Incorrect use of the three types of variables can cause unnecessary data scatter and some confusion. For example, hydrogen-bonded structure formation (12) might cause a sorption rate constant to be a function of the mole fraction of the sorption sites covered by pesticide molecules. A plot of the rate constants for several soils against pH would likely show excessive data scatter. At one and the same pH, different soils would have different numbers of protonated carboxyl groups and therefore different mole fractions of their sites covered. The outer variable pH would be no more than a pale, indirect reflection of the correct inner variable — the mole fraction of the sorption sites covered. If in this case pH were used for an empirical black box correlation, the resulting fitted curve would represent only the particular experiment from which it had come. Because it would not represent the actual molecular level phenomena, it would lack the generality necessary for good predictive calculations. For the above reasons, it is important to compare experimentally measured dependent variables with the proper independent variable or at least be aware of the danger of using a variable from the wrong category.

Materials and methods

The reagents, New Brunswick mineral soil, and the adaptation of the speciation–kinetics method to the mineral soil are reported in a separate article (2).

Results and discussion

The fraction of acidic sites on mineral soil that is available for binding atrazine was calculated. It was observed that about 0.44 mol% of the carboxyl groups accounted for the experimentally observed sorption on both mineral soil and dissolved fluvic acid while humic acid gave the higher value of 1.1 mol% (2). Since the value for the soil is less than the value for humic acid this observation is consistent with the postulate that a fraction of the humic acid carboxyl groups in the soil was the primary cause of atrazine sorption.

Sorption capacities are unavailable for the humic acid and organic soil used in previous studies (3, 6). It is important, however, to test the results for generality. Demonstration values have therefore been obtained for the humic acid and organic soil. This was done for the hypothetical case of 1 mol% of carboxyl groups available as sorption sites. Table 1 presents these estimates. The comparison of sorption capacities for different types of soil and organic matter warrants further investigation.

A number of authors have reported pesticide–soil sorption equilibration times that range from hours to weeks (10, 14–16). The sorption process has usually been assumed to follow first-order kinetics (15). According to the rate-law expressions previously developed (eqs. [8]–[13]) the kinetics are intrinsically second order, but should be pseudo-first order under appropriate experimental conditions. Figure 1 shows results of kinetic experiments obtained using the HPLC-microfiltration method (2) for the present case. The second-order rate constant k_{B1} has been calculated from these data. Any apparent deviation from linearity is less than the experimental errors. The function $F(t)$ is defined by eq. [13], and the calculations were done with a spreadsheet. The most general case is that the k_{B1} rate constants calculated as described above should depend on the mole fraction of sorption sites covered, because the sites would have a mixture of structural and chemical properties. Figure 2 shows that k_{B1} is dependent on the mole fraction of sorption sites covered. Duplicate subsaturation experiments, having site coverage of about 2 mol%, gave k_{B1} values an order of magnitude

greater than the saturation experiments also shown in Fig. 2. For comparison, a value from previous organic soil work (3) has been added. Now that the effectiveness of the experimental method has been demonstrated, it should be possible to check the generality of this trend and to map it out over the whole range of site coverages. That would permit the extrapolation of laboratory measurements to field conditions.

The pseudo-first order rate constant k_{S1} for atrazine sorption is inherently less rigorously correct than the second-order constant k_{B1}, especially at high site loadings. Figure 3 shows the plot of k_{S1} vs. χ_1 which is useful for two reasons. One is that the data scatter is less because of the partial cancellation of measurement errors. The other is that it provides a fast, convenient way of estimating sorption half-lives. The resulting list of sorption half-lives in Table 2 demonstrates a strong dependence on site loading. Two practical implications must be emphasized. The first is that sorption equilibrium is not instantaneous. The second is that any attempt to use a single, all purpose "black box" value of the half-life for modelling would almost certainly give flawed model predictions. The reason is that numerical values of the half-life would usually be wrong. The comparison of k_{S1} with k_{B1} can be made by multiplying k_{B1} by the number of vacant sorption sites in the slurry. For this mineral soil the sorption capacity is 6.56×10^{-7} mol/g of soil and the slurry contains 20 g of soil/L of water. Comparison shows that the k_{S1} value is dependent on the W_S/V_S ratio, and is thus an artifact of the experimental method.

The first-order rate constant for atrazine desorption in Fig. 4 has an appearance very similar to that of the first-order sorption rate constant. Desorption is evidently faster, however, as is indicated by the desorption half-lives in Table 3.

Perdue and Wolfe (11, 12) presented both theory and ex-

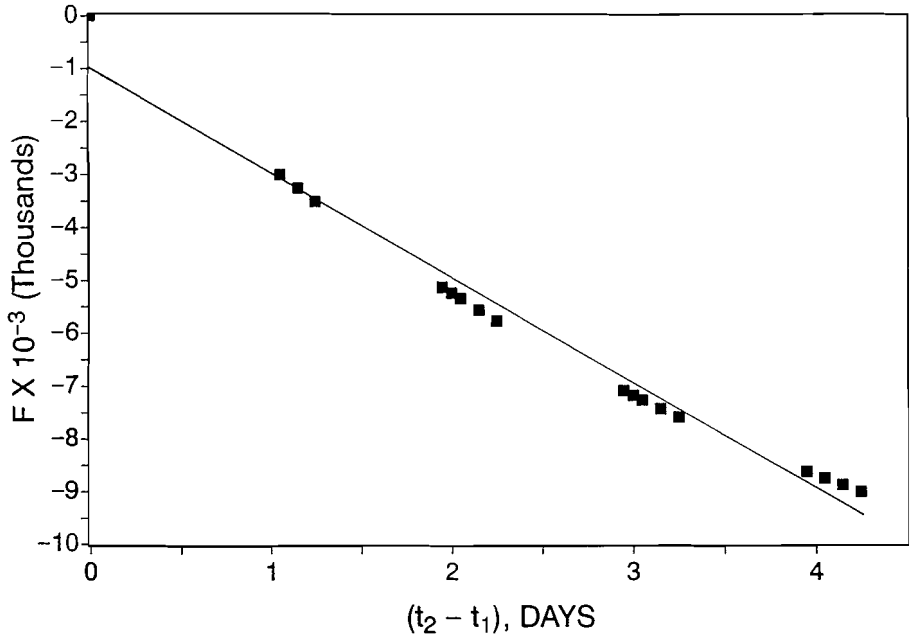

FIG. 1. Kinetic plot for atrazine sorption in a site saturation experiment. The slope gives the second-order rate constant, k_{B1}, at 25.0°C. The plot is based on eq. [12], with F defined by eq. [13].

perimental proof for the Brönsted acid catalyst properties of humic carboxyl groups. The pseudo-first-order rate constants for atrazine hydrolysis catalysed by humic carboxyl groups determined in this work are given in Table 4, together with K_A estimated for the corresponding soil. Table 4 shows that the higher K_A value of the organic matter gives a higher rate constant for atrazine hydrolysis which is consistent with the work of Perdue and Wolfe. The above correlation suggests that the Brönsted acid catalyst properties of the humic carboxyl groups in mineral soils should be systematically measured for correlation to the hydrolysis of atrazine. There is a possibility that this could contribute to the development of practical methods for predictive calculations. If hydroxyatrazine desorption were sufficiently fast

relative to its rate of production on the catalytic sorption sites, then its apparent rate constant k_{p3} would be described by eq. [18]:

$$[18] \quad k_{p3} = \left(\frac{W_S}{V_S}\right) \bar{K}_2 \theta_0 k_{r2}$$

There are three reasons why k_{r2} cannot at present be calculated from k_{p3} using eq. [18]. The first is that there is some doubt about whether the hydrolysis reaction rather than the desorption is rate determining in this case. The next reason is that the sorption sites and sorption capacity might very well be different from those for atrazine, and the chemical reaction did not produce enough hydroxyatrazine to saturate its sorption sites. The θ_c value for hydroxyatrazine could therefore not be measured. The third reason is a consequence of the other two. Without a numerical value for θ_c, $\bar{K}_2$ cannot be calculated. The apparent k_{p2} listed in Table 4 cannot of course be compared directly with k_{r2}.

Systematic material balance losses were always observed

in atrazine experiments with both the mineral soil used in the present study and the organic soil described earlier (3). As with the previous organic soil the loss was found, within the limits of analytical chemical errors, to be a linear function of time. While the site saturation experiments gave only qualitative results, the duplicate subsaturation experiments produced the rates, which compare favorably with each other as shown in Table 5. A ^{14}C atrazine experiment with the New Brunswick soil gave qualitative confirmation of the data in Table 5. Also, the use of a ^{14}C labelled atrazine sample in the organic soil experiments gave evidence that the material balance loss corresponded to a bound residue. While it might be thermal diffusion into the interiors of particles as some authors have suggested, the nature of this phenomenon requires further investigation.

Hydrology models such as those investigated by Villeneuve *et al.* (1) typically have two empirical parameters with which to account for the distribution of species and the rate of reaction. The distribution coefficient K_D, unlike the law of mass action function $\bar{K}_1$, does not account for changes in either sorption capacity or site coverage and thus leads to unnecessary data scatter. Use of $\bar{K}_1$ and its quantitative relationship to K_D should lead to a substantial reduction in data scatter. The other parameter is the rate constant k for the loss of a chemical species from solution. Without quantitative knowledge of the sorption, desorption, and catalysed chemical reaction rates, changes in these rates under field conditions cannot be predicted from laboratory column experiments. The practical solution to this problem is to develop mathematical equations that describe this k in terms of the quantitative behavior of the rate constants for sorption, desorption, and chemical reactions. The present work describes the sorption equilibrium function, sorption and desorption rate constants, and a pseudo-first-order reaction rate constant which results in a substantial reduction in data scatter and provides practical solutions for making the hydrology models more effective for prediction.

Future research should seek to determine the exact effects of humic carboxyl K_A values and sorption site loading on the various sorption and chemical reaction parameters. Much more information is needed on the relationship between sorption capacities and numbers of protonated carboxyl groups. In addition, the secondary effects of clays on the parameters should be assessed.

Mathematical analysis of reactive ion transport in dynamic equilibrium: The case of two ionic species

KOICHI IINUMA AND MASAHIRO TAKEBE
Department of Nuclear Engineering, Tohoku University, Sendai 980, Japan

Received August 19, 1991

KOICHI IINUMA and MASAHIRO TAKEBE. Can. J. Chem. **70**, 1604 (1992).

An exact solution for the transport of two reacting ion species in a drift tube is developed. The calculation of the temporal variation of ion fluxes is simplified using an approximate formulation in terms of the reaction frequencies, drift velocities, and longitudinal diffusion coefficients. The exact and approximate formulations are compared for the case of $(N_2^+, N_4^+)/N_2$ with a view to establishing the approach to equilibrium.

KOICHI IINUMA et MASAHIRO TAKEBE. Can. J. Chem. **70**, 1604 (1992).

On a développé une solution exacte pour le transport de deux espèces ioniques qui réagissent dans un tube à déplacement. Utilisant une formulation approximative en termes de fréquences de réaction, de vitesses de déplacement et de coefficients de diffusion longitudinaux, on a simplifié le calcul de la variation des flux ioniques en fonction du temps. Dans le but d'établir l'approche à l'équilibre, on a comparé les formulations exactes et approximatives pour le cas du $(N_2^+, N_4^+)/N_2$.

Introduction

The drift tube technique is a standard time-of-flight method for ion swarm experiments, where an instantaneous burst of ion swarms is released from a source and travels through the gas under the influence of an external electric field applied in a cylindrical tube. The times of arrival of the ions at the detector are measured and the data accumulated over many cycles until a statistically satisfactory spectrum of arrival times is obtained. Dynamic equilibrium is the final phase of the space-time evolution of interreacting ion swarms, where they reach stationary concentrations because of the dynamic balance between the forward and reverse reactions occurring in the system. One often observes in drift-tube experiments with mass spectrometers that the arrival time spectra (ATS) in this phase have similar Gaussian profiles at the same position with the same full width at half-maximum (FWHM). This similarity of profiles occasionally makes it difficult to determine accurately the kinetic coefficients of each ionic species. Another experimental difficulty arises from the fact that the profiles start to broaden so that the current intensities become much smaller than those in the nondynamic equilibrium phase. These difficulties have forced experimentalists to conclude that analysis in dynamic equilibrium should not be expected to be valid for determination of transport coefficients and that it is even incapable of fixing the forward and reverse reaction rates (see ref. 1 pp. 40–51 and the references cited therein). The conclusion is theoretically attributed to insufficient quantitative understanding of the ion-swarm behavior subject to inseparable interplay between their transport properties and reactions. If a better mathematical formulation is established, it may give us new insights that we have overlooked in the past in the analysis of reactive ion transport.

We recently developed a general solution of the coupled transport equations for the analysis of multiple ion swarms in gases (2). A noteworthy result derived therefrom is that any information on the initial conditions including flux will vanish completely in the dynamic equilibrium phase. This is useful in drift-tube analysis because the kinetic coefficients only characterize the shape and width of the ATS. Neither the initial number density of the ionic species, nor the geometrical form of an initial pulse of the ion swarm, need be considered. For this purpose we have explicitly derived the analytical expression of the ATS of two ionic species according to the general solution. This expansion–truncation technique is rather tedious, but an approximate solution yields surprisingly accurate profiles in the limit of infinite drift distance. This paper compares the approximate and exact solutions including a number of related formulas and their application to the $(N_2^+, N_4^+)/N_2$ system.

General analysis of two ion swarms

The general scheme of reactions of two ionic species is depicted as follows:

$$[1] \qquad \rho_1 \underset{\alpha_{12}}{\overset{\alpha_{21}}{\rightleftharpoons}} \rho_2$$

where ρ_1 and ρ_2 are the number densities of first and second species, respectively, and α_{ij} is the reaction frequency from species j to i ($i, j = 1, 2; i \neq j$). The space-time behavior of two ion swarms is governed by a coupled transport equation,

$$[2] \qquad \begin{cases} \dfrac{\partial \rho_1}{\partial t} = \nabla \cdot (\mathbf{D}_1 \cdot \nabla \rho_1) - v_{d1} \cdot \nabla \rho_1 - \alpha_{21}\rho_1 + \alpha_{12}\rho_2 \\ \dfrac{\partial \rho_2}{\partial t} = \nabla \cdot (\mathbf{D}_2 \cdot \nabla \rho_2) - v_{d2} \cdot \nabla \rho_2 - \alpha_{12}\rho_2 + \alpha_{21}\rho_1 \end{cases}$$

where $\mathbf{D}_i$ and v_{di} are the diffusion tensor and the drift velocity of the ith species, respectively. By introducing cylindrical coordinates (r,z) where the z axis is chosen to lie in the electric field direction, and using the method of separation of variables, we represent the solution as

$$[3] \qquad \rho_i(\boldsymbol{r},t) = \sum_{m=1}^{\infty} a_{im} J_0\left(\frac{\beta_m r}{r_0}\right) Z_{im}(z,t)$$

where a_{im} are constants to be determined from the initial

conditions, J_0 is the zeroth-order Bessel function, β_m is the mth root of the Bessel function, and r_0 is the drift-tube radius. Following the mathematical procedure in ref. 2, we solve the partial differential equation of $Z_{im}(z,t)$ by means of a Fourier transform. The solution is

$$[4] \quad Z_{im}(z,t) = \frac{1}{2\pi}\int_{-\infty}^{\infty} \mathcal{Z}_{im}(\omega,t)\exp(\iota\omega z)\,d\omega$$

where ι is the imaginary unit and

$$[5] \quad \mathcal{Z}_{1m}(\omega,t) = \frac{N_1(\lambda_1 - T_2) + N_2\alpha_{12}}{\lambda_1 - \lambda_2}\exp(\lambda_1 t) + \frac{N_1(\lambda_2 - T_2) + N_2\alpha_{12}}{\lambda_2 - \lambda_1}\exp(\lambda_2 t)$$

$$[6] \quad \mathcal{Z}_{2m}(\omega,t) = \frac{N_2(\lambda_1 - T_1) + N_1\alpha_{21}}{\lambda_1 - \lambda_2}\exp(\lambda_1 t) + \frac{N_2(\lambda_2 - T_1) + N_1\alpha_{21}}{\lambda_2 - \lambda_1}\exp(\lambda_2 t)$$

N_1 and N_2 are the transformed initial conditions of the first and second species, respectively, and λ_1 and λ_2 are

$$[7] \quad \lambda_{1,2} = \frac{[T_1 + T_2 \pm \sqrt{(T_1 - T_2)^2 + 4\alpha_{12}\alpha_{21}}]}{2}$$

where subscripts, 1 and 2, attached to λ correspond to the plus and minus sign in the brackets respectively. T_1 and T_2 are expressed as

$$[8] \quad \begin{cases} T_1 = -D_{z1}\omega^2 - \iota v_{d1}\omega - \alpha_{21} - \left(\dfrac{\beta_m}{r_0}\right)^2 D_{r1} \\ T_2 = -D_{z2}\omega^2 - \iota v_{d2}\omega - \alpha_{12} - \left(\dfrac{\beta_m}{r_0}\right)^2 D_{r2} \end{cases}$$

where D_{zi} and D_{ri} are longitudinal and transverse diffusion coefficients of ith species, respectively. By applying the expansion technique in [5] and [6], we can derive an explicit form of the solutions as follows:

$$[9] \quad Z_{1m}(z,t) = f_m(z,t)\sum_{p=0}^{\infty}\sum_{q=0}^{p}\sum_{s=0}^{2q} A_{pqs}(t)\left\{\left[N_1 + \frac{t}{2p+1}\left(\frac{N_1\zeta}{2} + N_2\alpha_{12}\right)\right]H_{2s}\left(\frac{\eta t - z)}{\sqrt{D_{za}t}}\right) - \frac{N_1 D_{zd}}{2(2p+1)D_{za}}H_{2s+2}\left(\frac{\eta t - z}{\sqrt{D_{za}t}}\right)\right\}$$

$$[10] \quad Z_{2m}(z,t) = f_m(z,t)\sum_{p=0}^{\infty}\sum_{q=0}^{p}\sum_{s=0}^{2q} A_{pqs}(t)\left\{\left[N_2 - \frac{t}{2p+1}\left(\frac{N_2\zeta}{2} - N_1\alpha_{21}\right)\right]H_{2s}\left(\frac{\eta t - z}{\sqrt{D_{za}t}}\right) + \frac{N_2 D_{zd}}{2(2p+1)D_{za}}H_{2s+2}\left(\frac{\eta t - z}{\sqrt{D_{za}t}}\right)\right\}$$

where the two delta-functions are adopted as the initial conditions so that N_1 and N_2 simply represent the input numbers of the first and second species, respectively.

$$[11] \quad f_m(z,t) = \frac{1}{\sqrt{2\pi D_{za}t}}\exp\left[\frac{v_{dd}}{2D_{zd}}z + \xi t - \frac{(z - \eta t)^2}{2D_{za}t}\right]$$

and H_{2s} and H_{2s+2} are the Hermite polynomials of $2s$th and $2s+2$th order, respectively. Other coefficients involved in [9]–[11] are listed below:

$$v_{dd} = v_{d2} - v_{d1}, \qquad v_{da} = v_{d1} + v_{d2}, \qquad D_{zd} = D_{z2} - D_{z1}, \qquad D_{za} = D_{z1} + D_{z2}, \qquad \xi = \frac{D_{za}v_{dd}^2}{8D_{zd}^2} - \frac{v_{da}v_{dd}}{4D_{zd}} - \frac{\alpha_a}{2}$$

$$[12] \quad \alpha_a = \alpha_{12} + \alpha_{21} + \left(\frac{\beta_m}{r_0}\right)^2 (D_{r1} + D_{r2}), \qquad \eta = \frac{[v_{da} - (D_{za}v_{dd}/D_{zd})]}{2}, \qquad \zeta = \alpha_{12} - \alpha_{21} + \left(\frac{\beta_m}{r_0}\right)^2 (D_{r2} - D_{r1}) + \frac{v_{dd}^2}{4D_{zd}}$$

$$A_{pqs}(t) = \frac{{}_pC_q\,{}_{2q}C_s}{(-1)^s 2^{2q}(2p)!}(\alpha_{12}\alpha_{21})^{p-q}\left(\frac{D_{zd}}{D_{za}}\right)^s \zeta^{2q-s}t^{2p-s}$$

Analysis in dynamic equilibrium

Owing to insufficient convergence of [9] and [10] we have to take into account an enormous number of terms (several tens of terms even for a normal spectrum profile) in the infinite sum to generate two realistic spectra. However, the solutions suggest an analytical expression of the ATS entirely independent of the initial condition in dynamic equilibrium. Namely, every term connected to N_1 and N_2 will automatically be cancelled, with the exception of the fundamental mode of the solution, $f_m(z,t)$. This mode generates a skewed Gaussian profile, similar to but not exactly the same as that we seek in this

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

phase. The reason may be attributed to the problem of the infinite sum in m in [3]. The final solution will therefore assume an appreciably different mathematical form even if the Gaussian shape still holds. We can infer the actual form from the solution of one ionic species accompanied by a depleting reaction as

$$[13]\quad \lim_{z\to\infty} \mathscr{J}_{im} = (K_{i0} + \iota K_{i1}\omega + \cdots) \times \exp(-D_{\text{eff}}t\omega^2 - \iota v_{\text{deff}}t\omega - \alpha_{\text{eff}}t)$$

Note that only the first terms in [5] and [6] will dominate the dynamical behavior of two ion swarms, because $\exp(\lambda_2 t)$ decreases much faster than $\exp(\lambda_1 t)$. The resulting coefficients are listed below:

$$[14]\quad K_{10} = \frac{(N_1 + N_2)\alpha_{12}}{(\alpha_{12} + \alpha_{21})}$$

$$K_{20} = \frac{(N_1 + N_2)\alpha_{21}}{(\alpha_{12} + \alpha_{21})}$$

$$K_{11} = v_{dd}\alpha_{12}\frac{[2N_1\alpha_{21} - N_2(\alpha_{12} - \alpha_{21})]}{(\alpha_{12} + \alpha_{21})^3}$$

$$K_{21} = -v_{dd}\alpha_{21}\frac{[2N_2\alpha_{12} + N_1(\alpha_{12} - \alpha_{21})]}{(\alpha_{12} + \alpha_{21})^3}$$

$$[15]\quad D_{\text{eff}} = \frac{D_{z1}\alpha_{12} + D_{z2}\alpha_{21}}{\alpha_{12} + \alpha_{21}} + \frac{v_{dd}^2}{4(\alpha_{12} + \alpha_{21})}$$

$$[16]\quad v_{\text{deff}} = v_{dm} = \frac{v_{d1}\alpha_{12} + v_{d2}\alpha_{21}}{\alpha_{12} + \alpha_{21}}$$

$$[17]\quad \alpha_{\text{eff}} = \left(\frac{\beta_m}{r_0}\right)^2 \frac{(D_{r1} + D_{r2})}{2}$$

An inverse Fourier transform of [13] is straightforward and the solution is

$$[18]\quad Z_{im}(z,t) = \frac{1}{\sqrt{4\pi D_{\text{eff}}t}}\left[\frac{K_{i1}(v_{dm}t - z)}{2D_{\text{eff}}t} + K_{i0}\right] \times \exp\left[-\frac{(z - v_{dm}t)^2}{4D_{\text{eff}}t} - \alpha_{\text{eff}}t\right]$$

A remarkable feature of [18] is that the effective drift velocity, v_{dm}, is exactly the same as that proposed by Voshall *et al.* (3) in their experimental analysis of negative ions in oxygen gas, because in the dynamic equilibrium phase the ratio of concentrations of two ionic species is in accord with the reaction-frequency ratio. Somewhat unexpected is the appearance of the second term in D_{eff}, [15], which is very much larger than the first term under the usual experimental conditions, and dominates the "apparent" diffusive effect.

The solution [18] gives us the following insights;

(*i*) the K_{i0}th term (i = 1, 2) is a fundamental term to determine the basic structure of the Gaussian profile

(*ii*) the ratio, K_{10}/K_{20}, yields the equilibrium constant independent of the initial conditions

(*iii*) the diminution of the ions arises only from the transverse-diffusion loss

(*iv*) the K_{i1}th term, which weakly depends on the initial conditions, is a subordinate term, producing a subtle shift in the peak position in the K_{i0}th term

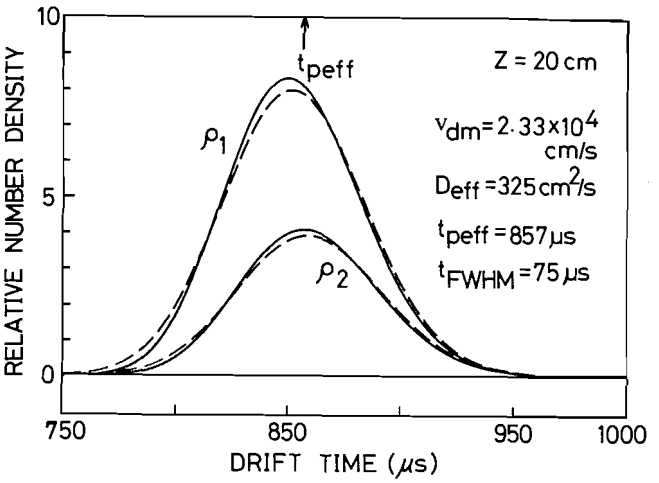

FIG. 1. Comparison of two sets of ATS in a dynamic equilibrium phase. $v_{d1} = 2.5 \times 10^4$ cm s^{-1}, $v_{d2} = 2 \times 10^4$ cm s^{-1}, $D_{z1} = D_{r1} = 125$ cm^2 s^{-1}, $D_{z2} = D_{r2} = 100$ cm^2 s^{-1}, $\alpha_{21} = 10^4$ s^{-1}, $\alpha_{12} = 2 \times 10^4$ s^{-1}. Two solid-line curves are exact arrival time spectra generated from [4]–[6] by using a numerical quadrature. The two broken-line curves are approximate ATS calculated from [18]. A delta-function was adopted as the initial condition for the first species.

(*v*) the FWHM of the arrival time spectrum, t_{FWHM}, is mainly determined by the K_{i0}th term and the influence of the K_{i1}th term is negligible,

$$[19]\quad t_{\text{FWHM}} \simeq \frac{3.33\sqrt{D_{\text{eff}}t_{\text{peff}}}}{v_{dm}}$$

$$[20]\quad t_{\text{peff}} = \frac{z}{v_{dm}}$$

and

(*vi*) the magnitude of the peak difference is independent of the initial conditions on account of the symmetric expression of K_{11} and K_{21} with respect to the ionic species.

A typical comparison of two hypothetical ATS generated from [4]–[6] (two solid-line curves) with those calculated from [18] (two broken-line curves) is shown in Fig. 1. Except for a slight decrease in the peak height in the approximate solution the agreement is quite good. Note that these are number density profiles, the area-ratio of which yields the reaction-frequency ratio; $\rho_1 : \rho_2 = \alpha_{12} : \alpha_{21} = 2 : 1$. Figure 2 depicts their component spectra calculated separately from each term in [13], in which the K_{i0}th, K_{i1}th, and K_{i2}th terms describe the first, second, and third component of each arrival time spectrum, respectively. As mentioned above, no peak difference between two first-component spectra can be observed. The FWHM of the composite arrival time spectra of primary ions agrees with that of secondary ions and is not seriously affected by the second and third components.

The expression of the peak difference can explicitly be derived from [18] as

$$[21]\quad \Delta t_{\text{peak}} = \frac{|v_{d1} - v_{d2}|}{v_{d1}\alpha_{12} + v_{d2}\alpha_{21}}$$

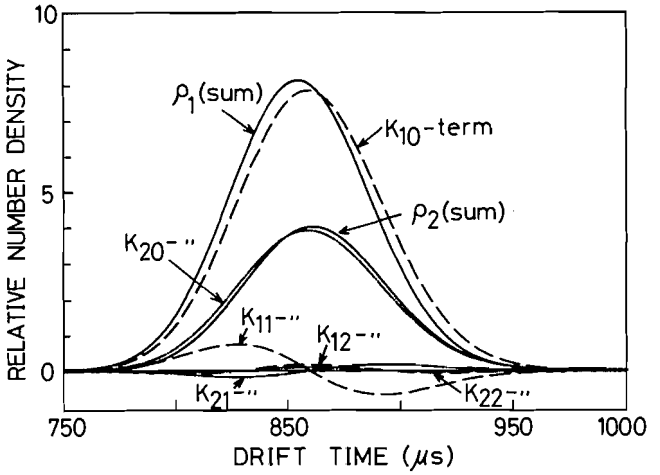

FIG. 2. Two composite ATS (two solid-line curves) and their components. ρ_1(sum) is composed of three subcomponents (three broken-line curves), K_{10}th, K_{11}th, and K_{12}th terms. 0, 1, and 2 refer to the first, second, and third component, respectively. ρ_2(sum) is also composed of K_{20}th, K_{21}th, and K_{22}th term (three dot–dash curves). Each subcomponent spectrum was generated from the corresponding term in [13] by using the quadrature with the same kinetic coefficients as those of Fig. 1.

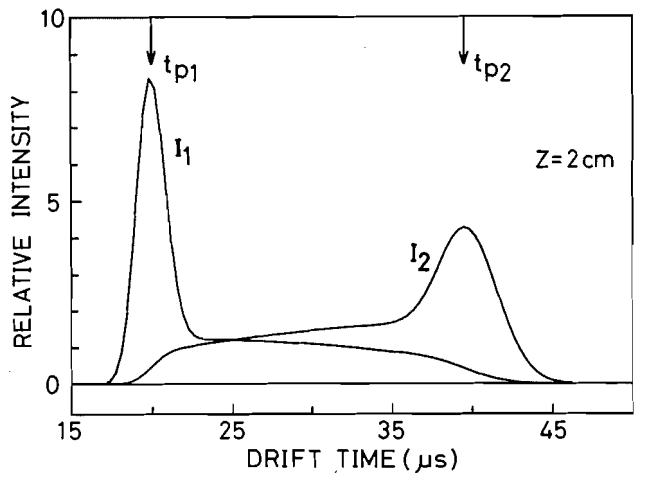

FIG. 3. Two ATS in a nondynamic equilibrium phase generated from [4]–[6]. z = 2 cm, $v_{d1} = 10^5$ cm s^{-1}, $v_{d2} = 5 \times 10^4$ cm s^{-1}, $D_{z1} = D_{r1} = 200$ cm^2 s^{-1}, $D_{z2} = D_{r2} = 100$ cm^2 s^{-1}, $\alpha_{21} = 5 \times 10^4$ s^{-1}, $\alpha_{12} = 2 \times 10^4$ s^{-1}. The ratio of the number densities adopted for the initial conditions was $I_1 : I_2 = 1 : 0.7$. $t_{p1} = 20$ and $t_{p2} = 39.5$ μs, which are peak times determined from the Gaussian components (two peaks on both sides) of I_1 and I_2, respectively.

The Δt_{peak} is a constant determined only from the drift velocities and reaction frequencies, and is completely independent of the initial conditions as well as the diffusion coefficients. As the drift distance increases, a peak difference between two general ATS asymptotically converges to the Δt_{peak}, which is substantial in the limit of infinite drift distance.

This formula is useful for determining the forward and reverse reaction frequencies. We now demonstrate this using two groups of simulation spectra calculated numerically from [4]–[6] with the same kinetic coefficients. The ATS in the first group shown in Fig. 3 correspond to the initial-phase (or

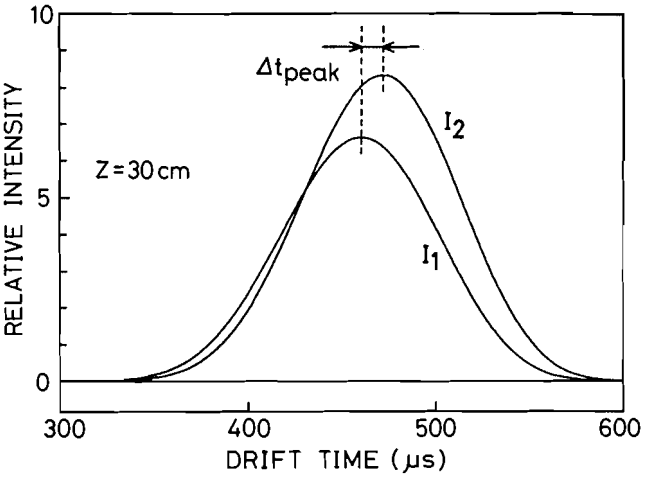

FIG. 4. Two ATS in a dynamic equilibrium phase. z = 30 cm, and other kinetic coefficients are the same as those of Fig. 3. Δt_{peak} = 11.4 μs.

nondynamic equilibrium phase) spectra computed at the drift distance of 2 cm, while those in the second group in Fig. 4 are the spectra in the dynamic equilibrium phase at 30 cm drift distance.

In Fig. 3 two sharp peaks on both sides arise from the initially injected ions of first kind (the left peak) and second kind (the right peak), which give us their approximate drift velocities. They are calculated from the drift distance divided by the peak time in each arrival time spectrum as $v_{d1} = 1.00 \times 10^5$ and $v_{d2} = 5.06 \times 10^4$ cm s^{-1}. The area-ratio of two profiles in Fig. 4 is evaluated as $I_1 : I_2 = 1 : 1.26$, which agrees with the ratio, $N_{1s}v_{d1} : N_{2s}v_{d2}$, provided that the drift component current dominates the arrival time spectrum profile. N_{1s} and N_{2s} are stationary concentrations of the first and second ionic species, respectively, in the dynamic equilibrium phase. This assumption holds in typical experimental conditions (2). By using the above drift velocities we can evaluate the ratio of the concentrations as $N_{1s} : N_{2s} = 1 : 2.49$, which is equivalent to the ratio, $\alpha_{12} : \alpha_{21}$. The magnitude of the peak difference is read from Fig. 4 as 11.4 μs. Substituting the value back into [21] and using the ratio $\alpha_{12} : \alpha_{21} = 1 : 2.49$, we determine the reaction frequencies to be $\alpha_{21} = 4.80 \times 10^4$ and $\alpha_{12} = 1.93 \times 10^4$ s^{-1}. The errors arising from this direct determination from the figures are −4% for α_{21} and −3.5% for α_{12}.

Despite its rather crude analysis, this method gives us surprisingly accurate reaction frequencies. If we require more precise measurements of the drift velocities, which are indispensable for the accurate determination of reaction frequencies, we can always resort to more sophisticated experimental techniques, including the use of a movable ion source and a suitable choice of the experimental conditions.

We now examine the final problem in this part. It is one of the most difficult problems in reactive ion transport analysis to predict exactly how long it takes before equilibrium is achieved. One seeks a relation between the kinetic coefficients and the drift distance where the dynamic equilibrium develops. For this purpose we first introduce an average drift velocity of two general ATS, which may asymptotically converge to v_{dm} as the drift distance increases. We define the velocity, $\langle v_d \rangle(z)$, as

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

$$[22]\quad \langle v_d\rangle(z) = \frac{\int_{-\infty}^{\infty}\int_{0}^{\infty} [\mathscr{J}_{1m}(\omega,t)v_{d1} + \mathscr{J}_{2m}(\omega,t)v_{d2}] \exp(\iota\omega z)\, d\omega\, dt}{\int_{-\infty}^{\infty}\int_{0}^{\infty} [\mathscr{J}_{1m}(\omega,t) + \mathscr{J}_{2m}(\omega,t)] \exp(\iota\omega z)\, d\omega\, dt} = \frac{I_n}{I_d}$$

Assuming the drift-tube radius to be infinite, we can obtain explicit forms of I_n and I_d as

$$[23]\quad I_n = \frac{(N_1 + N_2)}{2} + \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{e^{\iota\omega z}}{g(\omega)} (B_{n2}\omega^2 + \iota B_{n1}\omega + B_{n0})\, d\omega$$

$$[24]\quad I_d = \frac{(N_1 + N_2)}{2v_{dm}} + \frac{1}{2\pi}\int_{-\infty}^{\infty} \frac{e^{\iota\omega z}}{g(\omega)} (B_{d2}\omega^2 + \iota B_{d1}\omega + B_{d0})\, d\omega$$

where the resulting coefficients in the integrands are

$$B_{n2} = (N_1 + N_2)D_{z1}D_{z2}$$

$$[25]\quad B_{n1} = N_1 D_{z1}v_{d2} + N_2 D_{z2}v_{d1}$$

$$B_{n0} = (N_1 + N_2)(D_{z1}\alpha_{12} + D_{z2}\alpha_{21})$$

$$B_{d2} = \frac{B_{n2}}{v_{dm}}$$

$$[26]\quad B_{d1} = (N_1 + N_2)\frac{(D_{z1}v_{d2} + D_{z2}v_{d1})}{v_{dm}} - N_1 D_{z2} - N_2 D_{z1}$$

$$B_{d0} = (N_1 + N_2)\frac{(D_{z1}\alpha_{12} + D_{z2}\alpha_{21} - v_{d1}v_{d2})}{v_{dm}} + N_1 v_{d2} + N_2 v_{d1}$$

The $g(\omega)$ is expressed as

$$[27]\quad g(\omega) = -\iota D_{z1}D_{z2}\omega^3 + (D_{z1}v_{d2} + D_{z2}v_{d1})\omega^2 + \iota(v_{d1}v_{d2} - D_{z1}\alpha_{12} - D_{z2}\alpha_{21})\omega + v_{d1}\alpha_{12} + v_{d2}\alpha_{21}$$

Equation [27] states that the three singular points in I_n and I_d are all purely imaginary, and only one root, $\iota\omega_s(\omega_s > 0)$ for $g(\omega) = 0$, provides for the appropriate formula of $\langle v_d\rangle(z)$. Under typical experimental conditions, we can adopt the following approximate expression for the root as

$$[28]\quad \omega_s = \frac{v_{d1}\alpha_{12} + v_{d2}\alpha_{21}}{v_{d1}v_{d2} - D_{z1}\alpha_{12} - D_{z2}\alpha_{21}}$$

The percentage deviation of $\langle v_d\rangle(z)$ from v_{dm} is derived from [23], [24], and [28] as

$$[29]\quad \%\text{dev} = 100\,\frac{[\langle v_d\rangle(z) - v_{dm}]}{v_{dm}} \simeq \kappa \exp\left(\frac{-z}{z_s}\right)$$

where κ is a constant determined from both the initial conditions and the kinetic coefficients. The other constant, z_s, is

$$[30]\quad z_s = \frac{1}{\omega_s}$$

It has the capability of becoming an important measure for estimating the drift distance required to achieve the dynamic equilibrium phase. However, as will be discussed later, z_s appears to be much smaller than expected so that the ATS at this drift distance will not be close to the complete Gaussian shape. More realistic parameters can be derived from [19] and [21]. The ratio of Δt_{peak} to t_{FWHM}, which is expected to vanish in the limit of infinite drift distance, is a plausible parameter for this prediction. By setting the ratio equal to an appropriately small value as

$$[31]\quad \frac{\Delta t_{peak}}{t_{FWHM}} = \varepsilon$$

we can derive therefrom the drift distance z_r. If we set ε to be 0.1, z_r is expressed as follows:

$$[32]\quad z_r = \frac{9.02\,(v_{d1} - v_{d2})^2 v_{dm}}{D_{eff}(\alpha_{12} + \alpha_{21})^2}$$

Adopting a rather crude but reasonable approximation for [15] as

$$[33]\quad D_{eff} = \frac{(v_{d1} - v_{d2})^2}{4(\alpha_{12} + \alpha_{21})}$$

we obtain an extremely simple formula

$$[34]\quad z_r \simeq \frac{36\, v_{dm}}{\alpha_{12} + \alpha_{21}}$$

The magnitude of the first term in [15] is, in general, much less than one tenth of that of the second term. So, [34] certainly yields the expected drift distance and can be used as a rule of thumb.

The only problem left is the derivative of the time required to achieve dynamic equilibrium. Although [34] may suggest it to be $36/(\alpha_{12} + \alpha_{21})$, this is incorrect owing to the fact that the average drift velocity is a function of drift distance. An important clue is given by [29], which is considered to be a differential equation of drift distance with respect to time. The mathematical analysis is rather cumbersome and is now underway.

Application to experimental analysis

We now analyze reactive ion transport for a real ion–molecule combination. The determination of mobilities, diffusion coefficients, and reaction rates of nitrogen ions in

nitrogen has been the subject of a large number of investigations since 1930 (4–13), among which the $(N_2^+, N_4^+)/N_2$ system is one of the most extensively analyzed. It is well known that the dynamic balance between the forward and reverse reactions for N_2^+ and N_4^+ ions,

$$[35] \quad N_2^+ + 2N_2 \underset{k_{12}}{\overset{k_{21}}{\rightleftharpoons}} N_4^+ + N_2$$

occurs in the intermediate energy range.

Using the analysis in the nonequilibrium phase, McKnight *et al.* (5) and McDaniel and co-workers (6, 14, 15) measured the kinetic coefficients in a wide energy range. By using a flow-drift tube, Lindinger *et al.* (8) measured mobilities of N_4^+ in N_2. Böhringer and Arnold (11) also determined mobilities of N_2^+ and N_4^+ in the temperature range 20–420 K using a low-temperature drift tube. The comparison between those mobility data indicates that those of McDaniel and co-workers appear to be the more accurate. As far as the reaction rates of N_2^+ and N_4^+ are concerned, however, controversy still remains regarding their accuracy. So in this analysis we adopted the transport coefficients determined by McDaniel and co-workers and the reaction rates determined by McKnight *et al.* (5). Several useful ion-current profiles for the $(N_2^+, N_4^+)/N_2$ system were obtained by McKnight *et al.* (5), from which we find that the dynamic balance develops at E/N = 150 Td (1 Td = 10^{-17} V cm^2). E/N is the ratio of the electric field strength to the neutral drift gas number density. Unfortunately, no real current profiles at this energy are available so we numerically generate two hypothetical ATS from the data. Then, we examine whether their shape and width reproduce the same data according to the appropriate formulas. In fact this kind of procedure is not an adequate analysis for determining the unknown kinetic coefficients, because two groups of ATS should be measured and analyzed separately in two different phases in actual experiments. Nevertheless, it will lead us to confirm that the present formulation is consistent and useful.

Two ATS for N_2^+ and N_4^+ ions in the initial phase at 150 Td are shown in Fig. 5. We adopted a delta-function as the initial condition for N_2^+ ions only. By increasing the drift distance from 3 to 10 cm and the gas pressure from 0.845 to 2.0 Torr (1 Torr = 133.3 Pa), we can shift the initial phase of Fig. 5 into a dynamic equilibrium phase of Fig. 6. In this procedure two reaction rates were kept constant, viz. k_{21} = 2.7×10^{-29} cm^6 s^{-1} and $k_{12} = 2.0 \times 10^{-12}$ cm^3 s^{-1}. From the ATS in Fig. 6 four kinetic coefficients, α_{21}, α_{12}, D_{z1}, and D_{z2} can be determined directly with the help of [15], [16], and [19]–[21], provided that the two drift velocities are known. The following relation is also assumed;

$$[36] \quad v_{d1} : v_{d2} = D_{z1} : D_{z2}$$

The Δt_{peak} and t_{FWHM} in Fig. 6 are 2.1 and 20.0 μs, respectively. Using the method applied to Figs. 3 and 4, we obtain the reaction-frequency ratio as $\alpha_{21}:\alpha_{12}$ = 0.87:1. Determination of α_{21} and α_{12} by use of [21] is straightforward, and the calculated values are $\alpha_{21} = 1.14 \times 10^5$ and $\alpha_{12} = 1.31 \times 10^5$ s^{-1}. The corresponding values for generating the ATS were 1.12×10^5 and 1.29×10^5 s^{-1}, respectively. Moreover, determination of D_{z1} and D_{z2} is possible according to [15], [19], and [20]. The values evaluated are D_{z1} = 54.4 and D_{z2} = 91.1 cm^2 s^{-1}. The adopted D_{z1} and D_{z2} are 43.2 and 72.2 cm^2 s^{-1}, respectively. As far as the accuracy of the reaction frequency in this case is concerned, the discrepancy of less than 2% is surprisingly small, whereas that of the longitudinal diffusion coefficient exceeds 25%. Again, we emphasize that this test only proves the present method to be consistent. Without carrying out the separate measurements in different phases, we are not at the moment able to say anything about the measurement error of the kinetic coefficients.

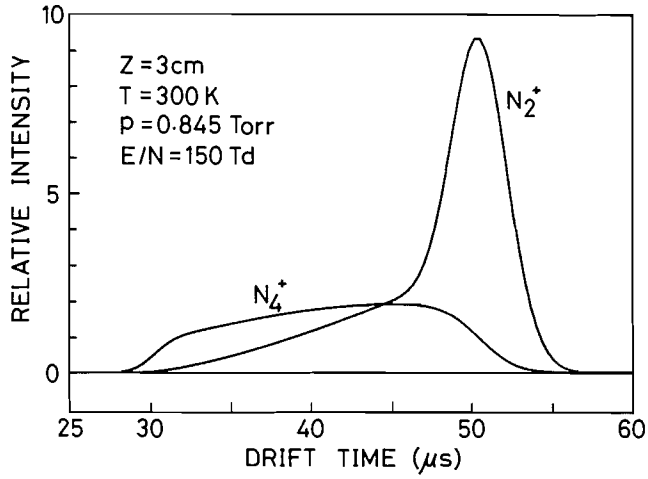

FIG. 5. The ATS of N_2^+ and N_4^+ ions in nitrogen in an initial phase. They were numerically generated from [4]–[6] by introducing the experimental data; v_{d1} = 5.92 × 10^4 cm s^{-1}, v_{d2} 9.91 × 10^4 cm s^{-1}, D_{z1} = 102 cm^2 s^{-1}, D_{z2} = 171 cm^2 s^{-1}, D_{r1} = 74 cm^2 s^{-1}, D_{r2} = 123 cm^2 s^{-1}, α_{21} = 2 × 10^4 s^{-1}, and α_{12} = 5.44 × 10^4 s^{-1}. A delta-function was adopted as the initial condition for the first species (N_2^+ ions; the labelled number as 1).

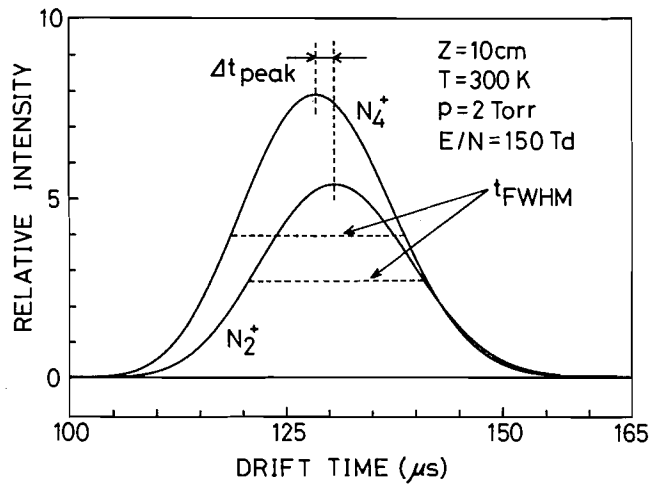

FIG. 6. The ATS of N_2^+ and N_4^+ ions in nitrogen in a dynamic equilibrium phase. The kinetic coefficients were D_{z1} = 43.2 cm^2 s^{-1}, D_{z2} = 72.2 cm^2 s^{-1}, D_{r1} = 31.1 cm^2 s^{-1}, D_{r2} = 52 cm^2 s^{-1}, $\alpha_{21} = 1.12 \times 10^5$ s^{-1}, and $\alpha_{12} = 1.29 \times 10^5$ s^{-1}. Two drift velocities were the same as those of Fig. 5. Δt_{peak} = 2.1 μs and t_{FWHM} = 20.0 μs.

Figure 7 presents the percent deviation of $\langle v_d \rangle(z)$ from v_{dm} as a function of drift length. The approximate formula [29] works well under the present conditions, although only the case where the initial condition is set as (N_1, N_2) = (0,1) appears to be unsatisfactory. The agreement between the re-

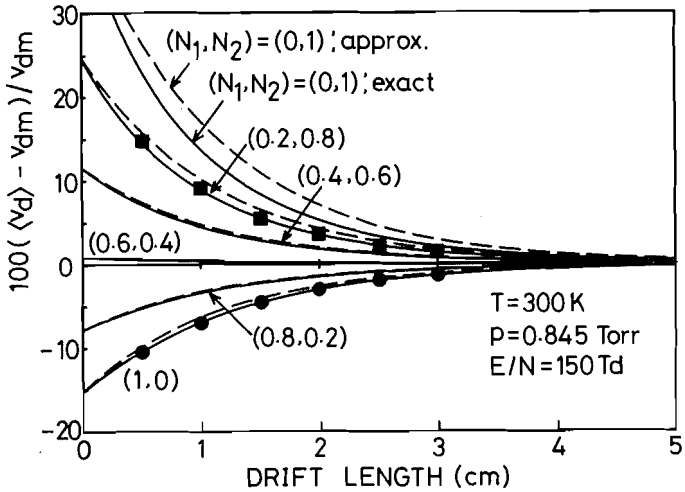

FIG. 7. The percent deviation of $\langle v_d \rangle(z)$ from v_{dm} as a function of drift length. The kinetic coefficients adopted are the same as those of Fig. 5 except for the ratio of the initial number densities of N_2^+ and N_4^+, which is represented as (N_1, N_2) on the drawing. The solid-line curves are the results calculated exactly from the solution according to [22]–[27]. The broken-line curves are from the approximate formula [29]. The filled circles and squares are obtained directly from the two arrival time spectra, the initial conditions of which are (1,0) and (0.2, 0.8), respectively.

sults calculated from the exact solution (the solid-line curves) and the values obtained directly from the ATS (the filled circles and squares) is excellent.

The percent deviation of the filled circle at $z = 3$ cm is -1.28%, which is calculated from the ATS in Fig. 5. Although this deviation is small enough to expect the ATS to be sufficiently close to equilibrium, the two profiles in Fig. 5 are far from those we expect in this phase. This is a clear indication that the z_s of [30] are not a suitable measure for predicting whether equilibrium has been achieved. The z_r, on the other hand, yields a much more appropriate value than z_s. The z_r calculated from [32] and that from [34] by using the same parameters are 33.2 and 33.8 cm, respectively. In fact we have confirmed that the dynamic equilibrium phase is reached at these drift distances.

Discussion

The accurate measurement of reaction frequencies is one of the long-standing aims in the field of reactive ion transport and gas-phase ion chemistry. In contemporary drift-tube experiments, ion mobilities (or drift velocities) can be determined with an accuracy of about $\pm 1\%$ in simple cases (1). Although measurement of longitudinal diffusion coefficients is much more difficult than that of mobilities, its experimental uncertainty is, in general, estimated to be less than $\pm 25\%$ (15). Reaction rates are very much more difficult to measure than the transport coefficients, and the total experimental error may exceed $\pm 50\%$ at mean collision energies ranging from thermal to several electronvolts (16). This may be attributed simply to the fact that most experimentalists have limited their measurements to the nondynamic equilibrium phase, where the appropriate estimation of the initial condition would become indeed troublesome. The difficulty is encountered in various kinds of apparatus, especially in the case of flow drift-tube instruments.

The peak-time difference method in the dynamic equilibrium phase has the potential to be useful in this respect. Even when the difference is difficult to measure under specific experimental conditions, we can resort to a numerical differential technique to determine the peak position in each ATS. Moreover, it has the advantage that the reaction frequency obtained from [21] is not very sensitive to the measured difference. On the contrary, the longitudinal diffusion coefficient calculated from [15], [19], and [20] is very sensitive to the FWHM of the ATS. If we fail to measure it accurately, the D_{eff} may occasionally be negative. This deficiency may suggest a further improvement in the present method.

This means that the diffusive effect in dynamic equilibrium is mainly dominated by the second term in [15], which is a function of the drift velocities and reaction frequencies. In other words, there is a possibility to determine the reaction frequencies from the FWHM of the observed spectrum. The accuracy anticipated therefrom would be within $\pm 5\%$ over a wide range of E/N. The most important conclusion to be drawn from the present analysis in dynamic equilibrium is that the shape and width of ATS depend strongly on the drift velocity and reaction frequency, and that the influence of the longitudinal diffusion coefficient is negligible. Again, the precise determination of the drift velocity is indispensable in carrying out the above procedure. As a final remark we strongly recommend a suitable choice of the above two methods, the initial phase analysis and the dynamic equilibrium phase analysis, for the sake of an accurate determination of the kinetic coefficients. The observation of reactive ion transport phenomena from two different aspects will certainly lead to much deeper understanding.

Conclusions

A method for analyzing the space-time behavior of two ion swarms in dynamic equilibrium has been proposed. The analytic solution of ATS in this phase has been explicitly derived. Two important parameters are the effective diffusion coefficient and the effective drift velocity. By combining these parameters with the peak-time difference and the FWHM of the ATS, the forward and reverse reaction frequencies and the longitudinal diffusion coefficients can be determined. Moreover, a measure of the drift distance where the dynamic equilibrium develops has been examined. The reactive transport process of the $(N_2^+, N_4^+)/N_2$ system has been tested to find out whether the present method has the potential to be useful in drift-tube analysis.

IDRISS EL BAKALI, ESSAÏD EL RHESS, CHRISTOPHE ROUSSELOT, RENÉ MERCIER, and MARIE-FRANCE MERCIER. Can. J. Chem. **70**, 1612 (1992).

Hydrolysis of $Si(OC_2H_5)_4$ by ammonia has been investigated using ^1H and ^{13}C NMR measurements in alcoholic media. Use of deuterated CD_3CD_2OD and CD_3OD solvents proves the absence of transesterification by alkoxy exchange between silicate and alcohols. The rate constant increases when CD_3OD replaces CD_3CD_2OD as the solvent ($k = 2.8 \times 10^{-3}$ L mol^{-1} min^{-1} in CD_3CD_2OD; 7.5×10^{-3} L mol^{-1} min^{-1} in CD_3OD for similar experiments).

Opérant en milieu alcoolique et utilisant des techniques de RMN du ^1H et du ^{13}C, on a étudié l'hydrolyse du $Si(OC_2H_5)_4$. L'utilisation du CD_3CD_2OD et du CD_3OD comme solvants permet de démontrer qu'il n'y a pas de transestérification par échange de groupes alcoxyles entre le silicate et les alcools. La constante de vitesse augmente lorsqu'on remplace le CD_3CD_2OD par du CD_3OD comme solvant ($k = 2{,}8 \times 10^{-3}$ L mol^{-1} min^{-1} dans le CD_3CD_2OD; $7{,}5 \times 10^{-3}$ L mol^{-1} min^{-1} dans le CD_3OD, pour des conditions expérimentales semblables).

[Traduit par la rédaction]

Introduction

Obtaining sol–gel materials has been extensively studied in the last decade. In particular, Stöber *et al.* (1) studied the hydrolysis of tetraethylorthosilicate $Si(OC_2H_5)_4$ as reported in a paper on colloidal silica synthesis. He used an ammonia reactant to obtain homodispersed particles in the range of 0.1–1 μm. He varied the ammonia and water concentrations, as well as the solvents, to obtain particles having final diameters that could be measured. Shimohira and Tomuro (2), Shimoda *et al.* (3), and Tan *et al.* (4) studied the effect of temperature on final-diameter size. They found that when temperature increases, the final-diameter size decreases. The influence of all of the above parameters acting on the hydrolysis and condensation of $Si(OC_2H_5)_4$ was reviewed in our laboratory by El Rhess (5). He studied the kinetics of the evolution of both particle diameter and particle concentration for silica particles having an initial diameter of 10 nm.

We wanted to observe the first steps of the hydrolysis and condensation of different alkoxyl silicates. The most efficient technique for this type of study is ^{29}Si Nuclear Magnetic Resonance (NMR). This technique has already been used by various researchers to follow the hydrolysis and condensation reaction of both methyl and ethyl silicate (in particular, Lin and Basil (6) for $Si(OC_2H_5)_4$ and Artaki *et al.* (7), Balfe and Martinez (8), and Klemperer *et al.* (9) for $Si(OCH_3)_4$). ^{29}Si NMR reveals the identity of hydrolyzed molecules such as $Si(OH)(OR)_3$, $Si(OH)_2(OR)_2$, $Si(OH)_3(OR)$, and $Si(OH)_4$ by a characteristic resonance line and the appearance of dimeric (Si-O-Si) and oligomeric species at distinct ranges of frequency. The experimental conditions used to study these hydrolyzed molecules do not, in general, coincide with the experimental conditions used in the synthesis of silica. This paper compares the kinetics of the hydrolysis of $Si(OC_2H_5)_4$ in two alcoholic media, CD_3OD and CD_3CD_2OD, using ^1H NMR spectroscopy. Our experimental conditions are the same as those required to obtain silica colloids by adding ammonia to alcoholic media. Assink and Kay (10–12) studied $Si(OC_2H_5)_4$ and $Si(OCH_3)_4$ using ^1H NMR, first in an acid medium and then in a basic (NH_4OH) medium.

We also wanted to determine if silicate and alcohol exchange alkoxy groups and thus cause transesterification

$$Si(OC_2H_5)_4 + 4\ CD_3OD \rightarrow Si(OCD_3)_4 + 4\ C_2H_5OD$$

This reaction could occur in competition with the hydrolysis reaction.

$$Si(OC_2H_5)_4 + 2\ H_2O \rightarrow Si(OH)_4 + 4\ C_2H_5OH$$

It is not possible, using solely ^1H NMR, to determine if there is competition because deuterical species such as $Si(O\text{-}CD_3)$ do not produce signals. Therefore, in certain experiments, we used ^{13}C NMR because it allowed us to distinguish $Si\text{-}OCD_3$ from $SiOCH_3$ using proton coupling techniques, which produce singlets for $^{13}CH_3$ and multiplets for $^{13}CD_3$.

Experimental conditions

We used wholly deuterated anhydrous alcohols (CD_3OD and C_2D_5OD from Aldrich) as solvents. The silicate and the ammonia solution (NH_3, H_2O) are in their protonated forms. Freshly distilled ethyl silicate was used to avoid atmospheric hydrolysis. $Si(OR)_4$, R'OD, and concentrated ammonia were successively added to NMR tubes at 20°C, for example: 500 μL C_2D_5OD + 15 μL $Si(OEt)_4$ + 90 μL NH_4OH (13.5 M). The different experiments are summarized in Table 1.

Immediately after adding NH_4OH, the tubes were stirred for 15 s and then placed in the NMR instrument (Bruker Spectroscopic AC 200 spectrometer linked to an ASPECT 3000 computer). The ^1H spectra were recorded at 200 MHz. The spectrum produced by the results of 16 pulses was immediately recorded,

TABLE 1. Designation of characteristics of the ^1H NMR experiments

Code	Solvent	Silicate	[Silicate] ($M\ L^{-1}$)	[NH_3] ($M\ L^{-1}$)	[H_2O] ($M\ L^{-1}$)	[H_2O]/[-O-C_2H_5]
ETET1	C_2D_5OD	$Si(OC_2H_5)_4$	0.4	0.56	1.64	1.025
ETET2	C_2D_5OD	$Si(OC_2H_5)_4$	0.12	2.0	5.9	12.3
MEET1	CD_3OD	$Si(OC_2H_5)_4$	0.4	0.56	1.64	1.025
MEET2	CD_3OD	$Si(OC_2H_5)_4$	0.2	0.59	1.72	2.15

giving a spectral record of 2 min. The ^{13}C spectra were recorded at 50 MHz by using ^1H broad-band decoupling: 256 pulses were recorded with a 5 s delay between each pulse. It took 30 min to record the ^{13}C spectrum. The NMR apparatus was calibrated for D resonances for the alcohol chosen, by using anhydrous mixtures (silicate + alcohol).

In Table 1, the four experiments are for the hydrolysis of $Si(OC_2H_5)_4$. The concentration of the solvent is about 14 $M\ L^{-1}$ (C_2D_5OD) and 20 $M\ L^{-1}$ (CD_3OD).

Chemical shifts, δ, are expressed in ppm (for ^{13}C and ^1H NMR), with respect to the zero value of TMS (1%). Using ^1H NMR, we can easily follow the disappearance of silicate species and the appearance of alcohol species formed during hydrolysis.

$$Si(OR)_4 + 2\ H_2O \rightarrow SiO_2 + 4\ ROH$$

At the beginning of the kinetic study, ^1H NMR signals correspond to Si-O-CH_2-CH_3 or Si-O-CH_3 protons and to only one broad peak for both NH_3 and H_2O protons. During hydrolysis, this last peak encompasses all hydroxyl groups (R-OH, Si(OH)).

Precise intensity measurements enable one to determine the exact [O-H]/[Si-O-R] ratio, as well as the evolution of [Si-O-R] groups as a function of time.

The ETET 2 mixture corresponds to experimental conditions required for the synthesis of 300-nm silica particles at 20°C (12 times more H_2O than (OC_2H_5) in concentration).

Results

^{13}C NMR

ETET 1

With C_2D_5OD, the solvent is characterized by a quintuplet at 56.8 ppm (CD_2) and a heptaplet at 17.5 ppm (CD_3). $Si(OC_2H_5)_4$ presents singlets at 59.74 and 18.39 ppm. After hydrolysis, there are CH_3-CH_2OH singlets at 57.68 ppm (CH_2) and 18.32 ppm (CH_3). If transesterification were to occur, one should note the appearance of a Si(O-CD_2-CD_3) quintuplet at about 59.7 ppm at the beginning of the experiment. We never observed quintuplets in this case.

MEET 1

By using CD_3OD as alcohol and $Si(OC_2H_5)_4$, a fast transesterification could be expected. CD_3OD is characterized by a heptaplet at 49.0 ppm and $Si(OC_2H_5)_4$ by singlets at 60.20 ppm (-OCH_2-) and 18.40 ppm (-O-CH_2-CH_3). After 8 days, without adding NH_4OH, the spectrum did not change. This indicates that no substitution was detected. Adding NH_4OH does not enhance substitution; only the hydrolysis of Si-OCH_2CH_3 is detected by ^1H NMR. When 80% of $Si(OC_2H_5)_4$ is hydrolyzed, the ^{13}C NMR spectrum shows only the appearance of a CH_3CH_2OH peak at 58.26 ppm and the residue of a Si(-OCH_2CH_3) peak at 60.20 ppm.

These experiments demonstrate that alkoxy groups do not substitute from the solvent to the silicate. The hydrolysis and condensation of $Si(OR)_4$ in R'OH as alcohol correspond to the following equation:

$$Si(OR)_4 + 2\ H_2O \xrightarrow{R'OH} SiO_2 + 4\ ROH$$

The solvent acts only as a solvent and not as a reactant, because the alkoxy group is not substituted.

^1H NMR

The solvents used for these experiments were C_2D_5OD and CD_3OD.

Because the solvents are deuterated, they are not detected by NMR. Therefore, the NMR spectra are very clear (Fig. 1) and they present the Si-O-CH_2-CH_3 quadruplet (J = 7 Hz; 3.870, 3.835, 3.800, 3.765 ppm) and the Si-O-CH_2-CH_3 triplet (1.242, 1.207, and 1.172 ppm). To determine if water vapor contaminated the preparation, test tubes without NH_3 were monitored during several weeks. After 1 month, only 4–6% of the solution was hydrolyzed, depending on the solvent. This contamination was not taken into account in the following kinetic studies, when adding NH_3.

In these four experiments, the evolution of the spectrum is identical. After adding NH_3, the mobile O-H species are characterized by a line at 4.8, 4.9 ppm and do not interfere with other ^1H signals. The quadruplet for CH_2 silicate does not shift, except for a slight shoulder on each quadruplet line for experiments 3 and 4. The same phenomenon occurs for the -OCH_2CH_3 triplet. The CH_3CH_2O H molecules appear as a quadruplet (3.63–3.53 ppm) and a triplet (1.20–1.13 ppm).

The two quadruplets are in separate ranges. This simplifies the kinetic study. Intensities are integrated for each quadruplet, and the sum total is kept constant (+/−1%) during the reaction.

To discuss the kinetic laws, a and b designate respectively the initial concentrations in $Si(OC_2H_5)_4$ and in H_2O. Many equations can be used to follow both the hydrolysis and the condensation. The simplest way is to consider the overall reaction.

$$\underset{a}{Si(OC_2H_5)_4} + 2\ \underset{b}{H_2O} \xrightarrow{k} SiO_2 + 4\ C_2H_5OH$$

If x is the molar concentration in SiO_2, one can imagine a kinetic law, in which v is the rate of the reaction:

$$v = k(a - x)\ (b - 2x) = dx/dt = -d(a - x)/dt$$

Integration of this differential equation gives rise to:

$$\ln \frac{(b/2) - x}{a - x} = 2(b/2 - a)\ kt + \ln(b/2a)$$

If the water concentration is much greater than that of the silicate, we find the classical law:

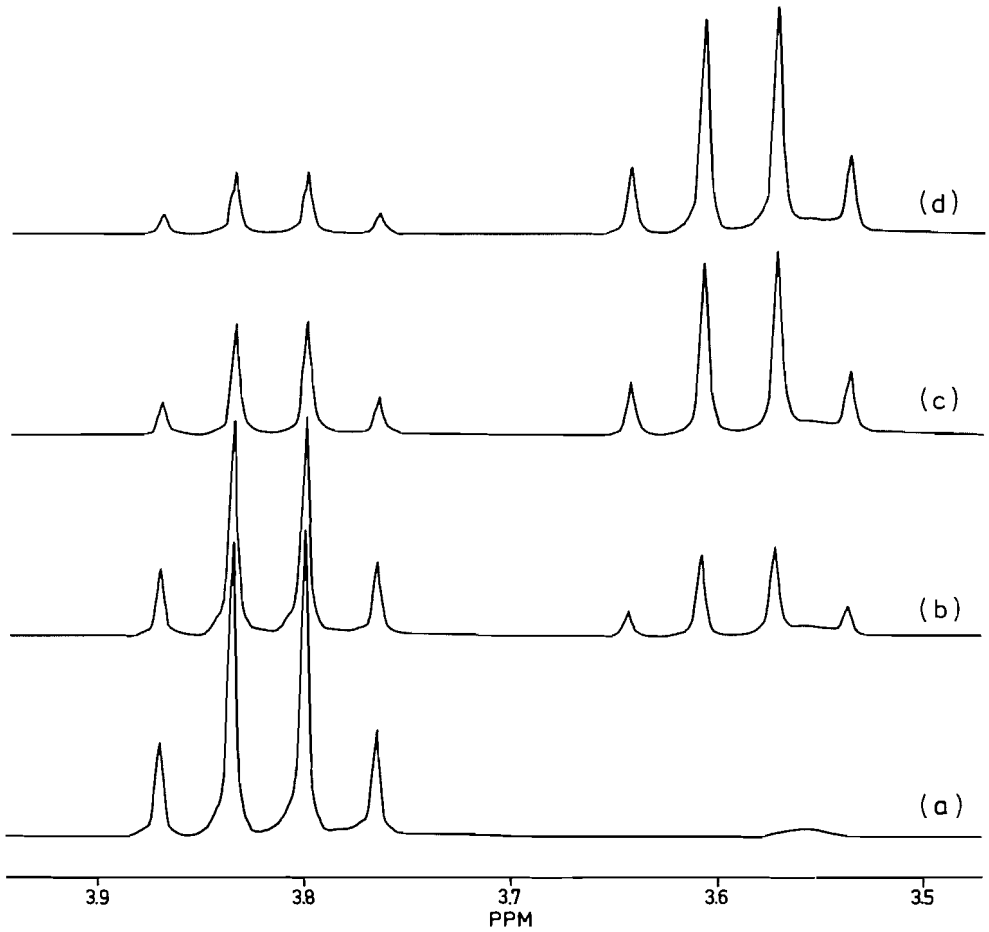

FIG. 1. ^{1}H NMR of $Si(OC_2H_5)_4$ hydrolysis in C_2D_5OD (ETET 1) after (*a*) 2 min; (*b*) 66 min; (*c*) 276 min; (*d*) 456 min.

$$\ln \frac{a}{a-x} \sim b'kt \quad \text{or}$$

$$\ln \frac{a-x}{a} \sim -b'kt \quad \text{with} \quad b' \sim b$$

As an example, Fig. 2 shows plots of the evolution of the silicate concentration (in ln units) as a function of time for the two experiments ETET 1 and ETET 2. In each experiment, more than 80% of the initial silicate has disappeared.

Two straight lines are obtained, which give rise to apparent rate constants $k' = 0.0033$ min^{-1} (ETET 1) and $k' = 0.043$ min^{-1} (ETET 2). The ratio of 12 between them should correspond to a mean ratio of 12 between the "mean" b' values. The initial b values are in the ratio 3.6 and the value 4.7 is obtained from the $(b\text{-}a)$ ratio.

For ETET 2 only, this approximation can be used ($b/a \sim 49$) and the linearity of the plot is a proof that the law is indeed of order 1 versus the silicate concentration.

In Fig. 2, we have plotted the comparison of the experiments ETET 1 and MEET 1 in which the concentrations of both silicate and water (and NH_3) are the same, the solvent being the only distinct parameter. The slopes of the lines show that, in CD_3OD, the apparent rate constant k' is three times greater than for C_2D_5OD (MEET 1, $k' = 9 \times 10^{-3}$ min^{-1}; ETET 1, $k' = 3.3 \times 10^{-3}$ min^{-1}). The k' values for all experiments are listed in Table 2.

As mentioned above and in Table 1, the ratio b/a is not very great for ETET 1, MEET 1, and MEET 2 and it could be four times smaller if we consider the ratio (H_2O/(Si-OC_2H_5 group).

We have imagined four reactions and the most probable kinetic laws:

[1] $\underset{a}{Si(OC_2H_5)_4} + \underset{b}{H_2O} \xrightarrow{k} SiOH(OC_2H_5)_3 + C_2H_5OH$

$$v = k(a\text{-}x)\,(b\text{-}x) = dx/dt$$

[2] $\underset{4a}{Si\text{-}OC_2H_5} + \underset{b}{H_2O} \xrightarrow{k} Si\text{-}OH + C_2H_5OH$

$$v = k(4a\text{-}x)\,(b\text{-}x) = dx/dt$$

[3] $\underset{a}{Si(OC_2H_5)_4} + 4\,\underset{b}{H_2O} \xrightarrow{k} Si(OH)_4 + 4\,C_2H_5OH$

(total hydrolysis)

$$v = k(a\text{-}x)\,(b\text{-}4x) = dx/dt$$

[4] $\underset{a}{Si(OC_2H_5)_4} + 2\,\underset{b}{H_2O} \xrightarrow{k} SiO_2 + 4\,C_2H_5OH$

hydrolysis + condensation

$$v = k(a\text{-}x)\,(b\text{-}2x) = dx/dt$$

or

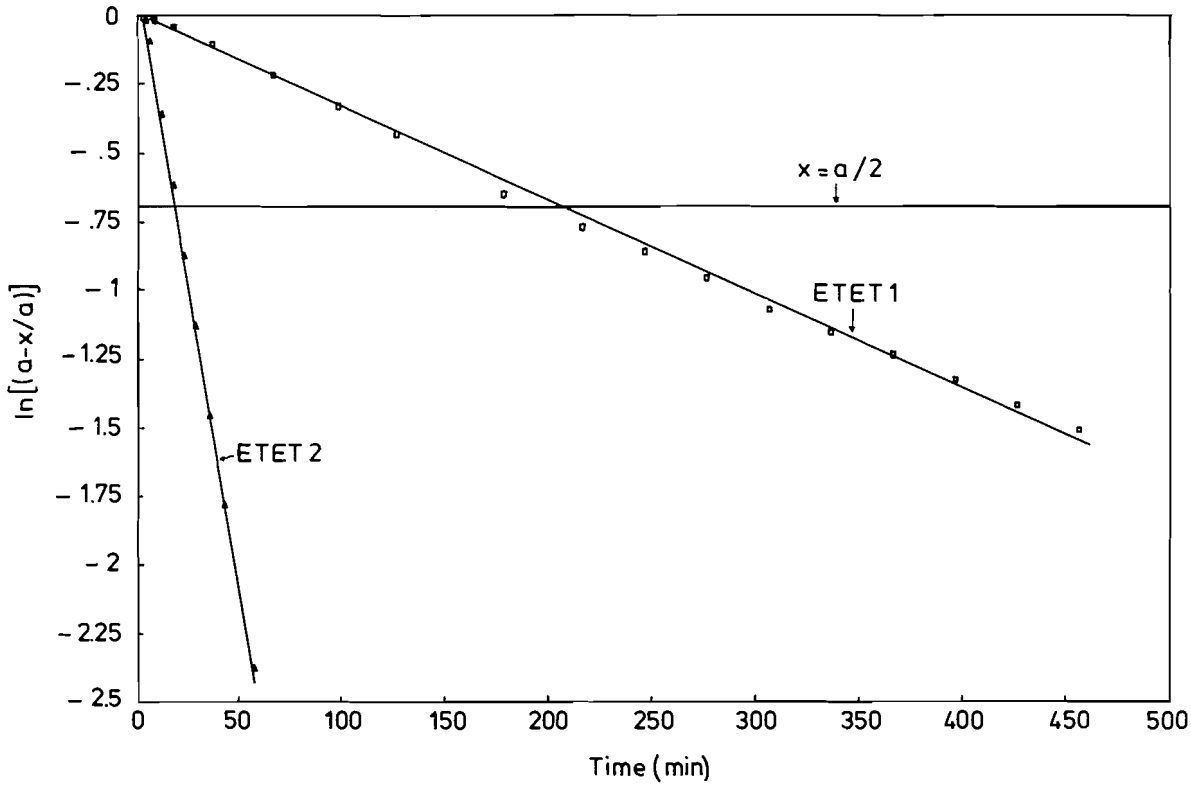

FIG. 2. Evolution of the ethyl silicate concentration during NH_3–H_2O hydrolysis in C_2D_5OD:$[H_2O]/[Si\text{-}OC_2H_5]$ = □, 12.3; Δ, 1.025.

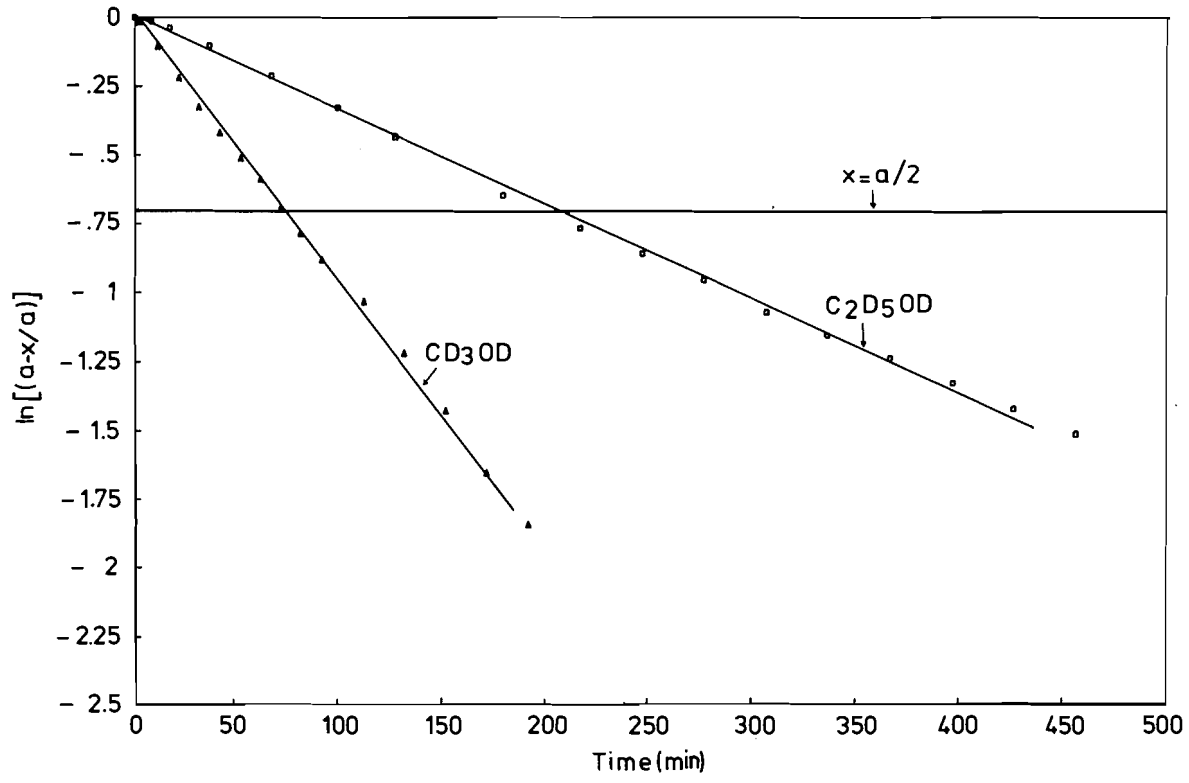

FIG. 3. Evolution of the ethyl silicate concentration during hydrolysis by NH_3–H_2O in Δ, CD_3OD and □, C_2D_5OD:$[H_2O]/[Si\text{-}OC_2H_5]$ = 1.025).

TABLE 2. Kinetic results of $Si(OC_2H_5)_4$ hydrolysis

Experiment	Solvent	$Si(OC_2H_5)$ ($M\ L^{-1}$)	$[H_2O]/[Si\text{-}OR]$	k' (min^{-1})	k $L\ mol^{-1}\ min^{-1}$
ETET1	C_2D_5OD	0.40	1.025	0.0033	0.0028
ETET2	C_2D_5OD	0.12	12.3	0.0430	0.0075
MEET1	CD_3OD	0.40	1.025	0.0096	0.0075
MEET2	CD_3OD	0.20	2.15	0.0134	0.0079

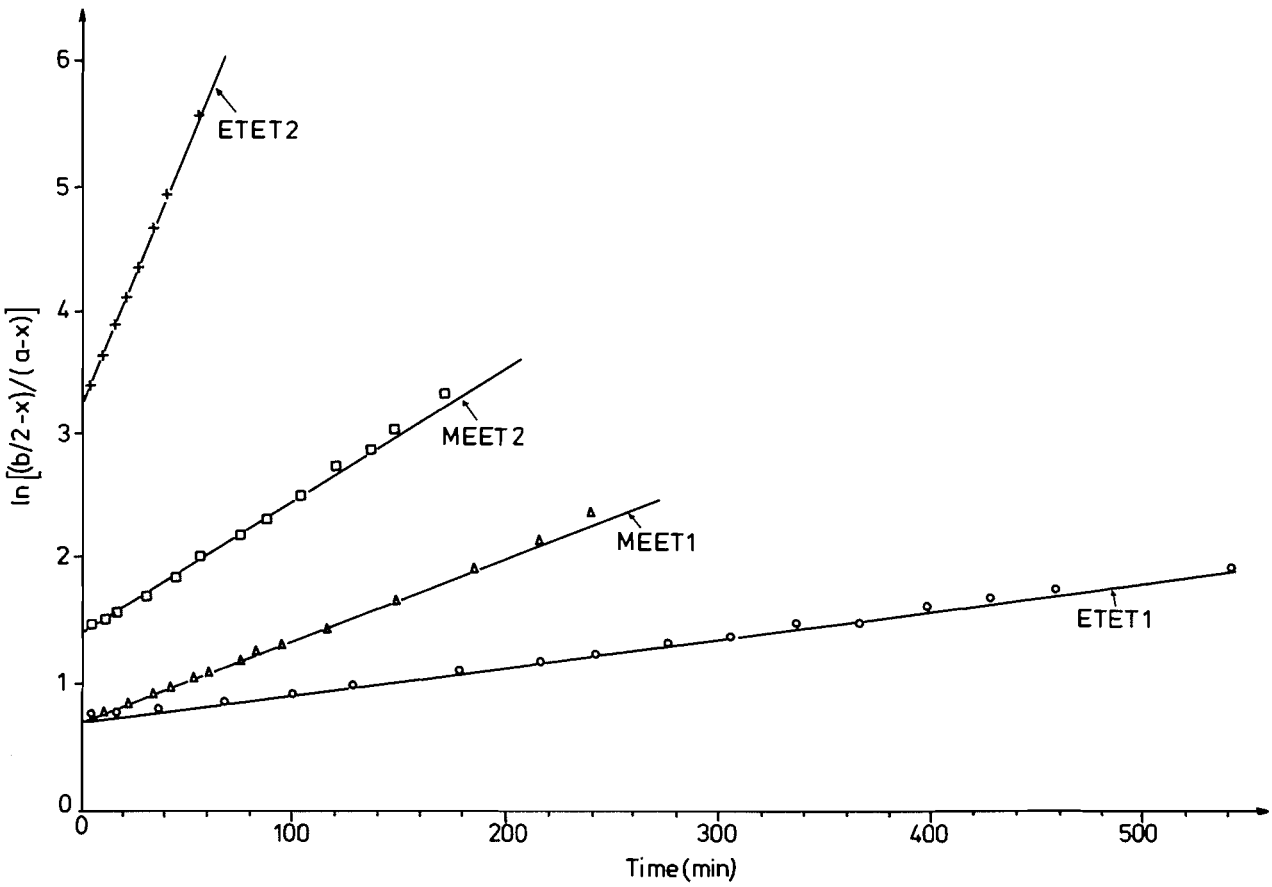

FIG. 4. Plots of $\ln[(b/2\text{-}x)/(a/x)]$ as a function of time for the four experiments corresponding to the global equation: $Si(OC_2H_5)_4 + 2H_2O \rightarrow SiO_2 + 4C_2H_5OH$. $v = k[Si(OC_2H_5)_4]\,[H_2O]$; $a = [Si(OC_2H_5)_4]_{initial}$; $b = [H_2O]_{initial}$.

$$v = k(a\text{-}x)\,(b\text{-}2x)^2 = dx/dt.$$

We have plotted, for these five kinetic laws, the evolution of a term that is linear versus time (example: case [1]: $\ln[(b\text{-}x)/(a\text{-}x)] = (b\text{-}a)kt + \ln(b/a)$.

The best linearity for the four experiments was obtained by using eq. [4] and the kinetic law $v = k(a\text{-}x)\,(b\text{-}2x) = dx/dt = -d(a\text{-}x)/dt$.

The four plots are collected in Fig. 4, in which $\ln[(b/2\text{-}x)/(a\text{-}x)]$ is plotted as a function of time; the mean slope of each fitted straight line corresponds to $2(b/2\text{-}a)k$. These values of k are listed in the last column of Table 2.

The experimental equation $v = k(a\text{-}x)\,(b\text{-}2x)$ followed by NMR measurements proves that the overall reaction [4] is not the elementary mechanism. It corresponds surely to a second-order hydrolysis reaction such as [1]. The decrease in silicate concentration, as measured by NMR, is slow compared to further condensation steps that release water.

Discussion

The solvent plays a considerable role. Hydrolysis rate increases by a factor of 3 when CD_3OD is used instead of C_2D_5OD.

We would expect two separate steps for Si-OCH-2-CH_3: (*i*) hydrolysis leading to monomeric or oligomeric Si-OH species; (*ii*) condensation of these hydrolyzed species leading to siloxane Si-O-Si bridges and to the growth of silica particles.

But at mid-stage, the liquid is already milky. Therefore, during the synthesis of homodispersed silica particles ($Si(OC_2H_5)_4 + C_2D_5OD$), particles grow during the hydrolysis step.

The presence of large particles ($\phi \sim 50$ nm) leading to a milky aspect is accompanied by nonhydrolyzed Si-O-CH_2-CH_3 groups. The Ostwald (13) ripening model, described by Fischmeister and Grimwall (14), implies that nuclei are

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

formed as they grow. As particles smaller than a critical size dissolve, they are surrounded by a zone of excess solute that finds its way to particles larger than r^*. This model does not seem in accordance with our experimental results in which large particles exist with Si-OR groups. Condensation and particle growth occur at the same time as hydrolysis.

One can suppose that condensation reactions leading to dimers, polymers, and particles occur very rapidly after SiOH groups are formed by hydrolysis. The hydrolysis rate is therefore the slow step, but the water concentration does not follow eq. [3] for hydrolysis because condensation gives rise to water. If the condensation rate was very slow, the kinetic law should follow reaction [3]. This last model gives rise to curves instead of straight lines, which suggests that condensation is the fast step. A similar point of view has been developed (8) in the case of the hydrolysis of $Si(OCH_3)_4$ in alkaline media (KOH 1 M) because the ^{29}Si NMR signals do not display any intermediate molecules which apparent Si-OH group. Even if the final state in basic media when $Si(OCH_3)_4$ is used is a gel, which we have also seen in kinetic experiments with much greater rates than for $Si(OC_2H_5)_4$, and even if homodispersed SiO_2 particles are obtained when $Si(OC_2H_5)_4$ is used as the starting material, this experiment suggests that, in both cases, condensation is the fast step, which enables one to give evidence of nonhydrolyzed Si-OC_2H_5 groups in silica particles. Even after a long time, such groups are still present and are only broken by a thermal treatment at 400°C (5).

Increase of the rate constant k by increasing the ratio H_2O/silicate in ETET 2 could result from differences in growth kinetics of the silica microparticles, because it has been proven[3] that smaller concentrations of NH_3 and H_2O give rise to smaller particles at the end of the experiments. The heterogeneity of these systems may therefore contribute to different rate constants. Nevertheless, we have definitely established that the role of the solvent (substitution of CD_3CD_2OD by CD_3OD) strongly modifies the kinetics law although we have proved that ethyl silicate does not lead to methyl silicate in CD_3OD by transesterification. The role of the solvent should involve the ionization of OH^- in these NH_3–H_2O solutions. The speciation of the protonic groups (OH^-, NH_3, H_2O) can be different in C_2D_5OD and CD_3OD, arising from different dielectric constants (ε methanol ~ 33; ε ethanol ~ 24); the viscosity of the solvent could be another factor explaining this behaviour difference (20°C; $\eta_{CH_3OH} \sim 6 \times 10^{-4}$ Pa s; $\eta_{CH_3CH_2OH} \sim 12 \times 10^{-4}$ Pa s).

[3]E. El Rhess, I. El Bakali, and R. Mercier. Manuscript submitted for publication.

Conclusion

The solvent affects the kinetics of hydrolysis. CD_3OD is more effective than C_2D_5OD. ^{13}C NMR demonstrates that no transesterification occurs between the silicate and the alcohol. $Si(OC_2H_5)_4$ produces stable colloidal systems with SiO_2 particles in the 0.1–0.5 μm range. The relative rates of hydrolysis and condensation differ for both systems; the condensation rate is much faster than the second-order hydrolysis reaction rate. A complete ^{29}Si NMR study in alkaline media should provide further information about hydrolysis and condensation.

Electron thermalization distances and free-ion yields in dense gaseous and liquid benzene

NORMAN GEE AND GORDON R. FREEMAN[1]

Chemistry Department and Radiation Research Centre, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received December 16, 1991

NORMAN GEE and GORDON R. FREEMAN. Can J. Chem. **70**, 1618 (1992).

Electron thermalization has been studied in gaseous and liquid benzene at $4.1 \leq d/\text{kg m}^{-3} \leq 878$ (temperatures 295–560 K) using measurements of the free-ion yield G_{fi}^{E} as a function of electric field strength E and temperature T. The measured (G_{fi}^{E}, E) values at each T were compared to those calculated using an extended Onsager model. Assumption of a three-dimensional Gaussian distribution of secondary electron thermalization distances YG resulted in too large a field dependence. The Gaussian with the small added tail, YGP, gave the correct dependence. Values of the yield extrapolated to zero field, G_{fi}^{0}, and of the most probable thermalization distance b_{GP} were obtained. Variation of the density-normalized distance $b_{\text{GP}}d$ with reduced density d/d_{c} (d_{c} = critical fluid density) was expected to be similar to that in ethene, due to the π-electrons in the two compounds. Instead, it was similar to that in ethane. Throughout the liquid range, epithermal electrons were de-energized less efficiently than in the gas at $d < 0.5\ d_{\text{c}}$ where the benzene molecules are further apart. As the density increases above $2\ d_{\text{c}}$ the values of $b_{\text{GP}}d$ decreased as in other hydrocarbons, rather than like those in hexafluorobenzene, which increased sharply. Dielectric constants were also measured up to 560 K.

NORMAN GEE et GORDON R. FREEMAN. Can. J. Chem. **70**, 1618 (1992).

On a étudié la thermalisation électronique en opérant en phase gazeuse et dans le benzène liquide, à $4{,}1 \leq d/\text{kg m}^{-3} \leq 878$ (températures de 295 à 560 K), en faisant appel à des mesures de rendement en ions libres, G_{fi}^{E}, en fonction de la force E du champ électrique et de la température T. On a comparé les valeurs mesurées (G_{fi}^{E} et E) à chaque température avec celles calculées en utilisant le modèle élargi de Onsager. En faisant l'hypothèse qu'il existe une distribution gaussienne tridimensionnelle des distances YG de thermalisation des électrons secondaires, on obtient une dépendance trop importante par rapport au champ. La gaussienne à laquelle on a ajouté une petite traînée conduit à la bonne dépendance. On a obtenu les valeurs des rendements extrapolés jusqu'à un champ nul, G_{fi}^{0}, ainsi que la distance de thermalisation la plus probable, b_{GP}. À cause de la présence d'électrons π dans les deux systèmes, on s'attendait à ce que la variation de la distance normalisée pour la densité, $b_{\text{GP}}d$, en fonction de la densité réduite, d/d_{c}(d_{c} = densité fluide critique) soit semblable à celle de l'éthène. Toutefois, elle est semblable à celle de l'éthane. Dans toute la phase liquide, les électrons épithermiques perdent leur énergie moins facilement que dans le gaz, à $d < 0{,}5\ d_{\text{c}}$, où les molécules de benzène sont plus éloignées les unes des autres. Lorsque la densité augmente au dessus de $2\ d_{\text{c}}$, les valeurs de $b_{\text{GP}}d$ diminuent comme dans les autres hydrocarbures plutôt que comme dans l'hexafluorobenzène dans lequel elles augmentent rapidement. On a aussi mesuré les constantes diélectriques jusqu'à 560 K.

[Traduit par la rédaction]

I. Introduction

Under irradiation by γ-rays or high-energy electrons, some molecules of a fluid ionize, ejecting secondary electrons with excess kinetic energy. These secondary electrons move away from their sibling cations, undergoing in the course of their flight energy-transfer collisions with the surrounding fluid molecules, and eventually become thermalized at distances y from the cations (1*a*). The thermalization distances have a distribution $F(y)$. The shape of $[F(y),y]$ can be examined using measurements of the free ion yield G_{fi}^{E} over wide ranges of applied field strength E and temperature T, because the shape of $F(y)$ affects the shape of the (G_{fi}^{E}, E) curve at each T(1*b*).

For over 100 liquids the most suitable form for $F(y)$ was found to be a hybrid function that is mainly a three-dimensional Gaussian, with a power tail that represents the outermost 5% of electrons (1*c*). This function, designated YGP, will be discussed further in Sect. III. The most probable thermalization distance b_{GP} is determined largely by the ability of the fluid to de-energize electrons from energies of ~200 zJ to ~10 zJ (160 zJ = 1 eV; z = zepto = 10^{-21});[2] stronger scattering of the electrons at these energies produces a smaller b_{GP} (2, 3). The thermalization distance is often inversely proportional to the mass density d (1*c*, 3), so variations in bd can be used to assess differences in the ability of fluids to de-energize (thermalize) epithermal electrons. It is assumed that any effects of temperature (other than that on the densities of liquids and vapors at equilibrium) are small. This assumption is supported by measurements in the *n*-alkanes: (*a*) In moderately dense gases of methane, ethane, propane, and *n*-butane away from the critical region, so that gas molecules were too far apart for conduction band formation, values of $b_{\text{GP}}d$ were constant, $(5.5 \pm 0.2) \times 10^{-6}$ kg m^{-2}, over ~4-fold variation in density, although the temperature ranges were quite different (158–183 K in methane compared with 365–409 K in *n*-butane) (4, 5). (*b*) In liquid *n*-undecane and in liquid *n*-tetradecane, $b_{\text{GP}}d$ values were constant (Δ_{av} ~3%) as densities were decreased ~25% and temperatures were concomitantly increased from 296 to 472 and 506 K respectively (6).

Electron thermalization has recently been studied in hexafluorobenzene (7). As the fluid density was increased from $0.5\ d_{\text{c}}$, values of $b_{\text{GP}}d$ increased monotonically. An especially sharp increase occurred in the dense liquid at $d > 2d_{\text{c}}$. This behavior is somewhat different from that in most hydrocarbons (1*c*). Measurements in its hydrocarbon analog, benzene, have been limited to $T < 370$ K ($d > 2.6\ d_{\text{c}}$), and reported free-ion yields have differed by up to 1.8-fold (3, 8).

In this work free-ion yields are given at densities of 4.1–878 kg m^{-3} (temperatures 295–560 K). Values of b_{GP} were then obtained using the extended Onsager model (1*b*), and thermalization of epithermal electrons in benzene, C_6H_6, is used to bridge the comparison of thermalization in hydrocarbons to that in hexaflurobenzene, C_6F_6.

II. Experimental

Materials and sample preparation

Benzene from Aldrich (HPLC grade, 99.9+%) was received stored under nitrogen. The liquid was poured into a storage bulb attached to a grease-free glass vacuum line, closed from the atmosphere, and degassed using two freeze–pump–thaw cycles. The liquid was then transferred, in turn, into storage bulbs containing sulfuric acid, lithium aluminum hydride, and sodium–potassium alloy. To effect the transfers, the source bulb was surrounded with a water bath at ~315 K and the receiver bulb was cooled using ice/water slurry. The benzene sample was stirred slowly on the acid for 1 day, on the $LiAlH_4$ for 4 days, and on the Na–K alloy for 7 days. The liquid was then held on the alloy until transfer to the conductance cell.

Apparatus and techniques

Details of the conductance cells, temperature control and measurement, irradiation and dosimetry procedure, and data collection are in, or cited in, refs. 6 and 7.

Physical properties

Values of liquid densities were compiled from refs. 9–13. The agreement between data sets was ~0.1% at $T < 380$ K and ~0.3% at $T < 559$ K. It might be noted that liquid densities reported in ref. 14 (not used here) were 0.9% higher than those in the other works. Critical fluid parameters reported by different sources varied widely but most values (refs. 9–14 and others cited by them) are within the limits $d_c = 303 \pm 3$ kg m^{-3} at $T_c = 562.3 \pm 0.4$ K. Vapor densities reported in refs. 9, 11, and 14 agreed within ~2%. Exceptions were densities from ref. 11 at 379–433 K, which oscillated about the values of refs. 9 and 14, and densities reported in ref. 14 at $T > 478$ K, which were up to 20% lower than those of refs. 9 and 11 at the same temperatures. The discordant values were not used.

Relative dielectric permittivity ε values reported in the literature (15–18) did not cover the complete range of the present experimental conditions, so values were measured as described in ref. 19. The most recent works concentrated on measurements at constant temperature and increasing density (17, 18). The most extensive earlier measurements in the liquid along the coexistence curve reported permittivities up to 473 K (15). The present measurements agreed with these values within 0.3%. Quadratic interpolation of the present data gave $\varepsilon = 2.274$ at 298.15 K, which is also the value recommended by the National Bureau of Standards (U.S.A.) at that temperature (20).

III. Results and discussion

Electron mobility

The radiation-induced electron conductance transient (ECT) was measured at 295 K as a check on the purity of the liquid. At $0.4 \leq E/\text{MV m}^{-1} \leq 1.3$ the ECT signals decayed with a half life $t_{1/2} = 2.2$ μs. Analysis by the conductance method (Appendix of ref. 19) gave the electron mobility $\mu_0 = 1.1 \times 10^{-5}$ m^2 V^{-1} s^{-1}, in reasonable agreement with previously reported values, 1.1×10^{-5} (21), 1.2×10^{-5} (22), and 1.4×10^{-5} m^2 V^{-1} s^{-1} (23).

Electron thermalization and the extended Onsager model

The passage of a high-energy (> 1 fJ) electron through a liquid results in a widely spaced sequence of activated microzones with diameters of a few nanometers and separated by a few hundreds of nanometers (1*d*). Each microzone contains one or more spatially correlated ion-electron pairs. (We previously called these microzones by the traditional jargon name "spur." The name microzone (1) seems to be clearer to nonspecialists.) The ion-electron separation distance y at which the electron thermalizes determines the probability that the electron will be drawn back to the cation to recombine (geminate neutralization), or will escape the cation to diffuse freely in the bulk medium (free-ion formation). The free ions can be collected at electrodes and measured. The process can be represented as:

[1] $M \rightsquigarrow [M^+ + e^-]$

[2] $[M^+ + e^-] \rightarrow M$ (geminate neutralization)

[3] $[M^+ + e^-] \rightarrow M^+ + e^-$ (free-ion formation)

[4] $\left.\begin{matrix} M^+ \xrightarrow{E} \\ e^- \xrightarrow{E} \end{matrix}\right\}$ electrodes

in which the wavy arrow indicates ionization and the square brackets indicate Coulombic attraction between the electron and the ion that is not negligible in comparison with k_BT. The total yield G_{tot} of reaction [1] (expressed as the number of ion pairs formed per 16 aJ (100 eV) of energy absorbed by the fluid) can be measured chemically in the liquid or electrically in the gas phase. For ion pairs formed in dense media by X or β rays, the competition between eqs. [2] and [3] was first treated by Onsager (1*d*, 24). The competition depends on the relative dielectric permittivity, temperature, and collecting field E as well as on y. An extended Onsager model expressed the free-ion yield as (1*d*)

$$[5] \qquad G_{fi}^{E} = G_{tot} \int_0^\infty F(y)\phi_{fi}^0(y)[1 + f(\varepsilon, E, y, T)]dy$$

where $\phi_{fi}^0(y)$ is the probability that an ion pair that becomes thermalized at a separation y will separate to form free ions when $E = 0$, $f(\varepsilon, E, y, T)$ is a field enhancement term, and $F(y)$ is the distribution of thermalization distances. Explicit forms for these terms and detailed discussions of them are given in ref. 1*d*, and in shortened form in refs. 5, 21, and 25. The most commonly used forms of $F(y)$ are based on a Gaussian or an exponential (1*b*, 3, 25–33). Comparison of free-ion yields calculated from eq. [5] with measured yields allows extrapolation to $E = 0$ to give G_{fi}^0, and gives information about $F(y)$ and thereby about electron energy-transfer interactions with the fluid.

In most liquids where both E and T have been varied over wide ranges a modified Gaussian (see YGP below) is most suitable, whereas at a single T more than one $F(y)$ might provide a fitting to the set of $[G_{fi}^E, E]$ data (25, 27–29). For example, either a one-dimensional exponential or a three-dimensional Gaussian fits the data from neopentane at 295 K (27). The problem was to find an $F(y)$ distribution that would fit the largest number of systems over the widest range of conditions.

The calculation of yields using eq. [5] also requires the value of G_{tot}. Most measurements were done in liquids below their normal boiling points, and often near 295 K. In such liquids, constant values of G_{fi}^E at high field identifiable with G_{tot} were not obtained even at $E \sim 20$ MV m^{-1} (29). Application of yet higher fields causes the ionization pulse to trigger dielectric breakdown. Thus G_{tot} can be used as a free parameter, but in most cases the low-density gas value was

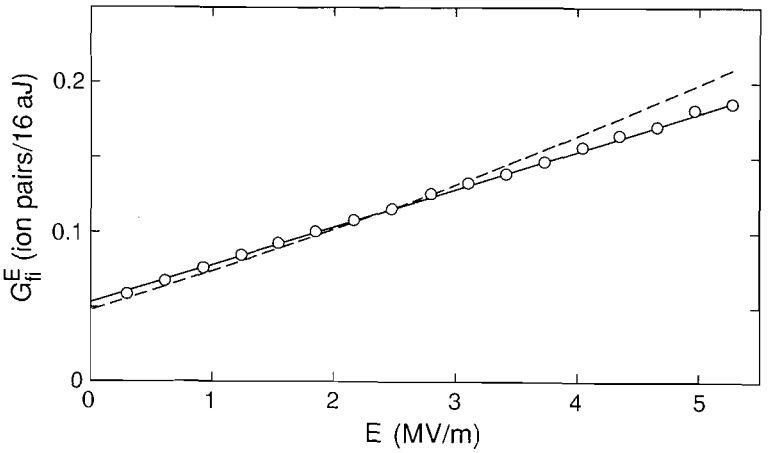

FIG 1. Free-ion yields in liquid benzene at 295 K and 878 kg m^{-3} plotted against electric field strength. ○, measurements. ——— and — — — were calculated from eq. [5], using G_{tot} = 4.3 (33) and $F(y)$ = YGP with b_{GP} = 3.4 × 10^{-9} m, and $F(y)$ = YG with b_G = 4.1 × 10^{-9} m, respectively.

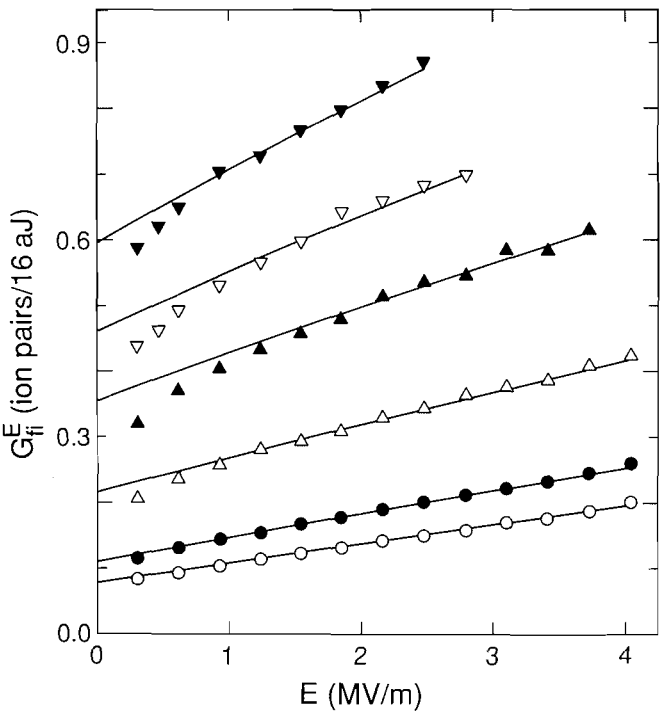

FIG. 2 Free-ion yields in liquid benzene against electric field strength at (T/K, d/kg m^{-3}): ○ (330, 841), ● (367, 798), △ (443, 703), ▲ (503, 609), ▽ (534, 530), and ▼ (556, 430). Lines were calculated from eq. [5], using G_{tot} = 4.3, $F(y)$ = YGP, and b_{GP} of Table 1.

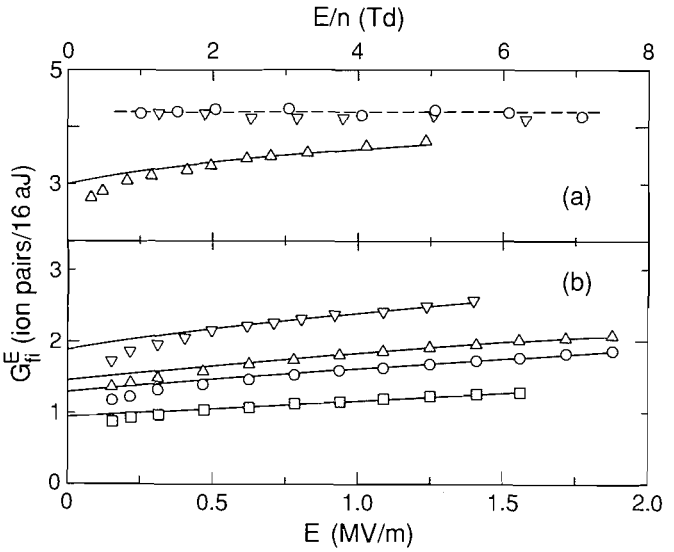

FIG. 3. Free-ion yields in gaseous benzene at (T/K, d/kg m^{-3}): (*a*) ○ (367, 4.1), ▽ (386, 6.5), and △ (453, 25) against electric field strength normalized by number density (Td = 10^{-21} V m^2 $molecule^{-1}$); (*b*) ▽ (514, 73), △ (535, 111), ○ (549, 148), and □ (560, 227). Solid lines calculated as in Fig. 2. Dashed line indicates low density gas G_{tot} = 4.3 (32).

used. Reference 1*f* and the entire Chap. 2 of ref. 1 should be read to understand this problem. If the value used for G_{tot} were 20% too small, the estimated value of b_{GP} would be 5–10% too large.

Measurements

The free-ion yield in liquid benzene at 295 K increases linearly with increasing field strength (Fig. 1). Using eq. [5] and taking $F(y)$ to be a three-dimensional Gaussian, designated YG,

$$[6] \qquad F(y) = \left(\frac{4y^2}{\pi^{1/2} b_G^3}\right) \exp\left(-\frac{y^2}{b_G^2}\right),$$

and G_{tot} = 4.3 (34), the best-fit value b_G = 4.1 × 10^{-9} m (where b_G is the dispersion parameter for the distribution and the most probable value of y) gave the dashed line in Fig. 1. The calculated field effect is greater than that observed experimentally. This means that $F(y)$ should extend more gradually to higher values of y than YG. The distribution YGP does this (1*b*):

$$[7] \qquad F(y) = \begin{cases} 0.96\ \text{YG}, & y < 2.4\ b_{GP} \\ 0.96[\text{YG} + 0.5\ (b_{GP}^2/y^3)], & y > 2.4\ b_{GP} \end{cases}$$

where b_{GP} has replaced b_G. This distribution with b_{GP} = 3.4 × 10^{-9} m and eq. [5] gave the solid line in Fig. 1. The extrapolated value for G_{fi}^0 is 0.053, which is the same as that measured directly in ref. 3. Hence the present set of measurements (examples of which are given in Figs. 2 and 3) was

[a]Mass density.
[b]Static relative permittivity.
[c]Free ion yield at $E = 0$ and most probable thermalization distance of $F(y)$ = YGP. Assumed $G_{tot} = 4.3$, the experimental value in the low density gas (32). Yields are in ion pairs/16 aJ (100 eV).
[d]Critical fluid values are $T_c = 562.3 \pm 0.4$ K and $d_c = 303 \pm 3$ kg m^{-3} (9–14).

fitted using eq. [5] with $F(y)$ = YGP. The required values for b_{GP} and extrapolated G_{fi}^0 values are summarized in Table 1. In Fig. 4 the present values of G_{fi}^0 are compared to those of refs. 3 and 21. Agreement with ref. 3 is within an average deviation of 3%. Values from ref. 21 were too high, likely due to inaccurate dosimetry (6).

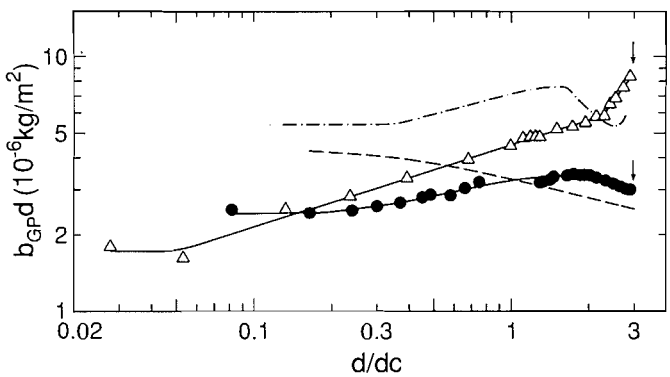

FIG. 5. Product of most probable thermalization distance and density, $b_{GP}d$, plotted against d/d_c for electrons in ethane (ref. 4, — · —), ethene (ref. 5, — — —), benzene (●), and hexafluorobenzene (ref. 7, △). Solid lines are visual aides. Arrows indicate liquid densities at freezing points.

It might be noted that the physical basis of $F(y)$ = YGP is the same as that of the Gaussian $F(y)$ = YG. Over 90% of the ion-pair thermalization distances are in the Gaussian core of YGP (1*b*). The tail is a correction to the Onsager model, which assumes that only one ion pair is formed in each microzone. This is the case in ~75% of the microzones but in ~15% two ion pairs are formed and in ~10% three or more are formed (1*b*). In these multipair microzones, the innermost electrons of the distribution are rapidly drawn back to the cluster of positive ions at the center (1*d*). Only one cation and the outermost electron remains. It is the separation distances of these surviving ion pairs that is represented by the tail of YGP. The inverse cube dependence of the tail was determined empirically by varying x in tails of y^{-x}. Examples of functions y^{-x} are given in refs. 1*b* and 26. In liquids where the values of ϕ_{fi}^0 are low, x converged towards 3. The crossover point $y > 2.4\ b_{GP}$ is related to the percent of contribution of the tail to $F(y)$ and affects d G_{fi}^E/dE. This point was also obtained experimentally. Hence both the power of the tail portion and the crossover point are simply empirical parameters.

In Fig. 3*a* the yields are shown against E/n(n = number

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

density), although E rather than E/n appears in the field enhancement term of eq. [5]. The reason is that in lower density gases the interval τ between collisions becomes significant because the space between molecules becomes large. The electrons are accelerated by the field during this time and the energy gained from the field depends on E/n (35). Hence in lower density gases the density-normalized field strength is a more suitable representation of the field strength.

Thermalizing ability

The ability of the fluid to de-energize epithermal electrons (thermalizing ability) is inversely proportional to $b_{GP}d$. In Fig. 5 values of $b_{GP}d$ are plotted against d/d_c for electrons in ethane (4), ethene (5), benzene (Table 1), and hexafluorobenzene (7). The lower $b_{GP}d$ values in ethene than in ethane indicate that the carbon-carbon π-bond in ethene de-energizes hot electrons more readily than does the carbon-carbon σ-bond in ethane. In ethene the thermalizing ability of the fluid increases monotonically with density. In ethane the behavior is complex.

Benzene molecules contain π-bonds. Hence it might be expected that the $b_{GP}d$ curve would be similar to that in ethene. Instead the variation of $b_{GP}d$ with d/d_c resembled that in ethane (Fig. 5). At liquid densities the $b_{GP}d$ values in benzene were larger than those in liquid ethene. The ability of benzene molecules to de-energize hot electrons is less when the molecules are close together than when they are far apart.

Replacing all of the hydrogen atoms in benzene with fluorine atoms decreases $b_{GP}d$ in the low-density gas, but increases it in the dense gas and liquid (Fig. 5). The curves for C_6F_6 and C_6H_6 are qualitatively similar up to $d \approx 2d_c$. However, as the density is further increased the molecules are squeezed closer together, and $b_{GP}d$ values in hexafluorobenzene increase sharply while those in benzene decrease as in other hydrocarbons. This is not a freezing point transition. In hydrocarbons the decrease in $b_{GP}d$ with increasing d/d_c has been attributed to stronger short-range interactions of the electron with the repulsive cores of the molecules, since the spaces between molecular cores are being decreased (1*e*, 25). In hexafluorobenzene, it might be that as the molecules are being squeezed together the fluorine atoms form a separate conduction band from that of the aromatic rings (36), so that the thermalizing electrons can travel further away from their cations before losing their excess kinetic energy. One might expect similar behavior in hexamethylbenzene. Unfortunately, that high-melting-point compound (T_m = 440 K) is difficult to purify sufficiently to obtain measurements over a wide range of temperatures (21).

The crystal structure of methyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-glucopyranoside

T. STANLEY CAMERON,[1] PRADIP K. BAKSHI, RASIAH THANGARASA, AND T. BRUCE GRINDLEY[1]
Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received June 13, 1991

T. STANLEY CAMERON, PRADIP K. BAKSHI, RASIAH THANGARASA, and T. BRUCE GRINDLEY. Can. J. Chem. **70**, 1623 (1992).

The determination of the crystal structure of methyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-glucopyranoside (**1**) was repeated from data collected at −70°C because the previous assignment had a large *R* value (10.9%) and because this structure was the key link in assignment of structures of all stannylene acetals in solution. Crystals of **1** are orthorhombic, of space group $P2_12_12_1$, with $a = 12.479(2)$, $b = 19.202(5)$, $c = 19.654(6)$ Å, $Z = 4$, $R = 0.0597$ ($R_w = 0.0612$) for 3623 independent reflections with $I > 3\sigma(I)$. Compound **1** is a dimer linked together by a four-membered 1,3-dioxa-2,4-distannetane ring containing the O-3 atoms from the two glucose units. Deviations from C_2 symmetry are much smaller than reported earlier and lie mainly in the orientations of the butyl groups. The butyl groups are still significantly disordered at −70°C. It is suggested that steric effects of these flexible butyl groups may be an important factor in the selectivity for dicoordinate oxygens previously observed in reactions of stannylene acetal dimers with electrophiles.

T. STANLEY CAMERON, PRADIP K. BAKSHI, RASIAH THANGARASA et T. BRUCE GRINDLEY. Can. J. Chem. **70**, 1623 (1992).

On a redéterminé la structure cristalline du 4,6-*O*-benzylidène-2,3-*O*-dibutylstannylène-α-D-glucopyranoside de méthyle (**1**) à partir de données recueillies à −70°C parce que l'attribution antérieure n'avait été déterminée qu'avec une valeur élevée de *R* (10,9%) et que cette structure est un lien important dans l'attribution des structures de tous les acétals de stannylène, en solution. Les cristaux du composé **1** sont orthorhombiques, groupe d'espace $P2_12_12_1$, avec $a = 12{,}479(2)$, $b = 19{,}202(5)$ et $c = 19{,}654(6)$ Å, $Z = 4$, $R = 0{,}0597$ ($R_w = 0{,}0612$) pour 3623 réflexions indépendantes avec $I > 3\sigma(I)$. Le composé **1** est un dimère relié par un cycle à quatre chaînons 1,3-dioxa-2,4-distannetane contenant les atomes O-3 de deux unités de glucose. Les déviations par rapport à la symétrie C_2 sont beaucoup plus faibles que celles rapportées antérieurement et elles se situent principalement dans les orientations des groupes butyles. Même à −70°C, les groupes butyles sont encore assez désordonnés. On suggère que les effets stériques de ces groupes butyles flexibles peuvent être un facteur important dans la sélectivité pour les oxygènes dicoordonnés observée antérieurement dans les réactions des dimères d'acétal stannylène avec les électrophiles.

[Traduit par la rédaction]

Introduction

Since the first reports of their use in 1974 (1), stannylene acetals have become widely employed as intermediates for the regioselective monosubstitution of diols and polyols (2). Interest in the use of these compounds continues (3).

Stannylene acetals exist as dimers and (or) higher oligomers in solution (4–6). When the two oxygen atoms in the stannylene acetal are diastereotopic, three dimers can be formed. We have shown that in many of the reactions of stannylene acetals where high regioselectivity is obtained, only one of the three possible dimers is present in solution at concentrations detectable by ^{119}Sn nmr spectroscopy (6). Only one of the several dibutylstannylene acetals studied by X-ray crystallography exists as a dimer in the solid state (7); the others are present as polymers (8–10) or, in one case, as a pentamer (11).

The one stannylene acetal that has been studied by X-ray crystallography and found to be a dimer was methyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-glucopyranoside (**1**). This compound was also present as a single dimer in solution and its structure was shown to be the same as that in the solid by comparison of the ^{119}Sn and ^{13}C nmr spectra of **1** from the two phases (6). Identification of the structures of the dimers present for other stannylene acetals were made by correlations of their spectral results with that of **1** and by reactivity arguments (6). The regioselectivities obtained in reactions of all stannylene acetals were then related to the structures of the dimers present. Thus, the conclusions drawn about the cause of the regioselectivity in the reactions of all stannylene acetals depend on the assignment of the structure of **1** in the solid state made by X-ray diffraction.

Unfortunately, there are several difficulties with this determination (7). The *R* value obtained was 10.9% and three carbon atoms were not located. We therefore considered it important to redetermine this structure using low-temperature data so that a better solution could be obtained. We also wanted accurate structural parameters for tin in this type of compound to obtain parameters for use in molecular mechanics calculations.

Experimental

Methyl 4,6-*O*-benzylidene-α-D-glucopyranoside was prepared as previously and had physical constants in accord with literature values (6). It was converted to its 2,3-*O*-dibutylstannylene acetal by refluxing with an equivalent amount of dibutyltin oxide in benzene in an apparatus for the azeotropic removal of water (5, 6). Evaporation of the solvent on a vacuum line yielded a white powder. Distillation of dried hexane and toluene onto the sample, followed by heating and cooling cycles, gave colourless crystals suitable for study by X-ray diffraction. The crystals were transferred into capillaries in a dry box and the capillaries were sealed. Crystal data and other experimental details are summarized in Table 1. The data were collected on an Enraf–Nonius CAD4 diffractometer using graphite monochromated MoK_α radiation ($\lambda = 0.70926$ Å) on crystals maintained at 203 ± 3 K. The temperature was maintained by heating a stream of very cold nitrogen gas at a rate determined by a thermister and a feedback loop using a modified Varian NMR temperature controller. Cell dimensions were calcu-

lated from 25 reflections with 2θ angles in the range 26–30°. The structure was solved by the direct (SHELXS-86) method (12). All non-hydrogen atoms were refined with anisotropic thermal parameters. One atom, C(20), was found to be 50% disordered and was assigned two positions C(20) and C(20′). Hydrogen atoms were placed geometrically and refined with individual isotropic thermal parameters. No correction was made for extinction but an absorption correction was applied using the program DIFABS (13). Atomic scattering factors for all atoms and corrections for anomalous dispersion for Sn, C, and O were taken from the International Tables for X-ray crystallography, Vol. IV (14), and applied by the program SHELX-76 (12).[2] Refinement using the program SHELX-76 (12) minimized the function $\Sigma w(|F_o|-|F_c|)$.[2] Structures were drawn with the program CHEMGRAF (15).

Results and discussion

The structure of the compound showing thermal ellipsoids is shown in Fig. 1; a different perspective is presented in Fig. 2. The crystal data, atomic coordinates, and selected bond lengths, interbond angles, and torsional angles are listed in Tables 1–4. The numbering system used is based on carbohydrate numbering; in the dimer unit, one monomer unit starts with C-1 as C(1). The tin atom in this first unit is Sn(1). The other monomer unit contains Sn(2) and numbering starts

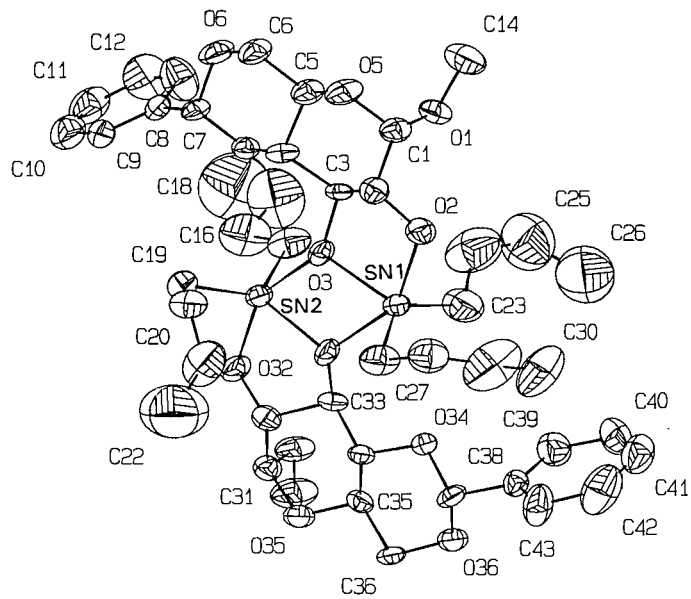

FIG. 1. The structure of methyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-glucopyranoside (**1**). Only one position is shown for the disordered atom, C(20).

[2]Supplementary tables providing full crystal data, anisotropic thermal parameters, hydrogen atom positions, all heavy-atom bond lengths, bond angles, and torsional angles, observed and calculated structure factors, and a comparison of the atomic positions from the previous study (7) with positions obtained from those in the current work transformed to the cell dimensions from the previous study may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K2A 0S2.

Tables of full crystal data, hydrogen atom positions, and bond lengths and angles have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW, U.K.

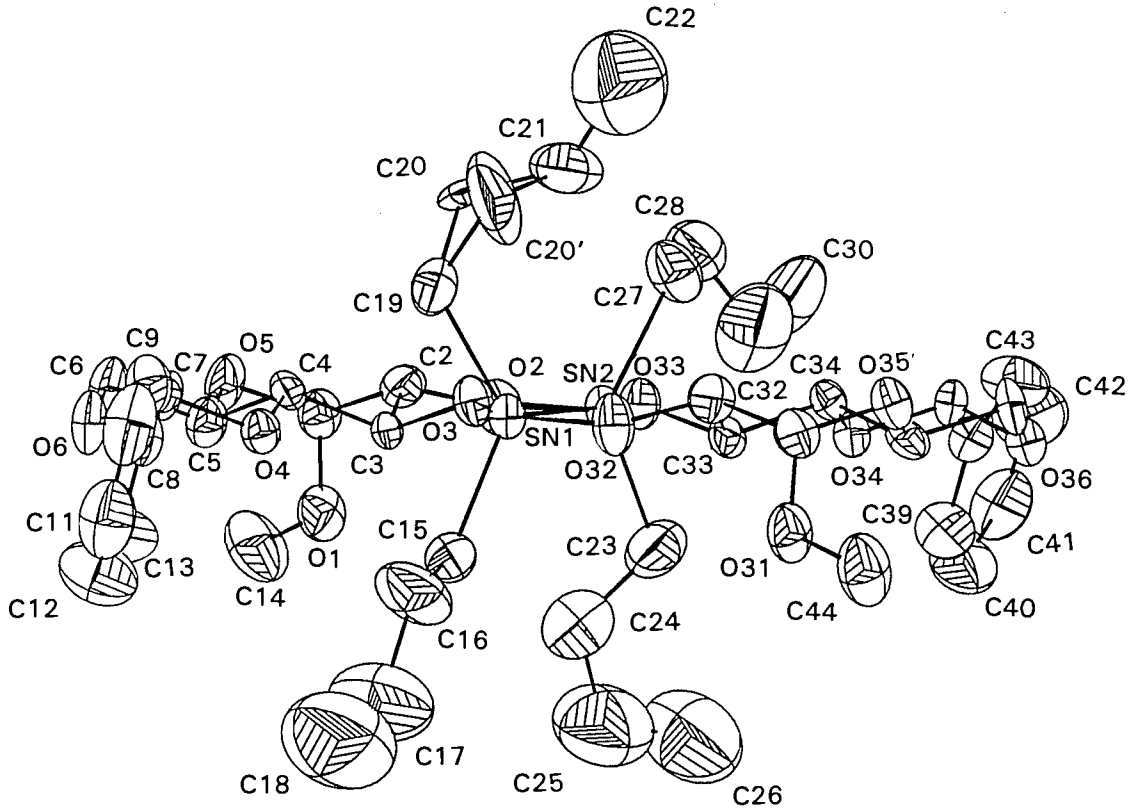

FIG. 2. A second view of the structure of methyl 4,6-*O*-benzylidene-2,3-*O*-dibutylstannylene-α-D-glucopyranoside (**1**), showing both positions for the disordered atom, C(20).

with its carbohydrate C-1 as C(31). In Tables 3–5, values from the same locations in the two monomer units are placed on the same line.

Although the space group and crystal dimensions are very similar here to the values obtained earlier (7), the atom positions calculated here are different mainly because we have chosen to label the cell dimensions in the conventional order. A supplementary table gives a comparison of the atomic positions from the earlier study (7) with the atomic positions from this study transformed to give positions based on the previous order of cell dimensions.[3] The resulting atomic positions are fairly similar to those from ref. 7 except for atoms in one of the butyl groups and the gross features of the present structure are the same as that obtained earlier (7). However, the small differences in atomic positions result in considerable differences in the structural details.

Two major differences can be noted first. The differences between the two monomer units constituting the dimer are smaller in this determination than in the previous one. Recording the data at low temperature yielded more than twice as many unique reflections with $I > 3\sigma(I)$. Because of the additional data and the lesser degree of motion at 203 K, it was possible to find all of the carbon atoms.

The three carbon atoms not found in the previous determination were on two of the butyl groups. A particularly clear representation of the structure found previously (7) is given as Fig. 2 in ref. 8. Comparison of this figure with Fig. 2 here shows that the carbon atoms not located are among those with the largest anisotropic thermal parameters. The disorder observed for one of the β-carbon atoms on a butyl group (C-20) was such that two positions could be defined for it. Although no other disordered atoms were resolved into two positions, it is evident from the large thermal ellipsoids for the terminal two or three atoms in each butyl group that these atoms occupy considerable regions of space. As will be discussed later, the thermal disorder is also evident in the value of one torsional angle. As a result, the value obtained for the goodness-of-fit parameter, S, is still rather high.

Compound **1** is present as a dimer. Formation of a dimer requires that one oxygen in each monomer unit becomes tricoordinate and dimer structures have been named by means of the numbers of the tricoordinate oxygens (6). Three different dimer structures are possible for **1**. The dimer observed here and previously (7) has the 3,3-structure. In theory, a 3,3-dimer has a C_2 axis of symmetry perpendicular to the plane of the central 1,3-dioxa-2,4-distannetane ring that relates the two tin atoms and the two glucose units. However, there are enough differences between the structures of the two monomer segments of the dimer in the crystal (see Tables 3 and 4) to explain the observation of two peaks in the ^{119}Sn nmr spectrum of **1** in the solid and the doubling of several of the peaks in the ^{13}C nmr spectrum of the solid (6).

The structure is composed of two sets of three fused rings from the two monomer units held together by a central 1,3-dioxa-2,4-distannetane ring plus terminal phenyl, butyl, and methoxy groups. The atoms in the seven fused rings have relatively small anisotropic thermal parameters. The aniso-

[3]The transformation used was $-0.25 - z$, $0.75 + y$, $0.75 + x$. We thank a referee for suggesting that we perform this comparison.

For personal use only.

tropic thermal parameters for all of the side groups are larger, but those for the butyl groups are particularly large.

The central 1,3-dioxa-2,4-distannetane ring is almost planar with torsional angles averaging 8.6(5)°. The fused 1,3,2-dioxastannolane rings adopt conformations intermediate between twist ($^{C(2)}T_{C(3)}$) and envelope conformations ($E_{C(3)}$). The bond about which the substituents are closest to being eclipsed is Sn(1)—O(2) (or in the other half of the dimer Sn(2)—O(32)) and the other small torsional angle is about the Sn(1)—O(3) (or Sn(2)—O(33)) bond.

Pyranose rings are normally flattened with the smallest torsional angles about the C(2)—C(3) and C(3)—C(4) bonds with values in the 50–55° range (16, 17). In this structure, the two C(1)—C(2)—C(3)—C(4) torsional angles average 61.1(20°). As a result of the ring flattening, the O(2)—C(2)—C(3)—O(3) torsional angle in pyranose rings is normally somewhat larger than 60° (17). Here, this torsional angle averages 52.3(8)°, about 10° smaller than the typical value. These deviations from values normally observed for torsional angles in pyranose rings suggest that formation of stannylene acetals across *trans*-diols on pyranose rings is accompanied by a certain amount of strain.

When carbohydrates having both *cis*- and *trans*-diol units unprotected are reacted with dibutyltin oxide, followed by an electrophile, substitution normally occurs regioselectively on one of the hydroxyls of the *cis*-diol unit (2, 18). These observations suggest that the strain involved in formation of a stannylene acetal across a *trans*-diol is sufficient to cause it to be present in too low concentrations to react to a significant extent when the substrate also contains a *cis*-diol unit.

Coordination about tin

The tin atoms are pentacoordinate in severely distorted trigonal bipyramids. The butyl carbon atoms are equatorial but the average C—Sn—C bond angle is large, 131.0(31)°. The two dicoordinate oxygen atoms are apical to the tin atoms while the tricoordinate oxygen atoms are apical to one tin atom but equatorial to the other. The average O—Sn—O bond angle involving the apical oxygens is 148.6(6)°, far from the ideal 180° value. The apical–equatorial O—Sn—O bond angles average 80.4(4)° inside the five-membered ring and 68.4(3)° inside the four-membered rings. The O—Sn—C bond angles between the dicoordinate oxygen atoms and the α-butyl carbon atoms average 99.8(17)° but in an ideal trigonal bipyramid would be 90°. The O—Sn—C bond angles between the apical tricoordinate oxygen atoms and the α-butyl carbon atoms have average values closer to ideal, 93.0(12)°. The O—Sn—C bond angles between the equatorial tricoordinate oxygen atoms and the α-butyl carbon atoms average 113.7(15)°, less than the expected 120° value.

The bond lengths inside the monomer units are shorter (average 2.073(25) Å) than those between monomer units (average 2.237(13) Å) but the difference is not nearly as large as in dibutylstannylene acetals in which the tin atom is hexacoordinate (8, 10).

Each of the four butyl groups adopt different conformations. The two butyl groups on Sn(1) assume *anti*, *gauche* and *gauche*, *anti* conformations about the C-α, C-β, and C-β, C-γ bonds respectively. As can be seen from Fig. 2, the carbon atoms become increasingly disordered away from the tin atom. One butyl group on Sn(2) adopts an *anti*, *anti* conformation while the other is disordered, adopting

(+)-*gauche*, *eclipsed* and (−)-*gauche*, *anti* conformations equally. The observed *eclipsed* conformation probably arises from 1:1 disordered arrangements between *gauche* and *anti* conformations of the terminal methyl with respect to C-α in the half of the butyl chains that have Sn and C-γ in the (+)-*gauche* conformation. These results suggest that each butyl group will rotate relatively freely among a number of conformational minima in solution.

Glucose units

The methoxy group adopts the conformation expected from the *exo*-anomeric effect and normally observed with methyl glycosides (16, 17). The normal pattern for 1,3-dioxane rings is to be puckered near the acetal centre but flattened at the other end (19, 20). One benzylidene ring fits this pattern exactly, the other to a lesser extent. The thermal parameters for the two phenyl rings suggest there is some motion occurring about the C(7)—C(8) and C(37)—C(38) bonds. The torsional angles about these bonds indicate that the average conformation of each of the phenyl rings is slightly different than the most favourable (19, 21) "parallel" conformation, which has the acetal hydrogen eclipsed with the phenyl ring. An angle of tilt can be calculated by averaging the differences between the torsional angles about the acetal carbon – phenyl ipso carbon and the ideal torsional angle for a parallel conformation, e.g. the difference between the O(6)—C(7)—C(8)—C(9) torsional angle and 120° or between the O(4)—C(7)—C(8)—C(13) torsional angle and 60°. The angles of tilt away from the parallel conformation calculated were 11.7 ± 0.3 and 17.7 ± 0.8° starting with the ring with the lower numbered atoms. The tilts of the two phenyl rings are in opposite directions; the phenyl ring tilted further from the parallel conformation had the carbon from the edge of its benzene ring on the same face of the molecule as the anomeric oxygen closer to O(34) than to O(36).

Cause of regioselectivity

Compound **1** was found to give exclusive reactions at O-2 under a variety of conditions: with benzoyl chloride in benzene or in dioxane containing triethylamine (22–24); with toluenesulfonyl chloride in dioxane containing triethylamine (22); and with bromine in dichloromethane to give the 2-keto derivative (23). Under more forcing conditions, specifically, on heating in *N,N*-dimethylformamide, it gave selective benzylation (7:2) (25) and methylation (57:30) (23) at O-2.

The regioselectivity obtained has been linked to the structures of the stannylene acetals present in solution. Highly

regioselective reactions of *trans*-diols on pyranose rings are obtained when one dimer predominates in the reaction mixture and the product results from substitution on the dicoordinate oxygen in the dimer as has been observed for **1** (6). One possible explanation for the regioselectivity was that the tricoordinate oxygen became positively charged on dimer formation as expected on the basis of Lewis structures and hence unreactive with electrophiles, whereas the dicoordinate oxygen atoms assumed apical positions at tin and became more reactive on dimer formation (4). This suggestion of positive tricoordinate oxygen atoms in dimeric structures was not supported by changes in the ^{13}C nmr chemical shifts of attached carbon atoms on stannylene acetal formation (6). An alternative suggestion was that electron shifts only took place in the transition state for reaction (6).

The present X-ray structure demonstrates that the two butyl groups on each tin atom are approximately perpendicular to the plane of the 1,3-dioxa-2,4-distannetane ring and are highly mobile. Another possible explanation of the regioselectivity is that the tricoordinate oxygens are simply better shielded from electrophiles by the four butyl groups on the two adjacent tin atoms than are the dicoordinate oxygens by the two butyl groups on their single adjacent tin atom. This explanation is currently being tested.

A model of nonelectrolytic behaviour: activity coefficients

PREM P. SINGH[1] AND SANJEEV MAKEN
Department of Chemistry, Maharshi Dayanand University, Rohtak-124001, Haryana, India

Received January 3, 1991[2]

PREM P. SINGH and SANJEEV MAKEN. Can. J. Chem. **70**, 1631 (1992).

A model is presented for binary mixtures of nonelectrolytes that reproduces successfully the activity coefficient (γ_i, γ_j; x_i) data for even those ($i + j$) mixtures that are known to be characterized by the presence of 1:1 or 1:1 and 1:2 molecular complexes or have components that differ appreciably in their molar volumes when only limited (γ_i^c, γ_j^c; x_i = 0.5) or (γ_i^∞; γ_i^c, x_i = 0.5) or (γ_i^∞) data are available).

PREM P. SINGH et SANJEEV MAKEN. Can. J. Chem. **70**, 1631 (1992).

On présente un modèle pour les mélanges binaires de non-électrolytes qui reproduit bien les données relatives aux coefficients d'activité (γ_i γ_j; x_i). Le modèle s'applique même aux mélanges ($i + j$) qui sont connus pour contenir des complexes moléculaires 1 : 1 ou 1 : 1 et 1 : 2 ou ceux qui contiennent des composants dont les volumes molaires diffèrent beaucoup et pour lesquels il n'y a que des données fragmentaires (γ_i^c, γ_j^c; x_i = 0,5) ou (γ_i^∞; γ_i^c, x_i = 0,5) ou (γ_i^∞) de disponibles.

Introduction

A binary ($i + j$) mixture is characterized by the replacement of like contacts in the pure components by unlike i–j contacts in the mixture. The activity coefficient of component i in such a mixture would then depend primarily on the i–j interactions and can, in principle; be computed (1) from the conventional molar excess Gibbs free energy G^E, provided a reliable equation of state is available for the mixture. The development (2) of the equation of state for a mixture via its canonical partition function involves the use of assumptions of doubtful validity (3–6) with the result that we are still far away (1*b*) from a general theory of liquid mixtures. Activity coefficients of the components of a binary mixture have, however, been evaluated from the compositional dependence of its G^E data, but most of the equations that relate G^E to the composition of the mixture are empirical (1) in nature. This calls for an alternative approach.

Theoretical aspects of the approach and results

If we consider the component i in the ($i + j$) mixture then the interaction of i with j would depend directly not only on the surface fraction of j that comes into effective i–j contacts but also on the magnitude of the molar i–j interaction energy, χ_{ij}. The thermal energy would also influence the magnitude of the χ_{ij} energy. Based on these considerations we expressed (7) the activity coefficient of i, γ_i, in an ($i + j$) mixture by the expression [1]

$$[1] \qquad \ln \gamma_i = \chi_{ij} x_j V_j / RT \Sigma x_i V_i$$

where the standard state of i is that of pure i. The activity coefficient of the jth component in the ($i + j$) mixture was then evaluated (7) via the Gibbs–Duhem equation, in the form

$$[2] \qquad \ln \gamma_j = (\chi_{ij} V_j / RTV_i)\left[\ln\left(\frac{\Sigma x_i V_i}{x_j V_j}\right) - x_i V_i / \Sigma x_i V_i\right]$$

In deriving eqs. [1] and [2] it was asumed that the ith and the jth components of the ($i + j$) mixture have nearly the same molar volumes so that the introduction of the jth component into the ith component does not cause drastic changes in their surroundings. This assumption is bound to fail if the components of the binary mixture differ in their molar volumes. In such a situation the activity coefficient of component i would be determined not only by the i–j interactions but also by the work done in accommodating the jth component into the matrix of the ith component. The introduction of the jth component into the matrix of the ith component would require that an appropriate cavity be first created in the matrix of i. This would then bring the jth component into i–j contact with the surrounding i molecules. The work necessary to accommodate the jth component into the matrix of the ith component would then be proportional not only to the difference ($V_i - V_j$) in the molar volumes of i and j but also to the interaction of the jth component with the i components in the cavity. The interaction of the jth component with the surrounding i components in the cavity would evidently be dictated by the mole fraction x_i of i so that if S_j is the surface fraction of j that is brought into i–j contact with the surrounding i molecules then the work due to i–j interactions between j and i components in the cavity will be proportional to $x_i S_j$. The net work done, G_W^E, to accommodate the jth component into the matrix of the ith component over and above the i–i or j–j interactions could then be expressed by $G_W^E \propto x_i S_j (V_i - V_j)$. But $S_j = x_j V_j / \Sigma x_i V_i$ (8), so that G_W^E would be given by

$$[3] \qquad G_W^E = \beta\, x_i x_j V_i V_j (1 - V_j/V_i)/(\Sigma x_i V_i)$$

where β is a constant. The activity coefficients of i and j in an ($i + j$) mixture, due to this effect, would then be given by

$$[4] \qquad RT(\ln \gamma_i)_W = [\partial(n_T G_W^E)/\partial n_i]_{n_j,T,P}$$

and

$$[5] \qquad RT(\ln \gamma_j)_W = [\partial(n_T G_W^E)/\partial n_j]_{n_i,T,P}$$

If the effects due to i–j interactions above (neglecting the difference in molar volumes of i and j) (eq. [1]) and that due to the difference in the molar volumes of i and j are assumed to make independent contributions to the activity

coefficients of the components of a binary $(i + j)$ mixture, then $\ln \gamma_i$ and $\ln \gamma_j$ would be given by

$$[6] \quad \ln \gamma_i = (\ln \gamma_i)_{i-j,V_i=V_j} + (\ln \gamma_i)_{W,V_i \neq V_j}$$

and

$$[7] \quad \ln \gamma_j = (\ln \gamma_j)_{i-j,V_i=V_j} + (\ln \gamma_j)_{W,V_i \neq V_j}$$

Substitution of eq. [3] into eqs. [4] and [5] then yields (in view of eqs. [6] and [7])

$$[8] \quad RT \ln(\gamma_i) = [\chi_{ij} x_j V_j / \Sigma x_i V_i] + \beta V_i V_j^2 x_j^2 (1 - V_j/V_i)/(\Sigma x_i V_i)^2$$

and

$$[9] \quad RT \ln (\gamma_j) = (\chi_{ij} V_j/V_i)[\ln (\Sigma x_i V_i / x_j V_j) - x_i V_i / \Sigma x_i V_i] + \beta x_i^2 V_i^2 V_j (1 - V_j/V_i)/(\Sigma x_i V_i)^2$$

It thus appears that if the two variables χ_{ij} and β of a binary $(i + j)$ mixture are evaluated from eqs. [8] and [9] using the activity coefficient data of its components at a single composition, then it should be possible to evaluate the activity coefficient data of these components of the binary mixture at any other composition. Such $(\gamma_i, \gamma_j; x_i)$ data[3] at various x_i values for some selected $(i + j)$ mixtures are recorded in Table 1 and are also compared with their corresponding experimental (γ_i^e, γ_j^e) values (9–13).

Examination of Table 1 clearly shows that such $(\gamma_i, \gamma_j; x_i)$ data for the components of the various $(i + j)$ mixtures compare well with their corresponding experimental $(\gamma_i^e, \gamma_i^e; x_i)$ values, even for those $(i + j)$ mixture that contain 1:1 or 1:1 and 1:2 molecular complexes though no direct cognizance has been taken of them in deriving eqs. [8] and [9]. The success of these expressions in reproducing well the $(\gamma_i^e, \gamma_j^e; x_i)$ data of the components of these mixtures may be ascribed to the fact that the use of the $(\gamma_i^e, \gamma_j^e; x_i = 0.5)$ data to evaluate them using eqs. [8] and [9] takes sufficient account of them.

Alternatively, as $x_i \rightarrow 0$, $x_j \rightarrow 1$ so that the activity coefficient of i at infinite dilution in j would be given (in view of eq. [8]) by

$$[10] \quad \ln \gamma_i^\infty = \chi_{ij}/RT + \beta V_i (1 - V_j/V_i)/RT$$

The activity coefficients of the ith and the jth components of an $(i + j)$ mixture can then be expressed in terms of $\ln \gamma_i^\infty$ by

$$[11] \quad \ln \gamma_i = (\chi_{ij} x_j V_j / RT \Sigma x_i V_i)[1 - x_j V_j / \Sigma x_i V_i] + (\ln \gamma_i^\infty) x_j^2 V_j^2 / (\Sigma x_i V_i)^2$$

and

$$[12] \quad \ln \gamma_j = (\chi_{ij} V_j / RTV_i)[\ln (\Sigma x_i V_i / x_j V_j) - x_i V_i / \Sigma x_i V_i - x_i^2 V_i^2 / (\Sigma x_i V_i)^2] + (\ln \gamma_i^\infty) x_i^2 V_i V_j / (\Sigma x_i V_i)^2$$

Consequently if the γ_i datum of i at any x_i is avaialble (or can be determined by appropriate experimentation) and as γ_i^∞ can be determined easily (14, 15) by gas–liquid chromatography, eqs. [11] and [12] should provide a convenient method to predict γ_i and γ_j data of both the components of an $(i + j)$ mixture at any x_i value. (The functional form of eq. [9] is such that it is not possible to derive an expression for $\ln \gamma_j^\infty$ analogous to $\ln \gamma_i^\infty$). Since it is the usual practice to report γ_i and γ_j data as functions of x_i, γ_i^∞ has to first be evaluated for the mixture by either plotting the experimental γ_i data (9–13) for the various $(j + j)$ mixtures as functions of x_i and then interpolating them to infinite dilution or from the compositional dependence of G^E data utilizing the reported compositional parameters. Such γ_i^∞ data for an $(i + j)$ mixture can next be combined with $(\gamma_i; x_i = 0.5$, arbitrary composition) data to calculate (via eqs. [10] and [11]) not only its χ_{ij}^+ and β^+ parameters but also the γ_i and γ_j data for both components of the mixture at various other x_i values. Such $(\gamma_i, \gamma_j; x_i)$ data for some selected $(i + j)$ mixtures are reported (as $\gamma_i^+, \gamma_j^+; x_i$) in Table 1 and are also compared with their corresponding experimental values (9–13).

Examination of Table 1 shows that such $(\gamma_i^+, \gamma_j^+; x_i)$ data for an $(i + j)$ mixture compare as closely with the corresponding experimental $(\gamma_i^e, \gamma_j^e; x_i)$ data as do those evaluated for it from the $(\gamma_i^e, \gamma_j^e; x_i = 0.5)$ data via eqs. [8] and [9], even for those binary mixtures that are known to be characterized by the presence of either 1:1 or 1:1 and 1:2 molecular complexes. The success of eqs. [11] and [12] to reproduce the experimental activity coefficient data may again be traced to the same reasons as were advanced to deduce them from $(\gamma_i^e, \gamma_j^e; x_i = 0.5)$ data using eqs. [8] and [9].

On the other hand, since the standard state of i in eq. [1] has been taken (7) to be that of the pure i, i.e., $\gamma_i = 1$ at $x_i = 1$, it may still be possible to predict $(\gamma_i, \gamma_j; x_i)$ data via eqs. [10]–[12] for an $(i + j)$ mixture when its γ_i^∞ datum alone is available or can be determined experimentally by gas–liquid chromatography.

To test this hypothesis we utilized (γ_i^∞) with $\gamma_i = 1$ at $x_i = 0.9999$ (the functional form of eq. [11] is such that we have to make this assumption about the γ_i value for an $(i + j)$ mixture) to evaluate its χ_{ij} and β parameters (via eqs. [10] and [11]), which were subsequently used to predict its $(\gamma_i, \gamma_j; x_i)$ data using eqs. [11] and [12]. Such $(\gamma_i, \gamma_j; x_i)$ data for some selected mixtures are recorded (as γ_i^*, γ_j^*) in Table 1 and are also compared with their corresponding experimental values, and it is apparent from Table 1 that such $(\gamma_i^*, \gamma_j^*; x_i)$ data compare well with the corresponding experimental data for those $(i + j)$ mixturees that are not characterized by specific interactions between their components. Examination of Table 1 further reveals that, barring the two extreme ends of the composition scale, the $(\gamma_i^*, \gamma_j^*; x_i)$ data calculated from eqs. [10]–[12] compare reasonably well with the corresponding experimental $(\gamma_i^e, \gamma_j^e; x_i)$ data even for those $(i + j)$ mixture that are known to contain 1:1 or 1:1 and 1:2 molecular complexes.

Again, if the boiling temperatures of i and j in an $(i + j)$ mixture do not differ significantly, the χ_{ij} and β_{ij} parameters may be taken, for practical applications, to be independent of temperature; the effect of pressure on liquid phase properties is usually small except at higher pressures and at conditions near the critical temperature. In that event, the V_i and V_j data at any temperature T coupled with the $(\gamma_i^e, \gamma_j^e; x_i =$ 0,5) or $\gamma_i^\infty; \gamma_i^e; x_i = 0.5)$ or $(\gamma_i^\infty; \gamma_i^e = 1, x_i = 0.9999)$ data at moderate pressures should be expected to yield a reasonably good estimate of the activity coefficient data of the

[3]Tables comparing $(\gamma_i, \gamma_j; x_i)$ data (evaluated from the experimental $(\gamma_i^e, \gamma_j^e; x_i = 0.5)$, $(\gamma_i^\infty; \gamma_i^e, x_i = 0.5)$, and $(\gamma_i^\infty; \gamma_i = 1, x_i = 0.9999)$ data) with their corresponding experimental $(\gamma_i^e, \gamma_j^e; x_i)$ data for some 30 mixturees may be purchased from: The Depository of Unpublished Data, Document Delivery CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

TABLE 1. Comparison of (γ_i, γ_j, x_i) data (evaluated from eqs. [8]–[12] (see text) utilizing (γ_i^e, γ_j^e; $x_i = 0.5$), (γ_i^∞; γ_i^e, $x_i = 0.5$), and (γ_i^∞; $\gamma_i = 1$, $x_i = 0.9999$) data) with their corresponding experimental data for the components of ($i + j$) mixtures; also included are the corresponding χ_{ij}, etc. and β, etc. parameters.

components of the mixture at any composition. Since the boiling temperatures for the components of the n-propanol (i) + water (j) mixture vary from 87.8 to 100°C at a constant pressure of 1.013 bar (1 bar = 100 kPa), it would be an ideal mixture to test the validity of this hypothesis.

For this purpose we utilized density data (16, 17) at 298.15 K to evaluate V_i and V_j data for the n-propanol (i) + water (j) mixture. These values of V_i and V_j were next coupled with the (γ_i^e, γ_j^e; $x_i = 0.5$) or (γ_i^∞; γ_i^e, $x_i = 0.5$) or (γ_i^∞; $\gamma_i = 1$, $x_i = 0.9999$) data (in the manner explained above) to yield activity coefficient (γ_i, γ_j; x_i) or (γ_i^+, γ_j^+; x_i) or (γ_i^*, γ_j^*; x_i) data. Such data are recorded in Table 1, and are also compared with the corresponding experimental data (13). It is apparent that the activity coefficient data evaluated by either of the present approaches reproduce reasonably well the corresponding experimental activity coefficient data.

The present study thus provides, for the first time, a very simple method that successfully reproduces the experimental (γ_i^e, γ_j^e; x_i) data for the components of an ($i + j$) mixture when only limited (γ_i^e, γ_j^e; $x_i = 0.5$) or (γ_i^∞; γ_i^e, $x_i = 0.5$) or (γ_i^∞; $\gamma_i = 1$, $x_i = 0.9999$) data are available.

The thermodynamics of the ionization of 3-hydroxypyridine and pyridoxine in water–dioxane mixtures

SALVADOR B. ASENSIO, ENRIQUE LOPEZ-CANTARERO, and JUAN LLOR[1]

Departamento de Quimica-Fisica, Facultad de Ciencias, Universidad de Granada, 18003 Granada, Spain

Received August 12, 1991

SALVADOR B. ASENSIO, ENRIQUE LOPEZ-CANTARERO, and JUAN LLOR. Can. J. Chem. **70**, 1635 (1992).

A potentiometric method has been used to determine the thermodynamic equilibrium constants for the macroscopic ionization processes of 3-hydroxypyridine and pyridoxine in water–dioxane mixtures (0–70% weight fraction in dioxane) at temperatures from 10 to 50°C. From these data the reaction standard thermodynamic function changes were obtained for the processes in various water–dioxane mixtures at 25°C. It was found, in both molecules, that during the first ionization process the contributions of entropy and enthalpy to free energy are similar but that during the second ionization the main contribution comes from entropy, especially in mixtures with a high dioxane content. The effect of the solvent on the tautomeric equilibrium in the net zero charge specie could explain this behaviour.

SALVADOR B. ASENSIO, ENRIQUE LOPEZ-CANTARERO et JUAN LLOR. Can. J. Chem. **70**, 1635 (1992).

On a fait appel à une méthode potentiométrique pour déterminer les constantes thermodynamiques d'équilibre des processus macroscopiques d'ionisation de la 3-hydroxypyridine et de la pyridoxine, dans des mélanges eau–dioxane (0–70% en poids de dioxane), à des températures allant de 10 à 50°C. À partir de ces données, on a évalué les changements dans la fonction thermodynamique standard de la réaction pour les processus qui se produisent dans des mélanges eau–dioxane, à 25°C. On a trouvé que, pour les deux molécules, les contributions de l'entropie et de l'enthalpie à l'énergie libre du premier processus d'ionisation sont semblables, mais que dans la deuxième ionisation la contribution principale provient de l'entropie, spécialement dans des mélanges contenant une grande quantité de dioxane. Ce comportement peut être expliqué par l'effet de solvant sur l'equilibre tautomérique sur la charge nette zéro.

[Traduit par la rédaction]

Introduction

We have reported in recent papers on the solution equilibria of compounds belonging to the vitamin B_6 group and other analogous compounds in water–dioxane, with special emphasis on the ionization processes (1–6). To carry out these studies we designed an experimental method that allows us to calculate the macroscopic ionization equilibrium constants corrected to zero ionic strength, that is to say, the thermodynamic ionization equilibrium constants (1–3), with great saving in time and materials.

Many of the studies carried out on vitamin B_6 dependent enzymes were directed to an understanding of the roles played by the chemical groups of the coenzyme in the catalytic mechanism. Since one important way that the enzyme can influence the reactivity of the coenzyme is through selective protonation or deprotonation of the various functional groups, it is important to understand these effects in the vitamin B_6 group.

A study of the ionization of this group of molecules in water and other solvents with less polarity than water, such as water–organic solvent mixtures, is of interest (7). Relatively little work has been done in general on the thermodynamics of the dissociation processes of acids in mixed solvent systems. These results are also of interest in order to know the properties and the solute–solvent interactions in these media.

In this paper we report the macroscopic ionization equilibrium constants of 3-hydroxypyridine and pyridoxine (pK_1 and pK_2 (see Scheme 1)) in water–dioxane mixtures (0–70% weight fraction in dioxane) at temperatures ranging from 10 to 50°C, from which we have obtained the standard thermodynamic function changes of the macroscopic ionization processes.

Experimental

Materials

Dioxane (Ferosa) was purified by the method described in ref. 1. 3-Hydroxypyridine (Merck–Schuchardt, synthesis grade) was transformed into its hydrochloride salt and crystallized by adding acetone–ethanol–ether. Pyridoxine hydrochloride (Fluka Puriss.) was dissolved in hydrochloric acid and recrystallized in a cold ethanol–ether mixture. Carbonate-free KOH was prepared as described elsewhere (8, 9). All the other chemicals used were of the

best quality available. All measurements were made under nitrogen.

3-Hydroxypyridine concentrations were obtained by weight. Pyridoxine concentrations were determined by dilution in 0.1 M NaOH (ϵ = 7000 M^{-1} cm^{-1} at 308 nm) (10). Concentrations of KOH and HCl were determined by titration with potassium acid phthalate and KOH, respectively. Three separate measurements were made each time.

pH measurements

The pH measurements were made with an Ingold EA 120 combined electrode and a Crison Digit 501 pH-meter, capable of detecting 0.01 pH units. The scale of the pH-meter was adjusted using standard aqueous buffers (Radiometer).

The pH-meter readings in dioxane–water mixtures (B) were corrected into pH ($-\log a_H$) according to van Uitert and Haas (11), using eq. [1]:

$$[1] \quad \mathrm{pH} = B + \log U_H^0$$

where $\log U_H^0$ is the correction factor (11, 12). This correction factor is a function of the temperature and solvent, but not of the ionic strength. The $\log U_H^0$ values in the different mixtures and temperatures were taken from ref. 13. All the pH values used in this work were calculated from the pH-meter reading (B) and the subsequent application of eq. [1].

Potentiometric measurements

The potentiometric data were obtained by a method similar to that described by Woolley and co-workers (14–16) based on the dilution of an aqueous solution with the organic cosolvent (1, 2). The advantage of this experimental procedure is that it makes it possible to determine the ionization equilibrium constants in a wide range of water–dioxane mixtures in one single experiment, saving both time and cosolvent.

Results and discussion

The thermodynamic ionization constants of acids in water–dioxane mixtures can be determined from pH measurements of solutions containing concentrations similar to the conjugated acidic and basic species. In this way the pH values are close to the pK value, thus reducing experimental error to a minimum.

The proper equation to be used for the calculation of pK depends upon the ionization to be measured (pK_1 and pK_2) and the initial ionic species of the substance in question (hydrochloride salt, free base, etc.) (2).

The calculation of pK_1 for both compounds was carried out using eq. [2],

$$[2] \quad \mathrm{p}K_1 = B + \log U_H^0 + \log \gamma_\pm + \log \left(\frac{a - b + \dfrac{K_W}{a_H \gamma_\pm} - \dfrac{a_H}{\gamma_\pm}}{b + \dfrac{a_H}{\gamma_\pm} - \dfrac{K_W}{a_H \gamma_\pm}} \right)$$

while eq. [3] was used to calculate pK_2:

$$[3] \quad \mathrm{p}K_2 = B + \log U_H^0 - \log \gamma_\pm + \log \left(\frac{2a - b + \dfrac{K_W}{a_H \gamma_\pm} - \dfrac{a_H}{\gamma_\pm}}{b - a + \dfrac{a_H}{\gamma_\pm} - \dfrac{K_W}{a_H \gamma_\pm}} \right)$$

[a]See footnote 2 in text.

where, for both eqs. [2] and [3], a is the analytical concentration of the compound to be studied and b that of the KOH added to the solution to make the conjugated acid and base concentrations analogous. Equations [2] and [3] were obtained from the corresponding defining expressions for the thermodynamic ionization constants and the charge and material balances. The activity coefficients of the uncharged species were always taken as being 1 and those of the chemical species with a net charge +1 and −1 were assumed to be equal to the average ionic activity coefficients of HCl ($\gamma\pm$) at the same ionic strength and in the same media and were calculated by Debye–Hückel's equation:

$$[4] \quad \log \gamma_\pm = -\frac{(1.825 \times 10^6)\sqrt{(d_0/\epsilon^3 T^3)}I}{1 + 229.8\sqrt{(d_0/\epsilon T)}I}$$

where d_0 is the density, ϵ the dielectric constant of the solvent, and I the ionic strength on the molal scale. The ionization constant of water (K_W) and the dielectric constants for the various water–dioxane mixtures and temperatures were taken from Harned and Owen (17). The densities of the mixtures come from Hovorka *et al.* (18).

This method is valid for both monoprotic and polyprotic acids whenever the successive pK's are sufficiently far apart (about 4 units or more), as is the case with 3-hydroxypyridine and pyridoxine in all of the water–dioxane mixtures and at all of the temperatures studied.

We determined the macroscopic ionization equilibrium constants for 3-hydroxypyridine and pyridoxine in water–dioxane mixtures between 0 and 0.7072 (expressed as a weight fraction of dioxane) at 10, 20, 30, 40, and 50°C (Table 1).[2] All these constants have been corrected to an ionic strength of zero, and thus are thermodynamic in character.

All the pK values are the average of at least two, and usually three, measurements carried out with solutions containing various concentrations of the substance in question (between 2×10^{-3} and 5×10^{-3} M), and thus different ionic

[2]Tables of pK_1 and pK_2 values for 3-hydroxypyridine and pyridoxine vs. temperature and the weight fraction of dioxane in water–dioxane mixtures may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

strengths. The mean errors in the measurements were always less than 0.05 pK units. According to Panichajakul and Woolley (16) discrepancies of around 0.08 unit are to be expected with this method and thus our error range is acceptable.

In the equations used to calculate the pK values the log(acid/base) term is usually close to zero because the conjugated acid and base concentrations are approximately the same. As the log $\gamma\pm$ term is also generally small it is clear that B and log U_H^0 are the measurements that have the greatest effect on the precision of the macroscopic ionization constants. Our pK_1 and pK_2 values (Table 1) (see footnote 2) for 3-hydroxypyridine and pyridoxine agree with those previously reported in the literature (19–22) in pure water. We have not found data for these compounds in water–dioxane or other water–organic solvent mixtures.

The uncharged species of 3-hydroxypyridine and pyridoxine are mixtures of two tautomeric forms (see Scheme 1). For this reason the pK values obtained are in fact macroscopic, i.e., they cannot be attributed to any particular ionizable group. By calculating the constants for the tautomerization processes we can then arrive at the microscopic ionization equilibrium constants, i.e., those attributable to a specific group. In general, the pK values corresponding to phenol ionization increase with the proportions of dioxane owing to the fact that two ions are generated for each neutral molecule. On the other hand, the pK's for the ionization of the pyridium ions either do not change or else diminish slightly with an increase in dioxane because no change in the number of ions occurs (23). In our case pK_1 for 3-hydroxypyridine decreases as dioxane increases while pK_1 for pyridoxine increases slightly under the same conditions (Table 1; see also footnote 2). pK_2, however, increases in both cases, more so with for 3-hydroxypyridine (Table 1; see also footnote 2).

As pK_1 is macroscopic (and thus reflects simultaneously the ionization of NH^+ and OH in the form ^+f (see Scheme 1)) we may say that the pK_1 values for 3-hydroxypyridine are mainly due to the ionization of NH^+ while for pyridoxine they are due to that of OH. This is confirmed by the tautomerization constant values for the equilibrium $^0f{=\!=}^{\pm}f$ (see Scheme 1) at 25°C for these two compounds (1), which indicate that the proportion of dipolar form is greater in pyridoxine than in 3-hydroxypyridine for the same water–dioxane mixture. The same reasoning is sufficient to explain the rise in the pK_2 values in both cases and that this increase is greater for 3-hydroxypyridine than for pyridoxine.

As the pK values are macroscopic, we have not studied the quantitative effect of the solvent on the equilibrium constants.

Using the pK_1 and pK_2 values for different temperatures we calculated the standard thermodynamic function changes for the first and second ionization of both compounds in the various water–dioxane mixtures. A general equation has been developed by Clarke and Glew (24) to represent the temperature dependence of reaction equilibrium constants in terms of the standard thermodynamic function changes at a chosen reference temperature, θ. This equation can be rewritten as

$$[5] \quad R \ln K = b_0 + b_1 t_1 + b_2 t_2 + b_3 t_3$$

where the terms t_i are a function of the temperature (25), and the b_i terms are directly proportional to the standard thermodynamic function changes at θ = 298.15 K. Equation [5] gives us a general representation of $R \ln K$ as a function of temperature and four undetermined constants containing ΔG_θ^0, ΔH_θ^0, $\Delta C_{p\theta}^0$, and $(d\Delta C_{p\theta}^0/dT)_\theta$.

We have made a regression analysis, successively increasing the number of terms in Eq. [5] and stopping when an F-test (25) revealed that the confidence level in the introduction of a new term was less than 95%.

To apply eq. [5] it is essential that the concentration scale used should not depend on temperature. Throughout the study, however, we have used the temperature-dependent molar scale and so it is necessary to obtain the equilibrium constants in the molal scale using

$$[6] \quad R \ln K(m) = R \ln K(c) - nR \ln d_0$$

where n is the increase in the stoichiometric number of particles whose activity is involved in the equilibrium constant, $K(m)$ and $K(c)$ are the equilibrium constants in the molal and molar scales, respectively, and d_0 the density of the solvent.

We obtained the values and the standard errors for the standard thermodynamic function changes by a least-squares fitting (26, 27). Typical standard errors in the determination of ΔG_θ^0, ΔH_θ^0, and $-\theta\Delta S_\theta^0$ turned out to be ± 0.12, ± 2, and ± 2 kJ mol^{-1}, respectively.

The optimum values, in the molar scale, of the standard thermodynamic function changes calculated in this way are given in Figs. 1–4. Because of the limited precision of our experimental pK values and the requirement of at least 95% confidence level, we have not calculated either the $\Delta C_{p\theta}^0$ values or their derivatives.

The dissociations of the two compounds studied have very similar characteristics. In the first ionization (Figs. 1 and 3) ΔH_θ^0 and $-\theta\Delta S_\theta^0$ are analogous, with $-\theta\Delta S_\theta^0$ somewhat higher in mixtures with high dioxane content and ΔH_θ^0 in low dioxane content. In the second ionization (Figs. 2 and 4), however, $-\theta\Delta S_\theta^0$ is always much higher than ΔH_θ^0 in all the water–dioxane mixtures studied. We may conclude that the values for $-\theta\Delta S_\theta^0$ are practically always larger than the corresponding ΔH_θ^0 and thus established the trend in ΔG_θ^0. Both components always contribute to the free energy in the same direction.

We can see that the $-\theta\Delta S_\theta^0$ values are partially compensated by the ΔH_θ^0 values so that changes in ΔG_θ^0 are smaller than the increments in either enthalpy or entropy with changes in the chemical systems. This sort of compensation has been observed many times before for other ionization reactions and also for other reactions in solution (14).

The similarity between the ΔH_θ^0 of the dissociation process of these acids in water and in water–dioxane mixtures indicates a similar pattern of solvation in these solvents. The $\theta\Delta S_\theta^0$ values are always negative but are more so in water–dioxane mixtures (except for the first ionization at low dioxane content). This may be due to the fact that the degree of reorientation and partial immobilization of the dioxane and water molecules by H^+ and the neutral and anionic species is greater in water–dioxane mixtures than in pure water.

It is difficult to interpret the effect of the solvent upon the ΔH_θ^0 and $-\theta\Delta S_\theta^0$ values. The trends in ΔH_θ^0 and $-\theta\Delta S_\theta^0$ (Figs. 1–4) could be interpreted in terms of the solvation of the reactant and products (16) but it must not be forgotten that these values correspond to the macroscopic ionization pro-

cesses and that the species with a zero net charge exists in two forms (neutral and dipolar (see Scheme 1), the proportion of which changes according to the solvent composition. The different effects of the solvent upon the two microscopic ionizations (NH^+ and OH) and the tautomeric process may explain the overall effect shown in Figs. 1–4.

Since polar solvents per se are usually more structured than apolar solvents, proportionally fewer negative entropy changes are obtained in the more polar solvent such as water (28). This occurs during the second ionization but not during the first (Figs. 1 and 3) where the values of $\theta\Delta S^0_\theta$, although negative, initially increase and then decrease with the

rise in dioxane content. This may be explained qualitatively if we accept that the overall effect upon entropy and enthalpy is the sum of two contributory factors: (*a*) the "normal" effect of the solvent, as mentioned above; (*b*) the effect of the solvent upon the tautomerization equilibrium ${}^{0}f = {}^{\pm}f$.

If we take into account the equations defining ΔS^0_θ for the first and second macroscopic ionization we get:

$$[7] \quad (\Delta S^0_\theta)_{1\text{st ion}} = (f({}^{\pm}f)S({}^{\pm}f) + f({}^{0}f)S({}^{0}f)) + S(H^+) - S({}^{+}f)$$

$$[8] \quad (\Delta S^0_\theta)_{2\text{nd ion}} = S({}^{-}f) + S(H^+) - (f({}^{\pm}f)S({}^{\pm}f) + f({}^{0}f)S({}^{0}f))$$

and thus:

$$[9] \quad (\Delta S^0_\theta)_{1\text{st ion}} - (\Delta S^0_\theta)_{2\text{nd ion}} = 2(f({}^{\pm}f)S({}^{\pm}f) + f({}^{0}f)S({}^{0}f)) - S({}^{+}f) - S({}^{-}f)$$

where $f(i)$ is the molar fraction of the i form in the net zero charge species (see Scheme 1).

This difference is always positive and increases, in both compounds, with increasing proportion of dioxane. Bearing in mind that $f({}^{0}f)$ rises with the quantity of dioxane (1) it would be appear that $S({}^{0}f) > S({}^{\pm}f)$, and that this disparity increases with the proportion of dioxane.

If this be the case, the effect of the tautomeric equilibrium for the first ionization (eq. [7]) should give rise to an increase in $(\Delta S^0_\theta)_{1\text{st ion}}$. This is in fact seen with low dioxane contents, whilst with high dioxane proportions $(\Delta S^0_\theta)_{1\text{st ion}}$ diminishes notably, owing to the fact that $f({}^{\pm}f)$ becomes very small and the "normal" effect of the solvent predominates.

With the second protonation (eq. [8]) the same line of reasoning leads us to believe that the $(\Delta S^0_\theta)_{2\text{nd ion}}$ should diminish because of the tautomerization equilibria, which, together with the decrease brought about by the "normal" effect of the solvent, causes its value to diminish steadily and significantly as the proportion of dioxane increases, and, in fact, this is what we observed experimentally.

Thus the above hypotheses (*a*) and (*b*) would explain the general behaviour of the thermodynamic magnitudes for the first and second macroscopic protonation (Figs. 1–4) and also the differences between the values of ΔH^0_θ and $-\theta\Delta S^0_\theta$ for both protonations (Figs. 1 and 2; Figs. 3 and 4).

Intramolecular hydrogen bonding in ribonucleoside sugar hydroxyls. An *ab initio* study

ENRIC BOSCH, MIQUEL MORENO, AND JOSÉ M. LLUCH[1]

Departament de Química, Universitat Autònoma de Barcelona, 08193 Bellaterra, Catalonia, Spain

Received October 21, 1991

ENRIC BOSCH, MIQUEL MORENO, and JOSÉ M. LLUCH. Can. J. Chem. **70**, 1640 (1992).

Ab initio self-consistent field (SCF) calculations were done for a model of a ribonucleoside where only the ring part of the furanoside form of D-ribose is considered. Full geometry optimization and direct location of stationary points were used in order to characterize the geometry of the minimum energy structure and of the transition state for the proton transfer reaction in the anion. Topological analysis of the charge density and its Laplacian for the minimum energy structure allow us to find clear electronic and geometrical evidence of an intramolecular hydrogen bond. On the other hand, our results show a very low energy barrier for the proton transfer so that the proton jumps easily between the two oxygen atoms.

ENRIC BOSCH, MIQUEL MORENO et JOSÉ M. LLUCH. Can. J. Chem. **70**, 1640 (1992).

On a effectué des calculs *ab initio* en champ auto-cohérent (SCF) sur un modèle de ribonucléoside dans lequel on ne considère que la partie cyclique de la forme furanoside du D-ribose. On a utilisé une optimisation complète de la géométrie et une location directe des points stationnaires pour caractériser la géométrie de la structure possédant une énergie minimale et de l'état de transition de la réaction du transfert de proton dans l'anion. Une analyse topologique de la densité de charge et de son laplacien pour la structure d'énergie minimale nous permet d'obtenir des données électronique et géométrique non-ambiguës concernant une liaison hydrogène intramoléculaire. Par ailleurs, nos résultats montrent que la barrière d'énergie pour le transfert du proton est faible; il en résulte que le proton passe facilement d'un oxygène à l'autre.

Introduction

It is well known that the sugar hydroxyls of ribonucleosides have enhanced acidities (1–3). This fact has been attributed to the presence of the vicinal *cis* 2'-OH and 3'-OH groups and the ability of these to stabilize the anionic form via an intramolecular hydrogen bond O(3')—H $\cdots$ O(2') or O(3') $\cdots$ H—O(2') (see Fig. 1).

The main goal of this paper is to present theoretical evidence of the existence of such an intramolecular hydrogen bond. This kind of work is of relevance given that Izatt *et al.* (1) have suggested that the acidity of the ribose in RNA is a result of the combined effect of both hydroxyl groups. Since the known chemical reactivity of the 2'- and 3'-positions in nucleic acids would be expected to parallel the acidity of the OH group, the different biological functions of RNA and DNA may be closely related to the acidity differences arising from the lack of the second hydroxyl group in DNA.

Analysis of the results will be performed by means of the theory of molecular structure proposed by Bader and coworkers (4–11). According to this methodology, the total electronic charge density $\rho(\boldsymbol{r})$ and its Laplacian $\nabla^2\rho(\boldsymbol{r})$ are considered.

The Laplacian of the charge density is defined as the sum of the three principal curvatures of the function at each point in space. That is:

$$\nabla^2\rho(\boldsymbol{r}) = \frac{\delta^2\rho}{\delta x^2} + \frac{\delta^2\rho}{\delta y^2} + \frac{\delta^2\rho}{\delta z^2}$$

When two neighbouring atoms are chemically bonded to one another, a bond critical point ($\boldsymbol{r}_c$) in the charge density appears between them. At the bond critical point $\nabla\rho(\boldsymbol{r}_c) = 0$, the charge density being a minimum at $\boldsymbol{r}_c$ along the bond path but a maximum along any orthogonal displacement. In turn, the Laplacian of the charge density at a point $\boldsymbol{r}$ in space determines where electronic charge is locally concentrated ($\nabla^2\rho(\boldsymbol{r}) < 0$) or depleted ($\nabla^2\rho(\boldsymbol{r}) > 0$). So when $\nabla^2\rho(\boldsymbol{r}_c)$ is negative the electronic charge is locally concentrated in the internuclear region. This occurs due to shared (covalent) interactions. Conversely, for closed-shell interactions $\nabla^2\rho(\boldsymbol{r}_c)$ is positive. These last kind of interactions are dominated by the contraction of charge away from the interatomic surface towards each of the nuclei. In a closed-shell interaction the atoms are bonded as a consequence of the charge that is concentrated within the basin of each atom. Taking all this into account, a hydrogen bond (11) is defined as one in which a hydrogen atom is bound to the acid fragment by a shared interaction and to the base by a closed-shell interaction.

Method of calculation

Ab initio self-consistent field (SCF) calculations were carried out with the GAUSSIAN 86 series of programs (12) using the split valence basis set 3-21+G (13, 14), which contains a diffuse *sp* shell on atoms other than hydrogens. To obtain a computationally available model of a ribonucleoside, only the ring part of the furanoside form of the D-ribose was considered. That is, we took into account neither the 5' carbon nor the heterocyclic nitrogenated base (see Fig 1).

Full geometry optimization and direct location of stationary points were done by means of the Schlegel gradient optimization algorithm (15). Analytical second derivatives of the energy with respect to the Cartesian coordinates (16) were computed to test the nature of each stationary point.

The influence of the correlation energy was determined by using the Møller–Plesset perturbation theory up to second order (MP2) (17).

Topological analysis of the charge density was performed by means of programs developed in our group that make use of the density matrix as obtained from a GAUSSIAN 86 run.

Results and discussion

In Fig. 2*a* the structure of minimum energy found for the anion is depicted along with the more significant bond lengths and angles. It has to be noted that the molecule is not planar, belonging to the C_1 symmetry group. The four carbon atoms lie almost in a plane but the oxygen in the furanoside ring is above this plane whereas the O(2′) and O(3′) atoms are placed below it.

Two facts seem to indicate the existence of a hydrogen bond. First, from a geometrical point of view, the short distance between hydrogen and oxygen (2′) is noteworthy (see Figure 2*a*). Second, the Mulliken population analysis (18) discloses that oxygen O(2′) and hydrogen atoms possess net charges of opposite sign (see Fig. 2*b*). This last point is of special importance as a reminder that hydrogen bonds are mainly due to electrostatic interactions.

Figures 3 and 4, respectively, present the isodensity contour plots of $\rho(r)$ and $\nabla^2\rho(r)$ in the O(3′)—H···O(2′) plane at the structure of minimum energy shown in Fig. 2. The positions of the bond critical points are marked with a dot in Figs. 3 and 4. Simultaneous inspection of topological properties of $\rho(r)$ and $\nabla^2\rho(r)$ allow us to identify four covalent bonds in the molecular region represented in Figs. 3 and 4: two C—O, one C—C, and the O(3′)—H bonds. In addition, a clear hydrogen bond H···O(2′) appears, its bond critical point being found clearly inside the positive region of the Laplacian.

As noted by Boyd and Choi (19), the charge density at the bond critical point of the hydrogen bond is paralleled by the increase in the hydrogen bond strength. In this sense, the

Dashed lines correspond to regions in which $\nabla^2\rho(r) < 0$, and solid lines correspond to regions in which $\nabla^2\rho(r) > 0$. Numbers indicate the $\nabla^2\rho(r)$ values at the bond critical points in au. The solid line closest to the dashed lines corresponds to the zero value. The increment between consecutive lines is 0.1 au.

present value of 0.055 is intermediate between the values we obtained for the water dimer (0.035) and the $H_2O \cdots OH^-$ hydrogen bond (0.15) at the same 3-21+G basis set level by using the corresponding optimized geometries. These values are always low when compared with the typical values of covalent bonds, as is readily seen by inspection of Fig. 3.

Interestingly, we have also seen that the proton is not attached to one oxygen but it may easily switch between oxygens O(2′) and O(3′). In fact a transition state for the intramolecular proton transfer has been localized (Fig. 5). This structure belongs to the C_s symmetry group as now both oxygen–hydrogen distances are equal.

Table 1 shows the total energies for the minimum energy

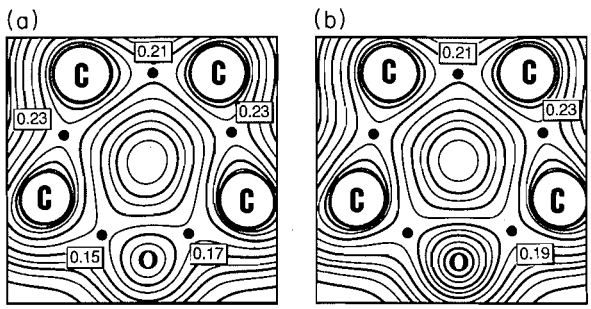

FIG. 8. Isodensity contour plots of $\rho(r)$ in the C(1′), C(2′), and C(3′) plane at the minimum energy structure (*a*) and the transition state (*b*) for intramolecular proton transfer reaction in the ribonucleoside model. Numbers indicate the $\rho(r)$ values at the bond critical points in au.

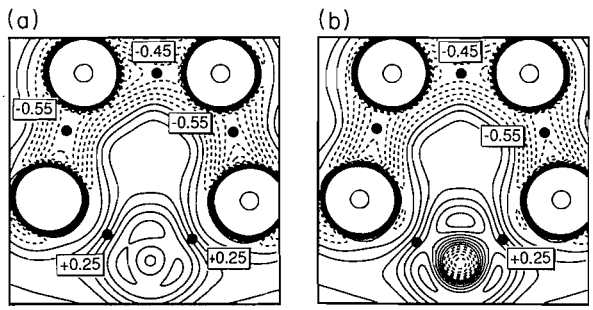

FIG. 9. Isodensity contour plots of the Laplacian $\nabla^2\rho(r)$ in the C(1′), C(2′), and C(3′) plane at the minimum energy structure (*a*) and the transition state (*b*) for intramolecular proton transfer in the ribonucleoside model. Dashed lines correspond to regions in which $\nabla^2\rho(r) < 0$, and solid lines correspond to regions in which $\nabla^2\rho(r) > 0$. Numbers indicate the $\nabla^2\rho(r)$ values at the bond critical points in au. The solid line closest to the dashed lines corresponds to the zero value. The increment between consecutive lines is 0.1 au.

structure and the transition state at the SCF 3-21+G level. Zero Point Energy (ZPE) and correlation energy corrections are also presented. From the data presented in Table 1 the energy barrier obtained for the proton transfer through this transition state is only 2.91 kcal/mol at the 3-21+G level, which reduces to 0.59 kcal/mol when ZPE is calculated through the harmonic frequencies obtained by diagonalizing the energy second derivatives matrix (20). This small barrier disappears when correlation energy is introduced within the Møller–Plesset perturbation theory up to second order (MP2), 3-21+G geometries being kept unchanged. Though it is known that the MP2 level tends to exaggerate the effect of electron correlation (21–23), this result confirms that the proton jumping between both oxygen atoms O(2′) and O(3′) is very easy.

To discuss the electronic distribution of the transition state, the isodensity contour plots of $\rho(r)$ and $\nabla^2\rho(r)$ in the O(3′)—H···O(2′) plane are respectively depicted in Figs. 6 and 7.

As seen in the figures, the transferring hydrogen is bonded with the same strength to both oxygens. In addition, the Laplacian plot discloses that the corresponding bond critical points are now inside the positive region of the Laplacian, so that these two bonds have a closed-shell character and the transferring hydrogen behaves as a proton. This situation is quite different to the one found for the minimum energy structure.

Another interesting point is to see what is happening in the rest of the anion while proton transfer is occurring. To this aim, in Figs. 8 and 9 we show the isodensity contour plots of $\rho(r)$ and $\nabla^2\rho(r)$, respectively, in the plane of the C(1′), C(2′), and C(3′) carbon atoms for both the minimum energy structure and the transition state. It has to be recalled here that the oxygen in the furanoside ring is above this plane in both structures. It is seen that the electronic distribution in the furanoside ring does not noticeably change along the reaction. Only minor modifications appear, due to the fact that the furanoside oxygen is closer to the plane in the transition state than in the minimum energy structure.

Conclusions

In this paper we have presented high level *ab initio* calculations for a model of a ribonucleoside. By analizing the topology of the total electronic charge density and its Laplacian, we have found clear evidence of the existence of an intramolecular hydrogen bond.

We have also seen that the hydroxylic hydrogen is not attached to one oxygen but it jumps between oxygens O(2′) and O(3′), through a small or null barrier. Analysis of the transition state reveals that the transferring hydrogen behaves as a proton.

Integral method for infinite dilution activity coefficients calculation

A. C. CHIALVO
Programa de Electroquímica Aplicada e Ingeniería Electroquímica (PRELINE), Facultad de Ingeniería Química (UNL), Santiago del Estero 2829, (3000) Santa Fe, Argentina

Received September 27, 1990

A. C. CHIALVO. Can. J. Chem. **70**, 1645 (1992).

An integral method to determine infinite dilution activity coefficients (γ_i^∞) from data sets of finite concentration activity coefficients is proposed for binary systems. This method is based upon the integration of the experimental dependence of $\ln \gamma_i/x_j^2$ over different composition ranges. The limiting behavior of this function is analysed, in order to improve the precision of its integration. The accuracy of this method is demonstrated by the calculation of γ_i^∞ for several systems.

A. C. CHIALVO. Can. J. Chem. **70**, 1645 (1992).

On propose une méthode d'intégration permettant, pour les systèmes binaires, de déterminer les coefficients d'activité à dilution infinie (γ_i^∞) à partir des données relatives aux coefficients d'activité à concentrations finies. La méthode est basée sur l'intégration de la relation expérimentale de $\ln \gamma_i/x_j^2$ sur différents ensembles de composition. Afin d'améliorer la précision de l'intégration, on a analysé le comportement limitant de cette fonction. On a démontré l'exactitude de la méthode par le calcul du γ_i^∞ de plusieurs systèmes.

Introduction

One of the sources more commonly used to obtain the infinite dilution activity coefficients (γ_i^∞) is undoubtedly the vapor–liquid equilibrium (VLE). The reduction of VLE data to obtain the γ_i^∞ values varies from the graphical or analytical extrapolation of a $\ln \gamma_i - x_i$ data set (1) to the determination of the limiting slope of temperature or pressure with respect to the liquid phase composition (2–6). All of these processes require experimental determinations in the composition range near to that of the pure components. However, a method that allows us to verify the thermodynamic consistency of these data is not available. The present work intends to cover these important aspects by the development of a process that permits us to evaluate the γ_i^∞ value starting from an entire or partial $\ln \gamma_i - x_i$ data set.

Fundamentals

The Gibbs–Dühem equation for activity coefficients at constant temperature and pressure in a binary system can be written in the form:

$$[1] \quad d \ln \gamma_j = -d\left(\frac{x_i}{x_j} \ln \gamma_i\right) + \frac{\ln \gamma_i}{x_j^2} dx_i$$

The integration of eq. [1] can be carried out using different limits. Taking into account the limiting behaviour of the activity coefficients (7), it is possible to arrive at the following useful expressions:

$$[2] \quad \ln \gamma_j^\infty = \int_{x_i=0}^{x_i=1} \frac{\ln \gamma_i}{x_j^2} dx_i$$

$$[3] \quad \ln \gamma_j^\infty = \frac{g^E}{x_j} + \int_{x_i=x_i}^{x_i=1} \frac{\ln \gamma_i}{x_j^2} dx_i$$

where $g^E = G^E/RT$ and G^E is the excess Gibbs energy.

These equations allow us to determine the infinite dilution activity coefficients. Nevertheless, in order to improve the evaluation of the integrals in eqs. [2] and [3] it is convenient to analyze the limiting behavior of the integrand function.

Limiting behaviour of the function ln γ_i/x_j^2

Taking into account that, when $x_i = 1$, $\ln \gamma_i = 0$ and $d \ln \gamma_i/dx_i = 0$:

$$[4] \quad \lim_{x_i \to 1}\left[\frac{\ln \gamma_i}{x_j^2}\right] = -\lim_{x_i \to 1}\left[\frac{\frac{d \ln \gamma_i}{dx_i}}{2x_j}\right] = \frac{1}{2}\lim_{x_i \to 1}\left[\frac{d^2 \ln \gamma_i}{dx_i^2}\right]$$

The right-hand side of eq. [4] can be evaluated by derivation of the classical form of the Gibbs–Dühem equation and application of limiting conditions:

$$[5] \quad \lim_{x_i \to 1}\left[\frac{d^2 \ln \gamma_i}{dx_i^2}\right] = -\left[\frac{d \ln \gamma_j}{dx_j}\right]^\infty$$

Substituting into eq. [4]:

$$[6] \quad \lim_{x_i \to 1}\left[\frac{\ln \gamma_i}{x_j^2}\right] = -\frac{1}{2}\left[\frac{d \ln \gamma_j}{dx_j}\right]^\infty$$

The behaviour of the integrand function on the other integration limit is

$$[7] \quad \lim_{x_i \to 0}\left[\frac{\ln \gamma_i}{x_j^2}\right] = \ln \gamma_i^\infty$$

Besides, by derivation of the integrand function with respect to x_i,

$$[8] \quad \frac{d}{dx_i}\left[\frac{\ln \gamma_i}{x_j^2}\right] = \frac{x_j\left[\frac{d \ln \gamma_i}{dx_i}\right] + 2 \ln \gamma_i}{x_j^3}$$

the limiting slopes can be found. For $x_i \to 0$:

$$[9] \quad \lim_{x_i \to 0} \frac{d}{dx_i}\left[\frac{\ln \gamma_i}{x_j^2}\right] = \left[\frac{d \ln \gamma_i}{dx_i}\right]^\infty + 2 \ln \gamma_i^\infty$$

TABLE 1. Limiting behavior of the integrand functions

Diisopropylamine(1)–water(2) 20°C (15)	3.5037 (33.238)	—	3.50 (33.115)	2.0454 (7.732)	—	2.03 (7.614)
1-Propanol(1)–*n*-heptane(2) 45°C (9)	3.325 (27.799)	3.287 (9) (26.762)	3.28 (26.576)	1.978 (7.228)	1.987 (9) (7.294)	1.98 (7.243)

For $x_i \to 1$, the right-hand side of eq. [8] becomes indeterminant. Through the application of L'Hopital's rule twice, the following limit is obtained:

$$[10]\quad \lim_{x_i\to 1}\frac{d}{dx_i}\left[\frac{\ln \gamma_i}{x_j^2}\right] = \lim_{x_i\to 1}\left[\frac{\frac{d^3 \ln \gamma_i}{dx_i^3}}{6}\right] = \frac{1}{6}\left[\frac{d^3 \ln \gamma_i}{dx_i^3}\right]^\infty$$

Estimate of the limiting values

As stated before, the evaluation of eqs. [2] and [3] can be improved if the limiting values of the integrand function are known. For such an estimate, the supplementary function g^E/x_i is used. It provides the following relationships:

$$[11]\quad \lim_{x_i\to 0}\left[\frac{g^E}{x_i}\right] = \ln \gamma_i^\infty = \lim_{x_i\to o}\left[\frac{\ln \gamma_i}{x_j^2}\right]$$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

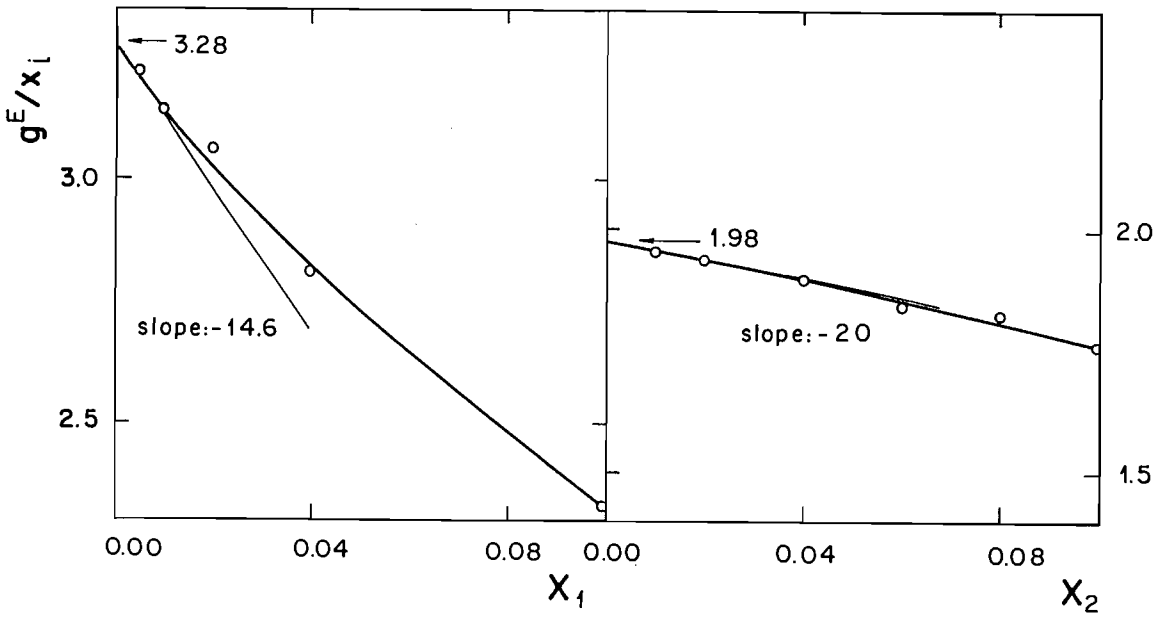

FIG. 1. Dependence of the function g^E/x_i upon the composition for the system 1-propanol(1)–*n*-heptane(2) at 45°C.

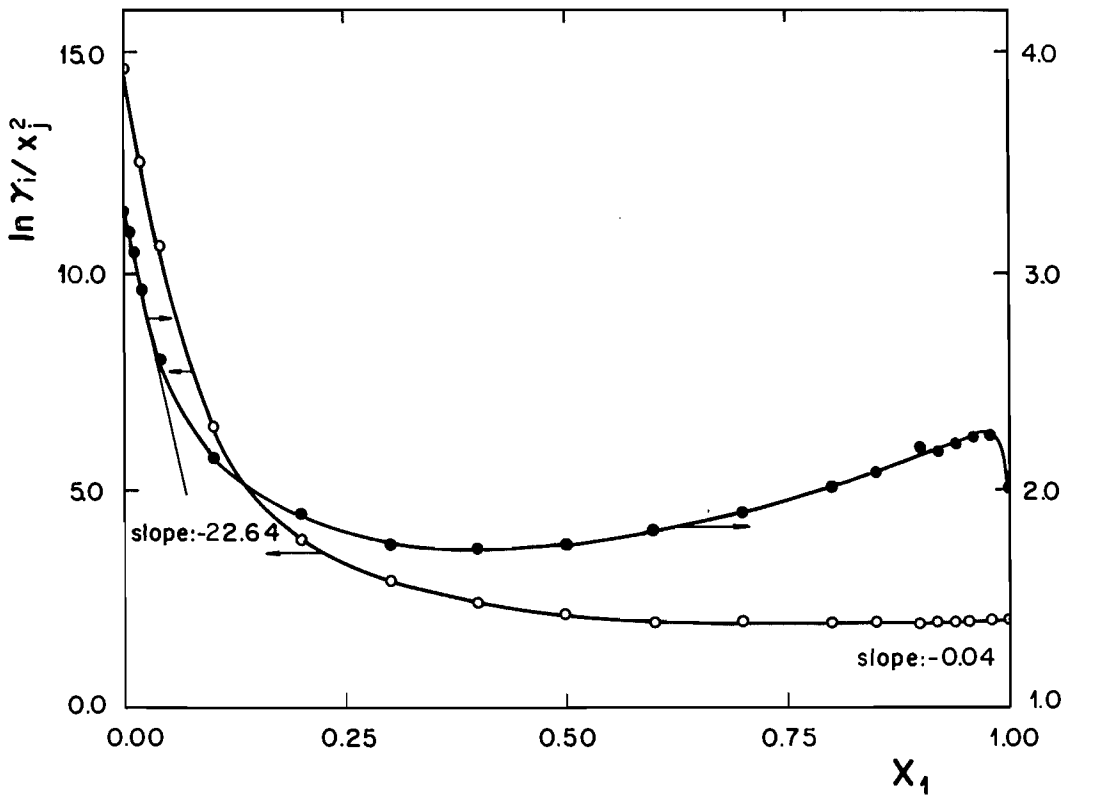

FIG. 2. Dependence of the integrand function upon the composition for the system 1-propanol(1)–*n*-heptane(2) at 45°C. (●) $i = 1$; (○) $i = 2$.

$$[12]\quad \lim_{x_i \to 0} \frac{d}{dx_i}\left[\frac{g^E}{x_i}\right] = \frac{1}{2}\left[\frac{d \ln \gamma_i}{dx_i}\right]^{\infty} = -\lim_{x_i \to o}\left[\frac{\ln \gamma_j}{x_i^2}\right]$$

Hence, eq. [9] can be rewritten as follows:

$$[13]\quad \lim_{x_i \to o} \frac{d}{dx_i}\left[\frac{\ln \gamma_i}{x_j^2}\right] = 2 \lim_{x_i \to 0}\left\{\frac{g^E}{x_i} + \frac{d}{dx_i}\left[\frac{g^E}{x_i}\right]\right\}$$

A summary of the limiting equations derived here is shown in Table 1. These expressions can be applied to evaluate the γ_i^{∞} from experimental isobaric (P) or isothermic (T) activity coefficient data, obtained from VLE studies. These data require a point-to-point temperature or pressure correction and therefore information about the excess enthalpy (h^E) or excess volume (v^E) function under the same conditions as the VLE measurements is necessary. However, the weak de-

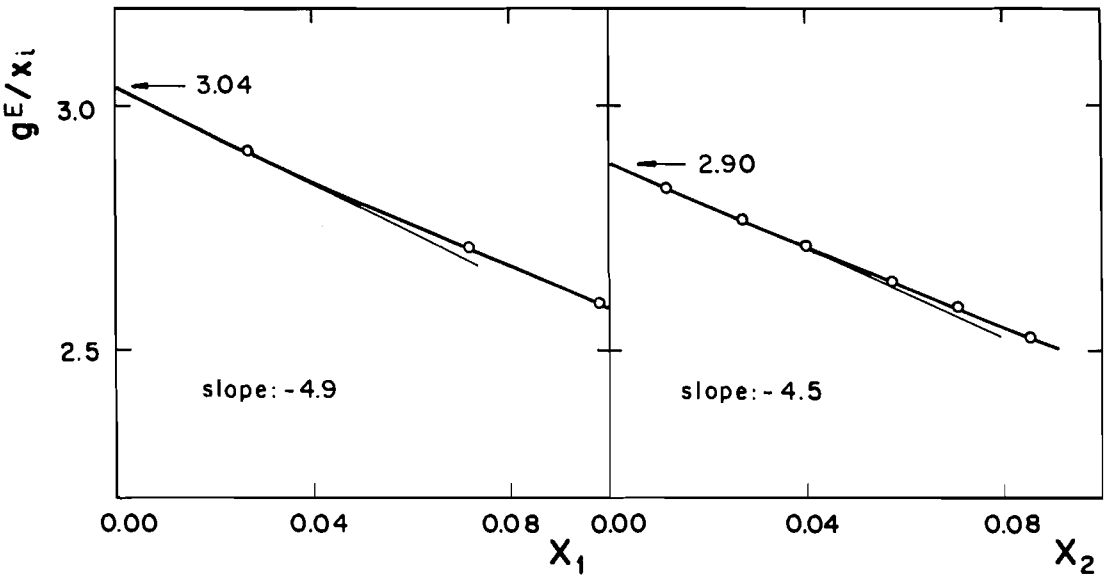

FIG. 3. Dependence of the function g^E/x_i upon the composition for the system methanol(1)–cyclohexene(2) at 45°C.

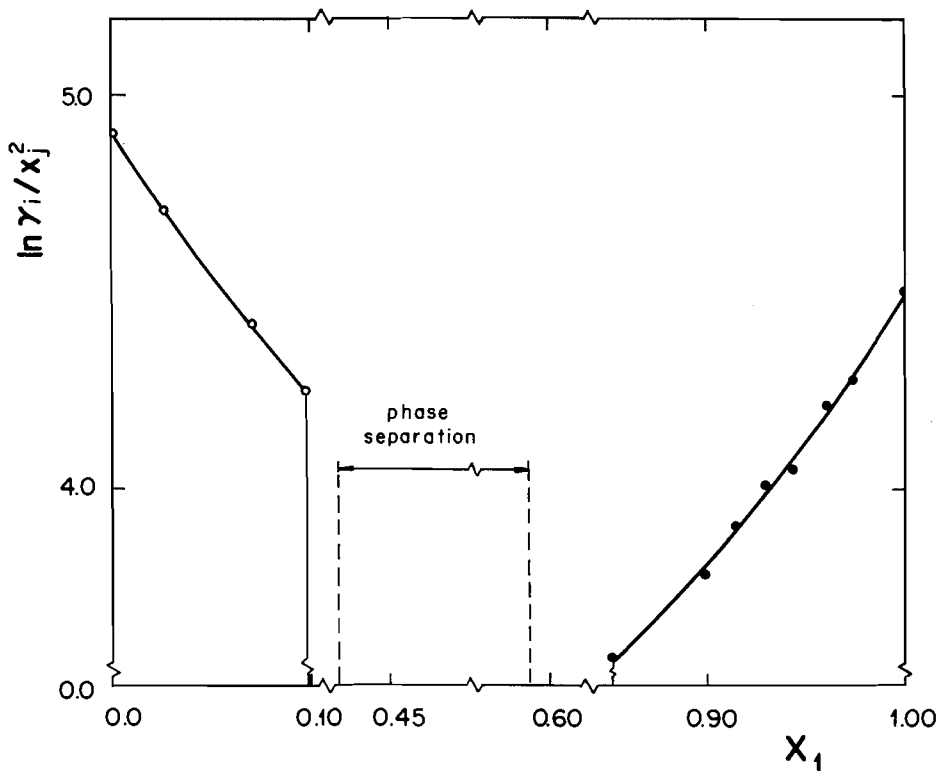

FIG. 4. Dependence of the integrand function upon the composition for the system methanol(1)–cyclohexene(2) at 45°C. (●) $i = 1$; (○) $i = 2$.

pendence of the activity coefficient on pressure makes the correction for isothermic data quite negligible. For this reason, isothermic data were used in this paper to illustrate the expressions obtained.

Applications

The following general procedure is proposed for the calculation of the infinite dilution activity coefficients on the basis of the expressions deduced above: (*i*) Estimation of the limiting behavior of the integrand function starting from the limiting behavior of g^E/x_i, through eqs. [11]–[13]. (*ii*) Evaluation of the integrand function from the corrected $\ln \gamma_i - x_i$ data set. (*iii*) Calculation of γ_i^∞ through eqs. [2] or [3] according to the data set used.

The proposed procedure was used to calculate γ_i^∞ for several systems. The experimental data were obtained from the literature and the results are summarized in Table 2. The calculations for two of these systems are described here in

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

order to illustrate the procedure. From data of Van Ness *et al.* (9) for the system 1-propanol(1)–*n*-Heptane(2) at 45°C, the auxiliary plots were drawn for the estimation of the limiting integrand functions (Fig. 1). With these values, the ln γ_i/x_j^2 vs. x_i plot was completed (Fig. 2). The following values were obtained from the integration: ln $\gamma_1^\infty = 3.325$ ($\gamma_1^\infty = 27.798$) and ln $\gamma_2^\infty = 1.978$ ($\gamma_2^\infty = 7.228$).

The second example is the methanol(1)–cyclohexane(2) system at 45°C reported by Madhovan and Murti (11). This mixture exhibits phase separation with the compositions (16): $x_1' = 0.425$ and $x_1'' = 0.590$. The g^E/x_i vs. x_i and ln γ_i/x_j^2 vs. x_i plots are shown in Figs. 3 and 4, respectively. The following integration limits were used: (*i*) for ln γ_1^∞, $x_2 = 0.902$ ($g^E = 0.25426$) and $x_2 = 1$, and (*ii*) for ln γ_2^∞, $x_1 = 0.8515$ ($g^E = 0.3407$) and $x_1 = 1$ (Fig. 4). The application of eq. [3] gave the following results: ln $\gamma_1^\infty = 3.043$ ($\gamma_1^\infty = 20.968$) and ln $\gamma_2^\infty = 2.889$ ($\gamma_2^\infty = 17.975$).

Discussion

The proposed method is based on a suitable solution of the Gibbs–Dühem equation at constant temperature (T) and pressure (P). It provides thermodynamically consistent $\gamma_i^\infty(T,P)$ values from corrected $\gamma_i(T,P^{exp},x_i)$ or $\gamma_i(T^{exp},P,x_i)$ data sets. In this work the calculations that illustrate the proposed procedure were made from isothermic data without pressure correction. The error of this approximation can be estimated with the following expression:

$$[14] \quad \ln \frac{\gamma_i(T,P,x_i)}{\gamma_i(T,P^{exp},x_i)} = \frac{(\bar{v}_i - v_i^0)}{RT}(P - P^{exp})$$

For the different systems analysed, eq. [14] shows that this correction term is less than 10^{-3} and therefore negligible compared to the ln γ_i values. Nevertheless, in the case where the pressure variation is appreciable, the correction should be made.

It is important to note that the limiting values were estimated from the g^E/x_i vs. x_i plot, which exhibits a limiting slope value that is one-half of that of the ln γ_i vs. x_i plot (eq. [12]) and consequently represents a better extrapolation condition. The accuracy obtained in the analysed systems was good, as can be observed in Table 2, for the final evaluation of the γ_i^∞.

A different approach could be made in order to take into account, for example, the pressure effect. In this case, eq. [1] becomes

$$[15] \quad d \ln \gamma_j = -d\left(\frac{x_i}{x_j} \ln \gamma_i\right) + \left[\frac{\ln \gamma_i}{x_j^2} + \frac{v^E}{x_j RT}\frac{\partial P}{\partial x_i}\bigg|_T\right] dx_i$$

The use of this expression is similar to that derived above and, in this case, information about the $v^E(x_i)$ at similar conditions of the activity coefficient data and the total vapor pressure dependence upon the composition of VLE is necessary. The corresponding form of eq. [6] is now

$$[16] \quad \lim_{x_i \to 1}\left(\frac{\ln \gamma_i}{x_j^2}\right) = \frac{1}{2}\left[\frac{\partial \ln \gamma_j}{\partial x_j}\bigg|_T + \frac{v^E}{x_j RT}\frac{\partial P}{\partial x_j}\bigg|_T\right]^\infty$$

It can be concluded, on the basis of the results obtained, that the proposed method allows us to evaluate the activity coefficient at infinite dilution with accuracy and reliability.

JEAN-LOUIS ROUSTAN, NASRIN ANSARI, YVON LE PAGE, and JEAN-PIERRE CHARLAND. Can. J. Chem. **70**, 1650 (1992).

The BPh_4^- and BF_4^- derivatives of $Co(NO)_2(Py)_2^+$ **3** (Py = pyridine) have been prepared. In solution, whereas $Co(NO)_2(L)_2^+BPh_4^-$ (L = phosphane) and **3**-BF_4^- are inert, **3**-BPh_4^- decomposes rapidly in the absence of an excess of Py. Complex **3**-BF_4^- crystallizes in the monoclinic system with two independent molecules, A and B, in the asymmetric unit, space group $P2_1/a$, a = 14.7633(6) Å, b = 13.9739(5) Å, c = 15.1667(6) Å, β = 109.334(4)°, 2225 reflections, R = 0.054, Rw = 0.023. The cobalt coordination polyhedron is a distorted tetrahedron. The comparison of the (O)N—Co—N(O) angles of 115.6(3)° (molecule A) and 115.9(3)° (molecule B) with those of other $D^{8+2}_{NO(M)}$ pseudotetrahedral dinitrosyl complexes suggests that the lability of the Py ligands of cation **3** reflects the compression experienced by the $Co(NO)_2^+$ molecular portion.

JEAN-LOUISE ROUSTAN, NASRIN ANSARI, YVON LE PAGE et JEAN-PIERRE CHARLAND. Can. J. Chem. **70**, 1650 (1992).

Les dérivés BPh_4^- et BF_4^- de $Co(NO)_2(Py)_2^+$ **3** (Py = pyridine) ont été préparés. En solution, alors que $Co(NO)_2(L)_2^+BPh_4^-$ (L = phosphane) et **3**-BF_4^- sont inertes, **3**-BPh_4^- est décomposé rapidement en l'absence d'un excès de Py. Le complexe **3**-BF_4^- cristallise dans le système monoclinique avec deux molécules indépendantes, A et B, dans l'unité asymétrique, groupe d'espace $P2_1/a$, a = 14,7633(6) Å, b = 13,9739(5) Å, c = 15,1667(6) Å, β = 109,334(4)°, 2225 réflexions, R = 0,054, Rw = 0,023. Le polyèdre de coordination du cobalt est un tétraèdre déformé. La comparaison des angles (O)N—Co—N(O) de 115,6(3)° (molécule A) et 115,9(3)° (molécule B) avec ceux d'autres complexes dinitrosyles pseudotétraédriques du type $D^{8+2}_{NO(M)}$ suggère que la labilité des ligands Py du cation **3** est la conséquence de la compression à laquelle est soumis le fragment moléculaire $Co(NO)_2^+$.

Introduction

Recently, the reaction of BPh_4^- with $Co(NO)_2(PN)I$ **1** containing the diphenyl(2-pyridyl)phosphine ligand $P(C_6H_5)_2$-(2-C_5H_4N) (abbreviated as PN henceforth) was shown (1) to yield the Co—Co bonded bimetallic $Co_2(NO)_3(PN)_2^+BPh_4^-$ **2**. Complex **2** can be viewed as containing two $Co(NO)_2$ subunits sharing the same μ_2-NO bridging ligand with one cobalt further bounded to two pyridyl N atoms and the other to two P atoms. To obtain information suggestive of a possible mode of formation, the previously unknown cobalt dinitrosyl bispyridine cation $Co(NO)_2(Py)_2^+$ **3** was synthesized with either BF_4^- or BPh_4^- as the gegenanion. In this paper, we report the observations pertaining to the behavior in solution of these complexes and the single crystal X-ray structure of the BF_4^- derivative that allow us to comment upon the possible role of BPh_4^- in the reactions ultimately yielding bimetallic **2**.

Experimental

All operations were conducted under argon or vacuum with argon saturated solvents. The IR spectra were recorded on a Perkin–Elmer 783. ^{11}B NMR spectra were recorded on a Varian FT80 with $BF_3(Et_2O)$ as external reference. Elemental analyses were performed by Guelph Chemical Laboratories Ltd, Guelph, Ontario.

Preparation of $Co(NO)_2(Py)_2^+BF_4^-$,3-BF_4^-

$(Co(NO)_2I)_2$ (2.38 g) (2) and 1.6 mL of pyridine (Py) were dissolved in 20 mL of absolute ethanol at 20°C. To the stirred solution was added dropwise 1.88 g of $AgBF_4$ in 10 mL of ethanol. After stirring an additional hour, solid AgI was separated by filtration and the solution was evaporated to dryness under vacuum at 20°C. The residue was recrystallized in CH_2Cl_2–hexane to yield 2.68 g of dark microcrystalline crystals. νNO (CH_2Cl_2) = 1876, 1798 cm^{-1}. Anal. calcd. (found) for $C_{10}H_{10}BCoF_4N_4O_2$: %C 33.0(33.2), %H 2.8(3.1), %N 15.4(15.0). In the solid state, the complex can be handled in air for a brief period of time, but is very air sensitive in solution. Under argon, it is stable in CH_2Cl_2 in the absence of added pyridine.

Preparation of $Co(NO)_2(Py)_2^+BPh_4^-$,3-BPh_4^-

To a stirred solution of 0.55 g of $(Co(NO)_2I)_2$ and 0.37 mL of pyridine in 22 mL of absolute ethanol was added dropwise 0.77 g of $NaBPh_4$ in 15 mL of ethanol. Olive-green microcrystals precipitated rapidly. After an additional 30 min of stirring, the crystals were separated by filtration and dried under vacuum (1.18 g). The compound was recrystallized in CH_2Cl_2–hexane in the presence of an excess of pyridine. νNO(CH_2Cl_2) = 1870, 1790 cm^{-1} (unstable in solution in the absence of added pyridine). (Anal. calcd.(found) for $C_{34}H_{30}BCoN_4O_2.CH_2Cl_2$: %C 61.7(62.4), %H 4.7(5.1), %N 8.2(9.0)).

Preparation of $Co(NO)_2(PN)_2^+BPh_4^-$

To a solution of 0.54 g of $(Co(NO)_2I)_2$ in 30 mL of absolute ethanol heated at 50°C in a water bath was added 0.30 g of $P(C_6H_5)_2$(2-C_5H_4N) (PN) (3). After stirring 20 min at the same temperature, 0.59 g of $NaBPh_4$ in 10 mL of ethanol was added dropwise. The reaction mixture was stirred an additional 20 min and subsequently cooled down to 20°C. The precipitate that had formed was separated by filtration and dried under vacuum to yield 0.49 g of product, recrystallized in CH_2Cl_2–ether. νNO(CH_2Cl_2) = 1845, 1795 cm^{-1} (stable in solution in the absence of added ligand). Anal. calcd. (found) for $C_{58}H_{48}BCoN_4O_2P_2.CH_2Cl_2$: %C 67.4 (67.7) %H 4.8(5.0), %N 5.5(5.4).

Crystallographic studies

[a] $I \geq 2.5\ \sigma(I_{net})$.
[b] $R_F = \Sigma[|F_o| - |F_c|]/\Sigma|F_o|$.
[c] $wR_F = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$.
[d] $GOF = [\Sigma w(|F_o| - |F_c|)^2/(m - n)]^{1/2}$.

fusion of an upper layer of toluene into a concentrated solution of the complex in methylene chloride. Crystals were mounted on a glass rod and subsequently coated with a protective layer of epoxy resin.

A dark crystal, 0.15 × 0.15 × 0.30 mm, was selected for intensity measurement at 296 K up to 2θ 45° with graphite monochromatized MoKα radiation on an Enraf–Nonius CAD-4 diffractometer (4). A total of 6038 intensity measurements were performed, which reduced to 3820 unique reflections. Among these, 2225 reflections having I_{net} larger than 2.5 counting statistic stigmas were considered to be observed. The $P2_1/a$ space-group assignment was made from the systematic absence of the classes of reflections $0k0$ with k odd and $h0l$ with h odd. The data reduction assuming this space group comprised corrections for Lorentz and polarization effects using the measured polarization ratio of 0.97 for the monochromator used, but no absorption correction (μ = 1.21/mm). The cell parameters (Table 1) were derived from the angular settings of 45 strong reflections in the 2θ range 40–45° using $MoK\alpha_1$ wavelength (0.70930 Å).

The initial positions for the heavy atoms were proposed by the MULTAN program (5). Successive refinement and difference-Fourier cycles progressively disclosed all atoms, including the hydrogens. The final refinement with full matrix was performed on all atoms minimizing $\Sigma w(|F_c|-|F_o|)^2$ where $w^{-1} = \sigma^2(F_0)$, with fixed isotropic thermal motion for the hydrogens and refined anisotropic motion for the other ones, and included an extinction correction. The scattering factors were those of Cromer and Mann (6). The final residuals on the 2225 observed reflections were R_F = 0.054 and wR_F = 0.023. The largest shift was 0.1σ in the final cycle and the highest residual density was 0.47 e/$Å^3$. All calculations were performed with the NRCVAX system of programs (7). The final atomic positions are given in Table 2. The list of observed and calculated structure amplitudes, parameters for the H atoms, and U_{ij}'s for the non-hydrogen atoms have been deposited as supplementary material.[3]

[3]These data may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 052.

Tables of H-atom parameters and bond lengths and angles associated with the pyridine and NO ligands have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Centre, University Chemical Laboratory, Lensfield Road, Cambridge CB2 1EW, U.K.

Results

Reactivity of cationic Co/NO/Py complexes

The cobalt dinitrosyl bispyridine cation $Co(NO)_2(Py)_2^+$ **3** was prepared by the room temperature reaction of an ethanolic solution of $(Co(NO)_2I)_2$ and pyridine in excess, with either $AgBF_4$ or $NaBPh_4$. The nature of the counteranion had a marked influence on the stability of cation **3** in solution. Whereas the BF_4^- derivative, **3**-BF_4^-, was inert in CH_2Cl_2 at room temperature, the BPh_4^- derivative, **3**-BPh_4^-, decomposed rapidly. Infrared monitoring of the decomposition showed the formation of a transient intermediate with at least one νNO at 1720 cm^{-1} clearly separated from those of **3**-BPh_4^- at 1870 and 1790 cm^{-1}. The magnitude of the νNO shift toward lower frequencies points to the formation of an uncharged intermediate. However, the latter is also very labile for after a few minutes no absorption remained in the 1900–1700 cm^{-1} region. No cobalt derivative could be isolated from the decomposed solutions. Under the same conditions, in the ^{11}B NMR spectra, the initial sharp BPh_4^- resonance of **3**-BPh_4^- at −5.9 ppm was rapidly replaced by a broad resonance centered at +6.0 ppm suggestive (8) of the formation of BPh_3.

Alternatively, **3**-BPh_4^- could be recrystallized without decomposition in CH_2Cl_2–hexane provided an excess of pyridine was also present. From this inhibitory effect of pyridine, it can be concluded that dissociation of a Py ligand from $Co(NO)_2(Py)_2^+$ is a prerequisite for the decomposition to proceed. Moreover, when dissociation occurs, the only ligand available in the medium for occupying the vacated coordination site has to come from BPh_4^-. Consequently, in line with the documented ability of BPh_4^- to phenylate metallic centers (9), the decomposition is likely to involve the formation of an uncharged σ-phenyl derivative such as $Co(NO)_2(Py)$-Ph with BPh_3 as a co-product. For comparison, with no excess of free ligand present, $Co(NO)_2(PN)_2^+BPh_4^-$, in which the two PN ligands should be P-bonded to Co, as in the structurally characterized BF_4^- derivative (10), was stable in solution, as well as $Co(NO)_2(PPh_3)_2^+BPh_4^-$(11) and $Co(NO)_2(P(OMe)_3)_2^+$ BPh_4^- (12). To identify a possible cause for the lability of the pyridine ligands of $Co(NO)_2(Py)_2^+$, an X-ray diffraction study was

undertaken with $Co(NO)_2(Py)_2{}^+BF_4{}^-$, which provided suitable crystals.

Single crystal structure of $Co(NO)_2(Py)_2{}^+BF_4{}^-$

The crystal structure consists of discrete $Co(NO)_2(Py)_2{}^+$ cations and $BF_4{}^-$ anions. The compound crystallizes with two independent molecules, A and B, in the asymmetric unit. A perspective view is presented in Fig. 1 together with the numbering scheme, and a summary of selected bond lengths and angles is given in Table 3. An ordered model for the $BF_4{}^-$ anion was considered as satisfactory, although a slight disorder of the F atoms around the calculated positions given in Table 2 might actually exist, in light of the values of their thermal parameters.

The general features are consistent in molecules A and B. Each cobalt is coordinated to two pyridyl and two nitrosylic N atoms located at the corners of a distorted tetrahedron. The (Py)N—Co—N(Py) and (O)N—Co—N(O) planes are perpendicular, with dihedral angles of 89.3(3)° and 89.2(3)° for molecules A and B respectively. The aromatic rings are planar within experimental errors (supplementary material, footnote 3). The Co—N(Py) distances of 2.012(6) Å for molecule A and 2.013(6) and 2.016(6) Å for molecule B fall near the lower range of the reported values for Co—N(Py) bond lengths, which can vary by ca. 0.2 Å, as shown for example by the values 1.917(2) and 2.203(10) Å for, respectively, $(\eta^5\text{-}C_5Me_5)CoCl(Py)$ (13) and $Co_2(DBA)_2(Py)_4$ (14) (DBA = 1,5-diphenyl-1,3,5-pentadionato). The Co—N and N—O bond lengths (Table 3) are normal when they are compared to other cobalt nitrosyl complexes (see for ex-

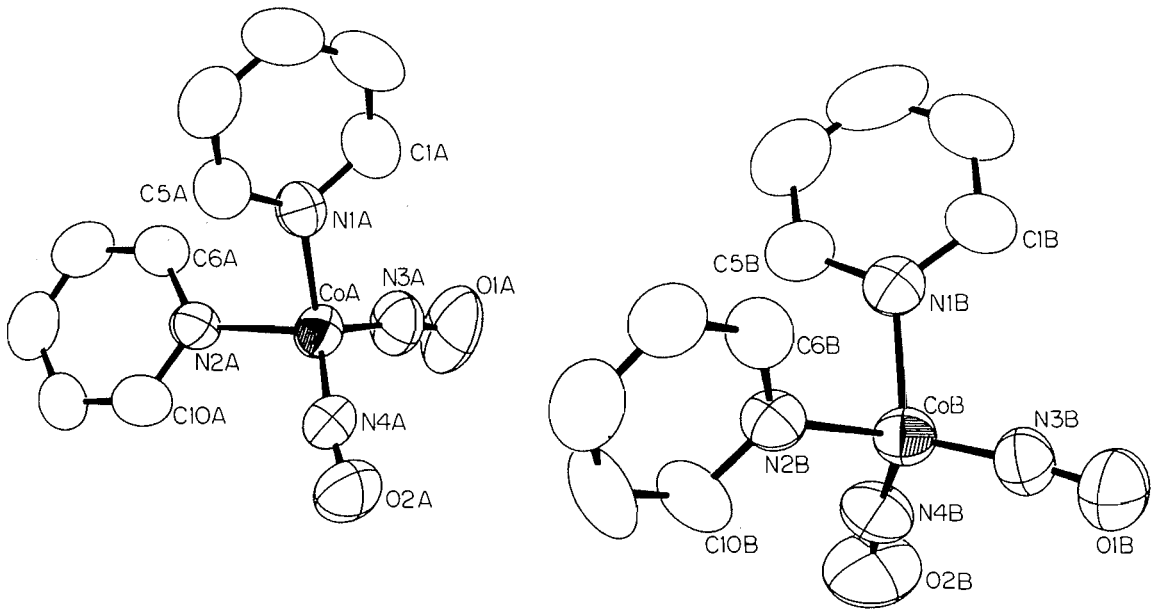

FIG. 1. Perspective view of the two independent cations of $Co(NO)_2(Py)_2^+$ **3** with the numbering scheme (the BF_4^- anions have been omitted for clarity).

ample the compilation in Table IV of Ref. 15 with ranges of 1.645(3)–1.68(2) Å for Co—N and 1.05(2)—1.174(6) Å for N—O). In both molecules, the O(N)..Co..(N)O angle sustended at Co by the two nitrosylic O atoms and the (O)N-Co-N(O) angle nicely follow the linear relationship of Martin and Taylor (16).

The shortest intramolecular nonbonded contacts (Table 3) involve the nitrosylic N atoms and the *ortho* H atoms of the Py ligands. They fall in the range 2.65(6)–2.86(7) Å, not significantly different from that of 2.66–2.89 Å reported (17) for the H(phenyl)...C/N intramolecular separations in $Co(CO)_x(NO)(PPH_3)_y$ ($x + y = 3$; $x = 1,2$). The latter have been regarded as reflecting short H...C/N contacts.

