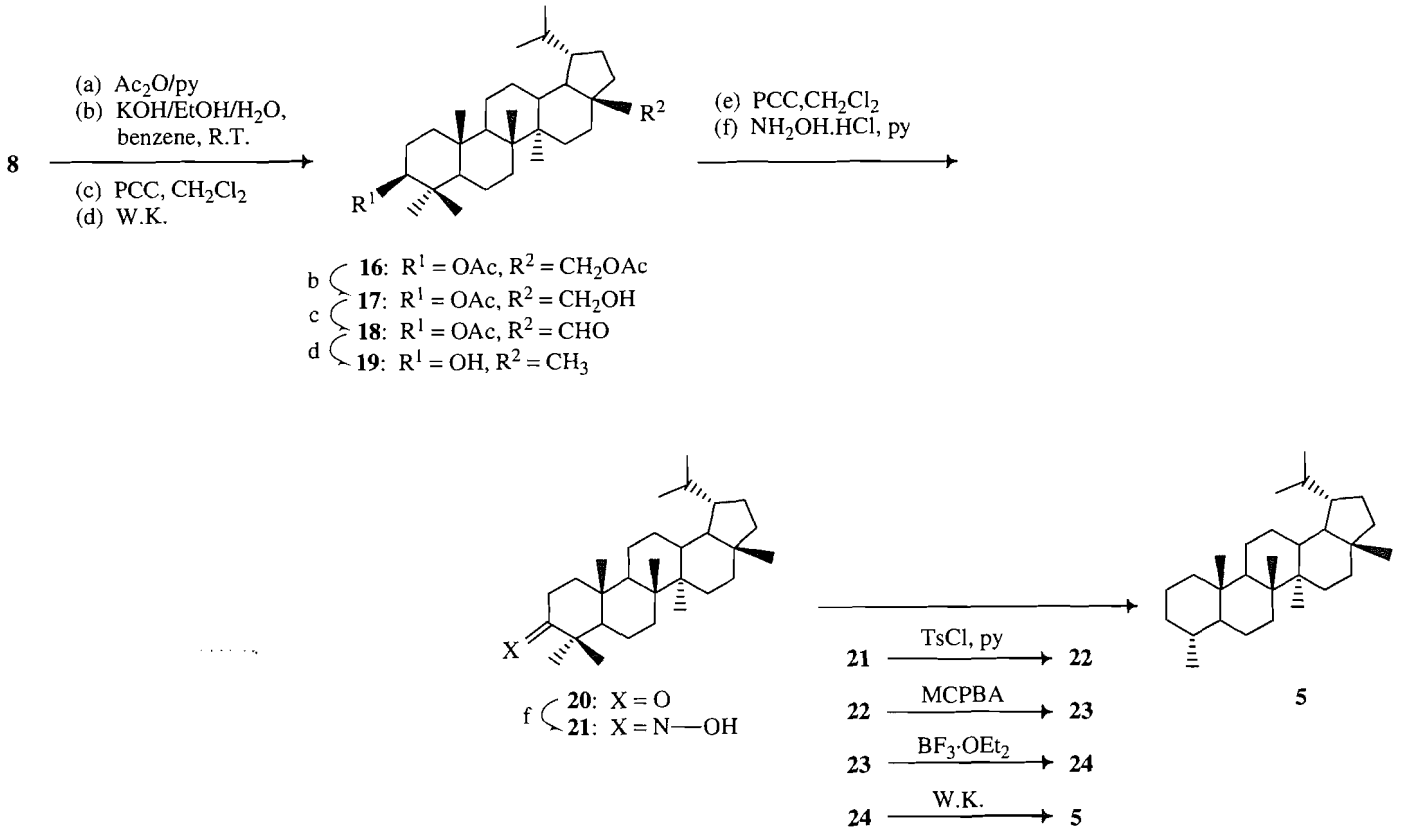
9 **10** **11** **2**

SCHEME 2



The most satisfactory results were obtained by refluxing **9** with $KMnO_4$ in acetone (16) for 1 h, giving crude **10** in 90% yield, mp 251–254°C (lit. (7) mp 258–260°C). The ^{13}C nmr spectrum of **10** showed the carboxylic acid carbon, C28, at 182.6 ppm, while betulinic acid shows the C28 signal at 178.9 ppm. Also, the C17 carbon appeared at 57.0 ppm while that in betulinic acid is reported at 56.3 ppm (17).

The critical step in the sequence to prepare **2** is the decarboxylation of **10**. The method of Crich *et al.* (18) was chosen, which involved the reaction of the acid chloride of **10** with *N*-hydroxypyridine-2-thione sodium salt in the presence of DMAP and *tert*-butyl mercaptan in benzene under reflux. 3-Oxo-28-norlupane (**11**) was obtained in 52% yield, but it was contaminated with $\Delta^{17,22}$-3-oxo-28-norlupene (10%), which was removed by chromatography on silica gel impregnated with 10% $AgNO_3$. The ir of **11** showed the carbonyl stretch at 1701 cm^{-1} and in the ^{13}C nmr spectrum C3 appeared at 218.37 ppm. The mass spectrum of **11** depicted the normal fragmentation of 3-oxolupanes, showing the molecular ion peak at m/z 412 and the base peak at m/z 205.



The final step in the synthesis of **2** was the Wolff–Kishner reduction of **11**. Applying the Huang–Minlon modification, **2** was obtained in 36.9% yield as a 9:1 mixture of two isomers, the major being the 17β(H) isomer and the minor the 17α(H) isomer, by comparison of their mass spectra from gc/ms with the results of Rullkötter *et al.* (4).

The second-order Beckmann rearrangement of the 3-oximino derivatives of 3-oxolupanes leading to unsaturated seconitriles was the key step in the preparation of 24,28-bisnorlupane (**4**) and 24-norlupane (**5**), as illustrated in Schemes 3 and 4. The reaction of 3-oxo-28-norlupane (**11**) with hydroxylamine hydrochloride according to the method of Valterová *et al.* (19) gave 3-oximino-28-norlupane (**12**) in 87% yield. Similarly, 3-oximinolupane (**21**) was prepared in 91% yield following the procedure of Klinot *et al.* (20). The Beckmann rearrangement of oximes **12** and **21** was carried out using *p*-toluenesulfonyl

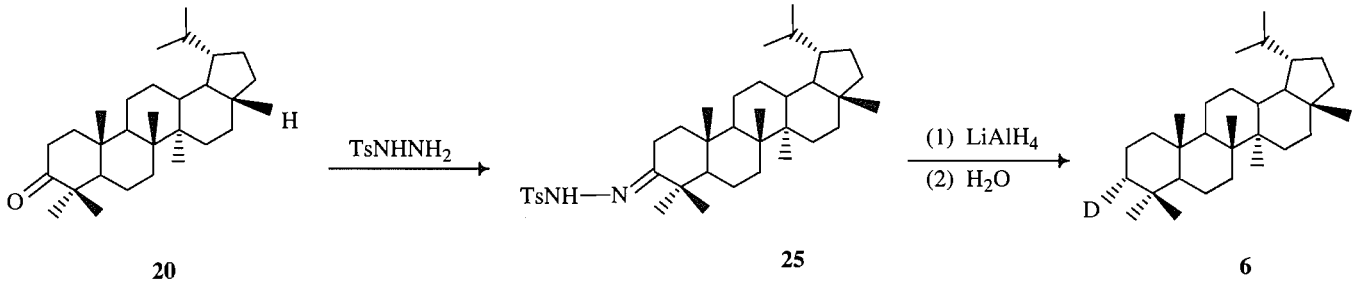
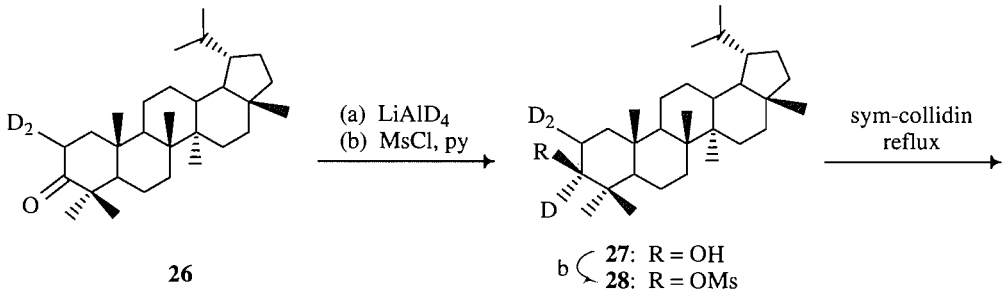
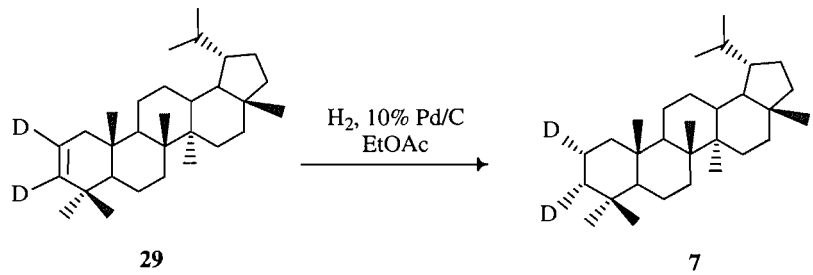


SCHEME 3



SCHEME 4



chloride in boiling pyridine as described by Klinot *et al.* (20). The pure seconitriles **13** and **22** were obtained in 67 and 57.9% yields respectively, after chromatography on basic alumina. In the infrared spectra, the nitrile stretch appeared at 2249 and 2242 cm^{-1}, and in the ^{13}C nmr spectra, the nitrile carbon appeared at 120.3 and 120.1 ppm (for **13** and **22** respectively). The vinyl methyl group in the ^1H nmr spectrum of **22** appeared at 1.74 ppm as a doublet (J = 0.5 Hz) showing long-range coupling with one of the terminal olefinic protons. Treatment of epoxynitrile **14** with $BF_3 \cdot Et_2O$ in dry toluene gave 24,28-bisnorlupan-3-one (**15**) in 63% yield. The carbonyl stretch of C3 appeared at 1708 cm^{-1}. Compound **15** was a mixture of isomers at C28, and hence the ^1H nmr spectrum was too complex to locate the methyl group at C4. Epoxynitrile **23**, when exposed to the same conditions as **14**, gave 24-norlupan-3-one (**24**) in 45.7% yield. From the ^1H nmr spectrum of **24**, the

SCHEME 5

SCHEME 6

compound appears to be a single epimer with the methyl group at C4 appearing as a doublet (J = 6.6 Hz) at 0.99 ppm. Pinhey and Cohen (21) reported that second-order Beckmann rearrangement of 3-hydroxyimino-4,4-dimethyl steroids followed by epoxidation to the epoxynitrile and cyclization with $BF_3 \cdot Et_2O$ yielded the 4α(CH_3)-3-ketones, which were not a mixture of C4 epimers. According to this, one would expect ketones **15** and **24** to be only the 4α(CH_3) epimers. The Wolff–Kishner reduction of **15** furnished 24,28-bisnorlupane (**4**) as a white waxy solid after chromatography on silica impregnated with 10% $AgNO_3$. The gc analysis of this compound showed it to be a mixture of three isomers. Attempts to separate these isomers by column chromatography failed. The major component (86.6%) was identified as 17β(H),4α(CH_3)-24,28-bisnorlupane by comparison of its mass spectrum with that reported by Rullkötter *et al.* (4). The second major component is thought to be the 17β(H),4β(CH_3) isomer, and the component of least abundance showed a more intense fragment in its mass spectrum at m/z 341 than that displayed by the 17β(H),4α(CH_3) isomer, and is comparable with the mass spectral data reported by Rullkötter *et al.* (4) for 17α(H),4α(CH_3)-24,28-bisnorlupane. Similarly, the Wolff–Kishner reduction of ketone **24** gave 24-norlupane (**5**) in 51.7% yield as a mixture of two epimers at C4. The major (86.4%) is thought to be the more stable 4α(CH_3) epimer, and the minor, the 4β(CH_3) epimer. In both **4** and **5**, epimerization at C4 is believed to have occurred under the Wolff–Kishner reduction conditions.

The monodeuterated lupane **6** was prepared in two steps starting from 3-oxolupane (**20**) as illustrated in Scheme 5. The reaction of **20** with tosylhydrazine and acetyl chloride in methanol gave 3-oxolupane tosylhydrazone (**25**) in 45% yield after chromatography. Reduction of **25** with excess $LiAlD_4$ in dry dioxane, and chromatography of the resulting product on silica impregnated with 10% $AgNO_3$, gave 3-deuterolupane (**6**), mp 188–189°C. The molecular ion peak in the mass spectrum of **6** appeared at m/z 413 and the base peak at mass 192, derived from the A/B rings, since the deuterium atom is in the A ring. The peak at m/z 191 is attributed to the D/E rings.

The preparation of 2,3-dideuterolupane (**7**), Scheme 6, proved to be more troublesome than anticipated. Most standard methods tried for the dideuteration of 3-oxolupane gave a mixture of both mono- and dideuteration products. However, dideuteration, 95%, was achieved by refluxing **20** with potassium carbonate in D_2O for 52 h, giving 2,2-dideutero-3-oxolupane (**26**) in 28.6% yield, contaminated with 5% of the monodeutero product. Reduction of **26** with $LiAlD_4$ followed by mesylation gave the 2,2,3-trideutero mesylate (**28**) in almost 60% yield from **26**. Elimination of mesylate **28** with *sym*-collidine at reflux gave crude 2,3-dideutero-2-lupene (**29**) in almost quantitative yield. The hydrogenation of crude **29** in ethyl acetate over 10% Pd/C was slow and required a large amount of catalyst. 2,3-Dideuterolupane (**7**) was obtained in 76.6% yield as a white waxy solid after 2 days of hydrogena-

For personal use only.

tion. The mass spectrum of **7** showed a molecular ion peak at m/z 414 and a base peak at mass 193, derived from the A/B rings. The peak at mass 191 had the same intensity as that in the monodeuterolupane **6**, confirming its origin in the D/E rings.

Experimental

General

Infrared spectra were recorded on a Nicolet DX FT-IR spectrophotometer connected to a 5DX processor and a 7470A Hewlett Packard plotter. The spectra of solid samples were run as KBr discs, while those of liquids and semisolids were run as thin films on KBr plates. Mass spectra of pure solid samples were obtained on a Kratos MS80 (RFA) mass spectrometer at 70 eV. Gas chromatography/mass spectra were run on a VG 70-SQ mass spectrometer controlled by a 112505 data system at 70 eV. The gas chromatograph used was an HP model 5890 fitted with a J and W Scientific 30-m DB-5 capillary column. Elemental analyses were carried out on a Perkin Elmer 240b elemental analyser. Melting points are uncorrected and were taken on an Electrothermal melting point apparatus. The ^{1}H and ^{13}C nmr spectra were recorded either on a Varian XL200 spectrometer or a Bruker AC200 student model connected to an MP3200 Graphtec XY plotter, using $CDCl_3$ as both the solvent and the internal standard. Chemical shifts are listed in ppm.

Silica gel 230–400 or 60–200 mesh and basic alumina (activity II–III E. Merck aluminum oxide/90) were used for column chromatography. For the separation of unsaturated compounds, $AgNO_3$ (10–15%) impregnated alumina or silica was used. Merck DC Alufolien Kieselgel 60 F_{254} tlc plates were used, and visualization of the developed plates was achieved by dampening the plate, placing it in a tank containing SO_2Cl_2, and then drying it in an oven at 100°C.

*Hydrogenation of betulin **3** to dihydrobetulin **8***

Betulin (310 mg) in ethyl acetate (200 mL) was hydrogenated in a Parr hydrogenator over 10% Pd/C (200 mg) under 2 atm (1 atm = 101.3 kPa) of hydrogen for 2 h. After filtration of the catalyst and evaporation of the solvent, **8** was obtained in 96% yield, mp 275–277°C (lit. (7) mp 278–280°C); ^{1}H nmr ($CDCl_3$) δ: 3.79 (d, J = 10 Hz, 1H, C28-H), 3.31 (d, J = 11 Hz, 1H, C28-H), 3.21 (dd, J = 5.5 and 10 Hz, 1H, C3-H), 1.03 (s), 0.98 (s), 0.97 (s), 0.85 (d, J = 6.6 Hz), 0.84 (s), 0.77 (d, J = 6.7 Hz), 0.774 (s); ^{13}C nmr δ: 79.0 (C3), 60.6 (C28).

*3-Oxo-28-lupanal **9***

Dihydrobetulin **8** (1.0 g, 2.25 mmol) in CH_2Cl_2 (100 mL) was oxidized with PCC (1.45 g, 6.75 mmol) according to procedures in refs. 18 and 19. The keto aldehyde **9** was obtained in 87.8% yield, mp 190–195°C (lit. (8) mp 196–198°C); ^{13}C nmr δ: 217.7 (C3), 206.9 (C28), 59.9 (C17); ms m/z (%): 440 (14, M^+), 412 (8), 411 (18), 205 (50), 177 (36), 135 (45), 109 (57), 95 (68), 81 (85), 55 (100).

*Wolff–Kishner reduction of **9** to lupane*

Following the procedure of Matlin *et al.* (9), a mixture of crude **9** (400 mg, 0.9 mmol), dry diethylene glycol (40 mL), 85% hydrazine hydrate (0.72 mL), and KOH (0.98 g) was heated for 1 h under nitrogen at 100°. The temperature was raised to 200–210°C and maintained for 4 h. After cooling, the mixture was diluted with water and extracted with ether. The ether extracts were washed with water, 5% $NaHCO_3$, and water, then dried over anhydrous $MgSO_4$ and filtered. Removal of the solvent and chromatography over basic alumina, eluting with 9:5 hexane/ether, furnished lupane in 56% yield, mp 186.5–188°C (lit. (7) mp 184–185°C). Both ^{1}H and ^{13}C nmr spectra agreed well with the reported data (10).

*Oxidation of **9** to keto acid **10***

The keto aldehyde **9** (500 mg, 1.1 mmol) and $KMnO_4$ (1.33 g, 8.4 mmol) in acetone (70 mL) were refluxed for 1 h (16). The mixture was cooled, acidified with dilute H_2SO_4, and 5% $NaHSO_3$ was added until the brown color disappeared. The aqueous mixture was extracted with $CHCl_3$, washed with 5% $NaHCO_3$ and water, dried over anhydrous $MgSO_4$, filtered, and the solvent removed *in vacuo*. The crude product (89.5% yield) was chromatographed on silica, eluting with 95:5 $CHCl_3$/MeOH, to give **10** as fine white needles, mp 251–254°C (lit. (7) mp 258–260°C); ir ν_{max}: 1701, 1687 cm^{-1}; ^{1}H nmr δ: 1.08 (s), 1.03 (s), 0.97 (s), 0.94 (s), 0.87 (d, J = 6.8 Hz), 0.77 (d, J = 6.6 Hz); ^{13}C nmr δ: 218.1 (C3), 182.6 (C28), 57.0 (C17).

*Decarboxylation of **10***

A mixture of keto acid **10** (1.4 g, 0.31 mmol), oxalyl chloride (1.5 mL, 17.6 mmol), and DMF (3 drops) in benzene was stirred at room temperature for 2 h under nitrogen according to the procedure of Crich *et al.* (18). The crude acid chloride was obtained by evaporation of the solvent and was used in the decarboxylation step without purification. *N*-Hydroxypyridine-2-thione sodium salt (554 mg, 3.7 mmol), DMAP (36.6 mg, 0.3 mmol), and *tert*-butyl mercaptan (1.5 mL, 13.3 mmol) in dry benzene (30 mL) were refluxed under nitrogen for 5 min, then the acid chloride in dry benzene (15 mL) was added dropwise over 20 min to the refluxing solution. After 6 h reflux, the mixture was cooled and transferred to a separatory funnel, washed with water and with saturated NaCl solution, then dried over anhydrous $MgSO_4$, filtered, and the solvent removed *in vacuo*. The residue was chromatographed on silica, eluting with 9:5 hexane/ether, to give a semisolid that could be made to precipitate by adding cold methanol. 3-Oxo-28-norlupane **11** was obtained in 52% yield by rechromatography over silica gel impregnated with 10% $AgNO_3$ to remove the by-product, 3-oxonorlupene; ir ν_{max}: 1701 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 2.48 (m, C2-H), 1.09 (s), 1.04 (s), 0.99 (s), 0.94 (s), 0.91 (s), 0.84 (d, J = 6.6 Hz), 0.82 (d, J = 6.6 Hz); ^{13}C nmr δ: 218.4 (C3); ms m/z (%): 412 (75, M^+), 369 (53), 206 (32), 205 (100), 177 (62), 135 (75), 81 (78).

*28-Norlupane **2***

The Wolff–Kishner reduction of **11** (170 mg, 0.4 mmol) with KOH (237 mg), diethylene glycol (20 mL), and 85% hydrazine hydrate (0.18 mL) was carried out as described for **9**. Chromatography of the crude product on basic alumina, eluting with 9:5 hexane/ether, gave 58.7 mg (36.9%) of a white waxy solid melting at 157–159°C. The gc–ms analysis showed the product to be composed of 2 isomers in a 9:1 ratio; ir (film) ν_{max}: 2952, 2868, 1455, 1384, 1082, 970 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 0.96 (s), 0.91 (s), 0.85 (s), 0.83 (s), 0.82 (s), 0.80 (s); ms m/z (%): major isomer 17β(H), 90%: 398 (35, M^+), 383 (16), 355 (11), 260 (10), 217 (11), 192 (36), 191 (100), 177 (27), 109 (30), 95 (40); minor isomer 17α(H), 10%: 398 (44, M^+), 383 (10), 355 (12), 260 (25), 191 (100), 177 (43), 123 (45), 81 (60).

*3-Oximino-28-norlupane **12***

The method of Valterová *et al.* (19) was used to react **11** (800 mg, 1.9 mmol) with hydroxylamine·HCl (800 mg, 11.5 mmol) and pyridine (24 mL). After diluting with water, the mixture was extracted with chloroform and the organic layer was washed with 3 N HCl, 5% $NaHCO_3$, and water, and then dried over anhydrous $MgSO_4$, filtered, and the solvent removed under reduced pressure. Oxime **12** (720 mg, 87%) was used for the next step without further purification; ir ν_{max}: 3255, 2945, 2868, 1462, 1384, 1258, 1019, 927 cm^{-1}.

*3,4-Seconitrile **13***

The reaction of oxime **12** (690 mg, 1.6 mmol) with *p*-toluenesulfonyl chloride (2.30 g, 10 mmol) in pyridine (23 mL) for 6 h under nitrogen according to the procedure of Klinot *et al.* (20) gave **13** (435 mg, 67%) as a pale yellow solid after chromatography on basic alumina, eluting with benzene; ir ν_{max}: 2945, 2849, 2249, 1455, 1384, 1152, 1177, 808 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 4.89 (m, 1H, =CH), 4.65 (m, 1H, =CH), 2.3 (m, 2H, -CH_2CN), 1.73 (d, J = 0.8 Hz, =CCH_3), 1.00 (s), 0.90 (s), 0.86 (s), 0.826 (s), 0.82 (d, J = 6.3 Hz); ^{13}C nmr δ: 147.1 (C4), 120.3 (CN), 114.0 (C24); ms m/z (%): 427 (2, M^+), 409 (14), 366 (17), 177 (31), 135 (62), 95 (71), 81 (93).

*Epoxynitrile **14***

To a solution of seconitrile **13** (470 mg, 1.1 mmol) in $CHCl_3$ at 0°C was added a precooled solution of *m*-chloroperbenzoic acid (376 mg, 2.2 mmol) in $CHCl_3$ (10 mL) according to the procedure of Valterová *et al.* (22). The reaction mixture was kept at 0°C in the dark for 67 h,

then washed with 5% KI, 5% $NaHSO_3$, 5% $NaHCO_3$, and water. The organic layer was dried over anhydrous $MgSO_4$, filtered, and the solvent removed under vacuum to yield epoxynitrile **14** (353 mg, 73% yield). An analytical sample was obtained by chromatography on basic alumina, eluting with 9:5 hexane/ether, mp 170–172°C; ir ν_{max}: 2952, 2249 (CN), 1455, 1384, 1265, 1152, 1089, 1019, 801, 519 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 2.73 (d, J = 4.4 Hz, 1H, C-CH_2-O), 2.63 (d, J = 4.4 Hz, 1H, C-CH_2-O), 2.2 (m, -CH_2CN), 1.28 (s, 3H, O-C-Me), 0.98 (s), 0.96 (s), 0.85 (s), 0.82 (s), 0.81 (d, J = 6.3 Hz); ^{13}C nmr δ: 119.8 (CN). Anal. calcd. for $C_{29}H_{47}NO$: C 81.82, H 11.13, N 3.29%; found: 82.02, H 11.28, N 3.30%.

3-Oxo-24,28-bisnorlupane ***15***

Epoxynitrile **14** (184 mg, 0.4 mmol) was refluxed with BF_3-etherate (0.4 mL) in toluene (50 mL) for 6 h under nitrogen according to the procedure of Valterová *et al.* (22). The reaction mixture was cooled and diluted with ether, and the ether layer was separated and washed with 3 N HCl, 5% $NaHCO_3$, and water, then dried over anhydrous $MgSO_4$, filtered, and the solvents removed under vacuum. The residue was chromatographed on basic alumina, eluting with 9:5 hexane/ether, to give **15** (108 mg, 63% yield), mp 160–164°C; ir ν_{max} (film): 2938, 2868, 1708, 1455, 1384 cm^{-1}; ^{13}C nmr δ: 213.5 (C3); ms m/z (%): 398 (75, M^+), 355 (63), 306 (8), 263 (7), 192 (100), 191 (95), 135 (77), 109 (56), 95 (63), 81 (81). Exact Mass calcd. for $C_{28}H_{46}O$: 398.35508; found: 398.3586.

24,28-Bisnorlupane ***4***

3-Oxo-24,28-bisnorlupane **15** (400 mg, 1.0 mmol) was reacted with KOH (490 mg) and 85% hydrazine hydrate (0.36 mL) in diethylene glycol (40 mL) as described for **9**. Chromatography of the crude product on silica impregnated with 10% $AgNO_3$, eluting successively with hexane, 9:1 hexane/ether, and 9:2 hexane/ether, gave a white waxy solid melting at 104–111°C (82 mg), which was a mixture of isomers, as shown by gc–ms. Attempts to separate this mixture by chromatography on Kiesel gel silica – 5% $CaSO_4$, eluting with cyclohexane and with 9:1 cyclohexane/ether, were not successful; ir ν_{max} (film): 2938, 2868, 1448, 1384, 1216, 759 cm^{-1}. The ^1H nmr spectrum was too complex and not well resolved. Mass spectra of isomers are listed in order of their elution from gc, m/z (%): isomer 1, most likely 17β(H),4β(CH_3), 1.9%: 384 (27, M^+), 369 (21), 341 (17), 217 (8), 192 (22), 177 (100), 135 (32), 109 (33), 95 (42), 81 (40); isomer 2, possibly 17β(H),4α(CH_3), 86.6%: 384 (28, M^+), 369 (17), 341 (7), 192 (24), 177 (100), 149 (22), 135 (36), 109 (47), 95 (38), 81 (62); isomer 3, most likely 4α(CH_3),17α(H), 11.5%: 384 (30, M^+), 369 (13), 341 (5), 217 (7), 177 (100), 149 (13), 135 (12), 109 (23), 95 (28), 81 (26).

3,28-Diacetoxylupane ***16***

Dihydrobetulin **8** (1.14 g, 2.6 mmol) was heated with acetic anhydride (23 mL) and freshly distilled pyridine (57 mL) on a steam bath for 2 h, then stirred at ambient temperature overnight (23). The mixture was diluted with water and extracted with ether, and the organic layer was washed with 3 N HCl, 5% $NaHCO_3$, and water, dried over $MgSO_4$, filtered, and the solvent removed under vacuum. Recrystallization from CH_2Cl_2/MeOH or chromatography on basic alumina, eluting with 9:5 hexane/ether, gave **16** (1.1 g, 82%), mp 256–257°C (lit. (7) mp 256–259°C); ^1H nmr ($CDCl_3$) δ: 4.48 (dd, J = 5.8, 9.4 Hz, 1H, C3-H), 4.25 (d, J = 11.2 Hz, 1H, C28-H), 3.82 (d, J = 10.5 Hz, C28-H), 2.07 (s, 3H, CH_3CO), 2.05 (s, 3H, CH_3CO), 1.04 (s), 0.95 (s), 0.86 (s), 0.855 (s), 0.847 (s), 0.83 (s); 0.77 (d, J = 6.6 Hz, C20-Me_2); ^{13}C nmr δ: 171.6 (C=O), 171.0 (C=O), 80.9 (C3), 62.8 (C28), 21.6 (CH_3 on C28 acetate), 21.4 (CH_3 on C3 acetate).

3β-Acetoxy-28-lupanol ***17***

Partial hydrolysis of **16** (1.4 g, 2.6 mmol) with KOH (145 mg) in MeOH (10 mL) and benzene (26 mL) at room temperature was carried out according to the reported procedure of Protiva *et al.* (24). The progress of the reaction was followed by tlc. The mixture was diluted with ether and the organic layer was separated and washed with water, dried over anhydrous $MgSO_4$, filtered, and the solvent removed under vacuum. Chromatography of the residue on basic alumina, eluting with 9:3 hexane/ether, gave **17** (580 mg, 70%), mp 250.5–253.5°C. A small amount of dihydrobetulin **8** and **16** (37 mg) was also recovered; ir ν_{max}: 3445, 1736, 1226, 1026 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.43 (m, 1H, C3-H), 4.08 (d, J = 7.1 Hz, 1H, C28-H), 3.72 (d, J = 10.9 Hz, 1H, C28-H), 2.05 (s, 3H, CH_3CO), 0.99 (s), 0.91 (s), 0.82 (s), 0.81 (s), 0.80 (s), 0.75 (s), 0.73 (d, J = 6.6 Hz); ^{13}C nmr δ: 171.1 (C=O), 81.0 (C3). Anal. calcd. for $C_{32}H_{54}O_3$: C 78.96, H 11.18; found: C 79.59, H 11.34%.

3β-Acetoxy-28-lupanal ***18***

Oxidation of monoacetate **17** (590 mg, 1.2 mmol) with PCC (376 mg, 1.8 mmol) in CH_2Cl_2 (40 mL) followed by chromatography on basic alumina, eluting with 9:3 hexane/ether, gave **18** (586 mg, 90%), mp 209–212°C; ir ν_{max}: 1736, 1708 cm^{-1}; ^1H nmr ($CDCl_3$) δ: 9.65 (s, 1H, CHO), 4.48 (m, 1H, C3-H), 2.06 (s, 3H, CH_3CO), 0.95 (s), 0.91 (s), 0.90 (s), 0.89 (s), 0.85 (s), 0.84 (s), 0.81 (s), 0.77 (s); ^{13}C nmr ($CDCl_3$) δ: 206.3 (C28), 170.1 (acetate carbonyl), 80.1 (C3).

Wolff–Kishner reduction of ***18***

The reaction of **18** (700 mg, 1.4 mmol) with KOH (860 mg) and 85% hydrazine hydrate (0.64 mL) in diethylene glycol (60 mL), as described for **9**, gave 3β-hydroxylupane **19** in 82% yield (503 mg) after chromatography on basic alumina, eluting with 9:5 hexane/ether, mp 207–208°C (lit. (25) mp 203–204°C).

3-Oxolupane ***20***

Oxidation of **19** (400 mg, 0.93 mmol) with PCC (300 mg, 1.4 mmol), as described for **8**, gave **20** in 88% yield (347 mg) after chromatography on basic alumina, eluting with 9:5 hexane/ether, mp 203.5–205.5°C (lit. (7) mp 209.5–210°C).

3-Oximinolupane ***21***

A mixture of 3-oxolupane **20** (210 mg, 0.49 mmol) and hydroxylamine hydrochloride (223 mg, 3.2 mmol) in pyridine (6.7 mL) was stirred at 100°C for 1 h, then at room temperature for 17 h according to the procedure of Klinot and co-workers (22). The reaction mixture was diluted with water and the precipitate was collected, washed with water, and air-dried overnight to give **21** in 91% yield (198 mg); ir ν_{max}: 3259 (HO-N), 1457, 1385, 945, 933 cm^{-1}.

Rearrangement of oxime ***21*** *to 3,4-seconitrile* ***22***

Oxime **21** (198 mg, 0.45 mmol) was reacted with tosyl chloride (0.66 g, 3.5 mmol) in pyridine (6.6 mL) as described for **12**. After chromatography on basic alumina, eluting with benzene, seconitrile **22** was obtained in 57.9% yield (110 mg); ir ν_{max}: 3072 (=CH_2), 2242 (CN), 1638 (C=C) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 4.89 (bs, 1H, =CH), 4.66 (bs, 1H, =CH), 1.74 (d, J = 0.5 Hz, 3H, =C-CH_3), 1.10 (s), 0.96 (s), 0.87 (s), 0.86 (d, J = 6.7 Hz), 0.78 (s), 0.785 (d, J = 6.5 Hz); ^{13}C nmr δ: 147.0 (=C), 120.1 (CN), 113.9 (=CH_2). Exact Mass calcd. for $C_{30}H_{49}N$: 423.3865; found: 423.3863.

Epoxynitrile ***23***

The reaction of seconitrile **22** (110 mg, 0.26 mmol) in $CHCl_3$ (3 mL) with *m*-chloroperbenzoic acid (90 mg, 0.52 mmol) in $CHCl_3$ (3 mL) at 0°C was carried out as described for **13**. Chromatography of the crude product on basic alumina, eluting with 9:5 hexane/ether, gave epoxynitrile **23** in 61.3% yield (70 mg); IR ν_{max}: 2249 (CN) cm^{-1}; ^1H nmr δ: 2.71 (d, J = 4.4 Hz, 1H, epoxy proton), 2.62 (d, J = 4.1 Hz, 1H, epoxy proton), 2.18 (m, 2H, -CH_2CN), 1.26 (s, O-C-Me), 1.06 (s), 0.94 (s), 0.88 (s), 0.83 (d, J = 6.8 Hz), 0.75 (d, J = 6.7 Hz), 0.74 (s); ^{13}C nmr δ: 119.7 (CN), 57.9 (epoxy carbon), 55.4 (quaternary epoxy carbon).

3-Oxo-24-norlupane ***24***

The reaction of epoxynitrile **23** (70 mg, 0.16 mmol) in dry toluene (22 mL) with $BF_3 \cdot Et_2O$ (0.1 mL) for 3.5 h as described for **14** gave **24** in 45.7% yield (30 mg) after chromatography on basic alumina, eluting with 9:5 hexane/ether; ir ν_{max}: 1710 (C3=O) cm^{-1}; ^1H nmr ($CDCl_3$) δ: 1.1 (s), 1.04 (d, J = 0.6 Hz), 0.99 (d, J = 6.6 Hz, CO-CH-CH_3), 0.92 (d, J = 0.6 Hz), 0.84 (d, J = 6.8 Hz, CH-CH_3), 0.77 (s), 0.76 (d, J = 6.7 Hz, CH-CH_3); ^{13}C nmr δ: 213.7 (C3).

3-Oxolupane tosylhydrazone ***25***

A mixture of 3-oxolupane **20** (100 mg, 0.28 mmol), tosylhydrazine (29) (120 mg, 0.6 mmol), and acetyl chloride (1 mL) in methanol (5 mL) was refluxed for 20 min, then water was added while the mixture was hot according to procedures in refs. 27 and 28. The mixture was cooled and the resulting precipitate filtered and vacuum-dried. Chromatography on basic alumina, eluting with 9:5 hexane/ether, gave **25** in 45% yield (50 mg), mp 169–171°C; ir ν_{max}: 3213, 1602 cm^{-1}; ^{1}H nmr ($CDCl_3$) δ: 7.84 (d, J = 8.2 Hz), 7.30 (d, J = 8.2 Hz), 2.42 (s, Me-C_6H_4), 1.08 (s), 1.03 (s), 0.94 (s), 0.89 (s), 0.86 (s), 0.82 (s), 0.78 (s), 0.77 (s), 0.75 (s).

3-Deuterolupane ***6***

A mixture of tosylhydrazone **25** (215 mg) and $LiAlD_4$ (227 mg) in freshly distilled dioxane (10 mL) was refluxed under nitrogen for 4 h (27, 30). After cooling the reaction mixture, excess $LiAlD_4$ was destroyed by careful addition of water and the product was extracted with ether. The ether extracts were washed with 5% $NaHCO_3$, water, dried over anhydrous $MgSO_4$, filtered, and the solvent removed *in vacuo*. Chromatography of the crude product on silica followed by recrystallization from MeOH and rechromatography on silica impregnated with 10% $AgNO_3$, eluting with 9:2 hexane/ether, gave 12 mg of 3-deuterolupane (**6**), mp 188–189°C; ms m/z (%): 413 (29, M^+), 398 (11), 370 (11), 259 (11), 231 (12), 205 (8), 193 (27), 192 (100), 191 (26), 177 (11), 123 (37), 95 (46), 81 (42), 69 (44), 55 (32).

Deuteration of 3-oxolupane ***20***

A mixture of 3-oxolupane **20** (611 mg, 0.4 mmol) and K_2CO_3 (6.25 mg) in D_2O (0.94 mL) was refluxed for 52 h according to the method of Fuhrer *et al.* (31). The mixture was saturated with NaCl and then extracted with ether, and the ether extracts were dried over anhydrous $MgSO_4$, filtered, and the solvent removed under vacuum to give 2,2-dideutero-3-oxolupane **26** in 28.6% yield (175 mg). The gc–ms analysis showed the material to be 95% dideutero and 5% monodeutero compound. Mass spectrum m/z (%): 428 (17, M^+), 427 (1.7), 385 (17), 207 (65), 163 (52), 123 (81), 95 (88), 69 (100).

Reduction of deuterated 3-oxolupane ***26***

The reduction of deuterated **26** (175 mg, 0.4 mmol) with $LiAlD_4$ as described for the reduction of **25** (32) gave 3-hydroxy-2,2,3-trideuterolupane (**27**) in 60.8% yield.

Preparation of 3-mesyloxy-2,2,3-trideuterolupane ***28***

Methanesulfonyl chloride (0.4 mL) was added to a solution of **27** (107 mg, 0.25 mmol) in pyridine (15 mL) at 0°C (32). After 3 h at 0°C, water was added and the mixture was extracted with ether. The ether extracts were washed with 3 N HCl, 5% $NaHCO_3$, and water, then dried over anhydrous $MgSO_4$, filtered, and the solvent removed under vacuum to give the crude mesylate **28** (164 mg); ^{1}H nmr ($CDCl_3$) δ: 3.02 (s, Me-SO_3), 1.03 (d, J = 4.4 Hz), 0.92 (s), 0.88 (s), 0.86 (s), 0.83 (s), 0.78 (s), 0.76 (s).

Elimination of mesylate ***28***

A mixture of crude **28** (164 mg, 0.3 mmol) in sym-collidine (1 mL) was refluxed for 5–6 h, then it was cooled, diluted with 3 N HCl, and extracted with ether (33). The ether extracts were washed with 3 N HCl, 5% $NaHCO_3$, and water, then dried over $MgSO_4$, filtered, and the solvent removed *in vacuo* to yield crude 2,3-dideuterolup-2-ene **29** (130 mg), which was used in the next step without purification.

Hydrogenation of ***29***

A mixture of **29** (130 mg), ethyl acetate (100 mL), and 10% Pd/C (150 mg) was shaken at room temperature for 2 days under 2 atm hydrogen in a Parr hydrogenator. Filtration of the catalyst and removal of the solvent under vacuum followed by chromatography on alumina, eluting with hexane, gave 2,3-dideuterolupane **7** (100 mg) in 76.6% yield as a white waxy solid, mp 129–148°C; ms m/z (%): 414 (36, M^+), 413 (1.5), 399 (17), 397 (1), 259 (14), 231 (13), 193 (100), 191 (20), 149 (18), 123 (37), 95 (46), 81 (37), 69 (33).

CLAUDIO J. SALOMON, ORESTE A. MASCARETTI, CHARLES E. STROUSE, and G. PUNTE. Can. J. Chem. **69**, 578 (1991).

A stereospecific synthesis of 6,6-dibromo-3α-cyano-2,2-dimethylpenam-(1*R*)-*S*-oxide (**2**) is described. The X-ray single crystal investigation of this compound shows that it crystallizes in the monoclinic system, space group $P2_1$, with cell parameters $a = 6.194(1)$, $b = 9.363(1)$, $c = 9.869(1)$ Å, $\beta = 96.55(2)°$, $V = 568(1)$ Å^3, and two molecules per unit cell. The structure was solved, from low temperature data, by direct methods, and refined, by least-squares procedures, to a final $R = 3.17\%$, $R_w = 3.38\%$, for 1221 observed independent reflections. The sulfoxide configuration is *R*. The thiazolidine presents an envelope shape with the C(3) atom 0.56 Å above the other four members of the ring mean plane. Therefore, it exhibits the conformation with α-CH_3 pseudoequatorial and β-CH_3 and α-CN both pseudoaxial. This conformation is different from the one reported for other penicillin sulfoxide derivatives. The geometry of the β-lactam ring is typical of the fused bicyclic penam nucleus. The ring is non-planar. The N(4) atom displays a pyramidial arrangement. The examination of crystal packing shows that molecules along *a* are connected by a short C—H...O contact.

Reported single crystal studies showed two dominant conformations for the thiazolidine ring in the fused bicyclic penam nucleus: the C(3) or 2β-3α substituents both pseudoaxial, as found in **2**, and the S(1) or 2β-3α substituents both pseudoequatorial, adopted by most sulfoxides. Neither of these conformations can explain the nuclear Overhauser effect data. A conformation with the substituents C2-β-methyl-C3-α-H and C2-α-methyl-C3-α-CN fully eclipsed is in accordance with the experimental results in the solution. The ^1H nuclear magnetic resonance data reflect the influence of the magnetic anisotropy of the CN triple bond on the *gem*-dimethyl groups, particularly in relation with the geometrical features of the molecule. Comparison of ^{13}C nuclear magnetic resonance chemical shifts for **2** and its parent penicillin sulfide (**1**) indicates configurationally dependent substituent effects, the magnitude of which can be used for the stereochemical assignment of sulfoxide groups in this series.

Key words: penicillin sulfoxide derivatives, di-halogen penicillanates, stereospecific synthesis, NMR studies, absolute configuration determination.

CLAUDIO J. SALOMON, ORESTE A. MASCARETTI, CHARLES E. STROUSE et G. PUNTE. Can. J. Chem. **69**, 578 (1991).

On décrit une synthèse stéréospécifique du 6,6-dibromo-3α-cyano-2,2-diméthylpénam-(1*R*)-*S*-oxyde (**2**). Une étude par diffraction des rayons-X par un cristal unique de ce composé montre qu'il cristallise dans le système monoclinique, groupe d'espace $P2_1$, avec $a = 6,194(1)$, $b = 9,363(1)$ et $c = 9,869(1)$ Å, $\beta = 96,55(2)°$, $Z = 2$ et $V = 568(1)$ Å^3. On a déterminé la structure par des méthodes directes à l'aide de données obtenues à basse température et on l'a affinée par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de $R = 0,0317$ et $R_w = 0,0338$ pour 1221 réflexions indépendantes. La configuration du sulfoxyde est *R*. La thiazolidine se présente sous la forme d'une enveloppe dans laquelle l'atome C(3) se trouve à 0,56 Å au-dessus du plan moyen formé par les quatre autres atomes. Elle se présente donc dans le conformation avec le α-CH_3 en position pseudo-équatoriale alors que le β-CH_3 et le α-CN sont tous les deux en positions pseudo-axiales. Cette conformation diffère de celle rapportée pour d'autres dérivés sulfoxydes de la pénicilline. La géométrie du cycle β-lactame est typique de celles observées avec les noyaux pénames bicycliques condensés. Le noyau n'est pas plan. L'atomic N(4) présente un arrangement pyramidal. L'examen de l'empilement cristallin montre que les molécules de l'axe *a* sont reliées par un faible C—H...O.

Les études qui ont été effectuées antérieurement sur les structures cristallines ont démontré l'existance de deux conformations prédominantes pour le cycle thiazolidine condensé dans des noyaux pénames bicycliques : les substituants C(3) ou 2β,3α en positions pseudo-axiales, comme dans **2**, ou les substituants S(1) ou 2β,3α en positions pseudo-équatoriales, adoptées dans la plupart des sulfoxydes. Aucune de ces conformations ne peut expliquer les données d'effet Overhauser nucléaire. Pour les données expérimentales obtenues en solution, on doit faire intervenir une conformation complétement éclipsée des substituants C2-β-méthyl-C3-α-H et C2-α-méthyl-C3-α-CN. Les données de la RMN du ^1H reflètent l'influence de l'anisotropie magnétique de la triple liaison CN sur les groupements *gem*-diméthylés, particulièrement en relation avec les caractéristiques géométriques de la molécule. Une comparaision des déplacements chimiques, en RMN du ^{13}C, du composé **2** et du sulfure correspondant (**1**) suggère la présence d'effets de substituants qui dépendent de la configuration; leur amplitude peut être utilisée pour l'attribution stéréochimique de groupements sulfoxydes dans cette série.

Mots clés : derivés de pénicilline sulfoxyde, di-halogène pénicillanates, synthèse stéréospecifique, études RMN, détermination de la structure absolue.

Introduction

There has been relatively little work reported on the conformation adopted by specific β-lactamase inhibitors in the solid state and in solution (1, 2). Greater attention has been directed to the study of the conformation of 6β-*N*-acylamino penicillins on the β-lactam binding proteins of bacteria for bacterial activities (3).

In recent years we have synthesized and examined with various techniques several penicillin derivatives (1, 4, 5). The aim of these investigations was to find the functional groups and conformations, the so-called topological and topographic patterns (6), essential for a good β-lactamase inhibitory activity. In the course of these comparative studies we became interested in introducing an oxygen atom at a specific site of the 6,6-dibromo-3α-cyano-2,2-dimethylpenam (**1**). Of special interest was the stereocontrolled access to (*R*)- and (*S*)-sulfoxides of dibromo derivatives like **2** and **3**, and also to their corresponding 6β- and

1 $n = 0$
2 $n = 1\alpha$ (*R*)
3 $n = 1\beta$ (*S*)

6α-bromo derivatives, to study the dependence of the ^{17}O and, particularly, the ^{33}S nmr parameters on the stereochemistry (7).

The conversion of penicillanates into the corresponding sulfoxides has been recently studied (for a recent review, see ref. 8). Conversion of sulfides into sulfoxides may be carried out by many oxidizing agents (for a review, see ref. 9). However, only a few of these permit oxidation to proceed in a selective manner with high yields under mild conditions (10).

Both 1α- (**2**) and 1β-6,6-dibromo-3α-cyano-2,2-dimethylpenam sulfoxide (**3**) have been observed in the mixture obtained when the parent penam sulfide (**1**) is treated with one equivalent of *m*-chloroperbenzoic acid (*m*-CPBA), in CH_2Cl_2 at 0°C for 12 h (1). We have now successfully used potassium hydrogen persulfate (11) (commercially sold as oxone),[4] in aqueous methanol as a selective oxidizing agent, for the synthesis of only one of the two sulfoxides expected.

An X-ray single crystal analysis of the synthesized compound (**2**) was performed in order to determine its absolute configuration.

The knowledge of the molecular geometry gathered by X-ray crystallography is essential in the study of the conformation–activity relationship and the mechanism of action of drugs. Notwithstanding, it has been proved to be important to ascertain by ^1H nmr studies the conformation of the molecule in solution (1, 12) as it can either be different from the solid state conformation, as we found to be the case for **2**, or the compound can be difficult to crystallize. A nuclear Overhauser effect study was therefore carried out to get information regarding the conformational nature of the thiazolidine ring of **2** in solution. In addition, ^{13}C nmr spectroscopy was applied to the study of the solution structures of **1** and **2**. This last technique has been reported effective for the study of sulfoxide configurations (1, 13, and, for a review, 14).

[4]Oxone contains 2 mol equiv. of $KHSO_5$, 1 mol equiv. of K_2SO_4, and 1 mol equiv. of $KHSO_4$, and was purchased from Aldrich Chemical Co.

Experimental

Routine ir spectra were obtained on a Beckman Acculab 8 spectrometer. The ^1H and ^{13}C nmr spectra were recorded on a Bruker WP 80 SY at 80.13 and 20.15 MHz; the chemical shifts are expressed in parts per million downfield from internal tetramethylsilane. Melting points were determined on a Kofler hot stage apparatus and are uncorrected. X-ray diffraction data were collected using a locally automated Picker Diffractometer.

4-Thia-1-azabicyclo[3.2.0]heptane-2-carbonitrile-6,6-dibromo-2,2-dimethyl-7-oxo [2S(2α,5α)][5] (**1**)

This compound was prepared from the corresponding 2-carboxamide as described in ref. 4. Mol. wt (hrms) calcd. for $C_8H_8Br_2N_2OS$: 337.8724; found: 337.8769.

4-Thia-1-azabicyclo[3.2.0]heptane-2-carbonitrile-6,6-dibromo-2,2-dimethyl-7-oxo-4-oxide (2S[2α,4α(R),5α]) (2)*

Compound **1** (2.00 g, 5.86 mmol) was dissolved in methanol (25 mL), the solution was cooled to 0°C, and a solution of oxone (containing 15.8 mmol of $KHSO_4$) in water (25 mL) was added. The resulting slurry was stirred for 24 h at room temperature, after which methanol was removed under reduced pressure, ethyl acetate (25 mL) added to the residue, and the layers separated. The aqueous layer was extracted with ethyl acetate (2 × 25 mL). The combined organic layers were washed with brine (2 × 20 mL), dried (Na_2SO_4), and concentrated. The resulting solid product was crystallized from chloroform to provide the pure α-sulfoxide **2** (1.350 g, 67.5%), mp 162–163°C; ir (KBr): 2225 (cyano), 1815 (β-lactam), and 1050 (SO) cm^{-1}; ^1H nmr ($CDCl_3$): 1.51 (s, 3H, 9-CH_3), 172 (s, 3H, 10-CH_3), 4.95 (s, 1H, C-3H), 5.32 (s, 1H, C-5H); cims *m/z*: 355, 357, 359 (MH^+) for $C_8H_8Br_2N_2O_2S$.[6]

A colorless parallelepiped-shaped crystal was used for the X-ray study. Crystal data are presented in Table 1. The unit cell parameters were obtained by least-squares refinement of the setting angles of 33 reflections ($8 < 2\theta < 21°$). Three standard reflections, measured every 100 reflections, showed only random intensity variations during data collection, max. 3.5%. Lorentz and polarization corrections were applied. An isotropic secondary extinction correction of the form $F' = F(1\text{-}CF^2/\sin\theta)$ was applied on F_c, refined *C* value: 7.7×10^{-4}. An absorption correction was done on I_o (15).

The structure was solved using direct methods, MULTAN80 (16). From the partial model obtained, all non-hydrogen atoms were located and refined from alternate difference Fourier and isotropic least-squares refinement cycles. The refinement was performed by full-matrix least squares based on *F*'s employing anisotropic thermal parameters. Quantity minimized: $\Sigma[w||F_o| - |F_c||]$. Hydrogens were stereochemically positioned (C—H = 1.08 Å); the H's bound to C(3) and C(5) atoms were refined, isotropically, with their thermal parameters fixed. The methyl hydrogens were refined with their positions riding on the bonded atoms and with overall temperature factor for each group.

The final refinement, converged to $R = 3.17$, $R_w = 3.38\%$, weighting scheme: $1.0709/\sigma^2$, where σ were based on counting statistics (no improvement could be seen with any other scheme). The biggest fluctuations of the electronic density were located near Br atoms. To establish the absolute configuration, an alternative refinement based on the mirror image of the molecule was performed to convergence. This led to $R = 4.02$, $R_w = 4.33$, and $R_g = 5.27\%$. Then, according to the Hamilton test (17), the non-inverted set of coordinates corresponds to the true configuration. Scattering factors for H and scattering factors and anomalous dispersion corrections for O, C, N, S, and Br were taken from SHELX76 (18).

[5]We used Systematic Chemical Abstracts names as headings for the title compound in the experimental section because they are the names most useful for literature searching, and non-systematic names in order to allow cross-reference correlations to the penicillins and penam nomenclature. For this naming and numbering see ref. 34.

[6]For this compound characteristic isotopic peaks were observed in the mass spectra.

Calculations were carried out on VAX systems using the following programs: UCLA crystallographic computing package. (15), MULTAN80 (16), SHELX76 (18), ORTEP (19), and PLUTO (20).

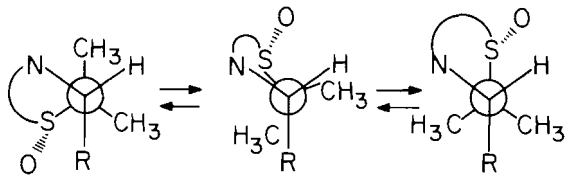
Fractional atomic parameters with equivalent isotropic thermal parameters for the refined atoms are given in Table 2.[7] The numbering scheme is shown in a stereoscopic view of the molecule, Fig. 1. Table 3 shows intramolecular bond lengths and angles.

Results and discussion

Chemistry

The oxidation of 6,6-dibromo-3α-cyano-2,2-dimethylpenam (**1**) afforded the sulfoxide **2** in good yield as the pure (*R*) isomer. The oxidation occurred at the sterically more accessible α-face.

Description and discussion of the crystal structure



We have recently analyzed the X-ray crystal structure and solution conformation of several pivaloyloxymethyl 6,6-dihalo- and 6-halopenicillanates and their corresponding 1-oxides and 1,1-dioxides (1, 5). We found, in agreement with earlier reports on 6β-*N*-acylated penicillin derivatives (21, 22), that four of the five atoms of the puckered thiazolidine ring tend to be coplanar and can adopt one of two extreme conformations, I and II, described in the literature. I is illustrated by the Newman projection **4***a*. It is usually referred to as conformation C(3) (after Domiano *et al.* (22)). II is exemplified by the Newman

[7]Tables of structure factors, H-atom parameters, anisotropic thermal parameters, and best least-squares planes may be purchased from The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

projection **4***c*. This is named conformation S(1) (22). An alternative identification, based on the relative position of the 2β-CH_3 and 3α-R substituents with respect to the thiazolidine ring, has been preferred by some crystallographers (see, e.g., refs. 23 and 24). Within this scheme, I is the 2β–3α pseudoaxial conformation and II is the 2β–3α pseudoequatorial conformation. I and II are interconvertible via the pseudo rotation associated with S(1)—C(2)—C(3)—N(4) torsion. In **2** the best plane (in the χ^2 sense) is defined by S(1), C(2), N(4), C(5); the C(3) atom is displaced from this plane by 0.560(7) Å *exo* to the

4*a* **4***b* **4***c*

nucleus. Therefore, as can be seen in Fig. 1, the five-membered ring exhibits a conformation close to the C(3) one with α-CH_3 pseudoequatorial and β-CH_3 and α-CN pseudoaxial. Endocyclic thiazolidine torsional angles and selected torsional angles involving C2 and C3 substituents are presented in Table 4. The conformation adopted by **2** is different from that reported for other penicillin sulfoxides such as phenoxymethyl penicillin-1β(1*S*)-sulfoxide (23), cloxacillin-1β(1*S*)-sulfoxide (24), pivaloyloxymethyl 6,6-dibromo penicillanate-1β(1*S*)-sulfoxide (**5**) (5), and methyl 6,6-dibromo penicillanate-1β(1*S*)-sulfoxide (**6**) (25). In compound **2** the value of the endocyclic bond angle at S(1), 92.0(3)°, though smaller than the expected value for the C(3) conformation, 96.1(2)° (3*d*), is higher than the values

R = $CO_2CH_2OCC(CH_3)_3$ R = CO_2CH_3

found in **5**, 88.4(4)°, and in **6**, 89.1(3)°, as expected, since **5** and **6** show the S(1) conformation. The methyl group at C(10) is on the same side of the best thiazolidine ring as the CN substituent at C(3). The torsion angle C(10)—C(2)—C(3)—C(11) = −35.7(8)° and the C(10)—C(11) distance, 2.88(1) Å, indicate that these atoms present a nearly eclipsed conformation.

The geometry of the 2-azetidinone (β-lactam) ring in **2** is typical for the fused bicyclic penam nucleus. The ring is not

planar; the N(4) atom shows a pyramidal arrangement, being out of the plane defined by its substituents. The value of the out-of-plane distance, 0.395(6) Å, and the sum of angles around N(4), 334.1°, compare well with the reported values for other penicillanates (21). The non-planarity of the 2-azetidinone ring can be assessed, as well, from the dihedral angle between the N(4)—C(5)—C(6) and N(4)—C(6)—C(7) planes, 7.4(2.0)°. Besides, it is found that the atoms N(4)—C(6)—C(7)—O(8) define a better plane than those forming the four-membered ring. The C(5) atom is displaced 0.178(7) Å on the same side of the mean four-membered ring plane as the sulfur atom.

Bond distances and angles within the nucleus, see Table 3, are in good agreement with those of other penicillin derivatives (21, 22).

The dihedral angle between the mean planes of the thiazolidine and 2-azetidinone rings, 117.5(3)°, is similar to that found in other C(3) penicillin derivatives (22).

The CN substituent geometry compares well with the geometry reported for CN groups bound to cyclic sp^3 carbon atoms (26).

The packing of the molecules in the crystal is shown in Fig. 2. Assuming as van der Waals radii for C, N, O, S, and Br atoms and for the CH_3 group, respectively, the values 1.6, 1.5, 1.4, 1.85, 1.95, and 2.0 Å, in agreement with Pauling (27), it has been found that some intermolecular distances are smaller than the sum of the corresponding van der Waals radii,[7] thus indicating that electrostatic interactions are contributing to the crystal structure stabilization. In particular the C(3)—H(3)....O(1) contact that is linking molecules along *a* may be considered as an H-bond, according to Taylor and Kennard (28), since C(3)....O(1) = 3.065(5) Å, H(3)...O(1) = 2.11(8) Å, and C(3)—H(3)—O(1) = 167(7)°. The existence of short C—H...O contacts, some of which can be described as hydrogen bonds according to Taylor and Kennard (28), has been recently reported by Verdilinde, Blaton, de Ranter, and Peeters from single crystal X-ray studies and CNDO/2 calculations performed on (1*S*,-5*R*,8*R*,9*R*)-2′-hydroxy-5,9-dimethyl-8,2-epoxyethano-6,7-benzomorphan hydrochloride (29). Taking account of the flexibility of the thiazolidine ring of the penam nucleus it can be assumed that the intermolecular interactions mentioned might force the conformation displayed by **2** in the solid state. This assumption is supported by molecular modelling studies of the nucleus (30, 31), which found energy barrier values of 0.5 and

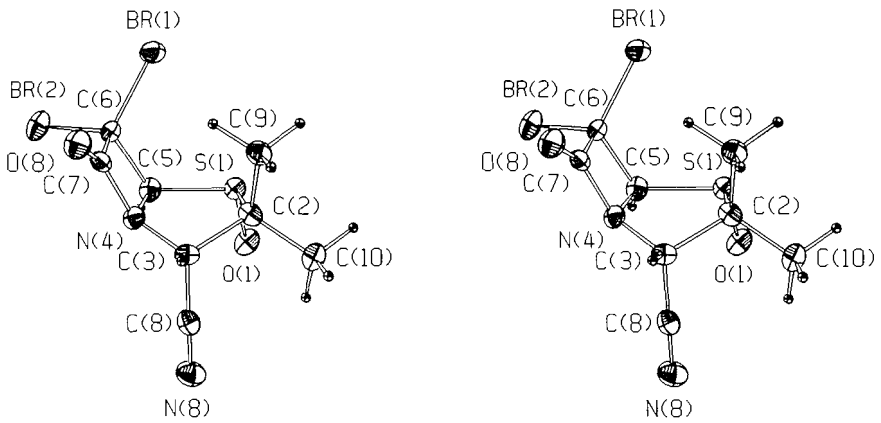

FIG. 1. Stereoscopic ORTEP drawing of the molecule, thermal ellipsoids 50%, showing non-hydrogen atoms labelling.

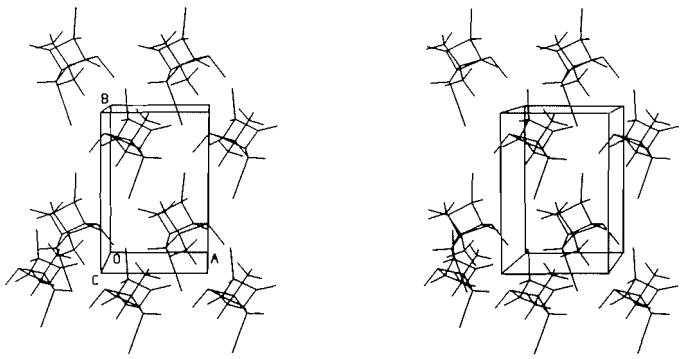

FIG. 2. Stereoscopic view of the molecular packing.

0.7 kcal respectively between conformers **4***a* and **4***c*, and by recent theoretical conformational analysis studies (32), which determined that global minima for various penicillins were 2.0–4.5 kcal/mol lower in energy than the corresponding crystal structure.

Spectroscopic data

Nuclear Overhauser effect

Results are presented in Table 5; they indicate an enhancement of 23.5% in the intensity of the H(3) resonance when the high-field methyl peak is saturated, whereas the enhancement of the H(5) resonance is negligible. Besides it can be seen that saturating the low-field methyl peak had no effect on the intensity of the H(3) and H(5) signals.

Neither of the two extreme conformations, C(3) or S(1), presented by the thiazolodine ring in the solid state can account for these experimental observations. Only in a conformation with the substituents C(2)-β-methyl-C(3)-βH and C(2)-α-methyl-C(3)-α-CN fully eclipsed, like **4***b*, can H(3) be relaxed by the 2β-methyl hydrogen. This would indicate that **2** in solution adopts a conformation different from that found in crystals.

Therefore, from single crystal and nOe data, it can be assumed that the thiazolidine ring in **2** is flexible enough to adopt whatever conformation may be energetically advantageous for the environment requirements. This is consistent with the reported theoretical conformational analysis studies (32), which predicted conformations of the methyl esters of penicillin G and bisnorpenicillin G in accord with the conformations observed in solution and suggested that neither penicillin V nor penicillin G retain their crystal structure in solution.

^{13}C and ^1H nuclear magnetic resonance spectroscopy

Table 6 displays ^{13}C nmr spectral data for **1** and **2**. Figure 3 illustrates the observed changes in the chemical shifts on going from **1** to **2**. We have reported a similar pattern of changes for the series of pivaloyloxy methyl 6,6-dihalo- and 6-halopenicillanates and their corresponding (*R*)-sulfoxide (1). Clear and markedly different patterns in the shifts in resonance position on going from a sulfide to its β-sulfoxide or to its α-sulfoxide, which remain despite substantial alterations in the substitution at C(6), have been reported by Harrison and Hodge (13). Therefore, the ^{13}C nmr results presented here, together with the knowledge of the configuration and solution conformation of **2**

provided by X-ray and nOe results, could be used to determine the penicillin sulfoxide configuration of mono- and dihalide derivatives of **1** from ^{13}C chemical shift data in solution.

The most remarkable feature of the ^1H nmr data is the strong magnetic anisotropy of the C≡N triple bond (33). The hydrogen atoms of the C(9) methyl group lie in the shielding region of the electron circulation induced by the magnetic field, that is, the magnetic anisotropy is negative. On the other hand, the hydrogen atoms of the C(10) methyl group are deshielded. This differential influence on the resonance of *gem*-methyl groups might be an important aid in the conformational analysis of the thiazolidine ring in the series 3α-cyano-2,2-dimethyl penam.

Acknowledgments

The authors thank CONICET (Consejo Nacional de Investigaciones Científicas y Técnicas de Argentina) and the Johns Hopkins University for financial support, Dr. E. G. Mata for skillful technical assistance, and Dr. M. G. Sierra for recording the nOe differential spectra and for helpful discussions.

Novel metal chelating chitosan derivative: attachment of iminodiacetate moieties via a hydrophilic spacer group

KEVIN R. HOLME[1] AND LAURANCE D. HALL[2]

Department of Chemistry, University of British Columbia, Vancouver, B.C., Canada V6T 1Y6

Received July 24, 1990

KEVIN R. HOLME and LAURANCE D. HALL. Can. J. Chem. **69**, 585 (1991).

Chitosan has been reductively N-alkylated with a 6-*O*-substituted galactose derivative bearing an iminodiacetate residue, to give a chitosan derivative having a hydrophilic branch and a metal chelating group. The Cu(II) binding capacity of the derivative was comparable to native chitosan, but showed better ion-exchange ability. The product was water soluble, giving viscous 1% aqueous solutions that showed decreased viscosity upon addition of Cu(II) ions.

Key words: chitosan, derivative, chelation, solubilization, viscosity.

KEVIN R. HOLME et LAURANCE D. HALL. Can. J. Chem. **69**, 585 (1991).

Dans le but d'obtenir un dérivé du chitosane portant une portion hydrophile et un groupement chélatant, on a procédé à une réduction N-alkylante du chitosane avec un dérivé 6-*O*-substitué du galactose portant une portion iminodiacétate. La capacité de chélation du Cu(II) de ce dérivé est semblable à celle du chitosane naturel; toutefois, il présente une meilleure habilité à l'échange ionique. Le produit est soluble dans l'eau et les solutions aqueuses à 1% sont visqueuses; ce résultat démontre que la viscosité diminue par addition d'ions Cu(II).

Mots clés : chitosane, dérivé, chélation, solubilisation, viscosité.

Introduction

The amino polysaccharide chitosan, a β-(1-4)-linked 2-amino-2-deoxy-D-glucopyranose homopolymer, has attracted considerable attention as a result of its physical and chemical properties (1, 2). Chitosan has been modified in order to prepare controlled solubility derivatives (3, 4), metal sequestrants (5–7), drug carriers (8), and immobilization supports (ref. 2, pp. 443–444). Although our main efforts have been directed toward controlled solubility compounds (3, 4), we felt that our experience in chitosan modification could be exploited in the synthesis of metal chelating, controlled solubility conjugates.

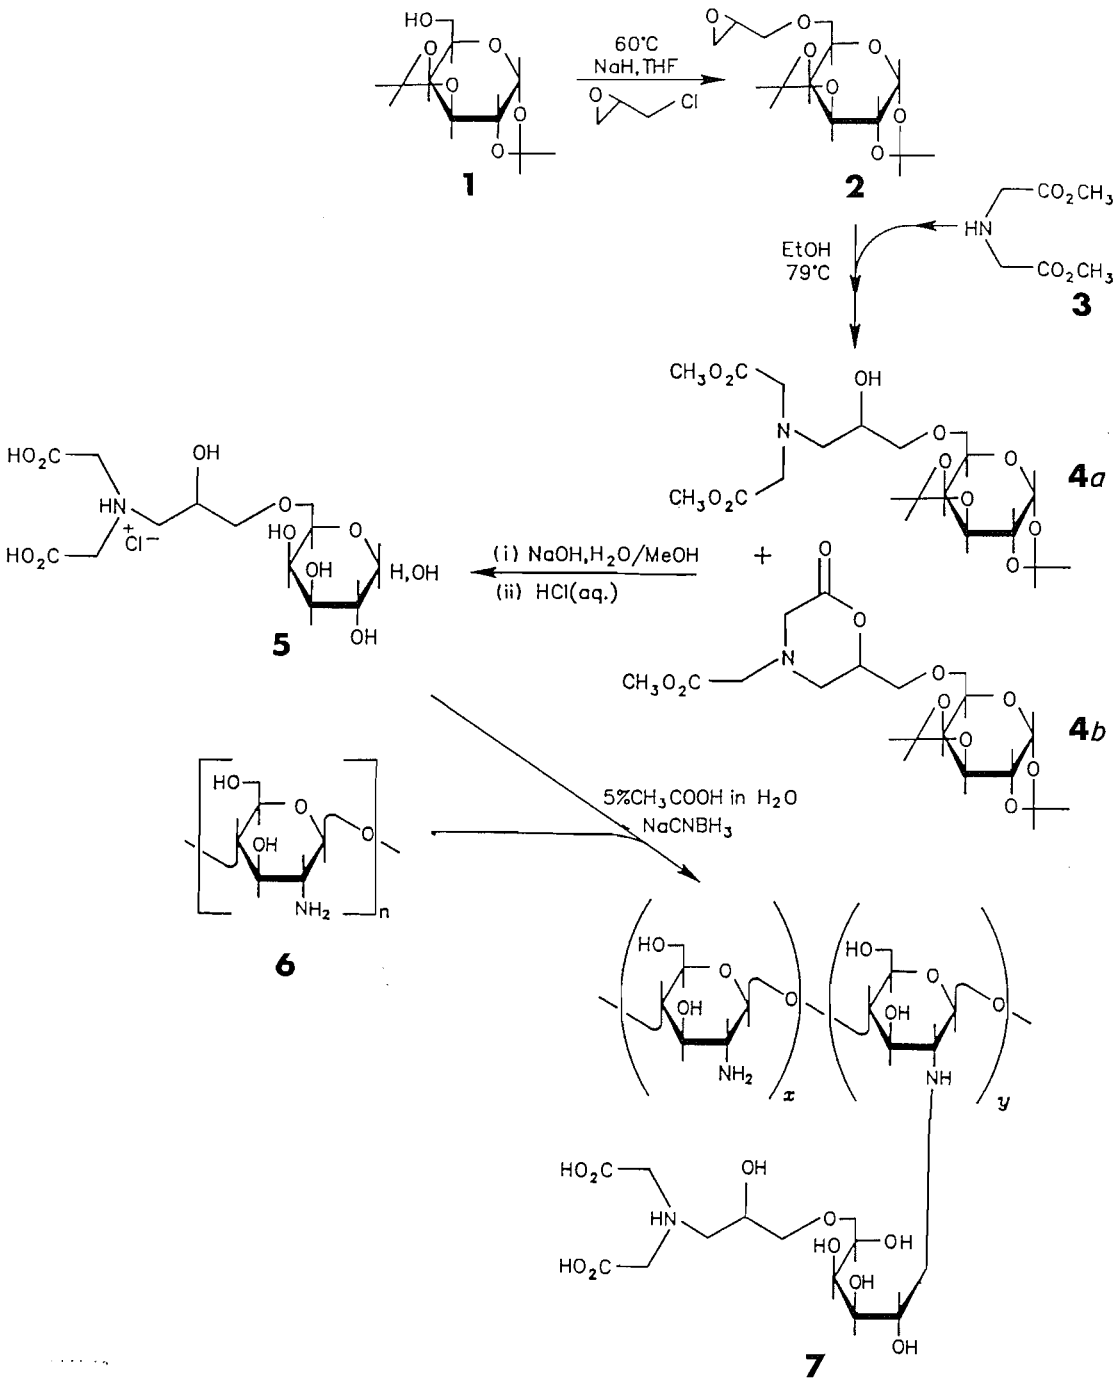
Some metal chelating chitosan derivatives have been described, in which phthalaldehyde (5), salicaldehyde (6), and glyoxilic acid (7) were reductively alkylated to chitosan. The objective of this work was to incorporate controlled solubility features in conjunction with chelating properties to create a novel chitosan derivative. This was felt to be best accomplished by incorporating a hydrophilic spacer arm between the chitosan backbone and the desired chelating group. Previous work from this laboratory in which free sugars were coupled to chitosan to give acyclic hydrophilic branches (3) provided an ideal route to such a spacer group. Iminodiacetic acid, essentially one half of the well-known chelate ethylene diamine tetraacetic acid (EDTA), was chosen as an appropriate chelating functionality. The synthetic route to a precursor having the desired structural features, and its attachment to chitosan, will be discussed.

Results and discussion

Synthesis

By design, it was decided to prepare a compound that contained both an iminodiacetic acid functionality for metal chelation, and an aldehyde for coupling to chitosan. A carbohydrate-derived, hydrophilic spacer arm was chosen in order to enhance the solubility characteristics of the final product, and to act as a spacer arm. Scheme 1 outlines the synthesis of the ligand precursor **5**.

The epoxide **2** was prepared from 1,2:3,4-di-*O*-isopropylidene galactose (**1**), by reaction with epichlorohydrin in the presence of sodium hydride. Subsequent reaction of the epoxide with dimethyliminodiacetate (**3**) gave a 4:1 mixture of the dimethyliminodiacetate **4***a* and the morpholone **4***b*. Although cyclizations similar to that producing **4***b* have been observed in reactions of epoxides with amino acid esters (9), it appears to be more favourable for the diester compounds described here. Total conversion of the mixture to the morpholone **4***b* was easily achieved by distillation. Liquid chromatography on silica gel afforded some separation of the mixture, but it was determined that further cyclization occurred on the column. Base hydrolysis of the **4** mixture, and subsequent treatment with acid at 50°C, gave the free sugar derivative **5**.



Compound **5** was coupled to chitosan via reductive amination (10), with sodium cyanoborohydride in 5% aqueous acetic acid, to give the derivative **7** at two levels of substitution (**7***a* and **7***b*). Control of the degree of substitution was achieved by varying the ratio of aldehyde to chitosan (A/C) as shown in Table 1. Derivative **7***a* was water soluble, giving a clear viscous solution at 5.0% (w/w) in distilled water. Compound **7***b*, on the other hand, gave an opaque gel at 5.0% (w/w) concentration and it retained much of its gelatinous nature at 1.0%.

Characterization

The solution state ^{13}C nmr spectrum of **7***a* was obtained, and resonances for the hydroxypropyl and iminodiacetate functionalities were easily discernible. Most of the carbohydrate resonances arising from the galactosyl branch were identifiable. The chitosan resonances, however, were very broad and assignment was difficult. Interestingly, the linewidth for C-1 of the chitosan backbone is of the order of 90 Hz, while the carbon resonances of C-6′ of the galactosyl group had a linewidth of 40 Hz, reflecting the relative mobilities of these portions of the molecule.

SCHEME 1

pH titration

The results for pH titrations of derivatives **7***a* and **7***b* gave inflection points corresponding to values of pK_a^1 2.1, pK_a^2 5.9, and p_i 3.9. These values are similar to those reported for *N*-carboxymethylchitosan (7), which contains similar functionalities. Some of the inflections are ill defined, probably because of the number of titratible groups present, and the insolubilization that occurs at pH values of approximately 10 and higher.

Copper (II) chelation

Table 1 summarizes the evaluation of copper(II) uptake of the derivatives **7***a* and **7***b*, and contrasts these with native lyophilized chitosan. The differential uptake of **7***a* and **7***b* reflects the higher degree of substitution (d.s.) value of **7***a*. The chelating capacity of native chitosan itself is 2.4 mmol/g and the percent uptake in terms of copper ions per residue corresponds to an average of 0.39. For the derivatives **7***a* and **7***b*, more than one ion binds per derivatized residue (i.e., uptake >100%), which indicates that additional binding to the backbone, over and above one equivalent binding per chelating branch, occurs in the derivative. The difference between the theoretical maximum (100%) expected for binding to the iminodiacetate moieties and the values determined for the derivatives is similar to the percent uptake of underivatized chitosan. This observation may indicate that two binding domains exist: specific chelation to the branch, and an apparently stronger nonspecific binding to functionalities

TABLE 1. Cu(II) chelating capacity for derivatives *7a* and *7b* contrasted with values obtained in parallel experiments for chitosan, and with literature values for chitosan

Sample	Degree of substitution (±0.05)	Cu (II) uptake[a] (mmol/g)	% Theoretical uptake[b]
7a	1.00	2.97	152
7a[c]	1.00	0.33	16.9
7b	0.50	2.45	87.5
Chitosan[d]		2.40	39.0
Chitosan[c,d]		1.15	18.5
Chitosan[e]		0.06	2.0
Chitosan[f]		3.12	51.0

[a]A 200 mg sample was dissolved or dispersed in ca. 15 mL of distilled water and treated with a 0.5 M Cu(II) acetate solution (15 mL), exhaustively dialysed, and freeze-dried.

[b]Based on the number of copper ions per GlcN residue.

[c]After saturation with Cu(II) these samples were dialysed for 3 days (3 × 250 mL) against water, 2 days against 0.1 M iminodiacetic acid solution, and finally, exhaustively with water, and freeze-dried.

[d]Precipitated, lyophilized chitosan.

[e]Chitosan flakes, ref. 6.

[f]Chitosan, ref. 1, p. 149.

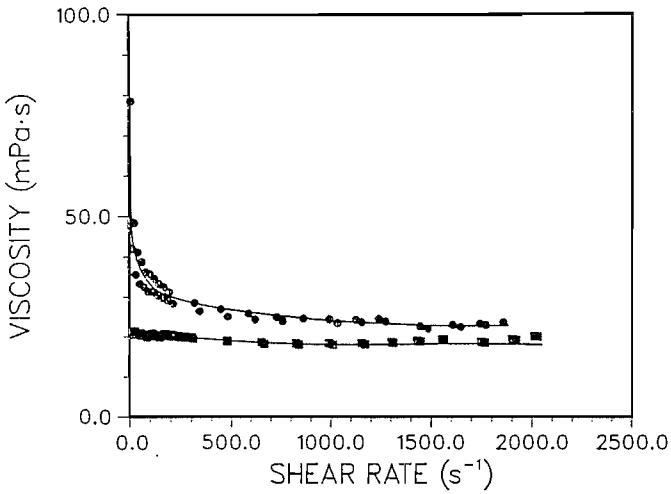

FIG. 1. Rheograms showing the steady shear flow behavior of derivative *7a*, at 1.0% w/w concentration in distilled water (●) and in 1.0 mM aqueous $CuSO_4$ (■), on linear coordinates.

on the polymer backbone. This point was further investigated by saturating both *7a* and chitosan with copper(II) ions, and then dialyzing the resulting chelates against 0.1 M iminodiacetic acid in distilled water for 48 h. The copper content of chitosan decreased by only half to 1.15 g/mmol or 18.5%, while most of the copper (89%) was removed from *7a*. Interestingly, the final percent copper contents of both *7a* and chitosan after dialysis were similar. The major limitation in making comparisons of this sort arises from the fact that the physical form of the polymer can be very important. This is illustrated in Table 1, which shows two very different values of copper(II) uptake for chitosan flakes (5) and lyophilized chitosan. It must also be noted that, in this study, the derivatives were dissolved prior to the addition of copper (II) acetate solution, while the lyophilized chitosan remained as a hydrated dispersion.

Viscometry

Compound *7a* formed viscous 1.0% (w/w) solutions, so it was of interest to evaluate its rheological properties. Also, it was felt that viscometry could offer some insight into the interaction of the polymer with copper(II) ions. The steady shear viscometric determinations are shown in Fig. 1 for 1.0% (w/w) solutions of *7a* in distilled water and in 1.0 mM aqueous copper-(II) sulfate. Interestingly, the viscosity of the solution containing copper ions is less than that for the distilled water solution. This is contrary to the known behaviour of other metal chelating polysaccharides, such as sodium alginate, which increase in viscosity or gel upon the addition of divalent metal ions such as calcium and copper (ref. 1, p. 149). This behaviour results from the crosslinking effect of the metal ions, something that is apparently not occurring in the samples described here. This leads us to believe that each branch or branched residue is a self-contained chelate for one copper ion. Thus, to satisfy the metal ion's ligand requirements, crosslinking is not necessary. The fact that the chelating results indicate >100% binding supports the conclusion that each branch chelates one ion.

Conclusion

We are gratified by the range of properties exhibited by this chitosan derivative as they reflect the success of a rational approach to tailoring the properties of polysaccharides. Thus, in accord with previous experience, the presence of the high level of N-substitution by a hydrophilic side chain resulted in a freely soluble derivative. Functional groups, in this case the chelating iminodiacetate, modifying the side chain offer access to additional properties. This encourages further research into the rational tailoring of chitosan for structure/property studies.

Experimental

General methods

All evaporations were performed under diminished pressure on a Buchi rotary evaporator. Melting points were determined using a Fischer–Johns melting point apparatus and are uncorrected. Infrared (ir) spectra were recorded on a Perkin–Elmer model 710B infrared spectrophotometer, and were calibrated using the 1601 cm^{-1} band of polystyrene film. Low resolution mass spectra (ms) were recorded on a Varian/MAT CH4B or Kratos/AEI MS 50 mass spectrometer. Analytical gas–liquid chromatography was performed on a Hewlett–Packard 5832A gas chromatograph with a 6 ft × 0.125 in. stainless steel column packed with 5% OV-17 on 80–100 mesh Chromosorb W (HP). Carbon, hydrogen, and nitrogen elemental microanalyses were performed by Mr. P. Borda, Microanalytical Laboratory, University of British Columbia. Copper microanalyses were done by Canadian Microanalytical Ltd., Vancouver, Canada. Analytical thin-layer chromatography (tlc) was done with 0.20 mm precoated aluminum back sheets of Silica Gel 60 F_{254} (E. Merck, Darmstadt, Germany). Solvent systems employed for tlc analyses were (A) ethyl acetate–hexane (3:2), (B) ethyl acetate–isopropanol–water (9:4:2). For detection of components, tlc sheets were sprayed with (a) 30% sulfuric acid in 95% ethanol followed by heating on a hot plate (for carbohydrates), or (b) 2.0% ammonium molybdate in 10% sulfuric acid – ethanol solvent, and subsequent heating on a hot plate. Flash liquid chromatography was performed using 230–400 mesh silica gel (Kieselgel 60, E. Merck, Darmstadt, Germany) according to the procedure of Still *et al.* (11).

Work-up and purification of reactions involving polysaccharides generally involved exhaustive dialysis (Spectrapor membrane tubing, M.W. cutoff 6000–8000) against distilled water, followed by freeze-drying. Polysaccharide samples were dried for 48 h at 70°C *in vacuo* (0.05 Torr; 1 Torr = 133.3 Pa) and stored in Schlenk tubes under nitrogen atmosphere prior to elemental microanalysis.

pH titration curves were determined on solutions of ~0.25 g of polysaccharide derivative in 0.1 N HCl (aq) solution (25.0 mL) with a pH meter. Copper chelation samples were prepared by dissolving the derivative (~200 mg) in distilled water (15 mL) and treating with 2.0 M copper(II) acetate (aq) solution (15 mL). After stirring for 24 h, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

suspensions were dialyzed against (1) distilled water exhaustively (6 × 1 L) or (2) distilled water for 3 days (3 × 1 L), 0.1 N iminodiacetic acid (250 mL) for 48 h, and then exhaustively with distilled water (6 × 1 L). The samples were freeze-dried and then dried *in vacuo* (70°C, 0.05 Torr).

^{1}H nuclear magnetic resonance: Proton nmr spectra were typically measured at 270 MHz using a home-built unit that comprised an Oxford Instruments 63.4 KG superconducting solenoid, a Nicolet model 1180 computer (32K), and a Bruker WP-60 console. Samples dissolved in deuterated chloroform were referenced relative to internal tetramethylsilane (TMS), those dissolved in deuterium oxide relative to internal sodium 3-trimethylsilylproprionate-2,2,3,3-d_4 (TSP).

^{13}C nuclear magnetic resonance: Proton-decoupled carbon-13 nmr spectra were recorded at 100.6 MHz on a Bruker WH-400 spectrometer, or at 75.5 MHz with a Varian XL-300 spectrometer. Spectra were typically obtained at temperatures of 305–310 K, unless otherwise specified. Polysaccharide samples were prepared directly in the 10 mm nmr tube to avoid handling of the viscous or gelatinous materials. Concentrations were typically 5% (w/w), unless further dilution was necessary for dissolution, in which case the concentrations are specified.

Materials

Boron trifluoride – methanol complex (50%), iminodiacetic acid, sodium cyanoborohydride, and sodium hydride (60% dispersion in oil) were obtained from Aldrich Chemical Co. Epichlorohydrin was from MC/B Chemical Co. and 1,2:3,4-di-*O*-isopropylidene-α-D-galactose was purchased from Koch–Light Laboratories. Chitosan (from crab shell, *N*-acetyl <5%) was supplied by Sigma Chemical Co.

Viscometry

For viscometry, sample solutions of 1.0% (w/w) concentration were prepared in distilled water (containing 5 ppm sodium benzoate as stabilizer) or in 0.1 mM copper(II) sulfate (aq) solution. Dissolution was aided by periodic mixing (Vortex–Genie) over a 24 h period. Entrapped air bubbles were removed by centrifugation for 30 min on a benchtop centrifuge. Viscometric measurements were performed with a rotational, controlled stress, rheometer (Visco-Elastic Analyzer, Sangamo Transucers, W. Sussex, England) with truncated cone and plate fixtures (diam. 50.0 mm, α 2.5°, gap 90 μm). A controlled temperature glycol bath under the plate provided temperature control. All measurements were recorded at 20.0 (±0.2)°C. The gap setting was zeroed with no sample present by lowering the cone fixture until contact was just made with the plate. The cone fixture was then raised ca. 2 mm to allow sample loading. A sample solution (~1.5 mL) was loaded into a syringe with an 18-gauge needle. The sample was then discharged onto the center of the plate, taking care to avoid the formation of air bubbles. The cone fixture was lowered onto the sample to the desired 90 μm gap setting. The sample was allowed to equilibrate to 20.0°C, as verified by measurement with a thermocouple. The sample was then stepped through a series of increasing torque settings, applied to the rotating cone fixture, typically from 0.1 to 60 G cm. For each torque setting, the resultant angular velocity (radians s^{-1}) was recorded on a strip chart, allowing the equilibrium value to be reached (usually within 30 s for the majority of samples). When either the maximum torque (60 G cm) or maximum angular velocity (100 radians s^{-1}) was approached, the torque was stepped through a similar decreasing series, and angular velocity was recorded. Duplicate measurements were performed on all samples. Three Newtonian standard oil samples were subjected to identical measurement, at all measured torque values, to calibrate the torque settings over the full range of observed viscosities. Shear stress (σ) is related to torque (T) according to eq. [1]:

$$[1] \quad \sigma = \frac{3T}{2\pi r^3}$$

where T is torque in dynes cm and r is radius; and shear rate ($\dot{\gamma}$) to angular velocity (ω) according to eq. [2]:

$$[2] \quad \dot{\gamma} = \frac{\omega}{\tan \alpha}$$

Substitution of values from cone geometry can provide shear stress and shear rate factors as seen in eqs. [3] and [4].

$$[3] \quad \sigma = 2996.7T \text{ (mPa)}$$

$$[4] \quad \dot{\gamma} = 22.92\omega \ (s^{-1})$$

Apparent viscosity will then be given by eq. [5]:

$$[5] \quad \eta = 130.76(T/\omega)$$

Corrected torque values (T_{corr}) were calculated from standard oil measurements by rearranging eq. [5] to give

$$[6] \quad T_{corr} = \frac{\eta_{oil}\omega}{130.76}$$

where η_{oil} is the known standard oil viscosity, and ω was the measured angular velocity. Corrected torque values and determined angular velocities provided shear stress, shear rates, and apparent viscosities from eqs. [3]–[5]. Rheograms of steady shear viscometric data were plotted on linear coordinates as apparent viscosity vs. shear rate.

Synthesis of chelating chitosan derivatives

Dimethyl iminodiacetate (iminodiacetic acid dimethylester) (3)

Iminodiacetic acid (5.15 g, 38.7 mmol) was stirred in anhydrous methanol (25 mL) to which was added 50% boron trifluoride–methanol complex (10 mL). The reaction mixture was refluxed for 9 h, cooled at room temperature, and poured into 150 mL of chloroform and 75 mL saturated sodium bicarbonate solution. Additional solid sodium bicarbonate was added until the aqueous layer was slightly basic (pH paper). The chloroform layer was separated, the aqueous layer was extracted twice more with chloroform (2 × 150 mL), and the chloroform extracts were combined. The chloroform solution was then dried over magnesium sulfate and filtered. Concentration gave 5.96 g (96%) of a liquid, which corresponded to the diester **3**. This material was one component by tlc analysis (R_f 0.27, solvent A); ir (film) ν_{max}: 1750 cm^{-1}; ^{1}H nmr (270 MHz, $CDCl_3$) δ: 2.07 (s, 1H, N*H*), 3.49 (s, 4H, -C*H*-), 3.74 (s, 6H, CO_2CH_3); ms, m/z (rel. intensity): 161 (15), 129 (6), 103 (7), 102 (94), 74 (37).

6-O-(2,3-Epoxypropyl)-1,2:3,4-di-O-isopropylidene -α-D-galactopyranose (2)

1,2:3,4-Di-*O*-isopropylidene-α-D-galactopyranose, **1** (10.00 g, 38.4 mmol), and epichlorohydrin (3.55 g, 38.4 mmol) were dissolved in anhydrous tetrahydrofuran THF, 100 mL). Sodium hydride (1.84 g, 60% oil dispersion, 46.1 mmol) was washed with three portions of hexane (10 mL) and added to the THF solution. The reaction mixture was refluxed for 9 h, and after dilution with methanol (2 mL) was cooled and poured into water (50 mL). The aqueous layer was extracted with three portions of ether (100 mL) and the combined ethereal extracts were washed twice with saturated brine solution (50 mL). The ether layer was dried with magnesium sulfate, filtered, and concentrated to give 11.40 g of a crude syrup. The tlc analysis (solvent A) of this material showed a major component at R_f 0.55 and minor components at lower R_f values. Flash liquid chromatography (2:1 ether–petroleum ether) afforded 6.88 (57%) of a white crystalline solid corresponding to diastereomeric **2**. Further processing of mixed fractions gave additional product; ir (KBr) ν_{max}: 1450 (CH deform), 1380 (-C(CH)$_2$ sym deform), 1250 (C—O epoxide) cm^{-1}; ^{1}H nmr (270 MHz, $CDCl_3$) δ: 1.34 (s, 6H, CH_3), 1.45 (s, 3H, CH_3), 1.54 (s, 3H, CH_3), 2.63 (m, 1H, *J* 5.5, 2.5 Hz, O-C*H*), 2.78 (t, 1H, *J* 5.5, 5.5 Hz, O-C*H*), 3.17 (m, 1H, -C*H*-C), 3.41, 3.49 (2dd, 1H, *J* 1.0, 5.5 Hz, H-1′aR,S), 3.59–3.83 (m, 3H, H-6a,6b, H-1bR,S), 3.98 (br t, 1H, *J* 5.5, 5.5 Hz, H-5), 4.24 (ddd, 1H, *J* 8.0, 2.0, 2.0 Hz, H-4), 4.30 (dd, 1H, *J* 5.5, 3.0 Hz, H-2), 4.57 (dd, 1H, *J* 8.0, 3.0 Hz, H-3), 5.52 (d, 1H, *J* 5.5 Hz, H-1); ms, m/e (rel. intensity): 316 (0.1), 301 (66), 258 (3), 243 (3), 229 (9). Anal. calcd. for $C_{15}H_{24}O_7$: C 56.95, H 7.65; found: C 56.95, H 7.78.

6-O-[2-Hydroxy-3-(methyliminodiacetate)propyl] - 1,2:3,4-di-O-isopropylidene-α-D-galactopyranose (4a and 4b)

6-*O*-(2,3-Epoxypropyl)-1,2:3,4-di-*O*-isopropylidene-α-D-galactopyranose (**2**, 2.00 g, 6.33 mmol) and dimethyliminodiaacetate (**3**, 1.00 g, 6.2 mmol) were dissolved in ethanol (50 mL) and refluxed for 8 h. The ethanol was removed and the resultant syrup dissolved in chlor-

oform (50 mL). The chloroform layer was washed with two portions (50 mL) of saturated brine, dried over magnesium sulfate, filtered, and concentrated to give 2.95 g of a syrup. The tlc analysis confirmed the absence of starting material and showed two major components (R_f 0.41, 0.34, solvent A). The glc analysis of the product showed one major peak (>95% peak area). The ^{1}H nmr spectrum of the syrup indicates a mixture of products **4***a* and **4***b* in a ratio of 2:1 respectively. After flash liquid chromatography purification, 2.45 g of a 1:4 mixture of **4***a* and **4***b* was obtained (86%). Early and late fractions from the chromatographic separation provided small quantities of pure **4***a* and **4***b*, respectively. Short path distillation (200°C, 0.05 Torr) gave 1.85 g of pure **4***b* by ^{1}H nmr spectroscopy. The glc analysis of this component gave one peak at the same retention time observed for the product mixture. **4***a*: ir (film) ν_{max}: 1755 (C=O ester), 3500 (OH) cm^{-1}; ^{1}H nmr (270 MHz, $CDCl_3$) δ: 1.33 (s, 6H, 2C*H*$_3$), 1.45 (s, 3H, C*H*$_3$), 1.54 (s, 3H, C*H*$_3$), 2.64 (ddd, 1H, *J* 12.5, 10.0, 2.0 Hz, -C*H*-N), 3.00 (dd, 1H, *J* 12.5, 2.0 Hz, -C*H*-N), 3.39–3.79 (m, 8H, H-6, H-6′, -C*H*$_2$O, 2 × -C*H*$_2$CO$_2$Me), 3.72 (s, 6H, 2CO$_2$C*H*$_3$), 3.83 (m, 1H, C*H*OH), 3.97 (br s, 1H, H-5), 4.25 (dd, 1H, *J* 8.0, 1.0 Hz, H-4), 4.33 (dd, 1H, *J* 5.0, 2.0 Hz, H-2), 4.61 (dd, 1H, *J* 8.0, 2.0 Hz, H-3), 5.54 (d, 1H, *J* 5.0 Hz, H-1). **4***b*: ir (film) ν_{max}: 1755 (C= ester, morpholone) cm^{-1}; ^{1}H nmr (270 MHz, $CDCl_3$) δ: 1.33 (s, 6H, 2C*H*$_3$), 1.44 (s, 3H, C*H*$_3$), 1.54 (s, 3H, C*H*$_3$), 2.86 (ddd, 1H, *J* 12.5, 10.0, 2.0 Hz, C*H*-N), 3.08 (dd, 1H, *J* 12.5, 2.0 Hz, -C*H*-N), 3.39 (s, 2H, -CH$_2$CO$_2$Me), 3.40–3.79 (m, 6H, H-6, H-6′, -C*H*$_2$CO$_2$Me, -C*H*$_2$O), 3.73 (s, 3H, C*H*$_3$), 3.97 (br t, 1H, *J* 5.0, 1.0 Hz, H-5), 4.25 (d, 1H, *J* 8.0, 1.0 Hz, H-4), 4.34 (dd, 1H, *J* 5.0, 2.0 Hz, H-2), 4.63 (dd, 1H, *J* 8.0, 2.0 Hz, H-3), 4.68 (m, 1H, C*H*OR), 5.54 (d, 1H, *J* 5.0 Hz, H-1). **4***a*, **4***b* mixture: ms, *m*/*z* (rel. intensity): 477 (5), 462 (10), 445 (2), 430 (6), 418 (30), 387 (12), 386 (14).

6-O-(2-Hydroxy-3-iminodiaceto-propyl)-D-galactose (5)

Compound **4** (2:1 mixture of **4***a* and **4***b*, 10.0 g, 21.4 mmol) was dissolved in 2 N sodium hydroxide in 9:1 methanol–water (100 mL). The reaction mixture was refluxed for 4 h and cooled in an ice bath. 6 N Hydrochloric acid (60 mL) was added to give a 1 N solution, which was then refluxed for 5 h. After cooling, the solution was filtered and the filtrate was concentrated to a volume of 10 mL. Ethanol (20 mL) was added and the mixture was cooled in ice, filtered, and concentrated. The residue was taken up in ethanol and precipitation was achieved by the addition of acetone. The gummy precipitate was taken up in ethanol and treated with decolourizing carbon, and the filtrate was treated with acetone to give a gummy precipitate. This material was a foamy hygroscopic solid (7.15 g, 86%) after drying *in vacuo* (25°C, 0.05 Torr) and consisted of a mixture of α and β 6-*O*-D-galactose isomers **5**; ^{13}C nmr (100.6 MHz, main isomer) δ (D_2O): 166.7 (COOH), 98 (C-1), 71.8, 71.2 (C-5,2), 69.3, 69.2 (CHOH), 67.9, 67.2 (C-3,4), 66.7 (C-6), 63.4 (CH_2O), 57.1, 57.2 (-CH_2NH), 54.3 (NHCH_2CO_2H).

6-O-[2-Hydroxy-3-(iminodiacetic acid hydrochloride) propyl]-D-galactitol (8)

Compound **5** (0.90 g, 2.3 mmol) was dissolved in 95% ethanol (10 mL) to which was added an aqueous solution of saturated sodium bicarbonate (2 mL). To this mixture, sodium borohydride (0.50 g, 13.2 mmol) was added and allowed to stir for 2 h at room temperature. The reaction was then acidified to pH 2 (pH paper) by dropwise addition of 6 N hydrochloric acid. The solution was filtered and the solvent removed. The residue was taken up in methanol and concentrated thrice more to remove borate salts. The residue was then dissolved in ethanol–methanol (1:1), and the resultant solution was filtered and precipitated with acetone to give 0.75 g (83%) of a foamy hydroscopic solid. Attempts to crystallize the diastereomeric mixture were unsuccessful; ^{13}C nmr (100.6 MHz) δ(D_2O): 167.3 (COOH), 71.7, 71.3, 69.1 (C-5,4,3,2), 68.8, 68.6 (CHOH), 67.3 (C-6), 63.3, 63.0 (CH_2O-), 62.0 (C-1), 56.37, 57.07, (CH_2NH), 54.1, 53.9 (NHCH_2CO_2H).

Chelating chitosan derivative (7)

(a) Chitosan (0.55 g, 3.4 mmol) was dissolved in 5% aqueous acetic acid (50 mL) and the galactose derivative **5** (2.0 g, 4.9 mmol) in 5% aqueous acetic acid (10 mL) was added to the resultant stirred solution. After 15 min, sodium cyanoborohydride (1.25 g, 20.0 mmol) in 5 mL of reaction solvent was added. After stirring for 24 h, the mixture was poured into a dialysis sac and dialyzed for 6 days (6 × 2 L) against distilled water and subsequently freeze-dried to give 1.62 g (84%) of a white fluffy solid; ^{13}C nmr (100.6 MHz) δ(D_2O): 168.6 (COOH), 98.4 (C-1′), 75.9 (C-4′), 73.2 (C-5′), 71.2, 71.1 (C-5,2), 68.9 (=CHOH), 67.9, 67.4 (C-3,2), 66.7 (C-6), 63.2 (-CH_2O-), 58.7 (-CH_2NH), 56.3 (NHCH_2CO_2H), 54.7 (C-1). Anal. calcd for $C_{19}H_{34}N_2O_{14}\cdot 1.56H_2O$: C 42.06, H 6.85, N 5.16; found: C 42.06, H 7.10, N 4.81.

(b) The procedure used for the preparation of **7***b* was as described for the preparation of **7***a*, with the exception that 1.00 g (2.45 mmol) of the galactose derivative **5** was used. The resultant yield was 1.16 g (63%) of a fluffy white solid. Anal. calcd. for $[(C_6H_{11}NO_4)_{0.50}\text{-}(C_{19}H_{34}N_2O_{14})_{0.50}]\cdot 1.1\ H_2O$: C 41.98, H 6.91, N 5.88; found: C 41.98, H 7.17, N 5.85.

Reactions of benzo[*b*]thiophene with some aqueous platinum metal species at elevated temperatures

PETER D. CLARK,[1] JAMES F. FAIT, COLIN G. JONES, AND MARTIN J. KIRK
Department of Chemistry, The University of Calgary, 2500 University Drive N.W., Calgary, Alta., Canada T2N 1N4

Received July 11, 1990

PETER D. CLARK, JAMES F. FAIT, COLIN G. JONES, and MARTIN J. KIRK. Can. J. Chem. **69**, 590 (1991).

The desulfurization of benzo[*b*]thiophene **1** with aqueous transition metal species in the presence of various hydrocarbons at elevated temperatures is described. Mechanistic studies have shown that treatment of **1** with solutions of $RuCl_3$ and other platinum metal species results in the formation of 2,3-dihydrobenzo[*b*]thiophene **2** and ethylbenzene **3** as major products. Metal coordinated species are probable intermediates in the formation of **2** and hydrocarbon products. **2** readily coordinates to $PdCl_2$ to form square-planar *trans*-dichlorobis(2,3-dihydrobenzo[*b*]thiophene) palladium(II), which decomposes to ethylbenzene at 300°C. The crystal structure of the complex was determined by a single crystal X-ray diffraction study. The complex crystallized in the monoclinic space group $C\,2/c$ with $Z = 8$ in a cell of dimensions $a = 23.057\ (3)$, $b = 9.711\ (1)$, $c = 15.227\ (2)$ Å and $\beta = 99.74(1)°$. The structure was solved by the Fourier method and was refined by full-matrix least-squares calculations to $R = 0.042$ for 2537 observed data with $I > 2.5\sigma(I)$.

Key words: benzo[*b*]thiophene, desulfurization, platinum metal species.

PETER D. CLARK, JAMES F. FAIT, COLIN G. JONES et MARTIN J. KIRK. Can. J. Chem. **69**, 590 (1991).

On décrit la désulfurisation du benzo[*b*]thiophène (**1**) réalisée à températures élevées, à l'aide de solutions aqueuses de dérivés de métaux de transition, en présence de divers hydrocarbures. Les études mécanistiques ont démontré que le traitement du composé **1** avec des solutions de $RuCl_3$ ou d'autres dérivés du platine conduit principalement à la formation du 2,3-dihydrobenzo[*b*]thiophène (**2**) et de l'éthylbenzène (**3**). Il est probable que les intermédiaires dans la formation des hydrocarbures et du produit **2** soient des espèces coordinées à des métaux. Le composé **2** se coordonne facilement avec le $PdCl_2$ pour former le *trans*-dichlorobis(2,3-dihydrobenzo[*b*]thiophène) palladium(II) plan carré qui se décompose en éthylbenzène par chauffage à 300°C. On a déterminé la structure cristalline par diffraction des rayons-X par un cristal unique. Les cristaux du complexe sont monocliniques, groupe d'espace $C\,2/c$, avec $a = 23{,}057(3)$, $b = 9{,}711(1)$ et $c = 15{,}227(2)$ Å, $\beta = 99{,}74(1)°$ et $Z = 8$. On a résolu la structure par la méthode de Fourier et on l'a affinée par la méthode des moindres carrés (matrice entière) jusqu'à une valeur de $R = 0{,}042$ pour 2537 réflexions avec $I > 2{,}5\sigma(I)$.

Mots clés : benzo[*b*]thiophène, désulfurisation, dérivés du platine.

[Traduit par la rédaction]

Introduction

Catalytic hydrodesulfurization of crude oil and bitumen is practiced widely by industry in order to produce low sulfur content transportation fuels (1), and is carried out industrially by passing the sulfur-containing oil over a γ-alumina-supported cobalt–molybdenum catalyst under hydrogen pressure (2). Catalysts based on the metal sulfides of ruthenium and osmium are known (3) to be much more active than commercial catalysts but, because of cost, they have not been used industrially.

The chemical mechanisms for catalytic hydrodesulfurization of simple compounds such as thiophene have been studied in detail (4, 5). However, despite the fact that benzothiophene **1**, its derivatives, and other condensed thiophenes are present in large quantities in many crude oils, mechanisms for their desulfurization are still open to debate (6, 7). It has been proposed (7) that **1** is activated to hydrogenation and desulfurization by coordination to active sites on the metal sulfide crystallites of the catalyst. The exact mode of the coordination is unknown but could occur through π-interactions centered either on the homocyclic or heterocyclic ring or, perhaps less likely, by a σ-interaction to the sulfur atom. Recently, Angelici and co-workers (7) prepared stable complexes of **1** based on rhodium, iridium, or ruthenium in which bonding to the metal takes place through a π-interaction centered on the homocyclic ring of the molecule. In contrast, complexes of **1** claimed to possess bonding interactions directly to the sulfur atom are very labile in the presence of coordinating solvents (8). Consequently, it is probable that initial coordination of **1** at catalyst surfaces involves π-interactions of the type described by Angelici.

Catalytic hydrodesulfurization of **1** under moderate conditions produces 2,3-dihydrobenzothiophene **2** and ethylbenzene **3** (9). The exact mechanisms leading to **2** and **3** are not known but it is clear that the mode of coordination of the molecule to the catalyst surface may change when **2** is formed since its sulfur atom is much more basic than either the sulfur or π-system of **1**. A plausible mechanism for the hydrodesulfurization of **1** is initial coordination via π-interaction to the homocyclic ring, hydrogenation of the 2,3-bond, and change to coordination via the sp^3 hybridized sulfur of **2** followed by hydrogenolysis of the C—S bonds to form **3** and H_2S.

We previously described studies on the desulfurization of thiophene and derivatives with aqueous metal species (10–12). This work showed that water is involved chemically, as ^{18}O-labelled oxygen from water was found in CO_2 formed during the desulfurizations. In this report we describe studies on the desulfurization of **1** to **2** and **3** using aqueous platinum metal species in the presence of alkanes but without molecular hydrogen. These conditions, although somewhat different from those encountered during heterogeneous catalytic hydrodesulfurization, provide metal and Brønsted acid sites and thus show similarity to conditions encountered during heterogeneous catalysis. Experiments using D_2O were conducted to help determine the mechanism of formation of **2** and **3**. In addition,

complex formation between **2** and a palladium(II) species was investigated to determine if such complexes are intermediates in the desulfurization process.

Experimental

Materials

Benzothiophene **1** and platinum metal salts were obtained from the Aldrich Chemical Company and solvents were purchased from the Fisher Chemical Company. These reagents were used without further purification. **2** was prepared using the general method of Bordwell and McKellin (13).

Desulfurization experiments

1 (5.0 g, 37.3 mmol), a solution of a platinum metal chloride (3.73 mmol) in water (50 g, 2.77 M), and either hexadecane, isooctane, or tetrahydronaphthalene (220 mmol) were placed in a cap enclosure autoclave (internal volume 300 mL, fabricated from Hastelloy 276C) fitted with a Magnedrive stirrer assembly and internal cooling coil. The system was flushed with nitrogen and the stirred reaction mixture (stirring rate was 1000 rpm) was heated to the desired reaction temperature. Heat-up time to 370°C was approximately 60 min. At the conclusion of the experiment (see Tables 6 and 7 for further reaction parameters) the system was cooled to ambient conditions, the amount of produced gases was measured, and their composition was determined using standard gas chromatographic techniques. Liquid and solid products were recovered and the amount of **1** remaining and amounts of major products such as **2** and **3** were determined using gas chromatography. This analysis was conducted by injecting a sample of the liquid product onto a 10% FFAP CN Chromosorb column (3 mm × 2 m) using the following temperature program: 60°C, 2 min, 60–220°C at 10°C/min, and 220°C for 6 min. Helium carrier gas at a flow rate of 30 mL/min was used throughout the analysis; compounds were detected using a flame ionization detector and were quantified by reference to calibration samples.

GC–MS (30 m × 0.25 mm DB-5 column) was used to detect the presence of new compounds (other than **2** and **3**) in the liquid products. Most of these products were identified by reference to library spectra and unknowns were identified by analysis of their mass spectra. These products were not quantified, as in most cases they were present in small quantities. The following minor products were identified:

Benzothiophene/hexadecane experiments: C_5–C_{15} alkanes and alkenes (mostly linear compounds), alkylbenzothiophenes **4** (alkyl = C_1–C_3, position of substitution not determined).

Benzothiophene/isooctane experiments: Only compounds reported in Table 7 were detected in these experiments.

Benzothiophene/tetrahydronapthalene experiments: Naphthalene was the only other product detected in addition to those reported in Table 7.

trans-*Dichlorobis(2,3-dihydrobenzo[*b*]thiophene) palladium(II)*

2 (1.63 g, 12 mmol) was added to a stirred solution of palladium(II) chloride (0.89 g, 5 mmol) in 90% aqueous ethanol (50 mL) at 50°C. After 1 h, the deep red solid produced in the reaction was filtered off and was crystallized from ethanol/chloroform. Filtration and washing yielded deep red plates, 3.7 g, 83%, mp >250°C (dec.); IR, ν (cm^{-1}): 425 (m), 475 (m), 692 (m), 754 (s), 778 (s), 1264 (m) and 1440 (m). Anal. calcd. for $C_{16}H_{16}Cl_2PdS_2$: C 42.6, H 3.55, Cl 15.8, S 14.3; found: C 42.5, H 3.6, Cl 15.4, S, 14.5. Note: variable temperature NMR data are given in Tables 9 and 10; s, m, and w denote strong, medium, and weak absorptions.

X-ray structure determination of trans-*dichlorobis(2,3-dihydrobenzo-[*b*]thiophene) palladium(II)*

A suitable transparent block-shaped crystal was wedged in a Lindemann glass capillary and was mounted on an Enraf–Nonius CAD4 diffractometer. Unit cell parameters and their standard deviations were derived from the setting angles of 25 reflections in the range $8.84 < \theta < 18.02°$. Reduced cell calculations did not indicate any higher metric symmetry. Crystal and instrument stability were monitored throughout the measurement of 3 standard reflections every hour of X-ray exposure. There was no evidence of crystal decomposition. The net intensities of the data were corrected for reflection width, scale variation, and Lorentz and polarization effects. Variance $\sigma^2(I)$ was calculated based on counting statistics. Crystal data and experimental details are summarized in Table 1.

The structure was solved by placing palladium at the two centres of symmetry and expanding the structure by difference Fourier methods. All non-hydrogen atoms were located in difference maps after refining the scale and thermal parameters on the palladium. At this stage of the refinement all of the hydrogen atoms were located in difference Fourier maps. All non-hydrogen atoms were refined anisotropically with the hydrogen atoms included in the refinements at geometrically idealized positions with C—H bond lengths of 0.95 Å. Convergence was reached at $R = 0.042$. The final values of the refined positional parameters are compiled in Table 2. Selected bond distances, bond angles, and close contacts are summarized in Tables 3–5. Tables of hydrogen atom positions, thermal parameters, lists of bond angles and bond distances, and tables of F_o, F_c, and σF are available as supplementary material to this paper.[2] Neutral atom scattering factors were used with anomalous dispersion corrections applied (14). No corrections were made for extinctions.

All calculations were carried out on a VAX 11/780 computer using the XTAL software package (15).

NMR specta

Proton and carbon spectra were recorded on a Bruker AM-400 in deuterochloroform solution using solvent resonances as internal references. Probe temperatures were determined by reference to methanol and 1,2-dihydroxyethane chemical shift data.

Results and discussion

*Reactions of benzothiophene **1** with aqueous platinum species*

Table 6 summarizes data obtained from the reaction of **1** with aqueous platinum metal species and hexadecane at 370°C. Note that the amount of water used in these experiments ensured that liquid water was present at 370°C. One of the goals of these experiments was to determine the extent to which desulfurization of **1** occurred. Since the reactions were conducted in an autoclave fabricated from Hastelloy 276C (an alloy of nickel, cobalt, molybdenum, and other metals), the potential of the vessel walls to promote desulfurization had to be ascertained. Fortunately, this effect was minimal since very little reaction (0–5% consumption of **1**) occurred when **1** was heated at 370°C with water and a variety of hydrocarbons (see Tables 6 and 7). In addition, minimal decomposition (<1%) of the hydrocarbons was observed in these experiments.

When similar reactions were conducted with the addition of various water soluble platinum metal salts in the presence of hexadecane, significant desulfurization of **1** occurred. **2**, **3**, H_2S, and metal sulfides (identified by qualitative techniques but exact composition not determined) were the major products. Quantification of the organic products (**2** and **3**) was relatively straightforward (see experimental section) but accurate quantification of H_2S (either as the gas or as metal sulfides) was

[2]Supplementary tables of hydrogen atom parameters. non-hydrogen thermal parameters, dihedral angles, and observed and calculated structure factors have been deposited and may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of hydrogen atom parameters and dihedral angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

[a]Estimated standard deviations are given in parentheses.

impossible because of difficulties in recovering metal sulfide products adhering to the autoclave walls and in accounting for H_2S that might have reacted with autoclave components. $PtCl_4$ and $RuCl_3$ solutions caused most reaction (24 and 22% respectively). In addition to products derived from **1**, GS–MS studies indicated that a variety of alkanes and alkenes (C_1–C_{12}) were produced from the hexadecane. These analyses also revealed the presence of small amounts of alkyl-substituted (C_1–C_4) benzothiophenes **4** in the liquid phase product. Similar experiments were conducted in which **1** was heated with aqueous $RuCl_3$ and either isooctane or tetrahydronaphthalene (Table 7) at 370°C. As in experiments using hexadecane, **2** and **3** were the major products derived from **1**. However, significantly more of **1** was consumed than was observed with hexadecane (29% with isooctane and 37% for tetrahydronaphthalene). GC–MS analysis of the liquid products showed that a variety of small hydrocarbons were produced in the experiment using isooctane and that naphthalene was the major hydrocarbon product from the tetrahydronaphthalene experiment.

The question arises as to whether it is the aqueous form of the added metal species, or the metal sulfide formed during the reaction, that is responsible for the desulfurization of **1**. If the formed metal sulfide plays a major role in the desulfurization, complete consumption of **1** would be expected at longer reaction times. However, experiments using $RuCl_3$ over 8 h (Table 6) showed only slightly more reaction than experiments over 3 h (34% compared to 22%). Also, when ruthenium sulfide prepared by passing excess H_2S through aqueous $RuCl_3$ was used, in place of the aqueous salt, less reaction was observed (12% compared to 22%, Table 6). Thus, it can be concluded that the largely insoluble sulfides produced during the reaction do not promote desulfurization as efficiently as the water soluble materials.

*Mechanisms of reaction of benzothiophene **1** with aqueous metal species*

Determination of exact mechanisms is very difficult since none of the usual techniques lend themselves to detecting intermediates in autoclaves at high temperatures (370°C) and pressures (ca. 30 MPa) in what, after formation of metal sulfides, is a three-phase system. Also, the nature of solutions of platinum metal species at high temperatures has not been studied. Thus, although the data show that metal species are

important in promoting desulfurization reactions, the exact nature of the reacting species is not known. However, any mechanism must account for the reaction pathways summarized in Scheme 1; i.e., the formation of ethylbenzene **3** from **1** via the dihydro intermediate **2** with participation of aqueous metal species. Also, any mechanism should account for the source of hydrogen needed to form **2** and to hydrogenolyse C—S bonds.

Since oxidation products of **1** were not observed in any significant amount, the water and hydrocarbons used in the

experiments (hexadecane, isooctane, and tetrahydronaphthalene) are the only possible sources of hydrogen. Evidence that the hydrocarbons supply some of the required hydrogen is given by the formation of alkenes and of naphthalene. The ability of tetrahydronaphthalene to donate hydrogen is well established (16) and, at high temperatures (>400°C), this usually occurs via a radical mechanism. It is not known if radicals are involved in hydrogen transfer in this work, but the formation of unsaturated hydrocarbons is clear evidence that the hydrocarbons provide some hydrogen. Aqueous solutions of platinum metal species are acidic (a 1 M solution of $RuCl_3$ has a pH of ca. 0.9) due to solvolysis of ligated water (for general discussion and further references, see ref. 17) and thus may promote protonation of the 2,3-bond of **1**. Protonation of **1** by moist $AlCl_3$ ($H^+AlCl_3OH^-$) is well known (18) and, if duplicated by the aqueous platinum metal species in this work, would produce benzothienyl carbocations that, in turn, could abstract hydrogen from hydrocarbons present in the reaction mixture. Such a mechanism explains the formation of alkenes from hexadecane (by standard β-scission chemistry) and the production of alkyl benzothiophenes (by electrophilic attack of carbocations resulting from β-scission on **1**). Admittedly, the same products could arise by radical mechanisms.

If protonation is the initial step in the reaction sequence, it could be argued that metal species are not required and that the same reactions would be promoted by mineral acids. However, experiments using sulfuric acid to generate a pH equivalent to that obtained in the experiments using $RuCl_3$ resulted in minimal reaction (Table 6). Thus, it appears that the ruthenium plays some role in the reaction sequence. This role likely involves formation of a coordination complex between **1** and the metal species. Initially, such a complex could be of the type described by Angelici (7) in which bonding occurs through the π-system on the carbocyclic ring of **1**. However, once saturation of the 2,3-bond occurs, coordination of the metal to the molecule should be via the sp^3 lone pair of electrons on sulfur, which become available as the sulfur is removed from participation in the aromatic system.

Once formed, **2** should form complexes with platinum metal species that could be intermediates in the formation of **3**. Although many thioether complexes have been prepared (19), none in-

volving the 2,3-dihydrobenzothienyl ligand has been reported. To establish that complexes with this relatively bulky ligand can exist, **2** was reacted with $PdCl_2$. A deep red solid was quickly produced on mixing the reactants at 50°C. This compound (see later sections for full characterization) was determined to be a mononuclear, bisthioether *trans* square-planar complex in which the metal was bonded to the sulfur atom via the sp^3 lone electron pair of sulfur (see Fig. 1).

When this complex was heated at 300°C for 12 h with a 10 mole excess of water and either hexadecane or tetrahydronaphthalene, decomposition to **3**, **1**, and **2** and palladium sulfide took place. Most reaction occurred in the experiment using tetrahydronaphthalene (85%). In comparison, similar experiments with uncomplexed **2** and with no added palladium chloride did not produce **3**. These observations suggest that complexes of the type described above are intermediates in the formation of **3**. The hydrogen required to cleave the C—S bonds and form **3** could originate from either the hydrocarbon or from the aromatization of **2** to **1**. Presumably, the gain in resonance energy of stabilization for the formation of **1** is the driving force for this reaction.

The formation of alkenes and naphthalene from experiments using hexadecane and tetrahydronaphthalene established hydrogen transfer from these hydrocarbons. If the protonation mechanism suggested earlier is important, then one of the hydrogens in the dihydro product **2** should originate from water. To investigate this possibility, a series of experiments using D_2O were planned. Data from these experiments would be useful only if it could be established that H–D exchange between D_2O and **1** was insignificant at the reaction conditions used in the study. This seemed to be the case since in an experiment in which **1** and D_2O were heated at 370°C for 3 h only minimal D-incorporation was observed (Table 8, D-incorporation was calculated by analysis of mass spectra obtained from GC–MS studies). However, when **1** and D_2O were heated at 370°C in the presence of $RuCl_3$ either with or without hexadecane, unreacted **1** and the products **2** and **3** had undergone almost complete exchange (Table 8; it should be noted that the $RuCl_3$ used in these experiments contained normal water of hydration and thus complete deuteration is not possible). Earlier studies (20) showed that Ru(III) species promote exchange between D_2O and H_2O. This work shows that ruthenium species promote H–D exchange in unsaturated systems and, most likely, do so by coordination to the compounds undergoing exchange. Unfortunately, the rapid H–D exchange makes it impossible to determine whether protonation of the 2,3-bond of **1** plays any role in the desulfurization mechanism. However, based on known mechanisms (21) for H–D exchange of aromatic compounds in acidic media, one could argue that proton/deuteron addition is the mechanism of exchange in this system.

Another interesting result was that when **2** was reacted with D_2O and $RuCl_3$ under similar conditions, unreacted **2** showed minimal incorporation of deuterium whereas **1** and product **3** (formed in H-donor type reactions as discussed previously) were almost fully deuterated (Table 8). This result can be rationalized on the basis that coordination of ruthenium to **2** is necessary before H–D exchange can take place. Of course, when such coordination does take place, not only does H–D exchange occur, but desulfurization ensues and almost fully deuterated **3** is observed as the product. Interestingly, the degree of D-incorporation into the product **3** (7.7 D per molecule) is somewhat less than was observed for **3** formed in the experiment starting with benzothiophene **1** (9.4 D per molecule). This suggests that the dihydro protons already present in **2** are more difficult to exchange than the aromatic protons. Also, it should be noted that benzothiophene **1** formed from **2** had undergone considerable H–D exchange (5.0 D per molecule). As suggested

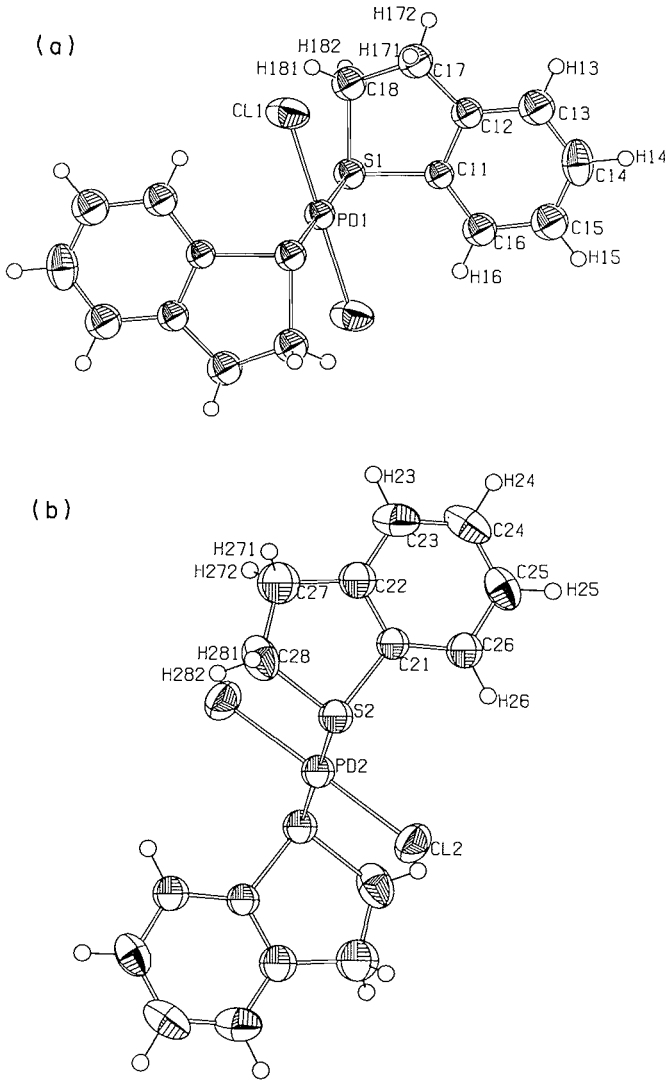

FIG. 1. (a) and (b) X-ray structures of bis-2,3-dihydrobenzo[*b*]-thienyl palladium dichloride.

earlier, **1** likely results from hydrogen donation from one molecule of the dihydro compound **2** to another undergoing desulfurization to **3**. It appears that the donor molecule must be activated towards H–D exchange during this process as it was shown that, in the absence of ruthenium species, **1** did not undergo H–D exchange (see Table 8).

X-ray study of trans-*dichlorobis(2,3-dihydrobenzo[*b*]-thiophene) palladium(II)*

Bond lengths, bond angles, and close contacts of atoms are compiled in Tables 3–5. Two discrete molecules were found in the unit cell and these structures are illustrated as ORTEP plots in Figs. 1a and 1b. The two molecules differ in a number of respects and each displays a variety of intramolecular and intermolecular hydrogen–chlorine contacts. Each molecule has a basic square-planar structure with like ligands *trans* to one another and Pd—S bond lengths of 2.320 (1) Å. This value is very close to the value obtained in other Pd–thioether complexes (2.30 Å, ref. 19) and only slightly shorter than the value obtained by summation of the Pauling radii (2.35 Å). The Cl—Pd—S bond angles of each molecule (Cl(1)—Pd(1)—S(1), 84.63, 95.37°, and Cl(2)—Pd(2)—S(2), 85.25, 94.75°) show that the chlorines are skewed towards the 2,3-dihydro portions

[c]Either none, or very minimal quantities, of these products were formed.

of the sulfur ligands. The through-space close contacts between the chlorines and the dihydro hydrogens (Cl(1)—H(181), 2.654 Å and Cl(2)—H(282), 2.699 Å) suggest that interactions between these atoms control the conformation of the molecule. The slightly different C—S—C bond angles for each molecule (C(11)—S(1)—C(18), 90.9°, and C(21)—S(2)—C(28), 92.3°) are most likely a consequence of different Cl—H interactions in each species. Besides the intramolecular close contacts, there are close contacts between the chlorines and hydrogens of the two molecules in the unit cell. The most marked of these is the interaction between Cl(2) and H(15) (2.661 Å).

NMR spectra of trans-*dichlorobis(2,3-dihydrobenzo[*b*]-thiophene) palladium(II)*

The ^1H and ^{13}C NMR data for the Pd complex recorded at temperatures between 228 and 330 K are compiled in Table 9. ^1H NMR spectra of metal–thioether complexes are often complicated by inversion of the sulfur-containing ligand about the sulfur lone electron pairs. This phenomenon has been investigated by Abel *et al.* (22, 23). In this case, inversion of the benzothienyl ligands causes broad signals for the dihydro protons at temperatures above 273 K. These signals begin to coalesce and sharpen at 330 K. ^1H NMR spectra at 250 K show sharp signals for all protons, indicating that inversion of the ligands at this temperature is slow. These results are shown in Fig. 2. At most temperatures, one of the aromatic protons is observed as a doublet ($J = 7.9$ Hz; this value is typical of *ortho* couplings in these systems) well downfield (centered at 7.82 ppm at 273 K) of the other aromatic protons. This coupling pattern suggests that this signal is due to either H-4 or H-7 *ortho* coupled to either H-5 or H-6. It is very likely that this downfield signal is due to H-7 as a result of interaction with an adjacent chlorine. However, obtaining absolute evidence to assign H-4 or H-7 proved quite difficult.

At low temperatures, signals for the dihydro protons on C-2 and C-3 occur as four complex multiplets, each of which integrate as one proton (see Fig. 2). Potentially, irradiation of the proton resonances on C-3 could cause an enhancement of the signal for H-4 and thus allow an assignment of H-4 and H-7. A ^1H–^{13}C correlation experiment was conducted to determine the assignment of the dihydro protons at C-2 and C-3. These data showed that, at 228 K, the resonances centered at 3.0 and 4.0 ppm were associated with one carbon (either C-2 or C-3) and the resonances at 3.25 and at 3.58 ppm were associated with the other. Unfortunately, because of the large chemical shift

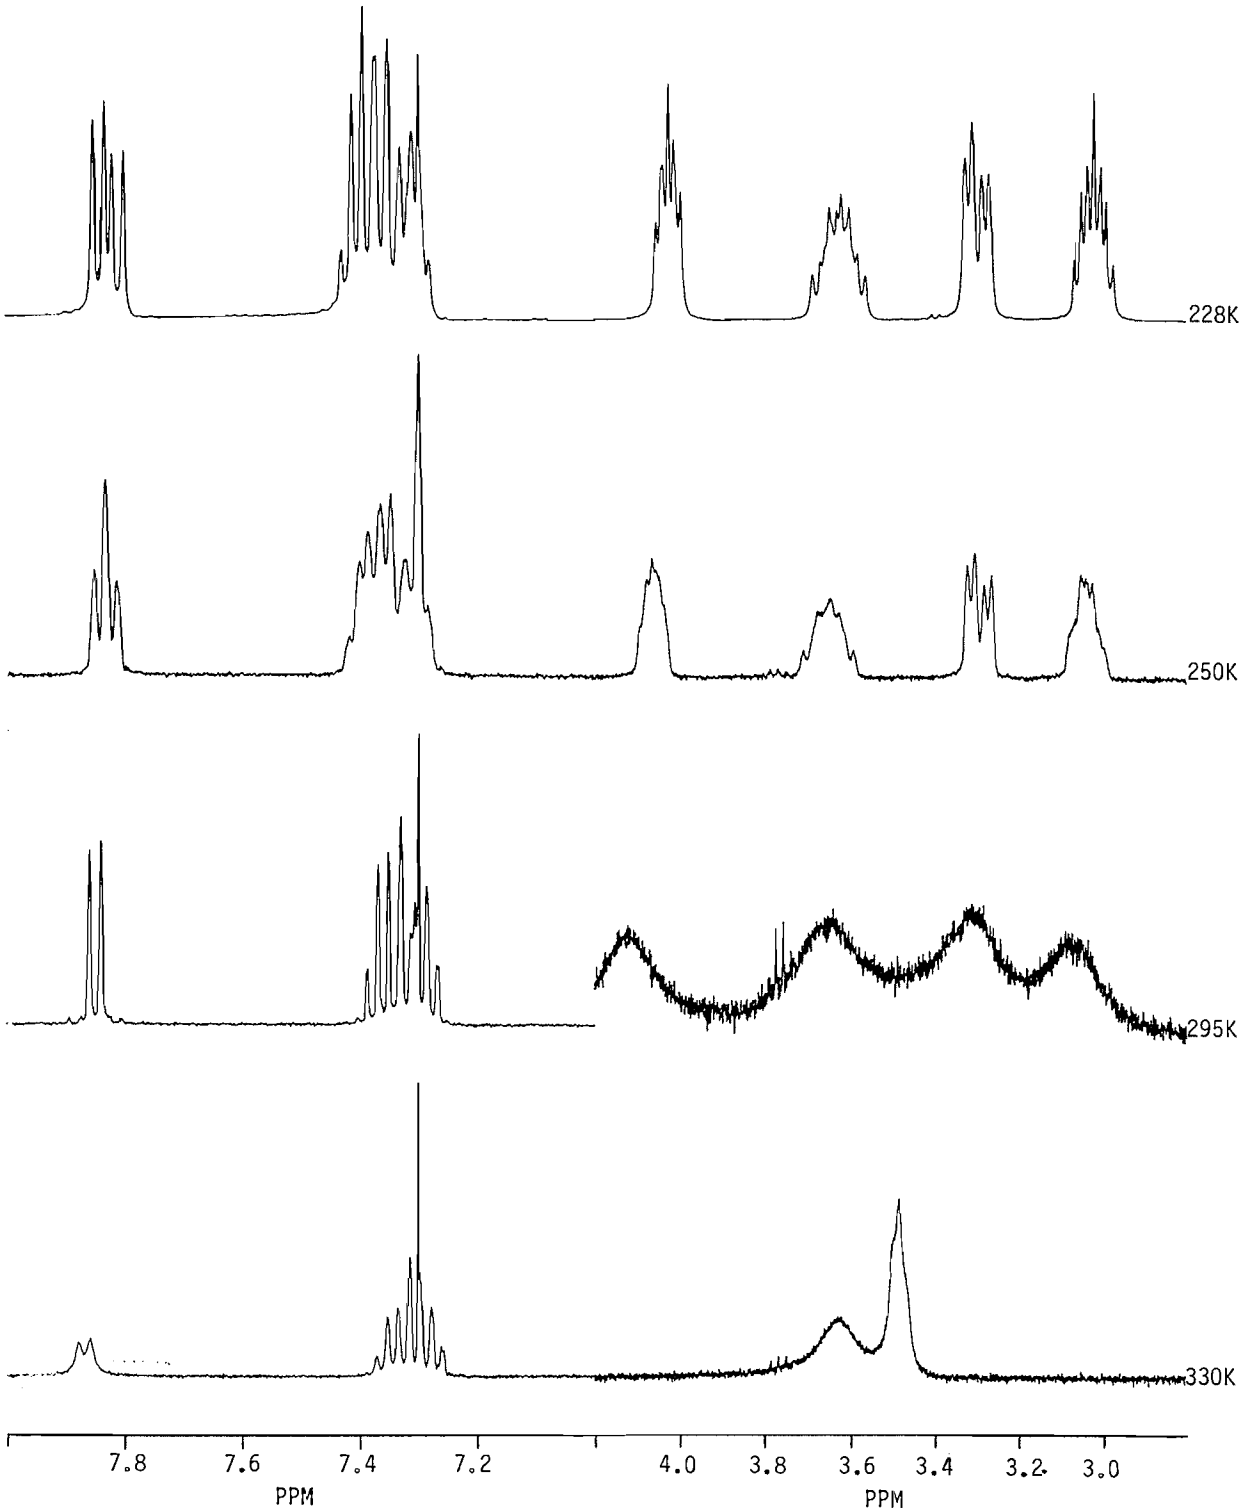

FIG. 2. Variable temperature ^{1}H NMR spectra of bis-2,3-dihydrobenzo[*b*]thienyl palladium dichloride.

differences of these proton resonances, nuclear Overhauser type experiments gave no clear assignment of H-4 and H-7. Other NMR techniques that could have resolved the assignment of H-4 and H-7, such as $^{13}C-^{13}C$ connectivity, proved impractical because of the insolubility of the complex.