Discussion

The structural result of interest pertains to the values of the (O)N—Co—N(O) angles of 115.6(3)° (molecule A) and 115.9(3)° (molecule B) when they are compared to that of 128.0(8)° reported (18) for $Co(NO)_2(P(OMe)_3)_2^+$ BPh_4^-, which, together with $Co(NO)_2(Py)_2^+BF_4^-$, is a member of the $D^{8+2}_{NO(M)}$ family of pseudotetrahedral monometallic dinitrosyl complexes of general formula $M(NO)_2(L)_2^x$ ($x = 0$, $+1$).[4]

In $D^{8+2}_{NO(M)}$ complexes, the standard model (16, 21–23) to account for the variations of the (O)N—M—N(O) angle (abbreviated as the α angle henceforth) places the emphasis on the electronic influence of the $M(L)_2$ molecular portion of the $M(NO)_2$ moiety. According to this model, an increase in the M to NO π back-bonding, as it increases the electronic population of the M···NO bonds, enhances their mutual electrostatic repulsions, which favors an opening of the α angle. The nonbonded repulsive influence of a NO ligand can therefore be considered as a sensitive increasing function of the M to NO back-bonding. In this model, the variations of α are considered to be largely independent of the steric requirement of the supporting ligands L (16).

Some observations are in agreement with this proposal. For example the closing of α from 136.7(4)° in $Co(NO)_2(PPh_3)_2^+PF_6^-$ (24) (νNO(Nujol) = 1836, 1784 cm^{-1} (25)) to 128.0(8)° in $Co(NO)_2(P(OMe)_3)_2^+BPh_4^-$ (18) (νNO(CH_2Cl_2) = 1876, 1817 cm^{-1} (12)) has been interpreted (18) in terms of a decrease in the ligand σ-donor/π-acceptor ratio.

However, other results are not as readily interpreted. For example, from $Fe(NO)_2(PPh_3)_2$(νNO(C_2Cl_4) = 1724, 1678 cm^{-1} (26)) to $Co(NO)_2(PPh_3)_2^+PF_6^-$, whereas the M to NO back-bonding decreases, as shown by an increase in the νNO values, the α angle opens up by ca. 13° from 123.8(4) (22) to 136.7(4)° (24). The same observation applies upon going from the neutral to the cationic complex of the isoelectronic pairs $\{M(NO)_2(PPh_3)_2$, $M'(NO)_2(PPh_3)_2^+\}$ containing second (Ru, Rh^+) or third row (Os, Ir^+) metallic elements (see the data in Table VIII of Ref. 27). We suggest that these angular variations are more easily accounted for by taking the alternate view that the nonbonded repulsions in the M(NO)(L) moieties might be at least as important as those in the $M(NO)_2$ molecular portion, and might eventually provide the controlling factor.

In Fig. 2 is shown an idealized representation of a pseudotetrahedral $D^{8+2}_{NO(M)}$ complex with *mm*2 point symmetry at M. A chemical change that would lessen the NO repulsive

[4] A monometallic complex $[M](NO)_n$ contains a $D^{a+n}_{NO(M)}$ metallic center M, when the formal removal of the *n* NO ligands as neutral NO leaves a $d^a = D^{a+0}_{NO(M)}$ metallic element in the NO-free species [M]. The numbers "*a*" and "*n*" are respectively the electronic and structural parameters; any change in the value of "*a*" during a reaction implies the occurence of a non-temporary redox change at M (see ref. 19). To derive the d^a configuration, the non-nitrosylic ligands are separated from the metal according to the usual rules (see for example ref. 20). By extension, the cation $[Co_2(NO)_3(PN)_2]^+$ contains a $D^{17+3}_{NO(2Co)}$ bimetallic core, for CO_2^+ with 17 valence electrons would be obtained following the formal removal of three NO molecules and of the two PN ligands.

influence, but leave invariant parameters r_N, r_L, and β, would result in either a decrease in the $d_{N..N}$ separation, and consequently a closing of α (eq. [1]), if the repulsions in $M(NO)_2$ are the predominant factor involved, or a decrease in $d_{L..N}$, and an opening of α (eq. [2]), if the M(NO)(L) repulsions are the most influential. Taking the structures of $Fe(NO)_2(PPh_3)_2$ and $Co(NO)_2(PPh_3)_2^+PF_6^-$ as a specific example, upon going from the Fe to the Co^+ derivative, the values of r_N, r_L, and β vary little, as shown by a comparison of the data given in refs. 22 and 24. The observed increase in α by ca.

$$[2]\quad d^2_{LN} = r^2_L + r^2_N + 2.r_N.r_L.\cos(\alpha/2).\cos(\beta/2)$$

FIG. 2. Distances and angles involving the L and NO ligands of a pseudotetrahedral $M(NO)_2(L)_2$ complex with C_{2v} symmetry.

13° supports the view that the repulsive interactions in M(NO)(L) have a predominent role.[5]

A similar situation is encountered in comparing the structure of $Co(NO)_2(P(OMe)_3)_2^+BPh_4^-$ ($\nu NO(CH_2Cl_2)$ = 1876, 1817 cm^{-1}) and $Co(NO)_2(Py)_2^+BF_4^-$ ($\nu NO(CH_2Cl_2)$ = 1876, 1798 cm^{-1}). Upon replacing the $P(OMe_3)$ ligands by pyridine, the closing of the α angle by ca. 13° from 128.0(8)° to 115.6(3)°/115.9(3)° is not associated with a decrease in the extent of Co to NO back-bonding, as inferred from the νNO values. Consequently, there should be no lessening of the nonbonded influence of the NO ligands. This implies that in the pyridine complex (*i*) the $Co(NO)_2$ moiety is more compressed than in the $P(OMe)_3$ derivative, (*ii*) the repulsions in $Co(NO)_2$ do not predominate over the Co(NO)(Py) ones in fixing the value of the α angle. This closing of α is interpreted as the response of the $Co(NO)_2$ moiety to the large decrease in the Co—L bond lengths from 2.209(4)–2.214(5) Å in the $P(OMe)_3$ complex (18) to 2.012(6)–2.016(6) Å in the pyridine derivative, in order to prevent an excessive buildup of compression in the Co(NO)(Py) fragments. The facile dissociation of a Py ligand from $Co(NO)_2(Py)_2^+$ becomes then easily understandable as a means to provide a decompression of the $Co(NO)_2$ molecular portion.

The lability of a Py ligand, when it is bound to a $Co(NO)_2^+$ functional group, might be a key factor for the synthesis of $Co_2(NO)_3(PN)_2^+BPh_4^-$ **2**. The formation of complex **2**, a $D^{17+3}_{NO(2Co)}$ bimetallic (see footnote 4), requires the condensation of two monometallic fragments derived from the $D^{8+2}_{NO(Co)}$ monometallic iodo reactant $Co(NO)_2(PN)I$ **1**. In addition, a reductive denitrosylation is necessarily involved, for a simple condensation of two $D^{8+2}_{NO(Co)}$ monometallic species would yield a $D^{16+4}_{NO(2Co)}$ bimetallic with an electronic parameter one unit less than in the observed product **2**, and the converse for the structural parameter (footnote 4).

An already documented (11), but less involved, case of a reductive denitrosylation also involving cobalt complexes of the same type as **1** is provided by the nearly quantitative formation of $Co(NO)(PPh_3)_3$ ($D^{9+1}_{NO(Co)}$) from a room temperature reaction in THF of $NaBH_4$ with a mixture of the $D^{8+2}_{NO(Co)}$ derivatives $Co(NO)_2(PPh_3)Cl$ and $Co(NO)_2(PPh_3)_2^+$-Cl^- in the presence of an excess of PPh_3. Together with the contrasting solution behaviour of $Co(NO)_2(L)_2^+$ (L = Py, phosphane), this allows us to consider the reaction scheme of Fig. 3 as a viable reaction pathway for the BPh_4^- induced transformation of complex **1** into bimetallic **2**. In an intermediate such as **4**, one of the two possible bimetallics that could result from the ionisation of the Co—I bond of **1**, only the cobalt center attached to the N sites of the PN ligand would be prone to a phenyl transfer involving BPh_4^-. However, contrary to $Co(NO)_2(Py)_2^+$ **3**, due to the geometry of the PN ligand, the pyridinyl moiety that has to dissociate prior to the phenylation step is forced to stay in the vicinity of the metallic center and remains available for recomplexation at a latter stage. It is recognized that alternatives in which formation of the Co—Co bond and (or) the μ_2-NO bridge precedes the reductive denitrosylation step cannot be dismissed at present, and synthesis of more stable analogs of the postulated intermediate **4** is therefore of interest.

Conclusion

In the single crystal X-ray structure of the two independent molecules of $Co(NO)_2(Py)_2^+BF_4^-$, the values of the (O)N—Co—N(O) angles, when they are compared to those of closely related structures, are not readily accounted for in terms of the usual assumption that in $M(NO)_2(L)_2^x$ (x = 0, +1) the repulsions in the $M(NO)_2$ portion are the most influential factor. Instead, the observed changes from one structure to another are more consistent with the notion that the repulsions in the M(NO)(L) fragments are the predominant ones, the same applies to pentacoordinated complexes containing one M(XO)(CO) (X=C, N) moiety (32).

[5]In the series of $M(NO)_2(L)_2^x$ (L = PPh_3, x = 0, +1) derivatives, the behaviour of both the α (N—M—N) and β (P—M—P) angles upon replacing a first row metal by the better back-bonder second row metal of the same group is of interest. Whereas α increases in every case, β is little affected in the cationic series (113.5(2)° (Co^+ (24)), 115.8(5)° (Rh^+ (28))), but decreases significantly in the neutral series (from 111.9(1)° (Fe (22)), to 103.85(6)° (Ru (21))), which increases the compression in $M(L)_2$. A simple rationalization would be to assume that in the Ru complex, in which the M to NO back-bonding should be the most intense, the nonbonded influence of a NO ligand has reached a threshold forcing the β angle to close, in order to achieve a more favorable rebalancing of the nonbonded forces within the $M(NO)_2$, M(NO)(L), and $M(L)_2$ moieties. In support of this hypothesis, based on the νNO values, the nonbonded influence of the NO ligands in $Ir(NO)(CO)(PPh_3)_2$ (νNO ($CHCl_3$) = 1640 cm^{-1} (29)) and in $Ru(NO)_2(PPh_3)_2$ (νNO (Nujol) = 1665, 1615 cm^{-1} (28), $\langle \nu NO \rangle$ = 1640 cm^{-1}) should be comparable, and the P—Ir—P angle of the Ir complex is found at 103.9(1)° (30), identical to the equivalent angle in the Ru derivative. In sharp contrast, in $Ir(NO)_2(PPh_3)_2^+$ with fewer electron-rich, and consequently fewer sterically demanding, NO ligands (νNO (Nujol) = 1760, 1715 cm^{-1} (28), $\langle \nu NO \rangle$ = 1738 cm^{-1}), the P—Ir—P angle has expanded to 116.3(2)° (31).

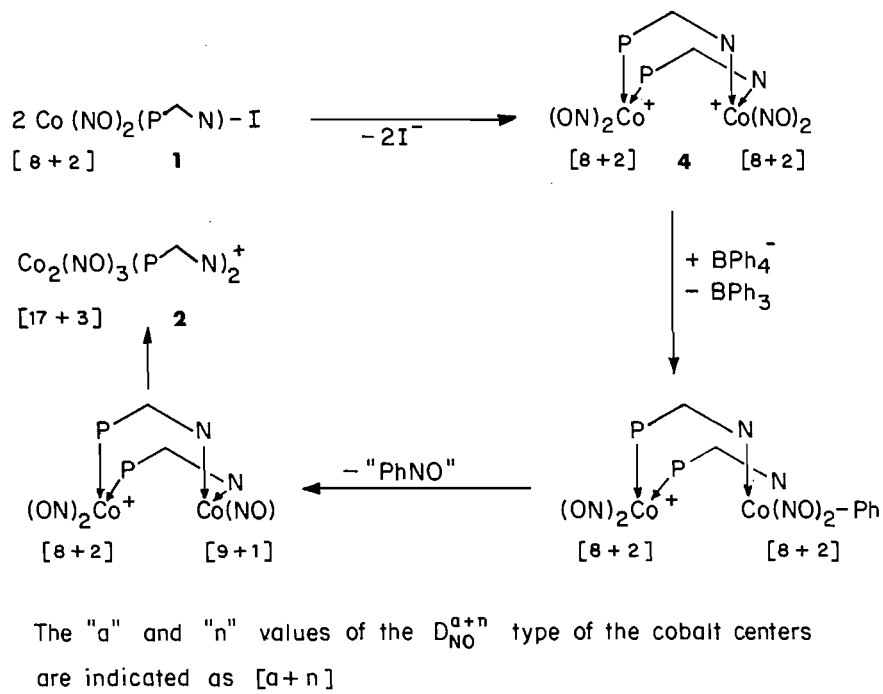

FIG. 3. Suggested reaction pathway for the formation of $Co_2(NO)_3(PN)_2^+BPh_4^-$ **2** in the BPh_4^- induced partial denitrosylation of $Co(NO)_2(PN)I$ **1**.

With respect to the reactivity of nitrosyl complexes, the facile dissociation of the Py ligand from $Co(NO)_2(Py)_2^+$ offers interesting prospects for catalysis (for example, BPh_4^- has a beneficial influence for the catalytic dimerization of norbornadiene in the presence of $(Co(NO)_2Cl)_2$ (33)). In addition, regarding the synthesis of polymetallics containing pyridylphosphines as bridging ligands (see for example the references quoted in ref. 34), the functionalization of their N(Py) donor sites with M(NO) first row metallic fragments might result in nonbonded repulsions within the M(NO)(Py) moieties that are sufficiently destabilizing for opening up reaction pathways leading to the formation of unusual structures, as exemplified by the formation of $Co_2(NO)_3(PN)_2^+BP_4^-$.

A pulse radiolysis study of the reaction of OH with I_2 and the decay of I_2^-

A. JOHN ELLIOT

AECL Research, System Chemistry and Corrosion Branch, Chalk River Laboratories, Chalk River, Ont., Canada K0J 1J0

Received January 16, 1992

A. JOHN ELLIOT. Can. J. Chem. **70**, 1658 (1992).

The rate constant for the reaction of the hydroxyl radical with iodine was estimated to be $(9.5 \pm 1.0) \times 10^9$ dm^3 mol^{-1} s^{-1} at 20°C from fitting the time dependence of the decrease in the absorption of iodine at 460 nm. A number of rate constants associated with the decay of I_2^- that were required for this fitting process were also determined. They were the reaction of I_2^- with I_2^-($2k = (4.60 \pm 0.05) \times 10^9$ dm^3 mol^{-1} s^{-1}) at an ionic strength of 1.2×10^{-2} mol dm^{-3}; I_2^- with I ($k = (4.6 \pm 1.6) \times 10^9$ dm^3 mol^{-1} s^{-1}); and I with I ($2k = (3.0 \pm 1.0) \times 10^{10}$ dm^3 mol^{-1} s^{-1}).

A. JOHN ELLIOT. Can. J. Chem. **70**, *1658* (1992).

En se basant sur un ajustement de la diminution de l'absorption de l'iode à 460 nm en fonction du temps, on a évalué que, à 20°C, la constante de vitesse de la réaction du radical hydroxyle avec l'iode est égale à $(9,5 \pm 1,0) \times 10^9$ dm^3 mol^{-1} s^{-1}. On a aussi déterminé un grand nombre de constantes de vitesses associées à la décroissance de I_2^- qui étaient nécessaires pour le processus d'ajustement. Il s'agit de la réaction de I_2^- avec I_2^- ($2k = 4,60 \pm 0,05) \times 10^9$ dm^3 mol^{-1} s^{-1}), à une force ionique de $1,2 \times 10^{-2}$ mol dm^{-3}; de I_2^- avec I ($k = 4,6 \pm 1,6) \times 10^9$ dm^3 mol^{-1} s^{-1}) et de I avec I ($2k = 3,0 \pm 1,0) \times 10^{10}$ dm^3 mol^{-1} s^{-1}).

[*Traduit par la rédaction*]

Introduction

Since the release of radioactive iodine compounds to the environment represents one of the hazards in a nuclear accident, considerable effort has been expended to understand iodine chemistry in order to contain these species. An intermediate goal of this research is to develop a computer simulation package that can be used to model the experimental results from such large-scale experiments as the Radioiodine Test Facility (RTF) at Whiteshell Laboratories in Manitoba, Canada (1, 2). Once this is successful, the simulation package can then be used to help develop containment procedures. As kinetic simulations are only as good as the rate constants which are used, many of the rate constants reported in the early literature of flash and pulse radiolysis need to be re-evaluated or confirmed in the light of the current understandings in iodine chemistry.

In this publication we report on the rate constants for reactions [1] and [5]–[7] at 20°C.

[1] $OH + I_2 \rightarrow I + HOI$

$k_1 = 9.5 \times 10^9$ dm^3 mol^{-1} s^{-1} (this work)

[2] $OH + I^- \rightarrow HOI^-$ $\quad k_2 = 1.1 \times 10^{10}$ dm^3 mol^{-1} s^{-1} (3)

[3] $HOI^- \rightarrow I + OH^-$ $\quad k_3 = 1.2 \times 10^8$ s^{-1} (4)

[4] $I + I^- \rightleftarrows I_2^-$ $\quad K_4 = 1.28 \times 10^5$ dm^3 mol^{-1} (see text)

$k_{4f} = 8.8 \times 10^9$ dm^3 mol^{-1} s^{-1} (this work)

[5] $I_2^- + I_2^- \rightarrow I_3^- + I^-$

$2k_5 = 4.6 \times 10^9$ dm^3 mol^{-1} s^{-1} (this work)

[6] $I_2^- + I \rightarrow I_3^-$

$k_6 = 4.6 \times 10^9$ dm^3 mol^{-1} s^{-1} (this work)

[7] $I + I \rightarrow I_2$ $\quad 2k_7 = 3.0 \times 10^{10}$ dm^3 mol^{-1} s^{-1} (this work)

[8] $I^- + I_2 \rightleftarrows I_3^-$ $\quad K_8 = 747$ dm^3 mol^{-1} (2)

$k_{8f} = 5.6 \times 10^9$ dm^3 mol^{-1} s^{-1} (2)

Based on the minimal loss of I_2 in steady-state γ-radiolysis of deaerated I_2 solutions, it was initially assumed that OH did not react with I_2 (5). However, Schwartz and Bielski (6), in a pulse radiolysis study on N_2O-saturated I_2 solutions, reported a rate constant of 1.1×10^{10} dm^3 mol^{-1} s^{-1} for reaction [1]. In their experiment they monitored the build-up of the absorption at 280 nm where HOI ($\epsilon = 200$ dm^3 mol^{-1} cm^{-1}) (7) and I ($\epsilon = 750$ dm^3 mol^{-1} cm^{-1}) (8) both absorb, but mentioned no measurements made at 460 nm, the λ_{max} for I_2.

This system was reinvestigated because the kinetics might have been distorted by the production of small amounts of I_3^- which absorbs strongly at 280 nm ($\epsilon = 37\,000$ dm^3 mol^{-1} cm^{-1}) (9). I_3^- can be produced through reactions [5] and [6] from I_2^- formed in equilibrium [4] and in reaction [9] from the atomic hydrogen formed in the radiolysis of water.

[9] $H + I_2 \rightarrow I_2^- + H^+$ $\quad k_9 = 3.5 \times 10^{10}$ mol dm^{-3} s^{-1} (6)

Furthermore, the solutions in this pulse radiolysis study (6) were multiply-pulsed for signal averaging purposes (dose per pulse about 3 Gy) so that other iodine species were also present during the experiments (Private communication from H.A. Schwartz to N.H. Sagert).

Experimental

Potassium iodide, sodium sulphate, and iodine (resublimed) were reagent grade quality and were purchased from Anachemia; perchloric acid (69–72%) was Baker Instra-analysed grade; all chemicals were used as supplied. The water used to prepare the solutions was distilled once, passed through a Millipore Milli-Q2 system, and then redistilled from alkaline permanganate.

The iodine solutions were prepared by stirring iodine crystals in perchloric acid solutions (pH 3.3) for about half an hour in the dark. Acidic solutions were used to minimize the hydrolysis of the iodine (reactions [10] and [11]) (7).

[10] $I_2 + H_2O \rightleftarrows HOI + I^- + H^+$

[11] $3HOI \rightarrow 2I^- + IO_3^- + 3H^+$

Immediately after the iodine solutions were prepared, they were saturated with N_2O by the syringe-bubbler technique. The concentrations of the iodine, I_3^-, and I^- in the solution were calculated from the UV-vis spectra recorded on a Hewlett-Packard HP

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

8450A diode array spectrometer. These spectra were run before and after the pulse radiolysis experiment using the solution from the syringe. For the calculations, the extinction coefficients of I_2 at 350 and 460 nm were taken to be 30 and 746 $dm^3\ mol^{-1}\ cm^{-1}$ respectively (J. Paquette, private communication); for I_3^-, values of 2.5×10^4 and 980 $dm^3\ mol^{-1}\ cm^{-1}$ (6), respectively, were taken. The value for K_8 of 747 $dm^3\ mol^{-1}$ was used (2). For the solutions used in rate constant calculations, the I^- concentration was always about 1% of the I_2 concentration.

Some studies were made with N_2O-saturated potassium iodide solutions. In these experiments, sodium sulphate was added to the KI solutions of concentration $3.7 \times 10^{-5} - 1.2 \times 10^{-2}$ mol dm^{-3} (natural pH) to keep the ionic strength constant at 1.2×10^{-2} mol dm^{-3}.

The solutions were irradiated with 3×10^{-7} s pulses of 2.25 MeV electrons from a van de Graaff generator at 20 ± 2°C in a 2-cm pathlength optical cell. Between pulses the cell was drained and filled twice to minimize contamination of the sample with products from the previous pulse (10). The optical detection system has been described elsewhere (11). The dosimeter was O_2-saturated 10^{-2} mol dm^{-3} KSCN solution; a $G^*\epsilon_{475}$ of 2.25×10^4 was assumed (11).

Results and discussion

Pulse radiolysis of N_2O-saturated KI solutions

The rate constants for reactions [6] and [7] are required to fit the experimental data for the reaction of OH with I_2 (next section). The only reported values appear to be those published by Grossweiner and Matheson (12) from a flash photolysis of iodide solutions in 1957. However, these data were measured at 405 nm where both I_2^- and I_3^- absorb and the rate constants calculations were based on incorrect values for K_4 and for the extinction coefficient for I_2^-. For this reason it was decided to remeasure k_6 and k_7.

N_2O-saturated solutions containing either 1.2×10^{-2}, 1.2×10^{-3}, 1.2×10^{-4}, or 3.7×10^{-5} mol dm^{-3} KI (at a fixed ionic strength of 1.2×10^{-2} mol dm^{-3}) were pulse irradiated (dose of 9–10 Gy) and the decay of I_2^- was monitored at 725 nm where I_2^- is the only absorbing species (13). Some representative decay profiles are shown in Fig. 1. The *observed* bimolecular rate constants for the two highest iodide concentrations, where reaction [5] is the only important reaction, were identical within experimental error. This confirms that ionic strength effects accounted for the differences observed in k_5 for 10^{-2} and 10^{-3} mol dm^{-3} iodide reported in an earlier publication from this laboratory (13).

The kinetic simulation package FACSIMILE/CHECKMATE (14) was used to fit the *total* absorbance profile of the pulse radiolysis traces so that no assumption needed to be made that equilibrium [4] is always maintained during the I_2^- decay (12). The reaction sequence [2]–[8] and [12] was used to describe the chemistry involved.

[12] $OH + OH \rightarrow H_2O_2$ $\quad k_{12} = 4.2 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$ (18)

The extinction coefficient for I_2^- at 725 nm was assumed to be 2560 $dm^3\ mol^{-1}\ cm^{-1}$ (13) and the yields of OH were taken from the scavenging curve given by Schuler and coworkers (15). K_4 at 20°C was calculated from the value of Schwartz and Bielski (6) at 25°C using a ΔH of −23 kJ mol^{-1} (16). In order to get the fits in Fig. 1, k_{4f} was allowed to vary in the fitting procedure (with k_{4b} being calculated from K_4 and k_{4f}). A value of k_{4f} of $8.8 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$ was obtained this way. This 20°C value can be compared to the 25°C value of $1.2 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$ reported by Schwartz and Bielski (6) and the value by Nagarajan and Fessenden (17) of $1.1 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$ where the temperature was not given.

The values for $2k_5$, k_6, and $2k_7$ were $(4.60 \pm 0.05) \times 10^9$, $(4.6 \pm 1.6)\ 10^9$, and $(3.0 \pm 1.0) \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$, respectively. The fits to the experimental data can be seen in Fig. 1. While the rate constants, $2k_5$ and k_6, are consistent with those expected for a nearly diffusion-controlled reaction, the value for $2k_7$ appears somewhat high. From the Smoluchowski equation (18), a value for $2k_7$ of $1.6 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$ was calculated using the estimated values of $2.5 \times 10^{-9}\ m^2\ s^{-1}$ and 0.215 nm for the diffusion coefficient and reaction radius, respectively, of the iodine atom.

Pulse radiolysis of N_2O-saturated iodine solutions

The kinetic data for reaction [1] were acquired at 385 nm as well as at 460 nm since the I_2^- produced in reaction [9] contributes significantly to the absorption changes at 460 nm. Two iodine concentrations of 6.7×10^{-5} and 1.1×10^{-4} mol dm^{-3} were studied. Representative traces observed for the later solution are shown in Fig. 2. Data was also acquired at 280 nm, but the poor signal-to-noise character of the signals precluded any quantitative kinetic analysis. In general, the dose per pulse fell in the range 6.5–10 Gy.

The FACSIMILE/CHECKMATE program was used to fit the data. For the simulations, the G values (number formed per 100 eV of energy absorbed) used for the primary species formed at the end of the spur reactions are given in parentheses in reaction [13] (19).

[13] H_2O -radn →

e_{aq} −(2.6), OH(2.7), H(0.55), H_2(0.42), H_2O_2(0.7)

The reactions [1]–[9], [12], [14] and [15] formed the chemical reaction set.

[14] $e_{aq}^- + N_2O - H_2O \rightarrow OH + OH^- + N_2$

$k_{14} = 9.1 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$ (3)

[15] $e_{aq}^- + H^+ \rightarrow H$ $\quad k_{15} = 2.3 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$ (3)

The extinction coefficients used at 285 and 460 nm, respectively, for I_2^- were 10 000 and 2100 $dm^3\ mol^{-1}\ cm^{-1}$ (13); for I_2, 746 and 106 $dm^3\ mol^{-1}\ cm^{-1}$ (J. Paquette, private communication); and for I_3^- 10 000 (9) and 980 $dm^3\ mol^{-1}\ cm^{-1}$ (6).

The procedure entailed fitting the 385-nm profile first as this predominantly arises from the I_2^- absorption. The time profile of the I_2^- absorption after the initial build-up is sensitive to the iodide ion concentration. This can be seen in Fig. 2 where simulations for three different iodide ion concentrations are given. The best fit was for 1.25×10^{-6} mol dm^{-3} which can be compared to the estimate of the concentration of iodide ion in the 1.1×10^{-4} mol dm^{-3} iodine solution of $(1.1 \pm 0.1) \times 10^{-6}$ mol dm^{-6} mol dm^{-3} made from the UV-vis spectrum. So, in practice, the iodide concentration was finally determined by the fit of the 285-nm kinetic data and this value was used in the fit of the 460-nm data. From these fits an estimate for k_1 of $(9 \pm 1) \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$ can be made for the 1.1×10^{-4} mol dm^{-3} iodine solution (see Fig. 2) and $(10 \pm 1) \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$ for the 6.7×10^{-5} mol dm^{-3} iodine solution. A best estimate for k_1 at 20°C would be $9.5 \times 10^9\ dm^3\ mol^{-1}\ s^{-1}$ with a 10% error, which is in reasonable agreement with the value of $1.1 \times 10^{10}\ dm^3\ mol^{-1}\ s^{-1}$ reported by Schwartz and Bielski (6) for 25°C.

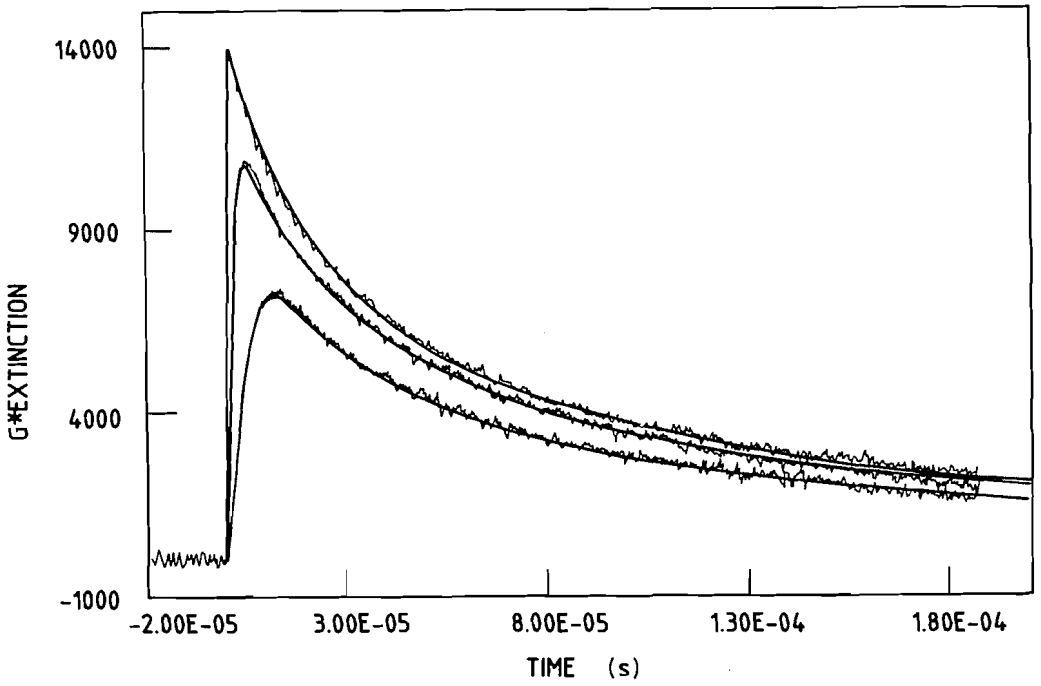

FIG. 1. The experimental and fitted time profile of the formation and decay of I_2^- at 725 nm in N_2O-saturated potassium iodide solutions. The iodide concentration and dose per pulse for upper, middle, and lower traces were: 1.2×10^{-3} mol dm^{-3} and 10.4 Gy; 1.2×10^{-4} mol dm^{-3} and 9.9 Gy; and 3.7×10^{-5} mol dm^{-3} and 9.2 Gy, respectively. The ionic strength was adjusted to 1.2×10^{-2} mol dm^{-3} with sodium sulphate.

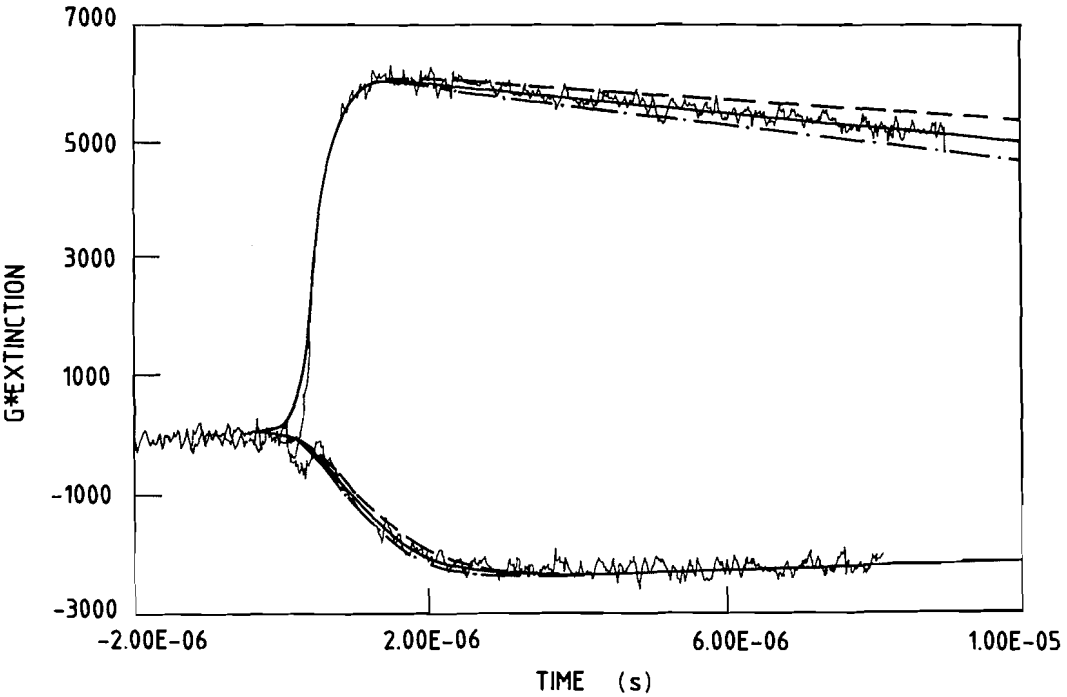

FIG. 2. The experimental and fitted time profiles of the absorption at 385 nm (upper) and 460 nm (lower) observed in N_2O-saturated 1.1×10^{-4} mol dm^{-3} iodine solution after a 9.8 and 7.8 Gy pulse, respectively. For the simulations of the 385-nm (upper) trace, the concentration of iodide ion was 1.0×10^{-6} mol dm^{-3} (–·–·–), 1.25×10^{-6} mol dm^{-3} (—), 1.5×10^{-6} mol dm^{-3} (– – –). For simulations of the 460-nm (lower) trace the value for k_1 was 10×10^9 dm^3 mol^{-1} s^{-1} (–·–·–), 9×10^9 dm^3 mol^{-1} s^{-1} (—), 8×10^9 dm^3 mol^{-1} s^{-1} (– – –), respectively.

Conclusions

The principal conclusion from this work is that the hydroxyl radical does react rapidly with iodine, in agreement with Schwartz and Bielski (6). However, the minimal loss of iodine observed in the γ-radiolysis of deaerated solutions of iodine referred to by Sellers (5) can be accounted for by regeneration of iodine from the overall reactions [16] and [17] (20) and the reduction of the iodate by the radiolytically generated hydrogen peroxide to iodine (20).

[16] $5HOI \rightarrow 2I_2 + IO_3^- + 2H_2O + H^+$

[17] $10HOI + 10I \rightarrow 9I_2 + 2IO_3^- + 4H_2O + 2H^+$

Several sugar glutaramide combinations, wherein the aldehyde group of the sugar was incorporated as C-4 of the imide ring, were prepared to provide molecules with chemotherapeutic potential. The most interesting bioassay results were seen in the inhibition of the bacteria *Mycobacterium intracellularae* by the glutarimide combinations with D- and L-xylose.

HEE MOON PARK, DAVID M. PIATAK, JOHN R. PETERSON et ALICE M. CLARK. Can. J. Chem. **70**, 1662 (1992).

Dans le but d'obtenir des molécules possédant un pouvoir chemothérapeutique, on a préparé plusieurs combinaisons de glutarimides de sucre dans lesquelles le groupe aldéhydique du sucre a été incorporé à la poisition C-4 du cycle imide. Les résultats d'essais biologiques les plus intéressants ont été obtenus lors de l'inhibition de la bactérie *Mycobacterium intracellularae* par les combinaisons de la glutarimide avec les D- et L-xyloses.

In an effort to identify new molecules with potential as chemotherapeutic agents, combination of the glutarimide ring, a salient feature of the antibiotic cycloheximide and the antineoplastic sesbanimide, with sugars seemed attractive. It was envisioned that such combinations might increase the solubility characteristics of molecules possessing a glutarimide ring and simulate a modified A/B ring partial structure of sesbanimide for evaluation. Although it has been demonstrated (1) that rings A and B of sesbanimide possess no antineoplastic activity, other biological properties, such as antibacterial and (or) anticonvulsant action, were envisaged. Our previous experience (2, 3) and reports by Makaiyama *et al.* (4) and Yamashita and co-workers (5) with cycloheximide analogues in this context, as well as a recent paper (6) on anticonvulsant activity for 2-benzylglutarimides, further stimulated exploration of other synthetic combinations incorporating a glutarimide ring.

To ensure appropriate inertness of the sugar hydroxyls in subsequent manipulations of the aldehyde group and to afford reasonable solubility in reaction media, the synthetic procedure began with protection of these moieties. Benzylation was most attractive since catalytic reduction could be employed in the final step for their removal without affecting the other functional groups. We had noted earlier (2, 3) that aqueous acidic or basic conditions that are often used to remove many other protecting groups sever the glutarimide ring amide linkage and generate a lactone ring in the presence of available hydroxyl groups. Accordingly, the aldehyde groups of the sugars **1** were first protected as di(ethylthio)acetals **2**, the hydroxyls were completely benzylated with NaH and benzyl chloride in DMSO, and then the aldehyde groups were regenerated with mercuric chloride and cadmium carbonate to finally afford the benzylated sugars **3***.

To provide for the incorporation of glyceraldehyde into the glutarimide ring 2,3-*O*,*O*-dibenzyl-D-glyceraldehyde **3***g** * was secured from D-mannitol by selective protection of the hydroxyl moieties, benzylation of the free hydroxyl groups, and periodate oxidation (7).

Construction of the glutarimide ring fragment was now begun as patterned after procedures used in the total synthesis of sesbanimide (8). First, the carbon chain was extended through Wittig condensation of the free aldehyde with $Ph_3P{=}CHCO_2Me$. Although both *Z* and *E* isomers **5*** ensued, the *E* form represented over 90% of the product as established by ^{1}H NMR signals at δ 6.88 (d, 1H, J = 7.9 Hz) and 5.99 (d, 1H, J = 7.9 Hz). Introduction of the remaining glutarimide ring components and closure to the imide ring **6*** was achieved in a one-pot procedure initiated by Michael condensation of the unsaturated ester and *tert*-butyl malonamide. These products **6*** were mixtures of diastereoisomers owing to the creation of new epimeric chiral centers at the *tert*-butyl ester group attachment site. Multiplicity of NMR signals, in particular, the ^{13}C NMR signals at δ 165–171 for the two orientations of the *tert*-butyl ester (see Table 2), permitted this evaluation.

Removal of the *tert*-butyl ester to yield **7*** proceeded in good yield by, first, expulsion of isobutylene with trifluoroacetic acid and then decarboxylation of the resultant acid by heating in 1,2-dimethoxyethane. It was noted later that the decarboxylation was best accomplished by stirring at room temperature for 16 h since this obviated glutarimide cleavage. Spectral characteristics of products **7*** included IR absorptions at 1720 and 1695 cm^{-1} for the imide system and two ^{13}C NMR signals at ca. δ 172 for the imide carbonyls.

To complete the synthetic sequence to the final products **8*** the benzyl protective groups were removed by catalytic reduction. The usual procedure utilizing 5% Pd–C was found to proceed very slowly, most likely owing to the multiple functionalities present. A more efficient catalytic transfer procedure (9) using 20% palladium hydroxide on carbon and cyclohexene as the hydrogen donor was eventually adopted. Complete displacement of the benzyl groups was established by the appearance of broad OH absorption in the infrared and the absence of any aromatic proton signals in ^{1}H NMR spectra. Signals at ca. δ 174 confirmed that the glutarimide ring remained intact (see Table 2).

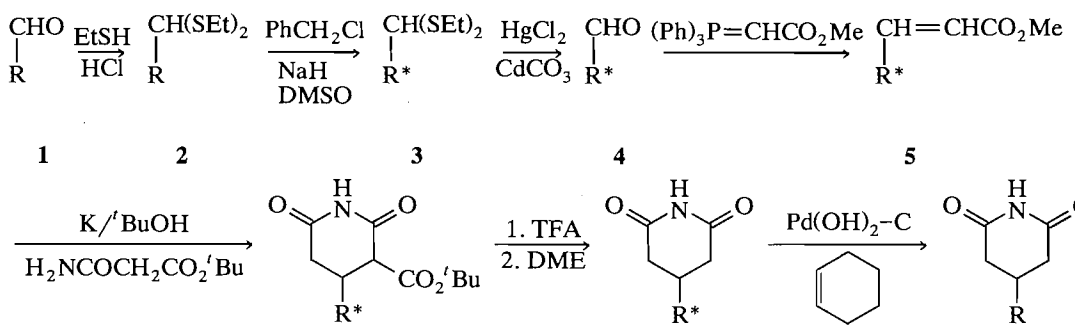
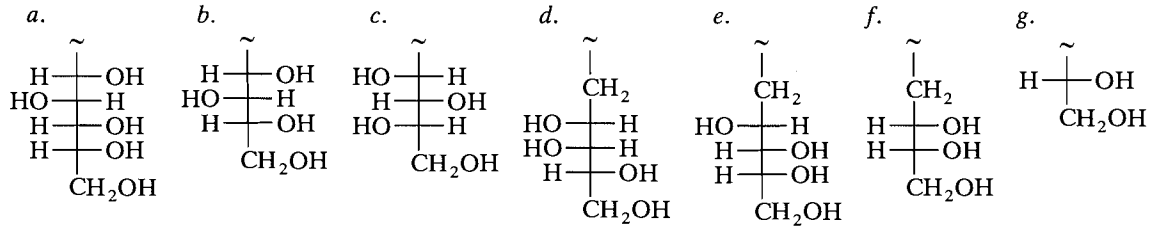
To determine the type of biological action of the sugar-glutarimide ring combination, in vitro assays for anti-candidal, antifungal, antibacterial, anti-Rhino viral, and anti-Herpes properties were undertaken. In the anticandidal test marginal activity was seen in a 48 h period, while in the antifungal procedures *Aspergillus flavus, Aspergillus fumigatus, Tricophyton mentagrophytes,* and *Sacchromyces cerevisiae* were unaffected. No effect was seen with both viral agents.

The most interesting results occurred with the bacteria *M. intracellularae* (see Table 3). Four of the six D- and L-xylose combinations had strong antibacterial action within the 72 h test period. Two of the target combinations **8***b* and **8***c* had reasonable activity, but the L-xylose intermediate **6***c** with the glutarimide ring epimerically substituted by the *tert*-butyl ester and the sugar portion fully benzylated exhibited the highest degree of inhibition. The structure–activity correlations are not yet fully apparent although it can be noted that combination with L-xylose appears to be favored. With the other bacterial agents employed, *Candida neoformans, Escherichia coli, Staphylococcus aureus, Bacillis subtilis,* or *Pseudomonas aeruginosa,* no positive results were seen.





Experimental

All commercial reagents were used as obtained unless otherwise specified. Melting points (mp) were taken on a Fisher–Johns block and are uncorrected. IR spectra were recorded with a Sargent-Welch 3-200 spectrophotometer as KBr pellets or neat; ^{1}H and ^{13}C NMR spectra were obtained with an IBM-NR 200 spectrometer on samples dissolved in deuteriochloroform with tetramethylsilane as an internal standard unless otherwise stated; and elemental analyses were performed on a Perkin–Elmer 240 elemental analyzer by Ms. P. Rider.

Column chromatography was done on Silica Gel 60, and analytical TLC on precoated sheets of Silica Gel 60 F_{254} supplied by EM Reagents. All solvents were redistilled in glass systems. Organic phases were dried over magnesium sulfate before solvent removal.

Formation of di(ethylthio)acetals

The thioacetals **2** were formed by reported procedures (10–13) using ethyl mercaptan and concentrated HCl (see Table 1).

Benzylation of thioacetals

In a typical experiment NaH (2.5 g, 50% oil dispersion) was added to DMSO (10 mL) under nitrogen. The dithioacetal of D-glucose (**1***a*, 2.0 g) dissolved in DMSO (10 mL) was added dropwise, then stirred for 40 min, after which benzyl chloride (4.8 mL) was added. The excess NaH was destroyed with methanol (2 mL) after 2.5 h, followed by 20 mL of water. The product was extracted into ethyl acetate (3 × 30 mL) and washed with water (2 × 20 mL). Purification of the oily syrup (4.2 g) by column chromatography afforded 3.4 g of product **2***a**. See Tables 1 and 2 for yield and spectral data for this compound and others.

Removal of the thioacetal moieties

Although mercuric perchlorate (13) reacted more quickly and gave somewhat better yields, mercuric chloride–cadmium carbonate was found to be less expensive for larger scale reactions. Typically, benzylated D-xylose thioacetal **3***b** (46.26 g), mercuric chloride (100 g), cadmium carbonate (100 g), acetone (750 mL), and water (125 mL) were stirred at ambient temperature for 22 h. The solids were removed by filtration, the residual oil from the filtrate was taken up into ethyl acetate, and the organic layer was washed with water, 10% potassium iodide, and water. The product was purified by column chromatography (20% ethyl acetate/hexane) to yield **4***b** as a colorless oil (30.6 g; 76%). See Tables 1 and 2 for additional data and other examples.

Wittig reaction with benzylated sugars

In a typical experiment a mixture of benzylated D-xylose **4***b** (685 mg) and methyl(triphenylphosphoranylidene)acetate (538 mg; 1.1 equiv.) in benzene (15 mL) was stirred in a nitrogen atmosphere at reflux for 24 h. The solution was filtered through a short silica gel column to remove triphenylphosphine oxide. Removal of the solvent gave an oily product, which was column chromatographed (10% ethyl acetate/hexane) to afford 671 mg (88%; R_f 0.35) of syrupy **5***b**. See Tables 1 and 2 for additional data and other examples.

[b]Taken in DMSO-d_6 solution.
[c]Multiple signals were seen in most instances owing to diastereomers formed.

Michael condensation of unsaturated sugar ester

Freshly cut potassium metal (17.2 mg; 0.44 mmol) was added to *tert*-butyl alcohol (3 mL) distilled from calcium hydride. After the metal had reacted, *tert*-butyl α-aminocarbonyl acetate (83.4 mg; 0.53 mmol) was added. After 30 min a solution of the 2-deoxy-D-ribose unsaturated methyl ester **5***f** (30 mg; 0.44 mmol) in *tert*-butyl alcohol (1.0 mL) was added and the reaction was stirred overnight under argon.

The reaction was quenched with acetic acid (1 mL), then with water (10 mL). The product was extracted into ethyl acetate (2 × 5 mL), washed with water (2 × 5 mL) and saturated sodium bicarbonate, and dried. The resultant yellow syrup was purified by column chromatography (30% ethyl acetate/hexane) to yield pure **6***f** (169 mg; 56%; R_f 0.40). See Tables 1 and 2 for additional data and other examples.

Removal of the tert*-butoxycarbonyl moiety*

In a typical experiment, the Michael product from 2-deoxy-D-ribose **6***f** (5.74 g) in methylene chloride (100 mL) was introduced into trifluoroacetic acid (50 mL) and the mixture was stirred at ambient temperature for 16 h. The solvent was then removed *in vacuo* overnight, and the residue was dissolved in dimethoxyethane (100 mL) and stirred at room temperature for 16 h. The crude benzylated sugar glutarimide was purified by column chromatography (10% acetone/chloroform) to give syrupy **7***f** (3.06 g; 68%). Additional data and other examples may be found in Tables 1 and 2.

Removal of benzyl protecting groups

Palladium hydroxide on carbon (14) (20%; 50 mg; usually 10:1 or 4:1 substrate:catalyst ratio by weight) was introduced into a solution of the benzylated L-xylose glutarimide **7***c** (441 mg) in ethanol (8 mL) and cyclohexene (4 mL). The suspension was stirred under reflux and monitored by TLC. The catalyst was removed by filtration, the filtrate evaporated to dryness, and the product crystallized directly or purified by column chromatography (30% methanol/chloroform). The yield of **8***c* was 321 mg (72%); mp 130–133°C. Tables 1 and 2 contain additional data and other examples.

Bioassays

Activity of a synthetic agent was measured with an in vitro assay in which the measure of effectiveness was achieved by the inhibition of candidal, fungal, microbial, or viral growth with a known amount of the agent. Antifungal and antimicrobial assays were conducted by an agar-well diffusion assay as described in ref. 15

[c]Zone of inhibition in mm.

with some minor modifications. Qualitative activity is reported as the average of the zone of inhibition measured in millimetres from the edge of the well containing the compound to the edge of the zone. A zone of 1–3 mm = marginal activity; 4–7 mm = moderate–good; 8–12 mm = good; and >12 = excellent.

Pure compounds were tested at 1 mg/mL with 100 μL applied, and the test was conducted for a specified time interval. The minimum inhibitory concentration (MIC) was also a factor since lower concentrations with similar zones of inhibition would denote a more active compound. The method used for the MIC determination was the twofold serial broth dilution assay (16). Test data were compared with standards such as amphotericin B and ketoconazole. See Table 3 for test data of compounds with more than marginal activity.

Antiviral assays (17) were performed on confluent monolayers of Vero cells infected by virus diluted with Eagle's Minimum Essential Medium (EMEM) in 6% bovine serum in microtiter plates wells. After 1 h adsorption time, 150 μL/well of each sample dilution was added and the plates incubated. Activity of a compound was defined as 50% or greater inhibition of the cytopathic effect, by comparison with viral controls, in at least one dilution of sample. For anti-Rhino assays, disoxiral was used as the positive control, and for anti-Herpes assays, ganciclovir was employed. Further details about either type of assay may be obtained from the authors.

Single-ion enthalpies and entropies of transfer from water to aqueous urea solutions at 298.15 K

ANDREW W. HAKIN[1] AND COLIN L. BESWICK
Department of Chemistry, University of Lethbridge, Lethbridge, Alta., Canada T1K 3M4

Received April 11, 1991[2]

ANDREW W. HAKIN and COLIN L. BESWICK. Can. J. Chem. **70**, 1666 (1992).

In this paper we report enthalpies of solution at infinite dilution (ΔH_s^θ) at 298.15 K for tetraphenylarsonium chloride (Ph_4AsCl), sodium tetraphenylborate ($NaBPh_4$), sodium chloride (NaCl), sodium bromide (NaBr), and sodium iodide (NaI) in water and aqueous solutions containing 5, 10, 20, and 30% urea by weight. Enthalpies of transfer from water to aqueous urea solutions are reported. Single-ion enthalpies of transfer (ΔH_t^θ) have been calculated using the tetraphenylarsonium tetraphenylborate, (TATB) reference electrolyte assumption. These single-ion enthalpy data have been combined with single-ion Gibbs functions of transfer (ΔG_t^θ) reported in the literature to obtain single-ion entropies of transfer (ΔS_t^θ) for the urea + water mixed solvent system. The results of this single-ion analysis are discussed in terms of the impact of electrolytes on the structure of aqueous urea solutions.

ANDREW W. HAKIN et COLIN L. BESWICK. Can. J. Chem. **70**, 1666 (1992).

Dans ce travail, on a mesuré les enthalpies de solution à dilution infinie (ΔH_s^θ), à 298,15 K, des chlorure de tétraphénylarsonium (Ph_4AsCl), tétraphénylborate de sodium ($NaBPh_4$), chlorure de sodium (NaCl), bromure de sodium (NaBr) et iodure de sodium (NaI) dans l'eau et dans des solutions aqueuses contenant 5, 10, 20 et 30% d'urée en poids. On rapporte aussi les enthalpies de transfert de l'eau vers les solutions aqueuses d'urée. On a calculé les enthalpies de transfert des ions uniques (ΔH_t^θ) utilisant l'hypothèse de l'électrolyte de référence tétraphénylborate de tétraphénylarsonium (TBTA). Dans le but d'obtenir les entropies de transfert pour ions uniques (ΔS_t^θ) pour le système de solvant mixte urée/eau, on a combiné ces données d'enthalpie pour ions uniques avec les fonctions de transfert de Gibbs pour des ions uniques (ΔG_t^θ) rapportées dans la littérature. On discute des résultats de cette analyse pour ions uniques en fonction de l'impact des électrolytes sur la structure des solutions aqueuses de l'urée.

[Traduit par la rédaction]

Introduction

Single-ion thermodynamic transfer functions of solutes from one solvent (often water) to another find applications in many areas of chemistry. By far the most studied of these thermodynamic properties are Gibbs energies of transfer (1–4). These data have been used to interpret patterns observed in rate constants (5), and also to relate pH values in a given solvent to the conventional aqueous pH scale (3). Less extensive compilations of single-ion data exist for enthalpies (6–8) and entropies (8–10) of transfer. These data provide information on the structural interactions of ions with surrounding solvent.

In this paper we concentrate on enthalpies and entropies of transfer for solutes in the urea + water solvent system. ΔG_t^θ data (5*a*, 10, 11), and the ΔH_t^θ and ΔS_t^θ data reported in this paper are some of the essential building blocks that provide a basis for a critical analysis of extrathermodynamic assumptions used in the calculation of single-ion thermodynamic properties, with particular emphasis on temperature and pressure derivatives of Gibbs energies (H, S, C_p).

This paper reports enthalpies of solution at infinite dilution (ΔH_s^θ) at 298.15 K for NaCl, NaBr, NaI, Ph_4AsCl, and $NaBPh_4$ in water and aqueous urea solutions containing 5, 10, 20, and 30% urea by weight. These data have been used to calculate enthalpies of transfer and subsequently single-ion enthalpies of transfer (ΔH_t^θ), using the tetraphenylarsonium tetraphenylborate (TATB) reference electrolyte assumption. In addition we report single-ion entropies of transfer (ΔS_t^θ) for solutes from water to aqueous urea solutions; these entropies have been calculated from the combination of our single-ion enthalpies with published (11–13) single-ion Gibbs energies.

Extensive thermodynamic functions of transfer for a 1:1 salt MX transferred from water (1) to another solvent, or solvent mixture (2), are defined by

$$[1]\quad \Delta Y_t^\theta(\mathrm{MX}: (1) \rightarrow (2)) = \Delta Y_s^\theta(\mathrm{MX}: (2)) - \Delta Y_s^\theta(\mathrm{MX}: (1))$$

where Y represents the extensive thermodynamic function of interest, for example Gibbs energy, enthalpy, or volume; subscript t indicates a transfer property, and subscript s refers to a solid → solution property. The symbol θ indicates that we are dealing with thermodynamic functions for infinitely dilute solutions.

Various extrathermodynamic assumptions have been used to convert the bulk thermodynamic functions of eq. [1] into single-ion properties (1). Of these we are especially concerned with the TATB reference electrolyte extrathermodynamic assumption (1).

The reference electrolytye assumption is based on the idea that specific, oppositely charged, large ions of equal size and similar structure have equal interactions with the solvent. The TATB reference electrolyte extrathermodynamic assumption method is summarized by eq. [2]:

$$[2]\quad \Delta Y_t^\theta(Ph_4As^+: (1) \rightarrow (2)) = \Delta Y_t^\theta(Ph_4B^-: (1) \rightarrow (2)) = (1/2)\,\Delta Y_t^\theta(Ph_4AsBPh_4: (1) \rightarrow (2))$$

Unfortunately Ph_4AsBPh_4 is only sparingly soluble in water and aqueous urea solutions, which complicates calorimetric measurements. It is convenient to obtain transfer data for

this salt by combining relevant transfer data for Ph_4AsCl, $NaBPh_4$, and NaCl using eq. [3].:

[3] $\Delta Y_t^\theta(Ph_4AsBPh_4: (1) \rightarrow (2))$
$= \Delta Y_t^\theta(NaBPh_4: (1) \rightarrow (2))$
$+ \Delta Y_t^\theta(Ph_4AsCl: (1) \rightarrow (2)) - \Delta Y_t^\theta(NaCl: (1) \rightarrow (2))$

Experimental

Urea (certified A.C.S. grade, Fisher Chemicals Ltd.) was used without further purification, after drying for 24 h in a vacuum oven at 50°C over phosphorus pentoxide. Sodium tetraphenylborate (99.5% +, Aldrich Chemical Company) was used without further purification. Tetraphenylarsonium chloride (K & K laboratories) was recrystallized several times, using the method of Kalfoglou and Bowen (14). NaI (Aldrich Chemical Company) was recrystallized from water and dried *in vacuo* at 100°C. NaCl and NaBr (Aldrich Chemical Company) were both 99.99% pure and were used without further purification. All of these inorganic salts were stored in a vacuum oven at 70°C over phosphorus pentoxide.

Doubly distilled water was used in all of our experiments.

Enthalpies of solution were measured with a homemade isoperibol solution calorimeter (15) and with a LKB 8700-1 precision calorimetry system. Both systems were tested at regular intervals by measuring the enthalpy of solution of tris(hydroxymethyl)-aminomethane in excess 0.1 M hydrochloric acid at 25°C (16). Results of these tests are reflected in estimates of our calorimetric uncertainties. Enthalpies of solution, at 298.15 K, were measured for tetraphenylarsonium chloride, sodium tetraphenylborate, sodium chloride, sodium bromide, and sodium iodide in water and in solutions containing 5, 10, 20, and 30% urea by weight. The molalities (defined as the number of moles of salt in 1 kg of mixed solvent) of the electrolyte solutions investigated were in the range $5 \times 10^{-4} - 5 \times 10^{-3}$ mol kg^{-1}. This focus on ions at low concentration provides information about ion–solvent interactions, and excludes effects of ion–ion interactions, which become increasingly important at higher concentrations.

Results

Single-ion enthalpies of transfer (ΔH_t^θ)

Enthalpies of solution at infinite dilution (ΔH_s^θ), were obtained from measured enthalpies of solution at finite concentration by using the extended Debye–Hückel extrapolation method proposed by Guggenheim and Prue (17) and developed by others (18, 19).

$$[4] \quad \rho = \Delta H_s^\theta - 2 \cdot 303\, RT^2 \left(\frac{dB}{dT}\right) (\upsilon_+ \upsilon_- m)$$

where

$$[5] \quad \rho = \Delta H_s - \frac{\upsilon}{2} |z_+ z_-|\, A_H \sqrt{I}\, \alpha$$

$$[6] \quad \alpha = \left[\frac{1}{(1 + \sqrt{I})} - \frac{\sigma(\sqrt{I})}{3}\right]$$

and

$$[7] \quad \sigma(\sqrt{I}) = \frac{3}{I^{1.5}}\left[1 + \sqrt{I} - \frac{1}{1 + \sqrt{I}} - 2 \ln (1 + \sqrt{I})\right]$$

Where $\sigma(\sqrt{I})$ is a function of the ionic strength, I, and B is a constant at a given temperature. Debye–Hückel limiting slopes, A_H, for aqueous urea solutions were interpolated from the data of Verrall and Dickson (20). Values for ΔH_s^θ obtained from plots of ρ vs. m are reported in Table 1, along with ΔH_s^θ values previously reported by others. We estimate that our total uncertainties (calorimetry, chemicals, and extrapolation) are about 0.25 kJ mol^{-1} for Ph_4AsCl and about 0.10 kJ mol^{-1} for the other salts. Our results are in good agreement with the few ΔH_s^θ values previously reported. Our ΔH_s^θ data were used in conjunction with eq. [1] to calculate the enthalpies of transfer reported in Table 2. Figure 1 illustrates the dependence of the transfer enthalpies for the salts investigated on the weight per cent of urea present in solution.

Single-ion enthalpy of transfer values reported in Table 3 were calculated using the TATB assumption (see eq. [2]). Although this method of calculation has been recommended, it should be noted that it represents only one approach to the calculation of single-ion thermodynamic quantities. The adoption of other assumptions (1) may lead to different single-ion values.

Included in Table 3 are single-ion enthalpies of transfer for other ions calculated from the combination of our own single-ion parameters with additional enthalpy of transfer data available in the literature (8, 33). Trends in these enthalpy data as functions of weight per cent urea present in solution are shown in Figs. 2–4.

Single-ion entropies of transfer (ΔS_t^θ)

Gibbs functions of transfer at 298.15 K have been calculated, on the molar (c) scale, using the solubility product data at 298.15 K reported by Kundu and co-workers (11, 12), and eq. [8]:

$$[8] \quad \Delta G_t^\theta(c) = 2.303RT(p_s K_{sp} - p_w K_{sp})$$

The TATB reference electrolyte assumption has been used to divide bulk Gibbs energies of transfer into single-ion contributions. Single-ion enthalpies of transfer for solutions containing 11.52, 20.31, and 29.64 wt.% urea pertinent to Kundu's ΔG_s^θ values were interpolated from our enthalpies. Single-ion entropies of transfer (molar scale), $\Delta S_t^\theta(c)$, were calculated by combining these enthalpies with single-ion Gibbs energies of transfer (molar scale), $\Delta G_t^\theta(c)$. The single-ion entropies calculated from this procedure are reported in Table 4.

Discussion

Comparison of our single-ion enthalpies of transfer with those that can be calculated from Gibbs energy and entropy data reported by Kundu and co-workers (11) identifies differences that are larger than the sum of estimated uncertainties in their results and ours. These discrepancies cannot be attributed to the choice of reference electrolyte assumption. In general, single-ion enthalpies calculated from calorimetric enthalpy data are supposed to be more reliable than their estimation from Gibbs energy data collected at various temperatures.

Several authors (20, 33, 34) have used changes in solvent organization brought about by cosphere overlap between cosolvent and transferred ion to explain patterns observed in single-ion entropies and enthalpies of transfer.

Urea is regarded as a hydrophilic structure disrupter in aqueous solution (21–23), the amount of structure disruption increasing with increased urea concentration. Hydrophilic cosolvent, hydrophobic ion cosphere overlap results in an overall loss of water molecules from the structured

TABLE 2. Enthalpies of transfer from water to aqueous urea solutions at 298.15 K (kJ mol^{-1})

Salt	Weight % urea 5%	10%	20%	30%
Ph_4AsCl	0.69	0.36	−0.21	−0.48
$NaBPh_4$	1.11	2.36	4.09	5.54
Ph_4AsBPh_4	2.69	4.47	6.86	9.09
NaCl	−0.90	−1.75	−2.98	−4.03
NaBr	−1.02	−1.96	−3.62	−4.75
NaI	−1.07	−1.90	−3.63	−5.08

hydration zones. In effect, the presence of urea diminishes the structure-promoting capacity of the hydrophobic ion. In the transfer processes water is released from the structured cosphere environment to the bulk solvent, hence increasing the disorder of the solvent system, which results in positive entropies of transfer. A loss of water molecules from the cospheres is accompanied by hydrogen bond breaking and therefore positive enthalpies of transfer are observed. Hydrophilic cosolvent, hydrophilic ion cosphere overlap results in an incorporation of water molecules from the bulk solvent into the more structured cosphere environment. This overlap process decreases the degree of disorder in the solvent system (i.e., negative entropies of transfer) and promotes hydrogen bonding in the cospheres (i.e., negative enthalpies of transfer). In other words both urea and the transferred ion disrupt water structure; therefore in aqueous urea solution the structure disrupting capacity of the ion is decreased.

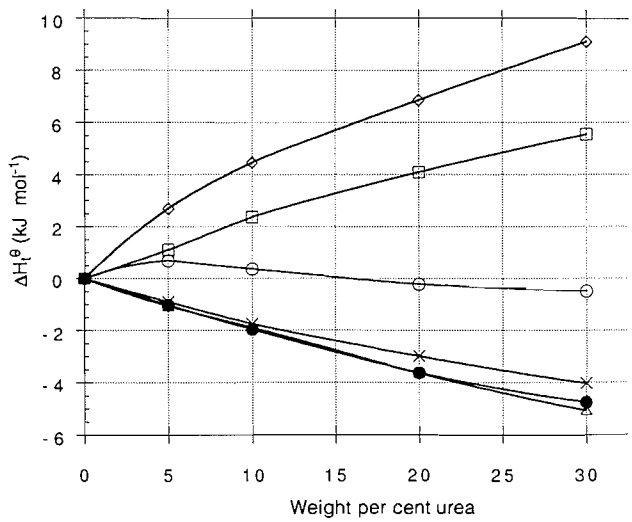

FIG. 1. Enthalpies of transfer (kJ mol^{-1}) from water to aqueous urea solutions at 298.15 K for selected electrolytes. (○) Ph_4AsCl; (□) $NaBPh_4$; (◇) Ph_4AsBPh_4; (×) NaCl; (●) NaBr; (△) NaI.

Figure 1 reports enthalpies of transfer for several salts as a function of urea concentration in aqueous solution. Four of these salts contain the same cation (sodium) and there-

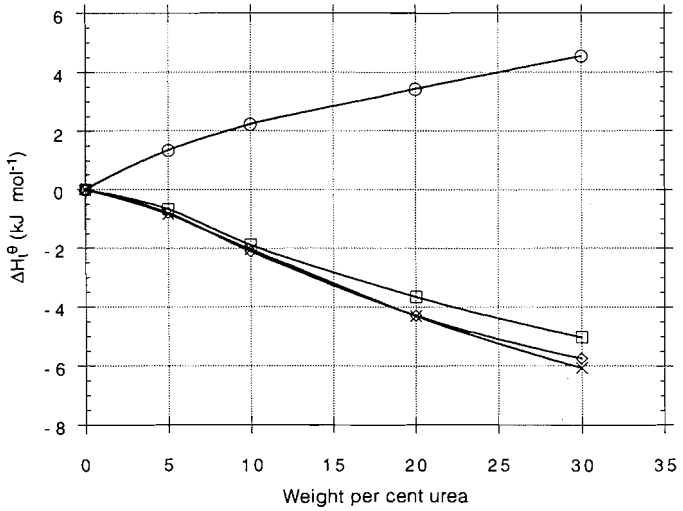

FIG. 2. Single-ion enthalpies of transfer (kJ mol^{-1}) from water to aqueous urea solutions at 298.15 K for selected anions. (○) BPh_4^-; (□) Cl^-; (◇) Br^-; (×) I^-.

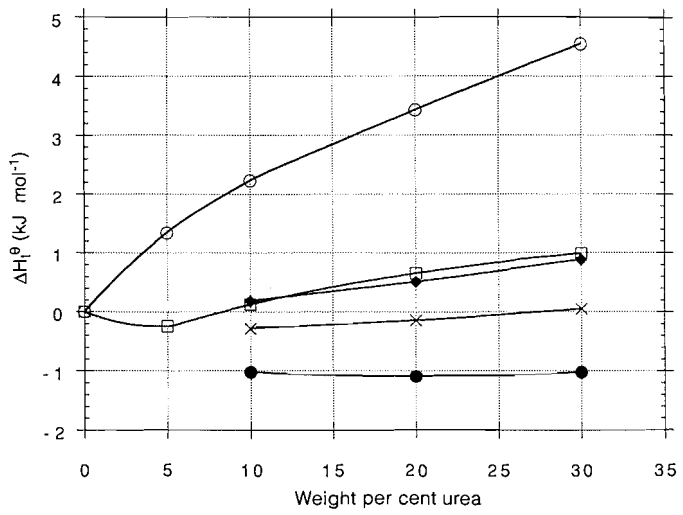

FIG. 3. Single-ion enthalpies of transfer (kJ mol^{-1}) from water to aqueous urea solutions at 298.15 K for selected cations. (○) Ph_4As^+; (□) Na^+; (◆) K^+; (×) Rb^+; (●) Cs^+.

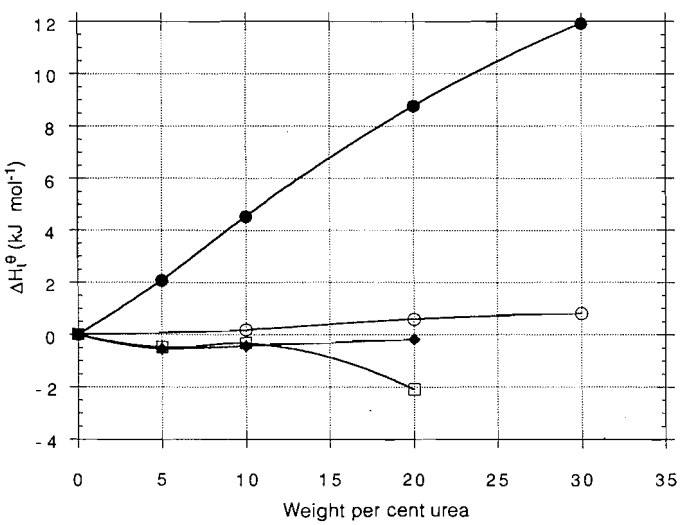

FIG. 4. Single-ion enthalpies of transfer (kJ mol^{-1}) from water to aqueous urea solutions at 298.15 K for the ammonium cation and alkylammonium cations. (○) NH_4^+; (□) Me_4N^+; (◆) Et_4N^+; (●) Bu_4N^+.

fore the differences observed in their enthalpies of transfer can be attributed to the effects of the anion. From this viewpoint it is clear that aqueous urea solutions accommodate Ph_4B^- ions in a different manner from the way in which they accommodate halide ions. Single-ion enthalpies of transfer calculated using the TATB assumption are reported for several anions and cations in Figs. 2 and 3 respectively. These figures indicate that Ph_4As^+ and Ph_4B^- can be regarded as structure enhancers (positive ΔH_t^θ) whereas the halide anions should be classed as structure disrupters (negative ΔH_t^θ) in aqueous urea solutions. The structuring capacity of the alkali metal cations appears to be linked to cation size. The structure disruption capacity following the order $Na^+ < K^+ < Rb^+ < Cs^+$. This relationship between ion size and structure disruption capacity appears to be paralleled by the halide ions. Figure 4 displays trends in single-ion enthalpies of transfer for ammonium and alkylammonium cations as a function of urea concentration in aqueous solution. The trends observed suggest that Me_4N^+ and Et_4N^+ behave as structure disrupters whereas Bu_4N^+ behaves as a structure enhancer in aqueous urea solutions. Such classifications are in agreement with previous studies (24–27). The trends observed in single-ion entropies reported in Table 4 are consistent with the structure enhancing/disrupting classifications described above.

The transfer of a halide ion from water to an aqueous urea solution is a spontaneous process, as indicated by a negative Gibbs energy of transfer (5*a*, 11). Halide ions are stabilized in aqueous urea solutions, and enthalpy/entropy compensation calculations suggest that the transfer processes are enthalpy controlled. However, the transfer of an alkali metal ion from water to an aqueous urea solution is a non-spontaneous process, i.e., positive ΔG_t^θ (5*a*, 11). Alkali metal cations are destabilized in aqueous urea solutions and enthalpy/entropy compensation calculations suggest that

Equilibrium constants and heats of formation of methyl esters and *N*,*N*-dimethyl amides of substituted benzoic acids

J. PETER GUTHRIE,[1] DAVID C. PIKE, AND YIU-CHUNG LEE
Department of Chemistry, University of Western Ontario, London, Ont., Canada N6A 5B7

Received July 15, 1991

J. PETER GUTHRIE, DAVID C. PIKE, and YIU-CHUNG LEE. Can. J. Chem. **70**, 1671 (1992).

Heats of methanolysis and dimethylaminolysis of substituted benzoyl chlorides (4-X-C_6H_4-COCl, X = H, CH_3, OCH_3, Cl, NO_2) have been measured, as have the heats of hydrolysis of the esters, permitting the calculation of the heats of formation of the benzoyl chlorides (4-X-C_6H_4-COCl, X, DH_f: CH_3O, −80.29 ± 0.70; CH_3, −48.10 ± 1.46; NO_2, −47.70 ± 0.87), methyl benzoate esters (4-X-C_6H_4-$COOCH_3$, X, DH_f: CH_3O, −124.50 ± 0.39; CH_3, −93.99 ± 0.58; Cl, −92.09 ± 0.53; NO_2, −92.55 ± 0.31), and *N*,*N*-dimethylbenzamides (4-X-C_6H_4-$CON(CH_3)_2$, X, DH_f: CH_3O, −75.87 ± 1.42; CH_3, −46.62 ± 1.99; H, −40.96 ± 1.41; Cl, −49.33 ± 1.09; NO_2, −48.05 ± 1.53). Free energies of transfer from methanol to water and from gas to water were determined for the esters and amides. Free energies of formation in aqueous solution were calculated for the acids, esters and amides, making use of thermodynamic estimation procedures where necessary. Equilibrium constants were measured for ester formation in water (X, K (M^{-1}): CH_3O, 0.14; CH_3, 0.14; H, 0.12; Cl, 0.15; NO_2, 0.13) and *N*,*N*-dimethylaminolysis in methanol (X, K (M^{-1}): CH_3O, 8.16; CH_3, 17.5; H, 26.5; Cl, 22.6; NO_2, 41.0). Partition constants for esters and amides were measured for methanol/dodecane and dodecane/water, permitting calculation of the free energy of transfer from methanol to water (4-X-C_6H_4-$COOCH_3$, X, DG_{mw}: CH_3O, 3.12; CH_3, 3.17; H, 3.01; Cl, 3.43; NO_2, 2.89; 4-X-C_6H_4-$CON(CH_3)_2$, X, DG_{mw}: CH_3O, 0.96; CH_3, 1.48; H, 0.92; Cl, 1.77; NO_2, 0.99). These data permit calculation of the equilibrium constants for dimethylaminolysis of substituted methyl benzoates in water, and for amide formation in water (4-X-C_6H_4-$CON(CH_3)_2$, X, K(M^{-1}, reactants and products as neutral molecules): CH_3O, 767; CH_3, 752; H, 2050; Cl, 1020; NO_2, 2350). In the course of our calorimetric measurements we derived an improved value for the heat of solution of HCl in methanol.

J. PETER GUTHRIE, DAVID C. PIKE et YIU-CHUNG LEE. Can. J. Chem. **70**, 1671 (1992).

On a mesuré les chaleurs de méthanolyse et de diméthylaminolyse de chlorures de benzyles substitués (4-X-C_6H_4-COCl, X = H, CH_3, OCH_3, Cl et NO_2) ainsi que les chaleurs d'hydrolyse des esters, permettant de calculer les chaleurs de formation des chlorures de benzoyles (4-X-C_6H_4-COCl, X, DH_f : CH_3O, −80,29 ± 0,70; CH_3, −48,10 ± 1,46; NO_2, −47,70 ± 0,87), des benzoates de méthyle (4-X-C_6H_4-$COOCH_3$, X, DH_f : CH_3O, −124,50 ± 0,39; CH_3, −93,99 ± 0,58; Cl, −92,09 ± 0,53; NO_2, −92,55 ± 0,31) et des *N*,*N*-diméthylbenzamides (4-X-C_6H_4-$CON(CH_3)_2$, X, DH_f : CH_3O, −75,87 ± 1,42; CH_3, −46, 62 ± 1,99; H, −40,96 ± 1,41; Cl, −49,33 ± 1,09; NO_2, −48,05 ± 1,53). On a aussi déterminé les énergies libre de transfert du méthanol à l'eau et de la phase gazeuse à l'eau pour les esters et les amides. Faisant appel à des méthodes d'évaluations thermodynamiques lorsque nécessaire, on a calculé les énergies de formation en solution aqueuse pour les acides, les esters et les amides. On a mesuré les constantes d'équilibre pour la formation des esters dans l'eau (X, K (M^{-1})) : CH_3), 0,14; CH_3, 0,14; H, 0,12; Cl, 0,15; NO_2, 0,13) et pour la diméthylaminolyse dans le méthanol (X, K (M^{-1})) : CH_3O, 8,16; CH_3, 17,5; H, 26,5; Cl, 22,6; NO_2, 41,0). On a mesuré les constantes de partition des esters et des amides entre le méthanol/dodécane et le dodécane/eau, ce qui permet de calculer les énergies libres de transfert du méthanol à l'eau (4-X-C_6H_4-$COOCH_3$, X, DG_{me} : CH_3O, 3,12; CH_3, 3,17; H, 3,01; Cl, 3,43; NO_2, 2,89; 4-X-C_6H_4-$CON(CH_3)_2$, X, DG_{me} : CH_3O, 0,96; CH_3, 1,48; H, 0,92; Cl, 1,77; NO_2, 0,99). Ces données permettent de calculer les constantes d'équilibre pour la diméthylaminolyse de benzoates de méthyle substitués dans l'eau et pour la formation des amides dans l'eau (4-X-C_6H_4-$CON(CH_3)_2$, X, K (M^{-1}), réactifs et produits sous la forme de molécules neutres) : CH_3O, 767; CH_3, 752; H, 2050; Cl, 1020; NO_2, 2350). Dans le cadre de nos mesures calorimétriques, on a obtenu une valeur améliorée pour la chaleur de solution du HCl dans le méthanol.

[Traduit par la rédaction]

Introduction

We have been interested for some time in the energetics of acyl transfer reactions (1) and in the energy levels of tetrahedral intermediates in ester (2, 3) and amide (4) hydrolyses. As part of a project aimed at extending this study to a series of substituted benzamides, we determined heats of formation of several *N*,*N*-dimethylbenzamides and methyl benzoates. These data permit calculation of the heats of aminolysis. Ester aminolysis is a curious reaction, which is not often useful because it is slow, even though it should be thermodynamically favorable. We find that the heats of dimethyl aminolysis for substituted methyl benzoates are small and not very sensitive to substituents. We also measured equilibrium constants for ester formation in water, and of dimethylaminolysis of the methyl esters in methanol, together with partition coefficients permitting the calculation of equilibrium constants for dimethylaminolysis in water. From equilibrium constants for ester formation and dimethylaminolysis we can calculate equilibrium constants for *N*,*N*-dimethylbenzamide formation.

Results

Heats of formation

In all cases the heat of formation of the substituted benzoic acid was known; methyl benzoate was the only ester for which a heat of formation had been reported (3). Heats of formation of the substituted methyl benzoates were determined by measuring the heat of reaction with tetraethylammonium hydroxide in aqueous DMSO. Heats of formation for benzoyl chloride and *p*-chlorobenzoyl chloride are known (14); for the others we determined the heat of formation by measuring the heat of reaction with methanol. The reaction of substituted benzoyl chlorides with methanol was slow; in

fact this was a serious source of experimental error. Although a heat of solution for HCl in methanol was available from the literature, this value led to inconsistent results. Accordingly we evaluated it by measuring the heat of reaction of several acid chlorides, (acetyl chloride, benzoyl chloride, and *p*-chlorobenzoyl chloride) with methanol; when the heat of formation of the acid chloride is known, the only unknown quantity is the heat of solution of HCl in methanol. Heats of formation of the amides were determined by measuring the heat of reaction of the substituted benzoyl chloride with methanolic dimethylamine. The reaction of substituted benzoyl chlorides with dimethylamine in methanol was fast. HPLC analysis showed that the product of reaction with methanolic dimethylamine was the amide. Heats of reaction and solution are found in Table 1. In this way we completed the set of heats of formation of the acid chlorides, esters, and *N*,*N*-dimethylamides of the five benzoic acids that we have studied. This allowed calculation of the heats of formation in Table 2.

Estimation of boiling points

For several of the solid esters, amides, and acid chlorides used in this work, no atmospheric pressure boiling points could be found in the literature, and, particularly for the nitro derivatives, the compounds are expected to be very high boiling. We endeavored to estimate approximate boiling points as a starting point for later estimation of the vapor pressure at 25°C, using the boiling point number approach of Kinney (5, 6). To do this we calculated the boiling point numbers for benzene, chlorobenzene, toluene, anisole, nitrobenzene, methyl benzoate, *N*,*N*-dimethylbenzamide, and benzoyl chloride using boiling points from ref. (7) and Kinney's formula (5).

$$bp = (230.14 \sqrt[3]{BPN}) - 543$$

$$BPN = ((bp + 543)/230.14)^3$$

We then calculated the increments for replacement of H on a benzene ring by Cl, 5.38; CH_3, 3.06; CH_3O, 8.05; NO_2, 15.31; $COOCH_3$, 13.75; $CON(CH_3)_2$, 24.56; and COCl, 13.40. With these values it was straightforward to estimate boiling points for the substituted derivatives as: ester, X = Cl, 234; X = CH_3, 217 (obs. 217 (8)); X = CH_3O, 250 (obs. 256 (8)); X = NO_2, 295; amide, X = Cl, 305; X = CH_3, 291; X = CH_3O, 319; X = NO_2, 357; acid chloride, X = Cl, 235 (obs. 221 (9)); X = CH_3, 219 (obs. 216 (10)); X = CH_3O,

252 (obs. 260 (11)); X = NO_2, 297. For the cases where atmospheric pressure boiling points were available the agreement is good.

Estimation of heats of vaporization

We estimated heats of vaporization from the boiling point data, using a method that we had previously devised to use boiling points at various pressures (12). The boiling points and derived heats of vaporization are found in Table 3. The expected error for this estimation procedure is 0.28 kcal mol^{-1} (12); the uncertainty limits in Table 3 are taken as 0.28 kcal mol^{-1} or the standard deviation of the various estimates from different boiling point values, whichever is larger. As a check and in order to estimate values where no vapor pressure data were available, we used an additivity scheme derived from the group additivity scheme we recently published (13). The value for the benzene nucleus with two *para* substituents was taken as 4[C_BH]; contributions for H and Cl were taken as [C_BH] and [C_BCl] respectively; the contribution for CH_3 was taken as [$C_B(C)$] + [$CH_3(C_B)$]; the contributions for O-CH_3, $-NO_2$, $-COOCH_3$, and $CON(CH_3)_2$ were calculated from the heats of vaporization of anisole (14), nitrobenzene (14), methyl benzoate (14), *N*,*N*-dimethylbenzamide (calculated from the boiling point, as already described), and benzoyl chloride (calculated from the boiling point, as already described). The values so obtained were: *p*-C_6H_4, 5.36; H, 1.34; Cl, 2.91; CH_3, 2.47; OCH_3, 4.49; NO_2, 6.45; $COOCH_3$, 6.58; $CON(CH_3)_2$, 11.30; COCl, 6.30. Using these values we could estimate heats of vaporization for the remaining compounds; the values so estimated are found in Table 3. Comparison of heats of vaporization estimated by additivity and corresponding values estimated from the boiling points at various pressures shows that the agreement is generally good, but differences can be as large as 1.5 kcal mol^{-1}; this is taken as the uncertainty in estimates based on additivity.

Estimation of heats of fusion

Fuchs and Rodewald have reported heats of solution of aromatic compounds in methanol (15). For the liquids, the heat of solution is invariably small, with a magnitude less than 1 kcal mol^{-1}. For solids the heat of solution is larger. For two 1,4-disubstituted benzenes both heat of solution and heat of fusion are available, allowing the calculation of the heat of solution for the hypothetical supercooled liquid; the values so calculated are again small, with magnitudes less than 1 kcal mol^{-1}. To obtain approximate values for the heats of fusion of the solid esters and amides studied here, we subtracted the average heat of solution of the liquid analog(s) from the observed heat of solution of the solid compounds. The values so obtained are found in Table 4. As a check we estimated the heats of fusion from the melting points, using the average value for the entropy of fusion, 13.0 cal deg^{-1} mol^{-1}, reported by Yalkowsky and co-workers (16). Yalkowsky and co-workers could find no dependence of the entropy of fusion upon structural features. The values of ΔS_{fus} ranged from 9.1 to 18.9 cal deg^{-1} mol^{-1} for disubstituted benzenes. The agreement between the two estimates for our compounds must be considered satisfactory, and the entropies of fusion calculated assuming the enthalpy values derived from heats of solution are not unreasonable. We consider the uncertainty in these estimated heats of fusion to be 1 kcal mol^{-1}, the approximate scatter in heats of solution in methanol for liquid aromatic compounds similar to those of interest here.

For *p*-nitrobenzoic acid we needed to estimate a heat of sublimation at 25°C. We have procedures for estimating the heat of vaporization of the liquid by atomic additivity (13), but need a heat of fusion. The heat of fusion has been reported at the melting point, 239.2°C (17), but this must be corrected to 25°C. To do this we need the heat capacity of fusion. The heat capacity of the solid at 25°C is available: 43.02 cal deg^{-1} mol^{-1} (17). We can estimate the heat capacity change on vaporization by additivity (18) as −28.48. To estimate the heat capacity of gaseous *p*-nitrobenzoic acid we need a contribution for the group [C_BNO_2]. This was calculated from C_p for nitrobenzene, which in turn was calculated by statistical mechanics from the vibrational spectrum (19) and barriers to internal rotation (20), as was done for entropy; *vide infra*. In this way we obtained: C_p (g, 25°C) [Ph-NO_2] = 28.56 cal deg^{-1} mol^{-1}; [C_BNO_2] = 12.36 cal deg^{-1} mol^{-1}; C_p (g, 25°C) [*p*-NO_2-C_6H_4-COOH] = 33.85 cal deg^{-1} mol^{-1} using a contribution for COOH based on C_p(g) for benzoic acid (21); C_p(1, 25°C) [*p*-NO_2-C_6H_4-COOH] = 62.33 cal deg^{-1} mol^{-1}; ΔC_p(fusion) [*p*-NO_2-C_6H_4-COOH] = 19.31 cal deg^{-1} mol^{-1}. Since ΔH_{fusion} (239°C) [*p*-NO_2-C_6H_4-COOH] = 8.84 kcal mol^{-1} (17), we can now calculate that ΔH_{fusion} (25°C) [*p*-NO_2-C_6H_4-COOH] = 4.71 kcal mol^{-1}. A similar calculation for benzoic acid using the heat of fusion (17), C_p(s) (17), C_p(g) (21), and ΔH_{sub} (14), leads to ΔC_p(fusion) = 10.70 cal deg^{-1} mol^{-1}, ΔH_{fusion}(25°C) = 3.76 kcal mol^{-1}, and, for the hypothetical supercooled liquid at 25°C, ΔH_{vap} = 18.52 kcal mol^{-1}. Then by group additivity estimation we arrive at a value, for the hypothetical

[ar]Literature values of bp (°C) [and associated heats of vaporization] were 154. at 12., Beil, 9, I, 162, [19.52[k]]; 197. at 73., Beil, 9, III, 1709, [19.13[k]]; 155. at 20., Beil, 9, III, 1709, [18.50[k]]; 136.1 at 4., Beil, 9, III, 1709, [20.02[k]]; 204. at 105., Beil, 9, H, 394, [18.75[k]]; 151. at 15., Beil, 9, H, 394, [18.75[k]]; average 19.11 ± 0.52; additivity 18.11[u].

supercooled liquid *p*-nitrobenzoic acid, of $\Delta H_{vap}(25°C)$ = 23.63 kcal mol^{-1}, and finally ΔH_{sub} = 28.33 kcal mol^{-1}.

Entropies

The entropy of gaseous nitrobenzene could be calculated by statistical mechanics from the vibrational spectrum (19), moments of inertia (22), and barrier to internal rotation (20).

The entropy of gaseous *N*,*N*-dimethylbenzamide was estimated, following Benson (23), by using estimated vibrational frequencies and rotational barriers. We took frequencies associated with the $N(CH_3)_2$ group from the assignment for *N*,*N*-dimethylacetamide (24) and the frequencies associated with the benzoyl portion from the assignment for methyl benzoate (25). The hindered rotations were assigned barriers of 20, CO-N; 5, C_B-CO; 3, N-CH_3. Moments of inertia for the molecule and fragments of it were calculated from the MM2 geometry.

For benzoyl chloride we calculated the entropy from the published frequencies (26), and the rotational barrier (27).

To estimate entropies for substituted benzoyl chlorides, benzoic acids, methyl benzoates, and *N*,*N*-dimethylbenzamides, we evaluated additivity contributions for the substituents, assuming no significant interactions. From the entropies for benzene, 64.34 (21), toluene, 76.64 (21), anisole, 87.01 (28), chlorobenzene, 74.92 (21), nitrobenzene, 77.28 (this work), methyl benzoate, 93.86 (28), benzoyl chloride, 87.36 (this work), *N*,*N*-dimethylbenzamide, 96.64 (this work), we evaluate the following increments in entropy for replacement of H: CH_3, 10.92; CH_3O, 21.29; Cl, 7.01; NO_2, 10.75; $COOCH_3$, 28.14; COCl, 19.45; $CON(CH_3)_2$, 34.49. In these calculations it is necessary to make suitable corrections for symmetry (23). The entropies so estimated are found in Table 2.

Equilibrium constants for ester formation

For each of the esters, the equilibrium constant was determined by direct analysis, approaching the equilibrium both from the acid and from the ester. The concentration of ester was determined by HPLC analysis, and from ester concentrations as a function of time, fitted to a pseudo-first-order rate law, we could calculate the equilibrium constant from the infinity values. The agreement for the two directions was good in each case. The results of these experiments are summarized in Table 5. The equilibrium constants for methyl

[e]Calculated from the mp (Table 3) and the value of ΔH_{fus} derived from ΔH_{soln} as described in the text.

ester formation show negligible effects of the substituent on the benzene ring ($\rho = -0.01 \pm 0.05$), in striking contrast to the strong dependence of ester formation equilibrium constants upon the nature of the alcohol (29).

Equilibrium constants for ester aminolysis

For each of the esters, we determined the equilibrium constant for dimethylaminolysis in methanol, using HPLC analysis. Analyses were carried out at intervals, and equilibrium constants calculated by the method of Fersht and Requenna (30), as well as being calculated from the final results when equilibrium could be attained. It was necessary to correct for a small amount of accompanying hydrolysis. The results of these experiments are summarized in Table 6. The equilibrium constants for aminolysis are, unlike the equilibrium constants for ester formation, moderately sensitive to the nature of the substituent upon the benzene ring; $\rho = 0.59 \pm 0.19$.

Free energies of transfer

Values for methyl benzoate and benzoic acid have been reported previously (3). To calculate the free energies of transfer we need solubilities and vapor pressures for each compound. The solubilities of the esters and amides were measured by determining the UV absorbance of saturated solutions; the values that we determined are found in Table 7. Vapor pressures were estimated as previously proposed (12) by a modification of an equation derived by Prausnitz and co-workers (31), using the boiling point at the lowest available pressure, the heat of vaporization, and the heat capacity of vaporization. The latter were estimated by atomic additivity as previously proposed (18). Where a compound is solid at room temperature, the vapor pressure was calculated at the melting point using the heat of vaporization and heat capacity of vaporization for the liquid to gas transition, and then from the melting point to 25°C the calculations were done in the same way, using the heat of sublimation, calculated as heat of vaporization + heat of fusion, and the heat capacity of sublimation, taken as $-2R$ (32, 33). Vapor pressures so calculated, and the values used to obtain them (Table 3), are found in Table 7, as are the free energies of transfer. Free energies of transfer for substituted benzoic acids were estimated using group additivity corrections, assuming no interactions of the *para* substituents.

For dimethylamine we could find no data in the literature for the activity of dimethylamine in methanol at low concentrations, but suitable data were available for a number of amines, including diethylamine (34), for which $\Delta G_{H_2O\text{-}MeOH} = -1.41$ kcal mol^{-1}. From the data in ref. 34 we could evaluate the contribution for $[CH_2(X)_2] = -0.67$ kcal mol^{-1}. This allowed the calculation of $\Delta G_{H_2O\text{-}MeOH} = -0.07$ kcal mol^{-1} for dimethylamine.

To calculate equilibrium constants in water from equilibrium constants in methanol it was necessary to determine free energies of transfer from methanol to water. This was done by the method of Toullec and El Alaoui (35), using dodecane as an intermediary solvent, immiscible with both water

[a]All at 25°C; standard states are the ideal gas at 1 atm, and 1 M aqueous solution with an infinitely dilute reference state.

[b]Vapor pressure at 25°C, estimated as described in the text.

[c]Solubility in water at 25°C, measured as described in the text.

[d]Free energy of transfer from gas at 1 atm to 1M ideal aqueous solution with an infinitely dilute reference state.

[e]Because the solubilities of *N,N*-dimethylbenzamide and *N,N*-dimethyl-*p*-methoxybenzamide were high, we calculated the "ideal solubility" from the experimentally determined solubilities in dodecane, 0.188 and 0.0693 M respectively, and the partition constants for transfer from dodecane to water (Table 8).

and methanol. Partition coefficients for water to dodecane and methanol to dodecane were determined, and from these we could determine partition coefficients from methanol to water; the values so determined are found in Table 8. Since methanol is not totally insoluble in dodecane (it is soluble to the extent of 0.3%, w/w (estimated), <0.5% (detection limit) (36)), it was important to determine whether it was necessary to make a correction for the difference in the nature of the dodecane solvent between experiments involving partition with methanol and water. We did this by determining the partition coefficient from water to dodecane and from water to dodecane containing 0.5% 1-octanol. This latter solvent would have the same hydroxyl group concentration as methanol-saturated dodecane, but would not lose any of the alcohol molecules upon extraction with water (34). In the event we found that the effect of the octanol cosolvent was negligible for the esters but not quite negligible for the amides. We made a small correction for the amides, assuming that the effect of the alcohol would be linear in alcohol content and in σ, from the values determined for *N,N*-dimethyl-*p*-methoxybenzamide and *N,N*-dimethyl-*p*-nitrobenzamide. The corrections were made for 0.3% alcohol in dodecane, based on a reasonable estimate of the unmeasurably low solubility (36). The correction is quite small, so even in the worst case the effect on the final result is essentially trivial.

Dodecane is appreciably soluble in methanol (8% w/w (36)) so that there could be a free energy of transfer from methanol to methanol saturated with dodecane. Our compounds are very soluble in methanol, so it is not easy to do direct experiments to determine the magnitude of this effect. Toullec *et al.* (36) demonstrated that the free energy correction was trivial (0.003 kcal mol^{-1} for 4-nitroacetophenone and 0.08 kcal mol^{-1} for 4-nitroacetophenone dimethyl acetal (36)). Since these model compounds are closely related to the compounds used in this work, we assume that the effects of dodecane in methanol will be similarly negligible. Because of these small errors we assign errors of 0.20 kcal mol^{-1} to the free energies of transfer from water to methanol.

As a check on the thermodynamic quantities evaluated in this work, we have calculated the appropriate group contributions to $\Delta H_f^0(g)$, ΔH_{vap}, ΔG_t, and $\Delta G_f^0(aq)$. These are preliminary values, because in many cases they are based on only one compound, but should be useful guides until more firmly established values become available. The source data are included in Table 2. The group contributions used for these checks on internal consistency of our values are found in Table 9.

Discussion

We have reported above experimental measurements of the heats of formation of a series of substituted benzoic acid esters and amides as the solid or liquid, and heats of solution in methanol permitting calculation of the heats of formation in methanolic solution. These values permit calculation of the heats of aminolysis of the esters for the reaction:

$$Ar\text{-}COOMe + HNMe_2 = Ar\text{-}CONMe_2 + HOMe$$

The values so calculated are found in Table 10. The average value is −1.97 ± 1.54 kcal mol^{-1}, and there is no discernible dependence upon substituents: ρ = 0.13 ± 2.4. The major impression is one of scatter, which caused us concern

[a]All at 25°C.
[b]MeOH/DOD means $[compound]_{MeOH}/[compound]_{DOD}$; DOD is dodecane.
[c]Free energy of transfer from methanol to water; standard states are 1 M ideal solutions in each solvent.
[d]Corrected for the presence of methanol in the dodecane phase as described in the text. The partition constants from water to dodecane containing 0.5% 1-octanol were as follows: *p*-NO_2-C_6H_4-COOMe, 29.4; *p*-MeO-C_6H_4-$CONMe_2$, 0.143; *p*-NO_2-C_6H_4-$CONMe_2$, 0.0752.
[e]Calculated as described in the text.
[f]Calculated from the free energies of formation of liquid methanol and 1 M aqueous methanol (60).

TABLE 9. Group contributions to thermodynamic quantities for substituted benzenes[a]

Group	ΔH_{vap}	ΔH_f (g)	S^0 (g)	ΔG_f^0 (g)	ΔG_t	ΔG_f^0 (aq)
$[C_BH]$	1.34	3.30	11.53	4.92	−0.15	4.77
$[C_BCH_3]$	2.47	−4.69	22.72	3.43	−0.11	3.32
$[C_BOCH_3]$[b]	4.51	−34.10	32.82[c]	−21.72	−0.27[c]	−21.99
$[C_BCl]$	2.91	−3.8	18.54	−1.09	−0.24	−1.33
$[C_BNO_2]$	6.45[d]	−0.37[d]	22.28[d]	13.21	−3.37	5.07

[a]All at 25°C. Dimensions are kcal mol^{-1} for enthalpy and free energy, and cal deg^{-1} mol^{-1} for entropy. For convenience the "groups" $[C_BCH_3]$ and $[C_BOCH_3]$ are defined by adding the contributions of the contributing groups, $[C_B(C)]$ + $[CH_3(C_B)]$ and $[C_B(O)]$ + $[O(C_B)(C)]$ + $[CH_3(O)]$ respectively. Unless otherwise noted, values for ΔH_f(g) and S^0(g) are from ref. 23, values for ΔG_t are calculated from values for log γ in ref. 37, and values for ΔG_f(g) and ΔG_f(aq) are calculated from other values in the table.
[b]Based on ΔH_{vap} for anisole: Table 2.

about possible errors. As a check we examined the data at each stage in the calculation procedure to see if our results were credible.

First we will look at the heats of formation in solution. Heats of formation in the standard state are not directly comparable because some of the compounds are solids, with contributions from the heat of fusion. We use instead the heat of formation in methanol, which can be calculated from data in Tables 1 and 2. We made the approximation that since $\Delta H_{solution}$ is small for the liquids, group contributions to ΔH_f(solution) will be equal to the contributions to ΔH_f(g) + ΔH_{vap}. We will compare the observed and expected increments in ΔH_f(solution) for replacement of 4-H by the various substituents. These increments are mostly within 1 kcal mol^{-1} or so of the expected value, which may be as much as can be expected, although for *p*-CH_3-$C_6H_4COOCH_3$, *p*-$CH_3OC_6H_4CON(CH_3)_2$, and *p*-$NO_2C_6H_4CON(CH_3)_2$ the deviations are larger. Only for *p*-CH_3-$C_6H_4COOCH_3$ is the deviation larger than twice the standard deviation.

It should be noted that in using Benson additivity for disubstituted benzenes we are in effect assuming negligible substituent effects, which may not be correct.

This assumption of Benson additivity also leads to an expectation of a constant value of $\Delta H_{aminolysis}$, which is approximately what we observe, though with considerable scatter.

Now we turn to the heats of formation in the gas phase. Here there is a test, since literature values are available for all but one of the acids. For the substituted benzoic acids the agreement with Benson additivity is quite good. For the acid chlorides, using our estimated heats of vaporization for the compounds for which experimental values are not avail-

[a]Standard states are 1 M ideal solution in the solvent indicated, with infinitely dilute reference states. The standard state for the solvent is either pure liquid or "1 M solution" in itself. Units are kcal mol^{-1} for free energies and enthalpies and cal deg^{-1} mol^{-1} for entropies.

[b]K = [amide]/[ester] [Me_2NH].

[c]K = [amide] [MeOH]/[ester] [Me_2NH].

[d]ΔG^0 and ΔS^0 refer to the 1 M standard state for methanol.

[e]Calculated from the equilibrium constant.

[f]Calculated from the heats of solution and reaction in Table 1.

[g]Calculated from the ΔG^0 and ΔH^0 values in this table.

[h]K = [acid] [MeOH]/[ester].

[i]ΔG^0 refers to the pure liquid standard state for water.

[j]K = [amide]/[acid] [amine], all reactants and products as the neutral molecules.

able, we again find good agreement, except for *p*-nitrobenzoyl chloride where the deviation from expectation is 4 kcal mol^{-1}. For the esters the agreement is reasonable except for methyl *p*-methylbenzoate, which deviates from expectation by 2.5 kcal mol^{-1}. For the amides both *N*,*N*-dimethyl-*p*-methoxybenzamide and *N*,*N*-dimethyl-*p*-nitrobenzamide differ from expectation by more than 3 kcal mol^{-1}.

Free energies of transfer were found to be in satisfactory agreement with expectation except for the *p*-methoxy compounds, where ΔG_t is more negative than expected by simple additivity. Since conjugative interactions might well lead to a distant polar interaction (37) for this substituent, this behavior is not necessarily surprising.

The striking feature of ester aminolysis is that the reaction is exergonic, yet is known to be a poor reaction synthetically. For unactivated alkyl esters the reaction with primary or secondary amines is generally quite slow, and must be accelerated either by heating (as in formation of benzylamides by boiling with benzylamine (38)) or by addition of base (as in the use of methoxide in methanol to catalyze aminolysis, and in the case of primary amines, to displace the equilibrium by salt formation from the secondary amide (39)). For formate esters, esters of α-haloacids, or esters with good leaving groups, the reaction is generally fast (40). Labelle and Gravel reported an unusually rapid reaction of β-ketoesters, the novelty of which emphasizes the normal unreactivity of simple esters (41). What we have found is that the equilibrium is favorable by about 4 kcal mol^{-1}, so that under synthetic conditions the amide would be overwhelmingly favored, i.e., over 99.9% at 1 M dimethylamine, but the reaction is quite slow at room temperature. In the case of *p*-CH_3O-C_6H_4-$COOCH_3$, attainment of equilibrium required months even with 0.5 M NaOMe. The equilibrium is dependent on the nature of the acyl substituent, even though ρ for benzoate esters seems quite small, 0.59 ± 0.19, because the equilibrium free energy changes for the dimethylaminolysis of methyl formate, methyl acetate, and methyl benzoate are −11.3 (4), −6.8 (4), and −5.0. This is in striking contrast to the analogous equilibrium for methyl ester formation, for which the free energy changes are 1.38 (42), 1.30 (42), and 1.26.

Free energies of ester hydrolysis in water are available both from direct measurement of equilibrium constants and from the free energies of formation of the esters and acids calculated, as summarized in Table 2. The values so calculated are found in Table 11. The agreement is quite reasonable in terms of the uncertainties in the thermochemical data.

Free energies of dimethylaminolysis in water are available both from direct measurements of the equilibrium constants, corrected from methanol to water using free energies of transfer, and by free energies of formation of the esters and amides, calculated as summarized in Table 2. The two sets of values are found in Table 11. The agreement is poorer than one would wish, though in fact about as good as can be expected given the cumulation of errors in calculating free energies of formation in aqueous solution from the avail-

[a]All in aqueous solution at 25°C; standard state for all species except water is 1 M ideal solution with an infinitely dilute reference state. For water the standard state is the pure liquid.

able information. Although we have tried to make realistic assessments of the uncertainties in the thermochemical calculations, the disagreements are in all but one case greater than the sum of the estimated standard deviations for the thermochemical and the equilibrium values. Thus we must consider the possibility of systematic errors.

Although we cannot see any source of systematic error in our measurements, there are some disturbing inconsistencies, particularly in the amide data. For the moment we conclude that the best values for the free energies of formation of substituted *N,N*-dimethylbenzamides in aqueous solution will come from the free energies of formation of the esters by way of the equilibrium constants for dimethylaminolysis. Values so calculated are included in Table 2.

From our measurements of equilibrium constants for methyl ester formation and dimethylaminolysis, we can calculate equilibrium constants and free energy changes for *N,N*-dimethylbenzamide formation. These are, we believe, the first measurements of equilibrium constants for benzamide formation. Attempts at direct measurement were carried out, but the amount of amide formed at equilibrium in alkaline solution was very small, and the reactions were slow, even at elevated temperatures.[2]

In the course of our investigations we found that we did not obtain consistent results using the heat of solution for HCl in methanol reported some years ago based on direct calorimetric studies. An indirect determination of the heat of solution of HCl, using the heats of methanolysis of three acyl chlorides, led to a value that gave us internally consistent results. We are forced to conclude that the earlier value is in error; the directly measured value is too high, suggesting that there might be a systematic error from carrying droplets of H_2SO_4 from the gas buret into the calorimeter. In any case we recommend our value for the heat of solution of HCl into pure methanol.

Experimental

Materials

Benzoyl chloride (BDH) was redistilled, bp 79–80°C (13 Torr; 1 Torr = 133.3 Pa) (lit. (7) bp 71°C (9 Torr)). *N,N*-Dimethylbenzamide (Pfaltz and Bauer) was redistilled, bp 76–78°C (0.3 Torr), mp 40–43°C (lit. (43) mp 43–44°C, (44) mp 43°C). *p*-Chlorobenzoyl chloride (Aldrich) was redistilled, bp 96–98°C (10 Torr) (lit. (45) bp 99.6°C (11 Torr)). *p*-Methylbenzoyl chloride (Aldrich) was redistilled, bp 102–104°C (15 Torr) (lit. (46) bp 102.7°C (14 Torr)). *p*-Nitrobenzoyl chloride (Aldrich), was sublimed, mp 71–72°C (lit. (47) mp 75°C).

N,N-Dimethyl *p*-chlorobenzamide was prepared from *p*-chlorobenzoyl chloride and dimethylamine, crystallized from CH_2Cl_2, and sublimed, mp 57.5–58.5°C (lit. (48) mp 59–60°C, (43) mp 58–59°C, (49) mp 58–59°C); ^{1}H nmr (200 MHz, $CDCl_3$/TMS) δ: 3.032 (d, 6H), 7.37 (d, 4H). *N,N*-Dimethyl *p*-methoxybenzamide was prepared from *p*-methoxybenzoyl chloride and dimethylamine, bp 107–108°C (0.25 Torr) (lit. (49) bp 122–123°C (0.4 Torr), (43) mp 29–32°C); ^{1}H nmr (60 MHz, $CDCl_3$/TMS) δ: 3.02 (s, 6H), 7.37 (d, 4H). Methyl *p*-methylbenzoate was prepared from *p*-methylbenzoyl chloride and methanol, mp 34–35°C (lit. (7) mp 33.2°C); ^{1}H nmr (200 MHz, $CDCl_3$/TMS) δ: 2.363 (s, 3H), 3.865 (s, 3H), 7.195 (d, 2H), 7.916 (d, 2H). *N-N*-Dimethyl-*p*-methylbenzamide was prepared from *p*-methylbenzoyl chloride and dimethylamine, bp 95–98°C (0.32 Torr) (lit. (48) bp 148–151°C (10 Torr), (49) bp 151–152°C (13 Torr), (50) bp 108°C (0.8 Torr); lit. (43) mp 37–40°C); ^{1}H nmr (200 MHz, $CDCl_3$/TMS) δ: 2.327 (s, 3H), 2.993 (d, 6H), 7.228 (dd, 4H). *N,N*-Dimethyl-*p*-nitrobenzamide was prepared from *p*-nitrobenzoyl chloride and dimethylamine, crystallized from ethanol, and sublimed, mp 97–98°C (lit. (48) mp 96°C, (43) 95–97°C, (51, 52) 97°C, (49) 96–97°C); ^{1}H nmr (60 MHz, $CDCl_3$/TMS) δ: 3.05 (bd, 6H), 7.85 (dd, 4H).

Methyl benzoate (Matheson), methyl *p*-chlorobenzoate (Aldrich), *p*-methoxybenzoyl chloride (Aldrich), methyl *p*-methoxybenzoate (Aldrich), methyl *p*-nitrobenzoate (Aldrich), dimethylamine (Eastman), and dimethylamine hydrochloride (Eastman) were used without further purification.

Calorimetry solvents: 0.1 M dimethylamine in methanol was prepared by adding 2.70 mL dimethylamine to 400 mL methanol with stirring. 0.1 M Tetraethylammonium hydroxide in aqueous DMSO was prepared by adding 70 mL tetraethylammonium hydroxide (Aldrich, 20 wt.%), and 30 mL water to enough DMSO to make up to 1.0 L. Methanol was Baker or BDH reagent grade, used without further purification.

Methods

Solubility: Saturated solutions were prepared in aqueous pH 7 phosphate buffer or dodecane, and equilibrated at 25°C with occasional shaking for 11 days. The solutions were centrifuged, and a sample of the supernatant was withdrawn. Analysis by uv spectroscopy, after suitable dilution, gave the concentration of the saturated solutions.

Calorimetry was carried out as previously described (4). Boiling points at various pressures were determined as previously described (53).

Equilibrium constants for ester formation in aqueous solution

$$\text{X-Ph-COOH} + \text{MeOH} \rightleftharpoons \text{X-Ph-COOMe} + H_2O$$

Four solutions were prepared by dissolving benzoic acid or methylbenzoate with methanol and hydrochloric acid in 100.0 mL with water. Six 2-mL aliquots of each of these solutions were sealed into glass tubes and immersed in a 25°C water bath. For each of the other esters, four pairs of solutions were prepared. For the nitro, methoxyl, and methyl *para*-substituted methyl benzoates and benzoic acids the acid or ester was weighed into a 1.0 L volumetric flask and the volume made up with 40.5 mL methanol, 80 mL concentrated hydrochloric acid, and water. Solution required several hours stirring. Because of the slower solution rate for *p*-chloro

[a]Eluted at 3.0 (esterifications) or 2.0 (aminolyses) mL min^{-1} through a C18 Waters radial Pak column. The effluent was monitored by a Waters 490 uv detector and the peak height for the ester in the resulting trace compared to the peak height from a standard solution.

[b]10 mM Aqueous ammonium phosphate pH 4.0 for analysis of esterifications, 20 mM aqueous ammonium phosphate pH 6.6 for analysis of aminolyses.

methyl benzoate and *p*-chlorobenzoic acid, the acid and ester were each dissolved in 100 mL methanol and then 25 mL diluted with 15.5 mL methanol, 80 mL concentrated hydrochloric acid, and water to 1.0 L. The initial concentration of reagents in the eight reaction mixtures was 1.0 M methanol, 1.0 M hydrochloric acid, and *para*-substituted methyl benzoate or benzoic acid as listed below. Seven 1-mL aliquots of each of these solutions were sealed into glass tubes and immersed in a 25°C water bath.

The concentrations of *para*-substituted methyl benzoates were determined by HPLC using the solvent mixtures and wavelengths listed in Table 12, with a C18 Waters radial Pak column and a flow rate of 3.0 mL min^{-1}. The effluent was monitored by a Waters 490 uv detector and the peak height for the ester in the resulting trace compared to the peak height from a standard solution. The criteria for the choice of an HPLC elution solvent were, first, that the peak height per mole of ester be as large as possible for maximum sensitivity and, second, that the ester peak be separate from that of other components. Each of the reaction solutions contains 1.0 M HCl. Injection of 1.0 M HCl into the HPLC system produces two peaks, a sharp one at 2–3 min, just after the void volume, and a broad peak at 5–7 min with a long tail. The exact retention times depended on the elution solvent. The peak heights increased with decreasing detector wavelength over the range 270–230 nm. The composition of these peaks is unknown although it is suspected that they are derived from an interaction between the acid and the pre-column or column packing material.

The concentration of substituted methyl benzoate in the reaction mixtures was assayed by HPLC every few days. The equilibrium constants were estimated at each time by the method of Fersht (30). These values were in good agreement with the final values calculated as described below.

We fitted the ester concentration vs. time data to equations of the form;

$$[\text{Ester}] = a_1 + a_2 \exp(-a_3 t)$$

Ester concentrations are in μM. Reaction pairs consist of those initiated with benzoate esters and those initiated with benzoic acids.

The equilibrium constants were calculated from the above data, using the infinity values of ester concentration, i.e., the a_1 values, and the final acid concentrations, calculated from the initial acid or ester concentration and the final ester concentration. The equilibrium constants so calculated are given in Table 5.

Equilibrium constants for dimethylaminolysis in methanol

Methanol was dried using magnesium (54). Dimethylamine was dried by passing as a stream of gas through a drying tower filled with sodium hydroxide pellets. Solutions of dimethylamine, sodium methoxide, and ester or amide were made up, and sealed in ampoules. The ampoules were incubated at 25°C, and analyzed at suitable times by HPLC. The analytical conditions are given in Table 12. To avoid interference between the acid and the amide it was necessary to use pH 6.6 buffer as the aqueous component of the mixed solvent for elution; this caused the acid to elute at or near the solvent peak, so that direct quantitation of the acid was not accurate. Hydrolysis to the acid was a side reaction, presumably the result of traces of water. This poses a problem for the calculation of equilibrium constants from data before equilibration was complete (30) because these calculations assume identical initial concentrations, yet hydrolysis at short times is more important for reactions starting with ester than with amide. We corrected for hydrolysis by scaling from the peak observed at a particular [ester] + [amide] to the hypothetical peak that would have been observed with no acid formation. Equilibrium constants calculated in this way are in good agreement with those calculated from data for fully equilibrated solutions. The equilibrium constants derived from these experiments are found in Table 6.

Medium effect on the second-stage dissociation constant of *N*-(2-acetamido)imino diacetic acid (H_2ADA)

AHMED HASSAN,[1] H. A. AZAB, S. A. EL GYAR, AND Z. A. KHAFAGY
Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

Received August 6, 1991

AHMED HASSAN, H. A. AZAB, S. A. EL GYAR, and Z. A. KHAFAGY. Can. J. Chem. **70**, 1684 (1992).

The second-stage dissociation constant values of *N*-(2-acetamido)imino diacetic acid (H_2ADA) were determined at 25 ± 0.1°C by potentiometric titration in different mixed-solvent mixtures (methanol, ethanol, dimethylformamide (DMF), dimethyl sulfoxide (DMSO), acetone, and dioxane). It was observed that the pK_a value is slightly influenced as the solvent is enriched in methanol and ethanol, and remains practically constant in the presence of different amounts of DMF and DMSO. A prounounced change in the pK_a value was observed as the solvent is enriched in acetone or dioxane. These results are discussed in terms of various solvent characteristics. It is concluded that the electrostatic effect has only a relatively small influence on the dissociation equilibrium of the imino group ($-NH^+<$). Other solvent effects such as solvent basicity, different stabilization of the free base of the conjugate acid by hydrogen bonding interactions in aquo-organic solvent media relative to pure aqueous media, as well as proton–solvent interaction play an important role in the acid dissociation equilibrium.

AHMED HASSAN, H. A. AZAB, S. A. EL GYAR et Z. A. KHAFAGY. Can. J. Chem. **70**, 1684 (1992).

Opérant à 25 ± 0,1°C et faisant appel à un titrage potentiométrique, on a déterminé le deuxième stade des valeurs des constantes de dissociation de l'acide *N*-(2-acétamido)iminodiacétique (H_2ADA) dans divers mélanges de solvants mixtes (méthanol, éthanol, diméthylformamide (DMF), diméthylsulfoxyde (DMSO), acétone et dioxane). On a observé que la valeur du pK_a est légèrement influencée lorsque le solvant est enrichi en méthanol ou en éthanol et qu'elle demeure pratiquement constante avec des concentrations de plus en plus grandes de DMF ou de DMSO. On observe une changement prononcé de la valeur du pK_a lorsqu'on enrichit le solvant en acétone ou en dioxane. On discute de ces résultats en fonction de diverses caractéristiques des solvants. On en conclut que l'effet électrostatique n'a qu'une légère influence sur l'équilibre de dissociation du groupe imino ($-NH^+<$). D'autres effets de solvant, tels la basicité du solvant, des stabilisations différentes de la base libre de l'acide conjugué par des liaisons hydrogènes dans les solvants mixtes organiques/eau par rapport au milieu aqueux pur ainsi que l'interaction proton/solvant, jouent un rôle important dans l'équilibre de dissociation de l'acide.

[Traduit par la rédaction]

Introduction

N-(2-Acetamido)imino diacetic acid (H_2ADA) was first prepared, by Schwarzenbach *et al.* (1), in 1955. The choice of alternative buffers has increased with the commercial availability of zwitterionic amino acids, mainly *N*-substituted taurines or *N*-substituted glycines prepared by Good *et al.* (2), so that organic buffers suitable for use in biochemistry now include *N*-(2-acetamido)imino diacetic acid (H_2ADA). Zwitterionic buffers, comparable to amino acids, show significant advantages over conventional buffers: insignificant penetration through biological membrane, maximum buffer capacity at physiological pH range 6–8.50, and no enzyme substrate or enzyme inhibitor properties. Though studies on the dissociation constants of acids and bases in mixed and nonaqueous solvents have been extensive, relatively little work has been done to determine the dissociation constants of the biologically important zwitterionic buffers (3–7).

In this paper the effect of the medium on the second dissociation constant of *N*-(2-acetamido)imino diacetic acid (H_2ADA) has been reported using potentiometric titrations. The organic solvents used are amphiprotic solvents (methanol and ethanol), dipolar aprotic solvents (DMF and DMSO), a low basic aprotic solvent (acetone), and a nonpolar solvent (dioxane).

Experimental

Chemicals and solutions: $H_2N\text{-}CO\text{-}CH_2\text{-}N(CH_2COOH)_2$ (H_2ADA) was analytical grade (BDH) with purity 98% and was used without further purification. Since the solubility of free acid *N*-(2-acetamido)imino diacetic acid is very low, the monosodium salt (NaHADA) was prepared by dissolving 0.1902 g H_2ADA in 10 mL NaOH (0.1 mol dm^{-3}) and diluting to 100 mL with bidistilled water.

The organic solvents methanol, ethanol, dimethylformamide, dimethyl sulfoxide, acetone, and dioxane were of high purity (A.R. or Spectrograde products).

Carbonate-free NaOH was prepared and was standardized by titration with KH-phthalate. The molarity of HNO_3 was checked by titration with standard NaOH solution. Generally, dilute solutions were prepared by appropriate dilution of the stock.

Procedure

The pK_{a_2} values of *N*-(2-acetamido)imino diacetic acid in the different organic solvent–water mixtures under investigation were determined by adopting the Irving and Rossotti pH-titration technique (8, 9). The following solutions were titrated potentiometrically against standard carbonate-free sodium hydroxide (0.1 mol dm^{-3}) solution: (a) 4×10^{-3} mol dm^{-3} HNO_3; (b) solution (a) in the presence of 1×10^{-3} mol dm^{-3} NaHADA. Both the solutions (a) and (b) contain the same proportion (w/w) of the different organic solvents studied.

The total volume was adjusted to 50 cm^3 in each case by adding double-distilled water. The titrations were performed at 25 ± 0.1°C and μ = 0.1 mol dm^{-3} (KNO_3). A Fisher Accumet pH/ion meter model 2301 was used for potentiometric measurements and calibrated by using two aqueous buffer solutions at pH 4.01 and 9.18.

The pH-meter readings were corrected in accordance with the method described by Douheret (10, 11). This was done to account for the difference in acidity, basicity, dielectric constant, and ion activities in partially aqueous solutions relative to the pure solvent.

The pK_{a_2} values were calculated by a graphical method (aver-

[a] $pK^*_{a_2}$: corrected pK_{a_2} values according to Douheret (10, 11).

age value method) and the linear plot method. A PDP-81E minicomputer was programmed to calculate pK_{a_2} values from simultaneous equations.

Results and discussion

The mean pK_{a_2} values of *N*-(2-acetamido)imino diacetic acid in the different aquo-organic solvent mixtures are given in Table 1. Careful examination of the results reveals three important features:

1. With an increase in amphiprotic methanol or ethanol solvent concentration in aqueous medium, the change in pK_{a_2} is quite small, in most cases it decreases slightly.

2. With an increase in the DMF or DMSO content, the pK_{a_2} remains practically constant.

3. By increasing the concentration of acetone or dioxane (nonpolar solvents) in aqueous medium, the pK_{a_2} value increases.

Effect of the amphiprotic solvent

Solvent effects on acid–base phenomena in amphiprotic media of intermediate and high dielectric constant (methanol, ethanol) are often successfully interpreted in terms of changes in the dielectric constant (electrostatic effects) and in the basicity (non-electrostatic effects).

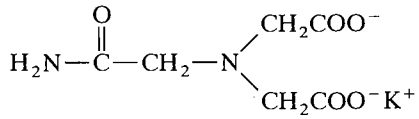
Consider an acid HA at molality m in mixed amphiprotic solvent (SH). It is assumed that the dielectric constant of the mixed solvent is sufficiently large to permit a certain amount of ionization. The proton activity a_H, as a measure of acidity, can be expressed (12) in terms of K_{HA} and K_{SH}, which are, respectively, the acidity constants of HA and SH_2^+; ν is the activity coefficient:

$$[1] \quad a_H = \sqrt{m\, K_{HA}\, K_{SH}\, \frac{\nu_{SH_2^+}\, \nu_{HA}}{\nu_{SH}\, \nu_{A^-}}}$$

A decrease in the dielectric constant usually causes $\nu_{SH_2^+}/\nu_{HA}$ and ν_{A^-}/ν_{HA} to increase, and it is possible that both of these ratios will increase by about the same amount (13). Hence, according to eq. [1], a lowering of the dielectric constant due to addition of methanol or ethanol may have a small effect on the acidity of an unbuffered solution of *N*-(2-acetamido)imino diacetic acid. With respect to the solvent basicity effect, the autoprotolysis constant of water is slightly influenced by addition of methanol or ethanol (pK of pure water is changed from 14.0 to 14.90 mol dm^{-3} for a 50% w/w ethanol–water mixture ($HA + SH \rightleftharpoons SH_2^+ + A^+$). Accordingly, one can deduce that changing the basicity of the medium by increasing additions of methanol or ethanol to the aqueous medium has a small influence on the second-stage dissociation constant of *N*-(2-acetamido)imino diacetic acid.

Generally, it is recognized that properties of solvents such as dielectric constant, acidic or basic strengths, play a major but not exclusive role. Other factors such as stabilization of the different species existing in equilibrium through hydrogen bonding together with ion–solvent interaction and dispersion forces play an important role in the ionization of weak acids. Accordingly, the observed slight changes in pK_{a_2} of H_2ADA as the solvent is enriched in methanol or ethanol can be mainly interpreted as resulting from the following two factors:

1. The relatively high stabilization of the conjugate base



by a donor hydrogen bond in a pure aqueous medium relative to that in the presence of methanol or ethanol. This is due to the greater tendency of water molecules as compared with other solvent molecules to donate hydrogen (14). Thus, an increase in the proportion of methanol or ethanol in the aqueous medium will result in an increase in the activity coefficient of the conjugate base, thereby causing a slight increase in the pK_{a_2} value.

2. The greater stabilization of the proton in methanol–water or ethanol–water mixtures relative to that in pure water through ion–solvent interaction (15, 16). This effect will generate a low activity coefficient of the proton in alcohol–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

water mixtures compared to that in pure aqueous medium, therefore causing a slight decrease in pK_{a_2}.

Effect of dipolar aprotic solvents (DMF and DMSO)

The observed constancy in the pK_{a_2} value of H_2ADA in the presence of varying amounts of DMF and DMSO can mainly be explained as resulting from the following two opposing effects:

1. A DMF–water or DMSO–water mixture is considered to be more basic than water (17). This behaviour is then based on the building up of a strong acceptor hydrogen bond from the $-NH^+$ group of the *N*-(2-acetamido)imino diacetic acid in the former medium as compared to that in water, thus facilitating the ionization process of the imino group i.e., a low pK_{a_2} value.

2. The expected low stabilization of the conjugate *N*-(2-acetamido)imino diacetic acid free base by hydrogen bonding with solvent molecules in the DMF–water or DMSO–water mixtures compared to its stabilization due to hydrogen bonding with water molecules in pure aqueous medium. This in turn results in a high pK_{a_2} value.

Effect of a low basic aprotic acetone solvent

The presence of acetone as co-organic solvent exerts a pronounced effect on the pK_{a_2} of H_2ADA as compared to the effect of the other co-organic solvents studied (methanol, ethanol, dimethyl sulfoxide, and DMF). Though ethanol and acetone have nearly the same dielectric constant (24.30 and 20.70, respectively), the pK_{a_2} values of H_2ADA in ethanol–water and in acetone–water mixtures of the same composition are different. This behaviour can be considered as convincing evidence for the above conclusion that the electrostatic effect will have a relatively small influence on the second-stage dissociation constant of *N*-(2-acetamido)imino diacetic acid. Thus, the observed increase in pK_{a_2} when the amount of the co-organic solvent acetone in the medium is increased can be mainly attributed to the following effects.

1. Solvent basicity effect: acetone is considered to be a very weakly basic solvent (18–21), therefore one can expect that the basicity of acetone mixtures with water is lower than that of a pure aqueous medium (17). This leads to lower ionization of the NH^+ group in the former media as compared to that in the latter one, i.e., a high pK_{a_2} value.

2. Solute–solvent interactions effect: acetone is considered to be both a poorer acceptor as well as donor of hydrogen bonds than is water (22). Thus, one may expect a low stabilization of the free H_2ADA conjugate base by hydrogen bonding interactions in the presence of this co-organic solvent. This leads to higher pK_{a_2} values in such media than those obtained in pure aqueous solution.

3. Proton–solvent interaction effect: it has been recognized that the special type of solvation of the H^+ ion, namely, hydrogen ion–solvent interaction, plays a vital role in acid–base equilibria (21). Since acetone is a weakly basic solvent, one must therefore expect that the H^+ ion becomes less stabilized in the presence of this co-organic solvent. Thus, increasing the acetone proportion in the aqueous medium results in a high activity coefficient of the proton, i.e., a high pK_{a_2} value.

Effect of an aprotic nonionizing dioxane solvent

The observed increase in the pK_{a_2} value of H_2ADA as the solvent is enriched in dioxane may be attributed to lowering of the dielectric constant, which increases the fraction of associated ions to form Bjerrum ion pairs (23) and higher aggregates such as triple ions and dipole aggregates (24). In this aprotic nonionizing medium, the concentration of free ions is very low and acidity phenomena are governed largely by ionic association reactions, as Kolthoff and Bruckenstein have shown so convincingly (25).

Conclusion

H_2ADA (pK_{a_2} 6.60) is a diprotic organic acid in the class of Good buffers (2). It is a potentially useful zwitterionic buffer for use in biochemistry in the physiological pH range (6–8.50), because of its low toxicity. This paper describes solvent effects on the measured ionization constants of H_2ADA. The organic solvents used are methanol, ethanol, DMF, DMSO, and acetone. Methanol and ethanol were chosen as representatives of amphiprotic solvents. We have chosen *N,N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) as aprotic polar solvents to study the pK_{a_2} variations of H_2ADA because their dielectric constants are relatively high, but lower than that of water. Acetone and dioxane have been chosen as a low basic aprotic solvent and an aprotic nonionizing solvent. All the solvents chosen are of frequent use in biochemistry and biology. The new experimental pH and pK_{a_2} data reported in this paper for H_2ADA dissolved in the above-mentioned binary aqueous–organic solvent mixtures should be of great use in a number of areas of chemistry, biochemistry, and biology.

G. W. Buchanan, Y. Lear, and C. Bensimon. Can. J. Chem. **70**, 1688 (1992).

The major isomer obtained by hydrogenation of dibenzo-24-crown-8 ether is shown to have the *cis-syn-cis* configuration as determined from the crystal structure of its sodium perchlorate complex. This material possesses eight-coordinate sodium with Na—O distances ranging from 2.54 to 2.78 Å. The complex is shown to exist in a single asymmetric conformation below 240 K as determined by ^{13}C NMR at 125 MHz. From NMR coalescence temperature measurement, the free energy of activation for cyclohexane ring inversion in this complex has been determined to be 51.0 ± 0.6 kJ/mol.

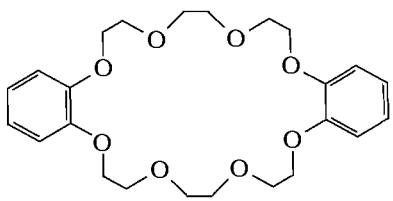
G. W. Buchanan, Y. Lear et C. Bensimon. Can. J. Chem. **70**, 1688 (1992).

En se basant sur la structure cristalline du perchlorate, on a déterminé que l'isomère majeur obtenu par hydrogénation de l'éther dibenzo-24-couronne-8 possède la configuration *cis-syn-cis*. Dans ce produit, il y a huit atomes de sodium de cordonnés et les distances Na—O varient de 2,54 à 2,78 Å. Grâce à la RMN du ^{13}C à 125 MHz, on a démontré que, à une température inférieure à 240 K, le complexe existe sous une seule conformation asymétrique. Sur la base de mesures de températures de coalescence, on a déterminé que l'énergie libre d'interconversion du cyclohexane est égale à 51,0 ± 0,6 kJ/mol.

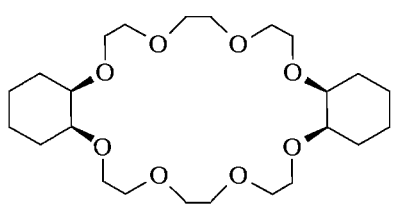
[Traduit par la rédaction]

Introduction

Although the dibenzo-24-crown-8 ether system shown below has been known since the pioneering work of Pedersen (1), the only report of its dicyclohexano derivatives is confined to that describing a mixture of isomers (2)



In view of our continuing interest in the solution and solid state stereochemistry of related molecules with a variety of macrocyclic ring sizes (3–7), we wish to report the determination of the configuration of the major isomer obtained from catalytic hydrogenation of dibenzo-24-crown-8. This isomer has been identified as the *cis-syn-cis* form (below) via the X-ray crystal structure of its sodium perchlorate complex.



High-field ^{13}C NMR measurements as a function of temperature have permitted assignment of the preferred conformation of this complex at low temperature in solution as well as representing a measure of the free energy for conformational interconversion.

Results and discussion

Figure 1 contains the structural formula and numbering scheme for the $NaClO_4$ complex of *cis-syn-cis*-dicyclohexano-24-crown-8 ether (**1**). Figure 2 shows the ORTEP plot for this complex, while Fig. 3 shows the ^{13}C NMR spectra of **1** at ambient temperature in CD_2Cl_2 solution as well as in the slow exchange limit of 240 K. Bond lengths and angles for **1** are listed in Table 1 while torsional angles involving ring skeletal atoms and the sodium ion are collected in Table 2. The ^{13}C chemical shifts are presented in Table 3, with the crystallographic data in Table 4 and the atomic parameters in Table 5. Lists of structure factors and anisotropic temperature factors are available as supplementary material.[3]

(i) X-ray crystallographic structure

The ORTEP diagram in Fig. 2 clearly shows that, in the crystal, the 24-membered ring adopts a conformation that allows all eight crown ether oxygens to be coordinated to the sodium ion. *This type of coordination of a sodium cation within a single crown ether appears to be unique*. The range of Na—O distances is from 2.54 to 2.78 Å. In the case of both 1:1 and 1:2 complexes of dibenzo-24-crown-8 with

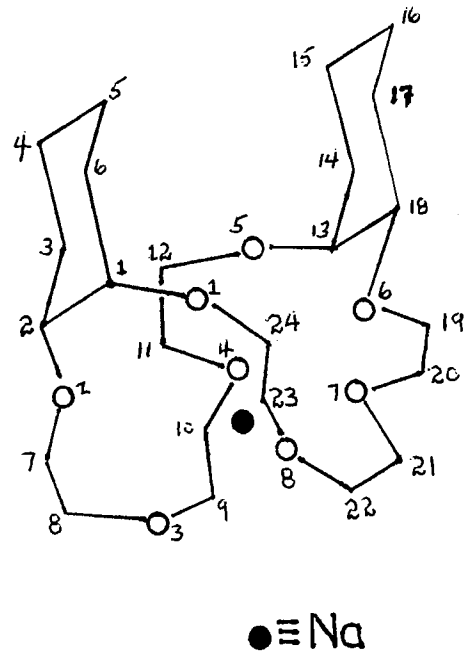

FIG. 1. Structure and numbering scheme

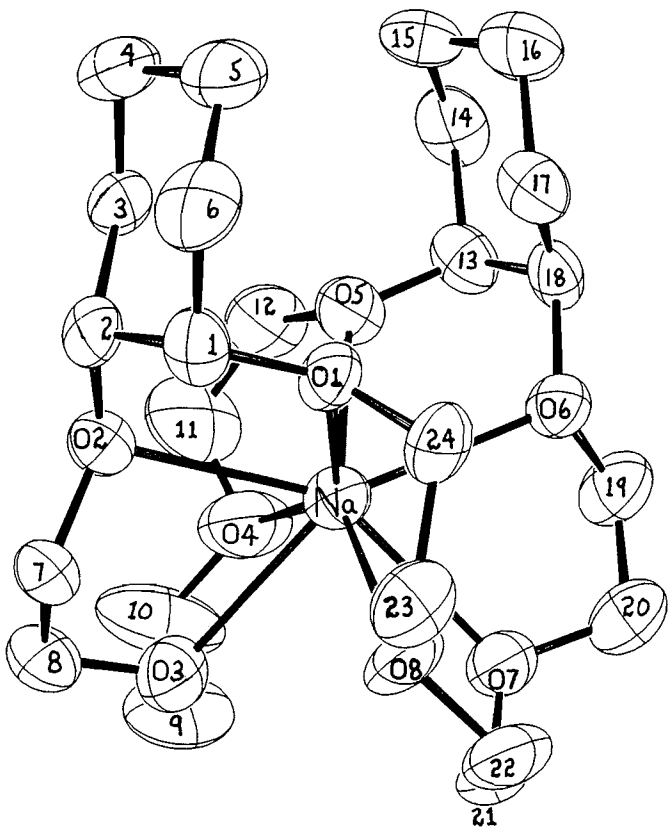

FIG 2. ORTEP diagram for **1**

sodium *o*-nitrophenolate, the coordination number is six, with distances from the crown ether oxygens to the Na^+ ion ranging from 2.47 to 2.61 Å (8). In the 18-crown-6 complex with $NaNCS \cdot H_2O$ (9) the Na^+ ion is heptacoordinate with the water molecule providing the extra coordination site, and the range of Na—O distances is from 2.32 to 2.62 Å. The only reported instance of eight-coordinate sodium in crown ether chemistry occurs in the 2:1 octahydrate complex of 12-crown-4 ether with NaOH (10). In this case the sodium ion forms an eight-coordinated sandwich complex of approximate D_4 symmetry with the two crown ether rings. The oxygen atoms are arranged at the corners of a square antiprism-type structure with an average Na—O distance of 2.49 Å. Thus in **1**, the Na—O distances are significantly longer than in other crown ether complexes involving sodium ions. Considering the atomic radii of Na^+ (0.97 Å) and O (1.40 Å), one would expect the optimal Na—O distance to be near the sum of these values, i.e., 2.37 Å. The stability of **1** in spite of the longer Na—O distances is, accordingly, remarkable.

With respect to the conformation of the crown ether moiety in **1**, the eight O—C—C—O networks of the macrocycle have torsional angles ranging from 49.9° for the O8—C23—C24—O1 unit to 62° for the O6—C19—C20—O7 case. These values are in the normal range for crown ethers where *gauche* O—C—C—O networks are energetically favoured (11). By contrast, the C—O—C—C networks, which in "ideal" crown ether conformations are *transoid* (11), show a wide range of values in **1**. In fact, of the 16 such networks in the macrocyclic portion of **1**, only eight have *transoid* geometries (i.e., 160–180°). Five others exhibit *gauche*-type geometries (70–79°) with the remaining three having dihedral angles of 117.6, 138.4, and 145.6° respectively. Despite the difference in coordination number at sodium, there are some common features between the macrocyclic ring conformation of **1** and that present in the 2:1 sodium-*o*-nitrophenolate complex of dibenzo-24-crown-8 ether (8). In both cases, there is a "propellor" type conformation present in the central portion of the macrocycle as depicted in Fig. 1.

Unfortunately, the free ligand is an oil, so that no direct comparison of "free" vs. complexed macrocyclic ring conformations can be made for this *cis-syn-cis*-dicyclohexano-24-crown-8 ether system.

(ii) ^{13}C NMR spectra

Figure 3 illustrates the 125.76 MHz ^{13}C NMR spectra of **1** in CD_2Cl_2 solution at 303 and 240 K. The spectrum recorded at 303 K is consistent with a situation in which all conformational interconversions in **1** are fast on the NMR time scale, giving rise to only six singlet resonances. The broadened high-field and low-field lines represent sites whose rates of conformational interchange are beginning to approach their slow exchange chemical shift differences (in Hz). From results of the APT test (12) the lowest-field resonance at 76.01 ppm arises from the methine carbons 1, 2, 13, and 18. From well-documented effects of oxygenated substituents on cyclohexyl carbon shifts (13), the highest-field line at 22.11 ppm can be confidently assigned to the carbons most remote from the oxygen atoms, namely C-4, 5, 15, and 16. By elimination, the resonance at 27.32 ppm can be attributed to the C-3, 6, 14, and 17 sites. In the ^1H spectrum at

[a] B_{iso} is the mean of the principal axes of the thermal ellipsoid.

303 K, the protons on the central carbons of the macrocycle, namely C-9, 10, 21, and 22 appear as a sharp singlet at 3.60 ppm. From the ^{1}J HETCOR experiment, these can be shown to correlate with the ^{13}C resonance at 66.62 ppm. By contrast, the protons on carbons 7, 8; 11, 12; 19, 20; and 23,24 give rise to complex AA′BB′ spin systems and extensive overlap is present even at 500 MHz, thereby precluding unambiguous assignment of the attached carbons.

As the temperature is lowered, decoalescence occurs, starting with the resonance for C-1, 2, 13, and 18 at 76.01 ppm. At 240 K, the limiting low-temperature spectrum is obtained wherein four resonances of approximately equal intensity are observed at 78.45, 78.17, 70.68, and 69.75 ppm. Based on well-documented trends of axial and equatorial substituent effects on oxygenated carbon chemical shifts (14, 15), one can attribute the most deshielded resonances to C-2 and C-18, i.e., the carbons bearing equatorial substituents. No unambiguous distinction between these, however, can be made, as is indicated in Table 3. The methine carbons bearing axial oxygen give rise to lines at 70.68 and 69.75 ppm, again with no distinction between C-1 and C-13 being possible at this time. The fact that four equally intense resonances are seen in the methine carbon region suggests that **1** exists at 240 K in a single conformation that lacks any symmetry elements.

The region of the spectrum (64.81–67.43 ppm) that contains the CH_2-O resonances shows eight resolved lines at 240 K in the ratio of 1:1:1:1:3:3:1:1 (high-field to low-field direction). The small chemical shift differences coupled with several instances of accidental chemical shift equivalence preclude any unambiguous assignment of resonances, but the pattern of relative intensities is consistent with the aforementioned conformational postulate. The cyclohexyl carbons β to oxygen show four resonances of approximately equal intensity in the range of 25.35–27.08 ppm at 240 K. This is also consistent with the notion of a single preferred asymmetric conformer at this temperature. The more deshielded pair are attributed to sites β to equatorial oxygen by analogy with earlier work (14, 15), although again no distinction between C-3 and C-17 is possible.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

Finally, the cyclohexyl sites most remote from the oxygen show only two separate resonances at 240 K. The most shielded, at 18.75 ppm, is attributed to the C-5,15 pair, which are γ-*gauche* to axial oxygen and thus most shielded (13–15). The corresponding C-4,16 sites, being *trans*-γ to the equatorial oxygens, are deshielded by ca. 5 ppm. Apparently the shift differences between C-5 vs. C-15 and C-4 vs. C-16 are too small to be resolved even at 125 MHz.

From the coalescence temperature of this upfield resonance (278 K) and the limiting low-temperature chemical shift difference of 5.11 ppm (642.9 Hz), one can employ the Eyring equation to obtain a free energy of activation, $\Delta G^{\pm}$, for the conformational interconversion process. With a temperature uncertainty of ∓3 K, $\Delta G^{\pm}$ is calculated to be 51.0 ∓ 0.6 kJ/mol. This value is ca. 8 kJ/mol higher than that for cycylohexane ring inversion in *cis*-1,2-disubstituted cyclohexanes (16) and 4 kJ/mol higher than for K^+ complexes of related dicyclohexano-18-crown-6 systems (15). The enhanced value of $\Delta G^{\pm}$ here can be attributed to the rigidity imposed on the macrocyclic portion of the molecule due to the coordination of all eight oxygen atoms with the Na^+ ion. Since conformational reorganization of the macrocycle must accompany cyclohexane ring reversal, any factors that retard the flexibility of the 24-membered ring will also retard the rate of chair–chair interconversion of the cyclohexyl moieties.

Experimental

(i) Materials

Dibenzo-24-crown-8 ether (**2**) was purchased from the Aldrich Chemical Co. Hydrogenation of **2** was accomplished using an American Instrument Co. 50 000 psi (1 psi = 6.9 kPa) maximum pressure high-pressure apparatus. In 60 mL of distilled 1-butanol, 1.0 g (0.0022 mol) of **2** and 0.75 g of 5% ruthenium on alumina catalyst were dissolved. A pressure of 1000 psi was used and the reaction was continued for 16 h at a temperature of 100°C. The catalyst was removed via filtration and the butanol by rotary evaporation at 70°C to yield 0.9 g of a yellow-brown oil. From ^{13}C NMR there appeared to be two configurational isomers present in the ratio of ca. 3:1. Column chromatography of the crude product using activated silica gel of mesh size 100–200 and a mixture of 25% hexane, 25% dichloromethane, and 50% diethyl ether afforded 0.1 g of an oil as the first fraction eluted. This material was deemed to be at least 90% pure by ^{13}C NMR, with characteristic resonances at 78.53, 71.64, 71.56, 69.07, 28.57, and 23.02 ppm. An equimolar amount of this material and $NaClO_4$ were dissolved in a minimum amount of dry ethanol. After allowing the mixture to stand for 3 h, the solvent was removed by rotary evaporation. Recrystallization from hexane – methylene chloride solvent pair yielded **1**, mp. 165–166°C.

(ii) Crystallographic measurements and structure solution

In Table 4 are collected the complete set of crystal data for **1**. A single crystal of **1** was mounted on a glass capillary and studied at 23°C on a Rigaku diffractometer with MoKα radiation. Cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of 25 reflections in the range $40 < 2\theta < 47$ corresponding to a monoclinic cell of dimensions as described in Table 4. Based on systematic absences the space group was determined to be $P21/n$. A total of 4480 reflections were collected. The unique data set contains only 4273 reflections. The standards were measured after every 150 reflections and no crystal decay was noticed. Data were corrected for Lorentz and polarization effects (17).

The structure was solved by direct methods. All the atoms were refined anisotropically except hydrogen. The hydrogen atom positions were calculated but not refined. Weights based on counting statistics were used and all calculations were performed using the NRCVAX crystallographic software package (18).

(iii) ^{13}C NMR spectra

The ^{13}C NMR spectra at 125.76 MHz were obtained on a Bruker AM-500 spectrometer under conditions of complete ^1H noise decoupling. The sample was at a concentration of 0.05 M in CD_2Cl_2 solution. Typical sweep width was 10 000 Hz, and acquisition time 1.6 s with 32 K data points, with a pulse delay of 1 s. Line broadening was 2.0 Hz. With 45° observed pulses under these conditions, satisfactory signal-to-noise ratios were obtained at 240 K after 200 accumulations. Temperatures are deemed accurate to ∓3° and chemical shifts are referenced to internal TMS.

The duodecet rule: Part 3. Fluoro species of the third period elements

E. A. ROBINSON

Department of Chemistry and the J. T. Wilson Research Laboratories, Erindale College, University of Toronto, Mississauga, Ont., Canada L5L 1C6

Received July 29, 1991

This paper is dedicated to the memory of Professor Thomas Birchall

E. A. ROBINSON. Can. J. Chem. **70**, 1696 (1992).

On the basis of the suggested new value of 54 pm for the single bond covalent radius of fluorine, the previously established *duodecet rule* for period 3 elements in molecular species with highly electronegative ligands is extended to fluorides. It is shown, for species such as SiF_4, $(F_3Si)_2O$, F_3SiNH_2, F_3PO, and PF_5, that the observed bond lengths are consistent with significant partial double bonding involving all the ligands, including fluorine, and with a total of six electron pairs in the valence shell of the central atom. Empirical rules based on d/d_1, the ratio of an observed bond length to the corresponding single bond length calculated from the sum of covalent radii, are developed as a simple approximate guide to the extent of partial double bonding in bonds to third period elements. It is also shown that bond lengths in species such as Al_2F_6, AlO_4^{5-}, and $Al(NH_2)_4^-$ are consistent with a duodecet rule.

E. A. ROBINSON. Can. J. Chem. **70**, 1696 (1992).

En se basant sur la nouvelle valeur de 54 pm pour le rayon covalent d'une liaison simple du fluor, on a étendu au fluor la règle du duodécet établie antérieurement pour les éléments de la période 3 dans des espèces moléculaires comportant des ligands fortement électronégatifs. Pour les espèces comme SiF_4, $(F_3Si)_2O$, F_3SiNH_2, F_3PO et PF_5, on montre que les longueurs de liaisons observées sont en accord avec la présence d'une double liaison partielle importante impliquant tous les ligands, y compris le fluor, et un total de six paires d'électrons dans la couche de valence de l'atome central. On a développé les règles empiriques basées sur d/d_1, le rapport d'une longueur de liaison observée sur la longueur de la simple liaison correspondante calculée à partir de la somme des rayons covalents, comme guide approximatif simple de l'étendue de la double liaison partielle dans les éléments de la troisième période. On montre aussi que les longueurs de liaison dans des espèces comme Al_2F_6, AlO_4^{5-} et $Al(NH_2)_4^-$ sont en accord avec une règle du duodécet.

Introduction

In previous papers, by combining linear relationships between log d and log k, and bond order, n, and k, where d is the observed length of a bond, k is its stretching force constant, and n is defined as the average number of electron pairs per bond, we estimated bond orders, n, from the observed bond lengths in many group 3 species (2). While the bond length – force constant relationships are established entirely on the basis of experimental results, the bond order – force constant relationships are based on the judicious choice of appropriate force constants for a minimum of at least two bonds of assumed order, most conveniently a single bond and a double bond. Justification for our choice was given previously (2). These calculations demonstrated that for a large number of species containing Si—O, P—O, S—O, Cl—O, Si—N, P—N, S—N, and S—C bonds, the calculated *total* bond order of all the bonds to the central atom was close to 6 when there are no unshared electron pairs in the valence shell of the central atom, as in Si(IV), P(V), S(VI), and Cl(VII) species. In other words, the structures are consistent with a *duodecet rule* rather than the octet rule.

This result is consistent with the generalized valence bond description proposed by Messmer (3), in contrast to the molecular orbital description of Reed and Schleyer (4), which gives a description of the bonding in isoelectronic species such as F_3PO, SO_4^{2-}, and SO_2Cl_2 in terms of four polar σ-bonds and partial π-bonding due to strong $n \rightarrow \sigma^*$ negative hyperconjugation as a consequence of donation of ligand lone pairs into the σ-antiboding orbitals concentrated between the central atom and adjacent ligands.

We noted previously (2), that a duodecet rule is consistent with the occurrence of species such as AlF_6^{3-}, SiF_6^{2-}, PF_6^-, SF_6, and $:ClF_5$. We also drew attention to the great variation in, for example, P—F bond lengths in a variety of P(V) and P(III) species, but were unable to further analyze X—F bond lengths because there was uncertainty about what length to assign to a single X—F bond. Single bond lengths calculated using either Pauling's value of 64 pm for the covalent radius of F, or half the bond length in the F_2 molecule of 72 pm, and other standard single bond covalent radii are much longer than those observed for the majority of fluoro species (Table 1). Recently, we proposed the new value of 54 pm for the covalent single bond radius of fluorine (1), which clears up many of the difficulties previously encountered in the interpretation of X—F bond lengths (Table 1) and enables observed bond lengths to fluorine to be discussed systematically.

Results and discussion

We have previously shown that the Douglas–Clark linear log d/log k relationship,

$$\log k_{XY} + A \log d_{XY} = \text{constant}$$

where k_{XY} is the stretching force constant of a bond XY of length d_{XY}, and A is a constant (5), is valid for many bond types (2), and that by combining it with our linear bond order, n_{XY}, force constant, k_{XY}, relationship (6),

$$n_{XY} = B_{XY} + \text{constant}$$

where B is a constant, correlations between bond lengths and bond orders can be obtained for a number of bond types. Unfortunately, it has previously not been possible to apply this approach to all bonds of interest because of the lack of

comprehensive stretching force constant data. However, it has been apparent from our work that most X—Y bonds of the same bond order have very similar values of the ratio d/d_1, where d is an observed bond length and d_1 is the single bond length calculated from the sum of the single bond covalent radii of X and Y, provided the Y atoms are from the same period (1, 2). This is illustrated in Table 2. Thus, it seems reasonable to extrapolate some of the relationships already established, for example those for X—O bonds, to X—N, X—C, and X—F bonds. In this paper we present some bond orders calculated using this method. Standard single bond lengths are calculated from standard single bond

covalent radii, except that we use the values 62 pm, and 54 pm for the radii of O, and F, respectively.[1]

Phosphorus(V) and fluorophosphorus species

On the basis of a single bond length of (110 + 62) = 172 pm for a PO single bond, and our previous analysis of PO bonds (2), we obtain the relationship

$$n = 0.35\left(\frac{d}{d_1}\right)^{-8.0} + 0.65$$

and we assume that the same equation applies to P—N bonds (d_1 = 180 pm), and to P—F bonds (d_1 = 164 pm). The choice of these standard single bond lengths is amply justified by the observed bond lengths in species where it seems reasonable to assume that the bonds are normal single bonds (Table 3). Bond orders calculated using this equation are give in Table 4. In all cases the total bond order at the central P(V) atom is close to six. Similar calculation of bond orders for P—F bonds in some P(III) species are shown in Table 5, which also lists the observed FPF bond angles in a variety of fluorophosphorus species. PF bond length and PF bond order are plotted against ∠FPF in Fig. 1. There is a steady increase in bond angle with increasing PF bond order, and diminishing bond length, as might be anticipated and has been shown to be the case previously for, for example, S—O bonds (7). As has also been observed for the O . . . . O distance in SO_2 groups (7), the F . . . . F distance in PF_2 groups is approximately constant (at about 235 ± 2 pm), which undoubtedly warrants further investigation. For P(V) species, when ligands with atoms such as N, O, and F compete for partial lone electron pair delocalization onto a central phosphorus atom, the extent of lone pair delocalization decreases in the order of increasing electronegativity, N > O

[1]Based upon a correlation of electronegativity with covalent radius, 62 pm for r_O is consistent with 54 pm for r_F, 70 pm for r_N, and 77 pm for r_C, and with the data in Table 3 (E. A. Robinson, unpublished).

> F. Moreover, for all the P(V) species, the calculated total bond order at phosphorus is found to be in the range 6.0 ± 0.1, in accord with the duodecet rule.[2] Although PF_4^+ salts have not yet been synthesized, the predicted bond length is close to 148 pm.

Silicon and fluorosilicon species

On the basis of a value of (62 + 117) = 179 pm for a single Si—O bond, our previous correlation for Si—O bonds (2) gives the equation

$$n = 0.30\left(\frac{d}{d_1}\right)^{-9.5} + 0.70$$

We will assume that the same equation also applies to Si—F bonds (d_1 = 171 pm), to Si—N bonds (d_1 = 187 pm), and to Si—C bonds (d_1 = 194 pm), (Table 3). Analysis of bond length data for some silicon species is shown in Table 6. In all cases the total bond order at silicon is close to six (average 5.9 ± 0.2).

Sulfur(VI) and fluorosulfur species

The calculated S—F single bond length is d_1 = (104 + 54) = 158 pm, and in most fluorosulfur species the S—F bond lengths are within 7% percent of this value (Table 7), compared to a variation of 10–11% for P—F bonds and Si—F bonds. Apparently lone pair delocalization from F to S is normally of lesser importance, consistent with the trend in which the extent of lone pair delocalization into an X—F bond diminishes with the increasing electronegativity of X, presumably as a consequence of the decreasing size of the valence shell of X with increasing electronegativity. Unlike SiF and PF species where bond lengths are always either equal or less than d_1, S—F bonds in molecules with lone pairs on sulfur, such as FSSF, NSF, and the axial bonds in SF_4 and $(CF_3)_2SF_2$ (Table 7), are anomalously long; there are more lone pairs, and the increased crowding in the valence shell of sulfur compared to that in Si or P lengthens the S—F bonds. Nevertheless, there are a few notably short S—F bond

[2]The calculated bond order is very sensitive to d/d_1. For most bonds an error of 1% in d/d_1 translates into a change in bond order of about 5%, or 0.2–0.3 for all the bonds to a central atom. Thus, a calculated total bond order of say 6.0 ± 0.2 may certainly be taken as consistent with a duodecet rule.

lengths, for example, in the ion OSF_3^+, and perhaps in molecules such as SO_2F_2 and the equatorial bonds in molecules such as SOF_4 (Table 7).

On the basis of d_1 (SO) = 166 pm and our previous correlation for SO bonds (2), we obtain

$$n = 0.41\left(\frac{d}{d_1}\right)^{-7.4} + 0.59$$

Assuming that this equation is also valid for S—C, S—N, and S—F bonds, with d_1(SC) = 186 (3), d_1(SN) = 174, d_1(SO) = 166, and d_1(SF) = 158 pm, some calculated bond orders are shown in Table 8. The average total bond order is 6.0 ± 0.05.

[a]AlO_6 octahedra.
[b]Monodentate $AlONO_2$ (191 pm avg.) and bidentate AlO_2NO groups.
[c]Contains AlO_2F_4 octahedra.

Chlorine(VII) and fluorochlorine species

Because chlorine is the most electronegative of the third period elements, substantial crowding of electron pairs is anticipated in its valence shell and almost all Cl—F bond lengths are longer than the sum of the covalent single bond radii, $d_1 = (99 + 54) = 153$ pm (Table 9). Only $ClF_2^+AsF_6^-$ (10), and for the apical bond in ClF_5, does the ClF bond length have the single bond value (1). Based on the previous correlations for Cl—O bonds, with d_1(ClO) = 161 pm, we derive the correlation

$$n = 0.47\left(\frac{d}{d_1}\right)^{-6.5} + 0.53$$

Assuming that this equation is valid for both Cl—O and Cl—F bonds, some calculated bond orders are given in Table 10; the total bond order at Cl(VII) is close to six.

Extension to some aluminum species

Since a duodecet rule seems to be justified for Si(IV), P(V), S(VI), and Cl(VII) species with electronegative ligands, such as N, O, and F, we will now consider some aluminum species.

Table 11 shows that for third period central atoms, bonds to second period atoms with a particular bond order, n, have essentially the same bond length/single bond length ratio, d/d_1. We will assume that the average values given in Table 11 are also valid for calculating bond orders for AlF, AlO, and AlN bonds. The sum of the single bond covalent radii of Al and F is (126 + 54) = 180 pm, which is the observed bond length in the AlF_6^{3-} ion (11), and this same distance is found for the Al—F bond in a number of species with presumed single Al—F bonds (Table 12). In dimeric Al_2F_6, the terminal and bridge Al—F bonds have lengths 160 pm and 172 pm, respectively (12). Applying the simple rules developed above to Al_2F_6, we obtain the following results: Al—$F_{terminal}$, $d/d_1 = 0.88$, $n = 1.7$; Al—F_{bridge}, $d/d_1 = 0.94$, $n = 1.2_5$, for a total bond order at Al of 5.8, strongly suggesting that, in Al_2F_6, aluminum also obeys the duodecet rule.

For AlO bonds, the AlO bond length in βLi_5AlO_4 containing the AlO_5^{5-} ion is 172 pm (13), and in a number of substances containing AlO_6 octahedra the bond length is close to 190 pm (Table 12). Thus, the predicted value for an AlO bond of order $1^1/_2$ is (0.90 × 190) = 171 pm. Apparently AlO_4^{5-}, isoelectronic with SiO_4^{4-}, PO_4^{3-}, SO_4^{2-}, and ClO_4^-, also obeys the duodecet rule.

For Al—N bonds, taking r_1 as 200 pm (Table 12), the expected length of a bond of order $1^1/_2$ is 180 pm, which is to be compared with 178 pm observed in cyclic $[CH_3AlNR_2]_3$, where R is 2,6-isopropylphenyl (14), and 180 pm in $MAl(NH_2)_4$ salts (M^+ = Na^+, K^+, and Cs^+) (15); apparently Al in $Al(NH_2)_4^-$ obeys the duodecet rule. In lithium tetrakis(di-*tert*-butylmethyleneamino)aluminate, two of the AlN bonds have lengths of 187 pm, and the other two have lengths of 178 pm (16). The corresponding d/d_1 values of 0.93 and 0.89 give bond orders of approximately 1.3 and 1.6, for an estimated total bond order at aluminum of close to six.

Conclusions

An estimate of the extent of partial X—F double bonding in many fluorosilicon and fluorophosphorus species, and a few fluorosulfur species, provides support for the extension to them of a duodecet rule for the third period elements. Apparently, when the valence shell of X is formally incomplete, ligands containing atoms such as N, O, and F delocalize unshared electron pairs into the valence shell of X until it contains 12 electrons. When these ligands compete, the extent of lone pair delocalization decreases in the order of their increasing electronegativities; N > O > F. We have also demonstrated that consideration should be given to a duodecet rule in interpreting bond length data for some aluminum species. Despite the controversy surrounding the theoretical treatment of bonding in third period species (3, 4), there seems to be growing support for the empirical interpretation of bond lengths for many species formed by the elements of the third period in terms of a duodecet rule, rather than the octet rule.

A. BRUCE MCKAGUE, DOUGLAS W. REEVE, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **70**, 1706 (1992).

Reaction of tetrachloro-*o*-benzoquinone **1** with aqueous sodium hydroxide resulted in a Cannizzaro-type disproportionation into tetrachloromuconic acid and tetrachlorocatechol. The tetrachloromuconic acid was isolated and identified by X-ray crystallography as the methyl ester of the cyclized lactone **3**. Crystals of $C_7H_3Cl_3O_4$, **4**, are orthorhombic, a = 9.991 (2), b = 7.981 (1), c = 24.626(2) Å, Z = 8, space group $Pna2_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.033 for 1609 reflections with $I \geq 3\sigma(I)$.

A. BRUCE MCKAGUE, DOUGLAS W. REEVE, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **70**, 1706 (1992).

La réaction de la tétrachloro-*o*-benzoquinone (**1**) avec une solution aqueuse d'hydroxyde de sodium donne lieu à une réaction de dismutation du type de Cannizzaro conduisant à de l'acide tétrachloromuconique et à du tétrachlorocatéchol. On a isolé l'acide tétrachloromuconique et, par diffraction des rayons X, l'a identifié comme l'ester méthylique de la lactone cyclique **3**. Les cristaux de $C_7H_3Cl_3O_4$, **4**, sont orthorhombiques, avec a = 9,991(2), b = 7,981(1) et c = 24,626(2) Å, Z = 8 et groupe d'espace $Pna2_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à une valeur de R = 0,033 pour 1609 réflexions avec $I \geq 3\sigma(I)$.

Introduction

Muconic acids can be produced from phenols or quinones by chemical or enzymatic oxidation (1–5). Depending on the substituents present and the geometry of the double bonds, the muconic acids may cyclize to form lactones. In the case of pulp bleaching with chlorine, chlorinated muconic acids have been proposed as the terminal products of chlorination of lignin-type phenols (6). To date, neither chlorinated muconic acids nor their cyclized lactone counterparts have been identified in effluents from chlorine bleaching. In the case of one report in which trichloro-β-methylmuconic acid was identified as a chlorination product of the model compound 4-methylguaiacol, firm structural evidence was not provided (7).

The chemistry of pulp bleaching with chlorine is extremely intriging and complicated. Regulatory and market pressures have now driven the pulp and paper industry to replace chlorine with bleaching agents such as chlorine dioxide and oxygen. As a result, chlorine bleaching may be phased out before its chemistry is well understood. In the accompanying paper (8) we report the conversion of the model compound 4-methyltrichlorocatechol to an unusual chlorohydroxycyclohexenone by aqueous chlorine. Treatment of the latter with aqueous sodium hydroxide results in a benzilic acid rearrangement to a chlorohydroxycyclopentenecarboxylic acid. This paper reports the conversion of tetrachloro-*o*-benzoquinone, a product of classical chlorine bleaching, to tetrachloromuconic acid via a Cannizzaro-type reaction with alkali in the absence of any oxidant.

Experimental

Melting points were taken on a Fisher Johns melting point apparatus and are uncorrected. Infrared (IR) spectra were recorded on a Perkin Elmer model 598 infrared spectrophotometer and ultraviolet (UV) spectra on a Beckman model DU-7U spectrophotometer. Carbon magnetic resonance (^{13}C NMR) spectra were recorded in CD_3OD or $CDCl_3$ solution using a Bruker AM 500 MHz high resolution spectrometer. Signal positions are given in ppm (δ) relative to Me_4Si. Mass spectra were obtained on a VG analytical ZAB-SE high-mass high-resolution mass spectrometer. Silica gel used for chromatography was 100–200 mesh. Gas chromatography (GC) was done on a Hewlett Packard HP 5890 gas chromatograph equipped with a flame ionization detector and 25 m HP1 capillary column. Temperature was programmed from 185 to 260°C at 10°/min.

*Reaction of tetrachloro-***o***-benzoquinone 1 with alkali*

Tetrachloro-*o*-benzoquinone (3.0 g) was added to 2.5% NaOH (300 mL) with stirring at 60°C. The resultant mixture was stirred 20 min at 60°C, then cooled to room temperature. Sodium chloride (30 g) was added, the product acidified with concentrated hydrochloric acid and extracted with ether (5 × 100 mL). The combined extracts were washed with water (3 × 25 mL), dried ($MgSO_4$), and evaporated to give the crude product (3.1 g). GC analysis showed the two products **3** and **5** with retention times of 2.5 and 5.3 min respectively. Fractionation on silica gel (250 g) and elution with hexane:ether, 2:1 gave the furanone **3** (0.8 g) as a light brown oil. Crystallization from hexane containing a little ether gave tan prisms of **3**; mp 164–165°C; IR (Nujol): 1815, 1720 cm^{-1}; UV (ethanol) λ_{max}: 310 nm (ε 20 800); ^{13}C NMR δ: 163.6 (C1 or C5), 160.9 (C1 or C5), 145.5, 139.9, 126.4, 112.6 (C3); MS *m/e*: 246 (7%), 244 (21), 242 (22), 200 (38), 198 (40), 165 (22), 163 (36), 122 (20), 89 (33), 87 (100). Anal. calcd. for $C_6HCl_3O_4$: C 29.60, H 0.41, Cl43.69; found: C 29.79, H < 0.5, Cl 42.78. Continued elution with the same solvent and hex-

[a]$B_{eq} = (8/3)\pi^2\Sigma\Sigma U_{ij}a_i^*a_j^*(a_i \cdot a_j)$.

ane:ether 1:1 gave a mixture of **3** and **5** (0.2 g) followed by **5** (1.6 g), identical to an authentic sample prepared by the chlorination of catechol.

Preparation of the methylester 4

The furanone **3** (150 mg) was dissolved in methanol (2 mL) and treated with a solution of diazomethane in ether (20 mL). The solution was allowed to stand at room temperature 1 h, then washed with water, dried ($MgSO_4$), and evaporated to give the product. Crystallization from hexane containing a little ether gave colourless prisms of **4**; mp 100–101°C; IR (Nujol): 1805, 1740 cm^{-1}; UV (ethanol) λ_{max}: 296 nm (ϵ 23 700); ^{13}C NMR δ: 161.3 (C1 or C5), 159.3 (C1 or C5), 145.1, 139.0, 125.6, 110.8 (C3), 54.0 (OCH_3); MS *m/e*: 258 (21), 256 (22), 225 (20), 227 (18), 141 (41), 143 (40), 87 (68), 59 (100). Anal. calcd. for $C_7H_3Cl_3O_4$: C 32.65, H 1.17, Cl 41.31; found: C 32.68, H 1.25, Cl 40.75.

X-ray crystallographic analyses of 4

Crystallographic data appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 55.0–86.4°. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, decreased uniformly by 5.5%. The data were processed[2] and corrected for Lorentz and polarization effects, decay, and absorption (empirical, based on azimuthal scans for four reflections).

The structure analysis was initiated in the noncentrosymmetric space group $Pna2_1$ on the basis of the *E*-statistics, this choice being confirmed by the subsequent successful solution and refinement of the structure. The structure was solved by direct methods, the coordinates of the non-hydrogen atoms being determined from an *E*-map. There are two molecules in the asymmetric unit, related to one another by a pseudo-inversion centre. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in calculated positions (orientation based on observed Fourier map positions, C—H = 0.98 Å, $B_H = 1.2\ B_{bonded\ atom}$). A correction for secondary extinction was applied, the final value of the extinction coefficient being 1.69×10^{-4}. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (9). A parallel refinement of the structure having the opposite polarity gave higher residuals, the *R* and R_w factor ratios being 1.05 and 1.04, respectively. Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, and bond angles appear in Tables 2–4, respectively. A stereoview of the packing arrangement, hydrogen atom parameters, anisotropic thermal parameters, bond lengths and bond angles involving hydrogen, torsion angles, intermolecular con-

tacts, least-squares planes, and measured and calculated structure factor amplitudes have been supplied as supplementary material.[3]

Results and discussion

The product resulting from treatment of tetrachloro-*o*-benzoquinone with alkali was found to consist of two components by GC analysis. Neither of the components had a retention time that matched that of chloranilic acid, a compound suggested as a possible product of this reaction (10). The retention time of one of the components matched that of tetrachlorocatechol and the identity of this component was confirmed by subsequent comparison of material isolated by fractionation of the product on SiO_2 with a standard. The other product eluted from SiO_2 prior to tetrachlorocatechol and gave crystals having melting point 164–165°C. This compound and its methyl derivative had infrared absorption bands at 1815 and 1805 cm^{-1} respectively, which suggested they were five-membered ring lactones. The structure of the methyl derivative was determined as the methyl ester **4** by X-ray crystallography described below.

Identification of the methyl derivative of one of the two major reaction products as the methyl ester of the lactone **3** indicated tetrachloro-*o*-benzoquinone **1** had undergone a simple oxidation–reduction with alkali, most likely via a Cannizzaro-type reaction as shown in Scheme 1. The intermediate muconic acid 2 has previously been reported to cyclize to the lactone (1).

The melting point of the lactone **3** obtained in this work is 164–165°C, close to that reported in the literature for the lactone formed on melting tetrachloromuconic acid and which was reported (1) to be a mixture of the two possible geometrical isomers of **3**. The melting point is also lower than that of 182°C reported by Karrer and Testa for the lactone obtained by peracetic acid oxidation of **1** (11). The material reported in the present work appeared homogeneous by GC and ^{13}C NMR, and gave almost entirely one product on methylation that had a melting point of 100–101°C, slightly lower than that of 107°C reported by Karrer and Testa for the methyl ester obtained in their work. Since the structure was determined as the isomer **4** by X-ray crystallography, it is not possible to explain the differences in the reported melting points for the lactone **3**.

The observation that tetrachloro-*o*-benzoquinone undergoes a Cannizzaro-type oxidation–reduction reaction with alkali indicates that chloromuconic acids may be formed in

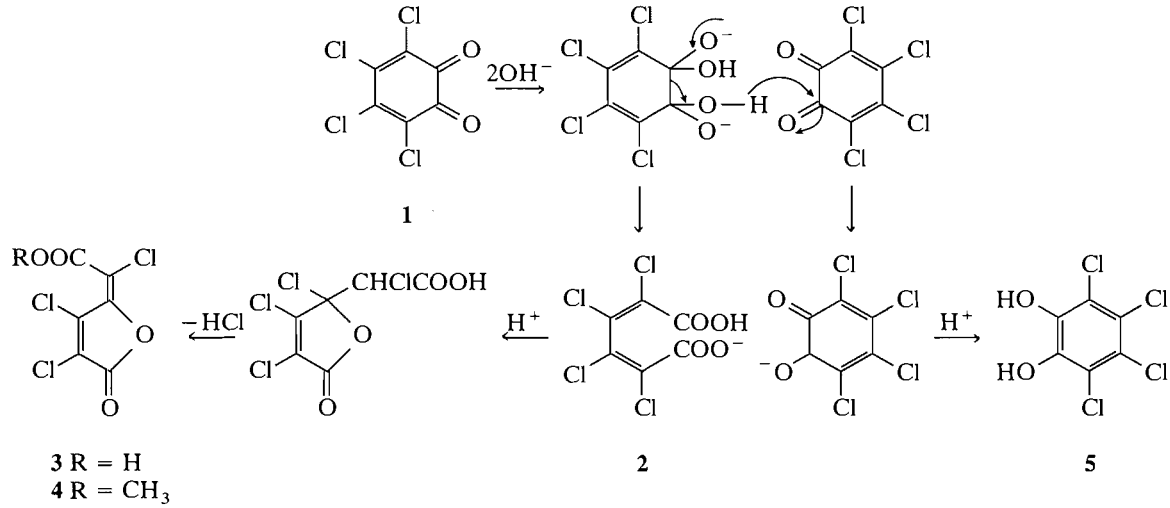

SCHEME 1

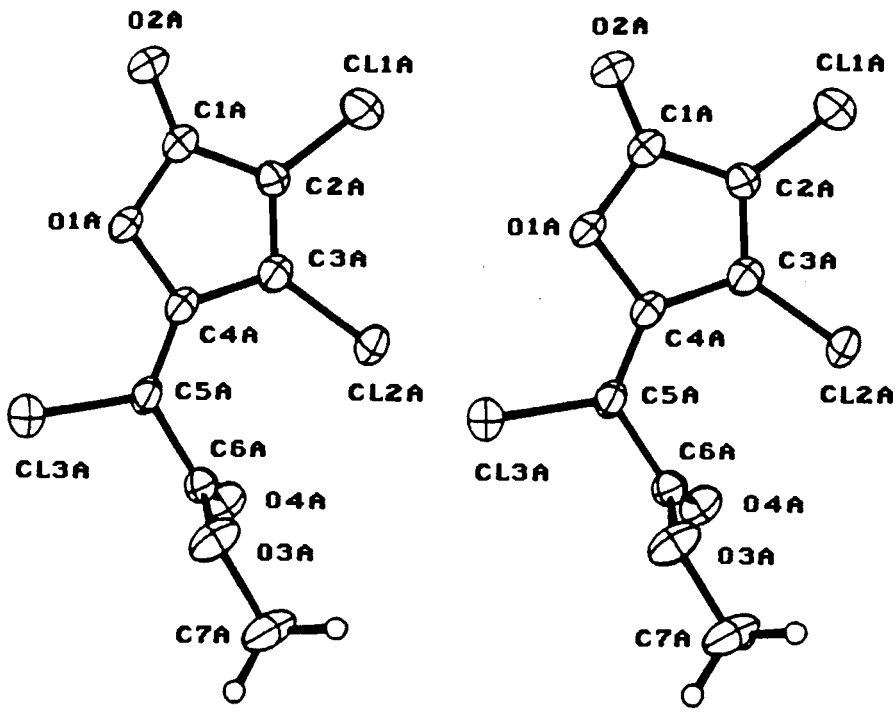

FIG. 1. Stereoscopic view of one of the two crystallographically independent molecules of **4** showing atom labelling; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms.

the alkaline (E) stage of bleaching rather than in the chlorination (C) stage.

Bond lengths and angles for the two crystallographically independent molecules of **4** (side-by-side in Tables 3 and 4 for ease of comparison, Fig. 1) are generally equal within experimental error and are as expected. The five-membered rings are planar within 0.020(7) and 0.025(7) Å in the A and B molecules respectively. The ester functions are planar within experimental error for both molecules and are oriented roughly perpendicular to the five-membered rings (angles between normals to the mean planes are 112.1° and 113.7° for the A and B molecules). The packing is dominated by a herring-bone arrangement of slipped stacks, the five-membered rings of one layer interacting with chlorine atoms or ester groups of the adjacent layer. The shortest intermolecular distances between adjacent layers are O(3A) ··· C(1A) = 2.963(8), O(3B) ··· C(1B) = 2.979(9), Cl(1A) ··· O(2A) = 3.076(5), and Cl(1B) ··· O(2B) = 3.010(4) Å.

Aqueous chlorination of 4-methyltrichlorocatechol **2** gave the tetrachlorohydroxycyclohexenone **4**, which crystallized as the hydrate **5**. Reaction of **4** with aqueous sodium hydroxide resulted in a benzilic acid rearrangement to the tetrachlorodihydroxycyclopentenecarboxylic acid **6**. These reactions have important implications with respect to understanding how lignin is removed during pulp bleaching. Crystals of the tetrachlorotrihydroxycyclohexenone **5** are monoclinic, a = 11.4420(6), b = 7.5873(9), c = 12.6443(6) Å, β = 101.266(4)°, Z = 4, space group $P2_1/c$, and those of the methyl tetrachlorodihydroxycyclopentenecarboxylate **7** are monoclinic, a = 28.447(1), b = 6.929(1), c = 12.597(1) Å, β = 103.074(5)°, Z = 8, space group $C2/c$. The structures were solved by direct methods and were refined by full-matrix least-squares procedures to R = 0.028 and 0.034 for 1716 and 2164 reflections with $I \geq 3\sigma(I)$, respectively.

A. BRUCE MCKAGUE, DOUGLAS W. REEVE, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **70**, 1711 (1992).

La chloration aqueuse du 4-méthyltrichlorocatéchol, **2**, conduit à la tétrachlorohydroxycyclohexénone, **4**, qui cristallise sous la forme de l'hydrate **5**. La réaction du composé **4** avec de l'hydroxyde de sodium aqueux donne lieu à un réarrangement benzylique conduisant à l'acide tétrachlorodihydroxycyclopentanecarboxylique, **6**. Ces réactions ont des implications importantes pour la compréhension de la façon dont la lignine est enlevée au cours du blanchiment de la pulpe. Les cristaux de la tétrachlorohydroxycyclohexénone, **5**, sont monocliniques, a = 11,4420(6), b = 7,5873(9) et c = 12,6443(6) Å, β = 101,266(4)°, Z = 4, groupe d'espace $P2_1/c$, et ceux du tétrachlorodihydroxycyclopentènecarboxylate de méthyle, **7**, sont monocliniques, a = 28,447(1), b = 6,929(1) et c = 12,597(1) Å, β = 103,074(5)°, Z = 8, groupe d'espace $C2/c$. On a résolu les structures par des méthodes directes et on les affinées par la méthode des moindres carrés (matrice complète) jusqu'à des valeurs de R = 0,028 et 0,034 respectivement pour 1716 et 2164 réflexions avec $I \geq 3\sigma(I)$.

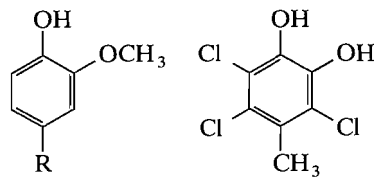
[Traduit par la rédaction]

Introduction

The chemistry of classical chlorine bleaching of wood pulp has been a subject of extensive study over the past 30 years. A number of reviews that describe our current understanding of how residual lignin is removed from pulp by bleaching (1–3) have been published in textbooks and scientific journals.

In spite of the large number of studies performed, there is still a basic lack of information regarding the mechanism of degradation of aromatic structures present in lignin. There are many examples in the literature that establish that loss of aromaticity can occur via chlorination and oxidation to quinones, but further reactions of the quinones have not been defined and it is not known whether other reaction mechanisms play a significant role in removing aromaticity. The proposed conversion of chlorinated quinones to muconic acids is supported by only one example in which the structure of the muconic acid was not rigorously established (4). Also it was recently reported that tetrachlorocatechol and tetrachloro-*o*-benzoquinone are converted to 2,2,4,5-tetrachlorocyclopentene-1,3-dione by aqueous chlorine (5), which indicates another mechanism is involved in this case.

In connection with studies designed to provide more information on the chemical structure of lignin degraded by chlorine bleaching, we have initiated studies to determine the fate of the more generalized lignin model structure **1**. In this paper we report the identification of products obtained by reacting 4-methyltrichlorocatechol **2** successively with aqueous chlorine and sodium hydroxide.



1 **2**

Experimental

Melting points were taken on a Fisher Johns melting point apparatus and are uncorrected. Infrared (IR) spectra were recorded on a Perkin Elmer model 598 infrared spectrophotometer and ultraviolet (UV) spectra on a Beckman model DU-7U spectrophotometer. Proton magnetic resonance (^{1}H NMR) spectra were recorded in $CDCl_3$ solution using a Bruker AM 500 MHz high resolution spectrometer. Signal positions are given in ppm (δ) relative to Me_4Si. Mass spectra were obtained on a VG analytical ZAB-SE high-mass high-resolution mass spectrometer. Silica gel used for chromatography was 100–200 mesh. Methyltrichlorocatechol was prepared by chlorinating 4-methylcatechol as described in the literature (4).

Values given for R, R_w, and gof are based on those reflections with $I \geq 3\sigma(I)$.

Chlorination of 4-methyltrichlorocatechol 2

Chlorine was gently bubbled through a stirred suspension of 4-methyltrichlorocatechol **2** (1.0 g) in water (500 mL) at 50°C for 15 min. After cooling to room temperature, the solution was extracted with ether. The combined extracts were washed with water, dried ($MgSO_4$), and evaporated to give a red gum (1.1 g). The product was fractionated on silica gel (50 g) and 4-methyltrichlorobenzoquinone **3** (130 mg, 13% yield) eluted with hexane:ether, 4:1. Treatment with ether gave **3** as a bright red powder, mp 103–104°C (lit. (6) mp 104–104.5°C); MS, *m/e*: 226 (21%), 224 (21), 200 (32), 198 (97), 196 (100), 191 (25), 189 (38), 170 (32), 168 (33), 163 (24), 161 (37), 135 (48), 133 (75). Reduction of **3** with $NaBH_4$ gave back **2**. Elution with hexane:ether, 1:1, then gave **4** (800 mg, 62% yield), which solidified on cooling. Crystallization from hexane gave tan needles of **4** as the hydrate **5**, mp 91–93°C; IR (Nujol):3460, 3370, 3270, 1720, 1570 cm^{-1}; UV ($CHCl_3$) λ_{max}: 266 nm (ε 11 400); ^{1}H NMR δ: 1.91 (s, 3H), 4.29, 4.49, 5.34 (s, s, s, 1H each, D_2O exchangeable); MS, *m/e*: 217 (32), 215 (97), 213 (100), 168 (40), 166 (57). Anal. calcd. for $C_7H_6Cl_4O_4$: C 28.41, H 2.04, Cl 47.92; found: C 28.70, H 1.95, Cl 47.50.

The same product **4** was obtained by chlorinating the quinone **3**.

Reaction of 4 with sodium hydroxide

A mixture of the crude chlorination product obtained above (1.1 g) and 2.5% NaOH (100 mL) was stirred in a bath at 60°C for 20 min. The product was cooled, acidified with concentrated hydrochloric acid, and extracted as described above to give a light brown gum (600 mg). One half the crude product **6** was treated with diazomethane in ether:methanol 9:1 (25 mL) for 1 h. After evaporation of the solvent the crude product was fractionated on silica gel (25 g) and the product **7** (205 mg) eluted with hexane:ether, 4:1. Crystallization from hexane gave colourless prisms of **7** mp 93–94°C; IR (Nujol):3300, 1720, 1630 cm^{-1}; ^{1}H NMR δ: 1.67 (s, 3H), 3.98 (s, 3H), 4.08 (s, 1H, D_2O exchangeable), 4.17 (m, 1H, D_2O exchangeable). Anal. calcd. for $C_8H_8Cl_4O_4$: C 31.00 H 2.60, Cl 45.76; found: C 30.84, H 2.40, Cl 45.92. The same product was obtained from crystallized **4** by the above procedure.

X-ray crystallographic analyses of the tetrachlorotrihydroxycyclohexenone, 5, and the methyl tetrachlorodihydroxycyclopentenecarboxylate, 7

Crystallographic data for **5** and **7** appear in Table 1. The final unit-cell parameters were obtained by least-squares on the setting angles for 25 reflections with 2θ = 80.9°–100.0° and 109.8°–114.0°, respectively. The intensities of three standard reflections, measured every 200 reflections throughout the data collections, showed only small random variations. The data were

[a] $B_{eq} = (\frac{8}{3})\pi^2\Sigma\Sigma U_{ij}a_i^*a_j^*(a_i \cdot a_j)$.

processed[2] and corrected for Lorentz and polarization effects, decay (for **5**), and absorption (empirical, based on azimuthal scans for four reflections).

The structure analysis of **7** was initiated in the centrosymmetric space group $C2/c$ on the basis of the E-statistics, this choice being confirmed by the subsequent successful solution and refinement of the structure. Both structures were solved by direct methods, the coordinates of the non-hydrogen atoms being determined from E-maps and those of the hydrogen atoms from subsequent difference Fourier syntheses. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms were refined with isotropic thermal parameters. Corrections for secondary extinction were applied for both compounds, the final values of the extinction coefficients being 4.58×10^{-4} for **5** and 2.48×10^{-4} for **7**. Neutral atom scattering factors and anomalous dispersion corrections for the non-hydrogen atoms were taken from the *International tables for X-ray crystallography* (7). Final atomic coordinates and equivalent isotropic thermal parameters, bond lengths, bond angles, and hydrogen bonding parameters appear in Tables 2–5, respectively. Hydrogen atom parameters, anisotropic thermal parameters, tables of bond lengths and bond angles involving hydrogen, torsion angles, intermolecular contacts, least-squares planes, and measured and calculated structure factor amplitudes are included as supplementary materials.[3]

Results and discussion

Chlorination of 4-methyltrichlorocatechol **2** gave the quinone **3** and the tetrachlorohydroxycyclohexenone **4** (Scheme 1), which crystallized as the hydrate **5** in yields of 13 and 62% respectively. The quinone **3** was readily identified by its melting point, which agreed with the literature, its mass spectrum, and reduction back to the starting catechol **2**. The hydrate **5** had hydrogen-bonded hydroxyl absorption at 3200–3500 cm^{-1} in the IR spectrum. Carbonyl absorption occurred at 1720 cm^{-1} and olefinic absorption at 1570 cm^{-1}. Ultraviolet absorption occurred at 266 nm, in good agreement for a substituted α, β-unsaturated ketone, but the presence of three D_2O exchangeable protons in the ^{1}H NMR spectrum initially caused some difficulty in determining the structure. As a result of a complete structure determination by X-ray crystallography described in the following pages, crystals of compound **4** were found to be in the hydrated form **5**. Isolation as the hydrate indicates that the electron-withdrawing chlorine atoms on the α-carbon atom activate the carbonyl group toward hydrate formation in a manner similar to that of the aldehyde chloral.

Formation of main product **4** is most easily explained by addition of hypochlorous acid to the quinone **3** as shown in Scheme 1. This is supported by the fact that chlorination of the quinone **3** also yields **4** as the major product. Other mechanisms involving chlorination of the catechol **2** at the carbon bearing the methyl group followed by displacement of the chlorine by water may also be involved in formation of the product **4**. A similar mechanism was previously proposed to account for the formation of a spirocyclohexenone obtained by chlorination of dihydroconiferyl alcohol (8).

Reaction of the cyclohexenone **4** with aqueous NaOH at 60°C rapidly produced a clear solution. The product of **6** could not be obtained crystalline but formed the methyl-ester **7** when derivatized with diazomethane. The ester had hydroxyl absorption at 3300 cm^{-1}, ester absorption at 1720 cm^{-1}, and olefinic absorption at 1630 cm^{-1} in the IR spectrum. The ^{1}H NMR had methyl singlets at δ 1.67 and 3.98, and D_2O-exchangeable hydroxyl groups at δ 4.08 and 4.17. The complete structure was determined by X-ray crystallography as described below.

The tetrachlorocyclohexenone **4** evidently undergoes a benzilic acid rearrangement in alkaline solution rather than displacement of chlorine at the position α to the hydrated carbonyl group as might be expected. This suggests the carbonyl group retains its geminal diol structure in solution, thus

protecting the chlorine atoms on the adjacent carbon atoms from simple nucleophilic displacement. The ^1H NMR spectrum had indicated that three D_2O-exchangeable protons were present. Also surprising was the fact that epoxide formation was not observed.

Elucidation of the reaction pathway of 4-methyltrichlorocatechol **2** under conditions of classical chlorine bleaching indicates further research on mechanisms for the degradation of aromatic structures in lignin is needed. Formation of the quinone **3** by chlorination of 4-methylguaiacol **1** (R = CH_3) and its subsequent conversion to 3-methyltrichloromuconic acid has been previously reported although, as mentioned in the introduction, structural proof was not provided. The results of the present study, as well as the previous report on the conversion of tetrachlorocatechol and tetrachloro-*o*-benzoquinone to 2,2,4,5-tetrachlorocyclopentene-1, 3-dione, indicate chlorinated muconic acids are not necessarily formed during chlorine bleaching. Further studies are presently underway to determine reaction pathways of the more generalized lignin model **1**.

Bond lengths and angles for the tetrachlorotrihydroxycyclohexenone **5** (Table 3, Fig. 1) are as expected, showing some lengthening of ring bonds between fully substituted carbon atoms. The cyclohexene ring has a C(5)-envelope conformation, C(5) being displaced 0.62 Å from the mean plane of the remaining five ring carbon atoms, which are coplanar to within 0.10 Å. There are two intramolecular O—H···O hydrogen bonds (see Table 5). In the solid state, molecules are linked into infinite chains about the twofold screw axis by O—H···O hydrogen bonding, all other intermolecular distances corresponding to normal van der Waals interactions.

The structure of the rearrangement product **7** is shown in Fig. 1. As noted above for **5**, bond lengths and angles for **7** (Table 4) are generally as expected with bonds between fully substituted carbon atoms showing significant lengthening (particularly those involving C(3) and C(4)). The cyclopentene ring has a C(4)-envelope conformation and the molecule is stabilized by by an intramolecular O—H···O hydrogen bond between the pseudo-axial hydroxyl substituent on C(5) and the carbonyl oxygen atom of the pseudo-axial carbomethoxy substituent on C(3) (see Table 5). In the solid, molecules are O—H···O hydrogen-bonded to form infinite chains along *b*, all other intermolecular distances corresponding to van der Waals interactions.

Thermolysis of 1-phenyl-4*H*-1,3,2-benzodioxaborins generated the corresponding *ortho*-quinone methides, which were found to undergo intermolecular cycloaddition reactions with ethyl vinyl ether, dihydropyran, β-methylstyrene, cyclohexene, and 1-ethoxy-1-*z*-trimethylsiloxy-1-propenes to give various substituted chromans. Intramolecular trapping of the quinone methides with an olefin led to the syntheses of several analogs of tetrahydrocannabinols. *ortho*-Quinone methides, generated by treatment of the 2-phenyl-4*H*-1,3,2-benzodioxaborins with a Lewis acid, react with various nucleophiles to give the corresponding 1,4-addition products. Thus, alkyl and aryl thiols, alcohols, amine, hydride, allyl trimethylsilane, acetophenone, and diethylmalonate as well as some aryl compounds react with the quinone methide to give various 2-substituted phenols. Intramolecular reaction of the quinone methide with an aryl group led to the preparation of some 4-phenylchromans and tetralins.

JEFFREY D. CHAMBERS, JASON CRAWFORD, HAYDN W. R. WILLIAMS, CLAUDE DUFRESNE, JOHN SCHEIGETZ, MICHAEL A. BERNSTEIN et CHEUK K. LAU. Can. J. Chem. **70**, 1717 (1992).

La thermolyse des 2-phényl-4*H*-1,3,2-benzodioxaborines conduit aux *ortho*-quinométhanes correspondantes qui subissent des réactions de cycloaddition intermoléculaires avec l'éthoxyéthène, le dihydropyrane, le β-méthylstyrène, le cyclohexène et les 1-éthoxy-1-*z*-triméthylsiloxyprop-1-ènes pour conduire à divers chromanes substitués. Le piégeage intramoléculaire des quinométhanes avec une oléfine permet la synthèse de plusieurs analogues des tétrahydrocannabinols. Les *ortho*-quinométhanes, préparés par traitement des 2-phényl-4*H*-1,3,2-benzodioxaborines avec un acide de Lewis, réagissent avec divers nucléophiles pour donner les produits d'additions-1,4 correspondants. Ainsi, les alkyl- et aryl-thiols, les alcools, les amines, les hydrures, l'allyltriméthylsilane, l'acétophénone et le malonate d'éthyle ainsi que certains composés aromatiques réagissent avec le quinométhane pour conduire à divers phénols substitués en position 2. La réaction intramoléculaire des quinométhanes avec un groupe aryle conduit à la préparation de quelques 4-phénylchromanes et de tétralines.

Introduction

ortho-Quinone methides **1** are known to be very reactive and unstable intermediates in synthesis (1, 2). As a consequence of this reactivity, di- or trimerization in which one molecule acts as heterodiene and another as dienophile has led to some interesting chroman fused-ring systems (3–6). However, in the presence of electron-rich dienophiles they often react preferentially with these species to form potentially complex chromans (7–11). Intramolecular trapping of these quinone methides by otherwise unreactive dienophiles has also been documented (12–18). In the presence of nucleophiles, *ortho*-quinone methides generated *in situ* undergo Michael addition to give *ortho*-substituted phenols (5, 17, 19).

A variety of methods of *ortho*-quinone methide generation have been reported (2), including pyrolysis of *ortho*-(methoxyalkyl)- or *ortho*-(hydroxyalkyl)phenols (3, 6–8, 12, 13), dehydrohalogenation of 2-chloromethylphenol (4, 20), one-electron oxidation of *ortho*-substituted phenols (5, 9), desilylation of disilylated *ortho*-hydroxybenzyl alcohol (15), photochemical decarbonylation of benzofuran-2(3*H*)-one (10) and treatment of *ortho*-(1-(alkylthio)alkyl)phenols with a variety of metal oxides under mild conditions (11, 16, 17). Recently we reported the preparation of a variety of *ortho*-alkyl, *ortho*-alkoxalkyl, and *ortho*-thioalkyl phenols from 2-phenyl-4*H*-1,3,2-benzodioxaborins, presumably via the quinone methide intermediate (21). Substituted 2-phenyl-4*H*-1,3,2-benzodioxaborins are stable compounds that can be stored indefinitely at room temperature. They are prepared by refluxing a mixture of the corresponding phenol, aldehyde, and phenyl boronic acid in the presence of a catalytic amount of propionic acid in toluene (22, 23). We now report the successful use of these benzodioxaborins as stable precursors of quinone methides in inter- and intramolecular cycloaddition reactions with different dienophiles under pyrolytic conditions as well as their reactions with aryl and alkyl nucleophiles under Lewis acid condition (Scheme 1).

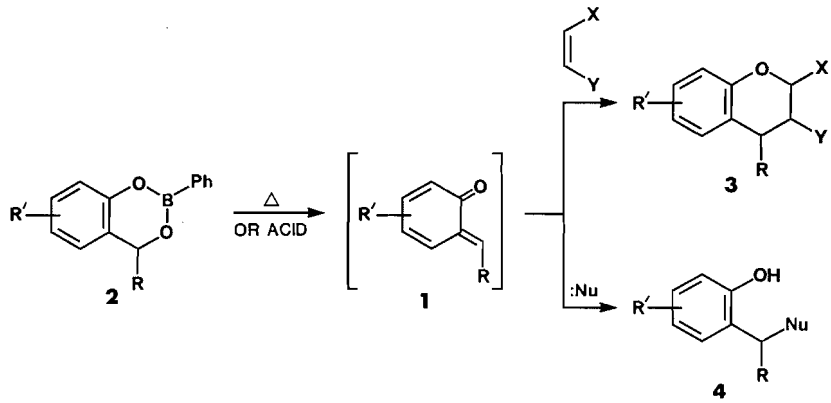
Results and discussion

Cycloaddition of ortho-quinone methides

ortho-Quinone methide has been generated by pyrolysis of the sulfite ester of 2-hydroxymethylphenol with elimination of sulphur dioxide (24). It was rationalized that 2-phenyl-4*H*-1,3,2-dioxaborin might eliminate phenylboronic anhydride in a similar fashion under pyrolytic condition to give the corresponding quinone methide. Thus, pyrolysis of the unsubstituted 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* in the presence of various dienophiles was studied first, to examine the scope and limitation of the reaction. Ethyl vinyl ether was known to trap *ortho*-quinone methides in a [4+2] cycloaddition fashion to give 2-ethoxy chromans (7–11). Heating a solution of **2***a* in ethyl vinyl ether in a base-washed degassed heavy-walled Pyrex tube at 300°C for 72 h gave a 75% yield of the corresponding 2-ethoxychroman **3***a* after chromatography. Similarly, pyrolysis of



SCHEME 1

2*a* in dihydropyran gave the expected tetrahydropyranobenzopyran **3***b* (4) in a 52% yield in only 5 h. As expected for a cycloaddition reaction, only the *cis*-fused ring compound was obtained. Thus the feasibility of the method as well as the quinone methide intermediacy was established. The results are summarized in Table 1. Attempts to trap the quinone methide with 1-ethoxy-1-trimethylsiloxypropene initially met with some difficulty, due to the extensive polymerization of the dienophile that made the isolation of the initial cycloadduct **3***c* impossible. Eventually, a solution of **2***a* and 1-ethoxy-1-trimethylsiloxypropene in benzene was heated in a sealed tube at 230°C for 18 h. After removal of the volatiles, the crude mixture was treated with tetra-*n*-butylammonium fluoride in tetrahydrofuran. Chromatography of the resulting crude product after normal work-up gave a 23% yield of 3-methyl-2-chromanone **3***d* and 10% of the ethyl 3-(2-hydroxyphenyl)-2-methyl propionate **4***a*. Both **3***d* and **4***a* are the expected desilylation products of the initially formed silyl orthoester **3***c*, as shown in Scheme 2. Pyrolysis of **2***a* with the less electron-rich dienophile, β-methylstyrene, in benzene at 240°C for 48 h in a stainless steel bomb gave the expected *trans*-3-methyl-2-phenylchroman **3***e* in a 50% yield. An unexpected product, 2-benzylphenol (**4***b*), was also isolated in a 20% yield. It is not unlikely that the solvent benzene may have participated in the reaction with the *ortho*-quinone methide to give **4***b*. The reaction was repeated in cyclohexane. Again, **3***e* was isolated in 50% yield and **4***b* was obtained in 20% yield. Similarly, reaction of **2***a* with cyclohexene in cyclohexane at 240°C for 48 h gave 22% of the expected hexahydrodibenzopyran **3***f* having a *cis*-fused ring junction, and 11% of 2-benzylphenol **4***b*. These results indicate that the phenyl group must have been derived from the benzodioxaborin. This was confirmed by thermolysis of **2***a* in cyclohexane at 240°C for 20 h, which gave **4***b* in ~20% yield. Scheme 3 outlines a proposed mechanism of the formation of **4***b* from **2***a*; this may also shed some light on the mechanism of the cycloaddition reaction. Presumably, thermolysis of **2***a* could generate the intermediate **5**, which could expel phenylboronic anhydride to give the free *ortho*-quinone method **1**. In the presence of electron-rich dienophile, either **1** or **5** could react to give the corresponding chroman. In the presence of a less reactive dienophile, compound **5** could undergo a phenyl migration analogous to a [1, 5] sigmatropic phenyl shift (25–29) to give intermediate **6**, which upon work-up gave compound **4***b*. Compound **6** most likely exists as the trimer **7** similar to the formation of trimethoxyboroxine (30). It is interesting to note that no dimer or trimer of the *ortho*-quinone methide was ever isolated in this study. It is likely that intermediate **5** is the reactive species in the cycloaddition reaction instead of the free quinone methide **1**, analogous to the Lewis-acid catalyzed Diels–Alder reaction. The bulky phenyl group on boron may hinder the formation of dimers and trimers.

Indole has been utilized as dienophile in inverse electron demand Diels–Alder reactions (31–33). It is of interest to see if indole would undergo cycloaddition with *ortho*-quinone methide. Pyrolysis of a solution of **2***a* and 5-methoxyindole in cyclohexane at 245°C for 6 h gave a 41% yield of 3-(2-hydroxyphenyl)methyl-5-methoxyindole **4***c* and 11% of 2-(2-hydroxyphenyl)methyl-5-methoxyindole **4***d*. Compound **4***c* may have formed directly from 1,4-addition of the indole to the *ortho*-quinone methide, or via ring opening of the cycloadduct **3***g* (Scheme 4). If the reaction is truly a [4+2] cycloadditon, the ring opening reaction of the resulting cycloadduct may be blocked by placing a substituent on the position 3 of indole. However, thermolysis of **2***a* with methyl 3-indolepropionate gave only methyl 3-(2-(2-hydroxyphenyl)methylindole)propionate **4***f* in a 40% yield. None of the cycloadduct **3***h* was obtained. Presumably, Michael addition of the indole to the *ortho*-quinone methide gave the 3,3-disubstituted compound **4***e*, which rearranged to give **4***f* (Scheme 4). Similarly, compound **4***d* is most likely the rearranged product of **4***c*.

The effect of substituents on the 2-phenyl-4*H*-1,3,2-benzodioxaborin upon the reactivity of the resulting *ortho*-quinone methide was also studied. Several substituted benzodioxaborin derivatives were pyrolized in the presence of ethyl vinyl ether and dihydropyran. The results are summarized in Table 1. Thus, reaction of 2-phenyl-4-ethyl-1,3,2-benzodioxaborin **2***b* with ethyl vinyl ether gave the expected 2-ethoxy-4-ethylchroman **3***i* in 90% yield as a 1:1 mixture of *cis*/*trans* isomers. In contrast, a predominant *cis* isomer was obtained by Inoue *et al.* (11, 17), and Arduini *et al.* (7) who prepared similar compounds using different methods of quinone methide generation. This is probably due to the presence of the phenylboron group on the *ortho*-quinone methide intermediate **5** (Scheme 3) that perturbed the normal *endo* approach of the ethyl vinyl ether towards the quinone methide in the transition state (7). When **2***b* was allowed to react with dihydropyran at various temperatures, no cycloaddition product was obtained. Instead, a 60:40 mixture of 2-(1-propenyl)phenol **8** and its corresponding

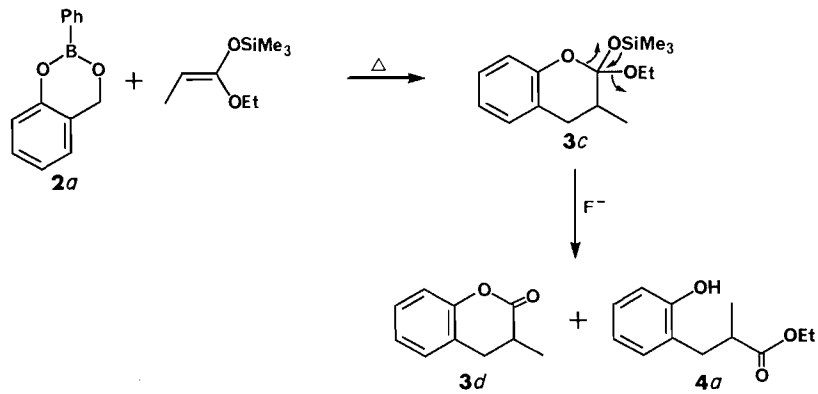

SCHEME 2

tetrahydropyranyl ether **9** was isolated in 72% combined yield. The reactivity of 2-phenyl-4-(2-phenoxyethyl)-1,3,2-benzodioxaborin **2***c* is very similar to the 4-ethyl analog just described. Reaction of **2***c* with ethyl vinyl ether at 250°C for 5.5 h gave 2-ethoxy-4-(2-phenoxyethyl)chroman **3***j* in 56% yield as a 1:1 mixture of *cis*/*trans* isomers. As well, no desired cycloaddition product was obtained with dihydropyran. The ^{1}H NMR spectra of **3***i* and **3***j* ($CDCl_3$ solution) were in accord with the observations made previously on similar compounds (7). Here, rapid interconversion of the half-chair conformation of the *cis* product results in smaller $J_{2,3}$ couplings being observed. In both cases spectral complexity precluded the measurement of $J_{3,4}$ and $J_{3,4'}$ at this field (300 MHz). Thus, $J_{2,3}$ = 4.4 Hz and $J_{2,3'}$ = 2.7 Hz for *trans* **3***j* ($\delta_{H\text{-}2}$ = 5.25), and $J_{2,3}$ = 4.9 Hz and $J_{2,3'}$ = 2.9 Hz for *cis* **3***j* ($\delta_{H\text{-}2}$ = 5.23). The relative stereochemistry was determined in a series of nuclear Overhauser effect (nOe) experiments. When the higher-field H-4 signal (δ 3.20) was irradiated, a 1.6% nOe was observed in that diastereomer's H-2 signal (δ 5.23). This must result from the close contact between these protons in the *cis* molecule where the involved protons are both pseudoaxial. No nOe resulting from such a 1,3 interaction was observed when the H-4 proton of the other diastereomer (δ 3.30) was irradiated. 2D COSY experiments confirmed the overall structure of the molecules.

An electron-withdrawing substituent like chlorine on the phenolic ring (**2***d*) appears to have no significant effect on the reactivity of the cycloaddition reaction with ethyl vinyl ether. The corresponding 2-ethoxychroman **3***k* was isolated in 77% yield. However, reaction of **2***d* with dihydropyran under various reaction conditions gave at best 10% yield of the corresponding tetrahydropyranobenzopyran **3***l*. Electron-donating groups on the phenolic ring seem to in-

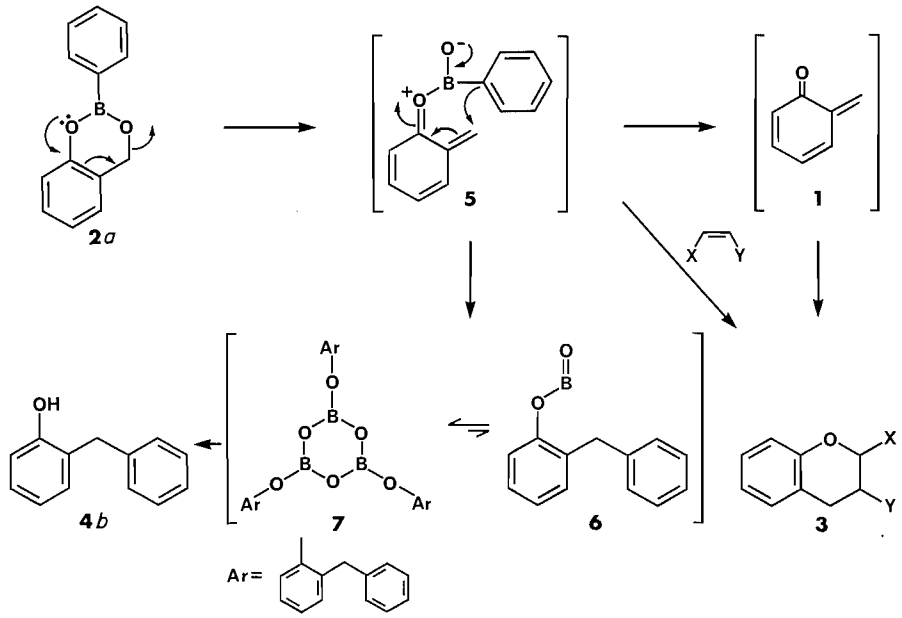
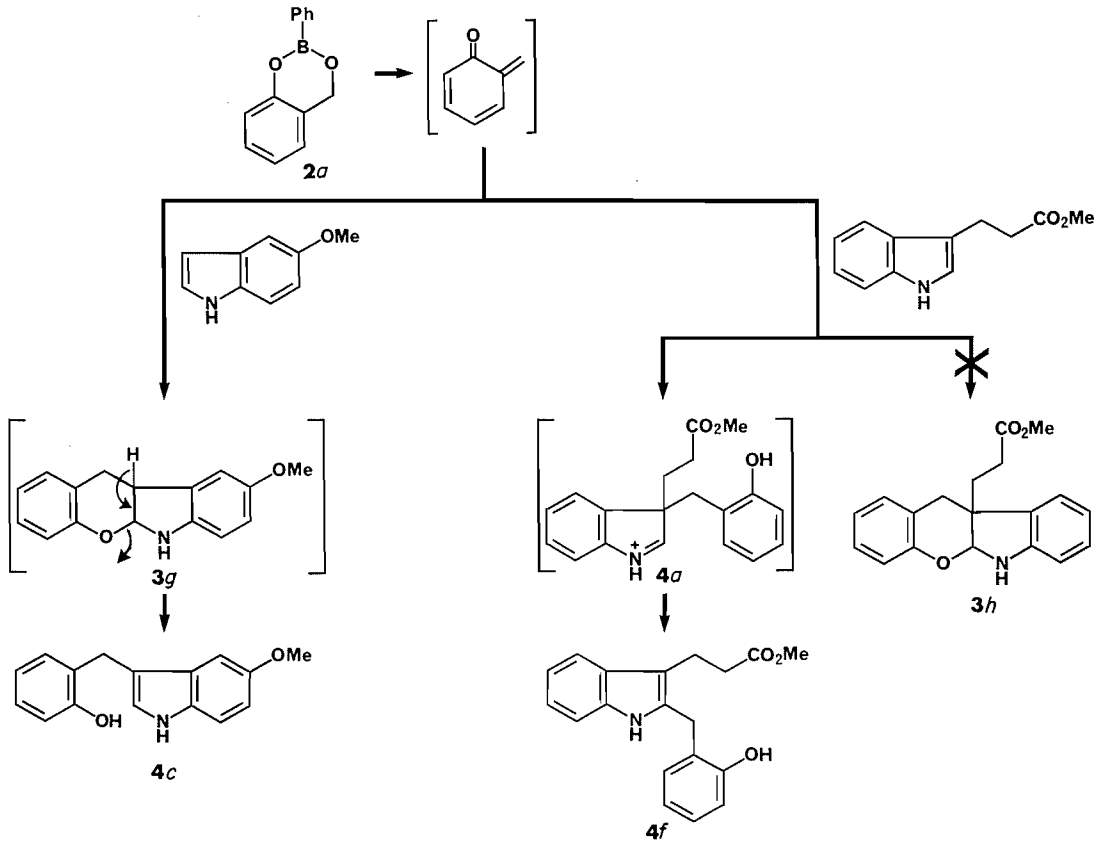


SCHEME 3



SCHEME 4

crease the reactivity of **2** in the cycloaddition reaction. Complete reaction of 4-ethyl-6-methoxy-2-phenyl-4*H*-1,3,2-benzodioxaborin **2***e* with ethyl vinyl ether occurred in only 3 h at 300°C compared to 72 h for **2***a* or 18 h for **2***b*. The desired product **3***m* was obtained in 56% yield as a 1:1 mixture of *cis*/*trans* isomers. Again, like other 4-substituted benzodioxaborins, **2***e* did not give any cycloadduct when reacted with dihydropyran. The more complex substrate methyl 9-methyl-2-phenyl-1,3,2-dioxaborinbenzofuran-8-carboxylate, **2***g*, was found to react readily with both ethyl vinyl ether and dihydropyran to give the corresponding benzopyran **3***o* and tetrahydropyranobenzopyran **3***p* in 44 and

TABLE 2. Intramolecular cyclization of 2-phenyl-4*H*-4-(4-pentenyl)-1,3,2-benzodioxaborins

	R	SOLVENT	TEMP (°C)	TIME (h)	PRODUCTS (YIELD, %)	
2*h*	H	$C_6H_5N(Et)_2$	270	0.5	**10***a* (44)	**11** (30)
		BENZENE	300	33	**10***a* (15)	**11** (32)
		$C_6H_4Cl_2$	230	7		**11** (48)
2*i*	7-OMe	BENZENE	230	48	**10***b* (43)	**11** (27)

42% yield respectively in less than 6 h. Again, compound **3***p* has the expected *cis* ring junction. The success of the latter reaction exemplifies the potential utility of the 2-phenyl-4*H*-1,3,2-benzodiozaborins in the formation of highly complex, functionalized fused-ring systems.

Intramolecular trapping of the *ortho*-quinone methide generated by this method was also achieved by heating 4-(4-pentenyl)-1,3,2-benzodioxaborin **2***h* in *N*,*N*-diethylaniline at 270°C for 0.5 h to give the hexahydrocyclopentabenzopyran **10***a* in 44% yield as a mixture of *cis*/*trans* (ratio, 15:85) isomers. A significant amount (30%) of *ortho*-(1,5-hexadienyl)phenol **11***a* was also isolated. The result is in contrast to the report by Hug *et al.* (12) that thermolysis of *ortho*-(1,5-hexadienyl)phenol at 270°C in diethylaniline yields a mixture of 2,6-methanol-3,4,5,6-tetrahydro-2*H*-1-benzoxocin and hexahydrocyclopentabenzopyran of almost equal proportion. The thermolysis of **2***h* in different solvents was studied and the results are summarized in Table 2. In benzene, at 300°C, only 15% yield of the desired cyclopentabenzopyran **10***a* was obtained after 33 h. The major product is diene **11***a* (32%). In *meta*-dichlorobenzene, after 7 h at 230°C, the only product isolated was the diene **11***a* (48%). At higher temperature and prolonged heating, extensive decomposition resulted. With an electron-donating group on the phenol ring, as in the 7-methoxy compound **2***i*, the increased reactivity due to the substituent allowed the reaction to be performed in benzene at lower temperature (230°C) to give 43% of the cyclopentabenzopyran **10***b* as a mixture of *cis*/*trans* isomers (ratio, 1:4) with only 27% yield of the diene **11***b*. The ring-junction stereochemistry of the major isomer of **10***b* was confirmed to be *trans* with ^{1}H NMR experiments. The two $J_{2,3}$ values were 11.3 and 4.1 Hz and this left the literature values (12) ambiguous. There, values of 10 and 4 Hz for these protons indicated a *trans*, and 9 and 5 Hz indicated a *cis*, ring junction. Careful analysis identified H-3 (δ 2.37) as having two large couplings of about 11.5 Hz, and a 6.8 Hz and a 1.25 Hz coupling. Upon irradiation of H-4 (δ 1.73), one of the large couplings collapsed. Molecular models predicted the *trans* isomer would have a 12.2 Hz coupling for the ring-junction protons, and 8.0 Hz for the *cis* compound.

Synthesis of cannabinoids

The successs with the intramolecular [4+2] cycloaddition of the *ortho*-quinone methides generated from the 2-phenyl-4*H*-1,3,2-benzodioxaborins described above prompted us to investigate its application to the synthesis of hexahydrocannabinol analogs. Stereocontrolled syntheses of enantiomeric pure (+)- and (−)-hexahydrocannabinols (HHC) and analogs via intramolecular Diels–Alder reactions of *ortho*-quinone methide have previously been rpeorted (2, 13, 15–18). Using the normal procedure to prepare 2-phenyl-4*H*-1,3,2-benzodioxaborins, reaction of 3-methoxyphenol with (*R*)-(+)-citronelal[2] gave a 70% isolated yield of the optically active (−)-hexahydrodibenzo[*b*,*d*]pyran **12***a* ($[\alpha]_D^{25}$ − 31 (*c* 0.7, $CHCl_3$)) in only 1.5 h. The expected initial product of this reaction, the dioxaborin derivative **2***m*, was also isolated in 10% yield as a mixture of diastereomers. Refluxing the latter in dichlorobenzene gave the same compound, **12***a*. The optical rotation of **12***a* is consistent with other HHC analogs (18). The stereochemistry of **12***a* was confirmed with NMR experiments and references to the analysis of similar compounds described elsewhere (34–36). The deshielded aliphatic signals corresponding to H-10a and H-10eq ($CDCl_3$ solution) at about δ 2.4 suffered considerable overlap and the vicinal coupling constant across the ring junction, *J*(6a, 10a) was measured to be 11.2 Hz from the H-6a signal (δ 1.34); this is consistent with a *trans* ring junction. The equatorial orientation of the 9-Me group and boat conformation of the saturated carbonaceous ring was deduced from analysis of the (highest field) H-10ax (δ 0.88). This proton signal appears as a quartet, due to approximately equal geminal and two *trans* diaxial vicinal *J*'s. H-9 is therefore axial, and the methyl substituent is equatorial. The nOe experiments (data not given) confirm these assignments and show H-10a clearly to be a doubleted triplet, as expected. Finally, ^{13}C NMR spectral analysis was consistent with the given structure (18).

Reaction of orcinol with (*R*)-(+)-citronellal gave a mixture of two regioisomers of the dioxaborin derivatives **2***o* and **2***p* in 82% yield, in the ratio of 2:3. Thermolysis of the mixture in benzene at 215°C for 18 h gave the desired HHC analogs **12***b* and **12***c* in 60% yield in the same ratio as the starting dioxaborin. Analytical samples of **12***b* and **12***c* were

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

obtained. The spectral data of **12***b* are virtually identically to those reported (18*b*). The results are summarized in Scheme 5.

Reaction of 3-methoxyphenol with citral gave 45% yield of the cannabichromene analog **13***a*. Similarly with farnesal, compound **13***b* was obtained in 80% yield. No trace of the corresponding dioxaborin intermediate was observed in either case. The formation of **13***a* and **13***b* has been interpreted as proceeding via the electrocyclization of the intermediate *ortho*-quinone methide with the α-double bond as shown in structure **14** of Scheme 5 (37, 38).

Alkylation of ortho-*quinone methides*

ortho-Quinone methide is known to react not only as heterodiene in the Diels–Alder reaction but also as a Michael acceptor (5, 17, 19). Previously we reported the reaction of 2-phenyl-1,3,2-benzodioxaborins with an alcohol, an alkylthiol, or *tert*-butylamine borane in the presence of a Lewis acid or protic acid to give the corresponding 2-substituted phenols (21). Presumably, the reaction involves Michael addition of nucleophiles to the *ortho*-quinone methide intermediate. We now report the alkylation of the *ortho*-quinone methide with carbon nucleophiles to give 2-alkyl phenols. Thus reaction of **2***b*, **2***e*, **2***d*, and **2***j* with allyl trimethylsilane in the presence of boron trifluoride etherate gave the corresponding 2-(3-butenyl)phenol derivatives **4***g*–**4***j*. The results are summarized in Table 3. With the exception of the 6-chloro derivative **2***d*, the yields are reasonable, between 70 and 80%. Reaction of **2***a* with acetophenone in the pres-

2*a*		CH_2ClCH_2Cl	70	0.5	$BF_3{\cdot}Et_2O$ (5)	 (31) **4***k*
2*f*		CH_2Cl_2	20	48	$TiCl_4$ (2)	 (25) **4***l*

ence of boron trifluoride etherate gave 31% of 2-(3-oxo-3-phenylpropyl)phenol **4***k*. Reaction of **2***f* with diethyl malonate in the presence of titanium tetrachloride gave ethyl 2-oxo-7-methoxybenzopyran-3-carboxylate **4***l* in 25% isolated yield. The latter is the result of lactonization of the initially formed 2-alkylphenol.

Arylation of ortho-*quinone methide*

ortho-Quinone methide generated from 2-phenyl-4*H*-1,3,2-benzodioxaborin under acidic conditions can be viewed as either a protonated quinone methide or a stabilized benzylic cation. Friedel-Crafts alkylations of aromatic systems with benzylic cations are well documented (39). It is thus expected that 2-phenyl-4*H*-1,3,2-benzodioxaborins should react readily with aromatic compounds under acidic conditions to give 2-arylmethyl phenols. Treatment of **2***a* with a Lewis acid in the presence of various aryl substrates gave the expected 2-substituted phenols **4***m*–**4***t*. The results are summarized in Table 4. With a less reactive substrate such as benzene or toluene, which also serves as the solvent, a stronger Lewis acid, titanium tetrachloride, was used as the catalyst. At room temperature after 1.5 h, benzene reacted with 2-phenyl-1,3,2-benzodioxaborin to give 2-benzyl phenol **4***b* in 23% yield. Toluene under similar conditions gave 76% of the 2-(4-methylbenzyl)phenol **4***m*. With the electron-rich anisole and phenol, the reaction was performed in dichloroethane at room temperature with boron trifluoride etherate as catalyst. Both gave a mixture of *ortho*- and *para*-substituted 2-benzyl phenol in the ratio of 1:4 and 1:2 respectively. With thiophene, the reaction was performed at 0°C using aluminum chloride as catalyst. The corresponding product **4***t* was isolated in 56% yield. Reaction of 4-ethyl-2-phenyl-1,3,2-benzodioxaborin **2***b* with toluene, anisol, and thiophene gave similar results to those obtained with **2***a* (Table 4). Reaction of the dioxaborin derivative of 2-(2-phenylethyl)-5-hydroxy-2,3-dihydrobenzofuran **2***j* with thiophene in trifluoroacetic acid at room temperature gave 54% of the desired 6-thiopenyl methyl derivative **4***y*.

Intramolecular alkylation of phenols via trapping of the *ortho*-quinone methide intermediate has been described (40). It was found that the *ortho*-quinone methides generated from 2-phenyl-1,3,2-benzodioxaborins under acidic conditions also react very readily intramolecularly with an aryl substituent. Treatment of 2-phenyl-4-(2-phenoxyethyl)-1,3,2-benzodioxaborin **2***c* with boron trifluoride etherate in dichloromethane at room temperature for 72 h gave the corresponding

4-(2-hydroxyphenyl)chroman **16***a* in 99% yield (Table 5). Similarly, with the dihydrobenzofuran derivative **2***k*, the corresponding 4-substituted chroman **16***b* was obtained in 78% yield. With 7-methoxy-2-phenyl-4-(3-(3-*tert*-butyldiphenylsiloxphenyl)propyl)-4*H*-1,3,2-benzodioxaborin **2***l*, the resulting tetraline **16***c* was obtained in 53% yield as a mixture of 6- and 8-*tert*-butyldiphenylsiloxy derivatives in the ratio of 1:3. These reactions represent a very efficient route to 4-phenyl substituted chromans and tetralins.

In summary, we have shown that 2-phenyl-1,3,2-benzodioxaborins serve as stable quinone methide precursors that can be prepared readily from phenols and aldehydes with varying degrees of substitution. These highly substituted benzodioxaborins can react inter- and intramolecularly with different dienophiles to generate potentially complex polycyclic chroman systems without any dimer- or trimerization of the corresponding quinone methide intermediate. Trapping of the *ortho*-quinone methide intermediates generated under acidic conditions with various carbon nucleophiles or an aryl substrate expands the utility of 2-phenyl-1-3,2-benzodioxaborins in the *ortho*-alkylation of phenols (20). Intramolecular trapping of the quinone methides with an aryl

substituent provides an efficient route to 4-phenyl-substituted chromans and tetralines (Scheme 6).

Experimental

General information

Proton nuclear magnetic resonance spectra were obtained on a Bruker AM250 spectrometer or AM300 spectrometer. Reported boiling points are those observed during distillation with a Kugelrohr apparatus and are uncorrected. Melting points were measured on a Buchi 510 melting point apparatus and are uncorrected. Low-resolution mass spectral analyses were performed by the Morgan-Schaffer Corporation, Montreal. Exact masses were obtained by high-resolution mass spectroscopy performed by Dr. O. Maimer of McGill University, Montreal, Quebec. Elemental analyses were performed by Guelph Chemical Laboratories Ltd., Guelph, Ontario. Flash chromatography was performed using Merck silica gel 60, 230–400 mesh, and tlc using Merck silica gel 60F 254 sheets.

General procedure A

Preparation of 4-ethyl-2-phenyl-4H-1,3,2-benzodioxaborin (2b)

A mixture of phenol (31 g, 0.33 mol), phenylboronic acid (64.5 g, 0.527 mol), propionaldehyde (58 g, 1 mol), and propionic acid (7.3 g, 0.1 mol) in toluene was heated under reflux for 20 h, with azeotropic removal of water using a Dean-Stark trap. The reaction mixture was concentrated and the resulting oil was chromatographed (eluting with 5% ethyl acetate in hexane) to give 64 g (82%) of the title compound; mp 43–45°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.05 (t, 3H, J = 8.34 Hz, CH_3), 1.75–2.1 (m, 2H, CH_2), 5.25 (dd, 1H, J = 8.34 Hz, J' = 4.1 Hz, benzylic), 7.00–7.55 (m, 7H), 8.0 (dd, 2H, J = 9.38 Hz, J' = 2.1 Hz). Anal. calcd. for $C_{15}H_{15}BO_2$: C 75.66, H 6.35, B 4.54; found: C 75.56, H 6.64, B 4.68.

4-(2-Phenoxyethyl)-2-phenyl-4H-1,3,2-benzodioxaborin (2c)

According to the general procedure A, using 3-phenoxypropionaldehyde, the title compound was obtained in 80% yield after chromatography; mp 91–93°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 2.18–2.35 (m, 1H), 2.35–2.51 (m, 1H), 4.08–4.20 (m, 1H, OCH_2), 4.26–4.40 (m, 1H, OCH_2), 5.50 (dd, 1H, J = 9.3 Hz, J' = 4 Hz, PhCH), 6.85–7.55 (m, 12H, 7.98, dd, 2H, J = 7.5 Hz, J' = 1.7 Hz). Exact Mass calcd. for $C_{21}H_{19}BO_3$: 330.1427; found: 330.1423.

6-Chloro-2-phenyl-4H-1,3,2-benzodioxaborin (2d)

According to the general procedure A, using 4-chlorophenol and paraformaldehyde, the title compound was obtained in 59% yield after chromatography; mp 86–90°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 5.34 (s, 2H, PhCH), 7.15–7.65 (6H, m), 8.05–8.10 (m, 2H), Anal. calcd. for $C_{13}H_{10}O_2BCl$: C 63.87, H 4.12, B 4.42, Cl 14.50; found: C 63.17, H 4.13, B 4.34, Cl 14.62.

4-Ethyl-6-methoxy-2-phenyl-4H-1,3,2-benzodioxaborin (2e)

According to the general procedure A, using 4-methoxyphenol, the title compound was obtained as an oil in 56% yield after chromatography on silica gel; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.05 (t, 3H, J = 7 Hz), 1.70–2.15 (m, 2H), 3.80 (s, 3H, OCH_3), 5.20 (t, 1H, J = 5.7 Hz, PhCH), 6.55 (d, 1H, J = 3 Hz), 6.75 (dd, 1H, J = 10 Hz, J' = 3 Hz), 7.0 (d, 1H, J = 10 Hz), 7.35–7.6 (m, 3H), 8.0 (d, 2H, J = 8 Hz). Anal. calcd. for $C_{16}H_{17}O_3B$: C 71.68, H 6.39, B 4.03; found: C 71.89, H 6.53, B 4.10.

4-Ethyl-7-methoxy-2-phenyl-1,3,2-benzodioxaborin (2f)

According to the general procedure A, using 4-methoxyphenol, the title compound was obtained as an oil in 56% yield after chromatography; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.00 (t, 3H, J =

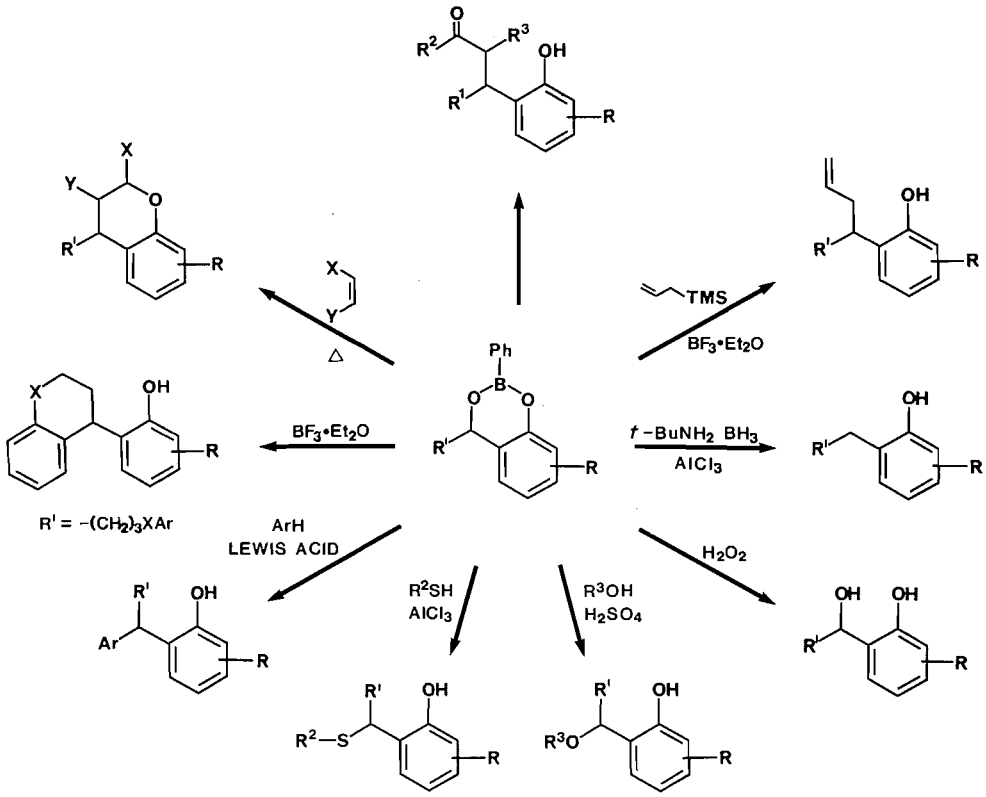

SCHEME 6

6.25 Hz), 1.69–2.05 (m, 2H), 3.8 (s, 3H, OCH_3), 5.19 (dd, 1H, J = 12.5 Hz, J' = 6.25 Hz, benzylic), 6.6 (dd, 1H, J = 12.5 Hz, J' = 3 Hz), 6.65 (d, 1H, J = 3 Hz), 6.9 (d, 1H, J = 12 Hz), 7.3–7.55 (m, 3H), 7.95 (d, 2H, J = 9.37 Hz). Exact Mass calcd. for $C_{16}H_{18}O_3B$ (M + 1): 269.1348; found: 269.1346.

4-(4-Pentenyl)-2-phenyl-1,3,2-benzodioxaborin (2h)

According to the general procedure A, using 5-heptenal, the title compound was obtained as an oil in 44% yield after chromatography; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.54–2.22 (m, 6H), 4.90–5.10 (m, 2H, $=CH_2$), 5.25 (dd, 1H, J = 7.8 Hz, J' = 3.8 Hz, PhCH), 5.70–5.90 (m, 1H, CH=), 7.0–7.6 (m, 7H), 7.97 (d, 2H, J = 8 Hz). Exact. Mass calcd. for $C_{18}H_{19}BO_2$: 278.1478; found: 278.1475.

7-Methoxy-4-(4-pentenyl)-2-phenyl-4H-1,3,2-benzodioxaborin (2i)

According to the general procedure A, using 5-heptenal and 3-methoxyphenol, the title compound was obtained as an oil in 85% yield after chromatography; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.55–2.2 (m, 6H), 3.78 (s, 3H), 4.95 (m, 2H, olefinic), 5.25 (dd, 1H, J = 9.37 Hz, J' = 6.25 Hz), 5.7–5.9 (m, 1H, olefinic), 6.62 (dd, 1H, J = 12.5 Hz, J' = 3 Hz), 6.65 (d, 1H, J = Hz), 6.95 (d, 1H, J = 10.9 Hz), 7.38–7.55 (m, 3H, aromatic), 8.0 (dd, 2H, J = 9.37, J' = 3 Hz). Exact Mass calcd. for $C_{19}H_{22}O_3B$(M + 1): 309.1662; found: 309.1658.

7,8-Dihydro-2-phenyl-2-(2-phenylethyl)-4H-furo[2,3-g]-1,3,2-benzodioxaborin (2j)

According to the general procedure A, using 2,3-dihydro-2-(2-phenyethyl)5-benzofuranol and paraformaldehyde, the title compound was obtained in 94% yield; mp 93–96°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.88–2.25 (m, 2H), 2,7–2.92 (m, 3H), 3.28 (dd, 1H, J = 7.5 Hz), 4.79 (m, 1H), 5.18 (s, 2H), 6.41 (s, 1H), 6.91 (s, 1H), 7.14–7.35 (m, 5H), 7.35–7.55 (m, 5H), 7.95 (d, 2H, J = 6 Hz). Anal. calcd. for $C_{23}H_{21}BO_3$: C 77.52, H 5.89, B 3.03; found: C 77.69, H 5.85, B 3.09. Exact Mass calcd. for $C_{23}H_{22}BO_3$(M + 1): 357.1662; found: 357.1659.

7,8-Dihydro-2-phenyl-7-(2-phenylethyl)-4-(2-phenoxyethyl)-4H-furo[2,3-g]-1,3,2-benzodioxaborin (2k)

According to the general procedure A, using 2,3-dihydro-2-(2-phenyethyl)5-benzofuranol and 3-phenoxypropionaldehyde, the title compound was obtained in 90% yield after chromatography; mp 90–92°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.88–2.07 (m, 1H), 2.07–2.27 (m, 2H), 2.34–2.48 (m, 1H), 2.70–2.91 (m, 3H), 3.27 (dd, J = 15 Hz, J' = 9 Hz), 4.09–4.18 (m, 1H), 4.25–4.36 (m, 1H), 4.70–4.75 (m, 1H), 5.45 (d br, 1H, PhCOH), 6.49 (d, 1H J = 2Hz), 6.90–6.97 (m, 3H), 7.16–7.52 (m, 11H), 7.94 (dd, 2H, J = 7 Hz, J' = 2 Hz). Exact Mass calcd. for $C_{31}H_{29}O_4B + NH_4^+$: 494.2502; found: 494.2499.

4-[3-(3-tert-Butyldiphenylsiloxphenyl)propyl]-4-phenyl-4H-1,3,2-benzodioxaborin (2l)

According to the general procedure A, using 3-methoxyphenol and 4-(3-*tert*-butyldiphenyl)butylaldehyde, the title compound was obtained in 66% yield; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.1 (s, 9H, *tert*-butyl), 1.6–1.85 (m, 4H), 2.45 (m, 2H), 3.75 (s, 3H, OCH_3), 5.15 (m, 1H, benzylic), 6.55–6.70 (m, 5H), 6.82 (d, 1H, J = 9.3 Hz), 6.95 (t, 1H, J = 7.5 Hz), 7.25–7.55 (m, 9H), 7.7 (d, 4H, J = 9.3 Hz), 7.95 (d, 2H, J = 9.3 Hz). Anal. calcd. for $C_{39}H_{41}O_4SiB$: C 76.47, H 6.70, B 1.76, Si 4.58; found: C 76.41, H 6.98, B 2.01, Si 4.75. Exact Mass calcd. for $C_{39}H_{41}O_4SiB$ − (*t*-Bu): 555.2162; found: 555.2162.

General procedure B

Thermolysis of 2-phenyl-4H-1,3,2-benzodioxaborin (2a) in ethyl vinyl ether and dihydropyran

A solution of the dioxaborin **2a** (0.212 g, 1 mmol) in ethyl vinyl ether (3 mL) was placed in a base-washed heavy-walled Pyrex tube equipped with a Teflon stopper. The solution was degassed for 2 min and then sealed under nitrogen. The tube was heated at 300°C for 72 h. Upon cooling, the reaction mixture was concen-

For personal use only.

trated under vacuum. The residual oil was chromatographed on silica gel (eluted with 2.5% ethyl acetate in hexane) to give 2-ethoxychroman **3***a* (0.134 g, 75%) (17); ^{1}H nmr (300 MHz, $CDCl_3$), δ 1.19 (t, 3H, J = 7 Hz), 1.89–2.10 (m, 2H), 2.57–2.72 (m, 1H), 2.90–3.07 (m, 1H), 3.57–3.71 (m, 1H), 3.83–3.97 (m, 1H), 5.26 (t, 1H, J = 3 Hz, OCHO), 6.80–6.92 (m, 2H), 7.02–7.17 (m, 2H). Anal. calcd. for $C_{11}H_{14}O_2$: C 74.13, H 7.92; found: C 74.14, H 8.15. Similarly, pyrolysis of **2***a* in dihydropyran for 5 h at 300°C gave the expected 3,4,4a,10a-tetrahydro-*cis*-2*H*, 5*H*-pyrano[2,3-*b*][1]benzopyran **3***b* (3) in 52% yield; ^{1}H nmr (300 MHz, $CDCl_3$), δ: 1.59–1.77 (m, 4H), 2.10–2.26 (m, 1H), 2.66 (dd, 1H, J = 16.6 Hz, J' = 4.8 Hz), 2.89–3.01 (dd, 1H, J = 16.6 Hz, J' = 4.8 Hz), 3.69–3.79 (m, 1H), 3.96–4.11 (m, 1H), 5.34 (d, 1H, J = 2.6 Hz, OCHO, *cis*-fused), 6.81–6.93 (m, 2H), 7.00–7.17 (m, 2H), Exact Mass calcd. for $C_{12}H_{14}O_2$: 190.0993; found: 190.0993.

*Thermolysis of 2-phenyl-4*H*-1,3,2-benzodioxaborin (**2**a) in 1-ethoxy-1-trimethylsiloxy-1-propene*

According to the general procedure B, a mixture of 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* (318 mg, 1.5 mmol) and 1-ethoxy-1-trimethylsiloxy-1-propene (1.04 g, 6 mmol) in benzene (6 mL) was heated to 230°C for 18 h in a stainless steel bomb. The crude reaction mixture was treated with 1 equivalent of tetra-*n*-butyl ammonium fluoride, followed by normal work-up and chromatography, to give a mixture of 3-methyl-2-chromanone **3***d* (23%) and ethyl 3-(2-hydroxyphenyl)-2-methylpropionate **4***a* (10%). **3***d*: mp 57–59°C; ir (film): 1770 (C=O) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.29 (d, 3H, J = 6.2 Hz, CH_3), 2.7–3.1 (m, 3H), 6.9–7.4 (m, 4H). Anal. calcd. for $C_{10}H_{10}O_2$: C 74.06; H 6.21; found: C 74.09, H 6.33. **4***a*: ir (film): 3400 (OH), 1710 (C=O) cm^{-1}; ^{1}H nmr (250 MHz, CD_3COCD_3), δ: 1.10 (t, 3H, J = 7 Hz, CH_3), 2.6–3.0 (m, 3H), 4.01 (q, 2H, J = 7 Hz), 6.60–7.10 (m, 2H), 8.28 (s, 1H, OH).

*Thermolysis of 2-phenyl-4*H*-1,3,2-benzodioxaborin (**2**a) in the presence of trans-β-methylstyrene*

According to the general procedure B, a mixture of 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* (420 mg, 2 mmol) and *trans*-β-methylstyrene (708 mg, 6 mmol) in benzene (6 mL) was heated to 240°C for 48 h in a stainless steel bomb. The *trans*-3-methyl-2-phenylchroman **3***e* was isolated in 50% yield after chromatography. Another product, the 2-benzylphenol **4***b* was obtained in 20% yield. **3***e*: mp 68–70°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 0.85 (d, 3H, J = 6.3 Hz, CH_3), 2.20 (m, 1H), 2.65 (dd, 1H, J = 16.8 Hz, J' = 11 Hz, PhCH), 2.87 (dd, 1H, J = 16.8 Hz, J' = 6.2 Hz, PhCH), 4.61 (d, 1H, J = 8.7 Hz, OCH), 6.7–7.5 (m, 9H). Anal. calcd. for $C_{16}H_{16}O$: C 85.68, H 7.19; found: C 85.73, H 7.27. **4***b*: ir (film): 3530 (OH) cm^{-1}; ^{1}H nmr (250 MH_3, $CDCl_3$), δ: 3.99 (s, 2H), 6.7–7.4 (m, 9H). Spectral data identical to commercial material.

The reaction was repeated in cyclohexane under identical condition. Compound **3***e* was obtained in 48% and **4***b* was isolated in 17% yield.

*Thermolysis of 2-phenyl-4*H*-1,3,2-benzodioxaborin (**2**a) in the presence of cyclohexene*

According to the general procedure B, a mixture of 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* (420 mg, 2 mmol) and cyclohexene (492 mg, 6 mmol) in cyclohexane (6 mL) was heated to 240°C for 48 h in a stainless steel bomb. The 1,2,3,4,4a,10a-hexahydrodibenzopyran **3***f* was isolated in 22% yield after chromatography on silica gel; mp 78–79°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.3–1.8 (m, 8H), 2.0 (m, 1H), 2.48 (dd, 1H, J = 16.7 Hz, J' = 2.6 Hz, PhCH), 3.0 (dd, 1H, J = 16.7 Hz, J' = 6 Hz, PhCH), 4.2 (m, 1H, OCH), 6.7–6.9 (m, 2H), 6.95–7.20 (m, 2H). Anal. calcd. for $C_{13}H_{16}O$: C 82.94, H 8.57; found: C 82.88, H 8.83. Compound **4***b* was also isolated in 11%.

*Thermolysis of 2-phenyl-4*H*-1,3,2-benzodioxaborin (**2**a) in the presence of 5-methoxy indole*

According to the general procedure B, a mixture of 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* (420 mg, 2 mmol) and 5-methoxyindole (883 mg, 6 mmol) in cyclohexane (6 mL) was heated to 245°C for 6 h in a stainless steel bomb. 3-(2-Hydroxyphenyl)methyl-5-methoxyindole **4***c* was isolated in 41% yield and 2-(2-hydroxyphenyl)methyl-5-methoxyindole **4***d* was obtained in 11% yield after chromatography of the crude mixture. Compound **4***c*: ^{1}H nmr (250 MHz, CD_3COCD_3), δ: 3.75 (s, 3H, OCH_3), 4.05 (s, 2H, $PhCH_2$), 6.65–7.20 (m, 7H), 7.25 (d, 1H, J = 8.9 Hz), 8.25 (s, 1H, OH), 9.85 (bs, 1H, NH). Exact Mass calcd. for $C_{16}H_{16}NO_2$(M + 1): 254.1181; found 254.1181. **4***d*: ^{1}H nmr (250 MHz, CD_3COCD_3), δ: 3.72 (s, 3H, OCH_3), 4.08 (s, 2H, $PhCH_2$), 6.12 (s, 1H, H-3 indole), 6.6–7.3 (m, 7H), 8.46 (bs, 1H, OH), 9.26 (bs, 1H, NH). Exact Mass calcd. for $C_{16}H_{16}NO_2$(M + 1): 254.1181; found 254.1181.

*Thermolysis of 2-phenyl-4*H*-1,3,2-benzodioxaborin (**2**a) in the presence of methyl 3-(3-indole)propionate*

According to the general procedure B, a mixture of 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* (420 mg, 2 mmol) and methyl 3-(3-indole) propionate (406 mg, 2 mmol) in cyclohexane (6 mL) was heated to 245°C for 4 h to give, after chromatography, 241 mg (40%) of methyl 3-(2-(2-hydroxyphenyl)methylindole)propionate **4***f*: ir (film): 3410 (OH, NH), 1715 (C=O) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 2.58 (t, 2H, J = 8 Hz), 3.10 (t, 2H, J = 8 Hz), 3.57 (s, 3H, OCH_3), 4.11 (s, 2H, PhCH), 6.65–7.10 (m, 6H), 7.26 (dd, 1H, J = 6 Hz, J' = 1.8 Hz), 7.47 (dd, J = 6 Hz, J' = 1.8 Hz), 8.55 (s, 1H, OH), 9.71 (s, 1H, NH). Anal. calcd. for $C_{19}H_{19}O_3N$: C 73.77, H 6.19, N 4.53; found: C 73.23, H 6.06, N 4.49. Exact Mass calcd. for $C_{19}H_{20}NO_3$(M + 1): 310.1443; found 310.1442.

*Thermolysis of 4-ethyl-2-phenyl-4*H*-1,3,2-benzodioxaborin (**2**b) in ethyl vinyl ether*

According to the general procedure B, thermolysis of **2***b* in ethyl vinyl ether at 300°C for 18 h gave 90% yield after chromatography of 2-ethoxy-4-ethylchroman **3***i* as a mixture of 1:1 *cis*/*trans* isomers (17); ^{1}H nmr (300 MHz, $CDCl_3$) assignment was based on nOe experiments; resolved signals of *cis*-**3***i*: δ: 2.75–2.88 (m, 1H, PhCH), 5.16 (dd, 1H, J = 7 Hz, J' = 3 Hz, OCHO); resolved signals of *trans*-**3***i*: δ: 2.90–3.03 (m, 1H, PhCH), 5.26 (t, 1H, J = 3 Hz). Other resonances: 0.94–1.05 (m, 3H), 1.15–1.33 (m, 3H), 1.53–2.23 (m, 4H), 3.56–3.73 (m, 1H), 3.83–4.10 (m, 1H), 6.80–6.99 (m, 2H), 7.06–7.29 (m, 2H). Anal. calcd. for $C_{13}H_{18}O_2$: C 75.69, H 8.80; found: C 75.71, H 8.82.

*Thermolysis of 4-ethyl-2-phenyl-4*H*-1,3,2-benzodioxaborin (**2**b) in dihydropyran*

According to the general procedure B, thermolysis of **2***b* in dihydropyran at 250°C for 9.5 h gave a mixture of *trans*-2-(1-propenyl)phenol **8** and its corresponding tetrahydropyranyl ether **9** in a ratio of 60:40 and a combined yield of 72%. Spectral data of compound **8** are identical to commercial material.

*Thermolysis of 4-(3-phenoxypropyl)-2-phenyl-4*H*-1,3,2-benzodioxaborin (**2**c) in ethyl vinyl ether*

According to the general procedure B, thermolysis of **2***c* in ethyl vinyl ether at 250°C for 5.5 h gave 56% yield of 2-ethoxy-4-(2-phenoxyethyl)chroman **3***j* as a 1:1 mixture of *cis-trans* isomer after chromatography; ^{1}H nmr (300 MHz, $CDCl_3$) assignment was based on nOe experiment; *trans*-**3***j*: δ: 1.21 (t, 3H, J = 3 Hz), 1.80–2.24 (m, 4H), 2.49–2.54 (m, 1H), 3.16–3.36 (m, 1H, 3.51–3.71 (m, 1H), 3.82–4.00 (m, 1H), 4.09 (t, 2H, J = 7 Hz), 5.25 (dd, 1H, J = 4.4 Hz, J' = 2.7 Hz), 6.73–7.39 (m, 9H); *cis*-**3***j*: δ: 1.19 (t, 3H, J = 7 Hz), 1.88–2.06 (m, 1H), 2.09–2.28 (m, 2H), 2.33–2.49 (m, 1H), 3.12–3.28 (m, 1H), 3.52-3.67 (m, 1H), 3.87–4.03 (m, 1H), 4.11 (t, 2H, J = 7 Hz), 5.23 (dd, 1H, J = 4.9 Hz, J' = 2.9 Hz), 6.76–7.37 (m, 9H); ms, *m*/*z*: 298 (M^+, 1.7), 253 (91), 177 (28), 159 (37), 133 (100), 131 (26). Exact Mass calcd. for $C_{17}H_{17}O_2$: (M − OC_2H_5): 253.1227; found: 253.1228.

*Thermolysis of 6-chloro-2-phenyl-4*H*-1,3,2-benzodioxaborin (**2**d) in ethyl vinyl ether*

According to the general procedure B, thermolysis of **2***d* in ethyl vinyl ether in a stainless steel bomb at 225°C for 18 h gave, after

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

chromatography, 77% yield of 6-chloro-2-ethoxychroman **3***k* as an oil; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.18 (t, 3H, J = 7 Hz), 1.85–2.15 (m, 2H), 2.59 (ddd, 1H, J = 16.3 Hz, J' = 5.8 Hz, J'' = 3.5 Hz, PhCH), 2.93 (m, 1H), 3.5–4.0 (m, 2H, OCH_2), 5.24 (t, 1H, J = 2.8 Hz, OCH), 6.74 (d, 1H, J = 8.4 Hz), 7.0–7.1 (m, 2H). Exact Mass calcd. for $C_{11}H_{13}ClO_2{\cdot}NH_4^+$: 230.0947; found: 230.0947.

*Thermolysis of 6-chloro-2-phenyl-4*H*-1,3,2-benzodioxaborin (2*d*) in dihydropyran*

According to the general procedure B, thermolysis of **2***d* in dihydropyran in a stainless steel bomb at 235°C for 18 h gave 10% yield of 7-chloro-3,4,4a,10a-tetrahydro-*cis*-2*H*,5*H*-pyrano[2,3-*b*][1]benzopyran **3***l* as an oil after chromatography; ^{1}H nmr (250 MHz, CD_3COCD_3), δ: 1.44–1.8 (m, 4H), 2.1–2.3 (m, 1H), 2.65 (dd, 1H, OCHO, J = 16.8 Hz, J' = 5 Hz, PhCH), 2.93 (dd, J = 16.8 Hz, J' = 5.8 Hz, PhCH), 3.55–3.70 (m, 1H, OCH), 3.80–4.00 (m, 1H, OCH), 3.80–4.00 (m, 1H, OCH), 5.30 (d, 1H, J = 2 Hz, OCHO), 6.77 (d, 1H, J = 8.5 Hz), 7.06 (s, 1H), 7.07 (d, 1H, J = 8.5 Hz). Exact Mass calcd. for $C_{12}H_{14}O_2Cl(M + 1)$: 225.0682; found: 225.0682.

*Thermolysis of 6-methoxy-2-phenyl-4*H*-1,3,2-benzodioxaborin (2*e*) in ethyl vinyl ether*

According to the general procedure B, thermolysis of **2***e* in ethyl vinyl ether at 300°C for 3 h gave, after chromatography, 56% yield of 2-ethoxy-4-ethyl-6-methoxychroman **3***m* as a mixture of 1:1 *cis/trans* isomers; ^{1}H nmr (250 MHz, $CDCl_3$), resolved signals of *cis*-**3***m*: δ: 2.75 (m, 1H, PhCH), 5.11 (dd, J = 7 Hz, J' = 2.7 Hz, OCHO); resolved signals of *trans*-**3***m*: δ: 2.95 (m, 1H, PhCH), 5.22 (t, 1H, J = 2.9 Hz, OCHO). Other resonances: 0.93–1.0 (3H, m), 1.15–1.27 (3H, m, J = 7 Hz), 1.57–2.20 (4H, m), 2.7–3.0 (1H, m), 3.55–4.10 (2H, m), 3.76 (3H, s), 5.10–5.25 (1H, m), 6.67–6.80 (3H, m). Anal. calcd. for $C_{14}H_{20}O_3$: C 71.16, H 8.53; found: C 71.08, H 8.54.

*Thermolysis of 9-methyl-2-phenyl-4*H*-1,3,2-dioxaborin[6,5-*e*]-benzofuran-8-carboxylate (2*g*) in ethyl vinyl ether*

According to the general procedure B, thermolysis of **2***g* in ethyl vinyl ether at 300°C for 0.5 h gave 44% yield of ethyl 3,4-dihydro-2-ethyoxy-9-methyl-2*H*-furo[2,3-*h*]-1-benzopyran-8-carboxylate **3***o* as an oil after chromatography; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.22 (t, 3H, J = 7 Hz), 1.43 (t, 3H, J = 7 Hz), 1.93–2.17 (m, 2H), 2.62–2.80 (m, 1H), 2.76 (s, 3H), 2.91–3.08 (m, 1H), 3.62–3.77 (m, 1H), 3.86–4.02 (m, 1H), 4.42 (q, 2H, J = 7 Hz), 5.30 (t, 1H, J = 3 Hz, OCHO), 7.00–7.10 (m, 2H). Anal. calcd. for $C_{17}H_{20}O_5$: C 67.09, H 6.62; found: C 66.92, H 6.56.

*Thermolysis of 9-methyl-2-phenyl-4*H*-1,3,2-dioxaborin[6,5-*e*]-benzofuran-8-carboxylate (2*g*) in dihydropyran*

According to the general procedure B, thermolysis of **2***g* in dihydropyran at 260°C for 5.5 h gave, after chromatography, 42% yield of ethyl-10-methyl-2*H*,5*H*-furo[2,3-*h*]pyrano[2,3-*b*][1]benzopyran-9-carboyxlate **3***p* as an oil; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.44 (t, 3H, J = 7 Hz), 1.58–1.78 (m, 4H), 2.17–2.31 (m, 1H), 2.63 (dd, 1H, J = 16 Hz, J' = 4.5 Hz), 2.79 (s, 3H), 3.01 (dd, 1H, J = 16 Hz, J' = 4.5 Hz), 3.70–3.85 (m, 1H), 3.97–4.13 (m, 1H), 4.42 (q, 2H, J = 7 Hz), 5.47 (d, 1H, J = 2 Hz, OCHO), 7.00–7.10 (m, 2H). Anal. calcd. for $C_{18}H_{20}O_5$: C 68.34, H 6.37; found: C 68.63, H 6.74.

*Thermolysis of 4-(4-pentenyl)-2-phenyl-4*H*-1,3,2-benzodioxaborin (2*h*)*

According to the general procedure B, thermolysis of **2***h* in *N*,*N*-diethylaniline at 270°C for 0.5 h gave, after chromatography, a mixture of *trans*-2-(1,5-hexadienyl)phenol **11***a* (30% yield) (12) and 1,2,3,3a,4,9b-hexahydrocyclopenta[*c*][1]benzopyran **10***a* (44% yield) as a mixture of *cis/trans* isomers (ratio 1:3)(6, 12); ^{1}H nmr (250 MHz, $CDCl_3$), resolved signals of *trans*-**10***a*: δ: 4.05 (dd, 1H, J = 10 Hz, J' = 10 Hz, OCH_2), 4.54 (dd, 1H, J = 10 Hz, J' = 4 Hz, OCH_2); resolved signal of *cis*-**10***a*: δ: 3.60 (t, 1H, J = 10 Hz, OCH_2); other resonances: 1.15–2.60 (m, 8H), 6.80–7.25 (m, 4H); ms, *m/z*: 174 (M^+, 100), 159 (35), 145 (65), 131 (98), 120 (30), 115 (20), 107 (35).

Thermolysis of **2***h* in benzene at 300°C for 33 h gave 15% yield of the 3,4-propanochroman **10***a* and 33% of the diene **11***a*. Thermolysis of **2***h* in *o*-dichlorobenzene at 230°C for 7 h gave only the diene **11***a* in 45% yield.

*Thermolysis of 7-methoxy-4-(4-pentenyl)2-phenyl-4*H*-1,3,2-benzodioxaborin (2*i*)*

According to the general procedure B, thermolysis of **2***i* in benzene (0.1 M) at 230°C for 48 h gave, after chromatography, 43% of the 7-methoxy-1,2,3,3a,4-9b-hexahydroxyclopenta[*c*][1]benzopyran **10***b* as a mixture of *cis/trans* isomers in the ratio of 1:4 respectively and 27% yield of the *trans*-2-(1.5-hexadienyl)-5-methoxyphenol **11***b*; ^{1}H nmr (250 MHz, $CDCl_3$), resolved signal of *trans*-**10***b*: δ: 1.73 (m, 1H, H-4, $J_{3,4}$ = 11 Hz), 2.37 (m, 1H, H-3), 2.80 (s, 3H, OCH_3), 3.97 (m, 1H, H-2a, $J_{2a,3}$ = 11.3 Hz), 4.45 (m, 1H, H-2e, $J_{2e,3}$ = 4.1 Hz); other resonances: δ 6.31 (dd, J = 2.7 Hz, J' = 2.7 Hz), 6.37 (ddd, J = 8.3 Hz, J' = 2.6 Hz, J'' = 2.6 Hz), 6.89 (dd, 1H, J = 8.3 Hz, J' = 1.1 Hz). Exact Mass calcd. for $C_{13}H_{17}O_2$ (M + 1): 205.1228; found: 205.1228. **11***b*: ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.95–2.4 (m, 4H), 3.75 (s, 3H, OMe), 4.9–5.05 (m, 2H), 5.7–6.10 (m, 1H), 6.3–6.55 (m, 2H), 7.15–7.30 (m, 3H).

*Preparation of (6a*R*,9*R*,10a*R*)-6,6,9-trimethyl-3-methoxy-6a,7,8,9,10,10a-hexahydro-6*H*-dibenzo[*b,d*]pyran (12*a*)*

According to the general procedure A, using 4-methoxyphenol and (*R*)-citronellal, the title compound **12***a* was obtained, after chromatography, as an oil in 70% yield after 1.5 h reflux in toluene; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 0.8–0.95 (m, 1H), 0.98 (d, 3H, J = 6.25 Hz), 1.0–1.1 (m, 1H), 1.05 (s, 3H), 1.2–1.35 (m, 1H), 1.38 (s, 3H), 1.5–1.7 (m, 1H), 1.8 (m, 2H), 2.35 (m, 2H), 3.75 (s, 3H, OCH_3), 6.35 (d, 1H, J = 3 Hz), 6.45 (dd, 1H, J = 12.5, J' = 3 Hz), 7.1 (d, 1H, J = 12.5 Hz). Exact Mass calcd. for $C_{17}H_{25}O_2$ (M + 1): 261.1854; found: 261.1853. The intermediate 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***m* was also isolated in 10% yield. Thermolysis of the dioxaborin **2***m* in refluxing *o*-dichlorobenzene for 18 h resulted in complete conversion to the title compound.

*Preparation of (6a*R*,9*R*,10a*R*)-1-hydroxy-3,6,6,9-tetramethyl-6a,7,8,9,10,10a-hexadyro-6*H*-dibenzo[*b,d*]pyran (12*b*) and (6a*R*,9*R*,10a*R*)-3-hydroxy-1,6,6,9-tetramethyl-6a,7,8,9,10,10a-hexahydro-6*H*-dibenzo[b,d]pyran (12*c*)*

According to the general procedure A, a mixture of orcinol (1.0 g, 7 mmol), citronelal (2.5 g, 14 mmol), phenyl boronic acid (1.36 g, 11.2 mmol), and propionic acid (30 μL, 0.35 mmol) in benzene (45 mL) was refluxed for 20 h. The reaction was quenched with NH_4OAc (100 mL) and extracted with ethyl acetate. The organic extract was dried over Na_2SO_4 and concentrated *in vacuo*. The residue was chromatographed on silica gel using 15% ethyl acetate/hexane as eluent to yield 3.3 g of a mixture of regioiosomer boronate (**2***o* and **2***p*) contaminated with citronelal. Flash distillation of the mixture (100°C, 0.1 Torr; 1 Torr = 133.3 Pa) gave 1.98 (77% yield) of boronates **2***o* and **2***p* in the ratio of 2:3. The mixture was pyrolyzed in benzene (36 mL) at 220°C in a stainless steel bomb for 2 days. After cooling, the mixture was chromatographed on silica gel and eluted with 2% ethyl acetate in hexane, yielding 0.33 g of **12***b* and 0.54 g of **12***c* (61% combined yield); ^{1}H nmr (500 MHz, $CDCL_3$) of **12***b*: δ: 0.78 (q, 1H, H-10_{ax}, J (10_{ax}, 10_{eq}) ≃ J (10_{ax}, 9) ≃ J (10_{ax}, 10a) ≃ 11.7 Hz), 0.95 (d, 3H, 9-Me, J = 6.5 Hz), 1.07 (s, 3H, 6-Me), 1.10 (m, 2H, 7_{ax}, 8_{ax}), 1.37 (s, 3H, 6-Me), 1.45 (dt, 1H, H-6a, J (6a, 10a) ≃ J (6a, 7_{ax} = 12.0 Hz), 1.6 (m, 1H, H-9), 1.8 (m, 2H, H-7, H-8), 2.19 (s, 3H, 3-Me), 2.45 (dt, 1H, H-10a, J (10a,6a) ≃ J (10a,10_{ax}) ≃11.0 Hz), 3.03 (br d, 1H, H-10_{eq}, J = 12.9 Hz), 6.08 (s, 1H, H-2 or H-4), 6.25 (s, 1H, H-2 or H-4); ^{13}C nmr (125 MHz, $CDCl_3$), δ: 19.0 (q, Me), 20.9 (q, Me), 22.6 (q, 9-Me), 27.7 (q, Me), 28.1 (t, C-7), 32.9 (d, C-9), 35.4 (d, C-10a), 35.5 (t, C-8), 39.0 (t, C-10), 49.2 (d, C-6a), 108.3 (d), 110.1 (s), 110.8 (d), 137.4 (s), 154.8 (s),

*Preparation of 7-methoxy-2-(4-methyl-3-pentenyl)-2H-1-benzopyran (**13**a)*

According to the general procedure A, using 4-methoxyphenol and citral, the title compound was obtained in 45% yield, after chromatography, as an oil after 1.5 h reflux in toluene; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.4 (s, 3H), 1.55 (s, 3H), 1.7 (m, 5H), 2.05–2.2 (m, 2H), 3.78 (s, 3H, OCH_3), 5.1 (t, 1H, J = 6.25 Hz), 5.45 (d, 1H, J = 12.5 Hz), 6.30 (d, 1H, J = 12.5 Hz), 6.35 (s, 1H), 6.38 (dd, 1H, J = 12.5, J' = 3 Hz), 6.85 (d, 1H, J = 12.5 Hz). Anal. calcd. for $C_{17}H_{22}O_2$: C 79.06, H 8.52; found: C 78.61, H 8.68. Exact Mass calcd. for $C_{17}H_{23}O_2$ (M + 1): 259.1696; found: 259.1698.

*Preparation of 7-methoxy-2-(4,8-dimethyl-3,7-nonadienyl)-2-H-1-benzopyran (**13**b)*

According to the general procedure A, using 4-methoxyphenol and farnesal, the title compound was obtained in 80% yield as an oil after 1.5 h reflux in toluene; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.38 (s, 3H), 1.55–1.75 (m, 13H), 1.90–2.2 (m, 4H), 3.75 (s, 3H, OCH_3), 5.1 (m, 2H), 5.45 (dd, 1H, J = 12.5 Hz, J' = 3 Hz), 6.35 (d, 1H, J = 12.5 Hz), 6.40 (m, 2H), 6.85 (d, 1H, J = 9.4 Hz).

General Procedure C

*Preparation of 2-(1-ethylbut-3-enyl)phenol (**4**g)*

To a solution of 4-ethyl-2-phenyl-1,3,2-benzodioxaborin (**2***b*) (0.238 g, 1.0 mmol) and allyltrimethylsilane (0.456 g, 4.0 mmol) in dichloroethane (10 mL) was added boron trifluoride etherate (0.568 g, 4.0 mmol). The mixture was warmed to 70°C for 20 h. The resulting solution was cooled, and then poured into an aqueous solution of ammonium acetate (20%). Extraction with ethyl acetate followed by chromatography of the concentrated extracts gave 136 mg (77%) of the title compound as an oil; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 0.82 (t, 3H, J = 7.3 Hz), 1.55–1.80 (m, 2H), 2.33–2.40 (m, 2H), 2.80–2.95 (m, 1H, PhCH), 4.60 (s, 1H), 4.70–5.0 (m, 2H, =CH_2), 5.55–5.80 (m, 1H, =CH), 6.5–7.2 (m, 4H). Exact Mass calcd. for $C_{12}H_{16}O{\cdot}NH_4^+$: 194.1544; found: 194.1544.

*2-(1-Ethylbut-3-ene)-4-methoxyphenol (**4**h)*

According to the general procedure C, from **2***e*, the title compound was obtained in 70% yield as an oil; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 0.82 (t, 3H, J = 7.3 Hz), 1.50–1.80 (m, 2H), 2.33–2.40 (m, 2H), 2.80–3.00 (m, 1H, PhCH), 3.76 (s, 3H, OCH_3), 4.67 (s, 1H, OH), 4.96 (m, 2H, =CH_2), 5.65–5.85 (m, 1H, =CH), 6.58–6.72 (m, 3H). Exact Mass calcd. for $C_{13}H_{18}O_2{\cdot}NH_4^+$: 224.1650; found: 224.1650.

*4-Chloro-2-(1-ethylbut-3-eneyl)phenol (**4**i)*

According to the general procedure C, from **2***d*, the title compound was obtained in 21% as an oil; ^{1}H nmr (300 MHz, $CDCl_3$), δ: 2.29–2.43 (m, 2H), 2.62–2.75 (m, 2H), 4.68 (s, 1H, OH), 4.97–5.15 (m, 2H, =CH_2), 5.78–5.97 (m, 1H, =CH), 6.69 (d, 1H, J = 7.5 Hz), 7.04 (dd, 1H, J = 7.5 Hz, J' = 2 Hz), 7.10 (d, 1H, J = 2 Hz). Anal. calcd for $C_{10}H_{11}ClO$: C 65.76, H 6.07, Cl 19.41; found: C 65.03 H 5.97, Cl 19.42.

*6-Butenyl-2,3-dihydro-2(2-phenylethyl)-5-benzofuranol (**4**j)*

According to the general procedure C, from **2***j*, the title compound was obtained in 80% as an oil; ir (film): 3401 (OH) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.85–2.20 (m, 2H), 2.30–2.45 (m, 2H), 2.60–2.90 (m, 5H), 3.50 (dd, 1H, J = 15.4 Hz, J' = 8.7 Hz), 4.31 (s, 1H, OH), 4.65–4.85 (m, 1H, OCH), 4.97–5.12 (m, 2H, =CH_2), 5.84–5.95 (m, 1H, =CH), 6.56 (s, 1H), 6.62 (s, 1H), 7.16–7.32 (m, 5H). Exact Mass calcd. for $C_{20}H_{22}O_2{\cdot}NH_4^+$: 312.1963; found: 312.1965.

*Preparation of 2-(3-oxo-3-phenylpropyl)phenol (**4**k)*

Boron trifluoride etherate (3.0 mL, 25 mmol) was added to a solution of 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* (1.05 g, 5 mmol) and acetophenone (1.8 g, 15 mmol) in 1,2-dichloroethane (15 mL). The mixture was refluxed for 30 min and then washed with water. The organic layer was dried ($MgSO_4$), filtered, concentrated, and the residue chromatographed using 5% ethyl acetate in hexane to give 350 mg (31%) of the title compound as an oil; ir (film): 1655 (C=O) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 2.6 (s, 4H), 7.1–8.1 (m, 9H).

*Preparation of ethyl 4-ethyl-2-oxo-7-methoxybenzopyran-3-carboxylate (**4**l)*

To a cooled (0°C) solution of $TiCl_4$ (90 μL, 0.82 mmol) in CH_2Cl_2 (10 mL) was added diethylmalonate (113 μL, 0.746 mmol). The mixture was stirred for 10 min at 0°C, then 4-ethyl-7-methoxy-2-phenyl-1,3,2-benzodioxaborin (0.2 g, 0.746 mmol) was added. After stirring for another 5 min, triethylamine (113 μL, 0.858 mmol) was added. The mixture was stirred at 9°C for 30 min and then overnight at room temperature. Another equivalent of $TiCl_4$ (0.746 μL, 82 mmol) was added. The mixture was stirred at room temperature overnight. The reaction mixture was quenched with cold ammonium acetate (20%) and extracted with ethyl acetate. The extract was dried over Na_2SO_4 and evaporated to dryness. The residue was chromatographed, eluting with 5% ethyl acetate/hexane. The title compound was obtained as an oil in 25% yield; ^{1}H nmr (250 MHz, $CDCl_3$) δ: 0.95 (t, 3H, J = 9.4 Hz), 1.05 (t, 3H, J = 9.4 Hz), 1.5–1.75 (m, 2H), 3.2 (m, 1H), 3.75 (d, 1H, J = 3 Hz), 3.80 (s, 3H, methoxy), 4.05 (m, 2H), 6.65–6.7 (m, 2H), 7.05 (d, 1H, J = 9.4 Hz). Exact Mass calcd. for $C_{15}H_{19}O_5$ (M + 1); 279.1232; found: 279.1232.

General Procedure D

*Preparation of 2-benzyl phenol (**4**b)*

Titanium tetrachloride (0.94 g, 5 mmol) was added to a solution of 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* (1.05 g, 5 mmol) in benzene (15 mL) and the resultant solution stirred for 1.5 h at room temperature. The solution was cooled to 5°C and excess 1 N HCl added. The mixture was stirred until two clear layers were formed. The organic layers was separated, dried ($MgSO_4$), filtered, and concentrated. The resulting oil was chromatographed on silica gel using 10% ethyl acetate in hexane as eluent to give 0.21 g (23%) of the title compound as an oil; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 3.99 (s, 2H, $PhCH_2$), 6.7–7.4 (m, 9H). Spectral data identical to commercial material.

*Preparation of 2-(4-methylbenzyl)phenol (**4**m)*

According to the general procedure D, using toluene as solvent, the title compound was obtained in 76% yield as an oil after 45 min at room temperature with only 2 mol equivalent of titanium tetrachloride; ^{1}H nmr (250 MHz, CDCl3), δ: 2.3 (s, 3H, CH_3), 3.9 (s, 2H, $PhCH_2$), 6.7–7.3 (m, 8H). Exact Mass calcd. for $C_{14}H_{15}O$ (M + 1): 199.1122; found: 199.1122.

*Preparation of 2-[1-(4-methylphenyl)propyl]phenol (**4**u)*

According to the general procedure D, using **2***b* in toluene as solvent, the title compound was obtained in 75% yield as an oil after 45 min at 0°C with only 2 mol equivalent of titanium tetrachloride; ^{1}H nmr (250 MHz, CDCl3), δ: 0.93 (t, 3H, J = 7 Hz), 1.9–2.2 (m, 2H), 4.01 (t, 1H, J = 7 Hz, PhCH), 4.61 (s, 1H, OH), 6.7–7.3 (m, 8H). Exact Mass calcd. for $C_{16}H_{19}O$ (M + 1): 227.1436; found: 227.1435.

For personal use only.

General Procedure E

Preparation of 2-(4-methyoxybenzyl)phenol (4q) and 2-(2-methoxybenzyl)phenol (4p)

Boron trifluoride etherate (3.0 mL, 25 mmol) was added to a solution of 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* (1.0 g, 5 mmol) and anisole (1.6 g, 15 mmol) in 1,2-dichloroethane (15 mL). After stirring for 2 days at room temperature the mixture was washed with H_2O, dried ($MgSO_4$), filtered, and concentrated. The residue was chromatographed using 15% ethyl acetate in hexane to give 0.63 g (58%) of an isomeric mixture of the title compounds in a ratio of 4:1 in favor of the more polar *para* isomer **4***q*: mp 80–82°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 3.8 (s, 3H, OCH_3), 3.9 (s, 2H, $PhCH_2$), 6.7–7.4 (m, 8H). Anal. calcd. for $C_{14}H_{14}O_2$: C 78.47, H 6.58; found: C 78.08, H 7.06; *ortho* isomer **4***p*: oil; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 3.92 (s, 2H, $PhCH_2$), 3.97 (s, 3H, OCH_3), 6.8–7.4 (m, 8H). Exact Mass calcd. for $C_{14}H_{15}O_2$ (M + 1): 215.1072; found: 215.1072.

Preparation of 2-(4-hydroxy)benzyl phenol (4s) and 2-(2-hydroxy)benzyl phenol (4r)

According to the general procedure E, using phenol, after 24 h an isomeric mixture of the title compounds was isolated in 66% yield in a ratio of 2:1 in favor of the more polar *para* isomer **4***s*: mp 115–117°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 3.9 (s, 2H, $PhCH_2$), 6.7–7.2 (m, 8H). Anal. calcd. for $C_{13}H_{12}O_2$: C 77.97, H 6.04; found: C 77.98, H 5.87; *ortho* isomer **4***r*: mp 112–114°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 3.9 (s, 2H, $PhCH_2$), 6.7–7.22 (m, 8H). Anal. calcd. for $C_{13}H_{12}O_2$: C 77.97, H 6.04; found: C 77.76, H 6.70.

Preparation of 2-[1-(4-methoxyphenyl)propyl]phenol (4w) and 2-[1-(2-methoxypheny)propyl]phenol (4v)

According to the general procedure E, using **2***b* and anisol, after 21 h an isomeric mixture of the title compounds was isolated in 60% yield in a ratio of 5:1 in favor of the more polar *para* isomer **4***w*: mp 69–71%C; ir (KBr): 3403 (OH) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 0.92 (t, 3H, J = 7 Hz), 1.90–2.20 (m, 2H), 4.0 (t, 1H, J = 7 Hz, PhCH), 4.68 (s, 1H, OH), 6.75 (d, 1H, J = 7.5 Hz), 6.82 (d, 2H, J = 8 Hz), 6.90–8.0 (m, 1H), 7.05–7.30 (m, 2H), 7.16 (d, 2H, J = 8 Hz). Anal calcd. for $C_{16}H_{16}O_2$: C 79.30, H 7.48; found: C 79.60, H 7.52. Exact Mass calcd. for $C_{16}H_{19}O_2$ (M + 1): 243.1385; found: 243.1385. *ortho* Isomer: oil; ir (film): 3432 (OH) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 0.91 (t, 3H, J = 7 Hz), 1.90–2.20 (m, 2H), 4.38 (t, 3H, J = 7 Hz, PhCH), 4.65 (s, 1H, OH), 6.7–7.3 (m, 8H). Exact Mass calcd. for $C_{16}H_{19}O_2$ (M + 1): 243.1385; found: 243.1384.

Preparation of 2-(2-thiophenylmethyl)phenol (4t)

To a solution of 2-phenyl-4*H*-1,3,2-benzodioxaborin **2***a* (0.848 g, 4 mmol) and thiophene (1.01 g, 12 mmol) in dichloromethane (12 mL) at 0°C was added aluminum chloride (1.6 g, 12 mmol) in portions. The reaction mixture was stirred at room temperature for 10 min. Ammonium acetate solution (20%) was added slowly and the mixture was extracted with ethyl acetate. The combined organic extract was dried over $MgSO_4$ and then concentrated *in vacuo*. Chromatography of the residue on silica gel, eluting with 10% ethyl acetate in hexane, gave 420 mg (56%) of the title compound as an oil; ir (film): 3459 (OH) cm^{-1}; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 4.18 (s, 2H, $PhCH_2$), 4.78 (s, 1H), 6.75–7.0 (m, 4H), 7.1–7.3 (m, 3H). Exact Mass calcd. for $C_{11}H_{10}OS$: 190.0452; found: 190.0453.

Preparation of 2-[1-(2-thiophenyl)propyl]phenol (4x)

Following the same procedure described for the preparation of **4***t*, using 4-ethyl-2phenyl-4*H*-1,3,2-benzodioxaborin **2***b* as starting material, the title compound was obtained as an oil in 75% yield; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 0.95 (t, 3H, J = 3.75 Hz), 2.15 (m, 2H), 4.35 (t, 1H, J = 11.25 Hz, PhCH), 4.85 (s, 1H), 6.75 (d, 1H, J = 7.5 Hz), 6.92 (m, 3H), 7.1–7.2 (m, 2H), 7.25 (d, 1H, J = 7.5 Hz). Anal. calcd. for $C_{13}H_{14}OS$: C 71.55, H 6.42, S 14.67; found: C 71.62, H 6.39, S 14.85.

Preparation of 2,3-dihydro-2-(2-phenylethyl)-6-(2-thiophenyl)methyl-5-benzofuranol (4y)

To a solution of **2***j* (1.3 g, 3.66 mmol) in trifluoroacetic acid (20 mL) was added thiophene (0.92 g, 10.98 mmol). The reaction mixture was stirred at room temperature for 2 h. The mixture was diluted with H_2O (50 mL) and neutralized with solid potassium carbonate. The mixture was extracted with ethyl acetate and the combined organic extract was concentrated *in vacuo* after drying over anhydrous $MgSO_4$. Chromatography of the residue on silica gel (eluted with 10% ethyl acetate) gave 600 mg (54%) of the title compound; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.9–2.05 (m, 1H), 2.05–2.25 (m, 1H), 2.7–2.95 (m, 3H), 3.22 (dd, 1H, J = 9.4 Hz), 4.1 (s, 2H, $PhCH_2$), 4.75 (m, 1H, OCH), 6.6 (m, 2H), 6.8–7.0 (m, 2H), 7.1–7.35 (m, 6H), Anal. calcd. for $C_{21}H_{20}O_2S$: C 74.97, H 5.99, S 9.52; found: C 74.88, H 6.32, S 9.60.

General Procedure F

Preparation of 2,3-dihydro-4-(2-hydroxyphenyl)benzopyran (16a)

Boron trifluoride etherate (0.5 mL, 4 mmol) was added to a solution of 2-phenyl-4-(2-phenoxyethyl)-4*H*-1,3,2-dioxaborin **2***c* (1.0 g, 3 mmol) in dichloromethane (10 mL). The mixture was stirred at room temperature for 72 h and then diluted with 1 N hydrochloric acid. After stirring for 5 min the organic layer was separated, dried ($MgSO_4$), filtered, and concentrated. The residue was chromatographed using 10% ethyl acetate in hexane to obtain 67 mg (99%) of the title compound; mp 81–86°C; ^{1}H nmr (250 MHz, $CDCl_3$), δ: 2.1–2.4 (m, 2H), 4.19 (t, 2H, J = 4.5 Hz, OCH_2), 4.4 (t, 1H, J = 5.5 Hz, PhCH), 4.75 (s, 1H, OH), 6.7–7.2 (m, 8H). Anal. calcd. for $C_{15}H_{14}O_2$: C 79.62, H 6.23; found: C 79.38, H 6.33.

2,3-Dihydro-6-(4-benzopyranyl)-2-(2-phenylethyl)-5-benzofuranol (16b)

According to the general procedure F, using **2***k*, the title compound was obtained in 78% as an oil; ^{1}H nmr (300 MHz, $CDCl_3$), δ: 1.87–2.01 (m, 1H), 2.03–2.30 (m, 3H), 2.65–2.89 (m, 3H), 3.20 (dd, 1H, J = 14.9 Hz, J' = 8.2 Hz), 4.10–4.28 (m, 2H, OCH_2), 4.38 (t, 1H, J = 5.6 Hz, PhCHPh), 4.63–4.77 (m, 1H, OCH), 6.34 (s, 1H), 6.61 (s, 1H, 6.76–6.95 (m, 3H), 7.08–7.32 (m, 6H); ^{13}C nmr ($CDCl_3$), δ: 155.25, 153.37, 147.00, 141.40, 131.13, 130.29, 128.40, 127.86, 125.91, 125.57, 123.94, 123.89, 120.56, 116.82, 112.58, 110.72, 82.53, 64.05, 63.99, 37.73, 37.67, 35.72, 35.44, 31.83, 29.05. Exact Mass calcd. for $C_{25}H_{24}O_3$: 372.1725; found: 372.1726.

3-Methoxy-6-(6-tert-butyldiphenylsiloxy-1,2,3,4-hexahydronaphthalenyl)phenol (16c) and 3-methoxy-6-(8-tert-butyldiphenylsiloxy-1,2,3,4-hexahydronaphthalenyl)phenol (16d)

According to the general procedure F, using **2***l*, the title compounds **16***c* and **16***d* were obtained in 53% yield as an oil in the ratio of 3:1 respectively; **16***c*: ^{1}H nmr (250 MHz, $CDCl_3$), δ: 1.1 (s, 9H), 1.55–2.0 (m, 4H), 2.6 (m, 2H), 3.75 (s, 3H, OCH_3), 4.35 (t, 1H, J = 6.25 Hz), 4.75 (s, 1H, OH), 6.25 (dd, 1H, J = 12.5, J' = 3 Hz), 6.35–6.60 (m, 5H), 7.3–7.45 (m, 6H), 7.75 (d, 4H, J = 9.4 Hz). Exact Mass calcd. for $C_{33}H_{37}O_3Si$ (M + 1): 509.2511; found: 509.2513. **16***d*: ^{1}H nmr (250 MHz, $CDCl_3$) δ: 1.1 (s, 9H), 1.6–2.05 (m, 4H), 2.6–2.75 (m, 2H), 3.75 (s, 3H, OCH_3), 4.05 (m, 1H), 4.6 (s, 1H, OH), 6.35–6.50 (m, 3H), 6.6 (d, 1H, J = 3 Hz), 6.7 (d, 1H, J = 9.4 Hz), 6.8 (d, 1H, J = 9.4 Hz), 7.4 (m, 6H), 7.7 (d, 4H, J = 9.4 Hz). Exact Mass calcd. for $C_{33}H_{37}O_3Si$ (M + 1): 509.2511; found: 509.2513.

Chiral organosilicon compounds in synthesis. Preparation and stereoselective alkylations of silylcinnamyl carbanions[1]

S. LAMOTHE,[2] K. L. COOK,[3] AND T. H. CHAN[4]
Department of Chemistry, McGill University, Montreal, P.Q., Canada, H3A 2K6

Received November 13, 1991

S. LAMOTHE, K. L. COOK, and T. H. CHAN. Can. J. Chem. **70**, 1733 (1992).

Silylallyl carbanions of type **13** bearing a chiral lithium complexing substituent remote from silicon can be alkylated regio- and stereoselectively at the α-position by small electrophiles in nonpolar solvents. The regiochemical outcome of the reaction was found to be highly dependent on the size of the incoming electrophile. Secondary alkyl halides react preferentially at the γ-center and good levels of stereoselectivity are still obtained in nonpolar solvents despite the rather long distance between the reacting center and the chiral auxiliary. Transformation of the alkylated allylsilanes into optically active alcohols and carboxylic acids may represent a potential synthetic application of the method.

S. LAMOTHE, K. L. COOK et T. H. CHAN. Can. J. Chem. **70**, 1733 (1992).

Des carbanions allyliques siliciés de type **13** porteur d'un substituant chiral pouvant complexer le lithium et distant de l'atome de silicium peuvent être alkylés régio- et stéréoselectivement à la position α par de petits électrophiles dans des solvants non-polaires. La régiosélectivité de la réaction est fortement influencée par le volume stérique de l'électrophile. Les halogénures d'alkyle secondaires réagissent préférentiellement à la position γ offrant tout de même de hauts niveaux de stéréosélectivité dans les solvants non-polaires malgré la grande distance entre le centre réactif et l'auxiliaire chiral. La transformation des allylsilanes alkylés en alcools et acides carboxyliques optiquement actifs représente une application synthétique potentielle pour la méthode.

Introduction

The extensive use of allylsilanes in organic chemistry clearly demonstrates the power of that synthetic tool (2). Among the various possible reactions available to these compounds are alkylations of their derived carbanions.[5] It is well-known that allylsilanes **1** (Scheme 1) can be deprotonated to give the corresponding silylallyl carbanions **2** which react with alkylating agents preferentialy at the γ-position yielding vinylsilanes **3** as major products (3).

However, it was recently demonstrated in this laboratory that the use of chelating substituents on silicon can favor the formation of α-alkylated derivatives **4** through internal complexation of lithium (4). Moreover, preliminary results have shown that in addition to regioselectivity, stereoselectivity of alkylations can also be controlled when using a chiral ligand. As an example, when proline derived ligand in **5** (Scheme 2) was used, the α-alkylated allylsilanes **6** were obtained as single diastereoisomers. Such an approach has also been used to control stereoselectivity in the alkylations of benzylic silane **7** (5). The alkylated derivatives **8** could then be transformed into alcohols **9** (>95% ee) via oxidative cleavage of the carbon-silicon bond with retention of stereochemical integrity (6). To extend the scope of this method we decided to investigate the alkylations of chiral silylcinnamyl carbanions.

Results

Preparation and methylations of **10**

Our first target was the chiral cinnamylsilane **10** (Scheme 3) which was readily prepared in two steps from commercially available starting materials.[6] In the event, allylbenzene (**11**) was metallated (7) with *sec*-BuLi in ether and the resulting allylanion was quenched with chloro(chloromethyl)dimethylsilane affording **12** in 90% yield. Condensation of **12** with (*S*)-(+)-methoxymethylpyrrolidine[7] gave the requisite chiral allylsilane **10** in 80% yield.

Deprotonation of **10** with *sec*-BuLi presumably leads to an internally chelated carbanion **13** (Scheme 4) on which lithium would lie closer to the α-position (4). Upon alkylation with various electrophiles, α-silylcinnamyl carbanion **13** can lead to 8 stereoisomers, depending on olefin stereochemistry and absolute configuration at the alkylated center. In all the reactions that were carried out, the α-*E* and γ-*E* isomers **14***a–d* and **15***a–d* accounted for most of the alkylated products balance. The remainder consisted of *Z*-isomers which were apparent by spectral analysis although further characterisation was not pursued.

Alkylation of **10** was first carried out in THF using methyl iodide as the electrophile (Table 1, entry 1). Deprotonation of **10** using *sec*-BuLi went smoothly at −78°C and alkylation was instantaneous at that same temperature. Although quite clean in giving essentially the α-*E* (**14***a*) and γ-*E* (**15***a*) isomers in high combined yield, the reaction showed disappointing regio- and stereochemical control. However, when THF was replaced by diethyl ether as the solvent (entry 2), the increase in α-regioselectivity was quite spectacular. Moreover, the α-*E* isomer was essentially obtained as a pure diastereoisomer and the absolute configuration of the newly created stereocenter was determined by oxidative cleavage of the carbon-silicon bond (*vide infra*). The fact that some starting material was recovered could have been due to the reduced rate of either deprotonation or alkylation in ether relative to THF. By carrying out the deprotonation over a longer period of time (3 h instead of 0.5, entry 3) we obtained after 0.5 h alkylation time essentially the same amount of starting material, showing that the alkylation process was the one that had slowed down upon solvent change. To speed

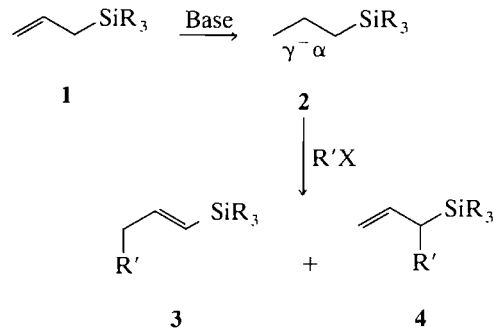
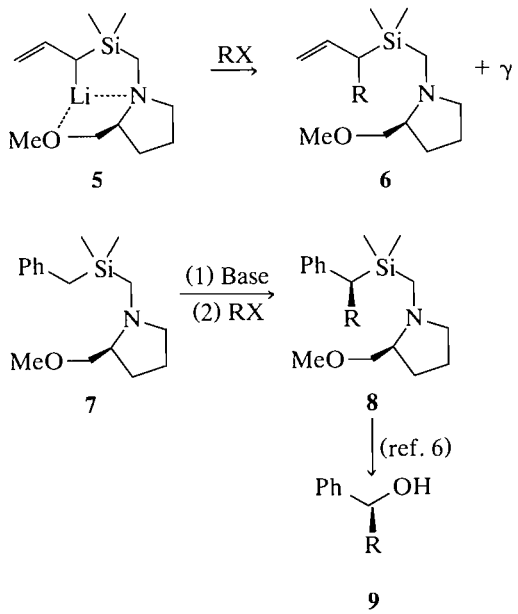


SCHEME 1



SCHEME 2

up the reaction, the mixture was allowed to warm up to room temperature after the addition of methyl iodide (entry 4). This procedure led to slightly lower α-selectivity while maintaining a high level of diastereoselectivity.

Another way to obtain a sufficient rate of alkylation at −78°C was to add a large excess of alkylating agent (entry 5). Under these conditions, the reaction was completed within 0.5 h at −78°C, thereby insuring excellent α-regio- and diastereoselectivity.

Among other solvents investigated, DME (entry 6) gave results comparable to THF while diisopropyl ether (entry 7) was comparable to diethyl ether. Since decreasing solvent polarity (or complexing ability) seemed to be the key to better control, the reaction was carried out in nonpolar media. While hexanes (entry 8) led to results comparable to ether, some solubility problems were encountered. However, when toluene was used (entry 9), the best overall results were obtained as the α-*E* adduct **14***a* accounted for 90% of the alkylation products. Moreover, excellent diastereoselectivity was obtained for this isomer. Since regioisomers can be separated easily by column chromatography on silica gel, pure α-*E* isomer can thus be obtained in high overall yield.

Other alkylations of **10**

Regioselectivity in the alkylation of the carbanion derived from **10** shows great dependence on the size of the incoming electrophile[8] (4). Reaction of carbanion **13** with ethyl iodide in THF (Table 2, entry 1) results in low regio- and diastereoselection reminiscent of the methyl iodide case. Use of ether (entry 2), again increased the ratio of α-*E* isomer **14***b* (68%) and at the same time provided excellent diastereoselectivity. To improve the extent of α-alkylation, leaving group ability was briefly examined as a potential source of regiochemical control. Reaction with ethyl bromide resulted in low yields and decreased α-selectivity (not shown in Table 2) while ethyl triflate (entry 3) gave α:γ (**14***b*:**15***b*) ratios comparable to those obtained with the corresponding iodide under similar conditions.

Equilibration of the carbanion by warming it up to room temperature prior to alkylation at −78°C (entry 4) did not affect the outcome of the reaction.

As in the case of methylation, it was found that alkylation with ethyl iodide at −78°C (entry 5) could improve α-selectivity at the expense of using a large excess of alkylating agent (20 equiv.) and longer reaction time.

Alkylations in DME (entry 6), diisopropyl ether (entry 7), and pentane (entry 8) followed the same trend as the methylation reactions. Again, use of toluene (entry 9) led to the cleanest reaction as only α-*E* (**14***b*) and γ-*E* (**15***b*) isomers were detected. In this case, α-selectivity was around 4:1 with excellent diastereoselection (>90%).

Alkylation of **10** with *n*-hexyl iodide (entries 10, 11) led to regioisomer as well as diastereoisomer ratios (**14***c*:**15***c*) similar to those obtained with ethyl iodide under similar conditions.

When a secondary iodide such as isopropyl iodide was used as the electrophile, the reaction showed a totally different outcome. As the bulk of the alkylating agent is increased, γ-alkylation takes over as the major pathway. Performing the reaction in THF (entry 12) offered as high as

[9]Ratios based on 25% starting material recovered.

90% γ-selectivity, but as for other reactions in that solvent, low diastereoselectivity (4%) was observed for the major adduct. Interestingly, changing the solvent to ether (entry 13) increased diastereocontrol on γ-adduct **15***d*, which was still the favored regioisomer. This control was even better in toluene (entry 14) where 85% γ-selectivity was observed with the major regioisomer obtained as an 8:1 mixture of diastereoisomers.

Effect of substitution on the aromatic ring

To improve α-regioselectivity we briefly examined the effect of adding an electron-releasing substituent on the aromatic ring. According to the allopolarisation concept on regioselectivity in reactions of ambident nucleophiles (10), the presence of such a substituent should drive alkylation away from its point of attachment which is in this case the γ-position. Allylsilane **16** bearing a *para*-methoxy group (Scheme 3) was prepared from *para*-methoxyallylbenzene (**17**) through chlorosilane **18** using the same strategy as before. In this case, however, yields were lower in the initial step leading to **18** due to problems associated with increased reactivity of the allylanion.

Nevertheless, methylation of silylallyl carbanion **19** (Scheme 4) in THF (Table 3, entry 1) afforded, as expected, increased α-selectivity relative to the parent non-methoxylated derivative as α-*E* isomer **20***a* accounted for 75% of the alkylated product mixture. However, as was noted in previous alkylations using this solvent, diastereoselection was poor. Using ether as the solvent (entry 2) increased stereoselectivity on all levels. Interestingly, alkylation with ethyl iodide (entry 3) furnished the α-*E* adduct **20***b* with 88% selectivity which represents an improvement in regioselectivity compared to ethylation of the parent unsubstituted derivative **10**.

Variations in the chiral auxiliary

Effects of the variations in the chiral auxiliary of the allylsilane were also investigated. Condensation of chlorosilane **12** (Scheme 5) with *O*-methylated (−)-ephedrin **22** (11) furnished allylsilane **23** using the standard procedure. Al-

kylations of this compound with methyl iodide in ether or THF (Table 3, entries 4 and 5) followed a regioselectivity pattern similar to the one observed for compound **10**. However, the diastereoselectivity of these reactions was poor in both solvents, making this auxiliary much less satisfactory than the pyrrolidine derivative.

Alternatively, (*S*)-(+)-1-(2-pyrrolidinylmethyl)pyrrolidine (**25**, Scheme 5) was used to prepare chiral allylsilane **26**. Unfortunately, its alkylation with methyl iodide in ether (Table 3, entry 6) led to no improvement in α-regioselectivity. On the other hand, diastereoselectivity of α-alkylation was maintained.

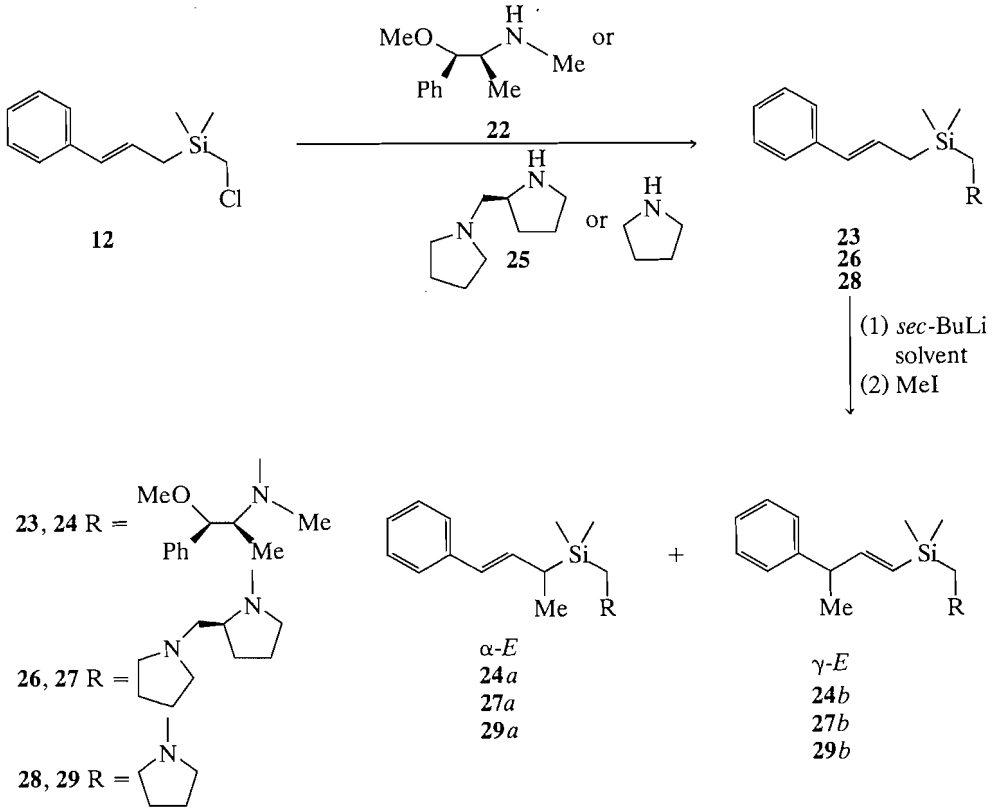
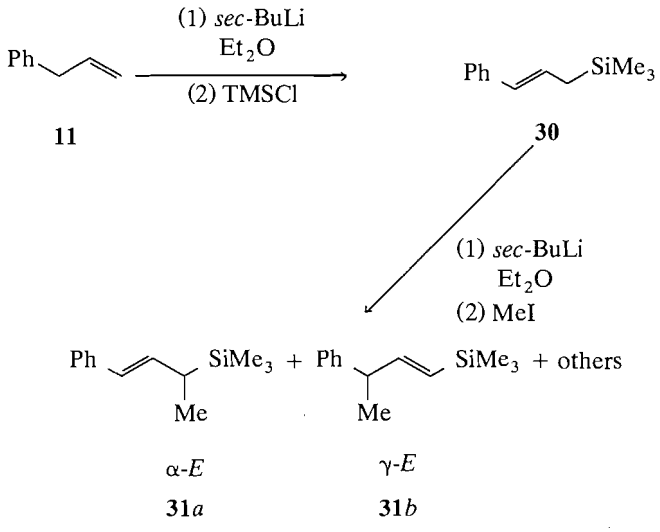


SCHEME 5



SCHEME 6

Determination of absolute configuration at alkylated centers

The absolute stereochemistry of the newly created asymmetric centers in alkylated allylsilanes was determined by chemical transformations into derivatives of known stereochemistry. The α-adducts were treated according to the procedure described for alkylated benzylic silanes **7** (Scheme 2) (5, 6). Methylated derivatives **14***a* and **24***a* (Scheme 7) afforded alcohol **32** (12) while ethyl alkylated derivative **14***b* gave alcohol **33** (13). For both **14***a* and **14***b* obtained by reaction in toluene or ether, the absolute configuration of the resulting alcohol was found to be "*S*" showing that reaction in these solvents afforded isomers **34** (Scheme 8).[9]

In the case of the γ-adducts **15***a* and **15***d* (Scheme 6), the olefin was cleaved by oxidation with $RuCl_3/NaIO_4$ according to the procedure described by Sharpless *et al.* (14). This reaction afforded substituted phenylacetic acids **35** and **36** (15) for which optical rotation values were compared with previously reported ones. As it turned out, the major enantiomer obtained for product **36** issued from alkylation in toluene or ether had the "*S*" configuration. This implies that the precursor allylsilane had the "*R*" configuration at the alkylated center[9] as shown in structure **37** (Scheme 8).

Reactions of achiral silylcinnamyl carbanions

We have also examined the alkylation reactions of simple silylcinnamyl carbanions in order to understand the factors controlling the regioselection in these systems. The allylsilane **28** (Scheme 5) was prepared from pyrrolidine and **12**. When compound **28** was reacted with methyl iodide in THF (Table 3, entry 7), the α-*E* and γ-*E* adducts **29***a* and **29***b* were obtained in a ratio (1:1.15) similar to the one observed with the methoxymethyl group present on the ring (i.e., 1:1.13). However, when this same reaction was carried out in ether (entry 8) and contrary to the case where oxygen function is present, the α:γ ratio remains essentially unchanged.

Furthermore, the alkylation of the carbanion derived from cinnamyltrimethylsilane **30** (prepared from **11**, Scheme 6) was also examined. Methylation under similar conditions

[9]The absolute configuration for the alkylated center in **15***d* and **36** have opposite "*R*, *S*" designations due to a change in priority sequence.

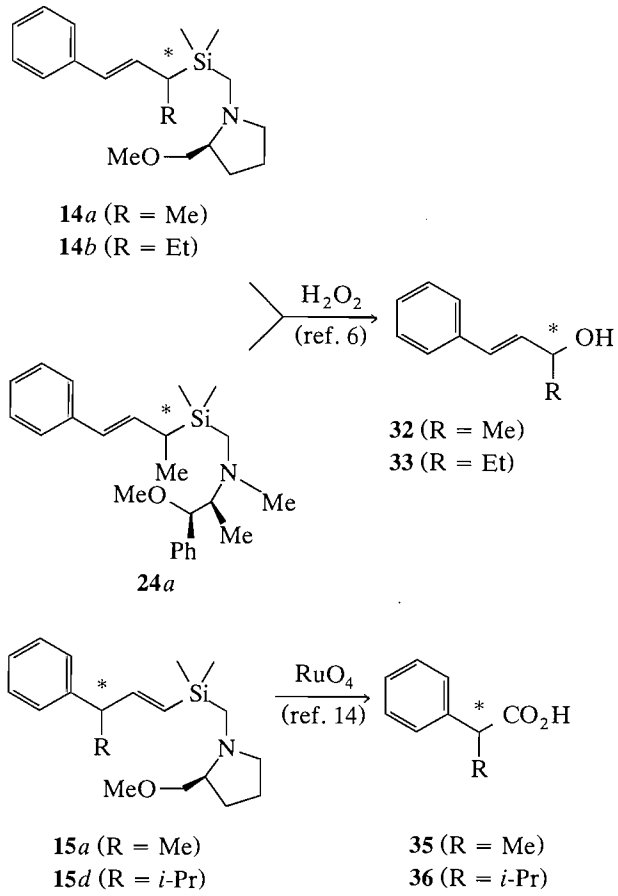
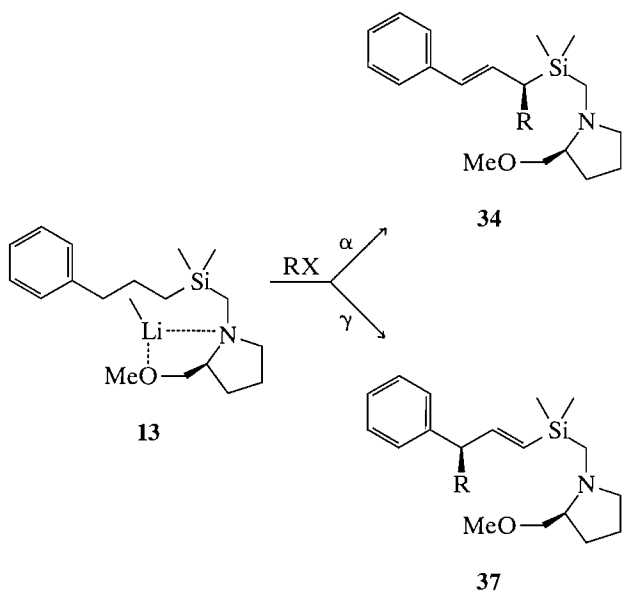


SCHEME 7



SCHEME 8

gave a low yield of the alkylated products due to competing reactions by addition of the base to the styrene system. Nevertheless, the alkylated products still showed an α-*E*:γ-*E* ratio (**31***a*:**31***b*) close to 1:1.

Discussion

In our previous study on the alkylation of silylallyl anions, we have demonstrated that the regioselectivity of the reactions can be controlled by having metal-ion complexing substituents on silicon (4). In the silylcinnamyl carbanions, the presence of the phenyl substituent on the allylic system modulates the regioselection somewhat. Whereas methylation of simple trimethylsilylallyl anion gives predominantly the γ-*E* alkylated product, the same methylation of trimethylsilylcinnamyl anion **30** gives an α-*E*:γ-*E* ratio close to 1:1. Regioselectivity of the reaction can be similarly affected by internal complexation with the introduction of metal-ion complexing substituents on silicon. The effective substituents seem to require a bidentate ligand since pyrrolidine itself in **28** does not give enhanced α-regioselection. Of the three carbanions with bidentate ligands derived from **10**, **23**, and **26**, the preference for α-alkylation is in fact poorer for **26** even though it is generally assumed that the diamino-type ligand complexes more strongly with lithium ion. A possible explanation is that the pyrrolidinylmethyl group in **26** is sterically bulkier, and it is well established that sterically bulky substituents on silicon favors γ-regioselection (3). Solvent plays an important role. In general, ether, toluene, and hexane favour higher α-alkylation whereas THF and DME reduce α-selection. This can be attributed to the competition of solvent with the internal complexation of the lithium ion. Of the three chiral auxiliaries used in **10**, **23**, and **26**, it is clear that the ephedrine ligand is relatively ineffective in conferring high stereoselectivity even though it is quite effective in controlling regioselectivity. All in all, methoxymethylprrolidine appears to be the ligand of choice in giving the best regioselection as well as stereoselection. In ether or toluene as the solvent, the carbanion derived from **10** alkylates with primary alkyl halides to give mainly the α-*E* alkylated products with excellent stereoselection (>90% de). Alkylation with isopropyl iodide gives mainly the γ-*E*-alkylated product with high stereoselection (78% de). This stereoselectivity is quite remarkable because the newly created asymmetric center is separated from the resident chiral center by a chain of 7 atoms. The absolute configurations of the major enantiomers obtained for the alkylation products **34** and **37** (Scheme 8) issued from alkylation in toluene or ether have "*S*" and "*R*" configurations respectively. These results show that for reactions occuring in less coordinating solvents (toluene or ether), the transoid silylallyl carbanion **13** is alkylated from the same face whether the electrophile is large (γ-selective) or small (α-selective).

Conclusion

This work shows that the use of chiral coordinating substituents remote from silicon can efficiently control alkylation pathways of silylallyl carbanions. The best substrate for that purpose was found to be allylsilane **10** bearing a proline derived chiral ligand. Alkylations of this compound with small electrophiles in non-polar solvents were highly α-selective and diastereoselectivity was excellent in all cases. Reaction with larger electrophiles favored γ-alkylation but still gave good diastereocontrol despite the distance between the chiral auxiliary and the reacting center. Transformation of the alkylated materials into optically active alcohols and carboxylic acids represents a potential synthetic application of the method.

Experimental

All reactions were carried out under argon atmosphere. The infrared spectra (IR) were recorded on an Analect FT, AQS-18 instrument. ^{1}H and ^{13}C NMR spectra were recorded on Varian XL-200

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

or XL-300 or on a Gemini-200 instruments. All NMR spectra were recorded in $CDCl_3$ as solvent and internal standard. Abbreviations used are m, multiplet, br, broad, s, singlet, d, doublet, t, triplet, q, quartet, qn, quintet, dd, double doublets, dt, double triplets. Low resolution mass spectra were recorded on a Kratos MS25RFA or on a HP-5980A instruments and are reported as mass (% intensity). High resolution mass spectra were recorded on a ZAB 2F HS spectrometer. Capillary gas chromatographic analysis was performed on a Hewlett-Packard 5890A instrument fitted with a 25 m × 0.2 mm high performance column (cross-linked methylsilicon, film thickness of 0.33 μm). GC/MS analysis were obtained using a Finnigan Mat 700 ion trap detector coupled to a Varian 3500 capillary gas chromatograph. Column chromatography purifications were performed on Merck silica gel 60 (230–400 mesh ASTM).

Cinnamyldimethyl-[(Ŝ)-2'-methoxymethylpyrrolidinyl]-methylsilane ***10***

A mixture of chloride **12** (1.53 g, 6.8 mmol) and (*S*)-2-methoxymethylpyrrolidine (1.57 g, 13.6 mmol) was heated at 80°C (oil bath temperature) for 24 h. After cooling to room temperature, ether and brine were added and the layers were separated. The aqueous layer was extracted with ether and the combined organic layers were dried over $MgSO_4$, filtered, and concentrated under reduced pressure to afford an oil which was purified by flash chromatography (25–100% ethyl acetate in hexane) yielding pure aminosilane **10** (1.69 g, 81%) as a pale yellow oil: $[\alpha]^{25}_D$ −77.8 (*c* 2.54, $CHCl_3$); IR ($CHCl_3$): 3023, 2955, 2875, 1113 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m), 6.40–6.20 (2H, m), 3.42 (1H, dd, *J* = 9 and 4.5 Hz), 3.34 (3H, s), 3.24 (1H, dd, *J* = 9 and 6.5 Hz), 3.09 (1H, m), 2.53 (1H, d, *J* = 14 Hz), 2.37 (1H, m), 2.09 (1H, q, *J* = 8.5 Hz), 2.00–1.50 (7H, m), 0.11 (3H, s), 0.08 (3H, s); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 138.32, 128.31, 128.26, 127.46, 126.04, 125.34, 76.34, 67.40, 58.90, 57.40, 44.70, 28.30, 23.10, 22.20, −3.10, −3.30; HRMS (CI, NH_3) calcd. for $C_{18}H_{29}ONSi + H^+$: 304.2098; found: 304.2097.

Chloromethyl(cinnamyl)dimethylsilane (12)

To a solution of allylbenzene (**11**) (1.0 g, 8.5 mmol) in ether (15 mL) at 0°C was added *sec*-BuLi (1.3 M in cyclohexane, 8.1 mL, 10.6 mmol). After the addition, the mixture was warmed to room temperature and stirred for 2 h after which time it was cooled to −78°C. Chloro(chloromethyl)dimethylsilane (1.34 g, 9.3 mmol) was added and the mixture was stirred for 30 min at −78°C. Saturated NH_4Cl was then added followed by ether. The layers were separated and the aqueous layer was extracted twice with ether. The combined organic layers were washed with brine, dried over $MgSO_4$, filtered, and concentrated under reduced pressure (0.1 Torr; 1 Torr = 133.3 Pa) to afford crude chloride **12** (1.7 g, 90%) as a pale yellow oil; IR (neat): 3082, 3060, 3023, 2960, 2925, 1643, 1598, 1496, 1250 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 7.1–7.4 (5H, m), 6.15–6.40 (2H, m), 2.86 (2H, s), 1.85 (2H, d, *J* = 7 Hz), 0.20 (6H, s); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 138.2, 129.5, 128.6, 126.6, 126.1, 125.7, 29.5, 20.38, −5.06; HRMS (CI, NH_3) calcd. for $C_{12}H_{17}SiCl + NH_4^+$: 242.1132; found: 242.1133.

General procedure for allylsilane alkylations

To a solution of allylsilane (50 mg) in solvent (1 mL) at −78°C was added *sec*-BuLi (1.3 M in cyclohexane). The amount of base and length of time needed for deprotonation are listed in Tables 1–3. The electrophile was then added and the various conditions used for alkylations are also listed in Tables 1–3. The resulting mixture was quenched with saturated NH_4Cl solution and was extracted with ether. The combined organic layers were washed with brine and dried over $MgSO_4$. Evaporation of the solvents gave crude alkylation products mixtures which were anlaysed by ^1H NMR as well as capillary GC and (or) GCMS. If desired, in most instances, regioisomers could be separated by column chromatography on silica gel using hexane/ethyl acetate mixtures as eluent. The following is a representative example.

Methyl alkylated derivatives ***14***a *("S"),* ***14***a *("R") and* ***15***a[10]

To a solution of allylsilane **10** (50 mg) in ether (1 ml) at −78°C was added *sec*-BuLi (2 equiv., 1.3 M in cyclohexane). The mixture was stirred for 60 min. To the mixture, methyl iodide (10 equiv.) was added and stirred for 1 h at −78°C. The resulting mixture was quenched with saturated NH_4Cl solution and extracted with ether. The combined organic layers were washed with brine and dried over $MgSO_4$. Evaporation of solvents gave the crude alkylation products mixture which was chromatographed on silica gel using hexane/ethyl acetate as eluent to give the methyl alkylated derivative **14***a* and **15***a* in 89 and 5% yield respectively based on GC and ^1H NMR analyses. ^1H NMR (300 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m, **14***a* ("*S*"), **14***a* ("*R*"), **15***a*), 6.38 (1H, dd, *J* = 16.0 and 8.0 Hz, **14***a* ("*S*"), **14***a* ("*R*")), 6.24 (1H, dd, *J* = 18.5 and 6.0 Hz, **15***a*), 6.21 (1H, dm, *J* = 16.0 Hz, **14***a* ("*S*"), **14***a* ("*R*")), 5.70 (1H, dd, *J* = 18.5 and 1.5 Hz, **15***a*), 3.48 (1H, qn, *J* = 7.1 Hz, **15***a*), 3.50–3.40 (1H, m, **14***a* ("*S*"), **14***a* ("*R*"), **15***a*), 3.34 (3H, s, **15***a*), 3.33 (3H, s, **14***a* ("*S*"), **14***a* ("*R*")), 3.30–3.15 (1H, m, **14***a* ("*S*"), **14***a* ("*R*"), **15***a*), 3.06 (1H, m, **14***a* ("*S*"), **14***a* ("*R*"), **15***a*), 2.57 (1H, d, *J* = 14.5 Hz, **14***a* ("*S*"), **14***a* ("*R*")), 2.48 (1H, d, *J* = 14.5 Hz, **15***a*), 2.37 (1H, m, **14***a* ("*S*"), **14***a* ("*R*"), **15***a*), 2.11 (1H, m, **14***a* ("*S*"), **14***a* ("*R*"), **15***a*), 2.00–1.50 (5H, m, **15***a* and 6H, m, **14***a* ("*S*"), **14***a* ("*R*")), 1.36 (3H, d, *J* = 7.0 Hz, **15***a*), 1.21 (3H, d, *J* = 7.0 Hz, **14***a* ("*R*")), 1.20 (3H, d, *J* = 7.0 Hz, **14***a* ("*S*")), 0.12 (3H, s, **15***a*), 0.11 (3H, s, **14***a* ("*S*")), 0.10 (3H, s, **14***a* ("*R*"), **15***a*), 0.04 (3H, s, **14***a* ("*R*")), 0.03 (3H, s, **14***a* ("*S*")); GCMS *m/e* (EI): isomers **14***a* ("*S*"), **14***a* ("*R*") (not resolved), 272 ($M^+ - CH_2OCH_3$, 100), 186 (81), 154 (38), 131 (26), 128 (56); isomers **15***a*, 272 ($M^+ - CH_2OCH_3$, 100), 166 (7), 131 (7), 128 (22).

Ethyl alkylated derivatives ***14***b *("S"),* ***14***b *("R") and* ***15***b

The general procedure was followed; for additional details see Table 2. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m, **14***b* ("*S*"), **14***b* ("*R*"), **15***b*), 6.26 (1H, d, *J* = 16.0, **14***b* ("*S*")), 6.25 (1H, d, *J* = 16.0, **14***b* ("*R*")), 6.17 (1H, dd, *J* = 18.5 and 7.0 Hz, **15***b*), 6.13 (1H, dd, *J* = 16.0 and 8.5 Hz, **14***b* ("*S*")), 6.09 (1H, dd, *J* = 16.0 and 9.0 Hz, **14***b* ("*R*")), 5.67 (1H, dd, *J* = 18.5 and 1.0 Hz, **15***b*), 3.50–3.35 (1H, m, **14***b* ("*S*"), **14***b* ("*R*"), **15***b*), 3.33 (3H, s, **15***b*), 3.32 (3H, s, **14***b* ("*R*")), 3.31 (3H, s, **14***b* ("*S*")), 3.30–2.95 (2H, m, **14***b* ("*S*"), **14***b* ("*R*") and 3H, m, **15***b*), 2.55 (1H, d, *J* = 14.0 Hz, **14***b* ("*S*"), **14***b* ("*R*")), 2.46 (1H, d, *J* = 14.5 Hz, **15***b*), 2.35–2.25 (1H, m, **14***b* ("*S*"), **14***b* ("*R*"), **15***b*), 2.20–2.00 (1H, m, **14***b* ("*S*"), **14***b* ("*R*"), **15***b*), 2.00–1.40 (7H, m, **15***b* and 8H, m, **14***b* ("*S*"), **14***b* ("*R*")), 0.95 (3H, t, *J* = 7.0 Hz, **14***b* ("*S*"), **14***b* ("*R*")), 0.85 (3H, t, *J* = 7.5 Hz, **15***b*), 0.11 (3H, s, **15***b*), 0.10 (3H, s, **14***b* ("*S*") and **15***b**), 0.08 (3H, s, **14***b* ("*R*"), **15***b*), 0.07 (3H, s, **15***b**), 0.04 (3H, s, **14***b* ("*R*")), 0.02 (3H, s, **14***b* ("*S*")); GCMS *m/e* (EI): isomers **14***b* ("*S*"), **14***b* ("*R*") (not resolved), 286 ($M^+ - CH_2OCH_3$, 89), 186 (91), 154 (40), 145 (15), 144 (17), 128 (100); isomers **15***b*, 286 ($M^+ - CH_2OCH_3$, 100), 166 (6), 135 (10), 128 (18), 115 (6).

Hexyl alkylated derivatives ***14***c *("S"),* ***14***c *("R") and* ***15***c

The general procedure was followed; for additional details see Table 2. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m, **14***c* ("*S*"), **14***c* ("*R*"), **15***c*), 6.24 (1H, d, *J* = 16.0, **14***c* ("*S*")), 6.23 (1H, d, *J* = 16.0, **14***c* ("*R*")), 6.16 (1H, dd, *J* = 18.5 and 7.5 Hz, **15***c*), 6.13 (1H, dd, *J* = 16.0 and 8.5 Hz, **14***c* ("*S*")), 6.09 (1H, dd, *J* = 16.0 and 9.0 Hz, **14***c* ("*R*")), 5.65 (1H, dd, *J* = 18.5 and 1.0 Hz, **15***c*), 3.45–3.35 (1H, m, **14***c* ("*S*"), **14***c* ("*R*"), **15***c*), 3.33 (3H, s, **15***c*), 3.32 (3H, s, **14***c* ("*R*")), 3.31 (3H, s, **14***c* ("*S*")), 3.30–3.15 (1H, m, **14***c* ("*S*"), **14***c* ("*R*") and 2H, m, **15***c*), 3.04 (1H, m, **14***c* ("*S*"), **14***c* ("*R*"), **15***c*), 2.55 (1H, d, *J* = 14.5 Hz, **14***c* ("*S*"), **14***c* ("*R*")), 2.46 (1H, d, *J* = 14.0 Hz, **15***c*), 2.40–2.25 (1H, m, **14***c* ("*S*"), **14***c* ("*R*"), **15***c*), 2.20–1.40 (5H, m, **15***c* and 6H, m, **14***c* ("*S*"), **14***c* ("*R*")), 1.35–1.10 (8H, m, **14***c* ("*S*"), **14***c* ("*R*"), **15***c*), 0.95–0.80 (3H, m, **14***c* ("*S*"), **14***c* ("*R*"), **15***c*), 0.11

[10]The "*S*", "*R*" designation refers to absolute configuration at the alkylated center.

*Isopropyl alkylated derivatives **14**d, **15**d ("R") and **15**d ("S")*

The general procedure was followed; for additional details see Table 2. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m, **15***d* ("*R*"), **15***d* ("*S*"), **14***d*), 6.35–6.20 (2H, m, **14***d*), 6.23 (1H, dd, *J* = 18.5 and 8.5 Hz, **15***d* ("*S*")), 6.22 (1H, dd, *J* = 18.5 and 8.5 Hz, **15***d* ("*R*")), 5.66 (1H, dd, *J* = 18.5 and 1.0 Hz, **15***d* ("*R*"), **15***d* ("*S*")), 3.40 (1H, dd, *J* = 9.5 and 4.5 Hz, **15***d* ("*R*")), 3.45–3.34 (1H, m, **15***d* ("*S*"), **14***d*), 3.33 (3H, s, **15***d* ("*R*"), **15***d* ("*S*")), 3.30 (3H, s, **14***d*), 3.19 (1H, dd, *J* = 9.5 and 6.5 Hz, **15***d* ("*R*")), 3.30–3.10 (1H, m, **15***d* ("*S*"), **14***d*), 3.10–2.92 (1H, m, **15***d* ("*R*"), **15***d* ("*S*"), **14***d*), 2.90 (1H, t, *J* = 8.5 Hz, **15***d* ("*R*"), **15***d* ("*S*")), 2.58 (1H, d, *J* = 14.5 Hz, **14***d*), 2.46 (1H, d, *J* = 14.5 Hz, **15***d* ("*R*"), **15***d* ("*S*")), 2.42–2.25 (1H, m, **15***d* (*R*), **15***d* ("*S*"), **14***d*), 2.20–1.40 (6H, m, **15***d* ("*R*"), 7H, m, **15***d* ("*S*"), 8H, m, **14***d*)), 1.74 (1H, d, *J* = 14.2 Hz, **15***d* ("*R*")), 1.00 (3H, d, *J* = 5.0 Hz, **14***d*), 0.97 (3H, d, *J* = 4.5 Hz, **14***d*), 0.94 (3H, d, *J* = 6.5 Hz, **15***d* ("*R*"), **15***d* ("*S*")), 0.75 (3H, d, *J* = 6.5 Hz, **15***d* ("*R*"), **15***d* ("*S*")), 0.15 (3H, s, **14***d*), 0.10 (3H, s, **15***d* ("*S*")), 0.09 (3H, s, **15***d* ("*R*")), 0.08 (3H, s, **15***d* ("*R*")), 0.07 (3H, s, **15***d* ("*S*")), 0.06 (3H, s, **14***d*); GCMS *m/e* (EI): isomers **15***d* ("*R*"), **15***d* ("*S*") (not resolved), 346 ($M^+ + H^+$, 10), 345 (M^+, 3), 330 (6), 314 (12), 300 (100), 257 (1), 186 (3), 166 (4), 128 (20); isomers **14***d* (resolved): isomer 1, 300 ($M^+ - CH_2OCH_3$, 99), 186 (100), 154 (41), 128 (65), 115 (20), 89 (25), 73 (48), 59 (50); isomer 2, 300 ($M^+ - CH_2OCH_3$, 100), 186 (98), 154 (38), 128 (56), 115 (20), 89 (24), 73 (39), 59 (54).

*Dimethyl-(*p*-methoxylcinnamyl)-[(S)-2'-methoxymethylpyrrolidinylmethyl]silane **16***

A mixture of chloride **18** (100 mg, 0.39 mmol) and methoxymethylpyrrolidine (91 mg, 0.79 mmol) was heated at 80°C (oil bath temperature) for 20 h. After cooling to room temperature, ether and brine were added and the layers were separated. The aqueous layer was extracted with ether and the combined organic layers were dried over $MgSO_4$, filtered, and concentrated under reduced pressure to afford an oil which was purified by column chromatography (25–100% ethyl acetate in hexane) yielding pure aminosilane **16** (112 mg, 85%) as a pale yellow oil: $[\alpha]^{25}_D$ -66.4 (*c* 2.49, $CHCl_3$); IR (neat): 3029, 3016, 2952, 2918, 2876, 2835, 2808, 1609, 1509, 1247, 839 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.25 (2H, m), 6.84 (2H, m), 6.21 (1H, d, *J* = 15.5 Hz), 6.10 (1H, dt, *J* = 15.5 and 7 Hz), 3.79 (3H, s), 3.41 (1H, dd, *J* = 9 and 4.5 Hz), 3.33 (3H, s), 3.23 (1H, dd, *J* = 9 and 6.5 Hz), 3.10 (1H, m), 2.50 (1H, d, *J* = 14 Hz), 2.38 (1H, m), 2.12 (1H, q, *J* = 8.5 Hz), 1.50–2.00 (7H, m), 0.09 (3H, s), 0.06 (3H, s); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 158.4, 131.5, 127.9, 125.4, 113.9, 76.3, 67.5, 59.0, 57.4, 55.1, 44.8, 28.2, 23.0, 21.9, −3.4, −3.5; MS *m/e* (CI, NH_3): 334 (MH^+, 100), 302 (0.1), 288 (2.3); HRMS (CI, NH_3) calcd. for $C_{19}H_{31}NO_2Si + H^+$:334.2202; found: 334.2202.

*Chloromethyl-dimethyl-(*p*-methoxycinnamyl)silane **18***

To a solution of 4-allylanisole (**17**) (10.0 g, 67 mmol) in ether (100 mL) at 0°C was added *sec*-BuLi (1.3 M in cyclohexane, 67.5 mL, 87 mmol). After the addition, the mixture was warmed to room temperature and stirred for 5 h after which time it was cooled to −78°C. Chloro(chloromethyl)dimethylsilane (11.6 mL, 87 mmol) was added dropwise and the mixture was stirred for 30 min at −78°C. Saturated NH_4Cl was then added followed by ether. The layers were separated and the aqueous layer was extracted twice with ether. The combined organic layers were washed with brine, dried over $MgSO_4$, filtered, and concentrated under reduced pressure (0.1 Torr, oil bath 85–90°C) to afford crude chloride **18**. This material was purified by column chromatography on silica gel (2% ethyl acetate in hexane) yielding pure **18** (1.94 g, 11%) as a pale yellow oil: IR (neat): 3005, 2958, 2933, 2913, 2836, 1609, 1577, 1514, 1509, 1260, 847, 815 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.25 (2H, m), 6.84 (2H, m), 6.25 (1H, br d, *J* = 16 Hz), 6.06 (1H, dt, *J* = 16 and 8 Hz), 3.80 (3H, s), 2.82 (2H, s), 1.78 (2H, dd, *J* = 8 and 1 Hz), 0.16 (6H, s); ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 158.6, 131.1, 128.8, 126.7, 123.7, 113.9, 55.1, 29.5, 20.1, −5.1; GC/MS *m/e* (EI): 254 (M^+, 75), 239 (44), 219 (33), 205 (6), 147 (100); HRMS (CI, NH_3) calcd. for $C_{12}H_{17}SiCl + H^+$: 255.0973; found: 255.0972.

*Methyl alkylated derivatives **20**a ("S"), **20***a* ("R") and **21**a*

The general procedure was followed; for additional details see Table 3. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.25 (2H, m, **20***a* ("*S*"), **20***a* ("*R*")), 7.10 (2H, m, **21***a*), 6.83 (2H, m, **21***a*), 6.82 (2H, m, **20***a* ("*S*"), **20***a* ("*R*")), 6.30–6.10 (2H, m, **20***a* ("*S*"), **20***a* ("*R*")), 6.20 (1H, dd, *J* = 18.5 and 6.0 Hz, **21***a*), 5.65 (1H, dd, *J* = 18.5 and 1.5 Hz, **21***a*), 3.79 (3H, s **20***a* ("*S*"), **20***a* ("*R*")), 3.78 (3H, s, **21***a*), 3.42 (1H, m, **20***a* ("*S*"), **20***a* ("*R*") and 2H, m, **21***a*), 3.34 and 3.33 (3H, 2s, both diastereomers of **21***a*), 3.32 (3H, s, **20***a* ("*S*"), **20***a* ("*R*")), 3.22 (1H, m, **20***a* ("*S*"), **20***a* ("*R*"), **21***a*), 3.05 (1H, m, **20***a* ("*S*"), **20***a* ("*R*"), **21***a*), 2.55 (1H, d, *J* = 14.5 Hz, **20***a* ("*S*"), **20***a* ("*R*")), 2.47 (1H, d, *J* = 14.5 Hz, **21***a*), 2.37 (1H, m, **20***a* ("*S*"), **20***a* ("*R*"), **21***a*), 2.10 (1H, m, **20***a* ("*S*"), **20***a* ("*R*"), **21***a*), 2.00–1.45 (5H, m, **21***a* and 6H, m, **20***a* ("*S*"), **20***a* ("*R*")), 1.31 (3H, d, *J* = 7.0 Hz, **21***a*), 1.18 (3H, d, *J* = 7.0 Hz, **20***a* ("*R*")), 1.17 (3H, d, *J* = 7.0 Hz, **20***a* ("*S*")), 0.11 (3H, s, **21***a*), 0.08 (3H, s, **20***a* ("*S*"), **21***a*), 0.078 (3H, s, **20***a* ("*R*")), 0.02 (3H, s, **20***a* ("*R*")), 0.01 (3H, s, **20***a* ("*S*")).

*Ethyl alkylated derivatives **20**b ("S") and **21**b*

The general procedure was followed; for additional details see Table 3. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.26 (2H, m, **20***b* ("*S*")), 7.07 (2H, m, **21***b*), 6.83 (2H, m, **20***b* ("*S*"), **21***b*), 6.30–6.00 (1H, m, **21***b*), 6.19 (1H, d, *J* = 16.0, **20***b* ("*S*")), 5.96 (1H, dd, *J* = 16.0 and 9.0 Hz, **20***b* ("*S*")), 5.63 (1H, dd, *J* = 19.0 and 1.0 Hz, **21***b*), 3.79 (3H, s, **20***b* ("*S*")), 3.78 (3H, s, **21***b*), 3.41 (1H, dd, *J* = 9.5 and 4.6 Hz, **20***b* ("*S*") and 2H, m, **21***b*), 3.33 (3H, s, **21***b*), 3.31 (3H, s, **20***b*) ("*S*")), 3.22 (1H, dd, *J* = 9.0 and 7.0 Hz, **20***b* ("*S*") and 1H, m, **21***b*), 3.05 (1H, m, **20***b* ("*S*"), **21***b*), 2.54 (1H, d, *J* = 14.5 Hz, **20***b* ("*S*")), 2.37 (1H, m, **20***b* ("*S*")), 2.08 (1H, q, *J* = 8.5 Hz, **20***b* ("*S*")), 1.70 (1H, d, *J* = 14.0 Hz, **20***b* ("*S*")), 2.00–1.30 (7H, m, **20***b* ("*S*")), 2.50–1.30 (7H, m, **21***b*), 0.94 (3H, t, *J* = 6.5 Hz, **20***b* ("*S*")), 0.83 (3H, t, *J* = 7.0 Hz, **21***b*), 0.09 (3H, s, **20***b* ("*S*")), 0.01 (3H, s, **20***b* ("*S*")), the singlets for methyl groups on silicon for isomer **21***b* were not characterised precisely but occur between 0.05 and 0.15 ppm.

*Cinnamyldimethyl-[1'-(R)-methyl-2'-(S)-phenyl-2-methoxyethyl-N-methylaminomethyl]silane **23***

A mixture of chloride **12** (467 mg, 2.1 mmol) and *O*-methylated (−) ephedrine (**22**) (11) (1.3 g, 7.3 mmol; this compound was contaminated with the bis-*O*,*N*-methylated derivative of (−) ephedrine) was heated at 135°C (oil bath temperature) for 15 h. After cooling to room temperature, ether and brine were added and the layers were separated. The aqueous layer was extracted with ether and the combined organic layers were dried over $MgSO_4$, filtered, and concentrated under reduced pressure to afford an oil (1.32 g). The remaining starting materials were distilled off (0.05 Torr, 40–45°C) and the residue was purified by column chromatography (10–50% ethyl acetate in hexane) yielding pure aminosilane **23** (285 mg, 37%) as a pale yellow oil: $[\alpha]^{25}_D$ −31.8 (*c* 2.0, $CHCl_3$); IR (neat): 3083, 3063, 3023, 2986, 2960, 2859, 2819, 1641, 1601, 1496, 1248, 1097, 835 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.10–7.45 (10H, m), 6.05–6.30 (2H, m), 4.17 (1H, d, *J* = 6 Hz), 3.21 (3H, s), 2.72 (1H, qn, *J* = 6.5 Hz), 2.24 (3H, s), 2.03 (2H, d, *J* = 3.5 Hz), 1.57 (2H, m), 1.05 (3H, d, *J* = 6.5 Hz), −0.03 (6H, s); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 141.7, 138.5, 128.7, 128.2, 128.0, 127.8, 127.1, 126.1, 125.5, 85.8, 66.7, 56.7, 44.3, 41.0, 22.2, 7.6, −3.2, −3.4; MS *m/e* (EI): 367 (M^+, 0.1), 352 (0.6), 336 (0.3), 246 (100); HRMS (EI) calcd. for $C_{23}H_{33}ONSi - CH_3$: 352.2098; found: 352.2097.

Methyl alkylated derivatives ***24****a ("R"), **24**a ("S"), and **24**b*

The general procedure was followed; for additional details see Table 3. ^{1}H NMR (200 MHz, $CDCl_3$) (in some sections of the NMR spectrum, the diastereoisomers of **24***b* could be distinguished and are designated as maj (major) and min (minor) δ: 7.45–7.10 (10H, m, **24***a* ("*R*"), **24***a* ("*S*"), **24***b*), 6.25 (1H, dd, *J* = 16.0 and 7.0 Hz, **24***a* ("*R*")), 6.23 (1H, dd, *J* = 16.0 and 6.5 Hz, **24***a* ("*S*")), 6.17 (1H, dd, *J* = 18.5 and 6.0 Hz, **24***b*maj), 6.16 (1H, dd, *J* = 18.5 and 6.0 Hz, **24***b*min), 6.12 (1H, d, *J* = 16.0 Hz, **24***a* ("*R*"), **24***a* ("*S*")), 5.61 (1H, dd, *J* = 18.5 and 1.5 Hz, **24***b*min), 5.60 (1H, dd, *J* = 18.5 and 1.5 Hz, **24***b*maj), 4.18 (1H, d, *J* = 6.0 Hz, **24***b*), 3.21 (3H, s, **24***b*), 3.20 (3H, s, **24***a* ("*R*"), **24***a* ("*S*")), 2.72 (1H, m, **24***a* ("*R*"), **24***a* ("*S*"), **24***b*), 2.23 (3H, s, **24***a* ("*R*"), **24***a* ("*S*")), 2.22 (3H, s, **24***b*), 2.10 (2H, m, **24***a* ("*R*"), **24***a* ("*S*"), **24***b*), 1.73 (1H, qn, *J* = 6.5 Hz, **24***a* ("*S*")), 1.70 (1H, qn, *J* = 7.0 Hz, **24***a* ("*R*")), 1.33 (3H, d, *J* = 7.0 Hz, **24***b*), 1.10 (3H, *d*, *J* = 7.0 Hz, **24***a* ("*S*")), 1.08 (3H, d, *J* = 6.0 Hz, **24***a* ("*R*")), 1.04 (3H, d, *J* = 6.5 Hz, **24***a* ("*R*"), **24***a* ("*S*")), 1.00 (3H, d, *J* = 6.5 Hz, **24***b*), −0.02 and −0.03 (6H, 4s, **24***b*), −0.05 (3H, s, **24***a* ("*S*")), −0.07 (6H, s, **24***a* ("*R*")), −0.08 (3H, s, **24***a* ("*S*")).

Cinnamyldimethyl-[(S)-2′-(pyrrolidinylmethyl)-pyrrolidinylmethyl]silane ***26***

A mixture of chloride **12** (280 mg, 1.29 mmol) and (*S*)-(+)-2-(1′-pyrrolidinylmethyl)pyrrolidine (**25**) (400 mg, 2.60 mmol) was heated at 80°C (oil bath temperature) for 15 h. After cooling to room temperature, ether and brine were added and the layers were separated. The aqueous layer was extracted with ether and the combined organic layers were dried over $MgSO_4$, filtered, and concentrated under reduced pressure to afford an oil which was purified by flash chromatography (hexane:EtOAc:CH_2Cl_2 80:10:10 then EtOAc:MeOH 50:50) yielding pure aminosilane **26** (174 mg, 40%) as a pale yellow oil: $[\alpha]^{25}_D$ −90.7 (*c* 1.7, $CHCl_3$); IR (neat): 3082, 3058, 3023, 2965, 2960, 2939, 2905, 2875, 2785, 1641, 1601, 1496, 1248, 862, 835 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m), 6.40–6.15 (2H, m), 3.10 (1H, m), 2.75–1.50 (20H, m), 0.11 (3H, s), 0.07 (3H, s); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 138.6, 128.5 (2C), 127.8, 126.3, 125.6, 67.9, 61.5, 57.2, 54.9, 44.4, 30.2, 23.2, 22.8, 22.2, −3.2, −3.4; MS *m/e* (EI): 342 (M^+, 0.1), 327 (0.6), 258 (100), 226 (17); HRMS (EI) calcd. for $C_{21}H_{34}N_2Si - CH_3$: 327.2256; found: 327.2256.

Methyl alkylated derivatives ***27****a, **27**b*

The general procedure was followed; for additional details see Table 3. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m, **27***a*, **27***b*), 6.38 (1H, dd, *J* = 16.0 and 7.5 Hz, **27***a*), 6.23 (1H, dd, *J* = 18.5 and 6.0 Hz, **27***b*), 6.20 (1H, dd, *J* = 16.0 and 1.0 Hz, **27***a*), 5.68 (1H, dd, *J* = 18.5 and 1.5 Hz, **27***b*), 3.48 (1H, m, **27***b*), 3.06 (1H, m, **27***a*, **27***b*), 2.70–1.50 (19H, m, **27***a* and 18H, m, **27***b*), 1.34 (3H, d, *J* = 7.0 Hz, **27***b*), 1.18 (3H, d, *J* = 7.0 Hz, **27***a*), 0.11 (3H, s, **27***b*), 0.10 (3H, s, **27***a*), 0.09 (3H, s, **27***b*), 0.01 (3H, s, **27***a*).

Cinnamyldimethylpyrrolidinylmethylsilane ***28***

A mixture of chloride **12** (11.0 g, 49.0 mmol) and pyrrolidine (13.9 g, 196 mmol) was heated at 80°C (oil bath temperature) for 20 h. After cooling to room temperature, ether and brine were added and the layers were separated. The aqueous layer was extracted with ether and the combined organic layers were dried over $MgSO_4$, filtered, and concentrated under reduced pressure to afford crude **28** (11.6 g, 91%) as an oil which was suitable for use in the next reaction. If desired, the compound could be purified by column chromatography (10–50% EtOAc in hexane); IR (neat): 3023, 2986, 2962, 2952, 2904, 2773, 1641, 1601, 1496, 1247, 861, 835 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m), 6.40–6.15 (2H, m), 2.48 (4H, m), 2.08 (2H, s), 1.75 (6H, m), 0.12 (6H, s); ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 138.5, 128.7, 128.5, 127.6, 126.3, 125.6, 58.1, 46.0, 23.7, 22.3, −3.4; MS *m/e* (EI): 259 (M^+, 1), 244 (1.1), 175 (0.5), 142 (100), 84 (76).

Methyl alkylated derivatives ***29****a, **29**b*

The general procedure was followed; for additional details see Table 3. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m, **29***a*, **29***b*), 6.35 (1H, dd, *J* = 16.0 and 7.0 Hz, **29***a*), 6.23 (1H, dd, *J* = 18.5 and 6.0 Hz, **29***b*), 6.20 (1H, d, *J* = 16.0 Hz, **29***a*), 5.70 (1H, dd, *J* = 18.5 Hz, **29***b*), 3.48 (1H, br qn, *J* = 6.0 Hz, **29***b*), 2.45 (4H, m, **29***a*, **29***b*), 2.08 (2H, s, **29***a*), 2.06 (2H, s, **29***b*), 1.89 (1H, qn, *J* = 6.8 Hz, **29***a*), 1.75 (4H, m, **29***a*, **29***b*), 1.35 (3H, d, *J* = 7.0 Hz, **29***b*), 1.19 (3H, d, *J* = 7.0 Hz, **29***a*), 0.13 and 0.12 (3H, s, **29***b*), 0.10 and 0.09 (3H, s, **29***a*).

Cinnamyltrimethylsilane ***(30)*** *(16)*

To a solution of allylbenzene (**11**) (1.0 g, 8.5 mmol) in ether (15 mL) at 0°C was added *sec*-BuLi (1.3 M in cyclohexane, 8.1 mL, 10.6 mmol). After the addition, the mixture was warmed up to room temperature and stirred for 2 h after which time it was cooled to −78°C. Chlorotrimethylsilane (1.01 g, 9.3 mmol) was added and the mixture was stirred for 45 min at −78°C. Saturated NH_4Cl was then added followed by ether. The layers were separated and the aqueous layer was extracted twice with ether. The combined organic layers were washed with brine, dried over $MgSO_4$, filtered, and concentrated under reduced pressure (0.1 Torr overnight) to afford allylsilane **30** (1.29 g, 80%) as a pale yellow oil: IR (neat): 3082, 3060, 3023, 2955, 2917, 2896, 1643, 1599, 1496, 1248, 962, 863, 841, 740, 694 cm^{-1}; ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m), 6.40–6.15 (2H, m), 1.68 (2H, m), 0.08 (9H, s); ^{13}C NMR (50.3 MHz,$CDCl_3$) δ: 138.6, 128.5, 128.4, 127.9, 126.3, 125.6, 23.7, −2.1; MS *m/e* (EI): 190 (M^+, 9.3), 175 (2.4), 117 (2.5), 73 (100).

Methyl alkylated derivatives ***31****a, **31**b*

The general procedure was followed. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.40–7.10 (5H, m, **31***a*, **31***b*), 6.32 (1H, dd, *J* = 16.0 and 7.0 Hz, **31***a*), 6.20 (1H, d, *J* = 16.0, **31***a*), 6.20 (1H, dd, *J* = 18.5 and 6.0 Hz, **31***b*), 5.68 (1H, dd, *J* = 18.5 Hz, **31***b*), 3.48 (1H, m, **31***b*), 1.80 (1H, m, **31***a*), 1.36 (3H, d, *J* = 7.0 Hz, **31***b*), 1.18 (3H, d, *J* = 7.5 Hz, **31***a*), 0.06 (9H, s, **31***b*), 0.03 (9H, s, **31***a*); other compounds owing to addition of the base to the starting olefin were detected in this reaction but did not interfere with the evaluation of the α/γ ratio.

Typical procedure for the oxidative degradation of α-alkylated derivatives

To a solution of allylsilane **14***a* (42 mg, 0.132 mmol) in methanol (0.5 mL) and THF (0.5 mL) were added potassium bicarbonate (26 mg, 0.26 mmol) and potassium fluoride (15 mg, 0.26 mmol) followed by hydrogen peroxide (30%, 0.125 mL). The resulting mixture was stirred at room temperature for 24 h after which time it was diluted with brine and ether. The layers were separated and the aqueous layer was extracted twice with ether. The combined organic layers were washed with bisulfite and brine and were dried over $MgSO_4$. The residue obtained after evaporation was purified by column chromatography on silica gel (eluent 25% ethyl acetate in hexane) to afford alcohol **32** (9.4 mg, 48%) as an amorphous solid; the $[\alpha]^{25}_D$ value was compared with values obtained elsewhere (12, 13) (see text).

Typical procedure for the oxidative degradation of γ-alkylated derivatives

To a solution of vinylsilane **15***d* (62 mg, 0.18 mmol) in acetonitrile (0.5 mL), water (0.5 mL), and carbon tetrachloride (0.5 mL) were added sodium periodate (232 mg, 1.07 mmol) and ruthenium trichloride heptahydrate (0.8 mg, 0.004 mmol). The resulting mixture was stirred at room temperature for 2 h after which time it was diluted with dichloromethane. The layers were separated and the aqueous layer was extracted twice with dichloromethane. The combined organic layers were washed with brine and were dried over $MgSO_4$. The residue obtained after evaporation was purified by column chromatography on silica gel (eluent 10–50% ethyl acetate in hexane) to afford acid **36** (12.2 mg, 42%); the $[\alpha]^{25}_D$ value was compared with values obtained elsewhere (15) (see text).

The reaction of $(C_5H_5)_2Mo_2(CO)_4$ with the steroidal hormone 11β-(4-dimethylaminophenyl)-17β-hydroxy-17α-(1-propynyl)-estra-4,9-dien-3-one (RU 38486) or with propynylborneol yields in each case a chiral cluster that exhibits two cyclopentadienyl resonances in both the ^1H and ^{13}C NMR regimes. At low temperature the interconversion of diastereomers arising from the different orientations of the semi-bridging carbonyl ligand can be slowed on the NMR time scale. The barrier to diastereomer interchange has been determined for the terpenoid cluster and the mechanism of this process is discussed.

Introduction

In continuation of our studies on metal complexes of hormonal steroids and related systems (1–6), we have synthesized a number of dimetalla-alkyne clusters, e.g., **1**, **2**, and **3**. These molecules, in which the M_2C_2 tetrahedral moiety is situated on the α-face of the steroid, are known to bind to various steroidal receptor sites (7, 8). Moreover, it has been demonstrated that one can take advantage of the intense metal carbonyl infrared stretching absorptions to assay the receptor sites without any of the inconveniences associated with radio-labels (9, 10). Perhaps the most fascinating of these is the dimolybdenum complex **3**, which is derived from 11β-(4-dimethylaminophenyl)-17β-hydroxy-17α-(1-propynyl)-estra-4,9-dien-3-one, **4**, the now famous "morning-after pill" originally known as RU 38486 and recently marketed by Roussel-Uclaf as Mifepristone.

Any attempts to carry out substitution reactions on these systems (either to displace a carbonyl ligand or to replace an entire metal vertex with an isolobal group) must take account of the chiral nature of the molecules and consequent diastereotopic character of the metal centers (11–13). This phenomenon is clearly reflected in the NMR spectra of molecules **2** and **3**, each of which give rise to two cyclopentadienyl resonances in both the ^1H and ^{13}C regimes (14). We were particularly intrigued by the observation that these pairs of cyclopentadienyl peaks were further split on cooling, thus indicating the presence of more than one diastereomer. We here describe a variable-temperature NMR study carried out to clarify and extend these observations.

Results and discussion

The molecular structures and fluxional behavior of clusters of the type $Cp_2(CO)_4M_2(R^1C{\equiv}CR^2)$, where M = Mo or W, were first described by Cotton and co-workers (15). In the solid state, three of the carbonyl ligands are terminally bonded while the fourth is in a semi-bridging environment. This situation also obtains in solution and the asymmetric nature of the bonding renders all four carbonyls nonequivalent as evidenced by the ^{13}C NMR spectrum at low temperature. Now, for those cases where $R^1 = R^2$, increasing the

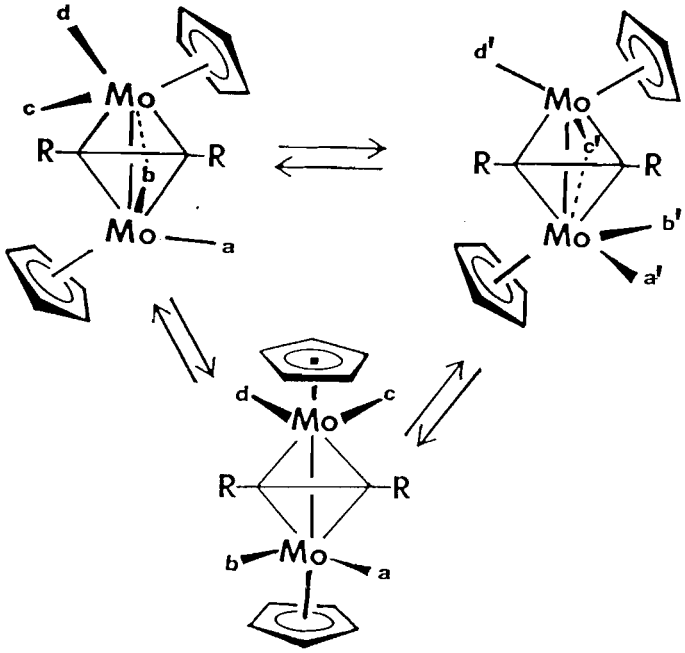
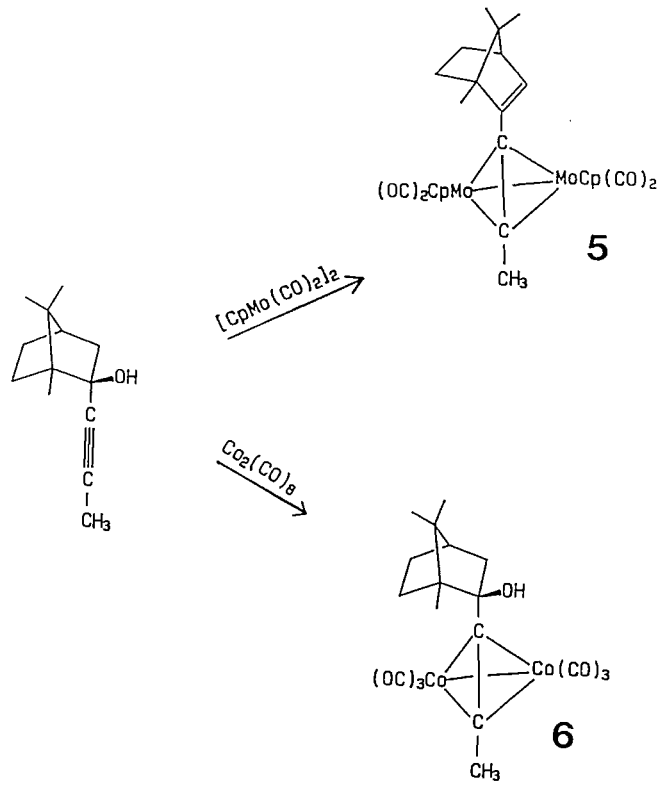


SCHEME 1. Exchange process that interconverts carbonyl ligands in semi-bridging and in terminal environments.

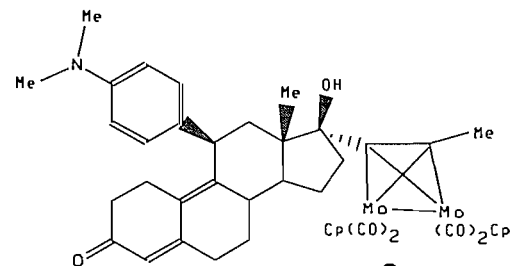


SCHEME 2. Synthetic routes to chiral clusters.

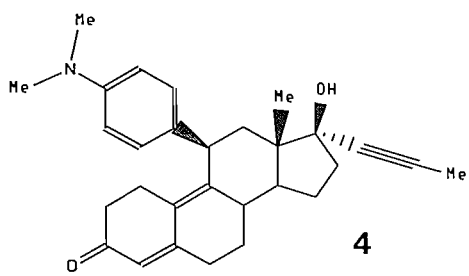
temperature brings about a coalescence of the four ^{13}CO NMR signals to two, and ultimately yields a single resonance. The first exchange process, which has an activation energy of approximately 8 kcal mol^{-1}, was suggested to involve a twitching motion by which the semi-bridging carbonyl on one molybdenum and a terminal CO ligand on the other molybdenum are equilibrated; the effective symmetry would then be C_2 rather than C_1 and this process would also interconvert the two cyclopentadienyl environments, as in Scheme 1. The observation of a single ^{13}CO peak requires that the time-averaged symmetry be raised to C_{2v} as would be the case if partial rotation of the $CpMo(CO)_2$ groups were to occur; this latter process has a barrier ranging from 9.5 to 12.5 kcal mol^{-1} depending on the steric bulk of the substituents borne by the cyclopentadienyl ligands (16, 17). A moment's reflection leads to the realization that for those systems where $R^1 \neq R^2$ the maximum symmetry attainable is C_s and so the four ^{13}CO resonances at low temperature can at best become two even when both fluxional processes are fast on the NMR time scale. It is further apparent that when one of the alkyne substituents is chiral the four carbonyl ligands are *always* nonequivalent. Likewise, in a molecule such as **3**, where the alkyne bears a hormonal steroid as one substituent, the cyclopentadienyl groups will also retain their chemical shift difference.

As shown in Fig. 1, the ^1H NMR spectrum of **3** in the cyclopentadienyl region changes quite noticeably upon raising the temperature from −40°C to +20°C. The low-temperature spectrum shows the presence of two molecular species in an approximate 80:20 ratio. Upon increasing the temperature, these two species are equilibrated and the four cyclopentadienyl resonances coalesce to yield only two peaks.

As shown in Fig. 2, the ^{13}C NMR spectrum of **3**, recorded at −40°C, reveals the anticipated eight resonances in the metal carbonyl region; four of these ^{13}CO peaks are assigned to the major diastereomer and the other four to its less abundant partner. Further examination of the ^1H spectra reveals that one of the C_5H_5 rings in the major diastereomer is markedly deshielded from the remaining cyclopentadienyl protons; one is led to the suspicion that this particular Cp ring may be situated near the edge of the aromatic ring attached



3



4

to C-11 of the steroid and so lies in the deshielding region of the diamagnetic anisotropy associated with the arene. This idea is buttressed by the observation that the resonances attributable to the Me_2N group and also the ring protons *ortho* to this substituent are clearly separated in the two diastereomers. Furthermore, these chemical shift differences are

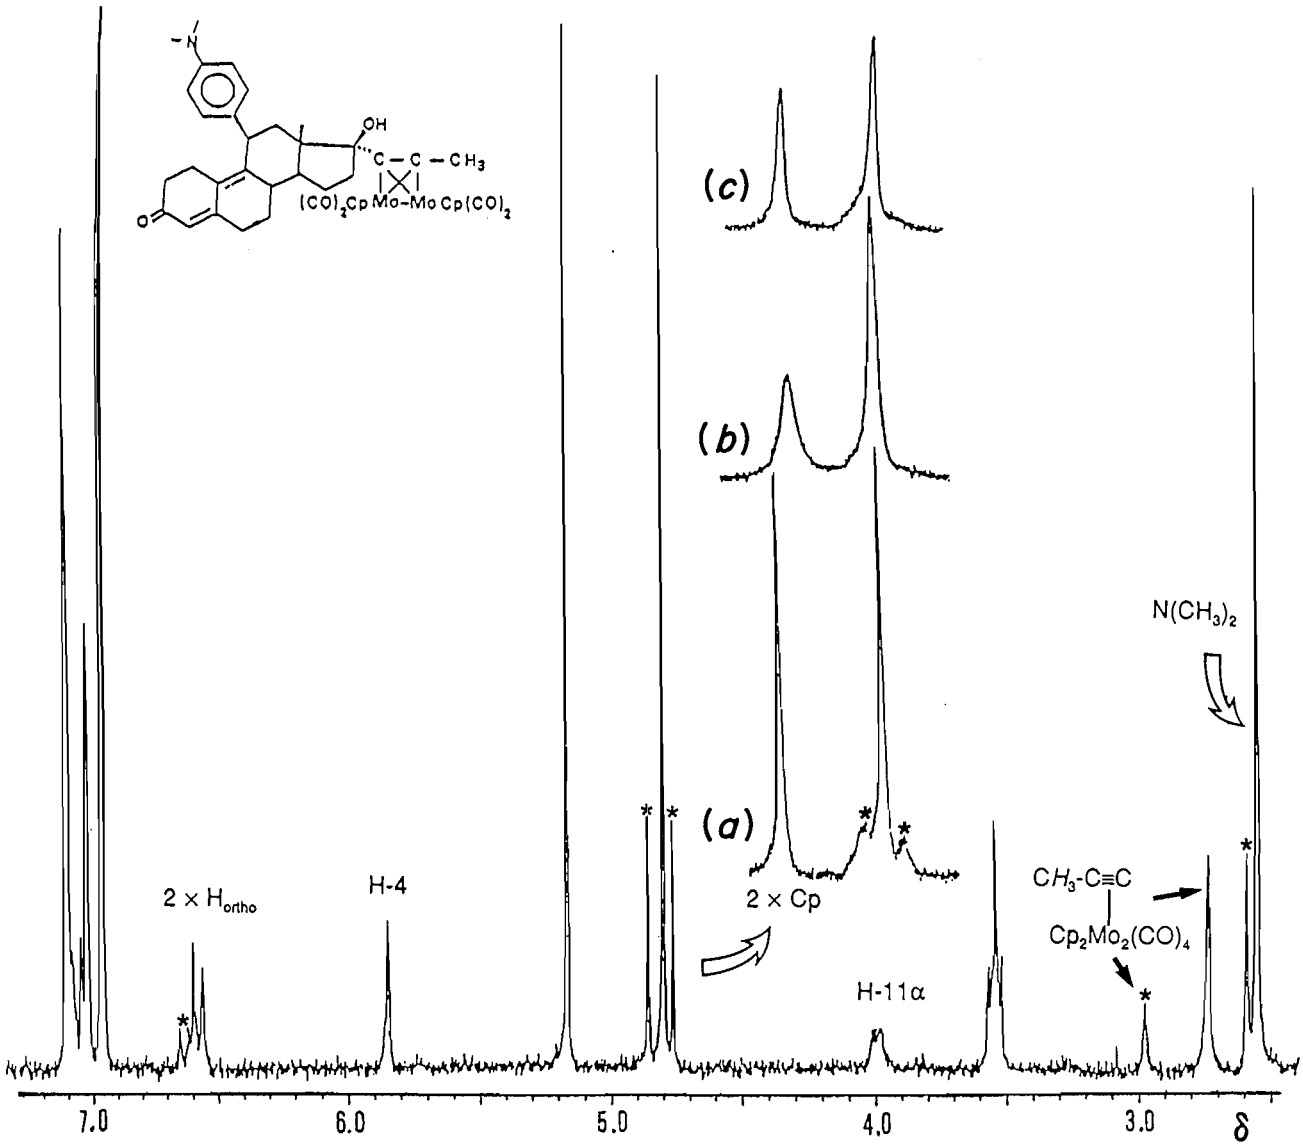


FIG. 1. Section of the 250 MHz ^{1}H NMR spectrum of **3** at 233 K. Peaks attributable to the minor diastereomer are marked with an asterisk (*). The cyclopentadienyl resonances are also shown (*a*) at 275 K, (*b*) at 283 K, and (*c*) at 293 K.

detectable not only for the methyl groups situated at C-13 but also for the CH_3's attached to the alkyne that are likewise split in a 4:1 ratio at low temperature. Clearly, X-ray crystallographic data would be valuable in elucidating the detailed structures of these diastereomers. These observations are relevant to the recent report describing the variable-temperature NMR spectra of the alkyne cluster $[(C_5H_5)_2Mo_2(HC{\equiv}CR)]^+$, where R is a cationic steroidal substituent (18). In this cation there are intimations of a very low-energy fluxional process in which extra cyclopentadienyl resonances are observed. Subsequently, there has been speculation about the possibility of evaluating the barrier to rotation of the $(C_5H_5)Mo(CO)_2$ vertices (19).

The results of these variable-temperature NMR experiments prompted us to look in more detail at another di-molybdenum cluster in which the alkyne possessed a chiral substituent. We recently described convenient routes to a variety of chiral di-cobalt, di-molybdenum, or di-tungsten clusters as well as those containing Co–Mo or Co–W units (12, 20). Molecules such as **5** or **6** are obtainable in multigram quantities by reaction of the appropriate organometallic precursor with 2-propynylborneol, as shown in Scheme 2. Furthermore, ^{13}CO enrichment of **5** is a straightforward process and greatly facilitates the acquisition of the variable-temperature spectra.

The ^{13}C NMR spectrum of **5** has been recorded over the temperature range +30°C to −80°C and a selection of these spectra appear in Fig. 3, together with those simulated by using the program EXCHANGE. We note immediately that there is a coalescence phenomenon that interchanges pairs of ^{13}CO resonances in quite different environments (see Fig. 4). This is in complete accord with Cotton's original proposal in which a semi-bridging carbonyl on one metal exchanges with a terminal CO ligand on the other metal. The X-ray crystal structure of **5** appears as Fig. 5 and reveals that the three terminal carbonyl ligands are oriented very differently with respect to the terpenoid substituent (20) and so would be expected to have noticeably different chemical shifts. The

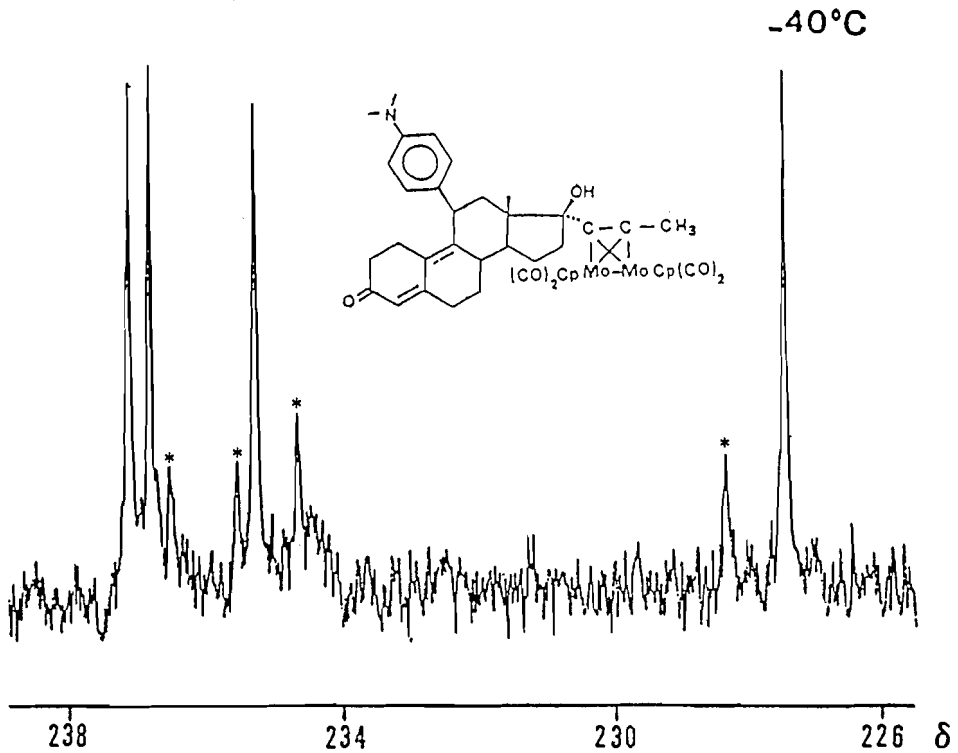

FIG. 2. Section of the 62.86 MHz ^{13}C NMR spectrum of **3**, in the metal carbonyl region, recorded at 233 K; data collection time 12 h.

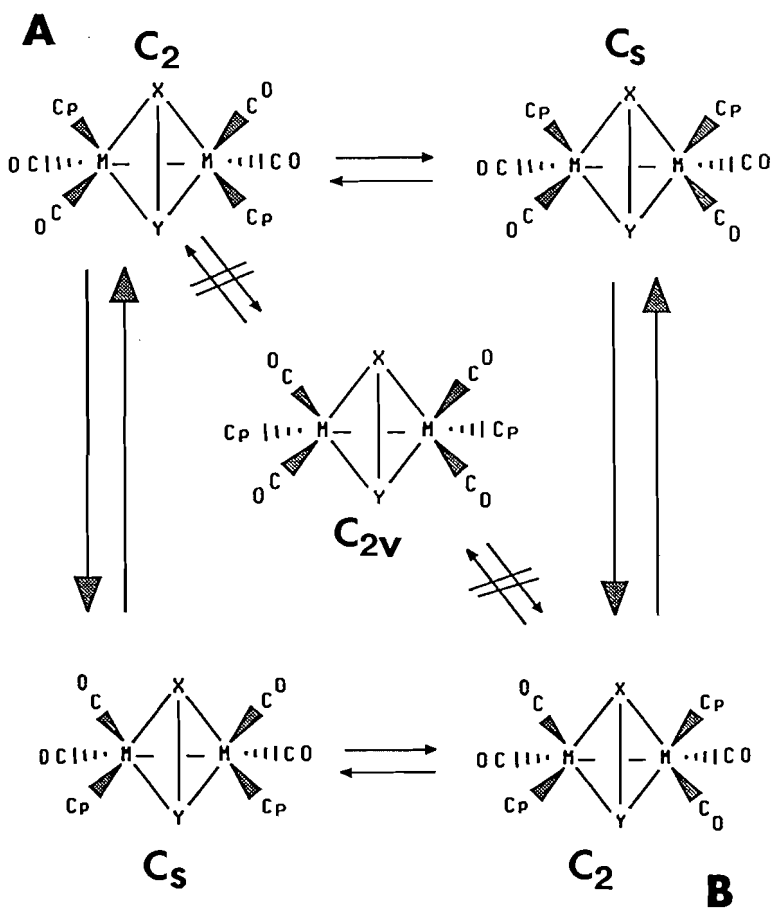

SCHEME 3. Proposed mechanism of interconversion of enantiomeric clusters via C_s rather than C_{2v} intermediates.

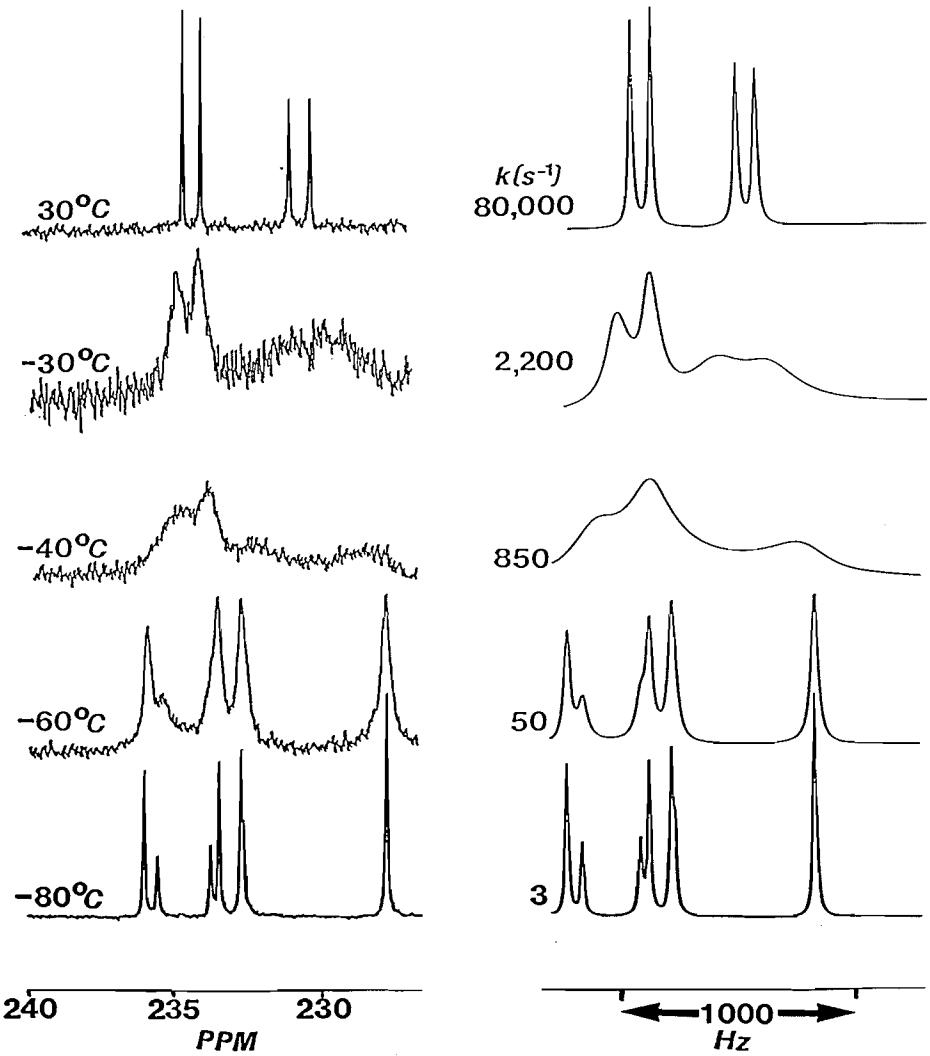

FIG. 3. Experimental and simulated 125.7 MHz ^{13}C variable-temperature NMR spectra of **5** in the metal carbonyl region.

crystallographically characterized molecule is presumably the major diastereomer and the minor isomer can arise simply by invoking semi-bridging of a different carbonyl ligand. The activation energy barrier for this fluxional process (obtained from a knowledge of the experimental temperatures and the rate constants given by the spectral simulations) is 11.2 ± 0.4 kcal mol^{-1} and is in the range found for other systems with modestly large steric requirements (16).

In this case the simulation is decidedly non-trivial since the relative populations of major and minor diastereomers change with temperature; that is, the simulation requires a knowledge not only of the rate constant but also of the equilibrium constant at each temperature for which experimental data are available. The ratio at the low-temperature limit is of course directly measurable from peak intensities; the diastereomer ratio at +30°C is calculable from the peak positions, which reflect the weighted average of the chemical shifts of the individual molecules. The equilibrium constants for the intermediate temperatures were obtained by interpolation of the measured values at −80°C and +30°C; these data allowed the simulation of the variable-temperature NMR spectra, shown in Fig. 3, and yielded the above-mentioned activation energy of 11.2 ± 0.4 kcal mol^{-1}. The variation of K_{eq} with temperature corresponds to a preferential stabilization of one of the two diastereomers by ≈0.2 kcal mol^{-1}.

As noted already, this chemical exchange process involves not merely the carbonyl ligands but also requires the swivelling of the $CpMo(CO)_2$ fragments so as to interconvert enantiomers (when $R^1 = R^2$) or diastereomers (when one of the R groups is chiral, as in the present case). The more fundamental question perhaps concerns the course of the molecular rearrangement that interconverts the rotamers **A** and **B** in Scheme 3. The low-energy twitching process generates a pair of molecules, each of which has effective C_2 symmetry; that is, when $R^1 = R^2$ we have an enantiomeric pair, that must be equilibrated by the high-energy process. Thus when both processes have large rate constants the time-averaged symmetry is C_{2v}. However, this does not mandate that the molecule actually adopt the C_{2v} geometry during the course of the rearrangement. Indeed, such a transition state would be disfavored on entropic grounds since this would require a synchronous swivelling motion of both $CpMo(CO)_2$ groups about imaginary axes joining each molybdenum to the tetrahedral center. One possible technique is to use the Bürgi–Dunitz approach in which the crystal structures of a

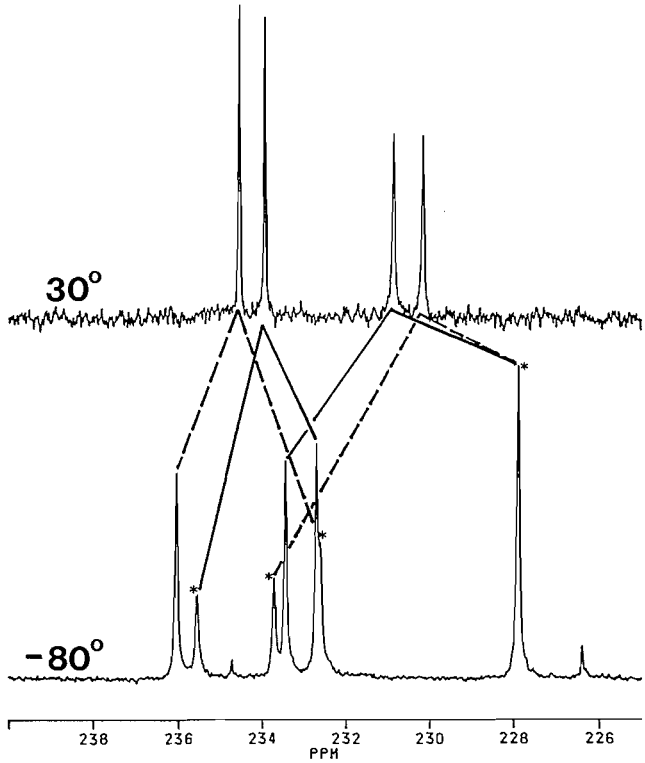

FIG. 4. Coalescence pattern of the metal carbonyl resonances of **5** over the temperature range −80°C to +30°C, showing equilibration of CO ligands in very different environments. Peaks of the minor diastereomer are labelled with an asterisk (*).

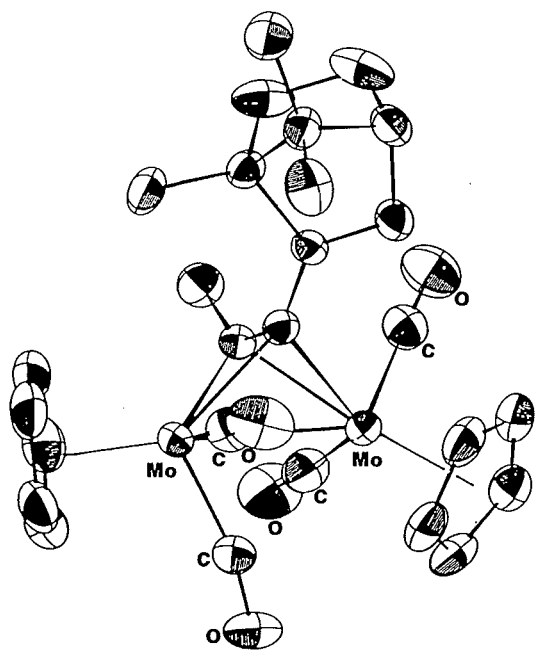

FIG. 5. X-ray crystal structure of **5** using data taken from ref. 20.

large number of closely related molecules are analyzed (21). By this means one can obtain a profile of the reaction pathway whereby a suitably arranged series of structures maps out the trajectory followed by the interacting species. This method has been adopted by Crabtree and Lavin who showed that there is a gradual bending of a carbonyl ligand (i.e., a decrease in the M═C═O bond angle) as it migrates from a terminal to a bridging environment (22). While the detailed analysis of more than 30 crystal structures is deferred to another paper,[3] we note that the published data on molecules of the type $[CpM(CO)_2]_2(X{\equiv}Y)$, where M = Mo or W, and X≡Y can be RC≡CR, RC≡ML_n, As≡As, P≡P, RN≡C, etc., are of the C_2 or C_S types than the C_{2v} structures (see Scheme 3). One might conclude that the reaction proceeds via successive rotations of single $CpM(CO)_2$ vertices rather than by concerted motion of both. These conclusions are supported by EHMO calculations, which likewise favor the stepwise process (23).

In summary, we present the first direct observations on chiral dimetal–alkyne clusters in which equilibration of a semi-bridging carbonyl on one metal and a terminal carbonyl ligand on the other brings about diastereomerization. The observation of four CO resonances at room temperature also provides definitive evidence that there is no intermetallic carbonyl migration.

Experimental

All reactions were carried out under an atmosphere of dry nitrogen employing conventional benchtop and glovebag techniques. All solvents were dried according to standard procedures before use (24). NMR spectra were recorded using Bruker AM500 and WM250 spectrometers; chemical shifts reported were referenced to tetramethylsilane. The ^{13}C spectra of **3** were acquired on a Bruker **WM** 250 spectrometer operating at 62.86 MHz at 5.87 T. The spectrum of the metal carbonyl region of **3** at 233 K was obtained as the result of an overnight run; the sample was not enriched in ^{13}CO. The ^{13}C spectra of **5** were acquired on a Bruker AM 500 spectrometer operating at 125.7 MHz at 11.74 T. Typically, 5000 scans were required to achieve adequate signal-to-noise with a digital resolution of 1.9 Hz/point. The complexes **3** and **5** were prepared via reaction of freshly prepared $(C_5H_5)_2Mo_2(CO)_4$ and the appropriate alkyne as described previously (10, 20); to facilitate the observation of minor isomers, in the ^{13}C spectra, **5** was enriched by stirring a dichloromethane solution for 1 week under an atmosphere of ^{13}CO. NMR spectral simulations were carried out on an IBM PS50 personal computer by using the multisite EXCHANGE program generously provided by Professor R.E.D. McClung (University of Alberta at Edmonton).

The solvent dependence of the small internal barrier to rotation in 3,5-dichlorobenzyl fluoride

TED SCHAEFER,[1] JAMES R. MANSFIELD, FRANK E. HRUSKA, AND RUDY SEBASTIAN
Department of Chemistry, University of Manitoba, Winnipeg, Man., Canada R3T 2N2

Received February 17, 1992

TED SCHAEFER, JAMES R. MANSFIELD, FRANK E. HRUSKA, and RUDY SEBASTIAN. Can. J. Chem. **70**, 1750 (1992).

The ^1H and ^{19}F nuclear magnetic resonance spectra of 3,5-dichlorobenzyl fluoride, dissolved in solvents of varying polarity, are analyzed to yield precise values of the long-range coupling constants between ring protons and the nuclei in the fluoromethyl group. The conformational properties of these coupling constants, dependent on the angle by which the C—H and C—F bonds of the side chain twist out of the aromatic plane, are used to determine the solvent dependence of the predominantly twofold barrier to rotation about the Csp^2—Csp^3 bond. In all solvents, the conformer in which the C—F bond lies in the aromatic plane represents the minimum in the internal rotational potential. The magnitude of the twofold potential changes from 3.2(2) kJ/mol in the nonpolar medium, C_6D_{12}, to 0.6(2) kJ/mol in the polar solvent, CD_3CN. Intermediate magnitudes occur for solvents of intermediate dielectric constant. Comparisons are made with the parent molecule, benzyl fluoride, for which the perpendicular conformer is most stable in the same solvents. Such comparisons indicate that for the free molecules, the in-plane conformer of the dichloro derivative is also more stable than the same conformer of benzyl fluoride. This indication is in qualitative agreement with molecular orbital predictions.

TED SCHAEFER, JAMES R. MANSFIELD, FRANK E. HRUSKA et RUDY SEBASTIAN. Can. J. Chem. **70**, 1750 (1992).

On a analysé les spectres en résonance magnétique nucléaire du ^1H et du ^{19}F du fluorure de 3,5-dichlorobenzyle dissous dans des solvants de polarités différentes pour obtenir des valeurs précises pour les constantes de couplage à longue distance entre les protons du cycles et les noyaux du groupe fluorométhyle. On utilise les propriétés conformationnelles de ces constantes de couplage, qui varient avec l'angle de torsion qui existe entre les liaisons C—H et C—F de la chaîne latérale et le plan du noyau aromatique, pour déterminer l'influence du solvant sur la barrière principalement binaire à la rotation autour de la liaison Csp^2—Csp^3. Dans tous les solvants, le conformère dans lequel la liaison C—F se trouve dans le plan du noyau aromatique correspond à un minimum dans le potentiel de la rotation interne. L'amplitude des potentiels binaires varie de 3,2(2) kJ/mol dans un solvant non-polaire, le C_6D_{12}, à 0,6(2) kJ/mol dans un solvant polaire, CD_3CN. Avec des solvants de constante diélectrique intermédiaire, on observe des amplitudes intermédiaires. On a effectué des comparaisons avec la molécule parente, le fluorure de benzyle, dans laquelle le conformère perpendiculaire est le plus stable dans les mêmes solvants. Ces comparaisons indiquent que, pour les molécules libres, le conformère dans le plan du dérivé dichloré est aussi plus stable que le même conformère du fluorure de benzyle. Cette indication est en accord qualitatif avec les prédictions faites à l'aide de calculs d'orbitales moléculaires.

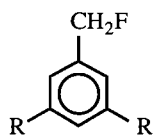
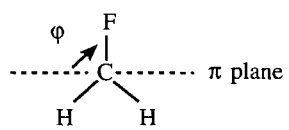
Introduction

The internal barrier to rotation in benzyl fluoride, **1**, is small and solvent dependent (1, 2). In solution, long-range

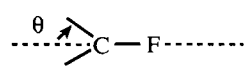


1 R = H
2 R = Cl

spin–spin coupling constants, between nuclei in the side chain and those in the phenyl group, imply an apparent twofold barrier to rotation about the Csp^2—Csp^3 bond that ranges from 3.2 ± 0.2 kJ/mol in the polar solvent, CD_3CN, to 0.7 ± 0.2 kJ/mol in the nonpolar solvent, C_6D_{12} (2). In both instances, the conformer corresponding to the minimum in the internal rotational potential is **3**. Such an interpretation



3



4

is consistent with motionally averaged dipolar coupling constants measured for **1** in liquid crystalline solvents. These measurements yield twofold barriers of 0.30 ± 0.02 and 1.50 ± 0.08 kJ/mol in two such solvents; the former number applies to the less polar solvent (1). Again, the temperature dependence of the ^{19}F chemical shift in acetone solution suggests **3** as the conformer of lowest energy (3). An extrapolation of the twofold barrier magnitudes, based on a dielectric model, yields **4** as the most stable conformer for the free molecule, perhaps by about 1 kJ/mol (2). This result agrees qualitatively with *ab initio* molecular orbital computations, various bases yielding **4** as the stable conformer but with large variations in the barrier height (2). Electron diffraction patterns of the vapor imply a conformer of minimum energy near a φ of 60° and a barrier height near 1.7 kJ/mol (4). Furthermore, excitation spectroscopy, mass-resolved, of a supersonic jet of benzyl fluoride has **3** as the conformation at very low temperatures (5), based on certain similarities in the spectra of **1** and benzyl alcohol. In view of all these results, it would be of interest to have rather higher level molecular orbital calculations on **1**, preferably those including (expensive) allowance for electron correlation, as well as studies using techniques such as far infrared and high-resolution microwave spectroscopies. A recent temperature-dependent, low-resolution, microwave study of the benzyl halides in the vapor phase (6) showed that the

heavier halides are nonplanar, but that the conformation of the fluoride was not deducible.

Now, the minimal basis set, of all those used, appears to agree best with the experimental indications of a very low barrier to internal rotation in **1**. Furthermore, this basis predicts a significant substituent dependence of the barrier height. Specifically, the twofold barrier is computed as 2.4 kJ/mol for **2**, R = Cl, that is, that **4** is about 1 kJ/mol lower in energy in **2** than in the parent molecule, **1**. Hence, depending on the accuracy of the computations and also on the extent by which the solvent shifts the minimum in the internal potential, perhaps towards **3** from **4**, the possibility arises that, in **2**, the lowest internal barrier will exist in the most polar solvent, in direct contrast to the behaviour of **1**. We report here the results of such experiments on **2** in six solvents, polar and nonpolar, using long-range ^1H, ^1H and ^1H, ^{19}F coupling constants.

Experimental

The fluorination of 3,5-dichlorobenzyl alcohol with morpholinosulfur trifluoride (morph-DAST), both compounds coming from Aldrich, followed the literature procedure (7) to give 3,5-dichlorobenzyl fluoride, **2**. Dilute solutions of **2** in various solvent mixtures (see Table 1 for details) were filtered into 5 mm o.d. nmr sample tubes, degassed by at least four freeze–pump–thaw cycles, and were then flame-sealed under vacuum.

The ^1H and ^{19}F nmr spectra were obtained with a $^1H/^{19}F$ probe on a Bruker AM300 spectrometer using acquisition times of 41 s and, typically, 32 free induction decays were coadded. The digital resolution was 0.012 Hz/point, followed by zero-filling to four times the original data table (8). A small amount of resolution enhancement produced line widths at half-height of as little as 0.05 Hz. Final shimming procedures used the free induction decays from the internal reference compounds. The probe temperature was maintained at 300 K.

Results and discussion

Spectral analyses

The ^1H and ^{19}F nmr spectra arise from an AB_2X_2R spin system. Relatively straightforward iterative analyses with the substantially modified algorithm, NUMARIT (9), produce the spectral parameters in Table 1. The standard deviations in chemical shifts and coupling constants are less than or equal to 0.001 Hz.

^6J(H,F) and ^6J(H,H) as indicators of the internal barriers

Previous, detailed, discussions concluded that ^6J(H,F) and ^6J(H,H) are σ–π coupling constants and, as such, are proportional, respectively, to $\sin^2\varphi$ and $\sin^2\theta$ (2, 10), as in eqs. [1] and [2].

$$[1]\quad {}^6J(H,H) = {}^6J_{90}(H,H)\,\langle\sin^2\theta\rangle$$

$$[2]\quad {}^6J(H,F) = {}^6J_{90}(H,F)\,\langle\sin^2\varphi\rangle$$

Together with the approximation, $\langle\sin^2\theta\rangle = 0.75 - 0.5\,\langle\sin^2\varphi\rangle$, obviously holding rigorously for a tetrahedral geometry at the side chain, angular brackets indicating expectation values arising from the internal rotation, only the extema in ^6J(H,F) and ^6J(H,H)), those for φ and θ at 90°, are needed to deduce $\langle\sin^2\theta\rangle$ and $\langle\sin^2\varphi\rangle$ in the various solvents. The extrema follow from simultaneous equations applicable to the different solvents. Picking a nonpolar solvent, say CS_2, and a polar solvent, say acetone-d_6, and noting that the expectation values are different in the two solvents, yields $^6J_{90}$(H,F) as −2.909(2) Hz and $^6J_{90}$(H,H) as −0.934(2) Hz for the two solutions. On the assumption that these extreme values are applicable to all the solvents in Table 1, values

TABLE 2. Apparent twofold barriers to internal rotation in 3,5-dichlorobenzyl fluoride, **2**, and benzyl fluoride, **1**, in various solutions

Solvent[a]	$\langle \sin^2\varphi \rangle$[b]	$\langle \sin^2\theta \rangle$[c]	V_2, **2**[e]	V_2, **1**[f]
C_6D_{12}	0.335	0.575	3.2(2)	0.7(2)
CS_2/C_6D_{12}	0.357[d]	0.572[d]	3.0	0.9
CCl_4/C_6D_{12}	0.370	0.569	2.7	1.1
CD_2Cl_2	0.424	0.539	1.6	2.8
$(CD_3)_2C{=}O$	0.432[d]	0.534[d]	1.4	2.6
CD_3CN	0.449	0.524	0.6	3.2

[a]See Table 1 for solvent details.
[b]Based on ^6J(H, F) in Table 1 and a $^6J_{90}$ (H, F) of −2.909 Hz, but see [d].
[c]Based on ^6J(H, H) in Table 1 and a $^6J_{90}$ (H, H) of −0.934 Hz, but see [d].
[d]These values obey exactly the equation, $\langle \sin^2\theta \rangle = 0.75 - 0.5 \langle \sin^2\varphi \rangle$, see text. The other values in these columns also satisfy this relationship to within an average deviation of 0.002.
[e]The formal error is less than 0.1 kJ/mol, but is quoted as 0.2 kJ/mol.
[f]From ref. 2.

of $\langle \sin^2\theta \rangle$ and $\langle \sin^2\varphi \rangle$ follow immediately from the ratio of the measured coupling constants, e.g., $\langle \sin^2\theta \rangle = {}^6J(\mathrm{H,H})/{}^6J_{90}(\mathrm{H,H})$. A check on self-consistency is then provided by the relationship above between $\langle \sin^2\theta \rangle$ and $\langle \sin^2\varphi \rangle$ (see footnotes to Table 2).

The $^6J_{90}$(H,H) of −0.934(2) Hz for 3,5-dichlorobenzyl fluoride differs by very little from that of −0.941(4) Hz deduced for benzyl fluoride (2), as expected from a large data set indicating that ^6J(H,H) in toluene and benzyl derivatives is sensitive to the electronegativity of the α substituent but insensitive to ring substitution. For benzyl fluoride, $^6J_{90}$(H,F) is −2.856(4) Hz (2), somewhat smaller in magnitude than the −2.909(2) Hz in the 3,5-dichloro derivative. It is anticipated that the composite, σ−π, hyperfine parameter for the C—F bond will evince a greater sensitivity to substitution than will that of a C—H bond.

The apparent twofold barrier to rotation about the Csp^2—Csp^3 bond follows from a hindered rotor model (11, 12), or from a classical averaging procedure, relating $\langle \sin^2\theta \rangle$ and $\langle \sin^2\varphi \rangle$ to the barrier magnitude. The two procedures yield the same barriers in the present instance, very likely because thermal energies at 300 K are large compared to the discrete spacings of the hindered rotor energies. The STO-3G MO computations (2) for **2** yield the internal rotational potential as $2.41(2) \sin^2\varphi + 0.13(2) \sin^2 2\varphi$, so that the fourfold is only about 5% of the twofold component.

The solvent dependence of the barrier

The apparent twofold barriers, V_2, are given in Table 2. With reference to the in-plane, **4**, and perpendicular, **3**, conformers, the $\langle \sin^2\varphi \rangle$ numbers demonstrate **4** as lying at the minimum of the twofold potential. A rigid **4** corresponds to a vanishing $\langle \sin^2\varphi \rangle$, a rigid **3** to unity, and a value of 0.5 to a negligible internal barrier. Similarly, $\langle \sin^2\theta \rangle$ for a rigid **3** is 0.25 and, for **4**, it is 0.75. The most polar solvent, CD_3CN, causes a decrease of 2.6(4) kJ/mol in V_2, reflecting the tendency, also seen for V_2 of benzyl fluoride, to shift the phase of V_2 by 90°. In other words, a medium of high dielectric constant stabilizes **3** relative to **4** for both molecules.

The opposite trend in V_2 for the two molecules in Table 2 simply reflects the greater stability of the in-plane conformer of 3,5-dichlorobenzyl fluoride, **2**, in the nonpolar solvents. For benzyl fluoride, the perpendicular conformer is most stable even in C_6D_{12} solution. If an extrapolation to a medium of unit dielectric constant is valid (2), then the free molecule of **2** is more stable in the in-plane than in the perpendicular conformation by 4.5–5.5 kJ/mol. For benzyl fluoride, **1**, this relative stability was estimated as 1.1 ± 0.7 kJ/mol (2). Qualitatively, the relative stability agrees with the STO-3G MO data (2).

Increased barriers to internal rotation, due to *meta* halogen substituents, are known experimentally for thioanisoles (13, 14), thiophenols (15), and theoretically for phenols (16). The hydroxyl and thiomethyl groups are π electron donors; the substituent effects on the barriers have been discussed in terms of perturbational molecular orbital (PMO) theory (15, 16). *meta* Substitution by fluorine in benzaldehyde causes a decrease in the internal barrier (17–19); the formyl group is a π electron acceptor. For benzyl fluoride, an interpretation of a stable in-plane conformer for the free molecule in terms of PMO theory is somewhat ambiguous; an attraction between C^+—F^- and *ortho* C^-—H^+ dipoles has been invoked (20). If this interpretation is correct, then it is possible that the electronegative chlorine substituents enhance the polarity of the *ortho* C—H bonds, accounting for the increased stability of the planar conformer.

According to Table 2, the stabilization by solvents of the perpendicular conformer is roughly the same for benzyl fluoride and its 3,5-dichloro derivative. The best estimates of the dipole moments of the perpendicular, 2.10 D, and in-plane, 1.74 D, conformers of **1** come from a 6–31G* basis (2). The difference is not large enough to account for the observed solvent stabilization of the perpendicular conformer in polar solvents (21, 22), so that quadrupolar terms in reaction field theory may be important. Similar remarks must apply to the 3,5-dichloro derivative, for which the minimal basis set predicts a dipole moment lower by 0.1 D for the perpendicular, relative to the in-plane, conformer.

The coupling constants, ^4J(H,F) and ^4J(H,H)

The *ortho* benzylic coupling constant, ^4J(H,H), in toluene has σ−π and σ components (23), written as $^4J(\mathrm{H,H}) = {}^4J_{90} \sin^2\theta + {}^4J^\sigma \cos^2\theta$, $^4J_{90}$ being −1.08 Hz and ^4J, −0.32 Hz (23, 24). Because $\langle \sin^2\theta \rangle$ is known for 3,5-dichlorobenzyl fluoride, derivations of $^4J_{90}$(H,H) and $^4J^\sigma$ are possible, assuming the applicability of such a relationship to this molecule. It turns out that $^4J_{90}(\mathrm{H,H})$ is -1.23_4Hz, while $^4J^\sigma$ is 0.002 Hz or less. Neglect of $^4J^\sigma$ and use of $\langle \sin^2\theta \rangle$ deduced from ^6J(H,H), together with this $^4J_{90}$(H,H), reproduces the ^4J(H,H) values in Table 1 to within a mean deviation of 0.002 Hz (for the CCl_4 solution the deviation is 0.005 Hz). The range of ^4J(H,H) is 0.062(2) Hz. The increase in magnitude of $^4J_{90}$(H,H) relative to toluene, whereas that of $^6J_{90}$(H,H) decreases (23), is perhaps unexpected, as is the apparent absence of a σ component of ^4J(H,H). The present compound may be unique in this respect; further work is indicated.

Turning to ^4J(H,F), the *assumption* of a θ dependence similar to ^4J(H,H) yields $^4J(\mathrm{H,F})/\mathrm{Hz} = -3.25_3 \langle \sin^2\varphi \rangle - 0.134_8 \langle \cos^2\varphi \rangle$. The values of $\langle \sin^2\varphi \rangle$ in Table 2, derived from ^6J(H,F), reproduce ^4J(H,F) in Table 1 with an average deviation of 0.004_6 Hz; the range of ^4J(H,F) is 0.283(2) Hz. Of course, this result does not prove the relationship, although a large σ−π component, proportional to $\sin^2\varphi$, is expected.

For personal use only.

Nevertheless, this discussion of ^4J(H,H) and ^4J(H,F) suggests the possibility of the derivation of internal rotational potentials in various solvents for a series of *para*-substituted benzyl fluorides; ^6J(H,H) and ^6J(H,F) are not present in such compounds.

The solvent dependence of $^4J_{24}$

This intraring coupling constant is sensitive to the polarity of the medium, increasing by 0.050(2) Hz between the solvents, C_6D_{12} and CD_3CN. A solvent dependence of[3,4,5] J(H,H) in various monosubstituted benzenes is known from unpublished work in this laboratory. A regular pattern is observed, apparently independent of the polarity of the substituent, X, being the same, for example, for phenylacetylene and phenyl cyanide. The magnitudes of the changes in these coupling constants are comparable to those of $^4J_{24}$ in **2**. This point is made to allay suspicion that the variation of $^4J_{24}$ in **2** might be an artifact of the analyses.

Synthesis of β-*O*-4 lignin model dimers and their chlorinated derivatives

XINHUA SHEN[1] AND ADRIAAN VAN HEININGEN[2]

Papricon and McGill Pulp and Paper Research Centre, 3420 University Street, Montreal, Que., Canada H3A 2A7

Received October 21, 1991

XINHUA SHEN and ADRIAAN VAN HEININGEN. Can. J. Chem. **70,** 1754 (1992).

The unknown lignin model dimers with hydroxymethyl group at the *para* position of the phenoxy moiety and their chlorinated derivatives (compounds **1**–**13**, except **8**) have been synthesized. During the preparation of **6** from **5**, a by-product was isolated and identified as **9**. The compounds **4**, **7**, and **8** were obtained as a mixture of *erythro* and *threo* isomers in the ratio of about 5:4, estimated from their ^{13}C NMR spectra, and the *erythro* isomer **8***a* was crystallized from the mixture. Chlorinated derivatives **12***a* (*erythro*) and **12***b* (*threo*) were also isolated. Their relative configuration was assigned on the basis of both ^{13}C and ^{1}H NMR spectroscopy.

XINHUA SHEN et ADRIAAN VAN HEININGEN. Can. J. Chem. **70**, 1754 (1992).

On a réalisé la synthèse des dimères modèles de la lignine inconnue portant un groupe hydroxyméthyle en position *para* de la portion phénoxy et de ses dérivés chlorés (composés **1**–**13**, à l'exception du produit **8**). Au cours de la préparation du composé **6** à partir du composé **5**, on a isolé un produit secondaire que l'on a identifié au composé **9**. On a obtenu les composés **4**, **7** et **8** sous la forme des isomères *érythro* et *thréo* qui, d'après la RMN du ^{13}C, sont présents dans un rapport de 5 : 4; on a isolé l'isomère *érythro* **8***a* du mélange. On a aussi isolé les dérivés chlorés **12***a* (*érythro*) et **12***b* (*thréo*). Les configurations relatives ont été attribuées à l'aide de la RMN du ^{13}C et du ^{1}H.

Introduction

Lignin is a crosslinked polymer with phenylpropane as the most prevalent monomer unit. The phenylpropane units are linked by ether and carbon–carbon bonds. Approximately half of all softwood lignin interunit linkages are of the arylglycerol-β-aryl ether (β-O-4) type. Therefore, synthesis of β-O-4 substructure models is very important for the study of chemical structure, reactivity, and biodegradation of lignin. Guaiacylglycerol-β-guaiacyl ether and veratrylglycerol-β-guaiacyl ether, widely used as model compounds for various reactions of lignin (1–3), were first synthesized by Adler *et al.* (4, 5). Since then, β-O-4 models have been synthesized by many investigators (6–11). During recent years, Hauteville and Duclos-Jordan (12) reported the synthesis of a series of syringyl type of β-O-4 lignin models. At the moment highly toxic organic chlorinated compounds released from bleach plant effluent make a notable impact on the environment. The present work reports the synthesis of non-phenolic and phenolic β-O-4 dimers with a hydroxymethyl group at the *para* position of the phenoxy moiety, as well as their chlorinated derivatives.

Results and discussion

The synthesis of compounds **1–4** in Scheme 1 was carried out by a modified Adler's procedure (4, 5). Acetoveratrone, commercially available, was brominated to α-bromoacetoveratrone (13), which was subsequently reacted with vanillyl alcohol in the presence of anhydrous potassium carbonate in absolute alcohol to yield a dimer **1**. Condensation of **1** with formaldehyde gave ketol derivative **2**. The ketones **1** and **2** were respectively reduced using sodium borohydride to give the corresponding compounds **3**, a crystalline product, and **4**, a mixture of two diastereomers. Compounds **5–8** were synthesized using acetovanillone as starting material. First, the phenolic hydroxyl group of acetovanillone was protected by benzylation (7) and then, via a similar reaction route to that used for the synthesis of compound **4**, compounds **5–7** were obtained. Compound **7** was a mixture of two diastereomers. Debenzylation of **7** by catalytic hydrogenation with 5% palladium on barium sulfate yielded compound **8**. The phenolic compound 8 was synthesized by Nimz (8) using a different method, in which the hydroxymethyl group was introduced by reduction of the aldehyde at a late stage, and also synthesized by Katayama *et al.* (11) using a different synthetic approach. Both of them obtained only the mixture of two isomers in viscous syrup or glass form. In the present work *erythro* isomer **8***a* was crystallized from the mixture of the two diastereomers in ethyl acetate. In the preparation of **6**, a by-product was isolated when **5** was treated with formaldehyde in the presence of potassium carbonate at a temperature over 40°C and identified as **9** by means of ^{1}H NMR, IR, mass spectra, and elemental analysis. This demonstrates that the ketol derivatives **6** or **2** were unstable during the reaction in alkaline solution at temperatures over 40°C and easily underwent dehydration to form α, β-unsaturated ketone compounds. Therefore, this reaction step should be carried out at low temperature in aqueous alcohol. The analytical and spectroscopic data for compounds **1–9** are listed in Tables 1–3.

The ratios of *erythro* and *threo* isomers of diastereomers **4**, **7**, and **8** were estimated to be about 5:4 by ^{13}C NMR spectroscopy (Table 4). The assignment of relative configuration was based on both ^{13}C NMR chemical shifts for α-C and β-C (Table 4) and ^{1}H NMR coupling constants, for α-H and β-H, and chemical shifts for β-H (Table 5). For ^{13}C NMR spectra the upfield shifts were attributed to the *erythro* isomer and downfield shifts were attributed to the *threo* isomer. For ^{1}H NMR spectra the smaller *J* values and downfield shifts (β-H) were attributed to the *erythro* isomer and the large values and upfield shifts (β-H) were attributed to the *threo* isomer; Similar assignments have been made in the literature (14–17) for analogous structures of β-O-4 lignin model compounds.

SCHEME 1

To prepare some chloro-organic products that are closer to those generated during pulp bleaching, compounds **3** and **4** were chlorinated with different ratios of chlorine in aqueous solution containing a small amount of alcohol at room temperature. The corresponding chlorinated derivatives **10**, **11**, **12***a*, **12***b*, and **13** in Scheme 2 were isolated from the chlorination products by column chromatography using toluene–ethyl acetate as eluent. Their analytical and spectroscopic data are summarized in Tables 1 and 3. The dichlorinated dimers **10** and **12** resulted from electrophilic substitution by chlorine, which took place predominantly at positions *para* to the methoxyl groups in both aromatic rings. No products substituted at the *ortho* positions were isolated. This demonstrates that the *para* position relative to the methoxyl group is much more reactive than the *ortho* position. The structures of compounds **10** and **12** (Fig. 1) were assigned by comparison of their ^{1}H NMR spectra with those of known monomers (18), chlorovanillyl alcohol diacetylated derivatives **14** and **15** (Fig. 1). It is found that when chlorine is substituted at the 6 position, as in **14**, no long-range coupling is observed between protons H-2 and H-5 of the aromatic ring, because these two protons are *para*. When the chlorine is substituted at the 5 position, as in **15**, because the two protons H-2 and H-6, are *meta*, their signals are split into a doublet in which $J_{2,6}$ = 1.7 Hz. The peak patterns of the protons of the two aromatic rings for compound **10** or **12** are similar to those of 6-chlorinated compound **14**. Furthermore, the results previously obtained for chlorination of the nonphenolic monomer, veratryl alcohol, in aqueous solution also showed that substitution by chlorine occurred at the position *para* to the methoxyl group (18). With increasing chlorine ratio, **11** and **13** were formed by electrophilic displacement of the hydroxymethyl group of **10** and **12** by chlorine. The chlorinated derivative, **13**, was obtained as a mixture of two diastereoisomers and **12** as pure isomers, **12***a* (*erythro* form) and **12***b* (*threo* form), respectively. Their configuration was assigned according to ^{13}C and ^{1}H NMR spectroscopy by comparison with the spectra of

compounds **4**, **7**, and **8**. Their ^{13}C and ^1H NMR data are listed, respectively, in Tables 4 and 5.

Experimental

General methods

Solutions were usually evaporated under diminished pressure at a bath temperature not exceeding 40°C. Melting points were determined with a Fisher–Johns melting-point apparatus, and are uncorrected. Elemental analyses were performed with a CEC model 240XA CHN analyzer. Thin-layer chromatography (TLC) was carried out with precoated silica gel plates using toluene and ethyl acetate in different ratios as developing solvent, and the spots were detected by charring with 8% aqueous sulfuric acid. All reactions were monitored by TLC. Column chromatography was performed on silica gel (Merck 230–240 mesh ASTM). ^1H and ^{13}C NMR spectra were recorded at 25°C with a Varian XL 200 or XL 300 NMR spectrometer and tetramethylsilane as an internal standard. Solid state infrared spectra were recorded using an FT-IR spectrometer (Mattson Instruments, model IR10100) equipped with a photoacoustic detector. Mass spectra were obtained with a Kratos MS25RFA analytic spectrometer with a direct insertion probe (70 eV at 250°C).

Analytical and spectroscopic data for the following compounds are summarized in Tables 1–3.

*α-(4-Hydroxymethyl-2-methoxyphenoxy)-3,4-dimethoxy acetophenone **1***

[c]From analysis of a diastereomeric mixture.

(100 mL), anhydrous potassium carbonate (18 g, 0.13 mol) was added, and the mixture was refluxed with vigorous stirring for about 1 h, then diluted with water and extracted with methylene chloride. The extract was freed from excess vanillyl alcohol by washing with sodium hydroxide solution, then with water, dried over anhydrous sodium sulfate, and evaporated to gave a yellow residue, which was recrystallized from methanol or methylene chloride–petroleum ether (bp 30–60°C) to yield 20 g (87%) of white crystalline **1**.

α-(4-Hydroxymethyl-2-methoxyphenoxy)-β-hydroxy-3,4-dimethoxypropiophenone 2

To a suspension of **1** (20.6 g, 0.062 mol) in ethanol (150 mL), potassium carbonate (1.1 g, 0.008 mol) and formalin (10 mL, 37%) were added and the reaction mixture was vigorously stirred for 1.5 h at about 35°C, then diluted with water and extracted with methylene chloride. The extract was washed, dried, and evaporated to yield a colorless syrup, which was crystallized from toluene–ethyl acetate to give 18 g (80%) of white crystalline **2**.

1-(3,4-Dimethoxyphenyl)-2-(4-hydroxymethyl-2-methoxyphenoxy)-1-ethanol 3

Sodium borohydride (1.6 g, 0.042 mol) was added to a suspension of compound **1** (20 g, 0.06 mol) in ethanol (160 mL) and the mixture was stirred at room temperature for approximately 1 h. The reaction solution was diluted with water and neutralized with diluted acetic acid, then extracted several times with methylene chloride. The extract was washed with aqueous sodium bicarbonate solution, then water, dried, and evaporated. The colorless residue was crystallized from acetone–petroleum ether (bp 30–60°C) to give 18.5 g (92%) of white crystalline **3**.

1-(3,4-Dimethoxyphenyl)-2-(4-hydroxymethyl-2-methoxyphenoxy)-1,3-propanediol 4

Compound **2** (18 g, 0.05 mol) was treated in the same way as for the synthesis of **3** and purified by column chromatography using toluene–ethyl acetate (1:4) as eluent to give 17.1 g (94%) of colorless foaming substance, **4** (a mixture of two diastereomers).

α-(4-Hydroxymethyl-2-methoxyphenoxy)-4-benzyloxy-3-methoxyacetophenone 5

A mixture of *O*-benzyl-α-bromo-acetovanillone (17 g, 0.051 mol) (7), vanillyl alcohol (9.4 g, 0.061 mol), and anhydrous potassium carbonate (13.8 g, 0.1 mol) in absolute alcohol (150 mL) was treated in the same way as for the preparation of **1** to yield 18.3 g (88%) of colorless prisms, **5**, from methanol.

α-(4-Hydroxymethyl-2-methoxyphenoxy)-β-hydroxy)-4-benzyloxy-3-methoxypropiophenone 6

A white powder **6** (14.9 g, 79%) was obtained from **5** (17.5 g, 0.043 mol) according to the procedure described for the preparation of **2**.

1-(4-Benzyloxy-3-methoxyphenyl)-2-(4-hydroxymethyl-2-methoxyphenoxy)-1,3-propanediol 7

The ketol derivative **6** (13.8 g, 0.031 mol) was treated in the same way as **4** to give 13 g (95%) of colorless foaming substance, **7**, a mixture of two diastereomers.

1-(4-Hydroxy-3-methoxyphenyl)-2-(4-hydroxymethyl-2-methoxyphenoxy)-1,3-propanediol 8

Compound **7** (10 g, 0.023 mol) was dissolved in methanol (100 mL) and 5% palladium on barium sulfate (10 g) was added.

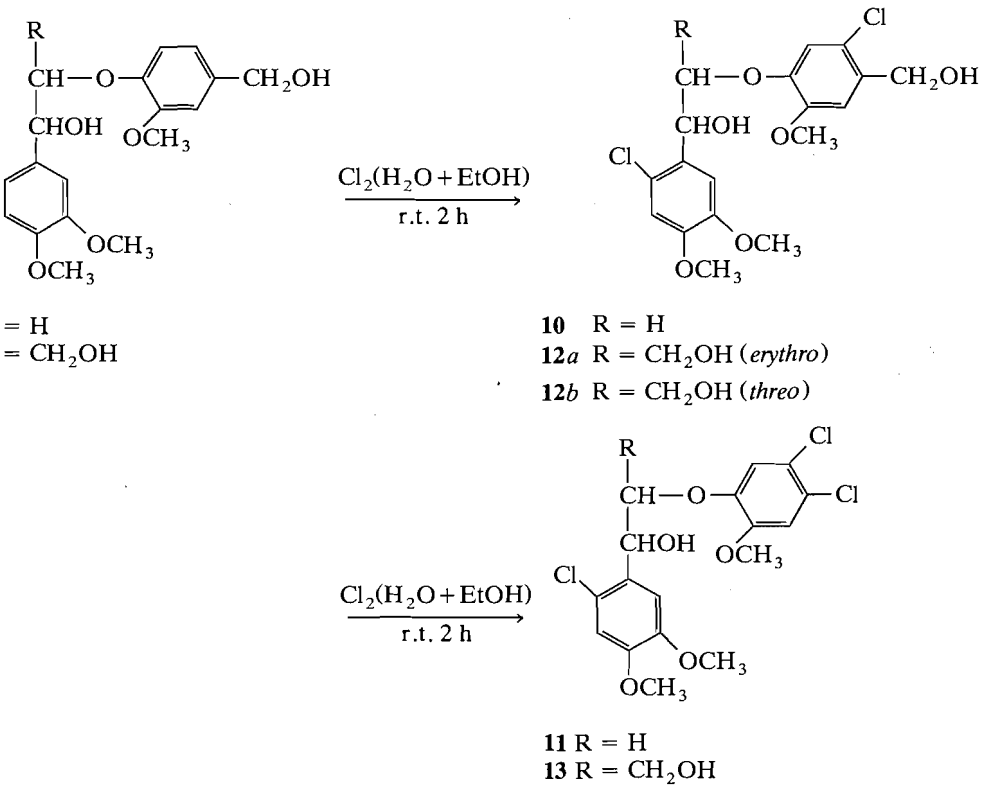

SCHEME 2

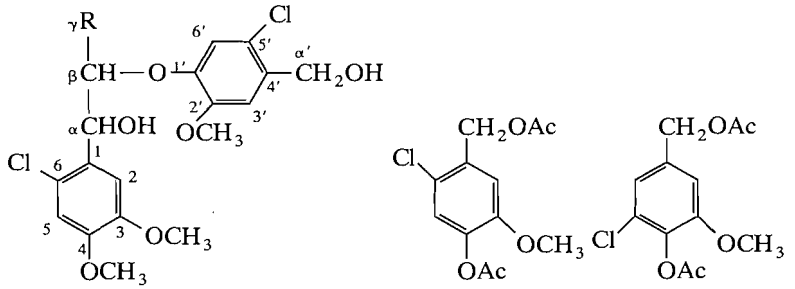

FIG. 1

The mixture was shaken for 2 h at room temperature under hydrogen. The catalyst was then filtered off and washed with methanol. The filtrate and the washings were combined and concentrated under reduced pressure to yield a colorless glass **8** (7.7 g, 96%), a mixture of two diastereomers. A white crystalline *erythro* isomer **8***a* (mp 106–107°C) was crystallized from the mixture of two diastereomers by adding ethyl acetate.

Chlorination treatment of compounds 3 and 4

Compound **4** (0.364 g, 1 mmol) was dissolved in ethanol (10 mL), diluted with distilled water (50 mL), and aqueous chlorine solution was added under vigorous stirring. The mixture was stirred at room temperature for 2 h. The reaction was stopped by adding a small amount of sodium sulfite and extracted with methylene chloride. The extract was washed with water, dried over anhydrous sodium sulfate, and evaporated. The mixture residue was separated by column chromatography with toluene–ethyl acetate (1:2) as eluent. White crystalline **12***a* (*erythro*) (0.108 g, 25%) and **12***b* (*threo*) (0.086 g, 20%) were sequentialy obtained as major products in a molar ratio of 2.5 (Cl_2:**4**). A colorless glass **13**, a mixture of two diastereomers (0.158 g, 36%), was isolated as a major product at a molar ratio of 3.5 (Cl_2:**4**).

Compound **3** (0.334 g, 1 mmol) was treated in the same way as for the preparation of **12** and **13**, and was separated by column chromatography with toluene–ethyl acetate (1:1) as eluent to yield compound **10** (0.185 g, 46%), at a molar ratio of 2.5 (Cl_2:**3**), and **11** (0.155 g, 38%), at a molar ratio of 3.5 (Cl_2:**3**).

Hydrogen bonding and internal rotation barriers of glycine and its zwitterion (hypothetical) in the gas phase

DAKE YU, DAVID A. ARMSTRONG, AND ARVI RAUK[1]
Department of Chemistry, The University of Calgary, Calgary, Alta., Canada T2N 1N4

Received November 29, 1991

DAKE YU, DAVID A. ARMSTRONG, and ARVI RAUK. Can. J. Chem. **70**, 1762 (1992).

The structures of the major glycine conformers, and several transition state structures, were optimized at HF/6-31G* and HF/6-31+G* levels of theory and the correlation energies were calculated at MP2/6-31G* and MP2/6-31+G** levels on these geometries, respectively. The heat of formation of gas phase glycine is calculated to be ΔH_f^0 (298.15) = −389.6 kJ/mol. Thermodynamic properties, C_p^0, S^0, $H^0 - H_0^0$, ΔH_f^0, etc. are calculated as functions of temperature using standard statistical thermodynamic methods. MP2/6-31+G* optimization was carried out on the zwitterion, found by HF/6-31+G* optimization to be a local minimum. The results suggest that glycine in the zwitterionic form in the gas phase is *not* a stationary point. Zwitterionic glycine does not exist in the gas phase.

DAKE YU, DAVID A. ARMSTRONG et ARVI RAUK. Can. J. Chem. **70**, 1762 (1992).

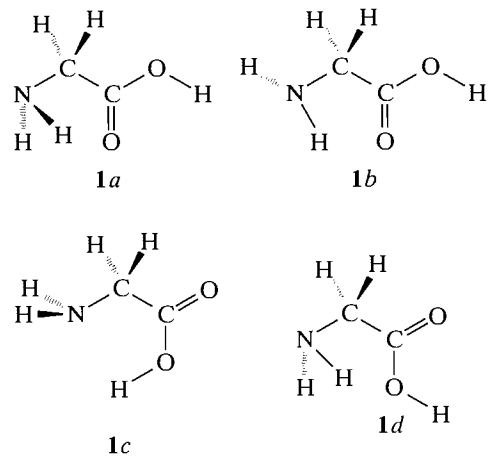
Opérant aux niveaux HF/6-31G* et HF/6-31+G*, on a optimisé les structures des principaux conformères de la glycine et de plusieurs états de transition et on a calculé les énergies de corrélation de ces géométries aux niveau MP2/6-31G* et MP2/6-31+G** respectivement. On a évalué que la chaleur de formation de la phase gazeuse de la glycine est ΔH_f^0(298,15) = −389,6 kJ/mol. Utilisant les méthodes standard de la thermodynamique statistique, on a calculé les propriétés thermodynamiques, C_p^0, S^0, $H^0 - H_0^0$, ΔH_f^0, etc. en fonction de la température. Opérant au niveau MP2/6-31+G*, on a effectué une optimisation du zwitterion qui, par une optimisation HF/6-31+G*, correspond à un minimum local. Les résultats suggèrent que la forme zwitterionique de la glycine en phase gazeuse *n'est pas* un point stationnaire. La glycine sous la forme zwitterionique n'existe pas en phase gazeuse.

[Traduit par la rédaction]

1. Introduction

Amino acids are the fundamental structural units of proteins. Glycine is the simplest of the α-amino acids and one of the first to be isolated. It serves as an important model compound in biophysics and biochemistry and, because of its small size, has been the subject of numerous theoretical investigations, by both semi-empirical (1–11), and *ab initio* (7–25) methods. Although it is the smallest amino acid, glycine is nevertheless sufficiently large and has enough conformational flexibility that its complete description poses a formidable challenge to computational chemists. All of the early work suffered to some extent or other from the necessity to use approximate theory or rather small basis sets, or from the inability to carry out complete searches of the conformational space. Indeed, specific knowledge of major aspects of its potential energy surface and its thermochemistry even in the gas phase are as yet lacking. Both are necessary for an understanding of protein conformations and dynamics (26). We review briefly below current theoretical and experimental knowledge of the structures and energetics of glycine and its zwitterion. The purpose of this communication is to extend the quantitative knowledge of the structures of glycine in the gas phase, specifically addressing the interplay of intramolecular hydrogen bonding as a structure determining factor. We also provide a detailed analysis of the thermodynamics of glycine. The work is directly relevant to the search for glycine in interstellar space (27) and is intended to lay the groundwork for a study of glycine in solution which is in progress. This study also serves to provide comparisons with experimental results.

Glycine is known to exist in a variety of structures depending on its environment. In water at neutral pH, it exists as the zwitterion, $H_3N^+CH_2COO^-$; at high pH, it exists as glycinate, $H_2NCH_2COO^-$; at low pH, as glycinium, $H_3N^+CH_2COOH$. In the solid state, glycine is zwitterionic. Measurements of the dielectric properties of amino acids in nonaqueous solutions suggests that the dominant form is probably the intermolecularly hydrogen-bonded neutral species (28). The insolubility of glycine in nonpolar solvents may be largely due to its crystal lattice strength. In the isolated state, glycine adopts the neutral form, H_2NCH_2COOH, as found by several independent millimeter wave (13, 14, 29) and microwave investigations (30), and by spectroscopic studies on the low-temperature matrix-isolated products of sublimation (31). Structures **1***a* and **1***c* have been identified as components in the gas phase. The structure deduced from the first spectroscopic experiments, **1***c*, did not correspond to the most stable structure, **1***a*, predicted by virtually all theoretical studies. The discrepancy has been explained (13, 18) as due to the rather weak dipole moment of **1***a* compared with that of the structure responsible for the observed rotational spectrum, **1***c*.



1*a* **1***b* **1***c* **1***d*

Clearly, glycine in the vapor phase exists as two and possibly more conformers. The strength of a hydrogen bond, 20–

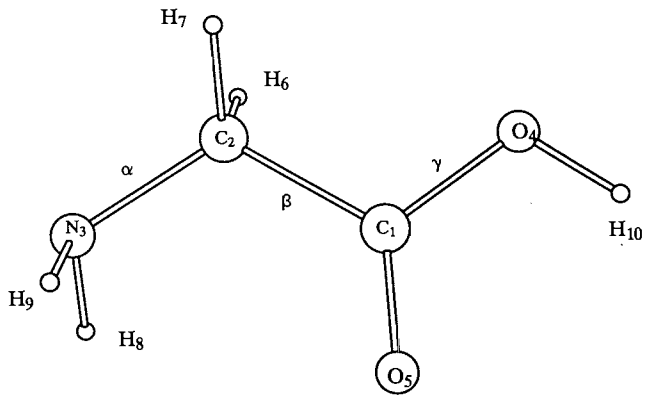

FIG. 1. Nuclear numbering system of glycine and definitions of α, β, and γ for their intermolecular rotations.

30 kJ/mol, is normally larger than rotational barriers about single bonds, which fall in the range 4–15 kJ/mol. Since glycine contains basic units NH_2 and =O, and polar NH and OH bonds, the conformations of glycine would be expected to be governed by several H-bonding possibilities. Relative stabilities of the conformers and magnitudes of internal rotation barriers will reflect the strength of the H bonds. There are three internal rotational degrees of freedom, which we define as α, β, and γ for C—N, C—C, and C—O rotations, respectively, as shown in Fig. 1. The first two correspond to the parameters, Φ and Ψ, respectively, used by biochemists to discuss the conformations of proteins. The structure observed experimentally in the gas phase, **1***c*, is unusual in having an *anti* orientation of the O—H bond relative to the C=O group. By analogy with esters (32), this orientation must be at the expense of approximately 20 kJ/mol stabilization. If it were quasiplanar, an additional cost of 6–8 kJ/mol would ensue from the eclipsing of the NH_2 group with the CH_2 group. Apparently, formation of the N···H—O bond more than compensates for these undesirable features. In the most stable structure, **1***a*, the O—H, NH_2, and CH_2 groups are in their normal orientations and additional stabilization may be obtained from a bifurcated hydrogen-bonding arrangement. The bifurcated arrangement of H bonds is itself unusual, an almost linear arrangement with a single hydrogen bridge being the norm (33).

The most thorough theoretical study to date, which appeared while the present work was in progress, is due to Jensen and Gordon (11) (JG), who determined all of the minima and transition structures at the restricted Hartree-Fock level of theory with the 6-31G* basis set (RHF/6-31G*). Correlation energy contributions were determined at the level of second-order Moller-Plesset perturbation theory. Eight stationary points corresponding to minima on the neutral glycine hypersurface were located. Structure **1***c* was found to be 7.5 kJ/mol less stable than **1***a*, the global minimum. A second structure, **1***d*, at relative energy 7.1 kJ/mol, was also found to be more stable than **1***c*, and a third structure, **1***b*, relative energy 8.9 kJ/mol, is slightly less stable. The population of **1***c* at 298°C in the vapour phase was predicted to be about 5%. Even given the higher dipole moment of **1***c*, it would appear that the spectroscopic data would indicate a higher proportion than the predicted 5%. The comprehensive work of JG follows partial *ab initio* investigations of the glycine potential energy surface by Vishveshwara and Pople (17), Schafer and co-workers (13, 18), Palla and co-workers (7, 22), Luck *et al.* (34), and Ramek and co-workers (24, 25), who investigated at various levels of theory structures **1***a*, **1***c*, **1***d*, and several other structures with C_s symmetry. All investigations agree on the global minimum, **1***a*.

The relationship between the neutral and zwitterionic forms of glycine has been the subject of several investigations. All calculations yield the same gas-phase structure for the zwitterion, namely **2***a*, but depending on the theoretical method, a wide range of values for the gas-phase energy difference has been obtained (kJ/mol): CNDO/2, 421 (2); MNDO, 257 (6); STO-3G, 344 (22); 4-31G, 121 (6, 19); 6-31G, 180 (20); Dunning's DZP, 156 (9). The high values obtained with the semiempirical methods reflect their inability to describe hydrogen bonding correctly. The effect of solvation on the relative stabilities has been simulated by MNDO using an effective charge model (6). Structures **1***a* and **2***a* were found also to be the most stable 'in solution' but the relative energies were reversed from 257 kJ/mol to −46 kJ mol. *Ab initio* calculations, wherein mutual solute–solvent polarization effects are accommodated by an additional potential term added to the Hamiltonian, have yielded accurate values for the heat of solvation at 298 K for the process, neutral (gas) → zwitterion (solution), $\Delta H = -81.6$ kJ/mol (22) at 4-31G level of theory, compared with experiment, -80 ± 4 kJ/mol (35). The relative energy of the two forms in solution by this approach is −79.0 kJ/mol. Specific solvation of three of the neutral forms of glycine by a single water molecule (the 'supermolecule' approach) has been investigated by Basch and Stevens (23) using a DZP basis set and compact effective potentials for the core electrons. The complex **1***a*-H_2O is still the most stable, while **1***c*-H_2O is 20.5 kJ/mol less stable than **1***d*-H_2O. The zwitterionic form was not considered.

In the present work, we have investigated the eight stable neutral glycine conformers and a number of the transition structures in the gas phase with the objective of refining existing estimates of relative stabilities and geometrical differences among glycine conformers. In Sect. 2, we briefly describe the levels of *ab initio* theory used for evaluating the conformational and energetic properties of glycine and its zwitterion. In Sect. 3 we present the results of stationary point calculations, reporting the fully optimized geometries for all of the minima and transition structures at the HF/6-31+G* levels, corrected for correlation effects by MP2/6-31+G** single point calculations on the HF/6-31+G* structures. For zwitterion glycine the results at this level indicated that it might not correspond to a stationary point in the potential energy surface. MP2/6-31+G* optimization was carried out and the results confirmed that the zwitterion form does not exist as a stable molecule in the gas phase at this level of theory. Also presented in this section are some thermodynamic properties, as functions of temperature, calculated with standard statistical thermodynamic methods. Then we discuss the general features of these calculations and the hydrogen bonding and rotation barriers of the glycine conformers. Finally in Sect. 4 we summarize our main results and conclusions.

2. Computational details

All *ab initio* calculations presented here were performed with the Gaussian 88 and Gaussian 90 (36) molecular orbital packages. The geometries were optimized with the

standard restricted Hartree-Fock method. Convergence of the geometry was to the limits imposed internally in Gaussian 90, which correspond approximately to ±0.002 Å and ±0.1°. The 6-31G* split-valence basis set was used for the initial evaluations. The larger 6-31+G* basis was used for the final geometry optimizations, as it has been quite successful in studies of hydrogen-bonding systems, where the need for diffuse functions was recognized (37). No symmetry constraints were assumed at the beginning of each geometry optimization, but if the optimization ended with a nearly symmetric structure, the conformer's symmetry was verified. Vibrational frequencies were calculated to confirm the nature of the stationary points and to provide the vibrational zero-point energy (ZPE). The ZPE values were scaled by a factor of 0.9 in considering the relative energies of the conformers to take account of known inadequacies in frequencies calculated at this level (38). The HF/6-31+G* structures were also used for single-point calculations with the 6-31+G** basis set, at the second-order Moller–Plesset (MP2) level of theory. The MP2 method with an extended basis such as 6-31+G** recovers much of the electron correlation energy neglected in HF theory, and significantly improves HF relative energies. For the zwitterionic form of glycine, MP2/6-31+G* optimization was also carried out, since it was apparent from single-point calculations that correlation has a significant effect on the geometry of this isomer.

Ideal gas thermodynamic functions C_p^0, S^0, $H^0 - H_0^0$, and $(G^0 - H_0^0)/T$ in the temperature range 0–1500 K and 1 atm pressure were calculated by standard statistical thermodynamic methods based on the rigid rotor – harmonic oscillator model. The computed vibrational frequencies were scaled by a factor of 0.9 in calculating the vibrational contributions to the above thermodynamic functions. The rotations about angles α and β were treated as hindered internal rotors in the first instance and an improved calculation was carried out by direct summation over the energy levels using rotational potentials as given by $V = \Sigma_n \frac{1}{2}V_n(1 - \cos n\phi)$ (ϕ = α or β). The calculation of the temperature dependence of $\Delta H_f^0(T)$, and hence $\Delta G_f^0(T)$ and $K_f(T)$, for glycine requires knowledge of the enthalpy of formation of at least one of its conformers at a reference temperature. In the absence of an experimental value for the heat of formation for glycine in the gas phase, the method of isodesmic reactions was used to determine a theoretical value. Thus, *ab initio* calculations were performed on the hypothetical reaction

$$H_2NCH_2CH_3 + H_3CCOOH \rightarrow \text{Glycine } (\mathbf{1}a) + C_2H_6$$

The experimental heats of formation for $H_2NCH_2CH_3$, H_3CCOOH, and C_2H_6 are available (39). These can be used together with the reaction energy for the above reaction from *ab initio* calculations (MP2/6-31+G**//6-31+G* + ZPE), to obtain a value for $\Delta H_f^0(T = 0)$. The reliability of such a procedure and the criteria for the choice of components for the hypothetical reaction have been discussed elsewhere (40). The thermodynamic properties listed in Table 4 are derived for the equilibrium mixture at a given temperature, assuming a Boltzman distribution of the conformers.

3. Results and discussion

Optimized geometric parameters of the seven most stable glycine conformers are reported in Table 1(*a* and *b*), in the *Z*-matrix format as actually used in the calculations. The nuclear numbering scheme is defined in Fig. 1 and the structures in Fig. 2. The data for a number of transition structures are also included in Table 1 and Fig. 2. Table 2 collects electronic energies at HF and MP2 levels, the zero-point vibrational energies, and the dipole moments for all of the structures. The transition structures are verified to have one and only one imaginary frequency (Table 2). All of the minimum energy and transition structures described in this work have also been described to some extent by JG (11). In addition, the basis set dependence of the relative SCF energies of structures **1***a*, **1***c*, **1***d*, **1***cc*, and **1***dd* has been investigated by Ramek, Cheng, Frey, Newton, and Schafer (RCFNS) (25). The present results, obtained with a somewhat better basis set than that of JG and approaching the best of RCFNS, are only quantitatively different from JG. Table 3 lists the relative energies at different levels of calculations, including the MP2/6-31G*//6-31G* results of JG and the largest basis set results of RCFNS. A curious consequence of the presence of diffuse functions in the basis set is that the relative (to **1***a*) energies of *all* structures are lower than those of JG. The differences are in the range 0.6–6.1 kJ/mol for the minima, and 1.5–8 kJ/mol for the transition structures (for which comparison could be made). In the few cases where comparison is possible, our results are within 0.3 kJ/mol of those obtained by RCFNS. We discuss the structures in some detail from the point of view of attempting to isolate structure-determining factors, hydrogen bonding, bond–bond repulsions, and special properties of carbonyl groups.

Hydrogen bonding, rotational barriers, and relative stability of neutral glycine conformers

Bifurcated H bonding? The most stable of the neutral glycine conformers is **1***a*, as previously found using other semiempirical and *ab initio* calculations. Structure **1***a* has two NH bonds which are symmetrically disposed to the carbonyl oxygen atom. The molecular point group is C_s. It is tempting to describe the configuration of **1***a* as evidence of bifurcated hydrogen bonding. As alluded to earlier, bifurcated H bonding is not the preferred mode in most H-bonded systems. Deviation of the NCC angle from its normal tetrahedral value, or proximity of the N—H protons to the oxygen atom may be sought as evidence of attractive or repulsive interactions. The extended value of the NCC angle (3-2-1, Table 1) of **1***a*, 115.4° is consistent with the lack of an attractive interaction. According to the calculations, the H···O nonbonded distance, 2.81 Å, is well outside of van der Waals separation, but the O and N, separated by 2.84 Å, are just in van der Waals contact. Indeed it is possible that there is little if any attractive interaction between the NH_2 and the carbonyl O. One must conclude that considerations other than hydrogen bonding are probably responsible for the predominance of **1***a*. It is well documented (for a review, see ref.41) that in compounds of the class, $XCH_2C(O)Y$, where X is a polar group or alkyl and Y is H, alkyl, or alkoxy, the group X tends to adopt a position eclipsing the carbonyl group. This occurs even in nonpolar solvents where the coalignment of bond dipoles is disfavoured. The explanation for this effect is uncertain. It may have little to do with the polar group itself, but rather may be driven by the necessity to optimize the orientation of the best donor group (the CH_2 group) for electron delocalization into the π* orbital of

the carbonyl group. In addition, structure **1***a* has the ideal staggered arrangement of N—H and C—H bonds.

Two other 'bifurcated' structures are shown in Fig. 2. A fourth, found by JG to be 35.1 kJ/mol higher than **1***a*, and GLY5 in their notation, is not considered here. Rotation about the C—C bond (β rotation) yields the 'bifurcated' structure, **1***d*, 6.4 kJ/mol less stable than **1***a*. This structure has an even more extended NCC angle, 118.2°, a consequence of steric repulsion between the NH_2 group and the OH group due to the highly constricted CCO(H) angle of the carboxylate group. Its skeletal point group is C_1. The C_s structure with two symmetric N—H bonds bracketing the OH group **1***dd* is a saddle point between **1***d* and its enantiomer, posing a barrier of only 0.2 kJ/mol for the interconversion. The energy of **1***d* relative to **1***a* may be taken to be the energy cost of assuming the *anti* orientation of the C—N and C=O bonds. The two transition structures between **1***a* and **1***d* have a nearly perpendicular orientation of the —COOH moiety, and present barriers of 10.3 kJ/mol from **1***a* to **1***d* and 3.9 kJ/mol in the reverse direction. Conformer **1***f* also has a bifurcated arrangement of N—H bonds. The NCC angle of **1***f* is almost identical to that found in **1***a*. Conformer **1***f* differs from **1***a* in having an *anti* orientation of the acidic O—H group. This orientation is known to be unfavorable in esters (32) and by extension should be unfavourable in acids as well. This structure lies 24.9 kJ/mol above **1***a*. The energy difference represents the energy cost of assuming the *anti* orientation of the OH group. The energy difference between structures **1***b* and **1***g*, which also differ in this one respect, is similar, 25.4 kJ/mol.

[a]Bond lengths in Å, angles in deg.
[b]The parameters are listed in Gaussian 90 'Z-matrix' format. See Fig. 1 for the numbering scheme.

Each of the structures **1***a*, **1***d*, and **1***f* has a corresponding structure in which a single N—H bond projects more or less toward an oxygen of the carboxylate group. These are **1***b*, **1***e*, and **1***g*, respectively. In each, the corresponding structure is higher in energy than the structure with the 'bifurcated' configuration, by 5.6, 3.3, and 6.2 kJ/mol. Nevertheless, the NCC angle in each case is less, by 4.9, 6.8, and 5.0°, respectively. The contraction of the angle would normally be interpreted as evidence of increased attraction, or decreased repulsion between the NH_2 group and the carboxyl oxygen atom, and a lowering of the energy would be expected. The nonbonded H···O separation in **1***b* is 2.45 Å, a value which is shorter than the sum of van der Waals radii for the two atoms, 2.6 Å. Evidence for a weak bonding interaction may also be gleaned from the observation that both the N—H and C=O bonds are twisted out of the NCC plane in such a way as to maintain contact. The higher energy of each of these three structures relative to the corresponding 'bifurcated' species probably ensues from the imposition of an eclipsing interaction between the N—H bond and the skeletal C—C bond in the 'singly H-bonded' configuration.

Conformer **1***b*, which we find to be second in stability, is connected to **1***a* through an α rotation (107°) without significant change of β and γ. This structure was calculated to be 9.2 kJ/mol above **1***a* by JG (11) and not considered by RCFNS (25). The barrier for conversion of **1***a* to **1***b* is 7.1 kJ/mol but only 1.5 kJ/mol in the reverse direction. Since **1***b* has comparable stability to **1***c*, the reason why **1***b* has not been observed experimentally is probably due to its relatively small dipole moment (Table 2). The enantiomeric form of **1***b*, namely $\overline{\mathbf{1}b}$, is reached via the transition structure **1***bb*, which has C_s symmetry. The rotation from **1***b* to $\overline{\mathbf{1}b}$ is also dominated by the α motion with a barrier of 12.5 kJ/mol. This relatively high barrier for α rotation is due to the eclipsed arrangement of hydrogen atoms in the CH_2 and NH_2 groups in **1***bb*. In fact, the energy difference between **1***bb* and **1***a*, 18 kJ/mol, may be

taken as a measure of the energy cost of assuming the eclipsed orientation of the CH_2 and NH_2 groups, as opposed to the staggered orientation.

The experimentally observed (29, 30) structure **1***c*, which is the obvious precursor to the zwitterionic form, has almost the same energy as that of **1***b*. The strong hydrogen bond between the basic nitrogen atom and the acidic carboxyl H is evidenced by the short N···H distance (2.06 Å compared with the van der Waals distance 2.7 Å). In **1***c*, the strong H bond is countered by a number of unfavorable interactions between the NH_2 and CH_2 groups (partially eclipsed, +18 kJ/mol), the arrangement of the hydrogen atom of the carboxylic acid group (*anti*, +25 kJ/mol), and the orientation of the C—N bond relative to the C=O (*anti*, +6 kJ/mol). The relative energy of **1***c* is 5.7 kJ/mol. The difference provides an estimate for the strength of the H bond between a carboxylic acid and an amine, approximately 43 kJ/mol. The relative stability of **1***c* is appreciably less than predicted by MNDO (4) and smaller basis set (4-21G) *ab initio* (13) studies and is essentially the same as found by JG (6.3 kJ/mol (11)). The MNDO method is unable to account for hydrogen bonding. The results also emphasize the inadequacy of small basis sets in *ab initio* studies. The only experimental value of relative energy of glycine conformers was for **1***c* (versus **1***a*), given by Schafer *et al.* (13) as 5.86 ± 1.79 kJ/mol. This is in excellent agreement with the present result. It should be noted that without the diffuse functions (i.e., MP2/6-31G*//6-31G*+ZPE, this work or ref. 11), a higher relative energy is predicted for **1***c*, 7.9 kJ/mol (the number listed in Table IV of ref. 11 does not include the ZPE contribution).

Structure **1***c* is isolated on the glycine hypersurface. The nearest conformer, **1***d*, is similar in energy, being less stable by 0.7 kJ/mol, but is separated from **1***c* by a substantial barrier of 46 kJ/mol. The rotational motion involves coupled α and β rotations. The barrier originates from the necessity to disrupt the π-bonding character of the C—O bond in a manner analogous to the C—N rotation of amides, and from the effort required to break the strong H bond in **1***c*. A notable change in NCC angle is found again, the angle decreasing by 6° from **1***d* to **1***c*. Structure **1***c* is chiral. An α rotation leads **1***c* to its mirror image conformer. The transition structure for the interconversion, **1***cc*, which has C_s symmetry, is only 0.4 kJ/mol above **1***c* at the MP2 level. Addition of the ZPE contribution reverses the relative stability to −0.6 kJ/mol, an indication that **1***c* exists in a very shallow double-welled potential and that the actual structure is probably planar in the heavy-atom skeleton. From **1***c* to $\overline{\mathbf{1}c}$ covers about 148° of α rotation with only 15° change in β and 1° in γ.

Parallel to the **1***a*–**1***d* pair, the interchange between **1***b* and **1***e* is also through the β rotation. **1***e* is only 3.3 kJ/mol above **1***b* but they are well separated by a barrier of 9.1 or 11.1 kJ/mol, if rotating along the opposite direction. Another possible change of conformer from **1***e* is through a simultaneous rotation of α and β, passing over a barrier of 7.4 kJ/mol to **1***d*. The β rotation introduces no significant change in bond lengths and bond angles, about 0.05 Å and 2.5° from

1*a* to **1***d* or **1***b* to **1***e*. Changing the 'bifurcated' bonds to hydrogen in **1***d* to a single hydrogen bridge in **1***e* narrows the NCC angle by 7°.

The two high-energy conformers **1***f* and **1***g* are characterized by the repulsions between the hydrogens from CH_2 and carbonyl groups. The connections with **1***a* or **1***b* through γ rotation is less likely to happen at room temperature. From **1***a* to **1***f* the rotational barriers are as high as 50.6 or 25.7 kJ/mol from the other side and it is expected that from **1***b* to **1***g* the barrier will be similar, if not higher.

The zwitterionic form of glycine, a hypothetical molecule in the gas phase

A number of theoretical studies on the zwitterionic form of glycine in the gas phase have been carried out. The results depend strongly on the methods or the basis sets used, the relative energy of the zwitterion relative to **1***a* ranging from 121–421 kJ/mol. Tse *et al.* (19) have reported the transition structure for proton transfer from neutral glycine to **2***a*. The barrier for the H migration was found to be only 2 kJ/mol, located at N—H distance 1.18 Å and H—O distance 1.41 Å. In the present work, a stationary point **2***a*, the zwitterion form of glycine was located on the HF potential energy surface by HF/6-31+G* optimization. It is characterized by a hydrogen bond between a single NH bond and one of the carbonyl oxygen atoms. The structure has C_s symmetry. The ammonium group conformation is such that one proton is in the molecular plane. At the present level of theory, the HF structure **2***a*, corresponding to zwitterionic glycine, is 80.6 kJ/mol less stable than the most stable neutral form, **1***a*. A second stationary point, **2***aa*, was also found at this level of calculation. It has one imaginary frequency and corresponds to the saddle point for CN rotation. The transition state for the neutral glycine–zwitterion exchange, **1***c*–**2***a*, was found by HF/6-31+G* geometry optimization. Harmonic frequency analysis shows one fairly large imaginary frequency (Table 2). Transition structure **1***c*–**2***a* is 2.4 kJ/mol above **2***a* and the geometric parameters are essentially the same as found by Tse *et al.* (19). However, at the MP2/6-31+G** level, the energy at this 'saddle point', **1***c*–**2***a*, is 13 kJ/mol *lower* than that of **2***a*! MP2/6-31+g* optimization, started at the HF/6-31+G* geomtry, **2***a*, results in a smooth transition to a structure similar to **1***c*. Thus, the present results suggest that the zwitterionic form of glycine rearranges without activation to conformation **1***c* of neutral glycine.

Effects of basis set, correlation, and zero point energy

A comparison of the relative energies of the glycine minima and transition structures as a function of level of theory is presented in Table 3. Data by the MP2/6-31G*//6-31G* method are those of JG (11). Correlation corrections have been previously shown to have significant effects on the structures and relative energies of H-bonded systems (42). Comparison of columns 2 and 3 of Table 3, reveals that *all* structures are stabilized by electron correlation relative to the global minimum, **1***a*. Stated a different way, structure **1***a* has a smaller correlation energy correction than any of the other structures. In most cases the differences are small, less than

2 kJ/mol. However, in the case of the two structures which have clearly defined H bonds, stabilization due to correlation is very important. The relative energy of **1***c* is reduced from 11.22 to 4.33 kJ/mol (from 12.40 to 2.93 kJ/mol after MP2/6-311G** optimization according to RCFNS (25), and the relative energy of the zwitterionic structure, **2***a*, is lowered by over 30 kJ/mol. The HF 'transition structure' for H transfer, **1***c*–**2***a*, is lowered even more, by 45.27 kJ/mol. In other words, a qualitative change in the nature of the potential energy surface is predicted. Of special interest is the comparison of the effect of the correlation correction on **2***a* and **2***aa*. The former has a strong single H bond, while the latter structure has a bifurcated geometry. Stabilization of the latter by correlation correction is only about half of the former, 16.24 kJ/mol.

The ZPE of neutral glycine conformers vary from 222 to 229 kJ/mol. The largest difference, after scaling (38), corresponds to a change of as much as 6 kJ/mol in relative stability or barrier height. As shown in Table 3, the vibrational contributuion makes **1***b* a more stable conformer than **1***c*, and the transition state **1***cc* for the interconversion of the enantiomeric forms of **1***c* is actually lower in energy than **1***c*. It is clear that it is important to include ZPE in considering the total energy in studies involving a few molecules or conformers with similar electronic energies. The relative energies of the glycine conformers as reported by JG (11), or RCFNS (25), and which are listed in Table 3 do not appear to include the ZPE correction.

The addition of diffuse functions on the heavy atoms and polarization functions on hydrogen atoms is normally not required to achieve qualitatively correct geometries and relative energies. The most pronounced effect of diffuse functions is on species which have nonbonded electron pairs, especially if they are also negatively charged. Polarization functions on H are most important when H bonding is involved. In this sense, glycine which has both nonbonded lone pairs (and a negatively charged region in the zwitterionic form) and H bonds is a worst case for description by use of the normally sufficient 6-31G* basis set. Some measure of the importance of the expansion of the basis set may be garnered by comparison of columns 3 and 5 of Table 3. The latter are the MP2/6-31G*//6-31G* results of JG (11), the former our MP2/6-31+G**//6-31+G* results. The comparison is not precise because our basis set contains the

additional diffuse functions. Neither set of data is corrected for ZPE. In every case, the *relative* energies of the structures are reduced using the larger basis set by amounts ranging from 1–5 kJ/mol. As with the effect of correlation alone, the most stable structure, **1***a*, is least affected by the change of basis set. Thus the extended basis set calculations predict a narrower spread of relative stabilities and lower internal rotation barriers. We illustrate the impact of the energy differences by noting the effect on the rate constants for **1***a*–**1***b* interconversion reactions. The free energy differences for these conformers, and the −2.6 and 0.8 kJ/mol change in barriers will contribute a factor of 2.8 for the forward reaction and 0.7 for the reverse reaction, or a factor of 4 to the equilibrium constant at 300 K.

Thermodynamic properties

Ideal gas thermodynamic functions C_p^0, S^0, $H^0 - H_0^0$, and $(G^0 - H_0^0)/T$ in the temperature range 0–1500 K and 1 atm pressure for the neutral and zwitterionic forms of glycine are listed in Table 4. In the case of the neutral form, the properties correspond to the composite mixture appropriate for a given temperature. The experimental heat of formation of solid-phase glycine at 298.15 K has been reported to be −528.6 kJ/mol (39). The enthalpy of sublimation of glycine has been measured experimentally at 418.93 K to be 136.5 kJ/mol (43). The heat capacity of solid glycine has been determined to be 99.2 J/mol (39). The present investigation provides a theoretical value of 93.0 J/mol (Table 4) for the heat capacity of glycine in the vapour phase at 298.15 K. These data permit the determination of an 'experimental' value for the heat of formation of glycine in the vapour phase, ΔH_f^0 (298.15) = −392.8 kJ/mol, which is in excellent agreement with the theoretical value, ΔH_f^0 (298.15) = −389.6 kJ/mol, derived using the isodesmic reaction described in Sect. 2.