Having exhausted the NMR spectroscopic techniques available to us for the assignment of H-4 and H-7, *trans*-dichlorobis-(2,3-dihydro-4-methylbenzo[*b*]thiophene) palladium(II) was synthesized. According to molecular models, the methyl substituent in this compound should have little effect on the overall geometry and the ^{1}H NMR spectrum should still show a downfield shift for H-7 because of close contact to the ligated chlorine. These predictions were borne out, as the ^{1}H NMR spectrum of the 4-methyl complex included an *ortho*-coupled doublet (J = 8 Hz) at 7.7 ppm. Full spectroscopic details and properties of the 4-methyl complex will be reported separately.

Having established that the signal at 7.8 ppm is most probably due to H-7, it is worthwhile to comment on the appearance of

[b]Two resonances were observed due to the presence of non-equivalent invertomers.

this resonance at low temperatures. At 250 K, the signal due to H-7 changed from the doublet observed at higher temperatures to a three-line resonance. At still lower temperatures further resolution of the signal occurred, so that at 228 K a pair of doublets was observed (each pair of lines separated by 7.9 Hz). The other resonances of the spectrum also changed as the temperature was lowered (see Fig. 2) although, because these signals occurred as complex multiplets, it was difficult to assign the exact changes. One explanation for these observations is that at 228 K the inversion of the benzothienyl ligands has ceased, and that each invertomer was observed.[3] Thus, the pairs of doublets centered at 7.8 ppm are simply the resonances of H-7 for each invertomer. Clearly, each invertomer must have a slightly different structure and, if this is the case, such differences should also be evident in a low temperature ^{13}C NMR spectrum. At 298 K, the proton decoupled ^{13}C spectrum is as expected (see Table 10). However, at 210 K, each of the eight lines observed at 298 K becomes split into two signals. When the same sample was warmed back to 298 K the normal eight-line spectrum was obtained. One further unusual feature of the ^{1}H spectra was that *meta* coupling of H-7 to H-5 could not be observed at any temperature. A possible explanation may be that the presence of two almost identical invertomers caused sufficient line broadening to wash out this small (ca. 2 Hz) coupling.

[3]One referee suggested that the spectra might be explained by the presence of rotamers.

The preceding data show that two structurally different invertomers are present in a solution of the complex but do not indicate what the differences are. This parallels the behaviour in the solid state. As for the structures found in the solid, the differences in solution may be controlled by interactions between hydrogens of the benzothienyl ligands and the chlorine substituents. Certainly, interactions between H-7 and chlorine in the complex must be quite significant, as uncomplexed 2,3-dihydrobenzothiophene has no signals downfield of 7.3 ppm in its ^{1}H NMR spectrum, whereas H-7 for the complexed ligand occurs at 7.8 ppm.

Conclusions

It has been demonstrated that benzothiophene **1** can be desulfurized using aqueous platinum metal species. The dihydro intermediate **2** is an important intermediate in the production of **3**. Experiments using D_2O suggest coordination of the metal species to **1** and **2** promotes the desulfurization reactions. The initial mode of coordination was not determined but σ-complexes via the sulfur atom of the 2,3-dihydro intermediate **2** are likely involved in the formation of **3**.

Kinetic and electrochemical analysis of Ni(II) reduction at the dropping mercury electrode in the presence of thiourea

ROSA M. VILLAMAÑÁN AND FERNANDO MATA-PÉREZ[1]

Departamento de Química-Física, Universidad de Valladolid, 47005 – Valladolid, Spain

Received May 1, 1990[2]

ROSA M. VILLAMAÑÁN and FERNANDO MATA-PÉREZ. Can. J. Chem. **69**, 599 (1991).

A study of the two polarographic prewaves of the Ni(II)–thiourea system has been made. The results were analysed by determining Koutecky's parameter from the ratio of the limiting current of the prewaves and the main wave. This parameter is considered an experimental rate constant and the influence of different variables on its value was analyzed. An electrochemical study of the prewaves was also made. Two formal mechanisms to explain both prewaves are proposed.

Key words: polarographic prewaves, electrochemical kinetics, reaction mechanisms.

ROSA M. VILLAMAÑÁN et FERNANDO MATA-PÉREZ. Can. J. Chem. **69**, 599 (1991).

On a réalisé une étude des deux pré-vagues polarographiques du système Ni(II)–thiourée. On a analysé les résultats en déterminant le paramètre de Koutecky à partir du rapport entre le courant limitant des pré-vagues et celui de la vague principale. On doit considérer ce paramètre comme une constante de vitesse expérimentale et on a analysé les effets de diverses variables. On a aussi réalisé une étude électrochimique des pré-vagues. On propose deux mécanismes formels qui expliquent l'apparition des deux pré-vagues.

Mots clés : pré-vagues polarographiques, cinétique électrochimique, mécanismes réactionnels.

[Traduit par la rédaction]

Introduction

In recent years, catalytic processes involving the discharge of metal ions in the presence of various additives have attracted the attention of chemists, and different experimental electrochemical techniques have been used to gain information about them. The most fruitful results have been obtained by means of polarography for several reasons (1). When Ni(II) ions are discharged on a dropping mercury electrode (DME) in aqueous solution, thiourea (Tu) exhibits a catalytic effect associated with the formation of electrochemically active species (1). We have shown (2), using different criteria, that the two prewaves observed in the polarograms exhibit a catalytic character, although the second prewave also has a small diffusive character.

Different papers (1–9) have appeared in the literature on the Ni(II)–Tu system, but only a schematic view of the mechanism has been given by refs. 1 and 4. In spite of its importance, the details on the formation of electrochemically active complexes responsible for the appearance of both prewaves are far from being clear. Thus we should first explore the characteristics of the kinetics of these discharges. From our experience with other systems (10, 11), we suggest that one can use Koutecky's parameter, x, as an experimental rate constant, implying that we employ a relaxation method. The study of the x-dependence of the different experimental variables is, in our opinion, a good way to understand the mechanism of this type of reaction. An electrochemical analysis of the prewaves is also made. Thus this paper is on a kinetic and electrochemical study of the Ni(II)–Tu system to enable us to improve the formulation of the reaction mechanisms responsible for the appearance of each prewave.

Experimental

Experimental conditions were optimized to resolve the two catalytic prewaves. Reagents used were Merck ($Ni(NO_3)_2$, Tu) and Panreac ($LiNO_3$, $NaNO_3$, KNO_3, $CsNO_3$, KOH, and HNO_3) of analytical grade.

The prewaves of Ni^{2+} ($1.3 \times 10^{-4} - 5.0 \times 10^{-4}$ mol dm^{-3}) were investigated in the presence of excess Tu ($3.4 \times 10^{-3} - 8.0 \times 10^{-2}$ mol dm^{-3}). An excess of electrolyte in the solutions was achieved by using KNO_3 ($LiNO_3$, $NaNO_3$, $CsNO_3$), at the time it provided a constant ionic strength conditions, I (0.1–0.5 mol dm^{-3}). Solutions were prepared from fresh twice distilled water. To avoid hydrolysis of Ni^{2+}, the pH of the solutions was maintained between 3.0 and 8.0. The acidity was adjusted to the desired values using very dilute solutions of HNO_3 and KOH. Oxygen in solutions was removed with a stream of purified nitrogen. The polarographic cell was thermostated from 293.15 to 304.15 K.

Polarographic measurements were made using a Radiometer-PO4g instrument equipped with a drop-life-timer unit. The drop life time was changed from 0.3 to 3.0 s, the blanking time is 80%. The sweeping rate was 0.4 V/min, and the voltage range between −0.3 and −0.6 V. Polarograms were recorded using a DME vs. the saturated calomel electrode (SCE), which was used as a reference electrode. Average currents were corrected for the residual current at given potentials.

Because of the sensitivity of catalytic prewaves to experimental conditions (12), heights of both first and second prewaves was recorded several times under a set of given conditions. The agreement between the experimental values was, in general, satisfactory and their average was taken.

Results

It seems reasonable to consider the appearance of a prewave as a special case of the irreversibility of the overall wave. Therefore we have taken the ratio $\bar{i}_k/\bar{i}_d$ ($\bar{i}_k$: limiting current for the first prewave, $\bar{i}_d$: limiting current for the main wave) and $\Sigma\bar{i}_k/\bar{i}_d$ ($\Sigma\bar{i}_k$: limiting current for the second prewave) as a function of $F(x)$ of the Koutecky's (13, 14) parameter x. Koutecky's tables contain a limited number of values for this parameter that are inadequate for our purpose. Our required x values were calculated using the following equation:

$$[1] \quad F(x) = (7\pi/12)^{1/2} \times \exp(7/12\, x^2)\, \mathrm{erfc}\, [(7/12)^{1/2}\, x]$$

In practice, values of $F(x)$ were determined experimentally and x values were obtained from eq. [1]. A similar equation has been used by different groups of researchers (15–18) and we have shown (2) that one can use this equation for determining parameter x for the present Ni(II)–Tu system. The meaning of this parameter depends on the rate-determining step of the

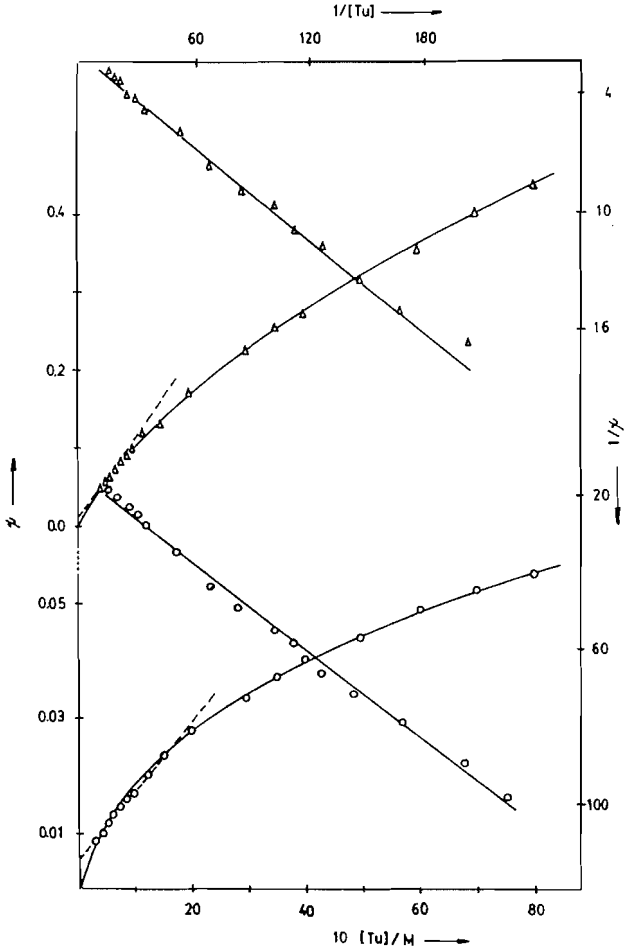

FIG. 1. Dependence of Koutecky's parameter x on the Tu concentration for the first prewave (○) and the second prewave (△). [Ni(II)] = 1.0×10^{-3} M; [Tu] = 5.0×10^{-3} M; [KNO_3] = 0.2 M; pH = 6.0.

mechanism, but in all cases x actually has all the characteristics of an experimental rate constant. The influence of different variables on this parameter has been analyzed to elucidate the reaction mechanism responsible of the appearance of each prewave.

The values of x obtained at different concentrations of Tu are given in Fig. 1. Analysis of these results leads to the following equations:

$$[2] \quad x_I = \frac{2.66[Tu]}{1 + 45.51[Tu]} \quad \text{and} \quad x_{II} = \frac{13.13[Tu]}{1 + 23.58[Tu]}$$

where I and II denote the first and second prewaves, respectively. Equations [2] have the formal structure of Langmuir's isotherm if it is assumed that Koutecky's parameter is proportional to the surface concentration of Tu. These equations are therefore evidence that both the first and second prewaves have a surface nature (5). Parsons and Symons (19) found that Tu adsorption can be expressed by a Frumkin isotherm. However, there is no unanimous view in the literature concerning the choice of isotherm for Tu. For example, Shopink *et al.* (20) described the adsorption of Tu in terms of Langmuir's isotherm. For [Tu] < 0.1 mol dm^{-3}, Lebedeva *et al.* (6) also found that the limiting current vs. [Tu] curve agrees better with Langmuir's isotherm than with Frumkin's isotherm. The causes of these disagreements have been discussed in detail (21). One

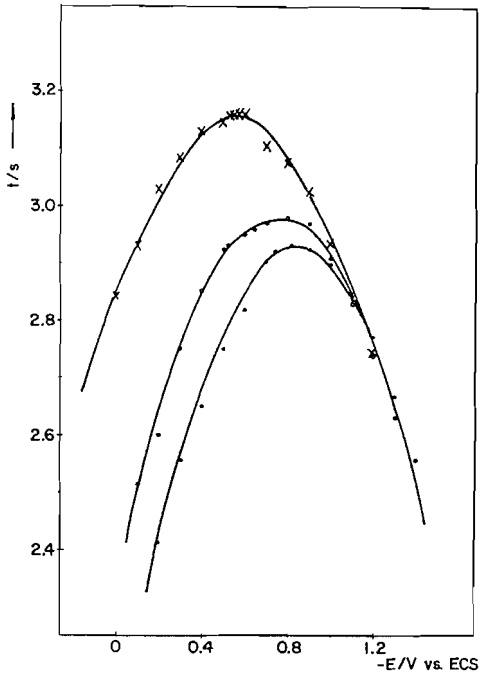

FIG. 2. Electrocapillary curves. (×): [KNO_3] = 0.2 M; (○): [KNO_3] = 0.2 M + [Tu] = 0.1 M; (●): [KNO_3] = 0.2 M + [Tu] = 0.1 M + [Ni(II)] = 0.001 M.

should note the sensitivity of the form of the isotherm to experimental conditions, in particular, to the drop formation time. This allows us to conclude that, under our experimental conditions, Langmuir's adsorption model is valid. In Fig. 1 the linear portion of the x vs. Tu concentration function remains valid if the reaction takes place partially or completely in the adsorption layer under the conditions of Henry's isotherm. The concentration interval where that occurs is greater for the first prewave than for the second. Let us examine the potential range where the prewaves are located. The first prewave is located ($E_{1/2} = -0.62 \pm 0.02$ V vs. SCE, t = 3 s) in the vicinity of the point of zero charge (p.z.c.) where the coverage of the DME surface by Tu is at a maximum. In contrast, the second prewave is located ($E_{1/2} = -0.83 \pm 0.02$ V vs. SCE, t = 3 s) in a potential range where that coverage is small. For comparative purposes the electrocapillary curves were obtained (Fig. 2), our results (p.z.c. values) are in good agreement with those found by Parsons and Symons (19). From radiotracer studies the adsorption equilibrium of Tu on iron was observed to take place within 5 min of the imposition of potentiostatic control (23). Hence one can consider that adsorption of Tu on the DME very quickly attains equilibrium conditions as the linear dependence of x vs. $t^{1/2}$ (Fig. 3) strongly suggests (24).

No changes were observed for the x values when the Ni(II) concentration was changed from 5.0×10^{-4} to 1.3×10^{-3} mol dm^{-3}.

In this work the range of pH is conditioned by both the protonation of Tu (which takes place (3) below pH = 1.0) and by the hydrolysis of Ni(II) ions; the latter being important for pH > 8.0. All experiments, however, were conducted in the range 3.0 < pH < 8.0. Under these conditions, the analytical Tu concentration equals, in practice, the concentration of the alkaline form of Tu, as one may deduce from the pK_a value reported for this compound (3). It is also possible to deduce that $1/[Tu]_s$ ($[Tu]_s$ = surface concentration of Tu) should be

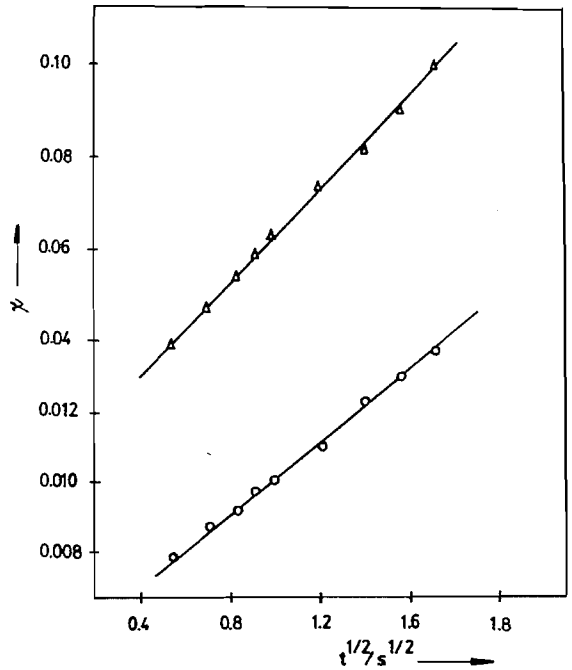

FIG. 3. Dependence of x on the drop life time for the first prewave (○) and the second prewave (△). [Ni(II)] = 1.0×10^{-3} M; [Tu] = 5.0×10^{-3} M; [KNO_3] = 0.2 M; pH = 6.0; T = 298.15 K.

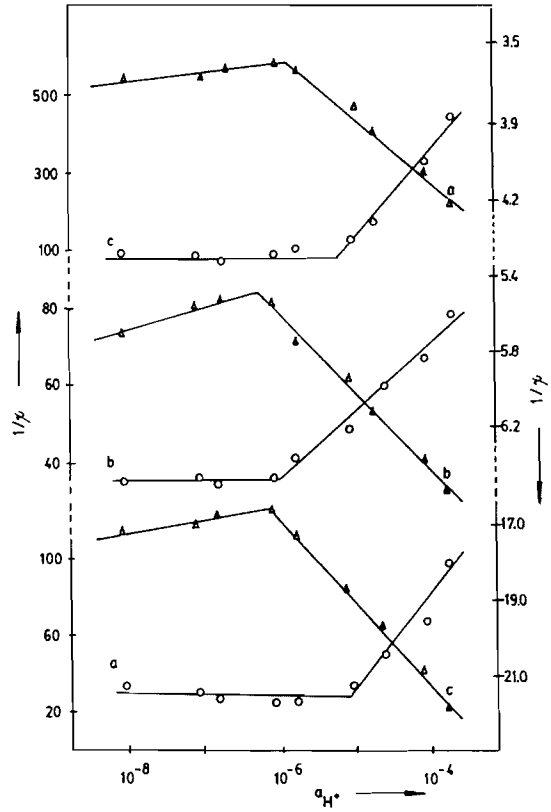

FIG. 4. Dependence of $1/x$ on proton activity for the first prewave (○) and the second prewave (△). [Ni(II)] = 1.0×10^{-3} M; [KNO_3] = 0.2 M; pH = 6.0; T = 298.15 K; [Tu]: (*a*) 4.0×10^{-2} M, (*b*) 2.0×10^{-2} M, (*c*) 5.0×10^{-3} M.

proportional to the activity, a_{H^+}. Hence, a plot of $1/x$ vs. a_{H^+} should be a straight line. However, this relation was not obtained (Fig. 4). A possible explanation is that the mechanisms which explain the appearance of both prewaves are preceded by an acid-catalyzed dehydration of $Ni(H_2O)_6^{2+}$ species (10, 11).

The dependence of x on the ionic strength (I) was also studied within the range 0.1 to 0.5 mol dm^{-3}, KNO_3 being the supporting electrolyte. A tentative fit of log x vs. $\sqrt{I}/(1+\sqrt{I})$ was made by using Guggenheim's correction (25) of the Debye–Hückel theory. In Table 1 the fit functions are given. There is no evidence of a kinetic salt effect for the reaction responsible for the first prewave. However, our results strongly suggest the existence of a kinetic salt effect for the reaction responsible for the second prewave. A high value of about −5 was found for the z_+z_- product. This number has to be taken with care because it could be the result of the limited validity of the Debye–Hückel–Guggenheim formula for interpreting the activity coefficients of reacting molecules and of the transition state. However, the unambiguous negative value of this product shows that the process responsible for the second prewave is partially controlled by a reaction between two species of opposite charge.

The double-layer effect (Ψ-effect) on the kinetics of this system was studied to determine the charge of the polarographic active compound (PAC) for both prewaves. In Fig. 5*a* plots of ln x vs. Ψ are given. The Ψ values were taken from Russell's tables (26) for the potential values (vs. SCE) of -0.65 ± 0.02 and -0.90 ± 0.02 V for the first and second prewaves, respectively. These potentials correspond to the limiting currents when serious interferences are not predicted (27). A charge of +1.35 was found for the polarographic active compound responsible for the second prewave. However, from our results no evidence for an Ψ-effect was found for the first prewave. This fact can be explained because the potential of −0.65 V is very close to the p.z.c. which is located (19) at about −0.58 V

for similar conditions. Russell's table has also been used by other researchers (4, 5) for this system. However, the Ψ values of Russell's table were obtained for the mercury – aqueous NaF interface according to the Gouy–Chapman theory with the assumption of no specific adsorption of sodium or fluoride ions. For all these reasons, these values are only an approximation to the actual potentials on the outer Helmholtz plane for a given electrolyte (KNO_3) under our experimental conditions. Hence, the preceding conclusions on the Ψ effect have to be taken with caution.

It is well known (28) that an increase in the concentration

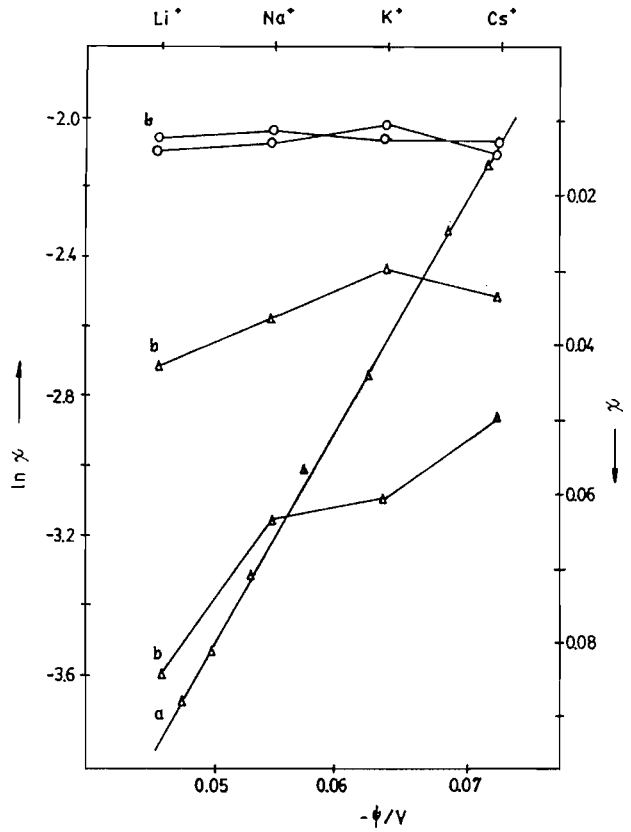

FIG. 5. Dependence of Koutecky's parameter x on the potential of the Helmholtz plane (a) for the second prewave (△), and on the cation nature (b) for the first prewave (○). [Ni(II)] = 1.0×10^{-3} M; [Tu] = 5.0×10^{-3} M; I = [XNO$_3$] = 0.2 M; pH = 6.0; T = 298.15 K.

of anions of the supporting electrolyte which are surface-active species gives rise to an increase in the limiting currents of the prewaves. Under our working conditions we have confirmed the adsorption of NO_3^- on the DME (22) using Langmuir's isotherm. The specific adsorption of this species is a factor that change the double-layer structure and, consequently, the potential on the outer Helmholtz plane. However, Parsons and Symons (19) found that the adsorption of NO_3^- species is reduced in the presence of Tu. Bockris *et al.* have shown (29) that the adsorption of NO_3^- is not important for $[NO_3^-] \leqslant 0.5$ mol dm^{-3}; so the adsorption of NO_3^- on the DME will have little effect on the magnitude of Koutecky's parameter. The only relevant role of anion of the supporting electrolyte appears to be conditioning the charge of the PAC (10, 11); this may be due to the association process of Ni^{2+} species with these anions in the surface layer (14). On the other hand, the effect of cation of the supporting electrolyte on the x values is only noticeable for the second prewave (Fig. 5b). This conclusion results from specific cation adsorption (3) because the second prewave is not located in the vicinity of p.z.c.

Our results on the effect of temperature on x allow us to determine both the activation enthalpy $\Delta H^{\neq}$ and the activation entropy $\Delta S^{\neq}$; these are given in Table 2. The existence of a compensation effect was confirmed, and the isokinetic temperature T_{iso} was determined.

$E_{1/2}$ values change with the drop life time, t. This is a sign that the electrode process is irreversible. Consequently the irreversibility of the polarographic curve was analyzed. Plots of $\ln \bar{i}/(\bar{i}_d - \bar{i})$ vs. $-E$ for different Tu concentrations are given

in Fig. 6. The hyperbolic profile is characteristic of a quasi-reversible process (30). Using Koryta's criterion (31), extrapolation of the first part of the plot gives $E_{1/2}$ for reversible conditions. From the slope of the same plot, we obtain the number of electrons, n, participating in the charge transfer process. Moreover, from the second part of the plot, both the transfer coefficient, α, and $E_{1/2}$ irreversible were obtained. Table 3 summarizes all these results.

The method described by Bard and Faulkner (32) was used to calculate the exchange current, i_0. It was thus verified that $\ln (\bar{i}_d - \bar{i})/\bar{i}$ vs. η (overpotential) are linear functions in the Tafel region under our experimental conditions (correlation coefficients >0.99). From the respective intercepts i_0 values

were obtained. Plots of ln i_0 vs. ln [Ni(II)] are linear (Fig. 7). The slopes are 1.0, an additional positive feature of the analysis.

In the region $\eta \rightarrow 0$ the stoichiometric number, ν, was determined from plots of η vs. $\bar{i}$. These plots yield $\nu = 1$, as Table 4 shows. However this analysis was only done for the first prewave, since η vs. $\bar{i}$ and i_0 are not sufficiently accurate for the second prewave.

Formal mechanism

The dependence of x on [Tu] shows that charge transfer is not (34) the rate-determining step for the reactions responsible for the appearance of the prewaves. On the contrary, the forms of eqs. [2] are consistent with the surface nature of both prewaves.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

Moreover, the electrocapillary curves (Fig. 2), together with the dependence of both $\Sigma \bar{i}_k$ and x_{II} on the nature of the cation species of the supporting electrolyte (Fig. 5*b*), are additional proofs of our thesis.

Figure 4 confirms that the alkaline form of Tu is the adsorbed species on the DME. From FTIR studies (24) it has been proved that the sulfur atom is attracted to the electrode surface by strong chemical interaction forces and not through electrostatic interactions as proposed by Parsons and Symons (19). On the other hand, the NO_3^- species are also adsorbed on the DME (19, 29), and a competitive process exists between these ions and the Tu molecules. Figure 8 shows the existence of this co-adsorption phenomenon.

Pulse polarograms for Ni^{2+}/Tu system show three distinct signals at certain ligand concentrations (33). However no comprehensive constants are given for the formation of the corresponding polarographic active compounds that can explain these signals.

Although our interest is centered on the two prewaves, a few considerations on the processes responsible for the main wave are given. The formal mechanism explaining the appearance of the main wave consists (10, 11, 34, 35) of diffusion and dehydration (acid catalyzed) by partial loss of water molecules of the $Ni(H_2O)_6^{2+}$ species, and the discharge of $Ni(H_2O)_x^{2+}$ species on the DME:

$$[3]\quad [Ni(H_2O)_6^{2+}]_{BS} \xrightarrow[\text{Slow}]{\text{Diffusion}} [Ni(H_2O)_6^{2+}]_{DLL} \underset{\text{Fast}}{\overset{\text{Adsorption}}{\rightleftharpoons}} [Ni(H_2O)_6^{2+}]_{ES}$$

$$H^+ \downarrow \text{ Fast}$$

$$[4]\quad [Ni(H_2O)_x^{1+}]_{ES} \xleftarrow[\text{Main wave}]{1\ e^-} [Ni(H_2O)_x^{2+}]_{ES} + (6-x)H_2O$$

$$[5]\quad 2[Ni(H_2O)_x^{1+}]_{ES} \underset{}{\overset{\text{Fast}}{\rightleftharpoons}} [Ni(H_2O)_x^{2+}]_{ES} + Ni(Hg)$$

where BS is bulk solution, DLL is double layer limit, and ES is electrode surface.

The formulation of the discharge giving the Ni(I) species (reaction [4]) is in agreement with our preceding results (10, 11); it has also been postulated by other workers (35).

The mechanism which explains the origin of the first prewave is:

$$[6]\quad [Ni(H_2O)_x^{2+}]_{ES} + [Tu]_{ES} \xrightarrow{\text{Slow}} [Ni(H_2O)_{x-1}Tu^{2+}]_{ES} + H_2O$$

$$1\ e^- \downarrow \text{ First prewave}$$

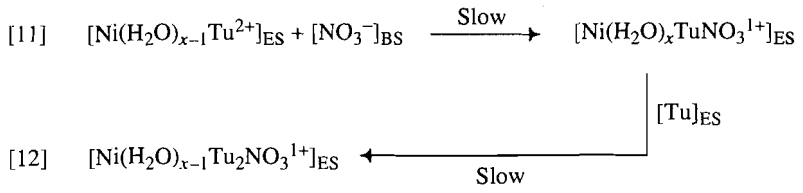
$$[7]\quad [Ni(H_2O)_{x-1}{}^{1+}]_{ES} + Tu \leftarrow$$

The discharge is a one-electron step (Table 3), its stoichiometric number being $\nu = 1$. Aggarwal and Crow (36) have studied the electrochemical behaviour of the Ni^{2+} species at the DME for several complexing ligands. Heterocyclic ligands share a common feature that their reduction involves two electrons. This contrasts with the other systems (e.g. Ni^{2+}/Tu) for which the transfer of one electron is involved. Reduction of the complex $[Ni(H_2O)_xTu^{2+}]_{ES}$ produces unattached ligand molecules which can be adsorbed immediately on the electrode surface. The reaction of adsorbed aquo-ions $[Ni(H_2O)_x^{2+}]_{ES}$ with adsorbed Tu is slower than the electron transfer process. Thus, the surface nature of the first prewave is explained. Regeneration of Tu occurs (reaction [7]) and this implies a catalytic character for the first prewave as found for other systems (37–39).

No other ionic species are implied in this formulation. This is consistent with the absence of a kinetic salt effect for the reaction responsible for the first prewave. In this case, co-adsorption of the NO_3^- species appears to be kinetically irrelevant.

The appearance of the second prewave can be explained, in a similar manner, as follows:

$$[8]\quad [Ni(H_2O)_xTu^{2+}]_{ES} + [Tu]_{ES} \xrightarrow{\text{Slow}} [Ni(H_2O)_{x-1}Tu_2{}^{2+}]_{ES} + H_2O$$



$$\text{I} \downarrow$$

$$[9]\quad [Ni(H_2O)_{x-1}Tu^{1+}]_{ES} + Tu \xleftarrow[\text{Second prewave}]{1\ e^-}$$

$$[10]\quad 2[Ni(H_2O)_{x-1}Tu^{1+}]_{ES} \underset{}{\overset{\text{Fast}}{\rightleftharpoons}} [Ni(H_2O)_{x-1}Tu^{2+}]_{ES} + Ni(Hg)$$

The experimental value of +1.35 for the electric charge of PAC I could be a consequence of the NO_3^- effect. The existence of the $Ni(H_2O)_xNO_3^{1+}$ species (39) has been confirmed. In this case, the existence of similar compounds seems to be unlikely from the dependence of x on the NO_3^- concentration. However, the kinetic salt effect for the reaction responsible for the second prewave points to the existence of a reaction where two species of opposite charges participate. On the other hand, the second prewave has a partial diffusive character. All these facts suggest that the PAC could be alternatively formulated as:

The NO_3^- species diffuses from the bulk solution to the electrode surface. Hence, the second prewave has a partial diffusive character. On the other hand, this alternative formulation for PAC reasonably explains the value of +1.35 found for its electric charge.

Ionic dissociation in complexes of iodine with triphenylarsine and triphenylstibine

YING RU ZHANG, IRA SOLOMON, AND SEYMOUR ARONSON[1]
Department of Chemistry, City University of New York, Brooklyn College, Brooklyn, NY, U.S.A. 11210
Received, July 6, 1990

YING RU ZHANG, IRA SOLOMON, and SEYMOUR ARONSON. Can. J. Chem. **69**, 606 (1991).

An electrochemical technique has been employed to study the ionization of the iodine complexes of $(C_6H_5)_3As$, $(C_6H_5)_3Sb$, and pyridine. Several different ionization mechanisms are proposed depending on the chemical nature and concentration of the reactants. A new ionic complex, $(C_6H_5)_3MI_2^{2+}$ is postulated for the interaction of iodine with $(C_6H_5)_3As$ and $(C_6H_5)_3Sb$ at high iodine concentrations. Equilibrium constants have been calculated from the emf data for the various ionization steps.

Key words: triphenylarsine, triphenylstibine, iodine, complex formation, ionization.

YING RU ZHANG, IRA SOLOMON et SEYMOUR ARONSON. Can. J. Chem. **69**, 606 (1991).

On a utilisé une technique électrochimique pour étudier l'ionisation des complexes de l'iode avec le $(C_6H_5)_3As$, le $(C_6H_5)_3Sb$ et la pyridine. On propose plusieurs mécanismes d'ionisation suivant la nature chimique et la concentration des réactifs. À des concentrations élevées d'iode, on suggère l'implication d'un nouveau complexe ionique, $(C_6H_5)_3MI_2^{2+}$, pour l'interaction entre l'iode et le $(C_6H_5)_3As$ ou le $(C_6H_5)_3Sb$. En se basant sur les fem des diverses étapes d'ionisation, on a calculé les constantes d'équilibre.

Mots clés : triphénylarsine, triphénylstibine, iode, formation de complexes, ionisation.

[Traduit par la rédaction]

Introduction

Several investigators have studied the interaction of iodine with $(C_6H_5)_3As$ and $(C_6H_5)_3Sb$ in organic solution. The spectroscopic studies of Bhaskar *et al.* (1) and Bhat and Rao (2) in CCl_4 and $CHCl_3$ demonstrated that the outer complex, which forms initially $(C_6H_5)_3MI_2$, transforms slowly into the inner complex $(C_6H_5)_3MI^+I^-$, and in the presence of excess iodine, into $(C_6H_5)_3MI^+I_3^-$. The conductance measurements of Beveridge and co-workers (3, 4) in acetonitrile and Sahai *et al.* (5) in dioxane and tetrahydrofuran demonstrated that significant ionization of the complexes occurs.

In a previous paper (6), we have reported on a quantitative study of the ionization of the pyridine–iodine complex in pyridine and in 1,2-dichloroethane using an electrochemical technique involving I_3^- concentration cells. It was found that 25% of the complex is present in ionized form. The study was made at high concentration ratios of pyridine to iodine.

In the present work, we have applied the electrochemical technique to the ionization of the complexes formed between iodine and $(C_6H_5)_3As$, $(C_6H_5)_3Sb$, and pyridine in 1,2-dichloroethane primarily at high concentration ratios of iodine to organic molecule. Quantitative information has been obtained on the ionization reactions which occur in these systems.

Experimental

Triphenylarsine (Ph_3As), triphenylstibine (Ph_3Sb), and tetraethylammonium iodide (TEAI) were obtained in the highest commercial grades available from Aldrich Chemical Co. Spectrophotometric grades of pyridine (Py) and 1,2-dichloroethane (DCE) and A.C.S. reagent grade iodine (I_2) were also obtained from Aldrich. The iodine was resublimed and kept in a tightly closed container.

The electrochemical measurements were made in a 2-compartment "H" cell. Conductivity measurements were made using a standard conductivity cell. Details of the methods have been described previously (6).

All solutions were kept in sealed flasks, in the dark, between measurements. Data presented in this report were obtained on solutions which had reached equilibrium as determined by conductivity or electrochemical measurements.

The term "total concentration" used in connection with I_2, Ph_3As, Ph_3Sb, Py, and TEAI refers to the number of moles added to a liter of DCE solution. Dissociation and interaction in solution are not considered. The symbol used for total concentration is "c" as in $c(I_2)$ and $c(Ph_3As)$. The actual concentrations are shown in brackets as in $[I_3^-]$ and $[Ph_3AsI_2]$.

Reaction mechanisms

Many reaction sequences and ionization mechanisms were considered. Those presented here were found to be in best accord with the experimental data.

A. High iodine concentrations

The following reaction scheme was used for high concentration ratios of iodine to organic molecule in 1,2-dichloroethane.

[1] $R + I_2 \rightarrow RI_2$

[2] $RI_2 + I_2 \rightleftharpoons RI^+ + I_3^-$

[3] $RI^+ + 2I_2 \rightleftharpoons RI_2^{2+} + I_3^-$

We assume that the addition of tetraethylammonium iodide results quantitatively in the following reaction:

[4] $I_2 + TEAI \rightarrow I_3^- + TEAE^+$

where R in reaction [1] represents the organic molecule. We assume that reaction [1] proceeds completely to the right and that sufficient time has elapsed so that the complex present is the inner complex, RI^+I^-, which, for convenience, we write as RI_2. The extent to which reactions [2] and [3] proceed to the right depends on the nature of the organic molecule. A further assumption, that concentrations can be substituted for thermodynamic activities, permits us to write the following expressions for the equilibrium constants.

[5] $$K_2 = \frac{[RI^+][I_3^-]}{[RI_2][I_2]}$$

[6] $$K_3 = \frac{[RI_2^{2+}][I_3^-]}{[RI^+][I_2]^2}$$

Complexes of the form RI^+ have been proposed by many investigators. A new complex, RI_2^{2+}, is being proposed by us on the basis of the experimental data to be presented below.

[7] Pt | R, I_2 || R, I_2, TEAI | Pt
(a) (b)

where the total concentrations of R and I_2 are the same on both sides of the cell, we propose the following virtual electrochemical reactions at the platinum electrodes.

[8] $3I_2(a) + 2e = 2I_3^-(a)$

[9] $2I_3^-(b) - 2e = 3I_2(b)$

The choice of electrode reactions is somewhat arbitrary. Species should be selected which are in reasonably high contration in the solution such as I_2 and I_3^-. The selection of a different pair of electrode reactions will give the same results if it is in accord with the equilibria specified in reactions [2] and [3].

The emf of such a cell is

$$[10] \quad E = -\frac{RT}{2F}\ln\frac{[I_3^-(a)]^2[I_2(b)]^3}{[I_3^-(b)]^2[I_2(a)]^3}$$

B. High concentrations of Ph_3As

The reaction scheme used for high concentration ratios of Ph_3As to I_2 is

[1] $R + I_2 \rightarrow RI_2$

[11] $RI_2 \rightleftharpoons RI^+ + I^-$

The expression for the equilibrium constant corresponding to reaction [11] is

$$[12] \quad K_{11} = \frac{[RI^+][I^-]}{[RI_2]}$$

For electrochemical cells of the type in [7] we propose the electrode reactions

[13] $RI^+(a) + 2e = R(a) + I^-(a)$

[14] $R(b) + I^-(b) - 2e = RI^+(b)$

The expression for the cell emf is

$$[15] \quad E = -\frac{RT}{2F}\ln\frac{[R(a)][I^-(a)][RI^+(b)]}{[R(b)][I^-(b)][RI^+(a)]}$$

The mathematical treatment used to obtain values for K_2, K_3, and K_{11} is discussed in the Appendix.

Results and discussion

A simple, approximate treatment can be performed using data at high iodine concentrations if the only equilibrium reaction of importance is reaction [2]. Such a treatment appears to be appropriate for the reaction between pyridine and iodine. If enough TEAI is added on side b of cell [7], the assumption can be made that reaction [2] is completely suppressed and that the concentration of I_3^- on side b is the total concentration of TEAI, c(TEAI), according to reaction [4]. An approximate form of eq. [10] can then be used.

$$[16] \quad E \approx -\frac{RT}{2F}\ln\frac{[I_3^-(a)]^2}{[I_3^-(b)]^2}$$

where $[I_3^-(a)]$ is the concentration of I_3^- for the intrinsic disociation of the complex according to reaction [2]. Therefore, in each experiment, a value for $[I_3^-(a)]$ can be calculated from the emf value and the value of c(TEAI) by substitution in reaction [16].

Data obtained for various iodine concentrations are shown in Table 1. The dissociation calculated using eq. [16] increases from 18% to 57% as we go from a $c(I_2)/c(Py)$ ratio of 25 to 200. The data in Table 1 do not yield a constant value for the equilibrium constant, K_2, below a $c(I_2)/c(Py)$ ratio of 100. The most probable reason for this is that the assumption that reaction [1] proceeds all the way to the right is not applicable at ratios lower than 100.

TABLE 1. Dependence of the ionic dissociation of the pyridine–iodine complex on the concentration of iodine; $c(Py) = 1.00 \times 10^{-3}$ M, $c(TEAI) = 3.00 \times 10^{-3}$ M

75	54.8	0.35
100	48.0	0.46
200	—	0.57*

*This value was calculated from the data in Table 2.

TABLE 2. Emf values for pyridine–iodine solutions at high iodine concentration*

$c(Py)$ $M \times 10^3$	$c(TEAI)$ $M \times 10^3$	Emf (mV) Experimental	Emf (mV) Calculated
2.00	0.400	7.5	6.7
2.00	1.00	11.6	11.1
2.00	1.40	15.5	15.1
2.00	2.00	25.2	25.8
1.00	0.400	10.9	10.7
1.00	1.00	21.5	22.3
1.00	1.40	26.1	28.2
1.00	2.00	31.5	35.4

*The total iodine concentration in all these measurements was 0.200 M. The equilibrium constants, K_2, used to calculate the emf values was 3.9×10^{-3}.

In Table 2 are emf data on the interaction between I_2 and Py which were used to calculate the equilibrium constant, K_2. Equations [2] and [5] and the treatment in Appendix A1 were used in this analysis. By computer calculation, using trial values of K_2 and successive approximation (see Appendix A1), a value of K_2 was selected which best fit the experimental emf data. The value selected was 3.9×10^{-3}. On the basis of the sensitivity of the calculated emf values to the choice of the equilibrium constant, the error in K_2 and the other equilibrium constants to be discussed is estimated to be within ±50%.

A check on the validity of the results presented in Tables 1 and 2 was made by comparing the electrical conductivity of a solution containing total concentrations of 2×10^{-1} M I_2 and 1×10^{-3} M TEAI with the conductivity of a solution with total concentrations of 2×10^{-1} M I_2 and 1×10^{-3} M Py. The conductivity values, 2.7×10^{-4} (ohm-cm)$^{-1}$ and 1.4×10^{-4} (ohm-cm)$^{-1}$, respectively, are shown in Table 3. The I_3^- concentrations for the two solutions are calculated to be 1×10^{-3} M and 0.57×10^{-3} M, respectively, on the basis of reactions [4] and [2]. If we make the crude assumption that the ionic conductivities of TEA^+ and PyI^+ are equal, the ratio of conductivities should equal the ratio of I_3^- concentrations. The conductivity ratio, 0.52, is in reasonable agreement with the concentration ratio, 0.57.

The above treatment for the pyridine–iodine system does not fit the data for the iodine complexes of Ph_3Sb and Ph_3As. An

*The total concentration of Ph_3Sb in all these measurements was 1.00×10^{-3} M. The equilibrium constant, K_3, used to calculate the emf values was $2.9 \times 10^{-2}\ M^{-1}$.

additional step, reaction [3], which postulated the existence of a new complex ion, RI_2^{2+}, was, therefore, invoked. The assumptions were made that reactions [1] and [2] proceed completely to the right and that the equilibrium process in reaction [3] is in operation.

In Tables 4 and 5 are emf data on the interaction between iodine and Ph_3Sb and Ph_3As which were used to calculate the equilibrium constant, K_3. Reactions [3] and [6] and the treatment in Appendix A2 were used in this analysis. The values of K_3 which best fit the data were $2.9 \times 10^{-2}\ M^{-1}$ and $3.8 \times 10^{-2}\ M^{-1}$, respectively, for Ph_3Sb and Ph_3As.

A comparison of conductivity data was again made as shown in Table 3. The I_3^- concentration values were calculated using the selected values of the equilibrium constant, K_3. The comparison is more complex than in the case of pyridine because of the presence of the two ionic species, Ph_3MI^+ and $Ph_3MI_2^{2+}$. The agreement between the conductivity ratios and the I_3^- concentration ratios is not as good as in the case of pyridine, especially for Ph_3As. The conductivity data do, at least qualitatively, support the assumption that the complexes are completely ionized.

Electrochemical data on the pyridine–iodine system at high ratios of pyridine to iodine were analyzed in a previous report (6) on the basis of the reaction which best fit the data

[17] $2PyI_2 \rightleftharpoons Py_2I^+ + I_3^-$

This reaction step does not appear to be useful in the case of the iodine complexes of Ph_3As and Ph_3Sb. In the case of Ph_3As, reactions [1] and [11] are in best agreement with the data. In the case of Ph_3Sb, the electrochemical data obtained could not be fitted with any simple mechanism and will not be discussed further.

For Ph_3As–I_2 solutions in DCE at concentration ratios of Ph_3As to I_2 of up to several hundred, reaction [2] occurs as well as reaction [11] as evidenced by the reddish-brown color of the solutions and the presence of I_3^- absorption bands in the UV–visible spectrum. At Ph_3As to I_2 concentration ratios of 500 and above, the solutions are colorless and no I_3^- is observed spectrophotometrically, indicating the absence of I_3^-.

Electrochemical data obtained on Ph_3As–I_2 solutions are shown in Table 6. Equations [11] and [12] and the treatment in Appendix B were used to obtain a value for the equilibrium constant, K_{11}. The value selected was 2.4×10^{-5} M. A comparison of conductivity data with an I_2–TEAI solution was

again made as shown in Table 3. The I_3^- concentration ratio, 0.13, is in good agreement with the conductivity ratio, 0.12.

We have observed that at high iodine concentrations Ph_3Sb and Ph_3As form the $Ph_3MI_2^{2+}$ ion as well as the Ph_3MI^+ ion whereas Py only forms the PyI^+ ion. Some factors that may play a roll in this difference of behavior are the differences in molecular geometry and ionization energy and the presence of empty *d* orbitals of fairly low energy in the arsenic and antimony atoms which can result in back-donation (7).

We have also observed that at high organic concentrations Ph_3As forms the I^- ion whereas Py forms the I_3^- ion (6). A probable reason for this difference is that the arsenic compound forms a stronger bond with iodine than the nitrogen compound. A reaction of the type

$$RI^+ + 2I^- \rightarrow R + I_3^-$$

is more likely to occur if the bond between the organic molecule and iodine is weaker.

Appendix. Mathematical treatment to obtain values for the equilibrium constants

A1. High iodine concentrations with reaction [2] as the relevant equilibrium reaction

In this case, eqs. [2] and [5] are the primary equations. For side a of [7] (no added TEAI), we have

$$[RI^+] = [I_3^-] = x$$
$$[RI_2] = c(R) - x$$
$$[I_2] = c(I_2) - c(R) - x$$

The expression for the equilibrium constant, K_2, in eq. [5] becomes

$$[18] \quad K_2 = \frac{x^2}{[c(R) - x][c(I_2) - c(R) - x]}$$

For side b of cell [7] (TEAI added), we have

$$[RI^+] = y$$
$$[I_3^-] = y + c(TEAI)$$
$$[RI_2] = c(R) - y$$
$$[I_2] = c(I_2) - y - c(TEAI) - c(R)$$

The expression for K_2 becomes

$$[19] \quad K_2 = \frac{y[y + c(TEAI)]}{[c(R) - y][c(I_2) - c(R) - y - c(TEAI)]}$$

The electrochemical equation [10] becomes

$$[20] \quad E = -\frac{RT}{F} \ln \frac{x[c(I_2) - y - c(TEAI) - c(R)]^{3/2}}{[y + c(TEAI)][c(I_2) - c(R) - x]^{3/2}}$$

The following algorithm was employed to calculate a value of K_2. An initial value of K_2 was used in the computer program to calculate x and y in eqs. [18] and [19]. A value of E was calculated in eq. [20] using these x and y values. The calculated E was compared to the experimental value of the emf. New values of K_2 were then employed until the calculated and experimental values of the emf were in agreement.

A2. High iodine concentrations with eq. [3] as the relevant equilibrium reaction

In this case, eqs. [3] and [6] are the primary equations. For side a of cell [7], we have

$$[RO_2^{2+}] = x$$
$$[I_3^-] = c(R) + x$$
$$[RI^+] = c(R) - x$$
$$[I_2] = c(I_2) - 2c(R) - 2x \approx c(I_2) - 2c(R)$$

The expression for the equilibrium constant, K_3, in eq. [6] becomes

$$[21] \quad K_3 = \frac{x[c(R) + x]}{[c(R) - x][c(I_2) - 2c(R)]^2}$$

For side b of cell [7], we have

$$[RI_2^{2+}] = y$$
$$[I_3^-] = c(R) + y + c(TEAI)$$
$$[RI^+] = c(R) - y$$
$$[I_2] = c(I_2) - 2c(R) - c(TEAI) - 2y \approx c(I_2) - 2c(R) - c(TEAI)$$

The expression for K_3 becomes

$$[22] \quad K_3 = \frac{y[c(R) + y + c(TEAI)]}{[c(R) - y][c(I_2) - 2c(R) - c(TEAI)]^2}$$

The electrochemical eq. [10] becomes

$$[23] \quad E = -\frac{RT}{F} \ln \frac{[c(R) + x][c(I_2) - 2c(R) - c(TEAI)]^{3/2}}{[c(R) + y + c(TEAI)][c(I_2) - 2c(R)]^{3/2}}$$

A computer program employing an algorithm similar to that described in Appendix A1 was used to calculate values of K_3 from eqs. [21], [22], and [23].

B. High Ph_3As concentrations with eq. [11] as the relevant equilibrium reaction

In this case, eqs. [11] and [12] are the primary equations. For side a of cell [7], we have

$$[I^-] = [RI^+] = x$$
$$[RI_2] = c(I_2) - x$$

The expression for the equilibrium constant, K_{11}, becomes

$$[24] \quad K_{11} = \frac{x^2}{c(I_2) - x}$$

For side b of cell [7], we have

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

$$[RI^+] = y$$

$$[I^-] = y + c(TEAI)$$

$$[RI_2] = c(I_2) - y$$

$$[R(a)] \approx [R(b)]$$

The expression for K_{11} becomes

$$[25] \quad K_{11} = \frac{[y + c(TEAI)]y}{c(I_2) - y}$$

The electrochemical equation [15] becomes

$$[26] \quad E = -\frac{RT}{2F} \ln \frac{y}{y + c(TEAI)}$$

A value for y is calculated from each experimental emf value. The equilibrium constant, K_{11}, is then calculated using eq. [25]. An average value of K_{11}, 2.4×10^{-5} M, was used in Table 6.

Institute for Marine Biosciences, National Research Council of Canada, 1411 Oxford Street, Halifax, N.S., Canada B3H 3Z1

Received August 17, 1990

A. S. W. DE FREITAS, A. W. MCCULLOCH, and A. G. MCINNES. Can. J. Chem. **69**, 611 (1991).

Reaction of aqueous silicate with ammonium molybdate at pH 1.5 affords the β form of silicomolybdic acid. The latter can be precipitated by the addition of a variety of quaternary ammonium salts. The precipitated silicomolybdate can then be decomposed to silica in a two-step combustion process (at 350 and 1000°C). Recoveries of Si are nearly complete, but the starting silicate solution must be made strongly basic prior to the reaction with molybdate. The overall process can be utilized for the recovery of silicon isotopes and as a method of silica purification.

Key words: silica, silicate, silicomolybdate, silicon-29.

A. S. W. DE FREITAS, A. W. MCCULLOCH et A. G. MCINNES. Can. J. Chem. **69**, 611 (1991).

La réaction d'un silicate aqueux avec du molybdate d'ammonium, à un pH de 1,5, conduit à la forme β de l'acide silicomolybdique. On peut le précipiter par addition de divers sels d'ammonium quaternaires. Utilisant un processus de combustion en deux étapes (à 350 et 1000°C), on peut alors décomposer le silicomolybdate précipité en silice. Les récupérations du Si sont pratiquement complètes; toutefois, on doit rendre la solution initiale de silicate très basique avant de la faire réagir avec le molybdate. On peut utiliser ce processus global pour récupérer des isotopes du silicium et pour purifier la silice.

Mots clés : silice, silicate, silicomolybdate, silicium-29.

[Traduit par la rédaction]

Introduction

During the course of a study of the processes involved in silicon biomineralization we conducted a number of biological experiments utilizing ^{28}Si- and ^{29}Si-labeled silica. Since these isotopes are both expensive and relatively difficult to obtain, we required a method to recover the material, typically from dilute aqueous solutions. An initial approach involving methylene chloride extraction of the tetrabutylammonium salt of the silicon–catechol complex was found to be inappropriate for recovery at low (20 ppm or below) Si concentrations.[2]

We now wish to report a successful procedure for removal and recovery of low concentrations of silicate, based on the formation of silicomolybdic acid and its precipitation from aqueous solution by the addition of appropriate organic counterions. Silica of high purity can then be recovered by stepwise combustion of the dried precipitate (1).

The interaction of silicate with molybdate is well-known and forms the basis of the traditional spectrophotometric determination of silicon (2–4), in which silicomolybdate is reduced and the products measured by colorimetric means. The reaction of silicate with ammonium molybdate produces a complex silicomolybdate of composition $H_4SiMo_{12}O_{40}$ (5). Two forms of the silicomolybdate may be obtained, depending on the pH of the reaction. At a pH of about 4 the α form is obtained, while the reaction at lower pH (1.5–2) yields the less stable β form, which has been shown to convert spontaneously to the α form (2, 4).

The silicomolybdate complex is water-soluble, but can be rendered less soluble by addition of a quaternary base. For example, the methyltricotylammonium derivative can be extracted from aqueous solution using chloroform (6). Addition of other bases such as quinoline causes precipitation of the complex, and this procedure has been used for analytical purposes (7–9). In the majority of our experiments we utilized readily available tetrabutylammonium bromide as the source of the organic counterion.

Results and discussion

The approach we have used to recover silicate from dilute aqueous environments consists of (*i*) formation of the β-silicomolybdate at pH 1.5, (*ii*) precipitation from solution as a tetrabutylammonium or analogous organic complex, and (*iii*) thermal decomposition of the complex to silica.

(i) Silicomolybdate formation

The stoichiometric requirements for the formation of $SiMo_{12}O_{40}^{4-}$ involve use of at least two molar equivalents of ammonium molybdate, $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, per mole of silicate. The following reaction parameters were found to be optimal: (*a*) addition of an excess (a total of 4 molar equivalents per Si); (*b*) immediate acidification to pH 1.5 using 2 N sulfuric acid (the formation of the β-silicomolybdate was indicated by the development of a bright yellow color); and (*c*) allowing the mixture to stand for at least 1 h at room temperature to ensure complete reaction.

(ii) Precipitation of tetraalkylammonium silicomolybdate

The second step of the procedure requires the addition of sufficient tetraalkylammonium halide to precipitate the silicomolybdate as $(R_4N)_4SiMo_{12}O_{40}$. The reaction of excess halide reagent with unreacted molybdate affords tetraalkylammonium molybdate, which co-precipitates. Such a co-precipitate may be of value as a carrier in the case of low Si concentrations, where the volume of precipitated silicomolybdate is small. We observed essentially quantitative precipitation when the concentration of Bu_4NBr was 12 molar equivalents per Si (i.e. 3 molar equivalents per molybdate). The precipitated solid was washed with 1 N nitric acid (to remove any adsorbed inorganic impurities) and with deionized water, and dried.

The completeness of the precipitation process was indicated by the fact that only trace levels of Si were observed in the reaction filtrate and washings.

TABLE 1. Recovery of Si from basic and acidic media

Si concentration in substrate μg/100 mL	% Si recovery	
	From basic substrate	From acidified substrate
4000	97	59
2000	94	64
800	92	61
400	91	51
200	92	49

(iii) Recovery of silica from tetraalkylammonium silicomolybdate

Thermal degradation of the organic derivative was best conducted in a two-step combustion process. The solid was first heated to 350°C and this temperature maintained for 20 min. This served to break down the organic component (about 35% weight loss was observed) in a controlled fashion. The second stage of the combustion procedure involved raising the temperature to 1000°C, just below sintering temperature, and holding at that temperature for 1 h. Above 800°C molybdenum oxide sublimed. In a series of reactions involving original Si concentrations of 2–40 ppm the colorless silica residue represented an overall recovery (Table 1) of 90–95%.

Effect of pH

We observed that the Si recovery was dependent on the history of the starting silicate solution. When acidified silicate solutions were employed using the standard conditions outlined above, the observed silica recoveries were only 49–64% (Table 1). The availability of Si for reaction with molybdate is clearly pH-dependent. Thus, intended substrates should be made strongly basic prior to reaction with molybdate. Under such conditions the predominant orthosilicate species is available for reaction; in more acidic solutions the silicate is in equilibrium with a mixture of oligomeric species, the composition of which is pH- and concentration-dependent (10).

Alternative counterions

Although the majority of our reactions were conducted using tetrabutylammonium bromide as the source of the organic counterion, we have established that a variety of simpler and more economical alternatives may be employed with equal success. In principle any tetraalkylammonium salt containing C_1 to C_4 alkyl groups can be used. We have shown that good recoveries are obtained using tetramethylammonium bromide, tetraethylammonium bromide, and even triethylamine hydrochloride. Interestingly, triethylammonium molybdate is water-soluble, and in this case the precipitate is predominantly the silicomolybdate derivative (see Experimental).

Silica purification

Our procedure for silica recovery and purification has several advantages: (*1*) The precipitation of silicomolybdate is practically quantitative, even at relatively low Si concentrations, and can be accomplished using a wide variety of quaternary ammonium salts. (*2*) Most contaminants remain in aqueous solution and are removed by filtration, while others are removed by acid washing. (*3*) The organic component is eliminated by combustion at 350°C, and molybdenum oxide sublimes at 800–1000°C. (*4*) Although elements such as phosphorus and arsenic, which form isomorphous derivatives, $H_3PMo_{12}O_{40}$ and $H_3AsMo_{12}O_{40}$ (6), will also be precipitated under similar conditions, the oxides of these elements are much more volatile than silica and hence are removed during combustion. A potential problem exists in the case of germanium. With the use of a ^{68}Ge tracer we have shown that complete precipitation of the analogous germanomolybdate occurs under similar reaction conditions.

TABLE 2. Trace elements in biosilica before and after purification

Element	Concentration, μg/g			
	Neutron activation		ICP	
	Before	After*	Before	After*
Ag	100	ND	—	—
Al	1440	220	126	ND
Ba	100	ND	47	ND
Ca	880	ND	758	ND
Cu	—	—	229	ND
Fe	3330	1000	2071	53
Mg	1650	ND	1517	ND
Mn	55	20	109	10
P	—	—	2042	163
Pb	—	—	269	ND
Ti	470	ND	—	—
Zn	500	ND	385	ND

*ND = not detected.

As an example we have applied the overall process to a crude biogenic silica sample obtained from diatom biomass. Neutron activation analyses of the starting material and recovered product (Table 2) indicated large scale removal of many elements. Similar results were observed when the original and product silicas were fused with sodium carbonate and aqueous solutions of the fusion products analyzed by ICP (Table 2).

After we had completed this work, a similar approach, designed for desilicification of water, was reported in the patent literature (11). In that case the α-silicomolybdate or silicotungstate was formed at a pH below 3.9 and was then either precipitated by one of a variety of ways, such as addition of a cationic surfactant (e.g. hexadecyl pyridinium salt) or an organic base, or adsorbed on an anion exchanger (loaded with dihexadecyldimethylammonium ion) or extracted into an organic solvent (e.g. trioctylamine in kerosene).

Although more exhaustive experimentation is required to fully demonstrate the usefulness of our procedure to silica purification, it is eminently suited to the recovery of costly Si isotopes or the removal and concentration of small quantities of Si from aqueous solution. We have in fact applied the process to recover silica from isotopically enriched silicate solutions.

Experimental

Sodium metasilicate, $Na_2SiO_3 \cdot 5H_2O$, and ammonium molybdate, $(NH_4)_6Mo_7O_{24} \cdot 4H_2O$, were obtained from BDH. Anhydrous sodium carbonate was obtained from Merck. Germanium dioxide (99.999%), tetraethylammonium bromide (99+%), tetramethylammonium bromide (98%), tetrabutylammonium bromide (99%), and tetrabutylammonium hydrogen sulfate were obtained from Aldrich Chemical Co. Triethylamine hydrochloride was prepared from triethylamine and recrystallized from acetonitrile. The ^{68}Ge tracer (as the chloride) was obtained from New England Nuclear.

Deionized water obtained from a Milli-Q water purification system (Millipore) was used for preparation of aqueous solutions and for aqueous washings. For Si analysis, the pH of the analyte was adjusted to 8–9 prior to analysis using the procedure of Smith and Milne (3).

Procedure for optimal recovery of silica from dilute aqueous silicate solutions

(*a*) *Formation of silicomolybdate*

A solution of $Na_2SiO_3 \cdot 5H_2O$ (120.6 g, 0.00056 mol, 16 mg Si) in water (100 mL) was treated with ammonium molybdate (2.83 g, 0.00228 mol) in water (120 mL). The pH was adjusted to 1.5 with 2 N sulfuric acid (10.4 mL), and the reaction mixture stirred for 1 h at room temperature. A yellow color indicated formation of silicomolybdic acid.

(*b*) *Precipitation of tetrabutylammonium silicomolybdate*

The mixture from (*a*) was treated with a solution of tetrabutylammonium bromide (2.216 g, 0.00688 mol) in water (40 mL). This caused the precipitation of yellow tetrabutylammonium silicomolybdate. Colorless tetrabutylammonium molybdate was also formed as a result of reaction between the excess ammonium molybdate and tetrabutylammonium bromide, and co-precipitated. The mixture was allowed to stand overnight to ensure complete precipitation. The precipitated yellow solid was then filtered (the filtrate was colorless), washed successively with water (70 mL), 1 N nitric acid (3 × 30 mL), and water (4 × 30 mL), and then air-dried at 45°C. Total Si in the filtrate and washings, as measured by the spectrophotometric method, was only 50 μg.

(*c*) *Combustion of precipitate and recovery of silica*

The dry solid (3.1 g) from (*b*) was placed in a quartz or platinum boat and combusted in air. The temperature was first raised (30°/min) to 350°C and maintained at that temperature for 20 min, to eliminate the organic component and to produce a greyish solid residue. (Uncontrolled and violent decomposition of the material may occur if the temperature is raised too quickly to above 400°C). The combustion temperature was then increased (30°/min) from 350 to 1000°C and held at 1000°C for 60 min to allow complete volatilization of molybdenum oxide (>800°C), leaving a white silica residue (33.2 mg).

(*d*) *Analysis of residue*

The silica residue from (*c*) was fused with sodium carbonate prior to the determination of Si by the colorimetric molybdate method.

Tetrabutylammonium hydrogen sulfate could be substituted for the Bu_4NBr used in step (*b*).

Recoveries at various Si concentrations

(*a*) Aliquots (10, 5, 2, 1, and 0.5 mL) of a stock solution of Na_2SiO_3 (760 mg) in water (250 mL) were diluted to 100 mL to give substrate solutions containing 4000, 2000, 800, 400, and 200 μg (40–2 ppm) Si, respectively. Each aliquot was treated with a solution of ammonium molybdate (707 mg) in water (30 mL), acidified to pH 1.5 with 2 N sulfuric acid and stirred for 1 h. Each mixture was then treated with Bu_4NBr (554 mg) in water (10 mL) and allowed to stand for 24 h.

The resulting precipitate was recovered and combusted as described above, and the residue fused with sodium carbonate. The fusion product was dissolved in water and the solution analyzed for Si by the molybdate colorimetric method. The results are recorded in Table 1.

(*b*) A solution of $Na_2SiO_3 \cdot 5H_2O$ (1.52 g) in water (250 mL) was acidified to pH 2 with 2 N sulfuric acid and the volume made up to 500 mL with deionized water.

Aliquots (10, 5, 2, 1, and 0.5 mL) of this acidified silicate solution were diluted to 100 mL to give substrate solutions containing 4000, 2000, 800, 400, and 200 μg (40–2 ppm) Si, respectively. Each aliquot was processed as in (*a*) above. Si recovery data are given in Table 1.

Recoveries using different counterions

Solutions of $Na_2SiO_3 \cdot 5H_2O$ (121 mg) in water (100 mL) were treated with ammonium molybdate (2.83 g) in water (60 mL) and acidified to pH 1.5. After 1 h each mixture was treated with a solution of (*i*) tetramethylammonium bromide (1.058 g), (*ii*) tetraethylammonium bromide (1.444 g), or (*iii*) triethylamine hydrochloride (944 mg) in water (10 mL). The yellow precipitates were processed and combusted as before to yield residues of colorless silica (Table 2). Recoveries of Si were in the range 97–100%.

Purification of biogenic silica

Detergent-cleaned diatom biomass (about 1 g dry weight) was combusted at the non-sintering temperature of 800°C for 5 h to remove organic material. The resultant "biosilica" (250 mg) was fused with sodium carbonate (1 g) and the fused material dissolved in deionized water (150 mL). Spectrophotometric analysis showed a Si level of 716 μg/mL.

This solution (100 mL) was diluted with water (100 mL) and then treated with ammonium molybdate (14.14 g) in water (100 mL). The mixture was acidified to pH 1.5 with 2 N sulfuric acid (44 mL). After stirring for 1 h, a solution of Bu_4NBr (11.08 g) in water (50 mL) was added and the mixture stirred overnight at room temperature. The precipitate was filtered, washed with 0.5 N sulfuric acid (100 mL) and then water (300 mL), and finally dried at 50°C to give a solid (18.06 g).

The above solid (16.325 g) was combusted as before in a platinum crucible in small (ca. 1.7 g) portions, to give a solid residue (142 mg). Direct analyses of the original and product silica samples were performed by neutron activation. Inductively-coupled plasma (ICP) emission spectroscopic analyses were performed in each case after sodium carbonate fusion. The analytical results are recorded in Table 2.

Recovery of silicon-29 labelled silica

A colorless silica was obtained when a basic solution of products from ^{29}Si labelling experiments was submitted to the above recovery process.

Other products

(*i*) *Tetrabutylammonium molybdate*

The pH (5.0) of a solution of ammonium molybdate (2.47 g) in water (40 mL) was adjusted to 1.5 by the addition of 2 N sulfuric acid (2.7 mL). The mixture was stirred for 1 h and then treated with Bu_4NBr (3.87 g) in water (60 mL). After stirring overnight the precipitated solid was filtered, washed with water (15 mL) and dried at 45°C to give the product (3.68 g).

(*ii*) *Tetrabutylammonium germanomolybdate*

A solution of sodium germanate was prepared by dissolving GeO_2 (209 mg, 0.002 mol) in NaOH (160 mg) in water (40 mL). This was treated with ammonium molybdate (4.94 g, 0.004 mol) in water (60 mL) and the pH adjusted to 1.5 with 2 N sulfuric acid (9 mL). The mixture was then treated as in (*i*) above to give the product (6.62 g).

A similar experiment was conducted in the presence of a ^{68}Ge tracer. No ^{68}Ge was observed in the reaction filtrate, establishing the completeness of the precipitation process.

(*iii*) *Tetraethyl and triethylammonium molybdate*

The pH of each of two solutions of ammonium molybdate (1.414 g) in water (30 mL) was adjusted to 1.5 with 2 N sulfuric acid (8 mL), and the solutions then treated with (*a*) Et_4NBr (722 mg), or (*b*) Et_3NHCl (566 mg) in water (10 mL). The addition of water (100 mL) followed by shaking left most of the Et_4N molybdate precipitate undissolved, while the addition of only 50 mL caused dissolution of all of the Et_3N molybdate.

Received February 9, 1990[3]

AKIKO NISHIDA, YOSHIFUMI AKAGAWA, SHINSUKE SHIRAKAWA, SHIZUO FUJISAKI, and SHOJI KAJIGAESHI. Can. J. Chem. **69**, 615 (1991).

Several 9-substituted 9-(*o*-methylthiomethylphenyl)fluorenes and their oxidation products, 9-substituted 9-(*o*-methylsulfinylmethylphenyl)fluorenes, were prepared. Each equilibrium constant at room temperature or at low temperature was investigated and the conformational equilibria (*ap* ⇌ *sp*) of these compounds are discussed by comparing them with those of the corresponding 9-substituted 9-(*o*-methylthiophenyl)fluorenes and 9-substituted 9-(*o*-methylsulfinylphenyl)fluorenes in which the *o*-substituents were one CH_2 unit shorter than those of the title compounds. Kinetic data for the internal rotation of several compounds are also given.

Key words: conformational isomerism, restricted rotation, 9-arylfluorenes.

AKIKO NISHIDA, YOSHIFUMI AKAGAWA, SHINSUKE SHIRAKAWA, SHIZUO FUJISAKI et SHOJI KAJIGAESHI. Can. J. Chem. **69**, 615 (1991).

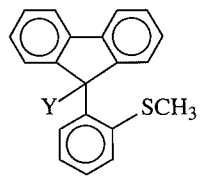
On a préparé plusieurs 9-(*o*-méthylthiométhylphényl)fluorènes substitués en position 9 ainsi que leurs produits d'oxydation, les 9-(*o*-méthylsulfinylméthylphényl)fluorènes substitués en position 9. On a étudié chacune des constantes d'équilibre, tant à la température ambiante qu'à basse température, et on discute des équilibres conformationnels (*ap* ⇌ *sp*) en les comparant à ceux des 9-(*o*-méthylthiométhylphényl)- et des 9-(*o*-méthylsulfinylméthylphényl)-fluorènes substitués en position 9 dans lesquels les *o*-substituants portaient une unité CH_2 de moins que ceux mentionnés dans le titre. On rapporte aussi les données cinétiques relatives à la rotation interne de plusieurs composés.

Mots clés : isomérie conformationnelle, rotation limitée, 9-arylfluorènes.

[Traduit par la rédaction]

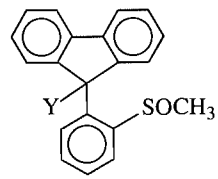
Introduction

Because the barriers to rotation about the C(9)—C(Ar) bond in 9-arylfluorene derivatives are remarkably high, some interesting stereochemical studies have been carried out on these systems (2). In connection with 9-substituted 9-(*o*-substituted phenyl)fluorenes, we have investigated the effects of 9- or *o*-substituents on the restricted rotation and the conformational equilibria (*ap* ⇌ *sp*) (3) of these compounds by means of their ^{1}H NMR spectra (1, 4–12).



It turned out that the conformational equilibria of these compounds were affected by nonbonding intramolecular interactions (electronic attraction, repulsion, and steric effect, etc.) between the *o*-substituents and the 9-groups or the fluorene ring.

We recently investigated the restricted rotation about the C(9)—C(Ar) bonds in 9-substituted 9-(*o*-methylthiophenyl)-fluorenes (**1**) and their oxidation products, 9-substituted 9-(*o*-methylsulfinylphenyl)fluorenes (**2**) (8). In this paper, we wish to report on the syntheses of some 9-substituted 9-(*o*-methylthiomethylphenyl)fluorenes (**3**) and 9-substituted 9-(*o*-methylsulfinylmethylphenyl)fluorenes (**4**), and to discuss the conformational equilibria of these compounds compared with those of **1** and **2**. As well, we give the activation parameters determined by line-shape analyses of the signals of *o*-substituents in their dynamic ^{1}H NMR spectra (13).



Results and discussion

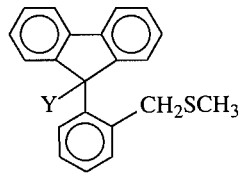
Preparation of 9-substituted 9-(o-methylthiomethylphenyl)-fluorenes (3) and 9-substituted 9-(o-methylsulfinylmethyl-phenyl)fluorenes (4)

The compound, 9-(*o*-bromomethylphenyl)-9-fluorenol (**6**),

1

2

was prepared by the reaction of 9-(*o*-tolyl)-9-fluorenol (**5**) with NBS in carbon tetrachloride (7). The reaction of **6** with hydriodic acid in acetic acid gave 9-(*o*-iodomethylphenyl)-fluorene (**7**) (7). The reaction of an isothiouronium salt, which was obtained by treatment of **7** with thiourea in methanol, with aqueous sodium hydroxide followed by methylation with dimethyl sulfate, afforded 9-(*o*-methylthiomethylphenyl)-fluorene (**3***a*). The compound **3***a* was converted to 9-(*o*-methylsulfinylmethylphenyl)fluorene (**4***a*) by oxidation with nitric acid ($d = 1.38$). 9-Lithio-9-(*o*-methylthiomethylphenyl)fluorene (**8**) was prepared by the reaction of **3***a* with butyllithium in ether under a nitrogen atmosphere. Bubbling oxygen into the ethereal solution of **8** gave 9-(*o*-methylthiomethylphenyl)-9-fluorenol (**3***b*); then, **3***b* was oxidized by nitric acid to give 9-(*o*-methylsulfinylmethylphenyl)-9-fluorenol (**4***b*). 9-Methyl-9-(*o*-methylthiomethylphenyl)fluorene (**3***c*) was obtained from **8** and methyl iodide; then, **3***c* was converted into 9-methyl-9-(*o*-methylsulfinylmethylphenyl)fluorene (**4***c*) by oxidation with nitric acid.



9-Acetyl- (**3***d*) and 9-benzoyl-9-(*o*-methylthiomethylphenyl)-fluorene (**3***e*) were obtained by treating the lithio compound **8** with acetic anhydride and benzoyl chloride, respectively. Then, **3***d* and **3***e* were treated with nitric acid to give 9-acetyl- (**4***d*) and 9-benzoyl-9-(*o*-methylsulfinylmethylphenyl)fluorene (**4***e*), respectively. 9-(*o*-Methylthiomethylphenyl)-9-fluorenecarboxylic acid (**3***f*) was prepared by the reaction of **8** with Dry Ice in ether.

[b]J = 13–15 Hz.

The melting points, yields, and spectral data (^{1}H NMR and IR) of these compounds **3** and **4** are shown in Tables 1 and 2.

Conformational equilibria of 3 and 4

Generally, two rotamers *ap* and *sp* of 9-(*o*-substituted phenyl)fluorenes are observed via their ^{1}H NMR spectra at room temperature or at low temperature, because of their high barriers to rotation about the C(9)—C(Ar) bond. In fact, as shown in Table 2, two signals (*ap* and *sp*) from the methylthiomethyl group of **3***a* and also from the methylsulfinylmethyl group of **4***a* are observed at room temperature. The isomerization process of **3***a* by the rotation about C(9)—C(Ar) bond is shown in Fig. 1.

As shown in Table 2, the methylene protons of the methylsulfinylmethyl groups in **4** give rise to two doublets in their ^{1}H NMR spectra at room temperature. These phenomena show that the sulfur atom of the methylsulfinyl group ($SOCH_3$) is a chiral center.

Since the predominant conformations of **3** and **4** (except **3***a* and **4***a*) were not elucidated on the basis of their ^{1}H NMR spectra at room temperature (see Table 2), dynamic NMR spectra of these compounds were measured. ^{1}H NMR data for the *o*-substituents in these compounds at low temperatures are shown in Table 3.

For compounds **3***c*, **4***c*, **4***d*, and **4***e*, the chemical shifts of

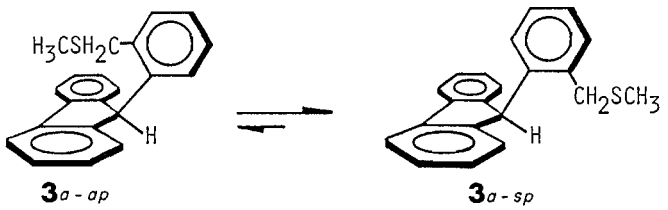

FIG. 1. Two rotamers of **3***a*.

their methyl and methylene protons are approximate, as are those for the methylthiomethyl proton of **3***a*–*ap* and the methylsulfinylmethyl proton of **4***a*–*ap*; these signals do not split even at −50 to −62°C (see Table 3). Thus, these results indicate that steric repulsion between the 9-substituents (CH_3, $COCH_3$, and COPh) and the *o*-substituents in **3***c*, **4***c*, **4***d*, and **4***e* makes the equilibria *ap* ⇌ *sp* shift exclusively to the *ap* form.

Two conformers *ap* and *sp* of **3***b*, **3***d*, **3***e*, **3***f*, and **4***b* were observed at low temperatures (see Table 3). Because compound **3***b* shows the equilibrium constant K as ap/sp = 3.7/1 at −43°C, the predominant conformer of **3***b* is the *ap* form. Thus, steric repulsion between the 9-hydroxyl and *o*-methylthiomethyl groups in the *sp* form may be larger than that between the fluorene nucleus and the *o*-methylthiomethyl group in the *ap* form, which controls the equilibrium of **3***a* ($K(ap/sp)$ = 1/5). On the contrary, however, the predominant conformer of **4***b* is the *sp* form ($K(ap/sp)$ = 1/1.7 at −48°C). We hypothesize that a dipole – lone pair electron attractive interaction between the methylsulfinylmethyl and hydroxyl groups exists in the *sp* form of **4***b*. We recently reported the same interaction between methylsulfinyl and hydroxyl groups in the *sp* form of 9-(*o*-methylsulfinylphenyl)-9-fluorenol **2***b* (8).

The predominant conformers of **3***d* and **3***e* at low temperature are the *sp* forms (**3***d*: $K(ap/sp)$ = 1/1.5, **3***e*: $K(ap/sp)$ = 1/2.1). We have recently shown that derivatives of 9-substituted 9-(*o*-methoxyphenyl)- (**9**) (5) and 9-(*o*-methylthiophenyl)-fluorenes (8), in which 9-substituents bear carbonyl groups such as $COCH_3$ and COPh, have an intramolecular attractive interaction between the carbonyl and the methoxyl or methylthio groups. Oki *et al.* have already shown that the same interaction exists in several 1,4-dimethoxy-9-(carbonylmethyl)triptycenes (**10**) (14) (Fig. 2). Thus, it is reasonable that a dipole – lone pair electron interaction between the carbonyl and methylthio groups in **3***d* and **3***e* makes the *sp* form more predominant.

It is particularly interesting that the methylene protons of the methylthiomethyl group in **3***d*-*sp* give rise to two doublets at low temperature (see Table 3). In the *sp* form of **3***d*, a dipole – unshared electron interaction between the carbonyl and methylthio groups, shown in Fig. 3, makes the sulfur atom a chiral center. Thus, the two protons of the methylene group may be revealed as diastereomeric protons. These phenomena have been observed for the *sp* form of 9-benzoyl-9-(*o*-methoxymethylphenyl)fluorene (**11***e*) at low temperature (7) as shown in Fig. 3.

In compound **3***f*, the predominant conformer is the *ap* form at low temperature ($K(ap/sp)$ = 2.6/1). Steric repulsion between the 9-carbonyl and *o*-methylthiomethyl groups in the *sp* form may control its equilibrium.

The rotational barriers about the C(9)—C(Ar) bonds in **3** and **4** were obtained by line-shape analyses of the methylthio and methylsulfinyl signals in their DNMR spectra. The results are tabulated, together with those for **1** and **2**, in Table 4.

From the values $K(ap/sp)$ in Table 4, it is noted that the equilibrium *ap* ⇌ *sp* in **3** and **4** (except for **3***c* and **4***c*) shifts predominantly to the *ap* form compared with the corresponding results for **1** and **2**, respectively. For example, in compounds **1***d*, **1***e*, **1***f*, **2***d*, and **2***e*, only the *sp* forms are detected, even at low temperature. However, in compounds **3***d*, **3***e*, **3***f*, **4***d*, and **4***e*, the *ap* forms are present along with the *sp* forms at low temperature. It seems that because the *o*-substituents in **3** or **4** are longer than the *o*-substituents of **1** or **2** because of one additional CH_2 moiety, the mobility of the *o*-substituents should increase. Thus, an attractive interaction between the *o*-substituents and 9-substituents (Y) of **3** or **4** may be reduced, in comparison with that of **1** or **2**.

Experimental

All melting points are uncorrected. The ^{1}H NMR spectra were recorded on a Jeol-MH-100 spectrometer with a Jeol model JES-VT-3 variable temperature controller. The chemical shifts are expressed in ppm, with tetramethylsilane as an internal standard. Dynamic NMR spectra were analyzed by using a modified version of the computer program DNMR 3 (13).

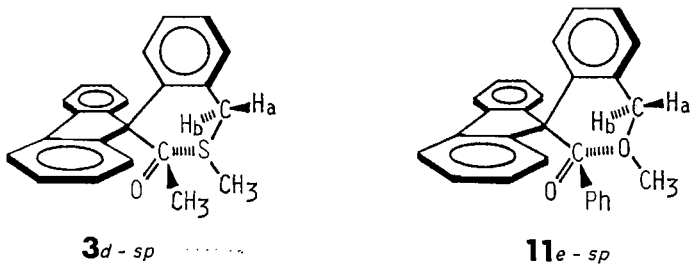

FIG. 3. Attractive interaction between carbonyl and CH_2OCH_3 or CH_2SCH_3.

9-(o-Methylthiomethylphenyl)fluorene (3a)

A solution of 9-(*o*-iodomethylphenyl)fluorene (**7**) (5 g, 13.1 mmol) and thiourea (1.3 g, 17.1 mmol) in methanol (40 mL) was refluxed for 5 h. After the solvent was distilled off, the isothiouronium salt obtained was dissolved in aqueous sodium hydroxide (10%) and the mixture was stirred for 30 min under a nitrogen atmosphere. Dimethyl sulfate (2.38 g, 19.7 mmol) was added dropwise to the above mixture and the precipitated solid was extracted with benzene. The benzene solution was washed with water, and then dried over $MgSO_4$. The solution was evaporated *in vacuo*, leaving a residue that was column-chromatographed on silica gel using carbon tetrachloride as eluent to give **3***a*; yield 3.06 g (77%); colorless crystals (from benzene–hexane); mp 72–74°C. Anal. calcd. for $C_{21}H_{18}S$: C 83.42, H 6.00%; found: C 83.35, H 6.03.

9-(o-Methylthiomethylphenyl)-9-fluorenol (3b)

9-Lithio-9-(*o*-methylthiomethylphenyl)fluorene (**8**) was prepared from the reaction of **3***a* (1 g, 3.3 mmol) in dry ether (30 mL) with a commercial solution of butyllithium in hexane (3.25 mL, containing 5 mmol of butyllithium) under a nitrogen atmosphere. Dry oxygen gas was bubbled into the above solution for 10 min. The reaction mixture was poured into water, and the organic layer was separated, washed with water, and dried over $MgSO_4$. The solution was evaporated *in vacuo*, leaving a residue that was column-chromatographed on silica gel using carbon tetrachloride as an eluent to give **3***b*; yield 0.3 g (29%); colorless needles; mp 124–126°C (from hexane). Anal. calcd. for $C_{21}H_{18}OS$: C 79.21, H 5.70; found: C 78.75, H 5.83.

9-Methyl-9-(o-methylthiomethylphenyl)fluorene (3c)

To a solution of **8** prepared from **3***a* (0.9 g, 3.0 mmol) in dry ether (40 mL) was added methyl iodide (0.68 g, 4.8 mmol) dropwise. The mixture was stirred for 30 min and was then poured into water. The organic layer was separated, washed with water, and dried over $MgSO_4$. The solution was evaporated *in vacuo*, leaving a residue that was column-chromatographed on silica gel using carbon tetrachloride as eluent to give **3***c*; yield 0.26 g (28%); colorless needles; mp 90–92°C (from benzene–hexane). Anal. calcd. for $C_{22}H_{20}S$: C 83.51, H 6.31; found: C 83.47, H 6.47.

9-Acetyl-9-(o-methylthiomethylphenyl)fluorene (3d)

To a solution of **8** prepared from **3***a* (0.6 g, 2.0 mmol) in ether was added a solution of acetic anhydride (2.7 mL, 2.6 mmol) in dry ether (20 mL) under cooling at −10°C; the mixture was stirred for 30 min and was then poured into water. The organic layer was worked up as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

described for the preparation of **3***c*, to give **3***d* as colorless prisms; yield 0.51 g (74%); mp 42–44°C. Anal. calcd. for $C_{23}H_{30}OS$: C 80.19, H 5.85; found: C 79.72, H 5.96.

9-Benzoyl-9-(o-methylthiomethylphenyl)fluorene (3e)

Compound **8** prepared from **3***a* (2.0 g, 6.6 mmol) was reacted with benzoyl chloride (1.4 mL, 9.9 mmol) instead of acetic anhydride; the reaction mixture was worked up as described for the preparation of **3***d*, to give **3***e* as colorless prisms; yield 1.91 g (71%); mp 56–58°C. Anal. calcd. for $C_{28}H_{22}OS$: C 82.72, H 5.46; found: C 82.38, H 5.57.

9-(o-Methylthiomethylphenyl)-9-fluorenecarboxylic acid (3f)

A solution of compound **8** from **3***a* (0.61 g, 2.0 mmol) in ether was poured into crushed Dry Ice and stirred for 30 min. The mixture was poured into dilute HCl solution. The organic layer was worked up as described for the preparation of **3***c*, to give **3***f* as colorless needles; yield 0.43 g (62%); mp 184–186°C (from hexane). Anal. calcd. for $C_{22}H_{18}O_2S$: C 76.28, H 5.24; found: C 76.56, H 5.39.

9-Substituted 9-(o-methylsulfinylmethylphenyl)fluorenes (4a–4d)

9-(o-Methylsulfinylmethylphenyl)fluorene (4a)

To a solution of **3***a* (0.25 g, 0.79 mmol) in acetic acid (30 mL) was added nitric acid (d = 1.39, 0.5 mL) dropwise at 18°C with stirring. After being stirred at 15–18°C for 5 h, the reaction mixture was poured into cold water. The precipitated solid was extracted with benzene. The benzene solution was washed with a $NaHCO_3$ solution and water, and then dried over $MgSO_4$. The solvent was distilled off to obtain a residue that recrystallized from hexane–benzene (1:1) to give **4***a* as colorless prisms; yield 0.20 g (75%); mp 148–150°C. Anal. calcd. for $C_{21}H_{18}OS$: C 79.22, H 5.70; found: C 79.44, H 5.75.

9-(o-Methylsulfinylmethylphenyl)-9-fluorenol (4b)

Colorless prisms (from hexane–benzene 1:1), yield 82%; mp 81–83°C. Anal. calcd. for $C_{21}H_{18}O_2S$: C 75.42, H 5.42; found: C 75.83, H 5.36.

9-Methyl-9-(o-methylsulfinylmethylphenyl)fluorene (4c)

Colorless needles (from hexane), yield 48%; mp 137–139°C. Anal. calcd. for $C_{22}H_{20}OS$: C 79.49, H 6.06; found: C 79.34, H 5.99.

9-Acetyl-9-(o-methylsulfinylmethylphenyl)fluorene (4d)

Colorless prisms (from hexane–chloroform 1:1), yield 79%; mp 98–100°C. Anal. calcd. for $C_{23}H_{20}O_2S$: C 76.63, H 5.59; found: C 76.21, H 5.70.

9-Benzoyl-9-(o-methylsulfinylmethylphenyl)fluorene (4e)

Colorless prisms (from hexane–benzene 1:1), yield 64%; mp 154–155°C. Anal. calcd. for $C_{28}H_{22}O_2S$: C 79.59, H 5.25; found: C 79.59, H 5.25.

The proximate coupling constants, ^5J, between *ortho* and methyl protons in thioanisole and 18 of its derivatives are discussed as conformational indicators. On the assumption that ^5J varies as $\cos^4\theta$, for $0° \leq \theta \leq 90°$, θ being the angle by which the methyl group twists out of the aromatic plane, ^5J for $\theta = 0°$ follows as -0.43 (2) Hz from the known internal barrier in thioanisole in solution. A measurement of ^5J in *meta*- or *para*-substituted thioanisole derivatives then yields an approximate value for the twofold barrier to rotation about the Csp^2—S bond. For derivatives containing an *ortho* substituent, ^5J yields an estimate of the torsion angle for the thiomethyl moiety. In some instances these angles are compared with those derived from long-range $^1H,^{13}C$ and $^{13}C,^{13}C$ coupling constants. The size of the *ortho* substituent appears to have only a small effect on the magnitude of ^5J. The major determinant of the latter appears to be the manner in which the substituent perturbs the mobile bond order of the Csp^2—S bond.

Key words: spin–spin coupling constants, thioanisole derivatives; ^1H NMR, thioanisole derivatives; conformations, thioanisole derivatives; conformations, torsional motion of SCH_3 group.

TED SCHAEFER, RUDY SEBASTIAN, SALMAN R. SALMAN, JAMES D. BALEJA, GLENN H. PENNER et DAVID M. MCKINNON. Can. J. Chem. **69**, 620 (1991).

On discute de l'utilité, comme indicateurs conformationnels, des constantes de couplage approximatives, ^5J, entre les protons *ortho* et ceux du méthyle du thioanisole et de 18 de ses dérivés. En faisant l'hypothèse que les valeurs de ^5J varient en fonction du $\cos^4\theta$, pour $0° \leq \theta \leq 90°$, où θ est l'angle entre le groupement méthyle et le plan du noyau aromatique, et en se basant sur la barrière interne connue du thioanisole en solution, ^5J pour $\theta = 0°$ est égal à $-0,143(2)$Hz. Une mesure de ^5J pour des dérivés du thioanisole substitués en *méta* ou en *para* fournit alors une valeur approximative de la barrière binaire à la rotation autour de la liaison Csp^2—S. Pour des dérivés contenant un substituant en *ortho*, la valeur de ^5J fournit une évaluation de l'angle de torsion de la portion thiométhyle. Dans quelques cas, on a pu comparer ces angles avec ceux dérivés des constantes de couplage à longue distance $^1H,^{13}C$ et $^{13}C,^{13}C$. La grosseur des substituants *ortho* ne semble avoir qu'une faible influence sur l'amplitude de ^5J. Le facteur déterminant de cette amplitude semble être la façon dont le substituant perturbe l'ordre de liaison mobile de la liaison Csp^2—S.

Mots clés : constantes de couplage spin–spin, dérivés du thioanisole; RMN ^1H, dérivés du thioanisole; conformations, dérivés du thioanisole; conformations, mouvement de torsion du groupe SCH_3.

[Traduit par le rédaction]

Introduction

While the conformational applications of the proximate proton–proton coupling constant over five formal bonds, $^5J(H,OCH_3)$, in anisole and its derivatives have been discussed in some detail (1–12), the analogous coupling constant, $^5J(H,SCH_3)$, in thioanisole has received relatively little attention.

An early experiment (13) implied the possible dependence of the magnitude of $^5J(H,SCH_3)$ on the size of the substituent, X, in 2-X-thioanisole derivatives. Presumably the bulky substituent forces a close approach of the methyl group to the *ortho* C—H bond in the ring, increasing the efficiency of a proximate (3, 9, 10, 14) or through-space coupling mechanism. By analogy to $^5J(H,OCH_3)$, such a mechanism would yield a negative $^5J(H,SCH_3)$. Indeed, this coupling constant was shown to be negative in 2,5-dichlorothioanisole (15), with a magnitude of $-0.352(9)$ Hz. This magnitude is twice as large as that reported (13) for 2-chlorothioanisole. It was suggested (8) that the *meta* substituent in 2,5-dichlorothioanisole could favor a more closely planar orientation of the SCH_3 group, as compared to 2-chlorothioanisole, thereby causing a larger coupling magnitude in the former compound. The barrier to rotation about the Csp^2—S bond in thioanisole is not large (16) and very likely 5–6 kJ/mol in solution (17, 18), in line with such a suggestion. Furthermore, it is known that $^5J(H,SCH_3)$ is not detectable when the SCH_3 is held in a plane perpendicular to that of the aromatic moiety (19), again implying its sensitive dependence on a proximate coupling mechanism.

In addition to the bulk of the *ortho* substituent, causing increased coplanarity of the thiomethyl group, the π acceptance or donation of the substituents should also play a role. Because the thiomethyl group is a π electron donor, a π electron acceptor placed *ortho* or *para* to it will increase the mobile bond order of, and therefore the internal barrier to rotation about, the Csp^2—S bond. The concomitant, larger, population of planar conformers at ambient temperatures entails a smaller average distance between the coupled protons in question and hence a larger magnitude of $^5J(H,SCH_3)$. A π electron-donating substituent, clearly, should cause a decrease in the magnitude of the coupling constant. The predictions about the perturbation of the internal barriers in thioanisole derivatives are borne out by deductions based on measurements of $^5J(^{13}C,^{13}C)$ and $^6J(H,^{13}C)$; these coupling constants involve a ^{13}C nucleus in the methyl group (17, 18). The change in the barrier caused by *meta* substituents can be rationalized with a perturbational approach to molecular orbital theory (20), as for the corresponding derivatives of thiophenol (21).

Because of the sensitivity of the magnitudes of proximate coupling constants to the separation between the atoms or bonds carrying the coupled nuclei (3, 9, 10, 14), the disentanglement

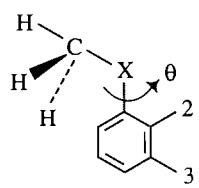
of steric or compressional from conjugational contributions to ^5J(H,SCH_3) can be beset with ambiguity. It turns out that, for many *ortho* substituents, the steric factor is not large, contrary to earlier reports.

Experimental

Those thioanisole derivatives not available commercially were obtained by methylation (22) of the commercial thiophenol derivative or were prepared from the corresponding commercial anilines by treatment of the aqueous diazonium hydrosulfate salt with cuprous methylmercaptide, as developed in this laboratory (23).

The ^{1}H nmr spectra were accumulated on a Varian HA100 or on Bruker WH 90 and AM 300 nmr spectrometers by methods described in detail previously (24, 25) and at probe temperatures ranging between 293 and 305 K. Tables 1 and 2 give conditions of solvents and concentrations. All sample tubes were, of course, degassed by at least four freeze–pump–thaw cycles and were flame-sealed.



The ^{1}H nmr spectra were analyzed with the computer program NUMARIT (26), greatly modified by R. Sebastian.

Results and discussion

Table 1 reproduces, as an example of the spectral analytical results, the ^{1}H nmr spectral parameters for 2-chlorothioanisole in acetone-d_6 solution. Figure 1 displays the experimental and theoretical spectra for the methyl protons of this compound, illustrating the attainable spectral quality.

The value of $^5J(H,SCH_3)$ in planar thioanisole

As a proximate coupling constant, ^5J(H,SCH_3) is expected to be small in magnitude unless the *ortho* C—H bond is close to the methyl group. For anisole, X = O in **1**, the INDO MO FPT

1

computations (3) for ^5J(H-6, OCH_3) are closely proportional (4) to $\cos^4\theta$ for $0° \leq \theta \leq 60°$. Furthermore, ^5J(H-2,OCH_3) in **1** (X = O) appears to be inconsequential in size in this range of θ (3, 6, 7). By analogy, we shall assume that ^5J(H,SCH_3) ≡ ^5J behaves in a similar manner.[2] A value of ^5J at θ = 0° can be estimated as follows.

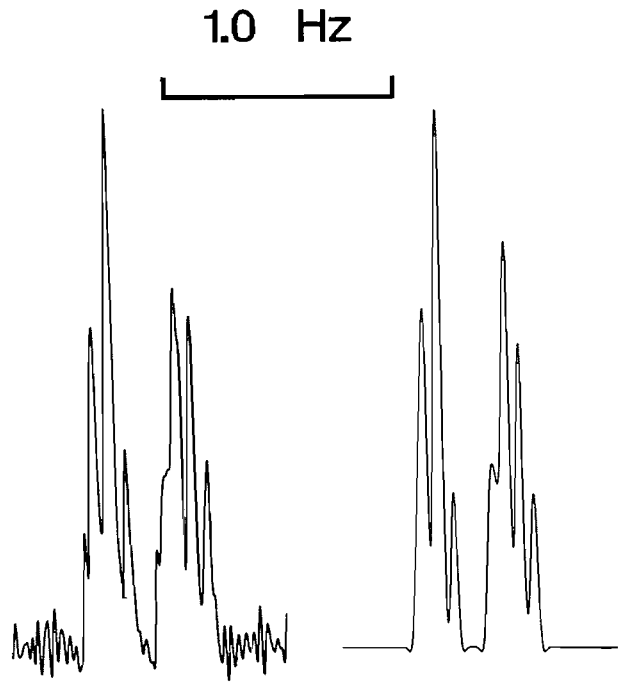


FIG. 1. The ^{1}H nmr spectrum of the methyl protons of 2-chlorothioanisole, as a 2.0 mol% solution in acetone-d_6 at 300 K and 300.135 MHz, is compared with the spectrum computed with the spectral parameters given in Table 1. The existence of coupling constants between the methyl protons and all four ring protons, together with the second-order nature of the ring proton spectrum, accounts for the appearance of the displayed peaks; none of the splittings is equal to a coupling constant.

For thioanisole in benzene-d_6 solution, ^5J(H,SCH_3) ≡ ^5J is −0.141 (0) Hz (27) and is −0.137 (0) Hz in acetone-d_6. Now, on the basis of $^6J(H,S^{13}CH_3)$ and $^5J(^{13}C,^{13}C)$ for thioanisole-α-^{13}C in benzene-d_6 (17) and acetone-d_6 (18) solutions, the twofold barrier to rotation about the Csp^2—S bond has been estimated to lie between 5.1 and 6.5 kJ/mol. That the barrier is predominantly twofold is attested by STO-3G MO computations on a series of *para*-substituted thioanisole derivatives (29), which find V_2 in thioanisole as 6.0(2) kJ/mol and V_4 as 0.4(2) kJ/mol. A classical calculation then yields the expectation value, $\langle\cos^4\theta\rangle$, as 0.64(3) at 300 K for the preceding range of twofold barriers. We have assumed that $^5J = {}^5J_0\langle\cos^4\theta\rangle$, where $^5J_0$ is the magnitude of ^5J at θ = 0°, this equation holding up to a θ of 60° and, trivially, up to 90° if ^5J is indeed a proximate coupling constant. Hence $^5J_0$ follows as $2J/\langle\cos^4\theta\rangle$, that is, as $2(-0.139(2))/0.64(3)$ or −0.43(2) Hz in thioanisole; the multiplier, 2, occurs because the conformation with θ = 0° has twofold degeneracy and ^5J is assumed to vanish for the remote *ortho* proton.

[2]For the STO 3G MO geometry (17) of planar thioanisole, ^5J is computed (unpublished work in this laboratory) as −0.59 Hz and is sensitive to the bond angles at sulfur, for example, as expected for a proximate coupling constant. However, there is a paucity of structural data for thioanisole compared to anisole (3) derivatives (the CSC bond angle is 102.6° for the STO-3G planar, but is apparently 105.6(7)° for the nonplanar, molecule according to electron diffraction data (28)). Accordingly, the empirical procedure in the text is probably more reliable.

[l]These angles follow from $2 \times {}^5J(H,CH_3) = -0.43(2)\langle\cos^4\theta\rangle$ for *ortho*-substituted derivatives. See text.
[m]It must be remembered that the torsion angles derived from arc cos $\langle\cos^4\theta\rangle^{1/4}$ and arc sin$\langle\sin^2\theta\rangle^{1/2}$ are the same only by coincidence. See text.

Some tests and applications of $^5J = -0.43(2)\langle\cos^4\theta\rangle$

For a vanishing barrier to rotation about the Csp^2—S bond, $\langle\cos^4\theta\rangle$ is 0.375, so that the minimum magnitude of ^5J in, say, a *para*-substituted thioanisole derivative is predicted as −0.081(4) Hz. If the conformation of minimum energy has $\theta \sim 90°$, and is very stable compared to kT, as in 2-hydroxythioanisole (19), then, according to the present formulation, ^5J should vanish, as it appears to do (19), unless another coupling mechanism is present. In 2-aminothioanisole it has been argued, on the basis of $^5J(^{13}C,^{13}C)$, that the S—C bond twists out of the aromatic plane by about 65° on average (18), a consequence of optimal hydrogen bonding between the N—H bond of the "bent" amino group and the 3p lone pair on the sulfur atom. For a 3 mol% solution of this molecule in CCl_4, our measurements imply ^5J as <0.05 Hz in magnitude, in line with a $\cos^4$ 65° of 0.03. In this situation, of course, one has $^5J = -0.43(2)\langle\cos^4\theta\rangle$ and the expectation value of $\cos^4\theta$ depends on the stability of the conformation with $\theta \sim 65°$. Nevertheless, the measurement is consistent with the $\cos^4\theta$ dependence of ^5J.

For 4-nitrothioanisole, the twofold barrier to rotation about the Csp^2—S bond has been assessed as 16.1 ± 1.5 kJ/mol in an acetone-d_6 solution (18). Hence $\langle\cos^4\theta\rangle$ at 300 K is 0.85(2). ^5J follows as $-0.43(2) \times 0.85(2)/2$ or −0.18(1) Hz; it is measured as (−)0.178(4) for a 2 mol% solution in acetone-d_6.

For 4-methoxythioanisole, the internal barrier appears (18) to be 0.7 ± 0.4 kJ/mol in acetone-d_6 solution; $\langle\cos^4\theta\rangle$ at 300 K is calculated as 0.41(2). ^5J follows as −0.09(1) Hz. It is measured as (−)0.093(1) Hz for a 5.0 mol% solution in acetone-d_6. Figure 2 displays the ^{1}H nmr spectrum of the thiomethyl protons under double resonance conditions and its caption describes the analytical procedure.

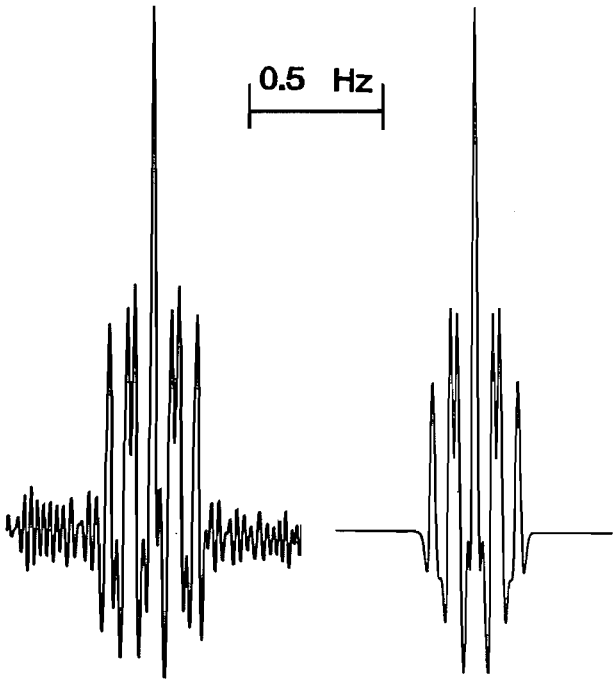
Again, the internal barrier in 3,5-dichlorothioanisole lies between 9.0 and 12.4 kJ/mol in acetone-d_6 solution (17, 18), corresponding to a $\langle\cos^4\theta\rangle$ of 0.77(3) at 300 K and hence a ^5J of $-0.16_5 \pm 0.015$ Hz. It is measured as −0.166(6) Hz in this solvent.

Because of its nature as a proximate interaction, ^5J in symmetrical *meta*- and *para*-substituted thioanisole derivatives is rather small in magnitude, being an average of a sizeable number and one which appears to be very small and assumed as zero. Consequently, very precise analyses of rather high resolution spectra (Fig. 1) are necessary if an estimate of the internal barrier is to follow from ^5J. Measurements of splittings in the ^{1}H nmr spectrum of the methyl protons do not necessarily yield ^5J, first because of the second-order nature of the ring proton spin system and, second, because the presence of coupling constants over six and seven formal bonds with other ring protons (Table 1) complicates the analysis.

However, if ^5J is extracted by an analysis of ^{1}H nmr spectra of sufficient quality, then it appears that reasonably accurate barriers to rotation about the Csp^2—S bond will follow.

Torsional mobility of the SCH_3 *group in thioanisole derivatives with one* ortho *substituent*

In 2-X-thioanisole derivatives, ^5J will be rather larger in magnitude, the remote *ortho* proton being absent. However, the



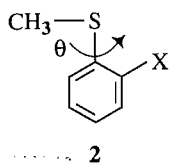


FIG. 2. The ^{1}H nmr spectrum of the thiomethyl protons is shown for a 5.0 mol% solution of 4-methoxythioanisole at 300 MHz and 300 K. $^5J(H,SCH_3)$ is $-0.093(1)$ Hz and $^6J(H,SCH_3)$ is 0.069(1) Hz, as obtained from a complete analysis of the spectrum in which the methoxy protons are decoupled. The simulated spectrum assumes a linewidth at half-height of 0.02 Hz and the experimental parameters used in resolution enhancement procedures on the free induction decay. The acquisition time of the latter is 60 s.

internal rotational potential is not easily determinable; presumably it will contain at least sizeable one- and twofold components, the former corresponding to the energy difference between the two planar conformers, the latter to the $3p\ldots\pi$ conjugation in the Csp^2—S bond. In the absence of reliable magnitudes for these components, recourse is had here to a comparison of estimates of the average out-of-plane motion of the SCH_3 group in the, at ambient temperatures, predominant conformer, **2**.

2

$^5J(^{13}C,^{13}C)$ yields an estimate (18) of $\langle\sin^2\theta\rangle$, whereas $^5J(H,SCH_3)$ indicates $\langle\cos^4\theta\rangle$ if X does not cause a significant compression of the CSC bond angle. For *some* of these expectation values, it happens that arc sin $\langle\sin^2\theta\rangle^{1/2}$ and arc cos $\langle\cos^4\theta\rangle^{1/4}$ are reasonable approximations to the expectation value of θ itself. For example, for a symmetrically substituted thioanisole and a V_2 of 16.0 kJ/mol, at 300 K one has $\langle\theta\rangle$ as 14°, arc sin $\langle\sin^2\theta\rangle^{1/2}$ as 17°, and arc cos $\langle\cos^4\theta\rangle^{1/4}$ as 16°, whereas for a V_2 of 8.0 kJ/mol, these angles are 22°, 26°, and 23°, respectively. As another example, in 2-bromothioanisole (18), $\langle\sin^2\theta\rangle$ is $<0.05_5$, corresponding to $<13.6°$ at 300 K for the torsion angle. $^5J(H,SCH_3)$ is $-0.387(2)$ Hz; hence $\langle\cos^4\theta\rangle$ is 0.90(4) and the arc cos value is 13 ± 3°. Table 2 gives some torsion angles derived in this fashion for a variety of thioanisole derivatives.

Conclusions

The coupling constants and approximate torsion angles, as defined in Table 2, lead to the following conclusions. First, π electron-donating (accepting) substituents in the *para* or *ortho* position decrease (increase) the mobile bond order of the Csp^2—S bond and cause smaller (larger) magnitudes of ^5J and the corresponding larger (smaller) torsion angles about this bond (entries 2, 3, 5, 14). Second, such substituents act in this manner in the *para* position also in the presence of *ortho* substituents (entries 10, 13, 15 in Table 2). Third, the compressional or steric perturbation of ^5J of an *ortho* substituent is not marked (entries 5, 6, 7, 8, 16), the rather lower magnitude of ^5J in 2-fluoroanisole arguably being due in some part to the π electron donation by fluorine (compare entries 7 and 13). Fourth, the dipole moments of 2-chloro- and of 2,4-dichlorothioanisole (30) should probably be reinterpreted in terms of the torsional angles in Table 2. Fifth, the value of -0.43 Hz in 2-nitrothioanisole (13) possibly indicates some steric compression of the thiomethyl group. This compression may, however, not be as large as implied by models because (31, 32) the nitro group twists out of the benzene plane in many *ortho* derivatives of nitrobenzene, thereby decreasing its effective size. Sixth, the steep dependence of ^5J on the torsion angle disallows the use of the latter for conformational deductions when, as in the 2-amino and 2-hydroxy derivatives, stereospecific intramolecular O—H...3*p* and N—H...3*p* hydrogen bonds cause very large out-of-plane torsion of the thiomethyl group (entries 17 and 18). Seventh, while ^5J is in principle available from a precise analysis of the ^{1}H nmr spectrum of a thioanisole derivative and is therefore a widely available conformational indicator, the less accessible $^6J(H,SCH_3)$ and $^nJ(^{13}C,^{13}C_3)$ are, of course, necessary for the di-*ortho*-substituted derivatives.

Synthèse d'isoxazoles substitués en α de l'oxygène et d'isoxazoles substitués en α de l'azote et de l'oxygène par des chaînes alkyle ou alcényle

JEAN-CLAUDE CHERTON,[1] M. LANSON,[2] D. LADJAMA, N. LEFEBVRE, Z. VOSSOUGH et J-J. BASSELIER

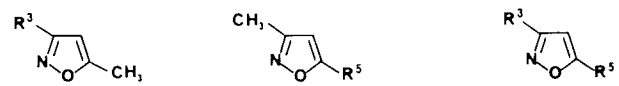
Laboratoire de chimie organique structurale, Unité de recherche associée n° 455, Université P. et M. Curie, 4 Place Jussieu, 75252 Paris CEDEX 05, France

Reçu le 25 juillet 1990

JEAN-CLAUDE CHERTON, M. LANSON, D. LADJAMA, N. LEFEBVRE, Z. VOSSOUGH et J-J. BASSELIER. Can. J. Chem. **69**, 625 (1991).

Deux séries d'isoxazoles substitués par de longues chaînes alkyle ou alcényle en α de l'oxygène ou en α des deux hétéroatomes ont été élaborées. La métallation/alkylation régiosélective sur le méthyle α-O du 3,5-diméthyl isoxazole constitue une synthèse de choix d'«isoxazoles α-O» diversement substitués. Appliquée à des isoxazoles méthylés en α de l'oxygène présentant déjà une chaîne alcényle en α de l'azote, cette séquence constitue une synthèse univoque et originale de 3,5-dialcényles isoxazoles lorsque l'agent alkylant est un halogénure d'alcényle. La cycloaddition dipolaire-1,3 employant des dièmes terminaux comme dipolarophiles et des dipôles alcèniques constitue un autre accès satisfaisant à de tels dialcényles isoxazoles, bien qu'impliquant l'élimination du sous-produit di-isoxazoline préalablement à l'oxydation de l'isoxazoline intermédiaire. Enfin, pour les isoxazoles simplement 3,5-dialkylés, la cycloaddition entre un alcyne vrai et un dipôle alkylé reste la méthode la plus directe.

Mets clés : isoxazoles, chaînes latérales alcényle, métallation–alkylation, régiosélectivité.



JEAN-CLAUDE CHERTON, M. LANSON, D. LADJAMA, N. LEFEBVRE, Z. VOSSOUGH, and J-J. BASSELIER. Can. J. Chem. **69**, 625 (1991).

Two series of isoxazoles substituted by long alkyl or alkenyl chains in the α position with respect to the oxygen atom or in the α position with respect to the two heteroatoms have been synthesized. Starting from 3,5-dimethylisoxazole, the regioselective metalation/alkylation on the α-O methyl group was a very convenient route to a large variety of "α-O substituted isoxazoles". When applied to α-O methylated isoxazoles bearing an α-N alkenyl chain the same method provides an original unequivocal approach to 3,5-dialkenyl isoxazoles. An alternative route to these compounds, despite the formation of di-isoxazoline as by-product and an additional step corresponding to the oxidation of the intermediate isoxazoline, is the 1,3-dipolar cycloaddition, by using terminal dienes as dipolarophiles with alkenyl dipoles. Nevertheless, the cycloaddition between monoalkylated alcynes and alkylated dipoles remains the most straightforward synthesis of 3,5-dialkyl isoxazoles.

Key words: isoxazoles, alkenyl side chains, metalation–alkylation, regioselectivity.

Nous nous intéressons dans la perspective de leurs propriétés pesticides (1) à des isoxazoles porteurs d'une ou de deux longues chaînes alkyles ou alcényles en α de l'azote ou (et) de l'oxygène (2). La synthèse des «isoxazoles α-N substitués» **1** constitue un cas bien particulier que nous avons précédemment abordé (3). Nous présentons maintenant celle des séries d'isoxazoles **2** substitués en α de l'oxygène et d'isoxazoles **3**, 3,5-disubstitués (cf. schéma 1).

Isoxazole α-N	Isoxazole α-O	Isoxazole 3,5 disubstitué
1 (2,3)	**2** (ce travail,2)	**3** (ce travail,2)

$R^3, R^5 = [CH_2]_m\text{-}{=}$ ou $[CH_2]_x\text{-}CH_3$

SCHÉMA 1. Isoxazoles substitués en α de l'oxygène et (ou) de l'azote par de longues chaînes alkyles ou alcényles.

Résultats et discussion

Nous avons employé deux grandes voies : soit des synthèses en ligne par métallation/alkylation de divers isoxazoles, soit des synthèses convergentes par cycloaddition dipolaire-1,3.

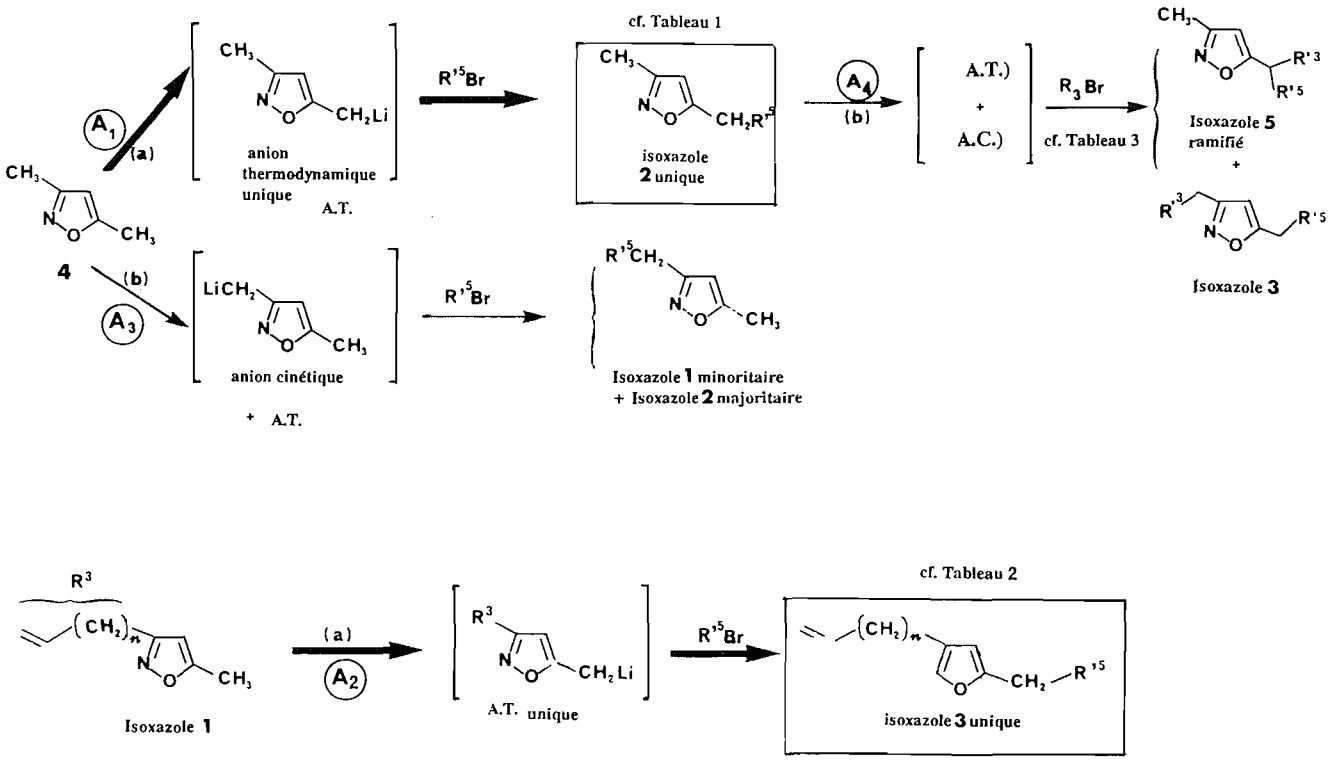
Introduction des chaînes latérales par métallation/alkylation de divers méthyl isoxazoles (voies A du schéma 2)

Nous avons mis à profit la régiosélectivité de la déprotonation des méthyles (ou méthylènes) α-O de divers isoxazoles[3] pour élaborer les séries d'isoxazoles **2** et **3**.

*Isoxazoles α-O substitués **2** à partir du diméthyl-3,5 isoxazole **4** (voie A_1)*

Nous avons procédé à une seule métallation/alkylation en opérant dans des conditions de contrôle thermodynamique (conditions (a) du schéma 2). En effet, lorsque la température est abaissée jusqu'à −105°C, on constate une compétition de la métallation des deux méthyles de l'isoxazole **4** (voie A_3 du schéma 2). L'addition ultérieure de différents électrophiles au milieu réactionnel maintenu à −78°C donne l'accès en bons rendements à des isoxazoles **2** portant des substituants très variés : chaînes alkyles, alcényles... (cf. tableau 1).

*Isoxazoles-3,5 disubstitués **3** par métallation/alkylation d'isoxazoles α-N **1** (voie A_2)*



En utilisant encore les conditions de contrôle thermodynamique (conditions (a) du schéma 2), on observe aussi la régiosélectivité de la métallation/alkylation des isoxazoles α-N, (cf. schéma 2 et tableau 2). Le seul site réactionnel est alors le méthyle α-O. Cette stratégie montre que la série des isoxazoles α-N intéressante en elle-même (1–3) offre en outre des synthons permettant un accès original et univoque aux isoxazoles **3** et en particulier à des dialcényles-3,5 isoxazoles.

[1]Auteur à qui adresser toute correspondance.

[2]Partie de thèse soutenue à l'Université P. et M. Curie, Paris, 1987.

[3]L'étude théorique du diméthyl-3,5 isoxazole **4** a montré que la déprotonation par les bases du méthyl α-O est thermodynamiquement favorisée (4). Ces travaux dûs à Kashima *et al.* ont été confirmés par les résultats expérimentaux de Micetich (5) et de Brunelle (6) obtenus avec diverses bases comme le BuLi, le LDA et $NaNH_2$.

SCHÉMA 2. Synthèse d'isoxazoles-3,5 disubstitués **3** par métallation/alkylation du diméthyl-3,5 isoxazole **4** (voies A).

*Essai d'obtention d'isoxazoles **3** par métallation/alkylation d'isoxazoles **2** sous contrôle cinétique[4] (voie A_4)*

La métallation/alkylation de divers isoxazoles **2** réalisée dans des conditions de contrôle cinétique (conditions (b) du schéma 2, voie A_4 et tableau 3) conduit quel que soit l'électrophile ultérieurement employé à des mélanges : isoxazole **3** attendu et isoxazole ramifié **5** obtenu comme sous-produit. En combinant toutes les conditions favorables à un contrôle cinétique, nous avons amélioré la régiosélectivité sans toutefois atteindre 100% d'isoxazole **3** (tableau 3, essai 2 et partie expérimentale).

L'obtention d'isoxazoles **3** par une synthèse en ligne comme la métallation/alkylation implique donc pour être univoque de partir d'isoxazoles α-N **1** et non pas d'isoxazoles α-O **2**. Nous avons également examiné pour ces isoxazoles **3** des voies d'accès par synthèse convergente.

Synthèse convergente d'isoxazoles par cycloaddition dipolaire-1,3 (voies B)

Les cycloadditions dipolaires-1,3 sont en général appliquées à des dipolarophiles présentant un groupe aryle ou un groupe électroattracteur (groupe R^5 du schéma 3). Pour notre part, nous avons néanmoins tenté leur application au cas de dipôles et de dipolarophiles porteurs de groupes R^3 et R^5 alkyle ou alcényle pour accéder aux isoxazoles de type **3**.

*Synthèse d'isoxazoles-3,5 disubstitués **3** avec au moins une chaîne alcényle (voie B_1)*

L'emploi d'alcènes comme dipolarophiles[5] (7) conduit intermédiairement à des isoxazolines **9** dont l'oxydation fournit les isoxazoles correspondants **3** (8). Pour tenter la synthèse d'isoxazoles à groupe R^5 insaturé, nous avons appliqué cette stratégie au cas de l'octadiène-1,7 **7** utilisé comme dipolarophile.

Les dipôles nitrile-oxydes **6** à groupe alkyle ou alcényle sont générés *in situ* en raison de leur instabilité (9). Nous avons adopté la méthode de Mukaiyama et Hoshino (7) ou celle de Larsen et Torsell (10) consistant respectivement en la déshydratation de nitroalcanes primaires ou en la déshydrohalogénation de chloroaldoximes. Les di-isoxazolines **10**, sous-produits résultant de deux additions du dipôle sur le dipolarophile double, sont facilement éliminées du milieu réactionnel par filtration. Les isoxazolines **9** obtenues par distillation du filtrat sont aisément oxydées en isoxazoles correspondants par le bioxyde de manganèse activé (8), (cf. tableau 4). Cette méthode plus longue et moins efficace que la voie A_2 présente néanmoins l'intérêt de fournir les intermédiaires ou sous-produits **9** et **10** dont nous avons pu tester quelques propriétés biologiques (1).

[4]Selon Brunelle, la métallation/alkylation sur le méthyle α-N est rendu régiospécifique par l'emploi de bases encombrées comme le *sec*-BuLi ou le *tert*-BuLi (6).

[5]En revanche, l'emploi d'alcynes comme dipolarophiles ne convient pas pour la synthèse d'isoxazoles à groupe R^5 alcénique puisqu'il impliquerait la mise en oeuvre d'un synthon dipolarophile double (alcène/alcyne). On obtiendrait alors majoritairement une isoxazoline à terminaison alcyne (9).

SCHÉMA 3. Synthèse d'isoxazoles-3,5 disubstitués par addition dipolaire-1,3 (voies B).

Synthèse de dialkyl-3,5 isoxazoles **3** *(voie B_2)*

L'addition dipolaire-1,3 d'un nitrile-oxyde sur un acétylénique conduit directement à un isoxazole (9). Cette voie nous a semblé particulièrement bien convenir pour une synthèse rapide et univoque d'isoxazoles-3,5 disubstitués **3** par deux chaînes alkyle, compte-tenu de la régiosélectivité de cyclisation[6] (9, 11) (schéma 3, voie B_2). Nous avons donc élaboré une série de dipôles-1,3 **6** à groupe R^3 saturé, la série des acétyléniques vrais **8** utilisés étant commerciale, à l'exception du dodécyne qui a été obtenu par homologation du bromodécane avec l'acétylure de sodium. Pour générer *in situ* les nitrile-oxydes **6** nous avons encore utilisé la méthode de Larsen et Torssell (10). Avec des rendements en produit purifié allant de 50 à 80% et la régiosélectivité déjà signalée pour d'autres substituants, les résultats montrent l'efficacité de cette voie pour la synthèse de dialkyl-3,5 isoxazoles **3** (cf. tableau 5).

Partie expérimentale

Les spectres d'absorption infrarouge ont été réalisés sur un appareil d'absorption infrarouge Pye Unicam modèle SP3-200, sous forme de film liquide entre pastilles de NaCl. Les bandes d'absorption sont exprimées en cm^{-1}. Les abréviations utilisées pour la description des bandes des spectres infrarouge sont les suivantes : l, large; F, forte; TF, très forte; m, moyenne; f, faible. Les spectres de rmn ^1H ont été effectués sur des appareils Bruker WP80, WM 250 et WM 500 dans le $CDCl_3$. Les déplacements chimiques sont exprimés en ppm par rapport au HMDS. Les abréviations suivantes sont employées : s, singulet; d, doublet; t, triplet; q, quadruplet; m, multiplet; M, massif. Les spectres de rmn ^1H et de rmn ^{13}C des isoxazoles **2** et **3** seront également présentés dans un article indépendant ainsi que les spectres de rmn ^{17}O et de rmn ^{15}N (12). Les spectres de masse ont été enregistrés par M^lle J. Mercier que nous remercions sur des spectrographes MS 30 et MS 50 sous impact électronique à 70 eV au centre de spectrochimie. Les pics sont exprimés en *m/z*, entre parenthèses figure leur intensité relative. Les analyses élémentaires ont été réalisées au service de microanalyse de l'Université Pierre et Marie Curie ou bien au service de microanalyse du CNRS à Vernaison. Le gel de silice Silicagel 60 PF_{254} (Merck) a été employé pour les ccm préparatives. Sauf précisions contraires les rendements indiqués sont calculés à partir des produits obtenus après distillation.

Introduction des chaînes latérales par métallation/alkylation de divers isoxazoles methylés (schéma 2, tableaux 1–3)

Synthèse des chaînes latérales

Le penténol et l'hexénol sont préparés selon la méthode de Brooks (13) et l'hepténol et le nonénol selon la méthode de Cahiez *et al.* (14). Les bromoalcènes sont obtenus par la méthode de Laforge *et al.* (15) à partir des alcools éthyléniques correspondants, excepté le bromo-7 octène-1 qui a été préparé à partir de l'octadiène-1,7 selon la référence 16. Les α-ω-bromofluoroalcanes sont synthétisés selon la méthode indirecte de Pattisson *et al.* (17) (monochloration des α,ω-diols puis fluoration du composé chloré intermédiaire par le fluorure de potassium).

Bromo-1 fluoro-6 hexane (71%), Eb_{30} = 117°C (litt. (17) Eb_{11} 67–68°C).

Bromo-1 fluoro-10 décane (80%), $Eb_{0,7}$ = 92°C (litt. (17) Eb_{11} 131°C).

Isoxazoles α-O substitués **2** *à partir du diméthyl-3,5 isoxazole* **4** *(voie A_1 du schéma 2, tableau 1)*

Ils sont obtenus à partir du diméthyl-3,5 isoxazole **4** en réalisant avec les différents électrophiles R'^5 Br du tableau 1 la métallation/alkylation dans des conditions de contrôle thermodynamique (conditions (a) du

[6]La cycloaddition d'un alcène ou d'un alcyne sur un dipôle se fait avec une remarquable régiosélectivité puisque des deux isomères possibles pour l'isoxazoline ou pour l'isoxazole, le seul composé 3,5-disubstitué est exclusivement obtenu.

[a]Conditions (b) : emploi de *sec*-BuLi, éther, −90°C, délai de 30 min entre les additions de lithien et d'électrophile pour tous les essais excépté pour l'essai 2 où l'on a utilisé le THF en opérant à −105°C et en supprimant le délai.

[b]Dosage par CPV capillaire pour la série *aa*. Séparation possible par distillation pour les séries *cf* et *ha*.

TABLEAU 4. Synthèse de divers mono- et di-alcényl isoxazoles **2** et **3** (voie B_1 du schéma 3)

R^{3a}	Isoxazoline **9**[b]	Rdt(%)	+ di-isoxazoline **10**[b]	Rdt(%)	Isoxazole[c]	Rdt(%)
CH_3-	**9***c*	56	+ **10***c*	5	**2***c*	85
=-$(CH_2)_8$- g	**9***cg*	52	+ **10***cg*	5	**3***cg*	80
=-$(CH_2)_7$- f	**9***cf*	48	+ **10***cf*	7	**3***cf*	80
C_2H_5- j	**9***cj*	47	+ **10***cj*	10	**3***cj*	85

[a]R^5 = c: $-(CH_2)_4-=$.

[b]Seules l'isoxazoline **9** et la di-isoxazoline **10** sont obtenues sans que l'on trouve trace de l'isoxazoline **9'** par rmn ^1H dans le mélange réactionnel.

[c]Pour les analyses et les caractéristiques physiques, cf. tableau 1 pour **2***c*, cf. tableau 2 pour **3***cg* et **3***cf* et cf. partie expérimentale pour **3***cj*.

schéma 2). Les solvants (THF, éther) employés lors des métallations sont distillés sur benzophénone et sodium et sous atmosphère inerte juste avant utilisation. Les réactions sont également effectuées sous atmosphère d'azote.