As discussed in the previous section, the zwitterionic form does not exist as a separate species in the gas phase. Nevertheless, in the absence of other information, we have adopted the structure obtained from the 6-31+G* calculations as representative of the solution phase or solid phase structure. The data presented in Table 4 represent the overall thermodynamic properties without contributions from solvent or solid state interactions. The reference value for the heat of formation of zwitterionic glycine is obtained by adding the stability of **2***a* relative to **1***a* to the heat of formation of glycine at 0 K. The thermodynamic data in Table 4 lay the groundwork for a solution phase study which is in progress.

4. Summary

The results of this study show that glycine exists only in the neutral form in the gas phase. The zwitterionic form is not a stationary point at MP2/6-31+G* level of theory. The theoretical 6-31+G* geometries and frequencies were used to calculate the heat of formation of gas phase glycine, ΔH_f^0 (298.15) = −389.6 kJ/mol, in excellent agreement with an estimate derived from experimental solid state and sublimation data.

Received August 25, 1991

SHUANG LIU, C. ROBERT LUCAS, ROSEMARY C. HYNES, and JEAN-PIERRE CHARLAND. Can. J. Chem. **70**, 1773 (1992).

Preparations of the ligands 1,9-bis(2-pyridyl)-2,5,8-trithianonane (L1) and 1,9-bis(2-pyridyl)-5-oxa-2,8-dithianonane (L2) and their copper(II) complex cations $[Cu(L1)]^{2+}$ and $[Cu(L2)]^{2+}$ as ClO_4^-, $CF_3SO_3^-$, or BF_4^- salts are described. X-ray structures of both complex cations as perchlorates are reported. For $[Cu(L1)](ClO_4)_2$: space group *Pbca*, $a = 10.4896(5)$, $b = 12.9376(6)$, $c = 33.3943(13)$ Å, $Z = 8$, $R_f = 0.067$, $R_w = 0.074$ for 1769 reflections. For $[Cu(L2)](ClO_4)_2$: space group $P2_1/c$, $a = 14.388(2)$, $b = 9.990(5)$, $c = 16.076(3)$ Å, $\beta = 107.919(12)°$, $Z = 4$, $R_f = 0.069$, $R_w = 0.089$ for 2813 reflections. Both are slightly distorted square pyramidal species having interactions in the solids between their ClO_4^- anions and one of the pyridine rings in the L1 complex and the copper atom in the L2 complex. The complexes have been examined by electron spin resonance, electronic spectroscopy, and cyclic voltammetry. The effects of anion coordination, solvation, and removal or alteration of the apical donor atom are assessed by comparisons involving the new complexes and published data on related substances.

SHUANG LIU, C. ROBERT LUCAS, ROSEMARY C. HYNES et JEAN-PIERRE CHARLAND. Can. J. Chem. **70**, 1773 (1992).

On décrit la préparation des ligands 1,9-bis(2-pyridyl)-2,5,8-trithianonane (L1) et 1,9-bis(2-pyridyl)-5-oxa-2,8-dithianonane (L2) ainsi que celle de leurs complexes cationiques du cuivre(II), $[CuL1)^{2+}]$ et $[Cu(L2)]^{2+}$, sous forme de sels du ClO_4^-, $CF_3SO_3^-$ ou BF_4^-. On a déterminé les structures cristallographiques des deux complexes cationiques, sous la forme de perchlorates. Pour le $[Cu(L1)](ClO_4)_2$: groupe d'espace *Pbca*, $a = 10{,}4896(5)$, $b = 12{,}9376(6)$ et $c = 33{,}3943(13)$ Å, $Z = 8$, $R_f = 0{,}067$ et $R_w = 0{,}074$ pour 1769 réflexions. Pour le $[Cu(L2)](ClO_4)_2$: groupe d'espace $P2_1/c$, $a = 14{,}388(2)$, $b = 9{,}990(5)$ et $c = 16{,}076(3)$ Å, $\beta = 107{,}919°$, $Z = 4$, $R_f = 0{,}069$ et $R_w = 0{,}089$ pour 2813 réflexions. Les deux cations sont des espèces pyramidales carrées légèrement déformées qui, dans le solide, possèdent des interactions avec leurs anions ClO_4^- et l'un des cycles pyridiniques dans le complexe L1 et avec l'atome de cuivre dans le complexe L2. On a examiné les complexes par résonance paramagnétique électronique, par spectroscopie électronique et par voltampérométrie cyclique. En se basant sur une comparaison de ces nouveaux complexes avec les données publiées pour des substances apparentées, on a évalué les effets de la coordination par l'anion, de la solvatation et de l'enlèvement ou de l'altération de l'atome donneur apical.

[Traduit par la rédaction]

Introduction

Continuing attempts to model the active sites in copper proteins have generated considerable new knowledge of the behaviour of simple coordination compounds of copper (1). Interest in the "type 1" copper site in proteins has led to successful mimicking of several of its distinctive features such as colour, redox potential, electron spin resonance (ESR) parameters, rapid electron transfer kinetics, and specific structural details using simple coordination compounds as models. A short, general discussion of these efforts has been given by Solomon (2) while individual properties of both the enzymes and the model compounds are addressed in greater detail by other authors (1, 2). Knowledge of the specific structural details to mimic in small model molecules has been greatly assisted by the availability of high-resolution X-ray structural determinations of poplar plastocyanin (1.6 Å resolution) (3) and *alcaligenes denitrificans* azurin (1.8 Å resolution) (4), both of which indicate that copper(II) is surrounded by two aromatic N-donors, a mercaptide-S and a thioether-S, and, in the case of the azurin, by a weakly bonded O-donor as well. Careful studies by several groups (5–8) of various specific characteristics of the "blue" or "type 1" copper centers have revealed the factors responsible for each property, with the possible exception of the unique ESR signature for which the explanation is still mostly phenomenological. The ESR properties have been examined in some detail by Addison and co-workers (6, 9, 10), Urbach and co-workers (5), and others (11) and it is clear that donor atom identity, coordination geometry, and, in particular, distortion from regular geometry are important influences, although in model compounds only limited success has been achieved in duplicating simultaneously both the ESR parameters and the other characteristics of the natural materials. As part of our continuing interest in the chemistry of sulfur-containing coordination compounds (12–14), we have examined the influence of adding a fifth donor of changeable type to the coordination sphere of copper atoms already surrounded by a pair of aromatic nitrogens and a pair of thioether sulfurs. Four-coordinate copper(II) surrounded by N_2S_2 ligands has been widely studied as a model of the "blue" copper centers and the literature provides many examples with which to compare our five-coordinate systems. In this report we examine the ESR, electronic spectroscopic, electrochemical, and structural properties of cop-

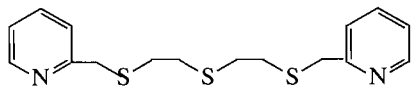
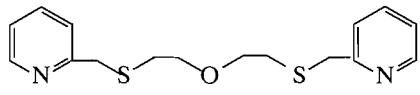
per(II) complexes of the ligands L1 and L2 and compare them to those of related four-coordinate copper complexes in the literature.



L1



L2

Experimental

Reagents were obtained from the Aldrich Chemical Co. or from Morton Thiokol Alfa Products and were used without further purification. Spectroscopic data were obtained using the following instruments: IR, Perkin Elmer model 283; NMR, General Electric 300-NB; mass spectra, VG micromass 7070 HS; UV/VIS, Cary model 17; ESR, Bruker ESP-300 X-band spectrometer. Cyclic voltammetry data were obtained using a BAS CV27 voltammograph with an electrode configuration designed to minimize *iR* drop and a Houston 2000 Omnigraph *X-Y* recorder. Electrochemical measurements were carried out under a nitrogen atmosphere at room temperature. Solution concentrations were 10^{-3} mol/L in complex and 10^{-1} mol/L in supporting electrolyte (tetraethylammonium perchlorate). Voltammograms were recorded using a glassy carbon working electrode, a platinum counter electrode, and an aqueous saturated calomel reference electrode checked periodically relative to a 1.0×10^{-3} mol/L solution of ferrocene in dimethyl sulfoxide containing 0.1 mol/L tetraethylammonium perchlorate for which the ferrocenium/ferrocene reduction potential was 400 mV and ΔE_p was 72 mV at a scan rate of 100 mV/s. The reference electrode was separated from the bulk of the solution by a porous Vycor tube. Junction potential corrections were not used and potentials reported versus the normal hydrogen electrode were obtained by adding 0.244 V to values obtained versus the saturated calomel electrode. X-ray diffraction data were collected using a Picker diffractometer. Analyses were performed by Canadian Microanalytical Service Ltd.

Preparative

(a) 1,9-Bis(2-pyridyl)-2,5,8-trithianonane (ligand L1)

Sodium (4.6 g, 0.2 mol) was dissolved in commercial absolute ethanol (300 mL) under an atmosphere of dry nitrogen and 2-mercaptoethyl sulfide (7.7 g, 0.05 mol) was added slowly. The resulting mixture was heated to reflux and a solution of 2-picolyl chloride hydrochloride (16.3 g, 0.1 mol) in absolute ethanol (200 mL) was added dropwise with stirring over 2 h. Refluxing and stirring were continued for an additional hour. Volatiles were removed on a rotary evaporator, the residue extracted with chloroform (3 × 50 mL), washed with water several times, dried over anhydrous $CaCl_2$, and taken to dryness to yield a brown oil that was further purified by chromatography on Al_2O_3 in $CHCl_3$/ethyl acetate (50:50) to give 15.5 g (92.2%) of a yellow oil. Attempts to purify the oil by vacuum distillation led only to decomposition. NMR spectrum ($CDCl_3$, ppm from TMS internal standard, assignments from heteronuclear and homonuclear correlation, position identification from Fig. 1), ^{13}C: 30.3 (C7,C10), 30.4 (C6,C11), 36.6 (C8,C9), 120.9 (C2,C15), 122.0 (C4,C13), 135.6 (C3,C14), 148.0 (C1,C16), 157.6 (C5,C12); ^1H: 8.49 (m,2H,C1,C16), 7.63 (m,2H,C3,C14), 7.35 (m,2H,C4,C13), 7.13 (m,2H,C2,C15), 3.84 (s,4H,C6,C11), 2.67 (m,8H,C7,C8,C9,C10). Mass spectrum: parent ion, calcd. for $[C_{16}H_{20}N_2S_3]^+$, m/e = 336; found: m/e = 336.

(b) 1,9-Bis(2-pyridyl)-5-oxa-2,8-dithianonane (Ligand L2)

This preparation was similar to that in (*a*) except that 6.9 g (0.05 mol) of 2-mercaptoethyl ether was used instead of 2-mercaptoethyl sulfide. The yield was 15.3 g (95.5%) of a yellow oil, which was decomposed by attempts at vacuum distillation. NMR spectrum ($CDCl_3$, ppm from TMS internal standard, assignments from heteronuclear and homonuclear correlation, position identification from Fig. 2), ^{13}C: 31.3 (C7,C10), 38.0 (C6,C11), 70.1 (C8,C9), 122.0 (C2,C15), 123.1 (C4,C13), 136.8 (C3,C14), 148.5 (C1,C16), 158.7 (C5,C12); ^1H: 8.51 (m,2H,C1,C16), 7.63 (m,2H,C3,C14), 7.35 (m,2H,C4,C13), 7.15 (m,2H,C2,C15), 3.87 (s,4H,C6,C11), 3.59 (t, J = 6.8 Hz, C8, C9), 2.66 (t, J = 6.8 Hz, C7, C10). Mass spectrum: parent ion, calcd. for $[C_{16}H_{20}N_2OS_2]^+$, m/e = 320; found: m/e = 320.

(c) [Cu(L1)](ClO$_4$)$_2$

CAUTION: *This compound explodes when melted or powdered by grinding. Use of the triflate salt, which appears to be similar in most respects, is recommended instead of the perchlorate.*

Solutions of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.37 g, 1.0 mmol) in methanol (20 mL) and ligand L1 (0.40 g, 1.2 mmol) in acetone (5 mL) were mixed. The resulting deep blue solution was filtered immediately and the filtrate left to evaporate slowly. The blue crystals that formed were separated, washed with acetone, and dried in air to give 0.48 g (80%) of product, mp 181°C (**explodes**). Anal. calcd. for $C_{16}H_{20}Cl_2CuN_2O_8S_3$: C 32.08, H 3.36, Cu 10.61; found: C 32.16, H 3.35, Cu 10.50.

(d) [Cu(L1)](CF$_3$SO$_3$)$_2$

Preparation of this compound is similar to (*c*) except that $Cu(CF_3SO_3)_2$ was used as starting material. Green crystals (mp 187–190°C (dec.)) were obtained in 85% yield. Anal. calcd. for $C_{18}H_{20}CuF_6N_2O_6S_5$: C 30.96, H 2.89, N 4.01; found: C 30.91, H 2.89, N 3.94.

(e) [Cu(L2)](ClO$_4$)$_2$

Solutions of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.19 g, 0.51 mmol) in methanol (15 mL) and ligand L2 (0.19 g, 0.60 mmol) in methanol (5 mL) were mixed by adding the ligand solution to the metal salt solution to give a deep green solution, which was filtered and left to evaporate slowly. The green crystals that formed were separated, washed with dichloromethane, acetone, and a small amount of diethyl ether to give 0.25 g (84%) of product. Anal. calcd. for $C_{16}H_{20}Cl_2CuN_2O_9S_2$: C 32.97, H 3.46, N 4.80, Cu 10.9; found: C 33.03, H 3.47, N 4.80, Cu 11.0.

(f) [Cu(L2)](BF$_4$)$_2$

Preparation of this green crystalline compound is similar to (*e*) except that $Cu(BF_4)_2 \cdot xH_2O$ was used as starting material. Anal. calcd. for $C_{16}H_{20}B_2CuF_8N_2OS_2$: C 34.46, H 3.62, N 5.02, Cu 11.4; found C 34.71, H 3.65, N 5.02, Cu 11.3.

X-ray

A summary of crystallographic data for $[Cu(L1)](ClO_4)_2$ and $[Cu(L2)](ClO_4)_2$ is given in Table 1. The diffraction intensities were collected at 295 K using the $\theta/2\theta$ scan technique with profile analysis (15) at a scan speed of 4°/min. Three standards were measured after every 100 reflections and no significant crystal decay was detected. The space group was determined by systematic absences. Unit cell parameters (Table 1) were determined by a least-squares refinement of the setting angles for 36 reflections ($90° \leq 2\theta \leq 100°$) for $[Cu(L1)](ClO_4)_2$ and of 26 reflections ($90° \leq 2\theta \leq 120°$) for $[Cu(L2)](ClO_4)_2$. Lorentz and polarization factors were applied and corrections were made for absorption. The structures were solved by MULTAN (16) plus a difference Fourier map and refined by full-matrix least squares with unit weights. H-atom positions were calculated but their parameters were not refined. All heavier atoms were refined anisotropically. All calculations were

[a]Throughout this work esd's are in parentheses and refer to the last digit printed.
[b]$R_f = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[c]$R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma(w|F_o|)^2]^{1/2}$ where $w = 1/\sigma^2 I$.
[d]Goodness of fit = $[\Sigma w(|F_o| - |F_c|)^2/(\text{no. of reflections} - \text{no. of parameters})]^{1/2}$.

performing with the NRCVAX Crystal Structure Programs (17). Scattering factors were taken from the usual source (18).

Results

The new ligands L1 and L2 and their complexes with copper(II) as perchlorate and triflate salts have been prepared and characterized. The final atomic positional parameters, equivalent isotropic temperature factors, and important bond lengths and angles from X-ray studies of the explosive perchlorate salt of $[Cu(L1)]^{2+}$ and of $[Cu(L2)]^{2+}$ are listed in Tables 2–5. Figures 1 and 2 show views of the cations and their atomic numbering schemes. Anisotropic thermal parameters, a full listing of bond lengths and angles, and final structure factors are available as supplementary data.[4] Electronic spectra in water, *N*,*N*-dimethylformamide, dimethyl sulfoxide, nitromethane, methanol, and acetonitrile, mull IR spectra, and ESR spectra of both microcrystalline samples and *N*,*N*-dimethylformamide solution glasses at 77 K have been determined as have the cyclic voltammograms of the compounds in acetonitrile and water. The spectroscopic and other data are given in Tables 6 and 7 and in Figures 3–6 and will be introduced at appropriate points in the discussion that follows.

Discussion

The cations $[Cu(L1)]^{2+}$ and $[Cu(L2)]^{2+}$ (Figs. 1 and 2) both have distorted square pyramidal arrays of ligand donor atoms about a copper atom. In both, there are N_2S_2 donor sets in the basal planes while the apical sites are occupied either by thioether sulfur S2 of ligand L1 or by the analogous ether oxygen in ligand L2. Although both cations have essentially square pyramidal arrangements of ligand donors about their central copper atoms, the conformations of the two ligands are different, which leads to a facial arrangement of the three sulfur atoms of L1 but a meridional arrangement of the analogous S_2O donor set of L2. For $[Cu(L2)][ClO_4]_2$, there is an interaction between copper and a perchlorate oxygen in the copper's sixth or octahedral coordination site

that has no parallel in the $[Cu(L1)][ClO_4]_2$ structure. This Cu—O(perchlorate) distance (2.469(10) Å) in $[Cu(L2)][ClO_4]_2$ is roughly comparable to others of its type that are normally in the range 2.52–2.68 Å, but it is significantly longer than the Cu—O(perchlorate) distance of 2.264(5) Å in perchlorato(1,8-bis-(2-pyridyl)-3,6-dithiaoctane)copper(II) ion (19). In the basal planes of the two ions, corresponding bonds are similar in length. For $[Cu(L1)]^{2+}$, Cu—N = 2.017(12) and 1.993(12) Å whereas for $[Cu(L2)]^{2+}$, Cu—N = 2.020(6) and 2.007(6) Å. For $[Cu(L1)]^{2+}$, Cu—S = 2.3324(5) and 2.360(5) Å whereas for $[Cu(L2)]^{2+}$, Cu—S = 2.373(2) and 2.376(3) Å. The apical bond lengths are unremarkable with apical Cu—S = 2.454(4) Å for $[Cu(L1)]^{2+}$ and apical Cu—O = 2.413(5) Å for $[Cu(L2)]^{2+}$.

These distances may be compared with Cu—S(basal) distances of 2.349(3) and 2.358(3) Å in $(CuCl_2 \cdot L)_2$ (L = 2,5,9-trithia[9](2,5)thiophenophane) (20), with Cu—S(apical) distances of 2.814(1) Å in the six-coordinate complex of 1,6-bis(5′-methylimidazol-4′-yl)-2,5-dithiahexane (21) and 2.398(2) Å in the five-coordinate complex of 1,4,7,10,13-pentathiacyclopentadecane (8) and with Cu—N(basal) dis-

tances of 1.997(4) and 1.950(4) Å in the five-coordinate complex of 1,7-bis(*N*-methylbenzimidazol-2′-yl)-2,6-dithiaheptane (22). The basal Cu—S and Cu—N distances are thus normal and the apical Cu—S in the L1 complex, while somewhat longer than the basal Cu—S distances, is significantly less than the sum of the van der Waals' radii (3.20 Å) (23) of copper and sulfur. There is no interaction in $[Cu(L1)][ClO_4]_2$ between copper and the perchlorate anions like that in $[Cu(L2)][ClO_4]_2$ (*vide supra*), the closest approach to copper in the L1 complex by a perchlorate oxygen being 3.727(4) Å. There is, however, a close approach by one of the perchlorate oxygens to hydrogens on both C15 and C16 of the pyridine ring of L1 that lies more or less in the base plane of the ion (Fig. 1). The distances between the perchlorate oxygen atom and both H15 and H16 are approximately equal to the sum of the oxygen and hydrogen van der Waals' radii (2.70 Å) (23). These contacts have a quite profound effect on the structure and properties of the cation (*vide infra*).

The copper atom in $[Cu(L1)]^{2+}$ is displaced 0.091 Å in the direction of N2 from the plane defined by the apical and two basal sites (N1 and S3) of the coordination sphere. The best plane in the ion, however, is that defined by three of the basal donors S1, S3, and N2. The copper atom lies 0.052 Å below that plane while N1, the other basal donor, lies 1.318 Å below the plane, indicating that it is bent down sharply from its expected position thereby giving an angle between the apex and N1 of 125.8(4)°. As usual with coordination number five, the question raised by this distortion is whether the complex is best regarded as trigonal bipyramidal or square pyramidal. The question is answered satisfactorily by the ESR spectrum (*vide infra*), which is that of a distorted square pyramid.

The copper atom in $[Cu(L2)]^{2+}$ is displaced 0.11 Å towards the apex from either of the planes defined by the two nitrogen atoms and one sulfur, while the remaining sulfur is also displaced towards the apex by 1.07 Å in each case. This ion's structure therefore appears less distorted than that of $[Cu(L1)]^{2+}$ and it is of interest that there is no difference near 1025 and 615 cm^{-1}, where perchlorate bands occur, between its perchlorate salt's mull IR spectrum and that of the perchlorate salt of the L1 complex cation. In other words, the perchlorate interaction with copper revealed by the X-ray study of the L2 complex must be weak. Finally, it may be noted that there is a change from *cis*-pyridines in $[Cu(L1)]^{2+}$ to *trans*-pyridines in $[Cu(L2)]^{2+}$ that is caused primarily by the apical bond length requirements and resulting chelate ring strain, which favour meridional coordination by the S—O—S system with its short apical bond while the S—S—S system with a longer apical bond favours facial coordination.

Comparison of ESR and electronic spectra and cyclic voltammetric behaviour of these compounds having N_2S_3, N_2S_2O, or $N_2S_2O_2$ donor sets with literature data from related species containing N_2S_2 donor sets reveals the influence of the added apical thioether or ether donor as well as the influence of anion or solvent interactions in vacant coordination sites. Table 6 contains electronic and ESR spectral data for the new compounds.

The structure of these complex cations is very sensitive to

the presence of coordinating anions or solvent. For example, ESR spectra of microcrystalline samples of the L1 complex are quite different depending upon the identity of the anion (Fig. 3, Table 6). When the anion is perchlorate, the spectrum shows only a minor rhombic distortion from a typical axial situation but when the anion is triflate, this distortion is much greater. Based on the X-ray results for $[Cu(L1)](ClO_4)_2$, it seems likely that this cation's preferred coordination geometry, in the absence of a donor in the sixth octahedral site, is that of a square pyramid distorted towards trigonal bipyramidal, as indicated by the ESR for $[Cu(L1)](CF_3SO_3)_2$. In solid state $[Cu(L1)](ClO_4)_2$, however, interaction between a perchlorate oxygen and hydrogens on C15 and C16, mentioned earlier, "lifts" one of the pyridine rings. The structure is then a square pyramid with the "unsupported" pyridine ring drooping. This anion-related structural change in the solid state has ramifications for the electronic structure of the cation that are immediately apparent simply from the colour of the compounds. The perchlorate salt is a deep rich blue in the solid state while the triflate salt is deep green. In the electronic spectra of these substances as Nujol mulls (Table 6), the effect is also apparent as a shift in the frequency of the *d–d* envelope as well as appearance in the spectrum of $[Cu(L1)](ClO_4)_2$ of a shoulder at 560 nm of nearly equal intensity to that of the main peak at 640 nm. Powder ESR spectra of the L2 complex cation (Fig. 4) also vary with the identity of the anion, indicating a rhombic distorted axial coordination sphere when the anion is perchlorate and interacting with copper, but indicating trigonal bipyramidal geometry about copper when the anion is BF_4^- and presumably not interacting.

In frozen solutions, all the ESR spectra (Fig. 5, Table 6) are indicative of axial species, which argues for a change of both $[Cu(L1)](CF_3SO_3)_2$ and $[Cu(L2)](BF_4)_2$ from their geometries in the solid state to pseudo-octahedral as a result of interactions either with solvent or with their anions. As noted above, the impact of this structural change in solution is visually apparent for $[Cu(L1)]^{2+}$. Upon dissolving green crystals of $[Cu(L1)](CF_3SO_3)_2$ in any of a variety of solvents (Table 6), the solution colour becomes blue. Solution elec-

tronic spectra of the triflate and perchlorate salts of $[Cu(L1)]^{2+}$ are indistinguishable and invariant with solvent except for dimethyl sulfoxide, which decomposes them affording green solutions with altered spectral characteristics. Several authors have noted a solvent dependence of the *d–d* band position or intensity in electronic spectra of planar or square pyramidal copper(II) species and have interpreted this as indication of solvent interactions in open coordination sites on copper(II) (5, 20). In this regard, it may be significant that, for $[Cu(L1)]^{2+}$, the electronic spectrum is invariant in the *d–d* region over a range of solvents, suggesting that its anions (ClO_4^- or $CF_3SO_3^-$) are associated with the copper atom in solution even though they are not in the solid state. This interpretation would account both for the axial species in solution detected by ESR and for the invariance of the electronic spectra with solvent. In support of this conclusion, it may be noted that spectra of $[Cu(L2)]^{2+}$ in acetonitrile as its ClO_4^- and BF_4^- salts have different values of λ_{max} in the *d–d* region, suggesting that the perchlorate anion associated with copper in the solid state as revealed by the X-ray study remains associated in solution while the BF_4^-, which is apparently not associated in the solid state, either associates in solution or solvent occupies the sixth coordination site on copper so that the two $[Cu(L2)]^{2+}$ species become different in solution. In this regard, it is relevant that Ochrymowycz, Rorabacher, and co-workers (24–26) have reported evidence for adduct formation between copper complexes and several anions, including both ClO_4^- and BF_4^-, that are normally considered to be noncomplexing. In view of the observation that the electrochemical behaviour of $[Cu(L2)]^{2+}$ as its perchlorate and tetrafluoroborate salts is quite different and yet the ESR behaviour of the two salts in *N*,*N*-dimethylformamide is similar, it seems likely that in acetonitrile the anions remain associated with copper but in *N*,*N*-dimethylformamide they are replaced by solvent.

It is interesting to note (Fig. 5) that at least for $[Cu(L1)]^{2+}$ in dimethylformamide, there is a dissociative equilibrium

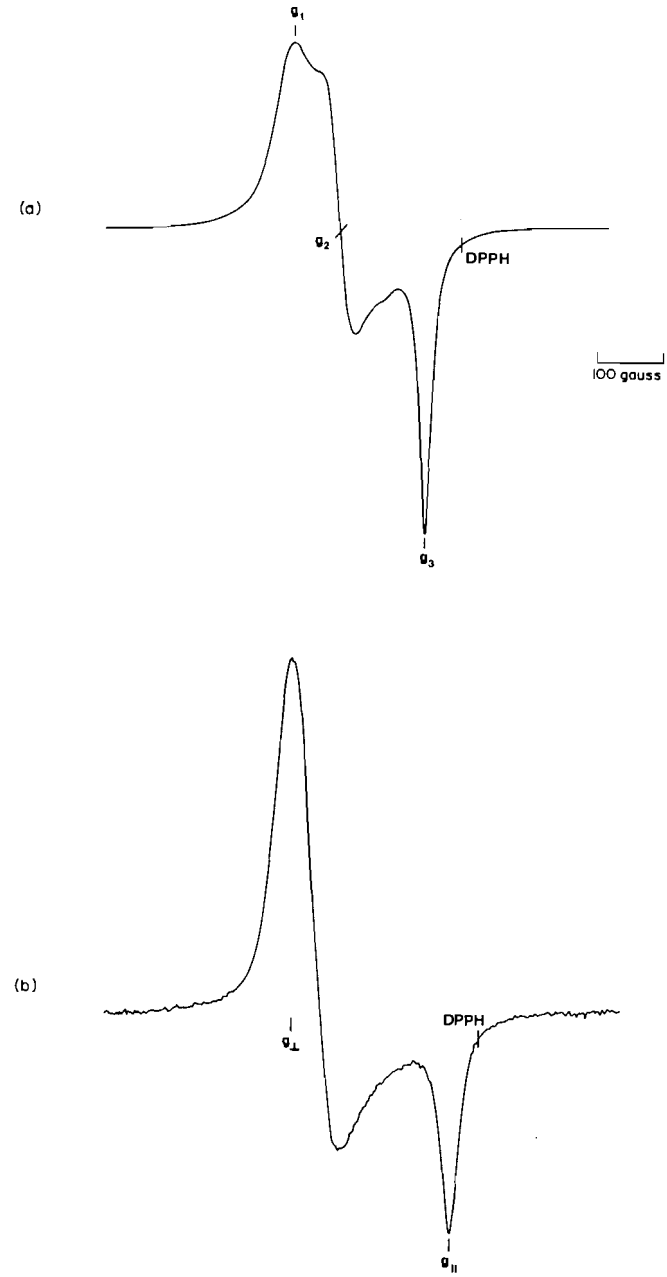

FIG. 4. ESR of microcrystalline samples of $[Cu(L2)]^{2+}$ as (*a*) ClO_4^- and (*b*) BF_4^-.

involving ligand and solvent revealed by the ESR spectra recorded at different concentrations. Spectra at 77 K of glasses formed from these solutions appear as a superpositioning of spectra of the cation and cupric triflate or perchlorate. The spectra show clearly separated peaks in the $g_\parallel$ region that belong to the two species and, as the solution is diluted, those belonging to cupric triflate or perchlorate grow relative to those due to the cation. The glass spectra show no resolved hyperfine structure or rhombic splitting in the $g_\perp$ region although the line width is at least as large as that in the corresponding part of the spectrum of $[Cu(bmdhp)(OH_2)](ClO_4)_2$ (bmdhp = 1,7-bis(*N*-methylbenzimidazol-2′-yl)-2,6-dithiaheptane) under similar conditions (22). For that compound, small rhombic splitting and hyperfine coupling in the $g_\perp$ region were proposed on the basis of spectral simulation. It may be, therefore, that $[Cu(L1)]^{2+}$ is also distorted in solution in a manner similar to the distortion we have shown for its perchlorate salt in the solid state. Unfortunately, the value of $|A_\parallel|$ (152×10^{-4} cm^{-1}) observed for this ion is far too large to be a satisfactory simulation of the values found in "blue" copper proteins (typically, $|A_\parallel| = 31 \times 10^{-4}$–$63 \times 10^{-4}$ cm^{-1}, $g_\parallel = 2.226$–2.288, $g_\perp = 2.052$–2.080) (27) even though other properties of the cation suggest similarities to the natural materials. Assuming the observations concerning the magnitude of $|A_\parallel|$ in four-coordinate structures (28) are applicable in a general way to five-coordinate structures, adjustment of some of the bond angles at copper should help to correct this model's shortcomings. We are addressing this problem and the results will be reported shortly.

Having established both the solid state and solution structures of the two cations, it is useful to compare their properties with each other and with related substances in the literature to observe the effects of replacing or removing axial donors. A similar evaluation of effects in equatorial positions was conducted by Urbach and co-workers (5) and their series of N_2S_2 ligand complexes are convenient for comparison. Electronic spectra of their compounds are similar to ours. Thus, bands near 260 nm are assigned to overlapping pyridine $\pi \rightarrow \pi^*$ and $N(\sigma) \rightarrow Cu(II)$ LMCT transitions; those near 360 nm to an $S(\sigma) \rightarrow Cu(II)$ LMCT, and those of wavelength 600 nm or greater to *d*–*d* transitions enhanced, particularly below 600 nm, by intensity borrowing from nearby charge transfer bands. Urbach and co-workers (5) proposed that $[Cu(pdthx)^{2+}$ consists of a Cu(II) surrounded by two *trans*-aromatic nitrogens, a thioether in the equatorial plane, and one in an axial position. From our work it seems likely there is also an associated perchlorate in the remaining axial position and solvent in the other equatorial site. Comparison of the data for this ion with that of our $[Cu(L1)^{2+}$ (Table 6) shows that adding a thioether to the equatorial plane has surprisingly little effect on the electronic spectrum. Replacing an apical thioether by ether, however, appears to alter significantly the relative spacings of the *d* orbital energies so that the various *d*–*d* transitions are much closer in energy and the longer wavelength transition near 915 nm in $[Cu(L1)]^{2+}$ (as either perchlorate or triflate) moves under other *d*–*d* bands at 675 nm in $[Cu(L2)]^{2+}$. These changes can be understood in terms of the differing abilities of O and S to participate in back-bonding and the differences in the size of their orbitals. Thus, the d_{z^2}–$d_{x^2-y^2}$ gap in $[Cu(L2)]^{2+}$ is somewhat larger than in $[Cu(L1)]^{2+}$ due to a lesser extension of the oxygen orbitals compared to sulfur. There is, hence, a lesser interaction by O than S with the d_{z^2} on copper so that d_{z^2} lies lower in energy. Both the d_{xz} and d_{yz} are less able to participate in back-bonding with O than they are with S so they are raised in energy in $[Cu(L2)]^{2+}$ making the d_{xz},d_{yz}–$d_{x^2-y^2}$ gap smaller and shifting the 596 nm band in $[Cu(L1)]^{2+}$ to 675 nm in $[Cu(L2)]^{2+}$.

Comparison of the electrochemistry of $[Cu(L1)]^{2+}$ with $Cu(pdthx)^{2+}$ (Table 7) shows that removal of a thioether donor causes a change in $E_{1/2}$ in acetonitrile from 734 to 510 mV, which is consistent with the influence of thioether sulfur previously reported (5). Unfortunately, we cannot view by itself the influence of adding a thioether donor in the apical site because changes in chelate ring size are also occurring in the present series of compounds and these are known

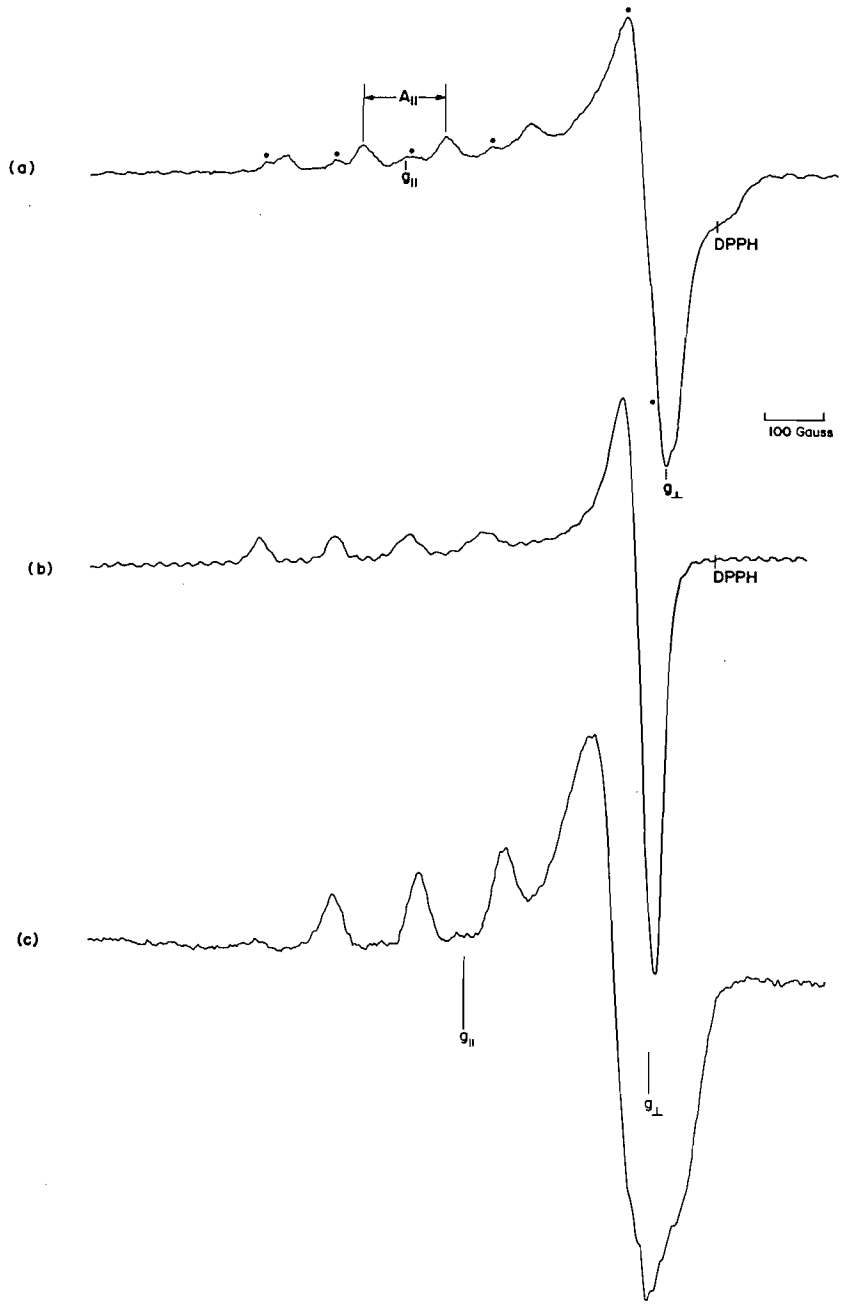

FIG. 5. ESR in DMF glass at 77 K of (*a*) $[Cu(L1)][CF_3SO_3]_2$,* = $Cu(CF_3SO_3)_2$ from dissociation of L1; (*b*) $Cu(CF_3SO_3)_2$ under identical conditions; (*c*) $[Cu(L2)][ClO_4]_2$.

(7) to affect $E_{1/2}$. We can estimate the effect of added apical thioether, however, by recognizing that the change from $Cu(pdthp)^{2+}$ to $Cu(pdtn)^{2+}$ (Table 7) gives a change in $E_{1/2}$ from 547 to 659 mV (or 112 mV) due to the change from 5-, 6-, and 5-membered chelate rings to 6, 6, and 6. Assuming a comparable effect upon changing from $Cu(pdthp)^{2+}$ to $[Cu(L1)]^{2+}$, the total observed change from 547 to 734 mV (or 187 mV) is due in part (~112 mV) to relieved strain between the two equatorial S atoms, and the remainder (~75 mV) is due to addition of an apical thioether donor. Likewise, the change from $[Cu(L1)^{2+}$ to $[Cu(L2)]^{2+}$, or changing apical S into O, changes $E_{1/2}$ from 734 to 696 mV (or −38 mV). These values are substantially smaller than the 150–350 mV changes observed (5, 7) when altering basal or equatorial sites from O or N to S. This observation is perhaps not so surprising if it is the apical donor that is lost when Cu(II) is reduced to Cu(I) and X-ray studies of the Cu(II) and Cu(I) complexes of pdto (19) show folding of the complex and loss of its apical donor on reduction. The cyclic voltammetric behaviour of $[Cu(L1)^{2+}$ in water (Fig. 6) is somewhat different from that in acetonitrile and may be related to solvation or anation changes in the apical sites as a result of the solvent change. Typical voltammograms (Fig. 6, Table 7) show that the potential but not the peak-to-peak separation of the wave is rather sensitive to solvent. In both water and acetonitrile, ΔE_p = 80 mV, but in water, $E_{1/2}$ = 524 mV instead of 734 mV versus NHE as in acetonitrile. These potentials do not match Addison's criteria for con-

verting potentials in CH_3CN to water (7) but it should also be noted that those criteria probably do not apply in this case because the ratio of i_{pc}/i_{pa} in water is not one, as it is in acetonitrile, although it approaches one as the scan rate is increased. It seems likely that the process in water is different than in acetonitrile and may involve rearrangement of a solvated species that occurs relatively slowly in water and either does not occur at all or is very rapid in acetonitrile. This aspect of the $[Cu(L1)]^{2+}$ cation's properties is under continuing investigation.

It is clear from comparison of the ESR parameters for $Cu(pdto)(ClO_4)^+$ in different solvents (5, 6) that axial solvent interactions affect both $g_\parallel$ and $|A_\parallel|$. This axial effect is apparent in spectra of $[Cu(L1)]^{2+}$ and $[Cu(L2)]^{2+}$ (Table 6) where replacement of apical S by O causes a decrease in $g_\parallel$ from 2.36 to 2.25 and a somewhat smaller decrease in $g_\perp$ from 2.05 to 2.04. Interestingly, there is almost no change in $|A_\parallel|$. Others have noted variations in $g_\parallel$ and $|A_\parallel|$ with structure and have commented on correlations with bond angle distortion at copper, with anionic charge, with thermodynamic stability, or with axial perturbations of the complex species' symmetry (6, 9–11, 29). Usually, there is an inverse relationship between $g_\parallel$ and $|A_\parallel|$ for a given donor set and it is probable that for the L1 and L2 complexes this rule is violated because of the change in ligand donor at the apical position.

Conclusions

Solid state and solution structures of the copper(II) species described in this report are very sensitive to interactions with anions and solvents. Structure changes that accompany anation or solvation may be as minor as small alterations of bond angles in the coordination sphere or they

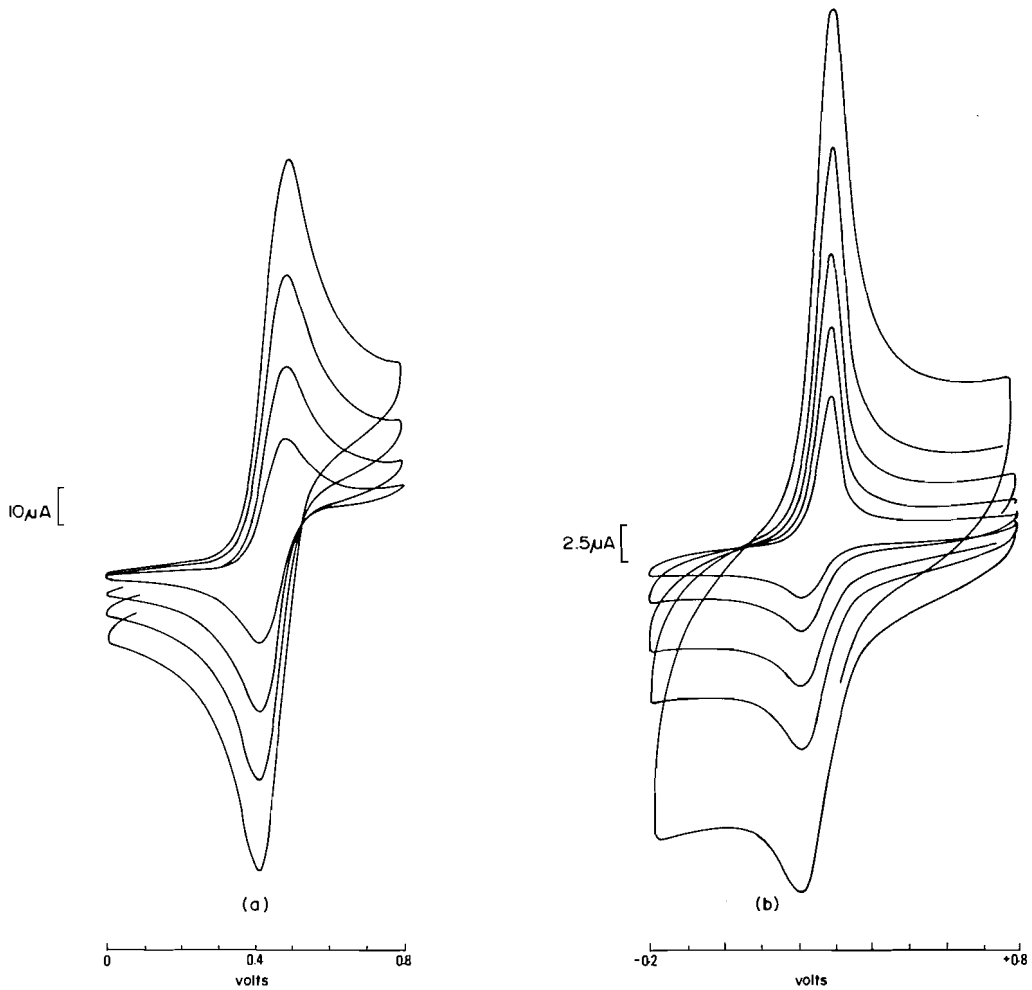

FIG. 6. Cyclic voltammograms of $[Cu(L1)][ClO_4]_2$ (*a*) in acetonitrile at scan rates of 50, 100, 200, and 400 mV s^{-1} and (*b*) in water at scan rates of 20, 50, 100, 200, and 400 mV s^{-1}.

may be as major as dissociation of the ligand but all affect significantly the electronic and ESR spectra as well as the redox properties of the copper complexes. The greatest effect of changes in ligand donor atom is expressed through the basal or equatorial planes of pseudo-square pyramidal or octahedral complexes while the effect at the apical site is smaller but still detectable by ESR, electronic spectroscopy, or cyclic voltammetry. Changing the apical donor to O from S shortens the metal–apex bond length, which may also change the way in which the ligand surrounds the metal from meridional to facial in order to minimize strain. Increasing the chain length between basal sites while spanning the apical site (or even linking basal sites directly) influences the ease with which tetrahedral geometry in Cu(I) can be achieved upon reduction, and consequently increases the magnitude of $E_{1/2}$. Changing from apical O to S increases $E_{1/2}$ by ~38 mV; it increases the wavelength of the d–d band envelope by ~240 nm; it increases $g_{\|}$ by ~0.11, $g_{\perp}$ by ~0.01, and leaves $|A_{\|}|$ unchanged within experimental error. Adding apical S or O donors, thereby converting formally four-coordinate species into five-coordinate ones, causes the expected appearance of a long-wavelength tail on the d–d band envelope or even appearance of a further low-intensity band at longer wavelength (~925 nm) and an increase in $E_{1/2}$ of 75–190 mV. Although different solvent systems were used for the five-coordinate and four-coordinate ESR studies and therefore conclusions about ESR trends should be treated with caution, a small increase in $g_{\|}$ accompanied by a small decrease in $|A_{\|}|$ while $g_{\perp}$ remains constant within experimental error is noted upon adding an apical donor. ESR evidence suggests that *N*,*N*-dimethylformamide competes with ligand for copper(II) in an equilibrium process.

The photolysis of several substituted phenyl(naphthyl)methyl triphenylphosphonium chlorides has been examined using a combination of laser flash photolysis experiments and product studies. Both carbocation and radical intermediates have been characterized in the transient experiments, with the relative yields depending strongly on the solvent. For example, in alcohols, acetonitrile, or aqueous solvents cation formation predominates while acetonitrile/dioxane mixtures (5–10%) are required for the observation of radicals. Quantum yields for cation formation vary from 0.79 in methanol to 0.093 in 1:4 acetonitrile/dioxane, as measured by product studies and transient experiments, respectively. The addition of perchlorate salts leads to dramatic enhancements in the cation lifetimes; the effects are particularly pronounced for acetonitrile/dioxane mixtures where the cation yields also increase by factors of 3–4. In this case the effects are attributed primarily to replacement of chloride by perchlorate in the initial ion pairs. The combined data from both solvent and perchlorate salt effects on the cation lifetimes and yields suggest that the excited state of the phosphonium salt cleaves homolytically, followed by electron transfer within the initial radical/triphenylphosphine radical cation pair to generate carbocation, as opposed to direct heterolytic cleavage. The cation yields also indicate that back reaction to regenerate starting material, as well as product formation within the initial geminate cage, occur in some solvents. The effects of solvent and added perchlorate salts on the rate constants for reaction with nucleophiles have been examined. For example, rate constants that vary by an order of magnitude have been measured for quenching by azide ion in various aqueous acetonitrile and trifluoroethanol mixtures.

E. O. ALONSO, L. J. JOHNSTON, J. C. SCAIANO et V. G. TOSCANO. Can. J. Chem. **70**, 1784 (1992).

Faisant appel à une combinaison d'expériences de photolyse éclair au laser et d'études des produits, on a examiné la photolyse de plusieurs chlorures de phényl(naphtyl)méthyl triphényl phosphonium. On a caractérisé des intermédiaires tant cationiques que radicalaires dans les expériences impliquant les espèces transitoires; les rendements relatifs dépendent beaucoup du solvant. Par exemple, dans les alcools, l'acétonitrile ou des solvants aqueux, il y a formation prédominante de cations alors qu'il faut un mélange d'acétonitrile/dioxane (5–10%) pour observer des radicaux. Les rendements quantiques pour la formation des cations, tels que mesurés respectivement par des études de produits et des expériences sur les espèces transitoires, varient de 0,79 dans le méthanol à 0,093 dans un mélange 1 : 4 d'acétonitrile/dioxane. L'addition de sels de perchlorate conduit à une augmentation dramatique des temps de vie des cations; les effets sont particulièrement prononcés pour les mélanges acétonitrile/dioxane dans lesquels les rendements en cations augmentent aussi par des facteurs de 3–4. Dans ce cas, on attribue les effets principalement à une substitution du chlorure par le perchlorate dans les paires d'ions initiales. Les données combinées des effets tant de solvant que de sel perchlorate sur les temps de vie des cations et sur les rendements suggèrent que l'état excité du phosphonium subit plutôt un clivage homolytique, suivie d'un transfert d'électrons à l'intérieur de la paire initiale radical/cation radicalaire de la triphénylphosphine conduisant à un carbocation qu'un clivage hétérolytique direct. Les rendements de cation indiquent aussi que la rétro-réaction régénérant le produit de départ, ainsi que le formation de produit à l'intérieur de la cage géminée initiale, se produit dans certains solvants. On a aussi examiné les effets du solvant et de l'addition de perchlorate sur les constantes de vitesse pour les réactions avec les nucléophiles. Par exemple, on a mesuré les constantes de vitesse qui varient par un ordre de grandeur en piégeant avec l'ion azoture, dans divers mélanges aqueux d'acétonitrile et de trifluoroéthanol.

[Traduit par la rédaction]

A number of recent reports demonstrate that a variety of di- and triarylmethyl substituted cations can be readily generated by photoheterolysis of suitable precursors. This technique was used to generate transient carbocations and to examine their reactivity using direct time-resolved techniques such as laser flash photolysis and time-resolved conductivity (1–15). These methods have considerable advantages over the use of acidic media to generate stable cations for spectroscopic studies and the examination of reactivities using indirect competitive product studies. The direct examination of transient cations allows the measurement of cation lifetimes and reactivities in a variety of reactive solvents such as alcohols and aqueous mixtures and does not rely on the use of nucleophiles such as azide ion as "clocks."

Precursors with leaving groups such as halide, acetate, tosylate, and 4-cyanophenoxide have been frequently used for the generation of cations via photoheterolysis. For many of these precursors homolysis to generate radicals competes with cation formation. We recently reported that phosphonium salts **1** and **2** show a marked preference for heterolysis to generate cations in a variety of polar solvents (16). Although the competition between homolysis and heterolysis in the photolysis of a variety of naphthylmethyl systems has been examined using conventional steady state techniques (17–22), transient techniques were not previously applied to the study of carbocations in these systems. We have now examined the generation of naphthylphenylmethyl cations and radicals from several phosphonium salts (**1–3**, **11**). The ef-

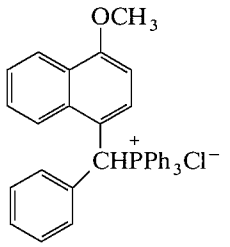
fects of solvent and added salts such as lithium perchlorate on the relative amounts of cation and radical and on the lifetimes of the cations have been examined. Further, we have observed a wide variation in the reactivity of the cation towards nucleophiles such as azide ion. Preliminary results for some of these systems have already been reported (16).

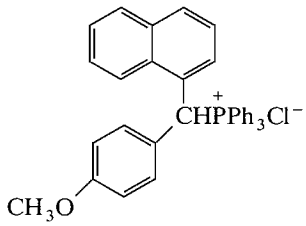
Results

Characterization of cations

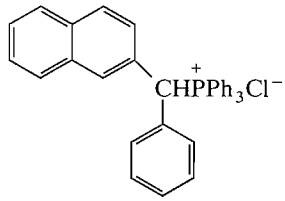
Laser excitation of phosphonium salt **1** (~5×10^{-5} M; 308 nm) has been demonstrated to result in efficient formation of cation **4** in a variety of polar solvents such as acetonitrile and 2,2,2-trifluoroethanol (TFE) (16). This cation has λ_{max}



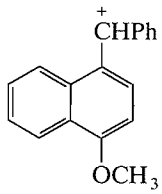
1



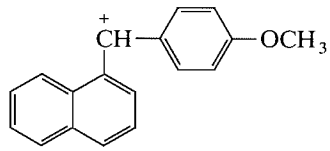
2



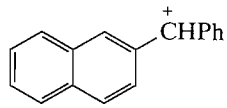
3



4



5



6

at 500 nm with a small second absorption band at ~360 nm and has lifetimes of ~2.5 μs in acetonitrile and in excess of 100 μs in TFE. The cation assignment was confirmed by quenching with nucleophiles such as azide and chloride ions and by the insensitivity of the transient lifetime to the presence of oxygen.

Similar to the results observed with salt **1**, laser excitation of salt **2** (~2.5×10^{-4} M) also produced a strongly absorbing transient with λ_{max} at 550 nm and a weaker absorption band at 370 nm in aerated or deaerated trifluoroethanol as shown in Fig. 1. This species had a lifetime of >35 μs, and was assigned to cation **5.** The same cation could be readily produced as a stable solution from the parent alcohol in TFE/trifluoroacetic acid, and under these conditions the spectrum was identical to that shown in Fig. 1. A similar transient was produced from salt **2** in acetonitrile, although in this case the lifetime was shortened to 350 ns (Table 1).

Excitation (308 nm) of 10^{-3} M salt **3** generated cation **6** with λ_{max} at 445 nm and with a weaker band between 500 and 600 nm (Fig. 1). Decay traces monitored at 445 or 560 nm gave identical lifetimes of 450 ns in TFE and 50 ns in acetonitrile. However, our previous observation of shorter lifetimes for cation **4** at higher concentrations of the precursor salt suggested that these lifetimes were at least partly a reflection of an increased rate for reaction with chloride ion (present as the phosphonium salt counterion) at the higher salt concentration required to obtain sufficient absorption at the laser wavelength. Accordingly, the same cation was produced via 266 nm excitation of 5×10^{-5} M salt **3** in acetonitrile; in this case the spectrum of the cation was identical to that measured using 308 nm excitation but the lifetime was 0.5 μs.

The assignment of the observed transients from salts **2** and **3** to cations **5** and **6**, respectively, was confirmed by their insensitivity towards oxygen and their characteristic quenching by azide ion. Rate constants of 2.4×10^9 and 4.5×10^9 M^{-1} s^{-1} were obtained from plots of the rate constant for cation decay (k_{obs}) versus [azide] for **5** and **6**, respectively, in 10% aqueous TFE (Table 2).

Cation **6** was also generated from 1-naphthyl(phenyl)methyl chloride (**7**) in acetonitrile. The cation spectrum using this precursor was identical to that obtained from the phosphonium salt (**3**) but the lifetime was substantially longer (1.0 μs) and was independent of the precursor concentration. Similarly cation **4** generated from chloride **8** was also longer-lived than that from the phosphonium salt precursor, and no difference in the spectra could be detected. The latter chloride was very rapidly solvolyzed in solvents containing small amounts of either water or alcohols and was, thus, not very suitable for the transient experiments. These observations suggest that reaction with the chloride ion associated with the phosphonium salts is responsible for the shorter cation lifetimes at higher salt concentrations. This is further supported by two additional observations. Firstly, chloride ion added as either the sodium or potassium salt reacted with various cations, as discussed in more detail below. Secondly, the lifetime of cation **6** generated from chloride **7** in acetonitrile decreased substantially in the presence of added phosphonium salts. For example, rate constants of 9×10^9 and ~1×10^{10} M^{-1} s^{-1} were measured for quenching of **6** by di-(4-methoxyphenyl)methyltriphenylphosphonium chloride (**9**) and (1-naphthylmethyl)triphenylphosphonium chloride (**10**) in acetonitrile. Note that excitation of these salts (**9** and **10**) alone in the absence of **7** and at the maximum concentra-

tions used in the quenching experiments did not produce any transients since they had very low optical densities at 308 nm. Furthermore, addition of 1-naphthylmethyltriphenylphosphonium tetrafluoroborate had no effect on the lifetime of cation **6**, indicating that a nucleophilic counterion such as chloride is required to observe the effect.

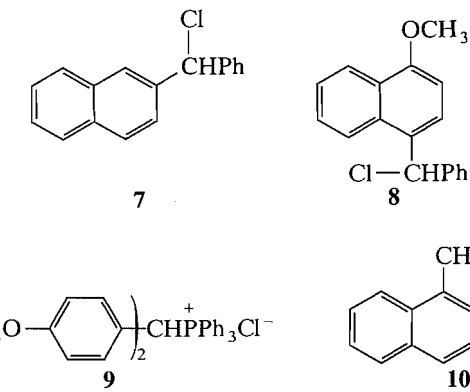
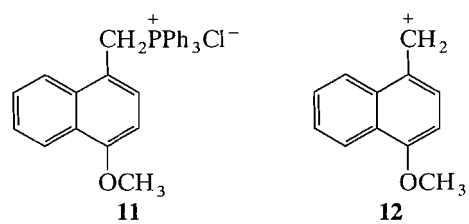
[b]308 nm excitation.
[c]266 nm excitation.



4-Methoxy-1-naphthylmethyltriphenylphosphonium chloride (**11**) was also examined in TFE using both 266 and 308 nm excitation. The spectrum of cation **12** produced by 266 nm excitation of **11** in oxygenated TFE is shown in Fig. 1. Under these conditions the cation lifetime was 7.5 μs. Surprisingly, repeating the same experiment using 308 nm excitation resulted in considerably weaker transient absorption signals due to **12**, despite the fact that the laser energies and optical densities of the precursor at the laser wavelength were comparable in each case. This wavelength dependence may be related to photochemistry from an upper dissociative state in the case of 266 nm excitation.[3]



[3]A detailed study of the photochemistry of salt **11** is obviously required to sort out this unusual wavelength dependence.

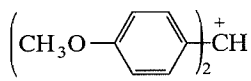
Table 1 gives lifetimes for cations **4**, **5**, and **6** under a variety of conditions. Since most of these were measured using phosphonium chlorides as precursors, they reflect a combination of reaction of the cation with chloride ion and solvent, with the relative importance of each varying with solvent. Note that the results are further complicated by the fact that the rate of chloride ion quenching is also expected to be solvent dependent (see below). However, the much shorter lifetimes in methanol are attributed to nucleophilic reaction with solvent, which is present in much larger concentration than chloride ion.

One rather surprising observation was the substantially longer lifetimes observed for cations **4** and **5** in aqueous acetonitrile as compared to acetonitrile (Table 1). In contrast, cation **6** generated from either the salt or chloride precursor reacted rapidly with small amounts of water and was too short-lived to measure in >5% water. Since solvolysis of the appropriate naphthylphenylmethyl chlorides in aqueous solvents was rapid, it was not possible to use these substrates to compare results obtained for the two precursors. Therefore, the effect of water on the lifetime of cation **13** produced from **9** was examined as a function of the concentration of water in acetonitrile. In this case literature results are available for the same cation generated from the 4-cyanophenoxy ether in aqueous acetonitrile mixtures (4). As observed for cation **4**, the lifetime of **13** (with **9** as the precursor) initially increased with added water and then levelled off to a constant value of 6 μs at 80% water (Fig. 2). This is in direct contrast to the literature results, which indicated lifetimes of 16.0, 7.3, and 10 μs for the same cation in 7, 17, and 80% aqueous acetonitrile.[4] These results appear to be specific to the phosphonium salt precursors and are thought to be related to variations in the rate constants for chloride quenching of **4** and **5** in the different solvent mixtures, as discussed below. Thus, even in aqueous solvents the lifetimes for **4**, **5**, and **13** are determined by reaction with chloride counterion. In the case of **6**, the cation is more reactive and its lifetime in aqueous acetonitrile is limited by reaction with water rather than chloride ion.



13

Characterization of naphthylphenylmethyl radicals

As previously reported (16), excitation of **1** in less polar solvents than TFE or acetonitrile (e.g., acetonitrile/dioxane

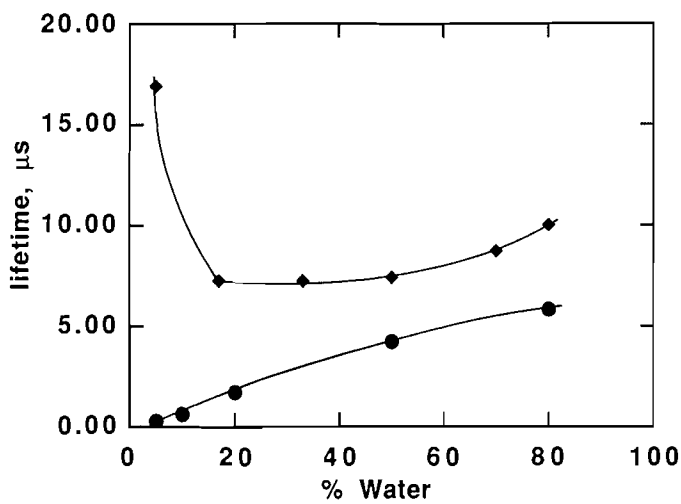


FIG. 2. Effect of water on the lifetime of cation **13** in acetonitrile: (●) this work; (◆) data from ref. 4.

[4]These are approximate values since they were read from a graph in ref. 4.

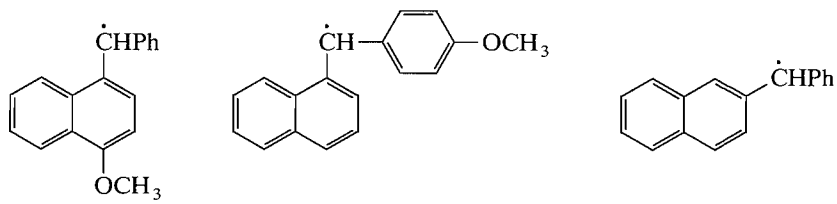
mixtures) led to the detection of radical **14** with λ_{max} at 400 nm. The yields of radical varied considerably with the solvent composition with only radical observed between 1 and 5% acetonitrile in dioxane and only cation in pure acetonitrile or in 4:1 acetonitrile/dioxane. As expected, the radical was relatively long-lived (>10 μs), did not decay by first-order kinetics, and reacted efficiently with oxygen, but not with 1,3-cyclohexadiene. The latter served to differentiate the radical from any naphthalene-containing triplet, which would be expected to absorb in a similar region (23) but which would be quenched by dienes. The same radical could be readily generated from (4-methoxy-1-naphthyl)-phenylmethyl chloride in nonpolar solvents such as cyclohexane.

Salt **2** also produced some radical in acetonitrile/dioxane mixtures, as shown in Fig. 3. In contrast to the large shifts that are observed in the cation spectra upon methoxy substitution, the spectrum of radical **15** is very similar to that of **14**. This is to be expected based on the known insensitivity of arylmethyl-substituted radicals to changes in substituents on the aromatic rings (10, 24, 25). Similarly to the results observed with salt **1**, mixtures of both radical and cation were produced by excitation of **2** in acetonitrile/dioxane mixtures.

The spectrum of the (2-naphthyl)phenylmethyl radical (**16**) was obtained by 266 nm excitation of salt **3** in acetonitrile/dioxane mixtures. The radical was clearly visible without interference from cation signals at >1 μs delays after the laser and had λ_{max} at 340 nm with weaker bands at 400 and 680 nm. The decay kinetics measured at the three wavelengths were similar, indicating that all three bands belonged to the same species. Further, this species reacted efficiently with oxygen, demonstrating that the observed transient is not a naphthalene radical cation, which has also been reported to absorb in the 650–700 nm region and which is readily detectable in oxygenated solutions (26*a*).[5] A similar spectrum for radical **16** was also observed from the chloride precursor in cyclohexane and acetonitrile (Fig. 3). The shift in λ_{max} from 400 nm for radicals **14** and **15** to 340 nm for **16** is in line with the reported spectra for the 1- and 2-naphthylmethyl radicals, which have absorption maxima at 365 nm, whereas the (1-bromo-2-naphthyl)methyl radical has λ_{max} at 350 nm (25, 27). The long-wavelength absorption is rather unusual since the lowest energy band in most naphthylmethyl radicals is too weak to be observed in absorption, although its fluorescence is readily detectable in various systems (24).

A variety of naphthalenes have triplet–triplet absorption



14 **15** **16**

spectra with maxima at ~420 nm (23). However, in none of the transient experiments with salts **1** and **2** did we find any evidence for species other than either the corresponding cations or radicals. Note that it is important to use flow system in these experiments to eliminate the possibility of signals due to the accumulation of photoproducts that have strong triplet absorptions. However, for salt **3** in deaerated acetonitrile/dioxane mixtures there was a weak triplet signal at 420 nm in addition to radical **16**. It was also possible to observe weak and long-lived transients at 420 nm due to the triplets of 2- and 3-methoxy-1-naphthylmethyl triphenylphosphonium chlorides.

Cation yields

Two approaches were used to measure the yields of cations produced by photolysis of the phosphonium salts. The first of these involves determination of quantum yields for product formation. The second method is based on measuring the yields of transient cations using a suitable actinometer.

Photolysis of salt **2** in methanol at low conversions gave a single product that was isolated and shown to be ether **17** (reaction [1]), the expected product of methanol trapping of the intermediate carbocation. Both triphenylphosphine and triphenylphosphine oxide were also observed by HPLC analysis. The latter may result from either the oxidation of triphenylphosphine or the reaction of triphenylphosphine radical cation with water (28). The quantum yield for formation of **17** upon 313 nm photolysis of 3×10^{-3} M **2** in methanol was measured using the formation of acetophenone from valerophenone in cyclohexane ($\Phi_{ACP} = 0.4$) as the actinometer (29, 30). An average of six determinations gave a value of 0.71 ± 0.10 (Table 3). A quantum yield for ether production of 0.39 (two determinations) was measured in 3:7 (v/v) methanol/TFE. This particular solvent was selected since 30% methanol was sufficient to give a clean yield of **17**. Irradiation of **2** in TFE alone gave a number of additional products. Irradiation of **2** in acetonitrile also gave a complex product mixture. Previous studies of diarylmethyl cations have shown that there is the added complication of reversible addition of the cation to the solvent, which results in lower than expected yields of amide products in acetonitrile (4). Therefore, quantitative measurements were not attempted in this solvent.

[5]In a few experiments using high 266 nm power there were some additional broad absorptions at λ > 650 nm that may be due to radical cations generated by photoionization. Note that reactions of radical cations with oxygen are relatively slow (10^6 M^{-1} s^{-1}) and do not compete with other decay pathways (under laser flash photolysis conditions) at the oxygen concentrations present in most organic solvents (26*b*).

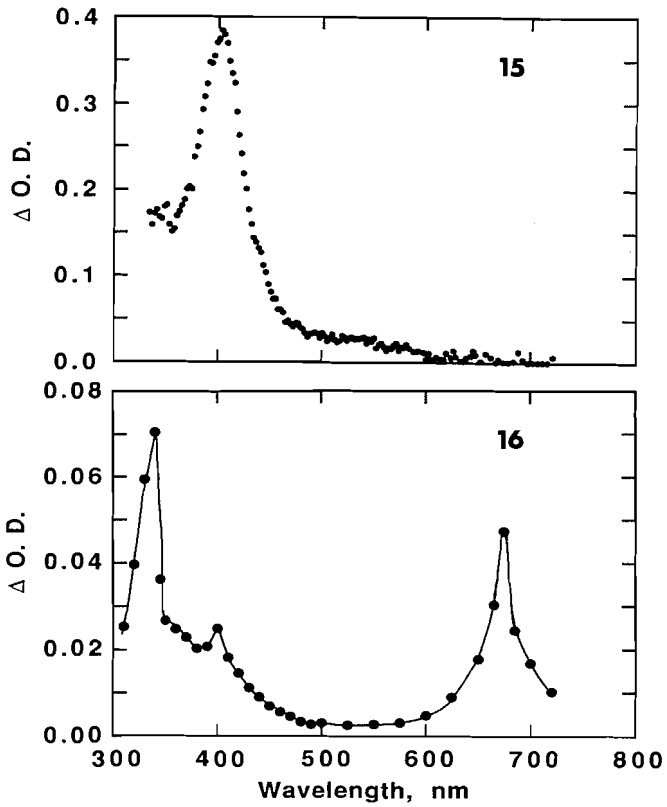


FIG. 3. Spectra of radicals **15** and **16** produced by 308 nm excitation of **2** in deaerated 5% acetonitrile/dioxane and 266 nm excitation of **7** in deaerated acetonitrile, respectively.

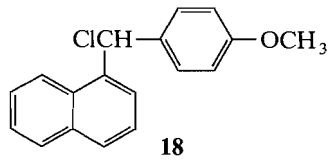
[1] 
2 **17**

It should be noted that trapping of cation **5** by chloride ion to give **18** might be expected to be a complication in the above quantum yield determinations. However, **18** was not stable in methanol due to its rapid solvolysis to ether **17**. Therefore, the measured quantum yields for ether formation are a suitable measure of the cation yields, since under our reaction conditions trapping by either solvent or chloride will give the same product. Another potential source of error is trapping of the cation by triphenylphosphine accumulated as a product of the reaction. To test whether this was a possible complication the reactivity of cation **6** (generated from chloride **7**) towards triphenylphosphine was examined. A rate constant of 5×10^9 M^{-1} s^{-1} was measured from a plot of the observed rate constant for cation decay as a function of added triphenylphosphine in acetonitrile. However, despite the high rate constant, at low conversions the amount of triphenylphosphine generated would not be able to compete with solvent for trapping of the cation, given the observed 20 ns lifetime for **6** in methanol.[6]

TABLE 3. Yields of cation **5** produced by photolysis of **2** under various conditions

Solvent	Φ	Method[a]
Methanol	0.71	Products
3:7 Methanol/TFE	0.39	Products
3:7 Methanol/TFE	0.18	Transient
TFE	0.15	Transient
Acetonitrile	0.53	Transient
Acetonitrile + 0.1 M $LiClO_4$	0.58	Transient
1:4 Water/acetonitrile	0.53	Transient
1:4 Acetonitrile/dioxane	0.093	Transient
1:4 Acetonitrile/dioxane + 0.1 M $LiClO_4$	0.32	Transient

[a]The quantum yields were determined from product studies or laser flash photolysis measurements.



18

The yields of cation **5** in a variety of solvents were measured using transient absorption techniques. This approach has the advantage of being readily applicable to solvents in which complex mixtures of products are formed. The technique requires a suitable actinometer that absorbs in the same region as the cation precursor and knowledge of the extinction coefficient of the cation. Aberchrome-540 (**19**), which undergoes photocyclization with a quantum yield of 0.20 in toluene, was used as the actinometer (31, 32). The extinction coefficient for **5** was measured by generating the cation from the parent alcohol in strong acid. The value of 43 000 M^{-1} cm^{-1} (at 550 nm) used in our experiments was the average of determinations in concentrated sulfuric acid, trifluoroacetic acid, and 1:1 TFE/trifluoroacetic acid, all of which gave similar results. The measured cation yields in various solvents are listed in Table 3. These numbers were calculated assuming that the extinction coefficient of **5** was identical in all the solvents. This is a reasonable assumption based on the fact that the transient spectra in various polar solvents are virtually superimposable with those for the cation in strong acid. Thus, a change in ϵ also implies a change in oscillator strength, which is unlikely (33).

The quantum yields in acetonitrile and aqueous acetonitrile are comparable to the value obtained by product analysis in methanol. It should be noted that the transient measurements are not affected by the decay pathway for the cation, although they will not account for cations that give products within the initial geminate cage. There is a substantial difference between the cation yields measured by transient techniques and product studies for 3:7 methanol/TFE. The lower yields in the transient experiment suggest that, at least in this particular solvent, there is a considerable amount of product formation within the initial geminate cage. Despite this discrepancy between the two methods,

[6]At 5% conversion the concentration of triphenylphosphine would be only 1.5×10^{-4} M, which in combination with the measured rate constant gives $k_{obs} = 7.35 \times 10^5$ s^{-1}. This is almost two orders of magnitude less than the measured rate constant for decay of **5** in methanol (5×10^7 s^{-1}).

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

both the transient experiments and the product studies indicate that the cation yields in TFE are significantly lower than those in other solvents. Thus, although TFE stabilizes the cation, less cation is actually generated by photolysis of the phosphonium salt in this solvent.

Salt effects on cation lifetimes and yields

Our previous observation (16) of the remarkable enhancement in cation lifetime in the presence of lithium perchlorate has now been investigated in more detail. Some of these results are tabulated in Table 4 and shown in Fig. 4. For example, the lifetime of **4** increased from 3 to 40 μs in the presence of 0.4 M $LiClO_4$ in acetonitrile, with a concomitant increase of ~80% in the signal intensity. Spectra of the cation in the presence and absence of $LiClO_4$ are shown in Fig. 5 and indicate that there is virtually no effect of the salt on the transient absorption. It should also be noted that the added salt did not have a measurable effect on the ground state absorption of the precursor (**1**). Much more modest effects on both the lifetime and signal intensities were observed in mixed solvents such as 10% aqueous acetonitrile or 15% methanol in acetonitrile and in TFE (Table 4). In acetonitrile, the effect of added $LiClO_4$ starts to appear at ~1×10^{-4} M, at which concentration the cation lifetime has increased by 50%.

The effect of added $LiClO_4$ was also examined in 1:4 acetonitrile/dioxane, under which conditions both radical and cation are readily detectable. In this case the effects were even more dramatic than those outlined above. Figure 6 shows spectra obtained in the mixed solvent with and without 0.2 M $LiClO_4$ under a nitrogen atmosphere. In the presence of perchlorate there is an approximately sevenfold increase in the amount of cation and the radical yield (λ_{max} 400 nm) is substantially lower; most of the radical has disappeared, although overlap of its spectrum with the 360 nm band of the cation would make it difficult to detect a small amount of this species. These results demonstrate that the added salt has a large effect on the processes occurring in the initial geminate cage. Under these conditions the cation lifetime increases from 0.7 μs in the absence of the salt to ~50 μs in the presence of 0.2 M $LiClO_4$. Furthermore, 0.01 M $LiClO_4$ is sufficient to almost completely suppress radical for-

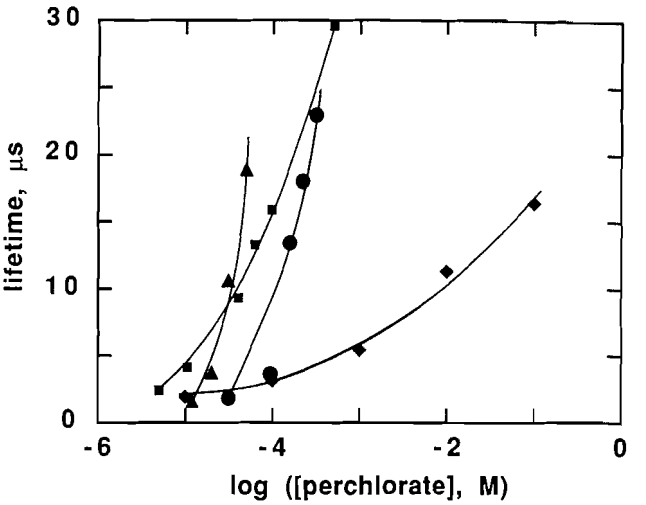


FIG. 4. Effect of added perchlorate salts on the lifetime of **4**: (◆), $LiClO_4$ in acetonitrile; (●) $NaClO_4$ in acetonitrile; (■) $MgClO_4$ in acetonitrile; (▲) $LiClO_4$ in 1:4 acetonitrile/dioxane.

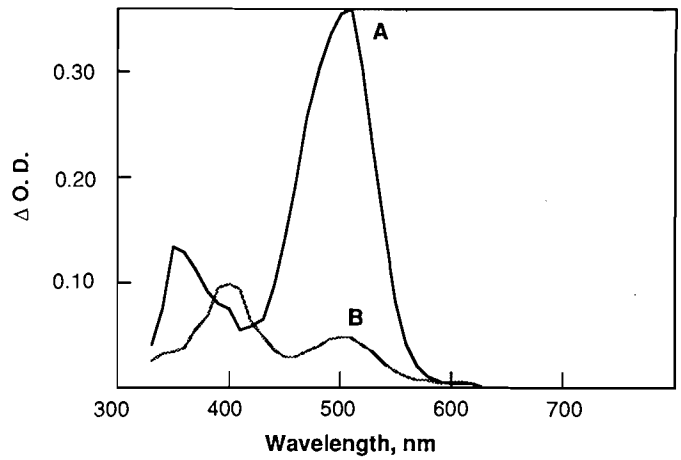

FIG. 6. Transient absorption spectra produced by 308 nm excitation of **1** in 1:4 acetonitrile/dioxane (A) with and (B) without 0.2 M $LiClO_4$.

mation and under these conditions the intensity of the cation signal has only increased by a factor of roughly 2.5. The effects of $LiClO_4$ on the cation lifetime start to appear at much more moderate concentrations than those discussed above. For example, the cation lifetime is already 16 μs at 2.9×10^{-4} M salt (Table 4). The lifetime of the radical is not affected by the addition of salt under any of these conditions.

Similar salt effects were also observed for cation **5**, which had a lifetime of 9.8 μs in the presence of 0.44 M salt in acetonitrile. The quantum yields of cation formation were also measured in acetonitrile and 1:4 acetonitrile/dioxane in the presence of 0.1 M $LiClO_4$ (Table 3). In the former solvent the addition of the salt gave only a modest increase in the yield of cation. In contrast, 0.1 M salt increased the yield of cation by a factor of 3.5 in the mixed solvent.

Sodium and magnesium perchlorates showed similar effects to those discussed above for $LiClO_4$. For the sodium salt the effects of **4** were larger than those for lithium at the same concentration (Fig. 4). This effect is consistent with the degree of dissociation of these salts in acetonitrile (34). A lifetime of 19.5 μs was measured for **4** in acetonitrile containing 10^{-4} M $MgClO_4$. The effect of potassium tetrafluoroborate was also examined. In this case the low solubility of the salt in acetonitrile required the use of a partly aqueous solution. The lifetime for **4** increased from 5.1 μs in 10% aqueous acetonitrile to 5.6 μs in the presence of 3.1×10^{-3} M KBF_4; use of $LiClO_4$ gave identical results.

Reactions of cations with nucleophiles

Rate constants for azide quenching for **4–6** in 10% aqueous trifluoroethanol are listed in Table 2. We also examined the quenching of **4** by azide in other solvents and in the presence of varying amounts of $LiClO_4$; representative plots are shown in Fig. 7. The results demonstrate an order of magnitude difference in the rate constant for azide quenching in going from 5% aqueous acetonitrile (1.8×10^{10} M^{-1} s^{-1}) to 5% aqueous TFE (1.7×10^{9} M^{-1} s^{-1}). Further, the addition of 0.01 and 0.1 M $LiClO_4$ to 5% aqueous acetonitrile causes 2- and 5-fold decreases, respectively, in the azide quenching rate constants.

The effects of the medium on bromide quenching of **4** were also examined and are listed in Table 2. The rate constant in 5% aqueous acetonitrile was close to diffusion controlled and again the measured rate constants were considerably lower in the presence of $LiClO_4$.

Quenching of **4** by chloride ion was examined under a variety of conditions (Table 2). Rate constants of $\sim 2 \times 10^{9}$ M^{-1} s^{-1} were measured for quenching by potassium chloride in 5% aqueous acetonitrile with and without 1.4×10^{-3} M $LiClO_4$. However, the rate constants for chloride quenching were quite sensitive to the water content. For example rate constants of 5.3×10^{9} and 9.5×10^{8} M^{-1} s^{-1} were measured in 3 and 10% aqueous acetonitrile, respectively.

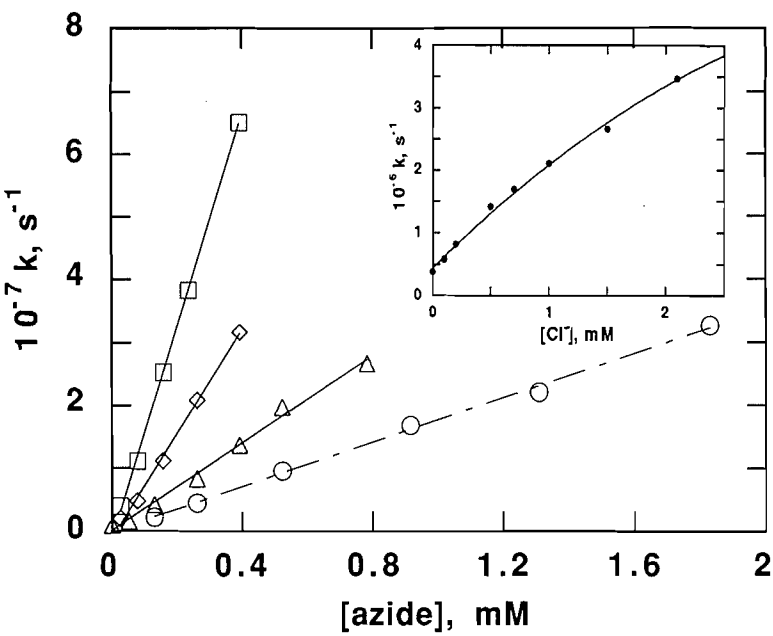

FIG. 7. Plots of the rate constant for decay of **4** as a function of the concentration of azide ion in 5% aqueous acetonitrile (□), 5% aqueous acetonitrile + 0.01 M $LiClO_4$ (◇), 5% aqueous acetonitrile + 0.1 M $LiClO_4$ (△), and 5% aqueous TFE (○); the insert shows the plot obtained for reaction of **4** with lithium chloride in 5% aqueous acetonitrile.

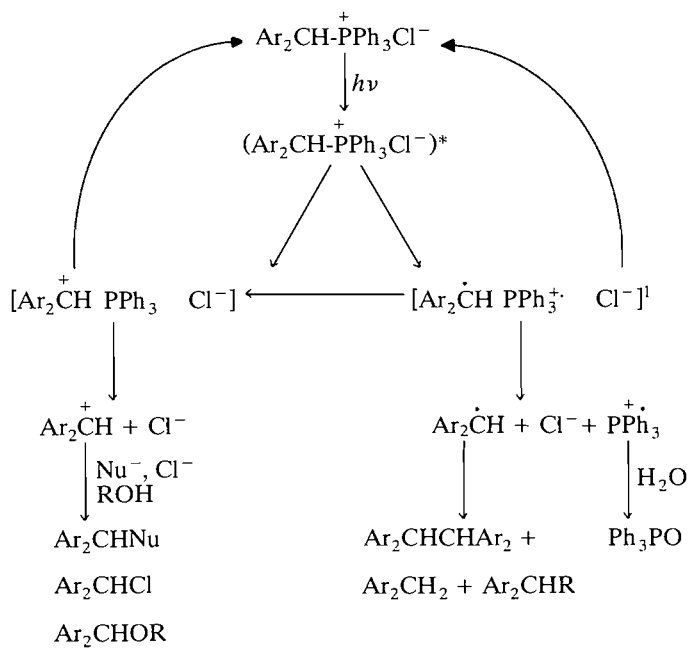
In some cases the plots of k_{obs} versus [Cl^-] showed negative curvature at higher concentrations (>1–2 mM; Fig. 7), probably as a result of changes in the ionic strength of the solution due to the addition of the salt. Solubility problems prevented the measurement of a rate constant for chloride quenching in neat acetonitrile. However, addition of 1.3×10^{-4} M lithium chloride to an acetonitrile solution of **1** containing 4.5×10^{-4} M 18-6 crown ether (to solubilize the lithium salt) decreased the lifetime of **4** to 0.56 μs. The crown ether alone had no effect on the cation lifetime. In 5% aqueous acetonitrile a rate constant of $\sim 1.4 \times 10^9$ M^{-1} s^{-1} was measured for quenching by LiCl; a curved quenching plot was obtained in this case and the estimated rate constant is based on the slope (based on a quadratic fit of the data) of the rate constant versus concentration plot at [Cl^-] = 0.

Discussion

The present laser flash photolysis results indicate that photolysis of diarylmethyl triphenylphosphonium salts such as **1–3** produces both radical and cation intermediates, with the relative yields of each depending on the solvent. For example, in polar solvents such as acetonitrile and alcohols these salts give exclusively cation formation, whereas in less polar solvents such as dioxane there are substantial yields of radical. These results are in line with those obtained for irradiation of similar iodonium and sulfonium salts for which heterolytic and homolytic cleavage reactions have been reported (35–37). One advantage of the phosphonium salts is their stability in aqueous and alcohol solvents under conditions where other typically used cation precursors, such as halides, undergo rapid ground state solvolysis.

The various mechanistic possibilities in the photochemistry of the phosphonium salts are outlined in Scheme 1. Note that the phosphonium salts will exist as either fully solvated species or solvent-separated or contact ion pairs, depending on the solvent, although these possibilities are not explicitly shown in the scheme. Cleavage of the C—P bond may occur either homolytically to give a diarylmethyl radical and triphenylphosphine radical cation or heterolytically to yield a diarylmethyl cation and triphenylphosphine. The excited state responsible for the photochemistry must be very short-lived based on the fact that we have been unable to observe any fluorescence that could be reliably assigned to emission from the first excited singlet states of salts **1–3**. This is in line with recent AM1 calculations for substituted arylmethylsulfonium salts that suggest that the lowest excited singlet is a dissociative σ* state centered on the C—S bond rather than a π* state when the aromatic substituent is phenyl, naphthyl, or anthryl (35). A similar ordering of the excited state energy levels has also been postulated for phosphonium salts (35). Further, there is no evidence for the intermediacy of a reactive triplet state for salts **1–3**. In those cases where a triplet has been observed, it is definitely not the precursor to either the cation or radical.



SCHEME 1

An alternate mechanism to heterolytic cleavage to produce the observed diarylmethyl cation is electron transfer within the initial radical/radical cation pair (Scheme 1). Such a pathway has recently been demonstrated to be responsible for cation formation in the photochemical cleavage of a series of substituted 1-naphthylmethyl esters (21). It is therefore of interest to investigate the generality of this process in the formation of carbocation intermediates. In our case an electron transfer pathway would be exothermic by approximately 1 V based on the redox potentials of 1.33 V (acetonitrile, vs. SCE) for triphenylphosphine (38) and 0.2–0.4 V for various substituted diarylmethyl radicals (39). This mechanism would be consistent with the increased yield of carbocation in polar solvents that would stabilize the carbocation. Compare, for example, the data for acetonitrile and 1:4 acetonitrile/dioxane in Table 3.

At first sight the low yield of cation **5** in TFE compared with acetonitrile (Table 3) may appear inconsistent with a mechanism where cation stabilization would determine the efficiency of radical pair to carbocation evolution via electron transfer. However, the dominant effect in this case is probably the difference in viscosity for the two solvents; thus, the viscosity of TFE is 1.99 cP (20°C) compared with 0.36 cP for acetonitrile. Therefore, one should anticipate increased geminate processes (including back reaction) in the case of TFE. The importance of geminate processes in modulating the observable cation yields is also apparent in the differences between "transient" and "product" determinations of quantum yields (see Table 3).

The diarylmethyl cation can decay by a number of pathways. Firstly, recombination with triphenylphosphine within the initial geminate cage can regenerate starting material. Note that the reaction of cation **6** with triphenylphosphine has been shown to occur at close to the diffusion-controlled rate. Secondly, in solvents where the phosphonium salt exists as ion pairs, reaction with chloride ion may also compete with cage escape. The cation can also be trapped with external nucleophiles such as solvent. The discrepancy between the cation yields measured by product studies and transient techniques for **5** in methanol/TFE suggests that there is a substantial fraction of the initial cations that reacts rapidly within the solvent cage to give product and, as a consequence, is not detectable in the transient experiments. This provides support for reaction with chloride before cage escape since trapping by triphenylphosphine would not account for the differences between the two methods for

For personal use only.

estimating the cation yields and since the cation lifetime (0.65 μs, Table 1) in this solvent is too long for methanol trapping to compete efficiently with cage escape.

The present results show that there are substantial effects of solvent and added salts on both the yields and lifetimes of cations **4**–**6**. For example, the yield of cation **5** varies from 0.71 in methanol to 0.093 in the less polar solvent 1:4 acetonitrile/dioxane. These observations could be explained by changes in the rate of the initial cleavage, the electron transfer, or the back reaction to regenerate starting material, or by some combination of these factors. The effects of added perchlorate salt on the cation yields are modest (≤20% increases, Table 4) in alcohols and acetonitrile and aqueous mixtures of these solvents, presumably due to efficient solvation of the ions in these solvents. However, the addition of even low concentrations of perchlorate (e.g., 0.29 mM) to 1:4 acetonitrile/dioxane leads to over a threefold enhancement in the yield of cation. In this less polar solvent the effect is best explained on the basis of replacement of chloride by perchlorate in the initial phosphonium salt ion pairs. The subsequent stabilization of the cation by the nonnucleophilic perchlorate ion prevents reaction with chloride or back reaction with triphenylphosphine. Note that stabilization of the triphenylphosphine radical cation by perchlorate may also lead to less back reaction from the radical/radical ion pair and this may be a factor if some or all of the cation is formed via the electron transfer route. The results shown in Fig. 6 for **4** indicate that the increased cation yield in the presence of perchlorate in acetonitrile/dioxane is accompanied by a concomitant decrease in the radical yield. This is consistent with homolytic cleavage to give a radical/radical cation pair, followed by electron transfer. The results also demonstrate the important role that salts can play in determining the outcome of cage processes.

The cation lifetimes tabulated in Table 1 are in many cases limited by reaction with the chloride counterion of the precursor salt. However, the short lifetimes in methanol reflect predominantly reaction of the cation with solvent. The unusual effects of water on the lifetime of **4** are also explicable on the basis of changes in the rate constants for chloride quenching for the various solvents. For example, the rate constant for reaction of **4** with chloride ion decreases by a factor of 5.6 when the water content is increased from 3 to 10%. Thus, the apparent increases in the cation lifetime in the presence of water are a result of the lower efficiency of chloride ion quenching in aqueous solution. For example, if we assume that in 5% aqueous acetonitrile all of the chloride counterions are available for quenching, then at 4×10^{-5} M salt precursor the rate for chloride quenching would be $\sim 10^6$ s^{-1}. The same calculation for 10% water gives a rate of 7.6×10^4 s^{-1}. The addition of perchlorate ion also has a substantial effect on the lifetimes of **4**–**6**, even at submillimolar concentration. These effects probably reflect a combination of both stabilization of the cation by ion pairing with the nonnucleophilic perchlorate anion and of ionic strength effects at higher salt concentrations.

The data in Table 4 demonstrate that there are very substantial effects of both solvent and added salt on the measured rate constants for reaction of **4** with nucleophiles. For example, even for azide ion the rate constants vary by over an order of magnitude in comparing aqueous acetonitrile and TFE. These effects are in line with those recently reported for substituent and solvent effects on the reactivities of triarylmethyl and diarylmethyl carbocations (40). Further, the addition of 0.1 M perchlorate decreases the rate constant for azide quenching by a factor of five in 5% aqueous acetonitrile. These effects are of considerable importance given the frequent assumption of a diffusion-controlled rate constant of 5×10^9 M^{-1} s^{-1} for reaction of azide with various cations and the use of this number as a "clock" to obtain absolute rate constants from product ratios measured in competitive experiments (41, 42).

Experimental

Materials and general techniques

Spectrograde solvents (Aldrich or BDH) and triphenylphosphine were used as received. Lithium, sodium, and magnesium perchlorates (Aldrich, anhydrous) were stored in a desiccator. Lithium chloride was dried at 160°C for 20 h and stored in a desiccator over P_2O_5. GC analyses were done on a Perkin–Elmer 8320 gas chromatograph with a 12-m BP1 on vitreous silica column. HPLC measurements were carried out on a Hewlett–Packard 1090 liquid chromatograph equipped with a diode array detector and a reverse-phase column (RP-18; 5 μm). Methanol/water solvent mixtures were used; analysis of the phosphonium salts required the addition of 4×10^{-3} M sodium dodecyl sulfate to the methanol. GC/MS measurements were done on a Hewlett–Packard 5995 instrument. NMR spectra were recorded on a Varian 200 MHz instrument. UV–visible spectra were measured using a Hewlett–Packard 8451A diode array spectrometer.

Synthesis

Phosphonium salts were synthesized by refluxing a mixture of the corresponding chlorides and triphenylphosphine (30% excess) for 12 h in benzene or toluene. In most cases the salt precipitated during the reaction or upon cooling and was filtered, washed with benzene or ether, and recrystallized from isopropanol/ethyl ether. The chlorides were obtained by refluxing the corresponding alcohols with thionyl chloride in benzene for 1.5 h and were recrystallized from hexane. The alcohol precursors for salts **1** and **2** were obtained by Grignard reactions of 4-methoxy-1-naphthaldehyde (**1**) with phenylmagnesium bromide and *p*-anisaldehyde (**2**) with 1-naphthylmagnesium bromide. The alcohol precursors for salts **3** and **9** were prepared by sodium borohydride reduction of the commercially available ketones. Analytical data for the various salts and chlorides are listed below.

Salt **1**: mp 183°C (dec.); ^{1}H NMR($CDCl_3$) δ(ppm): 8.6 (d, 1H), 8.3–6.5 (m, 26H), 3.9 (s, 3H). Anal. calcd. for $C_{36}H_{30}OPCl$: C 79.33%, H 5.55%; found: C 79.50%, H 5.66%.

Salt **2**: mp 160°C (dec.); ^{1}H NMR($CDCl_3$) δ(ppm): 8.8 (d, 1H), 7.8–6.6 (m, 26 H), 3.7 (s, 3H). Anal. calcd. for $C_{36}H_{30}OPCl$: C 79.33%, H 5.55%; found: C 79.15%, H 5.61%.

Salt **3**: mp 220°C (dec.); ^{1}H NMR($CDCl_3$) δ(ppm): 8.8 (d, 1H), 7.9–7.2 (m, 27H), 4.0 (s, 1H), 1.2 (d, 6H). Anal. calcd. for $C_{35}H_{28}PCl \cdot C_3H_8O$: C 79.36%, H 6.31%; found: C 79.03%, H 6.39%.

Chloride **7**: mp 70–72°C; ^{1}H NMR($CDCl_3$) δ(ppm): 7.9–7.2 (m, 12H), 6.3 (s, 1H). Anal. calcd. for $C_{17}H_{13}Cl$: C 80.79%, H 5.18%; found: C 81.00%, H 5.34%.

Chloride **8**: mp 117–121°C; ^{1}H NMR($CDCl_3$) δ(ppm): 8.3–6.7 (m, 11 H), 6.8 (s, 1H), 4.0 (s, 3H). Anal. calcd. for $C_{18}H_{15}OCl$: C 76.46%, H 5.35%, found: C 76.35%, H 5.47%.

Salt **9**: mp (dec.); ^{1}H NMR($CDCl_3$) δ(ppm): 8.3 (d, 1H), 7.8–6.6 (m, 23H), 3.7 (s, 6H). Anal. calcd. for $C_{33}H_{30}O_2PCl$: C 75.49%, H 5.76%; found C 73.41%, H 5.78%.

Salt **11**: mp 241–242°C (dec.); ^{1}H NMR($CDCl_3$) δ(ppm): 8.2–6.5 (m, 21H), 5.8 (s, 2H), 3.9 (s, 3H). Anal. calcd. for $C_{30}H_{26}OPCl$: C 76.83%, H 5.59%; found: C 77.09%, H 5.75%.

Laser flash photolysis

Detailed descriptions of the laser flash photolysis system have been published (43, 44). For these experiments either a Lumonics

TE-860-2 excimer laser with a Xe-HCl gas mixture (308 nm; ~5-ns pulses; <20 mJ/pulse) or a Lumonics HY750 Nd:YAG (fourth harmonic, 266 nm; 10-ns pulses; <25 mJ/pulse) was used for excitation. The samples were contained in 7 × 7 mm^2 quartz flow cells. The use of flow samples was essential to prevent signals due to the buildup of photoproducts. Samples were either aerated or were purged with nitrogen. Some of the transient spectra were recorded using an EG&G gated intensified optical multichannel analyzer equipped with a 20-ns gate.

The yields of cation **5** were determined by preparing samples of **2** and the actinometer (Aberchrome-540) with matched optical densities at 308 nm. The signals due to **5** at 550 nm and the colored form of Aberchrome-540 at 494 nm were then measured as a function of the laser intensity. The ratio of optical densities was taken as the slopes of the ΔOD versus laser intensity plots, extrapolated to zero laser intensity.

Product studies

Preparative photolysis of salt 2

A solution of **2** in methanol (250 mL, 3.7 × 10^{-3} M) was deaerated by nitrogen purging and irradiated for 3 h using 300-nm Rayonet lamps. The ether photoproduct (**17**) was isolated by column chromatography on silica using ethyl acetate/hexane mixtures and was further purified by chromatography on a Chromatotron (5% ethyl acetate/hexane). It was obtained as a colorless oil; GC/MS: *m/e* 278 (M^+).

Quantum yields

Samples of salt **2** in methanol (1 mL, 2.9 × 10^{-3} M) and valerophenone in cyclohexane (6.7 × 10^{-2} M) with matched optical densities at 313 nm were degassed by purging with nitrogen. The samples were irradiated in a merry-go-round in front of a Hanovia 200-W Hg/Xe lamp with a neutral density filter and a potassium chromate filter solution to isolate the 313-nm line. The valerophenone actinometer solutions were irradiated 1.5 h and the salt solutions for periods of 2–5 min at the beginning, middle, and end of the actinometer irradiations. An internal standard (biphenyl) was added to the irradiated salt solutions and they were analyzed by HPLC, using mixtures of pure compounds for calibration purposes. The production of acetophenone (Φ = 0.40) from the actinometer samples was measured by GC with hexadecane as the internal standard.

Received June 27, 1991

This paper is dedicated to Professor Kurt Dehnicke on the occasion of his 60th birthday

MARGARET ANN JAMES, OSVALD KNOP, and T. STANLEY CAMERON. Can. J. Chem. **70**, 1795 (1992).

The crystal structures of the following four compounds have been determined: $(n\text{-}Pr_4N)_2SnCl_6$ (**A**; *Pbca*, a = 29.073 Å, b = 15.825 Å, c = 14.851 Å, Z = 8), $(n\text{-}Pr_4N)[TeCl_4(OH)]$ (**B**; $C2/c$ or Cc, a = 10.800 Å, b = 17.429 Å, c = 10.604 Å, β = 93.81°, Z = 4), $(n\text{-}Pr_4N)_2[Te_2Cl_{10}]$ (**C**, nominal composition; $P\bar{1}$, a = 9.635 Å, b = 10.900 Å, c = 11.547 Å, α = 73.34°, β = 70.44°, γ = 68.15°, Z = 1), and $(n\text{-}Pr_4N)_2[Se_2O_2Cl_6]$ (**D**; $P\bar{1}$, a = 9.252 Å, b = 11.691 Å, c = 18.304 Å, α = 110.18°, β = 92.57°, γ = 97.72°, Z = 2). **B** contains a square-pyramidal $TeCl_4(OH)^-$ anion. The actual composition of the centrosymmetric μ_2-dimer in **C** is $Te_2Cl_8(Cl, OH)_2^{2-}$, the replacement of Cl by OH being at the axial ligand positions of the $TeCl_5^-$ halves of the dimer. In the centrosymmetric μ_2-$Se_2O_2Cl_6^{2-}$ dimer in **D** the Se—O bonds are perpendicular to the $Se(Cl)_2Se$ bridge plane and *trans* to the presumed lone-electron pairs on the Se atoms. It is shown that the Z—Hal bonds in the known centrosymmetric homoligand μ_2-$Z_2Hal_{10}^{2n-}$ (Z = Se, Te) and μ_2-$Z_2Hal_8^{2-}$ (Z = As, Sb, Bi) as well as in the μ_2-$Se_2O_2Hal_6^{2-}$ dimers exhibit a uniform stereochemistry, in which the d(Z—Hal) bond lengths in pairs of opposing bonds *trans* to each other are consistently related by the *trans* effect (TE). Empirical quantification of Te for the Se and Te dimers is exploited to authenticate the composition of the dimer in situations where the nature of the ligand is in doubt (in the present case on partial hydrolysis). The asymmetry of the $Z(Hal)_2Z$ double bridge is examined in relation to the overall stereochemistry of the dimer. Also examined are circumstances that may lead to the occurrence, in a crystal, of a $Z_2Hal_{10}^{2n-}$ dimer on the one hand and of a discrete $ZHal_5^{n-}$ monomer on the other, in situations which otherwise are chemically closely similar. TLS analysis of the thermal motion is used to judge the strength of association of the two monomer halves in a μ_2-dimer, with results that are important when correcting bond lengths for the effects of thermal motion. A variety of general observations on μ_2-dimers in crystals is proffered for good measure.

MARGARET ANN JAMES, OSVALD KNOP et T. STANLEY CAMERON. Can. J. Chem. **70**, 1795 (1992).

On a déterminé les structures cristallines des quatre composés suivants: $(n\text{-}Pr_4N)_2SnCl_6$ (**A**; *Pbca*, a = 29,073, b = 15,825 et c = 14,851 Å, Z = 8), $(n\text{-}Pr_4N)[TeCl_4(OH)]$ (**B**; $C2/c$ ou Cc, a = 10,800, b = 17,429 et c = 10,604 Å, β = 93,81°, Z = 4), $(n\text{-}Pr_4N)_2[Te_2Cl_{10}]$ (**C**, composition nominale; $P\bar{1}$, a = 9,635, b = 10,900 et c = 11,547 Å, α = 73,34, β = 70,44 et γ = 68,15°, Z = 1) et $(n\text{-}Pr_4N)[Se_2O_2Cl_6]$ (**D**; $P\bar{1}$, a = 9,252, b = 11,691 et c = 18,304 Å, α = 110,18, β = 92,57 et γ = 97,72°, Z = 2). Le composé **B** contient un anion $TeCl_4(OH)^-$ à pyramide carrée. La composition réelle du dimère-μ_2 centrosymétrique du produit **C** est $Te_2Cl_8(Cl,OH)_2^{2-}$, le OH qui remplace le Cl se trouvant dans les positions des ligands axiaux des portions $TeCl_5^-$ du dimère. Dans le dimère centrosymétrique μ_2-$Se_2O_2Cl_6^{2-}$ du composé **D**, les liaisons Se—O sont perpendiculaires au plan du pont $Se(Cl)_2Se$ et *trans* par rapport aux présumées paires d'électrons libres sur les atomes de Se. On a montré que les liaisons Z—Hal dans les dimères centrosymétriques homoligand μ_2-$Z_2Hal_{10}^{2n-}$ (Z = As, Sb, Bi) et μ_2-$Z_2Hal_8^{2-}$ (Z = Se, Te) connus ainsi que les dimères μ_2-$Se_2O_2Hal_6^{2-}$ présentent une stéréochimie uniforme dans laquelle les longueurs des liaisons d(Z—Hal) dans les paires des liaisons *trans* s'opposant les unes aùx autres sont toujours liées par l'effet *trans* (TE). On exploite une quantification empirique du TE pour les dimères du Se et du Te pour authentifier la composition de dimères dans des situations où la nature du ligand n'est pas certaine (dans le cas examiné ici, il s'agit du produit d'hydrolyse partielle). On a examiné l'asymétrie du double pont $Z(Hal)_2Z$ en rapport avec la stéréochimie globale du dimère. On a aussi examiné les circonstances qui peuvent conduire, dans un cristal, à la présence d'une part d'un dimère $Z_2Hal_{10}^{2n-}$ et d'un monomère $ZHal_5^{n-}$ individuel, dans des conditions chimiques qui sont par ailleurs chimiquement semblables. On a utilisé l'analyse TLS du mouvement thermique pour juger de la force de l'association de deux parties de monomères dans un dimère-μ_2; les résultats sont importants pour corriger les longueurs de liaison pour les effets des mouvements thermiques. On présente aussi un nombre d'observations générales sur dimères-μ_2 dans les cristaux.

[Traduit par la rédaction]

In the course of investigating the actual geometry of octahedral 12- and 14-valence-electron ML_6^{n-} anions in crystals (cf. ref. 1) we obtained, serendipitously, several tetra-*n*-propylammonium salts not useful for the intended purpose but interesting in their own right. Preliminary crystallographic studies showed three of them (see title) to contain uncommon Se(IV)- and Te(IV)-derived anions and thus to merit closer investigation. The crystal structures of these salts, together with that of $(n\text{-}Pr_4N)_2SnCl_6$ (**A**), are described below and the stereochemistry of the anions is compared with that previously reported in the literature. The conditions under which the three salts were formed were ill-

defined; the complexity of the solution and crystal chemistry of such anionic species, which is reflected in their compositions, can be gleaned from the recent review by Krebs and Ahlers (2) and from the references therein. Nor were the determinations of these three structures without problems, though in the end having to deal with some of the complications was repaid by a broadened chemical insight.

Preliminary observations (Sect. I) are followed by a description and discussion of the crystal structures of the title compounds (Sect. II) and by observations on the structural aspects of $Z_2Hal_{10}^{2n-}$, $Z_2Hal_8^{2-}$, and $Se_2O_2Hal_6^{2-}$ (Z = Se, Te; As, Sb, Bi) dimers (Sect. III). Experimental detail is relegated to the end of the paper (Sect. IV). Where no reference is given the result is from the present investigation. All bond lengths quoted are uncorrected for thermal motion except where stated otherwise; the appropriateness of corrections is discussed in Sect. III. The abbreviations TE and RBM stand for the *trans* effect and for rigid-body motion, respectively.

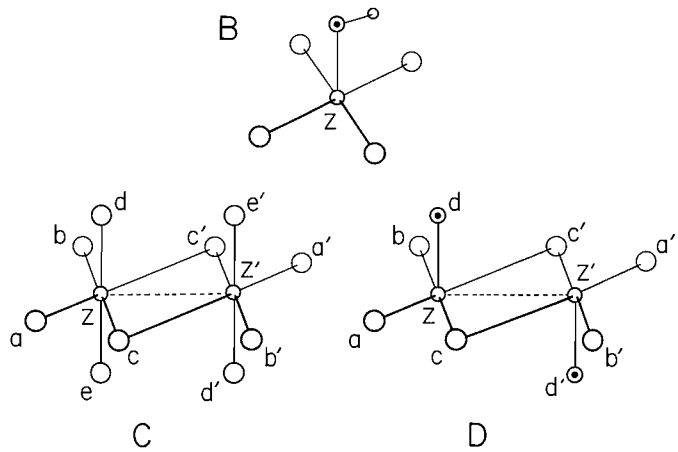

FIG. 1. Standardized anion configurations (schematic): $ZL'L_4^{n-}$ (in **B**, $TeCl_4(OH)^-$), $Z_2L_{10}^{2n-}$ (in **C**, nominally $Te_2Cl_{10}^{2-}$, actually $Te_2Cl_8(Cl, OH)_2^{2-}$ with L_a, L_a' mixed ligands), and $Z_2L'_2L_6^{n-}$ (in **D**, $Se_2O_2Cl_6^{2-}$). The longest Z–L distance in the dimers is Z–L_c'.

I. Preliminary observations

The crystal data of the title compounds are assembled in Table 1. Standard execution of the structure determinations (supported by evidence from ir spectra, see Sect. IV) showed unambiguously that the structures of **A** and **B** corresponded to the stated compositions. The structures of **C** and **D** turned out to contain centrosymmetric dimers $Te_2Cl_{10}^{2-}$ and $Se_2O_2Cl_6^{2-}$, respectively (Fig. 1). This finding was unexpected but accepted as correct, since the existence of these

and related dimers had been previously (2, 6–13) reported in salts of these anions with several organic cations. However, the thermal parameters of some of the anion ligand atoms in **C** were large and the Te···Te' distance, 4.418(1) Å, was well in excess of the corresponding distances in the Ph_4As^+ (**Ch**, Table 2) and Ph_3PCl^+ (**Ci**) salts, 4.033(1) and 4.040(1) Å, respectively. Closer attention to this difficulty revealed a precedent: the Te···Te' distance in **Cj** (originally reported as having the composition $(Ph_4As)_2[Te_2Cl_{10}]$, refs. 6 and 7) was 4.430(3) Å in one (**Cj1**) and 4.153(3) Å in the other (**Cj2**) of the two nonequivalent $Te_2Cl_{10}^{2-}$ anions in the unit cell. Moreover, the shortest bond, Te—Cl_a, was significantly shorter in **Cj** than in **Ch** and **Ci**, while the longest bond, Te—Cl_c' (bridging bond *trans* to Te—Cl_a), was significantly longer in **Cj** than in **Ch** and **Ci**. Because of these discrepancies the structure of **Cj** was later (B. Krebs, personal communication) reformulated as corresponding to $(Ph_4As)_4[Te_2Cl_{10}][Te_2Cl_8Cl_x(OH)_{2-x}]$, i.e., to partially hydrolyzed $(Ph_4As)_2[Te_2Cl_{10}]$. In view of this it appeared indispensable for a proper interpretation of our own results for **C** to establish a standard for the variation of the Z—Cl bond lengths in $Z_2Cl_{10}^{2-}$ and $Se_2O_2Cl_6^{2-}$ dimers with which the bond lengths observed in **C** and **D** could be compared. For this an analysis of the observed complete geometries of the

dimers is required. Two questions will be asked: (1) Are differences in the Z—Hal bond lengths within a dimer and between nonidentical dimers of the same composition random (i.e., due to accidents of crystal packing and interion interaction) or systematic? (2) If the differences are systematic, do relationships between the bond lengths exist and, if they do, can they be used to authenticate Z—Hal bond lengths in crystals?

Differences in bond lengths

The geometries of the $Z_2Hal_{10}^{2-}$ (Z = Se, Te) and $Se_2O_2Hal_6^{2-}$ dimers are standardized in Fig. 1, and Table 2 contains a synoptic presentation of the reported Z—Hal, Z···Z′, and Se—O distances ($d_a = d$(Z—Hal$_a$) etc.).

By and large, d_a appears to be the shortest and d_c' the longest of the Z—Hal bonds in a $Z_2Hal_{10}^{2-}$ dimer, the latter bond in $Te_2Cl_{10}^{2-}$ being at least 0.2 Å longer than any of the other bonds in this ion. The dimer may thus be regarded, at least formally at this point, as a pair of square-pyramidal $TeHal_5^-$ ions, with Hal$_a$ and Hal$_a$′ as the axial ligands, and weakly bonded through Z—Hal$_c$′. This is consistent with the observation that in the square-pyramidal TeF_5^- monomer the axial Te—F bond (corresponding to Z—Hal$_a$) is about 0.1 Å shorter than the equatorial Te—F bonds.[2] Furthermore, as pointed out by Krebs *et al.* (2, 10), the difference between the bridging bonds in a $Te_2Hal_{10}^{2-}$ dimer (and thus the asymmetry of the double bridge) increases with the decreasing atomic number of Hal, until ultimately for Hal = F the dimer becomes a centrosymmetric pair of TeF_5^- monomers with the Te···F$_c$′ distance (in **Cf**) about 60% longer than Te—F$_c$ and with the Te—F bond lengths in the monomer virtually indistinguishable from those in the discrete TeF_5^- ion.[3] In such circumstances one might expect the equatorial Te—Hal bond lengths in each $TeHal_5^-$ monomer half to be the same, save for possible differences arising from accidents of packing in each particular crystal structure.

In $Te_2Cl_{10}^{2-}$, for which three sets of authentic Te—Cl bond lengths are available (**Ch**, **Ci**, **Cj2**),[4] analysis of variance and *t* tests show that the following hypotheses can be *rejected* at the 99.5% significance level or better: (*i*) the means $\langle d_b\rangle$ = 2.416(17) Å, $\langle d_g\rangle$ = 2.683(27) Å, $\langle d_d\rangle$ = 2.503(16) Å, and $\langle d_e\rangle$ = 2.480(3) Å are from the same population; (*ii*) $\langle d_b\rangle$, $\langle d_d\rangle$, and $\langle d_e\rangle$ are from the same population; (*iii*) $\langle d_b\rangle$ and $\langle d_e\rangle$ are from the same population. Conclusions *ii* and *iii* in fact hold for the entire set **Ch**, **Ci**, **Cj1**, **Cj2**, and **C**. However, the hypothesis that $\langle d_d\rangle$ and $\langle d_e\rangle$ come from the same population can be rejected at only the 8% significance level for **Ch**, **Ci**, and **Cj2**, and at the 10% level for all five $Te_2Cl_{10}^{2-}$ sets in Table 2.

In sum, then, the differences between d_b, d_c, and (d_d, d_e) persist regardless of the nature of the counter cation and may be regarded as stereochemical class differences reflecting the existence of an underlying bonding scheme for the dimer. Significant for the view that the differentiation of the equatorial bonds in the monomer halves is due to the bridge formation is the fact that the bonds Te—Cl$_d$ and Te—Cl$_e$ perpendicular to the bridge plane remain undifferentiated between themselves, whereas those *in* the bridge plane and *trans* to each other, Te—Cl$_b$ and Te—Cl$_c$, now belong to different classes (contrast this with the lack of differentiation in the pseudo dimer $Te_2F_{10}^{2-}$ in **Cf**).[2,5]

Corresponding statistical scrutiny of the Se—Cl bond lengths in $Se_2O_2Cl_6^{2-}$ (**D1**, **D2**, **Da**, **Db**) shows that the means $\langle d_a\rangle$ = 2.266(12) Å, $\langle d_b\rangle$ = 2.355(22) Å, and $\langle d_c\rangle$ = 2.654(39) Å do not come from the same population (significance level, >> 99.9%), nor do $\langle d_a\rangle$ and $\langle d_b\rangle$ (significance level, >99.9%). These means differ from the bond lengths observed in the $SeOCl_3^-$ monomer (**De**): $\langle d_a\rangle$ is barely within 3σ of d_a in **De**, but d_b and d_c in **De** differ by 0.045 Å, whereas in the dimer the difference between $\langle d_b\rangle$ and $\langle d_c\rangle$ is 0.30(5) Å, i.e., there is disproportionation in the two *trans* Se—Cl bond lengths in the dimer. In $Se_2O_2Br_6^{2-}$ (**Dc**) the Se—Br$_c$ bond is clearly the longest of the three, but d_a and d_b are now almost identical, the asymmetry of the double bridge notwithstanding.[6]

Relationship between Z—Hal bonds: the trans *effect*

From the preceding it appears that Z—Hal bonds in a dimer that belong to distinct stereochemical classes are also metrically different. Closer examination of the spatial relationships of these bonds reveals that, in bonds *trans* to each other, the shorter the one bond the longer the other. This compensation, which is nonlinear but not severely so over the observed Z—Hal ranges, is referred to as the *trans* effect. The effect is electronic in nature and reflects in part the response of a molecule or molecule-ion to its incorporation in a crystal. The pervasive occurrence of TE in the structural chemistry of Se(IV) and Te(IV) halogeno species has been repeatedly pointed out by Krebs (11, 18, 19) and others (20). However, TE is not confined to these species or to halogens as ligands. It has been empirically quantified for L$_1$—Z—L$_2$ *trans* bonds with chemically nonequivalent ligands (21), and some of its general aspects are discussed in detail in ref. 22.

The regularity of TE, for a given pair of elements, should make it possible to demonstrate whether a set of *d*,*d** bond lengths (*d** ≥ *d*) in pairs of conjugate *trans* bonds[7] conforms to the same bonding principle, and to test whether a particular *d*,*d** pair can legitimately be included in the set.

[2]**Cf**, d(Te—F$_a$) = 1.872 Å; $\langle d$(Te—F$_{eq}$)$\rangle$ = 1.950(10) Å. Means from other monomers, $\langle d$(Te—F$_{ax}$)$\rangle$ = 1.868(33) Å, $\langle d$(Te—F$_{eq}$)$\rangle$ = 1.963(44) Å (cf. Table 10).

[3]The occurrence of the centrosymmetric pairs of TeF_5^- ions in **Cf**, with closest interion F···F approaches equal to or exceeding the sum of the van der Waals radii and with Te···F separations of ~3.2 Å raises the quation, to what extent is the existence of such pairs in $A^+TeHal_5^-$ crystals due to external factors (minimization of lattice energy, maximization of packing density) rather than to an intrinsic tendency of $TeHal_5^-$ to form $Te_2Hal_{10}^{2-}$ dimers (see Sect. III).

[4]The structures of **Ca**, **Ch**, and **De** were determined from low-temperature data (Table 2). It is difficult to know how to adjust the bond lengths obtained from these determinations to room-temperature values. The original bond lengths have therefore been retained throughout. From a qualitative estimate of the magnitude of the required corrections (based on the assumption that dV/dT ~ 0.01%/K and that the bond lengthening is isotropic) it appears doubtful that substitution of the true room-temperature bond lengths would significantly alter any of the conclusions below.

[5]Similar conclusions appear to hold for $Se_2Cl_{10}^{2-}$, $Te_2Br_{10}^{2-}$, $Te_2I_{10}^{2-}$, and also for the corresponding $Z_2Hal_{10}^{4-}$ dimers with Z from Group V (see III for details and further discussion.

[6]In $As_2Br_8^{2-}$ (**3**, **4**, and **5**; Table 9), the hypothesis that $\langle d_a, d_b, d_c\rangle$ comes from the same population as $\langle d_c, d_c'\rangle$ can be rejected absolutely. However, the hypothesis that $\langle d_a\rangle$, $\langle d_b\rangle$, and $\langle d_d\rangle$ come from the same population must be *accepted* at the 30% significance level, and ditto for $\langle d_c\rangle$, $\langle d_c'\rangle$, (21% significance level), and $\langle d_a\rangle$, $\langle d_d\rangle$ (62% significance level).

[7]In bridged species *d* refers to the terminal and *d** to the bridged ligands. In all the cases considered in this paper, $d_{terminal} \leq d_{bridge}$.

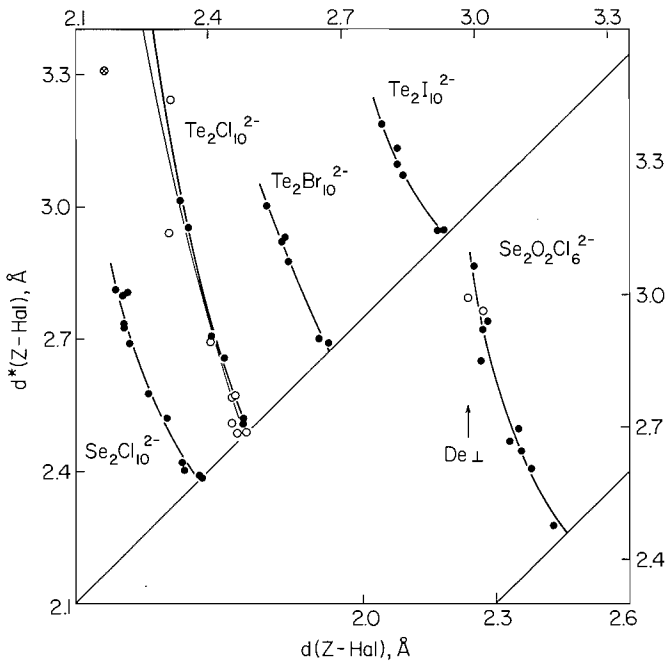

FIG. 2. Variation of the Z—Hal bond lengths d^* with $d \leq d^*$ in pairs of conjugated *trans* bonds in $Z_2Hal_{10}^{2-}$ and $Se_2O_2Cl_6^{2-}$ anions (cf. Table 2). The curves represent the DPF regressions of Table 3. $Te_2Cl_{10}^{2-}$: thick line and full circles, data set *a* ($n = 6$); thin line and full and open circles, data set *b* ($n = 14$); crossed circle, **Cjl**(d_a, d_c'), mixed-ligand Te—(Cl, OH) bond. $Se_2O_2Cl_6^{2-}$: the two open circles are for **Df** (not included in the regressions).

Specifically, TE should be able to indicate whether or not some of the bonds assumed in the structure refinement of **Cj** and **C** to be Te—Cl bonds had in fact undergone hydrolysis.

To date no satisfactory theory-based general function $d^* = f(d)$ appears to have been proposed. However, TE in Z(III)—Hal (AsBr, SbBr, SbI) bonds has recently been successfully quantified by Sheldrick et al. (23, 57), who modified Pauling's (24) relation $D(n) = D(1) - B \log n$ to

$$[1] \quad d^* = d_0 - B \ln s^*$$

assuming in addition that, for a d,d^* pair, $s + s^* = 1$ and $B = b_0 + b_1 (d - d_0)$. Here d_0 is the Z—Hal bond length in $ZHal_3(g)$, s and s^* are the conjugate bond orders, and b_0 and b_1 are parameters of least-squares refinement.[8] This treatment is referred to in the following as CSBO (constant sum of bond orders). A purely empirical alternative to CSBO, free from particular model assumptions, is the function

$$[2] \quad d^* - d_0 = K(d - d_0)^{-c}$$

(difference power fit, DPF; see ref. 22). To determine which of the bond lengths in **Cj** and **C** quality as proper Te—Cl bond lengths we examined the DPF, CSBO, and other schemes (Table 3, Fig. 2), using in the regressions (*a*) the Te—Cl distances in **Ch** and **Ci**, and (*b*) all the pairs of Te—Cl distances in Table 2 except d_a,d_c' in **Cj1**, which produced a gross visual misfit in the d^* vs. d plot and for which the reported d was unacceptably short for a Te—Cl bond length. Since the Te—Cl bond lengths in the free $TeCl_4$ molecule are not known, the limiting d_0 (Te—Cl) bond length was treated as a parameter of regression. The figures of merit resulting from the three-parameter nonlinear optimizations (Table 3 and Sect. IV) indicate that both CSBO and DPF (as well as PF2) are good approximations to the variation of d^* with d in $Te_2Cl_{10}^{2-}$ and that these regressions describe the variation in each of the two sets equally satisfactorily though not identically.

From Fig. 2 it is clear that the bond length in **Cj1** reported as d(Te—Cl_a) is inconsistent with any of the regressions. If the associated distance d(Te—L_c') is assumed to be the correct distance for L = Cl, then the reported d(Te—L_a) deviates by 57σ from the DPF regression line for data set *a* and by more than 9σ from that for set *b*. This legitimizes Krebs's reinterpretation (personal communication) of this distance as resulting from a partial replacement of Cl in the Te—L_a bond by OH. As for the Te—L_a bonds in **Cj2** and **C**, the point for **Cj2** is ~11σ below the regression line *a* and ~2.2σ below the regression line for *b*. The deviations of the other points for **Cj1** and **C** from the regression lines, however, are within ~3σ for line *a* and ~1σ for line *b*, in a region of the plot which is well determined by points of data set *a*. It thus appears that the partial hydrolysis of anion **Cj1** was sufficiently serious to reduce the apparent Te—L_a = Te—L_{ax} bond length to a value disqualified for inclusion in the d(Te—Cl) data set. However, the hydrolysis was selective in that it affected, preferentially, the axial ligand much more than any of the equatorial ligands; curiously enough, its effect on **Cj2**, the second anion in the same crystal, was considerably less.

If the difference between d(Te—Cl) and d(Te—O) is estimated as ~0.5 Å (see Sect. II), on the average less than one half of the Cl_a in the **Cj1** anions would seem to have been replaced by OH. However, this was sufficient to increase d(T···Te′) by ~0.4 Å relative to **Ch** and **Ci**. Significantly, the lesser degree of Cl_a substitution in **Cj2** is associated with a smaller increase in d(Te···Te′), only about 0.12 Å. Although these changes are relatively small and on the whole affect only one of the two types of anions in a structure otherwise chemically the same as **Ch**, they were sufficient to produce changes in the triclinic crystal structure such that Gretenkord (12) was unable to reconcile the unit cell of **Ch** (−130°C) with that of **Cj** (room temperature).

The implication of these findings is that our own compound **C** may also have undergone partial hydrolysis and that this may have been the reason for some of the unsatisfactory features of the structure refinement that assumed all the ligands to be Cl. The d(Te—L_a) and d(Te···Te′) values (Table 2) would support this possibility, but the position of the point for **C**(d_a,d_c') *above* the regression lines in Fig. 2 poses a contradiction. Attempts to resolve this problem are described in Sect. II.

The operation of TE in $Te_2Cl_{10}^{2-}$ receives support from an examination of the data available for $Se_2Cl_{10}^{2-}$, $Te_2Br_{10}^{2-}$, and $Te_2I_{10}^{2-}$ (Fig. 2, Table 2). The regressions (Table 3) gave on the whole satisfactory agreement for these data sets. Interestingly, the regression line for the $Te_2Br_{10}^{2-}$ set shows very little curvature although a curvature intermediate between $Te_2Cl_{10}^{2-}$ and $Te_2I_{10}^{2-}$ might be expected. Additional $Te_2Br_{10}^{2-}$ dimers are required to see whether the behaviour of the existing set is a real phenomenon or merely a statistical oddity.

The TE in the $Se_2O_2Cl_6^{2-}$ anions also exhibits good internal consistency (Fig. 2, Table 3). The regression line ac-

commodates well also the two d,d^* pairs in the linear $[SeOCl_2Cl_{2/2}]_\infty^-$ chains in **Df** and the *trans* Se—Cl pairs in the $SeOCl_3^-$ monomer **De**. The Se—Cl bond length involving the unopposed Cl ligand in the latter is at the limit of the $Se_2O_2Cl_6^{2-}$ data set (Fig. 2).

The data sets of Fig. 2 and Table 3 are statistically inadequate for trends in the fitted parameter values to emerge.[9] The exception is d_{equal}, which does not depend critically on the curvature of the regression line (i.e., on the distribution of the d,d^* pairs and the assumed model function), provided there are well-behaved d,d^* pairs sufficiently close to the $d = d^*$ line. Regression of the d_{equal} from the $Te_2Hal_{10}^{2-}$ ($n = 6$) data sets on Shannon's $r(Hal^-)$ radii (25) gave $d_{equal} = 0.4357 + 1.1368r(Hal^-)$, $r^2 = 0.999$, $\sigma = 0.009$ Å; extrapolation to $r(F^-) = 1.33$ Å yielded $d_{equal} = 1.948$ Å, which compares well with the $\langle d(Te—F_{eq})\rangle$ value of 1.964(33) Å (Table 10).

[9]For a discussion of the existence of such trends see ref. 22.

II. Crystal structures

The atom coordinates and thermal parameters of the nonhydrogen atoms in the title compounds are listed in Tables 4–7, and the bond lengths and bond angles for all four are

listed in Table 8. The atom coordinates of the hydrogen atoms and tables of structure factors have been deposited (see Sect. IV).

*(n-$Pr_4N)_2SnCl_6$ (**A**)*

The salt investigated here is probably the D_{2h} form of (*n*-$Pr_4N)_2SnCl_6$ of Ries (4, 5), although the density he reports is too low and the axial ratio from his optical measurements bears no obvious relation to the unit-cell dimensions of **A**.[10]

The structure consists of an *anti*-fluorite-type arrangement of fully extended *n*-Pr_4N^+ cations 1 and 2 and only slightly distorted $SnCl_6^{2-}$ octahedra of symmetry C_1 (Fig. 3). The $Pbca \subset Pa\bar{3}$ unit cell may be regarded as an *anti*-fluorite *Pbcm* cell doubled on the *a* axis, the contents of the two *Pbcm* halves being related by a chromatic $a/2$ translation; the chromatic operation on the Bravais P_a lattice is inversion of the ion orientation. The relation between the ion orientations in the structure can thus be described by the dichromatic space group $P_abca - 2Pbcm|Pbca$. This arrangement appears to be novel for A_2MX_6 salts containing small, relatively symmetric cations (cf. refs. 1 and 26).

The U_{ij} values of Sn and Cl are satisfactorily explained on the RBM model (cf. Table 11). The librational motion of the $SnCl_6$ octahedron is quite uniform; the libration axis L_2 is nearly parallel to *a*.

*(n-Pr_4N)[$TeCl_4(OH)$] (**B**)*

As described in Sect. IV, the structure was solved in the centrosymmetric space group $C2/c$ and subsequently refined both in $C2/c$ (with the Te and O atoms each in two-fold positional disorder) and in Cc (as a fully ordered structure). The two refinements differ essentially only in details of the anion structure.

The fully extended *n*-Pr_4N^+ cations and the $TeCl_4(OH)^-$ anions are arranged in an *anti*-NiAs-type packing.[11] The *c* axis of **B** corresponds to the *c* axis of the hexagonal NiAs structure ($P6_3mc \supset Cc \subset C2/c$), and $b(\mathbf{B})/a(\mathbf{B}) = 1.614 \sim \sqrt{3}$. The cations are arranged in columns parallel to *c*.

In the Cc refinement the spread of the Te—Cl bond lengths is considerably smaller than in the $C2/c$ refinement, but the means are the same, 2.49(1) and 2.50(1) Å, respectively. This compares with ⟨2.48(1)⟩ Å in $(Ph_4As)[TeCl_4(OH)]\cdot H_2O$ (56), ⟨2.496⟩ Å in $(H_9O_4)[TeCl_4(OH)]\cdot H_2O$ (2, 18), and ⟨2.51(4)⟩ Å for anion 1 and ⟨2.50(2)⟩ Å for anion 2 in $K(TeCl_4(OH)]\cdot\frac{1}{2}H_2O$ (58), the mean for the five anions being 2.50(10) Å.

The Te atom is on the opposite side of the best plane through the four Cl ligands from the oxygen atom, 0.06 Å from the plane in the Cc and 0.15 Å in the $C2/c$ refinement. This is consistent with the expectation from the VSEPR rules. These two distances are shorter than the corresponding distance in the ordered anion 2 of the K^+ salt, 0.21 Å; in the $C2/c$ refinement of the Ph_4As^+ salt the Te atom was placed at a centre of symmetry and is therefore coplanar with the Cl atoms.

Up to this point the refinements in $C2/c$ and Cc do not differ appreciably. However, the Te—O bond length is 1.87(1) Å in the $C2/c$ and 1.73(2) Å in the Cc refinement, a significant difference. Interestingly, the latter value is the same as in the Ph_4As^+ salt, 1.74(1) Å, whereas the values in the $H_9O_4^+$ and K^+ salts are 1.93 and 1.91(2) Å, respectively. The paucity of known $TeCl_4(OH)^-$ structures makes rationalization of these differences difficult, and there are other obstacles: a similar difficulty of choice between $C2/c$ and Cc was encountered in the structure refinement of the Ph_4As^+ salt; a full account of the $H_9O_4^+$ salt structure is yet to be published; one of the anions in the K^+ salt is partially disordered; and three of the four relevant compounds are hydrated. Nevertheless, since hydrogen bonding was suspected to be a possible factor responsible for the discrepancy, the four structures were examined in detail for whatever evidence for this possibility could be found. The pertinent structural detail is presented in Fig. 4.

In the $H_9O_4^+$ salt the hydroxyl oxygen is involved in an O—H···$O(H_2O)$ bond to the nearest water (*not* $H_9O_4^+$) oxygen. The O···O separation of 2.64 Å indicates a strong H-bonding interaction, comparable to that in $NaOH\cdot H_2O$.[12] The O(OH) oxygen is also hydrogen-bonded to a $H_9O_4^+$ oxygen at 2.84 Å.

In the other structure containing long Te—O bonds, $K[TeCl_4(OH)]\cdot\frac{1}{2}H_2O$, anion 1 is orientationally disordered, *d*[Te(11)—O(11)] = 1.905(17) Å, *d*[Te(12)—O(12)] = 2.15 Å (*sic*). In the ordered anion 2, *d*[Te(2)—O(2)] = 1.908(13) Å. Although the OH hydrogens in this structure have not been located, the direction of the Te(2)—O(2) bond is compatible with the existence of an almost symmetrically bifurcated O(2)—H(2)···Cl(23a),Cl(24b) hydrogen bond, in which *d*[O(2)···Cl(23a)] = 3.66 Å and *d*[O(2)···Cl(24b)] = 3.69 Å (Fig. 4; a, $(-x, -y, -z)$; b, $(-x, 1-y, -z)$). The midpoint M of the Cl(23a)···Cl(24b) distance forms a Te(2)—O(2)—M angle of 113°, i.e., not far from tetrahedral, and is ~2.40 Å from H(2), if the latter is placed in accordance with the geometry normally expected for a Te—O—H group. In that case, the H(2)···Cl(23a),Cl(24a) distance would be ~3.0 Å. which would qualify O(2)—H(2)···Cl(23a),Cl(24b) for at least a moderately strong hydrogen bond.[13,14]

By contrast, consideration of admissible atom···atom separations in the $(Ph_4As)[TeCl_4(OH)]\cdot H_2O$ structure (as refined in $C2/c$, oxygens in half occupancy) shows that the only atom that could conceivably function as an acceptor of the hydroxyl hydrogen H(1) is the water oxygen O(2) (Fig. 4). However, the large O(1)···O(2) distance, 3.04 Å, and the Te—O(1)—O(2) angle of 134° are both unfavourable to the existence of an effective hydrogen bond. The oxygen of the water molecule, O(2), is nominally ~3.2 Å from the nearest chlorines Cl(1′) and Cl(2). Weak O—H···Cl hy-

[10]The second form reported by Ries is triclinic, with the improbably high density of 1.548 g/cm³ (a misprint?).

[11]In the $(Ph_4As)[TeCl_4(OH)]\cdot H_2O$ structure the packing is regular but not clearly related to any of the simple types of 1:1 ionic structures. In $K[TeCl_4(OH)]\cdot\frac{1}{2}H_2O$ the ions are arranged in a distorted CsCl-type packing, with columns of K^+ ions and $O(H_2O)$ atoms parallel to *c*.

[12]In $NaOH\cdot H_2O$ the O(OH)···$O(H_2O)$ distances are reported as 2.64 and 2.66 Å (59, 60).

[13]The disorder proposed in ref. 58 for anion 1 complicates evaluation of the H-bonding engagement of this anion. The distance *d*[O(12)···$O(H_2O)$] = 2.26 Å is too short for any interaction that might occur in that crystal. However, at *d*[O(11)···$O(H_2O)$] = 2.52 Å the Te(11)—O(11)—$O(H_2O)$ angle is ~118°, which strongly implies the existence of a Te(11)—O(11)···$O(H_2O)$ bond of moderate strength.

[14]It should be possible to demonstrate the bifurcated character of this bond from the temperature dependence of the ν(OD) frequency of the weakly deuterated compound (cf. refs. 61 and 62).

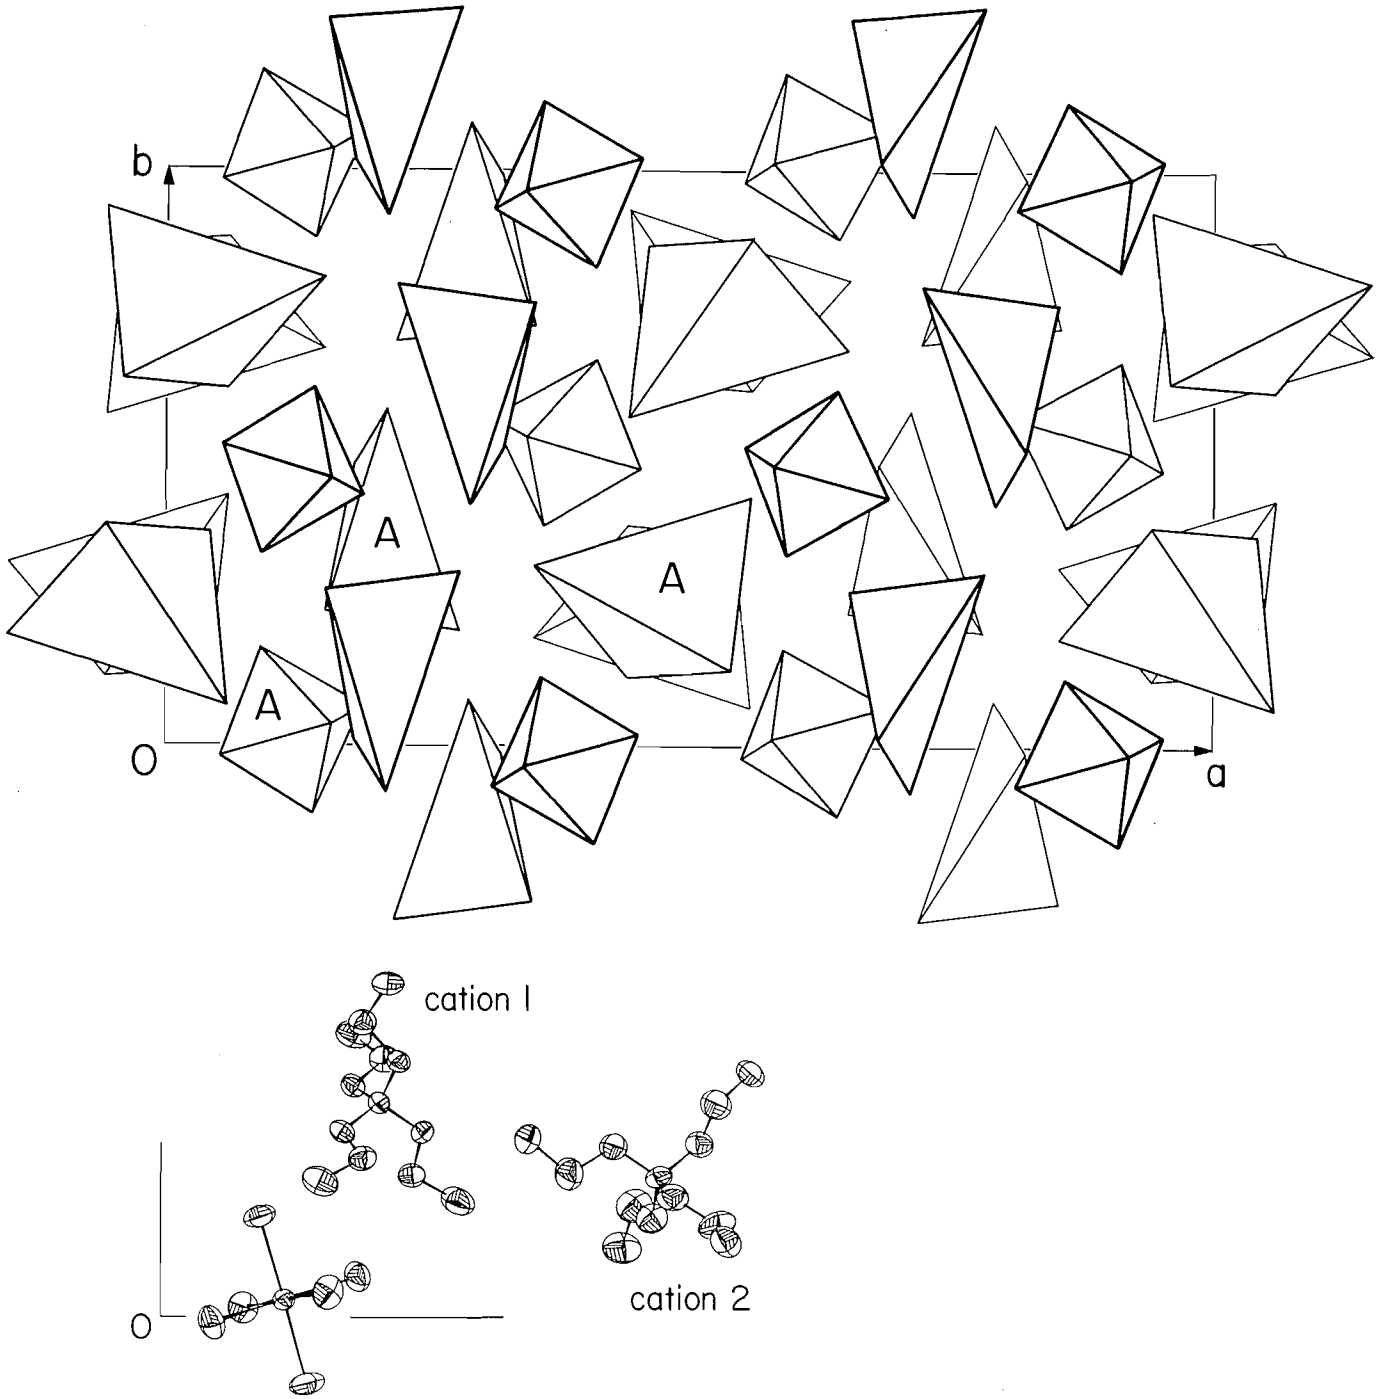

FIG. 3. Projection of the structure of $(n\text{-}Pr_4N)_2SnCl_6$ (**A**) on (001). The octahedra represent $SnCl_6^{2-}$, the tetrahedra $n\text{-}Pr_4N^+$. The anion and the cations in positions listed in Table 4 are marked A.

drogen bonding at this distance is possible, but it is unlikely that both H_2O hydrogens could be simultaneously engaged in hydrogen bonds unless dynamically. The large U_{iso}[O(2)], 0.113 Å^2 compared to 0.059 Å^2 for O(1), would support the latter, though it might be imprudent to place too much weight on the refinement of the water oxygen in half occupancy. It should be noted that although the placement of the oxygen atoms in the anion columns of Fig. 4 requires full order within a column, orientational disorder *between* columns will satisfy the oxygen disorder assumed in ref. 56.

If participation of the hydroxyl oxygen of the Ph_4As^+ salt in a hydrogen bond is improbable, it is no less so in the anhydrous **B**. The only possible H-bond acceptor for the OH group is Cl(2Ac), at 3.20 Å and a Te—O—Cl(2Ac) angle of 142°. This geometry would result at best in a weak O—H···Cl bond.

From this examination of the four structures it would seem that the discrepancy in the reported Te—O bond lengths *could* be explained by the presence or the absence of significant hydrogen bonding that involves the OH group of the anion.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

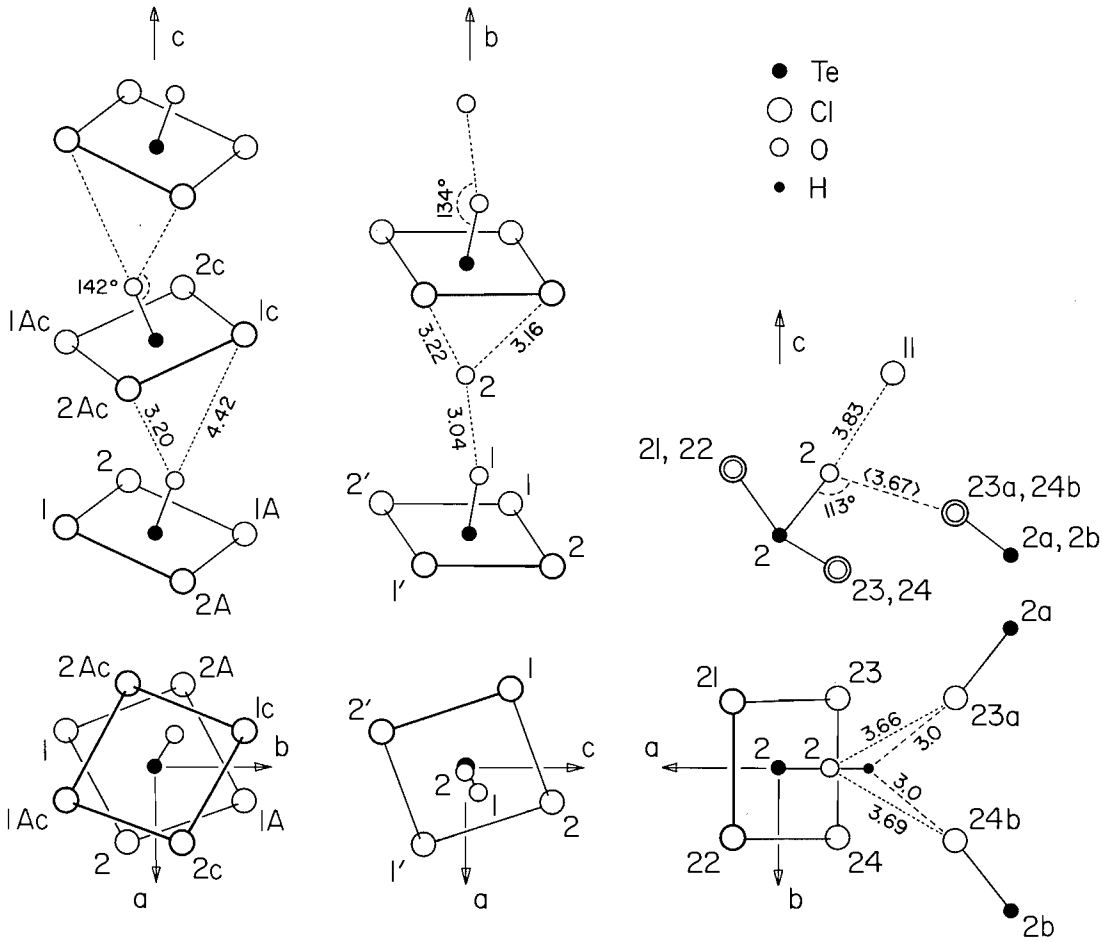

FIG. 4. Hydrogen bonding of the $TeCl_4(OH)^-$ anion in **B** (ordered structure; left), $(Ph_4As)[TeCl_4(OH)] \cdot H_2O$ (disordered oxygens; centre), and $K[TeCl_4(OH)] \cdot \frac{1}{2}H_2O$ (right). Double circles, atoms overlapping in projection; dashed lines, putative hydrogen bonds. Dotted lines indicate distances between atoms.

Still, a Te—O bond length of 1.74 Å seems rather short and the possibility that it may be, to some extent at least, an artefact of refinement cannot be discounted. Clearly, further accumulation of structural information is required. As for **B**, on balance the ordered structure, as refined in *Cc*, appears marginally preferable to the disordered structure as described in *C*2/*c*.

*(n-$Pr_4N)_2[Te_2Cl_{10}]$ (nominal) (**C**)*

The ion packing in **C** is of the *anti*-CdI_2 type (cf. Sect. III). The results of refinement on the assumption that all the Te ligands are Cl atoms are presented in Tables 2, 6, and 8. As pointed out in Sect. I, the short Te—Cl(1) (= "Te—Cl_a") bond length and the large U_{ij} of the Cl atoms were puzzling even for a structure containing the nonrigid *n*-Pr_4N^+ cations until Krebs's reinterpretation (personal communication) of the composition of the anion **Cj**, which had been reported previously (6, 7) as $Te_2Cl_{10}^{2-}$ but which in reality was partially hydrolyzed to $Te_2Cl_8(Cl, OH)_2^{2-}$. Comparison of the Te—Cl bond lengths with those in the **Cj** dimers on the one hand and those in the authentic $Te_2Cl_{10}^{2-}$ dimers **Ch** and **Ci** on the other revealed that only one bond length in **C** was shorter than expected for a Te—Cl bond, namely the presumed Te—Cl(1). It was about the same as d(Te—L_a) in **Cj2** but not nearly as short as d(Te—L_a) in **Cj1**. From this it was assumed that only Cl_a had undergone replacement by OH and then only in a minority of the dimers. The attempts made to refine the occupancy factor at the mixed-ligand site *a* in order to resolve the Cl_a and O_a positions are described in Sect. IV. However, these attempts cannot be regarded as completely successful. The seemingly large U_{ij} values in the "chlorines only" refinement can be accounted for on a RBM model (cf. Sect. III), but since the mixed ligands could not be cleanly resolved, the position of the d_a,d_c' point *above* the regression line in Fig. 2 remains unexplained. Additional elaboration of the mixed-ligands model having been deemed unpromising, further attempts to resolve the site occupancy at *a* were abandoned.

Since the partial hydrolysis made the **C** dimer unsuitable for a discussion of the Te—Cl bond lengths in $Te_2Cl_{10}^{2-}$, in the following we rely on the authentic $Te_2Cl_{10}^{2-}$ dimers **Ch** and **Ci**. A closer look at their geometry shows that in both these anions the Te atom is only 0.10 Å from the centroid of the $Cl_{a,b,c,c',d,e}$ octahedron. In **Ch** the Te atom is only 0.033 Å below the best plane through $Cl_{b,c,d,e}$, i.e., coplanar with these atoms (σ = 0.044 Å; Cl_a is 2.30 Å from this best plane).[15]

It is curious that partial replacement of Cl_a by OH should cause a 10% increase in the Te···Te' distance in $Te_2Cl_{10}^{2-}$ and have a significant effect on the shape of the unit cell

[15]For projections of the $Te_2Cl_{10}^{2-}$ dimer **Ch** see Fig. 12.

26 $(PCl_4)_2[Ti_2Cl_{10}]$ (49)
27 $(S_4N_5)_2[Ti_2Cl_{10}]$ (50)
28 $(S_4N_4Cl)_2[Zr_2Cl_{10}]$, anion 1 (51)
29 Ditto, anion 2
30 $(Ph_4P)_2[Mo_2Cl_{10}]$ (52)
31 $(n\text{-}Bu_4N)_2[Os_2Cl_{10}]$ (53)
32 $(n\text{-}Bu_4N)_2[Os_2Br_{10}]$ (54)
33 Nb_2Br_{10} in $\alpha\text{-}NbBr_5$, dimer symmetry C_s (55)

(cf. Sect. I). In our attempts to establish the site occupancy at *a* the Te···Te′ distance was noted to increase slightly with the degree of substitution of Cl by OH, but since the "chlorines only" refinement already gave a Te···Te′ of 4.42 Å, manipulating the Cl/OH ratio further seemed pointless.

[a]The number after the oblique stroke represents the number n of dimers in the sample. The figure in parentheses is the dispersion (standard deviation) σ of the n individual means.

[b]In the **Cf** monomer half, 1.934(32) Å, the same as in $KTeF_5$ (27). The mean for TeF_5^- in $KTeF_5$, NH_4TeF_5 (two anions) (28), $RbTeF_5$ (two anions) (78), $NaTeF_5$ (77), and $K_2[TeF_5]NO_3$ (29) is 1.943(51) Å (1.941(48) Å with the **Cf** monomer included). Overall means for Te—F_{ax} and Te—F_{eq}, 1.880(15) and 1.964(33) Å, respectively.

[c]In $(NH_4)_2[SbF_5]$, 2.043(64) Å; Sb—F_{ax}, 1.916(4), Sb—F_{eq}, 2.075(3) Å (30).

[d]Mean for $SbCl_5^{2-}$ in **10** and $(NH_4)_2SbCl_5$ (31), 2.628(40) Å; mean in **10** if formulated as containing a pseudo dimer $Sb_2Cl_{10}^{4-}$, 2.80(50) Å. Overall means for Sb—Cl_{ax} and Sb—Cl_{eq}, 2.37(2) and 2.64(9) Å, respectively.

[e]In the $SeOCl_3^-$ monomer (**De**), 2.380 Å.

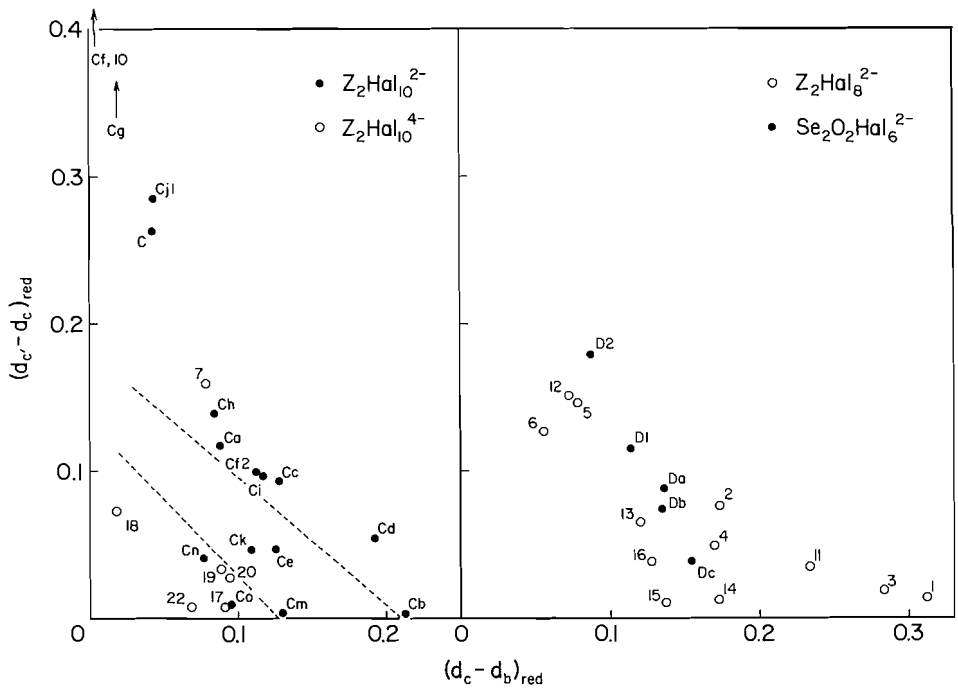

FIG. 5. Variation of the bridge asymmetry parameter $(d_c' - d_c)_{red}$ with $(d_c - d_b)_{red}$ in dimers. For code see Tables 2 and 9.

*(n-$Pr_4N)_2[Se_2O_2Cl_6]$ (**D**)*

The structure consists of *n*-Pr_4N^+ cations 1 and 2 and centrosymmetric $Se_2O_2Cl_6^{2-}$ anion dimers **D1** and **D2** arranged in a distorted *anti*-CdI_2-type packing, with the layers ∥(010). This is the same type of packing as is found, with varying degree of distortion, in the structures containing the **Da**, **Db**, and **Dc** dimers. Both cations have fully extended conformations.

The Cl atoms in the dimers are nearly coplanar, the mean deviation from the best plane p through the chlorines being

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

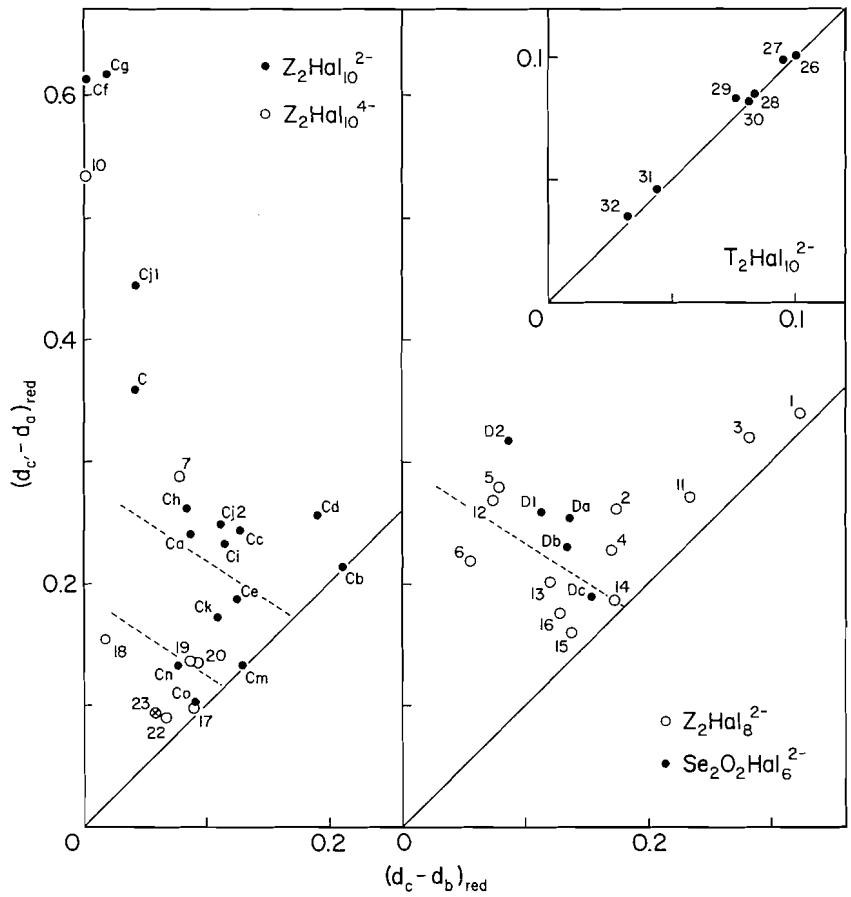

FIG. 6. Variation of $(d_c' - d_a)_{red}$ with $(d_c - d_b)_{red}$ in dimers. For code see Tables 2 and 9. Note the expanded scale in the inset.

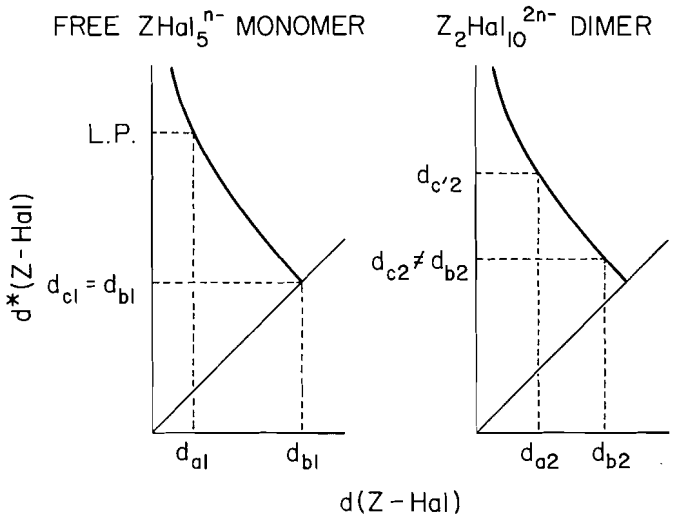

FIG. 7. Effect of dimerization on the Z—Hal bond lengths in $Z_2Hal_{10}^{2n-}$ dimers (cf. the *trans* effect plots of Fig. 2). d_{a1}, d_{a2}, Z—Hal_{ax}; d_{b1}, d_{b2}, d_{c1}, d_{c2}, Z—Hal_{eq}; d_{c2}', Z—Hal_{bridge}.

0.041 Å in **D1** and 0.014 Å in **D2**. The oxygen atom is 2.00 Å above p in **D1** and 1.91 Å in **D2**. The Se atom is on the same side of p as the respective oxygen atom (i.e., inside the distorted OCl_4 square pyramid), at 0.41 Å from p in **D1** and 0.35 Å in **D2**. This compares with 0.41 Å in **Da**, 0.31 Å in **Db**, and 0.39 Å in **Dc**. The angle formed by the Se–O vector with p is 88.6° in **D1** and 86.9° in **D2**. Interestingly, the perpendicular distances of O and Se from p and the p (Se—O) angles are not very different from those relative to the Cl_a—Cl_b—Cl_c plane in the $SeOCl_3^-$ monomer **De**: O–p, 1.90 Å; Se–p, 0.31 Å; p|(Se–O), 83.0°.

The d_a and d_b = d(Se—O) bond lengths in $Se_2O_2Cl_6^{2-}$, averaged over **D1**, **D2**, **Da**, and **Db**, are 2.266(11) and 1.588(10) Å, respectively,[16] and thus quite similar to the corresponding bond lengths in the $SeOCl_3^-$ monomer **De** and in the $[SeOCl_2Cl_{2/2}]_\infty^-$ chains in **Df**. However, the $\langle d_b \rangle$ and $\langle d_c \rangle$ for the dimers are significantly different from d_b and d_c in **De** and **Df**, although the mean $\langle d_a, d_b, d_c \rangle$ in the dimers, 2.43(17) Å, is statistically the same as the d(Se—Cl) mean in the monomer, 2.38(1) Å. These differences are consistent with the operation of TE in Se(IV)—Cl bonds (22).

The means of the O—Se—Cl angles over **D1**, **D2**, **Da**, and **Db** are 102.4(9)° for Cl_a, 98.6(17)° for Cl_b, 95.7(27)° for Cl_c, and 99.2(22)° for Cl_c'. Here again the angle involving Cl_a is the largest and compares to the corresponding (also largest) angles in **De** and **Df**, 105.1(1)° and 104.0(3)°, respectively.

III. Observations on dimers

Earlier on[3] the question was raised, is the formation of $Z_2Hal_{10}^{2n-}$ and $Se_2O_2Hal_6^{2-}$ dimers the result of exigencies of crystal packing, i.e., accidents of crystallization, or is there a genuine tendency of the ZL_5^- or ZL_4^- monomers (which

[16]The d(Se—O) average over **D1**, **D2**, **Da**, **Db**, **Dc**, **De**, and **Df** is 1.590(9) Å, i.e., indistinguishable from the above value.

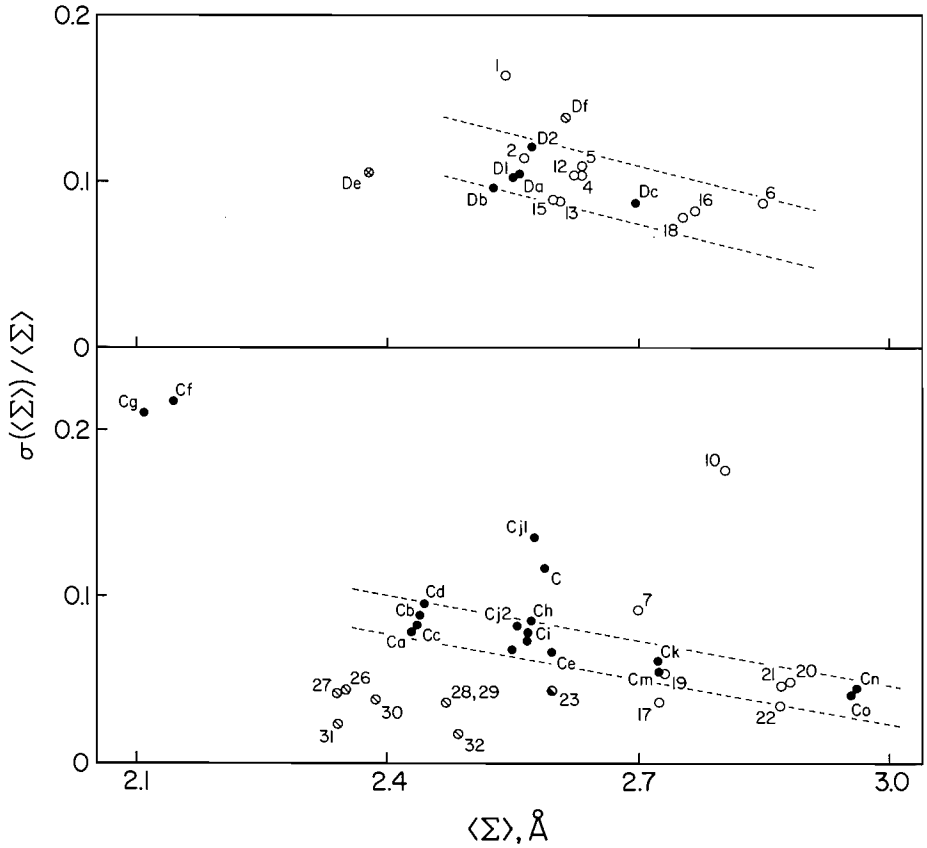

FIG. 8. Variation of the relative standard deviation $\sigma(\langle\Sigma\rangle)/\langle\Sigma\rangle$ with the mean $\langle\Sigma\rangle$ of all the Z—Hal bond lengths in a dimer: Z_2Hal_{10} and T_2Hal_{10} skeletons (bottom); Z_2Hal_8 and $Se_2O_2Hal_6$ skeletons (top). For code see Tables 2 and 9. The widths of the dashed-line bands are 2σ of the respective linear regression (see text).

For personal use only.

may not be known as discrete entities) to associate for reasons that are explicitly chemical? In an attempt to discover what evidence bearing on this question can be obtained from the available crystallographic[17] information, we shall examine (*a*) the asymmetry of the double bridge and (*b*) its rigidity, in so far as the latter is ascertainable from the parameters of thermal motion. In doing so we shall consider not only Group VI dimers but also the more abundant Group V $Z_2Hal_{10}^{4-}$ and $Z_2Hal_8^{2-}$ anion dimers (Table 9).

Bridge asymmetry

As mentioned in Sect. I, the decrease in the asymmetry of the bridge from $Se_2O_2Cl_6^{2-}$ to $Se_2O_2Br_6^{2-}$ has been pointed out by Krebs (10), who also notes (2, 18) that in **Cf** the centrosymmetric $TeF_5^-\cdots TeF_5^-$ pair may be regarded as a pseudo dimer $Te_2F_{10}^{2-}$ with the $Te\cdots F_c'$ distance about 60% longer than $Te—F_c$. This appears to suggest that the bridge asymmetry is a manifestation of a systematic effect that depends on the nature of the Z,Hal combination. It will be convenient to denote the mean of all the Z—Hal bond lengths in a dimer by $\langle\Sigma\rangle$ (Table 10). The asymmetry of the bridge can then be measured by the difference $d_c' - d_c$ or by the corresponding normalized difference $(d_c' - d_c)/\langle\Sigma\rangle = (d_c' - d_c)_{red}$.

The dependence of the bridge asymmetry on the Z,Hal combination emerges when $(d_c' - d_c)_{red}$ is plotted against $(d_c - d_b)_{red}$ (Fig. 5). Keeping in mind the various limitations of the available data set, one is bound to acknowledge that this plot for $Z_2Hal_{10}^{2n-}$ successfully maps the dimers, at first sight according to the type of ligand but more probably according to the mean Z—Hal bond length (see Table 10 and below).[18] The latter view is supported by the segregation of the Se and Te dimers in three clearly defined regions; the points for the Bi dimers appear to be out of place when only the size of the *ligand* is considered.

Since, in normalizing $d_c' - d_c$ and $d_c - d_b$ by $\langle\Sigma\rangle$, account has already been taken of the size disparity of the ligands, it is clear that the segregation of the dimers in Fig. 5 must reflect the effect of dimerization on the strength of the $Z—Hal_{eq}$ bonds, via TE in the $Hal_b—Z—Hal_c$ grouping. Stated differently, the variation in the bridge asymmetry cannot be considered in isolation but must be related to the dimer geometry as a whole and, more particularly, to the normalized magnitudes of TE in the bridge plane.

The interrelation of the bond length adjustments in $Z_2Hal_{10}^{2-}$ (Z = Se, Te) dimers is rendered even more impressive by comparing, instead of the bridge asymmetry, the normalized magnitudes of TE in the axial bond pairs, $(d_c' - d_a)_{red}$, and the equatorial bond pairs, $(d_c - d_b)_{red}$ (Fig. 6). Here again the dimers are segregated in a pattern similar to that in Fig. 5. However, whereas the $(d_c - d_b)_{red}$ and $(d_c' - d_c)_{red}$ values in a dimer are comparable in magnitude,

[17]For ambiguity of evidence from vibrational spectra see ref. 40.

[18]The mean $\langle d_d, d_e\rangle$ of the Z—Hal bond lengths perpendicular to the bridge plane would be an acceptable experimental variable in the present discussion.

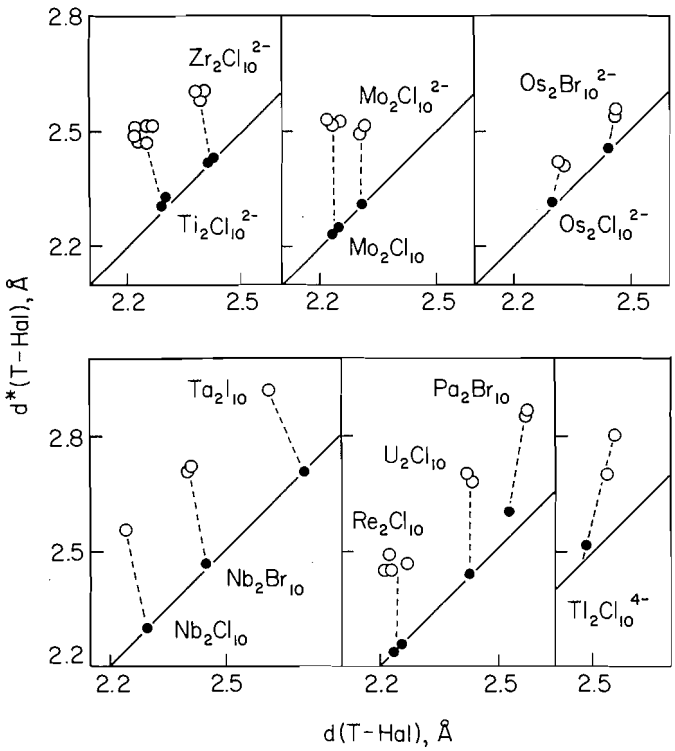

FIG. 9. Variation of d^* with d in $T_2Hal_{10}^{2-}$, T_2Hal_{10}, and $Tl_2Cl_{10}^{4-}$ dimers. Full circles, *trans* bonds perpendicular to bridge plane, T—Hal_d and T—Hal_e; open circles, T—Hal bonds in bridge plane. $T_2Hal_{10}^{2-}$: TiCl, **26**, **27**; ZrCl, **28**, **29**; MoCl, **30**; OsCl, **31**; OsBr, **32**. T_2Hal_{10}: $MoCl_5$ (63), $NbCl_5$ (64), TaI_5 (65); $ReCl_5$ (66), UCl_5 (67), β-$PaBr_5$ (68), α-$NbBr_5$, **33**. $Tl_2Cl_{10}^{4-}$, **23**.

the $(d_c' - d_a)_{red}$ value is significantly larger than the associated $(d_c - d_b)_{red}$ value, the difference decreasing from Cl to I. This indicates that the bridge asymmetry is ultimately determined by the difference in the Z—Hal_{ax} and Z—Hal_{eq} bond lengths in the free monomer limit and by the functional form of TE for Z,Hal (Fig. 7). It is therefore not surprising to find the points for the **C** and **Cj1** dimers in the partially hydrolyzed compounds away from the other $Z_2Cl_{10}^{2-}$ dimers in Fig. 6: replacement of Cl_a by OH in the two dimers further shortens the Te—L_a bond (without significantly affecting the Te—Cl_{eq} bonds) and thus directly affects the $(d_c' - d_a)$ value.

Although only one of the five $Se_2O_2Hal_6^{2-}$ dimers in Table 2 is a bromide, Figs. 5 and 6 seem to suggest that similar trends are followed as for the $Z_2Hal_{10}^{2-}$ dimers.

For the Group V $Z_2Hal_8^{2-}$ dimers the situation is less clear-cut. In some of them there is, in the crystal, covalent or hydrogen-bonding interaction between the bridging halogens and external atoms (**1**?, **3**, **11**).[19] However, even if these contentious cases are disregarded, the segregation is not nearly as well defined as for the Se and Te dimers. It is possible that the geometry of the Z_2Hal_8 skeletons is less rigid than that of the Z_2Hal_{10} (and perhaps even the $Se_2O_2Hal_6$) skeletons because of the incomplete coordination sphere of Z and is thus more susceptible to external influences in the crystal, which would account for the less regular trends.[20]

The desirability of considering the geometry of the whole dimer instead of focusing on the bridge asymmetry alone is demonstrated in yet another way by the variation of the standard deivation σ of ⟨Σ⟩ expressed as a fraction of ⟨Σ⟩. This fraction decreases as ⟨Σ⟩ increases, and although the variation is not strong, the trend is unmistakable (Fig. 8).[21] The distribution of the Z,Hal groups in this plot is well resolved and permits a comparison with $Tl_2Cl_{10}^{4-}$ (**23**) and the transition-element $T_2Hal_{10}^{2-}$ (**26–32**) dimers, none of which contains lone electron pairs on the nonhalogen atom.

Characteristically, the $T_2Hal_{10}^{2-}$ dimers show practically no bridge asymmetry (Fig. 9). Their $\sigma(\langle\Sigma\rangle)/\langle\Sigma\rangle$ values are less than half those encountered with $Z_2Hal_{10}^{2n-}$ dimers of comparable ⟨Σ⟩ (Fig. 8), i.e., the difference between the bridge and terminal bond lengths is small, ≤0.25 Å. The difference between $d_{terminal}$ for bonds in the bridge plane and those perpendicular to the bridge plane is well within 0.1 Å; the difference between T—Hal_d and T—Hal_e is very small, ~0.07 Å or less.

It is interesting that the d,d^* relations for the $T_2Hal_{10}^{2-}$ dimers in Fig. 9 are very similar to those in the neutral T_2Hal_{10} dimers (compare $Mo_2Cl_{10}^{2-}$ and Mo_2Cl_{10}), the more so as the molecular geometry of the neutral dimers results from the filling, by T atoms, of interstices in close-packed arrays of the halogen atoms in $THal_5$ crystals (cf. refs. 65 and 69), whereas the corresponding $T_2Hal_{10}^{2-}$ dimers in **26–32** are discrete anions in ionic structures containing composite univalent counter cations. The question as to whether the existence of a lone electron pair on the central atom is essential for a significant bridge asymmetry to be observed will be touched upon in ref. 22.

While the above account does not explain details of the geometry of the dimers in fundamental terms, it does offer a qualitative insight into the factors involved and sets forth criteria which a detailed model will have to satisfy. Clearly, the existing data set no more than sketches out the distribution of dimers in Figs. 5, 6, and 8. Although it is probable that subtler trends exist, e.g., those differentiating Group VI from Group V and $Se_2O_2Hal_6^{2-}$ dimers, it would be difficult at this stage to extract them with any confidence from the accidental causes of the observed spread (packing, hydrogen-bonding and interion effects, inadequacies of crystal-structure determinations).

Thermal motion: doing what comes naturally

If it is assumed that a centrosymmetric $Z_2Hal_{10}^{2n-}$ dimer consists of two $ZHal_5^-$ monomer halves held together by a $Z\cdots Hal_c'$,$Z'\cdots Hal_c$ interaction of a strength ranging (as measured by the $d_c' - d_c$ difference) from very weak to comparable to that in the Z—Hal_c bond, it is not unreasonable to suppose that the strength of this interaction will be reflected in the thermal motion of the dimer. More specifically, each monomer half by itself would be expected to approximate to RBM behaviour more closely than the dimer as a whole, if indeed the RBM model applies. The closeness of approximation to RBM behaviour is measured

[19]This is also the case for the $Z_2Hal_{10}^{2n-}$ dimers **8** and **9** and possibly also **7** and **17**.

[20]Results of TLS analysis (see below) are inconclusive on this point.

[21]Linear regression on the 21 $Z_2Hal_{10}^{2n-}$ points in Fig. 8 (excluding **Cf**, **Cg**, **10**, and the T dimers) gave $r^2 = 0.67$, $\sigma = 0.010$, $\sigma(\langle\Sigma\rangle)/\langle\Sigma\rangle = 0.317 - 0.0942\langle\Sigma\rangle$.

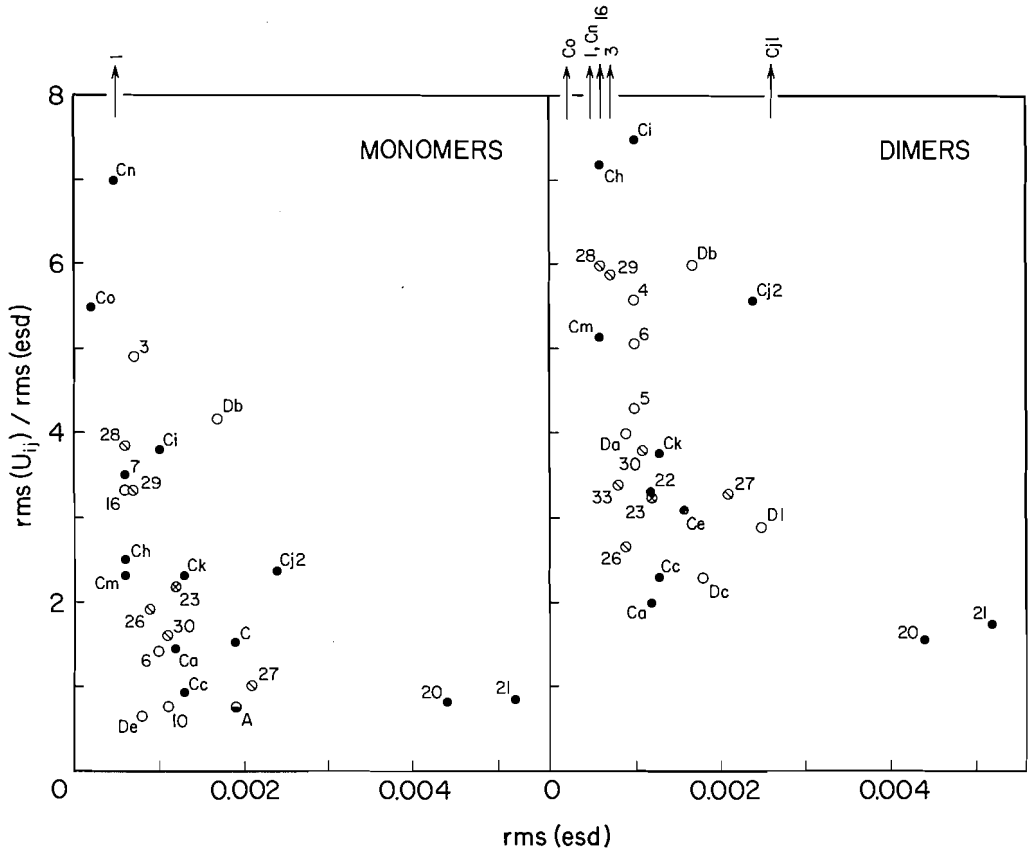

FIG. 10. Applicability of the RBM model to the thermal motion of $Z_2Hal_{10}^{2n-}$, $Z_2Hal_8^{2-}$, and $Se_2O_2Hal_6^{2-}$ anions considered as dimers (right) and as the respective monomer halves (left). For definitions of rms(U_{ij}) and rms(esd) (Å^2) see text. For code see Tables 2 and 9.

by the magnitude of $R(U_{ij})$ or rms(U_{ij}) as obtained from the TLS analysis, and by comparing rms(U_{ij}) = $[(1/n)\Sigma(\Delta U_{ij})^2]^{1/2}$ with the rms[esd(U_{ij})] = $[(1/n)\Sigma[\text{esd}(U_{ij})^2]^{1/2}$ (= rms(esd) for short) from the crystal-structure refinement. The decrease in rigidity of the binuclear unit relative to the monomer can then be estimated from the $\text{rms}_{2/1}$ = $\text{rms}(U_{ij})_{\text{dimer}}/\text{rms}(U_{ij})_{\text{monomer}}$ ratio.[22] The magnitude of this ratio can in turn be examined for dependence on the bridge asymmetry $d_c' - d_c$ or $(d_c' - d_c)_{\text{red}}$.

It must be emphasized that utilization of the results of TLS analysis can be fraught with uncertainties, and considerable caution must be exercised if the interpretation is to have physical meaning. The TLS figures of merit for a particular composite anion may vary widely from one structure to another, both because of real differences in the degree of applicability of the RBM model and because of the uneven quality of the crystal-structure determinations. In the present discussion we shall consider the $SnCl_6^{2-}$ ion in **A** and the undoubted $SeOCl_3^-$ monomer **De** (Fig. 10) as anions for which the TLS criteria of RBM are reasonably well satisfied and which may therefore be regarded as standards for judging the rigidity of the other anions. In neither case is there effective H-bonding interaction between the anion and the counter cation, and the single positive charge on the counter cation is in both crystals so diffuse that directional Coulombic interactions are unlikely to come into play. The $R(U_{ij})$ and rms(U_{ij}) values for both anions are small and the U_{ij} values are accounted for on the RBM model collectively within the experimental rms(esd). Similarly small figures of merit for the $ZHal_5^-$ monomers will therefore be taken to indicate that the RBM model adequately describes the thermal motion of the monomer as an independent inertial unit.

In the following the U_{ij} values of most of the reported $Z_2Hal_{10}^{2n-}$ as well as $Z_2Hal_8^{2-}$ and $Se_2O_2Hal_6^{2-}$ anions will have been subjected to scrutiny, some 35 species in all. The results are presented in Table J (deposited, see Experimental) and Figs. 10 and 11.[23]

[22] $R(U_{ij})$ is less suitable for this purpose than rms(U_{ij}), as the contribution to $R(U_{ij})$ of numerically small U_{ij} ($i \neq j$) values suffering from a large percentage error is out of all proportion to their importance and may create a misleading impression of how well the thermal motion approximates to RBM behaviour.

[23] In a number of cases execution of the standard TLS program (70) ended up in physically unreasonable results (not shown in Table J and Fig. 10), with negative values for the squares of one of the three mean librational amplitudes L about the principal axes of libration, in some instances for the monomer, in others for the dimer, and in yet others for both the monomer and the dimer. The reason for this behaviour appears to be a weak ill-conditioning of the U_{ij} data set. In general, a single minor adjustment of the tolerance criteria (70) will produce a set of positive L values, with only a small increase in rms(U_{ij}). The $\text{rms}_{2/1}$ ratios obtained in this way may, *faute de mieux*, still be considered reasonable indicators of the relative rigidity of the dimers, albeit inferior to $\text{rms}_{2/1}$ obtained from properly behaved U_{ij} sets and within the limitations discussed in the text. Such $\text{rms}_{2/1}$ values are indicated in Fig. 11 by underlining.

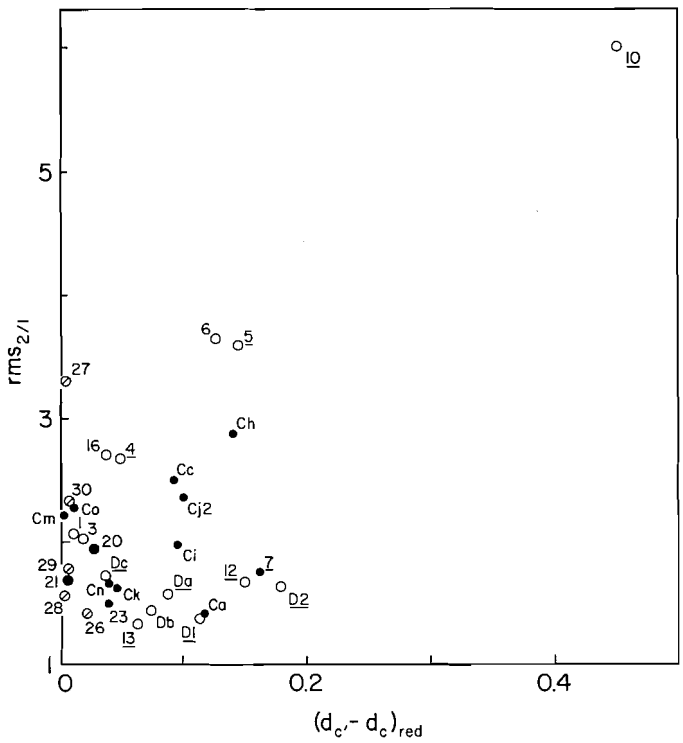

FIG. 11. Variation of the RBM "rigidity indicator" $rms_{2/1}$ = $rms(U_{ij})_{dimer}/rms(U_{ij})_{monomer}$ with the bridge asymmetry $(d_c' - d_c)_{red}$ in dimers. For code see Tables 2 and 9; for the underlined code numbers see text.

The rms(esd) values are, with the exception of **20** and **21**, all smaller than ~0.0025 Å^2, indicating that the quality of the U_{ij} data is generally acceptable. However, the $rms(U_{ij})$/rms(esd) ratio is greater than unity for all but a few of the species examined. This means that the RBM model does not describe the thermal motion of even the monomers adequately, the mismatch being the greater the larger the value of the ratio. This finding thus immediately calls for a scrutiny of the assumption that RBM is an appropriate model on which to correct bond lengths for the effects of thermal motion (see below).

The extent of conformity to the RBM model notwithstanding, the $rms(U_{ij})$/rms(esd) ratio for a dimer is always larger than that for the corresponding monomer, i.e., the rigidity of the dimer is always inferior to that of the monomer. Indeed, none of the dimers with rms(esd) $\leq$ 0.0025 Å^2 in Fig. 10 has an $rms(U_{ij})$/rms(esd) value smaller than 2. There are no clearly discernible trends in Fig. 10, not even between the 6-coordinate and the 5-coordinate Z species: statistical tests show that the probability of the $rms(U_{ij})$/rms(esd) means for the ZL_6 and the ZL_5 coordination classes to come from the same population is high. The incompleteness of the coordination sphere of Z in the ZL_5-type monomers *or* dimers does not therefore appear to be a significant rigidity-determining factor, at least in the present sample.

Since the rms(esd) for a centrosymmetric dimer is the same as for each of the monomer halves, $[rms(U_{ij})/rms(esd)]_{dimer}/[rms(U_{ij})/rms(esd)]_{monomer} = rms_{2/1}$. On plotting $rms_{2/1}$, which ranges from ~1.4 to ~3.6, against the bridge asymmetry parameter $(d_c' - d_c)_{red}$ a considerable scatter results (Fig. 11). The ratio can be claimed to increase with $(d_c' - d_c)_{red}$ if the TLS result for the clearly crystallographic dimer $Sb_2Cl_{10}^{4-}$ dimer in **10** is accepted as legitimizing the direction of the presumed trend.

Obviously, additional experimental data for dimers must be obtained before a statistically valid trend can be claimed. This conclusion is somewhat disappointing vis-à-vis the initial expectation that $rms_{2/1}$ as a measure of decrease of the rigidity of the dimer relative to the monomer varies with the bridge asymmetry, but if the existence of such a trend *is* substantiated, an augmented Fig. 11 would be a useful device for clarifying the relationship between chemical and crystallographic dimers.

Bond-length corrections for thermal motion

From the above it follows that the RBM model describes the motions of the anions only to the extent indicated by $rms(U_{ij})$. The results of a TLS analysis cannot be used as a basis of bond-length corrections unless $rms(U_{ij})$ is small, and where the latter is not stated, the meaning of the corrections is uncertain. However, where the observed U_{ij} *are* satisfactorily explained, collectively, on the assumption of RBM but significantly better so for the separate monomer halves than for the dimer, corrections to bond lengths and angles should be made on the basis of the monomer RBM rather than that of the dimer. This in practice may not make appreciable difference measured against the accuracy of the crystal-structure determination, but *in principle* the distinction of course matters, for the corrections in the two cases arise from RBM's about entirely different centroids and axes (cf. Figs. 12 and 13).

Some idea of the importance of the differences in the corrections to bond lengths calculated on the assumption of RBM in the monomer and the dimer, respectively, can be gained from Table K (deposited, see Experimental). The differences are small, but the corrections to the individual bond lengths in general follow a different pattern as to magnitude for the monomer and the dimer. These findings raise questions about the practical meaning of the corrected bond lengths when these are reported without indication of the comparative figures of merit and physical significance of the underlying TLS analysis.

Chemical or crystallographic dimers?

Where the d_c' distance in Groups VI and V dimers is long but explained without contradiction as a consistent response to TE, it qualifies as corresponding to a weak bonding interaction and the dimers qualify as "chemical" dimers. At the other extreme, a crystal structure may contain widely separated, clearly identifiable discrete monomers in positions and mutual orientations that give no indication of a tendency to dimerize, e.g., $Na^+[TeF_5]^-$ (see below).

We shall now turn to intermediate situations, i.e., to crystal structures in which $ZHal_5^{n-}$ or related anions reported as monomeric occur in centrosymmetric pairs and in mutual orientations such that the two monomers would form an undoubted μ_2-dimer if the distance between them were decreased. Examples of such *pro*-dimer pairs are $TeF_5^- \cdots TeF_5^-$ in **Cf** and **Cg** and the $SbCl_5^{2-} \cdots SbCl_5^{2-}$ pair in **10**; the description of the anions in **Cf** in ref. 2 as "quasi-monomeric pseudo-octahedral anions with almost negligible bonding interaction within the pseudo dimer" testifies to the ambiguity with which such situations are approached.

The centrosymmetric $ZHal_4^{n-}$ pairs in **Cf**, **Cg**, and **10** may be regarded formally as dimers in which d_c' is ~65% longer than the mean of the other five Z—Hal bond lengths in the

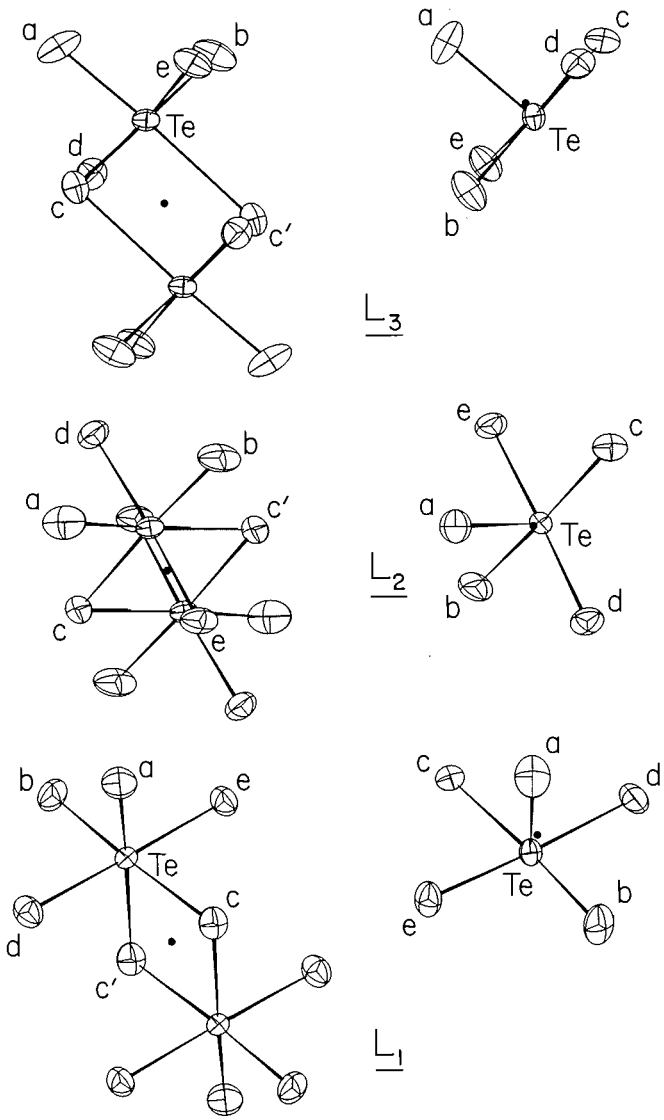

FIG. 12. Librational motions of the $Te_2Cl_{10}^{2-}$ (**Ch**) ion considered as a dimer (left) and as two monomer halves (right). Projection down principal axes of libration, in the decreasing order of the mean librational amplitude ($L_3 > L_2 > L_1$). The centroids of the motions are indicated by black dots.

Cf and **Cg** monomer halves and 50% longer in **10**. The positions of the points for **Cf** and **Cg** (regarded as dimers) in Figs. 5, 6, and 8 are extreme relative to the $Te_2Hal_{10}^{2-}$ (Hal $\neq$ F) dimers. It could conceivably be argued that a nonlinear relationship may exist in these plots that would reconcile the positions of these two points with the rest of the dimers, but such an argument would be difficult to sustain from these two isolated cases alone, no other $Z_2F_{10}^{2n-}$ dimer or pseudo dimer structures being known at present.

In **10** the orientation of the two $SbCl_5^{2-}$ ions is such as to suggest the existence of a highly asymmetric double bridge, but the Sb···Cl$_c$′ separation of 3.88 Å is not consistent with the presence of even a weak Sb···Cl bond. In addition, the very small rms(U_{ij}) and rms(U_{ij})/rms(esd) values for the monomer point to the autonomous character of the $SbCl_5^{2-}$ unit.

In none of the **Cf**, **Cg**, and **10** pairs can d_c' be related to the respective d_a by TE. In **10** this is obvious from the shape of the TE(Sb—Cl) line (22); the d_c'(Sb—Cl) expected for d_a (Sb—Cl) = 2.39 Å would be in the vicinity of 3.2 Å, i.e., ~0.7 Å below the observed d_c'. In **Cf** and **Cg** the d_c' to be expected from TE(Te—F) cannot be assessed, for the curvature of the TE line is very poorly defined by the data currently available. Such indications as there are seem compatible with the conclusion that the observed d_c'(Te—F) is longer than would be expected from TE.

From these observations one could conclude, tentatively, that the centrosymmetric $ZHal_5^{n-}$ pairs found in **Cf**, **Cg**, and **10** are "crystallographic" rather than "chemical" dimers, i.e., $ZHal_5^{n-}$ pairs that owe their existence to external factors and not to a strong intrinsic tendency of the $ZHal_5^{n-}$ units to dimerize. If such tendency exists, it is not sufficiently strong to overcome other forces implicit in the formation of the crystal from solution.

It is significant in this context that the compounds in Tables 2 and 9 that are of the [cation$^+$]$_2$[dimer^{2-}] type and in which the cation is composite but not highly asymmetric crystallize, without exception and regardless of the specific chemistry of the dimer (e.g., $Se_2Hal_{10}^{2-}$, $Se_2O_2Hal_6^{2-}$, $As_2Br_8^{2-}$, $Mo_2Cl_{10}^{2-}$, $Os_2Cl_{10}^{2-}$), in one of the three space groups $P\bar{1}$, $P2_1/c$ ($\equiv P2_1/a$, $P2_1/n$), or $Pbca$; $P\bar{1} \subset P2_1/c \subset Pbca$ ($\supset Pa3$). In *molecular* crystals these space groups (plus $C2/c$) describe the symmetries of closest-packed arrangements of molecules of C_i symmetry, but the $P\bar{1}$ and $P2_1/c$ symmetries can also be realized by close packing of completely asymmetric molecules (71). The close-packed layers are found in one, two, or three systems of planes, depending on the particular space group. The [cation$^+$]$_2$-[dimer^{2-}] crystals of course are not molecular, but the dimers, because of their size relative to the cations,[24] dominate the packing, with the result that the overall structure consists of a close packing of the dimers with the cations interstitial to it. The dimer centres form an oblique layer mesh with a coordination number 6 and a minimum plane-group symmetry $p2$; the Z···Z′ vectors are at an arbitrary tilt to the axial directions of the layer lattice. The cations are situated either between or in the close-packed dimer layers, depending on the cation shape and size and on the number of ligands in the dimer, the latter two factors determining the Z···Z′ tilt. The tendency of the dimers to form such layers explains the preponderance of the *anti*-CdI_2-type structures among these compounds.

When the cation is small, it will not fill the space between the dimers properly. This will result in an inefficient utilization of space. Furthermore, in contrast to composite cations, in which the distribution of ionic charge is diffuse, in a simple univalent cation the full charge is spatially much more concentrated and thus likely to lead to strong local interactions with atoms of the dimers.[25] If the monomer anions were to dimerize, the distribution of ionic charge in such a [cation$^+$]$_2$[dimer^{2-}] crystal would compete with the energetically more favourable as well as better space-filling ar-

[24]The nuclear skeleton of a $Z_2Hal_{10}^{2-}$ dimer may be approximated for the present purpose by an elliptical cylinder about 8 Å long and 4–6 Å in diameter.

[25]This is also the case with composite cations capable of hydrogen bonding, e.g., NH_4^+ and the alkylammonium cations.

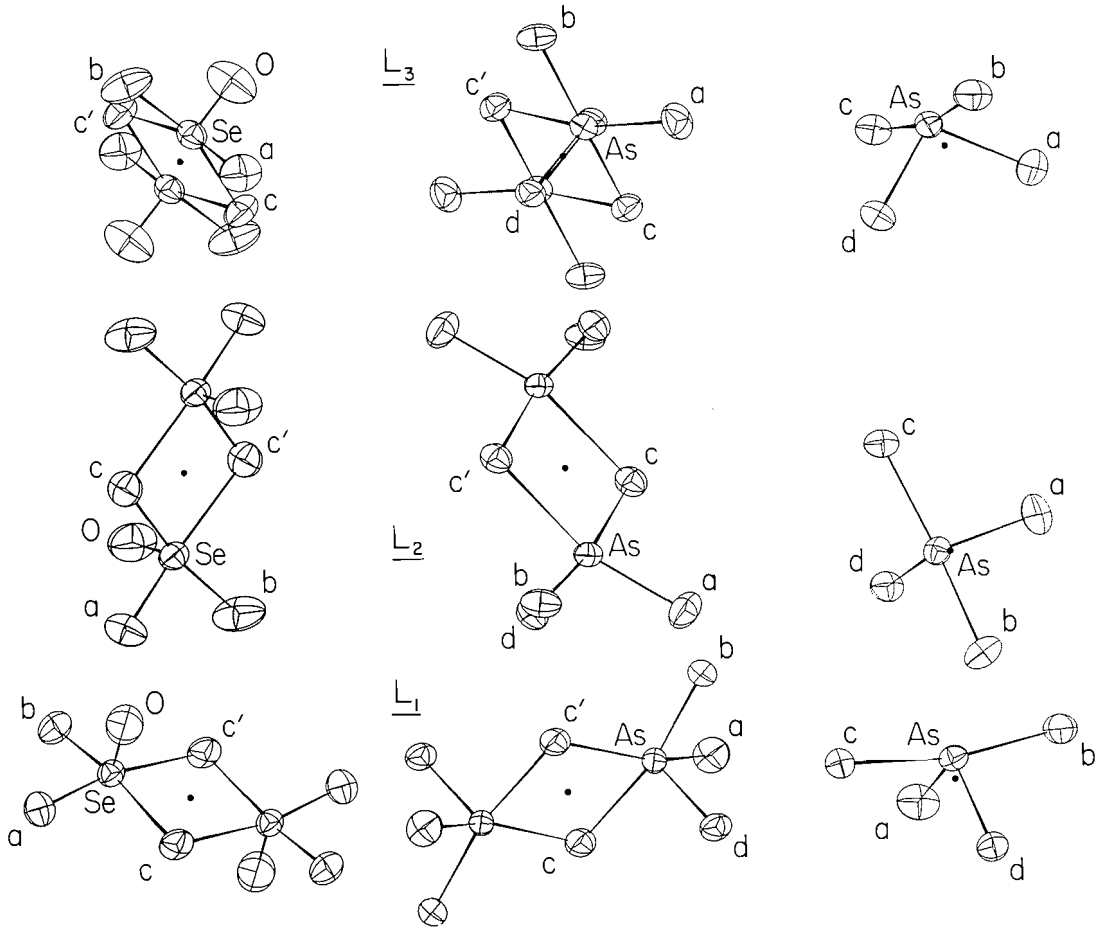

FIG. 13. Librational motions of the $Se_2O_2Cl_6^{2-}$ (**Db**, left) and $As_2I_8^{2-}$ (**6**, centre) dimers and of the monomer half of $As_2I_8^{2-}$ (right). TLS analysis based on parameter values from refs. 10 and 35, respectively. The oxygen atom in $Se_2O_2Cl_6^{2-}$ corresponds to the I_d atom in $As_2I_8^{2-}$. Cf. also caption of Fig. 12.

rangement that is obtained when the monomer halves in the crystal exist as separate anions. The close packing of the anion dimers is then likely to give way to a more typically ionic crystal structure with a regular three-dimensional cation–anion alternation. This is arguably the case with $K[TeF_5]$ (27, 72), which has a distorted (*Pbcm*) CsCl-type packing, and with $Na[TeF_5]$ (77), both of which contain discrete TeF_5^- monomers.

The centrosymmetric $TeF_5^-\cdots TeF_5^-$ pairs in **Cf** ($P2_1/n$) and **Cg** (*Pnma*) as well as the $SbCl_5^{2-}\cdots SbCl_5^{2-}$ pair in **10** ($P2_1/c$) constitute situations intermediate between obvious $Z_2Hal_{10}^{2n-}$ dimers and discrete $ZHal_5^{n-}$ monomers. While the Hal_a—Z—Hal_c' angle in these pairs is small compared to that in the true dimers (148° in **Cf**, 138° in **Cg**, 144° in **10**, but 177° in **Ch**), the relative orientation of the monomer halves is such that it would take only a minor adjustment of the tilt and of $d(Z\cdots Z')$ to convert the pair to a true dimer. These pairs may therefore be regarded as frustrated dimers. In $Rb[TeF_5]$ (*Pnma*, refs. 78 and 79) and $NH_4[TeF_4]$ ($Pn2_1a$, refs. 28 and 80) the situation is more complicated in that the two crystallographically nonequivalent TeF_5^- anions in a pair (d[Te(1)···Te(2)] = 4.40 Å in the Rb and 4.34 Å in the NH_4 compound) are not related by a symmetry operation, and single-bridging Te···F approaches at unfavourable Te···F distances (Te···F ~ 3.0, 3.4 Å) and F—Te—F angles occur between TeF_5^- pairs in the chain-like arrangements of anions. However, rotational adjustments about the Te atoms of the TeF_5^- units would result in pseudo dimer pairs similar to those in **Cf** and **Cg**.

These general arguments do not account completely for the differences between the four chemically closely similar structures containing the centrosymmetric $SeOCl_3^-\cdots SeOCl_3^-$ pairs and formulated (cf. Table 2) as

Db $(Ph_4P)_2[Se_2O_2Cl_6]$, $P\bar{1}$ **Dd** $(Ph_4As)_2[Se_2O_2Br_6]$, $P\bar{1}$

Dc $(Ph_4P)_2[Se_2O_2Br_6]$, $P2_1/c$ **De** $(Ph_4As)[SeOCl_3]$, $P2_1/c$

Examination of these crystal structures may in fact provide a clue to the above title question.

The dimensional and chemical differences between Ph_4P^+ and Ph_4As^+ being trivial, it is not surprising that **Db** and **Dd** are isostructural. They consist of almost close-packed planar layers of identically oriented $Se_2O_2Hal_6^{2-}$ dimers interleaved with planar layers of the cations; the P (or As) atoms in the cation layers are arranged in zigzag chains, d(P···P) ~ 6.5 Å (Fig. 14). The structure containing **Dc** approximates even more closely to the *anti*-CdI_2-type arrangement. The centres of the dimers form a slightly distorted hexagonal planar network with alternating orientations of the di-

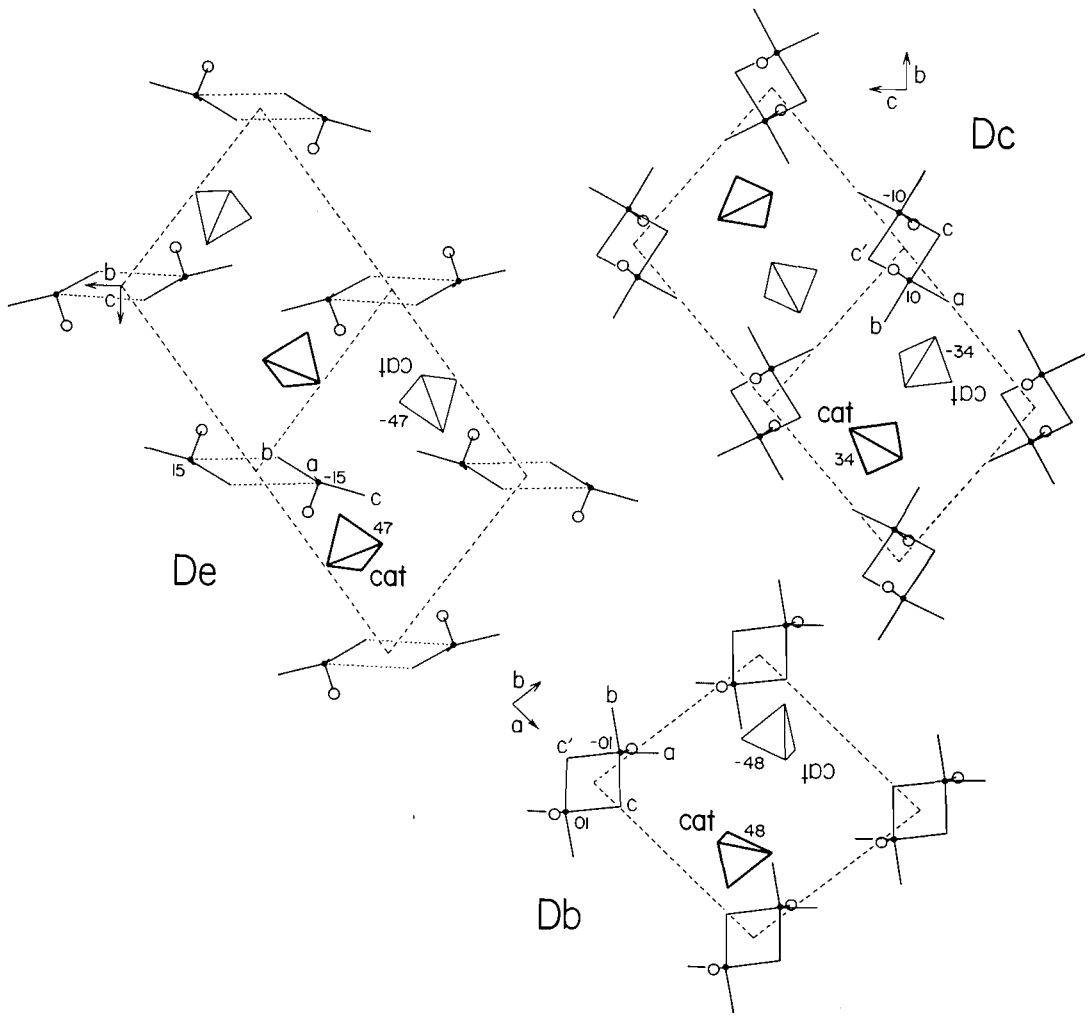

FIG. 14. Projections displaying the *anti*-CdI_2-type packing of cations and $SeOHal_3 \cdots SeOHal_3$ pairs in $(Ph_4P)SeOCl_3$ (**Db**), $(Ph_4P)SeOBr_3$ (**Dc**), and $(Ph_4As)SeOCl_3$ (**De**). Black circles, Se; open circles, oxygen atoms. The centres of the $SeOHal_3 \cdots SeOHal_3$ pairs (at zero elevation) are in the plane of the paper; the elevations of the Se and P (or As) atoms are indicated by the respective fractional coordinates × 100. The cations are represented by the PC_4 and AsC_4 tetrahedra. The basic *anti*-CdI_2-type cell in the $(Ph_4P)_2[SeOHal_3 \cdots SeOHal_3]$ and $(Ph_4As)_2[SeOCl_3 \cdots SeOCl_3]$ structures (dashed lines) contains a centrosymmetric cation pair (marked **cat**); in **Dc** and **De**, columns of these cells $\|a$ alternate in an *antiferro* arrangement.

mers at the corners of the *anti*-CdI_2 cells (Fig. 14), so that two cells are required to define the structure translationally.

When properly presented the structure containing **De** is seen to have an ion packing intermediate between those of **Db** and **Dc** (Fig. 14). The anions are arranged, formally, in centrosymmetric pairs the centres of which define a distorted hexagonal array at relative height $h = 0$, similar to **Db** and **Dc**, and with alternating orientations of these pairs, similar to **Dc**. However, unlike **Dc** but similar to **Db**, the centre atoms of all the cations are found in quasi-planar layers halfway ($h \sim \frac{1}{2}$) between the $h = 0$ layers of the anion-pair centres; in **Dc** half the P atoms are located at $h \sim \frac{1}{3}$, with the other half at $h \sim \frac{2}{3}$. The orientation of the $SeOCl_3^-$ units in these pairs is favourable to dimerization through Cl_b and Cl_b', but the $Se \cdots Cl_b'$,$Se' \cdots Cl_b$ distances are 5.3 Å, i.e., much too long for significant bonding interaction. The next-shortest $Se \cdots Cl$ distances, in centrosymmetric pairs involving other $SeOCl_3^-$ neighbours, are considerably longer, 6.23 and 7.76 Å, with less favourable $SeOCl_3^-$ orientations. The **De** structure, although *pro*-dimer, is therefore properly described as formulated above, viz. a monomer salt.

Comparison of the volumes per formula unit shows that the monomer-containing structure indeed represents a more efficient packing: V_1(**Db**) = 594 Å^3, V_1(**Dc**) = 617 Å^3, and V_1(**Dd**) = 619 Å^3, whereas V_1(**De**, −135°C) = 569 Å^3. The estimated (see footnote 4) room-temperature V_1(**De**) is 580 Å^3, i.e., still significantly inferior to V_1(**Db**).

Since the spatial organization of the ions in these structures is basically the same, one is led to the conclusion that there is no fundamental chemical difference between the $SeOCl_3^-$ monomer and the $Se_2O_2Cl_6^{2-}$ dimer anions in such crystals. Which of the two will prevail in any given situation will be determined by unpredictable details of ion packing. In any event the energy associated with the formation of the dimer from (or its dissocation into) $SeOCl_3^-$ monomer units is of a magnitude such that changes in lattice energy arising from relatively minor positional and orientational displacements of the ions are sufficient to decide

the outcome of the monomer/dimer competition. In other words, the dimer is always a *crystallographic* dimer, but once formed it assumes a chemical identity of its own and behaves like a chemical species in its own right (underlying bonding scheme, conformation to TE).

Conclusions

1. In a free $ZHal_5^{n-}$ (Z = Se, Te; Bi) ion, of symmetry C_{4v}, $d(Z—Hal_{ax}) < d(Z—Hal_{eq})$. When two such ions in a crystal associate to form a centrosymmetric $Z_2Hal_{10}^{2n-}$ dimer, the resulting differentiation in the $d(Z—Hal_{eq})$ and lengthening of $d(Z—Hal_{ax})$ are consistently interrelated through the operation of TE (Figs. 1 and 2). The asymmetry of the double bridge in $Z_2Hal_{10}^{2n-}$ is thus a property of the dimer as a whole; it decreases from Cl to I and with the increasing difference in the Z—Hal_{eq} bond lengths in the bridge plane (Fig. 5). The limits of the bridge asymmetry appear to be set by the $d(Z—Hal_{ax})$ and $d(Z—Hal_{eq})$ values in the free monomer (Fig. 7).

2. The empirical quantification of TE makes it possible to authenticate Z—L bonds as Z—Hal bonds in cases where the nature of the ligand is in doubt, e.g., on partial replacement of a Hal ligand by OH.

3. Where the RBM model is applicable, analysis of the thermal motion of a centrosymmetric $Z_2Hal_{10}^{2n-}$ dimer shows that the rigidity of the dimer is smaller than that of each $ZHal_5^{n-}$ nomoner half. As a consequence, corrections of bond lengths for the effects of thermal motion should be made on the basis of the monomer as the rigid inertial unit. In practice the differences between corrections made for the monomer and for the dimer are not large, but their magnitudes follow different patterns in the two models. There are indications that the rigidity of the dimer relative to the monomer half ($rms_{2/1}$, Fig. 11) may decrease with the increasing asymmetry of the bridge and thus in the direction of decreasing strength of association of the monomer halves.

4. All centrosymmetric $Z_2Hal_{10}^{2n-}$ dimers are crystallographic by virtue of the presence of a crystallographic inversion centre. The difference between a chemical and a crystallographic dimer is probably continuous, the limit for the latter being an inversion-related pair of well-separated monomers, and is believed to be the outcome of a fine balance of crystal forces, unpredictable at present.

IV. Experimental

Structure determination (Table 2)

A CAD-4 four-circle diffractometer (ω:2θ scans) was used in the data acquisition. Lorentz, polarization, and empirical absorption corrections (3) were applied. Scattering factors for neutral atoms and corrections for anomalous scattering were taken from ref. 73. The structures were solved with the SHELX-76 and SHELXS-86 programs (74, 75). After the nonhydrogen atoms had been located, full-matrix least-squares ($w\Delta|F|$ = minimum) refinement was carried out with isotropic temperature factors until R was reduced to a reasonably low value. The hydrogen atoms were then placed, consistent with the difference maps, and the refinement was continued with anisotropic temperature factors on the nonhydrogen and isotropic factors on the hydrogen atoms. The H atoms were constrained to ride on their respective C atoms. The final difference maps were featureless except as noted. The anisotropic temperature factor is defined as $\exp[-2\pi^2(U_{11}h^2a^{*2} + U_{22}k^2b^{*2} + U_{33}l^2c^{*2} + 2U_{23}klb^*c^* + 2U_{13}hla^*c^* + 2U_{12}hka^*b^*)]$. The TLS and best plane calculations were performed with CRYSTALS (70).

The following material has been deposited:[26]

Table A. (n-$Pr_4N)_2SnCl_6$ (**A**): positional parameters and isotropic temperature factors of hydrogen atoms.

Table B. (n-Pr_4N)[$TeCl_4$(OH)] (**B**): positional parameters and isotropic temperature factors of hydrogen atoms.

Table C. (n-$Pr_4N)_2[Te_2Cl_{10}]$ (**C**): positional parameters and isotropic temperature factors of hydrogen atoms.

Table D. (n-$Pr_4N)_2[Se_2O_2Cl_6]$ (**D**): positional parameters of hydrogen atoms.

Table E. Observed and calculated structure factors for **A**.

Table F. Ditto for **B** (refinement in $C2/c$).

Table G. Ditto for **C** (all ligands assumed to be Cl).

Table H. Ditto for **D**.

Table J. TLS analysis of anion dimers treated as monomers or dimers.

Table K. Corrections δd for thermal motion (in 10^{-3} Å) to be added to Z—Hal bond lengths in the anions.

Compound A

This salt was prepared by neutralizing aqueous n-Pr_4NOH with HCl, adding to the resulting solution an equivalent amount of $SnCl_4$ dissolved in water strongly acidified with HCl, and allowing **A** to crystallize by slow evaporation at room temperature.

Systematic absences: $hk0$, h odd; $0kl$, k odd; $h0l$, l odd; consistent with $Pbca$. The Sn position was found from a Patterson map and the remaining nonhydrogen atoms from Fourier syntheses. The isotropic temperature factors on the H atoms were refined, one value reported for each cation. The weighting scheme was $w = 1.18/[\sigma^2(F) + 0.005F^2]$. Two reflections were omitted from the final refinement because of suspected extinction. The highest residual peak in the final difference map, 0.68 e/Å^3, was near the Sn atom.

Compound B

Intended product composition, (n-$Pr_4N)_2TeCl_6$. The solution obtained by dissolving 0.56 g TeO_2 in 5 mL of 6 M HCl was added, with stirring, to 14 mL of a 0.5 M aqueous solution of n-Pr_4NCl. The resulting clear, colourless solution was allowed to crystallize by slow evaporation at room temperature. The crystal used in the structure determination came from the crop of clear, pale yellow crystals that appeared after 1 day.

The systematic absences (hkl, $h + k$ odd; $h0l$, h,l odd) pointed to $C2/c$ or Cc as possible space groups, the E-statistic favouring the centrosymmetric group. The Te atom was found from a Patterson map, at or near the origin. Only four instead of the expected six Cl atoms per Te were located in a Fourier map. The FT-ir spectrum of the product (Fluorolube mull, CaF_2 plates) taken at this stage contained a strong, broad ($\nu_{1/2} \sim 270$ cm^{-1}) OH-stretching absorption at 3397(10) cm^{-1} on a regular background but no discernible $\delta(H_2O)$ absorption. These findings, together with chemical considerations, suggested that the composition of the crystal was (n-Pr_4N)[$TeCl_4$(OH)], with $Z = 4$ and a square-pyramidal [$TeCl_4$(OH)]$^-$ anion. We therefore proceeded with solution of the structure on this assumption, all the remaining nonhydrogen atoms having been located from difference maps. It was clear, however, that for a solution in $C2/c$ the Te and O atoms had to be treated as positionally disordered. Both were placed in general positions with half occupancy, the Te atom close to the origin, and the structure was refined to $R = 4.6\%$, with anisotropic temperature factors on the nonhydrogen atoms and isotropic factors on the hydrogens. The weighting scheme was $w = 2.45/[\sigma^2(F) + 0.0015F^2]$.

[26]These tables may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0S2.

Tables A–D have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from The Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW, U.K.

Three reflections were omitted from the final refinement because of suspected extinction. The highest residual peak in the final difference map was 0.8 e/Å^3, near Cl(2).

The refined structure with Te and O in disorder gave reasonable bond lengths and confirmed the assumed anion geometry. The H atom of the OH group could not be located, but examination of the O···Cl separations and Te—O—Cl angles revealed that Cl(2) in a neighbouring anion was the only atom at a distance and angle that could qualify as an acceptor in a O—H···Cl hydrogen bond.

Since placing Te and O in the general position of the noncentrosymmetric subgroup *Cc* of *C*2/*c* would result in a fully ordered structure, **B** was also refined in *Cc*. The final *xyz* values from the refinement in *C*2/*c* were used as the initial parameters. With anisotropic temperature factors on the nonhydrogen atoms, one U_{iso} each for H(CH_3) and H(CH_2), and $w = 1.76/[\sigma^2(F) + 0.0015F^2]$, the structure refined to $R = 4.2\%$ ($R_w = 4.7\%$, d/p = 5.7, G.O.F. = 1.53). The highest residual peaks in the final difference map, 0.55 and 0.46 e/Å^3, were near Cl(2) and Cl(2A), respectively. The enantiomorph was also refined but the results were not significantly different.

While the refinement in *Cc* gave a lower *R* value and more uniform Te—Cl bond lengths, the Te—O bond length was significantly shorter than that from the refinement in *C*2/*c*. The ordered and partially disordered structures are compared in Sect. II.

Compound ***C***

Intended product composition, $(n\text{-}Pr_4N)_2TeCl_6$. The canary yellow paste that resulted on adding an equivalent amount of a concentrated aqueous solution of $n\text{-}Pr_4NCl$ to a solution of TeO_2 in a slight excess of concentrated HCl was separated from the mother liquor by decantation and redissolved in concentrated HCl. This solution was concentrated by heating and allowed to stand at room temperature. The deep yellow crystals that formed after 3 days were filtered off, pressed dry between layers of filter paper, and air-dried.

Systematic absences, none; consistent with $P\bar{1}$ and $P1$. The structure was solved in $P\bar{1}$. The Te atom was found in a general position from a Patterson map and the other nonhydrogen atoms from Fourier syntheses. It was clear at this stage that the composition of the crystal did not correspond to the above intended composition. From the combined crystallographic and chemical evidence the crystal was taken to be $(n\text{-}Pr_4N)_2[Te_2Cl_{10}]$, the essential correctness of which assumption was borne out by subsequent refinement. The isotropic temperature factors on the H atoms were refined, one for the methyl hydrogens and another for the remaining hydrogens. The weighting scheme was $w = 4.22/[\sigma^2(F) + 0.000633F^2]$. Six reflections were omitted from the final refinement because of suspected extinction. The highest residual peak in the final difference map, 1.1 e/Å^3, was near the Te atom.

After the realization that the $Te_2Cl_{10}^{2-}$ dimer in **C** was in fact partially hydrolyzed at the L_a site the refinement was repeated in order to estimate the degree of replacement of Cl_a by OH. The Te—O_a and Te—Cl_a distances were fixed to 1.90 and 2.33 Å, respectively, with a tolerance of 0.005 Å. All nonhydrogen atoms were refined with anisotropic temperature factors except Cl_a and O_a, which were refined with equal isotropic temperature factors, initially set at 0.06 Å^2; the site occupancy factor at *a* was fixed at 0.84 Cl + 0.16 O, as estimated from an exploratory refinement. After refinement to convergence the site occupancy factor was allowed to refine, giving 0.52 for Cl and 0.48 for oxygen. A final refinement fixing the site occupancy factor at these values and refining Cl_a and O_a with anisotropic temperature factors ($w = 5.30/[\sigma^2(F) + 0.000633F^2]$) gave the following result: $R = 7.3\%$, $R_w = 8.1\%$, G.O.F. = 6.53, d(Te—O_a) = 1.92(1) Å, d(Te—Cl_a) = 2.35(1) Å; population at site *a*, 0.515(2) Cl + 0.485(2) O; highest residual peak, 1.1 e/Å^3, near the Te atom.

Compound ***D***

Intended product composition, $(n\text{-}Pr_4N)_2SeCl_6$. Equivalent amounts of SeO_2 dissolved in 6 M HCl and a concentrated aqueous solution of $n\text{-}Pr_4NCl$ were combined and the resulting solution was allowed to stand at room temperature. The clear, pale yellow crystals that appeared after 3 months were dried between layers of filter paper and subsequently air-dried.

Systematic absence, none; consistent with $P\bar{1}$ and $P1$. When the two nonequivalent $SeCl_3$ units were found using SHELXS-86 and most of the nonhydrogen atoms were located from Fourier syntheses, it became clear that the cation:Se ratio was not 2:1 as intended but 1:1, with the Se and Cl atoms forming two distinct centrosymmetric μ_2-$Cl_2Se(Cl)_2SeCl_2$ dimers. Further refinement revealed the presence of oxygen as the ligand perpendicular to the bridge plane. This established the composition as $(n\text{-}Pr_4N)_2[Se_2O_2Cl_6]$. The refinement was continued on this basis to convergence at $R = 9.4\%$. The probable cause of this high *R* value was the progressive deterioration of the crystal, which on exposure to the X-ray beam turned black. The intensities of the three standard reflections dropped *unevenly* in the course of the collection by between 15 and 20%, most of the decrease occurring toward the end of the data collection. Omission of a block of these last reflections, deemed to be most affected (ca. 8% of the total used), and re-refinement reduced *R* insignificantly, leaving the final parameter values virtually unchanged. In spite of the large final *R* value the structure appears to be adequately refined (cf. the reasonable esd's on the final parameter values).

The highest residual peaks in the final difference map, 1.2 and 1.4 e/Å^3, were near the Se(1) and Se(2) atoms, respectively. The weighting scheme was $w = 4.17/[\sigma^2(F) + 0.100F^2]$. Ten reflections were omitted from the final refinement because of suspected extinction.

Nonlinear optimization

The model function was fitted to the d,d^* data pairs using a nonlinear least-squares procedure that minimizes SSE = $\Sigma(d^*_{obs} - d^*_{calc})^2$, and a statistical package comprising a Gauss–Newton algorithm described in ref. 76. Approximate standard errors on the parameter estimates were obtained from the inverse of the expected information matrix, which contains sums of squares and cross products of the model partial derivatives with respect to the parameters. A measure of the overall agreement between the observed and fitted values is given by $\hat{r}^2 = 1 - \text{SSE/TSS}$, where TSS = $\Sigma(d^*_{obs} - \overline{d^*}_{obs})^2$.

Acknowledgments

We are greatly indebted to Professor B. Krebs and Dr. F.-P. Ahlers for their generosity in providing us with details of a number of their crystal-structure determinations in advance of publication and with other valuable information. We thank Dr. David C. Hamilton for supplying much of the expertise needed for the statistical treatment of the data, and Mrs. Lorraine Fullum-Bouchard for her assistance with the preparative chemistry. This investigation was supported by grants from the Natural Sciences and Engineering Research Council of Canada to O.K. and T.S.C., and from the Mount Saint Vincent University Committee on Research and Publication to M.A.J.

Matrix Dirac–Fock–Coulomb and Dirac–Fock–Breit self-consistent field calculations are performed for a number of neutral atoms, He ($Z = 2$) through Xe ($Z = 54$), using the universal Gaussian basis set ($18s$, $12p$, $11d$) reported recently by Da Silva *et al.* The total Dirac–Fock–Coulomb, the Dirac–Fock–Breit, and the Breit interaction energies calculated with this universal Gaussian basis set are in good agreement with the corresponding values obtained by using an extensive well-tempered Gaussian basis set for the He through Ca ($Z = 20$) atoms. Although this universal Gaussian basis set is inadequate for the calculation of total Dirac–Fock–Coulomb and Dirac–Fock–Breit energies for the Kr, Sr, and Xe atoms, the Breit interaction energies calculated with this basis for these three atoms are in very good agreement with the corresponding Breit interaction energies obtained by using the extensive well-tempered Gaussian basis sets. Work is in progress to generate a more extensive and energetically better universal Gaussian basis set for He through Xe for its use in non-relativistic Hartree–Fock as well as Dirac–Fock self-consistent field calculations on polyatomics involving heavy atoms.

G. L. MALLI, A. B. F. DA SILVA et YASUYUKI ISHIKAWA. Can. J. Chem. **70**, 1822 (1992).

Utilisant la base gaussienne universelle ($18s$, $12p$, $11d$) proposée récemment par Da Silva *et al.*, on a effectué des calculs en champ auto-cohérent des matrices de Dirac–Fock–Coulomb et de Dirac–Fock–Breit d'un certain nombre d'atomes neutres, He ($Z = 2$) à Xe ($Z = 54$). Les énergies totales d'interaction de Dirac–Fock–Coulomb, et les énergies d'interaction de Dirac–Fock–Breit et de Breit sont en bon accord avec les valeurs correspondantes obtenues par l'utilisation d'une base gaussienne extensive bien tempérée pour les atomes de He à Ca ($Z = 20$). Même si cette base gaussienne universelle est inadequate pour calculer les énergies totales de Dirac–Fock–Coulomb et de Dirac–Fock–Breit des atomes de Kr, Sr et Xe, les énergies d'interaction de Breit calculées pour ces trois atomes à l'aide de cette base sont en bon accord avec les énergies correspondantes d'interaction de Breit obtenues en utilisant la base gaussienne extensive bien tempérée. Des travaux sont en cours dans le but de générer une base gaussienne universelle plus étendue et meilleure d'un point de vue de l'énergie que l'on pourrait appliquer du He au Xe et qui pourrait être utilisée dans des calculs en champ auto-coherent non-relativiste de Hartree–Fock ainsi que de Dirac–Fock pour des ensembles polyatomiques impliquant des atomes lourds.

[Traduit par la rédaction]

Introduction

Ab initio electronic structure calculations for atoms and especially for molecules in general are mostly carried out within the finite basis set expansion method of Roothaan (1). There is a considerable degree of freedom in choosing the basis functions for atomic and molecular calculations, since any complete set of functions can be employed.

Although Slater-type basis functions (STF) have been widely used for atoms and diatomics, Gaussian-type basis functions (GTF) are invariably the popular choice for polyatomic calculations. The prime reason for the preference of the GTF as basis for polyatomics lies in the fact that all the multicenter integrals can be evaluated exactly by closed analytical formulas. However, a much larger basis set of GTF is needed than the basis set of STF because the GTF's behave incorrectly both in the region near the nucleus (if approximated as a point nucleus) and in the long range.

These deficiencies are, however, relevant to the non-relativistic quantum chemistry based upon the Schrodinger equation where the point nucleus approximation is usually employed. Relativistic quantum chemistry, however, is based on the Dirac equation whose solutions for an electron in a finite nucleus have been shown to be Gaussians (2, 3). Thus the GTF basis set is the natural choice for *ab initio* relativistic quantum chemistry, and spherical Gaussians were introduced as basis sets in relativistic quantum chemistry more than a decade ago (4).

Since the computational cost of finite basis set atomic and molecular calculations increases as $\sim N^4$ (where N is the number of basis functions used), various attempts have been made to economize the cost as much as possible by adopting various strategies. One such approach was the introduction of the universal STF basis set (5) for atoms following the earlier work on the even-tempered STF and GTF basis sets (6, 7). As a result of extensive studies, it was observed that the optimum exponents of the rigorously optimized GTF for *ab initio* non-relativistic Hartree–Fock (HF) atomic calculations could be related by Gaussian rule (8). The existence of such a rule suggested a high degree of universality in the optimum GTF representation of different atoms, and it is obvious that considerable computational savings would accrue if a universal Gaussian basis set were employed for each atom in a molecular calculation. The transferability

alone of all the one- and two-electron integrals over the primitive universal GTF from system to system (with trivial multiplicative scale factors due to change in nuclear charges) would lead to remarkable computational savings. Therefore, there has been a considerable effort involved in the design of the so-called "universal Gaussian basis set" (8–10). A universal basis set is a single, sufficiently flexible basis set that can be used for any atomic or molecular environment without much loss of accuracy (9). Needless to reiterate, it is always possible to construct a basis set for an atom which is smaller and still as accurate as the universal basis set; however, the design of such basis sets involves nonlinear exponent optimization for each atom, which is computationally very expensive and time consuming.

Recently, well-tempered GTF (11), geometrical GTF, and various other GTF basis sets have been used for Dirac–Fock–Coulomb (DFC) and Dirac–Fock–Breit (DFB) (12–15) calculations without exponent reoptimization along with the "kinetic balance" and the finite model of the atomic nucleus. The results have been very encouraging not only for DFC and DFB calculations, but also for relativistic many-body perturbation theory calculations on atoms (16). In this paper, we report the results of the DFC and DFB calculations for a number of atoms, He ($Z = 2$) through Xe ($Z = 54$), using the universal Gaussian type functions (UGTF) (18*s*, 12*p*, 11*d*) basis set reported recently by Da Silva *et al.* (10). The purpose of the present study is to assess the performance of the UGTF in atomic Dirac–Fock calculations. The calculations are performed using the matrix Dirac–Fock–Breit SCF methodology detailed by us previously (15).

Gaussian basis set for relativistic calculations

The basis set expansion method for relativistic calculations was pioneered by Kim (17), who introduced the STF basis set with a non-integer exponent of r and developed the Dirac–Fock–Roothaan SCF method for closed-shell atoms. Kagawa (18) extended Kim's method to open-shell atoms and results were reported for a large number of transition elements (18) and Rn (19). In these studies, the same STF basis set was used for the large and small radial components, and often the problem of so-called variational failure was encountered. The spherical Gaussian basis set was introduced in relativistic atomic structure calculations by Malli (4), and in Dirac–Fock–Roothaan molecular calculations by Matsuoka *et al.* (21). Recently, there has been great interest in the use of GTF as a basis set for Dirac–Fock–Coulomb, Dirac–Fock–Breit, and relativistic many-body perturbation calculations (12–16). This is mainly due to the work of Ishikawa *et al.* (2, 3, 12, 15, 16), who have emphasized that the imposition of finite nuclear boundary conditions for solutions of the Dirac–Fock equation results in a solution that is Gaussian at the origin and, therefore, the GTF of integer power of r are appropriate basis functions for the finite nuclear model. Moreover, it has been shown that the failure to satisfy proper boundary conditions near the origin can lead to a spurious solution. The Gaussian-type functions that satisfy the boundary conditions for the finite nucleus automatically satisfy the condition of the so-called "kinetic balance" for a finite speed of light. This is due to the fact that the exponent of r for the GTF does not depend on the speed of light, c, in contrast to the non-integer STF whose exponent depends on the speed of light and, thus, does not satisfy the kinetic balance conditions for a finite value of c (3). The kinetic balance simply guarantees that the solutions of the matrix DFC and DFB equations approach the correct non-relativistic limit as c approaches infinity (3).

Choice of the universal Gaussian basis set

There are a great variety of GTF's to be used in relativistic atomic and molecular calculations; however, if the GTF basis is sufficiently large and flexible, the particular choice of the GTF basis is not expected to be reflected in the calculated properties. One is forced, however, to use a moderately large basis set, since its flexibility in general increases as it is extended. It is also well established that it is generally more profitable to increase the basis set size rather than optimize the individual basis function exponent since the exponent optimization is computationally very costly. The concept of a universal basis set arose from these considerations and basis set exponent non-optimization has been so far almost the rule in relativistic quantum chemistry. We chose to adopt the UGTF (18*s*, 12*p*, 11*d*) basis set recently reported by Da Silva *et al.* (10), which is based on the earlier work of Mohallem *et al.* (22). The significance of the UGTF basis set (10, 22) lies in the fact that no *a priori* information is forced on an atom, which is characterized in the SCF algorithm only by the atomic number in the Fock operator, i.e., an atom is characterized only by its Hamiltonian. This method of designing a UGTF basis introduces a new algorithm for basis set exponent selection. The basis set exponents are not adjustable parameters to optimize a property (e.g., energy), but values generated by a certain criterion for the integration of the SCF equations for the atom, i.e., the exponent values are generated by discretization of an integral equation (with the best numerical integration as the goal). The number of basis functions, N, is related to the number of discretization points, and as the number N is increased, better numerical integration is achieved. We believe that this procedure of generating UGTF basis has sound theoretical background and deserves further investigation both in non-relativistic and relativistic quantum chemistry.

Results and discussion

The UGTF (18*s*, 12*p*, 11*d*) basis set was used for the atoms He, Be, Ne, Mg, Ar, Ca, Kr, Sr, and Xe. The exponents of this basis set are derived from the non-relativistic generator coordinate version of the Hartree–Fock equations (22) and are collected in Table 1. The exponents were used in our DFC and DFB SCF calculations without further optimization. The radial functions with different κ quantum number but of the same ℓ quantum number are expanded in terms of the same set of basis functions, e.g., the radial functions of $p_{1/2}$ and $p_{3/2}$ symmetries are expanded in the same set of *p*-type GTF's listed in Table 1. The speed of light used in our calculations is 137.0370 au (atomic units). The nuclei are modeled as spheres as uniform proton charge distribution and the atomic masses used for the rare gas atoms He, Ne, Ar, Kr, and Xe are, respectively, 4.0026, 20.18, 39.948, 83.80, and 131.30. The atomic masses used for the alkaline earth atoms Be, Mg, Ca, and Sr are, respectively, 9.0122, 24.312, 40.08, and 87.62.

The results of the calculated DFC, DFB, and Breit interaction energies (designated as E_{DFC}, E_{DFB}, and E_B, respectively) using the UGTF (18*s*, 12*p*, 11*d*) basis are given in Table 2, where we have also included the results obtained using large well-tempered (11) GTF basis sets (6). In the last column of Table 2, the DFC energies obtained by using the numerical finite-difference Dirac–Fock program (20) are also tabulated. Here, E_B denotes the variational Breit interaction energy computed as the difference $E_{DFB} - E_{DFC}$. The variational Breit energy is the level shift in the total SCF energy due to the inclusion of the Breit term in the SCF process. The results clearly demonstrate that the total DFC and DFB energies computed with the UGTF basis set are in very good agreement with those obtained by using large well-tempered GTF for He, Be, Ne, Mg, Ar, and Ca atoms. However, for Kr, Sr, and Xe atoms, the calculated DFC and DFB energies are relatively poor in comparison with those obtained from the well-tempered GTF basis set calculations (15); the differences in E_{DFC} and E_{DFB} for the case of the Sr atom are 0.209448 and 0.208795 au, respectively. For the Xe atom, these differences are an order of magnitude larger than in the case of the Sr atom, viz., 2.31688 and 2.302588 au, respectively.

Moreover, it turns out that both E_{DFC} and E_{DFB} are in error by almost the same amount for each atom and, therefore, the variational Breit interaction energies predicted by using both the UGTF and well-tempered GTF basis sets are in excellent agreement for all the atoms, He through Xe, treated in this paper.

Although the UGTF (18*s*, 12*p*, 11*d*) basis is inadequate for the calculations of E_{DFC} and E_{DFB} for the Kr, Sr and Xe

[a]Computed by using UGTF basis set (18*s*, 12*p*, 11*d*) (10)
[b]Computed by using well-tempered 23*s*21*p*14*d* GTF basis set (15).

atoms, E_B calculated with this UGTF basis set is in very good agreement with the corresponding E_B obtained from using an extensive GTF basis set. We also performed calculations for these atomic systems using the UGTF (18*s*, 18*p*, 18*d*) basis set. Although the basis set is much larger for the *p* and *d* symmetries, only a marginal improvement in E_{DFC} and E_{DFB} over the results of UGTF (18*s*, 12*p*, 11*d*) was obtained for the heavier atoms Kr, Sr, and Xe.

The calculated orbital energies for the Xe atom obtained by using the UGTF and well-tempered GTF (15) are collected in Table 3. A comparison of the orbital energies calculated by using these two basis sets indicates significant differences for the innermost shells. An improvement of the UGTF basis is therefore expected to lead to better total DFC and DFB energies and also the orbital energies of the innermost shells.

Conclusion

The universal Gaussian basis set employed in our calculations is fairly good for the DFC and DFB calculations for the atoms He through Ca. However, this basis set needs much improvement for the Kr, Sr, and Xe atoms, since the DFC and DFB energies calculated with this basis set for these three atoms are rather poor. The errors in the calculated DFC and DFB energies are, however, of the same magnitude and, therefore, the calculated Breit interaction energies even for these three atoms are in perfect agreement with those obtained by using the well-tempered GTF basis set (11, 15).

It is clear that there is an urgent need for an improved UGTF basis set for He through Xe atoms. Work is in progress in the design of the improved UGTF basis set that can consistently provide more accurate results for the calculations of E_{DFC} and E_{DFB} for many-electron atoms. The improved UGTF basis set should lead to remarkable savings in computations for non-relativistic as well as relativistic calculations on molecular systems.

GARRY W. BUCHKO and JEAN CADET. Can. J. Chem. **70**, 1827 (1992).

Benzophenone-mediated photosensitization of 2′-deoxyguanosine (dG) and thymidylyl-(3′-5′)-2′-deoxyguanosine (d(TpG)) at 350 nm in oxygen-saturated aqueous solution produces 2-deoxy-D-ribono-1,4-lactone (dL) and thymidylyl-(3′-5′)-2-deoxy-D-ribono-1,4-lactone (d(TpL)), respectively. These photoproducts have been isolated by reverse phase high-performance liquid chromatography and characterized by proton magnetic resonance spectroscopy and fast atom bombardment mass spectroscopy. Conformational analysis of d(TpG) and d(TpL) in aqueous solution using coupling constant data suggests no major conformational differences between the two dinucleoside monophosphates.

GARRY W. BUCHKO et JEAN CADET. Can. J. Chem. **70**, 1827 (1992).

Les photosensibilisations de la 2′-désoxyguanosine (dG) et de la thymidylyl-(3′, 5′)-2′-désoxyguanosine (d(TpG)), à l'aide de la benzophénone, à 350 nm, dans une solution aqueuse saturée d'oxygène, conduisent respectivement à la 2-désoxy-D-ribono-1,4-lactone (dL) et à la thymidylyl-(3′-5′)-2-désoxy-D-ribono-1,4-lactone ((d(TpL)). On a isolé ces photoproduits par chromatographie liquide à haute performance en phase inversée et on les a caractérisés par spectroscopie de résonance magnétique nucléaire et par spectroscopie de masse avec bombardement avec des atomes rapides. L'analyse conformationnelle du d(TpG) et de la d(TpL) en phase aqueuse, en se basant sur les données relatives aux constantes de couplage, suggère qu'il n'y a aucune différence conformationnelle importante entre les deux monophosphates de dinucléoside.

[Traduit par la rédaction]

Introduction

The exposure of living organisms to solar radiation spanning the near ultraviolet (280–380 nm) to visible regions may induce mutagenic and lethal effects as a result of photooxidative modifications to genomic DNA (1, 2). The type of photochemical modifications that occur depend on the wavelength of the incident radiation. At wavelengths shorter than 290 nm the DNA directly absorbs the energy and the majority of photoproducts produced involve the pyrimidine bases. On the other hand, at wavelengths in the UV-A region (320–400 nm) the primary photochemical target is guanine (2–5). The latter reactions occur through the agency of endogenous and exogenous photosensitizers, which are initially excited to the triplet state and generate oxidation products via their decay to the ground state through two principal competitive mechanisms labelled Type I and Type II (6). Type I mechanisms involve initial electron or hydrogen transfer by the excited photosensitizer to, or from, the substrate. Type II mechanisms involve the initial generation of singlet oxygen by the excited photosensitizer and subsequent reaction with the substrate. The end result of these two mechanisms is a different set of photoproducts (2, 5, 7).

Benzophenone acts primarily through a Type I mechanism (8) and for this reason was chosen to investigate more specifically the formation of the related guanine photooxidation products. Even so, the benzophenone photooxidation of the dinucleoside monophosphate d(TpG) still produced a large variety of photoproducts involving (*i*) modified guanine bases, (*ii*) intrabase thymine–guanine covalent crosslinks, (*iii*) phosphodiester bond cleavages, and (*iv*) glycosylation (9). Our attention here focuses on one product of the later event, thymidylyl-(3′-5′)-2-deoxy-D-ribono-1,4-lactone, d(TpL). A 2-deoxy-D-ribono-1,4-lactone (dL) (Fig. 1) was previously identified at (*i*) the internal residue of d(ApCpA) (10) and d(GpCpG) (11) upon UV irradiation at acidic pH (4.0), (*ii*) the terminal residue of d(ApGpC) following reaction with the neocarzinostatin chromophore (12), and (*iii*) in oligonucleotide duplexes containing 5-bromouracil following photolysis (13). Exposure of 2′-deoxyguanosine (dG) to γ-radiation in oxygen-free aqueous solution (14) and to hydrogen peroxide (15) also produces this lactone. The isolation of dL and d(TpL) from the starting material dG and d(TpG), respectively, constitutes the first examples of the formation of 2-deoxy-D-ribono-1,4-lactone as a product of the photosensitization of DNA components.

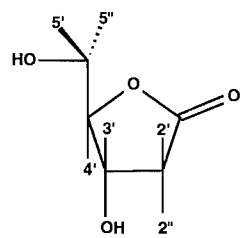

FIG. 1. Structure and proton numbering scheme for 2-deoxy-D-ribono-1,4-lactone, dL, the modified component of d(TpL).

Experimental

Materials and methods

The dinucleoside monophosphate d(TpG) was synthesized in solution by using the phosphotriester approach (16, 17). Benzophenone (1.0 mg) (Merck) was added to 50 mL of 1.0 mM d(TpG) in a flat, round-bottom flask and irradiated for 1 h with 16 350-nm black lamps in a photochemical reactor (Rayonet, Southern New

England Ultraviolet Company, Hander, Conn.). During the irradiation, oxygen was continuously bubbled through the solution to maintain its saturation with oxygen. The water was removed by rotary evaporation (30°C) and the solids resuspended in the minimum volume of water for high-performance liquid chromatography (HPLC). Identical conditions were employed for 2′-deoxyguanosine (Genofit) photosensitization using 50 mL of a 7.5 mM solution irradiated for 16 h. Control experiments with dG and d(TpG) were performed in the absence of photosensitizer.

Chromatography of photoproducts

Samples were injected onto a 5-μm Hypersil (10 mm × 25 cm) semipreparative octadecyl silica gel reverse-phase column. After 1 min of 100% 0.1 M ammonium acetate (pH = 6.0), a linear gradient of methanol was introduced at a rate of change of 0.5%/min and a flow rate of 2.0 mL/min. The product profile was monitored by UV absorbance at 230 nm. The major bands were collected, pooled, and concentrated by rotary evaporation. Fractions containing 2-deoxy-D-ribono-1,4-lactone were further purified by HPLC as described above, using acetonitrile instead of methanol. The products were then lyophilized a minimum of 3× to remove the ammonium acetate.

Fast Atom Bombardment (FAB) mass spectrometry

Negative ion mode FAB mass spectra (glycerol matrix, 8-keV xenon atoms) were obtained on a VG ZAB 2-EQ mass spectrometer. Some of the more prominent peaks are reported here as follows: *m/z*(relative intensity, [ionic species]), with the relative intensity normalized to the molecular ion $[M - H]^-$. *d(TpL)*: 435 (100, $[M - H]^-$), 527 (11, [M + glycerol − H]$^-$), 211 (56, [5′dLMP − H]$^-$), 321 (32, [3′dTMP − H]$^-$). *d(TpG)*: 570 (100, $[M - H]^-$), 346 (20, [5′dGMP − H]$^-$), 321 (42, [3′dTMP − H]$^-$), 150(51, [guanine − H]$^-$), 125 (72, [thymine − H]$^-$. *dL*: no prominent ions.

Proton Nuclear Magnetic Resonance (^{1}H NMR) spectroscopy

Samples were lyophilized twice from 99.8% D_2O prior to resuspension in 400 μL of NMR buffer (pD = 7.0) consisting of 0.1 M sodium chloride, 0.01 M sodium phosphate, and 0.001 M ethylenediaminotetraacetic acid. A trace of *tert*-butanol was added to serve as an internal NMR reference (assigned a chemical shift of 1.231 ppm on the DSS scale). The proton spectra were recorded at 400.135 MHz (Bruker AM400), except for d(TpG), which was obtained at 500.135 MHz (Bruker WM500). Free induction decay data were obtained in 16K of computer memory, processed with a Lorentz-to-Gaussian lineshape transform (GB = 0.2, LB = −2.0), and zero-filling to 32K prior to Fourier transformation. The digital resolution of the processed spectra was 0.23 (400.135 MHz) and 0.30 (500.135 MHz) Hz/point. Conventional homonuclear decoupling, nuclear Overhauser enhancement and two-dimensional coherence (18), and relay coherence spectroscopy (19) experiments were carried out for proton spectral assignments. The H5′ was assigned downfield of H5″ according to Remin and Shugar (20) whereas the H2′/H2″ assignments were based on coupling constant arguments (21, 22). To verify the assignments and to obtain accurate coupling constants, all the spectra were simulated using the Bruker PANIC program.

Results and discussion

Isolation and characterization of the lactone photoproducts

It is not surprising to observe d(TpL) as a final product of benzophenone-sensitized irradiation of d(TpG) after identifying dL as one of the final products of benzophenone photosensitization of dG in oxygen-saturated aqueous solution. Proton NMR evidence for the latter is apparent from the data in Tables 1 and 2 that illustrate the key spectral features of 2-deoxy-D-ribono-1,4-lactone: (*i*) the absence of an anomeric proton resonance, (*ii*) the absence of a downfield nonexchangeable base proton resonance, and (*iii*) a geminal coupling of −18.6 Hz between the 2′ and 2″ protons. The latter observation represents a 4.5 Hz increase relative to dG and is consistent with the addition of a substituent adjacent to C2′ containing a double bond (24, 25). Furthermore, the chemical shifts and coupling constants tabulated herein for dL are nearly identical to those published by Berger and Cadet (14) for authentic dL and dL obtained after γ radiolysis of a deaerated aqueous solution of dG. The only anomalies are misprints by Berger and Cadet that reverse $J(4'5')$ and $J(4'5'')$ and $J(2'3')$ and $J(2''3')$ (this is clearly evident in their published spectrum for dL).

The ^{1}H NMR features that distinguish dL also serve to identify the lactone in the dinucleoside monophosphate as tabulated in Tables 1 and 2 and illustrated in Fig. 2. First, only the H6 and H1′ resonances of the Tp unit appear in the downfield part of the spectrum; the guanine H8 and H1′ are absent. Moreover, these Tp H6 and H1′ resonances of d(TpL) are downfield relative to those of d(TpG) as expected in the absence of ring current effects from the pL unit. Second, the 2′ and 2″ protons assigned to the pL unit by COSY and relay coherence transfer experiments have a geminal coupling of −18.7 Hz and chemical shifts nearly identical to those of the nucleoside, dL. Third, the chemical shifts of the

pL protons are within 0.1 ppm of those for dL with the exception of H5′/H5″, which are downfield due to the presence of a phosphate group at the 5′ position.

FAB mass spectrometry

Figure 3 contains the negative ion mode FAB mass spectrum of d(TpL). A pseudomolecular ion at m/z 435 (100, $[M - H]^-$) and a glycerol adduct at m/z 527 (11, $[M +$ glycerol $- H]^-$) are indicative of a species with a molecular weight of 436. Fragmentation ions at m/z 211 (56, $[5'dLMP - H]^-$) and m/z 321 (32, $[3'dTMP - H]^-$) further support the structure implied from the ^{1}H NMR data.

Conformational features

(a) Sugar conformation

The 2-deoxyribose ring can be evaluated in terms of a 2′-*endo* (*S*) $\rightleftharpoons$ 3′-*endo* (*N*) equilibrium from the vicinal proton coupling constants $J(1'2')$ through $J(3'4')$, or from certain sums of these couplings (26). In this manner it is possible to estimate the *%S* conformer population from the equation $\%S = [(J(1'2') + J(1'2'')) - 9.8]/5.9$ (26) using the data in Table 2. It is observed (Table 3) that there is a decrease in the *%S* conformer of the Tp unit in going from d(TpG) (80%) to the apurinic d(TpL) (68%). Such an observation suggests more freedom of movement in d(TpL) in comparison to d(TpG), as may be expected in the absence of any possible base-stacking interactions.

The sum of $J(1'2')$ and $J(1'2'')$ cannot be used to analyse the 2-deoxy-D-ribono-1,4-lactone conformation because of the lack of an anomeric proton. However, the X-ray structure of a similar D-pentono-1,4-lactone, D-arabino-1,4-lactone, shows the 5-member ring to exhibit an ^3E envelope conformation with C3′ displaced 0.57 Å above the mean

[b]Calculated according to ref. 28.

plane of C4′—O1′—C1′—C2′ (27). In solution, the conformation of D-pentono-1,4-lactones has been described in terms of a dynamic equilibrium between this ^3E (*N*) conformer and an other E_3 (*S*) envelope form that has C3′ displaced below the plane of C4′—O1′—C1′—C2′ (14, 28, 29) (Fig. 4). The contribution of the ^3E conformer to the $^3E \rightleftharpoons E_3$ blend may be estimated using the equation $\%^3E = [J(2''3')/9.5] \times 100$ (28) and the data in Table 2. It is observed that the E_3 conformer predominates at both the nucleoside (71%) and the dinucleoside monophosphate level (77%) in the range typical of deoxyribodinucleoside monophosphates (56–81%*S*) (30).

(b) The C4′—C5′ (γ) bond

Table 3 gives the populations for the *gauche*$^+$ (g^+), *trans* (t), and *gauche*$^-$ (g^-) conformers about the γ bond of d(TpG), d(TpL), and dL calculated from the $J(4'5')$ and $J(4'5'')$ data according to Haasnoot *et al.* (31). In all cases there is a preference for g^+ followed by g^t, then g^-, as expected for small DNA oligomers (32). Also expected, and observed, are the smaller g^+ populations for the Tp units (53%) in comparison to the pN units (75 and 80%) due to more freedom of movement at the 5′-end of oligonucleotides (33).

(c) The C5′—O5′ (β) bond

Table 3 gives the populations of the preferred *trans* (t) conformation of the β bond of the pN units estimated from $\Sigma = J(5'P) + J(5''P)$ (32). For d(TpL) the $\%\beta^t$ population is 72% while for d(TpG) it is 88%, the former population below the low end of the range typically observed for deoxyribodinucleoside monophosphates composed of poorly stacking pyrimidine units (74–82%) (30). This observation, together with the γ-bond information, suggests that there are no gross distortions in the sugar-phosphate backbone of d(TpL) relative to d(TpG) but only less order in the former due to the lack of any base-stacking interactions.

Mechanisms and biological significance

Neither dL nor d(TpL) was detected by HPLC chromatography after 350 nm irradiation in the absence of benzophenone, even upon extension of the period of irradiation.

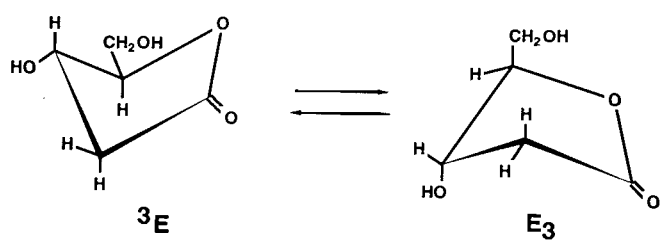

FIG. 4. Structures of the ^3E and E_3 envelope conformers of dL.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

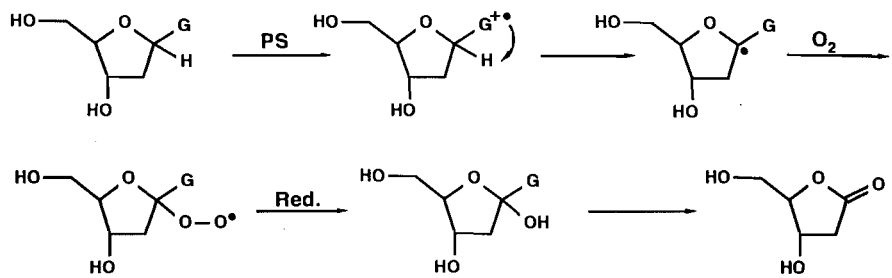

FIG. 5. Proposed mechanism for the free radical mediated formation of 2-deoxy-D-ribono-1,4-lactone. PS = photosensitizer, Red = reduction.

Such an observation dictates that the lactone is generated through a photosensitization process. Furthermore, neither dL nor d(TpL) was observed, at least in detectable quantities, when phthalocyanine derivatives, which generate products primarily through a Type II mechanism, were used as the photosensitizer (34). Hence, while the exact mechanism of lactone formation via benzophenone photosensitization is not clear, if it is occurring through a Type I pathway then proton or electron abstraction from the guanine base is likely the initial step as indicated in Figure 5. The next event may involve deprotonation at C1′ by the guanine radical cation (although another possible mechanism that cannot be ruled out is the photoexcited benzophenone directly abstracting this hydrogen). Molecular oxygen is expected to react with the C1′-centered radical producing a peroxyl radical intermediate, which is converted into the corresponding alcohol. Subsequent hydrolysis of the weakened *N*-glycosidic bond of the latter compound will give rise to the 2-deoxy-D-ribono-1,4-lactone with concomitant release of the free base (35).

While d(TpL) was not the major photoproduct of benzophenone-sensitized irradiation of d(TpG) (9), the biological significance of a DNA lesion is not determined solely by quantity but by its susceptibility to DNA repair systems (36). Lactone lesions show resistance to certain AP and UV endonucleases (37, 38) and, hence, may have great biological significance even though they are produced in low yield. Because the coupling constant data demonstrate no major conformational differences between d(TpG) and d(TpL) in aqueous solution, our data, if extendable to oligonucleotides, suggest such biological consequences are likely due to the presence of the C1′ keto group.

Acknowledgements

We thank Jacques Ulrich (Services d'études analytiques, Centre d'études nucléaires de Grenoble) for recording the mass spectra; Dr. Frank E. Hruska (Chemistry Department, University of Manitoba) for providing some protected d(TpG), and the French government for a postdoctoral fellowship for GWB.

Received July 15, 1991

YAN XIANG and GILLES VILLEMURE. Can. J. Chem. **70**, 1833 (1992).

The cyclic voltammograms of tris (2,2′-bipyridyl) iron(II) ($[Fe(bpy)_3]^{2+}$) adsorbed in clay-modified electrodes made from a range of different smectites were recorded. In all cases, at low scan speed (1 mV/s), the initial anodic peak current was much larger than the initial cathodic peak current. Partial reduction of the clay structural iron further increased the initial anodic to cathodic current ratio, suggesting that the discrepancy between the charge transferred in the anodic and cathodic scans was due to a slow electron transfer between the clay structural Fe(II) and the oxidized bipyridyl cations. However, no clear quantitative relation was found between the measured FeO contents of the different clays and the observed excess anodic currents. In fact, of all the clays tested only one, montmorillonite SWy-1, contained enough Fe(II) for it to account for all of the excess anodic charge transferred in the initial scan.

YAN XIANG et GILLES VILLEMURE. Can. J. Chem. **70**, 1833 (1992).

Une étude par voltamétrie cyclique de l'ion fer(II) tris(2,2′-bipyridyl) ($[Fe(bpy)_3]^{2+}$) adsorbé dans des électrodes modifiées par des films d'argile montre qu'au cours du premier cycle, le courant anodique est plus élevé que le courant cathodique, lorsque la vitesse de balayage est de 1 mV/s. Cette différence augmente lorsque la réduction partielle des sites Fe(III) de l'argile augmente son contenu en fer(II), ce qui suggère que le courant anodique supplémentaire est dû à un transfert d'électron entre les sites fer(II) de l'argile et les ions fer(III)tris(2,2′-bipyridyl). Cependant, il ne semble pas y avoir de relation quantitative entre cette différence et la quantité totale de fer(II) présente dans les argiles. En fait, de toutes les argiles étudiées une seule, la montmorillonite SWy-1, contenait suffisamment de Fe(II) pour que l'on puisse leur attribuer la totalité de l'excédant de charge anodique transférée au cour du premier cycle.

Introduction

Recently, we found that the anodic peak currents were much larger than the cathodic peak currents in the first scan of the cyclic voltammograms of $[Fe(bpy)_3]^{2+}$ cations adsorbed in electrodes modified with films of montmorillonite (1). Discrepancies between the charge transferred in the cathodic and anodic waves have also been reported for $[Ru(bpy)_3]^{2+}$ (2, 3) and $[Ru(NH_3)_6]^{3+}$ (4, 5) adsorbed in clay-modified electrodes. These differences have generally been attributed to electron transfer between the adsorbed electroactive cations and iron sites in the clay lattices. Iron atoms in clay minerals have been known to act as electron donor/acceptor sites since the work of Solomon, more than 20 years ago (6).

Electron transfer between acceptor/donor sites in the clay lattice and adsorbed cations could help alleviate the problem of electron transport in clay-modified electrodes (CME) (7, 8). The electronic conductivity of clay minerals is low (9). Electron transport in CME must therefore depend on a combination of diffusion of the adsorbates through the films, and electron hopping between adsorbed species. The low mobility of cations in clay films means that only a small fraction of them, only those that are adsorbed in the vicinity of defects in the film structure, can reach the conductive substrate to participate in the electrochemical reaction (1). These small electroactive fractions greatly limit the usefulness of clays as electrode surface modifiers (10, 11). A more efficient electron transport mechanism, one which would be independent of the adsorbate mobility, would greatly increase the usefulness of CME.

One way to improve charge transport in CME would be to make use of the clay lattice acceptor/donor sites as relays to transfer electrons from the adsorbed cations to the conductive substrates. We therefore undertook a systematic investigation of the electrochemical behaviour of $[Fe(bpy)_3]^{2+}$ adsorbed in CME made from a range of smectites containing different Fe(II) concentrations. The objective was to establish the involvement of structural iron(II) in the anomalous initial peak current ratios.

Experimental

Materials

$[Fe(bpy)_3]Cl_2$ was prepared by adding 3 equivalents of 2,2′-bipyridyl (Aldrich) to an aqueous solution of ferrous sulphate (12). Addition of a saturated solution of NaCl gave a dark red solid on cooling.

The clay samples used are listed in Table 1. They were obtained from the Source Clay Minerals Repository (University of Missouri, Columbia, Mo). Sodium forms were prepared and the <0.2 μm (esd) fractions separated by literature procedures (13, 14). The clays' Fe(II) and the total iron contents were determined by a spectrophotometric method using 1,10-phenanthroline according to a published procedure (15, 16). Results are shown in Table 2, along with corresponding literature data.

A fraction of the structural Fe(III) in samples of SWy-1 and STx-1 was reduced to Fe(II) by heating to 70°C with sodium dithionite for 8 days according to a literature procedure (18). For each clay, two identical samples were reduced in the same conditions. One of them was used to determine the iron(II) and the total iron contents of the treated clays by the above method, the other to prepare the clay-modified electrodes.[2]

Methods

Cyclic voltammetry experiments were performed using a Princeton Applied Research (Princeton, N.J.) PARC model 270-1

[1]Author to whom correspondence may be addressed.

[2]During the preparation of the modified electrodes the reduced clays were exposed to air. This could result in partial reoxidation even if clay oxidation by oxygen is slow at room temperature.

electrochemical analysis system. All electrochemical experiments were done in an undivided three-electrode cell. The counter electrode was a Pt gauze and the reference electrode was a saturated calomel electrode (SCE). The 0.1 M Na_2SO_4 electrolyte solutions were degassed by bubbling with N_2 prior to the measurements.

The clay-modified electrodes were prepared by spin coating (1, 20). The supports were 1 × 2 cm pieces of indium-doped SnO_2 coated glass (Delta Technologies, Stillwater, Minn.), cleaned by three cycles of sonication in EtOH. One drop of H_2SO_4 (10% v/v) was added to a 10 g/L suspension of the clay in distilled water to make a low-viscosity gel. Drops of the clay gel were spin coated at 3000 rpm (Headway Research, Photo-Resist spinner, Garland, Tex.). This gave films (1 cm^2) with interference colours from purple to yellow with estimated thickness of about 300 nm (1).

All the clay films were presoaked in 0.1 mM solutions of $[Fe(bpy)_3]^{2+}$ overnight. The volumes of the soaking solutions were selected so that the adsorption of the cations by the films would result in a 25–40% decrease of their concentrations. The amounts of $[Fe(bpy)_3]^{2+}$ adsorbed by the films were determined by measuring this decrease by UV–visible spectroscopy. As described in a previous report (19), this method gives more reliable measurements of the total amount of this type of cation adsorbed by clay films.

Results and discussions

The first three scans in the cyclic voltammogram of $[Fe(bpy)_3]^{2+}$ adsorbed in an electrode modified with a film of nontronite SWa-1, recorded at 1 mV/s, are shown in Fig. 1. In the initial scan the ratio of anodic to cathodic current was found to be 2.04. The anodic peak current I_{pa}, was much larger than the cathodic peak current I_{pc}. In subsequent scans this difference became smaller. By the third scan (dashed line) the ratio of I_{pa}/I_{pc} was down to 1.24. Table 3 shows that this was a general result for $[Fe(bpy)_3]^{2+}$ adsorbed in electrodes modified with a range of different montmorillonites and nontronites. Only for the electrode modified with hectorite (SHCa-1) was the initial current ratio close to 1, and for all CME the current ratio decreased in subsequent scans. The waves also became sharper (smaller ΔE) and shifted to lower potentials.

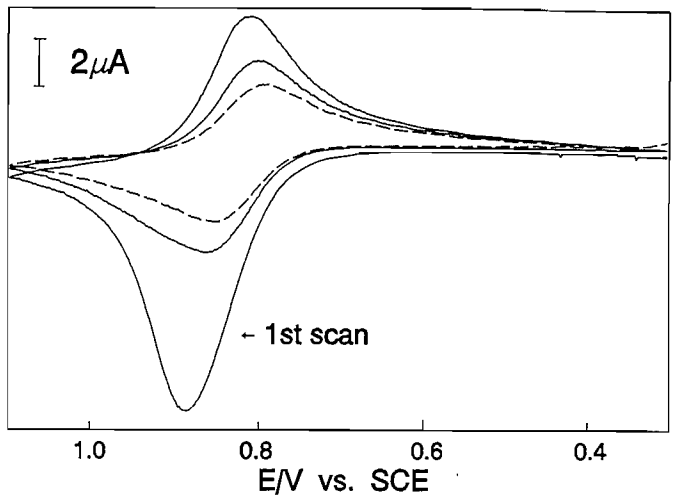

FIG. 1. Cyclic voltammogram of a SWa-1 CME (300 nm thick) presoaked overnight in 0.1 mM $[Fe(bpy)_3]^{2+}$, recorded at 1 mV/s in 0.1 M Na_2SO_4.

It appears that in the initial scan more electrons were passing during the oxidation than during the reduction of adsorbed $[Fe(bpy)_3]^{2+}$ cations. This would suggest that we are tapping an electron well in the clay films. One possible source of the additional electrons, first suggested by Oyama and Anson (4), is structural iron(II) sites in the clay lattice. To confirm the involvement of structural iron(II) sites in the anomalous initial current ratios, the concentrations of iron(II) in samples of montmorillonites STx-1 and SWy-1 were increased by the partial reduction of their iron(III). Figure 2 and Table 4 show that this resulted in a definite increase of the initial I_{pa}/I_{pc} ratios. However, Table 4 also shows that this increase was much smaller than could have been expected based on the 10-fold increase in the clay iron(II) contents.

That brings up the question of just how much additional anodic current can electron transfer from the clays' structural Fe(II) sites be expected to produce. To answer this

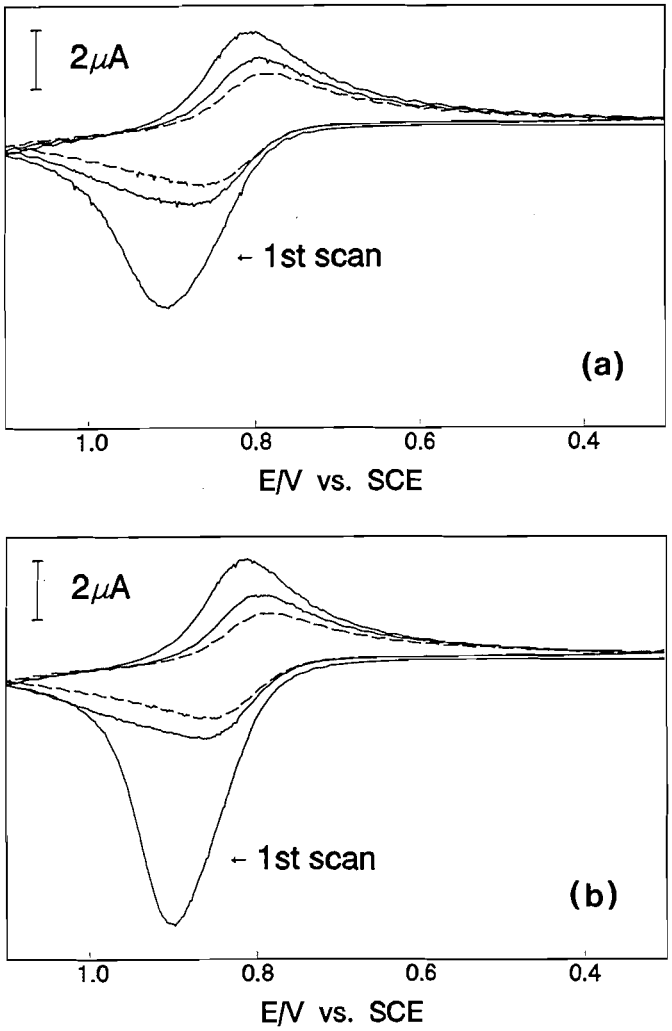

FIG. 2. Cyclic voltammograms of STx-1 CME (300 nm thick) presoaked overnight in 0.1 mM $[Fe(bpy)_3]^{2+}$, recorded at 1 mV/s in 0.1 M Na_2SO_4, prepared from (*a*) untreated and (*b*) partially reduced STx-1 (see Table 4).

TABLE 4. Effect of partial reduction of clay structural iron on the initial anodic to cathodic current ratio.

Clay	%FeO	I_{pa1}/I_{pc1}[a]
SWy-1	0.14	2.36
Reduced SWy-1	1.40	2.80
STx-1	0.03	2.29
Reduced STx-1	0.30	3.10

[a]Values of the current ratio are the averages of duplicate measurements. They were reproducible within ±0.05.

question we have to look, not at the initial current ratio, but at the difference between the first scan anodic and cathodic peak currents. The additional current due to electron transfer from the clay Fe(II) sites can be estimated from the film volume, the clay density, and its iron content, using the thin-layer equation (20).[3] When the results are compared with the observed current differences in Table 5, it is found that, except for SWy-1, the clays contained far too little iron(II) to account for the magnitude of the difference.

TABLE 5. Comparison of the observed difference between the initial I_{pa} and I_{pc} with that estimated from the clay FeO contents

Clay	%FeO	Estimated from %FeO $I_{pa} - I_{pc}/\mu A$	Observed $I_{pa} - I_{pc}/\mu A$

STx-1	0.03	0.31	3.3
Re-STx-1	0.30	3.11	5.8
SAz-1	0.02	0.21	4.9
Hectorite			
SHCa-1	0.01	0.10	0.4

Table 5 also shows that in the case of partially reduced STx-1 the increase in the $I_{pa} - I_{pc}$ difference of 2.5 μA found was close to the increase of 2.8 μA expected. But, in the case of partially reduced SWy-1, the small 0.4 μA increase found was nowhere near the 13 μA expected on the basis of the additional iron(II) present in the clay.

We also investigated the possibility that the discrepancy between the initial anodic and cathodic currents was due not only to an additional source of electrons, but also to the leaching of the adsorbed electroactive cations from the films by the electrolyte. Examination of Figs. 1 and 2 shows that there was a decrease in the magnitudes of both the anodic and cathodic peak currents. In Fig. 1, for example, I_{pc} was 2.7 μA lower in the third scan than in the first scan. Although this decrease was smaller than that of I_{pa}, 7.7 μA, it is not a negligible variation. This observation, combined with the finding that soaking the electrodes in the electrolyte solution for 24 h prior to recording the voltammograms reduced both the cathodic and anodic currents to less than 5% of their original values, suggests that the adsorbed electroactive $[Fe(bpy)_3]^{2+}$ cations were gradually washed away from the clay films by the electrolyte. This lost of activity was essentially unaffected by whether or not the potential was scanned continously, showing that the desorption of $[Fe(bpy)_3]^{3+}$ was not significantly faster than that of $[Fe(bpy)_3]^{2+}$.

A closer examination of the voltammograms, however, shows that the simple loss of electroactive $[Fe(bpy)_3]^{2+}$ cannot account for all of the change in the anodic current. For example, in Fig. 2*a* the second scan anodic peak current (I_{pa2}) is 2.7 μA larger than the first scan cathodic peak current (I_{pc1}), 2.6 μA. This is the reverse of what would be found if the decrease in current was due solely to a slow desorption of the $[Fe(bpy)_3]^{2+}$ cations with soaking time.

More convincing evidence that leaching of the adsorbed cations by the electrolyte does not account for all of the

[3]The additional currents obtained by this method are probably overestimated since the transfer of electron is not expected to be reversible, nor to be completed in the first scan, and the anodic peaks do not have the symmetrical shapes of surface waves.

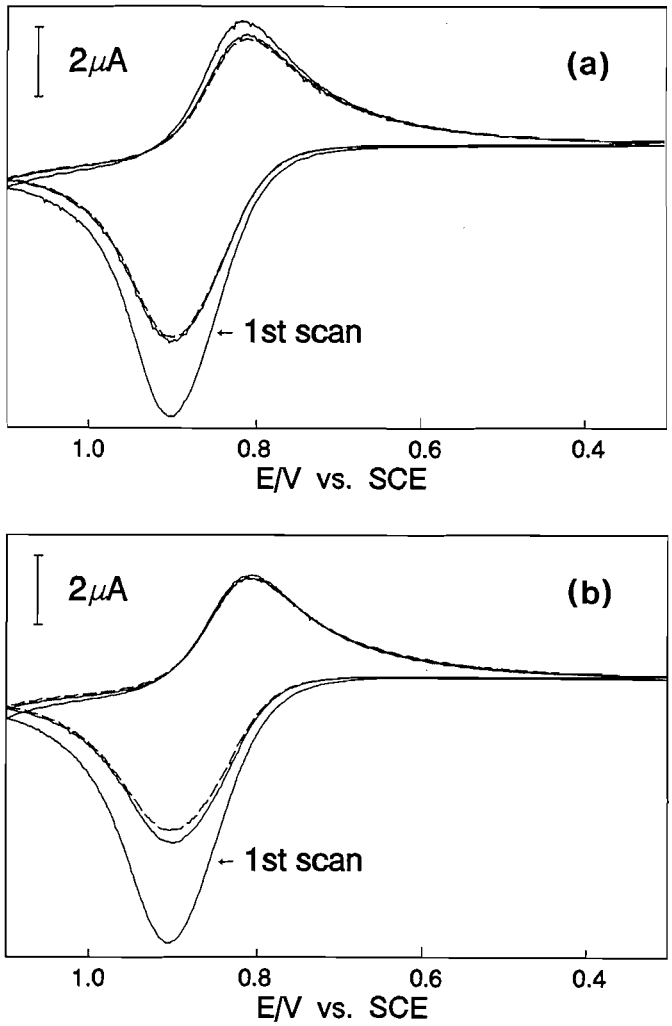

FIG. 3. Cyclic voltammograms of STx-1 CME (300 nm thick) presoaked overnight in 0.1 mM $[Fe(bpy)_3]^{2+}$, recorded at 1 mV/s in 0.1 M Na_2SO_4 electrolyte containing 0.04 mM $[Fe(bpy)_3]^{2+}$;(*a*) first three scans, (*b*) after 24 hours.

variation in anodic current is provided by the results shown in Fig. 3. To remove, or at least reduce, the importance of leaching, $[Fe(bpy)_3]^{2+}$ was added to the electrolyte solution in which the voltammograms were recorded. As expected, the variation of I_{pc} all but disappeared[4,5]. In fact, there was little change in I_{pc} even when the electrode was soaked in the electrolyte for 24 prior to recording the voltammograms (see Fig. 3*b*). As mentioned above, when there was no $[Fe(bpy)_3]^{2+}$ in the electrolyte, soaking of the electrode for 24 reduced I_{pc} by more than 95%. However Figs. 3*a* and 3*b* show that significant differences between the first and second scan I_{pa} remained. In fact the initial I_{pa}/I_{pc} ratio in Fig. 3*a* is 2.26, very close to the value found when there was no $[Fe(bpy)_3]^{2+}$ in the electrolyte solution (see Table 3). Despite the relatively rapid loss of adsorbed electroactive $[Fe(bpy)_3]^{2+}$ cations from CME when there was no $[Fe(bpy)_3]^{2+}$ in the electrolyte solution, this desorption does not appear to have a significant effect on the initial current ratio.

How then can we account for the excess anodic currents observed? Simply assuming that the oxidation of $[Fe(bpy)_3]^{2+}$ in CME is not reversible does not explain our results. Assuming that some of the $[Fe(bpy)_3]^{3+}$ produced is lost, either because of faster leaching or decomposition of the oxidized complex, would explain why I_{pc} is lower than I_{pa}. However, it would not account for the variation of the current ratio. Why would a process that is irreversible in the first scan become more reversible in subsequent scans? Further, an irreversible loss of $[Fe(bpy)_3]^{3+}$ would not allow for the second scan anodic current (I_{pa2}) to be larger than the first scan cathodic current (I_{pc1}). Although the difference between these two peak currents was generally small, it was quite common, especially for the montmorillonite electrodes, for I_{pa2} to be larger than I_{pc1}.

That leaves three possibilities to account for our results. First, there is an additional source of electrons we have not considered. For example, the iron(II) contents measured in the bulk clay powders may not reflect the state of oxidation of the clay in the film electrodes. All clay samples contained enough total iron that the reduction of only a fraction of it would account for the observed current differences.

A second possibility is that there are two types of electroactive $[Fe(bpy)_3]^{2+}$ cations. There are in the clay films a limited number of sites in which adsorbed $[Fe(bpy)_3]^{2+}$ can only be irreversibly oxidized. This irreversible oxidation is slow, so it takes several scans to complete. After it is completed, only the wave for the other type of electroactive cations, those that can be reversibly oxidized, remains.

Finally, we cannot exclude the possibility that the anomalous initial current ratios are due to more complex phenomena. For example, our results can be explained by assuming that there was an irreversible change in the film structure, induced by the electrogenerated $[Fe(bpy)_3]^{3+}$ cations, that was complete after a few scans and that reduced the mobility of the adsorbed cations. This would explain why both the anodic and cathodic current decreased with scanning, and how an oxidation that was initially not reversible becomes more reversible after a few scans, when this change was complete.

Support for the occurrence of an irreversible change of the clay films is provided by the observation that the activity of a CME that is resoaked in the $[Fe(bpy)_3]^{2+}$ solution after recording of the cyclic voltammograms does not recover. For example, the initial I_{pa} found for a STx-1 modified electrode was 5.9 μA. As mentioned above, this current was reduced by more than 95% after 24 h in the electrolyte. The initial anodic current found for this same electrode after it was resoaking in a solution of $[Fe(bpy)_3]^{2+}$ was only 1.5 μA. This change in the film structure would be analogous, in its effect on the current, to an increase in the cross-linking of a polymer-modified electrode (21). The problem with this interpretation is that it does not allow for the second scan anodic current (I_{pa2}) to be larger than the first scan cathodic current (I_{pc1}).

[4]Since the concentration of the $[Fe(bpy)_3]^{2+}$ in the electrolyte was lower than that of the soaking solution, some slight change in I_{pc} remained until complete equilibration occurred.

[5]Except for an increase in the background noise, stirring the solution during the measurement had no significant effect on the cyclic voltammograms, confirming that the waves were due only to the cations adsorbed in the clay films and not to solution cations.

Conclusion

At slow scan speed in the initial scan, the anodic peak current of $[Fe(bpy)_3]^{2+}$ adsorbed in a range of clay-modified electrodes is larger than the cathodic peak current, indicating that more electrons are passing during the oxidation than during the reduction of the adsorbed species. This remains true even after the rapid loss of activity of the films due to leaching is taken into account. Increasing the concentration of structural iron(II) sites in the clays, by the partial reduction of the their structural iron(III), was found to result in a further increase of the initial anodic to cathodic current ratio. However, except for montmorillonite SWy-1, the clays did not contain enough Fe(II) to account for all of the discrepancy between the charge transferred in the cathodic and anodic scans, unless we assume that the bulk FeO contents did not reflect the FeO contents of the clay films used to modify the electrodes.

Unless there is another source of electrons in the clay films that we have not considered, the remaining difference between the initial anodic and cathodic currents must be due to other phenomena. The most straightforward explanation is that the film contained two types of electroactive cations, one for which the oxidation was reversible and one for which the oxidation was irreversible. However, we cannot exclude the possibility of more complex mechanisms, such as changes in the film structure.

We are pursuing our study of the involvement of structural iron in the anomalous initial scan current ratio found for $[Fe(bpy)_3]^{2+}$ adsorbed in CME. Investigations of leaching, decomposition of the redox species, and the effect of oxidation state on transport in the clay films and on the film structures are also underway.

Radical-based syntheses of 5-benzoyl-1,2-dihydro-3H-pyrrolo[1,2-a]pyrrole-1-carboxylic acid (ketorolac)[1]

DEAN R. ARTIS, IN-SEOP CHO,[2] AND JOSEPH M. MUCHOWSKI[3]
Syntex Research, Institute of Organic Chemistry, 3401 Hillview Ave., Palo Alto, CA 94304, U.S.A.

Received January 21, 1992

DEAN R. ARTIS, IN-SEOP CHO, and JOSEPH M. MUCHOWSKI. Can. J. Chem. **70**, 1838 (1992).

Short, efficient, and convergent syntheses of ketorolac (**1**) based on the inter- or intramolecular oxidative addition of malonyl and substituted malonyl radicals to 2-benzoylpyrrole and derivatives thereof are described.

DEAN R. ARTIS, IN-SEOP CHO et JOSEPH M. MUCHOWSKI. Can. J. Chem. **70**, 1838 (1992).

On décrit des synthèses à la fois courtes, efficaces et convergentes du kétorolac **1** qui sont basées sur l'addition oxydante inter- ou intra-moléculaire de radicaux malonyles ou malonyles substitués sur le 2-benzoylpyrrole et ses dérivés.

[Traduit par la rédaction]

Ketorolac (5-benzoyl-1,2-dihydro-3*H*-pyrrolo[1,2-*a*]pyrrole-1-carboxylic acid (**1**, Scheme 1) is a powerful non-narcotic analgesic that is used clinically for the management of moderate to severe pain states (1). Both linear (2) and convergent (3, 4) syntheses of this compound, and its derivatives, based on "ionic" bond formation processes have been reported. This paper describes new synthetic approaches to ketorolac in which the salient feature is the oxidative addition of an "electrophilic" radical species to a 2-benzoylpyrrole derivative.

Malonate anions of type **2** (X = Cl, Br, SO_2Me) readily cyclize to the bicyclic esters **3** and consequently they are valuable intermediates in the synthesis of ketorolac and congeners thereof (3, 4). It seemed to us that the alkylmalonyl radical **4** might add intramolecularly to the relatively electron-rich pyrrole nucleus to give the bicyclic radical **5**, which on oxidation to the cationic species **6** and proton loss therefrom would provide another route to the diester **3**. The recently described manganese(III) acetate induced cyclizations of β-arylethyl-, λ-arylpropyl-, β-aryloxyethyl-, and λ-aryloxypropylmalonates are the first reported examples of just such a process (5).

To ascertain if ketorolac could indeed be obtained by an oxidative radical cyclization process, the known (6) *N*-chloroethylpyrrole **7** (Scheme 2) was converted into the corresponding solvolytically sensitive iodide **8** (sodium iodide in boiling acetonitrile), which was immediately reacted with the sodium salt of diethyl malonate in dimethylformamide (DMF) solution. Reaction of the alkylmalonate **9** thus obtained with 2.5 equivalents of manganese(III) acetate (generated *in situ* from $Mn(OAc)_2 \cdot 4H_2O$),[4] in acetic acid solution at 80°C, gave the cyclic diester **11** in nearly quantitative yield. The amount of Mn(III) could be reduced by 60%, without a diminution in the yield of **11**, by using sodium persulfate (in the presence of Ag(I) as a cocatalyst) to reoxidize Mn(II) to Mn(III) (8). This result indicates that the latter process might well be made catalytic in Mn(III) but this possibility was not examined. Saponification of **11** and decarboxylation of the diacid gave ketorolac (**1**) in over 50% yield based on 2-benzoylpyrrole, the immediate precursor of **7**.

The conversion of **9** to **11** could also be effected by abstraction of Br· from the bromomalonate **10** mediated by the aerial oxidation of triethylborane (9, 10). The nature of the specie(s) responsible for the transformation of the bicyclic radical (i.e., corresponding to **5**) to **11** is not known. Compound **10** was synthesized by bromination of the sodium salt of **9** with *N*-bromosuccinimide.

It was of considerable interest to determine if diethyl 5-benzoylpyrrole-2-malonate (**14**, Scheme 3) could be synthesized by the reaction of the diethyl malonyl radical with 2-benzoylpyrrole (**12**). Compound **14** is of obvious synthetic importance because base-induced alkylation with an appropriate 1,2-disubstituted ethane derivative would most certainly produce the bicyclic ester **11**.

The Mn(III)-induced reaction of diethyl malonate with 2-benzoylpyrrole gave the α-acetoxy derivative **13** as the major product. The formation of this substance was not unexpected (11) nor was it prevented by the use of diethyl chloromalonate, a stratagem that has been utilized to obviate such overoxidation (12, 13). The desired malonate **14** could be obtained from **13**, albeit in modest yield, by triethylsilane – trifluoracetic acid reduction. Compound **14** could, however, be directly prepared from 2-benzoylpyrrole in excellent yield (86%) when the diethyl malonyl radical was generated from diethyl bromomalonate by the triethylborane-autoxidation process.

As expected, potassium carbonate induced alkylation of **14** with 1,2-dichloroethane (reactant and solvent), in the presence of 1 equivalent of tetra-*n*-butylammonium bromide, gave the bicyclic ester **11** in ca. 70% yield.

We have recently shown (14) that electron-rich aromatic systems undergo Mn(III)-induced tri(ethoxycarbonyl)methylation with triethyl methanetricarboxylate and that the triester **15** is formed as the only product (86%) from 2-benzoylpyrrole. The dealkoxycarbonylation of trialkyl alkane-1,1,1-tricarboxylates under basic conditions is known to be facile (15) and the conversion of **15** to **14** could be efficiently effected with sodium ethoxide in DMF at room temperature. Thus, this process not only constitutes a simple solution to the overoxidation problem, it also means that **15** is functionally equivalent to the malonate ester **14**. Indeed, reaction of **15** with 1,2-dichloroethane under conditions identical to those used with **14** gave the bicyclic diester **11**

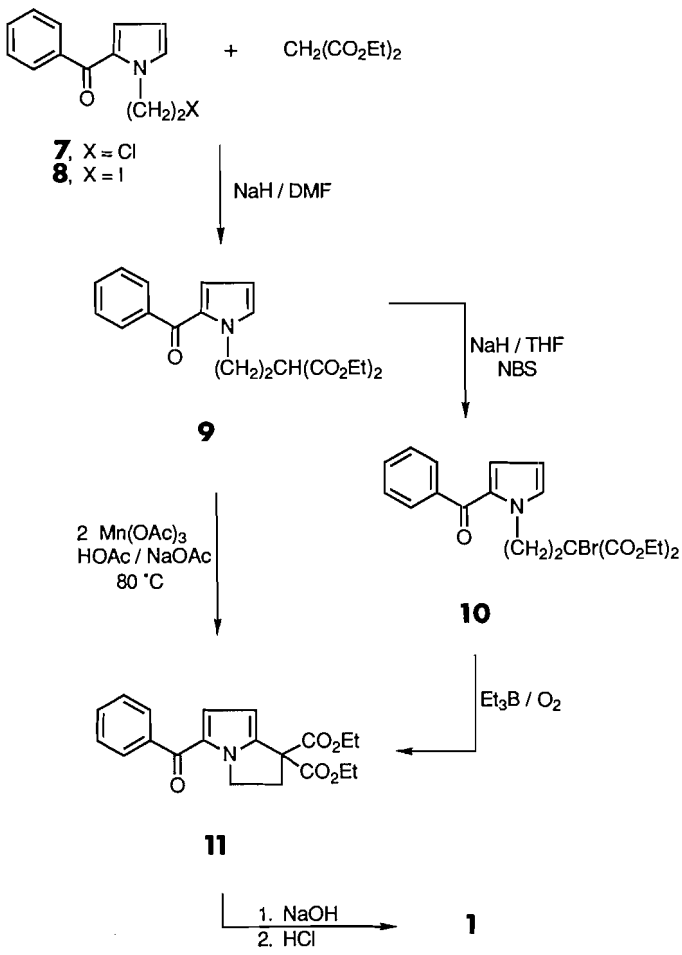

SCHEME 2

directly in 80% yield. This, therefore, is the shortest and most efficient (64% overall yield from 2-benzoylpyrrole) synthesis of ketorolac published to date.

The regiospecificity of the reaction of the diethyl malonyl, diethyl chloromalonyl, and tri(ethoxycarbonyl)methyl radicals with 2-benzoylpyrrole is especially noteworthy. The outcome of these reactions can be accounted for on the basis of the principles of the Frontier Molecular Orbital Theory, the regiospecificity being related to the relative values of the squares of the coefficients of the appropriate molecular orbitals of the potential positions of substitution (16). The attacking radicals are all electron deficient and therefore one would expect that the SOMO's thereof would interact preferentially with the HOMO of 2-benzoylpyrrole. Examination of the squares of the coefficients of both the HOMO and the LUMO of 2-benzoylpyrrole (Table 1) indicates a strong preference for substitution at C-5, as is observed, if the reactions occur through the HOMO.

Experimental

The melting points were determined in a Thomas Hoover "uni melt" capillary melting point apparatus and are not corrected. The infrared spectra were measured with a Nicolet 5 PC FT infrared spectrophotometer. The ^1H nmr spectra were recorded with a Bruker WM 300 or a Bruker AM 500 nmr spectrometer in deuteriochloroform and are expressed as parts per million (δ) from internal tetramethylsilane. The high-resolution mass spectra were obtained with a Finnigan MAT 311A mass spectrometer on samples that were at least 95% pure as judged by nmr spectrometry.

The terms "worked up in the usual manner" or "the usual work-up" signify that the extract was washed with water, dried over sodium sulfate, and evaporated *in vacuo*.

1-(2-Iodoethyl)-2-benzoylpyrrole (8)

A solution of the known (6) chloro compound **7** (11.4 g, 49 mmol) in acetonitrile (250 mL) containing sodium iodide (14.7 g, 98 mmol) was heated at reflux temperature for 24 h. The cooled solution was concentrated to a small volume *in vacuo*, water was added to the residue, and the product was extracted into ethyl acetate. After the usual work-up, the residue was subjected to column chromatographic purification on silica gel using hexane – ethyl acetate (97:3) as the eluting solvent. Compound **8**, which because of its solvolytic sensitivity should be used immediately in the next step, was obtained as an oil (12.7 g, 80%); ir (neat): 1623 cm^{-1}; nmr (300) δ: 3.58 (t, 2H, J = 6.84 Hz, CH_2I), 4.71 (t, 2H, J = 6.84 Hz, NCH_2), 6.20 (dd, 1H, $J_{3,4}$ = 4.06 Hz, $J_{4,5}$ = 2.58 Hz, H-4), 6.81 (dd, 1H, $J_{3,4}$ = 4.06 Hz, $J_{3,5}$ = 1.67 Hz, H-3) 7.04 (t, 1H, H-5), 7.43–7.58 (m, 3H), 7.79 (dd, 2H, J_o = 8.27 Hz, J_m = 1.4 Hz); *m/e* calcd. for $C_{13}H_{12}INO$: 324.9962; found: 324.9960.

1-(3,3-Diethoxycarbonylpropyl)-2-benzoylpyrrole (9)

Sodium hydride (60% in mineral oil, 1.35 g, 34 mmol) was added portionwise to a stirred solution of diethyl malonate (5.4 g,

Position	HOMO	LUMO
3	0.0920	0.1048
4	0.1483	0.0013
5	0.3347	0.0904

[a]The molecular orbital coefficients are derived from semi-empirical molecular orbital calculations on fully optimized structures. The calculations were carried out using the MNDO Hamiltonian within the implementation of MOPAC 4.0 as released in SYBYL 5.32.

34 mmol) in dry DMF (50 mL) at 0°C. The reaction mixture was then stirred at room temperature for 0.5 h after which time a solution of the iodo compound **8** (11.0 g, 34 mmol) in dry DMF (50 mL) was added. The reaction mixture was stirred at room temperature for 16 h, poured into water, and extracted with ethyl acetate. The extract was washed with water and with saturated NaCl solution, then it was dried (Na_2SO_4) and evaporated *in vacuo*. The residual oil was purified by column chromatography on silica gel using hexane – ethyl acetate (9:1) to elute the malonate ester **9** (9.85 g, 82%) as an oil; ir (neat): 1748, 1732, 1628 cm^{-1}; nmr (500) δ: 1.22 (t, 6H, J = 7.0 Hz, Me), 2.40 (q, 2H, J = 7.2 Hz, CH_2CH), 3.32 (t, 1H, J = 7.3 Hz, CH), 4.15 (q, 4H, J = 7.0 Hz, OCH_2), 4.47 (t, 2H, J = 7.0 Hz, NCH_2), 6.14 (dd, 1H, $J_{3,4}$ = 4.12 Hz, $J_{4,5}$ = 2.58 Hz, H-4), 6.70 (dd, 1H, $J_{3,4}$ = 4.12 Hz, $J_{3,5}$ = 1.76 Hz, H-3), 6.94 (t, 1H, H-5), 7.40 (m, 2H), 7.47 (m, 1H), 7.74 (m, 2H); *m/e* calcd. for $C_{20}H_{23}NO_5$: 357.1576, found: 357.1580.

*1-(3,3-Diethoxycarbonyl-3-bromopropyl)-2-benzoylpyrrole (**10**)*

Sodium hydride (60% in mineral oil, 0.14 g, 3.45 mmol) was added portionwise to a stirred solution of compound **9** (1.12 g, 3.14 mmol) in dry THF (50 mL) at 0°C. The reaction mixture was then agitated at room temperature for 0.5 h after which time *N*-bromosuccinimide (0.64 g, 3.45 mmol) was added. After a further 0.5 h, the reaction mixture was poured into water and the product was extracted into ether. The extract was washed with water and with saturated NaCl solution, and then it was dried and evaporated in *in vacuo*. The residue was subjected to column chromatographic purification on silica gel using hexane – ethyl acetate (9:1) to elute the bromo compound **10** (1.15 g, 84%) as an oil; ir (neat): 1741, 1627 cm^{-1}; nmr (300) δ: 1.29 (t, 6H, J = 7.13 Hz, Me), 2.87 (t, 2H, J = 7.37 Hz, CH_2), 4.26 (m, 4H, OCH_2), 4.61 (d, 2H, J = 7.37; NCH_2), 6.17 (dd, 1H, $J_{3,4}$ = 4.07 Hz, $J_{4,5}$ = 2.55 Hz, H-4), 6.73 (dd, 1H, $J_{3,4}$ = 4.07 Hz, $J_{3,5}$ = 1.68 Hz, H-3), 7.26 (t, 1H, H-5), 7.44–7.56 (m, 3H), 7.77 (dd, 2H, J_o = 8.2 Hz, J_m = 1.4 Hz). Anal. calcd. for $C_{20}H_{22}BrNO_5$: C 55.05; H 5.08, N 3.21; found: C 54.98, H 5.25, N 3.17.

*Diethyl 5-benzoylpyrrol-2-yl-(α-acetoxy)malonate (**13**)*

(a) From 2-benzoylpyrrole and diethyl malonate

A solution of 2-benzoylpyrrole (0.855 g, 5 mmol) and diethyl malonate (0.800 g, 5 mmol) in acetic acid (30 mL) containing manganese triacetate trihydrate (4.56 g, 15 mmol) and sodium acetate (0.820 g, 10 mmol) was stirred at 70°C under a nitrogen atmosphere for 4 h. The reaction mixture was cooled, diluted with ether, and filtered. The filtrate was washed with 10% NaOH solution and saturated NaCl solution, and then it was dried and evaporated *in vacuo*. The residue was subjected to column chromatographic purification on silica gel using hexane – ethyl acetate (7:3) to elute the α-acetoxy compound **13** (1.10 g, 57%) as an oil; ir (neat): 3426, 3263, 1753, 1629 cm^{-1}; nmr (300) δ: 1.30 (t, 6H, J = 7.13 Hz, Me), 2.25 (s, 3H, MeCO), 4.33 (m, 4H, OCH_2), 6.40 (dd, 1H, $J_{3,4}$ = 3.97 Hz, $J_{NH,3}$ = 2.65 Hz, H-3), 6.78 (dd, 1H, $J_{3,4}$ = 3.97 Hz, $J_{NH,4}$ = 2.65 Hz, H-4), 7.47–7.58 (m, 3H), 7.87 (dd, 2H, J_o = 8.30 Hz, J_m = 1.4 Hz), 10.31 (bs, 1H, NH); *m/e* calcd. for $C_{20}H_{21}NO_7$: 387.1318; found: 387.1326.

(b) From 2-benzoylpyrrole and diethyl chloromalonate

The reaction was carried out exactly as in (*a*) and on the same scale but diethyl chloromalonate was used. Compound **13** was obtained in 75% yield.

*Diethyl 5-benzoylpyrrole-2-malonate (**14**)*

*(a) By reduction of acetoxy compound **13***

Trifluoroacetic acid (0.168 g, 1.47 mmol) was added to a solution of the acetoxy compound **13** (0.142 g, 0.367 mmol) in dichloromethane (10 mL) containing triethylsilane (0.102 g, 0.440 mmol) and the solution was then stirred at 40°C for 24 h. Additional triethylsilane (0.102 g) and trifluoroacetic acid (0.168 g) were added and stirring at 40°C was continued for a further 24 h. The cooled solution was washed with cold 10% NaOH solution and then worked up in the usual manner. The residue was subjected to column chromatographic purification on silica gel, the product (0.060 g, 50%) being eluted with hexane – ethyl acetate (87:13) as an oil; ir (neat): 3264, 1739, 1611 cm^{1}; nmr (300) δ: 1.30 (t, 6H, J = 7.23 Hz, Me), 4.26 (m, 4H, OCH_2), 4.81 (s, 1H, CH), 6.29 (d, 1H, $J_{3,4}$ = 3.9 Hz, H-3),[5] 6.80 (d, 1H, $J_{3,4}$ = 3.98 Hz, H-4),[5] 7.45–7.56 (m, 3H), 7.88 (m 2H), 10.19 (bs, 1H, NH). Anal. calcd. for $C_{18}H_{19}NO_5$: C 65.64, H 5.81, N 4.25; found: C 65.61, H 5.80, N 4.25.

(b) From 2-benzoylpyrrole and diethyl bromomalonate

A 1.0 M solution of triethylborane in hexane (2 mL) was added to a stirred solution of 2-benzoylpyrrole (0.171 g, 1.0 mmol) and diethyl bromomalonate (1.185 g, 5.0 mmol) in benzene (20 mL) that was open to the atmosphere. Additional triethylborane solution was added at the end of 1 h (2 mL) and 2 h (1 mL) at room temperature. The reaction mixture was poured into water and extracted with ether. The ether extract was washed with saturated NaCl solution and then worked up in the usual manner. After purification of the crude product as described above, the pure malonate **14** was obtained as an oil (0.284 g, 86%) identical to that prepared by method (*a*).

*(c) By deethoxycarbonylation of triester **15***

Ethanol (0.176 mL, 0.138 g, 3.0 mmol) was added to a stirred suspension of 50% sodium hydride in mineral oil (0.048 g, 1.0 mmol) in anhydrous DMF (10 mL). After ca. 10 min a solution of **15** (0.403 g, 1 mmol) in dry DMF (5 mL) was added and stirring was continued for 2 h at room temperature. The reaction mixture was poured into aqueous ammonium chloride solution and the product was extracted into ethyl acetate. After the usual work-up the crude malonate ester **14** was purified by column chromatography on silica gel (40 g) using hexane – ethyl acetate (4:1) as the eluting solvent. Pure **14** was obtained as an oil (0.273 g, 83%) identical to material prepared by methods (*a*) or (*b*).

*Diethyl 5-benzoyl-1,2-dihydro-3H-pyrrolo[1,2-a]pyrrole-1,1-dicarboxylate (**11**)*

*(a) By Mn(III) induced cyclization of **9***

Potassium permanganate (0.138 g, 0.875 mmol), acetic anhydride (1.25 mL, 1.35 g, 10.5 mmol), and sodium acetate (0.420 g, 5 mmol) were added sequentially to a stirred solution of manganese diacetate tetrahydrate (0.858 g, 3.5 mmol) in acetic acid (8 mL) at 80°C. A solution of the malonate ester **9** (0.500 g, 1.40 mmol) in acetic acid (2 mL) was added thereto and the solution was stirred at 80°C for 6 h. The solution was poured into water and the product was extracted into toluene. After the usual work-up the bicyclic ester **11** was obtained as an oil (0.478 g, 96%), which was pure as judged by nmr spectroscopy; ir (neat): 1738, 1626 cm^{-1}; nmr (500) δ: 1.29 (t, 6H, J = 7.10 Hz, Me), 3.13 (t, 2H, J = 7.0 Hz, CH_2C), 4.26 (q, 4H, J = 7.10 Hz, OCH_2), 4.54 (t, 2H, J = 7.0 Hz, NCH_2), 6.27 (d, 1H, $J_{6,7}$ = 4.07 Hz, H-7), 6.84 (d, 1H, $J_{6,7}$ = 4.07 Hz, H-6), 7.43–7.54 (m, 3H), 7.82 (dd, 2H, J_o = 8.3 Hz, J_m = 1.4 Hz); *m/e* calcd. for $C_{20}H_{21}NO_5$: 355.1420; found: 355.1413.

*(b) From **9** using Mn(II) and sodium persulfate*

A solution of manganese diacetate tetrahydrate (0.343 g, 1.40 mmol), silver nitrate (0.024 g, 0.14 mmol), sodium acetate (0.420 g, 5 mmol), acetic anhydride (0.5 mL, 0.54 g, 4.20 mmol), and sodium persulfate (0.333 g, 1.40 mmol) in acetic acid (8 mL) was stirred at 80°C for 0.5 h. A solution of the malonate ester **9** (0.500 g, 1.4 mmol) in acetic acid (2 mL) and additional sodium persulfate (0.333 g, 1.4 mmol) were added and the solution was stirred at 80°C for 12 h. After work-up of the reaction mixture as described in (*a*) compound **11**, identical to that obtained above, was isolated as an oil (0.475 g, 95%).

*(c) By the triethylborane induced cyclization of bromomalonate **10***

This reaction was carried out exactly as described for the synthesis of compound **14** from 2-benzoylpyrrole and diethyl bromomalonate. The crude product was purified by column chromatography on silica gel using hexane – ethyl acetate (85:15). Compound **11** was isolated in 75% yield.

*(d) From malonate ester **14** and 1,2-dichloroethane*

A mixture of tetra-*n*-butylammonium bromide (0.130 g, 0.40 mmol) and potassium carbonate (2.76 g, 20 mmol) in 1,2-dichloroethane (16 mL) containing compound **14** (0.132 g, 0.40 mmol) was stirred at reflux temperature until the starting material had disappeared (~ 24 h). The mixture was filtered and the filtrate was evaporated *in vacuo*. The residue was taken up in ether and after the usual work-up the crude material was purified by column chromatography on silica gel using hexane – ethyl acetate (9:1) as the eluant. The product was isolated in 67% yield.

*(e) From triester **15** and 1,2-dichloroethane*

A reaction performed on a 5 mmol scale exactly as described in (*d*) gave **11** in 80% yield.

*5-Benzoyl-1,2-dihydro-3H-pyrrolo[1,2-a]pyrrole-1-carboxylic acid (**1**, ketorolac)*

A biphasic mixture of the diester **11** (0.600 g, 1.69 mmol) in ether (20 mL) and 20% aqueous NaOH (10 mL) was vigorously stirred at reflux temperature for 24 h. The aqueous layer was washed with ether, carefully made acidic with concentrated hydrochloric acid, and extracted with ethyl acetate. The extract was heated at 70°C for 4 h and then evaporated *in vacuo* to give **1** (0.400 g, 93%) as a solid identical in all respects to an authentic specimen of ketorolac.

[5]After exchange with D_2O.

Acknowledgement

We thank Saul Jaime for converting the triester **15** to the malonate ester **14** and for preparing an analytical specimen of the latter compound.

Détermination par voie électrochimique des propriétés acido-basiques et oxydo-réductrices des solutions concentrées en acide phosphorique progressivement neutralisées par la soude

J. BESSIÈRE[1] ET M. K. AROUA

Laboratoire de chimie et d'électrochimie analytique, Université de Nancy 1, 54506 Vandoeuvre-lès-Nancy, France

Reçu le 25 avril 1991[2]

J. BESSIÈRE et M. K. AROUA. Can. J. Chem. **70**, 1843 (1992).

Les propriétés acido-basiques des milieux H_3PO_4 7 M progressivement neutralisés par la soude sont caractérisés par la fonction d'acidité $R(H)$ et les fonctions basiques $R(H_2PO_4^-)$, $R(HPO_4^{2-})$, $R(PO_4^{3-})$ qui représentent repectivement l'activité du proton et le pouvoir donneur des ions $H_2PO_4^-$, HPO_4^{2-}, PO_4^{3-}. Le niveau d'acidité de ces milieux (Na/P = 0,0–1,6) passe de $R(H) = -2,7$ à $R(H) = +7,5$. Le domaine des potentiels accessibles dans les différents milieux est voisin de 1,23 V. Les valeurs de l'activité en eau des solutions varient entre 0,66 et 0,81. Les domaines d'électroactivité aux électrodes de platine, de carbone et de mercure sont également précisés.

J. BESSIÈRE and M. K. AROUA. Can. J. Chem. **70**, 1843 (1992).

Acid–base properties in 7 M H_3PO_4 medium neutralized by soda are characterized with an $R(H)$ acidity function and $R(H_2PO_4^-)$, $R(HPO_4^{2-})$, $R(PO_4^{3-})$ basicity functions, which respectively represent the H^+ activity in these media and their ability to donate $H_2PO_4^-$, HPO_4^{2-}, PO_4^{3-} ions. The acidity level of these media (Na/P = 0.0–1.6), changes from $R(H) = -2.7$ to $R(H) = +7.5$. The accessible potential domain for the media studied is close to 1.23 V. Activities of these solutions in water vary between 0.66 and 0.81. The ranges of electroactivity for platinum, carbon, and mercury electrodes are also determined.

Introduction

L'analyse et la prévision des réactions dans les milieux phosphoriques neutralisés présentent un intérêt majeur dans le domaine de la synthèse des engrais et de l'élaboration de produits purs destinés à l'industrie alimentaire et au traitement de surface (1–3). Au cours des opérations de synthèse, la concentration ainsi que le rapport base/acide sont susceptibles de varier dans une large gamme. De la teneur en acide et du rapport base/acide vont dépendre le pouvoir oxydo-réducteur des solutés, la stabilité de nombreux composés, la protonation des bases, la quantitativité des réactions de titrage *in situ*, le pouvoir extractant des agents chelatants en milieu non miscible ou des résines échangeuses d'ions. Les caractéristiques électrochimiques du solvant et des solutés sont également modifiées ainsi que les grandeurs cinétiques.

La prévision de nombreuses réactions dans les milieux concentrés s'effectue à partir des diagrammes potentiel – niveau d'acidité, en adoptant les mêmes raisonnements que dans l'eau (4–11).

On peut à partir de ces diagrammes évaluer les coefficients de transfert de solvatation des différentes espèces et prévoir les constantes thermodynamiques dans ces milieux réactionnels connaissant celles en solutions aqueuses diluées.

Plusieurs auteurs (7, 9) ont signalé l'importance du facteur activité de l'eau dans la fixation du niveau d'acidité des milieux eau–acide.

Comme dans les cas des solutions aqueuses concentrées en sel (12–16), la réctivité des espèces dans les milieux concentrés en acide, neutralisés ou non, dépend à la fois de l'activité de l'eau et de la solvatation spécifique des solutés par les ions du solvant. Il est important d'évaluer la part respective de ces deux influences pour prévoir ensuite les réactions en fonction de taux de neutralisation de l'acide. Cette démarche justifie donc la mesure de l'activité en eau dans une première étape. Il conviendra ensuite de comparer les équilibres dans les milieux phosphoriques et dans les milieux non complexants présentant la même activité en eau (milieux isopiestiques).

Avant d'envisager l'étude de la réactivité des solutés dans les milieux H_2O–H_3PO_4–NaOH, il importe, tant du point de vue industriel que du point de vue fondamental de la connaissance des milieux réactionnels, de préciser les propriétés caractéristiques du solvant : niveau d'acidité, propriétés redox, activité en eau, aptitude à céder les ions phosphate, domaine d'électroactivité aux électrodes de platine, mercure et carbone.

L'examen a porté sur la neutralisation de l'acide H_3PO_4 7 M par une solution de soude 18 M (50% en poids). Ces concentrations correspondent aux conditions habituellement rencontrées dans l'industrie du tripolyphosphate de sodium.

Partie expérimentale

Réactifs

Tous les réactifs utilisés sont de qualité pour analyse.

Acid phosphorique : Prolabo; soude en pastilles : Prolabo; ferrocène : Sigma; 3,4,5,6-tetrachloro-1,2-benzoquinone (*o*-chloranile) : Fluka; réactif de Karl–Fisher : Merck; phosphate acide mercureux : préparé par oxydation électrochimique du mercure dans H_3PO_4 5,5 M.

Préparation des solutions

L'acide phosphorique 7 M est neutralisé par une solution de soude 18 M (environ 50%). L'opération est réalisée à température contrôlée (80°C) et sous reflux. Le taux de neutralisation, exprimé par le rapport molaire Na/P, varie de 0,0 à 1,6. Au delà de cette valeur, il y a cristallisation à température ambiante. Les concentrations des espèces NaH_2PO_4 et Na_2HPO_4 sont alors respectivement égales à 1,7 et 2,6 M.

La solution mère de ferricinium (Fc^+ 0,1 M) est préparée en réalisant l'oxydation du ferrocène par le p-chloranile en milieu biphasique toluène–H_3PO_4 7 M (17).

Equipements

Les mesures potentiométriques à intensité nulle ont été faites au moyen du millivoltmètre Minisis 6000 Tacussel. Les tracés voltampérométriques sur électrodes solides ont été réalisés en utilisant un montage classique à trois électrodes et un ensemble Tipol EPL 2 Tacussel. Le dégazage des milieux réactionnels est effectué par barbotage d'azote.

Les différentes électrodes de travail utilisées sont l'électrode tournante de platine (EDI controvit Tacussel) et l'électrode tournante à pâte de carbone (EDI controvit Tacussel). La vitesse de rotation est de 600 tours/min.

L'électrode au calomel aqueuse, placée dans un compartiment séparé contenant H_3PO_4 0,1 M, est utilisée comme électrode de référence.

L'électrode auxiliaire est constituée par un fil de platine.

L'électrode à pâte de carbone, contenant l'*o*-chloranile peu soluble, est préparée selon le méthode décrite par Adams *et al.* (18, 19). L'*o*-chloranile insérée dans l'électrode est sous la forme quinonique. L'électrode est portée à un potentiel suffisamment réducteur pour que la forme réduite se forme à l'interface solide–liquide. On réalise ensuite les tracés voltampérométriques qui permettent d'apprécier la réversibilité et la rapidité du système considéré. Le mélange *o*-chloranile–hydrochloranile peut également être utilisé directement.

L'électrode à pâte de carbone, à base de phosphate mercureux, est préparée de la même manière que la précédente.

L'activité en eau des différents milieux est déterminée à 25°C par la méthode de transpiration, à partir de la mesure des pressions partielles d'eau. Le dispositif utilisé, représenté figure 1, est similaire à celui décrit par Davis et De Bruin (20), Bent et Francel (21) et Majima et coll. (22). Le capteur d'eau est remplacé par l'appareil Karl–Fisher Metrohm. On peut ainsi réduire considérablement le temps de mesure qui devient inférieur à 3 h.

L'eau contenue dans l'azote est éliminée par passage à travers un tamis moléculaire (3Å). L'azote, régulé à un débit constant, passe dans un présaturateur D, contenant 2–5 cm^3 de la solution à analyser, puis dans le saturateur E et la cellule de dosage coulométrique H. Le saturateur, contenant environ 40 cm^3 de la solution, et le pré-saturateur sont maintenus à température constante (25 ± 0,5°C). Le tube entre le saturateur et la cellule est chauffé pour éviter la condensation de l'eau.

La masse d'eau en gramme (W_{H_2O}) transportée par un volume (V_{N_2}) d'azote est déterminée par dosage coulométrique par la méthode Karl–Fisher.

La pression partielle de l'eau est donnée par la relation :

$$[1] \qquad p_{H_2O} = \frac{W_{H_2O}RT}{18\ V}$$

où W_{H_2O} est la masse d'eau dosée au cours de l'expérience et V est le volume de la phase gaseuse, donné par la relation :

$$[2] \qquad V = V_{N_2} + V_{H_2O}$$

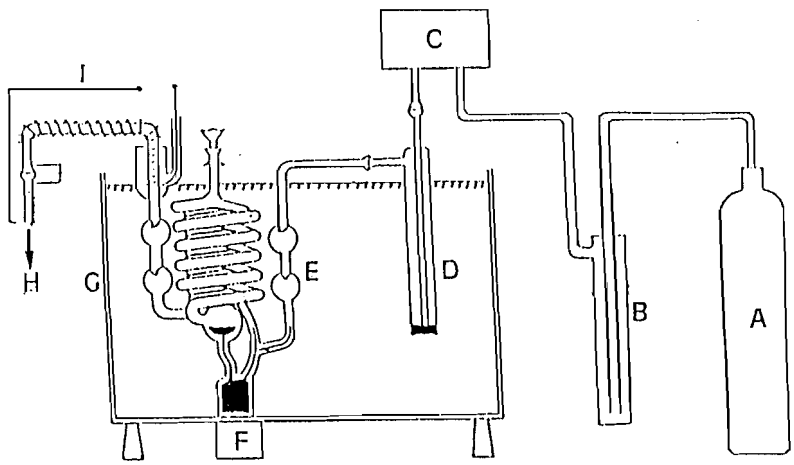
La valeur de V_{N_2} est calculée à partir du débit de gaz et de la durée de l'expérience, alors que V_{H_2O} est déterminé à partir de W_{H_2O} et de la pression atmosphérique pendant l'expérience.

Résultats et discussions

1. Fonction d'acidité R*(H) des milieux H_2O–H_3PO_4–NaOH*

Le niveau d'acidité est caractérisé par la fonction d'acidité R(H) qui peut être déterminée expérimentalement à partir de la mesure du potentiel pris par une électrode indicatrice de pH en utilisant le système ferricinium/ferrocène (Fc^+/Fc) comme référence de potentiel.

Lorsque l'on utilise le système quinone/hydroquinone (Q(s)/QH_2(s)), la fonction R(H) est donnée par la relation :



A: Bouteille d'azote

B: Tamis moléculaire (3 Å)

C: Débimètre

D: Pré-saturateur

E: Saturateur

F: Agitateur magnétique

G: Bain thermostaté

H: Vers la cellule de dosage Karl-Fisher

FIG. 1. Schéma du dispositif utilisé pour la mesure de l'activité en eau.

TABLEAU 1. Variation des propriétés acido-basiques des milieux H_3PO_4 7 M progressivement neutralisés par la soude, en fonction du taux de neutralisation (Na/P)

	Na/P									
	0,0	0,2	0,4	0,6	0,8	0,9	1,1	1,2	1,4	1,6
$E_{1/2}$ Fc^+/Fc (mV vs. ECS)	−85	−30	+30	+90	+130	+180	+190	+200	+220	+250
a_{H_2O}	0,66	0,72	0,70	0,75	0,78	0,81	0,80	0,80	0,75	—
R(H)	−2.7	−1.9	−0,8	+0,6	+1,9	+3,3	+4,9	+5,7	+6,9	+7,5
$R(H_2PO_4^-)$	+5,3	+4,5	+3,6	+2,8	+2,2	+1,8	+1,6	+1,5	+1,0	0.0
$R(HPO_4^{2-})$	+15,3	+13,6	+11,6	+9,5	+7,5	+5,6	+3,9	+3,0	+1,3	−0.2
$R(PO_4^{3-})$	+30,4	+27,9	+24,9	+21,3	+18,0	+14,7	+11,4	+9,7	+6,8	+4,7

$$[3] \quad R(\mathrm{H}) = \frac{E^{H_2O}_{Q(s)/QH_2(s)} - E^{S}_{Q(s)/QH_2(s)}}{0{,}058}$$

où $E^{H_2O}_{Q(s)/QH_2(s)}$ est le potentiel standard du système Q(s)/QH_2(s) dans l'eau et $E^{S}_{Q(s)/QH_2(s)}$ son potentiel dans la solution étudiée, exprimés par rapport au système Fc^+/Fc.

La fonction R(H) s'identifie au pH si l'on admet que le potentiel standard du système ferricinium/ferrocène est indépendant de la nature du solvant (23, 24). Dans la relation

$$[4] \quad \mathrm{pH} = R(\mathrm{H}) + \log \frac{f_{Fc}}{f_{Fc^+}}$$

les coefficients d'activité f_{Fc} et f_{Fc^+} sont alors égaux, l'état de réference étant la solution aqueuse infiniment diluée.

1.1. Système de comparaison : ferricinium/ferrocène (Fc^+/Fc)

La rapidité et la réversibilité du système Fc^+/Fc dans les milieux concentrés en acide phosphorique ont été démontrées par voltampérométrie cyclique sur électrode de carbone vitreux ainsi que sur électrode fixe de mercure (9, 28).

Dans tout le domaine Na/P envisagé, seul un signal correspondant à la réduction rapide de l'espèce Fc^+ est mis en évidence en voltampérométrie sur l'électrode tournante de platine : l'analyse mathématique des tracés voltampérométriques donne des pentes comprises entre 55 et 60 mV.

Étant données les caractéristiques de rapidité et de réversibilité du système Fc^+/Fc, son potentiel normal est pris égal au potentiel de demi-vague de réduction de Fc^+. Les valeurs expérimentales figurent dans le tableau 1.

1.2. Système indicateur de H^+ : chloranile/hydrochloranile ($C_{(s)}/CH_{2(s)}$)

Le système indicateur d'acidité engage le couple de l'*o*-chloranile. L'*o*-chloranile et l'hydrochloranile étant insolubles, le potentiel du système

$$[5] \quad C_{(s)} + 2H^+ + 2e^- \rightleftharpoons CH_{2(s)}$$

ne dépend que du niveau d'acidité. Le bon fonctionnement de l'électrode à pâte de carbone dans laquelle est inséré l'*o*-chloranile a été vérifié dans plusieurs milieux acides concentrés (7, 17). Les courbes intensité–potentiel montrent que le potentiel à intensité nulle est bien défini et stable.

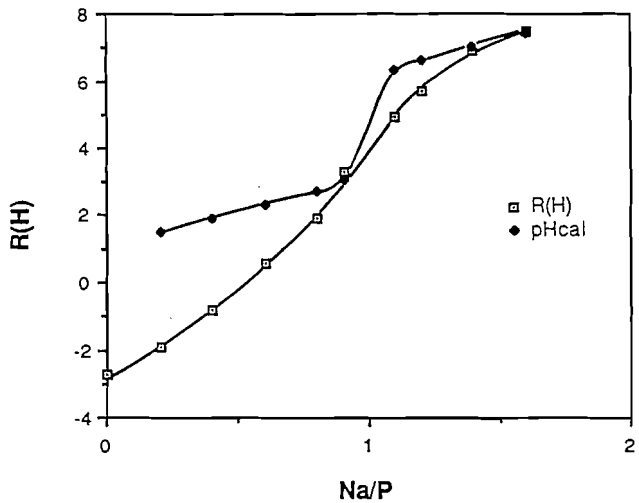


FIG. 2. Variation de la fonction R(H) des milieux H_3PO_4 7 M progressivement neutralisés par la soude, en fonction du rapport Na/P. Comparaison avec la variation de pH calculé.

1.3. Fonction R(H)

La fonction d'acidité R(H), représentée figure 2, varie de 10,2 unités lorsque le rapport Na/P passe de 0,0 à 1,6. Elle rend compte de deux effets : (*i*) le premier est directement lié au taux de neutralisation de l'acide fixé par la valeur du rapport Na/P; (*ii*) le second traduit l'influence de l'eau apportée d'une part par la solution aqueuse de soude et d'autre part par la neutralisation elle même.

Les résultats récents de N. Medouni (27) concernant la neutralisation de H_3PO_4 5,5 M par les pastilles de soude montrent que pour une même valeur du rapport (Na/P = 1,0), le niveau d'acidité est moins élevé (R(H) = +3,2 au lieu de +4,0 environ d'après la figure 2).

Il est intéressant de comparer la fonction R(H) des milieux neutralisés avec les valeurs du pH calculées en utilisant la formule appliquée en solution diluée. Pour un rapport Na/P inférieur à 1,0, on a la relation :

$$[6] \quad \mathrm{pH_{cal}} = 2{,}1 + \log \frac{\mathrm{Na/P}}{1 - \mathrm{Na/P}}$$

pour les rapports Na/P supérieurs à 1,0 et inférieurs à 2,0, on a la relation :

$$[7] \quad \mathrm{pH_{cal}} = 7{,}2 + \log \frac{\mathrm{Na/P} - 1}{2 - \mathrm{Na/P}}$$

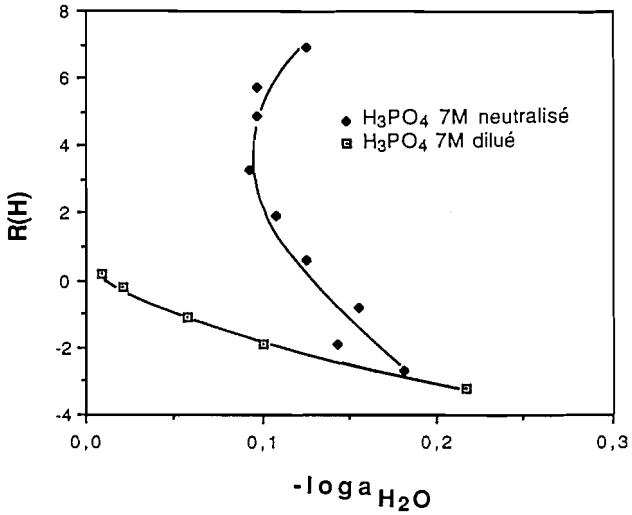

FIG. 3. Variation du niveau d'acidité avec l'activité en eau. Milieux H_3PO_4 7,0 M neutralisé et dilué.

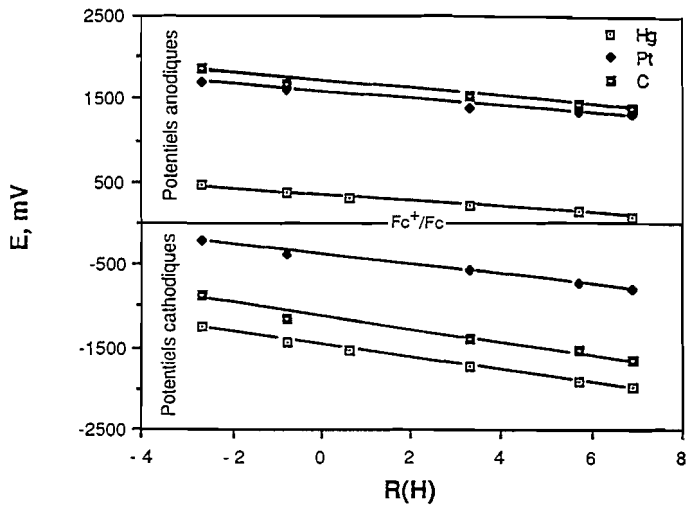

FIG. 4. Domaines d'électroactivité aux électrodes de mercure, carbone vitreux et platine dans les milieux H_3PO_4 7,0 M progressivement neutralisés par la soude (densité maximale de courant 0,2 m A/cm^2).

On constate (figure 2) que la différence $pH_{cal} - R(H)$ devient supérieure à 1,5 unités pour des taux de neutralisation Na/P inférieurs à 0,6. La fonction $R(H)$ ne fait pas apparaître l'effet tampon comme les valeurs du pH_{cal}. Par contre, pour des taux de neutralisation supérieurs à 0,6, on note des écarts réduits au voisinage de la demi-neutralisation de la deuxième fonction acide où les deux courbes sont pratiquement confondues.

2. Activité en eau dans les milieux H_2O–H_3PO_4–NaOH

Les valeurs de a_{H_2O}, regroupées dans le tableau 1, sont données à 5% près. La neutralisation de l'acide H_3PO_4 7 M se traduit par une faible variation de l'activité en eau des solutions. Celle-ci augmente légèrement jusqu'à Na/P = 0,9. Au delà de 1,2, l'activité en eau décroît.

La solution correspondant à Na/P = 1,0 a une molalité en NaH_2PO_4 de 7,3 mol/kg. La valeur correspondante de a_{H_2O} (0,80) est en bon accord avec les données de Robinson et Stokes (0,82) (25). Dans le cas où la neutralisation est réalisée avec de la soude en pastilles, l'activité en eau et le niveau d'acidité sont respectivement égaux à 0,74 et +3,2.

La comparaison des courbes $R(H) = f(\log a_{H_2O})$ (figure 3) relatives aux solutions diluées de l'acide 7 M d'une part et aux solutions neutralisées d'autre part montre que la variation du terme $\log a_{H_2O}$ est inférieur à 0,1 unité pour les solutions neutralisées. On peut dès à présent affirmer que la variation de réactivité des espèces ioniques qui sera observée au cours de la neutralisation est due principalement à une modification de leur solvatation spécifique par les ions phosphate du milieu, l'activité en eau ne variant pratiquement pas, contrairement à ce que l'on observe dans le cas de l'acide 7 M progressivement dilué.

3. Domaines d'électroactivité et de potentiel accessible dans les milieux H_2O–H_3PO_4–NaOH

Les domaines d'électroactivité aux électrodes de mercure, carbone vitreux et platine sont établis pour une densité de courant de 0,2 mA/cm^2. Les résultats sont présentés en fonction de $R(H)$ dans la figure 4. On remarque que l'étendue du domaine d'électroactivité varie légèrement avec le taux de neutralisation (0,3 V de Na/P = 0,0–1,4). Les électrodes étudiées permettent d'explorer un large domaine de potentiel, environ 3 V, peu différent de celui dans l'eau. On utilisera l'électrode de mercure pour explorer les potentiels réducteurs et l'électrode de platine pour les potentiels oxydants.

D'un point de vue thermodynamique, le domaine des potentiels accessibles dans les milieux H_2O–H_3PO_4–NaOH est limité par les propriétés oxydantes du proton et les propriétés réductrices de l'eau. Les limites sont fixées par la variation des potentiels des systèmes $H^+/H_2(g)$ et $O_2(g)/H_2O$ avec le taux de neutralisation.

La variation du pouvoir oxydant du solvant ne dépend que du niveau d'acidité : L'équilibre

[8] $$2H^+ + 2e^- \rightleftharpoons H_2(g)$$

est caractérisé par la relation

[9] $$E = -0{,}400 - 0{,}058\,R(H)$$

où −0,400 V représente le potentiel normal du système de l'hydrogène dans l'eau par rapport au système du ferrocène (23).

La limite thermodynamique des potentiels accessibles en oxydation correspond à l'oxydation des molècules d'eau. Elle dépend donc du niveau d'acidité et de l'activité en eau. À l'equilibre

[10] $$O_2(g)^+ + 4H^+ + 4e^- \rightleftharpoons 2H_2O$$

correspond la relation

[11] $$E = 0{,}829 - 0{,}058\,R(H) - 0{,}029 \log a_{H_2O}$$

La valeur 0,829 représente le potentiel normal de l'oxygène dans l'eau par rapport au ferrocène (9).

Les valeurs calculées à partir des expressions précédentes sont rassemblées dans le tableau 1 et présentées figure 5. L'étendue du domaine thermodynamique reste très proche de 1,23 V compte tenu de la faible variation de l'activité en

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

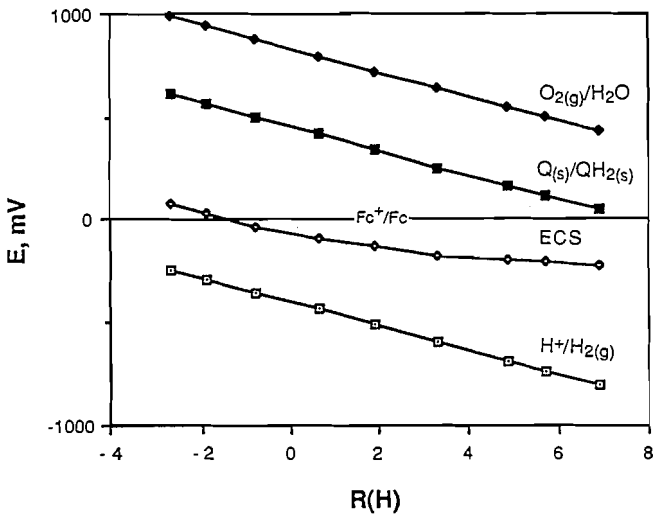

FIG 5. Propriétés oxydo-réductrices, déterminées par voie électrochimique, des milieux H_3PO_4 7,0 M progressivement neutralisés par la soude.

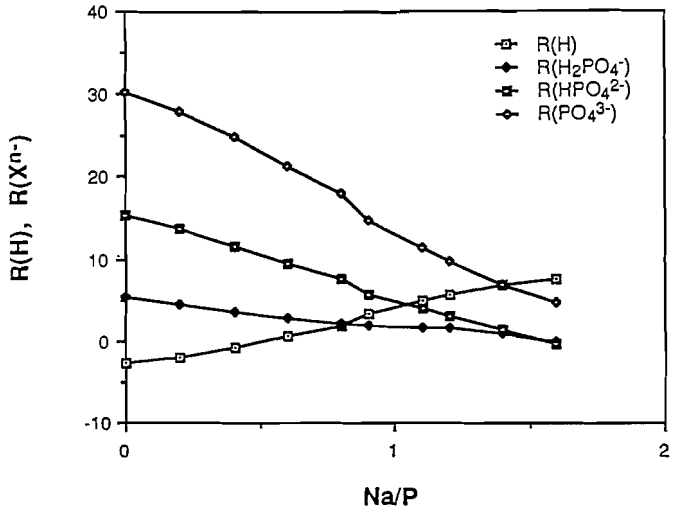

FIG. 6. Aptitude des milieux H_3PO_4 7,0 M progressivement neutralisés par la soude, à céder leurs espèces. Fonction d'acidité et fonctions basiques.

eau. On retrouve un résultat similaire dans les milieux H_2O–H_3PO_4 (7).

4. Fonctions basiques des milieux H_2O–H_3PO_4–NaOH

La fonction $R(H)$ traduit l'aptitude des milieux H_2O–H_3PO_4–NaOH à céder la particule H^+. Par analogie, les fonctions $R(H_2PO_4^-)$, $R(HPO_4^{2-})$ et $R(PO_4^{3-})$ sont définies pour caractériser l'aptitude des milieux H_2O–H_3PO_4–NaOH à céder les particules $H_2PO_4^-$, HPO_4^{2-} et PO_4^{3-}.

Elles peuvent être déterminées expérimentalement à partir de la mesure du potentiel pris par une électrode dont le fonctionnement fait intervenir un équilibre électrochimique engageant l'une des espèces phosphate comme seule espèce soluble. Ainsi, le potentiel d'une électrode phosphate mercureux/mercure, qui correspond à l'équilibre électrochimique

[12] $Hg_2HPO_4(s) + 2e^- \rightleftharpoons 2Hg(s) + HPO_4^{2-}$

ne dépend que de l'activité de l'espèce HPO_4^{2-} (l'état de référence étant la solution infiniment diluée dans l'eau) :

[13] $$E = E^0_{H_2O} - 0{,}029 \log a_{HPO_4^{2-}}$$
$$= E^0_{H_2O} + 0{,}029\, R(HPO_4^{2-})$$

$E^0_{H_2O}$ représente le potentiel normal du système $Hg_2HPO_4(s)$/Hg(s) dans l'eau exprimé par rapport au système Fc^+/Fc.

La connaissance de l'une des fonctions $R(HPO_4^{2-})$, $R(H_2PO_4^-)$ et $R(PO_4^{3-})$ permet de déterminer les deux autres à partir des relations

[14] $$R(H) + R(HPO_4^{2-}) - R(H_2PO_4^-) = 7{,}2$$

[15] $$R(H) + R(PO_4^{3-}) - R(HPO_4^{2-}) = 12{,}4$$

Les valeurs 7,2 et 12,4 représentent les valeurs de pK_2 et pK_3 de l'acide H_3PO_4 dans l'eau (26).

L'ensemble des résultats sont rassemblés dans le tableau 1 et figure 6.

La décroissance des fonctions basiques avec le taux de neutralisation indique clairement l'aptitude plus grande que présente ces milieux à céder les ions phosphate correspondants. Compte tenu de la valeur de $R(H)$ égale à 7,2 pour Na/P égal à 1,5, il est logique que les fonctions $R(HPO_4^{2-})$ et $R(H_2PO_4^-)$ soient dans ce cas égales. Elles sont proches de 0,0.

Ces fonctions sont nécessaires pour prévoir au cours de la neutralisation l'évolution de la solubilité de phosphates minéraux ou des équilibres de partage par solvant lorsque ceux-ci engagent les particules phosphates.

Conclusion

On a caractérisé le niveau d'acidité des solutions d'acide H_3PO_4 7 M progressivement neutralisées par la fonction d'acidité $R(H)$. Sa variation est de 10,2 unités lorsque le rapport Na/P passe de 0,0 à 1,6. Ces résultats permettront de préciser l'influence du niveau d'acidité sur le pouvoir oxydo–réducteur de nombreux systèmes. L'étendue thermodynamique du domaine des potentiels accessibles reste proche de 1,23 V. On dispose ainsi des limites thermodynamiques de stabilité des oxydants et des réducteurs dans ces milieux.

La faible variation de l'activité en eau observée au cours de la neutralisation implique que les changements de réactivité des solutés s'interprèteront essentiellement à partir d'intéractions spécifiques avec les ions du solvant.

L'utilisation du système électrochimique du mercure a permis de déterminer les fonctions $R(H_2PO_4^-)$, $R(HPO_4^{2-})$ et $R(PO_4^{3-})$. Elles seront utiles pour évaluer les variations thermodynamiques de solubilité des phosphates minéraux avec le taux de neutralisation.

The *trans–cis* isomerisation of bis(dioxolene)bis(pyridine) ruthenium complexes

YU-HONG TSE, PAMELA R. AUBURN, AND A. B. P. LEVER[1]

Department of Chemistry, York University, 4700 Keele St., North York (Toronto), Ont., Canada M3J 1P3

Received August 23, 1991[2]

YU-HONG TSE, PAMELA R. AUBURN, and A. B. P. LEVER. Can. J. Chem. **70**, 1849 (1992).

The isomerisation of *trans* to *cis* bis(3,5-di-*t*-butylbenzosemiquinonato)bis(R-pyridine)ruthenium, $Ru(R\text{-}Py)_2(DTBDiox)_2$, is induced by warming with an excess of R-pyridine, where R = 3-chloro, 4-methyl, 4-phenyl, or 4-butyl. The rates of these reactions, for the species with R-Py = 3-chloropyridine, were monitored in *o*-dichlorobenzene by UV–visible spectroscopy against varying 3-chloropyridine and varying *trans*-$[Ru(3\text{-}ClPy)_2(DTBDiox)_2]$ concentration. The data were found to obey first-order kinetics, $-d[Ru(3\text{-}ClPy)_2(DTBDiox)_2]/dt = k_{obsd}[Ru(3\text{-}ClPy)_2(DTBDiox)_2]$, over a considerable range of pyridine concentration. A plot of $1/k_{obsd}$ vs. [3-chloropyridine] is linear with a positive intercept. A dissociative mechanism is proposed for the isomerisation reaction. The activation parameters were determined for the specific case of R-Py = 3-chloropyridine. Electronic and electrochemical features of these species are briefly discussed.

YU-HONG TSE, PAMELA R. AUBURN et A. B. P. LEVER. Can. J. Chem. **70**, 1849 (1992).

L'isomérisation du bis(3,5-di-*tert*-butylbenzosemiquinonato)bis(R-pyridine)ruthénium, $Ru(R\text{-}Py)_2(DTBDiox)_2$, *trans* en *cis* est induite par un chauffage avec un excès de R-pyridine, où R = 3-chloro, 4-méthyl, 4-phényl ou 4-butyl. Opérant en solution dans le *o*-dichlorobenzène et faisant appel à la spectroscopie UV–visible, on a déterminé les vitesses de ces réactions, pour les espèces où R-Py = 3-chloropyridine, pour diverses concentrations de 3-chloropyridine et de *trans*-$[Ru(3\text{-}ClPy)_2(DTBDiox)_2]$. On a trouvé que, sur une plage importante de concentrations en pyridine, les données expérimentales peuvent être reliées par l'équation de cinétique du premier ordre, $-d[Ru(3\text{-}ClPy)_2(DTBDiox)_2]/dt = k_{obs}[Ru(3\text{-}ClPy)_2(DTBDiox)_2]$. Une droite de $1/k_{obs}$ vs. [3-chloropyridine] est linéaire, avec une ordonnée à l'origine qui est positive. On propose un mécanisme dissociatif pour la réaction d'isomérisation. On a déterminé les paramètres d'activation pour le cas spécifique de R-Py = 3-chloropyridine. On discute brièvement des caractéristiques électroniques et électrochimiques de ces espèces.

[Traduit par la rédaction]

Introduction

The series of complexes $Ru(NN)_2(diox)$ (1–3) and $Ru(NN)(diox)_2$ (3–7) have been described, where NN may be 2,2′-bipyridine or two substituted pyridines, R-Py, and (diox) is a dioxolene ligand which may exist in the catechol, semiquinone, or quinone oxidation states. These complexes form redox series whose electronic structures have been probed by a range of techniques including X-ray crystallography, NMR, ESR, magnetism and UV–VIS–FTIR, PES, and resonance Raman (rR) spectroscopy. The bipyridine-bis(dioxolene) complexes are necessarily *cis*, where the R-Py analogues could be either *cis* or *trans*.

The previously described *trans*-$Ru(R\text{-}Py)_2(diox)_2$ series of complexes (5, 7) are found to be isomerised to a *cis* configuration when warmed with an excess of pyridine. Here we describe studies of the isomerisation reaction and electrochemical and optical data characterising these new *cis* species.

Experimental section

Equipment

All absorbance measurements were performed on a Hitachi – Perkin Elmer microprocessor model 340 spectrometer equipped with an electrically heated cell compartment connected to a built-in thermostat for temperature measurement and control. Fourier transform infrared (FTIR) data were obtained using a Nicolet SX20 spectrometer. ^1H NMR and ^{13}C NMR spectra were obtained with a Bruker AM300FT NMR spectrometer using samples dissolved in $CDCl_3$.

Electrochemical data were obtained with a Pine Instruments RDE-3 potentiostat. Cyclic voltammetry was carried out, in dichloroethane (DCE), using platinum wires as working and counter electrodes, and a AgCl/Ag quasi-reference electrode with ferrocene (Fc) as an internal standard. The Fc/Fc^+ couple lies at +0.425 V vs. SCE (7).

Materials

Tetrabutylammonium perchlorate (TBAP, Kodak) was recrystallised from absolute ethanol and dried in vacuo at 50°C for 2 days. 1,2-Dichlorobenzene (DCB) (Aldrich, HPLC grade) and toluene-d_8 were used as supplied. 1,2-Dichloroethane (DCE) was fractionally distilled from P_2O_5. 3-Chloropyridine (Aldrich) and 4-methylpyridine (Aldrich) were fractionally distilled under reduced pressure. Other substituted pyridines (Aldrich) were used as supplied without any further purification.

Syntheses

The species *trans*-$Ru(R\text{-}Py)_2(DTBDiox)_2$ were prepared by the methods given previously (5, 7).

cis-*$Ru(R\text{-}Py)_2(DTBDiox)_2$*

Trans-$Ru(R\text{-}Py)_2(DTBDiox)_2$ (36 mg, ca. 5.0×10^{-2} mmol) was dissolved in toluene (10 mL). R-pyridine (R = 3-chloro, 4-methyl, or 4-phenyl) (2.1 mmol) was added. The resulting mixture was refluxed under nitrogen for 12 h, filtered hot, and then concentrated by rotary evaporation; methanol (1 mL) was then added to initiate crystallisation. The products were filtered, washed with cold methanol, and air dried; yield ~80%. Anal. found: C 59.48, H 6.27; N 3.64; calcd.: C 59.37, H 6.29, N 3.64 for R = 3-chloro; found: C 64.70, H 7.44, N 3.88; calcd.: C 64.40, H 7.60, N 3.76 for R = 4-methyl, monohydrate; found: C 68.70, H 6.86, N 3.53; calcd.: C 69.0, H 6.95, N 3.21 for R = 4-phenyl, monohydrate. The *trans* species used for the kinetic measurements had acceptable C, H, N analysis (7).

^1H NMR data for R = 3-chloropyridine species, in $CDCl_3$. Data for the *trans* isomer from ref. 7 (s = singlet, d = doublet, dd = doublet–doublet, m = multiplet): *trans* isomer, 7.74 (d, J = 2.2 Hz, 2H), 7.63 (d, J = 2.0 Hz, 2H), 7.6 (dd, J = 5.4, 1.1 Hz, 2H), 7.23 (m, 2H), 6.87 (dd, J 8.2, 5.7 Hz, 2H), 6.17 (br s, 2H),

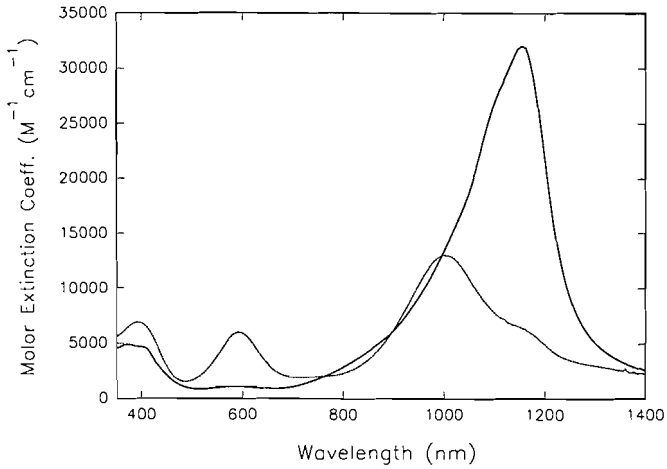

FIG. 1. Visible – near infrared spectra for (·) *cis*- and (-) *trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ in 1,2-dichloroethane.

1.62 (s, 18H), 1.35 (s, 18H); *cis* isomer, 8.54 (m), 8.27 (m), 8.04 (d, J = 2.2 Hz), 7.73 (m), 7.57 (m), 7.14 (m), 6.90 (m), 6.80 (m), 6.70 (d, J = 2.1 Hz), 1.77 (s), 1.67 (s), 1.37 (s), 1.36 (s), 1.33 (s), 1.20 (s), 0.89 (s), 0.88 (s).

Kinetic studies

DCB was used as the solvent for the rate studies unless otherwise stated. The liquid 3-chloropyridine (8.40×10^{-5} to 1.05×10^{-3} mol) was mixed with 4 mL of a stock solution of *trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ and diluted to 5 mL ((*trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ = (2.07×10^{-4} M)). The reaction mixture was transferred to a 1-cm cell which was placed into a preheated cell compartment; the temperature of the solution inside the cell was measured before and after each experiment (variation ±0.25°C). Successive spectra were collected at time intervals from 2.8 to 100 min, depending upon the temperature and concentration range involved.

The isomerisation from *trans*-to *cis*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ was monitored by observing the growth of a new absorption band lying close to 600 nm (6) observed for the *cis* isomer. The *trans* isomer possesses very weak absorption at this wavelength (Fig. 1).

For the pseudo-first-order conditions, the observed rate constants (k_{obsd}) were obtained from the Guggenheim plots (8). The reactions were allowed to proceed for 3–4 half-lives. The delay time was about 2 half-lives.

Rate constants for isomerisation of *trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ (2.07×10^{-4} M) in DCB at various temperatures from 91 to 110°C are presented here as a function of the concentration of 3-chloropyridine. Values of [3-chloropyridine] are tabulated, together with k_{obsd} (all values to be multiplied by 10^{-4} s^{-1}), followed by the standard deviation in parentheses.

T (°C)	0.016 M	0.03 M	0.06 M	0.08 M	0.1 M	0.2 M
91	1.64	1.24	0.89	0.857	0.787	0.496
	(0.01)	(0.02)	(0.01)	(0.002)	(0.001)	(0.001)
96	3.19	2.67	2.14	1.87	1.64	1.06
	(0.03)	(0.02)	(0.02)	(0.01)	(0.01)	(0.01)
100	5.97	5.33	3.99	3.71	3.50	2.24
	(0.04)	(0.06)	(0.01)	(0.04)	(0.03)	(0.01)
105	11.4	9.7	7.4	6.41	6.16	4.26
	(0.21)	(0.19)	(0.1)	(0.06)	(0.06)	(0.04)
110	18.89	18.1	14.61	13.3	12.1	9.02
	(0.73)	(0.5)	(0.07)	(0.15)	(0.2)	(0.07)

Data were also obtained, at 90°C, for constant [3-chloropyridine] = 0.16 M and varying [*trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$] over the range from about 1×10^{-4} to 3.4×10^{-4} M, with no significant variation in k_{obsd}.

The isomerisation of Ru(3-ClPy)$_2$(DTBDiox)$_2$ in toluene-d_8 at 93°C was followed by ^{1}H NMR ([Ru(3-ClPy)$_2$(DTBDiox)$_2$] = 2.72×10^{-3} M; [3-chloropyridine] = 0.5 M).

Results and discussion

The *trans*-Ru(R-Py)$_2$(DTBDiox)$_2$ species are best regarded as fully delocalised *trans*-Ru(III)(R-Py)$_2$(DTBCat(-2))(DTBSq(-1)) species (so-called (S) (starting) species in previous discussions) (3–5, 7). Their electronic spectra are typified by a very intense absorption near 1100 nm attributed to diox (π) → Ru($d\pi$) + diox (π^*) IL + LMCT (Fig. 1). They display only weak absorption in the visible region (near 580 nm (7)).

Synthesis of the cis *complexes and background literature*

When a *trans*-Ru(R-Py)$_2$(DTBDiox)$_2$ complex is warmed with a pyridine, a band near 600 nm (Table 1) grows in at a rate which depends upon temperature, concentration of pyridine, and nature of the R substituent (Fig. 2). Isomerisation proceeds within a fairly narrow range of pyridine concentrations. If a large excess of pyridine (>10^4 [Ru(R-Py)$_2$(DTBDiox)$_2$]) is used, a side reaction takes place, probably forming the tetrapyridine species, and the isosbestic point is lost. The *trans* isomer undergoes another side reaction if insufficient pyridine (<10 [Ru(R-Py)$_2$(DTBDiox)$_2$]) is used. Heating either the *cis* or *trans* isomer in an inert solvent, in the absence of an excess of pyridine ligand, led to eventual decomposition. Isomerisation occurs cleanly when the pyridine to ruthenium ratio lay approximately in the range $10^2 - 10^3$.

The final electronic spectrum has the same overall band envelope as that (6) of *cis*-Ru(bpy)(DTBDiox)$_2$ (save for the absence of the Ru → bpy CT transition), providing evidence that isomerisation has occurred. The absorption near 600 nm (Table 1) corresponds with an $n \rightarrow \pi^*$ semiquinone transition allowed in the *cis* isomer but forbidden in the *trans* isomer (5, 7). Further, *cis* complexes were isolated (see Experimental) and their NMR spectra (see Experimental) leave no doubt that *cis*-Ru(R-Py)$_2$(DTBDiox)$_2$ species have been formed. Under the experimental conditions used to prepare the *trans* isomer, no *cis* isomer is isolated (7).

A number of *cis–trans* isomerisations of ruthenium complexes have been previously reported. It is revealing to contrast their behaviour. The species *cis*-[Ru(bpy)$_2$(H$_2$O)$_2$]$^{2+}$ is photoisomerised to the *trans* species by a dissociative pathway (9), but no thermal route was reported. The species *trans*-Ru(dppm)$_2$Cl$_2$ (dppm = bis-diphenylphosphinomethane) can readily be thermally isomerised to the *cis* isomer in halocarbon solvents (at 83°C (reflux) in DCE) (10). This may be reversed (*cis* → *trans*) photochemically (10). Oxidation of *cis*-Ru^{II}(dppm)$_2$Cl$_2$ leads to isomerisation to the *trans*-Ru^{III} species and the formation of *trans*-Ru(dppm)$_2$Cl$_2$ upon subsequent reduction (10). The complex cation *trans*-[Ru(acac)$_2$(CH$_3$CN)$_2$]$^{2+}$ is thermally isomerised to the *cis* species at 30°C with a half-life of about 9 days (11). Data for *cis*- and *trans*-[RuCl(NO)(bpy)$_2$]$^{2+}$ have been reported (12), but no interconversion experiments were reported. Some bis(dithiocarbamate)nitrosyl complexes of ruthenium, such as *cis*-Ru(NO)(S$_2$CNMe$_2$)SCN, can be thermally converted to the corresponding *trans* isomer, in the solid

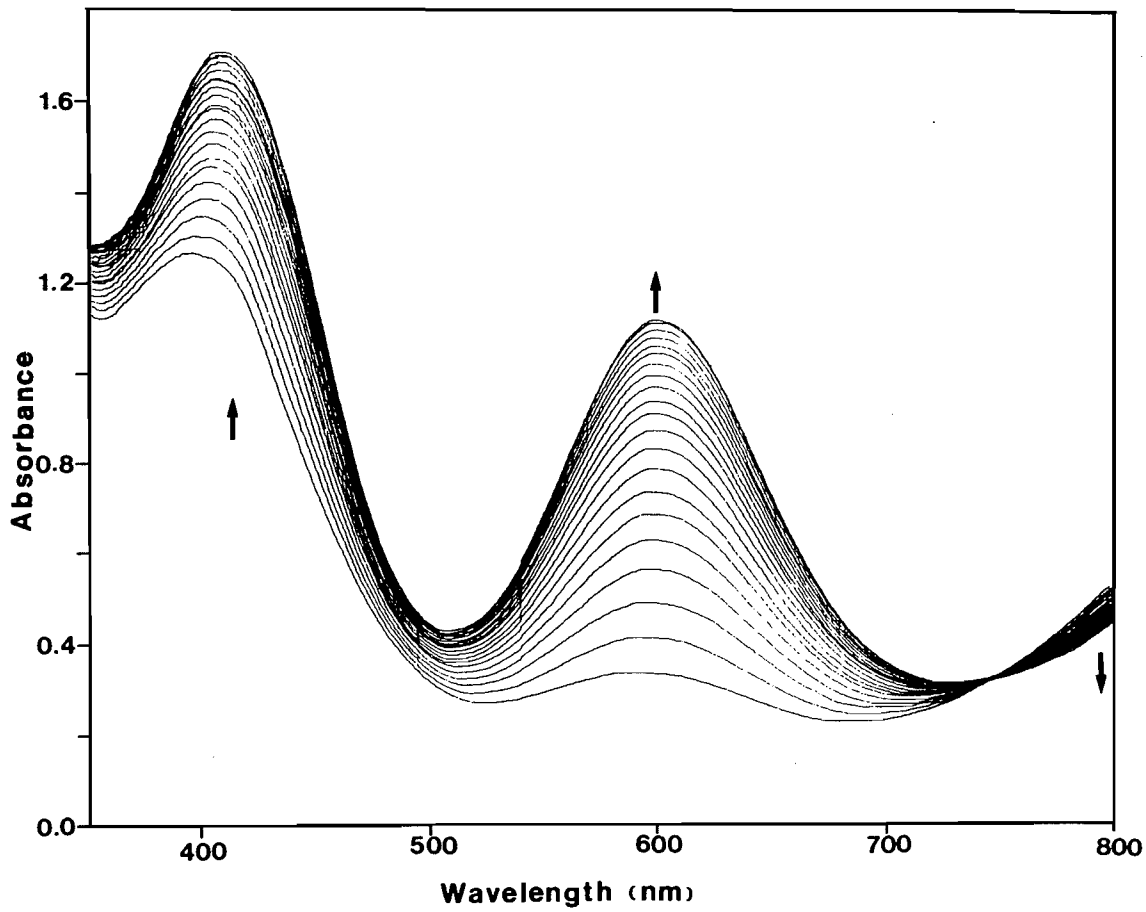

FIG. 2. A typical data set showing successive scans of the visible spectrum during the isomerisation of *trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ (2.07×10^{-4} M) in the presence of an excess of 3-chloropyridine (1.0×10^{-1} M) at 100°C in *o*-dichlorobenzene. The first scan in the experiment was not recorded on the spectrum.

state, at 220°C (13). Transformations in the rather more complex Ru(AzPy)$_2$Cl$_2$ (AzPy = 2-phenylazopyridine) have also been explored (14). A very detailed contribution discusses the formation of all *trans*, *ttt*-Ru(CO)$_2$Cl$_2$(PR$_3$)$_2$ species which isomerise in chloroform at from 50°C (actual temperature depending upon the phosphine) to the all *cis*, *ccc*-Ru(CO)$_2$Cl$_2$(PR$_3$)$_2$ species which then isomerise to the thermodynamically stable *cct*-Ru(CO)$_2$Cl$_2$(PR$_3$)$_2$ species (15). Our systems appear to be the first ruthenium species to be reported where isomers may be isolated by addition of an external common ligand (*vide infra*).

Nuclear magnetic resonance studies

trans-Ru(R-Py)$_2$(DTBDiox)$_2$ complexes can exist in two forms with C_{2h} and C_{2v} symmetry depending upon the relative orientation of the *t*-butyl groups. Previously we have demonstrated (7) that for all of these complexes, only two *t*-butyl resonances are observed for the DTBDiox ligands, indicative of a single isomer having been prepared. The X-ray data (3) for both the (S) *trans*-Ru(4-*t*-BuPy)$_2$(DTBDiox)$_2$ and the oxidised (O1) *trans*-[Ru(3-ClPy)$_2$(DTBDiox)$_2$]$^+$ cation show that these *trans* isomers in the solid state have C_{2h} symmetry.

TABLE 2. Rate constants k_1 and k_{-1}/k_r for isomerisation of *trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ at different temperatures[a]

T (K)	k_1 ($\times 10^{-4}$ s)	k_{-1}/k_r (M)
91	1.74(0.19)	12.7(2.2)
96	3.76(0.08)	12.7(0.4)
100	6.82(0.41)	10.2(1.0)
105	12.0(0.1)	9.4(1.5)
110	20.7(0.1)	6.7(0.5)

[a]Data derived from the k_{obsd} data cited in the experimental section. Standard deviation in parenthesis.

The *cis*-Ru(R-Py)$_2$(DTBDiox)$_2$ species can exist as three different geometric isomers that could give rise to eight *t*-butyl resonances in their ^{1}H NMR spectra (see Experimental). Four different *t*-butyl resonances arise from two *cis* isomers with same C_2 symmetry (so-called symmetric isomers). Another four different *t*-butyl resonances come from the third *cis* isomer which has C_1 symmetry (asymmetric isomer). In fact, these eight *t*-butyl resonances are observed for *cis*-Ru(3-ClPy)$_2$(DTBDiox)$_2$, although we have been unable to separate these three *cis* isomers.

When isomerisation of the *trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ species was followed by NMR, in toluene-d_8, the resonances for all three *cis* isomers grew at approximately the same rate.[3]

Electrochemistry

The electrochemical behaviour of the *cis*-Ru(R-Py)$_2$(DTBDiox)$_2$ species is very similar to that of the *trans* analogues (Table 3). Assignments have been discussed in depth previously (6, 7). Arguments have been expressed in the literature relating differences in the electrochemical behaviour of *cis* and *trans* pairs to differences in electronic structure. Thus the ruthenium-centred waves observed with the *cis*- and *trans*-[RuCl(NO)(bpy)$_2$]$^{2+}$ nitrosyl species (12) differ by only 10 mV, but there is a substantial difference (170 mV) in the nitrosyl reduction wave for these two isomers, implying some marked structurally dependent electronic changes localised on the nitrosyl group. The M^{III}/M^{II} potentials for the pairs of *cis* and *trans* isomers M(dppm)$_2$Cl$_2$ (M = Os, Ru) (10) differ by 370 mV (Ru) and 460 mV (Os) with the *cis* isomers being the most difficult to oxidise, the difference being attributed to the difference in π-backbonding capability in the pairs of isomers. Where more than one π-accepting ligand is present, such as in the series [Ru(dppm)$_2$(CO)X]$^+$ and [Ru(bpy)(dppe)(CO)X]$^+$ (X = Cl, Br, I) (16), the *trans* isomer is more difficult to oxidise by up to 450 mV. In our dioxolene system, couple V (Table 3) is most closely associated with the Ru^{III}/Ru^{II} couple (6, 7). The lack of any shift in this couple between *cis* and *trans* isomer arises because at this oxidation level the Ru^{II} is bound to the non-π-accepting catechol. The remaining couples involve redox processes which are more localised on the dioxolene residues and are, accordingly, less sensitive to the geometry of the isomer.

Kinetic studies

The kinetics of the isomerisation reactions of Ru(3-ClPy)$_2$(DTBDiox)$_2$ (2.07×10^{-4} M) were investigated at various temperatures with 3-chloropyridine concentrations ranging between 1.6×10^{-2} and 2×10^{-1} M (see Experimental). Values of k_{obsd} were derived from a Guggenheim plot (8) (Fig. 3). The reaction followed pseudo-first-order kinetics

$$[1] \quad -d[Ru(3\text{-}ClPy)_2(DTBDiox)_2]/dt = k_{obsd}[Ru(3\text{-}ClPy)_2(DTBDiox)_2]$$

over at least four half-lives. Values of k_{obsd} at constant [3-chloropyridine] were independent of the concentration of Ru(3-ClPy)$_2$(DTBDiox)$_2$.

Plots of $1/k_{obsd}$ against [3-chloropyridine] were linear (Fig. 4). This linearity is consistent with the following mechanism:

$$[2] \quad trans\text{-}Ru(3\text{-}ClPy)_2(DTBDiox)_2 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Ru(3\text{-}ClPy)(DTBDiox)_2 + 3\text{-}ClPy$$

$$[3] \quad Ru(3\text{-}ClPy)(DTBDiox)_2 \xrightarrow{k_r} [Ru(3\text{-}ClPy)(DTBDiox)_2]^*$$

$$[4] \quad [Ru(3\text{-}ClPy)(DTBDiox)_2]^* + 3\text{-}ClPy \rightleftharpoons cis\text{-}Ru(3\text{-}ClPy)_2(DTBDiox)_2$$

Assuming step [4] is fast and using the steady-state ap-

[3]This in fact differs from the behaviour of the corresponding bipyridine complexes, in which only two of the three possible isomers are obtained. Previously (6), we reported that all three isomers were present. This was in error, the seven peaks in the *t*-butyl region of the ^{1}H NMR spectra being due to two isomers (C_1 and C_2 symmetry) and to water. The presence of only two isomers was clearly confirmed by TLC.

TABLE 3. Electrochemical data for Ru(NN)$_2$(DTBDiox)$_2$ complexes[a]

Complex	$E_{1/2}$ (V) vs. SCE II	III	IV	V
trans-Ru(3-ClPy)$_2$(DTBDiox)$_2$[b]	+1.08	+0.30	−0.60	−1.51qr
cis-Ru(3-ClPy)$_2$(DTBDiox)$_2$	+1.01	+0.35	−0.71	−1.54qr
cis-Ru(bpy)(DTBDiox)$_2$[c]	+1.00	+0.31	−0.71	−1.42

[a]Measurements were made using 1,2-dichloroethane solutions of the starting materials (10^{-3} M) containing 0.2 M TBAP. $E_{1/2}$ values are obtained from cyclic voltammetry at 100 m V s^{-1}; qr = quasi-reversible.

[b,c]For assignment of the redox couples, see refs. 6 and 7: ref. 7[b]; ref. 6[c]. The assumed position of the Fc$^+$/Fc couple used in ref. 6 differed by +0.115 V relative to that assumed here. The potentials taken from ref. 6 have been appropriately corrected.

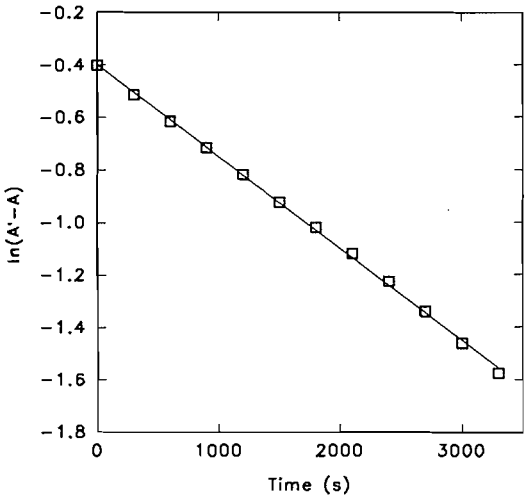

FIG. 3. Guggenheim plot using data from Fig. 2 at wavelength 600 nm for the isomerisation of the *trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ complex. The delay time in the Guggenheim plots is approximately two half-lives.

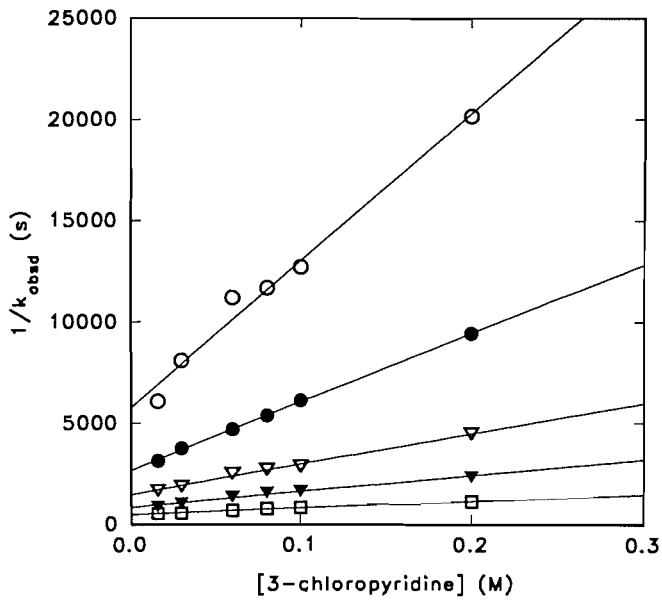

FIG. 4. Plots of $1/k_{obsd}$ vs. [3-chloropyridine] for the isomerisation of Ru(3-ClPy)$_2$(DTBDiox)$_2$ at 100°C in *o*-dichlorobenzene at (from upper to lower) 91, 96, 100, 105, and 110°C.

proximation (8) for [Ru(3-ClPy)(DTBDiox)$_2$], the rate of isomerisation is

$$[5] \quad -\mathrm{d}[\textit{trans}\text{-Ru(3-ClPy)}_2\text{(DTBDiox)}_2]/\mathrm{d}t = \{(k_1k_r/k_{-1}[\text{3-chloropyridine}] + k_r)\} \cdot [\textit{trans}\text{-Ru(3-ClPy)}_2\text{(DTBDiox)}_2] = k_{obsd}[\textit{trans}\text{-Ru(3-ClPy)}_2\text{(DTBDiox)}_2]$$

The calculated k_1 and k_{-1}/k_r derived respectively from the intercept $(1/k_1)$ and the slope (k_{-1}/k_1k_r) are listed in Table 2. An Arrhenius plot of $\ln(k_1)$ versus inverse temperature led to an activation energy of 148 ± 6 kJ/mol and, using the Eyring expression (8), an activation entropy of 88 ± 17 J/mol.

The data (Fig. 4) are consistent with a dissociative mechanism in which a pyridine ligand is lost to form a five-coordinate intermediate which can either reattach the pyridine ligand and return to the *trans* isomer or undergo a twist, first to form two different trigonal bipyramidal intermediates (e.g., see ref. 15) differing in the orientation of the *t*-butyl groups on the dioxolene ligands. These two intermediates can be interchanged by a pseudo-rotation. When the pyridine ligand is reattached to these intermediates, all three *cis* isomers are formed. Ligand loss and formation of the five-coordinate intermediate lead to alternative decomposition pathways when insufficient pyridine is present to trap the intermediate.

The positive activation entropy value associated with reaction [1] is consistent with the dissociative mechanism (15, 17–20). Indeed both the activation enthalpy and entropy have values close to those reported previously for mechanisms involving the loss of a ligand from a six-coordinate ruthenium(II) species (15, 19). Specifically there is a close similarity between the activation data reported here and those detailed for the isomerisation of the Ru(CO)$_2$Cl$_2$(PR$_3$)$_2$ species (15).

A mixed-ligand experiment shows that the rate of isomerisation of *trans*-Ru(3-ClPy)$_2$(DTBDiox)$_2$ in the presence of bulk 4-methylpyridine is different from that with bulk 3-chloropyridine (and vice versa). Although additional kinetic data cannot readily be extracted because the electronic spectra of the various R-Py species do not differ sufficiently, the result supports the proposed mechanism.

Electronic spectra

The electronic spectra of the new *cis* species reveal some subtle but important differences from the previously reported (7) spectra of the *trans* species. The NIR band in the *cis*-S species shifts slightly to lower energy with more electron-donating pyridine ligands (Table 1), consistent with the MLCT Ru(d) → semiquinone (π^*) transition previously assigned in the spectra of the analogous bipyridine species (6). The lower energy of this band in the pyridine series relative to the bipyridine series arises from the greater stabilisation of the d orbitals by the bipyridine ligand. There is no shift with pyridine substituent in the spectra of the *trans*-S species (7) for the corresponding band which has little CT character.

The behaviour of the second band, near 600 nm, is more ambiguous, but does shift to the red with the more electron-accepting 3-chloro substituent. This is an $n \rightarrow \pi^*$ transition that evidently has some LMCT character.

The third band, near 400 nm, is evidently Ru($d\pi$) → R-Py(π^*), since it shifts to lower energy in the sequence 4-methyl > 3-chloro > 4-phenyl, this last having an especially low energy π^* orbital extending over the phenyl group.

To confirm certain subtle conclusions concerning the differences in electronic structure between the *cis* and *trans* series, some of these species were oxidised with silver ion to the O1 species, to obtain their electronic spectra. These O1 complexes, which were not isolated, have spectra more closely related to the spectra of the *cis*-O1 bipyridine analogues (6) than to their *trans*-O1 relatives. Thus the main band has MLCT Ru($d\pi$) → semiquinone(π^*) character and shifts to lower energy with the more electron-donating pyridines. The corresponding band in the *trans* species (transition O1, II) (7) has LMCT character and shifts in the opposite sense with pyridine substituent. The shifts in the second band, near 520 nm, are too small to comment upon.

For personal use only.

These data support previous assignments (6, 7) and indeed add useful corroboratory evidence. The contrasting dependencies upon dioxolene and pyridine substituents arise from changes in the degree of mixing of metal and ligand orbitals owing to the symmetry restrictions imposed by the two geometries (7). The *cis* isomers are concluded to parallel the bipyridine species in having somewhat more Ru^{II} character than their *trans* analogues (7).

Conclusion

The *trans*-$Ru(R\text{-}Py)_2(DTBDiox)_2$ (C_{2h}) species are kinetically favoured products during synthesis and are isomerised to their corresponding *cis* isomers by warming with an excess of a pyridine. A dissociative mechanism for this *trans* → *cis* isomerisation is proposed.

The electrochemical and optical data for the *trans* and *cis* isomers of $Ru(R\text{-}Py)_2(DTBDiox)_2$ are compared. The electronic spectra support previous assignments given for the corresponding *cis*-bpy complexes (6). Detailed analysis further corroborates earlier arguments (5–7, 21) concerning the degree of mixing between metal and ligand orbitals and the formal oxidation states of the species.

Acknowledgments

We thank Dr. Dave Thompson, Dr. Elaine Dodsworth, and Prof. D. V. Stynes for useful discussion, Mr Hitoshi Masui and Mr. Jing Li for technical help, and the Johnson Matthey Company for the loan of ruthenium trichloride. The financial support of the Natural Sciences and Engineering Research Council (NSERC) (Ottawa) and the Office of Naval Research (Washington) is appreciated. Y-H Tse also thanks NSERC for an undergraduate scholarship during his undergraduate summer training at York University.

The molecular and electronic structure of 1-pyrazolylphosphazenes

KEITH D. GALLICANO, NORMAN L. PADDOCK, STEVEN J. RETTIG, AND JAMES TROTTER
Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, B.C., Canada V6T 1Z1

Received July 25, 1991[1]

KEITH D. GALLICANO, NORMAN L. PADDOCK, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **70**, 1855 (1992).

The nature of the interactions between pyrazolyl and phosphazene rings has been investigated through the study of the structures of bis(1-pyrazolyl)methane, $CH_2(H_2pz)_2$, **1**, bis[1-(3,5-dimethylpyrazolyl)]methane, $CH_2(Me_2pz)_2$, **2**, the pyrazolylphosphazenes $N_3P_3(Me_2pz)_6$, **3**, $N_4P_4(H_2pz)_8$, **4**, and $N_4P_4(Me_2pz)_8$, **5**, and the partially substituted *gem*-$N_3P_3Ph_2(Me_2pz)_4$, **6**. Crystal data are as follows: **1**, orthorhombic, $P2_12_12_1$, a = 7.997(2), b = 9.287(2), c = 10.049(2) Å, Z = 4, R = 0.034 for 647 reflections; **2**, monoclinic, $C2/c$, a = 19.115(4), b = 4.2690(8), c = 14.543(3) Å, β = 98.91(2)°, Z = 4, R = 0.064 for 528 reflections; **3**, monoclinic, $C2/c$, a = 16.778(2), b = 12.1083(9), c = 19.269(4) Å, β = 113.885(6)°, Z = 4, R = 0.039 for 2716 reflections; **4**, monoclinic $P2_1/n$, a = 10.4223(9), b = 8.1879(7), c = 19.403(2) Å, β = 94.381(7)°, Z = 2, R = 0.059 for 2937 reflections; **5**, triclinic, $P\bar{1}$, a = 11.516(2), b = 13.121(3), c = 18.142(3) Å, α = 77.96(1), β = 79.20(1), γ = 66.54(2)°, Z = 2, R = 0.036 for 5300 reflections; **6**, monoclinic, $P2_1/c$, a = 10.3598(4), b = 17.8827(4), c = 19.0851(6) Å, β = 94.675(2)°, Z = 4, R = 0.053 for 4867 reflections. Interpretation of the structures through iterative extended Hückel calculations shows that conjugative interactions lead to a quinonoid deformation of the pyrazole ring, similar to that in bis(1-pyrazolyl)carbonyl. π-Electron transfer to the phosphazene ring, facilitated by the use of acceptor *d* orbitals on phosphorus, is accompanied by a synergic σ transfer to the pyrazole ring. The pyrazolyl group acts both as a strongly electronegative group and as a good potential donor. The calculations account satisfactorily for the bond lengths in the pyrazolyl group, the large bond angles at nitrogen in **4** and **5**, the bond length inequalities in the phosphazene ring of **6**, and the reactivity of the pyrazolylphosphazenes.

KEITH D. GALLICANO, NORMAN L. PADDOCK, STEVEN J. RETTIG et JAMES TROTTER. Can J. Chem. **70**, 1855 (1992).

On a déterminé la nature des interactions entre les noyaux pyrazolyle et phosphazène grâce à une étude des structures du bis(1-pyrazolyl)méthane, $CH_2(H_2pz)_2$, **1**, du bis[1-(3,5-diméthylpyrazolyl)]méthane, $CH_2(Me_2pz)_2$, **2**, des pyrazolylphosphazènes $N_3P_3(Me_2pz)_6$, **3**, $N_4P_4(H_2pz)_8$, **4**, et $N_4P_4(Me_2pz)_8$, **5**, et du *gem*-$N_3P_3Ph_2(Me_2pz)_4$, **6**, partiellement substitué. Les données cristallographiques sont les suivantes: **1**, orthorhombique, $P2_12_12_1$, a = 7,997(2), b = 9,287(2) et c = 10,049(2) Å, Z = 4, R = 0,034 pour 647 réflexions; **2**, monoclinique, $C2/c$, a = 19,115(4), b = 4,2690(8) et c = 14,543(3) Å, β = 98,91(2)°, Z = 4, R = 0,064 pour 528 réflexions; **3**, monoclinique, $C2/c$, a = 16,778(2), b = 12,1083(9) et c = 19,269(4) Å, β = 113,885(6)°, Z = 4, R = 0,039 pour 2716 réflexions; **4**, monoclinique, $P2_1/n$, a = 10,4223(9), b = 8,1879(7) et c = 19,403(2) Å, β = 94,381(7)°, Z = 2, R = 0,059 pour 2937 réflexions; **5**, triclinique, $P\bar{1}$, a = 11,516(2), b = 13,121(3) et c = 18,142(3) Å, α = 77,96(1), β = 79,20(1) et γ = 66,54(2)°, Z = 2, R = 0,036 pour 5300 réflexions; **6**, monoclinique, $P2_1/c$, a = 10,3598(4), b = 17,8827(4) et c = 19,0851(6) Å, β = 94,675(2)°, Z = 4, R = 0,053 pour 4867 réflexions. L'interprétation des structures à l'aide de calculs de Hückel étendus montrent que les interactions de conjugaison conduisent à une déformation quinonoïdale du noyau pyrazole, semblable à celle observée dans le bis(1-pyrazolyl)carbonyle. Le transfert d'électrons π vers le noyau phosphazène, facilité par l'utilisation d'un accepteur d'orbitales *d* sur le phosphore, s'accompagne d'un transfert σ synergique vers le noyau pyrazole. Le groupe pyrazolyle agit à la fois comme une groupe fortement électronégatif et comme un bon donneur potentiel. Les calculs rendent bien compte des longueurs des liaisons dans le groupe pyrazolyle, des angles de liaison élargis au niveau de l'azote des composés **4** et **5**, des inégalités dans les longueurs des liaisons dans le cycle phosphazène du produit **6** ainsi que de la réactivité des pyrazolylphosphazènes.

[Traduit par la rédaction]

Introduction

Although the detailed electronic structure of phosphazenes is complex, the interaction of a phosphazene ring with its substituents is usually interpreted simply in terms of induction and conjugation, concepts primarily appropriate to organic molecules. Although such a classification seems valid, the details are different for phosphazenes, because the number of *d* orbitals available at phosphorus exceeds that formally required for π bonding, and their potential interactions are diverse. The balance of σ and π effects is different from that in carbon-based molecules and is an important topic of this paper. Apart from their specific applications, the results obtained may also help in the elucidation of the directional effects found in the substitution reactions of phosphazenes (1).

At the lowest level, Hückel methods applied to $d\pi$ interactions within the ring have proved valuable in the interpretation of the structures and behaviour of phosphazenes (2–4). Notably, the possibility of both homomorphic and heteromorphic interactions in both the in-plane (π) and out-of-plane π systems (π′) has been recognized. The homomorphic π′ system is presumably responsible for the oscillatory behaviour of the ionization energy of $(NPF_2)_n$ as a function of ring size (5), and the heteromorphic π system for the thermochemical stability of the high polymer relative to the halides of smaller ring size (6).

Calculations at this level suggest that ring perturbation involves significant charge transfer, showing the need for a theoretical method with some degree of self-consistency, so allowing for σ–π interaction. EHMO calculations on $(NPCl_2)_3$ showed the d_{xz},d_{yz} contributions to be unequal (7), and the possible importance in $(NPF_2)_4$ of such orbital combinations as $PX_2(\sigma^*)$, as acceptors alternative to atomic *d* functions (8). CNDO/2 calculations (9) show that the order of the π,π′ systems depends on the substituent, the HOMO being π′ in $(NPF_2)_3$ and π in $(NPCl_2)_3$. By the X_αSW method,

the HOMO is found to be homomorphic in both $(NPF_2)_{3,4}$ and $(NPCl_2)_3$, and contributions from $p\pi-p\pi$ and $d\sigma$ bonding were also recognized (10).

The first non-empirical study of cyclotriphosphazenes verfied the significant effect of *d* orbitals, beyond that of ordinary polarization functions, in inducing substantial π contractions; bond lengths and angles were satisfactorily reproduced (11). In later calculations (12) on $(NPH_2)_3$, $(NPF_2)_3$, and $(NPF_2)_4$, using a larger basis set, the *d* contributions were found to be smaller, but nevertheless involved in π and π' bonding, the dependence on substituent electronegativity being confirmed.

The experimental evidence on ring-substituent interactions is more extensive than the calculations relating to them. ^{19}F nmr spectroscopy (13) shows that the withdrawal of electrons from phenyl by a fluorophosphazenyl group is similar to that by a nitro group, but UV (14) and PE spectroscopy (15) suggest that conjugation is weak, the interaction being largely inductive, through the σ system. Experimentally, strong π conjugation requires donation from the substituent (16), inducing a planar configuration of the *exo*-N atoms in alkylamino derivatives, shortening the *exo*-P—N bond, and, in agreement with CNDO calculations of electron density (17), making a ring-nitrogen atom the basic centre (18). A band in the UV spectra of the 1-methyl-2-(fluorophosphazenyl)pyrroles $N_nP_nF_{2n-1}\cdot C_4H_3NMe$ (n = 3–6) is attributed to $d\pi-p\pi$ charge transfer, its variation with ring size and the conformation of the tetrameric molecule being consistent with conjugation to a homomorphic system (19). Later work (20) on the ESR spectrum of a phenalenylphosphazene radical specifically designed to allow spiro conjugation only through the phosphorus d_{xz} orbital showed at least half of the ring nuclei to be ESR active. π Interactions have also been detected by UV spectroscopy (21) between the l-aziridinyl and other groups attached to a phosphazene nucleus, but in this case the detailed mechanism is unknown.

HMO methods, although useful, cannot help if there is significant $\sigma-\pi$ mixing. At the other extreme, in an *ab initio* study of the model compound 1,1-diaminocyclodiphosphazene (22), the substituents were found to stabilize the ring inductively, without much mesomeric conjugation, though these latter contributions would be expected to be strengthened in corresponding halogeno derivatives.

The electronic structure of pyrazolylphosphazenes is of interest, because complex formation takes place through the pyridinic nitrogen atom rather than the phosphazene ring (23, 24), conjugative release being limited by the competition for π electrons between the pyrazolyl ring and the *exo*-P—N bond (Fig. 1). Because the pyrazolyl group is unsymmetrical, its geometry is sensitive to substitution and the changes induced in it by a phosphazenyl ring can be used to discriminate the interactions between the rings.

The structure of pyrazole itself, as determined by microwave spectroscopy (25), has limited comparative value, because the spectroscopic and X-ray diffraction results refer to molecules in different vibrational states (26) and, in the structures determined by X-ray (26) and neutron (27) diffraction, the ring geometry is affected by hydrogen bonding. We have therefore determined the structures of the dipyrazolylmethanes **1** and **2** (in which no conjugation is expected), the pyrazolylphosphazenes **3–5**, and the partially substituted derivative **6**.

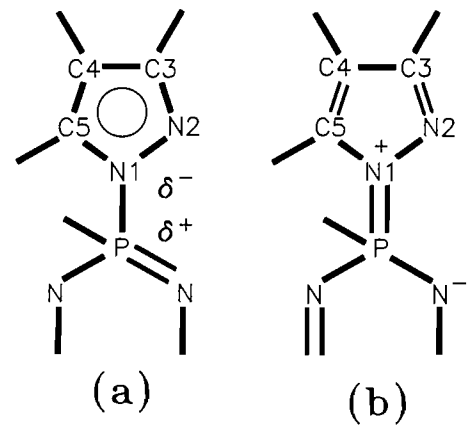

FIG. 1. Inductive (*a*) and conjugative (*b*) interactions of a pyrazolyl group with a phosphazene ring.

Experimental

The preparation of compounds **3–6** is described in ref. 2. Details on the preparation of **1** and **2** are reported in ref. 28.

Crystallographic analyses of 1–6

Crystallographic data for the six compounds appear in Table 1. Final unit-cell parameters were obtained from least-squares refinement of 2 sin θ/λ values for 25 reflections with 2θ = 22–31, 50–83, 35–44, 35–40, 35–41, and 64–84° for **1–6**, respectively. The intensities of three standard reflections, measured each hour of X-ray exposure time, were essentially constant throughout the data collections, except for compound **2** which showed a uniform decay of 32%. Data for compounds **2–4** and **6** were corrected for absorption (numerical integration)[2] and data for **2** were scaled for linear decay.

The structures of **1** and **2** were solved by direct methods and those of **3–6** by conventional heavy-atom methods. For **2**, **3**, and **5**, there were choices between centrosymmetric and noncentrosymmetric space groups, the structure analyses being initiated in the former in each case on the basis of the *E* statistics. These choices were confirmed by the subsequent successful solutions and refinements of the structures. The pyrazole rings in **4** were all found to be disordered, (1:1) twofold disordered models being refined for each ring. Attempts to refine an ordered model of **4** in the lower symmetry space groups $P2_1$ and *Pn* were not successful.

All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were refined with isotropic thermal parameters (**1–3**) or fixed in idealized positions (**4–6**, methyl orientations based on difference map peaks, $C(sp^3)$—H = 0.98 Å, $C(sp^2)$—H = 0.97 Å, $U_H \propto U_{\text{bonded atom}}$). Isotropic extinction parameters (29–31) were refined for **1** and **6**, the final values of g being $4.4(9)\times10^4$ and $0.66(9)\times10^4$, respectively. Neutral-atom scattering factors and anomalous dispersion corrections (for P) were taken from ref. 32. No attempt was made to determine the absolute configuration of **1**. Final coordinates and equivalent isotropic thermal parameters (U_{eq} = 1/3 trace of diagonalized U) for the non-hydrogen atoms are given in Table 2 (those for the disordered **4** are

in the Depository material[3]). Hydrogen-atom coordinates, anisotropic thermal parameters, bond lengths and angles, intra-annular torsion angles, and observed and calculated structure factor amplitudes for all six compounds are included as supplementary material.[3] Bond lengths for compounds **1**, **2**, and **5** have been corrected for thermal libration using the TLS model (33, 34). The structures **1**–**3**, **5**, **6** are shown in Figs. 2–6, respectively (**4** in Depository material[3]). The geometry of the phosphazene rings in **3**–**6** is summarized in Fig. 7 and comparison data for the tetrameric rings are given in Table 3.

[3]These may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada, K1A 0S2.

Tables of hydrogen atom coordinates, bond lengths and angles, and positional parameters and view for compound **4** have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW, U.K.

Results and discussion

General characteristics of the structures

The geometry of hexakis[1-(3,5-dimethylpyrazolyl)]cyclotriphosphazene, **3**, is based on a nearly planar N_3P_3 framework; the torsion angles about successive ring bonds are −2.0, 3.9, −1.9°, the remaining angles being related by the crystallographic C_2 axis through P(1) and N(2). The mean length of the exocyclic P—N bond (1.682 Å) suggests some exocyclic conjugation. The mean ring bond length (1.577 Å) is closer to the 1.581 Å in $N_3P_3Cl_6$ (35) than to the 1.605 Å in $N_3P_3Me_6$ (36) or 1.597 Å in $N_3P_3Ph_6$ (37), and the similarity of the structural effects of chlorine and the dimethylpyrazolyl group is confirmed by a comparison of the inequalities in the ring bonds of **6**, compared with those in $N_3P_3Ph_2Cl_4$ (38) and $N_3P_3Ph_2F_4$ (39). If methylation reduces electron withdrawal by the pyrazole group, the unsubstituted pyrazolyl group should be even more electronegative, in agreement with the structures of the two tetramers **4** and **5**, which are compared with other tetramers in Table 3. The mean angle at nitrogen in the phosphazene ring is larger in **4** (146.2°) than in **5** (136.8°), and the PN framework is therefore flatter in **4** (mean deviation of the phosphorus atoms from the plane of the nitrogen atoms = 0.08 Å) than in the two crystallographically independent molecules of **5** (mean deviations 0.28, 0.38 Å). The ring geometry of **4** resembles that of $N_4P_4F_8$ (45) more than that of the other tetramers (Table 3) and the possibility that the unsubstituted pyrazolyl group is almost as effectively electronegative as fluorine (to the phosphazene ring) is reinforced by the spectroscopic results (24). Steric interactions may also contribute to the apparent effects of methylation. Calculations of non-bonded interactions show that in the most stable conformations of an isolated $M(pz)_2$ group (M = C, P; pz = H_2pz, Me_2pz), the two pyrazolyl groups are related by a twofold axis, but the conformational energy is, over large ranges, insensitive to the torsion angle about the M—N bonds; measured angles are given in Table 4. The twofold axis is exact in **2** and at P(1) in **3**, and close in **1**. The approximate correspondence otherwise holds except at P(2) in **4** where, because of the disorder, the pyrazolyl groups are related by either an approximate local plane of symmetry or by an approximate twofold axis. In **3** and **6**, the three sets of torsion angles all have the same sign, so that, numerical inequalities apart, **3** approaches threefold symmetry. In **5**, the angles at the phosphazene nitrogen atoms are larger than those in the trimeric phosphazenes, **3** and **6**, tending to decrease Me···Me distances, unacceptably so if the torsion angle is increased. In fact, in **5** (both molecules) the pairs of pyrazolyl groups on alternate phosphorus atoms are enantiomerically related, so preserving locally favourable conformations while relieving steric repulsion between the groups on neighboring phosphorus atoms. Methyl–methyl interactions are still significant in controlling the conformation. In **5** (molecule 1) the shortest Me···Me distances are C(25)···C(27) (4.09 Å, same center) and C(25)···C(30) (4.27 Å, different); in molecule 2 they are C(38)···C(35′) (4.00 Å) and C(37)···C(36′) (4.05 Å) (both different), and C(33)···C(35) (4.25 Å, same). The results as a whole suggest no barrier to rotation about the exocyclic P—N bond other than that arising from non-bonded interactions.

Geometry of the pyrazolyl group

The nature of the electronic interactions between the rings is reflected in the detailed structures of the pyrazolyl groups.

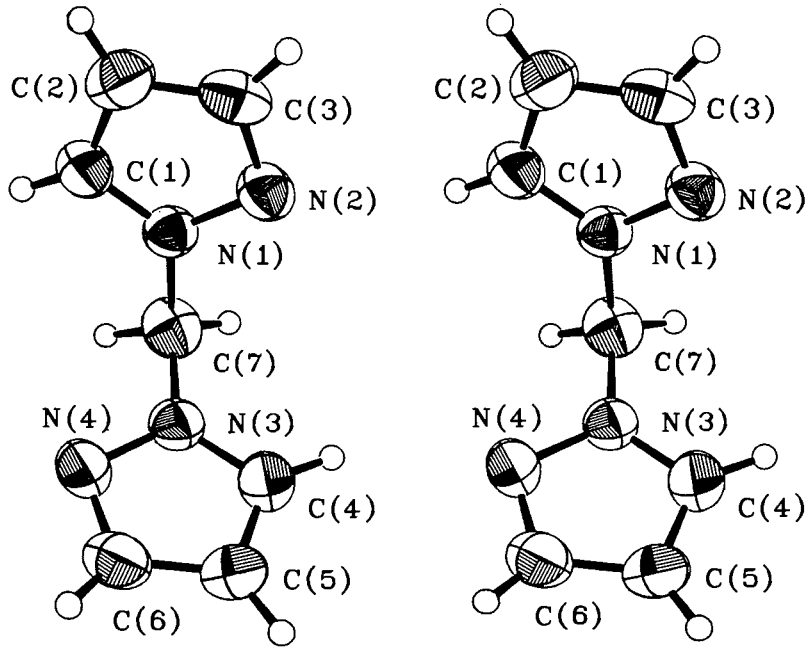

FIG. 2. Stereoview of bis(1-pyrazolyl)methane, **1**; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms.

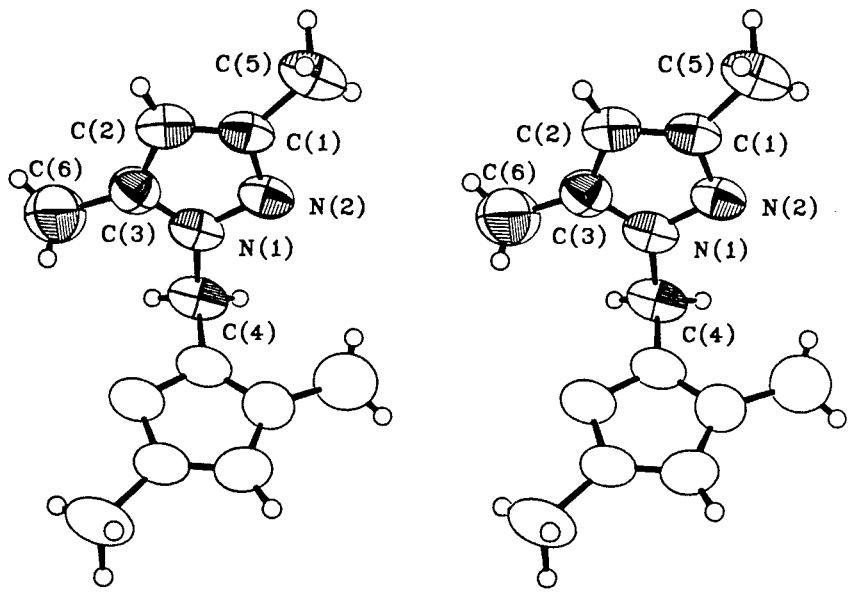

FIG. 3. Stereoview of bis[1-(3,5-dimethylpyrazolyl)]methane, **2**; 50% probability thermal ellipsoids are shown for the non-hydrogen atoms. Shaded non-hydrogen atoms comprise the asymmetric unit.

For each of molecules **1**, **2**, **3**, **5**, **6**, the pyrazolyl groups are insignificantly different; average structures are shown in Fig. 8. The structure of **4** is not included because the pyrazolyl rings are disordered.

Since the pyrazole ring is planar, the σ and π systems are geometrically separable, their mutual influence being indirect, through charge density effects; the π electrons have no direct effect on ring angles. The bond lengths can be expected to be controlled jointly by the electron density in both σ and π bonds. The measured length L is analyzed here in terms of a length L_1 characteristic of the σ bond, the difference $L_2 = L_1 - L$ being attributed solely to π bonding, and referred to below as a π contraction. L_1 is assumed to depend on the σ hybridization state only and, over a limited range, the atomic contribution to the σ-bond length is linearly related to the *p*-electron density in the relevant hybrid orbital (46), calculated from the geometry. This technique, which has been applied to phosphazenes (2), is appropriate to a discussion of the ring bonds; its limitations have been discussed by Salem (47). The molecules contain too many heavy atoms for the π contributions to be determined by non-empirical methods, but since substantial charge migration is involved, simple EHMO calculations are inadequate.

The geometrical changes induced by π bonding, how-

ysis (R = 0.997) showed the π populations to be related to the π contractions (L_2) by $L_2 = 0.657 \times (\pi$ popn.), with errors 0.005 Å (mean) and 0.010 Å (max., bond 5–1 in **1**), comparable to the experimental mean standard deviation of 0.005 Å. The individual bond lengths (measd. and calcd.) are given in Table 5. A more stringent test of the theoretical method is provided by the small differences in bond lengths between **1** and **2** that result from 3,5-dimethylation. Except for bond 5–1, for which the discrepancy between calculated and observed bond lengths is greatest, the predicted differences (Table 5) are of the right sign, though on average 0.008 Å too small. This underestimation of bond length changes may well be a limitation of the theoretical method, which nevertheless seems good enough to reproduce the main effects of substituent interactions.

Substituent effects on the pyrazolyl group

We are concerned with the effect of substituents on the pyrazole ring, chiefly at N(1) (where they may have both inductive and conjugative interactions), and at N(2), in relation to complex formation.[5] The effect of an electropositive interaction at N(1) is illustrated by comparative calculations on pyrazole and 1-methylpyrazole. Relative to hydrogen, the methyl group releases 0.068 electrons to the ring, raising α_p at N(1), N(2) by 0.38, 0.29 eV. Other aspects of methyl substitution are shown by the comparative calculated energy levels of pyrazole, 1-methylpyrazole, and 1,3,5-trimethylpyrazole (Fig. 9). All occupied levels are raised without change of order. The HOMO is the N(2) lone-pair orbital; the negative charge on this atom is increased from 0.332 to 0.343 to 0.365 electrons. The effect arises principally from the transfer of 0.174 electrons from the *N*-methyl group to the ring; the 3- and 5-methyl groups are themselves weak acceptors. The general effect of an electropositive perturbation at N(1) is to strengthen bonds 1–2, 3–4, and 5–1 at the expense of 2–3 and 4–5. A purely inductive interaction at N(2) is simulated by protonation of 1,3,5-trimethylpyrazole and is considered briefly at the end of the paper.

Conjugative interactions are to be expected between pyrazolyl and phosphazenyl rings, though they should be smaller than in pyrrolylphosphazenes (19). They are discussed first in relation to the simpler molecule bis(1-pyrazolyl)carbonyl **7** (48). Calculations of electron density are summarized in Table 6 for 1-methypyrazole and 1-formylpyrazole, both with and without[6] exocyclic N–C conjugation. The pyrazole ring is a net acceptor in all cases, the slight decrease (0.013) from (*a*) to (*b*) arising from the greater electronegativity of CHO relative to CH_3. Conjugation, in (*c*), greatly reduces the ring charge, as a result of a large π donation (0.175) to the formyl group, partly offset and facilitated by a σ transfer of 0.060 from the formyl group.

TABLE 4. Torsion angles (deg) about bonds to pyrazolyl group[a]

Compound	Torsion angles
1	−9, −5
2	−177, −177
3, P(1)	−28, −28
3, P(2)	−23, −48
4, P(1)	174, 180
4, P(2)	4, 177
5, molecule 1, P(1)	136, 143
5, molecule 1, P(2)	−22, −34
5, molecule 2, P(3)	30, 43
5, molecule 2, P(4)	−140, −155
6, P(2)	−22, −1
6, P(3)	−2, −26

[a]Pairs of angles θ, ψ are related enantiomerically to those with π−θ, π−ψ. The angles shown are torsion angles about the C—N(pz) or P—N(pz) bond, zero for the open-book conformation, in which the normal to the pyrazolyl ring is coplanar with the N(pz)—P(C)—N(pz) plane.

Structurally, the effect of conjugation is seen in the planarity of the molecule as a whole and in the calculated and measured differences in bond length between **7** and **1** (Table 7). The inductive and conjugative effects are of the same sign and qualitatively indistinguishable; both reproduce the pattern of bond lengths correctly. However, in the absence of conjugation, the characteristic shortening of bonds 2–3 and 4–5, ca. 0.005 Å, would be undetectable. The conjugative effects are not much greater, but correspond fairly well to the measured differences, though again the experimental values are significantly greater than those calculated. The mean error is 0.006 Å. As expected, the inclusion of conjugation decreases the total bond population in the ring (by 0.025) and in the carbonyl group (by 0.043), but the molecule as a whole is stabilized by the additional π population in the exocyclic N—C bond (0.116). The enhanced π donation from the ring makes the ring atoms more electronegative, but the competition for π electrons between the ring and the carbonyl group restricts conjugation, so that the exocyclic N—C (1.393 Å) and C—O (1.195 Å) bonds are, respectively, somewhat longer and shorter than those characteristic of simple amides (1.333, 1.235 Å) (49). The calculations agree with the earlier crystallographic investigation (48) that delocalization is not extensive, but add the point that the partial quinonoid localization is largely a result of conjugation with the carbonyl group.

Pyrazolyl–monophophazene interactions

The dimethylpyrazolyl group attached to a phosphazene ring shows the same structural evidence of bond localization, but the quinonoid shortening of bonds 2–3 and 4–5 is more marked. The pyrazolyl groups in **3** and **5** do not differ significantly, either within or between the separate molecules. Both show significant shortening of the 2–3 and 4–5 bonds relative to **2** (Fig. 10). The pattern of inequalities is the same as in **7**, and, although there are differences in detail, the mean absolute difference between **7** and **1** 0.019 Å) is almost the same as that between **3** and **2** (0.020 Å) and between **5** and **2** (0.018 Å). The interactions between the two rings in **3**, **4**, and **5** evidently have a significant conjugative component, comparable in magnitude to that in **7**. These interactions were modelled initially by calculations on 1-phosphinylpyrazole.

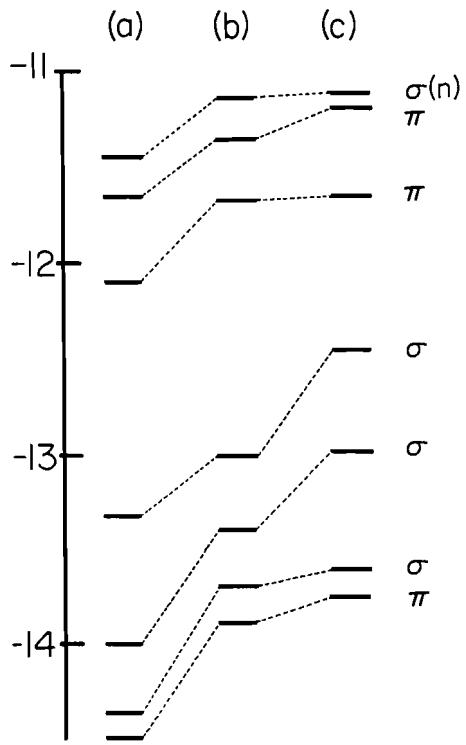

FIG. 9. The calculated highest occupied orbitals (eV) in (*a*) pyrazole, (*b*) 1-methylpyrazole, (*c*) 1,3,5-trimethylpyrazole. The LUMO (π) is higher by 3.58, 3.49, 3.45 eV respectively.

[a]Inductive only.
[b]Inductive plus conjugative effect.

The —H_2PO group differs from the —CHO group in that, in an *sp* basis, σ and π bonding are competitive. In valence-bond terms, all three *p* orbitals are formally required for σ bonding; none are available exclusively for π bonding. Deviations from formal charges are given in Table 6 (*d*, *e*). The ring is now a stronger acceptor, and in the absence of exocyclic N–P conjugation, the phosphinyl group transfers both σ and π electrons. When conjugation is permitted, the electron release to the ring is reduced, but not drastically. The biggest change from 1-formyl to 1-phosphinylpyrazole (*sp* basis, both conjugated) is in the reversal of sign of the large

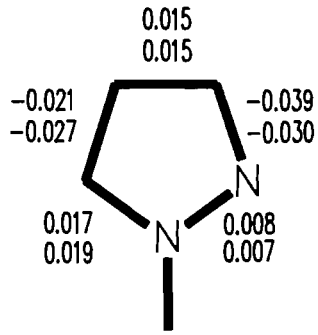

FIG. 10. Differences between average bond lengths (Å) in **3** and **2** (upper figures) and **5** and **2** (lower figures).

component of π charge, from -0.180 to 0.157 electrons (Table 6); the pyrazole ring is now a strong π acceptor. There is little competition from the phosphinyl bond, in which the π population is 0.098, compared with 0.315 for the carbonyl bond. The expected differences from **1** have the wrong pattern and the wrong sign, and are too small numerically. The *sp* basis does not allow the strengthening of the 2–3 and 4–5 bonds found for the dimethylpyrazolylphosphazenes (Fig. 10).

Comparability of phosphinyl and carbonyl compounds is achieved by the introduction of acceptor orbitals at phosphorus, which in the present semiempirical method are valence-shell *d* orbitals. Several comments are required. First, the geometry at phosphorus is non-planar, so that the simple σ/π division loses some of its value; a particular *d* orbital may contibute to bonding of both classes. Second, although π-bond populations can still be defined and assumed proportional to π contraction, the proportionality constant is unlikely to be the same as for $p\pi$–$p\pi$ bonding. Third, there is no agreement on the best *d*-orbital parameters. The exponent was taken to be 1.400, the Coulomb parameters being determined jointly by the assumed VSIE parameters and the electronegativities of the neighboring atoms. The final value, after iteration, was typically 2.5 eV more negative than the initial value (α_d), usually taken to be in the range 0 to -5 eV, the converged value then being about 8–10 eV above the 3*p* orbitals. Although α_d was frequently taken to be -3 eV, the bond populations (as distinct from charge densities) were found to be insensitive to the choice and, in spite of the limitations referred to above, useful conclusions are possible.

TABLE 8. Effect of exocyclic conjugation on π-bond population in $H_2pzP(H_2)O$[a]

	H_2pz ring	N–P	P–O	Total
(*a*)	0.958	0.0	0.106	1.064
(*b*)	0.951	0.043	0.098	1.093
(*c*)	1.020	0.132	0.318	1.470

[a](*a*) No P–N conjugation. (*b*) $p\pi$–$p\pi$ N–P conjugation only. (*c*) $p\pi$–$p\pi$ + $p\pi$–$d\pi$ conjugation: α_d = -1 eV.

We consider the three classes, phosphine oxides, pyrazolyl–monophosphazenes, and the pyrazolylcyclophosphazenes **3–6**. The effect of *d* orbitals on the charge distribution in 1-phosphinylpyrazole $H_2pzP(H_2)O$ is shown in Table 6*f*; compared with the *sp* basis, the phosphoryl group becomes a strong π acceptor rather than a strong π donor, the transfer being coupled with a return of electrons to the σ system of the pyrazole ring. The final distribution is similar to that in 1-formylpyrazole (Table 6). The synergic process by which it is attained is the key to the structural and chemical characteristics of the pyrazolylphosphazenes.

Although no structure of a pyrazolylphosphine oxide has been determined, there is extensive spectroscopic, thermochemical, and structural evidence for conjugative interactions in phosphine oxides R_3PO in which R is an electron-releasing group (50). Table 8 shows that the N–P π population characteristic of a conjugated system is small in an *sp* basis. The introduction of *d* orbitals strengthens this interaction significantly, and the π populations of the phosphoryl bond even more. The calculated π populations in the pyrazole ring show the expected strengthening of the 2–3 and 4–5 bonds, similar to that in 1-formylpyrazole.

More detail on the electronic effects of the pyrazolyl groups is provided by calculations on the monophosphazenes $RP(H_2)NH$ (R = Ph, Cl, Me_2pz) (Table 9) and the methyl derivatives 1-methylpyrazole and 1,3,5-trimethylpyrazole. To a methyl group, the pyrazolyl and dimethylpyrazolyl groups are poorer acceptors than a chlorine atom, their net charges being -0.174, -0.177, and -0.198 (Cl in MeCl). In the monophosphazenes, the negative charge on R increases in the order R = Ph < Cl < Me_2Pz, but although it decreases in the last case as the *d* orbitals are made more electronegative, the pyrazolyl group is still a better acceptor than chlorine. The phenyl group is calculated to be a weak

[a]$\alpha_d = -1.0$ eV.
[b]$\alpha_d = -3.0$ eV.

acceptor, and only weakly conjugated to the phosphazene group (in agreement with experiments (14, 15)). As α_d is made more electronegative, the *d* population and the π components increase greatly, while the positive charge on phosphorus decreases. Conjugation again strengthens, as expected, the 2–3 and 4–5 bonds of the pyrazolyl group at the expense of the others, to an extent which is embodied in the bond-length calculations (Table 10).

Cyclic phosphazenes

The phosphazene ring bonds, also, are affected by interaction with the pyrazolyl group. Although the cyclic phosphazenes **3–6** and even the mono(dimethylpyrazolyl)-cyclotriphosphazene are all too large for direct calculation, their structural and chemical properties can be elucidated by comparison of the effects of chlorine, fluorine, and the pyrazolyl group on the phosphazene ring. Comparative calculations on $N_3P_3H_6$ and $N_3P_3H_5Cl$ show the expected features; electron withdrawal by chlorine (greater than in the monophosphazene) and alternating π-bond populations, the largest being in the bonds to the P(H)Cl group (Table 11). The pyrazolyl group is a better acceptor than chlorine and, for the same α_d, the population alternation is more marked. In $N_3P_3Cl_5(H_2pz)$, the net negative charge on the pyrazolyl group is reduced, but because Cl is more electronegative than H, the scale of the alternation is decreased, though it still has the same sense. In $N_3P_3F_5(H_2pz)$, the negative charge on pyrazole is reduced further, but it is still greater than that on Cl in $N_3P_3H_5Cl$. The most important point is that the sense of the alternation in bond populations is reversed, the π bonds to P(F) (H_2pz) being the weakest. We can conclude that the structural effect of a pyrazolyl group is approximately the mean of those of the chlorine and fluorine atoms, i.e., it behaves as a strongly electronegative group. In view of these results, and the calculated minor effect of dimethylation on the acceptor properties of the pyrazole group, it is surprising that the difference between the Ph_2P—N and N—P $(Me_2pz)_2$ bonds in **6** (0.042 Å) is smaller than the corresponding difference in $Ph_2P_3N_3Cl_4$ (0.060 Å) (38). It may be that the calculational method is inadequate, as it is in predicting the difference between **1** and **2** (Table 5). The calculations nevertheless reproduce satisfactorily the bond lengths in the pyrazole rings of **5** (Table 10).

The remaining structural feature for comment is the length of the inter-ring P—N bond, which should reflect the degree of conjugative interaction between the rings. The (weighted) mean *exo*-P—N bond length in **3**, **4**, and **5** is 1.684 Å (mean derivation 0.009 Å), but the assessment of the π contraction is not straightforward, because the σ-bond length cannot be calculated accurately. We prefer to use a direct comparison, specifically with the structure of (octakisdimethylaminocyclotetraphosphazene)tetracarbonyltungsten (51), in which coordination of one dimethylamido group to tungsten prevents donation of its lone pair to the phosphazene ring. The *exo*-P—N bond length is increased to 1.77 Å. If we take this to be the appropriate σ-bond length, the π contraction in **3**, **4**, and **5** is 0.09 Å, compared with 0.11 Å for the comparison molecule. It is likely that this is an overestimate and we prefer to take 0.06 Å as a probable π contraction, though the quinonoid deformation of the pyrazolyl ring is better evidence of conjugation. The important point, however, is that although the demands of the aromatic sextet reduce the *exo*-P—N π bonding to about half what it might otherwise be, there is still an effective conjugative interaction between the rings.

We discuss two chemical points, reactivity and donor properties. An electronegative substituent on phosphorus increases the mean positive charge on phosphorus and, especially, the charge on the substituted atom. Accelerated nucleophilic attack is thereby promoted and in fact no partially substituted derivatives have yet been reported from the

reaction of a pyrazolide ion with $(NPCl_2)_n$. From Table 11, non-geminal derivatives might be most easily obtainable from reactions with $(NPF_2)_n$. The reactivity of a pyrazolyl–phosphazene bond, once formed, is less simple. In the related compound hexa(imidazolyl)cyclotriphosphazene (**8**), the calculated ligand–PN interactions are almost the same as in the pyrazolyl compounds, as shown by the *exo*-PN bond length (1.680 Å) (52), but **8** is nevertheless much less stable to hydrolysis. The kinetics of the reaction are complex (53), but the first step probably involves the electrophilic interaction of water with the pyridinic nitrogen atom. If the same mechanism applies to the hydrolysis of pyrazolylphosphazenes, the difference between the reactivity of the two series can be ascribed to a difference between electron availability there. Although the calculated negative charge is only 0.04 greater in imidazole, the lone-pair orbital lies 0.82 eV higher (probably because the two nitrogen atoms are further apart) and is expected to interact more strongly with a water molecule. In an apparently similar pair of reactions, *N*-acetylimidazole is hydrolysed 22 times faster than *N*-acetylpyrazole (54), the rates paralleling the base strengths of the parent heterocycles (pK_{BH^+} = 2.47(pzH), 6.95(imH)) (55). The calculations generally support Kauffmann's (56) suggestion that azoles containing more than one N atom bound by way of an N atom correspond to halogen and other good leaving groups.

The same considerations are important to complex formation. Dimethylamidophosphazenes ordinarily coordinate to a positive centre through the nitrogen atoms on the PN ring, the ligands having lost much of their electron density to the ring by conjugation. Such back-donation is sufficiently restricted in **3**–**6** to allow the formation of stable complexes through N(2) (23, 24). We mention two significant features of the calculations. (*a*) Because of the extensive σ withdrawal from the PN ring (simulated in the calculations by a phosphinyl group), the proton affinity of the dimethylpyrazolyl group is greater (by about 0.2 eV) than when it is attached to a methyl group at N(1). (*b*) As the *d* orbitals are made more electronegative, the phosphazene ring tends to be favoured as a protonation site. More detail is given elsewhere (see footnote 5).

Reçu le 8 août 1991[1]

J.-P. JAY-GERIN et C. FERRADINI. Can. J. Chem. **70**, 1869 (1992).

Un modèle concernant l'influence possible de l'ion positif géminé sur le destin de l'électron piégé incomplètement relaxé (e_{ir}^-) dans les liquides polaires irradiés est proposé. Ce modèle est basé sur l'éjection, par un mécanisme d'effet tunnel et (ou) de saut de piège à piège dans le champ coulombien du cation, des électrons occupant des états localisés peu profonds préexistant dans le solvant au-dessous du bas de la bande de conduction de celui-ci. Les électrons éjectés pourraient soit se recombiner avec l'ion positif géminé, soit se piéger à nouveau. Globalement, le vidage des pièges peu profonds se ferait au profit des pièges plus profonds, contribuant ainsi à la diminution de la partie infra-rouge du spectre d'absorption de l'électron traduisant les tout premiers stades de la solvatation. Un tel processus impliquerait donc l'existence d'un maximum du spectre d'absorption de l'électron e_{ir}^-.

J.-P. JAY-GERIN and C. FERRADINI. Can. J. Chem. **70**, 1869 (1992).

A model is proposed concerning the influence of the parent positive ion on the fate of the incompletely relaxed trapped electron (e_{ir}^-) in irradiated polar liquids. This model is based on the release, by a tunneling and (or) a trap-hopping mechanism in the Coulomb field of the cation, of the electrons captured in preexisting shallow localized states below the bottom of the conduction band of the solvent. The released electrons would either recombine with the parent positive ion or get retrapped. The net effect would be an accumulation of electrons in deeper traps. The removal of weakly trapped electrons would contribute to the decrease of the infrared part of the optical absorption spectrum during the very early time dynamics of electron solvation. Such a process would imply, as a consequence, the existence of a maximum of the e_{ir}^- absorption spectrum.

De nombreux travaux de radiolyse, tant théoriques qu'expérimentaux, concernant le processus de solvatation de l'électron dans les liquides polaires, ont été développés (pour des revues d'ensemble récentes, voir, par exemple, réfs. 1–4) sans toutefois que les mécanismes alors mis en jeu soient complètement élucidés. Bien que la recombinaison entre l'ion positif géminé et l'électron thermalisé ait toujours été considérée comme se produisant à un stade très primaire (voir, par exemple, réf. 2), un tel processus n'a été que rarement invoqué pour expliquer les anomalies spectrales ou cinétiques fréquemment observées dans cette même échelle de temps. Truong (5) a cependant suggéré que, dans certains verres non polaires irradiés, la décroissance rapide d'une partie des électrons piégés pourrait être attribuée au fait que ces électrons se trouvaient au voisinage de l'ion positif géminé et que la recombinaison par effet tunnel se trouvait ainsi facilitée. Une hypothèse analogue a été proposée par van Leeuwen *et al.* (6) pour expliquer le déclin de la composante absorbant dans le rouge du spectre de l'électron piégé mesuré dans un verre 8 M en NaOH. D'autres suggestions reposant sur des bases différentes ont également été émises (pour une revue d'ensemble récente, voir, par exemple, réf. 7), ainsi la partie «rouge» du spectre a été attribuée à l'électron piégé dans un environnement mettant en jeu des molécules d'eau non liées dans le verre (8). Cette dernière hypothèse est néanmoins difficile à généraliser à tous les cas pour lesquels des observations analogues ont été faites et en particulier l'eau et certains alcools en phase liquide.

Nous envisageons ici un modèle, inspiré de celui déjà proposé dans le cas de la radiolyse de solides amorphes (voir, par exemple, réfs. 9–11), visant à prendre en compte l'influence possible de l'ion positif lors de la description du spectre d'absorption de l'entité négative dans les phases liquides pendant les tout premiers stades de la solvatation de celle-ci.

Les conséquences spatiales et temporelles de la présence de l'ion positif peuvent être schématisées de la manière suivante (voir figure 1).

La figure 1*a* représente une distribution typique des distances de thermalisation d'un électron secondaire, l'ion positif géminé étant situé à l'origine des axes. À titre d'exemple, rappelons que, pour l'eau liquide irradiée, la distance (la plus probable) de thermalisation est estimée à environ 20 Å (voir, par exemple, réfs. 2, 12 et 13).

Une fois thermalisé au bas de la bande de conduction du solvant (que l'on dénote généralement par l'énergie V_0 en référence au niveau du vide), l'électron se localise dans un des pièges préexistants de celui-ci. Il devient alors un électron dit «incomplètement relaxé», noté e_{ir}^-, par opposition à l'électron après solvatation dit «complètement relaxé» (2).

[1]Révision reçue le 22 avril 1992.

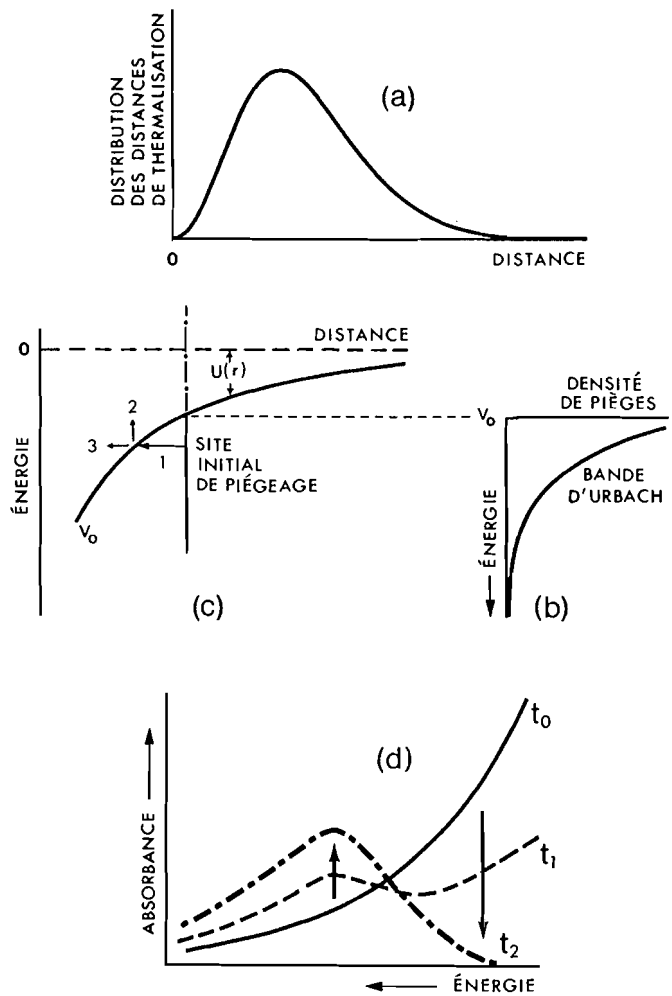

FIG. 1. (*a*) Allure de la distribution des distances de thermalisation en fonction de la distance entre l'électron éjecté et l'ion positif géminé, ce dernier étant supposé à l'origine des axes. (*b*) Allure de la distribution énergétique des pièges préexistants du solvant, décrite par une bande d'Urbach. Cette bande d'états localisés s'étend au-dessous du bas de la bande de conduction, dénoté par V_0, à l'intérieur de la bande d'énergie interdite du liquide. Sa décroissance suit une loi sensiblement exponentielle en fonction de l'énergie des états de piège. Cette loi est, bien sûr, caractéristique du solvant considéré. (*c*) Illustration de l'action de l'ion positif géminé. La courbe en trait plein montre la variation, due au champ coulombien $U(r)$ créé par l'ion positif, du bas de la bande de conduction V_0 du liquide en fonction de la distance r à celui-ci. L'échappement vers la bande de conduction, par effet tunnel et (ou) par saut de piège à piège à travers la barrière de potentiel, d'un électron localisé initialement dans un piège peu profond de la bande d'Urbach est indiqué par la fléche 1. L'électron ainsi éjecté à V_0 est quasi-libre. Il peut alors soit se recombiner avec le cation parent, soit se relocaliser sur un site voisin après un nouvel échantillonnage de l'ensemble de la distribution des pièges de la bande d'Urbach (nous supposons bien sûr que chaque piège possède la même section efficace de capture électronique). Ces deux processus ont été indiqués schématiquement par les fléches 2 et 3. Comme la probabilité d'échappement d'un électron piégé est d'autant plus faible que la profondeur du piège est plus grande, on voit ainsi que, globalement, le processus favorise le vidage des pièges de faible énergie au profit des pièges de grande énergie. (*d*) Évolution du spectre d'absorption de l'électron piégé incomplètement relaxé (e_{ir}^-) en fonction du temps. Le temps initial t_0 correspond au remplissage «primaire» uniforme de tous les pièges préexistants de la bande d'Urbach du solvant. Les temps t_1 et t_2 montrent la diminution progressive de l'absorbance dans la partie «rouge» du spectre par vidage des pièges de faible énergie et l'augmentation concomitante de celle-ci dans la partie «bleue» due au remplissage des pièges de grande énergie. Nous supposons ici que l'absorption optique observée résulte d'une transition électronique directe état lié – continuum à V_0 (voir, par exemple, réf. 19). L'intervention de l'ion positif géminé sur le destin de l'électron avant relaxation impliquerait donc, selon ce processus, l'existence d'un maximum du spectre d'absorption de l'électron e_{ir}^-, de sorte que le passage subséquent de l'électron e_{ir}^- à l'électron solvaté serait facilité.

La distribution énergétique de ces pièges peut être décrite par une bande d'Urbach, caractéristique des milieux désordonnés et située à l'intérieur de la bande d'énergie interdite du liquide, juste au-dessous du bas de la bande de conduction (14–16). De nombreux travaux ont montré que la densité d'états localisés dans cette bande d'Urbach décroissait à partir de V_0 selon une loi sensiblement exponentielle en fonction de l'énergie des états de piège (figure 1*b*) (voir, par exemple, réfs. 17–19).

Un électron ainsi piégé se trouve soumis à l'action de l'ion positif, régie par la loi coulombienne $U(r) = -|e|/(4\pi\varepsilon_0)\varepsilon r$, où e est la charge de l'électron, ε_0 la permittivité du vide, ε la constante diélectrique du milieu et r la distance séparant les deux charges (figure 1*c*). Cette action confère à l'électron e_{ir}^- une probabilité d'être éjecté de son piège par un mécanisme d'effet tunnel et (ou) de saut de piège à piège à travers la barrière de potentiel qui lui est offerte dans le champ coulombien du cation, et d'être ainsi ramené à l'état quasi-libre dans la bande de conduction à une distance plus rapprochée du cation. Compte-tenu de la forme sensiblement «triangulaire» de la barrière, cette probabilité est évidemment d'autant plus grande que la profondeur du piège est plus faible. Chaque fois qu'un électron est ainsi éjecté, il peut soit se recombiner avec l'ion positif géminé, soit se localiser à nouveau dans un piège de la bande d'Urbach après avoir eu une nouvelle chance d'échantillonner l'ensemble de la distribution des pièges existants. En supposant que chaque piège possède la même section efficace de capture électronique, le processus global favorise ainsi le vidage des pièges de faible énergie au profit du remplissage des pièges de grande énergie; l'absorption correspondante manquera donc dans le spectre de l'électron piégé, incomplètement relaxé. Typiquement, on peut estimer qu'un tel processus de vidage interviendrait à des énergies de piège inférieures ou de l'ordre de l'électron-volt.

L'évolution du spectre d'absorption de l'électron e_{ir}^- est schématisée sur la figure 1*d* pour trois temps t_0, t_1 et t_2. Le temps le plus initial, t_0, correspond au remplissage «primaire» uniforme des pièges préexistants de la bande d'Urbach du solvant. Les temps ultérieurs t_1 et t_2 montrent la disparition progressive, selon le processus précédent, des électrons faiblement piégés tandis que la redistribution conduit à une augmentation de la densité optique aux grandes énergies. Un tel processus impliquerait donc l'existence d'un maximum du spectre d'absorption de l'électron e_{ir}^- dans les solvants polaires irradiés. La plupart des expériences menées en radiolyse pulsée, autant dans le cas des alcools liquides à 300 K ou refroidis à basse température (20–24) que dans le cas d'alcools solides (7, 25, 26), n'ont toutefois pas permis, à ce jour, la mise en évidence d'un maximum du spectre des électrons avant relaxation. En raison surtout de leurs limitations à la région infra-rouge en deçà de 800–1300 nm, ces

expériences n'ont en fait montré, aux temps les plus courts, qu'une absorbance croissant de façon monotone dans toute la gamme des longueurs d'onde étudiées. Signalons cependant que Klassen et Teather (27), grâce à des mesures précises s'étendant jusqu'à 2200 nm, semblent avoir nettement établi l'existence d'un tel maximum, vers 2000 nm (~0,62 eV), dans le spectre «initial» à 100 ns des électrons piégés dans des verres irradiés de propanol-1, butanol-1 et pentanol-1 à 6 K.

Le destin des électrons avant relaxation dans les liquides irradiés et principalement l'évolution spectrale aux faibles énergies pourraient donc être expliqués, non pas uniquement par la dynamique de solvatation, mais aussi par l'action de l'ion positif géminé. Un tel effet devrait également être pris en compte dans l'interprétation des résultats concernant la dynamique de la solvatation de l'électron observée en photolyse ultra-rapide, compte-tenu de la proximité, au moment de leur création, de l'électron piégé et du cation parent (28). Le passage de l'électron e_{ir}^- à l'électron solvaté se trouverait ainsi favorisé. Les mesures récentes de Long *et al.* (29) en photolyse femtoseconde semblent d'ailleurs avoir révélé, dans le cas de l'eau, la présence d'un maximum dans le spectre d'absorption de l'électron e_{ir}^- situé vers 900 nm (~1,4 eV) à 180 fs. Ces auteurs ont de plus remarqué que ce spectre présentait une certaine similarité avec celui de l'électron hydraté, ce dernier se formant en 540 fs (29). Il est d'autre part fort probable que l'intervention de l'ion positif géminé dans les tout premiers stades de la solvatation conduirait à une non-conservation du nombre total d'électrons, empêchant ainsi l'observation d'un point isobeste. La possibilité pour l'électron e_{ir}^- de réagir chimiquement avec l'eau et les alcools avant solvatation, telle qu'évoquée précédemment par les auteurs (4, 30), pourrait aussi amplifier la non-conservation du nombre d'électrons. La question de l'existence ou non d'un point isobeste dans le cas de l'eau liquide fait actuellement l'objet d'une controverse (31, 32). Enfin, comme il a déjà été souligné auparavant (28, 33), le modèle proposé ici montre à nouveau l'intérêt d'inclure le rôle de l'ion positif dans les calculs de simulation numérique de la dynamique de solvatation de l'électron.

Remerciements

Les auteurs tiennent à exprimer leurs remerciements au Professeur René Voltz et au Dr Annette Bernas pour de très intéressantes discussions. Ce travail a été réalisé avec l'aide financière du Conseil de Recherches Médicales du Canada et du Programme de Subventions à la Recherche Coopérative de l'OTAN (subvention n° 91/0996).

Ted Schaefer, Kerry J. Cox, and Rudy Sebastian. The conformational distribution of 2-cyanobenzaldehyde and 3-cyanobenzaldehyde in solution and in the vapor. Can. J. Chem **69**, 1039 (1991).

In the fourth column of Table 1 the spectral data are incorrect. The correct Table 1 is presented here. There are two consequences. First, the fractional population of the *o-trans* conformer in CS_2 solution is now 0.55(2) instead of 0.52(2) and, in the vapor, is now 0.58(2) instead of 0.52(2). Second, the solvent dependence of the intraring proton coupling constants in 3-cyanobenzaldehyde, while present, is now similar to that observed for 2-cyanobenzaldehyde and not significantly larger, as previously stated.

TABLE 1. The ^{1}H nmr spectral data for 2-cyanobenzaldehyde and 3-cyanobenzaldehyde at 300 K

Studies of complex formation from permittivity measurements: a statistical reexamination

OTTO EXNER

Institute of Organic Chemistry and Biochemistry, Czechoslovak Academy of Sciences, 166 10 Prague, Czechoslovakia

Received May 1, 1991[1]

OTTO EXNER. Can. J. Chem. **70**, 1873 (1992).

Permittivity measurements on solutions of two compounds present in a variable ratio may reveal complex formation: both the equilibrium constant and the dipole moment of the complex can be in principle estimated. However, an incorrect statistical treatment involving transformation of variables is used quite often, for example, in the classical method of Few and Smith. In this case the estimates obtained are usually biased, or loaded with such a great uncertainty that they are practically worthless. The results of numerous papers, even some recent ones, are thus completely at variance with facts. This is shown in this paper by recalculating equilibrium constants and dipole moments of the complex in 17 examples from the literature. Simultaneously, a correct and simple statistical procedure is suggested. The danger of an incorrect and (or) incomplete statistical treatment may be encountered, for the same reason, even in other, quite different, areas.

OTTO EXNER. Can. J. Chem. **70**, 1873 (1992).

Des mesures de permittivité effectuées sur deux composés présents à des rapports variables peut permettre de déceler la formation de complexes : on peut en principe évaluer la constante d'équilibre ainsi que le moment dipolaire du complexe. Toutefois, un traitement statistique erroné, impliquant la transformation de variables, est souvent utilisé, comme dans la méthode classique de Few et Smith. Dans ce cas, les évaluations obtenues sont généralement biaisées ou elles comportent de telles incertitudes qu'elles sont pratiquement inutiles. Les résultats de plusieurs études antérieures, même de études récentes, diffèrent de la réalité. Dans ce travail, on démontre ce fait en recalculant les constantes d'équilibre et les moments dipolaires de complexes rapportés dans 17 exemples cités dans la littérature. Simultanément, on suggère une méthode statistique simple et correcte. Enfin, le danger d'un traitement statistique incorrect et (ou) incomplet peut être rencontré, pour la même raison, dans d'autres domaines très différents.

[Traduit par la rédaction]

Dielectric measurements have been used many times for detecting complex formation, either of the same or of different molecules (1). In the former case, the permittivity ϵ of a solution is measured by the dependence on concentration (expressed as the weight fraction w_2): three parameters, μ_M, μ_D, K, can be in principle estimated from eq. [1] where the function f has been theoretically derived (2–6). In the latter case (e.g., refs. 7–11) solutions of two components, A and B, are prepared in a variable ratio and eq. [2] contains four parameters, μ_A, μ_B, μ_{AB}, and K.

$$[1] \quad \epsilon = f(w_2, \mu_M, \mu_D, K)$$

$$[2] \quad \epsilon = f(w_A, w_B, \mu_A, \mu_B, \mu_{AB}, K)$$

Of all the parameters the dipole moments of the dimer, μ_D, or of the complex, μ_{AB}, are most valuable while the equilibrium constant K may also be determined by other, possibly more efficient, methods. The dipole moments of the components, μ_A and μ_B, are always obtainable from separate measurements and can be considered as known in eq. [2]: sometimes this holds also for the dipole moment of the monomer, μ_M. Nevertheless, μ_D and K in eq. [1] or μ_{AB} and K in eq. [2] are as a rule estimated simultaneously from the same set of data. This introduces serious statistical problems. Our recent reinvestigation (12, 13) revealed that almost all the values of K and μ_D published to date (e.g., refs. 2–4) are completely wrong due to two defects in the statistical processing. On the one hand eq. [1] was rearranged (2, 4) so that the same variable appeared on both sides; on the other hand the errors of the results were underestimated and their mutual dependence was not accounted for (6).

The whole problem has much broader consequences than those concerning dipole moments or complexes: it is a general problem of correct statistical processing of experimental data, in particular of the use or misuse of the linear regression. For this reason we considered this problem worth one more paper, in which we extend our criticism to the measurements of complex formation according to eq. [2]. Compared to eq. [1], this case seems to be more favourable since the weight fractions w_A and w_B can be varied independently and the data set obtained is more extensive. Nevertheless, some rearrangements of the equation had also been used, with the result that the statistical estimates are biased and their errors underestimated. This is the case with the classical method of Few and Smith (8), which has been used many times in the literature. The approach may be explained using three recent papers from this journal (9–11) that have the advantage of giving explicitly all the necessary data. The measurements are divided into subsets, each with a constant excess (w_B) of the component B. For each subset, the polarization P_A^* is obtained from the experimental permittivities with variable component A, considering B provisionally as a component of the solvent. Values of P_A^* are then input in the regression eq. [3] where P_A' is the value for $w_B = 0$, and P_B is determined separately on pure B. Equation [3] may be viewed as an implicit form of the general equation [2] since P_A^* involves ϵ and w_A.

$$[3] \quad \underbrace{\frac{1}{P_A^* - P_A'}}_{y} = \underbrace{\frac{1}{P_{AB} - P_A' - P_B}}_{\text{intercept}} + \underbrace{\frac{M_B}{K(P_{AB} - P_A' - P_B)}}_{\text{slope}} \underbrace{\frac{1}{w_B d}}_{x}$$

From the intercept of the regression one gets P_{AB} and from it the dipole moment of the complex μ_{AB}. From the slope one

gets K if P_{AB} is already known. The question is whether the premises of a linear regression (see, for example, ref. 14) are met. The explanatory variable x may be considered as a practically exact quantity since its combined error would be less than 0.1% according to the estimated errors (8) of w_B and d. However, the errors in the response function y are not independent of x but increase with decreasing concentration. In the examples of Table 1 this estimated rise might be at least from 1 to 3% in example 4, but from 4 to 100% in example 3. The measurements at the lowest concentrations could be better omitted but the number of degrees of freedom would be reduced too much. Another improvement with the same consequence was estimating P'_A in eq. [3] as the third disposable parameter (10), instead of using the experimental value measured with the pure component A. This value P'_A was essentially arbitrary since optimizing three parameters on the basis of five measurements cannot be trustworthy.

In this paper we have recalculated, according to a statistically correct procedure, several examples from the literature, where the method of Few and Smith (8) was applied. Our intention was to put right the previous erroneous results and to show clearly the difference between a correct and incorrect statistical treatment. Particular attention was given to recent papers (9–11) since it is important to stop proliferation of the error. It was not our intention to recalculate all the examples appearing in the literature: this was not even possible since the original data are not always published.

Results and discussion

Our approach to the problem will proceed in three steps:

1. Checking the calculated values of K and P_{AB} given in the literature (8–11, 15–20).

2. Suggesting an acceptable statistical method for unbiased estimation of these parameters.

3. Estimating the errors of these parameters with respect to their mutual dependence.

1. There is a simple and efficient procedure for testing any theory, with or without optimized parameters. It requires that we calculate back the expected original experimental values, as they should be to correspond to the theory exactly, and to compare with the values actually measured (12, 13, 21, 22). In our case the value of P^*_A may be taken as the original experimental quantity since it is obtained from independent experiments with a reasonably constant error. In this way we calculated the expected values P^*_A in 17 systems from the literature. The standard deviations, s, from the values actually measured are listed in the last column of Table 1, last line in each section. (Table 1 is divided into sections: the first line in each section represents the recalculation we consider our best one, the last line reproduces the parameters given in the literature and the pertinent standard deviation calculated by us.) The values of s range from 0.28 to as much as 206 cm^3. With respect to the estimated experimental error, less than 1 cm^3, values up to 1.5 cm^3 could be acceptable. It follows that in one half of all examples there is no fit of the theory with experiments. Note still that for a comparison not only the overall standard deviation is important but also the distribution of the errors on the individual points (see later Figs. 1 and 2).

2. The suggested statistical treatment is still based on the method of least squares but minimizes the sum of squares (SSQ) in P^*_A according to eq. [4], not in $1/(P^*_A - P'_A)$. The optimum values of the parameters K and P_{AB} can be calculated by successive approximations. For an assumed value of K one gets the corresponding best value of P_{AB} (i.e., optimized for this given K) by differentiating eq. [4] with respect to P_{AB}, eq. [5]. The corresponding SSQ and hence the standard deviation are given by eq. [4]. The procedure is repeated for various values of K to get the minimum SSQ: this may be easily programmed.

$$[4]\quad SSQ = \sum (P^*_A - P^*_A, \text{calc})^2 = \sum \left(P^*_A - P'_A - \frac{K(P_{AB} - P'_A - P_B)}{K + M_B/w_B d}\right)^2 = \min$$

$$[5]\quad P_{AB} = P'_A + P_B + \sum \frac{P^*_A - P'_A}{K + M_B/w_B d} \Big/ K \sum \frac{1}{(K + M_B/w_B d)^2}$$

In this way the optimum values of K and P_{AB} as well as the corresponding standard deviations were calculated for the 17 examples mentioned. The results are given in Table 1, first line of each section. Of course, the standard deviations must be smaller than those based on literature data since they are least-squares estimates (the same criterion both for optimization and estimation of accuracy). However, the difference is sometimes tremendous, e.g., in examples 11, 14, and 15. In these cases the calculations used in the literature have nothing in common with reality, as seen very objectively from a graphical comparison of experimental and calculated P^*_A values in one example (Fig. 1).

In the above calculations P'_A was the experimental quantity for the component A. It would be possible to treat even P'_A as a disposable parameter, but the number of available data (four to eight items) is too small for adjusting three parameters (K, P_{AB}, P'_A) reliably. Only in cases when an optimized P'_A was suggested in the literature (10) have we added calculations with this P'_A and with the optimum values of K and P_{AB} for this given P'_A. The results (Table 1, middle line in examples 3–5) are sometimes more precise than without adjusting P_A (first lines) but they have one less degree of freedom. Use of the third disposable parameter is in our opinion not justified. This conclusion is well demonstrated by the graphical representation (Fig. 2) in which the example selected was relatively the most favourable of those given in ref. 10. To show finer differences, relative P^*_A values were plotted instead of the absolute values as plotted in Fig. 1. The least-squares calculation with two parameters (K and P_{AB}) was chosen as a reference line (line 1, the x-axis). When the experimental points are pictured with an error of ± 2 cm^3, they are well distributed with almost random deviations. The calculations with three parameters (line 2) display only a little better fit for most points: the errors are concentrated on the first, rejected point, pertinent to the pure component A. In our opinion there is no reason for such a treatment. On the contrary, the first point should be known with a better accuracy than the others. Moreover it is not evident from Fig. 1 why P'_A should acquire just the particular value given; by no means can it viewed as an "extrapolated value of P_A to $w_B \rightarrow 0$" (10). Our results, recalculated with P'_A from the literature (10) and K and P_{AB} optimized (Table 1, middle line in example 4), are not much better than in the literature (last line in example 4), they only reveal that calculations with few degrees of freedom are sensitive to small changes. We consider as established that the treatment according to eq. [4],

[a]Experimental data taken from the references as given in the second column. Our calculations are based on eqs. [4] and [5], confidence intervals for $2s$ given in brackets only if they are of any significance. The results from the original literature given in italics.

[b]Equilibrium constant in $cm^3\ mol^{-1}$.

[c]Polarization of the complex in $cm^3\ mol^{-1}$.

[d]Dipole moment of the complex in D; in our calculations correction for the atomic polarization 5% of R_D.

[e]Standard deviation of the fit, calculated by us according to eq. [4], similarly also for parameters given in the literature (degrees of freedom in parentheses).

[f]No convergence.

[g]No convergence, not improved even when the first point is deleted.

[h]Calculated with P'_A as the third adjustable parameter, its value taken as it was given in the literature (10).

[i]With a special correction for solvent effect (8).

[j]The experimental data are of low quality: particularly, the fourth point is evidently in error and was omitted from the calculations. Omitting the third point still does not improve the precision significantly.

[k]Omitting the third point improves s only to 5.6, the enormous discrepancy with literature parameters is not removed.

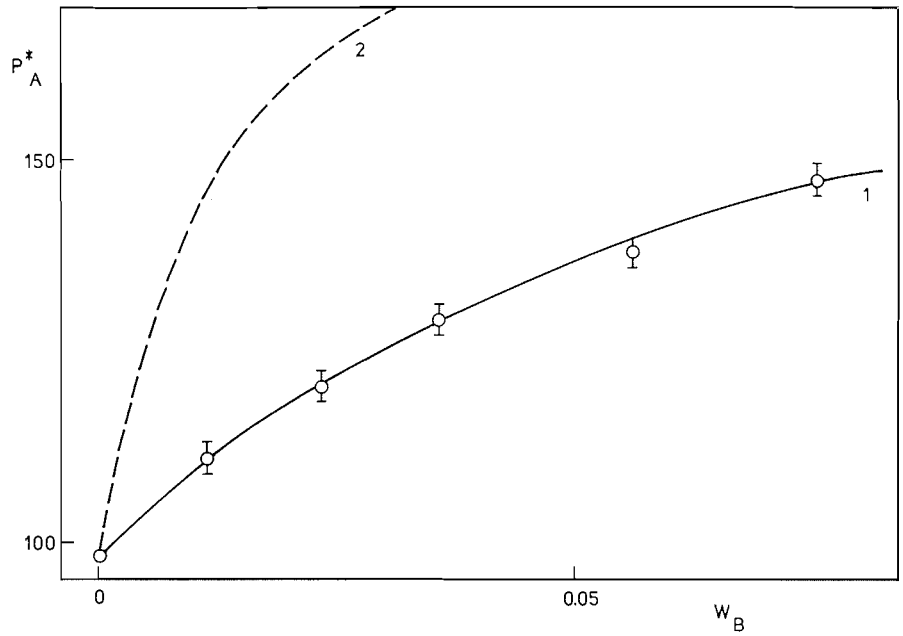

FIG. 1. Comparison of experimental and calculated polarizations P_A^* (absolute values) for complex formation of phenyl acetate with phenol in benzene; 1: the best least-squares fit with K = 1310 cm^3, P_{AB} = 275 cm^3; 2: calculated according to ref. 18. Experimental points (18) are shown with uncertainties ±2 cm^3. (Example 14, Table 1.)