(Butène-3 yl)-5 méthyl-3 isoxazole **2**a. À une solution refroidie à −80°C de 15 cm^3 de diméthyl isoxazole **4** (0,156 mol) dans 250 cm^3 de THF on ajoute 95 cm^3 d'une solution 1,6 M de BuLi (0,152 mol). Après 30 min d'agitation à −70°C 16 cm^3 (0,184 mol) de bromure d'allyle sont ajoutés et l'agitation est poursuivie 1 nuit. Après neutralisation, lavage à l'eau, évaporation et distillation, on isole l'isoxazole **2***a* (0,12 mol, 16,93 g) (80%), $Eb_{0,5}$ 38–39°C; ir : 3080(f), 2920(F), 2850(F), 1640(m), 1610(F), 1495(f), 1450(F), 1370(f), 1000(m), 930(F), 800(m); uv (CH_3CN) λ_{max} en nm (log ε_{max}) : 229(2,01); rmn ^1H : 5,8(m, 2H), 5(m, 2H), 2,1(s, 3H), 2,5–2,1(m, 4H); masse : 137(M^+), 96(100), 82(45), 68(75), 55(65), 41(45).

En opérant à basse plus température (−105°C) toujours avec le bromure d'allyle comme électrophile (voie A_3 du Schéma 2), on a observé la formation d'un mélange du produit cinétique, l'isoxazole α-N **1***a*, et du produit thermodynamique, l'isoxazole α-O **2***a*. La rmn ^1H du mélange brut permet d'estimer les proportions 23 : 77 de ces deux isomères en se basant sur l'intégration des signaux méthyles respectifs à 2,3 et 2,1 ppm (2, 12).

Méthyl-3 (pentène-4 yl)-5 isoxazole **2**b (76%), $Eb_{0,7}$ 54°C; ir : 3080(f), 2920(F), 1640(m), 1610(F), 1495(f), 1450(F), 1370(f), 1000(m), 930(F), 800(m); rmn ^1H : 6,0–5,4(m, 2H), 5–4,6(m, 2H), 2,65(t, 8 Hz, 2H), 2,1(s, 3H), 2,4–1,4(m, 4H); masse : 151 (M^+), 110(50), 97(50), 82(40), 68(25), 50(100), 41(70).

(Hexène-5 yl)-5 méthyl-3 isoxazole **2**c (65%), $Eb_{0,1}$ 68–70°C; ir : 3080(f), 2930(F), 2850(F), 1640(m), 1600(F), 1490(f), 1440(m), 1420(F), 1000(m), 900(m), 800(f); uv (CH_3CN) λ_{max} en nm (log ε_{max}) : 229 (3,52); rmn ^1H : 6,1–5,4(m, 2H), 5–4,6(m, 2H), 2,6(t, 2H), 2,1(s, 3H), 2,0–1,5(m, 6H); masse : 165(M^+), 109(50), 92(40), 67(50), 55(60), 54(35), 41(100).

(Heptène-6 yl)-5 méthyl-3 isoxazole **2**d (56%), $Eb_{0,07}$ 92°C; ir : 2930(F), 1640(m), 1600(F), 1490(f), 1440(F), 1420(F), 1370(f), 1260(f), 1000(m), 910(F), 795(m); rmn ^1H : 6–5,4(m, 2H), 5,0–4,7(m, 2H), 2,6(t, 8 Hz, 2H), 2,2(s, 3H), 2,0–1,2(m, 6H); masse : 179(M^+), 97(65), 82(35), 55(100), 54(30), 41(95).

Méthyl-3 (octène-6 yl)-5 isoxazole **2**e (60%), $Eb_{0,2}$ 65°C; ir : 3080(f), 2940(F), 2860(m), 1640(m), 1600(F), 1495(f), 1450(m), 1420(m), 1380(f), 1000(m), 920(m), 800(m); rmn ^1H : 6,0–5,4(m, 2H), 5–4,7(m, 2H), 2,65(t, 7 Hz, 2H), 2,15(s, 3H), 2,1–1,0(m, 10H); masse : 193(M^+), 97(35), 82(30), 55(75), 54(30), 41(100).

Méthyl-3 (nonène-8 yl)-5 isoxazole **2**f (50%), $Eb_{0,1}$ 126°C; ir : 3080(f), 2920(F), 2850(F), 1630(m), 1600(F), 1490(f), 1420(F), 1370(f), 1000(m), 900(m), 790(m); rmn ^1H : 6,0–5,4 (m, 2H), 5–4,6(m, 2H), 2,8–2,4(t, 6 Hz, 2H), 2,1(s, 3H), 2,05–1(m, 12H); masse : 207(M^+), 110(75), 97(45), 82(30), 55(80), 43(30), 41(100).

(Decène-9 yl)-5 méthyl-3 isoxazole **2**g (67%), $Eb_{0,5}$ 102°C; ir : 1640(m), 1610(F), 1495(f), 1450(F), 1370(f), 1000(m), 930(F),

[a]Seul l'isoxazole **3** est obtenu sans que l'on puisse déceler par rmn ^{1}H de traces de son isomère **3'** dans le mélange réactionnel.

800(m); rmn ^{1}H : 6,0–5,4(m, 2H), 5–4,6(m, 2H), 2,6(t, 8 Hz, 2H), 2,2(s, 3H), 2,1–1,0(m, 14H); masse : 221(M^+), 110(48), 97(30), 55(64), 41(100).

Méthyl-3 (undécène-10 yl)-5 isoxazole **2**h (95%), $Eb_{0,05}$ 113–114°C; ir : 1640(m), 1610(F), 1495(f), 1450(F), 1370(f), 1000(m), 930(F), 800(m); uv (CH_3CN) λ_{max} en nm (log ε_{max}) : 229(3,17); rmn ^{1}H : 6,0–5,4(m, 2H), 5–4,6(m, 2H), 2,6(t, 8 Hz, 2H), 2,2(s, 3H), 2,1–1,0(m, 16H); masse : 235(M^+), 110(100), 97(45), 55(45), 41(40).

(Dodécène-11 yl)-5 méthyl-3 isoxazole 2i (50%), Eb, 154–156°C; ir : 2920(F), 2860(F), 1640(F), 1600(F), 1480(f), 1440(F), 1410(m), 1380(f), 990(m), 900(m), 780(m); rmn ^{1}H : 6,0–5,4(m, 2H), 5–4,6(m, 2H), 2,6(t, 8 Hz, 2H), 2,2(s, 3H), 2,1–1,0(m, 18H); masse : 249(M^+), 110(80), 97(75), 82(30), 55(95), 41(100).

Méthyl-3 undécyl-5 isoxazole **2**j (76%), Eb_1 142°C; ir : 2920(F), 2850(m), 1600(m), 1490(f), 1460(m), 1420(m), 370(f), 790(f); masse : 237(M^+), 110(100), 97(90), 55(80), 43(90), 41(90).

(Fluoro-7 heptyl)-5 méthyl-3 isoxazole **2**k (33%), Eb inconnu car purification par ccm préparative (silice, cyclohexane/AcOEt 80 : 20); ir : 2930(F), 2850(m), 1600(F), 1480(f), 1450(m), 1420(m), 1000(f), 890(f), 790(f); rmn ^{1}H : 5,7(s, 1H), 4,6(dt, J_{HH} = 6 Hz, J_{HF} = 57 Hz, 2H), 2,6(t, 7 = Hz, 2H), 2,15(s, 3H), 2,1–1,0(m, 10H); masse : 199(M^+), 110(40), 97(100), 55(70), 41(60).

(Fluoro-11 undécyl)-5 méthyl-3 isoxazole **2**l (89%), $Eb_{0,7}$ 150–152°C; ir : 2950(F), 2880(m), 1610(m), 1430(m), 1010(f), 900(F), 800(f); rmn ^{1}H : 5,7(s, 1H), 4,6(dt, J_{HH} = 6 Hz, J_{HF} = 57 Hz, 2H), 2,6(t, 7 Hz, 2H), 2,15(s, 3H), 2,1–1,0(m, 18H); masse : 255(M^+), 193(30), 110(90), 97(80), 55(90), 43(55), 41(100).

Pour obtenir les isoxazoles **2***m* et **2***n* à terminaison époxydiques, nous avons employé le méthode de Kishi (18) recourant à l'acide métachloroperbenzoique.

Méthyl-3 [(oxiranyl-2)-5 pentyl]-5 isoxazole **2**m (60%), Eb inconnu car isolé par ccm préparative (silice, cyclohexane/AcOEt 80 : 20); ir : 3040(f), 2930(f), 2860(m), 1600(F), 1480(f), 1420(m), 1420(f), 1370(f), 1260(m), 1000(m), 890(m), 800(m); rmn ^{1}H : 5,8(s, 1H), 2,9(m, 1H), 2,74(dd, 8 Hz, 1H), 2,73(t, 8 Hz, 2H), 2,45(dd, 1H), 2,25(s, 3H), 1,67–1,40(m, 8H).

Méthyl-3 [(oxiranyl-2)-9 nonyl]-5 isoxazole **2**n (47%), $Eb_{0,3}$ 109°C; ir : 2940(F), 2860(F), 1600(F), 1480(f), 1450(m), 1420(m), 1370(f), 1260(f), 1000(f), 900(f), 800(f); rmn ^{1}H : 5,8(s, 1H), 2,9(m, 1H), 2,74(dd, 1H), 2,73(t, 8 Hz, 2H), 2,45(dd, 1H), 2,25(s, 3H), 1,67–1,40(m, 16H); masse : 251(M^+), 110(100), 97(60), 96(30), 84(30), 55(60), 41(60).

Isoxazoles-3,5 disubstitués **3** *par métallation/alkylation d'isoxazoles α-N* **1** *(voie A_2 du schéma 2 et tableau 2)*

Comme pour les isoxazoles α-O, on utilise des conditions de contrôle thermodynamique (conditions (a), schéma 2).

(Heptène-6 yl)-5 (pentène-4 yl)-3 isoxazole **3**db (44%), $Eb_{0,03}$ 95°C; ir : 3140(f), 3080(m), 2940(TF), 2860(F), 1640(F), 1600(TF), 1480(m), 1440(F), 1425(F), 1350(f), 1000(f), 910(TF), 800(m); rmn ^{1}H : 5,80(m, 3H), 5(m, 4H), 2,80(m, 2H), 2,60(m, 2H), 1,7–2,10(M, 12H); masse : 233(M^+), 136(50), 81(30), 80(25), 55(60), 41(100).

(Butène-3 yl)-5 (decène-9 yl)-3 isoxazole **3**ag (42%), $Eb_{0,8}$ 97°C; ir : 3080(f), 2920(F), 2850(m), 1640(m), 1600(m), 1480(f), 1460(m), 1440(m), 1410(m), 990(f), 810(m), 780(m); rmn ^{1}H : 5,80(m, 3H), 5(m, 4H), 2,80(m, 2H), 2,60(m, 2H), 1,60–2,45(M, 16H); masse : 261(M^+), 137(30), 110(5), 97(10), 55(75), 43(30), (100).

(Butène-3 yl)-5 (undecène-10 yl)-3 isoxazole **3**ah (61%), $Eb_{0,8}$ 97°C; ir : 3080(f), 2920(F), 2850(F), 1650(m), 1600(F), 1480(f), 1440(m), 1420(m), 990(m), 910(F), 790(m); rmn ^{1}H : 5,80(m, 3H), 5(m, 4H), 2,80(m, 2H), 2,60(m, 2H), 1,60–2,40(M, 18H); masse : 275(M^+), 69(15), 67(15), 55(45), 44(100), 41(80).

Essai d'obtention d'isoxazoles **3** *par métallation/alkylation d'isoxazoles* **2** *sous contrôle cinétique (voie A_4, tableau 3)*

En combinant différents facteurs favorables à un contrôle cinétique (température de −105°C, base encombrée comme *sec*-BuLi, suppression du délai entre l'addition du lithien et celle de l'électrophile) lors de la métallation/alkylation des isoxazoles **2**, il a été possible d'augmenter la proportion d'isoxazole **3** sans toutefois atteindre la régiospécificité.

(Butène-3 yl)-3 (butène-3 yl)-5 isoxazole **3**aa. Selon les conditions opératoires le mélange brut analysé par cpv capillaire (colonne WCOT CP Sil 5, longueur 25 m, diamètre int. 0,23 mm avec un appareil Hewlett–Packard (5880 A), l'isomère **3***aa* servant d'étalon ayant été préparé de façon indépendante (2, 3)) contient des proportions très différentes de **3***aa* : 34 et 79% pour les essais 1 et 2.

(Butène-3 yl)-3 (undécène-10 yl)-5 isoxazole **3**ha. Le produit brut (55%), uv (CH_3CN) λ_{max} en nm (log ε_{max}) : 229(3,17); masse :

275(M^+), 69(15), 67(15), 55(45), 44(100), 41(80), étant en fait un mélange d'isoxazoles **3** et **5** séparables par distillation : **5***ha* (43%), $Eb_{0,1}$ 146°C; **3***ha* (57%), $Eb_{0,1}$ 151°C.

(Hexène-5 yl)-5 (nonène-8 yl)-3 isoxazole **3**cf. Le produit brut (44%), ir : 3140(f), 3100(m), 2940(F), 2880(F), 1650(m), 1610(F), 1490(f), 1470(m), 1430(F), 1000(m), 920(F), 800(m); masse : 275(M^+), 110(1), 96(1), 82(2), 69(5), 67(5), 55(15), 43(10), 42(10), 41(100), étant en fait un mélange d'isoxazoles **3** et **5** séparables par distillation : **5***cf* (48%), $Eb_{0,1}$ 145°C et **3***cf* (52%), $Eb_{0,1}$ 152°C.

Synthèse convergente par cycloaddition dipolaire-1,3 (voies B)

Synthèse d'isoxazoles-3,5 disubstitués **3** *avec un moins une chaine alcényle (voie B_1 : via les isoxazolines* **9***)*

Les isoxazolines-1,2 **9***c* et **9***cj* sont préparées selon la méthode de Mukaiyama et Hoshino (7) que nous avons tranposée en l'appliquant à l'octadiène comme dipolarophile alors que les isoxazolines **9***cg* et **9***cf* sont obtenues en utilisant la méthode de Larsen et Torssell (10) pour générer *in situ* le nitrile-oxyde.

(Héxène-5 yl)-5 méthyl-3 dihydro-4,5 isoxazoline **9**c. À un mélange d'isocyanate de phényle (0,1 mol) et d'octadiène (0,055 mol) dans 25 cm^3 de benzène anhydre, on ajoute goutte à goutte une solution de nitroéthane (0,055 mol) dans 15 cm^3 de benzène sec contenant 10 gouttes de triéthylamine. Après le démarrage de la réaction (avec dégagement de CO_2 et précipitation de diphénylurée), on agite 1 h puis porte à reflux une autre heure. Après refroidissement, la solution est lavée à l'eau, puis séchée. L'évaporation du solvant suivie d'un refroidissement 1 nuit à −15°C permet de séparer la di-isoxazoline **10***c* cristallisée (Fi 75°C) d'une huile contenant l'isoxazoline **9***c* brute. La distillation fournit 4,73 g (56%), $Eb_{0,3}$ 92–93°C; ir : 3080(f), 1725(m), 1640(m), 1600(f), 900(m); rmn ^1H : 5,75(m, 1H), 5(m, 2H), 4,5(m, 1H), 2,60–2,80(m, 2H), 2,0(m, 2H), 1,90(s, 3H), 1,30(m, 6H).

Éthyl-3 (héxène-5 yl)-5 dihydro-4,5 isoxazoline **9**cj (47%), $Eb_{0,5}$ 82–85°C; ir : 3080(f), 1640(m), 1620(f), 1600(f), 1000(m), 920(m); rmn ^1H : 5,80(m, 1H), 5,00(m, 2H), 4,55(m, 1H), 2,90(m, 1H), 2,60(m, 1H), 2,30(m, 2H), 2,00(2H), 1,30(m, 6H), 1,10(t, 3H).

(Décène-9 yl)-3 (hexène-5 yl)-5 dihydro-4,5 isoxazoline **9**cg. À une suspension de *N*-chlorosuccinimide (26 mmol, 3,46 g) dans 18 cm^3 de chloroforme on ajoute en une seule fois l'oxime de l'undécénal (26 mmol, 4,76 g) à 25°C. La chloration de l'oxime intervient en général après 10 min et se manifeste par la disparition de la suspension. On ajoute alors l'octadiène (32 mmol, 4,6 cm^3) et la température est portée à 40–50°C avant d'ajouter goutte à goutte en 30 min la triethylamine (28 mmol, 2,82 g) en solution dans 4 cm^3 de $CHCl_3$. Le mélange est lavé à l'eau, seché et concentré après avoir été agité 30 min. Du concentrat visqueux on sépare la di-isoxazoline **10***cg* brute précipitée par refroidissement (0,35 g, ~5%) d'une huile contenant l'isoxazoline **9***cg*. La distillation fournit 3,74 g (52%), $Eb_{0,1}$ 135–137°C; ir : 3080(f), 1720(m), 1640(m), 1000(m), 900(m); rmn ^1H : 5,90(m, 2H), 5,00(m, 4H), 4,5(m, 1H), 2,90(m, 1H), 2,45(m, 1H), 2,00(m, 2H), 2,25(m, 2H), 1,30(m, 20H).

(Heptène-6 yl)-3 (héxène-5 yl)-5 dihydro-4,5 isoxazoline **9**cf (48%), Eb_1 180–185°C; ir : 3080(f), 1720(m), 1640(m), 1600(f), 1000(m), 910(m); rmn ^1H : 5,90(m, 2H), 5,00(4H), 4,50(m, 1H), 2,90(m, 1H), 2,45(m, 1H), 2,25(m, 2H), 2,00(m, 2H), 1,30(m, 18H).

Les isoxazoles sont obtenus par oxydation par le MnO_2 activé selon la référence 7.

Méthyl-3 (héxène-5 yl)-5 isoxazole **3**c (85%), $Eb_{0,5}$ 102–105°C; ir : 3080(f), 1640(m), 1600(m), 910(m); rmn ^1H : 5,6–6(m, 1H), 5,8(s, 1H), 4,9–5,10(m, 2H), 2,75(t, 2H), 2,25(s, 3H), 2,30–2(m, 2H), 1,25–1,8(m, 4H).

(Décène-9 yl)-3 (hexène-5 yl)-5 isoxazole **3**cg (80%), $Eb_{0,1}$ 140–142°C; ir : 3080(f), 1640(f), 1600(f), 910(m); rmn ^1H : 6–5,60(m, 2H), 5,80(s, 1H), 5,2–4,9(m, 4H), 2,8–2,5(m, 4H), 2,5–1,75(m, 4H), 1,75–1(m, 16H).

(Nonène-8 yl)-3 (hexène-5 yl)-5 isoxazole **3**cf (80%), $Eb_{0,1}$ 135–136°C; ir : 3080(f), 1640(f), 1600(f), 910(m); rmn ^1H : 6–5,60(m, 2H), 5,80(s, 1H), 5,2–4,9(m, 4H), 2,8–2,5(m, 4H), 2,4–1,8(m, 4H), 1,5–1(m, 14H).

Éthyl-3 (héxène-5 yl)-5 isoxazole **3**cj (85%), $Eb_{0,5}$ 110–111°C; ir : 3080(f), 1640(m), 910(m); rmn ^1H : 6–5,5(m, 1H), 5,75(s, 1H), 5,10–4,9(m, 2H), 2,62(q, 2H), 2(m, 2H), 1,25–1,75(m, 6H), 1,20(t, 3H).

Synthèse de dialkyl-3,5 isoxazoles **3** *(voie B_2, emploi d'alcynes)*

Nous avons utilisé la méthode de Larsen et Torssell (10).

Pentyl-5 phényl-3 isoxazole **3**a (79%), $Eb_{0,5}$ 120–122°C; ir : 2960(F), 2940(F), 2880(m), 1600(F), 1490(m), 1470(F), 1430(F), 1380(m), 790(m); rmn ^1H : 7,7(m, 2H), 7,4(3H), 6,2(s, 1H), 2,75(t, 2H), 1,75(m, 2H), 1,30(m, 4H), 0,9(t, CH_3).

Pentyl-5 propyl-3 isoxazole **3**b (69%), $Eb_{0,5}$ 75–77°C; ir : 2960(F), 2940(F), 2880(m), 1600(F), 1490(m), 1470(F), 1430(F), 1380(m), 790(m); rmn ^1H : 5,80(s, 1H), 2,67(t, 2H), 2,57(t, 2H), 1,65(m, 4H), 1,32(m, 4H), 0,9(m, 6H).

Butyl-5 propyl-3 isoxazole **3**c (65%), $Eb_{0,1}$ 60–63°C; ir : 2960(F), 2940(m), 2880(f), 1600(F), 1490(f), 1460(f), 1430(m); rmn ^1H : 5,80(s, 1H), 2,67(t, 2H), 2,56(t, 2H), 1,70(m, 4H), 1,4(m, 2H), 0.90(m, 6H); masse : 167(M^+), 139(95), 110(10), 68(35), 57(30), 55(30), 43(70), 41(100).

Butyl-5 décyl-3 isoxazole **3**d (61%), $Eb_{0,5}$ 120–125°C; ir : 2960(F), 2940(m), 2880(f), 1600(F), 1470(m), 1430(m), 1000(f), 760(f); rmn ^1H : 5,80(s, 1H), 2,67(t, 2H), 2,57(t, 2H), 1,30(m, 20H), 0.90(m, 6H); masse : 265(M^+), 139(40), 57(40), 55(50), 43(70), 42(30), 41(100).

Didécyl-3,5 isoxazole **3**e (55%), $Eb_{0,5}$ 138–140°C; ir : 3020(f), 2920(TF), 2860(TF), 1600(m), 1470(m), 1220(F), 670(m); rmn ^1H : 5,80(s, 1H), 2,67(t, 2H), 2,56(t, 2H), 1,30(m, 32H), 0,90(m, 6H); masse : 349(M^+), 236(45), 110(45), 97(20), 57(30), 55(50), 43(100), 41(100).

Hexyl-3 (hydroxy-1 hexyl)-5 isoxazole **3**f (52%), $Eb_{0,5}$ 120°C; ir : 3380(large), 2980(F), 2940(TF), 2860(F), 1600(m), 1460(m), 1430(m); rmn ^1H : 6,25(s, 1H), 4,80(m, 1H), 3,60(1H, mobile), 2,60(m, 2H), 1,30(m, 16H), 0.90(m, 6H).

Dihexyl-3,5 isoxazole **3**g (62%), $Eb_{0,5}$ 125°C; ir : 2940(TF), 2860(F), 1600(F), 1480(m), 1460(m), 1430(m); rmn ^1H : 5,80(s, 1H), 2,67(t, 2H), 2,57(t, 2H), 1,30(m, 16H), 0,90(m, 6H); masse : 237(M^+), 167(45), 55(60), 44(45), 43(80), 41(100).

Ab initio molecular orbital calculations of the infrared spectra of hydrogen bonded complexes of water, ammonia, and hydroxylamine. Part 6. The infrared spectrum of the water–ammonia complex[1]

GEOFFREY ANDREW YEO AND THOMAS ANTHONY FORD[2]
Department of Chemistry, University of the Witwatersrand, Johannesburg, Wits 2050, South Africa

Received July 20, 1990

GEOFFREY ANDREW YEO and THOMAS ANTHONY FORD. Can. J. Chem. **69**, 632 (1991).

The molecular structure, interaction energy, and infrared spectrum of the linearly hydrogen bonded 1:1 molecular complex of water and ammonia have been predicted by means of a series of *ab initio* molecular orbital calculations, at the level of second order Møller–Plesset perturbation theory, using the 6-31G** basis set. The calculated wavenumbers and intensities have been compared with those calculated earlier for the respective monomers, and the wavenumber shifts and intensity changes rationalized in terms of the hydrogen bond interaction responsible for the stability of the complex.

The calculated hydrogen bond energy of the complex has been compared with those of the linear water and ammonia dimers, reported in a previous publication, and the relative strengths of interaction of the three aggregates have been rationalized on the basis of the electron donor/acceptor capacities of the respective monomer units.

Key words: *ab initio*, infrared spectrum, water, ammonia.

GEOFFREY ANDREW YEO et THOMAS ANTHONY FORD. Can. J. Chem. **69**, 632 (1991).

En se basant sur des calculs d'orbitales moléculaires *ab initio* au second niveau de perturbation de Møller–Plesset et utilisant un ensemble de base 6-31G**, on a fait des prédictions concernant la structure moléculaire, l'énergie d'interaction et le spectre infrarouge du complexe moléculaire 1:1 de l'eau et de l'ammoniac réunie par une liaison hydrogène linéaire. On a comparé les valeurs calculées pour les nombres d'onde et pour les intensités avec celles calculées antérieurement pour les monomères respectifs; on a rationalisé les déplacements dans les nombres d'onde et les changements dans les intensités en fonction de l'interaction de la liaison hydrogène responsable de la stabilité du complexe.

On a aussi comparé la valeur de l'énergie de la liaison hydrogène du complexe avec celles des dimères linéaire de l'eau et de l'ammoniac, rapportées dans une publication antérieure; on a rationalisé les forces relatives des interactions de ces trois agrégats en fonction des capacités des unités monomères respectives à agir comme donneur ou accepteur d'électrons.

Mots clés : *ab initio*, spectre infrarouge, eau, ammoniac.

[Traduit par la rédaction]

1. Introduction

The molecules water, ammonia, and hydroxylamine form an interesting series for a systematic study of hydrogen bonding. Water is a common electron acceptor (proton donor or Lewis acid) in hydrogen bonded structures, and ammonia is well-known as an electron donor (proton acceptor or Lewis base). Hydroxylamine is expected to show some characteristics of both types of interaction; it is capable of donating either a proton through its OH group, or the lone pair of electrons on its nitrogen atom. Hydrogen bonded structures containing hydroxylamine could also be envisaged in which proton donation occurs through the NH groups, or electron donation through the oxygen lone pairs, although such structures are expected to be far less likely.

We have initiated a study of the infrared spectra of the binary complexes of these three molecules, by means of matrix isolation spectroscopy and *ab initio* molecular orbital theory. We have reported the infrared spectra, in nitrogen and argon matrices, of the water and ammonia (1) and hydroxylamine (2) monomers and homodimers, and have predicted the spectra of the monomers (3, 4) and the water (1), ammonia (1, 5, 6), and hydroxylamine (7) dimers, at both the Hartree–Fock and Møller–Plesset levels of theory, using a variety of basis sets. We now turn our attention to the heterodimer formed between water and ammonia.

The structure of the water–ammonia complex in the gas phase has been studied by Herbine and Dyke (8), by means of molecular beam electron resonance (MBER), and by Millen and Mines (9), by infrared spectroscopy. The MBER results showed that the complex was essentially linearly hydrogen bonded, with an O...N separation of 298.3 pm, and with the ammonia C_3 symmetry axis having a vibrationally-averaged displacement of 23.1° from the O...N axis (8) (structures **I** and **II**, see Fig. 1). *Ab initio* theoretical calculations on this complex by Kerns and Allen (10), who examined a bifurcated (OH_2...NH_3) structure (**III**) at the RHF/4-31G level, concluded that this geometry was a saddle point, and not a genuine minimum, on the potential energy surface. Kerns and Allen also considered a cyclic, doubly hydrogen bonded heterodimer, but found that its structure collapsed on optimization to the linearly bonded OH...N structure (**I** or **II**) (10). Del Bene (11) studied the RHF/6-31G* structures of the bimolecular complexes of water with the hydrides of the first- and second-row atoms, including ammonia, and found that the complexes exhibit conventional hydrogen bonded structures with virtually linear hydrogen bonds and directed lone pairs of electrons. A similar conclusion was reached by Diercksen *et al.* (12), who examined the hypersurface of the water–ammonia complex at a number of different intermolecular geometries, using a basis set containing *d*-type polarization functions on the oxygen and nitrogen atoms and *p*-type functions on the hydrogen atoms. While this work was still in progress, Latajka and Scheiner (13) published a similar study to this one, in which the structure of the complex in configuration **II** was computed using a basis set obtained from 6-31G** by the addition of a diffuse *sp*-shell on the non-hydrogen centres, with electron correlation included to second order Møller–Plesset theory (MP2).

Nelander and Nord (14), in a matrix isolation infrared study

[1]Part of this work was presented at the 73rd Canadian Chemical Conference, Halifax, N.S., July 15–20, 1990.

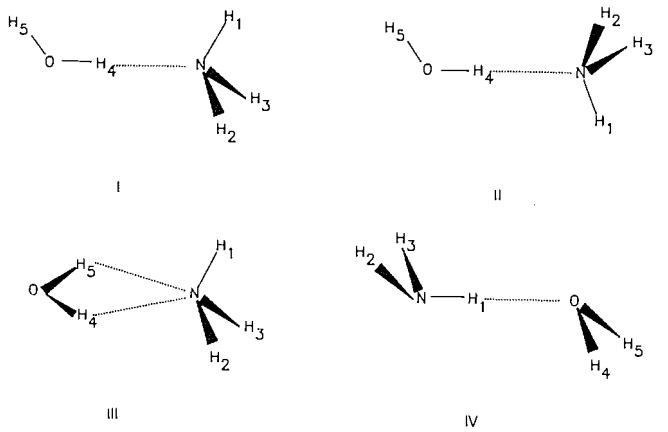

FIG. 1. Four possible structures for the water–ammonia complex (schematic).

using nitrogen and argon, and later Engdahl and Nelander (15) in neon and krypton matrices, have shown that the spectra in the region of the perturbed water fundamentals are consistent with a linear OH...N bonded structure (**I** or **II**). Our infrared spectra, obtained in both nitrogen and argon matrices (16), are in full agreement with those of Nelander *et al.* (14, 15).

In view of this earlier theoretical (10–13) and experimental (14, 15) evidence, we regarded the linear HOH...NH_3 hydrogen bonded geometries (**I** and **II**) to be the preferred structures of this complex, and used them as starting points for the geometry optimization, which is the first step in the *ab initio* prediction of vibrational spectra. Attempts to locate a minimum corresponding to the less probable linear $H_2NH...OH_2$ complex (structure **IV**), in which the electron donor and acceptor roles of the water and ammonia molecules were reversed, resulted in the starting structures invariably collapsing to the bifurcated $OH_2...N$ bonded geometry (**III**) proposed by Kerns and Allen (10). Accordingly, in addition to the computations on structures **I** and **II** we have performed some preliminary calculations, at lower levels of theory, on structure **III** as well.

2. Computational details

The computations on structures **I**, **II**, and **III** were performed using the GAUSSIAN-86 (17) and GAUSSIAN-88 (18) program packages on IBM 3083 and Convex C120 computers, respectively. The internally stored 6-31G** basis set was used (19, 20), and the calculations were carried out initially at the Hartree–Fock level of theory. In the light of these calculations, structure **III** was rejected as a plausible candidate for the correct structure, and the subsequent calculations, at the MP2 level (21), were limited to structures **I** and **II**. All molecular orbitals were included in the calculations. Total Berny geometry optimizations were employed, with the VERYTIGHT convergence criterion, subject to the conservation of C_s symmetry in each case. Dimerization energies were calculated, as reported earlier (6), and were corrected for basis set superposition error (BSSE) by the full counterpoise correction formula of Boys and Bernardi (22). The MASSAGE option of the programs was used for this phase of the computations (17, 18). The wavenumbers and infrared intensities were computed by means of the FREQ normal coordinate analysis option (17, 18).

3. Results

Ab initio calculations at the RHF/6-31G** level predict three stationary points on the potential energy surface of the hydrogen bonded water–ammonia complex, structures **I**, **II**, and **III**. The first of these configurations was obtained as a true minimum, and the second as a saddle point, with starting geometries in which ammonia was the electron donor. Starting geometries of type **IV**, with water as the electron donor, and with the symmetry constrained to C_s, invariably finally yielded the bifurcated structure **III**, with ammonia as the electron donor. At the MP2/6-31G** level, structure **II** was found to be the absolute minimum and structure **I** a transition state. A single, large negative eigenvalue calculated in the infrared spectrum of structure **III** at the RHF/6-31G** level indicated that this structure is also a transition state (23) (see later), confirming the findings of Kerns and Allen (10). Further analysis, at the MP2 level (21), was therefore confined to geometries **I** and **II**. The calculated geometries are presented in Table 1.

TABLE 1. Optimized geometrical parameters of the linear water–ammonia complexes, calculated at the MP2/6-31G** level of theory

Parameter	Structure **I**[a]	Structure **II**[a]
$r(NH_1)$/pm	101.2	101.2
$r(NH_2)$/pm	101.2	101.2
$r(N...H_4)$/pm	198.9	198.7
$r(OH_4)$/pm	97.2	97.2
$r(OH_5)$/pm	96.0	96.0
$\angle H_1NH_2$/deg	106.7	106.5
$\angle H_2NH_3$/deg	106.6	106.8
$\angle H_4...NH_1$/deg	121.7	102.4
$\angle H_4...NH_2$/deg	107.2	116.8
$\angle OH_4...N$/deg	175.7[b]	175.4[c]
$\angle H_4OH_5$/deg	103.9	103.9

	ν_{13}	γ (OH...N) (IM)	712	184
	ν_{14}	tw (NH_2) (76) + γ (OH...N) (13) (IM)	161	40
	ν_{15}	τ (HN...H) (IM)	30	77

[a]Numbers in parentheses indicate approximate percentage contributions to each normal mode (contributions > 10% only included). IP = in-phase, OP = out-of-phase, IM = intermolecular mode.

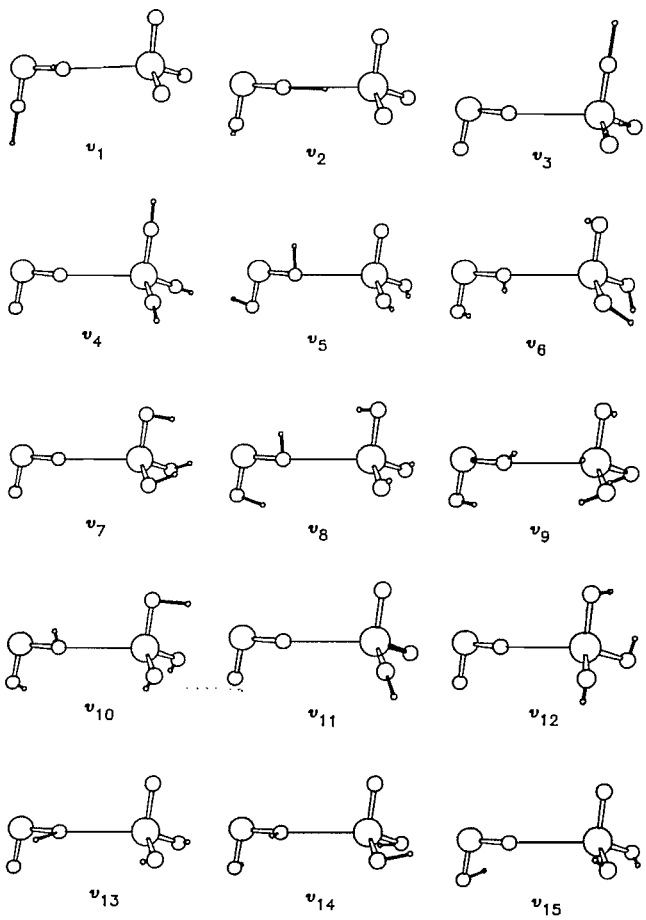

FIG. 2. Plots of the normal modes of vibration of the linear water–ammonia complex.

RHF/6-31G** and MP2/6-31G** levels, using the optimized geometries given in Table 1. At the lower level, no negative eigenvalues were predicted for structure **I**, while a single negative wavenumber was found for structure **II**. In contrast, calculations at the higher level yielded a single negative wavenumber for structure **I**, but no negative eigenvalues for structure **II**. This observation is consistent with the relative calculated minimum energies for the two structures at the two levels of theory, and the reversal of their relative stabilities at the MP2 compared with the RHF level. This confirms the implication of Table 2 that structures **I** and **II** are energetically very similar, and that prediction of the correct equilibrium structure is very sensitive to the level of theory employed. Apart from the negative eigenvalues, the calculated wavenumbers and intensities of both configurations, at both levels of theory, are very similar. Based on the calculations at the higher level of theory, however, structure **II** is predicted to be the preferred geometry. This is in agreement with other theoretical (10–13, 24–27) and experimental (8, 9, 14, 15) results. Thus the calculated wavenumbers and intensities of complex **II** only are presented in Table 3. Plots of the normal modes of vibration, which distribute between the irreducible representations a' and a'' according to

$$\Gamma_{vib} = 10a' + 5a''$$

are shown in Fig. 2.

4. Discussion

4.1. Molecular structures

A number of features are evident from the results of Table 1. The internal geometry of the water unit is the same in each case, remaining virtually unchanged from the calculated monomer geometry (1), except for the expected lengthening of the hydrogen bonded OH bond, whose length increases by 1.1 pm relative to the monomer value. Likewise, the geometries of the ammonia units are almost identical, with minimal changes in the bond angles only, compared with the monomer value (1). The local C_{3v} symmetry of the ammonia unit thus remains virtually intact. The hydrogen bond lengths, N...H_4, are also almost the same, differing by only 0.2 pm, and the hydrogen bonds deviate from linearity by less than 5° in each case, as measured by the value of the OH_4...N angle. The two angles H_4...NH_1 and H_4...NH_2 are quite different in the two isomers, however, and reference to Fig. 1 (structures **I** and **II**) shows that these are the angles which define the orientations of the ammonia molecules with respect to the N...H_4 hydrogen bond. In structure **I** hydrogen atoms H_1 and H_5 are in an eclipsed position and this,

together with a possible weak interaction between H_2 and H_3 and the lone pairs of electrons on the oxygen atom, has the effect of rotating the ammonia molecule into a position in which the $H_4 \ldots NH_1$ angle is 121.7°, rather than 112.7°, which would be the value of the angle if the C_3 axis were collinear with the $N \ldots H_4$ hydrogen bond. In structure **II** the H_2 and H_3 atoms are staggered with respect to H_5, and the H_1 atom interacts with the oxygen lone pairs such as to close the $H_4 \ldots NH_1$ angle to 102.4°.

The relative energies of structures **I** and **II** obtained at the MP2/6-31G** level, quoted above, indicate that structure **II** is the true minimum energy rotamer and **I** is a saddle point, separated from it by a barrier of only 42 J mol^{-1}. Del Bene has stated that the ammonia molecule is free to rotate about its own C_3 axis in the water–ammonia complex, this conclusion being based on calculations using the STO-3G basis set (25). The fact that structure **II** emerges only as a marginally preferred structure at the MP2/6-31G** level of theory supports this conclusion.

In the recent theoretical investigation of Latajka and Scheiner (13), the geometry was totally optimized at the RHF level of theory, using the augmented basis set referred to above, and the O...N distance only was then re-optimized at the MP2 level. The geometrical parameters found for structure **II** in this work are in good agreement with those of Latajka and Scheiner (13). The increase in the bonded OH bond length was computed to be 1.3 pm and the hydrogen bond was found to deviate from linearity by less than 5° (13). The O...N separation was calculated to be 294.2 pm, which compares with the value of 295.7 pm determined in this investigation. Moreover, the NH_3 unit was found to be tilted with respect to the O...N axis, with the pseudo C_3 axis following the bridging hydrogen atom H_4 (13), which is in agreement with the discussion above on the relative orientation of the NH_3 unit.

4.2. Dimerization energies

The interaction energies and BSSEs of the two linear water–ammonia structures, calculated at the MP2/6-31G** level, are virtually identical, and are shown in Table 2. For purposes of comparison, the same properties, calculated at the same level of theory, of the linear water and ammonia dimers (1), are also given. Calculations were also carried out at the RHF/6-31G** level on the bifurcated structure (**III**), and showed that this isomer is a much less stable configuration than structures **I** and **II** (corrected interaction energy 13.4 kJ mol^{-1} for **III**, compared with 31.4 kJ mol^{-1} for **I** and **II**). The hydrogen bond energy of 26.9 kJ mol^{-1} calculated here for structures **I** and **II** is in very good agreement with the most recently reported value of 26.6 kJ mol^{-1} obtained by Latajka and Scheiner (13). Del Bene has quoted a hydrogen bond enthalpy of 19.7 kJ mol^{-1} at the MP4/6-31+G(2*d*,2*p*) level, with corrections for zero-point and thermal vibrational contributions based on RHF/6-31G(*d*) wavenumbers (11). Millen and Mines (9) report a range of values from 24.7 to 43.5 kJ mol^{-1}, computed using a variety of basis sets, and our result accords well with those obtained using basis sets of comparable quality (12, 28). Comparing the hydrogen bond energy of the linear water–ammonia complex with those of the linear water and ammonia dimers (1), the observation that the interaction energy of $HOH \ldots NH_3$ is higher than that of $HOH \ldots OH_2$ is clearly due to the fact that ammonia is a stronger base than water, and the conclusion that the $HOH \ldots OH_2$ energy is higher than that of $H_2NH \ldots NH_3$ is rationalized by the fact that, although ammonia is a better proton acceptor than water, it is also a far poorer proton donor. Nelson *et al.*, in fact, have expressed doubts that ammonia is even capable of engaging in hydrogen bonds while acting as the proton donor (29).

4.3. Vibrational wavenumbers

In our previous discussion of the vibrational modes of the linear ammonia dimer (1, 5, 6), we pointed out that the intramolecular modes are almost completely localized in either the electron acceptor (EA) or the electron donor (ED) molecules and in essence are very similar to pure ammonia monomer vibrations. We also noted that, in the case of the linear water dimer (1), while the intramolecular modes of the ED are also virtually pure monomer vibrations, the OH-stretching vibrations of the EA are effectively decoupled by the interaction with the ED, which indicates that there is a much stronger hydrogen bonding interaction in $HOH \ldots OH_2$ compared with that in $H_2NH \ldots NH_3$ (see Table 2). This reasoning may also be extended to the linear water–ammonia complex. Modes ν_1 and ν_2 may be described as essentially free and bonded OH-stretching vibrations, respectively (see Table 3), since over 90% of each mode is localized in the individual bonds, compared with 80% in the EA of the linear water dimer. Modes ν_5 and ν_6, on the other hand, which are essentially the HOH-bending and NH_2-bending vibrations of the water and ammonia molecules, contain 17% and 19% contributions, respectively, from the appropriate group vibration of the partner monomer unit, a phenomenon which was not evident in either the linear water or ammonia dimers (1), and which also argues for a stronger interaction in the water–ammonia complex.

As was the case for the ED molecules in the linear water and ammonia dimers (1), the ammonia (ED) molecule in the water–ammonia complex is little perturbed by the presence of the water molecule. As noted above, its C_{3v} symmetry remains virtually intact, and a comparison of the percentage contributions of the motions of each atom in the intramolecular vibrations with those of the ammonia monomer shows that, except for the case of the ν_6 mode mentioned above, the forms of the vibrations are almost identical with their counterparts in the monomer.

The wavenumber shifts and intensity changes which occur on complex formation, expressed as the differences between the wavenumbers of the complex and of the corresponding modes of the relevant monomer, and the ratios of the complex to the relevant monomer band intensities, are shown in Table 4, along with the results of Latajka and Scheiner (13). Clearly, the largest wavenumber shifts in the complex are associated with the EA (water) molecule. The wavenumber of the non-bonded OH-stretching mode, ν_1, is red shifted by 45 cm^{-1}, which is a similar shift to that of the equivalent mode of the linear water dimer. The bonded OH-stretching mode (ν_2) wavenumber, however, is shifted to lower frequency by 167 cm^{-1}, which is more than double the shift calculated for the bonded OH-stretching mode of the water dimer. The complex HOH-bending mode, ν_5, is blue shifted by 60 cm^{-1} from the monomer value, a change which is also almost double that calculated for the water dimer. In contrast, the wavenumbers of the complex modes associated with the intramolecular modes of the ED (ammonia) molecule are changed very little from their monomer values, except for the bending vibration, ν_7, which is blue shifted by 36 cm^{-1} relative to the symmetric bending mode of the ammonia monomer.

Of the six intermolecular modes of the water–ammonia complex, the two modes identified as the in-plane and out-of-plane bendings of the hydrogen bond (ν_8 and ν_{13}) occur at the highest wavenumbers, and the more intense of these, ν_{13}, is

[c]RHF/augmented 6-31G**.

predicted to be the second most intense band in the spectrum (see Table 3). The two modes more closely associated with the ammonia molecule, ν_{10} and ν_{14}, occur at lower wavenumbers, consistent with the results obtained for other hydrogen bonded systems (13).

The predicted shifts in wavenumber undergone by the ammonia molecule on complexation are in general agreement with those calculated by Latajka and Scheiner at the SCF level (13), with some notable exceptions. For example, the blue shift of 36 cm^{-1} computed for the symmetric bending mode is less than half of that calculated by Latajka and Scheiner (13). In contrast, the computed wavenumber shifts experienced by the water molecule are all larger than those found by Latajka and Scheiner, although we are in agreement on the directions of the shifts. Also in contrast to the results of Latajka and Scheiner, our MP2/6-31G** calculations place the intermolecular hydrogen bond stretching mode, ν_9, at a higher wavenumber than the two modes, ν_{10} and ν_{14}, which they have described as the wagging vibrations of the proton acceptor molecule. Moreover, we predict that the torsional motion about the hydrogen bond, ν_{15}, will be a relatively intense band.

We shall be reporting the infrared spectra of this complex, in nitrogen and argon matrices, in the light of these theoretical predictions, in a forthcoming publication (16).

4.4. Infrared intensities

The familiar intensity enhancement which accompanies the red shift of the hydrogen bonded OH-stretching band on complex formation is also evident here, with an almost 90-fold increase over the monomer value (see Table 4). This again is double the 40-fold increase calculated for the corresponding mode of the EA molecule of the linear water dimer (1). The NH-stretching vibrations, ν_3, ν_4, and ν_{11}, all exhibit substantial intensity increases, which are all larger than the increases calculated for the corresponding modes (ν_1, ν_3, and ν_{12}) of the ED molecule of the linear ammonia dimer (1). It is interesting to note that the HOH-bending mode (ν_5), whose intensity decreases by a factor of 2.5 compared with its value in the water monomer, and the NH_2-bending mode, ν_6, which gains in intensity almost four-fold relative to the corresponding monomer mode, are the two modes of the water–ammonia complex in which there is considerable coupling between the vibrations of the two monomer units, and the intensity variations are thus due to the fact that there are contributions from both the EA and ED units to the total atomic displacements for each mode.

The relative intensity changes shown in Table 4, in particular those calculated for the bonded OH-stretching vibration of the water molecule, ν_2, and the NH-stretching modes of the ammonia molecule, ν_3, ν_4, and ν_{11}, are all considerably larger than those computed by Latajka and Scheiner (13). This is due to the relatively lower intensities calculated at the MP2/6-31G** level (1) for the corresponding monomer vibrations than at lower levels of theory (13). In particular, the ν_1 mode of the water monomer has a predicted intensity of 4.3 km mol^{-1} (MP2/6-31G**) (1), compared with 25 km mol^{-1} (RHF with the augmented 6-31G** basis set) (13). Similarly, the MP2/6-31G** intensities of the ν_1 and ν_3 modes of the ammonia monomer (1) are lower than the RHF/augmented 6-31G** values reported by Latajka and Scheiner (13). Nevertheless, the large increase in the intensity of the bonded OH-stretching band, and the increases in the NH-stretching band intensities on complex formation, are confirmed both by the present calculations and by those of Latajka and Scheiner (13).

The wavenumber shifts and intensity changes of the water and ammonia monomer modes, and the perturbations of the forms of those modes which are predicted to occur on formation of the water–ammonia complex, are consistent with those expected for a hydrogen bonded interaction (30). The larger wavenumber shifts and intensity enhancements, and the greater extent to which the normal modes of vibration of the water (EA) molecule in the complex are decoupled, compared with that of the EA molecule in the linear water dimer, are evidence that the hydrogen bond in the complex is stronger than that in the dimer, and this is supported by the higher calculated interaction energy reported in Table 2.

Dimerization and continuous association including formation of cyclic dimers[1]

ALEXANDER APELBLAT
Department of Chemical Engineering, Ben Gurion University of the Negev, Beer Sheva, Israel
Received November 30, 1989[2]

A. APELBLAT. Can. J. Chem. **69**, 638 (1991).

New aspects of the theory of ideal associated mixtures related to a differentiation between formed cyclic and linear dimers are discussed. A mathematical analysis is presented for the dimerization model, $A + B + A_2$, the continuous association (Mecke–Kempter) model, $A + B + A_2 + A_3 + A_4 + \cdots$, both coupled with the cyclic dimer $\longrightarrow$ linear dimer transformation and for the unsymmetrical (mixed) dimer formation model, $A + B + A_2 + B_2 + AB$. Introduction of the standard reaction enthalpies and volumes associated with transformations of dimers leads to a considerable change in behavior and symmetry properties of the excess thermodynamic functions. In terms of the modified Mecke–Kempter model, a consistent representation of the excess Gibbs energy of mixing G^E, heat of mixing H^E, and excess molar volume V^E is reported for the acetic acid – water system at 298.15 K.

Key words: association, dimerization, linear dimers, cyclic dimers, hydrogen bonding, carboxylic acids, alcohols, aqueous solutions.

A. APELBLAT. Can. J. Chem. **69**, 638 (1991).

On discute de nouveaux aspects de la théorie des mélanges associés parfaits qui sont reliés à une différentiation entre la formation de dimères cycliques et linéaires. On présente une analyse mathématique du modèle de dimérisation, $A + B + A_2$, du modèle d'association continue (Mecke–Kempter), $A + B + A_2 + A_3 + A_4 + \cdots$, ainsi que deux modèles couplés avec la transformation du dimère cyclique $\longrightarrow$ dimère linéaire et finalement du modèle de formation du dimère asymétrique (mixte), $A + B + A_2 + B_2 + AB$. L'introduction des enthalpies standard de réaction et des volumes associés avec les transformations des dimères conduit à un changement important dans le comportement et les propriétés de symétrie des fonctions thermodynamiques en excès. Pour le système acide acétique/eau, à 298,15 K et utilisant le modèle de Mecke-Kempter modifié, on a obtenu une représentation cohérente de l'énergie de mélange de Gibbs en excès, G^E, de la chaleur de formation, H^E et du volume molaire en excès, V^E.

Mots clés : association, dimérisation, dimères linéaires, dimères cycliques, liaison hydrogène, acides carboxyliques, alcools, solutions aqueuses.

[Traduit par le Rédaction]

Introduction

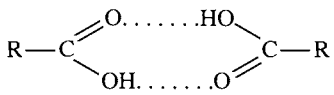
Dimerization of carboxylic acids in both gaseous and liquid states is a well-established experimental fact (1–4). Usually, dimer formation is a decisive, but not exclusive reason for observed deviations from ideality in investigated systems. Besides contributions coming from the "physical" effects, the formation of higher associates is also postulated (5–8). A quantitative description of the systems with carboxylic acids always includes an assumption that the "chemical" contribution to the excess Gibbs energy of mixing is more important than the "physical" one. In a first approximation, the "chemical" contribution is frequently represented by the ideal associated solution model. Bearing the same number of introduced parameters, the advantage of this model lies in its simplicity.

Since the formation of dimers is not limited to the systems with carboxylic acids, but considered in many other systems, a general interest in a description of the monomer $\longrightarrow$ dimer equilibrium is therefore understandable. The most complete mathematical treatment for the dimerization reaction in an ideal associated solution approximation was given by Kehiaian and Sosnkowska-Kehiaian (9).

In this work, some new aspects related to the ideal associated solution model will be discussed. They resulted from a thermodynamic analysis recently performed in the carboxylic acid – water and carboxylic acid – carboxylic acid systems (10, 11). It was observed that experimental data of a different kind (vapor pressures, heats of mixing, and excess volumes) cannot be represented with the same set of equilibrium constants and standard reaction changes of the association reactions. In other words, there is a possibility to correlate these particular data with a molecular model, but it is difficult to obtain for this model a consistent description which includes all excess thermodynamic function G^E, H^E, S^E, and V^E. A typical example is the aqueous solutions of carboxylic acids, where the excess Gibbs energy of mixing G^E, and the excess molar volumes, V^E, derived from vapor pressure and density measurements can be reproduced using the Mecke–Kempter model with the same equilibrium constant (10).

The Mecke–Kempter model, originally developed for mixtures of alcohols in nonpolar solvents, represents the formation of hydrogen-bonded associates of different lengths (dimer, trimer, tetramer, etc.) with the same equilibrium constant in consecutive reactions. However, if the excess enthalpy, H^E, is considered to be a function of composition in the carboxylic acid – water system, the model predictions totally disagree with the experimental heats of mixing, not only with respect to the shape of the curves, but sometimes even with the sign of the thermal effect. To add to the difficulty in interpretation, most of the thermodynamic and spectroscopic data are available for dilute solutions of carboxylic acids, where there is almost no possibility to distinguish between descriptions based on the Mecke–Kempter and dimer formation models.

The self-association of carboxylic acids in water and the existence of higher than dimer associates are evidently linked



[1]This paper is dedicated to Professor Friedrich Kohler on the occasion of his 65th birthday.

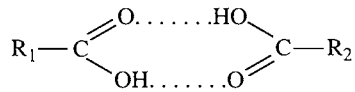
to the formation of two different types of dimers. The cyclic (closed) dimers are predominantly formed in pure acids or in mixtures with nonpolar solvents.

A

However, when a polar component (water) is added to the acid, only the linear (open) dimer is able to continue to form hydrogen-bonded chains

B



The linear dimers are formed with the nonpolar parts of molecules being in maximum contact with each other, minimizing their unfavorable contact with water (12). The cyclic and linear forms exist in different proportions in carboxylic acid – solvent mixtures. From the Raman, NMR, and ultrasonic absorption measurements it can be concluded that the presence of linear associates is significant even at low concentration of the acids (5, 6, 13, 14). In the case of alcohols, theoretical calculations and experimental results show that the linear dimer is more stable than the cyclic dimer (see, for example, Remko (15) and Brink and Glasser (16)).

In molecular association models, the excess Gibbs energy of mixing G^E depends on the total number of dimers in the system and a differentiation between the cyclic and linear dimers is not essential. This is evidently not true when the excess enthalpy of mixing H^E and the excess entropy of mixing S^E are considered, because the experimentally observed heat of mixing represents the over-all energetic balance associated with the monomer $\rightarrow$ dimer, cyclic dimer $\rightarrow$ linear dimer $\rightarrow$ higher polymers transformations.

The equality of equilibrium constants in the Mecke–Kempter continuous association model includes an assumption that the consecutive standard energy, enthalpy, entropy, and volume are proportional to the molecular size of associated molecules. However, a better agreement between theory and experiment is observed if two different constants are introduced, first a constant K_2 for dimer formation and second an equilibrium constant K for formation of higher associates with $K_2 < K$. Coggeshall and Saier (17) stated that in a linear polymer model of association, the energy released on forming a dimer is considerable smaller than the energy released on increasing the order of a higher polymer by one. The latter is almost independent of the degree of association for polymers larger than trimer. From the statistical mechanics of associated mixtures (18), the condition $K_2 < K$ as postulated by Coggeshall and Saier is related to a decrease in the number of possible orientations of associated molecules. During the formation of a dimer, two monomers lose their orientations, while in the case of higher associates, only one monomer loses its orientations when added to the already existing associate. On the basis of kinetic considerations, Ginell (19) showed that the Coggeshall-Saier modification of the Mecke–Kempter model represents a situation where all higher associates have the same number of modes of attachment and detachment of the monomer, except for the formation of dimers where the multiplicity (the number of ways in which each step can be taken) is different.

A quantitative description of the differentiation between linear and cyclic dimers requires the introduction of two equilibrium constants and the corresponding standard reaction changes. However, an almost original version of the Mecke–Kempter model with one equilibrium constant can be preserved if the cyclic dimer $\rightarrow$ linear dimer transformation is directly associated with the presence of polar molecules of solvent. For example, in the case of pure carboxylic acids, the existing dimers have a cyclic structure (**A**), but when a polar solvent is added, it changes its structure to a linear form (**B**) (one of two hydrogen bonds is broken). The simplest assumption about linear dimers is that they are formed in direct proportion to the number of solvent molecules. In this case, only one equilibrium constant is necessary, but the standard reaction changes (*e.g.*, the standard molar reaction enthalpy ΔH^0) are different for cyclic and linear dimers, In such modifications of the Mecke–Kempter or dimer formation models, the stoichiometry–concentration relations, the activity coefficients and the excess Gibbs energy of mixing remain the same as in original models. However, in the presentation of other excess thermodynamic functions we have more flexibility, We might be able to change the symmetry properties and to expect S-shaped (with double extrema) curves.

In binary mixtures of carboxylic acids we meet with the formation of symmetrical (structure **A**) cyclic dimers and asymmetrical (mixed) cyclic dimers, structure **C**.

C

There are only a few examples where the experimental data were described taking into account formation of mixed dimers (11, 20–23) and mathematically the mixed dimers formation model is far from being satisfactory.

To some extent, the formal theory of three types of ideal associated solution models are considered here. These include the dimer formation model, $A + B + A_2$, the Mecke–Kempter model, $A + B + A_2 + A_3 + A_4 + \cdots$, both linked to the cyclic dimer $\rightarrow$ linear dimer transformation, and the mixed dimers formation model, $A + B + A_2 + B_2 + AB$.

Dimerization reaction accompanied by a cyclic dimer $\rightarrow$ linear dimer transformation and the formation of unsymmetrical (mixed) dimers

If in a binary mixture, the nominal component 1 dimerizes, the species present in the mixture are monomers A and B and dimer A_2 (denoted by D). The actual mole fractions x_A, x_B, and x_D are related to the nominal mole fractions x_1 and x_2 in the following way:

$$[1] \qquad \begin{aligned} x_A &= x_1(1 + x_D) - 2x_D \\ x_B &= x_2(1 + x_D) \end{aligned}$$

In terms of the equilibrium constant K, the dimerization reaction, $2A \rightarrow A_2$, is expressed as

$$[2] \qquad K = \frac{x_D}{x_A^2}$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

where the mole fraction of the dimer is (9)

$$[3]\quad x_D = \left\{ \frac{x_1}{1+x_2} - \frac{\sqrt{1+4K_D x_1(1+x_2)}-1}{2K_D(1+x_2)^2} \right\}$$

The excess Gibbs energy of mixing is

$$[4]\quad G^E = RT\left\{ x_1 \ln\left[\frac{1}{x_A^0}\left((1+x_D) - \frac{2x_D}{x_1}\right)\right] + x_2 \ln(1+x_D)\right\}$$

where $x_A^0 = 1 - x_D^0$, is the mole fraction of the monomer A in the pure component 1

$$[5]\quad x_A^0 = \frac{\sqrt{1+4K_D}-1}{2K_D}$$

and

$$[6]\quad G^E = H^E - TS^E$$

where the excess enthalpy of mixing H^E, is given by

$$[7]\quad H^E = \Delta H^0 \left\{ \frac{x_D}{1+x_D} - \frac{x_1 x_D^0}{1+x_D^0} \right\}$$
$$\Delta H^0 = H^0_{A_2} - 2H^0_A$$

For any value of K and x_1, $H^E/\Delta H^0$ is always negative and since the standard molar enthalpy of the dimerization reaction, ΔH^0, is usually negative the heat of mixing (H^E) is expected to be positive. H^E has only one extremum (10) and for $K_D \rightarrow 0$ and $K_D \rightarrow \infty$, the heat of mixing of the monomers (A+B) and of the undissociated dimers (B+D) is zero.

Now, we will start to distinguish between cyclic and linear dimers. If x_D is the mole fraction of the total number of dimers (given by eq. [3]), then, as explained above, the mole fractions of the linear and cyclic forms are:

$$x_D(l) = x_D x_B = K_D x_A^2 x_B$$
$$[8]\quad x_D(c) = x_D(1-x_B)$$
$$= K_D x_A^2(x_A + x_D) = K_D x_A^3(1 + K_D x_A)$$

or

$$[9]\quad \frac{x_D(l)}{x_D(c)} = \frac{x_B}{1-x_B}$$

In this approach, the concentration of linear dimers is proportional to the concentration of the polar component in the mixture. The formation of linear dimers can be assumed to be two-step reaction. In the first step, an intermediate complex is formed between the cyclic dimer and the polar component and in the second step the short-living complex dissociates to giving the linear dimer. If eqs. [8] and [9] are treated as some kind of equilibrium expressions then the linear dimer has the same equilibrium constant at infinite dilution in B ($x_B \rightarrow 1$) as the cyclic dimer in pure A ($x_B \rightarrow 0$) and the cyclic dimer at infinite dilution in B obeys the equation for a trimeric equilibrium.[3] Cyclic dimers exist only in pure component 1, but with the addition of polar component 2, the number of cyclic dimers decreases and linear dimers gradually become the dominant

[3]I am indebted to a reviewer for this interpretation of eqs. [8] and [9].

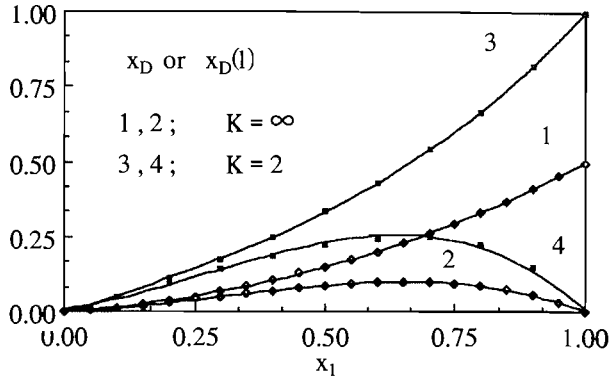


FIG. 1. Total mole fractions of dimers x_D (curves 1 and 3) and the mole fractions of linear dimers $x_D(l)$ (curves 2 and 4) as calculated for $K_D = 2$ and $K_D = \infty$.

form. This is illustrated in Fig. 1, where the mole fraction of the total (x_D) and the linear ($x_D(l)$) dimers are presented as a function of the mole fraction of the nominal (associating) component 1 for $K_D = 2$ and $K_D \rightarrow \infty$.

In the limiting case of complete dimerization ($K_D \rightarrow \infty$), the maximal values of x_D and $x_D(l)$ are

$$[10]\quad x_D^{max} = \frac{x_1}{1+x_2}$$
$$x_D^{max}(l) = \frac{2x_1x_2}{(1+x_2)^2}$$

For $0 < K_D < \infty$, the linear dimers have the maximum at $x = 2/3$, and

$$[11]\quad x_D^{max}(l) = \frac{1}{3}\left\{\left[\frac{\sqrt{1+q}-1}{q} - 1\right]^2 - \frac{1}{4}\right\} q = \frac{32K_D}{9}$$

The excess enthalpy of mixing H^E for the molecular model in question is given by a sum of two contributions $H^E(c)$ and $H^E(l)$ (dimerization reaction and cyclic dimer $\rightarrow$ linear dimer transformation). If the ratio of standard molar enthalpies of the transformation and dimerization reactions is introduced then H^E can be written in the form

$$[12]\quad H^E = \Delta H_D^0 \left\{ \frac{x_D(1+rx_D)}{1+x_D} - \frac{x_1 x_D^0}{1+x_D^0} \right\}$$
$$r = \Delta H_{tr}^0/\Delta H_D^0$$

where

$$[13]\quad \Delta H_D^0 = H^0_{A_2(c)} - 2H^0_A$$
$$\Delta H_{tr}^0 = H^0_{A_2(l)} - H^0_{A_2(c)}$$

In the case of complete dimerization, we have $H^E(c) = 0$ for $K_D \rightarrow \infty$ but $H^E(l) \neq 0$ and therefore

$$[14]\quad H^E(K_D \rightarrow \infty) = \Delta H_{tr}^0 \frac{x_1 x_2}{1+x_2}$$

with an extremum at $x^* = 2 - \sqrt{2}$, where

$$[15]\quad H^E(x^*, K_D \rightarrow \infty) = (\sqrt{2}-1)^2 \Delta H_{tr}^0$$

As explained above, the contribution coming from the formation of cyclic dimers $H^E(c)$ is positive, because usually $\Delta H_D^0 < 0$. The sign of the second term, $H^E(l)$, depends on the sign of ΔH_{tr}^0 and therefore the heat of mixing, H^E, can be negative, at least in part, only if $\Delta H_{tr}^0 < 0$. The S-shaped form of H^E can be expected if ΔH_D^0 and ΔH_{tr}^0 have the same sign (*i.e.*, r is positive).

Figure 2 presents a number of curves, $H^E/\Delta H_D^0 = f(x_1; r)$, which are calculated using the same dimerization constant, $K_D = 2$. The effect of K_D on $H^E/\Delta H_D^0 = f(x_1; K_D)$ for constant $r = 1$ is shown in Fig 3.

If the dimerization constant K_D is known independently from H^E (*e.g.*, from activity coefficients derived from vapor pressure measurements), the ratio of the standard enthalpies, r, can be determined from a knowledge of the experimental H^E curve and the location of composition, $x_1 = z$, at which $H^E(z) = 0$. Therefore

$$[16] \quad r = \frac{1}{(1-z)x_D}\left\{\frac{zx_D^0}{1+x_D^0} - \frac{x_D}{1+x_D}\right\}$$

where $x_D = f(K, z)$ is given by eq. [3].

The derivative of $H^E/\Delta H_D^0$ with respect to x_1 is

$$[17] \quad \frac{\partial(H^E/\Delta H_D^0)}{\partial x_1} = \left\{\left[rx_2 + \frac{1}{(1+x_D)^2}\right]\left(\frac{\partial x_D}{\partial x_1}\right) - rx_D - \frac{x_D^0}{1+x_D^0}\right\}\left(\frac{\partial x_D}{\partial x_1}\right) = \frac{2x_D(1+x_D)}{[x_1 + (1+x_2)x_D]}$$

Evidently, the extreme values of H^E are located at the compositions x_1 (min) and x_1 (max) where the derivative in eq. [16] is zero. Therefore, a numerical solution of simultaneous algebraic equations, $H^E(z) = 0$ and $\partial H^E/\partial x_1 = 0$ at x_1 (min) and x_1 (max), (eqs. [3], [16], and [17]) permits the evaluation of three parameters, $K_D, \Delta H_D^0$, and ΔH_{tr}^0 from the experimental H^E data. If the dimerization constant, K_D, is known and r is determined from the condition $H^E(z) = 0$ (eq. [16]), any other experimental point will give the value of ΔH_D^0 using eq. [12]. If the limiting slopes of the H^E curve at $x_1 \longrightarrow 0$ and $x_1 \longrightarrow 1$ are known with sufficient accuracy, $K_D, \Delta H_D^0$, and ΔH_{tr}^0 can be evaluated in a different way. From [17] we have

$$[18] \quad -\left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=0} = \frac{\Delta H_D^0 x_D^0}{(1+x_D^0)} = a_0$$

$$\left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=1} = \frac{\Delta H_D^0 x_D^0(1-x_D^0)}{(1+x_D^0)^2} + \Delta H_{tr}^0 x_D^0 = a_1$$

and therefore

$$[19] \quad r = \left\{\frac{(1+u)}{2u^2}\left[u\left(\frac{a_1}{a_0}\right) - 1\right]\right\}$$

$$u = \frac{1+x_D^0}{1-x_D^0} = \sqrt{1+4K_D}$$

Introducing [19] into [16] we have an algebraic equation which includes K_D as the only unknown parameter. Finally, ΔH_D^0 and ΔH_{tr}^0 can be calculated from the slopes a_0 and a_1 (eqs. [18]) by using the already determined value of the dimerization constant K_D. The same procedure can be applied to evaluation of $K_D, \Delta V_D^0$ and ΔV_{tr}^0 parameters when the excess molar volumes V^E are considered, because V^E are given by equations analogous to eqs. [12]–[19], but the standard molar reaction enthalpies should be replaced by the standard molar reaction volumes.

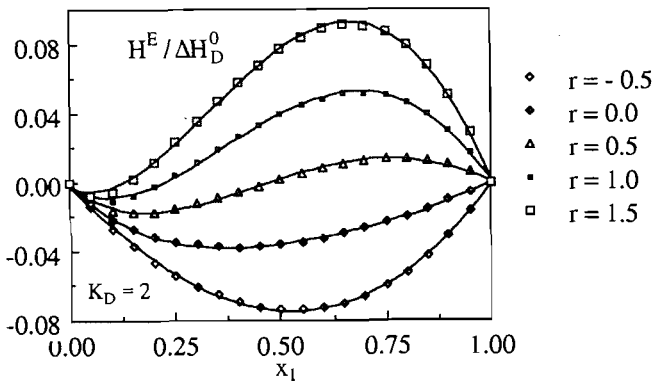

FIG. 2. Reduced excess molar enthalpies of mixing in the modified dimer formation model. Calculated for $K_D = 2$ and several values of r.

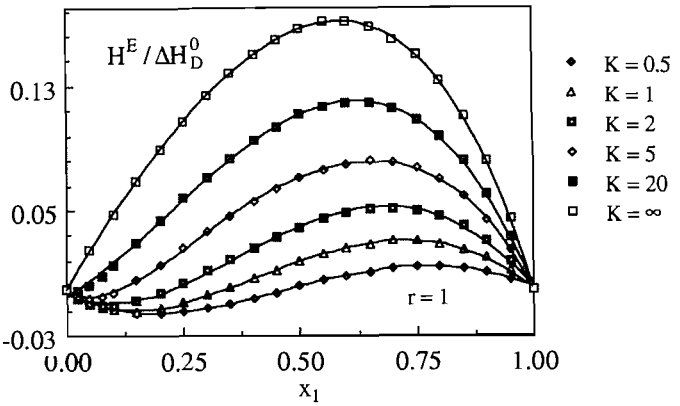

FIG. 3. Reduced excess molar enthalpies of mixing in the modified dimer formation model. Calculated for $r = 1$ and several values of K_D.

Dimers represented by structure **C** are expected to be present in systems where both nominal components are able to participate in dimerization reactions (*e.g.* in mixtures of carboxylic acids). Since only a few elements of the theory were studied in the literature (for details see Apelblat and Manzurola (11)), two cases of special interest (infinite dimerization constants and the pseudoideal behavior of mixtures) are discussed here. For an ideal association of the type $A + B + AB + A_2 + B_2$, we have

$$[20] \quad x_A + x_B + x_{AB} + x_{A_2} + x_{B_2} = 1$$

$$x_1 + x_2 = 1$$

and

$$[21] \quad K_1 = K_D(A_2) = \frac{x_{A_2}}{x_A^2}$$

$$K_2 = K_D(B_2) = \frac{x_{B_2}}{x_B^2}$$

$$K_{12} = K_D(AB) = \frac{x_{AB}}{x_A x_B}$$

where the actual and nominal mole fractions are related by:

$$[22]\quad \begin{aligned} x_A &= x_1(1 + x_{AB} + x_{A_2} + x_{B_2}) - 2x_{A_2} - x_{AB} \\ x_B &= x_2(1 + x_{AB} + x_{A_2} + x_{B_2}) - 2x_{B_2} - x_{AB} \end{aligned}$$

The mole fractions of monomers A and B in pure components 1 and 2 are

$$[23]\quad \begin{aligned} x_A^0 &= \frac{-1 + \sqrt{1 + 4K_1}}{2K_1} \\ x_B^0 &= \frac{-1 + \sqrt{1 + 4K_2}}{2K_2} \end{aligned}$$

with $x_A \leq x_A^0$ and $x_B \leq x_B^0$.

If the equilibrium constants of dimerization reactions are known, eqs. [20] and [21] lead to a fourth order algebraic equation which can be solved numerically to give the mole fractions of actual species as a function of x_1 or x_2.

For infinite dimerization constants ($x_A^0 = x_B^0 = 0$), if follows from [22] that

$$[24]\quad x_{AB} = 2(x_1 - x_{A_2}) = 2(x_2 - x_{B_2})$$

which is often expressed, basing on statistical arguments, as $x_{A_2} = x_1^2, x_{B_2} = x_2^2$, and $x_{AB} = 2x_1x_2$.

If the dimerization constants satisfy the condition (Gross and Wilson (28)):

$$[25]\quad (1 + 2K_{12})^2 = (1 + 4K_1)(1 + 4K_2)$$

the mixture A + B + A_2 + B_2 + AB obeys the Raoult law for any value of x_1. In this pseudoideal case we have $G^E = 0$ with $H^E = TS^E \neq 0$ and $V^E \neq 0$. For large equilibrium constants, K_{12} approaches its statistical value (Fowler and Guggenheim (29)):

$$[26]\quad K_{12}^2 = 4K_1K_2$$

This value of K_{12} satisfies eq. [25] only if the dimerization constants of symmetrical dimers K_1 and K_2 are equal (*i.e.*, $K_{12} = 2K_1 = 2K_2$).

The activity coefficients of the nominal components are

$$[27]\quad \begin{aligned} \gamma_1 &= \frac{x_A}{x_1x_A^0} \\ \gamma_2 &= \frac{x_B}{x_2x_B^0} \end{aligned}$$

With the exception of pseudoideal cases where $\gamma_1 = 1$ and $\gamma_2 = 1$ for any x_1, (eg. [25]), both activity coefficients are larger than unity and the excess Gibbs energy of mixing G^E is always positive reading its maximum at $x_1 = x^*$ where $\gamma_1 = \gamma_2 = \gamma^*$, *i.e.*

$$[28]\quad \frac{x_A}{x_B} = \frac{K_2x^*[\sqrt{1 + 4K_1} - 1]}{K_1(1 - x^*)[\sqrt{1 + 4K_2} - 1]}$$

From a knowledge of $x^*, G^E(x^*) = RT \ln \gamma^*$ and the limiting slopes

$$[29]\quad \begin{aligned} \left(\frac{\partial G^E}{\partial x_1}\right)_{x_1=0} &= RT \ln \gamma_1^\infty \\ \left(\frac{\partial G^E}{\partial x_1}\right)_{x_1=1} &= -RT \ln \gamma_2^\infty \end{aligned}$$

equilibrium constants can be evaluated because activity coefficients at infinite dilution are given by:

$$[30]\quad \begin{aligned} \gamma_1^\infty &= \frac{2K_1[1 + 4K_2 - \sqrt{1 + 4K_2}]}{(\sqrt{1 + 4K_1} - 1)[2K_2 + K_{12}(\sqrt{1 + 4K_2} - 1)]} \\ \gamma_2^\infty &= \frac{2K_2[1 + 4K_1 - \sqrt{1 + 4K_1}]}{(\sqrt{1 + 4K_2} - 1)[2K_1 + K_{12}(\sqrt{1 + 4K_1} - 1)]} \end{aligned}$$

Since K_{12} is difficult to determine independently, its value is usually replaced by [26] and this considerably simplifies the calculations.

The excess molar enthalpy of mixing H^E is a sum of three contributions:

$$[31]\quad \begin{aligned} H^E &= H^E(A_2) + H^E(B_2) + H^E(AB) \\ H^E(A_2) &= \Delta H_{A_2}^0 \left[\frac{x_{A_2}}{(2 - x_A - x_B)} - \frac{x_1(1 - x_A^0)}{(2 - x_A^0)}\right] \\ H^E(B_2) &= \Delta H_{B_2}^0 \left[\frac{x_{B_2}}{(2 - x_A - x_B)} - \frac{x_2(1 - x_B^0)}{(2 - x_B^0)}\right] \\ H^E(AB) &= \Delta H_{AB}^0 \frac{x_{AB}}{(2 - x_A - x_B)} \end{aligned}$$

where

$$[32]\quad \begin{aligned} \Delta H_{A_2}^0 &= H_{A_2}^0 - 2H_A^0 \\ \Delta H_{B_2}^0 &= H_{B_2}^0 - 2H_B^0 \\ \Delta H_{AB}^0 &= H_{AB}^0 - H_A^0 - H_B^0 \end{aligned}$$

A general analysis of eq. [31] is difficult, because the heat of mixing H^E, even if K_{12} is replaced by [26], depends on five adjustable parameters: two equilibrium constants and three standard molar reactions enthalpies. The sign of the first two terms is opposite to that of the standard enthalpies of dimerization reactions while the contribution coming from formation of mixed dimers has the same sign as the standard reaction enthalpy. However, for infinite dimerization constants, expressions [31] take a very simple form:

$$[33]\quad \begin{aligned} H^E &= \Delta H^0 x_1x_2/2 \\ \Delta H^0 &= 2H_{AB}^0 - H_{A_2}^0 - H_{B_2}^0 \end{aligned}$$

i.e., in this case, the excess molar enthalpy of mixing H^E is symmetrical with respect to composition. In pseudoideal mixtures, H^E is given by

$$[34]\quad \begin{aligned} H^E &= H^E(A_2) + H^E(B_2) + H^E(AB) \\ H^E(A_2) &= \Delta H_{A_2}^0 \left[\frac{x_1}{(2 - x_A - x_B)} - \frac{1}{(2 - x_A^0)}\right] \\ H^E(B_2) &= \Delta H_{B_2}^0 \left[\frac{x_2}{(2 - x_A - x_B)} - \frac{1}{(2 - x_B^0)}\right] \\ H^E(AB) &= \Delta H_{AB}^0 \frac{x_1x_2(2 - x_A^0 - x_B^0)}{(2 - x_A - x_B)} \end{aligned}$$

where $x_A = x_1x_A^0$ and $x_B = x_2x_B^0$ and x_A^0, x_B^0 are given by eq. [23].

If $K_{12} = 2K_1 = 2K_2$, then from [34] the heat of mixing is

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

$$[35]\quad H^E = \Delta H^0 \frac{x_1 x_2 (1 - x_A^0)}{(2 - x_A^0)}$$

and for infinite equilibrium constants, expressions in [34] and [35] are identical with [33].

In a general case, the derivative of H^E with respect to x_1 is given by a complex expression, but its limiting slope can be evaluated from

$$[36]\quad \left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=0} = \Delta H^0_{AB} \frac{K_{12} x_B^0}{1 + K_{12} x_B^0} - \Delta H^0_{A_2} \frac{(1 - x_A^0)}{(2 - x_A^0)} - \frac{\Delta H^0_{B_2}}{(2 - x_B^0)} \left[\frac{(1 - x_B^0)}{1 + 2K_2 x_B^0} + \frac{K_{12} x_B^0 (1 - x_B^0)}{1 + K_{12} x_B^0}\right]$$

and

$$[37]\quad \left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=1} = -\Delta H^0_{AB} \frac{K_{12} x_A^0}{1 + K_{12} x_A^0} + \Delta H^0_{B_2} \frac{(1 - x_B^0)}{(2 - x_B^0)} + \frac{\Delta H^0_{A_2}}{(2 - x_A^0)} \left[\frac{(1 - x_A^0)}{1 + 2K_1 x_A^0} + \frac{K_{12} x_A^0 (1 - x_A^0)}{1 + K_{12} x_A^0}\right]$$

These expressions take a simple form only for infinite equilibrium constants

$$[38]\quad \left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=0} = -\left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=1} = \frac{\Delta H^0}{2}$$

Excess molar volumes V^E are expressed by the same equations if the standard molar reaction enthalpies are replaced by the corresponding standard molar reaction volumes.

A large number of adjustable parameters and complexity of equations makes the mixed dimer formation rather difficult for a direct application. In the case of binary mixtures of carboxylic acids, the observed very small thermal effects (H^E is endothermic and symmetrical, Haase *et al.* (30, 31) and the absence of G^E, H^E, and V^E functions at the same temperature is an additional source of difficulties in the evaluation of these parameters. However, as has been shown in [11], the use of limiting expressions of the type [35], gives a reasonable representation of H^E and V^E functions in binary mixtures of carboxylic acids with the exception of the formic acid – acetic acid system. Mixing of formic acid with acetic acid is accompanied by contraction and expansion of the volume, but once again the overall effect is extremely small. The unusual form of V^E curve is probably associated with the presence of cyclic and linear dimers in the mixture. They can be included in the mixed dimers formation model in a similar way as previously (for example as in eq. [8]), but this procedure will introduce new parameters (one, two or even three standard molar reaction enthalpies) and increased complexity in model expressions. Evidently, such modification can only be justified if there is strong, experimental evidence on the importance of linear associates in the system.

The modified Mecke–Kempter models

If the association is not limited to the formation of dimers, but higher associates are also formed and the equilibrium constants of the consecutive reactions are independent of the degree of association

$$[39]\quad A + A_{n-1} \rightleftarrows A_n \qquad K_n = K^{n-1} \qquad n = 2, 3, 4, \ldots \infty$$

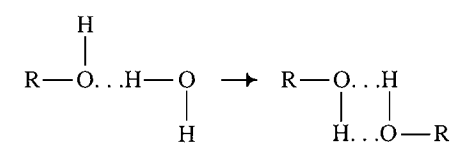
The continuous model ($A + B + A_2 + A_3 + A_4 + \cdots A_n + \cdots$) is called the Mecke–Kempter model. The model was modified by Coggeshall and Saier (1951) by introducing two equilibrium constants K_2 and K for $n > 2$. However, in both versions it is supposed that all associates have a linear form. The mathematical aspect of the ideal continuous association model was considered by Kehiaian (24, 25) and the most important results are presented here to provide a comparison between the different models. The material balance for the actually presented species is

$$[40]\quad x_A + x_B + \sum_{n=2}^{\infty} x_{A_n} = 1 \qquad x_{A_n} = K^{n-1} x_A^n$$

and the mole fractions of the monomers A and B are:

$$[41]\quad x_A = \frac{1}{(1 + K)} \left\{1 - \frac{2x_2}{1 + Q}\right\} \qquad x_B = \left\{1 - \frac{2x_1}{1 + Q}\right\} \qquad Q = \sqrt{1 + 4K x_1 x_2}$$

In the Mecke–Kempter model, the standard reaction enthalpies are assumed to be linearly related to the standard enthalpy of formation of one bond ΔH^0



$$[42]\quad \Delta H_n^0 = (n - 1)\Delta H^0 \qquad \Delta H_n^0 = H^0_{A_n} - n H^0_A$$

and the excess molar enthalpy of mixing H^E is

$$[43]\quad H^E = \Delta H^0 \left\{\frac{1 - Q}{2(1 + K)}\right\}$$

H^E is symmetrical with respect to the composition and the function $H^E/\Delta H^0 = f(x_1; K)$ is always negative and becomes zero for $K \to 0$ and $K \to \infty$. Since usually $\Delta H^0 < 0$, H^E is maximum at equimolar mixtures.

A distinction between linear and cyclic dimers in the Mecke–Kempter model can be introduced in the same way as previously (eq. [8]). The addition of component 2 to the associating component 1 will create mixtures with the same final states (monomers of A and B, cyclic and linear dimers and higher linear associates of A). However, with regard to pure component A we have to distinguish between different situations. If it is assumed that in pure alcohols there exist only monomers and linear associates, then an addition of nonpolar B molecules will facilitate the formation of cyclic dimers, *i.e.*, we have the linear dimer → cyclic dimer transformation:

and therefore

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

$$[44]\quad \begin{aligned} x_D(c) &= x_D x_B = K x_A^2 x_B \\ x_D(l) &= x_D(1 - x_B) \end{aligned}$$

On the other hand, in pure carboxylic acids the existence of monomers, cyclic dimers, and higher linear associates or only monomers with cyclic dimers can be assumed. An addition of polar molecules B will support the cyclic dimer → linear dimer transformation and therefore:

$$[45]\quad \begin{aligned} x_D(l) &= x_D x_B = K x_A^2 x_B \\ x_D(c) &= x_D(1 - x_B) \end{aligned}$$

In the case of excess Gibbs energy of mixing G^E, there is essentially no difference between the cases described by eqs. [44] and [45] because the initial states of the species (monomer, dimers and higher associates) are the same. However, if only monomers and cyclic dimers are present in pure component 1, then this model differs from the classical Mecke–Kempter association model because here the higher linear associates come only from that part of cyclic dimers which is converted to the linear form. This case, being more complex, requires a separate treatment.

The excess molar enthalpy of mixing, H^E, for the continuous association coupled with the linear dimer → cyclic dimer transformation (eq. [44]) is given by:

$$[46]\quad H^E = \left\{ \Delta H^0 \frac{(1-Q)}{2(1+K)} + \Delta H^0_{tr} x_2 K \left[\frac{(x_1 - x_2 + Q)}{(1+K)(1+Q)} \right]^2 \right\}$$

$$\Delta H^0 = H^0_{A_n(l)} - H^0_{A_{n-1}(l)}$$

$$\Delta H^0_{tr} = H^0_{A_2(c)} - H^0_{A_2(l)}$$

where Q is defined in [41].

H^E is a rather complex function of x_1 and the parameters K and $r = \Delta H^0_{tr}/\Delta H^0$. For any x_1 and r, the function tends to zero for $K \to 0$ and $K \to \infty$. For positive values of r, the reduced excess molar enthalpy of mixing, $H^E/\Delta H^0$ is a sum of two terms which have opposite signs. To put the modified Mecke–Kempter and the dimer formation models on the same basis, $H^E/\Delta H^0 = f(x_1; r; K = 1)$ in Fig. 4 were calculated for mixtures having the same mole fraction of the monomer in pure component 1. In this case, the dimerization constant K_D (in Fig. 2, $K_D = 2$) is correlated to the Mecke–Kempter constant K as follows

$$[47]\quad K_D = K(K+1)$$

The effect of the equilibrium constant K for the same r is shown in Fig. 5 by plotting

$$H^E/\Delta H^0 = f(x_1; K; r = 4)$$

The evaluation of parameters $K, \Delta H^0$, and ΔH^0_{tr} in eq. [46] can be performed by a number of procedures, using for example the slopes of H^E.

$$\left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=0} = \Delta H^0 \frac{K}{1+K}$$

$$[48]\quad \left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=1} = \Delta H^0 \frac{K}{1+K} - \Delta H^0_{tr} \frac{K}{(1+K)^2}$$

$$\left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=1/2} = \frac{\Delta H^0_{tr} K \sqrt{1+K}[2 - \sqrt{1+K}]}{[(1+K)(1+\sqrt{1+K})]^2}$$

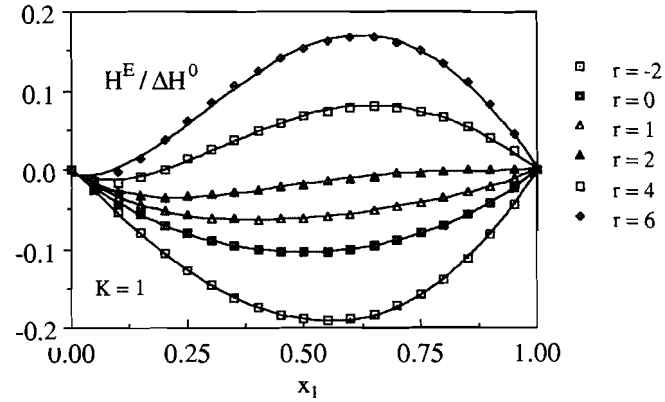


FIG. 4. Reduced excess molar enthalpies of mixing in the modified Mecke–Kempter model. Calculated for $K = 1$ and several values of r.

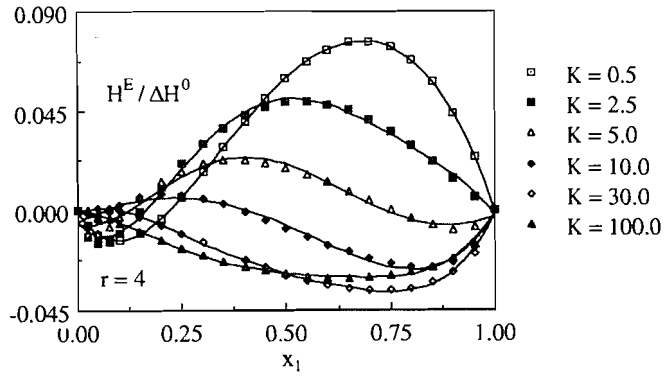

FIG. 5. Reduced excess molar enthalpies of mixing in the modified Mecke–Kempter model. Calculated for $r = 4$ and several values of K.

and the value of H^E at equimolar mixtures is

$$[49]\quad H^E\left(\frac{1}{2}\right) = \frac{\Delta H^0(1 - \sqrt{1+K})}{2(1+K)} + \frac{\Delta H^0_{tr} K \sqrt{1+K}}{2[(1+K)(1+\sqrt{1+K})]^2}$$

If the experiment H^E vanishes at some point, $x_1 = z$. For $H^E(z) = 0$, the ratio of standard reaction enthalpies is directly available from [46], if the equilibrium constant K is independently known.

When continuous association is coupled with the cyclic dimer → linear dimer transformation (eq. [45]), the excess molar enthalpy of mixing takes the form:

$$[50]\quad H^E = \left\{ \frac{\Delta H^0(1-Q)}{2(1+K)} + \frac{\Delta H^0_{tr} x_1 K}{(1-K)^2} \times \left[\frac{1}{1+K} - \frac{2x_2(x_1 - x_2 + Q)^2}{(x_2 - x_1 + Q)(1+Q)^2} \right] \right\}$$

$$\Delta H^0_{tr} = H^0_{A_2(l)} - H^0_{A_2(c)}$$

The reduced excess molar enthalpies of mixing, $H^E/\Delta H^0 = f(x_1; K; r)$ are plotted in Fig. 6, 7, and 8 to show the effect of the equilibrium constant K and the ratio of standard reaction enthalpies r on the behavior of H^E curves.

The parameters included in [50], $K, \Delta H^0$ and ΔH^0_{tr}, can be

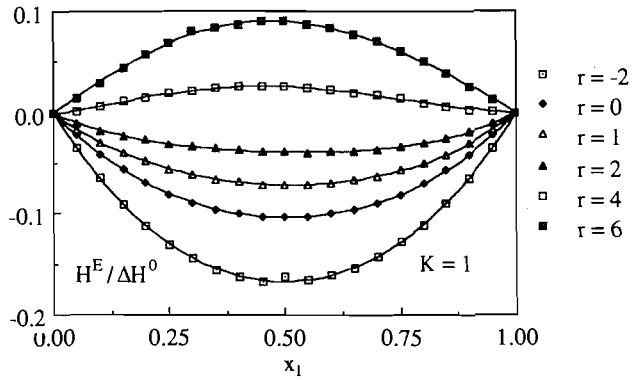

FIG. 6. Reduced excess molar enthalpies of mixing in the modified Mecke–Kempter model. Calculated for $K = 1$ and several values of r.

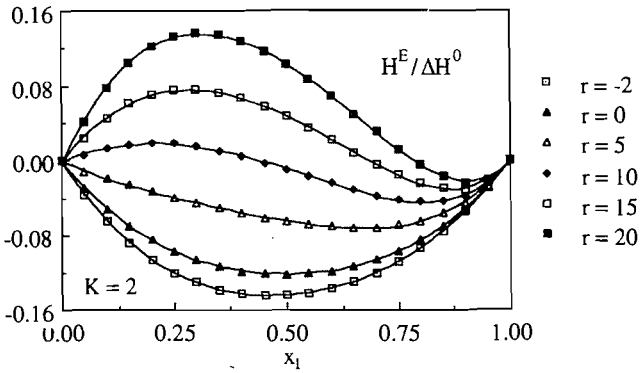

FIG. 7. Reduced excess molar enthalpies of mixing in the modified Mecke–Kempter model. Calculated for $K = 2$ and several values of r.

calculated from

$$\left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=0} = -\Delta H^0 \frac{K}{1+K} + \Delta H^0_{tr} \frac{K}{(1+K)^3}$$

[51]
$$\left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=1} = \Delta H^0 \frac{K}{1+K} - \Delta H^0_{tr} \frac{2K}{(1+K)^3}$$

$$\left(\frac{\partial H^E}{\partial x_1}\right)_{x_1=1/2} = \Delta H^0_{tr} \frac{K}{(1+K)^2} \cdots \times \left[\frac{1}{1+K} - \frac{1}{(1+\sqrt{1+K})^2}\right]$$

and

[52]
$$H^E\left(\frac{1}{2}\right) = \left\{\frac{\Delta H^0(1-\sqrt{1+K})}{2(1+K)} + \frac{\Delta H^0_{tr} K}{2(1+K)^2} \times \left[\frac{1}{1+K} - \frac{\sqrt{1+K}}{(1+\sqrt{1+K})^2}\right]\right\}$$

As can be seen in Fig. 4–8, the heat of mixing H^E (or V^E when ΔH^0 and ΔH^0_{tr} are replaced by the corresponding values of ΔV^0 and ΔV^0_{tr}) is always an asymmetrical function of composition in the modified Mecke–Kempter models ($r \neq 0$, eq. [46] or [50]). Depending on the chosen set of parameters, the function has one, two, or even three extrema (*e.g.* for $K = 1.40$ and $r = 4.98$, H^E calculated from [50] has two

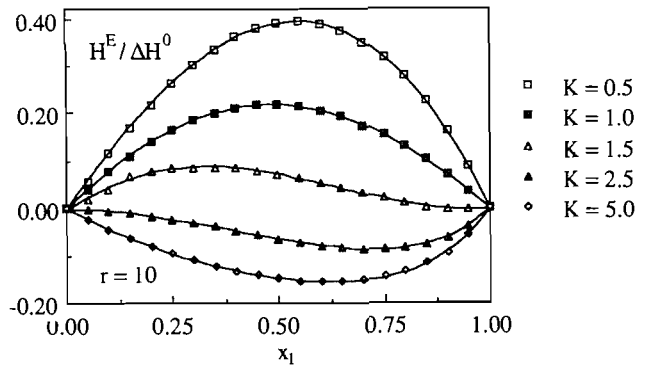

FIG. 8. Reduced excess molar enthalpies of mixing in the modified Mecke–Kempter model. Calculated for $r = 10$ and several values of K.

minima and one maximum). However, at finite concentrations, the first and second derivatives of H^E (or V^E) with respect to x_1 are given by complex algebraic expressions and therefore evaluation of the parameters from a knowledge of extremal properties of experimental H^E and V^E curves is rather difficult. Since G^E in both modified and classical Mecke–Kempter models is a symmetrical function of composition and experimental G^E curves are usually nearly symmetrical (in contrast to H^E curves), the equilibrium constant K can be derived from G^E values at equimolar mixtures (10):

[53]
$$G^E\left(\frac{1}{2}\right) = RT \ln\left[\frac{2\sqrt{1+K}}{1+\sqrt{1+K}}\right]$$

Evaluation of K from vapor pressure measurements (eq. [53]), permits a direct determination of other parameters from calorimetric measurements. We need heats of mixing at equimolar mixtures, $H^E(x_1 = 1/2)$, (eq. [49] or [42]) and one accurate value of the limiting slope of H^E (eq. [48] or [51]). Evidently, the ratio of standard reaction enthalpies r can be calculated from the condition $H^E(z) = 0$, if H^E as a function of composition changes its sign.

The acetic acid – water system

To illustrate the applicability of association models presented here, the acetic acid – water system at 298.15 K was chosen. In carboxylic acid – water mixtures, we have a complete set of the excess thermodynamic functions only for this system. Hansen *et al.* (26) measured vapor pressures in the system and expressed in the results in terms of activity coefficients. The excess Gibbs energy of mixing G^E is positive and almost symmetrical with respect to composition. Heats of mixing H^E (measured during the 1972–1977 period) were compiled by Christensen *et al.* (27). The form of H^E is strongly asymmetrical. In dilute aqueous solutions of acetic acid H^E is slightly negative and becomes positive with increasing acid concentration. The excess molar volumes V^E were determined in a number of works (for details see Apelbalt and Manzurola (10)). The experimental V^E curve is a nearly perfect symmetrical form (the minimal value is $V^E(x_1 = 1/2) = -1.16$ cm^3 mol^{-1}) and in very dilute solutions of the acid, V^E can be represented by:

[54]
$$V^E = -5.7548x_1 + 4.9285x_1^2$$

As has been demonstrated (10), predictions based on the formation of cyclic or open dimers are inconsistent with behavior

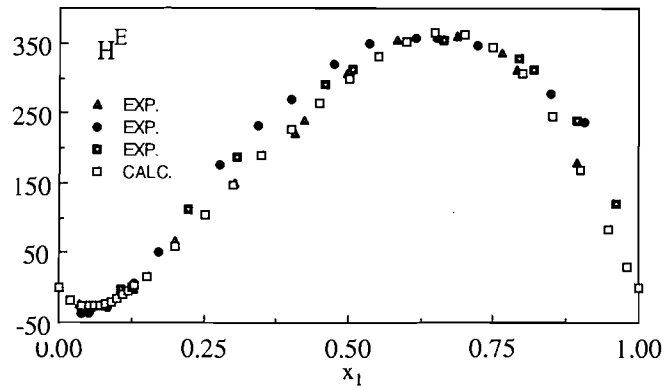

FIG. 9. Comparison between experimental and calculated values of H^E (J mol^{-1}) in the acetic acid – water system at 298.15 K (see text).

of the excess thermodynamic functions. On the other hand, the classical Mecke–Kempter model represents in a satisfactory way the excess Gibbs energy of mixing G^E and the excess molar volume V^E but is unable to predict the correct form of the excess molar enthalpy of mixing H^E. An adequate description of G^E and V^E is possible using the equilibrium $K = 1.40$ and the molar reaction volume, $\Delta V^0 = 10.14$ cm^3 mol^{-1}. Much against expectations, it was found that the continuous association coupled with the linear dimer $\rightarrow$ cyclic dimer transformation (eq. [44]) and not with the cyclic dimer $\rightarrow$ linear dimer transformation (eq. [45]) is suitable to represent G^E, H^E, and V^E functions in the acetic acid – water system. However, it should be mentioned that the initial state of the system is a mixture of linear associates (10, 12), and not the pure acetic acid where evidently the dimer is predominantly cyclic. Since both standard molar reaction enthalpies are endothermic and $\Delta G^0 < 0$, the standard entropy change ΔS^0 is positive and dominates the entropy – enthalpy relations. It seems the an increase in disorder results from a new arrangement of water molecules in the mixture, caused by the self-associated reaction of acetic acid. This indicates the importance of hydrated species which are completely excluded from our analysis. These species may facilitate the linear dimer $\rightarrow$ cyclic dimer transformation and not the opposite process, when water is added to acetic acid.

Introducing the equilibrium constant $K = 1.40$ into [46] and considering that H^E vanishes at about $x_1 = z = 0.125$, the ratio of standard reaction enthalpies is $r = 5.04$ and finally the standard enthalpies are $\Delta H^0_{tr} = 14.6$ kJ mol^{-1} and $\Delta H^0 = 2.9$ kJ mol^{-1}.

Using these parameters, the excess molar enthalpies of mixing H^E were calculated from [46] and compared with the calorimetric results compiled for the system by Christensen *et al.* (27). As can be seen in Fig. 9, there is quite a reasonable agreement between calculated and experimental results, especially a very satisfactory representation of a not-frequently observed form of H^E. In the case of V^E, it is possible to obtain an accurate value of the limiting slope of V^E at $x_1 = 0$ (eq. [54]) and compare it with [48]

$$[55] \quad \left(\frac{\partial V^E}{\partial x_1}\right)_{x_1=0} = -\Delta V^0 \frac{K}{1+K} = -5.7548$$

From [55], using the equilibrium constant $K = 1.40$, the standard reaction volume is $\Delta V^0 = 9.87$ cm^3 mol^{-1}. Introducing these parameters and the value of $V^E(x_1 = 1/2) = -1.16$ cm^3

mol^{-1} into [39] we have $\Delta V^0_{tr} = V^0_{A_2(c)} - V^0_{A_2(l)} = -0.684$ cm^3 mol^{-1}, *i.e.* as expected the molar volume of the linear dimer $V^0_{A_2(l)}$ is larger than that of the cyclic dimer $V^0_{A_2(c)}$.

Table 1 lists the calculated and experimental values (10) of V^E in the acetic acid – water system at 298.15 K. The calculations were performed using the classical Mecke–Kempter model ($K = 1.40$ and $\Delta V^0 = 10.14$ cm^3 mol^{-1}) and the modified Mecke–Kempter model ($K = 1.40, \Delta V^0 = 9.87$ cm^3 mol^{-1}, and $\Delta V^0_{tr} = -0.684$ cm^3 mol^{-1}, eq. [46]). As can be seen, both models reproduce values V^E nicely, but evidently an introduction of ΔV^0_{tr} to calculations slightly improves the agreement between the experimental and calculated results.

Thus, in terms of the modified Mecke–Kempter model, it is possible to present a consistent description of G^E, H^E, and V^E functions in the acetic acid – water system. Evidently, a successful description of the excess thermodynamic functions derived from different properties of the system (vapor pressures, heats of mixing, and densities) justifies the choice of molecular model, but without additional support (*e.g.* from spectroscopic measurements) the modified Mecke–Kempter model cannot be considered unique interpretation of experimental results. The excess molar enthalpy of mixing H^E can also be represented by the dimerization reaction coupled with the cyclic dimer $\rightarrow$ linear dimer transformation ($K_D = 3.30$ and $\Delta H^0_D = 4.1$ kJ mol^{-1}, $\Delta H^0_{tr} = 4.9$ kJ mol^{-1}), even better than by the modified Mecke–Kempter model, but such description is inconsistent with the behavior of the G^E and V^E functions.

The structure of the tetrachlorohydroxotellurate(IV) anion in $KTeCl_4(OH)\cdot 0.5H_2O$ and $KTeCl_4(OH)$

J. B. MILNE

Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

AND

E. J. GABE AND C. BENSIMON

Chemistry Division, National Research Council, Ottawa, Ont., Canada K1A 0R9

Received July 26, 1990

J. B. MILNE, E. J. GABE, and C. BENSIMON. Can. J. Chem. **69**, 648 (1991).

Three compounds containing the tetrachlorohydroxotellurate(IV) anion, $\phi_4As[TeCl_4(OH)]\cdot H_2O$, $K[TeCl_4(OH)]\cdot 0.5H_2O$, and $K[TeCl_4(OH)]$, have been prepared. The crystal structure of $K[TeCl_4(OH)]\cdot 0.5H_2O$ has been determined. The structure contains isolated square pyramidal $TeCl_4(OH)^-$ anions with OH axial. Vibrational spectroscopy shows that $\phi_4As[TeCl_4(OH)]\cdot H_2O$ and $K[TeCl_4(OH)]\cdot 0.5H_2O$ both contain isolated anions but that, in $K[TeCl_4(OH)]$, the anion is polymerized with chloride bridging. The hydroxo group, like the fluoro group, acts to hinder coordination at the site *trans* to it on Te(IV).

Key words: tellurium(IV) complexes, chlorotellurate(IV), X-ray structure, vibrational spectroscopy.

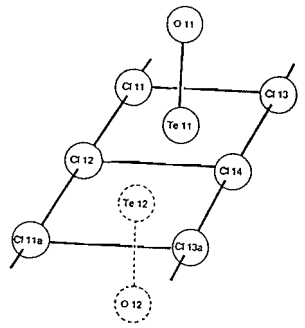
J. B. MILNE, E. J. GABE et C. BENSIMON. Can. J. Chem. **69**, 648 (1991).

Trois composés, qui contiennent l'anion tetrachlorohydroxotellurate(IV), $\phi_4As[TeCl_4(OH)]\cdot H_2O$, $K[TeCl_4(OH)]\cdot 0.5H_2O$ et $K[TeCl_4(OH)]$, ont été préparés. La structure crystallographique de $K[TeCl_4(OH)]\cdot 0.5H_2O$ a été déterminée. La structure contient les anions $TeCl_4(OH)^-$ en forme d'une pyramide à base carré avec le groupe hydroxo, axial. Les spectres de vibration montrent que $\phi_4As[TeCl_4(OH)]\cdot H_2O$ et $K[TeCl_4(OH)]\cdot 0.5H_2O$ contiennent les anions isolés alors que l'anion dans $K[TeCl_4(OH)]$ est polymerisé avec les ponts de chlore. Le groupe hydroxo agit, comme le groupe fluoro, pour gêner le liaison *trans* à par rapport lui sur Te(IV).

Mots clés : complexes de tellure(IV), chlorotellurate(IV), structure par diffraction des rayons X, spectroscopie de vibration.

Introduction

The stereochemical activity of the non-bonded valence electron pair in Te(IV) species has been the subject of many studies. The non-bonded pair is inactive in the hexacoordinate anions, TeX_6^{2-} (X = Cl, Br, I), which all possess an essentially octahedral structure (1, 2), except in some cases where hydrogen bonding is important (3). The corresponding hexafluorotellurate(IV) anion is unknown (4, 5). The TeF_5^- ion is square pyramidal (6) and shows no tendency to form condensed ions or to bind a sixth ligand even when a possible ligand (Cl^-, H_2O) is present in the structure (4, 7). On the other hand, $TeCl_5^-$ and $TeBr_5^-$ ions exhibit a pronounced tendency either to polymerize (8–10) or to attach a sixth ligand to form TeX_6^{2-} or $TeX_5Y^{-(2-)}$ (11–13). Vibrational spectroscopy indicates that the isolated $TeCl_5^-$ ion exists in some cases where bulky cations are present (14).



Raman studies have indicated that the hydrolysis of the $TeCl_6^{2-}$ ion does not yield $TeCl_5(OH)^{2-}$, as might be expected, but that the first equilibrium involves formation of the $TeCl_4(OH)^-$ ion (15). The crystal structure of $\phi_4As[TeCl_4O_2H_3]$ has been determined (16) but it was not possible to establish whether the tellurium-containing ion was an oxotellurate, $TeCl_4O^{2-}$, or a hydroxotellurate, $TeCl_4(OH)^-$. To establish the structure of the $TeCl_4(OH)^-$ anion and to provide a better understanding of the stereochemical effect of the non-bonded electron pair, a study of the salts containing this anion was carried out.

Experimental section

Materials and apparatus

Tellurium dioxide (Merck), hydrochloric acid (J. T. Baker), tetraphenylarsonium chloride (Merck), and potassium chloride (Fisher) were used directly in the preparation of the compounds.

Infrared spectra were measured with a Perkin–Elmer 283 spectrometer. Raman spectra were taken with a Jobin–Yvon RT 110 spectrometer, using 514.5 nm excitation from a Spectra Physics Ar ion laser. Samples were rotated. X-Ray powder patterns were determined with a calibrated Siemens powder diffractometer, using monochromatised Cu Kα radiation. Intensities were estimated visually.

Preparations

Preparation of $\phi_4As[TeCl_4O_2H_3]$ was by partial hydrolysis and crystallization of $[\phi_4As]_2TeCl_6$ (2) in 99% ethanol. *Anal.* calcd. for $\phi_4As[TeCl_4O_2H_3]$: Cl 20.62; found: Cl 20.38. The pale yellow crystals melted at 210–214°C, which compares with 211–213°C reported earlier (16). All of the X-ray diffraction reflexes observed in the powder diffraction pattern may be accounted for by the monoclinic unit cell reported earlier (16).

The $K[TeCl_4(OH)]\cdot 0.5H_2O$ was prepared from a stoichiometric mixture of 1:1:3 TeO_2/KCl/HCl (as concentrated HCl). This solution was concentrated to the point of crystallization by evaporation at 50°C or in a desiccator. The pale yellow product, which was very soluble in the solution, was filtered out, blotted dry, and stored in a desiccator over anhydrous calcium chloride. *Anal.* calcd. for $K[TeCl_4(OH)]\cdot 0.5H_2O$: Cl 42.39; found: 41.62. Attempts to prepare $K_2[TeCl_5(OH)]$ from 1:2:3 TeO_2/KCl/HCl solutions gave only $K[TeCl_4(OH)]\cdot 0.5H_2O$. The X-ray powder diffraction pattern for the compound was unique and showed no evidence of K_2TeCl_6 or TeO_2.

It was not possible to prepare other $TeCl_4(OH)^-$ salts by this

method. Using NaCl in place of KCl gave NaCl and TeO_2 upon evaporation; using Me_4NCl, NH_4Cl, and RbCl, gave the hexachlorotellurate(IV) and TeO_2. The Raman spectrum of the previously reported $Me_4NTeCl_4(OH)$ (15) can be interpreted in terms of a mixture of TeO_2 and $(Me_4N)_2TeCl_6$.

$KTeCl_4(OH)\cdot 0.5H_2O$ can be dehydrated at 50°C under high vacuum over a period of days. *Anal.* calcd. for $KTeCl_4(OH)\cdot 0.5H_2O$: H_2O 2.6; found by weight loss: H_2O 3.8. *Anal.* calcd. for $KTeCl_4(OH)$: Cl 43.56, Te 39.20; found: Cl 43.09, Te 38.96. This product was more yellow than its hydrate. $KTeCl_4(OH)\cdot 0.5H_2O$ also lost water when stored in a vacuum desiccator over phosphorus pentoxide.

Structure determination

Crystallographic data were collected for two crystals, both of which gave the same refinement. Final refinement was done with a crystal of dimensions 0.2 × 0.2 × 0.4 mm. Of the 2803 reflections measured, 2087 were unique. The crystals were monoclinic, space group $P2_1/c$, a = 9.2896(7) Å, b = 7.1503(7) Å, c = 24.3385(19) Å, β = 95.034(6), V = 1610.41(24) Å^3, Z = 8, calculated density: 2.743(6) g/cm^3. Throughout this work the estimated standard deviations are in parentheses and refer to the last digit printed. The diffraction intensities were collected on a Nonius diffractometer at 295 K with Mo Kα radiation, using θ/2θ scan technique, with profile analysis (17). The space group was determined from systematic absences. Unit cell parameters were obtained by least-squares refinement of the setting angles for 25 reflections with 2θ between 40 and 50°. Lorentz and polarization factors were applied. A Gaussian correction for absorption was made on the crystal (10 faces were measured). The minimum and maximum transmission factors were 0.10706 and 0.158889.

The structure was solved by direct methods and refined by full matrix least squares from 1891 reflections ($I_{net} > 2.5\sigma(I_{net})$) to a final R = 0.085 and R_w = 0.076 (significant reflections). There are two independent molecules in the asymmetric unit. One of the two telluriums is disordered between two positions with occupancies of 0.85 and 0.15. The occupancies of the two disordered telluriums were refined, using linked groups with complementary occupancies. The H atoms were not found because of the disorder. The highest peak (2.250 e/Å^3) in the last D-map is near tellurium 2.

All calculations were performed with the NRCVAX Structure Package (18). A list of the final structure factors is available as supplementary data from the author.[1]

Results and discussion

The solubility of the hexachloroplatinate(IV) salts in water decreases with cation size (19) and the tellurate(IV) salts exhibit parallel behaviour. For this reason, and because the tetrachlorohydroxotellurate(IV) salts are quite soluble, only mixtures of TeO_2 and M_2TeCl_6 were isolated from the 1:1:3 mixtures of TeO_2/MCl/HCl (MCl = RbCl, NH_4Cl, Me_4NCl) in aqueous solution, as shown by X-ray powder diffraction patterns. The relative solubilities are such that tetrachlorohydroxotellurate(IV) can be isolated only when KCl is used. The tetraphenylarsoniumtetrachlorohydroxotellurate(IV) is prepared by crystallization of the hexachlorotellurate(IV) from acetonitrile (16) or ethanol, containing a trace of water.

The crystal structure of $KTeCl_4(OH)\cdot 0.5H_2O$

The atomic positions for K, Te, Cl, and O atoms in $KTeCl_4(OH)\cdot 0.5H_2O$ are given in Table 1 and the temperature factors appear in Table 2. The interatomic distances and angles are listed in Table 3. The unit cell contains two types of $TeCl_4(OH)^-$ anion, one of which is disordered in the position of Te11[12] and O11[12]. The Te11[12] atoms occupy two possible sites along a double chain of Cl atoms as shown. The Te11 lie in alternate, approximately square planar sites, coordinated by four Cl atoms with O11 normal to the plane of chlorines. In the other occupancy, the Te12 lie in the other alternating square planar sites with O12 projecting to the opposite side of the plane from that of O11. Of these two Te and O positions 15% have one orientation (Te12/O12) and 85% (Te11/O11), the other. In Table 2 O12 has not been refined anisotropically, because of its low occupancy caused by the disorder. An ORTEP diagram of the asymmetric unit (1/4 of the unit cell), viewed along z, is given in Fig. 1. The orientation of the disordered ion with the greatest occupancy (Te11/O11) is shown. The structure consists of isolated square pyramidal $TeCl_4(OH)^-$ anions. There are four molecules of H_2O in the unit cell, which are not coordinated to Te(IV), but the oxygens of which lie at the van der Waals distance from K^+. The anion structure, which is consistent with that predicted by VSEPR theory (20), has the hydroxo oxygen in the axial position and all OTeCl angles less than 90° due to the repulsive effect of the stereochemically active non-bonded electron pair on tellurium. The TeCl bond distances are very similar to those observed for the equatorial chlorines in the isolated $TeCl_5^-$ ion (13). The mean TeCl distance is marginally shorter than that observed for the $TeCl_6^{2-}$ ion (2), reflecting the reduced negative charge as well as the repulsive influence of the $5s^2$ electron pair in the $TeCl_6^{2-}$ ion. The TeO distances (1.905, 1.908 Å) are marginally less than those normally observed (1.919–2.110 Å) (21, 22) for the Te(IV)—O bond but considerably greater than that reported by Collins and Webster (1.74 Å) (16).

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

Vibrational spectra

The Raman and IR spectra of the tetrachlorohydroxotellurate(IV) salts are given in Table 4. The anion bands of the two hydrate salts, $\phi_4As[TeCl_4(OH)]\cdot H_2O$ and $K[TeCl_4(OH)]\cdot 0.5H_2O$, show a close parallel. The frequency of the TeO stretching mode near 630 cm^{-1} confirms that both of these compounds contain hydroxo- and not oxo-tellurate(IV) anions. A TeO double bond stretch is expected to be above 800 cm^{-1}.

The skeletal bands have been assigned in square pyramidal symmetry (C_{4v}: $\Gamma_{vib} = 3A_1 + 2B_1 + B_2 + 3E$). The TeO ($\nu_1$) and [$TeCl_4$] in phase ($\nu_2$) stretching bands (both A_1 symmetry)

[a]Estimated standard deviations refer to the last digits.

are readily identified by their intensity and frequency. The ν_2 mode is very close in frequency to that of the related stretch for ICl_4^- (23) and the $TeCl_5^-$ (14) anions. The remaining bands were assigned by comparison with the assignment for $SeCl_5^-$ (24) and $TeCl_5^-$ (14) except for the TeO wag, ν_8, which was assigned to the remaining band near 226 cm^{-1}. The non-skeletal modes are assigned by analogy with the IR and Raman spectra of $KTeF_4(OH)^-$ (25). The spectrum of tetrachlorohydroxotellurate(IV) in these compounds parallels spectra observed for 0.5 M TeO_2 in 7–9 M HCl solutions (15), 2.0–3.0 M TeO_2 in 12.29 M HCl solutions and 1:1:3 and 1:2:3 TeO_2/KCl/HCl (12.29 M) solutions. This parallel and the fact that only $KTeCl_4(OH)\cdot 0.5H_2O$ can be isolated from both 1:1:3 and 1:2:3 TeO_2/KCl/HCl solutions confirms that $TeCl_4(OH)^-$ and not $TeCl_5(OH)^{2-}$ is formed in these solutions.

The tetrachlorohydroxotellurate(IV) salts are readily de-

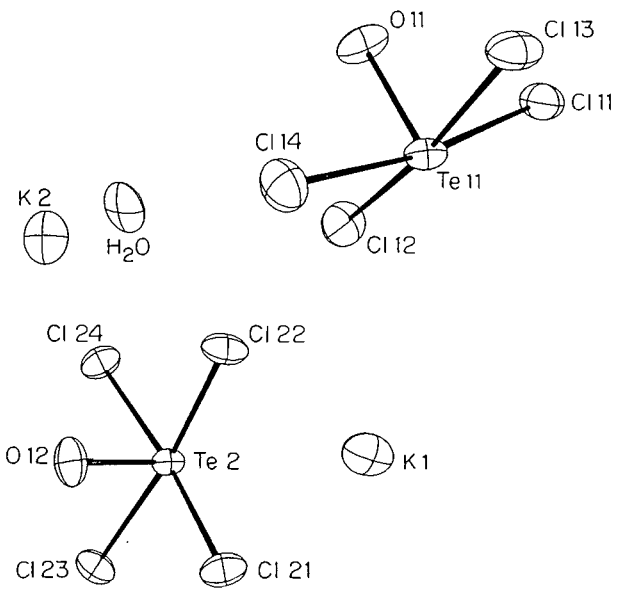

FIG. 1. ORTEP diagram of the asymmetric unit (1/4 of the unit cell), showing the two $TeCl_4(OH)^-$ ions. Of the two possibilities of the disordered anion (Te11[12] and O11[12]), the one with 85% occupancy is shown (Te11 and O11).

hydrated. Storage of $KTeCl_4(OH)\cdot 0.5H_2O$ in a vacuum desiccator over a period of weeks or dehydration under high vacuum at 50°C causes weight loss and the disappearance of the characteristic IR peak at 1605 cm^{-1} due to H_2O. Analysis shows the product to be $KTeCl_4(OH)$. The IR and Raman spectra are listed in Table 5. The appearance of a strong band near 355 cm^{-1}, accompanied by other changes, indicates that the structure of $TeCl_4(OH)^-$ in the dehydrated product is different from that in the hemihydrate. Decomposition to K_2TeCl_6 and TeO_2, according to

[1] $2KTeCl_4(OH)\cdot 0.5H_2O = K_2TeCl_6 + TeO_2 + 2HCl + H_2O$

does not fit the analysis or the observed spectra. Isomerization to an isolated trigonal bipyramidal $TeCl_4(OH)^-$ anion is unlikely in view of the tendency of Te(IV) halogen compounds to adopt structures based upon an octahedron. It has been shown that

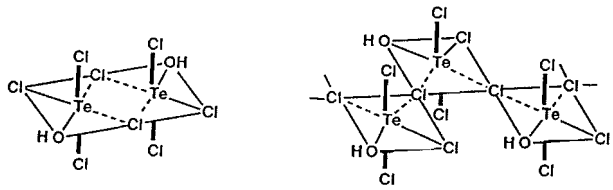
[b]Bridging Cl.
[c]Terminal Cl, out-of-plane.
[d]Terminal Cl, in plane.



$TeCl_5^-$ and $TeBr_5^-$ form condensed anions via halogen bridges (8–10). Dehydration of $K[TeCl_4(OH)]\cdot 0.5H_2O$ probably leads to a related condensed anion.

[2] $2KTeCl_4(OH)\cdot 0.5H_2O = K_2[Te_2Cl_8(OH)_2] + H_2O$

[3] $nKTeCl_4(OH)\cdot 0.5H_2O = K_n[TeCl_4(OH)]_n + (n/2)H_2O$

This conclusion is supported by chemical analysis and the disappearance of the 1605 cm^{-1} band in the IR spectrum. The spectrum of the dehydrated product still exhibits the TeO stretching frequency near 630 cm^{-1} as well as the OH wag at 670 cm^{-1} and the TeOH bend at 1165 cm^{-1}, showing that the hydroxo group is still present. The small shifts in frequency from those of the same bands in the hydrates show that the group occupies a terminal, not a bridging, position. Since the position *trans* to the hydroxo group is vacant in the isolated $TeCl_4(OH)^-$ ion, it is likely that the Cl atoms with weaker Te—Cl bonds, the bridging Cl's, will occupy this *trans* position in the dehydrated form. It is not possible to establish the degree of condensation of the $[TeCl_4(OH)^-]$ units from the spectra. The $TeCl_5^-$ ion is found in both dimeric and polymeric forms (8, 10). Analogous $[TeCl_4(OH)^-]$ structures with terminal hydroxo groups *trans* to bridging chlorines may take the forms below.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

Structures with a bridging Cl *trans* to two OH groups are not shown. These are unlikely, since such a coordination site would be unfavourable due to the *trans* repulsive effect of the OH groups. In the structures shown, each bridging Cl lies *trans* to only one OH group. The highest TeCl frequency observed near 355 cm^{-1} may be assigned to a mode involving the terminal Cl *trans* to the bridging Cl in these structures. The Cl *trans* to bridging Cl is expected to be more strongly bound than the axial Cl's *cis* to the bridging Cl's. A tentative assignment of the spectrum of $KTeCl_4(OH)$, which is independent of the degree of polymerisation, is given in Table 5.

Conclusion

A comparison of the ligand acceptor properties of the $TeCl_4(OH)^-$ and $TeCl_5^-$ ions shows important differences. The $TeCl_5^-$ ion exhibits a strong tendency to accept Cl^- ion forming $TeCl_6^{2-}$ and readily polymerizes to achieve hexacoordination. The $TeCl_4(OH)^-$ ion shows no tendency to accept Cl^- and form $TeCl_5(OH)^{2-}$ and exhibits a weaker tendency to polymerize or bind a sixth ligand to achieve hexacoordination. The hydrate water in $KTeCl_4(OH)\cdot 0.5H_2O$ is not even weakly coordinated to Te. Thus chloride and hydroxide ligands have differing effects on the ability of Te(IV) to bond to a ligand at the *trans* position. This "*trans*" effect has been reported for the $TeCl_3(O_2C_2H_4)^-$ ion (21), where the positions *trans* to the glycolate oxygens are either vacant or have a relatively weakly bonded Cl. The axial fluorine atom in the TeF_5^- ion and OH group in the $TeF_4(OH)^-$ ion (25) have the same effect on the *trans* position. Apparently the small size of the O and F ligands, compared to that of Cl and larger ligands, permits their close approach to the Te atom due to decreased interligand repulsions and consequent dominance or polarisation of the *p* orbital lying along this axis such that any *trans* ligand cannot bond to the Te atom effectively. The equatorial ligands of the TeF_5^- ion do not show this effect, since they can not approach the Te atom as closely as the axial F.

Synthesis, electrochemistry, and ligand substitution reactions of conducting copolymer films of ruthenium polypyridine complexes and aromatic heterocycles

JOLANTA OCHMANSKA[1] AND PETER G. PICKUP[2]

Department of Chemistry, Memorial University of Newfoundland, St. John's, NFLD., Canada A1B 3X7

Received September 14, 1990

JOLANTA OCHMANSKA and PETER G. PICKUP. Can. J. Chem. **69**, 653 (1991).

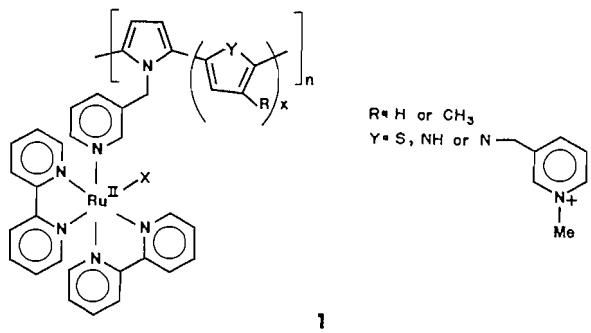
Conducting films containing ruthenium complexes of the general formula $[Ru(2,2'\text{-bipyridine})_2(pmp)X]^{2+}$ (pmp = 3-(pyrrol-1-ylmethyl)pyridine, X = Cl^-, ClO_4^-, pmp, CH_3CN, or H_2O) have been prepared by copolymerization of the Ru complex monomer with pyrrole, 3-methylthiophene, 1-methyl-3-(pyrrol-1-ylmethyl)pyridinium(1+), or 2,2′-bithiophene. The immobilized complexes exhibit rapid and reversible electrochemistry in acetonitrile. The perchlorate and water ligands are rapidly substituted to give the acetonitrile complex, while the chloride ligand is replaced more slowly. In aqueous media, both the perchlorate complex and chloride yield an aqua complex. The substitution rate of the chloride ligand is again low but is enhanced by photolysis. No substitution reactions were observed for the acetonitrile or pmp ligands under a variety of conditions tested. Infrared spectroscopy and fast atom bombardment mass spectroscopy indicate that attempts to isolate $[Ru(bp)_2(pmp)(ClO_4)]^+$ as a solid in fact give the aqua complex. The perchlorate complex may also rearrange to the aqua complex in polymer films. Films containing the aqua complex were not useful for electrocatalytic oxidation because of the instability of the conducting polymer matrix at low pH and the inactivity of the complex at higher pH values.

Key words: polythiophene, polypyrrole, electropolymerization, metallopolymer.

JOLANTA OCHMANSKA et PETER G. PICKUP. Can. J. Chem. **69**, 653 (1991).

On a préparé des films conducteurs contenant des complexes de ruthénium de formule générale $[Ru(2,2'\text{-bipyridine})_2(pmp)X]^{2+}$ (pmp = 3-(pyrrol-1-ylméthyl)pyridine, X = Cl^-, ClO_4^-, pmp, CH_3CN, ou H_2O) par copolymérisation du monomére du complexe de Ru avec du pyrrole, du 3-méthylthiophène, du 1-méthyl-3-(pyrrol-1-ylméthyl)pyridinium(1+), ou du 2,2′-bithiophène. Dans l'acétronitrille, les complexes imobilisés présentent une électrochimie rapide et réversible. Les coordinats perchlorate et eau sont rapidement substitués pour donner le complexe acétonitrile; par ailleurs, le coordinat chlorure est remplacé plus lentement. En milieu aqueux, les complexes tant perchlorique que chlorure conduisent au complexe aqua. Encore une fois la vitesse de substitution du chlorure est faible; elles est toutefois augmentée par photolyse. Pour toutes les conditions étudiées, on n'a pas pu observer de réactions de substitution des coordinats acétonitrile ou pmp. La spectroscopie ir et la spectrométrie de masse par bombardement avec des atomes rapides indiquent que les tentatives d'isoler le complexe $[Ru(bp)_2(pmp)(ClO_4)]^+$ n'ont en fait fourni que la complexe aqua. Dans les films de polymères, le complexe perchlorique peut aussi se transformer en complexe aqua. Do à l'instabilité de la matrice du polymère conducteur aux bas pH et à l'inactivité du complexe à des valeurs plus élevées de pH, les films contenant le complexe aqua ne sont pas utiles pour l'oxydation électrocatalytique.

Mots clés : polythiophène, polypyrrole, électropolymérisation, métallopolymère.



[Traduit par la rédaction]

Introduction

Pyrrole substituents have become very popular for facilitating electropolymerization of metal complexes (1). Since these metallopolymer films are most useful in electrocatalysis, it would be desirable if they also possess high electronic conductivity. This has been achieved by copolymerization of pyrrole-substituted complexes with unsubstituted pyrrole (2–5).

To further develop the synthetic chemistry of electronically conductive metallopolymers, we have prepared a number of copolymers (**I**) containing ruthenium polypyridine complexes of the general formula $[Ru(bp)_2(pmp)X]^{2+}$ (bp = 2,2′-bipyridine, pmp = 3-(pyrrol-1-ylmethyl)pyridine, X = Cl^-, ClO_4^-, pmp, H_2O, or CH_3CN). The above complexes have been copolymerized with pyrrole, 3-methylthiophene, 2,2′-bithophene, and/or 1-methyl-3-(pyrrol-1-ylmethyl)pyridinium(1+). The last pyrrole was chosen to enhance the hydrophilicity of the copolymer (6) while 3-methylthiophene and 2,2′-bithiophene were used to enhance its stability. The thermal and photolytic substitution reactions of the sixth ligand (X) in the copolymers have been investigated.

One of our main objectives was to develop synthetic routes to

I

conducting polymers containing an analogue of the versatile oxidation catalyst $[Ru(bp)_2(py)(H_2O)]^{2+}$ (py = pyridine) (7). This complex has previously been incorporated into polyvinylpyridine (8, 9) and Nafion (10) films.

Experimental

Electrochemistry

Electrochemical experiments were carried out in conventional three-compartment glass cells under an argon atmosphere at 23 ± 2°C. The working electrode was either a Pt disc sealed in glass (4.5×10^{-3} or 1.2×10^{-4} cm^2), or a glassy carbon disc (0.071 cm^2, Electrosynthesis Co., Inc.) sealed in epoxy (Lepage's). The counter electrode was a Pt wire and the reference electrode was either a saturated sodium chloride calomel electrode (SSCE) or a Ag/Ag^+ (0.1 M in CH_3CN) electrode which had a potential of 0.36 V vs. SSCE in CH_3CN. All

potentials are quoted with respect to the SSCE. The electrochemical instrumentation consisted of a HB-104 Hokuto Denko function generator, a HA-301 Hokuto Denko potentiostat/galvanostat, and a BBC SE780 X–Y recorder.

Spectroscopy

A Hitachi S570 scanning electron microscope operated at an accelerating voltage of 20 kV was used for X-ray emission spectroscopy (electron microprobe analysis). Emission spectra were collected using a Tracor Northern 5500 Energy Dispersive X-ray Analyzer equipped with a Microtrace 70152 silicon detector. Fast atom bombardment mass spectra of samples mixed with glycerol and *p*-toluene sulphonic acid were obtained using a VG Micromass 7070HS mass spectrometer. Infrared spectra were recorded using a Perkin-Elmer 283.

Synthesis of ruthenium complex monomers

$[Ru(bp)_2(pmp)Cl]PF_6$ (3) and **$[Ru(bp)_2(pmp)_2](ClO_4)_2$** (5) were prepared as previously described.

$[Ru(bp)_2(pmp)(ClO_4)]ClO_4$ was prepared following the literature procedure for $[Ru(bp)_2(py)(ClO_4)]ClO_4$ (11). Thus, $[Ru(bp)_2(pmp)_2](ClO_4)_2$ (100 mg) in dichloromethane (400 mL) was photolyzed until fully dissolved using a 150 W tungsten lamp (ca. 4 h). The volume was reduced to ca. 20 mL under reduced pressure and the product was precipitated with diethyl ether, collected by filtration, and dried in air (yield = 59%). The solid isolated this way appears to be $[Ru(bp)_2(pmp)(H_2O)](ClO_4)_2$ but produces $[Ru(bp)_2(pmp)(ClO_4)]^+$ in CH_2Cl_2 (see below).

$[Ru(bp)_2(pmp)(H_2O)](ClO_4)_2$ was prepared by the literature method for $[Ru(bp)_2(py)(H_2O)](ClO_4)_2$ (12).

$[Ru(bp)_2(pmp)(CH_3CN)]^{2+}$ was prepared *in situ* by dissolving $[Ru(bp)_2(pmp)(H_2O)](ClO_4)_2$ in acetonitrile.