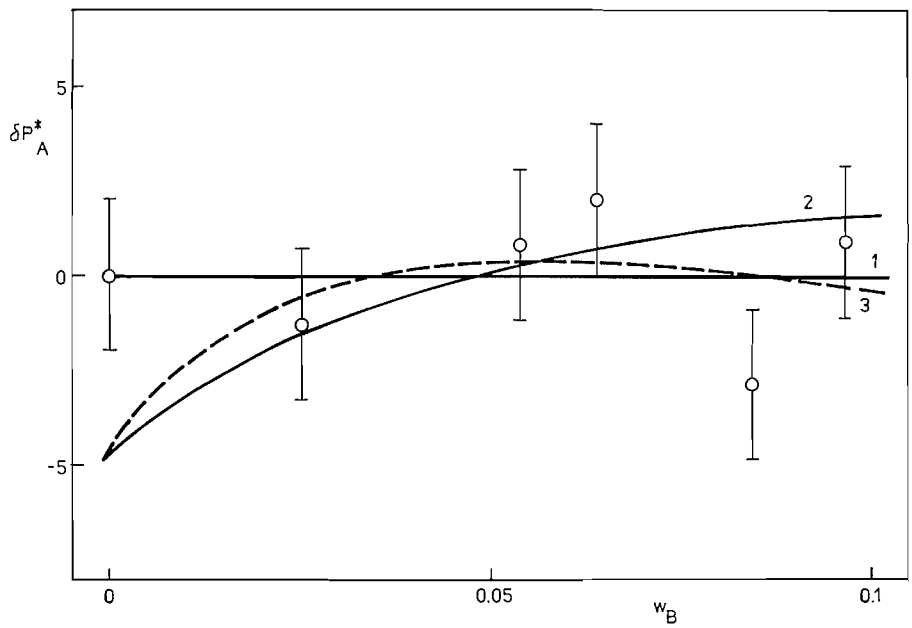

FIG. 2. Comparison of experimental and calculated polarizations P_A^* (relative values) for complex formation of benzoylacetone with triethylamine in cyclohexane; 1: the best least-squares fit with K = 1081 cm^3, P_{AB} = 427 cm^3, as reference line; 2: calculated according to ref. 10 with an arbitrary parameter P'_A = 226.7; 3: calculated with the same parameter and least-squares values for K and P_{AB}. Experimental points (10) are shown with uncertainties of ±2 cm^3. (Example 4, Table 1.)

with only two parameters adjusted, gives the most realistic estimates. It follows that almost one half of the examples of Table 1 do not yield acceptable results with any statistical treatment. Some possible reasons might be low experimental accuracy or too small a value of K (no complex formation).

3. To complete the statistical treatment it is necessary to give at least an estimate of the reliability of the parameters. Since the least-squares problem is not linear, we prefer the following simple and telling procedure (13). If the lowest possible standard deviation (in P_A^*) is known, one can choose its arbitrary multiple, usually between 2s and 3s, and calculate all possible combinations of the parameters (K and P_{AB}) that reproduce the experiments within this accuracy. It is very important that the parameters are strongly dependent on each other: one of them can even be strongly shifted from its op-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

timum value when the second is shifted too (in the opposite direction). Graphical representation of this dependence is a contour diagram (Fig. 3) where the same example was chosen as in Fig. 2, i.e., a relatively favourable one. The pairs of parameters giving the same overall fit (2*s* or 3*s*) are connected by a curve. The confidence interval is given by the extreme points of the whole curve and corresponds to the confidence coefficients 95% or 99.7%, respectively. These intervals are also given in Table 1, but only in those examples when they are actually meaningful. The mutual dependence of parameters is strong: the greatest K belongs to the smallest P_{AB}, and conversely. There is a widespread mistake (in the field of dipole moments, e.g., ref. 6) that the confidence interval of one parameter is given with the condition that the second one be kept constant. In the graphical representation it means to intersect the curve in Fig. 3 by a horizontal or vertical straight line and to read off the distance of the two points of intersection. In this way the actual uncertainty may be badly underestimated, e.g., in Fig. 3 by more than one order of magnitude. See also the unrealistic estimates of the errors in the literature (Table 1) compared to the actual uncertainty.

Until now, K and P_{AB} have been considered as parameters that are to be estimated by the statistical approach. Ultimately, it is necessary to calculate μ_{AB} from P_{AB} and from the molar refraction R_{AB}. We always estimated R_{AB} as the sum of molar refractions of the components: $R_{AB} = R_A + R_B$. The values of R_A and R_B themselves were known either from experimental determination on the liquids or were calculated by us from Vogel's increments (23). In the literature (9–11) a sophisticated procedure was also reported, determining R_{AB} similarly to P_{AB}, with the same statistical shortcoming. The results obtained are quite unreliable but affect the final values of μ_{AB} rather little: this mistake is negligible compared to the much more important mistake in determining P_{AB}. In some other cases our calculations might differ from the literature by applying a 5% correction for atomic polarization: even here the possible error is negligible.

Conclusions

It has been shown here that the method of Few and Smith (8) is principally wrong from the statistical point of view: all the results reported must be considered as untrustworthy. Note, however, that the results of a correct approach must be correct, while the results of an incorrect approach need not be always wrong. This means that they need not differ too much from the best estimates in each particular case. In our case the estimates of K are more sensitive to errors that than those of μ_{AB}. Among the 17 examples of Table 1 we may characterize the following typical cases:

(*a*) The fit in the correct treatment is acceptable in relation to the experimental error (s should be less than 1 cm^3 but we have allowed even 1.4 cm^3). The estimated parameters may be accepted within the given limits of uncertainty. The fit of the Few–Smith procedure is somewhat worse (still $s < 1.7$ cm^3) but the estimated parameters fall within the uncertainty limits (examples 6, 7, and 17 in Table 1), or exceed these limits but slightly (examples 9 and 16). In this case use of the Few–Smith method has no great consequences.

(*b*) The fit of the correct procedure is as good as above ($s < 1$ cm^3) but the Few–Smith procedure gives no fit and very biased estimates of the parameters (example 14). In this treatment the fit usually remains unknown and the results may be completely at variance with reality. On the other hand, we may say that in the six examples cited in (*a*) and (*b*) the parameters K and μ_{AB} have actually been determined when a correct procedure was used. Note that with few degrees of freedom the fit must be very good to accept the result as significant.

(*c*) The fit is as good as above but the uncertainty in the parameters is too great, particularly in K, including even the value $K = 0$ (examples 5 and 8). The reasons for this be-

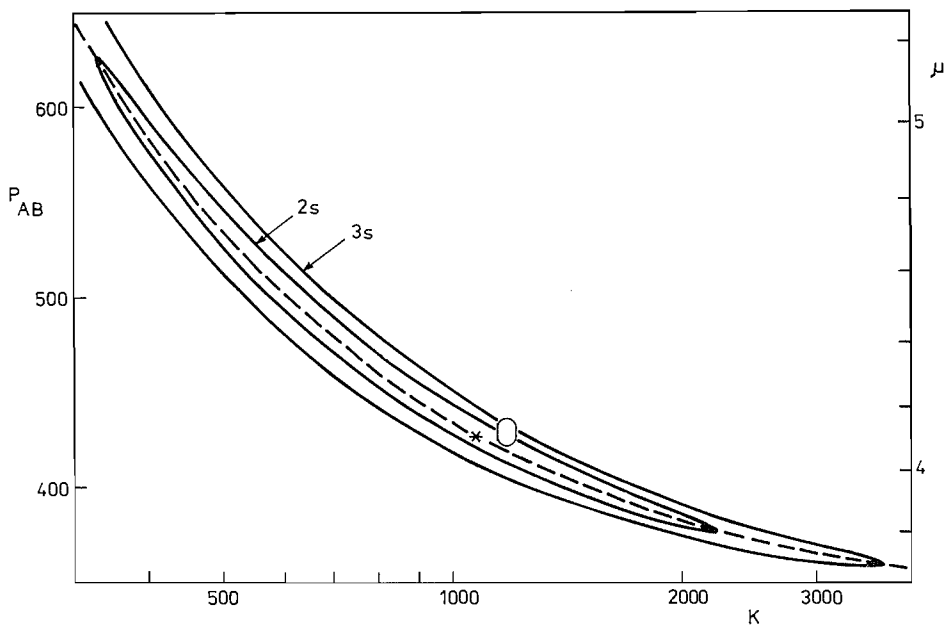

FIG. 3. Mutual dependence of parameters for the same example as in Fig. 2—the contour diagram. Full lines: the dependence of P_{AB} on K for a given standard deviation (twice or three times its minimum value); broken line: the optimum values of P_{AB} for a given K; *: absolute optimum values; empty oval: values from ref. 10, with their given uncertainties.

haviour are difficult to guess; possibly the experiments are insufficiently precise when K is small. The Few–Smith procedure is again at variance with facts: the estimates are biased and their errors badly underestimated.

(*d*) When a good fit cannot be obtained, there is no sense in discussing the values of the parameters and comparing correct and incorrect procedures (examples 10, 11, and 12). When s can be no longer considered as an estimate of the experimental error, our suggested confidence interval for the parameters has little meaning. The reasons may be bad experiments, sometimes even misprints in the literature, or a bad theoretical model (different stoichiometry of complex formation, large solvent effects of the component B). Again the Few–Smith procedure may be very untrustworthy since it does not reveal that the fit is bad. In two borderline cases the fit evidently exceeded the experimental error (s 2.8 cm^3) but the fit of the Few–Smith procedure was dramatically worsened (examples 13 and 15). In another case (example 4) the fit remained almost unchanged and the parameters were not much shifted. This example is shown in Fig. 2. The reason for this indeterminate behaviour may be that relatively imprecise data are connected with few degrees of freedom.

(*e*) In some cases no convergence was reached and the optimum value of K approached zero (examples 1, 2, and 3); simultaneously P_{AB} grew without limits. It is possible that practically no complex formation occurs but in this case P_A should be constant. The model evidently fails and the observed changes of P_A^* must have another reason, say, too large solvent effects of the component B. This cannot be unraveled within the framework of the Few–Smith approach: apparent values of the parameters that have no real significance are obtained instead.

Still more important than a criticism of the Few–Smith method are general conclusions for processing experimental data using regression analysis. In the time of computers there is no need for rearrangement into linear equations. The least-squares principle must be applied to the sum of squares in the original experimental quantity, not in any function. An additional problem arises when two or more parameters are estimated together from the same set of data: then their confidence intervals must be determined with respect to their mutual dependence. Neglecting these requirements has led to both biased estimates and overestimated reliability: this happened in quite different fields of chemistry (21, 22). The results of many papers are thus completely worthless. We dare to say that this is one of the most widespread mistakes in contemporary science. In same cases it cannot be either revealed or corrected since the original data were not published.

Intramolecular electron transfer in the photochemistry of substituted 1-naphthylmethyl esters of benzoic acids

D. P. DeCosta and J. A. Pincock[1]

Department of Chemistry, Dalhousie University, Halifax, N.S., Canada B3H 4J3

Received November 15, 1991

D. P. DeCosta and J. A. Pincock. Can. J. Chem. **70**, 1879 (1992).

Direct excitation of the esters **5** in methanol solvent leads to rapid intramolecular exciplex formation ($k_{ex} = 10^{10}$ s^{-1} for X = CH_3O, Y = CN) with electron transfer from the naphthalene to the benzoate ring. This process dominates the usual fluorescence and reaction of the excited singlet state. The rate of this process can be varied over 10^3 by suitable change in the substituents X and Y. The electron-transfer rates can be correlated with the two-parameter Hammett equation: $\log k_{ex} = 8.48 - 1.5\sigma^+ + 0.77\sigma$. For cases where the rate of exciplex formation is slow, the usual homolytic carbon–oxygen bond cleavage occurs from the excited singlet state. The eventual products result from the ion pair since the rate of electron transfer in the radical pair to form the ion pair is considerably faster than the rate of decarboxylation of the benzoyloxy radical.

D. P. DeCosta et J. A. Pincock. Can. J. Chem. **70**, 1879 (1992).

L'excitation directe des esters **5** dans le methanol conduit à une formation intramoléculaire rapide de l'exciplexe ($k_{ex} = 10^{10}$ s^{-1} pour X = CH_3O, Y = CN) impliquant un transfert d'électron du naphtalène vers le noyau benzoate. Ce processus domine la fluorescence habituelle et la réaction de l'état excité singulet. La vitesse de processus peut varier par un facteur de plus de 10^3 en faisant varier convenablement les substituants X et Y. Il existe une corrélation entre les vitesses de transfert de charge et les deux paramètres de l'équation de Hammett: $\log k_{ex} = 8{,}48 - 1{,}5\sigma^+ + 0{,}77\sigma$. Dans les cas où la vitesse de formation de l'exciplexe est lente, il se produit le clivage homolytique habituel de la liaison carbone–oxygène à partir de l'état singulet excité. Les produits éventuels proviennent de la paire d'ions puisque la vitesse de transfert d'électron dans la paire de radicaux, conduisant à la paire d'ions, est beaucoup plus rapide que la vitesse de décarboxylation du radical benzoyloxy.

[Traduit par la rédaction]

Introduction

The photochemistry of benzylic compounds with leaving groups ($ArCH_2$-LG) is well known (1) to give products that result from both arylmethyl cations and radicals. The partitioning between these two intermediates is controlled by a variety of factors such as the leaving group, the structure of the aromatic ring including substituent effects, the nature of the excited state (singlet or triplet), and the solvent. In general, these factors are still so poorly understood that a reliable prediction about the products for any new system is impossible.

Recently, we have reported (2–4) a detailed study of the photochemistry of 1-naphthylmethyl esters, **1**, in the nucleophilic solvent methanol. As shown in eq. [1] (A = $C_{10}H_{7-n}X_n$), three major products are normally observed. The ether **2** and the carboxylic acid **3** are formed by methanol trapping of the 1-naphthylmethyl cation and the carboxylate anion, respectively. The hydrocarbon **4** is formed by in-cage coupling of the 1-naphthylmethyl radical with R which is formed by loss of carbon dioxide from the initially formed acyloxy radical. The product-yield results for a large number of esters where both substituents on the naphthalene ring

$$[1]\quad \underset{\mathbf{1}(A = C_{10}H_{7-n}X_n)}{ACH_2\text{-}O_2C\text{-}R} \xrightarrow[CH_3OH]{h\nu} \underset{\mathbf{2}}{ACH_2\text{-}OCH_3} + \underset{\mathbf{3}}{H\text{-}O_2C\text{-}R} + \underset{\mathbf{4}}{ACH_2\text{-}R}$$

(2) and the structure of the R group (3,4) were varied could best be explained by the mechanism outlined in Scheme 1. We have suggested that for these esters the excited singlet state (the triplet state for 1-naphthylmethyl esters is unreactive (5,6)) cleaves exclusively to the radical pair. Competition between electron transfer converting the radical pair to the ion pair (k_{ET}) and decarboxylation (k_{CO_2}) then controls the product distribution. This proposal is quite different from previously suggested mechanisms that assumed that product distribution was mainly controlled by the initial competition between heterolytic and homolytic cleavage of the benzylic ester bond in the excited state.

During the course of these studies, we observed that 1-naphthylmethyl benzoate (eq. [1], R = Ph, $n = 0$) behaved anomalously. The first fact noticed was the abnormally long time required in preparative scale photolyses for conversion of the ester to products when compared with, e.g., 1-naphthylmethyl phenylacetate (eq. [1], R = $PhCH_2$, $n = 0$). Since the absorbing chromophore for both these esters is the naphthalene ring, a reasonable expectation would be that excited-state carbon–oxygen bond cleavage would occur with about the same efficiency. The second observation was the very low quantum yield of fluorescence for the benzoate esters. Normally unsubstituted 1-naphthylmethyl esters have values of about 0.14 (3,4) independent of the structure of R. However, for the benzoate with R = Ph, a value of 0.005 was obtained. Third, there was no observable phosphorescence although intersystem crossing followed by emission is a

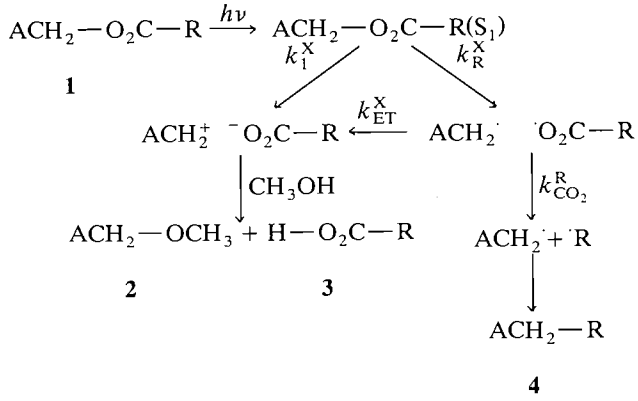

SCHEME 1. General mechanism for the photolysis of 1-naphthylmethyl esters (A = $C_{10}H_{7-n}X_n$) in methanol.

reasonably efficient process for naphthalene derivatives. Finally, the products obtained from the very slow photolysis were almost entirely those resulting from ionic intermediates, i.e., **2** and **3**.

A reasonable suggestion for these observations was that the excited singlet state was being quenched by intramolecular electron transfer, as is well documented for bichromophoric systems where the chromophores are separated by a three-carbon saturated chain (7,8). To investigate this possibility the set of substituted benzoates **5a**–*g* was synthesized and their excited-state behaviour examined. During the course of this work a similar electron-transfer pathway was proposed to explain the fluorescence behaviour of some 1-pyrenylmethyl esters **6** (R being 1-naphthyl, 9-anthryl, and 4-tolyl (9,10)) and **7** (R being 9-anthryl (11)). As will be discussed below these results can be usefully compared to ours.

Experimental

General experimental

All melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Infrared spectra were recorded on a Perkin–Elmer 237B spectrometer and are reported in wavenumbers (cm^{-1}). ^1H nmr spectra were recorded on a Nicolet-360 spectrometer and are reported with chemical shift relative to internal TMS. Mass spectra were obtained on a CEC 21–104 spectrometer; all signals greater than 10% of the base peak are reported as *m/e* (relative intensity). HPLC analyses were performed on a Waters system equipped with model 450 variable wavelength detector. A Brownlee RP-8 analytical column was used with the normal eluting solvent being an 80% methanol–water mixture and detection at 280 nm. Fluorescence spectra were obtained on a Perkin–Elmer MPF 66 spectrometer with samples in methanol that were degassed by three freeze-pump-thaw cycles; quantum yields were determined relative to a value of 0.21 (12) for 1-methylnaphthalene. Fluorescence lifetimes were obtained from the same samples using a PRA system 3000 instrument with a hydrogen flash lamp of pulse width 0.8 ns. Microanalyses were by Canadian Microanalytical Service Ltd., Delta, B.C., Canada.

Preparation of esters

To a solution of the alcohol (20 mmol) in 75 mL of benzene and 1 mL of pyridine was added a solution of the acid chloride (22 mmol) in 20 mL of benzene. After 6 h, the mixture was poured into 50 mL of water and the organic layer was separated, washed with 40 ml each of 10% HCl, 5% NaOH, and water, dried over $MgSO_4$, filtered, and the benzene evaporated. This crude material was chromatographed on silica gel with 30% dichloromethane/hexane as eluant. The esters were then purified by either recrystallization or bulb-to-bulb distillation. Physical properties are given below.

Benzoyl chloride and 4-cyanobenzoyl chloride were from Aldrich; 4-methoxybenzoyl chloride was made from the acid (Aldrich) with thionyl chloride.

1-Naphthylmethanol was from Aldrich; 4-methoxy-1-naphthylmethanol (13) and 4-cyano-1-naphthylmethanol (14) were prepared by literature procedures.

Photolysis of esters

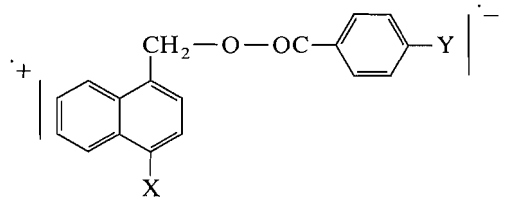
Irradiations were with a 200-W medium pressure Hanovia mercury lamp in a Pyrex immersion well. Normally about 300 mg of the ester was dissolved in 300 mL of methanol and irradiations were continued until more than 90% of the esters was consumed. Reactions were purged with a steady stream of nitrogen gas. Yields were determined by calibrated HPLC using solutions of the products of known concentration. Dark reactions were negligibly slow.

For isolation of the carboxylic acid photoproducts, the reaction mixtures were first concentrated under vacuum to about 10 mL and then dissolved in 30 mL of dichloromethane. The dichloromethane was extracted with 2 × 25 mL of 5% NaOH and the extract acidified with conc. HCl. Extraction and concentration gave the acid which was identified by ^{1}H nmr and the yield determined by weight.

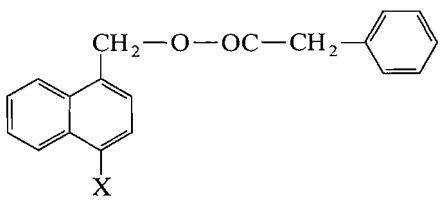
Results and discussion

Fluorescence quantum yields

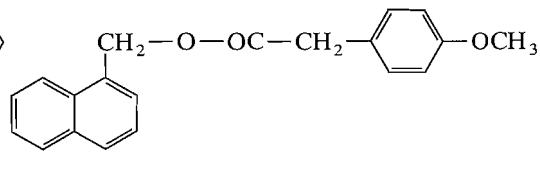
Fluorescence quantum yields for the esters **5***a–g* are reported in Table 1. Clearly, there is a large range in the values from a maximum of 0.20 for **5***g* to a minimum of 0.003 for **5***e*. If these changes reflect charge-transfer quenching of the excited singlet state by an intramolecular process, then the expected direction of this charge transfer should be towards the benzoate aromatic ring which is the better electron acceptor. This suggestion has been confirmed for **7** (11). The exciplex would have radical anion/radical cation character as in **8**. If this is true the efficiency of formation of this species should be highest when the naphthalene ring has a lower oxidation potential because of an electron-donating substituent (X = CH_3O) and the benzene ring a lower reduction potential because of an electron-withdrawing substituent (X = CN). This is the ester **5***e*, which has the lowest ϕ_F. The reverse case, **5***g* (X = CN, Y = CH_3O), has the highest ϕ_F. The obvious conclusion is that intramolecular charge transfer to form an exciplex in the excited singlet state completes with the usual fluorescence emission of the naphthalene ring.



8



9



14

Often, intramolecular exciplex formation of this type results in a new fluorescence emission (7). For the esters **5**, in methanol solvent, only **5***d* showed the expected broad structureless band at longer wavelength (λ_{max} ~ 440 nm) than

TABLE 1. Fluorescence quantum yields for esters **5***a–g*

Ester	X	Y	ϕ_f^5 [a]	ϕ_f^9 [a,b]	$\tau^{PA} \times 10^9$ [b] (s^{-1})	log k_{ex} [c]
5*a*	H	H	0.005	0.14	49	8.74 (0.08)
5*b*	H	CH_3O	0.030[d] (7.6)	0.14 (49)	49	7.87 (0.10)
5*c*	H	CN	0.004	0.14	49	8.84 (0.08)
5*d*	CH_3O	H	0.005	0.27	7.3	9.86 (0.08)
5*e*	CH_3O	CN	0.003	0.27	7.3	10.1 (0.08)
5*f*	CN	H	0.16 (5.0)	0.21 (5.2)	5.2	7.77 (0.48)
5*g*	CN	CH_3O	0.20 (5.0)	0.21 (5.2)	5.2	6.98 (0.70)

[a]Values in parentheses are singlet lifetimes in nanoseconds.
[b]For the corresponding phenylacetate **9**, see D. P. DeCosta and J. A. Pincock, to be published.
[c]The error in log k_{ex}, given in parentheses underneath, is calculated assuming a ±10% error in both ϕ_f^5 and ϕ_f^9.
[d]A value of 0.05 was obtained in hexane.

the normal fluorescence for 4-methoxy naphthalene derivatives at 340 nm. The intensity of this exciplex emission was about 20% that of the normal emission. The same compound in hexane solvent gave an exciplex band about seven times as strong as that observed in methanol. A more detailed study (10) of solvent effects on excimer emission for **6** (R = 9-anthryl) showed the same effect. In an earlier study (9), the same authors also confirmed that not all intramolecular exciplexes of this general structure are emissive. For **6** (R = 1-naphthyl), the quenching of the normal fluorescence occurred, but no new bands were observed.

The fluorescence quantum yield data for **5***a–g* can be analyzed in a more quantitative way as follows. As a model for the fluorescence of these compounds, the corresponding phenylacetate esters, **9**, seem ideal. The excited singlet-state properties of these substrates should be the same as those of **5**, except now intramolecular exciplex formation is no longer occurring. This must be so since the quantum yield (4) of fluorescence (0.14) of the phenylacetate ester **9***a* is identical to that of the related acetate ester (3) which does not have a good electron-accepting functional group. The quantum yield of fluorescence (ϕ_f^9) of the compounds **9** will be given by eq. [2], where the rate constants are for reactivity of the excited singlet state: fluorescence, radiationless decay (inter-

$$[2] \quad \phi_f^9 = k_f/(k_f + k_d + k_r) = k_f \tau_f^9$$

system crossing and internal conversion), and reaction (carbon-oxygen bond cleavage), respectively. The reciprocal of the denominator of eq. [2] is the singlet lifetime τ_f^9.

A similar expression for the compounds **5** is given in eq. [3], where the only additional term is k_{ex}, the rate of intramolecular exciplex formation.

$$[3] \quad \phi_f^5 = k_f/(k_f + k_d + k_r + k_{ex})$$

Division of eq. [2] by eq. [3] gives eq. [4].

$$[4] \quad \phi_f^9/\phi_f^5 = 1 + \tau_f^9 k_{ex}$$

Values for the fluorescence quantum yields and singlet lifetimes for **9***a–c* are given in Table 1, as are the calculated values for k_{ex} (in logarithmic form). The values of k_{ex} span almost three orders of magnitude and, as expected, the fastest rate is for **5***e* and the slowest for **5***g*. For **5***e*, therefore, exciplex formation dominates the processes available to the excited singlet, whereas for **5***g* exciplex formation is too slow to compete with normal emission.

Some comment is necessary concerning the accuracy of this method for determining k_{ex} values. For some cases, the ϕ_f values are very small (≤0.005). Determining accurate fluorescence efficiencies for weakly emissive compounds is inherently difficult but perhaps even more so for these cases. All the esters were made from the corresponding 1-naphthylmethanols which have high quantum yields of fluorescence (0.2–0.4). Therefore, if the alcohols (or other highly emissive naphthalene derivatives) are present as even very low percentage impurities in the esters, significant error in the quantum yields could result. We have, of course, used highly purified samples and made measurements on more than one sample of each compound. We therefore feel confident that the values reported are accurate within the ±10% error limits given in Table 1. Even these error limits can lead to quite large errors in the values estimated for log k_{ex}, particularly where ϕ_f^5 and ϕ_f^9 are quite similar as for **5***f* and **5***g*. A better experimental way to arrive at these values might be to use singlet lifetimes. Unfortunately most of the compounds studied here have singlet lifetimes which are shorter than the limit of ~1 ns for our single-photon counting equipment. For those cases (**5***b*, **5***f*, and **5***g*) where singlet lifetimes are available, the ratio of τ_f^9/τ_f^5 is, within experimental error, close enough to ϕ_f^9/ϕ_f^5 to give us confidence in the accuracy of the fluorescence quantum yields.

The values for log k_{ex} can be put on a more quantitative basis by application of a linear free energy approach. Assuming that the exciplex can be represented by a charge-separated structure like **8**, then the rates of its formation might be expected to follow a two-parameter Hammett function as in eq. [5].

[5] $\log k_{ex} = K + \rho^+\sigma^+ + \rho\sigma$

The $\rho^+\sigma^+$ term would be for the oxidation of the naphthalene ring. Recent results (15) for the electrochemical oxidation of substituted methylnaphthalenes show a good correlation of E_{ox} (CH_3CN vs. SCE) with σ^+ ($\rho^+ = -8.4$ *V*/σ^+). The $\rho\sigma$ term would be for the reduction of the benzoate functional group. There is some question of what sigma value to use here. The available literature data (16) for the reduction potentials of substituted benzoates or even substituted acetophenones or benzaldehydes with resonance electron-withdrawing groups is insufficient to decide if the reduction process should correlate with σ or σ^-. Recent *ab initio* calculations at the STO-3G level (17) for the radical anion of 4-cyanobenzaldehyde indicate that 27% of the negative charge is on the carbonyl oxygen and a similar amount is on the nitrile nitrogen.

A plot of the data in Table 1 according to eq. [5] is shown in Fig. 1. The calculated line is eq. [6] ($R^2 = 0.95$), where the values in parentheses are the standard deviations.[2] The

[6] $\log k_{ex} = 8.48(0.12) - 1.5(0.2)\sigma^+ + 0.77(0.37)\sigma$

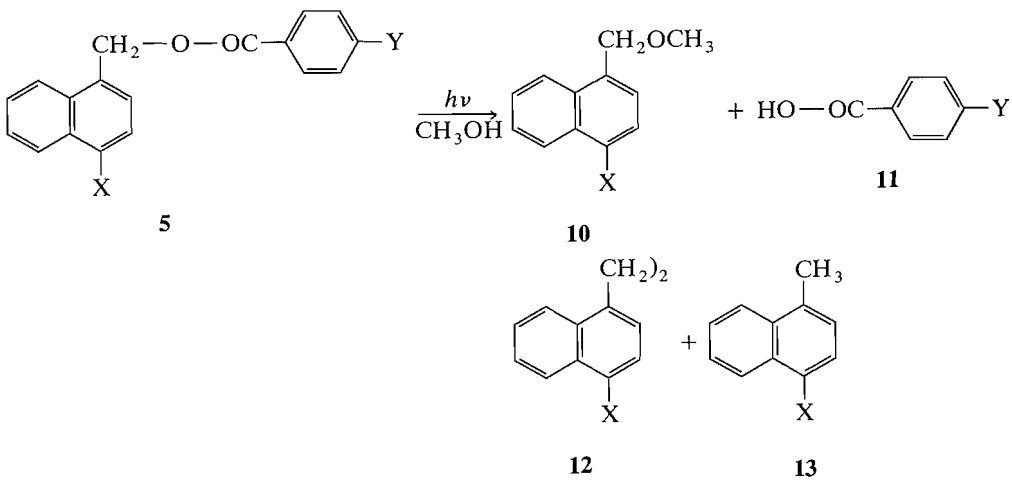
correlation is reasonably good and certainly shows the expected trend with a negative ρ^+ value for the naphthalene ring and a positive ρ for the benzoate ring.

As a confirmation of this electron-transfer quenching process, the intermolecular quenching of 1-methoxynaphthalene by methyl benzoate was examined. The fluorescence intensity results gave a good Stern-Volmer plot ($k_q\tau = 13.7 \pm 0.8\ M^{-1}$) which along with the measured singlet lifetime ($\tau = 11$ ns) gives a quenching rate constant $k_q = 1.2 \times 10^9\ M^{-1}\ s^{-1}$. The value for the similar intramolecular case, **5***d* is somewhat faster ($7.2 \times 10^9\ s^{-1}$). However, the two processes may not, in fact, be too closely related. The mechanism for intramolecular electron transfer in **7** has been suggested (11) to occur through the bonds followed by a Coulombic attraction that enables rotation about the ester functional group to the conformation with the two chromophores sitting face-to-face as required for a stable exciplex. The conclusion from this section is that for suitably substituted derivatives of **5**, intramolecular exciplex formation by charge transfer can be fast enough to dominate other possible processes of the excited singlet state. The effect that this process has on actual photoreactivity will be discussed next.

Photolysis of esters **5**

The products for the photolysis of the esters **5***b*, *d*, *f*, *g* are given in eq. [7] and the product yields in Table 2. The products **10** and **11** are those expected from the photolysis

[7]



5 **10** **11**

12 **13**

of other esters (eq. [1] and Scheme 1). However, the products **12** and **13** derived from the 1-naphthylmethyl radical intermediate are no longer resulting from decarboxylation of the acyloxy radical. This is not surprising since aromatic acyloxy radicals are known (18) to decarboxylate quite slowly ($k_{CO_2} \sim 10^6\ s^{-1}$). Therefore in Scheme 1, k_{ET} should dominate k_{CO_2}. Normally, this would lead to products resulting entirely from the 1-naphthylmethyl cation and the acyloxy anion. This is seen to be true for **5***b* and **5***d* where k_{ET} is expected to be relatively fast (2) because of the stability of the 1-naphthylmethyl cation that is formed. Note that the yield determined for the carboxylic acid **11** is lower than expected, but this is explicable since the value is obtained by weight of isolated material after extraction. The yield of the ether **10**, determined by calibrated HPLC on the photolysis solutions, gives a better measure of the intervention of ionic intermediates.

For the esters **5***f* and **5***g* significant yields of products derived from the 1-naphthylmethyl radical are now formed. As mentioned above, the coupling product **4** is not formed because decarboxylation of the aromatic acyloxy radical is slow. However, now k_{ET} is also expected to be slower because of the effect the 4-cyano group has on the oxidation potential of the 1-naphthylmethyl radical (2,15). Therefore, the process that competes with electron transfer in the radical pair is cage escape. Since the 1-naphthylmethyl radical is not expected to efficiently abstract a hydrogen atom from methanol (the process is endothermic by about 46 kJ mol^{-1}) (5), the product formed is the dimer. 1-Methylnaphthalene, **13**, is formed in low yield but the source of the hydrogen atom is likely the reactive methylene group in either the starting ester **5** or the product ether **10**. This conclusion is substan-

[2]The corresponding equation for σ^- ($\log k_{ex} = 8.43\ (0.16) - 1.6\ (0.3\ \sigma^+ + 0.55\ (0.36)\ \sigma^-$; $R^2 = 0.93$) is not significantly different.

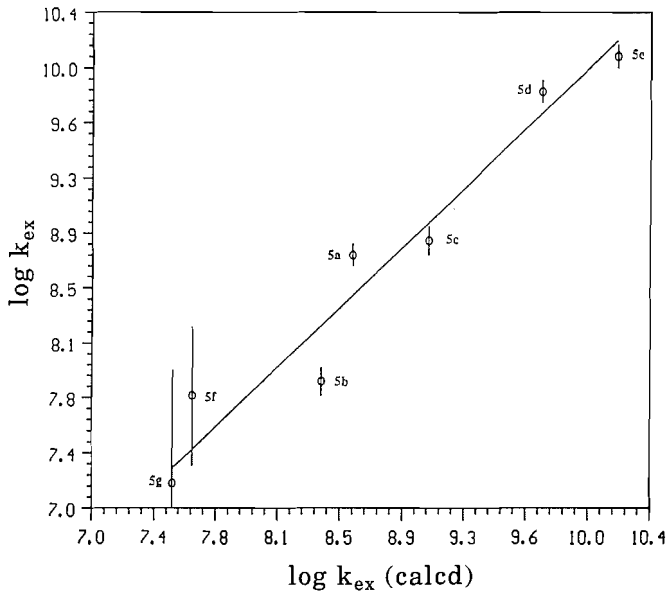


FIG. 1. Plot of log k_{ex} versus log k_{ex} (calcd.) = 8.48 − 1.5 σ^+ + 0.77 σ (R^2 = 0.95, s = 0.31) for intramolecular exciplex formation for the esters **5***a*–**5***g*. The error bars assume a ±10% error in the measurement of ϕ_f.

TABLE 2. Product yields (%) for photolysis of esters **5** in methanol

Substrate	**10**[a]	**11**[b]	**12**[a]	**13**[a]
5*b* (X = H, Y = CH_3O)	88	70	<2	<2
5*d* (X = CH_3O, Y = H)	92	80	<2	<2
5*f* (X = CN, Y = H)	66[c]	55	22	5
	55[d]	40	2	40
5*g* (X = CN, Y = CH_3O)	66[e]	100	22	5
	60[f]	61	2	39

[a]Yield determined by calibrated HPLC.
[b]Yield determined by weight of acid isolated by basic extraction of the phosolysis reaction mixture.
[c]Molarity of **5***f*: 8.1×10^{-4}.
[d]Molarity of **5***f*: 3.5×10^{-3}.

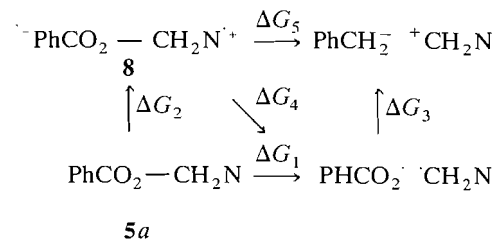
[f]Molarity of **5***g*: 2.2×10^{-3}.

tiated by the observation that the yield of **13** rises dramatically if the starting concentration of the ester **5** is increased (footnotes *d* and *f* in Table 2).

The conclusion from this section is that the product yields from these esters can be explained by the normal mechanism outlined in Scheme 1 with the change that k_{CO_2} is too slow to have any importance. For substrates like **5***b* and **5***d* where intramolecular exciplex formation (k_{ex}) is fast, the quantum efficiency for bond cleavage is very low but those molecules that do react behave normally. Inefficiency of bond cleavage for substrates **6** where intramolecular exciplex formation leads to fluorescence quenching has also been observed (9). For **5***f* and **5***g* where k_{ex} is small, normal efficiencies for the excited singlet-state carbon–oxygen bond cleavage reaction are observed.

It is perhaps surprising that the intramolecular exciplex, as described by structure **8**, does not react by efficient cleavage of the carbon–oxygen bond of the ester. We know this is not true since substrates like **5***b* and **5***d* must be forming **8** with efficiencies approaching 100%, but the reaction efficiency is extremely low (quantum efficiencies well below 1%). The process of bond cleavage in charge-transfer species has been well documented (19) for the intramolecular radical anion/radical cation pairs of highly substituted ethane carbon–carbon bonds. As the authors state, "Radical ion pairs of the kind described herein (and related ones) can, in principle, cleave to yield either a pair of ions or neutral radicals. This is easy to describe (on paper, at least) in terms of electron "pushing".[3] If the carbon–oxygen bond electron pair in **8** is shifted to the naphthalene side (heterolytic cleavage), then the radical pair results; if one electron is shifted to the naphthalene and one to the benzoate side (homolytic cleavage), then the ion pair results.



SCHEME 2. Thermodynamic cycle for estimating ΔG_4 (heterolytic cleavage) and ΔG_5 (homolytic cleavage) of the intramolecular exciplex **8**.

An estimate for the thermodynamic feasibility of these two processes can be made by the now very commonly used cycle shown in Scheme 2. The values of interest are ΔG_4 (heterolytic cleavage) and ΔG_5 (homolytic cleavage). A value of ΔG_1 = 268 kJ mol^{-1} can be estimated from the carbon–oxygen bond dissociation energy of 280 kJ mol^{-1} (20) for benzyl acetate minus 12 kJ mol^{-1} for the stabilization (21) of the 1-naphthylmethyl radical relative to the benzyl radical. A value of ΔG_2 = 355 kJ mol^{-1} is estimated from the oxidation potential of 1-methylnaphthalene (1.59 V vs. SCE in CH_3CN) (15) and the reduction potential of methyl benzoate (2.12 V vs. SCE in ethanol) (16). This ignores the electrostatic stabilization of **8**. Molecular models show that the two rings in **8** can be coplanar as close as 2 Å. Assuming the dielectric constant to be used is that the bulk medium, methanol, the value of this term[4] ($e^2/\epsilon r$) is about 21 kJ mol^{-1}. A value of ΔG_3 = −105 kJ mol^{-1} (in acetonitrile) can be estimated (15) from the oxidation potential of the 1-naphthylmethyl radical and the reduction potential of the acetyloxy radical. This leads to values of ΔG_4 = −66 kJ mol^{-1} and ΔG_5 = −192 kJ mol^{-1}. Both bond cleavage possibilities (heterolytic or homolytic) are clearly thermodynamically possible. The most reasonable explanation for lack of efficient bond cleavage in **8** is that back electron transfer to regenerate the ground state is faster. Note that molecular models indicate that there is no particular stereo-electronic inhibition to bond cleavage, as has been observed for some radical cations (22). Finally, as mentioned above, the

[3]Note that the authors have the electron "pushing" facts reversed in the rest of the paragraph and in Scheme II (19). If one apportions one electron of the central bond to each of the two parts, the result is the ion pair not the radical pair.

[4]NOTE ADDED IN PROOF: Suppan (23) recently proposed a very different model for contact ion pairs that gives this term a much larger value of ~150 kJ mol^{-1}. This, of course, leads to a very different conclusion about the stability of **8**.

phenylacetate esters **9** do not form intramolecular exciplexes. However, if an electron-donating group such as 4-CH_3O is on the benzene ring as in **14**, decreased fluorescence is again observed (3). The explanation again is intramolecular exciplex formation, but from the benzene ring to the naphthalene ring. Moreover, in this case, bond cleavage to radical pairs competes efficiently with back electron transfer.

Coordination chemistry of thioether–pyridazine macrocycles. I. Synthetic, structural, and spectroscopic studies of Cu(II) and Cu(I) complexes of novel thioether–pyridazine macrocycles that contain two or three pyridazine subunits

LIQIN CHEN, LAURENCE K. THOMPSON,[1] AND JOHN N. BRIDSON
Department of Chemistry, Memorial University of Newfoundland, St. John's, Nfld., Canada A1B 3X7

Received January 15, 1992

LIQIN CHEN, LAURENCE K. THOMPSON, and JOHN N. BRIDSON. Can. J. Chem. **70**, 1886 (1992).

The preparations of thioether–pyridazine macrocycles containing three (L1) and two (L2) pyridazine subunits and their copper complexes are described. The ligands are characterized by ^{1}H nuclear magnetic resonance and mass spectrometry and in one case by X-ray crystallography, and the complexes by infrared, electronic, and electron spin resonance (esr) spectra and in some cases by X-ray crystallography. The complex $[Cu_3(L1)_2Cl_6] \cdot 2CHCl_3$ (**1**) crystallized in the triclinic system, space group $P\bar{1}$ with a = 13.661(2) Å, b = 14.174(3) Å, c = 9.412(2) Å, α = 101.08(2)°, β = 96.94(2)°, γ = 75.76(2)°, V = 1728.2(6) Å^3, and Z = 2 (R = 0.056, R_w = 0.048 for 2080 reflections). Two monodentate pyridazine rings in each ligand bind to one square-planar copper centre with the third monodentate pyridazine in each ligand linking the two to the central square-planar copper. The complex $[Cu(L2)Cl_2]$ (**2**) crystallized in the orthorhombic system, space group *Pnma*, with a = 8.571(1) Å, b = 16.104(3) Å, c = 13.961(2) Å, V = 1927(1) Å^3, and Z = 4 (R = 0.037, R_w = 0.033 for 1070 reflections). A *cis* square-planar structure exists for **2** with monodentate pyridazines. $[Cu(L2)_2] \cdot (ClO_4)_2 \cdot CH_3CN \cdot CHCl_3$ (**5**) crystallized in the triclinic system, space group $P\bar{1}$, with a = 12.888(4) Å, b = 17.462(6) Å, c = 10.906(1) Å, α = 96.07(2)°, β = 104.18(2)°, γ = 94.51(2)°, V = 2352(1) Å^3, and Z = 2 (R = 0.053, R_w = 0.044 for 2941 reflections). Two ligands involving monodentate pyridazine rings bind to a square-planar copper(II) centre. The protonated ligand salt $[L2H](ClO_4) \cdot H_2O$ (**6**) crystallized in the monoclinic system, space group $P2_1/n$, with a = 14.762(4) Å, b = 8.637(5) Å, c = 16.267(4) Å, β = 92.78(2)°, V = 2072(1) Å^3, and Z = 4 (R = 0.064, R_w = 0.053 for 1456 reflections). No sulfur coordination is observed in these complexes and there is no apparent spin exchange in the trinuclear derivative.

LIQIN CHEN, LAURENCE K. THOMPSON et JOHN N. BRIDSON. Can. J. Chem. **70**, 1886 (1992).

On décrit les préparations de macrocyles de thioéther–pyridazine contenant trois sous-unités (L1) et deux (L2) et de leurs complexes de cuivre. Les coordinats ont été caractérisés par résonance magnitique nucléaire du ^{1}H et par spectrométrie de masse et, dans un cas, par diffraction des rayons X; les complexes ont été caractérisés par leurs spectres infrarouges, électroniques et résonance paramagnétique électronique et, dans quelques cas, par diffraction des rayons X. Le complexe $[Cu_3(L1)_2Cl_6] \cdot 2CHCl_3$ (**1**) cristallise dans le système triclinique, groupe d'espace $P\bar{1}$ avec a = 13,661(2), b = 14,174(3) et c = 9,412 Å, α = 101,08(2), β = 96,94(2) et γ = 75,76(2)°, V = 1728,2(6) Å^3 et Z = 2 (R = 0,056, R_w = 0,048 pour 2080 réflexions). Deux cycles pyridazines monodentates dans chaque coordinat se lient à un cuivre central plan-carré alors que la troisième pyridazine monodentate de chaque coordinat relie les deux au cuivre central du plan-carré. Le complexe $[Cu(L2)Cl_2]$ (**2**) cristallise dans le système orthorhombique, groupe d'espace *Pnma*, avec a = 8,571(1), b = 16,104(3) et c = 13,961(2) Å, V = 1927(1) Å^3 et Z = 4 (R = 0,037 et R_w = 0,033 pour 1070 réflexions). Pour le composé **2**, il existe une structure plan carré *cis* portant des pyridazines monodentates. Le $[Cu(L2)_2] \cdot (ClO_4)_2 \cdot CH_3CN \cdot CHCl_3$ (**5**) cristallise dans le système triclinique, groupe d'espace, $P\bar{1}$, avec a = 12,888(4), b = 17,462(6) et c = 10,906(1) Å, α = 96,07(2), β = 104,18(2) et γ = 94,51(2)°, V = 2352(1) Å^3 et Z = 2 (R = 0,053 et R_w = 0,044 pour 2941 réflexions). Deux coordinats impliquant les cycles pyridazines monodentates se lient à une cuivre(II) central plan-carré. Le sel du ligand protoné $[L2H](ClO_4) \cdot H_2O$ (**6**) cristallise dans le système monoclinique, groupe d'espace $P2_1/n$, avec a = 14,762(4), b = 8,637(5) et c = 16,267(4) Å, β = 92,78(2)°, V = 2072(1) Å^3 et Z = 4 (R = 0,064 et R_w = 0,053 pour 1456 réflexions). Aucun de ces complexes ne présente de coordination par le soufre et il ne semble pas se produire d'échange de spin dans le dérivé trinucléaire.

[Traduit par la rédaction]

Introduction

The discovery of the structure of the "blue" copper proteins plastocyanin (1, 2) and azurin (3, 4) has demonstrated thioether sulfur coordination to the copper ion and although the intense visible absorption in these systems is associated with cysteine (thiolate) to copper charge transfer (5), the high reduction potentials are likely to be a function of both types of sulfur site. To clarify the relationship between electronic and molecular structure numerous studies have been directed towards the synthesis of copper complexes with coordination spheres similar to those of the proteins (6–15). Homoleptic thioether complexes represent the most promising synthetic systems to explain the electronic consequences of thioether coordination. For this reason a considerable number of homoleptic, thioether complexes of four, five, and six-coordinate copper have been studied (16–23). In addition, the coordination chemistry of chelating agents with built-in thioether and azole groups (15), and macrocyclic ligands with thioether and amino, amido, pyridine, furan, and thiophene subunits, has also been explored (24–33).

Our interest in mixed sulfur–nitrogen ligands involving thioether and diazine linkages stems from our earlier studies on open-chain tetradentate (N_4) thioether–pyridazine ligands (34–39), which involved non-coordinating thioether linkages and formed binuclear copper(II) complexes with, in some cases, positive (0 → + 0.5 V vs. SCE) reduction potentials. The combination of pyridazine and thioether groups, suitably disposed for simultaneous coordination, might be expected to produce binuclear copper(II) com-

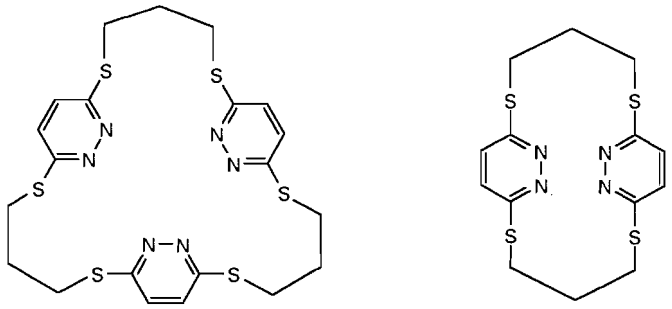

FIG. 1. Structural representation of the ligands.

plexes with more positive reduction potentials. Our initial studies in this area have involved the synthesis of a series of new macrocyclic thioether–pyridazine ligands and this paper describes the spectroscopic and structural investigation of copper(II) and copper(I) complexes of two oligomeric ligands (L1, L2, Fig. 1) derived from the reaction of 3,6-dichloropyridazine and 1,3-propanedithiol.

Experimental section

Commercially available reagents (Aldrich) were used without further purification. Infrared spectra were recorded using a Mattson Polaris FT instrument and electronic spectra with a Cary 17 spectrometer. The epr spectra were recorded with a Bruker ESP 300 X-band spectrometer at room temperature and 77 K. Mass spectra were obtained using a VG Micromass 7070 HS spectrometer and nmr spectra using a GE 300 MHz instrument. X-ray diffraction data were collected using a Rigaku AFC6S instrument and magnetic susceptibility data were measured by the Faraday method using a Cahn 7600 magnetic susceptibility system. Elemental analyses were performed by Canadian Microanalytical Service, Delta, British Columbia, Canada.

Synthesis of ligands and complexes

L1 and L2

1,3-Propanedithiol (2.82 g, 25 mmol) was added to anhydrous ethanol (100 mL), in which sodium metal (1.15 g, 50 mmol) had been dissolved and the resulting solution was stirred for 1 h. 3,6-Dichloropyridazine (3.84 g, 26 mmol) was dissolved in anhydrous ethanol (100 mL) and both solutions were added dropwise, simultaneously, to refluxing anhydrous ethanol (500 mL) by using pressure equalizing funnels, under a dry nitrogen atmosphere. The addition took place over a period of 6 h, during which time a white precipitate formed. The mixture was stirred and refluxed for a further 2 h and then stirred at room temperature overnight. The white solid (L1) was filtered off, washed with anhydrous ethanol (3 × 80 mL), and deionized water (3 × 100 mL), dried *in vacuo*, and recrystallized twice from $CHCl_3$. Yield: 150 mg (3.2%); mp 190–210°C. Further recrystallization from $MeNO_2$ produced white crystals, mp 188–190°C; ^1H nmr ($CDCl_3$) (δ (relative intensity)):2.25 (6) (multiplet, CH_2a), 3.36(12) (multiplet, CH_2b), 7.00 (6) (singlet, pyridazine). Mass spectrum, major mass peaks (*m/e* (relative intensity)):552(5) P, 519(4),367(7), 218(22), 184(43), 144(40), 106(39), 73(40), 41(100).

The initial filtrate obtained after isolation of L1 was removed on a rotary evaporator and the residual solid extracted with $CHCl_3$; the extract was washed several times with water and dried over Na_2SO_4. The concentrated extract was chromatographed on silica gel, eluted with $CHCl_3$, and the volume of the solution reduced to a few millilitres on a rotary evaporator and placed in a refrigerator. Colourless crystals of L2 were obtained. Yield: 0.52 g (11.3%); mp 215–217°C; ^1H nmr ($CDCl_3$) (δ (relative intensity)):2.43(4) (multiplet, CH_2a), 3.34(8) (multiplet, CH_2b), 7.00(4) (singlet, pyridazine). Mass spectrum, major mass peaks (*m/e* (relative intensity)):368(88) P, 217(33), 191(31), 185(66), 151(100), 144(81), 114(62), 96(34), 79(49), 73(66).

$[Cu_3(L1)_2Cl_6]\cdot 2CHCl_3$ (1)

$CuCl_2\cdot 2H_2O$ (0.17 g, 1.0 mmol) was dissolved in CH_3CN (20 mL) and added to a solution of L1 (0.11 g, 0.2 mmol) in $CHCl_3$ (20 mL). The resulting deep-green solution was filtered immediately and allowed to stand at room temperature overnight. A very small amount of an unidentified green solid formed, that was filtered off and the filtrate allowed to stand at room temperature for 1 week. Bluish-green crystals formed, which were filtered off, washed with CH_3CN and $CHCl_3$, and air dried (yield 31 mg). Anal. calcd. for $[C_{42}H_{56}N_{12}S_{12}Cl_6Cu_3]\cdot 2CHCl_3$: C 30.24, H 2.88, N 9.62; found: C 30.66, H 3.04, N 9.81.

$[Cu(L2)Cl_2]$ (2)

$CuCl_2\cdot 2H_2O$ (0.14 g, 0.80 mmol) was dissolved in CH_3CN (20 mL) and added to a solution of L2 (0.14 g, 0.38 mmol) in $CHCl_3$ (20 mL). The resulting dark-green solution was filtered immediately and allowed to stand at room temperature overnight. Bright green crystals formed, which were filtered off, washed with CH_3CN and $CHCl_3$, and air dried (yield 0.16 g). Anal. calcd. for $[C_{14}H_{16}N_4S_4Cl_2Cu]$: C 33.43, H 3.21, N 11.14; found: C 33.38, H 3.19, N 11.19.

$[Cu(L2)Br_2]$ (**3**) and $[Cu(L2)(NO_3)_2]$ (**4**) were prepared in a similar manner. Anal. calcd. for $[C_{14}H_{16}N_4S_4Br_2Cu]$ (**3**): C 28.41, H 2.72, N 9.47; found: C 28.31, H 2.67, N 9.49. Anal. calcd. for $[C_{14}H_{16}N_6O_6S_4Cu]$ (**4**): C 30.35, H 2.90, N 15.11 found: C 30.24, H 2.91, N 15.31.

$[Cu(L2)_2](ClO_4)_2\cdot CH_3CN\cdot CHCl_3$ (5), $[L2H](ClO_4)\cdot H_2O$ (6)

$Cu(ClO_4)_2\cdot 6H_2O$ (0.15 g, 0.40 mmol) was dissolved in CH_3CN (10 mL) and added to a solution of L2 (0.15 g, 0.40 mmol) in $CHCl_3$ (10 mL). The resulting brown solution was filtered and allowed to stand at room temperature for several days. A small quantity (15 mg) of pale yellow crystals (**6**) formed, which were filtered off and the brown filtrate evaporated slowly at room temperature. Red-brown crystals (**5**) formed, which were filtered off, washed with CH_3CN and $CHCl_3$, and air dried (yield 0.10 g). Anal. calcd. for $[C_{28}H_{32}N_8S_8Cu]\cdot(ClO_4)_2\cdot CH_3CN\cdot CHCl_3$ (**5**): C 32.10, H 3.13, N 10.87; found: C 32.11, H 3.20, N 10.90. Anal. calcd. for $[C_{14}H_{17}N_4](ClO_4)\cdot H_2O$ (**6**): C 34.53, H 3.93, N 11.50; found: C 34.23, H 3.96, N 11.46.

$[Cu(L2)Cl]$ (6)

Copper powder (0.19 g, 3.0 mmol) was added to a solution of $CuCl_2\cdot 2H_2O$ (0.051 g, 0.30 mmol) in CH_3CN (20 mL), the mixture stirred under a nitrogen atmosphere until the solution became colourless, and then filtered into a solution of L2 (0.074 g, 0.20 mmol) in $CHCl_3$ (20 mL) under a nitrogen atmosphere. The resulting orange solution was allowed to stand at room temperature overnight. Red crystals formed, which were filtered off, washed with CH_3CN and $CHCl_3$, and air dried (yield 0.058 g). Anal. calcd. for $[C_{14}N_{16}N_4S_4ClCu]$: C 35.96, H 3.45, N 11.98; found: C 36.06, H 3.44, N 11.94. [Cu(L2)Br] (**7**) was prepared in a similar manner and obtained as red-brown crystals. Anal. calcd. for $[C_{14}H_{16}N_4S_4BrCu]\cdot 0.5H_2O$: C 32.30, H 3.27, N 10.76; found: C 32.40, H 2.97, N 10.78.

X-ray crystallographic analysis of $[Cu(L2)Cl_2]$ (2)

The diffraction intensities of a green parallelepiped crystal of $[Cu(L2)Cl_2]$ of approximate dimensions 0.2 × 0.15 × 0.05 mm were collected using a Rigaku AFC6S diffractometer with graphite monochromatized MoKα radiation. Cell constants and the orientation matrix were obtained by the least-squares refinement of the setting angles of 25 carefully centred reflections in the range $26.23° < 2\theta < 38.84°$. Based on systematic absences, packing considerations, a statistical analysis of the intensity distribution, and the successful solution and refinement of the structure, the space group was determined to be *Pnma*. Machine and data collection

parameters and crystal data are given in Table 1. The data were collected at 25 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 50.0°. Omega scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.26° with a take-off angle of 6.0°. Scans of $(1.15 + 0.30 \tan\theta)°$ were made at a speed of 8.0°/min (in ω). The weak reflections ($I < 10.0\ \sigma(I)$) were rescanned (maximum of two rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1.

A total of 1979 reflections were collected. The intensities of three representative reflections, which were measured after every 150 reflections, remained constant during data collection (no decay correction applied). An empirical absorption correction was applied, using the program DIFABS (40), which resulted in transmission factors ranging from 0.94 to 1.08. The data were corrected for Lorentz and polarization effects.

The structure was solved by direct methods (41, 42). The non-hydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement was based on 1070 observed reflections ($I > 3.00\ \sigma(I)$) and 119 variable parameters and converged with unweighted and weighted agreement factors of $R = \Sigma||F_o| - |F_c||/\Sigma|F_o| = 0.037$ and $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)]^{1/2} = 0.033$. The standard deviation of an observation of unit weight was 1.26. The weighting scheme was based on counting statistics and included a factor ($p = 0.01$) to downweight the intense reflections. Plots of $\Sigma w(|F_o| - |F_c|)^2$ versus $|F_o|$, reflection order in data collection, $\sin\theta/\lambda$, and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.40 and −0.43 electrons/Å^3 respectively and have no chemical significance. Neutral atom scattering factors (43) and anomalous dispersion terms (44, 45) were taken from the usual sources. All calculations were performed using the TEXSAN (46) crystallographic software package using a VAX 3100 workstation. Hydrogen atoms were located in a difference map but not refined. Thermal parameters were set at 1.2 times the isotropic thermal parameter of the bonded C atoms.

ters (Table S-1), hydrogen atom parameters (Table S-2), a full listing of bond distances and angles (Table S-3), and observed and calculated structure factors ($10|F_o|$ and $10|F_c|$) (Table S-4) are deposited as supplementary material.[2]

X-ray crystallographic analysis of $[Cu_3(L1)_2Cl_6]\cdot 2CHCl_3$ (1)

The diffraction intensities of a blue-green regular polyhedral crystal of **1** of approximate dimensions 0.30 × 0.25 × 0.15 mm were collected in a similar manner to **2**. Crystal data, intensity collection, and refinement details are summarized in Table 1. Hydrogen atoms were placed in calculated positions (C—H 0.95Å) and not refined. Thermal parameters were set at 1.2 times the isotropic thermal parameter of the bonded C atoms. The chloroform molecule was disordered and was modelled with two chlorines and the carbon disordered over two positions with 50% occupancy. Atomic positional parameters are given in Table 3 and selected bond distances and angles are given in Table 6. Thermal parameters (Table S-5), hydrogen atom parameters (Table S-6), a full listing of bond distances and angles (Table S-7), and observed and calculated structure factors ($10|F_o|$ and $10|F_c|$) (Table S-8) are deposited as supplementary material.[2]

Least-squares planes data for **2**, **5**, **6**, (Tables S-17 to S-19 respectively) and torsional angles data for **1**, **2**, **5**, **6** (Tables S-20 to S-23 respectively) are deposited as supplementary material.[2]

X-ray crystallographic analysis of $[Cu(L2)_2](ClO_4)_2\cdot 2CH_3CN\cdot CHCl_3$ (5)

The diffraction intensities of a brown, regular polyhedral crystal of **5** of approximate dimensions 0.30 × 0.25 × 0.15 mm were collected in a similar manner to **2**. Crystal data, intensity collection, and refinement details are summarized in Table 1. Hydrogen atoms were placed in calculated positions (C—H 0.95 Å) and not refined. Thermal parameters were set at 1.2 times the isotropic thermal parameter of the bonded C atoms. Atomic positional parameters are given in Table 4 and selected bond distances and angles are given in Table 8. Thermal parameters (Table S-9), hydrogen atom parameters (Table S-10), a full listing of bond distances and angles (Table S-11), and observed and calculated structure factors ($10|F_o|$ and $10|F_c|$) (Table S-12) are deposited as supplementary material.[2]

X-ray crystallographic analysis of $[L2H](ClO_4)\cdot H_2O$ (6)

The diffraction intensities of a colourless, polyhedral crystal of **6** of approximate dimensions 0.25 × 0.25 × 0.20 mm were collected in a similar manner to 2. Crystal data, intensity collection, and refinement details are summarized in Table 1. Hydrogens on the water molecule and on N4 were located from difference maps. The position of HN4 was allowed to refine during an early round of least squares, where it remained in a sensible position. However, because of a somewhat limited data set, this hydrogen was fixed in final rounds. Other hydrogens including that at N1 were put in calculated positions (C—H 0.95 Å and isotropic thermal parameters set at 1.2 times the isotropic value of the bonded carbon). Occupancy of the hydrogens on N1 and N4 was set at 0.5, but no attempt was made to refine this. The final round of least squares included all hydrogen atoms, none of which were refined. The perchlorate ion appears to be disordered around the Cl—O1 axis and the occupancies of the two images used to model the disorder were arbitrarily set at 0.7 and 0.3. A limited data set was obtained for this compound and a sigma cut-off of 2.0 was chosen to give a better ratio of data to refined variables. Atomic positional parameters are given in Table 5 and selected bond distances and angles are given in Table 9. Thermal parameters (Table S-13), hydrogen atom parameters (Table S-14), a full listing of bond distances and angles (Table S-15), and observed and calculated structure factors ($10|F_o|$ and $10|F_c|$) (Table S-16) are deposited as supplementary material.[2]

Results and discussion

Although macrocyclic thioether ligands containing aromatic and heterocyclic rings, e.g., pyridine, are well known (28, 31, 47), we are not aware of any reports of such thioether macrocycles involving pyridazine subunits. Polythia(3,6)-pyridazinophanes can be synthesized, usually in reasonable

yields, by the condensation of 3,6-dichloropyridazine with a dithiol under high-dilution conditions in basic media. In this report we examine the copper coordination chemistry of two low-yield, oligomeric (3:3, L1; 2:2, L2; Fig. 1) thiapyridazinophanes derived from the reaction of 1,3-propane-dithiol with 3,6-dichloropyridazine. Other longer chain S_3 and S_4 α, ω-dithiols produce just 1:1 or 2:2 macrocycles on reaction with 3,6-dichloropyridazine and their coordination chemistry will be described elsewhere.[3]

The appearance of the perchlorate salt of L2 as a minor product during the synthesis of $[Cu(L2)_2](ClO_4)_2 \cdot CH_3CN \cdot CHCl_3$ (**5**) was a surprise, but nevertheless a fortuitous one since crystals of L2 itself, obtained after several recrystallizations, were found to be unsuitable for structural analy-

sis. We attribute the formation of the salt to the presence of residual perchloric acid impurity in the commercial copper(II) perchlorate.

Description of the structures of $[Cu_3(L1)_2Cl_6] \cdot 2CHCl_3$ (I), $Cu(L2)Cl_2$ (2), $[Cu(L2)_2](ClO_4)_2 \cdot CH_3CN \cdot CHCl_3$ (5), and $[L2H](ClO_4 \cdot H_2O$ (6)

The structure of $[Cu_3(L1)_2Cl_6]$ (**1**) is unique (Fig. 2) in that it contains a trinuclear arrangement of copper(II) centres in which the central copper (Cu1) bridges two ligands that encompass one copper each. The molecule has a centre of symmetry at Cu1 with the result that the three coppers are colinear. The Cu1—Cu2 separation is 7.360(2) Å. The central copper has an almost square-planar *trans*-CuN_2Cl_2 arrangement of ligand donors involving one pyridazine nitrogen from each ligand. Copper–nitrogen and copper–chlorine distances are normal for ligands of this sort. In contrast the terminal coppers (Cu2) have an almost square-planar *cis* structure, with comparable Cu—N and Cu—Cl separations to those around Cu1. Each ligand coordinates in a tridentate (N_3) fashion, with each pyridazine fragment utilizing one nitrogen only. L1 is a 27-membered macrocycle and effectively uses just two pyridazine nitrogens in coordination to the endocyclic metal (Cu2). This creates a most unusual situation where the ligand forms two very large chelate rings, one involving 11 atoms and the other 20. This is seen, in part, as a consequence of the juxtaposition of the sulfur and nitrogen centres, such that simultaneous coordination of adjacent sulfur and nitrogen atoms would be highly unlikely due to the formation of a four-membered chelate ring. The hard nature of the copper(II) centre and the presence of relatively strong chlorine ligands would also mitigate against sulfur coordination.

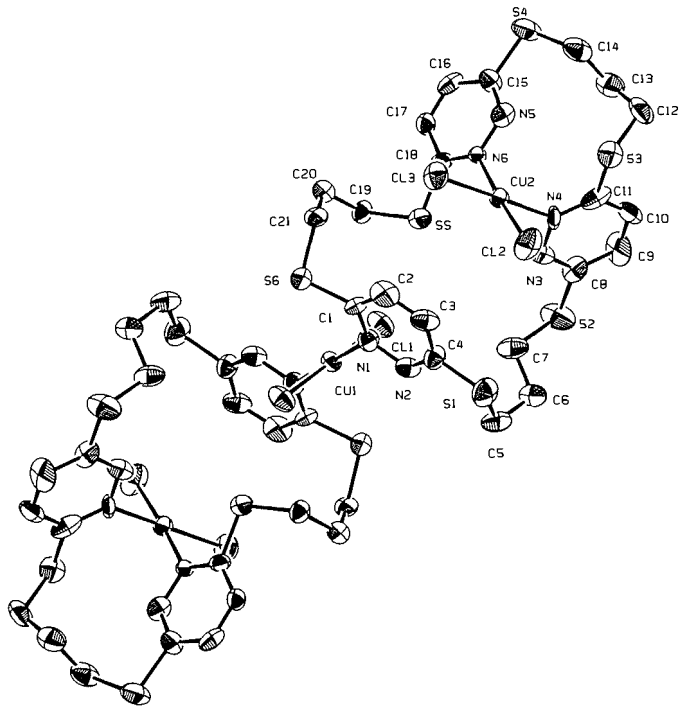

FIG. 2. Molecular structure of $[Cu_3(L1)_2Cl_6]$ (**1**) (40% probability ellipsoids).

The structure of $[CuL2Cl_2]$ (**2**) is illustrated in Fig. 3 and consists of an almost square-planar *cis* copper(II) centre bound by two pyridazine nitrogens, one from each pyridazine ring. Copper–chlorine (2.246(2) Å) and copper–nitrogen (2.028(4) Å) distances are normal and the square plane is slightly compressed (Cl1—Cu1—Cl1 94.39(8)°, Cl1—Cu1—N1 88.8(1)°) with the copper centre displaced by 0.082 Å from the mean Cl_2N_2 plane. The tetrathiapyridazinophane ligand L2 utilizes two nitrogen donor atoms on the same relative side of the macrocyclic ring as opposed to opposite sides for each *endo*-macrocyclic copper centre in **1**. This results in the creation of two chelate rings of different size (10-membered and 12-membered). The two pyridazine ring least-squares planes are separated by a dihedral angle of 83.5°.

The structure of $[Cu(L2)_2]^{2+}$ (**6**) is illustrated in Fig. 4 and involves two *cis*-bidentate N_2 ligands bound to a slightly distorted square-planar copper(II) centre. Each ligand uti-

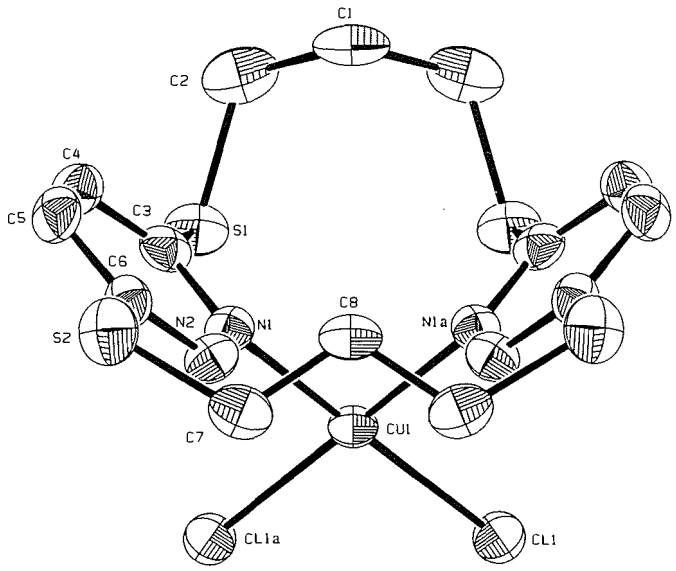

FIG. 3. Molecular structure of $[Cu(L2)Cl_2]$ (**2**) (40% probability ellipsoids).

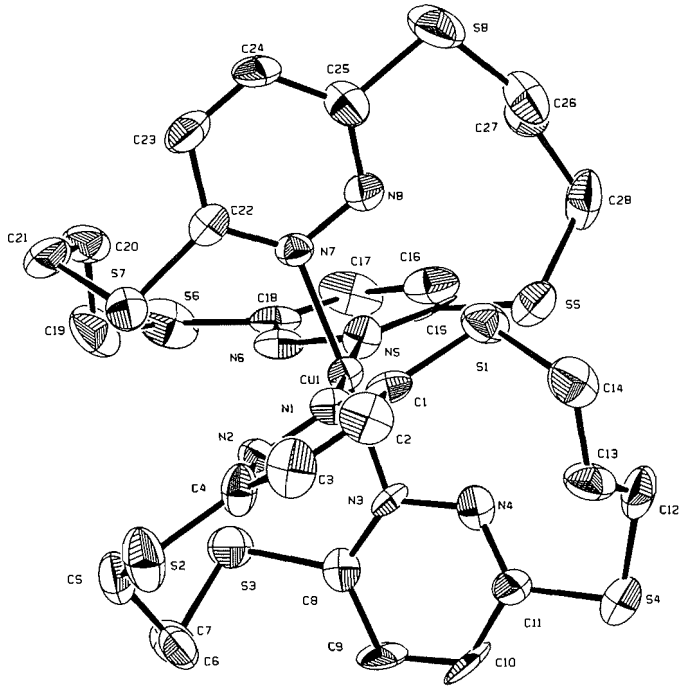

FIG. 4. Molecular structure of $[Cu(L2)_2]^{2+}$ (**5**) (40% probability ellipsoids).

lizes one nitrogen donor per pyridazine ring but, unlike the situation in **2**, opposite pyridazine nitrogens are involved. This produces a situation where the two chelate rings within each macrocyclic half are 11-membered. The four copper–nitrogen bond distances are very similar and the copper square plane is compressed slightly within each chelating half (N1—Cu1—N2 86.6(4)°, N5—Cu1—N7 86.3(4)°). The copper centre is displaced slightly from the mean N_4 plane by 0.011 Å. A packing diagram (Fig. 5) shows that there are no significant associations between cations and that perchlorate oxygens are not involved in coordination. The dihedral angle between the pyridazine rings defined by N1 and

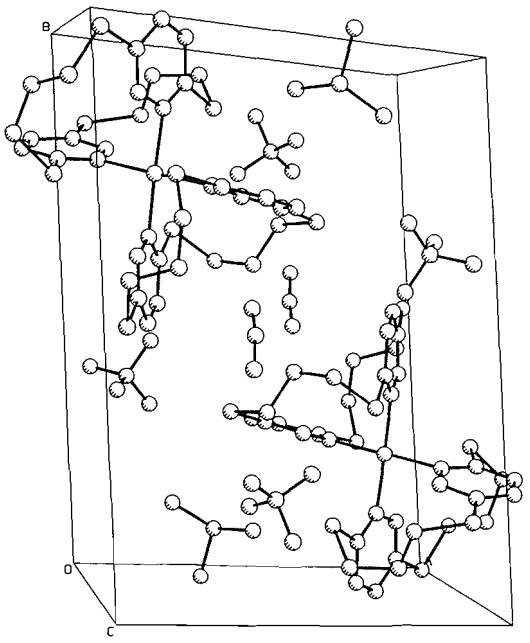

FIG. 5. Packing diagram for $[Cu(L2)_2](ClO_4)_2 \cdot CH_3CN \cdot CHCl_3$ (**5**).

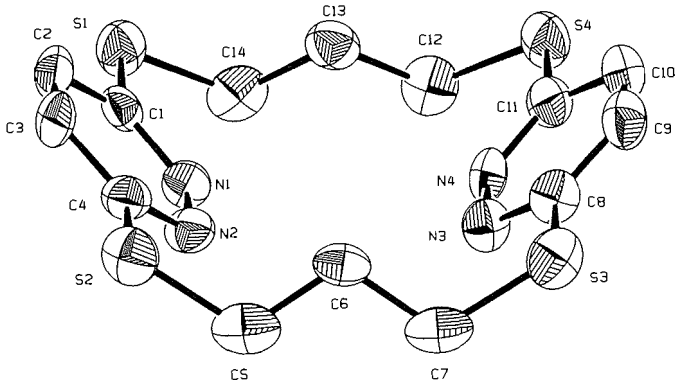

FIG. 6. Molecular structure of $[L2H]^+$ (hydrogens omitted) (40% probability ellipsoids).

N3 is 76.1°, while that between the pyridazine rings defined by N5 and N7 is 81.8°.

The structure of $[L2H]^+$ is illustrated in Fig. 6. The protonated ligand adopts a crownlike conformation with the pyridazine rings canted inwards such that the nitrogen lone pairs point towards the roof of the crown, and with a dihedral angle of 95.7° between the pyridazine least-squares planes. The sulfur lone pairs are exodentate to the ring. Torsional angles N1—C1—S1—C14 (−13(1)°), N2—C4—S2—C5 (12(1)°), N3—C8—S3—C7 (−10(1)°), and N4—C11—S4—C12 (11(1)°) indicate a slight twisting of the aliphatic C—S bonds relative to the pyridazine planes. The inward canting of the pyridazine rings appears to present the nitrogen lone pairs in a favourable orientation for coordination as a tetradentate N_4 ligand to two metal centres. Molecular models confirm these possibilities, although some reorganization of the aliphatic chains would be required to prevent serious steric problems involving the C—H bonds. However, even with anionic groups (e.g., Cl, Br) that could occupy vacant copper coordination sites, such binuclear

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

structures have not occurred with L2. This is somewhat surprising because for $[Cu(L2)Cl_2]$ (**2**) (Fig. 3) the torsional angle N1—C3—S1—C2 of −120.1(5)° indicates quite clearly that the aliphatic fragment can readily reorient to accommodate one planar copper(II) centre bound to nitrogen atoms N1. The other torsional angle, N2—C6—S2—C7 (13.6(6)°) is comparable with that in $L2H^+$. Molecular models indicate that an N—C—S—C torsional angle of about 120° at both ends of each pyridazine would be sufficient to accommodate two metals. The foregoing discussion makes the assumption that the conformation of the free ligand, L2, would be comparable with that in **6**.

The hydrogen atoms on the water molecule and that on N4 were located from difference maps and the location of H-N4 was tested by allowing its position to refine during an early round of least squares, where it remained at a sensible position and no peaks were seen at other possible protonation sites. Refinement was completed with the nitrogen-hydrogen located at N4 and a reasonable result was obtained (R = 0.064, R_w = 0.053, GOF = 1.99). However, significant differences in pyridazine nitrogen ring angles resulted in both pyridazine rings (C11—N4—N3 124.9(9)°, N4—N3—C8 115.2(9)°, N2—N1—C1 122.4(9)°, N1—N2—C4 117.4(9)°). This situation would not be anticipated if the N-H proton were located on just one pyridazine nitrogen. The unprotonated ligand 3,6-bis-(2-pyridylthio)pyridazine has two virtually identical ring nitrogen angles (119.3(2)°, 119.4(2)°) (39) and in compounds **1**, **2**, and **5** significant differences are observed in the pyridazine nitrogen ring angles with the larger angle occurring at the coordinated ring nitrogen site. With all these factors taken into account the refinement was redone with an arbitrarily chosen half occupancy of the N-H proton at N1 and N4, with a resulting slight improvement in R values. The pyridazine nitrogen ring angles (C11—N4—N3 123.8(9)°, N4—N3—C8 116.1(9)°, N2—N1—C1 123.7(9)°, N1—N2—C4 116.6(9)°) are again found to be significantly different consistent with this new model.

Spectroscopy and magnetism

Both ligands L1 and L2 have simple infrared spectra with weak νCN bands at 1573 and 1570 cm^{-1} respectively, strong bands at 1146 and 1150 cm^{-1} respectively, and weaker absorptions in the range 720–820 cm^{-1}. Coordination of the pyridazine rings, all of which are ligands in the compounds that have been structurally characterized, does not cause a major shift in the CN stretching frequency. Shifts of −10 (**1**), −11 (**2**), and −5 (**5**) cm^{-1} are observed for those cases where the pyridazine rings have been shown to coordinate via one nitrogen atom. In each case the absorption appears as a single, sharp band, even though two different CN groups would be expected in the coordinated ligand.

The infrared spectra of $[Cu(L2)Cl_2]$ (**2**) and $[Cu(L2)Br_2]$ (**3**) are identical in the range 4000–500 cm^{-1}, indicating an identical *cis* structure. The nitrate complex $[Cu(L2)(NO_3)_2]$ (**5**) exhibits a νCN band at 1564 cm^{-1}, shifted by 6 cm^{-1} to lower energy than the free ligand, indicating coordinated pyridazine. Prominent combination ($\nu_1 + \nu_4$) nitrate bands are observed at 1708 and 1747 cm^{-1} (48), and the difference between these bands (39 cm^{-1}) strongly suggests a bidentate role for coordinated nitrate. In view of the *cis* coordination of L2 in compounds **2** and **5** a similar bonding situation would be expected for **4** with a six-coordinate *cis* structural arrangement.

The copper(I) complexes Cu(L2)Cl (**6**) and Cu(L2)Br (**7**) have virtually identical infrared spectra, with a very slight increase in energy of the νCN band (+2, +1 cm^{-1} respectively) compared with the free ligand. This suggests that the pyridazine rings are not bound to the copper centres and that the likely donors are sulfur atoms. No structural data are available for these compounds, but the copper(I) chloride complex of the 1:1 macrocyclic ligand formed by condensation of 3,6-dichloropyridazine and 1,4,7,11-tetrathiaundecane involves a polymeric structure with just sulfur coordination and tetrahedral CuS_2Cl_2 metal centres (see footnote 3).

A comparison of the far infrared spectrum of **1** (Table 10) with that of the free ligand L1 reveals three strong bands associated with copper–ligand stretching. The bands at 320 and 308 cm^{-1} are assigned to Cu–Cl stretch, while the single band at 288 cm^{-1} is assigned to Cu–N stretch. A *cis*-CuN_2Cl_2 system, with local C_{2v} symmetry, would require the presence of two Cu–Cl stretching bands, while the *trans* square-planar CuN_2Cl_2 system, with local C_{2h} symmetry would require just one Cu–Cl stretch. Although **1** contains two pseudo *cis* square-planar centres and one pseudo *trans* square-planar centre, it does not appear to be reflected in the far-infrared spectrum and the third absorption is probably hidden in the general Cu–Cl stretching envelope.

The *cis* square-planar structure of $[Cu(L2)Cl_2]$ (**2**) is clearly reflected in the far infrared with two strong bands at 320, 304 cm^{-1} assigned to Cu–Cl stretch and two bands at 287, 273 cm^{-1} assigned to Cu–N stretch. The analogous bromo-complex (**3**) shows two pairs of bands at 264, 257 cm^{-1} (νCu–N) and 248, 235 cm^{-1} (νCu–Br) consistent with a *cis*-CuN_2Br_2 structure. The nitrate complex exhibits three very strong far-infrared bands associated with Cu–O stretch and two bands associated with Cu–N stretch, nominally consistent with the proposed structure. The perchlorate complex, $[Cu(L2)_2](ClO_4)_2 \cdot CH_3CN \cdot CHCl_3$ (**5**) involves a slightly compressed square-planar arrangement of four monodentate pyridazine rings from two ligands. The presence of two far infrared bands at 270, 264 cm^{-1}, assigned to Cu–N stretch, is consistent with such a structure, and assumes an idealized C_{2v} local site symmetry.

Room temperature magnetic moments for compounds **1**–**5** all exceed the spin-only value for a one-unpaired electron system and suggest the presence of dilute copper(II) centres in all cases, with no spin exchange. Solid state, mull transmittance electronic spectra are characterized by the presence of one major visible absorption for compounds **1**–**4**, while **5** exhibits two high-energy bands. No distinction can be made between the different CuN_2Cl_2 sites in **1**, while the slightly lower energy bands associated with $[CuL2Br_2]$, compared with $[CuL2Cl_2]$, are consistent with a structurally analogous bromo complex. The lower energy absorption associated with **4** is consistent with a six-coordinate copper(II) centre, especially when compared with the square-planar complex **5**.

The room temperature, solid state esr spectrum of **1** (Fig. 7) (Table 10) is rather complicated, but can be considered as the superposition of two axial species. A consideration of the solid spectrum of **2** is useful in assigning the g values. **2** exhibits an axial spectrum associated with a *cis*-CuN_2Cl_2, square-planar species, with $g_\parallel$ = 2.155 and $g_\perp$ = 2.081. Assuming that the *cis*-CuN_2Cl_2 centre in **1** is comparable with that in **2**, then the resonance with $g_\parallel$ = 2.125 and $g_\perp$ = 2.043

is assigned to the *trans*-CuN_2Cl_2 centre in **1**. Compounds **3** and **4** have uninformative isotropic spectra at both room temperature and at 77 K.

The square-planar perchlorate complex (**5**) exhibits a most unusual solid state spectrum (Fig. 8) at room temperature, which is not an averaged spectrum, but appears to be due to a unique axial species. A similar spectrum is also observed at 77 K. It closely resembles the frozen nitromethane glass (77 K) spectrum (Fig. 9) of the same compound. In fact values of $g_{\parallel}$, $g_{\perp}$, and $A_{\parallel}$ observed in the solid state are very close to those observed in the frozen glass (Table 10). The high values of $g_{\parallel}$ and $A_{\parallel}$ are typical of square-planar CuN_4

Reaction path Hamiltonian for the association reactions CH_3 + H and CH_3 + D

DAVID M. WARDLAW[1]
Department of Chemistry, Queen's University, Kingston, Ont., Canada K7L 3N6

Received January 21, 1992

DAVID M. WARDLAW. Can J. Chem. **70**, 1897 (1992).

Coupling coefficients and normal mode frequencies appearing in the reaction path Hamiltonian formulated by Miller, Handy, and Adams have been calculated for the title reactions as a function of distance along the reaction path. The calculation of the coupling coefficients requires the use of symmetry coordinates which are described herein. It is found that the carbon–hydrogen separation provides an excellent representation of the reaction path coordinate, being linearly related to it. The coupling coefficients for CH_3 + H and CH_3 + D are approximately the same in the region of variational transition states and do not support the suggestion that an apparent isotope anomaly in the experimentally derived rates of these reactions might be attributable to different dynamics along the reaction path. The relative magnitudes of coupling coefficients for CH_3 + H are used to assess some of the usual assumptions in variational transition state theory concerning separability of different types of motion in the transition state region.

DAVID M. WARDLAW. Can. J. Chem. **70**, 1897 (1992).

On a calculé les coefficients de couplage et les fréquences du mode normal apparaissant dans l'hamiltonien de la voie réactionnelle formulée par Miller, Handy et Adams pour les réactions mentionnées dans le titre, en fonction de la distance parcourue sur la voie réactionnelle. Pour calculer les coefficients de couplage, il est nécessaire d'utiliser les coordonnées de symétrie présentées ici. On a trouvé que la séparation carbone–hydrogène fournit une excellente représentation des coordonnées de la voie réactionnelle puisqu'elle lui est reliée d'une façon linéaire. Les coefficients de couplage pour les réactions CH_3 + H et CH_3 + D sont approximativement les mêmes dans la région des états de vibration variationnels et ils ne supportent pas la suggestion à l'effet qu'une anomalie isotopique apparente dans les vitesses obtenues expérimentalement pour ces réactions peut être attribuable à des dynamiques le long de la voie réactionnelle. On a utilisé les amplitudes relatives des coefficients de couplage pour CH_3 + H pour évaluer les hypothèses usuelles de la théorie de l'état de transition variationnel concernant la possibilité de séparer les divers types de mouvements dans la région de l'état de transition.

[Traduit par la rédaction]

Introduction

The reaction path (RP) Hamiltonian, as formulated by Miller *et al.* (1) in 1980, has provided a useful framework, both conceptual and practical, for theoretical treatments of chemical reaction dynamics. This approximation to the full Hamiltonian is parameterized by a reaction coordinate s which is defined as the distance along the steepest descent/ascent path (in mass-weighted Cartesian coordinates) from reactants to products. For an N-atom system with zero total angular momentum, the RP Hamiltonian is

$$[1]\quad H(p_s, s, \{P_i, Q_i\}) = V_o(s) + \sum_{i=1}^{3N-7} \frac{1}{2}(P_i^2 + \omega_i^2(s)Q_i^2) + \frac{1}{2}\frac{\left[p_s - \sum_{i,j=1}^{3N-7} Q_i P_j B_{i,j}(s)\right]^2}{\left[1 + \sum_{i=1}^{3N-7} Q_i B_{i,3N-6}(s)\right]^2}$$

Here p_s is the momentum conjugate to s (labelled as the $3N - 6$th degree of freedom) and $V_o(s)$ is the potential energy along the RP. $\{Q_i; i = 1,2,\ldots,3N - 7\}$ are normal mode displacement coordinates for the $3N - 7$ vibrations orthogonal to the RP and $\{P_i\}$ are the corresponding conjugate momenta. The six degrees of freedom not represented in eq. [1] are center-of-mass translation and rotation of the entire system about the center-of-mass ($i = 3N - 5,3N - 4,\ldots,3N$).

The normal mode frequencies $\{\omega_i(s); k = 1,2,\ldots,3N - 7\}$ are obtained by diagonalizing the projected force constant matrix

$$[2]\quad F^P(s) = [1 - P(s)] \cdot F(s) \cdot [1 - P(s)]$$

where F is the $3N \times 3N$ mass-weighted, Cartesian force constant matrix and P is a $3N \times 3N$ matrix which projects out motion directed along the normalized gradient vector (which locally defines the RP) and along unit vectors corresponding to infinitesimal rotations and translations of the entire system. The eigenvalues of F^P for these seven degrees of freedom ($i = 3N - 6,\ldots,3N$) are zero. Explicit forms for the gradient vector, the force constant matrix, and the projection matrix are provided in ref. 1. The sets of coefficients $\{B_{i,j}(s)\}$ and $\{B_{i,3N-6}(s)\}$ appearing in the last term of eq. [1] describe coupling between the pairs of normal modes induced by reaction coordinate motion, and between the reaction coordinate and individual normal modes, respectively. These coupling coefficients are defined in terms of the frequencies ω_i and eigenvectors $\mathbf{L}_i = (L_{1,i}, L_{2,i},\ldots,L_{3N,i})$ associated (1, 2) with the ith eigenvalue, ω_i^2, of F^P:

$$[3a]\quad B_{i,j}(s) = \sum_{k=1}^{3N} \frac{\partial L_{k,i}(s)}{\partial s} L_{k,j}(s), \quad i < j$$

$$[3b]\quad B_{i,i}(s) = -\frac{\partial \omega_i(s)}{\partial s} \Big/ (2\omega_i(s)), \quad \omega_i \neq 0$$

$$i = 1,2,\ldots,3N - 7$$

$$j = 1,2,\ldots,3N - 6$$

The general case of nonzero total angular momentum ($J \neq 0$) is treated in ref. 1; rotational effects within the RP Hamiltonian framework are under study in this laboratory but are not considered here.

In many applications it is satisfactory to retain only the first two terms of eq. [1], i.e., the coupling coefficients are implicitly set equal to zero, resulting in a separable approximation to the RP Hamiltonian,

$$[4] \quad H(p_s,s,\{P_i,Q_i\}) \approx \frac{p_s^2}{2} + V_o(s) + \sum_{i=1}^{3N-7} \frac{1}{2}(P_i^2 + \omega_i^2(s)Q_i^2)$$

A noteworthy example of this approach is the thorough RP Hamiltonian study of the isomerization of the methoxy radical by Colwell (3). Less effort has been made to exploit the dynamical information contained in the coupling coefficients. Miller (2, 4) has shown how symmetry along the RP leads to selection rules in the coupling embodied in the third term of eq. [1] and hence to a symmetry-adapted transition state theory (TST). For the particular case of formaldehyde decomposition the difference between symmetry-adapted and ordinary TST rate coefficients is found to be most pronounced at low energies just below and above threshold and to vanish at high energies. Miller has also demonstrated the role of the $B_{i,3N-6}$ coefficients in estimating a critical energy up to which TST is exact (5). Ryaboy (6) has shown how strong coupling of transverse vibrations to each other and to the reaction coordinate can significantly affect the kinetics of gas-phase nucleophilic substitution (S_N2) reactions. Explicit calculations of coupling coefficients for particular systems include $H^- + CH_3F \rightarrow CH_4 + F^-$ by Ryaboy (6), HNC → HCN isomerization by Gray *et al.* (7), three-dimensional $H + H_2$ by Shwartz and Miller (8), and vinylidene → acetylene isomerization by Carrington, Jr. *et al.* (9).

In this paper coupling coefficients for the radical recombination reactions

$$CH_3 + H \rightarrow CH_4$$

$$CH_3 + D \rightarrow CH_3D$$

on the so-called Hirst potential energy surface (10, 11) are presented and discussed. The motivation is twofold. First, it is of interest to compare coupling coefficients for these two reactions to assess the possibility that differential dynamical effects along the RP are responsible for an apparent isotope anomaly in the high-pressure rate coefficients determined by Pilling and co-workers (12, 13). Second, knowledge of the relative magnitude of the coupling coefficients for $CH_3 + H \rightarrow CH_4$ is useful in assessing assumptions about mode separability inherent in several versions of variational transition state theory (VTST) that have been applied to this reaction employing the same potential energy surface (10, 14, 15). In order to obtain $\{B_{i,j}\}$ and $\{B_{i,3N-6}\}$ for these reactions it is necessary to transform from Cartesian coordinates to symmetry coordinates; these are derived and discussed in Sect. 2. Symmetry coordinates are appealing because, as has been pointed out by Miller (2), coupling coefficients between modes belonging to different irreducible representations are identically zero. In the particular case of $CH_3 + X$ (X = H, D), which has C_{3v} symmetry along the RP and hence a doubly degenerate irreducible representation (E), it is essential to use them. Otherwise the (arbitrary) orientation of a pair of degenerate eigenvectors ($\boldsymbol{L}_i,\boldsymbol{L}_{i+1}$) in their two-dimensional subspace evolves erratically as a function of s and the derivative $\partial L_{k,i}/\partial s$ in eq. [3] is ill-defined. The results of the coupling coefficient calculation are presented in Sect. 3 and the implications discussed in Sect. 4.

Symmetry coordinates for $CH_3 + X$

The use and derivation of symmetry coordinates is standard practice in the field of molecular spectroscopy but this does not appear to be the case in the field of reaction dynamics where they are rarely required. Since symmetry coordinates are necessary for the calculation of RP coupling coefficients and since no details of the associated methodology have previously appeared in the literature on the RP Hamiltonian, their derivation is presented here for $CH_3 + X$. Adaptation of the method to systems having different symmetry along the reaction path should be straightforward.

The symmetry coordinates listed in Table 1 are linear combinations of the mass-weighted Cartesian atomic displacement coordinates $\boldsymbol{r}_i = (x_i,y_i,z_i)$ where $i = 1$ denotes the carbon atom, $i = 2,3,4$ denote the three (equivalent) hydrogen atoms, and $i = 5$ denotes atom X (X = H or D). The z axis is aligned with the C_3 axis of the $CH_3\ldots X$ reaction path structure and the orientation of the CH_3 about the z axis is chosen such that $y_2 = 0$. The 15 symmetry coordinates constitute an orthogonal set of unit displacement vectors and are related to the original mass-weighted Cartesian displacements by a 15×15 orthogonal transformation matrix S. In Table 1 the symmetry coordinates are labeled $\boldsymbol{S}_i^{(\gamma)}$, $i = 1,\ldots,n_\gamma$ where n_γ is the number of coordinates belonging to irreducible representation (species) $\gamma = A_1, A_2, E$. Coordinates belonging to irreducible representation E are further classified as $\boldsymbol{S}_{ia}^{(\gamma)}$ or $\boldsymbol{S}_{ib}^{(\gamma)}$ depending on the coordinate being even (a) or odd (b) with respect to reflection in the x–z plane. The derivation of the symmetry coordinates is described in the Appendix and follows the method of Wilson, Jr. *et al.* (16).

Since center-of-mass translation does not couple to any of the internal motions nor to overall rotation, it is expedient to construct a modified set of symmetry coordinates of which three are unit vectors $\boldsymbol{T}_x,\boldsymbol{T}_y,\boldsymbol{T}_z$ for infinitesimal translations. Explicit expressions for $\boldsymbol{T}_x,\boldsymbol{T}_y,\boldsymbol{T}_z$ are readily obtained as linear combinations within the respective subsets $\{\boldsymbol{S}_{ia}^{(E)}\}$, $\{\boldsymbol{S}_{ib}^{(E)}\}$, $\{\boldsymbol{S}_i^{(A_1)}\}$ ($i = 1,2,3$) of original symmetry coordinates by noting that the general form of $\boldsymbol{T}_\lambda$ ($\lambda = x,y,z$) is

$$[5] \quad \boldsymbol{T}_\lambda = \frac{1}{\sqrt{M}} \sum_{i=1}^{N} \sqrt{m_i}\,\lambda_i; \quad M = \sum_{i=1}^{N} m_i$$

where N is the number of atoms and m_i is the mass of the ith atom. The two remaining modified symmetry coordinates within each subset were obtained by inspection. The complete set of modified symmetry coordinates, expressed as linear combinations of the original symmetry coordinates, is provided in the lower portion of Table 1. The associated modified orthogonal transformation matrix S' which links the Cartesian displacement coordinates to the modified symmetry coordinates is used in Sect. 3.

TABLE 1. Symmetry coordinates for CH_3X

Original set in terms of mass-weighted Cartesian displacement coordinates

$$S_1^{(A_1)} = \frac{1}{\sqrt{3}}(z_2 + z_3 + z_4) \qquad S_2^{(A_1)} = z_1 \qquad S_3^{(A_1)} = z_5$$

$$S_4^{(A_1)} = \frac{1}{\sqrt{12}}(2x_2 - x_3 + \sqrt{3}y_3 - x_4 - \sqrt{3}y_4)$$

$$S_1^{(A_2)} = \frac{1}{\sqrt{12}}(2y_2 - \sqrt{3}x_3 - y_3 + \sqrt{3}x_4 - y_4)$$

$$S_{1a}^{(E)} = \frac{1}{\sqrt{3}}(x_2 + x_3 + x_4) \qquad S_{1b}^{(E)} = \frac{1}{\sqrt{3}}(y_2 + y_3 + y_4)$$

$$S_{2a}^{(E)} = x_1 \qquad S_{2b}^{(E)} = y_1$$

$$S_{3a}^{(E)} = x_5 \qquad S_{3b}^{(E)} = y_5$$

$$S_{4a}^{(E)} = \frac{1}{\sqrt{12}}(-2x_2 + x_3 + \sqrt{3}y_3 + x_4 - \sqrt{3}y_4) \qquad S_{4b}^{(E)} = \frac{1}{\sqrt{12}}(2y_2 + \sqrt{3}x_3 - y_3 - \sqrt{3}x_4 - y_4)$$

$$S_{5a}^{(E)} = \frac{1}{\sqrt{6}}(2z_2 - z_3 - z_4) \qquad S_{5b}^{(E)} = \frac{1}{\sqrt{2}}(z_3 - z_4)$$

Unit vectors for infinitesimal rotations

$$R_x = \frac{1}{\sqrt{I_{xx}}}\left(-\sqrt{m_H}\, a_{2z}\, S_{1b}^{(E)} - \sqrt{m_C}\, a_{1z}\, S_{2b}^{(E)} - \sqrt{m_X}\, a_{5z}\, S_{3b}^{(E)} + \frac{\sqrt{3m_H}}{2}\, a_{2x}\, S_{5b}^{(E)}\right)$$

$$R_y = \frac{1}{\sqrt{I_{yy}}}\left(+\sqrt{m_H}\, a_{2z}\, S_{1a}^{(E)} + \sqrt{m_C}\, a_{1z}\, S_{2a}^{(E)} + \sqrt{m_X}\, a_{5z}\, S_{3a}^{(E)} - \frac{\sqrt{3m_H}}{2}\, a_{2x}\, S_{5a}^{(E)}\right)$$

$$R_z = \sqrt{m_H}\, S_1^{(A_2)}$$

Modified set in terms of original set

$$S_1'^{(A_1)} = T_z = \frac{1}{\sqrt{M}}(\sqrt{3m_H}\, S_1^{(A_1)} + \sqrt{m_C}\, S_2^{(A_1)} + \sqrt{m_X}\, S_3^{(A_1)})$$

$$S_2'^{(A_1)} = \frac{1}{\sqrt{m_c+m_x}}(\sqrt{m_X}\, S_2^{(A_1)} - \sqrt{m_C}\, S_3^{(A_1)})$$

$$S_3'^{(A_1)} = \sqrt{3m_H/M/(m_C+m_X)}\left(-\frac{m_C+m_X}{\sqrt{3m_H}}\, S_1^{(A_1)} + \sqrt{m_C}\, S_2^{(A_1)} + \sqrt{m_X}\, S_3^{(A_1)}\right)$$

$$S_4'^{(A_1)} = S_4^{(A_1)})$$

$$S_1'^{(A_2)} = S_1^{(A_2)})$$

$$S_{1a}'^{(E)} = T_x = \frac{1}{\sqrt{M}}(\sqrt{3m_H}\, S_{1a}^{(E)} + \sqrt{m_C}\, S_{2a}^{(E)} + \sqrt{m_X}\, S_{3a}^{(E)})$$

$$S_{2a}'^{(E)} = \frac{1}{\sqrt{m_c + m_x}}(\sqrt{m_X}\, S_{2a}^{(E)} - \sqrt{m_C}\, S_{3a}^{(E)})$$

$$S_{3a}'^{(E)} = \sqrt{3m_H/M/(m_C+m_X)}\left(-\frac{m_C+m_X}{\sqrt{3m_H}}\, S_{1a}^{(E)} + \sqrt{m_C}\, S_{2a}^{(E)} + \sqrt{m_X}\, S_{3a}^{(E)}\right)$$

$$S_{4a}'^{(E)} = S_{4a}^{(E)}$$

$$S_{5a}'^{(E)} = S_{5a}^{(E)}$$

$$S_{1b}'^{(E)} = T_y = \frac{1}{\sqrt{M}}(\sqrt{3m_H}\, S_{1b}^{(E)} + \sqrt{m_C}\, S_{2b}^{(E)} + \sqrt{m_X}\, S_{3b}^{(E)})$$

$$S_{2b}'^{(E)} = \frac{1}{\sqrt{m_c + m_x}}(\sqrt{m_X}\, S_{2b}^{(E)} - \sqrt{m_C}\, S_{3b}^{(E)})$$

$$S_{3b}'^{(E)} = \sqrt{3m_H/M/(m_C + m_X)}\left(-\frac{m_C+m_X}{\sqrt{3m_H}}\, S_{1b}^{(E)} + \sqrt{m_C}\, S_{2b}^{(E)} + \sqrt{m_X}\, S_{3b}^{(E)}\right)$$

$$S_{4b}'^{(E)} = S_{4b}^{(E)}$$

$$S_{5b}'^{(E)} = S_{5b}^{(E)}$$

For completeness, the unit vectors $\boldsymbol{R}_x,\boldsymbol{R}_y,\boldsymbol{R}_z$ corresponding to infinitesimal rotations of the entire system are expressed as linear combinations of the original symmetry coordinates in the middle portion of Table 1. Note that $\boldsymbol{R}_z$ corresponds to the only symmetry coordinate belonging to A_2 whereas $\boldsymbol{R}_x$ and $\boldsymbol{R}_y$ form a doubly degenerate pair. Explicitly evaluating the expressions for $\boldsymbol{R}_x,\boldsymbol{R}_y,\boldsymbol{R}_z$ in Table 1 in terms of mass-weighted Cartesian displacements yields the

standard result (e.g., eq. (4.8*a*) of ref. 1, or p. 22 of ref. 16),

$$[6] \qquad \vec{\mathbf{R}} = (\mathbf{R}_x,\mathbf{R}_y,\mathbf{R}_z) = I_0^{-1} \sum_{i=1}^{5} \vec{\mathbf{a}}_i \times \vec{\mathbf{r}}_i$$

where I_o is the inertia tensor for the reaction path configuration which is specified by $\mathbf{a}_i$ (i = 1,...,5) in mass-weighted Cartesian coordinates.

Calculations

All numerical results reported herein were obtained by following the negative gradient vector (reaction path) on the Hirst potential energy surface for CH_3 + H using the VENUS program[2] with several modifications. The first modification consisted of applying a similarity transformation to F^P (eq. [2]) to yield the "symmetrized" projected force constant matrix $(F^P)_{S'}$ arising from the modified symmetry coordinate basis:

$$[7] \qquad (F^P)_{S'} = S' \cdot F^P \cdot (S')^{-1}$$

The matrix $(F_P)_{S'}$ has the anticipated block diagonal structure: one 1×1 block containing a zero and corresponding to $\boldsymbol{R}_z = \boldsymbol{S}_1'^{(A_2)}$; three 1×1 blocks each containing a zero and corresponding to $\boldsymbol{T}_x = \boldsymbol{S}_{1a}'^{(E)}$, $\boldsymbol{T}_y = \boldsymbol{S}_{1b}'^{(E)}$, and $\boldsymbol{T}_z = \boldsymbol{S}_1'^{(A_1)}$; one 3×3 block corresponding to the remaining coordinates of A_1 type; two identical 4×4 blocks corresponding to the remaining coordinates of E type. The evaluation of frequencies and coupling coefficients is now substantially simplified since it is only necessary to diagonalize one 3×3 and one 4×4 matrix. The square roots of the seven eigenvalues yield frequencies which will be labeled here by symmetry type and arranged in order of increasing magnitude: $\{\omega_1^{(A_1)},\omega_2^{(A_1)},\omega_3^{(A_1)}\}$, $\{\omega_1^{(E)},\omega_2^{(E)},\omega_3^{(E)},\omega_4^{(E)}\}$. In all calculations undertaken it was found, as expected, that one frequency in each group ($\omega_1^{(A_1)}$ and $\omega_1^{(E)}$) was zero (to two decimal place accuracy). The corresponding eigenvectors $\boldsymbol{S}_1''^{(A_1)}$ and $\boldsymbol{S}_1''^{(E)}$ are accordingly associated with reaction path motion (which always belongs to the totally symmetric representation) and rotational motion about the x (or y) axis. The remaining five nonzero frequencies agreed with values obtained from our previous reaction path analysis on the Hirst surface (14) in which symmetry coordinates were not employed and F^P was diagonalized. Equation [3a] for the coupling coefficients can be rewritten in terms of the eigenvectors $\{\boldsymbol{S}_1''^{(A_1)}\}$ and $\{\boldsymbol{S}_1''^{(E)}\}$ resulting from diagonalization of the 3×3 and 4×4 blocks, respectively, as

$$[8] \qquad B_{i,j}^{(A_1)} = \sum_{k=1}^{15} \frac{\partial S_{k,i}''^{(A_1)}}{\partial s} \cdot S_{k,j}''^{(A_1)}, \quad (i,j = 1,2,3;\ i < j)$$

$$B_{i,j}^{(E)} = \sum_{k=1}^{15} \frac{\partial S_{k,i}''^{(E)}}{\partial s} \cdot S_{k,j}''^{(E)}, \quad (i,j = 1,2,3,4;\ i < j)$$

where $S_{k,n}''^{(\gamma)}$ is the coefficient of the kth symmetry displacement coordinate of the eigenvector $S_n''^{(\gamma)}$. The diagonal coupling coefficients are given by eq. [3*b*] but, since $\omega_1^{(A_1)} = \omega_1^{(E)} = 0$, $B_{1,1}^{(A_1)}$ and $B_{1,1}^{(E)}$ are not defined. There are thus nine off-diagonal and five diagonal nonzero coupling coefficients to report and their evaluation required a second modification of the VENUS program as described immediately below.

Numerical values of $\omega_1^{(\gamma)}$ and $B_{i,j}^{(\gamma)}$ were determined on a grid of 31 values of the reaction coordinate, the grid corresponding to 0.1 Å increments of the C···X distance r_{CX} from 1.4 to 4.4 Å. To assess the suitability of r_{CX} as a convenient substitute for s, the derivative $\partial r_{CX}/\partial s$ was also determined. All derivatives $\partial f(s)/\partial s$ ($f = \omega_i^{(\gamma)}$, $S_{k,i}''^{(\gamma)}$, or r_{CX}) were approximated by

$$[9] \qquad \frac{\partial f(s)}{\partial s} \approx \frac{\Delta f}{\Delta s} = \frac{f(s + n\delta) - f(s - n\delta)}{2n\delta}, \quad n = 1, 2, 3$$

where $\delta = -0.000125$ amu$^{1/2}$ Å is the (fixed) step size supplied to the VENUS program for integration along the RP beginning at r_{CX} = 4.5 Å. At each grid value of s each coupling coefficient (eqs. [3b] and [9]), as well as $\partial r_{CX}/\partial s$, was calculated via eq. [10] for each of the three Δs values (2δ,4δ,6δ) to establish the accuracy of this approach.[3] For each quantity, the results for the three Δs values agreed to four significant figures. It was observed that r_{CX} and s are linearly related for both reactions: $\partial r_{CX}/\partial s$ = 1.034 ± 0.003 and 0.758 ± 0.003 for CH_3 + H and CH_3 + D, respectively, over the range of r_{CX} considered (1.4–4.4 Å). Note that the ratio of slopes $[\partial r_{CH}/\partial s]/[\partial r_{CD}/\partial s]$ = 1.36 is close to the mass ratio $\sqrt{m_D/m_H}$ = 1.41 of the mass scaled Cartesian coordinates for atom X. In applications of VTST to recombination processes having no intrinsic barrier to the reverse dissociation process, it is quite common to use a bond coordinate to represent distance along the RP. For CH_3 + H/D, such a substitution is certainly justified and is used in Sect. 4 to provide a common reaction coordinate to facilitate the comparison of CH_3 + H and CH_3 + D frequencies and coupling coefficients. The latter are thus re-expressed as

$$[10] \qquad B_{i,j}^{(\gamma)}(r_{CX}) = B_{i,j}^{(\gamma)}(s)/(\partial r_{CX}/\partial s) \approx \sum_k \frac{\partial S_{k,i}''^{(\gamma)}}{\partial r_{CX}} \cdot S_{k,j}''^{(\gamma)}$$

However, it must be emphasized that the more subtle and complex issue of the physically correct description of the transitional modes within VTST is not addressed by a simple change of variable (17). Within a RP Hamiltonian framework, the information pertinent to this issue is contained in the eigenvectors $S_i''^{(\gamma)}$ whose s-dependent composition requires an appropriate and detailed analysis.

Results and discussion

Frequencies

Figure 1 displays the five nonzero frequencies for CH_3 + H (solid curves) and CH_3 + D (dashed curves) as a function of r_{CX} (X = H,D) on the range 1.4–4.4 Å. The reaction path dependence of the CH_3 + H frequencies has been displayed and discussed elsewhere (15), but the comparison to the CH_3 + D frequencies has not previously been considered.

[3]With $f = S_{k,i}''^{(\gamma)}$ a minor technical difficulty was encountered. The sign of the coefficients $S_{k,i}''^{(\gamma)}$ was found to alternate unpredictably as a function of s because of the sign ambiguity in the eigenvectors $S_i''^{(\gamma)}$, i.e., the sets $+\{S_i''^{(\gamma)}\}$ and $-\{S_i''^{(\gamma)}\}$ are both acceptable, being physically indistinguishable. This ambiguity was removed by arbitrarily selecting a sign convention at a grid value of the reaction coordinate and requiring that the coefficients of adjacent eigenvectors at $s \pm \delta$, $s \pm 2\delta$, $s \pm 3\delta$ evolve smoothly as a function of s.

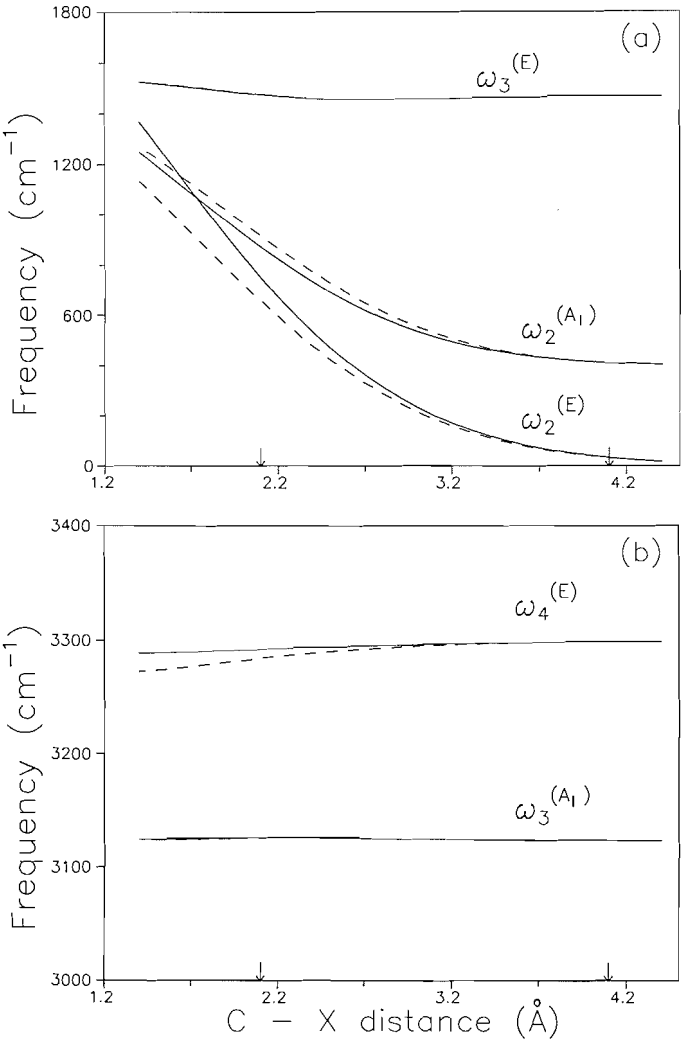

FIG. 1. Harmonic frequencies of modes orthogonal to the reaction path for CH_3 + H (solid curves) and CH_3 + D (dashed curves) as a function of distance along the reaction path as parameterized by the C–X distance (X = H or D).

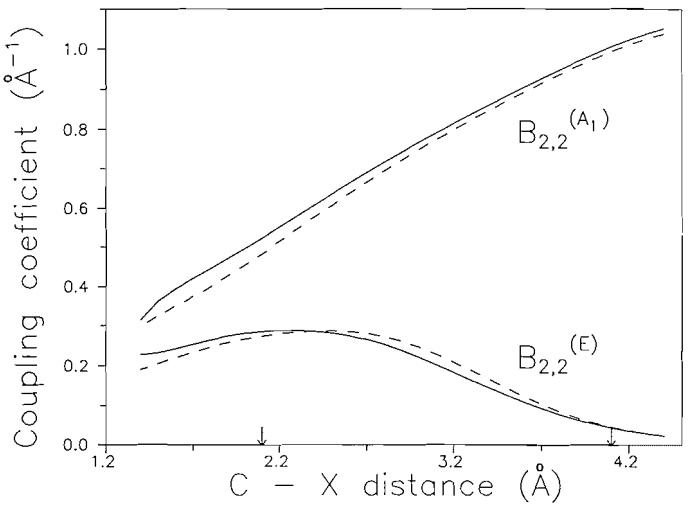

FIG. 2. Reaction path Hamiltonian coupling coefficients for CH_3 + H (solid curves) and CH_3 + D (dashed curves) as a function of C–X distance. The arrows on the abscissa indicate lower and upper bounds to the range of variational transition state locations as determined by flexible transition state theory.

At large separations, the frequencies are those of the normal modes of CH_3 reactant and are independent of the identity of X. A comparison of these methyl radical frequencies with experimentally derived ones and with another set of theoretical ones is provided in ref. 14. Small differences between some pairs of H and D frequencies appear as r_{CX} is decreased to the smallest value considered (1.4 Å). Between 1.4 Å and the equilibrium value in CH_3X (~1.1 Å), one anticipates a relatively rapid variation of some frequencies in order that the magnitudes and symmetry types of the CH_4 and CH_3D product frequencies be reproduced (19). Reaction path calculations were stopped at 1.4 Å since the fitting of $V_o(r_{CX})$ to Hirst's *ab initio* data was designed to be accurate only for r_{CX} larger than this value, i.e., the potential energy surface is intended to be reliable in the region of variational transition state locations. Three of the frequencies ($\omega_4^{(E)}$, $\omega_3^{(A_1)}$, $\omega_3^{(E)}$) are almost independent of r_{CX} and the remaining two ($\omega_2^{(A_1)}$, $\omega_2^{(E)}$) vary substantially with r_{CX}. Of the latter two frequencies, one ($\omega_2^{(E)}$) goes to zero as r_{CX} increases.

In a particular version of VTST, known as flexible transition state theory (FTST) and described elsewhere (15, 20), modes orthogonal to the reaction path are classified as conserved or transitional and coupling between a mode of one type and any mode of the other type is assumed neglible. Conserved modes are vibrations whose character is qualitatively the same in reactants and products, whereas transitional modes are inter-fragment relative motions whose attributes change drastically in going from reactants to products. On these grounds, the CH_3 umbrella vibration ($\omega_2^{(A_1)}$), the CH_3 in-plane bending ($\omega_3^{(E)}$), and the CH stretching ($\omega_3^{(A_1)}$, $\omega_3^{(E)}$) can be classified as conserved modes; the two transitional modes correspond to free relative rotation of reactants (with a frequency of zero and to degenerate CH_3 deformation in CH_3X. Within the RP Hamiltonian description, which is valid in the vicinity of the minimum energy path, the two transitional modes are doubly degenerate harmonic CH_3 rocking vibrations of frequency $\omega_2^{(E)}$. At intermediate and large separations the transitional motion is generally 2-*d* hindered rotation and 2-*d* free rotation, respectively. It is well known that such large amplitude motion renders the RP Hamiltonian treatment of the transitional modes invalid. A reliable treatment of these modes within the RP Hamiltonian framework can be achieved by the *ad hoc* replacement of their normal mode description with a hindered rotor model in which the dependence of the hindering barrier height on the reaction coordinate is obtained from the full potential energy surface. Several applications of VTST to CH_3 + X have adopted this approach (21, 22).

Coupling coefficients

Figures 2–6 display 12 of 14 coupling coefficients for CH_3 + H (solid curves) and CH_3 + D (dashed curves) versus r_{CX} in the range 1.4–4.4 Å. The two missing coefficients, $B_{3,3}^{(A_1)}$ and $B_{4,4}^{(E)}$, are each an order of magnitude less than the smallest coefficient included, $B_{3,3}^{(E)}$ in Fig. 6. The arrows in Figs. 1–6 indicate upper and lower bounds to the range of transition state locations $r_{CX}^{\dagger}$ ($2.1 < r_{CX}^{\dagger} < 4.1$ Å) determined by Aubanel and Wardlaw (14) in their application of microcanonical FTST to these reactions on the Hirst surface. This range of $r_{CX}^{\dagger}$ arose from the minimization, with respect to variation in the reaction coordinate, of the sum of states for motion orthogonal to the RP for the wide range of

energy and angular momentum values involved in the calculation of thermally averaged rate coefficients in the 300–2500 K temperature range.

Examination of Figs. 1–6 reveals no major differences in magnitude or r_{CX} dependence of the frequencies or coupling coefficients for these two related reactions on the range of variational transition states and does not support the conjecture that different dynamics along the RP might lead to "differences in recrossing of the dividing surface separating reactants and products" (12). This suggestion is one of several made by Pilling and co-workers as possible explanations of an apparent isotope anomaly in the experimental value of the ratio $\rho = k_H/k_D$ of thermal rate coefficients k_H and k_D for these two reactions. Specifically, these authors find (12, 13) the experimental ratio $\rho_{expt} \approx 2.5$ in the 300–400 K range, whereas VTST treatments on several potential energy surfaces by Hase *et al.* (10) and our FTST treatment on the Hirst surface (14) yield $\rho_{VTST} \approx 1.4 \approx \sqrt{m_D/m_H}$. In absolute terms, the VTST and experimental values for k_D agree but the experimental values for k_H in this temperature range significantly exceed the VTST values, contrary to the expectation that transition state theory should provide an upper bound to the rate. It is apparent from Figs. 1–6 that a sum-of-states calculation based on the RP Hamiltonian of eq. [1] would yield approximately the same results for CH_3 + H and CH_3 + D anywhere in the transition state range 2.1–4.1 Å. Such sums of states could then be used to determine VTST rate coefficients k_H and k_D whose ratio ρ_{RP} would be essentially determined by the ratio of reactant state densities. This latter ratio reduces to the ratio of partition functions for relative translation and thus $\rho_{RP} \approx \sqrt{m_D/m_H}$, in agreement with ρ_{VTST}. It is still conceivable, as suggested in ref. 12, that coupling differences in the product molecules CH_4 and CH_3D could be responsible for the isotope anomaly. Some coupling differences in CH_4 and CH_3D are certainly expected and indeed begin to appear in the 1.4–2.0 Å range in Figs. 2–6. Dynamical coupling mechanisms between C–H stretching vibrations and other normal modes in CHD_3, CHT_3, and CH_3D have been examined in a theoretical treatment by Voth *et al.* (23) who discuss the implications for intramolecular vibrational energy redistribution. Whether such differences can account for the anomaly in the

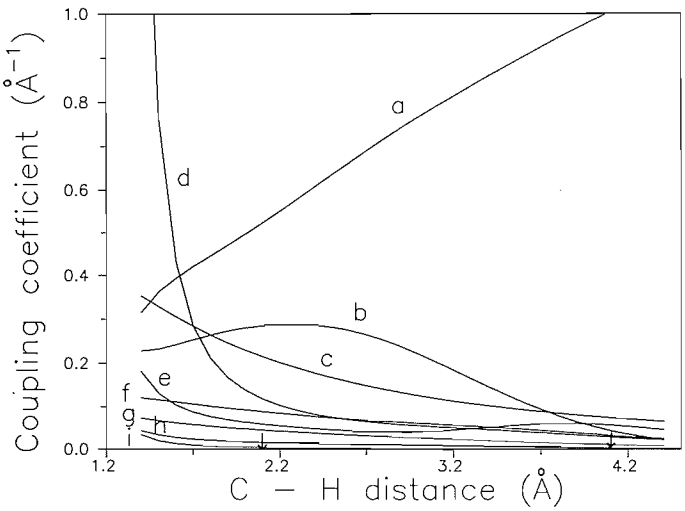

FIG. 7. The nine largest coupling coefficients for CH_3 + H as a function of r_{CH}. The arrows on the abscissa are as in Fig. 2. The connection between the alphabetic labels and coupling coefficients is as follows: (*a*) $B^{(A_1)}_{2,2}$, (*b*) $B^{(E)}_{2,2}$, (*c*) $B^{(E)}_{1,2}$, (*d*) $B^{(E)}_{2,3}$, (*e*) $B^{(A_1)}_{1,2}$, (*f*) $B^{(A_1)}_{1,3}$, (*g*) $B^{(E)}_{2,4}$, (*h*) $B^{(E)}_{1,4}$, (*i*) $B^{(E)}_{3,4}$.

observed rates for CH_3 + H and CH_3 + D cannot be ascertained from the present study since RP calculations were not done for $r_{CX} < 1.4$ Å, the region in which the potential is not accurately fit to the *ab initio* data. A recent trajectory study by Hu and Hase (24) on a modified version of the Hirst potential (so that it has proper asymptotic behavior at large r_{CX}) yields thermal rate coefficients (at 300 and 1000 K for CH_3 + H and at 300 K for CH_3 + D) that are in excellent agreement with microcanonical FTST values obtained by Aubanel and Wardlaw (14) and whose ratio $\rho_{traj} \approx 1.3$ at 300 K is close to $\rho_{VTST} \approx 1.4$. The trajectory results do not account for the isotope anomaly as characterized by $\rho_{expt} \approx 2.5$ on 300–400 K and suggest that the coupling differences in CH_4 and CH_3D are not responsible for it.

The paper concludes with an assessment of the relative magnitudes of the larger coupling coefficients for CH_3 + H $\rightarrow$ CH_4. The nine largest coefficients are presented in Fig. 7 where they are labeled (*a*)–(*i*); the arrows at 2.1 and 4.1 Å on the abscissa again denote the FTST range of transition states for this system. The two largest coupling coefficients in this range are the diagonal ones $B^{(A_1)}_{2,2}$ (curve *a*) and $B^{(E)}_{2,2}$ (curve *b*) arising from the variation in frequency with r_{CX} of the CH_3 umbrella motion and the transitional modes, respectively. That these two coefficients would be the largest diagonal ones is immediately evident from Fig. 1. The three remaining diagonal coefficients are sufficiently small on the scale of the ordinate in Fig. 7 that they could not be distinguished from the abscissa and were not included. The relatively large value of $B^{(A_1)}_{2,2}$ (curve *a*) indicates that, within a harmonic description of the umbrella mode, it may be important to observe semiclassical vibrational selection rules arising from the term involving $B^{(A_1)}_{2,2}$ in the RP Hamiltonian (2). Namely, if all other couplings among A_1-type modes (the next largest of which are $B^{(A_1)}_{1,2}$ and $B^{(A_1)}_{1,3}$ (curves *e*, *f*)) are ignored, then umbrella vibrational states with even and odd quantum numbers are uncoupled. The associated even and odd sums of states for motion orthogonal to the RP lead to even and odd microcanonical rate coefficients. The influence on thermal rate coefficients $k_H(T)$ is unknown but is likely small in the 300–2500 K temperature range. In any case, the umbrella mode is highly anharmonic in isolated CH_3 and becomes progressively more harmonic (for the Hirst potential) as r_{CX} is decreased to its equilibrium value in CH_4. Inclusion of this behavior in microcanonical FTST has been shown to affect significantly the magnitude and temperature dependence of $k_H(T)$.

Among off-diagonal coefficients of *E* type, we first examine those involving the transitional modes (mode 2): $B^{(E)}_{1,2}$ (curve *c*), $B^{(E)}_{2,3}$ (curve *d*), $B^{(E)}_{2,4}$ (curve *g*) which describe coupling of the transitional modes to overall rotation, to the degenerate CH_3 in-plane bend, and to degenerate C–H stretching, respectively. Notwithstanding the poor description of the transitional modes provided by the normal mode treatment of the RP Hamiltonian, the relative magnitudes agree with intuitive predictions based on the type and frequency of the modes involved. In all implementations of VTST for this reaction, coupling between transitional and conserved modes is assumed negligible. From a RP Hamiltonian perspective this corresponds to setting $B^{(E)}_{2,3}$ and $B^{(E)}_{2,4}$ to zero. The largest off-diagonal coefficient involving the transitional modes is $B^{(E)}_{1,2}$, which most implementations of VTST also ignore except for FTST which implicitly includes coupling between the transitional modes and overall rotation via a rigorous treatment of conservation of angular momentum. The two remaining off-diagonal *E*-type coefficients in Fig. 7 are $B^{(E)}_{1,4}$ (curve *h*) and $B^{(E)}_{3,4}$ (curve *i*). They describe coupling of (high frequency) C–H stretching to overall rotation and to CH_3 bending, respectively, and are relatively small on the entire range of r_{CX} values, as would be expected. The two off-diagonal A_1-type coefficients included in Fig. 7 are $B^{(A_1)}_{1,2}$ (curve *e*) and $B^{(A_1)}_{1,3}$ (curve *f*) describing coupling of the reaction path to the CH_3 umbrella mode and to (nondegenerate) C–H stretching, respectively. The fact that they are nonzero indicates that RP motion induces changes in the vibrational state of these two modes, an effect which is ignored in existing implementations of VTST but whose significance therein is unknown.

Acknowledgments

The author is grateful to Geoff Anderson for preliminary work in the form of a senior undergraduate research project and to Prof. R. D. Gordon for fruitful discussions concerning symmetry coordinates. This work was supported by an operating grant from the Natural Sciences and Engineering Research Council of Canada.

Appendix

The construction of symmetry coordinates is based on eq. [1] of Sect. 6–5 in ref. 16:

$$[A1] \quad S_k^{(\gamma)} = N \sum_R \chi_R^{(\gamma)} \hat{R}\xi$$

Here N is a normalization constant, $\hat{R}$ (= E, C_3, C_3^2, σ_v, σ_v', or σ_v'') is a symmetry operation of C_{3v}, $\chi_R^{(\gamma)}$ is the character of R in irreducible representation γ, and ξ is one of, or a simple linear combination of, the mass-weighted Cartesian displacement coordinates. $\hat{R}\xi$ is the result of operating on ξ with the symmetry operation $\hat{R}$ and, in this case, was determined diagramatically following Fig. 6–6 of ref. 16. The procedure is considerably simplified by identifying sets of atoms whose Cartesian displacements are not mixed by the group's symmetry operations. In the present case there are three such sets: $\{x_1,y_1,z_1\}$, $\{x_5,y_5,z_5\}$, and $\{x_2,y_2,z_2,x_3,\ldots,z_4\}$. A further simplification is achieved by subdividing each set into two groups on the grounds that none of the z coordinates are mixed with x or y coordinates by application of any of the symmetry operations of C_{3v}. This results in six sets: $\{x_1,y_1\}$, $\{x_5,y_5\}$, $\{x_2,y_2,x_3,y_3,x_4,y_4\}$, $\{z_1\}$, $\{z_5\}$, and $\{z_2,z_3,z_4\}$. For A_1, the symmetry coordinates are generated by applying eq. [A1] with $\gamma = A_1$ to x_1,x_5,x_2,z_1,z_5, and z_2; for A_2 to y_1,y_5,y_2,z_1,z_5, and z_2. This yields six symmetry coordinates for each species. However, two of these are zero for A_1 and five are zero for A_2; the surviving coordinates appear in Table 1. Applying eq. [A1] to all coordinates in a set with two or more members is unnecessary since no additional nonzero symmetry coordinates result. To generate symmetry coordinates belonging to the two-dimensional E representation it is necessary to select within each of the six sets listed above pairs (a, b) of Cartesian coordinates, or of linear combinations of Cartesian coordinates, that are orthogonal and are symmetric or antisymmetric with respect to a chosen set of group operations constituting a subgroup. This procedure removes the aforementioned ambiguity in the orientation of degenerate sets of symmetry coordinates belonging to species E. In this case we chose the subgroup (E, σ_v). Clearly such a pair which is even(a)/odd(b) with respect to σ_v cannot be created from the one element sets $\{z_1\}$ or $\{z_5\}$. The elements of the sets $\{x_1,y_1\}$, $\{x_5,y_5\}$ themselves provide two such pairs. The set $\{z_2,z_3,z_4\}$ provides the pair $(z_2,z_3 - z_4)$ and the set $\{x_2,y_2,\ldots,y_4\}$ provides two pairs: $(x_2 + x_3 + x_4,y_3 - y_4)$ and $(y_2 + y_3 + y_4,x_3 - x_4)$. Alternative combinations such as $(x_2,y_3 - y_4)$ or $(z_2 + z_3 + z_4,z_3 - z_4)$ satisfying the stated criteria are possible but not useful. Applying eq. [A1] with $\gamma = E$ to these five pairs yields the 10 E-type symmetry coordinates in Table 1.

Sirosterol and dehydroazasirosterol, unusual steroidal adducts from a *Sirococcus* species

WILLIAM A. AYER[1] AND YU-TING MA
Department of Chemistry, University of Alberta, Edmonton, Alta., Canada T6G 2G2

Received November 20, 1991

WILLIAM A. AYER and YU-TING MA. J. Chem. **70**, 1905 (1992).

Two unusual compounds, which are made up of a sterol portion fused at C-5 and C-6 to an atrovenetin-like part, have been isolated from a fungus that causes Sirococcus shoot blight of spruce. The structures of these compounds, sirosterol (**4**) and dehydroazasirosterol (**13**), were determined by spectroscopic methods and comparison with appropriate model compounds. Sirosterol is an adduct of ergosterol and atrovenetin (**5**) and dehydroazasirosterol is an adduct of 9(11)-dehydroergosterol and an azaatrovenetin. Both compounds give a monomethyl ether when treated with diazomethane and both have been transformed to the corresponding 3-ketosteroids. The preparation of the triol **6** resulting from the selective hydroxylation of the 5,6-double bond in ergosterol is described. A possible biogenesis of sirosterol from ergosterol endoperoxide and a desoxyatrovenetin is discussed.

WILLIAM A. AYER et YU-TING MA. Can. J. Chem. **70**, 1905 (1992).

On a isolé deux composés inhabituels, faits d'une portion stéroïdale condensée par les carbones 5 et 6 à une partie de type atrovénétine, à partir d'un champignon qui provoque la rouille des pousses de l'épinette par le Sirococcus. On a déterminé la structure de ces composés, le sirostérol (**4**) et le déhydroazasirostérol (**13**), grâce à des méthodes spectroscopiques et par comparaison avec des composés modèles appropriés. Le sirostérol est un adduit de l'ergostérol avec l'atrovénétine (**5**) alors que le déhydroazasirostérol est un adduit du 9(11)-déhydroergostérol avec une azaatrovénétine. Lorsqu'on les traite avec du diazométhane, les deux composés fournissent un éther méthylique; on a aussi pu les transformer tous les deux dans les 3-cétostéroïdes correspondants. On décrit la préparation du triol **6** qui résulte de l'hydroxylation sélective de la double liaison en 5,6 de l'ergostérol. On discute d'une voie de biogenèse possible à partir de l'endoperoxyde de l'ergostérol et d'une désoxyatrovénétine.

Introduction

We previously reported on the metabolites produced by two strains of fungi responsible for the so-called Sirococcus shoot blight of spruce (1). Our interest in these fungi arose from our work on the related disease of pine known as Scleroderris canker (2). We now report on two new metabolites isolated from the mycelium of a strain (strain 35B) of the Sirococcus disease fungus from the mountains of southern Germany.[2] In addition to the two previously unreported compounds, racemic sclerodin (**1**), atrovenetinone (**2**, as its acetone adduct), Scleroderris blue (**3**) (3), and the ubiquitous fungal sterols ergosterol and 9(11)-dehydroergosterol endoperoxide, were isolated from this stain.

Results and discussion

The methylene chloride extract of the mycelium of Sirococcus 35B (UAMH 5401) was separated by silica gel column chromatography into nonpolar, intermediate, and polar fractions and these fractions were further separated by flash chromatography to provide the individual components. When the yellow sirosterol (**4**) was initially isolated it appeared to be a mixture of a sterol and a phenalenone type compound. High-resolution electron impact mass spectrometry (hrms) and chemical ionization mass spectrometry (cims) gave confusing results. Methylation (diazomethane) provided a new material, which also showed a single spot on thin-layer chromatography (tlc). Fast atom bombardment mass spectrometry (fabms) of sirosterol (**4**) showed a peak at 737 $[M + H]^+$ corresponding to a molecular formula of $C_{47}H_{60}O_7$, suggesting that the compound was an adduct of a sterol and an atrovenitin (**5**) related compound. The ir spectrum of sirosterol shows hydroxyl absorption and a strongly chelated carbonyl at 1611 cm^{-1}. The phenalenone portion of the molecule gives rise to signals for: two exchangeable phenolic hydrogens, one strongly chelated (δ 17.16), one free (δ 9.56); an aromatic methyl (δ 2.83) and hydrogen (δ 6.93); signals due to the isopentyl portion (methyl singlets at δ 1.56 and δ 1.32, doublet at δ 1.47, methine quartet at δ 4.65). These chemical shifts are very similar to those of atrovenitin trimethyl ether (**5***a*) (4). The "sterol" portion of the molecule gave rise to ^1H nmr signals very similar to those of the triol **6** prepared (see below) from ergosterol. Thus, the methyl groups of the sterol portion give rise to singlets at δ 0.57 (C-18 in **6**, δ 0.57) and δ 1.14 (C-19 in **6**, 0.98), doublets at δ 0.80, 0.81, 0.88, and 1.00 (0.83, 0.84, 0.93, and 1.03 in **6**). The two side-chain alkenic hydrogens give rise to an unresolved multiplet at δ 5.15 in **4** and at δ 5.20 in **6**, and the steroidal C-7 hydrogen appears at δ 4.99 in **4** and δ 5.03 in **6**. The C-7″ hydrogen in **4** is vicinally coupled to the methine signal (H-6″) at δ 4.91. In **6**, the C-6 hydrogen appears at δ 3.98, indicating a difference in the C-6 substituent. The broad methine doublet at δ 4.05 in **4** and δ 4.01 in **6** has the normal complexity of a steroidal 3α-carbinol hydrogen. The downfield shift of the 3α hydrogen is characteristic of 3β-hydroxysterols bearing a 5α oxygen substituent (5). It seemed clear at this stage that sirosterol consisted

of an "atrovenitin" portion fused to an ergosterol-derived sterol portion through ether linkages at C-5 and C-6 of the sterol portion to C-1 and C-2 (or C-2 and C-3 of the tautomeric form) of atrovenitin. A strong nuclear Overhauser enhancement (nOe) effect between the hydrogen at C-6″ and the 19 methyl group in **4**, along with the very small coupling between this hydrogen and the C-7 hydrogen, indicates that the C-6″ substituent is in the α-orientation. To distinguish between **4** and the other structural isomers possible (**7**, **8**, and **9**), several derivatives of sirosterol were prepared.

Treatment of sirosterol with diazomethane in ether provided the monomethyl ether **10**. The fabms indicated a molecular weight of 750 amu. The ir spectrum shows the presence of hydroxyl (3300 cm^{-1}) and strongly chelated carbonyl (1611 cm^{-1}), and the ^1H nmr spectrum shows the hydrogen of the chelated carbonyl at δ 17.95, indicating that the non-chelated phenolic hydroxyl is the one methylated. The methoxyl hydrogens appear at δ 4.05. The remainder of the spectrum is very similar to that of sirosterol itself. Strong nOe enhancement of the aromatic hydrogen is observed when the methoxyl hydrogens are irradiated and when the aromatic methyl hydrogens are irradiated. This indicates that the methoxyl is located at C-9, thus the non-chelated phenolic hydrogen in **4** is at C-9. On this basis, structures **8** and **9** for sirosterol are ruled out. The nOe results with **10** also serve to confirm the stereochemistry at C-6″. Irradiation of the C-19″ methyl causes enhancement (10.4%) of the signal at

δ 4.83 (C-6″). Irradiation of the hydrogen at δ 4.83 also causes enhancement of the alkenic hydrogen at δ 4.99 (C-7″), and vice versa. This further supports the proximate relationship of these two hydrogens. The ^{13}C nmr spectrum of **10** adds further support to the structural assignment. As shown in Table 1, the signals for the "atrovenitin" portion correspond much better with those of atrovenitin trimethyl yellow (**11**) than with those of atrovenitin trimethyl orange (**5***a*) (4). A comparison of the ^{13}C nmr signals of the "sterol" portion of **10** with those of the triol **6** is provided in Table 2. The upfield shifts of C-1, C-4, C-7, and C-10 relative to those of **6** are consistent with the expected substituent steric effects (6).

Acetylation of sirosterol methyl ether (**10**) provided the acetyl derivative **10***a*. The C-3″ hydrogen is shifted downfield to δ 5.05, indicating the position of acetylation. Acetylation of sirosterol (**4**) itself provided the diacetyl derivative **10***b*. The ir spectrum of **10***b* shows chelated carbonyl (1620 cm^{-1}), alkyl acetate (1734 cm^{-1}), and aryl acetate (1753 cm^{-1}) absorption. The signal for the chelated phenolic hydrogen appears at δ 17.41 in the ^1H nmr spectrum. Comparison of the ^1H nmr spectra of sirosterol (**4**) and its derivatives **10**, **10***a*, and **10***b* leads us to favor structure **4** over structure **7** for the metabolites. Table 3 provides a comparison of the chemical shifts of H-6″ and H-7″ in these four compounds and Fig. 1 shows conformation drawings of **4** and

7. As can be seen in Fig. 1, the unchelated phenolic hydroxyl group (at C-9 in **4**) is much closer to H-6″ and H-7″ in **4** than in **7**. Methylation and, particularly, acetylation of the C-9 hydroxyl induces significant chemical shifts of H-6″ and, to a lesser extent, H-7″. We feel that these anisotropic shifts are best explained if sirosterol possesses structure **4**

rather than **7**. Since sirosterol was not available in large quantities (approximately 1 mg/L of culture broth) we carried out only a limited number of further experiments.[3] All attempts to bring about acid-catalyzed hydrolysis (aqueous trifluoroacetic acid, 50% sulphuric acid, *p*-toluenesulfonic acid in acetone) of sirosterol methyl ether (**10**) were unsuccessful. Aqueous base had no effect. Attempted hydrogenolysis of the allylic ether at C-6″ was unsuccessful, both with the ether **10** and the diacetate **10***b* and utilizing both platinum and palladium catalysts. In every case the side-chain double bond was hydrogenated and the corresponding dihydro compound was obtained. The C-7″, 8″ double bond was not reduced and no hydrogenolysis was observed. Oxidation of sirosterol using the Swern procedure (7) provided ketone **12**, which shows carbonyl absorption at 1722 cm^{-1} in the ir. The ^1H nmr spectrum of **12** is similar to that of sirosterol except that the signal at δ 4.05 (C-3″ H) is not present. Attempts to bring about (acid and base catalyzed) β-elimination of the C-5″ functionality in ketone **12** were not successful.

Sirosterol (**4**), which is optically active, is a mixture of diastereoisomers at C-2′ (ca. 2:1) as indicated by the multiplicity of the signal for H-2′ (two superimposed quartets, $J \approx 6$ Hz) in sirosterol and its derivatives. These diastereoisomers could not be separated (tlc, hplc). Since the phenalenone metabolites from Sirococcus are partially racemic (1), it is not surprising that sirosterol exists in diastereomeric forms.

A second yellow phenalenone-sterol adduct, which we call dehydroazasirosterol, was present (ca. 0.4 mg/L of culture) among the metabolites of Sirococcus 35B. The fabms showed an M + H^+ peak at 734 amu corresponding to a molecular formula $C_{47}H_{59}O_6N$. The ^1H nmr spectrum of dehydroazasirosterol (**13**) was very similar to that of sirosterol (**4**) with the exception of signals at δ 5.73 (1 H, d, $J \approx 6$ Hz) and at δ 4.01 (1 H, s, D_2O exchangeable). Since all the sig-

[3]Sirosterol and its derivatives are obtained as amorphous powders. All attempts to prepare suitable crystals for X-ray crystallographic studies were unsuccessful.

nals for the "atrovenitin" portion of the molecule were observed, the signal at δ 5.73 appeared to arise from the sterol portion of the molecule. The presence of an additional olefinic double bond was apparent from the ^{13}C nmr spectrum of **13**. Since 9(11)-dehydroergosterol endoperoxide (**14**) is

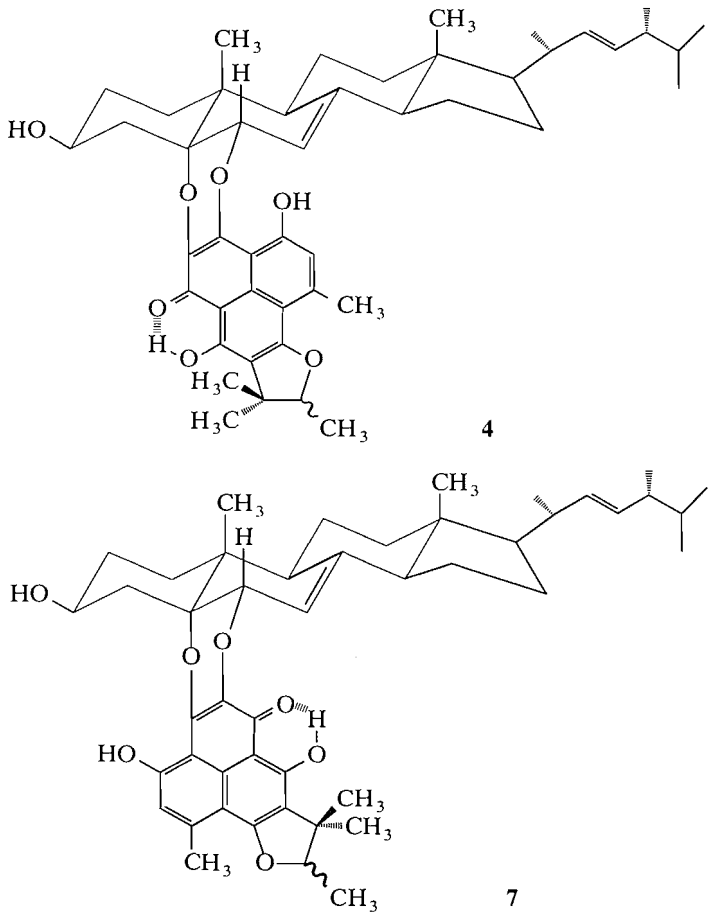

FIG. 1. Conformational drawings of possible structures of sirosterol.

present among the metabolites of this fungus, the location of the additional unsaturation at C-9, C-11 seemed reasonable. In fact, the chemical shifts (Table 4) of the non-side-chain alkenic carbons (δ 117.1, 124.8, 139.2, 140.6) suggest a conjugated diene (8). Whereas the ^{13}C nmr spectrum of **4** shows the presence of three oxygenated sterol carbons (δ 76.0 (s), 73.4 (d), 66.9 (d)), the spectrum of **13** (Table 4) shows only the secondary oxygenated carbons (δ 75.7, 66.9) and a new quaternary carbon signal at δ 55.7, consistent with the replacement of oxygen by nitrogen. The exchangeable hydrogen at δ 4.01 may then be assigned to NH and structure **13** (or **15**) results for dehydroazasirosterol.

Treatment of dehydroazasirosterol (**13**) with ethereal diazomethane provided the monomethyl ether **13***a*. The fabms shows the protonated molecular ion at 748 amu and the ^1H nmr spectrum shows an aromatic methoxyl (δ 4.07) and a chelated OH (δ 17.65). In the COSY 2D nmr spectrum the alkenic hydrogen at δ 5.67 (H-11″) is weakly correlated with a hydrogen at δ 5.03 (H-7″) and this in turn is coupled to the hydrogen at δ 4.81 (H-6″). The latter hydrogen is correlated with the NH hydrogen (δ 3.99). As with sirosterol methyl ether, nOe experiments confirmed the position of methylation and the stereochemistry at C-6″. Irradiation of the C-11″ hydrogen and the NH hydrogen did not lead to observable nOe enhancements. Acetylation of dehydroazasirosterol **13** provides the *O*, *O*-diacetyl derivative **13***b* and acetylation of methyl ether **13***a* provides the monoacetyl ether **13***c*. The *O*, *O*-diacetyl derivative **13***b* shows ir absorption bands for ar-

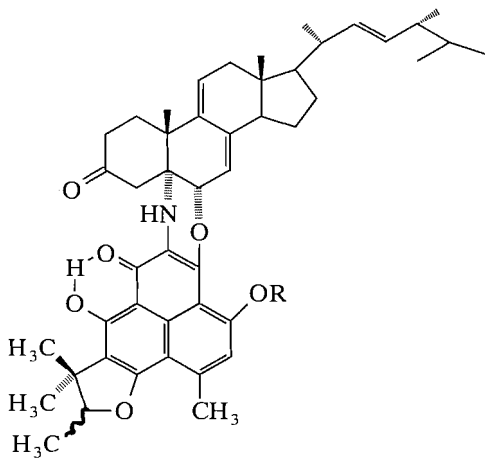
[a]APT spectrum measured at 75 MHz.
[b]Obtained at 90 MHz.

omatic acetate (1770 cm^{-1}) and aliphatic acetate (1739 cm^{-1}). The ^1H nmr spectrum shows acetate methyls at δ 2.40 and 1.96 and the chelated OH at δ 17.01. The remaining signals are similar to those of the parent compound **13**. As is the case with sirosterol (**4**, Fig. 1), the signals for H-6″ and H-7″ are shifted upfield in the derivatives **13***a*, **13***b*, and **13***c*, favoring structure **13** over structure **15** for dehydroazasirosterol. Biogenetic precedent for the location of nitrogen at C-2 in the atrovenitin portion of the molecule, as in Scleroderris blue (**3**), also argues in favor of this arrangement.

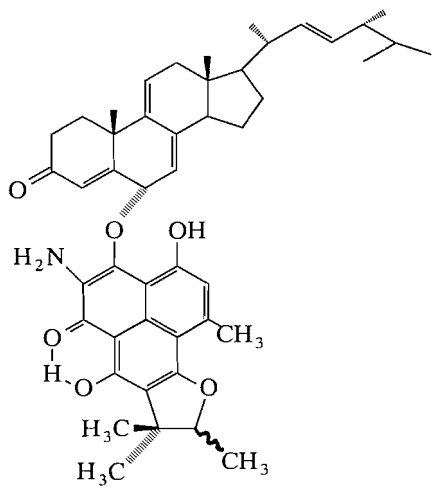
Oxidation of dehydroazasirosterol (**13**) using the Swern procedure (7) gave the 3″-ketone **16**, ir 1720 cm^{-1}. Attempts to bring about β-elimination to give the α,β-unsaturated enone **17** were unsuccessful. Considering that the "open" form **17** might be thermodynamically less favored than the "closed" form **16**, we heated **16** in acetic anhydride in the presence of triethylamine for 2 h in an attempt to trap **17** as the *N*-acetyl derivative. Only the *O*-acetyl derivative **16***a* and the $\Delta^{2''}$ enol acetate of **16***a* were obtained. The enol acetate does not show ketonic carbonyl absorption in the ir, only ester absorption (1753 cm^{-1}). The ^1H nmr spectrum of the enol acetate shows a signal for H-2″ at δ 5.50 (d, $J \approx 5$ Hz) and two acetyl methyls (δ 2.04, 2.41).

As is the case with sirosterol (**4**), dehydroazasirosterol (**13**) is isolated as a mixture of diastereoisomers at C-2′. This is indicated by two pairs of signals for the phenolic hydrogens at δ 17.84 and 9.76. The ratio of the two epimers for dehydroazasirosterol (ca. 5:1) is different than that for sirosterol (ca. 2:1).

Sirosterol (**4**) and dehydroazasirosterol (**13**) represent a unique combination of two different classes of natural products. We are not aware of other examples where sterols and phenalenones are fused by means of dioxene or dihydro-1,4-oxazine ring systems. A simplistic scheme that illustrates a possible biogenetic pathway uniting ergosterol endoperoxide and an atrovenitin-type molecule is shown in Scheme 1. A related free radical pathway may be written to achieve the same result.



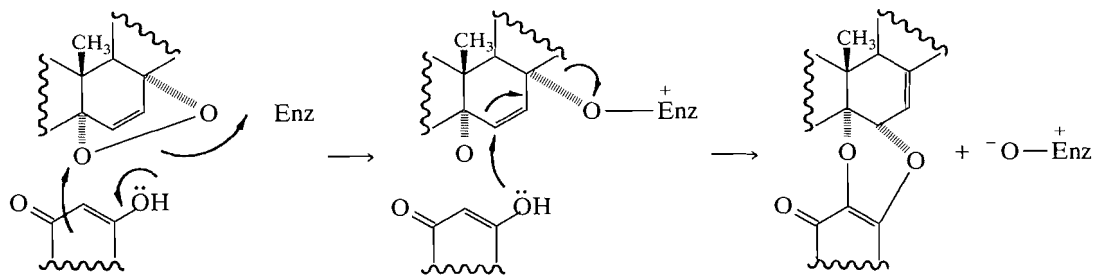
16 R = H
16*a* R = Ac



17

The triol **6** mentioned earlier was prepared by *m*-chloroperbenzoic acid oxidation of ergosterol that provides the ester **6***a*. Hydrolysis of **6***a* (KOH, methanol) gives triol **6**. Triol **6** was first prepared by Windaus and Luttringhaus in 1930 (9) by perbenzoic acid oxidation of ergosterol followed by hydrolysis of the benzoate thus obtained and later by Criegee *et al.* (10) by osmium tetroxide oxidation of ergosterol.[4] In agreement with the assigned stereochemistry, irradiation of the methyl group at C-10 in **6** gives rise to a nOe effect (7.5%) on the signal for H-6.

[4]For an interesting discussion of the proof of the stereochemistry of **6** see ref. 11.



SCHEME 1

Experimental

For general experimental details see ref. 1.

Growth and harvesting of the fungi

Stock cultures of Sirococcus 35B (UAMH 5401) were maintained in slant tube culture on potato dextrose agar at 4°C. To initiate large-scale cultures, small fragments of agar containing the mycelium were aseptically transferred to Erlenmeyer flasks containing sterile culture medium (200 mL). The medium used was Difco potato dextrose broth containing 0.04% (w/v) yeast extract. The cultures were shaken for 10 days at 15–17°C, then used to inoculate five 2.8-L Fernbach flasks containing the same liquid medium (1 L, still culture). After 50–60 days at 15–17°C, the mycelium was separated from the broth by gravity filtration through cheese cloth. The air-dried mycelium was extracted with methylene chloride in a Soxhlet extractor for 2 days. Concentration of the methylene chloride extracts gave the crude mycelial extract (3.0 g). Most of the metabolites were present in the mycelial extract and only a small amount (ca. 0.04 g) in the broth extract.

Separation of the metabolites

The methylene chloride extract (3.0 g) from the mycelium was separated into nonpolar, medium polar, and polar fractions by silica gel column chromatography (gradient elution; hexanes-toluene-ethyl acetate-methanol). The nonpolar and medium polar fractions were separated by repeated flash chromatography over silica gel. Fatty acids, triglycerides, sclerodin (**1**, 140 mg), ergosterol (36 mg), 9(11)-dehydroergosterol endoperoxide (3 mg), ergosta-4,6,8(14),22-tetraen-3-one (3 mg), sirocodilide (17 mg), sirosterol (**4**, 5 mg), and dehydroazasirosterol (**13**, 2mg) were isolated. Scleroderris blue (**3**, 3 mg) was isolated from the polar fraction by flash chromatography. Atrovenetinone (**2**) was isolated as its acetone adduct from the metabolites grown on Wort medium. Compounds **4** and **13** were not isolated from the Wort medium growth.

*Sirosterol (**4**)*

Sirosterol was isolated as an amorphous powder that showed a single spot on tlc. However, the ^{1}H nmr spectrum indicates that it is a mixture of diastereoisomers (both configurations at C-2′, superimposed quartets at δ 4.65 in $CDCl_3$); ir ν_{max}: 3390, 3384, 1730 (w), 1660 (w), 1611, 1576, 1444, 1416, 1375, 1339, 1307, 1281, 1239, 1190 cm^{-1}; ^{1}H nmr (360 MHz) δ: 0.57 (3 H, s, 18″-CH_3), 0.80 (3 H, d, 5.3 Hz, 26″-CH_3), 0.81 (3 H, d, 5.3 Hz, 27″-CH_3), 0.88 (3 H, d, 6 Hz, 28″-CH_3), 1.00 (3 H, d, 6 Hz, 21″-CH_3), 1.14 (3 H, s, 19″-CH_3), 1.25 (1 H, brs, OH), 1.32 (3 H, s, 4′-CH_3), 1.47 (3 H, d, 6 Hz, 1′-CH_3), 1.56 (3 H, s 5′-CH_3), 2.82 (3 H, s, ArCH_3), 4.05 (1 H, m, H-3″), 4.65 (1 H, q, 6 Hz, H-2′), 4.91 (1 H, brs, H-6″), 4.99 (1 H, brs, H-7″), 5.15 (2 H, m, H-22″, 23″), 6.83 (1 H, s, ArH), 9.56 (1 H, s, 9-OH), 17.16 (1 H, s, 4-OH); ^{1}H nmr ($CDCl_3$ + C_5D_5N, 360 MHz) δ: 0.57 (3H, s, 18″-CH_3), 0.80 (3 H, d, 5.3 Hz, 26″-CH_3), 0.82 (3 H, d, 5.3 Hz, 27″-CH_3), 0.90 (3 H, d, 6 Hz, 28″-CH_3), 1.02 (3 H, d, 6 Hz, 21″-CH_3), 1.14 (3 H, s, 19″-CH_3), 1.27 (1 H, brs, OH), 1.31 (3 H, s, 4′-CH_3), 1.45 (3 H, d, 6 Hz, 1′-CH_3), 1.59 (3 H, s, 5′-CH_3), 2.83 (3 H, s, ArCH_3), 4.16 (1 H, m, H-3″), 4.66 (1 H, q, 6 Hz, H-2′), 4.90 (1 H, brs, H-6″), 5.05 (1 H, brs, H-7″), 5.20 (2 H, m, H-22″, 23″), 6.88 (1 H, s, ArH), 9.82 (1 H, s, 9-OH), 17.55 (1 H, s, 4-OH); fabms, *m/z*: 737.48 (M + H$^+$, calcd. for $C_{47}H_{61}O_7$: 737.4417, 2.67%), 341 (6), 309 (9).

*Methylsirosterol (**10**)*

Sirosterol (5 mg) was treated with an excess of diazomethane in ether solution at room temperature for 24 hs. The solvent was evaporated and the residue was purified by flash chromatography (hexanes–acetone 3:1) to give an amorphous solid (**10**, 5 mg), [α]$_D$ + 79.1 (c 0.22, $CHCl_3$); ir ν_{max}: 3300, 2956, 2932, 1718 (w), 1642 (w), 1611, 1444, 1375, 1220, 1181, 1162, 1106, 1060, 1037, 1012 cm^{-1}; ^{1}H nmr (360 MHz) δ: 0.57 (3 H, s, 18″-CH_3), 0.81 (3 H, d, 5.3 H, 26″-CH_3), 0.82 (3 H, d, 5.3 Hz, 27″-CH_3), 0.89 (3 H, d, 6 Hz, 28″-CH_3), 1.09 (3 H, d, 6 Hz, 21″-CH_3), 1.13 (3 H, s, 19″-CH_3), 1.26 (1 H, brs, OH), 1.32 (3 H, s, 4′-CH_3), 1.48 (3 H, d, 6 Hz, 1′-CH_3), 1.57 (3 H, s, 5′-CH_3), 2.89 (3 H, s, ArCH_3), 4.05 (1 H, m, H-3″), 4.05 (3 H, s, OCH_3), 4.65 (1 H, q, 6 Hz, H-2′), 4.83 (1 H, brs, H-6″), 4.99 (1 H, brs, H-7″), 5.14 (2 H, m, H-22″, 23″), 6.85 (1 H, s, ArH), 17.95 (1 H, s, 4-OH); ^{13}C nmr (75 MHz) see Tables 1 and 2; hrms, *m/z*: 396.3385 (calcd. for $C_{28}H_{44}O$: 396.3392, (28%), 376 ($C_{28}H_{40}$, 13), 356 ($C_{20}H_{20}O_6$, 63), 341 ($C_{19}H_{17}O_6$, 100), 323 (20), 251 (33); fabms, *m/z*: 751.64 (M + H$^+$, calcd. for $C_{48}H_{63}O_7$: 751.4574, 10.1%), 377.53 (1.97), 357.14 (8.94), 341.07 (5.19).

*Methylacetylsirosterol (**10**a)*

Acetic anhydride (1 mL) and pyridine (1 mL) were added to a solution of methyl sirosterol (1 mg) in methylene chloride (2 mL). The mixture was stirred at room temperature for 18 hs. The solution was concentrated and the residue was purified by flash chromatography (hexanes–acetone 4:1) to give **10***a* (1 mg) as an oil, ir ν_{max}: 3320, 2957, 2936, 2933, 2870, 1736, 1614, 1590 cm^{-1}; ^{1}H nmr (360 MHz) δ: 0.56 (3 H, s, 18″-CH_3), 0.80 (3 H, d, 5.3 Hz, 26″-CH_3), 0.81 (3 H, d, 5.3 Hz, 27″-CH_3), 0.89 (3 H, d, 6 Hz, 28″-CH_3), 1.01 (3 H, d, 6 Hz, 21″-CH_3), 1.15 (3 H, s, 19″-CH_3), 1.32 (3 H, s, 4′-CH_3), 1.47 (3 H, d, 6 H, 1′-CH_3), 1.57 (3 H, s, 5′-CH_3), 1.91 (3 H, s, $COCH_3$), 2.90 (3 H, s, ArCH_3), 4.04 (3 H, s, OCH_3), 4.63 (1 H, q, 6 Hz, H-2′), 4.82 (1 H, brs, H-6″), 4.96 (1 H, brs, H-7″), 5.05 (1 H, m, H-3″), 5.16 (2 H, m, H-22″, 23″), 6.85 (1 H, s, ArH), 17.97 (1 H, s, 4-OH); fabms, *m/z*: 793.59 (M + H$^+$, calcd. for $C_{50}H_{65}O_8$: 793.4679, 2.46%), 356.85 (2.72), 340.80 (1.62), 308.80 (5.62).

*Diacetylsirosterol (**10**b)*

Sirosterol (0.5 mg) was dissolved in a solution of acetic anhydride (1 mL) and pyridine (1 mL) in methylene chloride (2 mL). The mixture was stirred at room temperature for 17 hs. The solvent was coevaporated with ethanol and the residue was purified by flash chromatography (hexane–acetone 5:1) providing **10***b* (0.5 mg); ir ν_{max}: 3400, 2975, 2927, 1753, 1734, 1620, 1593, 1456, 1443, 1376, 1366, 1265, 1242, 1226, 1195, 1176 cm^{-1}; ^{1}H nmr (360 MHz) δ: 0.56 (3 H, s, 18″-CH_3), 0.80 (3 H, d, 5.3 Hz, 26″-CH_3), 0.81 (3 H, d, 5.3 Hz, 27″-CH_3), 0.88 (3 H, d, 6 Hz, 28″-CH_3), 1.00 (3 H, d, 6 Hz, 21″-CH_3), 1.15 (3 H, s, 19″-CH_3), 1.32 (3 H, s, 4′-CH_3), 1.47 (3 H, d, 6 Hz, 1′-CH_3), 1.57 (3 H, s, 5′-CH_3), 1.96 (3 H, s, $COCH_3$), 2.38 (3 H, s, $COCH_3$), 2.86 (3 H, s, ArCH_3), 4.66 (1 H, q, 6 Hz, H-2′), 4.68 (1 H, brs, H-6″),

4.91 (1 H, brs, H-7″), 5.02 (1 H, m, H-3″), 5.16 (2 H, m, H-22″, 23″), 6.94 (1 H, s, ArH), 17.41 (1 H, s, 4-OH); fabms, *m/z*: 821.56 ($M + H^+$, calcd. for $C_{51}H_{65}O_9$: 821.5107, 0.87%).

*Dehydrosirosterol (**12**)*

Trifluoroacetic anhydride (10 μL) was added dropwise to a stirred solution of dimethyl sulfoxide (10 μL) in 3 mL of methylene chloride at −78°C. After 10 min, sirosterol (1 mg) in methylene chloride (2 mL) was added and the solution was stirred for 40 min at the same temperature. Triethylamine (50 μL) was then added and the reaction was kept for another 40 min at −78°C. The reaction mixture was allowed to warm to room temperature and water (3 mL) was added. The aqueous layer was separated and extracted twice with methylene chloride. The combined organic extracts were washed, dried, and evaporated. The residue was purified by flash chromatography (hexanes – ethyl acetate 7:3) providing **12** (0.8 mg) as an amorphous solid; ir ν_{max}: 3390, 2957, 2927, 2871, 2855, 1722, 1610, 1454, 1445, 1377, 1306, 1280, 1237, 1223, 1189, 1171, 1157, 1135, 1101, 1063, 1036 cm^{-1}; ^1H nmr (360 MHz) δ: 0.60 (3 H, s, 18″-CH_3), 0.81 (3 H, d, 6 Hz, 26″-CH_3), 0.83 (3 H, d, 6 H, 27″-CH_3), 0.90 (3 H, d, 6.5 Hz, 28″-CH_3), 1.02 (3 H, d, 6.5 H, 21″-CH_3), 1.31 (3 H, s, 19″-CH_3), 1.34 (3 H, s, 4′-CH_3), 1.49 (3 H, d, 6.5 Hz, 1′-CH_3), 1.56 (3 H, s, 5′-CH_3), 2.82 (3 H, s, $ArCH_3$), 4.65 (1 H, q, 6.5 Hz, H-2′), 5.03 (2 H, brs, H-6″ and H-7″), 5.18 (2 H, m, H-22″, 23″), 6.83 (1 H, s, ArH), 9.43 (1 H, s, 9-OH), 17.03 (1 H, s, 4-OH); fabms, *m/z*: 735.17 ($M + H^+$, calcd. for $C_{47}H_{59}O_7$: 735.4261, 6%), 394.16 (2), 340.68 (29).

*Dehydroazasirosterol (**13**)*

Dehydroazasirosterol (**13**) was isolated as an amorphous powder that showed a single spot on tlc. The ^1H nmr spectrum shows that it is a mixture of diastereoisomers (at C-2′). This is indicated by the fact that the phenolic hydrogens at δ 17.84 and δ 9.76 each appear as two closely spaced singlets. This is also true of the low-field chelated phenol signal in **13***a* and **13***b*. Dehydroazasirosterol shows the following spectral properties: ir ν_{max}: 3398, 3388, 3380, 2956, 2869, 1610, 1569, 1455, 1428, 1384, 1371, 1296, 1249, 1226, 1193, 1134, 1101, 1048, 1032 cm^{-1}; ^1H nmr (360 MHz) δ: 0.55 (3 H, s, 18″-CH_3), 0.80 (3 H, d, 6 Hz, 26″-CH_3), 0.82 (3 H, d, 6 Hz, 27″-CH_3), 0.89 (3 H, d, 6 Hz, 28″-CH_3), 1.00 (3 H, d, 6.5 Hz, 21″-CH_3), 1.29 (3 H, s, 19″-CH_3), 1.30 (3 H, s, 4′-CH_3), 1.48 (3 H, d, 6.5 Hz, 1′-CH_3), 1.57 (3 H, s, 5′-CH_3), 2.82 (3 H, s, $ArCH_3$), 4.01 (1 H, s, NH), 4.12 (1 H, m, H-3″), 4.89 (1 H, brs, H-6″), 5.04 (1 H, brs, H-7″), 5.16 (2 H, m, H-22″, 23″), 5.73 (1 H, d, 6 Hz, H-11″), 6.84 (1 H, s, ArH), 9.76 (1 H, s, 9-OH), 17.84 (1 H, s, 4-OH); ^{13}C nmr (75 MHz) see Table 4; fabms, *m/z*: 734.55 ($M + H^+$, calcd. for $C_{47}H_{60}O_6N$: 734.4421, 0.72%), 733.55 (0.81), 375.30 (2), 339.89 (9).

*Methyl dehydroazasirosterol (**13**a)*

Dehydroazasirosterol (**13***a*, 5 mg) was treated with an excess of diazomethane in ether at room temperature for 24 hs. Evaporation of the solvent and purification of the residue by flash chromatography (hexanes – ethyl acetate 5:1) provided **13***a* (5 mg) as an amorphous solid, ir ν_{max}: 3400, 2957, 2924, 2850, 1612, 1590, 1552 cm^{-1}; ^1H nmr (360 MHz) δ: 0.54 (3 H, s, 18″-CH_3), 0.80 (3 H, d, 6 Hz, 26″-CH_3), 0.81 (3 H, d, 6 Hz, 27″-CH_3), 0.89 (3 H, d, 6 Hz, 28″-CH_3), 1.00 (3 H, d, 6 Hz, 21″-CH_3), 1.27 (3 H, s, 19″-CH_3), 1.32 (3 H, s, 4′-CH_3), 1.48 (3 H, d, 6 Hz, 1′-CH_3), 1.55 (3 H, s, 5′-CH_3), 2.88 (3H, s, $ArCh_3$), 3.99 (1 H, s, NH), 4.07 (3 H, s, OCH_3), 4.13 (1 H, m, H-3″), 4.64 (1 H, q, 6 Hz, H-2′), 4.81 (1 H, brs, H-6″), 5.03 (1 H, brs, H-7″), 5.16 (2 H, m, H-2″, 23″), 5.67 (1 H, d, 6 Hz, H-11″), 6.90 (1 H, s, ArH), 17.65 (1 H, s, 4-OH); ^{13}C nmr (90 MHz) see Table 4; hrms, *m/z*: 394.3231 ($C_{28}H_{42}O$, 14%), 376 ($C_{28}H_{40}$, 16), 355.1419 ($C_{20}H_{21}O_5N$, 54), 340 ($C_{19}H_{18}O_5N$, 41), 251 (74), 57 (100); fabms, *m/z*: 748.33 ($M + H^+$, calcd. for $C_{48}H_{62}O_6N$: 748.4577, 7.27%), 747.32 (6.5), 354.19 (15).

*Methyl acetyldehydroazasirosterol (**13**c)*

Methyl dehydroazasirosterol (1 mg) was dissolved in acetic anhydride (2 mL), pyridine (1 mL), and methylene chloride (2 mL). The mixture was stirred at room temperature for 22 h. The solvent was coevaporated with ethanol. The residue was purified by flash chromatography (hexanes – ethyl acetate 5:1) providing **13***c* (0.9 mg). ir ν_{max}: 3398, 2956, 1729, 1610, 1590 cm^{-1}; ^1H nmr (360 MHz) δ: 0.53 (3 H, s, 18″-CH_3), 0.79 (3 H, d, 5.3 Hz, 26″-CH_3), 0.81 (3 H, d, 5.3 Hz, 27″-CH_3), 0.88 (3 H, d, 6 Hz, 28″-CH_3), 0.99 (3 H, d, 6 Hz, 21″-CH_3), 1.26 (3 H, s, 19″-CH_3), 1.30 (3 H, s, 4′-CH_3), 1.48 (3 H, d, 6.5 Hz, 1′-CH_3), 1.56 (3 H, s, 5′-CH_3), 1.94 (3 H, s, $COCH_3$), 2.87 (3 H, s, $ArCH_3$), 4.03 (1 H, s, NH), 4.06 (3 H, s, OCH_3), 4.62 (1 H, q, 6.5 Hz, H-2′), 4.81 (1 H, brs, H-6″), 5.01 (1 H, brs, H-7″), 5.15 (2 H, m, H-22″, 23″), 5.68 (1 H, d, 6 Hz, H-11″), 6.88 (1 H, s, ArH), 17.66 (1 H, s, 4-OH); fabms, *m/z*: 790.77 ($M + H^+$, calcd. for $C_{50}H_{64}O_7N$: 790.4683, 2.56%), 789.74 (2.36), 355.98 (7), 353.95 (8).

*Diacetyldehydroazasirosterol (**13**b)*

Acetic anhydride (1 mL) were added to a solution of sirocodinine (0.5 mg) in methylene chloride (1 mL). The mixture was stirred at room temperature for 16 hs. The solvent was evaporated and the residue was redissolved in methylene chloride. The organic phase was washed with 5% HCl, and then evaporated to dryness. The residue was purified by passing through a short Florisil column giving **13***b* (0.4 mg), ir ν_{max}: 3400, 2955, 2870, 1770, 1739, 1619, 1596 cm^{-1}; ^1H nmr (360 MHz) δ: 0.53 (3 H, s, 18″-CH_3), 0.78 (3 H, d, 6 Hz, 26″-CH_3), 0.80 (3 H, d, 6 Hz, 27″-CH_3), 0.91 (3 H, d, 6 Hz, 28″-CH_3), 0.99 (3 H, d, 6.5 Hz, 21″-CH_3), 1.31 (3 H, s, 19″-CH_3), 1.32 (3 H, s, 4′-CH_3), 1.48 (3 H, d, 6.5 Hz, 1′-CH_3), 1.57 (3 H, s, 5′-CH_3), 1.96 (3 H, s, $COCH_3$), 2.40 (3 H, s, $COCH_3$), 2.85 (3 H, s, $ArCH_3$), 4.06 (1 H, s, NH), 4.64 (1 H, brs, H-6″), 4.66 (1 H, q, 6.5 Hz, H-2′), 4.99 (1 H, brs, H-7″), 5.15 (2 H, m, H-22″, 23″), 5.68 (1 H, d, 6 Hz, H-11″), 6.93 (1 H, s, ArH), 17.01 (1 H, s, 4-OH); fabms, *m/z*: 818.80 ($M + H^+$, calcd. for $C_{51}H_{64}O_8N$: 818.4632, 0.99%), 817.78 (1.06), 382.33 (6), 368.37 (11), 340.12 (12).

*Oxidation of dehydroazasirosterol (**13**)*

Trifluoroacetic anhydride (30 μL) was added dropwise to a stirred solution of dimethyl sulfoxide (30 μL) in 3 mL of methylene chloride at −78°C. After 10 min, dehydroazasirosterol (2 mg) in methylene chloride (2 mL) was added and the solution was allowed to stir at the same temperature for 40 min. Triethylamine (100 μL) was then added and the mixture was kept at −78°C for another 40 min. The reaction mixture was allowed to warm up to room temperature. Water (3 mL) was added and the aqueous layer was separated and extracted twice with methylene chloride. The combined organic extracts were washed with brine, dried, and evaporated. Purification of the crude product by flash chromatography (hexanes – ethyl acetate 70:30) yielded **16** (1.2 mg), ir ν_{max}: 3420, 2958, 2927, 2871, 1720, 1607, 1571 cm^{-1}; ^1H nmr (360 MHz) δ: 0.57 (3 H, s, 18″-CH_3), 0.80 (3 H, d, 6 Hz, 26″-CH_3), 0.82 (3 H, d, 6 Hz, 27″-CH_3), 0.89 (3 H, d, 6.5 Hz, 28″-CH_3), 1.01 (3 H, d, 6.5 Hz, 21″-CH_3), 1.30 (3 H, s, 19″-CH_3), 1.32 (3 H, s, 4′-CH_3), 1.47 (3 H, d, 6.5 Hz, 1′-CH_3), 1.54 (3 H, s, 5′-CH_3), 2.82 (3 H, s, $ArCH_3$), 4.00 (1 H, s, NH), 4.66 (1 H, q, 6.5 Hz, H-2′), 5.01 (1 H, brs, H-6″), 5.10 (1 H, brs, H-7″), 5.20 (2 H, m, H-22″, 23″), 5.83 (1 H, d, 6 Hz, H-11″), 6.84 (1 H, s, ArH), 9.63 (1 H, s, 9-OH), 16.70 (1 H, s, 4-OH); fabms, *m/z*: 732.62 ($M + H^+$, calcd. for $C_{47}H_{58}O_6N$: 732.4264, 0.67%), 731.63 (1.02), 341.44 (11), 340.43 (11), 339.43 (21).

*Monoacetate **16**a and enol acetate of **16**a*

Ketone **16** (1.2 mg) in acetic anhydride (2 mL) and triethylamine (2 mL) was heated under reflux for 2 hs. The mixture was poured onto crushed ice. The aqueous layer was extracted with methylene chloride twice and the organic layer was washed with brine, dried, and evaporated. The residue was separated by silica gel chromatography (hexanes – ethyl acetate 70:30) giving monoacetate **16***a* (0.5 mg) and the $\Delta^{2\prime\prime}$ enol acetate (0.6 mg). **16***a*: ir ν_{max}: 3400, 2929, 1767, 1744, 1717, 1620, 1594 cm^{-1}; ^1H nmr (360 MHz) δ: 0.57 (3 H, s, 18″-CH_3), 0.80 (3 H, d, 6 Hz, 26″-CH_3), 0.81 (3 H, d, 6 Hz, 27″-CH_3), 0.88 (3 H, d, 6.5 Hz, 28″-CH_3), 1.00 (3

H, d, 6.5 Hz, 21″-CH_3), 1.30 (3 H, s, 19″-CH_3), 1.32 (3 H, s, 4-CH_3), 1.45 (3 H, d, 6.5 Hz, 1′-CH_3), 1.50 (3 H, s, 5′-CH_3), 2.38 (3 H, s, $OCOCH_3$), 2.85 (3 H, s, $ArCH_3$), 4.10 (1 H, s, NH), 4.67 (1 H, q, 6.5 Hz, H-2′), 4.78 (1 H, brs, H-6″), 5.05 (1 H, brs, H-7″), 5.20 (2 H, m, H-22″, 23″), 5.79 (1 H, d, 6 Hz, H-11″), 6.94 (1 H, s, ArH), 16.88 (1 H, s, 4-OH); fabms, *m/z*: 774.53 ($M + H^+$, calcd. for $C_{49}H_{60}O_7N$: 774.4370, 2.15%), 773.55 (1.65), 339.86 (6), 308.85 (9). *Enol acetate*: ir ν_{max}: 3400, 2957, 2925, 2869, 2853, 1753, 1621, 1596 cm^{-1}; ^1H nmr (360 MHz) δ: 0.55 (3 H, s, 18″-CH_3), 0.80 (3 H, d, 6 Hz, 26″-CH_3), 0.82 (3 H, d, 6 Hz, 27″-CH_3), 0.89 (3 H, d, 6.5 Hz, 28″-CH_3), 1.00 (3 H, d, 6.5 Hz, 21″-CH_3), 1.24 (3 H, s, 19″-CH_3), 1.32 (3 H, s, 4′-CH_3), 1.48 (3 H, d, 6.5 Hz, 1′-CH_3), 1.54 (3 H, s, 5′-CH_3), 2.04 (3 H, s, $COCH_3$), 2.41 (3 H, s, $COCH_3$), 2.85 (3 H, s, $ArCH_3$), 4.48 (1 H, s, NH), 4.67 (1 H, q, 6.5 Hz, H-2′), 4.83 (1 H, brs, H-6″), 5.09 (1 H, brs, H-7″), 5.16 (2 H, m, H-22″, 23″), 5.50 (1 H, d, 5 Hz, H-2″), 5.66 (1 H, d, H-11″), 6.95 (1 H, s, ArH), 16.96 (1 H, s, 4-OH); fabms, *m/z*: 816.67 ($M + H^+$, calcd. for $C_{51}H_{62}O_8N$: 816.4475, 0.28%), 815.68 (0.35), 339.89 (2).

*Preparation of 5α, 6α-dihydroxydihydroergosterol (**6**)*

m-Chloroperbenzoic acid (81 mg of 80%, 0.376 mmol) was added to a solution of ergosterol (149 mg, 0.376 mmol) in methylene chloride (12 mL). The mixture was stirred at room temperature for 5 hs, then further *m*-chloroperbenzoic acid (20 mg) was added and the mixture was stirred for 19 hs. The solution was washed twice with sodium thiosulfate solution, then twice with sodium bicarbonate solution. The organic layer was dried and evaporated. The residue was separated by flash chromatography (hexanes – ethyl acetate 8:3) to give the 6-*O*-*m*-chlorobenzoate **6***a* (95 mg): mp 196–198°C; ir ν_{max}: 3560, 3220, 2956, 2870, 1705, 1660, 1575 cm^{-1}; ^1H nmr (360 MHz) δ: 0.60 (3 H, s, 18-CH_3), 0.83 (3 H, d, 6 Hz, 26-CH_3), 0.84 (3 H, d, 6 Hz, 27-CH_3), 0.92 (3 H, d, 6.5 Hz, 28-CH_3), 1.04 (3 H, d, 6.5 Hz, 21-CH_3), 1.09 (3 H, s, 19-CH_3), 4.03 (1 H, m, H-3), 5.03 (1 H, brs, H-7), 5.19 (2 H, m, H-22, 23), 5.55 (1 H, brs, H-6), 7.40 (1 H, dd, 8, 8 Hz), 7.55 (1 H, ddd, 2, 2, 8 Hz), 7.95 (1 H, ddd, 2, 2, 8 Hz), 8.03 (1 H, dd, 2,2 Hz); ^1H nmr (C_6D_6, 360 MHz) δ: 0.47 (3 H, s, 18-CH_3), 0.84 (9 H, m), 0.91 (3 H, d, 7 Hz, 28-CH_3), 1.00 (3 H, d, 6 Hz, 21-CH_3), 4.07 (1 H, m, H-3), 5.11 (1 H, brs, H-7), 5.18 (2 H, m, H-22, 23), 5.72 (1 H, brs, H-6), 6.80 (1 H, dd, 8, 8 Hz), 7.12 (1 H, brd, 8 Hz), 7.89 (1 H, d, 8 Hz), 8.18 (1 H, brs); hrms, *m/z*: 412.3348 ($M^+ - C_7H_5O_2Cl$, calcd. for $C_{28}H_{44}O_2$: 412.3341, 4%), 394 ($M^+ - C_7H_5O_2Cl - H_2O$, 12), 376 ($M^+ - C_7H_5O_2Cl - 2\,H_2O$, 18), 251 (36), 158 (17), 156 (53), 139 (58), 69 (100). The *m*-chlorobenzoate **6***a* (61 mg) was stirred with 5% KOH in methanol for 24 hs. Removal of the methanol, addition of water, and extraction with ethyl acetate provided the crude product. Triol **6** (33 mg) was obtained after flash chromatography (methylene chloride – acetone 50:50) and crystallization from methanol: 227–229°C; $[\alpha]_D$ + 13.3 (c 0.18, $CHCl_3$); ir ν_{max}: 3323, 3273, 2889, 2870, 2850, 1660 cm^{-1}; ^1H nmr (360 MHz) δ 0.57 (3 H, s, 18-CH_3), 0.83 (3 H, d, 6 Hz, 26-CH_3), 0.84 (3 H, d, 6Hz, 27-CH_3), 0.93 (3 H, d, 7 Hz, 28-CH_3), 0.98 (3 H, s, 19-CH_3), 1.03 (3 H, d, 6.5 Hz, 21-CH_3), 3.98 (1 H, brs, H-6), 4.01 (1 H, m, H-3), 5.03 (1 H, brs, H-7), 5.20 (2 H, m, H-22, 23); ^{13}C nmr (90 MHz) see Table 2; hrms, *m/z*: 412.3341 ($M - H_2O$, calcd. for $C_{28}H_{44}O_2$: 412.3341, 100%), 394 ($M - 2\,H_2O$, 13), 379 (26), 269 (11), 251 (17).

Reduction of two-component $CuO–Cr_2O_3$ mixed oxides and their catalytic activity

V. MÚČKA

Technical University of Prague, Department of Nuclear Science and Physical Engineering, 115 19 Prague 1, Czechoslovakia

Received July 10, 1991.[1]

V. MÚČKA. Can. J. Chem. **70**, 1914 (1992).

The reduction with hydrogen of the two-component mixed oxides $CuO–Cr_2O_3$ containing various amounts of both components in the whole range from 0 to 100% was studied, as well as some physico-chemical and catalytic properties. The hydrogen peroxide decomposition served as a test catalytic reaction. A significant effect of the reduction on the rate constant of the test reaction was found, as well as on the value of its apparent activation energy. Pronounced changes were observed, especially in the border ranges of the composition. This fact may be connected with the mutual influence of both components in the catalyst.

V. MÚČKA. Can. J. Chem. **70**, 1914 (1992).

On a étudié quelques propriétés physico-chimiques et catalytiques ainsi que la réduction par de l'hydrogène des oxydes mixtes $CuO–Cr_2O_3$ à deux composants contenant diverses quantités de chacun sur l'ensemble des compositions allant de 0 à 100%. On a utilisé le décomposition du peroxyde d'hydrogène comme réaction catalytique témoin. On a trouvé qu'il existe un effet important de la réduction sur la constante de vitesse de la réaction témoin ainsi que sur la valeur de son énergie d'activation apparente. On a observé des changements importants, spécialement dans les régions de composition limite. On peut relier ce fait avec l'influence mutuelle des deux composants dans le catalyseur.

[Traduit par la rédaction]

Introduction

A notable effect of the degree of reduction on the catalytic properties of the $CuO–Cr_2O_3$ catalyst containing about 77 wt.% of CuO was found earlier (1). This phenomenon may be due to the changes in the oxidation state of both metals present in the catalyst after its reduction. The catalytic activity of the mixture composed of cupric and cuprous oxides was found (2) to be higher than the activity of the oxides CuO or Cu_2O separately. Hence, the catalytic sites of the CuO may be connected in some way with the redox $CuO–Cu_2O$ system (3). The catalytic activity of the chromium sesquioxide was found to be proportional to surface over-stoichiometric oxygen (4, 5), which is probably compensated by the presence of hexavalent chromium in the form of insoluble chromate (6–8). That is probably why the oxidized chromic catalysts showed notably higher activity than the reduced ones (9). Hence, one can assume (10) that the Cr^{3+} and Cr^{6+} ions serve as donor and acceptor sites, respectively. Nevertheless, no linear relation was found between the concentration of Cr^{6+} ions present in the chromium sesquioxide and the rate constant of hydrogen peroxide decomposition.

For this reason it seemed of interest to investigate systematically the catalytic properties of $CuO–Cr_2O_3$ two-component catalysts of various composition after reduction and to compare them with those of nonreduced samples.

Experimental

The mixed catalysts were prepared from the solutions of the respective nitrates (analytical grade) mixed in such ratios that the resulting catalysts covered the whole range of composition, i.e., from 0 to 100%. The nitrates were precipitated using a solution of sodium carbonate (analytical grade). After washing (until no sodium carbonate was detected) and after filtering, the precipitate was dried and calcinated for 4 h in air at a temperature of 400°C. The completeness of the decomposition of the carbonates under these conditions were confirmed by means of the study of thermal decomposition of the uncalcinated samples (the thermoanalyser of Netzsch was used for this purpose). The soluble chromates were washed out of the samples by distilled water. The washed samples were dried at room temperature for 7–10 days. Prior to their use all samples were reduced with hydrogen (at a hydrogen flow rate of 56 mL min^{-1}) at a constant temperature of 400°C. The reduction was performed in a glass basket hanging on the arm of a microbalance (Sartorius) and immersed in a hydrogen stream, up to the maximum loss in weight of the sample (maximum degree of reduction). The maximum degree of reduction R (%) was defined by the following relation

$$R = \frac{a - b}{p\,a\,[1 - (M_{Cu}/M_{CuO})]} \times 10^4$$

where a and b are the weights of the sample before and after the reduction, respectively, p is the percentage content of the CuO in the sample, and M_{Cu} and M_{CuO} represent the molecular weights of copper and cupric oxide, respectively. The decrease in the weight of the sample was monitored during its reduction. The reduction was stopped by introducing nitrogen instead of hydrogen afrer which weight loss was no longer detectable (the precision of this operation was determined by the sensitivity of the microbalance and was ±0.1 mg). After reduction, the samples were cooled to room temperature in a flow of nitrogen.

The catalytic activity of the samples was measured by the decomposition of the aqueous solution of hydrogen peroxide (analytical grade) in a concentration of 1.2 mol L^{-1} at temperatures of 30, 35, 40, and 45°C.

A more detailed description of the methods used for preparation, chemical analysis, measurement of some physical properties, and catalytic activities of the samples was reported earlier (1).

Results and discussion

The prepared catalysts were found to be composed mainly of cupric oxide, CuO, and chromium sesquioxide, Cr_2O_3 (Table 1). It is evident from the results of X-ray diffraction that the system also contains both the cubic and the tetragonal spinel structure of $CuCr_2O_4$ (Table 1), mainly in the middle region (samples 6–14) of composition of the sam-

ples (the creation of this substance has, of course, no effect on the weight of the reduced sample).

The reduction of the system studied leads, under the given conditions, just to the reduction of the cupric oxide to metallic copper while the Cr_2O_3 oxide remains unreduced. This was confirmed earlier (11) by thermal analysis of the samples. Nevertheless, the Cr^{6+} ions present in the chromium sesquioxide may be reduced to Cr^{3+} ions (8). As can be seen from the nonmonotonic and rather complicated dependence of the maximum degree of reduction on the catalyst composition (Fig. 1), the reduction of the CuO was, nevertheless, significantly affected by the presence of the Cr_2O_3 in the catalyst. According to earlier results (11) the samples containing a high excess of cupric oxide were fully reduced under these conditions. The degree of reduction dropped rapidly and nonmonotonically to a value of 10% for the sample containing about 70 wt.% of Cr_2O_3 with increasing content of Cr_2O_3 in the sample. The chromium sesquioxide probably blocks those centers serving as the sites initiating the reduction of the CuO. Further increase in the Cr_2O_3 content led, of course, to a higher degree of reduction, up to the maximum of 40% for the sample containing about 90 wt.% of Cr_2O_3 (i.e. of 10 wt.% of CuO). After this maximum the degree of reduction increased again with increasing content of the Cr_2O_3. The abovementioned maximum shows that the manner in which the chromium sesquioxide affects the cupric oxide reduction is probably more complicated than just the blocking of the reduction sites.

The reduction of the system studied resulted in an increase in values of the specific surface area of the samples. But the general character of the dependence of specific surface areas on sample composition was found to be maintained after the reduction (Fig. 2). That means that the mu-

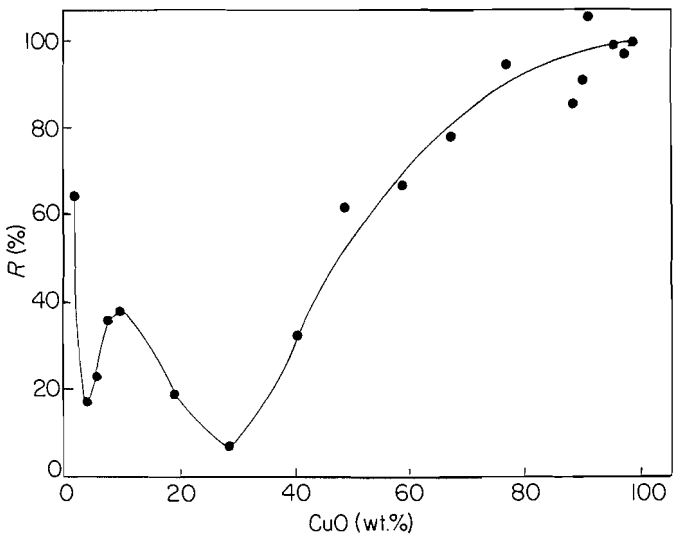

FIG. 1. Dependence of the maximum degree of reduction R on composition of the catalysts.

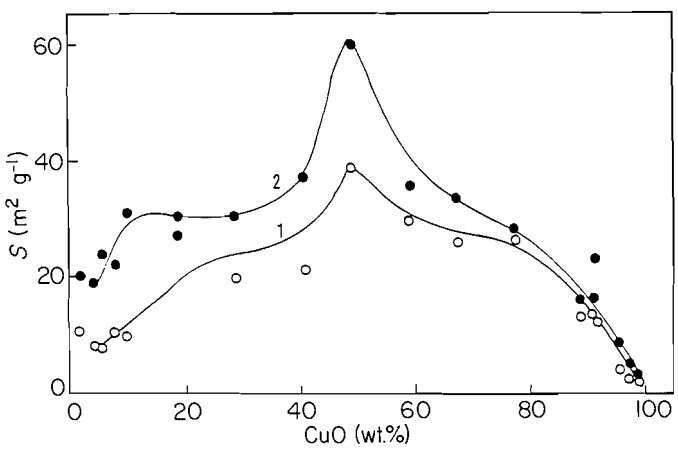

FIG. 2. Specific surface area values S of nonreduced (1) and reduced (2) samples of various composition.

tual interaction between the oxides, resulting also in the creation of spinel structures with a higher specific surface area, survives also after the reduction of the oxide.

The catalytic activity of the reduced samples (characterized by the first-order rate constant of the hydrogen peroxide decomposition normalized to the surface area of the catalysts) increased notably and nonlinearly with increasing content of the cupric oxide in the catalyst (Fig. 3, curve 2). Therefore one may assume that, similar to the case of nonreduced samples (Fig. 3, curve 1), the mutual influence of the catalytic properties of both oxides also takes place after the reduction of the samples. Hence, the resulting catalytic activities of the two-component reduced catalysts seem to be non-additive. As well, the catalytic activity values of most of the reduced samples were found practically unchanged. On the other hand, a significant difference in the extent of the catalytic activities of both reduced and the nonreduced samples of various compositions was observed: non-typical maxima at 10 and 95 wt.% of CuO were observed in the case of reduced samples (Fig. 3, curve 2) in contrast to the nonreduced ones (Fig. 3, curve 1). The maxima at 10 and 95 wt.% of CuO may be due to the mutual influence of the two basic oxides. The reduction leads, probably, to a system without this influence. As the reduction of the samples with 10 and 95 wt.% of CuO leads simultaneously to lower values of the apparent activation energy of the test reaction (Fig. 4), we may assume that some new catalytic centres with a higher efficiency are created in the course of the reduction. Their concentration is, of course, lower than those of the centres active before reduction. The stability of the newly created centres seems to be relatively high because the catalytic activity of the reduced samples remains unchanged during their storage at room temperature in air for a few months (Fig. 3, ⊙). These observations show that the catalysts with 10 and 95 wt.% of CuO possess the highest sensitivity to reduction.

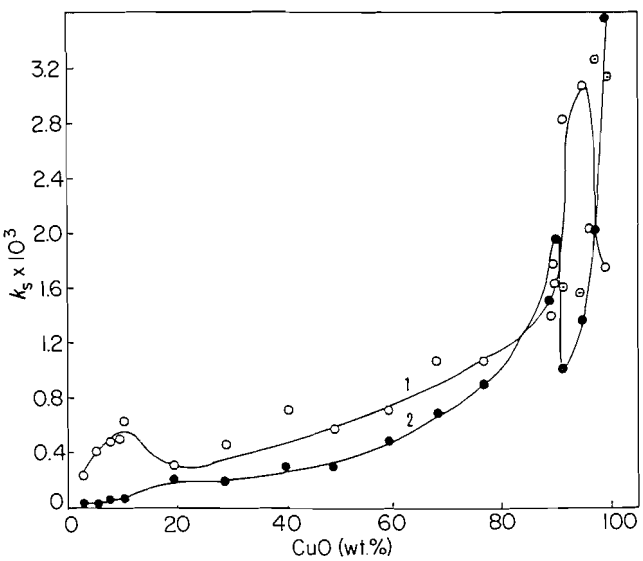

FIG. 3. Specific catalytic activity k_s (L m^{-2} min^{-1}) at 40°C prior to (1) and after (2) reduction of the catalysts of different composition; ⊙, stored reduced samples.

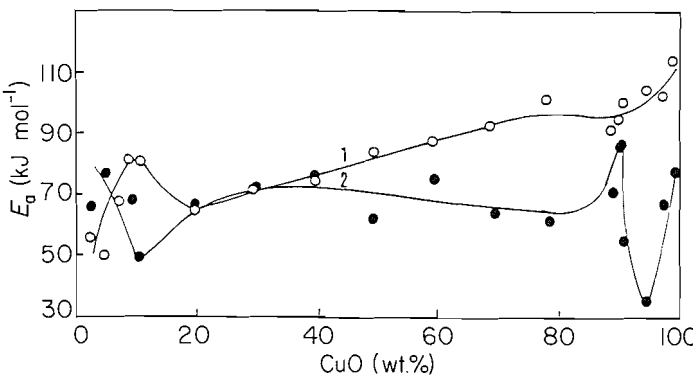

FIG. 4. Apparent activation energies E_a of the test reaction carried out on nonreduced (1) and reduced (2) catalysts of different composition.

Conclusions

The following conclusions can be drawn from the study of the two-component $CuO–Cr_2O_3$ catalysts after their reduction:

1. The presence of the chromium sesquioxide in the two-component $CuO–Cr_2O_3$ catalyst significantly affects the reducibility of the cupric oxide.

2. The changes in the oxidation state of the metal ions present in catalysts result in significant changes in the catalytic properties of the system studied.

Electronic configuration and structure of paramagnetic iron dinitrosyl complexes[1]

TRACI R. BRYAR AND DONALD R. EATON[2]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received September 18, 1991

TRACI R. BRYAR and DONALD R. EATON. Can. J. Chem. **70**, 1917 (1992).

The electronic and geometric structures of paramagnetic iron dinitrosyl complexes have been investigated using electron spin resonance, infrared spectroscopy, and X-ray crystallography. It is concluded that these compounds are best described as 17 electron complexes with a d^9 configuration rather than the d^7 configuration assumed by most previous investigators. The anisotropy of the g values, determined from the electron spin resonance spectra of frozen solutions, varies considerably from complex to complex. The results are consistent with the supposition that all of the complexes have a distorted tetrahedral geometry, but the nature of the distortion changes as the ligands are varied. As a result of this variation there are changes in the nature of the spin-containing d orbital. Ligands containing hard, nonpolarizable donor atoms such as oxygen or fluorine produce a distortion towards a planar geometry, placing the odd electron in a predominantly $d_{x^2-y^2}$ orbital, while those containing softer donor atoms such as phosphorus or sulfur give complexes with a different type of distortion, leading to placement of the odd electron in a predominantly d_{z^2} orbital. Nitrogen and halide donor ligands produce smaller distortions, leading to spin-containing molecular orbitals with contributions from a mixture of d orbitals. In accordance with this model, the crystal structure of $[Fe(NO)_2I_2]^-$ has been found to be only slightly distorted from regular tetrahedral coordination about the iron atom.

Faisant appel à la résonance paramagnétique électronique (rpe), à la spectroscopie infrarouge et à la diffraction des rayons X, on a étudié les structures électroniques et géométriques des complexes paramagnétiques du dinitrosyl fer. On en conclut que la meilleure façon de décrire ces composés est de les considérer comme des complexes à 17 électrons possédant une configuration d^9 plutôt que la configuration d^7 utilisée par la plupart des auteurs qui en ont traité antérieurement. L'anisotropie des valeurs g, déterminée par les spectres rpe de solutions congelées, varie beaucoup d'un complexe à l'autre. Les résultats sont en accord avec l'hypothèse selon laquelle tous les complexes possédent une géométrie tétraédrique déformée, mais que la nature de la distorsion varie avec la nature des ligands. Un résultat de cette variation amène des changements dans la nature de l'orbitale contenant le spin. Les ligands contenant des atomes donneurs durs et non-polarisables, comme l'oxygène ou le fluor, provoquent une distorsion vers une géométrie plane forçant l'électron célibataire à occuper une orbitale principalement $d_{x^2-y^2}$ alors que ceux qui contient des atomes donneurs plus mous, comme le phosphore ou le soufre, donnent des complexes avec un type de distorsion différent, conduisant à une présence de l'électron célibataire dans une orbitale qui est principalement d_{z^2}. Les ligands contenant des atomes d'azote et d'halogénure comme donneurs provoquent des distortions plus faibles conduisant à des orbitales moléculaires contenant le spin dans lesquelles un mélange d'orbitales d contribuent. En accord avec ce modèle, on a trouvé que la structure cristalline du $[Fe(NO)_2I_2]^-$ n'est que légèrement déformée par rapport à la coordination tétraédrique régulière autour de l'atome de fer.

[Traduit par la rédaction]

Introduction

The structure of paramagnetic iron dinitrosyl complexes was first investigated by McDonald, Phillips, and Mower in 1965 (1). These compounds are easily produced in aqueous solution from Fe(II) salts and nitric oxide. However, they have been found to be fairly unstable and difficult to isolate. The majority of researchers have used Electron Paramagnetic Resonance (EPR) spectroscopy to study the complexes (2). Most of these investigations were carried out at room temperature and in solution since the compounds were prepared in an aqueous medium. A wide variety of ligands, including halides, phosphines, mercaptans, and various nitrogen-bonded ligands, will complex to the $Fe(NO)_2$ group. The hyperfine coupling observed indicates that the complexes are four-coordinate with the general stoichiometry $[Fe(NO)_2XY]^n$. The only notable exception, established by the fluorine hyperfine coupling, is the six-coordinate complex, $[Fe(NO)_2F_4]^{3-}$, which can be prepared in solution if the fluoride concentration is high. The solution EPR spectra also have been used to demonstrate that the complexes are quite labile. The $Fe(NO)_2$ unit remains intact while the other two ligands exchange.

Potentially, solid state EPR studies are more informative than solution studies. Only a limited number of such studies, all carried out on frozen solutions, have been reported (3). In general, the components of the g tensor vary considerably for different dinitrosyl complexes, indicating the possibility of more than one structure for these compounds. The EPR data were interpreted on the basis of a d^7 electronic configuration for iron and the possible geometries suggested by these authors included tetrahedral, octahedral with *trans* NO groups, octahedral with *cis* NO groups, square-planar, and square-pyramidal.

The first successful isolation of one of these compounds occurred in 1973 when deep purple crystals of $Fe(NO)_2(PPh_3)Cl$ were prepared by the reaction of triphenylphosphine with $[Fe(NO)_2Cl_2]^-$ (4). In 1976, Connelly and Gardner reported the isolation and characterization of $[N(PPh_3)_2)][FE(NO)_2X_2]$ where X = Cl, Br, or I (5). The analytical data confirmed the stoichiometry and the EPR spectra were consistent with those obtained with dinitrosyl

[1]A preliminary description of these structures, based on data available in the literature, was presented at the 69th Conference of the Canadian Institute of Chemistry and is contained in the proceedings of an ESR symposium published as Electron Magnetic Resonance of the Solid State, edited by J. A. Weil.

complexes prepared in solution. Magnetic susceptibility measurements indicated the presence of one unpaired electron and revealed the absence of dimerization in the solid state. In 1986, black crystals of $[NEt_4][Fe(NO)_2(SPh)_2]$ (6) were synthesized from the diamagnetic cluster, $[Fe_4S_3(NO)_7]^-$ (2*k*). Only two other paramagnetic iron dinitrosyl compounds have been isolated. Both of these have the stoichiometry $Fe(NO)_2L$ where L is a bidentate ligand. In one case, the ligand is coordinated through sulfur atoms [-SCH_2CH_2NH-$(CH_3)CH_2CH_2CH_2N(CH_3)CH_2CH_2S$-] (7), while in the other molecule, the 2-methyl-8-quinolinolate ion is coordinated through N and O (8). X-ray structure determinations have been reported for only three of the six crystalline solids. The geometry of the $Fe(NO)_2$ complex with the bidentate sulfur ligand was found to be pseudotetrahedral, with the angles showing only small deviations from the true tetrahedral values (7). The $[Fe(NO)_2(SPh)_2]^-$ anion was described to be a distorted tetrahedron, but the deviations from tetrahedral were larger than for the other sulfur complex (6). Kopf and Schmidt described the structure of $Fe(NO)_2(PPh_3)Cl$ as a trigonal bipyramid with one axial ligand missing, although the angles deviate somewhat from this idealized geometry (9).

Although the stoichiometry of the paramagnetic iron dinitrosyl complexes has been clearly established, the literature contains ambiguous and conflicting reports for both the electronic and geometric structure. The question concerning the electronic structure revolves around the formal oxidation state of the iron atom. These are clearly 17-electron compounds, but it is plausible to assign either 7 *d* electrons to the metal atom, giving an Fe^{+1} ion, or 9 d electrons giving an Fe^{-1} ion. The original investigators of these complexes preferred the d^7 formulation, but three arguments have been used to favour the d^9 alternative. These arguments are based on Fe—N—O bond angles, on infrared NO stretching frequencies, and on the small values of the nitrogen hyperfine coupling constants observed by solution EPR. None of these arguments are unambiguous since the ranges of possible parameters tend to overlap. Thus the uncertainties caused by the use of infrared data to infer the bonding in the NO ligand, and by inference the oxidation state of Fe, have been discussed by Mingos and Ibexs (10). Most EPR investigators have opted for a d^7 configuration, although one recent group of publications, concerned with dinitrosyls with sulfur-containing ligands, assumed d^9 (2*k*–2*o*). The only evidence quoted was the small nitrogen hyperfine coupling constant compared to compounds of known d^7 configuration; this argument is not completely convincing. There are 17 electrons to be assigned to molecular orbitals whether the complex is regarded as d^7 or d^9, and so the nitrogen hyperfine coupling constant is determined by the detailed nature of the spin-containing molecular orbital. MO calculations (2*m*, 30), particularly at the EHMO level, are probably not sufficiently reliable to answer the question with certainty.

In the present paper we will use the *g* value anisotropies obtained from frozen solution EPR to argue for a d^9 configuration. This approach has two advantages. Firstly it relies on qualitative arguments on the relative magnitudes of the different components of the *g* tensor, rather than on quantitative calculations. The reliability of qualitative crystal field arguments in transition metal chemistry is generally accepted. Secondly it enables us to correlate electronic structure with molecular geometry. X-ray crystallographic evidence has proved the existence of at least two different structures in the solid state. At least one of these complexes has been shown to exhibit catalytic activity (11) and it is of interest to enquire whether this activity is related to structure. The objective of this paper is therefore to confirm the previously suggested d^9 configuration of these iron dinitrosyl complexes and to relate their electronic and molecular structures. Frozen solution EPR spectroscopy has been the primary method of investigation, but supporting data from X-ray crystallography and from IR spectroscopy will also be presented.

Experimental

All complexes were prepared using established literature techniques. Nitric oxide gas (Matheson) was purified by passage through aqueous NaOH and a −78°C trap. All reactions were carried out under argon or nitrogen atmospheres in dry, degassed organic solvents. $HNEt_3[Fe(NO)_2Cl_2]$ and $Fe(NO)_2(PPh_3)Cl$ were prepared using the method of Gwost and Caulton (4). $[N(PPh_3)_2][Fe(NO)_2I_2]$ and its precursor $[N(PPh_3)_2][Fe(CO)_3NO]$ were prepared by the method of Connelly and Gardner (5). $Fe(NO)_2$(thiourea)I was prepared from the addition of excess thiourea to $[Fe(NO)_2I_2]^-$ in CH_2Cl_2. $Fe(NO)_2$(thiourea)Cl was prepared in an analogous manner from $[Fe(NO)_2Cl_2]^-$ in ethanol. The identity of the two thiourea complexes prepared using this technique was confirmed by EPR spectroscopy but no analytical data are available since the compounds could not be isolated as pure crystalline solids. Solutions of the remaining complexes in methanol or ethanol were prepared by adding excess anionic ligand to 10^{-2} M $FeCl_2$ followed by the passage of NO gas for 5 min (2). The ligands used were MeO^-, EtO^-, and anions of urea and 4-nitroimidazole.

All EPR spectra were recorded on a Bruker ER-100D spectrometer, operated in the X-band microwave region. The wavemeter allowed measurements of microwave frequency to 0.08% precision. 10^{-2} M solutions of each complex in organic solvents were analyzed in 3 mm quartz tubes at ambient temperature and again at 125 K. The solvents used are listed in Table 4 with the EPR data. Aqueous solutions were avoided to circumvent experimental difficulties at 125 K. Each spectrum was simulated to confirm the choice of parameters (12). The same 10^{-2} M solutions of the $Fe(NO)_2$ complexes were then examined using a Nicolet model 7199 FT-IR spectrometer with 0.1 mm solution cells. Most of the vibration modes were masked by the solvent but in all cases the NO stretching bands were visible and provide significant information.

The X-ray crystal structure of $[N(PPh_3)_2][Fe(NO)_2I_2]$ was determined. Crystals of $[N(PPh_3)_2][Fe(NO)_2I_2]$ were grown from CH_2Cl_2/ethanol. The density was determined by suspension in CCl_4/$C_2H_2Br_4$. Red-black plate-shaped crystals were examined under a polarizing microscope for homogeneity. A well-formed crystal, 0.3 mm × 0.2 mm × 0.133 mm, was selected and sealed in a Lindemann capillary. Unit cell parameters were obtained from a least-squares fit of χ, ϕ' and 2θ for 15 reflections in the range $19.5° < 2\theta < 23.5°$, recorded on a Nicolet $P2_1$ diffractometer with the use of graphite monochromated MoKα radiation ($\lambda = 0.71069$ Å) at 22°C. Intensity data were also recorded on a Nicolet $P2_1$ diffractometer with a coupled θ(crystal)–2θ(counter) scan, over h, $\pm k$, $\pm l$ resulting in 4999 reflections with $2\theta \leq 45°$. Corrections for Lorentz–polarization effects and absorption were applied to all reflections. Two standard reflections (−4,3,4; 1.54% and 6,1,−7; 1.47%) monitored every 48 reflections showed no sign of crystal decomposition or instrument instability. After reduction and averaging of redundant data (agreement factor $R_{int} = 0.017$) there were 4791 unique reflections, and 4514 reflections with $I > 3\sigma(I)$. Maximum error in F_o was calculated to be 9.5%. Empirical absorption corrections were estimated from psi-scan observations on 19 selected reflections. The crystal data are summarized in Table 1.

The structure was solved by determination of the phases by direct methods with the use of 46 reflections with $E > |1.2|$ and 12 sets of starting phases. The positional parameters for the iodine and

[a] $R_{int} = \sqrt{\frac{\Sigma[N\Sigma(\omega(\langle F\rangle - F)^2)]}{\Sigma(N-1)\Sigma\omega F_o^2}}$.

[b] $R_1 = \frac{\Sigma\|F_o| - |F_c\|}{\Sigma|F_o|}$.

[c] $R_2 = \sqrt{\frac{\Sigma\omega(|F_o| - |F_c|)^2}{\Sigma\omega F_o^2}}$.

[d] $S = \sqrt{\frac{\Sigma\omega(|F_o| - |F_c|)^2}{m-n}}$; m = no. of reflections; n = no. of variables.

[e] $F^* = F\left(\frac{1 - 0.0001 \times F^2}{\sin\theta}\right)$.

iron atoms were found in the subsequent E-map. A series of full-matrix least-squares refinements that minimized $\Sigma w(|F_o| - |F_c|)^2$ ($w = 1/[\sigma^2F_o + 0.000323F_o^2]$) revealed the positional parameters of all non-hydrogen atoms. Temperature factors of all non-hydrogen atoms were then made anisotropic. Further least-squares refinement required the use of two block-matrices, one for $[N(PPh_3)_2]^+$ and the other for $[Fe(NO)_2I_2]^-$. Corrections were made for secondary extinction by the method in SHELX (13). Refinement was complete when the maximum shift/error reached 0.240 for the anion and 0.053 for the cation. Final $R^1 = 0.040$, $R^2 = 0.047$, and $S = 1.19$ for the iron dinitrosyl anion. The final difference map revealed no significant regions of electron density with a maximum of 0.476 and a minimum of −0.576 e Å^{-3}. Throughout refinement, scattering factors were taken from ref. 14 and anomalous dispersion corrections from ref. 15 were applied to the curve for iron. All calculations were performed on a VAX 8600 computer. Programs used: XTAL (16) for data reduction, TAPER (17) for absorption correction, SHELX-86 (13) for structure solution, SHELX-76 (18) for structure refinement, MOLGEOM (19) for molecular geometry and SNOOPI (20) for diagrams. The atomic positions are listed in Table 2, while the structure of $[Fe(NO)_2I_2]^-$ is shown in Fig. 1. Selected bond angles and bond lengths are listed in Table 3. An-

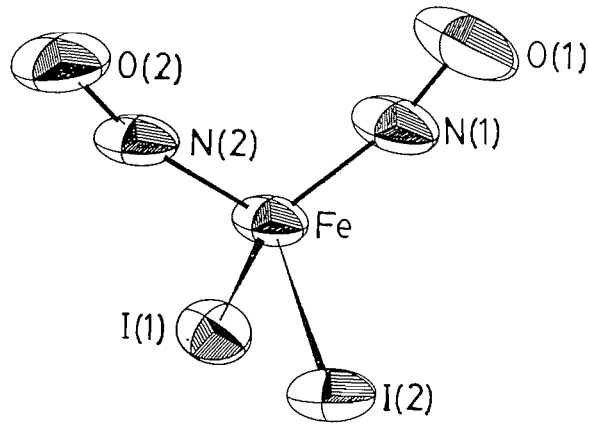

FIG. 1. ORTEP view of $[Fe(NO)_2I_2]^-$.

Extended Hückel molecular orbital calculations was made. The calculations were performed using the ICON8 package (21) with weighted H_{ij}'s (22). The d orbital exponents have been removed for Cl, I, and P. EHMO calculations were carried out for representative complexes of each geometry. Crystal structure parameters provided the positional coordinates for $Fe(NO)_2(PPh_3)Cl$ and $[Fe(NO)_2I_2]^-$, but it was necessary to estimate the Cartesian coordinates for $[Fe(NO)_2F_2]^-$.

Results

EPR spectra of each complex were recorded at ambient temperature and at 125 K. The g values and hyperfine coupling constants are given in Table 4 along with those for a few relevant complexes from the literature. The isotropic solution g values vary from 2.02 to 2.08 with no obvious correlation between g value and the type of ligand coordinated to iron. Examination of the hyperfine coupling constants in Table 4 reveals the presence of two NO groups and coupling from two other ligands can be resolved in some cases. The spectra for $[Fe(NO)_2I_2]^-$ are shown in Fig. 2 along with their simulations. The 11-line solution spectrum shows coupling from two iodine atoms ($I = 5/2$). The frozen solution EPR spectrum of $[Fe(NO)_2I_2]^-$ is much more complicated than the room temperature spectrum and simulation of the spectrum was necessary to confirm the correct choice of the three g values. Most frozen EPR spectra were far less complex than this, allowing unambiguous interpretation of the spectra. Two additional frozen solution EPR spectra are illustrated in Fig. 3. The spectrum for $[Fe(NO)_2Cl_2]^-$ (Fig. 3*a*) has three different g values, just like $[Fe(NO)_2I_2]^-$, but the spectrum is quite simple because the hyperfine coupling is not resolved. Not all spectra had three different principal values for the g matrix. Figure 3*b* illustrates the frozen solution spectrum of $[Fe(NO)_2(MeO)_2]^-$, which has only two g values. In this spectrum $g_\perp$ is upfield of $g_\parallel$, which indicates that $g_\parallel > g_\perp$. Overall, it was found that the frozen solution EPR spectra of all of the complexes fell into three categories. These are listed as parts A, B, and C of Table 4. Type A spectra had $g_\perp > g_\parallel$. Only complexes containing ligands bonded through phosphorus or sulfur gave this type of frozen solution spectrum. Dinitrosyl complexes with the halides, Cl, Br, I, or ligands bonded through nitrogen are listed in part B of the table. All of these spectra have three different principal values of the g matrix. Finally, the spectra in part C of Table 4 have $g_\parallel > g_\perp$. Only complexes containing fluoride or ligands bonded through oxygen have this

type of spectrum. In general, the nature of a frozen solution EPR spectrum depends upon the type of orbital that contains the unpaired electron. Therefore, to have three different types of frozen solution EPR spectra for a homologous series of complexes, there must be corresponding differences in the spin-containing orbital. If all the paramagnetic iron dinitrosyl complexes have the same electronic configuration, then there must be three different geometries for these compounds.

Further information on the structure and bonding of these complexes can be obtained from infrared spectroscopy and from X-ray crystallography. The NO^+ ion has a stretching

frequency of 2220 cm^{-1} while the frequency for the neutral NO molecule, with the extra electron in a π^* orbital, is 1876 cm^{-1} (23). These data reflect the increased multiple bond character in the cation. Complexation considerably reduces these frequencies since backbonding, increasing the positive charge on the nitrosyl group, is possible. Stretching frequencies in the range of 1940 to 1650 cm^{-1} are indicative of complexed NO^+, while neutral or negatively charged NO ligands have stretching frequencies even lower (1525–1690 cm^{-1}) (23, 24). Since there is considerable overlap in these frequencies, discretion must be used when attempting to determine the nature of NO ligands from IR data. The NO stretching frequencies for a selection of paramagnetic iron dinitrosyl complexes are shown in Table 5, with those for some diamagnetic complexes included for comparison. The paramagnetic dinitrosyls show two bands in the NO region corresponding to the symmetric and asymmetric stretches of the NO ligands. There is some variation in the frequencies for the different dinitrosyl complexes but, in general, the range of frequencies is reasonably small (1690–1808 cm^{-1}). In comparison, the nitroprusside ion, a diamagnetic, Fe^{2+} complex with formally NO^+ ligands, has an NO stretching frequency of 1939 cm^{-1} (25). If nitroprusside is reduced, $[Fe(CN)_5NO]^{3-}$, which has 19-electron configuration, is formed. Not surprisingly, the electron does not remain on the

X—Fe—X	109.4	109.7	111.0	90	109.5

metal but moves to the NO ligand. This formally reduces the NO^+ group to NO, leaving the iron in the +2 oxidation state. Accordingly, the stretching frequency for the NO group drops to 1580 wavenumbers (26). Usually, stretching frequencies for iron nitrosyl compounds are not quite as high as that for nitroprusside. For example, nitroprusside can also be reduced to five-coordinate $[Fe(CN)_4NO]^{2-}$ (26). The complex has lost a cyanide group and the nitrosyl group remains as NO^+. The NO stretching frequency for this complex is 1755 cm^{-1}. The NO stretching frequencies for the paramagnetic iron dinitrosyl compounds compare closely with this frequency. Overall, the frequencies are too high for the NO groups to be considered neutral or NO^-.

Data pertaining to the crystal structure determination of the $[Fe(NO)_2I_2]^-$ ion are given in Tables 1–3. The $[Fe(NO)_2I_2]^-$ anion is illustrated in Fig. 1. Bond lengths and bond angles are compared with those reported for $Fe(NO)_2(PPh_3)Cl$, $[Fe(NO)_2(SPh)_2]^-$, and for idealized geometries in Table 6. The structure of $[Fe(NO)_2I_2]^-$ obtained differs only slightly from that of a regular tetrahedral array of ligands around the iron atom. The deviations are markedly less than those found for $Fe(NO)_2(PPh_3)Cl$ and $[Fe(NO)_2(SPh)_2]^-$. It is notable that this complex occurs in part B of Table 4, showing three distinct g values. We would anticipate that other compounds in this group, with chloride or nitrogen-bonded ligands, would have similar close to regular tetrahedral geometries.

The relationship between molecular geometry and the EPR parameters

The components of the g tensor for a paramagnetic transition metal complex are determined by the nature of the orbital(s) containing the unpaired electron(s). The ordering of the metal d orbitals is in turn determined by the molecular geometry and can be predicted from crystal field theory. In the present section simple crystal field considerations are used to make qualitative predictions concerning the g tensor.

The geometries possible for a four-coordinated complex are square-planar, tetrahedral, and various distortions of these simple geometries. If the complex has a formula MX_4, the relevant point groups are T_d (tetrahedral) or D_{4h} (square-planar). If, as in the present case, the formula is MX_2L_2 the point group becomes C_{2v} (tetrahedral), D_{2h} (*trans*-square-planar), or C_{2v} (*cis*-square-planar). If the complex is of the form $MXYL_2$, or if the geometry is not regular tetrahedral or square-planar, less symmetry is present and any degeneracy of the d orbitals is completely removed. This is the case for the complexes under present consideration. As far as the g tensor is concerned, to zero-order approximation all the components will have a value equal to the free electron g value, g_e. To a first-order approximation, spin orbit coupling mixes the different d orbitals and deviations from the g_e will occur. This potentially leads to different values for different components of the g tensor. If the distortions are not too great, we would still expect to observe an EPR spectrum corresponding to separate $g_\parallel$ and $g_\perp$, if this is required by the undistorted symmetry. The differences in g values vary according to the geometry assumed, and this allows deductions concerning the molecular geometry to be made from qualitative observations on the form of the g tensor.

The necessary calculations involve first determining the nature of the orbital containing the odd electron, and then considering the contribution of spin orbit coupling for the different orientations of the molecule in the magnetic field. The theory for all the cases of interest is available in the literature (27). The resulting conclusions concerning the g value anisotropies are contained in Table 7. Thus for example, in a d^9 complex with a square-planar geometry, the odd electron will occupy the $d_{x^2-y^2}$ orbital and spin orbit coupling mixes this orbital with d_{xy}, leading to the prediction that $g_\parallel > g_\perp > g_e$. If the complex had a d^7 configuration, the odd electron would be in the d_{xy} orbital and the prediction becomes $g_\perp > g_e > g_\parallel$. A qualitative measurement of the g tensor will clearly distinguish between these possibilities. It should be noted that this result is also applicable to a tetragonally distorted octahedral complex, a conclusion that is pertinent to consideration of the complex $[Fe(NO)_2F_4]^{3-}$.

The situation is a little more complex for compounds that have an overall tetrahedral geometry. Even for an MX_4 complex, distortion from T_d symmetry will occur due to the Jahn–Teller effect. For a d^9 complex there can only be a single unpaired electron. Since the maximum symmetry is C_{2v}, the odd electron must be in an orbitally non-degenerate orbital. Three different g values are predicted, all of them being greater than g_e. The ordering of these g values depends on the nature of the distortion from T_d symmetry. A special case arises if the distortion is towards a complex with basically the geometry of a trigonal bipyramid that is missing an axial ligand, as has been suggested by an X-ray crystal structure (9). For this case the approximate threefold symmetry leads to the prediction of only two observable g values with $g_\perp > g_e$ and $g_\parallel = g_e$ (see Table 7). For a d^7 complex the nature of the spectrum depends on the magnitude of the distortion. If a threefold axis remains, there will be a very large positive shift in $g_\parallel$ and, if the molecule is fluxional, very rapid electron spin relaxation, preventing the

TABLE 7. Summary of conclusions for the EPR spectra of $Fe(NO)_2LX$ complexes

Configuration	Geometry	Conclusion
d^9	Square planar[a]	$g_1 > g_\parallel > g_\perp$
d^9	Distorted tetrahedral	$g_1 > g_2 > g_\perp > g_\perp$
d^9	Tetrahedral distorted towards tbp	$g_\perp > g_\parallel = g_e$
d^7	Square planar[a]	$g_\perp > g_e > g_\parallel$
d^7	Distorted tetrahedral (low symmetry)[b]	$g_1 > g_e > g_2 > g_3$
d^7	Distorted tetrahedral with 3-fold axis[b]	$g_\parallel \gg g_e > g_\perp$

[a]The same conclusion is true for tetragonally distorted octahedral complexes.
[b]If the molecule is fluxional the EPR spectrum will be unobservable as a result of very rapid spin relaxation.

observation of a solution EPR spectrum.[4] If the distortions are large and the symmetry is low, it is predicted that two of the g values will be less than g_e and one greater. For the special case of a d^7 complex with a distortion towards a pyramidal structure the most likely outcome is that the solution spectrum will be unobservable, contrary to experiment, due to rapid electron spin relaxation as noted above. All these deductions are summarized in Table 7.

Discussion

Our strategy for the interpretation of the present results is to first establish the d electron configuration of the complexes, to next use the EPR data to deduce the geometries, and to finally examine the data for internal consistency. We note initially that all the g values reported in Table 4 are comfortably greater than g_e, which considerably limits the geometries possible for a d^7 configuration. However, supporting evidence for the configuration is provided by the infrared results.

From an examination of the IR stretching frequencies, it can be concluded that the nitrosyl ligands in the paramagnetic $Fe(NO)_2$ complexes are better regarded as NO^+ rather than neutral or negatively charged NO. NO stretching frequencies vary considerably from compound to compound, even when the charges on the ligands are formally the same, and are therefore not reliable indicators of bond type. However, the frequencies reported in Table 5 are clearly closer to the literature examples containing formally positively charged NO than those containing formally neutral NO. This implies that the iron is formally Fe(−I) in these compounds, and the electronic configuration is d^9.

This conclusion has some structural implications. Nitrosyl ligands that are formally NO^- or NO^0 would theoretically result in a 120° Fe—N—O angle, while the Fe—N—O angle would be linear for NO with a formal +1 charge. In practice, the angles in dinitrosyl complexes tend to deviate from these theoretical values by as much as 20°. For example, the bent M—N—O group in $Ru(NO)_2(PPh_3)_2Cl$ is 138° rather than 120° (28). Linear Fe—N—O angles also show large deviations from 180° especially for dinitrosyl complexes with *cis* NO groups (29). Summerville and Hoffmann found that the large deviations were a direct result of the acute N—M—N angle in these dinitrosyl complexes (30). The bending of the NO ligand occurs to stabilize the interaction between the NO ligand and the metal. Crystallographic evidence shows that the Fe—N—O angles in paramagnetic iron dinitrosyl complexes range from 164° to 170°. These angles are indicative of the linear bonded nitrosyl with a +1 formal charge. Therefore, as inferred from the infrared results, $[Fe^{1-}(NO)^+(NO)^+]$ is the most appropriate representation of the complexes, resulting in a d^9 electronic configuration for iron.

Interpretation of the solid state EPR data by earlier authors was based on the assumption that all of the complexes had a d^7 electronic configuration. This led to some interpretational difficulties. These occurred particularly for frozen solution EPR spectra for complexes with F or O bonded ligands (3). These compounds all have EPR spectra with $g_\parallel > g_\perp > g_e$. If it is assumed that the iron complexes had a d^7 configuration, none of the geometries described above gave the appropriate EPR spectrum and it was necessary to postulate a compressed octahedral geometry with *trans*-NO groups for these complexes. However, this structure is not consistent with the available data because a complex with D_{4h} symmetry would have only a single NO stretching frequency in the infrared spectrum. All the paramagnetic iron dinitrosyl complexes have two NO stretching frequencies. These difficulties are removed if the iron dinitrosyl compounds are described as d^9 complexes. The EPR spectra of the fluorine and oxygen complexes then match that calculated for square-planar geometry. A coordination number of six is possible for complexes with the fluoride ion. Therefore, it is important to note that a tetragonally elongated octahedron with a d^9 electron configuration also results in a frozen EPR spectrum with $g_\parallel > g_\perp > g_e$ as is observed.

A second class of iron dinitrosyl compounds have completely different EPR spectra. For complexes with S or P bonded ligands, $g_\perp > g_\parallel > g_e$. The unpaired electron must occupy an orbital other than $d_{x^2-y^2}$. An example of a complex with $g_\perp > g_\parallel$ is $Fe(NO)_2(PPh_3)Cl$. Examination of the crystal structure of this compound shows a geometry that can be loosely described as a trigonal bipyramid with one axial ligand missing. This can be regarded as a distorted tetrahedron but the nature of the distortion differs from that observed with "hard" ligands. The phosphine is in the axial position, so that the d_{z^2} orbital becomes the highest energy metal orbital. If the paramagnetic iron dinitrosyl complexes have a d^9 configuration, the pyramidal structure predicts an EPR spectrum with $g_\perp > g_\parallel$ as observed. It is plausible that all paramagnetic iron dinitrosyl compounds with $g_\perp > g_\parallel$ have a similar structure.

The two suggested geometries represent the extremes of the possible distortions from a regular tetrahedron. The complexes with fluoride or oxygen are formed from a tetrahedron that is flattened towards a square-planar geometry

[4]We are indebted to a referee for drawing our attention to this case.

with increased solvent interaction. For the complexes with sulfur or phosphorus ligands, the tetrahedron is distorted by dropping the metal atom onto a triangular face with the nitrosyls at two of the apices of the triangle. The geometry does not fit this idealized geometry exactly. An examination of the bond angles in $Fe(NO)_2(PPh_3)Cl$ given in Table 6 indicates that the complex is better described as a tetrahedron distorted towards the trigonal bipyramidal (tbp) geometry. The existence of a third group of $Fe(NO)_2$ complexes, with three different principal values of the g matrix, suggests that intermediate geometries are also possible. These complexes would have low symmetry and could only be described as distorted tetrahedra. The considerations of the previous section confirm that d^9 complexes with this geometry do in fact have EPR spectra with three g values all greater than g_e.

Some extended Hückel calculations have been carried out to obtain further insight into the bonding in these complexes. The calculations indicate that the spin-containing molecular orbital (SOMO) is composed of approximately 70% d orbital character. This was expected since the hyperfine coupling constant A_N was only 2 G. Hyperfine coupling is normally much larger (ca. 10–14 G) in nitrosyls where nitrogen orbitals hold the unpaired electron. These results are in agreement with EHMO calculations carried out by Butler *et al.* for $[Fe(NO)_2(SR)_2]^-$ (2*m*). They found that the SOMO was a π-type orbital with respect to the Fe—N bonds. For $Fe(NO)_2(PPh_3)Cl$, the calculations indicate that the molecular orbital (MO) containing the unpaired electron is primarily composed of the d_{z^2} metal orbital as predicted. Since the geometry is not a perfect triangular pyramid, the MO also contains some d_{yz} orbital. This tilts the d_{z^2} to more effectively overlap with the Cl ligand. The spin-containing MO includes a slight bonding interaction between iron and the NO groups but iron is antibonding with respect to phosphorus and chloride. The unpaired electron in $[Fe(NO)_2I_2]^-$ resides in a molecular orbital that is primarily a mixture of metal d_{yz}, $d_{x^2-y^2}$, and d_{z^2} orbitals. This is also in agreement with predictions based on EPR data. The results obtained for $[Fe(NO)_2F_2]^-$ in a planar geometry were almost identical to those for tetragonally distorted $[Fe(NO)_2F_4]^{3-}$. In both of these complexes, the metal orbital containing the unpaired electron was $d_{x^2-y^2}$ as predicted. In addition, there was a slightly larger contribution to the singly occupied MO from the NO orbitals. There was a small bonding interaction between iron and nitrogen, but the N–O interaction was antibonding. In general, the molecular orbital calculations for the representative molecules support the conclusions drawn about the structure of the paramagnetic iron dinitrosyl complexes.

The chemistry of the iron dinitrosyl complexes is comparable to other first row d^9 transition metal compounds. Structural information for d^9 complexes is relatively rare compared to other first row transition metal configurations. Copper(II) compounds are the most common. These complexes are generally square-planar with weak interactions with fifth and sixth ligands (31). The iron dinitrosyl complexes with hard, ionic ligands such as fluoride, hydroxide, and methoxide are analogous to these Cu^{2+} compounds. In fact, it is possible to prepare six-coordinate $[Fe(NO)_2F_4]^{3-}$ under conditions with high fluoride concentrations. Softer donor ligands such as the halides and N-bonded ligands encourage more π bonding to the NO ligands. There is a subsequent change in the nature of the distortion to accommodate better π bonding. This case is analogous to nickel(I) complexes, which, although rare, are known to adopt tetrahedral geometries (32). X-ray crystal structure data have shown that a trigonal bipyramidal structure with one axial ligand missing is the approximate geometry adopted by the $Fe(NO)_2(PPh_3)Cl$ complex. With this arrangement, d_{xy} and $d_{x^2-y^2}$ can form in-plane π bonds with the nitrosyl ligands and d_{xz} and d_{yz} participate in out-of-plane π bonding. In this way, the d_{z^2} orbital is available to interact with the triphenylphosphine ligand. It is possible that another reason for the distortion from the tetrahedral shape is the maximization of π bonding within the $Fe(NO)_2$ moiety. Evidence in support of this is the higher NO stretching frequencies for $Fe(NO)_2$ complexes with π acceptor ligands such as CN^- or PPh_3, compared to those observed for the complexes with methoxide and ethoxide. Cobalt(0) complexes also have the d^9 electronic configuration. However, the structure and bonding in Co(0) compounds does not parallel that of Fe(−I) complexes as do the Cu(II) and Ni(I) species. Co–Co bonds tend to be formed in cobalt chemistry in accordance with the 18-electron rule. The paramagnetic iron dinitrosyls also dimerize to form diamagnetic compounds such as $[Fe(NO)_2(\mu-I)]_2$. However, the interaction is not as strong as in the case of cobalt. The interaction is better compared to Cu(II) dimers with carboxylate or triazinate bridges, in which there are antiferromagnetic couplings of the unpaired spins (33).

Montmorillonite is a natural layered clay mineral having myriad applications due mainly to its remarkable ion exchange, intercalation, and swelling properties. It can act as a good host for several compounds. Two intercalated coordination compounds of Cu(II) and Ni(II) with 2,2′-bipyridyl have been prepared in the interlayer spaces of montmorillonite structure. They are characterized on the basis of elemental analysis, infrared spectroscopy, magnetic studies, and X-ray diffraction. Both compounds show similarity in their structure and properties with the respective normal complexes of similar composition. These compounds show good thermal stability. The present intercalated compounds might be useful for their nitrogen-immobilizing properties and high-temperature applications.

N. K. LABHSETWAR et O. P. SHRIVASTAVA. Can. J. Chem. **70**, 1927 (1992).

La montmorillonite est une argile minérale naturelle en couche qui a des myriades d'applications reliées à ses propriétés remarquables pour l'échange ionique, l'intercalation et le gonflement. Elle peut agir comme hôte pour plusieurs composés. Dans les espaces interstitiels de la structure de la montmorillonite, on a préparé deux composés de coordination intercalés du Cu(II) et du Ni(II) avec le 2,2′-pyridyle. On les a caractérisés par des analyses élémentaires, par spectroscopie infrarouge, des études magnétiques et par diffraction des rayons X. Les deux composés ont des similarités de structure et de propriétés par rapport à leurs complexes respectifs normaux de composition semblable. Ces composés présentent une bonne stabilité thermique. Ces composés pourraient s'avérer utiles à cause de leurs propriétés permettant d'immobiliser l'azote et de leurs applications à hautes températures.

[Traduit par la rédaction]

Introduction

Ion exchange properties of clay minerals have been investigated by several workers with different cations and also with charged large organic moieties (1–5). The montmorillonite group of clays having the general formula $Al_4Si_8O_{20}(OH)_4 \cdot nH_2O$ show cation exchange and can also take up extraneous molecules between the structural layers (6, 7). Intercalation behaviour of montmorillonite clay is of interest and many attempts have been made to introduce macromolecules in the interlayer spaces of this layered clay mineral (7–30). Earlier Traynor *et al.* also reported tris-bipyridyl–metal complexes supported on the layer-lattice-silicate hectorite (31). Cruz *et al.* investigated the Ru-(bipyridyl)$_2$-$(H_2O)^{2+}$ complex adsorbed on hectorite (32). These compounds were prepared by ion exchange or adsorption of charged complex ions with layered clay. Traynor *et al.* observed that a metal–bipyridyl complex can be supported on hectorite beyond its ion-exchange capacity. This additional binding of the metal complex to the mineral occurs through intercalation of the metal complex salt. The present paper reports physicochemical data on intercalated coordination compounds of Cu(II)- and Ni(II)-exchanged montmorillonites with 2,2′-bipyridyl.

Experimental

Cu(II)- and Ni(II)-exchanged montmorillonites were prepared by shaking 5.0 g of finely powdered (mesh size 150) USGS montmorillonite clay sample with 0.5 M aqueous metal-ion solution at 25°C for 10 days (30). The metal-exchanged clay was separated and thoroughly washed with deionized water before drying at 70°C for 8 h. Cu(II)- and Ni(II)-saturated montmorillonites were thus obtained. The metal–bipyridyl complexes were prepared by refluxing the metal-exchanged montmorillonite with 0.5 M 2,2′-bipyridyl solution in acetone for 15 h. By the end of the reaction the colour of both compounds had changed completely. The products thus obtained were washed with acetone and dried over P_4O_{10} before analysis. In earlier studies most of the clay-supported coordination compounds were prepared either by ion-exchange of charged complex molecules with interlayer exchangeable cations of clay mineral or adsorption of complex molecules on a large surface area of clay. In the present case uptake of the bound metal–bipyridyl complex to the montmorillonite is within its ion-exchange capacity where the cation-exchanged clay is treated with a stoichiometric quantity of ligands.

The metal content was determined spectrophotometrically in both compounds using standard methods (33). Nitrogen was estimated using a Coleman Analyser. The IR absorption spectra of the compounds were recorded on a Perkin–Elmer-397 IR spectrophotometer. The sample was used as KBr pellets. Room temperature magnetic susceptibilities of the compounds were determined by Gouy's method using $Hg[Co(NCS)_4]$ as the standard. X-ray powder diffraction patterns of the compounds were recorded on a Phillips X-ray machine attached to a microprocessed PW-1700 diffractometric system using Cu-K_α radiation of wavelength 1.542 Å Thermogravimetric analysis was carried out on a Perkin–Elmer thermal analyser using inert atmosphere. The heating rate was maintained at 12.5°C min^{-1} in the temperature range 60–1000°C. All chemicals used were of A. R./E. Merck grade.

Results and discussion

The montmorillonite clay mineral consists of negatively charged aluminosilicate layers with interlayer cations compensating the positive charge deficiency. The empirical formula of the present montmorillonite sample is

$$(Ca_{0.90}Na_{0.16}K_{0.03})(Al_{1.48}Fe_{0.13}Mg_{0.4})\,[Si_{3.99}Al_{0.01}]O_{10}(OH)_2 \cdot nH_2O$$

The charge deficiency in montmorillonite is mainly due to isomorphous substitution of Si^{4+} by Al^{3+}. The interlayer spaces in montmorillonite clay are substantial enough for it

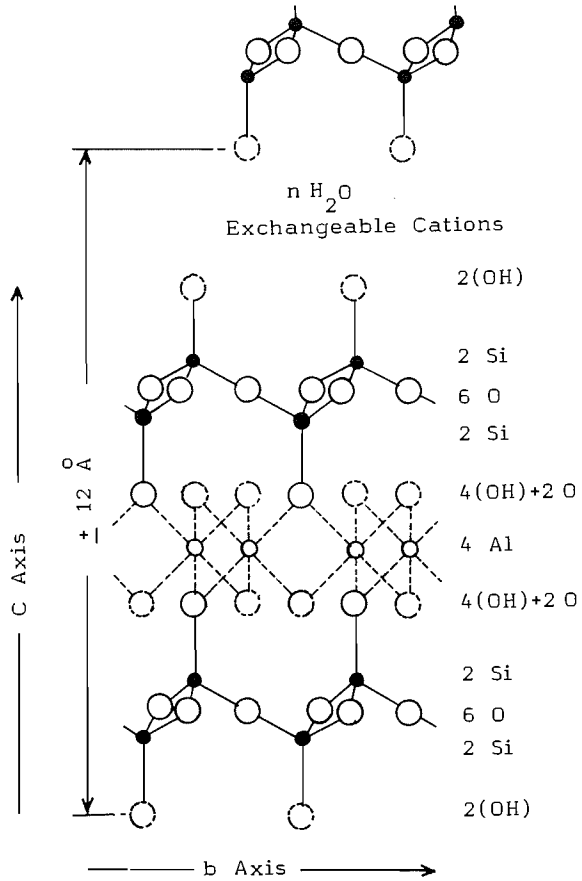

FIG. 1. Schematic presentation of the structure of montmorillonite (ref. 14).

to act as a host compound, and, therefore, it is possible to prepare intercalation compounds of the exchanged cations that are formed in the interlayer spaces along with water molecules (6, 30, 34, 35) (Fig. 1).

The treatment with 2,2′-bipyridyl (hereafter bipy) turns Cu(II)-montmorillonite to violet and Ni(II)-montmorillonite to pink-coloured materials. This indicates the interaction of the ligand molecules with cation-exchanged montmorillonite clay. Chemical analysis of the compounds is summarized in Table 1. The metal to ligand molar ratio is observed as 1:2 in both cases. This stoichiometric ligand content of intercalated compounds shows the formation of coordination compounds of Cu(II) and Ni(II) in montmorillonite. The IR absorption spectra of metal-exchanged montmorillonite show all the characteristic absorptions of montmorillonite clay (hereafter mnt) (Table 2). In addition to this, absorption due to coordinated water also appears in the case of metal-exchanged clay (Fig. 2). IR absorption spectra of intercalated compounds consist of several prominent absorptions, characteristic of bipy-complex with metal ions (Figs. 2, 3). These data have been presented in Table 2 along with their assignments. On comparison of IR spectra of the intercalated compounds with those of the free ligand (36–38) it is observed that the ring vibrations and other modes are shifted towards the higher energy side. This shift towards lower wavelength indicates the tightening of the ring on coordination through the nitrogen atoms of the ligand molecules. The Ni(II)-mnt compound also shows IR absorption due to coordinated water. A remarkable feature of the IR spectra of intercalated compounds is the broadening of the characteristic Si—O stretching absorption in comparison to that in metal-exchanged mnt. This absorption is directly related to the composition and structure of the silicate layers in mnt and is thus expected to alter with the changes in silicate layer (34, 39, 40). It is also established that the exchanged cations are present on the interlayer surfaces of the mnt (30, 34, 35). Chemical and IR absorption data suggest the formation of coordination compounds of the exchanged metal ions; therefore, the formation of these coordination compounds in the interlayer space of the clay structure may be predicted.

A significant increase in magnetic susceptibility of mnt is observed after exchange of metal ions (Table 1). This could be due to the incorporation of Cu^{2+} ions in mnt. The observed Bohr magneton value (μ_B) for bipy–Cu(II)-mnt is 2.18. Analytical data (Table 1) give the metal to ligand stoichiometry as 1:2. This ratio fits in well with the bidentate nature of the bipy ligand, satisfying the coordination number [4] for Cu(II). Square-planar is the most favourable geometry in a tetracoordinated Cu(II) complex. The presence of coordinated water in a Ni(II)-mnt intercalated compound suggests hexacoordinated nickel. The bipy adduct of Ni(II)-mnt has a μ_B value of 2.98. This value suggests the intercalated Ni ion in octahedral field corresponding to two unpaired electrons. Thus it may be concluded that the pres-

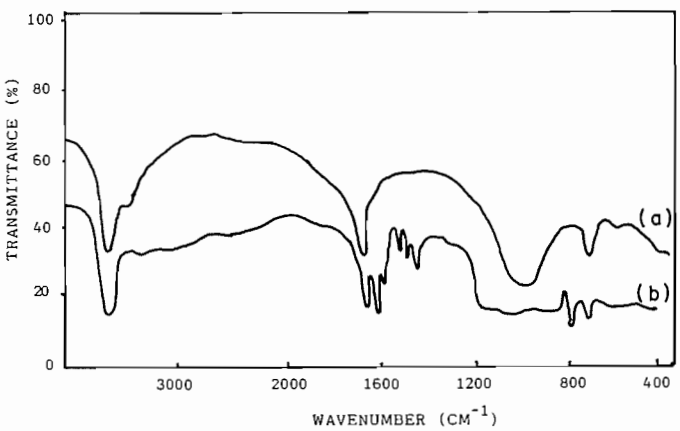

FIG. 3. IR absorption spectra: (*a*) Ni(II)-montmorillonite and (*b*) 2,2′-bipyridyl–Ni(II)-montmorillonite.

ent intercalated compounds show similarity in their magnetic behaviour to those of normal complexes of similar composition.

The position and orientation of intercalated compounds in layered clays can be investigated on the basis of X-ray diffraction patterns. The *c* lattice parameter (d_{001}) for a monoclinic cell of montmorillonite is dependent on its interlayer content, normally the interlayer water. A significant change in *c* value is reported with the change in interlayer content because of the inclusion of different cations/molecules in such available spaces of layered clays (9, 13, 17, 19–21, 30–32). In the present study the d_{001} spacing of montmorillonite clay is also, observed to be significantly changed after treatment with 2,2′-bipyridyl. The observed d_{001} spacing for 2,2′-bipyridyl–Cu(II)-montmorillonite is 18.3 Å. This shows that the interlayer is increased by 6.2 Å when compared with Cu(II)-exchanged montmorillonite (Table 3). Analytical and magnetic data for the $Cu(bipy)_2$-intercalated complex suggest square-planar geometry and bipyridyl planes parallel to the clay surface. Traynor *et al.* have also reported similar d_{001} spacing for bis-bipyridyl–copper complexes with hectorite, prepared by heating of a tris-bipyridyl–copper complex. The d_{001} value for 2,2′-bipyridyl–Ni(II)-montmorillonite is 18.8 Å. Thus an increase of 6.9 Å in the d_{001} spacing is observed after inclusion of 2,2′-bipyridyl molecules in Ni(II)-exchanged montmorillonite clay. Our analytical magnetic, thermal, and infrared absorption data suggest the formation of a hexacoordinated octahedral Ni(II) complex with chemical composition $[Ni(bipy)_2(H_2O)_2]^{2+}$. The estimated interlayer distance from the interatomic distances and the van der Waals radii (32, 45, 46) would be 6.40 Å for a pseudo-octahedral molecular model of the *cis* isomer of a complex molecule intercalated between two clay sheets with the bipyridyl planes parallel to the surface. X-ray diffraction and other investigations suggest that this is the most probable orientation of the Ni–bipy complex among the various possible orientations suggested by Cruz *et al.* (32). The Na-montmorillonite shows a d_{001} value of 10.3 Å while Ni(II)-

TABLE 3. d_{001} layer spacings of metal-exchanged montmorillonites and 2,2′-bipyridyl derivatives

Sample no.	Compound	d_{001} spacing (Å)
1.	Cu(II)-montmorillonite	12.1
2.	2,2′-Bipyridyl–Cu(II)-montmorillonite	18.3
3.	Ni(II)-montmorillonite	11.9
4.	2,2′-Bipyridyl–Ni(II)-montmorillonite	18.8

exchanged montmorillonite with interlayer-coordinated water gives d_{001} = 11.9 Å. This small difference in d_{001} could be due to "keying" of water molecules into the ditrigonal holes of the clay surface, as it is of small molecular size (7). Thus replacement of water molecules from interlayer spaces does not make a significant change in the interlayer spacings of the clay, as is evident from the thermal and X-ray diffraction data (Tables 1 and 3) of the intercalated compounds.

Thermogravimetric analyses of the intercalated compounds were carried out in order to investigate their thermal stability. Cu(II)- and Ni(II)-exchanged mnt show almost similar thermal decomposition patterns with about 19% weight loss up to ~180°C. This can be attributed to the loss of interlayer and coordinated water. The second weight loss step between 480 and 780°C is due to structural loss, i.e., breaking of OH groups (34, 41, 42). Intercalated compounds show an additional weight loss, which starts from 360°C in the case of the Cu(II) compound and from 470°C for the Ni(II) compound. In this major decomposition step the intercalated complex molecules break and oxidation of ligand takes place. The interlayer water content of metal-exchanged mnt is found to be significantly decreased after formation of intercalation compounds. This suggests the replacement of interlayer water of cation-exchanged montmorillonite by the bipy molecules. These intercalation compounds are observed to be thermally very stable in comparison to the corresponding complexes of Cu(II) and Ni(II) with similar composition (43, 44). This might be due to the silicate shielding of intercalated coordination compounds in the interlayer spaces of montmorillonite clay mineral.

Owing to the large-scale applications of intercalation and complex compounds in catalysis, N-fixation, medicines, and other important areas, the intercalation compounds of cation-exchanged expandable clays need to be explored thoroughly. Such compounds promise application as nitrogen-immobilizing and microencapsulating agents. It has been established that montmorillonite clay has extraordinary intercalation and retention properties; however, reported work (8–13, 19, 24, 25, 30) and the present study infer that these properties are even better in the case of a metal-exchanged clay mineral, particularly in respect of the substances that can form coordination compounds with those exchanged metal ions. High thermal stability of the intercalated compounds can be exploited in industrial applications. In this regard, the normal behaviour of the intercalated coordination compounds is remarkable.

Received February 26, 1992

HEMANT K. SINHA, S. MURALIDHARAN, and KEITH YATES. Can. J. Chem. **70**, 1932 (1992).

Electric field induced change in the absorption spectrum (electrochromism) has been employed to obtain the ground and excited state dipole moments of planar and sterically hindered (twisted) *p-N,N*-(dimethylamino)benzonitriles in dioxane solution. These studies support the twisted intramolecular charge transfer (TICT) hypothesis and provide additional insight to the TICT concept. The charge transfer nature of the excited state has been found to directly depend on the torsional angle of the *N,N*-dimethylamino group with respect to the benzonitrile moiety. It is suggested that solvent coupling is essential to initiate twisting by affecting the intramolecular degrees of freedom and the existence of the highly dipolar excited state is a result of such twisting of the donor–acceptor bond. Theoretical calculations have been performed to explain the observed changes in dipole moment values.

HEMANT K. SINHA, S. MURALIDHARAN et KEITH YATES. Can J. Chem. **70**, 1932 (1992).

On a utilisé le changement induit de champ électrique dans le spectre d'absorption (électrochromisme) pour obtenir les moments polaires des états fondamental et excité des conformations plane et stériquement empêchée (déformée) des *p-N,N*-(diméthylamino)benzonitriles, en solution dans le dioxane. Les résultats obtenus sont en accord avec l'hypothèse d'un transfert de charge intramoléculaire déformé (TCID) et ils fournissent des données supplémentaires pour comprendre le concept de TCID. On a trouvé que la nature du transfert de charge de l'état excité dépend directement de l'angle de torsion du groupe *N,N*-diméthylaminé par rapport à la portion benzonitrile. On suggère que le couplage de solvant est essentiel pour initier la déformation en affectant les degrés de liberté intramoléculaire et que l'existence d'états dipolaires hautement excités est un résultat d'une telle déformation de la liaison donneur/accepteur. On a effectué des calculs théorique pour expliquer les changements observés dans les valeurs des moments dipolaires.

[Traduit par la rédaction]

Introduction

The concept of twisted intramolecular charge transfer (TICT) has received considerable attention in the recent past owing to its intriguing characteristics (1). The most remarkable one is the idea that the charge transfer can be of maximum limiting value (complete one-electron transfer) when the molecular orbitals involved are orthogonally positioned rather than in the same plane, which was believed to be the case prior to the discovery of the TICT concept. This led to the proposition of a *minimum overlap rule*, which operates in certain types of molecules exhibiting TICT character.

The molecule that led to the foundation of TICT concept is *p-N,N*-(dimethylamino) benzonitrile (DMABN). This dates back almost to three decades when Lippert *et al.* reported the unusual nature of fluorescence from this molecule (2). However, the correct interpretation of results from Lippert's report was demonstrated by Grabowski *et al.* much later by their elegant experimental studies on the TICT concept (3). This mechanism suggests that the intramolecular charge transfer of the DMABN molecule is induced by rotation around the C—NMe_2 bond. The short-wavelength emitting species, identified with the planar form of DMABN, and the long-wavelength emitting species, the perpendicular form, are in equilibrium in the excited (S_1) state. Since then there have been numerous studies that have given this mechanism a strong basis.

However, controversy still exists regarding the role of solvent molecules in creating the TICT state (4, 5). For example, it has been proposed that local coupling of solvent molecules, with a particular local configuration, and the reactant (DMABN) is essential for the twisting of the C—NMe_2 bond (4*e*, 5). This is very clear from the fact that isolated DMABN molecules in the gas phase do not emit from the TICT state even when they are allowed to complex with a specific number of solvent molecules (6). On the other hand, the fact that 2,6-*N,N*-(tetramethylamino)benzonitrile (TMABN), which has the -NMe_2 group already twisted in the ground state, shows distinct TICT emission in the gas phase proves beyond reasonable doubt that internal twisting of the C—NMe_2 bond is the sole reason behind TICT emission (7). Recent results from advanced spectroscopic techniques suggest that solvent fluctuation plays a minor role, whereas the dominant contribution to intramolecular charge transfer involves fluctuations in the intramolecular degrees of freedom (8). If this is true, then the primary function of polar solvents in the formation of the TICT state is to induce twisting rather than charge transfer by disturbing the intramolecular vibrational modes. Once the twisting is achieved the resultant dipolar molecule can further interact electrostatically with solvent dipoles to produce strongly Stokes-shifted solvent dependent emission.

This paper attempts to clarify the above concept on the basis of experimental results obtained from electrochromic measurements. Electrochromism has been claimed to be the best method to probe the charge transfer characteristics of suitable molecules both in the ground and excited states (9). Both absorption and fluorescence electrochromic measurements are well documented in the literature (9, 10). The former method is employed here to examine the effect of internal twisting of the C—NMe_2 bond on the magnitude of

intramolecular charge transfer. Since this method looks at the vertical excited state, any contribution from solvent fluctuation modes to intramolecular charge transfer can be totally avoided. This has the advantage over fluorescence electrochromic methods because the latter probe the thermally relaxed excited state where the perturbation due to solvent coupling, if at all present, has already been manifested. However, comparison of results obtained from both methods will be useful in analysing the changes that take place when the molecule relaxes from its initially created vertical excited state to its thermally relaxed excited state. Our results mainly focus on the change in the dipole moment upon electronic excitation of planar vs. twisted DMABN systems and present a coherent picture that sudden polarization upon excitation can be achieved by orbitally decoupling the donor and acceptor groups and thereby affecting the intramolecular degrees of freedom. This study particularly emphasizes the fact that torsional motion of the C—NMe_2 bond should be initiated by solvent coupling during the relaxation from the initially created excited state. Theoretical dipole moments were also obtained from simple molecular orbital calculations and compared with the experimental values.

Theory of electrochromism

An intense electric field affects the intensity of both absorption and fluorescence, and such electric field effects were first quantitatively interpreted by Labhart (11), Czekalla (12), and Liptay (13) independently. The basic principles of electrochromic measurements with appropriate theoretical reasoning were reviewed by Liptay (*9b*). In addition, our previous papers also present a complete experimental and physical description of electro-optical absorption measurements on macroscopic systems (14). Hence this will not be repeated, but the basic principles will be summarized here.

For a dipolar molecule the perturbation due to the presence of an external electric field on the electronic absorption intensity is mainly due to two factors; (*i*) anisotropic molecular distribution and (*ii*) change in the electronic transition energy if the ground state dipole moment μ_g is different from the excited state dipole moment μ_e. The theoretical expression relating the change in extinction coefficient $\Delta\epsilon$ to the frequency ν of the incident light, the internal field strength F_{int}, and the angle χ between the direction of the applied field and the polarization direction of incident light, according to Liptay (*9b*), is

$$[1]\quad \Delta\epsilon = F_{int}^2\epsilon\left[A_\chi + B_\chi/15h\,\frac{\partial/\partial\nu(\epsilon/\nu)}{(\epsilon/\nu)} + C_\chi/30h^2\,\frac{\partial^2/\partial\nu^2(\epsilon/\nu)}{(\epsilon/\nu)}\right]$$

where

$$[2]\quad A_\chi = 1/30(3\cos^2\chi - 1)\beta^2[3(\hat{p}\cdot\mu_g)^2 - \mu_g^2]$$

$$[3]\quad B_\chi = 5\beta(\mu_g\cdot\Delta\mu) + (3\cos^2\chi - 1) \times \beta[3(\hat{p}\cdot\mu_g)(\hat{p}\cdot\Delta\mu) - (\mu_g\cdot\Delta\mu)]$$

$$[4]\quad C_\chi = 5\Delta\mu^2 + (3\cos^2\chi - 1)[3(\hat{p}\cdot\Delta\mu)^2 - \Delta\mu^2]$$

In these equations, $\hat{p}$ is a unit vector in the direction of the molecular transition moment, h is Planck's constant, and $\beta = (kT)^{-1}$ where k is Boltzmann's constant and T is the temperature.

Materials and methods

p-N,N-(Dimethylamino)benzonitrile (DMABN) was obtained from Aldrich chemicals. *N,N*-Dimethyl-2-(methylamino)benzonitrile (DMMBN) and *N,N*-2,6-(tetramethylamino)benzonitrile (TMABN) were prepared from the corresponding *p*-bromoaniline derivatives (obtained from Aldrich) by treating with CuCN, followed by *N*-methylation with freshly distilled dimethyl sulphate (15, 20*a*). All the compounds were recrystallized from appropriate solvents and the purity was checked by standard spectroscopic methods. Spectrograde dioxane and cyclohexane from Aldrich were used without further purification. Absorption spectra were recorded on a Cary 2000 spectrometer and their first and second derivatives (see eq. [1]) were computed numerically.

Ground state dipole moments

Dielectric constants and refractive indices of solutions were measured with a Dekameter (WTW GmbH DK 03), which uses resonance technique to measure cell capacitance, and a refractometer (Valentine 800) respectively. The μ_g's were calculated by the method of Guggenheim (16) as modified by Smith (17). Cyclohexane was used as solvent and all the measurements were done at 22°C. Assuming that $\xi \approx n_1^2$, Smith's equation for μ_g becomes

$$\frac{4\pi N}{9kT}\mu^2 = \frac{3M_1}{\rho_1}\left[\frac{a}{(\xi_1 + 2)^2} - \frac{c}{(n_1^2 + 2)^2}\right]$$

The subscript refers to the solvent, N is Avogadro's number, T is the temperature in K, M is the molecular weight in grams, ρ is the density in g/cm^3, ξ is the measured dielectric constant, and n is the refractive index. The parameters a and c are determined by assuming that the solution dielectric constant and refractive index vary linearly with mole fraction of the solute X_2 for dilute solutions, as

$$\xi_{solution} = \xi_1 + aX_2$$

$$n^2_{solution} = n_1^2 + cX_2$$

The complete dielectric constant data for the three compounds are compiled in Table 1.

Excited state dipole moments

The apparatus used for the μ_e determination has been described in detail elsewhere (14). The value of the effective external field F_{ext} is 3.768 × 10^4 V/cm for each molecule. The externally applied field was converted to an internal field by using the spherical cavity approximation (18), given by

$$F_{int} = F_{ext}\,\frac{3\xi}{2\xi + 1}$$

where ξ is the dielectric constant of the solvent. Since dioxane (ξ = 2.209) was used as solvent in the electric field experiment F_{int} = 1.224 F_{ext}.

For each molecule the electric field signals were collected at three different values of χ and for several wavelengths λ within the absorption band of interest. The experimentally obtained $\Delta\epsilon$, which is obtained from the equation

where ΔI is the difference in the transmitted light intensities in the presence and absence of the electric field, I is the transmitted light intensity in absence of the electric field, c is the concentration, and l is the path length of the electric field cell, was least-squares-fitted with the derivative terms, as shown in eq [1], to obtain the values of A_χ, B_χ, and C_χ. The contribution from the second derivative term (see eq. [1]) to the electric field signal was found to be very small, as observed for several other polar molecule (14, 19). Therefore this term has been neglected in the regression analysis. Finally, the molecular parameters were calculated from the slopes and intercepts of least-squares plots of A_χ and B_χ versus $(3\cos^2\chi - 1)$.

No correction was made for the effect of dipole reaction field or for the contribution of molecular polarizability to the electric field signal in the calculation of dipole moment parameters. Since these will be approximately of the same order of magnitude for each molecule studied here, direct comparison of their dipolar character will not be subject to serious error due to lack of the above corrections. In fact, a more detailed investigation on similar molecules shows that polarizability effects can be neglected as compared to dipole moments (20). Furthermore, recent electric field measurements comparing the gas phase and solution phase results on similar molecules show that the combined error due to lack of the above corrections amounts to less than 10% (21).

Theoretical calculations

The basic Hückel molecular orbital method was modified empirically as described earlier (14). The Coulomb integral H_{ii} and the bond integral H_{ij} terms used for heteroatoms, obtained after empirical modification, are given in Table 2. For the aromatic ring, standard values of H_{ii} and H_{ij} were used unmodified. The electron density distribution in the HOMO was used to calculate the ground state dipole moments. Excited state dipole moments were calculated by promoting one electron from the HOMO to the LUMO and recalculating the q_i terms. The calculated dipole moments are shown in Table 3. In addition, the symmetries of the calculated HOMO and LUMO could be used to predict the directions of the transition moments.

Results

The electric field signals for DMABN and TMABN at polarization angle $\chi = 0$ are shown in Fig. 1. The continuous lines in these figures were computed from the least-squares values of A_χ and B_χ using eq. [1]. The excellent agreement between the observed and calculated electric field spectrum suggests that eq. [1] adequately describes the field-induced changes in the absorption spectrum. The molecular parameters obtained from electric field experiments are compiled in Table 4. The dipole moment values reported from electro-optical emission measurements by Baumann and co-workers (20*b*, 22) are also shown in Table 4 for the sake of comparison.

The intensity of the strong charge transfer (CT) transition of DMABN (λ_{max} = 290 mm; ϵ = 26 870) was found to decrease significantly with a simultaneous red shift in the long wavelength absorption maxima upon twisting the C—NMe_2 bond by substituting the methyl group(s) at the *ortho* positions. Similar observations have also been reported for the *N*,*N*-dimethyl-4-nitroaniline system (19*b*). For DMMBN and TMABN the absorption maxima and the ϵ values are, respectively, 286 nm; 12 900 and 310 nm; 3450. Substitution of methyl group(s) at the 2 and 6 positions, as in TMABN, results in a ground state configuration where the -NMe_2 group lies in a plane that is twisted nearly 80° with respect to the phenyl plane (23). This angle would be close to 90° in the solution phase because of minimum steric repulsion. In the case of DMMBN, where only one *ortho* methyl group is substituted, this angle has been predicted to be nearly 40° (24), which is intermediate between 0° (DMABN) and 90° (TMABN) twist. The gradual decrease in the intensity of CT absorption upon increasing the twist angle could be explained on the basis of orbital decoupling of donor (D) and acceptor (A) groups, which inhibits the mixing of CT and LE (locally elicited) wave functions, consequently affecting the oscillator strength of the CT transition.

Further evidence for such decoupling comes from the μ_g values (see Tables 1, 3, and 4). Maximum resonance interaction in the planar form, where the D and A groups have maximum overlap of molecular orbitals, is the main reason for the high μ_g values observed for such systems. As a result, in such systems, μ_g generally exceeds the value predicted by the addition of corresponding group moments of the substituents. The μ_g values obtained by dielectric measurements, as shown in Table 1, indicate that μ_g decreases as the twisting angle increases. This behaviour is expected, since the contribution of ionic forms to the molecular wave functions in the HOMO will be maximum in the planar form (DMABN) and minimum for the perpendicular form (TMABN). This is also reflected in the calculated μ_g's obtained by the HMO method (see Table 3).

Assuming that these molecules belong to point groups of C_{2v} symmetry, which seems to be valid for DMABN and TMABN, the μ_g can be calculated from eq. [2]. This is because the dipole moment and the transition moment vectors must be either parallel or perpendicular in such a case. The μ_g values obtained by electrochromic measurements also manifest a similar trend (see Table 4); however, the magnitudes are smaller than those obtained from dielectric method. This discrepancy could be due to the uncertainty in the transition moment direction with respect to the dipole moment. However, a similar calculation done by Varma and co-workers using Baumann's experimental data shows better agreement in the μ_g's in the case of DMABN (25). The difference between the μ_g reported here and that by Varma for DMABN using the same method is nearly

[a]Obtained by assuming the $\hat{p}$ and μ_g are parallel (see eq 2).
[b]Obtained by electrochromism on the *b*-fluorescence band (S_1(sr) state) (see ref. 1*b*).
[c]Obtained by electrochromism on the *a*-fluorescence band (S_1(tict:sr) state) (see refs, 1*b*, 20*b* and 24). The μ_e value of DMMBN reported by Rotkiewicz (24) may have a large error due to strong overlap of *a*- and *b*-fluorescence.

5×10^{-30} C · m, which could arise due to the experimental uncertainties. This observation of decrease of dipole moment on deconjugation is in line with the generally accepted *maximum overlap rule*, which has always been understood to be the necessary condition for maximum charge transfer to occur.

However, μ_e values obtained by electrochromic measurements show a dramatically reversed trend (see Table 4). Similar results have also been reported from electro-optical fluorescence measurements (20). For example, the $\Delta\mu$ value, which is an absolute measure of the change in the charge distribution due to electronic excitation, reveals that CT is at a maximum when the orbitals involved are orthogonally positioned. Furthermore, comparison of values of $\Delta\mu$'s for the three compounds, where the twist angle is varied systematically, suggests that the extent of charge transfer in the excited state is directly related to the twist angle of the C—NMe_2 bond with respect to the benzene ring.

In all three cases the dipole moment and the transition moment vectors are found to be nearly in the same direction, i.e., along the direction of the long molecular axis. This

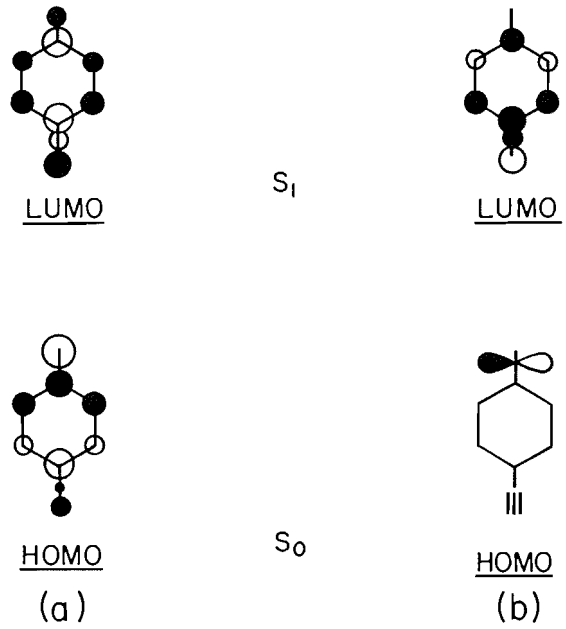

FIG. 2. Schematic drawings of the HOMO and LUMO of DMABN in both the planar (*a*) and perpendicular (*b*) conformations.

conclusion is made from the fact that for all three molecules the slope of A_χ vs. $(3\cos^2\chi - 1)$ plot was positive and large.

Even though a number of different types of semiempirical theoretical calculations have been reported, to rationalize the energetics of TICT formation (26), our attempt here employs a simple method to offer an explanation for the observed change in the dipole moments upon electronic excitation based on the molecular orbital diagram. The molecular orbital (MO) diagrams of planar and twisted DMABN systems are shown in Fig. 2. The symmetry characteristics of the HOMO and the LUMO obtained by this simple method are essentially the same as predicted by several other au-

thors (1*b*, 26), by adopting more sophisticated methods, such as PPP, CNDO, AM1, etc. It is apparent that the difference in the CT characteristics of the planar and twisted conformations arises primarily because of the specific localization of the HOMO and LUMO upon twisting the NMe_2 group. In the twisted conformation the electron density is completely localized on the NMe_2 group and the electronic excitation results in a LUMO where the charge localization is predominantly on the benzonitrile group. Therefore, electronic excitation results in extensive charge transfer from a pure -NMe_2 orbital to an antibonding orbital of the benzonitrile group. On the other hand, in the planar conformation both the HOMO and the LUMO have mixed character, where the charge is delocalized over the whole molecular skeleton. Hence the charge transfer upon electronic excitation is moderate. This is also indicated experimentally by a moderate change in the dipole moment upon electronic excitation. The calculated and the observed dipole moments (μ_g and $\Delta\mu$) essentially follow the same trend (see Tables 3 and 4).

As shown in Fig. 2, in the planar form the HOMO(b_2) to the LUMO(b_2) transition is A_1 type and hence, should be polarized along the M_z direction i.e., along the long molecular axis. However, other semiempirical methods that take into consideration configuration interaction (CI) predict that a B_1 type transition (M_x polarized), having a very low oscillator strength, will be the lowest energy transition and that the second transition is A_1 type with a very high oscillator strength (1*b*). The calculations also show that upon deconjugating the -NMe_2 group (twisted form) the ICT character of the ^1L_a state becomes more pronounced while the lowest energy transition becomes forbidden (A_2 type). This behaviour is also consistent with those predicted by other methods (1*b*, 26). It is worth pointing out that the simple calculations provide results that are very similar to those obtained by other theoretical methods, particularly in terms of the nature of the HOMO and the LUMO.

Discussion

The absorption and fluorescence characteristics of DMABN and TMABN can essentially be represented by the schematics shown in Fig. 3. The excitation of DMABN (initially planar) results in the normal fluorescence (F_b) from the state S_1(sr) (sr: solvent relaxed) and the second anomalous emission (F_a) originates from the state S_1(tict:sr) in polar solvents. From the solvent-dependent study (solvatochromism) it is evident that the intrinsic difference between these two emitting states is mainly in terms of polarity. This has also been directly identified by fluorescence electrochromic studies (20*b*, 22), which reveal that indeed the S_1(tict:sr) state is significantly more polar (16.2 D) than the S_1(sr) state (11.2 D). However, excitation of TMABN (initially nonplanar) results in direct population of the TICT state, and therefore only the band corresponding to F_a in DMABN is observed both in polar and nonpolar solvents (Fig. 3*b*). The observed μ_e ($\approx$15 D) from electrochromic fluorescence measurements also reflects a magnitude similar to that observed for the S_1 (tict:sr) state of DMABN. These observations provide clear evidence for the fact that F_a originates from a geometry that is twisted in the excited state and has a large intramolecular charge transfer character.

However, what is still ambiguous is the question of how the role of solvent can be defined in creating the TICT state

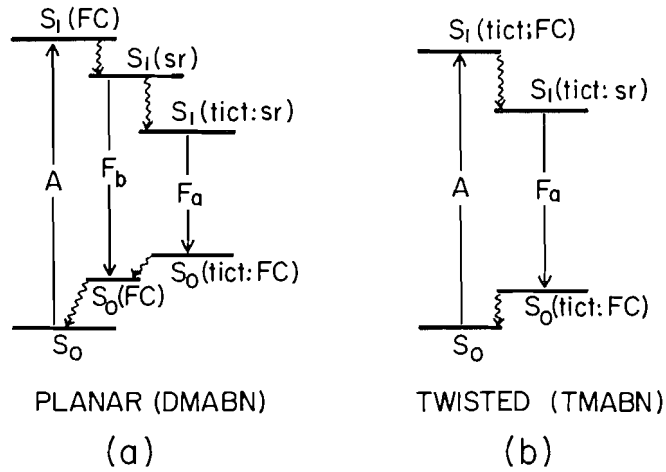

FIG. 3. Schematic representations of the absorption and fluorescence processes in planar and sterically hindered (twisted) conformations of DMABN showing the origin of the normal (F_b) and anomalous (F_a) fluorescence. (*a*) In planar DMABN, absorption of photons results in a planar Franck–Condon excited state (S_1(FC)). Emissions F_b and F_a occur from a solvent-relaxed planar excited state (S_1(sr)) and a solvent-relaxed twisted excited state (S_1(tict:sr)) respectively to give a FC ground state having a planar geometry (S_0(FC)) and a FC ground state having twisted geometry (S_0(tict:FC)). (*b*) In twisted DMABN (TMABN), absorption of photons results in a twisted FC excited state (S_1(tict:FC)) and the only emission F_a occurs from a solvent-relaxed twisted excited state (S_1(tict:sr)).

from the planar molecule. Does it have a direct role or an indirect one? The fact that solvent plays a direct role comes from the following experiments. Experimental studies on DMABN in a supersonic jet expansion show that isolated molecules show only F_b fluorescence and hence do not undergo twisting (6). Further evidence from spectroscopic and picosecond studies indicates that a short-range coupling interaction between a specific number of solvent molecules and the solute, either in the ground or exited state, is essential for TICT formation (4*e*, 5).

On the other hand, the fact that solvent does not play a major role can be argued on the basis of the fact that excitation of TMABN in a supersonic jet expansion gives prompt TICT emission even in the absence of the solvent (7). Furthermore, recent time-resolved emission studies to determine the electron transfer rate in DMABN indicate that the dominant contribution to the electron transfer rate comes from the fluctuation in intramolecular degrees of freedom and solvent fluctuation seems to play a minor role, though this seems to depend on the nature of the solvent (8).

Our results on experimental dipole moments may be considered as a method of resolving the above question and provide additional insight into the TICT concept. Since the measurements were done on the absorption spectrum, here we deal only with the Franck–Condon (FC) excited state. This is unlike the electro-optical fluorescence studies, which investigate the solvent-relaxed excited state, where all information concerning the transition from the S_1(FC) to the S_1(tict) state may be lost. In the FC excited state one would expect that the surrounding medium would be in the same arrangement as in the solvent-equilibrated ground state. Therefore, the solvent fluctuation mode, which would contribute to fluorescence electrochromic measurements, will not be of concern here.

The three model molecules studied here have different torsional angles between the -NMe_2 group and the phenyl ring, which range from 0° in the case of DMABN to nearly 80° in the case of TMABN. It can be clearly seen from Table 4 that as the torsional angle increases μ_g decreases, whereas $\Delta\mu$ and μ_e increase significantly. These dipole moments are a direct measure of the charge transfer. Since the solvent system remains the same, it can be concluded that it is the torsional angle which directly influences $\Delta\mu$. This observation is in agreement with the gas phase measurements, which clearly indicate that CT in the excited state is linked to the twisting of the phenyl–dimethylamino bond (6, 7).

Since the charge separation can be directly achieved in the vertical excited state it could be termed a sudden polarization, as indicated earlier by Salem (27). It is also clear that sudden polarization is more effective when the orbitals involved in charge transfer are totally decoupled. A direct comparison between our results and those from fluorescence electrochromism measurements (see Table 4) indicates that the solvent relaxation around the excited state dipole does not drastically affect the magnitude of charge transfer. In fact, within experimental uncertainty, μ_e(FC $\approx$ μ_e(sr) and μ_e(tict: FC) $\approx$ μ_e(tict: sr).

These results seem to provide a clear picture in regard to the role of the solvent in the TICT formation in DMABN. Since the charge transfer, as evident from $\Delta\mu$ and μ_e, is induced by twisting, it is not unreasonable to conclude that a polar solvent induces twisting motion by affecting the intramolecular degrees of freedom, and the result of such twisting motion is extensive charge transfer. Our explanation is in accord with those results reported by Su and Simon based on time-dependent spectroscopic studies (5), in which they suggested that fluctuations in the sorrounding solvent polarization may not play a dominant role in the rate of electron transfer in DMABN and the main contribution to the rate comes from the fluctuations in intramolecular vibrational coordinates. These results were interpreted in terms of the dynamical electron transfer theories of Nadler and Marcus (28), which address the influence of fluctuations in both solvent polarization and intramolecular vibrational coordinates on the rate of electron transfer. We would stress that this is different from solvent-induced charge transfer, where the solvent is directly involved, i.e., in cases where the rate of electron transfer correlates directly with the inverse of longitudinal relaxation time of the solvent (29). Since, μ_e(FC) is different from μ_e(tict), the TICT state should continuously evolve along the solvent relaxation coordinate in DMABN, which would be the prime reason for the time-dependent shift in the emission spectrum. Finally, the charge-separated species will be further stabilized by strong electrostatic interaction with the solvent, which would account for the strong solvent dependency of the emission spectrum of DMABN. This explanation also fits well with the recent theoretical model by Schenter and Duke, which was used to simulate the twisting dynamics of DMABN in polar solvent (30). In the case of TMABN, the TICT state charge distribution is directly produced in the FC excited state and then it responds to the electrostatic interaction with solvent. This phenomenon is strongly corroborated by the results obtained by Baumann and co-workers (20, 22). The strong solvent-dependent dipole moment obtained by electro-optical emission studies (20) can only be explained on the basis of a solvent-polarity-dependent average torsional angle around the phenyl to dimethylamino group bond since the magnitude of induced dipole moment has been found to be very small. Their results show excellent agreement with the results reported here.

It is very apparent from these results that the disturbance in the intramolecular degrees of freedom, which results in twisting, comes as a result of coupling of polar solvent molecules with the DMABN. *The solvent coupling is essential for the twisting motion and twisting is the requirement for strong charge transfer*. This explanation provides a consistent picture that the TICT state originates from a conformation where the -NMe_2 group is forced into a position nearly orthogonal to the phenyl plane.

The theoretical results reported here are almost parallel to those predicted by other methods, except for the fact that our approach is very simple. The dipole moments calculated are in fair to good agreement with the observed values and show similar trends. These values, combined with those recently obtained for several nitroaromatics (14*b*, 19*b*,*c*) suggest that this method can be used as a tool in predicting the charge transfer behaviour of molecules both in the ground and excited states. The difference in the charge transfer nature of the planar and twisted systems is a reflection of the nature of the HOMO and LUMO involved in the electronic transition. This can be seen from the fact that charge transfer can be directly related to the ionization potential (IP) and electron affinity (EA), whose values are dependent upon the nature of the HOMO and LUMO respectively (19*b*). A change in these values, which can be produced by deconjugating the functional groups, makes a direct impact on the charge transfer characteristics.

Introduction

Steroidal cardiotonic glycosides are of considerable importance in the treatment of heart disease (1, 2). However, the naturally occurring cardenolides show a rather narrow margin of safety as most patients receive 60% of the toxic dose (3). Cardenolides have thus stimulated several structural (4) and synthetic (5, 6) studies. In most synthetic studies, steroidal starting materials were employed (5) while in others (6), the construction of the skeleton was carried out by total synthesis via an intramolecular aldol addition of ABD tricyclic compounds. In the last approach, the tricyclic aldol precursors used were all synthesized via a modification of the original Torgov sequence (7).

An original report from our laboratories described the one-step stereocontrolled synthesis of 14α-hydroxy steroid **3** (Scheme 1) via a new polycyclization method (8). Anionic cycloaddition of 2-carbomethoxycyclohex-2-en-1-one (**1**) and cyclopentane-1,3-dione β-ketoester **2** first gave enolate **4** bearing three new stereocontrolled centers (9). This enolate was then trapped *in situ* to give tetracyclic compound **5** which gave 14α-hydroxy steroid **3** after selective decarboxylation. Further investigations allowed us to find two ways to correct the stereochemistries of the C13 and C14 carbon centers into the more desired 13β-methyl 14β-hydroxy configuration. The first way involved aldol addition of dienol **6** that gave a 3:2 mixture of steroids **7** and **8** as previously described in this journal (10). We also synthesized optically active 14β-hydroxy steroid **11** from anionic cycloaddition of chiral precursors **9** and **10***a* (11). This account describes the detailed synthesis of (+)-methyl 17β-benzoyloxy-14β-hydroxy-3β-methylethenyl-1,7-dioxo-5β-androstan-19-oate (**11**) as well as other results observed in the synthesis of related compounds. Preliminary results indicating that optically active 14β-hydroxy steroids can be synthesized from achiral cyclopentane-1,3-dione β-ketoester **2** and chiral cyclohexenone **9** are also included.

Results and discussion

1. Synthesis of substituted Nazarov reagents ***10****a and* ***10****b*

The synthesis of the requisite chiral substituted Nazarov reagent **10***a* (R = COPh) is depicted in Scheme 2. The sequence was also applied to *tert*-butyl ether **10***b* (R = $C(CH_3)_3$). Ozonolysis (12) of chiral enone **12** (13) gave ketoacid **13** in 71% yield. Selective borane reduction (14) of ketoacid **13** gave ketoalcohol **14** existing in solution as a 4:1 mixture of ketone-hemiketal forms. Diol **15***a* (**14***a*: **15***a*, 5.6:1) was also isolated from the reaction. This was obviously not a problem since the following oxidation step involving **14** and **15** gave the same desired ketoaldehyde **17**. Nevertheless, the absolute configuration assigned to the secondary carbinolic center in **15***a* was secured with the formation of its tribenzoylated derivative.

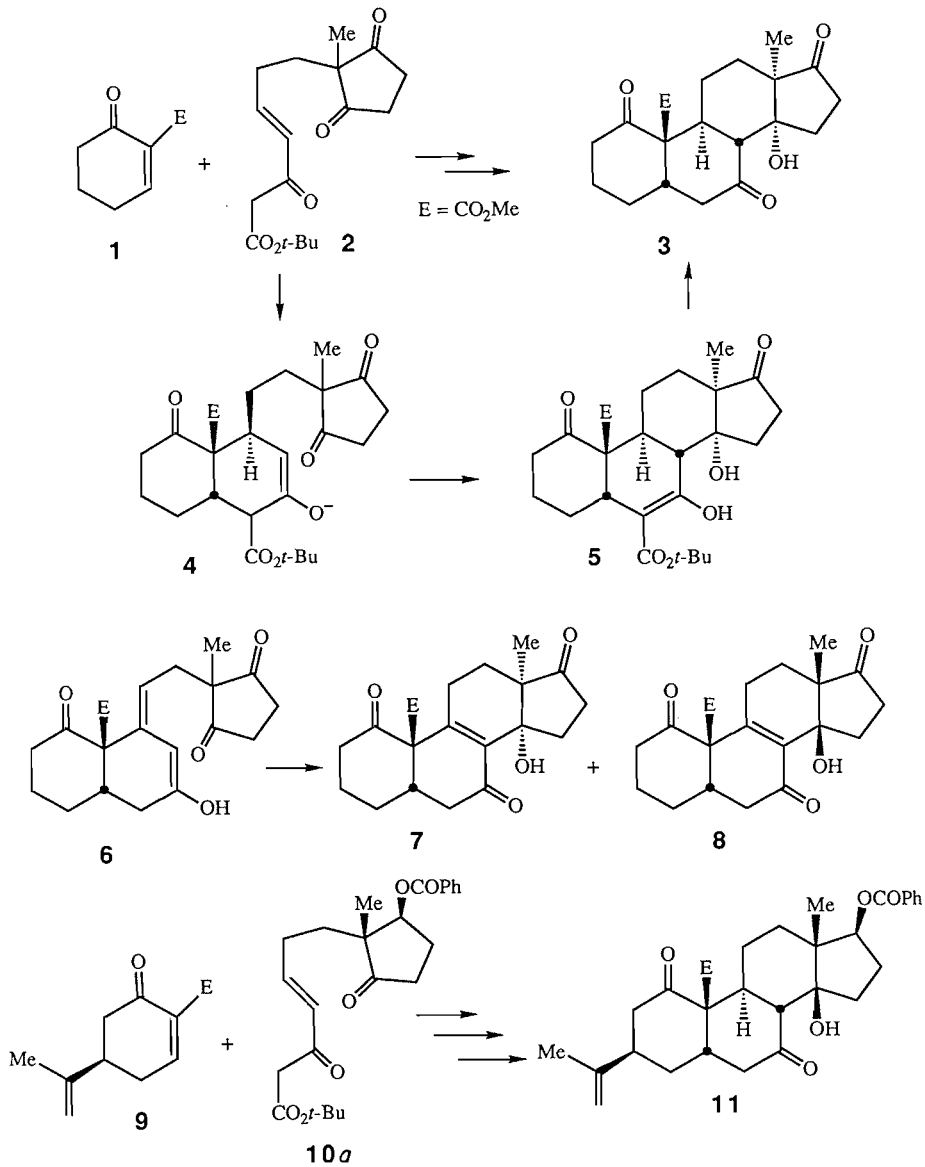
Dibenzoylation of diol **15***a* gave indeed tribenzoate **16**. The alternative *meso* structure was ruled out based on the following arguments. The methynes of the five-membered ring are not equivalent in the ^1H nmr spectrum and compound **16** is optically active ($[\alpha]_D^{25}$ +80.8 (*c* 1.3, $CHCl_3$)). Oxidation of the 5.6:1 mixture of alcohols **14** and **15** with pyridinium chlorochromate (15) then gave ketoaldehyde **17** in 50% yield from enone **12**. This aldehyde was treated with (formylmethylene)triphenylphosphorane (16) to give *trans* unsaturated aldehyde **18** along with traces of undesired *cis* isomer. The Reformatsky reagent of *tert*-butylbromoacetate was then added to unsaturated aldehyde **18** and the resulting diastereoisomeric allylic alcohols **19** were converted into the desired substituted Nazarov reagent **10** upon oxidation with manganese dioxide. Comparable yields for the transformation of enone **12** to β-ketoester **10** were obtained in both series (*a*, R = COPh and *b*, R = $C(CH_3)_3$) (25% overall).

2. Cycloadditions of 2-carbomethoxycyclohexenones with substituted Nazarov reagents

To compare the reactivity of substituted Nazarov reagents **10** with cyclopentanedione β-ketoester **2** (8), we first carried out the cycloaddition of *tert*-butyl ether **10***b* with 2-carbomethoxycyclohex-2-en-1-one (**1**) (Scheme 3). As will be evidenced by the following results, this model experiment clearly shows that, contrary to the case involving reagent **2**, polycyclization did not occur since no tetracyclic compound was obtained from the reaction. The reaction of precursors **1** and **10***b* with cesium carbonate in chloroform gave (after acid treatment that induced decarboxylation and cleavage of the *tert*-butyl ether) a ≈1:1 mixture of two diastereoisomers in 44% yield (two steps). One diastereoisomer has structure **20** whereas the other has the same absolute configuration around the five-membered ring, but with the opposite configuration at C5, C9, and C10. Upon oxidation with tetrapropylammonium perruthenate (17), this diastereoisomeric mixture led to racemic tetraketone **21** in 61% yield. Thus, while anionic cycloaddition of reagents **1** and **2** gave tetracyclic compound **5** (8), reaction of **1** and **10***b* did not yield directly any steroidal skeleton.

Cycloaddition of **1** and **10***b* generated enolate **22**, which,

[1]Author to whom correspondence may be addressed.



SCHEME 1

unlike enolate **4**, did not cyclize *in situ*, probably because isomerization to conjugated enolate **23** took place predominantly. Enolates related to **4** also failed to react in the polycyclization process as indicated by other results obtained in our laboratory (18).[2] The above results led us to reexamine the original polycyclization result (**1** + **2** → **5**). Although the direct formation of tetracyclic compound **5** was supported by strong spectroscopic arguments (19), these new results prompted us to find supplementary evidence. The crude compound obtained from cycloaddition of **1** and **2** was directly treated with sodium hydride and diethyl chlorophosphate in tetrahydrofuran (20, 21) to yield enol phosphate **24** in 76% yield (based on recovered starting material, see Experimental). Compound **5** was thus directly formed in a polycyclization process.

The chiral cyclohexenone **9** (Scheme 4), synthesized as previously described (18, 22), and compound **10***a* were treated with cesium carbonate in chloroform giving, after decarboxylation, triketone **25** (60% yield), which was obtained pure by chromatography. The cesium carbonate-catalyzed aldol condensation was then carried out in refluxing acetonitrile and produced 14β-hydroxy steroid **11** in 32% yield (47% based on recovered starting material). Although this reaction proceeded in low yield, it should be pointed out here that steroid **11** was the only new product formed in the aldol reaction we found to be at equilibrium. In fact, when the purified steroid **11** was resubmitted to the reaction conditions, a 1:1 mixture of compounds **25** and **11** was obtained. Structure **11** was secured by a single crystal X-ray analysis.[3]

Our next task then consisted in finding ways to improve the yield of the aldol reaction carried out on triketone **25**. All attempts to improve the yield by modifications of reaction conditions proved unsuccessful, but one case led to a very

interesting observation. Thus, warming a solution of potassium bis(trimethysilyl)amide and triketone **25** in tetrahydrofuran did not afford the expected *trans* (C8—C9) steroid **11**, but a new aldol product for which we have proposed structure **26** having the *cis* C8—C9 junction. Compound **26** was converted to **11** (Cs_2CO_3, CH_3CN, reflux) while dehydration under acidic conditions (PTSA, benzene, reflux) of both **11** and **26** gave the same compound **33** (Scheme 5). Also, compound **26** was further characterized through its conversion to the silyl ether derivative **27**. The implications of this observation on the aldol reaction transition state will be discussed in Sec. 3. To improve the yield of the aldol reaction, we also considered modifications on triketone **25**. Compounds **28** and **29** were then synthesized from benzoylated triketone **25**. Thus benzoate cleavage (MeONa, MeOH) gave alcohol **28** (73%), which afforded carbonate **29** (71%) upon treatment with phenyl chloroformate in pyridine. The cesium carbonate-catalyzed aldol condensation carried out on alcohol **28** gave diol **30** in low yield (30%). It was hoped that intramolecular hydrogen bonding between hydroxyl groups in **30** could eventually shift the equilibrium aldol reaction but starting material was again recovered as a result of the reversibility of this reaction. This idea was, however, the basis for the synthesis of carbonate **29**. Upon aldol condensation, the equilibrium reaction would hopefully be shifted through formation of six-membered ring carbonate **31**. Therefore, the cesium carbonate-catalyzed aldol condensation was then carried out on carbonate **29** and, as expected, starting material was totally consumed. However, six-membered ring carbonate **31** could not be isolated because of an elimination that gave allylic alcohol **32** (51%) and carbon dioxide.

Acid-catalyzed aldol condensation was also carried out on benzoate **25** and carbonate **29** (Scheme 5). Reaction of **25** and *p*-toluenesulfonic acid in refluxing benzene gave compound **33** in 77% yield. In this case, not only did dehydration occur but the C3 isopropenyl substituent also isomerized to the cyclohex-2-en-1-one **33**. Acid-catalyzed aldol condensation of carbonate **29** gave bis-enones **34** (74%) in a similar manner.

*3. Cycloaddition of chiral 2-carbomethoxycyclohexenone **9** with achiral substituted Nazarov reagent **2***
Application to the synthesis of 14β-hydroxy steroids

We described in Scheme 1 the one-step stereocontrolled construction of a 14α-hydroxy steroid from cycloaddition of compounds **1** and **2** (8). Our next goal was then to study the reactivity of chiral cyclohexenone **9** with achiral substituted Nazarov reagent **2**. Thus, a 1:1 mixture of tetraketone **35** and 14α-hydroxy steroid **36** (44% total yield, two steps) was obtained from selective decarboxylation of the cycloaddition product resulting from the reaction of precursors **2** and

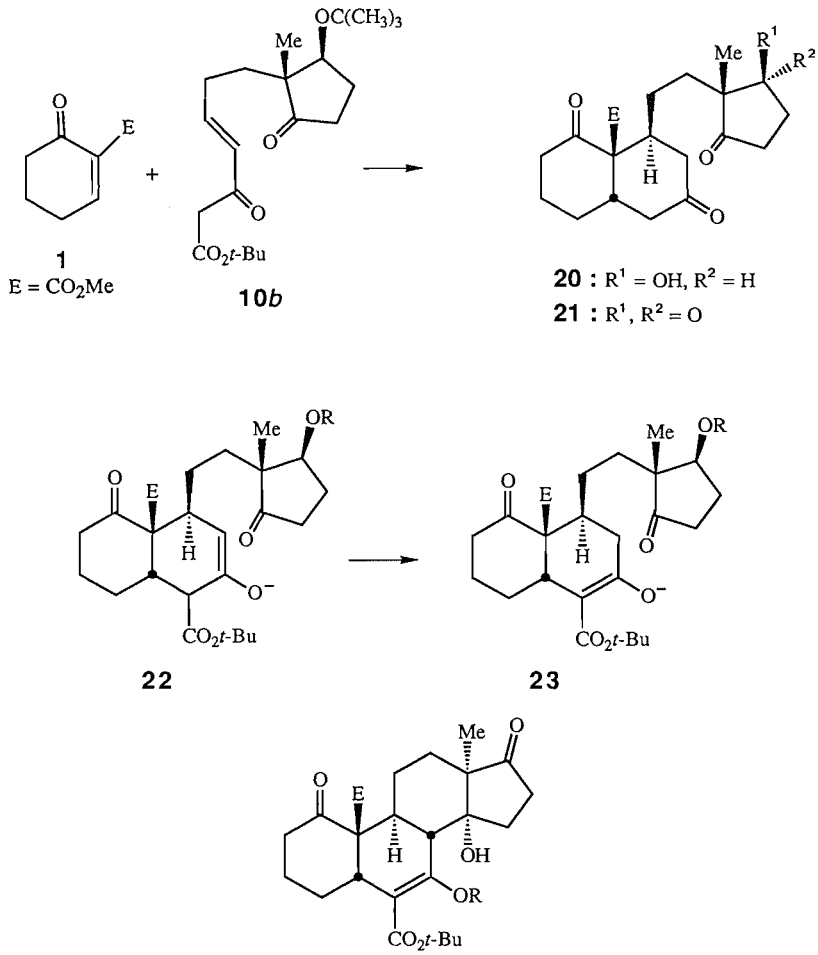

SCHEME 3

9 (Scheme 6). No tetraketone product (like **35**) was obtained in the previous reaction (**1** + **2** → **3**). This difference in reactivity might be explained on the following basis: as previously stated (8), tetracyclic compound **5** is likely to be formed from intermediate enolate **39** (Scheme 7); similarly, steroid **41** would arise from enolate **40** and decarboxylation of **41** would then give steroid **36**. The C3 isopropenyl substituent in **40** may, however, induce conformational change to **42**. If so, such conformational bias may then allow sufficient time for isomerization of the enolate to the more stable (C6—C7) position and a tetracyclic compound cannot be formed if such isomerization occurs.

With respect to the synthesis of 14β-hydroxy steroids, tricyclic compounds like **35** may be of considerable importance as suggested by the following preliminary results. Base-catalyzed aldol condensation (6) of tetraketone **35** gave 14β-hydroxy steroid **37** having a *cis* relationship between C8 and C9 carbon centers (Scheme 6). Equilibration of steroid **37** gave 14β-hydroxy steroid **38**. The structure of the latter compound was ascertained by chemical correlation since it was obtained from 14β-hydroxy steroid **11** by methanolysis and oxidation (see Experimental). Although the yield (29%) of the aldol condensation reaction (**35** → **37**) remains yet to be optimized, the synthesis of enantiomerically pure 14β-hydroxy steroid **37** (or **38**) is of interest since six new stereocenters were controlled starting from a single asymmetric center (i.e., **9** + **2** → **35** → **37**). Also, *cis* (C8—C9) isomer **37** could, like **26**, be effectively isolated. Compounds **26** and **37** were both showing a rather interesting characteristic in their ^{1}H nmr spectrum. They both displayed a doublet ($J \approx$ 2 Hz) for the tertiary alcohol, that usually stands as a singlet. A possible explanation for this is apparent considering the rigid structure **43** (Scheme 8). This phenomenon could originate from a W-type coupling between Hα at C15 and the hydroxyl group that would be involved in hydrogen bonding with the C7 carbonyl oxygen.

The formation of the *cis* B–C ring junction in products **26** and **37** must involve aldol addition on the β face of enolate **44**. Such aldol reaction would be precluded in the case of enolate **45** because of severe steric interactions involving the axial *tert*-butyl ester group (Scheme 8). Aldol addition on the β face of enolate **46** to give the *cis* B–C ring junction could also take place following stereoelectronic control requirements (23). However, the formation of *cis* B–C ring products **26** and **37** probably comes from the reaction on conformation **44** rather than **46**, because the resulting aldol

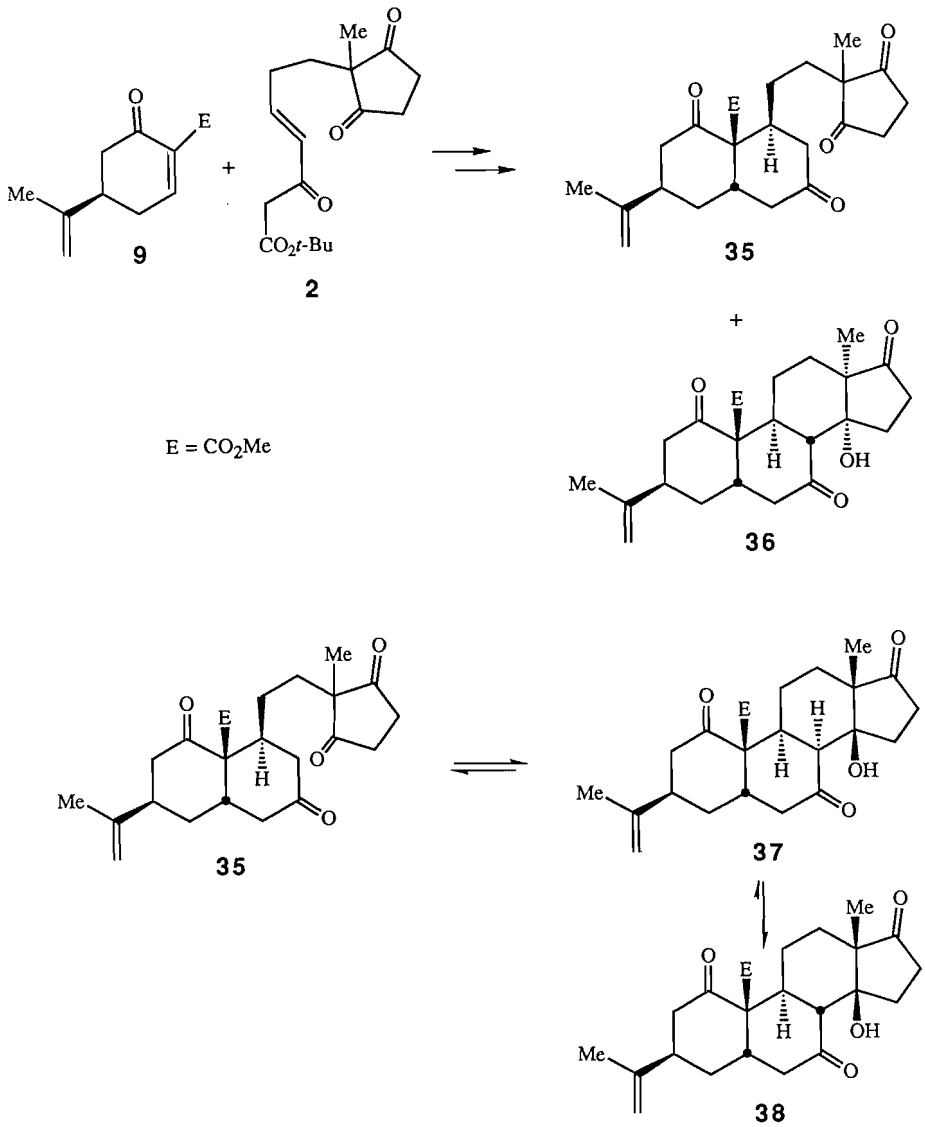

SCHEME 6

compound is produced having rings B and C in a chair conformation in the former case and in a boat conformation in the latter. In conclusion, the above considerations show that the stepwise synthesis of tetracyclic compounds **37** and **38** was by far more advantageous than the (synchronous) polycyclization leading to **41** (and **36** after decarboxylation) as only the former afforded 14β-hydroxy steroids.

Experimental

Melting points were determined on a Reichert Hot Stage apparatus and are uncorrected. Chromatographic separations were made using Merck Kieselgel 60 (230–400 mesh ASTM). The infrared (ir) spectra were taken on a Perkin–Elmer 681 spectrophotometer. Proton nuclear magnetic resonance (^{1}H nmr) and carbon (^{13}C nmr) spectra were recorded on a Bruker WM-250 instrument. Chemical shifts are reported in δ values relative to chloroform as internal standard. The following abbreviations have been used: s, singlet; d, doublet; t, triplet, dd, double doublets; m, multiplet; br, broad. Mass spectral assays were obtained using a VG Micromass ZAB-1F spectrometer. Optical rotation values ($[\alpha]_D$) were determined at 25°C in a 1-dm cell on a Perkin–Elmer 141-B polarimeter with chloroform as solvent. All reactions were carried out under an argon atmosphere unless otherwise noted.

*Ketoacid 13*a

Ozone is bubbled into a cold (−78°C) solution of enone **12***a* (10 g, 37.0 mmol) in methanol (200 mL) for 2.5 h (although the solution becomes bluish after 5 min, ozone bubbling is maintained until TLC analysis shows disappearance of starting material). Dimethyl sulfide (13.6 mL, 0.19 mol) is then added and the resulting yellow solution is stirred at room temperature for 12 h. Saturated sodium bicarbonate solution is then added until pH reaches 7 and the solution volume is reduced to 25% by evaporation under reduced pressure. Water (100 mL) and sodium periodate (9.0 g, 42.1 mmol) are added to the resulting mixture and the new mixture is vigorously stirred at room temperature for 2 h. The mixture is extracted with methylene chloride (5 × 100 mL) and the combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated. The crude ketoacid **13***a* can be used without purification but pure material can be obtained by liquid–liquid extraction involving the carboxylic acid salt of **13***a*: 1 N sodium hydroxide solution (37 mL) is added at 0°C to the crude ketoacid **13***a* (10.7 g, 37 mmol) in methylene chloride. The separated aqueous layer is acidified (pH = 2) with hydrochloric acid and ex-

Ketoacid ***13****b*

Ketoacid **13***b* is synthesized from enone **12***b* following the same procedure; ir (CH_2Cl_2, ν cm^{-1}): 3680–2400 (OH), 1750–1700 (C=O ketone and acid); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 3.87 (1H, t, J = 5.8 Hz, -C*H*OC(CH_3)$_3$), 2.53–1.71 (8H, m), 1.19 (9H, s, -C(C*H*$_3$)$_3$), 0.96 (3H, s, -C*H*$_3$); ms, *m/e*: 242 (weak, M^+), 186 ($MH^+-C_4H_9$). Exact Mass calcd. for $C_9H_{14}O_4$ ($MH^+-C_4H_9$): 186.0892; found: 186.0891.

Ketoalcohol ***14****a*

A solution of carboxylic acid **13***a* (11.3 g, 39.0 mmol) in tetrahydrofuran (250 mL) is added to a cold (0°C) stirred solution of borane–THF complex (1 M/THF, 40 mL) in tetrahydrofuran (250 mL). After stirring for 2 h at 0°C, water (100 mL) is added and the separated aqueous layer is extracted with ethyl acetate (5 × 200 mL). The combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated. The crude product is used without further purification. Pure materials may, however, be obtained by flash chromatography (ethyl acetate – hexane, 4:1) of a portion of the residue which yields a 5.6:1 mixture of alcohol **14***a* and diol **15***a*. Ketoalcohol **14***a*: $[\alpha]_D$ +36.3 (*c* 1); ir (CH_2Cl_2, ν cm^{-1}): 3620, 3500 (OH), 1745 (C=O ester), 1720 (C=O ketone); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 8.01, 7.56, 7.45 (5H, 3m, -C$_6$*H*$_5$), 5.52 (1H, t, J = 5.0 Hz, -C*H*OCOC$_6$H$_5$), 3.62 (2H, m, -C*H*$_2$OH, becomes t, J = 5.9 Hz upon exchange with D_2O), 2.45–1.56 (8H, m), 1.13 (3H, s, -C*H*$_3$), and the following signals can be attributed to the hemiketal form: 5.65 (<1H, br t, J = 6.2 Hz, -C*H*OCOC$_6$H$_5$), 1.11 (<3H, s, -C*H*$_3$); ^{13}C nmr (62.9 MHz, $CDCl_3$) δ ppm: 218.9, 165.8, 133.2, 129.5, 128.5, 103.5, 77.9, 76.5, 62.6, 60.9, 52.3, 35.7, 34.7, 31.5, 27.3, 27.1, 25.5, 25.3, 20.9, 18.5, 15.9; ms, *m/e*: 277 (MH^+), 261 (M^+-CH_3), 258 (M^+-H_2O). Exact Mass calcd. for $C_{16}H_{21}O_4$ (MH^+): 277.1440; found: 277.1434. Diol **15***a*: ir (CH_2Cl_2, ν cm^{-1}): 3620, 3400 (OH), 1715 (C=O ester); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 8.03, 7.55, 7.44 (5H, 3m, -C$_6$*H*$_5$), 5.24 (1H, dd, J = 8.5, 6.5 Hz, -C*H*OCOC$_6$H$_5$), 4.00 (1H, dd, J = 6.0, 2.4 Hz, -C*H*OH), 3.67 (2H, m, -C*H*$_2$OH), 2.45–1.47 (8H, m), 1.04 (3H, s, -C*H*$_3$); ms, *m/e*: 279 (MH^+). Dibenzoylation of this diol **15***a* gives tribenzoylated derivative **16**. Tribenzoate **16**: $[\alpha]_D$ +80.8 (*c* 1.3); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 8.04, 7.90, 7.45 (15H, m, 3 × -C$_6$*H*$_5$), 5.36, 5.26 (2H, 2m, 2 × -C*H*OCOC$_6$H$_5$), 4.26 (2H, m, -C*H*$_2$OCOC$_6$H$_5$), 2.60–1.60 (8H, m), 1.22 (3H, s, -C*H*$_3$); ms, *m/e*: 486 (M^+), 381 ($M^+-COC_6H_5$), 365 ($M^+-OCOC_6H_5$). Exact Mass calcd. for $C_{30}H_{30}O_6$ (M^+): 486.2042; found: 486.2038.

Ketoalcohol ***14****b*

Ketoalcohol **14***b* is synthesized from ketoacid **13***b* following the procedure described for the synthesis of ketoalcohol **14***a*. Ketoalcohol **14***b*: ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 3.95 (1H, t, J = 6.0 Hz, -C*H*OCC(CH_3)$_3$), 3.60 (2H, m, -C*H*$_2$OH), 2.53–2.40 (8H, m), 1.19 (9H, s, -C(C*H*$_3$)$_3$), 1.15 (<9H, s, -C(C*H*$_3$)$_3$, hemiketal form), 0.96 (3H, s, -C*H*$_3$), 0.88 (<3H, s, -C*H*$_3$, hemiketal form).

Aldehyde ***17****a*

To a stirred solution of crude alcohol **14***a* (10.8 g, 39.1 mmol) in methylene chloride (200 mL) at room temperature is added pyridinium chlorochromate (25.2 g, 117.4 mmol). After stirring at room temperature for 3 h, the mixture is diluted with ether (1.5 mL) and filtered on silica gel. Concentration under reduced pressure and flash chromatography (ethyl acetate – hexane, 2:3) of the resulting residue yields 5.4 g (50% from enone **12***a*) of aldehyde **17***a*; $[\alpha]_D$ +43.1 (*c* 4); ir (CH_2Cl_2, ν cm^{-1}): 1740 (C=O ester), 1720 (C=O ketone and aldehyde); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 9.76 (1H, s, -C*H*O), 8.01, 7.59, 7.45 (5H, 3m, -C$_6$*H*$_5$), 5.44 (1H, t, J = 5.0 Hz, -C*H*OCOC$_6$H$_5$), 2.73–1.80 (8H, m), 1.11 (3H, s, -C*H*$_3$); ms, *m/e*: 274 (M^+). exact mass calculated for $C_{16}H_{18}O_4$ (M^+): 274.1205; found: 274.1199.

Aldehyde **17**b: ir (CH_2Cl_2, ν cm^{-1}): 1730 (C=O ketone and aldehyde); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 9.75 (1H, t, J = 1.3 Hz, -C*H*O), 3.86 (1H, t, J = 5.9 Hz, -C*H*OC(CH_3)$_3$), 2.62–1.57 (8H,m), 1.19 (9H, s, -C(C*H*$_3$)$_3$), 0.96 (3H, s, -C*H*$_3$).

Unsaturated aldehyde ***18****a*

To a stirred solution of aldehyde **17***a* (1.0 g, 3.6 mmol) in benzene (70 mL) at room temperature is added (formylmethylene) triphenylphosphorane (1.3 g, 4.4 mmol). The mixture is heated at reflux for 48 h and then cooled down at room temperature. Concentration under reduced pressure and flash chromatography (ethyl acetate – hexane, 2:3) of the resulting residue yields 799 mg of the desired *trans* unsaturated aldehyde (73%) and a minor amount (<5%) of undesired *cis* isomer; $[\alpha]_D$ +65.9 (*c* 1); ir (CH_2Cl_2, ν cm^{-1}): 2880 (CH aldehyde), 1740–1720 C=O ester and ketone), 1680 (C=O conjugated aldehyde); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 9.48 (1H, d, J = 7.8 Hz, -CH=CH-C*H*O), 8.03, 7.58, 7.47 (5H, 3m, -C$_6$*H*$_5$), 6.80 (1H, dt, J = 15.7, 6.8 Hz, -C*H*=CH-CHO), 6.16 (1H, ddt, J = 15.7, 7.8, 1.5 Hz, -CH=C*H*-CHO), 5.52 (1H, t, J = 6.1 Hz, -C*H*OCOC$_6$H$_5$), 2.65–1.66 (8H, m), 1.16 (3H, s, -C*H*$_3$); ms, *m/e*: 298 (M^+-2H), 273 (MH^+-CO), 231 ($M^+-C_4H_5O$). Exact Mass calcd. for $C_{18}H_{18}O_4$ (M^+-2H): 298.1205; found: 298.1202.

Unsaturated aldehyde **18**b: ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 9.48 (1H, d, J = 7.8 Hz, -CH=CH—C*H*O), 6.81 (1H, dt, J = 15.6, 6.8 Hz, -C*H*=CH—CHO), 6.10 (1H, ddt, J = 15.7, 7.8, 1.5 Hz, -CH=C*H*—CHO), 3.92 (1H, m, -C*H*OC(CH_3)$_3$), 2.60–1.51 (8H, m), 1.20 (9H, s, -C(C*H*$_3$)$_3$), 0.98 (3H, s, -C*H*$_3$).

β-Hydroxyester ***19****a*

To a suspension of granular zinc (549 mg, 8.4 mmol) in tetrahydrofuran (20 mL) at room temperature are added *tert*-butyl bromoacetate (0.9 mL, 5.6 mmol) and one crystal of iodine. The resulting mixture is heated at reflux for 1 h and then cooled down at 0°C. A solution of *trans* unsaturated aldehyde **18***a* (1.1 g, 3.7 mmol) in tetrahydrofuran (20 mL) is then added to the reaction mixture at 0°C. After stirring at 0°C for 90 min, saturated aqueous ammonium chloride (20 mL), water (5 mL), and ether (20 mL) are added. The separated aqueous layer is extracted with ethyl acetate (4 × 15 mL) and the combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated. Flash chromatography (ethyl acetate – hexane, 2:3 to 3:2) of the residue yields 1.3 g (85%) of an unseparated (1:1) mixture of diastereomers; ir (neat, ν cm^{-1}): 3480 (OH), 1730 (C=O ester and ketone); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 8.01, 7.59, 7.45 (10H, 3m, 2 × -C$_6$*H*$_5$), 5.56 (6H, m, 2 × -C*H*=C*H* and -C*H*OCOC$_6$H$_5$), 4.43 (2H, m, 2 × -C*H*OH), 3.09, 3.07 (2 × 1H, 2d, J = 3.7 Hz, 2 × -O*H*), 2.60–1.50 (20H, m, 2 × -C*H*$_2$)), 1.46 (9H, s, -C(C*H*$_3$)$_3$), 1.45 (9H, s, -C(C*H*$_3$)$_3$), 1.12 (3H, s, -C*H*$_3$), 1.11 (3H, s, -C*H*$_3$); ms, *m/e*: 343 ($M^+-OC(CH_3)_3$).

β-Hydroxyester ***19****b:* ir (neat, ν cm^{-1}); 3460 (OH), 1730 (C=O ester and ketone); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 5.73–5.40 (4H, m, 2 × -C*H*=C*H*), 4.42 (2H, m, 2 × -C*H*OH), 3.92 (2H, m, 2 × -C*H*OC(CH_3)$_3$), 3.09 (2H, br s, 2 × -O*H*), 2.55–1.70 (20H, m, 2 × (5 × -C*H*$_2$)), 1.46 (9H, s, -OC(C*H*$_3$)$_3$), 1.45 (9H, s, -OC(C*H*3)$_3$), 1.20 (9H, s, -C(C*H*$_3$)$_3$), 1.19 (9H, s, -C(C*H*$_3$)$_3$), 0.94 (6H, s, 2 × -C*H*$_3$).

β-Ketoester ***10****a*

To a stirred solution of β-hydroxyester **19***a* (802 mg, 1.93 mmol) in ethyl acetate (80 mL) at room temperature was added manganese dioxide (3.35 g, 38.5 mmol). After vigorous stirring at room temperature for 8 h, the mixture is filtered on silica gel and evaporated under reduced pressure. Flash chromatography (ethyl acetate – hexane, 2:3) of the residue yields 464 mg (58%) of β-ketoester **10***a* along with 27% of recovered starting material; ir (neat, ν cm^{-1}): 1735 (C=O ester), 1690 (C=O conjugated ketone); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 12.00 (<1H, br s, -O*H*, enol form), 8.01, 7.57, 7.45 (5H, 3m, -C$_6$*H*$_5$), 6.85–6.55 (1H, 2dt, J = 15.9, 6.8 Hz, -CH$_2$C*H*=CH-, β-ketoester and enol forms), 6.15–5.75 (1H, 2m, -CH$_2$CH=C*H*-), 5.51 (1H, m, -C*H*OCOC$_6$H$_5$), 4.86 (<1H, s, -C=C*H*CO$_2$-, enol form), 3.45 (<2H, s, -COC*H*$_2$CO$_2$-), 2.65–1.58 (8H, m), 1.48, 1.47 (9H, 2s, -C(C*H*$_3$)$_3$, β-ketoester and enol forms), 1.14 (3H, s, -C*H*$_3$); ms,

m/e: 383 (M^+-OCH_3), 357 ($M^+-C_4H_9$). Exact Mass calcd. for $C_{20}H_{21}O_6$ ($M^+-C_4H_9$): 357.1338; found: 357.1333.

β-Ketoester ***10****b*: ir (neat, ν cm^{-1}): 1735 (C=O ester), 1690 (C=O conjugated ketone); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 12.00 (<1H, m, -O*H*, enol form), 6.85–6.51 (1H, 2dt, *J* = 15.9, 6.8 Hz, β-ketoester and enol forms), 6.17–5.70 (1H, 2m, $-CH_2-CH=CH-$), 4.88 (<1H, s, $-C=CHCO_2$, enol form), 3.92 (1H, 2t, *J* = 6.0 Hz, $-CHOC(CH_3)_3$), 3.47 (2H, s, $-COCH_2CO_2-$), 2.60–1.40 (8H, m), 1.49, 1.45 (9H, 2s, $-CO_2C(CH_3)_3$, β-ketoester and enol forms), 1.20 (9H, s, $-OC(CH_3)_3$), 0.96 (3H, s, $-CH_3$).

Triketone ***20***

A solution of 2-carbomethoxycyclohex-2-en-1-one (**1**) (42 mg, 0.27 mmol) in chloroform (2.0 mL) is added to a stirred mixture of β-ketoester ***10****b* (72 mg, 0.2 mmol) and cesium carbonate (32 mg, 0.1 mmol) in chloroform (3.0 mL) at room temperature over 20 mins. After stirring for 1 h at room temperature, the mixture is filtered on silica gel and evaporated under reduced pressure. The residue is dissolved in trifluoroacetic acid (4 mL) and evaporated under reduced pressure. The new residue is then dissolved in benzene (10 mL) and heated at reflux for 2 h. The solution is cooled down at room temperature and evaporated under reduced pressure. Flash chromatography (ethyl acetate – hexane, 9:1) of the residue yields 31.2 mg (44%) of a 1:1 mixture of diastereomers; ir (neat, ν cm^{-1}): 3450 (OH), 1740–1720 (C=O ester and ketones); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 4.10 (1H, m, -C*H*OH), 3.77, 3.76 (3H, s, $-CO_2CH_3$), 3.10 (1H, m, $-CH_2CH(CO_2CH_3)$), 2.74–0.95 (19H, m), 0.93, 0.92 (3H, s, $-CH_3$); ms, *m/e*: 364 (M^+), 346 (M^+-H_2O), 305 ($M^+-CO_2CH_3$).

Tetraketone ***21***

Tetrapropylammonium perruthenate (0.001 mmol) is added to a vigorously stirred mixture of alcohol **20** (9 mg, 0.025 mmol), 4Å molecular sieves (5 mg), and 4-methylmorpholine *N*-oxide (4.3 mg, 0.03 mmol) in methylene chloride (1 mL) at room temperature. After stirring for 15 h at room temperature, methylene chloride (20 mL), 5% aqueous sodium sulfite solution (10 mL), and brine (10 mL) are added. The separated organic layer is dried ($MgSO_4$), filtered, and evaporated. Flash chromatography (ethyl acetate – hexane, 3:2) of the residue yields 5.4 mg (61%) of tetraketone **21**: ir (CH_2Cl_2, ν cm^{-1}): 1740–1720 (C=O ester and ketones); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 3.76 (3H, s, $-CO_2CH_3$), 3.05 (1H, m, $-CH_2CH(CH_2CO-)$, 2.73 (4H, m, $-OC(CH_2)_2CO-$), 2.65–0.93 (15H, m), 1.07 (3H, s, $-CH_3$); ms, *m/e*: 362 (M^+), 344 (M^+-H_2O), 330 (M^+-CH_3OH). Exact Mass calcd. for $C_{20}H_{26}O_6$ (M^+): 362.1729; found: 362.1727.

Enol phosphate ***24***

A solution of crude compound **5** (60 mg, 0.13 mmol) in tetrahydrofuran is added to a stirred suspension of sodium hydride (6 mg, 0.26 mmol) in tetrahydrofuran (1 mL) at 0°C. Diethyl chlorophosphate (28 μL, 0.19 mmol) is then added to the resulting yellow solution at 0°C and the mixture is stirred at room temperature for 16 h. Saturated aqueous ammonium chloride (5 mL) and ethyl acetate (5 mL) are added and the separated aqueous layer is extracted with ethyl acetate (4 × 10 mL). The combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated. Flash chromatography (ethyl acetate – hexane, 4:1) of the residue yields 21.6 mg (28%) of enol phosphate **24** along with 63% of recovered starting material. Recovered starting material could be recycled to give the same compound **24** in comparable yield (to ascertain that the aldol reaction was not observed using these conditions, a control experiment was run without diethyl chlorophosphate. In this case, starting material remained unchanged); ir (CH_2Cl_2, ν cm^{-1}): 3580, 3470 (OH), 1740 (C=O ester), 1730–1710 (C=O ketones and conjugated ester); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 4.16 (4H, qd, *J* = 7.1, 4.0 Hz, $-OP(O)(OCH_2CH_3)_2$), 4.15 (1H, s, -O*H*), 3.69 (3H, s, $-CO_2CH_3$), 3.65 (1H, m, HβC5), 3.00–1.10 (16H, m), 1.50 (9H, s, $-CO_2C(CH_3)_3$), 1.35 (6H, td, *J* = 7.1, 1.1 Hz, $-OP(O)(OCH_2CH_3)_2$), 1.06 (3H, s, $-CH_3$); ms, *m/e*: 598 (M^+), 584 (MH^+-CH_3), 567 (M^+-OCH_3), 542 ($MH^+-C_4H_9$).

Triketone ***25***

A solution of chiral cyclohexenone **9** (567 mg, 2.9 mmol) in chloroform (18 mL) is added to a stirred mixture of β-ketoester ***10****a* (803 mg, 1.9 mmol) and cesium carbonate (285 mg, 0.9 mmol) in chloroform (30 mL) at room temperature. After stirring for 6 h at room temperature, the mixture is filtered on silica gel and evaporated under reduced pressure. The residue is dissolved in trifluoroacetic acid (20 mL) and evaporated under reduced pressure. The new residue is then dissolved in benzene (30 mL) and heated at reflux for 5 h. The solution is cooled down at room temperature and evaporated under reduced pressure. Flash chromatography (ethyl acetate – hexane, 1:3 to 2:3) of the residue yields 587 mg (60%) of compound **25** along with 104 mg (11%) of uncharacterized diastereomer; $[\alpha]_D$ +83.6 (*c* 1); ir (CH_2Cl_2, ν cm^{-1}): 1740 (C=O ester), 1720, 1710 (C=O ketones); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 7.99, 7.58, 7.43 (5H, m, $-C_6H_5$), 5.37 (1H, t, *J* = 5.6 Hz, $-CHOCOC_6H_5$), 4.80, 4.72 (2H, 2 br s, $-C=CH_2$), 3.73 (3H, s, $-CO_2CH_3$), 3.15 (1H, m, $-CH_2CH(C\text{-}COOCH_3)CH_2-$), 2.76–1.10 (18H, m), 1.71 (3H, s, $=C\text{-}CH_3$), 1.06 (3H, s, $-CH_3$); ms, *m/e*: 508 (M^+), 490 (M^+-H_2O), 476 (M^+-CH_3OH). Exact Mass calcd. for $C_{30}H_{36}O_7$ (M^+): 508.2461; found: 508.2457. Diastereoisomer: ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 8.01, 7.57, 7.45 (5H, 3m, $-C_6H_5$), 5.46 (1H, t, *J* = 6.7 Hz, $-CHOCOC_6H_5$), 4.82, 4.78 (2H, 2 br s, $-C=CH_2$), 3.73 (3H, s, $-CO_2CH_3$), 3.10 (1H, m, $-CH_2CH(C\text{-}CO_2Ch_3)CH_2-$), 2.46–1.20 (18H, m), 1.75 (3H, s, $=C\text{-}CH_3$), 1.06 (3H, s, $-CH_3$).

*Methyl 17β-benzoyloxy-14β-hydroxy-3β-methylethenyl-1,7-dioxo-5β-androstan-19-oate (****11****)*

To a stirred solution of triketone **25** (94 mg, 0.19 mmol) in acetonitrile (5 mL) at room temperature is added cesium carbonate (36 mg, 0.11 mmol). The mixture is heated at reflux for 20 h, cooled down at room temperature, filtered on silica gel, and evaporated under reduced pressure. Flash chromatography of the residue (ethyl acetate – hexane, 7:13) yields 30 mg (32%) of steroid **11** along with 31% recovered starting material; mp 156–157°C; $[\alpha]_D$ +61.5 (*c* 1); ir (CH_2Cl_2, ν cm^{-1}): 3520–3500 (OH), 1740 (C=O ester), 1720–1710 (C=O ketones); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 8.08, 7.53, 7.42 (5H, 3m, $-C_6H_5$), 5.01 (1H, m, HαC17), 4.84, 4.73 (2H, 2s, $-C=CH_2$), 4.01 (1H, s, -O*H*), 3.81 (3H, s, $-CO_2CH_3$), 3.19 (1H, m, HβC5), 2.79 (1H, d, *J* = 13.6 Hz, HβC8), 2.64–1.35 (16H, m), 1.72 (3H, s, $=C\text{-}CH_3$), 1.07 (3H, s, $-CH3$); ^{13}C nmr (62.9 MHz, $CDCl_3$) δ ppm: 214.8, 206.3, 171.5, 166.5, 146.0, 132.7, 129.6, 128.3, 111.1, 84.1, 82.9, 82.3, 62.8, 52.7, 52.4, 50.5, 45.2, 42.5, 40.8, 36.6, 35.1, 34.1, 32.6, 28.9, 28.0, 23.5, 20.7, 13.2; ms, *m/e*: 508 (M^+), 490 (M^+-H_2O), 476 (M^+-CH_3OH), 449 ($M^+-COOCH_3$). Exact Mass calcd. for $C_{30}H_{36}O_7$ (M^+): 508.2461; found: 508.2472.

Compound ***11*** *is also obtained from* ***26*** *under the same conditions.*

*Methyl 17β-benzoyloxy-14β-hydroxy-3β-methylethenyl-1,7-dioxo-5β,8α-androstan-19-oate (****26****)*

To a stirred solution of triketone **25** (16 mg, 0.03 mmol) in tetrahydrofuran (1 mL), at −78°C, is added a solution of potassium bis(trimethylsilyl)amide (82 μL, 0.5 M, 0.04 mmol) in toluene. After stirring for 30 min at −78°C, the reaction mixture is warmed to room temperature and, after an additional 20 min, quenched with saturated aqueous ammonium chloride (2 mL). Ethyl acetate (10 mL) is added and the separated aqueous layer is extracted with a 1:1 mixture of ether and ethyl acetate (4 × 10 mL). The combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated. Flash chromatography (ethyl acetate – hexane, 3:7) of the residue yields 4 mg (25%) of steroid **26** along with 30% recovered starting material; ir (CH_2Cl_2, ν cm^{-1}): 3500 (OH), 1740–1700 (C=O ketones and ester); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 8.07, 7.53, 7.43 (5H, 3m, $-C_6H_5$), 5.03 (1H, dd, *J* = 7.5, 2.5 Hz, $-CHOCOC_6H_5$), 4.82, 475 (2H, 2 br s, $-C=CH_2$),

For personal use only.

4.64 (1H, d, J = 2.0 Hz, -O*H*), 3.78 (3H, s, -CO_2CH_3) 3.30–1.00 (18H, m), 1.71 (3H, s, -C(CH_3)=CH_2), 1.09 (3H, s, -CH_3).

Methyl 17β-benzoyloxy-2β-methylethenyl-1,7-dioxo-14β-trimethylsilyloxy-5β,8α-androstan-19-aote (27)

Trimethylsilylchloride (5 μL, 0.04 mmol) is added to a stirred solution of alcohol **26** (9 mg, 0.02 mmol) and imidazole (3 mg, 0.04 mmol) in dimethylformamide (0.1 mL) at room temperature. After stirring for 12 h at room temperature, saturated aqueous ammonium chloride (1 mL) and ether (1 mL) are added. The separated aqueous layer is extracted with ether (3 × 10 mL) and the combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated. Flash chromatography (ethyl acetate – hexane, 1:4) of the residue yields 8 mg (79%) of trimethylsilyl ether **27**; ^{1}H nmr (250 MHz, $CDCl_3$) δ ppm: 8.08, 7.55, 7.44 (5H, 3m, -C_6H_5), 4.90 (1H, m, C*H*OCOC_6H_5), 4.81, 4.74 (2H, 2 br s, -C=CH_2), 3.76 (3H, s, -CO_2CH_3), 3.40–0.80 (18H, m), 1.72 (3H, s, -C(CH_3)=CH_2), 1.15 (3H, s, -CH_3), 0.08 (9H, s, -Si(CH_3)$_3$); ms, *m/e*: 580 (M^+), 565 (M^+-CH_3).

Tricyclic alcohol 28

To a stirred solution of benzoate **25** (95 mg, 0.19 mmol) in methanol (2 mL) at room temperature is added a solution of sodium methoxide (190 μL, 0.5 M) in methanol. After stirring for 15 h at room temperature, the mixture is neutralized with weakly acidic Dowex IRC-50 resin, filtered, and evaporated. Flash chromatography (ethyl acetate – hexane, 7:3) of the residue yields 55 mg (73%) of alcohol **28**; ^{1}H nmr (250 MHz, $CDCl_3$) δ ppm: 4.81, 4.73 (2H, 2 br s, -C=CH_2), 4.08 (1H, m, -*CH*OH) 3.76 (3H, s, -CO_2CH_3), 3.15 (1H, m, -CH_2CH(C-$COOCH_3$)CH_2-), 2.81–0.98 (19H, m), 1.72 (3H, s, -C=C(CH_3)), 0.94 (3H, s, -CH_3); ms, *m/e*: 404 (M^+), 386 (M^+-H_2O), 372 (M^+-CH_3OH). Exact Mass calcd. for $C_{23}H_{32}O_6$ (M^+): 404.2199; found: 404.2191.

Tricyclic carbonate 29

To a stirred solution of alcohol **28** (50 mg, 0.12 mmol) in pyridine (0.2 mL) at room temperature, is added phenyl chloroformate (23 μL, 0.18 mmol). After stirring for 24 h at room temperature, the mixture is quenched with ice and saturated aqueous sodium bicarbonate (10 mL) and ether (10 mL) are added. The separated aqueous layer is extracted with ether (3 × 10 mL) and the combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated. Flash chromatography (ethyl acetate – hexane, 7:13) of the residue yields 46 mg (71%) of carbonate **29**; ^{1}H nmr (250 MHz, $CDCl_3$) δ ppm: 7.40, 7.24 (5H, 2m, -C_6H_5), 5.07 (1H, br t, J = 6.0 Hz, -*CH*O$CO_2C_6H_5$), 4.81, 4.71 (2H, br s, -C=CH_2), 3.74 (3H, s, -CO_2CH_3), 3.18 (1H, m, -CH_2CH(C-CO_2CH_3)CH_2-), 2.72–1.20 (18H, m), 1.72 (3H, s, C=C(CH_3)), 1.04 (3H, s, -CH_3); ms, *m/e*: 524 (M^+), 506 (M^+-H_2O), 492 (M^+-CH_3OH). Exact Mass calcd. for $C_{30}H_{36}O_8$ (M^+): 524.2410; found: 524.2405.

Methyl 14β,17β-dihydroxy-3β-methylethenyl-1,7-dioxo-5β-androstan-19-oate (30)

To a stirred solution of triketone **28** (60 mg, 0.15 mmol) in acetonitrile (4 mL) at room temperature is added cesium carbonate (36 mg, 0.11 mmol). The mixture is heated at reflux for 20 h, cooled down at room temperature, filtered, and evaporated under reduced pressure. Flash chromatography (ethyl acetate – hexane, 7:3) of the residue yields 18 mg (30%) of steroid **30** along with 30% recovered starting material; ^{1}H nmr (250 MHz, $CDCl_3$) δ ppm: 4.84, 4.73 (2H, 2s, -C=CH_2), 4.21 (1H, s, -O*H* tertiary), 3.82 (3H, s, -CO_2CH_3), 3.55 (1H, m, HαC17), 3.16 (1H, d, J = 11.3 Hz, -O*H* secondary), 3.15 (1H, m, HβC5), 2.75 (1H, d, J = 13.6 Hz, HβC8), 2.60–1.20 (16H, m), 1.72 (3H, s, C=C(CH_3)), 1.10 (3H, s, -CH_3); ms, *m/e*: 386 (M^+-H_2O); 368 (M^+-2H_2O). Exact Mass calcd. for $C_{23}H_{30}O_5$ (M^+-H_2O): 386.2093; found: 386.2100.

Methyl 17β-hydroxy-3β-methylethenyl-1,7-dioxo-5β-androst-8(14)-en-19-oate (32)

Cesium carbonate (25 mg, 0.08 mmol) is added to a stirred solution of tricyclic carbonate **29** (100 mg, 0.19 mmol) in acetonitrile (15 mL) at room temperature. The mixture is heated at reflux for 6 h, cooled down at room temperature, filtered, and evaporated under reduced pressure. Flash chromatography (ethyl acetate – hexane, 1:1) of the residue yields 37.5 mg (51%) of allylic alcohol **32**; ir (CH_2Cl_2, ν cm^{-1}): 3600, 3500 (OH), 1740 (C=O ester), 1710 (C=O ketone), 1690 (C=O conjugated ketone); ^{1}H nmr (250 MHz, $CDCl_3$) δ ppm: 4.82, 4.73 (2H, 2s, -C=CH_2), 3.78 (3H, s, -CO_2CH_3), 3.71 (1H, m, HαC17), 3.43 (1H, m, HβC5), 3.15–1.23 (17H, m), 1.72 (3H, s, -C=C(CH_3)), 0.98 (3H, s, -CH_3); ms, *m/e*: 386 (M^+), 368 (M^+-H_2O), 354 (M^+-CH_3OH).

Tetraketone 35 and methyl 14α-hydroxy-3β-methylethenyl-1,7,17-trioxo-5β-13α-androstan-19-oate (36)

To a stirred mixture of cyclopentanedione β-ketoester **2** (80 mg, 0.3 mmol) and cesium carbonate (50 mg, 0.2 mmol) in chloroform (3 mL) at room temperature is added a solution of chiral cyclohexenone **9** (101 mg, 0.5 mmol) in chloroform (3 mL). After stirring for 6 h at room temperature, the mixture is filtered on silica gel and evaporated under reduced pressure. The residue is dissolved in trifluoroacetic acid (5 mL) and evaporated under reduced pressure. The new residue is then dissolved in benzene (15 mL) and heated at reflux for 5 h. The solution is cooled down at room temperature and evaporated under reduced pressure. Flash chromatography (ethyl acetate – hexane, 1:1) of the residue yields 22.5 mg (22%) of tricyclic compound **35** and 22.5 mg (22%) of steroid **36**. Tricyclic tetraketone **35** (R_f 0.31): ir (CH_2Cl_2, ν cm^{-1}): 1770 (C=O β-diketone), 1750–1710 (C=O ester and ketones); ^{1}H nmr (250 MHz, $CDCl_3$) δ ppm: 4.81, 4.72 (2H, 2 br s, -C(CH_3)=CH_2), 3.77 (3H, s, -CO_2CH_3), 3.10 (1H, m, -CH_2-$CHCH_2$-), 2.74 (4H, m, -OC(CH_2)$_2$CO-), 2.70–1.00 (18H, m), 1.71 (3H, s, -C(CH_3)=CH_2), 1.07 (3H, s, -CH_3); ms, *m/e*: 402 (M^+), 384 (M^+-H_2O), 352 (M^+-H_2O-CH_3OH); a minor diastereomeric compound corresponding to **35** was not isolated. 14α-Hydroxy steroid **36** (R_f 0.43): ir (CH_2Cl_2, ν cm^{-1}): 3500 (OH), 1735 (C=O ester), 1710 (C=O ketones); ^{1}H nmr (250 MHz, $CDCl_3$) δ ppm: 4.91, 4.72 (2H, 2br s, -C(CH_3)=CH_2), 4.15 (1H, s, -O*H*; exchanges upon treatment with D_2O), 3.73 (3H, s, -$COOCH_3$), 3.10 (1H, m, HβC5), 2.77 (1H, d, J = 12.4 Hz, HβC8), 2.70–1.15 (16H, m), 1.73 (3H, s, -C(CH_3)=CH_2), 1.01 (3H, s, -CH_3); ms *m/e*: 402 (M^+), 384 (M^+-H_2O). Steroid **36** was accompanied by a minor diastereomeric compound: its corresponding signals could be seen in the ^{1}H nmr spectrum at δ ppm: 4.82, 4.74 (2H, 2br s, -C(CH_3=CH_2), 4.32 (1H, s, -O*H*; exchanges upon treatment with D_2O), 3.76 (3H, s, -COl_2CH_3), 1.05 (3H, s, -CH_3).

Methyl 14β-hydroxy-3β-methylethenyl-1,7,17-trioxo-5β,8α-androstan-19-oate (37)

Potassium *tert* butoxide (44 mg, 0.4 mmol) is added to a stirred solution of tetraketone **35** (40 mg, 0.1 mmol) in a mixture of *tert*-butanol (0.3 mL), tetrahydrofuran (0.3 mL), and benzene (0.3 mL) at room temperature. After stirring for 15 min at room temperature, saturated aqueous ammonium chloride (5 mL) is added and the separated aqueous layer is extracted with ethyl acetate (4 × 10 mL). The combined organic layers are washed with brine, dried ($MgSO_4$), filtered, and evaporated under reduced pressure. Flash chromatography (ethyl acetate – hexane, 3:7) of the residue yields 11.6 mg (29%) of 14β-hydroxy steroid **37** and traces of isomer **38**; ir (CH_2Cl_2, ν cm^{-1}): 3500 (OH), 1750–1700 (C=O ester and ketones); ^{1}H nmr (250 MHz, $CDCl_3$) δ ppm: 4.82, 4.74 (2H, 2s, -C(CH_3)=CH_2), 4.66 (1H, d, J = 2.5 Hz, -O*H*), 3.77 (3H, s, -CO_2CH_3), 3.25–0.98 (18H, m), 1.72 (3H, s, -C(CH_3)=CH_2), 1.11 (3H, s, -CH_3); ms, *m/e*: 402 (M^+), 384 (M^+-H_2O), 369 (M^+-H_2O-CH_3).

Methyl 14β-hydroxy-3β-methylethenyl-1,7,17-trioxo-5β-androstan-19-oate (38)

From isomerization of 37

To a stirred solution of steroid **37** (8 mg, 0.02 mmol) in acetonitrile (2 mL) at room temperature is added cesium carbonate (6 mg, 0.02 mmol). The mixture is heated at reflux for 2 h, cooled down

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

at room temperature, filtered, and evaporated. Flash chromatography (ethyl acetate – hexane, 2:3) of the residue yields 3.5 mg (45%) of steroid **38** along with 13% of recovered starting material.

*From methanolysis and oxidation of steroid **11***

To a stirred solution of steroid **11** (20 mg, 0.04 mmol) in methanol (0.1 mL) at room temperature is added a solution of sodium methoxide (40 μL, 0.5 M) in methanol. After stirring for 16 at room temperature, weakly acidic Dowex IRC-50 resin is added to the reaction mixture until pH reaches ~7. The mixture is then filtered on Celite and evaporated under reduced pressure. The residue is dissolved in methylene chloride (5 mL) and pyridinium chlorochromate (25 mg, 0.12 mmol) is added portionwise. After stirring for 2 h at room temperature, ether (50 mL) is added and the mixture is filtered on silica gel and evaporated. Flash chromatography (ethyl acetate – hexane, 2:3) of the residue yields 4.5 mg (30%, 2 steps) of a material identical to that obtained from isomerization of **37**; ir (CH_2Cl_2, ν cm^{-1}): 3500 (OH), 1740 (C=O ester), 1715 (C=O ketones); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 4.85, 4.74 (2H, 2s, -C(CH_3)=CH_2), 3.97 (1H, s, -O*H*; exchanges upon treatment with D_2O), 3.82 (3H, s, -CO_2CH_3), 2.80 (1H, d, J = 12.3 Hz, HβC8), 3.15–1.00 (17H, m), 1.73 (3H, s, -C(CH_3=CH_2), 1.05 (3H, s, -CH_3); ms, *m/e*: 402 (M^+).

*Methyl 17β-benzoyloxy-3-isopropyl-1,7-dioxo-5β-androsta-2,8(14)-dien-19-oate (**33**)*

To a stirred solution of triketone **25** (60 mg, 0.12 mmol) in benzene (10 mL) at room temperature is added *p*-toluenesulfonic acid (34 mg, 0.18 mmol). The mixture is heated at reflux for 16 h and then cooled down at room temperature, Water (10 mL) is added and the separated aqueous layer is extracted with ether (3 × 10 mL). The combined organic layers are washed with saturated aqueous sodium bicarbonate (10 mL), brine, dried ($MgSO_4$), filtered, and evaporated. Flash chromatography (ethyl acetate – hexane, 2:3) of the residue yields 44.5 mg (77%) of **33**, which may be recrystallized from heptane; mp 137–139°C; $[\alpha]_D$ −106.4 (*c* 1); ir (CH_2Cl_2, ν cm^{-1}): 1740, 1720 (C=O esters), 1670 (C=O conjugated ketones); ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 8.05, 7.55, 7.45 (5H, 3m, −C_6H_5), 5.94 (1H, br s, HC2), 4.99 (1H, dd, J = 10.4, 7.6 Hz, HαC17), 3.75 (3H, s, -CO_2CH_3), 3.32–3.07 (2H, m, HβC5 and HαC9), 2.89–1.34 (13H, m), 1.36 (3H, s, -CH_3), 1.13, 1.12 (6H, 2d, J = 6.8 Hz, -CH(CH_3)$_2$); ms, *m/e*: 490 (M^+), 459 M^+−OCH_3), 431 (M^+−CO_2CH_3). Exact Mass calcd. for $C_{30}H_{34}O_6$ (M^+): 490.2355; found: 490.2352.

*This compound is also obtained by submitting **26** or **11** to the same conditions.*

*Methyl 3-isopropyl-1,7-dioxo-17β-phenyloxycarbonyloxy-5β-androsta-2,8(14)-dien-19-oate (**34**)*

The preceding procedure is applied using carbonate **29** (25 mg, 0.05 mmol) and *p*-toluenesulfonic acid (13.6 mg, 0.07 mmol) in benzene (5 mL). Flash chromatography (ethyl acetate – hexane, 2:3) of the residue yields 17.8 mg (74%) of compound **34**; ^1H nmr (250 MHz, $CDCl_3$) δ ppm: 7.38, 7.20 (5H, 2m, -OC_6H_5), 5.95 (1H, br s, HC2), 4.72 (1H, dd, J = 10.5, 7.4 Hz, HαC17), 3.75 (3H, s, -CO_2CH_3), 3.22–3.10 (2H, m, HβC5 and HαC9), 2.87–1.16 (13H, m), 1.30 (3H, s, -CH_3), 1.12 (6H, d, J = 6.8 Hz, -CH(CH_3)$_2$).

Combined use of NMR, distance geometry, and restrained energy minimization for the conformational analysis of 8-lysine–vasopressin

CHIN YU,[1] TA-HORNG YANG, CHAO-JUNG YEH, AND LI-CHIN CHUANG
Chemistry Department, National Tsing Hua University, Hsin Chu, Taiwan 30043, Republic of China

Received September 4, 1991

CHIN YU, TA-HORNG YANG, CHAO-JUNG YEH, and LI-CHIN CHUANG. Can. J. Chem. **70,** 1950 (1992).

The conformation of the neurohypophyseal hormone, 8-lysine–vasopressin, in DMSO solution has been determined from 2D-NMR and distance geometry followed by the restrained energy minimization calculation. The conformation of 8-lysin-vasopressin in the 20-membered ring region is well defined but the acyclic tripeptide tail region is disordered.

CHIN YU, TA-HORNG YANG, CHAO-JUNG YEH et LI-CHIN CHUANG. Can. J. Chem. **70,** 1950 (1992).

En se basant sur les spectres RMN-2D et la géométrie des distances, suivie de calculs de minimisation des énergies restreintes, on a déterminé la conformation de l'hormone neurohypophysaire, 8-lysine–vasopressine. La conformation de ce composé est bien définie dans la région du cycle à 20 chaînon; elle est toutefois désordonnée dans la région de queue comportant le tripeptide acyclique.

Introduction

8-Lysine–vasopressin (LysVP) consists of nine amino acid residues with the following sequence:

$$Cys^1\text{-}Tyr^2\text{-}Phe^3\text{-}Gln^4\text{-}Asn^5\text{-}Cys^6\text{-}Pro^7\text{-}Lys^8\text{-}Gly^9(NH_2)$$

It has a 20-membered disulfide-containing ring and an acylic tripeptide tail. LysVP has important biological properties (1, 2) such as milk ejecting, uterine contracting, and antidiuretic functions. It also interacts noncovalently with neurophysin protein (MW approx. 10 000) within the neurosecretory granules of the hypothalamo-neurohypophyseal tract (3). Many different models have been proposed for the 3D structure of LysVP on the basis of potential energy minimization (4), and NMR (5–11) and CD (12) spectroscopies. However, determination of the detailed structure of the LysVP molecule is incomplete and thus remains to be solved.

Recently, two-dimensional nuclear magnetic resonance (2D NMR) (13) and distance geometry (DG) (14–17) techniques have been combined to determine 3D molecular structure in solution. In DG techniques, a complete distance matrix is set up using a random choice of atom–atom distance (obtained by nuclear Overhauser enhancement (NOE) measurements and the covalent structure of the molecule). The matrix obtained is then embedded in 3D space and the resulting 3D structure is optimized to reduce the remaining atom–atom distance violations.

In the present study, the conformational properties of LysVP in DMSO solution were examined by NMR data and distance geometry calculation followed by restrained energy minimization.

Experimental

LysVP was obtain commercially (Auspep). LysVP (10 mg) was dissolved in 500 μL DMSO-d_6 (Aldrich) solution to make the concentration ~20 mmol L^{-1}. 4,4-Dimethyl-4-silapentane-1-sulfonate was used as an internal standard. The NMR tube was degassed and sealed. Phase-sensitive NOESY (18) spectra with four different mixing periods (τ_m = 60, 100, 180, and 300 ms) were recorded on a 400 MHz spectrometer (Bruker AM-400). Quadrature detection in w_1 was achieved using time-proportional phase incrementation (19); 512 t_1 increments were recorded, with 2048 complex data points. For each free induction, the decays were Fourier transformed in w_2 using a Kaiser window and in w_1 using a 45° phase-shifted sine-bell window. All two-dimensional data were processed on a computer (μVax III), using FTNMR software provided by Dr. D. Hare.

To plot the NOE buildup curves, the cross peaks of four NOESY spectra were volume integrated, and the curves were best fitted by least squares. The interproton distances, d_{ij}, were calculated according to the following relation (20)

$$d_{ij} = d_{lm}(\sigma_{lm}/\sigma_{ij})^{1/6}$$

in which d_{lm} stands for a known calibrated distance (1.78 Å for geminal protons), and σ_{lm}, σ_{ij} stand for the cross relaxation (NOE buildup) rate for spin l, m and spin i, j respectively (obtained from the initial slope of the NOE buildup curve). The DGEOM (21) program was acquired from QCPE, and pseudo atoms were taken into account in setting upper and lower bounds for the DG calculation (22). Restrained energy minimization calculations were performed on a Silicon Graphic 4D/25G computer by the program CHARMM (22). The molecular graphic program QUANTA (Polygen, Version 3.0) was used for displaying, analyzing, and plotting the structures.

A potential energy term representing the interproton distance restraints, $E_{NOE}(r_{ij})$, was added to the total energy of the system given by

$$E_{NOE} = \begin{cases} C_1(r_{ij} - r_{ij}^0), & \text{if } r_{ij} > r_{ij}^0 \\ C_2(r_{ij} - r_{ij}^0), & \text{if } r_{ij} < r_{ij}^0 \end{cases}$$

where r_{ij} and r_{ij}^0 are the calculated and target interproton distances respectively, and C_1 and C_2 are force constants given by

$$C_1 = \frac{k_B TS}{2(\Delta_{ij}^+)^2}, \qquad C_2 = \frac{k_B TS}{2(\Delta_{ij}^-)^2}$$

where k_B is the Boltzmann constant, T the absolute temperature, S a scale factor, and Δ_{ij}^+ and Δ_{ij}^- the positive and negative error estimates, respectively, of r_{ij}.

Structures were minimized by using the adopted basis Newton–Raphson algorithm (23). All hydrogen atoms capable of forming hydrogen bonds were included explicitly, but molecular bond lengths involving these atoms were kept fixed through the use of the constraint procedure SHAKE (24).

Results and discussion

Extraction of the NMR parameters

The ^{1}H NMR resonances were previously assigned (5–11). The NOESY spectra were particularly helpful in identifying

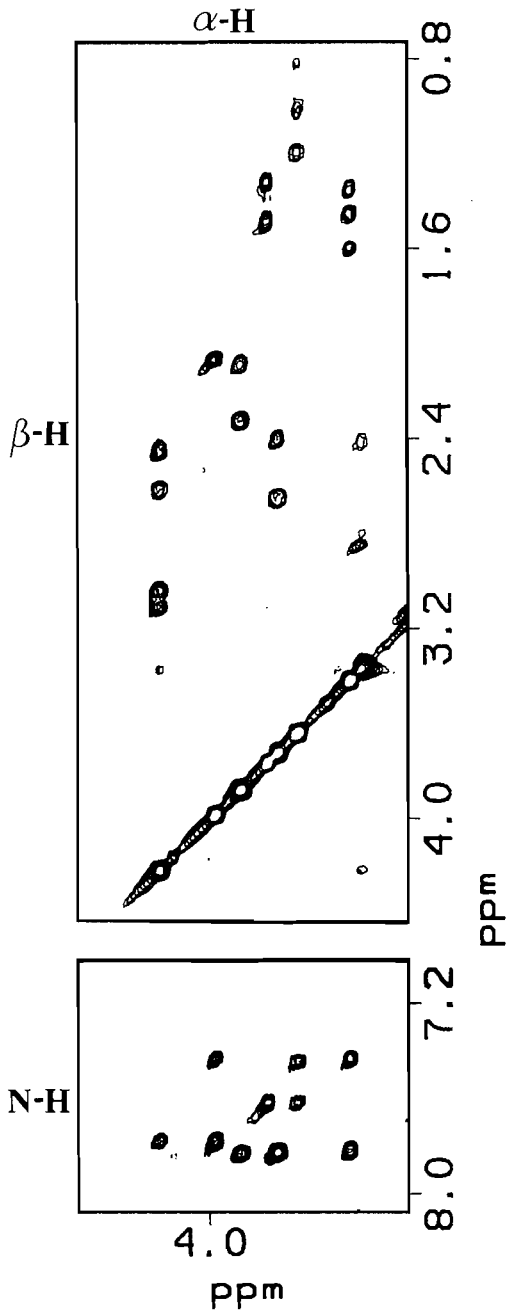

FIG. 1. NOESY spectrum (τ_m = 180 ms) of LysVP. Only amide protons are shown.

the conformation of LysVP. A contour plot of the NOESY (τ_m = 180 ms) spectrum observed for the amide proton range (w_2) is shown in Fig. 1. A total of 57 observable NOE's were used to set up distance constraints to define the conformation of the LysVP.

Initial cross-relaxation rates for each proton pair of NOE's were obtained from NOESY spectra recorded with four different mixing times and the interproton distances were calculated as described in the experimental section. The time dependence of some NOE's measured from NOESY spectra are shown in Fig. 2. Evaluation of the dependence of these cross peaks showed that the first few points were still in the domain in which buildup is linear with time.

The distances obtained by this approach were estimated

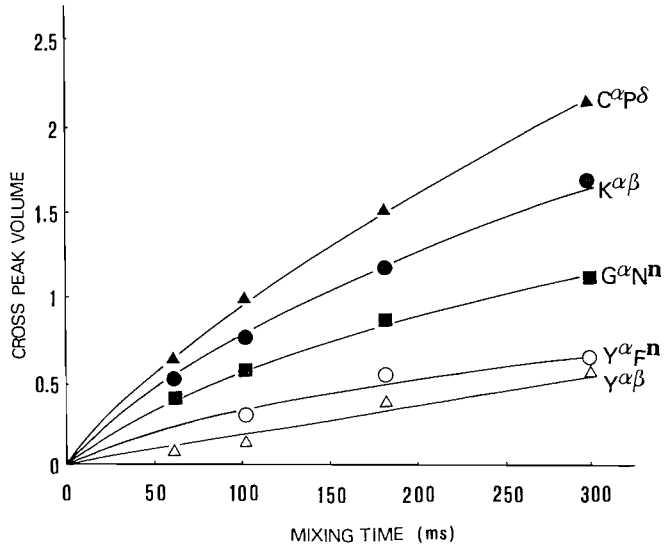

FIG. 2. Time dependence of some NOE's in LysVP measured from four different mixing times of NOESY spectra. The NOE buildup curves for corresponding cross peaks are identified by the IUPAC–IUB one-letter symbols for amino acids. The plot is of the volume of cross peaks against mixing time. The vertical scale is arbitrary since the cross-peak volumes were only measured relative to each other.

to have a precision better than ±0.5 Å, and the distance contraints used in the DG calculation are listed in Table 1. Pseudo atoms were taken into consideration as described by Wüthrich *et al.* (22).

Distance geometry structures

The distance geometry technique was repeatedly applied to LysVP using the 57 distance constraints given in Table 1. The 29 structures obtained were grouped into nine general conformational families by the SAS cluster analysis method (25). As shown in Table 2, root-mean-square distance (RMSD) values between all pairs among conformers are listed. The conformers correlated within a family are set off as rectangular sections.

Restrained energy minimization (REM)

For each of the nine families, we chose the structure nearest the center of the cluster as a representative,[2] and it was subjected to a final energy minimization with 57 distance restraints as described in the experimental section.

The results obtained by this procedure show that the coordinates of the side-chain atoms after restrained energy minimization (REM) vary somewhat from those of the DG structures, implying that the side chains move to energetically more favored positions. Figure 3 shows these nine REM structures (thin lines) superposed over the X-ray crystal structure (26) of pressionic acid (thick line), the cyclic moiety of vasopressin. It reveals clearly the similarities of solution conformations in the ring region of vasopressin with those of the crystal structure of pressionic acid. Table 3 shows the RMS difference values among nine REM structures. The positions of the backbone atoms of nine REM structures show smaller RMSD values in Table 3, indicating that the NMR constraints define the basic backbone folding of the molecule. From the superposition of nine REM structures (Fig.

Lower and upper bounds are given for each constraint. The letters a, b, c, and d after the upper distance bounds indicate that additional factors 1.0, 1.0, 0.6, and 2.4 Å, respectively, were added to the upper distance bounds. The additional terms corresponding to the letters a, b, c, and d account for lack of stereospecific assignments for methyl, methylene (long range), methylene (intraresidue), and ring protons, respectively.

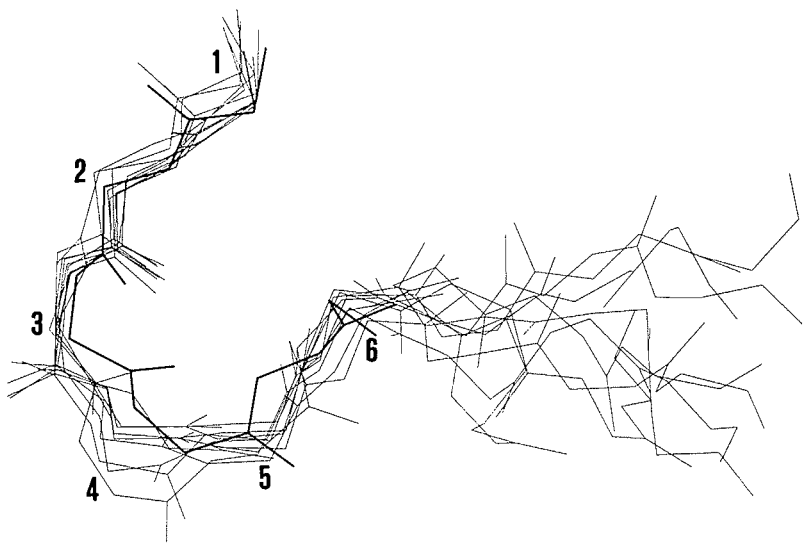

FIG. 3. Superposition of backbone atoms for nine restrained energy-minimized (REM) structures of LysVP (thin lines) and the X-ray crystal structure of pressionic acid (thick line), the cyclic moiety of LysVP. The sequence numbers are labeled at the C^{α} carbons in the 20-membered tocin ring. The disulfide bond is not shown.

3, thin lines), it is readily apparent that the overall shape of the vasopressin fold is well reproduced. To emphasize this, the backbone dihedral angles of the nine REM structures are listed in Table 4. All REM structures in Fig. 3 show a somewhat similar pattern of backbone folding in the 20-membered ring, forming a β-turn comprising the sequence Tyr^2-Phe^3-Gln^4-Asn^5. This is consistent with the observation of long-term stability of the 20-membered tocin ring in the vasopressin molecule by molecular dynamics simulation (27). On the other hand, the acyclic tripeptide tail does not have a defined conformation and there are no specific interactions between the core and tail regions. The disorder of the acyclic tripeptide tail might be due to its conformational freedom, and this is consistent with observations in thin-film dialysis (28) and ^{13}C spin-lattice relaxation studies (29).

Synthèses du β-L-rhamnopyranoside d'hordénine et d'acylgluco-L-rhamnopyranoses peracétylés

NADIA BOUGHANDJIOUA,[1] LIN RUI CHAO, ALEXIOS-LEANDROS SKALTSOUNIS, ELISABETH SEGUIN, FRANÇOIS TILLEQUIN ET MICHEL KOCH[2]

Laboratoire de pharmacognosie de l'Université René-Descartes, Unité associée au Centre national de la recherche scientifique, n° 1310, Faculté de pharmacie, 4, Avenue de l'Observatoire, 75006 Paris, France

Reçu le 5 décembre 1991

NADIA BOUGHANDJIOUA, LIN RUI CHAO, ALEXIOS-LEANDROS SKALTSOUNIS, ELISABETH SEGUIN, FRANÇOIS TILLEQUIN et MICHEL KOCH. Can. J. Chem. **70**, 1956 (1992).

La synthèse stéréosélective du β-L-rhamnopyranoside d'hordénine (**3**) a été possible grâce à l'emploi du bromure de 4-*O*-acétyl-2,3-*O*-carbonyl-α-L-rhamnopyranosyle (**14**). Les synthèses régiospécifiques des peracétyl-(*E*)-*O*-(6-*O*-cinnamoyl-β-D-glucopyranosyl)-(1 → 2)-, (1 → 3)- et (1 → 4)-α-L-rhamnopyranoses et de leurs homologues 4-acétoxycinnamiques ont été réalisées grâce à l'emploi de dérivés du rhamnose de type 1,2-*O*-orthoester pour la série (1 → 2), 2,3-*O*-orthoester pour la série (1 → 3) et 2,3-*O*-isopropylidène pour la série (1 → 4).

NADIA BOUGHANDJIOUA, LIN RUI CHAO, ALEXIOS-LEANDROS SKALTSOUNIS, ELISABETH SEGUIN, FRANÇOIS TILLEQUIN, and MICHEL KOCH. Can. J. Chem. **70**, 1956 (1992).

The stereoselective synthesis of hordenine β-L-rhamnopyranoside (**3**) was achieved using 4-*O*-acetyl-2,3-*O*-carbonyl-α-L-rhamnopyranosyl bromide (**14**) as key intermediate. The regiospecific syntheses of the peracetyl derivatives of (*E*)-*O*-(6-*O*-cinnamoyl-β-D-glucopyranosyl)-(1 → 2)-, (1 → 3)-, and (1 → 4)-α-L-rhamnopyranoses and of their 4-acetoxycinnamoyl counterparts were achieved through the use of various types of rhamnose-derived intermediates, i.e., 1,2-*O*-orthoester for the (1 → 2) series, 2,3-*O*-orthoester for the (1 → 3) series, and 2,3-*O*-isopropylidene for the (1 → 4) series.

L'étude chimique de *Selaginella doederleinii* Hieron, plante largement utilisée en médecine traditionnelle chinoise pour le traitement de diverses affections cardiovasculaires (1), a conduit antérieurement à l'isolement de divers glucoalcaloïdes dérivés de l'hordénine (2). Les deux constituants majoritaires sont l'α-L-rhamnopyranoside d'hordénine (**1**) et le (*E*)-*O*-(6-*O*-cinnamoyl-β-D-glucopyranosyl)-(1 → 3)-α-L-rhamnopyranoside d'hordénine (**2**). La structure de ce dernier a été définitivement établie à la suite d'une synthèse totale non régiospécifique de son dérivé acétylé (3). Par ailleurs, le mélange naturel des glucoalcaloïdes isolés de la plante montre, après administration orale chez le rat, une activité hypertensive marquée à rapprocher des effets thérapeutiques observés en médecine traditionnelle chinoise (4). Souhaitant disposer de glucoalcaloïdes purs et d'analogues en quantité suffisante pour étudier l'influence de divers paramètres structuraux sur l'activité pharmacologique, nous décrivons ici, d'une part la synthèse du β-L-rhamnopyranoside d'hordénine (**3**), d'autre part la synthèse régiospécifique des (*E*)-*O*-(6-*O*-cinnamoyl-β-D-glucopyranosyl)-(1 → 2)-, (1 → 3)- et (1 → 4)-α-L-rhamnopyranoses et des (*E*)-*O*-[6-*O*-(4-hydroxycinnamoyl)-β-D-glucopyranosyl]-(1 → 2)-, (1 → 3)- et (1 → 4)-α-L-rhamnopyranoses, sous forme de leurs dérivés peracétylés, précurseurs des glucoalcaloïdes correspondants, **4**, **5**, **6**, **7**, **8** et **9** (3).

La condensation de l'hordénine (**10**) avec le 1,2,3,4-tétra-*O*-acétyl-α,β-L-rhamnopyranose en présence de tétrachlorure d'étain avait conduit au 2,3,4-tri-*O*-acétyl-α-L-rhamnopyranoside d'hordénine (**11**) avec un rendement de 46% (3). L'étude des produits secondaires de cette réaction a permis ultérieurement l'isolement d'une faible quantité (rendement : 4%) de l'anomère β correspondant, **12**. Nous avons donc réalisé la même réaction en utilisant comme donneur de glycosyle le 1,4-di-*O*-acétyl-2,3-*O*-carbonyl-α,β-L-rhamnopyranose (**13**) (5), dépourvu de groupement acétyle participant en position 2, afin de favoriser la formation de l'anomère β (5–11). Le rendement global médiocre de cette dernière réaction (29%) et sa faible stéréosélectivité (α/β 7 : 3) nous ont conduit à envisager l'emploi du bromure de 4-*O*-acétyl-2,3-*O*-carbonyl-α-L-rhamnopyranosyle (**14**) (5) comme agent glycosylant. En effet, des réactifs associant des groupements 1-bromo et 2,3-*O*-carbonyl sur une unité rhamnose avaient été précédemment utilisés avec succès lors des synthèses des deux *O*-β-L-rhamnopyranosides d'aryle antérieurement décrits : ceux de 4-nitrophényle (12) et de quercet-3-yle (13). La condensation de l'hordénine (**10**) avec **14**, dans des conditions de transfert de phase, précédemment employées pour l'obtention de β-D-mannopyranosides d'aryle (14) et de β-L-rhamnopyranosides d'aryle (13), n'a toutefois pas conduit au produit escompté, mais au seul 4-*O*-acétyl-2,3-*O*-carbonyl-α-L-rhamnopyranoside d'hordénine (**15**) avec un rendement de 60%. Il semble donc probable que, sous l'influence du bromure de benzyltriéthylammonium, le bromure de 4-*O*-acétyl-2,3-*O*-carbonyl-α-L-rhamnopyranosyle (**14**) se soit transformé en anomère β correspondant avant la réaction de glycosidation. De telles inversions de configuration en position anomérique sous l'influence d'ammoniums quaternaires ont d'ailleurs été antérieurement observées en séries D-glucose, D-galactose et L-fucose (15). Finalement, la condensation de l'hordénine (**10**) avec le bromure **14**, en présence de carbonate d'argent (16, 17) a permis l'obtention, avec un rendement global de 83%, du mélange des glycosides anomères **15** (α) et **16** (β), dans un rapport 1 : 9, en faveur de l'anomère β. Les glycosides **15** et **16**, inséparables, ont été déprotégés par méthanolyse, puis acétylés pour donner les deux glycosides acétylés **11** (α) et **12** (β) qui ont pu alors être aisément séparés par chromatographie sur colonne de silice. Ils se différencient nettement

par leurs spectres de rmn ^1H. Les signaux des protons H-1′ et H-5′ de l'anomère β (**12**) apparaissent comme prévu (18) à champs plus forts que les signaux homologues de **11**. De plus, des expériences de COSY à acquisition retardée effectuées sur **11** et **12** ont permis, dans le cas de l'anomére α, l'observation de couplages à longue distance entre H-1′ et H-4′ d'une part et H-1′ et H-6′ d'autre part, couplages qui n'ont pas été observés dans le cas de l'anomère β (**12**) (19). La méthanolyse du dérivé acétylé **12** a fourni le β-L-rhamnopyranoside d'hordénine (**3**) recherché.

43	$R^1 = OCH_3$	$R^2 = R^5 = H$	$R^3 + R^4 = C(CH_3)_2$	

La synthèse régiospécifique des composés **4** et **7** suppose la synthèse préalable d'un dérivé du rhamnose convenablement protégé en positions 1, 3 et 4. Un tel dérivé peut être obtenu à partir d'un 1,2-*O*-alkylorthoester, selon une approche initialement développée en série mannose (20, 21). Le traitement du *O-exo*-3,4-di-*O*-benzyl-1,2-*O*-(1-méthoxyéthylidène)-β-L-rhamnopyranose (**17**) (22), par le tétrachlorure d'étain dans le dichlorométhane (23) a fourni le 2-*O*-acétyl-3,4-di-*O*-benzyl-α-L-rhamnopyranoside de méthyle (**18**) qui a été désacétylé par la méthode de Zemplén pour conduire au 3,4-di-*O*-benzyl-α-L-rhamnopyranoside de méthyle (**19**) (24). La glycosylation de ce dernier par le bromure de 2,3,4-tri-*O*-acétyl-6-*O*-chloroacétyl-α-D-glucopyranosyle (**20**) (25, 26), en présence de cyanure mercurique n'a permis l'obtention du disaccharide recherché **21** que lorsque la réaction a été effectuée dans le nitrométhane anhydre (27, 28). Tous les autres essais de couplage réalisés, en particulier dans l'acétonitrile, n'ont en effet permis l'obtention que du seul orthoester **22**. L'hydrogénolyse de **21** a fourni le diol **23**, aisément transformé en dérivé acétylé **24** par acétolyse–acétylation (5, 29). La déprotection sélective du groupement chloroacétyle de **24**, réalisée par action de la

For personal use only.

thiourée dans le méthanol (26), a permis l'obtention du disaccharide **25** qui, traité soit par le chlorure de (*E*)-cinnamoyle, soit par le chlorure de (*E*)-4-acétoxycinnamoyle (30), a conduit aux disaccharides recherchés **26** et **27**.

La synthèse régiosélective des composés **5** et **8** nécessite la préparation d'un dérivé du rhamnose protégé en positions 1, 2 et 4. Les seuls composés de ce type antérieurement décrits au début de ce travail étaient des 2,4-di-*O*-benzoyl-

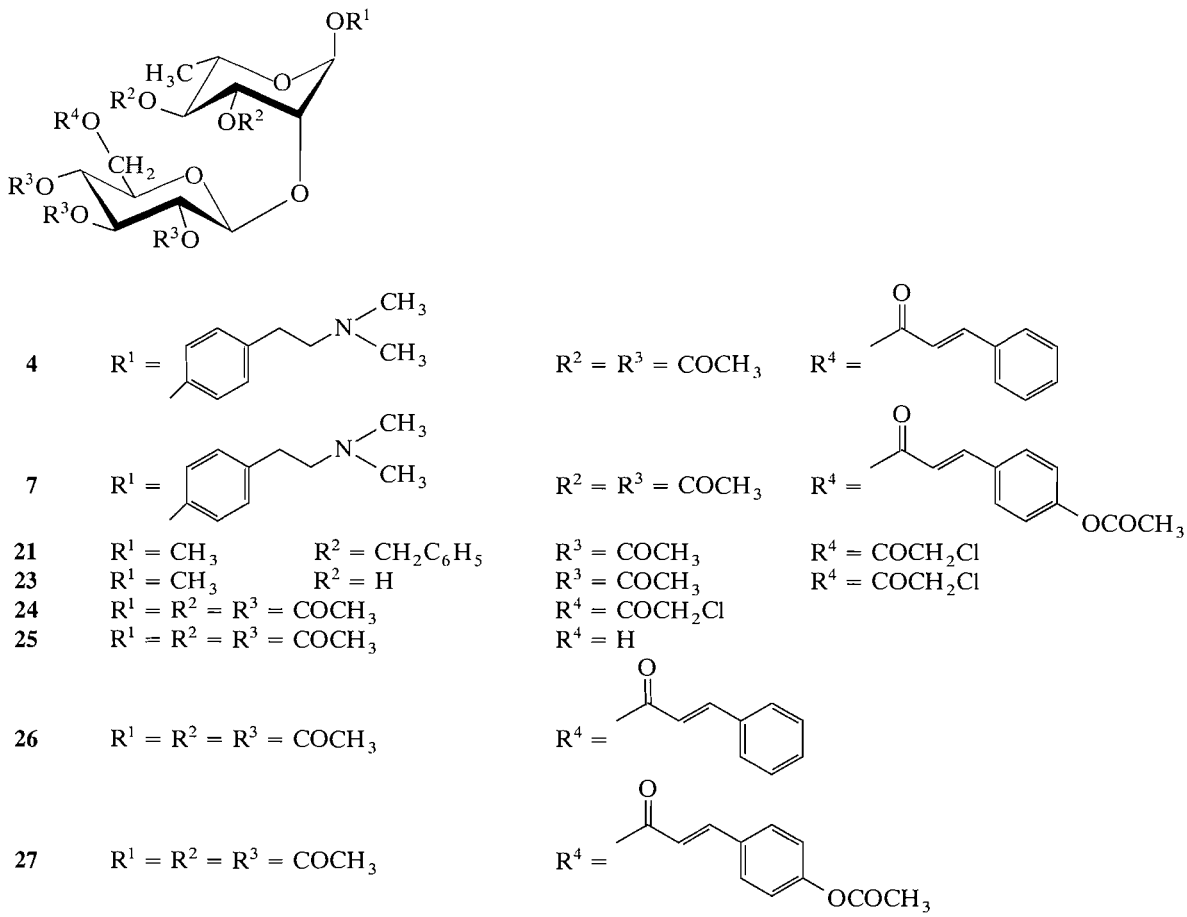
α-L-rhamnopyranosides (31, 32), préparés par benzoylation en 4 puis clivage sélectif, en milieu acide faible, de 2,3-*O*-orthobenzoates intermédiaires. Le 2,4-di-*O*-benzoyl-α-L-rhamnopyranoside de méthyle (**28**) (33) a été préparé à partir de l'α-L-rhamnopyranoside de méthyle (**29**) (29, 34) en utilisant cette méthode. Sa glycosylation par le bromure de 2,3,4,6-tétra-*O*-acétyl-α-D-glucopyranosyle (**30**), en présence de cyanure mercurique dans le nitrométhane (27, 28), a fourni le β-glucoside **31**, accompagné de traces de l'α-glucoside **32**. Le disaccharide **31** a été désacétylé pour donner **33** qui a été sélectivement tritylé en position 6′ par le chlorure de triphénylméthyle, puis peracétylé par l'anhydride acétique pour donner **34**. L'hydrogénolyse du trityle a permis l'accès à **35**, précurseur commun aux glucorhamnosides acylés **36** et **37**, par acylation avec le chlorure de (*E*)-cinnamoyle ou de (*E*)-4-acétoxycinnamoyle. L'acétolyse de **36** et **37** (5, 29) a finalement permis l'obtention des disaccharides **38** et **39** recherchés. Toutefois, le rendement global de cette suite de réactions est très faible. Nous avons donc tenté d'utiliser une approche similaire, mais en utilisant l'ouverture d'un orthoacétate au premier stade de la synthèse compte-tenu de données précédemment publiées sur le comportement en milieu acide de 3,4-*O*-orthoacétates de série galactose (36). Le traitement de l'α-L-rhamnopyranoside de

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

méthyle (**29**) par le triméthylorthoacétate, suivi de l'acétylation de l'orthoester intermédiaire et de son hydrolyse acide a conduit au 2,4-di-*O*-acétyl-α-L-rhamnopyranoside de méthyle (**40**), avec un rendement de 85%, en accord avec des données publiées très récemment en série rhamnose (37). La glycosylation de **40** par le bromure de (*E*)-2,3,4-tri-*O*-acétyl-6-*O*-cinnamoyl-α-D-glucopyranosyle (**41**) (3) ou de (*E*)-6-*O*-(4-acétoxycinnamoyl)-2,3,4-tri-*O*-acétyl-α-D-glucopyranosyle (**42**) (3) a donné ensuite les glucorhamnosides acylés **36** et **37** qui ont été soumis à une acétolyse pour fournir les disaccharides peracétylés **38** et **39**.

La synthèse régiospécifique des disaccharides peracétylés précurseurs des composés **6** et **9** (3) a mis à profit la condensation du 2,3-*O*-isopropylidène-α-L-rhamnopyranoside de méthyle (**43**) antérieurement décrit (29) avec les bromures de glucopyranosyle **41** ou **42** (3), en présence de cyanure mercurique dans l'acétonitrile. Les groupements isopropylidène des glucorhamnosides de méthyle **44** et **45** obtenus ont été ensuite hydrolysés par l'acide trifluoroacétique dans le chloroforme (29) pour conduire aux diols **46** et **47**. L'acétolyse–acétylation de ces derniers (5, 29) a fourni les disaccharides acétylés recherchés **48** et **49**.



Partie expérimentale

Méthodes générales

Les points de fusion sont déterminés au moyen d'un microscope à platine chauffante Reichert et ne sont pas corrigés. Les pouvoirs rotatoires sont mesurés à 20°C à l'aide d'un polarimètre Perkin–Elmer 241, les spectres ir enregistrés sur un appareil Unicam SP 3-200. Les spectres de masse sont effectués en désorption – ionisation chimique (dic) sur un spectromètre Nermag R10-10C, en utilisant l'ammoniac comme gaz réactant. Les spectres de rmn du proton sont réalisés en solution dans le $CDCl_3$ (sauf indication contraire), en utilisant le tétraméthylsilane comme étalon interne, à l'aide d'un appareil Bruker HX 270 (270 MHz).

Après extraction des milieux réactionnels, les solvants organiques sont séchés sur Na_2SO_4 et évaporés sous pression réduite à 40°C. Les chromatographies sur colonne sont réalisées à l'aide de gel de silice Merck 60 (230–400 mesh) ou 60H.

2,3,4-Tri-O-acétyl-β-L-rhamnopyranoside d'hordénine (12)

On ajoute, sous agitation magnétique, une solution de bromure de 4-*O*-acétyl-2,3-*O*-carbonyl-α-L-rhamnopyranosyle (**14**) (5) (0,6 g) dans le dichlorométhane anhydre (5 mL) à un mélange d'hordénine (**10**) (0,088 g, 0,53 mmol), de carbonate d'argent (0,7 g) et de tamis moléculaire 4 Å (1 g) dans du dichlorométhane anhydre (10 mL). Le milieu réactionnel est maintenu sous agitation à 20°C pendant 14 h, puis filtré et évaporé à sec. Après chromatographie (CH_2Cl_2–CH_3OH–ammoniaque à 34%, 90 : 10 : 1), on obtient 0,116 g (83%) d'un mélange non séparable de rhamnosides **15** et **16**. Ce mélange est additionné de méthanolate de sodium 0,1 N dans le méthanol (2 mL) puis maintenu 30 min sous agitation magnétique. La solution est neutralisée par addition de résine Amberlite IRC 50 H^+, filtrée et évaporée à sec. On obtient 0,130 g d'un mélange de rhamnosides **1** et **3** non séparables. Ce mélange, dissous dans la pyridine (1 mL), est additionné d'anhydride acétique (1 mL), abandonné 24 h à 20°C, puis évaporé à sec. Après chromatographie (CH_2Cl_2–CH_3OH, 95 : 5), on obtient successivement le 2,3,4-tri-*O*-acétyl-α-L-rhamnopyranoside

1,3,4-Tri-O-acétyl-2-O-(2,3,4-tri-O-acétyl-6-O-chloroacétyl-β-D-glucopyranosyl)-α-L-rhamnopyranose (24)

Une solution de diol **23** (0,100 g, 0,18 mmol) dans l'anhydride acétique (0,3 mL) est additionnée d'anhydride acétique contenant 1% d'H_2SO_4 (0,3 mL), puis agitée 1 h à 20°C. Après addition d'eau (20 mL), l'agitation est poursuivie pendant 2 h, puis la solution extraite par le dichlorométhane (2 × 20 mL). La solution organique est lavée par une solution aqueuse saturée de $NaHCO_3$ (2 × 20 mL), par de l'eau (20 mL), séchée, puis concentrée pour donner le disaccharide **24** (0,095 g, 77%) : $[\alpha]_D$ ±0 (*c* 1, MeOH); ir ($CHCl_3$) : 2920, 2840, 1750, 1600, 1370, 1130, 1035, 980, 910 cm^{-1}; rmn ^1H : 6,11 (1H, d, *J* 2 Hz, H-1), 5,22 (1H, t, *J* 9 Hz, H-3'), 5,16 (1H, dd, *J* 9, 3 Hz, H-3), 5,05 (2H, m, H-2', H-4'), 4,97 (1H, t, *J* 9 Hz, H-4), 4,53 (1H, d, *J* 8 Hz, H-1'), 4,33 (1H, dd, *J* 12, 7,5 Hz, H-6'a), 4,18 (1H, dd, *J* 12, 2 Hz, H-6'b), 4.14 (2H, s, OCOCH_2Cl), 4,01 (1H, dd, *J* 3, 2 Hz, H-2), 3,89 (1H, dq, *J* 9, 6,5 Hz, H-5), 3,75 (1H, ddd, *J* 9, 7,5, 2 Hz, H-5'), 2,11, 2,06, 1,99 (3 × 6 H, 3s, 6OCOCH_3), 1,19 (3H, d, *J* 6,5 Hz, CH_3-6); sm (dic) *m/z* : 674 $(M + NH_4)^+$, 672 $(M + NH_4)^+$, 638, 596, 480, 408, 365, 331, 155. Anal. calc. pour $C_{26}H_{35}O_{17}Cl$: C 47,67; H 5,38; Cl 5,41; trouvé : C 47,74; H 5,40; Cl 5,42.

1,3,4-Tri-O-acétyl-2-O-(2,3,4-tri-O-acétyl-β-D-glucopyranosyl)-α-L-rhamnopyranose (25)

On ajoute de la thiourée (0,1 g) dans le méthanol (5 mL) à une solution du disaccharide **24** (0,070 g, 0,11 mmol) dans le méthanol (18 mL). Le milieu réactionnel est agité 60 h à 20°C, puis évaporé à sec. Le résidu obtenu fournit, après chromatographie (CH_2Cl_2–CH_3OH, 99 : 1), l'alcool **25** (0,031 g, 50%) : $[\alpha]_D$ −19 (*c* 0,5, MeOH); ir ($CHCl_3$) : 3540, 1750, 1600, 1370, 1135, 1030, 950, cm^{-1}; rmn ^1H : 6,16 (1H, d, *J* 1,5 Hz, H-1), 5,24 (1H, t, *J* 9 Hz, H-3'), 5,14 (1H, dd, *J* 9, 2,5 Hz, H-3), 5,03 (1H, t, *J* 9 Hz, H-4'), 4,97 (1H, dd, *J* 9, 8 Hz, H-2'), 4,87 (1H, t, *J* 9 Hz, H-4), 4,49 (1H, d, *J* 8 Hz, H-1'), 4,01 (1H, dd, *J* 2,5, 1,5 Hz, H-2), 3,94 (1H, dq, *J* 9, 6,5 Hz, H-5), 3,59 (3H, m, H-5', H-6'a, H-6'b), 2,12, 2,06, 2,02 (3 × 6H, 3s, 6OCOCH_3), 1,21 (3H, d, *J* 6,5 Hz, CH_3-6); sm (dic) *m/z* : 596 $(M + NH_4)^+$, 306, 231. Anal. calc. pour $C_{24}H_{34}O_{16}$: C, 49,82; H, 5,92; trouvé : C, 49,91; H, 5,89.

(E)-1,3,4-Tri-O-acétyl-2-O-(2,3,4-tri-O-acétyl-6-O-cinnamoyl-β-D-glucopyranosyl)-α-L-rhamnopyranose (26)

On ajoute, à 0°C, du chlorure de (*E*)-cinnamoyle (0,10 g) et de la 4-diméthylaminopyridine (0,01 g) à une solution de l'alcool **25** (0,058 g, 0,1 mmol) dans la pyridine (3 mL). Le milieu réactionnel est agité à 20°C pendant 5 jours, puis évaporé à siccité. Le résidu obtenu fournit, après chromatographie (hexane–EtOAc, 90 : 10, 70 : 30, 50 : 50), le cinnamate **26** (0,059 g, 83%), identique à un échantillon authentique (3).

(E)-1,3,4-Tri-O-acétyl-2-O-[6-O-(4-acétoxycinnamoyl)-2,3,4-tri-O-acétyl-β-D-glucopyranosyl]-α-L-rhamnopyranose (27)

La technique décrite pour la préparation de **26** appliquée à **25** (0,058 g, 0,1 mmol) et au chlorure de (*E*)-4-acétoxycinnamoyle (0,10 g), permet d'obtenir le 4-acétoxycinnamate **27** (0,067 g, 87%), identique à un échantillon authentique (3).

2,4-Di-O-benzoyl-3-O-(2,3,4,6-tétra-O-acétyl-β-D-glucopyranosyl)-α-L-rhamnopyranoside de méthyle (31) et 2,4-di-O-benzoyl-3-O-(2,3,4,6-tétra-O-acétyl-α-D-glucopyranosyl)-α-L-rhamnopyranoside de méthyle (32)

La condensation du 2,4-di-*O*-benzoyl-α-L-rhamnopyranoside de méthyle (**28**) (33) (1,9 g, 5 mmol) avec le bromure de 2,3,4,6-tétra-*O*-acétyl-α-D-glucopyranosyle (**30**) (5 g), dans des conditions analogues à celles décrites pour la préparation de **21**, permit d'obtenir un résidu qui fournit successivement, après chromatographie (CH_2Cl_2), les deux disaccharides suivants.

(*i*) L'anomère α (**32**) (0,103 g, 2,8%) : $[\alpha]_D$ +86 (*c* 1,5, $CHCl_3$); ir (KBr) : 2995, 2940, 1755, 1725, 1600, 1450, 1370, 1270, 1220, 1180, 1110, 1070, 1040, 920, 800, 715 cm^{-1}; rmn ^1H : 8,15–7,46 (10H, m, 10Ar-*H*), 5,60 (1H, t, *J* 10 Hz, H-4), 5,51 (1H, dd, *J* 3, 1,5 Hz, H-2), 5,23 (1H, d, *J* 4 Hz, H-1'), 5,14 (1H, t, *J* 9 Hz, H-3'), 4,84 (2H, m, H-2', H-4'), 4,81 (1H, d, *J* 1,5 Hz, H-1), 4,40 (1H, dd, *J* 10, 3 Hz, H-3), 4,06 (1H, dq, *J* 10, 6 Hz, H-5), 3,86 (3H, m, H-5', H-6'a, H-6'b), 3,46 (3H, s, OCH_3), 2,07, 1,87, 1,64, 1,50, (4 × 3H, 4s, 4OCOCH_3), 1,35 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 734 $(M + NH_4)^+$, 331, 105. Anal. calc. pour $C_{35}H_{40}O_{16}$: C 58,65; H 5,62; Trouvé : C 58,57; H 5,65.

(*ii*) L'anomère β (**31**) (1,45 g, 55%) : $[\alpha]_D$ +38 (*c* 1, $CHCl_3$); ir (KBr) : 2990, 2940, 1755, 1720, 1600, 1450, 1370, 1320, 1265, 1220, 1180, 1110, 1070, 980, 910, 800, 715, cm^{-1}; rmn ^1H : 8,11–7,51 (10H, m, 10 Ar-*H*), 5,48 (1H, t, *J* 9 Hz, H-4), 5,44 (1H, dd, *J* 2,5, 1 Hz, H-2), 5,01 (1H, t, *J* 8 Hz, H-3'), 4,94 (1H, t, *J* 8 Hz, H-4'), 4,87 (1H, d, *J* 1 Hz, H-1), 4,86 (1H, t, *J* 8 Hz, H-2'), 4,67 (1H, d, *J* 8 Hz, H-1'), 4,35 (1H, dd, *J* 9, 2,5 Hz, H-3), 4,14 (1H, dd, *J* 12, 5 Hz, H-6'a), 4,08 (1H, dd, *J* 12, 2 Hz, H-6'b), 4,02 (1H, dq, *J* 9, 6 Hz, H-5), 3,66 (1H, ddd, *J* 8, 5, 2 Hz, H-5'), 3,48 (3H, s, OCH_3), 1,96, 1,94, 1,88, 1,38, (4 × 3H, 4s, 4OCOCH_3), 1,31 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 734 $(M + NH_4)^+$, 614, 331, 105. Anal. calc. pour $C_{35}H_{40}O_{16}$: C 58,65; H 5,62; trouvé : C 58,71; H 5,64.

O-β-D-Glucopyranosyl-(1 → 3)-α-L-rhamnopyranoside de méthyle (33)

Le disaccharide **31** (1,43 g, 2 mmol) est dissout dans une solution méthanolique de méthanolate de sodium (0,4 N, 6 mL) et le mélange est agité pendant 2 h à 20°C. La solution est neutralisée par addition de résine Amberlite IRC 50 H^+, filtrée et évaporée à sec. Après chromatographie du résidu obtenu sur silice greffée en phase inverse (Lichroprep RP 18, solvant : H_2O), on obtient le β-D-glucopyranosyl-α-L-rhamnopyranoside de méthyle (**33**) (0,666 g, 98%) : $[\alpha]_D$ −48 (*c* 0,5 EtOH); ir (KBr) : 3400, 2910, 1450, 1390, 1200, 1130, 1080, 1050, 980, 900, cm^{-1}; rmn ^1H (CD_3OD) : 4,63 (1H, d, *J* 1 Hz, H-1), 4,55 (1H, d, *J* 8 Hz, H-1'), 4,14 (1H, dd *J* 3, 1 Hz, H-2), 3,87 (1H, dd, *J* 12, 2 Hz, H-6'a), 3,77 (1H, dd, *J* 12, 4 Hz, H-6'b), 3,75–3,25 (7H, m, H-3, H-4, H-5, H-2', H-3', H-4', H-5'), 1,20 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 358 $(M + NH_4)^+$, 196, 180, 164. Anal. calc. pour $C_{13}H_{24}O_{10}$: C 45,88; H 7,11; trouvé : C 45,67; H 7,08.

2,4-Di-O-acétyl-3-O-(2,3,4-tri-O-acétyl-6-O-triphénylméthyl-β-D-glucopyranosyl)-α-L-rhamnopyranoside de méthyle (34)

On ajoute, sous agitation, du chlorure de triphénylméthyle (0,837 g, 3 mmol) à une solution de β-D-glucopyranosyl-(1 → 3)-α-L-rhamnopyranoside de méthyle (**33**) (0,438 g, 1,28 mmol) dans la pyridine (3 mL). L'agitation est poursuivie 15 h à 40°C. Après refroidissement à 25°C, le mélange est additionné d'anhydride acétique (2 mL), puis agité 4 h à température ambiante et concentré. Une chromatographie (CH_2Cl_2) du résidu donne le disaccharide **34** qui cristallise dans CH_2Cl_2 (0,62 g, 61%) : *F* 246–247°C; $[\alpha]_D$ +12,5 (*c* 1, $CHCl_3$); ir (KBr) : 3080, 3000, 2940, 1750, 1600, 1490, 1450, 1380, 1240, 1140, 1055, 980, 900, 770, 750, 710, 640 cm^{-1}; rmn ^1H : 7,51–7,28 (15H, m, 15 Ar-*H*), 5,33 (1H, dd, *J* 3, 1 Hz, H-2), 5,06 (4H, m, H-4, H-2′, H-3′, H-4′), 4,72 (1H, d, *J* 1 Hz, H-1), 4,64 (1H, d, *J* 8 Hz, H-1′), 4,24 (1H, dd, *J* 10, 3 Hz, H-3), 3,80 (1H, dq, *J* 10, 6 Hz, H-5), 3,58 (1H, m, H-5′), 3,28 (3H, s, OCH_3), 3,14 (2H, m, H-6′a, H-6′b), 2,16, 2,13, 2,04, 1,97, 1,73, (5 × 3H, 5s, 5-$OCOCH_3$), 1,24 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 810 $(M + NH_4)^+$, 568, 262, 243. Anal. calc. pour $C_{42}H_{48}O_{15}$: C 63,62; H 6,10; trouvé : C 63,67; H 6,12.

2,4-Di-O-acétyl-3-O-(2,3,4-tri-O-acétyl-β-D-glucopyranosyl)-α-L-rhamnopyranoside de méthyle (35)

Une solution du disaccharide **34** (0,3 g, 0,38 mmol) dans l'éthanol (15 mL) est additionnée de palladium à 10% sur charbon (0,2 g), puis maintenue sous atmosphère d'hydrogène, pendant 24 h, à la pression atmosphérique. Le mélange réactionnel est filtré, concentré et une chromatographie (CH_2Cl_2–CH_3OH, 99 : 1) du résidu donne l'alcool **35** qui cristallise dans CH_2CL_2 (0,18 g, 84%) : *F* 225°C; $[\alpha]_D$ +3 (*c* 1, $CHCl_3$); ir (KBr) : 3575, 2995, 2950, 1750, 1380, 1260, 1230, 1140, 1080, 1050, 980 cm^{-1}; rmn ^1H : 5,35 (1H, dd, *J* 3, 1 Hz, H-2), 5,23 (1H, t, *J* 9 Hz, H-3′), 5,04 (1H, t, *J* 10 Hz, H-4), 4,98 (1H, t, *J* 9 Hz, H-4′), 4,90 (1H, dd, *J* 9, 8 Hz, H-2′), 4,64 (1H, d, *J* 8 Hz, H-1′), 4,55 (1H, d, *J* 1 Hz, H-1), 4,02 (1H, dd, *J* 10, 3 Hz, H-3), 3,73 (1H, dq, *J* 10, 6 Hz, H-5), 3,67 (1H, m, H-5′), 3,55 (2H, m, H-6′a, H-6′b), 3,38 (3H, s, OCH_3), 2,16, 2,07, 2,05, 2,04, 2,01 (5 × 3H, 5s, 5$OCOCH_3$), 1,26 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 567 $(M + H)^+$. Anal. calc. pour $C_{23}H_{34}O_{15}$: C 48,76; H 6,04; trouvé : C 48,74; H 6,02.

2,4-Di-O-acétyl-α-L-rhamnopyranoside de méthyle (40)

Une solution d'α-L-rhamnopyranoside de méthyle (**29**) (29, 34) (3,8 g, 21,8 mmol) de triméthylorthoacétate (3,0 mL, 25,6 mmol) et d'acide toluène-4-sulfonique (0,05 g) dans la diméthylformamide (50 mL) est agitée 6 h à température ambiante. La solution est concentrée et on ajoute de l'anhydride acétique (5 mL) à une solution du résidu dans la pyridine (10 mL). Cette solution est agitée 18 h à température ambiante, diluée par du dichlorométhane (200 mL), lavée par une solution aqueuse d'HCl/N à 0°C (2 × 100 mL), par une solution aqueuse saturée de $NaHCO_3$ (2 × 100 mL), par l'eau glacée (2 × 100 mL), puis séchée et évaporée à sec. Le produit sirupeux obtenu est dissout dans l'acide acétique à 80% et la solution est agitée 30 min à température ambiante, puis évaporée. Le résidu d'évaporation permet d'isoler, après chromatographie (hexane-EtOAc, 70 : 30), le 2,4-di-*O*-acétyl-α-L-rhamnopyranoside de méthyle (**40**) qui cristallise dans EtOAc (4,74 g, 85%) : *F* 94°C; $[\alpha]_D$ −26 (*c* 1, MeOH); ir (KBr) : 3530, 2980, 2940, 2890, 1720, 1370, 1235, 1130, 1065, 1040, 970 cm^{-1}; rmn ^1H : 5,04 (1H, dd, *J* 3, 1 Hz, H-2), 4,85 (1H, t, *J* 9 Hz, H-4), 4,64 (1H, d, *J* 1 Hz, H-1), 3,98 (1H, ddd, *J* 9, 7, 3 Hz, H-3) 3,76 (1H, dq, *J* 9, 6 Hz, H-5), 3,39 (3H, s, OCH_3), 3,12 (1H, d, *J* 7 Hz, éch. D_2O, O*H*-3), 2,14, 2,09 (2 × 3H, 2s, 2$OCOCH_3$), 1,23 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 280 $(M + NH_4)^+$, 263 $(M + H)^+$. Anal. calc. pour $C_{11}H_{18}O_7$: C 50,37; H 6.92; trouvé : C 50,41; H 6,92.

(E)-2,4-Di-O-acétyl-3-O-(2,3,4-tri-O-acétyl-6-O-cinnamoyl-β-D-glucopyranosyl)-α-L-rhamnopyranoside de méthyle (36)

(*a*) L'acylation de l'alcool **35** (0,165 g, 0,3 mmol) par le chlorure de (*E*)-cinnamoyle (0,35 g), dans des conditions analogues à celles décrites pour la synthèse de **26**, fournit un résidu qui, après chromatographie (CH_2Cl_2), donne le cinnamate **36** (0,195 g, 96%) : $[\alpha]_D$ −9 (*c* 1, $CHCl_3$); ir (KBr) : 2950, 1760, 1710, 1640, 1380, 1250, 1225, 1070, 1055, 980, 910, 775 cm^{-1}; rmn ^1H: 7,82 (1H, d, *J* 16 Hz, H-7″), 7,62 (2H, m, H-2″, H-6″), 7,44 (3H, m, H-3″, H-4″, H-5″), 6,53 (1H, d, *J* 16 Hz, H-8″), 5,19 (1H, dd, *J* 3, 1 Hz, H-2), 5,14 (1H, t, *J* 9 Hz, H-3′), 5,09 (1H, t, *J* 9 Hz, H-4′), 5,05 (1H, t, *J* 10 Hz, H-4), 4,97 (1H, dd, *J* 9, 8 Hz, H-2′), 4,66 (1H, d, *J* 8 Hz, H-1′), 4,62 (1H, d, *J* 1 Hz, H-1), 4,35 (2H, m, H-6′a, H-6′b), 4,11 (1H, dd, *J* 10, 3 Hz, H-3), 3,81 (2H, m, H-5, H-5′), 3,28 (3H, s, OCH_3), 2,12, 2,11, 2,05, 2,04, 2,00 (5 × 3H, 5s, 5$OCOCH_3$), 1,21 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 698 $(M + NH_4)^+$, 280, 263, 245, 231. Anal. calc. pour $C_{32}H_{40}O_{16}$: C 56,47; H 5,92; trouvé : C 56,43; H 5,91.

(*b*) La condensation du 2,4-di-*O*-acétyl-α-L-rhamnopyranoside de méthyle (**40**) (0,262 g, 1 mmol) avec le bromure **41** (1 g, 2,1 mmol) dans des conditions analogues à celles décrites pour la préparation de **21**, permet d'obtenir un résidu qui donne, après chromatographie (CH_2Cl_2), le disaccharide **36** (0,414 g, 61%).

(E)-2,4-Di-O-acétyl-3-O-[6-O-(4-acétoxycinnamoyl)-2,3,4-tri-O-acétyl-β-D-glucopyranosyl]-α-L-rhamnopyranoside de méthyle (37)

(*a*) L'acylation de l'alcool **35** (0,165 g, 0,3 mmol) par le chlorure de (*E*)-4-acétoxycinnamoyle (0,45 g), dans des conditions analogues à celles décrites pour la synthèse de **26**, donne un résidu qui permet d'isoler, après chromatographie (CH_2Cl_2), l'acétoxycinnamate **37** (0,201 g, 94%) : $[\alpha]_D$ −8 (*c* 1 $CHCl_3$); ir (KBr) : 3000, 2950, 1830, 1790, 1740, 1710, 1610, 1540, 1480, 1330, 1270, 1165, 1035, 960, 910, 850, 775, cm^{-1}; rmn ^1H : 7,76 (1H, d, *J* 16 Hz, H-7″), 7,62 (2H, d, *J* 8 Hz, H-2″, H-6″), 7,13 (2H, d, *J* 8 Hz, H-3″, H-5″), 6,46 (1H, d, *J* 16 Hz, H-8″), 5,18 (1H, dd, *J* 3, 1 Hz, H-2), 5,15 (1H, t, *J* 9 Hz, H-3′), 5,09 (1H, t, *J* 9 Hz, H-4′), 5,05 (1H, t, *J* 10 Hz, H-4), 4,97 (1H, dd, *J* 9, 8 Hz, H-2′), 4,64 (1H, d, *J* 8 Hz, H-1′), 4,61 (1H, d, *J* 1 Hz, H-1), 4.33 (2H, m, H-6′a, H-6′b), 4,07 (1H, dd, *J* 10, 3 Hz, H-3), 3,75 (2H, m, H-5, H-5′), 3,26 (3H, s, OCH_3), 2,33 (3H, s, Ar$OCOCH_3$), 2,11, 2,10, 2,05, 2,04, 2,00, (5 × 3H, 5s, 5R$OCOCH_3$), 1,21 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 756 $(M + NH_4)^+$, 477, 245, 189, 147. Anal. calc. pour $C_{34}H_{42}O_{18}$: C 55,28; H 5,73; trouvé : C 55,21; H 5,77.

(*b*) La condensation du 2,4-di-*O*-acétyl-α-L-rhamnopyranoside de méthyle (**40**) (0,262 g, 1 mmol) avec le bromure **42** (1,2 g), dans des conditions analogues à celles décrites pour la préparation de **21**, permet d'obtenir un résidu qui, après chromatographie (CH_2Cl_2), donne le disaccharide **37** (0,435 g; 59%).

(E)-1,2,4-Tri-O-acétyl-3-O-(2,3,4-tri-O-acétyl-6-O-cinnamoyl-β-D-glucopyranosyl)-α-L-rhamnopyranose (38)

L'acétolyse du méthylglycoside **36** (0,100 g, 0,15 mmol), dans des conditions analogues à celles décrites pour la préparation de **24**, fournit un résidu qui, après chromatographie (hexane–EtOAc, 60 : 40), permet l'obtention du disaccharide **38** (0,082 g, 80%), identique à un échantillon authentique (3).

(E)-1,2,4-Tri-O-acétyl-3-O-[6-O-(4-acétoxycinnamoyl)-2,3,4-tri-O-acétyl-β-D-glucopyranosyl]-α-L-rhamnopyranose (39)

L'acétolyse du méthylglycoside **37** (0,120 g, 0,16 mmol), dans les conditions identiques à celles décrites pour la préparation de **24**, donne, après chromatographie (hexane–EtOAc, 60 : 40), donne le disaccharide **39** (0,094 g, 77%), identique à un échantillon authentique (3).

(E)-2,3-O-Isopropylidène-4-O-(2,3,4-tri-O-acétyl-6-O-cinnamoyl-β-D-glucopyranosyl)-α-L-rhamnopyranoside de méthyle (44)

On ajoute sous agitation du bromure **41** (1 g, 2,1 mmol) et du tamis moléculaire 3 Å (1 g) à une solution de 2,3-*O*-isopropylidène-α-L-rhamnopyranoside de méthyle (**43**) (29) (0,35 g, 1,6 mmol) et de cyanure mercurique (0,37 g) dans l'acétonitrile anhydre (10 mL). L'agitation est poursuivie pendant 5 h, puis le milieu réactionnel est filtré et concentré pour donner un résidu si-

rupeux qui est dissous dans du dichlorométhane (20 mL), puis lavé par une solution aqueuse 1 M de KBr (2 × 10 mL), par une solution aqueuse saturée de $NaHCO_3$ (10 mL), par de l'eau (2 × 10 mL), puis séché et concentré. Après chromatographie (hexane–EtOAc, 80 : 20), on obtient le disaccharide **44** (0,865 g, 85%) : $[\alpha]_D$ −8 (*c* 0,5, $CHCl_3$); ir (KBr) : 3000, 2950, 1760, 1720, 1640, 1455, 1380, 1250, 1225, 1170, 1090, 1045, 980, 910, 875, 775, 690 cm^{-1}; rmn ^1H : 7,72 (1H, d, *J* 16 Hz, H-7″), 7,56 (2H, m, H-2″, H-6″), 7,40 (3H, m, H-3″, H-4″, H-5″), 6,43 (1H, d, *J* 16 Hz, H-8″), 5,28 (1H, t, *J* 9 Hz, H-3′), 5,11 (1H, t, *J* 9 Hz, H-4′), 5,01 (2H, m, H-1′, H-2′), 4,86 (1H, d, *J* 1 Hz, H-1), 4,39 (1H, dd, *J* 12, 2 Hz, H-6′b), 4,28 (1H, dd, *J* 12, 5 Hz, H-6′a), 4,08 (2H, m, H-2, H-3), 3,79 (1H, ddd, *J* 9, 5, 2 Hz, H-5′), 3,59 (2H, m, H-4, H-5), 3,34 (3H, s, OCH_3), 2,07, 2,06, 2,05 (3 × 3H, 3s, $3OCOCH_3$), 1,54, 1,36 (2 × 3H, 2s, $C(CH_3)_2$), 1,29 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 654 $(M + NH_4)^+$, 234, 201, 143, 131. Anal. calc. pour $C_{31}H_{40}O_{14}$: C 58,48; H 6,33; trouvé : C 58,42; H 6,36.

(E)-2,3-O-Isopropylidène-4-O-[6-O-(4-acétoxycinnamoyl)-2,3,4-tri-O-acétyl-β-D-glucopyranosyl]-α-L-rhamnopyranoside de méthyle (45)

La condensation du 2,3-*O*-isopropylidène-α-L-rhamnopyranoside de méthyle (**43**) (29) (0,33 g, 1,5 mmol) avec le bromure **42** (1 g, 2,1 mmol), dans des conditions analogues à celles décrites pour la synthèse de **44** permet d'obtenir, après chromatographie (hexane–EtOAc, 80 : 20), le disaccharide **45** (0,780 g, 75%) : $[\alpha]_D$ −3 (*c* 1, $CHCl_3$); ir (KBr) : 3000, 2950, 1760, 1720, 1640, 1605, 1510, 1375, 1250, 1225, 1170, 1095, 1045, 1025, 985, 915, 865, 790, 740 cm^{-1}; rmn ^1H : 7,77 (1H, d, *J* 16 Hz, H-7″), 7,60 (2H, d, *J* 9 Hz, H-2″, H-6″), 7,19 (2H, d, *J* 9 Hz, H-3″, H-5″), 6.41 (1H, d, *J* 16 Hz, H-8″), 5,33 (1H, t, *J* 9 Hz, H-3′), 5,17 (1H, t, *J* 9 Hz, H-4′), 5,05 (2H, m, H-1′, H-2′), 4,88 (1H, d, *J* 1 Hz, H-1), 4,44 (1H, dd, *J* 12, 2 Hz, H-6′b), 4,29 (1H, dd, *J* 12, 6 Hz, H-6′a), 4,12 (2H, m, H-2, H-3), 3,81 (1H, ddd, *J* 9, 6, 2 Hz, H-5′), 3,61 (2H, m, H-4, H-5), 3,38 (3H, s, OCH_3), 2,35 (3H, s, $ArOCOCH_3$), 2,09, 2,08, 2,04 (3 × 3H, 3s, $3ROCOCH_3$), 1,55, 1,36 (2 × 3H, 2s, $C(CH_3)_2$), 1,29 (3H, d, *J* 6 Hz, CH_3-6). sm (dic) *m/z* : 712 $(M + NH_4)^+$, 234, 210, 143. Anal. calc. pour $C_{33}H_{42}O_{16}$: C 57,06; H 6,09; trouvé : C 56,98; H 6,10.

(E)-4-O-(2,3,4-Tri-O-acétyl-6-O-cinnamoyl-β-D-glucopyranosyl)-α-L-rhamnopyranoside de méthyle (46)

Une solution de l'acétal **44** (0,64 g, 1 mmol) dans le chloroforme (31,5 mL), est additionnée d'acide trifluoroacétique contenant 1% d'eau (3,5 mL), puis abandonnée 1 h à température ambiante. Le solvant est éliminé par évaporation et l'acide trifluoroacétique par codistillation avec le benzène. Le résidu obtenu fournit, après chromatographie (hexane–EtOAc, 80 : 20, 50 : 50), le diol **46** (0,44 g, 73%) : $[\alpha]_D$ −41 (*c* 0,5, $CHCl_3$); ir (KBr) : 3500, 2950, 1760, 1715, 1640, 1455, 1380, 1250, 1225, 1170, 1065, 1040, 980, 910, 775, 690 cm^{-1}; rmn ^1H : 7,74 (1H, d, *J* 16 Hz, H-7″), 7,57 (2H, m, H-2″, H-6″), 7,41 (3H, m, H-3″, H-4″, H-5″), 6,46 (1H, d, *J* 16 Hz, H-8″), 5,24 (1H, t, *J* 9 Hz, H-3′), 5,12 (1H, t, *J* 9 Hz, H-4′), 5,01 (1H, dd, *J* 9, 8 Hz, H-2′), 4,89 (1H, d, *J* 8 Hz, H-1′), 4,66 (1H, d, *J* 1,5 Hz, H-1), 4,41 (1H, dd, *J* 12, 2 Hz, H-6′b), 4,26 (1H, dd, *J* 12, 6 Hz, H-6′a), 3,92 (1H, dd, *J* 5, 1,5 Hz, H-2), 3,89 (2H, m, H-5, H-5′), 3,67 (1H, dd, *J* 9, 5 Hz, H-3), 3,56 (1H, t, *J* 9 Hz, H-4), 3,34 (3H, s, OCH_3), 2,80, 2,39 (2 × 1H, 2s larges, éch. D_2O, O*H*-2, O*H*-3), 2,08, 2,06, 2,01 (3 × 3H, 3s, $3OCOCH_3$), 1,31 (3H, d, *J* 6 Hz, CH_3-6); sm (dic) *m/z* : 614 $(M + NH_4)^+$. Anal. calc. pour $C_{28}H_{36}O_{14}$: C 56,37; H 6,08; trouvé : C 56,41; H 6,07.

(E)-4-O-[6-O-(4-Acétoxycinnamoyl)-2,3,4-tri-O-acétyl-β-D-glucopyranosyl]-α-L-rhamnopyranoside de méthyle (47)

Le traitement de l'acétal **45** (0.70 g, 1 mmol), dans des conditions analogues à celles décrites pour l'obtention de **46**, donne, après chromatographie (hexane–EtOAc, 60 : 40), le diol **47** (0,51 g, 78%) : $[\alpha]_D$ −32 (*c* 0,5, $CHCl_3$); ir (KBr) : 3500, 3000, 2950, 1760, 1710, 1640, 1455, 1380, 1310, 1250, 1225, 1160, 1060, 1040, 980, 910, 790, 740 cm^{-1}; rmn ^1H : 7,70 (1H, d, *J* 16 Hz, H-7″), 7,59 (2H, d, *J* 9 Hz, H-2″, H-6″), 7,14 (2H, d, *J* 9 Hz, H-3″, H-5″), 6,42 (1H, d, *J* 16 Hz, H-8″), 5,28 (1H, t, *J* 9 Hz, H-3′), 5,14 (1H, t, *J* 9 Hz, H-4′), 5,01 (1H, dd, *J* 9, 8 Hz, H-2′), 4,92 (1H, d, *J* 8 Hz, H-1′) 4,63 (1H, d, *J* 1,5 Hz, H-1), 4,42 (1H, dd, *J* 12, 2 Hz, H-6′b), 4,27 (1H, dd, *J* 12, 5 Hz, H-6′a), 3,90 (1H, dd, *J* 3, 1,5 Hz, H-2), 3,82 (2H, m, H-5, H-5′), 3,64 (1H, dd, *J* 9, 3 Hz, H-3), 3,55 (1H, t, *J* 9 Hz, H-4), 3,35 (3H, s, OCH_3), 2,92 (2H, m large, éch. D_2O, O*H*-2, O*H*-3), 2,31 (3H, s, $ArOCOCH_3$), 2,08, 2,06, 2,01 (3 × 3H, 3s, 3 $ROCOCH_3$), 1,30 (3H, d, *J* 6 Hz, CH_3-6). sm (dic) *m/z* : 672 $(M + NH_4)^+$. Anal. calc. pour $C_{30}H_{38}O_{16}$: C 55,04; H 5 85; trouvé : C 55,09; H 5,85.

(E)-1,2,3-Tri-O-acétyl-4-O-(2,3,4,-tri-O-acétyl-6-O-cinnamoyl-β-D-glucopyranosyl)-α-L-rhamnopyranose (48)

Le traitement du diol **46** (0,40 g, 0,67 mmol), dans des conditions identiques à celles décrites pour la préparation de **24**, fournit, après chromatographie (hexane–EtOAc, 60 : 40), le disaccharide **48** (0,325 g, 68%), identique à un échantillon authentique (3).

(E)-1,2,3-Tri-O-acétyl-4-O-[6-O-(4-acétoxycinnamoyl)-2,3,4-tri-O-acétyl-β-D-glucopyranosyl]-α-L-rhamnopyranose (49)

Le traitement du diol **47** (0,45 g, 0.68 mmol), dans des conditions analogues à celles décrites pour la préparation de **24**, fournit, après chromatographie (hexane–EtOAc, 60 : 40), le disaccharide **49** (0,344 g, 68%), identique à un échantillon authentique (3).

Remerciements

Nous remercions les Drs. G. Massiot et C. Lavaud (Laboratoire de pharmacognosie, Faculté de pharmacie, Université de Reims) pour de fructueuses discussions sur les expériences de COSY à acquisition retardée.

Diurnal and seasonal modelling of the tropospheric half-lives of polycyclic aromatic hydrocarbons

NIGEL J. BUNCE[1] AND HELENA G. DRYFHOUT
Department of Chemistry and Biochemistry, University of Guelph, Guelph, Ont., Canada, N1G 2W1

Received December 6, 1991

NIGEL J. BUNCE and HELENA G. DRYFHOUT. Can. J. Chem. **70**, 1966 (1992).

The half-lives of polycyclic aromatic hydrocarbons (PAH) were calculated under different conditions of location, season, and time of day, based on the reaction of PAH with the hydroxyl radical OH as the major sink. The calculations required a method of estimating the diurnal variation in the concentration of OH, which is not normally available experimentally. For naphthalene as a prototype PAH, the half-lives were of the order of several hours, but varied by more than an order of magnitude with season and geographical location. The previously developed model applicable to rural atmospheres was modified to estimate the half-lives of PAH in the urban troposphere by including of the reaction of OH with NO_2 as a major urban sink for OH. The half-lives of several PAH were estimated for North York, Ontario, under different conditions of NO_2 and ozone concentrations during a period of high tropospheric air pollution in July 1988.

NIGEL J. BUNCE et HELENA G. DRYFHOUT. Can. J. Chem. **70**, 1966 (1992).

Utilisant le réaction des HAP avec le radical OH comme modèle pour leur mode principal d'élimination, on a calculé les demi-vies des hydrocarbures aromatiques polycycliques (HAP) dans diverses conditions, comme le lieu, la saison et l'heure du jour. Pour ces calculs, il a été nécessaire d'évaluer la variation diurne de la concentration en OH; cette valeur n'est généralement pas disponible d'une façon expérimentale. Pour le naphtalène comme prototype des HAP, les demi-vies sont de l'ordre de plusieurs heures; elles varient toutefois par plus d'un ordre de grandeur avec la saison et l'emplacement géographique. Dans le but d'évaluer les demi-vies de HAP dans des troposphères urbaines, on a modifié le modèle développé antérieurement et applicable aux atmosphères ruraux en incluant le réaction de OH avec NO_2 comme piège urbain principal pour les OH. Utilisant diverses concentrations de NO_2 et d'ozone durant une période de haute pollution de l'air troposphérique, en juillet 1988, on a évalué les demi-vies de plusieurs HAP pour North York, Ontario.
[Traduit par la rédaction]

Introduction

Tropospheric pollutants may be removed from a given region of the atmosphere by physical removal involving either wet or dry deposition, by transport out of the area through the movement of air masses, and by chemical reaction. The tropospheric lifetime of the pollutant depends on the rates of all three processes, whereas the rate of chemical reaction relative to those of the other processes determines whether the pollutant will eventually be deposited in its original form or as a secondary pollutant.

Chemical transformation in the lower atmosphere may occur through photolysis by sunlight, provided that the pollutant contains a chromophore that absorbs in the range of wavelengths of tropospheric solar radiation ($\lambda > 290$ nm). Alternatively, a substrate may react with one of several reactive substances which are present at low concentrations in the troposphere. These include hydroxyl radicals, ozone, and nitrate radicals, the latter being significant only at night.

In daylight hours, the predominant reactive substance is usually the hydroxyl radical, whose characteristic reactions are hydrogen-atom abstraction and addition to an unsaturated centre, the latter process occurring both for inorganic molecules such as NO_2 and SO_2, and for unsaturated organic substances (alkenes and aromatics). The reaction with OH is normally second-order kinetically, and so both the rate constant and the concentration of OH must be known in order to estimate the rate of the reaction or the half-life of the substance (eq. [1]).

$$[1] \quad \text{rate} = k\,[\text{substrate}]\,[\text{OH}]$$

Many gas-phase rate constants of interest have been measured in the laboratory (1). Rates of reaction have often been calculated by using globally, seasonally, and diurnally averaged estimates of OH concentrations (2), an approach which is appropriate for long-lived tropospheric gases. However, the assumption of a constant concentration of OH fails for short-lived gases: the concentration of OH in the troposphere varies diurnally, seasonally, and geographically according to the solar photon intensity, since OH is formed by a photochemical reaction sequence (Scheme 1). These dependencies of the concentration of OH must be known in order to estimate the lifetimes of short-lived substrates. Unfortunately, the OH concentration is difficult to obtain in the field, because OH has few convenient absorption bands that are easily distinguished from those of other chemicals in the atmosphere and also because its concentration is always extremely low ($<10^{-14}$ atm).

$$[2] \quad NO_2 \xrightarrow{h\nu,\ \lambda < 400\ \text{nm}} NO + O(^3P)$$
$$[3] \quad O(^3P) + O_2 \longrightarrow O_3$$
$$[4] \quad O_3 \xrightarrow{h\nu,\ \lambda < 320\ \text{nm}} O_2(^1\Delta_g) + O(^1D)$$
$$[5] \quad O(^1D) + H_2O \longrightarrow 2OH$$

SCHEME 1

Polycyclic aromatic hydrocarbons (PAH) are tropospheric pollutants that result from incomplete combustion of fuels, notably vehicular emissions (e.g., ref. 3), and hence are present at higher concentrations in the urban troposphere than in the rural troposphere. PAH containing four or fewer benzene rings exist almost exclusively in the gas phase under tropospheric conditions. Previous research has shown that PAH are rather short lived in the troposphere and that

For personal use only.

they react predominantly by way of hydroxyl radical attack (4).

The fate of PAH in the troposphere is important because of the well-documented toxicity of some members of the family and because they are transformed in the troposphere into a wide variety of secondary pollutants, including phenolics, nitro-PAH, and nitrophenols. Although the complete spectrum of products has not yet been identified, even for reactants as simple as toluene and naphthalene (4), some of the known secondary products are more toxic than the parent PAH on the basis of mutagenicity assays (5).

Methodology

We recently developed a simple computational model to estimate the half-lives of pollutants in the atmosphere with respect to photolysis and (or) reaction with OH radicals (6). The model was developed following observations by Platt *et al.* (7) which imply that the OH concentration in the rural troposphere is directly proportional to the rate of photolysis of (tropospheric) ozone (eq. [6]).

$$[6] \quad [OH] = \text{constant} \times J(O_3) \times [O_3]$$

$J(O_3)$ is the rate constant for the photolysis of ozone, which depends on the intensity of sunlight. $J(O_3)$ can be calculated at any time of day for any location and date by making use of tables of tropospheric intensity vs. wavelength for defined zenith angles (8). The zenith angle can be calculated for any time, date, and location, and the solar intensities at each wavelength interpolated from the tabulated data. $J(O_3)$ can then be calculated at a single wavelength, knowing the absorption cross section of ozone σ_λ and the quantum yield ϕ_λ for reaction [4] at that wavelength (eq. [7]).

$$[7] \quad J(O_3)_\lambda = I_\lambda \cdot \sigma_\lambda \cdot \phi_\lambda$$

$J(O_3)_\lambda$ must then be summed over all the tropospheric wavelengths at which ozone absorbs. Once $J(O_3)$ is known, the rate of reaction of the pollutant with OH follows by application of eq. [6] and [1].

Equation [8] is the expression for the concentration of [OH], assuming an instantaneous steady state.

$$[8] \quad [OH] = \frac{\alpha J(O_3)[O_3] + \Sigma k_f[Y]}{\Sigma k_l[X]}$$

In eq. [8], α is the proportionality constant to convert the rate of photolysis of ozone to the rate of formation of OH, $\Sigma k_f[Y]$ is the rate of other source reactions of OH, and $\Sigma k_l[X]$ is the combined rate of all sink reactions (eq. [1]). The experimental finding that $[OH] \propto J(O_3)$, eq. [6], implies that the predominant source of OH is the photolysis of ozone ($\alpha J(O_3)[O_3] >> \Sigma k_f[Y]$), at least in the rural area where the measurements were made (7). Under these conditions, eq. [8] simplifies to eq. [9].

$$[9] \quad [OH]_r = \frac{\alpha J(O_3)[O_3]}{\Sigma k_l[X]}$$

The hydroxyl radical reacts rapidly and irreversibly with NO_2, eq. [10]. This reaction is relatively unimportant in the unpolluted troposphere where $[NO_2]$ is low, but becomes a major sink for OH in the urban troposphere whenever $[NO_2]$ exceeds a few ppbv (9).

$$[10] \quad NO_2 + OH \rightarrow HNO_3$$

$$k = 1.16 \times 10^{-11} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$$

The relationship between $[NO_2]$ and [OH] is therefore complex; NO_2 is both a precursor of OH (Scheme 1) and a sink (eq. [10]). The inclusion of reaction [10] as a major sink for OH changes eq. [9] to eq. [11], in which subscripts u and r refer to urban and rural.

$$[11] \quad [OH]_u = \frac{\alpha J(O_3)[O_3]}{\Sigma k_l[X] + k[NO_2]}$$

By equating $\Sigma k_l[X]$ in eqs. [9] and [11], the urban OH concentration can be approximated by eq. [12].

$$[12] \quad [OH]_u = \frac{\alpha J(O_3)[O_3][OH]_r}{\alpha J(O_3)[O_3] + k[NO_2][OH]_r}$$

This equation was incorporated into the model developed for rural atmospheres (6). An attempt to validate the revised model was made by using it to estimate the OH concentration for the data set reported by Dorn *et al.* (9).

TABLE 1. Rate constants for reaction of PAH with OH

Chemical	k (cm^3/(molec s))	$t_{1/2}$(h)
Acenaphthene	1.03×10^{-10}[a]	1.6
Acenapthylene	1.10×10^{-10}[a]	1.5
Anthracene	1.1×10^{-10}[b]	1.5
Biphenyl	8.1×10^{-11}[b]	1.9
Fluoranthene	5.0×10^{-11}[c]	2.5
Naphthalene	2.2×10^{-11}[b]	3.9
Phenanthrene	3.4×10^{-11}[b]	3.4
Pyrene	5.0×10^{-11}[c]	2.5
Styrene	5.9×10^{-11}[a]	2.2

Results and discussion

Although PAH can in principle be altered chemically both by photolysis and reaction with OH, the latter reaction is their principal chemical sink (4) and so quantum yields of photolysis were taken to be zero.

The half-lives of several PAH were estimated under different conditions of time, place, and date. Rate constants for the reaction of OH with several PAH are given in Table 1 along with half-life estimates for various PAH at latitude 43.70°N, the same latitude as Toronto, Ontario (43.70°N, 79.47°W) on March 21, starting at 8:00 a.m., and assuming a single, instantaneous emission of the PAH. These initial calculations employed the original (rural) model and hence apply to the latitude of Toronto, rather than to Toronto itself. Because of the high rate constants of OH with PAH, all the half-lives are very short, a few hours, hence a globally and seasonally averaged concentration of OH would be inappropriate for modelling the behaviour of PAH.

Figures 1–3 show the results of calculations involving naphthalene as a prototype PAH, again using the rural model. Figure 1 shows the half-life of naphthalene at 43.70°N on

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12

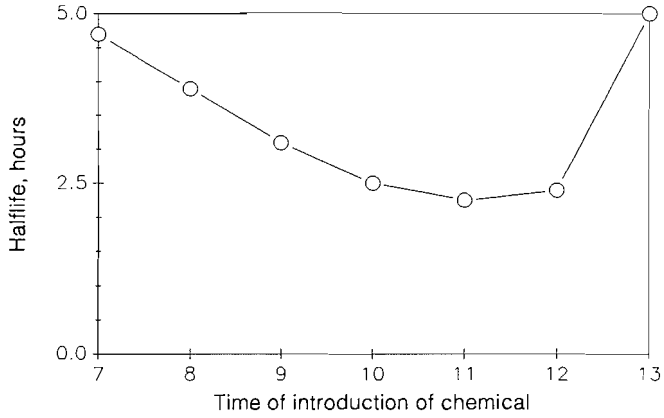

FIG. 1 Variation of the half-life of naphthalene using rural model at 43.7°N on March 21 according to the time of emission.

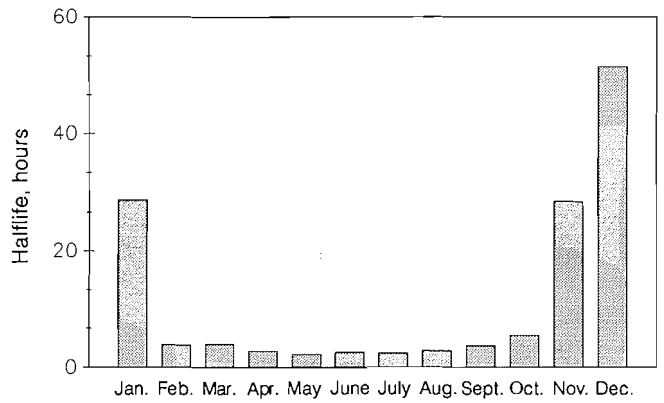

FIG. 2 Monthly variation of the half-life of naphthalene at 43.7°N using rural model: emission at 8:00 a.m. on the 21st of the month.

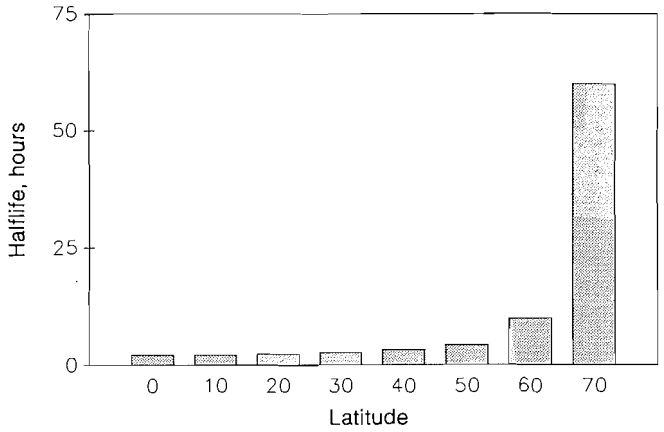

FIG. 3 Estimate of half-life of naphthalene at different latitudes using the rural model: emission at 8:00 a.m. on March 21.

March 21, with the single emission of naphthalene occurring at different times of the day. The half-life is, as expected, shortest when there is the maximum exposure to the highest solar intensities near noon. A late afternoon emission gives a longer lifetime, because any PAH not destroyed by sunset will survive the night unchanged.[2]

[2]In practice, this statement is an approximation, because the model does not take account of the nighttime reaction of PAH with the NO_3 radical.

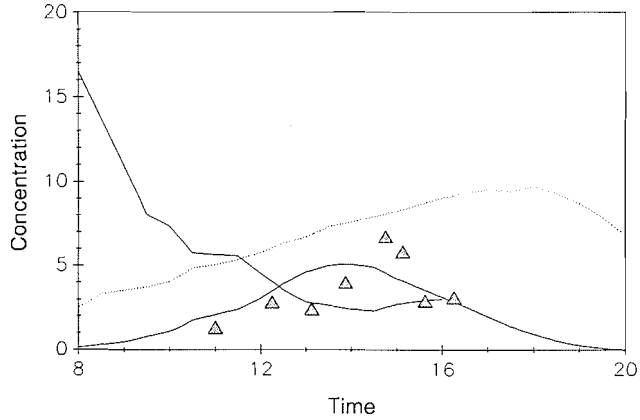

FIG. 4 Verification of urban model using experimental measurements from Dorn *et al.* (9) in Julich, Germany, on July 14, 1987. Symbols represent experimental measurements. Lower solid line, calculated OH concentration ($\times 10^{-6}$ radicals cm^{-3}); dotted line, ozone concentration ($\times 10^{-1}$ ppbv); upper solid line NO_2 concentration (ppbv).

Figure 2 is a similar calculation for a single emission of naphthalene at 8:00 a.m. at different seasons, again at 43.70°N. A substantial difference exists between winter ($t_{1/2}$ ~ 2 days) and summer ($t_{1/2}$ ~ 2–3 h). In winter the zenith angle of the sun is greater, leading to a slower rate of photolysis of ozone and therefore a lower OH concentration. Other calculations (not shown) demonstrate that the divergence between winter and summer increases at higher latitudes. Figure 3 illustrates the variation in half-life with latitude, again for a single emission of naphthalene at 8:00 a.m. on March 21. These calculations with the rural model exemplify the variation of half-life with time of day, season, and place for a short-lived tropospheric component such as PAH, but do not attempt to simulate urban conditions.

Verification of the urban model

The NO_2 and ozone concentrations reported by Dorn *et al.* (9) for Julich, Germany, for July 14, 1987, were used to determine how well the model reproduced the experimental concentrations of OH. The importance of this data set is that the diurnal variations of OH, NO_2, and O_3 were all measured. The calculated concentration of OH is shown in Fig. 4 along with the experimental values for the concentrations of NO_2, ozone, and OH. For purposes of calculation, the concentrations of NO_2 and O_3 from the paper were approximated by the functions below (t = hours elapsed since 8 a.m.).

$$O_3 \text{ (ppbv)} = 20 + 9.2t \text{ (time} < 1700 \text{ h)}$$

$$= 130 \text{ (time} > 1700 \text{ h)}$$

$$NO_2 \text{ (ppbv)} = 16.5 - 5.33t + 0.53t^2 \text{ (time} < 1320 \text{ h)}$$

$$= 3.0 \text{ ppb (time} > 1320 \text{ h)}$$

Figure 4 shows an acceptable concordance between the calculated and the experimental values of [OH]. In this context, acceptable means that the experimental trend in OH was reproduced and the quantitative agreement between calculation and experiment was within a factor of 2. As we have stated previously (10), the models presented here were designed to provide a rapid estimate of tropospheric lifetimes

using only spreadsheet software, and that additional precision would be computationally much more intensive.[3]

Reaction [10] is important in regulating the concentration of OH. The high NO_2 concentrations early in the day in Fig. 4 result from early morning rush hour traffic, which produces NO, subsequently oxidized to NO_2 by agents such as O_3 and HO_2. The OH concentration remains very low during this period due to low photon intensity (slow reaction [4]) coupled with high [NO_2] (fast reaction [10]). As the morning proceeds, rising solar intensity increases the rate of formation of OH, and the removal of NO_2 by reaction [10] outstrips its rate of emission. The concentration of NO_2 therefore falls, allowing the OH radical concentration to build up. The afternoon rush hour does not greatly increase the concentration of NO_2, since reaction [10] removes NO_2 as it forms.

A serious limitation of the present model is the lack of data with which to validate it—so far, only the set of measurements of OH concentrations in the urban troposphere reported by Dorn *et al.* (9). More measurements of this sort are clearly needed.

Application of the urban model

The data set of Dorn *et al.* (9) is unique in providing experimental measurements of the diurnal variation of O_3, NO_2, and OH. As stated earlier, [OH] cannot yet be routinely measured, and so its concentration must be calculated in order to estimate the half-lives of pollutants such as PAH. Calculations with the urban model require time-dependent concentrations of O_3 and NO_2 to be provided in order to calculate the time-dependent concentration of OH. The diurnal variations of O_3 and NO_2 are only available for a limited number of locations. An especially useful data set has been collected by the Ontario Ministry of the Environment.[4] The data used in the present paper are from the monitoring station at North York and relate to a period in July 1988 when Southern Ontario experienced a protracted hot, dry spell with severe air pollution. Three days were modelled on which very different NO_2 (actually measured as [NO_x – NO]) and ozone concentrations were recorded. The experimental and calculated OH concentrations for July 27, July 7, and July 18 are shown in Figs. 5–7.

The NO_2 and O_3 concentrations for July 27 (Fig. 5) exemplify a normal summer day. The pattern is similar both to the validation data set from Julich, Germany (except that the concentration of NO_2 increases in the afternoon rather than decreases), and to the "textbook" diurnal patterns of pollutants which have been observed in Los Angeles, California, since the late 1940's. The calculated OH concentration peaks at about 6×10^6 molec cm^{-3}.

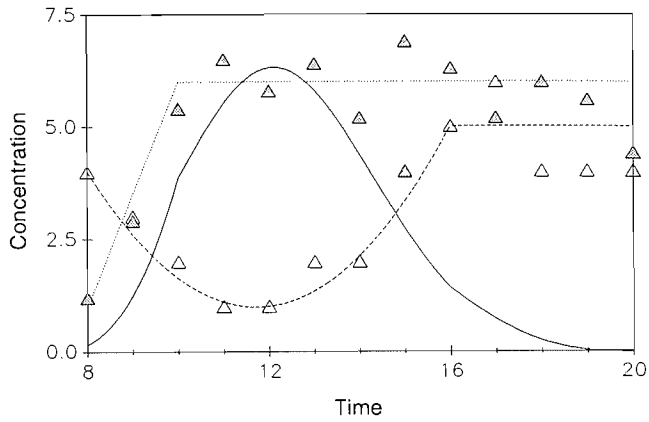

FIG. 5 Estimate of OH concentration in North York, Ont., on July 27, 1988. Symbols represent actual experimental measurements; symbols represent experimental measurements. Solid line (no symbols), calculated OH concentration ($\times 10^{-6}$ radicals cm^{-3}); symbols: dotted line and filled triangles, ozone concentration ($\times 10^{-1}$ ppbv); dashed line and open triangles, NO_2 concentration (ppbv).

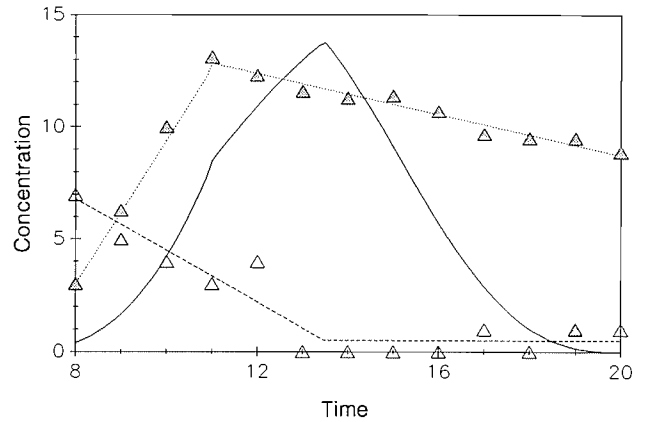

FIG. 6 Estimate of OH concentration in North York, Ont., on July 7, 1988. Symbols and lines as in Fig. 5.

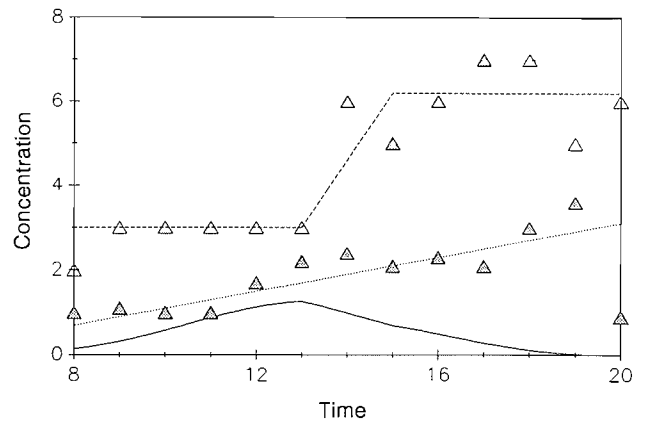

FIG. 7 Estimate of OH concentration in North York, Ont., on July 18, 1988. Symbols and lines as in Fig. 5.

[3]In particular, eq. [11] and [12] do not account for all sources and sinks of OH. For example, the photolysis of HONO is sometimes the chief source of OH in the early morning, and under some conditions reaction cycles involving OH-initiated reactions of hydrocarbons can be a net producer of OH. Under conditions of high [NO], the reaction of OH with CO may not lead to a net loss of OH due to the cycle below.

$$CO + OH \rightarrow CO_2 + H$$
$$H + O_2 \rightarrow HO_2$$
$$HO_2 + NO \rightarrow NO_2 + OH$$

Likewise, we have not included in the model the effect of the partial pressure of water (which affects the source strength of OH; Scheme 1) or other sinks for PAH such as reaction with NO_3 during darkness.

[4]Personal communication from Annette Deane, Air Resources Branch, Ontario Ministry of the Environment.

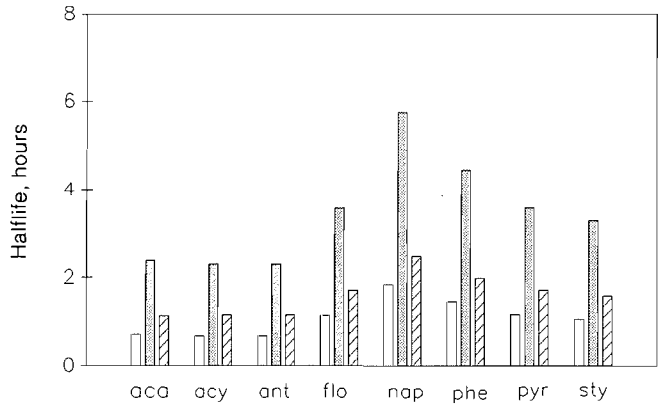

FIG. 8 Estimate of half-life of several PAH using the urban model in North York for the dates July 7, 18, and 27, 1988: emission of PAH at 8:00 a.m. Abbreviations: aca, acenaphthene; acy, acenaphthylene; ant, anthracene; flo, fluoranthrene; nap, naphthalene; phe, phenanthrene; pyr, pyrene; sty, styrene.

The ozone concentrations on July 7 (Fig. 6) were unusually high. This produced very high concentrations of OH because the rate of photolysis of ozone is proportional to the concentration of ozone. This is consistent with an experimental data set reported from Glendora, California, for August 1986 when, during a protracted period of high air pollution, 12-h average concentrations of OH of 2×10^6 radicals cm^{-3} were recorded (11). The negligible concentration of NO_2 in the afternoon of July 7 was presumably due to the efficient removal of NO_2 by the high concentration of OH (reaction [10]).

On July 18 (Fig. 7), the ozone concentration was unusually low and $[NO_2]$ increased as the day progressed. These factors combined to limit the rate of formation of OH and to maximize its rate of removal, and so on July 18 the OH concentration was unusually low.

The estimated half-lives of several PAH under these urban conditions are shown in Fig. 8. For example, the value for the half-life of naphthalene calculated on the "typical" day July 27 is about 2.5 h. On July 7, when the concentrations of OH were extremely high, the half-life was less than 2 h. Conversely on July 18, when concentrations of OH were very low, the half-life tripled to just under 6 h.

The OH concentration depends in a complex manner on the composition of the urban troposphere. According to Scheme 1, high $[NO_2]$ leads to high $[O_3]$, and hence to increased rates of formation of OH. High concentrations of NO_2 and PAH provide sinks for OH, while reactions with substances involved in cyclic reactions of OH (e.g., CO and aliphatic hydrocarbons) may cause a net increase or decrease in the concentration of OH, depending on the conditions. The instantaneous steady-state concentration of OH thus depends on the interplay of these factors. Recent work (12) implies that the long term *global* trend in [OH] may be downward, owing to greater sink strengths, especially increased global concentrations of methane. In the polluted urban troposphere, the trend in [OH] is predicted to be upward, due to high levels of ground level ozone.

Urban concentrations of PAH are important because of concerns over the toxicity of the parent PAH and some of their tropospheric products. The present work suggests that high levels of ozone should be associated with a greater sink strength for PAH, due to increased production of OH. A different explanation was provided by Flessel and Levaggi (13), who noted that high levels of ground level ozone were associated with low levels of PAH, and concluded that reaction with ozone itself must be a strong sink for PAH. However, later work (4) suggested that reaction with ozone is rapid only for five-membered ring PAH such as acenaphthylene. Trends in the concentration of PAH are important in assessing the success of vehicular emission controls; however, a lower ambient level of PAH could be achieved either by reduced emission, reducing the source strength, or by faster reaction due to a higher concentration of OH, increasing the sink strength. To distinguish these possibilities it will be necessary to monitor concurrently the diurnal variation of [PAH] and $[O_3]$ at different seasons, thus allowing the concentration of OH, and hence the sink strength, to be estimated.

Computational and ultraviolet photoelectron spectroscopic evidence that (*Z*)-2-methyl-1,3-pentadiene prefers twisted *s-cis* conformers in the gas phase

NICK HENRY WERSTIUK,[1] GEORGE TIMMINS, JIANGONG MA, AND TIMOTHY A. WILDMAN[1]
Department of Chemistry, McMaster University, Hamilton, Ont., Canada L8S 4M1

Received June 6, 1991[2]

NICK HENRY WERSTIUK, GEORGE TIMMINS, JIANGONG MA, and TIMOTHY A. WILDMAN. Can. J. Chem. **70**, 1971 (1992).

A redetermination of the ultraviolet photoelectron (pe) spectrum of (*Z*)-2-methyl-1,3-pentadiene has led to a correction of the published spectrum. By studying (*Z*)-2-methyl-1,3,-pentadiene (**1***a*) and (*E*)-2-methyl-1,3-pentadiene (**1***b*) with MMX, MNDO, AM1, and *ab initio* MO computational methods and pe spectroscopy, we have shown that a combination of these methods provides useful insights on the conformational behaviour of methyl-substituted 1,3-dienes in the gas phase. Synthetic pe spectra, derived from the computed potential energy surfaces and angle-dependent orbital energies, are in good agreement with experiment. Thus, the *E* isomer prefers the *s-trans* conformer but the *Z* isomer prefers twisted *s-cis* conformations in the gas phase.

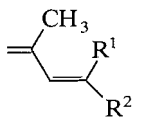
NICK HENRY WERSTIUK, GEORGE TIMMINS, JIANGONG MA et TIMOTHY A. WILDMAN. Can. J. Chem. **70**, 1971 (1992).

Une redétermination du spectre photoélectronique ultraviolet (pe) du (*Z*)-2-méthylpenta-1,3-diène a conduit à une correction du spectre publié antérieurement. En étudiant les (*Z*) et (*E*)-2-méthylpenta-1,3-diènes, respectivement **1***a* et **1***b*, par des méthodes de calculs d'orbitales moléculaires MMX, MNDO, AM1 et *ab initio* et par spectroscopie pe, on a montré qu'une combinaison de ces méthodes permet d'avoir des idées utiles sur le comportement conformationnel en phase gazeuse de ces 1,3-diènes substitués par des méthyles. Les spectres pe synthétiques, calculés à partir des surfaces d'énergie potentielle et des énergies orbitalaires qui dépendent des angles, sont en bon accord avec les valeurs expérimentales. Ainsi, en phase gazeuse, l'isomère *E* existe préférentiellement comme conformère *s-trans* alors que l'isomère *Z* préfère les conformations *s-cis* déformées.

[Traduit par la rédaction]

Introduction

A comprehensive study of the effect of methyl and ethyl substituents on the conformations of conjugated dienes by ultraviolet photoelectron spectroscopy (UPS) and by empirical (MMX), semiempirical (AM1, MNDO), and *ab initio* MO calculations was initiated recently (1, 2). This work was undertaken for several reasons. The primary goal was to establish whether or not AM1 (3) is useful for carrying out conformational analyses and for detailing conjugative and homoconjugative interactions in dienes. In our view, this research is timely because there is renewed interest (4–8) in the conformational analysis of dienes, a subject which occupied the attention of experimentalists and theoreticians for decades.[3] Our plan was to study a series of alkyl-substituted 1,3-dienes computationally to calculate heats of formation or total energies as a function of the dihedral (twist) angle between the double bonds in order to identify the stable conformations and to calculate the π_-, π_+ splittings of planar (*s-cis* and *s-trans*) and twisted conformations. By comparing the latter values with the splittings obtained experimentally by UPS, we hoped to establish whether combined AM1/UPS could be of general use in the study of conformational behaviour and of conjugative or homoconjugative interactions of alkyl-substituted polyenes in the gas phase. Moreover, because structure determines the conformational behaviour of these molecules, these studies would establish whether AM1/UPS could be used to elucidate the geometrical structure of highly alkylated dienes and polyenes, especially where there are no vicinal protons on the double bonds; the classical approach of using ^{1}H coupling constants to determine stereochemistry cannot be used in these cases. We were motivated to undertake this comprehensive study primarily by a report that the three lowest ionization energies of (*Z*)-2-methyl-1,3-pentadiene (**1***a*) and (*E*)-2-methyl-1,3-pentadiene (**1***b*) are identical within experimental error (8.43, 10.49, 11.53 eV for **1***a* and 8.42, 10.46, and 11.50 eV for **1***b*) (9). In preparing **1***a* in order to repeat the work of Masclet and co-workers (9), we established that the commercial product claimed to be predominantly (*Z*)-2-methyl-1,3-pentadiene was in fact the *E* isomer. The photoelectron (pe) spectra of **1***a* (Fig. 1A) and **1***b* (Fig. 1B) are different. On the basis of the π_+, π_- splitting and MMX calculations, we concluded that twisted *s-cis* conformers of **1***a* are preferentially populated in the gas phase and published a communication to document the results.