Preparation of copolymer films

All copolymers were deposited as thin films on Pt or carbon electrodes by simultaneous electrochemical oxidation of an aromatic heterocyclic monomer (pyrrole, 3-methylthiophene, 2,2′-bithiophene or 1-methyl-3-(pyrrol-1-ylmethyl)pyridium(1+)) and a Ru complex ($[Ru(bp)_2(pmp)X]^{2+}$) in a non-aqueous solution containing 0.1 M supporting electrolyte. Typical preparation conditions, and approximate compositions of the resulting films are given in Table 1. Film compositions and thicknesses were routinely extimated by cyclic voltammetry as previously described (3, 5). A typical voltammogram of a (3-methylthiophene)$_x$$[Ru(bp)_2(pmp)_2]^{2+}$ copolymer film is shown in Fig. 1. The thiophene-to-Ru ratio of 6.7 (x) was obtained by dividing four times the charge under the poly(3-methylthiophene) oxidation wave (to 1.15 V) by the charge under the Ru reduction wave at 1.2 V (5). This assumes that oxidation of the poly(3-methylthiophene) backbone involves 0.25 electrons per thiophene unit.

Chemicals and solvents

Pyrrole (Aldrich) was purified on a dry alumina column. 1-Methyl-3-(pyrrol-1-ylmethyl)pyridinium tetrafluoroborate was prepared as previously described (13). 3-Methylthiophene (Aldrich) and 2,2′-bithiophene (Aldrich) were used as received. Bu_4NClO_4 (purum, Fluka) was precipitated from hot acetone with water, filtered, and dried under vacuum at 50°C for 10 h. Et_4NClO_4 (Fluka), Bu_4NBF_4 (Fluka), and other electrolytes were used as received. Acetonitrile (Aldrich, HPLC) was consecutively distilled from $KMnO_4 + Li_2CO_3$, P_4O_{10}, and CaH_2. Dichloromethane (Mallinckrodt, HPLC), propylene carbonate (Aldrich, Gold Label), nitromethane (Fisher, Spectranalyzed) were used as received.

Results and discussion

Characterization of Ru complexes

Characterization of the complexes and copolymers prepared in this work and the observation of ligand substitution reactions of the complexes in the copolymers rely on electrochemical data. The formal potentials ($E^{0\prime}$) of the Ru complex monomers are presented in Table 2. These are in good agreement with those previously reported for the pyridine analogues of these complexes (11) which are also included in Table 2. Clearly,

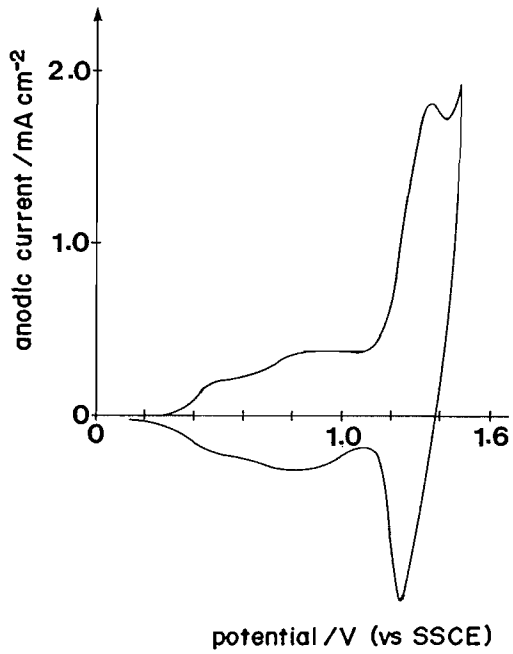

FIG. 1. Cyclic voltammogram at 10 mV/s of a (3-methylthiophene)$_7$–$[Ru(bp)_2(pmp)_2]^{2+}$ copolymer coated glassy carbon electrode in acetonitrile + 0.1 M Bu_4NClO_4.

formal potentials are acceptable for identifying most of the complexes used. The only difficulty arises in distinguishing between $[Ru(bp)_2(pmp)(ClO_4)]^+$ and $[Ru(bp)_2(pmp)(H_2O)]^{2+}$, since in this work we do not need to distinguish between $[Ru(bp)_2(pmp)(CH_3CN)]^{2+}$ and $[Ru(bp)_2(pmp)_2]^{2+}$. Infrared spectroscopy and fast atom bombardment mass spectroscopy were applied to this problem.

Infrared spectroscopy of $[Ru(bp)_2(pmp)(ClO_4)]ClO_4$ in CH_2Cl_2 revealed the bands at 1150 and 1015 cm^{-1} assigned to bound perchlorate for the pyridine analogue (11). The formal potential of this complex, from cyclic voltammetry in CH_2Cl_2, is also in agreement with that reported for the pyridine analogue (Table 2). However, fast atom bombardment mass spectroscopy of the solid isolated from CH_2Cl_2 revealed coordinated water but no evidence for perchlorate coordination. Peaks of similar intensity at m/z = 585, 431, and 414 were assigned to $[Ru(bp)_2]^{2+}[Me\text{-}4\text{-}C_6H_4SO_3]^-$, $[Ru(bp)_2(OH)]^+$, and $[Ru(bp)_2]^+$, respectively. No ions were observed at m/z = 671 ($[Ru(bp)_2(pmp)(ClO_4)]^+$), m/z = 513 ($[Ru(bp)_2(ClO_4)]^+$), m/z = 589 ($[Ru(bp)_2(pmp)(OH)]^+$), or m/z = 572 ($[Ru(bp)_2(pmp)]^+$). For comparison $[Ru(bp)_2(pmp)Cl]ClO_4$ produced peaks assigned to $[Ru(bp)_2(pmp)Cl]^+$ (m/z = 607, weak), $[Ru(bp)_2]^{2+}[Me\text{-}4\text{-}C_6H_4SO_3]^-$ (m/z = 585, weak), $[Ru(bp)_2Cl]^+$ (m/z = 449, strong), and $[Ru(bp)_2]^+$ (m/z = 414, strong). Infrared spectroscopy (Nujol mull) of the solid isolated from a CH_2Cl_2 solution of $[Ru(bp)_2(pmp)(ClO_4)]ClO_4$ was not significantly different from that of $[Ru(bp)_2(pmp)(H_2O)](ClO_4)_2$ and revealed no splitting of the perchlorate band at 1095 cm^{-1}. Both compounds exhibit broad bands in the 3000–3500 cm^{-1} region attributed to water. In CH_2Cl_2, the infrared spectrum of $[Ru(bp)_2(pmp)(H_2O)](ClO_4)_2$ revealed splitting of the perchlorate band similar to that observed for $[Ru(bp)_2(pmp)(ClO_4)]ClO_4$. Cyclic voltammetry indicated the same formal potential as for $[Ru(bp)_2(pmp)(ClO_4)]ClO_4$.

The above evidence indicates that the coordinated perchlorate complex was obtained in CH_2Cl_2. However, the solid isolated from this solution is the aqua complex, $[Ru(bp)_2(pmp)(H_2O)](ClO_4)_2$. Dissolution of the aqua complex in CH_2Cl_2 produces the perchlorate complex, as reported by Meyer and co-workers for the pyridine analogue (11).

Film synthesis

The compositions and quality of films resulting from the copolymerization of a pyrrole-substituted Ru complex and an aromatic heterocycle depend on many factors. These will be individually discussed and illustrated with specific examples.

Solvent

Acetonitrile was generally found to be the best solvent for incorporating Ru complexes into copolymer films. Propylene carbonate, nitromethane, and dichloromethane were also used but generally resulted in films with low Ru complex contents. This is illustrated by the data for (3-methylthiophene)$_x$–$[Ru(bp)_2(pmp)Cl]^+$ copolymers presented in Table 1. The films prepared from propylene carbonate and nitromethane contain only about a third as much Ru as the film prepared from acetonitrile under similar conditions. Bu_4NBF_4 was used as the electrolyte in propylene carbonate and nitromethane because copolymers could not be produced from these solvents when Bu_4NClO_4 was used. Bu_4NBF_4 was a satisfactory electrolyte for polymerization in acetonitrile.

Acetonitrile could not be used for the preparation of films containing $[Ru(bp)_2(pmp)(ClO_4)]^+$ or $[Ru(bp)_2(pmp)(H_2O)]^{2+}$ because of the rapid conversion of these complexes to $[Ru(bp)_2(pmp)(CH_3CN)]^{2+}$. Nor could films containing useful quantities of these complexes be prepared from propylene carbonate or nitromethane. Dichloromethane was found to be an acceptable

solvent from which to prepare copolymers of pyrrole or 1-methyl-3-(pyrrol-1-ylmethyl)pyridinium(1+) with $[Ru(bp)_2(pmp)(ClO_4)]^+$ (Table 1). However, $[Ru(bp)_2(pmp)(ClO_4)]^+$ failed to copolymerize with either 3-methylthiophene or 2,2′-bithiophene in dichloromethane. Oxidation of 3-methylthiophene, and hence polymerization, is blocked by a precipitate of $[Ru(III)(bp)_2(pmp)(ClO_4)](ClO_4)_2$ that rapidly forms on the electrode surface. Formation of this precipitated layer is demonstrated in Fig. 2*A*. The size of the Ru(III)/(Ru(II) voltammetric peaks of the complex increase with potential cycling, indicating that the complex is deposited on the electrode. After the potential scans depicted in Fig. 2*A* the electrode was visibly coated with an orange film of the complex and electrochemistry of the film could be observed in water (Fig. 2*B*). It is unlikely that this film is polymeric because it dissolves quite rapidly in acetonitrile. Copolymerization of $[Ru(bp)_2(pmp)(ClO_4)]^+$ with pyrrole or 1-methyl-3-(pyrrol-1-ylmethyl)pyridinium(1+) is not inhibited because these monomers polymerize at potentials below those required to rapidly form the blocking $[Ru(bp)_2(pmp)(ClO_4)](ClO_4)_2$ film. The copolymerization of 3-methylthiophene and $[Ru(bp)_2(pmp)(ClO_4)]^+$ does occur in nitromethane but only films with a low Ru complex content ($x > 50$) could be prepared.

Monomer ratio

As expected, the composition of all copolymers could be varied by changing the monomer ratio in the polymerization solution. This is demonstrated by the data for (3-methylthiophene)$_x$–$[Ru(bp)_2(pmp)_2]^{2+}$ copolymers presented in Table 3. Here the copolymer composition varies approximately linearly with monomer ratio over a wide range of compositions. The Ru complex is preferentially incorporated into the copolymer by a factor of about two. This is presumably the result of two pyrrole substituents on one Ru complex. This is supported by the fact that $[Ru(bp)_2(pmp)Cl]^+$, which has just one pyrrole substituent, is not preferentially incorporated into poly(3-methylthiophene) under similar conditions (Table 1). Copolymerization of the Ru complexes with pyrrole results in preferential incorporation of the unsubstituted polypyrrole which polymerizes at lower potentials than the pyrrole substituent of the complex (Table 1) (3).

Polymerization procedure and potential

All copolymers listed in Table 1 could be prepared under potentiostatic or potential cycling conditions. Generally, better reproductibility and more uniform coverage of the electrode were obtained with potential cycling. Film thicknesses could easily be controlled by the polymerization time or the number of cycles (Table 2). The optimum polymerization potentials (or upper potential limit for cycling) given in Table 1 are determined by the minimum potential required to produce satisfactory copolymer films and the potential at which oxidative deactivation of the copolymer becomes unacceptable. Within this range some control of composition is possible by varying the potential. The more easily polymerized monomer is favoured at lower potentials. This is particularly evident in the copolymerization of $[Ru(bp)_2(pmp)_2]^{2+}$ with 3-methylthiophene, where increasing the potential results in an increased thiophene:Ru ratio in the resulting film.

Monomer concentrations and residual water

The deposition of thiophene-based copolymers was inhibited by residual water in the polymerization solution. Reproduci-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

bility and homogeneity of electrode coverage were enhanced by increasing the 3-methylthiophene concentration, presumably by increasing the monomer-to-residual water ratio. A minimum 3-methylthiophene concentration of 20 mM was found to be satisfactory. Increasing the Ru complex concentration generally made the copolymerization less reproducible. This problem appears to be related to water associated with the complex and can be alleviated by thoroughly drying the complex in a vacuum oven.

Determination of composition by X-ray emission spectroscopy

Copolymer compositions quoted in this and our previous work are based on electrochemical measurements. The determination of compositions in this way requires a separation of the Ru complex and polymer backbone components of a cyclic voltammogram (e.g. Fig. 1) (3, 5). In addition, the number of electrons (n) involved in the electrochemistry of the polymer backbone must be known. Estimation of the Ru complex content of pyrrole$_x$–$[Ru(bp)_2(pmp)Cl]^+$ copolymers by cyclic voltammetry has been validated by electronic absorption spectroscopy (3). However, estimation of the heterocycle content by cyclic voltammetry has not been tested for any heterocycle–[Ru complex] copolymer.

Ideally, an elemental analysis would be obtained for each film. However, a 1 μm polymer film on a 1 cm^2 electrode typically has a mass of ca. 0.2 mg. Conventional elemental microanalysis of such a film is obviously impractical. Thicker films could be used but their compositions may be different from the thin films studied by electrochemistry. X-Ray emission spectroscopy, however, is well suited to the study of the samples used in this work.

Unfortunately, H, C, N, and O could not be detected by X-ray emission spectroscopy. The analysis therefore focused on heavy atoms in the monomers and counterions (Ru, S, Cl, and P). Analysis is further complicated by the overlap of the Cl-K emission line and the Ru-L emission line when an energy dispersive detector is used. Perchlorate counterions were therefore replaced with PF_6^- by ion-exchange in acetonitrile. Figure 3 shows an X-ray emission spectrum of a typical (3-methylthiophene)$_x$–$[Ru(bp)_2(pmp)_2](PF_6)_2$ copolymer film on a glassy carbon electrode. The Ru-L, P-K, and S-K emissions are well resolved. Background-corrected peak areas were calculated by the data anlysis system (Standardless Quantitative Analysis). Standards were prepared by depositing 2–10 μg mixtures of $[Ru(bp)_3](PF_6)_2$ and tetraethylammonium *p*-toluenesulfonate on carbon electrodes by evaporating acetone solutions. Four standards with S:Ru mole ratios between 3 and 12 were each analyzed twice. A plot of S:Ru ratios calculated directly from peak areas for these standards against the actual mole ratios had a slope of 0.97 (±0.12) and an intercept of 0.33. The standard deviation about the regression was 1.1. Therefore the S:Ru ratios for copolymer films were calculated directly from peak areas with no corrections. Compositions of a number of copolymers determined this way are plotted against the electrochemically determined compositions in Fig. 4. There is significant scattering of the data because both analytical techniques are only semi-quantitative. However, for thiophene-to-Ru mole ratios below 8 the agreement is good. At higher thiophene contents electrochemically determined thiophene-to-Ru ratios are higher than those determined by X-ray emission spectroscopy. The values from the X-ray data are more likely to be incorrect because they do not reflect an increasing thiophene content of the polymer as the thiophene-to-Ru ratio in the

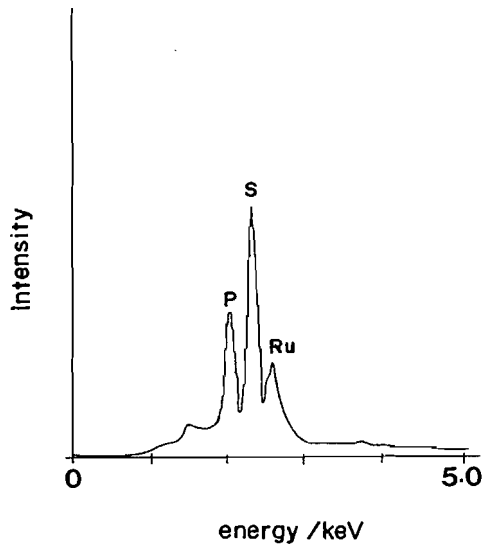

FIG. 3. X-Ray emission spectrum of a glassy carbon carbon electrode coated with a ca. 1.5 μm thick copolymer of 3-methylthiophene and $[Ru(bp)_2(pmp)_2](PF_6)_2$.

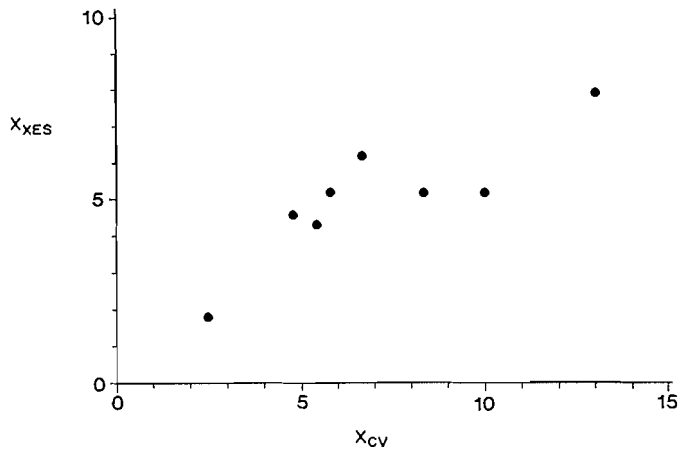

FIG. 4. Plot of thiophene-to-Ru ratios determined by X-ray emission spectroscopy (x_{XES}) against those determined by cyclic voltammetry (x_{CV}) for (3-methylthiophene)$_x$–$[Ru(bp)_2(pmp)_2](PF_6)_2$ copolymer films.

polymerization solution was increased. Further, the compositions from the X-ray data would require oxidation of the thiophene backbone of the copolymer to involve as few as two thiophene units per electron, which would be unusually low.

Electrochemistry and ligand substitution reactions of complexes in copolymers

$[Ru(bp)_2(pmp)Cl]^+$

Of the copolymers that could directly be prepared, (3-methylthiophene)$_x$–$[Ru(bp)_2(pmp)Cl]^+$ films offered the best precursors to electrocatalytic films containing $[Ru(bp)_2(pmp)(H_2O)]^{2+}$. Substitution of the chloride ligand by water has been shown to occur for an analogous complex immobilized in polyvinylpyridine (9, 14). This reaction is slow and incomplete under thermal conditions but facile under illumination (14).

Cyclic voltammograms of a (3-methylthiophene)$_8$–$[Ru(bp)_2(pmp)Cl]^+$ copolymer film in 1 M H_2SO_4(aq) before (—)and after (----) illumination with a 150 W tungsten lamp for 1 h are shown in Fig. 5*A*. After illumination, the peaks at $E^{0\prime} = 0.75$ V

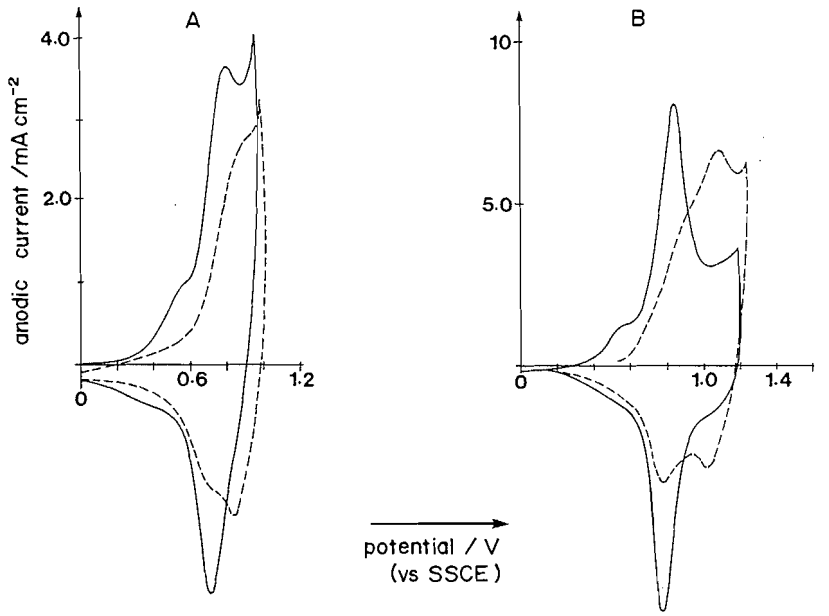

FIG. 5. (*A*) Cyclic voltammograms at 100 mV/s, in H_2SO_4(aq), of a Pt electrode coated with a copolymer of 3-methylthiophene and $[Ru(bp)_2(pmp)Cl]^+$. The solid line is the initial voltammogram, while the dashed line was recorded after ca. 1 h of photolysis in 1 M H_2SO_4. (*B*) Cyclic voltammograms of a similar electrode, in acetonitrile + 0.1 M Bu_4NBF_4, before (—) and after (---) ca. 1 h of photolysis in 1 M H_2SO_4(aq).

due to the chloro-complex had diminished and new peaks had appeared at $E^{0\prime} = 0.87$ V. This new formal potential can be assigned to the polymer-bound aqua complex, $[Ru(bp)_2(pmp)(H_2O)]^{2+}$, since it is close to the values observed for $[Ru(bp)_2(py)(H_2O)]^{2+}$ in 1 M $HClO_4$ (0.90 V) (11) and in polyvinylpyridine films (ca. 0.85 V) (14). The elctrochemistry of the polymer-bound aqua complex is more clearly observed in acetonitrile (Fig. 5*B*). From this voltammogram, the formal potential of the aqua complex in the polymer in acetonitrile is 1.08 V.[3] With potential cycling in the acetonitrile electrolyte, the waves due to the aqua complex were replaced by waves at $E^{0\prime} = 1.32$ V due to the acetonitrile complex.

Similar photosubstitution of the copolymer-bound chloro complex occurs in 1 M $HClO_4$(aq). The formal potentials of the chloro and aqua complexes are 0.59 and 0.79 V, respectively, in the 3-methylthiophene copolymer in this electrolyte solution. These potentials are similar to those reported for analogous complexes in polyvinylpyridine in 1 M $HClO_4$ (0.64 and 0.85 V) (14).

Substitution of the Cl^- ligand in (3-methylthiophene)$_x$–$[Ru(bp)_2(pmp)Cl]^+$ copolymers also occurs thermally in aqueous media but, as reported by Vos and co-workers (14) for $[Ru(bp)_2(py)Cl]^+$ in polyvinylpyridine, it is much slower than photosubstitution. This is demonstrated in Fig. 6. Immersion of the copolymer in 0.1 M $LiClO_4$(aq) for 15 h at room temperature resulted in only a partial decrease in the waves at $E^{0\prime} = 0.82$ V due to the chloro complex. New waves due to the aqua complex appeared at $E^{0\prime} = 1.12$ V. The difference of 40 mV between this formal potential and that obtained from Fig. 5*B* is too small to be regarded as significant. The voltammograms shown in Fig. 6 also exhibit small waves at $E^{0\prime} = 1.32$ V due to the acetonitrile complex which is formed from both the chloro and aqua complexes in acetonitrile (see below).

Thermal substitution of the Cl^- ligand of $[Ru(bp)_2(pmp)Cl]^+$ in copolymer films also occurs in acetonitrile. Figure 7 shows voltammograms of a (3-methylthiophene)$_9$–$[Ru(bp)_2(pmp)Cl]^+$ copolymer film in acetonitrile before (—) and after 1 h of heating at reflux in acetonitrile + 0.1 M $LiClO_4$ (---). The wave at $E^{0\prime} = 0.83$ V, due to the Cl complex, decreases and is replaced by a new wave at $E^{0\prime} = 1.34$ V, due to the acetonitrile complex. Interestingly, no substitution was observed under similar conditions in acetonitrile + 0.1 M Bu_4NClO_4. The latter result is most intriguing, indicating that Li^+ catalyzes the replacement of Cl^+ by CH_3CN.

The (3-methylthiophene)$_x$–$[Ru(bp)_2(pmp)H_2O]^{2+}$ copolymers prepared here did not prove to be useful for electrocatalysis because of the irreversible oxidation of the conducting backbone. As can be seen from the voltammograms shown in Fig. 5*A*, this occurs at potentials at which the electrocatalytic Ru aqua complex is oxidized. Poly(3-methylthiophene) was found to be a stable electrode material for the oxidation of [Ru(bp)(2,2′:6′,2″-terpyridine)$(H_2O)]^{2+}$ under basic conditions when the formal potential of the complex is much lower (15). However, the electrochemistry of the aqua complex in the copolymer film is suppressed in basic media. A similar phenomenon was reported for the aqua complex in polyvinylpyridine films (14). The more hydrophillic backbone of poly-[1-methyl-3-(pyrrol-1-ylmethyl)pyridium(1+)] was used to try to prevent this problem but irreversible oxidation of the resulting copolymers obscured any electrochemistry of the Ru aqua complex under all conditions tested.

$[Ru(bp)_2(pmp)(ClO_4)]^+$ and $[Ru(bp)_2(pmp)(H_2O)]^{2+}$

Copolymer films containing $[Ru(bp)_2(pmp)(ClO_4)]^+$ are attractive precursers to films containing the aqua complex because the perchlorate ligand is more easily replaced by water than is Cl^-. The infrared and mass spectroscopic data presented above for the perchlorate complex monomer suggest that substitution of perchlorate by adventitious water is likely to occur immediately upon removing the copolymer from the CH_2Cl_2 solution in which it is prepared. Evidence for this is

[3]Formal potentials in acetonitrile and water can not be directly compared because of junction potentials and solvent effects.

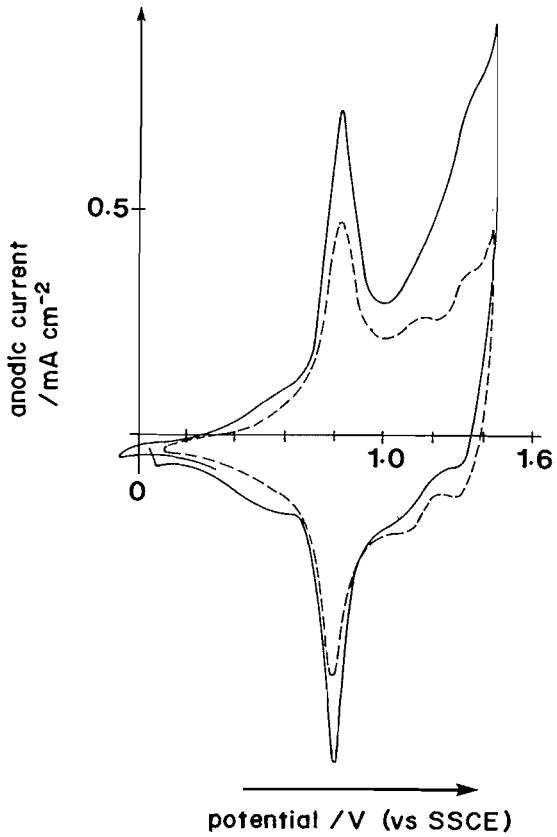

FIG. 6. Cyclic voltammograms at 100 mV/s, in acetonitrile + 0.1 M Bu_4NClO_4, of a Pt electrode coated with a copolymer of 3-methylthiophene and $[Ru(bp)_2(pmp)Cl]^+$. The solid line is the initial voltammogram, while the dashed line was recorded after ca. 15 h at room temperature in aqueous 0.1 M $LiClO_4$.

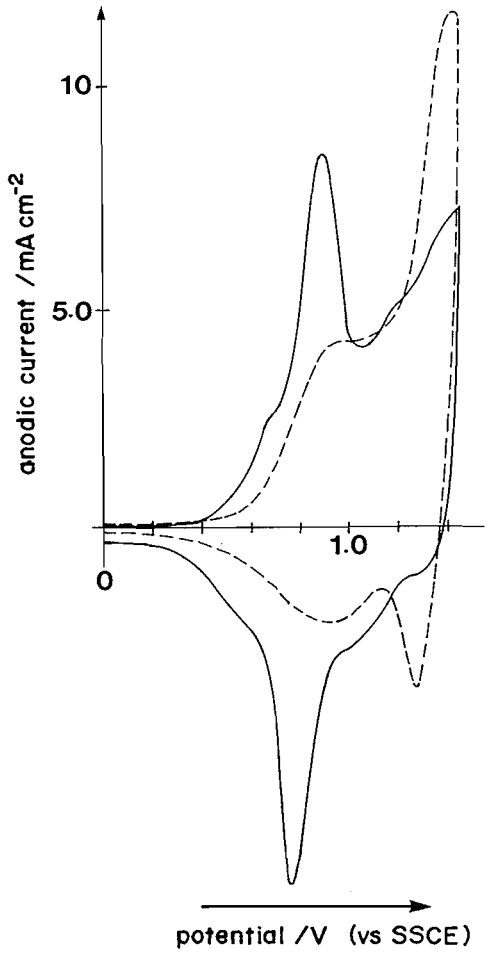

FIG. 7. Cyclic voltammograms at 100 mV/s, in acetonitrile + 0.1 M Bu_4NClO_4, of a Pt electrode coated with a copolymer of 3-methylthiophene and $[Ru(bp)_2(pmp)Cl]^+$. The solid line is the initial voltammogram, while the dashed line was recorded after ca. 1 h of heating at reflux in acetonitrile + 0.1 M $LiClO_4$.

presented in Fig. 8. Figure 8*A* shows cyclic voltammograms of a copolymer of pyrrole and $[Ru(bp)_2(pmp)(ClO_4)]^+$ in acetonitrile. The peaks at $E^{0\prime} = 1.13$ V could be due to either the perchlorate complex or the aqua complex. They decay rapidly and are replaced by peaks at $E^{0\prime} = 1.32$ V, characteristic of the acetonitrile complex, $[Ru(bp)_2(pmp)(CH_3CN)]^{2+}$. Figure 8*B* shows voltammograms of a similar film that had been soaked in aqueous KPF_6 overnight, to ensure substitution of the perchlorate ligand by water. These voltammograms are not significantly different from those in Fig. 8*A*, suggesting that both films contained the aqua complex. However, because of the similarity of the formal potentials of the perchlorate and aqua complexes (Table 2) we can not be sure that the voltammogram shown in Fig. 8*A* is not that of the perchlorate complex. No useful electrochemical data could be obtained for the pyrrole-based copolymers in aqueous media because electrochemical activity of the Ru complexes was obscured by irreversible oxidation of the polypyrrole.

The redox waves at $E^{0\prime} = 0.83$ V in Fig. 8*A* are due to $[Ru(bp)_2(pmp)(Cl)]^+$. This complex is present as an impurity in the $[Ru(bp)_2(pmp)(ClO_4)]^+$ polymerization solution and is preferentially incorporated into the copolymer film. Solid samples of "$[Ru(bp)_2(pmp)(ClO_4)]ClO_4$" slowly decompose to give $[Ru(bp)_2(pmp)(Cl)]^+$. Copolymers without this impurity can be prepared using freshly prepared $[Ru(bp)_2(pmp)(H_2O)](ClO_4)_2$.

The ligand substitution reactions of copolymers prepared from 1-methyl-3-(pyrrol-1-ylmethyl)pyridinium(1+) and $[Ru(bp)_2(pmp)(ClO_4)]^+$ are similar to those of the pyrrole-based films. Although this *N*-substituted polypyrrole is more stable to oxidation than polypyrrole, no voltammetric peaks due to the aqua complex could be observed in aqueous media.

$[Ru(bp)_2(pmp)(CH_3CN)]^{2+}$

The acetonitrile complex is remarkably stable in conducting copolymer films. Bithiophene$_x$–$[Ru(bp)_2(pmp)(CH_3CN)](ClO_4)_2$ copolymer films, immersed in either acetonitrile or dichloromethane containing Et_4NCl exhibited no voltammetric peaks due to formation of the chloro complex, even after more than 10 h at room temperature. A similar film exhibited no evidence of the formation of an aqua complex during 2 h of illumination in 1 M aqueous H_2SO_4.

$[Ru(bp)_2(pmp)_2](ClO_4)_2$

Photolysis of this complex in dichloromethane results in substitution of one of the pmp ligands by ClO_4^- (11). If this reaction could be reproduced in a conducting copolymer film it would be a usefuul route to make films containing the perchlorate complex and hence the aqua complex. However, 100 min of photolysis of a 3-methylthiophene$_x$–$[Ru(bp)_2(pmp)_2]^{2+}$ copolymer film on a Pt electrode in dichloromethane containing Bu_4NClO_4 produced no voltammetric evidence for the formation of the perchlorate complex. Similarly, photolysis in acetone + Et_4NCl resulted in no new voltammetric peaks due to the formation of the chloro complex.

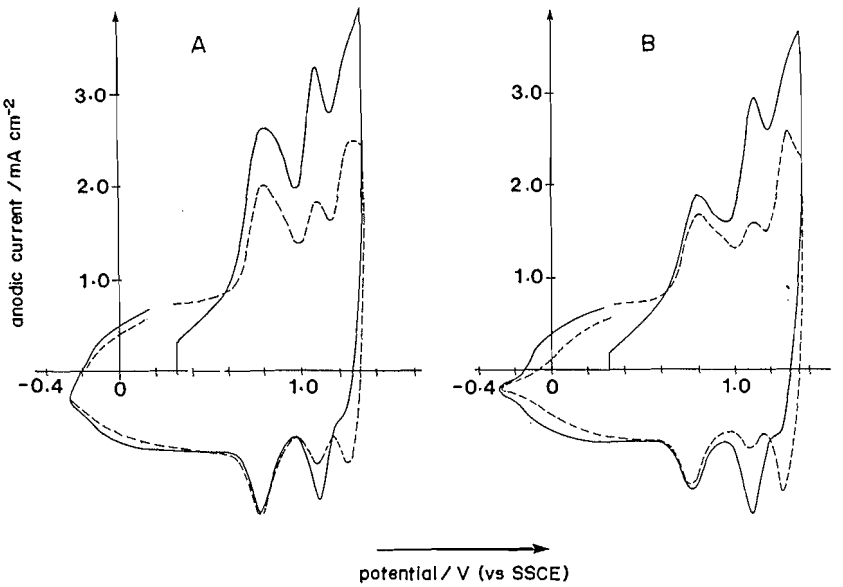

FIG. 8. Cyclic voltammograms at 100 mV/s, in acetonitrile + 0.1 M Bu_4NBF_4, of Pt electrodes coated with copolymers prepared from pyrrole and $[Ru(bp)_2(pmp)(ClO_4)](ClO_4)$ in CH_2Cl_2. The coated electrode for B was immersed in 0.1 M KPF_6(aq) at room temperature overnight before use. Solid lines are first scans while dashed lines as third (*A*) and fourth scans (*B*), respectively.

Kinetics

Ligand substitution reactions of the ruthenium complexes in the copolymer films studied in this work generally follow those observed in solution (11) and in polyvinylpyridine (9, 14). However, although no quantitative comparison has been made, it appears that these reactions are considerably slower than in solution. $[Ru(bp)_2(pmp)(CH_3CN)]^{2+}$ and $[Ru(bp)_2(pmp)_2)]^{2+}$ are particularly unreactive in the conducting copolymer films. Kinetic studies of these reactions may reveal important information about the chemical environment within the copolymers (16).

Acknowledgments

We gratefully acknowledge financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC) and from Memorial University. We also thank Carolyn Emerson for assistance with X-ray emission spectroscopy, Brian Gregory and Marion Baggs for running the mass spectra, and Kenneth Seddon and Johannes Vos for helpful discussions of this work.

Reçu le 26 juillet 1990

P. COURTOT, R. PICHON, J. Y. SALAUN et L. TOUPET. Can. J. Chem. **69**, 661 (1991).

La préparation des composés de type $(C_5Me_4H)_2MR^1R^2$ (M = Ti, Zr) et $(C_5Me_4H)(C_5H_5)MR^1R^2$ (M = Ti) a été réalisée (R^1 = R^2 = Cl, CH_3, C_6H_5, *p*-$C_6H_4CH_3$, CO ; R^1 = Cl, R^2 = CH_3, C_6H_5, *p*-$C_6H_4CH_3$). Les caractéristiques RMN et IR de ces complexes montrent que le ligand C_5Me_4H induit une influence électronique beaucoup plus importante que le ligand C_5H_5 et très légèrement inférieure à celle de C_5Me_5. Une étude structurale réalisée sur le complexe $(C_5Me_4H)_2Zr(C_6H_5)Cl$ ainsi que l'examen des propriétés des composés $(C_5Me_4H)_2MR^1R^2$ (M = Ti, Zr ; R^1 = R^2 = C_6H_5, *p*-$C_6H_4CH_3$; R^1 = Cl, Br ; R^2 = C_6H_5, *p*-$C_6H_4CH_3$) en RMN dynamique ont également mis en évidence pour le ligand C_5Me_4H une influence intermédiaire entre celle de C_5H_5 et celle de C_5Me_5. Enfin, l'encombrement stérique ainsi que l'effet électronique du ligand C_5Me_4H ont été mis à profit pour induire, à l'aide du complexe $(C_5Me_4H)_2Ti(CH_3)_2$, des réactions d'isomérisation spécifiques de divers alcènes.

Mots clés : zirconium, titane, tétraméthylcyclopentadiényle, photoassistée, isomérisation, alcènes.

P. COURTOT, R. PICHON, J. Y. SALAUN, and L. TOUPET. Can. J. Chem. **69**, 661 (1991).

The complexes $(C_5Me_4H)_2MR^1R^2$ (M = Ti, Zr) and $(C_5Me_4H)(C_5H_5)MR^1R^2$ (M = Ti) have been prepared (R^1 = R^2 = Cl, CH_3, C_6H_5, *p*-$C_6H_4CH_3$, CO; R^1 = Cl, R^2 = CH_3, C_6H_5, *p*-$C_6H_4CH_3$). The NMR and IR spectra of these complexes indicate that C_5Me_4H exhibits an electron-donor effect more important than C_5H_5 and a little bit weaker than that of C_5Me_5. A structural investigation of the complex $(C_5Me_4H)_2Zr(C_6H_5)Cl$ and the study of the ^1H or ^{13}C dynamic NMR properties of the compounds $(C_5Me_4H)_2MR^1R^2$ (M = Ti, Zr; R^1 = R^2 = C_6H_5, *p*-$C_6H_4CH_3$; R^1 = Cl, Br, R^2 = C_6H_5, *p*-$C_6H_4CH_3$) show clearly that C_5Me_4H has a steric effect intermediate between C_5H_5 and C_5Me_5. The steric or electronic effects of C_5Me_4H have been used to induce specific isomerization reactions of various alkenes by using $(C_5Me_4H)_2Ti(CH_3)_2$ as catalyst.

Key words: zirconium, titanium, tetramethylcyclopentadienyl, photo-assisted, isomerization.

Introduction

Le remplacement d'un ligand cyclopentadiényle par un ligand pentaméthylcyclopentadiényle dans les dérivés de métallocènes conduit à augmenter la stabilité des complexes en raison de l'effet inductif et d'hyperconjugaison des groupements méthyle et d'un plus grand encombrement stérique autour du métal. L'effet inductif des méthyles modifie également les propriétés physiques et chimiques des complexes en augmentant la densité électronique du centre métallique. Nous avons voulu mettre en évidence l'influence électronique et stérique des groupements méthyle substituant les ligands cyclopentadiényle en réalisant la préparation et l'étude de dérivés du titanocène et du zirconocène possédant des ligands susceptibles de présenter des effets électroniques et stériques intermédiaires entre les complexes des séries $(C_5H_5)_2MR_2$ et $(C_5Me_5)_2MR_2$ déjà décrits dans la littérature. Pour réaliser ce travail, nous avons entrepris d'étudier les dérivés du titanocène et du zirconocène dont les ligands cyclopentadiényle sont substitués par quatre groupements méthyle : $(C_5Me_4H)_2MR^1R^2$.

Nous décrirons dans cet article la préparation des différents complexes dont nous commenterons les propriétés physiques les plus intéressantes. L'étude structurale de $(C_5Me_4H)_2Zr(C_6H_5)Cl$ sera ensuite détaillée ainsi que le comportement particulier en RMN dynamique des complexes substitués par un ou deux groupements aryle. Enfin, nous évoquerons les réactions spécifiques induites photochimiquement à l'aide du complexe $(C_5Me_4H)_2Ti(CH_3)_2$. Ce travail a fait l'objet de deux communications préliminaires (1, 2).

Résultats et discussion

Préparation des complexes

Le ligand C_5Me_4H a été obtenu par réduction de la tétraméthyl-2,3,4,5 cyclopentèn-2 one (3) par $LiAlH_4$ puis par déshydratation de l'alcool ainsi formé par l'acide *p*-toluène sulfonique en tétraméthyl-1,2,3,4 cyclopentadiène-1,3 (Rdt : 85%). Le sel de lithium de ce composé diénique (C_5Me_4HLi) est préparé à 0°C par échange avec le butyllithium. La condensation de deux équivalents de C_5Me_4HLi sur $TiCl_3$ ou $ZrCl_4$ selon des modes opératoires décrits dans la littérature pour la préparation de composés voisins porteurs des ligands C_5H_5 ou C_5Me_5 (4*a*, 4*b*, 5) conduit aux $(C_5Me_4H)_2TiCl_2$ et $(C_5Me_4H)_2ZrCl_2$. Lorsque le métal est le zirconium, seul le complexe biscyclopentadiénylé est obtenu (Rdt : 60%). Par contre, lorsque le métal est le titane, quelle que soit la quantité de sel de lithium utilisée, la formation d'au minimum 30% de $(C_5Me_4H)TiCl_3$ accompagne celle de $(C_5Me_4H)_2TiCl_2$. Ces deux complexes sont séparés par extractions successives à l'hexane.

Le composé $(C_5Me_4H)TiCl_3$ est obtenu exempt de $(C_5Me_4H)_2TiCl_2$ selon la méthode de Clark et coll. (6) (Rdt : 65%) en faisant réagir $C_5Me_4HSi(Me)_3$ sur $TiCl_4$. Le triméthylsilyl-5 tétraméthyl-1,2,3,4 cyclopentadiène-1,3 est lui-même préparé par réaction de C_5Me_4HLi sur $ClSi(Me)_3$ (Rdt : 77%).

La méthode choisie pour l'obtention du complexe «mixte» $(C_5Me_4H)(C_5H_5)TiCl_2$ est la réaction de C_5H_5Li sur

[a]Dans C_6D_6 au lieu de $CDCl_3$.

$(C_5Me_4H)TiCl_3$ (Rdt : 80%). L'autre voie de synthèse possible : $(C_5H_5)TiCl_3$ + C_5Me_4HLi, conduit avec 67% de rendement à un mélange composé de 70% du produit désiré et de 30% de $(C_5H_5)_2TiCl_2$. Différents auteurs ont déjà rapporté dans la littérature de tels échanges de cycle. Cependant, ces échanges aboutissaient soit à l'élimination du cyclopentadiényle le plus petit stériquement et le moins électrodonneur (C_5H_5) soit à l'obtention en quantité équivalente de $(C_5H_5)_2TiCl_2$ et de $(C_5Me_5)_2TiCl_2$ (ref. 7 et références citées). Pour notre part nous n'avons pas pu mettre en évidence la formation de $(C_5Me_4H)_2TiCl_2$ dans le milieu réactionnel. Les différents mécanismes proposés dans la littérature ne semblent pas convenir pour expliquer nos résultats.

Les complexes dichlorés dont nous venons de décrire les préparations ont été utilisés comme composés de départ pour la synthèse de dérivés dialkylés, diarylés ou dicarbonylés. Les méthodes de préparation utilisées sont voisines de celles décrites pour l'obtention des analogues dicyclopentadiénylés ou bispentaméthylcyclopentadiénylés. Les dérivés diméthylés et diarylés sont obtenus avec des rendements variant de 50% (M = Zr, R = C_6H_5) à 80% (M = Ti, R = CH_3) par réaction à basse température (−80°C) du méthyl ou de l'aryl lithium sur les complexes dichlorés (*4b*, 8–11). De même les dérivés dicarbonylés sont préparés par réduction des complexes dichlorés par le magnésium activé en présence de chlorure mercurique sous atmosphère de CO (1 atm = 101,3 kPa) (12, 13), (rendements de 25 à 70%).

Les dérivés de type $(C_5Me_4H)_2MR^1R^2$ (M = Ti, Zr) ou $(C_5Me_4H)(C_5H_5)TiR^1R^2$ avec R^1 = Cl et R^2 = CH_3, C_6H_5 ou $p\text{-}C_6H_4CH_3$ sont obtenus quantitativement par addition d'un équivalent de HCl aux complexes $(C_5Me_4H)_2M(R^2)_2$ ou $(C_5Me_4H)(C_5H_5)Ti(R^2)_2$ en solution dans l'éther. L'addition d'un équivalent d'organolithien aux dérivés dichlorés conduit le plus souvent à l'obtention de mélanges composés du complexe dichloré de départ et des dérivés mono et dialkylés (ou arylés). Seul le complexe $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)Br$ a été obtenu par addition de $p\text{-}CH_3C_6H_4MgBr$ au dérivé dichloré. Un suivi de la réaction par RMN ^{1}H nous a permis de mettre en évidence la formation intermédiaire de $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)Cl$ (déjà préparé selon la méthode générale) qui subit à température ambiante un rapide échange chlore–brome.

Caractéristiques physiques des complexes de titane et de zirconium

Les caractéristiques RMN des composés préparés sont indiquées dans le tableau 1.

On peut noter que la dissymétrie au niveau du métal dans les complexes $(C_5Me_4H)_2MRCl$ ou $(C_5Me_4H)(C_5H_5)TiRCl$ se traduit en RMN ^{1}H par une différenciation des quatre méthyles des ligands C_5Me_4H. Ceci est particulièrement mis en évidence dans le deuxième type de complexes porteur d'un seul ligand C_5Me_4H alors que dans la première série de composés, les deux ligands C_5Me_4H sont équivalents. En RMN ^{13}C, les quatre méthyles sont également différents de même que les cinq car-

bones du cycle pentadiénique. Les ligands C_5H_5 sont vraisemblablement en rotation rapide. Les résultats RMN que nous avons obtenus (tableau 1) ne permettent pas d'affirmer qu'il en est de même pour les ligands C_5Me_4H. Bien que les intéractions stériques méthyle–méthyle entre deux C_5Me_4H ne soient pas négligeables (cf. étude structurale), les observations effectuées sur les complexes porteurs de ligands C_5Me_5 (rotation rapide) (4, 5, 7–9, 11) sont en faveur d'un comportement analogue de C_5Me_4H. Les spectres ^1H et ^{13}C des ligands aryle du complexe $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)_2$ seront, à titre d'exemple, détaillés ultérieurement.

Evaluation par infrarouge de la densité électronique au niveau du métal

Une évaluation de la densité électronique induite au niveau du métal par les différents ligands peut être réalisée par l'étude des variations des fréquences des deux vibrations d'élongation de la liaison C≡O dans les deux modes A_1 et B_1. Un accroissement de la densité électronique sur le métal se traduit par une augmentation de la force de la liaison π en retour vers le ligand carbonylé. La liaison métal–carbone se trouve renforcée alors que la force de la liaison C≡O est diminuée. Ceci se traduit par une diminution des fréquences infrarouges ν_{CO} observées. Les valeurs des fréquences des ν_{CO} mesurées pour nos composés ainsi que celles décrites dans la littérature pour des composés voisins sont rapportées dans le tableau 2.

Nous observons tant pour les complexes du titane porteurs de deux cyclopentadiényles tétraméthylés que pour ceux du zirconium une diminution de la fréquence des ν_{CO} variant de 27 à 37 cm^{-1} par rapport aux complexes porteurs de cyclopentadiényles non substitués. Ces variations de fréquence sont très proches de celles observées lorsque les ligands cyclopentadiényle sont remplacés par des pentaméthylcyclopentadiényles (de 30 à 41 cm^{-1}) (13, 14). Le complexe $(C_5Me_4H)(C_5H_5)Ti(CO)_2$ porteur d'un seul groupement C_5Me_4H présente des abaissements de fréquence de 15 et 19 cm^{-1} voisins de ceux observés pour son homologue pentaméthylé (15).

Les ligands C_5Me_4H exerçent donc sur le centre métallique une influence électronique très voisine de celle engendrée par C_5Me_5.

Evaluation par RMN de la densité électronique du métal

L'évaluation de la densité électronique au niveau du métal peut également être établie sur les complexes porteurs d'un groupement méthyle directement lié à ce métal, par les fluctuations des valeurs des constantes de couplage $J_{^{13}C-H}$ de ce groupement méthyle. Cette constante de couplage sera d'autant plus grande que le caractère *s* de la liaison C—H sera important. Une faible densité électronique au niveau du métal augmente l'effet électroattracteur de ce dernier, elle va donc diminuer la nature *s* de la liaison métal–carbone et laisser plus de caractère *s* aux liaisons C—H, ce qui entraîne une forte constante de couplage. Une augmentation de la densité électronique sur le métal va, de ce fait, diminuer la constante de couplage mesurée sur le méthyle. L'évaluation de cette constante $J_{^{13}C-H}$ qui est une mesure relative de l'hybridation de la liaison M–CH_3 doit permettre de connaître la densité électronique du centre métallique.

Les valeurs que nous avons mesurées pour nos complexes ainsi que celles décrites dans la littérature pour des composés voisins, sont rapportées dans le tableau 3.

Les mesures que nous avons effectuées confirment les résultats obtenus par Grubbs et coll. (16); plus la densité électronique du métal est élevée, plus la constante de couplage $J_{^{13}C-H}$ est faible, Le remplacement de C_5H_5 par C_5Me_4H fait varier sa valeur de 1,4 Hz alors que cette variation est de 1,7 Hz pour C_5Me_5. La substitution du deuxième C_5H_5 entraîne une modification moins importante (0,7 Hz) du paramètre mesuré.

Il est vraisemblable que la faible valeur de cette seconde variation soit due à l'effet stérique occasionné par la présence des deux ligands cyclopentadiényle sur le métal. L'effet électroattracteur du chlore est montré par une forte diminution de $J_{^{13}C-H}$ (4,4 Hz) lors du remplacement de cet atome par un groupement méthyle.

Cette méthode d'évaluation de la densité électronique au niveau du centre métallique montre (comme la méthode infrarouge) que l'influence électronique du ligand C_5Me_4H est voisine de celle de C_5Me_5 et très différente de C_5H_5; cependant, l'effet stérique de ce ligand reste à estimer. Une étude en RMN dynamique des complexes aryles de type $(C_5Me_4H)_2M(aryle)X$ (M = Ti, Zr; aryle = C_6H_5, $p\text{-}C_6H_4CH_3$; X = aryle, Cl, Br) nous a permis de réaliser cette estimation.

Étude de l'influence stérique des ligands C_5Me_4H

Mise en évidence par RMN ^1H et ^{13}C d'une restriction à la rotation des ligands aryle

La figure 1 présente l'évolution en RMN ^1H (300.13 MHz) du spectre des protons aromatiques du complexe $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)_2$ en fonction de la température.

À 223 K ses protons aromatiques se présentent sous forme de deux systèmes AB différents dont les déplacements chimiques déterminés par découplage de spin sont respectivement situés à 6,49; 6,51; 6,76 et 6,78 pour le premier AB et 6,78; 6,81; 6,87 et 6,90 ppm pour le second lorsque les spectres sont réalisés dans $CDCl_3$. L'existence de ces deux systèmes AB montre clairement l'inéquivalence des protons 2 et 6 d'une part et 3 et 5 d'autre part. Les deux groupements tolyle sont identiques. Cette non équivalence des couples de protons est plus clairement mise en évidence chez les complexes monoarylés, par exemple $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)Cl$, qui présentent des spectres similaires dans la région des protons aromatiques. L'existence en

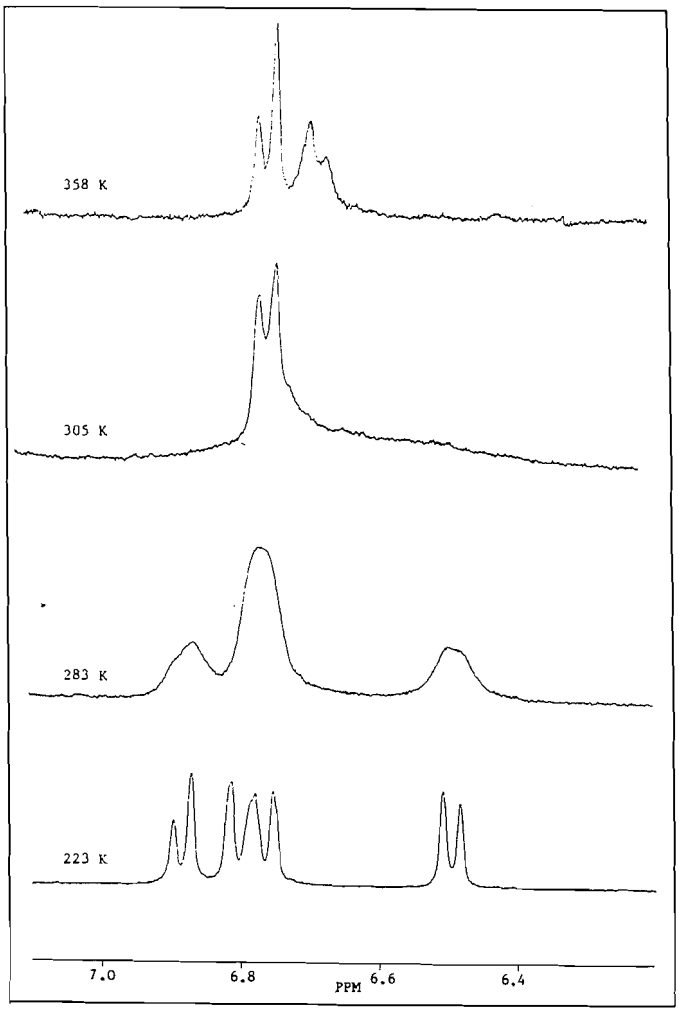

FIG. 1. Coalescence des signaux des protons aromatiques des groupements tolyle du complexe $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)_2$ en solution dans $CDCl_3$.

RMN ^1H de ces deux systèmes AB indique sans ambiguïté qu'à 223 K, la rotation des ligands tolyle autour de la liaison carbone–métal s'effectue lentement par rapport à la détection RMN. Lorsque les spectres sont réalisés à température plus élevée, nous observons à 283 K la coalescence des signaux préalablement situés à 6,76; 6,78; 6,78 et 6,81 ppm (protons 3 et 5), puis apparaît à plus haute température un doublet centré à 6,79 ppm qui sera la partie A d'un nouveau système AB.

De même à 305 K, la coalescence des signaux situés à 6,49; 6,51; 6,87 et 6,90 ppm, lorsque le spectre est réalisé à basse température, est effective. Elle conduit lorsque la température s'élève à un nouveau doublet centré à 6,71 ppm (partie B du nouveau système AB). Les signaux situés vers 6,79 ont été attribués aux protons 3 et 5 car ces deux protons sont vraisemblablement les moins perturbés par les ligands cyclopentadiényle quelle que soit la position adoptée par le ligand aryle. Les protons 2 et 6 plus proches du centre métallique se sont vus attribuer les signaux les plus éloignés en RMN à 6,50 et 6,88 ppm.

Aux températures supérieures à 305 K, il y a équivalence des protons 2 et 6 d'une part et 3 et 5 d'autre part, ce qui indique une rotation rapide des ligands tolyle autour de la liaison carbone–métal.

En RMN ^{13}C, nous observons un phénomène analogue : à 223 K, les quatre carbones (2, 6, 3 et 5) des groupements aryle sont distincts à 136,83; 134,68; 126,46 et 126,33 ppm. La coalescence des deux derniers signaux se réalise à 273 K et celle des deux premiers à 294 K.

TABLEAU 4. Paramètres d'activation du complexe $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)_2$

Mode de détermination RMN	$\Delta\nu$ (Hz)	T_c (K)	K_{T_c} (s^{-1})	$\Delta G^{0\neq}$ (kJ mol^{-1})
^1H	7,5	283	16,7	60,9 ± 4,0
^1H	111,55	305	256	60,7 ± 4,0
^{13}C	49,83	294	111	60,4 ± 4,0
^{13}C	3,05	273	6	62,2 ± 4,0

La température est sans effet sur les autres signaux ^1H ou ^{13}C du complexe.

La détermination des températures de coalescence a rendu possible l'évaluation des paramètres d'activation comme l'enthalpie libre d'activation $\Delta G^{0\neq}$ de la rotation des groupements tolyle autour de la liaison carbone–titane du complexe $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)_2$. Les valeurs de $\Delta G^{0\neq}$ sont calculées par les relations :

$$\Delta G^{0\neq}\ (\text{kJ mol}^{-1}) = 1{,}914 \times 10^{-2} T_c(9{,}972 + \log T_c/(\delta\nu^2 + 6J^2_{AB})^{1/2})$$

pour les spectres protons (coalescences de deux AB) et par

$$\Delta G^{0\neq}(\text{kJ mol}^{-1}) = 1{,}914 \times 10^{-2} T_c(9{,}972 + log\ T_c/\delta\nu)$$

pour les spectres ^{13}C (17, 18). T_c = température de coalescence et $\delta\nu$ = écart en Hz entre les signaux en échange lent.

Les valeurs calculées pour les paramètres d'activation sont indiquées dans le tableau 4. Une bonne corrélation est observée entre les quatre mesures réalisées.

Nous avons mis en évidence ce phénomène de coalescence pour tous nos complexes mono ou bis arylés du titane ou du zirconium possédant deux C_5Me_4H. Les valeurs des énergies d'activation calculées pour ces complexes sont les suivantes : $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)Cl$: 76,7 kJ mol^{-1}; $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)Br$: 76,8 kJ mol^{-1}; $(C_5Me_4H)_2Zr(C_6H_5)Cl$: 84,9 kJ mol^{-1}.

Les études concernant des restrictions à la rotation de groupements autour d'une liaison métal–carbone sont peu nombreuses dans la littérature (ref. 19 et références incluses). Lappert *et al.* ont mis en évidence une gêne stérique engendrée par un groupement volumineux : $CH(SiMe_3)_2$ dans la série des complexes $(C_5H_4R)_2Zr[CH(SiMe_3)_2]Cl$ (20). À notre connaissance, un seul travail concerne un groupement aromatique; il a été réalisé sur les complexes $(C_5Me_5)RhX(PMe_3)(C_6H_4R)$ (19). Ces deux exemples présentent des valeurs élevées de barrière à la rotation autour de la liaison métal–carbone : $\Delta G^{0\neq}$ varie entre 60 et 65 kJ mol^{-1} pour la série du zirconium (20) et de 50 à 60 kJ mol^{-1} pour les complexes du rhodium (19). Les valeurs encore plus élevées que nous mettons en évidence pour nos complexes sont sans aucun doute induites par la gêne stérique due à la présence des deux ligands (C_5Me_4H) sur le centre métallique.

Lorsqu'un des deux ligands C_5Me_4H est remplacé par un groupement moins encombrant, le cyclopentadiényle non substitué, les complexes ne présentent plus de coalescence. Le ligand aryle, même à très basse température, est animé d'une vitesse de rotation rapide au regard de la détection RMN. Par contre, en raison d'un effet stérique plus important des ligands

For personal use only.

C_5Me_5, le complexe $(C_5Me_5)_2Zr(C_6H_5)_2$ (11) ne présente pas de rotation des groupements phényle. (Ce complexe possède en effet en RMN ^{13}C quatre signaux différents pour les carbones 2, 3, 5 et 6 des ligands phényle.)

Cette étude en RMN dynamique nous a permis de confirmer que l'influence stérique engendrée par les ligands C_5Me_4H était intermédiaire entre les effets des ligands C_5H_5 et C_5Me_5. Une évaluation plus précise a pu être réalisée par une étude structurale radiocristallographique effectuée sur le complexe $(C_5Me_4H)_2Zr(C_6H_5)Cl$.

Étude radiocristallographique du complexe $(C_5Me_4H)_2Zr(C_6H_5)Cl$

Les cristaux ont été obtenus à −30°C dans l'hexane. Sur le tableau 5, nous avons indiqué les données cristallines ainsi que les paramètres d'acquisition de ces données. Les coordonnées des atomes (sauf hydrogènes) ainsi que les longueurs et les angles de liaison les plus représentatifs ont été rassemblés dans les tableaux 6, 7 et 8. Les figures 2 et 3 représentent les graphes ORTEP de la molécule. Les principales données structurales de composés voisins ont été reportées dans le tableau 9.[2]

L'atome de zirconium est au centre d'un tétraèdre déformé dont les angles sont de 99,0° (Cl—Zr—C19) et de 133,2° pour centroïde–Zr–centroïde. Afin de minimiser les interactions stériques, les deux ligands cyclopentadiényle sont décalés de 77° (figure 3) de façon analogue à la géométrie observée pour $Zr(C_4Me_4P)_2Cl_2$ (21). Les interactions stériques entre les deux ligands C_5Me_4H sont marquées par des distances Zr–centroïdes plus longues 2,240 et 2,347 Å et par un angle centroïde 1–Zr–centroïde 2 plus ouvert (133,2°) que dans les complexes porteurs de ligands cyclopentadiényle non substitués. Les distances moyennes entre l'atome de zirconium et les atomes de carbone des cyclopentadiényles (2,56 et 2,53 Å) sont supérieures à celles mesurées pour les complexes possédant des ligands C_5H_5 (2,52 Å) peu susceptibles de présenter de fortes interactions stériques. Il faut noter que les distances entre l'atome de zirconium et les carbones les moins encombrés des cyclopentadiényles sont les plus courtes (Zr—C_1 = 2,464 Å et Zr—C_{10} = 2,50 Å). De plus, les groupements méthyle des cyclopentadiényles sont, en regard du centre métallique, rejetés vers l'extérieur des plans des cyclopentadiényles. Les déviations par rapport à ces plans sont les suivantes : C_6 = 0,123 ; C_7 = 0,228 ; C_8 = 0,092 ; C_9 = 0,078 ; C_{15} = 0,187 ; C_{16} = 0,188; C_{17} = 0,061 ; C_{18} = 0,335. La longueur de la liaison Zr—Cl (2,443) est du même ordre de grandeur que celles mesurées dans d'autres complexes. Par contre, la valeur de l'angle Cl—Zr—C_{19} est anormalement élevée (99°) car généralement la présence de deux ligands cyclopentadiényle encombrés entraîne un resserrement de l'angle formé par le métal avec les deux autres substituants. Cette valeur est à rapprocher de celles observées pour les complexes $(C_5H_4CMe_3)_2ZrCl[CH(SiMe_3)_2]$ (26) et $(C_5H_5)_2Zr(C_6H_5)$-$[CH(SiMe_3)_2]$ (27) (98,2° et 100,4°). Elle résulte vraisemblablement de l'interaction stérique entre le phényle et le chlore. Cette interaction est également mise en évidence par l'angle de

Utilisation des propriétés particulières des complexes porteurs du ligand C_5Me_4H pour la réalisation de réactions catalytiques spécifiques : étude de l'isomérisation photoassistée d'oléfines

Nous avons tenté d'utiliser l'encombrement stérique mis en évidence dans nos complexes pour réaliser des réactions catalytiques stéréospécifiques. Nous nous sommes plus particulièrement intéressé aux isomérisations photoassistées et catalytiques thermiques d'oléfines initiées par les complexes du type $(C_5Me_4H)_2Ti(CH_3)_2$, $(C_5Me_4H)(C_5H_5)Ti(CH_3)_2$ et $(C_5H_5)_2Ti(p\text{-}C_6H_4CH_3)_2$. Une partie de cette étude concernant les résultats obtenus avec le complexe $(C_5Me_4H)_2Ti(CH_3)_2$ a fait l'objet d'une communication préliminaire (2).

La grande solubilité des complexes $(C_5Me_4H)_2Ti(CH_3)_2$ et $(C_5Me_4H)(C_5H_5)Ti(CH_3)_2$ dans les solvants hydrocarbonés, a permis d'effectuer les irradiations directement sur les solutions désoxygénées de ces complexes dans les oléfines (1 équivalent de complexe pour 400 équivalents d'oléfine) à l'aide d'un arc à vapeur de mercure Philips HPK 125 en filtrant les longueurs d'ondes inférieures à 310 nm.

Plusieurs types d'oléfines différant par la position de la double liaison, sa substitution et la position d'une ramification sur la chaîne hydrocarbonée ont été étudiés : pentène-1, hexène-1, octène-1, décène-1, pentènes-2 *E* et *Z*, hexènes-2 *E* et *Z*, hexènes-3 *E* et *Z*, octènes-2 *E* et *Z*, décènes-2 *E* et *Z*, décènes-5 *E* et *Z*, méthyl-2 pentène-1, méthyl-3 pentène-1 et méthyl-4 pentène-1.

Les irradiations des complexes $(C_5Me_4H)_2Ti(CH_3)_2$ et $(C_5Me_4H)(C_5H_5)Ti(CH_3)_2$ en présence d'oléfines à double liaison terminale et à chaîne aliphatique linéaire (pentène-1, hexène-1, octène-1, décène-1) conduisent à une réaction de migration sélective de la double liaison en position 2 sur la chaîne hydrocarbonée.

Ces isomérisations sont complètes après 3 h d'irradiation et dans tous les cas les mélanges obtenus contiennent 97% de l'isomère 2*E* (pentène-2*E*, hexène-2*E*, octène-2*E* ou décène-2*E*), 2% de l'isomère 2*Z* correspondant et 1% de l'oléfine

initiale. Aucun autre isomère possible tels que les hexènes-3 *E* ou *Z*, les octènes-3 ou -4, les décènes-3, -4, -5 n'est décelé en solution. Ces résultats mettent en évidence la grande stéréospécificité de la migration sigmatropique d'hydrogène induite chez les oléfines lors de l'irradiation de ces deux complexes.

Bien que nous n'ayons pas réussi à isoler les complexes responsables de ces réactions, l'étude des cinétiques de ces différentes isomérisations réalisées à l'aide du complexe $(C_5Me_4H)_2Ti(CH_3)_2$ apporte des éléments intéressants sur les processus mis en jeu au cours de ces irradiations.

Tout d'abord nous avons mis en évidence la présence d'une période d'induction au cours de laquelle les isomérisations des oléfines étudiées sont très faibles, 10–15% d'isomérisation en 1 h 40 min avec le complexe $(C_5Me_4H)_2Ti(CH_3)_2$, (cf. figure 4 : cinétique d'apparition des hexènes-2 lors de l'irradiation du complexe en présence d'hexène-1).

En suivant l'évolution des spectres de RPE des solutions irradiées, nous pouvons caractériser plusieurs espèces paramagnétiques de Ti(III) en solution. Dès le début des irradiations (30 s) on observe l'apparition d'un singulet large intense avec huit raies satellites (g = 1,979 et A(Ti) = 7,45 gauss). Le complexe de Ti(III) caractérisé par ce signal correspond très vraisemblablement à l'espèce $(C_5Me_4H)_2TiCH_3$ qui résulterait d'une coupure homolytique de la liaison Ti—CH_3. Ce type de réaction a été décrit dans la littérature pour d'autres complexes du titane, notamment par Samuel *et al.* (28) et constitue une réaction classique de la photochimie des complexes des métaux de transition (29–33).

En prolongeant les irradiations on voit ensuite apparaître progressivement deux autre signaux très larges (g = 1,992 et g = 1,973), le signal à champ faible devenant prépondérant. Il est intéressant de noter que la croissance de ce dernier signal correspond à l'accélération de la cinétique de l'isomérisation des oléfines.

Les caractéristiques RPE de ces complexes (g = 1,992 et ΔH = 6 gauss) étant très proches de celles des composés du type $(C_5H_5)_2Ti(\eta^3\text{-allyl})$ décrits dans la littérature (34–36), et bien que nous n'ayons pas réussi à le confirmer sans équivoque au cours des essais de synthèses que nous avons réalisé au laboratoire, nous pensons cependant que des complexes du type $(C_5Me_4H)_2Ti(\eta^3\text{-allyl})$ pourraient être impliqués dans une étape de ces réactions d'isomérisation d'oléfines.

L'étude des cinétiques permet également de montrer que ces réactions sont photoassistées et non photocatalytiques. L'excitation photochimique est nécessaire pour le déroulement de ces réactions à la température ordinaire, l'arrêt des irradiations

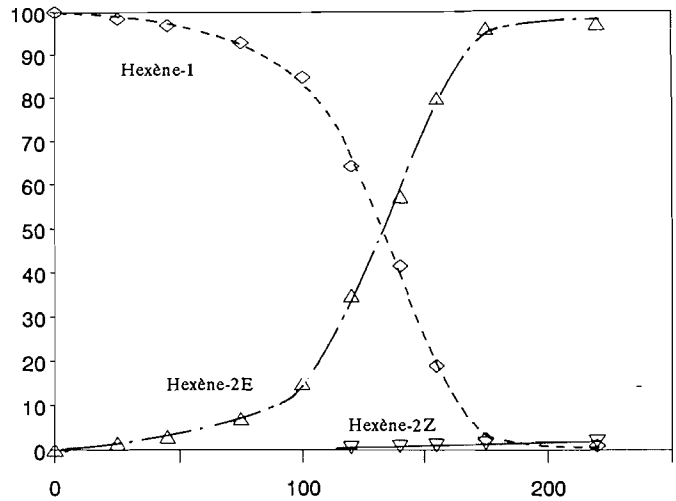

FIG. 4. Cinétique d'isomérisation photoassistée de l'hexène-1 initiée par le complexe $(C_5Me_4H)_2Ti(CH_3)_2$.

après 50% de transformation de l'oléfine initiale entraîne l'arrêt de l'isomérisation des oléfines. Les solutions peuvent être conservées une quinzaine d'heures à la température ordinaire, à l'abri de la lumière, sans évolution du mélange d'isomères. Par contre dès la reprise des irradiations l'isomérisation continue sans présenter de période d'induction.

Les irradiations des deux complexes $(C_5Me_4H)_2Ti(CH_3)_2$ et $(C_5Me_4H)(C_5H_5)Ti(CH_3)_2$ en présence d'oléfines α,β-disubstituées conduisent à une lente isomérisation *cis–trans* photoassistée de la double liaison carbone–carbone lorsque celle-ci se trouve en position 2 sur la chaîne hydrocarbonée, au delà de cette position nous n'observons pas de processus catalytique notable en solution. Ainsi quelle que soit la configuration de l'oléfine initiale (pentène-2, hexène-2 et décène-2 *E* ou *Z*) les irradiations aboutissent à des mélanges photostationnaires des deux isomères 2*E* et 2*Z* dans un rapport de concentration 80 : 20 en faveur de la configuration 2*E*, ceci après 35–40 h d'irradiation. Les essais réalisés en présence d'hexènes-3 ne donnent pas d'isomérisation notable même au cours d'irradiations prolongées (95% d'hexène-3*E* initial, 3% d'hexène-2*E*, 1% d'hexène-2*Z* et des traces d'hexène-3*Z* après 60 h).

À l'aide de ces résultats, en particulier la lenteur de l'isomérisation *cis–trans* de la double liaison en 2 sur la chaîne hydrocarbonée, nous mettons en évidence la stéréospécificité de la réaction de migration d'hydrogène. Elle conduit exclusivement au composé de configuration 2*E* à partir d'une oléfine à

double liaison terminale, les traces d'isomères de configuration 2*Z* présentes en solution à la disparition de l'oléfine initiale provenant d'une isomérisation *cis–trans* ultérieure de la double liaison carbone–carbone en 2.

Si le remplacement d'un ligand C_5Me_4H par un ligand C_5H_5 n'induit pas de perturbation appreciable de la réactivité du centre métallique vis-à-vis des oléfines précédentes, il n'en est pas de même lorsque les oléfines possèdent une chaîne ramifiée. En effet les méthyl-2 et méthyl-3 pentènes-1 qui ne sont pas isomérisés lors des irradiations en présence du complexe $(C_5Me_4H)_2Ti(CH_3)_2$ (moins de 5% après 30 h) s'isomérisent lentement en présence du complexe $(C_5Me_4H)(C_5H_5)Ti(CH_3)_2$ en méthyl-2 pentène-2 *E* et méthyl-3 pentène-2 *E* respectivement (environ 30 h d'irradiation). Par contre le méthyl-4 pentène-1 dont la ramification de la chaîne est plus éloignée de la double liaison terminale peut être isomérisé en méthyl-4 pentène-2 *E* par les deux complexes, (97% après 15 h d'irradiation avec $(C_5Me_4H)_2Ti(CH_3)_2$).

Ces résultats démontrent l'influence de la gêne stérique des ligands cyclopentadiényle au niveau du centre métallique et la sensibilité des réactions de migration d'hydrogène vis-à-vis de la position de la ramification sur la chaîne hydrocarbonée. Bien que les cinétiques soient nettement ralenties par les effets stériques des ligands d'une part, et de l'oléfine d'autre part, ces résultats confirment la sélectivité et la stéréospécificité de la réaction de migration d'hydrogène mises en évidence au cours des irradiations précédentes.

Le remplacement des deux ligands C_5Me_4H par des ligands C_5H_5 a été réalisé au cours de l'étude de la réactivité du complexe $(C_5H_5)_2Ti(p\text{-tolyl})_2$ en présence d'oléfines.

Bien que les conditions opératoires soient différentes compte tenu de la faible solubilité de ce complexe dans les oléfines, nous avons étudié les isomérisations sur des solutions d'un équivalent de complexe et de 40 équivalents d'oléfines dans le benzène ou le toluène.

Les irradiations en présence de pentène-1 ou d'hexène-1 conduisent à des mélanges photostationnaires de pentènes-2 *E* et *Z* ou d'hexènes-2 *E* et *Z* dans un rapport de concentration proche de 80 : 20 en faveur de la configuration *E*. Quel que soit l'avancement de la réaction, le rapport des concentrations des oléfines 2*E* sur les oléfines 2*Z* reste très proche de 80 : 20. Ces isomérisations bien qu'étant sélectives ne sont plus stéréospécifiques comme dans le cas des irradiations avec les deux complexes précédents. D'autre part ces réactions présentent également une période d'induction, mais elles sont ensuite extrêment rapides lorsque l'espèce active est générée.

Le remplacement des deux ligands C_5Me_4H par des ligands C_5H_5 modifie donc complètement la réactivité des complexes lors de leurs irradiations en présence d'oléfines. Ceci résulte très vraisemblablement de la modification de l'encombrement stérique de ces ligands mais également de la modification de la densité électronique un niveau du centre métallique.

Les isomérisations d'oléfines que nous venons de décrire peuvent être obtenues également par voie thermique à 130°C à l'aide de ces complexes (2).

Conclusion

L'étude des caractéristiques physiques des complexes du titane et du zirconium porteurs du ligand C_5Me_4H nous a permis d'évaluer l'influence électronique de ce ligand par rapport à celles de C_5H_5 et de C_5Me_5. Une étude radiocristallographique de $(C_5Me_4H)_2Zr(C_6H_5)Cl$ a mis en évidence les différentes contraintes stériques présentes dans cette molécule. Cet effet stérique du ligand C_5Me_4H, intermédiaire entre ceux présentés par C_5H_5 et C_5Me_5, a été évalué par une étude de RMN dynamique réalisée sur les complexes arylés. Ces composés, selon la température d'observation, présentent une restriction à la rotation du ligand aryle autour de la liaison métal – cycle aromatique. C'est la première fois, à notre connaissance, qu'une gêne stérique des ligands cyclopentadiényle a pu être ainsi démontrée et évaluée sur des complexes du titane et du zirconium. Enfin cet effet stérique a été utilisé pour réaliser à l'aide de certains de nos complexes des réactions spécifiques d'isomérisations photoassistées d'oléfines.

Partie expérimentale

La préparation des différents complexes a été réalisée sous argon en utilisant la technique des tubes de Schlenk. Les solvants sont séchés par distillation sous azote sur sodium–benzophénone (toluène, éther éthylique, THF), sur $LiAlH_4$ (hexane) ou sur hydrure de calcium (CH_2Cl_2); ils sont désoxygénés par cycles vide/argon avant utilisation.

Les spectres infrarouge ont été réalisés en solution dans l'hexane sur un spectrophotomètre Pye–Unicam SP2000. Les spectres de RMN ^1H et ^{13}C ont été effectués sur les spectromètres Jeol FX 100 ou Bruker A.C. 300 en solution dans $CDCl_3$ ou C_6D_6. Les spectres de masse ont été obtenus sur un appareil Hewlett–Packard 5995. Les spectres de RPE ont été tracés sur un appareil Jeol JES-FE2X. Les séparations en chromatographie en phase gazeuse ont été effectuées soit à l'aide d'un chromatographe Carlo–Erba 2300 muni d'une colonne remplie de 12 m de polypropylèneglycol à 30% sur Chromosorb P, soit sur un chromatographe Hewlett–Packard 5890 à colonne capillaire CPSIL greffée de 25 m. Les analyses chimiques ont été réalisées au centre de microanalyses du CNRS à Lyon.

Les données RMN indiquées au tableau 1 ne sont pas répétées en partie expérimentale.

Préparation du ligand $C_5(CH_3)_4H_2$

La tétraméthyl-2,3,4,5 cyclopentène-2 one obtenue par la méthode de Kohl et Jutzi (3) est réduite de façon classique par $LiAlH_4$ (37) et l'alcool ainsi obtenu est déshydraté à température ambiante par l'acide paratoluène sulfonique dans le benzène. Le rendement de la réaction est de 90% à partir de la cétone éthylénique. Le composé diénique est purifié par distillation ($Eb_{1\ Torr}$ = 24–26°C) (1 Torr = 133,3 Pa). RMN ^1H (δ ppm $CDCl_3$) : 1,78(s,6H); 1,90(s,6H); 2,72(m,2H).

Préparation de $C_5(CH_3)_4HLi$ ou C_5H_5Li

De façon classique, ces sels de lithium sont préparés par échanges avec le butyllithium. Les dienes sont dissous dans l'hexane à −10°C ; un équivalent de butyllithium est alors ajouté. Le milieu réactionnel est maintenu sous agitation pendant 18 h. Le précipité formé est filtré puis lavé deux fois à l'hexane (Rdt : 80%).

Préparation des complexes chlorés $(C_5Me_4H)_2MCl_2$: M = Ti,Zr et $(C_5Me_4H)TiCl_3$

$(C_5Me_4H)_2TiCl_2$ et $(C_5Me_4H)TiCl_3$

La préparation de ces composés est réalisée de façon analogue à celle décrite pour leurs homologues pentaméthylés (4, 5). À 28,16 g de C_5Me_4HLi (0,22 mol) en solution dans le THF on additionne soit 15,4 g (0,1 mol) soit 7,725 g (0,05 mol) de $TiCl_3$ solide. La solution devient rapidement noire; elle est portée 24 h à reflux du THF. Après refroidissement et évaporation du THF, le résidu est oxydé par une solution éther/hexane (50 : 50) saturée en HCl. Après évaporation du solvant, on obtient une poudre rouge composée des deux complexes dont les pourcentages varient selon la quantité de $TiCl_3$ ajoutée. Les deux composés sont séparés par extractions au soxhlet par de l'hexane saturé en HCl. Le composé le plus soluble $(C_5Me_4H)TiCl_3$ est obtenu après 5 h d'extraction, il contient 10% de $(C_5Me_4H)_2TiCl_2$. Il est purifié par recristallisation dans un mélange toluène/hexane pour donner de 4,1 à 13,7 g de $(C_5Me_4H)TiCl_3$ Rendements de 15 à 50%. SM, M^+ = 274. Anal. calc. : C 39.25; H 4,77; trouvé : C 39,10; H 4,75.

$(C_5Me_4H)_2TiCl_2$ est obtenu après une extraction ultérieure de 24 h et

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

recristallisé dans un mélange toluène/hexane. Rendements de 20 à 60% (7,2–21,6 g). SM, $M^+ = 360$. Anal. calc. : C 59,85; H 7,27; trouvé : C 59,75; H 7,21.

$(C_5Me_4H)_2ZrCl_2$

De façon analogue à l'obtention des complexes du titane ce composé est obtenu en faisant réagir 28,16 g de C_5Me_4HLi (0,22 mol) sur 23,3 g (0.1 mol) de $ZrCl_4$ dans le THF. La solution est maintenue 48 h à température ambiante puis le solvant est évaporé. Le résidu est extrait au toluène. Le résidu de cette extraction est lavé à l'hexane pour donner 60% (24,9 g) de complexe désiré (cristaux jaunes pâles). SM, $M^+ = 403$. Anal. calc. : C 53,44; H 6,49; trouvé : C 53,48; H 6,24.

Préparation spécifique de $(C_5Me_4H)TiCl_3$

Obtention de $C_5Me_4H\ SiMe_3$: À 16 g de tétraméthyl-1,2,3,4 cyclopentadiène-1,3 (0,13 mol) dissous dans 200 mL d'hexane, on ajoute, à 0°C, 0,13 mol de butyllithium puis 0,13 mol de tétraméthyl éthylène diamine (TMEDA). Le milieu réactionnel est maintenu sous agitation pendant 15 h à température ambiante puis le précipité jaune qui s'est formé est filtré et repris par 200 mL d'éther. On ajoute alors 0,13 mol de chlorotriméthyl silane avant de porter la réaction à reflux pendant 3 jours. Après refroidissement, le précipité de LiCl qui s'est formé est éliminé par filtration. La phase éthérée est lavée à l'eau, séchée sur sulfate de magnésium, puis le solvant est évaporé pour donner une huile jaune orangée qui sera utilisée sans purification ultérieure (19,5 g ; Rdt : 77%). RMN ^1H (δ ppm $CDCl_3$) : 2,86(s,1H); 1,97(s,6H); 1,86(s,6H); 0,01(s,9H). ^{13}C : 135,3; 133,08; 14,3; 11,23; 1,7.

Synthèse de $(C_5Me_4H)TiCl_3$: À 19,5 g de $TiCl_4$ ($1,03 \times 10^{-1}$ mol) en solution dans 150 mL d'hexane on additionne à 0°C 20 g ($1,03 \times 10^{-1}$ mol) de $C_5Me_4HSiMe_3$ L'agitation est maintenue 4.5 h à température ambiante. Le précipité brun qui s'est formé est filtré puis lavé à l'hexane. Il ne contient que le composé désiré (17 g ; Rdt : 60%).

$(C_5Me_4H)(C_5H_5)TiCl_2$

(a) $(C_5Me_4H)TiCl_3 + CpLi$: À 0,5 g de C_5H_5Li (8×10^{-3} mol) en solution à −20°C dans le THF on ajoute 2 g ($7,25 \times 10^{-3}$ mol) de $(C_5Me_4H)TiCl_3$ solide. La solution est ensuite maintenue pendant 30 min à la température ambiante. Après évaporation du solvant, le résidu rouge vif est lavé à l'hexane puis recristallisé dans un mélange toluène/hexane. On obtient 1,8 g de $(C_5Me_4H)(C_5H_5)TiCl_2$ (Rdt : 80%). SM, $M^+ = 304$. Anal. calc. : C 55,11; H 5,90; trouvé : C 55,05; H 6,00.

(b) $(C_5H_5)TiCl_3 + C_5Me_4HLi$: comme précédemment, 1 g (8×10^{-3} mol) de C_5Me_4HLi réagit sur 1,59 g ($7,25 \times 10^{-3}$ mol) de $(C_5H_5)TiCl_3$. Après lavage à l'hexane, on obtient 1,55 g (Rdt = 67%) de poudre cristalline composée à 70% du complexe désiré $(C_5Me_4H)(C_5H_5)TiCl_2$ et à 30% de $(C_5H_5)_2TiCl_2$. Nous ne sommes pas parvenus à séparer ces deux composés.

Préparation générale des complexes $(C_5Me_4H)_2MR_2$ et $(C_5Me_4H)(C_5H_5)TiR_2$: M = Ti, Zr; R = CH_3, C_6H_5, p-$C_6H_4CH_3$

À une suspension de $2,5 \times 10^{-3}$ mol de $(C_5Me_4H)_2MCl_2$ ou $(C_5Me_4H)(C_5H_5)TiCl_2$ dans 10 mL d'éther, on ajoute à −70°C 2,2 équivalents de R-Li en solution dans l'éther. On laisse le mélange réactionnel remonter à la température ambiante pendant 3 h lorsque M = Ti ou pendant 12 h lorsque M = Zr. La solution devient dans un premier temps limpide, puis lorsque M = Ti, elle prend une coloration jaune et on observe la formation d'un précipité de chlorure de lithium. L'excès d'alkyl ou d'aryllithium est neutralisé à −40°C par 30×10^{-3} mL de méthanol. L'éther est évaporé et le résidu est extrait par 3×10 mL d'hexane. Les complexes dialkylés ou diarylés sont recristallisés à − 70°C dans l'hexane.

$(C_5Me_4H)_2Ti(CH_3)_2$: Rendement : 80% cristaux jaunes d'or. SM, $M^+ = 320$. Anal. calc. : C 74,99; H 10,05; trouvé : C 74,80; H 9,95.

$(C_5Me_4H)_2Zr(CH_3)_2$: Rendement : 75% cristaux blancs. SM, $M^+ = 363$. Anal. calc. : C 66,06; H 8,86; trouvé : C 65,85; H 8,80.

$(C_5Me_4H)(C_5H_5)Ti(CH_3)_2$: Rendement : 60% cristaux jaunes d'or. SM, $M^+ = 264$. Anal. calc. : C 72,72; H 9,15; trouvé : C 72,87; H 9,22.

$(C_5Me_4H)_2Ti$(p-$C_6H_4CH_3)_2$: Rendement : 50% poudre orangée. SM : pas de pic correspondant au pic moléculaire du composé. Le premier pic détecté à 391 correspondant à $(C_5Me_4H)_2Ti(p$-$C_6H_4CH_3)^+$. Anal. calc. : C 81,35; H 8,52; trouvé : C 81,62; H 8,61.

$(C_5Me_4H)(C_5H_5)Ti$(p-$C_6H_4CH_3)_2$: Rendement : 50%. Poudre orangée. SM : pas de pic correspondant à la masse du composé. On observe $(C_5Me_4H)(C_5H_5)Ti(p$-$C_6H_4CH_3)^+$ à 325. Anal. calc. : C 80,76; H 7,74; trouvé : C 81,02; H 7,81.

$(C_5Me_4H)_2Ti(C_6H_5)_2$: Rendement 55%. Poudre orangée. SM : le premier pic observé correspond à $(C_5Me_4H)_2Ti(C_6H_5)^+$ à 367. Anal. calc. : C 81,07; H 8,16; trouvé : C 81,22; H 8,22.

$(C_5Me_4H)(C_5H_5)Ti(C_6H_5)_2$: Rendement 50%. Poudre orangée. SM : pic à 311 $(C_5Me_4H)(C_5H_5)Ti(C_6H_5)^+$. Anal. calc. : C 80,80; H 7,26; trouvé : C 80,50; H 7,27.

$(C_5Me_4H)_2Zr(C_6H_5)_2$: Rendement 50%. Cristaux blancs. Anal. calc. : C 73,87; H 7,43; trouvé : C 74,05; H 7,48.

Préparation des composés dicarbonylés

Méthode générale : $2,75 \times 10^{-3}$ mol de $(C_5Me_4H)_2M\ Cl_2$ (M = Ti, Zr) ou de $(C_5Me_4H)(C_5H_5)TiCl_2$ en solution dans 70 mL de THF sont traités par 334 mg ($1,375 \times 10^{-2}$ mol) de poudre de magnésium préalablement activée et par $2,75 \times 10^{-3}$ mol (750 mg) de $HgCl_2$. Le milieu réactionnel est maintenu sous forte agitation pendant 48 h sous une pression de 1,5 atm de CO. La solution sombre obtenue est filtrée (sur une petite colonne d'alumine neutre lorsque M = Ti) puis le solvant est évaporé. Le résidu est extrait trois fois par 20 mL d'hexane. Après filtration et concentration des filtrats, le composé désiré est obtenu par cristallisation à −50°C.

$(C_5Me_4H)_2Ti(CO)_2$: Rendement : 70%. Cristaux brun-rouge. Anal. calc. : C 69,36; H 7,56; trouvé : C 69,45; H 7,57.

$(C_5Me_4H)(C_5H_5)Ti(CO)_2$: Rendement 65%. Cristaux brun-rouge. Anal. calc. : C 66,22; H 6,25; trouvé : C 66,25; H 6,31.

$(C_5Me_4H)_2Zr(CO)_2$: Rendement 25%. Cristaux vert pâle. Anal. calc. : C 61,65; H 6,72; trouvé : C 61,78; H 6,75.

Préparation générale des complexes $(C_5Me_4H)_2MRCl$ ou $(C_5Me_4H)(C_5H_5)TiRCl$: M = Ti, Zr ; R = CH_3, p-$C_6H_4CH_3$, C_6H_5

À une solution de $3,75 \times 10^{-4}$ mol de $(C_5Me_4H)_2MR_2$ ou de $(C_5Me_4H)(C_5H_5)TiR_2$ dans 10 mL d'éther à −60°C, on ajoute 3.70×10^{-4} mol de HCl en solution éthérée préalablement dosée. On laisse revenir à température ambiante 30 min et l'éther est évaporé. Le résidu est repris à l'hexane, les différents extraits sont concentrés et le produit cristallise à −30°C dans ce solvant.

$(C_5Me_4H)_2Ti(CH_3)Cl$: Rendement quantitatif. Cristaux rouge-vif. SM : pic à 325 $(C_5Me_4H)_2TiCl^+$. Anal. calc. : C 66,96; H 8,56; trouvé : C 66,91; H 8,57.

$(C_5Me_4H)(C_5H_5)TiCH_3Cl$: Rendement quantitatif. Cristaux rouge vif. SM : pic à 269 $(C_5Me_4H)(C_5H_5)TiCl^+$. Anal. calc. : C 63,29; H 7,44; trouvé : C 63,32; H 7,44.

$(C_5Me_4H)_2ZrCH_3Cl$: Rendement quantitatif. Cristaux blancs. Anal. calc. : C 59,41; H 7,61; trouvé : C 59,28; H 7,55.

$(C_5Me_4H)_2Ti$(p-$C_6H_4CH_3)Cl$: Rendement 90%. Cristaux rouges. SM : pic à 325 $(C_5Me_4H)_2TiCl^+$. Anal. calc. : C 72,03; H 7,98; trouvé : 72,35; H 8,07.

$(C_5Me_4H)(C_5H_5)Ti$(p-$C_6H_4CH_3)Cl$: Rendement quantitatif. Cristaux rouges. Anal. calc. : C 69,91; H 6,98; trouvé : C 70,15; H 7,05.

$(C_5Me_4H)_2Zr(C_6H_5)Cl$: Rendement quantitatif. Cristaux blancs. Anal. calc. : C 64,61; H 7,00; trouvé : C 64,75; H 7,05.

Préparation de $(C_5Me_4H)_2Ti$(p-$C_6H_4CH_3)Br$: 100 mg de $(C_5Me_4H)_2TiCl_2$ ($2,77 \times 10^{-4}$ mol) sont dissous dans 10 mL d'éther. La solution est refroidie à −70°C et on ajoute 6×10^{-4} mol de p-$CH_3C_6H_4MgBr$ en solution dans l'éther. On laisse la température revenir à l'ambiante (2 h). L'excès de magnésien est neutralisé par addition de 30×10^{-3} mL de méthanol à −40°C. L'éther est évaporé et le résidu est extrait à l'hexane. Les extraits sont ensuite concentrés et le complexe est obtenu par cristallisation dans l'hexane à −40°C. Rendement 40%. Cristaux rouge-brun. SM : pic à 370 $(C_5Me_4H)_2TiBr^+$. Anal. calc. : C 65,09; H 7,21; trouvé : C 65,27; H 7,32.

Mise en évidence de la formation intermédiaire de $(C_5Me_4H)_2Ti(C_6H_4CH_3)Cl$: La réaction est réalisée comme la précédente. Lorsque la température atteint −20°C, l'excès de magnésien est neutralisé (−40°C). Le milieu réactionnel est ensuite traité comme précédem-

ment en prenant soin de ne pas dépasser −20°C. Le complexe $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)Cl$ formé est identifié par comparaison avec le spectre de RMN ^1H d'un échantillon de ce produit préparé selon la méthode générale. Le complexe $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)Cl$ représente 80% du mélange, $(C_5Me_4H)_2Ti(p\text{-}C_6H_4CH_3)Br$ 15% et $(C_5Me_4H)_2TiCl_2$ 5%.

Détermination de l'énergie libre d'activation

Les échantillons pour lesquels nous avons déterminé $\Delta G^{0\#}$ sont placés dans un tube de RMN en solution dans le toluène-d_8 ou dans $CDCl_3$. On fait varier la température jusqu'à ce que les spectres indiquent la coalescence des protons aromatiques *ortho* et *méta* (T_c) en ^1H ou, en ^{13}C, celle des carbones 2, 3, 5 et 6 des cycles aromatiques. La séparation entre les résonances des sites en échange est mesurée à la température la plus basse possible et est supposée être la même à la température de coalescence, $\delta\nu$ et T_c étant déterminés; $\Delta G^{0\#}$ est calculé comme indiqué en partie théorique.

Étude radiocristallographique de $(C_5Me_4H)_2Zr(C_6H_5)Cl$

Les cristaux nécessaires à une étude par diffraction de rayons X ont été obtenus à partir d'une solution diluée du complexe dans l'hexane à −30°C. Les mesures ont été effectuées sur un diffractomètre CAD-4 Enraf Nonius. Cristaux monocliniques, groupe spacial $P2_1/M$; a = 10,726 (4) Å; b = 14,724 (4) Å; c = 13,836 (6) Å, β = 96,07 (3)°; V = 2173,0 (6) Å^3, Z = 4; d(calc) = 1,62 g cm^3. La structure a été résolue par la méthode de Patterson et par différences de Fourier. Après affinage isotropique et anisotropique, les atomes d'hydrogène ont été localisés par différences de Fourier.

Irradiations des complexes en présence d'oléfines

Les irradiations des complexes $(C_5Me_4H)_2Ti(CH_3)_2$ et $(C_5Me_4H)(C_5H_5)Ti(CH_3)_2$ ont été réalisées d'une façon générale sur des solutions désoxygénées contenant un équivalent de complexe pour 400 équivalents d'oléfines placées dans des tubes de RMN scellés sous vide ou mises sous atmosphère d'argon. Ces solutions sont ensuite irradiées à l'aide d'un arc à vapeur de mercure de type Philips HPK 125 dont on filtre les longueurs d'ondes inférieures à 310 nm à l'aide d'une gaine en Pyrex. La température de la solution d'oléfine est maintenue à 18°C à l'aide d'une circulation d'eau. L'évolution du mélange réactionnel est suivi soit par RMN ^1H et ^{13}C soit par chromatographie en phase gazeuse.

Exemples de cinétiques d'irradiation des complexes $(C_5Me_4H)_2Ti(CH_3)_2$ et $(C_5Me_4H)(C_5H_5)Ti(CH_3)_2$ en présence d'oléfines

Isomérisations thermiques des oléfines catalysées par les complexes $(C_5Me_4H)_2Ti(CH_3)_2$ et $(C_5Me_4H)(C_5H_5)Ti(CH_3)_2$

Les isomérisations catalytiques thermiques initiées par les deux complexes sont réalisées sur des solutions identiques à celles utilisées pour les isomérisations photoassistées précédentes. Elles sont placées également dans des tubes RMN scellés sous vide et chauffées à 130°C. L'évolution du mélange réactionnel peut être suivi par RMN ^1H et ^{13}C. Le dosage final des différents constituants des mélanges est réalisé comme précédemment par chromatographie en phase gazeuse.

WOLFGANG KLIEGEL, MAHMOOD TAJERBASHI, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **69**, 673 (1991).

The reaction of 2,3-dihydro-3-hydroxy-2,2-tetramethylene-4*H*-benzoxazin-4-one, **2**, and diethyl ether–boron trifluoride yields the difluoroboron chelate 2,2-difluoro-4,4-tetramethylene-1,3,5-trioxa-3*a*-azonia-2-borata-2,3,4,5-tetrahydro-1*H*-cyclopenta[*a*]naphthalene, **6**, in high yield. There are two crystal forms of **2**: **2***a*, triclinic, $P\bar{1}$, $a = 8.551(1)$, $b = 9.331(3)$, $c = 7.236(1)$ Å, $\alpha = 103.38(2)$, $\beta = 104.68(1)$, $\gamma = 80.37(2)°$, $Z = 2$, $\rho_c = 1.35$ g cm^{-3}, and **2***b*, monoclinic, $C2/c$, $a = 17.41(2)$, $b = 10.665(6)$, $c = 12.427(8)$ Å, $\beta = 115.74(5)°$, $Z = 8$, $\rho_c = 1.40$ g cm^{-3}. Crystals of **6** are monoclinic, $P2_1/c$, $a = 5.354(1)$, $b = 17.654(2)$, $c = 12.844(1)$ Å, $\beta = 100.11(2)°$, $Z = 4$, $\rho_c = 1.48$ g cm^{-3}. The structures were solved by direct methods and were refined by full-matrix least-squares procedures to final *R* values of 0.046, 0.046, and 0.041 for 1712, 1505, and 1675 reflections with $I \geq 3\sigma(I)$, respectively. In both forms of **2**, the structures consist of centrosymmetric O—H···O hydrogen-bonded dimers (O···O = 2.633(2) Å for **2***a* and 2.682(3) Å for **2***b*). The difluoroboron chelate **6** features a five-membered chelate ring planar within 0.068(2) Å, and bond lengths O—B = 1.504(3) and 1.516(3), F—B = 1.358(3) and 1.359(3) Å indicate weak binding of the ligand to the F_2B moiety.

Key words: organoboron compound, crystal structure, boron compound

WOLFGANG KLIEGEL, MAHMOOD TAJERBASHI, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **69**, 673 (1991).

La réaction de la 2,3-dihydro-3-hydroxy-2,2-tétraméthylène-4*H*-benzoxazin-4-one, **2**, avec le complexe Et_2O/BF_3 fournit le chélate difluoroboré, 2,2-difluoro-4,4-tétraméthylène-1,3,5-trioxa-3*a*-azonia-2-borata-2,3,4,5-tétrahydro-1*H*-cyclopenta[*a*]-naphtalène, **6**, avec un excellent rendement. Il existe deux formes cristallines du produit **2**, soit **2***a*, triclinique, $P\bar{1}$, $a = 8{,}551(6)$, $b = 9{,}331(3)$ et $c = 7{,}236(1)$Å, $\alpha = 103{,}38(2)$, $\beta = 104{,}68(1)$ et $\lambda = 80{,}37(2)°$, $Z = 2$, $\rho_c = 1{,}35$ g cm^{-3} et **2***b*, monoclinique, $C2/c$, $a = 17{,}41(2)$, $b = 10{,}665(6)$ et $c = 12{,}427(8)$ Å, $\beta = 115{,}74(5)°$, $Z = 8$ et $\rho_c = 1{,}40$ g cm^{-3}. Les cristaux du produits **6** sont monocliniques, $P2_1/c$, $a = 5{,}354(1)$, $b = 17{,}654(2)$ et $c = 12{,}844(1)$ Å, $\beta = 100{,}11(2)°$, $Z = 4$ et $\rho_c = 1{,}48$ g cm^{-3}. On a déterminé les structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs finales de *R* de 0,046, 0,046 et 0,041 respectivement pour 1712, 1505 et 1675 réflexions avec $I \geq 3\sigma(I)$. Dans les deux formes du produit **2**, les structures se composent de dimères centrosymétriques réunis par des liaisons hydrogènes O—H···O (O···O = 2,633(2) Å pour **2***a* et 2,682(2) Å pour **2***b*). Le chélate difluoroboré **6** est caractérisé par un cycle à cinq chaînons, plan à 0,068(2) Å, dans lequel les longueurs des liaisons O—B = 1,504(3) et 1,516(3), F—B = 1,358(3) et 1,359(3) Å indiquent la présence d'une faible liaison entre le coordinat et la portion F_2B.

Mots clés : composé organoboré, structure cristalline, composé bore.

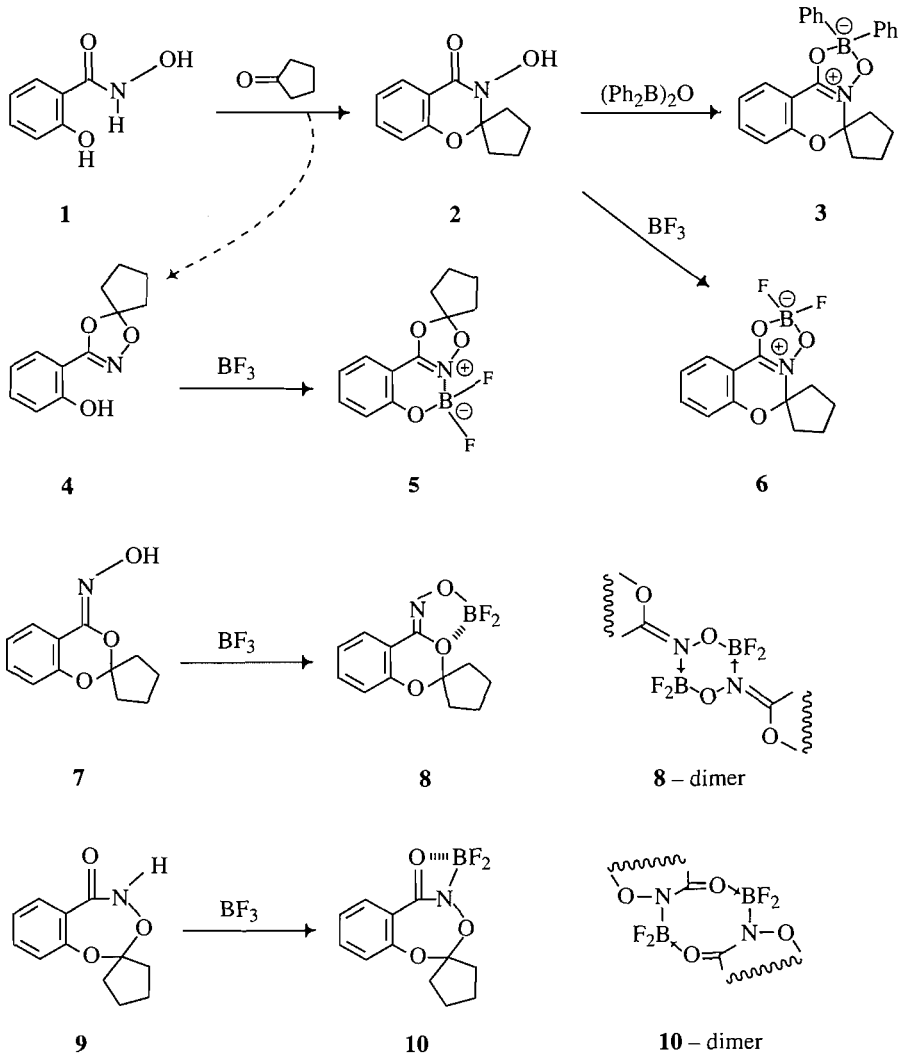
[Traduit par la rédaction]

Introduction

The synthesis of the diphenylboron chelate **3** via condensation of salicylohydroxamic acid, **1**, with cyclopentanone and subsequent reaction of the cyclocondensate **2** with oxybis-(diphenylborane) has been described in a previous report, along with the crystal and molecular structure of **3**(1).

In the course of this investigation we were interested in the reactivity of **2** towards the stronger Lewis acid BF_3 and also in the possible structural differences between the expected difluoroboron chelate **6** and the diphenylboron analog **3**. Thus we reacted **2** with boron trifluoride and obtained a crystalline product with the elemental analysis expected for the BF_2 chelate **6**. As for **3**, infrared and ^{1}H nmr data did not allow the exclusion of isomeric structures like **5**, **8**, **10**, or **12**, which, in part, have been discussed by analogy to the diphenylboron derivative **3**. An X-ray crystallographic analysis was undertaken in order to provide unambiguous proof of the structure **6**.

We also prepared single crystals of the hydroxamic acid with the assumed *O*,*N*-cycloacetal structure **2** in order to obtain data on the solid state structure of the free ligand. Formulae of the type **2** have generally been used for condensation products of salicylohydroxamic acid with aldehydes or ketones (2), but have never been proven. All subsequent reaction products, such as the chelates **3** and **6**, could also be the result of a rearrangement of possible educts like **4**, **7**, **9**, or **11** (which are isomers of **2**) during the reaction with the Lewis acid boron compound.



The five-membered cyclic *O*,*O*-acetal structure in **4** represents the well-known (3) 1,4,2-dioxazole ring system that can also be synthesized by condensation of hydroxamic acids with different carbonyl compounds (3*a*, 3*b*, 3*c*, 3*g*). The six- and seven-membered cyclic *O*,*O*-acetals, **7** and **9**, have not been reported in the literature, to the best of our knowledge. The 2*H*-1,3-oxazet *N*-oxide moiety of **11** (and of **12**) is an unknown type of heterocyclic *N*-oxide, and its formation seems unlikely under the applied reaction conditions. It is, however, reminiscent of the homologous dihydrooxazole *N*-oxide ring fragment

of **13**(4). For a definitive establishment of the hitherto postulated structure **2**, an X-ray analysis of this material has been performed.

A comparison of bond lengths in the free ligand **2** with those in the chelates **3** and **6** should give some indication of the influence of the different borenium ions, Ph_2B^+ and F_2B^+, on the bonding system of the hydroxamate and the *O*,*N*-acetal functions in these molecules.

Experimental

*2,3-Dihydro-3-hydroxy-2,2-tetramethylene-4*H*-benzoxazin-4-one, 2*

The compound was prepared according to our previous report (1). Crystals suitable for X-ray analysis were obtained by recrystallization from benzene/petroleum ether (**2***a*) or methanol (**2***b*).

*2,2-Difluoro-4,4-tetramethylene-1,3,5-trioxa-3*a*-azonia-2-borata-2,3,4,5-tetrahydro-1*H*-cyclopenta[a]naphthalene, 6*

2 (0.44 g, 2 mmol) was suspended in 30–50 mL diethylether. After addition of diethyl ether–boron trifluoride (0.57 g, 4 mmol) the suspension was refluxed for 30 min. The warm solution was filtered and the volume reduced by distillation of the solvent *in vacuo*, until only a few mL remained. Crystallization started during evaporation and was completed at room temperature. Yield: 0.49 g (91%), mp 125°C (from ether). *Anal.* calcd. for $C_{12}H_{12}BF_2NO_3$: C 53.97, H 4.53, N 5.24; found: C 54.03, H 4.60, N 5.22. Infrared (KBr): 1635 cm^{-1} (C=O/C=N). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.68–2.68 (m, —$(CH_2)_4$—), 6.94–7.78 (m, C_6H_4).

Crystals suitable for X-ray analysis were obtained by recrystallization from absolute diethylether.

X-ray crystallographic analyses of 2 and 6

Two crystalline modifications of the free ligand **2**, **2***a* and **2***b*, were analyzed. Crystallographic data for the three structures appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 35.9–40.2° for **2***a*, 16.2–19.2° for **2***b*, and 60.2–99.2° for **6**. The intensities of three standard reflections, measured every 150 reflections throughout the data collections, were essentially constant for all three compounds. The data were

[a]Temperature 294 K, Rigaku AFC6S diffractometer, Mo $K_{\bar{\alpha}}$ (λ = 0.71069 Å) or Cu $K_{\bar{\alpha}}$ (λ = 1.54178 Å) radiation, graphite monochromator, takeoff angle 6.0°, aperture 6.0 × 6.0 mm at a distance of 285 mm from the crystal, stationary background counts at each end of the scan (scan/background time ratio 2:1), up to eight rescans, $\sigma^2(F^2) = [S^2(C + 4B) + (pF^2)^2]/Lp^2$ (S = scan rate, C = scan count, B = normalized background count, p = 0.045 for **2***a*, 0.050 for **2***b*, and 0.040 for **6**), function minimized $\Sigma w(|F_o| - |F_c|)^2$ where $w = 4F_o^2/\sigma^2(F_o^2)$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|^2/\Sigma w|F_o|^2)^{1/2}$, and gof $= [\Sigma(|F_o| - |F_c|)^2/(m - n)]^{1/2}$. Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

processed[2] and corrected for Lorentz and polarization effects, and in the case of **6**, absorption (empirical, based on azimuthal scans for four reflections).

The structure analyses of both the triclinic and monoclinic forms of **2** were initiated in the centrosymmetric space groups $P\bar{1}$ and $C2/c$, respectively, on the basis of E-statistics, the choices being confirmed by subsequent calculations. The structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from E-maps and subsequent difference Fourier syntheses. The cyclopentane ring in compound **6** was found to be conformationally disordered. A twofold disordered model involving two ring carbon atoms was refined. Hydrogen atoms were refined with isotropic thermal parameters except for the disordered hydrogen atoms in **6** which were fixed in idealized positions (d_{C-H} = 0.98 Å, $B_H = 1.2B_{bonded\ atom}$). Neutral atom scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International tables for X-ray crystallography (5). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and intra-annular torsion angles appear in Tables 2–5, respectively. Hydrogen atom parameters, anisotropic thermal parameters, bond lengths and angles involving hydrogen, general torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor amplitudes for the three structures are included as supplementary material.[3]

Results and discussion

The condensation product of salicylohydroxamic acid with cyclopentanone has the cyclic O,N-acetal structure **2** (Fig. 1) and belongs to the class of intramolecular N-alkylated cyclic hydroxamic acids (6). There is little structural information on this type of ligand in the literature. Besides an ORTEP diagram of 5-methoxy-6-methyl-1-hydroxy-2(1*H*)-pyridinone without further structural data (7) and some calculated bond lengths for 1-hydroxy-2(1*H*)-pyridinone (8), the only complete crystallog-

raphic characterization of a 1-hydroxy-2-pyridinone derivative is that reported (9) for compound **14**.

Both crystal forms of the free hydroxamic acid **2** contain centrosymmetric O—H···O hydrogen-bonded dimers (**2*a***: O(2)—H(1)···O(3)($-x$, $1-y$, $1-z$), O···H = 1.72(2) Å, O···O = 2.633(2) Å, O—H···O = 168(2)°; **2*b***: O(2)—H(1)···O(3)($2-x$, $-y$, $-1-z$), O···H = 1.80(3) Å, O···O = 2.682(3) Å, O—H···O = 164(3)°). Similar hydrogen-bonded dimers are present in the solid-state structure of free salicylohydroxamic acid (10). This is in contrast to the intramolecular hydrogen bond in **14**, the "chelated proton" being located from a difference Fourier synthesis (9). Nevertheless, an intramolecular hydrogen bond can be expected for compound **2** in non-polar solvents or in the gas phase, and is indirectly demonstrated by the replacement of the chelated proton by the borenium ions Ph_2B^+ (in compound **3**) or F_2B^+ (in compound **6**). Apart from the above-mentioned hydrogen bonds, all other intermolecular distances in both **2*a*** and **2*b*** correspond to normal van der Waals interactions.

The average C(2)—O and C(2)—N distances in the cyclocondensate **2** (1.235 and 1.346 Å) are shorter and longer, respectively, than the corresponding values of 1.258 and 1.316 Å reported for salicylohydroxamic acid **1** (10). There is more

withdrawal of electron density from the carbonyl group of salicylohydroxamic acid **1**, which is involved in a bifurcated hydrogen bond with an *N*-hydroxy group and the free phenolic OH group of neighboring molecules (10). The phenol function of **2** is blocked by *O*,*N*-acetalization and has no proton available for participation in intermolecular hydrogen-bonding. Thus the carbonyl group of **2** takes part in only one hydrogen bond to the hydroxamic acid group of a neighboring molecule, and retains more of its double bond character. The partial loss of double bond character of the carbonyl group in **1**, caused by donating into the bifurcated intermolecular hydrogen-bonding system present in crystalline **1**, should be even more pronounced in the boron chelates **3** and **6** which employ the carbonyl group as ligand for the electron-deficient borenium ions. Indeed, the lengthened C=O bonds of **3** and **6**, and the correspondingly shortened (carbonyl)C—N distances, suggest an increased elec-

*Values for the two conformations of the disordered cyclopentane ring are given, those involving atoms C(10A) and C(11A) are on the right.

tron withdrawal out of the amide function accompanied by a more pronounced lone pair delocalization from the nitrogen atom towards the carbonyl group. The relatively small differences between the C=O and C—N bond distances in the boron chelates **3** and **6** reflect the higher Lewis acidity of the chelated borenium ion F_2B^+ in **6** relative to that of Ph_2B^+ in **3**. The C···O bond lengths increase from an average of 1.235 Å in **2**, 1.258 Å in **1** (10), 1.288 Å in **3** (1), to 1.295 Å in **6** while the amide C···N bond lengths decrease correspondingly: 1.346 (average), 1.316, 1.309, 1.294 Å. The π-bond orders of the C=O and C—N bonds have been estimated from plots of bond length vs. π-bond order (11): the C—O π-bond orders are 0.83, 0.70, 0.57, and 0.54 for **2**, **1**, **3**, and **6**, respectively, and the C—N π-bond orders are 0.53, 0.67, 0.72, and 0.79 for **2**, **1**, **3**, and **6**, respectively.

There is not much change in the bond lengths of the *O,N*-acetal grouping of the ligand **2** upon formation of the chelates **3** or **6**. The six-membered 1,3-oxazine heterocycle in the chelates **3** (1) and **6** have distorted "envelope" conformations. Compared to the less rigid tetrahydro-1,3-oxazin-4-one ring in compound **15** (12), the "semiplanar" skeleton of the dihydro-1,3-oxazin-4-one moiety in **2** shows slightly elongated bonds in the sterically less strained *O,N*-acetal fragment. The average C(1)—O and C(1)—N distances of 1.433 and 1.474 Å are slightly longer than the corresponding bond lengths of 1.417 and 1.469 Å in the saturated bicyclic system of **15** (12).

As discussed previously for the diphenylboron chelate **3** (1) an enhanced π-interaction between the hydroxamate system and the adjacent aryl group upon chelation can be observed by the shortening of the C(carbonyl)—C(aryl) bond of the ligand. The average C(2)—C(3) distance in **2** is 1.475 Å while the corresponding bond lengths in the diphenylboron chelate **3** and the difluoroboron chelate **6** are 1.438 and 1.436 Å, respectively. The B—O bonds of the difluoroborn chelate **6** (1.504 and 1.516 Å) are shorter by an average of 0.06 Å than those in the diphenylboron chelate **3** (1.558 and 1.578 Å) (1). This difference is similar to that observed for the difluoro- and diphenylboron chelates of *N*-methylacetohydroxamic acid (13, 14): about 0.05 Å. The mean F—B/mean O—B bond length ratio of 0.900 for **6** represents the weakest overall binding strength of the *O,O*-chelating ligand with respect to the "F_2B^+" moiety yet noted for a compound of this type having a five-membered chelate ring. These ratios range from 0.920 to 0.961 (mean 0.947) for other "F_2BO_2" compounds having five-membered chelate rings (13, 15, 16). The five-membered OBONC chelate ring in **6** has a flattened *B*-envelope conformation (Table 5) and is, in fact, planar to within 0.068(2) Å. The most significant intermolecular contact in the solid state structure of **6** corresponds to a weak C—H···O interaction: C(4)—H(1)···O(3)(1 − *x*,1 − *y*,1 − *z*), H···O = 2.45(3), C···O = 3.363(3) Å, and C—H···O = 151(2)°.

The free ligand, cyclic hydroxamic acid **2**, possesses a distinctly shorter C(2)—N amide bond (average 1.346 Å) than does the cyclic hydroxamic acid **14** (1.388 Å) which also has a six-membered ring skeleton (9). The difference between the C=O bonds in these two compounds is not very significant: average 1.235 Å in **2**, 1.241 Å in **14**. The N—O distance in **2** (average 1.398 Å) is longer by about 0.01 Å than that in **14** (1.387 Å) (9).

Received August 10, 1990

WOLFGANG KLIEGEL, UTE SCHUMACHER, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **69**, 681 (1991).

The reaction of *N*,2-dihydroxy-*N*-(1-hydroxycyclohexyl)methyl-2,2-diphenylacetamide with dimethyl ether-boron trifluoride gives 5,5-difluoro-2,2-pentamethylene-7,7-diphenyl-1,4,6-trioxa-3*a*-azonia-5-borata-2,3,4,5,6,7-hexahydroindene in nearly quantitative yield. Crystals of the product are triclinic, $a = 9.4555(5)$, $b = 9.9813(6)$, $c = 10.5139(9)$ Å, $\alpha = 72.654(7)$, $\beta = 77.140(5)$, $\gamma = 88.542(6)°$, $Z = 2$, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.044$ and $R_w = 0.060$ for 2971 reflections with $I \geq 3\sigma(I)$. The molecule has a six-membered difluoroboron chelate structure, confirming that the regioselective alkylation of *N*-substituted hydroxamic acids under non-basic conditions leads to imidate *N*-oxides in cases where intramolecular alkylation occurs. Bond lengths (corrected for libration): (N)O—B = 1.530(3), (C)O—B = 1.451(2), F—B = 1.389(3) and 1.379(3) Å indicate relatively strong binding of the BF_2^+ moiety by the *O*,*O*-chelating ligand.

Key words: organoboron compound, crystal structure, boron compound.

WOLFGANG KLIEGEL, UTE SCHUMACHER, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **69**, 681 (1991).

La réaction du *N*,2-dihydroxy-*N*-(1-hydroxycyclohexyl)méthyl-2,2-diphénylacétamide avec le complexe $(CH_3)_2O/BF_3$ fournit le 5,5-difluoro-2,2-pentaméthylène-7,7-diphényl-1,4,6-trioxa-3*a*-azonia-5-borata-2,3,4,5,6,7-hexahydroindène avec un rendement pratiquement quantitatif. Les cristaux de ce produit sont tricliniques, groupe d'espace $P\bar{1}$, avec $a = 9{,}4555(5)$, $b = 9{,}9813(6)$ et $c = 10{,}5139(9)$ Å, $\alpha = 72{,}654(7)$, $\beta = 77{,}140(5)$ et $\gamma = 88{,}542(5)°$ et $Z = 2$. On a résolu la structure par des méthodes directes et on l'affinée par la méthode des moindres carrés jusqu'à des valeurs respectives de $R = 0{,}044$ et $R_w = 0{,}060$ pour 2971 réflexions avec $I \geq 3\sigma(I)$. La molécule comporte une structure à six chaînons impliquant une coordination du difluorure de bore; ces données confirment que, dans les cas où une alkylation intramoléculaire se produit, l'alkylation régiosélective des acides hydroxamiques *N*-substitués, dans des conditions qui ne sont pas basiques, conduit à des *N*-oxydes d'imidate. Les longueurs des liaisons (corrigées pour la libration): (N)O—B = 1,530(3), (C)O—B = 1,451(2), F—B = 1,389(3) et 1,379(3) Å indiquent la présence d'une liaison relativement forte de la portion BF_2^+ avec le coordinat *O*,*O*-chélatant.

Mots clés : composés organoborés, structure cristalline, composé boré.

[Traduit par la rédaction]

Introduction

The reaction of the bis(hydroxyalkyl) substituted hydroxamic acid **1** with boron trifluoride did not lead to the difluoroboron chelate **2** having the "normal" BF_2 hydroxamate structure that usually results from reactions of *N*-alkylhydroxamic acids with boron trifluoride (1), and which has been established by an X-ray crystallographic study of the simple prototype **3** (2). The crystalline compound obtained from the reaction of **1** with $BF_3 \cdot OMe_2$ produced spectra and elemental analyses showing not only HF elimination but also loss of H_2O. Neither infrared bands for O—H stretching vibrations nor OH-proton signals in the ^1H nmr spectra, both of which would arise from the hydroxyl groups of **2**, were observed. These data suggest an intra- or intermolecular condensation of **1** and difluoroboron chelate formation leading to structures such as **4**–**7**.

A possible intermediate **2** could form the cyclic ether **4** by intramolecular condensation and still feature the five-membered BF_2 hydroxamate chelate, similar to the cyclic ether compound **8** with an identical difluoroboron chelate ring portion within the molecule (3). Another intramolecular condensation reaction of **1** in the presence of BF_3 could give rise to the difluoroboron chelate **5** with the newly formed 2-oxazoline *N*-oxide moiety as one of the chelating ligands. A similar intramolecular cyclization of an *N*-(2-hydroxyalkyl) hydroxamic acid in the presence of BF_3, including the formation of a BF_2 chelate, has already been documented by the synthesis and structure analysis of the salicylohydroxamic acid derivative **9** (4). Less likely under the applied conditions of BF_3 catalysis is an intramolecular alkylation of the *N*-hydroxy group of **1** by the *N*-(2-hydroxyalkyl) residue giving the four-membered oxazetidine ring with subsequent (or concerted) formation of a BF_2^+ chelate (compound **6**). Also unlikely is the intermolecular condensation product **7** containing eight-membered boron chelate rings, although eight-membered boron chelate rings are known and have been structurally characterized (5) and the 1,4,2,5-dioxadiazine ring system is thought to exist in certain dimers of nitrile oxides (6). However, an EI mass spectrum of the isolated crystals displays a molecular ion peak consistent only with a monomer like **4**, **5**, or **6**. The fragmentation pattern does not allow for a definite assignment of one of these isomeric structures, nor do the infrared and ^1H nmr spectral data. An X-ray crystallographic analysis has been carried out in order to provide an unambiguous decision between the possible isomeric structures **4**–**6**.

reacted with ethyl oxalyl chloride (30 mmol) and phenylmagnesium bromide (225 mmol) according to literature methods (8). The product crystallizes from ether/petroleum ether. Yield: 4.47 g (42%). Colorless crystals. Melting point 124–126°C (from ether/petroleum ether). *Anal.* calcd. for $C_{21}H_{25}NO_4$: C 70.96, H 7.09, N 3.94; found: C 70.89, H 7.07, N 3.91. Infrared (KBr): 3400–3360, 3140 (O—H), 1615 cm^{-1} (C=O). ^1H nmr (90 MHz, $CDCl_3$/TMS): δ (ppm) = 1.47 (s, $(CH_2)_5$), 2.40 (s, broad, exchangeable, 2OH), 3.75 (s, N—CH_2), 5.40 (s, broad, exchangeable, OH), 7.13–7.60 (m, $2C_6H_5$).

5,5-Difluoro-2,2-pentamethylene-7,7-diphenyl-1,4,6-trioxa-3a-azonia-5-borata-2,3,4,5,6,7-hexahydroindene, 5

1 (1.07 g, 3 mmol) is dissolved in 30–40 mL toluene and, after addition of dimethyl ether–boron trifluoride (0.34 g, 3 mmol), refluxed for 30 min. The solvent is removed *in vacuo*, until the volume of the reaction mixture is reduced to 3–5 mL. Crystallization starts during cooling. Yield: 0.89 g (77%). Colorless crystals. Melting point 192–193°C (from toluene). *Anal.* calcd. for $C_{21}H_{22}BF_2NO_3$: C 65.48, H 5.76, N 3.64; found: C 65.57, H 5.74, N 3.60. Infrared (KBr): 1670 cm^{-1} (C=O/C=N). ^1H nmr (90 MHz, d_6-DMSO/TMS): δ (ppm) = 1.22–1.63, 1.67–2.00 (2 m, 3:2 $(CH_2)_5$), 4.33 (s, N—CH_2), 7.34 (s, 2 C_6H_5). Crystals suitable for X-ray analysis are obtained by recrystallization from toluene.

X-ray crystallographic analysis of 5

A crystal ca. 0.28 × 0.32 × 0.53 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on 2 sin θ/λ values for 25 reflections (2θ = 38.6–41.4°) measured on a diffractometer with Mo-K_α radiation ($\lambda_{K\alpha1}$ = 0.70930, $\lambda_{K\alpha2}$ = 0.71359 Å). Crystal data at 21°C are as follows

$C_{21}H_{22}BF_2NO_3$ fw = 385.22

Triclinic, a = 9.4555(5), b = 9.9813(6), c = 10.5139(9) Å, α = 72.654(7), β = 77.140(5), γ = 88.542(5)°, Z = 2, ρ_c = 1.387 Mg m^{-3}, $F(000)$ = 404, μ(Mo-K$_\alpha$) = 0.98 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (No. 2, reduced cell) from structure analysis.

Intensities were measured with graphite-monochromated Mo-K$_\alpha$ radiation on an Enraf-Nonius CAD4-F diffractometer. An ω–2θ scan at 1.2–10.0° min^{-1} over a range of (0.80 + 0.35 tan θ)° in ω (scan extended by 25% on each side for background measurement) was employed. Data were measured to 2θ = 55°. The intensities of three check reflections, measured every hour of X-ray exposure time throughout the data collection, showed only small random variations. The data were processed[2] and corrected for Lorentz and polarization effects. Of the 4232 independent reflections measured, 2971 (70.2%) had intensities greater than or equal to $3\sigma(I)$ above background where $\sigma^2(I) = [C + 2B + (0.040(C - B))^2]$ with C = scan count, B = normalized total background count.

The analysis was initiated in the centrosymmetric space group $P\bar{1}$ on the basis of the E-statistics, this choice being confirmed by the subsequent successful solution and refinement of the structure. The structure was solved by direct methods, the coordinates of all non-hydrogen atoms being determined from an E-map. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were refined with isotropic thermal parameters. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 9. The weighting scheme $w = 1/\sigma^2(F)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 341 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.044 and R_w = 0.060 for 2971 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$. On the final cycle of refinement the maximum parameter shift corresponded to 0.07σ. The mean error in an observation of unit weight was 2.13. The final difference map showed maximum fluctuations of −0.31 to +0.24 e Å^{-3}.

The thermal motion has been analyzed in terms of the TLS model (10). The rms error in the temperature factors U_{ij} (derived from the least-squares analysis) is 0.0009 Å^2. Five structural subunits were separately analyzed (rms ΔU_{ij} = 0.0013–0.0023 Å^2). The bond lengths have been corrected for liberation (10, 11) using shape parameters q^2 of 0.08 for all atoms. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths (corrected and uncorrected) and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, bond lengths and angles involving hydrogen, torsion angles, and structure factors have been deposited.[3]

Results and discussion

As the structure analysis reveals, the intramolecular alkylation of **1** in the presence of BF_3 does not lead to the cyclic ether compound **4** having a BF_2 hydroxamate partial structure, but rather gives the 2-oxazoline *N*-oxide derivative **5** with a six-membered difluoroborn chelate ring (Fig. 1). This confirms the results of regioselective alkylation of *N*-substituted hydroxamic acids under non-basic conditions, leading to cyclic imidate *N*-oxides (4, 12) in the case of intramolecular alkylation or to acyclic imidate *N*-oxides (13) or thioimidate *N*-oxides (14) in the case of intermolecular alkylation.

The structure **5** contains a six-membered boron chelate ring analogous to the seven-membered chelate ring in compound **9**, which also has a cyclic imidate *N*-oxide oxygen atom serving as one of the donors of the bidentate ligand. The difference between these two compounds is found in the functionality of the second donor which is an alcoholate oxygen atom in **5** and a phenolate oxygen atom in **9**. To the best of our knowledge this is the first example of a six-membered boron chelate with this particular heterocyclic *B*,*N*-betaine structure. The formulation of **5** as an intramolecular iminium salt is justified by the extremely short C(2)—N bond[4] of the imidate *N*-oxide function: 1.281 Å, which is even shorter than the comparable C=N$^+$ bond in **9** (1.294 Å) (4), and also shorter than the C=N$^+$ bonds in the BF_2 hydroxamates **3** (1.289 Å) (2) and **8** (1.294 Å) (3). The π-bond order of the C(2)—N bond, estimated from bond length vs. π-bond order plots (15, 16), lies between 0.8 and 1.0 and is similar to that of C=N$^+$ bonds in boron complexes of oximes with bond lengths of 1.283 Å (17) and 1.287 Å (18).

In spite of the *O*-alkylation of the carbonyl oxygen atom O(3), the C(2)—O(3) bond shows some double bond character with a bond length of 1.310 Å. The estimated (16) π-bond order

between 0.4 and 0.5 indicates the participation of the C(2)—O(3) bond in the imidate π-bond system incorporating the adjacent C=N$^+$ bond. A similar situation has been noted for compounds of the type **9** (4). The C(3)—O(3) bond is very long (1.536 Å) compared to any other (sp^3)C—O bond lengths reported (19), and is also longer than the identical bond in compound **9** (1.512 Å) (4).

The boron atom has a slightly distorted tetrahedral geometry (see Table 3). The O—B bonds of **5** have the same average length of 1.491 Å as those in the seven-membered chelate **9** (4), but — as in **9** — they are markedly different from one another (by ~0.08 Å), B—ON = 1.530, B—OC = 1.451 Å. The distance between the *N*-oxide oxygen atom and the boron atom is longer than the distance between an alcoholate (or phenolate) oxygen atom and boron. This has also been noted for five- to seven-membered diphenylboron chelates of various *N*-oxides (4, 20–23). The B—F bond lengths in **5** (average 1.384 Å) are similar to those in **9** (average 1.387 Å), but distinctly longer than

C(2)—N—C(4)—C(3)	−4.8(2)
O(3)—C(3)—C(4)—N	6.5(2)
C(2)—O(3)—C(3)—C(4)	−6.8(2)

those in the five-membered hydroxamate **8** (1.358 Å) and slightly longer than those in **3** (average 1.377 Å). The mean F—B/mean O—B bond length ratio of 0.929 for **5** is at the high end of the range 0.884–0.949 (average 0.915) observed for other "F_2BO_2" compounds having six-membered chelate rings (ref. 4 and references therein), indicating relatively strong binding of the difluoroborenium ion (F_2B^+) by the chelating ligand.

The six-membered BONCCO chelate ring has an O(1),C(1)-twist-boat conformation, flattened somewhat at the C(1) end. The five-membered oxazoline ring, fused to the N,C(2) side of the above-mentioned six-membered ring, has a flattened C(3)-envelope conformation. O(3) and C(4) of the oxazoline ring are in axial and equatorial positions with respect to the cyclohexane ring, which has a relatively undistorted chair conformation (see Table 4 for torsion angles). The phenyl substituents at C(1) are oriented nearly perpendicular to one another (dihedral angles between normals to the mean planes is 81.3°), the bond to the pseudo-axial substituent being slightly longer than the other (1.541(2) vs. 1.534(2) Å). The O(3)—C(2)—N—C(4) and C(1)—C(2)—N—O(1) groups are both approximately planar (all six of these atoms are coplanar to within 0.015(2) Å), the former being planar within experimental error as a result of the more extended π-system of the imidate function. The most significant intermolecular contact in the solid state of **5** corresponds to a weak C—H···F interaction: C(20)—H(20)···F(2)($2 - x, - y, - z$), H···F = 2.51(2) Å, C···F = 3.240(2) Å, C—H···F = 131(2)°.

KIMBERLY A. WATSON, SUZANNE FORTIER, MICHAEL P. MURCHIE, and JOHN W. BOVENKAMP. Can. J. Chem. **69**, 687 (1991).

The crystal structures of three crown ether complexes (cyclohexano-15-crown-5·2LiOPh (**1**): $Li_2O_7C_{26}H_{36}$, M_r = 474.45, λ(CuKα)filt. = 1.5418 Å; cyclohexano-15-crown-5·2NaOPh (**2**): $Na_2O_7C_{26}H_{36}$, M_r = 504.54, λ(CuKα)filt. = 1.5418 Å; and 15-crown-5·2NaOPh (**3**): $Na_2O_7C_{22}H_{30}$, M_r = 452.46, λ(CuKα)mono. = 1.5418 Å) have been determined by X-ray diffraction at room temperature (T = 298 K). Complex **1** crystallizes in space group $P2_1/n$ with a = 15.032(5), b = 13.332(2), c = 13.533(3) Å, β = 106.28(2)°, V = 2603.2 Å^3, and Z = 4. Complex **2** crystallizes in space group $P2_1/n$ with a = 15.94(1), b = 12.194(7), c = 14.068(7) Å, β = 102.84(5)°, V = 2666.3 Å^3, and Z = 4. Complex **3** crystallizes in space group $P2_1/c$ with a = 12.451(3), b = 17.263(3), c = 12.659(6) Å, β = 115.74(3)°, V = 2450.8 Å^3, and Z = 4. The three structures were solved by direct methods and refined by full-matrix least-squares calculations to residuals, R, of 0.080, 0.069, and 0.081 for complexes **1**, **2**, and **3**, respectively. In each structure the macrocycle forms a 1:2 host–guest complex with the alkali metal. Each structure exhibits a dimer of the general form $(MAC{\cdot}2MOPh)_2$ where M = Li^+ and Na^+ for structures **1** and **2**, respectively, and MAC = cyclohexano-15-crown-5, while M = Na^+ and MAC = 15-crown-5 for structure **3**. In each case the two metals of the monomeric unit have different crystallographic and chemical environments. In structures **1** and **3** one alkali metal is coordinated to all five oxygens of the macrocycle and to one of the phenoxide oxygens, while the other alkali metal is coordinated to only one oxygen of the macrocycle and to three phenoxide oxygens. In structure **2**, one alkali metal is coordinated to only four of the five oxygens of the macrocycle and to two of the phenoxide oxygens, while the other alkali metal is coordinated to only one oxygen of the macrocycle and to three phenoxide oxygens (as in **1** and **3**).

Key words: crown ether, host–guest complexes, X-ray crystallography.

KIMBERLY A. WATSON, SUZANNE FORTIER, MICHAEL P. MURCHIE et JOHN W. BOVENKAMP. Can. J. Chem. **69**, 687 (1991).

Faisant appel à la diffraction des rayons-X à la température ambiante (T = 298 K), on a déterminé les structures cristallines de trois complexes d'éther-couronnes (cyclohexano-15-couronne-5·2LiOPh (**1**) : $Li_2O_7C_{26}H_{36}$, M_r = 474,45, λ(CuKα)filt. = 1,5418 Å; cyclohexano-15-couronne-5·2NaOPh (**2**) : $Na_2O_7C_{26}H_{36}$, M_r = 504,54, λ(CuKα)filt. = 1.5418 Å: 15-couronne-5·2NaOPh (**3**) : $Na_2O_7C_{22}H_{30}$, M_r = 452,46, λ(CuKα)mono. = 1,5418 Å). Le complexe **1** cristallise dans le groupe d'espace $P2_1/n$ avec a = 15,032(5), b = 13,332(2) et c = 13,533(3) Å, β = 106,28(2)°, V = 2603,2 Å^3 et Z = 4. Le complexe **2** cristallise dans le groupe d'espace $P2_1/n$ avec a = 15,94(1), b = 12,194(7) et c = 14,068(7) Å, β = 102,84(5)°, V = 2666,3 Å^3 et Z = 4. Le complexe **3** cristallise dans le groupe d'espace $P2_1/c$ avec a = 12,451(3), b = 17,263(3) et c = 12,659(6) Å, β = 115,74(3)°, V = 2450,8 Å^3 et Z = 4. On a résolu les trois structures par des méthodes directes et on les a affinées par la méthode des moindres carrés (matrice entière) jusqu'à des valeurs résiduelles de R de 0,080, 0,069 et 0,081 respectivement pour les complexes **1**, **2** et **3**. Dans chacune des structures, le macrocycle forme un complexe 1 : 2 hôte–invité avec le métal alcalin. Chaque structure comporte un dimère de la forme générale $(MAC{\cdot}2MOPh)_2$; pour les structures **1** et **2**, MAC = cyclohexano-15-couronne-5 et M = Li^+ et Na^+ respectivement alors que M = Na^+ et MAC = 15-couronne-5 pour la structure **3**. Dans chaque cas, les deux métaux de l'unité monomère sont dans des environnements cristallographiques et chimiques différents. Dans les structures **1** et **3**, un métal alcalin est coordiné aux cinq oxygènes du macrocycle et à un oxygène phénolique alors que l'autre métal alcalin est coordiné à un seul oxygène macrocyclique et à trois oxygènes phénoliques. Dans la structure **2**, un métal alcalin est coordiné à seulement quatre des cinq oxygènes du macrocycle et à deux oxygènes phénoliques alors que l'autre métal alcalin est coordiné à seulement un oxygène du macrocycle et à trois oxygènes phénoliques.

Mots clés : éther-couronne, complexes hôte–invité, diffraction des rayons-X.

[Traduit par la rédaction]

Introduction

The present paper reports the X-ray crystal structures of 1:2 host–guest complexes of cyclohexano-15-crown-5 with lithium and sodium phenoxides and of 15-crown-5 with sodium phenoxide. Over the last few years, we have studied several crown ether complexes that exhibit unusual host–guest ratios (1–3) and have shown that the resulting structural characteristics and stoichiometry were a result of concerted host, guest, anion, and solvent effects. The X-ray crystal structure analyses of many of these complexes have been reported (4–6). This paper is part of an investigation of the structural characteristics of these complexes.

There have been many alkali metal salt complexes of 15-crown-5 (7–10), cyclohexano-15-crown-5 (11), and benzo-15-crown-5 (12–14) synthesized and isolated. The X-ray crystal structures of several complexes of 15-crown-5 and of benzo-15-crown-5 have been determined; for example, 15-crown-5·X, where X = $NaSCN{\cdot}(1/2)H_2O$ (7), Na(ethyl acetoacetate) (8), and 2LiOPh (two polymorphs) (3), and benzo-15-crown-5·Y, where Y = $Li(pic){\cdot}2H_2O$ (15), Na(pic) (16), (1/2) (K(pic))

TABLE 1. Crystal data for complexes **1**, **2**, and **3**

Parameter	Complex 1	Complex 2	Complex 3

(17), and Cs(pic) (18) (where pic = 2,4,6,-trinitrophenolate). The stoichiometries of these systems have also been extensively discussed (19).

A search of the Cambridge Structural Database (20) for crystal structure analyses of 15-crown-5 with one cyclohexano substituent containing alkali metal salts revealed no such structures. Thus, this paper reports two of the first X-ray crystal structures of 1:2 host–guest complexes of cyclohexano-15-crown-5 with lithium and sodium phenoxides, complexes **1** and **2**, respectively. Also, the X-ray crystal structure results of a 1:2 complex of 15-crown-5 with sodium phenoxide, complex **3**, are reported and discussed.

Experimental

A standard method was used for the preparation of the three complexes in ethereal solvents. Using this method, 1 equivalent of the macrocycle was added to a solution containing 2 equivalents of the salt. Details of the syntheses of complexes **1**, **2**, and **3** have been reported in a previous publication (3).

The crystals used for the X-ray structure determinations were obtained from the following solutions: complex **1**, 0.084 g in 1,2-dimethoxyethane (5 mL); complex **2**, 0.098 g in tetrahydrofuran and hexane (11 mL/11 mL); and complex **3**, 0.085 g in tetrahydrofuran (5 mL). In all cases, the solutions were slowly (1–7 days) evaporated to dryness at room temperature in an argon atmosphere.

Data collection

Pertinent data about the crystals used and the measurement of diffraction intensities are summarized in Table 1. The crystals used in the diffraction experiments were mounted inside glass capillaries in a moisture-free environment. The intensity data were collected on an Enraf–Nonius CAD-4 diffractometer. In each case, intensities were collected by the $\omega/2\theta$ scanning procedure and three reflections were measured after every 7200 s of exposure time to check on the stability of the crystal. Evidence of crystal decay was detected only for complex **3**, with a total loss in intensity of 20.9%. A linear decay correction was applied to the data of complex **3** using the Enraf–Nonius SDP program DECAY (21); the maximum, minimum, and average corrections were 1.12414, 1.00009, and 1.06049, respectively. Data for all three complexes were corrected for Lorentz and polarization effects.

Structure and determination and refinement

All three structures were solved routinely by direct methods using

*Atoms were refined isotropically.
[a]$B_{eq} = (4/3)\Sigma_i\Sigma_j\beta_{ij}(a_i \cdot a_j)$.

the program MULTAN80 (22). Difference Fourier syntheses were used to locate the positions of the hydrogen atoms.

Complex **1**: The positions of 30 hydrogen atoms were located in the difference Fourier map and the remaining 6 were calculated. The structure was refined by full-matrix least squares using all reflections with $I \geq 3\sigma(I)$. Anisotropic temperature factors were used for the non-hydrogen atoms. The hydrogen atoms were assigned isotropic temperature factors equal in magnitude to the equivalent isotropic temperature factors of their parent atoms. They were included in the calculations but they were not refined. The function minimized was $\Sigma w||F_o| - |F_c||^2$, where $w = 1/\sigma^2(|F_o|)$. A correction for isotropic secondary extinction effect was included in the refinement. The scattering factors were taken from Cromer and Waber (23). The fractional coordinates and equivalent isotropic temperature factors of the non-hydrogen atoms are presented in Table 2.

Complex **2**: The positions of 25 hydrogen atoms were located in the difference Fourier map and the remaining 11 were calculated. The refinement procedure was the same as that given previously for complex **1** with the following exception: the isotropic secondary extinction coefficient was not included in the calculations. The fractional coordinates and equivalent isotropic temperature factors of the non-hydrogen atoms are presented in Table 3.

Complex **3**: The positions of 25 hydrogen atoms were located in the difference Fourier map and the remaining 5 were calculated. The refinement procedure was the same as that given previously for complexes **1** and **2** with the following exception: anisotropic temperature factors were used for the non-hydrogen atoms except for the carbon atoms of the phenoxide moieties. The 12 carbon atoms of the phenoxide moieties were refined isotropically. The fractional coordinates and equivalent isotropic temperature factors of the non-hydrogen atoms are presented in Table 4.

All calculations were done on a PDP11/23 computer using the Enraf–Nonius SDP program package (21).[1]

Results

ORTEP (24) drawings of complex **1**, **2**, and **3**, showing the atom numbering scheme, are given in Figs. 1, 2, and 3, respectively. Alkali metal–oxygen bond distances and angles, for all three complexes, appear in Table 5; average and range of bond distances and angles of the macrocyclic rings, cyclohexano rings, and phenoxide rings, for all three complexes, are given in

[1]A complete set of tables of positional parameters, temperature factors, and observed and calculated structure factors may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables of positional parameters for each complex have also been deposited with the Cambridge Crystallographic Data Centre, and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW, U.K.

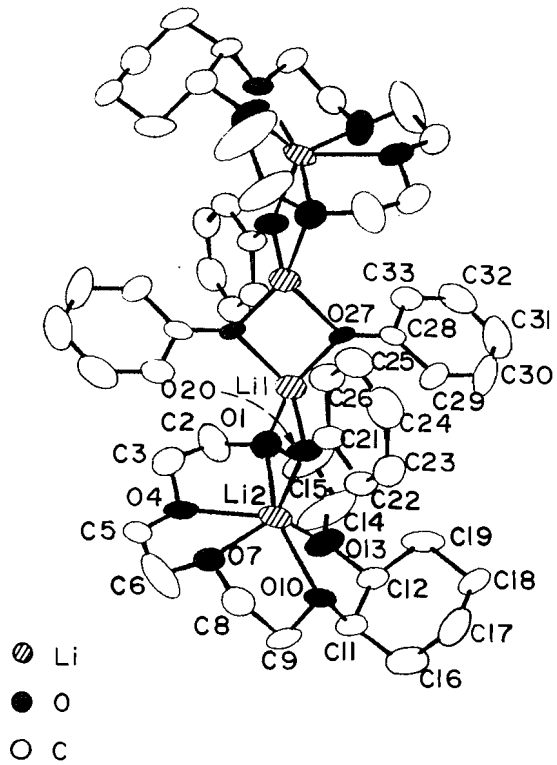

FIG. 1. ORTEP diagrams and atom numbering scheme for cyclohexano-15-crown-5·2LiOPh (**1**).

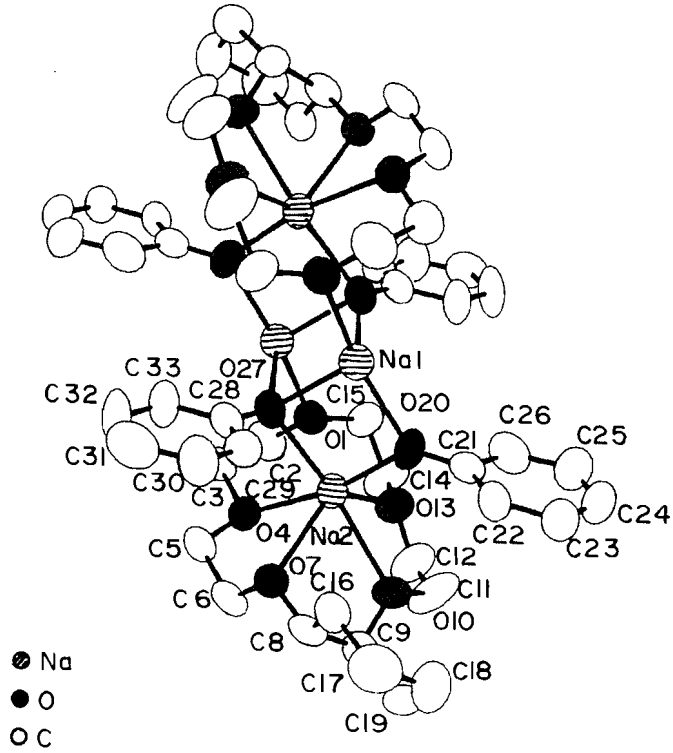

FIG. 2. ORTEP diagram and atom numbering scheme for cyclohexano-15-crown-5·2NaOPh (**2**).

Table 6; and macrocyclic ring torsion angles, for all three complexes, are presented in Table 7.

Host–guest interactions

Cyclohexano-15-crown-5·2LiOPh (1)

The structure may be described as an aggregate of four lithium phenoxide units complexed to two crown ethers. There is a center of symmetry in the dimer structure, easily located halfway between O27 and O27′. There are two different chemical environments for the lithium atoms of the monomeric unit. The coordination geometry of the two cations in complex **1** is very similar to that observed in the two polymorphs of 15-crown-5·2LiOPh (3). Li1 is coordinated to three phenoxide oxygens at an average distance of 1.89(3) Å and to only one crown ether oxygen at a distance of 2.194(9) Å. As can be seen in Fig. 1 and in the values of Table 5, the geometry around Li1 is that of a distorted tetrahedron. Li2 is coordinated to all five crown ether oxygens at an average distance of 2.3(2) Å and to only one phenoxide oxygen at a distance of 1.865(9) Å. The distances between the lithium ions and the phenoxide oxygens are all significantly shorter than those between the lithium ions and the crown oxygens, thus indicating stronger interactions between the lithium ions and the phenoxide oxygens of the aggregate. Li2 lies 0.63 Å out of the mean plane defined by the five crown ether oxygens. The average Li2–crown ether oxygen distance (2.3(2) Å) is longer than other lithium–crown ether oxygen distances found in the literature; however, we have found lithium–crown ether oxygen distances of similar length in other structures, for example 15-crown-5·2LiOPh (3), where the average lithium–crown ether oxygen distance was 2.3(1) Å. These observations provide further evidence of the strength of the lithium–phenoxide oxygen interactions. As a result, the $Li2^+$ ion is pulled out of the crown cavity with subsequent

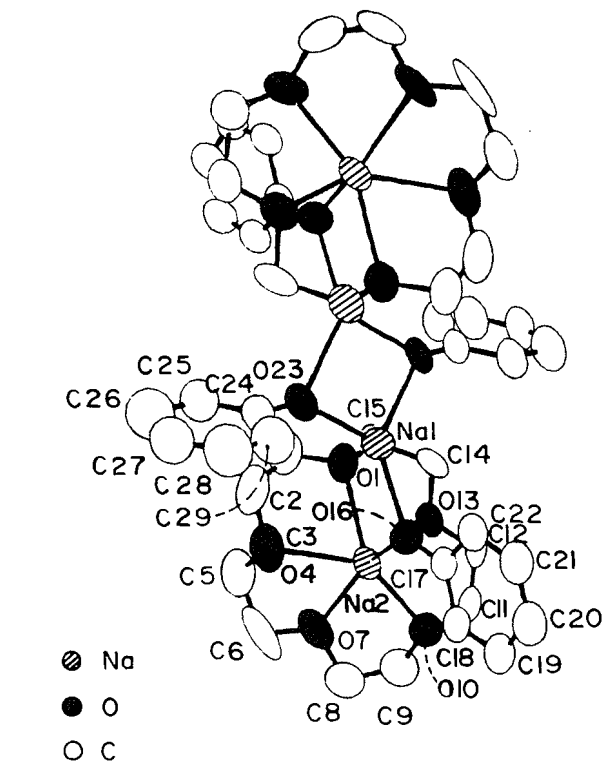

FIG. 3. ORTEP diagram and atom numbering scheme for 15-crown-5·2NaOPh (**3**).

TABLE 5. Oxygen – alkali metal bond lengths and angles for complexes **1**, **2**, and **3** with estimated standard deviations in parentheses[a]

TABLE 5. (*concluded*)

[a]The primed atoms are related to the unprimed atoms by the following symmetry operation: for **1**, $-x, -y, 1/2 - z$; for **2**, $-x, -y, -z$; for **3**, $1/2 - x, -y, 1/2 - z$.

lengthening of the Li2–crown ether oxygen distances. The lithium–phenoxide oxygen distances are consistent with previously reported literature values (ref. 3, and references therein).

The cyclohexano-15-crown-5·2LiOPh structure includes a $(Li^+O^-)_2$ four-membered ring similar to that reported for the two polymorphs of 15-crown-5·2LiOPh (3). In this case, the Li1—Li1′ distance is 2.56(2) Å compared to 2.55(1) and 2.58(1) Å found for the polymorphs **1***a* and **1***b* of 15-crown-5·2LiOPh. As shown in a previous publication (3), these distances are shorter than the Li—Li distance of 2.67 Å in Li2; however, other complexes with short lithium–lithium distances have been reported (13).

Cyclohexano-15-crown-5·2NaOPh (2)

As in structure **1**, structure **2** may be described as an aggregate of four sodium phenoxide units complexed to two crown ethers. Similarly, there is a center of symmetry in the dimer structure located halfway between O27 and O27′. The two sodium atoms of the monomeric unit have different chemical and crystallographic environments. Na1 is coordinated to three phenoxide oxygens at an average distance of 2.30(5) Å and to only one crown ether oxygen, O1, at a distance of 2.399(5) Å. Na2 appears to be coordinated to only four of the five crown ether oxygens, O4, O7, O10, and O13, with an average distance of 2.55(8) Å. The fifth crown ether oxygen, O1, is at a distance of 2.971(5) Å from Na2. In addition, Na2 is coordinated to two phenoxide oxygens at an average distance of 2.36(3) Å. Na2 lies 1.225(4) Å out of the mean plane defined by the five crown ether oxygens. As in complex **1**, the distances between the cations (in this case, sodium ions) and the phenoxide oxygens are consistently shorter than those between the cations and the crown ether oxygens. The average Na2–crown ether oxygen distance (2.55(8) Å) is consistent with other sodium–crown ether oxygen distances found in the literature. For example, the average sodium–crown ether oxygen distance is 2.54 Å for dibenzo-24-crown-8-bis(sodium *o*-nitrophenolate) (25), 2.40 and 2.77 Å for the 1:1 and 2:1 complexes of benzo-15-crown-5·Na[ClO_4], respectively (26), 2.83 Å for (benzo-15-crown-5)$_2$·Na[BPh_4] (26), 2.48 Å for dibenzo-30-crown-10·2Na[NCS] (27), 2.61 Å for the 1:1:1 complex of dicyclohexano-18-crown-6 (isomer A) with sodium phenoxide and phenol (4), 2.55 Å for dicyclohexano-18-crown-6·2NaOPH (5), 2.39(3) Å for benzo-15-crown-

example, distances of 3.383 Å in dibenzo-24-crown-8-bis(sodium *o*-nitrophenolate) (25), 3.940 Å in dibenzo-30-crown-10·2Na[NCS] (27), and, 3.147 and 3.392 Å, respectively, for the Na1—Na1′ and Na1—Na2 in dicyclohexano-18-crown-6 (isomer A)·2NaOPh (5), have been reported.

15-Crown-5-·2NaOPh (3)

The structure is similar to that described previously for structure **2**, in that it consists of an aggregate of four sodium phenoxide units complexed to two crown ethers. Again, there is a center of symmetry, located halfway between O27 and O27′, and the two sodium atoms of the monomeric unit have different chemical environments. Na1 is coordinated to three phenoxide oxygens at an average distance of 2.23(4) Å and to only one crown ether oxygen at a distance of 2.566(4) Å. Na2 is coordinated to all five crown ether oxygens with an average distance of 2.43(4) Å and to only one phenoxide oxygen at a distance of 2.232(3) Å. Na2 lies 0.829(4) Å out of the mean plane defined by the five crown ether oxygens. The average Na2–crown ether oxygen distance of 2.43(4) Å is consistent with those found in the literature and cited previously. Again we see that the cation–phenoxide oxygen distances are shorter than the cation–crown ether oxygen distances, resulting, as observed previously, in the sodium cation being pulled out of the crown cavity with a subsequent lengthening of the Na–crown ether oxygen distances. These observations provide further evidence that the complexing abilities of 15-crown-5 (and cyclohexano-15-crown-5) are not sufficient to break up the alkali metal–phenoxide aggregates into contact ion pairs. In structure **3**, there is a $(Na^+O^-)_2$ four-membered ring consisting of Na1—O23—Na1′—O23′ and giving a Na1—Na1′ distance of 3.172(4) Å, consistent with a value of 3.147 Å reported for the Na—Na1′ distance in dicyclohexano-18-crown-6 (isomer A)·2NaOPh (5).

Host geometry and conformation

Cyclohexano-15-crown-5·2LiOPh (1)

A search of the Cambridge Structural Database (20) for crown ether complexes containing "cyclohexano-15-crown-5" revealed that none have been reported so far. The X-ray crystal structure determinations of complexes **1** and **2** appear to be the first ones containing this particular host.

The C—C bond lengths in the macrocycle show the characteristic shortening with an average value of 1.44(8) Å (see Table 6). The C—O bond lengths have an average value of 1.40(3) Å, and the C—C—O and C—O—C angles have average values of 112.(3)° and 116.(2)°, respectively.

The torsion angles about the O7—C8, C15—O1, and C15—C14 bonds deviate notably from the expected antiperiplanar and synclinal arrangements expected for C—O and C—C bonds, respectively. An unusually short bond distance of 1.308(8) Å for the C15—C14 bond is found and may coincide with the torsion angle deviation found in this region of the macrocycle. Indeed, there are several deviations from the expected torsion angles, particularly in the region of the C14—C15 bond of this complex. In addition, there appears to be an overall lessening of the torsion angles, about the C—C bonds, from the expected synclinal arrangement.

The cyclohexano ring adopts a chair conformation with an average torsion angle value of 57.(1)°. The conformation of the cyclohexano substituent in this complex is comparable to the conformation of the cyclohexano rings in the complexes with dicyclohexano-18-crown-6 as a ligand (5).

Cyclohexano-15-crown-5·2NaOPh (2)

The macrocycles in complexes **1** and **2** exhibit similar structural features. The C—C bond length, again, shows the characteristic shortening with an average value of 1.45(8) Å (see Table 6). The C—O bond lengths have an average value of 1.42(2) Å, and the C—C—O and C—O—C angles have average values of 112.(5)° and 114.(1)°. These values are consistent with those found in complex **1**.

Deviations, from an antiperiplanar arrangement, in the torsion angles about the C6—O7, C9—O10, and O1—C2 bonds are found in this complex. In addition, complex **2** exhibits an unusually short bond distance of 1.321(10) Å for the C5—C6 bond, similar to that found in complex **1**.

The cyclohexano ring adopts a chair conformation with an

average torsion angle value of 53.(3)°. This value is consistent with the literature values.

15-Crown-5·2NaOPh (3)

In complex **3** the values for the macrocyclic ring (see Table 6) are comparable to those found for the macrocyclic rings of the two polymorphs of 15-crown-5·2LiOPh (3). Small deviations can be accounted for on the basis of the differences in the size of the cations and the distortions in the macrocycle necessary for optimum coordination geometry of the respective cations. In complex **3**, the C—C bond lengths have an average value of 1.52(4) Å, a value larger than that observed for the two polymorphs of 15-crown-5·2LiOPh (3) (1.500(5) and 1.46(3) Å for **1***a* and **1***b*, respectively). This is also larger than the values given previously for complexes **1** and **2**. In the macrocycle of complex **3**, the C—O bond lengths have an average value of 1.42(2) Å, and the C—C—O and C—O—C angles have average values of 107.(3)° and 114.(2)°, respectively. The torsion angle values for complex **3** are those expected, with the exception of the torsion angle around the O13—C14 bond, which shows a slight deviation from an antiperiplanar arrangement. A similar deviation is also observed in the two polymorphic structures of 15-crown-5·2LiOPh (3).

Discussion

The present work completes the systematic study of 15-crown-5 and cyclohexano-15-crown-5 ethers with lithium and sodium phenoxide guests. In these complexes, it is observed that the competition for the cation between the hard anions and the macrocyclic ligand can give rise to unusual host–guest stoichiometries and unexpected structural characteristics.

In previous examples of 15-crown-5 complexes, 1:1 host–guest stoichiometries, with lithium and sodium cations, were usually observed. The 1:1 complexes were indeed expected to form on the basis of the ion–cavity size principle. The present work clearly shows the effect of solvent and anion on the resultant stoichiometry. The 1:2 ratios found in the present complexes are attributed to the tendency of alkali metal phenoxides to form aggregates in ethereal solvents. It is believed that the complexing abilities of these 15-crown-5 ethers are not sufficient to induce a separation of the solvated alkali metal – phenoxide aggregates to form contact ion pairs. However, effects due to the ion – cavity size relationship are still observed (see below).

A comparison of the torsion angle values of the two polymorphs of 15-crown-5·2LiOPh (3) and complex **3** shows some similarities; however, there are a few areas showing distortions from the expected synclinal and antiperiplanar geometries. Overall, the torsion angles observed for complex **3** are much closer to the expected values. This may be indicative of a better fit of the sodium cation in comparison to the distortions required for complexation of the smaller lithium cations by the 15-crown-5 host in the two polymorphic structures. A similar comparison of the torsion angle values for complexes **1** and **2** indicates that there are many deviations from the expected synclinal and antiperiplanar arrangements. In complex **1**, there appears to be an approximately 20° deviation in all the synclinal (C—C) torsion angles, with the largest deviation for the angle O13—C14—C15—O1. The largest deviation from an antiperiplanar arrangement appears on either side of these atoms, namely, between atoms C12—O13—C14—C15 and C14—C15—O1—C2. In the case of complex **2**, large deviations from an antiperiplanar arrangement are found for atoms C5—C6—O7—C8, C8—C9—O10—C11, and C15—O1—C2—C3, while only a small deviation from a synclinal arrangement is observed (for atoms O4—C5—C6—O7).

In this study, we have also observed the effect of a substituent on the resulting complexes. An examination of the average bond lengths and angles for the 15-crown-5 macrocycle, and for the cyclohexano-15-crown-5 macrocycles, indicates that there is very little difference between the two ligands; the differences in the average values are within the estimated standard deviations. However, a comparison of the ranges of both bond lengths and angles shows that adjacent to the cyclohexano substituents of complexes **1** and **2** the bond lengths are slightly shorter, and the angles, particularly the C—C—O angles, are marginally larger than similar values for complex **3**. These differences, however small, may therefore be due to the presence of the cyclohexano substituent in complexes **1** and **2**. The C—C bonds at the points of fusion are observed to be longer (C11—C12 = 1.505 Å in complex **1**, and C8—C9 = 1.551 Å in complex **2**), and the adjacent C—C bonds, namely, C14—C15 in complex **1** and C5—C6 in complex **2**, appear to be shorter, with values of 1.308 and 1.320 Å, respectively. The shortening of the C—C bonds in this region appears to accompany a small increase in the bond angles at O1—C15—C14 for complex **1**, and O4—C5—C6 for complex **2**, respectively.

An examination of the torsion angle values for the lithium complexes of 15-crown-5 (3) and cyclohexano-15-crown-5 (complex **1**) reveals many more deviations from the expected values for the latter macrocycle. More specifically, in complex **1**, deviations are observed in all the expected synclinal arrangements, as well as notable deviations in the C6—O7—C8—C9, C12—O13—C14—C15, C14—C15—O1—C2, and C15—O1—C2—C3 angles. Since the cation size, crown cavity size, coordination geometry, and relative bond strengths in each lithium complex are the same, the conformational differences observed in the macrocycles must be a result of the addition of the cyclohexano substituent. A similar comparison of complexes **2** and **3** gives rise to the same trend and leads to the same conclusion. In the 15-crown-5 macrocycle of complex **3** there are fewer deviations than in the cyclohexano-15-crown-5 macrocycle of complex **2**, the most notable being that observed for the C12—O13—C14—C15 angle. However, in the cyclohexano-15-crown-5 macrocycle, in complex **2**, many deviations from the expected torsion angle values are observed, namely, O4—C5—C6—O7, C5—C6—O7—C8, C8—C9—O10—C11, C14—C15—O1—C2, and C15—O1—C2—C3. Furthermore, the coordination geometry found in complex **2** is somewhat unusual. The Na2 cation, coordinated primarily to the crown ether, is also coordinated to two phenoxide oxygen atoms, whereas in complex **3** the Na2 cation is coordinated to only one phenoxide oxygen atom. Moreover, in complex **2** the Na2 cation is at an unusually long distance (2.971 Å) from O1 of the crown ether. Furthermore, the Na2 cation of complex **2** lies much further out of the mean plane defined by the crown ether oxygens than does the Na^+ cation in complex **3**. A possible explanation for the observed differences in the coordination geometries of complexes **2** and **3** is that distortion in the cyclohexano-15-crown-5 ring of complex **2**, arising from the cyclohexano substituent, causes the cation to be *pushed* out of the crown ring and, therefore, does not allow coordination of Na2 with O1. Consequently, O27 of the phenoxide moiety is able to come into contact with Na2 in complex **2**, while contact of Na2 with O23 in complex **3** is essentially *blocked* by the optimum coordination of Na2 with all five crown ether oxygens.

A comparison of the torsion angle values for various benzo-15-crown-5 complexes (16, 26, 28) indicates that generally the values are very similar. This is consistent with the assumption that 15-crown-5 and cyclohexano-15-crown-5 macrocycles will be more flexible than the benzo- or dibenzo-15-crown-5 macrocycles, analogous to the observation that the 18-crown-6 and dicyclohexano-18-crown-6 ligands are more flexible than the dibenzo-18-crown-6 ligand (29). Thus, the more flexible ligands are readily able to undergo changes in conformation in order to accommodate a guest. This is observed in the sodium phenoxide complex with dicyclohexano-18-crown-6 (isomer A), where the large flexible ligand adopts an irregular conformation in order to envelop the sodium guest (5).

In the present substituted and unsubstituted 15-crown-5 complexes, and in the dicyclohexano-18-crown-6 (isomer A)·2NaOPh complex (5), the formation of a phenoxide aggregate is the dominant effect, and the cations are found to be located out of the ideal nesting position of the host cavity. Similarly, in the dicyclohexano-18-crown-6 (isomer B)·2KOPh complex (5), the potassium ions are pulled out of the host cavity and a potassium phenoxide dimer is observed. In each case, the unusual 1:2 ratio is attributed to the tendency of the alkali metal phenoxides to form aggregates in ethereal solutions. However, the tendency to form aggregates in ethereal solutions does not preclude the possibility of obtaining an optimal host–guest coordination geometry. A case in point is the 1:2 host–guest complex of 18-crown-6 with lithium phenoxide, which exhibits strong lithium phenoxide aggregate formation in addition to an ideal host–guest geometry where both lithium cations lie in the cavity outlined by the 18-crown-6 (6). In this case, the cavity of the relatively large ligand can accommodate the two small guests and, therefore, the resultant 1:2 host–guest stoichiometry is not unexpected. Thus, the 18-crown-6·2LiOPh complex (6) provides an example of the balance and intricacy of these associated effects and, together with the results of this study, supports the idea that the stoichiometries and structural features of the crown ether complexes are indeed a result of concerted host, guest, anion, and solvent effects.

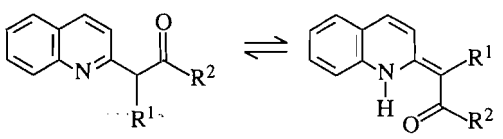
JOHN V. GREENHILL, HOSSEIN LOGHMANI-KHOUZANI, and DEREK J. MAITLAND. Can. J. Chem. **69**, 696 (1991).

A series of 4-ketomethylquinolines has been prepared and their tautomerism investigated. The compounds were prepared from 4-methylquinoline deprotonated with lithium diisopropylamide or potassium ethoxide and treated with esters. Attempted deprotonation with *tert*-butyllithium or phenyllithium led to 2-substituted-4-methylquinolines. The simple alkyl or aryl 4-ketomethylquinolines exist essentially as the keto forms, but the quinoline-4-pyruvates are exclusively or substantially in the enol forms.

Key words: ketomethyl quinolines, pyruvates, tautomerism, enols.

JOHN V. GREENHILL, HOSSEIN LOGHMANI-KHOUZANI et DEREK J. MAITLAND. Can. J. Chem. **69**, 696 (1991).



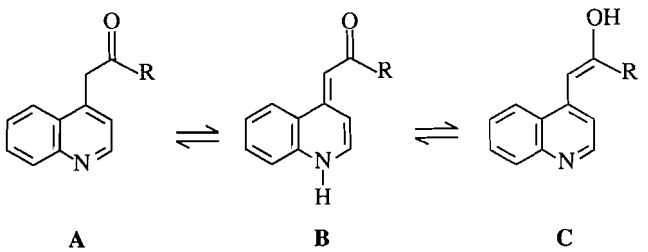
On a préparé une série de 4-cétométhylquinoléines et on a examiné leur tautomérie. On a préparé les produits à partir de la 4-méthylquinoléine déprotonée, à l'aide du diisopropylamide de lithium ou de l'éthylate de potassium, qui a été traitée par des esters. Des essais de déprotonation à l'aide du *tert*-butyllithium ou le phényllithium ont conduit à la formation de 4-méthylquinoléines substituées en position 2. Les 4-cétométhylquinoléines portant des groupements aryles ou alkyles simples existent essentiellement sous la forme cétonique; toutefois, les quinoléine-4-pyruvates existent exclusivement ou presque sous la forme énolique.

Mots clés : cétométhylquinoléines, pyruvates, tautomérie, enols.

[Traduit par la rédaction]

Introduction

We recently conducted detailed investigations into the tautomerism of 2-ketomethylquinolines (1), Scheme 1. By a combination of ir and nmr spectroscopy it was clearly shown that the enaminone form **B** was strongly favoured over the ketone form **A** for 2-ketomethylquinolines where R^1 = H, CN, or COOEt (R^2 = alkyl, aryl, CN, COOEt, etc.). For the compounds with R^1 = H, R^2 = Me, Et, *i*-Pr, or *t*-Bu, the tautomeric mixtures in chloroform had 12–20% of the ketone forms and signals for both forms **A** and **B** could clearly be seen in the ir and the ^{1}H, ^{13}C, and ^{15}N nmr spectra. The rest of the structures investigated showed only the enaminone signals. However, compounds of Scheme 1 where R^1 = Me or Br were found to be exclusively in the ketone form **A**.



A **B**

SCHEME 1

We have now undertaken a study of 4-ketomethylquinolines by preparing and examining the compounds of Table 1. The few literature reports had reached differing conclusions regarding the tautomerism of compounds of this type. In principle, three forms are possible, Scheme 2.

It was claimed by Stock *et al.* (2) that the pyruvate **6** had 76%

A **B** **C**

SCHEME 2

of the enol form (**C**) after 20 min in methanol, which dropped to 22% at equilibrium (time unspecified). This investigation made use of bromine titration to determine the enol content, and intermolecular (O—H...N) hydrogen bonded stabilization was suggested to account for the enolic content of the mixture. In an nmr study of the same compound, Golankiewicz and Golankiewicz assigned a singlet, which appeared at δ 6.38 in both $CDCl_3$ and DMSO-d_6, to the vinyl proton of the enol form and in the absence of a methylene signal the pyruvate was concluded to be 100% enol (3). Mondelli and Merlini claimed to detect a small proportion of the dienaminone form (**B**) of this pyruvate (4). The 8-cyano derivative of compound **1** was claimed by Higishino *et al.* to be exclusively in the dienaminone form, based on the ir (1680 cm^{-1}) and 60 MHz nmr spectra (5). Compound **11** has recently been shown by Fukata *et al.*, using potentiometric titration, to have log K_T 1.78 in favour of the keto form (**A**) (6).

Synthesis

Compared with the 2-ketomethylquinolines, only a few 4-ketomethylquinolines have been reported (7). Those made from 4-methylquinoline and an ester usually required sodium diisopropylamide (SDA) as base (8), although compound **11** was obtained in good yield from methyl benzoate in the

presence of sodium hydride (9). In our hands only **11** and the 2-pyridyl ketone **12** could be prepared by this technique.

Attempted use of *tert*-butyllithium or phenyllithium as ionizing bases with 4-methylquinoline, followed by a nitrile or an ester as the acylating agent, gave high yields of 2-*tert*-butyl-4-methylquinoline and 2-phenyl-4-methylquinoline respectively, see experimental section. No trace of any acylated product was detected. Attempted use of sodium hydride or N^1-*tert*-butyl-N^2,N^2,N^3,N^3-tetramethylguanidine (10) as base gave none of the required ketomethylquinolines; only starting materials were recovered. Finally, with lithium diisopropylamide (LDA), compounds **1**, **2**, **3**, and **4** were obtained in good yields. A literature report describes the preparation of ketone **3** from 4-methylquinoline and SDA followed by ethyl isobutyrate (8). The crude product was distilled and extracted with petroleum ether to give a soluble material, mp 45.5–46.6°C, and an insoluble product, mp 160–165°C. It was claimed that the low melting compound was the pure keto form and the high melting material was a mixture of the keto and enol forms. In our hands the same two products were obtained when LDA was substituted for SDA. The spectra of the low melting material showed it to be the required compound as a pure ketone, see experimental section. The nmr spectrum of the high melting material was as follows (δ $CDCl_3$): 1.28 (d), 1.52 (d), 2.94 (heptet), 3.45 (heptet), 4.55 (s), 7.86 (2H, m), 8.04 (2H, m), 8.85 (1H, d), 9.05 (1H, d), 9.40 (s, NH). We interpreted this to be a mixture of the required ketomethylquinoline hydrochloride and diisopropylamine hydrochloride (signals at δ 1.52, 3.45, and 9.4) in the proportions of 88:12. The mixture was dissolved in water, basified, and extracted with dichloromethane to give a further quantity of the low melting ketone.

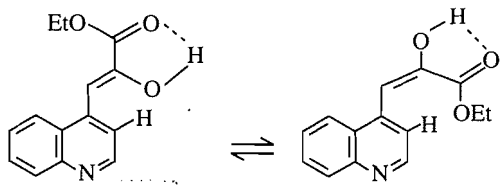
The ethyl pyruvate **6** has been prepared from 4-methylquinoline and diethyl oxalate in the presence of potassium ethoxide (11). However, we found this compound to be only sparingly soluble in chloroform so that it was difficult to get good spectra for the study of its tautomerism. Therefore, the further pyruvates **5**, **7**, **8**, **9**, and **10** were prepared in the hope of finding more soluble examples. In this we were frustrated and had to rely on KBr discs for the ir spectra and prolonged acquisition times for the FT nmr spectra. The new compounds were prepared by the potassium ethoxide method except for the methyl ester **5**, which resulted from a transesterification of the ethyl ester **6** in methanol containing boron trifluoride.

To get an example of a fixed dienaminone, compound **13** was prepared from 1,4-dimethylquinolinium iodide by a Schotten–Baumann procedure (6).

13

Discussion

Aliphatic 4-ketomethylquinolines **1**, **2**, **3**, and **4** were clearly in the simple keto forms in chloroform with no trace of any other tautomers. They all had strong carbonyl bands in their ir spectra at about 1715 cm^{-1}. The ^1H nmr spectra showed two-proton singlets for the methylene groups between δ 4.1 and 4.3 and the ^{13}C spectra were characterized by methylene signals between δ 40 and 48 and by unconjugated carbonyl carbon signals in the δ 204—211 region. The uv spectra, Table 2, were closely similar to those of 4-methylquinoline.



The pyruvic ester **9** proved to be in the enol tautomeric form. The ir spectrum showed a very broad, strong band centred at 2657 cm^{-1} for the hydrogen bonded enolic O–H stretch. A strong band at 1723 cm^{-1} represented both ester carbonyl groups and a medium band at 1639 cm^{-1} was in the range for enol C=C stretch. This was much weaker than the carbonyl

stretching band of the dienaminone **13** at 1631 cm^{-1}. In the uv spectrum the compound showed strong peaks at 479 and 453 nm, consistent with the proposed extended conjugated system. The ^1H nmr spectrum showed signals for the enol, in particular a full one-proton singlet at δ 6.74 for the vinyl proton. In the ^{13}C spectrum there were the expected signals for the enol and the highest field signal was at δ 165.12 for an ester carbonyl carbon. By contrast, the dienaminone carbonyl carbon of compound **13** absorbed at δ 187.96. Neither nmr spectrum had any sign of a methylene signal from the keto form or any other indication of a second tautomer. Thus both simple ketone and dienaminone forms were ruled out and the compound shown to exist as the enol form. The very low O–H band in the ir spectrum and the fact that the simple ketones **1**, **2**, **3**, **4**, **11**, and **12** showed negligible amounts of their enol forms strongly suggest that the hydrogen bond in **9** is intramolecular, and the compound adopts one of the planar forms **14***a* or **14***b*. Of these we prefer form **14***a*

14*a* **14***b*

since the steric interaction between the C3-H and the ethoxy group of **14***b* would be expected to destabilize it. The mixed ester **8** was also 100% enol, but the other pyruvates **5**, **6**, and **7** were mixtures of keto and enol forms. The tautomeric ratios, calculated from the ^1H nmr spectra, are given in Table 1. For ester **10** a complex proton nmr spectrum indicated the presence of two forms, but it was not possible to identify positively signals on which the tautomeric ratio could be calculated. In the ^{13}C nmr spectrum it was not possible to see two full sets of signals, but the methylene group (δ 42.49) of the keto form and the vinyl carbon (δ 99.24) of the enol form were clearly visible. Their relative intensities in the DEPT spectrum indicated an approximate tautomeric ratio of 18:82.

The aromatic ketone **11** was, like the simple aliphatic compounds, essentially in the keto form. The ir and nmr spectra gave no indication of a second tautomer, but there were two small long-wavelength absorptions in the uv spectrum. The 2-pyridyl derivative **12** was prepared in the hope that the pyridine nitrogen would stabilize the enol form. However, its lone pair is not ideally orientated for intramolecular hydrogen bonding in the way that the oxygen lone pairs of the pyruvates are. Again, it did show two weak long-wavelength absorptions in the uv spectrum. However, neither compound gave any clear signals for a second form in either the ^1H or the ^{13}C nmr spectrum.

The ultraviolet spectra in aqueous solutions for four of the compounds are given in Table 3. The simple ketones, compounds **1** and **11**, showed spectra little changed between water and molar acid, as would be expected. The pyruvates **6** and **10** showed long-wavelength absorption in water similar to that seen in ethanol. Clearly the enolic forms exist in neutral aqueous solution. In acid all four compounds gave very similar spectra. Under these conditions the pyruvates revert to the ketone structures, perhaps because the carbonyl groups are stabilized by hydrogen bonding to the H_3O^+ molecules. It was interesting that all four compounds showed strong absorption at 388–406 nm in molar sodium hydroxide. These conditions must be sufficiently basic to induce deprotonation of the methylene group.

In comparing the structures of the 2-ketomethylquinolines with those of the present report it is clear that the *intra*-molecular hydrogen bond in the enaminone form, Scheme 1, is essential for its stabilization. The energy difference between the two forms of Scheme 1 must be small since the simple alkyl derivatives (R^1 = H, R^2 = alkyl) show significant proportions of the ketone forms in solution. The equivalent compounds of the 4-ketomethyl series, Scheme 2, have no comparable *intra*-molecular hydrogen bonding available and show only ketone structures.

In comparing the freely chloroform-soluble compounds **1**–**4**, **11**, and **12** (all 100% ketones) with the esters **5**–**10** there was the possibility that the DMSO-d_6, which had to be used to obtain the ester nmr spectra, had helped to stabilize the enol forms detected. Compound **1** was therefore re-run in DMSO-d_6, but

11	H_2O		314 (6 200)	300 (7 000)	284 (8 600)	226 (42 200)
	M HCl		314 (10 200)			236 (40 800)
	M NaOH	406 (16 800)			257 (8 600)	223 (42 400)

neither the ^1H nor the ^{13}C spectrum was significantly different from the $CDCl_3$ spectrum (see experimental). The methyl (δ 2.29) and methylene (δ 4.38) proton signals were in an exact 3:2 ratio and there were no detectable signals for an enol form. Further evidence for the conclusions reached was provided by the uv spectra. The compounds of Scheme 1, which have been shown to be substantially enaminones in chloroform, had strong absorptions in ethanol and in water at 430–440 nm (for R^1 = H, R^2 = alkyl) or 450–460 nm (for R^1 = H, R^2 = aryl), establishing that the enaminone forms are dominant in these solvents also (14). Reference to Tables 2 and 3 shows that the alkyl 4-ketomethylquinolines **1**–**4** show no trace of long-wavelength absorption, and the aryl derivatives **11** and **12** have very low absorption in the 440–480 region.

It is reasonable to assume that other simple 4-ketomethylquinolines would exist as ketones, but that enol formation, giving a system conjugated to the quinoline ring, will always be a possibility where it can be stabilized by intramolecular hydrogen bonding. Whether any firm examples will be found in which dienaminone forms exist remains to be seen, but the loss of aromaticity in the heterocyclic ring cannot be compensated by hydrogen bonding as is the case with the enaminone forms of 2-ketomethylquinolines (1).

Experimental

The ir spectra were run on Perkin–Elmer 1700-X and 1720-X FT spectrophotometers. The 270 MHz ^1H and 67.8 MHz ^{13}C nmr (broad band decoupled and DEPT 135) spectra were run on a JEOL GX 270 spectrometer fitted with a 5 mm C/H probe. The uv spectra were obtained on a Perkin–Elmer Lambda 5 UV/VIS spectrophotometer and mass spectra on an AEI MS 902 spectrometer. Chromatography columns were prepared with Aldrich silica gel 70–230 mesh.

2-(1,1-Dimethylethyl)-4-methylquinoline

A solution of 4-methylquinoline (2.86 g, 0.02 mol) in dry ether (10 mL) was added dropwise to a solution of *tert*-butyllithium (11.76 mL of 1.7 M solution in pentane, 0.02 mol) in dry ether (20 mL) and stirred under nitrogen at room temperature for 1 h. Acetonitrile (5.0 g, 0.06 mol) in dry ether (10 mL) was added and stirring continued for a further 20 h. The product was washed with water and extracted with dilute hydrochloric acid. The aqueous extracts were neutralized with solid sodium carbonate and extracted with chloroform (2 × 50 mL). The chloroform solution was dried ($MgSO_4$) and the solvent removed to give *2-(1,1-dimethylethyl)-4-methylquinoline* as a colourless oil (3.4 g, 85%); ^1H nmr (δ $CDCl_3$); 1.46 (9H, s, 3 × CH_3), 2.67 (3H, s, CH_3), 7.34 (H, s), 7.47 (H, dt), 7.65 (H, dt), 7.93 (H, dd), 8.06 (H, dd); ^{13}C nmr (δ $CDCl_3$); 18.95 (CH_3), 30.10 (3 × CH_3), 37.88 (C), 118.87 (CH), 123.36 (CH), 125.36 (CH), 126.51 (C), 128.66 (CH), 129.91 (CH), 143.58 (C), 147.27 (C), 168.90 (C); *m/z* 199. It gave the *hydrochloride*, mp 225–226°C (from ethanol–ether). Anal. calcd. for $C_{14}H_{18}ClN$: C, 71.3, H 7.65, Cl 15.1, N 5.95%; found: C 71.2, H 7.5, Cl 15.2, N 5.9%.

4-Methyl-2-phenylquinoline was similarly prepared from 2-phenyllithium: 82%, mp 65°C (from methanol) (lit. (12) mp 67°C); ^1H nmr (δ $CDCl_3$, 60 MHz); 2.52 (3H, s, CH_3), 7.3–8.3 (10H, m, C_9H_5N + C_6H_5); *m/z* 219.

1-(4-Quinolyl)propan-2-one (1)

4-Methylquinoline (2.86 g, 0.02 mol) was added dropwise to a solution of lithium diisopropylamide (13.3 mL of a 1.3 M solution in cyclohexane, 0.02 mol) in THF (15 mL) with stirring under nitrogen at −78°C. After 20 min methyl acetate (1.5 g, 0.02 mol) was added and stirring continued for 30 min at −78°C. The mixture was allowed to warm to room temperature and stirred for a further 40 min. Water (2 mL) and ether (50 mL) were added, the cooled solution carefully acidified with hydrochloric acid, and the layers separated. The aqueous solution was treated with sodium hydroxide solution until nearly neutral and finally basified with solid sodium carbonate. The product was extracted with chloroform, dried ($MgSO_4$), the solvent evaporated, and the residue chromatographed on a silica column eluted with 1% methyl acetate in chloroform to give 1-(4-quinolyl)propan-2-one (1.37 g, 37%) mp 70–71°C (from petroleum ether 40–60) (lit. (8) mp 71.8–72.6°C); ir ($CHCl_3$): 1714(s), 1594(m), 1572(w), 1511(m) cm^{-1}; ^1H nmr (δ $CDCl_3$): 2.20 (3H, s, CH_3), 4.14 (2H, s, CH_2), 7.28 (H, d, C3-H, J = 4.40), 7.57 (H, t), 7.73 (H, t), 7.87 (H, d), 8.14 (H, d), 8.87 (H, d, C2-H, J = 4.39); ^1H nmr (δ DMSO-d_6): 2.29 (3H, s), 4.38 (2H, s), 7.39 (H, d, J = 4.29), 7.64 (H, t), 7.77 (H, t), 7.90 (H, d), 8.04 (H, d), 8.84 (H, d, J = 4.28); ^{13}C nmr (δ $CDCl_3$): 29.50 (CH_3), 47.91 (CH_2), 122.78 (CH), 123.62 (CH), 127.07 (CH), 127.54 (C), 129.50 (CH), 130.29 (CH), 140.43 (C), 148.42 (C), 150.16 (CH), 204.48 (C); ^{13}C nmr (δ DMSO-d_6): 30.24, 46.66, 123.56, 125.07, 126.90, 127.98, 129.60, 129.86, 141.96, 148.17, 150.53, 205.34; *m/z* 185.

The following were prepared similarly:

1-(4-Quinolyl)butan-2-one (2): 35%, bp 135–140°C (0.3 Torr; 1 Torr = 133.3 Pa) (lit. (8) bp 134–135°C (0.55 Torr)). Analytical sample purified via a silica column eluted with 1% ethyl acetate in chloroform; ir ($CHCl_3$): 1717 (s), 1593 (m), 1572 (w), 1511 (m) cm^{-1}; ^1H nmr (δ $CDCl_3$): 1.03 (3H, t, CH_3), 2.52 (2H, q, CH_2), 4.13 (2H, s, CH_2), 7.26 (H, d, C3-H, J = 4.39), 7.56 (H, t), 7.72 (H, t), 7.87 (H, d, J = 8.42), 8.14 (H, d, J = 8.42), 8.86 (H, d, C-2H, J = 4.39); ^{13}C nmr (δ $CDCl_3$): 7.70 (CH_3), 35.51 (CH_2), 46.69 (CH_2), 122.73 (CH), 123.70 (CH), 127.02 (CH), 127.60 (C), 129.47 (CH), 130.18 (CH), 140.73 (C), 148.34 (C), 150.08 (CH), 207.12 (C); *m/z* 199.

3-Methyl-1-(4-quinolyl)butan-2-one (3): 55%, bp 145°C (0.8 Torr) (lit. (8) bp 133–135°C (0.55 Torr)). The oil (2.1 g) was refluxed with petroleum ether 40–60, filtered, and the filtrate cooled in liquid nitrogen. The product was collected and chromatographed through a silica column eluted with 1% methyl acetate in chloroform to give the pure ketone (1.2 g), mp 43–44°C (lit. (8) mp 45.4–46.6°C); ir ($CHCl_3$); 1714 cm^{-1}; ^1H nmr (δ $CDCl_3$): 1.14 (6H, d, 2 × CH_3), 2.77 (H, heptet, CH), 4.17 (2H, s, CH_2), 7.23 (H, d, C3-H, J = 4.40), 7.54

(H, t), 7.68 (H, t), 7.82 (H, d), 8.13 (H, d), 8.84 (H, d, C2-H, J = 4.40); ^{13}C nmr (δ $CDCl_3$): 18.40 (CH_3), 40.48 (CH), 44.48 (CH_2), 122.76 (CH), 123.62 (CH), 126.86 (CH), 127.71 (C), 129.34 (CH), 130.17 (CH), 140.83 (C), 148.31 (C), 149.99 (CH, 210.20 (C); m/z 213. The petroleum ether insoluble residue (0.6 g) was dissolved in water, basified with dilute ammonium hydroxide, and extracted with dichloromethane. The extracts were dried ($MgSO_4$) and the solvent evaporated to give a residue identical (^{1}H nmr) with the pure ketone base prepared above.

3,3-Dimethyl-1-(4-quinolyl)butan-2-one (**4**): Purified through a silica column eluted with 1% ethanol in dichloromethane, 26.5%, mp 119–120°C (from petroleum ether 60–80) (lit. (8) mp 119–120°C); ir ($CHCl_3$): 1711 (s), 1596 (m), 1572 (w), 1512 (s) cm^{-1}; ^{1}H nmr (δ $CDCl_3$): 1.32 (9H, s, 3 × CH_3), 4.30 (2H, s, CH_2), 7.23 (H, d, C3-H, J = 4.40), 7.57 (H, t), 7.76 (2H, m), 8.20 (H, d, J = 8.43), 8.90 (H, d, C2-H, J = 4.40); ^{13}C nmr (δ $CDCl_3$): 26.65 (CH_3), 40.21 (CH_2), 45.07 (C), 122.84 (CH), 123.60 (CH), 126.94 (CH), 127.95 (C), 129.60 (CH), 129.64 (CH), 142.39 (C), 147.55 (C), 149.31 (CH, 211.01 (C); m/z 227.

Methyl 2-hydroxy-3-(4-quinolyl)propenoate (**5**)

A solution of ethyl 2-hydroxy-3-(4-quinolyl)propenoate (0.8 g) in 14% boron trifluoride – methanol complex (40 mL) was refluxed on a water bath for 12 h. Most of the solvent was removed and the residue basified with saturated potassium bicarbonate solution and extracted with chloroform (5 × 100 mL). The combined extract was dried ($MgSO_4$) and the solvent evaporated to give the methyl ester (0.6 g, 78%) mp 198–200°C (from pyridine); ir (KBr): 2665 (br s), 1727 (s), 1632 (m), 1601 (m), 1533 (vs), 1505 (vs) cm^{-1}; ^{1}H nmr (δ DMSO-d_6, 16°C): 3.77 (s, OCH_3), 3.86 (s, OCH_3, keto form), 4.76 (s, CH_2, keto form), 6.71 (s, =CH), 7.4–8.6 (6H, m, C_9H_6N), 12.40 (s, OH), ratio keto:enol 3:97; at 60°C the spectrum was the same, but the keto:enol ratio was 6:94; ^{13}C nmr (δ DMSO-d_6, 60°C): 41.87 (CH_2, keto form), 51.77 (OCH_3), 52.69 (OCH_3, keto form), 123.25, 123.53, 125.31, 126.43, 127.46, 129.12, 129.47, 131.00, 139.89, 147.86, 165.76 (C); it was not possible to identify the other carbon signals due to the low solubility; m/z 229. Anal. calcd. for $C_{13}H_{11}NO_3$: C 68.1, H 4.8, N 6.1%; found: C 67.9, H 4.85, N 6.15.

General method for the preparation of esters **6–10**

A solution of the appropriate oxalic acid diester (0.005) mol) in dry ether (10 mL) was added to potassium ethoxide (0.01 mol from potassium (0.4 g) and ethanol (1.8 mL) in dry ether (20 mL)). A solution of the 4-methylquinoline (0.005 mol) in dry ether (10 mL) was added dropwise and the mixture stirred for 3 days and allowed to stand for 4 days. The precipitate was collected rapidly and immediately added to dilute acetic acid (10 mL). After stirring for 2 h, the new precipitate was collected to give the required ester:

Ethyl 2-hydroxy-3-(4-quinolyl)propenoate (**6**): 70%, mp 192–194°C (from pyridine) (lit. (11) mp 196°C); ir (KBr): 2639 (br. s), 1716 (s), 1631 (m), 1602 (m), 1529 (s), 1505 (s) cm^{-1}; ^{1}H nmr (δ DMSO-d_6): 1.31 (t, CH_3), 4.24 (q, CH_2), 4.73 (s, CH_2, keto form), 6.70 (s, =CH), 7.4–8.5 (6H, m, C_9H_6N), keto:enol ratio 1:9; ^{1}H nmr (δ DMSO-d_6/TFA 1:2); 1.50 (t, CH_3), 4.52 (q, CH_2), 5.12 (s, CH_2, keto form), 7.45 (s, =CH), 8.0–9.0 (6H, m, C_9H_6N), keto:enol ratio 1:4; ^{13}C nmr (δ DMSO-d_6/TFA 1:2), strong signals (enol form); 14.14 (CH_3), 65.80 (CH_2), 100.97 (CH), 122.04 (CH), 122.19 (CH), 125.97 (CH), 128.11 (C), 131.53 (CH), 136.37 (CH), 139.12 (C), 143.61 (CH), 151.35 (C), 153.17 (C), 165.77 (C); weak signals (keto form): 14.02 (CH_3), 44.37 (CH_2), 65.63 (CH_2), 122.45 (CH), 125.22 (CH), 126.94 (CH), 130.26 (C), 132.27 (CH), 137.08 (CH), 138.99 (C), 144.48 (CH), 155.59 (C), 161.39 (C), 189.96 C); m/z 243.

Ethyl 2-hydroxy-3-(6-methoxy-4-quinolyl)propenoate (**7**): 49%, mp 188–190°C (from ethanol); ir (KBr): 2619 (br s), 1718 (s), 1606 (s), 1504 (vs), 1477 (vs) cm^{-1}; ^{1}H nmr (δ DMSO-d_6 70°C): 1.32 (3H, t, CH_3), 3.92 (3H, s, OCH_3), 4.27 (2H, q, CH_2), 4.68 (s, CH_2, keto form), 6.68 (s, =CH), 7.3–8.4 (5H, m, C_9H_5N), keto:enol ratio 19:81; ^{13}C nmr (δ DMSO-d_6 70°C): 13.71 (CH_3 keto form), 14.02 (CH_3), 41.92 (CH_2 keto form), 55.62 (OCH_3), 60.88 (CH_2), 62.07 (CH_2 keto form), 103.39 (CH), 121.24 (CH), 121.55 (CH), 122.64 (CH), 123.51 (CH), 124.38 (C), 128.52 (C), 131.08 (CH), 138.39 (C), 144.01 (C), 147.38 (CH), 157.06 (C), 157.59 (C), 160.47 (C), 165.20 (C), 190.56 (C=O keto form); clearly, two forms were present, but the other signals could not be distinguished because of low solubility; m/z 273. Anal. calcd. for $C_{15}H_{15}NO_4$: C 65.9, H 4.5, N 5.1%; found: C 65.8, H 4.55, N 5.0%.

Ethyl 2-hydroxy-3-(6-methoxycarbonyl-4-quinolyl)propenoate (**8**): 20%, mp 215–216°C (from methanol); ir (KBr): 2775 (br s), 1718 (s), 1635 (m), 1602 (w), 1538 (s), 1504 (s) cm^{-1}; ^{1}H nmr (δ DMSO-d_6 20°C); 1.37 (3H, t, CH_3), 3.78 (3H, s, OCH_3), 4.39 (2H, q, CH_2), 6.73 (H, s, =CH), 7.71 (H, d), 8.08 (H, br s), 8.19 (H, dd), 8.46 (H, d), 8.69 (H, s); ^{13}C nmr (δ DMSO-d_6 70°C): 14.11 (CH_3), 51.96 (OCH_3), 61.07 (CH_2), 79.07 (CH), 165.12 (C), 165.39 (C); due to low solubility only four aromatic carbons were clearly visible at 125.39, 126.32, 130.06, and 130.50; m/z 301. Poly(vinylbenzo macrocyclic polyethers). Synthesis and cation binding properties of 12-crown-4 derivatives

G. W. BUCHANAN[1] AND J. K. DENIKE

Ottawa–Carleton Chemistry Institute, Department of Chemistry, Carleton University, Ottawa, Ont., Canada K1S 5B6

Received August 20, 1990

G. W. BUCHANAN and J. K. DENIKE. Can. J. Chem. **69**, 702 (1991).

The synthesis of 4′-vinylbenzo-12-crown-4 ether is reported. Polymerization to relatively low molecular weight polymers can be accomplished with a free radical initiator. A copolymer with styrene can be prepared and the Li^+, Na^+, and K^+ binding properties of these polymers are compared to those of their monomeric analogs using salt distribution equilibria in water – methylene chloride. For all cations the homopolymer is found to extract the salts from the aqueous phase most effectively. The copolymer is slightly less effective than the homopolymer but more effective than either of the monomers by a factor of approximately 7, indicating that cooperative binding is likely. Na^+ is the most efficiently extracted cation, followed by K^+ and Li^+.

Key words: crown ether polymers, complexation properties.

G. W. BUCHANAN et J. K. DENIKE. Can. J. Chem. **69**, 702 (1991).

On a réalisé la synthèse de l'éther 4′-vinylbenzo-12-couronne-4. Sous l'influence d'une initiateur radicalaire, il est possible d'en faire une polymérisation qui conduit à des polymères de faibles poids moléculaires. On peut préparer un copolymère avec le styrène; utilisant l'équilibre de distribution des sels dans l'eau et le chlorure de méthylène, on a comparé les propriétés liantes de ces polymères avec le Li^+, le Na^+ et le K^+ à celles de leurs analogues monomères. Pour tous les cations, on a trouvé que l'homopolymère est le plus efficace pour extraire des sels de solutions aqueuses. Le copolymère est un peu moins efficace que l'homopolymère. Il est toutefois plus efficace que l'un ou l'autre des monomères par un facteur d'environ 7; ce résultat suggère qu'une liaison coopérative est probable. Le Na^+ est le cation qui peut être extrait le plus facilement, suivie par le K^+ et le Li^+.

Mots clés : polymères de l'éther-couronne, propriétés de complexation.

Introduction

Polymers bearing pendant crown ethers have generated a substantial amount of interest. The early work (1) demonstrated, for 15-crown-5 and 18-crown-6 derivatives, that the 4′-vinylbenzo polymers were considerably more effective in binding cations than their monomeric analogs. Differences in binding between polymers and monomers arises from the possibility of cooperative binding between proximate crown ethers on the polymer chain, which also leads to facile binding of cations whose ionic radii exceed that of the individual crown ether cavities.

A number of potentially practical applications of such ionophoric polymers exist in the areas of thin film sensors, ion exchange membranes, ion selective electrodes, and solid electrolytes (2, 3). A major review of the work in this area is available (4).

The present study was undertaken in view of the current interest in the complexation of Li^+ by 12-crown-4 systems (5, 6) and the lack of information on binding properties of copolymeric species. Accordingly, we prepared 4′-vinylbenzo-12-crown-4, its homopolymer, and copolymer with styrene and compared the cation binding properties of these systems as well as of 12-crown-4 and benzo-12-crown-4 with Li^+, Na^+, and K^+. The synthetic scheme is such that facile ^{13}C incorporation into the vinyl group of these monomers is possible, a factor that will facilitate mobility studies of the polymers and their complexes via ^{13}C NMR spin lattice relaxation time measurements.

Discussion

The present synthetic scheme (Fig. 1) is a modification of the approach reported by Smid *et al.* (7) for 15-crown and 18-crown-6 systems with the exception of the use of the Wittig reaction for direct conversion of the formyl to the vinyl function. It is of interest to note that in the cyclization reaction to form the 12-membered ring, two other products were obtained, namely an uncyclized monoadduct and the 24-membered dimer, with structures as depicted in Fig. 2. The ratio of 12- to 24-membered crown ethers obtained in this reaction is approximately 3 to 1.

We chose to carry out the polymerization with a radical initiator as previously employed by Smid and co-workers (1) because of the simplicity of the reaction and the availability of the necessary reagents. The polymer chains are much shorter than those previously reported. We used 0.5% initiator by weight and obtained a polymer with a mean mass number of 3800. The weight is just over 10% of the values of those obtained by Smid even though we used less initiator by a factor of approximately 1.5. The polymerization properties of vinylbenzo-12-crown-4 are not expected to be significantly different from those of vinylbenzo-15-crown-5, and because the reaction time and temperature used were the same as those reported we must conclude that either our initiator was more active or that our degassing procedure was slightly less effective and that residual oxygen may also be acting as an initiator.

The identical procedure was carried out for the synthesis of the copolymer. ^1H NMR integration of the polymer obtained comparing the CH_2-O and aromatic reagents showed that both monomeric components were present in essentially equal amounts within the precision of the electronic integration ($\pm 3\%$).

We repeated Smid's procedure for the extraction of metal picrates to compare the binding efficiencies of both polymers with each of benzo-12-crown-4 and 12-crown-4 ether. Benzo-12-crown-4 was chosen over vinylbenzo-12-crown-4 because we felt that it would give a better indication of the extraction capabilities of the monomer, as vinylbenzo-12-crown-4 has an extended conjugation not found in the polymer.

In all cases polyvinylbenzo-12-crown-4 extracted the metal picrate with the highest efficiency (Figs. 3–5). At low concentrations, values for the copolymer were close but became

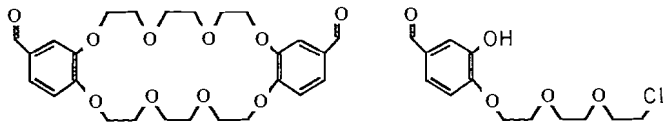

FIG. 2. Structures of the dimer and uncyclized monoadduct.

slightly lower as the concentrations increased. The values used to calculate the extraction efficiencies of the polymers are plotted as concentrations of crown ether units to concentration of picrate. If, however, the extraction efficiency was calculated on a basis of weight the homopolymer would be more efficient than the copolymer by an additional factor of 1.4, the ratio of molecular weight of repeating units. Both of the monomers were at least an order of magnitude less efficient than either of the polymers (Figs. 6–9). In all cases sodium extractions were the most efficient. This is consistent with the known stabilities of 12-crown-4 complexes (8). Lithium complexes of 12-crown-4 exhibit a 1:1 stoichiometry while analogous sodium complexes are 2:1. van Remoortere reported a complex of sodium chloride/12-crown-4 in which the sodium had a coordination number of eight binding to all eight crown ether oxygens (9). Potassium complexes are known to be less stable (8). Both of the polymers were also more than twice as effective when extracting potassium as when extracting lithium, supporting the idea of cooperative binding between adjacent crown ether moieties on the polymer chain. Of the monomers, benzo-12-crown-4 was the least effective. The benzo group increases the ridigity of the crown, thus reducing its binding capabilities relative to free 12-crown-4 ether.

Experimental

All ^{1}H NMR spectra were obtained on a Varian XL-200 200 MHz spectrometer using $CDCl_3$ as a solvent and TMS as an internal reference. ^{13}C NMR spectra were obtained at 50.3 MHz on a Varian XL 200 spectrometer using $CDCl_3$ as a solvent and TMS as an internal reference. The IR spectra were obtained on a Bomem Michelson-100 Fourier transform infrared spectrometer. The mass spectra were performed on a Finnigan VG 707E mass spectrometer.

3,4-Dihydroxybenzaldehyde was obtained from Aldrich. The ^{1}H NMR spectra indicated a high degree of impurity. Hence this material was recrystallized twice from three times its weight in water as suggested by Buck and Zimmerman (10), then judged to be pure by ^{1}H NMR; δ: 9.9 (1H, s, C*H*O), 8.7 (2H, s, O*H*), 7.4–6.9 (3H, m, aromatic *H*). ^{13}C NMR: 190.7 (*C*HO); 130.7, 115.9, 146.2, 152.1, 114.9, 125.3 (aromatic *C*) ppm.

slurry was dissolved in dichloromethane (500 mL). The water soluble salts were removed by filtration and subsequently washed with an additional 100 mL of dichloromethane. The combined organics were washed with HCl (1 M, 3 × 100 mL), water (3 × 100 mL), and saturated sodium chloride (1 × 100 mL), then dried over anhydrous sodium sulfate. The solvent was removed by evaporation at reduced pressure and the resultant black slurry was purified by column chromatography on silica gel (grade 923, 100–200 mesh) with 40% ethyl acetate in hexane as eluent. Three products, as well as starting material, were isolated. These were the desired product (recrystallized from ethyl acetate), its dimer, and the uncyclized mono adduct.

4′-Formylbenzo-12-crown-4: yield: 3.71 g, 14.72%; mp 81–82°C. IR: 1685.2 (CHO) cm^{-1}. ^1H NMR, δ: 9.84 (1H, s, C*H*O), 7.5–7.0 (3H, m, aromatic *H*), 4.38–3.79 (12H, m, CH_2). ^{13}C NMR: 190.6 (*C*HO); 156.5, 150.7, 131.1, 127.3, 118.2, 116.1 (aromatic *C*); 72.7, 71.3, 70.8, 70.7, 69.6, 69.4 (O-CH_2-CH_2-O). MS: M^+, 252; other peaks at 164, 149, 45. Anal. calcd. for $C_{13}H_{16}O_5$: C 61.90, H 6.39; found: C 61.66, H 6.64.

Dimer: yield: 0.63 g, 5.0%; mp 134–136°C. IR: 1685.2 (CHO) cm^{-1}. ^1H NMR, δ: 9.84 (1H, s, C*H*O), 7.5–7.0 (3H, m, aromatic *H*), 4.38–3.79 (12H, m, O-CH_2-CH_2-O). ^{13}C NMR: 190.8 (*C*HO); 154.1, 159.0, 130.1, 126.8, 111.7, 110.8 (aromatic *C*); 71.49, 71.40, 69.61, 69.44, 69.37, 69.30 (O-CH_2-CH_2-O). CIMS: M + 1, 505; other peaks at 149, 45.

Preparation of triphenylmethyl phosphonium bromide

The triphenylmethyl phosphonium bromide was prepared by the method outlined in Vogel (11). Yield: 44.98 g (98%); mp 231–233°C.

Preparation of 4′-vinylbenzo-12-crown-4

A dry 500-mL, three-necked round bottom flask, equipped with a magnetic stirrer, reflux condenser, and dropper funnel, was charged with 1,2-dimethoxyethane (60 mL) and triphenylmethyl phosphonium-bromide (6.32 g, 17.70 mmol). *n*-Butyllithium (1.6 M in hexane, 11.2 mL, 17.70 mmol) was added dropwise over a period of 10 min. The mixture turned orange and was stirred for an additional 90 min. 4′-Formylbenzo-12-crown-4 (2.98 g, 11.80 mmol) was dissolved in 100 mL of 1,2-dimethoxyethane and added dropwise over a period of 60 min. The resultant suspension was refluxed for 20 h, then cooled to room temperature. It was filtered and the filter cake was washed with ether (3 × 30 mL). The combined organics were washed with water (3 × 100 mL) followed by saturated sodium chloride (1 × 100 mL), then dried over anhydrous sodium sulfate and the solvent was removed by evaporation at reduced pressure. The resultant slurry was left at room temperature, causing triphenylphosphine oxide to crystallize out as colourless prisms. The remaining oil was purified by flash chromatography on silica gel (grade 923, 100–200 mesh) using 40% ethyl acetate in hexane as the solvent.

4′-Vinylbenzo-12-crown-4: yield 1.85 g, 62.6%. ^{13}C NMR, δ: 150.5 (C1′, C2′); 136.2 (vinyl methine); 132.5 (C4′); 121.1 (C5′);

117.7 (C6′); 115.7 (C3′); 112.5 (vinyl methylene); 71.8, 71.6, 70.8, 70.1, 69.7 (relative intensity 2) (OCH_2-CH_2O). CIMS: M + 1, 251 (100%); other peaks at 164, 149, 45.

Polymerization of 4′-vinylbenzo-12-crown-4

4′-Vinylbenzo-12-crown-4 (1.00 g, 4.0 mmol) and azobis(isobutyronitrile) (AIBN) (0.0051 g), a radical initiator, were dissolved in benzene (60 mL) and degassed using a high vacuum and four freeze–pump–thaw cycles. The ampoule was sealed under vacuum and heated to 70°C for 48 h. The solution was then slowly added to approximately 20 times its volume of petroleum ether and the white precipitate was filtered off. The polymer was reprecipitated once again and dried under vacuum. The polymer had an M_n of 3800 and a M_w of 5500 as determined by gel permeation chromatography. Yield: 96%; mp 115–133°C. ^{1}H NMR, δ: 6.62–6.11 (3H, aromatic *H*), 4.2–3.6 (12H, O-CH_2-CH_2-O), 1.16–2 (3H, benzylic *CH*, CH_2). ^{13}C NMR: 149.9, 148.2, 140.2, 128.3, 121.7, 117.9 (aromatic *C*); 71.6–69.8 (O-CH_2-CH_2-O); 40.2 (benzylic *CH*, CH_2).

The copolymer was also prepared by the same procedure using equimolar quantities of 4′-vinylbenzo-12-crown-4 and styrene with the same ratio of initiator. The polymer had an M_n of 2700 and a M_w of 3500 as determined by gel permeation chromatography. Yield: 92%; mp 118–134°C. ^{13}C NMR (APT), δ: 152.2, 149.4, 147.6–144.8, 142.5–139.6 (quaternary aromatic); 127.9, 125.6, 121.7, 118.8 (tertiary aromatic); 71.6–69.8 (O-CH_2-CH_2-O); 40.5–40.1 (benzylic *CH*, CH_2).

Extractions

A metal hydroxide solution (0.01 M) containing a small amount of picric acid (7×10^{-5} M) was vigorously shaken with an equal volume of methylene chloride solution of the crown ether. Molar ratios of 0, 1, 3, 5, 7, 10, 20, and 25 of crown ether to picrate were employed. The layers were separated and filtered to remove cloudiness. The concentration of picrate was determined by visible spectroscopy using the extinction coefficients reported by Pedersen (12) (λ_m 357 nm, ε 1.5×10^4 in water, and λ_m 378 nm, ε 1.8×10^4 in CH_2Cl_2). The results are shown in Figs. 3–9.

Using microwaves to carry out organic reactions does not significantly alter the product composition. The small changes in product composition that are observed when microwaves are used arise because the microwave reactions occur at higher temperatures than reflux reactions. The results demonstrate that ions in the reaction mixture alter the heating rate of the microwave reactions. Although scaling-up the reaction leads to a slightly lower rate of reaction (lower percentage yield), one still retains large rate enhancements.

Key words: microwave, synthesis, product composition, scale-up, ionic strength effects.

RICHARD N. GEDYE, WERNER RANK et KENNETH C. WESTAWAY. Can. J. Chem. **69**, 706 (1991).

L'utilisation de micro-ondes pour effectuer des réactions organiques ne modifie pas la composition des produits d'une façon importante. Les petits changements qui sont observés dans la composition des produits lorsqu'on utilise des micro-ondes proviennent du fait que les réactions effectuées sous l'influence de micro-ondes se produisent à des températures plus élevées que les réactions effectuées au reflux du solvant. Les résultats démontrent que les ions présents dans les milieux réactionnels influencent les taux de chauffage des réactions effectuées sous l'influence de micro-ondes. Les réactions sur de plus grandes quantités de substances condusient à des vitesses de réaction légèrement plus faibles (pourcentage de rendement inférieur); on observe toutefois des augmentations importantes des vitesses.

Mots clés : micro-onde, synthèse, composition des produits, reactions sur de plus grandes quantités, effets des ions.

[Traduit par la rédaction]

Introduction

Previous work has shown that organic reactions occur very much faster when carried out in sealed containers in a microwave oven than when they are done using conventional (reflux) techniques (1–4). In fact, rate enchancements of between 10 and 1200 were observed when a variety of organic reactions were carried out in sealed Teflon containers (2). However, it was not established whether the microwave technique only alters the rate of reaction or whether the microwaves influence the reaction pathways thereby leading to product compositions different from those obtained using conventional heating techniques. This issue is addressed in this report.

Results and discussion

Product composition in elimination–substitution reactions

The influence of microwave heating on product composition has been determined by examining the products from three different reactions. The first set of experiments studied the reactions of 1-bromooctane with (i) methoxide ion in methanol and (ii) with *tert*-butoxide ion in *tert*-butyl alcohol, eq. [1].

[1] $$CH_3(CH_2)_6CH_2Br + OR^- \longrightarrow CH_3(CH_2)_5CH{=}CH_2 + CH_3(CH_2)_6CH_2OR$$
$$(R = CH_3 \text{ and } (CH_3)_3C)$$

The ratios of the elimination/substitution products, expressed as the percent elimination product(s), obtained under normal reflux conditions were compared with those found when the reactions were done in a sealed Teflon container in the microwave oven.

The results in Table 1 indicate that neither reaction is affected significantly by a change in technique. Although more elimination product was obtained in the microwave oven experiments, the percent elimination in the methoxide ion reaction only changed from 2.4 to 4.4% when the reaction was carried out in the microwave oven rather than under reflux conditions.

[1]Authors to whom correspondence may be addressed.

TABLE 1. The product composition for the elimination–substitution reactions of 1-bromooctane and 2-bromooctane with alkoxide ion

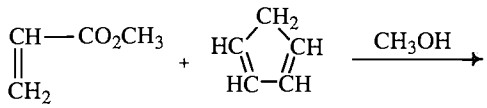
Substrate	Base/solvent	% Alkene (reflux)[a]	% Alkene (microwave)[b]
1-Bromooctane	CH_3O^-/CH_3OH	2.4±0.4	4.4±0.1
1-Bromooctane	t-BuO^-/t-BuOH	5.3±0.1	14±4
2-Bromooctane	CH_3O^-/CH_3OH	70±5	67±1
2-Bromooctane	t-BuO^-/t-BuOH	100	100

[a]All the reflux reactions were heated for 1 h.

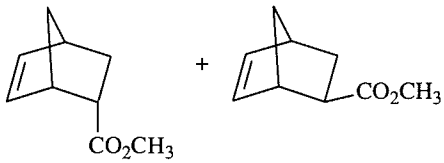
[b]The methoxide ion reactions were heated for between 45 s and 1.5 min at power level 7. The *tert*-butoxide ion reactions were heated for 10 min at power level 9.

The amount of elimination product was slightly higher when the base was changed from methoxide ion to *tert*-butoxide ion, Table 1. Again, changing the heating method did not markedly alter the amount of elimination product. The percent elimination increased from 5.3% under reflux conditions to 14% when the reaction was carried out in the microwave oven, i.e., the amount of substitution product only changes from 95% to 86%. Thus, from a synthetic point of view, the change in the product composition resulting from microwave irradiation is not significant.

This conclusion was corroborated by the product ratios from the reactions between 2-bromooctane and (i) methoxide ion in methanol and (ii) *tert*-butoxide ion in *tert*-butyl alcohol, eq. [2].



[2] $$CH_3(CH_2)_5CHBrCH_3 + OR^- \longrightarrow CH_3(CH_2)_5CH{=}CH_2 + CH_3(CH_2)_4CH{=}CHCH_3 + CH_3(CH_2)_5CHORCH_3$$
$$(R = CH_3 \text{ and } (CH_3)_3C)$$



Although the amount of elimination was much higher from the secondary bromide as expected (5), changing the heating method from the microwave to the reflux technique did not significantly alter the product composition, Table 1. In fact, within experimental error, the percent elimination from both reactions was identical for the two heating methods.

Product composition in a Diels–Alder reaction

The conclusion based on the elimination/substitution ratios was tested further by determining the product composition of a Diels–Alder cycloaddition reaction between cyclopentadiene and methyl acrylate, eq. [3].

[3] 

This particular Diels–Alder reaction was chosen because (i) it had been studied at several different temperatures by Berson *et al.* and (ii) it showed the greatest change in product composition with temperature (6). The product ratios obtained in this investigation and by Berson *et al.* are presented in Table 2. Since the only products were the *endo* and *exo* adducts, the product composition can be reported as the percent *endo* product. The product compositions reported by Berson *et al.* (6) are, within the experimental error of the method, identical to those found in this study.

Again, from a synthetic point of view, the product composition observed with the microwave method is not significantly different from that found when heating with the conventional technique. In fact, the *endo* product in the microwave experiment only differs by 6% from the reflux results reported by Berson *et al.* Furthermore, when the temperature effect is taken into consideration, the change in the product composition is even smaller. The pressures found when various volumes of methanol were heated in sealed Teflon reaction vessels in the microwave oven suggest that the reaction mixture would have been at a temperature of approximately 110°C (7). If one accepts this temperature for the Diels–Alder reaction in the microwave experiment, the product composition is almost exactly what would be expected. The plot of the temperature versus percent *endo* adduct reported by Berson *et al.* (6) is effectively linear between 0 and 60°C, Fig. 1. If one assumes the relationship remains linear to 110°C, the product composition should be approximately 80% *endo* at this temperature. Since the product from the microwave reaction is 79% *endo*, it appears that the change in product composition is due to the change in the reaction temperature rather than to any special effects of the microwaves on the reaction.

The small change in the product composition that is observed in these reactions would be expected if the microwave heating technique only causes the reaction to occur at a higher temperature in the sealed Teflon container. If one increases the temperature, one increases the rate constant for the formation of both products. However, if measurable amounts of two products are obtained from competing reactions, their rate constants, and probably their $\Delta H^{\neq}$ (enthalpy of activation) values, are comparable. Since the change in the rate constant with temperature depends on the $\Delta H^{\neq}$ values for the competing reactions (8), a temperature increase should have only a small effect on the composition of the product. In fact, the rate constant for the reaction with the higher $\Delta H^{\neq}$ (the slower reaction) will increase slightly more with an increase in temperature. As a result, the yield of the minor component should increase when the reaction temperature is increased. This is observed in the Diels–Alder reaction. The percent *endo*, the major product in the reaction, is lower when the reaction is done at the higher temperature in the microwave oven. The same trend is observed in the 1-bromooctane reactions (Table 1). The percent elimination, the minor product in the elimination–substitution reaction, is greater in the microwave reactions with both the methoxide ion and the *tert*-butoxide ion. Thus, the concentration of the minor product increases in these three reactions when the reaction temperature increases.

In contrast, the percent elimination does not increase when 2-bromooctane is reacted with methoxide ion in the microwave oven (Table 1). The elimination/substitution ratio is only 2.3:1 in this reaction. This suggests that the $\Delta H^{\neq}$ values for the elimination and the substitution reactions are almost equal. If this is the case, the product ratio should not change noticeably with a change in reaction temperature.

The results of these investigations, although not exciting from a synthetic point of view, are important because they confirm that the microwaves do not alter the reaction but simply provide a much faster and more efficient (higher temperature) method of carrying out organic reactions. The changes in

product composition caused by the higher temperatures in the microwave oven are small because the $\Delta H^{\neq}$'s of the two competing reactions are undoubtedly close.

It is possible, however, that microwave reactions could have different products from reactions done using the conventional reflux technique. Since microwave heating markedly increases the reaction temperature, it is possible that the microwave reaction temperature could exceed the temperature (activation energy) required for a new reaction that was not possible at the lower reflux temperature. If this were the case, different products could be obtained in the microwave and the conventional reactions. In these instances, however, the amount of the new product should be small.

In fact, one instance of this phenomenon may have been found. Lubec *et al.* (9) reported that a small amount of the amino acids *trans*-3- and *trans*-4-hydroxyproline isomerize to the corresponding *cis* isomers when they are heated in a microwave oven. This isomerization does not occur when these *trans* amino acids are heated using conventional techniques. Although the reaction conditions for this experiment were not clear, the isomerization could have occurred because a higher reaction temperature was reached in the microwave oven. In any case, it is important to note that microwave heating would not be expected to change the product composition significantly from a synthetic point of view.

The effect of ions on the heating rate of microwave reactions

We have also discovered that adding ionic compounds, or compounds that generate ions in solution, affects the heating rates in microwave reactions. For example, adding sulfuric acid, sodium hydroxide, or sodium chloride to a reaction mixture leads to an increased heating rate relative to that found for solvent alone, Fig. 2. The faster heating rate found for ionic solutions is presumably observed because a new heating mechanism, ionic conductance, is added to the normal (dielectric) heating mechanism (10).

In addition, the change in the heating rate with a change in volume is different for the solvent alone and when the solvent contains ions. In water, the maximum heating rate is found when 15 mL of water is in the sealed Teflon reaction vessel (2). However, when ions are present in the reaction mixture, the maximum heating rate is observed when the reaction volume is 5 mL, the smallest volume investigated, Figs. 3 and 4. Ions in a solution increase the absorption of microwave energy through ionic conductance (10). If one assumes that an ionic solution absorbs all, or almost all, of the microwave energy, larger volumes heat up more slowly because the same amount of microwave energy heats a larger number of molecules.

The discovery that ions affect the heating rates obviously has implications when planning a microwave reaction. Since the heating rate is greater when ions are present, the maximum safe pressure may be reached much faster than one would expect from the heating profile of the solvent alone. To avoid the possibility of an explosion (2), it is important to know the heating characteristics of the reaction mixture before one begins an experiment.

Scaling-up microwave reactions

We have also explored scaling-up the microwave reactions. The approach has involved heating larger volumes of reaction mixtures in sealed Teflon containers connected to a pressure gauge. In these experiments the reaction mixture was heated at maximum power (750 watts) until the pressure reached approximately 70 psi, the maximum pressure that was considered to be

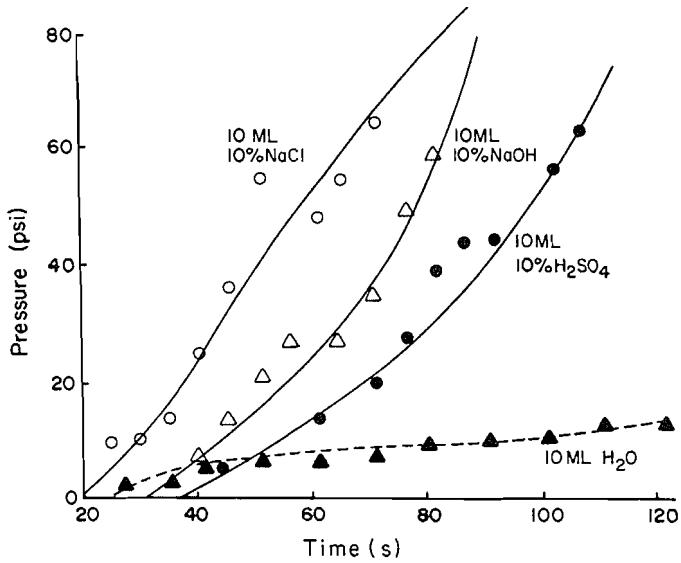

FIG. 2. The effect of the presence of ions in solution on the microwave heating rate in a 150-mL Savillex vessel.

safe (1 psi = 6.9 kPa). Then, the power setting was reduced to 2 or 3 (153 or 234 W) so that the pressure did not exceed a safe level. An alternative and equivalent programming technique is to operate the magnetron at full power for short periods to keep the pressure in the Teflon reaction vessel between 60 and 70 psi. Either programming technique allows the preparation of larger quantities of compounds while retaining the short reaction times and reducing the danger of an explosion.

Three reactions were investigated in the scaling-up experiments. These reactions were chosen because (i) they were relatively slow and (ii) the programming technique might be useful in driving them to completion. Two of the reactions, the hydrolysis of *N*-phenylbenzamide in 20% sulfuric acid, and the acid-catalyzed esterification of benzoic acid with 2-butanol, had ions in the reaction mixture. The third reaction, the hydrolysis of benzyl chloride, was done in water containing no ions.

Reactions with ions in the reaction mixture

In the acid-catalyzed hydrolysis of *N*-phenylbenzamide and in the acid-catalyzed esterification of benzoic acid, the yield obtained after identical reaction times (the rate of reaction), decreased as the reaction was scaled-up, Table 3. The percent yield decreased from 69 to 35% when the reaction volume was increased from 5 to 25 mL in the 8-min *N*-phenylbenzamide hydrolyses. This observation was confirmed by the fact that the yield (reaction rate) in the 16-min, 25-mL *N*-phenylbenzamide hydrolysis was lower than the yield in the 12-min, 10-mL hydrolysis reaction.

A similar trend was observed in the 8-min esterification reactions. The yield (rate) decreased from 53 to 42% when the reaction volume was increased from 10 to 30 mL. This decreased yield with increasing reaction volume is consistent with the heating rates observed when ions are present in solution, i.e., the greatest heating rate and fastest reaction (highest yield) were observed with the smallest (5 mL) reaction volume, Figs. 3 and 4.

It is important to note that although the rate of reaction decreased when the reactions were scaled-up, high rate enhancements were still observed. Rate enhancements of between 36 and 90 were observed in the scaled-up esterification and hydrolysis reactions.

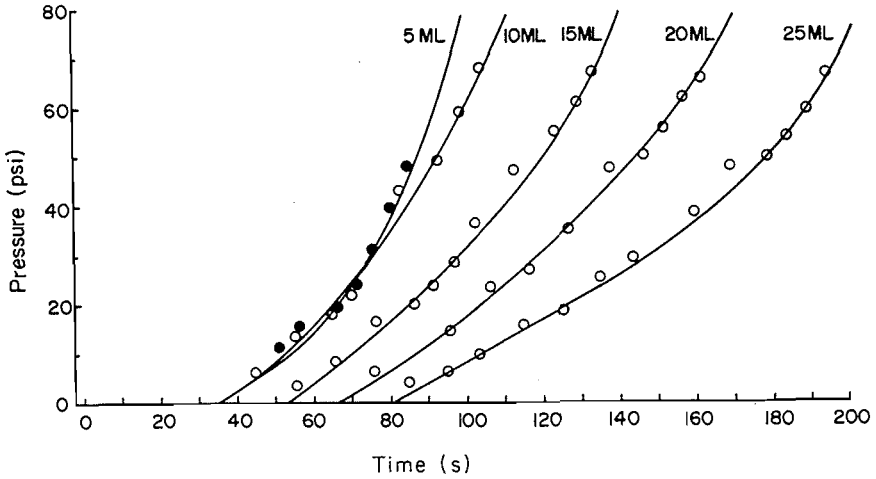

FIG. 3. Heating rates for various volumes of 10% sulfuric acid in a 150-mL Savillex vessel at 560 W in a microwave oven.

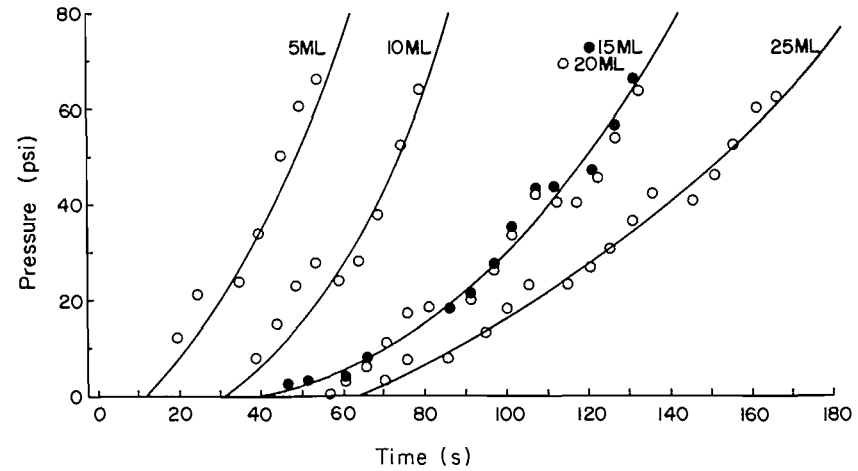

FIG. 4. Heating rates for various volumes of 10% sodium hydroxide in a 150-mL Savillex vessel at 560 W in a microwave oven.

TABLE 3. The reaction times, yields, and rate enhancements for different microwave reactions with programming

Weight reactant (g) / Volume solvent (mL)	Reaction time (min)	Yield (%)	Rate enhancement
Hydrolysis of *N*-phenylbenzamide			
0.5/5	8.0	69	—
1.0/10	8.0	47	—
2.5/25	8.0	35	—
1.0/10	12.0	74	90
2.5/25	16.0	52	68
Esterification of benzoic acid with 2-butanol			
1.3/10	8.0	53	—
2.6/20	8.0	49	36
3.9/30	8.0	42	—
3.9/30	30.0	70	—

Finally, programming was shown to be effective in increasing the yield. The yield in the *N*-phenylbenzamide hydrolysis reactions increased from 47 to 74% when the reaction time was increased from 8 to 12 min in the 10-mL experiments, and from 35 to 52% when the reaction time was increased from 8 to 16 min in the 25-mL experiments. Similarly, the yield increased from 42 to 70% in the esterification reaction when the reaction time was increased from 8 to 30 min in the 30-mL (the slowest) reaction.

Reactions with no ions in the reaction mixture

In the benzyl chloride hydrolysis in the absence of ions, the rate of reaction parallels the heating rate of the pure solvent, Table 4. The rate (yield/min) increases from 17%/min in the 3.0-min, 10-mL reaction to a maximum of 45%/min in the 2.0-min, 15-mL reaction. Then, the rate decreases slowly to a low of 9%/min as the reaction volume is increased to 50 mL. Thus the reaction rate is a maximum when the reaction volume is 15 mL, the volume of water for which the maximum heating rate was observed (2). This conclusion is confirmed by the fact that the rate enhancement and the heating rate (the time for the reaction mixture to reach a pressure of 60 psi is a minimum) are a maximum when the reaction volume is 15 mL.

Again, significant rate enhancements are observed at all

3.5/50	5.0	44	—	106

reaction volumes when programming is used in microwave reactions. The rate enhancements range from 8 to 20 depending on the reaction volume.

Finally, it is worth noting that the amount of product is actually greater in the scaled-up experiments even though the reaction rate (percentage yield) decreases when the reactions are scaled-up. For example, a 44% yield of benzyl alcohol in a 50-mL benzyl chloride hydrolysis reaction corresponds to 1.32 g whereas a 95% yield in a 20-mL reaction is only 0.82 g.

Conclusion

This study has shown that microwaves do not significantly alter the product composition of a reaction. Rather, small changes in product composition arise because microwave reactions occur at higher temperatures than reflux reactions.

The presence of ions in the reaction mixture increases the heating rate of microwave reactions. Also when ions are present in solution, the maximum heating rate is observed at the smallest volume rather than at the intermediate (specific) volumes found for the solvent alone. Scaling-up the reaction leads to a slightly slower reaction rate and a lower percentage yield of product after the same reaction time. However, scaling-up is useful from a synthetic point of view because the larger reactions yield more product even though the percent yield is lower. Although the reaction rate is reduced when the reactions are scaled-up, large rate enhancements are still observed.

Experimental

Apparatus

The microwave oven used for this study was a domestic Toshiba model ER-8000 BTC with nine power settings, starting at 72 W and increasing by 81-W increments to 720 W. Unless otherwise stated, microwave reactions were carried out in 150-mL PFA Teflon containers manufactured by the Savillex Corporation (11).

Product analysis

The nmr spectra were recorded on a Varian T-60 nmr spectrometer. The ir spectra were recorded using sodium chloride discs on a Beckman Acculab I double beam spectrophotometer. The product compositions were determined with a Varian Aerograph model 90-P-3 gas chromatograph and a Varian CDS 111 integrator. A 3 m × 3 mm stainless steel column containing 7% SE-30 on 80/100 Chromosorb W was used at 124°C and a helium flow rate of 50 mL/min to determine the elimination–substitution product ratios. A 2 m × 3 mm Carbowax 1500 column was used at 105°C and a helium flow rate of 85 mL/min to determine the *endo*/*exo* ratio in the Diels–Alder reaction. The product ratios are the average of at least three analyses of the same reaction.

Pressure measurements

Pressure measurements were carried out by connecting the cap of a 150-mL Savillex Teflon bottle to a pressure gauge outside the microwave oven. The bottle was connected to the Union Carbide, 0–100 psi, pressure gauge by a 1/4 in. to 1/8 in. Swagelok reducing adapter, a 1/8 in. Teflon tube that passed through a small hole drilled in the back of the oven, and a Swagelok fitting. The pressure was recorded at regular intervals (usually every 30 s) for the duration of the heating period.

Safety precautions

Increasing the volume of the reaction mixture causes an increase in pressure and temperature that can lead to deformation and (or) explosion of the Teflon vessel. To ensure a safe experiment, one should either monitor the pressure and reduce the power level to maintain the pressure at a safe value, or keep the reaction time very short and the reaction volume to 10% of the volume of the container. When volatile solvents are used in sealed reaction vessels, power levels of greater than 560 W should be avoided, except for very short periods of time. Experiments in microwave ovens should be carried out in a fumehood.

Rate enhancements

The rate enhancement for comparable microwave and conventionally heated reactions, using identical concentrations of reactants, were calculated in the following manner:

$$\text{Rate enhancement} = (\text{conventional reaction time}/\text{microwave reaction time})$$

where the conventional reaction time and the microwave reaction time are for reactions taken to the same extent of completion.

Elimination–substitution reactions

General procedure

All of these reactions were carried out (a) under reflux conditions and (b) under microwave conditions using 1- or 2-bromooctane (1.0 g, 5 mmol) and 10.0 mL of 2 M sodium methoxide in methanol or 10.0 mL of 2 M sodium *tert*-butoxide in *tert*-butyl alcohol.

The reflux reactions were carried out for 1 h, whereas the heating conditions, i.e., the time and power level, for the microwave reactions varied because of the different volatilities and heating rates of the solvents. For example, the microwave reactions in methanol took much less time than those in *tert*-butyl alcohol because methanol absorbs microwave energy much more rapidly than *tert*-butyl alcohol.

In the microwave oven reactions, the reactants were mixed in the Teflon vessel, and the sealed vessel was placed in the microwave oven and heated at the appropriate power level for the specified time. The reaction vessel was left for 2 min to reduce the pressure. Then the vessel was removed from the oven and cooled in ice-water for 5 min. Water was added to the cooled reaction mixture and the products were extracted with ether. The combined ether layers were dried over anhydrous $MgSO_4$ and the ether solution was filtered and evaporated. These products were analysed by ir, and glc, and, in some cases, nmr. The spectroscopic and glc data for each reaction are as follows.

Reaction of 1-bromooctane with sodium methoxide in methanol

(a) Under reflux conditions: ir ν: 2970–2930, 1450 and 1115 (ether) cm^{-1}; nmr δ: 0.60 (t, 3H, $-CH_2CH_3$), 0.80–1.10 (m, 12H, $-CH_2-$), 2.80 (s, 3H, $-OCH_3$) overlapping with 2.90 (t, 2H, $-OCH_2-$) ppm; glc: 2 product peaks, retention times 2.0 min (2.4%, alkene) and 5.0 min (97.6%, ether).

(b) Under microwave conditions: This reaction was carried out in a 300-mL Berghof Teflon bottle for 1.5 min at power level 7 (560 W). The ir and nmr spectra of the products were identical to those from the reflux reaction; glc: 2 product peaks, retention times 2.0 min (4.4%, alkene) and 5.1 min (95.6%, ether).

Reaction of 1-bromooctane with sodium tert*-butoxide in* tert*-butyl alcohol*

(a) Under reflux conditions: ir ν: 3000–2880, 1465, 1360, 1200 (ether), and 910 (alkene, $=CH_2$) cm^{-1}; nmr δ: 0.62 (t, 3H, $-CH_2CH_3$), 0.98 (s, 9H, $-C(CH_3)_3$) superimposed on 0.95–1.03 (m, 10H, $-CH_2-$),

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

2.88 (t, 2H, -OCH_2-) ppm; glc: 2 product peaks, retention times 1.9 min (5.3%, alkene) and 10.0 min (94.7%, ether).

(b) Under microwave conditions: The reaction time was 10 min at power level 9 (720 W). The ir and nmr spectra of the product were identical to those found in the reflux reaction; glc: 2 product peaks, retention times 1.9 min (14%, alkene) and 9.8 min (86%, ether).

Reaction of 2-bromooctane with sodium methoxide in methanol

(a) Under reflux conditions: ir ν: 2960–2860, 1430, 1370, 1180 (ether), 960 (*trans* alkene), and 910 (alkene, $=CH_2$) cm^{-1}; glc: 2 product peaks, retention times 2.25 min (70%, alkene) and 4.29 min (30%, ether).

(b) Under microwave conditions: Reaction times varied between 45 s and 1 min at power level 7 (560 W). The ir spectrum of the product was identical to that found for the reflux reaction; glc: 2 product peaks, retention times 2.24 min (67%, alkene) and 4.23 min (33%, ether).

Reaction of 2-bromooctane with sodium tert*-butoxide in* tert*-butyl alcohol*

(a) Under reflux conditions: ir ν: 2980–2880, 1460, 1375, and 910 (alkene, $=CH_2$) cm^{-1}; glc: 1 product peak, retention time 2.19 min (100%, alkene).

(b) Under microwave conditions: The reaction time was 10 min at power level 9 (720 W). The ir spectrum of the product was identical to that found for the reflux reaction; glc: 1 product peak, retention time 2.15 min (100%, alkene).

Diels–Alder reaction of cyclopentadiene with methyl acrylate

(a) Conventional method

A mixture of methyl acrylate (1.0 mL) and freshly distilled cyclopentadiene (1.0 mL) in methanol (7.5 mL) was allowed to react at 0°C. Aliquots were removed at regular intervals over a 67 h period and analysed by glc to determine the product ratio of the *endo* and *exo* isomers. This procedure was repeated at 21°C.

(b) Microwave method

A mixture of methyl acrylate (1.0 mL) and freshly distilled cyclopentadiene (1.0 mL) in methanol (7.5 mL) was placed in a 150-mL Savillex Teflon vessel. The sealed vessel was heated in the microwave oven for 2.5 min at power level 7 (560 W). The vessel was allowed to stand for 30 s and then cooled in an ice-bath. The product was analysed by glc.

Hydrolysis of benzyl chloride

The specified amounts of benzyl chloride and water were mixed in a 150-mL Savillex Teflon vessel. The sealed vessel was placed in the microwave oven, connected to a pressure gauge outside the oven (see pressure measurements), and heated at full power (750 W) until the pressure reached 70 psi. The pressure was then maintained at 60–70 psi by operating the magnetron for short periods of time at the maximum power (750 W). After heating for the specified time, the vessel was left for 2 min to reduce the pressure and then removed from the oven and cooled in ice-water. Water (25 mL) was added to the product and the mixture extracted with three 20-mL portions of ether.

The yield of benzyl alcohol was determined by titrating the chloride ion in the aqueous phase with 0.10 M $AgNO_3$ using sodium chromate (0.125 M) as an indicator (12).

Hydrolysis of N*-phenylbenzamide*

The specified amounts of *N*-phenylbenzamide and a 20% H_2SO_4 solution were mixed in the 150-mL Teflon vessel, and heated for the specified time in the microwave oven using the method described in the previous experiment. After cooling, the reaction mixture was made basic with 20% sodium carbonate and the aniline and unchanged amide extracted with three 20-mL portions of chloroform. The aqueous layer was acidified with 20% H_2SO_4 and the benzoic acid extracted with three 20-mL portions of ether. The ether extracts were dried over anhydrous $MgSO_4$ and the benzoic acid isolated by evaporation of the ether.

Esterification of benzoic acid with 2-butanol

A mixture of the specified amounts of benzoic acid, 2-butanol, and 10 drops of concentrated H_2SO_4 per 10 mL of 2-butanol was mixed in a 150-mL Teflon vessel and heated for the specified time in the microwave oven using the method described above. After cooling, the mixture was made basic with 20% Na_2CO_3 and the ester extracted with three 20-mL portions of ether. The aqueous layer was acidified with 20% H_2SO_4 and the unreacted benzoic acid extracted with ether. Both ether extracts were dried over anhydrous $MgSO_4$ and the ester and benzoic acid isolated by evaporation of the ether.

Synthetic studies towards bruceantin. Part 1. Establishment of the carbon network

SULTAN DARVESH, ANDREW S. GRANT, DAVID I. MAGEE, AND ZDENEK VALENTA[1]
Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received September 20, 1990

SULTAN DARVESH, ANDREW S. GRANT, DAVID I. MAGEE, and ZDENEK VALENTA. Can. J. Chem. **69**, 712 (1991).

In a synthetic approach to the biologically active quassinoid bruceantin **1**, intermediate **47** was prepared, which contains all required C-atoms, rings A and B, and four of the 10 chiral centers of bruceantin. The possibilities for a convergent strategy were explored, in which a 5-carbon unit would be joined to a 15-carbon unit by three bonds. After the study of various alkylations and Michael additions needed for the key step, it was found that 3-iodo-1-trimethylsilyl-5-hexenyne **44** adds to the dianion of methyl ketone nitriles **3** and **13** chemo-, diastereo-, and enantioselectively.

Key words: bruceantin, quassinoids, alkylation, Michael addition.

SULTAN DARVESH, ANDREW S. GRANT, DAVID I. MAGEE et ZDENEK VALENTA. Can. J. Chem. **69**, 712 (1991).

Dans une approche à la synthèse de la quassinoïde brucéantine (**1**) biologiquement active, on a préparé l'intermédiaire **47** qui contient tous les atomes de carbone requis, les cycles A et B ainsi que quatre des 10 centres chiraux de la brucéantine. On a exploré les possibilités de stratégie convergente dans lesquelles une unité de cinq atomes de carbone serait reliée à une unité de 15 atomes de carbone par trois liaisons. Après avoir étudié diverses alkylations et additions de Michael requises pour l'étape clé, on a trouvé que le 3-iodo-1-triméthylsilyl-hexén-5-yne (**44**) s'additionne aux dianions des méthylcétone-nitriles **3** et **13** d'une façon chémo-, diastéréo- et énantio-sélective.

Mots clés : brucéantine, quassinoïdes, alkylation, addition de Michael.

The last two decades have seen the *Simaroubaceae* family of the plant kingdom make a prominent mark in natural product chemistry. The bitter substances produced in plants of this family, known as the quassinoids (1, 2), have received increased attention with the finding that some of them possess strong antileukemic activity in the murine lymphocytic leukemia P-388 test system, in addition to antimalarial, amebicidal, and antiviral activities.

The wealth of information gathered in the last two decades has shown what structural features are required for the antineoplastic activity exhibited by the quassinoids (3). An A-ring enone function, a C6 or a C15 ester function, and an oxymethylene bridge between C8 and C11 or C13 are essential for optimal activity. Due to this functional and stereochemical complexity, coupled with the potential use in cancer and other therapies, a considerable amount of synthetic activity has been expended towards these compounds (4). Four tetracyclic members of the C20 picrasane family have been synthesized, all in racemic form (5), and just recently an enantioselective synthesis has been reported for three others (4*a*). Finally, the synthesis of racemic 15-deoxybruceolide and a relay conversion of the naturally derived (−)-form of this compound into (−)-bruceantin **1** have been reported (4*h*). From the scarcity of completed syntheses, it is evident that much work is still required in this area, especially on the design of an efficient general synthesis. We wish to report in full our work on the synthesis of the natural quassinoid bruceantin **1**.

Bruceantin contains 10 asymmetric carbon atoms, of which six are at the junctions of the three carbon rings and the lactone ring. Our strategy, therefore, consisted first of the formation of the skeleton with the proper relative stereochemistry, followed by the subsequent incorporation of the functional groups with the desired configuration (Scheme 1). It appeared to us that disconnection at the lactone ether oxygen, at C8 and at C12, would present two "relatively simple" halves. This convergent strategy, we felt, held great promise since the connection of these two halves could be achieved in any one of several possible sequences (Fig. 1, where the three arrows point towards the potential electrophilic centers).

SCHEME 1

Results and discussion

Our synthetic route to bicyclic ketone **3**, depicted in Scheme 2, was initiated by the reaction of 2-methyl-1,3-cyclohexane dione with ethyl vinyl ketone under basic conditions to yield the Michael adduct **7**. This compound was then directly subjected,

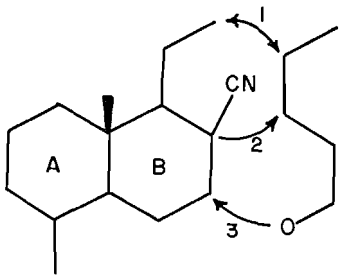

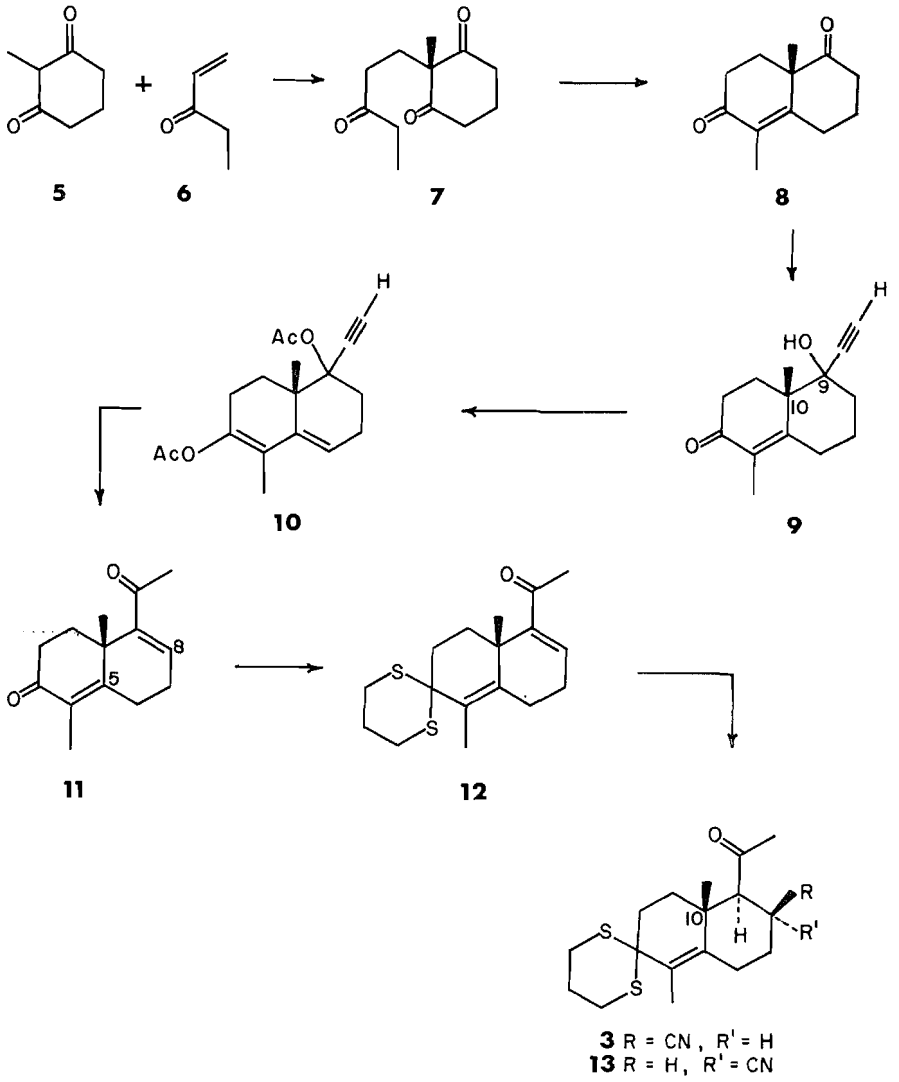

FIG. 1. Potential connecting points of the "two halves" for the synthesis of bruceantin.

without any purification, to pyrrolidine in refluxing benzene with azeotropic removal of water to furnish the enedione **8** in 67% overall yield (6). Ethynylation of **8** with lithium acetylide in liquid ammonia (*7a*) at −78°C proceeded smoothly and regioselectively to furnish the carbinol **9** in 71% yield. Treatment with acetic anhydride and a catalytic amount of *p*-toluenesulfonic acid (pTSA) (*7a*) resulted in clean conversion to the diacetate **10** in 94% yield. As Newman *et al.* (*7a*) found in a similar case, the transformation of the ethynyl carbinol to the diacetate became necessary due to the juxtaposition of the enone and the hydroxyl group in **9**. The acidic conditions and high temperatures required to produce the α,β-unsaturated acetyl group of **11** led to considerable destruction of the starting material when the direct **9** → **11** conversion was attempted. This was undoubtedly due to a reverse aldol process, which fragmented the C9—C10 bond. With the tertiary alcohol now protected, the Rupe rearrangement (*7a*, *7b*) proceeded as expected on treatment with refluxing formic acid (90%) for 2 h to produce the diene dione **11** in 70% yield as a crystalline solid. The remaining task was the installation of the nitrile at C8. We assumed that a regioselective hydrocyanation could be accomplished since C8 could be expected to be much less hindered than the corresponding C5 position. However, the best conditions found, sodium cyanide in dimethyl formamide (DMF) in the presence of sodium bicarbonate, led to a 1:1 mixture of regioisomers, and in only 40% conversion. To circumvent this problem, diene dione **11** was first treated with 1,3-propane dithiol and $BF_3 \cdot OEt_2$ in Et_2O to produce the protected enone **12** in 72% yield. Compound **12** then smoothly reacted with aqueous potassium cyanide in ammonium chloride buffered DMF to produce the epimeric nitriles **3** and **13** in a combined yield of 77%. The

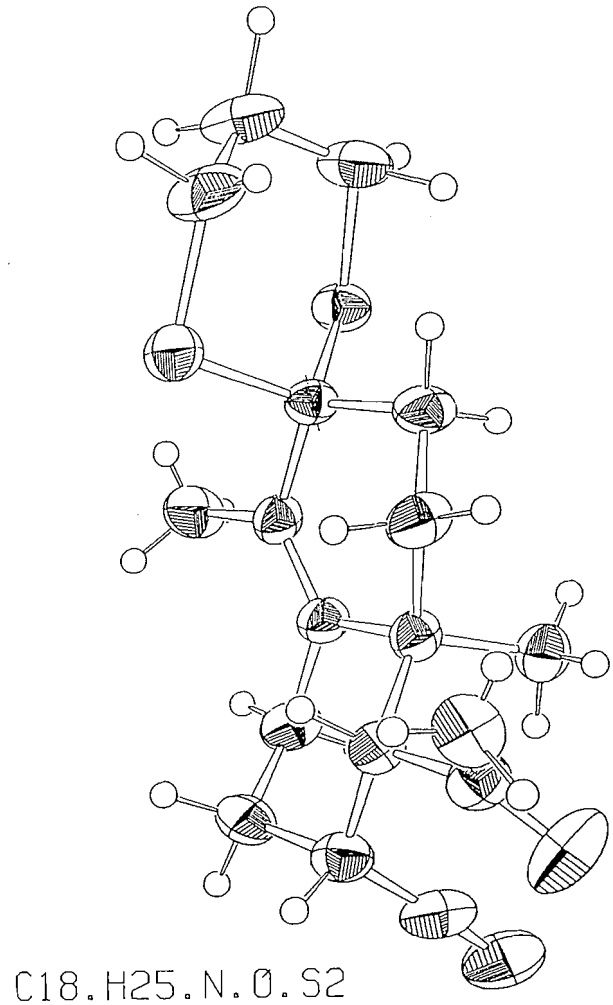

FIG. 2. X-ray structure of nitrile **3**.

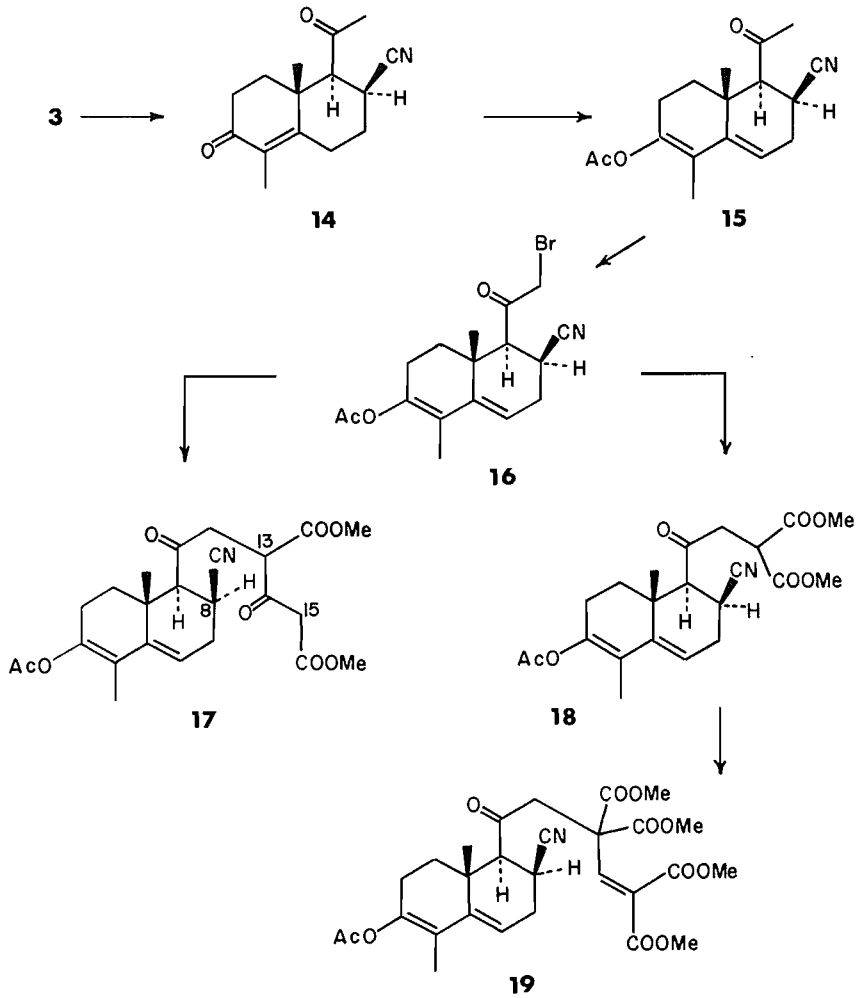
typical ratio of nitriles was 5:1 in favor of **3**; however, there were instances when the other epimer predominated. The reasons for this variability are unclear.

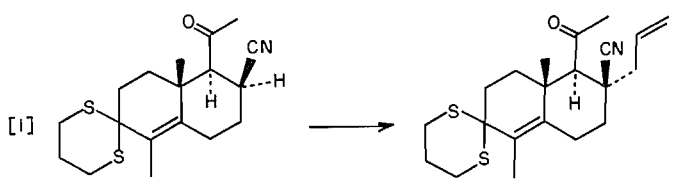


The structures of **3** and **13** were initially assigned as shown on ^{1}H NMR evidence. Epimer **3** showed a singlet at δ 1.47 for the C10 methyl group, while in **13** it appeared at δ 1.10. The difference in chemical shift was attributed to the fact that the C10 methyl group in **3** was deshielded by the nitrile. This assignment was later substantiated by single crystal X-ray crystallography (Fig. 2). From Fig. 2, it can be seen that the nitrile is in a quasi-axial position, while the acetyl group occupies the equatorial position. It was assumed, and later shown by chemical transformation, that both the acetyl group and the nitrile were equatorially disposed in nitrile **13**.

The next objective was to attach a suitable side chain, which would contain the remaining carbons required for the construction of the skeleton of bruceantin. Based on previous work done in these laboratories on the synthesis of 14β-hydroxysteroids (8), it was assumed that the best assembly sequence would be to form the C12—C13 bond first, followed by the C8—C14 bond (Fig. 1, arrows 1 and 2). In particular, this approach was expected to provide the desired stereochemistry at the quaternary C8 carbon.

Investigation of this strategy (Scheme 3) began by treating nitrile **3** with *N*-chlorosuccinimide and silver carbonate in aqueous acetonitrile (9) to give enone **14** in 80% yield. This was then simply protected as its dienol acetate **15** by treatment with acetic anhydride and a catalytic amount of hydrobromic acid (87% yield). Complete chemoselective bromination of C12 was accomplished with phenyl trimethyl ammonium perbromide (10) in tetrahydrofuran (THF) to give the unstable bromo ketone **16**. This bromo derivative became the pivotal point of further investigations in which C12 was used as an electrophilic center. Due to the instability of this compound, it was always used immediately after preparation. Bromide **16** was treated with the sodium salt of dimethyl acetone dicarboxylate to furnish diester **17** in 52% overall yield. Theoretically, this product could exist in eight different forms: the two diastereoisomers at C13, two geometrical isomers of the enol towards C12, and four isomers of the enol towards C15 (*E*/*Z* and diastereoisomers at C13). Three of these eight possible states were observed in the 200 MHz NMR spectrum, with the ratio of keto:enol forms being approximately 3:2. All the carbons required for the bruceantin skeleton were now present, and an aldol reaction between C8 and C14 would deliver the last crucial bond.

Before this aldol reaction could be accomplished, however, an obvious acidity problem had to be overcome. It was assumed that extending conjugation into ring B would give the C8 hydrogen an acidity comparable to those of H-atoms in the side chain. To meet this objective, direct bromination, via a variety of methods, was attempted on dienol acetate **17**, but only significant loss of starting material with no detection of the desired product was observed in all cases. These problems were attributed to the presumed high reactivity of the enol groups present in the side chain. All attempts to overcome these difficulties by conversion into a β-haloglutaconate or an enol acetate failed. Thus, unfortunately, compound **17** had to be discarded as a potential synthetic intermediate, in spite of its initially highly promising distribution of functional groups.

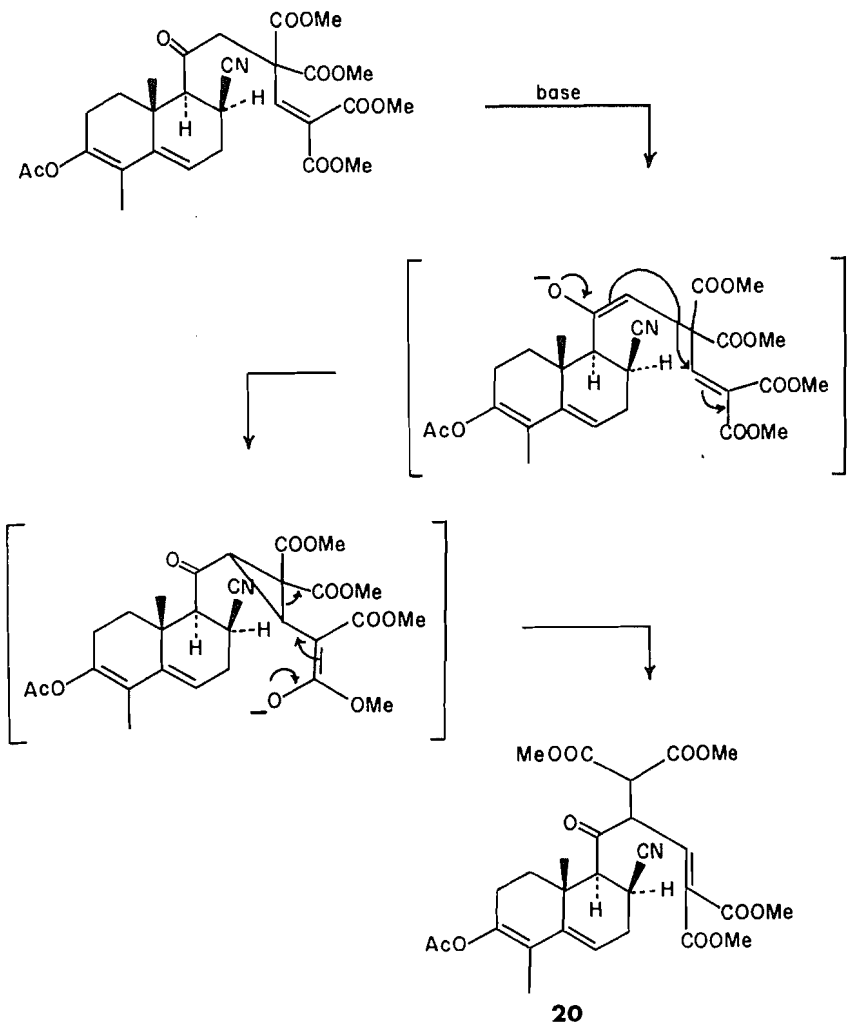


It was next attempted to remove the problem by incorporating a side chain that contained no acidic protons. Direct conversion of bromo acetate **16** to the malonyl adduct **18** proceeded uneventfully in 68% yield upon treatment with the sodium salt of dimethyl malonate. The sodium enolate of **18** was then quenched with chloromethylene malonate to yield the tetraester **19** in 75% yield. This compound now contained only the acidic protons at C9, C12, and C8, none in the added side chain. However, when tetraester **19** was treated with sodium hydroxide in the UV tube, it exhibited an unusual bathochromic shift to 400 nm. After inspection of the ^{1}H NMR spectrum, this shift was attributed to the rearranged product **20** (Scheme 4), presumably formed by addition of the C12 anion to the reactive Michael acceptor to form a cyclopropane intermediate, which subsequently reopened to give the more stable malonyl anion. It was also found that, in previous reactions, significant amounts of rearrangement product **20** were formed when, for the preparation of **19**, excess sodium hydride was used in the initial anion formation of **18**. All attempts to alleviate this problem failed; these included reduction of the C11 ketone with sodium borohydride, L-Selectride, or lithium borohydride and the extension of ring-A conjugation via bromination/dehydrobromination or selenation/elimination. However, when malonyl adduct **18** was treated with phenyl selenenyl chloride in benzene in the presence of silver trifluoroacetate (11), selenide **21** was produced in 70% yield as a single isomer (Scheme 5), the stereochemistry of which was not determined. Selenide **21** was then transformed into the tetraester **22** as before in a moderate 47% yield. Oxidation with *m*-chloroperbenzoic acid in methylene chloride then led, unfortunately, to the tertiary allylic alcohol **23** in 80% yield

SCHEME 3

via the [2,3]-sigmatropic rearrangement of the selenoxide (12). Clearly, the presence of the C3 keto group did not usefully slow down the allylic selenoxide rearrangement. Even though this rearrangement is an equilibrium reaction, prolonged treatment had no effect on the product distribution.

It now became clear that an efficient continuation of the synthesis required that the five additional carbon atoms and the method for joining them be kept relatively simple. While investigating other avenues, we became intrigued with the following serendipitous result; treatment of **3** with five equivalents of lithium diisopropyl amide in THF at −78°C, followed by excess allyl bromide, gave **24** as the sole product in 88% yield (eq. [1]).



3 **24**

While it was not surprising that the alkylating agent approached the molecule at C8 exclusively from the α-face, it was indeed surprising that no alkylation was observed at the enolate carbon since we were undoubtedly dealing with a dianion. It must be assumed that the enolate anion alkylates very slowly, if at all, after the first alkylation occurs.