1

a, $R^1 = CH_3$, $R^2 = H$

b, $R^1 = H$, $R^2 = CH_3$

In this paper, we give a full account of our study of **1***a* and **1***b* that includes comprehensive computational studies and synthetic pe spectra derived from those studies.

Results and discussion

Preparation and pe spectroscopy of (Z)-2-methyl-1,3-pentadiene (1a) and (E)-2-methyl-1,3-pentadiene (1b)

Samples that were supposedly **1***a* and **1***b* were first isolated from a commercial product that was labelled as 80% **1***a* and 20% **1***b* by Aldrich Chemical Co. The major com-

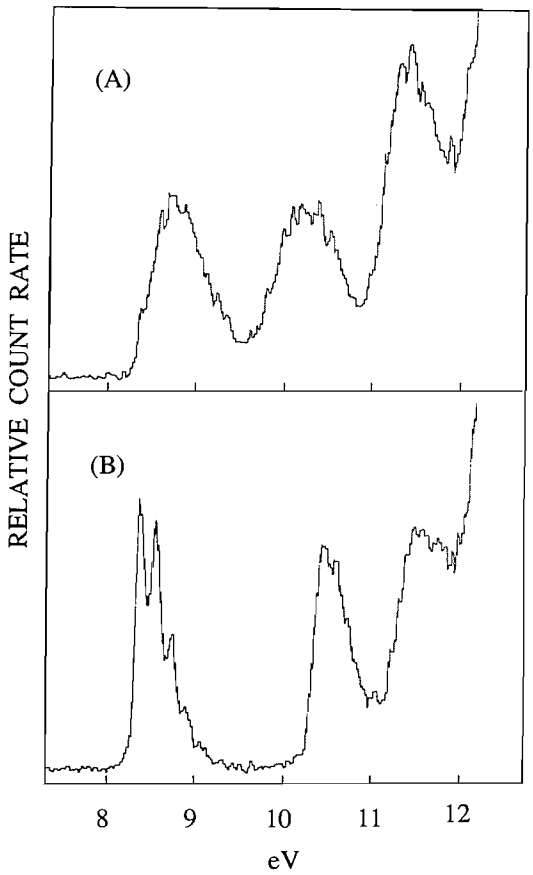

FIG 1. Partial ultraviolet photoelectron spectra of (*Z*)-2-methyl-1,3-pentadiene (A) and (*E*)-2-methyl-1,3-pentadiene (B) recorded at 300 ± 5 K.

ponent exhibited three discernable low-IE bands at 8.42 (π_-), 10.46 (π_+), and 11.50 eV, in agreement with the pe spectrum reported by Masclet and co-workers (9). The π_-, π_+ splitting was 2.04 ± 0.05 eV. However, the ^{1}H NMR spectrum of this sample corresponded closely to the spectrum of (*E*)-2-methyl-1,3-pentadiene (10). The key feature was that the vicinal vinylic ^{1}H coupling constant of 15.6 Hz fell in the range expected for *trans* vinylic hydrogens (11). Furthermore, the ^{1}H NMR spectrum of the sample which was supposedly **1***b* (20% of the commercial material) corresponded to the spectrum of 4-methyl-1,3-pentadiene (10). Here the key feature was a broad singlet at 1.75 ppm of relative area six. As was reported in the preliminary account of this work (1), different conformational preferences for **1***a* (crosses in Fig. 2) and **1***b* (circles in Fig. 2) were indicated by MMX calculations in which the nonplanar option was used for the double bonds. Unlike **1***b*, for which the planar *s-trans* conformation is the most stable structure, *s-cis* conformations with dihedral angles in the region of 60° are predicted to be the most stable structures of **1***a*. On this basis, a π_-, π_+ splitting less than the observed value of 2.04 eV would be expected for **1***a* (12). The NMR data and the MMX calculations coupled with the magnitude of the π_-, π_+ splitting indicated that the major component of the commercial material was not **1***a* and that the pe spectrum reported previously (9) was not the spectrum of (*Z*)-2-methyl-1,3-pentadiene (**1***a*).

Analysis of the Aldrich product on a 1,2,3-tris-(2-cyanoethoxy)-propane (TCEP) column at ambient temperature

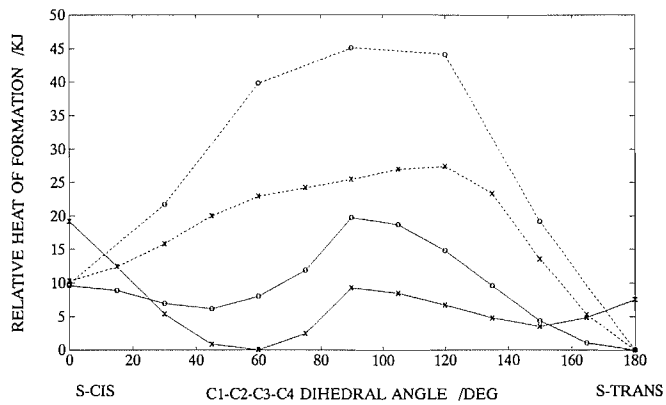

FIG. 2. Calculated relative heat of formation of 2-methyl-1,3-pentadiene from MMX. Dashed lines correspond to planar double bonds and solid lines correspond to twisted, nonplanar double bonds. Crosses correspond to **1***a*, circles to **1***b*.

established that three components, A, B, and C, with relative retention times of 1:1.40:1.55 were present in a ratio of 1 (2%): 39 (78%): 10 (20%) respectively. Based on the assumption that the commercial material was actually composed predominately of a mixture of (*E*)-2-methyl-1,3-pentadiene (**1***b*) (78%) and 4-methyl-1,3-pentadiene (20%), an attempt was made to prepare **1***a* by photochemical isomerization of **1***b* (13). To that end, the commercial product was photolyzed at 300 nm in pentane in a Rayonet reactor in the presence of acetophenone as a sensitizer. Photolysis reactions were monitored by gc (TCEP) and stopped when the yield of peak A reached a maximum, usually after 8–10 h. For one photolysis, the ratio of peaks A:B:C was 1:1.84:0.87 after 9 h. These components were isolated by preparative gc (TCEP) and ^{1}H NMR spectra were obtained. Because the ^{1}H NMR spectra of the compounds A, B, and C correspond closely to the spectra reported for **1***a* (14), **1***b* (10), and 4-methyl-1,3-pentadiene (10), the commerical product was deemed to be a mixture of **1***b* and 4-methyl-1,3-pentadiene, not **1***a* and **1***b* as indicated on the label. The partial pe spectra of **1***a* and **1***b* are shown as Fig. 1(A and B), respectively.

Computational studies of dienes **1***a and* **1***b*

The heats of formation (ΔH_f) of **1***a* and **1***b* were computed with MMX as the C1—C2—C3—C4 dihedral angle was driven from 180° to 0° in 15° increments. When planarity of the double bonds was enforced, planar *s-trans* conformations were computed to be the most stable structures of **1***a* and **1***b*, as shown by dashed lines in Fig. 2. On the other hand, when the non-planar optimization option was used, torsional distortion of the double bonds of **1***a* occurred and twisted *s-cis* conformers with C1—C2—C3—C4 dihedral angles in the region of 60° were the most stable structures, as shown by crosses on solid lines in Fig. 2. Clearly, this version of MMX (15) is not generally useful for studying conformational preferences of highly substituted 1,3-dienes.

MNDO and AM1 calculations were also carried out to compute ΔH_f as a function of the C1—C2—C3—C4 dihedral angle. The keyword PRECISE was specified in order to tighten the convergence criteria. As shown by the dashed lines in Fig.3(A and B), the MNDO results wrongly indicate that 90° conformations are the most stable structures of **1***a* and **1***b*. This is presumably a consequence of the underestimation of the resonance stabilization of the planar con-

[a]Heat of formation is given in kJ/mol.

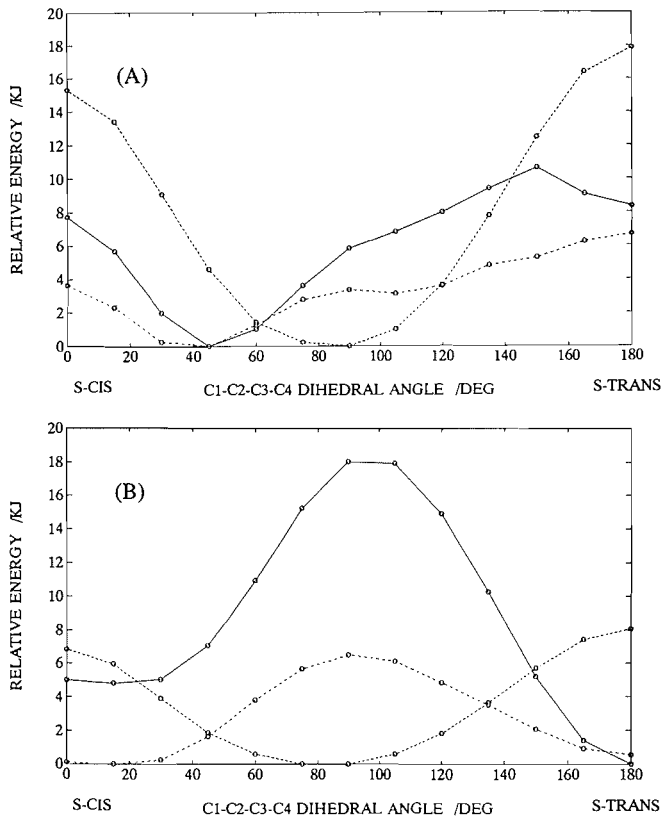

FIG. 3. Calculated heat of formation or relative total energy of 2-methyl-1,3-pentadiene from MNDO (dashed line), AM1 (dot–dashed line), and STO-3G (solid line): *Z* isomer (**1***a*) in A, *E* isomer (**1***b*) in B.

formations and the consistent overestimation of steric repulsions in MNDO (3).

According to the AM1 results (see Table 1 and the dot–dashed lines in Fig. 3) the planar *s-trans* conformation of **1***b* is only marginally less stable than the *s-cis* structure. The AM1 barrier to interconversion of the planar *s-trans* to the planar *s-cis* conformation is only 6.5 kJ/mol. This low barrier is consistent with the results of a previous AM1 computational study of butadiene (2). AM1 underestimates the torsional barrier in 1,3-butadiene by approximately 12 kJ/mol and $\Delta\Delta H_f$ between the planar *s-trans* and planar *s-cis* conformations by approximately 4 kJ/mol. Twisted (45°) *s-cis* conformations of **1***a* are computed to be more stable than the planar *s-trans* and *s-cis* conformations (Fig. 3A). Contrary to the MMX results, there is no significant torsional distortion of the double bonds at the AM1 level. It is not clear why the AM1 surface for **1***a* compares closely to the 4-31G// STO-3G surface (*vide infra*) and yet AM1 fails to reproduce the relative stabilities of the planar *s-cis* and planar *s-trans* conformations of **1***b*. A possible explanation runs as follows. As with MNDO, the AM1 torsional barrier for butadiene is low, probably because the resonance stabilization of the planar *s-cis* and planar *s-trans* conformations is underestimated. If the 1,3-methyl–methyl and methyl–vinyl steric interactions in the planar *s-trans* and planar *s-cis* conformations are also underestimated, a fortuitous cancellation of errors may occur for **1***a* but not for **1***b*, in which steric repulsions are less important.

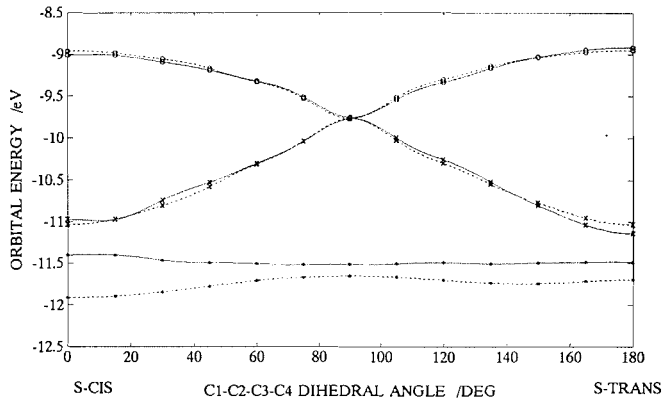

FIG. 4. Calculated angle dependence of the π_-, π_+ and highest σ MO energies of (*Z*)-2-methyl-1,3-pentadiene (solid lines) and (*E*)-2-methyl-1,3-pentadiene (dashed lines) from AM1.

Figure 4 shows how the π_-, π_+ and highest σ orbital energies of **1***a* and **1***b* change as a function of the C1—C2—C3—C4 dihedral angle with AM1. As for 2,3- and 2,4-dimethyl-2,4-hexadiene (2), π_- is less sensitive to twist angle than π_+. This can be rationalized on the basis of a homohyperconjugative interaction between the methyl group at C2 and the π system of the diene (16).

At the STO-3G level, the computed torsional barrier for conversion of *s-trans*-**1***b* to *s-cis*-**1***b* is 18 kJ/mol and ΔE for the planar *s-trans* and planar *s-cis* conformations is 5 kJ/mol, shown in Fig. 3B) as the solid-line plot. Like the AM1 results, the STO-3G calculations indicate that twisted *s-cis* conformers of **1***a* are the most stable. The results are shown graphically on the solid-line plot in Fig. 3A. The optimum STO-3G structures of four conformations of **1***a* (**1***a* (180°), **1***a* (90°), **1***a* (45°), and **1***a* (0°)) and three conformations of **1***b* (**1***b* (180°), **1***b* (90°), **1***b* (0°)) are given in Fig. 5. The point here is that the terminal methyl of **1***a* undergoes a 180° rotation as the C1—C2—C3—C4 dihedral is driven from 180° to 0°. The total energies are given in Table 2. The π_-, π_+ splittings from STO-3G, 4-31G//STO-3G, and AM1 calculations on **1***a* and **1***b* appear in Tables 3 and 4. On the basis of the STO-3G results, the π_-, π_+ splitting expected for **1***b* is about 2.99 eV. The experimental value is only 2.04 ±

0.05 eV.[4] Computations with the 4-31G basis at the STO-3G optimum geometry provide some reduction in the π_-, π_+ splitting, but the values are still significantly larger than that observed. On the other hand, AM1 provides 2.08 eV, in splendid agreement with the experimental value. All of the methods indicate that the π_-, π_+ splitting for **1***a* should be smaller than that for **1***b*. The AM1 orbital energies are used in the pe spectrum syntheses for two reasons: (*i*) STO-3G overestimates the π_-, π_+ splitting and (*ii*) AM1 computes these splittings with good accuracy for methyl-substituted 1,3-dienes (2). The AM1 π_-, π_+ splitting of the 45°-twisted *s-cis* conformation of **1***a* is 1.34 eV, in modest agreement with the experimental value of 1.50 ± 0.05 eV. The STO-3G and 4-31G//STO-3G values are 1.98 eV and 1.86 eV, respectively. However, such direct comparisons fail to account for conformational distribution.

Synthesis of photoelectron spectra

In this work, the bands of primary interest show sensitivity to conformational behaviour. The spectral intensity $S(I)$ at ionization energy I due to a particular conformation, corresponding to a dihedral angle ϕ, depends upon the thermal population density of conformations about ϕ and upon the angular dependence of I itself (17–19). Thus if I were independent of ϕ, the spectrum would consist of a sharp line

[4]This differs slightly from the value we reported previously (2.14 eV).

at this ionization energy, but if I were strongly angle dependent, the intensity would be distributed over a range of ionization energies, although the integrated intensity would be the same.

To provide a comparison between the experimental observations and the computational results, the relative conformational energies and angle-dependent orbital energies from the MO calculations were used to synthesize photoelectron spectra. Because these computational results form a discrete set, it was necessary to construct interpolating functions to represent them. The scheme is similar to one proposed by Honegger and Heilbronner (19), but more general.

Relative conformational energies and orbital energies are periodic functions of ϕ and can be expressed as Fourier series. For the molecules of present interest, these functions must also have even parity, i.e., they are symmetric with respect to reflection through $\phi = 0°$.

$$V(\phi) = \sum_{m=0}^{M} V_m \cos(m\phi)$$

and similarly

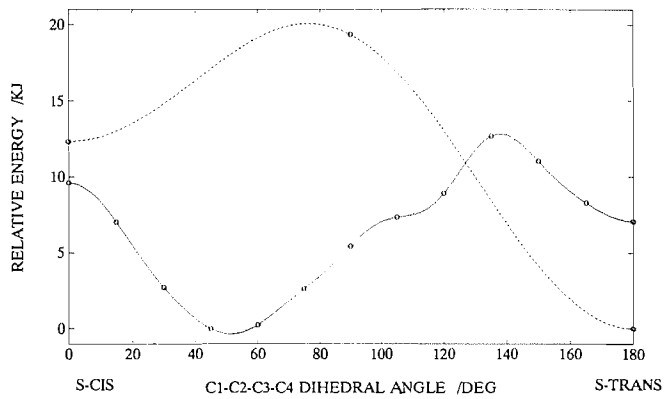

FIG. 6. Relative total energy of **1***a* and **1***b* (circles) from 4-31G//STO-3G calculations as a function of the C1—C2—C3—C4 dihedral angle. The interpolated angle dependence used in the synthesis of spectra is represented by a solid line for **1***a* and a dashed line for **1***b*.

$$I_a(\phi) = \sum_{n=0}^{N} c_{an} \cos(n\phi)$$

where a is an orbital label and V_m, c_{an} are coefficients. For a dataset $\{\{\phi\}, \{V(\phi)\}, \{I_a(\phi)\}, \{I_b(\phi)\},\ldots\}$, the coefficients are found by solution of the appropriate set of linear equations. In this work, $M = N$ is the number of angles for which data is available. Clearly, the dataset must include sufficient angles to define the features of $V(\phi)$ and all of the $I(\phi)$.

Spectral bands for each orbital, $s_a(I)$, were generated separately and then summed. For a particular spectral range, the ionization energy I was scanned at the desired digital resolution. When I fell within the range of $i_a(\phi)$, the corresponding angles were found as the zeros of $f(\phi) = I_a(\phi) - I$. In general, $\phi(I_a)$ is not single valued so the algorithm searches for a maximum of $2N$ angles. The spectral intensity due to orbital a, $s_a(I)\,dI$, is proportional to the Boltzmann population density, $\exp[-V(\phi)/k_BT]\,d\phi$, summed over all of the angles found. The intensity $s_a(I)$ in the digitized spectrum is given by

$$s_a(I) = \int_{\phi_1}^{\phi_2} \exp[-V(\phi)/k_BT]\,d\phi$$

where ϕ_1 and ϕ_2 correspond to the energies $I + \Delta I/2$, where ΔI is the digital resolution. The intensity distribution is folded with a Gaussian lineshape (FWHH = 0.3 eV) to approximate the Franck–Condon profile. The integrated intensity of each band $s_a(I)$ is normalized. Admittedly the Gaussian convolution is quite crude, but normal coordinate analyses for the electronic ground state and for each corresponding ion would be required in order to calculate Franck–Condon factors and thus more realistic vibrational fine structure. Such calculations are beyond our resources.

For **1***a*, $V(\phi)$ was satisfactorily defined by data at 15° increments on the interval [0°, 180°]. Relative energies from 4-31G//STO-3G calculations and relative heats of formation from AM1 were used. The *ab initio* potential energy surface appears in Fig. 6 (solid-line plot). Fourier coefficients appear in Table 5. The corresponding STO-3G energies are given in Table 2. The AM1 energies of the three highest occupied MOs appear in Fig. 4 and were used in the

TABLE 5. Fourier coefficients for computed diene potentials

12	−0.03	−0.11	0.00	

spectrum calculation, for reasons given above. Because the potential energy surface for **1***b* is adequately described by one- and two-fold components, only the data for $\phi = 0°$, 90°, and 180° were used to define the interpolating functions, as shown by the dashed-line plot of Fig. 6.

The synthetic spectra of **1***a* and **1***b* appear in Figs. 7A and 7B, respectively. The solid lines correspond to the 4-31G// STO-3G potentials and the dashed lines correspond to the AM1 potentials in Fig. 3. The spectra are clearly sensitive to details of the potentials. particularly if the thermal distribution of conformers is wide, as expected from Fig. 3A. Comparison of Fig. 1 and Fig. 7 suggests that the synthetic spectra from the 4-31G//STO-3G potentials correspond more closely to the experimental spectra than do those from AM1 potentials. The π_-, π_+ splitting for **1***a* is only 1.3 eV, both π bands are broader than for **1***b*, and the lower intensity maximum for the π_+ band indicates that π_+ has a stronger angle dependence than π_-.

Thermal [1,5] sigmatropic shifts in (Z)-1,3-pentadiene and ***1****a*

The thermal [1,5] sigmatropic hydrogen shift in (*Z*)-1,3-pentadiene has been the subject of much attention because the reaction proceeds via vibrationally assisted hydrogen transfer (20). Calculations on this molecule suggest that the twisted *s-cis* conformer, which is a secondary minimum on the potential energy surface, is the reactive species rather than the *s-trans*. The conformational equilibrium masks any indications of non-Arrhenius temperature dependence in the rate constant. However, if our understanding of the hydrogen transfer process in (*Z*)-1,3-pentadiene is good, we would predict more rapid intramolecular hydrogen transfer in (*Z*)-2-methyl-1,3-pentadiene. On the basis of the AM1 potential, k_{obs}^{H} for the 2-methyl derivative should be an order of magnitude larger (10^{-5}/s) at 475 K and two orders of magnitude larger (10^{-9}/s) at room temperature. The primary deuterium isotope effect should be near 5 at 475 K, as for (*Z*)-1.3-pentadiene itself, but it should increase dramatically as *T* decreases (20). Because the twisted *s-cis* conformer is preferred, non-Arrhenius behaviour should occur below 75 K, but k_{obs}^{H} is expected to be on the order of 10^{-19}/s at 75 K, which implies unobservably slow exchange.

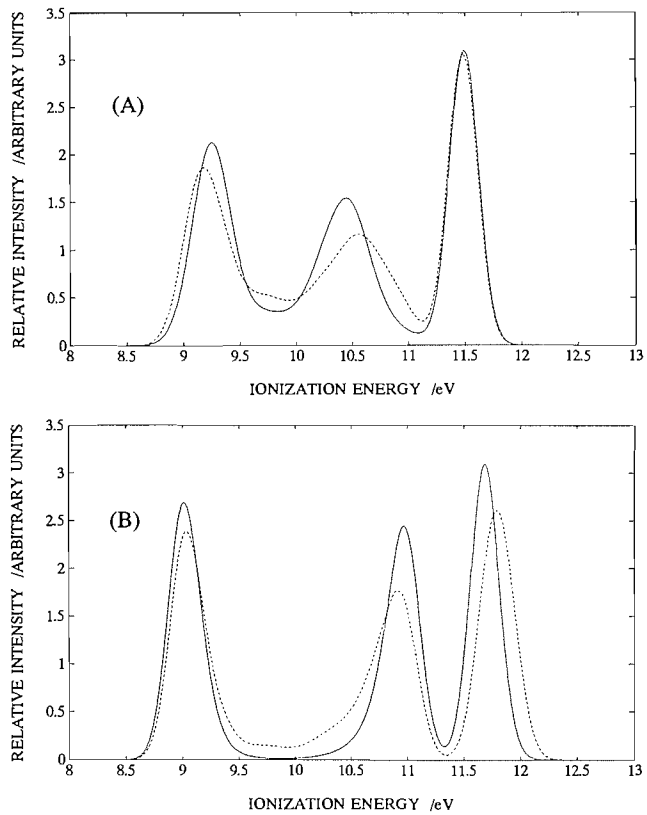

FIG. 7. Synthetic photoelectron spectra of **1***a* (A) and **1***b* (B) derived from the angle-dependent relative energies and orbital energies in Fig. 6. Solid lines are from 431G//STO-3G potentials. Dashed lines are from AM1 potentials. Spectra have been convoluted with a Gaussian lineshape with a full width at half height of 0.3 eV. The sample temperature was taken to be 300 K.

Conclusions

This study has shown that a combination of AM1, *ab initio*, and UPS studies coupled with synthesis of pe spectra will be generally useful for studying the conformational behaviour of alkyl-substituted 1,3-dienes. The results also confirm that the previous conclusions reached about the conformational behaviour of 2,3- and 2,4-dimethyl-2,4-hexadienes based solely on an AM1/UPS study are valid (2). Synthetic pe spectra derived from the computed potential energy surfaces and angle-dependent orbital energies are in good agreement with experiment. Thus, the *E* isomer prefers the *s-trans* conformer but the *Z* isomer prefers twisted *s-cis* conformations in the gas phase.

Experimental

*Preparation of (Z)-2-methyl-1,3-pentadiene (****1****a)*

A mixture of (*E*)-2-methyl-1,3-pentadiene (785), 4-methyl-1,3-pentadiene (20%), and (*Z*)-2-methyl-1,3-pentadiene (2%) (0.25 g) from Aldrich Chemical Co. and acetophenone (0.036 g) were dissolved in spectral grade pentane (30 mL) in a quartz vessel. The solution was cooled with ice-water, deoxygenated with N_2 for 20 min, and photolyzed at 300 nm for 9 h in a Rayonet reactor equipped with 8 lamps. Gc analysis of the mixture on a 3.3 m × 5 mm 18% TCEP on Supelcoport 100/120 column (He flow rate 40 mL/min) maintained at ambient temperature (~30°) showed that three major components, corresponding to peaks A (24.1%), B (44.4%), and C (21.1%), were present. These had the same relative retention times as the starting components (1:1.40:1.55). An

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

additional product (10.4%) not present in the starting material had a retention time only slightly longer than solvent pentane. The major components were separated and purified using the TCEP column. Peak A (**1***a*) exhibited resonances (500 MHz, $CDCl_3$) at 5.85 (d, J = 11.7 Hz, 1H), 5.51 (d of q, J = 11.7, 6.5 Hz, 1H), 4.96 (s, 1H), 4.83 (s, 1H), 1.88 (s, 3H), and 1.81 (d, 6.5 Hz, 3H) ppm. Peak B (**1***b*) exhibited resonances (200 MHz, $CDCl_3$) at 6.15 (d with fine structure, J = 15.6 Hz, 1H), 5.66 (d of 1, J = 15.6, 6.6 Hz, 1H), 4.83 (s, 2H), 1.82 (s, 3H), and 1.77 (d, J = 6.6, Hz, 3H) ppm. Peak C (4-methyl-1,3-pentadiene) exhibited resonances (200 MHz, $CDCl_3$) 6.55 (d of t, J = 16.8, 9.8 Hz, 1H), 5.81 (d, J = 10.8 Hz, 1H), 5.05 (d, J = 16.8 Hz, 1H), 4.94 (d, J = 9.8 Hz, 1H), and 1.75 (b, 3H) ppm.

Photoelectron spectra of **1**a *and* **1**b

The pe spectra of **1***a* and **1***b* were obtained on a non-commercial instrument (21). The spectra were obtained by signal averaging 20–30 scans and argon was used as a calibrant.

Computational studies

The MMX calculations were carried out using MMX Version 87.200 (15) running on an IBM PS/2 55Z microcomputer equipped with a math coprocessor. The MNDO and AM1 calculations were carried out using AMPAC Version 2.10 (22) ported to a MIPS 2030 workstation. All optimizations were carried out using the keyword PRECISE to tighten the convergence criteria. The *ab initio* calculations were carried out using GAMESS (23) ported to a MIPS 2030 workstation equipped with 16 MB RAM and a 1.2 GB Wren VII SCSI hard drive.

Synthetic spectra were calculated from the MO results using a FORTRAN program (PESPEC) written by TAW and running on a microcomputer or a Sun3/60 workstation. For convenience, the results were output in Matlab™ (The MathWorks Inc., 24 Prime Pkwy, Natick, MA 01760) file format for plotting.

R. SCOTT DANIELS, DONALD C. WIGFIELD, and KENNETH S. WILLIAMS. Can. J. Chem. **70**, 1978 (1992).

A mathematical model is presented to establish a relationship between the quantity of trace analyte vapor lost to the surface of delivery tubing and the tubing diameter, while in transit between stages of an instrument. Cold-vapor atomic absorption spectrometry for mercury, hydride generation techniques, and interfaces like the interface between electrothermal vaporization and inductively coupled plasma mass spectrometry all risk significant analyte loss before measurement. The results of this modelling substantiate the results of limited experimental work published elsewhere suggesting the use of the smallest possible tubing diameter for the delivery of atomic vapor through a tube. This diameter is calculable using Poiseuille's formula. Using this model, kinetic theory, and experimental data, the sticking probability for mercury on latex tubing is calculated to be approximately 1.6×10^{-6}.

R. SCOTT DANIELS, DONALD C. WIGFIELD et KENNETH S. WILLIAMS. Can. J. Chem. **70**, 1978 (1992).

On présente un modèle mathématique permettant d'établir une relation entre le diamètre du tube et la quantité d'une trace à analyser en phase vapeur qui est perdue sur la surface du tube de transfert entre deux stades d'un instrument. Dans les techniques de génération d'hydrure de la spectroscopie d'absorption atomique de vapeurs froides pour le mercure et dans les interfaces comme celle qui existe entre la vaporisation électrothermique et la spectrométrie de masse aux plasmas couplés d'une façon inductive, il existe des risques importants de perte des produits à analyser. Les résultats de notre modèle permettent de circonstancier les résultats expérimentaux limités qui ont été publiés ailleurs et qui suggèrent qu'il est utile d'utiliser des tubes ayant des diamètres les plus faibles que possible pour transférer une vapeur atomique à travers un tube. On peut calculer ce diamètre à l'aide de la formule de Poiseuille. Utilisant ce modèle, la théorie cinétique et les données expérimentales, on a calculé que le probabilité d'adhérence du mercure sur un tube de latex est approximativement $1{,}6 \times 10^{6}$.

[Traduit par la rédaction]

I. Introduction

The substance of this communication lies in a single question; that is, for a given standard flow rate of a carrier gas containing a trace analyte, which is the best for minimizing analyte loss to the surface of the delivery tubing: a small diameter tube, a large diameter tube, or is there an optimum diameter?[3]

Cold-vapor atomic absorption spectrometry, hydride generation techniques, electrothermal vaporization inductively coupled plasma mass spectrometry, and gas chromatography graphite furnace atomic absorption share one thing in common: the transport of trace molecular or atomic vapor, or aerosols, through delivery tubing. To ensure optimum analytical sensitivity, it is necessary to provide conditions to minimize analyte loss due to surface interactions along the walls of the delivery tubing. An earlier communication addressed the question of tubing type and optimum tubing diameter from an experimental perspective (1). Due to a limited number of available tubing diameters for testing, it was felt that a mathematical model of atom loss in tubing, particularly as a function of tubing diameter and flow rate, would add further justification to, and understanding of, the trends observed for the limited number of diameters tested. In addition, this model would permit predictions beyond the scope of readily available tubing diameters. A brief summary of transport efficiency and particle size is given by Lubman (2). Although omitting a sticking probability factor that is introduced in this model, a solution to the ratio of the number of particles at the exit of a tube to the number at the entrance is given by Gormley and Kennedy (3). Their model is most applicable to mass transport of larger particles and aerosols transported by a carrier gas through a horizontal tube.

The presentation of this model will be in two parts: a simple intuitive approach will be given, followed by a more detailed model of atom loss.

II. Experimental section

An evaluation of the atom loss dependence on the tubing diameter used 3.7 m lengths of latex tubing (Fisher Cat. No. 14-150) of varying diameters. While the tube was attached to the inlet of the spectrometer, and ambient air was being drawn by a pump through the tubing, 10 μL Hg^0 vapor (21–23°C, approximately 0.15 ng) injections were made alternately at a port directly adjacent to the inlet to the spectrometer and at an injection port attached to the end of the 3.7 m length of tubing.

Apparatus

A Laboratory Data Control/Milton Roy UVD 253.7 nm spectrometer was used for measuring the integrated absorbance signals. The fluid flow cell from the UVD monitor was removed and the detector was fixed to the end of a 30-cm double beam gas flow cell. Data acquisition was performed using a Jones Chromatography 6000 data system. Mercury vapor injections were performed using a 10-μL gas-tight syringe (Hamilton, 1801RN-3). The mercury vapor was housed in a septum-sealed 25-mL volumetric flask

[2]Revision received March 2, 1992.

[3]There is an analogous question, and an apparent lack of a scientific answer for this question, pertaining to minimizing the heat loss during the transport of a warm gas through optimum piping diameters.

containing 5 mL of elemental mercury. Temperature-sensitive fluctuations of the vapor pressure of mercury were minimized by partially immersing the volumetric flask in water contained in a double-insulated 200-mL beaker. The flow rate was monitored using a bubble-meter calibrated mass flow meter (Matheson 0–2000 standard mL min^{-1}, model 81111-0423).

III. Results and discussion

III.1. A simplified perspective of atom loss

Consider a segment of tubing of length l (cm), diameter d (cm), standard flow rate f (mL min^{-1}), volume v (cm^3), and internal surface area, s (cm^2). As a plug of vapor traverses the length of the tube there is some function h, describing atom loss, that depends both on the mean atom residence time τ (s) (4), and the tube surface to volume ratio s/v, eq. [1].

$$[1] \quad \text{loss} = h\left(\tau, \frac{s}{v}\right) = h\left(\frac{\pi l d^2}{4f}, \frac{4}{d}\right)$$

$$[2] \quad \text{loss} = h_1(d)$$

Since the standard flow rate is to be considered constant, then the new loss function h_1, eq. [2], is some unknown function of the delivery tube diameter. In eq. [1] it is not immediately clear how τ and s/v will be a function of atom loss, but it is reasonable to argue that an increased atom residence time, and (or) an increased surface to volume ratio (i.e., decreased diameter), would result in increased atom loss. A longer atom residence time would give a higher probability of a surface adsorption, and the greater the amount of surface, the higher would be the probability of a surface interaction. Clearly then, as the tube diameter is varied, these two factors act in opposition insofar as atom loss is concerned. To illustrate this Fig. 1 shows how τ and s/v vary with the tube diameter at a constant flow rate. If the loss function is an algebraic sum of the contributions from τ and s/v (curve 3, a simplistic view, yet mathematically incorrect), then there would be a local minimum in the loss function versus tube radius. This will be shown to be incorrect.

To overcome the inadequacies of this simplified view of atom loss, a detailed model of atom loss will permit a rigorous evaluation of h_1.

III.2. A detailed model of atom loss

The development of this detailed atom loss model entails 12 assumptions listed below:

1. N_0 mercury atoms are instantaneously injected into a flow of ambient nitrogen carrier gas such that the mercury atoms are evenly distributed across a plug volume of radius r and length x.

2. In the time increment $1/Z$, all atoms a distance λ or less from the tube surface are lost to the tube wall. Z is the collision frequency and λ is the mean free path of mercury atoms with nitrogen molecules under ambient conditions. This assumption disregards the sticking probability ρ, and the kinetic geometry term, g. See Appendix.

3. No pressure drop occurs along the tube length, for all tube radii and flow rates, omitting the Poiseuille pressure drop.

4. Following each $1/Z$ increment, the remaining atoms instantaneously redistribute themselves across the plug volume v.

5. No axial diffusional broadening of the plug occurs as it moves along the length of the tube.

6. There will exist a uniform non-parabolic velocity distribution along the tube cross section.

7. The tube wall surface is ideal: no eddies.

8. Syringe injection produces a homogeneous disk distribution of mercury vapor in nitrogen.

9. Nitrogen, N_2(g), and mercury, Hg^0(g), behave as ideal gases.

10. Flow is generated by draw from the atmosphere, through the tubing, to a vacuum pump.

11. The tube radius will not be less than the mean free path λ.

12. The tube wall is flat, not curved. See Appendix.

The philosophy adopted for developing this model has been to obtain a mathematical solution for the simplest case: making all the assumptions above, for model 1, then removing the assumptions sequentially until it is felt that there is sufficient agreement with experimental data. This outlook has resulted in three models presented in the order of making (1) all the assumptions above, (2) assumptions 3–8 above, and (3) assumptions 4–8 above.

III.3. Model 1

The goal of model 1 is to obtain a mathematical expression for the ratio of the number of atoms lost at the tube sur-

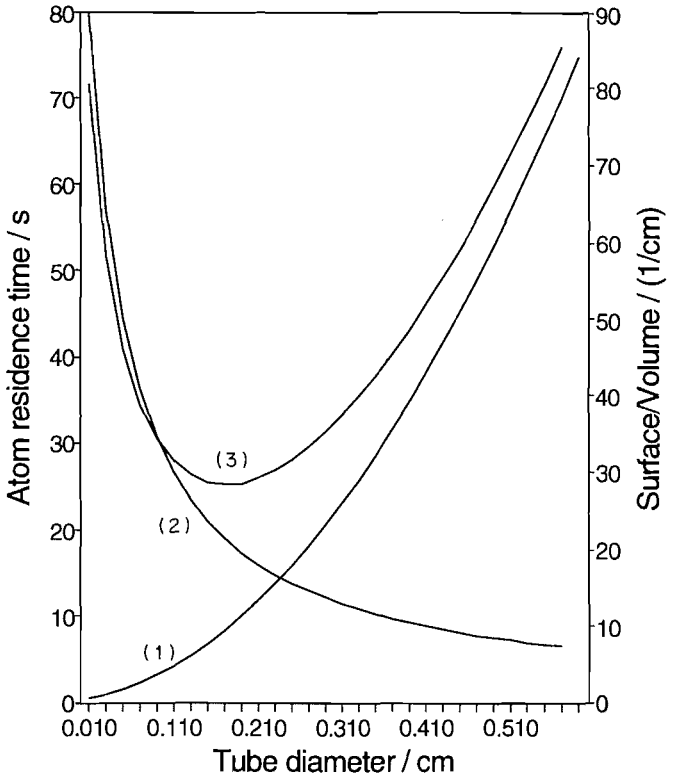

FIG. 1. Variation of atom residence time (1); surface to volume ratio (2); and their sum[4] (3); with tube diameter at 100 mL min^{-1}.

[4]Arithmetically incorrect, but presented for illustrative purposes.

TABLE 1. Model 1: incremental atom loss

Time	Number of atoms lost, N	Number of atoms remaining
0	0	N_0
$1/Z$	Atom density × rim volume $\frac{N_0}{v}[x\pi\{r^2 - (r-\lambda)^2\}] = N_0K$ where $K = \left[\frac{x\pi\{r^2 - (r-\lambda)^2}{v}\right]$ $= \frac{\text{rim volume}}{\text{plug volume}}$	$N_0(1-K)$
$2/Z$	$N_0K(1-K)$	$N_0(1-K)^2$
$3/Z$	$N_0K(1-K)^2$	$N_0(1-K)^3$
$4/Z$	$N_0K(1-K)^3$	$N_0(1-K)^4$

face to the number of atoms before any loss, N/N_0. The following notation will be used:

Term	Symbol	Units
Carrier gas	N_2	
Carrier gas viscosity	μ	kg m^{-1} s^{-1}
Flow rate	f	m^3 s^{-1}
Tube length	l	m
Tube radius	r	m
Plug length	x	m
Plug volume	v	m^3
Plug, atom residence time	τ	s
Mean free path of $Hg^0(g)$ in $N_2(g)$	λ	m
Collision frequency, $Hg^0(g)$ with $N_2(g)$	Z	s^{-1}

The total number of atoms lost is the sum of the number of atoms lost in each of η time increments of $1/Z$, where η is the floor[5] of the product of the collision frequency Z and the plug residence time τ. Table 1 lists the number of atoms lost to the tube wall, and the number of atoms remaining, for each of the first four of η, $1/Z$ increments of time. The number of atoms lost in the first time increment of $1/Z$ is the number of atoms contained in the rim of the disk whose thickness is λ, the mean free path of a mercury atom in nitrogen (approximately 45.7 nm, for 20°C), and whose length is x. This number is the product of the rim volume, $x\pi\{r^2 - (r-\lambda)^2\}$ and the initial atom density N_0/v.

Similarly, the number of atoms lost at the time $2/Z$ is the product of the new atom density $(N_0 - N_0K)/v$ and the rim volume. As shown in Table 1, this number is merely the product of the remaining number of atoms in the plug volume $(N_0 - N_0K)$ and K, where K is the ratio of the rim volume to the plug volume.

The total number N of atoms lost is

$$[3] \quad N_0K\sum_{n=0}^{n=\eta}(1-K)^n$$

where

$$[4] \quad \eta = \lfloor Z \times \tau \rfloor = \left\lfloor \frac{Z\pi l r^2}{f} \right\rfloor$$

Summing the geometric series gives eq. [5],

$$[5] \quad \frac{N}{N_0} = 1 - [1-K]^{\eta+1}$$
$$= 1 - \left\{1 - \frac{x\pi[r^2 - (r-\lambda)^2]}{v}\right\}^{\eta+1}$$
$$= 1 - \left[1 - \frac{(2r\lambda - \lambda^2)}{r^2}\right]^{\lfloor Z\pi l r^2/f \rfloor + 1}$$

where $v = x\pi r^2$.

Figure 2 is a plot of the adsorptional loss, N/N_0, versus the log of the tube radius. This model, like the simplified view of Fig. 1, also predicts a local minimum in the loss function versus tube radius. In model 1, increased tube length has two effects: a shift in optimum diameter to larger radii, and greater losses at all radii.

III.4. Model 2

Model 2 corrects for the certainty that not every atom striking the tube surface is lost. It also corrects for the fact that not all atoms at a distance λ or less from the tube wall will have trajectories in the direction of the wall. The correction terms will be ρ and g respectively. In fact, only one quarter of the atoms within the distance λ from the wall will strike the wall ($g = \frac{1}{4}$, Appendix). Table 2 is a modification of Table 1, taking into account the sticking probability ρ, and the geometry factor, g.

Summing the geometric series as in model 1, and substitution of $\frac{1}{4}$ for g, gives eq. [6],

$$[6] \quad \frac{N}{N_0} = 1 - \left[1 - \frac{\rho(2r\lambda - \lambda^2)}{4r^2}\right]^{\lfloor Z\pi l r^2/f \rfloor + 1}$$

Figure 3 is a plot of the adsorptional loss, N/N_0, versus the log of the tube radius, for ρ values of 10^{-4}, 10^{-2}, and 1. Like the previous model, this model also predicts the existence of a local minimum in the loss functions of Fig. 3 at radii of 7.6λ.

According to this intermediate and still very naive model,

[5]The floor operator ($[x]$) takes the integer portion of its argument; for example, $[3.7] = 3$.

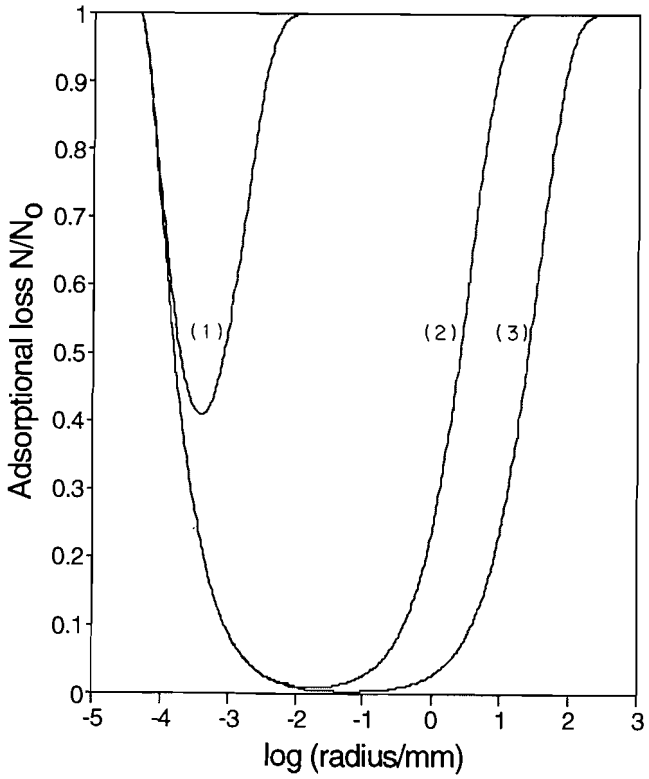

FIG. 2. Atom loss model 1. Plot of N/N_0 versus log(tube radius) for 100 mL min^{-1} and tube lengths/nm: (1) 10^{-6}; (2) 40; (3) 400.

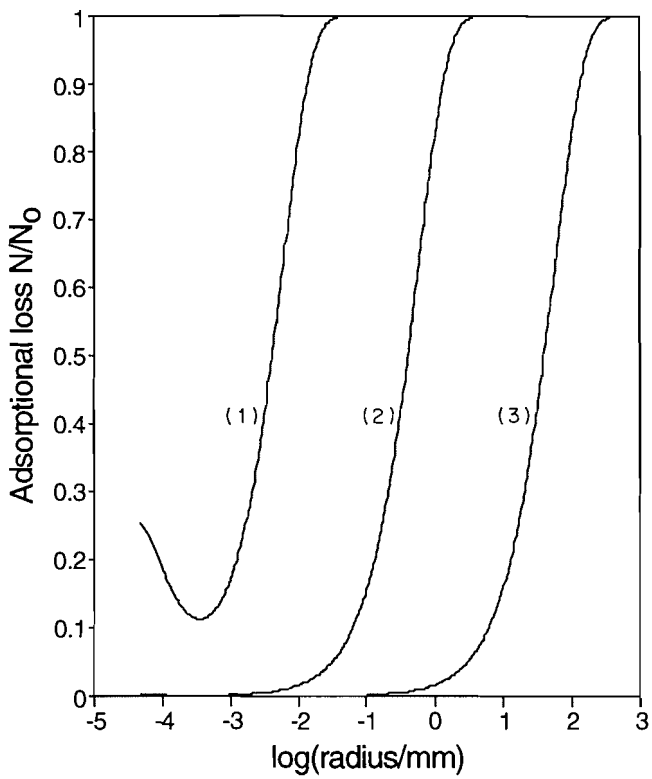

FIG. 3. Atom loss model 2. Plot of N/N_0 versus log(tube radius) for: f = 100 mL min^{-1}, l = 1.0 mm, and sticking probability, ρ: (1) 1; (2) 10^{-2}; (3) 10^{-4}.

TABLE 2. Model 2: incremental atom loss

Time	Number of atoms lost, N
$1/Z$	$g\rho \times$ atom density $\times$ rim volume
	$g\rho \frac{N_0}{v}\{x\pi[r^2 - (r-\lambda)^2]\} = \rho N_0 K$
	where $K = \left\{\frac{x\pi[r^2 - (r-\lambda)^2]}{v}\right\}$
$2/Z$	$g\rho N_0 K(1 - g\rho K)$
$3/Z$	$g\rho N_0 K(1 - g\rho K)^2$
$4/Z$	$g\rho N_0 K(1 - g\rho K)^3$

the limiting tube radius would be λ, when, in this limit, the loss, N/N_0, would approach a value of ρg. Very small diameters lead to the ludicrous situation of linear atomic trajectories surpassing the speed of light: in fact, $3c$, for a flow rate of 100 mL min^{-1} and a tube radius of $\lambda/2$! The real limiting diameter would be the diameter, calculable from the Poiseuille equation, for a given standard flow rate through a defined length of tubing, and the condition of a pressure drop of 1 atmosphere along the length of the tube. This limiting diameter is best illustrated in Model 3.

III.5. Model 3

This, the third and final model, takes into account the pressure drop at some distance y along the tube length l. As the pressure drops in the direction of the vacuum pump, from ambient pressure P_1 at the open end of the tube to some lower pressure P_2 at the pump end of the tube, the kinetic properties Z, the flow rate f, and λ change. P_2 is a function of y.

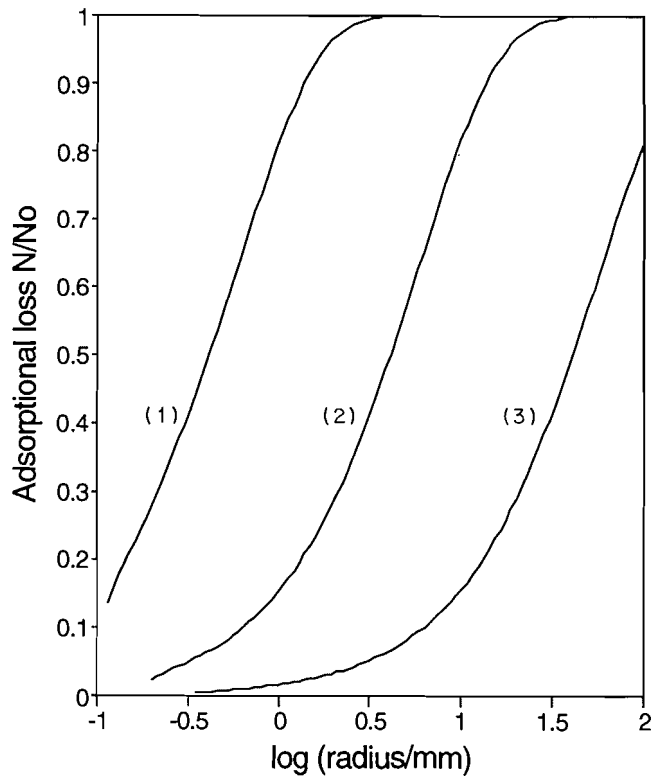

FIG. 4. Atom loss model 3. Plot of N/N_0 versus log(tube radius) for: l = 1.0 m, ρ = 10^{-6}, and f/(mL min^{-1}): (1) 10; (2) 100; (3) 1000.

To correct for this, the mean values of Z, f, and λ are calculated and used in place of the fixed values in model 2. The variables Z', f', and λ', are the values of Z, f, and λ respectively under ambient conditions, and are defined collectively in eq. [7] as follows:

$$\bar{Z} = \frac{1}{l}\int_{y=0}^{y=l} Z'\frac{P_2}{P_1}\,dy, \qquad Z = Z' \times \left(\frac{P_2}{P_1}\right)$$

$$[7] \qquad \bar{f} = \frac{1}{l}\int_{y=0}^{y=l} f'\frac{P_1}{P_2}\,dy, \qquad f = f' \times \left(\frac{P_1}{P_2}\right)$$

$$\bar{\lambda} = \frac{1}{l}\int_{y=0}^{y=l} \lambda'\frac{P_1}{P_2}\,dy, \qquad \lambda = \lambda' \times \left(\frac{P_1}{P_2}\right)$$

and dy is some infinitesimal of the tube length l. Solving the Poiseuille equation:

$$[8] \qquad f' = \frac{(P_1^2 - P_2^2)\pi r^4}{16y\mu P_1}$$

for P_2, and substitution into the previous integral eqs. [7] gives equation set [9].

$$\bar{Z} = \frac{Z'}{P_1 l}\int_{y=0}^{y=l}\sqrt{P_1^2 - \frac{16\mu P_1 f' y}{\pi r^4}}\,dy$$

$$[9] \qquad \bar{f} = \frac{f'P_1}{l}\int_{y=0}^{y=l}\frac{1}{\sqrt{P_1^2 - \frac{16\mu P_1 f' y}{\pi r^4}}}\,dy$$

$$\bar{\lambda} = \frac{\lambda' P_1}{l}\int_{y=0}^{y=l}\frac{1}{\sqrt{P_1^2 - \frac{16\mu P_1 f' y}{\pi r^4}}}\,dy$$

The solution for these integral equations is given in eq. [10].

$$\bar{Z} = \frac{Z'\pi r^4}{24P_1^2 l\mu f'}\left[P_1^3 - \left(P_1^2 - \frac{16\mu P_1 f' l}{\pi r^4}\right)^{3/2}\right]$$

$$[10] \qquad \bar{f} = \frac{\pi r^4}{8l\mu}\left[P_1 - \sqrt{P_1^2 - \frac{16\mu P_1 f' l}{\pi r^4}}\right]$$

$$\bar{\lambda} = \frac{\lambda'\pi r^4}{8\mu l f'}\left[P_1 - \sqrt{P_1^2 - \frac{16\mu P_1 f' l}{\pi r^4}}\right]$$

Substitution of these average values of Z, f, and λ into the general solution from model 2 gives eq. [11], the general solution for model 3.

$$[11] \qquad \frac{N}{N_0} = 1 - \left\{1 - \frac{\rho a r^4\left[P_1 - \sqrt{P_1^2 - \frac{b}{r^4}}\right]\left[2r - ar^4\left(P_1 - \sqrt{P_1^2 - \frac{b}{r^4}}\right)\right]}{4r^2}\right\}^{[cr^2\{2P_1^2 + P_1\sqrt{P_1^2 - (b/r^2)} - (b/r^2)\}]+1}$$

where

$$[12] \qquad a = \frac{\lambda'\pi}{8\mu l f'}, \qquad b = \frac{16\mu P_1 f' l}{\pi}, \qquad c = \frac{Z'\pi l}{3P_1^2 f'}$$

A plot of this equation using $l = 1.0$ m, $\rho = 10^{-6}$, and $\mu = 1.76 \times 10^{-5}$ kg m^{-1} s^{-1} is given in Fig. 4 for $f' = 10$, 100, and 1000 mL min^{-1}. The model 3 functions are truncated at radii predicted by the Poiseuille equation. These limiting radii get

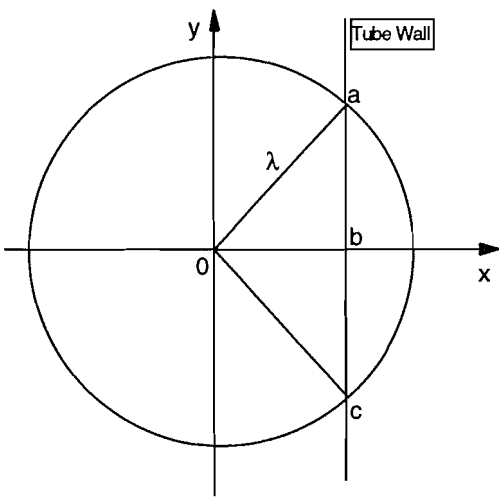

FIG. 5. Solution for the geometry term *g*: the fraction of atoms within the distance λ from the tube wall that strike the wall.

smaller as the flow rate decreases. Just as predicted by the experimental data of Table 3, the ideal conditions to minimize analyte loss to tubing surfaces are (1) use the smallest tube diameter possible, and (2) use the highest flow rate possible.

III.6. Estimating a value of ρ, the sticking probability for latex

Using the general solution of model 3 above, combined with experimental data for N/N_0, an estimate of the real value of ρ may finally be made. Variables are used in the model 3 solution of Table 3 according to the conditions that prevailed while data was collected. An estimate of $\rho = 1.6 \times 10^{-6}$ gives model 3 solutions for N/N_0 that agree satisfactorily with experimental values shown in Table 3. The mathematical model is more sensitive to a change in loss, with changing tube radii, than is observed experimentally. At higher flow rates, there is a larger uncertainty and poor reproducibility between days, in experimental values of N/N_0. This model, in addition to predicting trends, was expected to give values of ρ, at best, to within an order of magnitude of its real value. Calculated values are listed in Table 3 showing the model 3 estimates for N/N_0 at 50 mL min^{-1} and for three radii, when a value of ρ 1.6×10^{-7} was used, which varies by an order of magnitude from the best estimate of ρ.

IV. Conclusions

The atom loss model has been developed to the point at which it predicts loss trends as a function of varied tube radii for all possible flow rates, sticking probabilities, and tube lengths. The primary trend, that is, trace analyte loss increases with increasing tube diameter, was confirmed with this model, and corroborates inferences by the solution proposed by Gormley and Kennedy (2). Further to this and in conjunction with experimental data, the model allowed the estimation of a sticking probability. For latex tubing it was found that only one mercury atom in 0.83 million ($\rho = 1.2 \times 10^{-6}$) that strikes the tube wall surface actually remains adsorbed for a sufficient length of time to be termed "lost."

Appendix

Solution for the geometry term *g*: the fraction of atoms within the distance λ from the tube wall that strike the wall

In Fig. 5, consider a wall at some distance b, $0 \leq b \leq \lambda$, from an atom at the origin.[6] On this microscale, where λ is the mean free distance travelled by a mercury atom before collision with a nitrogen molecule, the tube wall will be considered to be flat and not curved.

The geometry term, g, represents the probability that an atom, at some distance less than or equal to λ from a wall, will strike the wall before hitting a nitrogen molecule. g is the ratio of the average sector-area of a sphere swept out by revolving the curve $y = (\lambda^2 - x^2)^{1/2}$, $b \leq x \leq \lambda$, for $0 \leq b \leq \lambda$, about the x-axis to the total sphere surface area $4\pi\lambda^2$.

The general area of a surface, a sector-area of a sphere, swept out by revolving the curve $y = f(x)$, $a \leq x \leq b$, about the x-axis (5) is given in eq. [13].

$$[13] \quad \int_a^b 2\pi y \sqrt{1 + (y')^2}\, dx$$

Therefore eq. [14] gives the sector-area of a sphere swept out by revolving the curve $y = (\lambda^2 - x^2)^{1/2}$, $b \leq x \leq \lambda$, about the x-axis, where λ is the sphere radius, and eq. [15] gives the general sector-area A_s swept out by revolving the curve $y = (\lambda^2 - x^2)^{1/2}$ about the x-axis.

[6]It is more convenient to consider an atom at the origin and the wall at different distances from the origin, than the reverse case.

$$[14] \quad \int_b^\lambda 2\pi \sqrt{\lambda^2 - x^2} \sqrt{1 + \frac{x^2}{\lambda^2 - x^2}}\, dx$$

$$= \int_b^\lambda 2\pi \sqrt{\lambda^2 - x^2} \sqrt{\frac{\lambda^2}{\lambda^2 - x^2}}\, dx$$

$$= \int_b^\lambda 2\pi\lambda\, dx$$

$$= 2\pi\lambda(\lambda - b)$$

$$[15] \quad A_s = 2\pi\lambda(\lambda - x), \qquad 0 \leq x \leq \lambda$$

Equation [16] gives the average $\bar{A}_s$ of the general sector-area A_s swept out by revolving the curve $y = (\lambda^2 - x^2)^{1/2}$ about the x-axis, for $0 \leq x \leq \lambda$.

$$[16] \quad \bar{A}_s = \frac{1}{\lambda}\int_0^\lambda A_s\, dx$$

$$= \frac{1}{\lambda}\int_0^\lambda 2\pi\lambda(\lambda - x)\, dx$$

$$= 2\pi\left[\int_0^\lambda \lambda\, dx - \int_0^\lambda x\, dx\right]$$

$$= 2\pi\left[\lambda^2 - \frac{\lambda^2}{2}\right]$$

$$= \pi\lambda^2$$

Therefore, g, eq. [17], is the ratio of $\bar{A}_s$ to the total sphere surface area $4\pi\lambda^2$

$$[17] \quad g = \frac{\bar{A}_s}{4\pi\lambda^2} = \frac{1}{4}$$

MARGARET M. KAYSER, KRISTA L. HATT, and DONALD L. HOOPER. Can. J. Chem. **70**, 1985 (1992).

The reactions of stabilized phosphoranes with cyclic anhydrides give enol-lactones as final products. The initial condensation, however, leads to the formation of acyclic adducts that are observable by NMR, can be easily trapped, and, in some cases, can be isolated. A study of the mechanism of these condensations by NMR spectroscopic methods and by various trapping experiments is described and the reaction pathway is proposed.

MARGARET M. KAYSER, KRISTA L. HATT et DONALD L. HOOPER. Can. J. Chem. **70**, 1985 (1992).

Les réactions des phosphoranes stabilisés avec des anhydrides cycliques fournissent des énol-lactones comme produit finals. Toutefois, la condensation initiale conduit à la formation d'adduits acycliques que l'on peut observer par RMN, qui peuvent facilement être piégés et qui, dans quelques cas, peuvent être isolés. On décrit une étude du mécanisme de ces condensations basée sur des méthodes de RMN et sur diverses expériences de piégeages et on propose la voie réactionnelle.

Introduction

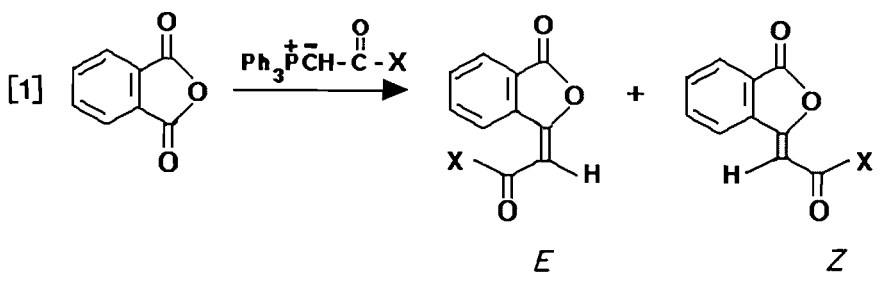
Originally, the reaction of an ylide and a simple aldehyde or ketone was described as a stepwise ionic process involving a betaine intermediate (1, 2). This mechanism, however, was challenged when studies on the solvent effects in Wittig condensations showed a nonpolar transition state for the reactions of stabilized ylides (3). Since lithium-free betaine intermediates have not been detected in the course of Wittig condensations, it was questioned whether such species could even exist in a "salt-free" environment (4). This problem was settled when independently generated lithium-free betaines were found to collapse to alkenes too rapidly to be detected by NMR (4–6).

While betaine in the "salt-free" environment remained elusive, for reactions of an ylide with aldehyde or ketone, experimental evidence was obtained for the formation of an oxaphosphetane (5, 7–9). *Ab initio* studies of a model reaction between $H_3P{=}CH_2$ and HCHO further supported the mechanism involving a direct formation of the oxaphosphetane via a concerted-low-energy addition of the ylide to the carbonyl substrate (10, 11).

Recently, Vedejs and Marth (7) demonstrated through a series of equilibrium studies on independently generated betaines, that betaines are unlikely intermediates in Wittig reactions for aldehydes and ketones, and that these condensations proceed via a "4-centre mechanism" leading directly to formation of more or less stable oxaphosphetane intermediates (7, 12, 13).

Carbonyl-stabilized phosphoranes are unreactive vis-à-vis ketones but are readily condensed with aldehydes and with 5-member cyclic anhydrides, the latter reactions leading to synthetically and biologically important enol-lactones (14). Although a number of researchers have employed these condensations as a route to enol-lactones (15), there has been no systematic investigation of their mechanism comparable to the studies carried out for the Wittig olefination of aldehydes and ketones (4–7).

The condensations of phthalic anhydride with various carbonyl-stabilized ylides were first investigated by Chopard *et al.* (reaction [1]). The enol-lactones produced in these reactions showed a surprisingly high stereoselectivity in favour of *E* geometry (16).



To account for this selectivity, Chopard suggested a cyclic transition state with the COX group of the ylide in the plane parallel to the phenyl ring of phthalic anhydride, Fig. 1.

According to this scheme, the electron-rich system interacts with the electron-deficient aromatic ring to give preferentially the *E* product (16). The fact that *E* selectivity was shown to increase with the electron-donating capacity of the X group gave support for the proposed transition state.

[1]Author to whom correspondence may be addressed.

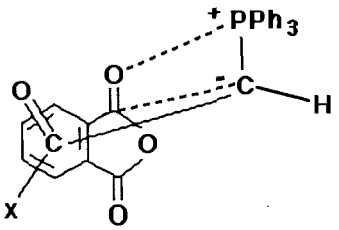


FIG. 1. Transition state proposed for the addition of stabilized ylides to phthalic anhydride (16).

Chopard's hypothesis appeared to be further strengthened by subsequent studies, indicating that the 4-centre mechanism is the only obligatory route in the kinetically controlled reactions of aldehydes with carbonyl-stabilized ylides, *vide supra* (7, 12, 13).

Two pieces of experimental evidence, however, put in question this interpretation. Firstly, it was soon discovered that the condensations of stabilized ylides with succinic and maleic anhydrides gave also *E* enol-lactones as major products (17). Secondly, open-ring acylated phosphoranes such as **3***b*. Scheme 1, were observed as intermediates in the condensations with cyclic anhydrides (16–20). The latter discovery suggested a mechanism that included betaine as an obligatory (albeit, possibly, very short-lived) intermediate (17).

The topic of the reversibility of Wittig reactions has been discussed extensively in relation to the stereochemistry of the products (21–24). The crossover experiments carried out by several groups showed that the formation of oxaphosphetane intermediates is reversible in the reactions of non-stabilized ylides with aromatic aldehydes (21) and appears to be irreversible with aliphatic aldehydes and ketones (22–24). Recently, parallel behaviour was observed for the reactions of moderated and ester-stabilized ylides with aromatic and aliphatic aldehydes (12).

Reversibility (or irreversibility) and its effects on the stereo- and regioselectivity of reactions is equally important in condensations of cyclic anhydrides with stabilized phosphoranes. Here an additional complication arises from the fact that acyclic adducts are produced as intermediates and consequently betaine as well as oxaphosphetane must be considered as an obligatory intermediate along the mechanistic pathway (26).

In this paper we report an NMR study of Wittig condensations between carbonyl-stabilized ylides and phthalic, phenyl maleic, and succinic anhydrides, all of which were found to be reversible at the stage of an acyclic intermediate. Various trapping experiments that support and refine the mechanistic pathway of these reactions are also discussed.

Results and discussion

Structural studies

During a low-temperature ^{1}H NMR study of the reaction between methyl (triphenylphosphoranylidene)acetate **2** and phthalic anhydride **1**, an intermediate with a signal for the methoxy group at an unusually high field (2.98 ppm) was observed and identified, from trapping experiments, as corresponding to the rapidly exchanging **3***a*–**3***b* pair produced as a result of the opening of the anhydride ring.

All trapping experiments, outlined in Schemes 1–4 *were carried out at the time of the highest build-up of the intermediate (70% after 30 min at 0°C)* as established from sev-

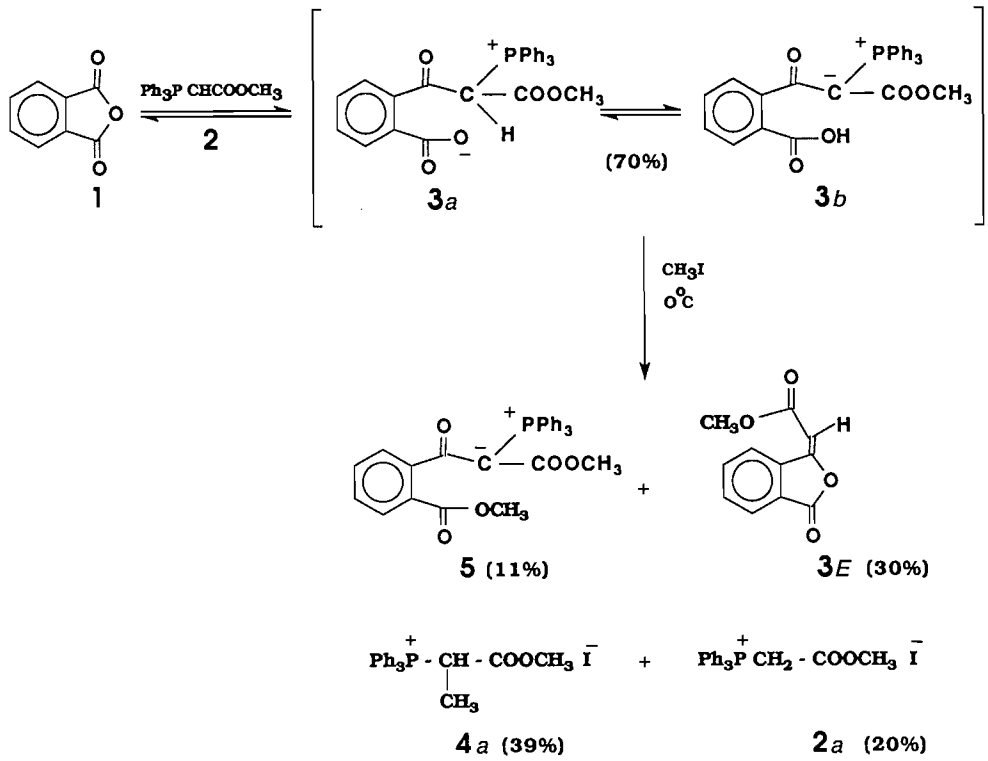
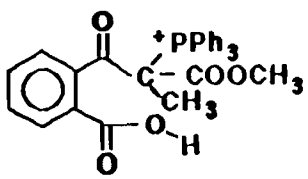


SCHEME 2

eral prior low-temperature studies. The reaction of the intermediate **3***a* with trimethyloxonium tetrafluoroborate, $(CH_3)_3OBF_4$, gave the *O*-alkylated compound **5** and some conjugate acid **2***a*, the latter resulting from proton exchange between the short-lived intermediate **5***a* and ylide **2** (Scheme 1).

The softer alkylating agent, methyl iodide, was expected to give the *C*-alkylated acid **6** (Scheme 2). However, under conditions similar to those for the reaction with $(CH_3)_3OBF_4$, trapping with methyl iodide produced a mixture consisting of **5** (11%), enol-lactone **3***E* (30%), and conjugate acids **2***a* (20%) and **4***a* (39%), the last resulting from the *C*-alkylation of **4** (Scheme 3). The large proportion of **2***a* and **4***a* (59% total) trapped at the time when the concentration of ylide **2** was reduced to 30%, indicates that the formation of acyclic intermediates is a reversible process.



6

The trapping with diazomethane, which reacts rapidly with acidic intermediate **3***b*, gave phosphorane **5** as the only product (Scheme 3). The above results indicate that the addition of ylide **2** to phthalic anhydride leading to the acyclic intermediates (**3***a* and **3***b*) is an equilibrium. Trimethyloxonium tetrafluoroborate reacts preferentially at the carboxylate oxygen atom, shifting the equilibrium from **3***b* to **3***a*. On the other hand, diazomethane reacts with **3***b*, shifting the equilibrium in the opposite direction. Methyl iodide does not react with **3***b* because the highly delocalized charge on the ylide's carbon atom is slow to *C*-alkylate, permitting the competing reactions, *O*-alkylation of **3***a* and *C*-alkylation of ylide **2**, to occur.

The reaction of phthalic anhydride with freshly crystallized ylide 4 leads to an intermediate, **7***a*, which does not possess an exchangeable proton. This unstable species (observable as a broad transient signal at 27.58 ppm in the ^{31}P NMR spectrum) exists at low temperatures (−35 to −30°C) in equilibrium with the reagents, but we were unable to trap it as its ethyl ester with triethyloxonium tetrafluoroborate. As **7***a* collapses to the product, only **7***E* and a slight excess of the conjugate acid of ylide **4** can be detected in the ^1H NMR spectrum of the reaction mixture (Scheme 4).

The structure of the *O*-methylated product **5** was verified by NMR studies and by derivatization. The methoxy group from the ylide appears at a relatively high field (3.01 ppm). In solution it apparently occupies the space in the shielding region of the phenyl rings similar to its conformation shown in the X-ray crystal structure of compound **5**, Fig. 2.[2] The low-field ^{13}C NMR signal for C1 of phosphorane **5** (71.17 ppm) suggests that ylide **5** should be quite unreactive (25). In fact all attempted condensations with benzaldehyde failed as only the starting materials were recovered, even after 24 h reflux in toluene.

Since the highly shielded methoxy group appears to be fixed in the vicinity of the triphenylphosphorane group, we expected an important contribution of the *trans*-enolate structure with the oxygen atom bearing a significant nega-

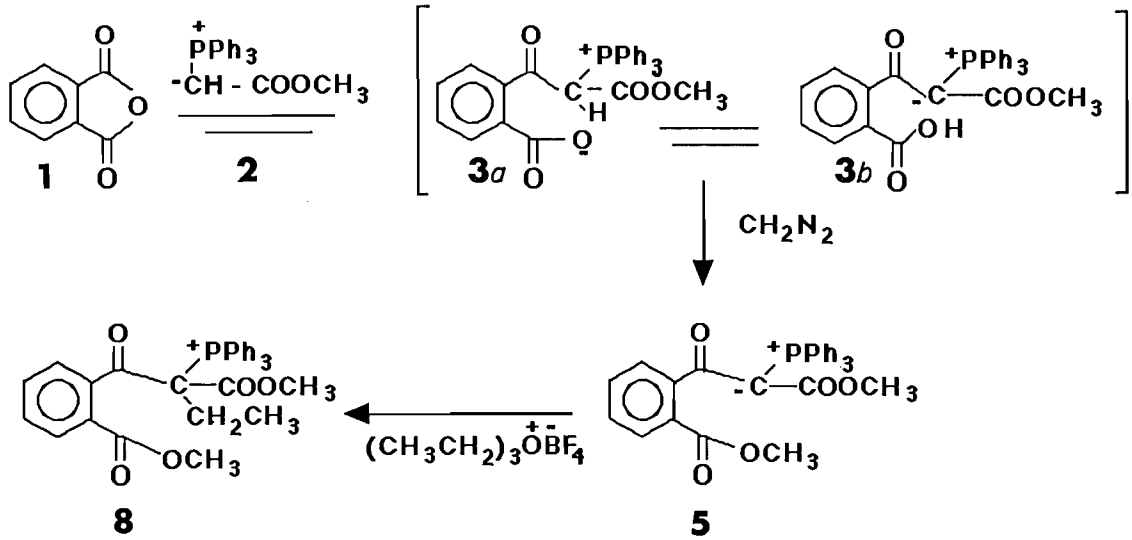
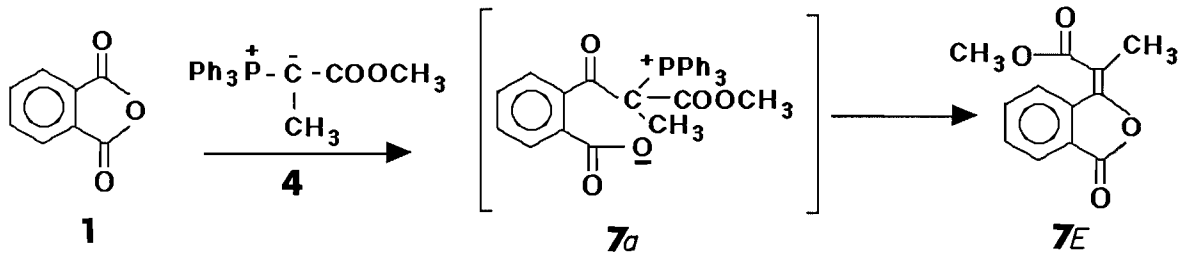
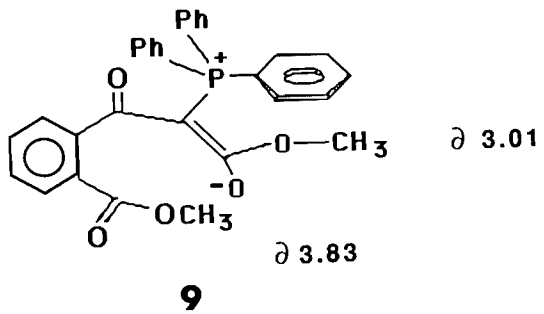


SCHEME 3



SCHEME 4

tive charge as shown in **9**. However, trapping with triethyloxonium tetrafluoroborane at 0 and −78°C gave only the *C*-alkylated product **8** as shown by ^1H and ^{13}C NMR, Fig. 3.



9

X-ray crystallographic analysis of the parent compound **5** provided some insight into its structure and the resulting preference for *C*-alkylation. Judging from the bond lengths, there is more delocalization of the negative charge into the neighbouring (C3—O3) keto group than toward the ester function. Predictably, the keto function occupies a position *cis* to the positively charged triphenylphospho group. As a result of such electron delocalization, if an *O*-alkylation were to occur, it should occur at O3 rather than O2. It appears, however, that the charge is too diffused for the *O*-alkylation to take place since only *C*-alkylation is observed.

Comparison of bond lengths in compound **5** with those reported for the related compound **11***b* (Table 1) shows that although the C1—C3 bonds are shorter than C1—C3 in both **5** and **11***b* the C3—O3 bond is significantly longer in the latter ylide. This suggests more single bond character and higher negative charge on the O3 atom of the keto carbonyl function in **11***b*, which should lead to a more facile *O*-alkylation. A series of parallel experiments carried out for the succinic anhydride **10** supports this forecast, as the alkylation with triethyloxonium tetrafluoroborate gives only one product, the *O*-alkylated compound **13** in 83% yield, Scheme 5.

Reactivities of stabilized ylides in condensations with phthalic anhydride

Once the identities of the observable intermediates were confirmed, we monitored by NMR the course of the reaction leading to their formation and we studied the conditions necessary for the re-cyclization to the corresponding enol-lactones. In the course of the reaction of phthalic anhydride with phosphorane **2**, followed by ^1H NMR, after 10 min at −30°C the mixture consisted of the acyclic intermediate (42%) and the ylide (52%). A typical run is shown in Table 2. When the temperature was not allowed to rise above 0°C, only 4% of the final product was formed after 2 h, while the intermediate and the ylide accounted for 66% and 30%, respectively.

The same reaction proceeded to completion quite rapidly at room temperature. Within 5 min at 25°C, 33% of the intermediate and 6% of the product could be observed in the ^1H NMR spectrum. After 90 min the reaction mixture contained 35% product, 20% intermediate, and 45% ylide. The signal for the ylide was broadened and had shifted to a

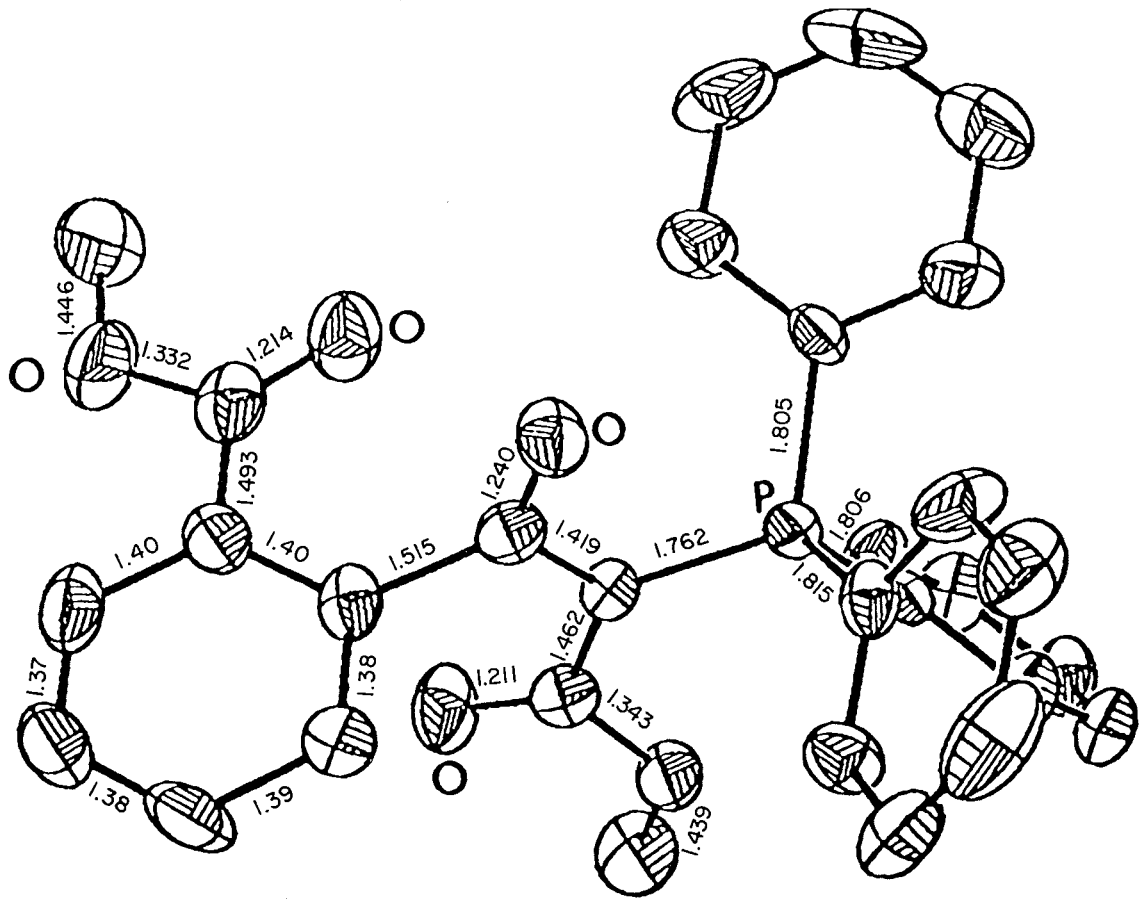

FIG. 2. The crystal structure of compound **5**.

slightly lower field, suggesting that equilibria are set up among the ylide, acyclic intermediates (**3***a* and **3***b*), and the conjugate acid **2***a*, formed as a by-product during the condensation reaction. After 18 h, the product accounted for 65%, the intermediate was gone, and so was the ylide, which had been converted completely into its conjugate acid **2***a*.

The downfield shifts of the ylide's signal were more pronounced during the experiments in which no particular precaution was taken to dry the solvent and to purify the ylide and phthalic anhydride. During several runs monitored by ^{31}P NMR, the ylide's signal drifted visibly downfield as shown in Fig. 4. When such a reaction was left overnight, the only signals remaining the following morning were the product Ph_3PO and the conjugate acid **2***a*.

The condensation carried out under anhydrous conditions between freshly recrystallized phthalic anhydride and ylide **2**, pretreated with BuLi (or NaH) to remove traces of its conjugate acid **2***a*, was initially slightly slower; however, as the reaction progressed, the rate became comparable to that measured in previous studies, as illustrated in Fig. 5.

This experiment supports the previously postulated catalytic effect of acidic protons on the reactivity of stabilized ylides (25*a*, *b*). In a prior communication we discussed experiments that established that removing all sources of acidic protons, including traces of the conjugated acid, results in a considerable slowing down of the reaction between a stabilized ylide and benzaldehyde (25*a*). In the absence of acidic protons, the stabilized ylides, $Ph_3PCHCOOR$, exist as the slow-reacting *cis–trans* enolate mixture. The presence of Li^+ or Na^+ counterions appears to stabilize the enolic forms, hence retarding rather than accelerating the reactions with aldehydes (25, 27). However, during the condensations of ylides such as **2** with anhydrides, even after *all sources of acidic protons are removed*, the first step generates an equilibrating pair of acyclic structures (**3***b* and **3***b*), each bearing an acidic proton that can serve as a catalyst. Thus, the reaction is self-catalyzed.

To further confirm the catalytic role of a proton, we studied the condensation of phthalic anhydride with ylide **4**, which leads to the formation of an intermediate lacking an acidic proton. Ylide **4** is more moisture sensitive than **2**, and commercial samples always contain small quantities of its conjugate acid **4***a*. The room temperature reaction between phthalic anhydride and **4**, in the presence of traces of **4***a*, is 50% complete in 5 mins. In contrast, when **4** is pretreated to remove traces of the conjugate acid **4***a* immediately prior to the addition of phthalic anhydride, the reaction run under anhydrous conditions is considerably slower. After 3 h at 25°C, only 40% of the enol-lactone is observable in the reaction mixture as shown in Fig. 6.

It is important to note that in the reaction of ylide **2** with phthalic anhydride, each of the intermediates within the **3***a*,**3***b* pair can be expected to undergo proton transfer to give the other member of the pair, at a rate very much faster than the recyclization and the cleavage to the products, enol-lactones and triphenylphosphine oxide. In view of the above, the lifetime of the **3***a*,**3***b* pair should be much longer than the lifetime of an intermediate with no internal proton transfer

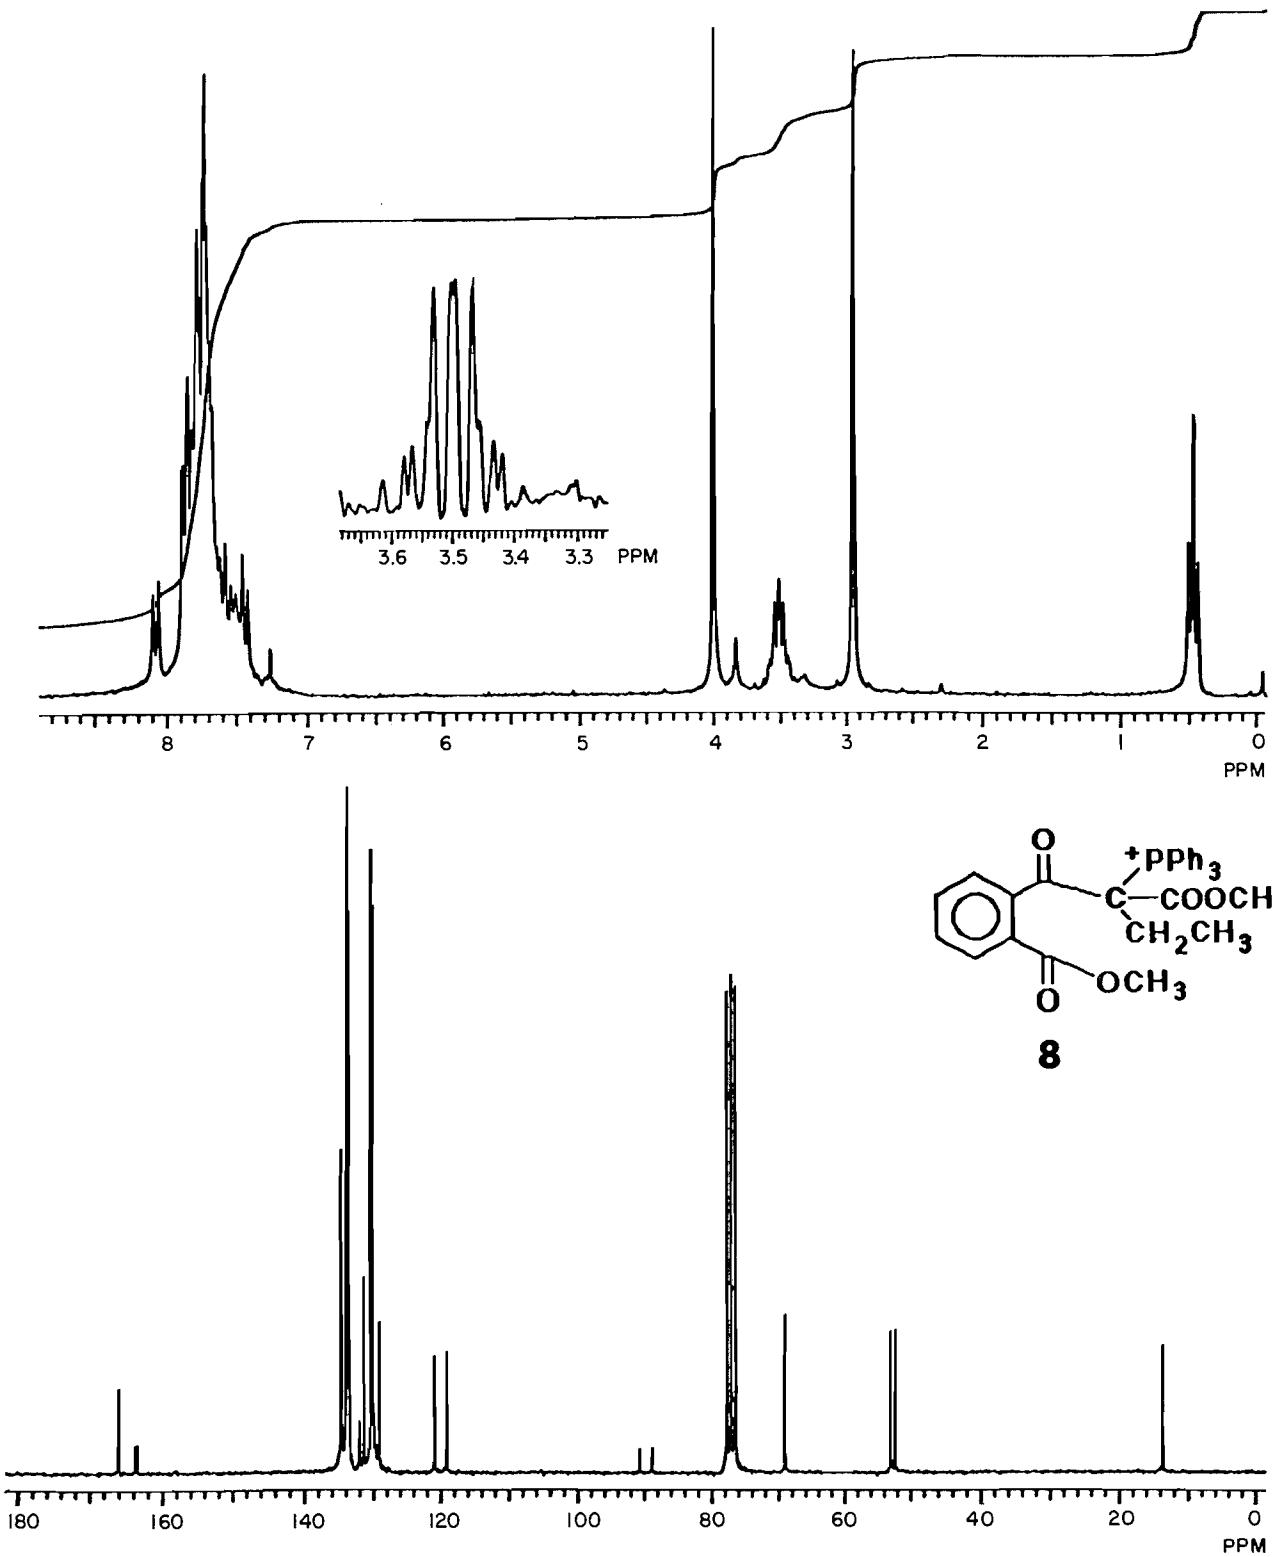

FIG. 3. The ^{1}H and ^{13}C NMR spectra of compound **8**.

to compete with the reaction leading to the Wittig product. The latter case is illustrated by the reaction of ylide **4**; here, the intermediate **7***a* is observable only as a transient species in the ^{31}P spectrum at $-35°C$ (a broad peak at 27.50 ppm). At $-20°C$ this intermediate exists in equilibrium with ylide **4** (a broad signal centred on 24.55 ppm) and collapses rapidly to the products. In this case the sluggishness of the reaction carried out *in the absence of acidic protons* can be directly linked to the slower initial attack of the ylide on the carbonyl group of the anhydride.

Study of the reversibility of the reaction between ylide 2 and 5-member cyclic anhydrides

The condensation of ylide **2** with several cyclic anhydrides was initially investigated by Abell and Westropp (18), who reported that the formation of an acyclic intermediate was reversible for the reaction with phthalic anhydride and irreversible with succinic anhydride. Our studies of the condensation of phthalic anhydride with ylide **2** monitored by NMR suggested that formation of the acyclic intermediate pair **3***a* and **3***b* is an equilibrium and hence reversible. Unequivocal proof for reversibility was provided by the following experiment.

Under the conditions corresponding to the maximum buildup of acyclic intermediates (**3***a* and **3***b*, 70%), a solution of freshly distilled benzaldehyde in $CHCl_3$ was added at 0°C, and the reaction, warmed to room temperature, was followed by NMR. After 2 h only methyl cinnamate and traces of products **3***E* and **3***Z* could be detected. Upon chromatography, methyl cinnamate was isolated in 87% yield (based on benzaldehyde).[3]

In a similar series of experiments we were able to establish the reversibility of phenyl maleic and succinic anhydrides; the last result is in contrast to the earlier report of Abell and Westropp (18). The condensation of succinic anhydride with ylide **2** was followed by ^1H NMR until the acyclic intermediates constituted 90% of the reaction mixture. At that stage freshly distilled benzaldehyde was added, and the room-temperature reaction was monitored by ^1H NMR. The reappearance of the succinic anhydride and the formation of cinnamate could be readily observed. After 70 h the reaction mixture consisted of methyl cinnamate, succinic anhydride, and traces of enol-lactone **11***E*, see Scheme 6.

The condensation of ylide **2** with unsubstituted maleic anhydride at −30°C leads to the formation of an acyclic intermediate, as witnessed by an instantaneous appearance of a new, highly shielded methoxy signal at 3.10 ppm. The reaction, however, does not lead to the corresponding enol-lactone since rapid polymerization competitively consumes the reagents, shifting the equilibrium and depleting the intermediate. Consequently, trapping experiments and re-

[3]One referee suggested a double crossover experiment to further confirm reversibility of these condensations. However, such an experiment, in which phthalic anhydride reacts with $Ph_3P{=}CHCOOMe$ to give intermediate A and 3-chlorophthalic anhydride reacts with $Ph_3P{=}CHCOOEt$ to give two intermediates B and C, leads to 12 overlapping products upon mixing of the A, B, and C, and is difficult to interpret.

versibility studies were carried out on phenylmaleic anhydride **14**. The principle acyclic intermediate **15***b* was trapped when the reaction carried out at −5°C for 35 min was treated with diazomethane to give the corresponding ester **16**. When acetaldehyde, instead of diazomethane, was added at that time, the product mixture consisted of methylcrotonate **17**, phenylmaleic anhydride **14**, and a small quantity of enol-lactone **18**, confirming that the reversibility of the first condensation step is general to the three classes of cyclic anhydrides, Scheme 7.

Conclusion

The principal goal of this study was to investigate the mechanism of the condensation of stabilized phosphoylides, such as $Ph_3PCHCOOCH_3$, **2**, with cyclic anhydrides. To accomplish that, the observable intermediates were trapped and their identity was established. The reversibility of the condensation step, leading to the formation of acyclic intermediates, was demonstrated for phthalic, phenyl maleic, and succinic anhydrides, in a series of reverse reactions between the acyclic intermediates and highly reactive aldehydes such as benzaldehyde or acetaldehyde.

Trapping experiments also confirmed that an equilibrium is established between reactants and acyclic intermediates and that the intermediates themselves are in equilibrium with a strong bias toward the stabilized ylide forms such as **3***b*, **11***b*, or **15***b*.

We were unable to observe directly any oxaphosphetane or betaine intermediates. This is not particularly surprising in view of unsuccessful efforts of other investigators to observe such species in the reactions between aldehydes and stabilized ylides (4, 12). Although the betaine intermediate was calculated to be of considerably higher energy than the corresponding oxaphosphetane for the model reaction of aldehyde with ylide (11), it seems to us that the most feasible route to the acyclic intermediates in the reactions of stabilized ylides with 5-member cyclic anhydrides is through a very short-lived betaine or a betaine-like transition state.

In all cases studied, the reversible formation of cyclic adducts is a lower energy process than the formation of product enol-lactones. This suggests that in the condensations of stabilized phosphoranes with cyclic anhydrides, the oxaphosphetane is formed either through betaine or a betaine-like transition state, or that there is an independent, competing, slightly higher energy pathway to enol-lactones via a 4-centre transition.[4] At this stage it is not possible to distinguish between the two mechanistic pathways.

The study of condensations of cyclic anhydrides with methyl (triphenylphosphoranylidene) acetate **2** and (carboethoxy-ethylidene) triphenylphosphorane **4** in the absence of all external sources of acidic protons (including traces of the corresponding conjugate acids), strengthens our earlier observation that Wittig condensations with stabilized ylides appear to be catalyzed by traces of protic acids (25, 27).

Experimental

Nuclear magnetic resonance spectra were recorded at 361 MHz (^1H), 91 MHz (^{13}C), and 146 MHz (^{31}P) on the Nicolet 360 NB spectrometer of the Atlantic Region Magnetic Resonance Centre, and some ^{31}P spectra were recorded at 81 MHz on the Varian XL-200 spectrometer of the University of New Brunswick. All spectra were in $CDCl_3$ solutions unless otherwise indicated. Calibration of the spectra was done with respect to TMS as internal

reference (^{1}H and ^{13}C) or 85% H_3PO_4 as external standard (^{31}P). Temperature control was by the usual Nicolet method. Calibration of the thermocouple showed an estimated error of less than 1°C in the temperature range used.

For all experiments carried out under anhydrous conditions, anhydrides were freshly crystallized from dry chloroform; methyl (triphenylphosphoranylidene)acetate **2** (obtained from Aldrich) and (carboethoxyethylidene)-triphenylphosphorane **4** (obtained from Lancaster) were subjected to azeotropic drying with benzene. To remove traces of conjugate acids, treatment with BuLi or MeLi was necessary. $CDCl_3$ (Silanor C*) was dried over molecular sieves and all glassware and NMR tubes were oven-dried at 150°C for 2 h and cooled under stream of argon.

spectra taken at regular intervals for 24 h. After approximately 20 h at room temperature the reaction was completed. The product, the (*E*/*Z*) mixture of enol-lactones (65%), was separated from the conjugate acid **2***a* (35%) and triphenylphosphine oxide by chromatography on silica gel. The major (*E*) isomer (80%) was eluted first (10:90 ether:petroleum ether) followed by the minor (*Z*) isomer (20%) (50:50 ether:petroleum ether). Methyl (*E*)-3-oxo-1,3-dihydro-isobenzofuran-1-ylideneacetate **3***E*, ^{1}H NMR δ: 3.77 (s, 3H, OCH_3), 6.09 (s, 1H, CH), 7.92–7.60 (m, 4H, aromatic), 9.05 (d, 1H, *o*-aromatic). Methyl (*Z*)-3-oxo-1,3-dihydroisobenzofuran-1-ylideneacetate **3***Z*, ^{1}H NMR δ: 3.79 (s, 3H, OCH_3), 5.83 (s, 1H, CH), 7.92–7.60 (m, 4H, aromatic).

*Room temperature reaction of phthalic anhydride **1** with ylide **2** pretreated with BuLi, monitored by ^{1}H NMR*

The solution of ylide **2** (100 mg, 0.3 mmol in 0.3 mL of $CDCl_3$) was treated with a few drops of BuLi until the spectrum resolved into two isomeric forms. At that point the suspension of phthalic anhydride (44.4 mg, 0.3 mmol) in $CDCl_3$ (0.5 mL) was added and the reaction was monitored by ^{1}H NMR as described above.

*Room temperature reaction of phthalic anhydride **1** with ylide **4** monitored by ^{1}H NMR Formation of 7*E

(Carbethoxyethylidene)triphenylphosphorane **4** (109 mg, 0.3 mmol) was dissolved in 0.3 mL of $CDCl_3$ and the spectrum was taken. Phthalic anhydride **1** (45 mg, 0.3 mmol) suspended in 0.5 mL of $CDCl_3$ was added to the ylide solution and a spectrum was recorded immediately after mixing. At this point, approximately half of the ylide was already converted to product. After 1 h all ylide was consumed. The products, (*E*) enol-lactone and triphenylphosphine oxide, were isolated by chromatography on silica gel. Ethyl (*E*)-3-oxo-1,3-dihydroiso-benzofuran-1-ylidene(2′-propanoate) **7***E*, 40 mg (61%) was eluted with ether:petroleum ether (20:80) ^{1}H NMR δ: 1.39 (t, 3H, OCH_2,CH_3), 2.27 (s, 3H, CH_3), 4.36 (q, 2H, OCH_2CH_3), 8.57–7.58 (m, 4H, aromatic); triphenylphosphine oxide, 67 mg (80%), was eluted with ether.

*Room temperature reaction of phthalic anhydride **1** with ylide **4** pretreated with BuLi, monitored by ^{1}H NMR*

The solution of **4** (109 mg, 0.3 mmol) in $CDCl_3$ (0.3 mL) was treated with a few drops of BuLi until the spectrum indicated presence of the two isomeric forms. At that point a suspension of phthalic anhydride (45 mg, 0.3 mmol) in $CDCl_3$ (0.5 mL) was added and the reaction was monitored by ^{1}H NMR as described above.

*Trapping with Me_3OBF_4: phthalic anhydride **1** + ylide **2***

Ylide **2** (571 mg, 1.71 mmol) dissolved in 15 mL of $CHCl_3$ and cooled to 0°C was added to an ice-cold suspension of phthalic anhydride **1** (253 mg, 1.71 mmol) in 15 mL $CHCl_3$. The reaction was allowed to proceed for 30 min at 0°C under N_2 atmosphere. After addition of Me_3OBF_4 (253 mg, 1.71 mmol) the reaction was stirred at 0°C for another 30 min. The solution was warmed to room temperature and the solvent was evaporated. The products were identified by ^{1}H NMR as a 50:50 mixture of the conjugate acid **2***a* and the *O*-alkylated acyclic intermediate **5**: ^{1}H NMR δ: 3.01 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 7.86–7.26 (aromatic H's).

*Trapping with MeI: phthalic anhydride **1** + ylide **2***

Ylide **2** (388 mg, 1.16 mmol) dissolved in 15 mL of $CHCl_3$ and cooled to 0°C was added to phthalic anhydride **1** (172 mg, 1.16 mmol) suspended in 15 mL $CHCl_3$ at 0°C. After 30 min at 0°C, the reaction mixture was treated with excess MeI (0.1 mL); and stirring was continued at that temperature for additional 30 mins. The solution was allowed to warm to room temperature and the solvent was evaporated. The products were identified by ^{1}H NMR as: conjugate acid **2***a* (20%), **4***a* (39%), **3***E*/*Z* mixture of enol-lactones (30%), and acyclic intermediate **5** (11%). **2***a*: ^{1}H NMR δ: 3.59 (s, 3H, OCH_3), 5.22 (d, 2H, 2, J_{PH} = 13.6 Hz, I^- counterion), 7.86–7.26 (aromatic H's); for **4***a*, 1.68 (dd, 3H, CH_3, J_{PH} = 18.3 Hz, J_{PH} = 7.3 Hz), 3.56 (s, 3H, OCH_3), 6.20 (m, 1H, CH, I^- counterion), 7.86–7.26 (aromatic H's); for **3***E* and **3***Z* enol-lactones; δ: 3.84 (s, 3H, OCH_3, *E* + *Z*), 5.96 (s, 1H, CH, *Z*), 6.13 (s, 1H, CH, E), 7.86–7.26 (Aromatic H's); **5**: ^{1}H NMR δ: 3.01 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 7.86–7.26 aromatic H's).

*Trapping with CH_2N_2: phthalic anhydride **1** + ylide **2**. Formation of **5***

Ylide **2** (670 mg, 2.0 mmol) was added to phthalic anhydride **1** (297 mg, 2.0 mmol) suspended in 10 mL $CHCl_3$ and cooled to 0°C. The reaction mixture was stirred for 30 mins at 0°C before quenching with excess ethereal solution of diazomethane (0.2 M in Et_2O). The product **5** was isolated by chromatography on silica gel using 100% ether as elutant and was subsequently recrystallized from ether to give pure **5** as white crystals, 660 mg (66%), mp 182–184°C; ^{1}H NMR δ: 3.01 (s, 3H, OCH_3), 3.83 (s, 3H, OCH_3), 7.25–7.92 (aromatic H's); ^{13}C NMR δ: 49.57, 51.85, 71.17 (J_{PC} 112 Hz), 133.4–125.3 (aromatic), 146.57 (J_{PC} 8.2 Hz), 167.12, 167.57 (J_{PC} 14.8 Hz), 192.68 (J_{PC} 5:4 Hz); ^{31}P NMR δ: 17.73; HRMS: *m*/*e* 496.1465; (M^+) requires 496.1439; 463, 437, 361, 262, 201, 183, 163.

*Trapping of compound **5** with Et_3OBF_4. Formation of **8***

1-Methoxycarbonyl-2-(2′-methoxy-carbonylphenyl)-2-oxoethylidene-triphenylphosphorane **5**, (225 mg, 0.45 mmol) was dissolved in 20 mL of CH_2Cl_2 (distilled from CaH_2) and cooled to 0°C in a dry three-necked flask under N_2 atmosphere. An excess of triethyloxonium tetrafluoroborate (300 mg, 1.6 mmol), dissolved in dry CH_2Cl_2, was added to the solution. The reaction mixture was stirred for 10 min at 0°C, then was allowed to warm to room temperature and the solvent was evaporated. The resulting creamy-white solid was recrystallized from ether to give 1-methoxycarbonyl-2-(2-methoxy-carbonylphenyl)-1-oxobutan-2-triphenylphosphonium tetrafluoroborate **8**, 195 mg (82%), mp 169–171°C; ^{1}H NMR δ: 0.46 (t, 3H, CH_2CH_3), 2.94 (s, 3H, OCH_3), 3.45 (dq, 2H, CH_2CH_3), 3.99 (s, 3H, OCH_3), 8.09–7.41 (aromatic H's); ^{13}C NMR δ: −13.62, 52.28, 53.03, 69.03, 89.73 (J_{PC} 92.5 Hz), 119.00, 120.84, 129.04–134.57 (aromatic), 163.53 (J_{PC} 10.0 Hz), 165.87, 182.22; ^{31}P NMR δ: 14.84; HRMS: *m*/*e* 496.1413; (M^+ − 29) requires 496.1439, 463, 277, 201, 187. The reaction carried out at −78°C for 3 h gave the identical product. Note: C7 was shown to be the correct assignment by APT experiments.

*Trapping with CH_2N_2: succinic anhydride **10** + ylide **2**. Formation of **12***

Ylide **2** (2.1 g, 6.3 mmol) was added to succinic anhydride **10** (631 mg, 6.3 mmol) suspended in 50 mL of $CHCl_3$. The reaction mixture was stirred for 2 h at room temperature, quenched with excess diazomethane, and left overnight to allow the excess diazomethane to escape. After evaporation of the solvent, the product mixture consisted of **12** (60%), dimethyl succinate (10%), and small quantities of unreacted ylide **2** and the conjugate acid **2***a* in addition to triphenylphosphine oxide. Triphenylphosphine oxide was removed by crystallization from ether. The trapped intermediate, dimethyl 3-oxo-2-(triphenylphosphoranylidene)adipate **12**, was isolated by chromatography on silica gel with 100% ether. The isolated yield was 914 mg (32%); mp 113–115°C; ^{1}H NMR δ: 2.53 (t, 2H, CH_2), 3.13 (s, 3H, OCH_3), 3.24 (t, 2H, CH_2), 3.53 (s, 3H, OCH_3), 7.70–7.34 (aromatic); ^{13}C NMR δ: 28.15, 34.32 (J_{PC} 3.8 Hz), 48.45, 50.23, 69.6 (J_{PC}, 110 Hz), 132.71–124.98 (aromatic), 167.05 (J_{PC} 15.4 Hz), 173.09, 193.97; ^{31}P NMR δ: 16.46; HRMS: *m*/*e*: 448.1560; (M^+) requires 448.1439, 417, 361, 277, 201, 183, 77.

*Trapping of compound **12** with Et_3OBF_4. Formation of **13***

Triethyloxonium tetrafluoroborate (0.25 mL, 0.25 mmol) was added to the solution of compound **12** (100 mg, 0.22 mmol) dissolved in 10 mL CH_2Cl_2 (freshly distilled from CaH_2) and cooled to −78°C under N_2. The reaction mixture was stirred for 1 h at −78°C, then warned to room temperature. The solvent was evaporated to give single product identified from its NMR spectra as O3 alkylated compound **13**. ^{1}H NMR δ: 0.51 (t, 3H, CH_3), 2.79 (t, 2H, CH_2), 3.24 (t, 2H, CH_2), 3.28 (s, 3H, OCH_3), 3.71 (s, 3H, OCH_3),

4.07 (q, 2H, OCH_2), 7.54–7.79 (m, 15H, aromatic H's); ^{13}C NMR δ: 13.49, 25.81, 31.61, 52.33, 52.49, 67.68, 91.00 ($^1J_{PC}$ 100 Hz), 117.74–135.27 (aromatic), 164.07 ($^2J_{PC}$ = 8.7 Hz), 171.89, 184.83 ($^2J_{PC}$ = 8.9 Hz).

*Trapping with CH_2N_2: phenylmaleic anhydride **14** + ylide **2**. Formation of **16***

Ylide **2** (835 mg, 2.5 mmol) was added to phenylmaleic anhydride **14** (435 mg, 2.5 mmol) suspended in 20 mL of $CHCl_3$ at −5°C. The reaction mixture was stirred for 35 min at 0°C. At that point only the intermediate pair **15***a*, **15***b* and the product **18** were observable in the ^1H NMR spectrum. After quenching with excess diazomethane, the reaction mixture was left overnight to allow the excess diazomethane to escape. The solvent was evaporated and triphenylphosphine oxide was removed by crystallization from ether. The remaining products were separated by chromatography on silica gel. The enol-lactone **18** was eluted first, followed by **16** eluted with ether: petroleum ether (50:50) to give 417 mg (32%): ^1H NMR δ: 3.17 (s.3H), 3.47 (s, 3H), 7.2–7.7 (m. 20H), 7.93 (s, 1H); ^{31}P NMR δ: 17.11; *m/e*: 522 (M^+), 277, 262, 201, 199, 174, 102.

*Reversibility study: phthalic anhydride **1** + ylide **2***

Phthalic anhydride **1** (100 mg, 0.7 mmol) was added to the solution of **2** (227 mg, 0.7 mmol) in 50 mL $CHCl_3$ cooled to 0°C. After 30 min at 0°C, the reaction was quenched with benzaldehyde and was stirred for an additional 2 h at 0°C. After evaporation of the solvent, the products were separated by chromatography on silica gel. *trans*-Methylcinnamate, 96 mg (87%), was eluted first with ether: petroleum ether (5:95); ^1H NMR δ: 3.79 (s, 3H, OCH_3), 6.44 (d, 1H, C*H*), 8.00–7.20 (m, 6H, aromatic + C*H*), followed by trace amounts of enol-lactone(s) eluted with ether: petroleum ether (10:90) and triphenylphosphine oxide 189 mg (79%) eluted with 100% ether.

A study of the nonstationary character of the methanol-to-hydrocarbons conversion

V. KANAZIREV[1] AND T. TSONCHEVA

Institute of Organic Chemistry with Centre of Phytochemistry, Bulgarian Academy of Sciences, Sofia 1040, Bulgaria

Received May 29, 1991[2]

V. KANAZIREV and T. TSONCHEVA. Can. J. Chem. **70**, 1997 (1992).

An important characteristic of the methanol-to-hydrocarbons reaction is its autocatalytic behaviour under certain conditions. In this paper, self-acceleration in the conversion of MeOH over various zeolites, e.g., H-ZSM-5, H-CaY, H-offretite, and H-mordenite, in a flow reactor is examined. Self-acceleration is considered as a step of the nonstationary state changes taking place as a result of the interaction between the reaction medium and the catalyst. The effect on this process of factors such as partial pressure of methanol and the presence of hydrogen in the reaction mixture are investigated. Conclusions regarding the mechanism of C—C bond formation are considered. The course of the nonstationary process may be used for preliminary selection of catalysts for synthesis of hydrocarbons from methanol.

V. KANAZIREV et T. TSONCHEVA. Can. J. Chem. **70**, 1997 (1992).

Une caractéristique importante de la réaction du méthanol en hydrocarbures est son comportement autocatalytique, dans certaines conditions. Dans ce travail, on a examiné l'auto-accélération de la conversion du MeOH sur divers zéolites, comme la H-ZSM-5, la H-CaY, la H-offretite et la H-mordenite dans un récteur à écoulement. L'auto-accélération est considérée comme une étape des changements de l'état non-stationnaire qui se produit par l'interaction entre le milieu réactionnel et le catalyseur. On a aussi examiné l'effet, sur ce processus, de facteurs comme la pression partielle du méthanol et la présence d'hydrogène dans le milieu réactionnel. On considère les conclusions à tirer au sujet du mécanisme de la formation de la liaison C—C. On peut utiliser le cours du processus non-stationnaire pour la sélection préliminaire des catalyseurs à utiliser pour la synthèse d'hydrocarbure à partir du méthanol.

Introduction

The methanol-to-hydrocarbons conversion is one of the most intensively studied catalytic processes because of its scientific interest and practical significance.

An important characteristic of this reaction is its self-acceleration, i.e., autocatalytic course under certain conditions (1–5). Self-acceleration during the conversion of methanol has been observed for different zeolites, i.e., ZSM-5 (1–3); X (5), Y (4), as well as for copper dodecatungstophosphate (6). Self-acceleration takes place in a recirculation system (3) as well as in an open flow reactor (1, 2, 4, 5), and has been indicated by characteristic temperature dependence (3–5), existence of an induction period (3–5), and an increase of activity during the experiments (5, 7). Additional evidence for the autocatalytic character of the conversion is the shortening of the induction period in the presence of certain substances, such as olefins (3, 21, 23) and alcohols (7). The induction period is also affected by the acidity of the catalyst (1, 21, 22), its particle size, methanol pressure, reaction temperature, and the presence of water in the reaction mixture (2).

The mechanism of self-acceleration is not completely known. In the case of zeolite catalysts, the autocatalytic course of the reaction is associated with the formation and generation of reactive intermediates (C_1 particles), which react at a high rate with olefins (or aromatics) (1–3, 7, 8, 21, 24). An alternative possibility is discussed by Baba and Ono (6). They show an increase in the number of acidic centres during the reaction on the copper dodecatungstophosphate catalyst due to the reductive influence of hydrogen molecules (or atoms) produced by the decomposition of methanol. Prinz and Riekert (22) assume that the formation of some reactive hydrocarbons in the zeolite is a necessary intermediate step in the reaction. Espinoza (25, 26) considers that C-containing particles modify the catalyst and because of that the reaction deviates into a faster course.

In the present investigation, self-acceleration is considered as a step in the nonstationary state changes taking place as a result of the interaction between the reaction medium and the catalyst. Also discussed is the extent to which the nonstationary process is indicative of the intrinsic capability of different zeolites to accelerate C—C bond formation from methanol. The effect on the nonstationary process of factors such as the partial pressure of methanol and the presence of hydrogen in the reaction flow is also investigated.

Experimental

Catalysts

H-ZSM-5

The sample was obtained via crystallization in the presence of tetrapropylammonium cations (9); SiO_2/Al_2O_3-89; (98% degree of decationization).

H-offretite (H-off)

The sample was obtained via crystallization in a tetramethylammonium cations medium according to known procedure (10); SiO_2/Al_2O_3-9, 9; (90% degree of decationization).

H-mordenite (H-mord)

The sample was prepared on the basis of synthetic mordenite kindly provided by Leuna, Germany; SiO_2/Al_2O_3-10; (90% degree of decationazation).

H-CaY

This was obtained on the basis of the sodium form of the zeolite kindly provided by Leuna, Germany; the content of each of the cations (H^+ and Ca^{2+}) is 36% equivalents, respectively.

The H-modifications of all samples were prepared via ion exchange with NH_4^+ followed by thermal decomposition of the ammonium at 813 K. The H-CaY sample was prepared via ion exchange in the presence of NH_4^+ and Ca^{2+} ions. The organic cations in the cases of H-ZSM-5 and H-off were removed beforehand by heating in an air flow at 813 K for 6 h. In the catalytic reactor all samples were subjected to additional thermal treatment

TABLE 1. Temperature dependence of the selective dehydration of methanol to DME, R_{CH_3OH} = 3.85 kPa

Catalyst	Temperature, K	Yield DME, %
	481	39.8
H-ZSM-5	517	76.0
	539	79.7
	419	18.9
	445	60.5
H-mordenite	458	74.7
	431	61.0
H-offretite	443	77.8
	486	50.2
	493	56.0
H-CaY	501	60.0
	559	70.0

by means of consecutive heating at 703 K for 6 h in air, argon, and hydrogen flow.

Procedure and apparatus

The flow system consists of a glass microreactor, a calibrated saturator, and a gas inlet system (for argon and hydrogen) (11). This instrumental setup permits easy variation of the temperature, flow rate, and partial pressure of the components; it also allows a periodic check of the catalyst activity under standard conditions, as well as monitoring colour changes in the catalyst during the experiments. The reaction mixture is analysed on-line by means of gas chromatography using a 2-m Porapak Q column. The quantitative evaluation was conducted using an absolute calibration with automatic computation of the chromatographic data. A carbon base was used for the product yield calculation.

The experiment includes the following stages: preliminary thermal treatment of the catalyst; adjustment and determination of the methanol partial pressure in a by-pass line; running the reaction mixture through the reactor, followed by chromatographic analysis at 4–7 min intervals. The catalytic experiments were carried out in a temperature range of 400–650 K at a weight hourly space velocity (WHSV) 1.5 h^{-1} and partial pressure of methanol 1.57–3.85 kPa. The catalyst (0.1 g), with a particle size of 0.2–0.8 mm, was diluted threefold with glass of the same particle size.

Results

Start and course of the nonstationary process

The temperature dependence of methanol (MeOH)-to-dimethyl ether (DME) conversion is registered for each sample (Table 1). With all samples examined, a near-equilibrium conversion into DME is reached. The nonstationary process under isothermal conditions (the temperature in the catalyst bed is kept constant within 1°) begins in all cases after the appearance of the first hydrocarbon products in the gas phase. As can be seen in Fig. 1, in the example of H-CaY and H-off zeolites the nonstationary process includes the following steps: (*i*) rapid increase of the hydrocarbon products, mainly C_2—C_4 olefins (only C_2—C_3 hydrocarbons are given in Fig. 1); (*ii*) decrease in the DME and methanol content; (*iii*) subsequent complex changes in the distribution of the products. The nonstationary process reveals in its course specific characteristics for each of the catalysts examined. Lower initial temperature, appearance of CH_4, significantly lower yields of C_2—C_3 hydrocarbons, and a specific change in the DME content are typical for the H-off sample. The H-mordenite catalyst behaves (Fig. 2) in a manner similar to that of the H-CaY and H-off samples. However, the changes take place more rapidly and in 1 h the catalytic activity is totally lost. In comparison with the other samples, the high methane concentration and the continuous decrease of the DME with time on-stream are worth noting. Among the hydrocarbons in the gas phase, the C_1—C_3 ones predominate (over 90%). The temperature at which the nonstationary process starts is higher than that for H-off but lower than for H-CaY.

In Fig. 3 data are presented for the H-ZSM-5 catalyst at three different temperatures. It can be seen that the C_2—C_3 hydrocarbons appear in the gas phase for the first time at 547 K, the ethylene yield being about 50% greater than the propylene yield; thus after 15 min there are 0.1% of C_2^{2-} and 0.06% of C_3^{2-}, while after 40 min there are 0.25% and 0.18%, respectively. The rate of composition change grows when the temperature is increased to 561 K: the C_2^{2-}/C_3^{2-} ratio is already in favour of propylene and small amounts of C_4 are also present. For example, 14 min after the temperature increase the amounts of C_2, C_3, and C_4 hydrocarbons are 2.88, 4.43, and 0.53% respectively, but after 38 min they are 3.87, 6.23, and 0.83%. A very sharp change in the product distribution is observed after further raising the temperature to 593 K.

Influence of the partial pressure (P) of MeOH and the presence of H_2 in the reaction flow

The effect of the partial pressure of MeOH was examined in the case of the H-CaY sample. The decrease of *P* from 3.6 down to 1.2 kPa was achieved by dilution with Ar or H_2 (Fig. 4).

Comparison of the data from Fig. 1 and Fig. 4 shows that the decrease in the methanol partial pressure and the presence of H_2 in the reaction mixture do not affect significantly the basic characteristics of the nonstationary process. A trend towards a smoother running of this process is, however, noticeable. The effect of H_2 is more pronounced in the formation of C_2—C_3 hydrocarbons when their yield decreases with a corresponding increase of C_4^+ hydrocarbons between the 20th and 120th minutes of the experiment (Table 2).

However, no increase of methane in the gas phase is observed. Its concentration remains, as in the case of Ar-dilution, lower than 0.5%.

Deposition of nondesorbable products during the experiment

The material balance during the experiments can be followed with an accuracy of about 5% using absolute calibration of the chromatographic signals. The material balance data indicate that a part of the carbon content of the reactant flow remains deposited on the catalyst, when the self-acceleration of the methanol conversion proceeds under isothermal conditions. The deposit formation, as evaluated from the deficiency of the material balance, decreases in the sequence: H-mord > H-off > H-CaY > H-ZSM-5, and can be determined with sufficient accuracy only in the case of the H-mord catalyst. The loss in the material balance together with the changes in the CH_4 concentration (Ar or H_2 as diluent gas) are shown in Fig. 5. It can be clearly seen that the rate of deposit formation follows the course of the nonstationary process, as presented with the typical changes in the methane content of the gas phase. The inclusion of H_2 in the reaction flow has no significant effect on this phenomenon.

It should also be mentioned that the deposition of nondesorbable products and the nonstationary state process are

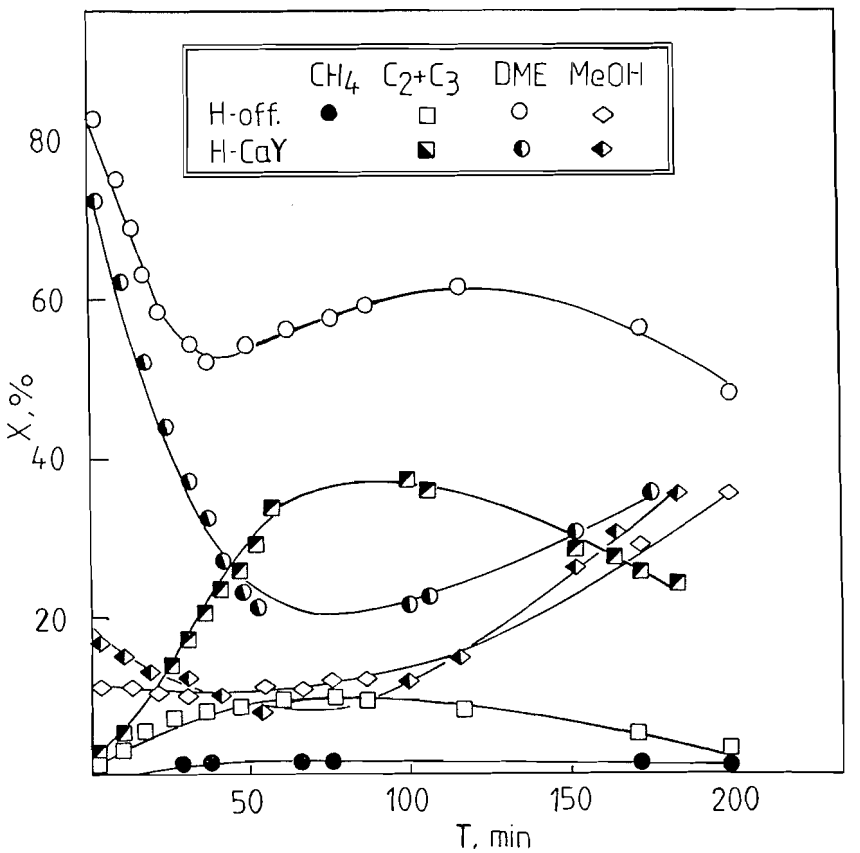

FIG. 1. Change in the distribution of the products (x, mol%) with time on-stream (t, min) in the MeOH conversion over H-off (T = 517 K) and H-CaY (T = 560 K), $P_{CH\,OH}$ = 3.85 kPa.

accompanied, in the case of all zeolites studied, by a series of colour changes of the catalyst, i.e., from light-yellow through dark-yellow to orange, also various shades of brown to dark-brown, dark-gray, and finally black. The rate of the colour changes generally follows the dynamics of the nonstationary process and, accordingly, is highest in the case of H-mord. The process is not so intensive and the colour changes are especially slow in the case of H-ZSM-5 zeolite.

Discussion

Autocatalysis during the methanol-to-hydrocarbons conversion was first observed in the case of ZSM-5 zeolites (1–3). It is found in the present study that this phenomenon may be even more marked in the presence of acidic forms of other structural types of zeolites. Moreover, the self-acceleration (autocatalysis) can be considered as one stage in the complex sequence of interactions between the reaction flow and the catalyst. The following stages of this nonstationary process can be distinguished under isothermal conditions:

A. An increase in the hydrocarbon concentration and simultaneous decrease in the MeOH and DME content (autocatalysis, self-acceleration).

B. A period of stable catalytic activity and selectivity.

C. A deactivation with respect to hydrocarbon formation. At the same time the activity in the dehydration of MeOH to DME resumes (H-off, H-CaY).

D. A continuing deactivation in both hydrocarbon as well as DME formation (H-off, H-mord).

The indicated stages take place to a different degree for the catalysts studied. The whole process in the case of H-mordenite is so fast that step B cannot practically be observed, while in the presence of the H-ZSM-5 sample step A is rather prolonged and hydrocarbons take several hours to form.

We assume that the self-acceleration and the deactivation during the methanol conversion are two sides of one and the same nonstationary process. There are some indications that deposits on the catalyst play an important role in this process: (*ii*) there is parallelism between the rate of deposit formation and the colour changes of the catalyst on the one hand and the changes in the composition of the gas phase with time on the other hand; (*ii*) the nonstationary process can be repeated in all its details after burning of the deposits in the presence of air; (*iii*) the autocatalytic stage can be stopped and even reversed in the presence of H_2 in the case of Pt-containing zeolites (11).

The chosen conditions, i.e., small amounts of catalyst diluted with an inert material, low partial pressure of methanol, and a high flow rate, preclude the influence of macrofactors, such as temperature and concentration gradients, and limit the process to the formation mainly of C_2—C_4 hydrocarbons. The general assumption in this paper is that the self-acceleration of the methanol conversion is closely associated with a buildup of reactive deposits on the zeolite catalyst. Similar, to some proposals in the relevant literature (29), we suggest that the carboneous residues at different stages of their growth may possess proton-donating capability and hence enhanced catalytic activity in the

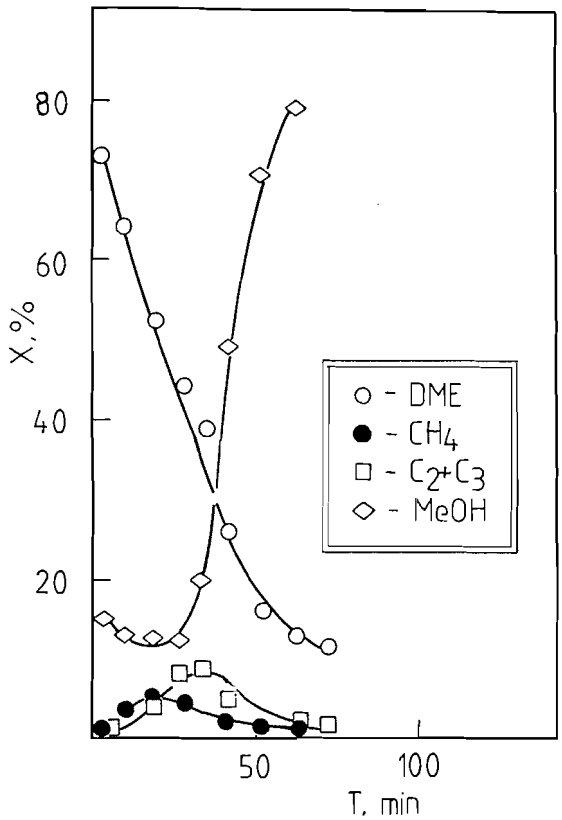

FIG. 2. Product distribution (x, mol%) in the MeOH conversion over H-mor vs. time on-stream (t, min) at 547 K.

methanol conversion. The increase of the catalytic activity with time on-stream is a well-known phenomenon in the case of the conversion of aromatic hydrocarbons on zeolite catalysts (30, 31). The following steps of the nonstationary process, i.e., the deactivation, can be envisaged as a further transformation of the deposits via hydrogen depletion. The observed decrease in the rate of deactivation, i.e., mordenite > offretite > type Y > ZSM-5, fully corresponds to the decrease in the tendency toward coke-formation, which is the same for other acid–base reactions (4).

The course of the nonstationary process in principle contains information regarding the capability of the catalyst to accelerate C—C bond formation from methanol. Ono *et al.* (1), on the basis of the observation that the autocatalytic reaction begins at different temperatures, concluded that the ZSM-5 sample with SiO_2/Al_2O_3-134 is less active than similar zeolites with a lower SiO_2/Al_2O_3 ratio.

In the present study the samples differ in the initial temperature at which, under isothermal conditions, an increase of the hydrocarbons formation starts:

H-offretite	H-mordenite	H-CaY	H-ZSM-5
517	547	559	561/593

Judging from this, it can be assumed that the capability of initiating and conducting the process of C—C bond formation from methanol is most pronounced in the case of the zeolite H-offretite. On the other hand, the behaviour of the ZSM-5 catalytic systems is characterized by a rather moderate rate of the nonstationary process. A much higher temperature, i.e., 593 K, is needed for the completion of the above process. Information regarding the primary products was obtained in the present study. All investigated zeolite catalysts favour ethylene production at the beginning of the self-acceleration, but the C_2/C_3 ratio quickly diminishes to finally become less than unity.

The H-mordenite catalyst only leads to methane preponderance after the initial appearance of C_2 and C_3 for a cer-

H	30.0	32.2	32.4	33.4	33.2

tain time period, after which the C_2—C_3 hydrocarbons begin to predominate. The results obtained from conducting the process under nonstationary conditions support the assumption that evolution of ethylene in the gas phase is favoured in the initial stage of the process. Under the reaction conditions employed in the present study, the partial pressure exerted by hydrogen exceeds that of methanol by about a factor of 20 and can therefore affect significantly the reaction steps proceeding with absorption or evolution of hydrogen. The observation that with the catalysts H-mordenite and H-CaY the reaction course remained essentially unaffected, the basic features of the nonstationary process being retained, indicates that hydrogen is unlikely to participate in the key step, directly or via adsorption–chemical equilibria. The observed changes in the product composition occurring during a part of the activity interval of the H-CaY catalyst can be explained by peculiarities in the secondary conversions undergone by olefins in the presence of hydrogen, as reported recently by Blackmond *et al.* (19) on the basis of IR data. In the literature (12–18) are discussed such key reactions and intermediates as should be significantly affected by the presence of hydrogen in the reaction mixture. Thus, the interaction between carbenes and hydrogen should shift the process towards methane formation, as illustrated in the photolysis reaction of ketene and diazomethane (20), or in the interaction between methylene and sodium vapours in a hydrogen atmosphere (11, 27, 28). The fact that the process

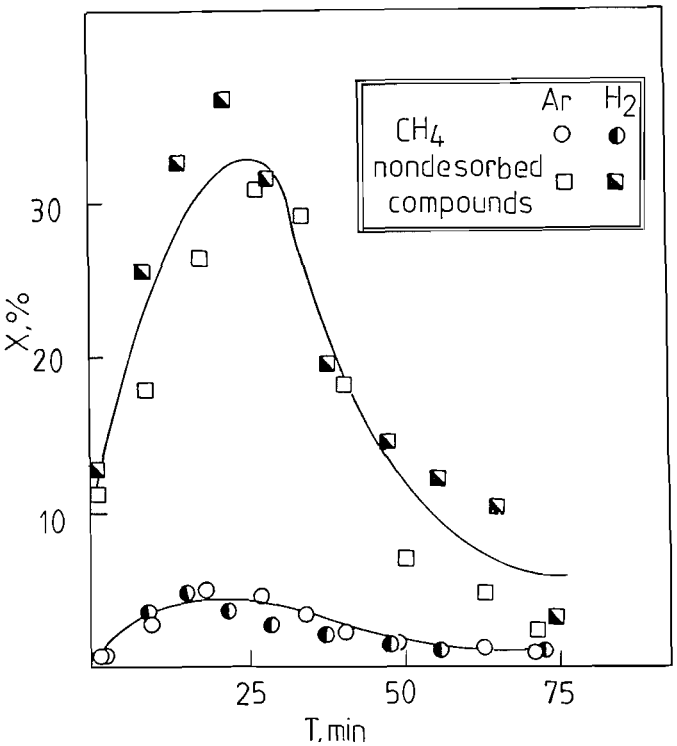

FIG. 5. Conversion of MeOH (x, mol%) to CH_4 and nondesorbable compounds during experiments in Ar or H_2 as diluent gases (T = 547 K).

preserves its nonstationary character in the presence of hydrogen also indicates a lower degree of dehydrogenation and hydrogenation reactions in the mechanistic route of the methanol-to-hydrocarbons reaction.

Conclusion

Self-acceleration in the methanol-to-hydrocarbons conversion is considered as one step of the nonstationary process taking place in the interaction between zeolite catalyst,

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 217.78.4.112 on 09/08/12
For personal use only.

methanol, and DME. This nonstationary process is more pronounced with catalytic systems possessing a higher density of active centers than in the case of high silica zeolites. The course of the nonstationary process over various catalysts reflects the importance of some surface reactions leading to the formation and conversion of coke precursors on the catalyst surface. The investigation of the nonstationary process and the tracing out of the influence of H_2 can be an important source of information about the mechanism of C—C bond formation and the choice of an appropriate catalyst for methanol-to-hydrocarbons conversion.

AND
ARTHUR G. WILLIAMSON[1]
Department of Chemical and Process Engineering, University of Canterbury, Christchurch, New Zealand

Received September 20, 1991

SHEN WEIGUO and ARTHUR G. WILLIAMSON. Can. J. Chem. **70**, 2003 (1992).

Measurements at 25°C are reported for the volumes of mixing of binary mixtures of *n*-dodecane + 2 methyl pentane and of ternary mixtures created by mixing an equimolar mixture of (*n*-decane + *n*-tetradecane) with each of the isomers of hexane. The results are compared with the work of Hamam *et al.* for binary mixtures of *n*-dodecane with the hexane isomers and shown to be in accord with the principle of congruence within the limits of experimental accuracy of the measurements.

SHEN WEIGUO et ARTHUR G. WILLIAMSON. Can. J. Chem. **70**, 2003 (1992).

Opérant à 25°C, on a effectué des mesures de volumes de mélanges binaries du *n*-dodécane avec le 2-méthylhexane et des mélanges ternaires obtenus par mélange d'une quantité équimoléculaire de (*n*-décane + *n*-tétradécane) avec chacun des isomères de l'hexane. On compare les résultats avec ceux obtenus par Hamam *et al.* pour des mélanges binaires du *n*-dodécane avec les isomères de l'hexane et on montre que, dans les limites de l'exactitude expérimentale des mesures, ces résultats sont en accord avec le principe de congruence.

[Traduit par la rédaction]

Introduction

As a part of the study of the applicability of the principle of congruence to ternary mixtures (1), this work reports the excess volumes of *n*-dodecane + 2-methylpentane and of pseudo *n*-dodecane prepared from equimolar quantities of *n*-decane and *n*-tetradecane + each of the four branched hexane isomers at 298.15 K.

Experimental

Volumes of mixing were deduced from accurate density measurements using a vibrating tube densimeter. As was pointed out by previous authors (2), a major problem with such measurements on mixtures of volatile components is the preparation of mixtures whose compositions are known to an accuracy consistent with that of the density measurements.

In an attempt to eliminate errors due to vaporization of volatile components we examined two methods of preparing mixtures. In the first procedure, the mixture was prepared by weighing the liquids into an evacuated cell shown in Fig. 1(*a*).

The weighing cell, which had two septa, was initially evacuated by inserting a hypodermic needle through one of the septa and drawing air out of the cell with a vacuum pump. The liquids were then injected into the weighed cell in succession and the cell was weighed after each addition. For any chosen composition the amounts of liquids were chosen so as to almost completely fill the cell. When the mixture was withdrawn from the cell through one septum with a hypodermic syringe a hypodermic needle was inserted into other septum and mercury was drawn into the vessel as the liquid was withdrawn. With these procedures buoyancy corrections and vapour corrections were kept to a minimum.

A second procedure used a Precision Safety Corporation "pressure lok" gas-tight glass and Teflon syringe with a built-in slide valve as shown in Fig. 1(*b*). In this case the syringe was weighed, then the liquids were drawn into the syringe in succession and the syringe was weighed after each addition. After mixing in the syringe, the mixture was injected directly into the densimeter. With both of these techniques of preparation of mixtures, the mole fraction is believed to be accurate to about 5×10^{-5}.

Pseudo dodecane was prepared in a stoppered flask by weighing an empty flask, then the flask with *n*-tetradecane, and finally the flask with *n*-decane + *n*-tetradecane.

Density measurements were made using a Mettler DMA 60/DMA 602H vibrating tube densimeter with a precision of $\pm 1.5 \times 10^{-6}$ g cm^{-3}. The stability of temperature in the sample chamber of the densimeter was ±0.003 K. The period of vibration τ for the vibrating capillary tube in the densimeter is related to the density ρ of the fluid in the tube by

$$[1] \quad \rho = a + b\tau$$

where a and b are constants. Degassed distilled water and air were used to calibrate the densimeter to obtain the instrument constants a and b. The density of water was taken from ref. 3 and the density of moist air was calculated by the following equation (3)

$$[2] \quad \rho_a/\text{g cm}^{-3} = 1.2929\,(273.13/T)(B - 0.3783e)/760$$

where B is the barometric pressure (Torr; 1 Torr = 133.3 Pa), T is absolute temperature (K), and e is the vapour pressure of the moisture in the air (Torr); which can be determined by the measurement of dew point (3). In this work the dew point was measured with an EG & G Digital Humidity Analyzer, model 911, with an accuracy of ±0.5 K.

To reduce the errors caused by the drift of the densimeter and the density change of the pseudo alkanes due to vaporization of volatile component, the densimeter was recalibrated and the densities of the "pure" components were measured again after each two or three measurements of the densities of mixtures.

To test the methods, measurements were made on the system benzene and cyclohexane at 298.15 K. The results for the system are believed to be reproducible to ±0.002 cm^3 mol^{-1}.

Materials

Benzene and cyclohexane were analytical reagents from M & B, and BDH, respectively, with quoted purities better than 99.8 and 99.5%. Branched hexanes were from Aldrich with quoted purities better than 98% for 2,2-dimethylpentane, 97% for 2,3-dimethylbutane, 99% for 2-methylpentane and 3-methylpentane, and *n*-al-

kanes were "puriss" grade from Koch-Light, with quoted purities of 99% minimum.

Their measured densities are compared with literature values in Table 1.

Results and discussion

Excess volumes were calculated from the densities of the two "pure" components and their mixtures in the whole range of mole fractions by the equation

$$[3] \quad V^E = x_1M_1\,(1/\rho - 1/\rho_1) + x_2M_2\,(1/\rho - 1/\rho_2)$$

where ρ, ρ_1, ρ_2 are the densities of mixture, component 1, and component 2, respectively, and x_1 is the mole fraction of component 1.

An equation of the type

$$[4] \quad V^E/\text{cm}^3\,\text{mol}^{-1} = x_i(1 - x_i)\,\Sigma\,A_j(1 - 2x_i)^{j-1}$$

was fitted to each set of results by the method of least squares with all points weighted equally.

The densities of mixtures of cyclohexane + benzene prepared by the mixing cell and syringe methods were measured separately and the excess volumes were determined from the measured densities of the pure components and their mixtures by eq. [3]. The results are listed in Table 2. The excess volumes were fitted to eq. [4] for which the parameters and the standard deviations (R) are listed and compared with the literature values in Table 3 in which N is the number of measurements in each set. The differences between the results of our work and those of other workers and between our two methods of preparation of mixtures were less than 4×10^{-3} cm^3 mol^{-1}. The deviations of the fitting eq. [4] are compared with literature data in Fig. 2.

The densities and the excess volumes of *n*-dodecane + 2-methylpentane (2-MP) determined by using the syringe method are listed in Table 4. The parameters in eq. [4] and the standard deviation (R) are listed and compared with those obtained by Hamam *et al.* (4) in rows 1 and 2 of Table 5. The two sets of measurements agreed within 5×10^{-3} cm^3

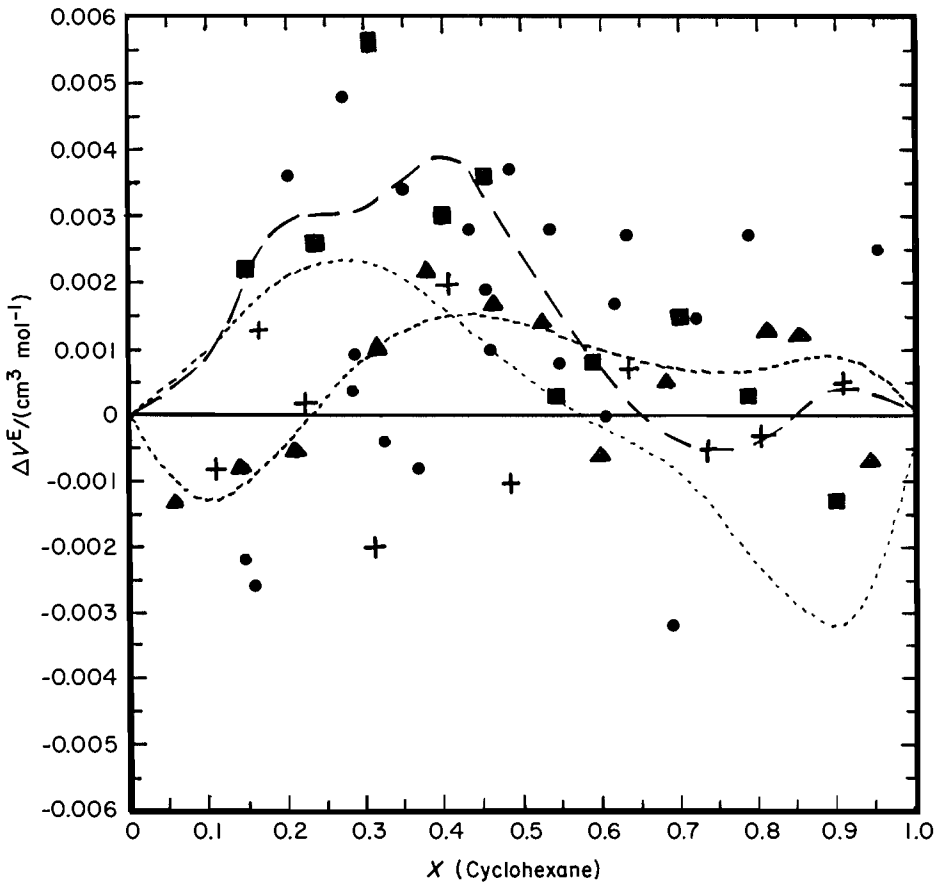

FIG. 2. Deviations of excess volumes for cyclohexane + benzene at 298.15 K. Curves: calculated with eq. [4] are (1) V^E (syringe method) − V^E (mixing cell); (2) V^E (syringe method) − V^E (Kiyohara *et al.*); (3) V^E (syringe method) − V^E (Goates *et al.*). +, V^E calculated with eq. [4] (syringe method) − V^E (exp) (syringe); ■, V^E calculated with eq. [4] (syringe method) − V^E (exp) (mixing cell); ●, V^E calculated with eq. [4] (syringe method) − V^E (exp) (Kiyohara *et al.*); ▲, V^E calculated with eq. [4] (syringe method) − V^E (exp) (Goates *et al.*).

mol^{-1}. The deviations from eq. [4] are compared with those of Hamam *et al.* in Fig. 3.

The measured densities and excess volumes of pseudo *n*-dodecanes + 2-MP are also listed in Table 4 and the parameters in eq. [4] and standard deviations are listed in Table 5. The magnitude of the excess volumes of pseudo *n*-dodecane + isomers of hexane decreases in order: 2,2-DMB > 2-MP > 2,3 DMB > 3-MP, just as Hamam *et al.* observed from their measurements for *n*-dodecane + hexane isomers.

We believe that the agreement of our results and those of Hamam *et al.* justifies direct comparison of our measurement for ternary mixtures with the corresponding binary data of Hamam *et al.* within 5×10^{-3} cm^3 mol^{-1}. These comparisons are shown in Fig. 4. The curves are from values calculated by eq. [4] with the parameters from this work for *n*-dodecane + 2-MP (dotted curve), and from Hamam *et al.* for *n*-dodecane + the other three hexane isomers (solid curve). The points are the experimental volumes for the ternary mixtures. The difference of less than 1% seems to be random in the range of experimental errors. This excellent agreement between binary and ternary mixture behaviour is consistent with the principle of congruence in its broader sense (11).

R. UMARANI and G. RADHAKRISHNAN. Can. J. Chem. **70**, 2009 (1992).

Systematic investigations of the kinetics of the reactions of ethyl bromoacetate (EBA) and of picryl bromide (PB) with 2-phenylthiazolidines (PT) in 100% ethanol were undertaken at 30, 35, 40, and 45°C. The most incisive information concerning the Hammett equation comes from the extensive studies on the substituted 2-phenylthiazolidines, establishing linear Hammett plots with negative ρ values. The kinetic data, plotted in a Brønsted fashion against pK_a of the corresponding thiazolidinium ions, yield linear relationships. The activation parameters were computed. The linear relationships between $\Delta H^{\neq}$ and $\Delta S^{\neq}$ signify a consistent mechanism throughout the series.

R. UMARANI et G. RADHAKRISHNAN. Can. J. Chem. **70**, 2009 (1992).

Opérant à 30, 35, 40 et 45°C, dans des solutions d'éthanol à 100%, on a entrepris une étude systématique de la cinétique des réactions du bromoacétate d'éthyle (BAE) et du bromure de picryle (BP) avec les 2-phénylthiazolidines (PT). L'information la plus pertinente concernant l'équation de Hammett provient d'études extensives sur les 2-phénylthiazolidines substituées qui permettent d'établir des courbes de Hammett linéaires comportant des valeurs de ρ négatives. Le graphique des données cinétiques, établi de la manière de Brønsted en fonction des pK_a des ions thiazolidinium correspondants, conduit à des relations linéaires. Les relations linéaires entre $\Delta H^{\neq}$ et $\Delta S^{\neq}$ signifient que le mécanisme est le même dans toute la série.

[Traduit par la rédaction]

Introduction

Studies of thiazolidines are of great interest because of the presence of the thiazolidine moiety in the important antibiotic, penicillin. 2-Phenylthiazolidine (PT) is a potential radioprotectant. (1) Antiradiation activity has been reported for a variety of thiazolidines, which could provide a means of latentiating a typical radioprotective thiol (NCS linkage) (2).

The transmission of electronic effects from the substituents to the thiazolidine heterocycle in substituted 2-phenylthiazolidines has been analyzed by ^{1}H NMR(3) and ^{13}C NMR. (4) Electron-withdrawing groups substituted at the nitrogen stabilize the thiazolidine ring. Because of their stability and their biological importance, (5) studies of *N*-substituted thiazolidines have assumed particular significance. Synthetic aspects of the acylation of the thiazolidines by benzoyl chloride, (6) acetic anhydride, (7) *N*-glycylation, (8) etc. have been studied so far. Detailed work on the kinetics of acidic and alkaline hydrolysis of *N*-butyl, *N*-phenyl, and *N*-acyl 2-phenyl-1, 3-thiazolidine derivatives has been presented by T. H. Fife *et al.* (9) and the alkaline hydrolysis of *N*-methyl compounds and its mechanistic aspects were studied by Luhowy and Meneghini (10). Recently the thiazolidine ring opening in penicillin derivatives was studied by A. M. Davis *et al.* (11) In the literature considerable interest has been focused on S_NAr reactions with amine nucleophiles, (12) and the most suitable mechanism has been the one that passes through Meisenheimer-type intermediates. Aminolysis of α-haloketones and α-halogeno esters with amines was studied by Pearson *et al.* (13*b*) and Mohanty *et al.* (13*a*) Because of the higher reactivity of α-halogeno esters towards nucleophiles, ethyl bromoacetate (EBA) was chosen for the reaction with 2-phenylthiazolidines. To compare the mechanistic aspects with the S_NAr reaction, the kinetics of PT with picryl bromide (PB) were also investigated. The detailed kinetic analysis of these reactions provides insight into the modified reactivities and activities of substituted thiazolidine rings.

Experimental

2-Phenylthiazolidine and its *meta*- and *para*-substituted compounds (**1***a*–**10***a*) were prepared by Tsukermann's general procedure, which is reported elsewhere. (3) Crystalline picryl bromide was synthesized and had a melting point of 120°C. (13) Ethyl bromoacetate (Fluka) was used after distillation. Studies of the kinetics of the reaction of ethyl bromoacetate with 2-phenylthiazolidines were carried out in 100% ethanol at 30, 35, 40, and 45°C. The experiments were done under second-order rate conditions, [PT] = 0.04 M; [EBA] = 0.01 M; and the rate of the reaction was monitored by Volhard's method. The rate constants were calculated using the second-order rate equation (eq. [1]) where a is the concentration of thiazolidine (PT), b is the concentration of ethyl bromoacetate (EBA), and x is the concentration of EBA reacted in time t.

$$[1] \quad k_2 = \frac{2.303}{t(a-b)} \log \frac{b(a-2x)}{a(b-x)}$$

The stoichiometry of the reaction was determined for the reaction of 2-phenylthiazolidine with ethyl bromoacetate by taking a known excess of EBA relative to the PT. Upon completion of the reaction the amount of EBA consumed was estimated by Volhard's method and the stoichiometry was found to be in the ratio 2:1 for PT:EBA. For product analysis the substrate and EBA were taken in the same proportion as used in the kinetic measurements, and were kept at 40°C in 100% ethanol for several days. The material obtained after work-up was purified by column chromatography on silica gel (1:1 petroleum ether – ethyl acetate). The low-melting products were characterized by elemental analysis and identified

as *N*-carbethoxymethylene-2-phenylthiazolidines (**1***b*–**10***b*). The details of their elemental analysis and spectral data are given below.

N-Carbethoxymethylene-2-phenylthiazolidine, ***1****b:* ^{1}H NMR ($CD-Cl_3$) δ: 1.1–1.3 (t, 3H, $NCH_2COOCH_2CH_3$), 2.7–3.1 (m, 4H, NCH_2CH_2S), 3.52 (s, 2H, NCH_2COO-), 3.9–4.2 (q, 2H, $COOCH_2CH_3$), 5.3 (s, 1H, SCHNPh), 7.2–7.4 (m, 5H, Ph). Anal. calcd.:C 62.12, H 6.82; found: C 62.6, H 6.7%.

N-Carbethoxymethylene-2(4′-methoxyphenyl)thiazolidine, ***2****b:* ^{1}H NMR ($CDCl_3$) δ: 1.1–1.3 (t, 3H), 2.2–3.2 (m, 4H), 3.5 (s, 2H), 3.8 (s, 3H), 4.0–4.3 (q, 2H), 5.4 (s, 1H), 7.2–7.7 (m, 4H). Anal. Calcd.: C 57.75, H 6.81; found: C 59.7, H 6.8%.

N-Carbethoxymethylene-2(4′-methylphenyl)thiazolidine, ***3****b:* ^{1}H NMR ($CDCl_3$) δ: 1.2–1.3 (t, 3H), 2.4 (s, 3), 2.6–3.3 (m, 4H), 3.32 (s.2H), 3.8 (s, 3H), 4.0–4.3 (q, 2H), 5.5 (s, 1H), 7.1–7.4 (m, 4H). Anal. calcd.: C 63.36, H 7.2; found: C 63.28, H 7.25%.

N-Carbethoxymethylene-2(4′-chlorophenyl)thiazolidine, ***7****b:* ^{1}H NMR ($CDCl_3$) δ: 1.2–1.4 (t, 3H), 2.2–3.4 (m, 4H), 3.3 (s, 2H), 4.1–4.4 (q, 2H), 5.4 (s, 1H), 7.2–7.7 (m, 4H). Anal. calcd.: C 54.63, H 5.64; found: C 54, 69, H 5.58%.

N-Carbethoxymethylene-2(4′-nitrophenyl)thiazolidine, ***10****b:* ^{1}H NMR ($CDCl_3$) δ: 1.2–1.4 (t, 3H); 3.2–3.5 (m, 4H); 2.42 (s, 2H); 4.1–4.4 (q, 2H); 5.5 (s, 1H); 7.1–8.5 (m, 4H). Anal. calcd.: C 52.58, H 5.44; found: C 52.58, H 5.49%.

The missing frequency at 3215 cm^{-1} in the IR spectra of these compounds shows that the substitution has taken place at the nitrogen atom. Due to the solubility problem in preparing a 0.04 M solution of 2(4′-nitrophenyl)thiazolidine in ethanol at 30 and 35°C, the kinetics measurements were not carried out for this compound at these temperatures and the activation parameters are not calculated for the reaction with 2(4′-nitrophenyl)thiazolidine.

The kinetics of the reaction of 2-phenylthiazolidines with picryl bromide was studied spectrophotometrically. A double-beam 810 UV/VIS Kontron spectrometer was used with 1 cm quartz cells. In all cases pseudo-first-order kinetics ([PT] = 5×10^{-3} M; [PB] = 0.8×10^{-4} M) were observed. The kinetics was followed by monitoring the increase in absorption at 400 nm corresponding to the products formed. The rate constants k_{obs} were calculated using eq. [2]:

$$[2] \quad k_{obs}\, t = \ln E_\infty - \ln(E_\infty - E_t)$$

where E_∞ is the optical density at infinite time, which was taken after at least 10 half-lives. E_t is the absorption at time t. The stoichiometry was determined by studying the reaction of 2-phenylthiazolidine with excess picryl bromide relative to 2-phenylthiazolidine at 45°C. After the completion of the reaction, the consumed picryl bromide was estimated by Volhard's method and it was found that 2 moles of PT reacted with 1 mole of PB, establishing a 2:1 stoichiometry. For the product analysis the substrate and picryl bromide were taken in the same proportion as that used in the kinetic measurements and allowed to react at 45°C for several days. After completion of the reaction, the product was purified by column chromatography on silica gel (petroleum ether – benzene (3:1)) as eluent. The products were identified as *N*-(2′,4′,6′-trinitrophenyl)-2-phenylthiazolidines (**1***c*–**10***c*) and their elemental analyses and ^{1}H NMR spectral values are as follows.

N-(2′,4′,6′-Trinitrophenyl-2-phenylthiazolidine, ***1****c:* ^{1}H NMR ($CDCl_3$) δ: 3.3–34.4 (m, 4H, NCH_2CH_2S), 3.9–4.2, 5.7 (s, 1H, SCHNPh), 7.0–7.4 (m, 5H, Ph), 3.7 (s, 2H, picryl). Anal. calcd.: C 47.87, H 3.19; found: C 47.58, H 3.23%.

N-(2′,4′,6′-Trinitrophenyl)-2(4′-methoxyphenyl)thiazolidine, ***2****c:* ^{1}H NMR ($CDCl_3$) δ: 3.1–3.7 (m, 4H), 3.93 (s, 2H), 5.7 (s, 1H), 7.0–7.8 (m, 4H), 9.1 (s, 2H). Anal. calcd.: C 47.28, H 3.47; found: C 47.2, H 3.51%.

N-(2′,4′,6′-Trinitrophenyl)-2(4′-methylphenyl)thiazolidine, ***3****c:* ^{1}H NMR ($CDCl_3$) δ: 2.4 (s, 3), 3.3–4.3 (m, 4H), 5.75 (s, 1H), 7.1–7.4 (m, 4H), 8.75 (s, 2H). Anal. calcd.: C 49.22, H 3.61; found: C 49.02, H 3.62%.

The UV spectra of these compounds in ethanol show λ_{max} at 260, 330, and 400 nm.

The energies of activation were calculated from the linear regression of ln k_2 versus $1/T$ by the least-squares method, and the entropies of activation $\Delta S^{\neq}$ and collision frequency factor (log PZ) were calculated by the standard formula derived from the absolute theory of reaction rates.

The dissociation constants (pK_a) of the conjugate acids of the substituted 2-phenylthiazolidines were determined by a potentiometric titration method. The pH meter was periodically calibrated by using a buffer solution of 0.05 M potassium hydrogen phthalate of pH 4.00 and a solution of 0.02 M KH_2PO_4 and 0.025 M Na_2HPO_4 with pH = 6.8. 2-Phenylthiazolidine was dissolved in HCl of known concentration and the ionic strength of the solution was maintained at 0.1 M using KCl. The temperature was held constant at 27°C. The acid dissociation constants were determined by titrating the acid in the absence and in the presence of a known concentration of the 2-phenylthiazolidines with a standard KOH titrant. The pK_a values of the conjugate acid were read from the half-neutralization point and were accurate to within ±0.02 units. The values for the different thiazolidines are shown in Table 1.

TABLE 1. The pK_a values of 2-phenylthiazolidinium ions at 27°C in water

Compound no.	Substituent X	pK_a
1	H	5.20
2	4′-OH	5.50
3	4′-OMe	5.45

7	4′-Br	5.05
8	4′-Cl	5.01
9	3′-I	4.93
10	3′-NO_2	4.63
11	4′-NO_2	4.55

Results and discussion

It was observed that these nucleophilic substitution reactions of (*i*) picryl bromide (*ii*) ethyl bromoacetate with 2-phenylthiazolidines followed second-order kinetics, first order in each reactant. Since the stoichiometry is 2:1, it is supposed that 2-phenylthiazolidine protonated preferentially by the acid liberated in the reaction, so that a second molecule reacts, but following the rate-determining step. The above situation describes that the reactions (eqs. [3] and [4]) are stoichiometrically termolecular but kinetically second order and the expected rate equation is then eq. [5], where a is the concentration of the nucleophiles (PT), b is the concentration of the EBA or PB, and x is the concentration of EBA or PB reacted in time t. The rate constants for various *meta*- and *para*-substituted 2-phenylthiazolidines reveal that electron-donating substituents increase the reaction rate while electron-attracting substituents decrease it. The observed rate conforms to the following order of reactivity for both reactions: 4′-OH > 4′-OMe > 4′-Me > 3′-Me > H > 3′-OMe > 4′-Br, 4′-Cl > 3′-I > 3′-NO_2 > 4′-NO_2.

$$[5] \quad \frac{dx}{dt} = k(a - 2x)(b - x)$$

The activation energies in both reactions thus show a regular variation with substituents: electron-releasing substituents decrease and electron-withdrawing substituents increase E_a as shown in Tables 2 and 3.

The entropies of activation are found to be negative as expected for bimolecular reactions with a highly polar transition state (ranges from −11.9 to 109.83 J M^{-1} K^{-1} in the EBA reaction and ranges from −169 to −223 J M^{-1} K^{-1} in the PB reaction). This is consistent with the fact that charge is developed in the transition state formed from neutral reactant molecules. Since the activated complex is more highly solvated than the neutral reactants, it is evident that the spontaneous process of solvation tends to reduce the potential energy. This type of solvent participation must, however, lower the entropy of activation because more molecules are now involved in the structure of the transition state species, and considerable loss of freedom of the solvent occurs. The transition state (Scheme 1) for the α-halogeno ester and amine analogous to the transition state for the aminolysis of α-halogeno ketone(13) has been formulated.

The transition state for the reaction of picryl bromide with 2-phenylthiazolidine has been assigned as in Scheme 2. This is similar to a mechanism suggested for related reactions(14). Some degree of hydrogen bonding between amino and *ortho*-nitro groups further decreases the entropy of activation and, as shown in Table 3, the $\Delta S^{\neq}$ for picryl bromide reactions (e.g., for compound **1**, $\Delta S^{\neq}$ −208.32 J M^{-1} K^{-1}) are more negative than those for the ethyl bromoacetate reactions (Table 2, for compound **1**, $\Delta S^{\neq}$ = −65.77 J M^{-1} K^{-1}).

Brønsted correlation

The magnitude of the Brønsted coefficient in the Brønsted relationship has usually been related to the extent of bond

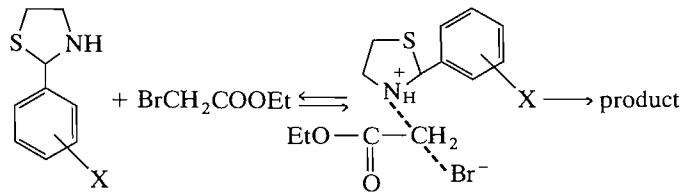


SCHEME 1

formation in the transition state, and when an intermediate is formed along the reaction path, a large Brønsted coefficient is expected. The correlation has been represented graphically by plotting the logarithm of the rate constants against the pK_a values of the corresponding conjugate acids in 100% water. A good Brønsted plot was obtained for these reactions, as shown in Fig 1.

The value of β, the Brønsted coefficient was found to be 0.584 for the PB reaction and 0.918 for the EBA reaction at 40°C. The positive value of β is in accordance with the expectation for the bimolecular nucleophilic substitution reaction, i.e., the rate increases with increasing basicity of the molecule. According to the significance generally attached to the Brønsted coefficient (15–17), $\beta > 0.3$ indicates that the bond formation between the nucleophile and the reaction centre at the rate-limiting transition state is pronounced in both the picryl bromide and the ethyl bromoacetate reactions.

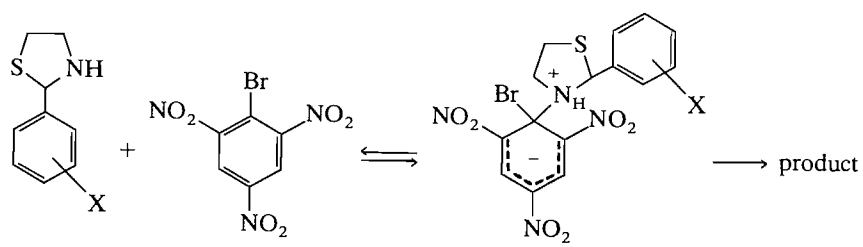
Hammett plot

The rate constants for reactions involving *meta*- and *para*-substituted 2-phenylthiazolidines very closely fit the Hammett equation ($\log k/k_0 = \rho\sigma$) for both reactions; the ρ values are negative in both cases, implying that a similar electronic transfer occurs from the nucleophile to the substrate. The ρ values are −0.647, −0.771, −0.843, and −0.959 at 45, 40, 35, and 30°C, respectively, for the EBA reaction and −0.418, −0.485, and −0.505 at 45, 40 and 35°C for the PB reaction. These values, according to the significance generally attached to them, seem to indicate that the substituent effect in the EBA reaction is greater than that in the PB reaction. A Plot of the logarithm of the rate constants of the nucleophilic substitution reaction of PB against the logarithm of the rate constants of the reaction of EBA of the correspondingly substituted 2-phenylthiazolidines at 45°C is shown as a straight line. The existence of a linear relationship in this case indicates that the charge delocalization that occurs with various substituents in the EBA reaction parallels that in the PB reaction. The positive slope of the plot indicates that the factors that favour the EBA reaction play a parallel role in the PB reaction.

Arrhenius plot

Linear relationships between the enthalpies of activation $\Delta H^{\neq}$ and the entropies of activation $\Delta S^{\neq}$ have been observed for the reactions of ethyl bromoacetate and picryl bromide with 2-phenylthiazolidines. In the Arrhenius equation $\Delta H^{\neq} = \Delta H^{\neq} + \beta\Delta S^{\neq}$; β has a value of 400 K in the ethyl bromoacetate reaction and 385 K for the picryl bromide reaction. The continuous relationship shown by the majority of the substituents signifies a mechanism constant in its main detail (18).

By Exner analysis (19), a plot of log k_2 (45°C) against log k_2 (35°C) for the PB reaction gives a least-squares slope of 0.836 ($r = 0.99$, $s = 0.061$). Using eq. [6]



SCHEME 2

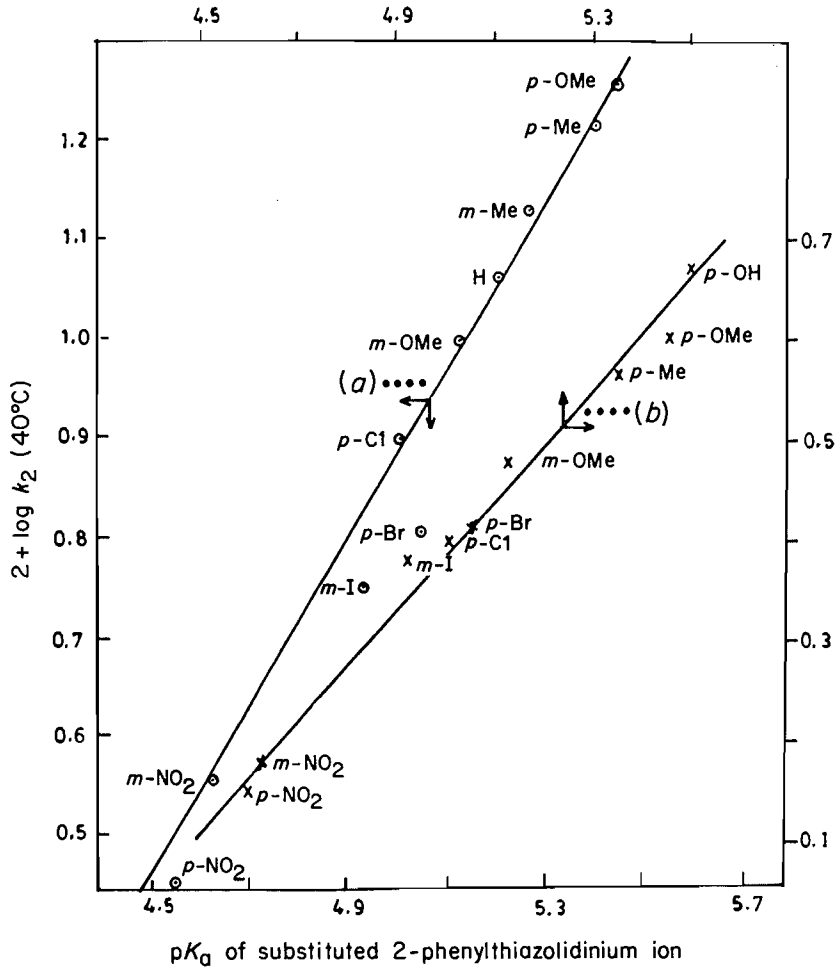

FIG. 1. (*a*) Brønsted plot for EBA reaction with PT; (*b*) Brønsted plot for PB reaction with PT.

$$[6] \quad \beta = T_2 \cdot \frac{1 - b}{1 - \tau b}$$

where $\tau b = T_2/T_1$, $T_2 > T_1$, β is predicted to be 379.8 K, which is in adequate agreement with the least-squares value of 385 K from the $\Delta S^{\neq}$ versus $\Delta H^{\neq}$ plot. From the plot of log k_2 (45°C) against log k_2 (40°C) for the EBA reaction, the least-squares slope b is 0.928 and therefore β is calculated to be 399 K (r = 0.986, s = 0.038), which closely corresponds to the value of 400 K obtained from the $\Delta H^{\neq}$ versus $\Delta S^{\neq}$ plot. These results indicate the experimental temperatures are well below the isokinetic temperature, and the mechanism for these reactions remains constant over the temperature range studied.

Conclusions

The Hammett relationship, Brønsted correlation, and activation parameters obtained in both reactions indicate that there is a constant mechanism in these reactions and that the reactivity depends on the substituents in the phenyl ring and the nature of the substrate.

Received March 14, 1991

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG, and JAMES TROTTER. Can. J. Chem. **70**, 2015 (1992).

The reaction of *N,N'*-diethyl-*N,N'*-dihydroxymethanediamine with oxybis(diphenylborane) in absolute ethanol yields *N*-ethylhydroxylamine(*O-B*)1,7-diethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane [3-(1-oxa-2-azoniabutyl)-1,7-diethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3,5-diboratabicyclo[3.3.0]octane], **7***b*, in good yield. Crystals of this material are monoclinic, $a = 16.396(2)$, $b = 11.303(2)$, $c = 22.898(4)$ Å, $\beta = 92.78(1)°$, $Z = 8$ (two molecules per asymmetric unit), space group $P2_1/a$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to $R = 0.041$ and $R_w = 0.050$ for 3602 reflections with $I \geq 3\sigma(I)$. The product **7***b* is formed by O→B coordination between *N*-ethylhydroxylamine and the bicyclic bis-phenylboronate of *N,N'*-diethyl-*N,N'*-dihydroxymethanediamine. Compound **7***b* is only the second structurally characterized example of an *N*-alkylhydroxylamine(*O-B*)boron complex having an open-chain *B,N*-betaine structure. Bond lengths about boron are: B—O(N) = 1.467(4)–1.527(4), B—O(B) = 1.433(4)–1.451(4), B—N = 1.688(4) and 1.707(4), B—C = 1.586(4)–1.606(5) Å.

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **70**, 2015 (1992).

La réaction de la *N,N'*-diéthyl-*N,N'*-dihydroxyméthanediamine avec l'oxybis(diphénylborane), dans l'éthanol absolu, fournit la *N*-éthylhydroxylamine(*O-B*)1,7-diéthyl-3,5-diphényl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo-[3.3.0]octane[3-(1-oxa-2-azoniabutyl)-1,7-diéthyl-3,5-diphényl-2,4,6-trioxa-7-aza-1-azonia-3,5-diboratabicyclo[3.3.0]octane], **7***b*, avec un bon rendement. Les cristaux de ce produit sont monocliniques, $a = 16,396(2)$, $b = 11,303(2)$, $c = 22,898(4)$ Å, $\beta = 92,78(1)°$, $Z = 8$ (deux molécules par unité asymétrique) et groupe d'espace $P2_1/a$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de $R = 0,041$ et $R_w = 0,050$ pour 3602 réflexions avec $I \geq 3\sigma(I)$. Le produit **7***b* est formé par une coordination O→B entre la *N*-éthylhydroxylamine et le bis-phénylboronate bicyclique de la *N,N'*-diéthyl-*N,N'*-dihydroxyméthanediamine. Le composé **7***b* n'est que le deuxième exemple de structure caractérisée d'un complexe *N*-alkylhydroxylamine(*O→B*)bore possédant une structure *B,N*-bétaïne en chaîne ouverte. Les longueurs des liaisons autour du bore sont : B—O(N) = 1,467(4)–1,527(4), B—O(B) = 1,433(4)–1,451(4), B—N = 1,688(4) et 1,707(4), B—C = 1,586(4)–1.606(5) Å.

[Traduit par la rédaction]

Introduction

The *N,N'*-dihydroxyaminal **1** was reacted with the anhydride of diphenylborinic acid in absolute ethanol with the intention of synthesizing the six-membered diphenylboron chelate **2**. Compound **2** would be analogous to the seven-membered ring derivative **3** which had been obtained by a similar method from an *N,N'*-dihydroxy-1,2-ethanediamine and diphenylborinic acid. The structure of **3** has been established by X-ray analysis (1). Contrary to expectations, the crystalline material obtained from the reaction of **1** and oxybis(diphenylborane) did not give the typical blue color reaction with diphenylcarbazone (2) which would indicate the presence of an intact diphenylboron moiety (by trapping of Ph_2B^+). The reddish color of this reaction solution indicated the presence of a monophenyl substitution at boron (2) suggesting that a dephenylation had taken place. The elemental analysis, however, did not agree with a simple cyclic phenylboronate **4** that could result from **2** by the elimination of 1 mol of benzene, but shows an additional content of 1 mol "PhBO" and 1 mol "EtNHOH". The ^{1}H nmr spectrum displays two signals for exchangeable OH/NH protons, one appearing at fairly low field ($\delta = 11.57$ ppm) as is usually observed for acidic protons and (or) strongly hydrogen-bonded protons. This is also confirmed by the infrared spectrum with lowered O—H/N—H stretching frequencies (between 2500 and 2700 cm^{-1}).

The analytical data are in agreement with several possible condensation and addition products. The six-membered cycloboronate **4** is not expected to be stable with respect to the substitution pattern. Stability of a type **4** compound could be achieved by reducing the basicity of the aminal nitrogen atoms (e.g., by α-cyanoalkyl or by β-nitroalkyl substitution) and, furthermore, by impeding the Lewis acidity of the boronic acid itself by a combination of steric and inductive/mesomeric effects (3). At best, an adduct of **4** to the phenylborinic monoester of *N*-ethylhydroxylamine could exist in the BONBON form **5***a* or in the BNOBON form **5***b*, the former

ring system being well documented in the literature (4). Other possible isomers that would be supported by the spectroscopic data are the bicyclic structures **6***a* (with a transannular N—B bridge) or **6***b* (containing a pyroboronate BOB bridge). Finally, an adduct of *N*-ethylhydroxylamine to an eight-membered bicyclic ring system, in which the hydroxylamine would coordinate either through the nitrogen atom (**7***a*) or through the oxygen atom (**7***b*) to the trigonal planar boron centre of the bicyclic compound, must also be considered. The structure of the bicyclic skeleton has been established by an X-ray crystallographic analysis of the *N*-methyl derivative **8** [crystal] (5). For a definite structural assignment (at least in the solid state) an X-ray analysis was undertaken.

Experimental

N-*Ethylhydroxylamine(*O-B*)1,7-diethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]-octane,* 7b

N,N'-Diethyl-*N,N'*-dihydroxymethanediamine, **1**, (6, 7) (0.54 g, 4 mmol) and oxybis(diphenylborane) (0.69 g, 2 mmol) was dissolved in 5 mL absolute ethanol and the reaction mixture was heated for several minutes until crystallization commenced.[3] Cooling of the solution yielded 0.55 g (71%, corresponding to 2 mmol $(Ph_2B)_2O$) of colorless material which was recrystallized from ethanol: mp 140–143°C. Infrared (KBr): 2700, 2550 cm^{-1} (N—H). ^1H nmr (400 MHz, $CDCl_3$/TMS) δ (ppm): 0.97–1.06 (m, $2CH_3$), 1.14–1.23 (m, CH_3), 2.29–2.41 (m, 1H, CH_2N^+), 3.01–3.09 (m, 1H, CH_2N^+), 3.12/4.14 (d/d, J = 7 Hz, N—CH_2—N), 7.08–7.29 (m, 6 arom. H and NH), 7.48 (s, broad, 2 arom. *ortho*-H), 7.78 (d, 2 arom. *ortho*-H), 11.57 (s, NH). ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$) δ (ppm): 10.0 (broad). Anal. calcd. for $C_{19}H_{29}B_2N_3O_4$: C 59.26, H 7.95, B 5.61, N 10.91; found: C 59.26, H 7.67, B 5.53, N 10.82.

The substance gives a reddish color reaction with diphenylcarbazone in methanol, indicating a phenylboronic acid component (2). Crystals suitable for X-ray analysis were obtained by recrystallization from absolute ethanol.

X-ray crystallographic analysis of 7b

A crystal ca. 0.40 × 0.45 × 0.50 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 20.0–24.1°) measured on a diffractometer with Mo-K_α radiation (λ = 0.71069 Å). Crystal data at 21°C are as follows

$C_{19}H_{29}B_2N_3O_4$ fw = 385.08

Monoclinic, a = 16.396(2), b = 11.303(2), c = 22.898(4) Å, β = 92.78(1)°, V = 4239(1) $Å^3$, Z = 8, ρ_c = 1.207 Mg m^{-3}, $F(000)$ = 1648, μ(Mo-K_α) = 0.77 cm^{-1}. Absent reflections $0k0$, k odd, and $h0l$, h odd, uniquely indicate the space group $P2_1/a$ (No. 14).

Intensities were measured with graphite-monochromated Mo-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of (1.25 + 0.35 tan θ)° in ω (with up to 8 rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 50°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random variations. After data reduction,[4] an empirical absorption correction, based on azimuthal scans for three reflections, was applied. Transmission factors range from 0.97 to 1.00. Of the 8146 reflections measured, 7893 were unique (R_{int} = 0.026) and 3602 had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.03F^2)^2]/Lp^2$ with S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by direct methods. Minor disordering of the terminal carbon atom of the C(25)—C(26) ethyl group was modelled by split-atom refinement. The relative site occupancy factors were estimated from Fourier map peak heights and were subsequently adjusted to give approximately equal equivalent isotropic thermal parameters for the two component atoms. All non-hydrogen atoms except the low-occupancy carbon atom C(26A) were refined with anisotropic thermal parameters and the hydrogen atoms were fixed in idealized positions (N—H/C—H = 0.98 Å, $B_H = 1.2\ B_{\text{bonded atom}}$). A correction for secondary extinction was applied, the final value of the extinction coefficient being 1.49×10^{-7}. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 8. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 506 variables. Reflections with $I < 3\sigma(I)$ were not included in the refinement. Convergence was reached at R = 0.041 and R_w = 0.050 for 3602 reflections with $I \geq 3\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||\Sigma w|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.01σ. The mean error in an observation of unit weight was 1.86. The final difference map showed maximum fluctuations of ±0.17 e $Å^{-3}$. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen-atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and structure factors have been deposited.[5]

[3]The reaction can also be carried out at room temperature, but more solvent and more time are required. The yield of crystals obtained from the cooled solution is smaller in this case.

[4]TEXSAN/TEXRAY structure analysis package which includes versions of the following: MITHRIL, integrated direct methods, by C. J. Gilmore; DIRDIF, direct methods for difference structures, by P. T. Beurskens; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; ORTEP II, illustrations, by C. K. Johnson.

[5]Supplementary material mentioned in the text may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A 0R6.

Tables of hydrogen atom coordinates and intermolecular distances have also been deposited with the Cambridge Crystallographic Data Centre and can be obtained on request from the Director, Cambridge Crystallographic Data Centre, University Chemical Laboratory, Lensfield Road, Cambridge, CB2 1EW, U.K.

Results and discussion

The X-ray analysis confirms the solid-state structure **7***b* (Fig. 1), formed by O→B coordination between *N*-ethylhydroxylamine and the bicyclic bis-phenylboronate of the *N,N'*-diethyl-*N,N'*-dihydroxyaminal **1**. If benzene is used as solvent (20 mL, 5 min reflux), and the product recrystallized from toluene/petroleum ether, only the bicyclic bisphenylboronate[6] (7) is isolated (70% yield) and not the *N*-ethylhydroxylamine adduct **7***b*. The two crystallographically independent molecules show some small, but statistically significant, geometrical differences (see Tables 2–4). The centrosymmetric crystal structure contains equal numbers of the (1*R*,3*R*,5*S*,7*R*) and (1*S*,3*S*,5*R*,7*S*) enantiomers, the former being depicted in Fig. 1.[7] The yield of the reaction between **1** and oxybis(diphenylborane) (over 70%) suggests that an extensive dephenylation of the diphenylborinic acid or of its primary reaction product (possibly the chelate **2**) has taken place. The subsequent formation of the

[6]The synthesis of the bicyclic bis-phenylboronate (1,7-diethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-3-bora-5-boratabicyclo[3.3.0]-octane) has already been described (7).

[7]The chiral centres correspond to atoms N(1), B(1), B(2), and N(2) in molecule 1 and N(4), B(3), B(4), and N(5) in molecule 2.

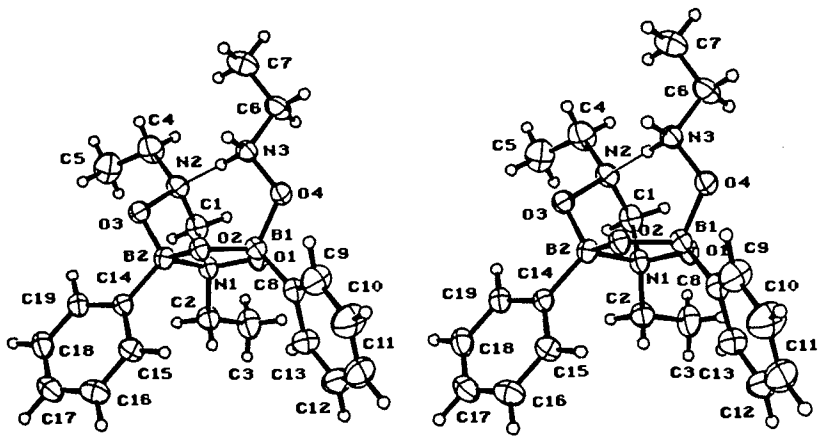

FIG. 1. Stereoview of one of the two independent *N*-ethylhydroxylamine(*O*-*B*)1,7-diethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane molecules; 33% probability thermal ellipsoids are shown for the non-hydrogen atoms. Fine line represents a hydrogen bond.

bicyclo[3.3.0]octane skeleton via the incorporation of a second molar equivalent of phenylboronic acid into the dephenylation product (a monophenylboronate of **1**) would liberate one mol of the dihydroxyaminal **1** as a potential source of the free *N*-ethylhydroxylamine base (7).

The O→B coordinated addition product is further stabilized by an intramolecular N—H···N hydrogen bond (N(3)—H(1)···N(2) and N(6)—H(3)···N(5), N···H = 1.88 and 1.97 Å, N···N = 2.863(3) and 2.977(4) Å, N—H···N = 177 and 178°, respectively), at least in the solid state of **7***b* (cf. formula **7***b*[crystal]). The N···N distances for the $^{+}$N—H···N interactions in **7***b* are longer than those observed for $^{+}$N—H···N hydrogen bonds in monocationic "proton sponge" compounds which range up to 2.626 Å for linear systems (9) and similar to the mean value of 2.949 Å for noncationic N—H···N hydrogen bonds in crystalline organic compounds (10). The remaining hydrogen atom of each protonated hydroxylamine nitrogen atom is hydrogen bonded to a pyroboronate oxygen atom to result in hydrogen-bonded, centrosymmetric dimers (N(3)—H(2)···O(2)(1 − *x*,−*y*,1 − *z*) and N(6)—H(4)···O(6)(−*x*,−*y*,−*z*), H···O = 1.81 and 1.79 Å, N···O = 2.762(3) and 2.753(3) Å, N—H···O = 163 and 165°, respectively).

Compared with the bicyclic compound **8** (5) containing one tetracoordinated sp^3 boron atom and one nearly planar trigonal sp^2 boron atom in a pyroboronate linkage with a typical short (sp^2)B—O(B) bond (typically about 1.34 Å in most BOBON rings of this type (5)) and a longer (sp^3)B—O(B) bond (about 1.46 Å), the hydroxylamine adduct **7***b* possesses a (sp^3)B—O—(sp^3)B system with two slightly different B—O bonds (1.435(4) and 1.451(3), 1.433(4) and 1.440(4) Å, respectively, for the two molecules). This demonstrates once again the strength of the O—B *pp*(π) interaction for trigonal planar boron, and the marked O—B bond length increase associated with tetracoordination of the boron atom. The transannular N—B bond in **7***b* (1.707(4) and 1.688(4) Å in the two molecules) is slightly shorter than the corresponding bond (mean 1.733(4) Å) in the bicyclic "parent" compound **8** (5). The intramolecular non-bonding distances N(2)···B(1) = 3.374(4) and N(5)···B(3) = 3.444(5) Å in **7***b*, however, are lengthened relative to the corresponding N···B distance in **8** (mean 3.083 Å) by the insertion of the *N*-ethylhydroxylamine moiety. The dihedral angles between the normals to the mean planes of the BOBON and the approximately planar OBNC portions of the BONCN rings average 113.6° in **8** whereas the corresponding values for the two molecules of **7***b* are 116.3 and 116.7°, the slightly larger value for molecule 2 of **7***b* being consistent with the longer N···N distance in the intramolecular N—H···N hydrogen bond. The five-membered BOBON

Can. J. Chem. Downloaded from www.nrcresearchpress.com by 109.225.110.28 on 09/08/12
For personal use only.

ring is nearly planar (mean deviations from the mean plane = 0.028 and 0.059 Å for the two molecules), whereas the BONCN ring has a slightly irregular N(2)/N(5)-envelope conformation (see Table 4). The degree of pyramidalization at N(2) and N(5) in **7***b* (bond angles sums = 321.7 and 315.1°) is essentially the same as that observed for the trivalent nitrogen atoms in **8** (bond angles sums = 319.3 and 317.5°).

The central N—C bond distances of the aminal group of **7***b* are different from one another, the differences being marginally smaller than those observed for **8** (5) (the mean N—C, mean C—N^+, and the difference between them are 1.447(4), 1.475(4), 0.028(6) Å for **8**; 1.448(4), 1.476(4), 0.028(6) Å for **7***b* (molecule 1); and 1.458(4), 1.468(4), and 0.010(6) Å for **7***b* (molecule 2)). The strength of the interaction between the tertiary amine function and the Lewis-acid boronate function in **8** appears to be similar to that between the tertiary amine and the proton-acid in **7***b*. The N—O bond lengths in the two molecules of **7***b* differ by less than one standard deviation. The longest of the N—O bonds is that involving the trivalent nitrogen atom in the BONCN ring (mean 1.453(2) Å for **7***b*, mean 1.459(1) Å for **8**), that in the BOBON ring being shorter (mean 1.426(2) Å for **7***b*, mean 1.447(4) Å for **8**), while the shortest N—O bond is that in the added *N*-ethylhydroxylamine base of the **7***b* molecule (mean 1.417(2) Å). As expected, the B—O bonds to the differently bound *N*-ethylhydroxylamines show the opposite trend, but there are some statistically significant differences between corresponding bonds in the two independent molecules. The longest B—O(N) bond involves the added *N*-ethylhydroxylamine base (1.508(4) and 1.494(4) Å) and is similar in length to the corresponding mean B—O(N) distance of 1.490(6) Å in the *N*-methylhydroxylamine complex **9** (11). The B—O(N) distances of 1.508(3) and 1.527(4) Å in the five-membered BOBON ring are somewhat shorter, whereas those in the five-membered BONCN ring are the shortest (1.467(4) and 1.470(4) Å). The B—C(phenyl) bond lengths range from 1.586(4) to 1.606(5) Å, typical values for compounds of this type (e.g., 1.581(5) Å in **8** (5) and 1.589(6) Å in **9** (11)).

The sum of bond lengths about B(1) and B(3), having "$PhBO_3$" ligand sets, are 6.065 and 6.067 Å, respectively. These values are similar to that of 6.100 Å for the "$PhBO_3$" compound **9** (11) and values of 6.083 to 6.101 Å reported for other related compounds (11 and references therein).

Reaction of the condensation product of *N,N'*-dimethyl-*N,N'*-dihydroxymethanediamine and phenylboronic acid with *N,N*-diethylhydroxylamine gives *N,N*-diethylhydroxylamine(*O-B*)1,7-dimethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane [3-(2-ethyl-1-oxa-2-azoniabutyl)-1,7-dimethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3,5-diboratabicyclo[3.3.0]octane, **3**] in high yield. Crystals of **3** are orthorhombic, a = 11.8132(11), b = 15.4768(11), c = 11.7325(16) Å, Z = 4, space group $P2_12_12_1$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.039 and R_w = 0.044 for 1729 reflections with $I \geq 2\sigma(I)$. The title compound is the second example of this recently characterized class of O-B coordinated hydroxylamine complexes, stabilized by an intramolecular $^+$N—H···N hydrogen bond (N···N = 2.796(6) Å). Bond lengths about boron are: B—O(N) = 1.482(4)–1.526(4), B—O(B) = 1.412(4) and 1.420(4), B—N = 1.712(4), B—C = 1.591(5) and 1.602(5) Å.

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **70**, 2022 (1992).

La réaction du produit de condensation de la *N,N'*-diméthyl-*N,N'*-dihydroxyméthanediamine et de l'acide phénylboronique avec la *N,N*-diéthylhydroxylamine fournit la *N,N*-diéthylhydroxylamine(*O-B*)1,7-diméthyl-3,5-diphényl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane [3-(2-éthyl-1-oxa-2-azoniabutyl)-1,7-diméthyl-3,5-diphényl-2,4,6-trioxa-7-aza-1-azonia-3,5-diboratabicyclo[3.3.0]octane], **3**, avec un excellent rendement. Les cristaux de ce produit sont orthorhombiques, a = 11,8132(11), b = 15,4768(11), c = 11,7325(16) Å, Z = 4 et groupe d'espace $P2_12_12_1$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de R = 0,039 et R_w = 0,044 pour 1729 réflexions avec $I \geq 2\sigma(I)$. Le composé **3** n'est que le deuxième exemple la classe des complexes de l'hydroxylamine comportant une coordination O-B qui a été caractérisée récemment et qui sont stabilisés par une liaison hydrogène intramoléculaire $^+$N—H···N (N···N = 2,796(6) Å). Les longueurs des liaisons autour du bore sont: B—O(N) = 1,482(4)–1,526(4), B—O(B) = 1,412(4) et 1,420(4), B—N = 1,712(4), B—C = 1,591(5) et 1,602(5) Å.

[Traduit par la rédaction]

Introduction

The findings reported in the preceding work (1) prompted us to attempt the addition of some Lewis bases to the bicyclic compound **2** synthesized by condensation of the *N,N'*-dihydroxyaminal **1** and phenylboronic acid (2, 3). The reaction of **2** with *N,N*-diethylhydroxylamine yielded a crystalline product having the elemental analysis of a 1:1 adduct and was expected to be a further example of an O-B coordinated hydroxylamine complex stabilized by an intramolecular hydrogen bond with the postulated structure **3**. Experiments with *tert*-amine *N*-oxides having no hydrogen available at the nitrogen atom for the formation of the intramolecular $^+$N—H···N interaction failed to give stable complexes by coordination of the *N*-oxide to the sp^2 boron centre at the trigonal boronate function of **2**. No adducts of this type have thus far been obtained from the reaction of **2** with simple primary or secondary amines that do offer an N—H group for intramolecular hydrogen bonding. Presumably an intramolecular $^+$N—H···N hydrogen bond is precluded on steric grounds in this case, disallowing the formation of stable crystalline addition compounds. In contrast, the reaction product of **2** and *N,N*-diethylhydroxylamine could be isolated in good yield.

Infrared and ^{1}H nmr spectra of the reaction product confirm the existence of a relatively strong hydrogen bond with a broad low-frequency band for the N—H stretch and a low-field signal for associated NH protons, respectively. The ^{11}B nmr spectrum displays one main broadened signal at $\delta(Et_2OBF_3)$ = 9.6 ppm which is consistent with tetracoordinated boron, comparable to the δ value observed for the *N*-ethylhydroxylamine derivative (1). A second less intense signal at 21.0 ppm is indicative of the presence of a small amount of the free bicyclic compound **2** which could originate from a dissociation process in solution.[3] Parallel ^{1}H nmr spin-decoupling experiments suggest that in $CDCl_3$ solution 27% of

[1]Previous paper in this series: ref. 1.

[2]3-(2-Ethyl-1-oxa-2-azoniabutyl)-1,7-dimethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3,5-diboratabicyclo[3.3.0]octane.

[3]An even less intense signal in the ^{11}B nmr spectrum, at $\delta(Et_2OBF_3)$ = 30.0 ppm, is consistent with the presence of a minor component containing a trigonal planar sp^2 boron (4), such as that in a trigonal planar phenylboronate grouping.

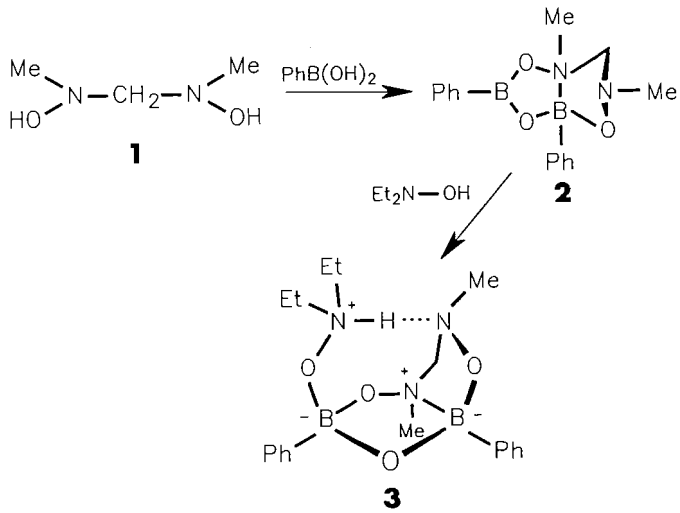
the uncoordinated species **2** and 27% of free *N,N*-diethylhydroxylamine accompany 73% of the intact 1 : 1 complex. To be sure that the postulated structure **3** is realized, rather than the possible alternatives discussed before (1) (an N-B coordinated adduct, for example), an X-ray crystallographic analysis has been carried out to allow an unambiguous assignment of the solid-state molecular structure.



Experimental

N,N-*Diethylhydroxylamine*(O-B)*1,7-dimethyl-3,5-diphenyl-2,4,6-trioxa-7-aza-1-azonia-3-bora-5-boratabicyclo[3.3.0]octane, 3*

Compound **2**, prepared by condensation of **1** and phenylboronic acid as previously reported (2), (0.59 g, 2 mmol) and *N,N*-diethylhydroxylamine (0.18 g, 2 mmol) were dissolved in 3 mL boiling ethanol. The hot solution was filtered, cooled, and kept at −18°C for 6 h. The precipitated substance was recrystallized from absolute ethanol. Yield: 0.65 g (84%); mp 125–126°C (from EtOH). Infrared (KBr): 2100–2800 cm^{-1} (N—H). ^{1}H nmr (400 MHz, $CDCl_3$/TMS) δ (ppm): 1.09–1.19 (m, 27% of 6H, $2CH_2CH_3$), 1.36 (t, J = 7.3 Hz, 73% of 3H, CH_2CH_3), 1.38 (t, J = 7.4 Hz, 73% of 3H, CH_2CH_3), 2.44 (s, 73% of 3H, N—CH_3), 2.67–2.74 (m, 27% of 4H, CH_2CH_3), 2.76 (s, 27% of 6H, 2N—CH_3), 2.84 (s, 73% of 3H, $^+$N—CH_3), 3.11–3.22 (m, 73% of 1H, CH_2CH_3), 3.22–3.31 (m, 73% of 1H, CH_2CH_3), 3.29 and 4.16 (d and d, J = 7.8 Hz, 73% of 2H, N—CH_2—N), 3.49–3.61 (m, 73% of 1H, CH_2CH_3), 3.71–3.84 (m, 73% of 1H, CH_2CH_3), 3.74 (s, 27% of 2H, N—CH_2—N), 7.19–7.45 (m, 6 arom. H), 7.65–7.85 (m, 4 arom. H), 12.40 (s, broad, 73% of 1H, $^+$NH, exchangeable).[4] ^{11}B nmr (64 MHz, $CDCl_3/Et_2OBF_3$) δ (ppm): 9.6 (broad, highest intensity), 21.0 (broad, small), 30.0 (broad, very small). Anal. calcd. for $C_{19}H_{29}B_2N_3O_4$: C 59.26, H 7.59, B 5.61, N 10.91; found: C 59.17, H 7.62, B 5.89, N 10.85.

X-ray crystallographic analysis of 3

A crystal ca. 0.25 × 0.35 × 0.45 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 54.9–88.6°) measured on a diffractometer with Cu-K_α radiation (λ = 1.54178 Å). Crystal data at 21°C are as follows

$C_{19}H_{29}B_2N_3O_4$ fw = 385.08

Orthorhombic, a = 11.8132(11), b = 15.4768(11), c = 11.7325(16) Å, V = 2145.0(3) Å^3, Z = 4, ρ_c = 1.192 Mg m^{-3}, $F(000)$ = 824, μ(Cu-K_α) = 6.27 cm^{-1}. Absent reflections: $h00$, h odd, $0k0$, k odd, and $00l$, l odd, uniquely indicate the space group $P2_12_12_1$ (No. 19).

Intensities were measured with graphite-monochromated Cu-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of (1.00 + 0.20 tan θ)° in ω (with up to 8 rescans, background/scan time ratio = 0.5) was employed. Data were

[4] 27% of 1H (free or otherwise associated Et_2NOH base) remained undetected.

measured to $2\theta = 155°$. The intensities of three check reflections, measured every 200 reflections throughout the data collection, showed a linear decline of 7.8%. After data reduction,[5] an empirical absorption correction, based on azimuthal scans for three reflections, and a linear decay correction were applied. Transmission factors range from 0.96 to 1.00. Of the 2269 independent reflections measured, 1729 had intensities greater than or equal to $2\sigma(F^2)$ above background, where $\sigma^2(F^2) = [S^2(C + 4B) + (0.01F^2)^2]/Lp^2$ with S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

[5]TEXSAN/TEXRAY structure analysis package which includes versions of the following: MITHRIL, integrated direct methods, by C. J. Gilmore; DIRDIF, direct methods for difference structures, by P. T. Beurskens; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; ORTEP II, illustrations, by C. K. Johnson.

The structure was solved by direct methods. The non-hydrogen atoms were refined with anisotropic thermal parameters, the N–H proton was refined with an isotropic thermal parameter, and the remaining hydrogen atoms were fixed in idealized positions (C—H = 0.98 Å, $B_H = 1.2B_{\text{bonded atom}}$). The C(6),C(7) ethyl group of the *N,N*-diethylhydroxylamine moiety was found to be 1 : 1 disordered over two positions; the split carbon atoms were refined with anisotropic thermal parameters. The site occcupancy factor of C(6A) was initially refined with the constraints that the occupancy factors for C(6A) and C(6B) sum to 1.00 and that site occupancies of the β-carbons (C(7A) and C(7B)) be equal to those of the α-carbons. The refined occupancy of C(6A) converged at 0.501. In the final stages of the refinement the occupancy factors were fixed at 0.50. The geometry at N(3) suggests that the entire Et_2NH^+ moiety may be disordered, but attempts to refine a disordered model for atoms N(3), C(4), C(5), and H(1) were not successful. A correction for secondary extinction was applied, the final value of the extinction coefficient being 8.43×10^{-6}. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 5. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and $\sin\theta/\lambda$ and was employed in the final stages of full-matrix least-squares refinement of 276 variables. Reflections with $I < 2\sigma(I)$ were not included in the refinement. Convergence was reached at $R = 0.039$, $R_w = 0.044$, and $S = 2.50$ for 1729 reflections with $I \geq 2\sigma(I)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$, $S = (\Sigma w(|F_o| - |F_c|)^2/(m - n))^{1/2}$ (where m = number of observations and n = number of variables).

On the final cycle of refinement the maximum parameter shift corresponded to 0.31σ. The final difference map showed maximum fluctuations of −0.10 to +0.13 e Å^{-3}. A parallel refinement of the opposite enantiomer resulted in marginally higher residuals, the R and R_w factors ratios being 1.002 and 1.003, respectively. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond

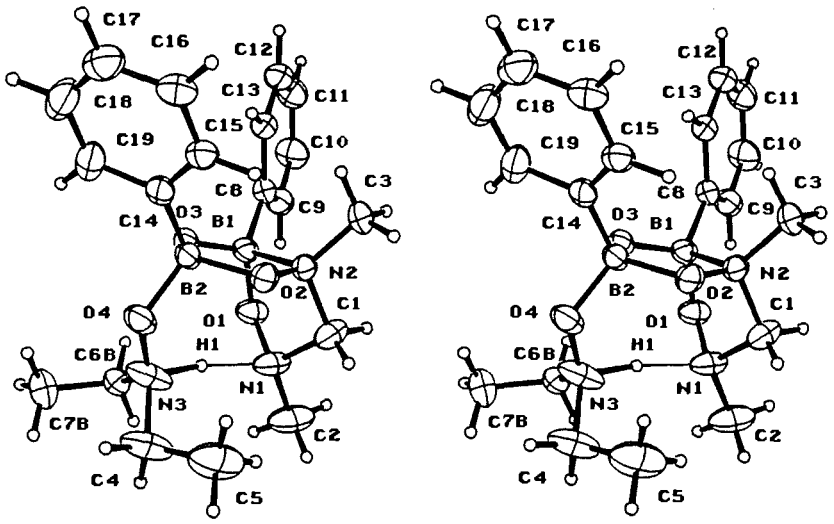

FIG. 1. Stereoview of **3**; 20% probability thermal ellipsoids are shown for the non-hydrogen atoms. For the sake of clarity, only one component of the disordered C(6),C(7) ethyl group is shown.

lengths and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen-atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, and structure factors have been deposited.[6]

Results and discussion

The postulated structure **3**, featuring O-B coordination of the *N,N*-diethylhydroxylamine, is established by the X-ray analysis. The molecule shown in Fig. 1 is the (1*S*,3*S*,5*R*,7*S*) enantiomer (chiral centres N(2), B(2), B(1), and N(1) respectively) and is the only one present in the particular crystal chosen for the X-ray analysis; the bulk sample is racemic. This type of adduct is essentially the same as that found for the *N*-monoethylhydroxylamine complex, **4**, reported in the preceding paper (1), the hydroxylamine being bonded through the oxygen atom of the *N*-oxide form to the acceptor boronate group. The complex is stabilized by a relatively strong intramolecular $^{+}$N—H···N hydrogen bond (N(3)–H(1)···N(1), N–H = 1.27(6) Å, N···H = 1.54(6) Å, N···N = 2.796(6) Å, N—H···N = 166(5)°). There are no additional *inter*-molecular hydrogen bonds involving the protonated nitrogen atom of **3** as were observed in the structure of **4** (1) which has two NH protons associated with the hydroxylamine ligand. All intermolecular distances correspond to normal van der Waals interactions, the shortest intermolecular contact involving non-hydrogen atoms being C(1)···C(13) = 3.363(5) Å.

The overall geometry of the ring system of **3** is quite similar to that reported for **4** (1) but there are several significant differences between the two molecules. The bonds at the pyroboronate connection are shorter in **3** than in **4**[7] (O—B = 1.412(4) and 1.420(4) vs. 1.434(4) and 1.446(4) Å), whereas the (N)O—B bond involving the hydroxylamine ligand is longer in the present complex (1.526(4) vs. 1.501(4) Å). The intramolecular $^{+}$N—H···N hydrogen bond is significantly stronger in **3**, the N···N distance being 0.124 Å shorter than the mean distance of 2.920 Å reported for **4**. The transannular non-bonding distance between N(1) and B(2) in **3** (3.318(5) Å) is shorter than the corresponding mean of 3.409 Å in the *N*-ethylhydroxylamine complex **4** (1), whereas both of these distances are longer than that in the parent compound **2** (3.083 Å) (3). Both the stronger $^{+}$N—H···N hydrogen bond and the shorter transannular non-bonding N···B distance in **3** relative to those in **4** may be a result of the absence of a second hydrogen (and the associated intermolecular hydrogen bonding) at the hydroxylamine nitrogen atom.

The five-membered BOBON ring in **3** has a flattened N(2)-envelope conformation (see Table 4) and is planar to within 0.083(3) Å, similar to the corresponding ring in **4**. The five-membered BONCN ring has a slightly distorted N(1)-envelope conformation. The angle between the normals to the mean planes of the BOBON ring and the approximately (to within 0.023(4) Å) planar O(1)B(1)N(2)C(1) portion of the BONCN ring of 116.0° is identical to the value reported for **2** (3). The degree of pyramidalization at N(1) in **3** is comparable to that observed for **4** (1), the sums of bond angles about N(1) being 319.7 and 318.4° (mean), respectively. The sum of the bond distances about B(2) (6.058 Å) is similar to those reported for **4** and other anionic $PhBO_3$ complexes (ref. 1 and references therein).

The synthesis of N^1-cyclohexyl-N^1,N^2-dihydroxy-1-phenyl-1,2-propanediamine and its reaction with phenylboronic acid to produce 4-cyclohexyl-2-methyl-3,6,8-triphenyl-5,7,9-trioxa-4-aza-1-azonia-8-bora-6-boratabicyclo[4.3.0]nonane, **5**, in moderate yield are described. Crystals of the organoboron derivative **5** are triclinic, a = 11.4142(8), b = 12.4719(8), c = 10.2154(6) Å, α = 75.177(6), β = 112.306(5), γ = 105.000(6)°, Z = 2, space group $P\bar{1}$. The structure was solved by direct methods and was refined by full-matrix least-squares procedures to R = 0.037 and R_w = 0.053 for 4232 reflections with $I \geq 3\sigma(I)$. The bicyclo[4.3.0]nonane system consists of a six-membered BONCNN ring and a five-membered BOBON ring *cis*-fused about the transannular N→B bond. Bond lengths involving boron are: (sp^2)B—O(B) = 1.336(2), (sp^2)B—O(N) = 1.411(2), (sp^2)B—C(aryl) = 1.557(2), (sp^3)B—O(B) = 1.457(2), (sp^3)B—O(N) = 1.434(2), (sp^3)B—N = 1.706(2), and (sp^3)B—C(aryl) = 1.593(2) Å.

WOLFGANG KLIEGEL, GOTTFRIED LUBKOWITZ, STEVEN J. RETTIG et JAMES TROTTER. Can. J. Chem. **70**, 2027 (1992).

On décrit la synthèse de la N^1-cyclohexyl-N^1,N^2-dihydroxy-1-phényl-propane-1,2-diamine et sa réaction avec l'acide phénylboronique pour donner le 4-cyclohexyl-2-méthyl-3,6,8-triphényl-5,7,9-trioxa-4-aza-1-azonia-8-bora-6-boratabicyclo[4.3.0]nonane, **5**, avec un modeste rendement. Les cristaux de ce produit sont tricliniques, a = 11,4142(8), b = 12,4719(8), c = 10,2154(6) Å, α = 75,177(6), β = 112,306(5), γ = 105,000(6)°, Z = 2 et groupe d'espace $P\bar{1}$. On a résolu la structure par des méthodes directes et on l'a affinée par la méthode des moindres carrés jusqu'à des valeurs de R = 0,037 et R_w = 0.053 pour 4232 réflexions avec $I \geq 3\sigma(I)$. Le système bicyclo[4.3.0]nonane comprend un cycle à six chaînons BONCCN et un cycle à cinq chaînons BOBON condensés d'une façon *cis* avec une liaison transannulaire N→B. Les longueurs des liaisons impliquant le bore sont: (sp^2)B—O(B) = 1,336(2), (sp^2)B—O(N) = 1,411(2), (sp^2)B—C(aryl) = 1,557(2), (sp^3)B—O(B) = 1,457(2), (sp^3)B—O(N) = 1,434(2), (sp^3)B—N = 1,706(2) et (sp^3)B—C(aryl) = 1,593(2) Å.

[Traduit par la rédaction]

Introduction

As part of our continuing study of polycyclic boron complexes with hydroxylamine ligands the N^1-substituted 1,2-bishydroxylamine **3** has been synthesized from the nitropropene derivative **1** (1) followed by the addition of *N*-cyclohexylhydroxylamine and a subsequent reduction of the nitro group of the addition product **2**.[2]

The bishydroxylamine **3** was then reacted with 2 molar equivalents of phenylboronic acid targeting the preparation of a cyclic pyroboronate with transannular N→B coordination, similar to the bicyclic compound **7** which had been obtained from a symmetrically substituted bishydroxylamine (3). A crystalline compound with an elemental analysis consistent with the desired 2:1 condensate of phenylboronic acid and **3** was isolated from this reaction, the infrared and ^{1}H nmr spectra confirming a bisphenylboronate constitution. Based on the crystallographically established structure **7** (3), a similar bicyclononane skeleton was also expected for this product. In contrast to compound **7**, the unsymmetrically substituted ligand of the new derivative allows two alternative transannular bonds between different nitrogen and boron bridgeheads, as in **4** and **5**, respectively. Structure **5** would furthermore offer another site for protonation and could isomerize by proton migration to **6**.[3]

Infrared and ^{1}H nmr data are insufficient for a definitive structural assignment. In the solid state (KBr tablet) infrared spectrum a sharp absorption band at 3210 cm^{-1} could be assigned to an N—H stretching mode, consistent with the ammonium function present in both **5** and **6**. Related hydroxylamine derivatives with quaternized nitrogen like **8** (4, 5) or **9** (6) also display distinct N—H bands in their infrared spectra, though at somewhat lower frequencies between 3050 and 3150 cm^{-1}. A compound of structure **4** would be expected to display an N—H stretching frequency similar to, but not as distinct as, those reported for O,N-disubstituted hydroxylamine derivatives which absorb at about 3200 cm^{-1} (7, 8). The ^{1}H nmr spectrum displays a signal for one exchangeable proton at δ = 6.50 ppm in $CDCl_3$ solu-

[1]Previous paper in this series: ref. 12.

[2]The addition of the *N*-cyclohexylhydroxylamine seems to be quite stereoselective since only one of the possible diastereomers of **2** was obtained (61%). Narrow melting ranges and unambiguous ^{1}H nmr spectra of **2** (as well as of the reduction product **3**) indicate the formation of only one of the diastereomers which should be present as a racemate. Similar diastereoselectivity has been reported for the addition of cyclohexylamine to 2-nitro-1-phenylpropene (2).

[3]Other less probable polycyclic skeleton isomers that could be formed have been discussed in a previous report (2) and will not be dealt with here.

tion and at 10.02 ppm in DMSO-d_6 solution. No coupling is observed between the N—H proton and the vicinal C—H proton which could be possible for all three structures **4**, **5**, and **6**. All of these isomers have structures consistent with the entire ^{1}H nmr spectra produced in either solvent. The possible temperature-dependent fluxional processes of topomerization (**4**↔**5**) and (or) prototropy (**5**↔**6**) could cause signal coalescence in the nmr experiments and must be taken into consideration.

The question of which of the three isomers **4**, **5**, or **6** would be "frozen" in a single crystal of this material was therefore of great interest. An X-ray crystallographic analysis was undertaken to establish the solid-state molecular structure.

Experimental

N-*Cyclohexyl*-N-*hydroxy-2-nitro-1-phenylpropanamine, 2 ($R = C_6H_{11}$)*

2-Nitro-1-phenylpropene (1) (4.89 g, 30 mmol) and cyclohexylhydroxylamine (3.46 g, 30 mmol) were dissolved in 50 mL of methanol and refluxed for 2 h. The solvent was removed *in vacuo* and the remaining oil was dissolved in 10 mL of absolute ethanol. Crystallization at −30°C yields 5.10 g (61%) of a colorless substance, mp 100–101°C (from absolute ethanol). Infrared (KBr): 3510 (O—H), 1550 cm^{-1} (NO_2). ^{1}H nmr ($CDCl_3$/TMS) δ (ppm): 0.85–2.05 (m, $(CH_2)_5$), 1.29 (d, J = 6 Hz, CH_3), 2.16–2.48 (m, N—C*H*$(CH_2)_5$), 4.30 (d, J = 11 Hz, C*H*—Ph), 4.80 (s, exchangeable, OH), 5.38 (m_c, C*H*—Me), 7.2–8.5 (m, C_6H_5). Anal. calcd. for $C_{15}H_{22}N_2O_3$: C 64.73, H 7.97, N 10.06; found: C 64.66, H 8.00, N 10.12.

N^1-*Cyclohexyl*-N^1,N^2-*dihydroxy-1-phenyl-1,2-propanediamine, 3 ($R = C_6H_{11}$)*

N-Cyclohexyl-*N*-hydroxy-2-nitro-1-phenylpropanamine, **2** (8.34 g, 30 mmol) was dissolved in 100 mL ethanol (96%). After addition of a solution of ammonium chloride (6 g) in 25 mL water, zinc dust (11 g) was added in small portions under vigorous stirring such that the temperature of the solution did not exceed 30°C. Stirring was continued for 2 h, the precipitate was filtered off and washed with boiling tetrahydrofuran (2 × 150 mL). The combined solutions were evaporated *in vacuo*, and the dry residue recrystallized from tetrahydrofuran. Yield: 5.91 g (75%), mp 168–169°C (from THF). Infrared (KBr): 3370 (O—H), 2260 cm^{-1} (broad, O—H, associated). ^{1}H nmr (DMSO-d_6/TMS) δ (ppm): 0.72 (d, J = 7 Hz, CH_3), 0.85–1.93 (m, $(CH_2)_5$), 1.98–2.30 (m, N—C*H*$(CH_2)_5$), 3.54 (m_c, C*H*—Me), 3.79 (d, J = 9 Hz, C*H*—Ph), 6.01, 6.89, and 7.58 (3 s, exchangeable, 2OH and NH), 7.1–7.4 (m, C_6H_5). Anal. calcd. for $C_{15}H_{24}N_2O_2$: C 68.15, H 9.15, N 10.60; found: C 68.04, H 9.27, N 10.44.

4-*Cyclohexyl-2-methyl-3,6,8-triphenyl-5,7,9-trioxa-4-aza-1-azonia-8-bora-6-boratabicyclo[4.3.0]nonane, 5 ($R = C_6H_{11}$)*

N^1-Cyclohexyl-N^1,N^2-dihydroxy-1-phenyl-1,2-propanediamine, **3** (0.53 g, 2 mmol) and phenylboronic acid (0.49 g, 4 mmol) were suspended in 10 mL of tetrachloromethane and refluxed for 1.5 h with continuous removal of reaction water. The solution was evaporated *in vacuo* to half of its original volume and diluted with 170 mL of petroleum ether (bp 30–70°C). At −18°C a colorless

H), 7.6–7.9 (m, 6 arom. H), 10.02 (s, exchangeable, NH). Anal. calcd. for $C_{27}H_{32}B_2N_2O_3$: C 71.40, H 7.10, B 4.76, N 6.17; found: C 71.48, H 7.22, B 4.86, N 6.14.

Crystals suitable for X-ray analysis were obtained by recrystallization from toluene/petroleum ether.

X-ray crystallographic analysis of 5 (R = C_6H_{11})

A crystal ca. 0.15 × 0.25 × 0.35 mm in size was mounted on a glass fiber. Unit-cell parameters were refined by least-squares on setting angles for 25 reflections (2θ = 101.7–120.6°) measured on a diffractometer with Cu-K_α radiation (λ = 1.54178 Å). Crystal data at 21°C are as follows

$C_{27}H_{32}B_2N_2O_3$ fw = 454.19

Triclinic, a = 11.4142(8), b = 12.4719(8), c = 10.2154(6) Å, α = 75.177(6), β = 112.306(5), γ = 105.000(6)°, V = 1279.2(2) Å^3, Z = 2, ρ_c = 1.179 Mg m^{-3}, $F(000)$ = 484, μ(Cu-K_α) = 5.60 cm^{-1}. Absent reflections: none, space group $P\bar{1}$ (No. 2) from structure analysis.

Intensities were measured with graphite-monochromated Cu-K_α radiation on a Rigaku AFC6S diffractometer. An ω–2θ scan at 32° min^{-1} over a range of (1.26 + 0.25 tan θ)° in ω (with up to 8 rescans, background/scan time ratio = 0.5) was employed. Data were measured to 2θ = 155°. The intensities of three check reflections, measured every 150 reflections throughout the data collection, showed only small random variations. After data reduction,[4] an empirical absorption correction, based on azimuthal scans for three reflections, was applied. Transmission factors range from 0.89 to 1.00. Of the 5486 reflections measured, 5206 were unique (R_{int} = 0.007), and 4232 had intensities greater than or equal to $3\sigma(F^2)$ above background where $\sigma^2(F^2) = [S^2(C + 4B) + (0.025F^2)^2]/Lp^2$ with S = scan speed, C = scan count, B = total background count, and Lp = Lorentz-polarization factor.

The structure was solved by direct methods. The non-hydrogen atoms were refined with anisotropic thermal parameters and the hydrogen atoms with isotropic thermal parameters. A correction for secondary extinction was applied, the final value of the extinction coefficient being 2.21 × 10^{-5}. Scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from ref. 9. The weighting scheme $w = 4F_o^2/\sigma^2(F_o^2)$ gave uniform average values of $w(|F_o| - |F_c|)^2$ over ranges of both $|F_o|$ and sin θ/λ and was employed in the final stages of full-matrix least-squares refinement of 436 variables. Reflections with $I < 3\sigma(F_o^2)$ were not included in the refinement. Convergence was reached at R = 0.037 and R_w = 0.053 for 4232 reflections with $I \geq 3\sigma(F_o^2)$. The function minimized was $\Sigma w(|F_o| - |F_c|)^2$, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $R_w = (\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2)^{1/2}$.

On the final cycle of refinement the maximum parameter shift corresponded to 0.006σ. The mean error in an observation of unit weight was 2.65. The final difference map showed maximum fluctuations of −0.12 to +0.14 e Å^{-3}. The final positional and (equivalent) isotropic thermal parameters for the non-hydrogen atoms appear in Table 1. Bond lengths and angles are given in Tables 2 and 3 and intra-annular torsion angles in Table 4. Hydrogen atom parameters, anisotropic thermal parameters, torsion angles, intermolecular contacts, least-squares planes, bond lengths and angles involving hydrogen, and structure factors have been deposited.[5]

Results and discussion

The structure analysis shows that in the solid state the bicyclic form **5** is present (Fig. 1). The transannular N→B coordinative bond dividing the cyclononane system into a six-membered BONCCN ring and a five-membered BOBON ring originates from the unsubstituted nitrogen atom N(2), presumably due to the presence of less steric hindrance (less "F-strain" (10)) at this Lewis-basic centre relative to that at N(1). The overall geometry of the bicyclo[4.3.0]nonane skeleton resembles that of compound **7** (3). The BOBON ring is axially fused to the side of the slightly distorted boat of the BONCCN ring, the annellation site being the coordinative B(2)–N(2) bond. The five-membered BOBON ring has a

[4]TEXSAN/TEXRAY structure analysis package which includes versions of the following: MITHRIL, integrated direct methods, by C. J. Gilmore; DIRDIF, direct methods for difference structures, by P. T. Beurskens; ORFLS, full-matrix least-squares, and ORFFE, function and errors, by W. R. Busing, K. O. Martin, and H. A. Levy; ORTEP II, illustrations, by C. K. Johnson.