Utilization of this chemistry began with investigating the coupling of the dianion with several functionalized Michael acceptors (Table 1). Although two new asymmetric centers were created (three in the case of **33**, entry i), only one was of particular concern, C8; the C14 stereochemistry could be adjusted at a later stage. Several results listed in Table 1 are noteworthy. The reaction with ethylene malonate (entry a) gave the same chemo- and stereoselectivity at C8 as was observed for the alkylation with allyl bromide, but in poorer yield. Compound **26**, which was designed to incorporate the added oxygen functionality required in bruceantin, failed badly, even though it did give a product with the correct C8 stereochemistry. We concluded that the isopropylidene moiety of **26** was experiencing severe steric interactions with the decalin system, and that appropriate changes would overcome this. As seen in entry c, changing to an acetylene moiety did indeed improve the yield drastically; unfortunately, it also had a deleterious effect on the chemo- and stereoselectivity. The reason for the marked difference in reaction course is not at all evident, especially considering the fact that no reaction was observed for the di-*tert*-butyl derivative **28** (entry d). Other simple Michael acceptors were tried (entries e–h) but either no reaction or complex mixtures were obtained. The most interesting result was that with α-bromocrotonolactone (entry i). A single isomer was obtained in a reaction in which two new chiral centers were created by the Michael addition and a third one by enolate protonation. In

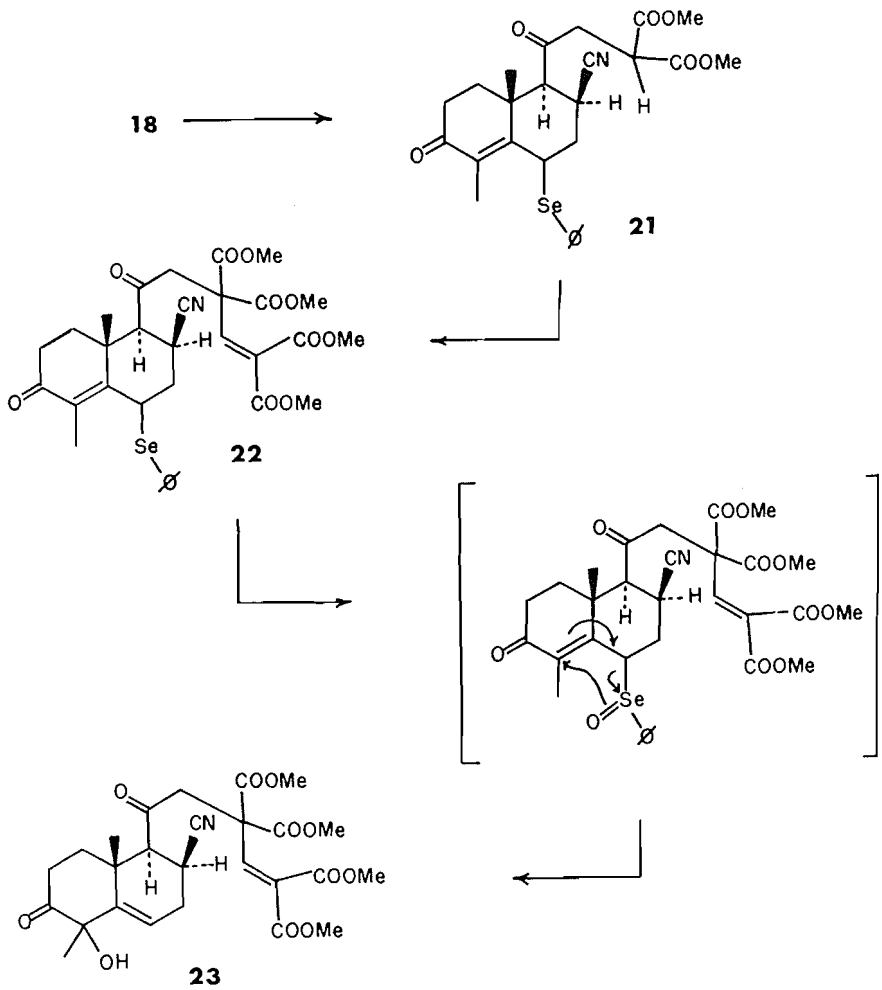
20

SCHEME 4

general, diastereoselective Michael reactions, in which two new chiral centers are generated, are not common. Reported cases include enamine and enolate additions to nitroolefins (13, 14).

The discouraging yields and selectivities in the Michael reactions forced us to consider "simple" alkyl halides, which would simulate the reactivity of allyl bromide but possess the required chain length and be functionalized enough to allow for further elaboration. After considerable experimentation, we decided to pursue haloenynes of type **38** as targets (eq. [2]). It should be noted that compounds **38** contain a chain of six carbons and that the double bond would therefore have to be cleaved at the appropriate time to give the desired chain length and terminal carboxylic acid functionality. Furthermore, the alkylation (eq. [2]) would only be efficient if, in addition to being chemoselective (attack at C8 rather than C12) and stereoselective at C8 (α-attack), it were also enantioselective (configuration at C14 of the product). Interestingly, however, *it should not matter which C14 diastereoisomer is formed*, as long as it is formed in high yield. Depending on the stereochemical outcome of the alkylation at C14, the acetylene would then be used either for the bond formation at C12 or at C7, while the other required bond (C7 or C12) would be formed using the allyl group. The C14 configuration of the alkylation product will thus dictate subsequent chemistry!



Our approach to the required compounds was initiated from the known aldehyde **39** (15), which was converted to propargylic alcohol **40** upon treatment with allyl magnesium bromide (Scheme 6). Mesylation under standard conditions gave **41**, which was then subjected to refluxing acetone with the appropriate potassium halide to give the corresponding chloride **42**,

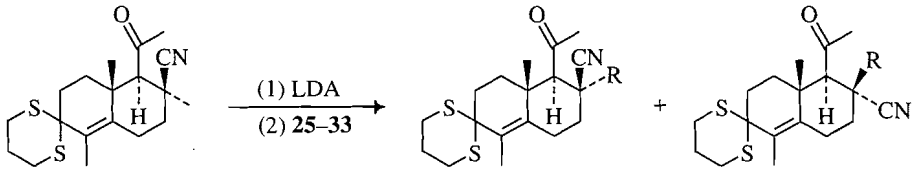
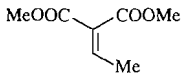
SCHEME 5

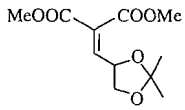
bromide **43**, and iodide **44** in 30–40% yield overall. With a convenient synthesis of these halides now in hand, the reactivity of each of them was investigated.

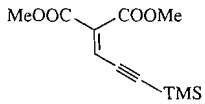
The dianions of nitriles **3** and **13** were generated by treatment with lithium pyrrolidide (LP)[2] in THF at −78°C for 2 h and then quenched with chloride **42** to give no alkylated product (Scheme 7). Upon recovery of the starting materials it was discovered that a significant quantity of the eliminated product **45** was obtained. This meant that the dianion, at least with this halide, acted as a base rather than a nucleophile. Treatment of the dianion, formed under identical conditions as before, with bromide **43** generated two new products, **46** and **47**, as a 1:1 mixture in 80% yield based on recovered starting material. These products arose from the two possible substitution pathways, namely S_N2 displacement to give **47** and S_N2' displacement to furnish **46**. Finally, treatment of the dianion with iodide **44** generated a single compound, **47**, in 95% yield and 50% conversion. Single crystal X-ray crystallography revealed that nitrile **47** possessed the correct C8 configuration and the indicated stereochemistry at C14 (Fig. 3). The enantioselectivity at C14 can possibly be explained by a transition state orientation of the two molecules indicated in Fig. 4. Placement of the acetylene under the decalin system and of the H-atom under the presumably strongly hindering ionic region would allow the more sterically demanding allyl

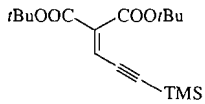


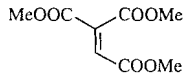
SCHEME 6

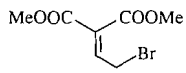


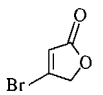






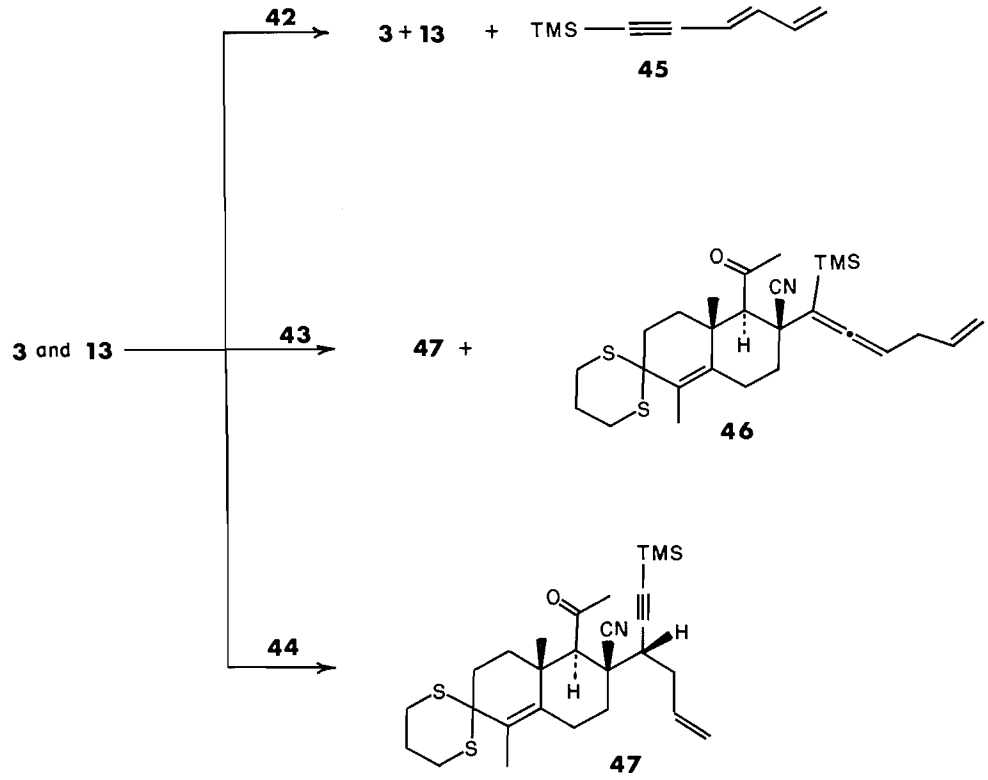






group to align itself away from the ring. This analysis not only rationalizes why the observed product is formed, but also why the process is so selective.[3]

[2]It was found that the nitriles could be used without separation when LP was used as a base instead of LDA. We have no evidence that LP or pyrrolidine reacted with the halides **42**–**44** under the reaction conditions used.



[3]The proposed transition state geometry (Fig. 4) finds some support in the fact that the conformation of the side chain in **47** as determined crystallographically is very similar.

TABLE 1. Michael additions

	Michael acceptor	34–37α product yield (α/β)	34–37β Ratio of stereoisomers (at C14-H of side chain; determined by ^{1}H NMR)
(a)	 **25**	**34** 49% (1/0)	2:1
(b)	 **26**	**35** 12% (1/0)	2:1

SCHEME 7

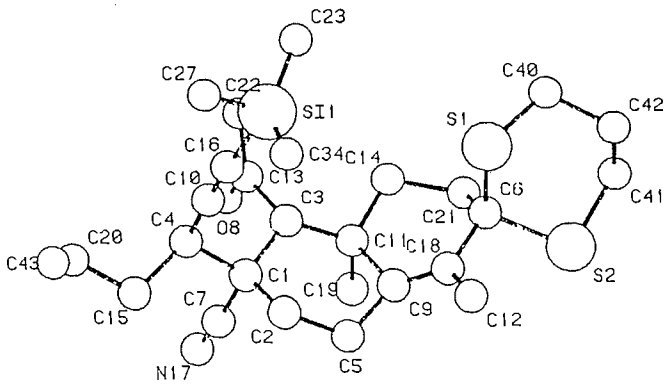

FIG. 3. X-ray structure of nitrile **47**.

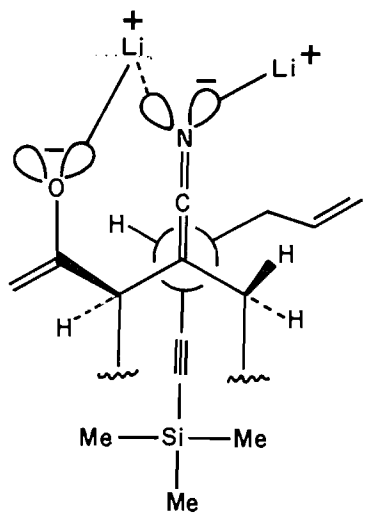

FIG. 4. Proposed transition state geometry of alkylation reaction.

Several attempts were made to improve the conversion of starting material. For example, HMPA was added (16), various concentrations of iodide **44** were used, and the temperature of the reaction was elevated, but no change was observed. This anomalous behavior has been observed in other alkylation systems (17). Regardless of the technical difficulties associated with only 50% conversion, the reaction was found to be high yielding, selective, and, most important, it provided the remaining carbon atoms required for the bruceantin skeleton in a simple yet differentiable form.

All compounds described here are racemic. Thus, in the alkylation reaction, each enantiomer of **3** (and **13**) selected the "fitting" enantiomer of racemic iodide **44**. Based on literature precedents (18), the formation of optically pure enedione **8** via an amino acid catalyzed aldol reaction of prochiral trione **7** will present no difficulties. It can then be anticipated that enantiomerically pure keto nitriles **3** and **13** thus prepared will react with only the fitting enantiomer of racemic iodide **44**. The nonreacting enantiomer of **44** will then either re-racemize by the action of the iodide ion generated in the alkylation reaction, or will be isolated and reconverted to the racemate in a separate reaction.

The next objective was to utilize alkylation product **47** for elaboration into compounds of type **2**. This work is reported in the following article.

Experimental section

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Infrared spectra (IR) were recorded on a Perkin–Elmer IR spectrophotometer model 717B using sodium chloride cells (0.5 mm) and are reported in wave numbers (cm^{-1}) with polystyrene as standard. Nuclear magnetic resonance (NMR) spectra were recorded on a Varian XL-200 (200 MHz) or a Varian T60 (60 MHz) spectrometer. Chemical shifts are reported in ppm (δ) downfield relative to tetramethylsilane as standard. Low resolution mass spectra were re-

corded on a Hitachi Perkin–Elmer RMU-6D spectrometer. High resolution mass spectra were recorded at the Mass Spectrometry Laboratory, Department of Chemistry, University of Alberta, Edmonton, Alberta. Elemental analyses were performed at Guelph Chemical Laboratories Ltd., Guelph, Ontario. Ultraviolet (UV) spectra were recorded on a Beckman spectrophotometer model 25, using quartz cells (4.5 mL capacity).

All reactions, unless otherwise specified, were run under an inert atmosphere of Ar or N_2, and reactions requiring anhydrous conditions were performed in a flame-dried or oven-dried (120°C) apparatus. Temperatures below room temperature refer to bath temperatures. Solvents and anhydrous reagents were dried according to established procedures by distillation under N_2 from an appropriate drying agent (19).

Analytical TLC was performed on E. Merck precoated silica gel plates (0.25 mm). Preparative TLC was performed on E. Merck precoated silica gel plates (1.0, 2.0 mm). Column chromatography was performed by the method of Still *et al.* (20) with E. Merck silica gel 60 (230–400 mesh).

Enedione 8

A solution of 100 g (0.79 mol) of 2-methyl-1,3-cyclohexanedione and 1.5 g (0.03 mol) of potassium hydroxide in 600 mL of anhydrous methanol was brought to reflux and 100 g (1.19 mol) of ethyl vinyl ketone was added dropwise over 1 h. The stirred solution was refluxed for an additional 3 h, and then the methanol was evaporated *in vacuo*. The residue was taken up in 400 mL of benzene and 5 mL (0.06 mol) of pyrrolidine was added. The solution was refluxed for 24 h with azeotropic removal of water. The dark reaction mixture was cooled and 200 mL of ether was added. The solution was washed once with 5% HCl, twice with brine, and then dried over anhydrous magnesium sulfate. The solvent was removed under reduced pressure to give a dark oil, which recrystallized from ether to give 76 g of solid. A further 26 g of compound was obtained after column chromatography of the mother liquor to give 102 g (67%) in total of enedione **8** (mp 46–48°C). IR ($CHCl_3$): 2950 (m), 2900 (m), 1720 (s), 1670 (s), 1610 (m), 1365 (m), 1340 (m), 1320 (m); NMR (200 MHz, $CDCl_3$): 3.0–2.0 (m, 9H), 1.83 (s, 3H), 1.83–1.7 (m, 1H), 1.43 (s, 3H); HRMS (EI) *m/e* (relative intensity): 192.1151 (M^+, 100).

Ethynylcarbinol 9

To a −78°C solution of 7.2 g (1.04 mol) of lithium metal in 2.5 L of ammonia, acetylene gas was bubbled in until the dark blue solution became colorless. To this was then added 100 g (0.51 mol) of **8** in 500 mL of anhydrous ether dropwise over 0.5 h. The reaction mixture was stirred for 1 h at −78°C and then carefully quenched with 600 mL of saturated ammonium chloride. After evaporation of the ammonia the aqueous phase was extracted with four 200-mL portions of chloroform. The combined organic phases were washed with water, brine, and then dried over anhydrous magnesium sulfate and filtered. Concentration of the filtrate gave a brown solid, which was recrystallized from ethanol to give 99.0 g (87%) of **9** (mp 135–138°C). IR ($CHCl_3$): 3610 (w), 3310 (m), 2950 (m), 1650 (s), 1610 (m), 1340 (m), 1310 (m); UV (95% ethanol): 251 nm (ϵ = 25 450); NMR (200 MHz, $CDCl_3$): 2.80–1.80 (m, 11H), 1.80 (s, 3H), 1.30 (s, 3H); HRMS (EI) *m/e* (relative intensity): 218.1308 (M^+, 100).

Dienol diacetate 10

A solution of 40.19 g (0.18 mol) of carbinol **9**, 3.0 g (0.016 mol) of *p*-toluenesulfonic acid, and 250 mL of acetic anhydride was stirred for 18 h. The reaction mixture was poured carefully into 500 mL of ice water, stirred for 1 h, and then filtered. The aqueous phase was extracted once with chloroform and combined with the solid obtained from the filtration. The combined organics were dried with anhydrous magnesium sulfate, filtered, and solvent evaporated under reduced pressure. The solid obtained was recrystallized from ethanol to give 51.0 g (92%) of diacetate **10** (mp 120–122°C). IR ($CHCl_3$): 3325 (s), 2950 (m), 1750 (s), 1740 (s), 1675 (m), 1370 (s), 1150 (s), 1095 (s); UV (95% ethanol): 235 nm (ϵ = 22 500); NMR (200 MHz, $CDCl_3$): 5.62 (t, J = 4 Hz, 1H), 2.93–2.78 (m, 1H), 2.54 (s, 1H), 2.18 (s, 3H), 2.06 (s, 3H), 1.65 (t, J = 1.5 Hz, 3H), 1.18 (s, 3H); HRMS (EI) *m/e* (relative intensity): 302.1523 (41).

Diene dione 11

A solution of 5 g (0.017 mol) of **10** in 20 mL of 88% formic acid was refluxed for 2 h. The formic acid was then removed under reduced pressure. The residue was taken up in 50 mL of ethyl acetate and washed with 5% $NaHCO_3$, water, and brine, dried with anhydrous $MgSO_4$, filtered, and solvent evaporated under reduced pressure. The solid was recrystallized from ether to give 2.45 g (68%) of diene dione **11** (mp 104–107°C). IR ($CHCl_3$): 2950 (w), 1660 (s), 1630 (m), 1370 (m); UV (95% ethanol): 240 nm (ϵ = 24 200); NMR (200 MHz, $CDCl_3$): 7.06–6.96 (m, 1H), 2.94–2.4 (m, 6H), 2.33 (s, 3H), 2.30–2.16 (m, 2H), 1.83 (s, 3H), 1.58 (s, 3H); HRMS (EI) *m/e* (relative intensity): 218.1308 (100).

Dithiane 12

A solution of 5 g (22.9 mmol) of **11** in 30 mL of anhydrous ether was cooled in an ice bath and 5 mL (40.7 mmol) of boron trifluoride etherate was added, followed by 3.5 mL (34.4 mmol) of 1,3-propane dithiol. The reaction mixture was stirred for 18 h and then poured carefully into 100 mL of 10% $NaHCO_3$. After separation of the layers the organic phase was washed with water and brine, dried with anhydrous $MgSO_4$, filtered, and evaporated *in vacuo*. The solid was recrystallized from ether to deliver 5.81 g (82%) of dithiane **12** (mp 148–150°C). IR ($CHCl_3$): 2920 (m), 1670 (s), 1360 (m); UV (95% ethanol): 230 nm (ϵ = 16 100), 209 nm (ϵ = 22 800); NMR (200 MHz, $CDCl_3$): 6.90–5.98 (m, 1H), 3.24–2.98 (m, 2H), 2.80–2.50 (m, 3H), 2.28 (s, 3H), 2.01 (s, 3H), 1.45 (s, 3H); HRMS (EI) *m/e* (relative intensity): 308.1270 (100).

Nitriles 3 and 13

A solution of 10 g (0.03 mol) of **12** in 100 mL of DMF was stirred until a uniform solution was obtained. Then a solution of 4.23 g (0.065 mol) of potassium cyanide and 2.68 g (0.05 mol) of ammonium chloride in 30 mL of water was added and the reaction mixture was heated at 80°C for 16 h. Upon cooling, 500 mL of water was added and the solution was thoroughly extracted with ethyl acetate (5 × 150 mL). The combined organic phases were washed with water, brine, dried over anhydrous $MgSO_4$, filtered, and evaporated under reduced pressure. Silica gel chromatography (4:1 hexane/ethyl acetate as eluant) gave 7.07 g of **3** and 1.28 g of **13** (77% combined yield). An analytical sample of each was obtained by recrystallization from ethyl acetate: **3** (mp 163–167°C, 192–197°C); IR ($CHCl_3$): 2950 (s), 2240 (m), 1720 (s), 1360 (s); NMR (200 MHz, $CDCl_3$): 3.18–2.96 (m, 3H), 2.78–2.50 (m, 5H), 2.29 (s, 3H), 1.98 (s, 3H), 1.96–1.56 (m, 4H), 1.48 (s, 3H); Anal. calcd. for $C_8H_{25}OS_2N$: C 64.43, H 7.51, N 4.17; found: C 64.50, H 7.52, N 4.19. **13** (mp 182–183°C); IR ($CHCl_3$): 2920 (m), 2240 (w), 1710 (s), 1350 (s); NMR (200 MHz, $CDCl_3$): 3.20–2.98 (m, 3H), 2.82–2.52 (m, 5H), 2.36 (s, 3H), 1.98 (s, 3H), 1.10 (s, 3H). Anal. calcd. for $C_8H_{25}OS_2N$: C 64.43, H 7.51, N 4.17; found: C 64.31, H 7.62, N 4.24.

Enone 14

A solution of 7.0 g (0.021 mol) of **3** in 100 mL of acetonitrile was treated with 6.98 g (0.052 mol) of *N*-chlorosuccinimide and 8.87 g (0.052 mol) of silver nitrate in 40 mL of 80% aqueous acetonitrile. The reaction mixture was stirred at room temperature for 2 h after which it was washed with saturated Na_2SO_3, saturated $NaHCO_3$, and brine. The organic solution was then dried over anhydrous $CaCl_2$ and filtered through Celite. The cake was thoroughly washed with methylene chloride/hexane (1:1), and the combined organic phases were evaporated under reduced pressure. Crystallization of the solid gave 4.1 g (80%) of **14** (mp 130–132°C). IR ($CHCl_3$): 2925 (m), 2240 (w), 1715 (s), 1660 (s), 1610 (m), 1360 (m); UV (95% ethanol): 246 nm (ϵ = 18 509); NMR (60 MHz, $CDCl_3$): 3.38–2.40 (m, 8H), 2.30 (s, 3H), 1.82 (s, 3H), 1.67 (s, 3H); MS (EI) *m/e* (relative intensity): 245 (M^+, 100).

Dienol acetate 15

A solution of 3.5 g (14.28 mmol) of **14** in 20 mL of acetic anhydride was treated with 0.5 mL of acetic anhydride/48% aqueous hydrobromic acid (3:2) and stirred for 16 h. The reaction mixture was then poured carefully into 100 mL of ice water and stirred for 1.5 h. The solidified product was taken up in chloroform and the aqueous phase was thoroughly extracted with chloroform (4 × 50 mL). The combined

For personal use only.

organic phases were carefully washed with saturated $NaHCO_3$, water, and brine, and dried over anhydrous $CaCl_2$. Filtration and evaporation of solvent gave a brown solid, which was purified on silica gel chromatography (hexane/ethyl acetate 3:2 as eluant) to give 3.6 g (88%) of product. An analytical sample of **15** (125–127°C) was obtained by recrystallization from ethanol. IR ($CHCl_3$): 2910 (m), 2240 (w), 1740 (s), 1700 (s), 1665 (m), 1365 (s), 1350 (s); NMR (200 MHz, $CDCl_3$): 5.65 (t, J = 4 Hz, 1H), 3.22–3.1 (m, 1H), 2.77–2.42 (m, 4H), 2.36 (s, 3H), 2.20 (s, 3H), 1.68 (t, J = 2 Hz, 3H), 1.40 (s, 3H); MS (EI) m/e (relative intensity): 287 (M^+, 100).

Bromo dienol acetate ***16***

A solution of 200 mg (0.69 mmol) of **15** in 10 mL of anhydrous THF was treated with 260 mg (0.69 mmol) of phenyl trimethyl ammonium tribromide. The reaction mixture was stirred for 0.75 h and then poured into saturated $NaHCO_3$. The layers were separated and the aqueous phase was washed with two 5-mL portions of ether. The combined organic phase was washed several times with aqueous Na_2SO_3 until the aqueous phase was clear. Drying over anhydrous $CaCl_2$, filtering, and evaporation of solvent under reduced pressure gave 280 mg of a mixture of unstable bromide **16** and acetate **15**. This compound was always generated *in situ* for use in the next synthetic transformation. IR ($CHCl_3$): 2920 (m), 2240 (w), 1745 (s), 1720 (s), 1660 (m), 1370 (m), 1360 (m); NMR (60 MHz, $CDCl_3$): 5.75–5.52 (m, 1H), 4.0 (s, 2H), 2.20 (s, 3H), 1.68 (s, 3H), 1.45 (s, 3H); MS (EI) m/e: 367/365 (M^+).

Diester ***17***

A solution of **16**, prepared as described above, was treated directly with the sodium anion of dimethyl-1,3-acetone dicarboxylate, generated by stirring a solution of 50.1 mg (2.09 mmol) of sodium hydride with 0.31 mL (2.09 mmol) of dimethyl-1,3-acetone dicarboxylate for 1 h, followed by addition of 0.1 mL of HMPA. The reaction mixture was allowed to stir overnight and then poured into saturated aqueous NH_4Cl. The aqueous phase was extracted with ethyl acetate and the combined organic washings were dried over anhydrous $CaCl_2$, filtered, and solvent evaporated. Purification on 1 mm silica gel preparative TLC plates (hexane/ethyl acetate 1:1 as eluant) furnished 80 mg starting dienol acetate **15** and 100 mg (52%) of diester **17**. IR ($CHCl_3$): 2920 (m), 2240 (w), 1740 (s), 1730 (s), 1710 (s), 1660 (m), 1430 (m), 1360 (m), 1350 (m); UV (95% ethanol) 234 nm (ϵ = 15 643), (95% ethanol + 5% NaOH): 240 nm (ϵ = 14 107) (hydrolysis of enol acetate to enone), 280 nm (ϵ = 12 286) (enolate of β-keto ester); NMR (200 MHz, $CDCl_3$): 5.64 (t, J = 4 Hz, 1H), 4.72 and 4.74 (s, 1H), 4.38–4.32 (m, 1H), 3.78 (s, 6H), 3.26–3.06 (m, 3H), 2.18 (s, 3H), 1.68 (s, 3H), 1.36, 1.38, and 1.42 (s, 3H); MS (EI) m/s: 459 (M^+).

Malonyl dienol acetate ***18***

To a solution of **16** in 15 mL of THF was added the sodium anion of dimethyl malonate, prepared from 101 mg (4.2 mmol) of NaH and 0.48 mL (4.2 mmol) of dimethyl malonate in 15 mL of THF. The reaction mixture was stirred for 2 h and then quenched with 10 mL of saturated aqueous NH_4Cl. The layers were separated and the aqueous phase was washed with three 10-mL portions of ether. The combined extracts were dried over anhydrous $CaCl_2$, filtered, and evaporated under reduced pressure. The residue was purified on 1 mm silica gel preparative TLC plates (two developments with hexane/ethyl acetate 3:2 as eluant) to give 100 mg of dienol acetate **15** and 99 mg (68%) of malonyl adduct **18**. IR ($CHCl_3$): 2910 (w), 2240 (w), 1730 (s), 1740 (s), 1430 (m), 1415 (m), 1350 (m); NMR (200 MHz, $CDCl_3$): 5.57 (t, J = 4 Hz, 1H), 4.01 (t, J = 8 Hz, 1H), 3.73 (s, 6H), 3.2–3.06 (m, 3H), 2.8–2.28 (m, 6H), 2.20 (s, 3H), 1.67 (t, J = 2 Hz, 3H), 1.40 (s, 3H); MS (EI) m/e: 417 (M^+).

Tetraester ***19***

To a solution of 60 mg (0.14 mmol) of **18** in 10 mL of THF was added 10 mg (0.42 mmol) of sodium hydride. The reaction mixture was stirred for 1.5 h and then 30 mg (0.17 mmol) of dimethyl chloromethylene malonate was added and stirring continued for 0.5 h. The reaction mixture was diluted with 10 mL of ether and then poured carefully into water. The layers were separated and the organic phase was dried with anhydrous $CaCl_2$, filtered, and evaporated under reduced pressure. The residue was purified on 1 mm silica gel preparative TLC plates (hexane/ethyl acetate 3:2 as eluant) to deliver 56 mg (72%) of tetraester **19**. IR ($CHCl_3$): 2940 (m), 2840 (w), 2240 (w), 1730 (s), 1430 (m), 1365 (m); UV (95% ethanol): 231 nm (ϵ = 16 765), 235 nm (ϵ = 16 646), (95% ethanol, 5% NaOH), 400 nm (ϵ = 11 353), 390 nm (ϵ = 10 176); NMR (200 MHz, $CDCl_3$): 7.79 (s, 1H), 5.64 (t, J = 4 Hz, 1H), 3.82 (s, 3H), 3.79 (s, 3H), 3.76 (s, 3H), 3.74 (s, 3H), 3.22–3.10 (m, 2H), 2.80–2.26 (m, 4H), 2.16 (s, 3H), 1.67 (s, 3H), 1.34 (s, 3H); MS (EI) m/e: 459 (M^+).

Phenyl selenide ***21***

A solution of 100 mg (0.24 mmol) of **18** in 15 mL of benzene was treated with 50.5 mg (2.5 mmol) of phenyl selenyl chloride followed by 58.3 mg (2.5 mmol) of silver trifluoroacetate. The reaction mixture was stirred at room temperature for 6 h and then filtered through Celite. The cake was washed thoroughly with chloroform and the combined organic phases were evaporated under reduced pressure. Purification on silica gel preparative TLC plates (hexane/ethyl acetate 3:2 as eluant) gave 95 mg (75%) of selenide **21**. IR ($CHCl_3$): 2940 (w), 2240 (w), 1750 (s), 1730 (s), 1660 (s), 1600 (w), 1430 (m), 1355 (m); NMR (200 MHz, $CDCl_3$): 7.83–7.70 (m, 2H), 7.58–7.45 (m, 3H), 4.48 (t, J = 2 Hz, 1H), 4.08 (t, J = 8 Hz, 1H), 3.86 (s, 6H), 3.72 (dd, J = 12 Hz, J = 20 Hz, 2H), 3.27 (dd, J = 12 Hz, J = 6 Hz, 2H), 2.86–2.13 (m, 6H), 2.02 (s, 3H), 1.65 (s, 3H).

Tetraester phenyl selenide ***22***

A solution of 40 mg (0.08 mmol) of **21** and 10 mL of THF was treated with 3.6 mg (0.15 mmol) of sodium hydride for 1.5 h. To this was added 30 mg (0.17 mmol) of dimethyl chloromethylene malonate and the reaction mixture was stirred for an additional hour. The solution was filtered through a glass wool plug and diluted with 10 mL of ethyl acetate. After washing with water and brine, the organic phase was dried over anhydrous $CaCl_2$, filtered, and the solvent evaporated. The yellow oil obtained was purified on silica gel preparative TLC plates (hexane/ethyl acetate 3:2 as eluant) to deliver 25 mg (47%) of phenyl selenide tetramethylester **22**. IR ($CHCl_3$): 2940 (m), 2920 (m), 2240 (w), 1740 (s), 1665 (m), 1430 (m), 1355 (m); NMR (200 MHz, $CDCl_3$): 7.85 (s, 1H), 7.80–7.64 (m, 2H), 7.51–7.38 (m, 3H), 4.38 (t, J = 2 Hz, 1H), 3.82 (s, 3H), 3.80 (s, 6H), 3.78 (s, 3H), 2.74–2.29 (m, 6H), 1.94 (s, 3H), 1.52 (s, 3H).

Tertiary alcohol ***23***

A solution of 30 mg (0.045 mmol) of selenide **22** in 10 mL of THF was treated with 17.7 mg (0.09 mmol) of 85% mCPBA and stirred for 2 h. The reaction mixture was washed with saturated Na_2SO_3, $NaHCO_3$, water, and brine. After drying over anhydrous $CaCl_2$ and filtering, the solvent was evaporated under reduced pressure. Purification on silica gel preparative TLC plates (hexane/ethyl acetate 3:2) gave 19 mg (80%) of alcohol **23**. IR ($CHCl_3$): 2940 (m), 2920 (m), 2840 (m), 2240 (w), 1740 (s), 1720 (s), 1430 (m), 1360 (m); NMR (200 MHz, $CDCl_3$): 7.78 (s, 1H), 6.22 (t, J = 2 Hz, 1H), 3.83 (s, 3H), 3.80 (s, 9H), 3.22–3.13 (m, 1H), 3.0–2.86 (m, 1H), 2.74–1.99 (m, 7H), 1.66 (s, 3H), 1.58 (s, 3H).

General procedure for Michael reactions with the dianion: Generation of ***34***

A solution of LDA in 5 mL of dry THF (0.64 mmol, 3.2 equiv.) was cooled to −78°C and 100 mg (0.2 mmol) of **3** in 5 mL of dry THF was added via syringe over 2 min. The reaction was stirred at this temperature for 2 h at which time 60 mg (0.38 mmol) of dimethyl ethylidene malonate **25** in 0.5 mL of THF was added in one lot. After stirring for an additional 15 min at −78°C, the reaction mixture was poured into saturated NH_4Cl. The layers were separated and the aqueous phase was extracted with ethyl acetate. The combined extracts were washed with water and brine, dried over anhydrous $CaCl_2$, and filtered. The solvent was evaporated *in vacuo* and the resultant oil was chromatographed on silica gel preparative plates (hexane/ethyl acetate 3:2 as eluant) to deliver 70 mg (49%) of Michael adduct **34** as a 1:2 mixture of C14 diastereoisomers. IR ($CHCl_3$): 2960 (s), 2240 (w), 1750 (s), 1730 (s), 1440 (s), 1380 (m), 1360 (m); NMR (200 MHz, $CDCl_3$), major diastereomer: 3.78 (s, 6H), 3.19–2.96 (m, 3H), 2.83–2.48 (m, 6H), 2.36 (s, 3H), 2.0 (s, 3H), 1.44 (s, 3H), 1.32 (d, J = 8 Hz, 3H); minor diastereomer: 3.80 (s, 6H), 3.19–2.96 (m, 3H), 2.83–2.48 (m, 6H),

2.37 (s, 3H), 2.0 (s, 3H), 1.44 (s, 3H), 1.12 (d, J = 8 Hz, 3H); MS (EI) m/e: 493 (M^+).

Enyne alcohol ***40***

A suspension of 4.29 g (0.18 mol) of magnesium metal in 150 mL of dry ether was treated with 21.5 g (0.18 mol) of allyl bromide in 50 mL of ether. When the metal had been completely consumed, 8.87 g (0.07 mol) of aldehyde **39** in 30 mL of ether was added dropwise from a dropping funnel over 15 min. The reaction mixture was stirred for 2 h and then poured into cold 5% HCl. The layers were separated and the organic phase was washed with water and brine. After drying over anhydrous $MgSO_4$ and filtration, the solvent was evaporated under reduced pressure. Pure alcohol **40** (bp 48–50°C, 10 Torr (1 Torr = 133.3 Pa)) was obtained by vacuum distillation, 8.24 g (62%). IR ($CHCl_3$): 3600 (m), 2960 (m), 2180 (m), 1650 (m), 1390 (m), 1260 (m), 1030 (s); NMR (200 MHz, $CDCl_3$): 6.02–5.76 (m, 1H), 5.50–5.36 (m, 2H), 4.44 (t, J = 6 Hz, 1H), 2.49 (dd, J = 6 Hz, J = 7 Hz, 2H), 0.17 (s, 9H).

Mesylate ***41***

A solution of 4.35 g (0.026 mol) of alcohol **40** in 10 mL of dry DMF was cooled in an ice bath and treated with 4.04 g (0.031 mol) of 2,4,6-collidine and 3.52 g (0.031 mol) of methane sulfonyl chloride. The reaction mixture was allowed to warm to room temperature and stir for 3 h. It was then poured into ice water and diluted with 100 mL of hexane. The layers were separated and the organic phase was washed with saturated $NaHCO_3$, water, and brine. After drying over anhydrous $MgSO_4$ and filtration, the solvent was evaporated under reduced pressure. The crude mesylate **41** obtained, 6.2 g (96%), was used without further purification. IR ($CHCl_3$): 2940 (w), 2170 (w), 1640 (w), 1415 (w), 1360 (s), 1330 (m), 1180 (s); NMR (200 MHz, $CDCl_3$): 5.96–5.72 (m, 1H), 5.30–5.08 (m, 3H), 3.11 (s, 3H), 2.62 (dd, J = 6 Hz, J = 6 Hz, 2H), 0.18 (s, 9H).

General procedure for halide formation: Preparation of iodide ***44***

A solution of 6.2 g (0.025 mol) of mesylate in 100 mL of anhydrous acetone and 9 g (0.059 mol) of KI was refluxed for 12 h. Upon cooling and evaporation of solvent under reduced pressure the residue was taken up in 200 mL of hexane and 100 mL of water. The layers were separated and the organic phase was successively washed with water, $Na_2S_2O_3$, and brine, dried over anhydrous $MgSO_4$, filtered, and solvent evaporated under reduced pressure. The oil was distilled under vacuum (0.01 Torr) to yield 4.25 g (61%) of iodide **44** (bp 53–56°C). IR ($CHCl_3$): 2960 (s), 2920 (s), 2180 (s), 1680 (m), 1650 (s), 1630 (m), 1420 (s); NMR (200 MHz, $CDCl_3$): 5.96–5.73 (m, 1H), 5.29–5.10 (m, 2H), 4.53 (t, J = 7 Hz, 1H), 2.72 (dd, J = 7 Hz, J = 7 Hz, 2H), 0.16 (s, 9H).

Alkylated adduct ***47***

A solution of 0.057 mL (0.69 mmol) of pyrrolidine in 10 mL of dry THF was cooled to −78°C and 0.43 mL (0.69 mmol) of 1.5 M *n*BuLi in hexane was added via a syringe. After stirring for 15 min, 100 mg (0.3 mmol) of nitriles **3** and **13** in 1 mL of THF was added and stirring was continued for 2 h. Then 0.066 mL (0.3 mmol) of iodide **44** was added neat in one lot. Following stirring at −78°C for 1 h the reaction mixture was poured into saturated NH_4Cl. The layers were separated and the organic portion was washed with water and brine, dried over anhydrous $MgSO_4$, and filtered. After evaporation of solvent under reduced pressure, the oil was purified by silica gel chromatography (hexane/ethyl acetate 9:1 → 3:1 as eluant) to give 61 mg (95%) of alkylation product **47** and 56 mg of nitriles **3** and **13**. IR ($CHCl_3$): 2950 (s), 2880 (m), 2250 (w), 2180 (m), 1710 (s), 1650 (m), 1420 (m), 1360 (m); NMR (200 MHz, $CDCl_3$): 5.98–5.72 (m, 1H), 5.23–5.06 (m, 3H), 3.17 (s, 1H), 3.16–2.96 (m, 3H), 2.80–2.46 (m, 8H), 2.38 (s, 3H), 2.05 (s, 3H), 2.04–1.42 (m, 4H), 1.41 (s, 3H), 0.18 (s, 9H); MS (EI) m/e: 485 (M^+).

Synthetic studies towards bruceantin. Part 2. The synthesis of a pentacyclic intermediate

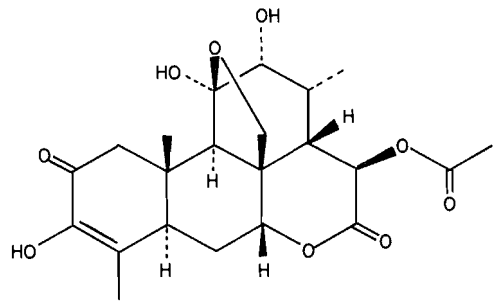
SULTAN DARVESH, ANDREW S. GRANT, DAVID I. MAGEE, AND ZDENEK VALENTA[1]
Department of Chemistry, University of New Brunswick, Fredericton, N.B., Canada E3B 6E2

Received September 20, 1990

SULTAN DARVESH, ANDREW S. GRANT, DAVID I. MAGEE, and ZDENEK VALENTA. Can. J. Chem. **69**, 723 (1991).

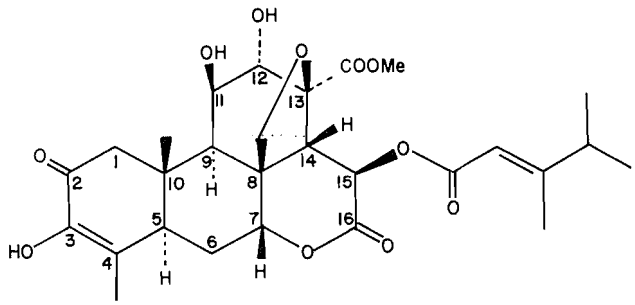
In a synthetic approach to the quassinoid bruceantin (**2**), the key intermediate **8** obtained via alkylation of a dianion has been transformed into the pentacyclic intermediate **33** via an ABDC ring forming strategy. The key steps involved in this route are as follows: a unique acid catalyzed cyclization, **19** → **20**; an intramolecular Michael reaction, **24** → **28**; and an allyl sulfoxide [2,3]-sigmatropic rearrangement to introduce the axial C12 alcohol, **31** → **33**.

Key words: bruceantin, quassinoids, cyclization, sulfoxides, sigmatropic rearrangement.



SULTAN DARVESH, ANDREW S. GRANT, DAVID I. MAGEE et ZDENEK VALENTA. Can. J. Chem. **69**, 723 (1991).

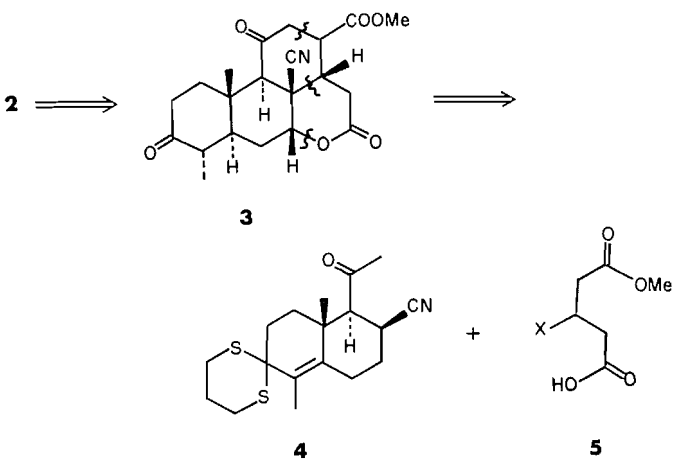
Dans une approche à la synthèse de la quassinoïde brucéantine (**2**), on a transformé l'intermédiaire clé (**8**), obtenu par alkylation d'un dianion, en intermédiaire pentacyclique **33** par le biais de la stratégie de formation des cycles ABDC. Les étapes clés impliquées dans cette voie sont : une cyclisation acido-catalysée unique de **19** en **20**, une réaction de Michael intramoléculaire de **24** en **28** et une transposition sigmatropique-[2,3] d'un sulfoxyde d'allyle pour introduire l'alcool axial en C12, **31** à **33**.



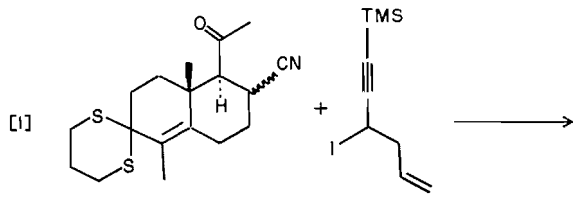
Mots clés : brucéantine, quassinoïde, cyclisation, sulfoxydes, transposition sigmatropique.

[Traduit par la rédaction]

Certain species of the *Simaroubaceae* family have traditionally been used as ingredients for the treatment of dysentery, amebiasis, and other ailments in folk medicine. However, increased attention developed with the report of antileukemic activity of holacanthone **1** (1–3). Since that report bruceantin **2**, a member of the same family, has undergone phase II testing

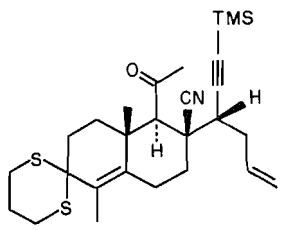


1 Holacanthone



2 Bruceantin

in the United States (4). Due to this biological activity, as well as the fundamental complexity, these compounds have received considerable synthetic attention (5). In the preceding paper (6), we outlined a simple strategy, shown in Scheme 1, which should allow a rapid construction of the quassinoid skeleton, and described a convergent method for the preparation of intermediate **8**, which included the alkylation of the mixture



SCHEME 1

of C8-epimers **4** and **6** as the key step (eq. [1]). We now wish to report on the elaboration of this compound into a key pentacyclic intermediate that contains the complete bruceantin skeleton, as well as seven of its 10 chiral centers.

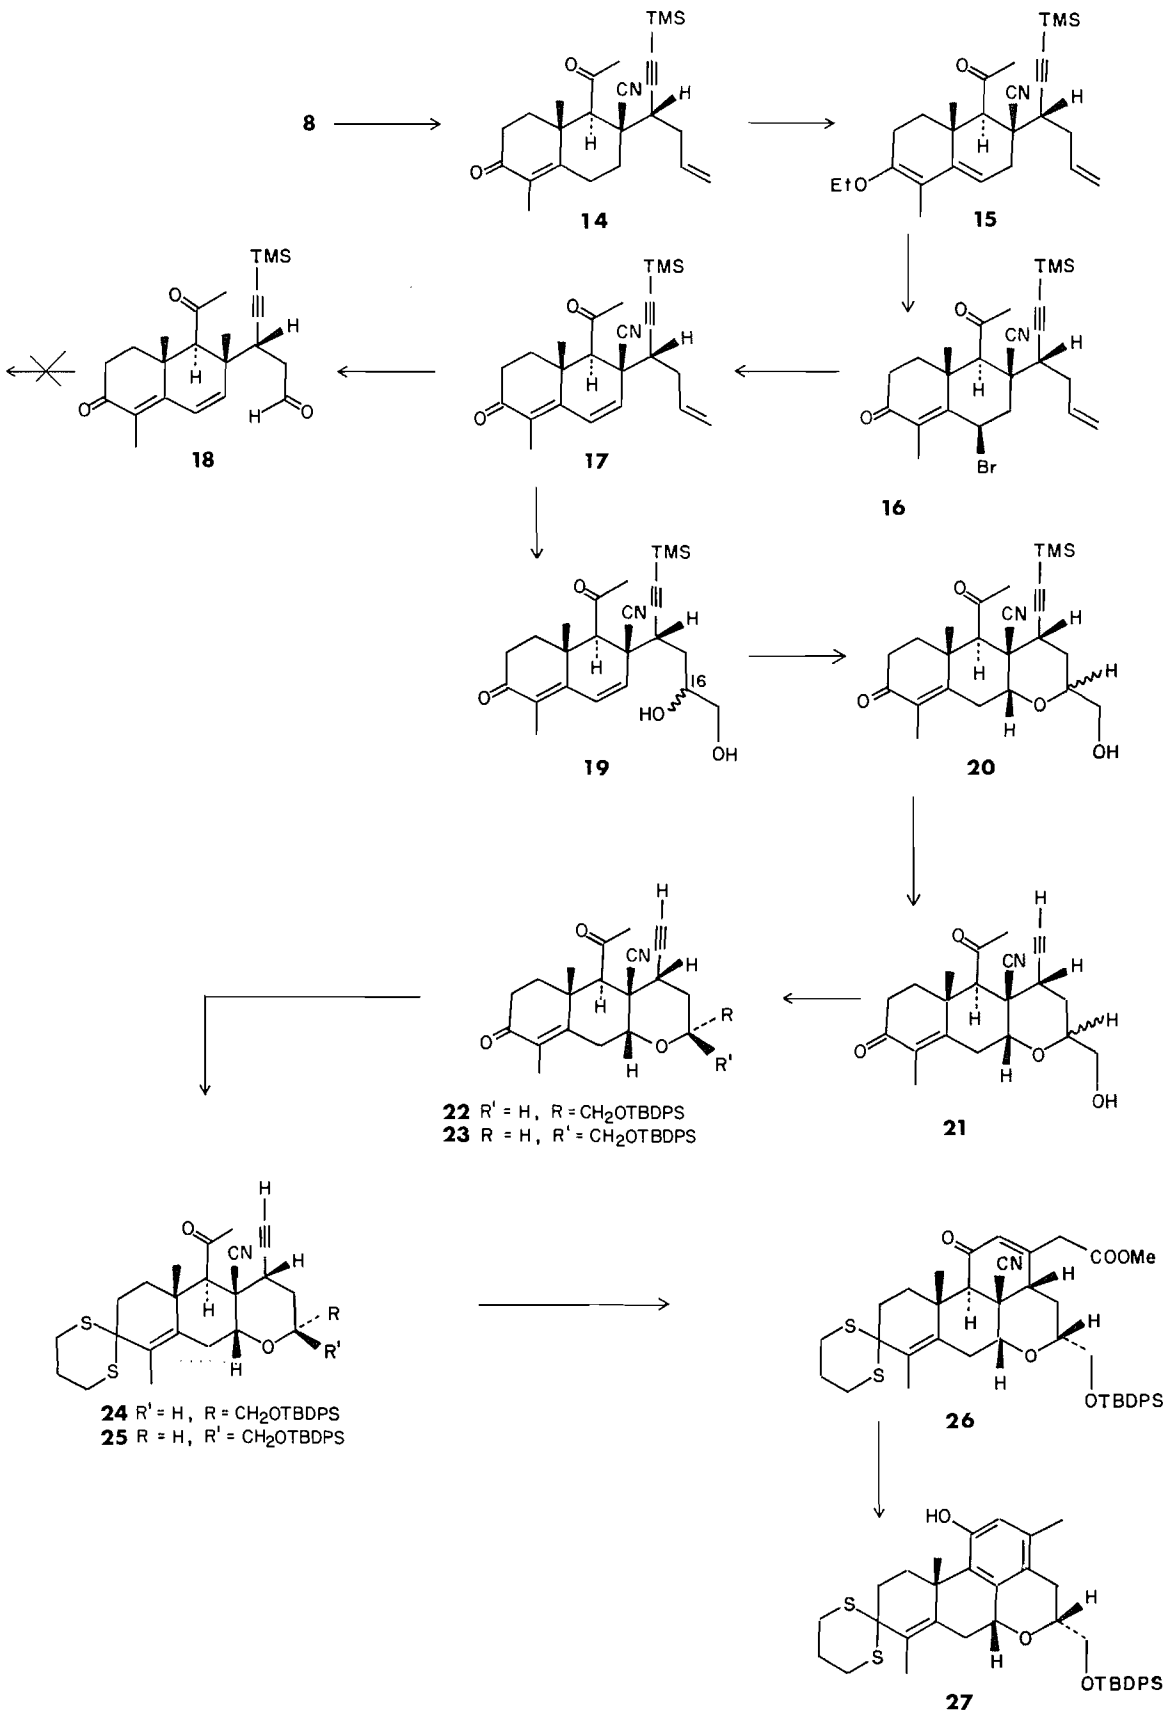
SCHEME 2

Results and discussion

The transformation of intermediate **8** into a compound of type **3** requires that the acetylene functionality be used for the construction of ring C, and that the side-chain double bond be utilized for the formation of lactone ring D. Formation of ring C was envisaged as arising from a simple three-step protocol: deprotection of the acetylene, carbomethoxylation, and an intramolecular Michael reaction. Oxidative cleavage of the olefin would then furnish the carboxylic acid required for lactone formation.

Development of this strategy began with treatment of **8** with tetrabutylammonium fluoride (7) in tetrahydrofuran (THF) to give acetylene **9** in good yield (82%) (Scheme 2). Reaction of the dianion of **9** (*n*BuLi in THF at −78°C) with methyl chloroformate furnished **10**, **11**, and **12** in a 2:1:1 ratio and a 65% combined yield. Conversion of carbonate **10** into ester **13** then proceeded smoothly on treatment with sodium methoxide in THF (25% from **9**). Although the strategy worked, the low yield coupled with 25% epimerization at C14 made this route unattractive. Concerning the epimerization, examination of molecular models revealed that a facile proton shift was possible from C14 to the proximate enolate anion after carbomethoxylation of the acetylene, and that reprotonation of the C14 anion would then occur preferably from the α-side. Constructing ring D first would clearly remedy this problem since the C14 proton could no longer be aligned for the intramolecular proton transfer.



This modified route began with the extension of ring-A conjugation into ring B (Scheme 3). Deprotection of the C3 ketone with mercuric oxide (8) in aqueous THF with a catalytic amount of acid gave enone **14** in quantitative yield. Treatment of **14** with trimethyl orthoformate (9) and a catalytic amount of *p*-toluenesulfonic acid in benzene afforded dienol ether **15** (89%), which was brominated with pyridinium bromide perbromide (10) in aqueous THF to deliver **16** as a single isomer (88%). The exclusive formation of the isomer with an axial bromine at C6 can only be attributed to a strong stereoelectronic effect (11). Efficient dehydrobromination to **17** was then achieved with 1,5-diazabicyclo[4.3.0]non-5-ene (DBN) in THF (78%). It was found that a significant reduction in yield occurred when the base was not used in large excess and when reaction times exceeded 20 min.

Our next objective was the conversion of the side-chain alkene to a suitably oxygenated derivative. Oxidation of **17** with sodium periodate and a catalytic amount of osmium tetroxide (12) in aqueous ether afforded aldehyde **18** in 73% yield. However, all attempts to oxidize **18** efficiently to the acid failed (PCC, PDC, and MnO_2). Direct oxidation of the olefin to the acid also met with no success. Fortunately, a regioselective incorporation of the diol proceeded with ease, on treatment of **17** under the conditions described by Van Rheenan *et al.* (13), to produce **19** as a mixture of the two C16 epimers (see below) in 84% yield.[2]

Initial attempts to effect cyclization of ring D with a variety of acids proved fruitless. For example, **19** was inert to *p*-toluenesulfonic acid, boron trifluoride etherate, Amberlyst-15 (14), and perchloric acid. However, when **19** was heated with 1,3-propane diol in benzene with one-half equivalent of *p*-toluenesulfonic acid and azeotropic removal of water, 15% of enone **20** was obtained, along with 85% of recovered starting material. *There were no traces of any dioxolane compounds,*

[2]In contrast, an unmediated oxidation with osmium tetroxide alone gave a lower yield of **19** and by-products containing carbonyl groups in the side chain.

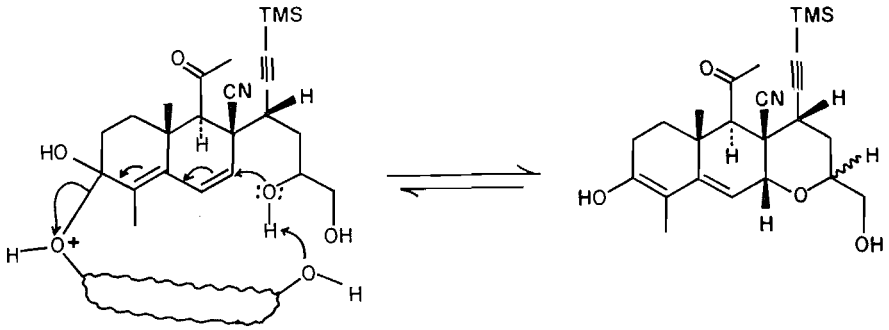

FIG. 1

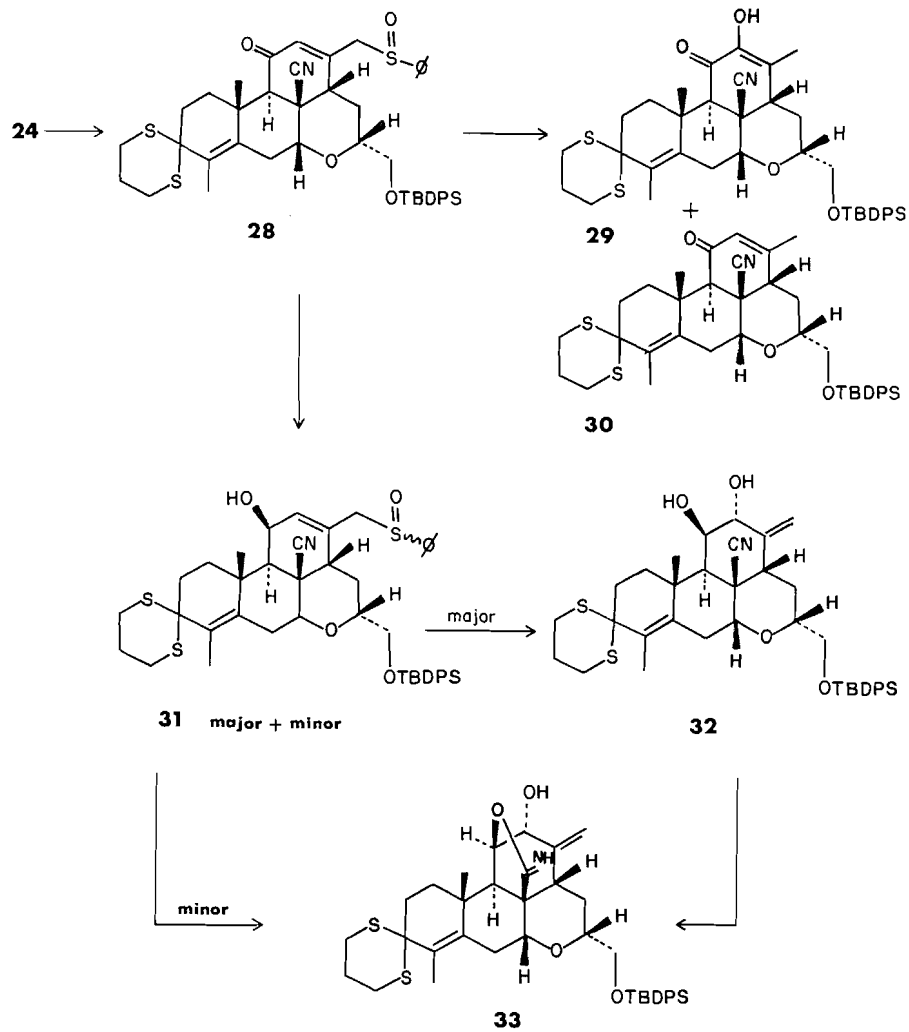
and under prolonged heating only destruction of starting material was observed. The only difference from previous reaction conditions was the addition of 1,3-propane diol. Therefore, it was postulated that the reaction takes place on the surface of the propane diol[3] in a two-phase reaction (Fig. 1). In one possible interpretation, as part of the surface promotes formation of the oxonium ion at C3, another part of the surface abstracts a proton from the charged ether oxygen before reversion to the open form can occur. Subsequent protonation at C6 can then similarly take place on the surface of protonated propane diol. After considerable experimentation, it was found that **20** (mixture of C16 epimers) could be obtained in 90% yield, based on 20% recovered starting material, by treating diol **19** with 60 equivalents of 1,3-propane diol and 30 equivalents of *p*-toluenesulfonic acid in benzene at 40°C for 4 h. The ^{1}H NMR signal corresponding to C7-H in **20** (δ 4.21, t, J = 3 Hz) showed clearly that the ether O-atom had the desired axial configuration relative to ring B.

With rings A, B, and D now established, the final task was to incorporate ring C via our previous cyclization protocol. This began by deprotection of acetylene **20** with tetrabutylammonium chloride and potassium fluoride in acetonitrile (15) to deliver **21** in a quantitative yield. Protection of the primary alcohol in **21** with *tert*-butyldiphenylsilyl (TBDPS) chloride and imidazole in dimethylformamide (DMF) (16) then gave a 6:1 mixture of products **22** and **23** in 84% yield. These could be cleanly separated by silica gel chromatography, the ^{1}H NMR spectra showing the predominance of **22** containing the -CH_2OTBDPS group in an equatorial position. The C3 ketone of **22** and **23** was protected as its 1,3-propane dithiane with 1,3-propane dithiol in THF (1:1) at room temperature to provide **24** and **25** in 96 and 84% yield, respectively. The major isomer **24** was then subjected to dianion formation with lithium hexamethyl disilazide in THF at −30°C, followed by a dimethyl carbonate quench to deliver ester **26** in 75% yield. Unfortunately, all attempts to modify this intermediate failed. For example, **26** was inert to reducing agents such as diisobutylaluminum hydride and lithium triethoxyaluminum hydride. Furthermore, attempts at hydrolysis of the ester and decarboxylation under a variety of conditions only led to recovered starting material or to phenol **27**, which was presumably formed as a result of enolization between C9 and C11, followed by elimination of the nitrile and subsequent aromatization.



Since, in addition to the lack of desired reactivity, ester **26** clearly did not possess the features most suitable for the development of the complex ring-C functionality of bruceantin, we decided to modify the acetylene activation–cyclization strategy in a way that would satisfy two conditions: (1) The Michael addition should be accomplished without the introduction of an unwanted extra carbon. (2) An acetylene activating group should be used that could subsequently be modified and (or) manipulated to furnish the desired ring-C functionality. As a result, we chose to use an acetylenic sulfoxide, rather than a carbomethoxy acetylene, as the Michael acceptor. Implementation of this strategy again began with the conversion of **24** into the dianion, this time using *n*-butyllithium in THF at −78°C, followed by addition of isopropyl *p*-toluenesulfinate (17) at −78°C to give adduct **28** as an amorphous solid (81%, λ_{max} = 369 nm) (Scheme 4). Upon heating of **28** in methanol with 10 equivalents of sodium thiophenolate (18), diosphenol **29** and enone **30** were obtained in 25 and 50% yield respectively. Compound **29** was the product expected from a [2,3]-sigmatropic rearrangement followed by a base-catalyzed double bond migration, but the formation of **30** was unexpected and could only be rationalized by a reductive elimination process (eq. [2]). This type of reductive desulfurization was demonstrated recently by Theobald and Okamura (19). These results clearly indicated that the α,β-unsaturated ketone is not compatible as such with the [2,3]-sigmatropic rearrangement. However, this situation can be remedied by reducing the C11 ketone first.

After considerable experimentation, reduction was effected by treatment of **28** with lithium borohydride in THF/methanol (20) to give alcohol **31** as a 3:2 mixture of sulfoxide diastereoisomers in 77% yield. Separation of the isomers was achieved by careful silica gel chromatography to give **31 major** and **31 minor**; their stereochemistry was not determined. Compounds **31 major** and **31 minor** were then each treated with 10 equivalents of triethyl phosphite (18) in ethanol at 40°C for 5 days but only **31 major** rearranged to give diol **32** (75%). The minor isomer, even after a prolonged reaction time, gave only recovered starting material.

However, when **31 minor** was heated at 80°C for 48 h under identical conditions, a new compound assigned to be imino ether **33** was obtained in 75% yield. This initially caused some concern but it was found that **33** was also obtained as the sole product when **31 major** was heated at 80°C in the presence of 10 equivalents of triethyl phosphite, or when diol **32** was simply heated in ethanol at 80°C. This clearly demonstrated that the rearrangement of the two sulfoxide diastereomers was proceeding to give the same stereochemistry at C12, but at very different reaction rates. This must mean that one transition state involves more steric interactions than the other. Examination of molecular models showed that this can only be explained if the rearrangement proceeds from the α-face to deliver an

[3]It was observed that the 1,3-propane diol was insoluble in benzene and formed globules on reflux.

SCHEME 4

axial alcohol at C12 (Fig. 2). To reinforce this stereochemical assignment, a 10% nOe enhancement was observed at one of the vinyl protons when the C12 proton of **32** was irradiated.

The α (axial) assignment to the C12-OH group is also in agreement with a study reported by Hoffmann *et al.* (21). Using a simple cyclohexene whose conformation was anchored by a 4-*tert*-butyl group and whose position of the arylsulfoxy group relative to the cyclohexene was the same as in sulfoxide **31**, these authors concluded that there is a 6.2-fold preference for the formation of the axial (versus the equatorial) C—O bond

and that there is a 3.1-fold preference for an *exo* (aryl group away from the molecule) versus an *endo* (aryl group towards the molecule) transition state in that particular case. Thus, there is clearly a "six-membered ring bias" towards a quasi-axial attack of the cyclohexene via a quasi-chair conformation. However, in contrast to Hoffmann *et al.*, we have not detected a trace of the C12-β isomer on rearrangement of **31**, in spite of the fact that the sulfoxide of **31** may be involved in a 1,3-*cis* diaxial interaction with the C14—C15 bond when attacking from the α-side (see Fig. 2). Further experiments are required to establish whether the greater stereoselectivity in the case of **31** arises from a reduced conformational flexibility of the cyclohexene in **31** or whether the axial C11 hydroxyl group in **31** exerts a stereoelectronic effect favouring an antiperiplanar addition.

In conclusion, an efficient 19-step synthesis of a pentacyclic intermediate has been achieved in a 3.5% overall yield from 2-methylcyclohexane-1,3-dione and ethyl vinyl ketone. This intermediate, **33**, contains four of the five rings and seven of the 10 chiral centers of bruceantin. Its further synthetic manipulation and the general utility of the sequence **24** → **28** → **32** are currently under investigation.

Experimental section

Melting points were determined on a Kofler hot stage apparatus and are uncorrected. Infrared (IR) spectra were recorded on a Perkin–Elmer IR spectrophotometer model 717B using sodium chloride cells

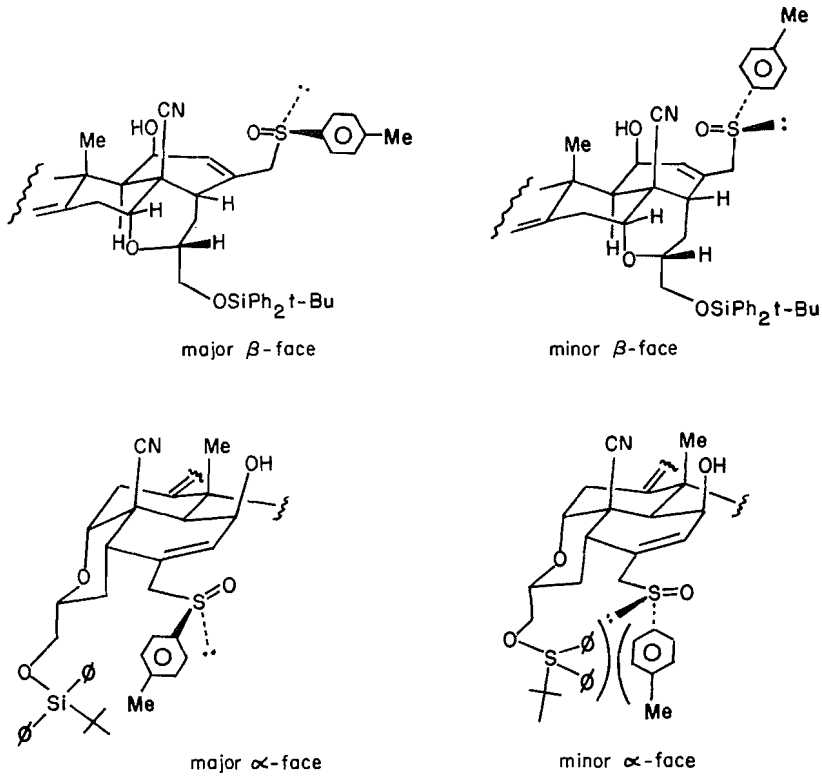

FIG. 2

(0.5 mm) and are reported in wave numbers (cm^{-1}) with polystyrene as standard. Nuclear magnetic resonance (NMR) spectra were recorded on a Varian XL-200 (200 MHz) spectrometer. Chemical shifts are reported in ppm (δ) downfield relative to tetramethylsilane as standard. High resolution mass spectra (HRMS) were recorded at the Mass Spectrometry Laboratory, Department of Chemistry, University of Alberta, Edmonton, Alberta. Ultraviolet (UV) spectra were recorded on a Beckman spectrophotometer model 25, using quartz cells (4.5 mL).

All reactions, unless otherwise specified, were run under an inert atmosphere of Ar or N_2, and reactions requiring anhydrous conditions were performed in a flame-dried or oven-dried (120°C) apparatus. Temperatures above or below room temperature refer to bath temperatures. All solvents used in the reaction flask were anhydrous, unless otherwise stated, and were dried according to established procedures by distillation under N_2 from an appropriate drying agent (22).

Analytical TLC was performed on E. Merck precoated silica gel plates (0.25 mm). Column chromatography was performed by the method of Still *et al.* (23) with E. Merck silica gel 60 (230–400 mesh).

Preparation of enone ***14***

A solution of 3.6 g (0.017 mol) of mercuric oxide, 120 mL of 0.5% H_2SO_4, and 200 mL of THF was heated to 40°C and 4.0 g (0.0082 mol) of **8** in 20 mL of THF was added. The reaction mixture was stirred at this temperature for 4 h, cooled, and filtered through Florisil. The filtrate was saturated with NaCl and extracted with ethyl acetate. The organic extract was washed with 10% $NaHCO_3$, water, and brine, and dried over anhydrous $MgSO_4$. After filtration and evaporation of solvent under reduced pressure, the solid was chromatographed on silica gel (hexane/ethyl acetate 4:1 as eluant) to give 3.26 g (100%) of enone **14**. An analytical sample of **14** (mp 158–159.5°C) was obtained by recrystallization from ether. IR ($CHCl_3$): 2950 (m), 2190 (w), 1720 (s), 1670 (s), 1610 (m), 1360 (m), 1320 (m); UV (95% ethanol): 243 nm (ε = 12 610); NMR (200 MHz, $CDCl_3$): 5.98–5.74 (m, 1H), 5.26–5.10 (m, 2H), 3.25 (s, 1H), 2.98–2.84 (m, 1H), 2.74–2.46 (m, 5H), 2.39 (s, 3H), 2.36–1.94 (m, 4H), 1.86 (s, 3H), 1.85–1.61 (m, 2H), 1.56 (s, 3H), 0.16 (s, 9H); HRMS (EI) *m/e* (relative intensity): 395.2277 (6.86).

Preparation of enol ether ***15***

A solution of 7.72 g (19.4 mmol) of **14** and 100 mL of dry benzene was treated with 6.47 mL (38.9 mmol) of triethylorthoformate and 0.7 g (4.07 mmol) of *p*-toluenesulfonic acid and stirred for 1 h. The reaction mixture was poured into saturated $NaHCO_3$ and the layers were separated. The organic portion was washed with water and brine, dried over anhydrous $MgSO_4$, filtered, and the solvent evaporated *in vacuo*. The yellow solid was purified by silica gel chromatography (hexane/ethyl acetate 6:1 as eluant) to yield 7.36 g (89%) of **17**. An analytical sample of **17** (mp 102–105°C) was obtained by recrystallization from ether/hexane. IR ($CHCl_3$): 2910 (s), 2240 (m), 2160 (m), 1710 (s), 1650 (s), 1380 (s), 1360 (s); UV (95% ethanol): 248 nm (ε = 10 582); NMR (200 MHz, $CDCl_3$): 5.96–5.74 (m, 1H), 5.47 (t, *J* = 4 Hz, 1H), 5.26–5.08 (m, 2H), 3.86 (q, *J* = 7 Hz, 2H), 3.28 (s, 1H), 2.86–2.46 (m, 4H), 2.40 (s, 3H), 2.39–2.06 (m, 3H), 1.96–1.84 (m, 1H), 1.81 (s, 3H), 1.78–1.56 (m, 1H), 1.36 (s, 3H), 1.29 (t, *J* = 7 Hz, 3H), 0.17 (s, 9H); HRMS (EI) *m/e* (relative intensity): 423.2604 (46.73).

Preparation of bromide ***16***

To a solution of 7.21 g (17 mmol) of enol ether **15** in 1.5 L of THF and 42 mL of water was added dropwise 5.97 g (18.7 mmol) of pyridinium bromide perbromide in 50 mL of THF over 5 min. Towards the end of the addition the solution became turbid, so an additional 25 mL of water was added. At the end of the addition the reaction mixture was stirred for 5 min. After the solution was washed with 10% $NaHCO_3$, water, and brine, it was dried over anhydrous $MgSO_4$, filtered, and evaporated under reduced pressure. Purification by silica gel chromatography (hexane/ethyl acetate 3:1 as eluant) furnished 7.07 g (88%) of **16**. An analytical sample of **16** (mp 134–137°C) was prepared by recrystallization from ether/hexane. IR ($CHCl_3$): 2970 (s), 2260 (w), 2190 (m), 1720 (s), 1680 (s), 1610 (m), 1360 (s), 1320 (s); UV (95% ethanol): 257 nm (ε = 15 083); NMR (200 MHz, $CDCl_3$): 5.90–5.70 (m, 1H), 5.40 (dd, *J* = 2 Hz, *J* = 2 Hz, 1H), 5.26–5.10 (m, 2H), 3.18 (s, 1H), 2.84–2.56 (m, 5H), 2.43 (s, 3H), 2.38–2.0 (m, 3H), 1.95 (s, 3H), 1.93 (s, 3H), 0.14 (s, 9H); HRMS (EI) *m/e* (relative intensity): 473.1395 (1.16).

Preparation of dienone ***17***

To a solution of 8.87 mL (71.7 mmol) of DBN and 100 mL of dry THF was added 6.83 g (14.4 mmol) of bromide **16** in 50 mL of THF via a dropping funnel over 10 min. After complete addition, the solution was stirred for 20 min and then quenched with 50 mL of saturated NH_4Cl. The layers were separated and the organic phase was washed with water and brine, dried over anhydrous $MgSO_4$, and filtered. After evaporation of solvent *in vacuo* and purification by silica gel chromatography (hexane/ethyl acetate 3:1 as eluant), 4.45 g (78%) of dienone **17** was obtained. An analytical sample of **17** (mp 167–168°C) was obtained by recrystallization from ether/hexane. IR ($CHCl_3$): 2970 (m), 2890 (m), 2250 (m), 2190 (m), 1720 (s), 1660 (s), 1630 (m), 1590 (m), 1360 (m), 1320 (m); UV (95% ethanol): 282 nm (ϵ = 17 300); NMR (200 MHz, $CDCl_3$): 6.85 (d, J = 10 Hz, 1H), 6.04 (d, J = 10 Hz, 1H), 6.02–5.82 (m, 1H), 5.36–5.17 (m, 2H), 3.53 (s, 1H), 2.88–2.44 (m, 5H), 2.42 (s, 3H), 1.93 (s, 3H), 1.57 (s, 3H), 0.17 (s, 9H); HRMS (EI) m/e (relative intensity): 393.2123 (8.18).

Preparation of diol ***19***

A mixture of 302 mL of *tert*-butanol, 38.2 mL of water, 114 mL of THF, 3.24 g (24 mmol) of *N*-methylmorpholine-*N*-oxide, and 8.59 g (21.8 mmol) of **18** was stirred until a homogenous solution was obtained, at which time 2 mL of a 4% (w/v) water solution of OsO_4 (0.3 mmol) was added and stirring continued for 18 h. To the solution was then added 2.2 g of Florisil and 1 g of $Na_2S_2O_4$; the solution was stirred for 5 min and then filtered through Celite. The solvent was evaporated under reduced pressure and the residue was taken up in ethyl acetate, washed with 5% HCl, water, and brine. After drying over anhydrous $MgSO_4$, filtration, and evaporation of solvent *in vacuo*, the solid was purified by silica gel chromatography (hexane/ethyl acetate 1:4 as eluant) to give 7.85 g (85%) of diol **19**. IR ($CHCl_3$): 3700–3300 (br, m), 2950 (s), 2250 (m), 2190 (m), 1720 (s), 1660 (s), 1630 (m), 1590 (m), 1380 (m), 1360 (s), 1330 (s); UV (95% ethanol): 278 nm (ϵ = 19 340); NMR (200 MHz, $CDCl_3$), major diastereomer: 6.81 (d, J = 10 Hz, 1H), 5.95 (d, J = 10 Hz, 1H), 4.05–3.92 (m, 1H), 3.84–3.40 (m, 3H), 3.08 (dd, J = 3 Hz, J = 12 Hz, 1H), 2.86–2.52 (m, 2H), 2.40 (s, 3H), 1.89 (s, 3H), 1.55 (s, 3H), 0.12 (s, 9H); minor diastereomer: 6.83 (d, J = 10 Hz, 1H), 5.97 (d, J = 10 Hz, 1H), 4.05–3.92 (m, 1H), 3.84–3.40 (m, 3H), 3.08 (dd, J = 3 Hz, J = 12 Hz, 1H), 2.86–2.52 (m, 2H), 2.40 (s, 3H), 1.89 (s, 3H), 1.55 (s, 3H), 0.14 (s, 9H); HRMS (EI) m/e (relative intensity): 427.2159 (1).

Preparation of enone ***20***

A solution of 300 mL of benzene, 21.4 mL (0.3 mol) of 1,3-propane diol, and 28.2 g (0.15 mol) of *p*-toluenesulfonic acid was brought to reflux for 2 h and the water was azeotropically removed via a Dean–Stark apparatus. The solution was cooled to 40°C and 2.11 g (0.005 mol) of diol **19** in 20 mL of dry benzene was added. The reaction mixture was rapidly stirred at this temperature for 4 h. The benzene was removed under reduced pressure and the residue was taken up in ethyl acetate and washed three times with saturated $NaHCO_3$, water, and brine. The organic phase was dried over anhydrous $MgSO_4$, filtered, and solvent evaporated. The solid was purified by silica gel chromatography (hexane/ethyl acetate 1:4 as eluant) to give 1.44 g (90%) of alcohol **20** and 0.5 g of starting material **19**. IR ($CHCl_3$): 3620 (m), 3600–3300 (br, m), 2950 (m), 2900 (m), 2260 (w), 2190 (w), 1720 (s), 1660 (s), 1620 (m), 1360 (s), 1320 (m); UV (95% ethanol): 245 nm (ϵ = 12 610); NMR (200 MHz, $CDCl_3$): 4.21 (t, J = 3 Hz, 1H), 4.16–3.86 (m, 3H), 3.78–3.52 (m, 2H), 3.36 (s, 1H), 3.36–2.72 (m, 5H), 2.44 (s, 3H), 1.81 (s, 3H), 1.60 (s, 3H), 0.18 (s, 9H); HRMS (EI) m/e (relative intensity): 427.2166 (12.82).

Preparation of acetylene ***21***

A solution of 5.3 g (0.012 mol) of enone **20** in 100 mL of dry CH_3CN was stirred with 11.8 g (0.042 mol) of tetrabutylammonium chloride and 5.61 g (0.097 mol) of potassium fluoride at room temperature for 0.5 h. The acetonitrile was evaporated under reduced pressure and the residue taken up in ethyl acetate and washed with saturated NH_4Cl, water, and brine. After drying over anhydrous $MgSO_4$ and filtering, the solvent was evaporated *in vacuo*. The solid obtained was purified by silica gel chromatography (hexane/ethyl acetate 1:2 as eluant) to give 4.4 g (100%) of acetylene **21**. IR ($CHCl_3$): 3320 (m), 2950 (m), 2880 (m), 2260 (w), 1720 (m), 1670 (s), 1625 (m), 1360 (m); UV (95% ethanol): 247 nm (ϵ = 12 739); NMR (200 MHz, $CDCl_3$): 3.93 (t, J = 4 Hz, 1H), 3.80–3.48 (m, 3H), 3.28–2.74 (m, 4H), 2.93 (s, 1H), 2.39 (d, J = 2.7 Hz, 1H), 1.18 (s, 3H), 1.59 (s, 3H); HRMS (EI) m/e (relative intensity): 355.1787 (96.25).

Preparation of silyl ethers ***22*** *and* ***23***

A solution of 4.40 g (0.012 mol) of acetylene **21** in 200 mL of dry DMF was stirred with 6.46 mL (0.025 mol) of *tert*-butyldiphenylsilyl chloride and 3.98 g (0.049 mol) of imidazole for 10 h at room temperature. The reaction mixture was poured into saturated NH_4Cl and diluted with 100 mL of benzene. The layers were separated and the organic phase was washed with water and brine, dried over anhydrous $MgSO_4$, filtered, and solvent evaporated under reduced pressure. Silica gel chromatography (hexane/ethyl acetate 7:3 as eluant) gave 5.31 g of **22** and 0.9 g of **23** (85% combined yield). An analytical sample of **22** (mp 199–200°C) and **23** (mp 207–208.5°C) was obtained by recrystallization from hexane/ethyl acetate. Major diastereomer **22**: IR ($CHCl_3$): 3310 (s), 2930 (s), 2860 (s), 2250 (w), 1720 (s), 1660 (s), 1620 (m), 1360 (s); UV (95% ethanol): 247 nm (ϵ = 13 260); NMR (200 MHz, $CDCl_3$): 7.74–7.34 (m, 10H), 3.88 (t, J = 3 Hz, 1H), 3.80–3.74 (m, 3H), 3.31 (s, 1H), 3.24–3.00 (m, 2H), 2.90–2.74 (m, 1H), 2.42 (s, 3H), 2.40 (d, J = 2 Hz, 1H), 1.84 (s, 3H), 1.61 (s, 3H), 1.03 (s, 9H); HRMS (EI) m/e (relative intensity): 536.2254 (M − C_4H_9, 100); minor diastereomer **23**: IR ($CHCl_3$): 3320 (m), 2940 (m), 2870 (m), 2260 (w), 1720 (m), 1670 (s), 1620 (s), 1360 (m); UV (95% ethanol): 247 nm (ϵ = 13 460); NMR (200 MHz, $CDCl_3$): 7.76–7.38 (m, 10H), 4.02 (t, J = 3 Hz, 1H), 4.01 (m, 1H), 3.92–3.80 (m, 2H), 3.31 (s, 1H), 3.31–3.20 (m, 1H), 2.96–2.60 (m, 2H), 2.44 (s, 3H), 2.35 (d, J = 2 Hz, 1H), 2.16–1.92 (m, 3H), 1.79 (s, 3H), 1.56 (s, 3H), 1.10 (s, 9H); HRMS (EI) m/e (relative intensity): 536.2267 (M − C_4H_9, 87.98).

Preparation of dithianes ***24*** *and* ***25***

A solution of 1.28 g (2.16 mmol) of ether **22** in 3 mL each of dry THF and Et_2O was treated with 4.0 mL (32.5 mmol) of $BF_3 \cdot OEt_2$ and 0.48 mL (4.77 mmol) of 1,3-propane dithiol at room temperature for 3 h. The reaction mixture was *carefully* poured into cold saturated $NaHCO_3$ and diluted with 50 mL of ethyl acetate. Separation of the layers and washing of the organic phase with water and brine, followed by drying over anhydrous $MgSO_4$, filtration, and evaporation of solvent under reduced pressure, gave a yellow solid. Purification by silica gel chromatography (hexane/ethyl acetate 3:1 as eluant) gave 1.42 g (96%) of dithiane **24**. An analytical sample of **24** (mp 180–183°C) was obtained by recrystallization from hexane/ether. IR ($CHCl_3$): 3310 (s), 2930 (s), 2860 (s), 2250 (w), 1720 (s), 1590 (w), 1420 (m), 1360 (s); NMR (200 MHz, $CDCl_3$): 7.76–7.36 (m, 10H), 3.80–3.44 (m, 3H), 3.75 (t, J = 3 Hz, 1H), 3.18–2.46 (m, 9H), 3.09 (s, 1H), 2.42 (s, 3H), 2.35 (d, J = 2 Hz, 1H), 2.28–1.72 (m, 7H), 2.00 (s, 3H), 1.48 (s, 3H), 1.08 (s, 9H); HRMS (EI) m/e (relative intensity): 683.2920 (39.45).

The same procedure was followed for the preparation of dithiane **25** (84%). An analytical sample of **25** (mp 196–198°C) was obtained by recrystallization from ether/hexane. IR ($CHCl_3$): 3320 (s), 2940 (s), 2860 (s), 2260 (m), 1710 (s), 1600 (m), 1420 (s), 1390 (m), 1360 (s), 1280 (s); NMR (200 MHz, $CDCl_3$): 7.78–7.38 (m, 10H), 4.12–3.99 (m, 1H), 3.89 (t, J = 3 Hz, 1H), 3.88–3.76 (m, 2H), 3.24–2.98 (m, 3H), 3.15 (s, 1H), 2.80–2.46 (m, 5H), 2.42 (s, 3H), 2.40–1.78 (m, 8H), 1.96 (s, 3H), 1.42 (s, 3H), 1.08 (s, 9H); HRMS (EI) m/e (relative intensity): 683.2906 (6.38).

Preparation of keto ester ***26***

A solution of 0.2 mL (0.98 mmol) of hexamethyldisilazine and 10 mL of dry THF was cooled to −30°C and 0.61 mL (0.98 mmol) of 1.6 M *n*BuLi in hexane was added dropwise via a syringe. The mixture was stirred for 15 min and then treated with acetylene **24** in 5 mL of dry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

THF. After 2 h of stirring the temperature was lowered to −78°C and 0.018 mL (0.21 mmol) of dimethyl carbonate was added. The reaction mixture was maintained at this temperature for 4 h and then poured into saturated ammonium chloride. The layers were separated and the organic portion was washed with water and brine, dried over anhydrous $MgSO_4$, filtered, and solvent evaporated *in vacuo*. Purification by silica gel chromatography (hexane/ethyl acetate 3:1 as eluant) gave 92 mg (84%) of keto ester **26**. An analytical sample of **26** (mp 176–178°C) was obtained by recrystallization from ether/hexane. IR ($CHCl_3$): 2820 (s), 2850 (s), 2240 (w), 1740 (s), 1680 (s), 1640 (m), 1600 (w), 1430 (s), 1380 (m), 1360 (m), 1340 (m); UV (95% ethanol + 5% NaOH): 390 nm (ϵ = 60 975); NMR (200 MHz, $CDCl_3$): 7.78–7.36 (m, 10H), 6.00 (s, 1H), 3.87 (t, J = 3 Hz, 1H), 3.84–3.52 (m, 3H), 3.73 (s, 3H), 3.34–2.40 (m, 11H), 2.0 (s, 3H), 1.45 (s, 3H), 1.04 (s, 9H).

Preparation of keto sulfoxide 28

A solution of 500 mg (0.73 mmol) of acetylene **24** and 60 mL of dry THF was cooled to −78°C. To this via a syringe was added 0.88 mL (2.2 mmol) of 2.5 M *n*BuLi in hexane, and after 15 min 261 mg (1.32 mmol) of isopropoxy-*p*-toluenesulfinate in 1 mL of THF was added. The reaction mixture was warmed to room temperature gradually and stirred for 5 h. The solution was poured into saturated NH_4Cl and the layers were separated. The organic phase was washed with water and brine, dried over anhydrous $MgSO_4$, filtered, and solvent evaporated under reduced pressure. Purification by silica gel chromatography (hexane/ethyl acetate 1:1 as eluant) gave 490 mg (81%) of keto sulfoxide **28**. IR ($CHCl_3$): 2940 (s), 2860 (s), 2240 (w), 1685 (s), 1640 (m), 1605 (m), 1500 (m), 1470 (m), 1440 (m), 1385 (m), 1370 (m), 1350 (m), 1310 (m); UV (95% ethanol + 5% NaOH): 369 nm (ϵ = 30 400); NMR (200 MHz, $CDCl_3$): 7.78–7.32 (m, 14H), 5.61, 5.56 (C13-H from each sulfoxide diastereomer), 3.96–2.48 (m, 16H), 2.44 (s, 3H), 2.00 (s, 3H), 1.46 (s, 3H), 1.06 (s, 9H).

Preparation of diosphenol 29 and enone 30

A solution of 31 mg (0.037 mmol) of keto sulfoxide **28** and 5 mL of anhydrous methanol was treated with 0.62 mL (0.17 mmol) of 0.11 M sodium thiophenolate and refluxed for 60 h. After cooling, the methanol was evaporated under reduced pressure. The residue was taken up in 10 mL of ethyl acetate and washed with saturated NH_4Cl, water, and brine. Following drying over anhydrous $MgSO_4$ and filtration, the solvent was evaporated *in vacuo*. Purification by silica gel chromatography (hexane/ethyl acetate 85:15 as eluant) gave 7 mg of diosphenol **29** and 14 mg of enone **30** (79% combined yield). Diosphenol **29**: IR ($CHCl_3$): 3600–3300 (br, w), 2930 (s), 2860 (s), 2250 (w), 1720 (w), 1675 (s), 1645 (m), 1595 (w), 1420 (m), 1380 (m), 1360 (m), 1340 (m), 1300 (m); UV (95% ethanol): 276 nm; (95% ethanol + 5% NaOH): 324 nm; NMR (200 MHz, $CDCl_3$): 7.72–7.34 (m, 10H), 3.82 (t, J = 3 Hz, 1H), 3.79–3.42 (m, 3H), 3.20–2.82 (m, 3H), 2.76–2.42 (m, 8H), 1.99 (s, 3H), 1.96 (s, 3H), 1.45 (s, 3H), 1.04 (s, 9H).

Enone **30**: IR ($CHCl_3$): 2930 (s), 2240 (w), 1680 (s), 1640 (m), 1600 (m), 1470 (m), 1450 (m), 1430 (m), 1380 (m); UV (95% ethanol): 256 nm; NMR: 7.74–7.36 (m, 10H), 5.89 (s, 1H), 3.96–3.50 (m, 4H), 3.20–2.84 (m, 2H), 2.78–2.38 (m, 5H), 2.26–1.58 (m, 9H), 1.98 (s, 3H), 1.46 (s, 3H), 1.04 (s, 9H).

Preparation of hydroxy sulfoxides 31 major and 31 minor

A solution of 25 mL of dry THF, 2.5 mL of anhydrous methanol, and 26 mg (1.19 mmol) of lithium borohydride was stirred at room temperature for 20 min. Then 100 mg (0.12 mmol) of keto sulfoxide **28** in 1 mL of THF was added and stirring was continued for 10 min. The reaction mixture was diluted with 20 mL of reagent grade ether and 1 mL of 10% HCl. The mixture was then washed with 10% HCl, water, and brine. The organic layer was dried over anhydrous $MgSO_4$, filtered, and solvent evaporated under reduced pressure. Silica gel chromatography (hexane/ethyl acetate 1:1 as eluant) furnished 46 mg of **31 major** and 31 mg of **31 minor** (77% combined yield). **31 major**: IR ($CHCl_3$): 3580 (w), 3500–3200 (br m), 2930 (s), 2850 (s), 2240 (w), 1600 (w), 1470 (m), 1420 (m), 1365 (m); NMR (200 MHz, $CDCl_3$): 7.78–7.32 (m, 14H), 5.44 (d, J = 4 Hz, 1H), 4.35 (dd, J = 3 Hz, J = 4 Hz, 1H), 3.87 (t, J = 2 Hz, 1H), 3.80–3.24 (m, 5H), 3.22–2.50 (m, 8H), 2.44 (s, 3H), 1.98 (s, 3H), 1.66 (s, 3H), 1.05 (s, 9H).

31 minor: IR ($CHCl_3$): 3580 (w), 3540–3300 (br, w), 2930 (s), 2850 (s), 2230 (w), 1600 (w), 1500 (m), 1470 (m), 1430 (s), 1390 (m); NMR (200 MHz, $CDCl_3$): 7.74–7.32 (m, 14H), 5.44 (d, J = 4.5 Hz, 1H), 4.32 (dd, J = 3 Hz, J = 4.5 Hz, 1H), 3.88 (t, J = 3 Hz, 1H), 3.76–3.60 (m, 4H), 3.28–2.48 (m, 8H), 2.44 (s, 3H), 2.30–1.72 (m, 7H), 1.96 (s, 3H), 1.66 (s, 3H), 1.04 (s, 9H).

Preparation of diol 32

A solution of 19 mg (0.023 mmol) of **31 major** and 5 mL of anhydrous ethanol was heated at 40°C for 5 days with 0.039 mL (0.23 mmol) of triethyl phosphite. After cooling and evaporation of solvent the residue was purified by silica gel chromatography (hexane/ethyl acetate 1:1 as eluant) to give 12 mg (75%) of diol **32**. IR ($CHCl_3$): 3610 (m), 3550–3250 (br, w), 2920 (s), 2850 (s), 2240 (w), 1590 (w), 1420 (m), 1380 (m), 1360 (m); NMR (200 MHz, $CDCl_3$): 7.78–7.34 (m, 10H), 5.34 (s, 1H), 5.28 (s, 1H), 4.32 (dd, J = 3.5 Hz, J = 8 Hz, 1H), 4.21 (d, J = 3.5 Hz, 1H), 3.80 (t, J = 2 Hz, 1H), 3.76–3.40 (m, 3H), 3.22–2.02 (m, 12H), 1.98 (s, 3H), 2.58 (s, 3H), 1.05 (s, 9H).

Preparation of imino ether 33

A solution of 14 mg (0.017 mol) of **31 minor** and 5 mL of anhydrous ethanol was heated at 80°C for 48 h in the presence of 0.029 mL (0.17 mmol) of triethyl phosphite. After cooling, and evaporation of solvent *in vacuo*, the residue was purified by silica gel chromatography (hexane/ethyl acetate 1:1 as eluant) to deliver 9 mg (75%) of imino ether **33**.

The other sulfoxide diastereoisomer **31 major** can be subjected to the same conditions to give **33** (76%). IR ($CHCl_3$): 3280 (w), 2820 (s), 2850 (s), 1695 (s), 1600 (w), 1470 (m), 1430 (m), 1380 (m), 1360 (m); NMR (200 MHz, $CDCl_3$): 7.78–7.56 (m, 10H), 5.24 (s, 1H), 5.19 (s, 1H), 4.50 (d, J = 5 Hz, 1H), 4.41 (d, J = 5 Hz, 1H), 4.00 (t, J = 3 Hz, 1H), 3.80–3.46 (m, 3H), 3.18–2.94 (m, 2H), 2.80–2.00 (m, 11H), 1.93 (s, 3H), 1.90–1.55 (m, 3H), 1.07 (s, 3H), 1.04 (s, 9H).

Acknowledgements

The support of the Natural Sciences and Engineering Research Council of Canada, Ottawa, in the form of operating grants and a fellowship to one of us (D.I.M.) is gratefully acknowledged. We also thank the Terry Fox Grant Fund of New Brunswick for support. Mr. Larry A. Calhoun of this department kindly helped with certain NMR measurements and interpretations. We thank Professor E. Piers, University of British Columbia, for the suggestion that the exclusive formation of the axial alcohol during the sigmatropic rearrangement could be aided by a stereoelectronic effect.

Received July 20, 1990

ANTONELLO FILIPPI, GIORGIO OCCHIUCCI, and MAURIZIO SPERANZA. Can. J. Chem. **69**, 732 (1991).

Phenylium ion, obtained from the spontaneous β decay of 1,4-ditritiobenzene, has been allowed to react with pyrrole, *N*-methylpyrrole, furan, and thiophene, in both the gaseous and liquid phases. The differences between the reactivity pattern of phenylium ion in the two environments can be essentially reduced to significant ion-neutral electrostatic interaction in the gas phase and to the much greater efficiency of collisional stabilization in the condensed phase, allowing a larger fraction of the excited ionic intermediates, from the highly exothermic attack of phenylium ion on the aromatic substrate, to survive dissociation and isomerization. The mechanism of the phenylation process and of the subsequent isomerization of the relevant ionic intermediates is discussed and the intrinsic substrate and positional selectivity of the phenylium ion evaluated. While the limited substrate discrimination of phenylium ion fully agrees with its well-known exceedingly high reactivity, its pronounced affinity toward the α carbons of the selected heteroarenes does not conform with the relatively "hard" character of the reactant, expected on the grounds of its STO-3G calculated LUMO energy. The conceivable occurrence of an intimate entropy-favored two-step addition mechanism, involving a preliminary single-electron transfer (SET) from the heteroaromatic substrate to the ionic electrophile, which is thermochemically allowed only for phenylium and methyl cations and prevented for other alkylating electrophiles, is discussed.

Key words: gas-phase ion chemistry, electrophilic heteroaromatic substitution, nuclear decay chemistry, phenylium ion, electron transfer.

ANTONELLO FILIPPI, GIORGIO OCCHIUCCI et MAURIZIO SPERANZA. Can. J. Chem. **69**, 732 (1991).

On a fait réagir l'ion phénylium, obtenu par une desintégration β spontanée du 1,4-ditritiobenzène, avec le pyrrole, le *N*-méthylpyrrole, le furane et le thiophène, tant en phase gazeuse que liquide. Les différences de comportement de l'ion phénylium observées entre les deux environnements peuvent être attribuées essentiellement à une interaction électrostatique ion-neutre importante en phase gazeuse et à une efficacité beaucoup plus grande de la stabilisation collisionnelle en phase condensée qui permettent à une fraction beaucoup plus grande des intermédiaires ioniques excités, provenant de l'attaque très exothermique de l'ion phénylium sur le substrat aromatique, de survivre à la dissociation et à l'isomérisation. On discute du mécanisme du processus de phénylation et de l'isomérisation subséquente des intermédiaires ioniques appropriés et on évalue le substrat intrinsèque et la sélectivité positionnelle de l'ion phénylium. Même si la discrimination limitée de l'ion phénylium par rapport aux substrats est en parfait accord avec son extrêmement grande réactivité bien connue, son affinité prononcés pour les carbones α des hétéroarènes choisie n'est pas conforme au caractère relativement « dur » du réactif auquel on s'attend sur la base de calculs STO-3G de l'énergie de son OM basse vacante. On discute de la possibilité d'existence d'un mécanisme d'addition intime en deux étapes, favorisé par l'entropie et impliquant un seul transfert préliminaire d'électron du substrat hétéroaromatique vers l'électrophile ionique qui, d'un point de vue thermochimique, n'est permis que pour les ions phénylium et méthyle et qui ne l'est pas pour tous les autres électrophiles alkylants.

Mots clés : chimie ionique en phase gazeuse, substitution hétéroaromatique électrophile, chimie de désintégration nucléaire, ion phénylium, transfert d'électron.

[Traduit par la rédaction]

Introduction

The general features of the electrophilic substitution on simple five-membered heteroaromatics by free alkylating electrophiles, such as CT_3^+ (2), $(CH_3)_2X^+X$ (X = F, Cl) (3), $C_2H_5^+$ (4), i-$C_3H_7^+$ (5), t-$C_4H_9^+$ (6), and $(CH_3)_3Si^+$ (1), in the dilute gas state have recently been investigated. It has been shown that the reactivity features of these alkylating carbocations toward the ring positions of selected heteroaromatic substrates, in particular pyrrole and *N*-methylpyrrole, can be linearly correlated with the electron distribution of the ionic reactants and, especially, with their LUMO energies (4), taken as a measure of their "hardness" character (7). Thus, "hard" electrophiles, such as t-$C_4H_9^+$, i-$C_3H_7^+$, $C_2H_5^+$, and $(CH_3)_2F^+$, are predominantly directed toward the ring positions of pyrroles with the highest net negative charge (the C_β and N centers), whereas the "soft" CT_3^+ cation attacks preferentially the C_α sites of the selected heteroarenes, characterized by the highest HOMO π-electron density (8). However, when the silylating electrophile $(CH_3)_3Si^+$ is included in the above linear correlation, an appreciable deviation is observed, reflecting a measured positional selectivity ($\log(\beta/\alpha) = 0.37$) that is lower than the one ($\log(\beta/\alpha) =$ ca. 1) expected on the grounds of its SCF STO-3G calculated LUMO energy ($\epsilon_L = -1.8$ eV) (1). Such an unexpectedly soft character of $(CH_3)_3Si^+$ is rationalized in terms of the larger $3p$ empty orbital of Si^+ if compared to the $2p$ orbitals of the C^+ center of carbocations, although other explanations related to the intimate nature of the energy profiles governing such reactions could not be a priori excluded (1).

The growing interest in the reactivity of heteroaromatic compounds in the gas phase, i.e., in the absence of the solvation and ion-pairing normally preventing related investigations in

solution (9), calls for further work aimed at resolving the doubt introduced by the $(CH_3)_3Si^+$ electrophile, namely whether the Charge and Frontier Orbital Control Concept (8, 10) is adequate by itself to describe the intrinsic reactivity and selectivity properties of gaseous electrophiles toward five-membered heteroarenes.

To this purpose, the investigation is now extended to another category of ionic electrophiles, namely unsaturated carbocations, whose stable singlet configuration presents a nominally vacant orbital at the electron-deficient carbon that is orthogonal to a more or less polarized π system (11). As a response to π-electron polarization, the positively charged carbon center of unsaturated carbocations may acquire a certain carbenoid character and, therefore, exhibit reactivity properties that may largely differ from those of saturated carbocations. As the most representative members of this category, the phenylium ion $C_6H_5^+$ and two acylium ions, i.e., CH_3CO^+ and $C_6H_5CO^+$, are selected.

Such a choice arises primarily from the expected different extent of polarization of the π system orthogonal to the empty orbital of the above ions, owing to the presence of groups of largely different electronegativity adjacent to the electron-deficient carbon. In addition, the hybridization of the C^+ center of the selected electrophiles is also different, being pure *sp*-type in the acylium ions and distorted sp^2-type in the phenylium ion. Despite such differences, a recently advanced empirical hardness scale, based exclusively upon thermochemical arguments, ranks $C_6H_5^+$, $C_6H_5CO^+$, and CH_3CO^+ among the hardest ionic electrophiles known (10). Accordingly, all three reactants should exhibit a high selectivity toward the reaction centers of simple five-membered heteroaromatics with the highest net negative charge, irrespective of the electron distribution on the corresponding HOMOs. From a detailed analysis of this correspondence, it was hoped to define the domain of applicability of the Charge and Frontier Orbital Control Concept (8, 10) to heteroaromatic substitution by selected gaseous electrophiles and to ascertain whether more refined reactivity models are required.

This paper presents the results of a comparative study of the reactivity and the selectivity properties of free phenylium ion $C_6H_5^+$ toward pyrrole (**1**), *N*-methylpyrrole (**2**), furan (**3**), and thiophene (**4**), carried out both in the gaseous and in the condensed phase, using an ionic reactant from the β^- decay of a T atom in 1,4-T_2-benzene (eq. [1]). The decay technique

Tritiated products

Y = NH (**1**); NMe (**2**); O (**3**); S (**4**)

affords a convenient means of introducing free cations of defined structure and concentration into any system of interest and to follow their reactions by radiotracer techniques (12). A comparative analysis of the reactivity and selectivity features of the acylating electrophiles, i.e., CH_3CO^+ and $C_6H_5CO^+$, toward the same substrates in the dilute gas state is left to the following paper.

Experimental section

Materials

The key substrate for the nuclear decay experiments, namely 1,4-T_2-benzene, was synthesized and purified according to described procedures (13). The heteroaromatic substrates and the gaseous additives used for the preparation of the decay mixtures were research grade chemicals from Fluka AG and Matheson Co., and were used without further purification. Not commercially available isomeric phenyl derivatives of **1**–**4**, used as carriers or as standards in the radio high-performance liquid chromatographic (radio-hplc) analysis, were prepared following well-established synthetic procedures (14). The identity of the synthesized products was checked by conventional IR and NMR spectroscopy.

Procedure

The gaseous samples were prepared by conventional vacuum techniques, introducing the 1,4-T_2-benzene mixture (ca. 1–2 mCi), diluted with inactive benzene to a specific activity of 86 mCi $mmol^{-1}$, into evacuated and carefully outgassed 100-mL Pyrex vessels containing a measured amount of the heteroaromatic substrate, together with O_2, used as a radical scavenger, and a powerful ion trap (NH_3 or NMe_3), when required. The vessels were than sealed off and stored in the dark, at room temperature, for ca. 6–8 months.

The liquid samples were prepared according to the following procedure: ca. 1 mCi of the 1,4-T_2-benzene mixture (specific activity: 86 mCi $mmol^{-1}$) was introduced into carefully evacuated and outgassed 0.5-mL Pyrex vials equipped with a long capillary arm closed by a fragile tip. Each vial was sealed off from the vacuum line, and its capillary arm was introduced into a cylindrical vessel containing at the bottom a layer of purified mercury and filled with ca. 1 mL of a 1:1 mixture of the heteroaromatic compound and benzene, used as a reference substrate. The fragile tip of the capillary arm was then broken under the level of the organic mixture, which was consequently forced into the evacuated vial. When only a small bubble of gas was left at the top of the vial, the capillary arm was lowered further into the mercury. In this way, the vial was entirely filled by the organic mixture, except for the lower portion of the capillary, where the mercury has risen, acting as a mobile seal. The vials were stored in the dark, at room temperature, for ca. 6–8 months.

After the storage period, the ampoules were opened and their content analyzed by the radio-hplc procedure. A Varian Vista 5500 high-pressure liquid chromatograph equipped with a 254-nm UV detector in series with a Berthold LB 503 HS flow liquid scintillation counter was used for the radio-hplc analyses.

The identity of the tritiated products was established by the coincidence of their retention volumes with those of authentic reference compounds on the following columns: (i) 25 cm × 5 mm Rosil C-18 HL from Alltech, Italy, using CH_3CN/H_2O = 1:1; (ii) 30 cm × 5 mm μBondapak from Waters, U.S.A., using CH_3CN/H_2O ranging from 42%:58% to 70%:30%. The absolute yields of the tritiated products correspond to the ratio of their activity to the activity of the labelled decay ions formed during the storage period in the reaction mixture from the β decay of 1,4-T_2-benzene.

Computational details

Standard quantum-mechanical calculations, with the GAUSSIAN 80 (15) set of programs, were performed in order to evaluate the STO-3G (16) SCF eigenvalues of the LUMOs of ground-state singlet phenylium ion and of its vibrationally excited form with the same regular hexagonal geometry of benzene. Geometry optimization of the ground-state ion was carried out in the C_{2v} symmetry framework. The LUMO energies for ground-state phenylium ion and for the vibrationally excited ion with the same geometry as the benzene precursor are −3.5 and −5.5 eV, respectively.

Results

Table 1 shows the absolute and relative yields of tritiated products recovered from the liquid decay samples, containing 1:1 mixtures of each selected heteroarene and benzene, used as competing substrate. The results concerning similar competition experiments, carried out in the gas phase in the pressure range 13–134 Torr (1 Torr = 133.3 Pa), are given in Table 2. Reaction conditions were chosen to span several orders of

magnitude for the relative concentrations of the two competing aromatic substrates. Occasionally, from ca. 8 to over 33 mol% of a powerful ion trap, such as NH_3 or NMe_3, was added to the mixtures. The absolute yields, defined by the ratio of the activity of the products to the total activity of the nucleogenic (nuclear-decay generated) *para*-T-phenylium precursor, can be calculated from the initial activity and the isotopic composition of tritiated benzene, the decay rate of tritium, the abundance (72%) of the phenylium ions among the decay fragments (17), and the absolute counting efficiency of the detector employed.

The overall absolute yields of the tritiated aromatic products from the liquid systems of Table 1 are quite close to the theoretical limit and are found to depend upon the nature of the heteroarene employed, increasing in the order: **3** (66.9%) < **4** (72.1%) < **2** (96.7%) < **1** 98.6%). Radio-chromatographic analyses showed that low-boiling fragmentation products account

[a]The formation enthalpies of the ion and the neutrals used for these calculations have been taken from ref. 20. An estimate of the ΔH^0_f of **5** (Y = S) was obtained by assuming that the proton affinity of the *ipso* position of phenylthiophene is equal to that of thiophene, taken from ref. 20. The ΔH^0_f's of **5** (Y = NH, NMe, and O) were roughly estimated by assuming the same ΔH^0_f scale calculated for the corresponding methylated intermediates (ref. 2).

[c]Estimated as due to the presumably higher strain energy of **8** relative to phenylium ion.

for only a very limited fraction of the missing activity (0–6%), the remainder being attributable to polymerization products. A similar trend is observed in the corresponding gaseous samples of Table 2. Here, the absolute yields of low-boiling products increase appreciably, especially in the case of furan **3**. However, if analysis is restricted to the absolute yields of the heteroaromatic products recovered under comparable conditions, a rather different trend emerges, increasing in the order **3** < **4** < **1** < **2** in the liquid samples (Table 1) and in the order **3** << **1** < **4** < **2** in the gaseous systems (Table 2). In general, while substantial amounts of phenylated derivatives of pyrrole **1**, *N*-methylpyrrole **2**, and thiophene **4** are invariably recovered from the decay samples under all conditions, those of the phenylated products from furan **3** are comparatively much lower, especially in the gas phase. In the gaseous samples, the absolute yields of the phenylated products appear to increase with the total system pressure and to decrease significantly (from 62 to 85%) by addition of ca. 30 mol% of a base (NH_3 or NMe_3). It is noteworthy that such a decrease is not accompanied by an appreciable change in the product pattern and in the apparent phenylation rate constant ratios k_S/k_R. Only a slight change in the relative distribution of the phenylated heteroarenes is observed, which, however, is always characterized by the predominance of the α-substituted isomer (65–88%).

Discussion

Nature of the reagent

The formation of *para*-T-phenylium cation from the decay of 1,4-T_2-benzene has been discussed in detail elsewhere (18). The phenylium ion, formed in its most stable singlet configuration for more than 72% of the decay events (17), is characterized by a certain excess of internal energy due *inter alia* to the relaxation from the regular hexagonal structure of its 1,4-T_2-benzene precursor to the vibrationally most stable distorted hexagonal geometry (19). In the extreme hypothesis of an overall adiabatic process for the formation of *para*-T-phenylium ion from the nuclear transition in 1,4-T_2-benzene, theoretical calculations set an upper limit of ca. 32 kcal mol^{-1} to the vibrational excitation energy of the decay phenylium ion (19).

Concerning the energetic β particle from the decay, it should be considered that the reaction conditions have been specifically selected to make negligible any contribution to the products of Tables 1 and 2 from β radiolytic processes. In fact, the very low activity employed in the experiments and concentrated in the molecules of 1,2-T_2-benzene, highly diluted into the systems ($<3 \times 10^{-7}$ mol%), makes the probability of β-particle induced processes, such as direct radiolysis of labeled benzene and (or) combination of reactive species from radiolysis of **1**–**4** with labeled benzene, vanishingly small. Furthermore, in the gaseous systems, wherein the 1,2-T_2-benzene concentration is higher (5×10^{-3} to 7×10^{-2} mol%) and thus the probability of secondary radiolytic processes is higher as well, the presence of an effective radical scavenger, such as O_2, is expected to cut off any conceivable thermal radical component to the products formation. Such circumstances, as well as the pronounced effect of the added bases on the absolute yields of the products of Table 2, allow one to conclude that singlet phenylium ion is the very major primary species responsible for the formation of the labeled products of Tables 1 and 2.

Several reaction channels are accessible to the tritiated phenylium ion in its attack on the heteroaromatic substrates **1**–**4** as well as on the reference benzene, as illustrated in Table 3, where the approximate ΔH^0 values for the relevant gas-phase processes are reported. The enthalpy changes have been

calculated from the ΔH^0_f value of gaseous phenylium ion in its vibrational ground state (269.3 kcal mol^{-1}) (20). If allowance is made for a certain excess of vibrational energy in the decay phenylium ion, the actual enthalpy changes of reactions [2]–[5] (Table 3) may be further lowered by up to 32 kcal mol^{-1}. Of course, the calculated ΔH^0 values of reactions [2]–[4] are much less cogent if referred to processes occurring in the liquid systems, where ion solvation might intervene. At any rate, the highly exothermic addition reacton [2] is recognized as the main source of the labelled phenylated products of Tables 1 and 2.

Conceivably, there are at least two "blind" (i.e., not leading to identifiable labeled products, other than the starting benzene) reaction channels, namely eqs. [3] and, perhaps, [5], which may be allowed on thermochemical grounds (Table 3) and may account for the activity loss observed, especially in the furan systems. However, reaction [3] would lead to the inactive molecular ion of the heteroarene **6** and to tritiated phenyl radical, whose contribution, if any, to the identified products is strongly depressed by the presence of the thermal radical trap O_2. Further evidence against occurrence of a free tritiated phenyl radical from path [3] as a significant source of phenylated products is provided by the equally high yields of labeled products recovered from pyrroles **1** and **2**, in view of the well-documented ability of radicals to efficiently abstract hydrogen atom from the methyl group of **2**, giving tritiated benzene and 1-pyrrolyl methyl radicals, a route that is not available for **1** (21). The high yields of phenylated products measured in both the gaseous and the liquid decay, except perhaps in the gaseous furan systems, rule out significant occurrence of the secondary processes [4] and [5] as well (Table 3). This conclusion is further supported by the absence of appreciable amounts of both tritiated **1–4**, obtained via eq. [4] from a largely "automerized" phenylium ion (18*a*,*b*) and tritiated 1,4-dihydro-1,4-epoxynaphthalene from Diels–Alder [$\pi 4s + \pi 2s$] cycloaddition of benzyne from eq. [4] to furan (22).

Reaction in the liquid phase

It is suggested that formation of the tritiated products listed in Table 1 from the decay of 1,2-T_2-benzene in liquid heteroarene/benzene mixtures occurs via the exothermic process [2] of Table 3, and the corresponding process [2] on the benzene competitor to produce the *ipso*-protonated biphenyl intermediate **9**. Following collisional stabilization, very effective in the liquid system, the primary intermediates **5** and **9** undergo deprotonation by a base to yield the observed phenylated derivatives. As to the nature of the base, it should be noted that deprotonation of both ground-state **5** and **9** by a single heteroarene molecule may be in most instances rather endothermic (18*c*, 20). However, the deprotonation process may occur, if excited **5** and **9** from the relevant highly exothermic formation process (eq. [2]) are involved. Besides, cooperative deprotonation by several molecules of heteroarene is likely to occur in the liquid, and even in the gaseous systems within an ionic cluster. Additional bases able to efficiently deprotonate the intermediates **5** and **9** can be generated by the passage of the highly energetic β particles through the liquid medium, which normally induces extensive fragmentation of inactive bulk molecules to yield highly reactive species. The efficiency of collisional stabilization of the excited intermediates **5** and **9** in the liquid systems is apparent from the exceedingly high absolute yields of phenylated products and from the absence of appreciable amounts of low-boiling fragmentation products, even in the case of furan **3** where the lowest product yield is measured. As pointed out in related studies (1–6, 23), the comparatively low absolute yield of products from furan **3** (ca. 25%) may be attributed, apart from possible fragmentation processes, to the typical bidentate nature of the substrate, where the *n*-electron pair of oxygen competes efficiently with the π system for the electrophile. Such a competition may increase the extent of processes consuming phenylium ion, such as formation of a stable oxonium ion or its ring opening to reactive species ending with polymeric products. Similar paths appear much less pronounced in the case of thiophene **4** and totally absent in the case of pyrroles **1** and **2**, as demonstrated by the much higher absolute yields of the corresponding phenylated derivatives (ca. 45% (**4**); ca. 82% (**1**); ca. 89% (**2**)).

The conceivable occurrence of fragmentation and, perhaps, isomerization of the intermediates **5** and **9** from the corresponding formation processes undoubtedly complicates the precise evaluation of the substrate and positional selectivity of the phenylium ion toward the selected substrates. However, in view of the large predominance of the phenylation channel [2], the present results (Table 1) point to the free phenylium ion as a rather selective electrophile, which is capable of discriminating between the heteroaromatic substrate and the reference benzene (k_S/k_R = 4.9 (**1**); 12.0 (**2**); 0.6 (**3**); 1.6 (**4**)). The positional selectivity deduced from the isomeric distribution of the phenylated heteroarenes must be regarded as a lower limit, because of the possible occurrence of isomerization of a minor fraction of the initially formed α-substituted intermediate **5**α to the more stable isomeric structure **10** (*vide infra*), already pointed out in related studies (1, 2).

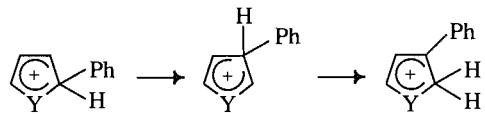
9 **10**

The emerging picture is characterized by a pronounced preference of the phenylium ion for α-substitution on **1–4**, as shown by the isomeric composition of their phenylated derivatives (β/α = 0.22 (**1**); 0.13 (**2**); 0.19 (**3**); 0.29 (**4**)).

Reaction in the gas phase

In contrast with the efficiency of collisional deactivation and neutralization of the primary excited ionic intermediates **5** and **9**, observed in the liquid, the gas phase picture reflects partial isomerization and fragmentation processes affecting the primary excited adducts from attack of phenylium ion on the aromatic substrates. Such a trend is evidenced by the appreciable decrease of the absolute yields of the tritiated aromatic products recovered in the gaseous systems (Table 2), if compared to the liquid systems (Table 1), which is counterbalanced by a parallel increase in the yields of polymerization and fragmentation products. Furthermore, the apparent relative reactivity of the competing substrates toward the phenylation channel (k_S/k_R in Table 2) is significantly modified with respect to the liquid phase. In most cases, but especially in the case of furan **3**, this appears to be mainly due to a substantial decrease of the absolute yield of the phenylated heteroarene (<1.3% vs. 25%), which presumably is superimposed on the variation of intrinsic reactivity of the two competing substrates in the two phases. Finally, the composition of the isomeric phenylated heteroarenes of Table 2 is also appreciably different from the corresponding composition measured in the liquid phase (Table 1). In fact, although α substitution is always predominant, the

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.



relative yields of the β-substituted isomers generally increase in the gas phase at the expense of the α-substituted isomers.

All such differences can be reasonably traced to the typical features of ionic processes in the gas phase at relatively low pressures. In these media, ion–molecule reactions are dominated by preliminary long-range electrostatic interactions, which lead to an encounter complex, characterized by a local energy minimum on the potential energy hypersurface, at a rate corresponding to the physical capture cross section. In agreement with the apparent k_S/k_R values of Table 2, classical theories predict similar rate coefficients for reactions involving a given ionic electrophile, such as phenylium ion, and molecules, such as the selected arenes, with comparable polarizability ($\alpha(A^3)$ = 7.94 (**1**); 7.23 (**3**); 9.00 (**4**); 10.39 (benzene) (24)) and dipole momentum (μ(Debye) = 1.84 (**1**); 2.12 (**2**); 0.66 (**3**); 0.55 (**4**) (9, 24)). Accordingly, a qualitative correspondence between the apparent k_S/k_R ratios and the α and μ values of each heteroarene is observed, except for furan **3**, whose exceedingly low k_S/k_R value (≤ 0.01) confirms the view, based on the liquid phase results, of extensive formation of stable oxonium ion or its ring opening to reactive species ending with polymeric products.

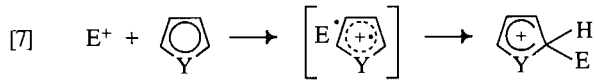
In the dilute gas state, the encounter complex, excited by the exothermicity of the ion–molecule electrostatic interactions, may either evolve to σ-bonded intermediates **5** or, alternatively, unimolecularly dissociate into the starting reactants. The branching ratio for these competing processes depends on the relative free energy activation barriers. In this view, the observation that the apparent rate constant ratios k_S/k_R are not affected by an over sixfold variation of the total pressure and by the presence of ca. 30 mol% of a powerful base points to a high efficiency for the conversion of the electrostatic complexes into the σ-bonded intermediates **5** relative to their back-dissociation to reactants.

In principle, σ-bonded intermediates **5**, excited by the exothermicity of their formation processes (Table 3), may rearrange themselves to give a thermodynamically more stable isomer before collisional quenching and neutralization. This may account for the small, but appreciable, increase in the relative yields of the β-substituted isomers recovered in the gaseous systems, whose formation is favored at low pressures and in the absence of added bases. It is, therefore, suggested that, after attack of phenylium ion on the gaseous aromatic compound occurring at the encounter rate, the ensuing electrostatic adduct efficiently evolves to the isomeric σ-bonded intermediates **5** and **9**. Their individual formation rates follow the inherent substrate and positional selectivity of the reactant, described by the k_S/k_R ratios and the relative distribution of the phenylated products, measured at the highest total system pressure and in the presence of a base, namely under conditions where fragmentation and isomerization processes are minimized. At low pressures and in the absence of bases, partial isomerization of the excited α-phenylated intermediates **5α** to the more stable structure **10**, via the β-phenylated isomers **5β** (eq. [6]), appreciably modifies the isomeric distribution of the phenylated products, recovered in the gaseous decay samples. The limited extent of isomerization, however, suggests that the α → β transfer of the phenyl group within **5α** is effectively contrasted by competing 1,2-shifts of the *ipso* hydrogen, leading to immediate quenching of the position of the phenyl group in the relevant intermediates.

The intrinsic directive properties of the selected heteroarenes **1–4** toward gas-phase phenylium ion attack confirm the

[6] 

5α **5β** **10**



tendency of the substrate to direct the electrophile preferentially toward its C_α sites (β/α : 0.38 (**1**); 0.33 (**2**); 0.13 (**3**); 0.42 (**4**)), as already observed in the liquid phase.

Comparison with related gas-phase data

The gas phase reactivity order, expressed by the k_S/k_R ratios of Table 2, indicates that phenylium ion attacks the selected aromatic substrates at rates falling within the same order of magnitude. The result is in good agreement with the remarkably low discriminating ability of other gaseous alkylating electrophiles toward the same substrates (1–6). In contrast with its limited substrate discrimination, the phenylium ion exhibits a significant positional selectivity toward **1–4**, much like other ionic electrophiles (1–6).

The evident preference of the free phenylium ion for the α-positions of pyrroles **1** and **2**, observed in both gaseous (β/α : 0.38 (**1**); 0.33 (**2**)) and liquid phase (β/α : 0.22 (**1**); 0.13 (**2**)), conforms better to the site selectivity of a soft electrophile, e.g., CT_3^+ ($\epsilon_L = -6.4$ eV; β/α : 0.30 (**1**); 0.64 (**2**)) (2), rather than to that of typical hard alkylating species, such as bridged $C_2H_5^+$ ($\epsilon_L = -1.9$ eV; β/α : 7.7 (**1**), 4.3 (**2**)) (4); *i*-$C_3H_7^+$ ($\epsilon_L = -3.9$ eV; β/α : 3.5 (**1**), 1.6 (**2**)) (5); *t*-$C_4H_9^+$ ($\epsilon_L = -3.1$ eV; β/α : 3.4 (**1**), 1.1 (**2**)) (6); $(CH_3)_2F^+$ ($\epsilon_L = +1.8$ eV; β/α : 3.3 (**1**); 2.3 (**2**)) (3*a*); $(CH_3)_3Si^+$ ($\epsilon_L = -1.8$ eV; β/α : 2.3 (**1**); 3.0 (**2**)) (1). Accordingly, one is inclined to conclude that phenylium ion behaves as a typical soft electrophile toward pyrroles, although it exhibits a STO-3G calculated LUMO energy ranging between −3.5 eV (ground-state singlet configuration) to −5.5 eV (vibrationally excited singlet configuration), which would rather confer upon it a borderline character lying between that of the soft methyl cation and the very hard *i*-$C_3H_7^+$ ion. This peculiar behavior of a nucleogenic phenylium ion emerges as well from the significant deviation from the liner correlation between the site selectivity of gaseous ionic electrophiles toward **1** and their STO-3G calculated LUMO energy, proposed in previous papers of this series (Fig. 1) (1, 4).

Such outstanding discrepancy calls in question Klopman's Charge and Frontier Orbital Control Concept (8, 10) as a self-consistent reactivity model for the intrinsic behavior of gaseous electrophiles toward five-membered heteroarenes. Rather, rationalization of the peculiar reactivity and selectivity features of phenylium ion requires a more comprehensive reactivity model, accounting for the opposite site selectivity toward pyrroles (log(β/α) in Fig. 1) of methyl (2) and phenylium ions, on the one side, and all the remaining alkylating electrophiles studied (1, 3–6), on the other. A plausible rationale for the different behavior of the two families of reactants can be found in a possible difference in their intimate substitution mechanism. In particular, while *t*-$C_4H_9^+$, *i*-$C_3H_7^+$, $C_2H_5^+$, $(CH_3)_2F^+$, and $(CH_3)_3Si^+$ ions add to pyrroles via the classical two-electron S_E2 mechanism, methyl and phenylium ions may follow the alternative entropy-favored two-step mechanism shown in eq. [7], involving a preliminary single-electron transfer (SET)

[7] 

I **5α**

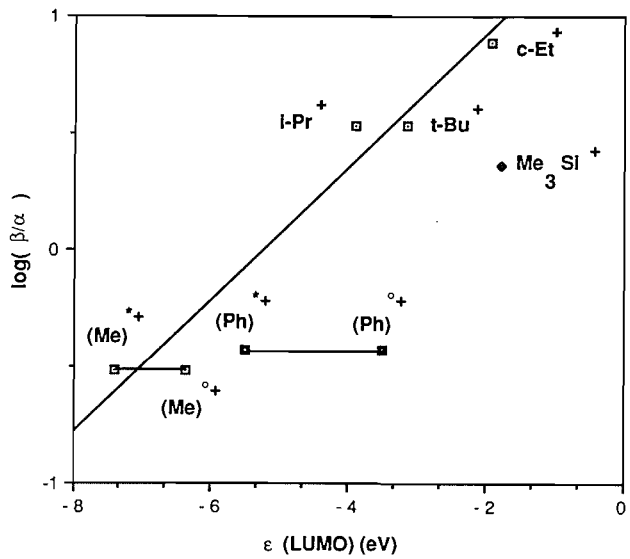


FIG. 1. Plot of site selectivity of ionic electrophiles toward the β and α carbons of pyrrole, expressed as log(β/α), as a function of SCF STO-3G calculated LUMO eigenvalues of the ionic electrophiles; (*) vibrationally excited; (°) ground state.

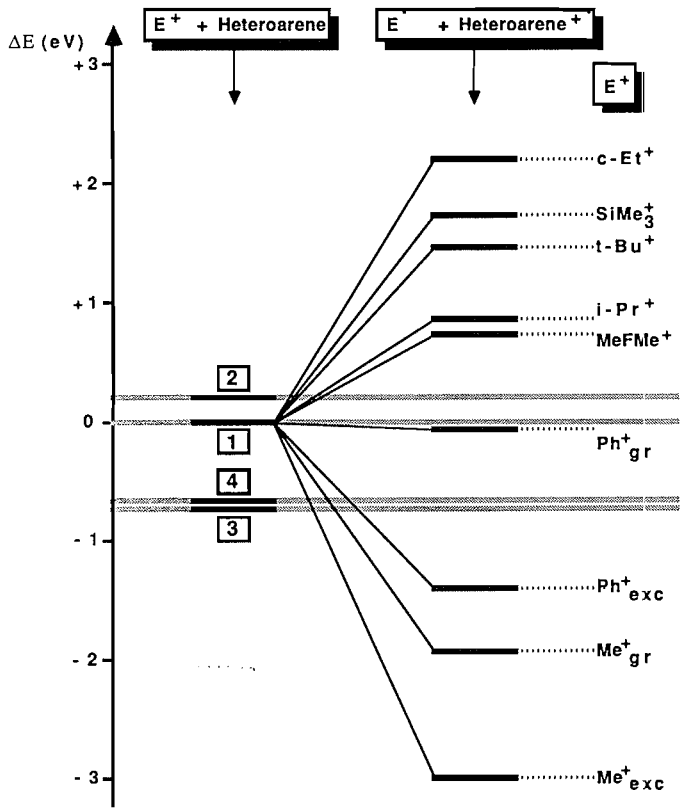

FIG. 2. Energetics of the vertical electron transfer from simple five-membered heteroarenes **1–4** to the electrophile E^+ (c-Et^+ = bridged ethyl cation; gr = ground state; exc = vibrationally excited). The relevant thermochemistry is equal to IP_v(heteroarene) + $EA_v(E^+)$. For electrophiles E^+ with the same geometry of ground state E·, IP_v(heteroarene) + $EA_v(E^+)$ is expressed by IP_v(heteroarene) − IP_v(E·). When, instead, the geometry of E^+ differs significantly from that of ground state E·, IP_v(heteroarene) + $EA_v(E^+)$ can be roughly expressed by IP_v(heteroarene) − IP_a(E·) (refs. 9, 10, 19, 20; see also ref. 28. If the E·/heteroarene$^{+\cdot}$ pair is considered electrostatically bonded in the encounter complex **I** of eq. [7], the energetics reported may be further lowered by several kcal mol^{-1} (ref. 29).

step yielding the two-body complex **I**. Under the conditions of the decay experiments, unimolecular disociation of **I** via eq. [3] (Table 3) is prevented by the rapid radical – radical ion recombination to give the σ-bonded intermediate **5**. This possibility is supported by inspection of Fig. 2, which visualizes the thermochemistry of the vertical SET step of sequence [7] for any given electrophile E^+. Accordingly, only for phenylium and methyl cations is the entropy-favored SET step accessible, leading to an encounter complex **I** (eq. [7]), wherein collapse between E· and the positions of the pyrrole molecular ion with the highest spin density, i.e., the C_α atoms (25), is mostly favored. The SET step of sequence [7] is highly endothermic (0.7–2.2 eV) for the other alkylating electrophiles, which therefore add directly to the most negatively charged centers of pyrroles, i.e., the C_β atoms, via the classical two-electron S_E2 mechanism (eq. [2] of Table 3). Conceivable occurrence of sequence [7] may justify the preferred α-substitution observed in the attack of phenylium and methyl cations on furan **3** and thiophene **4** as well, although such an explanation is not as exclusive as for pyrroles **1** and **2**. In other words, as proposed in related studies (1–6), predominant α-attack on **3** may find an alternative explanation in the presence of the negatively charged oxygen atom of the substrate, which is able to coordinate the electrophile, yielding an electrostatically bonded adduct, wherein subsequent attack on the adjacent C_α is favored by the proximity effect (26). The same effect may be operative in thiophene **4** as well, although to a much lesser extent, and may be superimposed on its normal α > β > S distribution of the net negative charge (27), which favors α substitution.

Conclusions

The results of the present study provide some information about the applicability of Klopman's Charge and Frontier Orbital Control Concept (8, 10) to the electrophilic attack of free ionic reactants on simple five-membered heteroarenes. In analogy with gas-phase heteroaromatic substitution by charged alkylating electrophiles, attack of nucleogenic phenylium ion on **1–4** is characterized by a limited substrate discrimination, which sharply contrasts with a remarkable positional selectivity both in the gaseous and liquid phase. Such a high selectivity is inferred from the kinetic predominance of the phenylium-ion attack on the α carbons of the selected heteroarenes. In pyrroles **1** and **2**, the preferred α phenylation does not correlate satisfactorily with the expected hard properties of a ground-state singlet phenylium ion (ϵ_L = −3.5 eV), nor with the expected borderline character of the vibrationally excited ion (ϵ_L = −5.5 eV).

Such a discrepancy seems to preclude the extension of Klopman's concept to phenylium ion and calls for some novel, more comprehensive, model for heteroaromatic reactivity in the gas phase. A plausible rationale for the diverging behavior of phenylium ion is based upon the possible occurrence of an entropy-favored two-step mechanism, involving preliminary single-electron transfer (SET) from the heteroarene to the electrophile prior to recombination of the ensuing radicals to the σ-bonded intermediate **5** (eq. [7]). The same sequence may, in principle, be operative in another strictly related process, i.e., methylation by free CT_3^+ of **1–4** (2), wherein a similar site discrimination is observed. A SET step in the alkylation of **1–4** by other alkylating electrophiles, i.e., $C_2H_5^+$, i-$C_3H_7^+$, t-$C_4H_9^+$, $(CH_3)_2F^+$, and $(CH_3)_3Si^+$, is made unlikely by unfavorable thermochemical constraints. Direct evidence for the predominant occurrence of a SET-induced energetically

Received July 20, 1990

ANTONELLO FILIPPI, GIORGIO OCCHIUCCI, CINZIA SPARAPANI, and MAURIZIO SPERANZA. Can. J. Chem. **69**, 740 (1991).

The results of a study of the gas-phase reactions of unsaturated carbocations, such as the CH_3CO^+ ion from γ-radiolysis of CH_3F/CO mixtures, and the $C_6H_4TCO^+$ ion from the β-decay of 1,4-ditritiobenzene in the presence of CO, with pyrrole, *N*-methylpyrrole, furan, and thiophene, are reported. In all systems investigated, acylated heteroarenes represent the predominant reaction products, accompanied by the methylated derivatives in the CH_3F/CO radiolytic mixtures, and by the phenylated ones in the 1,4-ditritiobenzene/CO decay samples. All substrates investigated are found to undergo predominant α substitution by both acetyl (88.6–98.4% (pyrrole); 90.8–98.7% (*N*-methylpyrrole); 97.2–98.9% (furan); 94.9–98.6% (thiophene)) and benzoyl cations (92.6–96.5% (pyrrole)) under all conditions. The predominant formation of the α-acylated pyrroles from both reactants (>88%), whose relative yields appear unaffected within the temperature interval from 303 to 383 K, indicates, in agreement with ancillary FT-ICR mass spectrometric evidence, that gas-phase acylation reactions toward simple five-membered heteroarenes proceed via a two-step substitution mechanism, involving a quasi-resonant single-electron transfer (SET) step followed by recombination of the ensuing radical – radical ion pair. By virtue of this entropy-favored mechanism, gaseous electrophiles with relatively high SCF STO-3G calculated LUMO energies such as CH_3CO^+ and $C_6H_4TCO^+$ are effectively oriented toward the "soft" C_α sites of the selected heteroarenes, at variance with Klopman's Charge and Frontier Orbital Control predictions. The behavior of gaseous acylating reactants toward simple heteroarenes is discussed and compared with that of other gaseous electrophiles, whose reactivity appears instead in qualitative agreement with Klopman's model.

Key words: gas-phase ion chemistry, electrophilic heteroaromatic substitution, nuclear decay and radiolysis, acylium ions, electron transfer.

ANTONELLO FILIPPI, GIORGIO OCCHIUCCI, CINZIA SPARAPANI et MAURIZIO SPERANZA. Can. J. Chem. **69**, 740 (1991).

On rapporte les résultats obtenus au cours d'une étude des réactions de carbocations insaturés, comme l'ion CH_3CO^+ obtenu par radiolyse γ de mélanges de CH_3F/CO et l'ion $C_6H_4TCO^+$ obtenu par désintégration β du 1,4-ditritiobenzène en présence de CO, avec le pyrrole, le *N*-méthylpyrrole, le furane et le thiophène. Dans tous les systèmes étudiés, les produits réactionnels prépondérants sont les hétéroarènes substitués; ils sont accompagnés des dérivés méthylés (dans les mélanges radiolytiques de CH_3/CO) et des dérivés phénylés (dans les échantillons provenant de la désintégration du 1,4-ditritiobenzène/CO). On a trouvé que, dans toutes les conditions, tous les substrats étudiés subissent principalement une substitution α par les cations acétyle (88,6–98,4% avec le pyrrole; 90,8–98,7% avec le *N*-méthylpyrrole; 97,2–98,9% avec le furane; 94,9–98,6% avec le thiophène) et benzoyle (92,6–96,5% avec le pyrrole). La formation prépondérante de pyrroles α-acylés à partir des deux réactifs (>88%), alors que leurs rendements relatifs ne semblent pas affectés dans l'intervalle de température allant de 303 à 383 K, suggère, en accord avec des données supplémentaires de spectrométrie de masse FT-ICR, que les réactions d'acylation en phase gazeuse d'hétéroarènes à cinq chaînons simples se produisent par un mécanisme de substitution en deux étapes impliquant une étape de transfert d'un seul électron quasi-résonant suivie d'une recombinaison de la paire de radical – ion radical qui s'en suit. En vertu de ce mécanisme favorisé par l'entropie, les électrophiles gazeux, comme le CH_3CO^+ et le $C_6H_4TCO^+$ dont les énergies d'OM basses vacantes calculées par des méthodes STO-3G auto-cohérentes sont élevées, sont de fait orientées vers les sites C_α «mous» des hétéroarènes choisis; ces résultats sont en opposition avec les prédictions du contrôle de la charge et des orbitales frontières de Klopman. On discute du comportement des réactifs gazeux acylants vis-à-vis des hétéroarènes simples et on le compare à celui d'autres électrophiles gazeux dont la réactivité semble plutôt se rapprocher qualitativement du modèle de Klopman.

Mots clés : chimie des ions en phase gazeuse, substitution hétéroaromatique électrophiles, désintégration nucléaire et radiolyse, ions acylium, transfert d'électron.

[Traduit par la rédaction]

Introduction

In previous papers of this series (1, 2), attention has been focussed on Klopman's Charge and Frontier Orbital Concept (3) as a general model for intrinsic heteroaromatic reactivity of gaseous ionic electrophiles. According to Klopman's model (3), kinetic studies on the reactivity of gaseous alkylating electrophiles, i.e., $t\text{-}C_4H_9^+$ (2*e*), $i\text{-}C_3H_7^+$ (2*d*), $C_2H_5^+$ (2*c*), and CH_3^+ (2*b*), toward simple five-membered heteroarenes allowed establishment of an approximately linear correlation between the "hardness" of the alkylating reactants, taken as a function of their SCF STO-3G calculated LUMO energy (4), and their positional selectivity toward pyrroles (log (β/α)). However, when a Si-centered, $(CH_3)_3Si^+$ (2*a*), or an unsaturated electrophile, $C_6H_5^+$ (1), is included in this correlation, an appreciable deviation from linearity is observed, reflecting an experimental positional selectivity (log (β/α)) that is appreciably different from that expected on the basis of their

calculated LUMO energies. Pronounced orbital control of orientation in the encounter complex, due to the comparatively large empty $3p$ orbital of Si in $(CH_3)_3Si^+$, is likely responsible for the relatively low log (β/α) value and thus for the relatively "soft" character of trimethylsilyl cation toward pyrroles ($2a$). The same factor cannot be operative in the phenylium ion $C_6H_5^+$, whose exceedingly high affinity for the α positions of pyrroles (log $(\beta/\alpha) = -0.42$ (pyrrole); -0.48 (*N*-methylpyrrole)) may be related to a conceivable change of the intimate substitution mechanism (eq. [1]). The two-step sequence [1a]

E = CH_3CO; C_6H_5CO
Y = NH (**1**); NMe (**2**); O (**3**); S (**4**)

was advanced, wherein the preliminary single-electron transfer (SET) step from the heteroarene to the electrophile is thermochemically allowed only for the α-oriented $C_6H_5^+$ and CH_3^+ electrophiles, and forbidden for the other β-directed alkylating species (1). In this view, the distinct preference of phenylium and methylium cations for the α-carbons of pyrroles arises directly from the favored radical – radical ion recombination in the intermediate adduct **I** (eq. [1a]) between phenyl or methyl radical and the positions of the heteroarene molecular ion with the highest spin density, i.e., the C_α atoms (5). Since the same SET step of sequence [1a] is energetically inaccessible to the other alkylating species investigated, these add to the heteroaromatic molecule via the classical two-electron S_E2 mechanism [1b] governed by electrostatic interactions in the encounter complex (2).

Although adoption of sequence [1a] for $C_6H_5^+$ (and CH_3^+) would satisfactorily account for the peculiar affinity of the electrophile for the α positions of pyrroles, no direct experimental evidence for its actual occurrence in the relevant systems is presently available. To gain further insight into the kinetic role of the proposed two-step mechanism [1a] in the gas-phase electrophilic attack of unsaturated cations on heteroarenes, we have now extended the investigation to the acylating electrophiles CH_3CO^+ and $C_6H_5CO^+$, which can be conveniently generated in the gas phase by γ-radiolysis (6) and nuclear decay (7) procedures. Both acylating ions exhibit rather unique features. On the one hand, they are ranked among the "hardest" ionic electrophiles known (8) and, therefore, they are expected to be oriented toward the ring positions of the heteroaromatic substrate with the highest net negative charge (e.g., the C_β's of pyrrole), if the classical S_E2 mechanism [1b] is operative (3, 4). On the other hand, these species can accept an electron from the heteroaromatic molecule via a very efficient quasi-resonant vertical transition (first step of eq. [1a]) (Fig. 1). In this case, a pronounced α substitution on the heteroaromatic ring would be actually observed, in spite of the "hard" character of the acylating reactants. By virtue of such a favorable combination of properties, it was hoped to provide firm indication of the kinetic role of thermochemically allowed SET processes in the gas-phase electrophilic attack of unsaturated carbocations on fundamental five-membered heteroarenes (eq. [1a]).

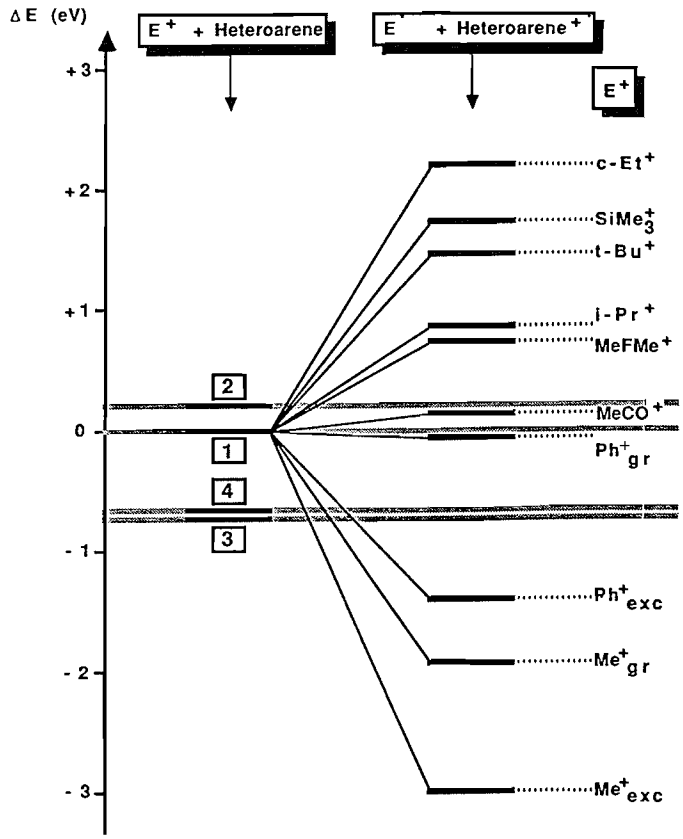

FIG. 1. Energetics of the vertical electron transfer from simple five-membered heteroarenes **1**–**4** to the electrophile E^+ (c-Et^+ = bridged ethyl cation; gr = ground state; exc = vibrationally excited). The relevant thermochemistry is equal to IP_v(heteroarene) + $EA_v(E^+)$. For electrophiles E^+ with the same geometry of ground-state E·, IP_v(heteroarene) + $EA_v(E^+)$ is expressed by IP_v(heteroarene) − IP_v(E·). When, instead, the geometry of E^+ significantly differs from that of ground-state E·, IP_v(heteroarene) + $EA_v(E^+)$ can be approximately expressed by IP_v(heteroarene) − IP_a(E·) (refs. 8 and footnote 5). If the E·/heteroarene$^{+\cdot}$ pair is considered electrostatically bonded in the encounter complex **I** of eq. [1a], the energetics reported may be further lowered by several kilocalories per mole (ref. 23).

Experimental section

Materials

1,4-Ditritiobenzene was prepared and purified according to described procedures (9) and diluted with benzene to a specific activity of 86 mCi mmol^{-1}. Methyl fluoride, carbon monoxide, oxygen, and trimethylamine were high-purity gases from Matheson Co., used without further purification. All the heteroaromatic substrates and the reference compounds used for the preparation of the reaction mixtures and their analysis were research grade chemicals from Fluka AG and were analyzed by gas chromatography (glc) and high-performance liquid chromatography (hplc) to check the absence of any acylated and alkylated products. Not commercially available isomeric acetylated, benzoylated, phenylated, and methylated derivatives of the selected heteroaromatic substrates, used as carriers or as standards in the chromatographic analyses, were prepared following well-established synthetic procedures (10). The identity of the synthesized products was checked by conventional ir, nmr, and glc – mass spectrometry (glc–ms).

Procedure

The gaseous mixtures for the radiolytic acetylation experiments were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

prepared according to standard procedures using a greaseless vacuum line and were introduced into carefully evacuated and outgassed 135-mL Pyrex vessels. Typical experimental conditions were as follows: CH_3F/CO: 1:4; total pressure: 100–760 Torr (1 Torr = 133.3 Pa); heteroaromatic substrate: 1–2 Torr; O_2: 4 Torr; NMe_3: 0–17 Torr. The irradiations were carried out in a 220 Gammacell (Atomic Energy Canada Ltd.) to a total dose of 1×10^4 Gy at a dose rate of ca. 1×10^4 Gy h^{-1}, at a temperature of 30°C. A set of experiments with pyrrole as the substrate was carried out at temperatures ranging from 30 to 110°C.

The gaseous samples for the decay benzoylation experiments were prepared by introducing ca. 1 mCi of 1,4-ditritiobenzene into evacuated and carefully outgassed 100-mL Pyrex vessels containing a measured amount of pyrrole (ca. 4 Torr), together with CO (127–634 Torr), O_2 (4 Torr), used as a radical scavenger, and a powerful ion trap (NMe_3: 12.5 Torr) when required. The vessels were then sealed off and stored in the dark, at room temperature, for ca. 6–8 months. After the storage period, the ampoules were opened and their content analyzed by a radio-hplc procedure. A Varian Vista 5500 high-pressure liquid chromatograph, equipped with a 250 nm UV detector in series with a Berthold LB 503 HS flow scintillation counter, was used for the radio-hplc analyses.

The radiolytic samples were analyzed by glc and glc–ms using, respectively, Perkin–Elmer 8320 and Sigma 3 gas chromatographs, equipped with FID units, and a Hewlett–Packard model 5970B mass selective detector. To avoid selective losses of the products from both radiolytic and decay experiments by adsorption on the glass walls of the vessels, the analyses were carried out after washing the bulb walls with freshly purified toluene. The identity of the products was established by comparison of their retention volumes with those of authentic standards, as well as from their glc–ms spectra measured from the radiolytic runs. The amounts of the products formed were determined from the areas of the corresponding elution peaks using the internal standard calibration method.

The irradiated samples were analyzed on the following glc columns: (i) 1.5 m × 1/8 in. stainless steel column packed with 10% Bentone-34/6% diisodecylphthalate on Chromosorb W, operated between 110 and 120°C; (ii) 0.6 m × 1/8 in. stainless steel column packed with 5% SP1000/5% Bentone-34 on Chromosorb W, operated between 70 and 120°C; (iii) 2 m × 1/8 in. stainless steel column packed with KOH-treated activated carbon, operated between 100 and 190°C.

For the radio-hplc analysis of the decay samples, a 15 cm × 5 μm C-18 Violet column, eluted with H_2O/CH_3CN = 70%:30% was employed.

Fourier-transform (FT-ICR) mass spectrometry

The measurements were performed with a Nicolet FT-MS 1000 ICR spectrometer, equipped with a 2.54-cm cubic cell installed between the poles of a 2.0-T superconducting magnet. The pressure measurements (uncorrected) were obtained with a Granville–Philips 280 Bayard–Alpert ion gauge. Resolution was typically 1000 fwhh (full width half height) at m/e 100. The inlet system and the trapping cell were kept at room temperature, the ions being trapped within the cell by a differential voltage of ca. 1.0 V. Typical operating conditions were as follows: nominal electron energy: 12 eV; electron beam pulse time: 5 ms; emission current: 0.800 μA; total pressure: 5×10^{-7} Torr. The acetyl and benzoyl cations, conveniently generated by electron impact on acetone and acetophenone, respectively, were isolated from other ions by the triple-resonance technique, and their reactions with the heteroaromatic substrates were monitored by analyzing any daughter cations formed.

Computational details

Standard quantum-mechanical calculations, with the GAUSSIAN 80 (11) set of programs, were performed in order to evaluate the STO-3G (12) SCF eigenvalues of the LUMOs of acetyl and benzoyl cations. The optimized geometries of these ions were obtained at the SCF STO-3G level of theory by gradient-based techniques, C_{3v} point group symmetry framework being assumed for CH_3CO^+ and C_{2v} for $C_6H_5CO^+$. The LUMO energy of both CH_3CO^+ and $C_6H_5CO^+$ ions is −2.4 eV.

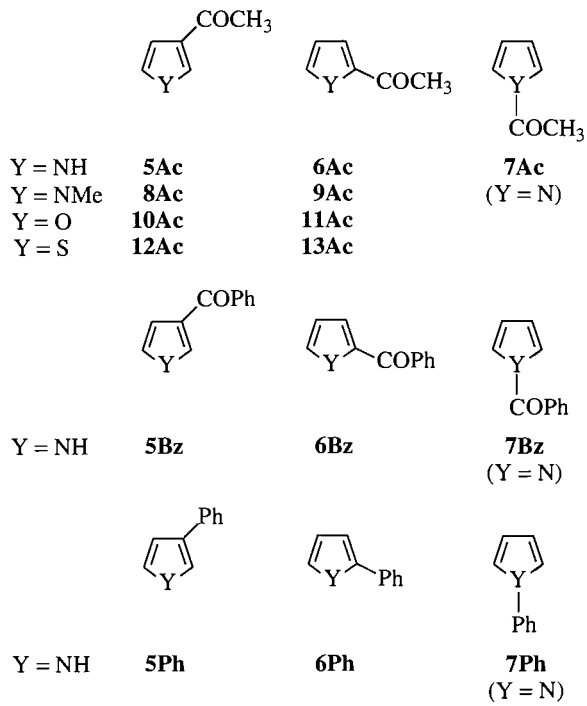

CHART 1

Results

Gas-phase attack of acetyl cation, generated by γ-radiolysis of CH_3F/CO mixtures in the presence of a thermal radical scavenger, such as O_2, on the selected heteroaromatic substrates **1–4** yields the corresponding acetylated derivatives, namely **5Ac–7Ac** from **1**, **8Ac** and **9Ac** from **2**, **10Ac** and **11Ac** from **3**, and **12Ac** and **13Ac** from **4** (Chart 1). Their absolute yields are expressed as the percent ratio between their G(M) values, i.e., the number of molecules M produced per 100 eV of energy absorbed by the gaseous mixtures, and the $G(CH_3CO^+)$ = ca. 2, estimated under comparable conditions from previous investigation (13). The results of these calculations, while largely approximate,[3] represent nevertheless an estimate of the relative efficiency order of the reaction channel leading to the acetylated products (69–84% (**1**); 44–74% (**2**); 10–24% (**3**); 13–40% (**4**)). The ionic character of the acetylation process is ensured by the presence of an effective thermal radical scavenger (O_2), contained in the gas at concentrations even higher than those of **1–4**, and confirmed by the dramatic decrease of the overall product yields caused by addition to the gaseous mixture of variable concentrations of the base NMe_3 (up to 91% (**1**); 89% (**2**); 80% (**3**); 77% (**4**), at ca. 2.0 mol% of NMe_3).

The isomeric distribution of the products from gas-phase acetylation of heteroarenes **1–4** has been measured under largely different experimental conditions. The results concerning pyrroles are illustrated in Tables 1 and 2 and Fig. 2.[4]

[3]There are considerable uncertainties as to the radiation dose actually absorbed by the gas and the precise value of $G(CH_3CO^+)$ and its dependence upon the mixture pressure. In addition, there are several reaction channels available to CH_3CO^+ ions following their attack on the heteroarene that represent only one of the nucleophiles present in the irradiated systems.

[4]For the sake of clarity, the relative distribution of methylated heteroarenes from the $(CH_3)_2F^+$ ion invariably accompanying formation of CH_3CO^+ from γ-radiolysis of CH_3F/CO mixtures (ref. 13) has not been included in Tables 1–4.

acetylated derivatives of furan **3** (Table 3) and thiophene **4** (Table 4) as a function of the experimental conditions. Accordingly, the relative extent of α acetylation of these substrates remains around 97.2–98.9% (**11Ac** from **3**) and 94.9–98.6% (**13Ac** from **4**) within the entire interval of system pressures (100–760 Torr) and NMe_3 concentrations (0–16 Torr) investigated.

The features of the gas-phase attack of the acetyl cation on pyrrole **1** have been investigated as well at low pressures (5×10^{-7} Torr) in a FT-ICR ion source. Figure 3 shows the experimental results, which indicate that competing single-electron-transfer (SET) and proton-transfer (PT) processes take place. It should be noted that, while the measured bimolecular rate constant for the latter process ($k_{PT} = 7.8 \times 10^{-9}$ cm^3 mole-

cule^{-1} s^{-1}) closely approaches the ADO calculated collision limit ($k_{ADO} = 8.0 \times 10^{-9}$ cm^3 molecule^{-1} s^{-1}) (14), that of the SET reaction exceeds such a limit by a factor of ca. 4 ($k_{SET} = 3.1 \times 10^{-8}$ cm^3 molecule^{-1} s^{-1}).

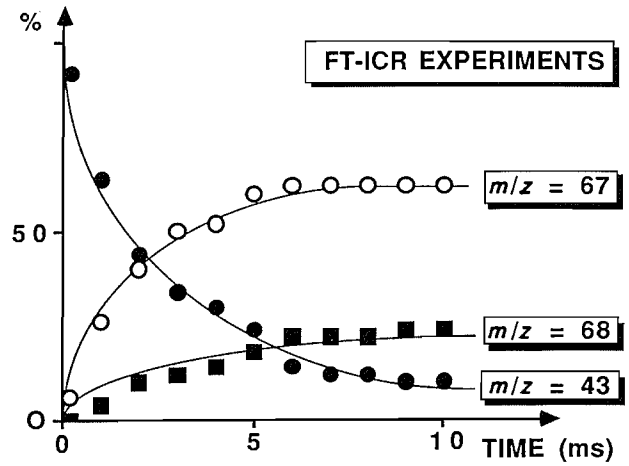
The yields of the labeled products from the decay of 1,4-ditritiobenzene in gaseous CO, containing minor amounts (0.7–3.4 mol%) of pyrrole **1**, are given in Table 5. In the absence of other nucleophiles, the combined yields of the pyrrole derivatives identified range from 30 to 79% of the activity of the nucleogenic (formed by nuclear decay) *para*-T-phenylium ions formed in the system, which represents the maximum activity theoretically incorporable in the products. The sharp decrease of the absolute yields of the heteroaromatic products (73–90%) from the systems containing NMe_3 (1.9 mol%) supports the ionic nature of their formation processes, since the amine is known to be an effective interceptor of gaseous cations.

The isomeric composition of benzoylpyrroles **5Bz–7Bz** of Table 5 closely reproduces that of their acetylated analogues **5Ac–7Ac** from the radiolytic experiments (Table 1). In fact, pyrrole **1** undergoes predominant benzoylation at its α positions under all conditions (92.6–96.5% (**6Bz**)). Labeled phenylpyrroles **5Ph–7Ph** accompany formation of the benzoyl derivatives of **1** in yields largely exceeding those expected on the grounds of the CO/pyrrole concentration ratios. The relative yields of labeled **5Ph–7Ph**, as well as their isomeric distribution, depend upon the composition of the gaseous mixture. In particular, a fivefold increase of the CO partial pressure causes a ca. threefold decrease of the relative yield of phenylpyrroles, while the **5Ph**:**6Ph** yield ratio changes from 32%:68% to 41%:59%. A noteworthy feature is that under no circumstances does substitution take place at the N center of **1**, in qualitative agreement with the acetylation results and with those of pyrrole phenylation reported in the preceding paper (1).

Discussion

Nature and properties of the acylating reagents

Detailed investigation (13, 15) of the γ-radiolysis and the related ion chemistry of gaseous CH_3F/CO mixtures indicates



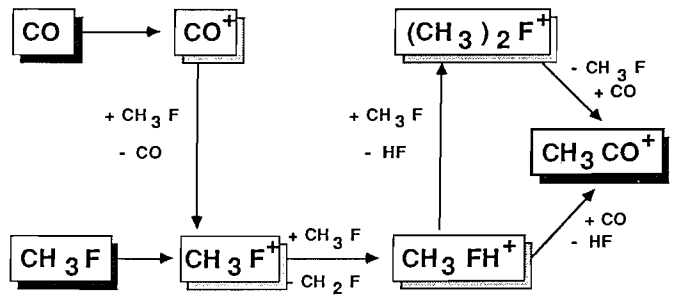


FIG. 3. Relative abundances of CH_3CO^+ (●), $C_4H_5N^{+\bullet}$ (○), and $C_4H_6N^+$ (■) ions as a function of time, observed in FT-ICR experiments of CH_3COCH_3/pyrrole **1** = 1:1 mixtures.

SCHEME 1

that, at CH_3F molar fractions ranging around 0.2, CH_3CO^+ represents the major ionic species formed, whose G(M) amounts to ca. 2.0 at 760 Torr total pressure. In agreement with the well-established reaction network given in Scheme 1 (16), γ-radiolysis of CH_3F/CO gaseous mixtures leads to the formation of CO^+ and CH_3F^+ as the most abundant primary species, which immediately react with CH_3F to yield eventually CH_3CO^+ and $(CH_3)_2F^+$. All individual steps of the reaction network of Scheme 1 are very efficient, as shown by related ICR kinetic studies (10). Thus, only a few collisions between the primary ionic species and the parent molecules are sufficient to establish stationary concentrations of CH_3CO^+ and $(CH_3)_2F^+$ ions, whose yield ratio depends on the system composition and reaches the maximum value at a CH_3F molar fraction equal to ca. 0.2.

Spontaneous nuclear decay in 1,4-ditritiobenzene (ca. 1 mCi), diluted in a large excess of CO (127–634 Torr), was used to generate free benzoyl cation $C_6H_4TCO^+$ in the gas phase (eq. [2]) (17).

Nuclear transition in 1,4-ditritiobenzene yields the daughter *para*-T-phenylium ion in its most singlet configuration (18) for more than 72% of the decay events (19). The primary daughter species is characterized by a certain excess of internal energy (<32 kcal mol^{-1}), due to the relaxation of its initial regular structure, reminiscent of that of the parent benzene, to the distorted hexagonal geometry of the ground-state singlet phenylium ion (20).

Nucleogenic phenylium ion is preferentially directed toward the O atom of CO in its first encounter with the bath gas (17), yielding **III** as the major primary adduct (eq. [2]). *Ab initio*

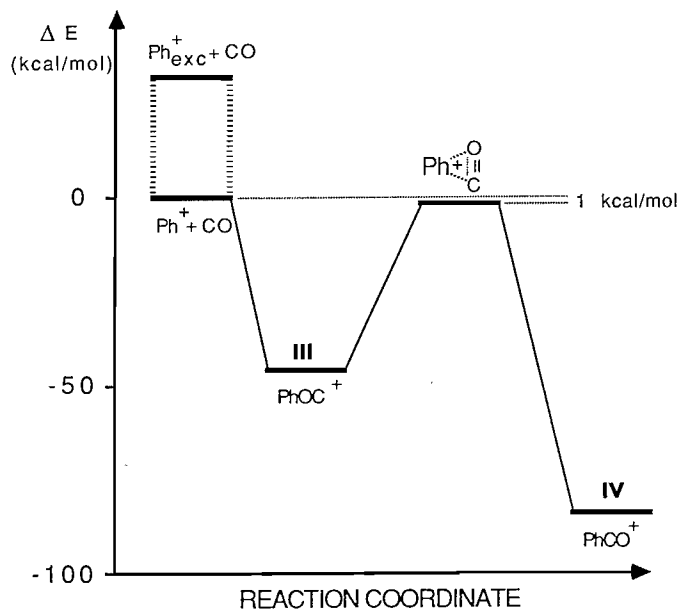

FIG. 4. Schematic energy profile for formation and rearrangement of $C_6H_5OC^+$ (**III**) and $C_6H_5CO^+$ (**IV**) from attack of $C_6H_5^+$ on CO.

calculations have been performed for the benzoyl cation **IV** and its isomer **III**, showing that the latter is less stable by 37.3 kcal mol^{-1} at the STO-3G level of calculation, while the calculated energy barrier for the **III** → **IV** isomerization along the reaction coordinate is very close (83.0 kcal mol^{-1}) to the energy required for the dissociation of **IV** into relaxed phenylium ion and CO (84.0 kcal mol^{-1}) (Fig. 4).[5] It follows that, in our decay systems, formation of benzoyl cation **IV** arises essentially from that restricted family of the primary intermediates **III** that, while sufficiently stabilized by collisional deactivation to escape back dissociation to phenylium and CO, still retain sufficient internal energy to overcome the activation barrier of the **III** → **IV** isomerization. The rather narrow energy window leading to isomerization explains the relative inefficiency of the benzoylation channel, in spite of the exceedingly high excess of CO relative to the heteroaromatic substrate in the corresponding nuclear decay systems. Most of the encounters between nucleogenic phenylium ion leads therefore to CO-solvated phenylium ion **III**, whose relative stationary distribution with respect to **IV** depends upon the efficiency of its collisional quenching and, thus, the partial pressure of CO. Ions **III** can generate the phenylated products of Table 5 by nucleophilic displacement of the CO moiety of **III** by the heteroaromatic substrate.

Although the energetics of the formation processes of both the radiolytic CH_3CO^+ ion (Scheme 1) ($-\Delta H^0$ = 23–46 kcal mol^{-1})[6] and the nucleogenic benzoyl cation (eq. [2]) ($-\Delta H^0$ = 68–100 kcal mol^{-1}) (21) are rather different, the large molar fraction of the bath gas(es) in both systems (>0.97), compared to the trace concentrations of the heteroaromatic substrate (molar fraction from ca. 2×10^{-3} to ca. 3×10^{-2}), ensures in both cases the efficient thermalization of the ionic acylating reactants by unreactive collisions with the bath gas(es) before their encounter with a heteroarene molecule. Moreover, the composition of the systems is such that undesired secondary processes, e.g., direct radiolysis of the heteroaromatic substrate or of its reaction products, can be safely neglected.

Rough thermochemical calculations, performed by using a heat of formation of 156 kcal mol^{-1} (21*b*) for CH_3CO^+ and of 175 kcal mol^{-1} (21*d*) for benzoyl cation, indicate that acylation of heteroarenes **1–4** by both ions is an energetically allowed

process,[7] which represents the predominant ionic pathway in the relevant samples, since other conceivable ionic processes are either energetically forbidden (e.g., hydride ion abstraction) or, although energetically allowed, kinetically insignificant (e.g., methyl and proton transfer) (*vide infra*) (22). This conclusion is corroborated by the substantial absolute yields of acylated products, recovered in both the radiolytic and the decay systems. Significant energy release is involved in the efficient addition on **1–4** of $(CH_3)_2F^+$ (*2f*), formed together with CH_3CO^+, and of **III**,[5] accompanying formation of **IV**.

The gas-phase acylation mechanism

In the framework of a classical S_E2 mechanism [1b] following Klopman's reactivity model (3), gas-phase attack of hard ionic electrophiles, such as acetyl and benzoyl cations (ε(LUMO) = −2.4 eV), on pyrroles **1** and **2** is expected to be predominantly governed by electrostatic interactions within the encounter pair and, therefore, directed mostly toward the carbon centers of the substrate with the highest net negative charge, i.e., the C_β atoms (1, 2). On the contrary, a conspicuous α substitution is *de facto* invariably observed in the gas-phase acylation of the selected heteroarenes by both electrophiles. This peculiar behavior is reflected in the large deviation of both acetyl and benzoyl cations from the linear correlation between the site selectivity of gaseous alkylating carbocations toward **1** and their STO-3G calculated LUMO energy, expected from Klopman's model (3) and verified in related studies (g and h in Fig. 5) (2). Such an outstanding discrepancy makes it opportune to inquire whether the unexpectedly large α acylation in **1–4** reflects indeed some peculiar reacting mode of the acylating electrophiles or, rather, a possible mechanistic changeover in the attack of alkylating (b–e in Fig. 5) and acylating carbocations (g and h in Fig. 5) on heteroarenes.

In fact, apart from the classical S_E2 pathway, a conceivable additional route to formation of acetyl derivatives of pyrroles **1** and **2** might involve the intermediacy of ketene, which may add to the heteroarene yielding its acetylated derivatives. Ketene, in fact, may arise from the exothermic proton transfer from CH_3CO^+ to pyrroles **1** ($-\Delta H^0$ = 10 kcal mol^{-1}) and **2** ($-\Delta H^0$ = 17 kcal mol^{-1}) (*21a,b*), a process that has been directly observed from FT-ICR experiments (Fig. 3). However, taking into account that, at the low pressures (5×10^{-7} Torr) prevailing in FT-ICR experiments, unimolecular fragmentation of the primary adduct **II** represents the main route for dissipating its excess energy, it is possible that a sizeable amount of the observed protonated pyrroles (*m/e* = 68) from CH_3CO^+ is due to back dissociation of **II** with a proton left to the most basic moiety, i.e., the pyrrole molecule (*21a,b*). Since back dissociation of **II** is hardly effective at the much higher pressures (up to 760 Torr) typical of the radiolytic and nuclear decay experiments, owing to the very rapid removal of the excess energy of **II** by collisional quenching with the bath gas(es), a question arises as to whether, at high pressures, direct proton loss from CH_3CO^+ to pyrroles and subsequent addition of the ensuing ketene to the heteroarene actually represents a significant route to its acetylated products. A first answer to this question arises from the FT-ICR results of Fig. 3, showing that in spite of the favorable experimental conditions proton transfer is only a minor path open to CH_3CO^+ in its attack on pyrroles, the major channel being direct charge exchange with the substrate. Furthermore, the complete correspondence between the isomeric distribution of the acylated pyrroles from both acetyl and benzoyl cations does not support the intermediacy of the corresponding ketene in their formation, proton transfer from benzoyl cation to **1** (or **2**) to give the relative ketene being energetically inaccessible.

Extensive intramolecular isomerization of the primary intermediates **II**, excited by the exothermicity of their formation processes (eq. [1b]), might in principle be responsible for the predominance of the α-substituted isomers among the acylated products. However, such a possibility can be safely ruled out in the light of the following considerations. Extensive isomerization within excited **II** is hardly consistent with the observation that the same isomeric distribution of products is measured at largely different ion lifetimes, namely at low pressure (100 Torr) in the absence of NMe_3 and at high pressure (760 Torr) in the presence of the base (15–17 Torr) (Tables 1–4). Nevertheless, such a discrepancy would be settled if one admits exceedingly rapid intramolecular acyl-group shifts within **II**, involving activation barriers so low as to make them very fast relative to the competing proton transfer within **II** as well as to NMe_3. This latter hypothesis contrasts strikingly with the very limited extent of isomerization of σ-intermediates from CH_3CO^+-ion attack on substituted arenes observed in related studies (13, *15b*). Moreover, negligible activation barriers for acyl-group shifts within excited **II** would mean that, under long-lived excited ion conditions (at low pressures and in the absence of NMe_3), the thermodynamic distribution of the acylated heteroarenium intermediates would be readily reached, irrespective of the initial composition of their primary precursors **II** (eq. [3]). As a consequence, under such conditions, predominance of the most stable heteroarenium isomer, i.e., the β-acylated intermediate **V**, and therefore of its neutral β-acylated product, would be expected, in contrast with the experimental evidence.

[3] 

In the light of the above considerations, it is legitimate to conclude that the exceedingly high yields of α-acylated heteroarenes, recovered in both the radiolytic CH_3CO^+ and decay $C_6H_4TCO^+$ systems, actually reproduce the predominant formation of their ionic primary precursors $\mathbf{II}_\alpha$ relative to their β-substituted isomers $\mathbf{II}_\beta$ (eq. [3]).

Concerning their detailed formation mechanism, the results of the FT-ICR experiments (Fig. 3) suggest exceedingly fast occurrence of a quasi-resonant SET event in the primary encounter complexes **I** (eq. [1a]), which, at the low pressures (5×10^{-7} Torr) prevailing in the FT-ICR ion source, ends up

[7]The ΔH^0 values for the CH_3CO^+ ion attack on **1–4** can be estimated as equal to ca. −32 (**1**), −48 (**2**), and −18 kcal mol^{-1} (**3** and **4**), by assuming that the proton affinity of the *ipso* position of an acetylated heteroarene is equal to that of the unsubstituted molecule, taken from ref. *21a*. Further support for exothermic acetylation of **1–4** is provided by the fact that CH_3CO^+ ion attack on the less activated methylbenzenes is still thermochemically allowed (ref. 13). The ΔH^0 values for the benzoyl cation attack on **1–4** are expected to be similar to those for acetylation.

with their unimolecular dissociation to E· and heteroarene $^{+\cdot}$. At the high pressures (100–760 Torr) typical of the radiolytic and nuclear decay experiments, where unimolecular fragmentation of ion-neutral complexes is efficiently prevented by collisional deactivation, the radical – radical ion pair in **I** is able to survive until recombination to produce the σ-bonded intermediates **II**.

Further evidence in favor of the two-step acylation mechanism [1a] is provided by analysis of the Arrhenius plot relative to gas-phase acetylation of pyrrole **1** by CH_3CO^+ (Fig. 2). The essential constancy of the site selectivity of CH_3CO^+ toward gaseous pyrrole **1** (log (β/α) ≃ −2.1 ± 0.1) within a wide temperature interval (80°) is only consistent with a CH_3CO^+ ion attack on the α and β positions of **1** governed by either negligible or very similar activation barriers ($\Delta E^* = E_\alpha^* - E_\beta^* = 0.6 \pm 0.8$ kcal mol^{-1}) and by largely different Arrhenius preexponential factors (log $(A_\beta/A_\alpha) = -2.4 \pm 0.6$). These conditions appear rather awkward if referred to a gas-phase acylation process following the classical S_E2 mechanism. It should be considered, in fact, that the hypothesis of largely different preexponential terms and, therefore, entropy factors in the attack of an ionic electrophile on isomeric unencumbered positions of a neutral molecule, such as **1**, appears unfounded. Furthermore, both acetyl and benzoyl cations are revealed as very selective, mild electrophiles toward arenes, displaying partial rate factors (up to 470) that are exceedingly high for the gas phase ion–molecule reaction standard (13, 15, 17). It follows that the hypothesis of negligible or equal activation barriers for S_E2 acylation of the differently activated positions of **1** is untenable as well. On the contrary, once extensive intramolecular rearrangements of primary **II** are excluded (*vide supra*), the experimental evidence of Fig. 2 can only be accounted for by a gas phase CH_3CO^+ acylation of **1** proceeding via the two-step mechanism [1a]. In fact, both the quasi-resonant SET step of eq. [1a] to yield **I** and the following recombination of the acyl radical and the pyrrole radical ion of **I** to yield **II** are expected to take place with negligible activation barriers, if any, irrespective of the particular position of the electron vacancy in the pyrrole radical ion. In the meantime, the probability of recombination between the acyl radical and each position of pyrrole radical ion in adduct **I** is determined by the largely uneven spin density distribution over the pyrrole$^{+\cdot}$ ring (5) and is reflected in the pronounced preexponential factor ratio arising from the Arrhenius plot of Fig. 2.

On the grounds of the above considerations, the experimental features of gas-phase attack of both acetyl and benzoyl cations on the selected heteroarenes conform to a simple two-step mechanistic model (eq. [1a]), involving a quasi-resonant SET step followed by radical – radical ion recombination, rather than to the classical S_E2 mechanism governing the gas-phase attack of alkylating carbocations on the same substrates (2). Such a mechanistic changeover causes dramatic differences in the relative isomeric distribution of the substitution intermediates **II** and, therefore, precludes extension of Klopman's concept (3) to gas-phase heteroaromatic acylation reactions.

Concerning the origin of the deviation of nucleogenic phenylium ion from the linear log (β/α) vs. ε (LUMO) correlation (*f** in Fig. 5) reported in the preceding paper (1), it should be considered that, if nucleogenic phenylium (1) (and methylium) (2*b*) cations follow the energetically allowed mechanism [1a] in much the same way as the acylating reactants, the same exceedingly high extent of α substitution in **1** would be observed, since it is essentially determined by the high spin density at the C_α's of the pyrrole radical ion (5). On the contrary, attack of nucleogenic phenylium (and methylium) cations on gaseous **1** is characterized by a site selectivity (log (β/α) = −0.42 (phenylium ion (1)); −0.51 (methylium ion (2*b*)) that diverges substantially from that of acetyl and benzoyl cations (log (β/α) < −1.1). Moreover, the relative distribution of the phenylated derivatives of **1**, recovered from the decay benzoylation samples under kinetically favored conditions (Table 5), appears significantly different (log (β/α) = −0.11) from that of direct pyrrole phenylation by nucleogenic phenylium ion (log (β/α) = −0.42) previously measured under comparable conditions (1). Such a marked selectivity difference can be accounted for by considering that, in the decay benzoylation systems, phenylpyrroles are generated from CO-solvated phenylium ion (**III**) (17). In this perspective, the higher log (β/α) values of phenylpyrroles recovered in the benzoylation mixtures are qualitatively consistent with the expected harder character of CO-solvated phenylium ion **III** relative to vibrationally excited phenylium ion (1). This conclusion lends support to the view that the deviation of nucleogenic phenylium ion from the linear correlation of Fig. 5 is likely due to factors related to the intimate nature of the relevant energy profile, rather than to a conceivable mechanism for its attack on pyrrole proceeding via a preliminary *exothermic* SET step (eq. [1a]).

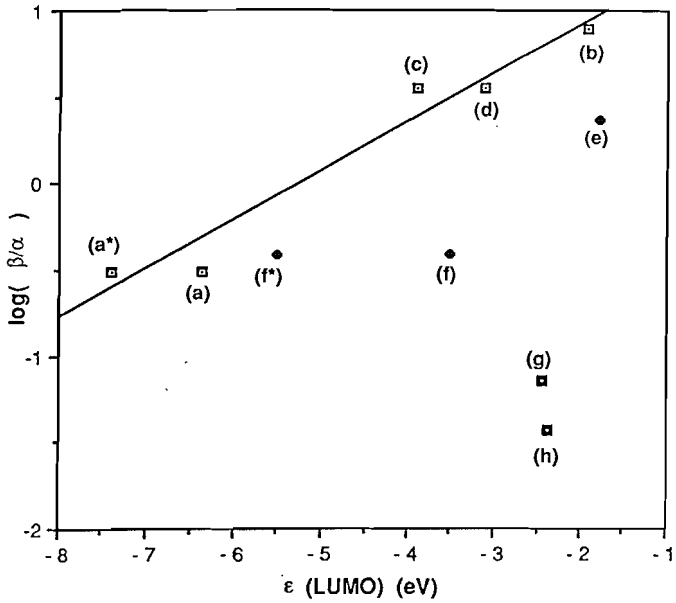

FIG. 5. Plot of site selectivity of ionic electrophiles toward the β and α carbons of pyrrole, expressed as log (β/α), as a function of SCF STO-3G calculated LUMO eigenvalues of the ionic electrophiles, (*) vibrationally excited: (a) CH_3^+; (b) proton-bridged $C_2H_5^+$; (c) *i*-$C_3H_7^+$; (d) *t*-$C_4H_9^+$; (e) $(CH_3)_3Si^+$; (f) $C_6H_5^+$; (g) CH_3CO^+; (h) $C_6H_5CO^+$.

In conclusion, the present acylation results answer the question of a possible mechanistic changeover in the gas-phase attack of carbocations on simple five-membered heteroarenes, providing firm evidence that electrophilic substitution generally proceeds via the classical S_E2 mechanism, except when an entropy-driven *quasi-resonant* single electron transfer (SET) from the substrate to the ionic electrophile is allowed, as for the CH_3CO^+ and $C_6H_5CO^+$ cations (respectively, g and h in Fig. 5). In spite of favorable entropy factors, a gas-phase SET process from the heteroarene to the ionic electrophile is

prevented when markedly *endothermic*, as for proton-bridged $C_2H_5^+$, *i*-$C_3H_7^+$, *t*-$C_4H_9^+$, and $(CH_3)_3Si^+$ (respectively, b, c, d, and e in Fig. 5). No definitive answer can, at the moment, be provided as regards the actual occurrence of an *exothermic* SET event between a heteroarene molecule and CH_3^+ or $C_6H_5^+$ ions (respectively, a and f in Fig. 5). More information on the efficiency of *exothermic* SET processes in electrophilic heteroaromatic substitutions in the gas phase will be given in a forthcoming paper. In general, when the gas-phase two-step sequence [1a] is inaccessible, gaseous ionic electrophiles react with heteroarenes via the classical S_E2 mechanism, qualitatively obeying Klopman's reactivity model (3), although several discrepancies are observed from the quantitative standpoint whose nature deserves further attention.

Acknowledgments

The authors wish to express their gratitude to Prof. F. Cacace for his interest in the present work and to Dr. F. Grandinetti for performing the theoretical calculations. The mechanochemical reactions between CsBr and kaolinite that occur during shaking, grinding at ambient atmosphere (air grinding), and grinding in the presence of a few drops of water (wet grinding), were investigated by photoacoustic and diffuse reflectance infrared spectroscopy and by thermal weight loss. An intercalation complex was formed by the wet grinding technique but not by mixing or air grinding. For comparison, the mechanochemical reactions of kaolinite with CsCl and CsI were also investigated. No complex of CsI was formed but CsCl gave an intercalation complex by air or wet grinding and, after an aging period of 3 months, also by mixing. A structure is suggested for the intercalation complex in which a water molecule coordinated to the large caesium cation donates one proton to an inner surface oxygen and another proton to the halide, while accepting a proton from an inner surface hydroxyl group.

Key words: kaolinite, infrared spectroscopy, intercalation.

KIRK H. MICHAELIAN, SHMUEL YARIV et AHMED NASSER. Can. J. Chem. **69**, 749 (1991).

Faisant appel à la spectroscopie infrarouge photoacoustique et de réflexion diffuse ainsi qu'à la perte thermique de poids, on a étudié les réactions mécanochimiques du CsBr et de la kaolinite qui se produisent par agitation (mélange), broyage dans un atmosphère ambiant (broyage à l'air) ainsi que par broyage en présence de quelques gouttes d'eau (broyage humide). Par la technique du broyage humide, il se forme un complexe d'intercalation; ce n'est pas le cas avec lors du mélange ou du broyage à l'air. Pour fins de comparaison, on a aussi examiné les propriétés mécanochimiques de la kaolinite avec le CsCl et le CsI. Il ne se forme pas de complexe avec le CsI; toutefois, avec le CsCl il se forme un complexe d'intercalation par broyage humide ou à l'air et, après une période de vieillissement de trois mois, aussi par mélange. On suggère une structure pour le complexe d'intercalation dans laquelle une molécule d'eau coordinée au volumineux cation de césium donne un proton à un oxygène de la surface interne et un autre proton à l'halogénure tout en acceptant un proton du groupement hydroxyle d'une surface interne.

Mots clés : kaolinite, le spectroscopie infrarouge, intercalation.

[Traduit par la rédaction]

Introduction

The grinding of a mineral of the kaolin sub-group with CsCl leads to its delamination and the formation of an intercalation complex in which CsCl, together with water adsorbed from the atmosphere, is located between the layers of the mineral (1–5). In this "intercalation complex" hydrogen bonds are formed between hydroxyl groups of the octahedral sheet of the kaolin-like layers and oxygens of sorbed water molecules, as well as between protons of sorbed water molecules and siloxane oxygens of the tetrahedral sheet. Both reactions, namely delamination and intercalation, occur during the grinding of the mineral with CsCl. However, the intercalation reaction associated with adsorption of water from the atmosphere is much slower than the delamination, and an aging period longer than a month is sometimes needed to complete the reaction.

Delamination of minerals of the kaolin sub-group has been proven from deuteration reactions (6). Washing of the intercalated minerals with D_2O resulted in the deuteration of inner surface hydroxyls of the minerals. In contrast, if the clay was not delaminated, only surface OH groups could be deuterated by this treatment. The formation of hydrogen bonds between OH groups of the octahedral sheet and sorbed water molecules, as well as between sorbed water molecules and basal siloxane oxygens of the tetrahedral sheet, was concluded from significant changes in the infrared spectra of the intercalated complexes.

The exact structure of the intercalation complex is not known. Yariv (1, 3, 6) suggested that the large Cs^+ ion, which may serve as a water "structure breaker", perturbs the ice-like structure of water clusters in the vicinity of the clay. The monomeric water molecules coordinated to Cs^+ are able to form hydrogen bonds to inner surfaces of kaolin-like layers by donating protons to basal oxygens and by accepting protons from inner surface hydroxyls. To obtain a better knowledge of the structure of the intercalation complex the study of intercalation of other salts and water is desirable.

In the present investigation mechanochemical reactions occurring during the grinding of kaolinite with CsBr were studied. In addition to the two techniques which were previously employed for the preparation of the intercalated CsCl complexes of kaolinite, shaking and dry grinding in ambient atmosphere (air grinding), both followed by aging, we studied possible intercalation in a wet technique. In this procedure a few drops of H_2O were added to the mixture from time to time during grinding in order to keep it moist. However, the mixture was never allowed to become too wet since this would prevent mechanochemical delamination.

Infrared spectroscopy is established as a reliable tool for the characterization of intercalation complexes (7, 8). The present study is concerned mainly with the infrared spectra obtained for the CsBr–kaolinite mixture after shaking or after air and wet grinding, supplemented by thermal weight loss. For comparison, the shaking and the air and wet grinding of CsCl– and

CsI–kaolinite mixtures were also investigated, and the spectra were compared to those of the equivalent CsBr–kaolinite mixtures.

In the previous studies on the mechanochemical interactions between alkali halides and kaolinite, conventional infrared absorption spectra were obtained after the samples were pressed into disks with alkali halides as matrices. Possible reactions between the mineral and the salt during the preparation of the disk may affect the recorded spectra, but this effect could not be accurately determined. In the present study we employed photoacoustic and diffuse reflectance FT-IR spectroscopy. These techniques yield spectra of powders without the requirement that they be pressed into disks. To avoid complications that might arise from further kaolinite/alkali halide interactions, the mixtures were investigated "as is", that is, they were not diluted in a nonabsorbing alkali halide matrix as is the customary practice in diffuse reflectance spectroscopy. Photoacoustic FT-IR spectra are commonly obtained for undiluted powders.

The results obtained by diffuse reflectance FT-IR spectroscopy are complementary to the photoacoustic study, with the advantage that one obtains higher signal-to-noise ratios in the former case. However, the diffuse reflectance spectra of the undiluted samples are not useful below 1000 cm^{-1} because the strong absorption by the lattice vibrations obscures all of the detail. Therefore, diffuse reflectance spectroscopy is used only for the study of the OH stretching region in the present work. The low frequency data reported are from the photoacoustic spectra.

Experimental

Materials

Natural jurassic kaolinite from Makhtesh Ramon, Israel (kindly donated by Dr. Shlomo Shoval from the Open Univesity of Tel Aviv) was manually ground using an agate mortar. The fraction passing an 80 mesh (0.177 mm) sieve was used. The IR spectrum of this sample shows a very weak absorption at 3601 cm^{-1}, originating from a very small degree of substitution of Fe for octahedral Al (9, 10). The sample contains ≈5% quartz but this mineral does not react with alkali halides. Caesium halides (Suprapur) were purchased from Merck.

Methods

Mixtures consisting of 500 mg kaolinite and 500 mg of a particular caesium halide were prepared by three different techniques. In the first, the components were thoroughly mixed in small test tubes by manual shaking for about 5 min. In the second technique, the mixtures were ground in a mechanical "Fisher" mortar grinder for 30 min at ambient atmosphere (air grinding). In the third technique the mixtures were ground mechanically for 60 min but 2–3 drops of water were added every 5 min in order to keep the mixture moist (wet grinding). In the latter case we took care that the mixture did not become too wet, so that the mechanochemical process would not be interrupted. For comparison, 1000 mg kaolinite were ground with no additives for 30 min in the same grinder. Mixtures prepared by the first two methods were aged for three months before determination of thermal weight loss or measurement of infrared spectra.

Thermal weight loss

Weight losses were determined for 200 mg of air-dried pure kaolinite (both ground and unground), and for 400 mg of the various CsCl-, CsBr-, and KBr-treated kaolinites. Samples were heated at 100, 150, and 200°C (24 h at each temperature), and at 250, 300, 350, 400, and 450°C (2.5 h).

Infrared measurements

Infrared spectra were obtained using a Bruker IFS 113v FT-IR spectrometer and two different sample accessories. Photoacoustic spectra were recorded with a Princeton Applied Research Corporation model 6003 cell and model 6005 preamplifier; the spectrometer was filled with nitrogen during the measurements. Diffuse reflectance spectra were recorded with a Harrick "praying mantis" attachment and a mercury cadmium telluride detector. The spectrometer was evacuated while the diffuse reflectance data were obtained. These reflectance spectra were later converted to pseudo-absorbance spectra and plotted in Kubelka-Munk units, even though that analysis is strictly applicable only for dilute samples. Hence the intensity scale for these spectra should be regarded as arbitrary.

Several photoacoustic spectra were also recorded using a Bruker IFS 88 spectrometer and an MTEC model 200 photoacoustic cell. The spectrometer was operated in the step-scan, or step-and-integrate, mode rather than the more conventional procedure in which the interferometer mirror moves rapidly and continuously (11). The intensity distributions in the step-scan spectra are slightly different from those in the rapid-scan spectra because of the lower modulation frequencies in the former case; this leads to a small degree of saturation of band intensities, and facilitates identification of weak bands in some situations.

Results

Thermal weight loss

Thermal weight losses of kaolinite treated with CsBr (mixed and air or wet ground) are shown in Table 1. For comparison, thermal weight losses of kaolinite ground for half an hour without any salt or together with CsCl (air and wet) and KBr (air) are also shown in the table. In the temperature ranges 0–250 and 250–450°C unground kaolinite lost 0.5 and 5.5% (not shown in Table 1), due to the removal of "free" water and partial dehydroxylation of the kaolinite, respectively. After grinding, kaolinite contains amorphous material and consequently much "free" water, losing 12.59 and 5.95%, respectively. Kaolinite mixed with CsBr lost 1.86 and 23.49%, respectively. According to Heller-Kallai (12) and Gabor *et al.* (13) the difference in the weight loss occurring during the dehydroxylation stage is in part due to the evolution of hydrogen halide which results from the following thermal hydrolysis:

$$2SiO_2 \cdot Al_2O_3 \cdot 2HOH + 2nCsBr \rightarrow 2SiO_2 \cdot Al_2O_3 \cdot nCs_2O + 2nHBr + (2 - n)HOH$$

On the clay surface a liberated water molecule associates with Br^- to form volatile HBr. The volatilization of HBr is responsible for great thermal weight losses of air ground kaolinite CsBr or KBr mixtures, especially at 400°C. A similar thermal hydrolysis occurs with alkali chlorides.

The thermal behaviour of the wet ground CsBr treated kaolinite shows some similarities to the wet ground CsCl treated kaolinite, but differs from that of the unground or ground kaolinite and from the other bromide-treated samples by losing much weight in the temperature range 150–350°C. This is probably due to the loss of intercalated water and, in part, the evolution of HBr which is formed in the interlayer. The loss at 400°C is much smaller than that found for mixed and air ground CsBr- or KBr-treated kaolinite, indicating the absence of a "free" CsBr phase due to the fact that the salt intercalated the clay.

Infrared studies

The effect of CsBr treatment on the IR spectrum of kaolinite

Figure 1 shows the infrared spectrum of untreated kaolinite (subjected only to the initial grinding to pass 80 mesh) and the spectra of CsBr treated kaolinites prepared by the following techniques: (*1*) air grinding, and (*2*) wet grinding. Band positions and assignments for the wet ground sample are summarized in Table 2. The spectra of kaolinite either mixed or air

TABLE 1. Percentage weight loss during the thermal treatment of kaolinite, air ground; kaolinite, air and wet ground with CsCl; kaolinite, mixed, air and wet ground with CsBr; and kaolinite, air ground with KBr (percentage losses for all mixtures are calculated on the basis of kaolinite).

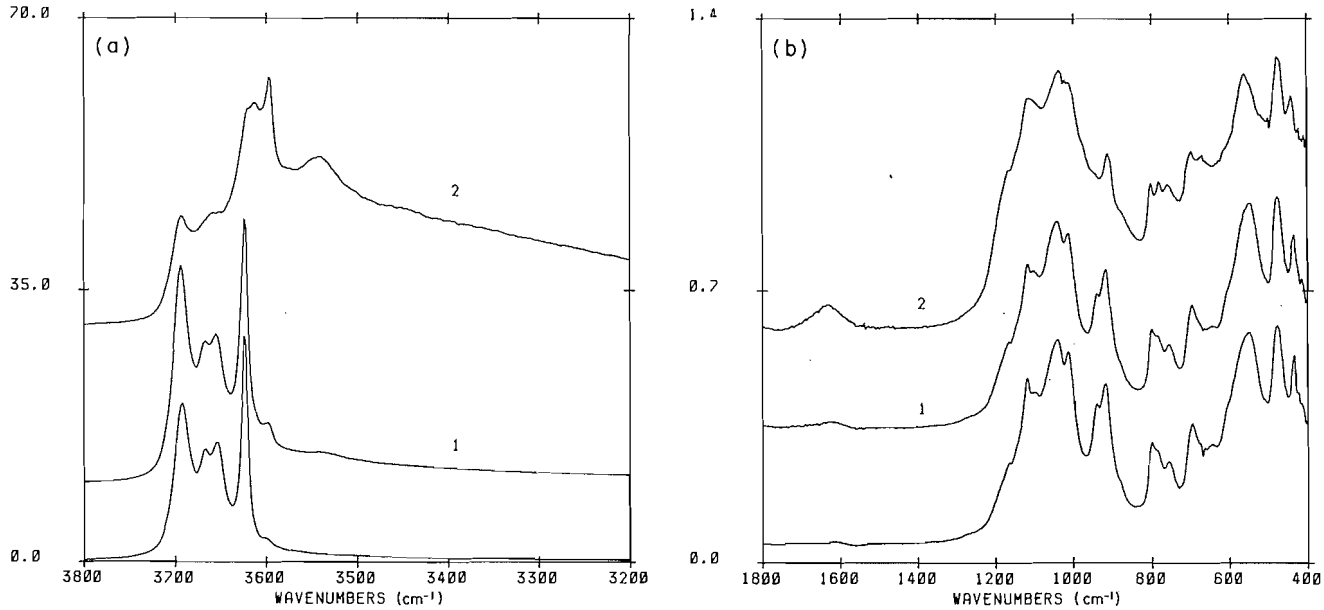

FIG. 1. (*a*) Diffuse reflectance FT-IR spectra of untreated kaolinite (lower curve) and of CsBr–kaolinite mixtures: (*1*) air ground and (*2*) wet ground. The intensity scale is arbitrary, and the curves are offset for clarity. (*b*) Photoacoustic FT-IR spectra of untreated kaolinite (lower curve) and of CsBr–kaolinite mixtures; identification of the samples is the same as in (*a*). Spectra have been ratioed against carbon black, rescaled and shifted in order to prevent overlap.

ground with CsBr are similar to those of unground kaolinite and of kaolinite which has been ground without additives, respectively. Aging of these samples has no effect on their spectra, implying that no intercalation complex was formed with CsBr in these techniques. On the other hand, the spectrum of the kaolinite/CsBr mixture ground under wet conditions shows similarities with that of CsCl treated kaolinite, indicating the intercalation of CsBr and H_2O (1–6). This is manifested by (*a*) diminution of the lattice OH stretching bands A, B, and C and the appearance of a new band A′, which is attributed to a perturbed OH stretching vibration and is characteristic for hydrogen bonded inner surface hydroxyls; (*b*) shifts of Al—OH and Al—O deformation vibrations to lower and higher frequencies, respectively; (*c*) shifts of the Si—O stretching and deformation vibrations; and (*d*) appearance of HOH stretching and bending vibrations which do not occur in the spectrum of untreated kaolinite (Table 2).

The weakening of bands A, B, and C and the appearance of band A′, as well as the shifts of the Al—OH deformation vibrations, indicate that hydrogen bonds are formed between adsorbed water molecules and inner surface hydroxyls; moreover, the shifts of the Si—O vibrations suggest that hydrogen bonds are formed between adsorbed water molecules and inner surface oxygens. However, if this spectrum is compared to

[a]s, m, w, vw, and sh denote strong, medium, weak, very weak, and shoulder, respectively.
[b]From step-scan photoacoustic spectrum (18).
[c]This band cannot be detected in the spectra of the mixtures because of overlap with other bands.

those obtained for CsCl-treated kaolinite, it is obvious that the degree of intercalation was smaller even than that of the aged mixed CsCl–kaolinite (see below). Consequently, bands A, B, and C, although relatively weak, are visible in the spectrum (curve *2*, Fig. 1) whereas band Z, which is located in the envelope of band A, cannot be detected. We tried to increase the period of wet grinding, but this resulted in the amorphisation of the kaolinite framework, as shown by broadening and disappearance of hydroxyl and lattice vibrations.

A band at 3582 cm^{-1} in the spectrum of CsCl-treated kaolinite was previously assigned by Yariv (6) as perturbed bands B and/or C. The 3582 cm^{-1} band does not appear in the spectrum of CsBr-treated kaolinite; instead, a band of similar shape occurs at 3612 cm^{-1}. It is therefore not plausible to assign this absorption either to perturbed band B or to band C.[2] A more satisfactory interpretation would be to assign this band to the asymmetric stretching vibration of HOH coordinated to CsBr, and the 3541 cm^{-1} band to the symmetric stretching vibration of HOH coordinated to this salt. Similarly, the 3582 and 3522 cm^{-1} bands in the spectra of CsCl-treated kaolinite should be assigned as the asymmetric and symmetric stretching vibrations, respectively, of HOH coordinated to CsCl.

Differences greater than 20 cm^{-1} in either the asymmetric or the symmetric stretching frequencies of HOH when CsCl is replaced by CsBr are indications of hydrogen bond formation between the coordinating water molecule and the coordinated halide. Data in the literature on hydrogen bond formation between halides other than F^- and proton donors is rare. However, neutron diffraction experiments for several heavy water electrolyte solutions at various concentrations recently established that the hydration geometry of a chloride is independent of the cation, and that a nearly linear Cl—D—O arrangement occurs with a Cl···O distance shorter than that expected for dipole interactions (14). The nearly linear geometry and the short Cl···O distance support the idea that hydrogen bonds exist between chloride ion and coordinating water molecules in aqueous solutions. Bromide is less electronegative and consequently less effective than chloride, forming weaker hydrogen bonds. The compound $Cs_3Br_3(H_3O^+)(HBr_2^-)$ provides an example in which a hydrogen bond involving Br^- occurs. The O—H···Br distance calculated from van der Waals radii of O and Br is 335 pm whereas the measured distance in this compound is only 304 pm (15).

The effect of CsCl treatment on the IR spectrum of kaolinite

Figure 2 shows the infrared spectra of CsCl-treated kaolinites prepared by the following three techniques: (*1*) mixing, (*2*) air grinding, and (*3*) wet grinding. Band positions are again summarized in Table 2. The mixtures were aged at ambient atmosphere for 3 months before recording the spectra. The appearance and intensity of the different absorption bands in the spectra of mixtures 1 and 2 depend on the aging period whereas the spectrum of mixture 3 hardly changes with time.

The spectra show that all three methods of treatment led to the formation of an intercalation complex. By comparing the three spectra of CsCl-treated kaolinite to the spectrum of the untreated

[2]Second derivative and curve-fitting calculations show that bands B and C occur near 3640 cm^{-1} in spectra of these complexes. These results will be described more fully in a separate publication.

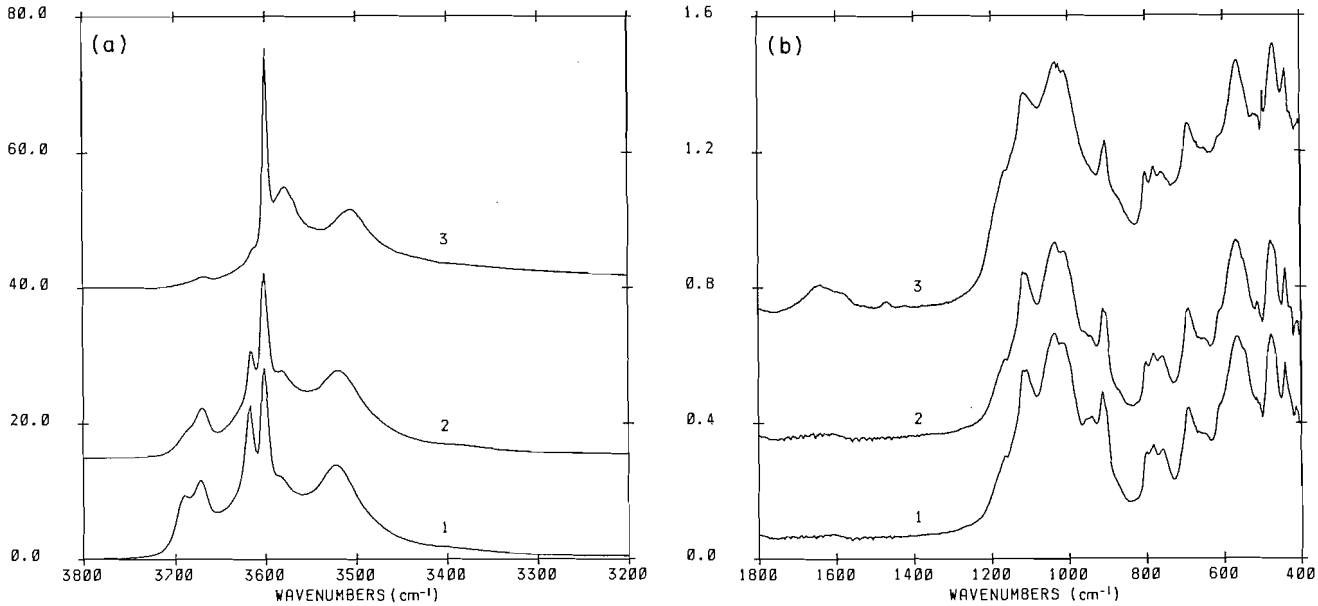

FIG. 2. (*a*) Diffuse reflectance FT-IR spectra of CsBr–kaolinite mixtures: (*1*) dry mixed, (*2*) air ground, and (*301*) *wet ground*. (*b*) Photoacoustic FT-IR spectra of CsBr–kaolinite mixtures; identification of the samples is the same as in (*a*). Plotting strategy is the same as in Fig. 1.

kaolinite, it is possible to follow the degree of intercalation. In the spectrum of sample 1 recorded after a period of 3 months, band A is very weak in comparison to its intensity in the spectrum of untreated kaolinite, but is still observed. The fact that unperturbed band A still occurs in the spectrum indicates that some of the inner surface hydroxyl planes did not react with water molecules. An OH band at about 3684 cm^{-1} (band Z) was previously observed by Michaelian (16) in the Raman spectrum of kaolinite and tentatively assigned as an uncoupled inner surface hydroxyl stretching. This assignment was supported in a separate infrared deuteration study (17). This band is not observed in the conventional IR spectrum of kaolinite because it is located in the envelope of band A. It is, however, observed in the step-scan photoacoustic spectrum of kaolinite (18). This band is clearly observed in the spectrum of aged mixture 1, after the diminution of band A.

In the diffuse reflectance spectrum of sample 2 band A is reduced to a barely identifiable shoulder. A curve-fitting analysis of this spectrum confirms that this band still exists, although with greatly reduced intensity. These data indicate that only very few of the hydroxyl inner surfaces did not react with adsorbed water.

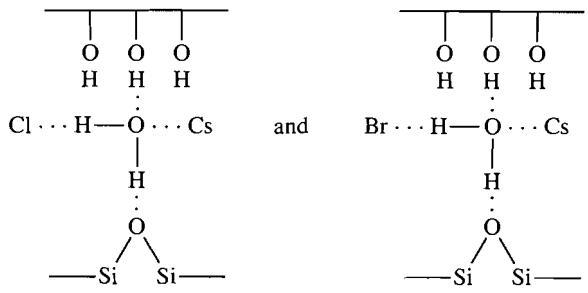
In sample 3 delamination seems to be completed; the water band is broadened, shifted slightly to 3508 cm^{-1}, and its relative intensity is increased. Both kaolinite bands A and D are not observed in the diffuse reflectance spectrum. Based on deuteration studies, band D was assigned to an inner OH vibration (19). As such, it is expected that this band should not be affected by intercalation. The perturbation that is observed in the present study is probably due to the complete delamination of the kaolinite tactoid. The symmetry of a single alumino-silicate layer may be slightly altered relative to the symmetry of the layer in the tactoid, causing band D to become broad and shift slightly to a lower frequency. Since it is located in the envelope of band A′, it may be undetectable in the spectrum. It should be noted that the present spectrum of sample 3 is very similar to the spectrum obtained previously for CsCl-treated halloysite (4). It is therefore concluded that the wet grinding leads to complete delamination and intercalation of the kaolinite.

The three spectra of the CsCl-treated kaolinite show shifts of the lattice vibrations in comparison with the spectrum of the untreated kaolinite. Most of these shifts become progressively greater as the degree of intercalation increases. For example, several of the Si—O stretching and the Al—OH deformation vibrations (bands E, F, G, and I) shift gradually to lower frequencies from sample 1 through sample 2 to sample 3, whereas the Al—O deformation frequency displays the opposite trend. The latter shift may be real, but it may also be possible that it results from incomplete resolution of two vicinal maxima, one arising from the hydrogen bonded layer and one from the layer which did not react with the hydrated salt. In the latter case only sample 3 would yield the true spectrum of the intercalation complex.

The effect of CsI treatment on the IR spectrum of kaolinite

The spectra of kaolinites, either mixed or ground (air or wet) with CsI, are similar to that of kaolinite which has been ground without additives. The same spectrum is obtained even after an aging period of three months in the ambient atmosphere. This indicates that no intercalation complex was formed with CsI.

Discussion



A system consisting of CsCl and kaolinite sorbs water from the atmosphere upon aging, forming an intercalation complex. If the mixture is ground, the formation of the complex is faster than when it is only shaken. If water is added during grinding, the intercalation complex is formed in situ. The present IR study showed that dry grinding of CsBr or CsI with kaolinite at ambient atmosphere did not result in any spectroscopic changes. This indicates that salt or water molecules from the atmosphere do not react with kaolinite to form an intercalation complex. Aging, which improves the intercalation in a CsCl–kaolinite system, does not help in the CsBr– or CsI– kaolinite systems. However, CsBr and water, but not CsI and water, formed a

For personal use only.

kaolinite intercalation complex during wet grinding. It may be concluded that in the intercalation of kaolinite by caesium halide hydrates, the caesium halide salt as a whole is responsible for the intercalation, the activity of the salt decreasing with increasing size of the halide ion.

There are two possible reasons for this phenomenon: (*1*) I^- is too big and cannot penetrate into the interlayer space of the kaolinite, Br^- can penetrate only when forced to do so, whereas Cl^- is small enough to enter between the layers; (*2*) hydrogen bonds between sorbed water molecules and the anions are essential for the intercalation reaction. Such bonds, although weak, can be formed with Cl^-. They are very weak with Br^-, and still weaker and very rare with I^- (15). Our study shows that they are not formed at all in the CsI–kaolinite system. The varying strengths of these hydrogen bonds give rise to the differences which are observed between HOH absorption frequencies in the CsBr system as compared to the CsCl system (Table 2).

The shifts observed for the OH stretching and lattice vibrations in the spectra of the intercalation complexes as compared to the spectrum of untreated kaolinite, as well as the locations of the HOH vibrations in CsCl-and CsBr-treated kaolinite, lead us to suggest the following structures for the intercalaction complexes. A water molecule coordinated to the large Cs cation donates one proton to a siloxane oxygen and the other to the halide, while accepting a proton from an inner surface hydroxyl group:

Conclusions

Intercalation complexes of kaolinite are formed with CsCl or CsBr and water, but not with CsI. The CsBr complex is formed by grinding a mixture of CsBr and kaolinite in the presence of a few drops of water, whereas it is not necessary to add water during grinding with CsCl because water is sorbed from the atmosphere. However, in the presence of water the mechanochemical intercalation of CsCl is fast.

Internal standards in differential pulse anodic stripping voltammetry

ANGELO RANSIRIMAL FERNANDO AND BYRON KRATOCHVIL
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received September 27, 1990

ANGELO RANSIRIMAL FERNANDO, and BYRON KRATOCHVIL. Can. J. Chem. **69**, 755 (1991).

The use of lead and cadmium as internal standards for each other in anodic stripping analysis was investigated. Although accuracy was not affected, precision was significantly improved. The surface active agents Triton-X 100 and starch affected the sensitivity of the anodic stripping procedure for lead and cadmium, leading to error if a calibration curve is used. Data for application of the procedure to the analysis of the marine biological reference material LUTS-1 and soil reference materials SO-2, SO-3, and SO-4 are provided.

Key words: internal standard, anodic stripping voltammetry, calibration curve, standard addition, lead determination, cadmium determination.

ANGELO RANSIRIMAL FERNANDO et BYRON KRATOCHVIL. Can. J. Chem. **69**, 755 (1991).

On a étudié la possibilité d'utiliser le plomb et le cadmium comme étalons internes réciproques lors de l'analyse par redissolution anodique. Même si l'exactitude n'est pas affectée, la précision est de beaucoup améliorée. Les agents tensioactifs, comme le Triton-X 100, affectent la sensibilité de la méthode par redissolution anodique pour le plomb et le cadmium; il en résulte qu'une erreur est introduite lorsqu'on utilise une courbe de calibration. On fournit des données concernant l'application de la méthode à l'analyse du LUTS-1, le produit de référence en biologie marine, et des matériaux de référence des sols, SO-2, SO-3 et SO-4.

Mots clés: étalon interne, voltammétrie par redissolution anodique, courbe de calibration, addition de référence, détermination du plomb, détermination du cadmium.

[Traduit par la rédaction]

Introduction

Although internal standards have been used in a variety of analytical techniques such as polarography to compensate for variations associated with poorly reproducible operations, their application in anodic stripping analysis was not described until 1988 by Pratt and Koch (1), who used indium as an internal standard along with a calibration curve for the quantification of several trace metals in water samples. While this approach has wide applicability under conditions where the background is constant for sample and standards, it is not so satisfactory when the background varies in composition. Voltammetric and potentiometric techniques require direct contact of the sample solution with the probe or the sensor and are more sensitive to matrix matching problems than many other methods.

Pratt and Koch (1) showed that use of an internal standard tends to eliminate random errors originating from the variations in mercury drop size and stirring. This work was to evaluate the merits of a combination of an internal standard and a standard addition procedure, using either lead or cadmium as analyte and the other as internal standard. The samples were biological materials and soils that had to be digested under conditions where the resulting solutions did not provide highly reproducible backgrounds.

Experimental

Instrumentation

A PAR model 303 stationary mercury drop electrode (SMDE) and a PAR Model 174A polarographic analyzer coupled to a MACSYM 150 (Analog Devices) microcomputer was used to perform all anodic stripping measurements. A detailed description of the instrument system appears elsewhere (2).

Reagents

Distilled deionized water was obtained from a Barnsted Bantam still. Lead and cadmium levels in acidified solutions (10^{-2} M HNO_3) were well below the detection limit (ca. 0.03 ppb) under the analytical conditions used.

Nitric and perchloric acids (ultra pure grade, Seastar Chemicals, Sidney, B.C., Canada) and sodium hydroxide (suprapure grade, Merck) were used as received.

An aqueous stock solution of KNO_3 was prepared from reagent grade salt and further purified by bulk electrolysis in a large volume cell with a mercury cathode. Triply distilled mercury was purified in a similar cell via anodic oxidation (2). Reagent grade potassium chloride, further purified by recrystallization and crystal adsorption, was used for the salt bridges (3). Reagent grade acetic acid was purified by isopiestic distillation (4–6). High purity nitrogen was passed through acidified vanadium(II) chloride/zinc amalgam scrubbers followed by aqueous washing towers to remove trace oxygen (7). All other chemicals were reagent grade.

Stock solutions (1000 ppm) of $Pb(NO_3)_2$ and $Cd(NO_3)_2$ (analytical grade) were used to prepare working standards.

Digestion of LUTS-1 samples

The marine biological reference material LUTS-1, obtained from the Marine Standards Analytical Program, Division of Chemistry, National Research Council of Canada, Ottawa, Canada, is a slurry obtained through mechanical homogenization of lobster hepatopancreas tissue. The bottles were sonicated for 30 min prior to opening and before removal of subsequent samples. Approximately 1-mL portions were pipetted directly from the bottles and weighed to ±0.01 mg on a Mettler H-51 semimicro balance into Savillex 60-mL Teflon PFA digestion vessels (Savillex Corp., Minnetonka, MN). After adding 3 mL of nitric acid, the vessels were closed and placed on a turntable in a microwave oven (Sears Kenmore, Model No. 88760) and heated for 2 min at 100% power followed by 10 min at 15% power. After cooling, the samples were transferred to 10-mL volumetric flasks and diluted to volume with water.

A 1-mL portion of this HNO_3 digested solution was placed in a Teflon PFA voltammetric cell (Princeton Applied Research GO 174) with 1 mL of $HClO_4$ and heated under cover (Teflon TFE cover plate) for 2 h at ca. 200°C. The covers were then removed and the solution was allowed to evaporate to dryness (2 to 3 h) at a temperature near 240°C. Heating was done on a sandbath covered with aluminum foil to prevent contamination and adherence of sand particles to the hot Teflon. The evaporation procedure was carried out in a stainless steel fumehood designed to handle perchloric fumes. (Caution: the usual precautions must be taken when working with hot concentrated $HClO_4$.)

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 198.100.157.202 on 09/07/12
For personal use only.

Residue from the above procedure was dissolved in 5 mL of 0.01 M HNO_3 pipetted directly into the cell, a Teflon-coated stirbar was added, and the cell was placed in the electrode assembly for subsequent anodic stripping analysis.

Digestion of standard soils SO-2, SO-3, and SO-4

These reference materials, obtained from Canadian Reference Materials Project, Energy Mines and Resources Canada, were digested with nitric, perchloric, and hydrofluoric acids according to recommended procedures (2, 8). Briefly, 1-g portions, dried at 110°C overnight, were weighed into 100-mL Teflon beakers, heated with 20 mL of concentrated HNO_3 under cover for 30 min at 100 to 150°C, allowed to cool, then treated with 20 mL of concentrated $HClO_4$, followed by another 30 min of heating at 200 to 250°C. Subsequent cooling was followed by 20 mL of concentrated HF and 1-h heating under cover at 80°C. The resultant solution was evaporated to near dryness, dissolved in 25 mL of 1 M HNO_3, then diluted with water to 50 mL in a polypropylene volumetric flask.

Anodic stripping voltammetry

Anodic stripping analyses of LUTS-1 samples for cadmium were performed after adding 20 μL of 5 ppm Pb standard solution to 5-mL portions of the digestion solution. Since the final step of the digestion was performed in a voltammetric cell no sample transfer was needed.

Analyses of digested standard soil samples for lead were done in acetate buffer containing 0.1 M acetic acid and 0.1 M KNO_3 which was adjusted to pH 4 with sodium hyroxide. A 100-μL portion of the digested solution was added to 5 mL of the buffer solution in a voltammetric cell. To serve as internal standard 2 μL of 20 ppm Cd standard solution was added.

In all analyses a 5-min deaeration period was followed by a 2-min deposition step at −0.8 V vs. SCE. A differential pulse anodic scan was initiated after a 0.5-min equilibration. Measurement conditions were scan rate 5 mV/s, modulation 25 mV, and clock 1 s. Solutions were stirred magnetically during the deposition step. Three measurements were made on each solution.

Data aquisition and peak height evaluation was done using a Macsym 150 microcomputer and associated programs (2).

Results and discussion

In general the results obtained confirmed the findings of Pratt and Koch (1) with respect to precision of the anodic stripping determination. Data shown in Table 1 for a solution prepared using standard solutions of cadmium and lead illustrate this point. While relative standard deviations for individual peaks are around 7%, those for peak ratios drop to around 0.1%. This increase in precision stems from elimination or reduction of variations associated with stirring conditions and reproducibility of the mercury drops. Since a normal laboratory magnetic stirrer was used, reproducibility of stirring was the least controlled parameter in the system. In general, relative standard deviations of the order of 10% are typical (2) for ppb level determinations using anodic stripping voltammetry. Use of an internal standard, therefore, provides a considerable increase in the precision of the measurements. It is important, however, to realise that this improvement stems from the elimination of variability associated with parameters that cannot be readily controlled, rather than from inherent chemical or physical limitations.

Results obtained from analyses of digested LUTS-1 samples for cadmium using lead as an internal standard are listed in Table 2; those for analyses of standard soils SO-2, SO-3, and SO-4 appear in Tables 3, 4, and 5. These were obtained using at least two standard additions of either lead or cadmium. Additions were made directly into the cell with a micropipet. For LUTS-1 5 μL additions of a 20 ppm standard cadmium solution resulted in a 20 ppb change. For SO-2, SO-3, and SO-4, 5 μL additions of a 5 ppm standard lead solution increased the lead level in the solution by 5 ppb for each addition. The results given in Table 2 to 5 were calculated by procedures normally employed for standard addition calculations, using as the measured parameter either the direct peak height (μA) of the analyte or the ratio of the analyte peak height to that of the internal standard.

TABLE 1. Peak height and peak ratio data for analysis by anodic stripping of a solution containing 40 ppb cadmium and 20 ppb lead in 0.5 M KNO_3 and 0.01 M HNO_3

	4.40	1.00	4.40
Mean	4.68	1.06	4.40
Std. dev.	0.35	0.08	0.004
RSD (%)	7.4	7.3	0.1

In all cases the use of an internal standard improves precision. It should be noted, however, that the accuracy of the determination when peak heights are used without the internal standard does not seem to be affected provided one acquires sufficient data. In general, triplicate measurements per sample tend to provide means that agree well between samples. Thus use of an internal standard improves precision markedly, but does not affect the accuracy of the overall procedure.

In trace analysis the definition of accuracy is affected by the width of the confidence interval. Improvement in the precision of an analysis has an important effect on the reliability of the determination. Therefore, even though in a statistical sense accuracy may not have been improved, the improvement in precision possible with an internal standard may significantly improve the reliability of a final result without requiring large numbers of analyses.

Table 6 shows results obtained for SO-4 analyses using a calibration curve obtained by adding appropriate amounts of a 5-ppm lead standard solution directly to 5 mL of 5 ppb cadmium in acetate buffer. Anodic stripping voltammograms obtained for these solutions were used to prepare two calibration curves, one of lead peak height vs. lead concentration and the other of the ratio of lead peak height/cadmium peak heights vs. lead concentration. The former calibration curve was used with peak height values obtained for soil SO-4 to calculate results reported under the "without internal standard" heading in Table 6. The lead/cadmium peak height ratios obtained for soil SO-4 with the latter calibration curve gave the values reporetd under the "with internal standard" heading. In this study the SO-4 solutions were also spiked to a level of 5 ppb with respect to cadmium.

It can be seen that agreement between the results obtained from standard additions and those obtained from calibration curves using peak size measurements is poor. This lack of agreement stems from the sensitivity of the direct method to the sample matrix; here a 100-μL aliquot of digested solution was added to 5 mL of acetate buffer. On the other hand, data from peak ratio measurements for the different sample matrices are in good agreement. Thus, when employing a calibration curve, use of an internal standard provides improved accuracy. In light of this result we consider the loss of accuracy in the analysis of

SO-4 samples to stem from a process that affects equally either the deposition or the oxidation of lead and cadmium. Trace level organic compounds that adsorb on to the mercury surface can interfere. In any case an interference that selectively affects one of the metals will interfere with the use of a calibration curve approach, leading to a systematic error. Standard additions results will, however, still be valid.

To investigate the effect of organic adsorbents on the internal standard procedure, several experiments were carried out using acetate buffer solutions containing lead and cadmium in parts per billion levels, with and without added Triton X-100, a known surface active agent. Addition of Triton X-100 (in the form of a 0.06% (v/v) aqueous solution) in μL quantities to 5 mL of a solution containing Pb and Cd led to a decrease in peak height for both metals. Lead showed a linear decrease, but cadmium did not, which suggests that different forms of inhibiting actions are operating on these metals.

Under these conditions the ratios of the lead and cadmium signals varied significantly with concentrations of both metals and surfactant, confirming the earlier conclusion. Triton-X has been regarded as a neutral surface active agent in polarography, with an ability to form a uniform adsorbed organic layer upon the mercury surface. If the presence of adsorbed surfactant inhibited movement of both Cd and Pb between bulk solution

and the interfacial region to a similar extent, a constant Pb/Cd signal ratio with changing surfactant level should be observed. We observed, however, that the Pb/Cd signal ratio shows a complex dependence on the level of surfactant. Slower charge transfer kinetics exhibited by cadmium in aqueous media and possible potential dependence of the adsorption energy can be suggested as factors responsible for this observation. Similar results were observed upon addition of starch, though μL quantities of a 10% starch solution were needed to yield an observable change in signal level.

In light of these results the use of an internal standard/calibration curve approach with undigested environmental materials such as natural water may be affected by the presence of surface active macromolecules. On the other hand, the favorable results obtained for digested SO-4 soil samples indicate the applicability of this approach to samples that have been treated to destroy all potentially interfering macromolecules. Application of the standard addition procedure to peak heights obtained for a 9-ppb lead solution containing 2 μL of 0.06% Triton-X per 5 mL resulted in a value of 7.6 ± 0.5 ppb, while the same solution, using peak ratios with Cd as the internal standard, gave a value of 8.9 ± 0.1 ppb. This indiactes the merits of using an internal standard in a standard addition procedure.

In summary, we observe a significant improvement in precision in anodic stripping analytical data when an internal standard is employed. Whether use of this approach eliminates interferences to an extent sufficient to recommend replacement of standard addition procedures with a calibration curve depends on the nature of the sample matrix, but is likely to lead to improved results in many cases.

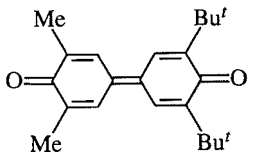
Amorphous molecular composites of *N,N,N',N'*-tetra(*m*-tolyl)-1,3-diaminobenzene as an electron donor and 3,5-dimethyl-3',5'-di-*tert*-butyl-4,4'-diphenoquinone as an electron acceptor have been found to be capable of transporting both hole and electron. Based on drift mobility measurements, it is demonstrated that the donor and acceptor components function independently as hole- and electron-hopping sites, respectively, with no electronic interaction between them.

Key words: bipolar charge transport, arylamine, diphenoquinone, molecular solid solution.

YASUHIRO YAMAGUCHI, TAKAHIRO FUJIYAMA et MASAAKI YOKOYAMA. Can. J. Chem. **69**, 759 (1991).

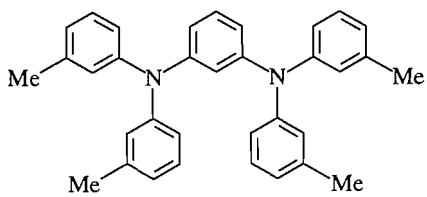
On a observé qu'un matériau composite moléculaire amorphe de *N,N,N',N'*-tétra(*m*-tolyl)-1,3-diaminobenzène agissant comme donneur d'électron et de 3,5-diméthyl-3',5'-di-*tert*-butyl-4,4'-diphénoquinone agissant comme accepteur d'électron peut transporter des trous ainsi que des électrons. Sur la base de mesures de la mobilité, on a démontré que les composantes donneur et accepteur respectivement agissent indépendamment comme sites de saut de trou et d'électron et qu'il n'existe aucune interaction électronique entre elles.

Mots clés : transfert de charge bipolaire, arylamine, diphénoquinone, solution solide moléculaire.



[Traduit par la rédaction]

Amorphous organic thin films have attracted much attention as a class of charge transport materials from both phenomenological and technological viewpoints. Most of such materials, however, are provided largely in the form of polymers or dispersions of transport-active molecules in inert polymeric binders, since generally low molecular weight organic compounds have no amorphous film forming capability. Only a few studies have been reported on charge transport in amorphous molecular solids (1–4). Amorphous molecular materials are not only important for the theoretical study of the transport mechanism, but are also very promising in a growing field of optoelectronics, where materials are required that permit easy film processibility by vacuum deposition or the solvent-cast technique.



We present herein a novel class of amorphous molecular materials, i.e., solid solutions of *N,N,N',N'*-tetra(*m*-tolyl)-1,3-diaminobenzene (PDA) and 3,5-dimethyl-3',5'-di-*tert*-butyl-4,4'-diphenoquinone (MBDQ), which function as bipolar-charge (i.e., hole and electron) transport materials. We believe that the present work introduces the first molecular material in which both hole and electron mobilities have been measured in an amorphous state.

PDA was synthesized by the Ullmann condensation of 1,3-diaminobenzene and *m*-iodotoluene and purified by column chromatography on alumina and vacuum distillation (5). MBDQ, synthesized by the oxidative coupling of 2,6-dimethylphenol and 2,6-di-*tert*-butylphenol, was purified by column chromatography on silica gel and recrystallization from hexane (6).

Molecularly dispersed polymeric materials of charge-transporting small compounds are well known as the most successful class of functional organic materials. A large number of *hole* transport molecules that have high polymer compatibility have been reported and some of them form stable amorphous solids in

MBDQ

PDA

themselves (1–3). On the contrary, a limited number of *electron* transport molecules are known (4, 6–9) and, among these, 2,4,7-trinitro-9-fluorenone (TNF) is the only example whose electron mobility (although very unstable) has been measured in the amorphous solid (4).

Our previous studies revealed that PDA and MBDQ are capable of transporting hole and electron, respectively, in their polymeric dispersions (5, 6). PDA forms a stable amorphous state (3), but MBDQ itself does not. Fortunately, the mixture of PDA and MBDQ forms amorphous composite films from the solvent-cast method by the wired-bar technique. The amorphous films incorporating less than about 60 wt.% of MBDQ are relatively stable and show few signs of crystallization over several weeks at room temperature. Using differential scanning calorimetry, PDA and the composites were found to show a glass transition near 300 K. It is interesting that no charge transfer absorption appeared in the composite films, which is presumably because of no close contact due to the non-planarity of PDA and the presence of the bulky substituents in MBDQ.

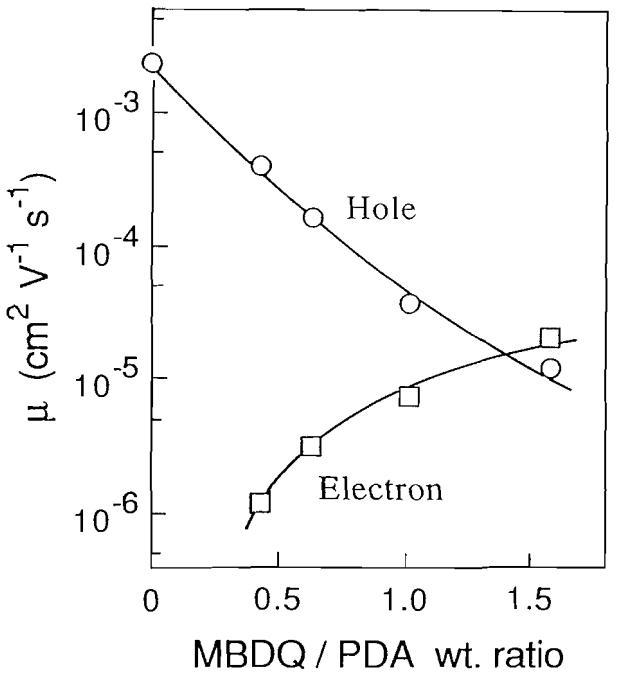

FIG. 1. The dependence on composition of the hole (○) and electron (□) mobilities in molecular composite films (thickness ~10 μm) of PDA and MBDQ; measured in a field of 5×10^5 V cm^{-1} at room temperature.

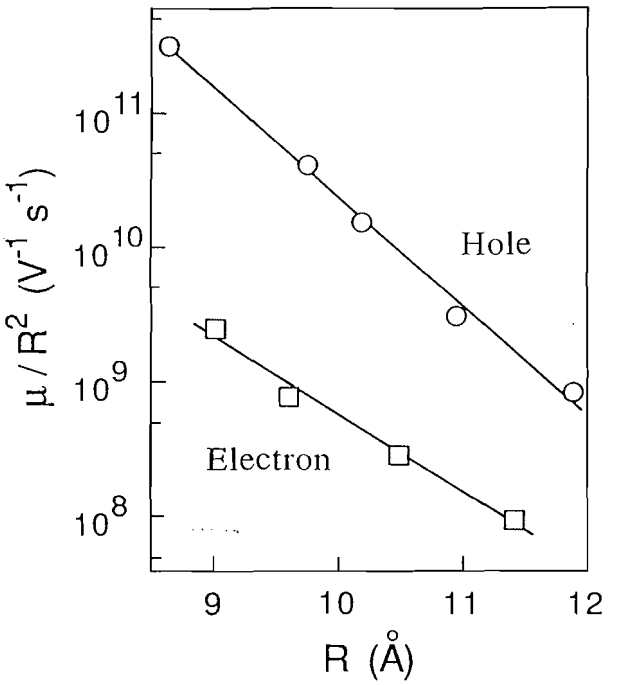

FIG. 2. The hole (○) and electron (□) mobilities as a function of the average intermolecular distance R of PDA and MBDQ, respectively. R for each component was calculated according to the equation $R = (M/NdC)^{1/3}$, where M is the molecular weight, N Avogadro's constant, d the density (1.2 g cm^{-3} for both), and C the fractional weight concentration.

As a result, PDA and MBDQ are each expected to function independently in the composite films. To our knowledge, MBDQ is the first electron-transporting electron acceptor that is compatible with hole-transporting electron donors, such as aromatic amine and hydrazone derivatives, with no or little charge transfer interaction.

The hole and electron transport properties of the amorphous composite films were examined by the standard time-of-flight method using a nitrogen gas laser pulse. Figure 1 shows the composition dependence of the hole and electron drift mobilities. The hole mobility increases, predominantly, with an increase in the PDA content and the electron mobility also increases with an increase in the MBDQ content. A composite film composed of ca. 40 wt.% PDA and 60 wt.% MBDQ exhibits almost the same hole and electron mobilities, which both exceed 10^{-5} cm^2 V^{-1} s^{-1} in an electric field of 5×10^5 V cm^{-1} at room temperature. These values are about 100 times as high as those of the charge transfer complex of poly(*N*-vinylcarbazole) (PVK) and TNF, a well-known bipolar charge transporting amorphous organic material (7). We believe that the high mobility of the present composite originates from no charge transfer interaction, as well as the excellent charge-transporting nature of both PDA and MBDQ, since it was reported that charge transfer complexation reduces charge-transporting ability in the PVK–TNF system (7). The variation of the mobilities with the composition gives important information about the nature of the transport mechanism. The strong dependence on composition of the mobilities shown in Fig. 1 suggests the intermolecular hopping mechanism through each component. For a hopping mechanism, the mobility μ can be expressed as

$$[1] \quad \mu/R^2 \propto \exp(-2R/R_0)$$

where R is the average intermolecular distance hopped and R_0 is a constant defined as the localization radius for a charge carrier (7). The data from Fig. 1 are replotted in Fig. 2 according to eq. [1]. Each plot for PDA and MBDQ gives a good fit to the form of eq. [1]. Moreover, the localization radii (1.1 and 1.5 Å) for hole and electron are approximately the same as those (1.3 and 1.5 Å) of PDA and MBDQ dispersed separately in polycarbonate.

From these results, we conclude that PDA and MBDQ function independently as hole- and electron-hopping sites, respectively, even in their molecular composite films. The details of bipolar charge transport properties in the amorphous solid solution, including the activation energy for hopping conduction, will be presented in a forthcoming paper.

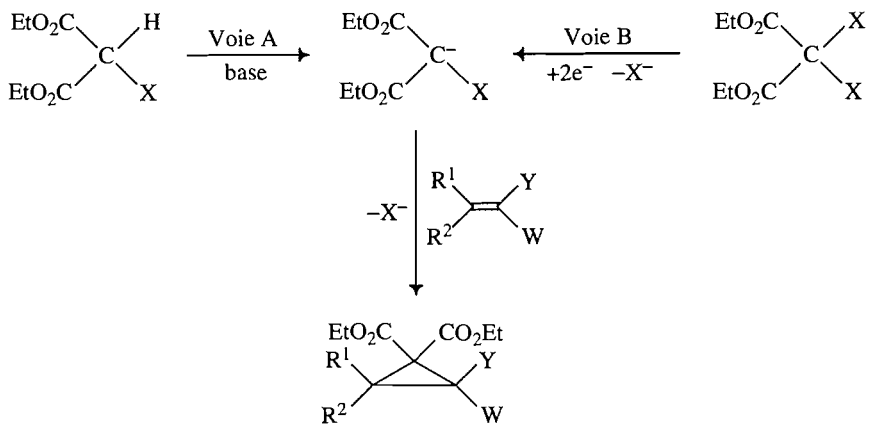
JEAN-CHRISTOPHE LE MENN, ANDRÉ TALLEC et JEAN SARRAZIN. Can. J. Chem. **69**, 761 (1991).

Des cyclopropanes *gem*-dicarboxylate sont préparés par réaction de cyclocondensation d'un carbanion chloro- ou bromomalonate sur des alcènes électrophiles. Le carbanion peut résulter de la déprotonation du monohalogénomalonate par du carbonate de potassium en suspension dans le THF; le chloromalonate conduit alors à de meilleurs rendements. L'influence de la nature et du nombre de substituants portés par l'alcène a été étudiée. Lorsque des réactions parasites (en particulier la protonation d'intermédiaires anioniques par le monohalogénomalonate) peuvent se produire, de meilleurs rendements sont obtenus en formant le carbanion par réduction électrochimique du dihalogénomalonate en présence d'alcène.

Mots clefs : halomalonates, cyclopropane *gem*-dicarboxylates, électroréduction.

JEAN-CHRISTOPHE LE MENN, ANDRÉ TALLEC, and JEAN SARRAZIN. Can. J. Chem. **69**, 761 (1991).

Cyclopropane *gem*-dicarboxylates are prepared through cyclocondensation of chloro or bromomalonate carbanion and electrophilic alkenes. The carbanion can be formed in THF by deprotonation of the monohalomalonates with powdered potassium carbonate; the chloromalonate always leads to better yields. The influence of the nature and the number of substituents on the alkene reactivity has been investigated. If side reactions (for instance protonation of anionic intermediates by halomalonate) can take place, better yields are obtained when the carbanion is generated by electroreduction of dihalomalonate in the presence of the Michael acceptor.



Key words: halomalonates, cyclopropane *gem*-dicarboxylates, electroreduction.

Introduction

Les cyclopropanes électrophiles et plus particulièrement les cyclopropanes *gem*-dicaboxylate sont des intermédiaires de synthèse intéressants. Sous l'action d'un nucléophile, ils sont susceptibles de subir une réaction d'ouverture du cycle, constituant souvent une étape-clé dans la synthèse de certains hétérocycles ou encore dans la chimie des stéroïdes; deux revues ont été consacrées à ce type d'application (1). Ainsi, récemment, des cyclopropanes *gem*-dicarboxylate, substituées par un groupement carbonyle, ont été utilisés pour la préparation de lactones bicycliques, précurseurs de produits d'intérêt pharmaceutique (2).

Les synthèses de ces cyclopropanes se sont développées selon deux approches : (i) soit par une réaction d'addition, sur un alcène *gem*-dicarboxylate, de réactifs variés : diazo-composés (3), anions nucléophiles (4), carbanions porteurs d'un groupe nucléofuge (5); (ii) soit à partir de dérivés du malonate : carbanion malonate (6), radical bromomalonate (7), carbanions halogénomalonate (8–11).

Cette dernière voie d'accès aux cyclopropanes *gem*-dicarboxylate met en jeu l'attaque nucléophile du carbanion sur un accepteur de Michaël (schéma 1) :

La réaction, réalisée par voie chimique (Voie A), a fait l'objet de travaux ponctuels (8–11), mais aucune étude systématique ne lui a été consacrée; de plus, elle n'a pratiquement été envisagée qu'à partir du carbanion bromomalonate, l'anion chloré n'ayant, à notre connaissance, donné lieu qu'à un essai préliminaire (8). En règle générale, les rendements obtenus à partir du bromomalonate ne sont pas très élevés, que la réaction soit conduite en milieu homogène (8), à l'aide de fluorures solides en suspension dans les réactifs liquides (6*d*) ou dans les conditions de catalyse de transfert de phase liquide–liquide (10); ces rendements limités résultent de l'existence d'une réaction, compétitive de la cyclocondensation, conduisant à l'éthylène tétracarboxylate :

Pour notre part, nous avons montré qu'il est possible de réaliser la cyclocondensation par voie électrochimique (Voie B) : le carbanion est formé par réduction biélectronique du dibromo- ou du dichloromalonate (12); cette étude a mis en évidence d'une part un effet de cation très prononcé sur le comportement de l'anion bromomalonate, d'autre part l'obtention de rendements plus élevés avec le carbanion chloré.

Ces résultats nous ont incités à rechercher des conditions optimales de formation du carbanion par déprotonation d'un halogénomalonate. Nous nous sommes orientés vers l'utilisation d'une base inorganique solide en suspension dans un solvant aprotique suffisamment volatil. Des essais préliminaires nous ont conduits à retenir le système K_2CO_3/THF.

Sur le plan synthétique, deux objectifs ont guidé notre démarche : (1) explorer la réactivité d'une gamme d'alcènes variés (les résultats sont rassemblés dans les tableaux 1 et 2); (2) exploiter la réactivité supérieure du carbanion chloré pour améliorer la sélectivité et le rendement de la réaction.

Enfin, lorsque des réactions secondaires de protonation d'intermédiaires anioniques par l'halogénomalonate ont été observées, nous avons utilisé la méthode électrochimique de formation du carbanion.

Résultats et discussion

1. Alcènes monoactivés

1.1 Limitations synthétiques de la méthode

Le tableau 1 regroupe les résultats obtenus par réaction mole à mole des halogénomalonates et des alcènes porteurs d'un seul groupement électroattracteur.

De l'examen de ce tableau, il ressort que les alcènes qui ne portent pas d'autre substituant (**1**–**3**) conduisent à d'excellents rendements en cyclopropane (**1***a*–**3***a*), et que la réaction est plus rapide avec le chloromalonate. Ces résultats sont comparables à ceux obtenus par voie électrochimique (12).

Les alcènes **4**–**9**, porteurs d'un substituant sur le carbone éthylénique en β du groupement activant, présentent des réactivités variées. Dans cette série, l'activation par le groupement attracteur croît dans l'ordre (8) : -CN< -COR< -CHO< $-NO_2$. D'autre part, la présence du second substituant sur la double liaison ralentit la réaction de cyclocondensation, l'effet du groupement aryle étant plus marqué que celui du groupement méthyle. Bien que les réactions ne soient pas toujours quantitatives, les rendements en cyclopropanes **4***a*–**8***a* observés sont nettement plus élevés que ceux obtenus avec les méthodes précédemment rapportées (8–10). Par ailleurs, le tableau 1 montre que le carbanion bromomalonate ne donne pas de cyclocondensation avec les alcènes **6**, **7** et **8** alors que le carbanion chloromalonate réagit avec ces accepteurs. La limite semble atteinte avec le cinnamonitrile **9** : après 10 h de chauffage à reflux avec le chloromalonate, celui-ci est récupéré quantitativement à côté de produits de condensation du malonate.

Avec les dérivés cycliques exométhyléniques **10**–**12**, on observe la formation des cyclopropanes spiranniques **10***a*–**12***a*. Cependant, la réaction n'est pas toujours sélective, ni quantitative.

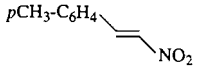
Ces résultats montrent clairement la portée synthétique de la méthode et expliquent pourquoi nous n'avons pas envisagé la réaction d'un cinnamate d'alkyle, le pouvoir activant d'un groupement ester étant inférieur à celui d'un groupement nitrile.

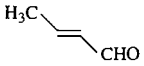
1.2. Analyse des résultats

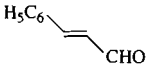
Alcènes 7 et 8. Ces deux accepteurs conduisent à environ 50% de cyclopropane lorsque la réaction est conduite pendant 10 h au reflux du THF, en présence d'un équivalent de chloromalonate (cf. schéma 1 : **7**, $R^1 = C_6H_5$, W = $COCH_3$; R^2 = Y = H; **8**, $R^1 = CH_3$, W = CN; R^2 = Y = H).

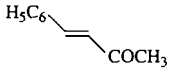
Lorsque la réaction est réalisée en utilisant deux équivalents de chloromalonate, on obtient un taux de conversion de l'alcène en cyclopropane de l'ordre de 80%. On notera l'intérêt de l'utilisation du chloromalonate; en particulier, le rendement obtenu en cyclopropane **7***a* est supérieur à celui que l'on peut atteindre à partir du magnésien du dibromomalonate (9*c*).

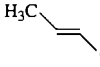
β-*Nitrostyrene* ***4***. L'action du bromomalonate conduit au cyclopropane **4***a* accompagné de produits de polymérisation de l'alcène. Avec le chloromalonate, on obtient uniquement l'adduit de Michaël correspondant **4***b*. Ceci peut être interprété par les réactions du schéma 2. Par suite de la présence du groupement nitro, le carbanion intermédiaire, résultant de l'addition du carbanion halogénomalonate sur le β-nitrostyrène, est très stabilisé et peu nucléophile; la cyclisation en cyclopropane ne s'observe qu'avec le bon nucléofuge Br^-. Dans le cas de l'intermédiaire chloré, la réaction de protonation par le chloromalonate est plus rapide.

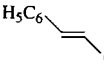






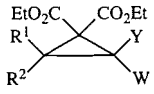






Alcènes formylés 5 et 6. Ces deux alcènes ont la particularité de posséder deux groupements électrophiles, susceptibles de réagir avec les anions halogénomalonate; des réactions d'époxydation du cyclopropane, formé dans un premier temps, ont été signalées dans le cas du crotonaldéhyde et de l'acroléine (10).

Le crotonaldéhyde **5** réagit avec les deux carbanions halogénomalonate formés dans le système K_2CO_3/THF.



Avec le chloromalonate, il se forme un mélange de cyclopropane **5***a* et de produit **5***b* provenant d'une addition de Michaël. Le schéma 2 rend compte des réactions qui interviennent. La cyclisation du carbanion intermédiaire est plus rapide que dans le cas du β-nitrostyrène mais la réaction de protonation par le chloromalonate se produit avec une vitesse comparable.

Notons en outre que la durée de vie suffisamment importante du carbanion intermédiaire apparaît à l'analyse stéréochimique des produits : la réaction du crotonaldéhyde *trans* conduit à un

mélange contenant 93% du cyclopropane *trans* et 7% d'isomère *cis* : une rotation partielle, non signalée dans les travaux antérieurs (8, 10), semble donc se produire au niveau de l'intermédiaire anionique.

La réaction de protonation n'est pas possible si l'on part du dichloromalonate (absence de donneur de protons) : effectivement, la réduction électrochimique du dichloromalonate, dans le système CH_3CN, CH_2Cl_2/Bu_4NBr conduit quantitativement au cyclopropane **5***a*.

Avec le bromomalonate, la cyclisation du carbanion intermédiaire du schéma 2 est plus rapide et il n'y a pas formation de l'adduit **5***b*. Cependant, comme cela a déjà été observé (8), il se produit partiellement une condensation du carbanion bromomalonate sur le groupement carbonyle du cyclopropane **5***a*, conduisant à l'époxycyclopropane **5***c* (schéma 3).

La réactivité élevée de ce groupe carbonyle est retrouvée lors de la réduction électrochimique du dibromomalonate dans le système CH_3CN, CH_2Cl_2/Bu_4NBr. Celle-ci conduit exclusivement à l'époxyde **5***c*, résultat semblable à celui obtenu dans les conditions de catalyse par transfert de phase (10).

Ainsi, le bromomalonate peut être mis en oeuvre pour réaliser sélectivement deux réactions avec le crotonaldéhyde **5** dans le

SCHÉMA 2. Compétition entre la protonation et la cyclisation de l'adduit intermédiaire.

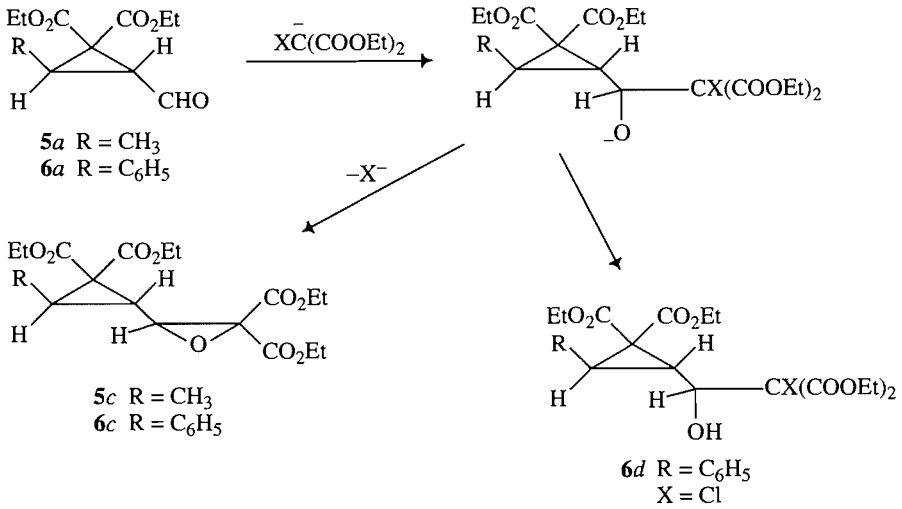

SCHÉMA 3

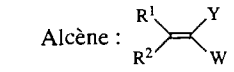
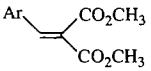
système K_2CO_3/THF : (i) en utilisant 0,5 équivalent d'alcène **5**, on obtient quantitativement l'époxyde **5***c*; (ii) en utilisant 5 équivalents d'alcène **5**, on obtient 95% de cyclopropane **5***a* après distillation.

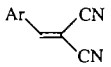
Le cinnamaldehyde **6** ne réagit, dans le système K_2CO_3/THF, qu'avec le chloromalonate. Lorsque les réactifs sont introduits mole à mole, on obtient un mélange de cyclopropane **6***a* (25%) de stéréochimie *trans*, et d'halohydrine **6***d* (72%). Cette dernière résulte (schéma 3) de la protonation de l'anion intermédiaire, formé par addition du chloromalonate sur le carbonyle du cyclopropane **6***a*.

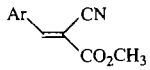
Cette protonation par le chloromalonate est donc plus rapide que la substitution nucléophile interne, avec élimination d'un chlorure, qui aurait conduit à l'époxycyclopropane correspondant **6***c*.

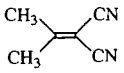
Il est cependant possible d'obtenir, avec un bon rendement, soit le cyclopropane **6***a*, soit l'halohydrine **6***d* dans le système K_2CO_3/THF : (i) la réaction d'un équivalent de carbanion chloromalonate sur 0,5 équivalent d'alcène **6** conduit quantitativement à l'halohydrine **6***d*; (ii) inversement, l'utilisation d'un excès d'alcène **6** (5 équivalents) fournit le cyclopropane **6***a*, qui n'avait pas encore été synthétisé par cette voie (3*b*), avec un rendement de 72% après distillation.

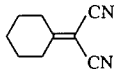


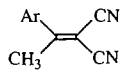






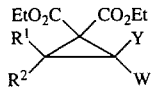






Si la réaction est réalisée mole à mole par voie électrochimique, en réduisant le dichloromalonate dans le système CH_3CN, CH_2Cl_2/Bu_4NBr ou bien le dibromomalonate dans le système $CH_3CN/LiBF_4$, on obtient un mélange de cyclopropane **6***a* (25%) et d'époxycyclopropane **6***c* (75%). En effet, la réaction est dans ces conditions effectuée en l'absence de donneurs de protons, ce qui permet à l'alcoolate intermédiaire de se cycliser en époxyde (schéma 3). Ainsi, lorsque l'électrolyse est réalisée en présence de 0,5 équivalent de cinnamaldéhyde **6**, on obtient quantitativement l'époxycyclopropane **6***c*.

*Alcènes **10**, **11** et **12***. Avec le bromomalonate, il y a formation des cyclopropanes spiranniques correspondants avec un rendement qui n'est limité que par la formation parasite d'éthylène tétracarboxylate.



Avec le chloromalonate, seule la cétone **12** conduit uniquement au cyclopropane. Dans le cas des lactones **10** et **11**, l'addition du carbanion chloromalonate à la double liaison

conduit à un intermédiaire anionique dont la cyclisation lente permet une protonation partielle en adduits de Michaël **10***b* et **11***b* par le chloromalonate (schéma 2).

Cependant, la formation de l'adduit de Michaël peut être évitée en formant le carbanion par réduction électrochimique du dichloromalonate dans le milieu CH_3CN, CH_2Cl_2/Bu_4NBr; on obtient alors sélectivement les cyclopropanes **10***a* et **11***a* avec des rendements respectifs de 81 et 79% après purification.

2. Alcènes diactivés

Les résultats sont regroupés dans le tableau 2.

Dans le cas des composés **13**–**15**, portant un seul substituant sur le carbone éthylénique en β des groupements activants, le seul produit de condensation obtenu est le cyclopropane.

L'effet du second groupement activant se manifeste puisque l'alcène dicyané **14** conduit en rendement quasi-quantitatif au cyclopropane **14***a* (en 6 h à la température ambiante avec le chloromalonate ou en 2 h au reflux du THF avec le bromomalonate) tandis que le cinnamonitrile **9** ne réagissait pas.

La réactivité du diester **13** est plus faible. En particulier, avec le bromomalonate, la réaction parasite de formation de l'éthylène tétracarboxylate devient prépondérante. Cette réaction compétitive ne se produit pas avec le chloromalonate qui fournit un excellent rendement en cyclopropane **13***a* après 6 h au reflux du THF.

Enfin, le cyanoester **15** présente une réactivité intermédiaire entre celles des deux alcènes précédents. On notera de plus que la réaction de cyclocondensation est alors stéréospécifique.

Compte tenu de la réactivité du composé **14**, les alcènes dicyanés **16**–**18** ont été choisis pour étudier l'influence de la disubstitution sur le carbone en β de la double liaison. Les réactions n'ont été réalisées qu'avec le chloromalonate.

Les rendements en cyclopropanes sont encore satisfaisants avec les alcènes **16** et **17**. Cependant, le milieu réactionnel se colore en noir et l'on constate une polymérisation partielle de l'alcène.

L'alcène **18** est très peu réactif : la polymérisation est importante et le rendement en cyclopropane **18***a* est limité à 10%. Divers essais de modification des conditions expérimentales n'ayant pas permis d'améliorer ce rendement, nous avons envisagé la formation du carbanion par voie électrochimique.

La réduction du dichloromalonate dans le système CH_3CN, CH_2Cl_2/Bu_4NBr ou du dichloromalonate dans le système $CH_3CN/LiBF_4$, en présence de l'alcène **18**, conduit encore à 10% de cyclopropane **18***a* et à des polymères; l'anion $(EtO_2C)_2CCl^-$, non complexé, ou même l'anion $(EtO_2C)_2CBr^-$ complexé par Li^+, sont donc suffisamment basiques pour induire la polymérisation.

Nous avons alors effectué la réduction du dichloromalonate dans le système $CH_3CN/LiBF_4$; il ne se produit plus de polymérisation (la solution ne noircit pas en cours d'électrolyse) mais on n'obtient toujours que 10% de cyclopropane **18***a* à côté d'une quantité importante de chloromalonate. La basicité de l'anion $(EtO_2C)_2CCl^-$, associé à Li^+, est suffisamment atténuée pour ne pas provoquer de polymérisation, mais la nucléophilie est également affaiblie et la réaction sur l'alcène devient trop lente.

Un dernier essai d'électrolyse a été réalisé dans le système $CH_3CN/NaBF_4$; le rendement en cyclopropane **18***a* est alors de 35%. Cependant, le chlorure de sodium, peu soluble dans

l'acétonitrile, précipite en masse à la moitié de l'électrolyse; la solution noircit si l'on poursuit l'électrolyse et il y a à nouveau formation de polymères. Cette expérience montre néanmoins que seule la méthode électrochimique permet de générer le carbanion, dans des conditions suffisamment douces, pour réaliser la cyclopropanation d'un alcène susceptible de se polymériser rapidement en milieu basique.

Conclusion

La mise au point d'une technique simple et performante de déprotonation des halogénomalonates d'éthyle, par l'utilisation du système biphasique solide–liquide K_2CO_3/THF, nous a permis de comparer la réactivité des carbanions chloro- et bromomalonate vis-à-vis d'alcènes électrophiles; en particulier, nous avons pu tirer pleinement partie de la réactivité plus favorable du carbanion chloré, dont le potentiel synthétique n'avait pas été exploité.

En règle générale, de bons rendements en cyclopropanes sont réalisés. Tel est le cas lorsque l'intermédiaire carbanionique, résultant de l'addition du carbanion halogénomalonate sur l'alcène, est suffisamment nucléophile; la cyclisation par substitution nucléophile intramoléculaire qui suit cette addition est alors assez rapide pour que l'on n'observe pas de protonation concurrente. Dans le cas contraire, la réduction électrochimique du dihalogénomalonate peut permettre l'obtention du cyclopropane attendu.

Partie expérimentale

1. Réactifs

Les chloro- et bromomalonate d'éthyle sont des produits commerciaux. Les dichloro- et dibromomalonate ont été synthétisés par réaction du malonate d'éthyle avec le dihalogène en milieu aqueux basique (13).

Les alcènes **1–3** et **5–9** sont des produits commerciaux. Les autres ont été synthétisés par réaction de Knoevenagel, selon des protocoles expérimentaux décrits dans la littérature : **4** (14), **10–12** (15), **13** (16) et **14–18** (17).

2. Mode opératoire

2.1 Électrochimique

Les électrolyses sont réalisées à intensité imposée, sous argon, à température ambiante dans une cellule à compartiments séparés. Le dichloromalonate est réduit sur une cathode en mercure et le dibromomalonate sur une cathode en platine. Le générateur est un appareil PAR EG&G modèle 362.

Le compartiment anodique, séparé du compartiment cathodique par un verre fritté, contient 20 mL de (CH_3CN/CH_2Cl_2 50 : 50; Bu_4NBr 0,1 M) ou 20 mL de (CH_3CN; Me_4NCl saturé). On y ajoute 1 mL de cyclohexène pour piéger le dihalogène formé.

Trois millimoles (3 mmol) du dihalogénomalonate et 3 mmol d'alcène sont dissous dans 30 mL de (CH_3CN/CH_2Cl_2 50 : 50; Bu_4NBr 0,1 M) ou de (CH_3CN; $LiBF_4$ 0,1 M) et la solution est électrolysée sous 20 mA pendant 8 h (2 F mol^{-1}). À la fin de l'électrolyse, le catholyte est évaporé; on ajoute alors 60 mL d'éther au résidu et on lave avec une solution de NaCl semi saturée (2 × 10 mL). La phase organique est séchée sur $MgSO_4$ et évaporée. Le résidu est ensuite distillé ou recristallisé.

2.2. Chimique

Trois millimoles (3 mmol) d'halogénomalonate et 3 mmol d'alcène sont dissous dans 5 mL de THF distillé. On ajoute 6 mmol de K_2CO_3 commercial finement broyé et la solution est maintenue sous bonne agitation pendant la durée et à la température indiquées. La réaction est suivie par chromatographie en couche mince sur silice, utilisant comme éluant : AcOEt/hexane 20 : 80. Les durées des expériences n'ont pas été optimisées.

À la fin de la réaction, on ajoute 15 mL de CH_2Cl_2. Les solides inorganiques sont filtrés, lavés avec 15 mL de CH_2Cl_2, et les solvants sont évaporés. Le résidu est purifié par distillation au moyen d'un four à boules ou par recristallisation.

3. Caractéristiques physico-chimiques et spectroscopiques des produits obtenus

Les produits de condensation ont été analysés par infra-rouge, RMN à 60 MHz, le cas échéant à 300 MHz; les masses molaires ont été déterminées par spectroscopie de masse.

Des microanalyses ont été réalisées sur les composés nouveaux à l'exception de l'adduit de Michaël **5***b*, qui n'a pu être obtenu sélectivement et dont l'intérêt synthétique est limité.

Chromodorane diterpenes from the tropical dorid nudibranch *Chromodoris cavae*

SANDRA A. MORRIS, E. DILIP DE SILVA, AND RAYMOND J. ANDERSEN[1]

Departments of Chemistry and Oceanography, University of British Columbia, Vancouver, B.C., Canada V6T 1Z1

Received November 14, 1990

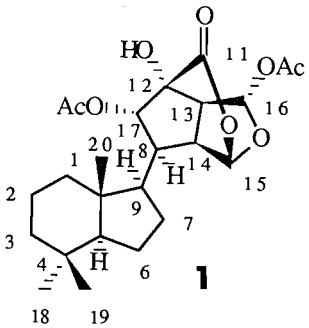
SANDRA A. MORRIS, E. DILIP DE SILVA, and RAYMOND J. ANDERSEN. Can. J. Chem. **69**, 768 (1991).

Two novel diterpenoids, chromodorolides A (**1**) and B (**2**), have been isolated from skin extracts of the tropical dorid nudibranch *Chromodoris cavae*. Complete NMR assignments are presented for chromodorolide A (**1**). The structure of chromodorolide B (**2**) has been solved by spectroscopic analysis. Chromodorolides A (**1**) and B (**2**) are the first examples of diterpenoids with the highly rearranged chromodorane carbon skeleton.

Key words: nudibranch, diterpene, chromodorane, *Chromodoris*.

SANDRA A. MORRIS, E. DILIP DE SILVA et RAYMOND J. ANDERSEN. Can. J. Chem. **69**, 768 (1991).

On a isolé deux nouveaux diterpénoïdes, les chromodorolides A (**1**) et B (**2**), à partir des extraits de pelures de *Chromodoris cavae* tropicales. On présente des attributions complètes du spectre RMN du chromodorolide A (**1**). On a résolu la structure du chromodorolide B (**2**) par des analyses spectroscopiques. Les chromodorolides A (**1**) et B (**2**) sont les premiers exemples de diterpénoïdes comportant le squelette carboné chromodoragne fortement réarrangé.



Mots clés : diterpène, chromodoragne, *Chlorodoris*.

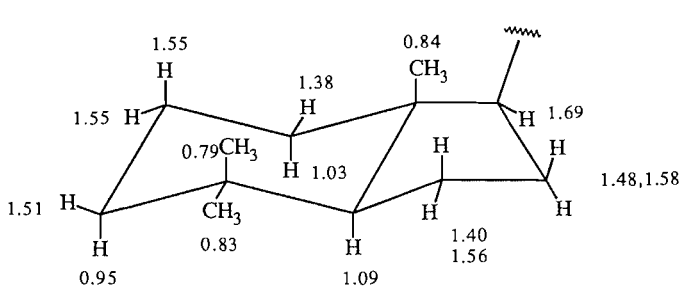
Introduction

It is well documented that many dorid nudibranchs employ secondary metabolites sequestered from sponges in their diets as defensive allomones to thwart predation (1–3). As part of our ongoing studies of molluscan chemical defenses (4–7), we have examined the tropical dorid nudibranch *Chromodoris cavae* for the presence of novel secondary metabolites. Skin extracts from specimens of *C. cavae* (90 individuals) collected in nearshore waters near Jaffna, Sri Lanka, in January 1989 yielded a single major metabolite, chromodorolide A (**1**), and traces of a companion metabolite. The structure of chromodorolide A (**1**) was solved by single crystal X-ray diffraction analysis (7). Chromodorolide A (**1**) represents the first example of a diterpenoid with the highly rearranged "chromodorane" carbon skeleton. Skin extracts of a second collection of *C. cavae* (January 1990; 54 individuals) once again yielded chromodorolide A (**1**) as the major component (7 mg), but fortunately they also yielded a reasonable quantity of the companion metabolite, chromodorolide B (**2**) (2 mg). We now wish to report the structure of chromodorolide B (**2**) and complete ^{1}H and ^{13}C NMR assignments for the previously reported metabolite, chromodorolide A (**1**).

1

2



The details of the structure determination of chromodorolide A (**1**) by single crystal X-ray diffraction analysis have already been reported (7). A detailed analysis of the HMQC and COSY data for chromodorolide A (**1**) provided complete ^{1}H and ^{13}C NMR assignments for the molecule and these are presented in Table 1.

[1]Author to whom correspondence may be addressed.

Chromodorolide B (**2**) was isolated as an optically active colorless oil that gave a parent ion in the EIHRMS at m/z 492.2361 Da appropriate for a molecular formula of $C_{26}H_{36}O_9$ (ΔM, +0.2 mmu). Resonances at δ 170.2, 170.0, 169.2, and 169.1 (Table 1) in the ^{13}C NMR spectrum of **2** were assigned to four ester carbonyl carbons. The lack of ^{13}C NMR evidence for the presence of additional unsaturated functionalities indicated that chromodorolide B (**2**) had to be pentacyclic to satisfy the unsaturation number required by its molecular formula. Resonances at δ 2.04 (s,3H), 2.11 (s,3H), and 2.19 (s,3H) in the ^{1}H NMR spectrum of **2** were assigned to the methyl protons of three acetates. An intense IR band at 1751 cm^{-1} was assigned to the acetate carbonyl stretching vibrations and a second carbonyl stretching band, observed at 1812 cm^{-1}, suggested that the fourth ester functionality might be part of a small ring lactone.

Comparison of the ^{1}H and ^{13}C NMR data for chromodorolide B (**2**) with those for chromodorolide A (**1**) showed that the two molecules were closely related (Table 1). Thus, the $C_{12}H_{21}$ hydrocarbon fragment "**i**" found in chromodorolide A (**1**) could also be identified in chromodorolide B (**2**) by a detailed analysis of the data generated in COSY and HMQC experiments. The proton assignments for this fragment in **2** are shown on "**i**" and the observed COSY correlations are listed in Table 1. COSY correlations due to long range W coupling between the Me20 protons (δ 0.84) and the H1$_{ax}$ (δ 1.03) proton, and between the Me18 protons (δ 0.79) and the H3$_{ax}$ (δ 0.95), H5$_{ax}$ (δ 1.09), and Me19 (δ 0.83) protons (Table 1) provided crucial connectivities through the quaternary centers at C10 and C4.

The remaining fragment of chromodorolide B (**2**) had to have

the elemental composition $C_{14}H_{15}O_9$, it had to be tricyclic, and it had to contain the acetate and lactone functinalities identified from the IR and ^{13}C NMR data. Resonances at δ 97.8 and 103.4 in the ^{13}C NMR spectrum of **2**, which were correlated in the HMQC spectrum to ^1H NMR resonances at δ 6.50 and 6.08 respectively, revealed that there were two acetal functionalities present in this fragment. COSY correlations connected the acetal methine resonance at δ 6.50 (H15) through two intervening methine resonances at δ 2.93 (H14) and 3.79 (H13) to the second acetal methine resonance at δ 6.08 (H16). The methine resonance at δ 2.93 (H14) showed an additional COSY correlation to a methine resonance at δ 2.57 (H8) that was in turn correlated to a deshielded methine resonance at δ 5.30 (H17) and to a resonance at δ 1.69, which had already been assigned to H9 of the hydrocarbon fragment (Table 1). The six-proton spin system elaborated above for the tricyclic fragment of chromodorolide B (**2**) corresponded exactly to the six-proton spin system (H8, H13, H14, H15, H16, and H17) present in the tricyclic fragment of chromodorolide A (**1**) (Table 1). In addition, with the exception of the resonances assigned to the acetate functionalities, the ^{13}C NMR resonances assigned to the tricyclic fragments of chromodorolides A (**1**) and B (**2**) also showed a direct one-to-one correspondence (i.e., C8 and C12 to C17: Table 1). We concluded, therefore, that chromodorolide B (**2**) also had the chromodorane skeleton with a bisacetal-oxolane ring fused 3,4 to a similarly functionalized cyclopentane ring (C8 and C12 to C17). Once we had reached this conclusion, it was apparent that there was a systematic difference in the relative chemical shifts of both the proton and carbon resonances assigned to C15 and C16 in the two metabolites.

In chromodorolide A (**1**), the most deshielded acetal proton resonance and the most shielded acetal carbon resonance were assigned via COSY and HMQC experiments to the acetal functionality that was bonded to the acetate (i.e., C16: ^1H, δ 6.30; ^{13}C, δ 95.5) and the most shielded acetal proton resonance and the most deshielded acetal carbon resonance were assigned to the acetal carbon bonded to the C11 δ-lactone carboxyl (i.e., C15: ^1H, δ 5.73; ^{13}C, δ 104.2) (Table 1). By analogy, the relative chemical shifts of the proton and carbon resonances assigned to the C15 and C16 acetal functionalities in chromodorolide B (**2**) (Table 1) indicated that the C15 acetal carbon was bonded to an acetate (^1H, δ 6.50; ^{13}C, δ 97.8) and that the C16 acetal carbon was bonded to the C11 lactone carboxyl (^1H, δ 6.08; ^{13}C, δ 103.4). The resulting tricyclic structure contained the γ-lactone that was suggested by the stretching band observed at 1812 cm^{-1} in the IR spectrum of **2**.

Placement of the two remaining acetate functionalities at C17 (^1H, δ 5.30: ^{13}C, δ 73.9) and C12 (^{13}C, δ 81.4), positions occupied in chromodorolide A (**1**) by acetate and tertiary hydroxyl functionalities respectively, was consistent with the

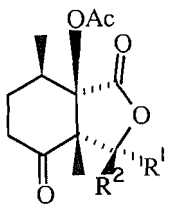

SCHEME 1

^1H and ^{13}C NMR data of chromodorolide B (**2**) (Table 1). Difference nOe experiments (Table 1) were in complete agreement with the proposed structure **2** for chromodorolide B and they defined the relative stereochemistry in the tricyclic fragment as shown. We have assumed that C8 and C9 in **2** have the same relative stereochemistries found in chromodorolide A (**1**) (7).

The rather high frequency of the stretching vibration for the γ-lactone carbonyl in **2** (1812 cm^{-1}) parallels the elevated stretching frequencies of the lactone carbonyl bands in chromodorolide A (**1**) (1770 cm^{-1}) (7) and cadlinolide A (**3**) (1789 and 1760 cm^{-1}) (8). Presumably the unusually high frequency in **2** is due to a combination of effects resulting from the attachment of the γ-lactone alkoxy oxygen to an acetal carbon (C16) and to the presence of an α-acetoxy functionality (attached to C12). The γ-lactones in the monoterpenes **4** and **5** isolated from *Nepeta tuberosa* also experience both of these effects and their carbonyl stretching freqencies are reported to be at 1810 and 1820 cm^{-1}, respectively (9).

3

4 $R^1 = OAc\ R^2 = H$

5 $R^2 = OAc\ R^1 = H$

Scheme 1 shows a proposed biogenetic pathway to the new chromodorane carbon skeleton found in chromodorolides A (**1**) and B (**2**). This proposal suggests that the chromodorane skeleton is formed from a spongian diterpenoid precursor by creation of a new carbon–carbon bond (C12—C17) subsequent to a series of degradation and rearrangement steps that generate the norrisane skeleton (10). Scheme 1 also illustrates that chromodorolides A (**1**) and B (**2**) represent alternate modes of cyclization of the C11 carboxyl group with the bisacetal-oxolane ring to generate a pair of densely functionalized heterocycles. Chromodorolide A (**1**) displays moderate cytotoxic (L1210 ED_{50} 20 μg/mL; P388 T/C 125% at 4 mg/kg) and antimicrobial (*Bacillus subtilis* MIC 60 μg/disc; *Rhizoctonia solani* MIC 60 μg/disc) activities. The limited quantity of chromodorolide B (**2**) that was available was not sufficient for biological testing.

Experimental

Extraction and purification procedure

Freshly collected animals were immediately immersed in methanol/dichloromethane (1:1) and stored in a freezer. At the time of work-up, the organic solvents were decanted from thawed samples and evaporated *in vacuo* to give an oily residue that was partitioned between water and dichloromethane. Fractionation of the dichloromethane soluble materials by sequential application of silica-gel flash chromatography (ethyl acetate/hexane 5:2) and normal phase HPLC (ethyl acetate/hexane 1:2) yielded pure metabolites.

Received August 2, 1990

YOULA S. TSANTRIZOS and KELVIN K. OGILVIE. Can. J. Chem. **69**, 772 (1991).

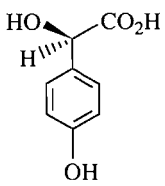
The antifungal antibiotic pisolithin B (*p*-hydroxymandelic acid, 2-(4′-hydroxyphenyl)-2-hydroxyethanoic acid, **1***a*) was shown to have the absolute (*R*) configuration. The stereochemistry was established via comparison of its optical rotation to that of its synthetic (*R*) and (*S*) enantiomers. The synthetic samples were prepared by the stereospecific reduction of the prochiral α-keto acid, *p*-hydroxybenzoylformic acid (2-(4′-hydroxyphenyl)-2-oxoethanoic acid, **2***a*), with (*R*) or (*S*)-2,2′-dihydroxy-1,1′-binaphthyl lithium aluminum hydride (BINAL-H). The absolute configuration and enantiomeric purity of both products were determined using the ^{1}H NMR of their isobutyl esters in the presence of the chiral solvating agent (*R*)-(−)-2,2,2-trifluoro-1-(9-anthryl)ethanol.

Key words: pisolithin B, *p*-hydroxymandelic acid, antifungal, absolute configuration.

YOULA S. TSANTRIZOS et KELVIN K. OGILVIE. Can. J. Chem. **69**, 772 (1991).

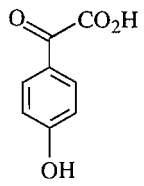
On a démontré que la configuration absolue de l'antibiotique fongicide pisolithine B (acide *p*-hydroxymandélique, acide 2-(4′-hydroxyphényl)-2-hydroxyéthanoïque, **1***a*) est (*R*). On a établi cette stéréochimie par comparaison de sa rotation optique avec celle de ses énantiomères de synthèse (*R*) et (*S*). On a préparé les échantillons de synthèse sur une réduction stéréospécifique de l'acide cétonique prochiral, l'acide *p*-hydroxybenzoylformique (2-(4′-hydroxyphényl)-2-oxoéthanoïque, **2***a*), avec les hydrures (*R*) et (*S*) du 2,2′-dihydroxy-1,1′-binaphtyl lithium et aluminium (BINAL-H). On a déterminé les configurations absolues et les puretés énantiomériques de chacun des produits à l'aide de la RMN du ^{1}H de leurs esters isobutyliques en présence de l'agent de solvatation chiral (*R*)-(−)-2,2,2-trifluoro-1-(9-anthryl)éthanol.

Mots clés : pisolithine B, acide *p*-hydroxymandélique, fongicide, configuration absolue.



[Traduit par la rédaction]

Introduction

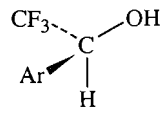


The antifungal antibiotic pisolithin B (*p*-hydroxymandelic acid, 2-(4′-hydroxyphenyl)-2-hydroxyethanoic acid, **1***a*) was isolated from the extracellular metabolite mixture of the mycorrhizal fungas *Pisolithus tinctorius* (Pers.) Coker & Couch (synonym to *P. arhizus* (Scop. pers Pers.) Rauschert) (1). This microorganism lives symbiotically on the roots of many plants and forest trees (2, 3) and is well known for is ability to promote its host's growth, especially in habitats characterized by poor environmental conditions and low fertility soils (4). The beneficial effects of *P. tinctorius* are attributed primarily to its large network of mycelia, which support the accumulation and transfer of minerals through the fungus to the host plants (5), and partly to its production of indoleacetic acid, cytokinin, and giberellin having phytohormonal activity (6).

Recently, the compounds *p*-hydroxybenzoylformic acid (2-(4′-hydroxyphenyl)-2-oxoethanoic acid, **2***a*) and *p*-hydroxymandelic acid (2-(4′-hydroxyphenyl)-2-hydroxyethanoic acid, **1***a*) were isolated from the culture media of *P. tinctorius* and they were given the trivial names pisolithin A and B respectively (1). Both compounds were shown to exhibit strong antifungal activity, causing hyphal lysis and inhibition of spore germination, against many phytopathogenic and dermatogenic fungi. Their production by *P. tinctorius* indicates an additional mechanism by which this microorganism aids in the development of its host plants, in that it provides protection to them against disease-causing fungi.

Racemic *p*-hydroxymandelic acid has been synthesized (7) and resolved by chiral stationary (8) and mobile (9) phase HPLC techniques, as well as by enzymatic methods (10). However, a facile approach to the synthesis of enantiomerically enriched samples is not yet available. Furthermore, the relationship between the optical rotation and absolute stereochemistry of each enantiomer has not been previously assigned. Hence, to determine the absolute stereochemistry of the optically active metabolite pisolithin B, a stereoselective synthesis of both the (*R*) and (*S*) enantiomers of this compound was carried out. ^{1}H NMR in the presence of a chiral shift reagent was used to determine the enantiomeric purity and absolute stereochemistry of the samples. The natural product and synthetic samples were subsequently utilized in a number of studies for the investigation of their antifungal activity. Preliminary results on their possible mode of action indicate that they possess metal-binding properties (ionophore type antibiotics), with the (*S*)-(+)-*p*-hydroxymandelic acid being the more potent antifungal agent of the two compounds (1).

Pisolithin B (**1***a*)



Pisolithin A (**2***a*)

Results and discussion

Chiral solvating agents are useful probes for obtaining stereochemical information through NMR experiments. Pirkle

a, **Ar** = phenyl
b, **Ar** = 9-anthryl

et al. (11) have shown that chiral alcohols, of the general structure **3**, permit the direct determination of enantiomeric purity, and often allow correlations to be made regarding the absolute configuration of a compound.

These compounds were originally used to study the optical purity of chiral sulfoxides (11*a*), methyl esters of amino acids (11*b*), and the enantiomeric composition and absolute stereochemistry of chiral oxaziridines (11*c*, *d*). Their ability to hydrogen bond with two basic substituents of a compound (B^1 and B^2) leads to the formation of short-lived, chelate-like, diastereomeric complexes (**4** and **5**) (11*c*). It is expected that the

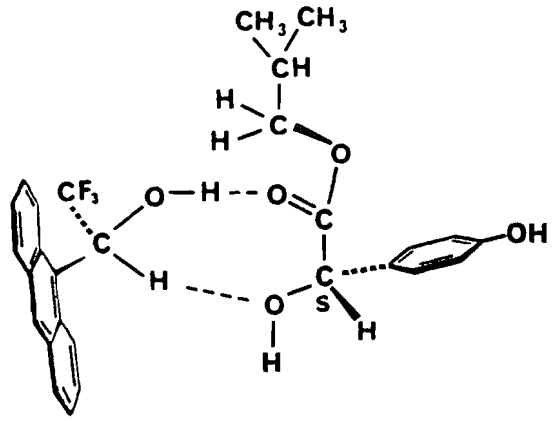
4

5

more basic substituent (B^1) will hydrogen bond preferentially to the hydroxyl proton of the solvating agent, where the less basic group will form a non-classical hydrogen bond with the acidic carbinyl hydrogen (11*c*). The inductive effects of the adjacent electron-withdrawing groups (trifluoromethyl, hydroxyl, 9-anthryl[2]) serve to render this hydrogen somewhat acidic so that it is able to participate in a dipole–dipole interaction (12). The magnetic field contributions of the aromatic electron cloud of the shift reagent induce nonequivalence to the substituents R^1 and R^2 in the two complexes **4** and **5**.

Application of this model to a suitable analogue of the natural product **1***a* (pisolithin B) would predict an upfield shift of the C-2 proton in the (*S*) enantiomer (but not in the (*R*)) upon chelation with the (*S*) enantiomer of the solvating agent, due to the location of that proton over the region of the diamagnetic

[2]Replacement of the phenyl group with 9-anthryl provides greater shielding ability, leading to a larger degree of nonequivalence.



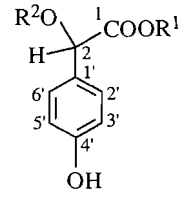


FIG. 1. Chelate complex of the (*S*) *p*-hydroxymandelate ester with the (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol.

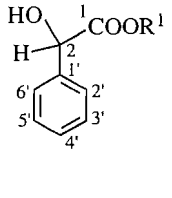
field of the aromatic ring (Fig. 1). Ideally, NMR experiments of this nature should be conducted in nonpolar solvents such as CCl_4 or C_6D_6. Any dipole–dipole interactions, other than those between the compound of interest and the shift reagent, would decrease the effectiveness of the latter. In an effort to obtain a nonpolar analogue of metabolite **1***a*, esters of the commercially available (racemic) *p*-hydroxymandelic acid were prepared. Since the methyl and ethyl esters were found to be practically insoluble in $CDCl_3$, the isobutyl ester (**1***b*) was synthesized along with a minor side product, compound **1***c*. The isobutyl ester was only moderately soluble in $CDCl_3$, hence it was expected that neither CCl_4 or C_6D_6 would be suitable solvents for these NMR experiments. Although $CDCl_3$ is not the ideal solvent for this work, since it can itself hydrogen bond to the shift reagent, moderate amounts of nonequivalence were observed, which were sufficient for the purpose of this investigation.



To verify the applicability of Pirkle's theory to metabolite **1***a*, the procedure was first tested on the closely related natural product mandelic acid (**6***a*). It was postulated that any observed ^1H NMR differences between optically pure (*R*) and (*S*) mandelic acid, in the presence of the solvating agent **3***b*, should be analogous to those expected for compound **1***a*.

Commercially available samples of optically pure (*R*) and (*S*) mandelic acid were converted to their respective isobutyl esters (**6***b*). The ^1H NMR of the enantiomerically pure esters **6***b* showed the C-2 hydroxyl as a doublet at 3.53 ppm, the two C-1″ protons as a multiplet at 3.93 ppm, and the C-2 proton as a doublet at 5.17 ppm. To a known enantiomeric mixture of compound **6***b* (*R*/*S* ~ 4:1), (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol (**3***b*) was added in portions of 0.2 equivalents.

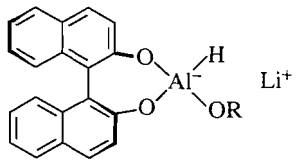
Fast proton exchange between the shift reagent and compound **6***b* caused the disappearance of coupling between C-2 H and C-2 OH at low concentrations of shift reagent. At ratios of 1:1, two singlet peaks were observed for the C-2 protons, with the lower intensity signal ((*S*) enantiomer) upfield from the higher intensity one ((*R*) enantiomer), and an integration of approximately 4:1 as was expected.

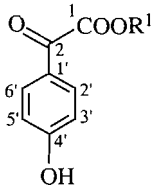
Optimum results were achieved at excess concentrations of solvating agent (1.5–2 equiv.). Under these conditions, coupling between the C-2 H and the C-2 OH was once again evident (Fig. 2: expansion of the spectral region of interest in the presence of the solvating agent), indicating maximum chelation through hydrogen bonding. These observations are consistent with those reported by Pirkle *et al.*, who noted that maximum nonequivalence was obtained at a two- to threefold excess of solvating agent to the compound of interest (13). Although the induced shift differences were very small (~0.014 ppm), the integration ratio of the two non-overlapping peaks of each doublet of the C-2 protons (peaks R and S in Fig. 2) were very close to the actual ratio of 4:1. Nonequivalence was also observed for the -COOCH_2- protons, where the downfield signal was assigned to the (*S*) enantiomers. This assignment was based on the speculation that deshielding of the -CH_2- protons (C-1″) of the (*S*) enantiomer could occur if these protons were placed close to the paramagnetic field of the 9-anthryl ring system and almost on the same plane. Molecular modeling calculations[3] suggested a distance of 3.97 Å between the C-1″ and the aromatic protons and showed them to be almost coplanar. Theoretical NMR calculations (14) predict that at such a distance, a downfield shift of about 0.2 ppm should be observed for the C-1″ protons of the (*S*) enantiomer, which was consistent with the shift observed. The greater sharpness of the C-1″ proton signal is most likely due to the absence of coupling with an exchangeable proton (Fig. 2).



The experimental data for mandelic acid were in excellent agreement with the predictions made. Hence, the synthesis and subsequent determination of the absolute stereochemistry of the two enantiomers of pisolithin B (**1***a*) were attempted.

The ability of the solvating agent (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol (**3***b*) to induce a useful degree of nonequivalence between the two enantiomers of ester **1***b* was confirmed through the ^{1}H NMR of a racemic mixture, which showed two equally intense signals for the C-2 proton ($\Delta\delta$ = 0.03 ppm). According to the model, the upfield signal corresponds to the (*S*) enantiomer and the downfield corresponds to the (*R*).

The simplest way to obtain *p*-hydroxymandelic acid in high enantiomeric purity would have been via stereospecific reduction of the easily obtainable α-keto acid or its ester analogue. The enantioselective reducing agents (*R*)- and (S)-2,2′-dihydroxy-1,1′-binaphthyl lithium aluminum hydride (BINAL-H, **7***a* and **7***b*) provide a useful method for the conversion of prochiral carbonyl compounds to either their (*R*) or (*S*) enantiomer.



7*a*

7*b*

The preparation of these reagents was developed by Noyori *et al.* (15), who proposed that the reaction mechanism proceeds via a six-membered ring transition state in the chair conformation. The chirality of the product can be predicted by taking into consideration the steric and electronic effects that would give the most favorable energy for that particular transition state (Fig. 3). Hence, the reduction of the isobutyl ester **2***b* with the (*S*)-BINAL-H (**7***b*) should proceed via transition state **8** to give the (*R*) enantiomer of alcohol **1***a* (Fig. 3). In the transition state, the aromatic substituent is placed at the equatorial position in order to avoid electronic repulsion between the aromatic ring and the lone pair of electrons of the binaphthol oxygen. However, the 1,3-diaxial steric repulsion becomes increasingly significant as the bulkiness of the axial substituent increases, which leads to both low reactivity and low enantioselectivity (15).

Quantitative yields of the isobutyl *p*-hydroxybenzoylformate ester (**2***b*) were obtained by refluxing the free acid **2***a* in isobutyl alcohol containing catalytic amounts of *p*-toluenesulfonic acid. The esterification reaction was also attempted using the commercially available sodium salt of **2***a* as the starting material but this resulted in low yields of the desired product (due to a competing decarboxylation reaction leading to the formation of *p*-hydroxybenzaldehyde).

2

a, R = H
b, R = isobutyl

The BINAL-H reagents (16)[4] were prepared following Noyori's procedure (15), and used in threefold excess in an effort to reduce the isobutyl *p*-hydroxybenzoylformate ester (**2***b*) to the (*R*) and (*S*) enantiomers of alcohol **1***b*. When the (*S*)-BINAL-H reagent was reacted for 3.5 and 2 h with **2***b*, at −100°C and −78°C respectively, an insignificant amount of product was detected and most of the starting material was recovered. Noyori reported that the threefold excess of BINAL-H reagent is critical for the completion of these types of reactions in reasonable rates. Hence, taking into consideration that the phenolic proton will immediately be extracted by one equivalent of hydride, a fourfold equivalence of reducing agent to compound **2***b* was used. (The ionization of the phenol to the phenoxide ion was evident immediately upon addition of the

[3]Minimization of the conformational energies of compound **1***b*, using PCMODEL via MMX molecular mechanics, indicated that the *cis* ester (C-1″ *cis* to the carbonyl) was ~8 kcal lower in energy than the *trans*. Both compounds were first minimized separately and then minimized as a hydrogen-bonded complex. Only one hydrogen bond, between the C-1 carbonyl and the -OH group of the shift reagent, was allowed by this program; "hydrogen bonding" between the α-hydroxyl of **1***b* and the carbinyl hydrogen of the **3***b* solvating agent was not recognized. However, the two molecules were still placed close enough to give a distance of 3.97 Å between the C-1″ and the aromatic protons, and they were placed approximately on the same plane. The PCMODEL program was obtained from Serena Software, P.O. Box 3076, Bloomington, Indiana 47402-3076, USA.

[4]The optically pure binaphthol used was a generous gift of Dr. R. J. Kazlauskas.

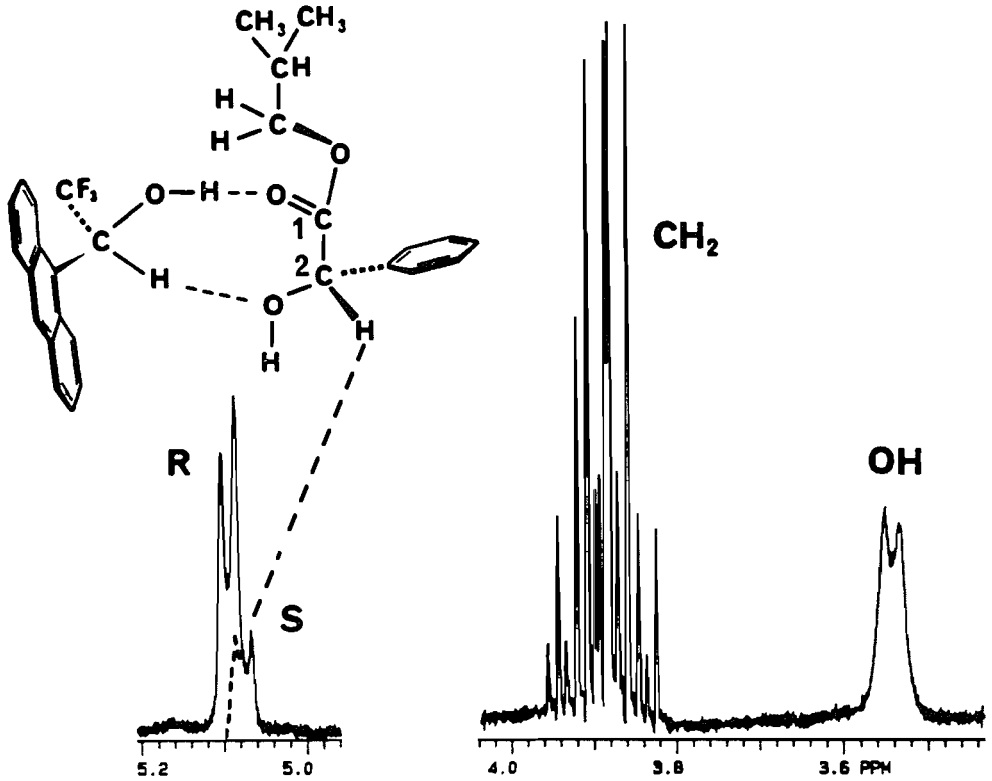


FIG. 2. ^{1}H NMR (300 MHz, $CDCl_3$) of chelate complex between **6***b* (*R*/*S* mixture of 4:1) and (*S*)-**3***b*.

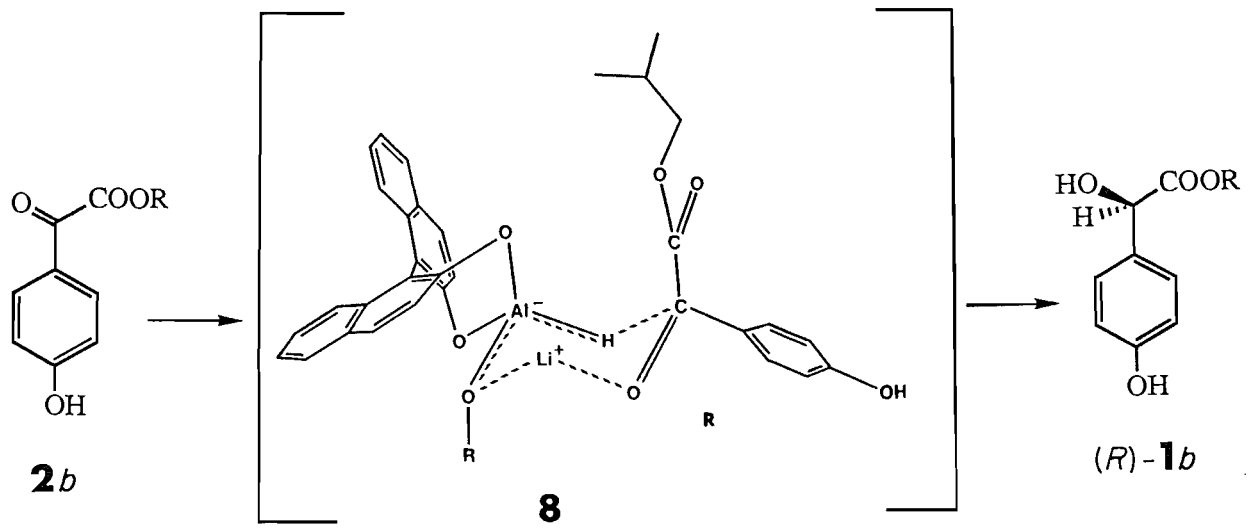

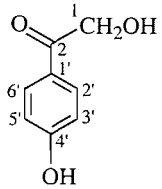

FIG. 3. (*S*)-BINAL-H reduction of *p*-hydroxybenzoylformate ester **2***b*.

substrate to the reagent by the change in colour of the reaction mixture from colourless to intense yellow.) Under these conditions and using (*S*)-BINAL-H, at −78°C for 2 h, the (*R*) enantiomer of compound **1***b* was formed at approximately 35% enantiomeric excess. In addition, the primary alcohol **9** was formed as a major side product; the isolated yields after column chromatography were 7% of **1***b*, 29% of **9**, and ~50% starting material.

Although a low degree of stereospecificity was obtained, the overall results were consistent with the proposed mechanism. It was speculated that a decrease of the %ee value could be caused either by the bulkiness of the isobutyl ester group, which would decrease the stability of the expected transition state **8**, or racemization of the chiral center (C-2) in the presence of base. The strongly basic conditions that result upon quenching of the

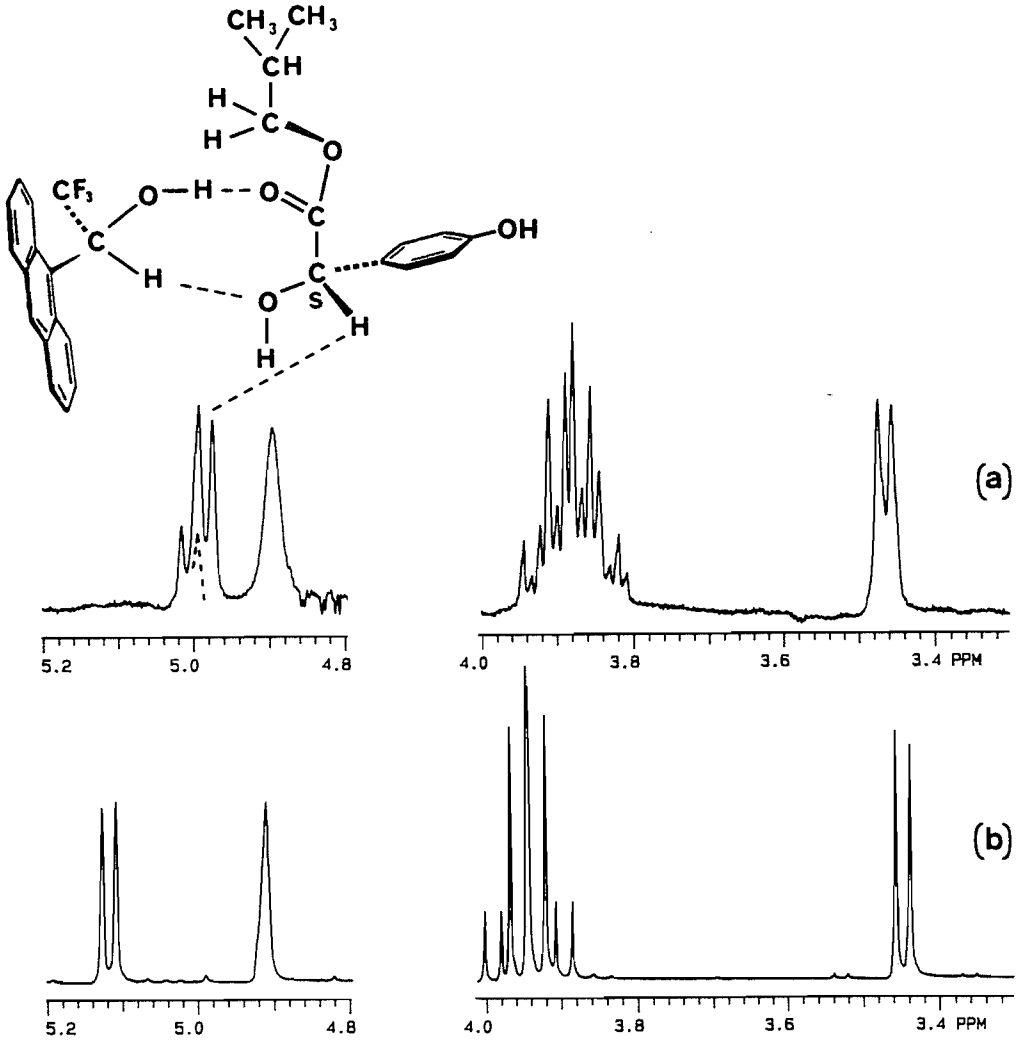

FIG. 4. ^{1}H NMR (300 MHz, $CDCl_3$) of compound (*S*)-**1***b*; (*a*) with solvating agent (*S*)-**3***b*; (*b*) pure.

excess hydride at the end of the reaction could cause not only racemization but low chemical yields due to possible hydrolysis of the ester. In an attempt to further investigate this reaction, the (*S*) enantiomer of **1***b* was synthesized, using the (*R*)-BINAL-H reagent, and quenching the reaction mixture with approximately 3 equivalents of glacial acetic acid. The pH of the reaction mixture was adjusted to about 6.5 before the temperature was allowed to rise above 0°C. After column chromatography, the desired (*S*) enantiomer of compound **1***b* was isolated in 15% yield, in addition to 10% of the primary alcohol (**9**) and more than 40% of unreacted starting material. The optical purity of **1***b* was determined to be 80% (*S*) to 20% (*R*) (60% ee) from its ^{1}H NMR in the presence of the chiral solvating agent (*S*)-**3***b* (Fig. 4a). The formation of the side product **9** clearly indicates the existence of competing reactions. Further investigation of this reaction would be required in order to determine conditions at which complete conversion of starting material to the desired product and better stereocontrol can be attained. However, the information thus far obtained was sufficient to permit the determination of the absolute configuration of the natural product pisolithin B (**1***a*).

Ester hydrolysis of the (*R*)- and (*S*)-**1***b* compounds was carried out with 3 equivalents of hydroxide base in dioxane. The reaction was almost complete after a period of 12 h at room temperature without racemization. (When the reaction was carried out in a solution of 50% dioxane/50% D_2O, deuterium exchange was not observed in the ^{1}H NMR of the carboxylic acid product.) Measurements of the optical rotation of natural pisolithin B along with both enantiomers of the synthetic material (Table 1) indicated that the metabolite has the absolute (*R*) stereochemistry. However, the [α] values obtained were not consistent, most likely due to autocatalysed racemization of the compound upon standing in solution at room temperature. This type of racemization was strongly suggested by the compound's inherent acidic nature and the decrease of its optical rotation value when left in aqueous solution at 23°C for a period of 24 h (refer to the values of the synthetic (*R*)-**1***b* in Table 1).[5]

Experimental

General methods

Ultraviolet spectra were recorded on a Hewlett Packard 8451A diode array spectrophotometer. Nuclear magnetic resonance spectra were

[5]The low measured optical rotation of the natural product pisolithin B ($\alpha = -0.029 \pm 0.002°$, $[\alpha] = -2.7°$, $c = 1.0$) indicates that this chiral metabolite of *Pisolithus tinctorius* slowly racemizes during isolation and purification. The rate of racemization would likely be greater in concentrated aqueous solutions of the pure compound ($pK_a = \sim 3.5$) than in the buffeted fungal medium (pH = ~5.5–6).

obtained at 20–22°C using Varian XL-200, XL-300, and Bruker 500 MHz instruments. ^{1}H and ^{13}C NMR chemical shifts are quoted in ppm and are referenced to the internal deuterated solvent downfield from tetramethylsilane (TMS). The samples used for D_2O ^{1}H NMR were first dissolved in ~1 mL of 99.8% D_2O and lyophilized twice before their data were recorded in 99.96% D_2O. All mass spectra were measured at the Biomedical Mass Spectrometry Unit, McGill University, unless otherwise indicated. The low resolution chemical ionization (NH_3) spectra were obtained using a HP 5980A spectrometer. FAB and high resolution chemical ionization spectra (NH_3) were obtained using a ZAB 2F HS instrument. Optical rotations were measured using a Jasco DIP-140 digital polarimeter.

Silica gel chromatography was performed on Merck Kieselgel 60 (230–400 mesh, no. 9385) using flash chromatography (17). Desalting of compounds was carried out on an ion exchange column packed with pre-swollen and washed Dowex 50W-X8 (H^+ form, 20–50 mesh) resin (J. T. Baker Chemical Co., Phillipsburg, NJ). All chromatographic solvents were fractionally distilled prior to use with the exception of acetic acid.

Sodium *p*-hydroxybenzoylformate, (*R*) and (*S*) mandelic acid, racemic *p*-hydroxymandelic acid, and the chiral solvating agents were obtained from Aldrich Chemical Co (Milwaukee, WI).

Synthesis of racemic methyl p-*hydroxymandelate (**1**d)*

A racemic mixture of *p*-hydroxymandelic acid (~1 g) was refluxed overnight in methanol (50 mL) in the presence of catalytic amounts of *p*-toluenesulfonic acid (~0.5 mg). Evaporation of the solvent gave a reddish oil containing the desired methyl ester (**1***d*) in ~50% yield, the minor product methyl 2-methoxy-*p*-hydroxymandelate (a red oil) in ~5% yield, and unreacted starting material. The mixture was separated by flash column chromatography using $EtOAc/CH_2Cl_2$ (1:1) as the eluting solvent.

(R/S)-*Methyl*-p-*hydroxymandelate* (**1**d): TLC: $EtOAc/CH_2Cl_2$ (1:1), R_f 0.38. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.36 (d, J = 6.5 Hz, 1H, C-2 OH), 3.78 (s, 3H, $-CH_3$), 4.9 (bs, 1H, C-6 OH), 5.13 (d, J = 6.5 Hz, 1H, H2), 6.82 (d, J = 8.7 Hz, 2H, H5), 7.29 (d, J = 8.7 Hz, 2H, H4) ppm. MS (C.I.(NH_3), direct inlet, ~105°C), *m/z* (% relative intensity assignment): 200 (10.6, $M^+ + NH_3$), 182 (13, M^+), 165 (100, $M^+ - OH$), 123 (20.4, $M^+ - COOMe$).

(R/S) *Methyl 2-methoxy*-p-*hydroxymandelate* (**1**e): TLC: $EtOAc/CH_2Cl_2$ (1:1), R_f 0.52. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 3.36 (s, 3H, C-8 CH_3), 3.70 (s, 3H, C-7 CH_3), 4.69 (s, 1H, H2), 4.84 (s, 1H, C-6 OH), 6.80 (d, J = 8.3 Hz, 2H, H5), 7.29 (*d*, J = 8.3 Hz, 2H, H4) ppm. MS (C.I. (NH_3), direct inlet, ~70°C), *m/z* (% relative intensity, assignment): 214 (4.7, $M^+ + NH_3$), 182 (18.0, $M^+ + NH_3 - MeOH$ or $M^+ + 1 - Me$), 165 (100.0, $M^+ - OMe$), 137 (61.9, $M^+ - COOMe$).

Synthesis of racemic isobutyl p-*hydroxymandelate (**1**b)*

A racemic mixture of *p*-hydroxymandelic acid (**1***a*, 1.02 g) was refluxed in isobutyl alcohol (75 mL) in the presence of catalytic amounts of *p*-toluenesulfonic acid (~0.5 mg) for 12 h. Evaporation of the solvent gave a reddish oil, which was a mixture of two products and some starting material. After flash column chromatography with pet. ether/EtOAc (3:1) compound **1***b* was isolated as the major product (40% yield after chromatography and recrystallization) and its 2-isobutyloxy derivative (**1***c*) as a minor side product (6% yield).

(R/S) *Isobutyl* p-*hydroxymandelate* (**1**b): TLC: pet. ether/EtOAc (3:1), R_f 0.18. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.80 (2d, J = 7.6 Hz, 6H, 2 × CH_3), 1.86 (m, 1H, H8), 3.44 (d, J = 5.4 Hz, 1H, C-2 OH), 3.93 (m, 2H, H7), 4.94 (s, 1H, C-6 OH), 5.11 (d, J = 5.4 Hz, 1H, H2), 6.80 (d, J = 8.5 Hz, 2H, H5), 7.26 (d, J = 8.5 Hz, 2H, H4) ppm. ^{13}C NMR (300 MHz, $CDCl_3$) δ: 18.8 (C-9, C-10), 27.7 (C-8), 72.1 and 72.5 (C-7 and C-2), 115.5 (2C-4), 128.0 (2C-5), 130.5 (C-3), 155.9 (C-6), 174.0 (C-1) ppm. MS (C.I. (NH_3), direct inlet, ~60°C), *m/z* (% relative intensity, assignment): 242 (0.8, $M^+ + NH_3$), 224 (11.8, M^+), 207 (100, $M^+ - OH$), 123 ($M^+ - CO_2CH_2CHMe_2$).

(R/S) *Isobutyl 2-isobutyloxy*-p-*hydroxymandelate* (**1**c): TLC: pet. ether/EtOAc (3:1), R_f 0.53. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.81 (d, J = 6.7 Hz, 6H, C-9 and C-10 2 × CH_3), 0.89 (dd, J = 6.7 and 2.2 Hz, 6H, C-13 and C-14 2 × CH_3), ~1.85 (m, 1H, H8), ~1.95 (m, 1H, H12), 3.23 (m, 2H, H11), 3.80 (m, 2H, H7), 4.77 (s, 1H, H2), 5.70 (s, 1H, C-6 OH), 6.78 (d, J = 8.7 Hz, 2H, H5), 7.28 (d, J = 8.7 Hz, 2H, H4) ppm. A number of selective decoupling experiments had to be carried out in order to correctly assign all proton signals as indicated. ^{13}C NMR (300 MHz, $CDCl_3$) δ: 18.9 (C-9 and C-10), 19.3 (C-13, C-14), 27.7 (C-12), 28.4 (C-8), 71.3 (C-11), 76.4 (C-7), 80.9 (C-2), 115.6 (2 × C-5), 128.3 (C-3), 128.6 (2 × C-4), 156.5 (C-6), 172.3 (C-1) ppm.

Synthesis of optically pure (R)-(−)-*isobutyl mandelate (**6**b)*

R-(−)-Mandelic acid (**6***a*, 1.0 g) was refluxed in isobutyl alcohol (~75 mL) in the presence of catalytic amounts of *p*-toluenesulfonic acid (~0.5 mg) for 12 h. Evaporation og the solvent followed by flash column chromatography with a solvent gradient of pet. ether/CH_2Cl_2 (1:1) to CH_2Cl_2 gave the (*R*)-(−)-isobutyl mandelate (**6***b*) as a clear liquid (which solidified under vacuum, mp 35–36°C) in quantitative yields. Using the same procedure the (*S*)-(+)-isobutyl mandelate was prepared from the (S)-(+)-mandelic acid.

(R)-(−)-*isobutyl mandelate ester* (**6**b): TLC: pet. ether/EtOAc (6:1), R_f 0.3–0.45. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.80 (2d, J = 6.7 Hz, 6H, 2 × CH_3), 1.86 (m, 1H, H8), 3.53 (d, J = 4.8 Hz, 1H, C-2 OH), 3.93 (m, 2H, H7), 5.17 (d, J = 4.8 Hz, 1H, H2), 7.32–7.44 (m, 5H, aromatic) ppm.

Synthesis of isobutyl p-*hydroxybenzoylformate (**2**b)*

Commercially available sodium salt of *p*-hydroxybenzoylformic acid (**2***a*, 0.85 g) was refluxed in isobutyl alcohol (~40 mL) in the presence of catalytic amounts of *p*-toluenesulfonic acid (~0.5 mg) for 24 h. Evaporation of the solvent gave a purple-brown oil that, after flash column chromatography with CH_2Cl_2/EtOAc (10:0.5), was found to contain approximately an equal mixture of the desired product **2***b* (0.2 g, 20% yield), its decarboxylated analogue *p*-hydroxybenzaldehyde, and starting material. The reaction was repeated with the protonated form of the starting material in which case **2***b* was formed in nearly quantitative yields. The free acid was obtained by passing the salt through an ion exchange column (Dowex 50W-X8, H^+, 20–50 mesh) and removing the water on a lyophilizer.

p-*Hydroxybenzoylformic acid* (**2**a): IR (KBr): 3150–3380, 1735, 1654, 1608, 1586, 1443, 1400, 1252, 1173, 979, 855, 621 cm^{-1}. UV (0.1 M HCl, nm): max 296, min 226 and 206; (0.1 M NaOH, nm): max 334, min 240. ^{1}H NMR (500 MHz, DMSO) δ: 6.88 (dd, J = 8 and 0.9 Hz, 2H, H4), 7.75 (dd, J = 8 and 0.9 Hz, 2H, H5), 10.74 (s, 1H, -COO*H*) ppm. ^{13}C NMR *free acid* (300 MHz, DMSO + D_2O) δ: 116.0 (C-5), 123.3 (C-3), 132.3 (C-4), 163.8 (C-6), 166.8 (C-1), 187.0 (C-2) ppm. ^{13}C NMR *sodium salt* (300 MHz, DMSO) δ: 115.2 (C-5), 125.7 (C-3), 131.5 (C-4), 162.2 (C-6), 171 (br, C-1) 195 (br, C-2) ppm.

Isobutyl-p-*hydroxybenzoylformate* (**2**b): TLC CH_2Cl_2/EtOAc (10:0.5), R_f 0.40. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 0.97 (d, J = 6.7 Hz, 6H, 2 × CH_3), 2.08 (m, 1H, H8), 4.15 (d, J = 6.7 Hz, 2H, H7), 6.95 (d, J = 9.0 Hz, 2H, H5), ~7.3 (br s, 1H, C-6 OH) and 7.93 (d, J = 9.0 Hz, 2H, H4) ppm. ^{13}C NMR (300 MHz, $CDCl_3$) δ: 19.0 (C-9 and C-10), 27.7 (C-8), 72.4 (C-7), 116.2 (2C-4), 125.0 (C-3), 133.2 (2C-5), 162.8 (C-6), 164.7 (C-1), and 185.6 (C-2) ppm.

Synthesis of optically active S-(+)-*isobutyl*-p-*hydroxymandelate ester* **1**b)

Isobutyl-*p*-hydroxybenzoylformate (**2***b*, 603 mg, 2.72 mmol), dissolved in dry THF (15 mL) was added dropwise to an (*R*)-(+)-BINAL-

H (11) reagent solution (4 equiv.) at −78°C over a period of 10–15 min. The reaction was stirred at −78°C for 3.5 h and quenched with 3 equivalents of glacial acetic acid (~0.5 mL, the excess hydride was estimated to be ~3 equiv.). EtOAc (100 mL) and H_2O (50 mL) were added, and the mixture was filtered through Celite and allowed to separate to room temperature. The EtOAc layer was removed; the aqueous layer was further adjusted to pH 6–7 and reextracted with EtOAc (3 × 50 mL). Flash column chromatography of the organic layer with pet. ether/EtOAc (3:1) afforded the (*S*) enantiomer of compound **1***b* (90 mg, 15% yield after chromatography) in ~60% enantiomeric purity (as determined by ^{1}H NMR), the side product alcohol **9** (40 mg, 10% yield), binaphthol, and unreacted starting material.

(S)-(+) *Isobutyl*-p-*hydroxymandelate* (**1***b*): TLC: pet. ether/EtOAc (3:1), R_f 0.18. $[\alpha]_D$ +26.3°. ^{1}H NMR and ^{13}C NMR were identical to the racemic **1***b* reported previously. However, in the presence of (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol (1.5–2 equiv.) the proton spectra (300 MHz) clearly showed two sets of peaks for the C-2 proton; the (*S*) enantiomer upfield from the (*R*) with integration of S/R = ~4:1 (~60% ee).

2-(4-Hydroxyphenyl)-2-oxoethanol (**9**): TLC: pet. ether/EtOAc (3:1), R_f 0.08. ^{1}H NMR (200 MHz, acetone-d_6) δ: 4.79 (s, 2H, CH_2), 6.95 and 7.87 (dd, 4H, Ar) ppm, exchangeable protons were not seen. ^{13}C NMR (300 MHz, acetone-d_6) δ: 65.6 (C-1), 116.3 (2C-4), 127.1 (C-3), 131.1 (2C-5), 163.9 (C-6), and 198.6 (C-2) ppm. APT (D2 = 2 ms) NMR (300 MHz, acetone-d_6) δ: 127.1, 163.9, and 198.6 ppm. DEPT NMR (300 MHz, acetone-d_6) δ: 1CH_2 (65.6 ppm), 2CH (116.3, 131.1 ppm).

Hydrolysis of (R)-(−)-*isobutyl*-p-*hydroxymandelate ester* (**1***b*) *to* (R)-(−)-p-*hydroxymandelic acid* (**1***a*)

To a solution of ester (*R*)-**1***b* (60 mg, 0.27 mmol, 35% ee) in dioxane (3 mL), 2 equivalents of NaOH were added (1 M solution, 535 μL). The reaction was stirred at room temperature for 15 h, at which point 10 mL of H_2O was added and the pH adjusted to ~6.5 with 0.1 N HCl. The aqueous layer was extracted with EtOAc (3 × 15 mL) in order to remove unreacted starting material. The aqueous layer was evaporated to dryness under high vacuum at 40°C, redissolved in H_2O (~5 mL), and passed through an ion exchange resin (Dowex 50W-X9, H^+, 20–50 mesh) in order to remove Na^+. The free acid (*R*)-**1***a* was isolated in 90% yield (41 mg). Its optical rotation, $[\alpha]_D^{25}$ −10.2° (*c* = 0.98, H_2O), was compared to that of the natural product pisolithin B, $[\alpha]_D^{25}$ −2.7° (*c* = 1.0, H_2O). Although it was concluded that the metabolite must have the absolute (*R*) configuration, the values for the optical activity obtained were inaccurate; in solution, compound **1***a* is acidic enough to catalyze its own racemization.

Hydroylsis of (*S*)-**1***b* (60% ee), following exactly the same procedure, led to the isolation of the (*S*) enantiomer of pisolithin B, which showed an optical rotation $[\alpha]_D^{25}$ +26.3° (*c* = 0.16, H_2O).

(R)-(−)-p-*Hydroxymandelic acid* (**1***a*): UV (0.1 M HCl, nm); max 228, min 206 and 274; (0.1 M NaOH, nm): max 248, min 292. ^{1}H NMR (300 MHz, D_2O) δ: 5.0 (s, 1H, H2), 6.7 (d, *J* = 8.2 Hz, 2H, H5), 7.1 (d, *J* = 8.2 Hz, 2H, H4) ppm. ^{13}C NMR (300 MHz, DMSO + D_2O) δ: 74.4 (C-2), 117.3 (C-5), 130.4 (C-4), 132.3 (C-3), 157.5 (C-6), 178 (C-1) ppm. ^{252}Cf-plasma desorption MS (18): *electrosprayed sample*, *m/z*: 213.2 $(M^{2-} + H^+ + 2Na^+)^+$, 167.1 $(M^{2-} + H^+)^-$; *tridodecylmethylammonium chloride salt*, *m/z*: 167.1 $(M^{2-} + H^+)^-$, 869.9 $[(TDMA^+)(M^{2-} + H^+)_2^-]^-$, 1776.6 $[(TDMA^+)_3\ M^{2-}]$, 121.1 $(M^{2-} - HCO_2H)^-$.

Acknowledgments

We wish to thank Dr. J. André Fortin and Mr. Harry Kope, Forestry Department, Laval University, for carrying out the biological testing of pisolithin B and its synthetic enantiomer. We are also indebted to NSERC of Canada and FCAR of Quebec for financial support.

Free-radical based cycloalkanol synthesis and annulation from thioacetal precursors

VEEJENDRA YADAV AND ALEX G. FALLIS

The Ottawa–Carleton Chemistry Institute, Department of Chemistry, University of Ottawa, Ottawa, Ont., Canada K1N 6N5

Received June 27, 1990

VEEJENDRA YADAV and ALEX G. FALLIS. Can. J. Chem. **69**, 779 (1991).

A general procedure for the synthesis of diverse cyclopentanols via free-radical cyclization of unsaturated 1,3-oxathiolanes and 1,3-oxathiolan-5-ones is described. The scope of these reactions, including preliminary rate studies that indicate that the 1,3-oxathiolan-5-ones cyclize at a useful rate ($1.4 \times 10^6\ M^{-1}\ s^{-1}$ at 80°C), has been examined. This permits the rapid assembly, by intramolecular annulation, of various additional ring systems, including bicyclo[3.3.0]octanols, bicyclo[4.3.0]nonanols, and bicyclo[3.2.1]octanols for use in total synthesis.

Key words: radical cyclization, oxathiolanes, oxathiolanones.

VEEJENDRA YADAV et ALEX G. FALLIS. Can. J. Chem. **69**, 779 (1991).

On décrit une méthode générale de synthèse de divers cyclopentanols qui implique une cyclisation radicalaire de 1,3-oxathiolanes et de 1,3-oxathiolan-5-ones insaturés. On a étudié les possibilités de ces réactions, y compris des études préliminaires de leurs vitesses; elles indiquent que les 1,3-oxathiolan-5-ones se cyclisent à des vitesses utiles ($1,4 \times 10^6\ M^{-1}\ s^{-1}$, à 80°C). Cette procédure permet de faire un assemblage rapide, par annelation intramoléculaire, de divers systèmes cycliques additionnels, y compris les bicyclo[3.3.0]octanols, bicyclo[4.3.0]nonanols et bicyclo[3.2.1]octanols qui peuvent être utilisés dans des synthèses totales.

Mots clés : cyclisation radicalaire, oxathiolanes, oxathiolanones.

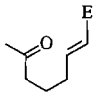
[Traduit par la rédaction]

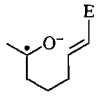
Introduction

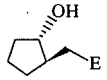
Over the past decade significant progress in the study and synthetic application of free-radical reactions to a variety of challenging targets has been achieved. Thus free-radical processes have evolved to join their counterparts, electrophilic, nucleophilic, and pericyclic reactions, in the arsenal of the synthetic organic chemist. This rapid, recent progress is summarized in several reviews (1–4). The established preference of 5-hexenyl radicals to form five-membered rings (5) allows rapid construction of complex systems, particularly cyclopentanoid natural products (6, 7). A liability inherent in classical radical precursors such as unsaturated organic halides is the net loss of the two functional groups that results. This severely limits, at an early stage in a synthetic sequence, the use of conventional radical cyclizations.

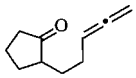
One potential solution to this problem is to employ α-heteroatom radical intermediates in the cyclization step in order to generate products that retain synthetically useful functionality for subsequent manipulation. At the outset of this study relatively few substituted systems of this type had been reported. The examples most studied concerned the intramolecular cyclization of α-nitrogen substituted radicals to olefins and the reductive cyclization of alkenyl ketones via radical anion intermediates (6*a*, 8). Representative examples of some of the oxygen related cases are summarized in Table 1 (9, 10). In addition to entry 4, Giese and Erfort have examined the conjugate addition of α-acetoxy radicals (9*d*) and more recently there have been reports of closely related systems (entries 5–8). However, in the case of entry 5 the method proved unsatisfactory with more complex examples and required high dilution when the α-*gem*-dimethyl functionality was absent (10*b*). In a different context, the cytotoxicity of the antitumor antibiotic bleomycin is believed to arise via an oxygen stabilized nucleotide radical intermediate, and thus there is added incentive to understand related species (11).

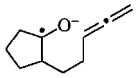
To employ the tin hydride mediated reductive cyclization procedure it is necessary to utilize a relatively reactive precursor in which hydrogen atom transfer from the stannane will be sufficiently slow so that ring closure may compete effectively. Beckwith and Pigou demonstrated that a methylthio substituent reacted so slowly with tributyltin radicals that they were unable to obtain accurate relative rate values (9*j*). This study established that for S_H2 attack by tributyltin radicals the relative order was I > Br > PhSe > Cl > PhS > MeS. In addition, it was noted that one of the important factors that affected the reactivity of RX with tributyltin radicals was the degree of stabilization of the product radical R·, particularly in the case of attack on sulfur. Nevertheless the kinetic data indicated that aryl sulfides were of borderline utility and were usually unsatisfactory for reactions involving alkyl radicals, although cyclizations from diphenyldithioacetals have been reported recently (8*k*).

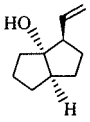


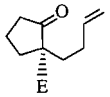


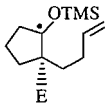


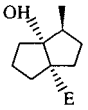


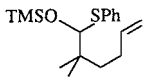


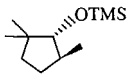


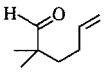


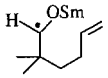


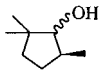


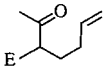


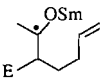


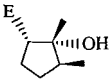


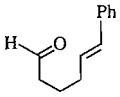


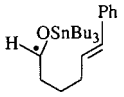


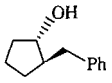






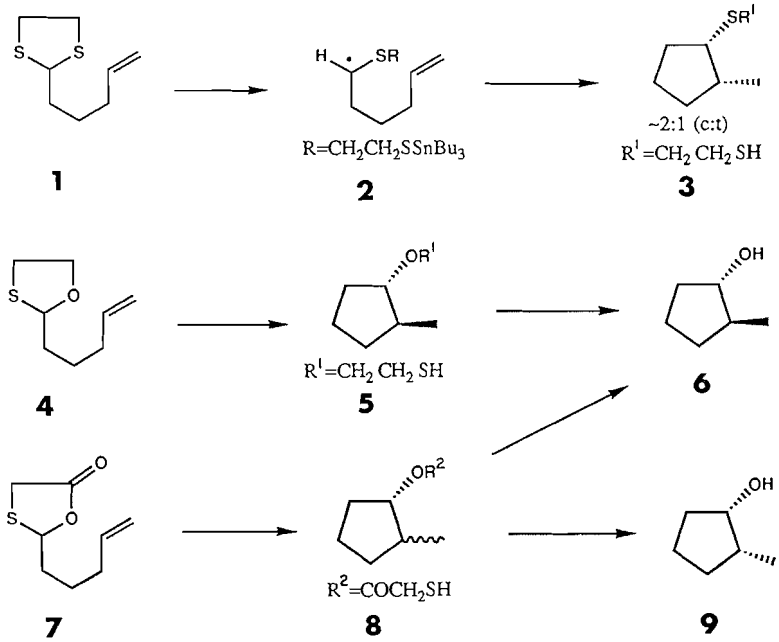






Several years ago Guiterrez *et al.* established that tri-*n*-butyltin hydride, plus azobis(isobutyronitrile) (AIBN) as initiator, was effective for desulfurization of dithioacetals and that this process involved a stepwise radical chain reaction (12). In the present context this demonstrated that sufficient strain will also assist the radical cleavage of alkyl sulfides. Consequently it appeared likely that quenching of a radical intermediate such as **2** (Scheme 1) would be slow relative to cyclization when a suitable unsaturated centre was also present in the thioacetal. We have demonstrated that this is indeed the case and wish to report the details for the ring closure of 5-hexenyl-1,3-thiolane (**1**) and related 1,3-oxathiolanes and 1,3-oxathiolan-5-ones to a variety of oxygenated cycloalkanes (13).

Results and discussion



Treatment of **1** in refluxing benzene, to which tributyltin hydride and AIBN were added by syringe pump, resulted in 60% conversion to the cyclopentane **3** as a 2:1 *cis/trans* isomeric mixture (Scheme 1). Cyclization of the diphenyldithioacetal corresponding to **1** was recently reported to give a 35:65 *cis/trans* ratio (8*k*). Similar treatment of **4** afforded, after chromatography, a 60% isolated yield of the *trans* substituted system **5** as a single isomer. Ether cleavage was effected with boron trichloride (14) to provide *trans*-2-methylcyclopentanol (**5**) whose structure and stereochemistry were confirmed by comparison with an authentic sample prepared from cyclo-

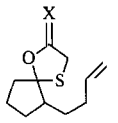
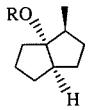
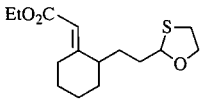
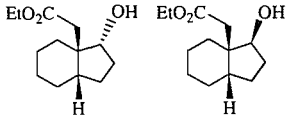
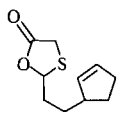
R = CH_2CH_2SH or H.

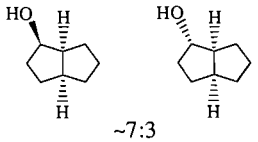


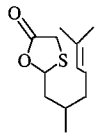


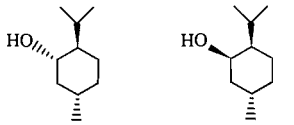


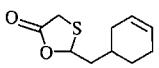


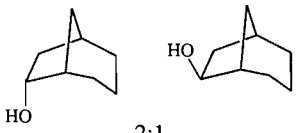


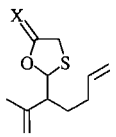


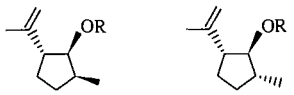


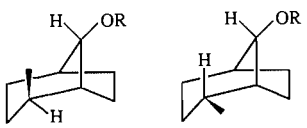












pentene oxide. Stereochemical assignments are often difficult in cyclopentanols compared to cyclohexanols, thus the key nmr data for several related 1,2-disubstituted cyclopentanes are summarized in Table 2. In the simplest systems a consistent trend was observed. The hydrogen signal for the *cis* methyl signal resonated at lower field than the *trans*. In contrast, in the ^{13}C nmr spectrum, as a consequence of the γ-*gauche* effect, the relative field positions were reversed and the *trans* methyl group appeared at lower field. Generally the signal for the proton on the carbon bearing oxygen in the *cis* series resonated at lower field than the *trans* isomer, while the opposite trend was evident for the relative positions of this carbon. These features facilitated the stereochemical assignments when both isomers were available, and was consistent with related observations (15*a*) that a *trans* relationship between vicinal hydrogens in cyclic systems caused a downfield shift for each of the carbon atoms involved. Additional useful compilations of several cyclopentane and quinane systems may be found in previous papers by others (15).

The cleavage of the ether side chain (-OCH_2CH_2SH) was sluggish in sterically demanding cases. Consequently the behaviour of 5-oxo-1,3-oxathiolanes was also investigated, and was shown to provide an even more useful route to cyclic systems in which the initial ester, such as **8**, was readily cleaved by base hydrolysis to afford the parent alcohols **6** and **9** in 74% yield as a 3:2 isomer mixture. The versatility of these approaches is reflected in several diverse examples that are summarized in Table 3.

The requisite heterocycles were prepared from the appropriate carbonyl compound in dioxane containing $ZnCl_2$ and 2-mercaptoethanol (16) or in refluxing benzene containing β-mercaptoacetic acid and *p*-toluenesulfonic acid as catalyst with azeotropic removal of water (17). The required substrates were synthesized, as illustrated briefly in Scheme 2, from commercially available starting materials. This involved alkylation, hydrolytic decarboxylation, and acetalation for **12** and **13**, while **16** was generated by alkylation of cyclohexanone followed by Horner–Wadsworth–Emmons olefination. The routes to **21** and **26** required lithium aluminum hydride reduction of the requisite carboxylic acids (18), bromination (Ph_3PBr_2), substitution (NaCN), reduction (diisobutylaluminum hydride), and acetalation. This sequence finds a close parallel in earlier work by Wilt, Massie, and Dabek (18*a*). Similarly, deconjugative alkylation of ethyl 3,3-dimethylacrylate with lithium diisopropyl amide (LDA) and 4-bromo-1-butene, lithium aluminum hydride reduction of the ester **27**, pyridinium chlorochromate oxidation, and protection of the aldehyde **29** afforded **30** and **31**.

Examination of Table 3 reveals that these free-radical based cyclizations may be utilized for a variety of substitution patterns and ring systems. In a formal sense, this amounts to an intramolecular Grignard addition that is accomplished under neutral conditions. Indeed, direct intramolecular cyclization of halides onto carbonyl centres is usually difficult and requires the use of nickel complexes (19*a*), although samarium(II) iodide may be employed with iodo substituted β-keto esters or amides (19*b*). In addition, oxidation of the cyclized alcohol product to the ketone makes this two-step procedure equivalent to an acyl radical cyclization. This is a topic of considerable current interest (20), since in many circumstances the direct use of carbonyl systems is inhibited by decarbonylation.

For future synthetic applications several features may be

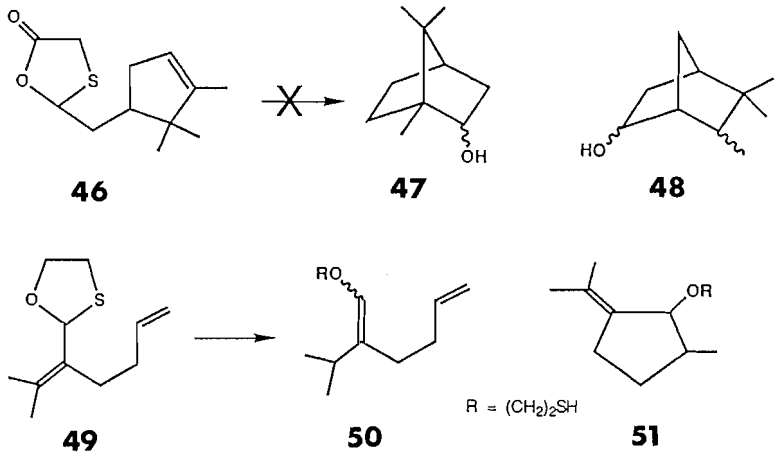

SCHEME 2

noted. These include the ease with which fused ring systems such as quinanes and hydrindanes bearing a variety of substitution patterns may be prepared (entries 1–3). Methyl substituted olefins such as **37** (prepared from citronellal) also reacted, providing menthol (**38**) and its epimer **39** in a 1:1 ratio via a 6-*exo-trig* ring closure. However, more sterically encumbered species such as the acetal **46** (Scheme 3) derived from α-campholenic aldehyde (21) failed to cyclize after carbon–sulfur bond cleavage. Neither of the bicyclic products **47** nor **48** were detected, although there is precedence for the formation of bicyclo[2.2.1]heptanes in simpler unsubstituted systems (18*a*). Cleavage of the carbon–sulfur bond in diene **49** (Scheme 3) afforded an allylic radical that could cyclize to **51**. However, this intermediate was insufficiently reactive and the major product was the enol ether **50**. Enol ethers of aldehydes are often difficult to prepare and thus this method for the generation of protected enols from conjugated acetals under neutral conditions should have further utility.

In principle, the cyclohexene **26** may cyclize via either a 5-*exo-trig* or 6-*exo-trig* pathway to generate the bicyclo[3.2.1]-octane and (or) bicyclo[2.2.2]octane skeletons. In practice, only the 6-bicyclo[3.2.1]octanols **40** and **41** were formed in a 70:30 *endo*/*exo* ratio accompanied by 12% of the non-cyclized product, 2-(3-cyclohexenyl)ethanol. An authentic sample of 2-bicyclo[2.2.2]octanol was prepared and shown to be both absent and different from **40** and **41**.

It was also of interest to examine the dienes **30** and **31**, which in principle are capable of tandem cyclization of the appropriate *cis* isomer to a bicyclo[2.2.1]heptane and (or) a bicyclo[3.2.1]octane nucleus. In the case of **30**, no bicyclic material was detected. In contrast, after cyclization and hydrolysis, four alcohols (**42**–**45**) were isolated from the reaction of **31**. The major cyclopentane component from both **30** and **31** had the isopropenyl and alcohol substituents in a *trans* orientation. The assignment was based on spectral data and comparison with related compounds including racemic (1*R**,2*R**,5*S**)-2-

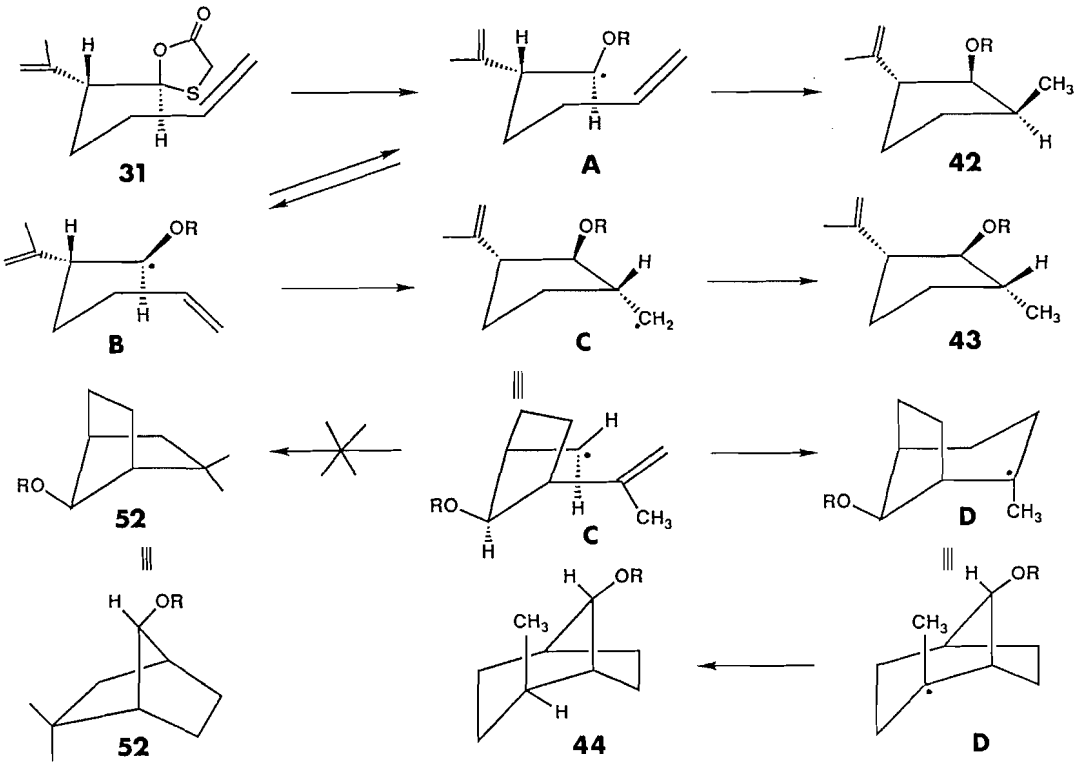
49 50 51

SCHEME 3

methyl-5-isopropylcyclopentanol obtained by hydrogenation (Table 2, entry 7). The minor product from the initial ring closure was **43**. There was no evidence for a 5-*exo-trig* cyclization to a bicyclo[2.2.1]heptane system such as **52** (Scheme 4). The other products (10%) were the methyl epimers **44** and **45** from a 6-*endo-trig* ring closure. The major alcohol **44** (8%) contained an axial methyl group, as illustrated, with the hydroxyl function *anti*. A previous study has also observed this preference for *endo* closure to a bicyclo[3.2.1]octane when this choice is available (22). Thus both **26** and **31** provide a rapid preparation of the bicyclo[3.2.1]octane nucleus that is present in many terpenoid natural products. Unfortunately the yield in the latter case is rather low due to the requirement for *cis* substituents and the presence of the substituted double bond.



Studies of the stereochemistry of simple substituted 5-hexenyl radical cyclizations have allowed the formulation of guidelines to predict product stereochemistry. These are based on the assumption that the preferred transition state geometry resembles the most favorable cyclohexane chairlike conformation (23). Based on these studies, it has been established that, for simple monoalkyl substituted 5-hexenyl cyclizations, *cis* dialkylcyclopentanes predominate with 1- and 3-substituted systems. In contrast, *trans* products are formed preferentially when 2- and 4-substituted cyclopentanes are generated. The *cis* vs. *trans* selectivity is affected significantly by C4 substituents, a feature that has been used in synthesis (24). Less was known about the behaviour of C1, C2-disubstituted systems until recent investigations of highly functionalized carbohydrate derivatives revealed that these additional substituents may alter the expected 1,5 stereochemistry, and a boat conformation is often preferred (25). This led to exclusive 1,5-*trans* selectivity in highly functionalized systems. On the basis of theoretical calculations Spellmeyer and Houk (23*d*) estimated that the boatlike transition states lie only ~0.5 kcal/mol above the chairlike structures for these reactions. In the case of **30** and **31** the major product arose from an intermediate of type **A** (Scheme 4) with a chairlike conformation in which the substituents were equatorial. This species is in equilibrium with the boatlike radical **B**. Upon cyclization, intermediate **C** is generated, in which the carbon side chains bear a *cis* relationship. Approximately half of this material is quenched to give the minor isomer **43** while the rest cyclized further to form **D** and hence **44**. The preference for the *endo* vs. *exo* closure is apparent from inspection of **C**, since the 6-*endo-trig* cyclization involves both a less strained transition state and addition to the less substituted end of the double bond, as illustrated in Scheme 4.

As noted above, the oxathiolane **4** gave only the *trans* isomer **6**, while for the lactone **7** the *cis* isomer **9** was dominant. This difference reflects the faster cyclization rate for the oxathiolanone case, a consequence of the diminished stability of the intermediate radical due to an acyl rather than an ether substituent. Rapid cyclizations have an early transition state and give rise preferentially to 1,5-*cis* products. In contrast, eclipsing interactions become more important in longer lived intermediates as a consequence of the slower rate and later transition state, so that more 1,5-*trans* product is formed. Calculations indicated that the radical stabilization energies of monosubstituted methyl radicals were 2.38 kcal/mol ($\cdot CH_2OCOH$) and 5.30 kcal/mol ($\cdot CH_2OCH_3$), respectively (26). This order parallels the extent of delocalization of the unpaired electron in related radicals that is reflected by ESR hyperfine splitting constants (27) ($RCH_2OCH_2\cdot > RCO_2CH_2\cdot > RCH_2\cdot$). Intramolecular cyclization rates do not appear to have been determined previously for oxygen substituted radicals. In preliminary experiments,[1] which employed the radical clock based on the corresponding 5-hexenyl system (28), we established that the relative cyclization rate for **7** is approximately six times faster than for **4**. These values of $0.25 \times 10^6\ M^{-1}\ s^{-1}$ for **4** and $1.4 \times 10^6\ M^{-1}\ s^{-1}$ for **7** at 80°C may be compared to the corresponding k_c for 1-bromo-5-hexene at the same temperature, $1.5 \times 10^6\ M^{-1}\ s^{-1}$ (28). Thus the 1,3-oxathiolan-5-ones cyclize at a similar rate to 5-hexenyl cases, which will allow this oxygen containing system to be employed in a variety of synthetic endeavours.

To extend the versatility of these procedures, the use of allyl stannanes was also investigated (29). It was suspected that the allyl stannanes might be more reactive than simple monosubstituted alkenes, a result that was confirmed experimentally when either allyltri-*n*-butylstannane or methallyltri-*n*-butylstannane were employed with **4**, **7**, and **21** respectively. Allyl transfer worked efficiently but in each case the intermediate radical was trapped directly upon carbon–sulfur bond cleavage prior to cyclization to afford the 1,8-nonadiene product. Clearly, for this strategy to succeed, both a more rapid cyclization step and a slower trapping sequence will be required. Very recently, rate studies have demonstrated that the rate constant for the addition of cyclohexyl radicals to allyltriphenyl tin is $1 \times 10^5\ M^{-1}\ s^{-1}$

[1] M. Charron. Honours B.Sc. Thesis, University of Ottawa, Ottawa, Canada, April 1989. Rates were also measured at 58.5°C. The k_c values at 58.5°C were 0.12×10^6, 0.71×10^6, and $0.76 \times 10^{-6}\ M^{-1}\ s^{-1}$ for **4**, **7**, and 1-bromo-5-hexene respectively.

SCHEME 4

at 80°C (30). Thus allyltriphenylstannane is approximately 10 times less reactive than methyl acrylate, whereas 1-hexene is 10^3 less reactive than acrylate. Consequently substitution of at least one electron-withdrawing group will be required in compounds **4**, **7**, and the other examples so that the cyclization can compete with allyl transfer. Nevertheless, Keck and Tafesh (*10g*) conducted an effective cyclization – allyl transfer sequence with an unsaturated α-silyloxy phenylselenide.

In conclusion, thioacetals such as 1,3-oxathiolanes and 1,3-oxathiolan-5-ones are useful precursors of radical intermediates for intramolecular ring closure. This provides a facile route to both tertiary and secondary cyclic alcohols with a reasonable level of stereochemical control. The products retain synthetically useful functionality for subsequent manipulation, unlike conventional unsaturated organic halide precursors in which a net loss of two functional groups results. These features should facilitate the extended use of these methods in synthesis.

Experimental

Melting points were determined in capillary tubes with a Thomas–Hoover Uni-Melt apparatus, or on a Fisher–Johns melting point apparatus, and are uncorrected. Infrared (ir) spectra were recorded on a Perkin–Elmer 783 or 983G infrared spectrophotometer. Proton magnetic resonance spectra (^{1}H nmr) were measured in deuterochloroform at 60 MHz with a Varian model EM 360 spectrometer or at 200 MHz with a Varian Gemini spectrometer or at 300 MHz with a General Electric GN 300 or a Varian XL-300 spectrometer. Carbon magnetic resonance spectra (^{13}C nmr) were measured at 75 MHz with a General Electric GN 300 or a Varian XL-300 spectrometer. Chemical shifts are reported in ppm downfield from tetramethylsilane (δ scale) as an internal standard; the multiplicity, numbers of protons, and coupling constants are indicated in parentheses. Mass spectra were determined on a V.G. Micromass 7070 HS instrument using an ionization energy of 70 eV, or on a Hewlett Packard 5890A gas chromatograph 5970B mass selective detector equipped with a 12.5 m capillary column (0.2 mm i.d.) coated with cross-linked dimethyl silicone (0.33 μm). Flash column chromatography using E. Merck silica gel 60 (230–400 mesh) was employed for all column chromatography. Analytical thin-layer chromatography (tlc) was carried out on aluminum sheets precoated (0.2 mm layer thickness) with silica gel 60 F_{254} (E. Merck). The purity of all title compounds was judged to be ≥95% as determined by a combination of gc–ms, ^{1}H nmr, and ^{13}C nmr analysis.

Petroleum ether refers to a fraction with boiling range 30–60°C. Anhydrous diethyl ether (ether), tetrahydrofuran (THF), dimethoxyethane (DME), and dioxane were obtained by distillation from $LiAlH_4$ or potassium/benzophenone. Methanol and absolute ethanol were dried by distillation from magnesium. Dry hexamethylphosphoramide (HMPA), dimethylformamide (DMF), dimethyl sulfoxide (DMSO), and diisopropylamine were prepared by distillation from calcium hydride. Solutions in organic solvents were dried over anhydrous magnesium sulfate and stripped of solvent with a Büchi rotary evaporator connected to a water aspirator. Unless otherwise indicated, all reactions were conducted under an atmosphere of dry nitrogen.

Acetal preparation

2-(4-Pentenyl)-1,3-dithiolane (1)

5-Hexenal (1.19 g, 12.2 mmol) in $CHCl_3$ (5 mL) was added dropwise over 10 min to a chloroform solution (22 mL) containing ethane dithiol (1.15 g, 12.2 mmol), $BF_3 \cdot Et_2O$ (1.5 mL, 12.2 mmol), and glacial acetic acid (3 mL) maintained at −22°C with an external (solid CO_2/CCl_4) bath. Stirring was continued at −22°C for 30 min, at 0°C for 30 min, and 10% aqueous potassium hydroxide (50 mL) was then added with vigorous stirring. The aqueous layer was extracted with $CHCl_3$ (2 × 15 mL) and the combined chloroform extracts washed sequentially with 10% aqueous KOH, water, and brine, dried, filtered, and concentrated. The product was purified by chromatography (5% ethyl acetate/petroleum ether) to afford the dithioacetal **1**, 1.8 g (85%); ^{1}H nmr (60 MHz) δ: 1.4–2.4 (m, 6H), 3.2 (s, 4H, SCH_2CH_2S), 4.45 (t, 1H, J = 6 Hz, H-C(S)), 4.8–5.2 (m, 2H, H_2C=C), 5.4–6.2 (m, 1H, HC=C); ^{13}C nmr δ: 137.1, 115.5, 46.4, 34.3, 30.2, 30.0, 29.6, 25.7.

2-(4-Pentenyl)-1,3-oxathiolane (4) (Procedure based on ref. 16)

A dioxane solution (10 mL) containing 6-hexenal (1.47 g, 15 mmol) and 2-mercaptoethanol (1.40 g, 22 mmol, Aldrich) was cooled to 0°C with an external ice–water bath. Sodium sulfate (2 g) and freshly fused, powdered zinc chloride (2.05 g, 15 mmol) were added. After 10 min

the ice bath was removed and stirring was continued for a further 20 h at 22°C. The reaction mixture was diluted with water (20 mL) and extracted with ether (3 × 15 mL). The combined ether extracts were washed with water (3 × 10 mL), then with brine, dried, filtered, and concentrated. The product was purified by flash chromatography (10% ethyl acetate/petroleum ether) to give **4**, 1.66 g (70%); ^{1}H nmr δ: 1.44–1.62 (m, 2H, -CH_2-), 1.70–1.83 (m, 1H, CH_2-CH-O), 1.86–1.98 (m, 1H, CH_2-CH-O), 2.05–2.13 (m, 2H, CH_2-C=C), 2.98–3.03 (m, 2H, CH_2-S), 3.71–3.80 (m, 1H, O-CH_2), 4.28–4.35 (m, 1H, O-CH_2), 4.93–5.09 (m, 3H, H_2C=C, H-CO), 5.72–5.86 (m, 1H, HC=C); ^{13}C nmr δ: 138.2, 114.9, 86.8, 71.2, 35.8, 33.4, 32.6, 25.6. Exact Mass calcd. for $C_6H_{10}OS$ (M − C_2H_4): 130.0452; found: 130.0458.

The 1,3-oxathiolane-5-one acetals were prepared from the corresponding aldehyde in refluxing benzene containing β-mercaptoacetic acid and *p*-toluenesulfonic acid as catalyst with azeotropic removal of water according to the procedure of Satsumabayashi *et al.* (17).

2-(4-Pentenyl)-1,3-oxathiolan-5-one (7): ir (neat): 3090 (H-C=C), 1775 (C=O) cm^{-1}; ^{1}H nmr δ: 1.55 (m, 2H, CH_2), 1.90 (m, 2H, CH_2), 2.07 (m, 2H, CH_2), 3.63 (AB m, 2H, J = 16 Hz, S-CH_2-C=O), 4.95 (br s, 1H, HC=C), 5.02 (br d, 1H, J ~ 12 Hz, HC=C), 5.47 (t, 1H, J = 6.0 Hz, HC-S(O)), 5.75 (m, 1H, J = 12, 3.5 Hz, HC=C); ^{13}C nmr δ: 172.8, 137.6, 115.4, 82.1, 35.9, 32.8, 31.4, 23.9.

2-(2,6-Dimethyl-5-heptenyl)-1,3-oxathiolan-5-one (37): ^{1}H nmr δ: 0.92, 0.93 (d, 3H, J = 6.5 Hz, CH_3C, 2 diastereomers, ~1:1), 1.57 (s, 3H, CH_3C=C), 1.65 (s, 3H, CH_3C=C), 3.62 (2 AB m, 2H, J ~ 16 Hz, S-CH_2-C=O), 5.05 (t, 1H, J = 6.0 Hz, HC-S(O)), 5.53 (m, 1H, HC=C); ^{13}C nmr δ: 172.9, 131.7, 124.0, (2 diastereomers, ~1:1, 81.4, 80.8), (43.9, 42.4), 36.7, (31.6, 31.4), 29.5, 25.4, 25.0, (19.2, 19.0), 17.4.

2-(3-Buten-1-yl)-cyclopentanone (11)

A heterogeneous mixture of methyl-2-oxocyclopentylcarboxylate (5.68 g, 40 mmol, Aldrich), 4-bromo-1-butene (6.48 g, 48 mmol, Aldrich), K_2CO_3 (11 g, 80 mmol, ground to a fine powder before use), and sodium iodide (0.45 g, 3 mmol) was stirred vigorously under reflux in acetone (150 mL) for 48 h. The reaction mixture was filtered, concentrated, and a solution of hexamethylphosphoramide (HMPA)/water (9:1, 40 mL) and sodium iodide (60 mmol) added. The resulting solution was heated at 160° for 5 h. The reaction was cooled to room temperature, extracted with ether, the combined ether extracts washed with water, dried, filtered, and concentrated. The crude product was purified by flash chromatography (10% ethyl acetate/petroleum ether) to give ketone **11**, 2.26 g (50%); ^{1}H nmr (60 MHz) δ: 1.2–2.5 (m, 11H), 4.8–5.2 (m, 2H, H_2C=C), 5.4–6.2 (m, 1H, HC=C). Exact Mass calcd. for $C_9H_{14}O$: 138.1044; found: 138.1044.

5-(3-Buten-1-yl)-1,4-oxathiaspiro[4.4]nonane (12)

Prepared in 80% yield (0.317 g) after chromatography (20% ethyl acetate/petroleum ether); ^{1}H nmr (60 MHz) δ: 1.2–2.4 (m, 11H), 3.1–2.8 (m, 2H, CH_2-S), 3.6–4.4 (m, 2H, CH_2-O), 4.8–5.2 (m, 2H, H_2C=C), 5.4–6.2 (m, 1H, HC=C). Exact Mass calcd. for $C_{11}H_{18}OS$: 198.1077; found: 198.1080.

2-(2-Iodoethyl)-1,3-oxathiolane (14)

Dry sodium iodide (18.0 g, 120 mmol) was dissolved in acetonitrile (200 mL), followed by freshly distilled acrolein (5.60 g, 100 mmol) and chlorotrimethylsilane (15.4 mL, 120 mmol) (compare ref. 31). The reaction was stirred for 10 min and 2-mercaptoethanol (9.40 g, 120 mmol) was added. After a further 10 min the reaction was poured into aqueous 5% $NaHCO_3$ solution (100 mL) overlaid with pentane (300 mL). The organic phase was separated, washed with aqueous 5% $Na_2S_2O_3$ solution (100 mL), and repeatedly with brine (6 × 100 mL until a single organic phase was obtained). The organic phase was dried (K_2CO_3), filtered, and concentrated. The residue obtained was filtered through neutral alumina to provide the iodo-acetal **14**, 17.5 g (73%); ^{1}H nmr δ: 2.1–2.6 (m, 2H, CH_2-CH_2I), 2.8–3.4 (m, 4H, CH_2-I, CH_2-S), 3.6–4.1 (m, 1H, CH_2-O), 4.1–4.5 (m, 1H, CH_2-O), 5.2 (t, 1H, J = 6.5 Hz, H-C-O,S).

2-(2-(Oxocyclohexan-2-yl)ethyl)-1,3-oxathiolane (15)

A few drops of dimethyl sulfoxide (DMSO) were added to a THF (15 mL) suspension of KH (0.205 g, 5.1 mmol) maintained at 0°C with an external ice bath. A cold solution (0–5°C) of cyclohexanone (0.490 g, 5 mmol) in THF (5 mL) was added dropwise. After 10 min, a THF solution (5 mL) of iodide **14** (1.22 g, 5 mmol) was added. The resulting reaction mixture was stirred at 0°C for 30 min, warmed to 22°C, and stirred for a further 1 h. The reaction was quenched with saturated aqueous NH_4Cl solution, extracted with ether, dried, filtered, and concentrated. The product was purified by chromatography (20% ethyl acetate/petroleum ether) to give **15**, 0.640 g (60%); ^{1}H nmr (60 MHz) δ: 1.2–2.5 (m, 12H), 3.05 (m, 2H, CH_2S), 3.8 (m, 1H, CH_2O), 4.3 (m, 1H, CH_2O), 5.05 (t, 1H, J = 6 Hz, H-C-O,S); ^{13}C nmr δ: 212.8, 86.8, 71.3, 50.1, 41.8, 33.8, 32.4, 27.7, 26.0, 25.9, 24.7. Exact Mass calcd. for $C_{11}H_{18}O_2S$: 214.1026; found: 214.1028.

2-[(2-(2-Ethyl methylenecarboxylate)cyclohexyl)ethyl]-1,3-oxathiolane (16)

A suspension of NaH (0.09 g, 80% dispersion in oil, Aldrich) in THF (4 mL) was cooled to 0°C and a solution of triethyl phosphonoacetate (0.70 g, 3 mmol, Aldrich) in THF (4 mL) added dropwise. Approximately 10 min later, after hydrogen evolution had ceased, HMPA (0.8 mL) was added, followed by a THF solution (6 mL) of ketone **15** (0.321 g, 1.5 mmol). The ice bath was removed and the reaction stirred at 22°C for 48 h. The reaction was quenched with saturated aqueous NH_4Cl (10 mL), extracted with ether (3 × 10 mL), and the combined extracts washed with water and brine, dried, filtered, and concentrated. The product was purified by radial chromatography on silica gel (20% ethyl acetate/petroleum ether) to give **16**, 0.384 g (90%); ^{1}H nmr δ: 1.24 (t, 3H, J = 7 Hz, CH_3), 3.00 (m, 2H, H_2C-S), 3.75 (m, 1H, H_2C-O), 4.10 (m, 2H, H_2C-OC=O), 4.28 (m, 1H, H_2C-O), 5.03 (m, 1H, HC-S(O)), 5.55 (m, 1H, HC=C); ^{13}C nmr δ: 165.7, 114.5, 112.7, 86.9, 71.1, 60.0, 45.4, 34.1, 33.8, 32.5, 28.2, 27.4, 22.8, 20.4, 14.0. Exact Mass calcd. for $C_{15}H_{24}O_3S$: 284.1445; found: 284.1421.

2-(Cyclohexen-4-yl)methyl-1,3-oxathiolan-5-one (26)

An ether solution (20 mL) containing 3-cyclohexenyl-1-carboxylic acid (5.04 g, 40 mmol, Aldrich) was added dropwise to a stirred suspension of $LiAlH_4$ (3.0 g) in ether (40 mL) at 22°C (18*b*). The reaction was stirred at this temperature for 12 h, refluxed for 4 h, cooled to 0°C, and excess $LiAlH_4$ destroyed by dropwise addition of ethyl acetate and water. The reaction mixture was filtered, the precipitate washed with ether, and the combined filtrates were dried, filtered, and concentrated to give the alcohol **22**, 4.46 g (100%); ^{1}H nmr (60 MHz) δ: 1.2–2.3 (m, 7H), 2.4 (s, 1H, OH), 3.5 (bd, 2H, J ~ 5 Hz, CH_2-O), 5.65 (bs, 2H, HC=CH).

Bromine (7.03 g, 44 mmol) in benzene (15 mL) was added dropwise to a cold (external ice bath) mechanically stirred benzene solution (40 mL) containing triphenylphosphine (11.5 g, 44 mmol). After addition was complete, stirring was continued for a further 1 h at 22°C, pyridine (3.48 g, 44 mmol) was added, the reagent recooled to 0°C, and a benzene solution (15 mL) of the alcohol **22** (4.46 g, 40 mmol) was added dropwise. After this addition was complete, the ice bath was removed and stirring was continued for 6 h at 22°C. Petroleum ether was added (200 mL) and the mixture placed in the freezer at −20°C for 2 h. The precipitate was removed by filtration, washed thoroughly with petroleum ether, the filtrate concentrated, and the product purified by distillation (bp 68–70°C/12 Torr; 1 Torr = 133.3 Pa) to give the bromide **23**, 5.86 g (84%); ^{1}H nmr (60 MHz) δ: 1.2–2.4 (m, 7H), 3.40 (bd, 2H, J ~ 6 Hz, CH_2-Br), 5.65 (bs, 2H, HC=CH).

Sodium cyanide (3.73 g, 76 mmol) was added to a 90% aqueous ethanol solution (40 mL) containing the bromide **23** (6.64 g, 38 mmol) and the resulting suspension stirred under reflux for 16 h. The bulk of the ethanol was removed under reduced pressure, water was added, and the reaction extracted with ether. The combined ether extracts were washed with water and brine, dried, filtered, and concentrated. The product was purified by chromatography (10% ethyl acetate/petroleum ether) to give the nitrile **24**, 4.24 g (92%); ^{1}H nmr (60 MHz) δ: 1.2–2.5 (m, 9H), 5.65 (bs, 2H, HC=CH).

An *n*-hexane solution (60 mL) of the nitrile (0.605 g, 5 mmol) was cooled to −78°C with an external (solid CO_2/acetone) bath and a toluene solution of diisobutylaluminium hydride (6 mL, 6 mmol, 1.0 M, Aldrich) added dropwise over 15 min. After 30 min the cooling

For personal use only.

bath was removed and stirring continued for a further 3 h. The reaction was quenched with saturated aqueous NH_4Cl (50 mL) and, 20 min later, 5% aqueous H_2SO_4 (20 mL) was added.

The reaction was extracted with ether, the combined ether extracts washed sequentially with 5% aqueous HCl, water, and brine, and dried, filtered, and concentrated carefully at 22°C to provide the aldehyde **25**, 0.62 (100%).

A benzene solution (20 mL) of mercaptoacetic acid (1.84 g, 20 mmol) was added to benzene (100 mL) and the aldehyde **25** (2.48 g, 20 mmol) in a flask equipped with a Soxhlet extractor containing a thimble packed with 4 Å molecular sieves. The bulk of the benzene was removed under reduced pressure, ether (100 mL) added, and the solution washed with saturated aqueous $NaHCO_3$ (2 × 30 mL), water (30 mL), and brine (30 mL), and dried, filtered, and concentrated. The product was purified by chromatography (10% ethyl acetate/petroleum ether) to give the acetal **26**, 1.73 g (44%, two diastereomers); ir (neat): 3030 (H-C=C), 1770 (C=O) cm^{-1}; ^1H nmr (300 MHz) δ: 1.22–1.29 (m, 1H), 1.63–2.20 (m, 8H), 3.60 (d, 2H, J = 16.6 Hz, CH_2-S), 5.52–5.63 (m, 3H, HC=CH, H-CO,S); ^{13}C nmr δ: 172.5, (126.7, 125.3 two diastereomers), (80.6, 80.5), 43.0, (31.4, 31.2), 31.0, 30.3, (28.3, 28.2), 24.4. Exact Mass calcd. for $C_6H_8O_2S$ (M − C_4H_6): 144.0245; found: 144.0216.

*2-(Cyclopenten-3-yl)ethyl-1,3-oxathiolan-5-one (**21**)*

A parallel series of reactions to those described above (18), commencing with 2-cyclopentene-1-acetic acid, were utilized to prepare **21** in 40% overall yield; ir (neat): 3025 (H-C=C), 1775 (C=O) cm^{-1}; ^1H nmr (60 MHz) δ: 1.2–3.0 (m, 9H), 3.7 (s, 2H, CH_2-S), 5.5 (t, 1H, J = 6 Hz, H-CO,S), 5.7 (m, 2H, HC=CH). Exact Mass calcd. for $C_{10}H_{14}O_2S$ − $C_2H_3O_2$: 139.0581; found: 139.0571.

*2-Isopropenyl-6-hexenal (**29**) and 2-methyl-3-formyl-2,6-heptadiene*

Lithium diisopropylamide (LDA), in THF (200 mL), prepared from *n*BuLi (45 mL, 2.7 M, hexane) and diisopropylamine (16.8 mL, 0.12 mol), was cooled to −78°C and HMPA (20.9 mL, 0.12 mol) added, followed by a THF solution (15 mL) containing ethyl 3,3-dimethylacrylate (12.8 g, 0.10 mol, Aldrich). After 15 min 4-bromo-1-butene (15 g, 0.11 mol) was added dropwise over 10 min, the reaction stirred at −78°C for 1 h, at 22°C for 5 h, and then quenched with saturated aqueous NH_4Cl (25 mL). Ether was added and the combined ether extracts (3 × 50 mL) were dried, filtered, and concentrated. The residue was redissolved in ether (150 mL), washed with water (4 × 25 mL) and then with brine (25 mL), dried, filtered, and concentrated and the product purified by distillation, bp 85–87°C/10 Torr, to give the diene-ester **27**, 14.6 g (80%); ^1H nmr (CCl_4, 60 MHz) δ: 1.1–1.4 (t, 3H, J = 7 Hz, -OCH_2CH_3), 1.7 (s, 3H, CH_3-C=C), 1.4–2.3 (m, 4H, CH_2-C=, CH_2-$CHCO_2Et$), 2.7–3.1 (t, 1H, J = 7 Hz, HC-CO_2Et), 3.8–4.3 (q, 2H, J = 7 Hz, CH_2-O), 4.7–5.2 (m, 4H, H_2C=C), 5.3–6.2 (m, 1H, H-C=).

An ether solution (50 mL) containing the diene-ester **27** (18.2 g, 0.1 mol) was added dropwise, over 30 min, to a stirred ether suspension (250 mL) of $LiAlH_4$ (1.9 g, 0.05 mol). The mixture was refluxed for 50 min after addition was complete. Excess hydride was destroyed by dropwise addition of ethyl acetate, then water (100 mL) was added and the organic layer separated. The aqueous fraction was extracted with ether (2 × 30 mL), and the combined extracts were washed with 10% aqueous H_2SO_4 (50 mL), 10% aqueous $NaHCO_3$ (50 mL), and brine (50 mL). These extracts were dried, filtered, concentrated, and the product was purified by distillation, bp 66–68°C/1.2 Torr, to give the alcohol **28**, 13.7 g (98%); ir (neat): 3360 (OH), 1645 (C=C) cm^{-1}; ^1H nmr δ: 1.2–2.5 (m, 5H), 1.7 (s, 3H, CH_3-C=C), 2.8–3.1 (t, 1H, J ~ 5 Hz, HO-CH_2), 3.2–3.5 (d, 2H, J ~ 6.5 Hz, CH_2-O), 4.7–5.2 (m, 4H, H_2C=C), 5.4–6.2 (m, 1H, H-C=C).

A dichloromethane solution (2 mL) of the alcohol **28** (0.140 g, 1 mmol) was added to a stirred dichloromethane suspension (3 mL) containing pyridinium chlorochromate (PCC) (0.324 g, 1.5 mmol) and NaOAc (0.017 g, 0.2 mmol). After 1.5 h the reaction appeared complete (tlc); ether (5 mL) was added and the suspension was filtered through silica gel. The residual dark gum was triturated with ether (2 × 5 mL), filtered, and concentrated to give 0.130 g of the aldehyde **29** and the conjugated isomer (non-conjugated/conjugated aldehydes, 5:1), which were separated by chromatography on silica gel (5% ethyl acetate/petroleum ether). For **29**: ^1H nmr δ: 1.2–2.4 (m, 4H, CH_2-CH_2), 1.7 (s, 3H, CH_3-C=), 2.7–3.1 (m, 1H, H-C-C=O), 4.6–5.2 (m, 4H, H_2C=C), 5.2–6.1 (m, 1H, H-C=C), 9.4 (d, 1H, H-C=O).

2-Methyl-3-formyl-2,6-heptadiene: ir (neat): 1670 (C=O), 1640 (C=C) cm^{-1}; ^1H nmr δ: 1.8–2.5 (m, 4H, CH_2-CH_2), 1.95 (s, 3H, CH_3-C=C), 2.2 (s, 3H, CH_3-C=C), 4.6–5.2 (m, 4H, H_2C=C), 5.4–6.1 (m, 1H, H-C=C), 10.0 (s, 1H, H-C=O).

General procedure for radical generation and cyclization

A solution of tributyltin hydride (1.5 mmol) and azobis(isobutyronitrile) (AIBN) (4 mol% with respect to *n*-Bu_3SnH) in dry benzene (9 mL) was added to a refluxing benzene solution (16 mL) containing the radical precursor (1.0 mmol) at a rate of 0.49 mL/h, using a syringe pump. Reflux was continued for a total reaction time of 24–30 h. Rigorous exclusion of oxygen was found to inhibit the cyclizations and thus they were conducted open to the atmosphere. The solvent was removed and the residue purified by flash chromatography on silica gel (eluting with 5–10% ethyl acetate/petroleum ether) to afford the cyclized products. Ester hydrolysis with 5% aqueous ethanolic sodium hydroxide gave the alcohol.

*1-Methyl-2-(1-oxa-4-mercaptobutyl)cyclopentane (**5**)*: ^1H nmr (300 MHz) δ: 0.99 (d, 3H, J = 6.5 Hz, CH_3C), 1.1–1.3 (m, 2H), 1.62 (m, 4H), 1.86 (m, 2H), 2.65 (m, 2H, H_2C-S), 3.4–3.55 (m, 3H, HC-O, H_2C-O); ^{13}C nmr δ: 88.0, 70.8, 39.8, 31.8, 31.0, 24.7, 22.0, 18.8.

On the reaction of *A*-nor-5α-cholestan-2-one with benzeneseleninic anhydride

JACEK W. MORZYCKI[1] AND JOLANTA OBIDZIŃSKA
Institute of Chemistry, University of Warsaw, Bialystok Branch, Al. 1-go Maja 11/4, 15-443 Bialystok, Poland

Received July 16, 1990

JACEK W. MORZYCKI and JOLANTA OBIDZIŃSKA. Can. J. Chem. **69**, 790 (1991).

A-Nor-5α-cholestan-2-one (**1**) was oxidized with BSA under various conditions. The stoichiometric reaction afforded diketones (**3** and **4**) and α-phenylseleno-ketone (**2**) while catalytic oxidation with the BSA/$PhIO_2$/*p*-TsOH system resulted in lactones (**7***a* and **7***b*) and anhydrides (**5** and **6**). The mechanism of these reactions is discussed.

Key words: benzeneseleninic anhydride, *A*-nor-5α-cholestan-2-one, catalytic oxidation.

JACEK W. MORZYCKI et JOLANTA OBIDZIŃSKA. Can. J. Chem. **69**, 790 (1991).

On a oxydé la *A*-nor-5α-cholestan-2-one (**1**) avec de l'ABS, sous diverses conditions. La réaction stoechiométrique conduit aux dicétones (**3** et **4**) et à l'α-phénylséléno-cétone (**2**) alors que l'oxydation catalytique par le système ABS/$PhIO_2$/*p*-TsOH conduit aux lactones (**7***a* et **7***b*) et aux anhydrides (**5** et **6**). On discute du mécanisme de ces réactions.

Mots clés : anhydride benzènesélénique, A-nor-5α-cholestan-2-one, oxydation catalytique.

[Traduit par la rédaction]

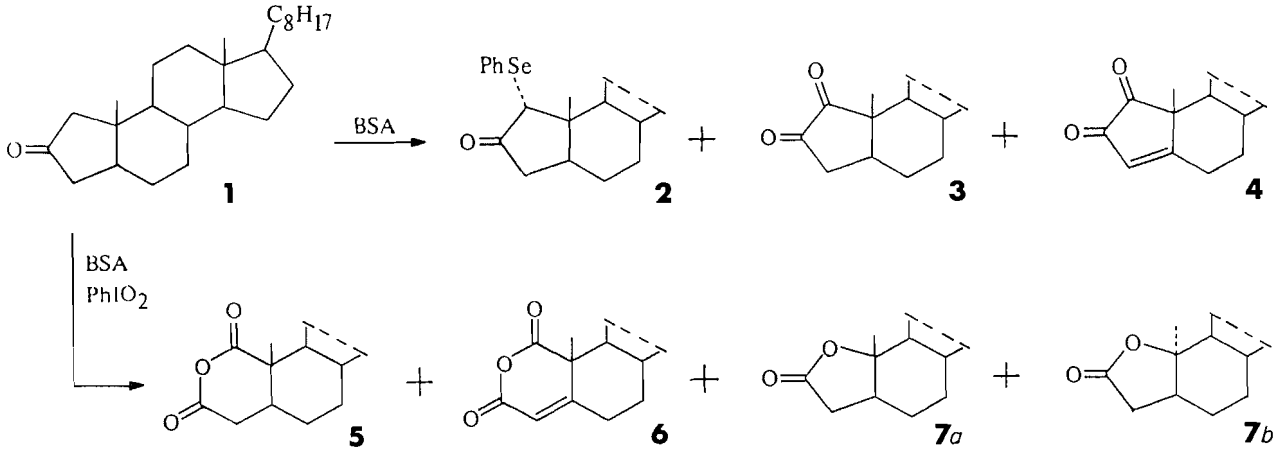
Introduction

It has previously been shown that benzeneseleninic anhydride (BSA) is an excellent reagent for dehydrogenation of ketones (1). Many biologically important steroidal cyclohexa-1,4-dien-3-ones can be obtained in high yields by dehydrogenation of the corresponding 3-oxo-steroids with BSA. Though having certain advantages over the commonly used methods employing dichlorodicyanoquinone, selenium dioxide, or bromination–dehydrobromination, the BSA method possesses two disadvantages. These are the need to use large amounts of toxic and expensive BSA, and the unwanted secondary reactions with benzeneselenenic acid or its anhydride formed in the elimination step. The development of a catalytic cycle (2, 3) based on immediate and efficient reoxidation of the reduced organoselenium species by iodoxybenzene (4, 5) obviated both these problems. Thus cyclic six-membered ketones are smoothly dehydrogenated in high yields using benzeneseleninic anhydride generated *in situ* by oxygen atom transfer from $PhIO_2$ to catalytic amounts of diphenyl diselenide. The five-membered ketones, however, are resistant (e.g., steroidal 17-ketones) to oxidation under the conditions commonly used for dehydrogenation of steroidal 3-ketones (2, 3). The examination of a reaction of *A*-nor-5α-cholestan-2-one (as a model five-membered ketone) with BSA under various conditions is the subject of this paper.

Results and discussion

It was proved that *A*-nor-5α-cholestan-2-one (**1**) is resistant to BSA in benzene at reflux. The reaction in boiling toluene is rather sluggish and gives a streak in TLC.

Further oxidations were carried out in refluxing chlorobenzene solutions. The reaction of **1** with two equivalents of BSA was quite fast and did not require acid catalysis. There were three main products of the oxidation (Scheme 1), which were separated by silica gel column chromatography: 1α-phenylseleno-*A*-nor-5α-cholestan-2-one (**2**), *A*-nor-5α-cholestane-1,2-dione (**3**), and *A*-nor-5α-cholest-3-en-1,2-dione (**4**). The structures of these products were determined on the basis of their ^1H NMR, IR, UV, and mass spectra (see Table 1 in Experimental). The data given in the literature (6) on the previously described compound **4** confirm the proposed structure. The relative yields of the isolated products **2**, **3**, and **4** were 28, 16, and 56%, respectively.



The oxidation of *A*-nor-5α-cholestan-2-one (**1**) was carried out once again using a diphenyl diselenide/iodoxybenzene system instead of BSA prepared in advance. To our surprise, completely different oxidation products were obtained than in the previous case. We also noted that the addition of *p*-toluenesulfonic acid in trace amounts leads to a faster rate of the reaction; probably for this reason the reaction is then cleaner. Strong acid activates both *A*-nor-5α-cholestan-2-one (facilitates enolization) and iodoxybenzene (protonation of the highly polarized iodine–oxygen bond reduces the kinetic activation energy barrier of oxidation). It was also found that the oxidation product distribution varies in the reactions with or without *p*-TsOH.

In a typical experiment, *A*-nor-5α-cholestan-2-one (**1**) was treated with an oxidizing mixture prepared from five equivalents of iodoxybenzene, diphenyl diselenide (0.1–0.3 equiv.), and traces of *p*-TsOH in chlorobenzene at reflux for 0.5–1 h. The main products of oxidation were identified as 1,3-seco-2-nor-5α-cholestane-1,3-dioic acid anhydride (**5**), 1,3-seco-2-nor-5α-cholest-4-en-1,3-dioic acid anhydride (**6**), and 10-hydroxy-3,10-seco-1,2-dinor-5α-cholestan-3-oic acid lactone (**7**). The last product proved to be a mixture (by ^1H NMR at 500 MHz) of 10*S* (the natural configuration) and 10*R* epimers (**7***a* and **7***b*) in a ratio 4:1. The epimeric mixture of lactones **7***a* and **7***b* can be separated by fractional crystallization from hexane (compound **7***a*) and then from acetone (compound **7***b*). The structures of the products were determined on the basis of their spectral properties (see Table 1 in Experimental), the relative yields of **5**, **6**, and **7** being 13, 24, and 63%, respectively. The oxidation of **1** carried out in the absence of *p*-TsOH afforded more of **5**, less of **6**, **7**, and a small amount of **4**.

The tentative mechanism of *A*-nor-5α-cholestan-2-one (**1**) oxidation with BSA is shown in Scheme 2. The favoured enolization of **1** is toward C-1 and this position is attacked in the first step of oxidation. It is known (7) that if carbon α to the carbonyl group is adjacent to the tertiary centre, α-hydroxylation with BSA takes place instead of dehydrogenation. However, under the reaction conditions (excess of the oxidizing agent, high temperature of the reaction) α-hydroxylation is followed by immediate further oxidation with BSA to α-diketone (**3**). This compound appeared to be a minor product of the reaction with

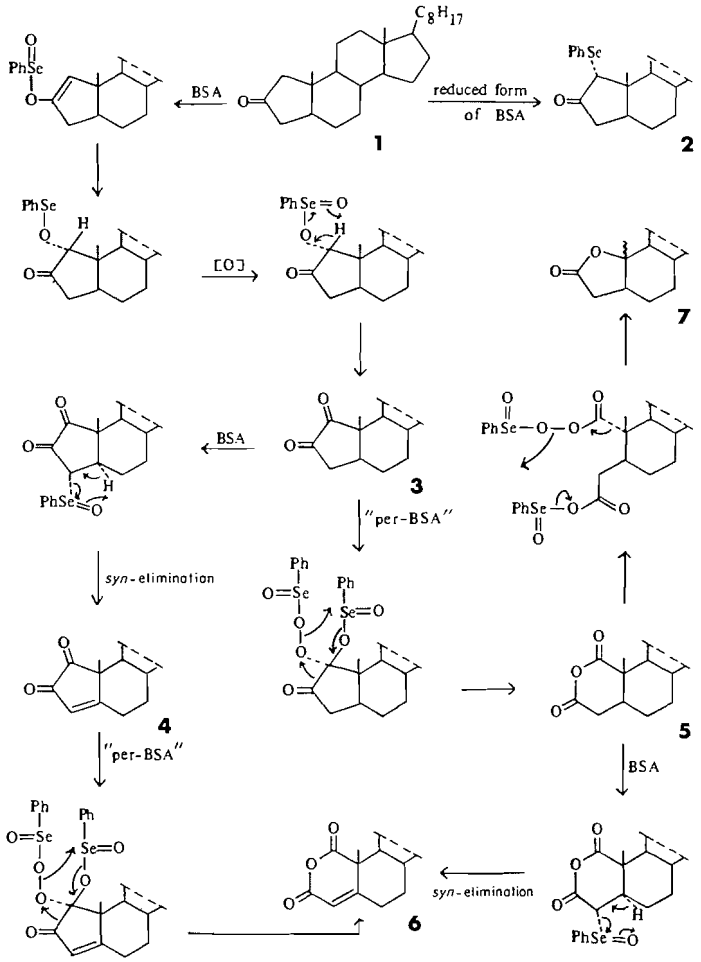
SCHEME 1



BSA alone but it was not present among the products of oxidation by the catalytic method. This is due to the high reactivity of this intermediate. In the stoichiometric reaction it is then dehydrogenated to the major product, *A*-nor-5α-cholest-3-en-1,2-dione (**4**). The third product of the oxidation, α-phenylselenoketone **2**, is formed from the reaction of **1** with a reduced form of BSA. Products of this type have never been obtained in catalytic BSA oxidations because all reduced forms of the anhydride are immediately reoxidized by iodoxybenzene. It was shown that both 1,2-dicarbonyl compounds **3** and **4** undergo further oxidation in the BSA/$PhIO_2$ system, under the reaction conditions, to the corresponding anhydrides **5** and **6**. Blank experiments proved that this transformation cannot be accomplished when using benzeneseleninic anhydride or iodoxybenzene separately. It is known (8) that α-diketones are oxidized to anhydrides with peroxycarboxylic acids. We assume that a certain peroxy species "per-BSA" is formed in a low concentration in the BSA/$PhIO_2$ system at 132°C. An alternative structure for per-BSA with Se(VI) may also be considered. All our attempts to isolate and identify this species failed. It is possible that the same per-BSA is responsible for further oxidation of anhydride **5** to the major product **7**. It was found in a separate experiment that **5** is a precursor of both lactones (**7***a* and **7***b*) and unsaturated anhydride **6**. Presumably a mixed anhydride is formed from **5** and per-BSA. This intermediate loses carbon dioxide to afford a carbocation at C-10. A similar mechanism has been proposed (9) for oxidation of 1,3-seco-2-nor-5α-cholestane-1,3-dioic acid to the same mixture of lactones with lead tetraacetate. The unsaturated anhydride **6** proved resistant to this type of transformation under the reaction conditions.

The following conclusions can be drawn from the experiments described:

1. The five-membered ketone **1** cannot be dehydrogenated with BSA (either by using stoichiometric amounts of BSA or by the catalytic method).

2. *A*-Nor-5α-cholestan-2-one (**1**) undergoes oxidation with BSA in both systems at 132°C but the reaction is not of any great practical importance.

3. The BSA/$PhIO_2$ (with or without *p*-TsOH) system is not always equal to BSA alone and special attention has to be paid to the reactions performed at a higher temperature. It is very likely that a highly reactive, more oxidated, species (per-BSA) is formed under these conditions.

SCHEME 2

Experimental

NMR spectra were taken with AM-500 Bruker and Gemini 200 Varian spectrometers using $CDCl_3$ solutions with TMS as an internal standard. Infrared spectra were recorded on a Specord 75 IR as CCl_4 solutions or as KBr pellets. Mass spectra were obtained at 110–120°C above ambient temperature at 70 eV with a LKB GCMS 2091 spectrometer. Ultraviolet absorption spectra were recorded in absolute ethanol with a Specord UV–VIS recording spectrometer. High-

pressure liquid chromatography was performed on a Laboratorni Pristroje Praha liquid chromatograph equipped with an LCD 2563 UV detector and a RIDK-102 differential refractometer unit. Column chromatography was performed on silica gel 70–230 or 230–400 mesh ASTM (Merck). Thin-layer chromatograms were developed on aluminium TLC sheets precoated with silica gel F_{254} and visualized with 50% sulfuric acid after heating. All solvents were dried and freshly distilled prior to use. The starting *A*-nor-5α-cholestan-2-one (**1**) was prepared analogously to the procedure described in ref. 10. Benzeneseleninic anhydride (BSA) was obtained (11) from diphenyl diselenide (Aldrich) by nitric acid oxidation followed by dehydration at 120°C. For preparation of iodoxybenzene a direct method (3), sodium hypochlorite oxidation of iodobenzene in acetic acid solution, was used (see also ref. 12).

Stoichiometric oxidation with BSA (typical procedure)

A solution of *A*-nor-5α-cholestan-2-one (372 mg, 1 mmol) and BSA (720 mg, 2 mmol) in chlorobenzene (15 mL) was refluxed under an argon atmosphere for 45 min. After cooling, the reaction mixture was filtered through a silica gel (70–230 mesh) column, washed with hexane to remove chlorobenzene, and then with benzene. The benzene fractions were combined, the solvent was evaporated under reduced pressure, and the residue was subjected to rechromatography (silica gel 230–400 mesh). Compounds **2**, **1** (starting material), **3**, and **4** were eluted consecutively with benzene–hexane mixtures.

Catalytic oxidation with BSA and iodoxybenzene (typical procedure)

The oxidizing mixture, consisting of diphenyl diselenide (78 mg, 0.25 mmol), iodoxybenzene (1180 mg, 5 mmol), and trace amounts of *p*-toluenesulfonic acid in chlorobenzene (20 mL), was intensively stirred and heated under reflux until the yellow colour disappeared (about 2 min; in the absence of *p*-TsOH, 10 min).

To the above mixture *A*-nor-5α-cholestan-2-one (372 mg, 1 mmol) was added, stirring was continued, and the reaction mixture was refluxed under an argon atmosphere for 45 min (in the absence of *p*-TsOH, for 1.5 h). After cooling, the reaction mixture was filtered through a silica gel (70–230 mesh) column, washed with hexane to remove chlorobenzene, and then with benzene. The benzene fractions were combined, the solvent was evaporated under reduced pressure, and the residue was subjected to rechromatography (silica gel 230–400 mesh). Compounds **5**, **1** (starting material), **6**, **7** (a mixture of C-10 epimers) were eluted consecutively with benzene–hexane mixtures (in the absence of *p*-TsOH after elution of **7**, a trace amount of compound **4** was also eluted with benzene).

Chiral recognition in aqueous solutions at 25°C. A calorimetric study of the interaction between enantiomeric α-amino acids of different alkyl chain length

GIUSEPPINA CASTRONUOVO,[1] VITTORIO ELIA, AND MICHELA MAGLIULO
Department of Chemistry, University "Federico II" of Naples, Via Mezzocannone 4, 80134 Naples, Italy

Received January 10, 1990[2]

GIUSEPPINA CASTRONUOVO, VITTORIO ELIA, and MICHELA MAGLIULO. Can. J. Chem. **69**, 794 (1991).

Cross-homo- and cross-heterotactic enthalpic coefficients, $h_{x_Dy_D}$ or $h_{x_Ly_L}$ and $h_{x_Dy_L}$ respectively, were determined at 25°C, measuring the enthalpies of dilution of ternary aqueous solutions containing two different α-amino acids of the same or different chirality. Differences of about 200–300 J mol^{-2} kg between cross-homo- and cross-heterotactic coefficients were found, well beyond the experimental uncertainty. The role of the zwitterionic interaction, already proposed to explain the nature of chiral recognition, was strengthened.

Key words: α-amino acids, excess enthalpy, chiral recognition.

GIUSEPPINA CASTRONUOVO, VITTORIO ELIA et MICHELA MAGLIULO. Can. J. Chem. **69**, 794 (1991).

Opérant à 25°C et faisant appel à des mesures d'enthalpie de dilution de solutions aqueuses ternaires contenant deux acides α-aminés différents dont la chiralité est la même ou différente, on a déterminé les coefficients enthalpiques homo- et hétéro-tactiques croisés, respectivement $h_{x_Dy_D}$ ou $h_{x_Ly_L}$ et $h_{x_Dy_L}$. On a trouvé des différences d'environ 200–300 J mol^{-2} kg entre les coeffiients homo- et hétéro-tactiques croisés; ces différences sont beaucoup plus grandes que les incertitudes expérimentales. Le rôle de l'interaction zwitterionique, qui a déjà été proposé pour expliquer la nature de la reconnaissance chirale, est affirmé.

Mots clés : acides α-aminés, enthalpie en excès, reconnaissance chirale.

[Traduit par la rédaction]

Introduction

Differences in the thermodynamic properties of aqueous solutions containing two optically active solutes often cannot be distinguished. However, these differences in the excess properties, which depend on the interactions between solvated solutes (solute–solute interactions), must in principle be expected.

In recent years a number of papers have appeared concerning the possibility of demonstrating chiral recognition in aqueous solutions by means of calorimetric (1–6) or volumetric (7) techniques. Stereoselective interactions were identified for the first time for aqueous solutions of uncharged amide derivatives of some amino acids and dipeptides (3). Recently, the attractive interaction between the zwitterions present in aqueous solutions of α-amino-acids has been proposed as the main contribution to chiral recognition (1, 8). That is, the favourable electrostatic zwitterion–zwitterion interaction makes more probable one of the possible orientations responsible for chiral recognition in aqueous solutions. When the attractive interaction between the dipolar ions disappears, for instance for the protonation of the COO^- group, chiral recognition does not occur (8). Moreover, analysis of the enthalpic pairwise coefficients, by means of a group additivity approach (9), reveals a dramatic change in the prevailing mechanism of interaction when the electrostatic interactions are perturbed. The aim of the present work is to gain more information about the factors that determine chiral recognition, by studying the interactions, in aqueous solutions, between optically active α-amino acids bearing different alkyl chains (alanine, α-aminobutyric acid, valine, norvaline, leucine, isoleucine, norleucine). The pairwise interaction coefficients of the excess enthalpies are evaluated from the enthalpies of dilution of ternary solutions containing the same or different chiral forms of two different α-amino acids.

Experimental

Materials and methods

Amino acids (Sigma) were of the highest purity commercially available. Tests of purity for these substances were extensively reported in a preceding paper (1). Solutions were prepared by weight using double distilled water. The heats of dilution were measured by means of an LKB standard flow microcalorimeter at 25°C. Details of the experimental procedure are reported in the literature (10–13).

Thermodynamic treatment

The excess enthalpy of a solution is defined as (14):

$$[1] \quad H^E = H - H_w^0 - \Sigma_x m_x \bar{H}_x^0$$

The symbols have the usual meaning: H is the total enthalpy referred to 1 kg of solvent, H_w^0 the standard enthalpy of 1 kg of solvent, $\bar{H}_x^0$ the limiting partial molal enthalpy of the solute x. H^E, as any thermodynamic property, can be expressed as a virial expansion of the molalities as follows:

$$[2] \quad H^E = \Sigma_x \Sigma_y h_{xy} m_x m_y + \text{higher terms}$$

The pairwise coefficients appearing in eq. [2] represent the enthalpic contribution to the free energy coefficient for pair and higher order interactions (14–17). They give information about all the variations of the thermodynamic function when two isolated molecules are brought together to interact (18). The enthalpies of dilution of a solution containing n solutes can be expressed as a function of the interaction coefficients and as a function of the excess enthalpies as follows:

$$[3] \quad \Delta H^{dil} \quad (\text{J/kg}) = H^E(\bar{m}\ ) - (m_x^f/m_x)\, H^E(\bar{m}^f) = \Sigma_x \Sigma_y h_{xy} m_x^f m_y^f - (m_x^f/m_y)\, \Sigma_x \Sigma_y h_{xy} m_x m_y + \ldots$$

where m_x, m_y,..., m_x^f, m_y^f..., are the molalities of each solute before and after the process of diluting the ternary solution and $\bar{m} = \Sigma_x m_x$, $m^f = \Sigma_x m_x^f$ are the osmolalities.

[b]The values for the self-coefficients are from ref. 1.
[c]This work.

Usually, an auxiliary function ΔH^{n}* (8) is used, which is the difference between the enthalpy of dilution of a solution containing n solutes and the sum of the enthalpies of dilution of the solutions containing each solute:

[4] $$\Delta H^{n}* = \Delta H^{\mathrm{dil}}(\bar{m}) - \Sigma \Delta H^{\mathrm{dil}}(m_x)$$

where $\bar{m}$ is the osmolality of the solutions. For a ternary solution, in the case where only pairwise coefficients are needed to obtain the best fit of the experimental data, the auxiliary function is given by:

[5] $$\Delta H^{**}(x,y) = \Delta H^{\mathrm{dil}}(x,y) - \Delta H^{\mathrm{dil}}(x) - \Delta H^{\mathrm{dil}}(y) = 2h_{xy}m_x^{\mathrm{f}}(m_y^{\mathrm{f}} - m_y)$$

For the sake of clarity, since the solutes used in the ternary solutions are different with respect to chirality, we are forced to introduce more complex symbols to define cross-coefficients. Thus, the interaction coefficient characterizing the ternary solution of a solute x in the D chiral form and of a solute y in the D chiral form, $h_{x_{\mathrm{D}}y_{\mathrm{D}}}$, will be defined as a cross-homotactic coefficient. The interaction coefficient between the two solutes x and y in different chiral sequence, $h_{x_{\mathrm{D}}y_{\mathrm{L}}}$, will be defined as a cross-heterotactic coefficient.

Results

The calorimetric experimental data, from which the enthalpic interaction coefficients are derived, have been deposited as supplementary material.[3]

In Table 1 the cross-homotactic and the cross-heterotactic coefficients, $h_{x_{\mathrm{D}}y_{\mathrm{D}}} = h_{x_{\mathrm{L}}y_{\mathrm{L}}}$, $h_{x_{\mathrm{D}}y_{\mathrm{L}}}$ respectively, are reported for all the α-amino acids studied, together with the values of the self- (homo and hetero) coefficients taken from the literature (1).

[3]Complete tables of the auxiliary function ΔH^{**} for the ternary solutions (each containing two different amino acids of the same or different chirality), along with the initial and final concentrations of each substance for every experiment, have been deposited, and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, Canada K1A OS2.

The self-homotactic coefficients ($h_{x_{\mathrm{D}}x_{\mathrm{D}}} = h_{x_{\mathrm{L}}x_{\mathrm{L}}}$) increase with increasing alkyl chain length, as do the self-heterotactic ones ($h_{x_{\mathrm{D}}x_{\mathrm{L}}} = h_{x_{\mathrm{L}}x_{\mathrm{D}}}$). For leucines the latter are smaller than the self-homotactic values, beyond the experimental uncertainty, thus indicating that chiral recognition occurs (1). The same happens for the cross-homotactic coefficients ($h_{x_{\mathrm{D}}y_{\mathrm{D}}}$), which are always higher than the corresponding cross-heterotactic ones ($h_{x_{\mathrm{D}}y_{\mathrm{L}}}$). In the case of the system norleucine/leucine, the difference between the cross-homo- and the cross-heterotactic coefficient reaches the highest value found in the literature (319 J mol^{-2} kg).

In Fig. 1, part A, the self- and cross-homotactic coefficients for the amino acids bearing linear alkyl chains are reported as a function of the half-sum of the aliphatic carbon atoms present on both molecules. A linear trend is obtained, as described by the following equation:

[6] $$h_{x_{\mathrm{D}}y_{\mathrm{D}}} = -798(61) + 445(18)\, n_{\mathrm{C}}$$

where $n_{\mathrm{C}} = 1/2\,(n_{\mathrm{C}}^{x} + n_{\mathrm{C}}^{y})$ and the figures in parentheses are the 68% confidence limits.

In the same figure, part B, the self- and cross-heterotactic coefficients are reported for the same linear α-amino acids against the same abscissa. Again a linear trend is obtained, whose equation is

[7] $$h_{x_{\mathrm{D}}y_{\mathrm{L}}} = -758(73) + 411(21)\, n_{\mathrm{C}}$$

It is worthwhile to emphasize that, for systems corresponding to the same abscissa (norvaline/aminobutyric acid and norleucine/alanine, norvaline/norvaline and norleucine/aminobutyric acid, aminobutyric acid/aminobutyric acid and norvaline/alanine), the coefficient is smaller for the system showing the greater difference between the length of the alkyl chains.

Discussion

The experimental data concerning dilute solutions can be rationalized using a simple model that postulates the overlap of the cospheres of solvated molecules (14) with subsequent release of the solvent to the bulk. This model qualitatively

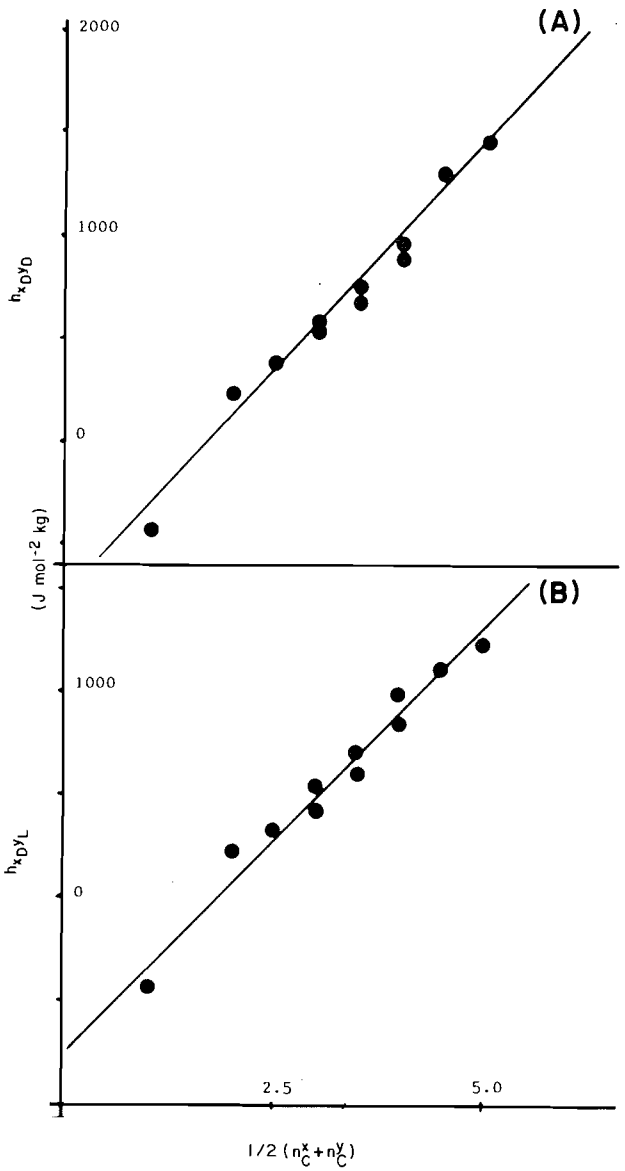

FIG 1. Self- and cross-homotactic (Part A) or self- and cross-heterotactic (Part B) enthalpic interaction coefficients vs. the half-sum of the number of aliphatic carbon atoms for α-amino acids bearing linear alkyl chains.

accounts for the sign, and to some extent for the magnitude, of the parameters that are used to characterize such "non-bonding" interactions, namely, the interaction coefficients of the virial expansion of the excess thermodynamic properties. More elaborate models have been proposed to gain a deeper insight into the interactions in these solutions. For instance, the Savage and Wood group additivity approach (SWAG) (9) considers the overall pairwise coefficient as due to additive contributions of the groups into which a molecule can be divided. However, if the SWAG approach is applied to positional isomers or stereoisomers, it obviously fails. This work, which continues a series of papers concerning enthalpic and volumetric differences between the pairwise coefficients of positional isomers (19–21), configurational isomers (22), and stereoisomers (1, 2, 4, 5, 7, 8), emphasizes that, for non-bonding interactions, preferred orientations of the interacting molecules play a major role.

For α-amino acids in aqueous solution at room temperature, hydrophobic interactions have been found to be negligible compared to the mixed interactions between zwitterions and alkyl chains (1, 8). This has been the main factor leading to the hypothesis that the most probable orientation is the one that allows the opposite charges of the zwitterions to interact. Inspection of molecular models shows that in this orientation both alkyl chains belong to the same half-space, when the two molecules are of the same chirality (cross- or self-homotactic interaction). Obviously, the opposite occurs for two molecules of different chirality (cross- or self-heterotactic interaction). The two different reciprocal positions of the alkyl chains in this orientation must play an important role in differentiating the interaction between stereoisomers. Also, the homotactic interaction coefficients are expected to be systematically larger than the heterotactic ones, because of the better juxtaposition of the hydrophobic alkyl chain cospheres for the homo interactions in this orientation. This is what actually happens (see Table 1). In fact, the cross-homotactic coefficients ($h_{x_D y_D}$) determined here are always larger than the corresponding cross-heterotactic ones ($h_{x_D y_L}$). It is important to point out that this orientation is not the only one that contributes to build up the pairwise coefficients or the difference between steroisomers, but it is the orientation that prevailingly contributes to chiral recognition.

As shown by the enthalpic (8) and volumetric (7) excess properties data, chiral recognition disappears when pure water is replaced by H_2O/HCl (1 M) mixed solvent. In the latter medium, the attractive dipolar interaction working in pure water is replaced by the +/+ repulsive interaction. Thus it seems that favourable interaction between zwitterions is needed for chiral recognition or, more generally, a "forced" orientation enhancing steric differences is necessary to detect chiral recognition in aqueous solutions or to make evident differences in excess enthalpies of aqueous solutions of positional, configurational, and stereo isomers. An analysis of the enthalpic data by means of the SWAG approach, restricted to homologous series of α-amino acids in water and in the mixed solvent (1 M, H_2O/HCl), indicates the changes in the interaction mechanism in the two solvents (8). However, this approach can give only qualitative indications, because the presence of a forced orientation is in contrast with the SWAG statistical principle. Then in the mixed solvent the absence of the "forced head–head" (+/−, +/− favourable interaction) orientation, substituted by the "side-on" (-COOH, -COOH and hydrophobic–hydrophobic interaction) orientation (19), could be the most significant process that cancels out the differences between stereoisomers. As reported in Fig. 1, the self- and cross-homotactic coefficients of the linear amino acids increase linearly with the half-sum of the number of the aliphatic carbon atoms present on both molecules. The linear dependence is a clear indication that the CH_2–CH_2 interaction is not cooperative. In fact, the trend should depend on the sum of both hydrophobic and mixed interactions, the first having a quadratic dependence on the number of aliphatic carbon atoms and the latter proportional to the number of carbon atoms. Probably the zwitterion–zwitterion interactions compete with the mixed and with the hydrophobic ones, so that the cooperativity of the hydrophobic interaction is attenuated. For α-amino acids in the HCl/H_2O mixed solvent, the hydrophobic interactions are instead found to prevail because of the disappearance of the favourable zwitterion–zwitterion interaction. In this case the homotactic coefficients show a quadratic dependence on the number of aliphatic carbon

atoms (8):

$$[8] \quad h_{x_D x_D} = -256(56) + 64(4)\, n_C^2$$

On the other hand, it has been found that for alkane-1,2-diols, a linear trend is obtained when the enthalpic self-coefficients are plotted against the third power of the number of aliphatic carbon atoms, thus indicating that the CH_2–CH_2 interaction is more than statistical. Therefore, in some way, it is a forced interaction and the CH_2–CHOH interaction is negligible. This and other considerations led to the hypothesis that there is a double simultaneous interaction between the hydroxyl groups that makes the interaction between the hydrophobic groups more effective (19, 20).
